experiments for measuring the relative affinities toward cationic species has been recently reviewed.[22]

Conclusion

In conclusion the possibility to select and trap ions in a defined region of space with relatively simple devices (ITMS), together with the development of electrospray ionization, has added interesting new perspectives to the study of inorganic and organometallic compounds for the possibility to perform collisional experiments and/or gas-phase ion-molecule reactions on the isolated ionic species. Furthermore, this technique is particularly useful in the analysis of highly labile and reactive intermediates, such as peroxidic species[23] and of rapidly exchanging systems.[21]

We would like to thank the *Servizio Spettrometria di Massa CNR Area di Ricerca di Padova* for the use of their instrumentation and for stimulating discussion. We are indebted to the referees for their very helpful comments and suggestions. Financial support from the *Italian Research Council* (CNR) and from the *Italian Ministry of the University and of the Scientific Research* (MURST) is gratefully acknowledged.

Experimental Section

General Remarks: The ESI-MS measurements were obtained using a Finnigan MAT LCQ instrument (San Jose, CA). The samples were introduced by direct injection of NH_4VO_3 (0.0005 M), dissolved in CH_3OH/H_2O (1:1; pH = 1, $HClO_4$), in the absence or in the presence of an equimolar amount of H_2O_2. The same experiments were also performed using perdeuterated solvents, in

the presence of $DClO_4$. Solution flow rate 8 μl min^{-1}, capillary temperature 145°C, spray voltage 2.4 kV, capillary voltage 14 V, nebulizing gas N_2 (40 units flow rate). The parameters related to octapoles and detector were those achieved by the automatic set-up procedure. Collision-induced decompositions of selected ions were obtained by applying a supplementary r.f. voltage (tickling voltage) to the end-cap electrodes of the ion trap (resonance activation). Typical V_{tickle} values for fragmentation were up to 3 V. For ion-molecule reaction studies, a tickling voltage of 15 mV was employed. − All calculations were carried out with *Spartan* v. 4[24] and *Gaussian 94*,[25] running on IBM RS/6000 workstations. Hartree-Fock calculations were run with the 3-21G(*) basis set.[16] Density functional theory (DFT) calculations were carried out with Becke′s hybrid 3-parameter functional with Lee-Yang-Parr non-local correlation (B3LYP);[17][26] these calculations had to be run with the (99,302) numerical integration grid[25] and full accuracy at all stages in order to achieve SCF convergence. Hay and Wadt′s effective core potentials (ECP)[18][26] for vanadium were employed in DFT calculations. However, V^V compounds have a $3d^0$ configuration, and therefore ECP′s incorporating up to the outermost core orbitals ($3s^23p^6$) will not give satisfactory results. Accordingly, the ECP′s developed specifically for these cases[26] (i.e., explicitly treating $3s^23p^6$ electrons), were employed; this basis set is denoted as LANL2DZ in *Gaussian 9x*. Atomic charges were calculated by fitting to electrostatic potential maps (CHELPG method).[27] NMR experiments were carried out as already described.[1]

Keywords: Organometallic compounds / Nickel complexes / Crystal structures

The compound *cis*-$[Ni(C_6F_5)_2(PhCN)_2]$ has been used as the starting material for the preparation of the bimetallic complexes $[(C_6F_5)_2Ni(\mu\text{-}X)_2Ni(C_6F_5)_2]^{2-}$ (X = SCN, OCN, N_3), $[(C_6F_5)_2Ni(\mu\text{-}SCN)_2Pd(C_6F_5)_2]^{2-}$, $[(C_6F_5)_2Ni(\mu\text{-}NCS)_2Pd(dppe)]$ [dppe = 1,2-bis(diphenylphosphanyl)ethane], and the trimetallic$[(C_6F_5)_2Ni(\mu\text{-}NCS)_2Pd(\mu\text{-}SCN)_2Ni(C_6F_5)_2]^{2-}$. The mononuclear compounds $[(C_6F_5)_2NiLX]$ (L = PPh_3, $P(C_6H_4MeO\text{-}p)_3$; X = SCN, OCN) are obtained by reaction between $[(C_6F_5)_2Ni(\&\mu\text{-}X)_2Ni\text{-}(C_6F_5)_2]^{2-}$ and L. The treatment of *cis*-$[Ni(C_6F_5)_2(PhCN)_2]$ with $[M(SAr)_2(dppe)]$ leads to the formation of the arylthiolate complexes $[(C_6F_5)_2Ni(\mu\text{-}SAr)_2M(dppe)]$ (Ar = Ph, $C_6H_4Me\text{-}p$, $C_6H_4NO_2\text{-}p$; M = Ni, Pd, Pt). The X-ray diffraction study of $[(C_6F_5)_2Ni(\mu\text{-}SPh)_2Pd(dppe)]$ shows that both metal atoms, Ni and Pd, are coordinated in a slightly distorted square-planar geometry and the μ-thiolato groups are in the *syn* conformation.

Introduction

Anionic complexes of the group-10 elements of the type $[M_2R_4(\mu\text{-}X)_2]^{2-}$ (M = Ni, R = C_6F_5, X = F or Cl; M = Pd or Pt, R = C_6F_5, X = Cl, Br, I or SCN; M = Pd, R = $C_6F_3H_2$-2,4,6, X = Cl, Br, I, SCN) have been reported[1][2][3][4]. Labile complexes such as $[MR_2(tht)_2]$ (M = Pd or Pt; R = C_6F_5)[5] and $[PdR_2(PhCN)_2]$ (R = C_6F_5, $C_6F_3H_2$-2,4,6)[6] have shown to be excellent precursors for the synthesis of asymmetric homo- and hetero-bimetallic complexes with halide bridges.

Symmetric or antisymmetric binuclear complexes can be obtained by treating the labile complex R_2ML_2 with the appropriate reagent [Eq. (1) and (2)]. The reaction represented by Eq. (1) was used for the preparation of bis(μ-hydroxo) complexes of nickel[7] and palladium[8] $[(C_6F_5)_2M(\mu\text{-}OH)_2M(C_6F_5)_2]^{2-}$ from the reaction between *cis*-$[M(C_6F_5)_2(PhCN)_2]$ and OH^-, but the platinum anologue[9] could not be prepared by this method because the nucleophilic attack of coordinated PhCN by OH^- was competitive. The process represented by Eq. (2) was used for the preparation of bimetallic (Pd−Ni, Pd−Pd, or Pd−Pt) palladium complexes[6]. We report here the preparation and study of a number of new bimetallic pseudohalide-bridged complexes derived from the $Ni(C_6F_5)_2$ starting from the labile complex *cis*-$[Ni(C_6F_5)_2(PhCN)_2]$.

$$2\ R_2ML_2 + 2\ X^- \rightarrow R_2M(\mu\text{-}X)_2M'R_2 + 4\ L \quad (1)$$

$$R_2ML_2 + X_2M'L'_2 \rightarrow R_2M(\mu\text{-}X)_2M'L'_2 + 2\ L \quad (2)$$

The above method has been extended to the preparation of some bimetallic arylthiolate-bridged complexes of nickel. The relevance of transition-metal complexes with aliphatic thiolate ligands as models of biologically redox-active metalloproteins[10] has stimulated interest in the chemistry of metal thiolates[11]. Nickel(II) thiolates are generally square-planar species with a strong tendency to form dimers and oligomers[12][13][14][15]. We have prepared a number of di- and trinuclear nickel(II) complexes with bridging thiolate groups by reaction of $[(C_6F_5)_2Ni(\mu OH)_2Ni(C_6F_5)_2]^{2-}$ with thiols[16]. Now we report the preparation of asymmetric bimetallic complexes of the type $[(C_6F_5)_2Ni(\mu\text{-}SAr)M(dppe)]$ [dppe = 1,2-bis(diphenylphosphanyl)ethane] starting from the precursor *cis*-$[Ni(C_6F_5)_2(PhCN)_2]$.

Results and Discussion

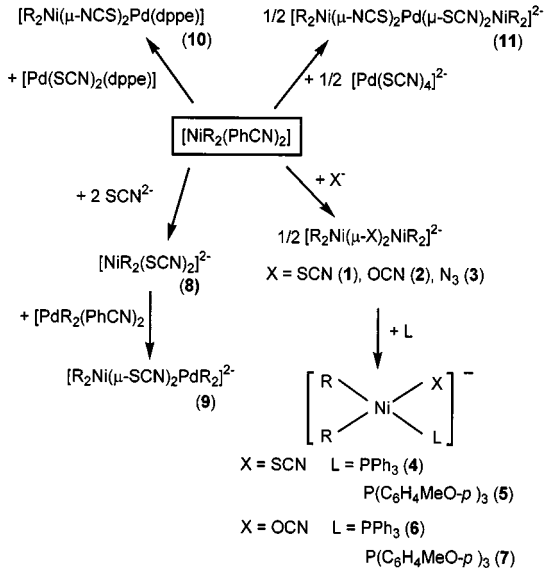
1. Pseudohalide Complexes

The reaction (1:1 molar ratio) between $[Ni(C_6F_5)_2(PhCN)_2]$ and the pseudohalides SCN^-, OCN^-, and N_3^- gives the pseudohalide-bridged complexes **1−3** (Scheme 1) in 60−85% yields. The new complexes are air-stable solids and their acetone solutions exhibit conductances in the range 207−217 S cm^2 mol^{-1}, corresponding to 2:1 electrolytes[17]. The infrared spectra of the complexes show bands attributed to the C_6F_5 group[18] at ca. 1630 m, 1495 vs, 1460 vs, 1050 vs, 950 vs, and 780 br., s cm^{-1}. Complex **1** gives a ν(CN) band at 2158 cm^{-1} consistent with the presence of bridged thiocyanate[19] and the ^{19}F-NMR spectrum indicates that there are two sorts of C_6F_5 rings, so the sym-

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1434−1948/98/0808−1199 $ 17.50+.50/0

metric structure Ni(SCN)(NCS)Ni is proposed for this complex. The infrared spectrum of the cyanate complex **2** shows a band at 2168 cm^{-1} supporting the bridging character of the cyanate group by means of the nitrogen atom[20]. The ^{19}F-NMR spectrum is consistent with the presence of four equivalent pentafluophenyl groups. The IR[21] and NMR data of complex **3** are consistent with a binuclear structure contaning two azide bridges. The electronic spectra of complexes **1**−**3** show an absorption band which may be assigned to the $^1A_{1g} \rightarrow {}^1A_{2g}$ transition in a square-planar ligand field[22].

Scheme 1. Pseudohalide complexes (R = C_6F_5)



Complexes **1** and **2** react with triphenylphophane and tris(*p*-methoxyphenyl)phosphane to give the mononuclear complexes $(PPh_4)[Ni(C_6F_5)_2XL]$ [X = SCN, OCN; L = PPh_3, $P(C_6H_4MeO\text{-}p)_3$] (**4**-**7**) (Scheme 1). However, similar reactions with pyridine or triethylphosphane give a mixture of $[Ni(C_6F_5)_2(SCN)_2]^{2-}$ and $[Ni(C_6F_5)_2L_2]$. The azide-bridged complex **3** does not react with neutral ligands. The IR data of the mononuclear complexes **4**−**7** are consistent with terminal S-thiocyanate or N-cyanate. The ^{19}F-NMR spectra exhibit six signals corresponding to two inequivalent C_6F_5 rings, one *trans* to the pseudohalide and the other *trans* to the neutral ligand. Their acetone solutions show conductance values (83−95 S cm^2 mol^{-1}) corresponding to 1:1 electrolytes[17]. The elemental analyses of complexes $(PPh_4)[Ni(C_6F_5)_2XL]$ (**4**−**7**) showed no significant variation when the crystals were twice recrystallized from acetone/diethyl ether and the spectroscopic data also supported that a mixture of $[Ni(C_6F_5)_2L_2]$ and $(PPh_4)_2[Ni(C_6F_5)_2X_2]^{2-}$ should be discarded. For example, $(PPh_4)[Ni(C_6F_5)_2(SCN)(PPh_3)]$ gives a single IR band for the ν(CN) vibration (at 2102 cm^{-1}) while $(PPh_4)_2[Ni(C_6F_5)_2(SCN)_2]$ gives a split band for the same vibrational mode (2112 and 2124 cm^{-1}).

The reaction between $[Ni(C_6F_5)_2(PhCN)_2]$ and SCN^- (molar ratio 1:2) gives the corresponding mononuclear complex $(PPh_4)_2[Ni(C_6F_5)_2(SCN)_2]$ (**8**). However, similar complexes with cyanate and azide anions could not be obtained. Complex **8** behaves as a 2:1 electrolyte in acetone solution (molar conductance 224 S cm^2 mol^{-1}) and the infrared band observed at 2112 cm^{-1} indicates that the thiocyanate ligand is S-bonded[19]. The expected three signals (4 F_o/2 F_p/4 F_m) of two equivalent C_6F_5 groups are observed in the ^{19}F-NMR spectrum. In dichloromethane, complex **8** reacts with the labile *cis*-$[Pd(C_6F_5)_2(PhCN)_2]$ to give the binuclear heterobimetallic complex $[(C_6F_5)_2Ni(\mu\text{-}SCN)(\mu\text{-}NCS)Pd(C_6F_5)_2]^{2-}$ (**9**). The IR spectrum shows a band at 2144 cm^{-1} which is consistent with a bridging thiocyanate[19] and four signals observed in the ^{19}F-NMR spectrum for the pentafluorophenyl *ortho*-fluorine atoms indicate that there are four different C_6F_5 rings, in accordance with the structure proposed above.

The asymmetric binuclear complex **10** (Scheme 1) is prepared by reaction between the labile nickel complex $[Ni(C_6F_5)_2(PhCN)_2]$ and the thiocyanate palladium complex $[Pd(SCN)_2(dppe)]$. The infrared absorption found at 2158 cm^{-1} for complex **10** is consistent with the presence of bridging thiocyanate[19] and the ^{19}F-NMR spectrum exhibits two signals in the *ortho*-fluorine region attributed to the structure $[(C_6F_5)_2Ni(\mu\text{-}SCN)(\mu\text{-}NCS)Pd(dppe)]$, i.e., one C_6F_5 ring *trans* to N and one C_6F_5 ring *trans* to S.

The trinuclear complex **11** (Scheme 1) is obtained by reaction of *cis*-$[Ni(C_6F_5)_2(PhCN)_2]$ with the thiocyanate complex $[Pd(SCN)_4]^{2-}$. The absorption found at 2146 cm^{-1} for complex **11** indicates the presence of bridging thiocyanate[27]. The ^{19}F-NMR spectrum shows three signals (intensity ratio of 2:1:2) corresponding to the *ortho*-, *para*-, and *meta*-fluorine atoms of four equivalent C_6F_5 rings, in accord with the structure $[(C_6F_5)_2Ni(\mu\text{-}NCS)_2Pd(\mu\text{-}SCN)_2Ni(C_6F_5)_2]^{2-}$.

2. Thiolate Complexes

In methanol, *cis*-$[Ni(C_6F_5)_2(PhCN)_2]$ reacts with $[M(SAr)_2(dppe)]$ (M = Ni, Pd, Pt; Ar = Ph, $C_6H_4Me\text{-}p$, $C_6H_4NO_2\text{-}p$) to give the corresponding asymmetric binuclear thiolate complexes shown in Scheme 2. They are orange or red, air-stable solids which in acetone solution behave as non-electrolytes.

Scheme 2. Arylthiolate complexes (R = C_6F_5)

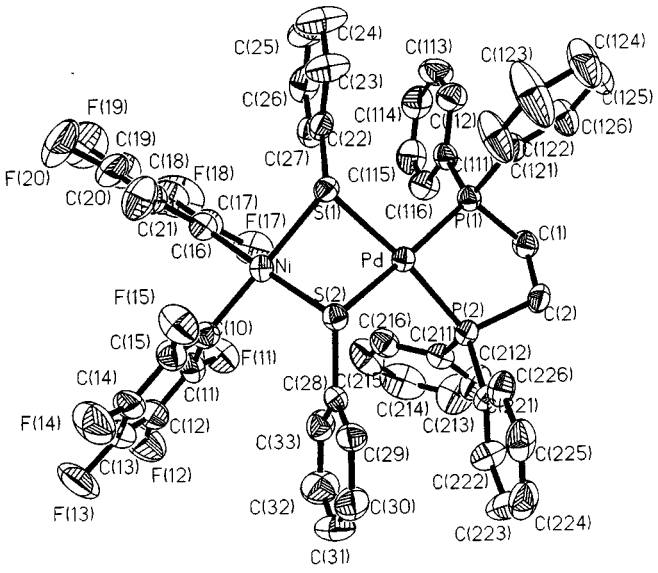
	M = Ni	Pd	Pt
Ar = Ph	(12)	(13)	(14)
$C_6H_4Me\text{-}p$	(15)	(16)	(17)
$C_6H_4NO_2\text{-}p$	(18)	(19)	(20)

The infrared spectra of these *gem* derivatives show the bands attributed to the C_6F_5 group[18] at ca. 1630 m, 1490 vs, 1050 vs, and 950 vs cm^{-1}, as well as a broad or split band at 780 cm^{-1} for the so-called "X-sensitive" mode of C_6F_5 which is characteristic of the *cis*-$M(C_6F_5)_2$ fragment[23][24]. The ^1H-, ^{19}F-, and $^{31}P\{^1H\}$-NMR data for the binuclear complexes are in agreement with the formula $[(C_6F_5)_2Ni(\mu\text{-}SAr)_2M(dppe)]$. As expected, the ^{31}P-NMR spectra show a single resonance and that of the platinum complexes are flanked by the satellites by coupling to ^{195}Pt, the coupling constant being in the range 2900−3100 Hz. The three signals observed in the ^{19}F NMR correspond to the A_2MX_2 spin system of two equivalent pentafluorophenyl groups freely rotating around the Ni−C bond and with the coupling constant $J_{AX} = 0$. The ^1H-NMR data also give evidence of free rotation of the thiolate aryl group around the C−S bond, although in complexes **18** and **19** the resonance signals of the $C_6H_4NO_2$-*p* substituent are overlapped with the dppe phenyl resonances.

3. Crystal Structure of $[(C_6F_5)_2Ni(\mu\text{-}SPh)_2Pd(dppe)]\cdot Me_2CO$

Figure 1 represents an ORTEP[25] projection of the molecular structure with the atom numbering and Table 1 shows some selected bond lengths and bond angles. Both metal atoms, Ni and Pd, are coordinated in a slightly distorted square-planar geometry and the μ-thiolato groups are in the *syn* conformation.

Figure 1. Molecular structure of compound **13**



The main distortion of the square-planar coordination is a slight twist of de PdS_2 plane relative to the PdP_2 plane, by 9.4°. The Ni−C and Ni−S distances are similar to values reported in the literature[16][26]. The Ni−S and Pd−S distances are also similar to values found in other homonuclear complexes[27][28]. The distortion of the square-planar coordination in the Ni atom is a slight twist of the NiS_2 plane relative to the NiC_2 plane, by 9.6°.

The phosphane has a strong *trans* influence, lengthening the Pd−S bonds. So, the Pd−S distances are 2.356(2) and 2.360(2) A giving a weighted mean distance of 2.358(2) A, significantly longer than distances with other ligands[27][28].

Table 1. Selected intramolecular distances [A] and angles [°] for **13**

a) Distances		b) Angles	
Pd−P(2)	2.2720(14)	P(2)−Pd−P(1)	84.27(5)
Pd−P(1)	2.2973(14)	P(2)−Pd−S(2)	99.76(5)
Pd−S(2)	2.3564(13	P(1)−Pd−S(2)	171.10(4)
Pd−S(1)	2.3597(13)	P(2)−Pd−S(1)	173.40(4)
Pd···Ni	3.1157(10)	P(1)−Pd−S(1)	101.73(5)
Ni−C(10)	1.900(5)	S(2)−Pd−S(1)	74.70(4)
Ni−C(16)	1.906(5)	C(10)−Ni−C(16)	87.0(2)
Ni−S(2)	2.214(2)	C(10)−Ni−S(2)	95.05(14)
Ni−S(1)	2.2509(14)	C(16)−Ni−S(2)	177.82(14)
		C(16)−Ni−S(2)	177.82(14)
		C(10)−Ni−S(1)	169.3(2)
		C(16)−Ni−S(1)	98.46(14)
		S(2)−Ni−S(1)	79.69(5)
		C(10)−Ni−Pd	132.91(14)

The Ni···Pd distance is 3.116(2) A, showing no significant metal-metal interaction. The NiSPdS ring adopts a hinged square-planar geometry with a dihedral angle of 120.4° along the S···S line.

As expected, the two carbon atoms of the aliphatic chain of dppe ligand lie on each side of the PdP_2 plane. Thus, C(1) lies 0.067 to one side, while C(2) lies 0.640 A to the other side of the plane, the PdP_2C_2 chelate ring adopting a twist conformation. The non-planarity of the PdP_2C_2 ring is a consequence of the tetrahedral geometry at the carbon and phosphorus atoms and the square-planar coordination of the metal center.

The two pentafluorophenyl rings are planar and rotated 83.5° with respect to each other. The rings present distortions as indicated by the values of the C−C−C angles which range from 112.5(4) to 125.5(5). This type of distortion has already been observed in other fluorophenyl rings[29].

Experimental Section

General Methods: C, H, N, and S analyses were carried out with a Carlo Erba instrument. − Infrared spectra were recorded with a Perkin-Elmer 1430 spectrophotometer using Nujol mulls between polyethylene sheets. − ^1H-, ^{19}F-, and ^{31}P-NMR spectra were recorded with a Bruker AC 200E or a Varian 300 spectrometer. − Conductance measurements were performed with a Crison 525 conductimeter (in acetone, $c \approx 5\cdot10^{-4}$ mol dm^{-3}). − Decomposition temperatures were determined with a Reichert microscope. − All solvents were dried by conventional methods. − The compounds $[Ni(C_6F_5)_2(PhCN)_2]$[7], $(PPh_4)SCN$[30], KN_3[31], $Pd(dppe)(SCN)_2$[32], $(NBu_4)_2[Pd(SCN)_4]$[33], $[Ni(SAr)_2(dppe)]$[34] and $[M(SAr)_2(dppe)]$ (M = Pd, Pt)[35] were prepared as described elsewhere.

$(PPh_4)_2[Ni_2(C_6F_5)_4(\mu\text{-}SCN)_2]$ (**1**) *and $(PPh_4)_2[Ni(C_6F_5)_2(SCN)_2]$* (**8**): A solution of $(PPh_4)SCN$ (1.33 mmol for **1** and 2.66 mmol for **8**) in dichloromethane (10 ml) was added to a solution of $[Ni(C_6F_5)_2(PhCN)_2]$ (0.8 g, 1.33 mmol) in dichloromethane (15 ml) and the mixture was stirred (**1**) or boiled under reflux (**8**) for

30 min. The solution was then concentrated under reduced pressure to half the original volume. Addition of diethyl ether caused the precipitation of a yellow solid which was filtered off, washed with diethyl ether and air-dried.

1: Yield 84%. − $C_{74}H_{40}F_{20}N_2Ni_2P_2S_2$ (1580.58): calcd. C 56.2, H 2.6, N 1.8, S 4.1; found C 56.7, H 2.3, N 1.8, S 3.7. − M.p. 211°C (dec.). − Λ_M = 193 S cm^2 mol^{-1}. − IR (Nujol): ν = 2158 cm^{-1} (CN str). − UV/Vis (acetone): λ_{max} [cm^{-1} × 10^{-3}] (ε) = 22.6 (1088). − ^{19}F NMR ([D$_6$]acetone, $CFCl_3$): δ = −115.4 (m, 4 F$_o$), −116.9 (m, 4 F$_o$), −165.2 (t, 2 F$_p$, J_{pm} = 19.7), −165.6 (t, 2 F$_p$, J_{pm} = 21.7 Hz), −167.3 (m, 4 F$_m$), −167.5 (m, 4 F$_m$). − ^{31}P NMR ([D$_6$]acetone, H_3PO_4): δ = 24.6.

8: Yield 58%. − $C_{62}H_{40}F_{10}N_2NiP_2S_2$ (1187.77): calcd. C 62.7, H 3.4, N 2.4, S 5.4; found C 62.6, H 3.6, N 2.5, S 5.3. − M.p. 189°C (dec.). − Λ_M = 224 S cm^2 mol^{-1}. − IR (Nujol): ν = 2112 cm^{-1}, 2124 (sh) (CN str). − UV/Vis (acetone): λ_{max} [cm^{-1} × 10^{-3}] (ε) = 23.4 (752). − ^{19}F NMR ([D$_6$]acetone, $CFCl_3$): δ = −115.9 (d, 4 F$_o$, J_{om} = 29.9 Hz), −166.9 (t, 2 F$_p$, J_{pm} = 20.3 Hz), −167.9 (m, 4 F$_m$). − ^{31}P NMR ([D$_6$]acetone, H_3PO_4): δ = 24.6.

(PPh$_4$)$_2$[Ni$_2$(C$_6$F$_5$)$_4$(μ-NCO)$_2$]; X = NCO (**2**) *or N$_3$* (**3**): An acetone (20 ml) solution containing [Ni(C$_6$F$_5$)$_2$(PhCN)$_2$] (100 mg, 0.17 mmol) and KNCO or KN_3 (0.17 mmol) was stirred at room temperature for 15 min and then a solution of $(PPh_4)Cl$ (62.6 mg, 0.17 mmol) in hot acetone (15 ml) was added. The mixture was stirred at room temperature for 30 min. The KCl formed during the reaction was removed by filtration, and the resulting solution was then concentrated under reduced pressure to ca. 10 ml. Addition of diethyl ether (for **2**) or hexane (for **3**) resulted in the precipitation of an orange solid. This was filtered off, washed with water and diethyl ether (**2**) or ethanol and hexane (**3**) and air-dried. Complexes **2** and **3** were recrystallized from acetone/diethyl ether and acetone/hexane respectively.

2: Yield 61%. − $C_{74}H_{40}F_{20}N_2Ni_2O_2P_2$ (1548.45): calcd. C 57.4, H 2.6, N 1.8; found C 57.5, H 2.7, N 1.8. − M.p. 187°C (dec.). − Λ_M = 207 S cm^2 mol^{-1}. − IR (Nujol): ν = 2168 cm^{-1} (CN str). − UV/Vis (acetone): λ_{max} [cm^{-1} × 10^{-3}] (ε) = 21.6 (798). − ^{19}F NMR ([D$_6$]acetone, $CFCl_3$): δ = −115.4 (d, 8 F$_o$, J_{om} 29.1 Hz), −165.9 (t, 4 F$_p$, J_{pm} 20.0), −167.7 (m, 4 F$_m$). − ^{31}P NMR ([D$_6$]acetone, H_3PO_4): δ = 24.6.

3: Yield 79%. − $C_{72}H_{40}F_{20}N_6Ni_2P_2$ (1548.45): calcd. C 55.9, H 2.6, N 5.4; found C 55.9, H 2.9, N 5.5. − M.p. 196°C (dec.). − Λ_M = 217 S cm^2 mol^{-1}. − IR (Nujol): ν = 2063 cm^{-1} (CN str). − UV/Vis (acetone): λ_{max} [cm^{-1} × 10^{-3}] (ε) = 21.7 (1165). − ^{19}F NMR ([D$_6$]acetone, $CFCl_3$): δ = −115.3 (d, 8 F$_o$, J_{om} = 29.1), −165.1 (t, 4 F$_p$, J_{pm} = 19.2 Hz), −167.2 (m, 8 F$_m$). − ^{31}P NMR ([D$_6$]acetone, H_3PO_4): δ = 24.6.

(PPh$_4$)[Ni(C$_6$F$_5$)$_2$XL]; X = SCN, L = PPh$_3$ (**4**) *or P(C$_6$H$_4$CH$_3$O-p)$_3$* (**5**); *X = NCO, L = PPh$_3$* (**6**) *or P(C$_6$H$_4$CH$_3$-O-p)$_3$* (**7**): A solution of $(PPh_4)_2[Ni_2(C_6F_5)_4(\mu\text{-}X)_2]$ (X = SCN or NCO; 0.094 mmol) and the corresponding neutral ligand (PPh_3 or $P(C_6H_4CH_3O\text{-}p)_3$; 0.22 mmol) in dichloromethane (15 ml) was stirred at room temperature for 30 min. The resulting solution was concentrated under reduced pressure to half the original volume. Addition of diethyl ether precipitated a yellow solid which was filtered off, washed with diethyl ether and air-dried.

4: Yield 79%. − $C_{55}H_{35}F_{10}NNiP_2S$ (1052.58): calcd. C 62.8, H 3.4, N 1.3, S 3.1; found C 62.9, H 3.4, N 1.5, S 3.2. − M.p. 190°C (dec.). − Λ_M = 91 S cm^2 mol^{-1}. − IR (Nujol): ν = 2102 cm^{-1} (CN str). − UV/Vis (acetone): λ_{max} [cm^{-1} × 10^{-3}] (ε) = 24.9 (868). − ^{19}F NMR ([D$_6$]acetone, $CFCl_3$): δ = −116.2 (m, 2 F$_o$), −117.7 (m, 2 F$_o$), −166.2 (t, 1 F$_p$, J_{pm} = 19.7 Hz), −166.9 (m, 1 F$_p$ + 2 F$_m$), −167.4 (m, 2 F$_m$). − ^{31}P NMR ([D$_6$]acetone, H_3PO_4): δ = 24.6, 23.1.

5: Yield 77%. − $C_{58}H_{41}F_{10}NNiO_3P_2S$ (1141.69): calcd. C 61.0, H 3.6, N 1.2, S 2.8; found C 61.3, H 3.4, N 1.4, S 2.9. − M.p. 171°C (dec.). − Λ_M = 94 S cm^2 mol^{-1}. − IR (Nujol): ν = 2106 cm^{-1} (CN str). − UV/Vis (acetone): λ_{max} [cm^{-1} × 10^{-3}] (ε) = 25.0 (931). − ^{19}F NMR ([D$_6$]acetone, $CFCl_3$): δ = −115.6 (m, 2 F$_o$), −116.9 (m, 2 F$_o$), −165.8 (t, 1 F$_p$, J_{pm} = 22.6 Hz), −166.4 (m, 1 F$_p$ + 2 F$_m$), −166.8 (m, 2 F$_m$). − ^{31}P NMR ([D$_6$]acetone, H_3PO_4): δ = 24.6, 19.5.

6: Yield 75%. − $C_{55}H_{35}F_{10}NNiOP_2$ (1036.51): calcd. C 63.7, H 3.4, N 1.4; found C 63.6, H 3.6, N 1.3. − M.p. 175°C (dec.). − Λ_M = 95 S cm^2 mol^{-1}. − IR (Nujol): ν = 2222 cm^{-1} (CN str). − UV/Vis (acetone): λ_{max} [cm^{-1} × 10^{-3}] (ε) = 24.2 (572). − ^{19}F NMR ([D$_6$]acetone, $CFCl_3$): δ = −115.6 (m, 2 F$_o$), −117.1 (m, 2 F$_o$), −167.1 (m, 2 F$_p$ + 2 F$_m$), −167.7 (m, 2 F$_m$). − ^{31}P NMR ([D$_6$]acetone, H_3PO_4): δ = 24.6, 22.7.

7: Yield 65%. − $C_{58}H_{41}F_{10}NNiO_4P_2$ (1126.59): calcd. C 61.8, H 3.7, N 1.2; found C 61.6, H 3.5, N 1.3. − M.p. 98°C (dec.). − Λ_M = 83 S cm^2 mol^{-1}. − IR (Nujol): ν = 2218 cm^{-1} (CN str). − UV/Vis (acetone): λ_{max} [cm^{-1} × 10^{-3}] (ε) = 24.5 (663). − ^{19}F NMR ([D$_6$]acetone, $CFCl_3$): δ = −115.6 (m, 2 F$_o$), −116.9 (m, 2 F$_o$), −167.1 (m, 2 F$_p$), −167.7 (m, 4 F$_m$). − ^{31}P NMR ([D$_6$]acetone, H_3PO_4): δ = 24.6, 18.9.

(PPh$_4$)$_2$[(C$_6$F$_5$)$_2$Ni(μ-SCN)$_2$Pd(C$_6$F$_5$)$_2$] (**9**): A solution of (**8**) (0.15 g, 0.126 mmol) and [Pd(C$_6$F$_5$)$_2$(PhCN)$_2$] (81.6 mg, 0.126 mmol) in dichloromethane (15 ml) was stirred at room temperature for 30 min. The resulting solution was concentrated under reduced pressure to half the original volume. Addition of hexane precipitated a yellow solid which was filtered off, washed with hexane and air-dried. The compound was recrystallized from dichloromethane/hexane. − Yield 84%. − $C_{74}H_{40}F_{20}N_2NiP_2PdS_2$ (1628.31): calcd. C 54.6, H 2.5, N 1.7, S 3.9; found C 54.3, H 2.2, N 1.7, S 3.8. − M.p. 221°C (dec.). − Λ_M = 197 S cm^2 mol^{-1}. − IR (Nujol): ν = 2144 cm^{-1} (CN str). − UV/Vis (acetone): λ_{max} [cm^{-1} × 10^{-3}] (ε) = 22.8 (731). − ^{19}F NMR ([D$_6$]acetone, $CFCl_3$): δ = −113.2 (d, 2 F$_o$, J_{om} = 29.6 Hz), −114.4 (m, 2 F$_o$), −114.8 (m, 2 F$_o$), −116.3 (m, 2 F$_o$), −164.2 (m, 2 F$_p$), −164.7 (t, 1 F$_{p,\,Jpm}$ = 19.2 Hz), −165.1 (t, 1 F$_p$, J_{pm} = 19.7 Hz), −165.7 (m, 1 F$_m$), −166.2 (m, 1 F$_m$), −166.7 (m, 1 F$_m$), −167.0 (m, 1 F$_m$). − ^{31}P NMR ([D$_6$]acetone, H_3PO_4): δ = 24.6.

[(C$_6$F$_5$)$_2$Ni(μ-SCN)$_2$Pd(dppe)] (**10**): A solution of [Pd(SCN)$_2$(dppe)] (0.134 g, 0.21 mmol) and [Ni(C$_6$F$_5$)$_2$(PhCN)$_2$] (0.129 g, 0.21 mmol) in dichloromethane (20 ml) was stirred at room temperature for 20 min. The resulting solution was concentrated under reduced pressure to half the original volume. Addition of diethyl ether precipitated a yellow solid which was filtered off, washed with diethyl ether and air-dried. The compound was recrystallized from dichloromethane/diethyl ether. − Yield 73%. − $C_{40}H_{24}F_{10}N_2NiP_2PdS_2$ (1013.82): calcd. C 47.4, H 2.4, N 2.8, S 6.3; found C 47.1, H 2.5, N 2.9, S 6.2. − M.p. 177°C (dec.). − Λ_M = 6 S cm^2 mol^{-1}. − IR (Nujol): ν = 2158 cm^{-1} (CN str). − UV/Vis (acetone): λ_{max} [cm^{-1} × 10^{-3}] (ε) = 29.7 (7564). − ^{19}F NMR ([D$_6$]acetone, $CFCl_3$): δ = −116.2 (m, 2 F$_o$), −117.6 (m, 2 F$_o$), −164.3 (t, 1 F$_p$, J = 19.7 Hz), −164.8 (t, 1 F$_p$, J = 19.7 Hz), −167.0 (m, 4 F$_m$). − ^{31}P NMR ([D$_6$]acetone, H_3PO_4): δ = 71.5 (br.).

[NBu$_4$]$_2$[(C$_6$F$_5$)$_2$Ni(μ-SCN)$_2$Pd(μ-SCN)$_2$Ni(C$_6$F$_5$)$_2$] (**11**): A solution of $[NBu_4]_2[Pd(SCN)_4]$ (0.130 g, 0.15 mmol) and [Ni(C$_6$F$_5$)$_2$(PhCN)$_2$] (0.2 g, 0.33 mmol) (molar ratio 1:2.2) in acetone (10 ml) was stirred at room temperature for 20 min. The re-

sulting solution was concentrated under reduced pressure to half the original volume. Addition of diethyl ether precipitated a red solid which was filtered off, washed with diethyl ether and air-dried. The compound was recrystallized from dichloromethane/diethyl ether. – Yield 54%. – $C_{60}H_{72}F_{20}N_6Ni_2PdS_4$ (1609.31): calcd. C 44.8, H 4.5, N 5.2, S 8.0; found C 45.1, H 4.7, N 5.4, S 7.7. – M.p. 180°C (dec.). – Λ_M = 164 S cm^2 mol^{-1}. – IR (Nujol): ν· = 2146 cm^{-1} (CN str). – UV/Vis (acetone): λ_{max} [cm^{-1} × 10^{-3}] (ε) = 29.7 (10320). – ^{19}F NMR ([D$_6$]acetone, $CFCl_3$): δ = −117.4 (m, 8 F$_o$), −164.9 (m, 4 F$_p$), −167.1 (m, 8 F$_m$).

[(dppe)M(μ-SAr)$_2$Ni(C$_6$F$_5$)$_2$] (**12–20**) (see Scheme 2): Complexes **12–20** were obtained by treating *cis*-[Ni(C$_6$F$_5$)$_2$(PhCN)$_2$] with [M(SAr)$_2$(dppe)] (molar ratio 1:1) in MeOH according to the following general method. To a MeOH (10 ml) solution of the *cis*-[Ni(C$_6$F$_5$)$_2$(PhCN)$_2$] (0.174 mmol) was added [M(SAr)$_2$(dppe)] (0.174 mmol), and the solution was stirred at room temperature for 30 min. It was concentrated under reduced pressure to ca. one fifth of the initial volume obtaining an orange or red precipitate, which was filtered off, washed with hexane and air-dried.

12: Yield 75%. – $C_{50}H_{34}F_{10}Ni_2P_2S_2$ (1068.27): calcd. C 56.2, H 3.2, S 6.0; found C 55.9, H 3.1, S 5.8. – M.p. 215°C (dec.). – ^{1}H NMR ([D$_6$]acetone, TMS): δ = 2.5 (d, 4 H, dppe), 6.7 (t, 4 H, Ph), 6.9 (t, 2 H, Ph), 7.3 (d, 4 H, Ph), 7.5 (m, 12 H, dppe), 7.9 (m,8 H, dppe). – ^{19}F NMR ([D$_6$]acetone, $CFCl_3$): δ = −115.2 (d, 4 F$_o$, J_{om} = 28.8 Hz), −165.3 (t, 2 F$_p$, J_{pm} = 19.7 Hz), −166.6 (m, 4 F$_m$). – ^{31}P NMR ([D$_6$]acetone, H_3PO_4): δ = 58.7.

13: Yield 68%. – $C_{50}H_{34}F_{10}NiP_2PdS_2$ (1116): calcd. C 53.8, H 3.1, S 5.8; found C 53.5, H 3.3, S 5.6. – M.p. 119°C (dec). – ^{1}H NMR ([D$_6$]acetone, TMS): δ = 2.6 (d, 4 H, dppe), 6.7 (t, 4 H, Ph), 6.9 (t, 2 H, Ph), 7.3 (d, 4 H, Ph), 7.5 (m, 12 H, dppe), 7.9 (m, 8 H, dppe). –^{19}F NMR ([D$_6$]acetone, $CFCl_3$): δ = −115.3 (d, 4 F$_o$, J_{om} = 28.3), −165.6 (t, 2 F$_p$, J_{pm} = 19.8), −166.8 (m, 4 F$_m$). – ^{31}P NMR ([D$_6$]acetone, H_3PO_4): δ = 58.6.

14: Yield 65%. – $C_{50}H_{34}F_{10}NiP_2PtS_2$ (1204.66): calcd. C 49.9, H 2.8, S 5.3; found C 49.8, H 3.0, S 5.2. – M.p. 235°C (dec.). – ^{1}H NMR ([D$_6$]acetone, TMS): δ = 2.7 (d, H, dppe), 6.6 (t, 4 H, Ph), 6.8 (t, 2 H, Ph), 7.2 (d, 4 H, Ph), 7.5 (m, 12 H, dppe), 7.8 (m, 8 H, dppe). – ^{19}F NMR ([D$_6$]acetone, $CFCl_3$): δ = −116.9 (d, 4 F$_o$, J_{om} = 24.5 Hz), −164.4 (m, 2 F$_p$), −166.2 (m, 2 F$_m$). – ^{31}P NMR ([D$_6$]acetone, H_3PO_4): δ = 43.3 [J(PPt) = 3076.5 Hz].

15: Yield 73%. – $C_{52}H_{38}F_{10}Ni_2P_2S_2$ (1096.32): calcd. C 57.0, H 3.5, S 5.9; found C 56.7, H 3.4, S 5.7. – M.p. 213°C (dec.). – ^{1}H NMR ([D$_6$]acetone, TMS): δ = 2.1 (s, 6 H, C$_6$H$_4$Me-*p*), 2.4 (d, 4 H, dppe), 6.5 (d, 4 H, C$_6$H$_4$Me-*p*), 7.2 (d, 4 H, C$_6$H$_4$Me-*p*), 7.5 (m, 8 H, dppe). –^{19}F NMR ([D$_6$]acetone, $CFCl_3$): δ = −115.4 (d, 4 F$_o$, J_{om} = 28.8 Hz), −166.0 (t, 2 F$_p$, J_{pm} = 19.7 Hz), −167.1 (m, 4 F$_m$). – ^{31}P NMR ([D$_6$]acetone, H_3PO_4): δ = 57.9.

16: Yield 89%. – $C_{52}H_{38}F_{10}NiP_2PdS_2$ (1144.05): calcd. C 54.6, H 3.4, S 5.6; found C 54.5, H 3.3, S 5.5. – M.p. 224°C (dec.). – ^{1}H NMR ($CDCl_3$, TMS): δ = 2.1 (s, 6 H, C$_6$H$_4$Me-*p*), 2.3 (d, 4 H, dppe), 6.4 (d, 4 H, C$_6$H$_4$Me-*p*), 7.2 (d, 4 H, C$_6$H$_4$Me-*p*), 7.4 (m, 12 H, dppe), 7.6 (m, 8 H, dppe). – ^{19}F NMR ($CDCl_3$, $CFCl_3$): δ = −115.6 (d, 4 F$_o$, J_{om} = 28.8 Hz), −166.2 (t, 2 F$_p$, J_{pm} = 20.0 Hz), −167.3 (m, 4 F$_m$). – ^{31}P NMR ($CDCl_3$, H_3PO_4): δ = 57.8.

17: Yield 81%. – $C_{52}H_{38}F_{10}NiP_2PtS_2$ (1232.71): calcd. C 50.7, H 3.1, S 5.2; found C 50.8, H 3.3, S 5.1. – M.p. 205°C (dec.). – ^{1}H NMR ($CDCl_3$, TMS): δ = 1.5 (s, 6 H, C$_6$H$_4$Me-*p*), 2.2 (d, 4 H, dppe), 6.4 (d, 4 H, C$_6$H$_4$Me-*p*), 7.1 (d, 4 H, C$_6$H$_4$Me-*p*), 7.4 (m, 12 H, dppe), 7.6 (m, 8 H, dppe). – ^{19}F NMR ($CDCl_3$, $CFCl_3$): δ = −116.9 (d, 4 F$_o$, J_{om} = 29.1 Hz), −164.6 (t, 2 F$_p$, J_{pm} = 19.7 Hz), −166.3 (m, 4 F$_m$). – ^{31}P NMR ($CDCl_3$, H_3PO_4): δ = 46.3 [J(PPt) = 2899.2 Hz].

18: Yield 88%. – $C_{50}H_{32}F_{10}N_2Ni_2O_4P_2S_2$ (1158.27): calcd. C 51.9, H 2.8, N 2.4, S 5.5; found C 51.7, H 3.1, N 2.6, S 5.4. – M.p. 184°C (dec.). – ^{1}H NMR ($CDCl_3$, TMS): δ = 2.1 (d, 4 H, dppe), 7.4 (m, 20 H, dppe + C$_6$H$_4$NO$_2$-*p*), 7.8 (m, 8 H, dppe). – ^{19}F NMR ($CDCl_3$, $CFCl_3$): δ = −116.9 (d, 4 F$_o$, J_{om} = 27.6 Hz), −162.5 (t, 2 F$_p$, J_{pm} = 19.7 Hz), −165.0 (m, 4 F$_m$). – ^{31}P NMR ($CDCl_3$, H_3PO_4): δ = 59.0.

19: Yield 70%. – $C_{50}H_{32}F_{10}N_2NiO_4P_2PdS_2$ (1205.99): calcd. C 49.8, H 2.7, N 2.3, S 5.3; found C 49.9, H 2.5, N 2.4, S 5.1. – M.p. 180°C (dec.). – ^{1}H NMR ($CDCl_3$, TMS): δ = 2.4 (d, 4 H, dppe), 7.4 (m, 28 H, dppe + C$_6$H$_4$NO$_2$-*p*). – ^{19}F NMR ($CDCl_3$, $CFCl_3$): δ = −117.1 (d, 4 F$_o$, J_{om} = 27.3 Hz), −162.7 (t, 2 F$_p$, J_{pm} = 19.7 Hz), −165.1 (m, 4 F$_m$). – ^{31}P NMR ($CDCl_3$, H_3PO_4): δ = 58.9.

Determination of the X-ray Crystal Structure of **13**: A single crystal of complex **13** (approximate dimensions 0.42 × 0.35 × 0.20 mm) was mounted on an Enraf-Nonius CAD4 diffractometer equipped with a graphite monochromator for Mo-K_α radiation. The crystallographic data are shown in Table 2. Accurate cell parameters were determined by least-squares fitting of 25 high-angle reflections. The scan method was ω-2Θ with the range of *hkl* (−16 ≤ h ≤ 16, −19 ≤ k ≤ 19, 0 ≤ l ≤ 22) corresponding to $2\Theta_{max}$ = 60.88°. Empirical ψ-scan mode absorption was made. The structure was solved by heavy-atom methods SHELXS-86[36] and refined by full-matrix least-squares techniques using anisotropic thermal parameters for non-H atoms. Hydrogen atoms were introduced in calculated positions and were refined during the last stages of the refinement. The final R factor was 0.0539 [R_w = 0.0984, where w = $1/\sigma^2(F_o^2)$ + (0.0465 P)^2 and P = (F_o^2 + 2 F_c^2)/3] over 5879 ob-

Received March 19, 1998

Keywords: Terpyridine / Stille coupling reaction / Microwave

The new ligands 4′-nitro-2,2′:6′,2′′-terpyridine and 4′-amino-2,2′:6′,2′′-terpyridine and their homoleptic and heteroleptic iron(II) and ruthenium(II) complexes have been prepared and the electrochemistry of the complexes has been investigated.

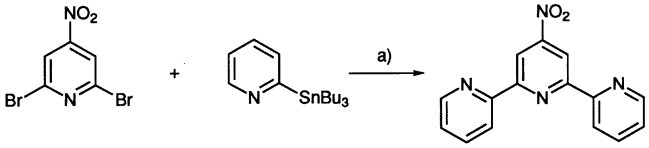
2,2′:6′,2′′-Terpyridine (tpy) is a versatile ligand for complex formation with transition metals. Particular interest rests in 4′-substituted tpy ligands and many substituents can be directly inserted by the Kröhnke methodology[1]. Some of these substituents may then be further derivatised. Some functionalised 2,2′:6′,2′′-terpyridines, such as 5,5′′-dimethyl-4′-hydroxy-2,2′:6′,2′′-terpyridine (Me_2-HO-tpy)[2], 4′-hydroxy-2,2′:6′,2′′-terpyridine (HO-tpy)[3] and 4′-chloro-2,2′:6′,2′′-terpyridine (Cl-tpy),[3] in which the functional groups are directly linked to C-4′, have also been reported. The placing of electron-withdrawing or electron-donating substituents in the 4′-position of 2,2′:6′,2′′-terpyridine alters the electronic properties of the whole ligand. A nitro substituent is electron-withdrawing with respect to hydrogen, whilst the amino group is electron-donating.

To the best of my knowledge, only one synthesis of a nitrogen substituent directly attached to C-4′ of tpy, 4′-dimethylamino-2,2′:6′,2′′-terpyridine (Me_2N-tpy), has been reported[4]. Dimethylamine and Cl-tpy were allowed to react in the presence of iron(II) salts to give the iron(II) complex of Me_2N-tpy, which was then oxidised with hydrogen peroxide under basic conditions to yield the free ligand Me_2N-tpy. In this communication the synthesis of 4′-nitro-2,2′:6′,2′′-terpyridine (O_2N-tpy) and 4′-amino-2,2′:6′,2′′-terpyridine (H_2N-tpy) is reported. These compounds are precursors for new ligands and complexes.

Although electrophilic reactions on pyridine rings do not normally occur, oxidation of the ring nitrogen atom to form pyridine *N*-oxide facilitates electrophilic attack at C-4 of the pyridine ring. By utilising standard methods, commercially available 2,6-dibromopyridine was converted to 2,6-dibromopyridine *N*-oxide, which was then treated with nitric acid in sulphuric acid to give 2,6-dibromo-4-nitropyridine *N*-oxide[5]. Subsequent deoxygenation with phosphorus trichloride in chloroform produced 2,6-dibromo-4-nitropyridine (**1**) in 43% overall yield.

Compound **1** was then used in a Stille coupling reaction[6] with 2 equivalents of tributyl(pyridin-2-yl)stannane (**2**)[7] in the presence of 1 mol-% of $Pd(PPh_3)_4$ to give O_2N-tpy (**3**) in 50% yield as a pale yellow microcrystalline solid (Scheme 1).

Scheme 1. a) 1 mol-% of $Pd(PPh_3)_4$, toluene, 110°C, 16 h, 50%



1 2 3

This is the first example of a tpy with such a strong electron-withdrawing group directly linked to C-4′. The withdrawing effect of this group can be observed in the deshielding of protons at C-3′ in the ^{1}H-NMR spectrum, and this is consistent with the known σ values[8]. The shifts of the signals of protons at C-3′ of this new tpy may be compared with two related ligands with electron-withdrawing groups at C-4′ (Table 1).

Table 1. Shifts of protons at C-3′ of tpy in $CDCl_3$ solution

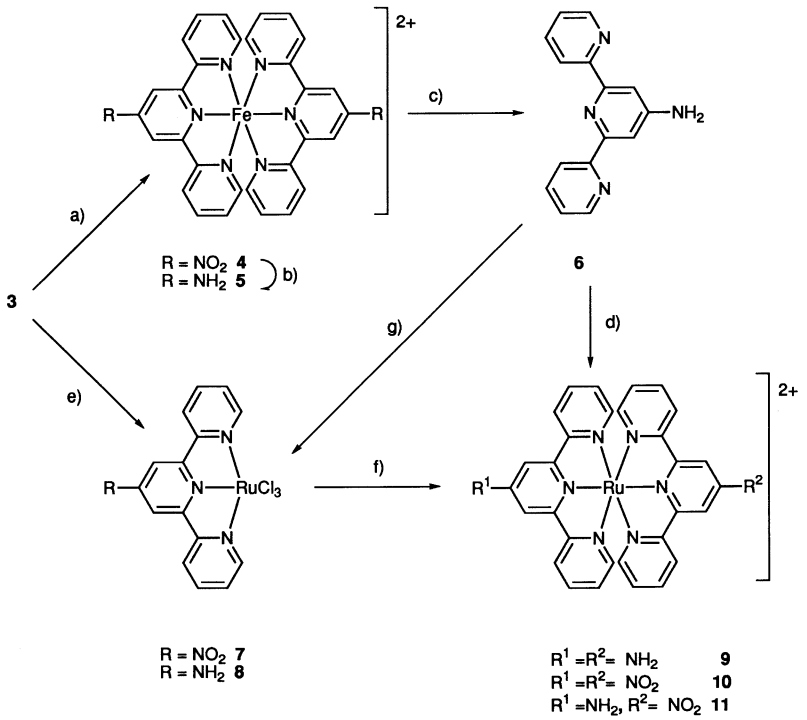
tpy	σ	δ	ref.
Cl-tpy	0.24	8.48	[3]
$MeSO_2$-tpy	0.73	8.97	[9]
O_2N-tpy	0.81	9.16	

The homoleptic complex $[Fe(O_2N\text{-tpy})_2][PF_6]_2$ (**4**) (95%) was obtained as a blue microcrystalline solid from the reaction of **3** with $FeCl_2 \cdot 4\ H_2O$ in ethanol, followed by precipitation with $[NH_4][PF_6]$ (Scheme 2).

All spectroscopic data (^{1}H NMR, IR, UV, MS), as well as elemental analysis, confirmed the formation of this homoleptic iron(II) complex. Complex **4** exhibits the expected MLCT absorption at 605 nm in the electronic spectrum and, as a consequence of the strong electron-withdrawing effect of the nitro group, the compound appears blue.

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1434–1948/98/0909–1205 $ 17.50+.50/0

Scheme 2. a) $FeCl_2 \cdot 4\ H_2O$, ethanol, 25°C, 30 min, 95%. – b) Fe/HCl, ethanol, 78°C, 30 min, 96%. – c) **5**, NaOH, H_2O_2, 25°C, 70%. – d) $RuCl_3 \cdot 3\ H_2O$, ethylene glycol, microwave, 30 min, 95%. – e) $RuCl_3 \cdot 3\ H_2O$, ethanol, 78°C, 1 h, 95%. – f) ethanol, *N*-ethylmorpholine, 1 h; **7** → **10** (10%); **8** → **11** (20%). – g) as (e), 95%



When coordinated, ligand **3** may be reduced with metallic iron and hydrochloric acid in ethanol. Reduction of the blue iron(II) complex **4** gave the purple amino complex **5** in 96% yield. All data are consistent with the assigned structure. This complex exhibits an MLCT absorption at 566 nm in the electronic spectrum due to the presence of the electron-releasing group.

The iron(II) complex **5** was cleaved with hydrogen peroxide under basic conditions to give H_2N-tpy (**6**) as yellow monoclinic crystals in 70% yield. All data are consistent with the proposed structure of this free tpy ligand. Ligand **6** was also prepared directly, in 90% yield, by selective reduction of the nitro group of **3** in refluxing ethanol over palladium on charcoal in the presence of hydrazine hydrate[10].

Ruthenium(II) complexes of tpy ligands have always been of interest to chemists due to their photochemical and photophysical properties[11][12]. The formation of kinetically inert ruthenium(II) complexes of these ligands, i.e. $[Ru(H_2N\text{-}tpy)_2][PF_6]_2$ (**9**), $[Ru(O_2N\text{-}tpy)_2][PF_6]_2$ (**10**), and $[(H_2N\text{-}tpy)Ru(O_2N\text{-}tpy)][PF_6]_2$ (**11**), was also investigated. The synthesis of the three ruthenium(II) complexes was carried out in two stages to allow for the synthesis of heteroleptic species[4].

Alternatively, the homoleptic complexes **9** and **10** could also be obtained by direct reaction of the ligands **3** and **6** with $RuCl_3 \cdot 3\ H_2O$ in ethylene glycol in a microwave oven for 10 min. The resulting ruthenium(II) complexes were precipitated as their hexafluorophosphate salts. While the amino complex **9** can be prepared without any side reactions, some reduction of the nitro groups of **3** was observed in this protic solvent.

In the ^{1}H-NMR spectra of ruthenium(II) complexes **9**, **10**, and **11** in CD_3CN solution, the chemical shifts of the 3′-H protons are of interest. These protons were observed as a singlet [$\delta = 7.91$ (**9**), $\delta = 9.47$ (**10**)] in the homoleptic complexes. The protons of the amino groups in **9** were observed as broad singlets at $\delta = 5.84$. The situation, however, changed in the heteroleptic complex **11**. While the signals of the 3′-H protons of the nitro-substituted ligand were shifted to higher field and observed at $\delta = 9.40$, those of the 3′-H protons of the amino-substituted ligand were shifted to lower field, appearing at $\delta = 7.97$. More dramatically, the signals of the amino protons were shifted to lower field in this electron-donating/accepting complex and were observed at $\delta = 6.06$.

All five complexes are electrochemically active in acetonitrile solution, exhibiting waves corresponding to the iron(II)/iron(III) or ruthenium(II)/ruthenium(III) processes. As expected, the introduction of the electron-releasing amino and the strongly electron-withdrawing nitro substituents has a dramatic influence on these redox processes. The iron(II) complex **5** has a potential of 0.356 V (versus ferrocene/ferrocenium) while **4** exhibits a potential of 0.963 V, shifted by about 60 mV with respect to $[Fe(MeSO_2\text{-}tpy)_2][PF_6]_2$ ($E^0 = 0.904$ V). This effect is in accord with the strength of the electron-withdrawing nitro group (cf.

Table 1). This means that this ligand is the strongest electron-withdrawing tpy ligand yet synthesised. The potential difference between the electron-acceptor and electron-donor iron complexes **4** and **5**, respectively, is 0.607 V.

The homoleptic ruthenium(II) complex **9** showed a potential of 0.474 V, which is shifted by 32 mV with respect to $[Ru(Me_2N\text{-}tpy)_2][PF_6]_2$[4]. This is consistent with the electron-donating effect of the two methyl groups in the latter complex. The potential of the homoleptic complex **10** was 1.114 V in comparison to $[Ru(MeSO_2\text{-}tpy)_2][PF_6]_2$ (E^0 = 1.10 V)[4]. In the donor/acceptor complex **11** the potential was shifted by 266 mV and 374 mV with respect to the ruthenium(II) complexes **9** and **10**, respectively, and was observed at 0.740 V. The potential difference between the electron-donor and electron-acceptor complexes **9** and **10** is 0.640 V.

In conclusion, a new method has been established for the synthesis of novel 4′-nitro-2,2′:6′,2′′-terpyridine and 4′-amino-2,2′:6′,2′′-terpyridine, which are precursors for new heterocycles and oligopyridines. These new tpy ligands may be incorporated in metal complexes, which are under current investigation.

I would like to thank Prof. *Edwin C. Constable* for his generous support and Dr. *Carol Pohl-Ferry* for critical reading of the manuscript. I should also like to thank the *Schweizerischer Nationalfonds zur Förderung der wissenschaftlichen Forschung* and the *University of Basel* for support.

Experimental Section

Palladium-Catalysed Coupling Reaction. − General Procedure: Compound **1** (1 mol) or **2** (2 mol) and $Pd(PPh_3)_4$ (1 mol-%) were heated under nitrogen in 50 ml of toluene for 16 h. Upon cooling to room temperature 10 ml of saturated ammonium chloride was added and the organic phase separated. The aqueous phase was extracted with toluene (3 × 20 ml). The combined organic phases were dried ($MgSO_4$) and the solvent was removed. Concentrated hydrochloric acid (30 ml) was added to the residue and this was extracted with dichloromethane (3 × 30 ml). The aqueous phase was cautiously neutralised by the addition of solid sodium hydroxide. The ligand **3** was then filtered off and purified by chromatography on silica gel with dichloromethane to give 50% yield.

3: m.p. 177°C. − IR (KBr): $\tilde{\nu}$ = 1531, 1359 cm^{-1}. − UV (CH_3CN): λ_{max} = 279, 345 nm; λ_{min} = 305 nm. − ^1H NMR ($CDCl_3$): δ = 9.16 (s, 3′-H, 2 H), 8.76 (d, 6-H, *J* = 7.80 Hz, 2 H), 8.64 (d, 3-H, *J* = 7.80 Hz, 2 H), 7.91 (ddd, 4-H, *J* = 8.30, 7.80, 1.95 Hz, 2 H), 7.42 (ddd, 5-H, *J* = 8.30, 7.80, 1.95 Hz, 2 H). − ^{13}C NMR ($CDCl_3$): δ = 158.44, 156.33, 154.05, 149.47, 136.97, 124.77, 121.33, 113.33. − MS (Maldi-TOF); *m*/*z*: 278. − $C_{11}H_{10}N_4O_2$ (278.273): calcd. 6: m.p. 179−180°C. − IR (KBr): $\tilde{\nu}$ = 3226 cm^{-1}. − ^1H NMR ($CDCl_3$): δ = 8.67 (d, 6-H, *J* = 7.80 Hz, 2 H), 8.60 (d, 3-H, *J* = 7.80 Hz, 2 H), 7.84 (ddd, 4-H, *J* = 8.30, 7.80, 1.95 Hz, 2 H), 7.75 (s, 3′-H, 2 H), 7.32 (ddd, 5-H, *J* = 8.30, 7.80, 1.95 Hz, 2 H), 4.33 (br. s, NH_2, 2 H). − ^{13}C NMR ($CDCl_3$): δ = 156.52, 156.23, 154.55, 148.89, 136.76, 123.61, 121.30, 106.77. − MS (Maldi-TOF); *m*/*z*: 248. − $C_{15}H_{12}N_4$ (248.21): calcd. C 72.56, H 4.87, N 22.57; found C 72.01, H 4.93, N 22.55.

Synthesis of the Homoleptic Ruthenium(II) Complexes in a Microwave Oven. − General Procedure: A suspension of tpy **3** or **6** (1 mol) and $RuCl_3 \cdot 3\ H_2O$ (0.5 mol) in ethylene glycol (5 ml) was heated in a microwave oven at 600 W during 10 min. In each case the red solution was then poured into water (40 ml). Upon adding $[NH_4][PF_6]$ the desired complexes were isolated and purified by chromatography on silica gel followed by recrystallisation by diffusion of diethyl ether into the acetonitrile solution.

9: ^1H NMR (CD_3CN): δ = 9.47 (s, 3′-H, 4 H), 8.73 (d, 3-H, *J* = 7.80 Hz, 4 H), 7.98 (ddd, 4-H, *J* = 8.30, 7.80, 1.95 Hz, 4 H), 7.37 (d, 6-H, *J* = 7.80 Hz, 4 H), 7.24 (ddd, 5-H, *J* = 8.30, 7.80, 1.95 Hz, 4 H). − MS (Maldi-TOF); *m*/*z*: 657.

10: ^1H NMR (CD_3CN): δ = 8.24 (d, 3-H, *J* = 7.80 Hz, 4 H), 7.91 (s, 3′-H, 4 H), 7.83 (ddd, 4-H, *J* = 8.30, 7.80, 1.95 Hz, 4 H), 7.40 (d, 6-H, *J* = 7.80 Hz, 4 H), 7.11 (ddd, 5-H, *J* = 8.30, 7.80, 1.95 Hz, 4 H), 5.84 (br. s, NH_2, 4 H). − MS (Maldi-TOF); *m*/*z*: 627.

Synthesis of the Heteroleptic Ruthenium(II) Complex: Compounds **3** and **6** (1 mol) were hated separately with $RuCl_3 \cdot 3\ H_2O$ (1 mol) in ethanol at reflux during 1 h. The insoluble dark solids **7** and **8** were filtered off in yields of 95%. These salts (1 mol) were treated with 1 mol of tpy **6** and **3**, respectively, in ethanol for 1 h to yield complex **11**. This compound was purified by the addition of water (50 ml) as described above.

Alternatively, the reaction of the salts **7** and **8** with tpy ligands **3** and **6**, respectively, gave the homoleptic complexes **9** and **10** under the same conditions.

Keywords: Beryllium(II) hydrolysis / Beryllium(II) complexes / Carboxylate ligands / Thermodynamics of complex formation / ^{9}Be-NMR spectra

The hydrolysis of beryllium(II) and its complexation by oxalate, malonate, and succinate in 0.5 mol dm^{-3} $NaClO_4$ aqueous solution at 298 K has been studied by means of potentiometric (pH-metric), microcalorimetric, and multinuclear NMR-spectroscopic measurements. The protonation properties of the three ligands have also been investigated by potentiometry and microcalorimetry under the same experimental conditions. Thermodynamic results are consistent with a previously proposed chemical model for beryllium(II) hydrolysis, involving the species $[Be_2OH]^{3+}$, $[Be_3(OH)_3]^{3+}$, $[Be_5(OH)_6]^{4+}$, $[Be_6(OH)_8]^{4+}$, and $Be(OH)_2$. Complex formation of beryllium(II) with the dicarboxylate ligands is invariably promoted by favourable entropic contributions ($\Delta S^\circ > 0$), while the enthalpic terms are always unfavourable ($\Delta H^\circ > 0$). Malonate forms by far the most stable complexes owing to a more favourable (less endothermic) enthalpic contribution. These data reflect the fitting of the "bites" of the ligands with the stereochemically required tetrahedral coordination geometry about the metal ion, as well as the ligand preorganization.

Introduction

Beryllium is the most toxic non-radioactive element[1][2]. However, in spite of its particular toxicity, which to a large extent prevents the expansion of its applications, there is an increasing demand for beryllium, principally associated with the major use of this light metal in the nuclear, aerospace, and electronics industries[1][2][3]. The most notable biochemical effects resulting from beryllium contamination in mammalians include permanent cell modification, alteration of DNA replication, interference in enzymatic reactions, and impairment of cell division[1][2][3]. Nevertheless, there is not yet a clear rationalization of the relationships between beryllium toxicity and the chemical species formed in biological and environmental systems, principally because this depends very much on the particular tissue or cell type exposed to contamination, and because the actual speciation of the poisoned systems is still rather an obscure area.

The solution chemistry of Be^{2+} coordination compounds has been the subject of a limited number of studies, which have been included in two recent chemical databases[4]. The paucity of data is most likely attributable to the high toxicity exhibited by the metal ion and its complexes. In several cases, the results obtained appear to be inconsistent because of the different experimental conditions employed and, where considered, the disparate chemical models proposed for Be^{2+} hydrolysis[4].

Recently, some of us commenced a re-examination of Be^{2+} hydrolysis and Be^{2+} interaction with naturally occurring ligands by means of pH-metric measurements and NMR spectroscopy[5][6][7][8]. In one of these studies, which was concerned with the determination of equilibrium constants for the coordination of oxalate and malonate anions[8], a rational approach to the synthesis of beryllium complexes in water was also developed, leading to the isolation of crystalline $K_3[Be_3(OH)_3(oxalate)_3]\cdot 3\ H_2O$ and $K_3[Be_3(OH)_3(malonate)_3]\cdot 6\ H_2O$ and, furthermore, to the determination of the crystal structure of the latter compound.

In the present paper, we complete a first set of thermodynamic data for the coordination chemistry of beryllium

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1434–1948/98/0909–1209 $ 17.50+.50/0

ion with dicarboxylate ligands in aqueous solution, integrating the previously determined equilibrium constants for oxalate and malonate complexes[8] with new stability data for succinate and the enthalpy changes determined microcalorimetrically for the formation of beryllium complexes with the three ligands. Naturally, the hydrolysis of Be^{2+} and the protonation of the ligands have also been the subject of microcalorimetric investigations.

Results and Discussion

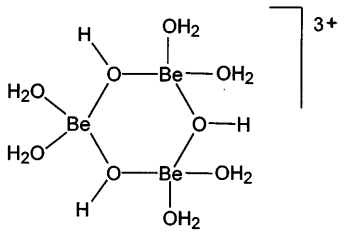
Be^{2+} Hydrolysis

The microcalorimetric determination of the complexation enthalpies of beryllium(II) in aqueous solution necessarily requires knowledge of the enthalpy changes associated with formation of the species produced upon Be^{2+} hydrolysis. Hence, the complexation experiments were preceded by a calorimetric study of beryllium(II) hydrolysis.

The $[Be(H_2O)_4]^{2+}$ cation exists only in very acidic solutions. In less acidic media, several polynuclear hydrolytic species are formed: in the most recent investigations (performed in 3.0 mol dm^{-3} $NaClO_4$[9] and in 0.5 mol dm^{-3} $NaClO_4$[6]) the species $[Be(OH)_2]$, $[Be_2OH]^{3+}$, $[Be_3(OH)_3]^{3+}$, $[Be_5(OH)_6]^{4+}$, and $[Be_6(OH)_8]^{4+}$ were identified, with the $[Be_3(OH)_3]^{3+}$ cation predominating over almost all of the pH range up to the precipitation of $Be(OH)_2$, which takes place at pH > 5. In solution, tetracoordination of Be^{2+} is preserved by coordinated water molecules, and tetrahedral arrangements are also to be expected for the species formed upon hydrolysis. Tentative structures for these polynuclear hydrolytic species have been suggested previously[9]; in particular, a cyclic structure for $[Be_3(OH)_3(H_2O)_6]^{3+}$, already indicated by a ^{1}H-NMR study[10], has been corroborated by a recent X-ray investigation[11]. The cyclic arrangement of this trimeric unit, where water molecules are replaced by bidentate ligands, has also been found in some crystalline complexes[8][12][13].

The equilibrium model and the values of the equilibrium constants for the hydrolysis of beryllium(II) were taken from a previous work[6]. The species formed in appreciable amounts in 0.5 mol dm^{-3} $NaClO_4$ solution at 298 K and the relevant thermodynamic data are listed in Table 1. In spite of various experimental modifications, it was not possible to obtain appreciable formation of the soluble species $[Be(OH)_2]$ in the microcalorimetric experiments. Therefore, the corresponding formation enthalpy was not determined.

Scheme 1



The enthalpy changes determined in the present study for $[Be_2OH]^{3+}$, $[Be_3(OH)_3]^{3+}$, and $[Be_6(OH)_8]^{4+}$ are in good agreement with those quoted in previous reports[14], while no reference values could be found in the literature for $[Be_5(OH)_6]^{4+}$[4].

It is worthy to note that the formation of these species is promoted by both favourable enthalpic and entropic contributions. The thermodynamic data reported in Table 1 can be interpreted in terms of metal-to-OH^- bonding interactions and solvation/desolvation equilibria. The reaction between Be^{2+} and OH^--solvated ions gives rise to considerable charge neutralization, resulting in the release of water molecules from the interacting species. This desolvation process is accompanied by an entropy gain, due to the increasing number of species, and by an enthalpy loss, owing to the cleavage of $Be^{2+}-OH_2$ bonds. This entropy gain seems to be the main contribution to the favourable entropic terms observed in the formation of the hydrolytic species, while the favourable formation enthalpies are most likely attributable to contributions deriving from strong covalent bonding interactions between Be^{2+} and OH^- ions, which are only partly cancelled out by the desolvation enthalpy loss.

The balance of these opposing contributions leads to almost constant increments per OH^- group in the enthalpic and entropic terms ($-\Delta H^\circ$ = 31 ± 4 kJ mol^{-1}, ΔS° = 97 ± 10 J K^{-1} mol^{-1}) for the formation of the hydrolytic species, which is reflected by the almost steady increase of the species stability ($-\Delta G^\circ$) with the number of bonded OH^- groups (Figure 1).

Protonation of the Ligands

Table 2 reports the thermodynamic functions for the protonation of the three ligands investigated. There is a good

general agreement with previously reported values[4], in spite of the rather different conditions of temperature and/or ionic strength used in the various investigations. The well-known increase in basicity observed in the series oxalate < malonate < succinate, as a consequence of the increasing length of the aliphatic chain, appears to be accompanied by a corresponding increase of the enthalpic contribution, while the entropic terms do not show any particularly evident trend.

Complex Formation

The thermodynamic parameters for the complexation of Be^{2+} by oxalate, malonate, and succinate are listed in Table 3.

In a previous paper, dealing with the determination of the stability constants of beryllium(II) complexes with oxalate and malonate[8] under the same experimental conditions as in the present study, it was noted that malonate complexes are significantly more stable than their oxalate counterparts. This enhanced stability can be ascribed to the formation of 6-membered chelate rings in the malonate complexes, which, compared to the 5-membered chelate rings formed by oxalate, produce less distortion in the preferred tetrahedral coordination geometry around the beryllium ion. As a matter of fact, in the molecular structures of the complexes $[Be(malonate)_2]^{2-}$[15], $[Be_3(OH)_3(malonate)_3]^{3-}$[8], $[Be(salicylate)_2]^{2-}$[16], and $[Be(acac)_2]$[17], which all feature 6-membered chelate rings, the O−Be−O bite angles imposed by the ligands range between 104.3(7) and 109.3(2)°, comparing well with the angles in an ideal tetrahedron (109.5°), while the corresponding bite angles in the 5-membered chelate rings formed by oxalate in the crystal structure of $[Be(oxalate)_2]^{2-}$ [99.6(2) and 99.7(2)°][18] deviate considerably from this value. More recently, it has been shown that the bite angles [109.1(1), 110(1)°] in the unique example of 7-membered chelate rings seen in the crystal structure of $[Be(o\text{-phthalate})_2]^{2-}$ are also very similar to the ideal tetrahedral angle, with the Be−O distances falling within the range exhibited by related compounds, and the phthalate anion not showing any structural anomalies[19]. Furthermore, in an earlier paper, it was noted that phthalate and oxalate have comparable abilities in forming [BeL] and $[BeL_2]^{2-}$ complexes[20]. On the other hand, the complexes formed by Be^{2+} with succinate, which can in principle involve 7-membered chelate rings, are largely less stable than the corresponding species formed with malonate and oxalate (Table 3), although the difference in stability between the [BeL] complexes of oxalate and succinate is not as large as in the case of the $[BeL_2]$ and $[Be_3(OH)_3L]^+$ species. Probably as a result of this reduced stability, in the case of succinate the $[Be_3(OH)_3L_3]^{3-}$ (L = dicarboxylate ligand)

[a] Values in parentheses are standard deviations in the last significant figure. − [b] Values taken from ref.[8].

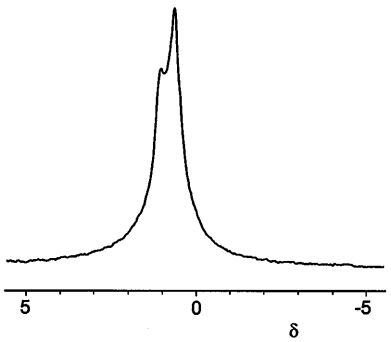
complex is not formed in appreciable amounts, at least under our experimental conditions, and its presence was not detected by means of the techniques employed in this study. Conversely, in a previous paper[21], the stability constant of this species was reported, together with that for the formation of the complex $[Be_3(OH)_3(HL)]^{2+}$ (L = succinate), containing the monoprotonated form of the ligand. In view of this report, we performed some experimental work aimed at identifying these two species in our systems, but no evidence of their formation was obtained.

Considering the low stability of the Be^{2+} complexes with succinate, a doubt arose concerning the possible monodentate coordination of the dicarboxylate anion. Nevertheless, this type of coordination should, in principle, favour the formation of complexes with the monoprotonated form of the ligand, although as mentioned above, such complexes were not detected in our experiments. In order to assess the ability of dicarboxylate ligands to bind Be^{2+} through a single carboxylate group, we also investigated the Be^{2+}/acetate system by both potentiometric and NMR techniques. The results indicated that, at least under our experimental conditions, the formation of acetate complexes is not appreciable. As a matter of fact, the ^{9}Be-NMR spectra of aqueous solutions of the system $BeSO_4/CH_3COOH$ (molar ratio 1:4) at various pH values fully resemble those of $BeSO_4$[22], indicating that acetate does not significantly coordinate the Be^{2+} ion.

On the basis of this evidence, it seems reasonable to assume that, in accordance with the behaviour of oxalate and malonate, succinate also acts as bidentate ligand towards Be^{2+}, and consequently its complexes can be formulated as Be(succinate)$(H_2O)_2$, $[Be(succinate)_2]^{2-}$, and $[Be_3(OH)_3$-(succinate)$(H_2O)_4]^{+}$, where water molecules preserve the Be^{2+} tetrahedral coordination geometry.

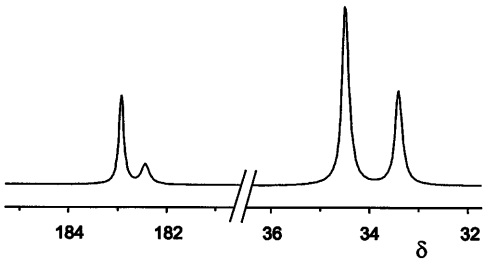
Evidence of a weak coordination of Be^{2+} by succinate comes from ^{9}Be-NMR spectra. Indeed, the ^{9}Be spectra of aqueous solutions containing $BeSO_4$ and succinic acid in a molar ratio of 1:2 in the pH range of 4−6, before the occurrence of $Be(OH)_2$ precipitation, show a signal at δ = 1.05 overlapping the broad resonance due to $[Be_3(OH)_3(H_2O)_6]^{3+}$ at δ = 0.7 (Figure 2). The new resonance must be attributed to a succinate−beryllium complex, probably the [Be(succinate)$(H_2O)_2$] species. Accordingly, the corresponding $^{13}C\{^{1}H\}$ spectrum shows in both the CH_2 and COO regions a signal due to the uncoordinated ligand (these bands have been assigned by comparison with the spectra of free succinic acid under the same pH conditions) and a less intense resonance attributable to coordinated succinate (Figure 3).

Figure 2. $^{9}Be\{^{1}H\}$-NMR spectrum of an aqueous solution containing 0.2 mol dm^{-3} $BeSO_4$ and 0.4 mol dm^{-3} succinate at pH = 5.90



Therefore, assuming the bidentate coordination of succinate, in the absence of direct structural information on Be^{2+} derivatives with this ligand, it seems reasonable to assume that no special strain is accumulated in the 7-membered chelate rings of such complexes compared to the analogous chelate rings in $[Be(o\text{-phthalate})_2]^{2-}$. The principal reason for the lower stability of the succinate complexes might have its origins in the greater flexibility of this rather long ligand, which necessitates a considerable organization to achieve the coordinative conformation. Similar structural changes

Figure 3. $^{13}C\{^1H\}$-NMR spectrum of an aqueous solution containing 0.2 mol dm^{-3} $BeSO_4$ and 0.4 mol dm^{-3} succinate at pH = 5.90



are not necessary for the rigid and preorganized *o*-phthalate ligand.

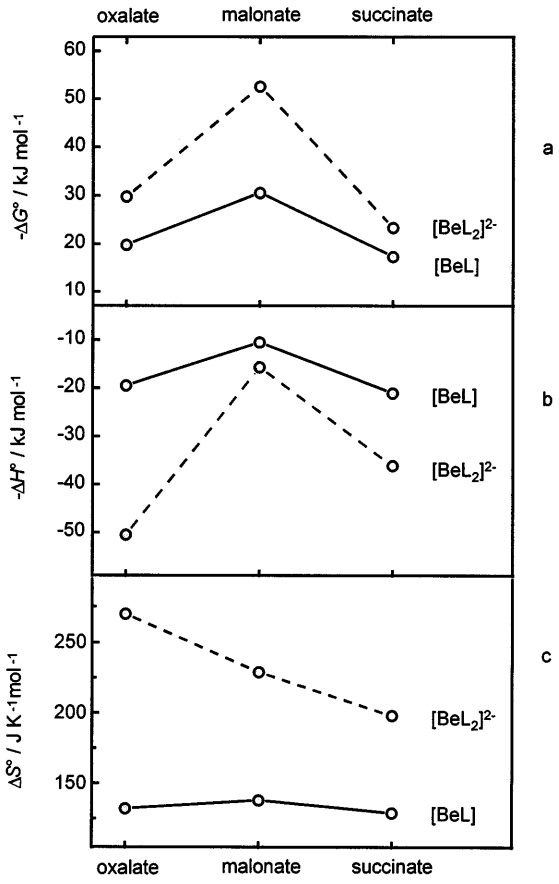
Considering the thermodynamic results reported here, different reasons can be advanced to account for the lower stability of beryllium complexes with oxalate and succinate compared to those with malonate: inadequate ligand-binding bite in the case of oxalate and considerable reorganization of ligand structure upon coordination of succinate.

As shown in Table 3, the stability of the Be^{2+} complexes with oxalate, malonate, and succinate is invariably determined by favourable entropic contributions, with the enthalpic terms always being unfavourable. This behaviour is typical of reactions between oppositely charged partners, in which charge neutralization and associated desolvation effects are of major importance. Nevertheless, energetic effects due to non-optimal matching between the stereochemical requirements of the ligand and metal ion and ligand conformational changes required for coordination also have to be taken into account. Considering the $-\Delta G°$ values obtained for [BeL] and $[BeL_2]^{2-}$, it appears that malonate forms by far the most stable complexes, as depicted in Figure 4a, as a consequence of the most favourable enthalpic contribution (less endothermic) shown in Figure 4b. The entropic contributions are very similar for the three [BeL] complexes, while in the case of $[BeL_2]^{2-}$ a greater $\Delta S°$ value favours the formation of the bis(oxalate) complex (Figure 4c).

It is noteworthy that the equilibrium constants for the binding of oxalate to Be^{2+} and $[Be_3(OH)_3]^{3+}$ are very similar, as is also the case for malonate. This is de facto due to a compensation between the enthalpic and entropic terms (Table 3), the reaction of these ligands with the trinuclear $[Be_3(OH)_3]^{3+}$ species being less endothermic than the analogous reaction with Be^{2+}. The presence of OH^- anions in $[Be_3(OH)_3]^{3+}$ produces a partial neutralization of charge on the metal ion, weakening the $Be-OH_2$ bonds, and hence the replacement of these coordinated water molecules by the ligands becomes less expensive from an enthalpic point of view. On the other hand, similar features are not operative in the succinate complexes, where a very unfavourable enthalpic contribution reduces the stability of the $[Be_3(OH)_3(succinate)]^+$ species, the formation of which is accompanied by the largest entropic gain for this type of reaction.

Since no anomalies are observed in the thermodynamic parameters for the formation of [BeL] (L = oxalate, malonate, succinate) complexes, it seems that the peculiar enthalpic and entropic terms for the formation of $[Be_3(OH)_3(succinate)]^+$ are not attributable to a special binding mode of succinate, but most likely to a loosening of the complex structure, which might originate from the hindrance brought about by the bulkier ligand, producing weakening of the binding interaction within the complex and increasing the disorder of its structure. As a matter of fact, we did not observe the addition of more than one dicarboxylate ligand in the case of succinate.

Figure 4. Plot of the thermodynamic functions $\Delta G°$ (a), $\Delta H°$ (b), and $\Delta S°$ (c) in relation to the cumulative formation of [BeL] and $[BeL_2]^{2-}$, where L = oxalate, malonate, and succinate



Conclusion

On the basis of the thermodynamic data obtained in this work concerning the solution chemistry of Be^{2+}, including metal ion hydrolysis and coordination equilibria with oxalate, malonate, and succinate ligands, the following points can be made:

1. Calorimetric data are consistent with a chemical model for Be^{2+} hydrolysis involving the species $[Be_2OH]^{3+}$, $[Be_3(OH)_3]^{3+}$, $[Be_5(OH)_6]^{4+}$, and $[Be_6(OH)_8]^{4+}$.

2. Considering a homogeneous series of chelating ligands containing the same binding groups, such as that constituted by oxalate, malonate, and succinate as investigated here, there is a distinct selectivity for the binding of Be^{2+} species by those ligands capable of forming 6-membered chelate rings.

3. Chelation of Be^{2+} ions is promoted by favourable entropic terms ($\Delta S° > 0$), the unfavourable enthalpic contributions ($\Delta H° > 0$) reflecting the fitting of ligand binding bites with the stereochemically required tetrahedral coordination geometry about the metal ion, as well as ligand preorganization.

Experimental Section

Caution: In view of the extreme toxicity of beryllium compounds all experimental work was carried out in a well-ventilated fume cupboard used exclusively for this work. Established procedures for handling dangerous materials were followed rigorously at all stages of the preparations and measurements.

General Remarks: High-purity oxalic, malonic, and succinic acids were purchased from Merck. Be^{2+} stock solutions (0.02 mol dm^{-3}) were prepared by reacting metallic Be (Aldrich, 99.99% purity) with a slight excess of $HClO_4$. Be^{2+} and free acid concentrations were checked periodically by means of standard methods.

All potentiometric (pH-metric) measurements ($pH = -\log[H^+]$) used for the determination of ligand protonation and metal ion complexation constants were performed in 0.5 mol dm^{-3} $NaClO_4$ at 298.1 ± 0.1 K using the apparatus described previously[8]. The combined Ingold 405 S7/120 electrode was calibrated as a hydrogen concentration probe by titrating known amounts of HCl with CO_2-free NaOH solutions and determining the equivalent point by Gran's method[23]. This allows one to determine the standard potential $E°$ and the ionic product of water [pK_w = 13.69(1) at 298 K in 0.5 mol dm^{-3} $NaClO_4$]. In the complex formation experiments care was taken to verify the attainment of equilibrium after each titrant addition: a few minutes were necessary to reach constant emf readings. The potentiometric data were analysed using the computer program HYPERQUAD[24]. Experimental details of the potentiometric measurements are given in Table 4.

Table 4. Summary of experimental conditions for the beryllium−succinate system

Solution composition	
$[T_L]$ range [mol dm^{-3}]	0.003−0.010
$[T_M]$ range [mol dm^{-3}]	0.003−0.004
I [mol dm^{-3}], electrolyte	0.50, $NaClO_4$
pH range	3.0−6.0
Experimental method	pH titration, calibrated in concentration
T [°C]	25
Total number of data points	
Protonation	103 (2 titrations)
Beryllium complexation	387 (5 titrations)
Method of calculation	HYPERQUAD[24]
Protonation constants	
(ligand = H_2L, errors as σ)	
log β (HL)	5.041 ± 0.003
log β (H_2L)	8.950 ± 0.003
Stability constants	
log β ([BeL])	3.04 ± 0.01
log β ($[BeL_2]^{2-}$)	4.1 ± 0.2
log β ($[Be_3(OH)_3L]^+$)	−6.65 ± 0.06

The enthalpies of reaction were determined in 0.5 mol dm^{-3} $NaClO_4$ solution by means of an automated system consisting of a Thermometric AB thermal activity monitor (model 2277) equipped with perfusion-titration device and a Hamilton pump (model Microlab M) coupled with a 0.250-cm^3 gas-tight Hamilton syringe (model 1750 LT). The measuring vessel was housed in a 25-dm^3 thermostatted water bath, which was maintained at the chosen temperature within $\pm 2 \cdot 10^{-4}$ K. The microcalorimeter was checked by determining the enthalpy of reaction of strong base (NaOH) with strong acid (HCl) solutions. The value of −56.7(2) kJ mol^{-1} obtained was in agreement with literature values[4]. The protonation enthalpies of the ligands were determined as previously reported for other compounds[25]. In a typical complexation experiment, a solution containing the disodium salt of the ligand (0.08 mol dm^{-3}, ionic strength adjusted to 0.5 mol dm^{-3} by $NaClO_4$) was added in successive steps (15 μl) to acidic solutions of Be^{2+} (0.02 mol dm^{-3}, ionic strength adjusted to 0.50 mol dm^{-3} by $NaClO_4$, 1.5 cm^3) until a 1:1 metal-to-ligand molar ratio was reached. The complexation experiments were set up in such a way so as to produce a change of solution pH in the calculated range of ca. 3.7−5.0. Corrections for the heats of dilution were applied. At least three titrations (about 110 data points) were performed for each system. The corresponding enthalpies of reaction were determined from the calorimetric data by means of the AAAL program[26].

^{9}Be- and ^{13}C-NMR spectra were recorded with a Bruker AC 200 spectrometer at 28.18 MHz and 50.32 MHz, respectively. Chemical shifts are quoted with respect to external 0.10 mol dm^{-3} $BeSO_4$ in H_2O for ^{9}Be and external TMS for ^{13}C. All measurements were carried out in aqueous solutions, in the pH range of 2.3−6.0, using a coaxial inner tube containing D_2O to provide a lock signal.

Vinylidene Transition-Metal Complexes, 46[◇]

Di- and Trinuclear Alkyne- and Vinylidenerhodium(I) Complexes Including the X-ray Crystal Structure of a Dendrimer-Like Rh_3 Compound☆

Helmut Werner*, Petra Bachmann, Matthias Laubender, and Olaf Gevert

Am Hubland, D-97074 Würzburg, Germany

Received April 21, 1998

Keywords: Rhodium / Alkyne complexes / Alkynyl(hydrido) complexes / Vinylidene complexes / Dendrimer-like structure

The dimer $[RhClL_2]_2$ (**1**; L = P*i*Pr$_3$) reacts with 1,3,5-$C_6H_3(C{\equiv}CH)_3$ to give in the initial step the tris(alkyne)trirhodium compound **2**, which rearranges in toluene at 60 °C to yield the isomeric tris(vinylidene) complex **3**. Treatment of either **2** or **3** with pyridine affords the trinuclear tris(alkynyl)trihydridorhodium(III) complex **4**. The trisilyl derivative 1,3,5-$C_6H_3(C{\equiv}CSiMe_3)_3$ reacts with **1** to form the mononuclear compound **5**, in which only one of the C≡C bonds is coordinated to Rh. The diynes 1,3- and 1,2-$C_6H_4(C{\equiv}CH)_2$ behave analogously to 1,3,5-$C_6H_3(C{\equiv}CH)_3$ and upon treatment with **1** yield initially the bis(alkyne)dirhodium complexes **6** and **7** and subsequently the bis(vinylidene)dirhodium isomers **8** and **9**. The reactions of 1,2-, 1,3-, and 1,4-$C_6H_4(C{\equiv}CSiMe_3)_2$ with **1** take a similar course and give the bis(alkyne) and bis(vinylidene) compounds **10**–**12** and **13**–**15**, respectively. In the same way, the dinuclear bis(alkyne) and bis(vinylidene) complexes **16** and **17** have been prepared from **1** and the naphthalene derivative 1,5-$C_{10}H_6(C{\equiv}CH)_2$. The molecular structures of **17** and of the dendrimer-like Rh_3 compound **3** have been determined by X-ray crystallography.

We have recently shown that terminal alkynes HC≡CR are easily converted to the isomeric vinylidenes :C=CHR in the coordination sphere of rhodium(I).[1][2] This process is thermodynamically preferred,[3] and based on ab initio MO studies its mechanism is quite well understood.[4] Besides acetylene and monosubstituted derivatives HC≡CR with R = alkyl, aryl, vinyl, SiR_3 or CO_2R, also butadiyne[5] and 1,4-bis(ethynyl)benzene[6] have been used as substrates and, in the presence of $[RhCl(PiPr_3)_2]$ as the template, transformed to the isomeric bridge-forming bis(vinylidenes).

The present paper reports that likewise to 1,4-$C_6H_4(C{\equiv}CH)_2$ not only the 1,3- and 1,2-bis(ethynyl)benzene isomers but also the trisubstituted benzene derivative 1,3,5-$C_6H_3(C{\equiv}CH)_3$ forms alkyne- and vinylidenerhodium(I) complexes upon treatment with $[RhClL_2]_2$ (**1**; L = P*i*Pr$_3$). An interesting facet of this work is that while the disilylated compounds 1,3- and 1,2-$C_6H_4(C{\equiv}CSiMe_3)_2$ behave similarly to the parent diynes and yield dinuclear rhodium complexes, the trisilylated triyne 1,3,5-$C_6H_3(C{\equiv}CSiMe_3)_3$ reacts with **1** to give a mononuclear alkynerhodium(I) compound, leaving two of the three triple bonds of 1,3,5-$C_6H_3(C{\equiv}CSiMe_3)_3$ uncoordinated.

Rhodium Complexes from 1,3,5-$C_6H_3(C{\equiv}CH)_3$ and the Trisilylated Derivative

Treatment of a solution of the reactive dimer **1**[7] with 1,3,5-tris(ethynyl)benzene in pentane leads even at −60°C to a rapid change of colour and, after warming to room temperature and removal of the solvent, gives the triyne complex **2** in ca. 80% yield. The yellow microcrystalline solid is moderately air-sensitive and easily soluble in most organic solvents.

The proposed structure of **2** (see Scheme 1) is fully supported by the spectroscopic data. The IR spectrum displays only one strong C≡C stretch at 1795 cm^{-1} indicating that all three triple bonds are involved in the coordination to the rhodium center. In agreement with this, the ^{1}H-NMR spectrum of **2** shows one signal for the ≡CH protons at δ = 4.02, which due to Rh-H coupling is split into a doublet. For the CH_3 protons of the P*i*Pr$_3$ units a doublet of virtual triplets appears being consistent with the *trans* disposition of the two phosphane ligands at each metal center.[8]

Although **2** is stable both in the solid state and in solution at room temperature, on warming in toluene at 60°C it slowly rearranges to the tris(vinylidene) complex **3**. In contrast to **2**, the isomer **3** is a dark green solid, the NMR spectra of which indicate a symmetrical structure as shown in Scheme 1. There is only one resonance for the P*i*Pr$_3$ phosphorus atoms in the ^{31}P-NMR and only one set of signals for the phosphanyl CH_3 protons in the ^{1}H-NMR spectrum. The most characteristic feature in the ^{13}C-NMR spectrum of **3** is the position of the signal of the α-C atom of the vinylidene ligands which appears at δ = 292.9 as a doublet of triplets. Both the Rh-C and P-C couplings are significantly larger than those of the resonance for the vinylidene β-C atom at δ = 111.1.

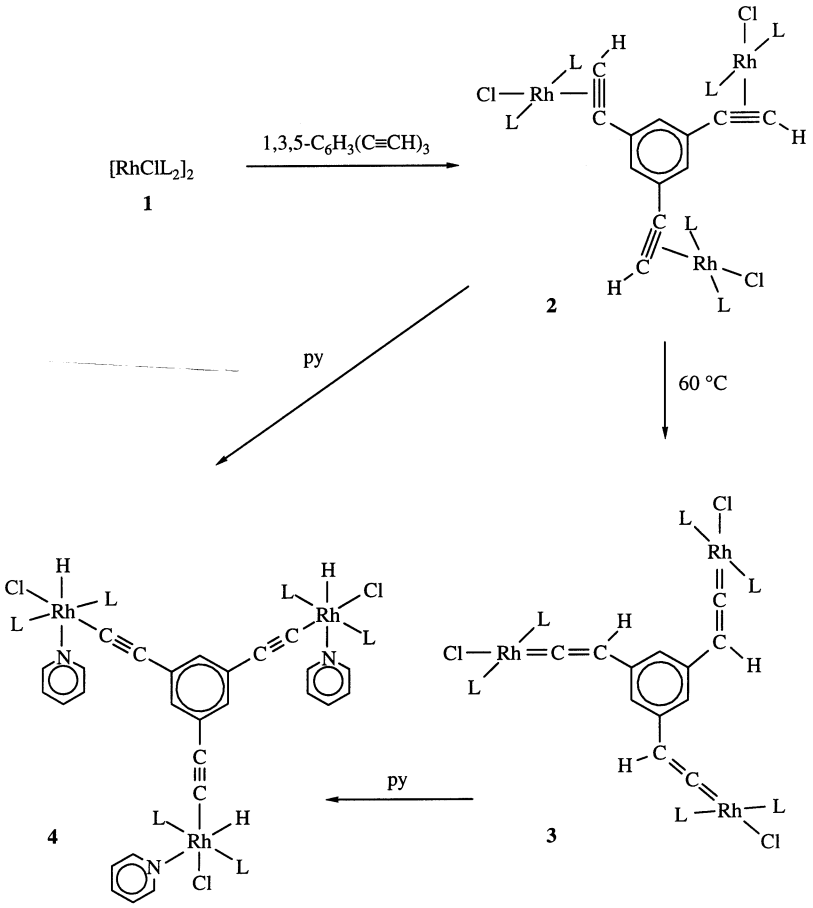
Scheme 1. L = P*i*Pr$_3$

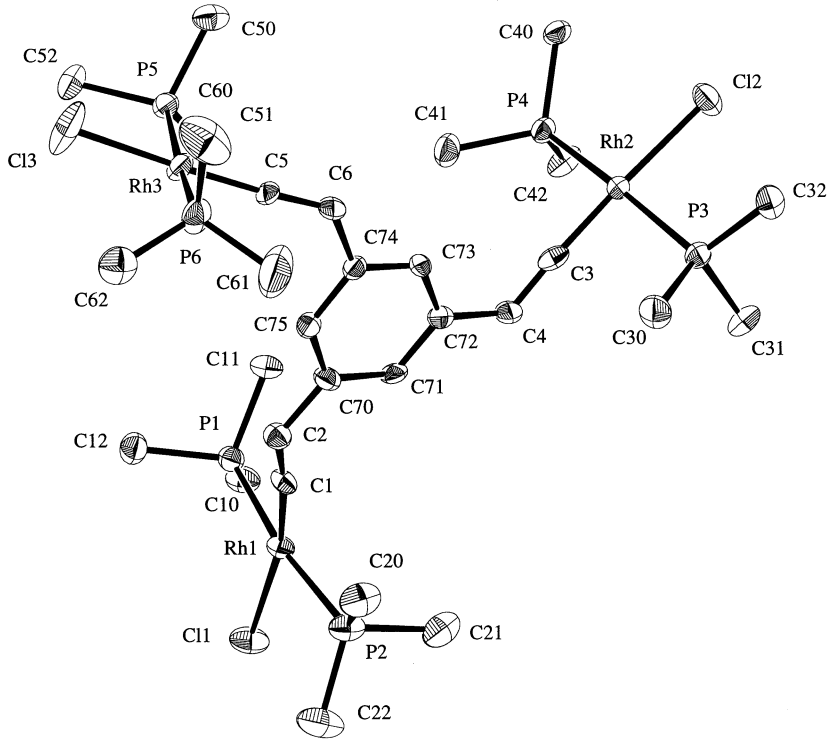


The result of the X-ray crystal structure analysis of **3** is shown in Figure 1. The coordination geometry around the three rhodium centers is square-planar with bond angles (mean values) P−Rh−C of 89.9° and P−Rh−Cl of 90.3°. The axes Cl−Rh−C and P−Rh−P are not exactly linear, the bond angles lying between 166.5° and 177.4° (for Cl−Rh−C) and between 171.09° and 173.61° (for P−Rh−P), respectively. The Rh−C and C−C distances of the vinylidenemetal units are in the expected range, i.e., they are almost identical to the corresponding bond lengths in *trans*-[RhCl(=C=CHMe)(P*i*Pr$_3$)$_2$] and *trans*-[RhCl(=C=CHC(Me)=CH$_2$)(P*i*Pr$_3$)$_2$].[9][10] An unexpected result is that the planes formed by each rhodium center, the α- and β-carbon atoms of the vinylidene ligand and the *ipso*-C atom of the substituted benzene are not coplanar with the central six-membered ring; the respective dihedral angles are between 10° and 15°. The plane of the C$_6$ ring is not exactly perpendicular to the three [Rh,P,P,Cl,α-C] planes, in this case the dihedral angles being 81−89°. The molecule of **3** as a whole can be described as a dendrimer-like species (zero-order dendrimer) with three branched organometallic moieties around the planar C$_6$ core.

The mechanism of the isomerization of **2** to **3** is not clear as yet. Due to theoretical studies[4] it is conceivable that in the initial step an intramolecular oxidative addition occurs and a tris(alkynyl)trishydridotrirhodium complex is generated. In the second step, this intermediate could rearrange to the vinylidene isomer **3**. The assumed stepwise mechanism is supported by the observation that on treatment of **2** with pyridine the trinuclear compound **4** containing three rhodium(III) centers is formed. The same product is also obtained from **3** and excess pyridine. The ^{1}H-NMR spectrum of **4** displays in the high-field region a signal at δ = −17.64 (with the intensity of 3 H) which is consistent with the proposed structure.

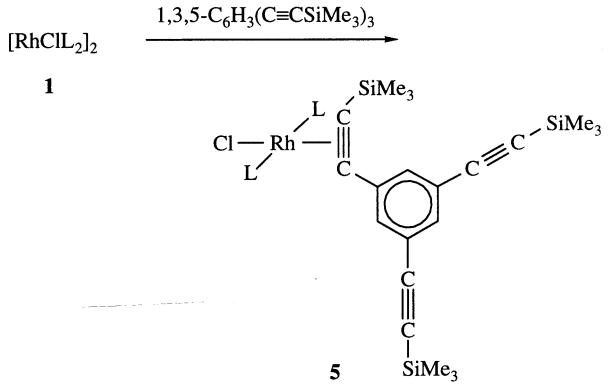
In contrast to 1,3,5-C$_6$H$_3$(C≡CH)$_3$, the trisilylated derivative 1,3,5-C$_6$H$_3$(C≡CSiMe$_3$)$_3$ reacts with **1** to afford the mononuclear alkyne complex **5** (Scheme 2). The IR spectrum of the bright orange solid shows besides the expected band at ca. 1800 cm^{-1} for the C≡C stretching frequency of a metal-bonded alkyne, another absorption at 2140 cm^{-1} which is typical for non-coordinated C≡C bonds. In agreement with this result, the ^{13}C-NMR spectrum of **5** displays two signals at δ = 103.7 and 95.9 for the carbon atoms of the uncoordinated and two signals at δ = 86.4 and 82.2 for those of the coordinated triple bonds. Owing to the Rh-C coupling, the latter resonances are split into doublets with *J*(RhC) of 13.5 Hz.

Figure 1. Molecular structure (ORTEP plot) of **3**[a]; the methyl groups of the isopropyl units are omitted for clarity



[a] Selected bond lengths [Å] and angles [°]: Rh1−Cl1 2.381(2), Rh1−P1 2.348(2), Rh1−P2 2.357(2), Rh1−C1 1.790(6), C1−C2 1.319(9), C2−C70 1.471(9), Rh2−Cl2 2.394(2), Rh2−P3 2.345(2), Rh2−P4 2.346(2), Rh2−C3 1.809(6), C3−C4 1.323(9), C4−C72 1.503(9), Rh3−Cl3 2.399(2), Rh3−P5 2.362(2), Rh3−P6 2.357(2), Rh3−C5 1.820(6), C5−C6 1.327(9), C6−C74 1.483(8); P1−Rh1−P2 171.09(7), Cl1−Rh1−C1 166.5(2), P1−Rh1−Cl1 91.10(6), P1−Rh1−C1 89.0(2), P2−Rh1−Cl1 92.15(7), P2−Rh1−C1 89.8(2), Rh1−C1−C2 172.1(6), C1−C2−C70 125.5(6), P3−Rh2−P4 171.97(6), Cl2−Rh2−C3 175.9(2), P3−Rh2−Cl2 90.20(6), P3−Rh2−C3 89.4(2), P4−Rh2−Cl2 90.32(6), P4−Rh2−C3 89.5(2), Rh2−C3−C4 175.8(5), C3−C4−C72 129.2(6), P5−Rh3−P6 173.61(7), Cl3−Rh3−C5 177.4(2), P5−Rh3−Cl3 92.31(7), P5−Rh3−C5 87.9(2), P6−Rh3−Cl3 85.95(7), P6−Rh3−C5 93.6(2), Rh3−C5−C6 176.6(5), C5−C6−C74 128.5(6).

Scheme 2. L = P*i*Pr$_3$



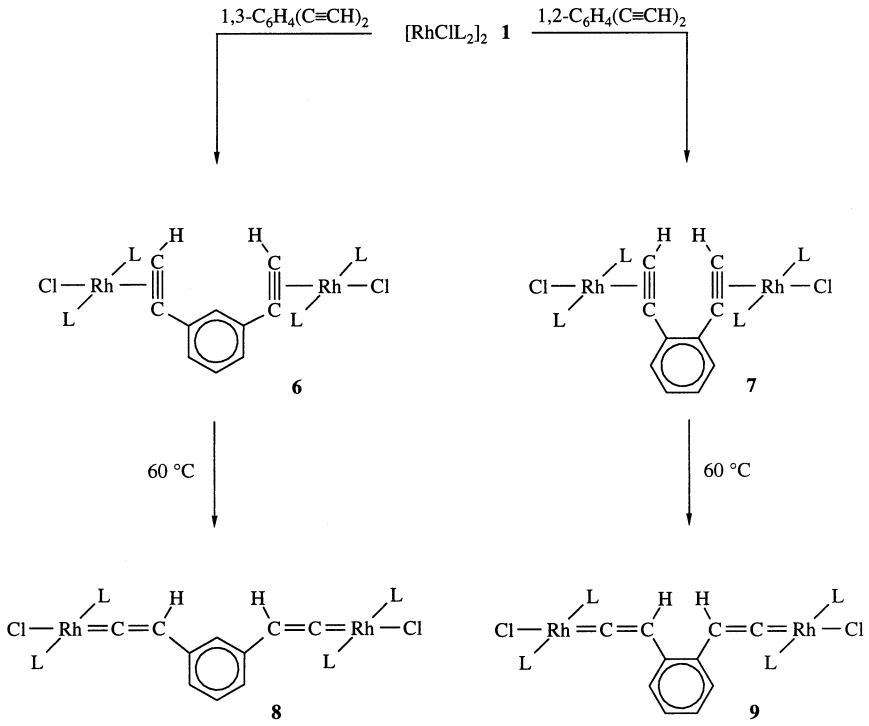
Dinuclear Complexes from Bis(ethynyl)benzene and -naphthalene Derivatives

Likewise to 1,3,5-$C_6H_3(C{\equiv}CH)_3$, the isomers 1,3- and 1,2-$C_6H_4(C{\equiv}CH)_2$ also react with **1** at low temperatures to give the bis(alkyne) complexes **6** and **7** as orange-yellow or yellow microcrystalline solids. The position of the ν(C≡C) stretches in the IR and the chemical shift of the single resonance for the P*i*Pr$_3$ phosphorus nuclei in the ^{31}P-NMR spectra of **6** and **7** are almost identical to those of **2** and thus the proposed structure as shown in Scheme 3 seems to be correct. When heated in toluene, compounds **6** and **7** behave analogously to **2** and afford by an intramolecular rearrangement the isomeric bis(vinylidene) complexes **8** and **9** in excellent yield. Again the spectroscopic data of **8** and **9** are very similar to those of **3** and deserve no further comments.

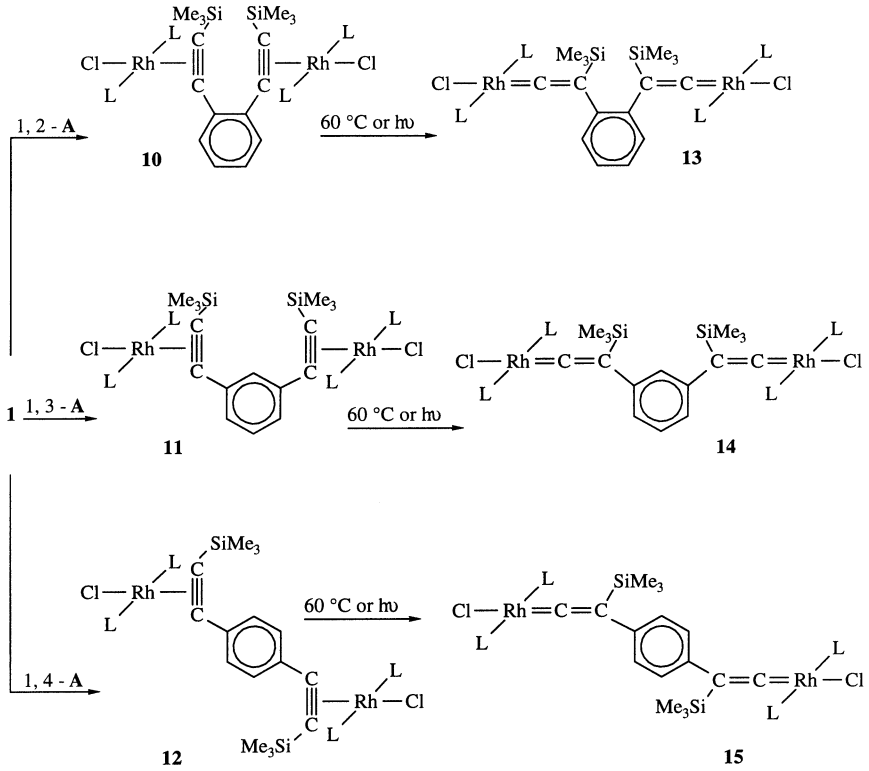
While 1,3,5-$C_6H_3(C{\equiv}CH)_3$ and 1,3,5-$C_6H_3(C{\equiv}CSiMe_3)_3$ behave differently toward the starting material **1**, the disilyl derivatives 1,2-, 1,3-, and 1,4-$C_6H_4(C{\equiv}CSiMe_3)_2$ react in the same way as the parent diynes 1,2-, 1,3-, and 1,4-$C_6H_4(C{\equiv}CH)_2$. In the presence of **1**, they afford the dinuclear dirhodium compounds **10**−**12**, respectively. Since the spectroscopic data of **6**, **7**, and [1,4-$C_6H_4(C{\equiv}CH)_2\{RhCl(P{i}Pr_3)_2\}_2$][6] on one hand and those of **10**−**12** on the other are quite similar, a related structure can be assumed (Scheme 4).

In contrast to compound **5**, which is rather inert, the dinuclear complexes **10**−**12** smoothly rearrange to the vinylidenerhodium compounds **13**−**15** (Scheme 4). The isomerization can be performed either thermally (in toluene at 60 °C) or photochemically and leads to the dark-red moisture-sensitive solids in 60−70% yield. Compounds **13**−**15** were identified by IR, NMR, and UV/Vis spectroscopy as well as by satisfactory microanalyses. In analogy to the re-

Scheme 3. L = P*i*Pr$_3$



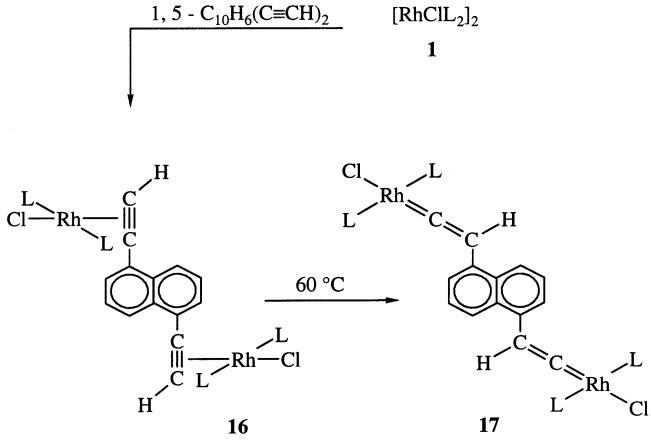
Scheme 4. A = $C_6H_4(C{\equiv}CSiMe_3)_2$; L = P*i*Pr$_3$



arrangement of the mononuclear complexes *trans*-[RhCl(RC≡CSiR′$_3$)(P*i*Pr$_3$)$_2$] to *trans*-[RhCl{=C=C(SiR′$_3$)R}(P*i*Pr$_3$)$_2$],[11] there is no evidence that the isomerization of **10**–**12** to **13**–**15** occurs stepwise and thus a concerted mechanism is most likely.[4][12] Although there might be some steric hinderance between the two bulky RhCl(alkyne)(P*i*Pr$_3$)$_2$ units, particularly in compounds **10** and **11**, the reaction of the bis(alkyne) to the bis(vinylidene)

complexes proceeds very cleanly and is not accompanied by the formation of oligomeric or polymeric by-products.

Scheme 5. L = P*i*Pr$_3$



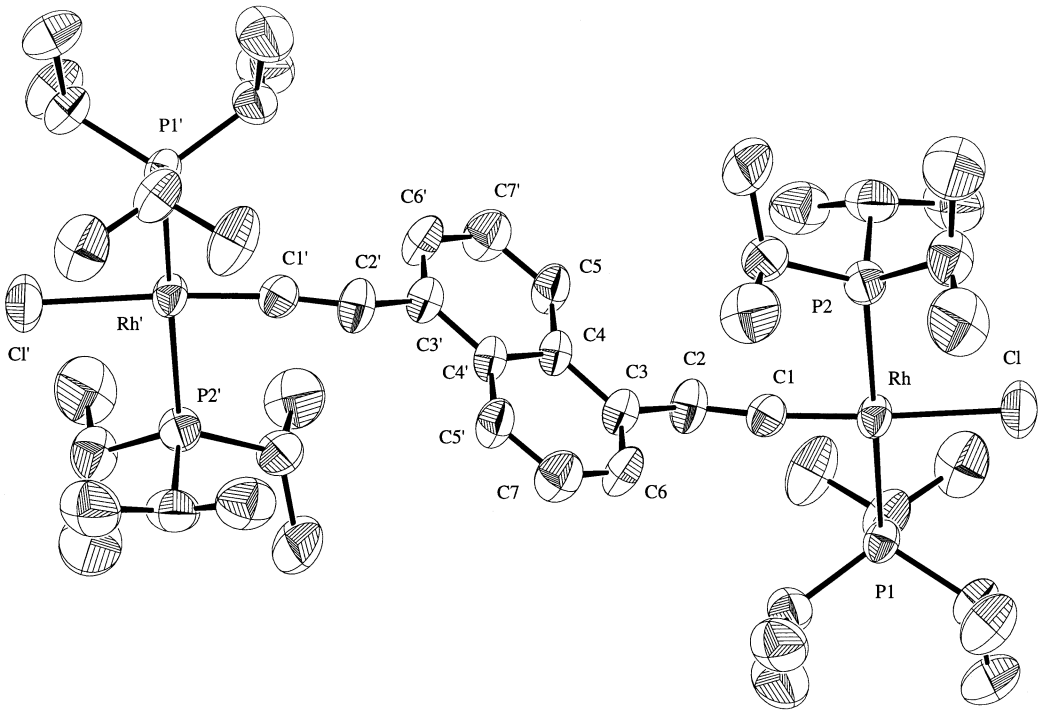
Not only 1,2-, 1,3-, and 1,4-bis(ethynyl)benzene but also 1,5-bis(ethynyl)naphthalene reacts with the starting material **1** in a stepwise manner to give initially the bis(alkyne) and then the bis(vinylidene) compounds **16** and **17**, respectively (Scheme 5). Both have been isolated as red-violet or violet solids in good yield. Single crystals of **17** could be grown from toluene and the molecular structure was determined by X-ray crystallography. As is shown in Figure 2, the dinuclear complex contains a center of inversion which is the midpoint of the C4−C4′ bond. Both rhodium atoms possess a square-planar coordination sphere with axes P1−Rh−P2 and Cl−Rh−C1 that deviate slightly from linearity. The distances Rh−C1 and C1−C2 are almost the same as in the tris(vinylidene) complex **3** and agree with the cumulene-like arrangement. A characteristic structural feature of **17** in the crystal is that the dihedral angle between the planes [Rh,P1,P2,Cl] and [C3,C4,C5,C6,C7] is 78.8(3)° and the torsional angle C1−C2−C3−C4 is 137(1)°. In order to explain these unexpected values, we assume that the non-perpendicular arrangement between the coordination planes [ClRhP$_2$C] and the naphthalene minimizes the steric repulsion between the two space-filling [RhCl(P*i*Pr$_3$)$_2$] units.

This work was supported by the *Deutsche Forschungsgemeinschaft* (SFB 347) and the *Fonds der Chemischen Industrie*. We are grateful to Dr. *B. Stempfle* and Dr. *C. Grünwald* for NMR spectra, to Mrs. *R. Schedl* and Mr. *C. P. Kneis* for performing the elemental analyses and DTA measurements, and to the *Degussa AG* for the gifts of chemicals.

Experimental Section

All operations were carried out under argon using Schlenk techniques. The starting materials **1**,[7a] the diynes 1,2-C$_6$H$_4$(C≡CH)$_2$, 1,3-C$_6$H$_4$(C≡CH)$_2$, and 1,5-C$_{10}$H$_6$(C≡CH)$_2$, the triyne 1,3,5-C$_6$H$_3$(C≡CH)$_3$, and the trimethylsilyl derivatives 1,2-C$_6$H$_4$(C≡CSiMe$_3$)$_2$ and 1,3,5-C$_6$H$_3$(C≡CSiMe$_3$)$_3$ were prepared analogously as described in the literature.[13] 1,3- and 1,4-C$_6$H$_4$(C≡CSiMe$_3$)$_2$ were commercial products from ABCR. − IR: Perkin-Elmer 1420. − UV/Vis: Hewlett Packard 8452 A. − NMR: Bruker AC 200 and AMX 400 [dvt = doublet of virtual triplets; $N = {}^3J(\mathrm{PH}) + {}^5J(\mathrm{PH})$ or ${}^2J(\mathrm{PC}) + {}^4J(\mathrm{PC})$, respectively]. − Melting points determined by DTA.

Figure 2. Molecular structure (ORTEP plot) of **17**[a]



[a] Selected bond lengths [Å] and angles [°]: Rh−Cl 2.374(2), Rh−P1 2.360(2), Rh−P2 2.359(2), Rh−C1 1.780(8), C1−C2 1.30(1), C2−C3 1.48(1), C3−C4 1.42(1), C4−C5 1.42(1), C6−C7 1.41(1), C4−C4′ 1.42(1); P1−Rh−P2 172.30(8), Cl−Rh−C1 174.2(3), P1−Rh−Cl 90.96(8), P1−Rh−C1 89.3(2), P2−Rh−Cl 90.28(8), P2−Rh−C1 88.7(2), Rh−C1−C2 173.1(7), C1−C2−C3 126.9(8).

1. Preparation of [1,3,5-C_6H_3(C≡CH)$_3${RhCl($PiPr_3$)$_2$}$_3$] (**2**): A solution of 126 mg (0.14 mmol) of **1** in 20 ml of pentane was treated dropwise at −60°C with a solution of 14 mg (0.09 mmol) of 1,3,5-C_6H_3(C≡CH)$_3$ in 3 ml of pentane. A fairly rapid change of colour from dark red to orange occurred. After the solution was warmed to room temperature, it was stirred for 10 min and then the solvent was removed in vacuo. The yellow microcrystalline residue was repeatedly washed with small portions (1−2 ml) of pentane (0°C) and dried; yield 106 mg (77%); m. p. 125°C (dec.). − IR (KBr): $\tilde{\nu}$ = 3070 cm^{-1} (≡CH), 1795 (C≡C). − ^{1}H NMR (200 MHz, C_6D_6): δ = 8.70 (s, 3 H, C_6H_3), 4.02 [d, J(RhH) = 2.4 Hz, 3 H, ≡CH], 2.36 (m, 18 H, PCHCH$_3$), 1.27 [dvt, N = 12.8, J(HH) = 6.1 Hz, 54 H, PCHCH_3], 0.98 [dvt, N = 13.9, J(HH) = 7.0 Hz, 54 H, PCHCH_3]. − ^{31}P NMR (81.0 MHz, C_6D_6): δ = 33.3 [d, J(RhP) = 117.0 Hz]. − $C_{66}H_{132}Cl_3P_6Rh_3$ (1526.7): calcd. C 51.92, H 8.71; found C 51.80, H 8.91.

2. Preparation of [1,3,5-C_6H_3{CH=C=RhCl($PiPr_3$)$_2$}$_3$] (**3**): A solution of 106 mg (0.07 mmol) of **2** in 10 ml of toluene was stirred for 2 h at 60°C, which led to a change of colour from orange-yellow to dark green. After cooling to room temperature, the solvent was removed in vacuo. The residue was dissolved in ca. 2 ml of toluene, and the solution was chromatographed on Al_2O_3 (neutral, activity grade V, height of column 6 cm). With toluene, a blue-green fraction was eluted which was brought to dryness in vacuo. The remaining green solid was washed twice with 2-ml portions of pentane (0°C) and dried; yield 78 mg (73%); m. p. 159°C (dec.). − IR (CH_2Cl_2): $\tilde{\nu}$ = 1620 cm^{-1} (C=C). − UV (hexane): λ_{max} = 580, 438, 294, 242, 224 nm. − ^{1}H NMR (200 MHz, C_6D_6): δ = 6.77 (s, 3 H, C_6H_3), 2.74 (m, 18 H, PCHCH$_3$), 1.31 [dvt, N = 13.4, J(HH) = 7.0 Hz, PCHCH_3], signal of =CH protons partially covered by signal of PCHCH_3 protons. − ^{13}C NMR (50.3 MHz, C_6D_6): δ = 292.9 [dt, J(RhC) = 59.8, J(PC) = 15.8 Hz, Rh=C], 133.2, 129.7 (both s, C_6H_3), 111.1 [dt, J(RhC) = 15.2, J(PC) = 6.3 Hz, Rh=C=C], 23.8 (vt, N = 20.2 Hz, PCHCH$_3$), 20.2 (s, PCHCH$_3$). − ^{31}P NMR (81.0 MHz, C_6D_6): δ = 43.1 [d, J(RhP) = 135.1 Hz]. − $C_{66}H_{132}Cl_3P_6Rh_3$ (1526.7): calcd. C 51.92, H 8.71; found C 51.25, H 8.79.

3. Reaction of Compounds **2** *and* **3** *with Pyridine: a)* A mixture of 115 mg (0.08 mmol) of **2** and 0.1 ml (1.22 mmol) of pyridine was heated for 10 min at ca. 100°C, which led to a change of colour from yellow to off-white. After the reaction mixture was cooled to room temperature, 2 ml of pentane was added, and the solution was stored for 12 h at −78°C. A white solid precipitated which was separated from the mother liquor, washed twice with 2-ml portions of pentane (0°C) and dried; yield 82 mg (58%). Although the ^{1}H- and ^{31}P-NMR spectra confirmed that the isolated sample was pure, no reliable elemental analysis of **4** could be obtained. − *b)* Analogously as described for a), by using 102 mg (0.07 mmol) of **3** and 0.1 ml (1.22 mmol) of pyridine as the starting materials. White solid; yield 99 mg (80%). − IR (KBr): $\tilde{\nu}$ = 2150 cm^{-1} (RhH), 2080 (C≡C). − ^{1}H NMR (200 MHz, $CDCl_3$): δ = 9.51, 7.68−6.50 (both m, 18 H, C_6H_3 and NC_5H_5), 2.71 (m, 18 H, PCHCH$_3$), 1.26 [dvt, N = 13.0, J(HH) = 6.2 Hz, 54 H, PCHCH_3], 1.11 [dvt, N = 13.2, J(HH) = 6.3 Hz, 54 H, PCHCH_3], −17.64 [dt, J(RhH) = 13.8, J(PH) = 13.7 Hz, 3 H, RhH]. − ^{31}P NMR (81.0 MHz, $CDCl_3$): δ = 37.7 [d, J(RhP) = 97.4 Hz].

4. Preparation of trans-[RhCl{η^2-Me_3SiC≡CC_6H_3-3,5-(C≡$CSiMe_3$)$_2$}($PiPr_3$)$_2$] (**5**): A solution of 200 mg (0.22 mmol) of **1** in 20 ml of pentane was treated dropwise at −60°C with a solution of 144 mg (0.44 mmol) of 1,3,5-C_6H_3(C≡$CSiMe_3$)$_3$ in 3 ml of pentane. After the solution was worked up as described for **2** a bright orange solid was obtained; yield 222 mg (61%); m. p. 66°C (dec.). − IR (KBr): $\tilde{\nu}$ = 2140 cm^{-1} (C≡C)$_{uncoord}$, 1795 (C≡C)$_{coord}$. − ^{1}H NMR (200 MHz, C_6D_6): δ = 7.68−7.38 (m, 3 H, C_6H_3), 2.28 (m, 6 H, PCHCH$_3$), 1.29 [dvt, N = 13.5, J(HH) = 6.7 Hz, 18 H, PCHCH_3], 1.01 [dvt, N = 12.8, J(HH) = 6.3 Hz, 18 H, PCHCH_3], 0.27 (s, 9 H, $SiMe_3$), 0.17 (s, 18 H, $SiMe_3$). − ^{13}C NMR (100.6 MHz, C_6D_6): δ = 135.3, 134.8, 125.6, 124.3 (all s, C_6H_3), 103.7, 95.9 (both s, C≡C$_{uncoord}$), 86.4, 82.2 [both d, J(RhC) = 13.5 Hz, C≡C$_{coord}$], 22.6 (vt, N = 17.1 Hz, PCHCH$_3$), 21.0, 19.5, (both s, PCHCH$_3$], 1.0, 0.5 (both s, $SiMe_3$). − ^{31}P NMR (81.0 MHz, C_6D_6): δ = 33.1 [d, J(RhP) = 116.3 Hz].

5. Preparation of [1,3-C_6H_4(C≡CH)$_2${RhCl($PiPr_3$)$_2$}$_2$] (**6**): Analogously as described for **2**, by using 147 mg (0.16 mmol) of **1** and 20 mg (0.16 mmol) of 1,3-C_6H_4(C≡CH)$_2$ as starting materials. Orange-yellow solid; yield 128 mg (77%); m. p. 118°C (dec.). − IR (KBr): $\tilde{\nu}$ = 3070 cm^{-1} (≡CH), 1790 (C≡C). − ^{1}H NMR (200 MHz, C_6D_6): δ = 7.08−6.42 (m, 4 H, C_6H_4), 3.73 [d, J(RhH) = 2.8 Hz, 2 H, ≡CH], 2.06 (m, 12 H, PCHCH$_3$), 1.03 [dvt, N = 13.8, J(HH) = 7.3 Hz, 36 H, PCHCH_3], 0.87 [dvt, N = 13.1, J(HH) = 7.3 Hz, 36 H, PCHCH_3]. − ^{31}P NMR (81.0 MHz, C_6D_6): δ = 33.8 [d, J(RhP) = 116.3 Hz]. − $C_{46}H_{90}Cl_2P_4Rh_2$ (1043.8): calcd. C 52.93, H 8.69; found C 53.02, H 8.94.

6. Preparation of [1,2-C_6H_4(C≡CH)$_2${RhCl($PiPr_3$)$_2$}$_2$] (**7**): Analogously as described for **2**, by using 117 mg (0.13 mmol) of **1** and 16 mg (0.13 mmol) of 1,2-C_6H_4(C≡CH)$_2$ as starting materials. Yellow solid; yield 88 mg (65%); m. p. 135°C (dec.). − IR (KBr): $\tilde{\nu}$ = 3070 cm^{-1} (≡CH), 1790 (C≡C). − ^{1}H NMR (200 MHz, C_6D_6): δ = 8.73−7.29 (m, 4 H, C_6H_4), 4.53 [d, J(RhH) = 2.2 Hz, 2 H, ≡CH], 2.25 (m, 12 H, PCHCH$_3$), 1.21 [dvt, N = 13.1, J(HH) = 6.9 Hz, 36 H, PCHCH_3], 1.07 [dvt, N = 12.6, J(HH) = 6.4 Hz, 36 H, PCHCH_3]. − ^{13}C NMR (100.6 MHz, C_6D_6): δ = 131.8, 127.4, 127.0 (all s, C_6H_4), 88.3, 85.2 [both d, J(RhC) = 17.8 Hz, C≡C], 22.9 (vt, N = 17.6 Hz, PCHCH$_3$), 20.5, 20.3 (both s, PCHCH$_3$). − ^{31}P NMR (81.0 MHz, C_6D_6): δ = 34.0 [d, J(RhP) = 116.3 Hz]. − $C_{46}H_{90}Cl_2P_4Rh_2$ (1043.8): calcd. C 52.93, H 8.69; found C 53.13, H 8.63.

7. Preparation of [1,3-C_6H_4{CH=C=RhCl($PiPr_3$)$_2$}$_2$] (**8**): Analogously as described for **3**, by using 134 mg (0.13 mmol) of **6** as starting material. Blue-green solid; yield 102 mg (75%), m. p. 82°C (dec.). − IR (pentane): $\tilde{\nu}$ = 1620 cm^{-1} (C=C). − UV (hexane): λ_{max} = 580, 446, 282, 240, 224, 210 nm. − ^{1}H NMR (200 MHz, C_6D_6): δ = 7.29−6.54 (m, 4 H, C_6H_4), 2.63 (m, 12 H, PCHCH$_3$), 1.16 [dvt, N = 13.7, J(HH) = 6.7 Hz, PCHCH_3], signal of =CH protons partially covered by signal of PCHCH_3 protons. − ^{13}C NMR (50.3 MHz, C_6D_6): δ = 293.1 [dt, J(RhC) = 60.0, J(PC) = 15.9 Hz, Rh=C], 135.7, 132.2, 125.6, 122.5 (all s, C_6H_4), 111.3 [dt, J(RhC) = 15.3, J(PC) = 6.4 Hz, Rh=C=C], 23.7 (vt, N = 20.3 Hz, PCHCH$_3$), 20.1 (s, PCHCH$_3$). − ^{31}P NMR (81.0 MHz, C_6D_6): δ = 43.2 [d, J(RhP) = 133.9 Hz]. − $C_{46}H_{90}Cl_2P_4Rh_2$ (1043.8): calcd. C 52.93, H 8.69; found C 53.29, H 9.08.

8. Preparation of [1,2-C_6H_4{CH=C=RhCl($PiPr_3$)$_2$}$_2$] (**9**): Analogously as described for **3**, by using 121 mg (0.12 mmol) of **7** as starting material. Bright green solid; yield 84 mg (67%); m. p. 128°C (dec.). − IR (KBr): $\tilde{\nu}$ = 1620 cm^{-1} (C=C). − UV (hexane): λ_{max} = 574, 436, 280, 240, 222 nm. − ^{1}H NMR (200 MHz, C_6D_6): δ = 7.80−6.48 (m, 4 H, C_6H_4), 2.70 (m, 12 H, PCHCH$_3$), 2.25 [dt, J(PH) = 3.1, J(RhH) = 1.0 Hz, 2 H, =CH], 1.29 [dvt, N = 13.0, J(HH) = 6.2 Hz, 72 H, PCHCH_3]. − ^{13}C NMR (100.6 MHz, C_6D_6): δ = 292.2 [dt, J(RhC) = 59.6, J(PC) = 15.3 Hz, Rh=C], 132.9, 128.9, 127.1 (all s, C_6H_4), 110.3 [dt, J(RhC) = 15.5, J(PC) = 5.7 Hz, Rh=C=C], 24.0 (vt, N = 20.2 Hz, PCHCH$_3$), 20.3 (s, PCHCH$_3$). − ^{31}P NMR (81.0 MHz, C_6D_6): δ = 43.6 [d, J(RhP) =

133.7 Hz]. − $C_{46}H_{90}Cl_2P_4Rh_2$ (1043.8): calcd. C 52.93, H 8.69; found C 52.72, H 8.29.

9. Preparation of [1,2-C_6H_4(C≡$CSiMe_3$)$_2${RhCl($PiPr_3$)$_2$}$_2$] (**10**): Analogously as described for **2**, by using 157 mg (0.17 mmol) of **1** and 46 mg (0.17 mmol) of 1,2-C_6H_4(C≡$CSiMe_3$)$_2$ as starting materials. Light orange solid; yield 156 mg (77%); m. p. 112°C (dec.). − IR (KBr): $\tilde{\nu}$ = 1810 cm^{-1} (C≡C). − ^{1}H NMR (400 MHz, C_6D_6): δ = 9.93−6.64 (m, 4 H, C_6H_4), 2.98 (m, 12 H, PC*H*CH_3), 1.33 [dvt, *N* = 13.9, *J*(HH) = 7.0 Hz, 36 H, PCHC*H*$_3$], 1.08 [dvt, *N* = 11.7, *J*(HH) = 6.1 Hz, 36 H, PCHC*H*$_3$], 0.6 (s, 18 H, $SiMe_3$). − ^{13}C NMR (100.6 MHz, C_6D_6): δ = 138.2, 132.2, 126.5 (all s, C_6H_4), 109.2 [d, *J*(RhC) = 18.8 Hz, *C*≡C], 85.1 [d, *J*(RhC) = 12.5 Hz, C≡*C*], 22.9 (vt, *N* = 15.6 Hz, P*C*HCH$_3$), 21.3, 19.6 (both s, PCH*C*H$_3$], 0.7 (s, $SiMe_3$). − ^{31}P NMR (162.0 MHz, C_6D_6): δ = 29.5 [d, *J*(RhP) = 117.7 Hz]. − $C_{52}H_{106}Cl_2P_4Rh_2Si_2$ (1188.2): calcd. C 52.56, H 8.99; found C 52.84, H 9.02.

10. Preparation of [1,3-C_6H_4(C≡$CSiMe_3$)$_2${RhCl($PiPr_3$)$_2$}$_2$] (**11**): Analogously as described for **2**, using 121 mg (0.13 mmol) of **1** and 36 mg (0.13 mmol) of 1,3-C_6H_4(C≡$CSiMe_3$)$_2$ as starting materials. Light orange solid; yield 114 mg (74%); m. p. 106°C (dec.). − IR (KBr): $\tilde{\nu}$ = 1800 cm^{-1} (C≡C). − ^{1}H NMR (200 MHz, C_6D_6): δ = 7.54−6.75 (m, 4 H, C_6H_4), 2.40 (m, 12 H, PC*H*CH_3), 1.37 [dvt, *N* = 13.5, *J*(HH) = 6.8 Hz, 36 H, PCHC*H*$_3$], 1.10 [dvt, *N* = 12.4, *J*(HH) = 6.2 Hz, 36 H, PCHC*H*$_3$], 0.46 (s, 18 H, $SiMe_3$). − ^{13}C NMR (100.6 MHz, C_6D_6): δ = 134.2, 130.8, 126.3, 125.8 (all s, C_6H_4), 105.8 [d, *J*(RhC) = 19.8 Hz, *C*≡C], 80.6 [d, *J*(RhC) = 16.8 Hz, C≡*C*], 22.5 (vt, *N* = 16.0 Hz, P*C*HCH$_3$), 21.3, 19.5 (both s, PCH*C*H$_3$), 0.9 (s, $SiMe_3$). − ^{31}P NMR (81.0 MHz, C_6D_6): δ = 33.2 [d, *J*(RhP) = 117.9 Hz]. − $C_{52}H_{106}Cl_2P_4Rh_2Si_2$ (1188.2): calcd. C 52.56, H 8.99; found C 52.75, H 8.93.

11. Preparation of [1,4-C_6H_4(C≡$CSiMe_3$)$_2${RhCl($PiPr_3$)$_2$}$_2$] (**12**): Analogously as described for **2**, by using 139 mg (0.15 mmol) of **1** and 41 mg (0.15 mmol) of 1,4-C_6H_4(C≡$CSiMe_3$)$_2$ as starting materials. Yellow solid; yield 128 mg (72%); m. p. 108°C (dec.). − IR (KBr): $\tilde{\nu}$ = 1790 cm^{-1} (C≡C). − ^{1}H NMR (200 MHz, C_6D_6): δ = 8.65−6.51 (m, 4 H, C_6H_4), 2.40 (m, 12 H, PC*H*CH_3), 1.38 [dvt, *N* = 13.6, *J*(HH) = 6.9 Hz, 36 H, PCHC*H*$_3$], 1.08 [dvt, *N* = 12.8, *J*(HH) = 6.2 Hz, 36 H, PCHC*H*$_3$], 0.37 (s, 18 H, $SiMe_3$). − ^{13}C NMR (100.6 MHz, C_6D_6): δ = 132.1, 122.3 (both s, C_6H_4), 106.4 [d, *J*(RhC) = 18.7 Hz, *C*≡C], 80.6 [d, *J*(RhC) = 14.4 Hz, C≡*C*], 22.4 (vt, *N* = 17.1 Hz, P*C*HCH$_3$), 21.0, 19.4 (both s, PCH*C*H$_3$), 0.8 (s, $SiMe_3$). − ^{31}P NMR (81.0 MHz, C_6D_6): δ = 33.1 [d, *J*(RhP) = 116.9 Hz]. − $C_{52}H_{106}Cl_2P_4Rh_2Si_2$ (1188.2): calcd. C 52.56, H 8.99; found C 52.14, H 8.68.

12. Preparation of [1,2-C_6H_4{C($SiMe_3$)=C=RhCl($PiPr_3$)$_2$}$_2$] (**13**): *a)* A solution of 134 mg (0.11 mmol) of **10** in 10 ml of toluene was stirred for 1.5 h at 60°C. A change of colour from orange-red to dark brown occurred. After the solution was cooled to room temperature, it was concentrated to ca. 2 ml in vacuo and then 5 ml of pentane was added. A redbrown solid precipitated which was filtered, washed twice with 2-ml portions of pentane and dried; yield 81 mg (62%). − *b)* A solution of 106 mg (0.09 mmol) of **10** in 10 ml of benzene was irradiated for 2 h at room temperature with a UV lamp (500-W mercury arc). After the solvent was removed, the remaining residue was recrystallized from pentane (20°C to −60°C). Dark red crystals; yield 69 mg (65%); m. p. 109°C (dec.). − IR (KBr): $\tilde{\nu}$ = 1610 cm^{-1} (C=C). − UV (hexane): λ_{max} = 568, 440, 280, 240, 222, 206 nm. − ^{1}H NMR (400 MHz, C_6D_6): δ = 7.82−6.48 (m, 4 H, C_6H_4), 2.71 (m, 12 H, PC*H*CH_3), 1.27 [dvt, *N* = 13.6, *J*(HH) = 6.9 Hz, 36 H, PCHC*H*$_3$], 0.87 [dvt, *N* = 13.5, *J*(HH) = 6.8 Hz, 36 H, PCHC*H*$_3$], 0.25 (s, 18 H, $SiMe_3$). − ^{13}C NMR (100.6 MHz, C_6D_6): δ = 286.4 [dt, *J*(RhC) = 60.3, *J*(PC) = 15.9 Hz, Rh=C], 131.6, 126.7, 124.7 (all s, C_6H_4), 110.7 [dt, *J*(RhC) = 10.5, *J*(PC) = 3.8 Hz, Rh=C=*C*], 22.6 (vt, *N* = 20.1 Hz, P*C*HCH$_3$), 21.3 (s, PCH*C*H$_3$), 0.7 (s, $SiMe_3$). − ^{31}P NMR (81.0 MHz, C_6D_6): δ = 43.6 [d, *J*(RhP) = 133.7 Hz]. − $C_{52}H_{106}Cl_2P_4Rh_2Si_2$ (1188.2): calcd. C 52.56, H 8.99; found C 52.11, H 8.96.

13. Preparation of [1,3-C_6H_4{C($SiMe_3$)=C=RhCl($PiPr_3$)$_2$}$_2$] (**14**): *a)* A solution of 132 mg (0.11 mmol) of **11** in 10 ml of toluene was stirred for 2.5 h at 60°C. A change of colour from orange-red to dark brown occurred. After the solution was worked up as described for **13**, a dark red solid was obtained; yield 85 mg (65%). − *b)* A solution of 118 mg (0.10 mmol) of **11** in 10 ml of benzene was irradiated for 2 h at room temperature with a UV lamp (500-W mercury arc). The work-up procedure was the same as for **13**. Dark red crystals; yield 72 mg (61%); m. p. 81°C (dec.). − IR (KBr): $\tilde{\nu}$ = 1620 cm^{-1} (C=C). − UV (hexane): λ_{max} = 502, 358, 240, 222, 204 nm. − ^{1}H NMR (200 MHz, C_6D_6): δ = 7.67−6.72 (m, 4 H, C_6H_4), 2.71 (m, 12 H, PC*H*CH_3), 1.33 [dvt, *N* = 13.4, *J*(HH) = 6.4 Hz, 36 H, PCHC*H*$_3$], 0.86 [dvt, *N* = 13.2, *J*(HH) = 6.2 Hz, 36 H, PCHC*H*$_3$], 0.27 (s, 18 H, $SiMe_3$). − ^{13}C NMR (100.6 MHz, C_6D_6): δ = 291.3 [dt, *J*(RhC) = 60.2, *J*(PC) = 15.8 Hz, Rh=C], 133.4, 130.2, 126.5, 125.0 (all s, C_6H_4), 110.2 [dt, *J*(RhC) = 9.8, *J*(PC) = 3.7 Hz, Rh=C=*C*], 22.1 (vt, *N* = 19.9 Hz, P*C*HCH$_3$), 21.1 (s, PCH*C*H$_3$), 0.9 (s, $SiMe_3$). − ^{31}P NMR (81.0 MHz, C_6D_6): δ = 42.5 [d, *J*(RhP) = 135.2 Hz]. − $C_{52}H_{106}Cl_2P_4Rh_2Si_2$ (1188.2): calcd. C 52.56, H 8.99, Rh 17.32; found C 52.09, H 8.94, Rh 17.15.

14. Preparation of [1,4-C_6H_4{C($SiMe_3$)=C=RhCl($PiPr_3$)$_2$}$_2$] (**15**): *a)* A solution of 137 mg (0.12 mmol) of **12** in 10 ml of toluene was stirred for 3 h at 60°C. A change of colour from orange-red to dark brown occurred. After the solution was worked up as described for **13**, a dark brown solid was obtained; yield 91 mg (64%). − *b)* A solution of 121 mg (0.10 mmol) of **12** in 10 ml of benzene was irradiated for 2 h at room temperature with a UV lamp (500-W mercury arc). After the solvent was removed, the remaining residue was recrystallized from pentane (20°C to −60°C). Dark red crystals; yield 75 mg (63%); m. p. 60°C (dec.). − IR (KBr): $\tilde{\nu}$ = 1620 cm^{-1} (C=C). − UV (hexane): λ_{max} = 536, 346, 248, 222, 202 nm. − ^{1}H NMR (400 MHz, C_6D_6): δ = 7.62−6.95 (m, 4 H, C_6H_4), 2.75 (m, 12 H, PC*H*CH_3), 1.31 [dvt, *N* = 13.0, *J*(HH) = 6.5 Hz, 36 H, PCHC*H*$_3$], 0.85 [dvt, *N* = 13.4, *J*(HH) = 6.6 Hz, 36 H, PCHC*H*$_3$], 0.28 (s, 18 H, $SiMe_3$). − ^{31}P NMR (81.0 MHz, C_6D_6): δ = 43.2 [d, *J*(RhP) = 135.1 Hz]. − $C_{52}H_{106}Cl_2P_4Rh_2Si_2$ (1188.2): calcd. C 52.56, H 8.99; found C 52.14, H 9.23.

15. Preparation of [1,5-$C_{10}H_6$(C≡$CH)_2${RhCl($PiPr_3$)$_2$}$_2$] (**16**): Analogously as described for **2**, by using 123 mg (0.13 mmol) of **1** and 23 mg (0.13 mmol) of 1,5-$C_{10}H_6$(C≡$CH)_2$ as starting materials. Red-violet solid; yield 95 mg (67%); m. p. 122°C (dec.). − IR (KBr): $\tilde{\nu}$ = 3070 cm^{-1} (≡CH), 1795 (C≡C). − ^{1}H NMR (400 MHz, C_6D_6): δ = 9.17 [d, *J*(H_cH_b) = 6.8 Hz, 2 H, H_c and $H_{c'}$], 8.44 [d, *J*(H_aH_b) = 8.4 Hz, 2 H, H_a and $H_{a'}$], 7.61 {dd, *J*(H_bH_a) = *J*(H_bH_c) = 1/2 [*J*(H_bH_a) + *J*(H_bH_c)] = 7.6 Hz, 2 H, H_b and $H_{b'}$}, 4.37 [d, *J*(RhH) = 2.4 Hz, 2 H, ≡CH], 2.34 (m, 12 H, PC*H*CH_3), 1.29 [dvt, *N* = 13.2, *J*(HH) = 6.7 Hz, 36 H, PCHC*H*$_3$], 1.28 [dvt, *N* = 13.4, *J*(HH) = 6.8 Hz, 36 H, PCHC*H*$_3$]. − ^{31}P NMR (81.0 MHz, C_6D_6): δ = 33.9 [d, *J*(RhP) = 117.7 Hz]. − $C_{50}H_{92}Cl_2P_4Rh_2$ (1093.9): calcd. C 54.90, H 8.48, Rh 18.82; found C 54.73, H 8.88, Rh 18.48.

16. Preparation of [1,5-$C_{10}H_6${CH=C=RhCl($PiPr_3$)$_2$}$_2$] (**17**): Analogously as described for **3**, by using 132 mg (0.12 mmol) of **16** as starting material. Violet solid; yield 96 mg (73%); m. p. 196°C (dec.). − IR (KBr): $\tilde{\nu}$ = 1620 cm^{-1} (C=C). − ^{1}H NMR (400 MHz, C_6D_6): δ = 7.82 [dd, *J*(H_bH_a) = *J*(H_bH_c) = 7.6 Hz, 2 H, H_b and

or (CH=C){RhCl(P*i*Pr$_3$)$_2$}

$H_{b'}$], 7.11 [d, J(HH$_b$) = 7.6 Hz, 2 H, H_a or H_c], 7.01 [d, J(HH$_b$) = 7.6 Hz, 2 H, H_a or H_c], 2.72 (m, 12 H, PC*H*CH$_3$), 2.27 [t, J(PH) = 3.2 Hz, 2 H, =CH], 1.28 [dvt, N = 13.6, J(HH) = 6.9 Hz, 72 H, PCHC*H*$_3$]. – ^{13}C NMR (100.6 MHz, C_6D_6): δ = 137.8 (s, C^1 and C^5), 130.3 (s, C^9 and C^{10}), 129.3, 128.5, 125.6 (all s, C^2 and C^6, C^3 and C^7, C^4 and C^8), 107.6 [dt, J(RhC) = 15.3, J(PC) = 5.8 Hz, Rh=C=*C*], 24.1 (dvt, N = 20.0 Hz, P*C*HCH$_3$), 20.4 (s, PCH*C*H$_3$), signal of Rh=C could not be observed. – ^{31}P NMR (81.0 MHz, C_6D_6): δ = 43.4 [d, J(RhP) = 135.1 Hz]. – $C_{50}H_{92}Cl_2P_4Rh_2$ (1093.9): calcd. C 54.90, H 8.48, Rh 18.82; found C 54.51, H 8.30, Rh 19.17.

17. Determination of the X-ray Crystal Structure of **3**[14]: Single crystals were grown upon cooling of a saturated solution of **3** in acetone from 50°C to 25°C. Crystal data (from 25 reflections, 10° < Θ < 15°): monoclinic; space group $P\,2_1/c$ (No. 14); a = 29.729(5), b = 11.2733(9), c = 26.579(5) Å, β = 114.406(8)°; V = 8112(2) Å^3, Z = 4; $d_{calcd.}$ = 1.250 gcm^{-3}; μ(Mo-K_α) = 0.853 mm^{-1}; crystal size 0.72 × 0.44 × 0.40 mm; Enraf-Nonius CAD-4 diffractometer, Mo-K_α radiation (λ = 0.71073 Å), graphite monochromator, zirconium filter (factor 16.4); T = 173(2) K; ω-2θ scan, max. 2θ = 48°; 13712 reflections measured, 12400 independent ($R_{int.}$ = 0.0395), 8211 with $I > 2\sigma(I)$. Intensity data were corrected for Lorentz and polarization effects and an empirical absorption correction (Ψ scan method) was applied (min. transmission 82.49%). The structure was solved by direct methods (SHELXS-86)[15]. Atomic coordinates and the anisotropic thermal parameters of non-hydrogen atoms were refined by full-matrix least squares on F^2 (SHELXL-93)[16]. The positions of all hydrogen atoms except H(2), H(4), H(6), H(71), H(73), and H(75) were calculated according to ideal geometry and were refined by using the riding method. The positions of H(2), H(4), H(6), H(71), H(73), and H(75) could be located in a final difference Fourier synthesis and refined without restrictions. Conventional R = 0.0505 [for 8211 reflections with $I > 2\sigma(I)$], and weighted wR_2 = 0.1218 for all 12400 located reflections; reflection/parameter ratio 16.2; residual electron density +0.869/−0.842 eÅ^{-3}.

18. Determination of the X-ray Crystal Structure of **17**[14]: Single crystals were grown upon cooling of a saturated solution of **17** in toluene from 80°C to 25°C. Crystal data (from 25 reflections, 10° < Θ < 15°): triclinic; space group $P\bar{1}$ (No. 2); a = 8.843(2), b = 12.093(3), c = 15.496(3) Å, α = 107.45(1), β = 96.65(1), γ = 94.51(1)°; V = 1559.1(6) Å^3, Z = 2; $d_{calcd.}$ = 1.267 gcm^{-3}; μ(Mo-K_α) = 0.744 mm^{-1}; crystal size 0.2 × 0.3 × 0.45 mm; Enraf-Nonius CAD-4 diffractometer, Mo-K_α radiation (λ = 0.7093 Å), graphite monochromator, zirconium filter (factor 15.4); T = 293(2) K; ω-θ scan, max. 2θ = 60°; 6930 reflections measured, 6500 independent ($R_{int.}$ = 0.0243), 4675 with $I > 2\sigma(I)$. Intensity data were corrected for Lorentz and polarization effects. The structure was solved by direct methods (SHELXS-86)[15]. Atomic coordinates and the anisotropic thermal parameters of non-hydrogen atoms were refined by full-matrix least squares on F^2 (SHELXL-93)[16]. The positions of all hydrogen atoms were calculated according to ideal geometry and were refined by using the riding method. One half of multi-disordered toluene is present in the asymmetric unit. Though two alternative positions were found and refined anisotropically (with occupation factor of 0.5 each), bond lengths and angles within this molecule could not be refined properly. Conventional R = 0.0775 [for 4675 reflections with $I > 2\sigma(I)$], and weighted wR_2 = 0.4229 for all 6500 located reflections; reflection/parameter ratio 16.2; residual electron density +1.473/−0.860 eÅ^{-3}.

Pentacarbonyl(dimethylvinylidene)chromium, $[(CO)_5Cr{=}C{=}CMe_2]$ (**1**), reacts with the butadiynyl complexes $[Cp(CO)_2FeC{\equiv}CC{\equiv}CR]$ [**2**; R = $SiMe_3$ (**a**), *n*Bu (**b**), Ph (**c**)] and $[Cp(CO)(PPh_3)FeC{\equiv}CC{\equiv}CSiMe_3]$ (**3a**) by regiospecific cycloaddition of the $C^{\alpha}{\equiv}C^{\beta}$ bond of the butadiynyl complexes to the C=C bond of **1** to form the 1,3-*hetero*binuclear cyclobutenylidene complexes **4a–c** and **5a** with an alkynyl substituent at C-2 of the bridging ring. Desilylation of the 2-$C{\equiv}CSiMe_3$ substituent in **4a** and **5a** with tetrabutylammonium fluoride affords the 2-$C{\equiv}CH$-substituted complexes **6** and **7**. Complex **4a** reacts with $HNMe_2$ and $HN(CH_2)_5$ by substitution of NR_2 for the 3-$Fe(CO)_2Cp$ fragment to form the corresponding 3-aminocyclobutenylidene complexes **10** and **11**. Sequential reactions of **4a** with $[n Bu_4N]F$ and $n Bu_3SnNEt_2$ give the trinuclear 2-$C{\equiv}CSn n Bu_3$-substituted complex **12**. Coupling of **12** with $C_6H_4I_2$-*p* yields the 2-$C{\equiv}CC_6H_4I$-*p*-substituted complex **13**. Coupling of **7** with $C_6H_4I_2$-*p* yields a mixture of the mono-coupling product **14** and the tetranuclear $C{\equiv}C{-}C_6H_4{-}C{\equiv}C$-bridged bis(cyclobutenylidene) complex **15**. Coupling of **7** with *trans*-$[(Et_3P)_2MCl_2]$ in the presence of CuI/$[Pd(PPh_3)_4]$ gives the trinuclear 2-$C{\equiv}C{-}M(PEt_3)_2X$-substituted complexes **16** (M = Pd, X = I) and **17** (M = Pt, X = Cl). The spectroscopic data as well as the results of the X-ray-structural analysis of **5a** indicate strong electronic communication between the metal centers. In the solid state, **5a** exhibits a "butterfly" conformation.

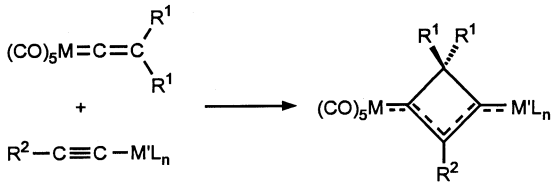
Introduction

Electronic communication between the metal centers in bi- and polynuclear transition-metal complexes containing unsaturated carbon bridges should lead to unusual physical and chemical properties[1]. For example, carbon-bridged bimetallic π-conjugated complexes of the type $[L_nMC_mM'(L')_{n'}]$ have been proposed as a new class of one-dimensional molecular wires[2]. Rigid-rod polymers like $[L_nMC{\equiv}CXC{\equiv}C]_m$ (X = aryl) can exhibit both liquid-crystalline[3] and nonlinear optical properties[4] similar to certain metal acetylides[5]. Binuclear complexes with different L_nM end groups at a conjugated π system should exhibit second-order nonlinear optical (NLO) properties.

Related to linear C_n bridges are rigid cyclic bridges with a delocalized π system. We recently reported on the syntheses of 1,3-*hetero*binuclear complexes with a cyclic C_4R_3 bridging ligand (cyclobutenylidene complexes)[6]. By variation of the substituents at the bridging ligand a fine-tuning of the magnetic, electronic, and spectroscopic properties of such binuclear complexes should be possible. Until now, 1,3-*hetero*binuclear cyclobutenylidene complexes with alkyl and aryl substituents as well as with functional groups at the bridging ligand, and with various metal-ligand fragments in 1- and 3-position of the ring have been prepared by reaction of suitable vinylidene complexes of chromium and tungsten, $[(CO)_5M{=}C{=}CR^1{}_2]$, with alkynyl complexes, $[L_nM'{-}C{\equiv}CR^2]$ (Scheme 1)[6a].

Cyclobutenylidene complexes with an exocyclic C=C bond were accessible by a regiospecific cycloaddition of alkynyl complexes to the $C^{\alpha}{=}C^{\beta}$ bond of allenylidene(pentacarbonyl)chromium and -tungsten complexes[6b]. The properties of these 1,3-*hetero*binuclear complexes are strongly influenced by the substituents at both non-metal-bonded ring atoms.

Scheme 1

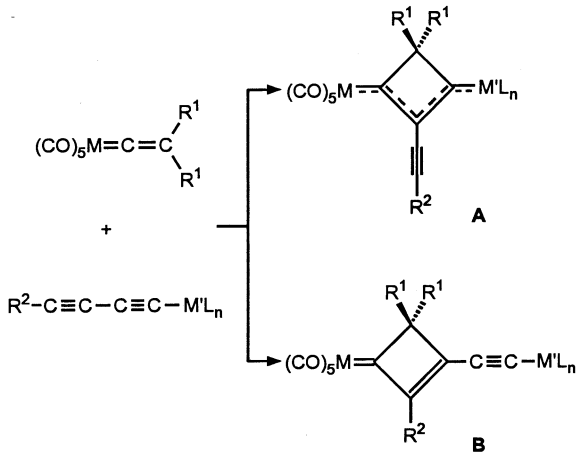


Transition-metal butadiynyl complexes, $[L_nMC^{\alpha}{\equiv}C^{\beta}C^{\gamma}{\equiv}C^{\delta}R]$, are related to alkynyl complexes $[L_nMC{\equiv}CR]$. In alkynyl complexes the HOMO is mainly localized at the terminal C atom. Therefore, electrophiles add to this carbon atom. Spectroscopic investigations of butadiynyl complexes indicate a strong communication between the metal center and the butadiynyl ligand[7][8]. In contrast to alkynyl complexes, two pathways are conceivable for the reactions of butadiynyl with vinylidene complexes as electrophiles depending on whether initial electrophilic attack of the vinylidene C^{α} atom in $[L_nM{=}C^{\alpha}{=}C^{\beta}R^1{}_2]$ is directed towards the C^{β} or the C^{δ} atom of the butadiynyl ligand. Attack at the C^{β} atom and subsequent ring closure would lead to 1,3-*hetero*binuclear cyclobutenylidene complexes with an alkynyl functionality at C-2 of the ring (**A**; Scheme 2). Such complexes should constitute inter-

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1434−1948/98/0909−1225 $ 17.50+.50/0

esting starting compounds for further derivatization by coupling reactions. An attack at the butadiynyl C^{δ} atom followed by ring closure would lead to complexes of type **B** (Scheme 2) thus extending the conjugated system between the metal centers in cyclobutenylidene complexes.

Scheme 2

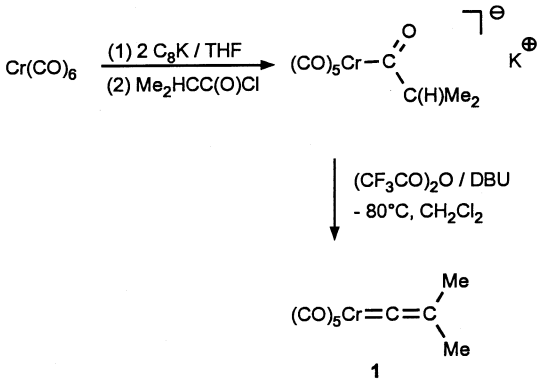


In this paper we report on the syntheses of the first 1,3-*hetero*binuclear cyclobutenylidene complexes with an alkynyl substituent at the bridging ring and on coupling reactions of these complexes leading to new di-, tri-, and tetrametallic systems.

Results and Discussion

The vinylidene complex $[(CO)_5Cr{=}C{=}CMe_2]$ (**1**)[6a] was chosen as the starting compound. Complex **1** was generated by the reaction sequence shown in Scheme 3.

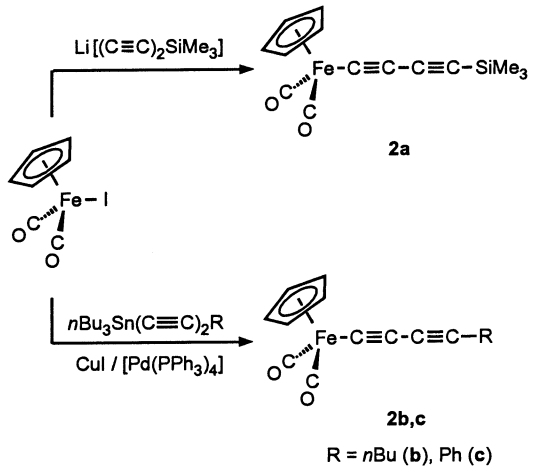
Scheme 3



Reduction of $Cr(CO)_6$ with potassium-graphite (C_8K) laminate in tetrahydrofuran at 0°C followed by reaction with isobutyryl chloride afforded pentacarbonyl(isobutyryl) chromate by a method described by M. F. Semmelhack et al.[9]. Treatment of the chromate with trifluoroacetic anhydride/DBU finally gave the vinylidene complex **1**. Compound **1** is thermally very labile. Therefore, **1** was not isolated and its solutions were immediately employed in the subsequent reactions with butadiynyl complexes.

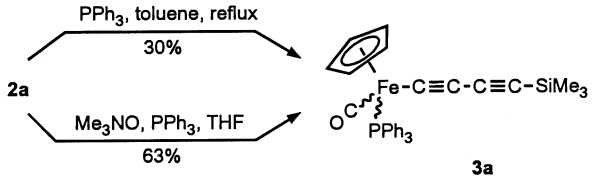
The dicarbonyl-butadiynyl complex $[Cp(CO)_2FeC{\equiv}CC{\equiv}CSiMe_3]$ (**2a**) was prepared in analogy to a previously published procedure[7a] by reaction of $[Cp(CO)_2FeI]$ with $Li[(C{\equiv}C)_2SiMe_3]$, obtained by monodesilylation of 1,4-bis(trimethylsilyl)-1,3-butadiyne with MeLi·LiBr (Scheme 4)[10]. The corresponding phenyl- and *n*-butyl-substituted butadiynyl complexes [**2b** (R = *n*Bu) and **2c** (R = Ph)] were accessible by coupling of $[Cp(CO)_2FeI]$ with $nBu_3Sn{-}C{\equiv}CC{\equiv}C{-}R$ (R = *n*Bu, Ph) in THF with CuI/$[Pd(PPh_3)_4]$ as the catalyst (Scheme 4).

Scheme 4



Thermal decarbonylation of **2a** by refluxing in toluene in the presence of PPh_3 yielded the monocarbonyl-butadiynyl complex $[Cp(CO)(PPh_3)FeC{\equiv}CC{\equiv}CSiMe_3]$ (**3a**)[7a] albeit in rather low yield (about 30%). Significantly higher yields were achieved by oxidative decarbonylation of **2a** with trimethylamine *N*-oxide in the presence of PPh_3 at room temperature. By this procedure, complex **3a** was obtained in 63% yield (Scheme 5). The lower yield in the former route is presumably due to competition between formation and decomposition of **3a** at the temperature of boiling toluene.

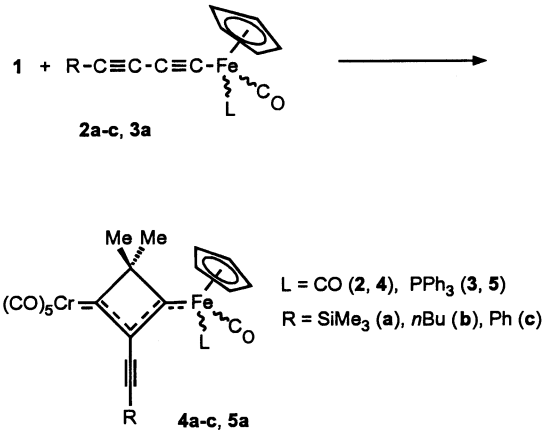
Scheme 5



When solutions of the vinylidene complex **1** and the butadiynyl complexes **2a−c** or **3a** in CH_2Cl_2 were combined at −60°C and then warmed to room temperature, the color of the solutions changed within about 30 minutes from green to red. Chromatographic workup of the reaction mixtures afforded the novel 2-alkynyl-substituted 1,3-*hetero*binuclear cyclobutenylidene complexes **4a−c** and **5a** (Scheme 6) in 45−65% yield. Alternatively, complex **5a** was also formed

when **4a** was oxidatively decarbonylated with trimethylamine *N*-oxide in the presence of PPh_3.

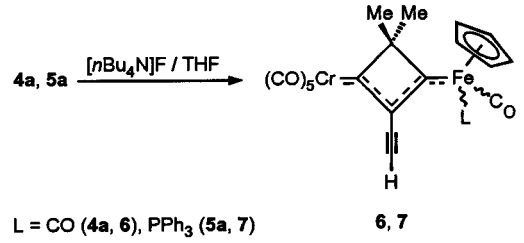
Scheme 6



The addition of the butadiynyl complexes $[L_nM-C^{\alpha}\equiv C^{\beta}-C^{\gamma}\equiv C^{\delta}-R]$ to the vinylidene ligand in **1** is highly regioselective. In each case, only the product of cycloaddition of the $C^{\alpha}\equiv C^{\beta}$ bond to the C=C bond of the vinylidene ligand was obtained (complex type **A**; Scheme 2). The formation of isomers derived from cycloaddition of the $C^{\gamma}\equiv C^{\delta}$ bond to the C=C bond of the vinylidene ligand (complex type **B**; Scheme 2) was not detected. Likewise, 1,2-dimetallated cyclobutenylidenes, derived from the inverse regiochemistry of the cycloaddition of either the $C^{\alpha}\equiv C^{\beta}$ or the $C^{\gamma}\equiv C^{\delta}$ bond of the butadiynyl ligand to the C=C bond of the vinylidene ligand, were not observed.

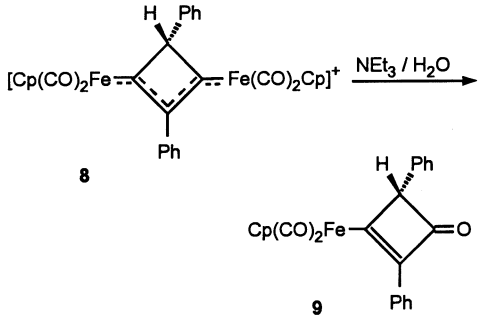
Desilylation of **4a** and **5a** with tetrabutylammonium fluoride (TBAF) in THF afforded the 2-ethynylcyclobutenylidene complexes **6** and **7** after chromatographic workup in 67% and 57% yield, respectively (Scheme 7). The highest yields were obtained when 0.4 equivalents of TBAF was used instead of the stoichiometric amount. Similar observations have been reported for the desilylation of other compounds with TBAF[7a].

Scheme 7



The complexes **4a**, **5a**, **6**, and **7** should constitute convenient starting compounds for the synthesis of tri- and tetranuclear complexes by coupling reactions. In coupling reactions, often amines are employed as the solvent. Therefore, we investigated the reactivity of these 2-alkynyl-substituted cyclobutenylidene complexes towards amines with the example of **4a** and **5a**. In earlier experiments it was observed that a cationic 1,3-*homo*binuclear cyclobutenylidene complex **8** reacts with aqueous Et_3N yielding the iron complex **9** by a formal substitution of "O" for $[Cp(CO)_2Fe]^+$ (Scheme 8)[11]. In contrast, 2-*alkyl*-substituted 1,3-*hetero*binuclear cyclobutenylidene complexes are inert towards amines.

Scheme 8



The dicarbonyl complex **4a** reacted rapidly at room temperature in THF with aqueous dimethylamine or with piperidine by substitution of NR_2 for the 3-dicarbonyl(cyclopentadienyl)iron fragment to form the 3-aminocyclobutenylidene complexes **10** and **11** (Scheme 9).

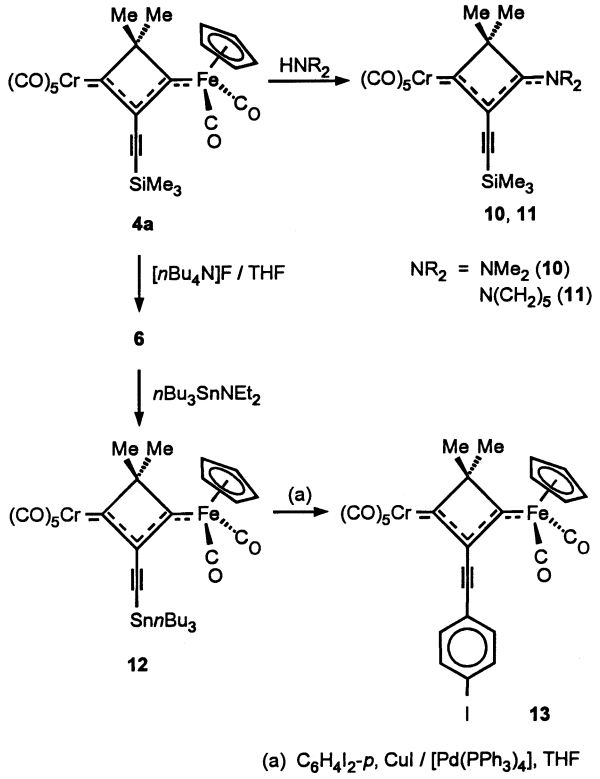
3-Alkoxy-substituted cyclobutenylidene complexes of chromium analogously react with secondary amines HNR_2 by displacement of OR by NR_2 to form 3-aminocyclobutenylidene complexes[12]. These substitution reactions are reminiscent of the aminolysis of alkoxycarbene complexes[13] and emphasize the close relationship of these cyclobutenylidene complexes with π-donor-substituted carbene complexes. Thus, cyclobutenylidene complexes can be regarded as a novel type of vinylogous heteroatom-stabilized carbene complexes. However, the ready displacement of the substituent in 3-position of the cyclobutenylidene complex by amines excludes the use of primary and secondary amines as solvents in coupling reactions with **4a** and **6**. Therefore, palladium-catalyzed C−C coupling reactions require the use of the corresponding *C*-stannylated compound (Stille coupling)[14].

The heterotrinuclear tributyltin-substituted compound **12** was obtained as a red oil by transformation of **4a** with $[nBu_4N]F$ in THF into **6** and subsequent reaction of **6** with nBu_3SnNEt_2 in toluene[15] (Scheme 9). The palladium-catalyzed coupling of **12** with half an equivalent of 1,4-diiodobenzene in the presence of CuI[16] afforded only the monocoupling product **13** (Scheme 9). The formation of a tetranuclear complex by coupling of two molecules of **12** with one molecule of 1,4-diiodobenzene was not observed.

In contrast to **4a**, the triphenylphosphane-substituted cyclobutenylidene complex **5a** did not react with amines to give 3-aminocyclobutenylidene complexes but was inert towards amines presumably due to the better back-bonding properties of $Cp(CO)(PPh_3)Fe$ compared to $Cp(CO)_2Fe$ and thus the reduced electrophilicity of 3-C in **5a**. Therefore, coupling reactions of 3-$Cp(CO)(PPh_3)$Fe-substituted cyclobutenylidene complexes in amines as the solvent should be possible.

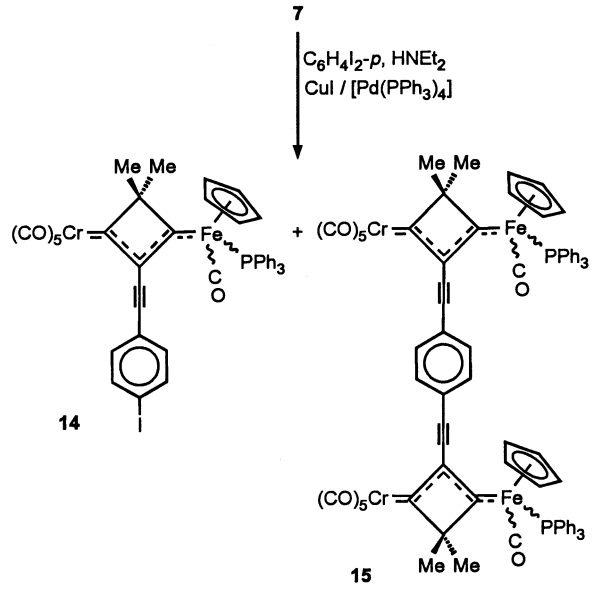
This was confirmed by the reaction of **7** with half an equivalent of 1,4-diiodobenzene in $HNEt_2$ and $[Pd(PPh_3)_4]$/

Scheme 9



CuI as the catalyst. The mono-coupling product **14** as well as the tetranuclear complex **15** were formed within several hours (Scheme 10) and, after chromatographic workup, obtained in 35% (**14**) and 10% (**15**) yield. Complex **15** was isolated in form of a single diastereomer (*meso* or *R*/*S*).

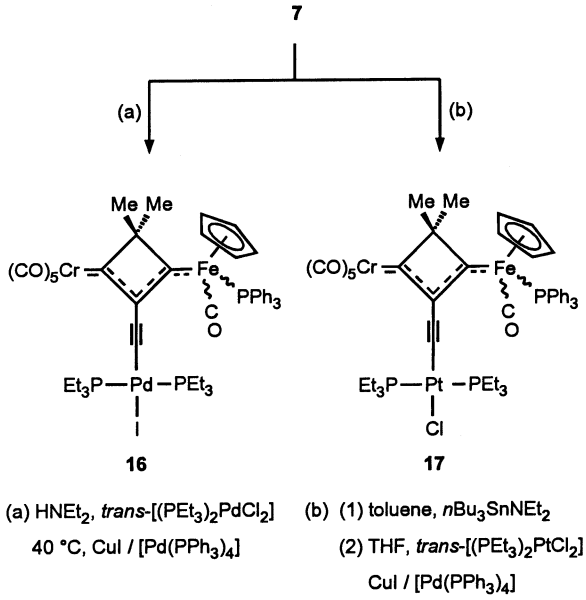
Scheme 10



The $[Pd(PPh_3)_4]$/CuI-catalyzed reaction of **7** with *trans*-$[(PEt_3)_2PdCl_2]$ in $HNEt_2$ afforded the mono-coupling product **16** in 23% yield (Scheme 11). In addition to the coupling of both complexes, Pd-coordinated chloride was replaced by iodide from CuI. Presumably, the substitution took place in the trinuclear complex initially formed from **7** and *trans*-$[(PEt_3)_2PdCl_2]$. The displacement of Cl^- for X^- in *trans*-$[(PEt_3)_2Pd(C{\equiv}CR)Cl]$ complexes in the presence of NaX (X = Br, I) has been observed several times[17]. Although a threefold excess of **7** over *trans*-$[(PEt_3)_2PdCl_2]$ was used, the formation of a pentanuclear complex by coupling of *trans*-$[(PEt_3)_2PdCl_2]$ with two molecules of **7** was not detected.

The trimetallic *trans*-chloroplatinum complex **17** was obtained by initial *C*-stannylation of **7** with nBu_3SnNEt_2 in toluene followed by $[Pd(PPh_3)_4]$/CuI-catalyzed coupling of the product with *trans*-$[(PEt_3)_2PtCl_2]$ in THF. A halide exchange was not observed in these reactions. Presumably, free iodide was trapped as nBu_3SnI (Scheme 11). A pentanuclear complex was likewise not detected.

Scheme 11



When **11** was stannylated in situ and the resulting derivative then coupled with iodobenzene under Stille conditions complex **5c** was obtained (see Scheme 6).

Spectroscopic Investigations and Molecular Structure of 5a

All new compounds were stable at room temperature and fully characterized by spectroscopic means and by elemental analyses.

The $\tilde{\nu}$(CO) absorptions of the pentacarbonyl chromium moiety in **4**–**7** and **10**–**17** are at rather low wave numbers indicating considerable transfer of electron density from C_4R_3–FeCO(L)Cp to $(CO)_5Cr$. The $\tilde{\nu}$(CO) spectra are similar to those of aminocarbene complexes (e. g. $[(CO)_5Cr{=}C(NHMe)Me]$)[18] and 3-amino-substituted cyclobutenylidene complexes[19] as well as to those of the previously described 1,3-*hetero*binuclear[6] cyclobutenylidene complexes. The positions of the absorptions are strongly influenced by the donor capacity of the substituent in 3-position and shift in the series $Fe(CO)_2Cp$, NR_2, $Fe(CO)(PPh_3)Cp$ towards smaller wave numbers. In contrast, the influence of the substituent in 2-position (alkyl,

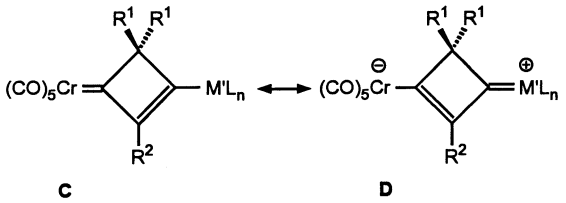
C≡C−R) is only small. With increasing donor capacity of R the $\tilde{\nu}$(C≡C) absorption shifts towards smaller wave numbers [R = $SiMe_3$: $\tilde{\nu}$(C≡C) = 2141 cm^{-1} (**5a**); R = *trans*-$(PEt_3)_2PdI$: $\tilde{\nu}$(C≡C) = 2092 cm^{-1} (**16**)].

The ^{13}C resonances of both the chromium- (1-C) and the iron-bound (3-C) ring carbon atoms appear at low field. The 1-C resonance is in the range usually observed for alkoxycarbene complexes (δ = 290−320)[20]. The resonance of the 3-C atom is in the region characteristic for alkenyliron complexes[21]. Increasing the ability of the alkynyl group C≡C−R at 2-C to donate electron density {R = Ph (**4c**) → $SiMe_3$ (**5a**) → *trans*-[$(PEt_3)_2PdI$] (**16**)} leads to an upfield shift of the 1-C and 3-C resonances and to a downfield shift of the 2-C resonance. These results are consistent with earlier observations with 1,3-*hetero*binuclear cyclobutenylidene complexes[6].

In general, the UV/Vis spectra of these cyclobutenylidene complexes are solvent-dependent. The UV/Vis absorption at lowest energy is shifted to shorter wavelength when a nonpolar solvent like pentane is replaced by a more polar one (DMF). However, whereas the solvent dependence of the 3-aminocyclobutenylidene complexes **10** and **11** is pronounced [$\Delta\tilde{\nu}$ = 1930 (**10**), 1820 cm^{-1} (**11**)] that of the 3-Fe(CO)LCp-substituted complexes **5a**, **7**, **14**, and **15** is rather small [$\Delta\tilde{\nu}$ = 80−300 cm^{-1}].

The structure of the complex **5a** was additionally established by an X-ray-structural analysis (Table 1, Figure 1). The C(6)−C(9) [1.401(4) Å] and the C(8)−C(9) distance [1.410(5) Å] are almost equal in length indicating that the resonance structures **C** and **D** (Scheme 12) contribute to almost the same extent to the overall bonding description. The distances are in between the characteristic bond lengths of a $C(sp^2)-C(sp^2)$ single bond (1.46 Å)[22] and a $C(sp^2)=C(sp^2)$ double bond (1.32 Å)[22]. The Cr(1)−C(6) distance [2.054(4) Å] is typical for heteroatom-stabilized carbene complexes[13].

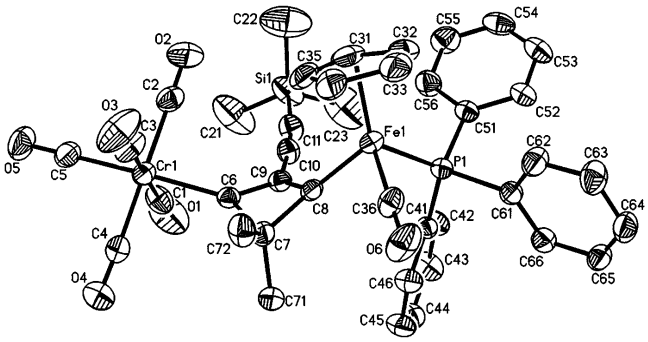
Scheme 12



The Fe−C(8) distance is comparable to that in cyclobut-1-en-3-one complexes[21a][21c]. The Fe−C(36) axis in **5a** is almost coplanar with the plane formed by the atoms C(7), C(8), C(9) [torsion angle C(9)−C(8)−Fe(1)−C(36) = 170.9°]. This conformation allows for maximal Fe→C(8) backdonation.

The most striking feature is the nonplanarity of the bridging ligand in **5a**. The puckering angle [angle between the planes formed by the atoms C(7), C(6), C(9) and C(7), C(8), C(9)] is 148.2°. A similar puckering has been observed with other 1,3-*hetero*binuclear cyclobutenylidene complexes[6], however, usually the four-membered ring in 3-amino- and 3-ethoxy-substituted cyclobutenylidene complexes[19], (cyclobut-1-en-3-one)iron complexes[21a][21c], free cyclobut-1-en-3-ones[23], and 1,3-*homo*binuclear cyclobutenylidene complexes[24] is nearly planar. As a consequence of the puckering, the transannular distance C(6)−C(8) in **5a** is small (1.986 Å) and the distance is well below the sum of the van der Waals radii. Therefore, direct electronic exchange cannot be excluded.

Figure 1. Molecular structure of complex **5a** in the crystal (hydrogen atoms are omitted for clarity)[a]



[a] Selected bond lengths [Å], bond angles, and torsion angles [°]: Cr(1)−C(6) 2.054(4), C(6)−C(9) 1.401(4), C(8)−C(9) 1.410(5), C(9)−C(10) 1.428(4), C(10)−C(11) 1.199(5), C(8)−Fe(1) 1.910(4); C(6)−C(9)−C(8) 89.9(3), C(7)−C(6)−C(9) 91.3(3), C(7)−C(8)−C(9) 91.0(3); C(7)−C(6)−C(9)−C(8) 22.7(2).

Conclusion

Our results demonstrate that an alkynyl functionality is readily introduced into the 2-position of 1,3-*hetero*binuclear cyclobutenylidene complexes by [2+2] cycloaddition of butadiynyl complexes to vinylidene complexes. These cyclobutenylidene complexes offer an easy access to a wide range of di-, tri-, and tetranuclear cyclobutenylidene complexes by derivatization of the alkynyl group and coupling reactions. In addition, the substituents in 4- and 3-position can be modified by use of other vinylidene complexes and by variation of the starting butadiynyl complexes.

By substitution of amines for the $Fe(CO)_2Cp$ fragment in **5a** a large variety of amines such as chiral amines can be introduced into the 3-position which is crucial for the nonlinear optical properties of these compounds. Thus, the synthesis of butadiynes $R-C{\equiv}CC{\equiv}C-NR_2$[25], which are rather difficult to prepare, can be avoided.

The nonplanarity of the cyclobutenylidene ring in **5a** decreases the symmetry of the molecule. Thus, taking into account the chirality of the iron center the existence of two diastereomers might be expected. However, only one isomer of **5a** could be isolated and the NMR spectra of **5a** exhibit only one set of signals. Obviously, in solution a rapid inversion of the four-membered ring occurs. For the analogous compound with an *n*Bu substituent at 2-C and a $Cp(PEt_3)Ni$ fragment at 3-C this dynamic process is still fast even at −80 °C[6a].

The geometry of the complexes **7** and **15** is similarly flexible. However, for the diastereoselective coupling of **7** to **15** a second effect has to be considered. Probably due to the steric demand of the bulky PPh_3 substituent, only one isomer of **15** (*meso* or *R*/*S*) was formed. A similar selectivity

has been reported by Gladysz et al. for the formation of comparable cyclobutenylidene complexes[24a].

Support of this work by the *Deutsche Forschungsgemeinschaft* and the *Fonds der Chemischen Industrie* is gratefully acknowledged. We also thank *B. Weibert* for collecting the data set for the X-ray-structural analysis.

Experimental Section

General: All operations were performed under either nitrogen or argon by using standard Schlenk techniques. Solvents were dried by refluxing over CaH_2 (CH_2Cl_2) or sodium/benzophenone ketyl (pentane, Et_2O, THF) and were freshly distilled prior to use. Silica gel (Fa. J. T. Baker; silica gel for flash chromatography) and alumina (Fa. Fluka) used for chromatography were nitrogen-saturated. Flash chromatography was performed at a nitrogen pressure of 1.4 bar. The complexes **1**[6a], **2a**[7a], **3a**[7a], $[Cp(CO)_2FeI]$[26], and $[Pd(PPh_3)_4]$[26] as well as R−C≡C−C≡C−Sn*n*Bu$_3$ (R = *n*Bu, Ph)[27] and *n*Bu$_3$SnNEt$_2$[28] were prepared according to literature procedures. − NMR: Bruker AC 250 (^{1}H and ^{13}C) and Jeol JNX 400 (^{1}H, ^{13}C, and ^{31}P); chemical shifts are reported relative to internal TMS (^{1}H and ^{13}C) or external H_3PO_4 (^{31}P). Unless mentioned otherwise, NMR spectra were recorded in $CDCl_3$ at room temperature. − IR: Biorad FTS 60. − MS: Finnigan MAT 312, modified either for EI or FAB (NBOH or NBOE used as solvent for FAB). − UV/Vis: Hewlett-Packard diode-array spectrophotometer 8452A. − Elemental analyses: Heraeus CHN-O-RAPID.

Dicarbonyl(η^5-cyclopentadienyl)(octa-1,3-diynyl)iron (**2b**): 9.9 g (25.0 mmol) of *n*Bu$_3$Sn−C≡C−C≡C−*n*Bu, 0.3 g (2.0 mmol) of CuI, and 2.5 g (2.0 mmol) of $[Pd(PPh_3)_4]$ were added to a solution of 6.1 g (20.0 mmol) of $[Cp(CO)_2FeI]$ in 150 ml of THF. The reaction mixture was stirred at room temp. for about 1 h. The solvent was evaporated in vacuo and the residue was chromatographed at −20°C first two times with pentane/CH_2Cl_2 (ratio decreasing from 1:0 to 4:1) on alumina and then two times with pentane/CH_2Cl_2 (ratio decreasing from 1:0 to 3:2) on silica gel. The solvent was evaporated in vacuo. The residue was recrystallized from 40 ml of pentane/CH_2Cl_2 (3:2) to give **2b** as a yellow powder. Yield: 2.3 g (32%, based on $[Cp(CO)_2FeI]$), m.p. 45°C. − IR (CH_2Cl_2): $\tilde{\nu}$(CO) = 2040 cm^{-1} vs, 1997 vs; $\tilde{\nu}$(C≡C) = 2203 cm^{-1} vw. − ^{1}H NMR (250 MHz): δ = 0.88 (t, $^3J_{HH}$ = 7.0 Hz, 3 H, CH_3), 1.32−1.51 (m, 4 H, CH_2), 2.24 (t, $^3J_{HH}$ = 6.7 Hz, 2 H, CH_2), 5.06 (s, 5 H, C_5H_5). − ^{13}C NMR (250 MHz): δ = 13.5 (CH_3), 18.7, 21.9, 30.9 (CH_2), 67.1, 67.9, 83.8 (C≡C), 85.2 (C_5H_5), 97.4 (C≡C), 211.4 (CO). − $C_{15}H_{14}FeO_2 \cdot CH_2Cl_2$ (367.0): calcd. C 52.36, H 4.39; found C 51.86, H 3.97.

Dicarbonyl(η^5-cyclopentadienyl)(phenylbuta-1,3-diynyl)iron (**2c**): The synthesis of **2c** from 6.1 g (20.0 mmol) of $[Cp(CO)_2FeI]$, 10.4 g (25.0 mmol) of *n*Bu$_3$Sn−C≡C−C≡C−Ph, 0.3 g (2.0 mmol) of CuI, and 2.5 g (2.0 mmol) of $[Pd(PPh_3)_4]$ in 150 ml of THF and the purification of the product by chromatography first with pentane/CH_2Cl_2 (ratio decreasing from 1:0 to 3:1) on alumina and then with pentane/CH_2Cl_2 (ratio slowly decreasing from 1:0 to 1:1) on silica gel] were carried out similarly to that of **2b**. Recrystallization from 40 ml of pentane/CH_2Cl_2 (1:1) gave **2c**. Yellow powder. Yield: 2.7 g (45%, based on $[Cp(CO)_2FeI]$), m.p. 91°C. − IR (CH_2Cl_2): $\tilde{\nu}$(CO) = 2042 cm^{-1} vs, 1994 vs; $\tilde{\nu}$(C≡C) = 2184 cm^{-1} m. − ^{1}H NMR (250 MHz): δ = 5.06 (s, 5 H, C_5H_5), 7.24, 7.39 (m, br., 5 H, C_6H_4). − ^{13}C NMR (250 MHz): δ = 64.8, 77.3 (C≡C), 85.4 (C_5H_5), 96.2, 97.3 (C≡C), 123.6, 127.5, 128.1, 132.4 (C_6H_5), 211.1 (CO). − MS (EI, 70 eV); *m/z* (%): 302 (38) [M$^+$], 274 (23), 246 (100) [M$^+$ − *n* CO; *n* = 1, 2]. − Although the product was chromatographed several times, it still contained small amounts of tin compounds. Therefore, a satisfactory elemental analysis could not be obtained.

Carbonyl(η^5-cyclopentadienyl)(trimethylsilyl-1,3-diynyl)(triphenylphosphane)iron (**3a**): A THF solution (50 ml) of 3.0 g (10.0 mmol) of **2a**, 0.8 g (10.0 mmol) of Me_3NO, and 4.0 g (15.0 mmol) of PPh_3 was stirred at room temp. The reaction was monitored by IR spectroscopy. After ca. 2 h, the solvent was removed in vacuo, the residue dissolved in 30 ml of CH_2Cl_2 and transferred to a column packed with silica gel. Gradient elution at 0°C with a mixture of pentane/CH_2Cl_2 (ratio slowly decreasing from 1:0 to 3:7) yielded the product as an orange band. After evaporation of the solvent in vacuo, the product was obtained as an orange oil. Yield: 3.4 g (63%, based on **2a**). The product was identified by comparison with literature data.[7a]

Pentacarbonyl{3-dicarbonyl(η^5-cyclopentadienyl)ferrio]-4,4-dimethyl-2-(trimethylsilylethynyl)cyclobut-2-en-1-ylidene}chromium (**4a**): At −60°C, a solution of 1.49 g (5.0 mmol) of **2a** in 50 ml of CH_2Cl_2 was added to a solution of **1**[6a]. The reaction mixture was allowed to slowly warm up to room temp. Then, 50 ml of pentane was added. The resulting suspension was filtered through a 2-cm layer of alumina and the alumina was eluted with CH_2Cl_2. The solvent was removed in vacuo and the residue was chromatographed at −30°C on silica gel. Elution with pentane/CH_2Cl_2 (ratio decreasing from 1:0 to 4:1) gave a red solution. The solvent was removed in vacuo and the residue recrystallized from 20 ml of pentane/CH_2Cl_2 (3:1). Red crystals of **4a**. Yield: 1.79 g (65%, based on $[Cr(CO)_6]$), m.p. 84°C. − IR (CH_2Cl_2): $\tilde{\nu}$(CO) = 2053 cm^{-1} s, 2034 s, 1990 s, 1939 vs; $\tilde{\nu}$(C≡C) = 2148 cm^{-1} vw. − UV/Vis (pentane): λ_{max} (lg ε) = 494 nm (4.212); (DMF): λ_{max} (lg ε) = 492 nm (4.178). − ^{1}H NMR (250 MHz): δ = 0.25 (s, 9 H, $SiMe_3$), 1.33 (s, 6 H, CH_3), 5.25 (s, 5 H, C_5H_5). − ^{13}C NMR (CD_2Cl_2, 250 MHz): δ = −0.4 ($SiMe_3$), 26.4 (CH_3), 74.3 (4-C), 87.1 (C_5H_5), 100.2, 104.4 (C≡C), 180.6 (2-C), 211.9 (Fe−CO), 217.9 (*cis*-CO), 229.2 (*trans*-CO), 251.5 (3-C), 313.3 (1-C). − $C_{23}H_{20}CrFeO_7Si$ (544.3): calcd. C 50.75, H 3.70; found C 50.52, H 3.88.

Pentacarbonyl{3-dicarbonyl(η^5-cyclopentadienyl)ferrio]-4,4-dimethyl-2-(hexa-1-ynyl)cyclobut-2-en-1-ylidene}chromium (**4b**): The synthesis of **4b** from **1** and 1.4 g (5.0 mmol) of **2b** in 50 ml of CH_2Cl_2 at −60°C and the purification of the product with pentane/CH_2Cl_2 (ratio decreasing from 1:0 to 2:1) were carried out analogously to that of **4a**. Red oil. Yield: 1.19 g (45%, based on $[Cr(CO)_6]$). − IR (CH_2Cl_2): $\tilde{\nu}$(CO) = 2051 cm^{-1} m, 2031 s, 1981 vs, 1935 vs; $\tilde{\nu}$(C≡C) = 2142 cm^{-1} vw. − UV/Vis (solvent): λ_{max} (lg ε) = (pentane) 490 nm (4.116), (DMF) 486 nm (4.161). − ^{1}H NMR (CD_2Cl_2, 250 MHz): δ = 0.86 (t, $^3J_{HH}$ = 7.1 Hz, 3 H, CH_3), 1.27 (s, 6 H, CH_3), 1.39−1.54 (m, 4 H, CH_2), 2.41 (t, $^3J_{HH}$ = 6.9 Hz, 2 H, CH_2), 5.14 (s, 5 H, C_5H_5). − ^{13}C NMR (CD_2Cl_2, 250 MHz): δ = 13.8 (CH_3), 19.8, 22.5 (CH_2), 26.8 (CH_3), 30.9 (CH_2), 74.3 (4-C), 75.9 (C≡C), 86.9 (C_5H_5), 100.6 (C≡C), 182.7 (2-C), 212.1 (Fe−CO), 218.3 (*cis*-CO), 228.9 (*trans*-CO), 245.3 (3-C), 304.8 (1-C). − $C_{24}H_{20}CrFeO_7$ (528.0): calcd. C 54.55, H 3.82; found C 54.29, H 4.11. − MS (FAB); *m/z* (%): 528 (22) [M$^+$], 500 (14), 472 (38), 444 (10), 416 (100), 388 (50), 360 (10), 332 (12) [M$^+$ − *n* CO; *n* = 1−7].

Pentacarbonyl{3-dicarbonyl(η^5-cyclopentadienyl)ferrio]-4,4-dimethyl-2-(phenylethynyl)cyclobut-2-en-1-ylidene}chromium (**4c**): The synthesis of **4c** from **1** and 1.5 g (5.0 mmol) of **2c** and the purification of the product were carried out analogously to **4b**. Recrystallization from 20 ml of pentane/CH_2Cl_2 (3:1) gave red crystals of **4c**. Yield: 1.65 g (60%, based on $[Cr(CO)_6]$), m.p. 84°C. − IR (CH_2Cl_2): $\tilde{\nu}$(CO) = 2052 cm^{-1} m, 2033 m, 1989 m, 1937 vs; $\tilde{\nu}$(C≡C) = 2146 cm^{-1} vw. − UV/Vis (pentane): λ_{max} (lg ε) = 494

nm (4.062); (DMF): λ_{max} (lg ε) = 492 nm (4.183). − ^{1}H NMR (CD_2Cl_2, 250 MHz): δ = 1.40 (s, 6 H, CH_3), 5.29 (s, 5 H, C_5H_5), 7.38−7.56 (m, 5 H, C_6H_5). − ^{13}C NMR (CD_2Cl_2, 250 MHz): δ = 26.6 (CH_3), 74.8 (4-C), 84.8 (C≡C), 87.0 (C_5H_5), 98.0 (C≡C), 123.3, 128.9, 131.5, 132.3 (C_6H_5), 180.7 (2-C), 211.9 (Fe−CO), 218.1 (*cis*-CO), 229.0 (*trans*-CO), 250.6 (3-C), 311.5 (1-C). − $C_{26}H_{16}CrFeO_7$ (548.3): calcd. C 56.96, H 2.94; found C 57.12, H 3.06. − MS (FAB); *m/z* (%): 548 (38) [M^+], 520 (22), 492 (40), 464 (10), 436 (100), 408 (52), 380 (10), 352 (30) [$M^+ - n$ CO; n = 1−7].

Pentacarbonyl{3-[carbonyl(η^5-cyclopentadienyl)(triphenylphosphane)ferrio]-4,4-dimethyl-2-(trimethylsilylethynyl)cyclobut-2-en-1-ylidene}chromium (**5a**): The synthesis of **5a** from **1** and 2.7 g (5.0 mmol) of **3a** in 50 ml of CH_2Cl_2 at −60°C, the purification, and the chromatography of the product were carried out analogously to that of **4a**. The red fraction was eluted with pentane/CH_2Cl_2 (ratio decreasing from 1:0 to 1:1). Recrystallization from 20 ml of pentane/CH_2Cl_2 (3:1) gave red crystals of **5a**. Yield: 2.53 g (65%, based on [$Cr(CO)_6$]), m.p. 152°C. − IR (CH_2Cl_2): $\tilde{\nu}$(CO) = 2043 cm^{-1} m, 1950 sh, 1927 vs; $\tilde{\nu}$(C≡C) = 2141 cm^{-1} vw. − UV/Vis (pentane): λ_{max} (lg ε) = 520 nm (4.246); (DMF): λ_{max} (lg ε) = 512 nm (3.889). − ^{1}H NMR (CD_2Cl_2, 250 MHz): δ = 0.26 (s, 9 H, $SiMe_3$), 0.49 (s, 3 H, CH_3), 1.25 (s, 3 H, CH_3), 4.82 (d, $^3J_{PH}$ = 1.5 Hz, 5 H, C_5H_5), 7.41−7.56 (m, 15 H, Ph). − ^{13}C NMR (CD_2Cl_2, 250 MHz): δ = −0.1 ($SiMe_3$), 25.8, 27.9 (CH_3), 76.2 (4-C), 87.2 (C_5H_5), 102.9, 104.1 (C≡C), 128.9, 129.0, 130.8, 130.9, 133.7, 133.9, 135.2, 135.9 (C_6H_5), 183.2 (2-C), 218.4 (d, $^2J_{PC}$ = 30 Hz, Fe−CO), 219.1 (*cis*-CO), 228.6 (*trans*-CO), 276.5 (d, $^2J_{PC}$ = 19 Hz, 3-C), 288.5 (1-C). − $C_{40}H_{35}CrFeO_6PSi$ (778.6): calcd. C 61.69, H 4.53; found C 61.91, H 4.63.

Decarbonylation of **4a** *with Me_3NO in the Presence of PPh_3:* A solution of 1.6 g (3.0 mmol) of **4a**, 0.3 g (3.0 mmol) of Me_3NO, and 1.6 g (6.0 mmol) of PPh_3 in 30 ml of THF was stirred at room temp. The progress of the reaction was monitored by IR spectroscopy. After about 1 h, the solvent was removed in vacuo, the residue dissolved in 15 ml of CH_2Cl_2, and the solution transferred to a chromatography column packed with silica gel. Gradient elution at −20°C with pentane/CH_2Cl_2 (ratio slowly decreasing from 1:0 to 1:1) yielded 1.71 g (72%, based on **4a**) of **5a**.

Pentacarbonyl{3-[carbonyl(η^5-cyclopentadienyl)(triphenylphosphane)ferrio]-4,4-dimethyl-2-(phenylethynyl)cyclobut-2-en-1-ylidene}chromium (**5c**): A solution of 1.4 g (2.0 mmol) of **7** in 5 ml of toluene was treated at room temp. with 0.5 g (2.5 mmol) of Me_3SnNMe_2. The reaction was followed by thin-layer chomatography. After 30 min, the solvent was removed in vacuo. The remaining oil was dissolved in THF (30 ml) and 0.5 g (2.5 mmol) of iodobenzene, 30 mg (0.2 mmol) of CuI, and 280 mg (0.2 mmol) of [$Pd(PPh_3)_4$] were added. The reaction mixture was stirred for 30 min at 40°C. The solvent was removed in vacuo, the residue dissolved in 15 ml of CH_2Cl_2 and chromatographed at −30°C with pentane/CH_2Cl_2 (ratio decreasing from 1:0 to 3:2) on silica gel. A red band was eluted. Recrystallization from 20 ml of pentane/CH_2Cl_2 (1:1) gave red crystals of **5c**. Yield: 1.25 g (76%, based on **7**), m.p. 95°C (dec.). − IR (CH_2Cl_2): $\tilde{\nu}$(CO) = 2043 cm^{-1} m, 1950 sh, 1925 vs, 1901 sh. − UV/Vis (pentane): λ_{max} (lg ε) = 522 nm (3.891); (DMF): λ_{max} (lg ε) = 516 nm (4.122). − ^{1}H NMR (250 MHz): δ = 0.56 (s, 3 H, CH_3), 1.27 (s, 3 H, CH_3), 4.80 (d, $^3J_{PH}$ = 1.5 Hz, 5 H, C_5H_5), 7.28−7.57 (m, 20 H, C_6H_5, PPh_3). − ^{13}C NMR (250 MHz): δ = 25.5, 27.7 (CH_3), 76.0 (4-C), 86.5 (C_5H_5), 97.5, 123.6 (C≡C), 128.2, 128.4, 128.6, 129.5, 130.5, 131.1, 132.8, 133.2, 134.1, 134.4, 134.8, 135.5 (C_6H_5, PPh_3), 182.0 (2-C), 217.8 (d, $^2J_{PC}$ = 29 Hz, Fe−CO), 218.7 (*cis*-CO), 228.1 (*trans*-CO), 275.8 (d, $^2J_{PC}$ = 17 Hz, 3-C), 291.8 (1-C). − ^{31}P NMR: δ = 68.8 (s). − $C_{43}H_{31}CrFeO_6P \cdot 1/2\ CH_2Cl_2$ (824.6): calcd. X-ray-Structural Analysis of **5a**: $C_{40}H_{35}CrFeO_6PSi$ (778.6), crystal size 0.3 × 0.3 × 0.3 mm (obtained from pentane/CH_2Cl_2, 3:1), triclinic, $P\bar{1}$, a = 11.555(2), b = 12.599(2), c = 15.382(2) Å, α = 83.83(2), β = 75.10(1), γ = 63.62(1)°, V = 1937.4(5) Å^3, Z = 2, $d_{calcd.}$ = 1.335 g cm^{-3}, μ(Mo-K_α) = 0.760 mm^{-1}, F(000) = 804, Wyckoff scan 4° < 2Θ < 54°, scan rate variable 4.00−30.00° min^{-1} in ω; Δω = 1.40°, T = 244 K, 8873 reflections collected, 8446 independent reflections, 6373 reflections with $F > 4.0\ \sigma(F)$; 451 refined parameters; R = 0.047, R_w = 0.051. Largest difference peak (hole): +0.45 e Å^{-3} (−0.38 e Å^{-3}). Data were collected with a crystal mounted in a glass capillary on a Siemens P4 diffractometer (graphite monochromator, Mo-K_α radiation, λ = 0.71073 Å). The structure was solved by Patterson methods and refined by full-matrix least-squares techniques (Siemens SHELXTL PLUS program package). The positions of the hydrogen atoms were calculated by assuming ideal geometries (d_{C-H} = 0.96 Å) and their coordinates were refined together with the attached C atoms as "riding models". Complete lists of atom coordinates and their thermal parameters have been deposited[29].

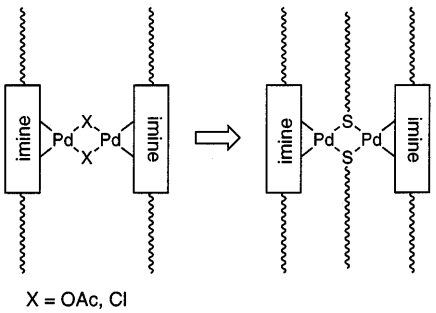
Keywords: Liquid crystals / Palladium / Metallomesogens / Orthometallated imine / Thiolate

The dinuclear cyclopalladated compounds $[Pd(\mu\text{-}Cl)Ln]_2$ (**2**) [HLn = *p*-$C_nH_{2n+1}OC_6H_4CH{=}NC_6H_4OC_nH_{2n+1}$-*p* (*n* = 6, 8, and 10)] react with silver thiolates AgSRm (Rm = C_mH_{2m+1}, *m* = 6, 8, 10, and 18) to give dinuclear derivatives with mixed bridges $[Pd_2(\mu\text{-}Cl)(\mu\text{-}SRm)Ln_2]$ (**3**). Treatment of derivatives **2** with silver acetate (Pd/AgOAc = 2:1) or treatment of $[Pd(\mu\text{-}OAc)Ln]_2$ (**1**) with thiols HSRm (Pd/thiol = 2:1) affords acetato-thiolato bridged complexes $[Pd_2(\mu\text{-}OAc)(\mu\text{-}SRm)Ln_2]$ (**4**). In addition to their mesogenic behavior, the most interesting feature of these complexes is the *cis* disposition of the palladium-imine moieties, that can be inferred from their ^{1}H-NMR spectra. The *cis* structure as well as the disposition of the bridges was confirmed by the X-ray diffraction study of **3** (*n* = *m* = 4).

The synthesis of metal-containing liquid crystals is an area of research which has seen a fast development in the last two decades[1]. Cyclometallated compounds of Pd^{II} with imines and related groups have received much attention due to: i) their thermal stability; ii) the variety of ligands useful for orthometallation leading either to calamitic or to discotic mesogens; and iii) the possibility of tuning the mesogenic properties not only by varying the nature or the length of the chains, but also the nature of the bridges in dinuclear complexes. The imine moiety provides the rigid core and flexible chains needed for liquid-crystal behavior, and two of these moieties are fused together upon orthometallation to give a X-bridged dinuclear complex (Figure 1). We have reported in the last years several types of cyclopalladated imine complexes and studied the structure-mesogenic activity relationships[2][3]. It seems from these studies that the acetato-bridged derivatives $[Pd(\mu\text{-}OAc)Ln]_2$ (**1**) are rigid non-planar dimers ("open book" or "butterfly" shaped), both in the solid state and in solution. Because of this unfavorable molecular shape the compounds do not display mesogenic behavior (there are, however, a few exceptions: some chiral-carboxylate derivatives[3], as well as certain carboxylate complexes using azine instead of imine as ligand[4], are mesomorphic). Their NMR spectra show that the acetato-bridged complexes are in fact a mixture of two isomers, depending on the relative arrangement of the two imine moieties (ca. 96% *trans* versus 4% *cis*). On the contrary, planar ("H" shaped) chloro-bridged dimers $[Pd(\mu\text{-}Cl)Ln]_2$ (**2**) contain only the *trans* isomer, and show the widest mesophase ranges (compared to other derivatives with azobenzene or azine as ligands)[5], although both the melting and the clearing points are quite high, above 100 and 200°C respectively. In both structures the separation between the two imine fragments leaves a wide empty space in the central part of the dimer, which could be filled using bridges that contained long alkyl chains. This should have a noticeable effect on the thermal properties of the material.

Figure 1. Sketch of the different space-filling efficiencies for complexes having bridges without or with long alkyl chains



In this paper we report on the attempt of replacing the chloro or acetato groups by thiolates bearing long alkyl chains. They were chosen taking advantage of the tendency of such ligands to form very stable Pd^{II}- or Pt^{II}-bridged complexes[6]. Furthermore, they could be expected to produce a basically planar dimer[7]. The results have shown that using silver thiolates only one of the chloro bridges is displaced, leading to mixed-bridged derivatives.

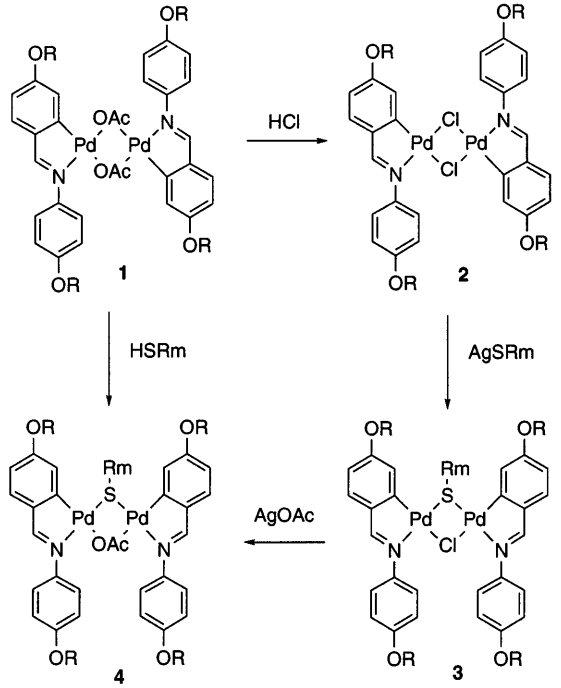
Scheme 1



Results and Discussion

Synthesis of the Complexes

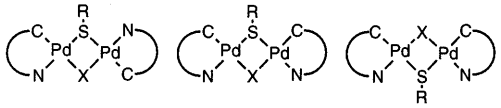
Mixed-bridged chloro-thiolate or acetato-thiolate complexes were prepared as shown in Scheme 1. The syntheses of the precursors **1** and **2** have been recently described by our group[3]. Treatment of $[Pd(\mu\text{-Cl})Ln]_2$ (**2**) with the appropriate silver thiolate (AgSRm) in CH_2Cl_2 (Pd/thiolate = 2:1.1) afforded $[Pd_2(\mu\text{-Cl})(\mu\text{-SRm})Ln_2]$ (**3**) in good yields (73−91%). It should be noted that, regardless of the reaction conditions or the ratio Pd/AgSRm used, only monosubstitution was obtained. The replacement of the second chloro bridge yielding $[Pd_2(\mu\text{-OAc})(\mu\text{-SRm})Ln_2]$ (**4**) was achieved by treating derivatives **3** with silver acetate in CH_2Cl_2 (Pd/acetate = 2:1, method A). This kind of complexes could also be obtained by displacement of one acetato bridge in complexes **1** using the corresponding thiol (Pd/thiol = 2:1, method B). Yields were similar (64−86%) in both cases.

All the complexes gave satisfactory elemental analyses, and were characterized by IR and ^{1}H-NMR spectroscopy. The latter is very informative, because both the iminic proton and H^3 are very sensitive to changes in the molecular structure, and the reactions can be monitored using these signals. These ^{1}H-NMR parameters are summarized in Table 2 only for complexes **3** and **4** with $n = m = 6$; the rest of complexes show little variation, within ± 0.03 ppm for the chemical shifts, and unnoticeable for the coupling constants.

Characterization of Complexes 3

The ^{1}H-NMR spectra of these complexes indicate that there is only one thiolato group in the dinuclear molecule. Three isomers are possible (Figure 2), but only one is formed since only one set of signals is observed in the aromatic region.

Figure 2. Sketch of the three possible isomers in mixed-bridged complexes **3** and **4**



The *trans*-I structure can be discounted since the different environment of the two imines should give rise to two sets of signals. Thus, the disposition of the palladium-imine moieties must be *cis*. The *cis*-II structure is favored because the antisymbiotic behavior of the palladium atom should place the thiolate group *cis* to the metallated carbon

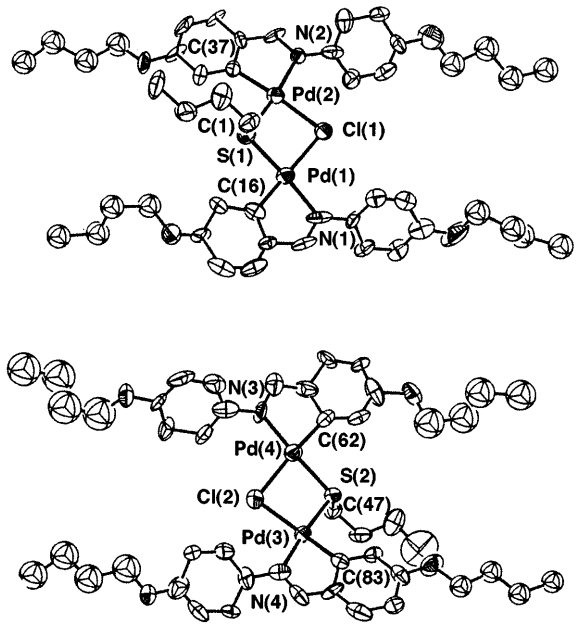
atom[8]. In fact, this structure has been observed in complexes $[M_2(\mu\text{-Cl})(\mu\text{-SR})Cl_2(PR_3)_2]$ (M = Pd or Pt)[9]: for M = Pd only the *cis* isomer was obtained, whereas for M = Pt a mixture of *cis* and *trans* isomers was found. On the contrary, cycloplatinated complexes similar to **3** lead only to the *cis* isomer[10]. Complexes **3** are expected to be basically planar both in solution and in the solid state and the comparable sizes of the chloro- and sulfur-bridging atoms should lead to an approximately parallel arrangement of the two imines.

Bridged dimers with orthopalladated ligands either have *trans* structure, or are mixtures of *cis*/*trans* isomers (*cis* being the minor isomer). Thus, these complexes are interesting for they afford isomerically pure *cis*-cyclopalladated derivatives in high yields. The *cis* arrangement is particularly interesting in view of possible application where a net dipolar moment on the material is required. The proposed structure was confirmed by the X-ray crystal analysis of the complex with $n = m = 4$. This is one of the few X-ray crystal structures of a cyclopalladated mesogen[11], probably due to the difficulty to obtain crystals suitable for X-ray analysis when long aliphatic chains are present. This complex displays an S_A mesophase between 175 and 235°C on heating.

The crystal structure consists of four molecules per unit cell, grouped in pairs. There are two different molecules in each pair (labelled as M1 and M2) in a disposition perpendicular to one another, and parallel to the molecules of the other pair. A perspective ORTEP view of these independent molecules is given in Figure 3. Selected bond lengths and angles are listed in Table 2.

Figure 3. ORTEP view of the two independent molecules, M1 and M2, of complex **3** ($n = m = 4$) showing the atom-labelling scheme



The coordination at each palladium atom is approximately square planar, with maximum deviations from the mean plane of 0.019 (Pd1) and 0.053 (Pd2) Å on M1 and 0.017 (Pd3) and 0.028 (Pd4) Å on M2. The Pd−C bond lengths in the two molecules are slightly different: 2.03(2) and 1.99(2) Å in M1 and 1.93(2) and 1.98(2) Å in M2. They are in good agreement with those described for $[Pd_2(\mu\text{-Cl})_2(\text{imine})_2]$ 1.97 Å[11]. The distances Pd−Cl and Pd−S are also quite similar to those found in complexes of the type $[Pd_2(\mu\text{-Cl})(\mu\text{-SR})Cl_2(PR'_3)_2]$ (R = alkyl or aryl; R′ = Me, Et, Ph)[12]. The small bite of the bidentate imine ligands produces the deviation of the angles around the palladium atoms from the ideal square disposition, 84.2(6) and 79.3(8)° in M1, and 77.8(7) and 83.1(6)° in M2. The angle between the two palladium-imine moieties is small, 16.5(2)° in M1 and 9.1(2)° in M2. The non-bonding Pd−Pd distances within each molecule are 3.443 Å in M1 and 3.437 Å in M2. Due to the tetrahedral coordination of the sulfur atom the first methylene of the thiolate group lies out of the mean Pd−S−Pd plane. The CH_2−S bond makes an angle with this Pd−S−Pd plane of 106° in M1 and 105.2° in M2. However, in both molecules the thiolato chains align themselves in the direction of the long molecular axis.

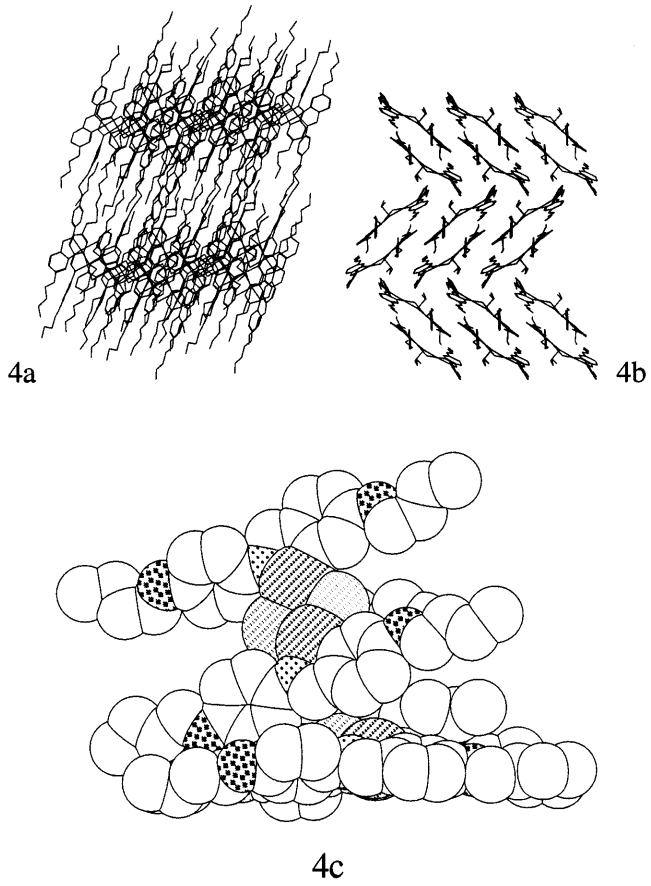
Figure 4a shows the crystal packing viewed perpendicular to the long molecular axis. A layer structure can be easily recognized where the molecular long axis is tilted respect to the layer plane, reminiscent of the S_C packing. The molecular arrangement within the layers is better seen in Figure 4b, which shows a view approximately along the molecular axis. It consists in arrays of pairs of molecules in alternate (zig-zag) directions. The minimun Pd−Pd distance between the antiparallel molecules making a pair is Pd(2)−Pd(4) = 4.024 Å. Some other non-bonding distances between the palladium atom and the carbon atoms of the other antiparallel molecule are quite short [e.g. Pd(2)−C(62) = 3.34 Å]. One of the rings linked to the nitrogen atom lies close to the empty space between the cyclopalladated moieties (Figure 4c), thus filling this space. The angles between the free-to-rotate phenyl ring linked to the

nitrogen atom and the cyclometallated ring are quite different 38.7(4)° and 47.2(5)° in M1 and 21.5(4)° and 57.6(5)° in M2, indicating poor conjugation along the imine ligands.

Figure 4. Crystal packing viewed (a) perpendicular to, and (b) approximately along the major molecular axis, (c) Chem3D view of the closest perpendicular molecules; hydrogen atoms are omitted for clarity



Characterization of Complexes 4

As for **3**, there is only one set of signals in the aromatic region of the ^{1}H-NMR spectra of complexes **4**, indicating the presence of only one isomer. It is assigned the structure *cis*-II (Figure 2) for the same reasons discussed for complexes **3**, and for the previously reported mixed-bridged thiolate-chiral carboxylate derivatives[13]. Both the signal of the first methylene group of the thiolate (δ = 2.47) and the methyl group of the acetato bridge (δ = 1.60) appear upfield with respect to their parent complexes **3** and **1**, respectively. The proposed disposition of the ligands is in agreement with the X-ray structures of similar orthopalladated complexes $[Pd_2(\mu\text{-OAc})(\mu\text{-SR})(\text{imine})_2]$[14] or $[Pd_2(\mu\text{-}CF_3CO_2)(\mu\text{-}t\text{BuS})(\text{C-N})_2]$[15], (C-N = cyclopalladated 8-methylquinoline). According to these structures complexes **4** are not planar in the solid state, showing a folded structure with an average angle of 98° between the two moieties of the molecule in the acetate-thiolate complex above mentioned. In solution the NMR spectra observed are those expected for a planar complex, due to a fast inversion at the sulfur atom[17]. Furthermore, the different size of the two bridges leads to a non-parallel arrangement of the long axes of the imine ligands.

Mesogenic Behavior

All the complexes display liquid-crystal behavior. Their mesophases, nematic (N) and smectic A (S_A), and/or smectic C (S_C) have been identified by their characteristic textures, noticeably more viscous than in organic mesogens[18]. The transition temperatures, as well as the corresponding enthalpies were determined by differential scanning calorimetry and are given in Tables 3 and 4 (in a few cases the transitions could not be detected by DSC and microscope data are given). Figure 5 shows this mesogenic behavior compared to that of the parent dinuclear complexes **2** (for complexes **3**) or **1** (for complexes **4**).

Complexes **3** show lower melting and clearing temperatures than the chloro complexes **2**. In all cases there is some decomposition at the clearing point. In complexes **4** the improvement of the mesogenic properties is clear, since the acetato complexes **1** are not mesogenic. Furthermore, compared to **1** these complexes display nematic phases for short

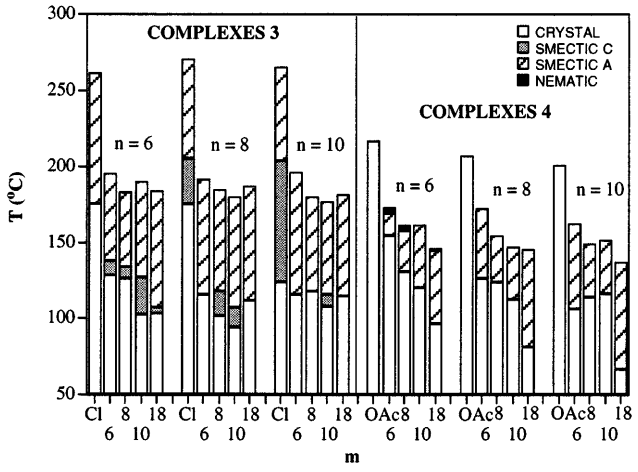
[a] C = crystal; N = nematic; S_A = smectic A. – [b] Combined enthalpies.

chains in the imines and the thiolate. This phase is not usual in dinuclear cyclopalladated imine mesogens. It is also remarkable that complexes **4** are able to display lyotropic behavior on mixing with linear alkanes or chiral solvents. The derivatives with $n = m = 6$ display broad ranges of nematic (or chiral nematic) lyomesophases, which are maintained until room temperature[16].

Figure 5. Thermotropic behavior of complexes **3** and **4**; *n* and *m* represent the number of carbon atoms in the imine and thiolate, respectively; the left bar on each group corresponds to the chloro-brigded derivative in complexes **3**, and to the acetato-brigded derivative in complexes **4**



Comparing the properties of compounds **3** and **4**, the influence of the structure on the liquid crystal behavior appears clearly. Planar complexes **3** display quite high transition temperatures as a consequence of the strong intermolecular interactions as well as a good packing of molecules leading to ordered smectic mesophases (S_A, S_C). Changing to the folded structure in complexes **4**, a less efficient packing of molecules leads to lower molecular interactions, less ordered mesophases (appearance of nematic phases), and lower transition temperatures. The stronger molecular interactions in complexes **3** can be also verified looking at the enthalpy figures of the same transition in both families: The crystal to smectic A mesophase gives a value of 21.4 and 18.7 kJ mol^{-1} for the complexes **3** and **4** ($n = 10$, $m = 6$), respectively.

Conclusions

i) Isomerically pure dinuclear complexes with mixed bridges leading to a *cis* structure can be easily prepared. ii) These complexes improve the mesogenic properties of the starting materials, either by decreasing the transition temperatures or by generating new mesophases . iii) The mesogenic properties of this kind of compounds can be doubly tuned, either by varying the nature of the thiolato bridge, or by replacing the second bridge with other bridging groups.

Experimental Section

General Procedures and Measurements:. ^{1}H-NMR spectra: Bruker AC-80 or AC-300 MHz spectrometers using $CDCl_3$. – Elemental analyses: Perkin-Elmer 2400 microanalyzer. – IR spectra: Perkin-Elmer 843 spectrophotometer using KBr pellets, unless otherwise noted. – The textures of the mesophases were studied with a Leitz Laborlux-D polarizing microscope, equipped with a Leitz 350 hot stage. – Transition temperatures and enthalpies were measured by differential scanning calorimetry, with a Perkin-Elmer DSC-7 operated at a scanning rate of 5°C min^{-1} on heating, using aluminium crucibles and N_2 as inert gas. The apparatus was calibrated with indium (156.6°C, 28.5 J g^{-1}) as standard.

Materials: CH_2Cl_2 was distilled from CaH_2. Literature procedures were used to synthesize the silver thiolates (AgSRm)[19], [Pd(μ-OAc)Ln]$_2$ (**1**) and [Pd(μ-Cl)Ln]$_2$ (**2**)[3]. AgOAc and aliphatic thiols (HSRm) were obtained from commercial sources and were used without further purification.

Preparation of [Pd_2(μ-Cl)(μ-SRm)Ln_2] (**3**): A solution of **2** (0.2 mmol) in 25 ml of CH_2Cl_2 was treated with a slight excess of the correspondig silver thiolate (Pd/AgSRm = 1:1.1), and the mixture was stirred in the dark for 5 h. The AgCl formed, as well as the excess thiolate, were filtered off and ethanol was added to the solution. Evaporation of the CH_2Cl_2 gave complexes **3** as yellow crystalline solids, which were filtered, washed with ethanol and air-dried. Yields were in the range 75–92%. – IR (KBr): $\tilde{\nu}$ = 1603 s (C=N), 1247 s 1028 m (C–O–C), 1574 s 829 m (Ar) cm^{-1}. – Analysis (%) for each *n*/*m* compound: **6/6**: calcd. C, 59.70; H, 7.24; N, 2.49; found C, 59.64; H, 7.10; N, 2.53. **6/8**: calcd. C, 60.33; H, 7.42; N, 2.43; found: C 60.07, H 7.28, N 2.64. **6/10**: calcd. C 60.93,

Crystal-Structure Determination of **3** (*n* = *m* = 4)[20]: Details of the crystal and refinement data for the structure are given in Table 5.

Suitable yellow single crystals were grown by slow diffusion of a $CHCl_3$ solution of the complex into ethanol at room temperature. All diffraction measurements were made with an Enraf-Nonius CAD-4 single-crystal diffractometer. The unit-cell dimensions were determined from the angular settings of 25 reflections in the range 15° < θ < 22°. The intensity data of 8915 reflections were measured, using the ω-2θ scan technique and a variable scan rate with a maximum scan time of 60 s per reflection. The intensity of the primary beam was checked throughout the data collection by monitoring three standard reflections every 60 min. The final drift correction factors were between 0.96 and 1.09. On all reflections profile analysis was performed[21][22]. 8230 reflections were "observed" with $I > 2\sigma(I)$. Lorentz and polarization corrections were applied and the data were reduced to F_o values. The structure was solved by Patterson methods using the program DIRDIF[23]. After isotropic least-squares refinement, using SHELXL93[24], an empirical absorption correction was applied using DIFABS[25]. The maximum and minimum absorption correction factors were 0.48 and 0.41, respectively. During the final stages of the refinement on F^2, the positional parameters and the anisotropic thermal parameters of the non-H atoms were refined, except the carbon atoms of the *n*-butoxy groups, which were refined isotropically as a rigid group with a common thermal parameter for each group. Hydrogen atoms were isotropically refined riding on their parent atoms with a common thermal parameter. The final conventional agreement factors were $R = 0.042$ and $wR^2 = 0.115$ for the 8230 "observed" reflections and 775 variables. The function minimized was $\Sigma w(F_o - F_c)^2$, $w = 1/[\sigma^2(F_o^2) + 0.0868 \cdot P)^2]$ with $\sigma(F_o)$ from counting statistics and $P = [\max(F_o^2,0) + 2 \cdot F_c^2]/3$. The maximum shift/e.s.d. ratio in the last full-matrix least-squares cycle was 0.019. Atomic scattering factors were taken from International Tables for X-ray Crystallography[26]. Geometrical calculations were made with PARST[27]. The figure showing the coordination and the atomic numbering scheme was drawn by EUCLID package[28]. All calculations were made with VAX computers at the Scientific Computer Center of the University of Oviedo.

Keywords: Ruthenium / α-Diimine ligand / Carbonylmetal compounds / Isomers /X-ray structure / Resonance Raman spectra

The syntheses, structures, and spectroscopic properties are reported for *trans,cis* and *cis,cis* isomers of [Ru(I)(Me)(CO)$_2$(α-diimine)] [α-diimine = *N,N′*-diisopropyl-1,4-diazabutadiene (*i*Pr-DAB), pyridine-2-carbaldehyde *N*-isopropylimine (*i*Pr-PyCa), 4,4′-dimethyl-2,2′-bipyridine (dmb)] which differ in their photochemical behaviour. The structures of *trans,cis*- and *cis,cis*-[Ru(I)(Me)(CO)$_2$(*i*Pr-DAB)] have been determined by a single-crystal X-ray diffraction study. The crystals of both isomers are monoclinic and belong to the same $P2_1/n$ space group with $Z = 4$. Refinement converged to $R = 0.043$ for the *trans,cis* isomer and to $R = 0.065$ for the *cis,cis* isomer. Both complexes have a distorted octahedral geometry, in the *cis,cis* isomer the methyl ligand is located in an equatorial, the iodide in an axial position. According to the ^{1}H- and ^{13}C-NMR and resonance Raman spectra the imine groups of the *i*Pr-DAB ligand are inequivalent in the *cis,cis* isomer. The absorption spectra vary with the α-diimine, not so much with the isomeric structure of the complex. Both isomers possess two visible absorption bands, which, according to the resonance Raman spectra, belong to charge transfer transitions from mixed metal-halide orbitals to the α-diimine. The resonance Raman spectra show that this charge transfer excitation is accompanied, for both isomers, with an angular distortion of the methyl ligand. These spectral data show that the difference in photochemical behaviour of the two isomers is not due to a change in the excited state character.

Introduction

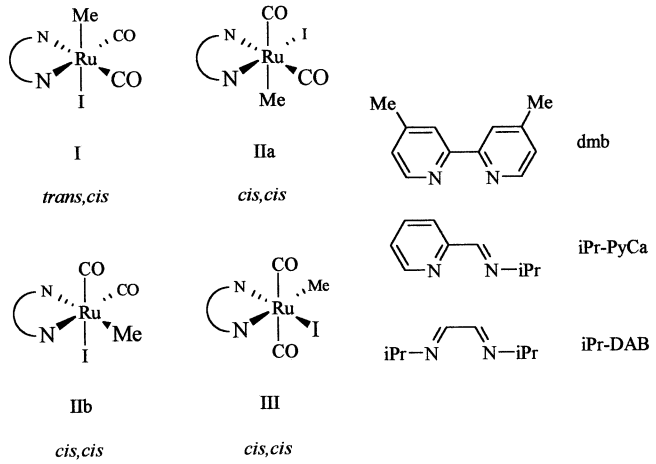
Many transition metal complexes having a lowest metal-to-ligand charge transfer (MLCT) excited state undergo efficient energy and electron transfer processes. Best studied in this respect are the complexes $[Ru(bpy)_3]^{2+}$[1][2][3] and $[Re(L')(CO)_3(bpy)]^{n+}$ ($n = 0$, 1; bpy = 2,2′-bipyridine; L′ = halide, O- or N-donor ligand)[4][5][6][7][8], and their derivatives. The $[Re(L')(CO)_3(\alpha\text{-diimine})]^{n+}$ complexes have the special property that variation of L′ not only influences the energy and character of the lowest excited state but may also change its reactivity. For instance, the metal−metal-bonded complexes [(L$_n$M)Re(CO)$_3$(α-diimine) [L$_n$M = (CO)$_5$Mn, (CO)$_5$Re, (CO)$_4$Co, Cp(CO)$_2$Fe] show a homolytic splitting of the Re−metal bond on irradiation with visible light.[4][9][10][11][12][13][14][14][15][16][17][18][19][20][21][22][23] Such homolysis reactions have also been observed for the Mn complexes [(CO)$_5$Mn−Mn(CO)$_3$(α-diimine)][13][18] and the Ru compounds [(L$_n$M)Ru(Me)(CO)$_2$(α-diimine)] [L$_n$M = (CO)$_5$Mn, (CO)$_5$Re, (CO)$_4$Co][24][25] and [Ru(SnPh$_3$)$_2$(CO)$_2$(α-diimine).[25][26] Similar photoreactions occur for the metal−alkyl (R) complexes [M(R)(CO)$_3$(α-diimine)] (M = Mn, Re)[27][28][29][30][31], [Ru(X)(R)(CO)$_2$(α-diimine)] (X = halide)[31][32], [Ir(R)(CO)(PAr$_3$)$_2$(mnt)][33], [Pt(Me)$_4$(α-diimine)][34], and [Zn(R)$_2$(α-diimine)][35], and even for the metal−halide complexes *mer*-[Mn(X)(CO)$_3$(α-diimine)].[36][37] These homolysis reactions are assumed to occur from a reactive $^3\sigma\pi^*$ state in which σ represents the high-lying σ-bonding orbital, and π* the lowest unoccupied orbital of the α-diimine ligand. Nearly all metal−metal-bonded complexes show at room temperature an efficient homolysis reaction, whereas the reactivity of the metal−alkyl complexes strongly depends on the nature of the alkyl group. For instance, the complexes [Re(R)(CO)$_3$(α-diimine)] (R = Et, Bzl) photodecompose into radicals with high quantum yield ($\Phi > 0.8$), whereas the quantum yield is only 0.05 for the corresponding [Re(Me)(CO)$_3$(*i*Pr-DAB)] complex.[27] Similarly, in the case of [Ru(X)(R)(CO)$_2$(*i*Pr-DAB)] (X = halide; R = Me, Et, *i*Pr, Bzl), the isopropyl and benzyl complexes show a high efficiency for their homolysis reaction, whereas the methyl and ethyl complexes do not undergo such a reaction.[32] A preliminary study showed that the complex *trans,cis*-[Ru(I)(Me)(CO)$_2$(dmb)] does not undergo a homolysis reaction, but is yet photolabile. It photoisomerises from its thermally stable *trans*(I,Me),*cis*(CO,CO) conformation into one of the two *cis,cis* isomeric forms. This photoproduct is photostable but thermally regenerates the parent *trans,cis* complex. In order to understand this remarkable behaviour, we have undertaken a structural and spectroscopic study of the *trans,cis* and *cis,cis* isomers. The results of this study are presented in this article.

The syntheses and molecular structures of several of these complexes have been first described by tom Dieck and

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1434−1948/98/0909−1243 $ 17.50+.50/0

co-workers[38][39], while the complexes have been used for an acylation reaction by Vrieze and co-workers.[40][41] The related complexes $[Ru(Cl)_2(CO)_2(\alpha\text{-diimine})]$ are known to form selectively stereoisomers.[42] It will be shown that in the case of the complexes under study only one of the possible four stereoisomers presented in Figure 1 [structure **IIb**] is formed.

Figure 1. General molecular structures of the different isomers of $[Ru(I)(Me)(CO)_2(\alpha\text{-diimine})]$ and of the α-diimine ligands used



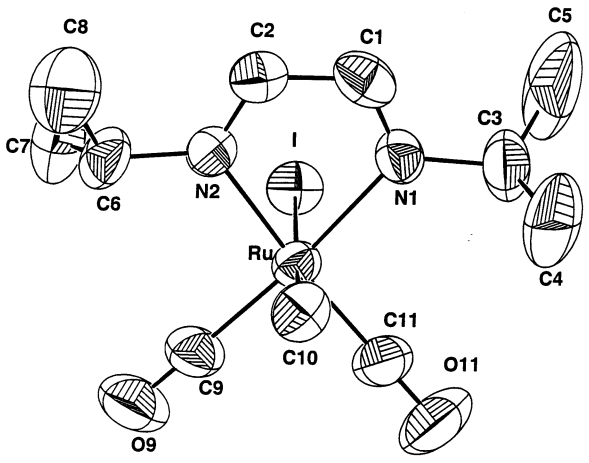
Results and Discussion

From the various *trans,cis*- and *cis,cis*-$[Ru(I)(Me)(CO)_2(\alpha\text{-diimine})]$ complexes which were synthesised, two isomers are structurally characterised by X-ray diffraction, the others by spectroscopic means. After presentation of the X-ray data, attention will be paid to several aspects of the synthesis procedure, in particular to the identity of the intermediates **1** and **2** of this reaction. Finally, the spectroscopic data of the complexes will be reported and discussed.

Crystal Structure of *trans,cis*-[Ru(I)(Me)(CO)$_2$(*i*Pr-DAB)]

Table 1 presents the bond lengths and bond angles of the non-hydrogen atoms of the complex. The ORTEP drawing of Figure 2 shows its *trans,cis* geometry.

Figure 2. Molecular structure and selected atom numbering of the non-hydrogen atoms (ORTEP drawing at 50% probability) of *trans,cis*-$[Ru(I)(Me)(CO)_2(i\text{Pr-DAB})]$



The *i*Pr-DAB ligand is σ(N1)−σ(N2)-bonded to the ruthenium centre, just as in the case of $[Ru(Me)(CO)_2(i\text{Pr-DAB})]^+OTf^-$[43], [Ru(I){C(O)Me}(CO)$_2$(*i*Pr-DAB)][43] and [Ru(I)(Me)(*i*Pr-DAB)(nbd)].[44] The bite angle of 76.8(2)°, which causes the deviation from a regular octahedral structure, has also been found for these complexes. The Ru−Me bond length [2.183(9) Å] is comparable with those of the Ru−C bonds in the complexes $[Ru(Me)(CO)_2(i\text{Pr-DAB})]^+OTf^-$ [2.122(9) Å][43], [Ru(Me)(Mn(CO)$_5$)(CO)$_2$(*i*Pr-PyCa)] [2.148(5) Å][45], $[Ru(Me)(CO)_2(i\text{Pr-DAB})]_2$ [2.152(5) Å][39] and [Ru(I)(Me)(*i*Pr-DAB)(nbd)] [2.222(13) Å].[44] The Ru−I bond length [2.7998(9) Å] is comparable with that of the same bond in $[Ru(I)(Si(Me)_2Ph)(CO)_2(NH_2CH_2C_6H_5)_2]$ [2.848(1) Å][46], [Ru(I){C(O)Me}(CO)$_2$(*i*Pr-DAB)] [2.811(9) Å][43] and [Ru(I)(Me)(*i*Pr-DAB)(nbd)] [2.878(1) Å].[44] It is somewhat larger than found for this bond in $[Ru(I)_2(CO)_2(i\text{Pr-DAB})]$ [2.711(8) Å][32] and $[Ru(I)_2(CO)_2(\text{pTol-DAB})]$ [2.708(1) Å][47] due to the much larger *trans* influence of the methyl group compared to I^-. The Ru−CO bonds (ca. 1.870 Å) are slightly longer than those of $[Ru(Me)(CO)_2(i\text{Pr-DAB})]^+OTf^-$ [1.847(9) Å][43], but comparable in length with those of [Ru(I){C(O)Me}(CO)$_2$(*i*Pr-DAB)] [1.874(7) Å].[43]

Crystal Structure of *cis,cis*-[Ru(I)(Me)(CO)$_2$(*i*Pr-DAB)]

The bond lengths and angles are collected in Table 2, while the ORTEP drawing of the complex is presented in Figure 3.

Figure 3 confirms the *cis,cis* conformation of the complex with the methyl ligand in the equatorial plane and the iodide in an axial position. The structural data agree well with those of the *trans,cis* isomer discussed above and with those of the related complexes [Ru(I){C(O)Me}(CO)$_2$(*i*Pr-DAB)][43], $[Ru(Me)(CO)_2(i\text{Pr-DAB})]^+OTf^-$[43], $[Ru(I)_2(CO)_2(\text{pTol-DAB})]$[47], $[Ru(I)_2(CO)_2(i\text{Pr-DAB})]$[32], and [Ru(I)(Me)(*i*Pr-DAB)(nbd)].[44] The complex has a distorted octahedral geometry [I−Ru−C(10) 176.8(7)°]. The *i*Pr-DAB ligand has a bite angle of 75.7(5)°, which is slightly smaller than found for the corresponding *trans,cis* complex [76.8(2)°]. Since the CO ligand has a smaller *trans* influence than the methyl group, the Ru−I bond is shorter [2.754(2) Å] than in the case of *trans,cis*-[Ru(I)(Me)(CO)$_2$(*i*Pr-DAB)] [2.7998(9) Å]. The bond lengths given in Table 2 for Ru−C(9) and Ru−C(11) are not very accurate. In the complex O(9) is divided in such a way that the CO and Me ligand are both equally distributed over the two possible positions, resulting in the introduction of two half O positions [O(9) and O(11)].

Mechanism of the Complex Formation

The reactions leading to the formation of the two isomers are presented in Scheme 1. The reaction of $[Ru_3(CO)_{12}]$ with MeI in acetonitrile (MeCN) results in the formation of an unknown product **1a**, which has ν(CO) vibrations at 2058(s), 1996(s), and 1637 cm^{-1}, and which is converted thermally into a second species **2a** having ν(CO) bands at 2041(s) and 1974(s) cm^{-1}. Both **1a** and **2a** react with an α-

diimine ligand. Thus, adding one equivalent of the α-diimine to a solution of **2a** results in the formation of *cis,cis*-[Ru(I)(Me)(CO)$_2$(α-diimine)], which has been structurally characterised with X-ray diffraction for α-diimine = *i*Pr-DAB (vide supra). The *cis,cis* isomers transform thermally within 3−7 days into the *trans,cis* isomers. On reaction of a *cis,cis* isomer with AgOTf, the halide (I^-) is replaced by OTf^-. This OTf complex can easily be converted into the *trans,cis* isomer by adding an excess of (nBu)$_4$NI.

In order to elucidate the structure of the first product in the reaction sequence, **1a**, the reaction between [Ru$_3$(CO)$_{12}$] and MeI was first brought to completion with formation of product **2a**. This solution was then put under 1 atm of CO and after 2 h **2a** was completely converted into **1a**. On addition of one equivalent of *i*Pr-DAB, **1a** produced a mixture of two complexes in a 4:1 ratio, which are assigned to *cis, cis*- and *trans,cis*-[Ru(I){C(O)Me}(CO)$_2$(*i*Pr-DAB)], respectively, with the use of their ^{1}H-NMR spectra.[48] Attempts to separate the two isomers failed. From the formation of these products by reaction of **1a** with *i*Pr-DAB it is tentatively concluded that **1a** is the acyl derivative of **2a**.

The structure of intermediate **2a** could not be determined by ^{1}H-NMR spectroscopy because of its low solubility and dynamic behaviour on the NMR time scale. Because of this, [Ru$_3$(CO)$_{12}$] was allowed to react with benzyl bromide (BzlBr) instead of with MeI. Intermediate **2b** is then formed as a major product with ν(CO) bands at 2042(s) and 1979(s) cm^{-1}, very similar to those of product **2a**. On addition of one equivalent of *i*Pr-DAB to **2b**, *cis,cis*-[Ru(Br)(Bzl)(CO)$_2$-(*i*Pr-DAB)] is formed, which in turn transforms within 30 min into the thermodynamically more stable *trans,cis* isomer. As **2a** and **2b** selectively produce the *cis,cis* isomers, these intermediates will neither represent *trans,cis,cis*-[Ru(X)(R)(CO)$_2$(MeCN)$_2$], analogous to *trans,cis,cis*-[Ru(Cl)$_2$(CO)$_2$(C$_6$H$_5$CN)$_2$][49] and *trans,cis,cis*-[Ru(Cl)$_2$-(CO)$_2$(pyridine)$_2$][50], nor the thermodynamically unfavourable all-*cis*-[Ru(I)(Me)(CO)$_2$(MeCN)$_2$]. The ^{1}H-NMR spectrum of **2b** shows that the complex possesses one equivalent of both the Bzl and acetonitrile (MeCN) ligands. Intermediates **2** are therefore proposed to be the dimeric species [Ru(X)(R)(CO)$_2$(MeCN)]$_2$ [X = I, R = Me (**2a**); X = Br, R = Bzl (**2b**)]. Figure 4 presents four possible structures of this dimer. The ^{1}H-NMR spectrum of **2b** clearly shows a diastereotopic effect on the CH_2 group of the benzyl ligand. Since a similar effect is observed for *cis,cis*-[Ru(Br)(Bzl)(CO)$_2$(*i*Pr-DAB)] it is concluded that structures **2.II** of Figure 4 are the most likely ones of **2**. For, if **2** had one of the **2.I** structures, a single resonance would have been observed for the CH_2 group, just as in the case of *trans,cis*-[Ru(Br)(Bzl)(CO)$_2$(*i*Pr-DAB)]. The formation of the *cis,cis*-[Ru(X)(R)(CO)$_2$(α-diimine)] complexes from the dimeric intermediates [Ru(X)(R)(CO)$_2$(MeCN)]$_2$ (**2**) is then straightforward. The α-diimine substitutes MeCN (L) and chelation of this ligand occurs after rupture of an Ru−X bond. As the weaker Ru−X bond *trans* to R will preferably be broken, this celation reaction leads to the formation of

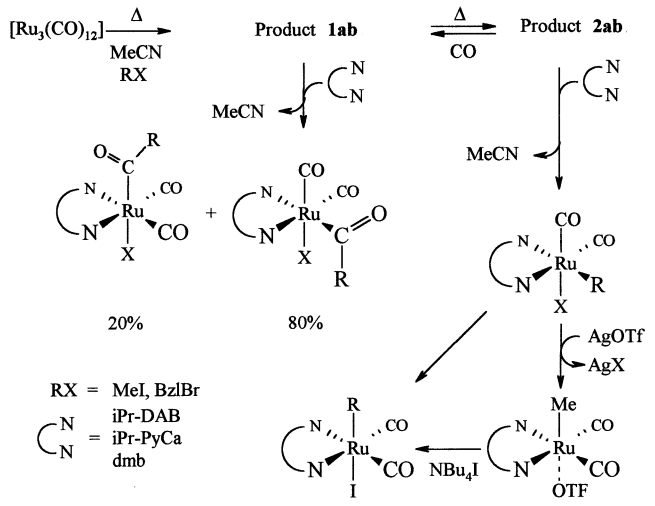
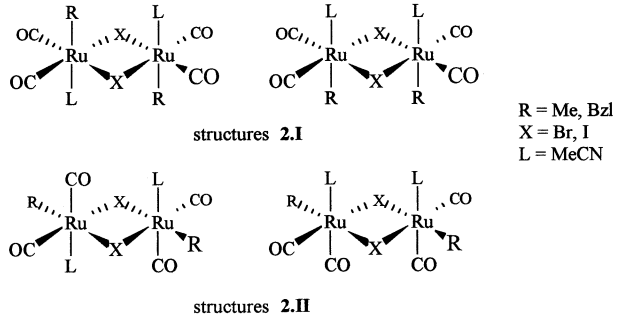
Scheme 1. Proposed mechanism for the reaction of [Ru$_3$(CO)$_{12}$] with RX and α-diimine



a *cis,cis* isomer in which R occupies an equatorial position and the remaining halide an axial one.

Figure 4. Relevant structures of [Ru(X)(R)(CO)$_2$(MeCN)]$_2$



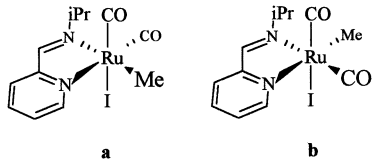
^{1}H- and ^{13}C-NMR Spectra

The structures of the *cis,cis* and *trans,cis* isomers of the *i*Pr-PyCa and dmb complexes were not determined by X-ray diffraction but were instead deduced from their ^{1}H- and ^{13}C-NMR spectra. The *trans,cis*-[Ru(I)(Me)(CO)$_2$(*i*Pr-DAB)] complex has C_s symmetry, and in agreement with this a simple pattern for the ^{1}H and ^{13}C resonances is observed.[40] The corresponding *cis,cis* complex has no symmetry anymore and two sets of proton and carbon signals are therefore expected for the coordinated *i*Pr-DAB ligand. These sets are indeed observed (see Experimental Section). However, due to the small difference in resonance frequencies in both the ^{1}H- and ^{13}C-NMR spectra, the sets of signals can not be assigned separately to the two imine parts of the *i*Pr-DAB ligand positioned *trans* to the methyl and CO ligand, respectively.

For the complex *trans,cis*-[Ru(I)(Me)(CO)$_2$(dmb)] only one set of signals is observed in the NMR spectra, just as for *trans,cis*-[Ru(I)(Me)(CO)$_2$(bpy)].[51] The *cis,cis* isomer shows again two sets of resonances in the ^{1}H- and ^{13}C-NMR spectra, with small shifts comparable to those observed for the *i*Pr-DAB complex. These ^{1}H-NMR data exclude the formation of the *cis*(I,Me),*cis*(CO,CO) complex, with the iodide equatorial and the methyl group axial. The ^{1}H-NMR spectrum of *cis,cis*-[Ru(Cl)$_2$(CO)$_2$(R-PyCa)], with the chloride *trans* to the imine moiety, shows a resonance for H^6, which is shifted down field by approximately 0.5 ppm with respect to that of H^6 in the *trans,cis*-[Ru(Cl)$_2$(CO)$_2$(R-PyCa)] complex.[42] This shift is not found for *cis,cis*-[Ru(I)(Me)(CO)$_2$(dmb)], and these signals are accordingly assigned to the latter conformation, with the methyl in an equatorial and the iodide in an axial position.

The complexes of the asymmetric ligand *i*Pr-PyCa can in principle form two diastereoisomers (Figure 5), both con-

Figure 5. General molecular structures of the diastereoisomers of *cis,cis*-[Ru(I)(Me)(CO)$_2$(*i*Pr-PyCa)]



a **b**

sisting of two enantiomers. ^{1}H- and ^{13}C-NMR data reveal that only one diastereoisomer of *cis,cis*-[Ru(I)(Me)(CO)$_2$-(*i*Pr-PyCa)] is formed, since only one set of resonances is observed for the pyridine and imine moieties of the *i*Pr-PyCa ligand. This diastereoisomer is proposed to have structure **a** (see Figure 5) with a carbonyl ligand *trans* to the strongly σ-donating and weakly π-accepting pyridine moiety and the methyl *trans* to the more weakly σ-donating and more strongly π-accepting imine part of the *i*Pr-PyCa ligand. A similar structure had been found for *cis,cis*-[Ru(Cl)$_2$(CO)$_2$(R-PyCa)], which has the chloride in a *trans* position with respect to the imine moiety.[42] Based on the ^{1}H- and ^{13}C-NMR data alone, it is not possible to assign the position of the halide ligand. In order to confirm this proposal and prove the structure, an NOE-difference experiment was performed. These spectra show that an interaction exists between the methyl ligand and H^6 of the pyridine moiety. Thus, the methyl ligand coordinates selectively *trans* with respect to the imine group, which confirms that the complex has the structure (**a**) of Figure 5.

It has been shown above that replacement of the methyl ligand by CO has hardly any influence on the NMR resonances of the *trans*-positioned α-diimine ligand. In contrast with this, changing the position of the methyl ligand from axial (*trans* to I$^-$) to equatorial (*trans* to the α-diimine) on going from the *trans,cis* isomer to the *cis,cis* isomer, has a pronounced effect on the NMR signals of the methyl group. The methyl signals of the *cis,cis* complexes are observed in the region δ = 0.78−0.93, and those of the *trans,cis* complexes in the region δ = 0.08−0.10 (^{1}H NMR).[40][41] This shift is most probably due to through-space interaction between the methyl and the iodide, when these ligands are in a *cis* position.[42]

Electronic Absorption Spectra

The absorption spectral data of the complexes are collected in Table 3. Figure 6 (left) presents the spectra of the complexes *cis,cis*-[Ru(I)(Me)(CO)$_2$(L)] (L = dmb, *i*Pr-PyCa, and *i*Pr-DAB) in toluene. For comparison the spectra of both *trans,cis*- and *cis,cis*-[Ru(I)(Me)(CO)$_2$(*i*Pr-DAB)] in toluene are depicted in Figure 6 (right).

In a previous article it was shown that the *trans,cis*-[Ru(X)(Me)(CO)$_2$(α-diimine)] (X = halide) complexes possess two visible absorption bands, the relative intensities of which depend on the halide used.[51] In accordance with a similar behaviour observed for the corresponding *fac*- and *mer*-[Mn(X)(CO)$_3$(bpy)] complexes[36], these two bands were then assigned to charge transfer transitions to the α-diimine ligand from two sets of orbitals having metal (d$_\pi$)−halide (p$_\pi$) bonding and anti-bonding character, respectively. In the case of the iodide complexes one of the iodide p$_\pi$ orbitals has the largest contribution to the HOMO and the lowest-energy transition of *trans,cis*-[Ru(I)-(Me)(CO)$_2$(α-diimine)] has therefore predominant halide to α-diimine (XLCT) character. The transitions of the higher energy band have mainly MLCT character.[51]

Table 3. Absorption maxima [nm] and solvatochromism [Δ is σ_{max}(MeCN) − σ_{max}(toluene) in cm^{-1}] of *trans,cis*- and *cis,cis*-[Ru-(I)(Me)(CO)$_2$(α-diimine)]

Compound	λ_{max} (MeCN)	λ_{max} (THF)	λ_{max} (toluene)	Δ
cis,cis-[Ru(I)(Me)(CO)$_2$(dmb)]	384; 344	405; 363	416; 374	2003; 2331

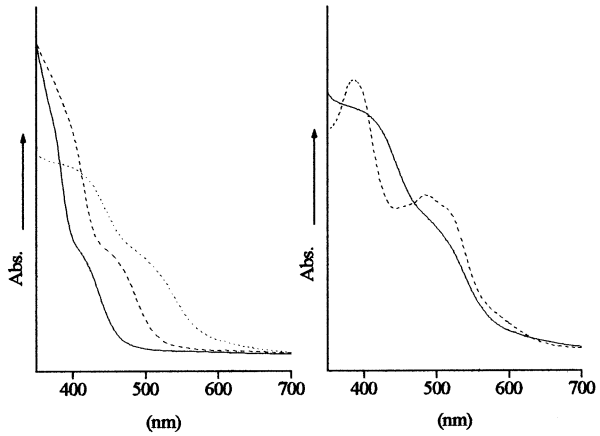
[a] From ref.[51].

Figure 6. Left: Electronic absorption spectra of *cis,cis*-[Ru-(I)(Me)(CO)$_2$(α-diimine)] (dmb = ——, *i*Pr-PyCa = ----- and *i*Pr-DAB = ·····) in toluene; right: electronic absorption spectra of *trans,cis*- (-----) and *cis,cis*-[Ru(I)(Me)(CO)$_2$(*i*Pr-DAB)] (——) in toluene



A similar two-band system is observed in the spectra of the complexes *cis,cis*-[Ru(Me)(I)(CO)$_2$(α-diimine)]. Varying the α-diimine ligand from *i*Pr-DAB to *i*Pr-PyCa and dmb causes a shift of both absorption bands to higher energy (Figure 6). The shifts are closely related to the changes in energy of the lowest π* orbital of the α-diimine ligand.[15][52] In the case of the dmb complex these shifts are so large, that the second absorption band has almost completely disappeared under the much stronger absorptions at higher energy. In agreement with its CT character, the lowest-energy band is solvatochromic, shifting to lower energy

by ca. 2000 cm^{-1} on going from acetonitrile to toluene (Table 3).

Resonance Raman Spectra

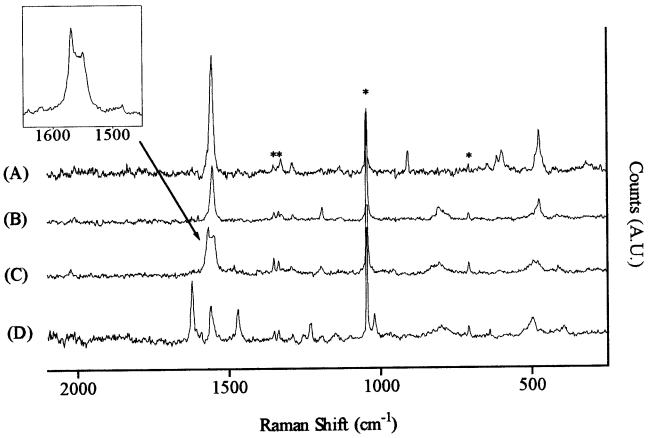
Resonance Raman (rR) spectroscopy is a very valuable technique for the assignment and characterisation of allowed electronic transitions.[53][54][55][56] Since only those vibrations are normally resonance-enhanced, which are vibronically coupled to the electronic transitions, these transitions can be characterised by the observed resonance effects. From the three *cis,cis* isomers rR spectra could only be recorded for the *cis,cis*-[Ru(I)(Me)$(CO)_2$(*i*Pr-DAB)] and *cis,cis*-[Ru(I)(Me)$(CO)_2$(*i*Pr-PyCa)] complexes. The corresponding dmb complex is too photolabile to provide reliable spectra. Spectra were obtained by excitation with the 488.0-nm line of an argon ion laser into the lowest-energy absorption band of the complexes. The resonantly enhanced Raman bands of the complexes are collected in Table 4. Figure 7 shows the rR spectra of *trans,cis*-[Ru(I)(R)$(CO)_2$(*i*Pr-DAB)] (R = CD_3, CH_3) and *cis,cis*-[Ru(I)$(CH_3)(CO)_2$(α-diimine)] (α-diimine = *i*Pr-DAB, *i*Pr-PyCa), respectively. The spectra of *trans,cis*-[Ru(I)(R)$(CO)_2$(*i*Pr-DAB)] (R = CD_3, CH_3) show a strong rR effect for a band at approximately 1555 cm^{-1}, which belongs to ν_s(CN), the symmetrical stretching mode of the imine groups of the *i*Pr-DAB ligand. This band is split in the rR spectra of the *cis,cis* isomer, indicating that the two imine groups of the *i*Pr-DAB ligand are inequivalent due to the different *trans* influences of the Me and CO groups. This effect is not evident from the X-ray structures, but is also observed in the ^1H- and ^{13}C-NMR spectra (vide supra). The Raman spectrum of *cis,cis*-[Ru(I)(Me)$(CO)_2$(*i*Pr-PyCa)] is very similar to that of its *trans,cis* isomer.[51]

Table 4. Resonantly enhanced Raman bands of *trans,cis*- and *cis,cis*-[Ru(I)(R)$(CO)_2$(α-diimine)] (R = CH_3, CD_3; α-diimine = *i*Pr-DAB, *i*Pr-PyCa), measured at 80 K in KNO_3 ⊥ft parenthesisλ_{exc} = 488.0 nm)

Compound	Raman shift [cm^{-1}]
trans,cis-[Ru(I)$(CD_3)(CO)_2$(*i*Pr-DAB)]	1555, 1328, 1287, 1132, 909, 615, 599, 475
trans,cis-[Ru(I)(Me)$(CO)_2$(*i*Pr-DAB)]	2010, 1553, 1328, 1287, 1194, 806, 475
cis,cis-[Ru(I)(Me)$(CO)_2$(*i*Pr-DAB)]	2022, 1568, 1550, 1293, 1198, 806, 486, 395
cis,cis-[Ru(I)(Me)$(CO)_2$(*i*Pr-PyCa)]	1620, 1560, 1471, 1291, 1254, 1230, 1194, 1151, 1021, 801, 500, 395

The rather strong rR effect of ν_s(CN) confirms the charge transfer character of the electronic transition in which excitation takes place. For both isomers there is hardly any rR effect for ν_s(CO). This means that their charge transfer transitions do not originate from a central metal orbital since this would involve a change of metal-to-CO π backbonding and invoke an rR effect for ν_s(CO). Instead, the transition takes place from an orbital having mainly halide character just as for the *trans,cis* isomer.[51] In addition, the rR spectra of *trans,cis*- and *cis,cis*-[Ru(I)(Me)$(CO)_2$(*i*Pr-DAB)] show weaker rR effects for bands at 1328, 1194, 806, and 475 cm^{-1}. Replacement of CH_3 by CD_3 in the *trans,cis* isomer causes a shift of the 1194 cm^{-1} band to 909 cm^{-1}, while the 806 cm^{-1} band is both shifted and split, giving rise to two new bands at 615 and 599 cm^{-1}, respectively. The positions of the other bands are not affected.

Figure 7. Resonance Raman spectra of (A) *trans,cis*-[Ru(I)(CD_3)-$(CO)_2$(*i*Pr-DAB)], (B) *trans,cis*-[Ru(I)(Me)$(CO)_2$(*i*Pr-DAB)], (C) *cis,cis*-[Ru(I)(Me)$(CO)_2$(*i*Pr-DAB)], (D) *cis,cis*-[Ru(I)(Me)$(CO)_2$(*i*Pr-PyCa)] in KNO_3 at 80 K, λ_{exc} = 488.0 nm (* = NO_3^-)



In agreement with the vibrational spectra of [M$(CH_3)(CO)_5$] and [M$(CD_3)(CO)_5$] (M = Mn, Re)[57], the bands at 1194/909 cm^{-1} are assigned to $\delta_s(CH_3/CD_3)$ and those at 806/615;599 cm^{-1} to $\rho(CH_3/CD_3)$. The doublet spacing of the $\rho(CD_3)$ band in [Ru(I)$(CD_3)(CO)_2$(*i*Pr-DAB)] (16 cm^{-1}) is rather small compared with that observed for [Re$(CH_3)(CO)_5$] (44 cm^{-1})[57] and [Re$(CD_3)(CO)_3$(dmb)] (51 cm^{-1}).[58] The rR effect of the two methyl vibrations is clearly an electronic effect and not the result of a coupling to other vibrations since the deuteration does not affect the frequencies of other Raman bands. The observation of these CH_3/CD_3 bands implies that the charge transfer transition influences the bond angles of these ligands, most probably as a result of a change of the hybridisation of the C atom of the CH_3 ligand due to a charge redistribution during the charge transfer transition.

The observation that deuteration of the methyl ligand does not affect the frequency of any Raman bands below 800 cm^{-1}, leads to the following conclusions. First of all, the Raman band at approximately 500 cm^{-1} does not belong to ν(Ru−CH_3) and is assigned to ν_s(Ru−CO), expected in this frequency region. Secondly, the absence of a rR effect for ν(Ru−CH_3) implies that the electronic transition, in which the excitation takes place, does not influence the Ru−methyl σ bond, although it affects the bond angles of the methyl ligand. This result agrees with the proposed XLCT character of the transition and excludes the possibility that the lowest-energy absorption band belongs to an allowed σ(Ru-methyl)→π*(α-diimine) transition instead.

According to the rR spectra, the *trans,cis* and *cis,cis* isomers of the [Ru(I)(Me)$(CO)_2$(*i*Pr-DAB)] complexes have very similar low-energy transitions. The difference in photo-

chemistry between *trans,cis*- and *cis,cis*-[Ru(I)(Me)-(CO)$_2$(dmb)], viz. photoisomerization of the *trans,cis* into the *cis,cis* isomer and no apparent product formation of the *cis,cis* isomer, can therefore not be ascribed to a different character of the lowest excited state. This difference in photochemical behaviour is the subject of a detailed photochemical study of these complexes, the results of which will be published in a forthcoming article.

Prof. *A. Oskam* is gratefully acknowledged for advice and for critical reading of the manuscript. Mr *J. M. Ernsting* is thanked for measuring the NOE-difference spectrum. Experimental Section

Materials, Apparatus and Preparations: [Ru$_3$(CO)$_{12}$], MeI, BzlBr, silver triflate (AgOTf), (*n*Bu)$_4$NI, and 4,4′-dimethyl-2,2′-bipyridine (dmb) were used without further purification. Silica gel for column chromatography (Kieselgel 60, 70−230 mesh, Merck) was activated by heating overnight in vacuo at 160°C. Solvents for synthetic purposes were of reagent grade and carefully dried over sodium wire (THF, *n*-hexane, diethyl ether) or $CaCl_2$ (CH_2Cl_2) and freshly distilled under nitrogen prior to use. Acetonitrile was used without further purification. Solvents for spectroscopic measurements were of analytical grade, dried over sodium and distilled under N_2 before use. *i*Pr-DAB and *i*Pr-PyCa were synthesised according to literature procedures.[59] Electronic absorption spectra were measured with a Varian Cary 4E spectrophotometer, infrared spectra with an FTS-60A FTIR spectrometer equipped with a liquid-nitrogen-cooled MCT detector. − The ^{1}H-, NOE-difference, and ^{13}C-NMR spectra were recorded with a Bruker AMX 300 spectrometer (300.13, 75.46 MHz, respectively) at 293K. Resonance Raman measurements were performed with a Dilor XY spectrometer, using an SP Model 2016 argon ion laser as excitation source. To avoid photodecomposition the spectra of the complexes (dispersed in a KNO_3 pellet) were measured at 80K. Typical concentrations were 30 mg of complex and 150 mg of KNO_3.

Synthesis of cis,cis-[Ru(I)(Me)(CO)$_2$(L)] (L = iPr-DAB, iPr-PyCa, dmb): Ru$_3$(CO)$_{12}$ (300 mg, 0.46 mmol) and MeI (1.5 ml, excess) were refluxed in 20 ml of acetonitrile at 100°C. After 10 min, a product with CO-stretching frequencies at 2058 (s), 1996 (s) and 1637 (w) was obtained. The reaction was brought to completion within ca. 1 h; a yellow solution was then obtained which contained product **2a** with CO-stretching frequencies of 2041 (s) and 1974 (s) cm^{-1}. After evaporating the solvent, product **2a** was dissolved in 10 ml of diethyl ether together with 0.5 mmol of the α-diimine ligand. After stirring for 1 h, the solution was filtered off and the residue was washed with hexane (2 × 10 ml). The complex was purified by column chromatography on silica gel using gradient elution with CH_2Cl_2/THF. Yield 80−90%.

cis,cis-[Ru(I)(Me)(CO)$_2$(iPr-DAB)]: ^{1}H NMR ($CDCl_3$): δ = 8.26/8.20 (s, 1 H, H_{im}), 4.64/4.20 [sept, *J* = 6.6 Hz, 1 H, C*H*(CH$_3$)$_2$], 1.63/1.55/1.49/1.40 [d, *J* = 6.6 Hz, 3 H, CH(C*H*$_3$)$_2$], 0.78 (s, 3 H, Ru−Me). − ^{13}C NMR APT ($CDCl_3$): δ = 200.8 (Ru-*C*O$_{eq}$), 193.3 (Ru-*C*O$_{ax}$), 160.1/157.7 (*C*H$_{im}$), 65.6/57.2 [*C*H(CH$_3$)$_2$], 24.8/23.5/23.3/22.2 [CH(*C*H$_3$)$_2$], −14.7 (Ru-*C*H$_3$). − IR (CH_2Cl_2): ν(CO) = 2028 (s), 1958 (s) cm^{-1}. − MS (FAB$^+$): M(calcd.) 439.95, M(found) 439.95.

cis,cis-[Ru(I)(Me)(CO)$_2$(iPr-PyCa)]: ^{1}H NMR ($CDCl_3$): δ = 9.01 (d, *J* = 5.1 Hz, 1 H, py-H^6), 8.48 (s, 1 H, H_{im}), 8.05 (t, *J* = 7.7 Hz, 1 H, py-H^4), 7.85 (d, *J* = 7.7 Hz, 1 H, py-H^3), 7.61 (t, *J* = 5.1 Hz, 1 H, py-H^5), 4.20 [sept, 6.3 Hz, 1 H, C*H*(CH$_3$)$_2$], 1.64/1.52 [d , 6.3 Hz, 6 H, CH(C*H*$_3$)$_2$], 0.93 (s, 3 H, Ru-Me). − ^{13}C NMR APT ($CDCl_3$): δ = 201.1 (Ru-CO$_{eq}$), 194.0 (Ru-CO$_{ax}$), 160.2 (H_{im}), 155.5 (py-C^2), 149.7 (py-C^6), 138.8 (py-C^3), 127.7 (py-C^5), 126.6 (py-C^4), 65.3 [*C*H(CH$_3$)$_2$], 24.6/23.7 [CH(*C*H$_3$)$_2$]. −13.4 (Ru-*C*H$_3$). − IR (CH_2Cl_2): ν(CO) = 2027 (s), 1956 (s) cm^{-1}. − MS (FAB$^+$): M(calcd.) 449.92, M(found) 449.92.

cis,cis-[Ru(I)(Me)(CO)$_2$(dmb)]: ^{1}H NMR ($CDCl_3$): δ = 8.85 (d, *J* = 5.6 Hz, 2 H, py-H^6), 7.99/7.96 (s, 2 H, py-H^3/py-H$^{3'}$), 7.38/7.27 (d, *J* = 5.6 Hz, 1 H, py-H^5/py-H$^{5'}$), 2.58/2.55 (s, 6 H, py-Me/py-Me′), 0.89 (s, 3 H, Ru-Me). − ^{13}C NMR APT ($CDCl_3$): δ = 200.7 (Ru-CO$_{eq}$), 195.6 (Ru-CO$_{ax}$), 156.0/153.5(py-C^2/py-C$^{2'}$), 153.0/148.8 (py-C^6/py-C$^{6'}$), 150.2/149.8 (py-C^4/py-C$^{4'}$), 127.1/126.7 (py-C^3/py-C$^{3'}$), 123.4/123.2 (py-C^5/py-C$^{5'}$), 21.2 (py-*C*H$_3$), −14.3 (Ru-*C*H$_3$). − IR (CH_2Cl_2): ν(CO) = 2025 (s), 1952 (s) cm^{-1}. −MS (FAB$^+$): M(calcd.) 483.92, M(found) 483.92.

Synthesis of trans,cis-[Ru(I)(Me)(CO)$_2$(L)] (L = iPr-DAB, dmb): The complexes *trans,cis*-[Ru(I)(R)(CO)$_2$(*i*Pr-DAB)] (R = CH_3, CD_3), which were used for X-ray structure analysis and Raman spectroscopic measurements, were prepared by the procedure described by Kraakman et al.[40] The corresponding dmb complex was prepared from its *cis,cis* isomer according to the following procedure. One equivalent of AgOTf was added to a solution of *cis,cis*-[Ru(I)(Me)(CO)$_2$(dmb)] in CH_2Cl_2, which was then stirred for 2 h. The residue, AgI, was filtered off and 1 g (excess) of (*n*Bu)$_4$NI was added while light was excluded to prevent photodecomposition. This solution was stirred for 3 h. The excess of (*n*Bu)$_4$NI and (*n*Bu)$_4$NOTf was filtered off and the solvent was evaporated. The complex was purified by column chromatography on silica gel using gradient elution with CH_2Cl_2/THF. Yield 80−90%.

trans,cis-[Ru(I)(Me)(CO)$_2$(dmb)]: ^{1}H NMR ($CDCl_3$): δ = 8.83 (d, *J* = 5.7 Hz, 2 H, py-H^6), 7.96 (s, 2 H, py-H^3), 7.30 (d, *J* = 5.7 Hz, 2 H, py-H^5), 2.56 (s, 6 H, py-Me), 0.10 (s, 3 H, Ru-Me). − ^{13}C NMR APT ($CDCl_3$): δ = 202.2 (Ru-CO), 153.4 (py-C^2), 151.6 (py-C^6), 150.2 (py-C^4), 127.2 (py-C^3), 123.5 (py-C^5), 21.3 (py-*C*H$_3$), −4.8 (Ru-*C*H$_3$). − IR (CH_2Cl_2): ν(CO) = 2030 (s), 1962 (s) cm^{-1}.

Synthesis of cis,cis-[Ru(I){C(O)Me}(CO)$_2$(iPr-DAB)]: Ru$_3$-(CO)$_{12}$ (300 mg, 0.46 mmol) and MeI (1.5 ml, excess) were refluxed in 20 ml of acetonitrile at 100°C. The reaction was completed after ca. 1 h; a yellow solution was then obtained containing product **2a** with ν(CO) frequencies of 2041(s) and 1974(s) cm^{-1}. The solution was pressurised with CO (1 atm) and stirred for 2 h. Product **1a** was obtained with ν(CO) of 2058(s) and 1996(s) cm^{-1}. After evaporation of the solvent, product **1a** and 75 mg (0.5 mmol) of *i*Pr-DAB were dissolved in 10 ml of diethyl ether. After stirring for 1 h, the solution was filtered and the residue was washed with hexane (2 × 10 ml). The complex was purified by column chromatography on silica gel using gradient elution with CH_2Cl_2/THF. Total yield 75% {the ^{1}H-NMR spectrum shows that *trans,cis*-[Ru(I){C(O)Me}(CO)$_2$(*i*Pr-DAB)] and *cis,cis*-[Ru(I){C(O)Me}(CO)$_2$(*i*Pr-DAB)] are formed in a 1:4 ratio}.

trans,cis-[Ru(I){C(O)Me}(CO)$_2$(iPr-DAB)]: ^{1}H NMR ($CDCl_3$): δ = 8.20 (s, 2 H, H_{im}), 4.24 [sept, *J* = 6.6 Hz, 2 H, C*H*(CH$_3$)$_2$], 2.53 [s, 3 H, Ru-C(O)Me], 1.43/1.38 [d, *J* = 6.6 Hz, 6 H, CH(C*H*$_3$)$_2$]. − IR (CH_2Cl_2): ν(CO) = 2040 (s), 1974 (s), 1640 (w) cm^{-1}.

cis,cis-[Ru(I){C(O)Me}(CO)$_2$(iPr-DAB)]: ^{1}H NMR ($CDCl_3$): δ = 8.20/8.18 (1 H, s, H_{im}), 5.15/4.17 [sept, *J* = 6.6 Hz, 2 H, C*H*(CH$_3$)$_2$], 2.81 [s, 3 H, Ru-C(O)Me], 1.69−1.38 [m, *J* = 6.6 Hz, 12 H, CH(C*H*$_3$)$_2$]. − IR (CH_2Cl_2): ν(CO) = 2040 (s), 1974 (s), 1640 (w) cm^{-1}.

Synthesis of Product **2b**: $Ru_3(CO)_{12}$ (300 mg, 0.46 mmol) and BzlBr (0.5 ml, excess) were refluxed in 20 ml of acetonitrile at 100°C. After completion of the reaction (ca. 0.5 h), a yellow solution was obtained with product **2b** having ν(CO) frequencies of 2042(s) and 1976(s) cm^{-1} and a product with ν(CO) bands at 2077(s) and 2020(s), in a 2:1 ratio. After evaporation of the solvent, the complex was washed with diethyl ether (2 × 10 ml). Yield 30%.

Product **2b**: ^1H NMR ($CDCl_3$): δ = 7.25−7.15 (m, 4 H, H_{Ph}), 7.01 (m, 1 H, H_{Ph}), 2.96/2.89 (d, ^2J = 8.5 Hz, 2 H, PhCH_2), 2.29/2.26 (s, 3 H, CH_3CN). − IR (MeCN): ν(CO) = 2042 (s), 1976 (s) cm^{-1}.

Synthesis of cis,cis-[Ru(Br)(Bzl)(CO)$_2$(iPr-DyAB)]: Product **2b** was prepared in acetonitrile. After evaporation of the solvent, complex **2b** and 0.5 mmol of *i*Pr-DAB were dissolved in 10 ml of diethyl ether. After stirring for 0.5 h, the solution was filtered off and the residue was washed with hexane (2 × 10 ml). Yield 50%.

cis,cis-[Ru(Br)(Bzl)(CO)$_2$(iPr-DAB)]: ^1H NMR ($CDCl_3$): δ = 8.26/8.24 (s, 1 H, H_{im}), 7.37 (d, *J* = 7.5 Hz, 2 H, H_{Ph}), 7.17 (t, *J* = 7.5 Hz, 2 H, H_{Ph}), 6.95 (t, *J* = 7.5 Hz, 1 H, H_{Ph}), 4.64/4.11 [sept, *J* = 6.6 Hz, 1 H, C*H*(CH_3)$_2$], 3.57 (d, ^2J = 7.8 Hz, 1 H, PhCH_2), 2.98 (d, ^2J = 7.8 Hz, 1 H, PhCH_2), 1.56−1.41 [m, 12 H, CH(CH_3)$_2$]. − IR (CH_2Cl_2): ν(CO) = 2030 (s), 1962 (s) cm^{-1}.

Synthesis of trans,cis-[Ru(Br)(Bzl)(CO)$_2$(iPr-DAB)]: This complex was prepared by the procedure of Kraakman et al.[40]

trans,cis-[Ru(Br)(Bzl)(CO)$_2$(iPr-DAB)]: ^1H NMR ($CDCl_3$): δ = 8.16 (s, 2 H, H_{im}), 7.10 (t, *J* = 7.6 Hz, 2 H, H_{Ph}), 7.02 (t, *J* = 7.5 Hz, 1 H, H_{Ph}), 6.88 (d, *J* = 7.5 Hz, 2 H, H_{Ph}), 4.22 [sept, *J* = 6.6 Hz, 2 H, C*H*(CH_3)$_2$], 2.36 (s, 2 H, PhCH_2), 1.61/1.38 [d, 12 H, CH(CH_3)$_2$]. − IR (CH_2Cl_2): ν(CO) = 2033 (s), 1969 (s) cm^{-1}.

Crystal Structure Determination of trans,cis-[Ru(I)(Me)(CO)$_2$-(iPr-DAB)] and cis,cis-[Ru(I)(Me)(CO)$_2$(iPr-DAB)]: Crystals of both compounds were grown from a saturated CH_2Cl_2 solution at 293 K. Crystals with approximate dimensions 0.20 × 0.30 × 0.40 mm (0.15 × 0.20 × 0.60 mm) were used for data collection with an Enraf-Nonius CAD-4 diffractometer with graphite-monochromated Mo-K_α radiation and ω-2θ scan. Totals of 4661 (4819) unique reflections were measured. Of these, 3168 (1931) were above the significance level of 2.5 σ(*I*). The maximum value of (sinθ)/λ was 0.70 $Å^{-1}$. Unit-cell parameters were refined by a least-squares fitting procedure using 23 reflections with 40° < 2θ < 41° (40° < 2θ < 42°). Corrections for Lorentz and polarization effects were applied. The structures were solved by the PATTY option of the DIRDIF-94 program system.[60] Hydrogen atom positions were calculated. Full-matrix least-squares refinement of *F*, anisotropic for the non-hydrogen atoms and isotropic for the hydrogen atoms, with a fixed temperature factor of $U = 0.15$ $Å^2$ and restraining the latter in such a way that the distance to their carrier remained constant at approximately 1.0 Å, converged to $R = 0.043$ (0.065), R_w = 0.045 (0.063), $(\Delta.\sigma)_{max} = 0.45$ (0.61), $S = 0.81$ (1.49). An empirical absorption correction (DIFABS[61]) was applied, with coefficients in the range of 0.68−1.22 (0.40−1.53). A final difference Fourier map revealed a residual electron density between −0.7 and 0.7 e$Å^{-3}$ (−1.2 and 1.0 e$Å^{-3}$) in the vicinity of the heavy atoms. Scattering factors were taken from Cromer and Mann.[62][63] The anomalous scattering of Ru and I was taken into account.[64] All calculations were performed with XTAL[65], unless stated otherwise. Both isomers were refined in the same way but after isotropic refinement of the starting model of the *cis,cis* isomer some atoms had a rather high temperature factor (C5, C8 and O9). C5 and C8 could be split into two positions a and b with occupancy factors for a = 0.35 and for b = 0.65. O9 was divided in such a way that the CO and CH_3 were both equally distributed over the two possible positions and thus resulting in the introduction of two half occupied O positions (O9 and O11). The disordered C atoms were kept isotropic during refinement. No attempts were made to calculate the H atoms for C5a, C5b, C8a and C8b and the H atoms for C3 and C6 were divided into separate positions and kept fixed entirely at their calculated position. The experimental data for the crystal structure determinations and refinements are listed in Table 5.

Table 5. Crystallographic data and details of the structure determinations of *trans,cis*-[Ru(I)(Me)(CO)$_2$(*i*Pr-DAB)] (**A**) and *cis,cis*-[Ru(I)(Me)(CO)$_2$(*i*Pr-DAB)] (**B**)

Reactions of $Cp_2Ti(CO)_2$ (**3**) with two equivalents of α,β-unsaturated ketones **4** yield the novel titana-2,9-dioxacyclonona-3,7-dienes **5**. Cross-coupling of **3** with two different ketones **4** and **6** to give **7** can be achieved under certain reaction conditions. Hydrolysis of **5** or **7** may generate diketones **9**, cyclopentanols **10/11**, or cyclopentenes **12/13**, depending on substituents and conditions. The X-ray crystal structure of **5a**, the first nine-membered bis(η^5-cyclopentadienyl)-substituted titanaheterocycle containing carbon, is presented. Ab initio calculations were performed for **5a** and for titana-2-oxacyclopentene **1**, a conceivable intermediate in the coupling reaction.

Introduction

Titanaheterocycles are known with ring sizes ranging from three to ten and with different degrees of "unsaturation". Whereas most of the publications focussed on systems featuring four-[1], six-[2][3][4], eight-[4][5] or ten-membered[5] rings, we were interested in the chemistry of the odd-numbered chelate complexes, like titanaheterocyclopropanes,[3] titanaheterocyclopentanes and -pentenes,[4][5][6][7][8][9][10][11] or titana-2,7-dioxacyclohepta-3,5-dienes.[6][11][12] Structurally characterized nine-membered titanacycles are known as well, but most of them lack carbon in their metallacycle, as for instance TiS_8 systems.[4][13] We reported[14] on the synthesis of "carbon-rich" bis(η^5-cyclopentadienyl)titanadioxacyclononadienes **5** by a novel coupling of two α,β-unsaturated ketones with $Cp_2Ti(CO)_2$, and recently Okuda[15] published the X-ray structures of nine-membered titanacycles built up from a 2,2′-ethylenebisphenol and simple TiR_4 precursors. We now present the structure and preparative use of the titanacycles **5**, as well as cross-coupling variants of our reaction with two different ketones. We also took a closer look at the mechanism of the coupling process and performed ab initio calculations on the title complexes **5** and on conceivable intermediates like titana-2-oxacyclopent-3-enes **1**, which are hitherto unknown[16] in contrast to their zirconium analogues[17] and their isomers, the titanacyclopent-4-enes **2**.[9][10]

Results and Discussion

Synthesis of "Symmetric" Titana-2,9-dioxacyclonona-3,7-dienes 5; Scope and Limits

We have recently shown that α,β-unsaturated arylketones (e.g. **4a**) readily react under mild, non-basic conditions with dicarbonyltitanocenes **3**[18] to furnish the corresponding nine-membered bis-unsaturated metallacycles **5** right away without five-membered species of type **1** being detectable intermediates[14]. Oxidative addition of two ketone units, loss of two equivalents of CO and exclusive *trans*-β,β coupling are the features of this reaction, which at first seemed to be restricted to bis(aryl)-substituted ketones, though.

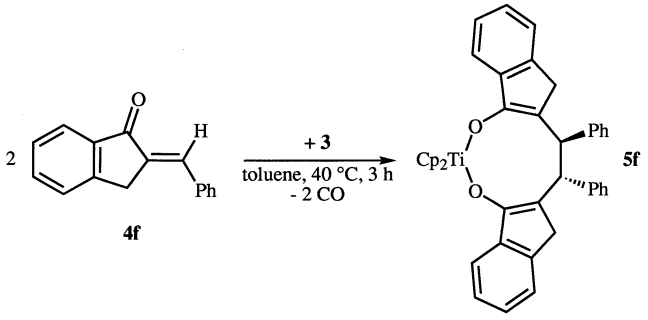
We now found, that the residues R^2 may also be aliphatic to give equally high yields of **5** (**5b**), whereas R^1 adjacent to the carbonyl function is more crucial to the course of the reaction. Aryl groups, alkyl systems not bearing an α-hydrogen atom, like *tert*-butyl (**5c**), or vinyl units are compatible as R^1. Ketones **4** with methyl or saturated primary or secondary alkyl groups next to the carbonyl function do usually not give any metallacycles **5** on reaction with **3** in isolable yields.

α,β;γ,δ-Bis(unsaturated) ketones (**4d**) do not give metallacycles with larger rings but merely the corresponding vinyl-substituted cyclononadienes (**5d**). Remarkably, reaction of **3** with the tris(unsaturated) ketone **4e** yields exclusively the symmetric 5,6-diphenyl-substituted derivative **5e** by a β,β-C−C coupling at the "short ends" of the trienones. This pathway may be preferred due to kinetic reasons or due to the highest degree of olefinic conjugation of the product compared with 11- or 13-membered metallacycles, which would result from β,δ-C−C and δ,δ-C−C coupling reactions, respectively. Reactions of **3** with carbocyclic ketones like **4f** also give rise to the corresponding metallacycles like **5f** without providing evidence for the intermediacy of − now bicyclic and thus in principle more stable − species of type **1**. **5f** is also the first derivative carrying substituents at each ring carbon atom.

Scheme 2



The most attractive extension of this basic reaction would be cross-coupling variants of **3** with two different unsaturated carbonyl moieties. *Intra*molecular cross-coupling does not take place, however, with ketones bearing a second unsaturated keto or ester group at an appropriate distance. Reaction of **3** with the keto ester **4g**, for instance, proceeds with 1:2 stoichiometry and with formation of titanacycle **5g** in low yield. Although bearing an α-hydrogen atom at a saturated residue R^1, complex **5g** is as stable as more typical derivatives of **5** bearing vinyl, aryl or *tert*-butyl residues at C3 and C8. **5g** is the only example of a titanacycle with this structural feature.

Table 1 shows a representative collection of new "symmetric" titanadioxacyclononadienes prepared from **4** and **3** in a 2:1 stoichiometry.

X-ray Crystal Structure of Complex 5a

So far, only a few titanaheterocycles with ring sizes larger than six have been characterized by X-ray analysis[5][13]. Single crystals of **5a** suitable for an X-ray crystal structure analysis could be obtained from a solution in toluene kept in the dark at room temperature for twenty days. To our knowledge, the structure obtained from these crystals is the first one of an unsaturated nine-membered titanacycle except for the non-cyclopentadienyl systems Ti[2,2′-ethylenebis(6-*tert*-butyl-4-methylphenolato)]X_2[15] [X = Br, O*i*Pr, $CH_2(SiMe_3)_2$].

8: A = C = R^3, B = D = R^4

5a features roughly C_2 symmetry about an axis through the titanium atom and the opposite ring bond between C5 and C6. All bonds of the chelate have lengths as expected, with only small differences for the pairs of corresponding bonds. Only the C5−C6 bond (1.59 Å) is slightly longer than an average carbon−carbon single bond (1.55 Å).The adjoining bonds (C4−C5 and C6−C7) are both roughly 1.50 Å long. The C=C bonds C3−C4 and C7−C8 have lengths of 1.34 and 1.35 Å. Both C−O bonds have very similar lengths (1.36 Å), as have the Ti−O bonds (1.89 Å). The cyclopentadienyl rings in **5a** are staggered by an angle of 132°. In contrast, the few other published nine-membered Cp_2Ti-chelates all show eclipsed Cp ligands.[13] The titanium atom is coordinated pseudo-tetrahedrally, with the angle O−Ti−O being 102°, which is in the typical range. The metallacyclic system is puckered about the C_2 axis, the angle between the O−Ti−O plane and the opposite C5−C6 bond is roughly 90°, both C=C bonds are *cis* configured. In **5a**, the angles Ti−O−C are 143° and 145°, which are common values for unstrained cycles. All four dihedral angles including Ti−O segments are close to 70°, the dihedral angles C3−C4−C5−C6 and C5−C6−C7−C8 are ca. 60°, and the angle C4−C5−C6−C7 is 151°. This results in coplanarity of the phenyl groups at C5 and C6, which are oriented formally *trans* to each other. Crystals of **5a** pertinaciously contain half an equivalent of toluene per molecule.

Synthesis of Cross-Coupled Nine-Membered Metallacycles 7

"Unsymmetric" cross-coupled titanacycles **7** can be prepared in special cases from two unsaturated ketones **4** and **6** of sufficiently different reactivity towards **3**. In principle, three distinct products could result from reactions of a mixture of **3**, **4**, and **6**. Formation of complex **8** from **3** and two equivalents of the more reactive ketone **6** can be supressed by dropwise addition of **6** to a mixture of **4** (lower reactivity) and **3**. The ratio of chelate complexes **5** and **7** is strongly influenced by the reaction temperature. The yields of the cross-coupled products **7** increase markedly with increasing temperature. Best results are obtained by preparing a mixture of **3** and **4** at 50°C, followed immediately by dropwise addition of **6**. Only cases where **7** is formed exclusively are of synthetic interest, as separation of mixtures of **5**, **7**, and **8** is cumbersome due to their lack of air-stability and to similar chromatographic behaviour. Table 2 shows a couple of such well-defined examples.

Hydrolysis of Titanadioxacyclononadienes 5 and 7

Acidic hydrolysis of the "symmetric" titanacycles **5** leads to only one racemic pair of highly substituted cyclopentanols **10**, bearing four stereocentres, by a selective aldol reaction.[14] In most cases some diketone **9** and/or cyclopentene **12** is formed as well but can be easily removed by column chromatography. The *trans* orientation of the substituents at C3 (B) and C4 (D) is defined in the course of the β-β coupling leading to **5**. The keto function at C2 then is oriented *trans* to B and the hydroxy group at C1 is finally formed *cis* to this keto group due to favourable hydrogen bond interactions. The unambiguous assignment of the relative stereochemistry of **10** and proof of the absence of further diastereomers (or epimers) is based on NMR spectra. Table 3 shows some new examples for the formation of cyclopentanols **10** from titanacycles **5** to illustrate the widened scope and the limits of the method and the influence of the solvent used for hydrolysis. As a rule of thumb, low temperatures and the use of ethereal instead of aqueous solutions of hydrogen chloride favour the formation of cyclopentanols **10** over that of diketones **9**. Hydrolysis of the unusual titanacycle **5f** gives rise to the interesting spiro compound **10b** (besides minor amounts of diketone **9b**) featuring five stereocentres about the central cyclopentane core, although rather unselectively. All possible eight isomers (plus enantiomers), when a *trans* orientation of the phenyl groups is assumed, are found in rather arbitrary ratios and can be separated by HPLC. Hydrolyses of the "un-

[a] If **5** is involved instead of **7**, for all compounds applies $R^1 = R^3$ and $R^2 = R^4$; only one regioisomer of cyclopentanol (designated **10** in Table 3) or cyclopentene is possible.

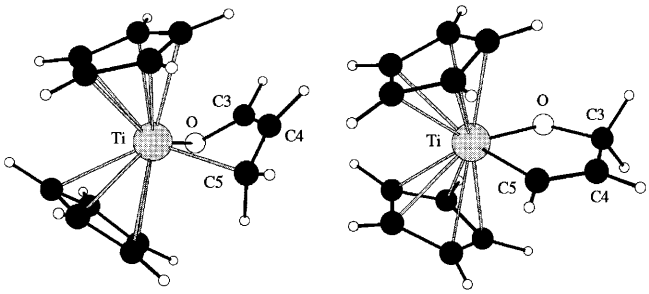
symmetric" titanacycles **7** are of little synthetic use, as leading merely to mixtures of alcohols **10/11** and of cyclopentenes **12/13**. Two typical examples are enclosed in Table 3.

Ab Initio Calculations on Five- and Nine-Membered Metallacycles

As mentioned above, all our attempts to obtain even trace amounts of the expected intermediate titana-2-oxacyclopent-3-enes **1** instead of the exclusively formed corresponding nine-membered titanacycles **5** were unsuccessful. On the other hand, stable examples of the isomeric titana-2-oxacyclopent-4-ene **2** have been reported by several research groups. In order to understand this difference, we performed ab initio (MP2) and hybrid density functional (B3LYP) calculations on **1**, **2**, **5**, and some related species.[19][20][21][22][23] With one exception (see below), both methods yield essentially the same results. The calculated geometries are in good agreement with available experimental data. Figure 3 shows the MP2-optimized structures of **1** and **2**.

Titana-2-oxacyclopent-3-ene **1** is computed to be 10 kcal/mol more stable than its isomer **2**. The five-membered ring in **2** is planar, with bond lengths and angles indicating regular C–C single and double bonds (bond lengths are 1.506 and 1.343 Å, respectively). The computed values agree well with those obtained in the crystal structure determination of the diphenyl derivative, the main difference being a slight folding of the five-membered ring in the experimental structure.[9][10] In the computed structure of **1**, however, the ring is strongly folded, with significant delocalization (C–C bond lengths are 1.446 and 1.394 Å for the formal single and double bonds, respectively). As far as we know, no bis(cyclopentadienyl)-substituted five-membered titanacycles with structures deviating significantly from planarity are published. Thus, instead of a titanacyclopentene with a Ti–C σ bond, our calculations predict a strong interaction of the titanium centre with the CH_2 moiety and the C–C double bond in a π-allylic fashion. While unusual in organotitanium compounds, π-allylic bonding is common for the later transition metals. With 2.267 Å, the computed Ti–CH_2 distance is roughly 0.1 Å longer than a regular Ti–C single bond. The distances to the double bond carbon atoms are 2.451 and 2.520 Å. Due to the short distance between the metal centre and the double bond, an exceptionally small value of 94° results for the Ti–O–C angle. Analysis of the electronic structure reveals a strong donation from the π-bond to the metal centre and an increased polarity of the Ti–CH_2 σ bond. Thus, **1** is best described as a C-nucleophilic electron-rich (18 valence electrons) allyl complex.

Figure 3. MP2-optimized structures of titana-2-oxacyclopentenes **1** ($R^{1,2}$ = H), left, and **2** ($R^{1,2}$ = H), right[a]



[a] Selected bond lengths [Å] and angles [°]: **1**: Ti–O 1.9734, Ti–C3 2.4512, Ti–C4 2.5199, Ti–C5 2.2670, C3–C4 1.3942, C4–C5 1.4461; Ti–O–C3 93.8; **2**: Ti–O 1.8280, Ti–C5 2.1638, C3–C4 1.5031, C4–C5 1.3524; Ti–O–C3 125.2.

Two conformations are possible for **5**, which differ in the orientation of the organic fragment with respect to the Cp_2TiO_2 moiety. The geometric data of the experimental conformer are in good agreement with the X-ray structure. The relative stability of the two conformers is predicted differently by the MP2 and B3LYP methods, although the actual difference is small. At MP2/TZ2p, the experimental conformer is 1.2 kcal/mol more stable, whereas B3LYP/TZ2p predicts it to be less stable by 1.1 kcal/mol.

A possible route to **5** involves addition of **1** to propenal. This reaction is calculated to be 49 kcal/mol exothermic. The activation barrier appears to be very low: several attempts, with different starting geometries, were made to compute the structure of the initial complex for the addition but in all cases, the structure collapsed to **5** during the optimization. We believe the combination of the unusual bonding features in **1**, in particular the lengthening and corresponding weakening of the $Ti-CH_2$ bond, and the significant exothermicity of the reaction to be responsible for this behaviour.

We probed alternative mechanisms via complexes of titanocene and two propenal moieties. These gave the same result as above (optimization leads to **5** without activation barrier), but in all cases, high-energy intermediates must be involved. Hence, we consider these alternatives less probable than reaction via **1**.

Conclusions

By careful choice of conditions, novel nine-membered titanadioxacycles **5** and **7** can be prepared from α,β-unsaturated ketones with a broad variety of substituents. The X-ray analysis of the tetraphenyl derivative **5a** revealed a C_2-symmetric puckered structure with two *Z*-configured C=C bonds and a *trans* orientation of residues about the newly formed C−C bond. Acidic hydrolysis of these chelate complexes is synthetically useful in case of "symmetrically" substituted derivatives **5**, where highly substituted cyclopentanes **10** are obtained as one racemic pair of stereoisomers out of eight possible ones, due to selectivity in the C−C bond formation process and to steric restraints and preferences. Ab initio calculations on the nine-membered rings **5** and on conceivable five-membered intermediates were performed. For the expected intermediate complex **1** of our coupling reaction, an unusual structure of high reactivity of the Ti−C σ bond due to an interaction of the titanium centre with the CH_2 moiety and the C−C double bond in a π-allylic fashion was calculated, thus providing an explanation for its elusive character. Further work is in progress now to prepare titanacycles with even larger rings by similar C−C coupling reactions or by Cope rearrangement of aptly substituted nine-membered systems like **5d**.

Experimental Section

General Information: All reactions involving organometallic compounds were carried out in an inert atmosphere (argon) using Schlenk-type glassware. Solvents were dried and distilled under argon prior to use according to standard procedures. The starting complex **3**[18] as well as most of the unsaturated ketones were prepared as published [**4b**[24] by Wittig reaction, **4c−e**[25], **4f**[26], **4h** [1-(*p*-methoxyphenyl)-5-phenylpentadien-1-one][25], **6b−d**[25] by aldol condensation]. Compound **4a** (= **6a**) is commercially available (Fluka). − Melting points are not corrected, boiling points quoted for Kugelrohr distillations refer to the temperature of the air bath. − NMR: Jeol JNMX GX-400 and PMX-60; δ given in ppm; TMS as internal standard. − IR: Bruker IFS 48, Beckmann Acculab A1, A3. − MS: Varian MAT CH-4B (EFO-4B-source), Varian MAT 311A (EI/FD source). − MA: Heraeus Mikromat C-H-N. − HPLC: Shimadzu LC-10 AT, SIL-10 A, CBM 10 A, SPD-10 M A, FCV-10 AL; column: Macherey-Nagel Nucleosil ET 200/4. − Isomeric ratios were determined from the relative intensities of the pertaining ^{1}H-NMR signals or by analytic HPLC.

1. *Synthesis of Ketone* **4g**. − *Synthesis of Methyl (o-Formyl-trans-cinnamate):* 2.24 g (16.7 mmol) of phthaldialdehyde were dissolved in 40 ml of THF and stirred at 60°C. A solution of 4.95 g (16.7 mmol) of (methoxycarbonylmethylene)triphenylphosphorane[27] in 100 ml of THF was added dropwise over a period of 1 h and the mixture was then stirred overnight. The solvent was then removed in vacuo and most of the PPh_3O by repeated chromatography over silica gel using neat CH_2Cl_2 as the eluent. GC analysis of the eluate showed 58% of product, 17% of starting dialdehyde, 10% of double-olefination product, and 8% of PPh_3O. Final purification by Kugelrohr distillation (110−120°C, 0.5 mbar) gave 1.54 g (8.0 mmol; 48%) of the cinnamate as a bright yellow viscous oil. − ^{1}H NMR (60 MHz, $CDCl_3$): δ = 3.8 (s, 3 H, CH_3), 6.3 (d, ^3J = 16 Hz, 1 H, CH=C*H*C=O), 7.4−7.9 (m, 4 H, H^{ar}), 8.5 (d, ^3J = 16 Hz, 1 H, C*H*=CHC=O), 10.2 (s, 1 H, CHO). − $C_{11}H_{10}O_3$ (190.20): calcd. C 69.47, H 5.30; found C 69.11, H 5.63. − *Synthesis of Methyl [(o-3′-Oxobutenyl)-trans-cinnamate]* (**4g**): 1.54 g (8.08 mmol) of methyl (*o*-formyl-*trans*-cinnamate) was dissolved in 30 ml of THF and stirred at 40°C. A solution of 2.37 g (8.08 mmol) of (2-oxopropylene)triphenylphosphorane[28] in 50 ml of THF was added dropwise and the resulting mixture was stirred at 50°C overnight. The solvent was then removed to leave a crude product which was purified by CC (silica gel; CH_2Cl_2): 1.15 g (4.99 mmol; 62%); pale solid; m.p. 46°C. − ^{1}H NMR (60 MHz, $CDCl_3$): δ = 2.4 (s, 3 H, CH_3CO), 3.8 (s, 3 H, OCH_3), 6.30 (d, ^3J = 16 Hz, 1 H, CH=C*H*CO_2CH_3), 6.55 (d, ^3J = 16 Hz, 1 H, CH=C*H*$COCH_3$), 7.2−7.65 (m, 4 H, H^{ar}), 7.85 (d, ^3J = 16 Hz, 1 H, C*H*=CHCOCH_3), 8.0 (d, ^3J = 16 Hz, 1 H, C*H*=CHCOOCH_3) .− $C_{14}H_{14}O_3$ (230.27): calcd. C 73.03, H 6.13; found C 73.14, H 5.90.

2. *Synthesis of* **5**. − *General Procedure (A):* The respective α,β-unsaturated ketone **4** (2 mmol) was added to a solution of **3** (234 mg; 1 mmol) in toluene (15 ml) and the resulting mixture stirred at 40°C for 3 h. Once the starting materials were completely consumed, 5 ml of hexane was added to give a precipitate which was collected on a sinter funnel, washed twice with hexane and dried in vacuo. For analytical purposes samples of **5** were recrystallized from CH_2Cl_2/hexane (2:1).

(±)-(5,6-threo-3Z,7Z)-1,1-Bis(η^5-cyclopentadienyl)-3,5,6,8-tetraphenyl-1-titana-2,9-dioxacyclonona-3,7-diene (**5a**)[29]: 3.50 g (5.89 mmol; 52%) from 2.65 g of **3** and 4.71 g of **4a**; dark red air-sensitive crystals from toluene; m.p. 204°C. − IR (KBr): $\tilde{\nu}$ = 3040 cm^{-1}, 3030, 3020, 1600, 1490, 1450, 1330, 810, 750, 700. − ^{1}H NMR (400 MHz, C_6D_6)[30]: δ = 5.03 (d, ^3J = 5.50 Hz, 2 H, 5-H, 6-H), 5.89 (d, ^3J = 5.50 Hz, 2 H, 4-H, 7-H), 5.95 (s, 10 H, Cp), 7.07 (m, 10 H, H^{ar}), 7.21 (t, ^3J = 7.15 Hz, 2 H, H^{ar}), 7.31 (t, ^3J = 7.15 Hz, 4 H, H^{ar}), 7.59 (d, ^3J = 7.15 Hz, 4 H, H^{ar}). − ^{13}C NMR

4. *Synthesis of* **9**, **10**, **11**, **12**, *and* **13**. − *General Procedure (C):* Complex **5** or **7** (1 mmol) was dissolved in CH_2Cl_2 (10 ml). 5 mmol of HCl in 5 ml of diethyl ether was added at −10°C and the mixture was then stirred for 5 h, whereupon the colour turned from dark red to bright red. The solvent and excess HCl were removed at reduced pressure, Cp_2TiCl_2 was removed by CC on silica gel (CH_2Cl_2). The eluate was concentrated and the products **9**−**13** were separated by using preparative TLC (silica gel, CH_2Cl_2). Separation of the respective diastereomers was done by TLC (silica gel 60, diethyl ether/petroleum ether, 1:2) or by HPLC (silica gel 60, heptane/ethyl acetate, 9:1). For analytical purposes samples were recrystallized from chloroform or CH_2Cl_2/hexane, 3:1. − *General Procedure (D):* Complex **7** or **5** (1 mmol) was dissolved in CH_2Cl_2 (10 ml). At ambient temperature 5 ml of aqueous HCl (6%) was added. After stirring this mixture for 3 h, the layers were separated, the aqueous one was washed twice with 5 ml of CH_2Cl_2 and the combined organic extracts thus obtained were dried with sodium sulphate. Separation of the products **9**−**13** and Cp_2TiCl_2 was accomplished as described in General Procedure (C).

1,6-Diphenyl-3,4-bis-β-(trans-phenylethenyl)hexan-1,6-dione (**9a**): According to general procedure D: 418 mg (0.89 mmol; 89%) from 646 mg of **5d**; yellow needles from chloroform; m.p. 140°C. − IR (film): $\tilde{\nu}$ = 3050 cm^{-1}, 2980, 2960, 1680, 1650, 1490. − ^1H NMR (400 HMz, $CDCl_3$): δ = 3.09−3.27 (m, 6 H, 2-H, 3-H, 4-H, 5-H), 6.16 (dd, ^3J = 15.62/8.97 Hz, 2 H, C*H*=CHPh), 6.42 (d, ^3J = 15.62 Hz, 2 H, CH=C*H*Ph), 7.21−7.93 (m, 20 H, H^{ar}). − ^{13}C NMR (100.4 MHz, $CDCl_3$): δ = 42.2 (C-2, C-5), 43.0 (C-3, C-4), 124.0, 126.2 (*C*H=*C*HPh), 128.5, 128.9, 132.9, 132.1, 137.0, 137.2 (CH^{ar}), 137.8, 138.2 (*ipso*-C), 198.8 (C-1, C-6). − MS (70 eV); *m/z* (%): 470 (7) [M^+], 350 (80), 235 (92), 105 (100). − $C_{34}H_{30}O_2$ (470.62): calcd. Ab initio Calculations: The ab initio and density functional calculations were performed with the Gaussian 94 suite of programs.[19] Structures were optimzed with no constraints other than symmetry at the B3LYP/SVp level, i.e. using the B3LYP[20] density functional and a split valence basis set[21], augmented with standard polarization functions on the non-hydrogen atoms.[22] Vibrational frequencies and zero-point energy corrections, scaled by 0.98[23], were computed at this level. Refinement of the structures was performed at the MP2/SVp level. Energy calculations were done at MP2/TZ2p level (i.e., using a triple-zeta basis set[21] and split polarization functions).

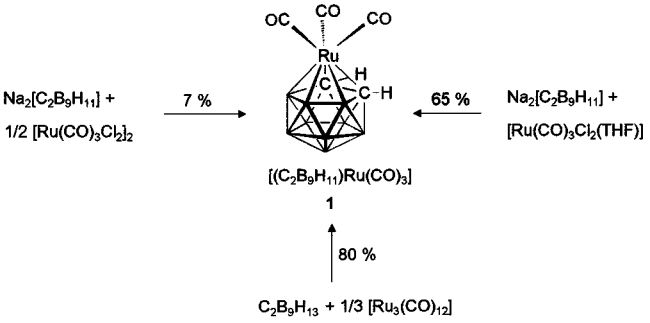
Keywords: Cluster chemistry / Silaborane clusters / Carbonyl complexes / Silicon coordination / Ruthenium complexes

Reaction between three equivalents of the silaborate $[NEt_4][MeSiB_{10}H_{12}]$ (**2**) and one equivalent of $[Ru_3(CO)_{12}]$ resulted in almost quantitative formation of the mononuclear transition metal complex $[NEt_4][Ru(CO)_3(\eta^5\text{-}MeSiB_{10}H_{10})]$ (**5**), which was characterized by X-ray structure analysis. The trinuclear ruthenium complex $[NEt_4][Ru_3(CO)_8(\eta^5\text{-}MeSiB_{10}H_{10})]$ (**7**) was synthesized in high yield from the reaction of one equivalent of **2** and $[Ru_3(CO)_{12}]$. The cluster **7** reacts with two equivalents of PMe_2Ph with substitution of two carbonyl groups to give the substitution product $[NEt_4][Ru_3(CO)_6(PMe_2Ph)_2(\eta^5\text{-}MeSiB_{10}H_{10})]$ (**8**).

The coordination chemistry of the dicarbollide ligand $[C_2B_9H_{11}]^{2-}$ has been investigated for almost 35 years. Metallocene-like complexes, mixed cyclopentadienyl dicarbollide sandwich species, and carbonyl dicarbollide transition metal complexes are described in the literature[1]. Many of these metallacarboranes have compositions and structures which are related to their cyclopentadienyl counterparts. One of the most surprising properties of the dicarbollide coordination products is their remarkable stability towards air oxidation and hydrolysis. After 35 years of research in the field of metallacarborane chemistry a dicarbollide coordination product of almost every transition metal is known. In 1969 Hawthorne described for the first time the synthesis of a carbonyliron dicarbollide complex[2] and 20 years later he developed an organometallic chemistry based on the dimeric dicarbonyliron carborane [*closo*-3-CO-3,3′-(μ-CO)-3,1,2-$FeC_2B_9H_{11}]_2^{2-}$[3]. In the case of ruthenium Siedle[4] reported for the first time on the successful preparation of *closo*-3,3,3-$(CO)_3$-3,1,2-$RuC_2B_9H_{11}$ (**1**) (Figure 1). From the reaction between $[Ru(CO)_3Cl_2]_2$ and $[7,8\text{-}C_2B_9H_{11}]^{2-}$ in refluxing THF 7% of **1** has been isolated.

The yield of dicarbaruthena-*closo*-dodecaborane was improved nine years later by Hawthorne[5] to 65% by treating $[7,8\text{-}C_2B_9H_{11}]^{2-}$ with $[Ru(CO)_3Cl_2(THF)]$ in THF at 0°C. In 1995 Stone[6] published a further improvement of the yield to 80% with $[Ru_3(CO)_{12}]$ as a starting material. Reaction between $[C_2B_9H_{13}]$ and $[Ru_3(CO)_{12}]$ results exclusively in the formation of the mononuclear complex **1**. Whereas the carborane with methyl groups attached to the carbon atoms produces in the corresponding reaction a 1:2 mixture of mononuclear complex $[Ru(CO)_3(\eta^5\text{-}7,8\text{-}Me_2\text{-}7,8\text{-}C_2B_9H_{11})]$ and trinuclear cluster $[Ru_3(CO)_8(\eta^5\text{-}7,8\text{-}Me_2\text{-}7,8\text{-}C_2B_9H_{11})]$.[7] The trinuclear ruthenium and osmium clusters $[M_3(CO)_8(\eta^5\text{-}7\text{-}NMe_3\text{-}7\text{-}CB_{10}H_{10}]$ (M = Os[8] and Ru[9]) were synthesized from the reaction of the zwitterionic monocarborane $7\text{-}NR_3\text{-}7\text{-}CB_{10}H_{10}$ and the respective carbonylmetal complexes. In both cases no mononuclear transition metal complex is known.

Figure 1. Syntheses of the tricarbonylruthenium dicarbollide complex



We have recently presented the first examples of transition metal complexes of the 7-sila-*nido*-undecaborate(1−) (**2**) cluster.[10] In the reaction of the deprotonated silaborate with iron(II) bromide we found with **3** (Figure 2) an unprecedented structural motif for cluster coordination chemistry.[11] The coordination of the silaborate cluster trianion is realized in the series of the cyclopentadienyl complexes of cobalt, rhodium **4** (Figure 2) and iridium.[12]

In this paper we report on the formation of silaborate ruthenium complexes. These complexes can be either mononuclear or trinuclear in dependency of the chosen stoichiometry between $[Ru_3(CO)_{12}]$ and $[MeSiB_{10}H_{12}]^-$.

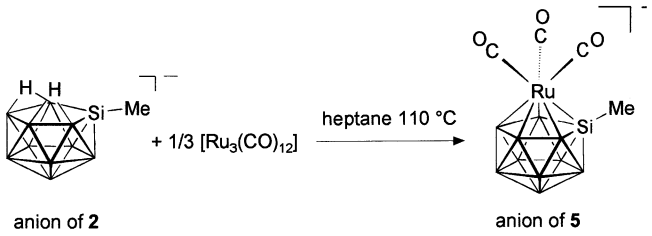
Results

Mononuclear Complexes

The mononuclear tricarbonylruthenium complex is readily formed by heating a suspension of three equivalents of $[NEt_4][MeSiB_{10}H_{12}]$ with one equivalent of $[Ru_3(CO)_{12}]$ in heptane for 15 h at 110°C (Scheme 1). The resulting dark brown oil was recrystallized by slow diffusion of Et_2O into a CH_2Cl_2 solution of the reaction mixture to give colourless crystals of $[NEt_4][Ru(CO)_3(MeSiB_{10}H_{10})]$ (**5**) in 92% yield.

Scheme 1. Synthesis of **5**



anion of **2** anion of **5**

The metallasilaborate **5** was characterized by elemental analyses, NMR spectroscopy, mass spectrometry, and single crystal X-ray structure analysis. Six signals in the ^{11}B-NMR spectrum for ten boron atoms with an intensity ratio of 1:2:2:1:2:2 are consistent with C_s symmetry of the cluster anion of **5** in solution. In the two-dimensional $^{11}B\{^1H\}$-$^{11}B\{^1H\}$ COSY-NMR spectrum the cross peak between B3/6 and B4/5 is missing due to bridging by the silicon atom. The effect, that connections between boron atoms, which are bridged by hetero atoms, are not visible in the two-dimensional COSY ^{11}B-NMR spectrum, is known from other heteroboranes like carboranes[13].

The ^{11}B-NMR chemical shifts in heteroborane clusters are governed by the antipodal effect[14]. Substitution of a heteroatom in a borane cluster is equivalent to changes of the electronic structure of the cage compound, with the strongest variations at the antipodal atom. In the anion of **5** the two heteroatoms Ru and Si are opposite to the boron atoms B9 and B12. As expected the chemical shift for B12 opposite to the silicon atom appears at high field ($\delta = -9.7$) in the range of values which are known from other metallasilaboranes ($\delta = -5.3$ to -19.4)[11][12] (Figure 3). In comparison to B12 the resonance for B9, the boron atom opposite to the transition metal center, appears at lower field ($\delta = +4.1$ to -0.1; M = Fe, Co, Rh, Ir)[12]. In the presented complex for B9 a value of $\delta = 12.2$ was determined. This chemical shift represents the resonance at lowest field in the series of the so far known metallasilaboranes. It can be interpreted as an indicator for the electron-withdrawing ability of the tricarbonylruthenium group.

The stretching frequencies for the terminal carbonyl substituents of 2075 and 2002 cm^{-1} are smaller than the comparable values in **1** (2114, 2058 cm^{-1}). Obviously, π-back bonding in MCO is not as much reduced in **5** as in **1**, which could be attributed to stronger σ-donation by the silaborate ligand.

A perspective view of the anion of **5** is presented as the result of the X-ray crystal structure analysis in Figure 4 and selected interatomic distances are listed in the Table. The structural study confirms the prediction of the spectroscopic analyses, a *closo* structure for the ruthenasilaborate. The $Ru(CO)_3$ fragment is η^5-coordinated at the silaborate ligand. As a common structural motif for transition metal coordination on the silaborate ligand the distances to B7/11 [2.292(6), 2.300(6) Å] are shorter than to B3/6 [2.372(6), 2.377(6) Å][11][12].

The short Ru−Si distance of 2.396(2) Å can be compared with distances in silyl complexes[15]. The short Ru−B7/11 and Ru−Si distances indicate a major contribution to these atoms of the pentagonal open face of the ligand for transition metal coordination. Tilley described in 1994 the synthesis of $(\eta^5\text{-}C_5Me_5)Ru[\eta^5\text{-}Me_4C_4SiSi(SiMe_3)_3]$ a stable silacyclopentadienyl complex of ruthenium[16]. In the case of the protonated derivative $[Cp^*Ru(H)\{\eta^5\text{-}Me_4C_4SiSi(SiMe_3)_3\}][BPh_4]$ a Ru−Si distance of 2.441(3) Å was determined by X-ray structure analysis.

Based on the isolobal analogy the $Ru(CO)_3$ fragment donates two electrons to the cluster electron count. Summation over the complete skeleton gives a total of 26 electrons, which corresponds to $2n+2$ electrons for a *closo* cluster with 12 edges.

The degradation product of *o*-silaborane **2** reacts with the trinuclear dodecacarbonyltriiron to give the tricarbonyliron silaborate cluster **6** in quantitative yield based on the ^{11}B-NMR spectra. The pattern in the two-dimensional $^{11}B\{^1H\}$-$^{11}B\{^1H\}$ COSY-NMR spectrum (Figure 5) and the ^{11}B chemical shifts of the iron derivative are strongly related to the ruthenium complex **5**.

6 was also characterized by mass spectrometry and IR spectroscopy. Unfortunately, the elemental analyses failed due to carbonyliron impurities.

Trinuclear Metallasilaborates

The *nido*-silaborate **2** reacts with $[Ru_3(CO)_{12}]$ in heptane at reflux temperatures to give the trinuclear rutheniumsilaborate cluster **7** (Scheme 2). The cluster was obtained in almost quantitative yield as yellow crystals by slow diffusion of Et_2O into a CH_2Cl_2 solution of the reaction mixture.

As with **5**, **7** was characterized by elemental analyses, mass spectrometry, IR spectroscopy, and NMR spec-

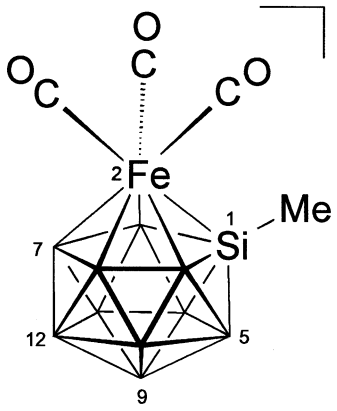
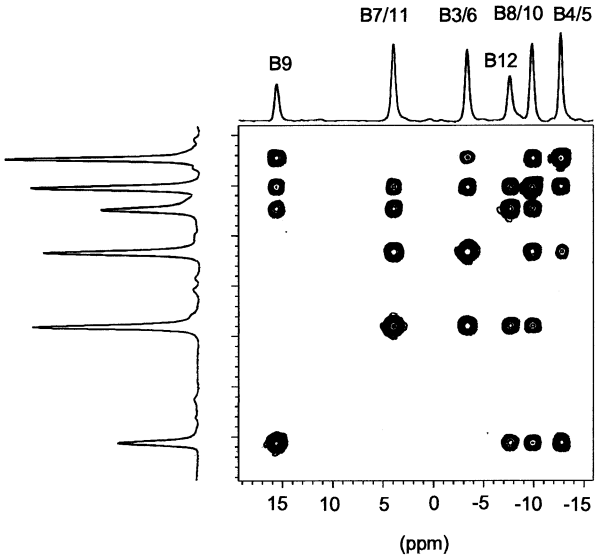
troscopy. On the basis of these spectroscopical data the constitution of **7** was unequivocally determined. The silaborate ligand is η^5-coordinated at one ruthenium atom replacing two carbonyl substituents. Two BH units coordinate at the other two ruthenium atoms of the Ru_3 cluster, replacing each one carbonyl substituent. Coordination of the BH units of B7/11 is proven by the reduced coupling constant of $^1J_{BH}$ = 67 Hz, the shift to low field in the ^{11}B-NMR spectrum for the resonances of B7/11 (Figure 3), and the cross peak in the two dimensional HMQC $^1H\{^{11}B\}$-$^{11}B\{^1H\}$ NMR spectrum between the resonances for B7/11 and a broad quadruplet in the ^{1}H-NMR spectrum at $\delta = -10$. Longer reaction times resulted in the decomposition of **7** and the isolation of the mononuclear cluster **5** together with the formation of a tetranuclear ruthenium cluster anion $[NEt_4][(\mu\text{-}H)_3Ru_4(CO)_{12}]$[17]. In contrast to the inertness of **5** towards nucleophiles **7** reacts readily with phosphanes (Scheme 2) to give the disubstituted derivative **8**. Carbonyl substitution at the ruthenium cluster skeleton is known from the dicarbollide analogues. **7** reacts with two equivalents of PMe_2Ph under substitution of one carbonyl group at each $Ru(CO)_3$ unit. In contrast to the analogue reaction of $[Ru_3(CO)_8(C_2B_9H_{11})]$ leading to oxidative addition of one coordinated BH unit at a ruthenium centre in the silaborane case the coordinated BH units of B7/11 remain unchanged. The constitution of **8** was deduced from the spectroscopical data together with elemental analysis and mass spectrometry. As in **7** a reduced coupling constant ($^1J_{BH}$ = 83 Hz) for the BH units of B7/11, a low-field chemical shift in the ^{11}B NMR for B7/11 and a cross peak in the HMQC $^1H\{^{11}B\}$-$^{11}B\{^1H\}$ between the resonances for B7/11 and a signal at $\delta = -10.6$ indicates the coordination

Figure 5. $^{11}B\{^1H\}$-$^{11}B\{^1H\}$ COSY-NMR spectrum of the anion of **6**



anion of **6**



of these BH units at the ruthenium centres. The C_s symmetry of the cluster anion in solution is proven by five signals in the ^{11}B NMR for ten boron atoms, the resonances for B3/6 and B9 are accidentily isochronic, and one ^{31}P-NMR resonance for the two phosphane ligands. **8** crystallizes with one equivalent of dichloromethane in the space group $P2_1/a$ with a = 13.881(3), b = 12.773(7), c = 27.2800(9) Å, and β = 97.99(2)°. Due to an immediate loss of cocrystallized CH_2Cl_2 after isolation from the solution, no crystals of good quality could be obtained. Reflections were broad and of relative low intensity. In addition the atoms of the CH_2Cl_2 show large displacement parameters. Therefore no geometric details of the structure will be discussed but the constitution of **8** was confirmed.

Conclusion

The anionic degradation product of *o*-silaborane reacts with dodecacarbonyltriruthenium to give the first carbonyl transition metal complexes with a silaborate ligand. In contrast to the syntheses of the carbonylruthenium dicarbollide and monocarbollide complexes the formation of the mononuclear or trinuclear ruthenium complex is determined by the stoichiometry of silaborate and carbonylruthenium.

Scheme 2. Syntheses of **7** and **8**

Received April 24, 1998

Keywords: Oxidation / Catalysis / Phthalocyanine / Iron / Anthracene

Iron(III) tetrasulfophthalocyanine (FePcS) was shown to catalyze the oxidation of polycyclic aromatic hydrocarbons by H_2O_2. Benzo[*a*]pyrene and anthracene were converted to the corresponding quinones while biphenyl-2,2′-dicarboxylic acid was the main product of phenanthrene oxidation. The mechanism of the anthracene oxidation by H_2O_2 in the presence of FePcS or by $KHSO_5$ with iron(III) *meso*-tetrakis(3,5-disulfonatomesityl)porphyrin (FeTMPS) (see Figure 1 for catalyst structures) has been investigated in details by using kinetic isotope effects (KIEs) and ^{18}O labeling studies. KIEs measured on the substrate consumption in the competitive oxidation of [H_{10}]anthracene and [D_{10}]anthracene by FePcS/H_2O_2 and FeTMPS/$KHSO_5$ were essentially the same, 0.75 ± 0.02 and 0.76 ± 0.06, respectively. These inverse KIEs on the first oxidation step can be explained by the sp^2-to-sp^3 hybridization change during the addition of an electrophilic oxoiron complex to the sp^2 carbon center of anthracene to form a σ adduct (this inverse KIE being enhanced by stronger stacking interactions between the perdeuterated substrate with the macrocyclic catalyst). Although the first oxidation step seems to be the same, different distribution of the oxidation products of anthracene and very different ^{18}O incorporation into anthrone and anthraquinone in catalytic oxidations performed in the presence of $H_2{}^{18}O$ suggested that different active species should be responsible for anthracene oxidation in both catalytic systems. All the results obtained are compatible with an involvement of $TMPSFe^{V}=O$ (or $TMPS^{+}Fe^{IV}=O$), having two redox equivalents above the iron(III) state of the metalloporphyrin precursor, while $PcSFe^{IV}=O$ (one redox equivalent above Fe^{III} state of FePcS) was proposed to be the active species in the metallophthalocyanine-based system.

Introduction

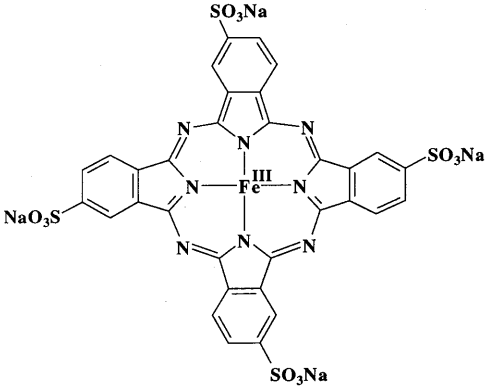
Polycyclic aromatic hydrocarbons (PAH) belong to environmental pollutants because of their rather slow biodegradation. PAHs can be metabolized by bacteria, fungi or algae. Three main degradation pathways have been identified for the microbial catabolism of polycyclic aromatic hydrocarbons[1]. Cytochrome P-450 monooxygenases catalyze the formation of arene oxides, which are then transformed to phenol or epoxy-diol derivatives. Ligninases are capable of oxidizing PAH to quinones followed by ring cleavage[2]. For example, benzo[*a*]pyrene was oxidized to a mixture of 1,6-, 3,6- and 6,12-quinones[3], pyrene to 1,6- and 1,8-quinones[4] and anthracene to 9,10-anthraquinone[2]. The third enzymatic degradation process involves dioxygenase enzymes to incorporate both atoms of molecular oxygen into the aromatic ring to form *cis*-dihydrodiols. After a dehydrogenase-catalyzed rearomatization to produce catechols, a subsequent enzymatic cleavage by intradiol or extradiol dioxygenases gives *cis,cis*-muconic acid or 2-hydroxymuconic semialdehyde as products of aromatic cycle cleavage, respectively[5]. Although biodegradation of PAHs is the major decontamination process, along with photochemical oxidation with dioxygen[6], microorganisms capable of rapidly and efficiently mineralizing recalcitrant and potentially carcinogenic PAHs needs to be found[1]. Chemical oxidation of PAH[7] needs elevated temperatures and/or powerful oxidants, e.g. chromium compounds which constitute environmental problems. For example, phenanthrene has been oxidized to phenanthrenequinone by CrO_3 at 55°C (yield 80%)[8], by the system $Ce^{IV}/H_2SO_4/(NH_4)_2SO_4$ at 50°C (yield 42%)[9], by $KMnO_4/Al_2O_3/H_5IO_6$ (yield 25%)[10]. Arenes can be oxidized to quinones by H_2O_2/hexafluoroacetone at 70°C[11]. In this latter case, biphenyl-2,2′-dicarboxylic acid was the only isolated oxidation product of phenanthrene[11]. Obviously, there is a need for environmental-friendly chemical catalysts to oxidize PAH. An alternative approach using biomimetic metalloporphyrin catalysts[12] has been shown to be useful in the oxidation of 2-methylnaphthalene[12a]. Phenanthrene and naphthalene were oxidized by a porphyrinruthenium/2,6-dichloropyridine *N*-oxide system to give the corresponding quinones with 40% and 29% yields, respectively[13]. Recently, the oxidation of naphthalene and methylnaphthalenes by peracetic

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1434–1948/98/0909–1269 $ 17.50+.50/0

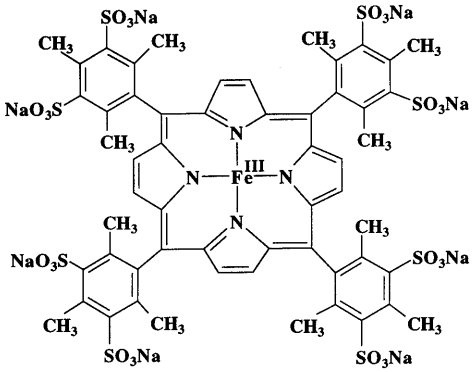
acid catalyzed by octanitrophthalocyanine Mn^{III} and Fe^{II} complexes has been reported[14].

We recently developed a new efficient catalytic system for the oxidative degradation of polychlorinated phenols based on the association of iron(III) or manganese(III) complexes of tetrasulfophthalocyanine (FePcS, MnPcS) and the rather inexpensive and "green" oxidant H_2O_2[15][16]. This biomimetic system is able to cleave the aromatic cycle of 2,4,6-trichlorophenol with the formation of chloromaleic acid as the main product[15]. Besides FePcS and MnPcS, CoPcS is also highly efficient in the oxidation of catechols[17]. Having on hands these efficient catalysts for the oxidation of recalcitrant pollutants such as chlorinated phenols, we decided to investigate the activity of these catalysts in the oxidation of other poorly biodegradable molecules. Here we report the catalytic oxidation of polycondensed aromatics (mainly anthracene, but also phenanthrene and benzo[*a*]pyrene) by hydrogen peroxide or potassium monopersulfate ($KHSO_5$) and FePcS as catalyst [FeTMPS, a water-soluble iron(III) porphyrin, was also used for comparison]. Detailed mechanistic studies involving kinetic isotope effects (KIEs) and ^{18}O labeling experiments are also reported.

Figure 1. Structures of iron(III) complexes of tetrasulfophthalocyanine (FePcS) and *meso*-tetrakis(3,5-disulfonatomesityl)porphyrin



Iron tetrasulfophthalocyanine (FePcS)



Iron meso-tetrakis(3,5-disulfonatomesityl)porphyrin (FeTMPS)

Results

Products and Reactivity Order in PAH Oxidations by FePcS/H_2O_2

We checked the oxidations of benzo[*a*]pyrene, phenanthrene and anthracene, performed in a MeCN/H_2O mixture (3:1, v/v) using $KHSO_5$ and H_2O_2 as oxidants. The final concentrations of oxidant and substrate were 5 mM and 1 mM, respectively. The catalyst concentrations were 10 μM, 37 μM and 100 μM corresponding to 1, 3.7 and 10% catalyst/substrate ratios, respectively. The data of Table 1 indicated that FePcS was also an efficient catalyst for the oxidation of these polyaromatic hydrocarbons. The oxidation of benzo[*a*]pyrene by FePcS/$KHSO_5$ (run 1) and by FePcS/H_2O_2 (run 4) at pH = 7 was complete within in a few minutes leading to an orange material isolated by precipitation with water. DCI-CH_4 mass spectrometry analysis gave peaks at 282 (M^+, 100), 254 [$(M - CO)^+$, 17.4], 226 [$(M - 2\ CO)^+$, 17.4] indicating the final product was a quinone (or a mixture of quinone isomers) with a molecular weight equal to 282. Three components were isolated by dry column chromatography (neutral Al_2O_3, benzene) after oxidation of benzo[*a*]pyrene in conditions used for run 4 of Table 1 and characterized by UV spectroscopy according to ref.[18] (Scheme 1). The UV/Vis spectra for all three quinones were in an excellent agreement with the data previously published[18]. Based on reported extinction coefficients, the distribution of quinones was as follows: 6,12-benzo[*a*]pyrenedione (32%, first eluted product from column), 1,6- benzo[*a*]pyrenedione (44%, second eluted product) and 3,6- benzo[*a*]pyrenedione (24%, third eluted product). The total yield for all three quinones was quantitative

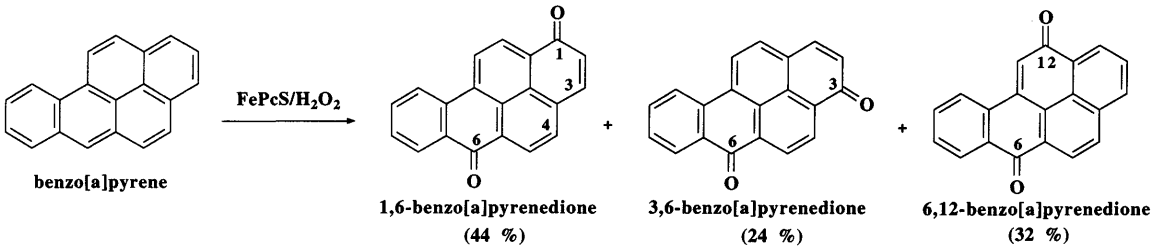
[a] n.d.: not determined.

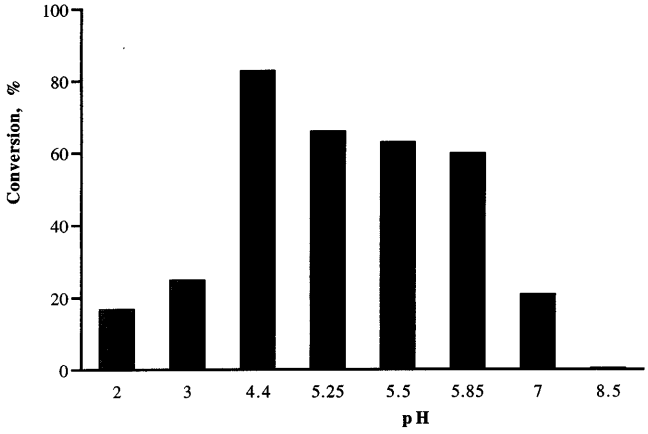
The H_2O_2 oxidation of phenanthrene is pH-dependent. Using a 10% catalyst/substrate ratio the highest conversion of phenanthrene was obtained at pH = 4.4 (conversion be-

Scheme 1. Oxidation products of benzo[*a*]pyrene by $FePcS/H_2O_2$



ing rather low at pH = 7) (Figure 2). But it should be noted that anthracene was quickly and completely oxidized within 1 min at pH = 7 (Table 1, run 6) while 1 hour was necessary to reach 96% conversion at pH = 4.4 (the pH optimum for phenanthrene). At pH = 7 the order of substrate reactivity was in agreement with oxidation potentials: benzo[*a*]pyrene > anthracene > phenanthrene (the ionization potentials being 7.2, 7.4 and 8.1 eV, respectively[2]).

Figure 2. pH dependence of phenanthrene oxidation by FePcS/H_2O_2[a]



[a] Reaction conditions: [catalyst] = 0.1 mM, [oxidant] = 5 mM, [substrate] = 1 mM, acetonitrile/50 mM phosphate buffer at pH = 7 (3:1, v/v). Reaction time 60 min.

The FePcS-catalyzed oxidation of anthracene by H_2O_2 resulted in the formation of anthrone (tautomeric form of 9-hydroxyanthracene), oxanthrone (tautomeric form of anthrahydroquinone) and anthraquinone (Scheme 2). The yields of oxanthrone (5%) and anthraquinone (25%) were determined after 1 h by HPLC using calibration curve and molar extintion coefficients obtained with authentic samples.

Biphenyl-2,2′-dicarboxylic acid (product of cleavage of one aromatic cycle) was the main oxidation product of phenanthrene, 9,10-phenanthrenequinone being the second main product. Three other minor products of the oxidative degradation of phenanthrene were also identified by GC-MS analysis: 2-formyl-2′-hydroxybiphenyl, 2-carboxy-2′-hydroxybiphenyl and 2,2′-biphenylcarbolactone (Scheme 3). So, the $FePcS/H_2O_2$ system is able to cleave the aromatic cycle of phenanthrene and to perform oxidative decarboxylation.

Oxidation of Anthracene by $FeTMPS/KHSO_5$

We also checked the oxidation of anthracene by $FeTMPS/KHSO_5$ performed in an MeCN/25 mM phosphate buffer mixture (3:1, v/v) at pH = 7. The concentrations of oxidant, substrate and catalyst were 5 mM, 1 mM and 37 μM, respectively. The anthracene conversion was complete after 60 min (run 9, Table 1). The yields of oxanthrone and anthraquinone were determined by HPLC. Differing from the $FePcS/H_2O_2$ mediated oxidation, the main product with $FeTMPS/KHSO_5$ was oxanthrone (yield by HPLC = 60%), while only 3% of anthraquinone were found. Isolation of reaction products from a large scale anthracene oxidation by $FeTMPS/KHSO_5$ followed by NMR analysis gave 43% yield for oxanthrone, 16% yield for anthraquinone and 14% yield of non-identified compounds (probably coupling products). A partial oxidation of oxanthrone to anthraquinone might have occured during the sample preparation for NMR analysis, explaining the discrepancy with the HPLC analysis of the reaction mixture. This rather unexpected result, oxanthrone, an easily oxidizable compound, as main reaction product in the presence of strong oxidants, stimulated us for a detailed mechanistic study of anthracene oxidation by both catalytic systems, $FePcS/H_2O_2$ and $FeTMPS/KHSO_5$.

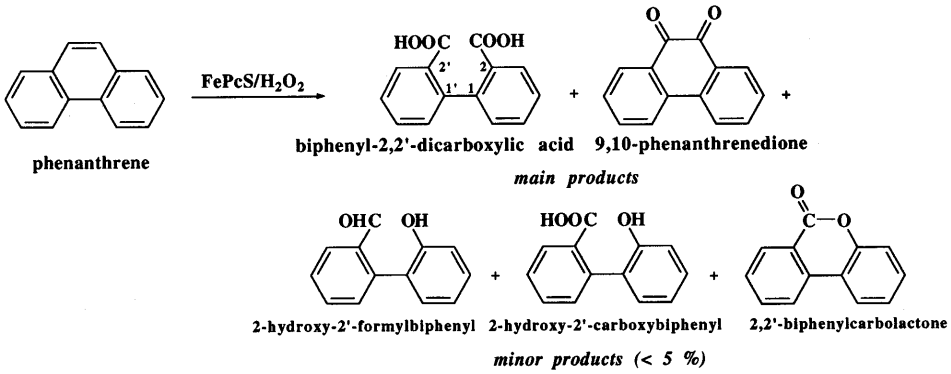
Scheme 3. Oxidation products of phenanthrene by $FePcS/H_2O_2$



Stability of Anthrone, Oxanthrone and Anthraquinone in the Presence of $FePcS/H_2O_2$ and $FeTMPS/KHSO_5$

In these experiments we used the same reaction conditions as those for anthracene oxidation: a MeCN/50 mM phosphate buffer pH = 7 reaction medium (3:1, v/v), [catalyst] = 37 μM, [oxidant] = 5 mM, [substrate] = 1 mM, except for anthraquinone (its concentration was reduced to 0.5 mM because of its low solubility in the reaction mixture). Under these reaction conditions the conversions of anthrone in the presence of $FePcS/H_2O_2$ and $FeTMPS/KHSO_5$ were 23% and 38%, respectively, after 1 h, indicating that anthrone oxidation was slightly faster with $FePcS/KHSO_5$. Oxanthrone was easily oxidized to anthraquinone by $FePcS/H_2O_2$: the conversion was 90% after only 5 min. Again, oxanthrone was relatively stable with $FeTMPS/KHSO_5$: the conversions were only 18 and 23% after 30 and 60 min, respectively. Finally, we checked that anthraquinone was stable in both catalytic systems. There was no observable conversion after 60 min with $FeTMPS/KHSO_5$ and only 10% with $FePcS/H_2O_2$. These results on stability of products of anthracene oxidation were in good agreement with the composition of the reaction products for both catalytic systems.

Method of Determination of Kinetic Isotope Effects

Kinetic isotope effects (KIEs) can be determined in intra- or intermolecular competitive experiments by the analysis of the ratios of reaction products resulting from C−H versus C−D bond transformations. Such analyses are reliable when the oxidation products, different only in their isotopic substitution, are primary oxidation products and are stable in the reaction conditions. Since this is not a case in PAH oxidations by $FePcS/H_2O_2$ system we decided to determine the KIE values by analyzing of the competitive consumption of the deuterated versus the non-deuterated substrate. In this case intermolecular KIE values of the initial oxidation reaction can be obtained. In order to determine these KIEs concentrations of labeled and unlabeled substrates should be determined before and after the oxidation reaction by monitoring the isotopic composition of the initial reaction mixture, the substrate conversion and the isotopic composition of the remaining substrate after reaction. Isotopic compositions of substrates were determined by GC-MS analyses and substrate conversions were obtained by HPLC analyses (see Experimental Section). Equations to calculate KIEs depend on a reaction order in substrate[19]. When the reaction is first order in substrate KIEs can be determined from equation (1) where a_H°, a_D° and a_H, a_D denote initial and current substrate concentrations of H-labeled and D-labeled substrates, respectively.

$$k_H/k_D = \log (a_H/a_H^\circ) / \log (a_D/a_D^\circ) \quad (1)$$

Determination of the Reaction Order for the Substrate in Anthracene Oxidation by $FePcS/H_2O_2$

The reaction order in anthracene was determined with concentrations of H_2O_2, anthracene and FePcS being 5 mM, 1 mM and 37 μM, respectively. The reactions were carried out in an MeCN/50 mM phosphate buffer mixture at pH = 7 (3:1, v/v). Under these conditions the catalytic reaction follows a first-order kinetic in substrate at least for 2 times the reaction half-time and KIEs could be then determined according to equation (1).

KIEs in Anthracene and Phenanthrene Oxidation by $FePcS/H_2O_2$ and $FeTMPS/KHSO_5$

Analysis of the reaction mixture after 3−5 min of reaction (conversions being 40−60%) indicated a preferential consumption of $[D_{10}]$anthracene corresponding to an inverse isotope effect. The kinetic isotope effect in anthracene oxidation by the $FePcS/H_2O_2$ system was determined to be equal to 0.75 ± 0.02. Oxidation of anthracene by $FeTMPS/KHSO_5$ presented the same isotope effect of 0.76 ± 0.06 (Table 2). In contrast, oxidation of phenanthrene by both catalytic systems proceeds with no significant isotope effect: 0.96 ± 0.04 and 1.02 ± 0.01 for $FePcS/H_2O_2$ and $FeTMPS/KHSO_5$, respectively (Table 2).

In order to find the origin of this inverse isotope effects we prepared 9,10-dideuterioanthracene and determined the KIE value in the competitive oxidation of the mixture of 9,10-dideuterioanthracene and $[H_{10}]$anthracene. In this latter case the KIE value were 0.90 ± 0.05 and 0.95 ± 0.01 with the $FePcS/H_2O_2$ and $FeTMPS/KHSO_5$ systems, respectively.

Table 2. Kinetic isotope effect[a] in anthracene and phenanthrene oxidation by $FePcS/H_2O_2$ and $FeTMPS/KHSO_5$ at 20°C

Catalytic system	KIE in the competitive oxidation of [H_{10}]anthracene/[D_{10}]anthracene[b] ([H_{10}]anthracene/9,10-[D_2]anthracene)	[H_{10}]phenanthrene/[D_{10}]phenanthrene[c]
$FePcS/H_2O_2$	0.75 ± 0.02 (0.90 ± 0.05)	0.96 ± 0.04
FeTMPS/$KHSO_5$	0.76 ± 0.06 (0.95 ± 0.01)	1.02 ± 0.01

[a] These data are the mean values obtained from 3 independent oxidation reactions. – [b] Reaction conditions: [catalyst] = 37 μM, [oxidant] = 5 mM, [substrate] = 1 mM, MeCN/50 mM phosphate buffer pH = 7 (3:1, v/v). – [c] Reaction conditions: [catalyst] = 100 μM, [oxidant] = 5 mM, [substrate] = 1 mM, MeCN/33.3 mM phosphate buffer pH = 4.6 (1:1, v/v).

Analysis of Isotopic Composition of Products of Anthracene Oxidation

Anthrone, oxanthrone and anthraquinone were identified as oxidation products of anthracene by NMR and GC-MS techniques. GC-MS analysis of the reaction mixture indicated that anthrone, the primary oxidation product, was enriched in the deuterated derivative as expected from the inverse isotope effect on the first step of anthracene oxidation. In contrast, anthraquinone, a second oxidation product, was enriched in unlabeled product indicating a KIE value > 1 during the oxidation of anthrone to this quinone. Oxanthrone was unstable under GC-MS analysis conditions and its isotopic composition could not be determined. The molecular peak of deuterated anthrone formed after 3 min of reaction was 202 corresponding to a [D_8]-containing molecule, not a [D_9]-molecule as expected for 9-hydroxyanthracene. This result suggested that the equilibrium between the two tautomeric forms, anthrone and 9-hydroxyanthracene, was rather fast (Scheme 4). Consequently, a putative σ adduct with a Fe–O–arene bond, which should stabilize the 9-hydroxyanthracene tautomer, could not be a long-lived intermediate as previously observed in the metalloporphyrin-catalyzed oxidation of 2-methylnapthalene[12a].

^{18}O-Labeling Experiments

Oxidations of organic substrates catalyzed by metalloporphyrin[12][20][21] and metallophthalocyanine[16] complexes in the presence of ^{18}O-labeled water or dioxygen provided valueable mechanistic information. In order to investigate the mechanism of these catalytic PAH oxidations we performed the oxidation of anthracene by $FePcS/H_2O_2$ and $FeTMPS/KHSO_5$ in reaction mixtures containing ^{18}O-labeled water. In control experiments we checked that light oxygen atoms of anthraquinone did not exchange with heavy oxygen atoms of ^{18}O-labeled water under the used reaction conditions, i.e. a mixture of acetonitrile/50mM phosphate buffer (3:1, v/v) at pH = 7. Also, $KHSO_5$ itself does not exchange its oxygen atoms with water[20c]. FePcS-mediated oxidations of anthracene were performed under standard conditions (run 7 of Table 1) either under air or under nitrogen, using a 50:50 mixture of [H_{10}]anthracene and [D_{10}]anthracene. The oxygen atom distribution was analyzed in both deuterated and non-deuterated products for each experiment. In all cases, the oxygen atom distribution for a defined product was exactly the same. For example, the ^{18}O incorporation into anthraquinone was followed by determination of the molecular ion percentages at 208/216 [M], 210/218 [M + 2] and 212/220 [M + 4] corresponding to the incorporation of none, one or two ^{18}O oxygen atoms in [H_8]anthraquinone and [D_8]anthraquinone, respectively. In both cases, under air or under nitrogen, anthrone, the primary oxidation product, contained only a light oxygen atom. This result indicates that this oxygen atom originated from H_2O_2, the non-labeled oxidant. In contrast, both ^{16}O and ^{18}O atoms were incorporated into anthraquinone. When the reaction was performed under air, the molecular cluster consisted of M (68%) and M + 2 (32%) peaks, meaning that the ^{18}O atom was unambiguously only located in one carbonyl group of this quinone. If ^{18}O would occupied both carbonyl positions, the molecular cluster would have consisted on three peaks: M, M + 2 and M + 4. So, anthraquinone contained 100% of ^{16}O in one carbonyl position, 36% of ^{16}O and 64% of ^{18}O in another one (Figure 3). When the reaction was performed under nitrogen, again, only two peaks were found in the molecular cluster: M (56%) and M + 2 (44%). Consequently, ^{16}O incorporation in one carbonyl position was complete, another carbonyl position was enriched with heavy oxygen: 12% of ^{16}O and 88% of ^{18}O (Figure 3). This more significant incorporation of ^{18}O at the second carbonyl position produced in the absence of dioxygen suggests a possibility of O_2 involvement into oxidation pathway from anthrone to anthraquinone.

We also studied the ^{18}O incorporation from labeled water into the oxidation products of anthracene mediated by $FeTMPS/KHSO_5$. In this latter case, the mass spectrum of anthrone indicated the incorporation of ^{18}O atom, unlike with the $FePcS/H_2O_2$ oxidation. The percentage of ^{18}O found in anthrone was 63%, ^{16}O incorporation being only 37% (Figure 3). The MS molecular cluster of anthraquinone consisted of 3 peaks: M (16%), M + 2 (59%) and M

Scheme 4. Deuterium exchange during the formation of anthrone in aqueous medium

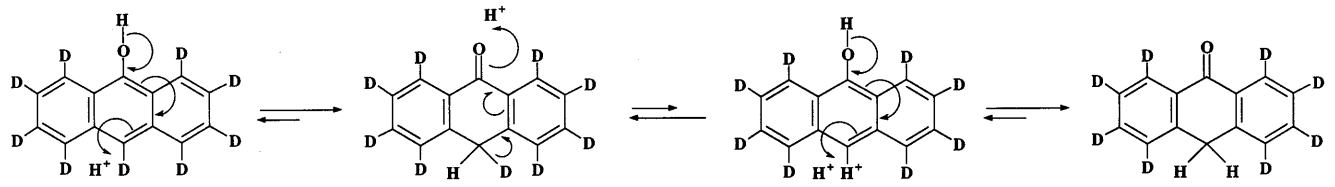


Figure 3. ^{18}O incorporation into anthrone and anthraquinone during the oxidation of anthracene by $FePcS/H_2O_2$ and $FeTMPS/KHSO_5$ in the presence of $H_2{}^{18}O$

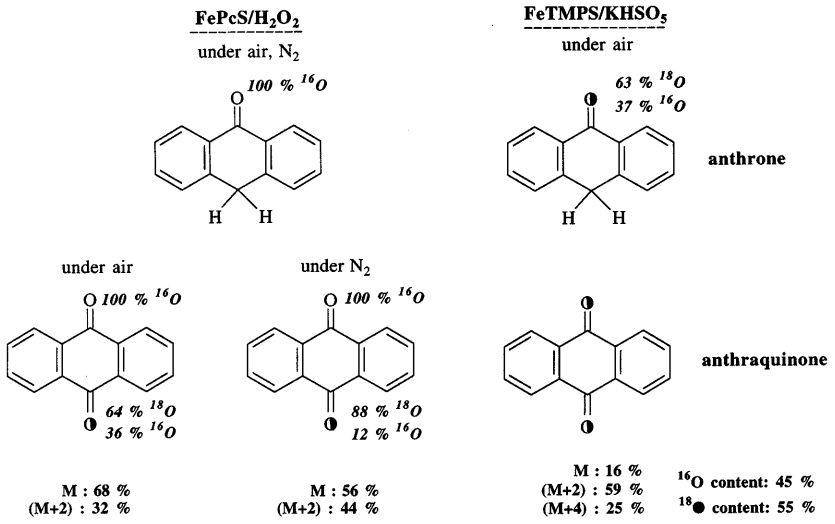


+ 4 (25%), indicating that ^{18}O was incorporated in both carbonyl groups of the quinone (the amount of ^{16}O and ^{18}O being 45 and 55%, respectively) (Figure 3). From these labeled water experiments we concluded that active species involved in the oxidation of anthracene by $FePcS/H_2O_2$ or by $FeTMPS/KHSO_5$ must be different.

Discussion

We found that FePcS associated with H_2O_2 can be useful in oxidation of polycyclic aromatic compounds. Anthracene was used as substrate to perform kinetic isotope studies and oxygen labeling experiments. Then we compared the results of the catalytic oxidations of anthracene by $FePcS/H_2O_2$ with those obtained with $FeTMPS/KHSO_5$ in order to gain a more complete view on the mechanisms of these oxidation reactions catalyzed by two related iron macrocyclic complexes. High-valent oxometal complexes have been proposed as active intermediates in hydrocarbon oxygenations (hydroxylations and epoxidations) using $KHSO_5$, NaOCl or *m*CPBA as oxidants and porphyriniron or -manganese compounds as catalysts[20][21][22]. We recently proposed a nucleophilic peroxoiron(III) complex of tetrasulfophthalocyanine, $PcSFe^{III}OOH$, as active species responsible for the oxidative cleavage of quinones generated during the oxidation of 2,4,6-trichlorophenol by $FePcS/H_2O_2$[15][16].

In the present work, several important differences must be noted in anthracene oxidations performed by $FePcS/H_2O_2$ or $FeTMPS/KHSO_5$. These differences are (i) a different composition of oxidation products depending on the oxidation system used (Scheme 2), (ii) a different reactivity of oxanthrone, which is relatively stable in the presence of $FeTMPS/KHSO_5$, but very quickly oxidized by $FePcS/H_2O_2$, (iii) and very different ^{18}O incorporations into anthrone and anthraquinone in experiments performed in the presence of $H_2{}^{18}O$ (Figure 3). On the other side, both catalytic systems, $FePcS/H_2O_2$ and $FeTMPS/KHSO_5$, showed essentially the same KIE values in the oxidation of anthracene (KIE = 0.75 and 0.76, respectively) or phenanthrene (KIE = 0.96 and 1.02, respectively) (Table 2).

Mechanistic Significance of Inverse Isotope Effects

The observation of a significant inverse isotope effect in the anthracene oxidation by $FePcS/H_2O_2$ or $FeTMPS/KHSO_5$ indicated that these KIEs could not be interpreted as primary KIEs involving a C−H(D) bond cleavage in the rate determining step of the initial step of the oxidation reaction. Consequently, these inverse KIEs precluded an oxygen rebound mechanism which involves a hydrogen atom abstraction from substrate by an electrophilic high-valent oxoiron complex to give a short-life radical intermediate followed by rapid recombination step[23]. Inverse KIEs are usually associated with secondary KIEs when no C−H(D) bond is cleaved or formed, but this bond should modify some parameters in the transition state (TS). This is usually the case when a C−H(D) bond is located at the reaction site itself, containing the leaving group (α secondary KIE) or at the adjacent carbon atom (β secondary KIE). In the case of the intermolecular $[H_{10}]$anthracene/$[D_{10}]$anthracene competitive oxidation an α secondary KIE is observed. Generally, the magnitude of an α-secondary KIE is determined by an inverse stretching and a normal bending contribution to the KIE value[24][25]. For example, in S_N2 reactions, a tighter TS, with short nucleophile α-carbon and/or α-carbon leaving group bond lengths, the KIE values would be inverse or normal and small[24]. Based on calculations with model systems, the α-secondary KIEs have been interpreted as reflecting the changes in the out-of-plane bending motion, i.e. hybridization changes or differences in the loose/tight character of the TS[26]. The activation energy for $sp^2 \rightarrow sp^3$ change in hybridization is lower for the deuterated substrate compared to the non-deuterated analogue, creating then an inverse KIE[27]. When the TS of the reaction occurs very late along the reaction coordinate, i.e. the TS exhibits essentially a fully sp^3-hybridized

carbon atom like in the reaction product, the k_H/k_D value will be more pronounced, the maximum KIE expected for a $sp^2 \rightarrow sp^3$ rehybridization will be 0.71[27]. Values of k_H/k_D ranging from 0.8 to 0.9 correspond to TS geometries somewhere between sp^2 and sp^3 and are more frequently observed. Inverse secondary KIEs have been measured for the addition of a variety of electrophilic reagents to olefins and aromatics, e.g. for the reaction of 1-naphthylcarbene to toluene ($k_H/k_D = 0.52$)[28]. An other example of an inverse α-secondary k_H/k_D equal to 0.83 has been recently observed during of the [2 + 2] photocycloaddition of arylalkenes to C_{60}[29]. Inverse KIEs have been reported for styrene epoxidations catalyzed by cytochrome P-450 ($k_H/k_D = 0.93$) or performed with *m*-chloroperbenzoic acid ($k_H/k_D = 0.82$)[27a] or by hexacyanoferrate(III) in acid medium ($k_H/k_D = 0.80$)[27b]. The cytochrome P-450 catalyzed oxidation of isotopically labeled chlorobenzenes provides also an inverse KIE (0.95)[30]. This result has been explained by an initial attack of an activated triplet-like oxygen atom on the π-system of substrate to generate a tetrahedral intermediate followed by rearrangement to phenol directly or via epoxide or ketone intermediates[30]. The aromatic hydroxylation of *o*- and *p*-xylene, catalyzed by cytochrome P-450, showed also an inverse α-secondary isotope effects (0.83−0.94) which were consistent with an addition reaction of a oxoiron species onto an sp^2-hybridized carbon atom[31]. The inverse nature of KIEs was anticipated for sp^2-to-sp^3 rehybridization during the covalent modification of human 5α-reductases by finasteride (a specific inhibitor) by a nucleophilic N addition to the double bond of this steroid-type molecule[32]. The reaction of the nitroethane anion (the α-carbon atom is sp^2-hybridized) with D-amino acid oxidase proceeds with an inverse $k_H/k_D = 0.84$ which was indicative of significant sp^2-to-sp^3 rehybridization in the TS[33]. Apart from the sp^2-to-sp^3 rehybridization, inverse isotope effects can be due to the difference in C−H and C−D distances, C−D bond being slightly shorter than corresponding C−H bond (d = 1.112 and 1.107 Å, respectively)[34]. The racemization of 2,2′-dibromo-4,4′-dicarboxybiphenyl[35] and 9,10-dihydro-4,5-dimethylphenanthrene[36] showed inverse KIEs of 0.85 and 0.88, respectively. The origin of a large inverse secondary KIE in the bromination of a sterically congested olefin (0.36−0.65) has been attributed to the fact that C−D bonds are shorter and less sterically demanding[37]. Large inverse equilibrium isotope effects have also been observed for the oxidative addition of H_2 to *trans*-$W(PMe_3)_4I_2$ ($K^H_{eq}/K^D_{eq} = 0.63$)[38a] and cyclohexane to $CpRh(CO)_2$ ($K^H_{eq}/K^D_{eq} = 0.1$, at 163−193 K)[38b]. Recently, a substantial inverse isotope effect of $k_H/k_D = 0.48$ has also been published in Co^{III}-catalyzed polymerization of ethylene[39] and explained by the presence of a β-agostic Co···H···C (Co···D···C) interaction, the inverse KIE being associated with the release of the agostic bond. Related to this interpretation of an inverse KIE, it must be noted that complexation of *n*-heptane with double A-frame porphyriniron(III) has been recently observed in crystals[40]. An out-of-plane displacement of the iron center of 0.26 Å and an Fe···C distance of 2.5 Å strongly suggest moderate to weak agostic interactions between C−H bonds of the alkane and the metal center. *p*-Xylene can interact with the metal center of an porphyriniron(III), the smallest Fe−C distance was 2.94 Å and the iron atom was drawn 0.07 Å out of the mean plane of the porphyrin core indicating a possible weak agostic interaction[41].

In the present case of the oxidation of anthracene catalyzed by phthalocyanine- or porphyriniron complexes, anthracene, a polyaromatic substrate, should have a pronounced tendency to form a stacking complex with FePcS or FeTMPS. A rather polar reaction medium (an acetonitrile/water mixture) should favor stacking interactions between two large planar hydrophobic molecules. Then a question arises: can the difference in C−H/C−D substitution on anthracene generate different stacking interactions between $[H_{10}]$anthracene or $[D_{10}]$anthracene with the macrocyclic plane molecule of FePcS or FeTMPS? In other words, are the observed KIEs only related to hydrophobic interactions between the aromatic substrate and the macrocyclic catalyst? The differences observed on inverse KIEs during the $[H_{10}]$anthracene/$[D_{10}]$anthracene and $[H_{10}]$anthracene/$[D_2]$anthracene competitive oxidations (Table 2) could be due to possible differences in stacking interactions between $[D_{10}]$anthracene and $[D_2]$anthracene with the macrocycle of the catalyst resulting from a slight difference of the nature of C−H bonds compared to C−D bonds. So, the stacking interactions should increased with the deuterium content of anthracene. This is the case with both catalytic systems: the KIE is 0.90 for $[D_2]$anthracene and 0.75 with $[D_{10}]$anthracene with $FePcS/H_2O_2$ (0.95 and 0.76 with $FeTMPS/KHSO_5$, respectively) (Table 2). Consequently, the value of the inverse KIE due to the sp^2-to-sp^3 hybridization change should be enhanced in a highly stacked substrate-catalyst intermediate during the addition of an electrophilic oxoiron complex to the sp^2-carbon atom of anthracene to give a σ adduct. The data on ^{18}O labeling experiments are also consistent with this proposal (see below).

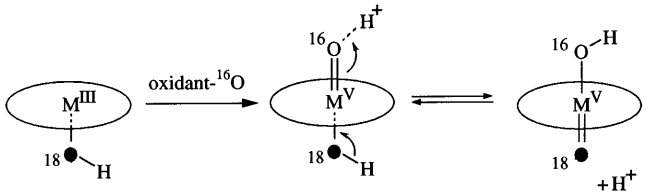
The quasi-absence of KIE observed in the phenanthrene oxidation by $FePcS/H_2O_2$ or by $FeTMPS/KHSO_5$ (0.96 and 1.02, respectively) can be due to the reduction of stacking interactions compared to anthracene and also to the different nature of C9−H and C10−H bonds in phenanthrene. The C9−C10 bond of phenanthrene exhibits a relatively high bond order, indicating that it possesses a considerable degree of double bond character (K region bonds of polyaromatics), while anthracene bonds show essentially an aromatic character (*meso* region bonds)[42]. As a result, the main product of phenanthrene oxidation was biphenyl-2,2′-dicarboxylic acid. A similar cleavage of the double bond of styrene was observed when oxidized by $FePcS/H_2O_2$[16].

Mechanistic Significance of ^{18}O Labeling Experiments

In aqueous media oxo(porphyrin)metal(V) complexes have an axial hydroxo ligand. In order to explain the observed 50% ^{18}O incorporation from $H_2{}^{18}O$ in epoxides during olefin epoxidations by a metalloporphyrin/$KHSO_5$ system[20a][21b][21c], hydroxylation of DNA deoxyriboses[20b] or

C−H bond hydroxylation of 4-isopropylbenzoic acid[20c] it was proposed that the active hydroxo(oxo)(porphyrin)metal(V) complex undergoes a "redox tautomerism" (Figure 4). The ^{18}O incorporation depends on the reaction conditions[21b], primarily on relative kinetics of oxidation step and ligand exchange processes between the hydroxo ligand and bulk water and the nature of the catalyst. The rate of the oxo-hydroxo interchange in the oxo(porphyrin)manganese(V) complex was estimated to be about 10^3 s^{-1}[21c].

Figure 4. Redox tautomerism in a hydroxo(oxo)metal(V) species having a water-soluble porphyrin ligand (O = ^{16}O, black O = ^{18}O)



The large ^{18}O incorporation into anthrone (63%) and anthraquinone (55%) observed during FeTMPS/KHS$^{16}O_5$ anthracene oxidation in the presence of $H_2{}^{18}O$ is consistent with the involvement of oxo(porphyrin)iron complex as active species. By contrast, the absence of ^{18}O incorporation into anthrone, produced in the oxidation by FePcS/H_2O_2, could be explained by the involvement of an active oxo-metal species unable to undergo such an oxo-hydroxo equilibrium (in particular if there is no hydroxo ligand in the axial position *trans* to the oxo group).

Tautomeric Equilibria in Oxidation Products of Anthracene

The sequence of anthracene oxidation to anthraquinone and the relation between tautomeric forms of products are depicted in Scheme 5. The first oxidation product, 9-hydroxyanthracene is in fast keto-enol equilibrium with anthrone, which is the predominant form. The anthrone/9-hydroxyanthracene ratio determined by NMR in $CDCl_3$ at 25°C was estimated to be 80:20[43]. 9,10-Dihydroxyanthracene exists in solution in equilibrium with oxanthrone (K_{eq} = 0.13) and is the major tautomer (89%)[44]. However, the equilibrium is reached very slowly. The rate constants for the 9,10-dihydroxyanthracene-oxanthrone interconversion were determined to be $k_{-2} = 3 \times 10^{-6}$ s^{-1} and $k_2 = 4 \times 10^{-7}$ s^{-1}[45]. It means that in 1 mM solution only 1% of oxanthrone will be transformed into 9,10-dihydroxyanthracene after 1 h at room temperature.

Mechanism of Anthracene Oxidation by FeTMPS/$KHSO_5$

The oxidation of anthracene by FeTMPS/$KHSO_5$ was significantly faster than those of anthrone and oxanthrone. Under the same conditions the conversions of anthracene, anthrone and oxanthrone after 30 min were 100, 38 and 18%, respectively. These data indicated that there was an oxidation pathway to give directly oxanthrone, the main oxidation product, without intermediate formation of anthrone.

An electrophilic attack of a high-valent oxo(porphyrin)-iron complex at a central sp^2-carbon atom of anthracene to give a σ complex is probably the initial oxidation step (Figure 5). The inverse isotope effect, indicative of an sp^2-to-sp^3 rehybridization in the TS containing both substrate and catalyst stacked and the observed ^{18}O incorporation into anthrone, the first oxidation product, typical for oxoiron complex mediated oxidation in aqueous medium strongly suggested the formation of a new carbon−oxygen bond to form a σ complex **A**. This intermediate **A** can be trapped by O_2 to produce oxanthrone and anthraquinone via an intermediate radical **B**. An intramolecular electron transfer in intermediate **A** can lead to an intermediate carbocation **C**, which can undergo either a proton elimination to give a σ complex **D** or a nucleophilic attack of water to produce an intermediate **E**, providing a reaction pathway for oxanthrone formation without intermediate formation of anthrone. The hydrolysis of the Fe^{III}−O−aromatic bond in both intermediates **D** and **E** gave 9-hydroxyanthracene (quickly tautomerized to anthrone) and 9,10-dihydro-9,10-dihydroxyanthracene **F**. Then **F** can be further oxidized by a $2e^-$ process with the release of $2H^+$, producing oxanthrone with an increased ^{18}O content, or by oxidation of a C−H bond by an oxygen rebound mechanism. The GC-MS analysis of [H_{10}]anthracene/[D_{10}]anthracene oxidation products after 6 min of reaction revealed that anthraquinone was enriched with nondeuterated material: 57% of [H_8]anthraquinone and 43% of [D_8]anthraquinone, indicating a KIE value > 1 on the anthrone-to-anthraquinone oxidation step. The ^{18}O content in anthraquinone (55%) was not increased compared to that in anthrone (63%). Both findings suggest that oxidation of intermediate **F** proceeds by an oxygen rebound mechanism followed by H_2O elimination to generate oxanthrone. The fact that the metallopor-

Scheme 5. Oxidation products of anthracene and tautomeric equilibria for anthrone and oxanthrone

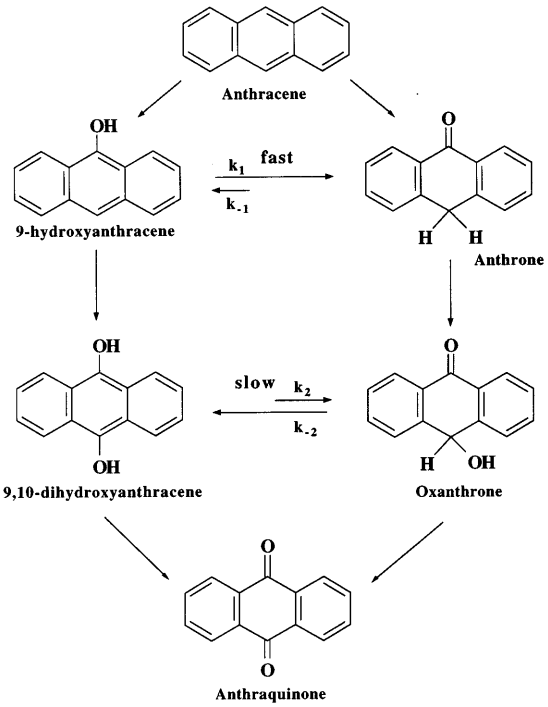


Figure 5. Proposed mechanism for anthracene oxidation by FeTMPS/$KHSO_5$ (O = ^{16}O, black ● = ^{18}O)

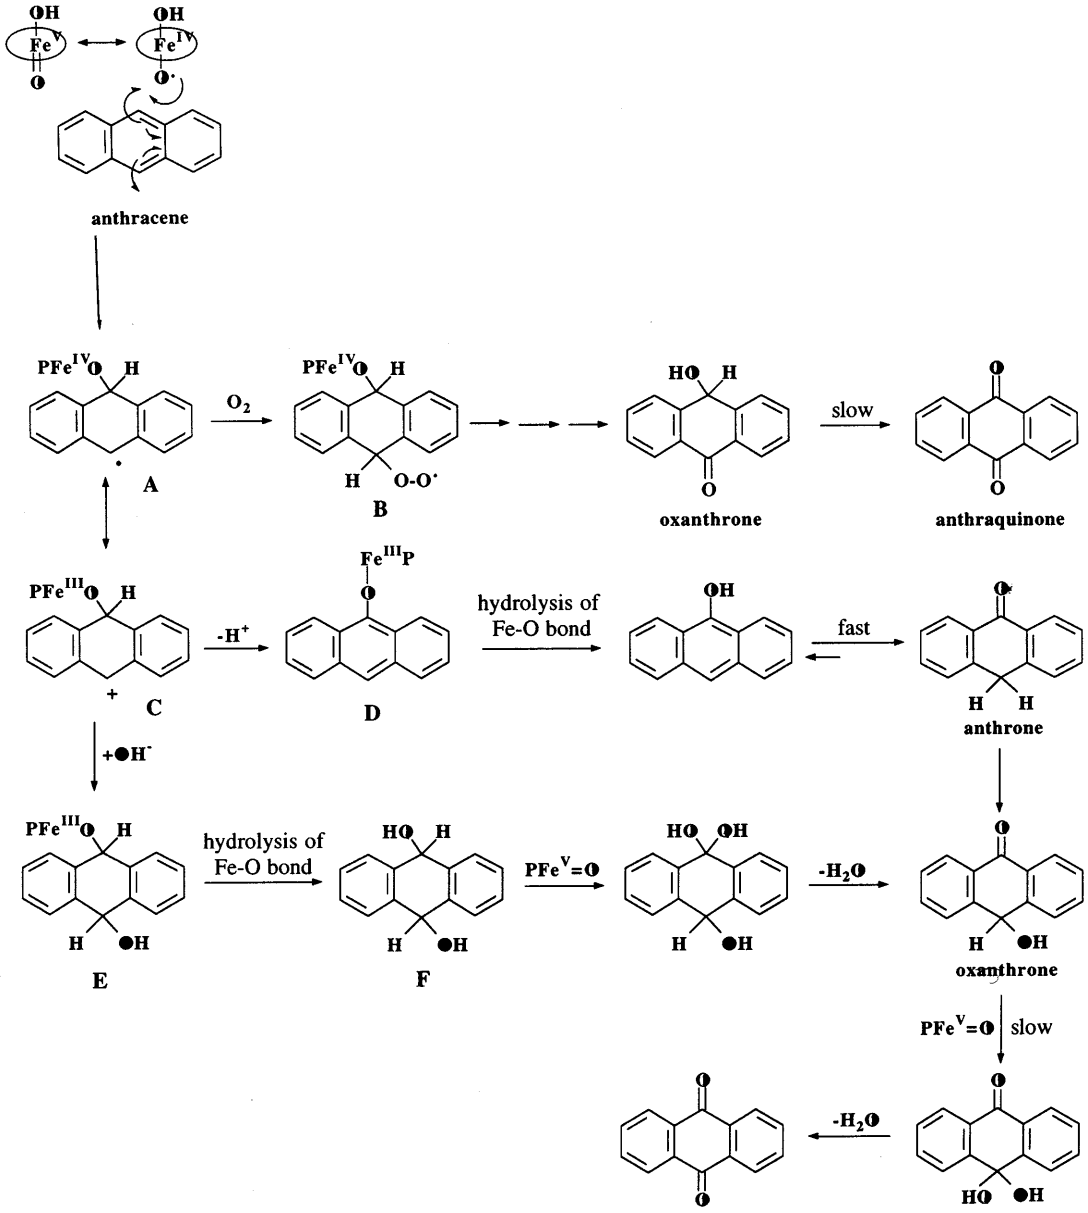
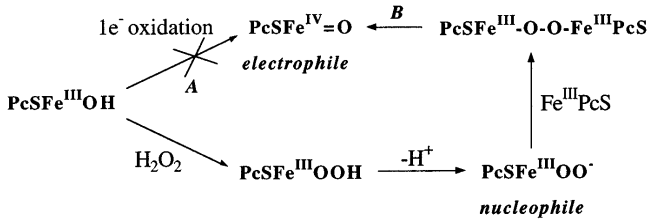


phyrin-catalyzed oxidation of anthracene gave oxanthrone, not the more oxidizable 9,10-hydroxyanthracene tautomeric form, explains the rather low yield of anthraquinone, since oxanthrone is relatively stable under the reaction conditions (oxanthrone conversion being only 23% after 60 min).

Active Species in FePcS/H_2O_2 Oxidations

In the FePcS/H_2O_2 mediated oxidation of trichlorophenol[15][17] a nucleophilic $PcSFe^{III}OO^-$ complex was proposed to be the active species, able to perform two key steps: (i) a nucleophilic addition to the electron-deficient double bond of intermediate quinones to provide epoxy quinones and (ii) a nucleophilic attack on the carbonyl group of the different quinones, leading to their ring cleavage[16]. Although the addition of nucleophiles to polyarenes, e.g. the addition of alkyllithium reagents to anthracene, has been published[46], such a peroxoiron(III) complex is probably not nucleophilic enough for a direct attack onto an sp^2-carbon atom of a PAH. Another possible active metal-oxygen species could be a high-valent oxoiron complex, having two redox equivalents above the Fe^{III} state. Several lines of evidence indicate that it is not the case for the FePcS/H_2O_2 system[15b]. The fact that the oxygen atom in anthrone originated from H_2O_2 (Figure 3) also indicated that an oxoiron(V) complex was not involved in anthracene oxidation by FePcS/H_2O_2. With such an oxoiron(V) complex we could expect both ^{16}O and ^{18}O incorporations due to redox tautomerism, as observed in anthracene oxidation by FeTMPS/$KHSO_5$. The other possible formulation of the active species involved in PAH oxidations by FePcS/H_2O_2 is a $PcSFe^{IV}=O$ species[15b]. It can be formed by a $1e^-$ oxi-

Figure 6. Generation of peroxoiron(III) and oxoiron(IV) species by activation of FePcS with hydrogen peroxide

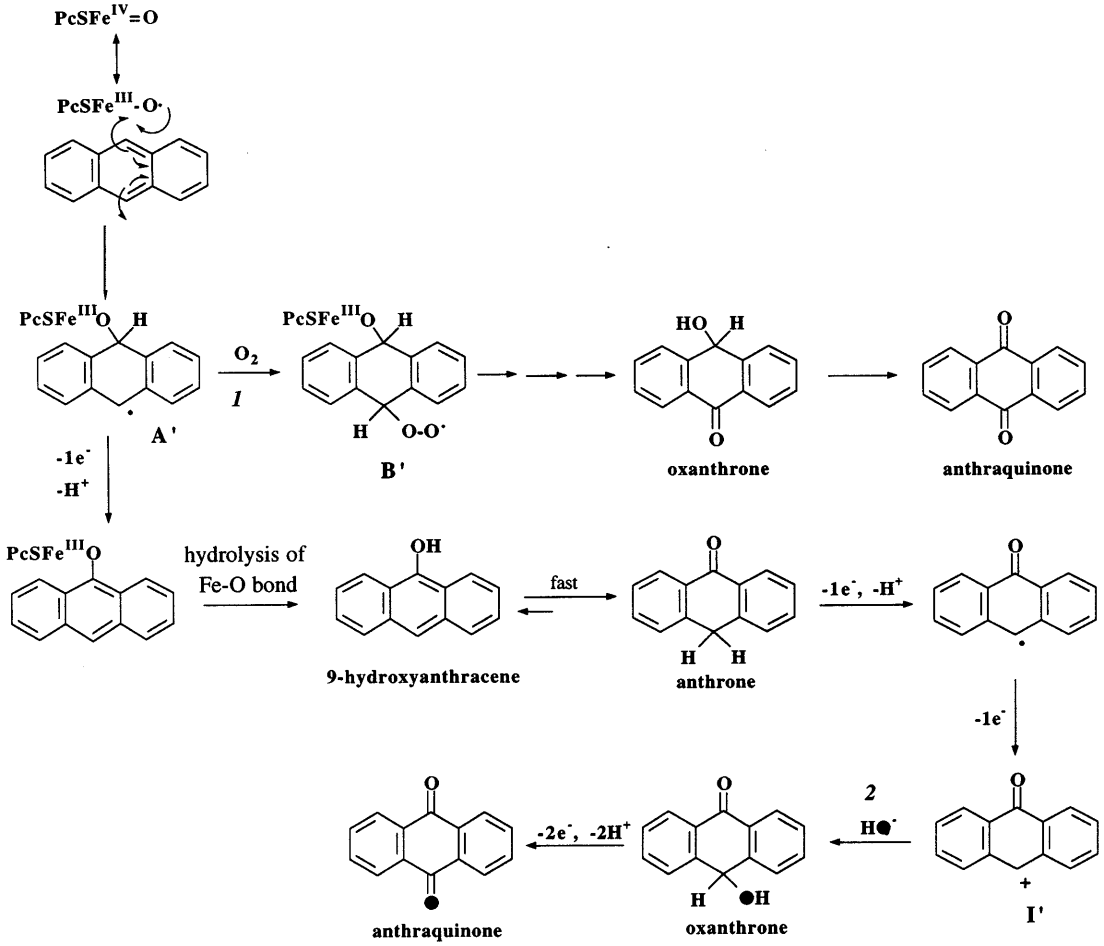


dation of $PcSFe^{III}OH$ complex (Figure 6, pathway *A*) or by the intermediate formation of a μ-peroxo dimer (pathway *B*). In the former case ^{18}O from water should be found in anthrone obtained in the presence of $H2^{18}O$. The absence of ^{18}O incorporation into anthrone during the oxidation of anthracene by $FePcS/H_2O_2$ in $H_2{}^{18}O$ eliminated this possibility. Consequently, $PcSFe^{IV}=O$ should be formed by pathway *B* by the homolytic cleavage of a μ-peroxo dimer (we proposed the pathway *A* in ref.[15b] before having on hands the data of these labeling studies). This $PcSFe^{IV}=O$ species is neutral and does not require the presence of an anionic axial anion ligand (e.g. HO^-) to compensate a charge. Consequently, no redox tautomerism is possible in the absence of HO^- ligand *trans* to the oxo entity. This absence of redox tautomerism for $PcSFe^{IV}=O$ explained the 100% incorporation of ^{16}O into anthrone during the $FePcS/H_2O_2$ oxidation of anthracene performed in heavy water.

Mechanism of Anthracene Oxidation by $FePcS/H_2O_2$

The first step of the $FePcS/H_2O_2$ mediated oxidation of anthracene resembles that described in the FeTMPS/$KHSO_5$ oxidation (Figure 7). The nearly identical inverse KIE (0.75) found for the first reaction step suggested also the formation of a σ complex, intermediate **A′** which can be trapped by O_2 to produce oxanthrone and anthraquinone via a radical intermediate **B′**. The significant ^{16}O incorporation in anthraquinone when the oxidation was performed under air compared to that obtained under nitrogen (Figure 3) was strongly indicative of this pathway 1. Hydrolysis of the $Fe^{III}-O-$aromatic bond followed by proton elimination and $1e^-$ oxidation generated 9-hydroxyanthracene which rapidly tautomerized to the thermodynamically favored anthrone. Successive $1e^-$ oxidation and proton elimination steps gives rise to carbocation **I′**, which can react with water (pathway 2) to produce oxanthrone and anthraquinone. $PcSFe^{IV}=O$ complex is not such a strong oxidant to perform the abstraction of an H atom of a aliphatic or aromatic C−H bond. However, $PcSFe^{IV}=O$ is

Figure 7. Proposed mechanism for anthracene oxidation by $FePcS/H_2O_2$ (O = ^{16}O, black ● = ^{18}O)



probably a sufficiently good $1e^-$ oxidant to perform $1e^-$ oxidations of intermediate products or of oxanthrone by successive $1e^-$ oxidations and proton eliminations to provide anthraquinone.

The rather low yields of anthrone and anthraquinone after 30 min (5 and 21%, respectively) might be due to radical intermediates capable of undergoing side reactions, e.g. coupling reactions. Accordingly, the presently proposed mechanism, the first oxygen atom incorporated into the different products originates from $PcSFe^{IV}=O$ (^{16}O in labeling experiments), and the value of ^{18}O incorporation of the second oxygen atom of anthraquinone from $H_2{}^{18}O$ will depend on the relative rates of the different pathways indicated on Figure 7. Very significant ^{18}O incorporation into the second oxygen position of anthraquinone under air (64%) and, especially under nitrogen (88%), strongly suggest that pathway 2 is the major reaction pathway.

Conclusion

The (tetrasulfophthalocyanine)iron/hydrogen peroxide oxidation system, based on an easy-to-prepare catalyst and a "clean" oxidant, is capable of oxidizing polycyclic aromatic hydrocarbons, like anthracene, phenanthrene and benzo[*a*]pyrene. Data obtained from product distribution, kinetic isotope effects and ^{18}O labeling studies, as well as a comparative study of anthracene oxidation by FeTMPS/$KHSO_5$ allowed us to propose that an oxo(phthalocyanine)iron(IV) complex, is probably responsible of these PAH oxidations. Consequently, taking in consideration the previously reported mechanistic studies on quinone cleavage by the same $FePcS/H_2O_2$ system, two kinds of the active species can be generated from FePcS in the presence of H_2O_2: (i) a nucleophilic peroxoiron complex $PcSFe^{III}OO^-$ responsible for double carbon−carbon bond cleavage in the deep oxidation of trichlorophenol[15][16] and (ii) an electrophilic $PcSFe^{IV}=O$ complex capable of oxidizing aromatic hydrocarbons by the formation of a σ adduct. This versatility makes (tetrasulfophthalocyanine)iron in association with hydrogen peroxide a suitable catalytic method for the chemical degradation of different pollutants.

Experimental Section

Instrumentation: Gas chromatography-mass spectrometry (GC-MS) was performed with a Hewlett-Packard 5890 instrument using electron-impact ionization at 70 eV. The carrier gas for GC-MS was He, and a 12 m × 0.2 mm HL-1 (Crosslinked Methyl Silicone Gum) capillary column was used. − High performance liquid chromatography (HPLC) analyses were performed with a Waters-486 Liquid Chromatograph equipped with a μ-Bondapak C18 column, eluent being a mixture of methanol and water (85:15, v/v) at a flow rate of 1 ml min^{-1}, detection at 242 nm for anthracene, 252 nm for phenanthrene and 280 nm for benzo[*a*]pyrene analyses. − UV/Vis spectra were recorded with a Hewlett-Packard 8452A diode array spectrophotometer. − ^1H NMR spectra were recorded with Bruker WM 250 spectrometer.

Materials: All chemicals used were of reagent grade. Potassium monopersulfate was a gift from Interox (Curox^R) and is the triple salt $2KHSO_5{\cdot}KHSO_4{\cdot}K_2SO_4$. Hydrogen peroxide was obtained from Janssen Chimica as a 35% aqueous solution. $H_2{}^{18}O$ (98 atom-%) was supplied by Eurisotop (Gif-sur-Yvette, France). Lithium aluminum deuteride was purchased from Fluka (minimum 99 atom-% D). (Tetrasulfophthalocyanine)iron (FePcS) was prepared according to the method of Weber and Busch.[47] The iron complex of octasodium *meso*-tetrakis(3,5-disulfonatomesityl)porphyrin (TMPS) was synthesized according to ref.[48]. Anthracene (97%), phenanthrene (98%), benzo[*a*]pyrene (98%), [D_{10}]anthracene (> 98 atom-% D), [D_{10}]phenanthrene (97 atom-% D), anthrone (96%), anthraquinone (97%), phenanthrenequinone (99%), 9,10-dibromoanthracene (98%) were purchased from Aldrich. Oxanthrone was prepared from anthrone via 10-bromoanthrone according to ref.[45]. NMR (CD_2Cl_2): δ = 2.47 (d, 1 H, *J* = 9.5 Hz, OH), 5.78 (d, 1 H, *J* = 9.5 Hz, H_{10}), 7.54 (td, 2 H, *J* = 7.5 and 0.7 Hz, H_3), 7.73 (td, 2 H, *J* = 7.5 and 1.5 Hz, H_2), 7.90 (dd, 2 H, *J* = 7.5 and 0.7 Hz, H_4), 8.25 (dd, 2 H, *J* = 7.5 and 1.5 Hz, H_1); (CD_2Cl_2 + small amount of D_2O): the same signals, except doublet at δ = 2.47 disappeared and the doublet at δ = 5.78 became a singlet.

Preparation of 9,10-Dideuterioanthracene: The procedure was adapted from ref.[49]. Dibromoanthracene (1.008 g, 3 mmol) and $LiAlD_4$ (504 mg, 12 mmol) were added under nitrogen to 15 ml of anhydrous dimethoxyethane. The reaction mixture, contained in a 50-ml round-bottom single-neck flask and maintained under nitrogen, was partly submerged in a ultrasonic laboratory cleaner Branson 2200 (working frequency 47 kHz, 205 W) at 35−40°C. The reaction was monitored by GC-MS. After 13 h, all dibromoanthracene was reduced and the reaction mixture contained 9,10-dideuterioanthracene accompanied by minor amount of 9-bromo[D_1]-anthracene.The reaction mixture was cooled at −40°C and 1 ml of D_2O (99%) was slowly added. The temperature was allowed to return to 20°C and hydrolysis of the excess of $LiAlD_4$ was performed for 30 min. Then the resulting mixture was pourred into 30 ml of water and extracted with diethyl ether (4 × 40 ml). The combined organic extracts were washed with saturated NaCl solution, dried with Na_2SO_4 and concentrated. The white precipitate was separated by filtration and recrystallized from diethyl ether to give 148 mg (27% yield) of the pure 9,10-dideuterioanthracene material. The isotopic purity was determined by NMR and GC-MS methods. The material contained 72.8% of 9,10-dideuterioanthracene and 27.2% of 9-deuterioanthracene.

General Catalytic Procedure for PAH Oxidation: Oxidation of anthracene was carried out in a mixture of acetonitrile/50 mM phosphate buffer at pH = 7 (3:1, v/v) at 20°C under aerobic conditions. Oxidations of phenanthrene and benzo[*a*]pyrene were performed in acetonitrile/33.3 mM phosphate buffer at pH = 4.6 (1:1, v/v). The reaction mixture (2 ml) contained 2 μmol of substrate introduced as a 4 mM acetonitrile solution and 0.074 or 0.1 μmol of catalyst, introduced as a 1.28 mM solution in water, and the required amounts of acetonitrile and stock buffer solution to obtaine the desired organic solvent/water ratios. Oxidations were started by addition of 10 μmol of oxidant (10 μl of 3.5% H_2O_2 solution or 3.1 mg of potassium monopersulfate). The final concentrations of the catalyst, substrate and oxidant were 37 (or 100) μM, 1 mM and 5 mM, respectively. The reactions were followed by HPLC and GC-MS techniques. Anthraquinone and anthrone were identified by comparison of its GC-MS behavior (retention time and mass spectrum) with those of an authentic sample. Oxanthrone was identified by comparison of its NMR spectrum with that of an authentic sample.

$H_2{}^{18}O$ Experiments: Reactions were carried out using $H_2{}^{18}O$ (98 atom-%) according to the following procedure. A mixture of 25 μl of 0.5 M phosphate buffer pH = 7 and 29 μl of catalyst stock solution (1.28 mM in water) was dried under vacuum. The dry residue was then dissolved in 250 μl of $H_2{}^{18}O$ and 250 μl of [H_{10}]anthracene and [D_{10}]anthracene stock solutions (50:50 mixture, 4 mM total concentration in MeCN) and 500 μl of MeCN were added. The oxidations were performed under air and under nitrogen. In the latter case the reaction mixture was submitted to 3 freeze-pump-thaw cycles and the reaction flask was filled up with nitrogen. The reaction was started by the addition of 5 μl of 3.5% H_2O_2 (for FePcS oxidation) or 1.6 mg of $KHSO_5$ (for FeTMPS oxidation). The substrate conversion was monitored by HPLC and isotopic compositions of products were analyzed by GC-MS.

Determination of Isotopic Composition of Substrates and Products: Mass spectra of [H_{10}]anthracene and [D_{10}]anthracene show very strong molecular peaks accompanied with little fragmentations. [H_{10}]anthracene: MS; *m/z* (%): 178 (100) [M^+], 176 (18) [M − 2 H]$^+$, 152 (8) [M − C_2H_2]$^+$, 89 (13) [M − C_7H_5]$^+$. [D_{10}]anthracene: MS; *m/z* (%): 188 (100) [M^+], 184 (13) [M − 2 D]$^+$, 160 (9) [M − C_2D_2]$^+$, 94 (17) [M − C_7D_5]$^+$. So, under conditions of GC-MS analysis, within experimental error, there is no isotope effect on fragmentation and isotopic compositions of [H_{10}]anthracene and [D_{10}]anthracene can be determined from the intensities of corresponding molecular peaks. The mass spectra of phenanthrene and products of oxidation of anthracene and phenanthrene showed the same features and their isotopic compositions were determined from the intensities of the molecular peaks of deuterated and non-deuterated compounds.

KIE determinations based on [H_{10}]anthracene/9,10-dideuterioanthracene oxidations were performed taking into account admixture of monodeuterated anthracene, the presence of [M + 1] peaks due to ^{13}C natural content and [M − 1] and [M − 2] fragmentations according to the following formalism:

$$I_{178} = [D_0]\text{-A} + F_{M-1}\cdot[D_1]\text{-A} + F_{M-2}\cdot[D_2]\text{-A} \quad (2)$$

$$I_{179} = [D_1]\text{-A} + F_{M+1}\cdot[D_0]\text{-A} + F_{M-1}\cdot[D_2]\text{-A} \quad (3)$$

$$I_{180} = [D_2]\text{-A} + F_{M+1}\cdot[D_1]\text{-A} \quad (4)$$

where I_{178}, I_{179}, I_{180} were intensities of peaks at *m/z* 178, 179 and 180, respectively; [D_0]-A, [D_1]-A, [D_2]-A were percentages of corresponding isotopomers of anthracene; F_{M+1}, F_{M-1}, F_{M-2} were relative intensities of [M + 1], [M − 1] and [M − 2] peaks. The latter intensities were determined in separate GC-MS experiments to be $F_{M+1\,=\,0}$.15, F_{M-1} = 0.11, F_{M-2} = 0.18. KIEs were calculated from the data obtained on conversions and the percentages of [H_{10}]anthracene and 9,10-dideuterioanthracene in an initial reaction mixture and after several minutes when the substrate conversion was near 50%.

Keywords: MRI Contrast agents / Gd^{III} complexes / Relaxometry / Water exchange / Prototropic exchange

A thorough investigation of the proton and oxygen-17 relaxation rates of water nuclei has been carried out for a solution containing an amphiphilic, paramagnetic Gd^{III} chelate of potential interest as a contrast agent for MRI. It has been found that at pH = 7, 298 K and 20 MHz (proton observation frequency), the contribution to the overall relaxation enhancement from the water molecule in the inner coordination sphere is dominated by the relaxation time (T_{1M}^H) of its protons. However, upon formation of a slowly tumbling adduct with β-cyclodextrin, the observed relaxation enhancement is also affected by the exchange lifetime (τ_M^H) of the coordinated water and by the transfer rate of its protons. This situation has been exploited to assess the prototropic exchange rate from the coordinated water to the bulk, which is base-catalyzed. In fact, under these experimental conditions, at basic pH, the proton transfer is faster than the exchange of the whole water molecule, and it becomes the factor determining the observed relaxation enhancement. The effect is further enhanced at low temperature as a consequence of the concomitant lengthening of either τ_R (which causes a reduction of T_{1M}^H) and/or the exchange lifetime of the coordinated water molecule.

Introduction

Recently, it has been shown that the exchange rate of the coordinated water molecule in Gd^{III} complexes of octadentate ligands may be markedly slower than in chelates with ligands of lower denticity.[1] The observed behaviour has been accounted for in terms of the occurrence of a dissociative exchange mechanism, the rate-determining step of which is determined by the energy difference between the nonacoordinated ground state and the octacoordinated activated state.[2] The actual value of the exchange rate of the water molecule coordinated at the paramagnetic metal site may be accurately evaluated by measuring the temperature dependence of the transverse relaxation rate of the ^{17}O-NMR water resonance of an aqueous solution containing the Gd^{III} chelate.[3]

Currently, the main interest in water-soluble Gd^{III} complexes stems from their use as contrast agents for MRI, owing to their remarkable ability to enhance the relaxation rate of water protons in the tissues in which they are distributed.[4] The contribution to the overall relaxation rate arising from the metal-bound water molecule in a Gd^{III} chelate may result either from the exchange of the whole water molecule or from the exchange of just its protons. At physiological pH, the latter process is much slower than the former,[5] making the assessment of the prototropic exchange rate for the protons of the metal-bound water molecule rather difficult.

Recently, we showed that the determination of the exchange rate for the protons of the water molecule in the inner coordination sphere of a Gd^{III} chelate may be successfully pursued by quantitative analysis of the pH dependence of the water ^1H-NMR longitudinal relaxivity, provided that the exchange lifetime of the whole metal-bound water molecule (τ_M^O) is longer than, or at least of the same order of magnitude as, the longitudinal relaxation time of its protons (T_{1M}^H).[6][7]

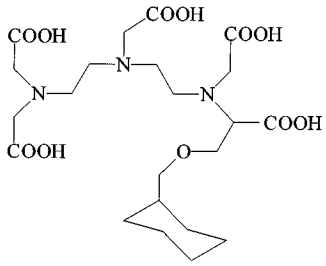
Until now, this behaviour has been observed only for Gd^{III} chelates endowed with a cationic or neutral residual charge. In the most commonly encountered anionic Gd^{III} complexes, τ_M^O is shorter than T_{1M}^H at ambient temperature. Thus, in such systems, the assessment of the prototropic exchange rate first requires a reduction of T_{1M}^H.

In principle, one may envisage several ways of shortening T_{1M}^H, e.g. by increasing the molecular correlation time through the formation of reversible adducts between the Gd^{III} chelate and a slowly tumbling substrate, or by lowering the temperature. In the latter case, besides the reduction of T_{1M}^H, a further advantage may be obtained by the decrease of τ_M^O as well.

In this work, we deal with the assessment of the prototropic exchange rate at the metal-bound water molecule in a derivative of $Gd(DTPA)^{2-}$, in which one acetate proton is replaced by a cyclohexyloxymethyl residue [$Gd(COPTA)^{2-}$; COPTA = 4-carboxy-5,8,11-tris(carboxymethyl)-1-cyclohexyl-2-oxa-5,8,11-triazatridecan-13-oic acid, Chart 1]. On the basis of the data collected to date for polyaminocarboxylate Gd^{III} chelates, we would expect the exchange lifetime at room temperature of the metal-bound water molecule in

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1434–1948/98/0909–1283 $ 17.50+.50/0

this anionic complex to be lower than T_{1M}^H. However, the presence of the hydrophobic tail should allow this chelate to reversibly form an adduct with a slowly tumbling substrate such as β-cyclodextrin (β-CD). The consequent lengthening of the reorientational correlation time, τ_R, of the complex should result in a decrease of T_{1M}^H, allowing the prototropic exchange rate to be determined through its effect on the overall water proton relaxation rate.



Results and Discussion

Determination of the Water Proton Exchange Lifetime τ_M^H

Analysis of the temperature dependence of the transverse relaxation rate for the ^{17}O water nuclei is the most accurate method for evaluating the exchange lifetime of the water molecule/s directly coordinated to the metal in a paramagnetic Gd^{III} chelate.

This approach allows assessment of the exchange lifetime of the metal-bound water oxygen nucleus which, at neutral pH and in non-buffered solutions, corresponds to the exchange lifetime of the metal-bound water protons, i.e. $\tau_M^H = \tau_M^O$.

The paramagnetic contribution (R_{2p}^O) to the observed transverse relaxation rate of water ^{17}O nuclei (R_{2obs}^O) is given by equation (1)

$$R_{2p}^O = R_{2obs}^O - R_{2d}^O \tag{1}$$

where R_{2d}^O is the transverse relaxation rate measured in a solution containing a diamagnetic chelate of the corresponding ligand at the same concentration.

According to the theory first proposed by Swift and Connick[8], R_{2p}^O depends on several parameters [equation (2)]

$$R_{2p}^O = P_M(\tau_M^O)\frac{R_{2M}^{O2} + (\tau_M^O)^{-1}R_{2M}^O + \Delta\omega_M^{O2}}{R_{2M}^{O2} + (\tau_M^O)^{-1})^2 + \Delta\omega_M^{O2}} \tag{2}$$

such as the chemical shift difference between the metal-bound and bulk water ^{17}O nuclei $\Delta\omega_M^O$, the molar fraction of the metal-bound water molecules P_M, their intrinsic ^{17}O transverse relaxation rate R_{2M}^O, and the exchange rate τ_M^O.

For quickly tumbling Gd^{III} chelates and at relatively low magnetic field strength (as used in this work), R_{2M}^O is dominated by the nucleus-electron scalar relaxation mechanism, which may be evaluated using equation (3).

$$R_{2M}^O = \frac{1}{3}\left(\frac{A}{\hbar}\right)^2 S(S+1)\left(\tau_{E1} + \frac{\tau_{E2}}{1+\omega_s^2\,\tau_{E2}}\right) \tag{3}$$

Here, S is the electronic spin quantum number [7/2 for Gd^{III}], $A/\hbar$ is the Gd-^{17}O scalar coupling constant, and τ_{Ei} (i = 1,2) are the correlation times for the dynamic processes modulating the scalar interaction. Both the longitudinal and the transverse electronic relaxation times (T_{1E} and T_{2E}), as well as the exchange lifetime of the metal-bound water molecule, may modulate the scalar interaction. The correlation time for this process is given by equation (4).

$$\tau_{Ei}^{-1} = \tau_M^{O^{-1}} + T_{iE}^{-1} \tag{4}$$

The scalar coupling constant is related to the unpaired electron spin density at the ^{17}O nucleus and it mainly depends on the distance between the metal ion and the metal-bound ^{17}O nucleus. Since for polyaminocarboxylate Gd^{III} chelates with a single inner-sphere water molecule this distance does not seem to vary significantly, for the $Gd(COPTA)^{2-}$ complex we used the same value as that reported for the closely related $Gd(DTPA)^{2-}$ chelate (-3.8×10^6 rad s^{-1}).[1]

For Gd^{III} complexes, T_{iE} values are basically related to the modulation of the transient zero-field splitting (ZFS) of the electronic spin states arising from the dynamic distortions of the ligand field caused by the solvent collision and, according to the Bloembergen-Morgan and Rubinstein theory,[9][10] they are expressed by equations (5) and (6)

$$T_{1E}^{-1} = \frac{1}{25}\Delta^2[4S(S+1)-3]\left[\frac{\tau_v}{1+\omega_s^2\,\tau_v^2} + \frac{4\tau_v}{1+4\omega_s^2\,\tau_v^2}\right] \tag{5}$$

$$T_{2E}^{-1} = \frac{1}{50}\Delta^2[4S(S+1)-3]\left[3\tau_v + \frac{5\tau_v}{1+\omega_s^2\,\tau_v^2} + \frac{2\tau_v}{1+4\omega_s^2\,\tau_v^2}\right] \tag{6}$$

where Δ^2 is related to the square of the mean transient ZFS energy, τ_v is the correlation time for the collision-related modulation of the ZFS hamiltonian, and ω_s is the electronic Larmor frequency.

The temperature dependence of R_{2M}^O is, therefore, expressed by the temperature effect on τ_M^O, τ_v, and $\Delta\omega_M^O$ according to equations (7) and (8)

$$\tau_j^{-1} = \frac{(\tau_j^{-1})^{298.15}\,T}{298.15}\exp\left[\frac{\Delta H_j}{R}\left(\frac{1}{298.15} - \frac{1}{T}\right)\right] \tag{7}$$

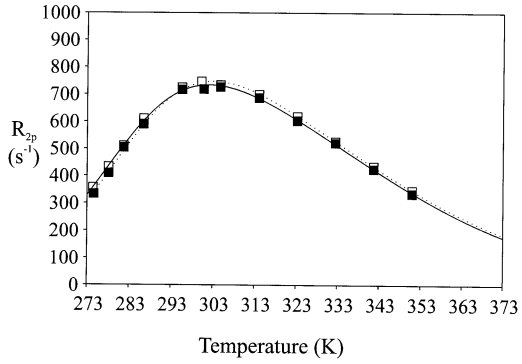
$$\Delta\omega_M^O = \frac{g_e\mu_B S(S+1)B}{3k_B T}\frac{A}{\hbar} \tag{8}$$

where the subscripts j refer to the two dynamic processes (j = M, v), ΔH_j is their activation enthalpy, B is the magnetic field strength, k_B is the Boltzmann constant, g_e is the free-electron Landè factor (2.0023), and μ_B is the Bohr magneton.

In Figure 1, we present a comparison between the temperature dependence of ^{17}O-R_{2p}^O for $Gd(COPTA)^{2-}$ and for the

parent Gd(DTPA)$^{2-}$, both recorded at 2.1 T, pH = 7 and at a concentration of 50 mM.

Figure 1. Temperature dependence of the transverse water ^{17}O relaxation rate at 2.1 T and pH = 7 for 50 mM solutions of Gd(COPTA)$^{2-}$(■) and Gd(DTPA)$^{2-}$ (□)



The two profiles appear to be superimposable, both being characterized by a relaxivity maximum centered at about 300 K. This means that the introduction of the hydrophobic substituent on one acetate arm of the Gd(DTPA)$^{2-}$ chelate does not significantly affect the exchange process of the metal-bound water molecule. An analogous observation has been recently reported by Muller et al. for the related Gd(EOB-DTPA)$^{2-}$ complex [EOB-DTPA = 3,6,9-triaza-3,6,9-tris(carboxymethyl)-4-(4-ethoxybenzyl)undecanedicarboxylic acid].[11] The fitting of the data afforded a τ_M^O value at 298 K for Gd(COPTA)$^{2-}$ of 290 ns, a value very close to those obtained for Gd(DTPA)$^{2-}$ (320 ns) and Gd(EOB-DTPA)$^{2-}$ (201 ns)[11] chelates.

Determination of the Longitudinal Water Proton Relaxation Time of the Coordinated Water Molecule τ_{1M}^H

In principle, the observed longitudinal relaxation rate of the water protons (R_{1obs}^H) of an aqueous solution containing a paramagnetic Gd^{III} chelate is given by the sum of three terms [equation (9)]

$$R_{1obs}^H = R_{1p}^{His} + R_{1p}^{Hos} + R_{1d}^H \quad (9)$$

where R_{1p}^{His} represents the paramagnetic contribution from the metal-bound water molecule, R_{1p}^{Hos} is the contribution from the water molecules that diffuse around the complex, and R_{1d}^H corresponds, in analogy to the ^{17}O approach, to the diamagnetic contribution measured in the presence of an equimolar amount of a diamagnetic analogue of the chelate.

The paramagnetic contribution to the observed relaxation rate ($R_{1p}^{His} + R_{1p}^{Hos}$) for a 1 mM solution of the paramagentic complex is called "relaxivity" and it is commonly indicated as r_{1p}.

According to the established theory,[12] R_{1p}^{His} for a 1 mM concentration of a Gd^{III} chelate with one exchanging metal-bound water molecule is given by equation (10)

$$R_{1p}^{His} = \frac{1.8 \cdot 10^{-5}}{T_{1M}^H + \tau_M^H} \quad (10)$$

where T_{1M}^H is the longitudinal relaxation time of the exchangeable metal-bound water protons.

This parameter is related to the dipolar interaction between the unpaired electrons of the metal and the inner-sphere water proton nuclei through equation (11)

$$(T_{1M}^H)^{-1} = \frac{2}{15}\frac{\gamma_I^2 g_e^2 \mu_B^2 S(S+1)}{r_H^6}\left[\frac{3\tau_{C1}}{1+\omega_I^2\tau_{C1}^2} + \frac{7\tau_{C2}}{1+\omega_S^2\tau_{C2}^2}\right] \quad (11)$$

where γ_I is the proton gyromagnetic ratio, r_H is the mean distance between the metal and the inner-sphere water protons, and ω_I and ω_S are the nuclear and electronic Larmor frequencies, respectively.

The two correlation times (τ_{ci}; i = 1,2) associated with the modulation of the proton-electron dipolar coupling are given by equation (12)

$$\tau_{ci}^{-1} = \tau_R^{-1} + (\tau_M^H)^{-1} + T_{iE}^{-1} \quad (12)$$

where τ_R is the reorientational correlation time for the Gd^{III} chelate. Since the rotational motion of the whole complex is assumed to be isotropic, τ_R may be simply related to its molecular size and, for relatively small Gd^{III} chelates, it usually dominates τ_{ci} at the magnetic field strengths routinely employed for MRI applications (0.2−1.5 T).

On the contrary, the outer-sphere contribution, R_{1p}^{Hos}, is not affected by the exchange process occurring at the metal site, since it basically depends, according to the model developed by Hwang and Freed,[13] on the distance of minimum approach between the metal and the diffusing water molecules a, the relative diffusion coefficient D, and the electronic relaxation times (T_{iE}) [equation (13)]

$$R_{1p}^{Hos} = C^{os}\left(\frac{1}{aD}\right)[7J(\omega_s) + 3J(\omega_I)] \quad (13)$$

where C^{os} is equal to 5.8×10^{-13} M^{-1} s^{-2} for a 1 mM concentration of the paramagnetic chelate and $J(\omega_i)$ represents the non-Lorentzian spectral density functions, including the dependence of T_{iE}, a and D.

The large number of parameters responsible for the water proton relaxation enhancement in the presence of a paramagnetic chelate makes their simultaneous and precise evaluation rather difficult. Nevertheless, this goal may be achieved by measuring the water proton relaxation rate over an extended range of magnetic field strengths.[14] The resulting plot of R_{1obs}^H vs. the proton Larmor frequency, called the NMRD profile (Nuclear Magnetic Relaxation Dispersion), is then fitted through eqs. 9−13 to obtain reliable values for the relaxation parameters. The possibility of fixing the values of some of the parameters involved makes the determination of others more accurate. The analysis of the NMRD profiles collected in recent years for a series of structurally similar Gd^{III} polyaminopolycarboxylate chelates provided us with reliable estimates for some relaxation parameters. In particular, values of 2.96 Å, 3.6 Å and 2.6×10^{-5} cm^2 s^{-1} (at 298 K) were obtained for $r_H a$ and D, respectively, from the fitting of the NMRD data for the strictly analogous Gd(BOPTA)$^{2-}$ chelate.[15] On this basis, we have assumed that these parameters do not change for the two complexes and, with these constraints, along with the values of q (1) and τ_M^H (290 ns as obtained from ^{17}O data), we carried out the fitting of the NMRD data for Gd(COPTA)$^{2-}$.

In Figure 2, the NMRD profile (25°C and pH = 7) of $Gd(COPTA)^{2-}$ is presented, along with the outer-sphere contribution to the relaxivity, while in Table 1 the best-fitting parameters are compared with those reported for $Gd(DTPA)^{2-}$.[15]

Figure 2. $1/T_1$ NMRD profile of a 1 mM aqueous solution of $Gd(COPTA)^{2-}$ at pH = 7 and 298 K. The dotted curve represents the outer-sphere contribution to the overall relaxivity

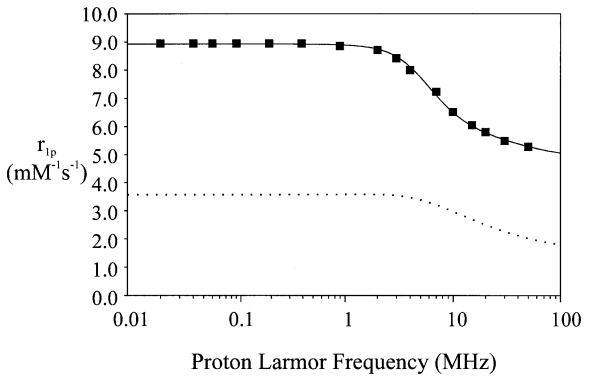


Table 1. Relaxation parameters calculated from NMRD data for $Gd(COPTA)^{2-}$ and $Gd(DTPA)^{2-}$ complexes at pH = 7 and 298 K[a]

Parameter	$Gd(DTPA)^{2-}$[b]	$Gd(COPTA)^{2-}$
Δ^2 ($/10^{19}$ s^{-2})	5.3 (0.3)	4.0 (0.2)
τ_V^{298} (ps)	19.0 (1.0)	25.0 (1.4)
τ_M^H (ns)	320[c]	290[c]
τ_V^{298} (ps)	73.0 (2.0)	80.1 (4.1)

[a] Numbers in parentheses represent standard deviations in mean parameter estimates on 1000 simulated relaxation rate data sets obtained by repeatedly introducing a random error of 1% into the experimental data set and estimating best parameters. – [b] From ref.[15]. – [c] The value was obtained in this work from the ^{17}O data and it has been kept fixed in the fitting of the NMRD profiles.

The main differences between the two sets of parameters lie in the higher τ_R value and the smaller r value obtained for $Gd(COPTA)^{2-}$. A longer reorientational correlation time may be easily accounted for in terms of a larger molecular size for this chelate and very similar τ_R values at 298 K have been reported for both $Gd(BOPTA)^{2-}$ (88.0 ps)[15] and Gd(EOB-DTPA)$^{2-}$ (84.0 ps)[11] complexes.

Once the relaxation parameters for the metal-bound water protons are known, it is possible to calculate their T_{1M}^H at 25°C. We obtained a value (5.3 μs) an order of magnitude larger than the water exchange lifetime (0.29 μs), indicating that for the $Gd(COPTA)^{2-}$ complex at 0.47 T, 298 K and pH = 7, the condition $T_{1M}^H > \tau_M^H$ is undoubtedly fulfilled.

Determination of the Prototropic Exchange Lifetime for the Metal-Bound Water Proton τ_M^{Hp}

The exchange lifetime of the protons of water molecules is strongly pH-dependent, being very long at neutral pH (of the order of ms) and significantly shorter (down to ns values) as the pH is adjusted to values either side of 7. The prototropic exchange process may be adequately treated as a pseudo-first-order mechanism, characterized by a rate constant k_p^i, the values of which for pure water at 301 K were reported to be in the range $4.1-7.1 \times 10^9$ M^{-1} s^{-1} and $2.2-4.3 \times 10^9$ M^{-1} s^{-1} for the acidic (k_p^a) and basic (k_p^b) catalysis, respectively.[5]

The prototropic exchange lifetime for the protons of a water molecule coordinated to a paramagnetic Gd^{III} chelate may be determined by analyzing the pH dependence of the water proton relaxivity. As it is well-known that the Gd^{III} chelates derived from the DTPA ligand are not sufficiently stable under very acidic conditions, we are forced, in the case of $Gd(COPTA)^{2-}$, to deal only with the base-catalysis of the prototropic exchange.

In order to account for the contribution arising from the prototropic exchange rate 1, the relaxation data are fitted to a modified version of equation 10, where τ_M^H is replaced by [equation (14)]

$$\tau_M^H = [(\tau_M^O)^{-1} + (\tau_M^{Hp})^{-1}]^{-1} \quad (14)$$

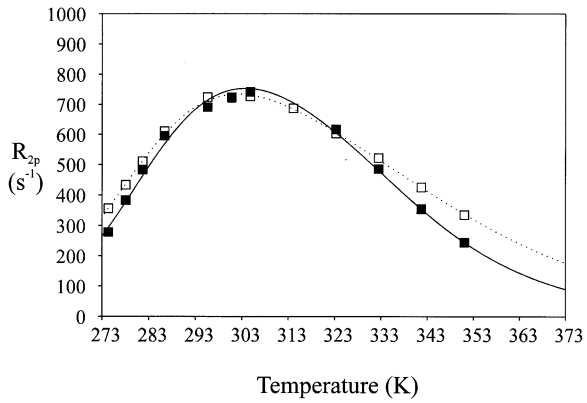
and [equation (15)]

$$\tau_M^{Hp} = \left(k^b \frac{Kw}{[H_3O^+]}\right)^{-1} \quad (15)$$

As it is reasonable to assume that the outer-sphere contribution to the observed relaxivity is unaffected by the pH of the solution, the reliability of the method is based on two main assumptions: (i) T_{1M}^H does not change over the investigated pH range, and (ii) at neutral pH the observed relaxivity has to be affected by the water exchange lifetime, i.e the condition $T_{1M}^H \approx \tau_M^H$ has to be fulfilled.

The temperature dependence of the water ^{17}O-R_{2p} is particularly sensitive to changes of the coordination cage of the chelate, thus allowing assessment of whether the pH of the solution causes either structural changes or variations in the exchange lifetime of the whole water molecule (τ_M^O). In Figure 3, the temperature dependence ^{17}O-R_{2p} profiles for $Gd(COPTA)^{2-}$ at pH = 7 and pH = 12 are shown.

Figure 3. Temperature dependence of the transverse water ^{17}O relaxation rate at 2.1 T and pH = 7 for 50 mM solution of $Gd(COPTA)^{2-}$ at pH = 7 (□) and pH = 12 (■)

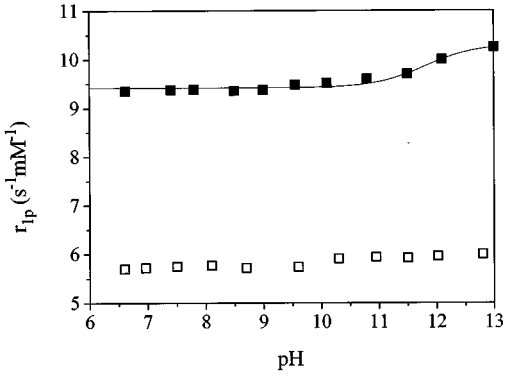


The two profiles are rather similar, being the differences observed in the best fitting parameters within experimental error. These findings support the view that the structure of this Gd^{III}

chelate, and consequently its T_{1M}^H value, is not affected by the pH of the solution.

On the contrary, as emphasized in the previous paragraph, the second condition is not valid for $Gd(COPTA)^{2-}$ at 298 K and 0.47 T and, therefore, the water proton relaxivity is not affected by the pH of the solution (Figure 4, bottom). Thus, this behaviour prevents the determination of the prototropic exchange rate for this chelate under these experimental conditions.

Figure 4. pH dependence of the longitudinal water proton relaxivity at 20 MHz and 298 K of $Gd(COPTA)^{2-}$ free (□) and bound to β-CD (■)



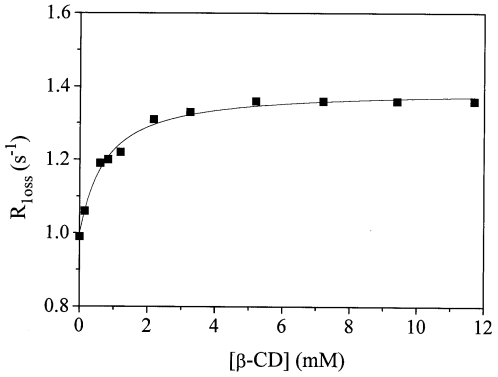
In order to meet the conditions under which the prototropic contribution to the overall relaxation rate can be expressed, we followed two different approaches: (i) formation of a paramagnetic adduct with a slowly tumbling substrate, such as β-cyclodextrin, in order to reduce T_{1M}^H, and (ii) decrease of the experimental temperature in order to either reduce T_{1M}^H or increase τ_M^H.

Reduction of T_{1M}^H Through Non-Covalent Interaction with β-Cyclodextrin

The increase of the relaxivity of a Gd^{III} chelate caused by the lengthening of its reorientational correlation time τ_R is a well-known phenomenon. In fact, it represents the most useful approach to enhance the effectiveness of a CA for MRI applications.[16] Usually, the increase of τ_R is pursued through the formation of adducts between the paramagnetic chelate and slowly tumbling substrates. For this purpose, it is necessary to have a complex endowed with a suitable substituent able to interact with the macromolecular substrate. The benzyloxymethyl residue has been reported to be an excellent recognition synthon that is able to interact with many substrates such as β-cyclodextrin, albumin and micelles.[17][18][19] As the interaction of this group is basically hydrophobic in origin, we expect that the replacement of the phenyl group by cyclohexyl should not significantly modify the interaction properties of the former substituent. Furthermore, in the context of this work, we have to choose a macromolecular substrate, the chelate adduct of which affects the exchange mechanism of the metal-coordinated water molecule as little as possible. For this reason, β-cyclodextrin is the best candidate, since in this case the non-covalent interaction should involve only the hydrophobic tail of the amphiphilic complex and its coordination cage should remain unchanged.

The increase of relaxivity resulting from this interaction may be also exploited for evaluating the affinity of the chelate for β-cyclodextrin. In fact, by measuring the longitudinal water proton relaxation rates of a solution of $Gd(COPTA)^{2-}$ in the presence of increasing amounts of β-CD, we obtained the saturation profile shown in Figure 5, fitting of which allows derivation of an association constant of $(1.5 \pm 0.1) \times 10^3\ M^{-1}$ and a relaxivity for the bound complex of $9.2 \pm 0.1\ s^{-1}mM^{-1}$ (25°C and pH = 7), i.e. 1.6 times larger compared to the unbound chelate.

Figure 5. Longitudinal water proton relaxation enhancement of a 0.11 mM solution of $Gd(COPTA)^{2-}$ upon addition of β-CD (20 MHz, pH = 7, 298 K)

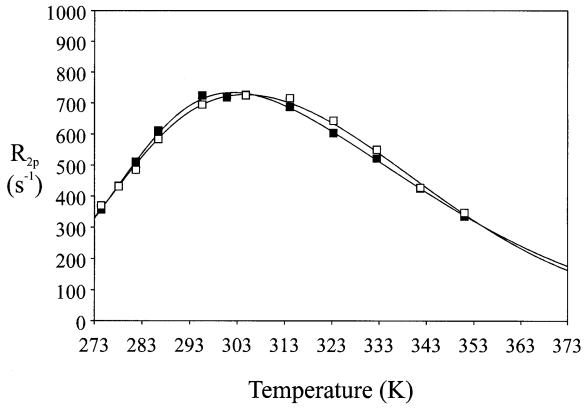


As the interaction with the β-CD essentially causes a lengthening of the reorientational correlation time of the Gd^{III} chelate, the outer-sphere contribution to the overall relaxivity of the bound complex is not expected to be significantly different compared to that of the unbound chelate. From the quantitative analysis of the NMRD profile of $Gd(COPTA)^{2-}$ shown in Figure 2, an R_{1p}^{Hos} value of $2.45\ s^{-1}mM^{-1}$ at 20 MHz and 25°C was obtained. Therefore, the inner-sphere contribution for the $Gd(COPTA)^{2-}$/β-CD adduct is $6.75\ s^{-1}mM^{-1}$ under the same experimental conditions.

In order to calculate the value of T_{1M}^H for the metal-bound water protons in the paramagnetic inclusion compound, it is also necessary to evaluate the value of their exchange lifetimes τ_M^H (equal to τ_M^O at neutral pH). The temperature dependence of the ^{17}O water transverse relaxation rate for the $Gd(COPTA)^{2-}$ chelate bound to β-CD is almost superimposable on the profile recorded for the unbound complex (Figure 6), confirming that τ_M^H does not vary appreciably upon interaction.

On this basis, a value of T_{1M}^H of 2.4 μs for the metal-bound water protons in the inclusion compound may be calculated through eqs. 9–10. This value is only 2.2 times lower than that for the unbound chelate and the condition $T_{1M}^H \approx \tau_M^H$ is not yet met. Nevertheless, the pH dependence of the longitudinal water proton relaxivity for the $Gd(COPTA)^{2-}$/β-CD adduct measured at 298 K (Figure 4, top) is characterized by a slight increase of relaxivity at pH > 11. As the binding with β-CD basically occurs through van der Waals' forces,[20] the affinity of the Gd^{III} chelate for the cyclic oligosaccharide should not

Figure 6. Temperature dependence of the transverse water ^{17}O relaxation rate at 2.1 T and pH = 7 for 50 mM solution of $Gd(COPTA)^{2-}$ free (■) and bound to β-CD (□)



depend on the pH of the solution. Moreover, from the close similarity between the ^{17}O data for the free chelate and those of the adduct with β-CD (either at neutral or basic pH), we can safely rule out the possibility that the relaxation enhancement observed at basic pH is due to structural changes of the Gd^{III} complex. Therefore, the increase of relaxivity may be ascribed to the occurrence of a fast base-catalyzed prototropic exchange of the metal-bound water protons, which results in a reduction of τ_M^H at pH > 11. This hypothesis was further confirmed through a quantitative analysis of the data using equations 10, 14−15. The best fitting parameters (T_{1M}^H, τ_M^O and k_p^b) were in good agreement with the expected values at 298 K. In fact, values of 2.3 ± 0.02 μs and 0.29 μs were obtained for T_{1M}^H and τ_M^O, respectively. As far as the base-catalyzed prototropic exchange rate constant is concerned, we obtained a value of (7.3 ± 2.6) × 10^8 s^{-1} M^{-1}, which is lower than the value measured in pure water and similar to the value determined for the Gd(DTPA-BBA) chelate.[7]

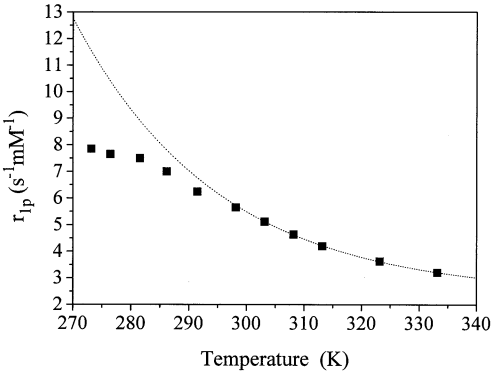
In conclusion, the reduction of T_{1M}^H caused by the formation of an inclusion compound with β-CD allows detection of the effect on the relaxivity arising from the prototropic exchange at the metal-bound water molecule of the Gd^{III} chelate. Unfortunately, the effect of the interaction on R_{1M}^H is not particularly marked owing to the small increase of τ_R for the chelate bound to the β-CD. For this reason, the associated relaxivity enhancement observed at basic pH is relatively small and the error in the estimation of k^b is consequently rather large (ca. 36%).

Reduction of T_{1M}^H by Lowering the Temperature

Another possible approach to achieve the condition $T_{1M}^H \leq \tau_M^H$ is to exploit the opposite temperature dependence of these two parameters. In particular, at low temperature, one can expect a decrease of T_{1M}^H (due to the increase of τ_R) and a simultaneous lengthening of τ_M^H. The temperature dependence of the longitudinal water proton relaxivity for $Gd(COPTA)^{2-}$ complex is depicted in Figure 7.

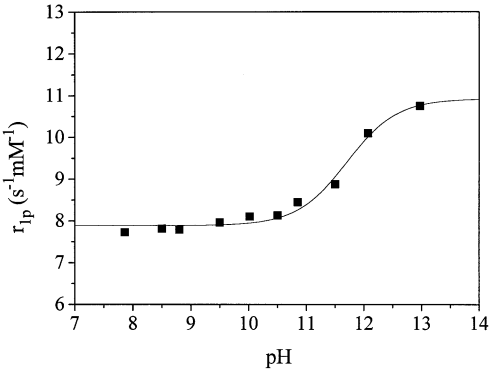
The profile may be split in two regions: at temperatures higher than 288 K, the relaxivity decreases pseudo-exponentially owing to the increase of T_{1M}^H, whereas at lower temperature, the elongation of τ_M^H and the simultaneous decrease of R_{1p}^{Hos} causes a flattening of the profile. On the basis of these data, at a temperature lower than 288 K, the condition $R_{1M}^H \approx \tau_M^H$ can be expected to hold.

Figure 7. Temperature dependence of the water proton relaxivity of $Gd(COPTA)^{2-}$ at 20 MHz and pH = 7



The pH dependence of the relaxivity of the $Gd(COPTA)^{2-}$ complex recorded at 278 K is shown in Figure 8.

Figure 8. pH dependence of the longitudinal water proton relaxivity at 20 MHz and 278 K of $Gd(COPTA)^{2-}$



At this temperature, the relaxivity enhancement promoted by the activation of the prototropic exchange appears to be much more pronounced compared to the effect observed at room temperature for the same system. Before carrying out a quantitative analysis of the data reported in Figure 8, it was thought useful to gain more information about the relaxation parameters of the chelate at 278 K. In particular, by fixing a value of D of 1.1 × 10^{-5} cm^2 s^{-1},[21] the fitting of the NMRD data recorded at this temperature and at pH = 7 afforded a value of 4.4 s^{-1} mM^{-1} for the outer-sphere contribution to the relaxivity and values of 3.2 ± 0.2 μs and 2.4 ± 0.1 μs for T_{1M}^H and τ_M^H (equal to τ_M^O at neutral pH), respectively. Interestingly, we obtained very similar T_{1M}^H and τ_M^H values (2.8 ± 0.1 μs and 2.4 ± 0.1 μs) from the fitting of the data shown in Figure 8. Furthermore, it is noteworthy that the values obtained for the water proton exchange lifetime at pH = 7 ($\tau_M^H = \tau_M^O$) from the analysis of both magnetic field and pH dependence of the ^1H relaxivity are in good agreement with the value calculated at 278 K from the ^{17}O data (1.3 ± 0.1 μs). As expected, the value of the rate constant for the base-catalyzed prototropic ex-

change process is lower [$(1.5 \pm 0.3) \times 10^8$ s^{-1} M^{-1}], but more accurate (standard deviation ca. 20%), compared to the value obtained at room temperature in the case of the Gd^{III} complex incorporated into β-CD.

Conclusion

In this work, we have shown that NMR (^1H and ^{17}O) relaxometric methods provide a powerful tool for assessing the exchange rate of the coordinated water molecule, as well as the proton transfer rate, in a paramagnetic Gd^{III} complex.

This has been possible through the decrease of the relaxation time of the protons of the coordinated water (T_{1M}^H) upon formation of a paramagnetic adduct with the slowly tumbling β-cyclodextrin substrate.

When T_{1M}^H becomes smaller than the exchange lifetime of the coordinated water, the prototropic contribution to the overall proton relaxation enhancement may be evaluated, since, at basic pH, the proton transfer rate becomes faster than the exchange of the whole water molecule.

Support from *MURST* CNR is gratefully acknowledged.

Experimental Section

Synthesis: The COPTA ligand and its Gd^{III} chelate were prepared using a procedure analogous to that previously reported for the BOPTA ligand[15] starting from diethylenetriamine and 2-bromo-3-(cyclohexylmethoxy)propanoic acid, followed by peralkylation of the monoalkylated intermediate with sodium bromoacetate in water at pH = 10. 2-Bromo-3-(cyclohexylmethoxy)propanoic acid was obtained by alkaline hydrolysis of the corresponding methyl ester, which was prepared according to a reported procedure.[22]

^1H-NMR Measurements: Longitudinal water proton relaxation rates were measured at 25°C and 0.47 T with a Stelar Spinmaster spectrometer [Stelar, Mede (PV), Italy] by using the inversion recovery (180° − τ − 90°) pulse sequence. A phase cycle ($+x$, $-x$, $-x$, $+x$) was applied on the 90° observation pulse in order to cut off the y scale receiver offset. Each measurement consisted of 4 scans and the values of the magnetization were obtained in the time domain by averaging the first 128 points of the free induction decay. The reproducibility in T_1 measurements was ±0.4%. The temperature was controlled with a Stelar VTC-91 air-flow heater equipped with a copper-constantan thermocouple; the actual temperature was measured inside the probehead (uncertainty of ±0.1 °C) by using a Fluka 52 k/j digital thermometer.

The ^1H-NMRD profiles were recorded on a Koenig-Brown field-cycling relaxometer by measuring water proton longitudinal relaxation rates at magnetic field strengths in the range from 2.4×10^{-4} to 1.5 T (corresponding to 0.01−50 MHz proton Larmor frequencies) with a T_1 uncertainty of ±1%.

^{17}O-NMR Measurements: The measurement of the ^{17}O transverse relaxation rates was carried out with a JEOL EX-90 spectrometer operating at 2.1 T (corresponding to a ^{17}O Larmor frequency of 12.2 MHz) by using an external D_2O lock. The temperature calibration was performed following the same procedure described for the Stelar SpinMaster spectrometer.

The value of the transverse relaxation rate was obtained by evaluating the linewidth at half-height ($\Delta\nu_{1/2}$) of the water ^{17}O signal ($R_2 = \pi\Delta\nu_{1/2}$). Solutions containing 2.6% of the ^{17}O isotope were used. ^{17}O-enriched (10.4%) water was purchased from Yeda (R. & D. Co., Rehovot, Israel).

Keywords: Asymmetric catalysis / Hydrogenations / Hemilabile ligand / Hydroxy phosphane / Methoxy phosphane

The influence of two *threo*-arranged methoxy or hydroxy groups as hemilabile ligands in seven-membered (diphosphane)Rh^I chelates upon the asymmetric hydrogenation is studied. In comparison to the parent complex based on 1,4-bis(diphenylphosphanyl)butane (DPPB) a lowering of the reaction rate is caused by the hemilabile ligands. The catalyst bearing the hydroxy groups gives significantly higher enantioselectivities than the corresponding methoxy complex (by ca. 35 % ee). X-ray structural analysis reveals that the oxygen atom of the hydroxy group is by 0.9 Å closer to the metal center than that of the methyl ether. ^{31}P-NMR studies give evidence that the dihydroxy diphosphane ligand binds at low temperature exclusively in the η^3-coordination mode, whereas for the dimethoxy complex also an η^2-coordinated isomer can be found. These differences in complexation could be responsible for the superior enantioselectivities achieved with this and other hydroxy catalysts.

Introduction

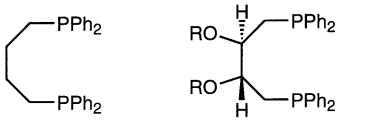
(Alkoxyaryl and -alkyl)phosphanes have seen broad application in asymmetric hydrogenations[1] as well as in numerous other metal-catalyzed stereodifferentiating reactions.[2] For example, (*R*,*R*)-DIPAMP [(*R*,*R*)-1,2-bis(*o*-anisylphenylphosphanyl)ethane] was the first industrially applied ligand.[3] The unique role of the alkoxy and preferentially that of the methoxy group is attributed to their property to act as hemilabile ligands[4] or intramolecular solvent,[5] which may temporarily coordinate to the metal center in the course of the catalytic cycle.[6][7]

Despite this, much less information is available on the influence of the related hydroxy group,[8] although it deserves particular attention due to its potential to create secondary interactions with a suitable substrate and to enhance the solubility of the catalyst in water.[9][10]

In recent investigations with a (diphosphane)rhodium complex bearing a single methoxy group we could show that the replacement of the latter by the hydroxy group increased the enantioselectivity of the hydrogenation in methanol.[11] Simultaneously, a conspicuous loss of reactivity was observed. To date there is no explanation for this unique behaviour of this and other catalysts bearing hydroxy groups.[12]

Herein, we report on a study concerning the synthesis, catalytic properties, and structure elaboration of cationic Rh^I complexes based on the ligands (*R*,*R*)-1,4-bis(diphenylphosphanyl)butane-2,3-diol (**1-OH**)[13a] and its bis(methyl ether) **1-OMe**[14] which may have important implications to the aspects discussed above. Both ligands are related to 1,4-bis(diphenylphosphanyl)butane (DPPB) which forms with metals seven-membered chelate rings.

Scheme 1



DPPB **1-OH** (R = H) **1-OMe** (R = Me) **1-OSiPh$_3$** (R = Ph_3Si)

In general, Rh catalysts based on such large and highly flexible chelates are more active in asymmetric hydrogenations than rigid five-membered chelates e.g. (DIPAMP)Rh^I, but require additional stabilization in order to provide for appreciable enantioselectivity. Due to the absence of any other stabilizing groups in our model complexes chosen catalytic effects can be clearly traced to the effect of the oxy functionalities.

Results and Discussion

The Rh^I complexes were synthesized by reaction of the C_2-symmetric diphosphanes with $[Rh(COD)_2]BF_4$ [COD = (*Z*,*Z*)-cycloocta-1,5-diene] (Scheme 2). The COD complex of **1-OH** was converted into the better crystallizing complex [Rh(NBD)(**1-OH**)]BF_4 by treatment with norbornadiene (NBD).[15]

The complexes obtained catalyze the hydrogenation of itaconic acid (ItH_2) and (*Z*)-2-*N*-acetylaminocinnamic acid (AH) in methanol (Table 1). The Rh complex of DPPB is

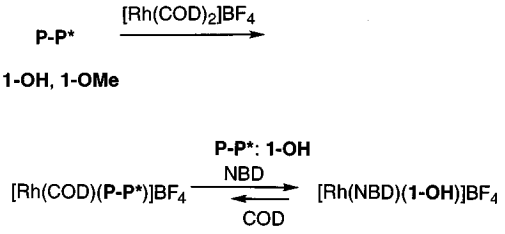
Scheme 2



the most active catalyst in the series. It is remarkable that the incorporation of the methoxy groups diminishes seriously the rate of the reaction, however, the selectivity observed is low. This gives a clear indication that the ether groups are not able to stabilize certain conformations of the highly flexible seven-membered chelate. The exchange of the methoxy by the hydroxy groups gives rise to a further loss of reactivity, however, affords a significant gain in selectivity by approximately 35% ee.

Table 1. Asymmetric hydrogenation of prochiral olefins in methanol[a]

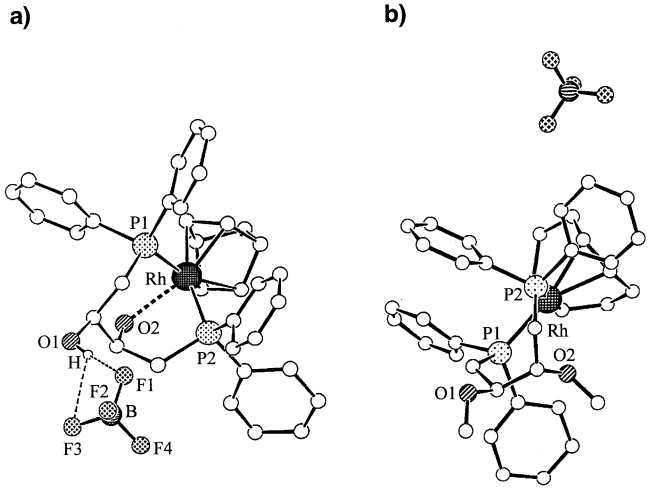
Precatalysts	Substrate	$t/2$ [min][b]	ee [%] (config.)
$[Rh(COD)(DPPB)]BF_4$	ItH_2	<2	–
$[Rh(COD)(\mathbf{1\text{-}OMe})]BF_4$	ItH_2	3.7	22.4 (*S*)
$[Rh(NBD)(\mathbf{1\text{-}OH})]BF_4$	ItH_2	6.0	56.8 (*S*)
$[Rh(COD)(DPPB)]BF_4$	AH	<2	–
$[Rh(COD)(\mathbf{1\text{-}OMe})]BF_4$	AH	145	0.6 (*S*)
$[Rh(NBD)(\mathbf{1\text{-}OH})]BF_4$	AH	190	36.3 (*R*)

[a] Conditions: 0.01 mmol of precatalysts, 1.0 mmol of substrate in 15 ml of MeOH at 25°C and at 0.1 MPa H_2 pressure. – [b] Corresponds to that time, when 50% of substrate is converted.

In order to explain these differences, X-ray structural analyses of the precatalysts were performed and their $^{31}P\{^1H\}$-NMR spectra recorded. Suitable crystals of $[Rh(NBD)(\mathbf{1\text{-}OH})]BF_4$ and $[Rh(COD)(\mathbf{1\text{-}OMe})]BF_4$ were obtained from methanol. The single-crystal X-ray structural analyses established the structures as shown in Figure 1a and 1b, respectively, along with selected bond lengths and interbond angles.[17] The inspection of the data shows some agreements but also striking differences.

In the complex $[Rh(NBD)(\mathbf{1\text{-}OH})]BF_4$[17a] both phosphorus atoms are differently bound to the rhodium center; the distances are 2.283 Å and 2.377 Å. One of the enantiotopic hydroxy groups interacts with the metal center (distance 2.396 Å) never before observed to such an extent in related (methyl phosphanylaryl ether)rhodium[6c] or -palladium complexes[1e]. The BF_4 anion binds via a hydrogen bond to the second hydroxy group. In the IR spectrum (KBr) appear two bands at 3508 and 3441 cm^{-1} also clearly indicating two different hydroxy groups.[18] One important force for the formation of the five-membered O–Rh–P ring is apparantly the pseudo-equatorial arrangement of the hydroxy group in the fused six-membered ring being fixed in a distorted chair conformation, since the interaction could not be found in the corresponding monohydroxy complex.[11] The dihedral angle formed by the two hydroxy groups is 157.3° which reveals a strong deviation from the *anti* arrangement.

Figure 1. Structures of $[Rh(NBD)(\mathbf{1\text{-}OH})]BF_4$ (Figure 1a) and $[Rh(COD)(\mathbf{1\text{-}OMe})]BF_4$ (Figure 1b) in the crystalline state; hydrogen atoms are omitted for clarity[a]



[a] Selected atomic distances [Å] and torsional angles [°]: $[Rh(NBD)(\mathbf{1\text{-}OH})]BF_4$: Rh(1)–P(1) 2.283(2), Rh(1)–P(2) 2.377(2), Rh(1)–O(2) 2.396, F(1)–O(1) 2.717; O(1)–C–C–O(2) 157.3; $[Rh(COD)(\mathbf{1\text{-}OMe})]BF_4$: Rh(1)–P(1) 2.320(2), Rh(1)–P(2) 2.333(2), Rh(1)–O(2) 3.282; O(1)–C–C–O(2) 169.1.

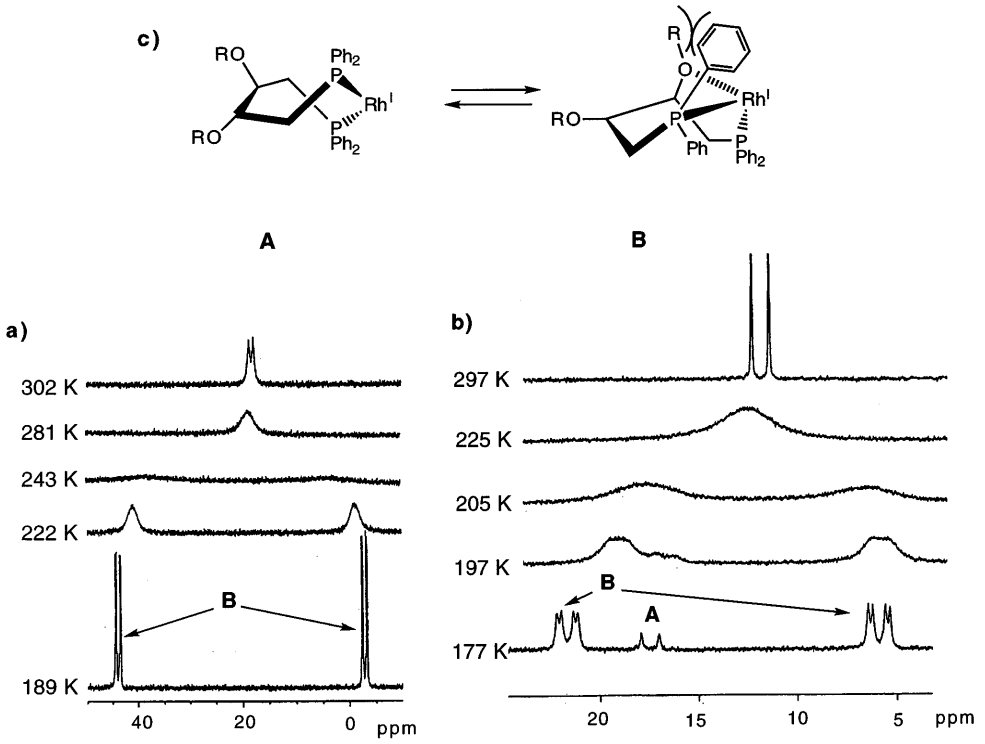
For the structure of $[Rh(COD)(\mathbf{1\text{-}OMe})]BF_4$ different features are noted.[17b] Thus, both phosphorus atoms are bound in approximately equal distances to the metal center. Due to the absence of a hydrogen-bond donor the BF_4 anion is located far away from the oxy groups. The most important difference in comparison to the hydroxy compound is the distance between the rhodium and the oxygen atom O(2) of the neighboured ether group (3.282 Å). This is a difference of more than 0.9 Å. The dihedral angle O(1)CCO(2) is widened to 169.1°.

In the $^{31}P\{^1H\}$-NMR spectra in CD_3OD also remarkable differences exist (Figure 2). $[Rh(NBD)(\mathbf{1\text{-}OH})]BF_4$ is characterized at 302 K by a doublet at $\delta = 18.1$. The decrease of the temperature caused the broadening of the signal. At 222 K the initial resonance had disappeared and two new signals could be observed at $\delta = 40$ and 0. Finally, the spectrum at 189 K displays two sets of well-separated double doublets at $\delta = 44.0$ ($J_{Rh\text{-}P} = 141.5$ Hz, $J_{P\text{-}P} = 41.4$ Hz) and $\delta = -2.7$ ($J_{Rh\text{-}P} = 129.1$ Hz, $J_{P\text{-}P} = 41.4$ Hz) produced by two nonequivalent phosphorus atoms. These results are consistent with one oxygen atom being attached to the metal center. The resonance at $\delta = 44.0$ has to be assigned to a phosphane which is involved in an O–P five-membered chelate.[19] Compared to related seven-membered chelate complexes {e.g. $[Rh(COD)(DPPB)]BF_4$} the downfield shift observed is caused by the increased ring strain in the newly formed five-membered ring. The fused O–P six-membered ring is characterized by a considerable shift of the concerned signal to higher field and the decrease of the ^{103}Rh-^{31}P coupling. The coordination of the oxygen atom causes the formation of the boat conformation (**B**) (Figure 2c). The typical change of the band shapes with

decreasing temperature gives clear evidence that the doublet observed at room temperature characterizes a rapid exchange of the phosphane signals. This exchange caused by the alternate coordination of the two oxygen atoms is not distinguishable on the NMR time scale at elevated temperatures.

ylsilyl ether) **1-OSiPh$_3$** (Scheme 1) recently published by Tamao.[20] In contrast to the complexes considered herein, [Rh(COD)(**1-OSiPh$_3$**)]SbF_6 is fixed in the C_2-symmetric conformation **A**.[21] This feature is explained by repulsive interactions between the bulky silyl groups and the phenyl rings of the phosphanyl moiety (Figure 2c). Clearly, these

Figure 2. $^{31}P\{^1H\}$-NMR spectra of the complexes [Rh(NBD)(**1-OH**)]BF_4 (Figure 2a; the small $J_{P\text{-}P}$ couplings of 41.4 Hz are not visible in the presentation) and [Rh(COD)(**1-OMe**)]BF_4 (Figure 2b) in CD_3OD at different temperatures; the relevant equilibrium of conformers is depicted in Figure 2c



The methoxy complex [Rh(COD)(**1-OMe**)]BF_4 shows a different behaviour with decreasing temperature. Thus, in comparison to the hydroxy complex the coalescence temperature is 35 K lower. Even at 177 K the doublets of doublets are less separated. Additionally, at $\delta = 17.2$ a doublet can be observed which corresponds in shift and coupling to that of the Rh(DPPB) complex. The signal can be unambigeously attributed to a C_2-symmetric complex and gives proof that at low temperatures [Rh(COD)(**1-OMe**)]BF_4 exists also in a conformation where the oxygen atoms do not interact with the metal center (twisted chair conformation **A**).

Due to the temperature dependency of the coupling constants and the inaccessibility of the data of the twisted chair conformation of Rh(NBD)(**1-OH**)]BF_4 we were not able to calculate the concentrations of the conformers at room temperature. However, taking the differences in the low-temperature spectra and the coalescence temperatures into account considerable differences in the populations of the conformers **A** and **B** of hydroxy und methoxy complex can be concluded.

The observation of these differences between hydroxy and methoxy complex provoked the comparison with the structure of a Rh complex based on the related bis(triphen-

interactions are also responsible for the fact that none of the oxygen atoms approaches the rhodium center, as found in [Rh(NBD)(**1-OH**)]BF_4 and [Rh(COD)(**1-OMe**)]BF_4. Taking our and the results of Tamao into consideration the preference for the shift of the boat (**B**) into the twisted chair conformation (**A**) is in the order $Ph_3Si > Me > H$. In other words, large groups at the oxygen atom prevent by interactions with the phenylphosphanyl groups the ligand to bind in the η^3-coodination mode. The η^2-coordination mode is responsible for a high hydrogenation activity as seen for the $(DPPB)Rh^I$ complex. Apparently, the tripodal coordination hinders the hydrogenation. However, only by this arrangement the highly flexible seven-membered chelate can be sufficiently stabilized which is the precondition to achieve conspicuous enantioselectivity.[22][23]

Conclusion

The conformation of chiral, highly flexible rhodium diphosphane chelates can be stabilized by the incorporation of hemilabile oxy groups. Due to the additional interaction of the ligand with the metal center a deceleration of the rate of the asymmetric hydrogenation results. With the hydroxy group significant higher enantioselectivities were achieved in comparison to the usually applied methoxy group. This

observation can be rationalized by the stronger preference of the hydroxy diphosphane ligand to bind in the η^3-coordination mode. In the precatalysts investigated herein the tripodal coordination is forced by the interplay of two *erythro*-arranged functional groups. The interaction between the hemilabile ligand and the rhodium center is counterbalanced by the repulsive interaction of the substituent at the oxygen atom with one phenylphosphanyl unit, which is stronger for the methyl group than for the proton of the hydroxy group.

In extension of these conclusions we suggest that in the catalytic cycle also other interactions between the hydroxy group and the metal center become operative,[24] since a significant gain of selectivity could be also noted in the hydrogenation with complexes bearing only one hydroxy group.[11][12] In general, these results and preliminary investigations with catalyst−substrate complexes clearly show that the main differences between hydroxy and methoxy group are preserved during the asymmetric hydrogenation. In combination with other conformation-stabilizing features selectivities of ≥ 90% ee can be achieved.[8][25] Therefore, the assistance of hemilabile hydroxy groups should be recommended also in other stereoselective reactions.

It is a pleasure to thank Prof. Dr. *K. Tamao* (Kyoto), Prof. Dr. *U. Rosenthal* und Prof. Dr. *R. Selke* (Rostock) for fruitful discussions.

Experimental Section

General: All reagents were obtained from Aldrich and Merck. Solvents were dried and freshly distilled under argon before use. Reactions were performed under argon by using standard Schlenk techniques. (*Z*,*Z*)-Cycloocta-1,5-diene (COD) and norborna-2,5-diene (NBD) were dried with CaH_2 and distilled under argon. (*R*,*R*)-1,4-bis(diphenylphosphanyl)butane-2,3-diol (**1-OH**) was synthesized by cleavage of the acetal group of (*R*,*R*)-3,4-bis(diphenylphosphanylmethylene)-2,3-dimethyl-1,3-dioxolane (DIOP) according to an already published procedure.[13a][13b] (*R*,*R*)-1,4-bis(diphenylphosphanyl)-2,3-dimethoxybutane (**1-OMe**) was prepared starting from (*R*,*R*)-tartaric acid as described in ref.[14]. Commercially available (*Z*)-2-(acetylamino)cinnamic acid (AH) and itaconic acid (ItH_2) were recrystallized under argon. − NMR: Bruker ARX 400 (400.13 MHz, 100.63 MHz, and 161.98 MHz for ^1H, ^{13}C and ^{31}P, respectively); for ^1H and ^{13}C NMR TMS as internal standard; for ^{31}P NMR H_3PO_4 as external standard. − X-ray: STOE-IPDS diffractometer. − IR: Nicolet Magna − IR 550 instrument. − MS: AMD 402 (Firma Intectra) − Elemental analysis: LECO CHNS-932. − The hydrogenation experiments were carried out under normal pressure and isobaric conditions with an automatically registrating gas-measuring device (1.0 atm overall pressure over the solution). The experiments were carried out under standard conditions with 0.01 mmol precatalyst, 1.0 mmol of prochiral olefin in 15 ml of solvent at 25°C. The conversion of the prochiral olefins was determined by GC. The acids were esterified with trimethylsilyldiazomethane before the GC measurements: GC 5890 Serie II; FID, carrier gas: argon: 1 ml/min. Methyl *N*-acetylphenylalaninate: fused silica; 10 m, XE-60-L-valin-*tert*-butylamide; ID 0.2 mm; oven temperature: 150°C. Dimethyl methylsuccinate: fused silica, Lipodex E (Machery and Nagel), 25 m, ID 0.25 mm; oven temperature: 85°C.

*[Rh(COD)(***1-OH***)]BF$_4$:* (*R*,*R*)-1,4-Bis(diphenylphosphanyl)butane-2,3-diol (120 mg, 0.262 mmol) and $[Rh(COD)_2]BF_4$ (106 mg, 0.262 mmol) were stirred in THF (2 ml) at ambient temperature for 1.5 h. After the addition of diethyl ether (8 ml), a precipitate formed which was filtered off and washed with a small quantity of diethyl ether to give 182 mg (92%) of the complex as a yellow-orange powder. − ^{31}P NMR ($CDCl_3$, 297 K): δ = 15.0 (d, *J* = 148.1 Hz). − ^{13}C NMR ($CDCl_3$, 297 K): δ = 133.9−128.5 (Ar), 95.9 (s, COD-*CH*), 95.5 (s, COD-*CH*), 71.7 (s, O*CH*), 33.0 (m, PCH_2), 28.7 (s, COD-CH_2). − ^1H NMR ($CDCl_3$, 297 K): δ = 7.70−7.34 (m, 20 H, Ar), 4.52 (m, 2 H, COD-*CH*), 4.17 (m, 2 H, COD-*CH*), 4.04 (m, 2 H, O*CH*), 2.84 (m, 2 H, H_b of PCH_2), 2.62−2.18 (m, 8 H, COD-CH_2), 2.01 (m, 2 H, H_a of PCH_2). − IR (KBr): $\tilde{\nu}$ = 3548, 3463, 3053, 2946, 2919, 2882, 2835, 2361, 1894, 1844, 1480 cm^{-1}. − FAB MS (3-nitrobenzyl alcohol matrix): *m*/*z* = 668.6 $[M - BF_4]^+$, 560.7 $[M - BF_4 - COD]^+$. − $C_{36}H_{40}BF_4O_2P_2Rh$ (756.37): C 57.17, H 5.33; found C 56.78, H 5.35.

*[Rh(NBD)(***1-OH***)]BF$_4$:* To a suspension of [Rh(COD)(**1-OH**)]BF_4 (151 mg, 0.2 mmol) in THF (45 ml) freshly distilled NBD (10 ml, 100 mmol) was added. Stirring over a period of 48 h yielded a dark orange solution. After the addition of diethyl ether (200 ml), an orange powder precipitated, which was filtered off and dried to give 133 mg (90%) of the desired NBD complex. − ^{31}P NMR (CD_2Cl_2, 297 K): δ = 18.1 (d, *J* = 146.2 Hz). − ^{13}C NMR (CD_2Cl_2, 297 K): δ = 134.3−129.2 (Ar), 72.2 (m, *CH*), 71.7 (m, *CH*), 70.6 (m, *CH*), 66.2 (s, *CH*), 31.9 [t, ^1J(P-C) = 12.3 Hz, PCH_2]. − ^1H NMR (CD_2Cl_2, 297 K): δ = 7.38−7.06 (m, 20 H, Ar), 3.97 (s, 2 H, *CH*), 3.85 (s, 2 H, *CH*), 3.76 (m, 2 H, *CH*), 3.62 (m, 2 H, *CH*), 2.65 (m, 2 H, H_a of PCH_2), 2.19 (m, 2 H, H_b of PCH_2), 1.23 (s, 2 H, NBD-CH_2). − IR (KBr): $\tilde{\nu}$ = 3508, 3441, 3056, 3003, 2952, 2920, 2848, 2681 cm^{-1}. − IR (CD_2Cl_2) $\tilde{\nu}$ = 3410, 3396 cm^{-1}. − FAB MS (3-nitrobenzyl alcohol matrix): *m*/*z* = 652.7 $[M - BF_4]^+$. − $C_{35}H_{36}BF_4O_2P_2Rh$ (740.33): C 56.78, H 4.90; found C 56.96, H 4.93.

*[Rh(COD)(***1-OMe***)]BF$_4$:* (*R*,*R*)-1,4-Bis(diphenylphosphanyl)-2,3-dimethoxybutane (290 mg, 0.6 mmol) and $[Rh(COD)_2]BF_4$ (243 mg, 0.6 mmol) were stirred in THF (2 ml) at ambient temperature for 2 h. After the addition of diethyl ether (8 ml), a precipitate formed which was filtered off and recrystallized from THF and diethyl ether to give 367 mg (78%) of the complex as a orange powder. − ^{31}P NMR ($CDCl_3$, 297 K): δ = 12.3 (d, *J* = 144.0 Hz). − ^{13}C NMR ($CDCl_3$, 297 K): δ = 134.5−128.9 (Ar), 99.4 (s, COD-*CH*), 95.0 (s, COD-*CH*), 78.0 (s, O*CH*), 58.5 (s, OCH_3), 31.8 [t, ^1J(P-C) = 13.2 Hz, PCH_2], 30.7 (s, COD-CH_2). − ^1H NMR ($CDCl_3$, 297 K): δ = 7.82−7.08 (m, 20 H, Ar), 4.38 (m, 2 H, *CH*), 4.25 (m, 2 H, *CH*), 3.46 (m, 2 H, *CH*), 3.27 (s, 6 H, OCH_3), 2.84−2.01 (m, 12 H, PCH_2 and COD-CH_2). − IR (KBr): $\tilde{\nu}$ = 3047, 2951, 2920, 2882, 2837, 1480, 1433 cm^{-1}. − FAB-MS (3-nitrobenzyl alcohol matrix): *m*/*z* = 696.6 $[M - BF_4]^+$, 588.6 $[(M - BF_4) - COD]^+$. − $C_{38}H_{44}BF_4O_2P_2Rh$ (784.42): C 58.19, H 5.65; found C 58.33, H 5.54.

Keywords: Metalloenzymes / Copper / Copper-containing monooxygenase / Dopamine β-hydroxylase / Copper–oxygen radical species / RPY2 ligand / Oxygen atomtransfer

The stereochemistry of oxygen atom transfer mediated by copper–oxygen species has been studied through a substrate binding ligand approach. Copper(II) [(IndPY2)Cu]$(CF_3SO_3)_2$ (**2a**) and copper(I) [(IndPY2)Cu]PF_6 (**5a**) complexes were prepared and exposed to O_2 in media of benzoin/NEt_3/CH_2Cl_2 and CH_2Cl_2, respectively. In both cases, highly regio- and stereoselective oxygen atom transfer to the benzylicC–H bond of the indane ligand occurred. Using deuterium-labelled copper complexes **2b** and **5b**, we found that, in both cases, the oxygen atom transfer occurs with retention of configuration. The high deuterium kinetic isotope effects (7.6 and 11, respectively), determined by ^{13}C-NMR spectroscopy, strongly suggest the intermediacy of two different copper–oxygen reactive species.

Introduction

The mechanism of dioxygen activation by copper-containing monooxygenases such as dopamine β-hydroxylase (DBH)[1], peptidylglycine α-hydroxylating monooxygenase (PHM)[2], and particulate methane monooxygenase (pMMO)[3] is of current interest.[4] Given that these enzymatic processes involve the formation of highly reactive copper/oxygen radical species, which are responsible for hydrogen atom abstraction from the substrate, the Cu/O_2 chemistry has been the subject of recent investigations.[5] From these studies, it has become apparent that copper(I) complexes derived from tridentate ligands {RPY2[5a][6], $HB(3,5\text{-}i\text{Pr}_2\text{pz})_3$[5b][7], $P(2,4\text{-}i\text{Pr}_2\text{im})_3$[8], and $i\text{Pr}_3$tacn[9]} lead to side-on $[L_2Cu_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}O_2)]^{2+}$ species upon reaction with O_2. In some cases, these side-on peroxo species are capable of inserting an oxygen atom into a C−H bond of the ligand.[10] In earlier papers, we described the substrate binding ligand approach in the chemical modelling of the copper-containing monooxygenase active site.[11] This approach involves the study of copper complexes derived from RPY2-type ligands in which a "substrate" is covalently bound to the tertiary amino group of the ligand such that an intramolecular oxygen atom transfer from copper to the ligand is favoured. Using such complexes, both ourselves[11b] and Itho's group[12] have described hydroxylation at the β-position of the tertiary amino group (Scheme 1). Herein, we describe the study of new RPY2 ligands in which we chose to attach a 2-aminoindane group as the "substrate". This substituent possesses two stereogenic centres in benzylic positions, each bearing two hydrogen atoms, and thus the stereochemistry of aminoindanols obtained after hydroxylation can be regarded as indicating the stereoselectivity of the oxygen atom transfer.

dane[13], respectively, to freshly distilled vinylpyridine in a MeOH/AcOH mixture.[10a] The corresponding copper(II) complexes **2a** and **2b** were quantitatively prepared by reaction of **1a** and **1b**, respectively, with $Cu(CF_3SO_3)_2$ in MeOH. Crystallization of $[(IndPY2)Cu](CF_3SO_3)_2$ (**2a**) from CH_2Cl_2/Et_2O gave blue crystals suitable for X-ray analysis (Table 1, Figure 1).

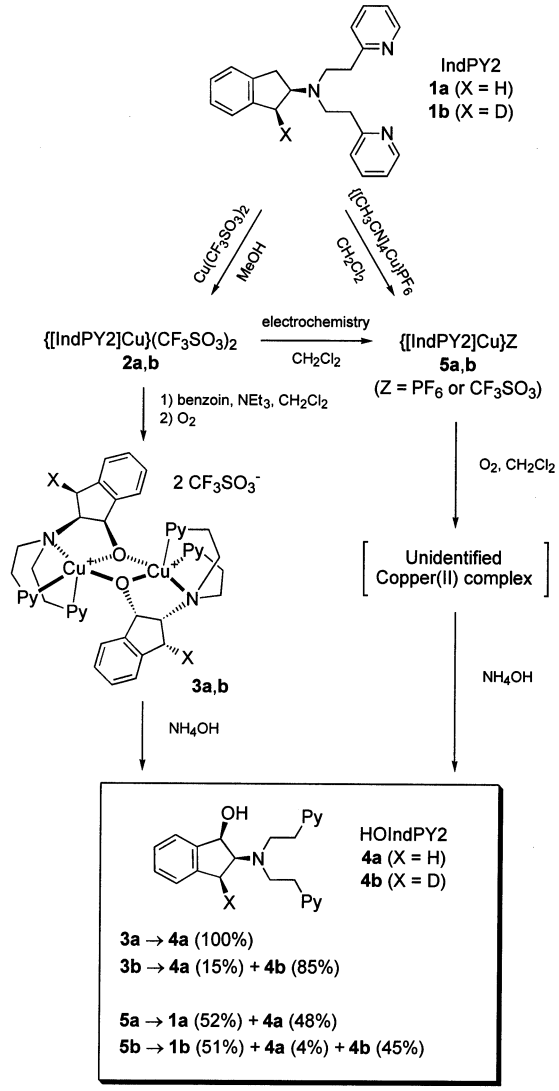
Reactions with Dioxygen

When the copper(II) complex **2a** was treated with 2 equiv. of benzoin/NEt_3 in CH_2Cl_2 at 25°C under Ar[14], reduction to a copper(I) complex occurred in less than one hour. This was clearly demonstrated by the complete disappearance of the *d-d* absorption at 671 nm in the electronic spectrum, which is characteristic for copper(II) complexes, and the silent EPR spectrum of the reaction mixture obtained after 40 min. Upon exposure to O_2 atmosphere, a new copper(II) complex **3a** was obtained in quantitative yield. Demetallation with 35% aqueous ammonia and analysis of the organic products indicated that complete conversion to the *cis*-2-amino-1-indanol derivative (**4a**) had occurred (Scheme 2). The stereochemistry of **4a** was assigned by comparison of its spectral data with those of an authentic sample prepared by Michael-type addition of *cis*-2-amino-1-indanol[15] to vinylpyridine, and was confirmed by X-ray analysis of the green crystals of complex **3a** obtained after recrystallization from CH_2Cl_2/MeOH (Table 1, Figure 2).

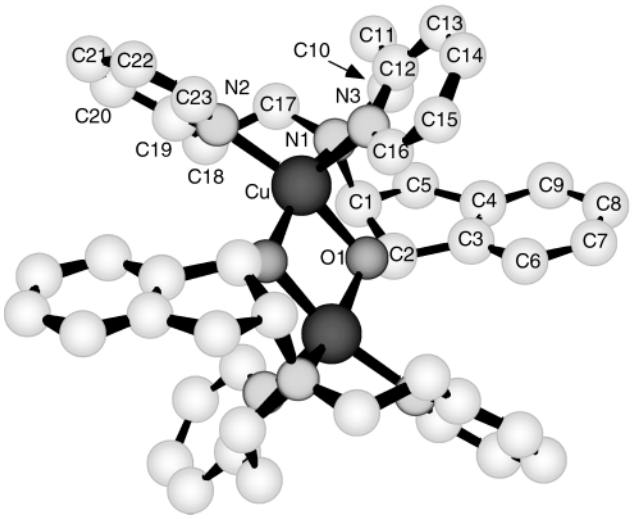
Scheme 2. Reactions with O_2 involving copper complexes **2a** and **5a**



Since the first step in this reaction sequence is reduction to a copper(I) complex, we examined the reaction of the copper(I) complex [(IndPY2)Cu]Z (**5a**; Z = PF_6 or CF_3SO_3) with O_2 in CH_2Cl_2. Complex **5a** was either prepared in situ by reaction of ligand **1a** with $[(CH_3CN)_4Cu]PF_6$ in CH_2Cl_2, or by electrolysis of the copper(II) complex **2a**. The voltammetric behaviour of **2a** is depicted in Figure 3, which shows a single quasi-reversible process characteristic of the Cu^{II}/Cu^{I} transition. Upon electrolysis of **2a** under a constant potential of 0 V vs. SCE, the solution turned from blue to pale-yellow after an equivalent charge of 1 electron had been passed. As expected for a reversible electron transfer, the cyclic voltammetry (CV) curve relating to the Cu^{II}/Cu^{I} couple had not changed.

When copper(I) complex **5a** (Z = PF_6 or CF_3SO_3) was placed under an O_2 atmosphere, the pale-yellow solution rapidly turned green. A new copper(II) complex was quantitatively obtained. Demetallation with 35% aqueous am-

Figure 2. Perspective view of copper(II) complex **3a** displaying the numbering scheme and selected bond distances and angles[a]



[a] Bond lengths in Å: Cu−O1 1.927(5), Cu−N1 2.057(7), Cu−N2 2.208(7), Cu−N3 1.984(7). Bond angles in°: O1−Cu−N1 85.7(2), O1−Cu−N2 96.5(2), O1−Cu−N3 165.0(3), N1−Cu−N2 99.0(2), N1−Cu−N3 94.5(3), N2−Cu−N3 98.3(3). Numbers in parentheses denote the estimated standard deviation in the least significant digits.

monia and analysis of the organic products revealed that 52% of unchanged ligand **1a** had been recovered, besides 48% of the *cis*-2-amino-1-indanol derivative **4a**. The reaction of **5a** (Z = CF_3SO_3) with O_2 was followed by CV. As can be seen in Figure 3, consumption of **5a** by O_2 progressively gives rise to a double-wave electrochemical signal. This result, as well as the smaller value of the peak currents, is consistent with either: (i) the formation of a dimeric complex with two non-equivalent copper(II) ions such as **A** (Scheme 5), or (ii) the formation of a mixture of symmetrical dimeric complexes such as **3a** and $[(IndPY2)_2Cu_2(\mu\text{-}OH)_2]^{2+}$ **B**. This second hypothesis is supported by the fact that two types of crystals (green and blue) are obtained after crystallization of the copper(II) complex from CH_2Cl_2/MeOH. Unfortunately, these crystals were not suitable for carrying out an X-ray structure analysis.

Stereoselectivity of Oxygen Atom Insertion

The aforementioned hydroxylations are highly stereoselective, and we propose, as is generally accepted, a process involving oxygen atom insertion into the benzylic C−H bond. The question then arises as to whether this insertion occurs with retention or inversion of configuration. Indeed, the hydroxylation can be envisaged as being either the result of a concerted mechanism in which oxygen atom insertion occurs at a *cis* C−H bond, or the result of a two-step process in which C−H bond scission and formation of the C−O bond occur at the same face (*cis* with respect to the amino group). In both cases, the product would be formed with retention of configuration at the benzylic carbon atom (Scheme 3). Another possibility is that the hydroxylation takes place via a two-step process involving *trans* C−H bond scission and *cis* formation of the C−O bond. If this

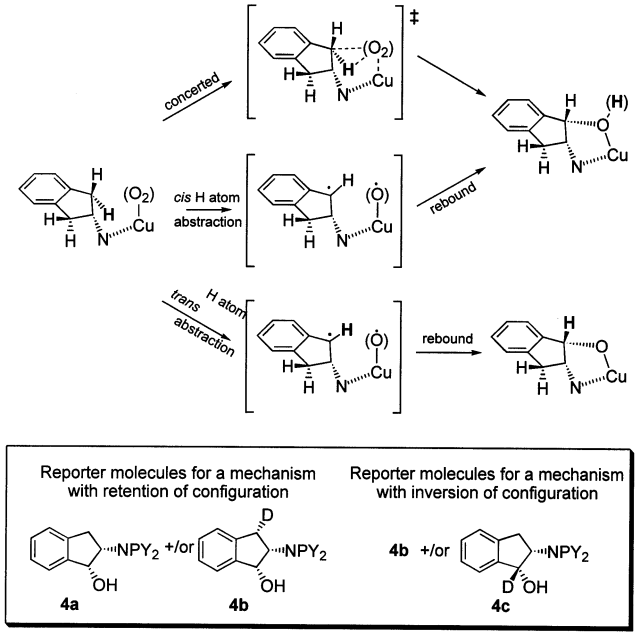
were the case, we should observe inversion of configuration. In order to decide in favour of one of these mechanisms, we studied the reaction of deuterium-labelled copper complexes **2b** and **5b**. If the stereochemical course were to proceed with inversion of configuration, we would expect the formation of a mixture of deuterated compounds **4b** and **4c**. However, if the configuration was retained, we would expect the formation of a mixture of non-deuterated **4a** and its deuterated analogue **4b**.

Under standard conditions (benzoin, NEt_3, CH_2Cl_2, 25°C), the copper(II) complex {(*cis*-[D]-IndPY2)Cu}$(CF_3SO_3)_2$ **2b** (D content of 99 ± 0.1% determined by FAB-MS) was quantitatively transformed into complex **3b** (D content of 87.57 ± 0.16%). Demetallation with 35% aqueous ammonia gave the deuterated hydroxy ligand **4b** as the main product of the reaction. This is clearly evident from the ^{1}H-NMR spectrum, which shows a doublet of doublets at δ = 3.41 ($^3J_{2\text{-H,3-H}cis}$ = 7 Hz and $^3J_{2\text{-H,1-H}cis}$ = 5 Hz) instead of the doublet of doublet of doublets ($^3J_{2\text{-H,3-H}trans}$ = 9 Hz, $^3J_{2\text{-H,3-H}cis}$ = 7 Hz and $^3J_{2\text{-H,1-H}cis}$ = 5 Hz} observed for the non-deuterated hydroxy ligand **4a**. The ^{13}C-NMR spectrum reveals the

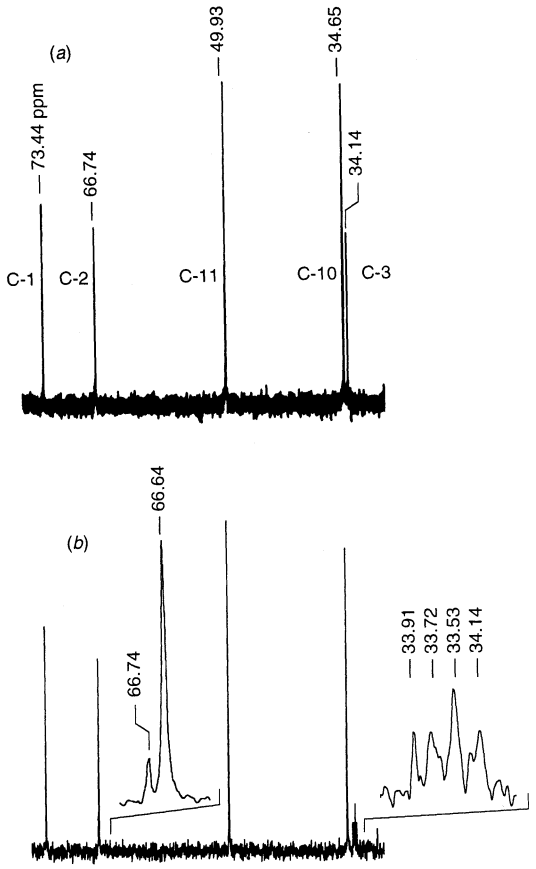
Scheme 3



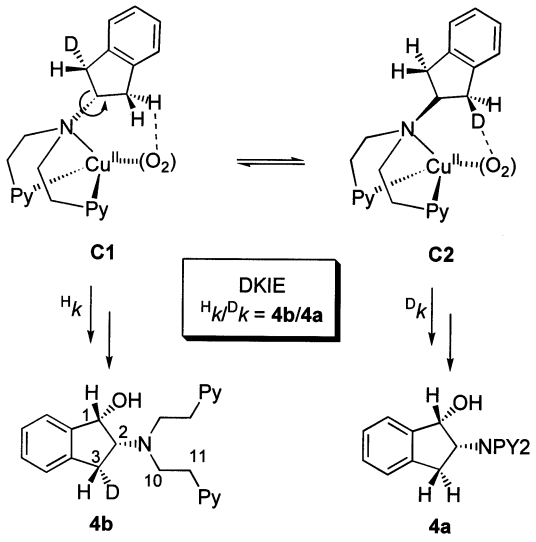
presence of a small amount of **4a** (singlet at δ = 34.14, C-3; Figure 4a) in addition to **4b** (triplet at δ = 33.72, $^1J_{13C,D}$ = 21 Hz, C-3; Figure 4b), but no signals corresponding to a hypothetical deuterated hydroxy ligand **4c**, which might have arisen from a mechanism involving inversion of configuration, were observed. Moreover, the ^{13}C-NMR spectrum shows a singlet at δ = 66.64 attributable to C-2 of compound **4b**, in addition to the corresponding signal of **4a** (δ = 66.74). Integration of these signals after a DEPTCH sequence led to a **4b**/**4a** ratio of 7.6 ± 0.5. This ratio was confirmed by mass spectrometry analysis (FAB-MS) of complex **3b**, for which an 87.57 ± 0.16% deuterium content was found [**4b**/**4a** = 87.57/(100 − 87.57) = 7.04 ± 0.02]. Using the same methodology under standard conditions (O_2, CH_2Cl_2, 25°C), the deutero-copper(I) complex **5b** was quantitatively transformed into a copper(II) complex, which, after demetallation with 35% aqueous ammonia, also gave a mixture of **4b** and **4a** (**4b**/**4a** = 11.0 ± 0.7).

In both reactions, ratios of non-deuterated **4a** to the deuterated compound **4b** are very large (7.6 and 11). These findings can be explained if we assume that the copper/oxygen species responsible for the observed hydroxylations exist as two conformers, **C1** and **C2**, which are in equilibrium (Scheme 4). It is clear that conformer **C2**, which exposes a deuterium atom to the copper−oxygen core, must react with a lower rate than conformer **C1**, which exposes a hydrogen atom. Since conformers **C1** and **C2** are in rapid equilibrium, the deuterium kinetic isotope effect (DKIE) expressed by the k_H/k_D ratio is directly related to the **4b**/**4a** ratio.[16] The large DKIEs (7.6 vs. 11) indicate that the hydroxylations occur with retention of configuration in a process in which the benzylic C−H bond is broken in the rate-determining step.[17]

Figure 4. Aliphatic region of ^{13}C-NMR spectra of aminoindanols **4a**, **b**: (*a*) reaction of **2a** with benzoin/NEt_3/O_2 or **5a** with O_2 in CH_2Cl_2; (*b*) reaction of **2b** with benzoin/NEt_3/O_2 or **5b** with O_2 in CH_2Cl_2



Scheme 4.



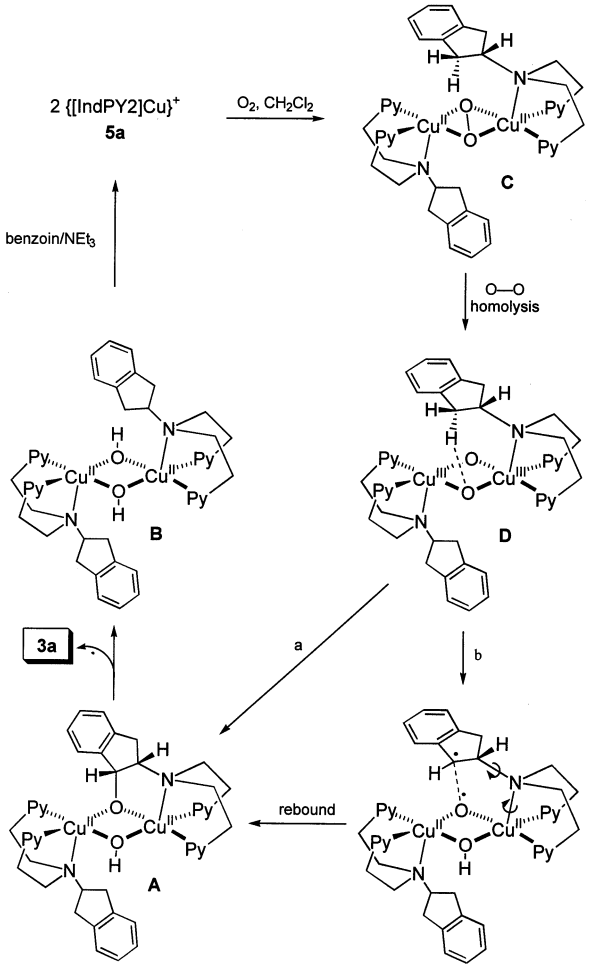
Dioxygen Adducts and Mechanistic Hypothesis

Finally, we turn to the question of the dioxygen adduct that may be involved in these hydroxylations. At present, for the reaction of the copper(I) complex **5a** with O_2 in CH_2Cl_2, it is difficult to obtain structural information con-

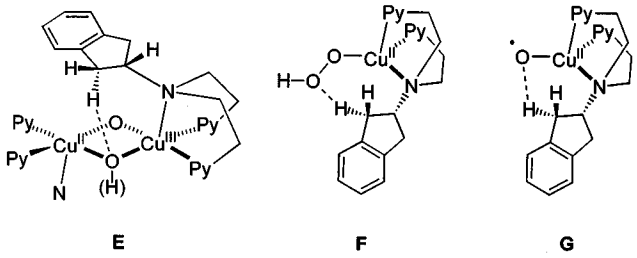
cerning copper/oxygen species, because, even at −80°C, such species are too reactive to be amenable to structural analysis, e.g. by UV/vis or X-ray spectroscopy. However, since copper(I) complexes derived from tridentate ligands are known to lead to $[L_2Cu_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}O_2)]^{2+}$ species by reaction with O_2[5a][6], we can reasonably expect the formation of this type of intermediate (**C**) upon reaction of **5a** with O_2 (Scheme 5). Kitajima has observed that the $\{[HB(3,5\text{-}Me_2pz)_3]_2Cu_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}O_2)\}$ complex is capable of oxidising cyclohexene to 2-cyclohexen-1-ol and 2-cyclohexen-1-one.[18] To account for this finding, a mechanism was proposed involving: (i) formation of the radical $\{[HB(3,5\text{-}Me_2pz)_3]Cu-O^{\bullet}\}$ by homolysis of the peroxo bond; (ii) abstraction of a hydrogen atom from cyclohexene, and (iii) subsequent reaction of these intermediates with O_2 to generate the observed products. Given that we did not observe any formation of an indanone derivative, and that the oxygen atom transfer proceeds with high DKIEs and high *cis* stereoselectivity, we can rule out the possibility that the hydroxylated ligand is formed by a mechanism akin to that postulated for Kitajima's cyclohexene oxidation. More recently, Tolman has reported that $[Cu^{II}_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}O_2)]^{2+}$ species exist in equilibrium with a bis(μ-oxo)dicopper species with a formal $[Cu^{III}_2(\mu\text{-}O)_2]^{2+}$ oxidation state, and it was demonstrated that these species behave like electrophilic radicals.[19] Considering these findings and the fact that oxidation of **5a** by O_2 results in stereospecific *cis*-hydroxylation in yields not exceeding 50%, Scheme 5 illustrates possible pathways whereby hydroxylation can occur via the $\{[IndPY2]_2Cu^{III}_2(\mu\text{-}O)_2\}^{2+}$ species (**D**): (i) by a concerted mechanism (pathway *a*), or (ii) by abstraction of a *cis* benzylic hydrogen atom forming a benzylic radical and a copper/oxygen radical species, which recombine at the same face to give the observed copper(II) complex in an overall mechanism with retention of configuration (pathway *b*).

Concerning the reaction of **2a** with benzoin/NEt_3, we have shown that under Ar the first step is the reduction to the cuprous state. Upon exposure to O_2, the next step could then be the formation of the peroxo complex **C** and/or its subsequent species **D**. As already described, this reaction sequence could lead to the observed compounds. As an explanation for the quantitative yield of oxidised complex **3a**, we can assume that a 1:1 mixture of complexes **3a** and **B** is obtained, and that only **B** is reduced to the copper(I) complex **2a** by excess benzoin/NEt_3 and is thus able to participate in the hydroxylation reaction once more (Scheme 6). We can effectively demonstrate that complex **3a** does not react with benzoin/NEt_3, even after several hours, but the higher DKIE observed for the reaction of **2a**/O_2 compared to that of **5a**/benzoin/NEt_3/O_2 (11 vs. 7.6) suggests the intermediacy of another reactive species, for which several structures can be proposed. As previously assumed for the active species in pMMO[3], a μ-oxo mixed-valence Cu^{II}/Cu^{III} species **E** derived from a one-electron reduction of species **C** or **D** could be responsible for the present ligand hydroxylation. However, as it is known that the reaction of copper salts with O_2 in the presence of a reducing agent leads to hydroperoxo species[20], another possibility could be the formation of the hydroperoxo species **F** or its subsequent (one-electron reduction) copper radical species **G**. Structural studies of the copper/oxygen species involved in these hydroxylations aimed at elucidating details of the reaction mechanism are currently in progress.

Scheme 5. Proposed mechanism for the ligand hydroxylation



Scheme 6. Possible copper/oxygen intermediates in the reaction of copper(II) complex **2a** with O_2/benzoin/NEt_3



Conclusion

Once again, we have shown that a conformationally-restricted substrate approach can provide valuable information about the mechanism of oxygen atom transfer from copper to a ligand. On the basis of deuterium-labelling experiments, we have demonstrated that oxygen atom insertion into a C−H bond of the ligand occurs at a benzylic

position with retention of configuration. This is an important approach, which is of interest because of the possibility of performing parallel enzymatic studies. For example, we have recently found that the DBH-catalysed hydroxylation of 2-aminoindane produces exclusively *trans*-(1*S*,2*S*)-2-amino-1-indanol with 93% *ee*. Studies with stereospecifically deuterium-labelled 2-aminoindanes have further shown that the formation of (1*S*)-aminoindanol is the result of stereospecific *pro*-(*S*) hydrogen abstraction followed by oxygen binding, with overall retention of configuration.[21] Nevertheless, for modelling reactivity of the order of that of DBH, we have to admit that our approach needs to be improved and that we have to find a copper complex with catalytic properties towards an exogenous 2-aminoindane (oxygen atom transfer that does not involve the ligand). To achieve this goal, the problem of 2-aminoindane association in the copper coordination sphere still has to be solved.

This research was supported by the *CNRS* and the *French Ministry of Universities*. The authors are grateful to Dr. *A. Heumann* for a number of enlightening discussions.

Experimental Section

General: Solvents were freshly distilled under Ar (MeOH/Mg, Et_2O/Na-benzophenone ketyl, CH_3CN/CaH_2, and CH_2Cl_2/P_2O_5). Deoxygenation of solvents and solutions was carried out by 3 vacuum/purge cycles. Preparation and handling of air-sensitive compounds was carried out by using standard Schlenk techniques. Commercial starting materials were used without further purification, except for 2-vinylpyridine, which was distilled prior to use; *cis*-1-deutero-2-aminoindane was obtained by $LiAlD_4$ reduction of *trans*-2-azido-1-bromoindane.[13] – $^1H\{^{13}C\}$-NMR spectra were recorded at 25°C on a Bruker AC-400 spectrometer. Chemical shifts are reported in ppm as δ values downfield from an internal standard of TMS. – IR spectra were recorded on a Nicolet MX 5 spectrometer. – Elemental analyses were obtained with a CHN Technicon microanalyser. – FAB-MS were obtained by the LSIMS ionization technique in thioglycerol (TG) or nitrobenzyl alcohol (NB) lattices.

Ligands **1a** *and* **1b**: To absolute MeOH (8 ml) were added 2-vinylpyridine (3.785 g, 36 mmol), 2-aminoindane (798 mg, 6 mmol) and acetic acid (900 mg, 15 mmol). After refluxing for 5 days, the MeOH was evaporated and 15% NaOH (10 ml) was added. The product was extracted with CH_2Cl_2 (3 × 20 ml) and the combined organic layers were dried over Na_2SO_4. Evaporation of the CH_2Cl_2 under reduced pressure (18 mmHg) left the crude product. Flash chromatography (SiO_2, CH_2Cl_2/MeOH, 90:10) afforded ligand **1a** (**1b**). – **1a**: Yield: 800 mg (2.3 mmol, 40%). – ^1H NMR ($CDCl_3$): δ = 8.51 (ddd, *J* = 5, 2 and 1 Hz, 2 CH-pyr), 7.55 (td, *J* = 8 and 2 Hz, 2 CH-pyr), 7.15–7.07 (m, 8 CH-aryl), 3.74 (qt, *J* = 9 Hz, 2 2-H), 3.07–2.95 (m, 10 H), 2.83 (dd, *J* = 15 and 9 Hz, 2 1-H_{cis}). – ^{13}C NMR ($CDCl_3$): δ = 160.65 (2 C-pyr), 149.25 (2 CH-pyr), 141.75 (2 C-ind), 136.15 (2 CH-pyr), 126.26 (2 CH-ind), 124.42 (2 CH-pyr), 123.36 (2 CH-pyr), 121.07 (2 CH-pyr), 63.25 (C-2), 51.50 (2 C-10), 36.93 (2 C-11), 36.11 (2 C-1). – IR (neat): $\tilde{\nu}$ = 1595 cm^{-1} (C=N), $\tilde{\nu}$ = 1570, 1480, 1440 cm^{-1} (C=C). – **1b**: Yield: 930 mg (2.7 mmol, 45%). – ^1H NMR ($CDCl_3$): δ = 8.50 (ddd, *J* = 5, 2 and 1 Hz, 2 H), 7.53 (td, *J* = 8 and 2 Hz, 2 H), 7.15–7.05 (m, 8 H), 3.74 (q, *J* = 9 Hz, 1 H), 3.07–2.96 (m, 10 H), 2.85 (dd, *J* = 15 and 9 Hz, 1 H). – ^{13}C NMR ($CDCl_3$): δ = 160.70 (2 C-pyr), 149.30 (2 CH-pyr), 141.84 (2 CH-pyr), 141.75 (2 C-ind), 136.19 (2 CH-pyr), 126.32 (CH-ind), 126.35 (CH-ind), 124.49 (CH-ind), 124.46 (CH-ind), 123.41 (2 CH-pyr), 121.11 (2 CH-pyr), 63.21 (C-2), 51.55 (2 C-10), 36.96 (2 C-11), 36.62 (t, $^1J_{13\,C,D}$ = 21 Hz, C-1), 36.17 (C-3).

Complexes **2a** *and* **2b**: To a solution of $Cu(CF_3SO_3)_2$ (362 mg, 1 mmol) in MeOH (15 ml), a solution of **1a** (**1b**) (344 mg, 1 mmol) in MeOH (15 ml) was added dropwise and the mixture was stirred for 30 min. The MeOH was then evaporated in vacuo and Et_2O (50 ml) was added. The resulting precipitate was filtered off, washed with further Et_2O, and dried in vacuo to give complex **2a** (**2b**) as a blue solid. – **2a**: Yield: 634 mg (0.9 mmol, 90%). Recrystallization from CH_2Cl_2/Et_2O gave blue crystals suitable for X-ray analysis. – $C_{25}H_{25}CuF_6N_3O_6S_2$ (705.15): calcd. C 42.58, H 3.57, N 5.96; found C 42.98, H 3.52, N 6.05. – MS (FAB); *m*/*z* (%): 344 (100) [IndPY2 + H]$^+$, 345 (27) [*p* + 1], 343 (2.6) [*p* – 1]. – **2b**: Yield: 635 mg (0.9 mmol, 90%). – MS (FAB); *m*/*z* (%): 345 (100) [*d*-IndPY2 + H]$^+$, 346 (26.54) [*p* + 1], 344 (3.44) [*p* – 1]; deuterium content 99 ± 0.1%.

Complexes **3a** *and* **3b**: To a solution of **2a** (**2b**) (70 mg, 0.1 mmol) in degassed CH_2Cl_2 (6 ml) were added benzoin (42 mg, 0.2 mmol) and NEt_3 (20 mg, 0.2 mmol). This mixture was stirred under Ar for 2 h and then exposed to an O_2 atmosphere for 24 h. The CH_2Cl_2 was subsequently evaporated in vacuo and Et_2O (20 ml) was added. The precipitate thus obtained was filtered off, washed with Et_2O, and dried in vacuo to give complex **3a** (**3b**). – **3a**: Yield: 49 mg (86 μmol, 86%). Recrystallization from CH_2Cl_2/MeOH gave green crystals suitable for X-ray analysis. – $C_{24}H_{24}CuF_3N_3O_4S$ (571.08): calcd. C 50.48, H 4.24, N 7.36; found C 50.55, H 4.27, N 7.56. – MS (FAB); *m*/*z* (%): 360 (100) [IndOHPY2 + H]$^+$, 361 (27.7) [*p* + 1], 359 (1.7) [*p* – 1]. – **3b**: Yield: 48 mg (85 μmol, 85%). – MS (FAB); *m*/*z* (%): 361 (100) [*d*-IndOHPY2 + H]$^+$, 362 (29.7) [*p* + 1], 360 (14.0) [*p* – 1]; deuterium content 87.57 ± 0.16%.

In situ Preparation and Oxidation of Complexes **5a** *and* **5b**: To a solution of $[CH_3CN]_4CuPF_6$ (37.3 mg, 0.1 mmol) in degassed CH_2Cl_2 (50 ml), a solution of **1a** (**1b**) (34.4 mg, 0.1 mmol) in CH_2Cl_2 (50 ml) was added dropwise. The mixture was stirred under Ar for 1 h, and then exposed to an O_2 atmosphere for 24 h. The CH_2Cl_2 was subsequently evaporated in vacuo, Et_2O (50 ml) was added, and the precipitate thus obtained was filtered off, washed with Et_2O, and dried in vacuo to give a mixture of copper(II) complexes. This mixture was redissolved in CH_2Cl_2 (20 ml), washed with 35% NH_4OH (5 ml) and brine (3 × 5 ml), and dried over Na_2SO_4. Evaporation of the CH_2Cl_2 under reduced pressure (18 mmHg) gave the crude product. Flash chromatography (SiO_2, CH_2Cl_2/MeOH, 90:10) afforded ligands **1a** (**1b**) and **4a** (**4b**). – **4a**: Yield: 17.3 mg (48 μmol, 48%). – ^1H NMR ($CDCl_3$): δ = 8.51 (ddd, *J* = 4, 2 and 1 Hz, 2 H-pyr), 7.54 (td, *J* = 8 and 2 Hz, 2 H-pyr), 7.43 (d, *J* = 6 Hz, 1 H-ind), 7.49–7.17 (m, 3 H-ind), 7.11–7.06 (m, 4 H-pyr), 4.97 (d, *J* = 5 Hz, 1-H), 3.41 (ddd, *J* = 9, 7 and 5 Hz, 2-H), 3.24–3.09 (m, 4 H), 3.07–2.95 (m, 6 H). – ^{13}C NMR ($CDCl_3$): δ = 160.05 (2 C-pyr), 149.34 (2 CH-pyr), 143.28 (C-ind), 141.77 (C-ind), 136.50 (2 CH-pyr), 128.70 (CH-ind), 126.95 (CH-ind), 125.52 (CH-ind), 124.81 (CH-ind), 123.57 (2 CH-pyr), 121.39 (2 CH-pyr), 73.44 (C-1), 66.74 (C-2), 49.93 (2 C-10), 34.65 (2 C-11), 34.14 (C-3). – **4b**: Yield: 17.4 mg (48 μmol, 48%). – ^1H NMR ($CDCl_3$): δ = 8.50 (d, *J* = 5 Hz, 2 H-pyr), 7.54 (td, *J* = 8 and 2 Hz, 2 H-pyr), 7.44 (d, *J* = 7 Hz, H-ind), 7.24–7.17 (m, 3 H-ind), 7.11–7.06 (m, 4 H-pyr), 4.96 (d, *J* = 5 Hz, 1-H), 3.41 (dd, *J* = 7 and 5 Hz, 2-H), 3.23–3.10 (m, 4 H), 3.05–2.94 (m, 5.28 H). – ^{13}C NMR ($CDCl_3$): δ = 160.05 (2 C-pyr), 149.26 (2 CH-pyr), 143.30 (C-ind), 141.65 (C-ind), 136.34 (2 CH-pyr), 128.56 (CH-ind), 126.84 (CH-ind), 125.40 (CH-ind), 124.72 (CH-ind),

X-ray Structure Analysis: Crystals of complexes **2a** and **3a** of suitable quality and size were mounted in glass capillaries and examined on an Enraf-Nonius CAD4 diffractometer [Mo-K_α radiation, λ(Mo-K_α) = 0.71073 Å]. During data collection, three standard reflections were measured periodically as a general check of crystal and instrument stability. The data reduction was performed with Begin in SDP-Plus.[22] The structures were solved by the Patterson method for **2a** and by direct methods with MULTAN80[23] for **3a**, and were refined with LSFM-Plus. The scattering factors were taken from the International Tables for X-ray Crystallography.[24]

Crystallographic data for the structure(s) reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-101037. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [fax: int. code +44(0)1223/ 336-033, e-mail: deposit@chemcrys.cam.ac. uk].

Electrochemical Measurements: Cyclic voltammetric (CV) experiments were carried out using an EG&G 263A potentiostat with EG&G M270 software. CV curves were obtained at a scan rate of 50 mVs^{-1}. A three-electrode system consisting of a saturated calomel reference electrode, a platinum wire auxiliary electrode, and a gold microelectrode (surface area: 7.8×10^{-3} cm^2) was used throughout. Both the reference and auxiliary electrodes were connected to the solution through porous bridges. Coulometric measurements were made using an EG&G 379 coulometer. Electrolyses were performed using a gold grid (geometric surface: 7 cm^2) under a constant potential.

Keywords: *O*-Coordinated amides / Platinum / *O*-to-*N* Isomerization / Atropisomers

O-bonded amide complexes of platinum(II), which are stable in acetone solution and which undergo solvolysis in neat water with a rate constant as slow as $8.7 \cdot 10^{-5}$ s^{-1}, are reported. The structure of a sample compound $[Pt(Me_5dien)\{O\text{-}MeC(O)NH_2\}](CF_3SO_3)_2$ has been solved by X-ray diffraction allowing comparison with related *N*-bonded (amide)platinum complexes. Isomerization from *O*-amide to *N*-amidate species takes place instantaneously under basic conditions. Protonation of the amidate species leads to the *N*-bonded amide. *N*-bonded amides, like the *N*-bonded amidates, represent the thermodynamically preferred species due to the higher affinity of platinum for nitrogen donors. In contrast *O*-bonded amides owe their stability to their kinetic inertness, where a high pH is required for deprotonation of the NH_2 moiety, the leading step in the isomerization process. In the case of the 2-pyridone complex, the *O*-bonded form is unstable and isomerizes spontaneously to the *N*-bonded form, due to the higher acidity of the protonated pyridine-like nitrogen atom. Two rotamers are present in both the *N*-pyridone and *N*-pyridonate species. Hindered rotation stems from the steric rigidity of both rotating moieties [(Me_5dien)Pt and pyridone/pyridonate].

Introduction

Amides of carboxylic acids can be either *O*- or *N*-donor ligands[1]. In the case of *N*-coordination, they can adopt different tautomeric forms {oxo amine $[RC(O)NH_2]$ and iminol $[RC(OH)NH]$}[2].

Changes in the metal center, the R group, or the solvent system can influence the mode of coordination. For complexes of metal ions which are considered to be "hard" Lewis acids, such as $[M(NH_3)_5(amide)^{3+}$ (M = Co[3], Cr[4], Ru[5], and Rh[6]), the *O*-bonded form was found to be thermodynamically as well as kinetically favored over the *N*-bonded form.

The "softer" platinum(II) species, on the other hand, usually exhibits only a weak affinity for *O*-donor ligands[7] and therefore a thermodynamic preference for *N*-bonded amides is expected. In accordance with this, all platinum compounds characterized by X-ray diffraction analysis[8] contained the amide ligands in the *N*-coordinated tautomeric iminol form. They were prepared by direct reaction with the preformed amide[9] or by hydrolysis of a coordinated nitrile[10][11][12][13][14][15]. However, since these ligands are known to protonate the carbonyl oxygen atom rather than the nitrogen atom[16], there could also be a kinetic preference for *O*-coordination in the case of platinum(II). This possibility has recently been demonstrated in a study showing that acetamide can displace a weakly coordinated water molecule from the $[Pt(dien)(OH_2)]^{2+}$ species (dien = diethylenetriamine) acting as an oxygen donor ligand[17][18] in solution. The kinetically preferred *O*-bonded complex can then undergo an intramolecular rearrangement to the thermodynamically more stable *N*-bonded iminol complex[18].

The $[Pt(dien)\{O\text{-}RC(O)NH_2\}]^{2+}$ complexes isomerize to the corresponding *N*-bonded form, as well as undergoing displacement of the *O*-bonded amide by weak nucleophiles such as water. This instability prevented their characterization by X-ray crystallography. In this paper we present the conditions for stabilization of such a species. It was found that using a substituted dien ligand, such as *N*,*N*,*N*′,*N*′′,*N*′′-pentamethylethylenediamine (Me_5dien), *O*-bonded amide complexes, which are infinitely stable in acetone solution and which undergo solvolysis in neat water with a rate constant as low as $8.7 \cdot 10^{-5}$ s^{-1}, can be prepared. The structure of the complex $[Pt(Me_5dien)\{O\text{-}MeC(O)NH_2\}](CF_3SO_3)_2$ (**4b**) has been solved by X-ray diffraction allowing comparison to *N*-bonded platinum amides. Furthermore this investigation has allowed a deeper insight into the mechanism of isomerization from *O*- to the *N*-bonded amides, and other conformational restraints within the coordination sphere.

Results and Discussion

Stereochemistry of the Me_5dien Ligand in Solution

The ^{1}H-NMR spectrum in D_2O solution of the aqua species $[Pt(Me_5dien)(H_2O)](CF_3SO_3)_2$ (**2**) shows three signals for the *N*-Me groups (relative intensities of 3:6:6) and four signals for the protons of the ethylene chains linking

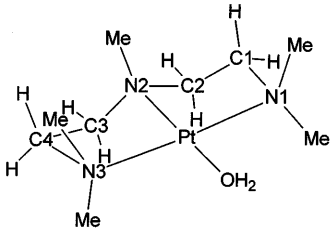
the central nitrogen atom with the terminal nitrogen atoms (each signal integrating for two protons) (Table 1).

There is a geminal coupling (13 Hz) between the signals at δ = 3.68 and 2.96 and between the signals at δ = 3.51 and 3.04, indicating that the two signals of each couple belong to the same methylene group. From the observation of distinct signals for the two protons of a given methylene group, it is possible to conclude that the two condensed rings have a fixed puckering[19][20]. Two vicinal protons (signals at δ = 3.68 and 3.51) are strongly coupled (ca. 13 Hz), therefore they are both axial (torsion angle of ca. 180°). The other two vicinal protons (δ = 3.04 and 2.96) are weakly coupled (3 Hz) and therefore they are both equatorial (forming a torsion angle of ca. 60°). It is also possible to assign the signals at δ = 3.51 and 3.04 to the methylene group adjacent to the terminal nitrogen atoms (corresponding to $C1H_2$ and $C4H_2$ in Scheme 1) because the axial protons (δ = 3.51) have NOE cross peaks with the central *N*-Me group (δ = 3.07) and two equivalent terminal *N*-Me groups (δ = 2.77). In contrast, the couple of signals at δ = 3.68 and 2.96 can be assigned to the methylene groups adjacent to the central nitrogen atoms (corresponding to $C2H_2$ and $C3H_2$ in Scheme 1) because the axial protons (δ = 3.68) have NOE cross-peaks only with terminal *N*-Me groups (δ = 2.94).



The *N*-Me signal at δ = 2.77, which has NOE cross-peaks with the axial protons of $C1H_2$ and $C4H_2$ methylene groups (δ = 3.51), must belong to the terminal *N*-Me groups which are on the same side of the coordination plane as the central methyl group. The *N*-Me signal at δ = 2.94, having NOE cross-peaks with the axial protons of the $C2H_2$ and $C3H_2$ methylene groups (δ = 3.68), must belong to the terminal *N*-Me groups which are on the opposite side of the coordination plane from the central methyl group.

O-Amide Complexes Formed in the Reaction of the Aqua Species 2 with Free Amide

Reaction of the aqua species **2** with free amide in acetone solution leads to displacement of the coordinated water molecule by the free amide, and formation of the $[Pt(Me_5dien)\{O\text{-}RC(O)NH_2\}]^{2+}$ complex [**4**; R = *t*Bu (**a**),

Me (**b**), or Ph (**d**)]. The reaction is rather slow (k_{obs} = $3.5 \cdot 10^{-5}$ s^{-1} for 0.1 M acetamide) and requires a slight excess of amide to go to completion. The isolated species, however, can be dissolved in pure water, where they undergo solvolysis at a very slow rate (k_{obs} = $8.7 \cdot 10^{-5}$ s^{-1} for **4b**). It has already been reported that the presence of *N*-substituents can reduce the reactivity of dien complexes by a factor of 300[20][21].

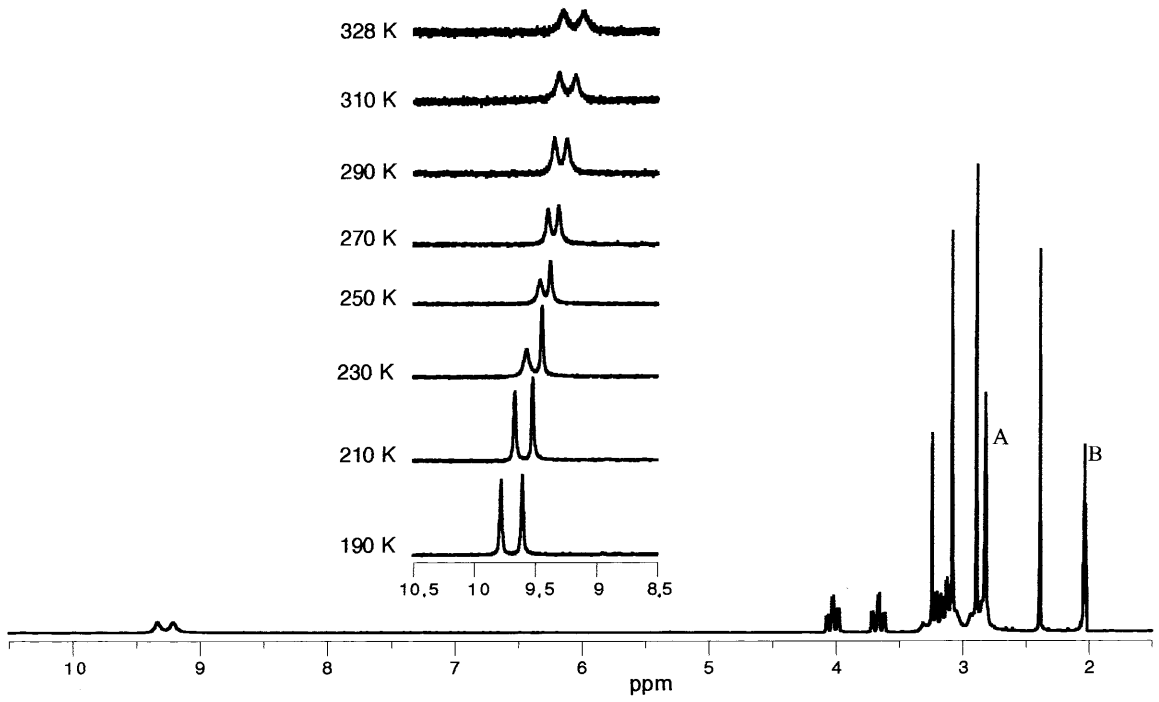
The ^{1}H-NMR spectral features of the Me_5dien ligand are very similar to those observed for the aqua species, indicating a similar structure with fixed puckering of the two condensed chelate rings. The *O*-coordination of the amide is deduced from the presence of two close NH_2 ^{1}H-NMR signals which are ca. 2 ppm downfield with respect to those of the free amide (in contrast, *N*-coordination is undoubtedly accompanied by a switch to the iminol tautomer with chemical shifts of the NH and OH protons ca. 2 and 4 ppm, respectively, downfield with respect to the NH_2 signals of the free ligand). The two NH_2 proton signals are rather sharp at low temperature (ca. −80°C) and both undergo broadening and a shift to higher field as the temperature is raised (Figure 1).

lead to the formation of two rotamers, differing in the relative position of the amide aminic group and the Me_5dien central *N*-Me group with respect to the platinum coordination plane (A and B in Scheme 2); (ii) ligand-coordination isomerism with the Pt atom either *cis* to NH_2 or *cis* to R with respect to the C=O double bond (C and D in Scheme 2). Observed similarities among the three complexes with R = *t*Bu (**a**), Me (**b**), or Ph (**d**) suggests that the first hypothesis is more correct.

Conversion of *O*-Bonded to *N*-Bonded Amides by Base Catalysis

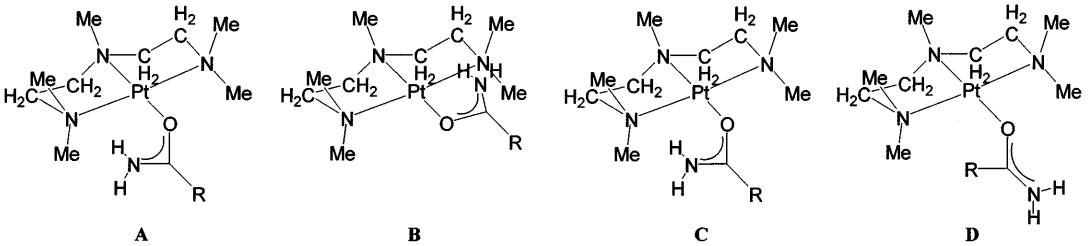
The *O*-bonded amide complexes **4a−c** are stable for weeks in acetone solution under neutral conditions. Treatment with bases, however, leads to instant formation of the corresponding *N*-bonded amidate species. Alkaline bases can be used, but, since they are not soluble in acetone, they must be added in powdered form and with concomitant addition of a few drops of water. Organic nitrogen bases (such as triethylamine) can also be used but displacement of the *O*-bonded amide by the amine can also take place. Treatment of the amidate with an acid (such as triflic acid, CF_3SO_3H) restores the amide, but to the *N*-bonded form

Figure 1. ^{1}H-NMR spectrum (δ, downfield from $SiMe_4$; [D_6]acetone as solvent) of [Pt(Me_5dien){*O*-MeC(O)NH_2}](CF_3SO_3)$_2$ (**4b**); assignment of resonances as reported in Table 1; A: water moisture, B: [D_6]acetone



The shift in field and the broadening are more pronounced for one signal. The signal is found more downfield at −80°C and more upfield at +50°C. A possible explanation for this behavior is that at low temperature there is preference for a given isomer and that, as the temperature is raised, a second isomer contributes to the stereochemistry of the complex causing the observed spectral changes. There are two possible causes for isomerism: (i) Restricted rotation of the amide ligand about the Pt−O bond would

(compounds **5a−c**). The identification of the *N*-bonded amides was facilitated by the preparation of the same species by an alternative route, that is, by hydrolysis of the corresponding nitrile complexes as already reported[11]. The *N*-bonded amides invariably adopt the iminol form with two downfield signals at δ ≈ 12 and 8−9 assigned to the OH and NH protons, respectively. The OH proton generally gives a very broad signal because, being rather acidic ($pK_a \approx 3.7$), it exchanges rapidly with water. With time, the



A B C D

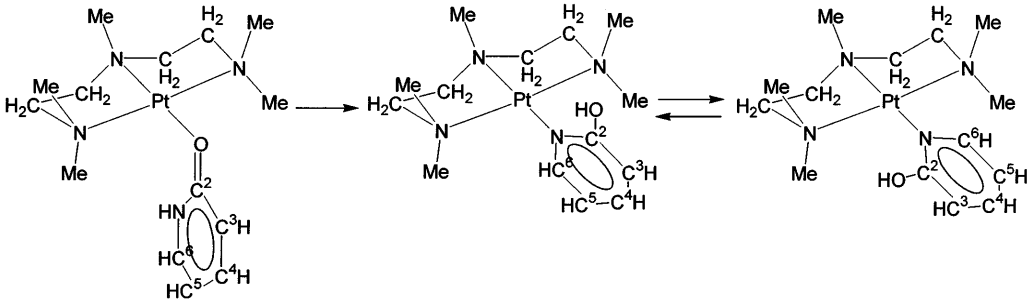
intensities of the OH and H_2O peaks decrease and eventually disappear. However, the intensity of the partially deuterated acetone ([D_5]acetone) peaks increases. Although this type of reaction is not new, in the present case it is exceptionally fast ($k_{obs} = 1.0 \cdot 10^{-4}$ s^{-1} at 24°C).

Spontaneous Isomerization of *O*-Bonded to *N*-Bonded 2-Pyridone − Formation of *N*-Bonded Rotamers

The reaction of the aqua species **2** with pyridone leads initially to product **6** which is not stable but isomerizes over time to a new species (**7**) ($k_{obs} = 4.5 \cdot 10^{-5} s^{-1}$ for a pyridone concentration of 2.2 mM at 24°C) (Scheme 3). The NMR spectrum of **6** is in agreement with an *O*-bonded pyridone complex, analogous to the *O*-bonded species (**4a−c**) obtained with other amides. A broad signal at δ = 13.2 was identified as an *N*-bonded proton, the other signals at δ = 8.07, 7.08, 8.16, and 7.86 were easily identified as C^6H, C^5H, C^4H, and C^3H signals, respectively, on the basis of H,H coupling.

Me$_5$dien ligand. At equilibrium, the two species are present in comparable yields ([**7**]/[**7′**] ≈ 40:60). It is most likely that **7** and **7′** are rotamers resulting from the non-C_2 symmetry of the Me$_5$dien ligand. This hypothesis has been fully confirmed by an NOE experiment showing that the C^6H signals of the two isomers have cross peaks with different couples of terminal *N*-Me groups: isomer **7′** with the *N*-Me groups which are on the same side of the platinum coordination plane as the central *N*-Me group and isomer **7** with the *N*-Me groups which are on the opposite side of the platinum coordination plane from the central *N*-Me group. It is interesting to note that one of the two rotamers (**7**) is kinetically favored in the isomerization from *O*- to *N*-bonded form, while at equilibrium the two rotamers are nearly equally abundant.

Treatment with base also causes instant isomerization of the *O*-bonded amide complex **6** to the *N*-bonded amidate complex. Furthermore, the amidate species formed first, like the *N*-amide formed first, also isomerizes to a new



6 7 7′

In the isomerization from **6** to **7**, the signals assigned to C^5H and C^4H remain nearly unchanged (Δδ ≈ 0.2). In contrast, the signal of the C^6H proton undergoes a downfield shift of ca. 1 ppm (δ = 9.04) and couples to platinum (30 Hz), while the signal of the C^3H proton undergoes an upfield shift of ca. 0.6 ppm (δ = 7.26). The changes in chemical shifts and the coupling with platinum are in agreement with **7** being an *N*-bonded 2-hydroxypyridine complex (2-pyridone and 2-hydroxypyridine are the equivalents of the oxo amine and iminol tautomers of amides).

A peculiar feature of the *N*-bonded pyridone complex **7** is its slow isomerization to a new species (**7′**) (Scheme 3). The rate of isomerization of **7** to **7′** is much slower than the isomerization of **6** to **7**, occurring over several days as compared to a few hours. The new species (**7′**) has spectral features which are also in agreement with an *N*-bonded pyridone (C^6H coupled to platinum, 30 Hz) and a tricoordinate species (presumably a rotamer). At equilibrium, the ratio of the two rotamers is similar to that observed for the corresponding *N*-amides (**7** and **7′**). Obviously, starting from an equilibrium mixture of **7** and **7′**, treatment with base leads to the corresponding *N*-amidate in the equilibrium isomer composition.

Insight into the Mechanism of *O*- to *N*-Isomerization of Amides

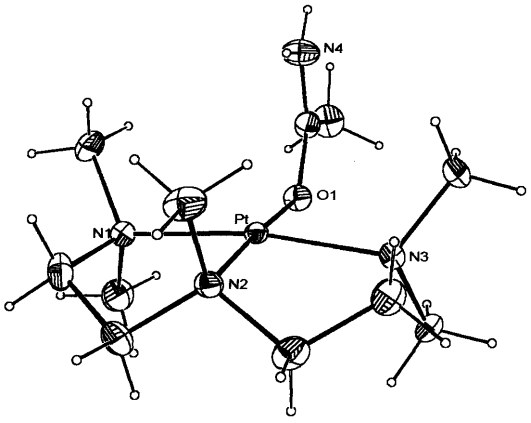
The reason why the isomerization from the *O*- to the *N*-bonded form takes place for the pyridone and not for the other amide complexes under similar experimental conditions (acetone solution, in the absence of added base), deserves further discussion. It has been hypothesized that *O*- to *N*-isomerization of coordinated amides takes place intramolecularly through a transition state in which both N and O atoms of the amide are equally predisposed towards nucleophilic attack on Pt^{II}[18]. It is impossible for the *O*-

bonded amide ligand to adopt a conformation with lone pairs of electrons at the O and N atoms pointing towards the same metal center because of the π-electron delocalization of the nitrogen lone pair of electrons. Therefore the isomerization process ought to take place by deprotonation of the nitrogen atom and conversion of the amide to an amidate species. The latter species can have convergent lone-pairs of electrons at the O and N atoms and can promote a transition state in which both atoms donate a lone pair of electrons to the platinum center. Protonation of the amidate would revert it back to the amide, but in the isomerized *N*-bonded form. On this basis the slow isomerization from *O*- to *N*-coordination of the pyridone, even in the absence of added base, can be explained in terms of the higher acidity of the NH protons in 2-pyridone, as compared to that in acyclic amides.

X-ray Structure Analysis of the (*O*-Acetamide)platinum Complex 4b

An X-ray Structure analysis of complex **4b**, for which the *O*-coordination of the amide had already been established by NMR experiments, has been carried out in order to compare structural features of the amide functionality in the *O*- and *N*-coordinated linkage isomerism. An ORTEP drawing of **4b** is shown in Figure 2. Selected bond lengths and angles are given in Table 2. The crystals of **4b** consist of the complex cation $[Pt(Me_5dien)\{O\text{-}MeC(O)NH_2\}]^{2+}$ and triflate anions in a 1:2 molar ratio. The platinum atom has the usual square-planar ligand coordination sphere in which the three nitrogen atoms from Me_5dien and the oxygen atom from the acetamide act as donors.

Figure 2. ORTEP drawing of $[Pt(Me_5dien)\{O\text{-}MeC(O)NH_2\}](CF_3SO_3)_2$ (**4b**) with the labelling scheme; the ellipsoids enclose 30% probability



The Pt−N(1) and Pt−N(3) bonds (terminal aminic groups) have similar lengths [2.056(5) and 2.065(5) Å, respectively] and both are significantly longer than the Pt−N(2) bond [2.007(5) Å] (central aminic group). The N(1)−Pt−N(2) and N(2)−Pt−N(3) angles of the two condensed chelate rings are significantly smaller than 90° [86.3(2) and 86.5(2)°, respectively]. In contrast, the N(1)−Pt−O(1) and N(3)−Pt−O(1) angles are significantly larger than 90° [93.0(2) and 93.6(2)°, respectively]. The strain within the tridentate ligand appears to be responsible for the observed deviation from planarity of the (Me_5dien)Pt moiety, where the platinum atom is displaced by 0.140 Å above the plane of the three nitrogen donors)[23].

Table 2. Selected bond lengths [Å] and angles [°] of $[Pt(Me_5dien)\{O\text{-}MeC(O)NH_2\}](CF_3SO_3)_2$; standard deviations are in parentheses

The Pt−O bond length [2.038(4) Å] is in agreement with the values of Pt−O lengths previously reported for *N,O*-2-pyridonate complexes $[Pt_2(en)_2(C_5H_4NO)_2]_2^{4+}$ [2.049(6) Å][24] and $[Pt_2(NH_3)_4(C_5H_4NO)_2]^{2+}$ [2.024(5) Å] (where C_5H_4NO = 2-pyridonate)[25].

The acetamide molecule is strictly planar, with deviations of the heavy atoms from the least-square plane of ca. 0.004(6) Å, and orthogonal to the coordination plane where the dihedral angle between the planes is 89.4(3)°. The C−O and C−N bond lengths within the acetamide ligand [1.262(7) and 1.303(9) Å, respectively] are very similar to those previously found for acetamide *O*-coordinated to nickel [1.248(3) and 1.311(4) Å, respectively][26] and for free amides [1.23(1) and 1.32(1) Å, respectively][27] and indicate an extensive π-bond delocalization over the O=C=N functionality. Compared to the *N*-coordinated (acetamide)platinum species, the trend in C−O and C−N bond lengths is reversed [1.321(14) and 1.275(13) Å, for C−O and C−N, respectively][13]. This is in agreement with the different tautomerism of the acetamide in the two cases (oxo amine in the *O*-bonded and iminol in the *N*-bonded forms). The platinum−donor distances are also comparable to *O*- and *N*-bonded acetamide (within 0.01 Å).

The NH_2 group of the amide ligand is *cis* to the platinum center with respect to the C=O double bond and comes close to it. The intramolecular distance between the platinum atom and one proton of the amide [H(a)] is 2.86(9) Å

(as compared to the sum of the van der Waals radii for Pt and H of 2.9−3.2 Å)[28] and the Pt···H(a)−N(4) angle is 114(7)°. These data indicate the existence of an attractive Pt···H(a) interaction. Similarly, an interaction between the hydroxy group and the platinum atom was observed in the *N*-bonded acetamide [Pt···HO = 2.56(2)Å, Pt···H−O = 124(8)°] and was believed to be responsible for the stabilization of the isomer with the OH group, instead of the isomer with the Me group *cis* to the Pt center across the C=N double bond. The same conclusion can be drawn in the present case, although the Pt···HN interaction appears to be slightly weaker than the Pt···HO interaction.

The N(2)−Pt−O axis is slightly bent [175.4(2)°] in the same direction as the N(1)−Pt−N(3) axis [169.6(2)°] and, as a consequence, the coordination sphere of the platinum center assumes a pyramidal distortion, with the Pt atom displaced by 0.104(1) Å above the average plane of the donor atoms. This distortion contrasts with the tetrahedral distortion observed in the related $[Pt(Me_5dien)I]^+$ complex[29].

The triflate anions are kept in the vicinity of the metal center by a hydrogen bond between a triflate oxygen atom and the NH_2 group of the amide. The hydrogen bonds have geometrical parameters: O(2)−N(4) 2.837(9) Å, O(2)−H(b) 2.02(9) Å, O(2)−H(b)−N(4) 175.9(9)°, and O(5)−N(4) 3.050(11) Å, O(5)−H(a) 2.35(9) Å, O(5)−H(a)−N(4) 149(9)°[22].

Conclusions

In spite of the higher affinity of platinum(II) for *N*- over *O*-donor ligands, suitable platinum substrates react preferentially with the oxygen terminus to give the *O*-bonded amide complexes. Although the *O*-bonded species are very labile, since the amide can be displaced by water, they are indefinitely stable in acetone solution under neutral conditions. In contrast, isomerization from *O*- to *N*-bonded species takes place instantly under basic conditions. Therefore, the deprotonation of the aminic group ($pK_a > 11$) is accompanied by the shift of the metal center from the *O*- to the *N*-atom, leading to the formation of *N*-bonded amidate species. The main factor leading to the isomerization is the higher affinity of platinum to the nitrogen over the oxygen donor atom.

Protonation of the amidate species under acidic conditions leads to the *N*-bonded amide. The *N*-bonded amides, like the *N*-bonded amidates, represent the thermodynamically preferred species due to the higher affinity of platinum to nitrogen donors. In contrast, *O*-bonded amides owe their stability to their kinetic inertness, where a high pH is required for deprotonation of the NH_2 functionality. In the case of the pyridone complex, the *O*-bonded form is unstable and isomerizes spontaneously to the *N*-bonded form. The isomerization from the *O*- to the *N*-bonded species can take place in the absence of added base because of the higher acidity of the protonated pyridine-like nitrogen atom.

Differently to dien, Me_5dien adopts a fixed puckering of the two condensed chelate rings. Due to the rigidity of the puckered ring, the methyl groups at the terminal nitrogen atoms are held in fixed positions and strongly hinder the rotation of the amide. The steric hindrance is expected to be particularly severe in the case of cyclic pyridone. In this case, we have convincing evidences for the presence of two rotamers in both the *N*-amide and the *N*-amidate species. Hindered rotation stems from the steric rigidity of both rotating fragments, namely the (Me_5dien)Pt moiety and the pyridone. Slow rotation (on the NMR time scale) of aryl[22], pyrimidine, and purine rings in $(Me_5dien)Pd^{2+}$ complexes has already been reported[20]. This, however, is the first case that such a rate has been measured and found to be exceptionally low.

Comparison of the X-ray structure analysis of *O*- and *N*-coordinated (acetamide)platinum complexes has confirmed that because of the change in the ligand tautomerism (oxo amine and iminol for *O*- and *N*-bonded amides, respectively), the two isomeric amide functionalities are nearly superimposable.

The data collections were carried out by Mr. *A. Laurita, Università della Basilicata*.

Experimental Section

Starting Materials: Commercial reagent-grade chemicals were used without further purification.

Preparation of the Complexes: $[Pt(Me_5dien)I]_2(Pt_2I_6)$ (**1**) was prepared by direct reaction of $K_2[PtI_4]$ with free amine. In a typical experiment K_2PtCl_4 (0.5 g, 1.2 mmol) was dissolved in water (5 ml) and treated with excess KI (0.82 g, 4.9 mmol). After 5 min of stirring at 50°C, a stoichiometric amount of Me_5dien (0.207 g, 1.2 mmol) was added and the reaction mixture was kept stirring at 50°C for 1 h. The yellow-green precipitate which formed was separated, washed with water, and dried in dry air. Yield: 0.55 g, 67%. − $C_{18}H_{46}I_8N_6Pt_4$ (**1**; 2141.5): calcd. C 10.1, H 2.2, N 3.9; found C 10.0, H 2.2, N 3.9.

$[Pt(Me_5dien)(H_2O)](CF_3SO_3)_2$ (**2**) was prepared from $[Pt(Me_5dien)I]_2(Pt_2I_6)$ (**1**) (0.3 g, 0.14 mmol), suspended in water (20 ml) and treated with silver triflate (0.15 g, 0.58 mmol). The reaction mixture was kept stirring for about 16 h at room temperature in the dark. The solution was then filtered through Celite and concentrated to dryness. The oily residue was triturated with diethyl ether to give a white hygroscopic solid. Yield: 0.150 g, 40%. − $C_{11}H_{27}F_6N_3O_8PtS_2$ (**2**; 702.1): calcd. C 18.8, H 3.9, N 6.0; found C 18.8, H 3.8, N 5.8.

The complexes $[Pt(Me_5dien)(N{\equiv}CR)](CF_3SO_3)_2$ (**3**) were prepared by reaction of the aqua species $[Pt(Me_5dien)(H_2O)](CF_3SO_3)_2$ (**2**) with free nitrile. In a typical experiment, $[Pt(Me_5dien)(H_2O)](CF_3SO_3)_2$ (**2**) was dissolved in the minimum amount of the appropriate nitrile [N≡CR, R = *t*Bu (**a**), Me (**b**), and Ph (**c**)] (ca. 1 mmol of complex in about 10 ml of nitrile) and then kept stirring for 1 h at room temperature. In the case of *tert*-butyl cyanide, the complex **3a** precipitated from the reaction solution and was recovered by filtration of the mother liquor. In the case of acetonitrile, the complex **3b** was recovered after evaporation of the solvent and trituration of the oily residue with diethyl ether. Finally, in the case of benzonitrile, an excess of *n*-hexane was added

Table 3. Selected crystallographic data of $[Pt(Me_5dien)\{O\text{-}MeC(O)NH_2\}](CF_3SO_3)_2$

Empirical formula	$C_{13}H_{28}F_6N_4O_7PtS_2$	$d_{calcd.}$ [Mg m^{-3}]	1.940

Radiation (λ [Å])	1.5418		

[a] $R1 = \Sigma\|\|F_o| - |F_c\|\|/\Sigma|F_o|$. – [b] $wR2 = [\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]]^{1/2}$; $w = 1/[\sigma^2(F_o^2) + (0.0631 \times P)^2 + 21.74 \times P]$ where $P = [\text{Max}(F_o^2,0) + 2 \times F_c^2]/3$.

to the solution and the mixture kept in the refrigerator for 1 d. The sticky precipitate which formed was washed three times with *n*-hexane and then treated with diethyl ether to give a solid product **3c**. In all cases the yields were above 75%. – $C_{16}H_{32}F_6N_4O_6PtS_2$ (**3a**; 749.1): calcd. C 25.6, H 4.3, N 7.5; found C 25.4, H 4.4, N 7.4. – $C_{13}H_{26}F_6N_4O_6PtS_2$ (**3b**; 707.1): calcd. C 22.1, H 3.7, N 7.9; found C 21.7, H 3.6, N 7.7. – $C_{18}H_{28}F_6N_4O_6PtS_2$ (**3c**; 769.1): calcd. C 28.1, H 3.7, N 7.3; found C 27.8, H 3.5, N 6.9.

The *O*-bonded amide complexes $[Pt(Me_5dien)\{O\text{-}RC(O)NH_2\}](CF_3SO_3)_2$ (**4**) [R = *t*Bu (**a**), Me (**b**), and Ph (**c**)] were prepared by reaction of the aqua species $[Pt(Me_5dien)(H_2O)](CF_3SO_3)_2$ (**2**) with the free amide according to a slight modification of the method of Woon and Fairlie[18]. In a typical experiment, compound **2** (0.07 g, 0.1 mmol) was dissolved in acetone (10 ml), treated with the free amide [$RC(O)NH_2$, R = *t*Bu (**a**), Me (**b**), and Ph (**c**)] (0.15 mmol) and then kept stirring for 16 h at room temperature. Addition of a large excess of diethyl ether induced complete precipitation of the compound. The white precipitate was collected and dried in a vacuum desiccator in the presence of KOH pellets as the drying agent, with the yields always above 90%. In the case of acetamide, suitable crystals for X-ray diffraction were obtained by slow crystallization from an acetone solution layered under diethyl ether. – $C_{16}H_{34}F_6N_4O_7PtS_2$ (**4a**·H_2O; 767.1): calcd. C 25.0, H 4.5, N 7.3; found C 24.9, H 4.6, N 7.1. – $C_{13}H_{28}F_6N_4O_7PtS_2$ (**4b**·H_2O; 725.1): calcd. C 21.5, H 3.9, N 7.7; found C 21.4, H 3.9, N 7.7. – $C_{18}H_{30}F_6N_4O_7PtS_2$ (**4c**·H_2O; 787.1): calcd. C 27.4, H 3.8, N 7.1; found C 26.8, H 3.9, N 7.1.

The *N*-bonded amide complexes $[Pt(Me_5dien)\{N\text{-}RC(OH)NH\}](CF_3SO_3)_2$ (**5**) [R = *t*Bu (**a**), Me (**b**), and Ph (**c**)] were prepared either by hydrolysis of the corresponding nitriles (procedure 1) or by isomerization of the *O*-bonded amides (procedure 2). – Procedure 1: In a typical experiment, the nitrile complex $[Pt(Me_5dien)(N{\equiv}CR)](CF_3SO_3)_2$ (0.1 mmol), dissolved in water (10 ml), was treated with a slight excess of KOH (0.12 mmol in 10 ml of water) with stirring, in an ice bath. After 1–2 h reaction time, the resulting solution was brought to pH = 2–3 with triflic acid, the solvent was evaporated, and the sticky residue crystallized from acetone/diethyl ether. The products **5a–c** are hygroscopic and must be stored under anhydrous conditions. Yields 70%. – Procedure 2: In a typical experiment, the *O*-bonded complex $[Pt(Me_5dien)\{O\text{-}RC(O)NH_2\}](CF_3SO_3)_2$ (**4**) (0.1 mmol), was dissolved in acetone (25 ml) and treated with powdered KOH (0.7 mmol). A few drops of water were added to the reaction mixture, which was kept stirring for about 5 min. The solution was filtered, acidified with triflic acid, and then treated with diethyl ether to allow precipitation of a white product which was recrystallized from acetone/diethyl ether. Yields 70%. – $C_{17}H_{34}F_9KN_4O_{10}PtS_3$ (**5a**·KCF_3SO_3·H_2O; 955.1): calcd. C 21.4, H 3.6, N 5.8; found C 21.3, H 3.8, N 5.7. – $C_{27}H_{56}F_{15}KN_8O_{17}Pt_2S_5$ (**5b**·KCF_3SO_3·2 H_2O; 1638.1): calcd. C 19.8, H 3.4, N 6.8; found C 19.5, H 3.5, N 6.6. – $C_{19}H_{30}F_9KN_4O_{10}PtS_3$ (**5c**·KCF_3SO_3·H_2O; 975.0): calcd. C 23.4, H 3.1, N 5.7; found C 23.3, H 3.5, N 5.6.

The reaction of the acqua species **2** with pyridone leading to a first reaction product (*O*-coordinated pyridone; **6**) which is not stable but isomerizes with time to a new species (*N*-coordinated pyridone; **7**) which, in turn, gives rise to formation of an equilibrium mixture of two rotamers (**7** and **7′**) was performed in the NMR tube and no attempt to isolate isomerically pure species was made.

Physical Measurements: IR spectra in the range 4000–400 cm^{-1} were recorded as KBr pellets; spectra in the range 400–200 cm^{-1} were recorded as polythene pellets with Perkin Elmer 283 and FT 1600 spectrophotometers. ^{1}H-NMR spectra were obtained with a Bruker AM 300 spectrometer and are collected in Table 1. Rate constants were calculated from plots of $\ln(C_t - C_{inf.})$ against time where C_t and $C_{inf.}$ are concentrations at time t and after at least six half-lives, respectively.

X-ray Crystallographic Study[30]: Colorless crystals of $[Pt(Me_5dien)\{O\text{-}RC(O)NH_2\}](CF_3SO_3)_2$ (**4b**) were obtained from acetone/diethyl ether solution. X-ray data were collected with an Enraf-Nonius CAD4 single-crystal diffractometer by using graphite-filtered Cu-K_α radiation (λ = 1.5418 Å). The unit-cell dimensions were refined by a least-squares algorithm using 25 automatically centered reflections. A total of 5101 reflections were collected in the range $-14 \le h \le 14$, $0 \le k \le 15$, $0 \le l \le 21$; 4705 independent reflections. Four reflections were monitored during data collection, no decay was observed. Crystallographic data are summarized in Table 3. The full data set was corrected for Lorentz and polarization effects. A correction for absorption effects was applied using the DIFABS package[31] at the isotropic stage of refinement.

The structure was solved using Patterson and Fourier techniques, in the $P21/n$ space group. The model was refined by full-matrix least-squares methods. Anisotropic thermal parameters were applied for all non-hydrogen atoms. The NH_2 hydrogen atoms of the amide were found in the final Fourier difference map, the other hydrogen atoms were placed at their geometrically calculated positions and included in the full-matrix least-square cycles with iso-

tropic thermal parameters (U) tied at 1.2 times the values of U of the relative carbon or nitrogen atoms.

All calculations were carried out with Vax 11/750 and AST Pentium 100 MHz computers using the SHELX-86[32], SHELXL-93[33], and PARST97 packages[34].

Reaction of H_2L (**1**) with potassium or strontium hydride, or lanthanum(III) chloride, followed by iron(III) chloride, yielded the {2}-ironcryptates **2a–c**. The mono-, di-, and trivalent guest cations are endohedrally encapsulated. In contrast, the dinuclear trispyridinium ironcryptand **2d** was generated from the reaction of H_2L (**1**) with only iron(III) chloride. The potassium metallacryptate **2a′** was formed from the triple-helicate **2d** by addition of potassium carbonate. The new compounds **2b**, **2c**, and **2d** were unequivocally characterised by X-ray diffraction analyses.

Introduction

The selective complexation of guest molecules and metal cations is an essential prerequisite for the proper functioning of enzymes and biological receptors. In order to mimic the geometric and electronic requirements necessary for selective complexation as observed in nature, many different model compounds with cavities of variable size and electronic structure have been constructed[1]. Examples are the well-known crown ethers, cryptands, spherands and their inclusion complexes[1][2], along with the corresponding metallatopomers, which are easily accessible by self-organisation[3][4][5]. Recently, the bicyclic metallacryptate $[K\subset Fe_2L_3][PF_6]$ (**2a**) was synthesised and characterised by X-ray crystallographic analysis[6][7][8] (Scheme 1).

Results and Discussion

Herein we describe the formation of the bicyclic ironcryptates **2b** and **2c**, with endohedrally encapsulated divalent alkaline earth or trivalent rare earth metal ions, and the cation-free trispyridinium {2}-ironcryptand **2d** (Scheme 1). Upon reaction of H_2L (**1**)[9] in THF with strontium hydride or lanthanum(III) chloride, followed by iron(III) chloride, and subsequent workup with dichloromethane, a dark-red solid was isolated. The FAB-MS spectra (FAB-MS = Fast Atom Bombardment) of the solid materials showed peaks at *m*/*z* 1187 and 985, corresponding to the dication $[Sr\subset Fe_2L_3]^{2+}$ of **2b**, and the trication $[La\subset Fe_2L_3]^{3+}$ of **2c**, indicating the formation of strontium- and lanthanum-containing bicyclic metallacryptates, respectively. Ruby-red crystals of the strontium complex, suitable for X-ray analysis, were prepared by a slightly modified procedure. Strontium chloride was added to a solution of H_2L (**1**; R = *t*Bu) and iron(III) chloride in THF, and the crude material was crystallised from dichloromethane by diffusion of a mixture of diethyl ether and hexanes (1:5). The X-ray diffraction analysis of these crystals proved the formation of a strontium-containing bicyclic ironcryptate $[(Sr\cdot H_2O)\subset Fe_2L_3]$-$[FeCl_4]_2$ (**2b**) with two ferric tetrachloride counterions (Figure 1).

The encapsulated strontium dication does not lie perfectly on the iron−iron axis (Fe−Sr−Fe 174.39°). Strontium is deca-coordinated by six oxygen and three nitrogen atoms of the three ligands, and one molecule of water. In addition, water forms a hydrogen bond to a molecule of diethyl ether solvent. The ligands are approximately octahedrally coordinated to the iron center in a helical fashion. In the chiral complex of racemic **2b**, both iron centers are identically coordinated. Therefore, **2b** is either a (Δ,Δ)-*fac*- or (Λ,Λ)-*fac*-{2}-metallacryptate. The crystals obtained were composed of the homochiral {2}-metallacryptate **2b**. The iron−iron distance in **2b** (715 pm) is identical to the Fe−Fe distance observed in the potassium-containing ironcryptate **2a**.

Scheme 1. Reaction scheme for the formation of $[M\subset Fe_2L_3]Y_n$ [**2a**: R = *t*Bu, M = K^+, $Y_n = PF_6^-$; **2a′**: R = *t*Bu, M = K^+, $Y_n = FeCl_4^-$; **2b**: R = *t*Bu, M = $(Sr^{2+}\cdot H_2O)$, $Y_n = (FeCl_4^-)_2$; **2c**: R = Me, M = $(La^{3+}\cdot H_2O\cdot THF)$, $Y_n = (FeCl_4^-)_3$] and $[Fe_2(LH^N)_3]Y_n$ [**2d**: $Y_n = (FeCl_4^-)_3$]

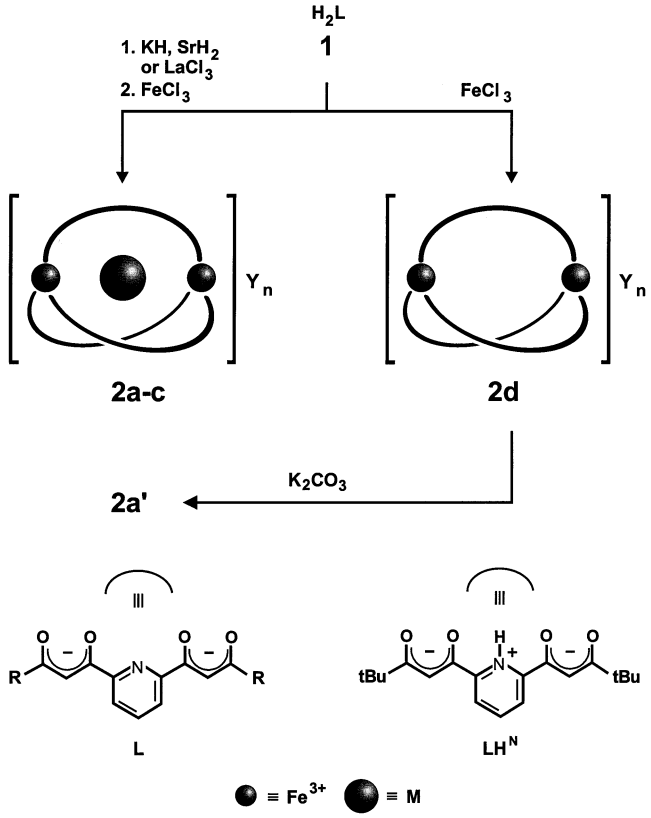

Figure 1. Molecular structure of the dication $[(Sr\cdot H_2O)\subset Fe_2L_3]^{2+}$ of {2}-ironcryptate **2b** (hydrogen atoms, counterions and solvent molecules omitted for clarity; O atoms black, C atoms shaded, N atoms net, Sr atoms segment, Fe atoms diagonal)

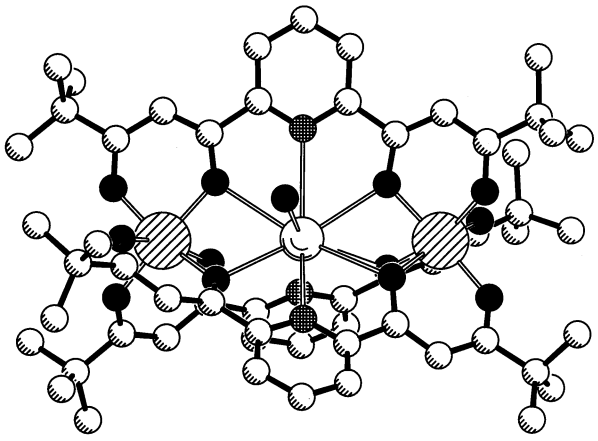
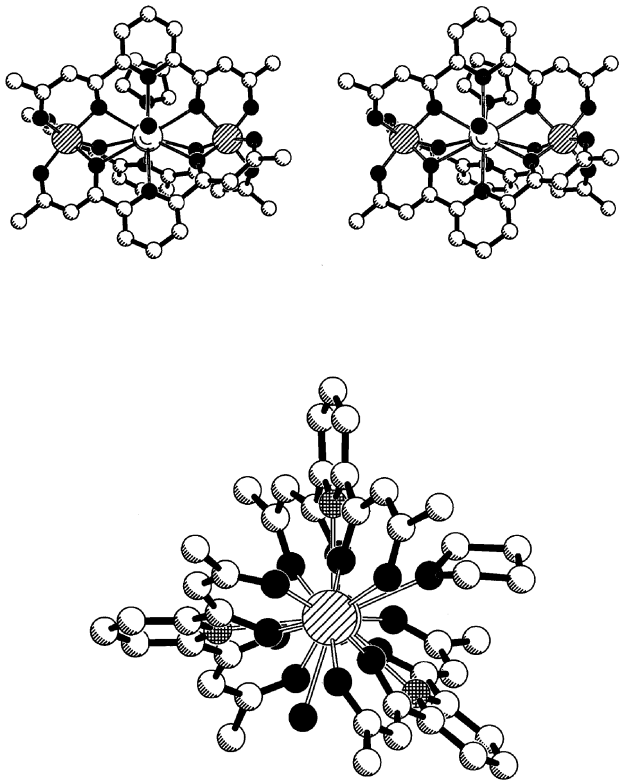


Single crystals suitable for an X-ray diffraction analysis of the chiral racemic lanthanum-containing compound were obtained by diffusion of diethyl ether into a dichloromethane solution of **2c**. There are two slightly different, independent, homochiral ironcryptates (Δ,Δ)- or (Λ,Λ)-$[(La\cdot THF\cdot H_2O)\subset Fe_2L_3][FeCl_4]_3$ (**2c**) of the same chirality present in the asymmetric unit (Figure 2).

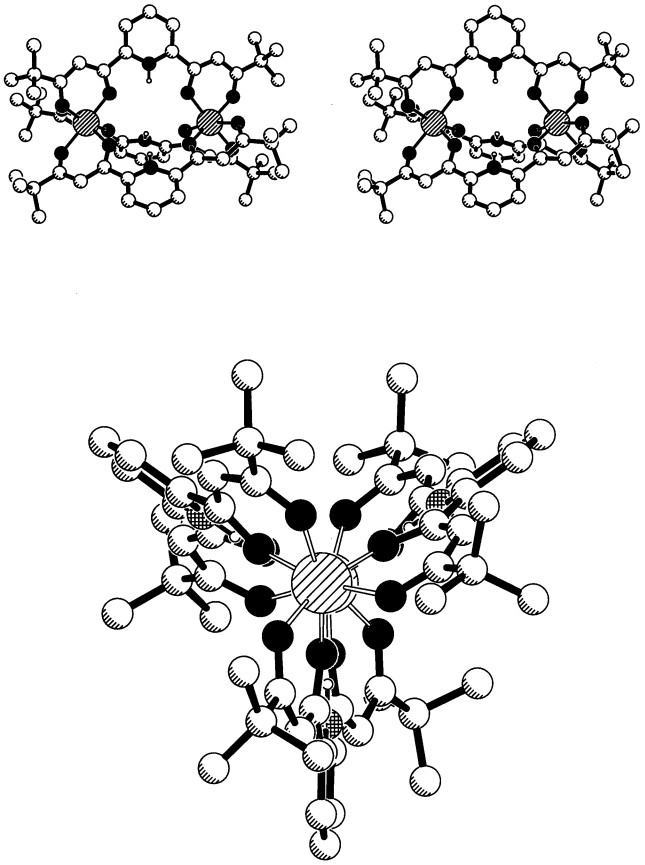
Figure 2. Molecular structure of the trication $[(La\cdot H_2O\cdot THF)\subset Fe_2L_3]^{3+}$ of {2}-ironcryptate **2c**; top: stereo view; bottom: view along the Fe−Fe axis (hydrogen atoms, counterions and solvent molecules omitted for clarity; O atoms black, C atoms shaded, N atoms net, La atoms segment, Fe atoms diagonal)



The two iron(III) cations (d_{Fe-Fe} = 719 pm) in the molecule are each approximately octahedrally coordinated by six oxygen atoms of three ligands. They are located on the idealised C_3 axis of the D_{3h}-symmetric molecule. The incorporated lanthanum(III) cation is eleven-coordinate. The six internal oxygen atoms of the ligands form a trigonal prismatic coordination sphere around the lanthanum center. The three nitrogen atoms of the ligands, a THF molecule, and a water molecule coordinate the lanthanum center equatorially in a near perfect plane. The lanthanum−iron distances are similar within each molecule ($\bar{d}_{Fe-La}$ = 360 pm). The encapsulated lanthanum trication lies almost on the Fe−Fe axis (Fe−La−Fe 176.93°). In contrast to the aforementioned potassium-containing (Δ,Λ)-*fac* (*meso*) ironcryptate **2a**, the lanthanum-containing analogue **2c** forms a racemic mixture of the homochiral (Δ,Δ)-*fac* and (Λ,Λ)-*fac* stereoisomers.

Upon addition of iron(III) chloride to a solution of H_2L (**1**; R = *t*Bu) in dry THF, followed by workup with dichloromethane, and crystallisation by diffusion of diethyl ether into a dichloromethane solution of the crude solid material, ruby crystals were obtained. The crystal structure determination revealed the formation of bicyclic metallacryptand $[Fe_2(LH^N)_3][FeCl_4]_3$ (**2d**). In **2d** the pyridine nitrogen atoms of the three ligands are protonated, and the re-

Figure 3. Molecular structure of the trication $[Fe_2(LH^N)_3]^{3+}$ of {2}-ironcryptand **2d**; top: stereo view; bottom: view along the Fe−Fe axis (pyridinium hydrogen atoms shown; counterions and solvent molecules omitted for clarity; H atoms void, O atoms black, C atoms shaded, N atoms net, Fe atoms diagonal)



sulting charge of the complex is compensated by three $FeCl_4^-$ counterions. In addition to the two molecules of **2d** in the asymmetric unit, there are four dichloromethane molecules (Figure 3).

The mean Fe−Fe distance of **2d** (642 pm) is much smaller than those in the metallacryptates **2a**, **b**, and **c** (715 and 719 pm). Inclusion of a cation in **2a**, **b**, and **c** causes an expansion of the ligands of the metallacryptates, and an elongation of the iron−iron distances. The average N−N distance for **2d** (539 pm) is considerably larger than that of the ironcryptate **2c** (481 pm). In the chiral, racemic complex **2d**, both iron centers are identically coordinated to six oxygen atoms. Therefore, the {2}-metallacryptand **2d** is either a (Δ,Δ)-*fac* or (Λ,Λ)-*fac* dinuclear triple helicate. A racemic mixture of complex **2d** self-selectively sorts by chirality to generate an enantiomerically pure crystal. As only one crystal was analysed by X-ray, there possibly exists crystals of opposite chirality, forming a conglomerate.

The {2}-ironcryptand **2d** can be converted into the potassium {2}-ironcryptate $[K\subset Fe_2L_3][FeCl_4]$ (**2a′**) on addition of an excess of potassium carbonate to a solution of complex $[Fe_2(LH^N)_3][FeCl_4]_3$ (**2d**) in THF. After stirring of the reaction mixture for one day at room temperature and workup with dichloromethane, a red solid was obtained, which was characterised by FAB-MS, microanalysis, and IR to be **2a′**.

Conclusion

In summary, a series of bicyclic ironcryptates with encapsulated alkaline, alkaline earth, and rare earth metal cations was synthesised, as was a bicyclic metallacryptand with pyridinium units in the ligands. According to X-ray analyses, the strontium- and lanthanum-containing ironcryptates and the bicyclic pyridinium ironcryptand form helical structures, in contrast to the known *meso*-potassium ironcryptate. Future work will concentrate on possible interesting physical and chemical properties of rare earth metallacryptates and the potential use of the ironcryptates as selective complexation agents for certain cations.

Experimental Section

General: The compounds H_2L (**1**) [1,1′-(2,6-pyridyl)bis-1,3-butanedione and 1,1′-(2,6-pyridyl)bis-4,4′-dimethyl-1,3-pentanedione] were prepared according to a literature procedure[9]. − IR: Bruker IFS 25. − FAB-MS: Micromass ZabSpec. − Microanalysis: Heraeus CHN-Mikroautomat; **2a−d** lose crystal solvent during drying.

General Procedure for the Synthesis of the Dinuclear Iron(III) Complexes **2b** *and* **2c**: To a solution of H_2L (**1**) (2 mmol) in 75 ml of dry THF, 359 mg (4 mmol) of strontium hydride, or 491 mg (4 mmol) of lanthanum(III) chloride was added. The mixture was stirred for 15 min at 20°C. Iron(III) chloride (216 mg, 1.33 mmol) was then added, and the dark red solution was stirred for 16 h at 20°C. The solvent was removed in vacuo, and the residue was suspended in 50 ml of dichloromethane. After standing for 16 h at 20°C, the red solution was filtered, the solvent removed, and the remaining crude product dried under vacuum (oil pump).

$[(Sr{\cdot}H_2O)\subset Fe_2L_3][FeCl_4]_2{\cdot}CH_2Cl_2{\cdot}Et_2O$ (**2b**): Ruby-coloured crystals were obtained according to the general procedure using 634 mg (4 mmol) of strontium chloride instead of strontium hydride and diffusion of a mixture of diethyl ether and hexanes into a dichloromethane solution. Yield 676 mg (76%), m. p. > 250°C (decomp.). − IR ($CHBr_3$): $\tilde{\nu}$ = 1721 cm^{-1} (C=O), 1553, 1515 (C=C). − FAB MS (3-nitrobenzyl alcohol matrix); *m/z*: 1222 ($Sr\subset Fe_2L_3{\cdot}2H_2O$), 1187 ($Sr\subset Fe_2L_3$). − $C_{63}H_{85}Cl_{12}Fe_4N_3O_{14}Sr$ (1844,77): calcd. C 41.02, H 4.64, N 2.28; found C 40.81, H 4.71, N 2.02.

$[(La{\cdot}THF{\cdot}H_2O)\subset Fe_2L_3][FeCl_4]_3{\cdot}2CH_2Cl_2$ (**2c**): Ruby-coloured tablets were obtained by diffusion of diethyl ether into a dichloromethane solution. Yield 898 mg (80%), m. p. > 250°C (decomp.). − IR ($CHBr_3$): $\tilde{\nu}$ = 1736 cm^{-1} (C=O), 1603, 1586 (C=C). − FAB MS (3-nitrobenzyl alcohol matrix); *m/z*: 1020 ($La\subset Fe_2L_3{\cdot}2H_2O$), 985 ($La\subset Fe_2L_3$), 757 ($La\subset Fe_2L_2{\cdot}H_2O$). − $C_{43}H_{45}Cl_{12}Fe_5LaN_3O_{14}$ (1687.41): calcd. C 30.61, H 2.69, N 2.49; found C 30.71, H 3.12, N 2.31.

$[Fe_2(LH^N)_3][FeCl_4]_3{\cdot}2CH_2Cl_2$ (**2d**): To a solution of 662 mg (2 mmol) of H_2L (**1**) in 75 ml of dry THF, 216 mg (1.33 mmol) of iron(III) chloride was added and the dark red solution was stirred

for 16 h at 20°C. The solvent was removed in vacuo and the residue was suspended in 50 ml of dichloromethane. After standing for 16 h at 20°C, the red solution was filtered, the solvent removed and the remaining crude product dried under vacuum (oil pump). Ruby-coloured crystals were obtained by diffusion of diethyl ether into a dichloromethane solution. Yield 1094 mg (97%), m. p. > 250°C (decomp.). – IR ($CHBr_3$): $\tilde{\nu}$ = 3217 cm^{-1} (N=H), 1587 (C=O), 1494 (C=C). – FAB MS (3-nitrobenzyl alcohol matrix); *m/z*: 1155 $[Fe_2(LH^N)_3 \cdot Fe]$, 1099 (Fe_2L_3), 771 (Fe_2L_2). – $C_{57}H_{72}Cl_{12}Fe_5N_3O_{12}$ (1695.88): calcd. C 40.37, H 4.28, N 2.48; found C 39.93, H 4.52, N 2.70.

[K⊂Fe$_2$L$_3$][FeCl$_4$] (**2a′**): To a solution of 102 mg (0.06 mmol) of $[Fe_2(LH^N)_3][FeCl_4]_3$ (**2d**) in 50 ml of dry THF, 24 mg (0.18 mmol) of potassium carbonate was added and the dark-red solution was stirred for 16 h at 20°C. The solvent was removed in vacuo, and the residue was suspended in 25 ml of dichloromethane. After standing for 16 h at 20°C, the red solution was filtered, the solvent removed, and the remaining crude product dried under vacuum (oil pump). Ruby-coloured microcrystals of **2a′** were obtained by diffusion of diisopropyl ether into a dichloromethane solution. Yield 67 mg (72%), m. p. > 250°C (decomp.). – IR ($CHBr_3$): $\tilde{\nu}$ = 1723 cm^{-1} (C=O), 1573, 1514 (C=C). – FAB MS (3-nitrobenzyl alcohol matrix); *m/z*: 1138 ($[K\subset Fe_2L_3]$), 809 ($[K\subset Fe_2L_2]$). – $C_{69}H_{93}Cl_5Fe_3KN_3O_{15}$ ($[K\subset Fe_2L_3][FeCl_4]\cdot 3THF$; 1552.96): calcd. C 53.37, H 6.04, N 2.71; found C 53.44, H 5.99, N 2.62.

Crystal Structure Determination of Compound **2b**: $C_{61}H_{81}Cl_8Fe_4N_3O_{14}Sr$, M = 1674.91, monoclinic, space group $P2_1/c$, a = 1735.6(4), b = 1925.7(4), c = 2299.6(5) pm, β = 98.35(3)°, V = 7.60(1) nm^3, Z = 4, $\rho_{calcd.}$ = 1.463 Mg/m^3, $F(000)$ = 3432, λ = 71.073 pm, T = 133 K, μ(Mo-K_α) = 1.781 mm^{-1}, min/max transmission: 0.470/0.776, crystal dimensions 0.50 × 0.28 × 0.15 mm; 3.48° ≤ 2Θ ≤ 50.00°; 110590 measured reflections of which 13252 were independent (R_{int} = 0.0672) and employed in the structure refinement (884 parameters, 492 restraints). The R values are $R1 = \Sigma|F_o - F_c|/|\Sigma F_o$ = 0.0465 [$I > 2\sigma(I)$] and $wR2 = [\Sigma w(F_o^2 - F_c^2)^2/\Sigma wF_o^4]^{1/2}$ = 0.0831 (all data); min/max residual electron density: −599 e nm^{-3}/602 e nm^{-3}. Two *tert*-butyl groups show two different rotameric conformations. One tetrachloroferrate anion is disordered over two sites[18].

Crystal Structure Determination of Compound **2c**: $C_{45}H_{47}Cl_{16}Fe_5LaN_3O_{14}$, M = 1839.27, triclinic, space group $P\bar{1}$, a = 1535.04(7), b = 2131.21(9), c = 2175.03(9) pm, α = 102.948(1), β = 91.732(1), γ = 97.320(1)°, V = 6.8654(5) nm^3, Z = 2, $\rho_{calcd.}$ = 1.78 g/cm^3, $F(000)$ = 3636.00, λ = 71.069 pm, T = 182 K, μ(Mo-K_α) = 0.2312 mm^{-1}, min/max transmission: 0.899/0.670, crystal dimensions 0.35 × 0.18 × 0.08 mm, 3.00° ≤ 2Θ ≤ 46.5°; 29795 collected reflections of which 19097 were independent (R_{int} = 0.046) and employed in the structure refinement (11762 parameters, 0 restraints). The R values are: $R1 = R = \Sigma\ F_o - F_c\ / \Sigma F_o$ = 0.057 [$I > 3\sigma(I)$] and $wR2 = R_w = [\Sigma w(F_o - F_c)^2 / \Sigma wF_o^2]^{1/2}$ = 0.065 (all data), where

$$w = \frac{1}{\sigma^2(F_o^2)} = \frac{4F_o^2}{\sigma^2(F_o^2)};$$

max/min residual electron density: 0.76 $e^-/Å^3$/−0.86 $e^-/Å^3$.

Crystal data were collected using a Siemens SMART diffractometer equipped with a CCD area detector. Data were integrated using SAINT and were corrected for Lorentz- and polarization effects. An empirical absorption correction was applied using XPREP (ellipsoidal model); equivalent reflections were merged. The structure was solved by direct methods and was refined on F using the teXsan crystallographic software package. The non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included but not refined.

Crystal Structure Determination of Compound **2d**: $C_{59}H_{76}Cl_{16}Fe_5N_3O_{12}$, M = 1875.68, monoclinic, space group $P2_1$, a = 1467.8(3), b = 4000.1(8), c = 1511.4(3) pm, β = 111.20(3)°, V = 8.27(1) nm^3, Z = 4, $\rho_{calcd.}$ = 1.498 Mg/m^3, $F(000)$ = 3796, λ = 71.073 pm, T = 133 K, μ(Mo-K_α) = 1.4251 mm^{-1}, min/max transmission: 0.467/0.675, crystal dimensions 0.63 × 0.40 × 0.30 mm, 3.54° ≤ 2Θ ≤ 50.34°; 93692 measured reflections of which 23822 were independent (R_{int} = 0.0381) and employed in the structure refinement (1878 parameters, 1027 restraints). The R values are $R1$ = 0.0518 [$I > 2\sigma(I)$] and $wR2$ = 0.1136 (all data); min/max residual electron density: −752 e nm^{-3}/727 e nm^{-3}. Three *tert*-butyl groups and one tetrachloroferrate anion are disordered over two sites. Crystallographic data for **2b** and **2d** were collected with a Stoe-Siemens-Huber four-circle diffractometer with Siemens CCD area detector by using φ and ω scans on a shock-cooled crystal in an oil drop[15]. Data integration was performed with the program SAINT. A semi-empirical absorption correction was applied. The structures were solved by direct methods (SHELXS-97)[16]. Refinement of F^2 was accomplished by the least-squares method[17]. All non-hydrogen atoms were refined anisotropically. For the hydrogen atoms, the riding model was used. The hydrogen atoms attached to the nitrogen atoms in **2d** could be located in the difference Fourier synthesis. NH distances were restrained to a target value of 95 pm. All disordered components were refined anisotropically with the assistance of distance and ADP restraints[18].

Keywords: Titanium / C–H activation / Amido complexes / Bridging imide ligands / Bridging imine group

The new organometallic binuclear complexes $[\{Cp^*Ti(NEt_2)\}_2(\mu\text{-}NEt)_2]$ (**1**), $[(Cp^*Ti)_2(NMe_2)(NHMe_2)(\mu\text{-}NMe)(\mu\text{-}NCH_2)]$ (**2**), and $[(Cp^*TiCl)_2(\mu\text{-}NMe)_2]$ (**3**) have been obtained by heating the dialkylamido derivatives $[Cp^*Ti(NR_2)_nCl_{3-n}]$ (R = Et, n = 3; R = Me, n = 2, 3) ($Cp^* = \eta^5\text{-}C_5Me_5$) in solution and at different temperatures. The thermal decomposition of $[Cp^*Ti(NMe_2)Cl_2]$ at temperatures above 145 °C caused the activation of the pentamethylcyclo-pentadienyl ligand to give the new, geometrically constrained, complex $[\{\eta^5:\eta^1\text{-}C_5Me_4CH_2CH_2N(Me)\}TiCl_2]$ (**5**). Addition of the isocyanide 2,6-$Me_2C_6H_3NC$ to the solution obtained in this last process led to the isolation of the complex $[\{\eta^5:\eta^2\text{-}C_5Me_4CH_2CH_2N(Me)CN(C_6H_3Me_2)\}\text{-}TiCl_2]$ (**6**) by insertion of one isocyanide molecule into the titanium–nitrogen bond in **5**. The structure of **6** has been proved by an X-ray diffraction study which showed the organic ligand, $C_5Me_4CH_2CH_2N(Me)CN(C_6H_3Me_2)$, to be coordinated to the titanium atom via the cyclopentadienyl ring and a η^2-iminocarbamoyl fragment. Heating of the trinuclear oxo derivative $[\{Cp^*Ti(NMe_2)\}_3(\mu\text{-}O)_3]$ at 110 °C gave the complex $[\{Cp^*{}_3Ti_3(NMe_2)(\mu\text{-}\eta^2\text{-}CH_2NMe)\}(\mu\text{-}O)_3]$ (**4**) where an imine ligand bridges two of the three metallic centres.

Studies on the decomposition of inorganic or organometallic complexes and polymers is currently a fast emerging area in chemistry. The preparation of ceramic materials from precursor complexes is a fascinating challenge for inorganic or solid-state chemists involved in the design of routes to new or improved refractory metal oxides, carbides, and nitrides.[1]

For instance, titanium nitride possesses a number of useful properties, including extreme hardness, excellent chemical resistance, desirable optical properties, and good electrical conductivity.[2] The current trend to obtain this material in low-temperature processes necessitates the use of inorganic precursors, and in particular amido complexes $Ti(NR_2)_4$ have been extensively used.[3] Their thermal decomposition in vapour-phase CVD processes has been shown to lead to the incorporation of carbon and hydrogen in the desired nitride.[4] These impurities can be reduced by reaction with ammonia[5] but in all cases, the carbon percentage is significant, and attributed to the formation of metallacycles, as has been described in solution.[6]

In our research into the stability of mono(pentamethylcyclopentadienyl)titanium derivatives, we have recently reported on the formation of alkylidyne complexes by the thermal decomposition of the alkyl precursors[7] and we were interested in expanding these studies to other ligands attached to the metal centre. Here we describe the synthesis and characterisation of several organometallic derivatives obtained by heating the dialkylamido complexes of titanium, $[Cp^*Ti(NR_2)_nCl_{3-n}]$ and $[\{Cp^*Ti(NMe_2)\}_3(\mu\text{-}O)_3]$ in solution.[8]

Results and Discussion

A toluene solution of the complex $[Cp^*Ti(NEt_2)_3]$ was heated at 70°C for 20 d in a Carius tube (to guarantee the purity of the atmosphere); subsequent evacuation of the volatiles under vacuum and crystallisation from hexane allowed the isolation of $[\{Cp^*Ti(NEt_2)\}_2(\mu\text{-}NEt)_2]$ (**1**) as a pure complex (see Scheme 1).

The spectroscopic and analytical data (Experimental Section) are consistent with a dimeric structure of **1**, with two bridging ethylimide ligands. According to the ^{1}H-NMR data, this complex is characterised by a *cis* arrangement[9] of both the terminal diethylamido and pentamethylcyclopentadienyl ligands with respect to the central $Ti_2(\mu\text{-}NEt)_2$ core.

Complex $[Cp^*Ti(NMe_2)_3]$ decomposed between 120 and 150°C with elimination of $NHMe_2$ and formation of the organometallic derivative $\{[Cp^*Ti]_2(NMe_2)(NHMe_2)(\mu\text{-}NMe)(\mu\text{-}N{=}CH_2)\}$ (**2**) (see Scheme 1 and Experimental Section). Complex **2** was isolated in a yield of 64% as a dark-green crystalline solid. The ^{13}C-NMR spectrum of **2** shows one doublet of doublets at δ = 100.8 (^1J = 154.1 Hz, ^1J = 159.6 Hz) while its ^{1}H-NMR spectrum presents two signals at δ = 3.79 (1 H) and 3.81 (1 H) (^2J < 0.2 Hz), corresponding to the existence of a bridging $\mu\text{-}N{=}CH_2$ ligand.[10] Two broad signals for the methyl groups of the

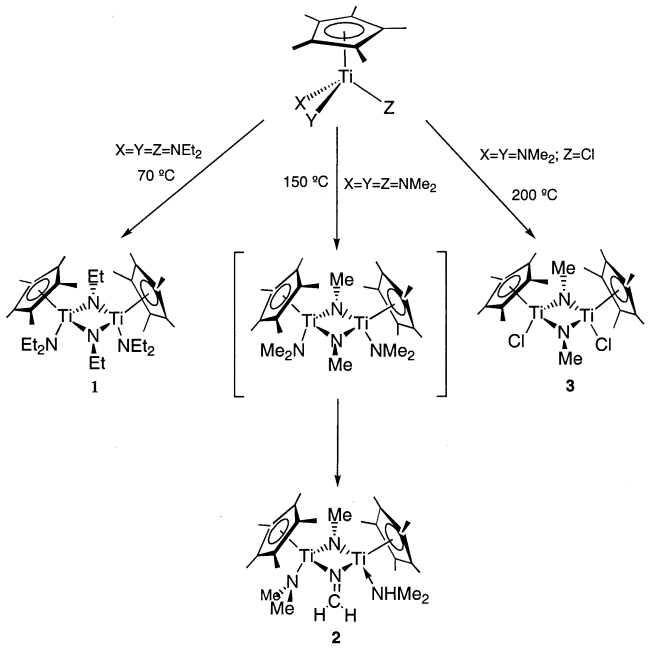
Scheme 1. Thermolyses of the complexes $[Cp^*Ti(NEt_2)_3]$, $[Cp^*Ti(NMe_2)_3]$ and $[Cp^*Ti(NMe_2)_2Cl]$



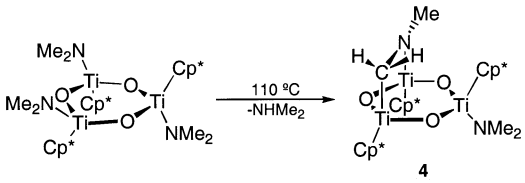
terminal NMe_2 ligands were also observed in the spectra at room temp., which collapsed together at 313 K ($\Delta G^{\#} \approx 63$ kJ/mol). This spectral behaviour is based on the slow rotation around the Ti−N bond, indicating π-donation of the nitrogen electron pair to the titanium centre. The value of the Gibbs free energy is similar to those reported for other dimethylamido complexes (46−100 kJ/mol).[11] Finally the ^{1}H-NMR spectrum exhibits two doublets at δ = 1.6 (^3J = 6.0 Hz) and 1.7 (^3J = 6.0 Hz) for the diastereotopic methyl groups, and one septuplet at δ = 4.01 for the amine proton of the coordinated $HNMe_2$ ligand. This ligand remains in the complex after several hours under vacuum (10^{-2} Torr) or even in THF solution. The formation of complex **2** might be explained by the activation of one C−H bond in a methylimide group[12] from a "$[\{Cp^*Ti(NMe_2)\}_2(\mu\text{-}NMe)_2]$" intermediate, similar to **1** (Scheme 1), and formation of one equivalent of $NHMe_2$ which is retained in the complex.

In an analogous procedure, heating a solution of $[Cp^*Ti(NMe_2)_2Cl]$ in toluene at 135−200°C afforded the compound $[(Cp^*TiCl)_2(\mu\text{-}NMe)_2]$ (**3**) in a yield of 63%. The analytical and spectroscopic data of **3** agree with a dimeric formulation where the Cp* rings appear in a *cis* arrangement, as proposed for **1** (Scheme 1).

In order to explain the formation of the complexes **1**−**3**, we suggest that the thermal decomposition of the compounds $[Cp^*Ti(NR_2)_nCl_{3-n}]$ (R = Et, n = 3; R = Me, n = 2, 3) produces azatitanacyclopropane or imine intermediates similar to those described in the literature for other dialkylamido derivatives.[6] The evolution of these intermediates at high temperatures would give rise to Ti=NR groups; processes which are well-documented for tantalum complexes.[6b][13] However, titanium derivatives with terminal imido ligands are only known in the presence of donor molecules,[14] and in their absence binuclear arrangements with $[Ti_2(\mu\text{-}NR)_2]$ cores are usually found.[15]

The proposed azatitanacyclopropane intermediates were not detected in the case of mononuclear precursors, but fortunately we could isolate and characterise the complex $[Cp^*_3Ti_3(NMe_2)(\mu\text{-}\eta^2\text{-}CH_2NMe)(\mu\text{-}O)_3]$ (**4**) with the imine group bridging two titanium centres, as mentioned above (see Scheme 2). This compound was obtained as a crystalline red solid (63% yield) by heating a toluene solution of the trinuclear oxo derivative $[Cp^*_3Ti_3(NMe_2)_3(\mu\text{-}O)_3]$.

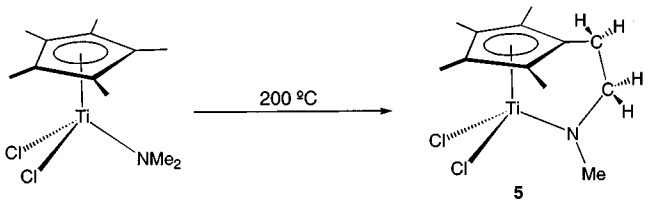
Scheme 2. Thermal evolution of the trinuclear oxo compound $[\{Cp^*Ti(NMe_2)\}_3(\mu\text{-}O)_3]$



The ^{1}H- and ^{13}C-NMR data of **4** show three resonances for the Cp* ligands and one signal for the terminal NMe_2 group, while the signal of the CH_2 moiety of the bridging imine fragment appears as a triplet of quadruplets (δ = 87.9, ^1J = 149.5 Hz, ^3J = 3.7 Hz) in the ^{13}C-NMR spectrum and as an AB spin system (δ = 1.82, 2.86; J_{AB} = 5.9 Hz) in the ^{1}H-NMR spectrum. The formation of this kind of bridging imine groups from an amido ligand has been already reported by Chisholm et al. for the complex $[W_2Cl_3(NMe_2)_2L_2(\mu\text{-}CHCH_2)(\mu\text{-}CH_2NMe)]$.[6e]

Different results than those described above were observed when a [D$_6$]benzene solution of the $[Cp^*Ti(NMe_2)Cl_2]$ derivative was heated above 140°C. Not only did the activation of the amido group take place, but also the activation of the Cp* unit, yielding the compound $[\{\eta^5\text{:}\eta^1\text{-}C_5Me_4CH_2CH_2N(Me)\}TiCl_2]$ (**5**) (see Scheme 3).

Scheme 3. Thermal decomposition of the complex $[Cp^*Ti(NMe_2)Cl_2]$

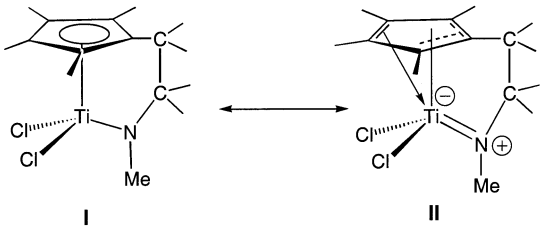


The ^{1}H-NMR spectrum of **5** in $CDCl_3$ shows two resonances for the α- and β-methyl groups of the C_5Me_4 ring [δ = 2.11 (6 H), 2.17 (6 H)] and an AA′BB′K$_3$ spin system [δ = 3.32 (2 H), 4.54 (2 H) and 3.55 (3 H)] assigned to the CH_2CH_2NMe moiety, supporting the hypothesis of C−H activation giving rise to the chelating ligand $[C_5Me_4(CH_2)_2NMe]$. This ligand is linked to the titanium atom via the cyclopentadienyl ring and the amido group in a similar fashion to those reported for the $\{[\eta^5\text{:}\eta^1\text{-}C_5H_4(CH_2)_nNR]MX_2\}$ (M = Ti, Zr) complexes.[16]

The most important features of the ^{13}C-NMR spectrum (see Experimental Section) are the downfield shift (Δδ =

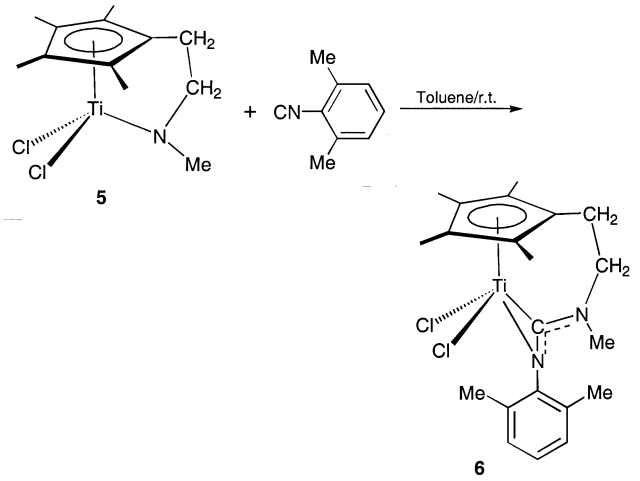
11.3) of the $C_{ipso}CH_2$ resonance (δ = 139.7) with respect to the starting complex [Cp*Ti(NMe_2)Cl_2], and the observation of the CH_2NMe signal at δ = 79.4. These data are best accounted for if a high contribution of the constrained geometry resonance structure **II** depicted in Figure 1 is assumed.

Figure 1. Resonance structures proposed for compound **5**



The addition of excess of 2,6-dimethylphenyl isocyanide to a solution of **5** causes the insertion of one molecule of isocyanide into the Ti−N bond affording the iminocarbamoyl derivative [{η^5:η^2-$C_5Me_4CH_2CH_2N(Me)CN(C_6H_3Me_2)$}$TiCl_2$] (**6**) (Scheme 4).

Scheme 4. Insertion reaction of isocyanide in complex **5**



The complex **6** was obtained as an orange solid, insoluble in hexane, slightly soluble in benzene or toluene, and soluble in chloroform or dichloromethane. The most prominent band in the IR spectrum is the very intense ν_{CN} absorption at 1668 cm^{-1}, in agreement with the insertion of xylyl isocyanide.

In order to confirm the Cp* activation and assess its structural consequences, the molecular structure of this compound was determined by an X-ray diffraction study (see Figure 2). Selected bond lengths and angles of **6** can be found in Table 1. The compound is a monomer with the ligand [$C_5Me_4CH_2CH_2N(Me)CN(C_6H_3Me_2)$] linked to the metal centre through the cyclopentadienyl ring (η^5) and both the carbon and the nitrogen atoms (η^2) of the inserted isocyanide.

The molecule exhibits a four-legged stool geometry for the titanium atom [Cl(1), Cl(2), C(1), N(2)] where the N(2) atom lies down from, and C(1) is shifted up to, the cyclopentadienyl ring due to the side chain [N(1), C(3), C(16)]; this shows a zigzag disposition similar to those found in the complexes [{η^5:η^1-$C_5Me_4CH_2CH_2NMe_2$}CoI_2],[17] [{η^5:η^1-$C_5H_4CH_2CH_2NMe_2$}$Mo(CO)_2I$],[18] and [{η^5:η^2-$C_5H_4CH_2CH_2N(Me)CO$]Re(CO)SePh].[19] The carbon−carbon bond lengths in the cyclopentadienyl ring are in the normal range [1.395(12)−1.420(12) Å]. The methyl groups in the C_5Me_4 fragment are displaced with respect to the metal centre, in particular C(16), which is placed 0.23 Å above the cyclopentadienyl ring plane.

Figure 2. ORTEP drawing of [{η^5:η^2-$C_5Me_4CH_2CH_2N(Me)CN(C_6H_3Me_2)$}$TiCl_2$] (**6**); thermal ellipsoids at a 50% level are shown

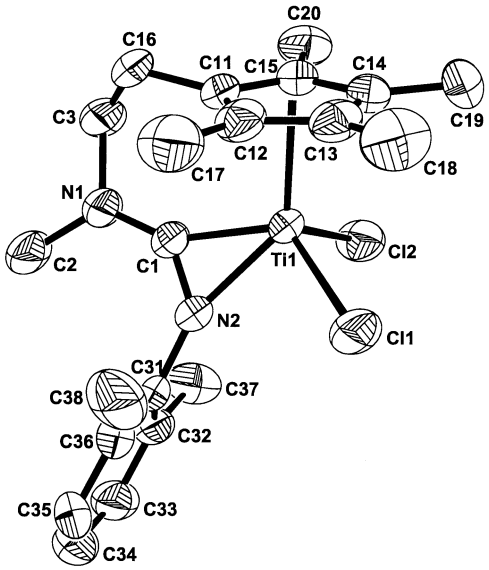


Table 1. Selected bond lengths [Å] and angles [°] for the compound [{η^5:η^2-$C_5Me_4CH_2CH_2N(Me)CN(C_6H_3Me_2)$}$TiCl_2$] (**6**); Cp* and E are the centroids of the cyclopentadienyl ring and the N(2)−C(1) bond, respectively

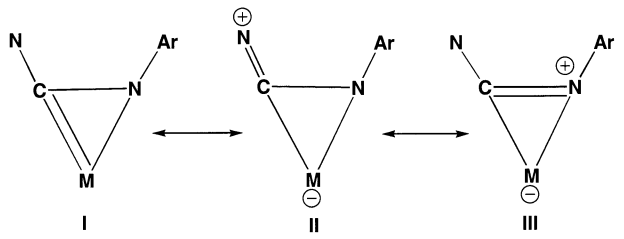
E−Ti(1)−Cl(2)	100.7	Ti(1)−C(1)−N(2)	73.5(5)
Cp*−Ti(1)−Cl(1)	112.7	N(2)−C(1)−N(1)	135.5(8)
Cp*−Ti(1)−Cl(2)	112.5	C(1)−N(1)−C(2)	126.2(7)
Cp*−Ti(1)−N(2)	136.5	C(1)−N(1)−C(3)	115.5(7)
Cp*−Ti(1)−C(1)	105.7	C(2)−N(1)−C(3)	118.3(7)
Cp*−Ti(1)−E	121.8	N(1)−C(3)−C(16)	111.6(8)
N(2)−Ti(1)−Cl(2)	99.3(2)	C(3)−C(16)−C(11)	117.3(8)

The inserted isocyanide has an N(2)−C(1) bond length of 1.284(9) Å, which is consistent with a double bond,[20] while Ti(1)−N(2) [2.047(6) Å] is in agreement with the Ti−N distances found in η^2-iminoacyltitanium complexes,[20b][21] and is very similar to those of [Cp*$_2$Ti^{III}(NMePh)] [2.054(2) Å][22] and [(CO_5)W{C(NMe$_2$)O}TiCp*(NMe$_2$)$_2$] (av. 2.058 Å)[23] where a single bond with absence of multiple bonding is suggested. The Ti(1)−C(1) [2.000(8) Å] distance is not significantly different to that found in the comparable acyl complex [Cp*Ti(η^2-COMe)Cl$_2$] [2.021(6) Å].[24]

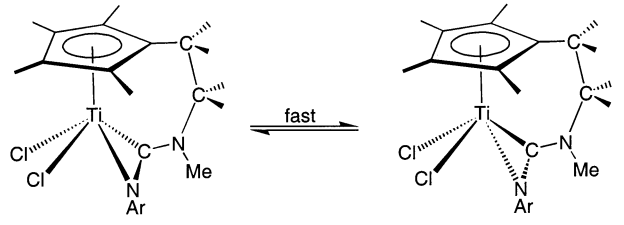
On the other hand, N(1)(sp^2) has a planar environment and its bond length with C(1)(sp^2) [1.316(10) Å] is only slightly longer than the double bond N(2)(sp^2)−C(1)(sp^2) and 0.1 Å shorter than the single bond N(2)(sp^2)−C(31)(sp^2) [1.421(10) Å]. All these data, together with the planarity of the C(3)C(2)N(1)C(1)N(2)C(31)Ti(1) system, are indicative of an extensive π delocalisation along the N(1)C(1)N(2) fragment, while the xylyl group is twisted 80.5(4)° with respect to this fragment. Analogous structural features have been reported in the literature for other η^2-iminocarbamoyl complexes, and are explained by the contribution of the three resonance forms shown in Figure 3.[25]

Figure 3. Resonance forms for the η^2-iminocarbamoyl group in complex **6**



The ^{1}H-NMR spectrum indicates two signals for methyl groups of the C$_5$*Me*$_4$ ring and an AA′BB′K$_3$ spin system for the C*H*$_2$C*H*$_2$N*Me* fragment. The C_s symmetry observed in solution is due to a very fast exchange, on the NMR time scale and even at low temperature, between the two enantiomers present (Figure 4).

Figure 4. The two enantiomers of complex **6**



In the ^{13}C-NMR spectrum we observed a signal at δ = 197.2 associated with the (η^2-iminocarbamoyl)Ti entity and a considerable higher field displacement for the carbon resonances of C_{ipso}CH$_2$ [δ = 123.4, Δδ = δ(**5**) − δ(**6**) = 16.3], N*C*H$_2$ (δ = 56.3, Δδ = 23.1) and CH$_2$N*C*H$_3$ (δ = 35.9, Δδ = 9.8). This spectral behaviour is attributable to the isocyanide insertion into the titanium−nitrogen bond of **5**, the consequent backbone expansion and the π delocalisation proposed for the iminocarbamoyl fragment (structures **I** and **III** in Figure 3).

Conclusions

In our exploration of the thermal decomposition of the titanium complexes [Cp*Ti(NR$_2$)$_n$Cl$_{3-n}$] we have observed the formation of binuclear derivatives with [Ti$_2$(μ-NEt)$_2$] and [Ti(μ-NMe)(μ-N=CH$_2$)Ti] cores, and a mononuclear compound with the interesting methyl activation of the pentamethylcyclopentadienyl ligand. This last observation was definitely confirmed by the characterisation of the complex [{η^5:η^2-C$_5$Me$_4$CH$_2$CH$_2$N(Me)CN(C$_6$H$_3$Me$_2$)}TiCl$_2$], which is one of few examples known of isocyanide insertion into metal−nitrogen bonds. The thermal evolution of the trinuclear oxo compound [{Cp*Ti(NMe$_2$)}$_3$(μ-O)$_3$] seems to be facilitated by a cooperative effect between the metallic centres to form a bridging imine group [−CH$_2$−N(Me)−] supported on a TiO$_2$-like arrangement.

Financial support from the Spanish *DGICYT* (PB93-0476), *CAM* (C198/91) and the *Universidad de Alcalá* (E001/97) is gratefully acknowledged. C. Y. also thanks the *CAM* for a Predoctoral Fellowship.

Experimental Section

All reactions were carried out under argon by Schlenk techniques or in an M. Braun glovebox.[26] Hexane was refluxed over Na/K amalgam, toluene over sodium, and both distilled under argon prior to use. NMR solvents were dried with P_2O_5 (CDCl$_3$) or Na/K amalgam (C$_6$D$_6$) and vacuum-distilled from 4 Å molecular sieves. Oven-dried glassware was repeatedly evacuated with a pumping system (ca. 1×10^{-3} Torr) and subsequently filled with inert gas. 2,6-Me$_2$C$_6$H$_3$NC (FLUKA) was used as received. [Cp*Ti(NR$_2$)$_n$Cl$_{3-n}$] and [{Cp*Ti(NMe$_2$)}$_3$(μ-O)$_3$] were prepared by known procedures.[8] − IR (KBr): Perkin-Elmer 883 spectrophotometer. − ^{1}H and ^{13}C NMR: Varian Unity-300 and/or 500-Plus spectrometer, trace amounts of protonated solvents were used as references, and chemical shifts are reported relative to TMS. − EI MS: 70 eV with a Hewlett-Packard 5988 spectrometer. − Elemental analyses: Heraeus CHN-O-Rapid microanalyzer. − Thermolyses: Roth autoclave model III (300 ml), with heater model 30S (20−300°C) and temperature regulator model DR 500.

*Synthesis of [{Cp*Ti(NEt$_2$)}$_2$(μ-NEt)$_2$]* (**1**): A solution of [Cp*Ti(NEt$_2$)$_3$] (0.55 g, 1.38 mmol) in toluene (20 ml) was transferred via cannula into a Carius tube (40 ml capacity) ready to be sealed by flame in vacuum. This solution was heated at 70°C for 20 d. The Carius tube was opened in a glovebox and the volatiles were removed under vacuum. The oily red solid obtained was dissolved in 15 ml of hexane and cooled overnight at −40°C to afford a red solid which, after several hours under vacuum, was characterised as the complex **1** (0.14 g, 37%). − IR (KBr): $\tilde{\nu}$ = 1439 cm^{-1} s, 1372 s, 1322 m, 1142 m, 1118 s, 1000 s, 875 m, 787 s, 584 s, 508 s, 419 m. − ^{1}H NMR (C$_6$D$_6$, 20°C): δ = 3.85 [q, ^3J = 7.2 Hz, 8 H, N(C*H*$_2$CH$_3$)$_2$], 3.66 [q, ^3J = 7.2 Hz, 4 H, μ-N(C*H*$_2$CH$_3$)], 2.04 (s, 30 H, C$_5$*Me*$_5$), 1.15 [t, 12 H, N(CH$_2$C*H*$_3$)$_2$], 1.11 [t, 6 H, μ-N(CH$_2$C*H*$_3$)]. − ^{13}C{^{1}H} NMR (C$_6$D$_6$, 20°C): δ = 118.3 (*C*$_5$Me$_5$), 55.6 [μ-N(*C*H$_2$CH$_3$)], 50.5 [N(*C*H$_2$CH$_3$)$_2$], 20.3 [(μ-N(CH$_2$*C*H$_3$)], 16.1 [N(CH$_2$*C*H$_3$)$_2$], 12.3 (C$_5$*Me*$_5$). − EI MS (70 eV); *m/z* (%): 523 (3) [M$^+$ − NHEt$_2$], 448 (17) [M$^+$ − 2NHEt$_2$], 313 (7) [M$^+$ − 2 NHEt$_2$ − Cp*]. − C$_{32}$H$_{60}$N$_4$Ti$_2$ (596.65): calcd. C 64.42, H 10.14, N 9.39; found: C 64.00, H 10.24, N 8.42.

*Synthesis of [{Cp*Ti}$_2$(NMe$_2$)(NHMe$_2$)(μ-NMe)(μ-N=CH$_2$)]* (**2**): As for compound **1**, a hexane solution (40 ml) of 1.00 g (3.17 mmol) of [Cp*Ti(NMe$_2$)$_3$] was heated in an autoclave at 150°C for 8 d. The solution was cooled at −40°C for 1 d to yield dark-green crystals of **2**. After washing with hexane (20 ml) and drying under vacuum, 0.52 g (64%) of the complex **2** was isolated. − IR (KBr): $\tilde{\nu}$ = 1437 cm^{-1}s, 1373 s, 1304 m, 1233 m, 1131 s, 1023 m, 930 s, 902 m, 787 s, 638 m, 595 s, 518 s, 460 m, 350 m. − ^{1}H NMR (C$_6$D$_6$, 20°C): δ = 4.54 (s, 3 H, μ-N*Me*), 4.01 (spt, 1 H, N*H*Me$_2$), 3.81 (s, 1 H, NC*H*H), 3.79 (s, 1 H, NCH*H*), 2.22 (br., 3 H, N*Me*Me), 2.05 (br., 3 H, NMe*Me*), 2.04 (s, 15 H, C$_5$*Me*$_5$), 1.94 (s, 15 H, C$_5$*Me*$_5$), 1.70 (d, ^3J = 6.0 Hz, 3 H, NH*Me*Me), 1.61 (d, ^3J = 6.0 Hz, 3 H, NHMe*Me*). − ^{13}C{^{1}H} NMR (C$_6$D$_6$, 20°C): δ = 115.4 and 114.8 (*C*$_5$Me$_5$), 100.8 (N=*C*H$_2$), 50.6 (μ-N*Me*), 44.6 and 42.0 (br. s, N*Me*$_2$), 39.0 and 38.9 (NH*Me*$_2$), 11.5 and 11.3 (C$_5$*Me*$_5$). − EI MS (70 eV); *m/z* (%): 467 (51) [M$^+$ − NHMe$_2$], 448 (29) [M$^+$ − 2 NHMe$_2$]. − C$_{26}$H$_{48}$N$_4$Ti$_2$ (512.49): calcd. C 60.94, H 9.44, N 10.93; found C 61.18, H 9.34, N 10.87.

*Synthesis of [{Cp*TiCl}$_2$(μ-NMe)$_2$]* (**3**): After heating 1.06 g (3.46 mmol) of [Cp*Ti(NMe$_2$)$_2$Cl] in toluene (25 ml) at 200°C for 6 d, the resulting solution was left at room temp. affording a first portion of red crystals of **3**, which were collected by filtration. A second portion of crystals was obtained from the filtrate after cooling at −40°C. The combined yield of the imido complex **3** was 0.54 g (63%). − IR (KBr): $\tilde{\nu}$ = 1488 cm^{-1} m, 1427 s, 1377 s, 1107 vs, 1024 m, 785 vs, 730 m, 581 vs, 521 m, 444 s, 407 m, 357 m, 314 m. − ^{1}H NMR (C$_6$D$_6$, 20°C): δ = 3.41 (s, 6 H, μ-N*Me*), 1.98 (s, 30 H, C$_5$*Me*$_5$). − ^{13}C{^{1}H} NMR (C$_6$D$_6$, 20°C): δ = 124.1 (*C*$_5$Me$_5$), 48.6 (μ-N*Me*), 11.4 (C$_5$*Me*$_5$). − EI MS (70 eV); *m/z* (%): 495 (19) [M$^+$], 465 (100) [M$^+$ − 2 Me], 360 (37) [M$^+$ − Cp*], 330 (52) [M$^+$ − 2 Me − Cp*]. − C$_{22}$H$_{36}$Cl$_2$N$_2$Ti$_2$ (495.25): calcd. C 53.36, H 7.33, N 5.66; found C 53.10, H 7.42, N 5.71.

Synthesis of [{Cp$_3$Ti$_3$(NMe$_2$)(μ-η^2-CH$_2$NMe)}(μ-O)$_3$]* (**4**): In a similar procedure, 1.04 g (1.43 mmol) of [{Cp*Ti(NMe$_2$)}$_3$(μ-O)$_3$] in 70 ml of toluene was heated at 110°C for 17 d to give a dark solution. Red crystals of complex **4** were obtained when the solution was allowed to cool to room temp. Other fractions of the product were collected by concentration to half of the initial volume and cooling at −40°C for 5 d. The combined yield was 0.62 g (63%). − IR (KBr): $\tilde{\nu}$ = 1438 cm^{-1} s, 1372 s, 1235 s, 1172 m, 1074 m, 956 s, 717 vs, 681 s, 645 s, 617 s, 567 m, 402 vs. − ^{1}H NMR (C$_6$D$_6$, 20°C): δ = 2.97 (s, 6 H, N*Me*$_2$), 2.86 and 1.82 (AB spin system, ^2J = 5.9 Hz, 2 H, C*H*$_2$NMe), 2.71 (s, 3 H, CH$_2$N*Me*), 2.01 (s, 15 H, C$_5$*Me*$_5$), 1.98 (s, 15 H, C$_5$*Me*$_5$), 1.91 (s, 15 H, C$_5$*Me*$_5$). − ^{13}C{^{1}H} NMR (C$_6$D$_6$, 20°C): δ = 120.1, 118.7 and 118.5 (*C*$_5$Me$_5$), 87.9 (*C*H$_2$NMe), 48.5 (N*Me*$_2$), 48.2 (CH$_2$N*Me*), 11.7, 11.4 and 11.1 (C$_5$*Me*$_5$). − EI MS (70 eV); *m/z* (%): 639 (9) [M$^+$ − NHMe$_2$], 625 (67) [M$^+$ − NMe$_3$], 611 (90) [M$^+$ − NMe$_2$ − C$_2$H$_5$], 596 (76) [M$^+$ − NHMe$_2$ − NC$_2$H$_5$], 477 (84) [M$^+$ − NMe$_2$ − C$_2$H$_4$ − Cp*], 341 (63) [M$^+$ − NMe$_2$ − C$_2$H$_4$ − 2 Cp*], 206 (58) [M$^+$ − NMe$_2$ − C$_2$H$_4$ − 3 Cp*]. − C$_{34}$H$_{56}$N$_2$O$_3$Ti$_3$ (684.53): calcd. C 59.66, H 8.25, N 4.09; found C 58.83, H 8.19, N 4.09.

Synthesis of [{η^5:η^1-C$_5$Me$_4$CH$_2$CH$_2$NMe}TiCl$_2$] (**5**): Heating for 15 d at 200°C 2.06 g (6.91 mmol) of [Cp*Ti(NMe$_2$)Cl$_2$] in 50 ml of toluene afforded a dark-red solution. The volatiles were removed under vacuum to give a dark red solid. All attempts to obtain a pure fraction of **5** failed and it could be characterised only by NMR spectroscopy. − ^{1}H NMR (C$_6$D$_6$, 20°C): δ = 3.88 (m, 2 H, NC*H*$_2$), 3.37 (m, 3 H, N*Me*), 2.66 (m, 2 H, C$_5$Me$_4$C*H*$_2$), 1.97 (s, 6 H, C$_5$*Me*$_4$), 1.82 (s, 6 H, C$_5$*Me*$_4$). − ^{13}C{^{1}H} NMR (C$_6$D$_6$, 20°C): δ = 139.7, 133.9 and 125.6 (*C*$_5$Me$_4$), 79.4 (NCH$_2$), 45.7 (N*Me*), 24.4 (C$_5$Me$_4$*C*H$_2$), 12.9 and 12.6 (C$_5$*Me*$_4$).

Synthesis of [{η^5:η^2-C$_5$Me$_4$CH$_2$CH$_2$N(Me)CN(C$_6$H$_3$Me$_2$)}TiCl$_2$] (**6**): 0.45 g (3.43 mmol) of 2,6-Me$_2$C$_6$H$_3$NC was added to the solution obtained in the thermal decomposition of 1.00 g (3.35 mmol) of [Cp*Ti(NMe$_2$)Cl$_2$] in 40 ml of toluene. Strong magnetic stirring overnight at room temp., followed by slow deposition during 1 d, afforded an orange powder and a red solution. After filtration, the orange solid was washed with hexane (2 × 20 ml) and dried under vacuum to yield 0.40 g (28% with respect to the initial [Cp*Ti(NMe$_2$)Cl$_2$]) of compound **6**. − IR (KBr): $\tilde{\nu}$ = 3065 cm^{-1} w, 2952 m, 2917 s, 1668 vs, 1587 m, 1467 s, 1422 s, 1378 s, 1326 m, 1238 m, 1206 m, 814 m, 771 s, 679 m, 447 m, 405 m, 379 m, 298 m. − ^{1}H NMR (CDCl$_3$, 20°C): δ = 7.00 (m, 3 H, C$_6$*H*$_3$Me$_2$), 3.82 (m, 2 H, NC*H*$_2$), 3.05 (m, 2 H, C$_5$Me$_4$C*H*$_2$), 2.85 (m, 3 H, N*Me*), 2.18 (s, 6 H, C$_5$*Me*$_4$), 2.04 (s, 6 H, C$_6$H$_3$*Me*$_2$), 1.78 (s, 6 H, C$_5$*Me*$_4$). − ^{13}C{^{1}H} NMR (CDCl$_3$, 20°C): δ = 197.2 (*C*N), 142.9, 132.2, 128.0 and 125.5 (*C*$_6$H$_3$Me$_2$), 128.9, 125.4 and 123.4 (*C*$_5$Me$_4$), 56.3 (N*C*H$_2$), 35.9 (N*Me*), 25.4 (C$_5$Me$_4$*C*H$_2$), 19.5 (C$_6$H$_3$*Me*$_2$), 13.0 and 12.4 (C$_5$*Me*$_4$). − EI MS (70 eV); *m/z* (%): 426 (4) [M$^+$], 295 (17) [{(C$_5$Me$_4$CH$_2$CH$_2$NMe)TiCl$_2$}$^+$], 252 (100) [{(C$_5$Me$_4$CH$_2$)TiCl$_2$}$^+$], 216 (35) [{(C$_5$Me$_3$(CH$_2$)$_2$)TiCl}$^+$].− C$_{21}$H$_{28}$Cl$_2$N$_2$Ti (427.27): calcd. C 59.04, H 6.61, N 6.56; found C 59.20, H 6.37, N 6.93.

X-ray Structure Determination of **6**: An orange block of **6** crystallised from hexane at room temp. and was mounted in a glass capillary in a random orientation on an automatic Enraf-Nonius Cad-4 four-circle diffractometer with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). Crystallographic and experimental details of **6** are summarised in Table 2. Intensities were corrected for Lorentz and polarisation effects in the usual manner. No absorption or extinction corrections were made. Intensity measurements were performed by ω-2θ scans in the range 6° < 2θ < 50°.

Table 2. Crystal and X-ray structural analysis data for the compound [{η^5:η^2-C$_5$Me$_4$CH$_2$CH$_2$N(Me)CN(C$_6$H$_3$Me$_2$)}TiCl$_2$] (**6**)

Empirical formula	$C_{21}H_{28}Cl_2N_2Ti$
Formula weight	427.25
Temperature	293(2) K
Crystal system	orthorhombic
Space group	*Pbca*
a, *b*, *c* [Å]	14.780(3), 16.059(3), 18.356(4)
V [Å^3], *Z*	4357(2), 8
Density (calculated)	1.303 g/cm^3
μ (Mo-K_α)	0.645 mm^{-1}
F(000)	1792
Crystal size	0.38 × 0.35 × 0.19 mm
Index ranges	$0 < h < 17, -19 < k < 0, 0 < l < 21$
Reflections collected	3904
Independent reflections	3834 (R_{int} = 0.0228)
Observed reflections [$I > 2\sigma(I)$]	1924
Data/restraints/parameters	3827/0/235
Goodness-of-fit on F^2	1.029
Final *R* indices [$I > 2\sigma(I)$]	*R*1 = 0.069, *wR*2 = 0.166
R indices (all data)	*R*1 = 0.200, *wR*2 = 0.260
Largest diff. peak and hole	0.382 and −0.377 eÅ^{-3}

The structure was solved by direct methods (SHELXS-90)[27] and refined by least squares against F^2 (SHELXL-93).[28] Of the 3904 measured reflections, 3834 were independent; *R1* = 0.069 and *wR2* = 0.166 [for 1924 reflections with $F > 4\sigma(F)$]. The values of *R1* and *wR2* are defined as $R1 = \Sigma||F_o| - |F_c||/[\Sigma|F_o|]$; $wR2 = \{[\Sigma w(F_o^2$

$- F_c^2)^2]/[\Sigma w(F_o^2)^2]\}^{1/2}$, where $w = 1/[\sigma^2(F_o^2) + (0.114P)^2 + 15.092P]$, $P = (F_o^2 + 2F_c^2)/3$ and σ was obtained from counting statistics. All non-hydrogen atoms were refined anisotropically, and the hydrogen atoms were introduced in the last cycle of refinement from geometrical calculations and refined using a riding model with thermal parameters fixed at $U = 0.08$ Å^2.

Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-101283. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44(0)1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Received April 3, 1998

Keywords: Barium / Zirconium / O ligand / Heterometal alkoxides

Manipulable metal ratios are accessible in a series of heterometal Ba-Zr alkoxides by changing the size and the charge of the ligands. The synthesis and characterisation of four mixed-metal Ba-Zr species $[BaZr_2(OtBu)_{10}]$ (**1**), $[Ba_2Zr(OtBu)_8(tBuOH)(THF)_2]$ (**2**), $[BaZr(OtBu)_6(THF)_2]$ (**3**) and $[BaZr(OH)(OiPr)_5(iPrOH)_3]_2$ (**4**), based on different Ba/Zr stoichiometries, are reported. The molecular structures of **1**, **2**, and **4** have been determined by single-crystal X-ray diffraction studies. **1** exhibits a bow-tie structural motif in which a trigonally distorted six-coordinate barium atom is chelated by two bipyramidal $\{Zr(OtBu)_5\}^-$ units. **2** reveals a triangular "$Ba_2Zr(\mu_3\text{-}OtBu)_2(\mu_2\text{-}OtBu)_3$" core structure formed by the fusion of three octahedra built about two Ba atoms and a Zr atom. The structure is unique in terms of the distribution of terminal ligands at each of the metal centers. One of the barium atoms possesses one –O*t*Bu and one *t*BuOH as terminal ligands, while the terminal ligands on the second barium atom are two THF molecules; the zirconium center bears –O*t*Bu groups as the terminal ligands. Hydrolysis of compound **3** with one equivalent of water, followed by alcoholysis (*i*PrOH) of the resulting product, gave **4**. The structure of **4** shows a planar tetrametallic Ba_2Zr_2 frame capped by two μ_3-hydroxo ligands. The coordination figure of the zirconium atoms resembles a distorted octahedron, whereas the geometry of the barium centers is best described as capped trigonal prisms. Both **3** and **4** are excellent precursors to morphologically pure $BaZrO_3$ ceramic by the sol-gel process.

Interest in metal alkoxides is stimulated by their suitability as useful reagents for chemical synthesis of high-purity oxides and metal oxide/metal composites.[1][2] The insoluble and polymeric nature of simple alkoxides of alkaline earth elements $[M(OR)_2]$[3] limits their direct application in sol-gel techniques, however, solubilisation can be achieved by the addition of transition metal alkoxides [e.g., $Ti(OR)_4$, $Zr(OR)_4$].[4] Although this strategy of forming soluble heterometallic preceramic aggregates is advantageous, particularly in view of the mixed-metal composition of most of the advanced ceramics [e.g., $YBa_2Cu_3O_{7-\delta}$, $MM'O_3$ (M^{IV} = Ti, Zr, Sn; M′ = Ca, Sr, Ba, Pb)], the nature (with regard to the metal stoichiometry) of product(s) formed in such "heterometal solutions" remains ambiguous or poorly characterised.[5] Furthermore, the equilibrium among various heterometal species existing in the solution, and the kinetics of their formation, complicate the precursor chemistry. Since various heterometal combinations are possible due to the structure potential (terminal, μ_2 or μ_3) of the alkoxo ligand,[6] the consequences (e.g., metal segregation, phase inhomogeneity) are encountered during the processing of ceramic material.[5] Of principal interest in this context are heterometal molecules, tailored to the need of the targeted ceramic which in turn requires (i) the development of synthetic and chemical approaches for a precise control over the metal stoichiometry, and (ii) the unequivocal characterisation of molecular precursors as well as the products obtained from their partial hydrolysis reactions (oxo-alkoxides) as they are the real intermediates of a sol-gel process and can therefore reveal how a molecular compound begins to form extended networks. A recent study on the solubility isotherms of $Ba(OR)_2$–$Zr(OR)_4$–ROH (R = Et, *i*Pr) ternary systems reports the formation of various heterobimetallic alkoxides with different Ba/Zr ratios. An oxo-alkoxide of composition $BaZrO(OR)_4 \cdot n(ROH)$ is reportedly formed in the equimolar alcoholic solution of barium and zirconium alkoxides.[2d] To the best of our knowledge, a synthetic approach for a rational control over the Ba/Zr metal stoichiometry has not been described so far.

Results and Discussion

Using $[Ba(OtBu)_2]_n$ and $Zr(OtBu)_4$ as building "bricks", we have synthesised a series of molecular alkoxides with different (1:2, 2:1, 1:1) Ba/Zr stoichiometries. The manipulation of metal ratios in well-defined molecular derivatives provides optimism when looking towards tailor-made molecules and demonstrates the governing role that ligands [alkoxo (OR), oxo (O^{2-}), or neutral (ROH, THF)] can play in anchoring stable mixed-metal clusters. The Ba/Zr derivatives based on 1:1 stoichiometry of the metals have proved to be excellent precursors for clean and selective synthesis (sol-gel) of $BaZrO_3$ ceramic at much lower sintering temperatures than are usually required for the solid-state synthesis.[7]

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1434–1948/98/0909–1327 $ 17.50+.50/0

The reaction (1:2 molar ratio) of $[Ba(OtBu)_2]_n$ with $Zr(OtBu)_4$ in refluxing toluene (Eq. 1) produces a clear pale yellow solution which on cooling (0°C) offers $BaZr_2(OtBu)_{10}$ (**1**) as large transparent crystals (72% yield).

$$1/n\ [Ba(OtBu)_2]_n + 2\ Zr(OtBu)_4 \rightarrow \underset{\mathbf{1}}{BaZr_2(OtBu)_{10}} \quad (1)$$

The analytical data are compatible with the formulation of **1**, and the molecule is found to be monomeric in benzene (cryoscopy). The NMR data are deceptively simple and only a single set of ligand resonances is observed in the room-temperature ^{1}H- and ^{13}C-NMR spectra in contrast to the solid-state NMR spectrum (vide infra). The low-temperature NMR studies ([D_8]toluene) show **1** to be highly fluxional and the intramolecular ligand rearrangements or site exchange processes, causing equivalence (on an NMR time scale) of all 10 O*t*Bu groups could not be frozen out, even at −80°C. **1** is stable up to 200°C/10^{-2} Torr; at higher temperatures (> 230°C) partial decomposition was observed with $Zr(OtBu)_4$ as the only volatile material.

The result of the single crystal X-ray diffraction analysis of $BaZr_2(OtBu)_{10}$, including the numbering system, is shown in Figure 1a, and the pertinent bond lengths and angles are compiled in Table 1. The central barium atom, encapsulated by six bridging (μ_2-)O*t*Bu groups of two tridentate monoanionic $[Zr(OtBu)_5]^-$ units, is present in a trigonally distorted octahedral geometry. The crystallographically inequivalent Zr centers [Zr(1) and Zr(2)] are present in distorted trigonal bipyramidal environments. With respect to Ba−O distances (Table 1) in the molecule (Figure 1a), the two $[Zr(OtBu)_5]^-$ units are coordinated to Ba^{2+} in an asymmetric fashion. The Ba−O distances clearly fall in three ranges [Ba−O(1) = 2.651(3), Ba−O(6) = 2.656(3); Ba−O(8) = 2.768(3), Ba−O(3) = 2.806(3); Ba−O(2) = 2.947(3), Ba−O(7) = 2.965(3) Å] and the barium coordination sphere can be precisely defined as "2 + 2 + 2". The Ba−O(1) and Ba−O(6) distances are significantly shorter than the remaining four Ba−O contacts, and in a "building block" approach, the architecture of **1** can also be described as an interaction of two tetrahedral $Zr(OtBu)_4$ moieties with a bent O(1)−Ba−O(6) unit. The terminal (av. 1.951 Å) and bridging (av. 2.064 Å) Zr−O distances are comparable with those observed in $[KZr(OtBu)_5]_2$.[8] To our knowledge, **1** reveals a structural type unprecedented among metal alkoxides, however, the $BaZr_2O_6$ core in **1** is comparable with the molecular structures of $[M(\mu_2\text{-}OtBu)_3M'(\mu_2\text{-}OtBu)_3M]$ (M = Ge^{I}, Sn^{II}, Pb^{II}; M′ = Mg, Ca, Sr, Ba or Pb) alkoxide derivatives.[9] However, in contrast to the linear arrray of metallic elements in $M'M_2(OtBu)_6$ compounds, the Zr···Ba···Zr arrangement in **1** is bent (149.61°) due to the violation of the three-fold symmetry of $Zr(OtBu)_5^-$ units and as an effect of the two different orientations of the ZrO_5 bipyramids, with respect to the central BaO_6 unit. An interesting influence of the alkoxide steric profile on the structural type (resulting from same metal stoichiometry) is observed on comparing **1** with the corresponding isopropoxy derivative $[BaZr_2(OiPr)_{10}]_2$[4b]; whereas **1** is monomeric and displays a bow-tie structural motif with a slightly bent arrangement of metal atoms, $[BaZr_2(OiPr)_{10}]_2$ is dimeric and the metallic elements form a closed triangular structure. The relative and total intensities of the signals in the ^{13}C CP-MAS/NMR spectrum of **1** (Figure 1b) corroborates the observed solid-state structure. A line deconvolution experiment corresponds to the presence of 10 O*t*Bu groups and the observed spectral pattern arises from the accidental overlapping of some of the O*t*Bu groups.

Figure 1a. Ball-and-stick representaion of the molecular structure of **1** with selected atom labelling; hydrogen atoms of the *tert*-butyl moieties are omitted for clarity

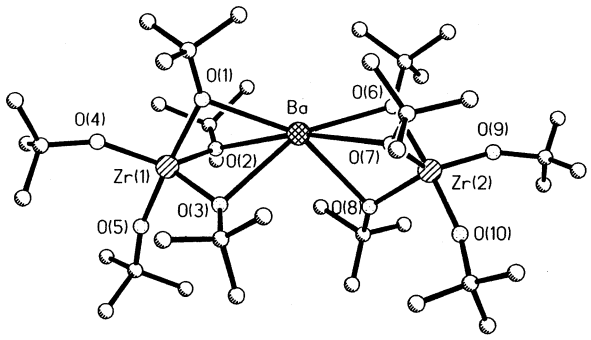

Figure 1b. Solid-state ^{13}C CP-MAS NMR spectrum of **1**

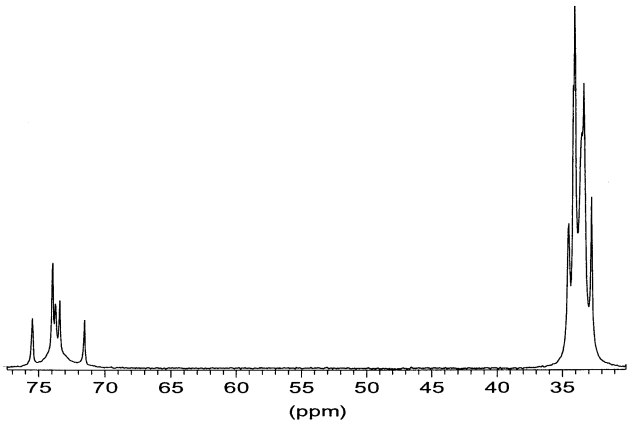

Table 1. Selected bond lengths [Å] and angles [°] of compound **1**

Ba−O(1)	2.651(3)	Ba−O(2)	2.947(3)
Ba−O(3)	2.806(3)	Ba−O(6)	2.656(3)

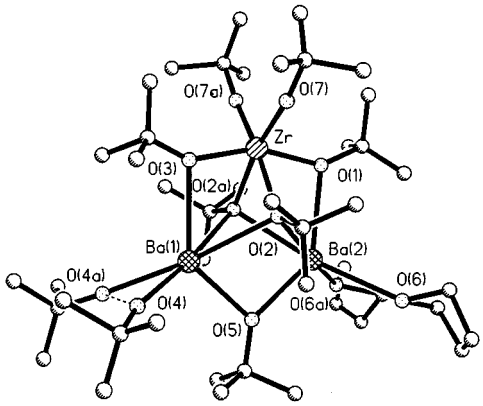
In order to investigate the nature of product formed by reversing the metal ratios in **1**, two equivalents of $[Ba(OtBu)_2]_n$, dissolved in a THF/*t*BuOH mixture were treated with $Zr(OtBu)_4$ (1 equiv.) to obtain $Ba_2Zr(OtBu)_8$(*t*-

BuOH)$(THF)_2$ (**2**) in a yield of 45% (Eq. 2). Compound **2** is readily soluble in benzene, toluene, and chloroform.

$$2/n\,[Ba(OtBu)_2]_n + Zr(OtBu)_4 + tBuOH + 2\,THF \rightarrow \underset{\mathbf{2}}{Ba_2Zr(OtBu)_8(tBuOH)(THF)_2} \quad (2)$$

The room-temperature ^{1}H-NMR spectrum exhibits two resonances for *tert*-butyl protons in a 4:5 integration ratio. The presence of the alcoholic proton is discerned from the NMR signal observed at $\delta = 4.31$ and a broad IR band at 3160 cm^{-1} (ν OH) indicating an R(M)−O···H−OR bonding.[10] The THF chemical shifts are observed in the region typical for THF molecules coordinated to metal centers. To probe the persistence of solid-state structure (Figure 2) in solution, low-temperature NMR studies were performed on a [D_8]toluene solution of **2**. The methyl signal intensities decoalesce on lowering the temperature and the best resolved spectrum at −30°C displays four sharp resonances in an intensity ratio of 4:2:1:2. This spectral pattern is characteristically observed for heterometal systems containing the triangulo-$MM'_2(OR)_9$ unit,[4][11] which in case of **2** can be assigned to the "$ZrBa_2(OtBu)_8(tBuOH)$" substructure, if the *tert*-butyl resonances of the alcohol ligand overlaps with the resonances of three terminal alkoxo ligands present at Ba and Zr centers. These findings are supported by the ^{13}C-NMR spectrum (−30°C) which exhibits four resonances each for methyl and tertiary carbon atoms.

Figure 2. Ball-and-stick drawing of the molecular structure of **2**; hydrogen atoms are not drawn for clarity; the dotted line represents the hydrogen bonding between O4 and O4′



The X-ray study established compound **2** to be $Ba_2Zr(OtBu)_8(tBuOH)(THF)_2$ as depicted in Figure 2. The structure is comprised of a trimetallic framework which, although common among $MM'_2(OR)_x$ alkoxides[12], is worthy of special note due to the unique ligand (terminal) environments of the metal centers and the inequivalence of the two barium atoms. One of the barium atoms [Ba(1)] achieves an octahedral environment by adding an alcohol (*t*BuOH) ligand, whereas the coordination sphere of Ba(2) is completed by two THF molecules. In contrast to **1**, the zirconium atom in **2** is surrounded by six O*t*Bu groups. The molecule possesses a crystallographic mirror plane passing through the metal atoms and the three doubly bridging oxygen atoms [O(1), O(3), and O(5)]. Owing to the much larger size of Ba^{2+} (1.34 Å) compared to Zr^{IV}, the triangular Ba_2Zr core exhibits a long Ba···Ba [3.8617(15) Å] nonbonding contact; the Ba···Zr distances [3.7165(19) Å) and 3.7109(18) Å] are almost symmetrical. In view of the published data on other related compounds,[13] the terminal Ba−O bond lengths clearly allow the distinction of metal−ligand distances; the Ba−O(THF) distances (av. 2.831 Å) being significantly longer than the Ba−O(terminal) bond lengths involving alkoxo or alcohol ligands (av. 2.565 Å). Among the triply bridging (μ_3-)oxygen atoms, O(2) [O(2a)] binds strongly to Ba(2) center [2.687(8) Å] in comparison to Ba(1) [2.740(8) Å]. Although the hydroxylic hydrogen atom could not be located crystallographically, an intramolecular hydrogen bond is evident in the short O(4)···O(4a) (2.471 Å) contact [cf. O(6)···O(6a) = 3.589 Å; O(7)···O(7a) = 2.989 Å]. Furthermore, **2** shows no significant intermolecular contacts of oxygen atoms to other oxygen or metal atoms (> 4 Å) in the crystal as would be the case for intermolecular hydrogen bonding. The Zr−O distances (Table 2) follow the trend: Zr−OR(terminal) (av. = 1.998 Å) < Zr−μ_2-(OR) (av. = 2.105 Å) < Zr−μ_3-(OR) (av. = 2.245 Å). Curiously, the doubly bridging (μ_2-)Ba−O bond lengths (av. = 2.768 Å) are longer than the triply bridging (μ_3-)Ba−O distances (av. = 2.706 Å) which, in analogy to **1**, could lead to the conceptual fragmentation of **2** into neutral building units, $Zr(OtBu)_4$ and $(tBuOH)(OtBu)Ba(\mu_2\text{-}OtBu)_3Ba(THF)_2$. Apparently, the coordinating solvents employed in the synthesis of **2** effectively change the degree of aggregation of $[Ba(OtBu)_2]_n$ which seems to alter its Lewis acid-base reaction with $Zr(OtBu)_4$ to form **2** (Figure 2). Interestingly, the reaction (2:1 molar ratio) of Ba and Zr *tert*-butoxides in the absence of donor solvents produces only $BaZr_2(OtBu)_{10}$ (**1**) as the soluble species, leaving 1.5 equiv. of Ba alkoxide unreacted, which further supports the preceding argument.

The successful switching of metal ratios from $BaZr_2$ (**1**) to Ba_2Zr (**2**) prompted us to explore a molecule with a Ba/

Zr stoichiometry of 1:1 which could act as a model precursor to $MM'O_3$ ceramics. A solution of $Ba(OtBu)_2$ in THF was treated with one equivalent of $Zr(OtBu)_4$ and the reaction mixture was heated. The clear solution was concentrated in vacuo and cooled (−30°C) to obtain colorless crystals of analytical composition $BaZr(OtBu)_6(THF)_2$ (**3**) in 65% yield (Eq. 3a). The ^{1}H-NMR spectrum of **3** displays at room temperature a single resonance for the methyl protons of O*t*Bu groups which integrates approximately 6:2 with the resonances corresponding to the two coordinated THF molecules. The ^{13}C-NMR spectrum also shows a single ligand environment. Structurally diagnostic spectra could not be obtained until −73°C. **3** rapidly looses the crystallinity upon removal of the mother liquor, even under a cold stream of nitrogen which precluded a single crystal X-ray diffraction study.

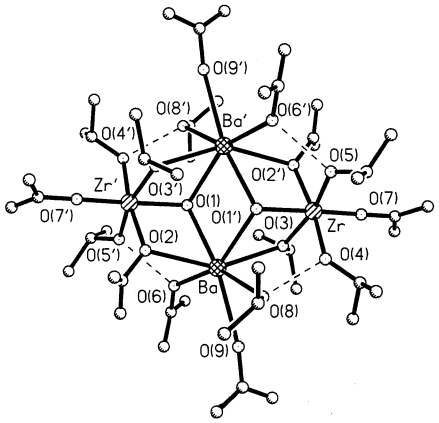
$$1/n\ [Ba(OtBu)_2]_n + Zr(OtBu)_4 + 2\ THF \rightarrow \underset{\mathbf{3}}{1/m\ [\{BaZr(OtBu)_6\}\cdot 2\ THF]_m} \quad (3a)$$

$$\mathbf{3} + H_2O + 6i\text{PrOH} \rightarrow \underset{\mathbf{4}}{[BaZr(OH)(OiPr)_5(i\text{PrOH})_3]_2} + 6\ t\text{BuOH} + 2\ THF \quad (3b)$$

Heterometal aggregates supported by oxo- or hydroxo-assembling ligands are intermediates to oxide ceramics and their characterisation is likely to feature the inital steps of sol-gel chemistry. The hydrolysis of **3** with one equivalent of water followed by alcoholysis with 2-propanol (see Experimental Section) offered $[BaZr(OH)(OiPr)_5(i\text{PrOH})_3]_2$ (**4**) in a high yield (70%) (Eq. 3b). The room-temperature spectra (^{1}H and ^{13}C NMR) of **4** are too complex to be diagnostic. The ^{1}H-NMR spectrum displays several closely associated doublets for the *gem*-dimethyl protons; the methine protons are observed as two multiplets formed by various overlapping septuplets. A similar spectral pattern is observed in the ^{13}C-NMR spectra (solution and solid-state CP MAS). The presence of hydroxylic groups in **4** is established by the intense ν(OH) band (3340 cm^{-1}) observed in both the solution ($CDCl_3$) and the solid-state IR spectra and is corroborated by the ^{1}H-NMR observation (δ = 4.65). The spectral pattern of **4** remains complex even at low temperature (−40°C), however, a downfield migration of −OH chemical shift is observed on decreasing the temperature. Thus, the fate of compound **4** in solution can not be discerned from the available data.

The solid-state structure of $[BaZr(OH)(OiPr)_5(i\text{PrOH})_3]_2$ (**4**) reveals a tetranuclear cluster (Figure 3) where the four metal atoms are coplanar due to the requirements of the crystallographic inversion center. The gross structural features of the oxo-metalate framework in **4** are comparable with other compounds adopting an M_4O_{16} edge-shared octahedral arrangement [e.g., $Ti_4(OEt)_{16}$,[14] $W_4(OEt)_{16}$[15]], however, the solvating 2-propanol molecules in **4** provide different coordination numbers to Ba and Zr centers. The Zr atoms are present at the center of slightly distorted octahedra, whereas Ba centers (being seven-coordinate) display a trigonal-prismatic face-capped geometry. The

Figure 3. Ball-and-stick drawing of the molecular structure of **4**; hydrogen atoms are not drawn for clarity



$Ba_2Zr_2O_6$ core is built up from two analogous *seco*-norcubane units fused along one face defined by two barium atoms and two oxygen atoms of the hydroxo groups. A similar face-capping arrangement of hydroxo ligand against a planar tetrametallic (M_4) frame has been observed in $[Eu_4(OC_6H_3iPr_2\text{-}2,6)_6(OH)_2(NCMe)_6]$[16] and $[Nd_4(\mu_3\text{-}OH)_2(\mu_2,\mu_1\text{-}acac)_6(acac)_4]$.[17] Whereas the doubly bridging oxygen atoms [O(2) and O(3)] are nearly planar (sum of angles = av. 356.61°), the angles around O(1) sum to 316.64° (see Table 3) accounting for a tetrahedral geometry (sp^3 hybridisation) that support the assignment of O(1) [O(1a)] as a μ_3-hydroxo ligand. The expected dispersion of metal−oxygen bond lengths [M−μ_3-OR > M−μ_2-OR > M−O(terminal)] is found in ZrO_6 polyhedron with Zr−O (terminal) distances (av. 2.048 Å) being the smallest [cf. Zr−O (terminal) in $Zr_2(OiPr)_8(i\text{PrOH})_2$ = 1.984 Å].[10b] On the contrary, all the terminal Ba−O distances in **4**, are extremely large (av. 2.836 Å) which can be understood in terms of much reduced donor capacity of the alcohol (ROH) in comparison to the alkoxo (RO^-) ligand. Out of the three terminal alcohol ligands at barium [O(6), O(8), and O(9)], O(6) and O(8) are involved in an intramolecular hydrogen bonding with the terminal alkoxo ligands [O(5) and O(4)] of neighbouring Zr atoms (Figure 3). The short O(5)···O(6′) (2.664 Å) and O(4)···O(8) (2.614 Å) separations, together with the bent orientation (away from the O···O vector) of −*i*Pr fragments, is in accord with the proposed hydrogen bonding.

The authors gratefully acknowledge the continuing support of the *Deutsche Forschungsgemeinschaft* under the framework of research programme SFB-277. Authors also thank Dr. *Michael Zimmer* for recording the solid-state ^{13}C CP-MAS NMR spectra. S. M. thanks the *Alexander von Humboldt Foundation* (Germany) for a research fellowship.

Experimental Section

General: All operations were carried out under a dry nitrogen with rigorous exclusion of oxygen and moisture. Tertiary butyl alcohol was dried by distillation from potassium metal and aluminium *tert*-butoxide. All other solvents were distilled from Na/K alloy or $LiAlH_4$, prior to use. $Ba(OtBu)_2$ was prepared by the reac-

tion of barium metal and alcohol in the presence of dry ammonia following a published procedure[18] ($C_8H_{18}BaO_2$: calcd. C 33.88, H 6.39, Ba 48.42; found C 33.01, H 6.43, Ba 48.52). $Zr(OtBu)_4$ was obtained by the alcoholysis of $Zr(NEt_2)_4$ which was synthesised following the literature method.[19] − ^1H and $^{13}C\{^1H\}$ NMR: Bruker AC-200 spectrometer and chemical shifts referenced to residual solvent peaks. − ^{13}C CP-MAS NMR: Bruker MSL 200S spectrometer. − IR: Bio-Rad FTS-165 spectrometer. − Elemental analyses: LECO CHN 900 elemental analyser. Established analytical procedures were used to determine the metal contents in the new derivatives.

Synthesis of [$BaZr_2(OtBu)_{10}$] (**1**): $Zr(OtBu)_4$ (4.45 g; 11.59 mmol) in toluene (15 ml) was added to a slurry of $Ba(OtBu)_2$ (1.64 g; 5.78 mmol) in toluene. The clear solution obtained after the dissolution of $Ba(OtBu)_2$ was refluxed (16 h) and cooled at 0°C for 24 h, whereupon colourless crystals of **1** were formed (4.36 g; 72%). − ^1H NMR (C_7D_8, 20°C): δ = 1.51 (CH_3). − ^{13}C NMR (C_7D_8, 20°C): δ = 32.88 (CH_3); 73.12 (CMe_3). − ^{13}C CP-MAS NMR: δ = 32.74, 33.32 33.50, 34.02 34.14, 34.49 (CH_3); 71.51, 73.37, 73.72, 73.89, 75.47 (CMe_3). − MW: calcd. 1069; found 1051. − $C_{40}H_{90}BaO_{10}Zr_2$: calcd. C 45.71, H 8.29, Ba 13.06, Zr 17.36; found C 45.37, H 8.29, Ba 12.95, Zr 17.05.

Synthesis of [$Ba_2Zr(OtBu)_8(tBuOH)(THF)_2$] (**2**): To $Ba(OtBu)_2$ (1.08 g; 3.80 mmol), dissolved in a mixture of *tert*-butyl alcohol (5 ml) and THF (30 ml), was added $Zr(OtBu)_4$ (0.74 g; 1.93 mmol) in 30 ml of hexane. The reaction mixture was stirred overnight at 50°C. The clear pale yellow solution obtained was reduced to one fourth and left at ambient temperature. Colourless cubes of $Ba_2Zr(OtBu)_8(tBuOH)(THF)_2$ (**2**) grew over a period of two weeks. Yield: 0.98 g [45% based on $Zr(OtBu)_4$]. − ^1H NMR (C_7D_8, 20°C): δ = 1.35 [$HOC(CH_3)_3$ + CH_3]; 1.56, 1.84 (CH_3); 1.47 (OCH_2CH_2); 3.57 (OCH_2CH_2); 3.35 (OH). − ^1H NMR (C_7D_8, −30°C): δ = 1.40, 1.66, 1.73, 1.75 (CH_3); 1.42 (OCH_2CH_2); 3.52 (OCH_2CH_2). − ^{13}C NMR (C_7D_8, −30°C): δ = 25.74 (OCH_2CH_2); 33.20, 34.72, 35.01, 35.57 (CH_3); 67.94 (OCH_2CH_2); 69.19, 70.76, 71.89, 75.18 (CMe_3). − $C_{44}H_{128}Ba_2O_{11}Zr$: calcd. C 45.39, H 11.07, Ba 23.59, Zr 7.83; found C 45.08, H 10.85, Ba 23.18, Zr 7.70.

Synthesis of [$BaZr(OtBu)_6(THF)_2$] (**3**): To $Ba(OtBu)_2$ (1.78 g; 6.27 mmol) in THF (40 ml) was added $Zr(OtBu)_4$ (2.42 g; 6.30 mmol) and the resulting mixture was stirred at 50°C for 16 h. The sticky solid obtained after the removal of volatiles in vacuo was dissolved in a minimum amount of THF and cooled (−30°C) to yield $BaZr(OtBu)_6(THF)_2$ (**3**) as a crystalline material which turned into a waxy solid, on removing the mother liquor. Yield: 3.22 g [63% based on $Zr(OtBu)_4$]. − ^1H NMR (C_7D_8, 20°C): δ = 1.48 (CH_3), 1.44 (OCH_2CH_2), 3.60 (OCH_2CH_2). − ^{13}C NMR (C_7D_8, 20° C): δ = 25.19 (OCH_2CH_2), 32.95 (CH_3), 67.61 (OCH_2CH_2), 73.08 (CMe_3). − $C_{32}H_{70}BaO_8Zr$: calcd. Ba 16.92, Zr 11.24; found Ba 16.47, Zr 11.30.

[$BaZr(OtBu)_6$]$_n$: Obtained by prolonged pumping of **3** in vacuo at 50°C. − ^1H NMR (C_6D_6, 20°C): δ = 1.50 (CH_3). − ^{13}C NMR (C_6D_6, 20°C): δ = 32.95 (CH_3), 73.08 (CMe_3).

Synthesis of [BaZr(OH)(OiPr)$_5$(iPrOH)$_3$]$_2$ (**4**): To a THF (50 ml) solution of 1.67 g (2.50 mmol) of [BaZr(O*t*Bu)$_6$]$_n$, 2.5 mmol solution of water in THF (20 ml) was added dropwise. The workup of the reaction mixture gave a pasty mass poorly soluble in non-polar solvents even on heating and in the presence of *t*BuOH, however, it readily dissolved in hot 2-propanol to give a clear solution. 2-Propanol was pumped off and the resulting solid was redissolved in a minimum amount of *i*PrOH. Large colourless cubes of [BaZr(OH)(O*i*Pr)$_5$(*i*PrOH)$_3$]$_2$ (**4**) were formed after 2 d. Yield: 1.26 g {70%, based on the initial amount of [BaZr(O*t*Bu)$_6$]$_n$}. – ^{1}H NMR ($CDCl_3$, 20°C): δ = 1.16, 1.17, 1.24, 1.27, 1.29, 1.43, 1.50 (C*H*$_3$); 4.43, 4.74 (C*H*); 4.65 (O*H*). – ^{13}C NMR ($CDCl_3$, 20°C): δ = 26.12, 27.10, 27.37, 27.49, 27.60, 27.75, 28.27, 28.38, 28.52 (*C*H$_3$); 66.66, 68.28, 68.78, 69.45, 70.03, 71.17, 71.33, 71.52, 71.76, 71.97 (*C*H). – ^{13}C CP-MAS NMR: δ = 27.22, 27.68, 28.15 (*C*H$_3$); 63.37, 63.60, 67.44, 68.43, 69.19, 69.60, 70.00, 70.82 (*C*H). – $C_{24}H_{60}BaO_9Zr$: calcd.C 39.96, H 8.37, Ba 19.04, Zr 12.64; found C 39.22, H 8.13, Ba 18.79, Zr 12.40.

Crystallography: Monocrystalline specimens were selected from the bulk samples of compounds **1**, **2**, and **4** and sealed in Lindemann capillaries of appropriate dimensions, under inert gas. Crystal data and structure refinement parameters are given in Table 4. Diffraction data were collected with Stoe AED 2 (**1** and **2**) and Stoe IPDS (**4**) diffractometers. The intensities were corrected for Lorentz and polarisation factors, and a semi-empirical absorption correction (ψ scans) was applied for **1** and **2**. The structures were solved by direct methods (SHELXS-86)[20a] and refined by full-matrix least-squares procedures on all F^2 values (SHELXS-97).[20b] All non-hydrogen atoms were refined anisotropically. The two hydroxylic protons in **4** were located by difference Fourier techniques and were refined together with the geometrically fixed hydrogen atoms. Crystallographic data for the structure(s) reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no CCDC-101435. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: int. code + 44(1223)336-033; E-mail: deposit@ccdc.cam.ac.uk].

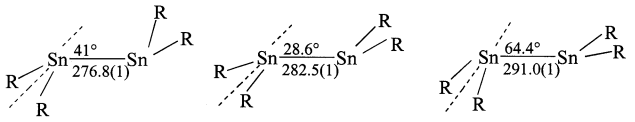
Keywords: Tin / Silicon / Chalcogens / Cluster compounds

Reaction of tin(II) chloride with RNa(THF)$_2$ (R = tBu$_3$Si) in THF at –30 °C led to a complex reaction mixture, from which the compounds $R_4Sn_4(THF)_2$, R_2SnSnR_2 (**5**), R–R (**7**), and a brownish black compound **6** were isolated. In toluene as solvent, the zwitterionic distannene **5** was obtained together with **7** and **6** which upon treatment with Et_3PX, furnished the cluster compounds $(RSnX)_4$ (**10**: X = Se; **11**: X = Te). The X-ray structure analyses of the isotypic compounds **10** and **11** revealed that the tin atoms occupy the corners of an undistorted tetrahedron with weak tin–tin interactions. The chalcogen atoms form a plane which bisects the Sn_4 tetrahedron.

Lappert's distannene **1** was the first molecule with a formal homonuclear double bond between the heavier elements of group 14 to be prepared.[2][3] Although compound **1** was prepared in 1976 and characterized by X-ray crystallography almost twenty years passed before the compounds **2**[4] and **3**[5] could be isolated as further examples of this class of compound.

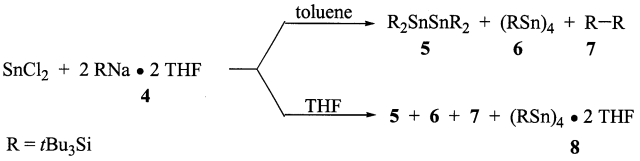


1, R = CH(SiMe$_3$)$_2$ **2**, R = Si(SiMe$_3$)$_3$ **3**, R = 2-tBu-4,5,6-Me$_3$C$_6$H

The three crystalline distannenes possess widely differing structures. While the centrosymmetrical compound **1** exhibits an undistorted *trans*-bent arrangement of its substituents with a fold angle of 41° – which closely approaches the theoretically predicted fold angles of 46–51° for the parent compound $[Sn_2H_4]$[3][5] – the sterically overloaded compound **2** avoids interactions between its substituents by adopting a twist angle of 63.2° and a fold angle of 28.6°.[4] The behavior of compound **3** is even more surprising. The markedly lengthened tin–tin bond length and the differing environments of the two tin atoms possibly suggest that merely an interaction between the fully occupied 5s orbital of one tin atom with the empty 5p orbital of the other tin atom is operative. The zwitterionic structure of **3** that could be deduced from this assumption, however, is not supported by the ^{119}Sn CP-MAS NMR spectrum in which only one signal at δ_{iso} = 819 is observed.[6] Similar to **1**, the recently described heteroleptic distannene RR′Sn=SnRR′ [R = Si(SiMe$_3$)$_3$, R′ = 2,4,6-(CF$_3$)$_3$C$_6$H$_2$] exhibits a centrosymmetric structure with an Sn–Sn bond length of 283.3(1) pm and a fold angle of 41.5°.[7]

The distannenes **1**–**3** decompose in solution to the respective stannylene molecules R_2Sn:. We have now examined whether a distannene that is stable both in the solid state and in solution can be obtained by use of other substituents R. Our first choice of substituent was the tri-*tert*-butylsilyl group with its extremely high steric requirements for which we reported a simple access more than 20 years ago[8] and which in the mean time has been used successfully by Wiberg et al. in the syntheses of many interesting compounds including the tetrahedral molecules $(RSi)_4$ and $(RGe)_4$.[9]

We now report on a zwitterionic distannene as well as a tin cluster compound for which, however, characterization was only possible on the basis of the products of subsequent reactions.

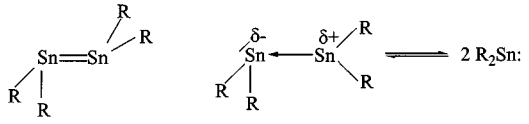


Reaction of tin(II) chloride with the tri-*tert*-butylsilylsodium · THF adduct **4**[10] in toluene furnished a black-brown

[◇] Part 24: Ref.[1].

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1434–1948/98/0909–1333 $ 17.50+.50/0

solution from which three products were isolated by fractional crystallization. First of all, a black-brown, finely crystalline precipitate was obtained but its constitution could not be determined neither by analytical nor spectroscopic means, an account of its poor solubility and extreme sensitivity to air. Only the subsequent reactions described below allowed conclusions to be drawn about the structure of this compound **6**. Colorless needles of the known hexa-*tert*-butyldisilane (**7**)[11] were obtained as a second fraction. Finally, upon longer standing of the solution at −25°C, dark brown, fibrous crystals separated, complete elemental analysis data of which are indicative of the distannene **5** or the corresponding stannylene R_2Sn:.



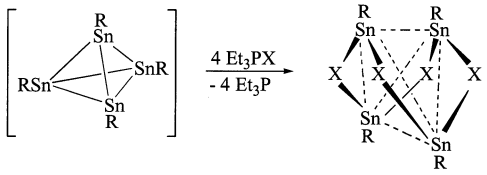
5a, R = *t*Bu$_3$Si **5b** **9**

Since we have not yet been able to obtain crystals of **5** suitable for X-ray diffraction analysis, its structural elucidation is based on NMR examinations of all nuclei present in **5** (C, H, Si, Sn). The presence of two singlet signals of equal intensity in the ^{1}H-NMR spectrum as well as the presence of two signals each for the primary and quaternary carbon atoms in the ^{13}C-NMR spectrum clearly show that two sorts of differently bonded *tert*-butyl groups are present. This is supported by the observation of two signals with different $^1J(^{29}Si,^{119}Sn)$ coupling constants in the ^{29}Si-NMR spectrum. Unambiguous information about the structure of **5** is provided by the ^{119}Sn-NMR spectrum in which two signals with chemical shifts of $\delta = -690$ and $+413$ and a coupling constant of $^1J(^{119}Sn,^{117}Sn) = 2135$ Hz demonstrate the presence of two tin atoms bonded to each other but having widely differing electronic environments.

It would seem that neither the stannylene **9** nor the centrosymmetric distannene **5a** exists in the solution. The data rather support the zwitterionic structure **5b** with the tin atom producing the ^{119}Sn signal shifted to low field acting as an electron donor from its doubly occupied 5s orbital to the unoccupied 5p orbital of the electron-accepting tin atom giving rise to the ^{119}Sn-NMR signal shifted to high field. An adduct of tin(II) chloride and a four-coordinated stannylene was recently reported;[12] the X-ray crystallographic analysis and ^{119}Sn-NMR spectrum of this adduct are, in spite of the different bonding partners and coordination numbers, suggestive of a bonding situation similar to that in **5b**.

The behavior of **5** as well as that of the $SnCl_2$ adduct is not self-evident since the distannenes **1**,[13] **2**,[4] and **3**[6] – which are stable in the solid state – do not give rise to any ^{119}Sn-NMR signals in solution at room temperature. This is assumed to be due in all cases to the rapid equilibrium distannene $\rightleftarrows$ stannylene. In order to determine whether **5** is also subject to a similar equilibrium the molecular mass of **5** was determined in dilute solution (dilution from 4 g/100 ml to 0.6 g/100 ml). The measured value of 520 g · mol^{-1} was in good agreement with the calculated value of 517.5 for the stannylene **9**. The appearance of only one ^{1}H-NMR signal at $\delta = 1.35$ and of two ^{13}C-NMR signals at $\delta = 27.74$ (C_p) and 32.12 (C_q) is a further indication for the equilibrium **5** $\rightleftarrows$ 2 **9**; ^{29}Si-and ^{119}Sn-NMR signals could not be recorded from this dilute solution.

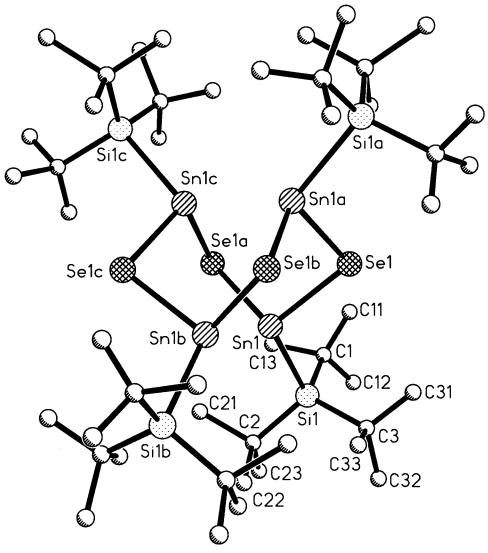
When the reaction of tin(II) chloride with **4** was performed in THF instead of toluene a dark-blue, fine crystalline solid was isolated in addition to compounds **5**–**7**. The analytical and spectroscopic data of this solid are indicative of the THF adduct **8**. However, the broad signals in the ^{1}H-NMR spectrum and the failure to observe ^{29}Si- and ^{119}Sn-NMR signals suggest that, like compounds **1**, **2**, and **3**, rapid exchange processes are in operation. Spectroscopic measurements at lower temperatures did not furnish a different result.



6, R = *t*Bu$_3$Si **10**, X = Se; **11**, X = Te

In order to obtain information about the structure of the practically insoluble and highly sensitive compound **6** we attempted to convert it to better characterizable products by treatment with the heavier chalcogenes. Although no rections with selenium or tellurium were observed, treatment of **6** with triethylphosphane selenide or telluride furnished the compounds **10** or **11**, respectively, in a smooth reaction. NMR data of these products indicate the existence of highly symmetrical molecules.

Figure 1. Molecular structure of **10** in the crystal (hydrogen atoms omitted)[a]

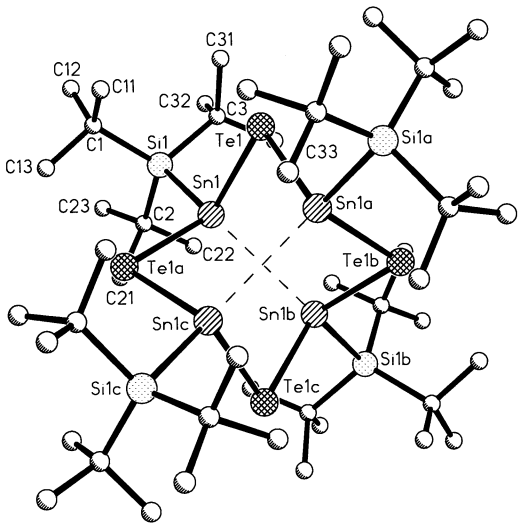


[a] Selected bond lengths [pm] and angles [°]: Sn–Se 255.2(2), Sn–Sn 301.8(3), Sn–Si 265.6(5); Sn–Se–Sn 94.8(1), Se–Sn–Se 101.5(1), Se–Sn–Si 108.0(1), Se–Sn–Sn 100.2(1).

The X-ray crystallographic analysis of **10** (Figure 1) confirmed the deductions from the NMR data and additionally

provided some noteworthy details. In the crystal the asymmetrical unit contains a quarter of the molecule. The equivalent positions are designated by the letters a, b, and c in the figure. Accordingly, the respective Sn−Se, Sn−Si, and also Sn−Sn bond lengths are the same. The structure of **10** is not only unusual but also without precedent in the chemistry of tin chalcogenides. The four tin atoms form an undistorted tetrahedron that is divided into two equal parts by a quadratic layer of selenium atoms. The structure resembles that of the arsenic sulfide mineral realgar in which the arsenic and chalcogen atoms have a similar arrangement.[14] The tin−tin separations of 301.8 pm markedly exceed the normal value of 278 pm for the single bond in the reference substance hexamethylditin.[15] The long tin−tin bonds become reasonable upon simple electron counting. Merely four electrons are available for a total of six Sn−Sn bonds (one from each tin atom) within the tetrahedron so that the existence of a delocalized electron system with bond orders of markedly less than one may be assumed.

Figure 2. Molecular structure of **11** in the crystal (hydrogen atoms omitted)[a]



[a] Selected bond lengths [pm] and angles [°]: Sn−Te 274.2(1), Sn−Sn 328.1(2), Sn−Si 265.2(3); Sn−Te−Sn 95.1, Te−Sn−Te 101.8(1), Te−Sn−Si 109.1(1), Fe−Sn−Sn 100.3(1).

These structural peculiarities are even more pronounced in **11**, which is isotypical with **10** and is shown in a different perspective in Figure 2 in order to emphasize the unusual atomic arrangement. The tin−tin separation in **11** of 328.1(2) pm is even larger than that in **10** and again supports a low bond order for the Sn−Sn bonds.

The isolation of compounds **10** and **11** allows the conclusion, albeit with some reservations, that compound **6** could be a representative of the long sought *tetrahedro*-tetrastannane system and that chalcogen insertion into four of the six Sn−Sn bonds has given rise to these unequivocally characterized cage compounds. Wiberg et al. also obtained a product from similar reactions that they held to be **6** but which could not, on account of its above-mentioned properties, be characterized further.[9][16]

The various products arising from the action of **4** on tin(II) chloride can be most simply explained in terms of the primary formation of the stannylene **9** which either dimerizes to give the zwitterionic distannene **5** or reacts further with cleavage of tBu$_3$Si radicals[9] to furnish **7** and **6** (or **8** in THF). Hexaarylcyclotristannanes also behave similarly: their pyrolyses furnish, by suitable choice of the aryl groups, a wide variety of tin cluster compounds.[17]

Financial support of our work by the *Deutsche Forschungsgemeinschaft* and the *Fonds der Chemischen Industrie* is gratefully acknowledged.

Experimental Section

All manipulations were performed by using standard Schlenk techniques under dry argon. − ^{1}H and ^{13}C NMR: Bruker AM 300. − ^{29}Si and ^{119}Sn NMR (inverse gated, ^{1}H-decoupled, Me$_4$Sn external): Bruker AMX 300. − MS: Varian MAT 212. − Elemental analyses: Analytische Laboratorien, D-51789 Lindlar, Germany.

Reactions of Tin(II) Chloride with **4**: A solution of anhydrous tin(II) chloride (2.11 g, 11.8 mmol) in 25 ml of THF was added dropwise to a solution of **4** (7.70 g, 22.4 mmol) in 50 ml of toluene at −30°C over a period of 3 h with stirring. The brownish black reaction mixture was stirred for an additional 1 h at −20°C and the insoluble compound **6** (0.38 g, 11% yield), m.p. 182°C, was filtered off. The solvents were removed and the residue redissolved in 30 ml of *n*-hexane. Precipitated NaCl was filtered off and the solution cooled to −50°C. After 12 h at this temperature, colorless crystals of **7** (1.0 g, 24% yield) were isolated and identified by comparison with literature data.[11] Concentration of the solution to a volume of 20 ml and cooling at −24°C for 3 d yielded dark brown, fibrous crystals of **5** (1.2 g, 21% yield).

Tetrakis(tri-tert-butylsilyl)distannene (**5**): M.p. 104°C. − ^{1}H NMR (C_6D_6, 25°C): δ = 1.40 [s, 54 H, $^4J(^1H,^{119}Sn)$ = 17.7 Hz], 1.51 [s, 54 H, $^4J(^1H,^{119}Sn)$ = 17.9 Hz]. − ^{13}C NMR (C_6D_6, 25°C): δ = 26.27 (C_q), 28.90 (C_q), 32.42 (C_p), 34.54 (C_p); C_p and C_q refer to primary and quaternary carbon atoms. − ^{29}Si NMR (C_6D_6, 25°C): δ = 24.99 [s, $^1J(^{29}Si,^{13}C)$ = 35 Hz, $^1J(^{29}Si,^{119}Sn)$ = 85.5 Hz], 54.49 [s, $^1J(^{29}Si,^{13}C)$ = 42.1 Hz, $^1J(^{29}Si,^{119}Sn)$ = 11.6 Hz]. − ^{119}Sn NMR (C_6D_6, 25°C): δ = 412.6 [s, $^1J(^{119}Sn,^{117}Sn)$ = 2135 Hz], − 689.9. − MS (CI, isobutane); *m/z* (%): 1037 (1) [MH$^+$], 519 (16) [MH$^+$ − SnR$_2$]. − $C_{48}H_{108}Si_4Sn_2$ (1035.1): calcd. C 55.70, H 10.52, Sn 22.93; found C 55.34, H 10.36, Sn 23.20.

A similar reaction in which toluene was replaced by THF led to the same products in comparable yields. However, in addition to compounds **5**, **6**, and **7**, 0.29 g of the dark blue, microcrystalline compound **8**, m.p. 76°C was isolated.

(tBu$_3$Si)$_4$Sn$_4$(THF)$_2$ (**8**): ^{1}H NMR ([D$_8$]toluene, 243 K): δ = 1.31 (br. s, 54 H), 1.43 (br. s, 54 H), 1.89 (m, 8 H), 3.57 (m, 8 H). − ^{13}C NMR ([D$_8$]toluene, 243 K): δ = 25.84 (C_q), 26.09 (C_q), 31.89 (C_p), 33.16 (C_p). − The ^{29}Si- and ^{119}Sn-NMR signals could not be observed. − $C_{56}H_{124}O_2Si_4Sn_4$ (1179.1): calcd. C 47.48, H 8.82; found C 47.40, H 8.91.

Formation of the Cluster Compound **10**: A solution of triethylphosphane selenide (0.32 g, 1.62 mmol) in 10 ml of *n*-hexane was added dropwise to a suspension of **6** (0.51 g, 0.40 mmol) in 100 ml of toluene at ambient temperature over a period of 30 min. The reaction mixture was stirred for 3 d in the dark. All insoluble components were filtered off and the solvents removed. The residue was redissolved in 10 ml of DME. Cooling of the yellow, light-sensitive solution to −24°C afforded 0.42 g (66% yield) of pale yellow, rectangular crystals of **10**, m.p. 115°C. − ^{1}H NMR (C_6D_6, 25°C): δ = 1.38 (s). − ^{13} C NMR (C_6D_6, 25°C): δ = 31.87 (C_q),

32.48 (C_p). – ^{119}Sn-NMR (C_6D_6, 25°C): δ = 120.21. – MS (CI, isobutane); *m/z* (%): 1112 (8) [$tBu_3Sn_3Se_3$]. – $C_{48}H_{108}Se_4Si_4Sn_4 \cdot 2$ DME (1768.6): calcd. C 38.03, H 7.29; found C 38.80, H 7.43.

Formation of the Cluster Compound **11**: A solution of triethylphosphane telluride (0.98 g, 3.99 mmol) in 10 ml of *n*-hexane was added dropwise to a suspension of **6** (0.80 g, 0.63 mmol) in 60 ml of toluene over a period of 30 min. The reaction mixture was stirred in the dark for 3 d at room temperature. The solvents were removed and the residue was dissolved in 10 ml of *n*-hexane. All insoluble components were filtered off and the remaining red solution was stored for 4 d at 4°C. Excess triethylphosphane telluride was filtered off, the solvent removed and the residue redissolved in 8 ml of DME. Cooling to −24°C for 4 d furnished 0.64 g (57% yield) of air- and light-sensitive red crystals of **11**, m.p. 183°C. – ^{1}H NMR (C_6D_6, 25°C): δ = 1.37 (s). – ^{13}C NMR (C_6D_6, 25°C): δ = 32.03 (C_q), 34.02 (C_p). – ^{119}Sn NMR (C_6D_6, 25°C): between δ = +300 and −500 no signal could be observed. – $C_{48}H_{108}Si_4Sn_4Te_4$ (1782.9): calcd. C 32.34, H 6.11; found C 33.43, H 6.62.

X-ray Structure Analyses of **10 and 11**: Crystal data and numerical data of the structure determinations are given in Table 1. Crystals were obtained by cooling a solution of **10** in diethyl ether to −24°C (**10**) or by cooling a DME solution of **11** to 4°C. In each case, the crystal was mounted in a thin-walled glas capillary. The structures were solved by direct phase determination using the SHELXTL PLUS program system and refined by full-matrix least-squares techniques. Hydrogen atoms were placed in the calculated positions, and all other atoms were refined anisotropically.[18]

The ligand bis(2-benzimidazolyl)propane coordinates to Ni^{II} with chloride as an anion, thereby forming a dinuclear compound with the formula: $[NiCl_2(tbz)_2]_2(C_2H_6O)_2$. This compound crystallizes in the space group $P2_1/c$. Each five-coordinated Ni^{II} ion has a distorted trigonal bipyramidal environment which consist of two asymmetrically bridging Cl anions with distances of 2.3556(17) and 2.4275(16) Å, a terminal Cl anion with a distance of 2.3496(17) Å and two nitrogen atoms of the ligand with distances of 2.022(4) and 2.000(4) Å. The Ni–Ni distance is 3.5891(12) Å, while the Ni–Cl–Ni angle is 97.23(6)°. The magnetic properties of the compound, as studied in the range 5–280 K, have been fitted with a zero-field splitting parameter D (–14.3 cm^{-1}) and a ferromagnetic exchange between the Ni ions in the dinuclear unit (J = +2.5 cm^{-1}). The title compound appears to be the second example for a five-coordinated ferromagnetic dinuclear Ni^{II} compound of this type, and its magnetic properties appear to correlate with the ligand structure. With the availability of an increasing number of examples of such species it appears that antiferromagnetic exchange is found for all cases with the chromophore $N_2ClNiCl_2NiClN_2$ where the MN_2 ring is 5-membered. In the case, where this ring is six-membered, the exchange is ferromagnetic.

During the last 2 decades only a few dichloro-bridged Ni^{II} dimers have been studied in detail both structurally and magnetically[1][6][7][8][9]. Such compounds all contain a sterically crowded didentate amine or imine ligand (NN) resulting in the centrosymmetric chromophore $(NN)ClNiCl_2NiCl(NN)$. The geometry of Ni^{II} in all cases is trigonal bipyrimidal with varying degrees of distortion to tetragonal pyramidal[1][6][7][8][9]. The $NiCl_2Ni$ rectangle has Ni−Cl−Ni angles of 97.5 ± 0.9° and the Ni−Cl distances vary from 2.296 to 2.456 Å, Ni−Ni varies from 3.56 to 3.65 Å.

Magnetically these compounds are very interesting as both Ni ions interact, albeit weakly, through the Cl bridges. In fact, this only leaves the chelating ligand (NN) as a possible synthetic variable. Most of the earlier antiferromagnetically coupled systems have a rigid N−C−C−N structure with a five-membered chelate ring. Only one system[1] has a flexible non-conjugated ligand with a six-membered chelate ring.

By using parameters for both the zero-field splitting (D) and the exchange J and zJ' (the latter being a parameter which describes lattice effects on the exchange), the low-T magnetic data can be fitted accurately. So far most compounds of this category $[\{Ni(NN)Cl_2\}_2]$ have shown the commonly observed antiferromagnetic exchange and only in one case[1] has ferromagnetic exchange been reported. No correlations with any structural parameter (Ni−Cl−Ni angle, Ni−Cl distances) could be found at the time, although the more recently developed parameter[2] to describe the degree of deviation from trigonal-bipyrimidal (τ) gave a clue that an increased distortion towards square pyrimidal could be the origin.

To investigate whether this hypothesis is useful, a new system had to be investigated. Bis(2-benzimidazoles) have been shown to be useful tools in the coordination chemistry of azoles which act as ligands in the context of mimicking biological systems[3]. The ligands bis(2-benzimidazolyl)propane and bis(2-benzimidazolyl)butane form dinuclear alkoxo-bridged compounds[4] with Cu^{II} and less strong anions, such as tetrafluoroborate, triflate, perchlorate, and nitrate. With strong anions, such as the halides, mononuclear Cu^{II} compounds are formed[5]. With Ni^{II} chloride, bis(2-benzimidazolyl)propane (abbreviated as tbz) yields a dinuclear chloride-bridged compound. As this compound has the flexible ligand chelate ring, it was expected to yield a ferromagnetically coupled system, if our hypothesis were true. Therefore the title compound was studied both structurally and magnetically in detail. The results which are described below, show that they indeed agree with our hypothesis.

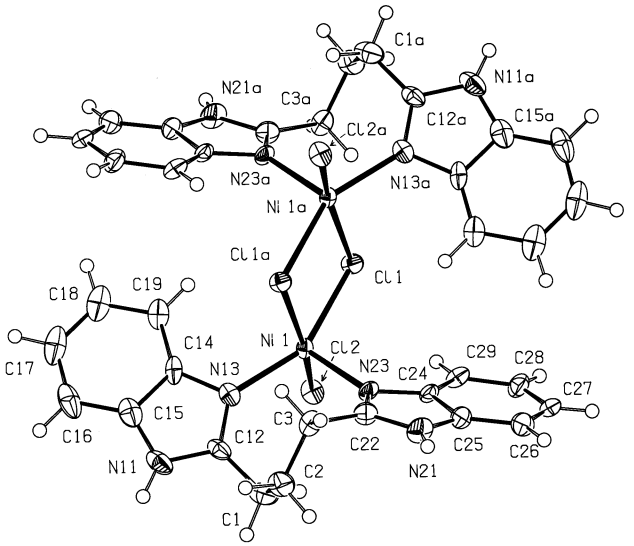
Results and Discussion

Description of the Crystal Structure of $[NiCl_2(tbz)_2]_2(C_2H_6O)_2$

The dinuclear unit consists of two $NiCl_2(tbz)$ units, which are related by the crystallographic center of symmetry. Each unit consists of a five-coordinate Ni^{II} ion, surrounded by two N atoms of the ligand [Ni1−N13 2.022(4), Ni1−N23 2.000(4) Å], a terminal Cl ion [Ni1−Cl2 2.3496(17) Å], a bridging Cl ion [Ni1−Cl1 2.3556(17) Å], and a second bridging Cl ion [Ni1−Cl1a 2.4275(16) Å], belonging to the other half of the dimer, resulting in a slightly asymmetric bridge.

The structure is depicted in Figure 1. The Ni−Ni distance is 3.5891(12) Å, while the Ni−Cl−Ni angle is 97.23(6). The Ni−Cl distances and angles are comparable with those distances known for such Ni^{II} species[1b][6a][7a], while the distances and angles of the ligand are comparable with other structures known for this ligand[4].

Figure 1. ORTEP plot showing the structure $[NiCl_2(tbz)_2]_2$ with atom-labeling scheme; ethanol molecules are ommitted for clarity; atoms marked with an "a" are generated by an inversion centre



[a] Selected bond lengths [Å] and angles [°]: Ni(1)−Ni(1)a 3.5891(12), Ni(1)−Cl(1) 2.3556(17), Ni(1)−Cl(2) 2.3496(17), Ni(1)−N(13) 2.022(4), Ni(1)−N(23) 2.000(4), Ni(1)− Cl(1)a 2.4275(16); Cl(1)−Ni(1)−Cl(2) 88.45(6), Cl(1)−Ni(1)−N(13) 150.00(14), Cl(1)−Ni(1)−N(23) 104.31(13), Cl(1)−Ni(1)−Cl(1)a 82.77(6), Cl(2)−Ni(1)−N(13) 91.01(13), Cl(2)−Ni(1)−N(23) 102.05(12), Cl(1<9a−Ni(1)−Cl(2) 162.85(7), N(13)−Ni(1)−N(23) 105.13(18), Cl(1)a−Ni(1)−N(13) 98.33(12), Cl(19a)−Ni(1)−N(23) 94.40(12), Ni(1)−Cl(1)−Ni(1)a 97.23(6).

The coordination around the Ni ion can be best described as basically trigonal bipyramidal with a distortion towards square pyramidal. The two largest angles are 162.85(7)° and 150.00(14)°, yielding the structural parameter $\tau = 0.21$ (τ describes the relative amount of trigonality; $\tau = 0$ for square pyramid and $\tau = 1$ for trigonal bipyramid)[2].

When comparing the structural parameters to the other four five-coordinated structures listed in Table 2, the τ value is in fact closer to the structures **1**−**3** than to structure **4** from this table.

The crystal packing is dictated by van der Waals contacts and by a quite strong hydrogen bonding network with $N\cdots O_{ethanol}$ [N(11)−H(11)···O(1) 2.722(8) Å] and $O_{ethanol}\cdots Cl$ contacts [O(1) H(1)···Cl(2) 3.077(6) Å].

Ligand Field and Infrared Spectra

The ligand field and far-infrared spectra of the considered five-coordinated Ni^{II} compounds are given in Table 1. Comparing the ligand-field maxima of the present compound with other five-coordinated Ni^{II} compounds, it is shown that the d-d transitions fall all in the same range, with no significant differences between the various compounds (**1**−**5**).

As also shown in Table 1 the Ni−N far infrared vibrations are found at ca. 290 cm^{-1}, all in the range found in the literature[13]. The Ni−Cl stretch vibrations are found between 245 and 260 cm^{-1} and the Ni−Cl bridging vibrations in the range 198−218 cm^{-1}, which is also in agreement with the literature[13]. In fact, further evidence for this assignment is found with the Ni^{II}(bbdhp) compounds [in which bbdhp = 1,7-bis(benzimidazol-2-yl)-2,6-dithiaheptane][14]. The monomeric compound $[Ni(bbdhp)Cl_2]\cdot 4\ H_2O$ shows the Ni−Cl vibrations at 260 cm^{-1} and the Ni−N vibration at 320 cm^{-1}, while the dinuclear compound $[Ni_2(bbdhp)_2(\mu\text{-}Cl_2]Cl_2\cdot 5\ H_2O\cdot 2$ EtOH, which has only bridging chloride ions, has the Ni-μ-Cl−Ni vibration at 220 cm^{-1}, with the Ni−N vibrations at 315 cm^{-1}.

Magnetic Properties

Magnetic susceptibility data in the range 5−280 K were collected. The molar susceptibility data (corrected for diamagnetism) is plotted in Figure 2. In this figure the μ_{eff} values and the results of the fitting procedure are also included. The values listed are normal, as is the small value for zJ'.

The magnetic moment μ_{eff} was found to be 3.5 B.M. at 140 K, slightly increasing to a maximum 3.6 B.M. at 30 K and decreasing rapidly at lower temperatures, typical for a weak ferromagnetic interaction between the Ni^{2+} ions in the dinuclear unit, with a zero-field effect dominating at lower temperatures.

For the description of the susceptibility data the equation obtained by Ginsberg et al[10] using the Hamiltonianin

$$H = -2\cdot J\hat{S}_1\cdot\hat{S}_2 - D(\hat{S}1_z{}^2 + \hat{S}_{2z}{}^2) - 2\cdot ZJ'\hat{S}_i\langle\hat{S}_i\rangle - g_i\beta H\hat{S}_i$$

which the symbols have their usual meanings[10], was employed.

The J value of +2.5 cm^{-1} calculated from the best fit indeed shows the ferromagnetic exchange hypothised above. So far, such a ferromagnetic interaction has also been known to occur in dimeric chloride-bridged Ni^{II} compounds that have an octahedral geometry; in these case the J values vary from +4.8 to +9 cm^{-1}[1b][8][12]. To develop a magneto-structure relationship we have concentrated on the 5-coordinated cases.

As shown in Table 2 three chloride-bridged Ni compounds seem to have an antiferromagnetic behaviour (compounds **1**−**3**) with J values varying from −4.4 to −10.45

Table 1. Ligand field and far-infrared data of five-coordinated dimeric chloro-bridged Ni^{II} units

Compound	Ligand field [a] (10^3 cm^{-1})						FIR [cm^{-1}] Ni−N	Ni−Cl	Ni−$Cl_{(br)}$	
1. $[Ni(qnqn)Cl_2]_2$	6.5		13.0	19.6(sh)	22.8	[d]	285	228		[d]
2. $[Ni(dmp)Cl_2]_2$	6.4	10.6(w)	13.8	19.8(sh)	23.3	[b]	294	260	198	[b]
3. $[Ni(biq)Cl_2]_2$	6.3	10.5(w)	13.8	19.8(sh)	23.4	[c]	298	275	203	[c]
4. $[Ni(CH_2(dmpz)_2)Cl_2]_2$	7.0		12.5	19.2(sh)	21.7	[e]	290	267	210	[e]
5. $[Ni(tbz)Cl_2]_2(C_2H_6O)_2$	6.1		12.5(vbr)	19.6(sh)	22.0		289	245	218	

[a] Abbreviations: sh = shoulder, w = weak, vbr = very broad. − [b] Synthesized according to ref.[9] and re-measured. − [c] Synthesized according to ref.[7a] and re-measured, the bridging Ni−Cl vibration can be at 198 cm^{-1} or at 203 cm^{-1}, as a ligand vibration occurs in this area. − [d] Data from ref.[6b], assignement of the FIR vibrations is uncertain as the compound was measured in CsI to ca. 200 cm^{-1}. This compound could not be synthesized to be re-measured. − [e] Data from ref.[1a] and[1c].

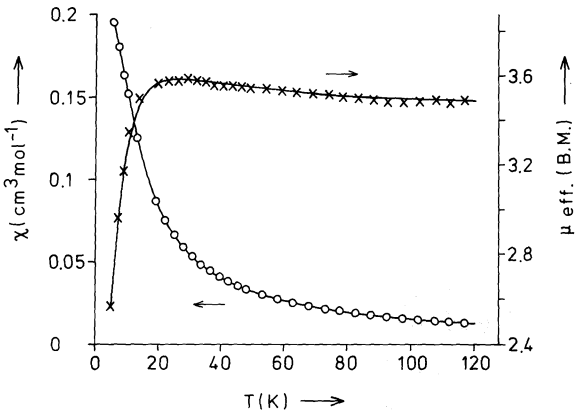
[a] Ligand abbreviations: qnqn = *trans*-2(2′-quinoly)methylene-3-quinuclidinone, dmp = 2,9-dimethyl-1,10-phenantroline (neocuproine), biq = 2,2′-biquinolyl, $CH_2(dmpz)_2$ = bis(3,5-dimethylpyrazolyl)methane. − [b] See ref.[2], τ = defined as α − β/60. − [c] Another crystal structure with this ligand was solved, i.e. $[Ni(dmp)Cl_2]_2 \cdot 2\ CHCl_3$;[9] some distances slightly differ from those from the $[Ni(dmp)Cl_2]_2$ compound.

Figure 2. Molar susceptibility (o) and effective magnetic moment per Ni^{II} ion (×) of $[NiCl_2(tbz)_2]_2(C_2H_6O)_4$ as a function of the temperature; the full curves represent the theoretical curves for J = +2.5 cm^{-1}, D = −14.3 cm^{-1}, zJ' = −0.36 cm^{-1} and g = 2.14 (see text), with an R value of $3.20 \cdot 10^{-3}$ (in which $R = \Sigma\ \chi_{obs} - \chi_{calc}{}^2 / \Sigma\ \chi_{obs}{}^2$)



cm^{-1}. Compound **4**, however, shows a ferromagnetic behaviour, as is also the case in the title compound **5**. In fact, such a weak ferromagnetic interaction was also observed in another compound $[Ni(dae)Cl_2]_2$[11] {dae = *N,N′*-[2-(3,5-dimethyl-1-pyrazolyl)ethyl]ethylamine}, but in this case, the J value had not been reported.

For di-μ-hydroxo-bridged copper compounds a well-known correlation holds between the J vs. the bridging Cu−O−Cu angle and for a change of 1° a change of approx. 40 cm^{-1} is expected in the J value[12][15]. As seen from Table 2, for di-μ-chloride-bridged Ni^{II} compounds a quantitative correlation is not found. However, it appears that antiferromagnetic exchange is found for all cases with the chromophore $N_2ClNiCl_2NiClN_2$ where the MN_2 ring is 5-membered. In the case, where this ring is six-membered, the exchange is ferromagnetic. In general the variation in the extreme values of the exchange parameter J vary between −10 cm^{-1} and +19 cm^{-1}, the geometries of the Ni^{II} compounds are often difficult to compare, from hexacoordinate octahedral to pentacoordinate trigonal bipyramide intermediates. Different geometries usually result in different energies (and orientation) of the orbitals of the unpaired electrons. This in contrary to the di-μ-hydroxo-bridged copper compounds were the variation in the J value vary from +172 cm^{-1} to −509 cm^{-1}[15] and the geometries are mostly all square planar. It must also

be pointed out that the energy differences are very weak (ca. 10 cm^{-1}) and the J value itself must be regarded as an estimate of the exchange interaction, since the J value can be affected slightly by other parameters[12] (see compound **2** in Table 2 in ref.[1b]).

Although we did find, for the first time, a qualitative structure-magnetism relation for 5-coordinated di-μ-chloronickel(II) species, a quantitative conclusion about the magnetic behaviour in relation to the structural component for such Ni^{II} compounds cannot be drawn at this moment.

Experimental Section

General: C, H, N, and Ni determinations: Microanalytical Laboratory of University College, Dublin, Ireland. − UV/Vis spectra: Perkin-Elmer 330 spectrophotometer using the diffuse reflectance technique, with MgO as a reference. − FTIR spectra: Bruker 113v infrared spectrophotometer, polyethylene mulls (600−100 cm^{-1}, mirror velocity 0.099 cm/s, resolution 2 cm^{-1}, Mylar 3.5 μ beam splitter). − Magnetic susceptibility: The title compound was measured in the temperature range 4.2−300 K with a fully automated Manics DSM-8 susceptometer equipped with a TBT continuous-flow cryostate and a Drusch EAF 16 NC electromagnet, operating at ca. 1.4 T. Data were corrected for magnetization of the sample holder and for diamagnetic contributions, which were estimated from the Pascal constants[16]. Magnetic data were fitted to a theoretical expression minimizing the function $R = \Sigma|\chi_{obs} - \chi_{calc}|^2/\Sigma|\chi_{obs}|^2$.

Synthesis of the Compound: The synthesis of the ligand bis(2-benzimidazolyl)propane has been described earlier[4c]. The nickel compound was prepared according to the following procedure: 1.2 mmol of Ni^{II} chloride and 1.2 mmol of the ligand were each dissolved in 10 ml of ethanol. The Ni^{II} salt solution was then added slowly to the ligand solution preventing any precipitation, filtered to remove any solids and after a few days the yellow-orange crystals separated. − $C_{19}H_{22}Cl_2N_4NiO$ (452.0): calcd. C 50.49, H 4.91, N 12.39, Ni 12.99; found C 50.25, H 4.60, N 12.80, Ni 13.80.

Crystal Structure Determination and Refinement of the Structure: The X-ray diffraction data were collected with an Enraf-Nonius CAD4T diffractometer at 150 K [rotating anode, 60 kV, 50 mA, graphite-monochromated Mo-K_α radiation, ω-scan mode]. Unit-cell parameters were checked for the presence of higher lattice symmetry[17]. The structure was solved by Direct Methods DIRDIF[18]. Neutral atom scattering factors and anomalous dispersion factors were taken from ref.[19]. Calculations were performed with programs SHELXL93[20] and PLATON[21] on a DEC-5000 cluster. The structure was refined on F^2 to $R1 = 0.0612$ for 2093 reflections for with $F_o > 4\ \sigma(F_o)$. ($wR2 = 0.105$ for 3562 unique reflections, $S = 0.968$, $-0.49 < \Delta\rho < 0.41$). A summary of the crystallographic data is given in Table 3. Anisotropic thermal parameters were used for all non-hydrogen atoms. Hydrogen atoms were included in the refinement cycle at calculated positions, riding on their carrier atoms except for the one on the ethanol molecule that was located from a difference map and its parameters refined.

8-Aminoquinoline reacts with (dimethylamino)trimethylstannane in a 2:1 molar ratio, undergoing transamination to the distannylamine **1a**. The 9-[bis(trimethylstannyl)amino]-9-borabicyclo[3.3.1]nonane (**1b**) is obtained by the stannazane cleavage reaction of tris(trimethylstannyl)amine with 9-chloro-9-BBN. The cleavage of one Sn–N bond of the distannylamines **1a** and **1b** with MeLi yields the first two monomeric *N*-lithioaminostannanes, **2a** and **2b**, which can be stored at ambient temperature without decomposition. The molecular structures of **1a**, **1b**, **2a**, and **2b** have been determined by multinuclear magnetic resonance spectra in solution, as well as by X-ray structure analysis. Characteristic features are the intramolecular adduct formation of the quinoline ring nitrogen atom with one of the stannyl groups in **1a**, as well as with the lithium cation in **2a**, and the surprisingly short bonds between the central nitrogen atom and the adjacent elements [$d_{(NSn)}$: 2.02 Å, $d_{(NB)}$: 1.38 Å, $d_{(NC)}$: 1.34 Å, $d_{(NLi)}$: 1.95 Å] detected in the molecular structures of the lithium salts.

Introduction

Distannylamines have been shown to be useful precursors for the synthesis of novel main-group element nitrogen compounds[1]. Stannazane cleavage reactions, proceeding under mild conditions, may also serve for the preparation of doubly metallated alkali metal imides, RNM_2 (e.g. with M = Li, Na, K). Their molecular structures in solution as well as in the solid state are scarcely known, with the exception of the complex structure of dilithiated α-naphthylamine, which crystallizes as a cyclooligomeric aggregate containing ten molecular units with intermolecular Li−N bridging bonds[2]. Monometallated metal organostannylamides of the type $RN(SnMe_3)M$ (**2**) which, in contrast to some silylated homologues[3], have hitherto been unknown, should be accessible as intermediates en route to doubly metallated species.

Investigations of the stabilities, structures, and reactivities of the metal amides of primary amines, bearing one N−Li and one N−Sn bond instead of two N−H bonds, are of potential importance with regard to the synthesis of new main-group element nitrogen heterocycles, as well as of unsaturated Sn−N compounds under kinetically controlled conditions. Moreover, the influence of the electropositive lithium atom on the electron densities of the nitrogen atom and its adjacent bonds could be of particular interest.

We describe here the syntheses, structures, and spectroscopic properties of two distannylamines of the type $R-N(SnMe_3)_2$ (**1**) and of their *N*-lithiated derivatives **2**.

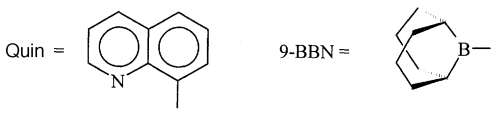
[+] X-ray structure analysis.

Results and Discussion

8-[Bis(trimethylstannyl)amino]quinoline (**1a**) was obtained by a well-established transamination reaction[4]. A 2:1 molar ratio of $Me_2N-SnMe_3$ and 8-aminoquinoline was heated at 80°C for 25 h, leading to reaction according to Eq. 1. No further purification was needed after removal of the volatile components in vacuo, since the reaction proceeded quantitatively. **1a** was recrystallized from hexane in good yield.

(1)

(2)



9-[Bis(trimethylstannyl)amino]-9-borabicyclo[3.3.1]nonane (**1b**) was formed in quantitative yield by mixing CH_2Cl_2 solutions of 9-chloro-9-BBN and $N(SnMe_3)_3$ at −40°C, according to Eq. 2. The distannylaminoborane **1b**, purified by crystallization from hexane at −20°C, is the only such compound yet to be characterized in the solid state.

The spectroscopic data of compounds **1a** and **1b** are listed in Table 1, and confirm the proposed structures. At room temperature, the ^{119}Sn-NMR signal of **1a** at δ = 26.4

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1434−1948/98/0909−1343 $ 17.50+.50/0

indicates a remarkably better shielding of the tin nuclei relative to all known distannylamines. However, at −80°C, the ^{119}Sn-NMR spectrum shows two different signals at δ = 61.6 and −18.4, the latter falling in the range of pentacoordinated tin atoms. This is possibly due to the interaction of one tin atom with the lone-pair electrons of the quinoline nitrogen atom. At −60°C, the two signals collapse and only one fairly broad signal is observed. Furthermore, two resonance signals are detected in the ^{15}N-NMR spectrum at ambient temperature; the signal at δ = −318 can be assigned to the nitrogen atom of the exocyclic amino group, and that at δ = −89 to the nitrogen nucleus of the quinoline ring.

Table 1. ^{7}Li-, ^{11}B-, $^{14/15}$N-, and ^{119}Sn-NMR data of the distannylamines **1**, the lithioaminostannanes **2**, and another compound for comparison

I

These findings are in good agreement with investigations on compounds of type **I**[5], which have been proposed to form an intramolecular Sn−N adduct. The NMR data and the X-ray structure analysis of **1a** (see below) also confirm this hypothesis. The ^{119}Sn- and ^{15}N-NMR data of the borylated distannylamines **1b** are in good agreement with the data of known compounds[6]. However, the ring strain of the bicyclic boryl group causes a deshielding of the boron nucleus (Δδ = 5 ppm), as well as a modest upfield shift of the nitrogen signal (Δδ = 17 ppm) relative, for example, to $Me_2BN(SnMe_3)_2$ (see Table 1). However, the data still indicate multiple bonding between the boron and the nitrogen atoms, in accordance with previous data[7].

The reaction of aryldistannylamines with R = C_6H_5 (**1c**), 2,4,6-$Me_3C_6H_2$ = Mes (**1d**), and 2,6-*i*$Pr_2C_6H_3$ = Dipp (**1e**), in the presence of L = 1,4,7-pentamethyldiethylenetriamine (pmdta), with organolithium compounds in a 1:1 molar ratio led to a mixture of products according to Eq. 4[8]. The monolithium salts **2c** to **2e**, which form even at −50°C, decompose at ambient temperatures, probably under dismutation into the distannylamines **1c** to **1e** and the dilithioamines **3** according to Eq. 4. The species **1c** to **1e** and the byproduct $SnMe_4$ (see Eq. 3) can be detected by NMR, but there is no spectroscopic evidence for the dilithioimines, which are thought to be the main components of the insoluble residue obtained.

$$\underset{\mathbf{1}}{R{-}N(SnMe_3)_2} \xrightarrow[-\ SnMe_4]{+\ MeLi/\ L\ /\ tBuOMe} \underset{\mathbf{2}}{R{-}N(SnMe_3)Li\cdot L} \qquad (3)$$

The following combinations of R and L have been investigated:

	1a/2a	**1b/2b**	**1c/2c**	**1d/2d**	**1e/2e**
R	Quin	9-BBN	Ph	Mes	Dipp
L	tmeda	pmdta	pmdta	pmdta	pmdta

$$\underset{\mathbf{2}}{2\ ArN(SnMe_3)Li\cdot L} \longrightarrow \underset{\mathbf{1}}{ArN(SnMe_3)_2} + \underset{\mathbf{3}}{[ArNLi_2]} + 2\,L \qquad (4)$$

$$\underset{\mathbf{3}}{[ArNLi_2]} + 2\ Me_3SiCl \longrightarrow \underset{\mathbf{4}}{ArN(SiMe_3)_2} + 2\,LiCl \qquad (5)$$

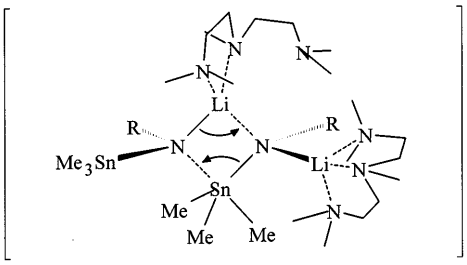
Treatment of this residue with Me_3SiCl according to Eq. 5 gave a mixture of products, which did not unambiguously confirm the presence of dilithioimides of type **3**. The disilazane derivatives **4** could only be detected in trace amounts, since silylstannylamines, $Ar{-}N(SiMe_3)SnMe_3$, are also formed under the chosen reaction conditions. Details of these investigations will be discussed elsewhere[9].

In contrast, the treatment of **1a** with LiMe·L (L = tmeda) in *tert*-butyl methyl ether (diveron) solution gave the lithium aryl(trimethylstannyl)amide **2a** in good yield under mild conditions (−30°C). This product is stabilized by complexation of the lithium cation by one equivalent of the diamine tmeda. It is very soluble in diveron, and moderately soluble in petroleum ether, benzene, and hexane. **2a** can be recrystallized from a hexane/diveron mixture by storing the solution at −20°C for 2 days. It can be stored for weeks at ambient temperature under argon without decomposition.

The NMR spectra in diveron solution show a sharp resonance signal of the ^{7}Li nuclei at δ = 3.12 and a broad signal of the ^{119}Sn nuclei at δ = 5.39. The ^{15}N-NMR spectrum shows two signals, one due to the amido nitrogen atom at δ = −214.2 and another due to the ring nitrogen atom at δ = −96.4. Compared to the starting material **1a**, the substitution of the stannyl group for the lithium cation causes a large downfield shift of the amido nitrogen signal (Δδ = 100 ppm) and a significant upfield shift of the ring nitrogen signal (Δδ = −7 ppm), due to the influence of the electropositive lithium atom on the paramagnetic term of the ^{15}N shielding[9]. In analogy to information obtained from a low-temperature ^{119}Sn-NMR study of the distannazane **1a** the ^{15}N-NMR data of **2a** clearly indicate a coordination of the lone-pair electrons of the quinoline nitrogen atom to the lithium cation, as well as high electron density concentrated at the amido nitrogen atom. Single-crystal structure determinations of the species **1a** and **2a** confirm the nature of the bonding, as deduced from the NMR data in solution. Clearly, the chelation of the lithium atom is responsible for the stability of the stannylated lithium amide **2a**.

The function of the amidoquinoline group as a chelate ligand presumably prevents the dismutation postulated for the derivatives **2c**, **2d**, and **2e** according to Eq. 4. The decomposition could probably proceed, with the formation of a dimer as an intermediate, under partial displacement of the chelate ligand pmdta by the amido nitrogen atom (Figure 1).

Figure 1. Postulated dimeric intermediate of $RN(SnMe_3)Li{\cdot}L$ (**2**)



After the dismutation of **2**, the products **1** and **3** (see Eq. 4) can be formed by simultaneous 1,2-migration of a lithium atom and a stannyl group.

If the course of the dismutation reaction of compounds of type **2** is dependent on the basicity of the central nitrogen atom, then Lewis acidic substituents R that reduce the basicity of the nitrogen atom should be as significant as sterically hindering or chelating groups in controlling the reaction. Therefore, the introduction of dialkylboryl groups can be expected to reduce the bridging tendency of the nitrogen lone-pair electrons through π-bonding with boron.

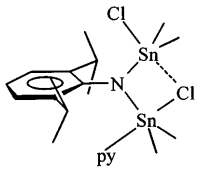
In fact, the synthesis of the monomeric *N*-lithiostannylaminoborane **2b** from distannylaminoborane **1b** proceeds under mild conditions in the presence of pmdta, which stabilizes the Li cation by complexation according to Eq. 3. Product **2b** can be stored indefinitely at ambient temperatures and can even be warmed to 50°C in diveron solution without decomposition.

In all probability, effective (pp) π interaction of the lone-pair electrons at the nitrogen atom with the vacant p orbital of the B atom reduces the donor ability of the nitrogen atom, thereby preventing dimerization and subsequent decomposition of the lithium amide **2b**.

The metallation of the nitrogen atom leads to a large upfield shift of the boron signal of about $\Delta\delta = 8$ ppm compared to that in the distannylamine **1b**. One common explanation would be a strengthening of the B−N π bond[10], due to the high electron density concentrated at the nitrogen atom as a consequence of the polar Li−N bond. An alternative explanation might be the decreased polarity and increased s electron density of the B−N σ bond. However, the unexpectedly large downfield shift of the ^{15}N-NMR signal ($\delta = -228$, recorded at −50°C to depress quadrupolar relaxation with the boron nucleus) is supportive of the first explanation. Surprisingly though, the ^{119}Sn-NMR signal, like the boron NMR signal, is shifted upfield by $\Delta\delta \approx 50$ ppm ($\delta = 0.08$). This can only be due to a significant change in electron density in the Sn−N σ bond, since ab initio calculations rule out any significant Sn−N π interaction[11]. The increase of s electron density in the Sn−N single bond is also indicated by the small but negative $^1J(^{119}Sn^{15}N)$ coupling[1c]. Further conclusions can be drawn from the molecular structures in the solid state (see below).

Molecular Structures

The structures of the distannylamines and of the *N*-lithiostannylamines were determined by X-ray crystallography. Figures 2, 3, 4, and 5 show ORTEP plots of the molecules **1a**, **1b**, **2a**, and **2b**, respectively. Selected bonding parameters are listed in the caption of each figure. Contrary to the structural information implied by the NMR data in solution at ambient temperatures, the characteristic features of the molecular structure of **1a** (Figure 2) in the solid state are determined by an intramolecular donor−acceptor interaction between the quinoline nitrogen atom and the tin atom of one of the trimethylstannyl groups. Compared to the adduct $Me_3SnCl{\cdot}py$ (d_{SnN}: 2.26 Å)[12] and the distannylamine pyridine adduct **5** (d_{SnN}: 2.426 Å)[13], the Sn2−N2 bond of 2.531 Å is remarkably long, owing to the ring strain arising from the formation of the intramolecular adduct.



5

As a consequence of the relatively weak N2−Sn2 interaction, the trigonal-bipyramidal environment of the Sn2 center is considerably distorted, as shown by the 12° deviation of the angle N2−Sn2−C13 from 180°. Moreover, the sum of the angles of the trigonally coordinated ligands at the tin center is only 348° rather than 360°.

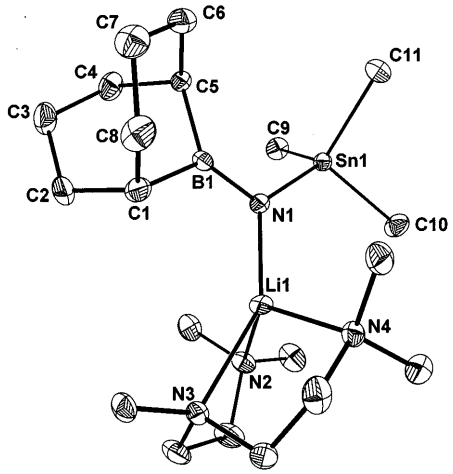
Figure 5. Molecular structure of 9-BBN−N(Li)Sn(CH_3)$_3$ (**2b**) with an ORTEP-type description; thermal ellipsoids represent a 25% probability; hydrogen atoms are omitted for the sake of clarity[a]



[a] Selected bond lengths [Å] and bond angles [°] (estimated standard deviations are given in parentheses as units in the last digit): Sn1−N1 2.020(3), B1−N1 1.381(6), Li1−N1 1.945(8), Li1−N2 2.144(8), Li1−N3 2.337(8), Li1−N4 2.149(8), B1−C1 1.623(6), B1−C5 1.608(6), Sn1−C9 2.159(5), Sn1−C10 2.161(5), Sn1−C11 2.154(5); Sn1−N1−Li1 126.7(3), Sn1−N1−B1 117.7(3), B1−N1−L1 115.6(3), N1−Li1−N2 111.4(4), N1−Li1−N3 147.7(4), N1−Li1−N4 112.1(4), C9−Sn1−C10 105.6(2), C9−Sn1−N1 113.1(2), C11−Sn1−N1 112.8(2).

Surprisingly, the Sn−C bond lengths are rather insensitive to the different coordination numbers of Sn1 and Sn2. The ring strain may also be responsible for the large N1−Sn2 distance of 2.099(3) Å, which represents the largest nitrogen−tin distance yet found in distannylamines[14]. The N1−Sn1 bond length of 2.064(3) Å is, however, in good accord with those found for other Sn−N−Sn units. The sum of the angles at the amino nitrogen atom of 360° confirms this to be a planar unit, as is usually the case. The fairly short N1−C1 distance of 1.381(4) Å can be explained by the strong σ-N−C bond, due to the large overlap of the sp^2-sp^2 bond orbitals of each atom.

The distannylamine **1b** (Figure 3), with a cyclic dialkylboryl group attached to the nitrogen atom, also shows planar coordination at the central nitrogen atom. It represents the first example of this class of compounds for which the molecular structure has been determined in the solid state. Characteristic features are the large Sn−N−Sn angle of 126.1°, as also found in aryldistannylamines[15], and the fairly small C−B−C angle of 107.8(7)° in the boryl group, probably due to the ring strain of the bicyclic substituent. Compared to the quinoline group in **1a**, the 9-borabicyclo[3.3.1]nonyl group is sterically less demanding. This might account for the larger Sn−N−Sn angle in **1b** (difference ca. 8°) compared to that in **1a**. Moreover, the stannylaminoborane **1b** shows a significant elongation of the Sn−N bonds [$d_{(SnN)}$ = 2.07 Å] compared to those in other distannazanes with bulkier groups R attached to the nitrogen atom [$d_{(SnN)}$ = 2.05 Å][15]. This is presumably due to the electron-withdrawing properties of the boryl group on the pair of electrons at the central nitrogen atom. There-

fore, the ^2J(Sn/Sn) coupling transmission, which has been thought to be dependent on the Sn−N−Sn angle[16] and on the Sn−N bond lengths[1c], seems to be particularly predominated by the position of the lone-pair electrons at the nitrogen atom (see NMR discussion).

The effective (pp) π interaction of the lone-pair electrons of the nitrogen atom with the vacant p orbital of the boron atom is indicated by the short B−N bond of 1.42(1) Å. The small torsion angle Sn1−N1−B1−C11 of about 2° additionally underlines the double bond character of this bond.

Instead of the associated structures usually found for R_2NLi compounds[17], the *N*-lithiostannylamines **2a** and **2b**, derivatives of the distannylamines **1a** and **1b**, crystallize as monomeric molecular units (shown in Figures 4 and 5). The unit cell in the crystal of compound **2a** contains two independent molecules, which show slightly different bond lengths and angles. Significant differences in bond lengths are only detectable in case of the N−Li distances (ca. 0.04 Å). The characteristic features of both lithioamines are the surprisingly short Sn−N bonds of 2.028(3) for **2a** and 2.020(3) Å for **2b**, respectively. The sum of the covalent radii of the elements is 2.033 Å[18]. Moreover, the N2−C8 distance of 1.339(5) Å in **2a** is considerably shorter than that in **1a** (see above), indicating a significant enhancement of the N−C double bond character. These findings can be explained in terms of the transfer of the high electron density, primarily located at the nitrogen atom of the amino group (as a consequence of the polar and indeed essentially ionic character of the Li−N bond[17]), into the adjacent bonds. Support for this explanation comes from the NMR studies, which indicate a remarkable high-field shift of the ^{119}Sn signals of **2a** and **2b** relative to those of the distannylamines **1a** and **1b**. The sum of the angles at the amine nitrogen atom, as well as at the quinoline nitrogen atom, is 360°, confirming the sp^2 hybridization of these centers. Therefore, two different Li−N bond lengths have been found, taking the lithium cation to be the center of a spirocyclic ring fragment. Short distances are present due to the typical sp^2-hybridized nitrogen atoms of the chelating aminoquinoline group acting as a donor ligand [$d_{(LiN)}$: ca. 1.97/2.03 Å]. Two long Li−N bonds are formed with the sp^3-hybridized nitrogen atoms [$d_{(LiN)}$: ca. 2.11 Å] of the chelating diamine tmeda. The tetrahedral symmetry around the metal cation is slightly distorted. There is no simple explanation for the deviation of the coordination of the lithium center from tetrahedral symmetry other than packing effects.

The structure of the *N*-lithiated stannylaminoborane **2b** is the third example of a monomeric *N*-lithioaminoborane[10][19], but it is the first one with essentially planar cores of $C_2BN(Li)Sn$ atoms with only small dihedral angles between the boron and nitrogen planes. The structure indicates the influence that the electropositive metal cation attached to the nitrogen atom exerts on the adjacent B−N and Sn−N bonds. Compared to the distannylborylamine **1b**, the B−N bond of **2b** [$d_{(BN)}$: 1.381(6) Å] is shortened by about 0.04 Å, and represents one of the shortest B−N double bonds yet found[10].

Short B−N bonds in aminoboranes are usually explained in terms of an enhancement of B−N π bonding. However, short B−N bonds are also present in lithioaminoboranes, such as tBu$_2$B−N(Li)tBu·OEt$_2$, although here there is a fairly large dihedral angle of 30.4° between the boron and nitrogen planes[19]. Moreover, the B−N bond length of 1.40 Å in the *N*-silylated lithioaminoborane 9-BBN−NLi−$SiMe_3$, which crystallizes as a trimer with pseudo-tetracoordinated nitrogen atoms, is indicative of B−N double bonds[1a]. Therefore, the short bonds are more likely to be attributable to the positive inductive effect of the lithium atom, which strengthens the σ bonds. This is also the case for the adjacent Sn−N bond, which is extremely short compared to that in the starting material **1b**. Taking into account that, on the basis of ab initio calculations, any π-bonding in Sn−N bonds is negligible, the electron-donating property of the lithium atom, as discussed above, is solely responsible for the strengthening of the σ bonds.

We gratefully acknowledge the support of this research by the *Deutsche Forschungsgemeinschaft*, the *Fonds der Chemischen Industrie*, and the *Chemetall GmbH*. We also thank Prof. Dr. *H. Nöth* for helpful discussions and comments, Prof. Dr. *W. Wrackmeyer* (low-temperature NMR measurements), and Mrs. *C. Neumann* (essential support of synthetic work).

Experimental Section

General: All operations were performed under dry argon. Glassware was dried prior to use by heating in vacuo. − NMR spectra were recorded with Bruker AC P 200 (^{11}B), Jeol GSX 270 (^{15}N, ^{119}Sn), and Jeol EX 400 (^{1}H, ^{7}Li, ^{13}C) instruments; standards: TMS (internal, ^{1}H, ^{13}C), ext. 1 M LiCl solution (^{7}Li), ext. $BF_3·Et_2O$ (^{11}B), ext. CH_3NO_2 (^{15}N), tetramethyltin (external ^{119}Sn). ^{15}N-NMR spectra were recorded by polarization transfer techniques: refocused INEPT pulse sequence based on the $^2J(^{15}N^1H)$ and the $^3J(^{15}N^1H)$ coupling constants of ca.12 Hz and ca.1.5−2 Hz, respectively, (assumed values). The notation $^nJ(^{119/117}Sn^mX)$ represents the coupling of both isotopomers with X if the coupling cannot be observed separately. Chemical shifts, δ, are given in ppm, coupling constants, *J*, in Hz. − Mass spectra: Varian CH7 instrument with electron impact ionization at 70 eV. The masses found refer to the isotopes ^{1}H, ^{7}Li, ^{12}C, ^{11}B, ^{14}N, ^{120}Sn. − Elemental analyses: Microchemical Laboratory of the Institute. − X-ray: Siemens P4 diffractometer, CCD area detector with Siemens LT 2 device; Mo-K_α radiation, λ = 0.71063 Å, graphite monochromator; single crystals, coated with perfluoro ether oil, were mounted on a glass fibre. Crystal data were determined and intensity data recorded at 173−193 K (see Table 2); data reduction was performed with the program SAINT, structure solution by Patterson method and refinement using the SHELXTL system[20]; final refinement was performed using the SHELX-97 programs[21]. All atoms except the hydrogen atoms were described with anisotropic temperature factors; all hydrogen positions were geometrically placed [d(CH) = 0.96 Å] and refined by using the riding model and fixed U_i. Details of the crystal structure determinations are available on request from Cambridge Crystallographic Data Centre (CCDC), 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) + 44-1223/336033; E-mail: deposit@ccdc.cam.ac.uk] on quoting the depository numbers CSD-101616 (**1a**), -101617 (**1b**), -101618 (**2a**), -101619 (**2b**), the names of the authors, and the full journal citation.

Starting Materials: $N(SnMe_3)_3$[22] was prepared according to a modified literature procedure[23] from $NaNH_2/NH_3/OEt_2$/

Me_3SnCl; 9-chloro-BBN[24] and Me_2NSnMe_3[25] were prepared according to literature procedures. The MeLi solution (ca. 1.6 M in Et_2O) was supplied by Chemetall, Frankfurt.

8-[Bis(trimethylstannyl)amino]quinoline (**1a**): A mixture of 8-aminoquinoline (5.0 g, 35 mmol) and Me_2NSnMe_3 (20.8 g, 92 mmol) was stirred at room temp. A slighty exothermic reaction occurred, with evolution of Me_2NH. After heating the reaction mixture at 80°C for 25 h, so as to complete the elimination of Me_2NH, the excess Me_2NSnMe_3 was condensed at 10^{-3} Torr into a cold trap at −60°C. The residual orange, viscous liquid was dissolved in 40 ml of hexane and kept at 4°C for 4 d, yielding 14.1 g (86%) of **1a** as orange crystals suitable for X-ray analysis; m.p. ca. 12−15°C. − ^{1}H NMR (C_6D_6): δ = 0.38 [s, $^2J(^{119/117}Sn^1H)$ = 53.7 Hz, 18 H, $SnMe_3$], 6.74 (dd, 1 H, 7-H), 6.82 (m, 2 H, 5-H/6-H), 7.24 (dd, 1 H, 3-H), 7.61 (dd, 1 H, 4-H), 8.87 (dd, 1 H, 2-H). − ^{13}C NMR: δ = −0.75 [$^1J(^{119/117}Sn^{13}C)$ = 389.1 Hz, $SnMe_3$], 117.5 [$^3J(^{119/117}Sn^{13}C)$ = 35.1 Hz, C-7], 120.7 (C-5), 129.5 (C-3), 136.2 (C-10), 136.5 (C-6), 138.3 (C-9), 142.7 (C-4), 149.2 (C-8), 154.9 (C-2). − ^{15}N NMR: δ = −318.0 [$^1J(^{117/119}Sn^{15}N)$ = 28.8 Hz, Sn*N*Sn], −89.0 [$^1J(^{117/119}Sn^{15}N)$ = 35.0 Hz, C*N*C]. − ^{119}Sn NMR: δ = 26.2 [$^2J(^{119}Sn^{117}Sn)$ = 46.7 Hz]. − $C_{15}H_{24}N_2Sn_2$ (469.8): calcd. C 38.35, H 5.16, N 5.96; found C 40.10, H 5.15, N 6.74. − Mol. mass: 470 (MS).

9-[Bis(trimethylstannyl)amino]-9-borabicyclo[3.3.1]nonane (**1b**): $N(SnMe_3)_3$ (12.1 g, 24 mmol) was dissolved in 20 ml of CH_2Cl_2. At −40°C, this solution was added dropwise with stirring to a solution of 9-chloro-9-borabicyclo[3.3.1]nonane (3.7 g, 24 mmol) in 10 ml of CH_2Cl_2. After allowing the reaction mixture to slowly warm to ambient temp. (15 h), all volatile components were removed in vacuo (25−80°C/10^{-3} Torr). From a solution of the colourless non-volatile residue in 50 ml of hexane, 9.1 g (82%) of **1b** crystallized after storing the mixture at −20°C for 10 d; m.p. 60−62°C. The crystals were found to be suitable for X-ray analysis. − ^{1}H NMR (C_6D_6): δ = 0.24 [s, $^2J(^{119/117}Sn^1H)$ = 53.9 Hz, 18 H, $SnMe_3$], 1.21 (m, 4 H, BCCCH), 1.42−1.46 (m, 2 H, BCH), 1.78−1.86 (m, 8 H, BCCH). − ^{13}C NMR δ = −2.07 [$^1J(^{119/117}Sn^{13}C)$ = 363.5 Hz, $SnMe_3$], 23.7 (BCC*C*H), 31.4 (BCH), 34.2 (BC*C*H). − ^{11}B NMR: δ = 56.2. − ^{15}N NMR: δ = −289.0 [$^1J(^{117/119}Sn^{15}N)$ = 31.9 Hz, Sn*N*Sn]. − ^{119}Sn NMR: δ = 48.6. − $C_{14}H_{32}BNSn_2$ (462.6): calcd. C 36.35, H 6.97, N 3.03; found C 36.24, H 6.73, N 2.96. − Mol. mass: 463 (MS).

(8-Aminoquinolyl)(lithio)(trimethylstannyl)amine·tmeda (**2a**): To 5 ml of an MeLi solution (1.6 M in diethyl ether) at 25°C, tmeda (0.97 g, 8.33 mmol) was added dropwise, and then the solvent was removed in vacuo at 25°C/10^{-1} Torr. The colourless solid residue was dissolved in 30 ml of *tert*-butyl methyl ether, and to this solution 14.9 ml (8.33 mmol) of a solution of **1a** (0.56 M in *tert*-butyl methyl ether) was added dropwise at −30°C, resulting in a deep-red colouration. After stirring for 2.5 h, the reaction mixture was allowed to warm to ambient temp. Filtration of the slightly cloudy solution (G4), concentration of the filtrate to a volume of ca. 25 ml under reduced pressure, and storing the concentrate at −20°C for 20 d gave **2a** as dark-red crystals, suitable for X-ray analysis: yield 2.43 g (68%); m.p. 134−136°C. − ^{1}H NMR (C_6D_6): δ = −0.69 [s, $^2J(^{119/117}Sn^1H)$ = 53.9 Hz, 9 H, $SnMe_3$], 2.70 (s, 12 H, NCH_3), 2.89 (s, 4 H, NCH_2-), 6.70 (m, 2 H, 5-H, 6-H), 7.41 (t, 1 H, 3-H), 7.52 (dd, 1 H, 7-H), 8.28 (dd, 1 H, 4-H), 8.61 (dd, 1 H, 2-H). − ^{13}C NMR: δ = −1.32 ($SnMe_3$), 46.2 (N*C*H$_3$), 58.2 (N*C*H$_2$-), 114.2 [$^3J(^{119/117}Sn^{13}C)$ = 77.6 Hz, C-7], 120.0 (C-5), 130.2 (C-3), 136.8 (C-10), 137.2 (C-6), 141.4 (C-4), 155.2 (C-9), 163.6 (C-8),

Keywords: ε-Caprolactone complexes / Zirconocene / Ring-opening polymerization

The reactions of $Cp_2Zr(L)(\eta^2\text{-}Me_3SiC_2SiMe_3)$ (L = THF, pyridine) with ε-caprolactone, cyclohexanone and cycloheptanone result in an insertion of the carbonyl group into the zirconacyclopropene ring system of the alkyne complexes to yield the five-membered metallacyclic spirozirconadihydrofurane complexes **1**, **3**, **4**. The product with ε-caprolactone is not stable at room temperature and was identified only by NMR spectra and chemical reactions. Starting from *rac*-(ebthi)$Zr(\eta^2\text{-}Me_3SiC_2SiMe_3)$ with ε-caprolactone and ethylene carbonate under analogous conditions more stable complexes (**2**, **5**) were obtained. Complexes **2** and **3** were characterized by X-ray crystal-structure analysis. Complexes **1** and **2** react with further ε-caprolactone in a catalytic ring-opening polymerization. The polymerization reactions were monitored by NMR spectroscopy.

Introduction

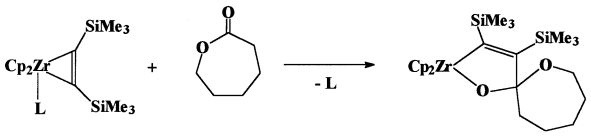
Group-4 transition-metal and lanthanide complexes containing one or two cyclopentadienyl ligands (metallocenes) have emerged as a new class of initiators of the polymerization of various polar monomers including methacrylate, epoxides, lactones.[1] The polymerization of lactones is known to give polyesters, which are becoming an increasingly important class of versatile biodegradable and biocompatible polymeric materials.[2] Since ε-caprolactone is rapidly polymerized by many metal complexes, little information is available on the details of the first steps in metal-mediated polymerization process. For example, only *mer*-YCl_3(ε-caprolactone)$_3$,[2b] in which the caprolactone is coordinated by a carbonyl oxygen atom, has been characterized by an X-ray structure analysis. Recently, we described how (alkyne)zirconocene and -titanocene complexes are capable of polymerizing ε-caprolactone with living characteristics and high yield.[3a] Lactams react with (alkyne)titanocene or -zirconocene complexes to yield different complexes, depending on the nature of the metal and the ring size. These complexes have been discussed as elemental steps in the ring-opening polymerization.[3b]

Here we report on reactions of (alkyne)zirconocene complexes with cyclic carbonyl compounds such as ε-caprolactone, giving cyclic acetals, postulated as intermediates in the well-established ring-opening polymerization reaction.

The reactions of (alkyne)zirconocene and olefin complexes with carbonyl compounds have been well investigated.[4] For the complexes $Cp_2Zr(L)(\eta^2\text{-}Me_3SiC_2SiMe_3)$ (L = THF,[6] pyridine[7]) the reaction with acetone, formaldehyde or benzaldehyde[5] leads to insertion products of the carbonyl unit into the zirconacyclopropene ring of the alkyne complex giving zirconadihydrofuranes $[Cp_2Zr\{-C(SiMe_3)=C(SiMe_3)-CRR'-O-\}]$, which, in the case of the aldehydes, were additionally stabilized by formation of a coordination dimer. Benzophenone reacted by apparent displacement of the alkyne by the ketone to give the complex $Cp_2Zr(THF)(\eta^2\text{-}O=CPh_2)$.

Results and Discussion

ε-Caprolactone (CL) reacts with $Cp_2Zr(L)(\eta^2\text{-}Me_3SiC_2SiMe_3)$ (L = THF, pyridine) and forms, comparable to the reaction with acetone[5a], in a single step, the five-membered metallacyclic spiroacetal **1** (Eq. 1).



(1)

L = py, THF **1**

Complex **1** is an orange solid, which is not stable at room temperature and decomposes in toluene to poly-ε-caprolactone (PCL) and a mixture of as yet unidentified zirconocene complexes.

The reaction of *rac*-(ebthi)$Zr(\eta^2\text{-}Me_3SiC_2SiMe_3)$ with ε-caprolactone yields the analogous *ansa*-metallocene compounds **2a** and **2b** (Eq. 2).

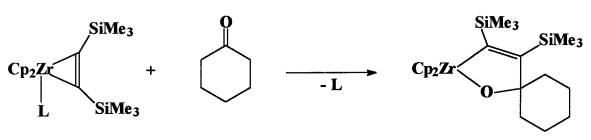
Complex **2a** crystallizes as orange yellow prisms, which, in contrast to complex **1**, are stable at room temperature under argon. It was therefore possible to obtain crystals for an X-ray structure analysis. The enhanced stability of complex **2** when compared to **1** seems to be a consequence of the steric shielding of the ebthi ligand system that has been found in other reactions, e.g., with substituted olefins[8] and with ethylene carbonate (see below). In solution complex **2** has C_1 symmetry, and both diastereomers (**2a**, **2b**) could be observed by NMR investigations. The ratio of the diastereomers formed is strongly influenced by temperature: for the product of this reaction, conducted at −10°C, we observed by NMR investigations at room temperature the stereoselective formation of the major complex **2a** (ratio **2a**/**2b** = 6:1), while running the same reaction at room temperature the ratio of the diastereomers formed was 1:1.

In a similar reaction a cycloreversion of the metallacycle formed was found by heating the coupling product of the nonsymmetrically substituted alkyne *t*BuC≡CSiMe$_3$ with acetone. The kinetically preferred zirconacycle with an SiMe$_3$ group in the β position rearranges at higher temperature to the thermodynamically more stable α-SiMe$_3$ product.[5b]

Heating of pure complex **2a**, up to 50°C, gave no inversion of the configuration at the acetal C and thus no complex **2b**, rather only decomposition products. It seems reasonable to assume that the ebthi ligand, in comparison to the sterically less demanding Cp ligand, prevents the cycloreversion by allowing less space for the ring-opening process. It therefore seems that there is no equilibrium between the two diastereomers and that the kinetically favoured product should be **2a**. The ratio of the formed diastereomers cannot be explained by the steric restriction coming from the ebthi ligand. The formation of **2a** as the major isomer indicates that there is no steric repulsion between the ebthi ligand and the seven-membered ring in the β position of the metallacycle due to the similarity of **2a** and **2b**. Investigations concerning coupling reactions with substituted olefins show the same stereochemical behaviour.[8]

Additionally, for comparison, other cyclic carbonyl compounds with a different number of oxygen atoms in the ring, such as ketones (no O atoms) and ethylene carbonate (two O atoms) were also investigated.

The reaction of Cp$_2$Zr(L)(η^2-Me$_3$SiC$_2$SiMe$_3$) (L = THF, pyridine) with cyclohexanone yields, by an insertion of the carbonyl compound into a Zr−C bond, the metallacyclic complex **3** (Eq. 3).



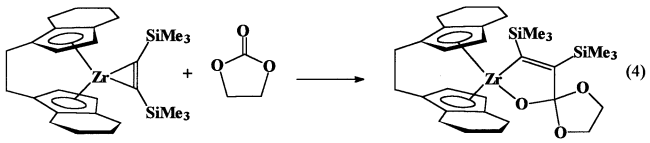
(3)

L = py, THF

3

In the reaction with cycloheptanone the analogous complex **4** was obtained. Both complexes are orange solids (**3**: m.p. 136°C; **4**: 138°C), which were characterized using NMR spectra (**3**, **4**) and X-ray crystal-structure analysis (**3**).

In addition, the reaction of *rac*-(ebthi)Zr(η^2-Me$_3$SiC$_2$SiMe$_3$) with ethylene carbonate results in an insertion of the carbonyl compound into a Zr−C bond of the zirconacyclopropene to yield the five-membered metallacyclic complex **5** (Eq. 4). Complex **5** is a yellow crystalline substance (m.p. 120°C).



(4)

5

From reactions of Cp$_2$Zr(L)(η^2-Me$_3$SiC$_2$SiMe$_3$) (L = THF, pyridine) with ethylene carbonate no defined product could be isolated. The ^{1}H-NMR spectra showed within a mixture of products the formation of a small amount of a metallacyclic complex analogous to **5** and free ethylene carbonate; no polymeric product was obtained.

Spectroscopic Characteristics

The NMR spectra of complexes **1**−**5** are very similar to those reported earlier for such metallacycles, obtained from reactions of (alkyne)zirconocene complexes with acyclic carbonyl compounds such as aldehydes, ketones and esters.[5] Table 1 lists the relevant NMR data in comparison to the acetone metallacycle [Cp$_2$Zr{−C(SiMe$_3$)=C(SiMe$_3$)−CMe$_2$−O−}] (**6**).

Table 1. Selected NMR data of zirconacyclic complexes **1**, **2a**, **3**, **4** and **6**

	1	**2a**	**3**	**4**	**6**[5a]
^{1}H NMR					
Cp	6.07 6.16		6.32	6.11	6.12
SiMe$_3$	0.19 0.47	0.35 0.51	0.13 0.20	0.20 0.35	0.19 0.29
^{13}C NMR					
C$_\alpha$,C$_\beta$ (alkyne)	214.7 190.0	219.6 187.4	215.3 192.8	211.6 195.3	211.7 193.5
C(CO)	106.8	105.5	93.0	95.2	89.0

These data allow a clear distinction between the C_1- (**1**, **2**) and the C_s-symmetric (**3**, **4**, **6**) complexes to be made. While the coupling of Cp$_2$Zr(L)(η^2-Me$_3$SiC$_2$SiMe$_3$) with the prochiral carbonyl compound ε-caprolactone leads to a C_1-symmetric complex with two signals for the inequivalent Cp ligands (**1**: 2 s, each 5 H, δ = 6.07 and 6.16), the reaction product formed by the coupling with symmetrically substi-

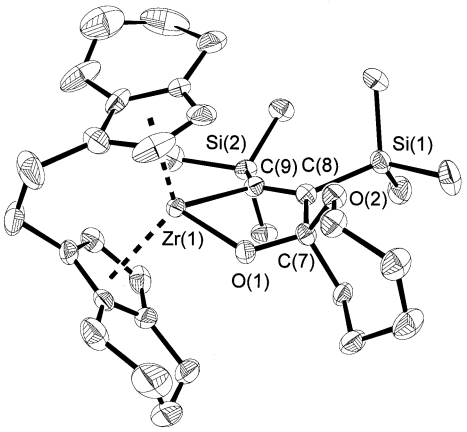
tuted carbonyl compounds is C_s-symmetric and exhibits one signal for the two Cp rings (**3**, **4**, **6**, cf. Table 1).

Starting from the C_2-symmetric alkyne complex *rac*-(ebthi)Zr(η^2-$Me_3SiC_2SiMe_3$) we obtained as coupling products with the prochiral ε-caprolactone a mixture of two diastereomers (see above) for which each diastereomer shows four doublets for the Cp′ protons. By coupling the C_{2v}-symmetric ethylene carbonate with *rac*-(ebthi)Zr(η^2-$Me_3SiC_2SiMe_3$) the C_1-symmetric complex **5** is formed quantitatively, as shown by NMR investigations, and the spectra exhibit four characteristic doublets in the Cp region.

Structural Investigations

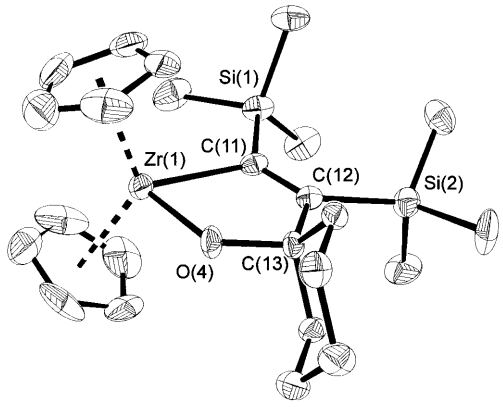
Complexes **2a** and **3** were investigated by an X-ray crystal structure analysis (Figure 1 and 2).

Figure 1. Molecular structure of complex **2a**, shown by an ORTEP plot at the 30% probability level[a]



[a] Selected bond lengths [Å] and bond angles [°]: Zr1−C9 2.320(6), O1−C7 1.402(7), Zr1−O1 1.972(4), C7−C8 1.549(8), C8−C9 1.367(8), C9−Zr−O1 77.7(2), C7−O1−Zr 120.0(4), C8−C9−Zr 106.7(4).

Figure 2. Molecular structure of complex **3**, shown by an ORTEP plot at the 30% probability level[a]



[a] Selected bond lengths [Å] and bond angles [°]: Zr1−C11 2.324(5), C11−C12 1.358(7), C12−C13 1.527(7), C13−O4 1.441(5), Zr−O4 1.922(3); C11−Zr1−O4 76.2(2), C12−C11−Zr1 110.1(4).

The obtained data for the five-membered zirconacyclic ring of complexes **2a** and **3** are listed in Table 2 and compared with those of complex **6**.

Table 2. Selected bond lengths [Å] and angles [°] for compounds **2a**, **3** and **6**

	2a	**3**	**6**[5a]
Bond lengths [Å]			
Zr−O	1.972(4)	1.922(3)	1.936(3)
Zr−C_α	2.320(6)	2.324(5)	2.324(5)
C_α−C_β	1.367(8)	1.358(7)	1.371(7)
C_β−CR_2	1.549(8)	1.527(7)	1.544(7)
O−CR_2	1.402(7)	1.441(5)	1.426(6)
Bond angles [°]			
O−Zr−C_α	77.7(2)	76.2(2)	76.4(2)
Si−C_α−Zr	125.8(2)	120.9(3)	121.6(2)
Si−C_α−C_β	127.4(5)	129.0(4)	128.4(4)
C_α−C_β−Si	126.6(5)	125.7(4)	125.6(4)
Si−C_β−CR_2	115.9(4)	115.3(4)	116.1(3)
O−CR_2−C_β	111.8(5)	108.2(4)	108.7(4)

Both structures correspond very well to that of the acetone product **6**[5a] and show as a result of a coupling of the alkyne with the carbonyl compound the metallacyclic ring substituted by an intact lactone or cyclohexane ring system. The C_α−C_β bond lengths [**2a**: 1.367(8); **3**: 1.358(7) Å] are in the expected range for C−C double bonds and the C−O distances [**2a**: 1.402(7); **3**: 1.441(5) Å] are in the C−O single-bond range. All bond lengths and angles of the five-membered zirconacycle in the three compounds compared are very similar.

Stoichiometric Reactions

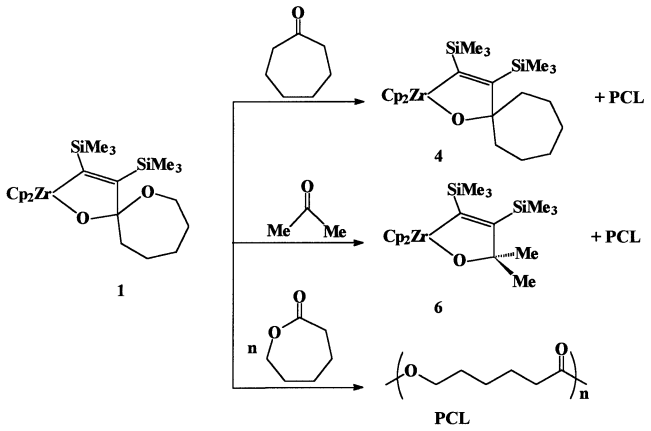
The reaction behaviour of [Cp_2Zr{−C($SiMe_3$)=C($SiMe_3$)−CMe_2−O−}] (**6**) has been well studied.[5a] In solutions containing **6** and acetone an equilibrium with an "opened form" [$Cp_2Zr(Me_2CO)(\eta^2$-$Me_3SiC_2SiMe_3)$] was proposed, the latter paving the way to numerous ligand replacements. These reactions are reversible and degenerate, and were studied by NMR methods.[5c] With another alkyne, e.g. tolan, complex **6** reacts with substitution of the silylalkyne to yield the analogous thermodynamically more stable phenyl-substituted metallacyclic complex.

In reactions of **1**, **4** and **5** with carbonyl compounds similar behaviour was expected and the stability of the complexes depending on different carbonyl compounds was investigated.

In the reaction of **1** with equimolar amounts of cycloheptanone the ε-caprolactone (CL) part of the metallacycle is substituted by cycloheptanone, and **4**, as well as poly-ε-caprolactone (PCL), are formed. It is reasonable to assume that the substitution to give **4** is slow and the free CL can react quickly with unchanged **1** to give PCL. This substitution also proceeds very well with acetone to give the corresponding metallacycle **6**.

Complex **1** alone reacts with further CL under ring-opening polymerization to PCL. **1** is thermally unstable, and decomposes at room temperature to form PCL. In contrast, the cyloheptanone complex **4** is thermodynamically so

Scheme 1



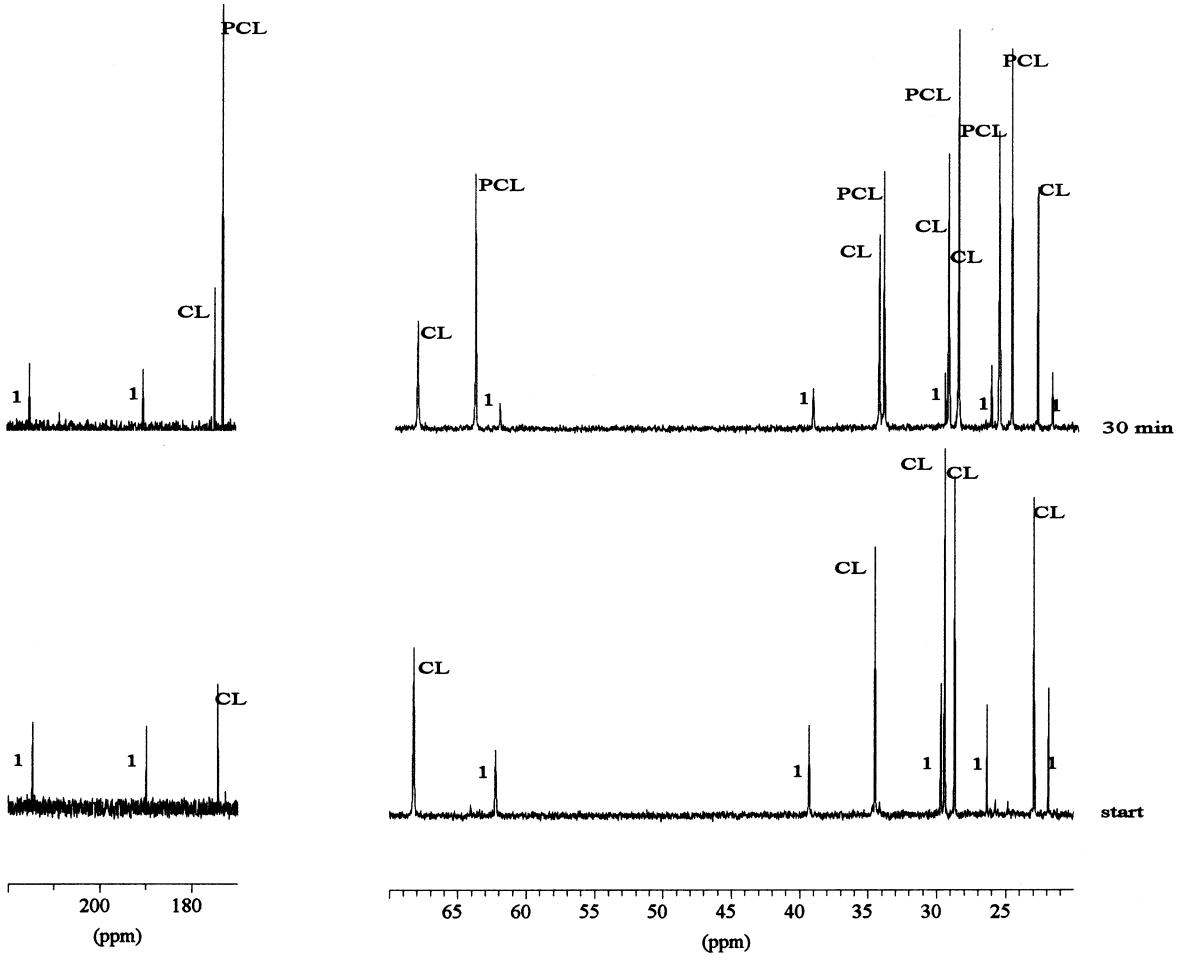
stable that it is unreactive toward ethylene carbonate (EC) or ε-caprolactone (toluene, 75°C, 1 h). It could be handled for a short time in air. The acetone complex **6** also forms compound **4** with cycloheptanone. The comparison of stabilities and reactivities thus shows the following trend: **4** > **6** > **1**. In this series, complex **4** is the most stable and complex **1** the most reactive compound.

The differences in the reaction behaviour, which were observed in spite of the accordance in structural parameters of the metallacycles, can be explained on the basis of steric and/or electronic factors of the substituents of the metallacyclic ring.

NMR Investigations of the Catalytic Ring-Opening Polymerization

The (alkyne)zirconocene complexes with additional ligands $Cp_2Zr(L)(\eta^2\text{-}Me_3SiC_2SiMe_3)$ (L = THF, pyridine) and the corresponding compound without stabilizing ligands *rac*-(ebthi)$Zr(\eta^2\text{-}Me_3SiC_2SiMe_3)$ are active in catalytic ring-opening polymerizations of ε-caprolactone. The poly-ε-caprolactone (PCL) produced was shown to possess a very high molecular weight (M_w = 73 000) and a narrow molecular weight distribution (M_w/M_n = 1.4) by GPC analysis.[3a] In order to learn about the polymerization mechanism, the ring-opening process was monitored directly by NMR spectroscopy (Figure 3). $Cp_2Zr(L)(\eta^2\text{-}Me_3SiC_2SiMe_3)$ (L= pyridine, THF) was treated with ε-caprolactone (1−10 equivalents) in an NMR tube. The ^{1}H- and ^{13}C-NMR spectra recorded immediately after the addition of CL showed at the initial stage the resonances arising from complex **1**, which is rapidly formed and indicated by

Figure 3. ^{13}C-NMR spectra of $Cp_2Zr(py)(\eta^2\text{-}Me_3SiC_2SiMe_3)$ with 10 equivalents of ε-caprolactone in C_6D_6; (CL = ε-caprolactone, PCL = poly-ε-caprolactone, complex **1**)



the shift of the CO signal from δ = 174.8 (free CL) to 106.8 (complex **1**). With an excess of the substrate free CL was also observed. NMR spectra taken 30 minutes after mixing showed signals arising from complex **1**, from free substrate (CL) and from poly-ε-caprolactone (PCL). The signals of monomeric ε-caprolactone (CL) disappeared within 1 h, the solution becoming highly viscous. No other species and unfortunately no end-group signals could be detected.

By combining ε-caprolactone with ethylene carbonate, polymers containing parts of PCL as well as polyethylenecarbonate (PEC) were indicated. The ^{13}C-NMR spectra of the copolymer exhibit, in addition to the carbonyl peaks of PCL (δ = 172.8), one of PEC (δ = 155.0). The amount of ethylene carbonate in the copolymer can be calculated from the ratio of the areas of these peaks and was in the range of about 8 mol-%. In contrast to this observation, ethylene carbonate is not homopolymerized in toluene or THF even at reflux (see above). Also $Cp^*_2Sm(THF)_2$ systems, which could not polymerize ethylene carbonate, form copolymers, derived from CL and EC.[9]

Based on the results discussed for the ring-opening polymerization of ε-caprolactone by Cp^*_2SmMe[1c] and $Cp^*_2LnOMe(THF)$,[1c] as well as our results mentioned above, we propose that at an early stage an exchange of the ligand L (L = THF or pyridine) takes place; ε-caprolactone approaches through the carbonyl oxygen atom. Examples of this interaction can be found in the crystallographically characterized complexes *mer*-YCl_3(ε-caprolactone)$_3$[2b] and $Cp_2Zr(Me_3SiC_2SiMe_3)$(Me-ε-caprolactam),[3b] or in the ^{1}H-NMR-spectroscopically identified initiator complex $Cp^*_2Y(OMe)$(ε-caprolactone).[1c] The next step is the insertion of the carbonyl group of the lactone into the zirconacyclopropene ring system to yield the five-membered metallacyclic complex **1**. On the basis of ^{13}C-NMR studies in the initiation of the ring-opening polymerization of ε-caprolactone and δ-valerolactone by Cp^*_2SmMe,[1c] the formation of an acetal has also been discussed.

The results of the NMR studies are disappointing. All subsequent steps of the catalytic cycles such as propagation and chain termination are very fast on the NMR time scale, and could not be detected. This is consistent with the results obtained by other groups in monitoring lactone polymerization by NMR.[1] Furthermore, no end-group signals were found. This has also been explained in some other works,[1b][1f] by the formation of a cyclic polymer as the termination step.

Conclusion

The present study demonstrated that in the reaction of the (alkyne)zirconocene complexes $Cp_2Zr(L)(\eta^2\text{-}Me_3SiC_2SiMe_3)$ (L= THF, pyridine) and *rac*-(ebthi)$Zr(\eta^2\text{-}Me_3SiC_2SiMe_3)$ with ε-caprolactone the five-membered spirocyclic zirconadihydrofuranes **1** and **2** are formed. Both complexes are intermediates in the catalytic ring-opening polymerization of ε-caprolactone. Complex **2** is the first well-characterized example for the formation of such an acetal, which was proposed as an elemental step of the ring-opening polymerization of lactones.[1] NMR studies showed that further steps of the catalytic cycle such as propagation and chain termination are very fast on the NMR time-scale and could not be detected.

The reaction of (alkyne)zirconocene complexes with other cyclic carbonyl compounds such as ketones or ethylene carbonate yields analogous metallacycles, but no polymerization was observed.

Work is in progress to expand the ring-opening capability to other heterocyclic substrates and to utilize the chiral initiator for stereoselective ring openings.

We thank the *Fonds der Chemischen Industrie* and the *Max-Planck-Gesellschaft* for financial support.

Experimental Section

General: All operations were carried out under argon using standard Schlenk techniques. Prior to use, solvents were freshly distilled from sodium tetraethylaluminate and stored under argon. Deuterated solvents were treated with sodium or sodium tetraethylaluminate, distilled and stored under argon. ε-Caprolactone (Aldrich) was dried over molecular sieves and degassed before use. − Mass spectra: AMD 402. − NMR spectra: Bruker ARX 400. Chemical shifts referenced to signals of the solvents used: [D_6]benzene (δ_H = 7.16; δ_C = 128.0). The spectra were assigned with the help of DEPT and COLOC experiments. − Melting points: sealed capillaries, Büchi 535 apparatus. − Elemental analyses: Leco CHNS-932 elemental analyzer.

Preparation of **1**: To a solution of 377 mg (0.80 mmol) of $Cp_2Zr(py)(\eta^2\text{-}Me_3SiC_2SiMe_3)$ in 10 ml of diethyl ether was added at −10°C 92 μl (0.80 mmol) of ε-caprolactone. The mixture was stirred for 30 min at this temperature and the colour changed to orange. After concentration to dryness, *n*-hexane was added. The solution was filtered, and after 12 h at −78°C orange crystals formed. The crystals were washed with cold *n*-hexane and dried in vacuo to give 210 mg (51%) of **1**. − ^{1}H NMR (C_6D_6): δ = 0.19, 0.47 (s, 2 × 9 H, $SiMe_3$), 1.4−2.1 (m, 6 H, CH_2), 3.5−3.6 (m, 2 H, CH_2), 3.83 (m, 2 H, CH_2), 6.07, 6.16 (s, 2 × 5 H, Cp). − ^{13}C{^{1}H} NMR (C_6D_6): δ = 4.4, 4.8 ($SiMe_3$), 21.9, 26.4, 29.7, 39.3, 62.3 (CH_2), 106.8 (CO), 113.1, 114.3 (Cp), 190.0 (β-*C*$SiMe_3$), 214.7(α-*C*$SiMe_3$). − MS (70 eV); *m/z* (%): 220 $[Cp_2Zr]^+$, 170 $[Me_3SiC_2SiMe_3]^+$, 114 [ε-caprolactone]$^+$. − $C_{24}H_{38}O_2Si_2Zr$ (505.96): calcd. C 56.97, H 7.57; found C 56.83, H 7.63.

Preparation of **2a and 2b**: To a solution of 140 mg (0.266 mmol) of *rac*-(ebthi)$Zr(\eta^2\text{-}Me_3SiC_2SiMe_3)$ in 10 ml of *n*-hexane, 28.1 μl (0.266 mmol) of ε-caprolactone was added. The colour of the reaction mixture changed from green to red-orange after a few seconds. After standing for two weeks at −78°C, red crystals separated which were suitable for X-ray structure analysis (crystals were the pure diastereomer **2a** as checked by NMR). Evaporation of the solvent at room temperature yielded 73 mg (43%) of an orange foam of **2a** and **2b**. − **2a** (major isomer): ^{1}H NMR (C_6D_6): δ = 0.35 (s, 9 H, $SiMe_3$), 0.51 (s, 9 H, $SiMe_3$), 1.4−3.2 (m, 28 H, CH_2), 3.57 (1 H, OCH_2), 3.90 (1 H, OCH_2), 5.12 (d, *J* = 2.8 Hz, 1 H, Cp′), 5.39 (d, *J* = 3.0 Hz, 1 H, Cp′), 6.58 (d, *J* = 3.0 Hz, 1 H, Cp′), 6.85 (d, *J* = 2.8 Hz, 1 H, Cp′). − ^{13}C{^{1}H} NMR (C_6D_6): δ = 4.6, 6.2 ($SiMe_3$), 21.2, 22.6, 23.0, 23.0, 23.2, 23.3, 23.5, 24.0, 24.0, 24.6, 25.5, 28.0, 28.1, 28.9 (CH_2), 44.0 [CH_2C(O)], 60.8 (CH_2O), 107.7, 109.5, 110.6, 114.7, 122.1, 122.9, 129.3, 129.4 (CH) 105.5 (CO), 187.4 (β-*C*$SiMe_3$), 219.6 (α-*C*$SiMe_3$). − $C_{34}H_{52}O_2Si_2Zr$ (640.2): calcd. C 63.79, H 8.19; found C 64.00, H 8.16. − **2b** (minor

isomer, could only be obtained in a mixture with **2a**): ^{1}H NMR (C_6D_6): δ = 0.29 (s, 9 H, $SiMe_3$), 0.34 (s, 9 H, $SiMe_3$), 5.15 (d, J = 2.7 Hz, 1 H, Cp′), 5.33 (d, J = 3.2 Hz, 1 H, Cp′), 6.35 (d, J = 3.2 Hz, 1 H, Cp′), 6.76 (d, J = 2.7 Hz, 1 H, Cp′), further signals could not be assigned. – ^{13}C{^{1}H} NMR (C_6D_6): δ = 5.4, 6.2 ($SiMe_3$), 39.5 [CH_2C(O)], 61.2 (CH_2O), 106.7, 108.7, 112.1, 116.5, 123.1, 123.5, 126.2, 127.3, 130.0, 130.6 (CH-ebthi), 105.0 (CO), 191.4 (β-CSiMe$_3$), 216.6 (α-CSiMe$_3$).

Preparation of **3**: An amount of 250 mg (0.54 mmol) of $Cp_2Zr(THF)(\eta^2$-$Me_3SiC_2SiMe_3)$ was dissolved in 10 ml of THF, and cyclohexanone (56 μl, 0.54 mmol) was added to the solution. The mixture was stirred, whereupon the colour changed from orange to yellow. The solution was concentrated to dryness and the residue was dissolved in *n*-hexane. On standing at −78°C for 2 d, orange crystals deposited which were dried in vacuo to give 210 mg (79%) of **3**, m.p. 136°C. – ^{1}H NMR (C_6D_6): δ = 0.13, 0.20 (s, 2 × 9 H, $SiMe_3$), 0.90−1.0 (m, 2 H, CH_2), 1.30−1.41 (m, 4 H, CH_2), 1.61−1.70 (m, 4 H, CH_2), 6.32 (s, 10 H, Cp). – ^{13}C{^{1}H} NMR (C_6D_6): δ = 5.2, 5.4 ($SiMe_3$), 22.7, 26.1, 35.4 (CH_2), 93.0 (CO), 113.9 (Cp), 192.8 (β-CSiMe$_3$), 215.3 (α-CSiMe$_3$). – MS(70 eV); m/z (%): 220 Cp_2Zr^+, 170 $[Me_3SiC_2SiMe_3]^+$, 98 [cyclohexanone]$^+$. – $C_{24}H_{38}OSi_2Zr$ (489.94): calcd. C 58.83, H 7.82; found: C 58.53, H 8.13.

Preparation of **4**: The reaction was carried out in the same manner as described for complex **3** with an amount of 420 mg (0.89 mmol) of $Cp_2Zr(py)(\eta^2$-$Me_3SiC_2SiMe_3)$ and cycloheptanone (104 μl, 0.89 mmol) to give 330 mg of **4** (74%), orange crystals, m.p. 138°C. – ^{1}H NMR (C_6D_6): δ = 0.20, 0.35 (s, 2 × 9 H, $SiMe_3$), 1.51 (m, 4 H, CH_2), 1.66 (m, 4 H, CH_2), 1.83 (m, 2 H, CH_2), 2.03 (m, 2 H, CH_2), 6.11 (s, 10 H, Cp). – ^{13}C{^{1}H} NMR (C_6D_6): δ = 5.0, 5.2 ($SiMe_3$), 22.8, 27.6, 38.4 (CH_2), 95.2 (CO), 113.2 (Cp), 195.3 (β-CSiMe$_3$), 211.6 (α-CSiMe$_3$). – MS(70 eV); m/z (%): 220 Cp_2Zr^+, 170 $[Me_3SiC_2SiMe_3]^+$, 112 [cycloheptanone]$^+$. – $C_{25}H_{39}OSi_2Zr$ (489.94): calcd. C 59.70, H 7.82; found C 58.83, H 8.11.

Preparation of **5**: To a solution of 310 mg (0.589 mmol) of *rac*-(ebthi)$Zr(\eta^2$-$Me_3SiC_2SiMe_3)$ in 3 ml of diethyl ether, 52 mg (0.589 mmol) of ethylene carbonate was added . The colour of the reaction mixture changed from green to red-orange after stirring for 5 min. Addition of 3 ml of pentane and standing for 12 h at −40°C gave 310 mg of **5** (85%), yellow crystalline solid, m.p. 120°C. – ^{1}H NMR (C_6D_6): δ = 0.19, 0.27 (s, 2 × 9 H, $SiMe_3$), 1.1−3.4 (20 H, CH_2), 3.51(2 H, OCH_2), 3.59 (1 H, OCH_2), 4.91 (1 H, Cp′), 5.20 (d, 1 H, Cp′), 6.65 (d, 1 H,Cp′), 6.70 (d, 1 H, Cp′). – ^{13}C{^{1}H} NMR (C_6D_6): δ = 3.3 ($SiMe_3$), 5.6 ($SiMe_3$), 22.3, 22.9, 23.0, 23.1, 23.1, 23.6, 23.9, 24.6, 27.3, 27.6 (CH_2-ebthi), 62.3, 62.6 (CH_2O), 108.4, 109.4, 111.0, 118.2 (CH-ebthi) 119.0, 122.9, 123.7, 128.7, 129.5, 131.6 (C_q), 181.5 (β-CSiMe$_3$), 227.7 (α-CSiMe$_3$). – $C_{31}H_{46}O_3Si_2Zr$ (614.10): calcd. C 60.63, H 7.55; found C 60.59, H 7.47.

Polymerization of ε*-Caprolactone in an NMR Tube:* In a 5-mm NMR tube the catalyst (20−30 mg) was dissolved in C_6D_6 (0.6 ml). ε-Caprolactone (1−10 equivalents) was placed at the upper end of the tube to prevent early mixing. The NMR tube was closed and vigorously shaken just before running the spectra.

X-ray-Crystallographic Study of Complexes **2 and 3**: Diffraction data were collected on a STOE-IPDS diffractometer using graphite-monochromated Mo-K_α radiation. Crystal data, details of the data collections and structure refinement are compiled in Table 3. The structures were solved by direct methods (SHELXS-86: G. M. Sheldrick, *Acta Crystallogr., Sect. A* **1990**, *46*, 467) and refined by full-matrix least-squares techniques against F^2 (SHELXL-93: G. M. Sheldrick, University of Göttingen, Germany, **1993**). Further details of the crystal-structure investigations are available on request from the Cambridge Crystallographic Data Centre, on quoting the depository number CCDC-101309. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44(0)1223/336033; E-mail: deposit@ccdc.cam.ac.uk].

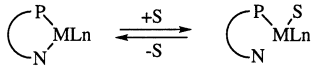
Received March 23, 1998

Keywords: β-Ferrocenylvinyl azide / Polyphosphanes / Iminophosphoranes / *P,N*-Difunctional ligands / Palladium

Staudinger reactions of the β-ferrocenylvinyl azide **1** with several diphosphanes in a 1:1 molar ratio afford the monoiminophosphorane derivatives **2**–**4**, whereas with a 2:1 stoichiometry these reactions afford the bis(iminophosphoranes) **5**–**7**. Similar results are obtained for the reactions of **1** with tris(diphenylphosphanylmethyl)ethane (*triphos*) and tris[2-(diphenylphosphanyl)ethyl]phosphane (*tetraphos*). Reaction of these *P,N*-difunctional ferrocene ligands with dichlorobis(benzonitrile)palladium(II) leads to the Pd^{II}-metallacycle derivatives **13** and **14**. The molecular structures of **5d** and **13** have been established by X-ray crystallography.

Ferrocene derivatives containing phosphane groups have proved to be very useful in coordination chemistry[1] and have found application in enantioselective transition-metal-catalyzed reactions[2]. In contrast to the large number of ferrocene-derived phosphanes and their complexes in which the phosphorus atom is directly bonded to a cyclopentadienyl ring, ligands with a tether connecting the two functionalities are less common[3], although chiral analogues have been attracting interest owing to their catalytic activity[4].

There is also a general interest in transition-metal complexes with heterodifunctional ligands because of their potential as catalysts[5] and their proven usefulness in the preparation of heterobimetallic species[6]. Heterodifunctional ligands provide versatile binding sites for metals, and thus effective catalysts may be generated from complexes of bifunctional chelate ligands in which one arm of the chelate is more loosely bound than the other, so that an equilibrium opening a coordinate site and thus providing access to a reactive intermediate can be established.



Since M−N π bonds are known to be more labile than M−P π bonds in some complexes[7], the use of bidentate ligands containing one phosphorus and one nitrogen donor can be expected to improve the catalytic activity. In this context, the preparations and catalytic activities of a number of rhodium, iridium, palladium and platinum *P,N* complexes, which contain a soft phosphorus(III) center at one end and a hard nitrogen center (amino, amido, imine or pyridine ring) at the other, have been reported[8].

Following our work on the preparation of new ferrocene derivatives by means of aza Wittig reactions[9], we now wish to report on the efficient synthesis of *P,N*-heterodifunctional ferrocene-based ligands. Our approach is based on the Staudinger imination[10] of trivalent phosphorus compounds with azides to produce an iminophosphorane function after nitrogen evolution. This method, which allows the partial oxidation of diphosphanes using the β-ferrocenylvinyl azide **1**, is applicable to diphosphanes of various alkene chain lengths, and even to tri- and tetraphosphanes.

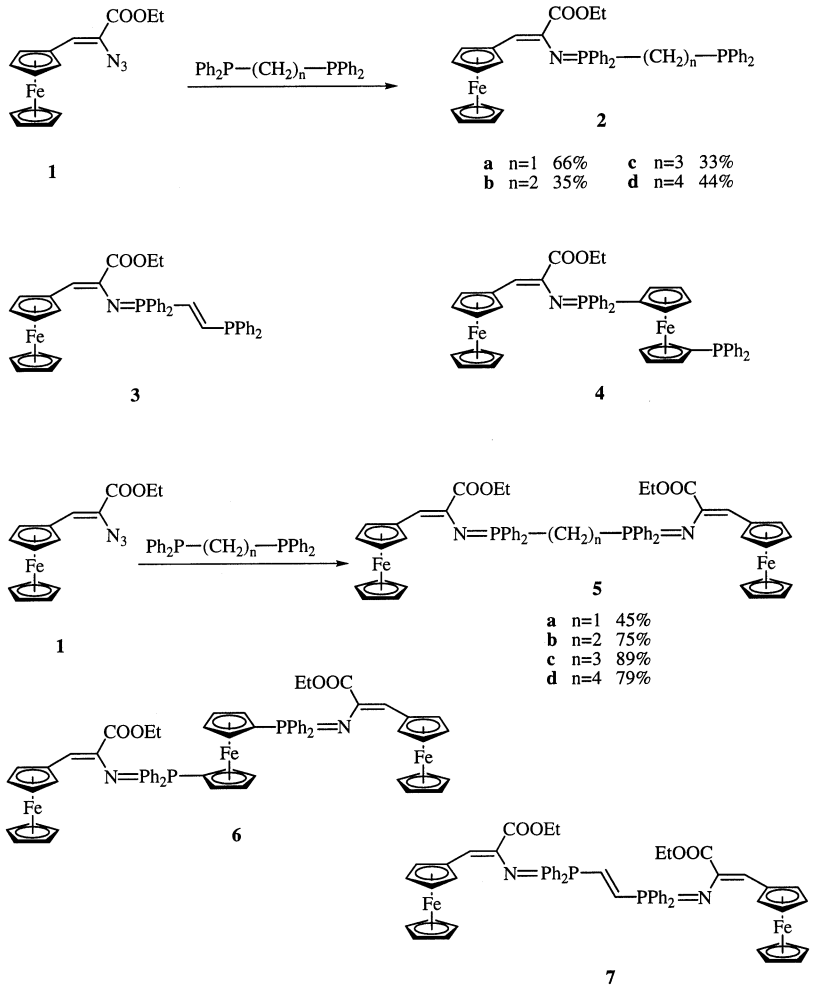
Results and Discussion

Reaction of the starting β-ferrocenylvinyl azide **1**[9] with the appropriate diphosphane (1:1 molar ratio) in dry dichloromethane for 15 h at room temperature provides the corresponding monoiminophosphorane **2**, along with trace amounts of the bis(iminophosphorane) **5**. Compounds **2** could be isolated in yields ranging from 33 to 66% after purification by column chromatography and recrystallization. Similarly, reactions of **1** with (*E*)-1,2-bis(diphenylphosphanyl)ethene and 1,1′-bis(diphenylphosphanyl)ferrocene afford the monoiminophosphoranes **3** (46%) and **4** (21%), respectively. However, when reactions of azide **1** with diphosphanes (2:1 molar ratio) were carried out in diethyl ether at −15°C, the major product is the corresponding bis(iminophosphorane) **5** (45−89%), together with a small amount of the monoiminophosphorane **2**. Under these conditions, reaction with 1,1′-bis(diphenylphosphanyl)ferrocene provides the bis(iminophosphorane) **6**, while

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1434−1948/98/0909−1359 $ 17.50+.50/0

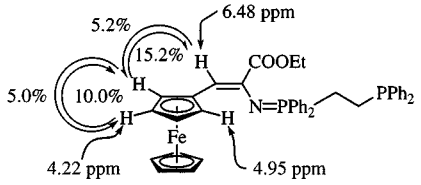
that with (*E*)-1,2-bis(diphenylphosphanyl)ethene afforded **7**, albeit in very low yield (9%) (Scheme 1).

Scheme 1



The ^{1}H-NMR spectra of compounds **2** and **5** show characteristic features: the ferrocenyl hydrogen atoms give a singlet at $\delta = 4.01-4.12$ for the unsubstituted cyclopentadienyl ring, and two pseudo triplets at $\delta = 4.17-4.59$ and $\delta = 4.90-5.06$, corresponding to an AA′MM′ pattern for the monosubstituted ring, while the vinylic proton signal appears as a doublet at $\delta = 6.14-6.53$ due to P^V coupling. The ^{13}C{^{1}H}-NMR spectra also exhibit the typical signals for monosubstituted ferrocenes. NOE experiments performed on compound **2b** allowed us to assign the α- and β-protons of the substituted cyclopentadienyl ring (Figure 1).

Figure 1. Selected NOE correlations for compound **2b**



Some salient ^{13}C{^{1}H}- and ^{31}P{^{1}H}-NMR data for compounds **2** and **5** are compiled in Table 1. The ^{13}C-NMR spectrum of monoiminophosphorane **3** can be described as an AMX system, the ethylenic carbon atom $C-P^{III}$ signal appears at $\delta = 148.41$ as a doublet ($^1J_{P\text{-}C} = 23.4$ Hz), while the ethylenic $C-P^V$ signal appears at $\delta = 134.73$ as a doublet of doublet ($^1J_{P\text{-}C} = 87.2$ Hz, $^2J_{P\text{-}C} = 10.5$ Hz). In the bis(iminophosphorane) **7**, the two ferrocene subunits are equivalent; the C=O carbon atom signals appear as an apparent triplet and the ethylenic carbon atom signals $C-P^V$ appear at $\delta = 141.16$ as five-line multiplets. The ^{31}P{^{1}H}-NMR spectrum of **3** features two doublets centered at $\delta = 1.04$ and $\delta = -7.25$, attributable to the pentavalent and trivalent phosphorus atoms, respectively, whereas the spectrum of bis(iminophosphorane) **7** shows only one singlet at $\delta = 0.63$. In the ^{1}H- and ^{13}C-NMR spectra of compounds **4** and **6**, the characteristic signals of mono- and disubstituted ferrocenes are observed. In the ^{13}C-NMR spectrum of compound **4**, the disubstituted ferrocene ring signals appear as a set of six pairs of doublets, whereas in compound **6** it gives rise to a set of three pairs of doublets, besides only one set of signals for the two monosubstituted ferrocenes, indicating that they are equivalent. The ^{31}P-NMR spectrum of compound **4** shows two singlets at $\delta = 4.40$ and $\delta = -19.04$, assigned to the pentavalent and trivalent phosphorus atoms respectively, while that of compound **6** shows

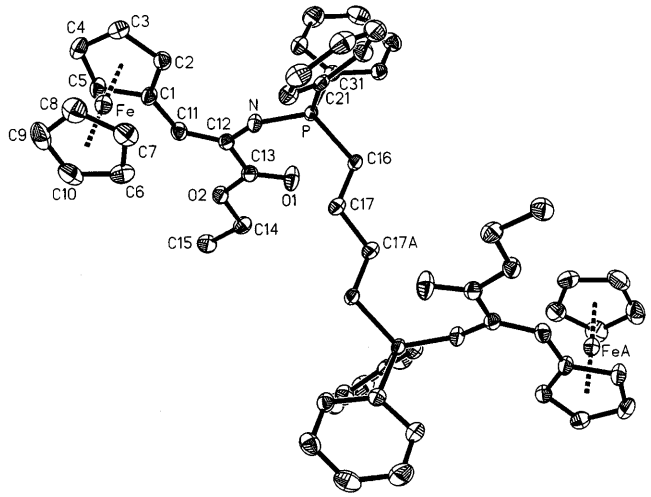
only one singlet at δ = 5.34. The constitution of compound **5d** was further corroborated by a single-crystal X-ray diffraction study. The molecular structure shows an inversion centre in the C17−C17a bond mid point. The P−N bond lenght [1.566(2) Å] is within the expected values. An ORTEP drawing of **5d** is shown in Figure 2; selected bond lengths and angles are given in the caption.

Figure 2. ORTEP plot of compound **5d**[a]



[a] 50% probability ellipsoids; selected bond lengths [Å] and angles [°]: P−N 1.566(2), N−C(12) 1.384(3), C(1)−C(11) 1.453(3), C(11)−C(12) 1.350(3); C(12)−N−P 131.6(2), C(12)−C(11)−C(1) 127.5(2), C(11)−C(12)−N 122.8(2).

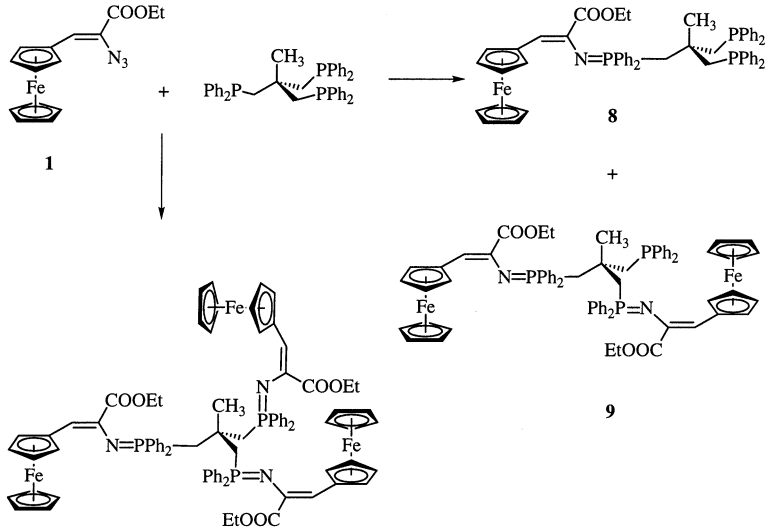
Reaction of the β-ferrocenylvinyl azide **1** with tris(diphenylphosphanylmethyl)ethane (*triphos*) (1:1 molar ratio) in dry dichloromethane at room temperature afforded a mixture of the monoiminophosphorane **8** (21%) and the bis(iminophosphorane) **9** (7%), which were readily separated by column chromatography. However, when the reaction was carried out in diethyl ether at −15°C in a 3:1 molar ratio, the corresponding tris(iminophosphorane) **10** was obtained in good yield as the sole reaction product (77%) (Scheme 2).

The ^1H-NMR spectrum of the bis(iminophosphorane) **9** shows two sets of signals for the two ferrocene subunits, indicating that they are non-equivalent. ^1H-, ^{13}C- and ^{31}P-NMR data of the *triphos* framework in compounds **8**, **9** and **10** are compiled in Table 2.

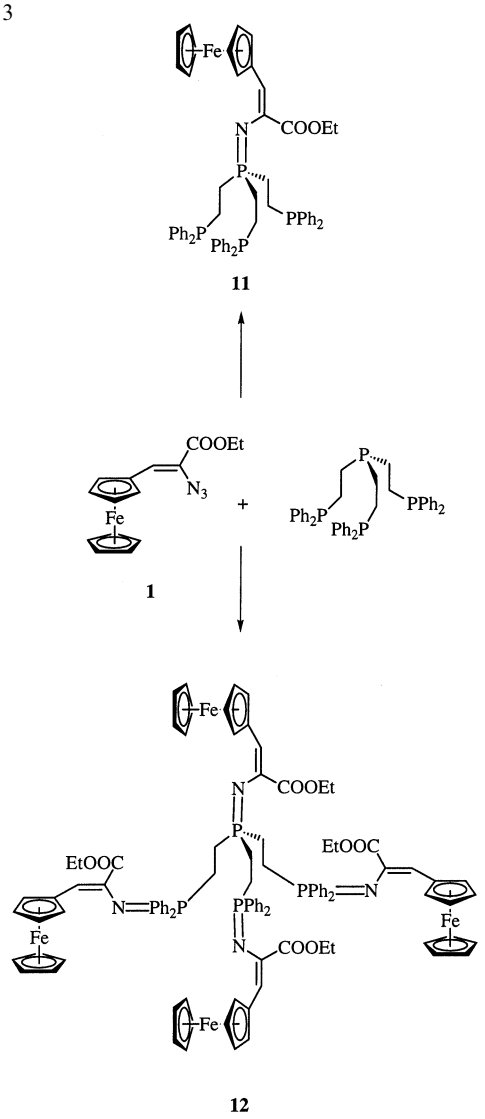
Reaction of azide **1** with tris[2-(diphenylphosphanyl)-ethyl]phosphane (*tetraphos*) in a 1:1 molar ratio in dichloromethane at room temperature afforded the monoiminophosphorane **11** in 31% yield. However, when the reaction was carried out in a 4:1 molar ratio in diethyl ether at −15°C, the main product was found to be the tetra(iminophosphorane) **12** (28%) (Scheme 3). The ^1H- and ^{13}C-NMR spectra of compound **12**, which bears four ferrocene subunits, showed the non-equivalence of one ferrocene group.

At this point, it seemed interesting to assess the complexation behavior of these heterodifunctional ferrocene derivatives **2** and **8** with palladium(II) (Scheme 4), as these compounds possess a complex-forming diphenylphosphanyl group and an iminophosphorane function, which has also demonstrated its versatility in forming M−N σ bonds to transition metals[11].

Scheme 2



Scheme 3



The ferrocene derivative **2a** was found to react cleanly with dichlorobis(benzonitrile)palladium(II) in toluene at −15°C affording the new *P,N*-chelate **13**, the structure of which has been determined by X-ray analysis (Figure 3). The ^{31}P-NMR spectrum of **13** features two doublets, with the iminophosphorane unit resonating at lower field (δ = 44.23) than the diphenylphosphanyl center (δ = 14.16).

Complex **13** represents the first example of a ferrocene derivative containing an iminophosphorane phosphane ligand. The palladium atom has a distorted square-planar coordination geometry. The large Pd−Cl1 bond length (2.3719 Å) compared to Pd−Cl2 (2.3133 Å) is consistent with the larger *trans* influence of P compared to N. The P−N bond length (1.628 Å) indicates that this bond is slightly elongated due to the coordination, since free iminophosphoranes show shorter P−N bond lengths (1.567 Å). The P^V atom geometry corresponds to a distorted tetrahedron, with the N−P−C angle [102.3(1)°] being the smallest. The distortion is probably due to the chelate ring stress.

The complexation behavior of **8** with Pd^{II} under the same reaction conditions was found to be different from that of **2a** and the *P,P*-chelate **14** was formed (Scheme 4). The ^{31}P-NMR spectrum showed this clearly, featuring only two singlets at δ = 0.1, characteristic of a non-coordinated iminophosphorane function, and at δ = 15.60, attributable to the coordinated diphenylphosphane groups.

The difference of 26.6 ppm between the chemical shifts of the P^{III} and P^V centers in **8** is reduced to 15.7 ppm in **14**. The ^{13}C-NMR spectrum of **14** shows two sets of signals for the aromatic rings of the diphenylphosphanyl groups and phosphorus-coupled resonances split into "a non 1:2:1 triplet". Such a triplet could be observed due to a ^{13}C nucleus and two ^{31}P nuclei forming an AXX′ spin system, as characteristic splitting clearly indicates that the two chemically equivalent phosphorus atoms are bound to palladium in a *cis* manner[12]. The differing complexation behavior of

[a] 50% probability ellipsoids; selected bond lengths [Å] and angles [°]: Pd−N 2.062(3), Pd−P(1) 2.2259(11), Pd−Cl(2) 2.3133(9), Pd−Cl(1) 2.3719(11), P(2)−N 1.628(2); N−Pd−P(1) 87.35(8), P(1)−Pd−Cl(2) 88.71(4), N−Pd−Cl(1) 91.75(9), Cl(2)−Pd−Cl(1) 93.10(3), C(6)−P(1)−Pd 105.60(12), N−P(2)−C(6) 102.32(14), P(2)−N−Pd 112.5(2), P(2)−C(6)−P(1) 108.8(2).

2a and **8** may be due to their structural features, since the second diphenylphosphanyl group of **8** has stronger coordination ability toward Pd^{II} that the iminophosphorane group of **2a**.

A final word about the conformation of the ligand **8** and of its complex **14** is relevant. In triphos[13] the signal of the CH_3C protons exhibits a chemical shift of δ = 0.95, while in transition-metal complexes[14] these protons give rise to a signal in the range δ = 1.12−2.09. In the ^{13}C-NMR spectra, the signal of the CH_3C carbon atom appears at δ = 29.5 in the free ligand, while in complexes it appears at δ = 36−40. In all these cases, the triphos fragment adopts a "CH_3-*out*" conformation. The ^{1}H-NMR spectra of compounds **8** and **14** show the signal of the CH_3C protons at δ = 0.85 and δ = 0.14, respectively, while in the ^{13}C-NMR spectra the signal of this methyl carbon atom appears at δ = 28.08 and δ = 28.15, respectively. In view of the fact that in cyclic compounds with bridgehead 1,1,1-trisubstituted ethane fragments, the signal of the "CH_3C-*in*" group is shifted upfield relative to that of the "CH_3-*out*" group[15], the conformation of the triphos fragment in compounds **8** and **14** seems likely to be another than the "CH_3-*out*" one.

We gratefully acknowledge the financial support of the *Dirección General de Investigación Científica y Técnica*, project number PB95-1019.

Experimental Section

All experiments were carried out with the exclusion of air and moisture under nitrogen. Solvents were purified and dried according to standard methods. Compound **1** was prepared according to a literature procedure[9]. − NMR: Bruker AC200 or Varian Unity 300. − MS: Fisons Autospec 5000 VG. − IR: Nicolet Impact 400. − Elemental analyses: Perkin-Elmer 240c. − Melting points were determined with a Kofler hot-plate and are uncorrected.

Preparation of Monoiminophosphoranes **2** *and* **4**. − *General Procedure:* To a solution of the β-ferrocenylvinyl azide **1** (0.50 g, 1.53 mmol) in 10 ml of dry CH_2Cl_2, an equimolar amount of the appropriate diphosphane in 10 ml of dry CH_2Cl_2 was added at room temperature. The reaction mixture was stirred for 15 h. The solvent was then removed in vacuo and the remaining residue was chromatographed on a silica gel column using ethyl acetate/*n*-hexane (1:3) as eluent.

C 61.19, H 4.95, N 1.27; found C 61.31, H 5.07, N 1.04.

X-ray Crystallographic Studies: Crystal data are given in Table 3. Crystals of **5d** suitable for X-ray diffraction were prepared by slow difussion of *n*-hexane in a dichloromethane solution. Slow concentration of a solution of compound **13** in chlroform affords crystals suitable for X-ray diffraction studies. Crystals of **13** · 2 CHCl$_3$ and **5d** were mounted in inert oil on a glass fibre and transferred to the diffractometer (Siemens P4 with LT2 low-temperature attachment). Measurements were made at −100°C using monochromated Mo-K_α radiation (λ = 0.71073 Å). Unit-cell parameters were determined from a least-squares analysis of ca. 70 accurately centered reflections (10° < 2θ < 27°). Intensities were measured using ω scans. Absorption corrections were based on ψ scans. The structures were solved by direct methods (**13** · 2 CHCl$_3$) or by the heavy-atom method (**5d**) and refined anisotropically on F^2 (program SHELXL-93).[16] Hydrogen atoms were included using a riding model or as rigid methyl groups. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-101187. Copies of the

Keywords: Cluster / Metal-rich antimonides / Magnetism / Sb–Sb bonds / Structure and bonding

The metal-rich antimonide $Zr_2V_6Sb_9$ has been prepared by arc-melting of stoichiometric mixtures of Zr, V, and VSb_2. $Zr_2V_6Sb_9$ is the first example of a ternary ordered (filled) variant of the unusual $V_{15}Sb_{18}$ structure type. In addition to strong metal–antimony bonding, the crystal structure is significantly stabilized by bonding V–V and Sb–Sb interactions, whereas the Zr atoms do not form short metal–metal bonds. Band structure calculations using the Extended Hückel approximation reveal $Zr_2V_6Sb_9$ being metallic, in agreement with the Pauli paramagnetism experimentally observed.

Introduction

Several different binary pnictides and chalcogenides of the valence-electron-poor ("early") transition elements with a metal/pnicogen ratio of ca. 1 or higher have been uncovered in the past[1]. Only very few antimonides and bismuthides form structures with short contacts between the pnicogen atoms Q, which are not found among the phosphides and arsenides or the chalcogenides. The fact that short Q−Q distances occur only in case of metal-rich antimonides and bismuthides can be explained with the relatively high electronegativities of phosphorus and arsenic, compared to the early transition-metal atoms. Similarly, the absence of chalcogen−chalcogen bonds in metal-rich chalcogenides can be deduced from the large differences in the electronegativities of the chalcogen atoms sulfur, selenium and tellurium on one hand and of the valence-electron-poor transition metals on the other hand. Especially the occurrence of Q−Q bonds in metal-rich antimonides appears to be somewhat special, because bismuth is classified as a metal, whereas antimony is rather a metalloid or nonmetal. From this point of view, the antimonides are the only metal-rich pnictides whose structures consist in part of nonmetal−nonmetal bonds and thus not completely reduced Q(−III) species.

The only known Bi-rich binary bismuthides of the early transition metals containing Bi−Bi bonds are $Ti_{8-x}Bi_9$ and Hf_8Bi_9[2] which crystallize in the $V_{15}Sb_{18}$ structure type[3]. As for the antimonides, ZrSb[4] and V_3Sb_2[5] both occur in structures consisting in part of hexagonal antimony layers with Sb−Sb distances between 320 pm and 325 pm. These distances are too short for van-der-Waals interactions, as a comparison with the bonding Sb−Sb contacts in the elemental form of antimony (3 × 290.8 pm and 3 × 335.5 pm) reveals[6]. It is worthwhile to note that both vanadium antimonides mentioned, i. e. $V_{15}Sb_{18}$ and V_3Sb_2, are low-temperature phases, and that no Sb−Sb contacts occur in the structure of the high-temperature form $V_{1+x}Sb$ (NiAs structure type)[7]. That leaves ZrSb and the isostructural HfSb[8] as the only binary metal-rich antimonides with Sb−Sb bonds being stable in an inert atmosphere above 1000°C with respect to disproportionation. This paper presents the synthesis, structure and properties of the new antimonide $Zr_2V_6Sb_9$. Furthermore, attempts to replace zirconium by titanium, hafnium and vanadium are discussed.

Experimental Details

The antimonides discussed below were prepared in a two-step synthesis. To avoid substantial loss of antimony during the process of arc-melting, VSb_2 was synthesized first in a fused silica tube at 650°C, starting from the elements in the stoichiometric 1:2 ratio (V: ABCR, powder, −45 micron, 99.7%, first cleaned in a 10% HCl solution, then washed with distilled water and acetone, finally dried under dynamic vacuum at approximately 500 K; Sb: MERCK, powdered, >99%). Second, stoichiometric mixtures of Zr, Ti, or Hf [Ti: VENTRON, powder, −325 mesh, 99%; Zr: ALFA, powder, 4−20 mesh, 99.6%; Hf: STREM, powder, 99.6% (including up to 2.2% Zr)], and V and VSb_2 were pressed into pellets using a force of 20 kN. The pellets were arc-melted twice after inversion under a dynamic flow of Argon (3 l/min) on a water-cooled copper hearth. The reactions of the starting compositions "$M_2V_6Sb_9$" (with M = Ti, Zr, Hf) led to homogenous products, according to the powder diagrams obtained with Cu-$K_{\alpha1}$ radiation (λ = 154.05 pm, using silicon as internal standard). The lattice dimensions as obtained from the powder diagrams are listed in Table 1. In addition to the fact that here the $V_{15}Sb_{18}$ structure type was found after the rapid cooling in the arc melter, the significant increase of the lattice dimensions in comparison to $V_{15}Sb_{18}$ prove the incorporation of the larger atoms of the titanium group.

Attempts to determine the phase range of $Zr_{2-x}V_{6+x}Sb_9$ did not result in homogenous samples when $x \neq 0$. The

[a] Single crystal data. – [b] Powder data. – [c] Obtained with the postulation of mixed Zr/V but full occupation of the "Zr1" and "Zr2" sites.

Zr-poor samples contained $V_{1+x}Sb$, and the Zr-rich phases ZrSb. EDX investigations of selected crystals showed only a minor phase range of $Zr_{2-x}V_{6+x}Sb_9$, i. e. the Zr content varied from 7 to 15 atom-%. These variations may in part be due to different orientations of the crystals to the incident beam. Indexing of the powder diagrams, however, led to different lattice dimensions of the $Zr_{2-x}V_{6+x}Sb_9$ phases, which increase with increasing x (see Table 1). This is a consequence of the larger atomic radius of zirconium, compared to vanadium. However, based on the fact that the V(1) site is not completely occupied in the structure of $V_{15}Sb_{18}$, it may be possible that comparable voids occur in the structures of the $Zr_{2-x}V_{6+x}Sb_9$ phases.

In order to determine the site preferences of the Zr atoms, plate-like single crystals were selected for structure investigations of the phases of the starting compositions "$Zr_1V_7Sb_9$", "$Zr_2V_6Sb_9$" and "$Zr_3V_5Sb_9$". In all three cases, the unit-cell dimensions obtained from the single-crystal diffractometer were in good agreement with those calculated from the powder diagrams of the corresponding bulk samples. In all cases, numerical absorption corrections were performed.

As a starting model, the atomic positions of the binary antimonide $V_{15}Sb_{18}$ were used. The V(1) and V(2) positions were tentatively assigned to Zr sites, because of the higher Sb coordination numbers [eight for V(1) and V(2), and six for V(3) and V(4)]. The refinements of the three different data sets (using SHELXL93[9]) converged smoothly to reasonable residual factors, i. e. conventional R values of $R(F) = 0.0316$ for "$Zr_1V_7Sb_9$", $R(F) = 0.0216$ for "$Zr_2V_6Sb_9$" and $R(F) = 0.0342$ for "$Zr_3V_5Sb_9$". Since the thermal displacement parameters of the Zr positions of the first two data sets were significantly higher than those of the V sites, and at least some mixed occupancies were expected because of the differences in the lattice dimensions, the occupancy factors of all metal sites were refined in order to check for deviations from the ideal stoichiometries. Only the occupancy factors of the Zr sites of the first two data sets differed more than 2% from 100%. Since these sites are completely filled in case of "$Zr_3V_5Sb_9$", corresponding to the formula $Zr_2V_6Sb_9$, they were refined as being statistically mixed occupied by Zr and V to 100% in cases of "$Zr_1V_7Sb_9$" and "$Zr_2V_6Sb_9$". This model led in both cases to more uniform displacement parameters and lower residual factors [R(F) = 0.0295 for "$Zr_1V_7Sb_9$" and $R(F) = 0.0210$ for "$Zr_2V_6Sb_9$"]. The formulas were finally refined to $Zr_{1.61(6)}V_{6.39}Sb_9$, $Zr_{1.80(4)}V_{6.20}Sb_9$, and $Zr_2V_6Sb_9$, respectively. More details about the structure determinations are given in Table 2[10], and atomic parameters are listed in Table 3. It should be noted, however, that two other models, based on the occurrence of voids, would also be in agreement with these experimental data. First, the assumption of no incorporation of V on the Zr sites would result in the formulas $Zr_{1.85(2)}V_6Sb_9$ and $Zr_{1.93(2)}V_6Sb_9$, and second, one might also assume voids, V and Zr atoms on the two Zr sites.

Results and Discussion

$Zr_2V_6Sb_9$ is the first ternary ordered substitution variant of the $V_{15}Sb_{18}$ structure type. For easier comparisons, the setting and the atomic labeling of $V_{15}Sb_{18}$ are used throughout this article, but, of course, V(1) and V(2) of $V_{15}Sb_{18}$ are replaced by Zr(1) and Zr(2). The structure of $Zr_2V_6Sb_9$ is shown in a projection along the crystallographic c axis in Figure 1.

The $Zr_2V_6Sb_9$ structure contains chains of face-sharing square Zr-centered Sb_8 antiprisms, which are surrounded by V layers, where the V atoms are situated in severely distorted Sb_6 octahedra. The Zr(1) and Zr(2) atoms, alternating in each chain along [001], have different distances to the eight surrounding Sb atoms, i. e. 4 × 305.1(2) pm and 4 × 309.2(2) pm for Zr(1), and 4 × 293.2(2) pm and 4 × 293.4(1) pm for Zr(2). The latter distances correspond to those found in the ternary ZrNiSb [TiNiSi-type, five Zr–Sb bonds per Zr atom between 291.44(7) pm and 296.65(6) pm][11]. The differences in the averaged bond lengths occur

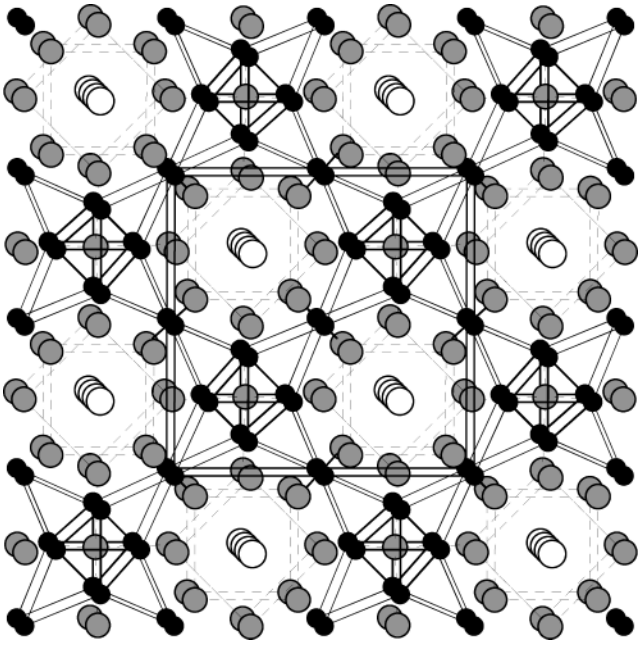
Figure 1. Projection of the structure of $Zr_2V_6Sb_9$ along [001]; large, white circles: Zr; small, black: V; medium, gray: Sb; metal−Sb bonds omitted for clarity



to a comparable extent in the structures of $V_{15}Sb_{18}$ and $Ti_{8-x}Bi_9$ (17.2 pm in both structures), also. The V(1) position, being the one which is occupied only to 50% in the structure of $V_{15}Sb_{18}$, shows very high displacement parameters. Similarly, the displacement parameters of that position in $Zr_2V_6Sb_9$ and $Ti_{8-x}Bi_9$ are approximately between 50% and 100% higher than those of the other metal sites, but the position is filled completely in both cases. The high displacement parameters can be understood as a consequence of the large metal−pnicogen distances, pointing to a "rattling" in a large Sb_8 (or Bi_8) cage, which might result in an unusually low thermal conductivity, as observed for the antimonides LnM_4Sb_{12} (M = Fe, Co, ...)[12].

Each V atom in $Zr_2V_6Sb_9$ is situated in a distorted Sb_6 octahedron with V−Sb distances between 271.3(2) pm and 283.1(1) pm. The averaged distances are slightly enlarged compared to the distances in $V_{15}Sb_{18}$ [between 272.3(4) pm and 279.2(2) pm]. The shorter V−Sb distances, compared to the Zr−Sb distances, most likely inhibit a significant incorporation of the larger Zr atoms on the V positions. The V layers (Figure 2) contain V(4) tetrahedra, which are interconnected via common V(3) atoms capping four edges of each V(4) tetrahedron.

The description based on V tetrahedra should not imply the existence of localized bonds within the tetrahedral units. In contrast, the V−V bonds between the tetrahedra and the bridging V(3) atoms are shorter than the edges capped by the V(3) atoms [291.2(1) pm vs. 304.2(3) pm]. The shortest V−V bond [275.9(4) pm] is situated at the edge of the tetrahedron capped by an Sb(1) atom. The lengths of these bonds are just between the two shortest distances observed in the body-centered cubic (*bcc*) element V (262 pm and 303 pm)[13].

The Sb_4 units of the $ZrSb_8$ square antiprisms are exactly planar squares with Sb−Sb distances of 336.65(9) pm in the $Sb(2)_4$ square and 342.76(8) pm in the $Sb(3)_4$ plane. These

Figure 2. Projection of the V layer along the slightly tilted *c* axis

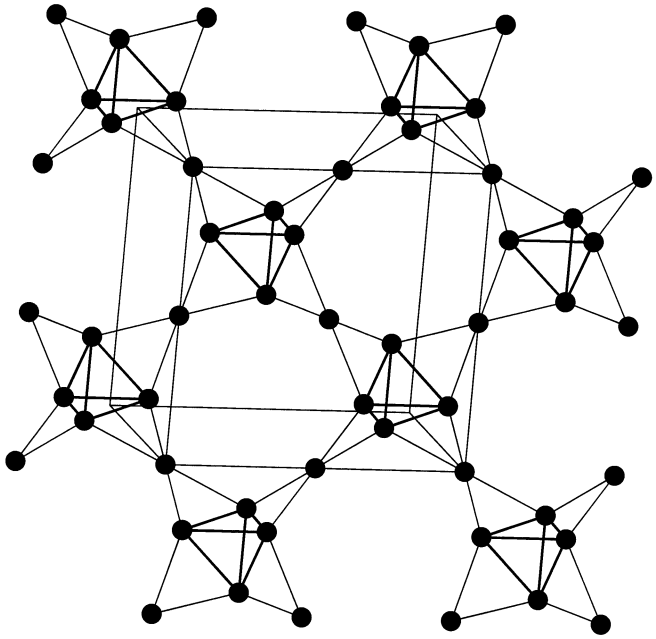


Figure 3. Projection of the puckered Sb(1),Sb(3) layer along the slightly tilted *c* axis

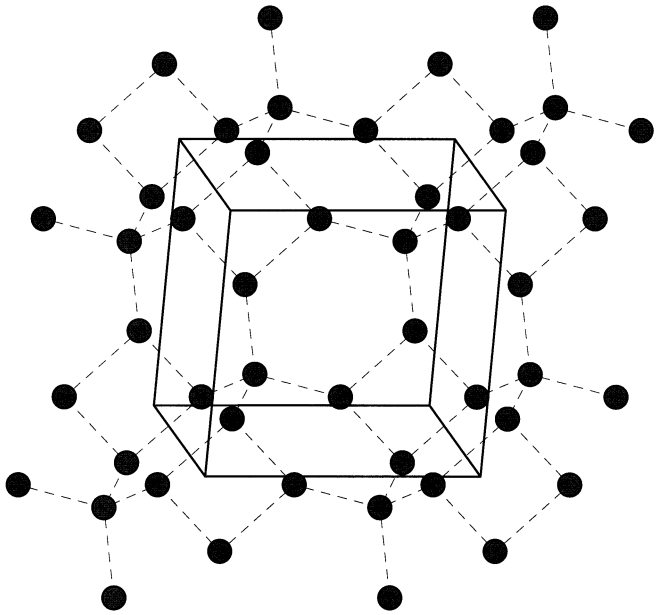
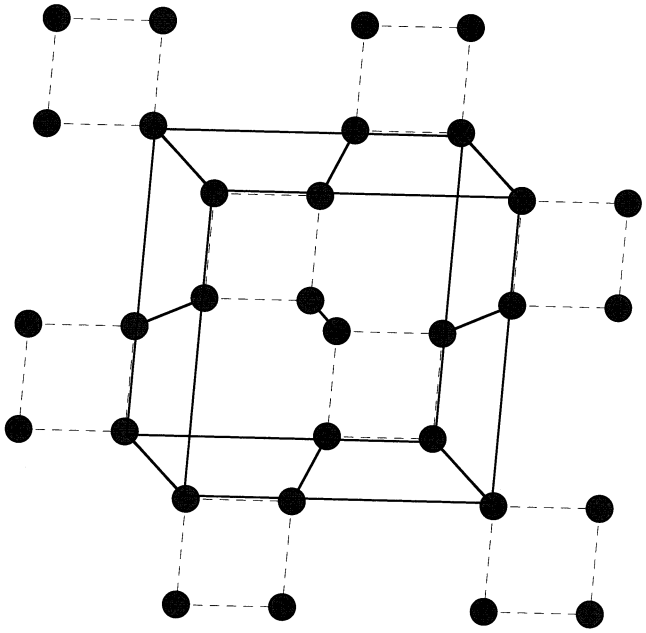


distances, being significantly larger than in the structure of $V_{15}Sb_{18}$ [319.0(1) pm and 322.9(1) pm], may be compared to the second shortest Sb−Sb bonds in elemental antimony of 335.5 pm. The latter, connecting the layers in the element, have to have bonding character because elemental antimony does not exhibit two-dimensional physical properties. The similar lengths in case of the structure of $Zr_2V_6Sb_9$ might occur with similar bond strengths, however, the shorter contacts of ca. 320 pm in $V_{15}Sb_{18}$ correspond most likely to stronger, but still somewhat weak, Sb−Sb bonds. Three causes complement each other: first, the larger size of Zr, compared to V, results in enlarged lattice parameters and therefore in longer Sb−Sb separations; second, the higher amount of valence electrons of the Zr phase (4.22 vs. 4.17 per Sb atom) and third the lower electronegativity of Zr, compared to V, both lead to higher negatively charged Sb atoms in case of $Zr_2V_6Sb_9$. As a consequence, more antibonding Sb−Sb states are filled in case of $Zr_2V_6Sb_9$, compared to $V_{15}Sb_{18}$, leading to weaker net bonding.

Additional Sb−Sb interactions between the Sb(1) and Sb(3) atoms of comparable length [335.89(7) pm] connect the $Sb(3)_4$ planes to infinite puckered layers consisting of planar Sb_4 and Sb_6 rings, as emphasized with dashed lines in Figure 3. The latter rings were also observed in the structure of the low-temperature phase V_3Sb_2 with shorter Sb−Sb distances of 320 pm.

On the other hand, the Sb(2) squares are interconnected via the shortest Sb−Sb contacts in this structure [306.3(2) pm] to puckered layers, which contain puckered eight-membered Sb(2) rings in addition to the $Sb(2)_4$ squares. The short Sb−Sb bonds are shown as bold lines in Figure 4, whereas the longer distances of 336.65(9) pm correspond to the dashed lines.

Figure 4. Projection of the puckered Sb(2) layer along the slightly tilted *c* axis



The Sb(2)−Sb(2) distance of 306.3(2) pm may be compared to other intermediate Sb−Sb distances in rather Sb-rich phases without metal−metal bonding, such as $LaCrSb_3$ with distances between 305.81(5) pm and 317.5(2) pm[14] and La_3TiSb_5 with a linear Sb chain consisting of Sb−Sb separations of 314.00(5) pm[15]. In both cases, it was concluded that all electrons from the metal atoms were transferred to the Sb atoms, leading to the tentative ionic formulations $(La^{3+})(Cr^{3+})(Sb^{2.5-})_2(Sb^{1-})$ and $(La^{3+})_3(Ti^{4+})(Sb^{3-})_3(Sb^{2-})_2$. These assignments are in agreement with a consideration of the above mentioned

Sb−Sb contacts as 1-electron-2-center bonds in a local view. In case of $Zr_2V_6Sb_9$, a comparable classification is less straightforward because of the different V−V bond lengths and the occurrence of the longer Sb−Sb distances > 330 pm. Neglecting the longer Sb−Sb distances and considering the shortest Sb−Sb bond as a one-electron bond would result in the formal ionic formulation $(Zr^{4+})_2(V^{2.83+})_6(Sb^{3-})_5(Sb^{2.5-})_4$, if one also ignores in a zeroth approximation the large Zr−Zr and Zr−V distances (> 350 pm). The ionic formulation is not meant to imply ionic character of $Zr_2V_6Sb_9$, but it may be helpful in understanding the bonding situation. According to this electron counting, 2.17/6 = 0.36 electrons remain available for V−V bonding per V atom, i. e. four V−V bonds per V(3) atom [291.2(1) pm] and five V−V bonds per V(4) atom [between 275.9(4) pm and 304.2(3) pm]. This very crude approximation gives an explanation for the occurrence of fractional bond orders of the V−V and Sb−Sb bonds. In case of $V_{15}Sb_{18}$, a similar discussion would result in the electron counting scheme $(V^{5+})_3(V^{2.92+})_{12}(Sb^{3-})_{10}(Sb^{2.5-})_8$, and therefore 0.35 electrons for each V(3) and V(4) atom to form V−V bonds. In the latter case, however, the Sb−Sb contacts of ca. 320 pm should not be neglected.

Calculations of the electronic structure using the Extended Hückel approximation (EH)[16,17,18] were performed in order to evaluate the bonding situation (and the physical properties) of the structure of $Zr_2V_6Sb_9$. Since the standard values of the metal parameters are usually energetically lower than the parameters in low-valent compounds, the metal parameters were optimized by charge iteration of vanadium in $V_{15}Sb_{18}$ with constant Sb parameters[19], followed by the optimization of zirconium in $Zr_2V_6Sb_9$. The parameters used are summarized in Table 4. The calculated densities of states (Figure 5) show a significant number of states at the Fermi level, which basically are centered at the vanadium atoms. The Zr orbitals are much less filled than the V orbitals, confirming the electron-counting scheme mentioned above. The *p* states of antimony are found in a wide peak between −10 eV and −15.5 eV, with a tail going up above the Fermi level. The latter is a hint to not completely reduced antimony ions, in agreement with the occurrence of rather small Sb−Sb distances. The fact that the Sb(2) atoms have shorter Sb−Sb contacts, compared to Sb(1) and Sb(3), expresses itself in smaller Mulliken gross populations calculated with the EH method [Sb(2): 5.23; Sb(3): 5.35; Sb(1): 5.53 electrons], supporting the trend implied but certainly overestimated by the electron-counting scheme $(Zr^{4+})_2(V^{2.83+})_6(Sb^{3-})_5(Sb^{2.5-})_4$. The differences between Sb(1) and Sb(3) also show the treatment of both atoms as Sb^{III} as being a crude approximation. Furthermore, the covalent mixing of the Sb states with the V and Zr states, as can be seen from the contribution of the *d* states of both different kinds of metal atoms to the Sb peak below −11 eV, imply $Zr_2V_6Sb_9$ being a compound with covalent Zr−Sb and V−Sb interactions.

The vanadium substructure with fractional V−V bonds should occur with metallic properties in the *a*,*b* plane, especially under consideration of the huge contribution of V states to the densities of states at the Fermi level. In addition, the occurrence of Zr states at the Fermi level and the somewhat long Zr−Zr distances parallel to the *c* axis might lead to metallic conductivity along the *c* direction, also. However, since the antimony atoms, having holes in the *sp* band, certainly contribute to the metallic properties, three-dimensional metallic properties are assumed. The temperature-independent Pauli paramagnetism experimentally obtained from the $Zr_2V_6Sb_9$ bulk sample (Figure 6) shows the presence of itinerant electrons, and thus metallic properties, but it provides no information on the dimensionality of the physical properties. Attempts to synthesize crystals suitable for direction dependent measurements were unsuccessful.

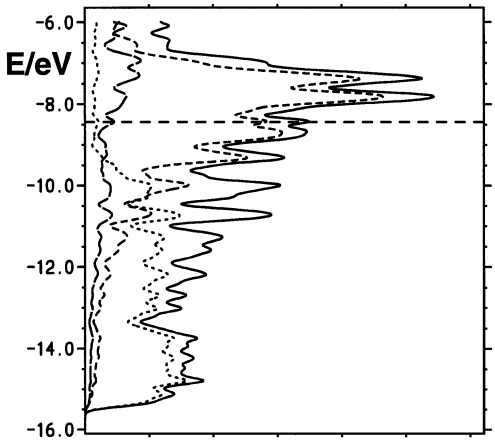
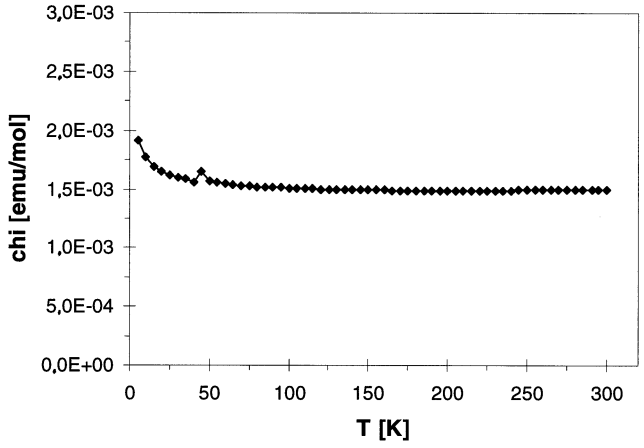
Figure 5. Calculated densities of states for $Zr_2V_6Sb_9$; horizontal line: Fermi level; solid line: total DOS; long dashes: Zr contribution; short dashes: V; dots: Sb



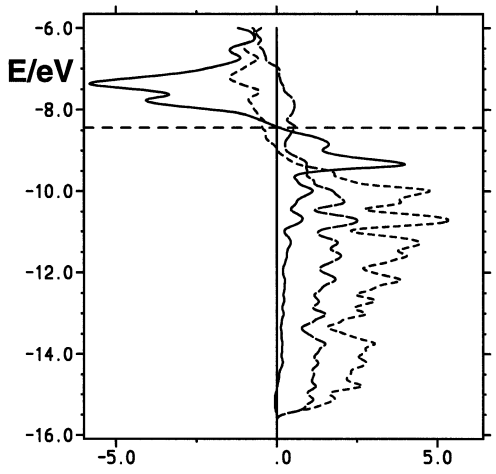
A discussion of the total crystal orbital overlap populations of all Zr−Sb, V−Sb and V−V interactions is instructive. These interactions are depicted in Figure 7, whereas the Zr−Zr states are neglected because of their small contributions. Mainly bonding interactions are found between −15.5 eV and the Fermi level at −8.44 eV, which are dominated by the V−Sb bonds. Only very few antibonding V−Sb states are filled below the Fermi level. Although the Zr−Sb peak area is roughly half as large as the V−Sb peak area, the Zr−Sb interactions play a similar role per bond, because 2 × 8 = 16 Zr−Sb bonds and 6 × 6 = 36 V−Sb bonds exist per formula unit. The V−V bonds are precisely optimized in the structure of $Zr_2V_6Sb_9$, according to the results of the EH calculations. Altogether,

Figure 6. Temperature dependence of the magnetic susceptibility of $Zr_2V_6Sb_9$



the V−V interactions play a minor but still significant role for the stability of $Zr_2V_6Sb_9$, compared to the Zr−Sb and V−Sb bonds. This can be taken from a rough optical estimation of the sizes of the different areas under the different COOP curves as shown in Figure 7, which reflect the different sums of the overlap populations. This simplistic view should be regarded cautiously, because a Zr−Sb bond may be a much stronger bond than a V−V bond of a comparable overlap population.

Figure 7. Selected total COOP curves for $Zr_2V_6Sb_9$; horizontal line: Fermi level; solid line: V−V interactions; long dashes: Zr−Sb; short dashes: V−Sb; right part of the diagram: bonding interactions (+); left: antibonding (−)



The concrete Mulliken overlap populations (MOPs) of selected interatomic interactions are listed in Table 5. The V−V interactions have significant positive MOP values, ranging from 0.184 and 0.096 within the tetrahedral units to 0.145 for every V(3)−V(4) bond. This may be compared to the values calculated for the shortest interaction of 262 pm (0.298) and for the longer ones of 303 pm (0.120) in elemental vanadium[20]. As proposed above, the Zr−Zr and Zr−V interactions have only weak bonding character, if any, with overlap populations between 0.029 and 0.065 electrons per bond. Similar values (i.e. between 0.025 and 0.048) also are found for the Sb−Sb interactions between 330 pm and 350 pm. The small positive net overlap populations are the result of the sum of bonding and antibonding Sb−Sb states, as shown in the averaged Sb−Sb COOP curves in Figure 8. The positive but small values point to weak bonding character for these interactions. The overlap population of 0.077 for the comparable Sb−Sb bond in elemental antimony (335.5 pm) is of the same magnitude.

Table 5. Selected interatomic distances and overlap populations of $Zr_2V_6Sb_9$

interaction	length/pm	MOP[a]
Zr(1)−1 Zr(2)	357.4(3)	0.041
Zr(1)−1 Zr(2)	362.1(3)	0.065
Zr(1)−4 V(3)	351.06(5)	0.053
Zr(1)−4 V(4)	355.7(2)	0.029

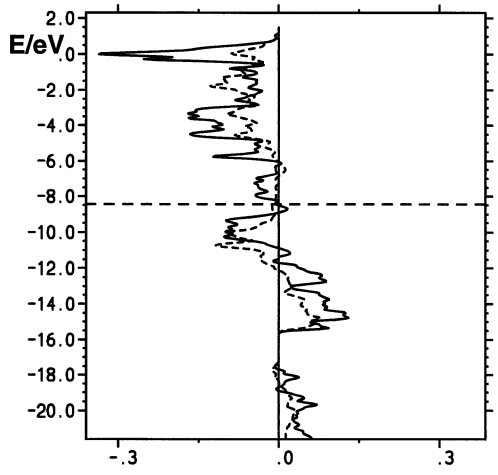
[a] MOP = Mulliken Overlap Population [electrons per bond].

Figure 8. Selected averaged COOP curves for $Zr_2V_6Sb_9$; horizontal line: Fermi level; solid line: Sb−Sb interactions < 310 pm; dashed: Sb−Sb interactions between 310 pm and 350 pm; right part of the diagram: bonding interactions (+); left: antibonding (−)



Fewer antibonding states are filled in case of the shortest Sb−Sb interaction in the structure of $Zr_2V_6Sb_9$ [d = 306.3(2) pm, MOP = 0.339]. The COOP curves also show the presence of antibonding Sb−Sb states above the Fermi level, supporting the model of not completely reduced Sb^{III}

anions. For an evaluation of the bond strength, the short Sb−Sb bond may be compared with shorter Sb−Sb bonds, i.e. in the element (d = 290.8 pm, MOP = 0.530[20]), with the Sb_2 pair in (α-)$ZrSb_2$ (d = 288 pm, MOP = 0.51[4]) or the $^1_\infty[Sb^{1-}]$ chain in KSb with $\bar{d}$ = 284 pm[21] and an averaged MOP of 0.645[20]. Since the latter bonds may be described to a first estimation as 2-electrons-2-center bonds (i. e. corresponding to a bond order of one), the crude approximation of a half bond order for the short Sb−Sb bond in $Zr_2V_6Sb_9$ is supported by the calculations of the electronic structure. It is thus concluded that the Sb−Sb interactions contribute significantly to the formation energy of $Zr_2V_6Sb_9$, although $Zr_2V_6Sb_9$ is to be considered a low-valent antimonide because of the V−V bonds.

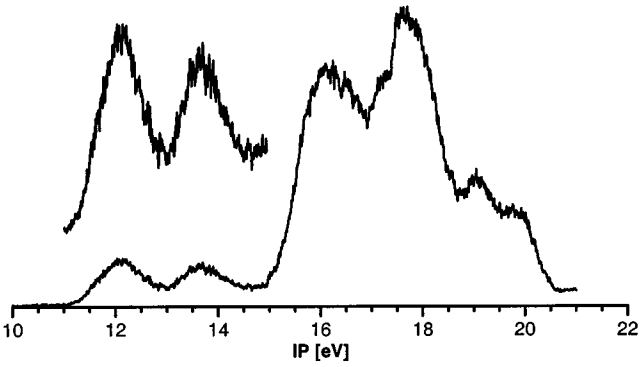
Keywords: Ab initio calculations / Electronic structure / Photoelectron spectroscopy

The electronic structure of the title compound **1** has been investigated by UV photoelectron spectroscopy and quantum chemical calculations. **1** has two nearly degenerate n_N lone-pair orbitals which form the two highest occupied MOs. The third highest occupied MO is mainly localized at the oxygen atom (n_O). All calculations indicate that the molecule has a twisted C_2 conformation.

We have recently reported a synthesis and gas-phase electron-diffraction structure analysis of perfluoro(2,4-dimethyl-3-oxa-2,4-diazapentane), $(CF_3)_2N–O–N(CF_3)_2$ (**1**).[1] This compound consists of an N–O–N chain that is substituted by four CF_3 groups. The structure analysis indicated that the molecule has C_{2v} symmetry and an sp,sp conformation in which both nitrogen electron lone-pairs are synperiplanar to the vicinal N–O bond. The electronic structure of this molecule is characterized by electron lone-pairs on three neighbouring (directly bound) atoms which makes it an ideal candidate to study the mutual interactions of such orbitals. We have investigated the electronic structure of **1** by photoelectron (PE) spectroscopy and quantum chemical calculations. The measured ionization potentials are summarized in Table 1 together with the relevant results of the calculations. The PE spectrum of **1** is depicted in Figure 1. In Figure 2 plots of the three highest occupied molecular orbitals are shown.

The PE spectrum consists of two broad bands with minor intensities, centred at about 12.2 and 13.7 eV, and several broad bands with larger intensities between 15 and 21 eV. Since the intensity of the first band is somewhat larger than that of the second, two ionization events contribute to it although it is not possible to assign different *IP* values to them. For the first band beginning ionization corresponding to the adiabatic ionization energy can be localized at 11.0 eV while the vertical *IP* is at 12.15 eV. For the second band the adiabatic value can be estimated to 12.7 eV.

Figure 1. PE spectrum of $(CF_3)_2N–O–N(CF_3)_2$ (**1**)



For analysis of the electronic structure of **1** and the interpretation of the PE spectrum quantum chemical calculations on different levels of theory were performed. Semi-empirical methods like AM1[2] and PM3[3] are known to be superior to simple ab initio methods, in particular for the

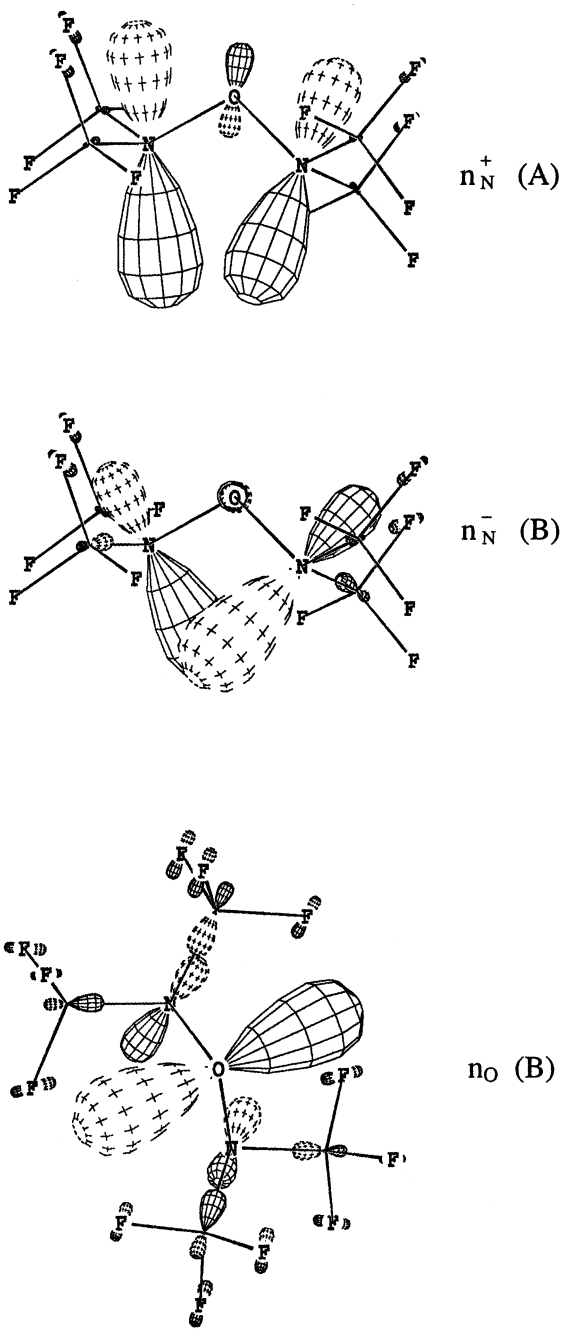
Figure 2. Plots of the three highest occupied MOs of $(CF_3)_2N-O-N(CF_3)_2$ (**1**) (PM3 results)



calculation of orbital energies ε_i which can be used to assign ionization potentials (IP_i) making use of the Koopmans theorem, $IP_i = -\varepsilon_i^{SCF}$.[4] These methods are, however, often of limited value for molecules like **1** with vicinal electron lone-pairs since their interaction is not correctly reproduced which often leads to wrong conformations. Good results have been obtained for a variety of molecules with the Becke3LYP (B3LYP) method,[5] a hybrid Hartree-Fock/density functional theory (HF/DFT) method.[6][7] This method also leads to excellent values for the first adiabatic ionization potential, $IP_{1,a}$, as the energy difference of the molecule and the radical cation. By performing single-point energy calculations for the radical cation on the molecule's geometry, i.e. without allowing for relaxation during ionization, the first vertical *IP*, $IP_{1,v}$, is accessible. Total energies from these calculations are given in Table 2; orbital energies and calculated *IP* values are listed in Table 1.

All theoretical methods lead to a C_2 structure as the most stable conformer of **1** that is twisted from the C_{2v} structure by about 30° as measured from the C−N···N−C dihedral angles. For the untwisted C_{2v} structure higher energy values of 1.0−5.8 kcal mol^{-1} were obtained. These results indicate that the molecule has a double minimum (W shaped) energy potential for its deformation, both C_2 minima are equally populated, and transition between the conformers through the C_{2v} conformation is rapid. This makes it difficult to distinguish experimentally between C_2 and C_{2v} symmetry. In Table 3 the structure parameters of **1** as obtained from electron diffraction,[1] from HF and from B3LYP calculations using the basis set 6−31+G* are compared. The agreement between experimental and theoretical data is generally not quite satisfactory. Deviations are smaller for the B3LYP than for the HF results and for C_2 than for C_{2v} symmetry. The latter observation may be considered as an additional indication for a twisted conformation of **1**.

The orbital energies given in Table 1 refer to the more stable C_2 conformer and correspond to the structure of minimum energy found by the respective method. All calculations lead to the same interpretation of the spectrum: The first two ionizations, which are nearly degenerate, are assigned to the two n_N MOs, and the third ionization is assigned to the $n_O{}^p$ MO. The strong bands centred at about 16.0 and 17.5 eV are mainly composed of n_F ionizations. When only the first three MOs are considered, the energies calculated for ε by the AM1 method show the best agreement with the *IP* values, but there is only a minor difference to the PM3 results, while − as expected − the orbital energies of the ab initio methods cannot be used equally well. Deviations from the Koopmans theorem[4] of 0.3−0.8 eV are found for the AM1 results, the PM3 values are more uniformly wrong by 0.7−0.9 eV, and the deviations of the ab initio methods range from −1.4−(−1.5) eV (B3LYP/6−31+G*) to 1.8−2.5 eV (HF/6−31+G*). Although it has to be admitted that caution is necessary, the AM1 and the PM3 method can be praised for their performance in the interpretation of the PE spectrum of **1**. In comparing the quality of the computational methods, not only the size of the deviations but also their uniformty has to be considered and according to this aspect the B3LYP/6−31+G* results rank first.

Leaving the limitations of the Koopmans theorem,[4] and calculating the first adiabatic and vertical *IP* from the energy difference of molecule and radical cation, the values obtained on the B3LYP/6−31+G* level of theory are in quite satisfactory agreement with the experimental ones (Table 1).

As is evident from Figure 2, there are coefficients on all atoms of the N−O−N chain in the three highest occupied

MOs of **1** indicating mutual interaction of n_N and n_O orbitals. The nearly degenerate energy levels of the two n_N MOs are closely related to the sp,sp conformation of **1** in which both nitrogen electron lone-pairs are synperiplanar to the opposite N−O bonds;[1] $n_N{}^+$ and $n_N{}^-$ are the symmetric and antisymmetric linear combination of the two nitrogen lone-pair orbitals (n_1 and n_2), respectively, with reference to the relevant symmetry operation. The MOs depicted in Figure 2, which correspond to the C_2 structure obtained with the PM3 method (torsional angle 31.3°), should be considered as qualitative illustrations, since the shape of the MOs varies with the structure and the method used in the calculation.

The energy difference Δn_N of $n_N{}^+$ and $n_N{}^-$ is attributed to the interaction of n_1 and n_2 and is dependent on their mutual geometrical orientation.[8] In 1,3-diamines Δn_N values between 0 and more than 1 eV have been observed by PE spectroscopy.[9] The PE spectrum of 1,3-diazaadamantane[10] shows two well-separated n_N ionization bands at 7.75 ($n_N{}^-$) and 8.78 eV ($n_N{}^+$). The orientation of the lone-pairs in this compound corresponds to the ap,ap conformation of **1**,[1] in which the nitrogen electron lone-pairs are antiperiplanar to the vicinal N−O bonds, and the splitting is dominated by through-space interaction. On the other hand, 2-substituted 1,3-dimethylimidazolidines[11] have a single broad band, and the energies of the two n_N orbitals are split by only 0.0−0.3 eV indicating little interaction, which is consistent with envelope conformations of the five-membered ring and an axial-equatorial orientation of the two *N*-methyl groups.

For the sp,sp conformation of **1** one would expect good through-space interaction of the nitrogen lone-pair orbitals n_1 and n_2 leading to a sizeable Δn_N value and an energy sequence $n_N{}^- > n_N{}^+$. However, this interaction would have its maximum value in the undistorted C_{2v} conformation (see below), whereas the torsion in the C_2 form will reduce the overlap of n_1 and n_2 and thus result in a smaller Δn_N. The splitting is then obviously overcompensated by n_N/n_O interactions. The $n_O{}^p$ orbital is geometrically orthogonal to n_1 and n_2 in the C_{2v} form so that there will be some interaction only in twisted C_2 conformations. On the other hand, the $n_O{}^s$ orbital overlaps effectively with n_1 and n_2. However, only the linear combination $n_N{}^+$ has the same symmetry as $n_O{}^s$ so that this orbital is destabilized while $n_N{}^-$ remains unaffected. This vicinal n_N/n_O interaction is also conformation dependent having its maximum extent in the untwisted C_{2v} form. For this conformation the following MO energies are calculated with the B3LYP/6−31+G* method: −9.75 eV ($n_N{}^+$, A_1), −10.22 eV ($n_N{}^-$, B_2), −10.78 eV (n_O, B_1). In this case the two n_N MOs would no longer be nearly degenerate, and accordingly the first two *IP*s of the PE spectrum should be sufficiently split in order to be detected separately. The actual PE spectrum is thus an indication of the twisted C_2 form. Here the $n_N/n_O{}^s$ interaction is obviously approximately of the same magnitude as the 1,3-n_N/n_N interaction which explains the observed orbital degeneracy $n_N{}^+ \approx n_N{}^-$ of **1**.

That the conformational properties of **1** are mainly determined by the mutual interactions of the electron lone-pairs is also indicated by the large difference between adiabatic and vertical *IP* values of more than 1 eV for the first and the third *IP*. The ionizations reduce the electrostatic repulsion of the electron pairs and lead to a less twisted, i.e. more C_{2v} like, conformation of the radical cation than in the neutral molecule.

We thank the *Fonds der Chemischen Industrie*, Frankfurt am Main, for financial support.

Experimental Section

The PE spectrum of **1** was recorded with a Leybold-Heraeus UPG200 spectrometer equipped with an He(I) radiation source (21.21 eV). The spectrum was calibrated with the lines of xenon at 12.130 and 13.436 and of argon at 15.759 and 15.937 eV. The accuracy of the measurements was approximately ± 0.03 eV for ionization energies, for broad and overlapping signals it was only ± 0.1 eV.

Semi-empirical AM1[2] and PM3[3] calculations were performed with the MOPAC[12] program package (version 6.1, IBM version of MOPAC 6.00), ab initio HF[13] and Becke3LYP[5] calculations with the program GAUSSIAN 94.[14] Geometries were fully optimized at the respective levels of theory. In the AM1 and PM3 calculations the keyword "PRECISE" was used to tighten the convergence criteria. MOs were plotted by using the program PERVAL.[15]

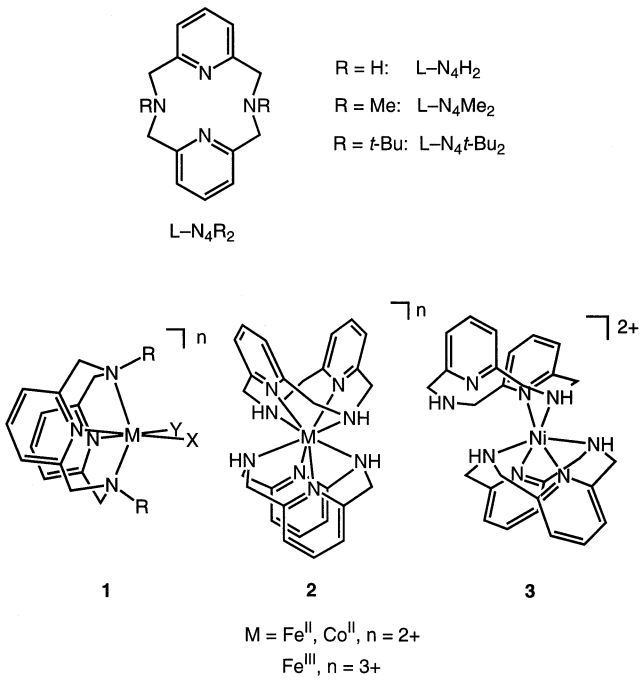
Keywords: Carbonyl complexes / Coordination modes / Fluxionality / Macrocyclic ligands / N ligands

Tridentate coordination of the potentially tetradentate ligand *N*,*N*′-dimethyl-2,11-diaza[3.3](2,6)pyridinophane (L–N_4Me_2) has been structurally established in the tricarbonylmolybdenum(0) complex [Mo(L–N_4Me_2)$(CO)_3$]. The fluxional behavior of the coordinated tetraazamacrocyclic ligand is demonstrated by a variable-temperature ^{1}H-NMR study. The relevance of the tridentate coordination mode of the ligand is discussed with respect to its intermediacy in the reaction mechanism for the formation of *cis* octahedral metal complexes containing tetradentate 2,11-diaza[3.3](2,6)-pyridinophane derivatives as ligands.

Introduction

The macrocyclic ligand 2,11-diaza[3.3](2,6)pyridinophane (L−N_4R_2) disposes of four potential nitrogen donor atoms for the complexation of metal ions. Due to its small ring size, the tetraazamacrocycle generally forms *cis* octahedral coordination geometries (**1**) with all nitrogen donor atoms bound to the metal ions.[1][2] With iron(II), iron(III), and cobalt(II) ions, eight-coordination has been observed in complexes of the composition $[M(L-N_4H_2)_2]^{n+}$ (**2**), in which both diazapyridinophane units act as tetradentate ligands.[3][4] In contrast, the nickel(II) ion in the complex $[Ni(L-N_4H_2)_2]^{2+}$ (**3**) is coordinated to all nitrogen donor atoms of one of the tetraazamacrocyclic ligands and to one each of the pyridine and amine nitrogen atoms of the second ligand.[4] Thus, in octahedral metal complexes only the tetra- and bidentate coordination modes have been structurally established with 2,11-diaza[3.3](2,6)pyridinophane ligands. Because we are interested in the general coordination chemistry of this type of ligand, we decided to explore the possibility of a tridentate coordination of the diazapyridinophane ligands in octahedral metal complexes. It is known that tricarbonylmolybdenum(0) fragments can sustain the tridentate coordination mode with the tetraazamacrocycles **4**−**7** which possess 12-, 14-, 15-, and 16-membered rings.[5][6] In one instance a structure analysis has been reported.[5] Tridentate coordination may, however, be more difficult to achieve with the macrocyclic ligand L−N_4R_2, since this type of ligand is, relative to the tetraazamacrocycles **4**−**7**, significantly more rigid due to the presence of two pyridine units in the ring and therefore has considerably fewer degrees of conformational freedom. The initial results of a study directed towards the feasibility of the tridentate coordination of 2,11-diaza[3.3](2,6)pyridinophane ligands are described here.



1 **2** **3**

Results and Discussion

The reaction of the ligand L−N_4Me_2 with an equivalent amount of $[Mo(CO)_6]$ in refluxing toluene yields a dark red complex whose elemental analysis is consistent with its formulation as [Mo(L−N_4Me_2)$(CO)_3$] (**8**). The IR spectrum of the compound is dominated by a very intense, narrow ($\Delta\nu_{1/2}$ = 30 cm^{-1}) band at 1893 cm^{-1} and an equally intense, rather broad ($\Delta\nu_{1/2}$ = 60 cm^{-1}) band at 1762 cm^{-1}; these bands are assigned to the two CO stretching vibrations (A_1 and E) expected for a *fac*-Mo$(CO)_3$ fragment with a local C_{3v}-symmetry. The ν(CO) frequencies for the

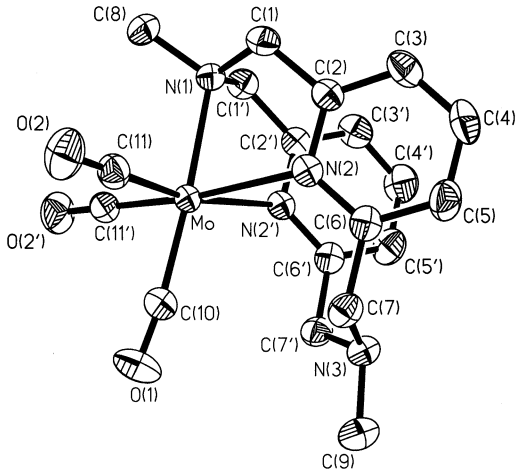
terminally bound carbonyl ligands lie in the same range as those observed for other octahedral tricarbonylmolybdenum(0) complexes with C_3N_3 coordination environments.[6][7][8] The relatively low energy of these ν(CO) frequencies, indicating strong π-back bondings between the metal and the carbon atoms, is attributed to the presence of strong σ-only donors with no or rather weak π-acceptor capabilities, such as amines and pyridines.

A perspective view of the structure of **8** is presented in Figure 1. The molecule possesses crystallographically imposed C_s symmetry. The most noteworthy structural aspect of complex **8** is the finding that the potentially tetradentate ligand $L-N_4Me_2$ acts only as a tridentate ligand here. Thus, the somewhat distorted octahedral coordination environment around the molybdenum atom is composed of three carbonyl ligands occupying one face of the octahedron and three nitrogen donor atoms of the macrocyclic ligand coordinated to the opposite face. By maintaining a *syn* chair-boat conformation, $L-N_4Me_2$ is bound to the metal ion only through the two pyridine and one of the amine nitrogen atoms. In contrast to previously discussed octahedral complexes where the tetraazamacrocyclic ligand is bound to a metal ion in a tetradentate fashion,[1][2] here the bond from the metal ion to the amine nitrogen atom ($Mo-N_{amine}$ bond, 2.306 Å) is considerably shorter than that to the pyridine nitrogen atoms ($Mo-N_{py}$ bond, 2.342 Å). Overall the lengths of the Mo^0-N bonds are similar to those observed in other six-coordinate molybdenum complexes with the same ligand donor set (2.242–2.407 Å with the mean at 2.314 Å).[5][8][9][10] Presumably due to steric interactions between the methylene protons next to the uncoordinated amine nitrogen atom and the axial carbonyl ligand [containing C(10) and O(1)], the coordination of the macrocycle to the metal ion is considerably distorted, as demonstrated, for example, by the rather small N–Mo–N angles of 68.7° and 75.5°. In agreement with the rather low ν(CO) frequencies, the Mo–C bond lengths of 1.933 and 1.943 Å indicate substantial Mo=C double bond character.[9] These bond lengths fall into the general range observed for Mo–CO bonds in complexes with an octahedral MoC_3N_3 coordination sphere (1.898–1.952 Å with the mean at 1.923 Å).[5][8][9][10]

Figure 1. Perspective view of the structure of $[Mo(L-N_4Me_2)(CO)_3]$ showing thermal ellipsoids at 50% probability and the atom-numbering scheme; the primed and unprimed atoms are related by a mirror plane[a]

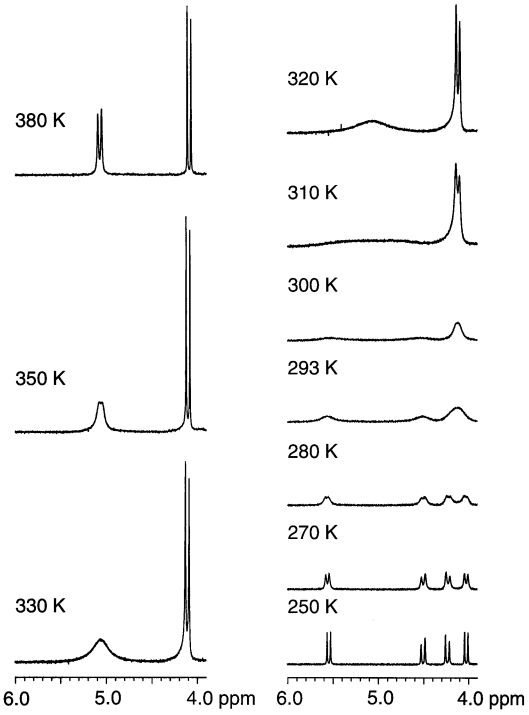


[a] Selected bond lengths [Å] and angles [°]: Mo–N(1) 2.306(3), Mo–N(2) 2.342(2), Mo–C(10) 1.943(4), Mo–C(11) 1.933(3), C(10)–O(1) 1.167(5), C(11)–O(2) 1.172(3); C(10)–Mo–C(11) 83.4(1), C(11)–Mo–C(11′) 88.0(2), N(1)–Mo–N(2) 75.49(8), N(1)–Mo–C(11) 94.3(1), N(1)–Mo–C(10) 176.7(1), N(2)–Mo–N(2′) 68.7(1), N(2)–Mo–C(10) 107.2(1), N(2)–Mo–C(11) 100.9(1), N(2)–Mo–C(11′) 166.79(9).

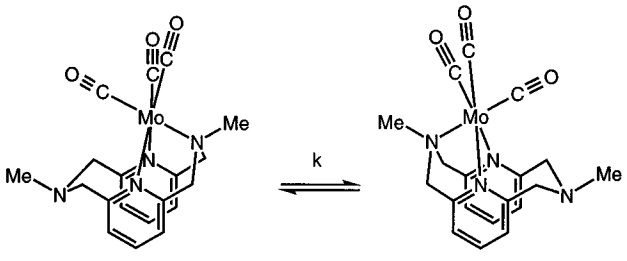
In solution, fluxional behavior is observed for the coordinated macrocyclic ligand by a variable-temperature ^{1}H-NMR study. Thus, at low temperatures (240 K), the methylene proton signals appear as two well separated AB systems in the ^{1}H-NMR spectrum (Figure 2). The first AB system occurs at $\delta = 4.02$ and 5.51 with a coupling constant $J_{AB} = 14$ Hz and the second at $\delta = 4.23$ and 4.51 with $J_{AB} = 15$ Hz. Raising the temperature causes the two AB systems to be replaced by a new AB system at $\delta = 4.1$ and 5.1 with $J_{AB} = 15$ Hz by coalescence of the signals at $\delta = 4.02$ and 4.23 and those at $\delta = 4.51$ and 5.51. In a similar way, the two signals corresponding to the protons of two methyl groups which are found at $\delta = 2.50$ and 3.23 at low temperatures coalesce to a singlet at $\delta = 2.9$. In analogy, the slightly different signals attributed to the 3-pyridine and 5-pyridine protons appear at higher temperatures as one signal. The dynamic NMR study clearly demonstrates that, when the complex is dissolved, an intramolecular substitution reaction takes place in which, as depicted in Scheme 1, the uncoordinated amine nitrogen donor replaces the bound one. Simulations of the NMR subspectra corresponding to the methylene protons at different temperatures yield the reaction velocities k for this process at each temperature; at room temperature, k and the free activation energy $\Delta G^{\neq}$ were determined to be 286 s^{-1} and 59.0 kJ mol^{-1},

respectively. From a plot of $\ln(k/T)$ vs $1/T$, the free activation parameters $\Delta H^{\neq} = 58.1$ kJ mol^{-1} and $\Delta S^{\neq} = -3.14$ J K^{-1} mol^{-1} were obtained. Since the experimental error in determining the value of the entropy of activation by NMR spectroscopy is inherently quite large, this rather small value for the entropy of activation prohibits its use in a discussion of the possible mechanism of the reaction. The reaction mechanism is currently being investigated with a series of tricarbonyl metal complexes $[M(L-N_4R_2)(CO)_3]$ (where M = Cr^0, Mo^0, or W^0 and R = H, Me, or *t*Bu). Preliminary results of this kinetic study suggest that the reaction proceeds either by an associative or an associative interchange mechanism.

Figure 2. ^{1}H-NMR signals of the methylene protons of $[Mo(L-N_4Me_2)(CO)_3]$ in deuterated dimethylformamide at different temperatures (360 MHz)



Scheme 1



The tridentate coordination mode of the ligand $L-N_4Me_2$ has only been observed here because the tricarbonylmolybdenum(0) fragment is quite stable. Since adequate π-back-bonding from the metal ion to the carbonyl ligands is required to stabilize the molybdenum(0) atom, the presence of only two carbonyl ligands is apparently not sufficient to stabilize a molybdenum(0) atom if it is coordinated to four relatively strong σ-donors, such as amines or pyridines, with no or only rather weak π-acceptor capabilities. Therefore, the molybdenum(0) atom prefers the coordination of three carbonyl ligands and forfeits ligation of one of the four possible nitrogen donors of the macrocyclic ligands. However, it is interesting to point out that for all diamagnetic *cis* octahedral metal complexes investigated thus far the NMR spectra demonstrate that the tetraazamacrocycle, once coordinated as tetradentate ligand, stays bound to the metal ion through all its nitrogen donor atoms.

The structures of the complexes **3** and **8** provide some quite interesting insights into mechanistic aspects of the coordination of octahedral metal ions by diazapyridinophane ligands. Thus, the bidentate and tridentate coordination modes of the tetraazamacrocyclic ligands observed in these complexes can be viewed as intermediates in the formation of tetradentate chelation of the ligand. As uncoordinated macrocycle the dialkyl-substituted diazapyridinophane is present as *syn* chair-chair conformer. The reaction sequence depicted in Figure 3 starts with the coordination of just one nitrogen atom, most likely one of the amine nitrogen donors since these can be approached by the metal ion more easily because of steric considerations. Next, by changing the chair-chair conformation of the ligand to a boat-chair conformation, bidentate chelation over one amine and one pyridine nitrogen atom occurs, similar to that found in **3**. The macrocyclic ring slides further over the metal ion, and the second pyridine nitrogen atom forms a bond to the metal ion, yielding a facial coordination of the ligand like that observed in **8**. By converting the chair-boat conformation to a boat-boat conformation, the last amine nitrogen donor atom is then able to interact with the metal ion and, thus, tetradentate chelation of the ligand is completed.

Conclusion

Tridentate coordination has been structurally established for the ligand $L-N_4Me_2$ in a tricarbonylmolybdenum(0) complex. In solution, an intramolecular rearrangement of the ligand occurs where the uncoordinated amine nitrogen atom replaces the coordinated one at the molybdenum atom. In general, 2,11-diaza[3.3](2,6)pyridinophanes display a decisive tendency to form preferentially *cis* octahedral complexes; only in very specific cases, e.g. when the other ligands in the complex are very strongly bound as in $[Mo(L-N_4Me_2)(CO)_3]$ or when no further coordination sites are available in the octahedral complex as in $[Ni(L-N_4H_2)_2]^{2+}$, do these ligands relinquish tetradentate chelation and become tri- or bidentate chelators. Similar bi- and tridentate coordination modes of the macrocyclic ligand are proposed to occur in the intermediates in formation of *cis* octahedral complexes.

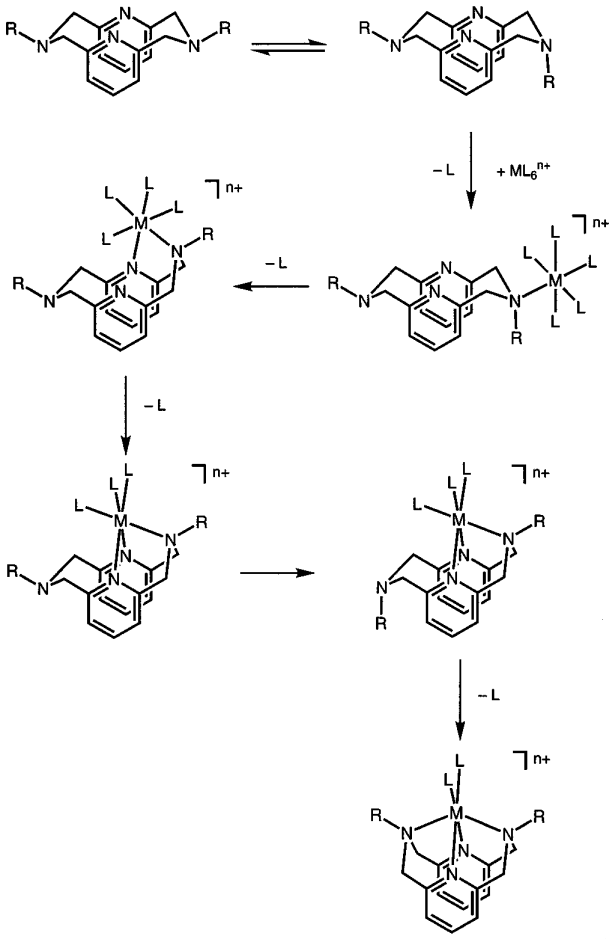
Figure 3. Possible mechanism for the formation of octahedral metal complexes by reaction of hydrated metal ions (L = H_2O) with ligands of the type $L-N_4R_2$



Experimental Section

Physical Methods: ^{1}H-NMR: Bruker AM 360, TMS as internal standard. The spectra of the dynamic NMR study were simulated using the program geNMR Version 3.4, IvorySoft, 1993. – UV/Vis: Varian Cary 5 E. – IR: Perkin-Elmer 1720 FT-IR.

Preparation of the Ligand: The tetraazamacrocyclic ligand $L-N_4Me_2$ was synthesized according to already published procedures, employing some slight modifications.[11]

[Mo(L−N$_4$Me$_2$)(CO)$_3$] (**8**): A solution of $[Mo(CO)_6]$ (134 mg, 0.5 mmol) and $L-N_4Me_2$ (134 mg, 0.5 mmol) in toluene (30 ml) was refluxed for 5 h under anaerobic conditions. The resulting red precipitate was collected by filtration, washed with toluene, and dried. Recrystallization by diffusion of ether into a solution of the solid in dimethylformamide (40 ml) afforded analytically pure product (127 mg, 57% yield) as a dark red crystalline material. – $C_{19}H_{20}N_4MoO_3$ (448.33): calcd. C 50.90, H 12.50, N 4.50; found C 50.72, H 12.45, N 4.57. – UV/Vis (dimethylformamide): λ_{max} (ε_M) = 407 (3090) and 315 (3610) nm. – IR (KBr): $\tilde{\nu}$ = 2933, 2898, 2766, 1893, 1762, 1604, 1570, 1464, 1449, 1431, 1374, 1163, 1093, 1020, 976, 819, 765 cm^{-1} (strong bands only).

Crystal Structure Analysis: Slow mixing by diffusion of two layers consisting of hexane and a solution of $[Mo(L-N_4Me_2)(CO)_3]$ in dimethylformamide afforded single crystals. Formula $C_{19}H_{20}N_4MoO_3$; M_r 448.33 g mol^{-1}; crystal dimensions 0.25 × 0.4 × 0.4 mm; crystal system monoclinic; space group $P2_1/m$ (No. 11); Z = 2; cell dimensions: a = 9.371(3), b = 11.780(3), c = 9.551(2) Å, β = 118.96(2)°; V = 922.5(4) Å^3; $\rho_{calcd.}$ = 1.614 g cm^{-3}; $F(000)$ = 456; graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å); μ = 7.39 cm^{-1}; T = 293 K; Hilger & Watts diffractometer; ω-2Θ scans in the range 4.90° ≤ 2Θ ≤ 55.10°; 2167 unique reflections [1994 reflections with $F_o > 4\,\sigma(F_o)$]; 136 variables; GooF on F^2 [$F_o > 4\,\sigma(F_o)$] = 1.181; R [$F_o > 4\,\sigma(F_o)$] = 3.11% with $R = \Sigma\|F_o| - |F_c\|/\Sigma|F_o|$; wR^2 [$F_o > 4\,\sigma(F_o)$] = 7.05% with $wR^2 = \{\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]\}^{1/2}$; largest peak (hole) = 0.58 (−0.92) e Å^{-3}. The positions of the non-hydrogen atoms were determined by SHELXS 86[12] and by Fourier difference maps using the program SHELXL-93.[12] The structural parameters were refined with the program SHELXL-93, using F^2 of all symmetry-independent reflections except those with very negative F^2 values. All non-hydrogen atoms were refined anisotropically. The complex is bisected by a crystallographical mirror plane passing through the molybdenum ion, one of the carbonyl ligands, the two amine nitrogen atoms, and the carbon atoms of the two methyl groups. Hydrogen atoms were assigned idealized locations and their isotropic temperature factors were refined.

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Center as supplementary publication no. CCDC-101671. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (Fax: int. code + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk).

Oxametallacycles $[Fe(C_5Me_5)(CO)\{C_3(C_6H_4\text{-}o\text{-}Cl)(CO_2Me)(R)O^a\}(Fe\text{–}O^a)]$ (**2**, R = OMe; **4**, R = Me) are accessible from the chelate (chloroaryl)carbene complex $[Fe(C_5Me_5)(CO)\{C(OMe)C_6H_4\text{-}o\text{-}Cl^a\}(Fe\text{–}Cl^a)][OTf]$ (**1**) upon treatment with the appropriate carbanions. Their formation arises from the lability of the chlorine atom. The related phosphonium salt $[Fe(C_5Me_5)(CO)\{C_3(C_6H_4\text{-}o\text{-}PMe_3)(CO_2Me)(OMe)O^a\}(Fe\text{–}O^a)][OTf]$ (**3**) is formed only for the bis(ester) derivative, via Ar–Cl bond activation. No reaction occurs for **4**, for which the coordination of the acetyl group has been supported by an X-ray analysis.

Aryl halides coordinating to metal centers are the focus of general interest especially for the functionalization of aromatic rings.[1] Halogenoarenes can be activated towards nucleophilic displacement by η^6 complexation to electron-deficient transition-metal centers.[2] We have previously reported that Ar−Cl bond cleavage can be achieved by complexation of the halide group.[3] Moreover, alkyl halide complexes $M(\eta^1\text{-}XR)$ have been shown to undergo nucleophilic attack at the α-carbon atom in the presence of Lewis bases.[4][5][6] This led us to investigate the reactivity of the electrophilic chelate (chloroaryl)carbene complex[7] $[Fe(C_5Me_5)(CO)\{C(OMe)C_6H_4\text{-}o\text{-}Cl^a\}(Fe-Cl^a)][OTf]$ (**1**) towards stabilized carbanions possessing coordinating carbonyl groups. Here, we report the access to new oxametallacycles, the lability of the chelated group, Cl versus C=O, involved in the formation of these species allows to induce nucleophilic aromatic substitution.

Complex **1** reacts at −80°C (1 h) with a THF solution of $NaCH(CO_2Me)_2$ affording the oxametallacycle $[Fe(C_5Me_5)(CO)\{C_3(C_6H_4\text{-}o\text{-}Cl)(CO_2Me)(OMe)O^a\}(Fe-O^a)]$ (**2**) which is isolated after chromatography as a green powder (Scheme 1). The complexation of the carbonyl group is evidenced by the ^{13}C-NMR spectrum ($CDCl_3$); the most characteristic features are the signals at δ = 262.4 ($Fe-C_\alpha$), 124.9 [$C(CO_2Me)$], and 177.3 ($C-O$) for the carbon atoms of the metallacycle. The low-field ^{13}C shift of the C_α resonance is intermediate between that of a carbene carbon atom and that of an alkenyl group, in agreement with two possible mesomeric forms. We assume that the formation of **2** results from an α attack by the nucleophile to give the C−C intermediate adduct, subsequent dissociation of the chlorine atom by the coordinating carbonyl group leads to the formation of a new five-membered ring (Scheme 2). Eventually, a spontaneous elimination of MeOH produces a more stable conjugated ring, i.e. the final product. Subsequent addition of PMe_3 to the reaction mixture affords the corresponding phosphonium salt $[Fe(C_5Me_5)(CO)\{C_3(C_6H_4\text{-}o\text{-}PMe_3)(CO_2Me)(OMe)O^a\}(Fe-O^a)][OTf]$ (**3**). The presence of the PMe_3 group is clearly established by NMR spectroscopy; its resonance is located at δ = 24.1 in the $^{31}P\{^1H\}$-NMR spectrum ($CDCl_3$). The $^3J(P-H_{Ar})$ and $^1J(P-C_{Ar})$ coupling constants of 15.6 Hz and 89 Hz, respectively, support the presence of the phosphorus atom on the aromatic ring. We assume that the formation of such species requires the activation of the Ar−Cl bond by the organo−iron fragment, the C=O group would be labile enough to be in equilibrium with the corresponding chloro-chelated species.

Scheme 1. Reagents and conditions: i) $NaCH(CO_2Me)_2$, THF, −80°C; ii) PMe_3

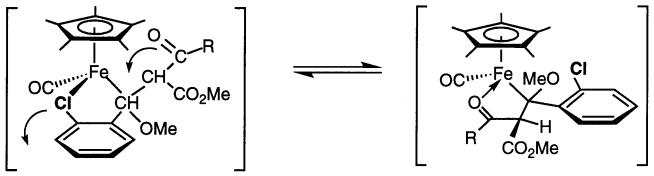
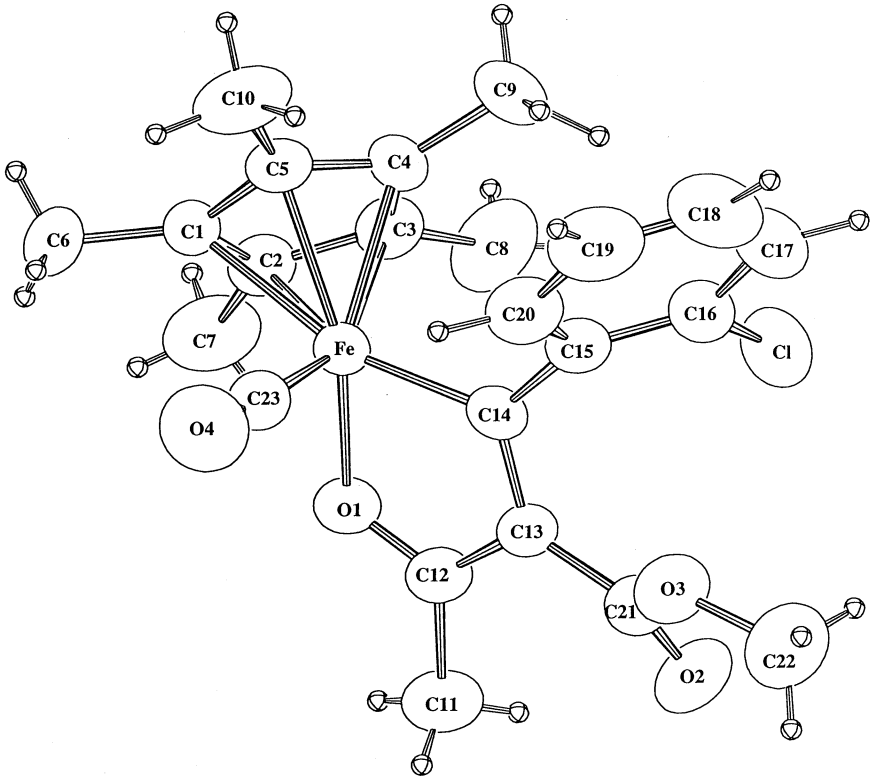
Scheme 2



not dissociate in such conditions, the phosphorus-substituted derivative is only formed for the bis(ester)-containing complex.

In summary, oxametallacycles − depending on the labile character of the chelated group − allow Ar−Cl bond activation under mild conditions, a process which is mediated by the organo−iron fragment acting as a Lewis acid.[10] Studies on carbanions possessing other functional groups with different labile properties are under progress.

Figure 1. Molecular structure (ORTEP drawing) of **4**[a]



[a] Selected bond lengths [Å] and angles [°]: Fe−O1 1.951(3), O1−C12 1.254(6), C12−C13 1.429(6), C13−C14 1.387(6), Fe−C14 1.920(5); O1−Fe−C14 81.4(2), C14−Fe−C23 90.7(2), O1−Fe−C23 98.1(2), Fe−O1−C12 115.6(3), O1−C12−C13 116.9(4), C12−C13−C14 112.2(4), C13−C14−Fe 113.8(3).

Treatment of **1** with $NaCH(CO_2Me)(COMe)$, in which two different coordinating functions are present, gives $[Fe(C_5Me_5)(CO)\{C_3(C_6H_4\text{-}o\text{-}Cl)(CO_2Me)(Me)O^a\}(Fe-O^a)]$ (**4**) in which the acetyl group is complexed to the iron center. Green crystals are obtained in 50% yield after purification by chromatography. The ^{13}C resonances of the metallacycle [δ = 277.4 (Fe−C_α), 126.0 $C(CO_2Me)$, 207.6 (C−O)] are similar to those of **2**, the acetyl group giving rise to a lower field signal. The molecular structure[8] of **4** (Figure 1) confirms the proposed structure. The acetyl fragment coordinated to the iron center displays bond lengths which are closely similar to those of the chelate complex $[Fe(C_5H_5)(t\text{BuNC})[C_6F_4\text{-}o\text{-}C(O)Me](Fe-O^a)]$.[9] The bond lengths of the five-membered ring are in agreement with a delocalized system.

By contrast, no reaction with PMe_3 is observed in the case of complex **4**. This suggests that the acetyl group does

Experimental Section

A THF solution of **1** (520 mg, 1 mmol) was treated at −80°C with a freshly prepared THF solution of 2 equiv. of $NaCH(CO_2Me)(COR)$ (R = OMe, Me). After stirring for 3 h, the solution was concentrated to dryness. Compounds **2** and **4** were extracted with CH_2Cl_2 and chromatographed on alumina (eluent: pentane/Et_2O). Complex **2** (25%): ^1H NMR (200 MHz, $CDCl_3$): δ = 7.48 (dd, $^3J_{HH}$ = 7.8 Hz, $^4J_{HH}$ = 1.7 Hz, 1 H, Ar), 7.34 (dd, $^3J_{HH}$ = 8.8 Hz, $^4J_{HH}$ = 1.3 Hz, 1 H, Ar), 7.29 (td, $^3J_{HH}$ = 7.6 Hz, $^4J_{HH}$ = 1.3 Hz, 1 H, Ar), 7.11 (td, $^3J_{HH}$ = 7.5 Hz, $^4J_{HH}$ = 1.7 Hz, 1 H, Ar), 3.89 (s, 3 H, OMe), 3.49 (s, 3 H, OMe), 1.45 (s, 15 H, C_5Me_5). − $^{13}C\{^1H\}$ NMR (50.3 MHz, $CDCl_3$): δ = 262.4 (Fe−C_α), 218.2 (CO), 177.3 (C−O), 161.9 (C=O), 150.9 (Ar_{ipso}), 128.7 (Ar), 127.1 (Ar), 126.9 (Ar), 126.5 (Ar), 126.3 (Ar_{Cl}), 124.9 ($C$$CO_2Me$), 92.6

(C_5Me_5), 54.1 (OMe), 51.4 (OMe), 9.3 (C_5Me_5). − IR (pentane, cm^{-1}): $\tilde{\nu}$ = 1934 (s, ν_{CO}), 1724.8 (m, $\nu_{C=O}$). − HRMS for $C_{23}H_{25}ClFeO_5$; *m/z*: calcd. 472.0740 [M^+]; found 472.0738. − It is noteworthy that the disubstituted complex [Fe(C_5Me_5)(CO)-{$C_3(C_6H_4$-*o*-CH(CO_2Me)$_2$)(CO_2Me)(OMe)O^a}(*Fe*−*O*^{a})], in which the chloride has been replaced by the dimethylmalonate anion, is detected from the crude reaction mixture by HRMS (FAB) for $C_{29}H_{36}FeNaO_{10}$; *m/z*: calcd. 623.1556; found 623.1543 [M^+ + Na].

Complex **3** is obtained by addition of 3 ml of PMe_3 (1 M in toluene) at −80°C to the reaction mixture prepared as decribed above. Extraction with CH_2Cl_2 and crystallisation in CH_2Cl_2/Et_2O gave green microcrystals (17%). − ^{1}H NMR (300 MHz, $CDCl_3$): δ = 7.86 (dd, $^3J_{PH}$ = 15.6 Hz, $^3J_{HH}$ = 7.9 Hz, 1 H, Ar), 7.55 (m, 1 H, Ar), 7.45 (m, 2 H, Ar), 3.84 (s, 3 H, OMe), 3.49 (s, 3 H, OMe), 2.28 (d, $^2J_{PH}$ = 13.8 Hz, 9 H, PMe_3), 1.42 (s, 15 H, C_5Me_5). − ^{13}C{^{1}H} NMR (75.47 MHz, $CDCl_3$): δ = 261.5 (Fe−C_α), 218.3 (CO), 176.1 (C−O), 162.1 (C=O), 155.1 (d, $^2J_{PC}$ = 8.7 Hz, Ar_{ipso}), 132.5 (d, $^4J_{PC}$ = 3 Hz, Ar), 131.2 (d, $^2J_{PC}$ = 12 Hz, Ar), 127.1 (d, $^3J_{PC}$ = 13 Hz, Ar), 126.5 (*C*CO_2Me), 126.4 (d, $^3J_{PC}$ = 11 Hz, Ar), 115.6 (d, $^1J_{PC}$ = 89 Hz, Ar), 92.0 (C_5Me_5), 54.1 (OMe), 51.5 (OMe), 13.1 (d, $^1J_{PC}$ = 56.7 Hz, PMe_3), 9.4 (C_5Me_5). − ^{31}P {^{1}H} NMR (121.5 MHz, $CDCl_3$): δ = 24.11 (s, PMe_3). − IR (CH_2Cl_2, cm^{-1}): $\tilde{\nu}$ = 1938 (s, ν_{CO}), 1752 (m, $\nu_{C=O}$). − $C_{27}H_{34}FeF_3O_8PS$: calcd. C 48.96, H 5.17; found C 48.95, H 5.27.

Complex **4** (50%). − ^{1}H NMR (200 MHz, $CDCl_3$): δ = 7.43 (dd, $^3J_{HH}$ = 7.7 Hz, $^4J_{HH}$ = 1.8 Hz, 1 H, Ar), 7.36 (dd, $^3J_{HH}$ = 8 Hz, $^4J_{HH}$ = 1.3 Hz, 1 H, Ar), 7.29 (td, $^3J_{HH}$ = 7.8 Hz, $^4J_{HH}$ = 1.4 Hz, 1 H, Ar), 7.12 (td, $^3J_{HH}$ = 7.5 Hz, $^4J_{HH}$ = 1.7 Hz, 1 H, Ar), 3.50 (s, 3 H, OMe), 2.55 (s, 3 H, Me), 1.48 (s, 15 H, C_5Me_5). − ^{13}C{^{1}H} NMR (50.3 MHz, $CDCl_3$): δ = 277.4 (Fe−C_α), 217.3 (CO), 207.6 (C−O), 163.7 (C=O), 151.9 (Ar_{ipso}), 128.7 (Ar), 127.2 (Ar), 126.9 (Ar), 126.6 (Ar), 126.5 (Ar_{Cl}), 126.0 (*C*CO_2Me), 94.3 (C_5Me_5), 51.3 (OMe), 27.8 (Me), 9.3 (C_5Me_5). − IR (CH_2Cl_2, cm^{-1}): $\tilde{\nu}$ = 1930 (s, ν_{CO}), 1694 (m, $\nu_{C=O}$). − $C_{23}H_{25}ClFeO_4$: calcd. C 60.48, H 5.52; found C 60.43, H 5.47.

The sandwich complexes bis(η^6-triphenylene)chromium (**12**) and bis(η^6-fluoranthene)chromium (**13**) have been prepared by means of metal atom/ligand vapor cocondensation. Whereas for triphenylene exclusive coordination to the peripheral rings is observed, the situation is more complicated for fluoranthene. According to NMR evidence initial metal coordination to the benzene (B) as well as to the naphthalene (N) section of the fluoranthene ligand occurs, leading to the isomers **13**(I) (η^6-B, η^6-B), **13**(II) (η^6-B, η^6-N) and **13**(III) (η^6-N, η^6-N). Since the substitutional lability of the chromium–naphthalene bond largely exceeds that of the chromium–benzene bond, the isomer distribution depends on the workup conditions; **13**(I) is clearly the most stable isomer. Crystal structure determinations performed for the salts [**12**][BPh_4] and [**13**][I] point to the preference for *syn* orientation of the polycyclic aromatic hydrocarbons and to a minute metal slippage in the peripheral direction. The triphenylene complex **12** features the electrochemically reversible redox couples **12** (+/0, metal-centered), **12** (0/–, ligand-centered) and **12** (–/2–, ligand-centered), the latter displaying a redox splitting of 300 mV. Conversely, for the fluoranthene complex **13**, secondary reduction **13** (–/2–) is irreversible. This finding is consistent with the larger redox splitting of ca. 480 mV which indicates more extensive interligand interaction in the dianion $\mathbf{13}^{2-}$, thereby favoring metal–ligand cleavage. While the radical cations $\mathbf{12}^{+\cdot}$ and $\mathbf{13}^{+\cdot}$ are amenable to EPR study, the radical anions $\mathbf{12}^{-\cdot}$ and $\mathbf{13}^{-\cdot}$ are too unstable. Instead, the radical anions of the free ligands are observed by EPR upon electrochemical reduction. In the case of **12**, the temporary existence of the radical anion $\mathbf{12}^{-\cdot}$ is indicated, however.

Introduction

Polycyclic aromatic hydrocarbons (PAHs)[2] have played an important role as potential ligands in sandwich complexes from the onset of bis(arene)metal chemistry. Fundamental questions deal with regioselectivity of coordination and the possibility of preparing oligonuclear complexes or even polymers with novel properties. PAHs as π ligands are encountered in a large number of carbonylmetal derivatives $[(PAH)metal(CO)_m]^{n+}$, in $[(PAH)metal(cyclopentadienyl)]^{n+}$ cations, in $[(PAH)metal(olefin)_m]^{n+}$ cations and in a few complexes of the type [(PAH)metal(phosphane)$_n$][3]. Conversely, the number of sandwich complexes (η^6-PAH)$_2$metal is very limited, the species $\mathbf{1}^{2-}$[4], $\mathbf{2}$[5a], $\mathbf{3}$[5], $\mathbf{4}$[6], $\mathbf{5}^{2+}$[7], $\mathbf{6}$[8], $\mathbf{7}^{+}$[9], $\mathbf{8}$[10] being the only examples characterized to date. The dianion $[(C_{10}H_8)_3Zr]^{2-}$ features bent naphthalene ligands and η^4 coordination[11]. The synthesis of binary complexes of transition metals and polycyclic hydrocarbons is desirable since it is only in the absence of auxiliary ligands that the basic questions addressed below may be studied unequivocally.

An ubiquitous feature of the coordination chemistry of polycyclic aromatic hydrocarbons is the ease of ligand hydrogenation during the course of wet chemical synthesis. Thus, early attempts to prepare bis(naphthalene)chromium by means of the Fischer−Hafner synthesis afforded bis(tetralene)chromium and the Nesmeyanov reaction was frequently accompanied by partial hydrogenation of the PAH. Therefore, metal atom/ligand vapor cocondensation techniques were originally used. Recently, the reaction of conventionally generated alkali metal naphthalenides with $MCl_3(THF)_3$ (M = V, Cr, Mo) and $MoCl_4(THF)_2$ has been introduced as a convenient method for the synthesis of bis(η^6-naphthalene)metal complexes[12]. Here we report on the binary chromium complexes of triphenylene **9** and fluoranthene **10**. These ligands are examples of the two types of condensation, triphenylene (**9**) representing the *kata* and fluoranthene (**10**) the *peri* principle. Furthermore, **9** is an alternant and **10** a nonalternant PAH. **9** and **10** may also be regarded as benzene rings with a biphenyl or a naphthalene unit, respectively, fused to them.

Fundamental questions in PAH coordination chemistry relate to site selectivity of bonding and to the possibility of

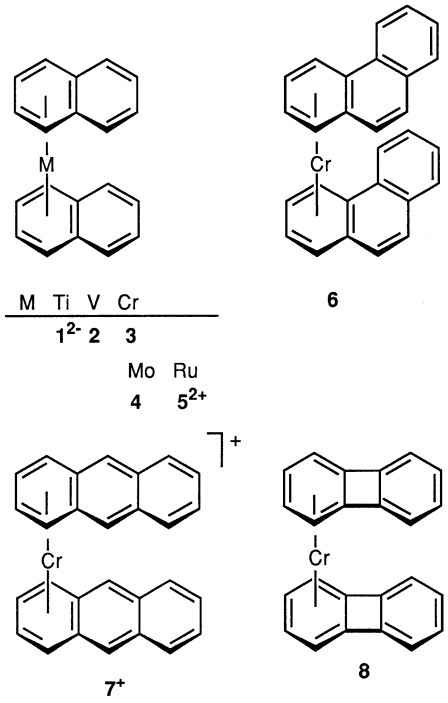
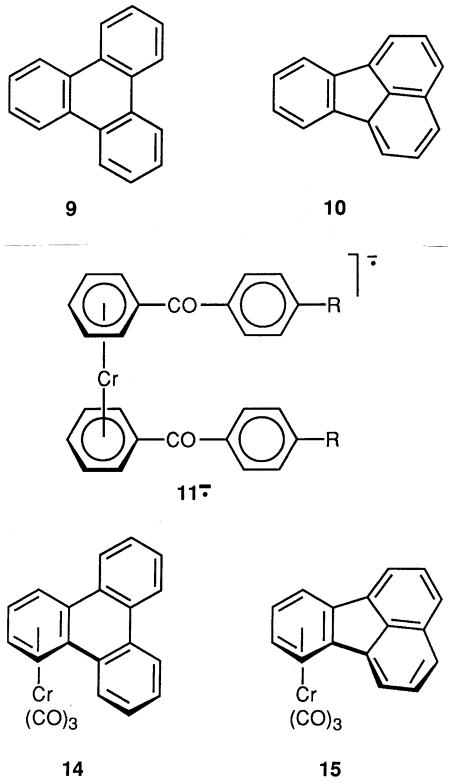
Scheme 1



Scheme 2



haptotropic shifts. Furthermore, in the case that in their η^6-coordinated state the ligands **9** and **10** maintain their ability to accept an additional electron forming radical anions, the question as to the rate of intramolecular electron transfer (ET) arises, since spin localization in one ligand as well as rapid interligand ET (delocalization) is conceivable. This dichotomy has previously been studied using EPR for benzoyl derivatives of bis(benzene)chromium ($\mathbf{11}^{-\cdot}$)[13]. Finally, interligand communication should also be apparent from an eventual redox splitting $\delta E_{1/2}$ exhibited by primary and secondary reduction of the complexes (η^6-PAH)$_2$Cr.

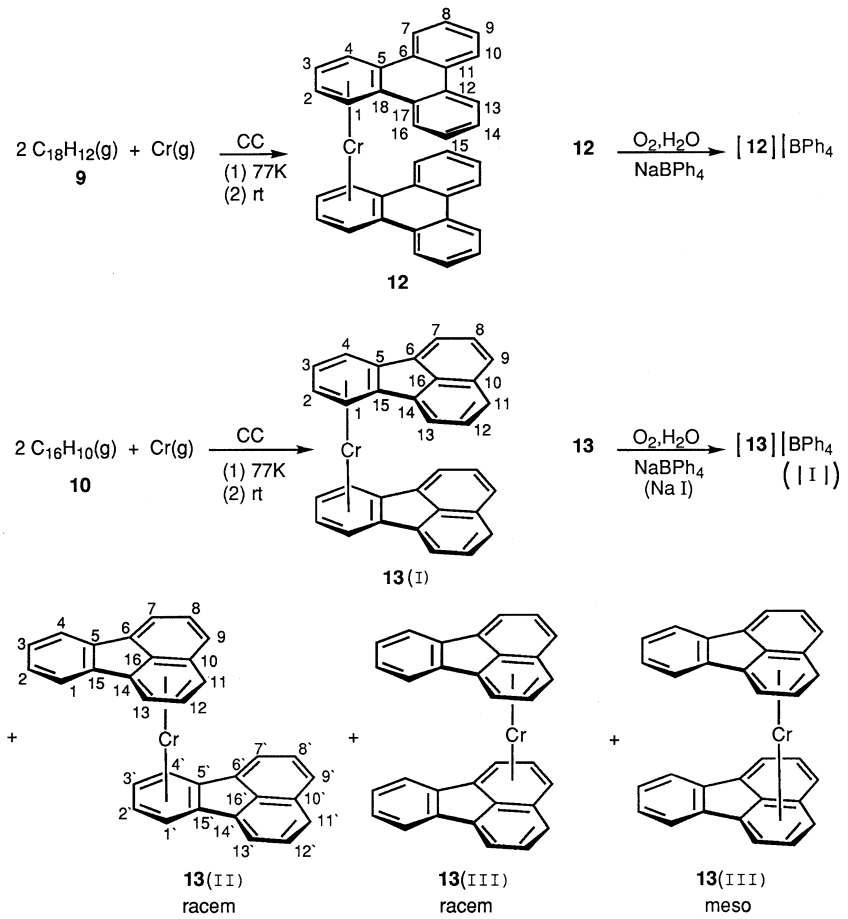
Results and Discussion

As has been demonstrated in the past for PAHs, metal atom/ligand vapor cocondensation techniques (CC) circumvent the problem of ligand hydrogenation and we therefore applied this method to the synthesis of bis(η^6-triphenylene)chromium (**12**) and bis(η^6-fluoranthene)chromium (**13**) (Scheme 3). The new complexes **12** and **13** were obtained in low yield as, respectively, brown or dark-violet air-sensitive solids which were only sparingly soluble in common organic solvents. The isomers **13**(II) and **13**(III) will be dealt with later. The separation of excess ligand from metal complex is a common problem in the metal-vapor technique of synthesis; it is particularly aggravating in the case of PAHs since the solubilities of the ligands and of the neutral complexes are often very similar. Conversion of the complex to its radical cation and extraction with water is not generally applicable since certain complex cations (η^6-PAH)$_2$Cr$^+$ are labile with respect to solvolysis (example: PAH = naphthalene[5]). However, the radical cations $\mathbf{12}^{+\cdot}$ and $\mathbf{13}^{+\cdot}$ are moderately inert in aqueous solution if kept in the dark; the photolability of $\mathbf{13}^{+\cdot}$ clearly exceeds that of $\mathbf{12}^{+\cdot}$. Thus, the redox cycle [**12** (**13**) $-$ e$^-$ $\rightarrow$ $\mathbf{12}^{+\cdot}$ ($\mathbf{13}^{+\cdot}$); extraction; $\mathbf{12}^{+\cdot}$ ($\mathbf{13}^{+\cdot}$) + e$^-$ $\rightarrow$ **12** (**13**)] can be utilized to effect separation of the complex from excess free ligand.

Single crystals suitable for X-ray diffraction could only be obtained for the complex cations $\mathbf{12}^{+\cdot}$ and $\mathbf{13}^{+\cdot}$ with BPh_4^- or I$^-$ serving as the counterion. Views of the structures are presented in Figures 1 and 2; bond lengths and bond angles are collected in the captions. Structural discussions of the class of compounds treated here should address the conformation in the solid state, ring slippage and the modification of ligand geometry induced by metal coordination. In **12**, as well as in **13**, chromium coordinates to the ring with the highest index of local aromaticity (ILA)[14] i.e. the ring which among the canonical forms most frequently appears with a Kekulé structure; this is a peripheral ring in **12** and the benzene (rather than the naphthalene) unit in **13**. The same site preference is adopted by the Cr(CO)$_3$ fragments in **14**[15] and **15**[16]. The complex cation in [**12**][BPh_4] adopts a conformation with regard to the sandwich axis which may be designated as synclinal, the torsional angle being 23.6°. This differs from the exact synperiplanar conformation which prevails in the related neutral complexes **3**[5b] and **8**[10]. Conceivably, the twisted disposition of the two ligands in $\mathbf{12}^+$, which is reminiscent of the graphite lattice, reduces interannular π-electron repulsion and is favored by the less dense packing in the complex salt [**12**][BPh_4] compared to the neutral complexes **3** and **8**.

For the salt [**13**][I], which contains the less bulky counterion I$^-$, the conformation with regard to the sandwich axis is synperiplanar. Interestingly, incorporation of solvent

Scheme 3



molecules in the lattice, as well as the use of a larger counterion, causes deviations of the conformation of $\mathbf{13}^{+\cdot}$ from exact synperiplanarity; for specimens of [**13**][I]·0.5 acetone and [**13**][BPh_4] torsional angles of 6.7° and 16.5° respectively were determined using X-ray diffraction[17]. Obviously, for sandwich complexes of PAHs packing forces are an important factor in the establishment of a certain ligand−metal−ligand disposition, probably overriding electronic factors. Ring slippage is minute in the structures of the cations $\mathbf{12}^{+\cdot}$ and $\mathbf{13}^{+\cdot}$; it is directed toward the ligand periphery and amounts to 3.9 pm ($\mathbf{12}^{+\cdot}$) and 5.2 pm ($\mathbf{13}^{+\cdot}$). A similar slippage has been reported for the half-sandwich complex (η^6-triphenylene)$Cr(CO)_3$[15]. Ring tilting is small as well, in that the deviations of the PAH ligands from a parallel disposition amount to 3.5° only for $\mathbf{12}^{+}$ and $\mathbf{13}^{+}$, the larger interplanar distance being encountered in the noncoordinated region; η^6 coordination renders the three peripheral rings of triphenylene structurally inequivalent in that the metal-bonded ring features significantly enlarged C−C bond lengths. Although the weighted average bond length of the free peripheral C rings amounts to 139 pm, that of the η^6-arene is 141 pm. The average C−C bond length for the central ring, which contributes two carbon centers to the coordinate bond, is 144 pm. This value exceeds the respective number for the free ligand triphenylene[18] by 1 pm and reflects the usual finding that in bis(arene)metal coordination δ backbonding M-δ→L is slightly more effective than σ, π donation M←σ,π-L. Bond length alternation in the central ring reflects the existence of three largely independent 6-π-electron systems in the peripheral rings and is, of course, also observed for the complex cation $\mathbf{12}^{+\cdot}$.

A similar trend is exhibited by the C−C bond lengths in (η^6-fluoranthene)$_2Cr^{+\cdot}$ ($\mathbf{13}^{+\cdot}$); the geometry of the naphthalene moiety is identical to that in the free ligand fluoranthene[19] while the η^6-benzene unit shows the typical increase of 2 pm for the C−C distances. The bonds C(5)−C(6), C(5′)−C(6′) and C(14)−C(15), C(14′)−C(15′) which connect the benzene and naphthalene moieties possess a mean length of 147 pm; thus, in the complex **13**, as well as in the free ligand **10**, naphthalene is linked to benzene by single bonds.

The site of chromium coordination in **12** and **13** follows, inter alia, from the ^{1}H-NMR spectra which in the case of the triphenylene complex **12** unambiguously demonstrate η^6 bonding to a peripheral ring. The relevant data are found

Figure 1. Molecular structure of compound [**12**][BPh_4]; top: SHELXTL/XP drawing with 50% probability ellipsoids; bottom: SHELXTL/XP drawing showing the ligand−metal−ligand torsion; C−*H* atoms omitted for clarity[a]

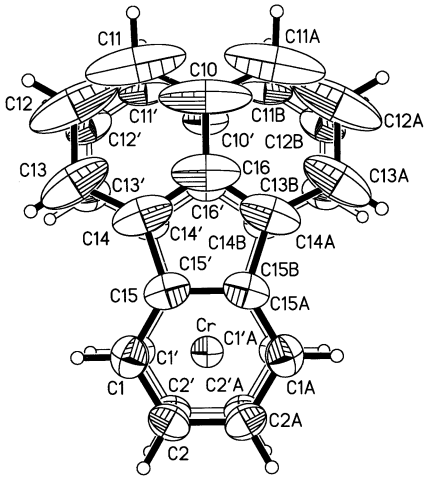
in Table 1. The spectrum initially obtained is unaffected by heating, therefore isomerization by haptotropic metal shifts is absent. Assignment of the chemical shifts δH(1, 4) and δH(2, 3) is based on their coordination shifts and on linewidth considerations; unresolved inter-ring coupling broadens the multiplet at lower field compared to that at higher field. Differentiation between δH(7, 16) and δH(10, 13) is achieved by means of selective homonuclear decoupling in that irradiation at δH(7) = 7.4 sharpens the signal δH(1, 4); differentiation between δH(8, 15) and δH(9, 14) follows from the effect of irradiation at δH(10) = 7.78 on the former two multiplets. It may be noted that apart from the usual, large coordination shifts Δδ*H* = −3.1 experienced by the protons H(1−4) which are directly bonded to an η-C atom, the protons H(7−10, 13−16) on the noncoordinated rings in **12** also display considerable upfield shifts.

Figure 2. Molecular structure of compound [**13**][I], SHELXTL/XP drawing viewed perpendicular and parallel to the sandwich axis; C−*H* atoms omitted for clarity[a]



[a] Selected bond lengths [Å]: C1−C2 1.401(5), C2−C2A 1.407(7), C1−C15 1.393(5), C15−C15A 1.457(7), Cr−C1 2.149(3), Cr−C2 2.135(4), Cr−C2A 2.135(4), Cr−C1A 2.149(3), Cr−C15A 2.179(3), Cr−C15 2.179(3); interplanar angle [Å]: tilt of best ligand planes 3.70(8); torsional angle C1−C2−C1′−C2′ 0.2°; ring slippage [Å]: (Cr displacement toward ligand periphery) 0.036(6).

This probably reflects the temporary existence in solution of rotamers, which place one ligand in the shielding region (ring current) of the other. ^{13}C NMR of **12** suffers from low solubility; this calls for broad-band proton decoupling. A compilation of the chemical shifts and their provisional analysis is also given in Table 1. Whereas the differentiation between metal-coordinated and free positions is trivial in view of the large coordination shifts of the former, specific assignments are less secure. They are based on intensity criteria and on comparisons with the related complexes bis(naphthalene)chromium (**3**)[5c], bis(fluorene)chromium[20], and bis(9,10-dihydroanthracene)chromium[9] for which unequivocal analysis has been possible.

While NMR study of the *triphenylene* complex **12** was straightforward, essentially confirming the structural characteristics gleaned from X-ray diffraction, more complicated, albeit informative, NMR behavior is exhibited by the *fluoranthene* complex **13**. The complications arise from isomerism for which the spectra provide evidence; the additional information concerns the occurrence of haptotropic shifts which explain the spectral changes effected by modifying the workup conditions and upon thermal treatment of solutions of neutral **13**. As shown in Scheme 3, complex **13** may exist as an achiral bis(η^6-benzene) form (I), a pair of enantiomers featuring (η^6-benzene)(η^6-naphthalene) coordination (II) and a bis(η^6-naphthalene) variant (III) which should generate a pair of enantiomers and a *meso* form. Experimental evidence,[2][3][4] as well as local aromaticity (ILA) considerations,[14] suggest that coordination to a benzene ring is favored over bonding to a naphthalene unit, rendering isomer I the thermodynamically most stable product. Therefore, if the purification process, which consists of separating the water-soluble cation $\mathbf{13}^+$ from excess ligand is carried out at leisure, i.e. exposing $\mathbf{13}^+$

to the aqueous medium for one hour or more, the isomers featuring the labile (η^6-naphthalene) coordination are solvolytically cleaved and pure **13**(I) is isolated after reduction. The ^{1}H-NMR pattern in the η^6-arene region is depicted in Figure 3a; spectral parameters are collected in Table 2. Thermal treatment of this probe does not cause spectral changes, thereby confirming that in fact, **13**(I) is the most stable isomer.

With the aim of identifying the less stable isomers, the redox procedure which effects the separation of unreacted excess ligand which is soluble in benzene from the water-soluble complex cation $\mathbf{13}^{+\cdot}$ was performed expeditiously, such that the mixture of primary cocondensation products was exposed to the aqueous medium for less than 10 minutes. After reduction to the neutral complex stage, ^{1}H NMR indicated the presence of two species A and B in a ratio of ca. 1:6. Attempts to isolate in pure form the species giving rise to spectrum B failed; however, after repeated crystallization of the product mixture, species B could be enriched to a composition A/B = 1:20 (Figure 3b). The ^{1}H-NMR spectrum of this sample was unchanged up to 80°C, whilst heating to 100°C led to the gradual disappearance of spectrum B and to the emergence of two new spectra C and D. During prolonged heating, spectrum D grew at the expense of spectrum C (Figures 3c−e). During all these manipulations the intensity of A remained approximately constant.

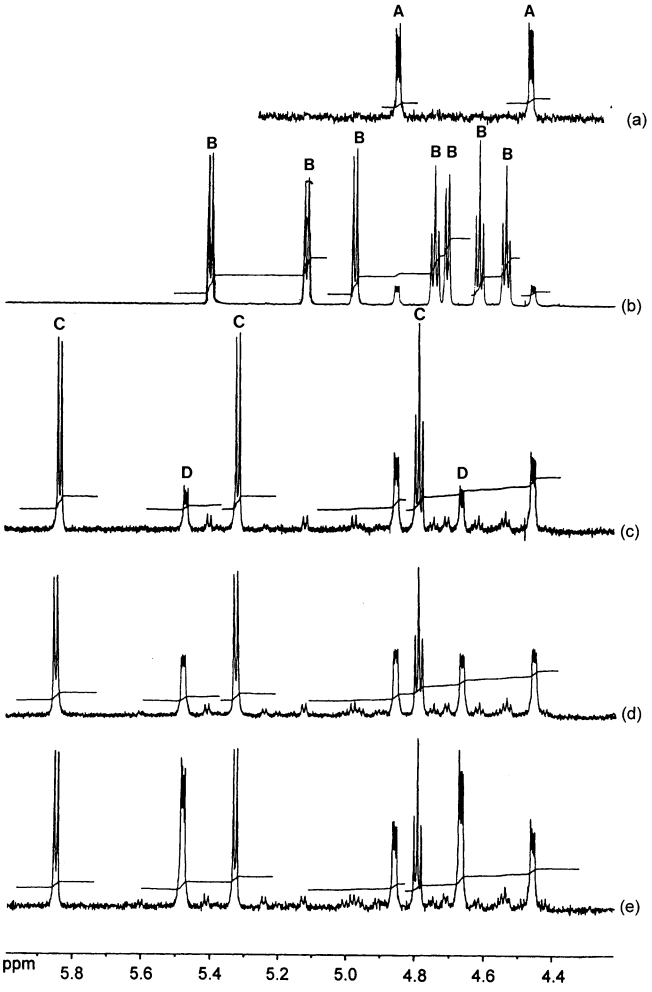
[a] δ^{13}C in C_6D_6; for the numbering see Scheme 3. − [b] In **13**(II). − [c] Triplet.

In order to interpret this evolution we start from the premise that the metal−ligand cocondensation process initially yields a mixture of isomers stemming from statistical, unspecific coordination of chromium atoms to all of the available benzenoid moieties. Extended exposure to an aqueous medium will lead to solvolytic cleavage of all of those species which contain either one or both sandwich ligands in an η^6-naphthalene coordination mode. Therefore, only **13**(I) survives in which both fluoranthene ligands bind to chromium via their benzene section. It is well known that in bis(naphthalene)chromium (**3**) the "first" naphthalene ligand is substitutionally more labile than the "second"[6a]. Thus, spectrum B, which is detected in addition to A after fast workup, should belong to isomer **13**(II). This suggestion is borne out by the observation of seven inequivalent proton signals, four doublets and three triplets, in the shift range characteristic for η-arene protons. The assignment given in Table 2 is based on HH-COESY and NOESY experiments. Spectrum C which dominates after thermal treatment points to isomer **13**(III) in which both ligands engage in coordination to chromium via a benzenoid system belonging to the naphthalene section. Apparently **13**(II) and **13**(III) exist in thermal equilibrium, the less stable isomer **13**(III) being formed at higher temperature, albeit at a small rate of interconversion. The room-temperature spectrum Figure 3d may therefore reflect a metastable state. Spectrum D which is also visible at this stage shows a simple AA′XX′ pattern, thereby indicating the presence of only *one* coordination mode, namely η^6 bonding via the benzene moiety. Since the chemical shifts in spectrum D differ from those observed for **13**(I) it must be assumed that

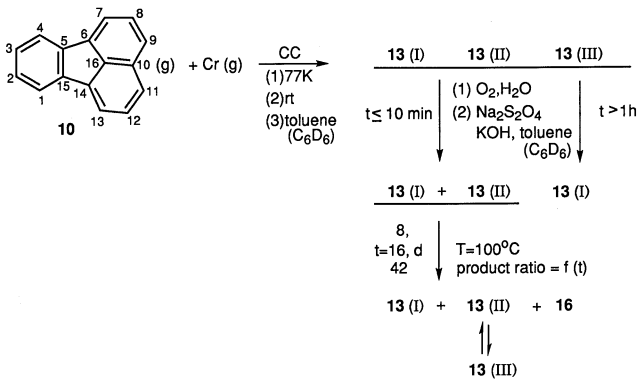
Figure 3. ^{1}H-NMR spectra (η^6-arene shift range, C_6D_6, room temperature) of the products from cocondensing fluoranthene vapor with chromium atoms; (a) after workup with extended (90 min) exposure to an aqueous medium; (b) after workup with short ($\leq$ 10 min) exposure to an aqueous medium and repeated recrystallization to enrich component B (A/B $\approx$ 1:20); (c) after subjecting probe b to 100°C for 8d; (d) after 16 d at 100°C; (e) after 42 d at 100°C



a second ^{1}H-NMR-silent ligand completes the coordination sphere. C_6D_6, the solvent molecule, could be a likely candidate, introduced by ligand substitution leading to (η^6-fluoranthene)(η^6-deuterobenzene)chromium (**16**). In order to test this hypothesis, thermal treatment of a mixture of **13**(I) and **13**(II), dissolved in C_6D_6, was repeated and at various time intervals, after having recorded the ^{1}H-NMR spectrum, the solvent C_6D_6 was removed in vacuo and replaced by C_6H_6. The solutions thus obtained were subjected to ^{2}H NMR. It was found that build-up of the ^{1}H-NMR spectrum C correlates with the observation in ^{2}H NMR of a singlet at δ = 3.76, the characteristic chemical shift for η^6-benzene. This attests to ligand substitution of fluoranthene by benzene. Based on the NMR observations, the course of events may therefore be sketched as shown in Scheme 4.

The redox behavior of the complexes **12** and **13**, not surprisingly, reflects the properties of the bis(η^6-arene)chromium core and those of the ligands triphenylene **9** and fluoranthene **10**. Cyclovoltammetric traces are depicted in Figures 4 and 5; the electrochemical parameters are given in

Scheme 4



the captions. The redox couples $E_{1/2}$ ($\mathbf{12}^{+/0}$) = -0.62 V and $E_{1/2}$ ($\mathbf{13}^{+/0}$) = -0.64 V are reversible and deviations from the peak current ratio $p_c/p_a = 1$ are probably due to adsorption effects. The magnitudes of the potentials differ only marginally, which is plausible in view of the fact that the redox orbital is essentially metal centered[21]. Changes in the ligand periphery therefore exert only an indirect influence. Conversely, the reduction processes as gauged by the potentials $E_{1/2}$ ($\mathbf{12}^{0/-}$), E($\mathbf{12}^{-/2-}$) and E($\mathbf{13}^{0/-}$), E($\mathbf{13}^{-/2-}$), respectively, mirror the differing electron affinities of triphenylene and fluoranthene, again in accord with the electronic structure of bis(arene)chromium which assigns considerable ligand participation to the LUMO. Thus, compared to **12**, electron transfer to **13** occurs at a somewhat more positive potential. This gradation also applies to the free ligands **10** and **9**[22]. Relative to the free ligands **9** and **10**, reduction of the complexes **12** and **13** features cathodic shifts; this accords with the ligand-dominated nature of the LUMO in bis(arene)metal complexes and the fact that the η^6-arenes bear a negative partial charge[21b]. For the triphenylene complex, a second reduction step can be observed which, as judged from the peak separation, appears to be reversible too. The peak current ratio is difficult to assess at this negative potential near the cathodic limit imposed by the medium. It is worth mentioning that the cyclovoltammogram of **12** does not feature waves which indicate the presence of free ligand. Therefore, bis(triphenylene)-chromium must be fairly robust, at least in the oxidation states $\mathbf{12}^{+,0,-}$, although the potential separation δE(0/$-$, $-$/2$-$) = 300 mV between primary and secondary reduction demonstrates appreciable interligand interaction. For the fluoranthene complex **13** this interaction seems to be even more pronounced since δE(0/$-$, $-$/2$-$) = 480 mV is larger. Consequently, the second reduction step $\mathbf{13}^{-/2-}$ is irreversible and the cyclovoltammogram contains weak waves which point to the presence of free fluoranthene, generated through metal$-$ligand bond cleavage. Therefore, strictly speaking, the value $\delta E(\mathbf{13}^{0/-,\ -/2-})$ given above is only a rough estimate.

The differing robustness of **12** and **13** against solvolytic cleavage also emanates from the EPR spectra; these are depicted in Figures 6 and 7, with the EPR parameters listed

Figure 4. Cyclic voltammogram of complex **12** at −40°C in 1,2-dimethoxyethane/0.1 M tetrabutylammonium perchlorate: working electrode, glassy carbon; reference electrode, SCE; v = 100 mVs^{-1}. $E_{1/2}$(**12** +/0) = −0.62 V, ΔE_p = 44 mV, r = 0.7; $E_{1/2}$(**12** 0/−) = −2.31 V, ΔE_p = 90 mV, r = 1.0; $E_{1/2}$(**12** −/2−) = −2.61 V, $\Delta E_p \approx$ 80 mV, $r \approx 0.5$; E_{pa} = 0.85 V (irreversible secondary oxidation)

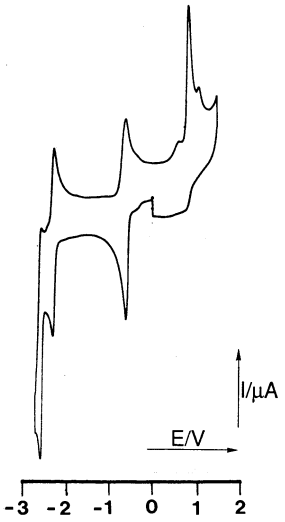


Figure 5. Cyclic voltammogram of complex **13** at −40°C in dimethoxyethane/0.1 M tetrabutylammonium perchlorate: working electrode, glassy carbon; reference electrode, SCE. v = 100 mVs^{-1}; $E_{1/2}$(**13** +/0) = −0.62 V, ΔE_p = 60 mV, r = 0.7; $E_{1/2}$(**13** 0/−) = −1.87 V, ΔE_p = 86 mV, $r \approx 1.1$ (cannot be measured accurately due to overlap with free ligand reduction); E_{pc} = −2.39 V (irreversible secondary reduction); E_{pa} = 0.65 (irreversible secondary oxidation); the shoulders marked L, are caused by first and second reduction of the free ligand **10**: $E_{1/2}$(**10** 0/−) = −1.73 V, ΔE_p = 54 mV, r = 0.76; E_{pc} = −2.21 V (irreversible secondary reduction); these data agree with those obtained from a control experiment with pure **10**

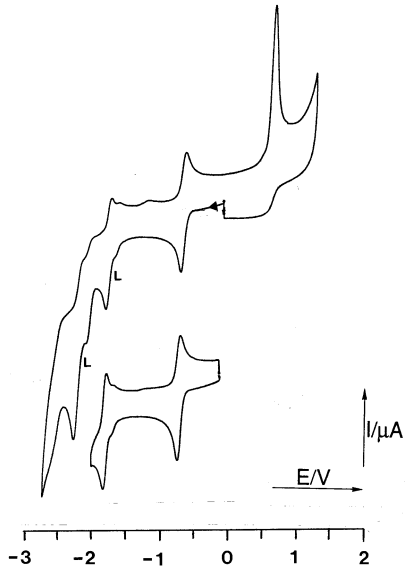
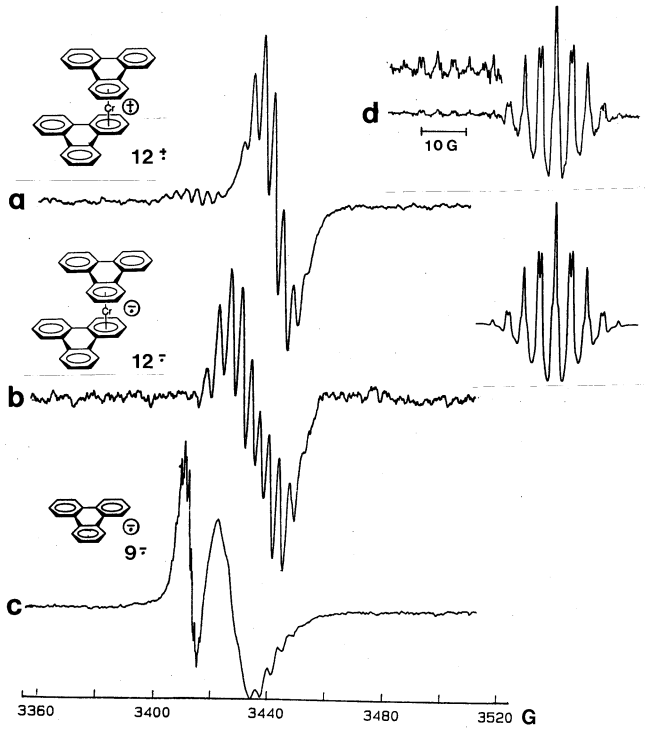


in the captions. The EPR spectra of the radical cations $\mathbf{12}^{+\cdot}$ and $\mathbf{13}^{+\cdot}$, generated either by air oxidation or electrochemically, differ in the extent to which chemically nonequivalent proton sites are resolved in the hyperfine structure. For $\mathbf{13}^{+\cdot}$ (Figure 7c) a pattern is observed which is consistent with eight equivalent protons, a(8 ^{1}H) = 0.34 mT, the difference between the coupling constants a(4 ^{1}H 1, 4) and a(4 ^{1}H 2, 3) not being resolved. Conversely, for $\mathbf{12}^{+\cdot}$ experiment and simulation yield the parameters a_1(4 ^{1}H) = 0.32 mT and a_2(4 ^{1}H) = 0.395 mT. Independent assignment of these coupling constants to positions at the ring cannot be made in the absence of specific deuteration. Thus, taking into consideration the aggregate nature of the mechanism of spin transfer from the central metal to ring protons in bis(arene)metal complexes[23], attempts to interpret in detail the 20% difference in the two experimental proton coupling constants for $\mathbf{12}^{+\cdot}$ would not be worthwhile. An aspect which should be addressed here, however, is the isomerism of the fluoranthene complex **13** which was discussed in the NMR section and which would be expected to manifest itself in the EPR spectra of the corresponding radical cations as well. As in the NMR study, we therefore varied the workup protocol in order to search for spectral differences. The results are depicted in Figure 7. A surprising observation is the detection of an EPR signal in the original cocondensation *before* oxidation to the radical cation (Figure 7a). While the basic features of this spectrum are characteristic of a bis(π-perimeter)chromium(d^5) species, the hyperfine pattern is unexpected since it shows coupling to *four* equivalent protons only. This can only be reconciled with a structure in which one of the fluoranthene ligands is η^6-bonded via its benzene moiety, the remainder of the coordination sphere being EPR silent. A possibility would be that the second fluoranthene ligand binds to chromium with the central, five-membered ring which is devoid of protons. Interestingly, the EPR parameters observed for this species [a(4 ^{1}H) = 4.38, a(^{53}Cr) = 15.4 G], apart from proton hyperfine multiplicity, differ significantly from the data typical for a bis(η^6-arene)Cr$^{+\cdot}$ radical cation such as $\mathbf{13}^{+\cdot}$ [a(8 ^{1}H) = 3.4, a(^{53}Cr) = 18.3 G]; they are very similar to the coupling constants reported for (η^5-C_5H_5)Cr(η^6-C_6H_6) [a(5 ^{1}H) = 2.35, a(6 ^{1}H) = 4.65, a(^{53}Cr) = 14.68 G[24]], however, thereby lending support to the proposal given above. On the other hand, coordination of chromium to the central five-membered ring is difficult to reconcile with the structural data of the ligand **9.** For this ligand the lengths of the bonds connecting the benzene and the naphthalene moieties are close to those of single bonds[18]. Furthermore, the presence of Cr(d^5), formally Cr^{1+}, would require a negatively charged ligand in the species under consideration, assuming that the latter is neutral. While in the parent complex (η^6-C_6H_6)Cr^{I}(η^5-C_5H_5) the negative charge of the cyclopentadienyl ligand results from deprotonation of C_5H_6, in the case of the primary radical complex in the cocondensation of chromium atoms with fluoranthene metal→ligand single-electron transfer could lead to an anionic ligand. This would, however, generate a biradical for which EPR fails to provide evidence. The nature of the species giving rise to the primary EPR signal cannot, therefore, be determined definitively.

In the NMR study, the critical factor leading to differences in the product distribution was the duration of exposure to an aqueous medium during the workup process.

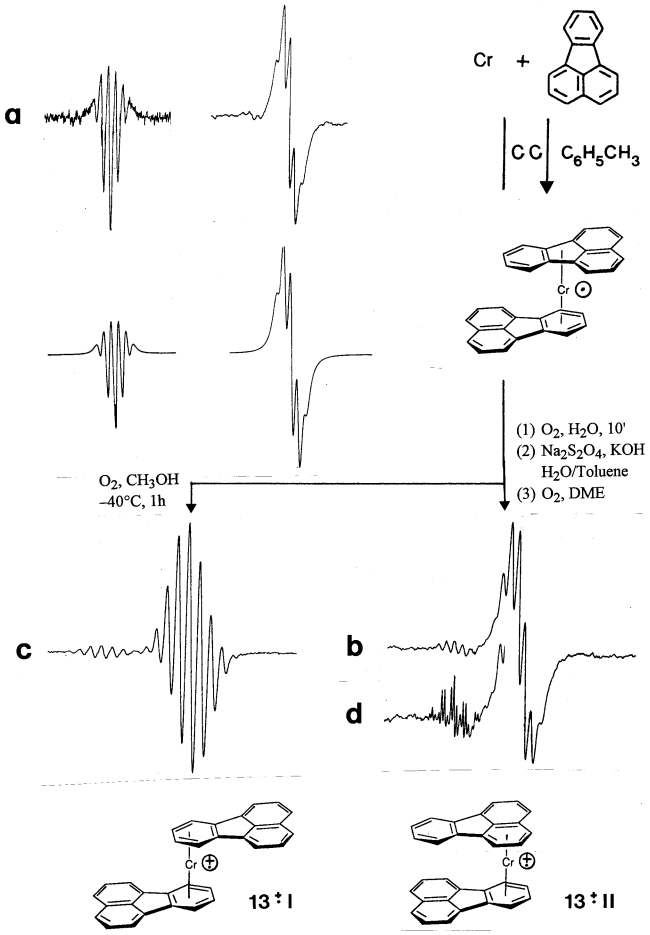
Figure 6. EPR spectra of (a) the radical cation $\mathbf{12}^{+\cdot}$, (b) the radical anion $\mathbf{12}^{-\cdot}$ and (c) the radical anion $\mathbf{9}^{-\cdot}$ of the free ligand, generated electrochemically in situ (gold cathode, DME, nBu$_4$NPF$_6$, −40°C); the applied potential was gradually increased to 5 V; (d): $\mathbf{12}^{+\cdot}$ in CH_3OH at −30°C, second derivative trace and simulation; $\mathbf{12}^{+\cdot}$: $\langle g\rangle = 1.986$, $a_1(4\ ^1H) = 3.2$ G, $a_2(4\ ^1H) = 3.95$ G, $a(^{53}Cr) = 18.22$ G; $\mathbf{12}^{-\cdot}$: $\langle g\rangle = 1.991$, hyperfine pattern irregularly spaced; $\mathbf{9}^{-\cdot}$: $\langle g\rangle = 2.0037$; 1 G = 0.1 mT



This parameter also governs the nature of the EPR spectra obtained. The fast workup variant led to a sample which gave rise to the ^{1}H-NMR spectrum shown in Figure 3b, which was assigned to isomer **13**(II). When this sample was oxidized in DME as a solvent to its radical cation, the EPR spectrum depicted as Figure 7b was observed. The hyperfine pattern points to seven protons which are equivalent within the resolution attained. The detection of an even number of lines clearly demonstrates that one ligand must coordinate to Cr(d^5) via benzene and the other via a naphthalene π subsystem [isomer $\mathbf{13}(II)^{+\cdot}$]. If, alternatively, the cocondensate is taken up in methanol and extensively oxidized with air, the spectrum shown in Figure 7c arises. This spectrum is also obtained from analytically pure [**13**][BPh_4]. The well-resolved nonuplet is in accord with the coordination mode of isomer $\mathbf{13}(I)^{+\cdot}$.

The reversible nature of the redox couples **12** (0/−) and **13** (0/−) suggested that intra muros reduction in the cavity of an EPR instrument[25] should yield spectra of the radical anions $\mathbf{12}^{-\cdot}$ and $\mathbf{13}^{-\cdot}$. However, experiments were frustrated by metal−ligand cleavage, possibly at the dianion stage, which could not be avoided due to insufficient control of the potential in the two-electrode set-up. A typical course of events is shown in Figure 6. Upon applying a negative potential to the gold spiral in the electrochemical cell the EPR spectrum due to $\mathbf{12}^{+\cdot}$ (a) becomes gradually superimposed by a new signal, shifted to a g factor which is closer

Figure 7. EPR spectra of products from the cocondensation of fluoranthene **10** with chromium atoms; (a) initial product mixture extracted with toluene, exclusion of oxygen $\langle g\rangle = 1.9892$, $a(4\ ^1H) = 4.38$ G, $a(^{53}Cr) = 15.4$ G, lower trace simulated; (b) spectrum observed after short exposure of the cocondensate to oxygen, reduction and reoxidation in an aprotic medium (DME), $\langle g\rangle = 1.9888$, $a(7\ ^1H) = 3.43$ G, $a(^{53}Cr) = 18.13$ G; (c) spectrum observed upon extraction of cocondensate with CH_3OH, access of oxygen, for 1 h, −40°C, $\langle g\rangle = 1.9871$, $a(8\ ^1H) = 3.40$ G, $a(^{53}Cr) = 18.3$ G; (d) spectral change caused by electrochemical intra muros reduction of probe b, applied potential −3.8 V; the well-resolved spectrum at low field belongs to the free ligand radical anion $\mathbf{10}^{-\cdot}$.



to the free spin value (b). This is in accord with the spectrum expected for the radical anion $\mathbf{12}^{-\cdot}$ since the metal contribution to the LUMO of bis(arene)chromium falls short of that which is contained in the HOMO. Before reaching the stage of reduction where $\mathbf{12}^{-\cdot}$ is the only species present, line broadening sets in which presumably stems from self exchange either of the $\mathbf{12}/\mathbf{12}^{-\cdot}$ or of the $\mathbf{12}^{-\cdot}/\mathbf{12}^{2-}$ type. Alternatively, line broadening could be caused by spin−spin interaction in a biradical dianion $\mathbf{12}^{2-\cdot\cdot}$ generated in the second reduction step. This dianion is very labile, however, since concurrently a signal with $g = 2.0037$ builds up which, upon expansion, is identified as being caused by $\mathbf{9}^{-\cdot}$, the radical anion of the free ligand[26] (c). Unequivocal analysis of the EPR spectrum of $\mathbf{12}^{-\cdot}$ is therefore prevented and the extent of electron delocalization cannot be determined. An analogous situation is encountered in the reduction of **13**; here, as demonstrated by the cyclovoltammetric results, the tendency toward metal−ligand cleavage

of the anion is even more pronounced. As shown in Figure 7d, the EPR spectrum of the free fluoranthene radical anion $\mathbf{10}^{-\cdot}$[27] appears at a stage where the radical cation $\mathbf{13}^{+\cdot}$ is still present in large excess. While $\mathbf{10}^{-\cdot}$ would be expected to be removed instantaneously through electron transfer to $\mathbf{13}^{+\cdot}$, simultaneous observation of both paramagnetic species may be traced to the cell construction[25]. A high local concentration of electrochemical reduction products is generated in a region where EPR sensitivity is maximal, namely near the surface of the gold spiral which serves as the cathode.

We thank the *Deutsche Forschungsgemeinschaft* and the *Fonds der Chemischen Industrie* for support. This work is a part of cooperative project between Ch. E. and A. V. sponsored by the *Volkswagen Stiftung* which we gratefully acknowledge. We are indebted to Prof. *M. Zander* for a gift of triphenylene and for helpful comments.

Experimental Section

General: All manipulations were carried out with exclusion of air under dinitrogen or argon (CV) unless stated otherwise. Physical measurements were performed with the equipment specified previously[28].

Bis[η(1,2,3,4,5,18)triphenylene]chromium (**12**): 5 g (22 mmol) of triphenylene was evaporated from an electrically heated internal

glass vessel held at 10^{-4} Torr within a 6-l glass reactor which was cooled with liquid N_2. Simultaneously, 1.8 g (34.6 mmol) of chromium, contained in a spiral of tungsten wire (∅ 1 mm), was evaporated by a heating current of 40 A at 8 V. The brownish black cocondensate was warmed to room temperature and suspended in 100 ml of toluene. After the access of air, 200 ml of water was added and the red aqueous phase washed with two portions (50 ml) of toluene and one portion of petroleum ether. The aqueous phase was then layered with 150 ml of toluene, exclusion of air provided for and ca. 10 g of $Na_2S_2O_4$ and 10 g of KOH added. Stirring was continued for about 2 h, the aqueous phase then turned colorless and the organic phase brown. Toluene was removed in vacuo and the residue kept at 10^{-4} Torr for 6 h. **12** (280 mg, 1.6% referred to Cr evaporated) was obtained as a dark brown microcrystalline product. Recrystallization was effected by layering a solution of **12** in toluene with petroleum ether (boiling range 40−60°C) and cooling to −20°C. − MS (EI, 70 eV); *m/z* (%): 508 (3.2) [M^+], 280 (4.3) [$M^+ - C_{18}H_{12}$], 228 (100) [$C_{18}H_{12}^+$], 52 (10.9) [Cr^+]. − $C_{36}H_{24}Cr$ (508.58): calcd. C 85.04, H 4.72; found C 84.77, H 4.83.

Bis[η(1,2,3,4,5,18)triphenylene]chromium Tetraphenylborate ([**12**][BPh_4]): To the aqueous solution of $\mathbf{12}^{+\cdot}$ obtained from a cocondensation of chromium (1.2 g, 23 mmol) and triphenylene (2 g, 8.7 mmol) performed as described above was added, under stirring, 0.5 g (1.46 mmol) of $NaBPh_4$. The reddish brown precipitate was washed with water and dried in vacuo. − Yield 530 mg (2.8% referred to Cr evaporated). Crystals suitable for X-ray diffraction were obtained by layering of solution of [**12**][BPh_4] (100 mg in 40 ml of acetone) with 120 ml of diethyl ether at 0°C. − $C_{60}H_{44}BCr$ (827.81): calcd. C 87.06, H 5.32; found C 85.67, H 5.41.

Bis[η(1,2,3,4,5,15)fluoranthene]chromium (**13**, isomer I): Chromium (2.1 g, 40.4 mmol) and fluoranthene (8 g, 39.6 mmol) were cocondensed during 2 h at 77 K as described for **12**. The workup procedure followed that given for **12**; in order to generate the radical cation $\mathbf{13}^{+\cdot}$ a stream of air was applied for 1 h before phase separation and reduction. − Yield: 110 mg (0.24 mmol, 0.6% based on Cr evaporated) of **13** as a dark violet microcrystalline product. − ^{1}H- and ^{13}C-NMR: Tables 2 and 3. − MS (EI, 70 eV); *m/z* (%): 456 (2.0) [M^+], 254 (5.1) [$M^+ - C_{16}H_{10}$], 202 (100) [$C_{16}H_{10}^+$], 52 (10.0) [Cr^+]. − $C_{32}H_{20}Cr$ (456.51): calcd. C 84.21, H 4.39; found C 84.95, H 5.18.

Bis[η(1,2,3,4,5,15)fluoranthene]chromium Tetraphenylborate ([**13**][BPh_4], isomer I): The reaction mixture from a cocondensation of chromium (1.9 g, 36.5 mmol) and fluoranthene (8 g, 39.6 mmol) was air-oxidized for 1 h. Subsequent manipulations and precipitation of the salt [**13**][BPh_4] followed the instructions given for [**12**][BPh_4]. − Yield: 310 mg (0.40 mmol, 1.1%) of [**13**][BPh_4] as dark red material. Crystals suitable for X-ray diffraction were grown by layering a solution of 140 mg of [**13**][BPh_4] in 60 ml of acetone with 100 ml of diethyl ether at ambient temperature.

Bis[η(1,2,3,4,5,15)fluoranthene]chromium Iodide ([**13**][I], isomer I): Cocondensation of chromium (1.6 g, 30.7 mmol) with fluoranthene (8 g, 39.6 mmol) and subsequent air oxidation (1 h) in the two-phase system H_2O/toluene led to an aqueous solution of $\mathbf{13}^+$ from which dark red [**13**][I] was precipitated by addition of KI (1.0 g, 6.0 mmol). The product was dried in vacuo. − Yield: 470 mg (0.8 mmol, 2.6%). Crystalline material for X-ray diffraction was obtained by layering a solution of 200 mg of [**13**][I] in 80 ml of acetone with 120 ml of diethyl ether. − $C_{32}H_{20}CrI$ (583.41): calcd. C 65.87, H 3.43; found C 66.28, H 3.81.

[η(1',2',3',4',5',15')fluoranthene][η(10,11,12,13,14,16)fluoranthene]chromium (**13**, isomer II): The preparation followed the instructions given for isomer I apart from a shorter (10 min) duration of air oxidation. − Yield 380 mg (0.83 mmol, 2.4%) of a dark violet microcrystalline material. According to ^{1}H NMR, this product was a mixture of ca. 85% of **13**(II) and 15% of **13**(I), see Tables 2 and 3. − $C_{32}H_{20}Cr$ (456.41): calcd. C 84.21, H 4.39; found C 84.87, H 4.93. − The mother liquor of the initial crystallisation was enriched in the more soluble isomer **13**(II). Repeated recrystallisation of the contents of this solution led to a product with the isomer distribution **13**(II)/**13**(I) = 95:5 as gleaned from ^{1}H NMR (see Figure 3 and Tables 2 and 3).

X-ray Crystal Structure Analysis of [**12**][BPh_4] *and* [**13**][I]: The crystal structures were solved by direct methods. Non-hydrogen atoms were refined anisotropically, hydrogen atoms on calculated positions with isotropic temperature factors $U(H) = 1.2\ U_{eq}(C)$. An inspection of the thermal parameters of [**13**][I] indicated unresolved disorder with respect to the crystallographic mirror symmetry. A refinement in the space group $Pna2_1$ (without this mirror symmetry) was not successful. Further details of the crystal structure determinations are given in Table 4.

Keywords: Rare earth metal complexes / Anionic phosphanes / Phosphanylethylcyclopentadienyl complexes

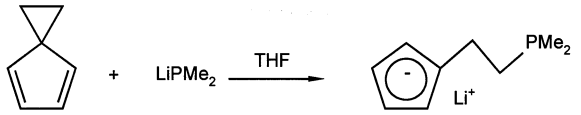
The reactions of $Li[C_5H_4(CH_2)_2P(CH_3)_2]$ (**1**) with $La(CF_3SO_3)_3$ and $Y(CF_3SO_3)_3$ are described. Three equivalents of **1** reacted with $La(CF_3SO_3)_3$ under formation of $La[C_5H_4(CH_2)_2P(CH_3)_2]_3$ (**2**). Two equivalents of **1** with one equivalent of $Y(CF_3SO_3)_3$ in the presence of LiBr yielded $BrY[C_5H_4(CH_2)_2P(CH_3)_2]_2$ (**3**). Both complexes **2** and **3** have been characterized by X-ray structure analysis. In both cases an intramolecular coordination of the phosphanoethyl chain is established in the solid state by X-ray crystallography as well as in solution by NMR spectroscopy.

In general, neutral phosphane ligands do not form stable donor complexes with rare earth metals. Only a few complexes with neutral phosphane ligands are found in the literature: $La[TeSi(SiMe_3)_3]_3(Me_2PCH_2CH_2PMe_2)_2$[1], $[(C_5Me_4SiMe_2N\mathit{t}Bu)Sc(PMe_3)\mu\text{-}H]_2$[2], $[N(SiMe_3)_2]_2Yb(Me_2PCH_2CH_2PMe_2)$[3], $(C_5Me_5)_2YbCl(Me_2PCH_2PMe_2)$[4], and $(C_5H_4Me)_3CePMe_3$[5]. Stable complexes are known with anionic phosphane ligands like phosphanides[6], phosphanomethanides[7], phosphanoalkoxides[8], and amidophosphanes[9]. Phosphanomethanides were found to stabilize even high phosphane coordination numbers (up to 8 P−Ln bonds).

Continuing our investigations on phosphane compounds of rare earth metals we now focus on phosphanoalkylcyclopentadienide ligands. The characteristic feature of this ligand system is the linkage of a cyclopentadienyl and a phosphane moiety by means of an alkyl chain. Similar cyclopentadienyl-based ligands with amino- or alkoxyalkyl side chains coordinated to lanthanoide centers have been described[10][11][12][13][14][15]. However, the strong coordination of the heteroatom to the metal center normally is irreversible in these cases.

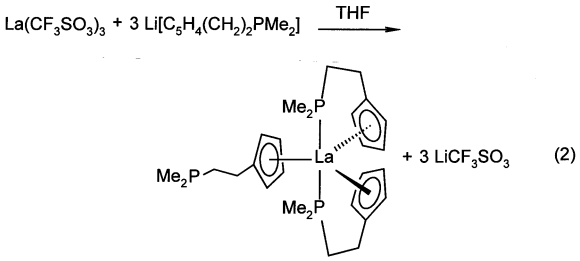
The additional phosphane functionality, in contrast, should provide a more labile and hence reversible coordination to the metal center which should enable enhanced reactivity and in particular is of great interest for catalytic reactions.

Only a restricted number of phosphanylcyclopentadienyl complexes have been reported so far and only a few are characterized by X-ray structure determinations[16][17][18][19][20]. Several independent routes have been applied for the synthesis of phosphanoalkyl-substituted cyclopentadienyl ligands, depending on the length of the alkyl chain connecting the cyclopentadienyl and the phosphane functionality.[21][22][23][24][25]. Phosphanoethyl-substituted cyclopentadienides {$M[C_5H_4(CH_2)_2PR_2]$, M = Li, Na, K} best are prepared by reaction of the corresponding phosphanide with spiro[2.4]hepta-4,6-diene[26] and anionic ligands with R = Ph, *i*Pr, *t*Bu are known[18]. The ligand $Li[C_5H_4(CH_2)_2P(CH_3)_2]$ (**1**) was newly synthesized using this method (Eq. 1).



(1)

The reaction of three equivalents of $Li[C_5H_4(CH_2)_2P(CH_3)_2]$ with one equivalent of $La(CF_3SO_3)_3$ led to the homoleptic compound $La[C_5H_4(CH_2)_2P(CH_3)_2]_3$ (**2**) in good yield (Eq. 2).



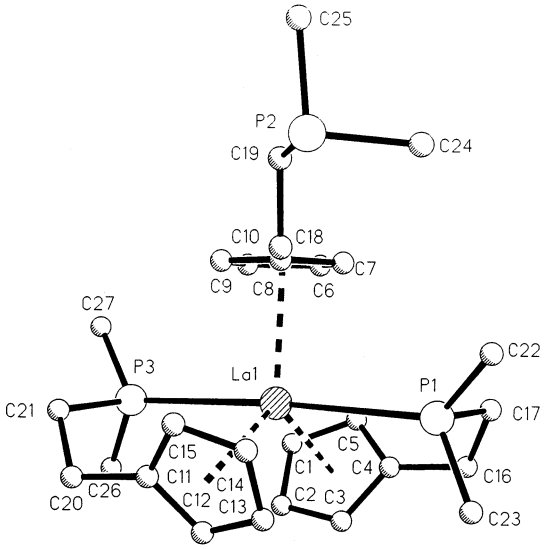
(2)

Colorless crystals were obtained from a concentrated solution of **2** in toluene. The complex is soluble in THF and aromatic hydrocarbons. At −90°C the $^{31}P\{^1H\}$-NMR shows two signals at δ = −39.91 and δ = −51.24 of intensity 2:1 which coalesce at −50°C, and at room temperature only one broad singlet at δ = −43.62 is observed. This is explained by a fast exchange of two coordinated and one "dangling" phosphano groups with the low-field signal being assigned to the coordinating phosphane ligands and the signal at δ = −51.24 being assigned to the noncoordinating phosphorus nucleus. This latter chemical shift corresponds to that of the neutral phosphane $[C_5H_5(CH_2)_2P(CH_3)_2]$

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1434−1948/98/1010−1403 $ 17.50+.50/0

($\delta = -51.42$; -51.54). Careful analysis of the spectra at various temperatures led to the conclusion that two phosphano groups throughout remain coordinated to the metal center during the exchange process, i. e. a dissociative pathway is unlikely. The ^{139}La NMR ($I = 7/2$, 99.1%) resonance of **2** is observed at $\delta = -509.92$ (cf.: $Cp_3LaNCCH_3$, $\delta = -578$[27]) as a broad singlet. These spectroscopic findings are also consistent with the result of an X-ray structure determination (Figure 1).

Figure 1. Molecular structure of **2**



Lanthanum is trigonal planar, surrounded by three cyclopentadienyl rings, as it is the case in other cyclopentadienyllanthanum compounds[28]. Additionally, two phosphorus atoms complete the coordination sphere to a trigonal bipyramid by occupying the axial positions.

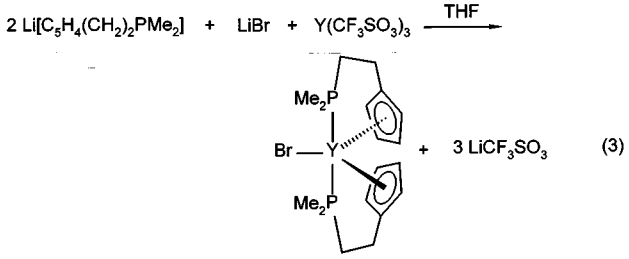
The lanthanum−phosphorus bond lengths [La−P1 = 3.211(5), La−P3 = 3.186(5) Å] are in the expected range for a lanthanum interaction with a phosphorus atom of covalency 3[1][7]. The molecular geometry and atom numbering scheme are shown in Figure 1, selected bond lengths [Å] and angles [°] are listed in Table 1.

Table 1. Selected bond lengths [Å] and angles [°] of compounds **2** and **3**

	1		**2**
La−X1a[a]	2.622(1)	Y−X1a[b]	2.386(1)
La−X1b	2.621(1)	Y−X1b	2.392(1)
La−X1c	2.621(1)	Y−P1	2.960(1)
La−P1	3.211(5)	Y−P2	2.933(1)
La−P3	3.186(5),	Y−Br	2.7939(5)
P1−La−P3	176.17(1)	X1a−Y−X1b	129.9(1)
X1a−La−X1c	118.7(1)	X1a−Y−Br	117.1(1)
X1b−La−X1a	121.6(1)	X1b−Y−Br	113.0(1)
X1c−La−X1a	119.7(1)	X1a−Y−P1	91.6(1)
X1a−La−P1	85.3(1)	X1a−Y−P2	99.9(1)
X1a−La−P3	91.6(1)		

[a] X1a, b, c: centroids of the Cp rings (C1 to C5, C6 to C10, C11 to C15). − [b] X1a, b: centroids of the Cp rings (C111 to C115 and C211 to C215).

The reaction of two equivalents of $Li[C_5H_4(CH_2)_2P(CH_3)_2]$ with one equivalent of $Y(CF_3SO_3)_3$ in the presence of LiBr proceeds under formation of the disubstituted yttrium bromide derivative **3** (Eq. 3).



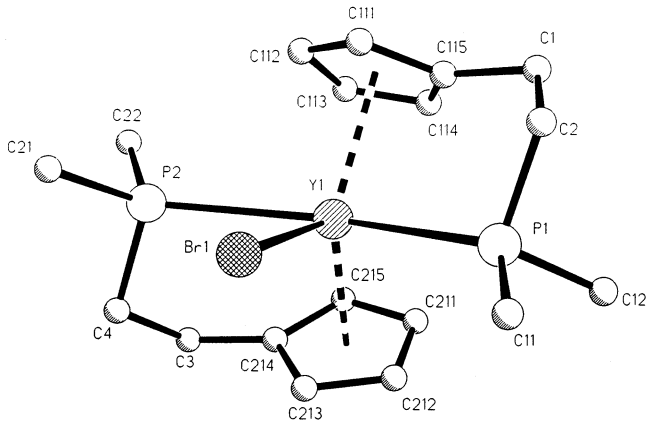
The product is obtained as colorless solid, soluble in aromatic solvents. The stabilisation by intramolecular coordination of the two phosphano functionalities is a dominant feature: this additional coordination prevents the dimerisation of the system and also the coordination of donor solvents, which otherwise are common features of bis(cyclopentadienyl)lanthanoid halides[29]. The $^{31}P\{^1H\}$-NMR spectrum shows a doublet at $\delta = -36.53$ with a $^1J_{PY}$ coupling constant of 72.8 Hz (^{89}Y, $I = 1/2$, 100%)[30] which remains unchanged over a temperature range from +30 to −100°C. This indicates that the system is not involved in dynamic processes.

Single crystals for an X-ray study were grown by slowly cooling a solution of **3** in toluene to low temperature. The compound crystallizes with one molecule of toluene in the formular unit. Both phosphano groups are bonded to the yttrium center (Figure 2) which confirms the spectroscopic findings. Similar to compound **2**, the two phosphorus atoms occupy the apical positions of a slightly distorted trigonal bipyramid. The Y−P bond lengths [2.960(1) and 2.933(1) Å] are only slightly longer than in $\{Y[N(SiMe_3CHPMe_2)(SiMe_2CH_2PMe_2)[N(SiMe_2CH_2PMe_2)_2]\}$ (2.817, 2.896, and 2.903 Å)[30]. Compound **3** represents the second hitherto known (and the first mononuclear) yttrium bromide featuring a terminal Y−Br bond, which is slightly longer [2.7939(5) Å] than that in $Y_3(OCMe_3)_7Br_2(THF)_2$ (Y−Br = 2.782 Å)[31]. Together with two cyclopentadienyl moieties of the $CpCH_2CH_2PMe_2$ ligands, the bromine completes the trigonal plane of the tbp molecular skeleton. With regard to the center of the Cp rings, the Cp(1)−Y−Cp(2) angle amounts to 129.9°, which gives an indication for the steric demand of the terminal bromine ligand. The average Y−Cp(center) distance (2.39 Å) agrees well with that found in other Y^{III} cyclopentadienyl complexes[32]. The molecular geometry and atom numbering scheme are shown in Figure 2, selected bond lengths [Å] and angles [°] are listed in Table 1.

Experimental Section

All operations were performed under dry, oxygen free nitrogen and with thoroughly dried solvents and glassware. Standard high-vacuum-line techniques were used. − Elemental analyses were ob-

Figure 2. Molecular structure of **3**



tained with a Vario EL CHN elemental analyzer of the microanalytical laboratory of the TU München. No attempts were made to further ameliorate the analytical data, which were not satisfying in all cases due to the high sensitivity of the compounds. – MS: Varian MAT 70 eV, CI. – NMR: Jeol GX 270 (^{1}H 270.17 MHz, ^{13}C 67.94 MHz, ^{31}P 109.4 MHz), Jeol GX 400 (^{1}H 399.65 MHz, ^{31}P 161.7 MHz, ^{13}C 100.40 MHz, ^{139}La 56.35 MHz), Jeol JNM Lambda 400 (^{7}Li 155.40 MHz). Chemical shifts (^{1}H, ^{13}C) refer to TMS ($\delta = 0$) as internal standard. For ^{31}P, 80% H_3PO_4, for ^{139}La, $LaCl_3$ (0.1 M in D_2O, $\delta = 0$) and for ^{7}Li, LiBr (20% in D_2O, $\delta = 0$) as external standards. All chemical shifts are reported in ppm and coupling constants J in Hz. In case of high-order spin systems, the distance "N" [Hz] between the two outermost lines of the multiplet is given. All measurements were carried out at 25°C in C_6D_6 as solvent. Temperature-dependent NMR spectra were recorded with [D_8]toluene as solvent. $LiPMe_2 \cdot 0.5\ Et_2O$[33], $La(CF_3SO_3)_3$, $Y(CF_3SO_3)_3$[34], and spiro[2.4]hepta-4,6-diene[26] were prepared according to literature procedures.

Li[$C_5H_4(CH_2)_2P(CH_3)_2$] (**1**): To a solution of 0.024 mol (2.5 g) of $LiPMe_2 \cdot 0.5\ Et_2O$ in 50 ml of THF, 0.024 mol (2.19 g) of spiro[2.4]hepta-4,6-diene in 20 ml of THF was added by pipette. After stirring the reaction mixture for 12 h at room temperature, the solvent was removed and the product was washed three times with pentane. After drying the residue, 3.15 g (82%) of a colorless solid was obtained. – ^{1}H NMR ([D_8]dioxane, 293 K): 1.06 [d, $^2J_{HP} = 1.24$, 6 H, $P(CH_3)_2$], 1.75 [dt, $^2J_{HP} = 1.95$, $^3J_{HH} = 7.32$, 2 H, $CpCH_2CH_2P(CH_3)_2$], 2.75 [dt, $^3J_{HP} = 12.21$, $^3J_{HH} = 7.32$, 2 H, $CpCH_2CH_2P(CH_3)_2$], 5.65 [A_2B_2: $\delta_A = 5.68$, $\delta_B = 5.61$, $J_{AB} = 2.44$, 4 H, $C_5H_4CH_2CH_2$]. – ^{13}C {^{1}H} NMR ([D_8]dioxane, 293 K): $\delta = 12.07$ (d, $^1J_{CP} = 2.59$, CH_3), 25.10 (d, $^2J_{CP} = 11.92$ CH_2P), 39.32 (s, $CpCH_2$), 101.62 (s, CH_2CCH), 101.90 (s, $CCHCH$), 119.84 (d, $^3J_{CP} = 9.33$, C-*ipso*). – ^{31}P{^{1}H} NMR ([D_8]dioxane, 293 K): $\delta = -56.34$ (s). – ^{7}Li NMR ([D_8]dioxane, 293 K): $\delta = -8.21$ (s). – $C_9H_{14}LiP$ (160.13): calcd. C 67.51, H 8.81, Li 4.33, P 19.35; found C 65.67, H 8.74, Li 4.35, P 18.37.

La[$C_5H_4(CH_2)_2P(CH_3)_2$]$_3$ (**2**): To a mixture of 6.2 mmol (1.0 g) of **1** and 2.05 mmol (1.2 g) of $La(CF_3SO_3)_3$, 40 ml of THF was added at –78°C. The reaction mixture was slowly warmed up to room temperature and stirred for another 12 h. The solvent was removed and the product was extracted with 40 ml of toluene. The toluene extract was concentrated and **2** was isolated as colorless crystals, 1.14 g, (92%), dec. 138°C. – ^{1}H NMR (C_6D_6, 293 K): $\delta = 0.92$ [s, 18 H, $P(CH_3)_2$], 1.56 ["t", $N = 14.29$, 6 H, $CpCH_2CH_2P(CH_3)_2$], 2.60 [m, $N = 30.27$, 6 H, $CpCH_2CH_2P(CH_3)_2$], 5.76 [A_2B_2 spin system, uncompletely resolved, $\delta_A = 5.72$, $\delta_B = 5.79$, 12 H, $C_5H_4CH_2CH_2$]. – ^{13}C{^{1}H} NMR (C_6D_6, 293 K): $\delta = 12.99$ (s, CH_3), 25.68 (s, CH_2P), 35.05 (s, $CpCH_2$), 109.03 (s, CH_2CCH), 110.12 (s, $CCHCH$), 128.90 (s, C-*ipso*). – ^{31}P{^{1}H} NMR (C_6D_6, 293 K): $\delta = -43.62$ (s, br). – ^{31}P{^{1}H} NMR ([D_8]toluene, 203 K): $\delta = -39.91$ (s, br, 2P, La-PMe_2), –51.24 [s, br 1P, $C_5H_4(CH_2)_2PMe_2$]. – ^{139}La NMR (C_6D_6 293 K): $\delta = -509.92$. – MS (70 eV); *m/z* (%): 445 (100) [$M^+ - C_5H_4(CH_2)_2P(CH_3)_2$], 384 (50) [$M^+ - C_5H_4(CH_2)_2P(CH_3)_2 - P(CH_3)_2$], 154 (13.9)

Crystal Structure Determination: Suitable crystals of **2** and **3** were sealed into glass capillaries. The structures were solved by direct methods and refined by full-matrix least-squares calculations against F^2 (SHELXL-93)[35][36]. Crystal data and numerical data of the structure determinations are given in Table 2. The thermal motion of all non-hydrogen atoms was treated anisotropically. All hydrogen atoms were calculated in ideal positions. Further informations may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (Germany), on quoting the depository numbers CSD-408608 (**2**) and CSD-408609 (**3**).

Keywords: Functionalized tripod ligands / Mixed donor set ligands / Solubilized tripod ligands / Molybdenum / Iron /

Neopentane-derived tripod ligands of the general type $HOCH_2C(CH_2PPh_2)(CH_2Y)(CH_2Z)$ (**1**; Y, Z = PPh_2, SR) are notoriously resistant to ether formation at their hydroxy group. Two routes have been found, which allow the transformation of **1** into ether functionalized tripod ligands $ROCH_2C(CH_2PPh_2)(CH_2Y)(CH_2Z)$ (Y = Z = PPh_2: **5**, Y = Z = SR: **8**). One of these strategies relies upon the η^3 coordination of **1** in **1**·$Mo(CO)_3$ (**2**). By this way the donor groups are efficiently protected and the steric encumbrance of the CH_2OH group at the backbone of the ligands is greatly reduced by fixing three arms of the neopentane scaffolding to the metal center. After deprotonation, reaction with electrophiles will produce the corresponding ether derivatives $ROCH_2C(CH_2PPh_2)(CH_2Z)_2$ (**3**). Mesylation of **2** leads to $MeSO_2OCH_2C(CH_2PPh_2)3{\cdot}Mo(CO)_3$ (**4**), which reacts with alkoxides to produce **3** in a sequence of reversed polarity. Ligands **5** [$ROCH_2C(CH_2PPh_2)_3$] are liberated from **3** by UV irridation of their solutions in the presence of pyridine *N*-oxide. Direct etherification of **1** is also possible in some cases after deprotonation of **1** by KO*t*Bu and subsequent reaction with an electrophile RX in the narrow temperature range between –10 and +20 °C. By this way, ω-methyl polyglycol ether functions are easily introduced resulting in $H_3C(OC_2H_4)_nOCH_2C(CH_2PPh_2)_3$ (**5g**, **h**).

Introduction

One of the properties of a ligand which has not been generally considered to be too important is its solubility in different solvents and the herewith introduced solubility of its coordination compounds. On the other hand it has been shown how solubility properties may considerably improve processes which rely on the catalytic activity of ligand-metal templates, one of the examples of even technical importance being the Rhone-Poulenc process.[1] In this case hydrophilic phosphane ligands are the reason for the advance.[2] Many other catalytic processes do in principle allow for this kind of modification[3], given that the ligand can be appropriately modified. Modifying ligands to enhance and specify solubility is thus of basic interest. Modifying ligands by attaching auxiliary groups, such as to allow the attachment of ligand-metal templates to a surface is another reason for putting more weight to the question of an appropriate functionalizability of a ligand.[3] Homogeneous processes may be transferred to heterogenous ones using this approach combining the advantages of both homogeneous and heterogeneous catalyses.[4] Modifying ligands such as to induce a self-assembly type of order in the phases derived from their coordination compounds is yet another point of interest in this topic.[5] The rapid development of chemical sensors[6] as well as of non-linear optical materials[7] will further increase the demand for ligands which do not only have the appropriate coordinative capabilities but do at the same time allow for easy-to-achieve modifications by additional functionalities in order to imprint the specific properties which are needed in each case to their coordination compounds.

As a consequence a well-thought-of strategy for designing a particular class of ligands will from the very beginning incorporate a functionality which may serve as a linker group such as to allow for all the modifications eventually needed. In a project concerned with the synthesis and application of tripod ligands $RCH_2C(CH_2X)(CH_2Y)(CH_2Z)$ much work has been devoted to the problem of designing a convergent strategy to introduce different donor groups[8a][8b][8c][8d][8e][8f][8g][8h], even enantioselective procedures have been worked out.[9a][9b][9c] The problem of introducing a linker group at the backbone has, however, not yet been solved in a convergent way. Wherever syntheses of ligands modified in this sense had been reported, the modified groups were incorporated from the very beginning of the syntheses.[8k][8m] Even though with the synthesis of $HOCH_2C(CH_2X)(CH_2Y)(CH_2Z)$[8k] the alcohol function appears to naturally lend itself to further functionalization, the steric bulk of the neopentane system hitherto precluded the scope of this reaction. Only silylation and esterification[8k] leading to R_3Si- and $RCOO-$ derivatives had been found to work. And even with these reactions the protection of donor functions X, Y, Z like PR_2 was found to be necessary. The functionalizations thus introduced strongly limit the potential application of these ligands due to their sensitivity to hydrolysis. An ether functionality would be far more superior. Despite continued efforts[8k][8l] to achieve etherification of the hydroxymethyl group of these neopentane-based ligands definitive solutions of this problem have only now been found. We report here on methods which allow for this type of modification of tripod ligands and which are at the same time tolerant to a broad

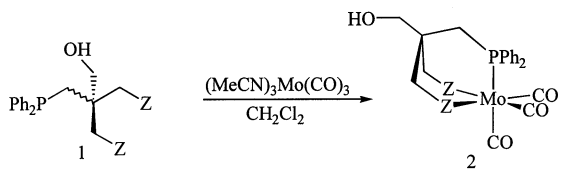
range of functionalities in the auxiliary group as well as in the donor set of the ligands.

Results and Discussion

Modification of Coordinated Ligands

There are two main reasons for the failure of the transformation of the CH_2OH group in $HOCH_2C(CH_2X)(CH_2Y)(CH_2Z)$ into an ether function: one of them being the sluggish reactivity of the neopentane system[10] and the other one being inherent in the sensitivity of the donor groups to electrophilic attack.[8k][8l] This second impediment may in part be overcome by appropriate protection of the donor groups e.g. adduct formation of PR_2 donors with borane to give protected PR_2-BH_3 entities which are less prone to electrophilic attack. A strategy which solves both problems at the same time may be envisaged in η^3-coordinating all three donor groups to one metal center. This should protect the donor groups and should at the same time reduce the steric crowding around the CH_2OH group at the neopentane framework with this steric crowding being the main reason for the reduced reactivity of neopentane derivatives.[10] It is observed that the tricarbonylmolybdenum fragment serves as an efficient template in this sense. Tripod tricarbonylmolybdenum complexes are easily accesible and remarkably stable.[8i][8k][8l] Thus, ligands **1** are transformed into their $Mo(CO)_3$ derivatives **2** (Scheme 1) with excellent yields (Experimental Section).

Scheme 1



1a: Z = PPh_2
1b: Z = SBzl

2a: Z = PPh_2
2b: Z = SBzl

Their ν(CO) IR spectra (Experimental Section) are in accord with the C_3 symmetry of the $Mo(CO)_3$ chromophore which is somewhat disturbed by the two different donor functions in **2b** so that the E band is split into two discernable components. The NMR data (Tables 1 and 2, Experimental Section) are in full accord with the assigned constitution. Compound **2a** is deprotonated at the alcohol function by KO*t*Bu (Scheme 2). The potassium alkoxide thus obtained reacts with various electrophiles to produce the corresponding ethers **3**. The infrared and ^{31}P-NMR spectra (Experimental Section) as well as the ^{13}C- and ^{1}H-NMR data (Tables 1 and 2) are in full accord with the structures. Compounds **3** are obtained as analytically pure pale yellow microcrystalline solids, the structures of **3a** and **3b** have been determined by X-ray crystallography.[16]

While the above procedure relies upon transforming the CH_2OH function of **2a** into a nuleophilic group, a method

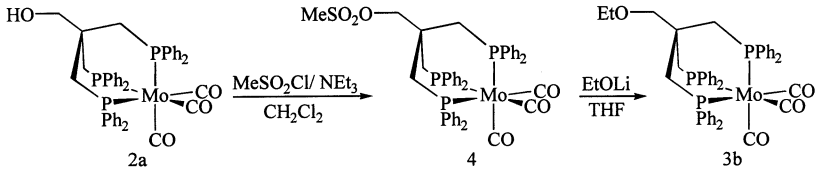
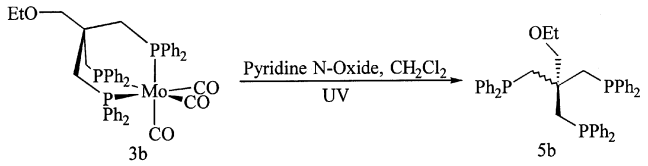


Scheme 4



inverting the polarity by mesylation of the hydroxy group is also possible.

2a, when treated with an excess of mesyl chloride in the presence of NEt_3 (Scheme 3), gives the mesylate **4** which after chromatography is obtained analytically pure as a pale yellow microcrystalline solid (Experimental Section; Tables 4 and 5). The mesylate **4** reacts with LiOEt to give **3b** albeit in lower yields as compared to the yields obtained using the above procedure based on an inverted polarity. The procedure starting from **4** was therefore not further generalized. It should be noted that the free ligand $HOCH_2C(CH_2PPh_2)(CH_2Y)(CH_2Z)$ can not be mesylated[11] and even a change of the reaction conditions as described later did not work with mesyl chloride.

In order to make the above procedure useful for the synthesis of the corresponding free ligands decoordination of the $Mo(CO)_3$ template in **3** is necessary. An especially useful approach for this purpose has been developed by H. A. Mayer et al.[12], who found that tripod ligands containing P-donor functions may be decoordinated from their $Mo(CO)_3$ complexes by irridating their CH_2Cl_2 solutions in the presence of pyridine *N*-oxide. With **3b** as an example this procedure was shown to work equally well for the class of tripod ligands which are of concern in this paper. **3b** liberates the tripod ligand **5b** (Scheme 4).

The ligand has to be purified by chromatography since even under these specialized conditions oxidation at the phosphorus atoms is a minor side reaction. **5b** is obtained as an analytically pure colorless viscous material, the identity of which is evident from the ^{31}P-NMR and analytical data (Experimental Section) as well as from ^{1}H- and ^{13}C-NMR results (Tables 4 and 5).

Modification of Free Ligands

It had been shown that ether formation from **1a** is not possible under standard Williamson conditions.[8k] Neither change of the solvent nor change of the counter ion (Na^+, Li^+) was found to be a remedy in this situation[8k], nor did BH_3 protection of the phosphane donors cause a positive change. Lacking reactivity or quaternization at the phosphorus atoms were the seemingly unavoidable problems.[8k][11] We found now that **1a** after deprotonation with KO*t*Bu in THF does react with various electrophiles at temperatures below 20°C to give the corresponding ethers (Scheme 5).

Scheme 5

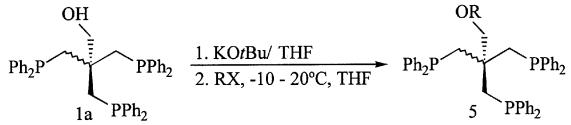


Table 3. Alkylation reagents RX and yields for the reaction of **1a** to **5a–h**

	R	X	Yield (%)
5a	Me	I	72
5b	Et	I	69
5c	$CH_3[CH_2]_9$	OTs	33
5d	$CH_3[CH_2]_{21}$	OTs	44
5e	$H_2C{=}CH[CH_2]_9$	OTs	38
5f	$Cl[CH_2]_6$	OTs	52
5g	$Me[OC_2H_4]_3$	OTs	53
5h	$Me[OC_2H_4]_n$, $n = 4-13$	OTs	[a]

[a] Yield cannot be determined due to separation problems of **5h** from the starting compounds.

The relative rates of ether formation or quaternization at the phosphorus atoms are different enough under these conditions to impede the extensive formation of quaternization products. As minor side products the phosphonium salts are separated by chromatography from the products **5** and the ligands **5** are obtained in fair yields by this procedure. They are colorless viscous oils in general; only **5a** could be obtained as a microcrystalline solid by recrystallization from CH_2Cl_2. The compounds **5a–5g** are obtained in an analytically pure state; the polyoxyethylene derivative **5h** is not completely separated from the starting materials.

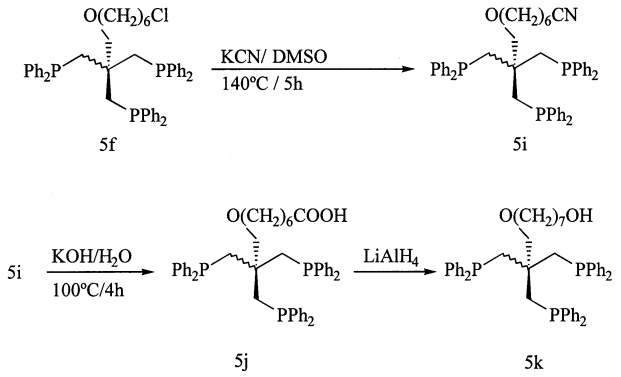
[a] **3** and **4** in CD_2Cl_2, **5** in $CDCl_3$. – [b] $^3J_{CP}$. – [c] $^2J_{CP}$. – [d] $^1J_{CP}$ in Hz. – [e] Due to worse solubility not observed.

The presence of different chain lengths in the product **5h** is evident from the mass spectra (Experimental Section) as well as from individual chromatographic bands for the major congeners of the mixture of oligomers acting as the auxiliary groups in **5h**. All compounds **5** show their ^{31}P resonances as a singlett at $\delta \approx -28$ (Experimental Section) as usual for the CH_2PPh_2 groups in tripod ligands.[8l] The ^{1}H-NMR spectra of **5a–5g** (Table 4) show the signals of all the chemically different groups of **5** in the correct integral ratio and with the expected J_{CP} couplings. The ^{13}C-NMR data (Table 5) are equally conclusive as to the constitution of the compounds.

It is observed that while iodide as a leaving group of the electrophile used to form the ether linkage works well in MeI and also in EtI as the electrophilic components, it is not apt for the introduction of components which contain longer chain alkyl constituents (**5e–5f**). In these cases, presumably by the elimination of HI, no products **5** are obtained. Using tosylate instead of iodide as the leaving group allows for the introduction of long-chain residues (**5c–5f**). These residues may well contain ω-olefinic functionalities (e.g. **5f**). The monomethylpolyoxyethylene function (**5g**, **5h**) may as well be introduced, with the corresponding tosylates which are themselves easily obtained from the commercial alcohols.[13] With the tris(oxyethylene) building block, which is commercially available as its analytically pure alcohol derivative **5g**, is formed correspondingly. The distribution characterizing the polymer mixture $Me(OC_2H_4)_nOH$

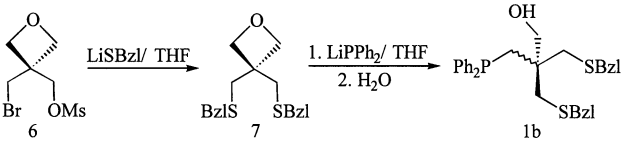
leads to a corresponding distribution of chain lengths in the product. The spread of compounds **5a**−**5h** shows that lipophilizing as well as hydrophilizing (**5g**, **h**) auxiliary groups may equally well be introduced by the above procedure. Examples **5e**, **5f** show that ω functionalization of alkyl chains is tolerated by the synthetic procedure, while further functionalization of the terminal double bond in **5e** has not yet been analyzed. Substitution of the chlorine function in **5f** has been investigated: **5f** in DMSO reacts with an excess of KCN to give the nitrile derivative **5i** which lends itself to a variety of further transformations (Scheme 6).

Scheme 6



In order to test whether the reaction conditions just described would also work when other donor groups besides phosphanes are present in hydroxy-functionalized ligands of type **1** the mixed-donor set ligand **1b** was synthesized.

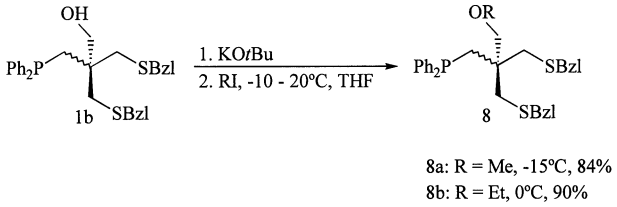
Scheme 7



The functionalized oxetane **6** was transformed into **7** by reaction with LiSBzl. In a consequent step the oxetane ring in **6** was nucleophilically opened by $LiPPh_2$ (Scheme 7). After workup, **1b** was obtained as a colorless oil of moderate viscosity. The sequence of reactions used to form **1b** from the functionalized oxetane **6** had already been successfully applied in several principally analogous cases.[8a][8b][8c][8d][8l] It corresponds to an entry into the chemistry of hydroxy-functionalized tripod ligands which is of rather broad scope. While **6** has already been described[8g] compounds **7** and **1b** have been unknown and have therefore been fully characterized by elemental analysis, mass spectrometry and ^{31}P-NMR data where appropriate (Experimental Section) as well as by ^{1}H- and ^{13}C-NMR data (Tables 1 and 2).

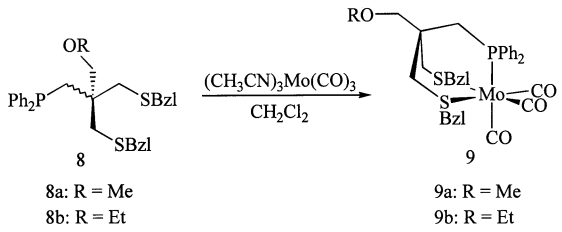
The hydroxy function in **1b** is indeed transformed into an ether functionality under the conditions which have been found to be productive in the transformation of **1a**−**5** (Scheme 8). Compounds **8** are colorless oils which are unequivocally characterized by their analytical and spectroscopic data (Experimental Section; Tables 1 and 2).

Scheme 8



Compounds **8** contain three different ligand functionalities in principle (PPh_2, SBzl, OR). If they undergo η^3 coordination, different possibilities with respect to the formation of isomers exist in principle. It is observed that with the "soft" template $Mo(CO)_3$ only the P- and S-donor functions coordinate.

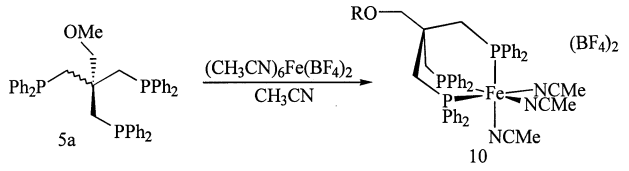
Scheme 9



Upon reaction of **8** with $(CH_3CN)_3Mo(CO)_3$[14] the derivatives **9** are formed which contain the ligand in an η^3 coordination mediated by the two SBzl functions and the PPh_2 group (Scheme 9). Compounds **9** are microcrystalline yellow solids which are fully characterized with their analytic and spectroscopic data (Experimental Section; Tables 1 and 2). In compounds **9** as in compound **2b** two sets of carbonyl groups are expected. The ^{13}C-NMR resonances clearly distinguish between these two sets: the CO group *trans* to the phosphorus donor shows a large $^2J_{CP}$ coupling constant: (**2b**: 34.9 Hz; **9b**: 35.0 Hz) while the two carbonyl groups *cis* to the phosphorus atom are characterized by coupling constants of around 9 Hz (Table 2). The idealized symmetry of the $Mo(CO)_3$ entity is thus disturbed and as described for **2b** the ν(CO)-IR E bands of **9a** and **9b** are split into two distinct components (Experimental Section). The diastereotopicity of some of the CH_2 groups in **9** is only occasionally resolved in their ^{1}H-NMR (Table 1). The same statement applies for the diastereotopic differentation of some of the CH_2 groups in **8**, **1b**, and **2b** (Table 1). While with the selective coordination of P and S donors in **9** and the consequent exclusion of the OR donor from coordination, no problems arise with respect to the formation of a mixture of isomers it might well be that a template less soft than $Mo(CO)_3$ might change the situation. To test this hypothesis **5a** containing three phosphorus and one oxygen

donors was treated with $[Fe(CH_3CN)_6](BF_4)_2$[8l][8m][8n][8o] (Scheme 10).

Scheme 10



The propensity of the starting material to form tris(acetonitrile)iron cations had already been demonstrated.[8l][8m][8n][8o] With **5** as the ligand compound **10** is obtained as the only product. No signs of oxygen coordination are thus observed even when the less soft metal center Fe^{II} as compared to Mo^0 in **9** is coordinated. **10** is fully characterized by the usual analytical and spectroscopic techniques (Experimental Section).

Experimental Section

General: All manipulations were carried out under argon by means of standard Schlenk techniques. All solvents were dried by standard methods and destilled under argon. The $CDCl_3$, CD_2Cl_2, and $[D_8]$THF used for the NMR-spectroscopic measurements were degassed by three successive "freeze-pump-thaw" cycles and dried over 4-Å molecular sieves. The silica gel (Kieselgel z.A. 0.06−0.2 mm, J. T. Baker Chemicals B.V.) used for chromatography was degassed at 1 mbar for 24 h and saturated with argon. − NMR: Bruker Avance DPX 200 at 200.13 MHz (^1H), 50.323 MHz ($^{13}C\{^1H\}$), 81.015 MHz ($^{31}P\{^1H\}$)); chemical shifts (δ) in ppm with respect to $CDCl_3$ (^1H: δ = 7.27; ^{13}C: δ = 77.0), CD_2Cl_2 (^1H: δ = 5.32; ^{13}C: δ = 53.5) and $[D_8]$THF (^1H: δ = 3.58; ^{13}C: δ = 67.7) as internal standards, and chemical shifts (δ) in ppm with respect to 85% H_3PO_4 (^{31}P: δ = 0) as external standard. − IR: Bruker FT-IR IFS-66; CaF_2 cells. − MS: Finnigan MAT 8400; FAB: Nibeol (4-nitrobenzyl alcohol) or TEA (triethanol amine) matrices, respectively; EI: 70 eV. − Elemental analyses: Microanalytical laboratory of the Organisch-Chemisches Institut, Universität Heidelberg: With the equipment used, carbon values tend to be systematically too low in the presence of molybdenum or/and boron. Some of the analytical data given have to be interpreted with this in mind. − Melting points: Gallenkamp MFB-595 010; melting points are not corrected. − The oxetane **6** was prepared according to ref.[8g]. $[(CH_3CN)_3Mo(CO)_3]$ was obtained as described in ref.[14]. All other chemicals were commercially obtained and used without further purification.

Preparation of **1b**: A solution of lithium diphenylphosphide in THF (100 ml) was prepared by deprotonation of diphenylphosphane (8.2 g; 44 mmol) with *n*-butyllithium (17.6 ml; 44 mmol; 2.5 M in *n*-hexane) at 0°C. After stirring for 30 min, a solution of **7** (13.2 g; 40 mmol) in THF (100 ml) was added and the mixture refluxed for 2 h. The solvent was removed, water (100 ml) and diethyl ether (100 ml) were added, and the mixture was neutralized with 37% HCl. The aqueous phase was extracted with diethyl ether (2 × 100 ml) and the combined organic phases were dried and concentrated. The resulting residue was chromatographed on silica gel (20 cm, Ø = 10 cm). The fraction eluted with a mixture of petroleum ether (40/60)/diethyl ether (6:4; TLC control: R_f = 0.48) gave 15.5 g of **1b** as a colorless oil in 75% yield. − $C_{31}H_{33}OPS_2$ (516.7): calcd. C 72.07, H 6.44; found C 71.72, H 6.49. − MS(FAB); *m/z* (%): 517 (18) $[M^+ + 1]$, 425 (100) $[M^+ - C_7H_7]$. − $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = −26.0 (s). − For ^1H- and ^{13}C-NMR data see Tables 1 and 2.

General Procedure for the Preparation of the Molybdenum Complexes **2** *and* **9**: The given tripod ligands (vide infra) were dissolved in CH_2Cl_2 (30 ml), solid $(CH_3CN)_3Mo(CO)_3$ was added (302 mg; 1 mmol) and the mixtures were stirred for 1 h at room temperature. During the reactions the $(CH_3CN)_3Mo(CO)_3$ slowly dissolved and the colors of the solutions turned from light-yellow into yellow-brown. The reaction mixtures were concentrated to 5 ml and slow stepwise addition of 50 ml of petroleum ether (40/60) gave yellow to yellow-brownish, microcrystalline solids. The crude products were washed with petroleum ether (40/60) (2 × 50 ml) and diethyl ether (2 × 50 ml) and dried in vacuo.

Follwing the above procedure using **1b** (517 mg; 1 mmol) as the tripod ligand yielded 490 mg (70%) of **2b**, m.p. 220°C (dec.). With **1a** (640 mg; 1 mmol) as the tripod ligand 740 mg (90%) of **2a** were obtained, m.p. 225°C (dec.). Starting the procedure described above with **8a** (530 mg; 1 mmol) led to 600 mg (84%) of **9a**, m.p. 210°C (dec.). Crystals suitable for an X-ray analysis were obtained for **9a** by slow diffusion of diethyl ether into a solution of 100 mg of the microcystalline product in 5 ml of a mixture of CH_2Cl_2/toluene (1:1) at room temperature after 2 d. 650 mg (90%) **9b**, m.p. 205°C (dec.) was obtained if the starting compound for the above procedure was **8b** (545 mg; 1 mmol).

2a: $C_{44}H_{39}MoO_4P_3$ (820.7): − MS (EI); *m/z* (%): 822 (4) $[M^+]$, 738 (60) $[M^+ - 3\ CO]$, 523 (100) $[M^+ - 3\ CO - C_7H_7]$. − IR (CH_2Cl_2): $\tilde{\nu}$(CO) = 1937 cm^{-1} (s), 1845 (s, br.). − $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = 14.5 (s).

2b: $C_{34}H_{33}MoO_4PS_2$ (696.7): calcd. C 58.45, H 4.76, P 4.44, S 9.16; found C 57.39, H 4.99, P 4.29, S 8.87. − MS (FAB); *m/z* (%): 698 (36) $[M^+]$, 614 (44) $[M^+ - 3\ CO]$, 523 (100) $[M^+ - 3\ CO - C_7H_7]$. − IR (CH_2Cl_2): $\tilde{\nu}$(CO) = 1932 cm^{-1} (s), 1829 (s, br.); 1817 (vs, br.). − $^{31}P\{^1H\}$ NMR ($[D_8]$THF): δ = 20.2 (s).

9a: $C_{35}H_{35}MoO_4PS_2$ (710.7): calcd. C 59.15, H 4.96, P 4.36, S 9.03; found C 57.66, H 5.06, P 4.16, S 8.80. − MS (FAB); *m/z* (%): 712 (14) $[M^+]$, 537 (4) $[M^+ - 3\ CO - C_7H_7]$. − IR (CH_2Cl_2): $\tilde{\nu}$(CO) = 1932 cm^{-1} (s), 1829 (v, br.), 1815 (s, br.). − $^{31}P\{^1H\}$ NMR ($[D_8]$THF): δ = 17.2 (s). − X-ray analysis see ref.[16].

9b: $C_{36}H_{37}MoO_4PS_2$ (724.7): calcd. C 59.66, H 5.15, P 4.27, S 8.85; found C 58.94, H 4.99, P 4.21, S 8.86. − MS (FAB); *m/z* (%): 726 (18) $[M^+]$, 642 (5) $[M^+ - 3\ CO]$, 551 (20) $[M^+ - 3\ CO - C_7H_7]$. − IR (CH_2Cl_2): $\tilde{\nu}$(CO) = 1932 cm^{-1} (s), 1829 (s, br.), 1815 (s, br.). − $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = 16.1 (s).

For ^1H- and ^{13}C-NMR data see Tables 1 and 2.

General Procedure for the Preparation of the Molybdenum Complexes **3** *by Alkylation of* **2a**: Compound **2a** (815 mg; 1 mmol) was dissolved in THF (50 ml) and deprotonated with KO*t*Bu (112 mg; 1 mmol). While stirring the mixture for 1 h a light-yellow precipitate of the potassium salt of **2a** formed. The alkylation reagent as specified below was added. The mixture was stirred for 2 h during which the precipitate formed in the deprotonation step slowly dissolved again. The completion of the reaction was determined by TLC control: CH_2Cl_2/petroleum ether (40/60), 3:1; **2a**: R_f = 0.35 (tailing); **3**: R_f = 0.67−0.74 (no tailing). After removal of the solvent, the resulting residue was chromatographed on silica gel (10 cm, Ø = 4 cm). The fractions eluted with a mixture of CH_2Cl_2/petroleum ether (40/60), 3:1 (TLC control: R_f = 0.67−0.74) gave pale-yellow microcrystalline solids.

Following the above procedure compounds **3** were obtained by using as alkylation reagent CH_3I (284 mg, 2 mmol) to prepare **3a**

(790 mg, 95%), triethyloxonium tetrafluoroborate (380 mg, 2 mmol) to prepare **3b** (510 mg, 60%), benzyl bromide (340 mg, 2 mmol) to prepare **3c** (820 mg, 91%), 4-chloromethylstilbene (460 mg, 2 mmol) to prepare **3d** (960 mg, 95%), and 6-bromo-*n*-hexyl *p*-toluenesulfonate (670 mg, 2 mmol) to prepare **3e** (360 mg, 37%). Crystals suitable for X-ray analyses were obtained for **3a** and for **3b** by slow diffusion of diethyl ether into a solution of 100 mg of the microcystalline products in 5 ml of CH_2Cl_2 at room temperature after 1 d.

3a: $C_{45}H_{41}MoO_4P_3$ (834.7): calcd. C 64.58, H 4.92, P 11.12; found C 63.90, H 5.24, P 10.89. − MS (EI); *m/z* (%): 836 (30) [M^+], 808 (36) [M^+ − CO], 780 (60) [M^+ − 2 CO], 752 (100) [M^+ − 3 CO]. − IR (CH_2Cl_2): $\tilde{\nu}$(CO) = 1932 cm^{-1} (s), 1835 (s, br.). − $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = 16.0 (s). − X-ray analysis see ref.[16].

3b: $C_{46}H_{43}MoO_4P_3$ (848.7): calcd. C 64.93, H 5.10, P 10.93; found C 64.87, H 5.26, P 10.76. − MS (EI); *m/z* (%): 850 (20) [M^+], 821 (30) [$M^+ - CH_2CH_3$], 793 (58) [M^+ − CO − CH_2CH_3], 766 (100) [M^+ − 3 CO]. − IR (CH_2Cl_2): $\tilde{\nu}$(CO) = 1929 cm^{-1} (s), 1833 (s, br.). − $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = 15.9 (s). − X-ray analysis see ref.[16].

3c, $C_{51}H_{45}MoO_4P_3$ (910.7): calcd. C 67.26, H 4.98, P 10.20; found C 66.78, H 5.18, P 10.06. − MS (FAB); *m/z* (%): 912 (46) [M^+], 884 (30) [M^+ − CO], 856 (34) [M^+ − 2 CO], 828 (35) [M^+ − 3 CO]. − IR (CH_2Cl_2): $\tilde{\nu}$(CO) = 1929 cm^{-1} (s), 1829 (s, br.). − $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = 15.8 (s).

3d: $C_{59}H_{51}MoO_4P_3$ (1012.9): calcd. C 69.96, H 5.54; found C 69.40, H 5.54. − MS (FAB); *m/z* (%): 1014 (80) [M^+], 986 (36) [M^+ − CO], 958 (64) [M^+ − 2 CO], 930 (54) [M^+ − 3 CO]. − IR (CH_2Cl_2): $\tilde{\nu}$(CO) = 1937 cm^{-1} (s), 1844 (s, br.). − $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = 15.7 (s).

3e: $C_{50}H_{50}BrMoO_4P_3$ (983.7): calcd. C 61.05, H 5.12; found C 62.18, H 5.51. − MS (FAB); *m/z* (%): 984 (80) [M^+], 956 (50) [M^+ − CO], 928 (68) [M^+ − 2 CO], 900 (100) [M^+ − 3 CO]. − IR (CH_2Cl_2): $\tilde{\nu}$(CO) = 1937 cm^{-1} (s), 1844 (s, br.).

For ^1H- and ^{13}C-NMR data see Tables 3 and 4.

Preparation of **4**: NEt_3 (600 mg, 6 mmol) and methanesulfonyl chloride (570 mg, 5 mmol) were added to a solution of **2a** (819 mg, 1 mmol) in CH_2Cl_2 (50 ml). After stirring the light-yellow mixture for 30 min, water was added (50 ml). After separation of the phases, the aqueous phase was extracted with CH_2Cl_2 (2 × 50 ml) and the residue of the dried ($MgSO_4$) and concentrated organic phases was chromatographed on silica gel (10 cm, Ø = 4 cm). Concentrating the fractions eluted with a mixture of CH_2Cl_2/petroleum ether (40/60) (3:1; TLC control: R_f = 0.50) gave **4** as a pale-yellow microcrystalline product (810 mg, 90%). − $C_{45}H_{41}BrMoO_6P_3S$ (898.7): calcd. C 60.14, H 4.60; found C 58.71, H 4.73. − MS (EI); *m/z* (%): 899 (20) [M^+ − 1], 872 (26) [M^+ − CO], 844 (60) [M^+ − 2 CO], 816 (100) [M^+ − 3 CO]. − IR (CH_2Cl_2): $\tilde{\nu}$(CO) = 1927 cm^{-1} (s), 1844 (s), 1826 (s). − $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = 14.0 (s). − For ^1H- and ^{13}C-NMR data see Tables 3 and 4.

Preparation of **3b** *Starting from* **4**: To a solution of lithium ethoxide in THF (50 ml), prepared by deprotonation of ethanol (138 mg, 3 mmol) with 1.2 ml of *n*-butyllithium (2.5 M in *n*-hexane) at 0°C, **4** (450 mg, 0.5 mmol) was added. After stirring the yellow mixture for 4 h at 50°C, the solvent was removed and the residue chromatographed on silica gel (10 cm, Ø = 4 cm). Concentrating the fractions eluted with a mixture of CH_2Cl_2/petroleum ether (40/60) (3:1; TLC control: R_f = 0.73) gave **3b** as a pale-yellow microcrystalline product (148 mg, 35%). − Analytical data: vide supra.

Liberating **5b** *from* **3b**: Compound **3b** (829 mg, 1 mmol) was dissolved in CH_2Cl_2 (200 ml), pyridine *N*-oxide was added (1.90 g, 20 mmol) and the reaction mixture was irradiated in a "Duran 50" ("Pyrex") apparatus with a mercury lamp (TQ 150 Hanau) at −5°C for 1 h. After removal of the solvent the brownish residue was chromatographed on silica gel. The fractions eluted with a mixture of petroleum ether (40/60)/diethyl ether (9:1; TCL control: R_f = 0.40) gave 401 mg (60%) of **5b** as a colorless, viscous oil. − Analytical data: vide supra.

Preparation of **7**: Compound **6** (13.0 g; 50 mmol) was dissolved in THF (100 ml) and the solution cooled to 0°C. A solution of lithium benzylthiolate (100 mmol in 300 ml of THF), obtained by deprotonation of 12.4 g (100 mmol) of benzylthiole with 40 ml of *n*-butyllithium (2.5 M in *n*-hexane) at 0°C, was slowly added and the mixture stirred for 4 h at room temperature to give a voluminous white precipitate of lithium mesylate and lithium bromide. The solvent was removed in vacuo, water (200 ml) and diethyl ether (200 ml) were added and the mixture was neutralized with 37% HCl. The aqueous phase was extracted with diethyl ether (2 × 150 ml) and the combined organic phases were dried and concentrated. Destillation of the residue (b.p. 205−210°C/1 mbar) yielded 14.9 g (90%) of **7** as a viscous, colorless oil. − $C_{19}H_{22}OS_2$ (330.5): calcd. C 69.07, H 6.72, S 19.37; found C 68.81, H 6.50, S 18.68. − MS (FAB); *m/z* (%): 331 (72) [M^+ + 1], 239 (100) [$M^+ - C_7H_7$]. − For ^1H- and ^{13}C-NMR data see Tables 1 and 2.

Preparation of **8a** *and* **8b**: For the synthesis of **8a** a solution of **1b** (5.17 g; 10 mmol) in THF (100 ml) was deprotonated with KO*t*Bu (1.12 g; 10 mmol). The mixture was cooled to −15°C, then CH_3I (1,42 g; 10 mmol) was slowly added (temperature was held below −10°C) and a white precipitate of potassium iodide instantaneously formed. The progress of the reaction was determined by TLC [petroleum ether (40/60)/diethyl ether, 6:4; **1b**: R_f = 0.48; **8a**: R_f = 0.80].

To synthesize **8b** a slightly modified procedure was applied: A solution of **1b** (2.58 g, 5 mmol) in 50 ml of THF was deprotonated with KO*t*Bu (560 mg, 5 mmol). The mixture was cooled to 0°C, iodethane (780 mg, 5 mmol) was slowly added and a white precipitate of potassium iodide slowly formed. After 10 min, the progress of the reaction was determined by TLC control [petroleum ether (40/60)/diethyl ether, 6:4; **1b**: R_f = 0.48; **8b**: R_f = 0.81]. After the first "deprotonation-alkylation" sequence, the reaction was incomplete. For obtaining higher yields it was necessary to repeat this sequence five times. The isolation procedures for **8a** and **8b** were similar:

After completion of the reaction, water was added (1 ml) and the mixture was allowed to warm to 20°C. The solvent was removed, water (100 ml) and diethyl ether (100 ml) were added und the mixture was neutralized with 37% HCl. The aqueous phase was extracted with diethyl ether (2 × 100 ml) and the combined organic phases were dried and concentrated. The resulting residue was chromatographed on silica gel (15 cm, Ø = 6 cm).

8a: The fraction eluted with a mixture of petroleum ether (40/60)/diethyl ether (6:4; TLC control: R_f = 0.8) gave 3.45 g of **8a** as a colorless oil in 65% yield. − $C_{32}H_{35}OPS_2$ (530.7): calcd. C 72.42, H 6.65, P 5.84; found C 71.95, H 7.03, P 5.46. − MS (FAB); *m/z* (%): 531 (34) [M^+ + 1], 439 (100) [$M^+ - C_7H_7$]. − $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = −26.4 (s).

8b: The fraction eluted with a mixture of petroleum ether (40/60)/diethyl ether (9:1; TLC control: R_f = 0.4) gave 1.91 g of **8b** as a colorless oil in a 70% yield. − $C_{33}H_{37}OPS_2$ (544.8): calcd. C 72.75, H 6.85, P 5.59, S 11.77; found C 72.77, H 7.13, P 5.58, S 11.75. − MS (FAB); *m/z* (%): 545 (18) [M^+ + 1], 453 (100) [$M^+ - C_7H_7$]. − $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = −26.8 (s). −For ^1H- and ^{13}C-NMR data see Tables 1 and 2.

General Procedure for the Preparation of Ethers **5** *by Direct Alkylation of* **1a**: Compound **1b** (640 mg; 1 mmol) was dissolved in THF (20 ml) and cooled to −5°C by means of an ice/salt bath. 1.5 equivalents of KO*t*Bu were added to the colorless solution, which immediately turned yellow. The mixture was stirred for 5 min and the given alkyl iodides or toluenesulfonic esters (vide infra) were added. In case of the alkyl iodides the mixture immediately became turbid white, in case of the toluenesulfonic esters the mixture was slowly brought to room temperature and the mixture became turbid yellow-brown. The completion of the reaction was determined by TLC control. Water (0.5 ml) was added and the solvent was removed in vacuo. The residue was dissolved in dichloromethane and filtered through silica gel. The solvent was removed and the residue was chromatographed on silica gel (15−25 cm, ∅ = 4 cm).

Following the above procedure compounds **5** were obtained by using as alkylation reagents iodomethane (982 mg, 6.91 mmol) to prepare **5a** (470 mg, 72%), iodoethane (200 mg, 1.33 mmol) to prepare **5b** (461 mg, 69%), *n*-decyl *p*-toluenesulfonate (667 mg, 2.14 mmol) to prepare **5c** (253 mg, 33%), *n*-docosanyl *p*-toluenesulfonate (510 mg, 1.06 mmol) to prepare **5d** (425 mg, 44%), undecenyl *p*-toluenesulfonate (475 mg, 1.46 mmol) to prepare **5e** (300 mg, 38%), 6-chloro-*n*-hexyl *p*-toluenesulfonate (347 mg, 1.2 mmol) to prepare **5f** (394 mg, 52%), triethyleneglycol monomethyl ether *p*-toluenesulfonic ester (400 mg, 1.25 mmol) to prepare **5g** (415 mg, 53%).

5a: $C_{42}H_{41}OP_3$ (654.1): calcd. C 77.04, H 6.32; found C 76.79, H 6.37. − MS (EI); *m/z* (%): 654 (11) [M^+], 577 (100) [M^+ − Ph], 469 (16) [M^+ − PPh_2]. − $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = −28.4 (s).

5f: $C_{47}H_{50}ClOP_3$ (759.3): calcd. C 74.35, H 6.58; found C 73.77, H 7.10. − MS (EI); *m/z* (%): 758 (10) [M^+], 681 (100) [M^+ − PPh_2], 573 (10) [M^+ − PPh_2]. − $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = −25.1 (s).

5g: $C_{48}H_{53}OP_3$ (786.9): calcd. C 73.27, H 6.79; found C 73.10, H 6.83. − MS(EI); *m/z* (%): 786 (9) [M^+], 709 (100) [M^+ − PPh_2], 601 (11) [M^+ − PPh_2]. − $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = −28.6 (s).

For ^{1}H- and ^{13}C-NMR data see Tables 3 and 4.

Preparation of **5i**: A solution of **5f** (759 mg, 1 mmol) in DMSO (3 ml) was slowly added to a stirred mixture of 1 g of KCN in 5 ml of DMSO at 90°C. After the addition, the mixture was heated to 140°C for 5 h. The solvent was removed and the residue was chromatographed on silica gel. The fractions eluted by a mixture of petroleum ether (40/60)/diethyl ether (3:1) at R_f = 0.30 were collected to give 300 mg (40%) of **5i** as a colorless oil after evaporation of the solvent. − $C_{48}H_{50}NOP_3$ (749.8): calcd. C 76.89, H 6.72, N 1.87; found C 76.40, H 6.75, N 1.61. − MS (FAB); *m/z* (%): 750 (33) [M^+], 672 (100) [M^+ − PPh_2], 564 (16) [M^+ − PPh_2]. − $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = −28.3 (s). − For ^{1}H- and ^{13}C-NMR data see Tables 3 and 4.

Preparation of **5j**: A solution of **5i** (430 mg , 0.6 mmol) in a 1:1 mixture of ethanol/water (25 ml) and KOH (580 mg, 10.4 mmol) was heated under reflux for 4 h. After cooling, the reaction mixture was acidified with 37% hydrochloric acid. The water phase was extracted with dichloromethane (3 ×), the organic phase was dried with $MgSO_4$, the solvent was removed in vacuo and the residue was chromatographed on silica gel. The fractions eluted with diethyl ether at R_f = 0.40 were collected to give 220 mg (48%) of **5j** as a colorless oil after evaporation of the solvent. − $C_{48}H_{51}O_3P_3$ (768.8): calcd. C 74.99, H 6.69; found C 74.42, H 6.82. − MS (FAB); *m/z* (%): 768 (35) [M^+], 691 (100) [M^+ − PPh_2], 582 (21) [M^+ − PPh_2]. − $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = −28.2 (s). − IR (Nujol): $\tilde{\nu}$(COO) = 1708 cm^{-1} (m). − For ^{1}H- and ^{13}C-NMR data see Tables 3 and 4.

Preparation of **5k**: A solution of **5j** (50 mg, 0.07 mmol) in THF (5 ml) was added to a stirred suspension of $LiAlH_4$ (30 mg, 0.8 mmol) in THF (5 ml). The mixture was heated under reflux for 2 h and after cooling to 20°C hydrolized with water. The products of hydrolysis were washed with dichloromethane, the combined organic phases were dried ($MgSO_4$) and the solvents were removed in vacuo. The residue, a colorless oil, was investigated by mass spectrometry and NMR spectroscopy. − $C_{48}H_{53}O_2P_3$ (755). − MS (FAB); *m/z* (%): 755 (27) [M^+], 678 (100) [M^+ − PPh_2], 571 (18) [M^+ − PPh_2]. − $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = −28.1 (s). − For ^{1}H-and ^{13}C-NMR data see Tables 3 and 4.

Preparation of **10**: Compound **5a** (654 mg, 1 mmol) was dissolved in acetonitrile (20 ml) and 476 mg (1 mmol) of $[Fe(CH_3CN)_6](BF_4)_2$, dissolved in 10 ml of acetonitrile, was added. The mixture immediately turned red and was stirred at room temperature for 1 h. The solvent was removed and the residue was washed with diethyl ether (3 ×). After drying in vacuo, 930 mg (92%) of **10** was obtained as a red powder. Crystals suitable for X-ray analysis were obtained by diffusion of diethyl ether into a solution of **10** in CH_2Cl_2 within 1 d at room temperature. − $C_{48}H_{50}B_2F_8FeN_3OP_3$ (1007.4): calcd. Keywords: Tripod ligands / Molybdenum / Mixed donor set ligands / Thiole ligands / Thiolate ligands

Tripod ligands $RCH_2C(CH_2PPh_2)(CH_2X)(CH_2Y)$ (**1**) with X, Y = SAlkyl, SBzl selectively undergo reductive cleavage of the SBzl function with Li/NH_3/THF at –40 °C to produce $RCH_2C(CH_2PPh_2)(CH_2X)(CH_2Y)$ (**2**) (X, Y = SAlkyl, SH). In these mixed donor set ligands the SH functions are the least coordinative ones such that $[\eta^2$-$\{CH_3C(CH_2PPh_2)(CH_2SEt)$-$(CH_2SH)\}(CO)_4Mo]$ (**5**) is a stable compound with an uncoordinated SH function at the dangling arm of the ligand. If the SH functions of a potential tripod ligand are deprotonated the resulting thiolate functions are found to strongly coordinate in compounds such as $[\eta^3$-$\{CH_3C(CH_2PPh_2)_2(CH_2S)\}(CO)_3Mo]^-$ which are obtained as their lithium and sodium salts **6**. These highly reactive species may be stabilized by encapsulating their alkali counter ions in cryptands and the corresponding salts with [2,1,1]cryptand (**7a**) and [2,2,2]cryptand (**7b**) are far easier to handle than the cryptand-free progeners **6**. Alkylation of the coordinatively bound thiolate function in **6** leads to the corresponding thioether derivatives $[\eta^3$-$\{CH_3C(CH_2PPh_2)_2$-$(CH_2SR)\}(CO)_3Mo]$ (**8**).

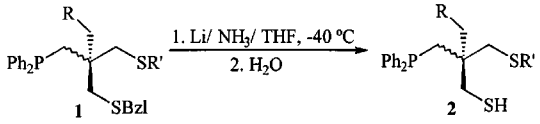
Introduction

The coordination chemistry of tripod ligands $CH_3C(CH_2PPh_2)_3$ developed by L. Sacconi and his school has quite some unconventional features which show that the η^3 coordination of a neopentane-based tripod ligand is able to induce a reactive potential at the metal center which is otherwise not accessible[1][2]. The potential of this type of ligand should be greatly enhanced by an appropriate variation of the donor functions and in fact there is a promising chemistry with ligands of type $RC(CH_2X)_3$ containing donor functions X other than PPh_2[2][3][4]. A still broader scope of this chemistry could be envisaged if it were possible to synthesize ligands $CH_3C(CH_2X)(CH_2Y)(CH_2Z)$ with up to three different phosphorus donor groups. The difficulties characterizing the neopentane chemistry, which is at the basis of such syntheses, had only recently been overcome and neopentane-based tripod ligands with up to three different phosphorus donors have been described[5][6][7][8][9][10][11][12][13] with even enantioselective syntheses of such ligands having been reported[10]. The introduction of sulfur and nitrogen donors instead of phosphorus donor functions in this type of tripod ligand has by now not yet found a general solution. Even though different strategies for introducing these types of donor functions have been worked out for special cases[14][15][16][17][18]. It is shown in this paper how tripod ligands containing one or more thioether or thiolate donor functions may be obtained and how these molecules behave as ligands in their $[(CO)_3Mo]$ and $[(CO)_4Mo]$ derivatives.

Results and Discussion

Preparation of the Ligands

There are two main pathways to obtain tripod ligands containing thiole functions, one of them being the nucleophilic cleavage of thietanes by phosphides[15][16] and the other one relying upon the reductive cleavage of SBzl groups by lithium[15].



1	R	R′	**2**	R	R′
1a	H	Et	**2a**	H	Et
1b	H	*i*Pr	**2b**	H	*i*Pr
1c	H	Bzl	**2c**	H	H
1d	CH_3O	Bzl	**2d**	CH_3O	H

This second method was used to transform compounds **1**[18][19], containing at least one SBzl group into tripod ligands containing thiole functions (**2**).

Starting from compounds **1**[18][19] applying the "lithium reduction step"[15] to **1**, followed by hydrolytic workup gives the thiole tripod ligands **2**. **2a** and **2b**, containing one thiole function, are obtainted as colorless oils while **2c** and **2d**, bearing two thiole functions, are colorless microcrystalline solids. Their identity is proven by NMR and mass spectra

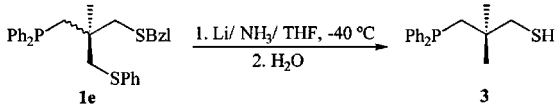
as well as by elemental analyses (Tables 1 and 2, Experimental Section). Judging from the variety of groups present in the starting compounds **1** the scope and selectivity of the applied method − i.e. generating thiole functions in tripod ligands by the reductive cleavage of SBzl functions − are quite broad. A limitation is, however, met when an SPh and an SBzl function are both present in **1**.



1e **3**

In this case the CH_2SPh group is cleaved at the CH_2S bond as is shown by the transformation of **1e** to **3** (Experimental Section, Tables 1 and 2).

Coordination Chemistry

The coordination chemistry of tripod ligands containing thiole functions has not been worked out in much detail. There are some compounds derived from such ligands with manganese[14] or nickel[15] as the coordinated metals; in each of these cases, however, the thiole function had been transformed into a thiolate functionality during the process of coordination. The coordination of RSH functions themselves is not too common even if they are not part of a tripod ligand[20]. Although even the coordination of H_2S as a two-electron donor has been observed[21] the reaction of RSH with coordinatively unsaturated ligand-metal entities appears to be hampered with difficulties. It has been found that the reaction of [$Cp(CO)_2MnTHF$], which in itself is a precursor of the 16-electron [$Cp(CO)_2Mn$] fragment, with RSH leads to the formation of the radical compunds [$Cp(CO)_2MnSR$] with a concommitant hydrogen abstraction of the thiole function[22]. It is not astonishing therefore that the reaction of $CH_3C(CH_2PPh_2)_2CH_2SH$ (**4**)[15] with [$(MeCN)_3(CO)_3Mo$] in CH_2Cl_2 does not result in isolabable and well-charcterizable tripod compounds of the hypothetical formula [η^3-{$CH_3C(CH_2PPh_2)_2CH_2S$}$(CO)_3Mo$]. Instead a yellow to brownish solution of what is obviously a mixture of compounds is obtained. Trying to isolate a definite compound from this mixture by transforming any SH functions into thiolate groups by NaH or *n*BuLi leads to a brownish product from which, however, no definite compounds could be isolated even after addition of crown ethers or cryptands as potential precipitating agents (see, however, the preparation of **7**, below).The yellow to brownish solutions which result from the deprotonation step (see above) are highly sensitive to air. They immediately change color at the first contact with a trace of oxygen to give deep blue solutions.

While the deep color reminds of the radical compounds [$Cp(CO)_2MnSR$][22] no definite product could be isolated either and the blue powders which remain after evaporation

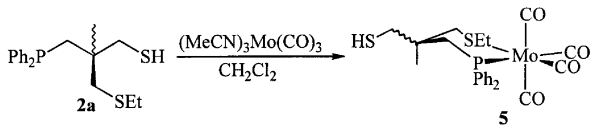
[x] **2** and **3** in $CDCl_3$, **5** and **8** in CD_2Cl_2, **6** in [D_8]THF, **7** in CD_3CN – [a] $^1J_{CP}$ – [b] $^3J_{CP}$ – [c] $^2J_{CP}$ – [d] Due to worse solubility no ^{13}CO resonances observed. – [e] $^2J_{CPtrans}$. – [f] $^2J_{CPcis}$. – [g] CH_2O. – [h] CH_2N.

of the solvent give only very weak EPR signals and are not highly paramagnetic as would be expected for radical species when analyzed on a magnetic balance. Chromatography of the blue solutions on silica gel is of no help since the blue phase rather rapidly desintegrates during the process of elution. The nature of the compounds and intermediates obtained from **4** by the above procedure does remain unknown (see, however, the transformation of **4** to **7**, below).

In contrast to the reaction of **4** with $[(MeCN)_3(CO)_3Mo]$ the ligand **2a** reacts with the same reagent to produce the $(CO)_4Mo$ derivative **5** in fair yields.



The formation of $(CO)_4Mo$ derivatives from $[(MeCN)_3(CO)_3Mo]$ is not an uncommon observation[17]. Even though no single crystals suitable for an X-ray analysis could be obtained from **5** its constitution as given is clear from spectroscopic data.

The $\tilde{\nu}_{CO}$ spectrum is characteristic for a $[(CO)_4Mo]$ entity[23]. The coordination of the phosphorus function is evident from its ^{31}P-NMR resonance which is found at δ = 20.0 in constrast to the chemical shift of the free ligand (δ = −26.9). The coordination of the SEt group is evidenced by a $^3J_{CP}$ coupling of 5.6 Hz to the α-carbon atom of the ethyl group (Table 2). There is no such coupling to the proton of the SH group of the dangling arm with the ^{1}H-NMR signal

Table 3. Infrared data of **5–8**

	Solvent	$\tilde{\nu}_{CO}$ [cm^{-1}]		
5	CH_2Cl_2	2020 (s)	1901 (s, br.)	1870 (s)
6a	THF	1911 (s)	1816 (s)	1787 (s)

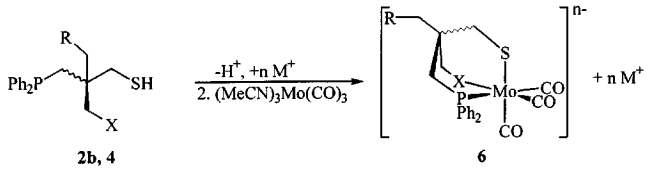
8b	CH_2Cl_2	1929 (s)	1837 (s)	1811 (s)
8c	CH_2Cl_2	1934 (s)	1844 (s, br.)	

referring to this group being a clear-cut triplet as expected (Table 1). The CH_2 protons of the dangling arm are diastereotopic which, together with a coupling to the SH proton, results in a pattern of two doublets of doublets. ^{31}P decoupling substanciates the assignments. With correct mass spectra and elemental analyses the identity of **5** as shown is beyond doubt therefore.

The observation that in **5** the thiole function cannot compete with the donors present in the reaction solution suggests a different strategy: if the thiole function of the ligand is deprotonated the thiolate function thus formed should have better ligand capabilities such that tripodal coordination of the anionic ligands might ensue. If salts of these derivatives could be isolated protonation of the coordinated thiolate functions might well lead to coordinated SH functions in tripodal metal compounds.



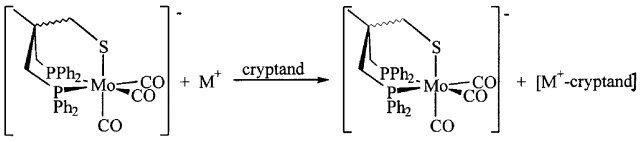
2b, 4 6

	R	X	6	R	X	M	*n*
4	H	PPh_2	**6a**	H	PPh_2	Li	1
2d	CH_3O	SH	**6b**	H	PPh_2	Na	1
			6c	CH_3O	S	Na	2

If the ligand **4** is deprotonated by *n*BuLi in THF and the resulting solution is treated with $[(MeCN)_3(CO)_3Mo]$ the lithium salt **6a** results, in which all three donor functions of the tripod ligand are engaged in coordination. **6a** is isolated from the reaction solution as its adduct with two molecules THF per unit by evaporating the solvent and washing the brown oily residue with petroleum ether in an ultrasonic bath. The product as isolated is very sensitive to oxygen and moisture so that its yellow solutions turn first green and finally blue under atmospheric conditions. Under unaerobic conditions the solutions are stable enough to warrant detailed analyses by NMR. The ^{1}H-, ^{13}C-, and ^{31}P-NMR spectra are in accord with the formula as given (Tables 1 and 2). The coordination of both phosphorus centers is apparent from the appearance of one single signal at $\delta = 21.6$. The coordination of the sulfide function is not definitely established by $^3J_{CP}$ coupling constants between the phosphorus nucleus and the methylene carbon atom to which the sulfur atom is bound, since $^3J_{CP}$ coupling through the ligand framework gives rise to values of similar magnitude[15]. From the three CH_2 groups of the chelate cage the one linked to the sulfur atom has two chemically equivalent hydrogen atoms and a singlet is observed for this group in the ^{1}H-NMR spectrum. The hydrogen atoms at the CH_2 groups linked to the phosphorus atoms are diastereotopic and give rise to two doublets of doublets (Table 1). The symmetry of **6a** is thus clearly reflected by its ^{1}H-NMR spectrum. The tridentate binding mode of the ligand on the other hand is not a necessary prerequisit to explain the spectra. Since **6a** contains two THF solvate molecules per formula unit (the ratio of THF/**6** is determined by integration of the $[H_8]$THF signals apparent for solutions of the compounds in isotopically pure $[D_8]$THF) it might be argued that the ligand is only acting in the bidentate fashion with one THF molecule occupying the vacant coordination site at the metal. Even the observation of a $\tilde{\nu}_{CO}$ IR pattern which corresponds to a $[(CO)_3Mo]$ entity (Table 3) does not differentiate between the two possibilities. An indication that the constitution of **6** as shown might be correct may be found in the values of the chemical shifts of the carbonyl carbon atoms of **6**. The two different classes of carbonyl groups (*trans* to P, *trans* to S) have their resonances in close vicinity which is well expected if the sulfur and phosphorus atoms act as the *trans* ligand but would not be easily explained if THF and P were in the corresponding positions. The pattern of the $^2J_{CP}$ coupling constants (Table 2) is in accord with an overall octahedral geometry of the compound. One argument in favor of the η^3 coordination of the ligand in **6a** comes from a comparison of the ^{13}C-NMR resonances observed for compounds which definitely contain the ligands in η^2 coordination (e.g. **5**) and a series of examples in ref.[18] where it was found that the relevant resonances of **6a** occur at different shift values which are much closer to the values characterictic for compounds with η^3 coordination (**8**) and a series of compounds in ref.[18]. Yet a stronger argument comes from the observation that the solvent-free salt obtained from **6a** by the addition of [2,1,1]cryptand (**7a**, see below) have their NMR resonances at approximately the same values as observed for **6a** (Tables 1 and 2).

Observations very similar to the results reported for **6a** are made for its sodium analogue **6b** which results when NaH is used as the deprotonating agent in the transformation of **4** to **6** (Tables 1−3). With **2d** as the starting material **6c** is formed under these conditions. **6b** as well as **6c**, when isolated as yellow powders following the workup procedure described for the synthesis of **6a**, are both found to contain two THF molecules per formula unit. The chemical shifts observed for the constitution of the compounds in the various NMR spectra are close to the ones reported for **6a** (Tables 1−3). In contrast to the situation in **6a**, instead of the protons at the CH_2S group now the protons at the CH_2P entity are chemically equivalent with the remaining two CH_2S groups showing the phenomenon of diastereotopicity in the case of **6c**. This symmetry property is clearly evident from the ^{1}H-NMR spectrum (Table 1).

Compounds **6** are rather difficult to handle due to their high sensitivity to oxygen and moisture as well as to the fact that the only solvent in which comparatively stable solutions are formed is THF while solvents with higher proton activity and/or oxidation power (e.g. CH_3CN, CH_3NO_2) lead to desintegration of the compounds.



6 7

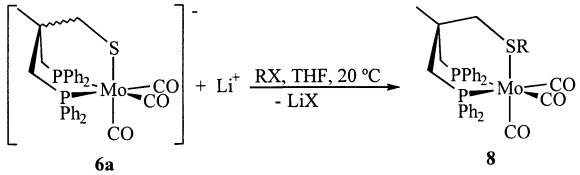
6	M	**7**	M	Cryptand
6a	Li	**7a**	Li	[2,1,1]cryptand
6b	Na	**7b**	Na	[2,2,2]cryptand

In the hope to increase the stability of the salt-like compounds cation scavengers were used to transform the lithium salt **6a** into its lithium [2,1,1]cryptand derivative **7a** and the sodium salt **6b** into its sodium [2,2,2]cryptand analogue **7b**. When the cryptand ligands are added to THF solutions of **6** the salts **7** form and precipitate from the solutions in the form of light-yellow microcrystalline powders. With respect to sensitivity and solubility compounds **7** differ

strongly from compounds **6**. Solutions of **7** in contrast to solutions of **6** do not undergo a rapid color change when exposed to the atmosphere even though a slow color change from light-yellow to light-green is observed on prolonged exposure to air. In constrast to compounds **6** which dissolves in THF, compounds **7** are only very sparingly soluble in this solvent. They are soluble, however, in CH_3CN or CH_3NO_2 without desintegration. The salt of type **7** formed from **6c** by the addition of [2,2,2]cryptand does not dissolve, neither in THF, nor in CH_3CN or CH_3NO_2, so that it could not be characterized. The identity of the anions present in **7** is clear from the negative-ion FAB mass spectra which show the peak for the molecule anion at $m/z = 653$ for both **7a** and **7b**. The close similarity of the anionic parts of **6** and **7** is evident from the close similarity of the relevant NMR data (Tables 1, 2). Shifts as well as coupling constants show only minor differences between the compounds **6** and **7**. Due to the low solubility of compounds **7** and due to an overlap of some of the signals arising from the cryptand ligands a detailed comparison is not possible for all of the signals (Tables 1, 2). The $\tilde{\nu}_{CO}$ IR spectra of compounds **6** and **7** are rather similar as well (Table 3). Taken together the similarity of all the spectral data obtained for **6** and **7** corroborates the structural assignments as elaborated for **6**. Comparing the spectral data obtained for **6a** and **6b** slight differences in chemical shifts as well as in the $\tilde{\nu}_{CO}$ IR data are apparent, the most propable explanation for this observation being that the counter ions are in some form associated with the complexes. It is astonishing to note that the ^{1}H-NMR data of **7a** and **7b** (Tables 1, 2) as well as the IR data (Table 3) of these compounds are slightly different as well. It must be assumed that the compounds are at least in part dissolved as ion pairs such that different properties of the cations are reflected by these data. The identity of the anionic part of **6** and **7** is as well documented by their cyclovoltammogrammes. Both the compounds **6a** and **7a** show a quasi-reversible oxidation at −410 mV vs. S.C.E. The slight difference between the values observed for **7a** and **7b**, if not due to experimental uncertainty, might again indicate that ion pairs are still solvated even with the alkali cation embedded in cryptands. The ratio of the anodic current to the cationic current is around 1.7 and the slope of the anodic current versus the scan rate (50−800 mV) is lower than the one predicted by the square root law[24] for a reversible process. When comparing **7a** and **7b** it is found that the quasi-reversible oxidation occurs at almost the same potential for both compounds (**7b**: −420 mV vs. S.C.E.).

To further corroborate the identity of **6** compound **6a** was treated with alkylating reagents which, based on the constitution assigned to **6**, should lead to the corresponding thioether-functionalized species. In fact **6a** reacts with a variety of electrophilic reagents to produce compounds **8**.

Mass spectra of **8** (FAB or EI) show the molecular ion peak in each case and elemental analyses correspond to the assigned constitution. The NMR data (Tables 1, 2) are as well in accord with their constitution; specifically, they show that the tripod ligand coordinates in a tridentate way.



6a **8**

8	R	X
8a	Me	I
8b	Et	$Et_2O{\cdot}BF_4$
8c	Bzl	Br

This is evidenced by $^3J_{CP}$ coupling constants of around 6 Hz between the coordinated phosphorus atom and the α-carbon atom bonded to the coordinated sulfur center. The coupling constants should be zero if the SR entities would not be coordinated. In the case of **8c** the spectral data obtained for the free ligand[14] show that no P-$C_{\alpha S}$ coupling is observed if not both phosphorus and sulfur atom are coordinated to the same metal center. The presence or absence of diastereotopicity of the protons at the CH_2 groups of the chelate cage (Table 1) does again reflect the symmetry of the compounds as already discussed for **6**. The local symmetry of the $[(CO)_3Mo]$ chromophore reflects the constitutional C_s symmetry which is characteristic for all the compounds **6−8** so that instead of a two-band pattern (A_1, E) as expected for C_{3v} symmetry 3 $\tilde{\nu}_{CO}$ IR bands are observed in general. Only for **8c** the splitting of the E band is not large enough to make the two components derived from it decernible (Table 3).

A comparison of the IR data obtained for **6−8** is rewarding: the anionic compounds **6** and **7** show their absorptions at distinctly lower energy than the neutral compounds **8**. Within each class of compounds the differences are only minor as expected. The dianionic species **6c** has its absorptions at by far the lowest energies. The observed trends are in accord with the well-established rule that the higher the charge density at the metal center the lower the frequencies of the corresponding $\tilde{\nu}_{CO}$ absorptions. With respect to this rule trends observed for compounds **6−8** are in full agreement with their structural assignment derived by other methods as discussed before.

With the identity of **8** established beyond doubt it is clear that the SR group is coordinated in each case. For the type of ligand as present in **6a** and **6b** it had been shown for the neutral complex $[\eta^3\text{-}\{CH_3C(CH_2PPh_2)_2CH_2S\}(CO)_3Mn]$ that alkylation at the sulfur atom may well lead to decoordination with the vacant coordination site being occupied by the nucleofugic group of the alkylation reagent used (e.g. I^- with MeI as the reagent)[16]. This type of reaction is not observed when **6a** is treated with alkylation reagents independent of whether the nucleofugic group is I^- (MeI), Et_2O ($Et_3O{\cdot}BF_4$) or Br^- (BzlBr) even though the neutral manganese compound and the anionic molybdenum compound are isoelectronic ($[(CO)_3Mn]^+$ to $[(CO)_3Mo]$). The coordination of the nucleofugic group of the anionic part of the

electrophile to the metal center can well compete with the coordination of the neutral SR function in the presence of the cationic metal center in $[\eta^3\text{-}\{CH_3C(CH_2PPh_2)_2CH_2SR\}(CO)_3Mn]^+$ while with the neutral compounds $[\eta^3\text{-}\{CH_3C(CH_2PPh_2)_2CH_2SR\}(CO)_3Mo]$ (**8**) the anionic nucleophile is not competitive.

Conclusion

Taken together the observations described in this paper allow for the following statements:

– Neopentane-based tripod ligands $CH_3C(CH_2X)(CH_2Y)(CH_2Z)$ (X, Y, Z = PR_2, SR, S^-) are accessible by a convergent set of reactions. The reductive cleavage of SBzl functions in tripod ligands (some of the groups X, Y, Z = SBzl)[15][17][18][19] by lithium under spezialized conditions has a broad scope of application in this context.

– Tripod ligands containing thiolate functions (some of the groups X, Y, Z = S^-) form anionic $[(CO)_3Mo]$ derivatives which contain the ligands in a tridentate binding mode. The coordinatively bound thiolate functions are transformed into coordinated thioether functions upon reaction of the anions with alkylating reagents.

The financial support by the *Deutsche Forschungsgemeinschaft* (SFB 247) and the *Fonds der Chemischen Industrie* is gratefully acknowledged. We are grateful to *D. Günauer* (cyclovoltammetry), to *R. Rupp* (ESR) and to *P. Schober* (magnetic balance) for various help. One of us is indepted to the Graduierten Kolleg *Selektivität und Reaktivität in der organischen Synthese* for a fellowship.

Experimental Section

General: All manipulations are carried out under argon by means of standard Schlenk techniques. All solvents are dried by standard methods and destilled under argon. Water was degassed by five "pump-thaw" cycles and stored under argon. The $CDCl_3$, CD_2Cl_2 and $[D_8]$THF used for the NMR spectroscopic measurements were degassed by three successive "freeze-pump-thaw" cycles and dried over 4-Å molecular sieves. The silica gel (Kieselgel z.A. 0.06–0.2 mm, J. T. Baker Chemicals B.V.) used for chromatography was degassed at 1 mbar for 24 h and saturated with argon. – NMR: Bruker Avance DPX 200 at 200.13 MHz (^{1}H), 50.323 MHz ($^{13}C\{^1H\}$), 81.015 MHz ($^{31}P\{^1H\}$), 77.779 MHz (^{7}Li); chemical shifts (δ) in ppm with respect to $CDCl_3$ (^{1}H: δ = 7.27; ^{13}C: δ = 77.0), CD_2Cl_2 (^{1}H: δ = 5.32; ^{13}C: δ = 53.5) and $[D_8]$THF (^{1}H: δ = 3.58; ^{13}C: δ = 67.7) as internal standards, and chemical shifts (δ) in ppm with respect to 85% H_3PO_4 (^{31}P: δ = 0) and 1 M LiCl in D_2O (^{7}Li: δ = 0) as external standards. – IR: Bruker FT-IR IFS-66; CaF_2 cells. – MS: Finnigan MAT 8400; FAB: Nibeol (4-nitrobenzyl alcohol) or TEA (triethanol amine) matrices, respectively; EI: 70 eV. Mass spectra are referenced relative to the most abundant Mo isotop ($^{98}_{42}$Mo). Elemental analyses: Microanalytical laboratory of the Organisch-Chemisches Institut, Universität Heidelberg. With the procedures used carbon contents tend to be found too low in the presence of molybdenum. Some of the analytical data have to be interpreted with this in mind. – Melting points: Gallenkamp MFB-595 010; melting points are not corrected. – Cyclovoltammetry: EG&G Princeton Applied Research model 273; potentials in mV versus S.C.E at a glassy carbon electrode at 25°C; solutions of the compounds: 10^{-3} M in 0.1 M Bu_4NPF_6 in CH_2Cl_2. – **1a–c** and **e** were prepared accordingto ref.[18], **1d** was prepared according to ref.[19]. **4** can be obtained according to ref.[14]. $[(CH_3CN)_3(CO)_3Mo]$ was synthesized as described in ref.[25] and was always freshly prepared (using always fresh batches); [2,1,1]cryptand and [2,2,2]cryptand are abbreviations for 4,7,13,18-tetraoxa-1,10-diazabicyclo[8.5.5]eicosane and 4,7,13,16,21,24-hexaoxa-1,10-diazabicyclo[8.8.8]hexacosane, respectively. The latter ones and all other chemicals are commercially obtained and used without further purification.

Preparation of **2**: The given amount (vide infra) of **1** was dissolved in THF (50 ml), the solution was cooled to −50°C and liquid NH_3 was added (50 ml). After stirring for 10 min, the given amount (vide infra) of lithium was added. During the reaction the color of the mixture turned from deep blue to red. The reaction was finished when all lithium was consumed (4 h). Then water was added (5 ml) and the NH_3 was cautiously removed by letting the reaction mixture slowly warm up to 20°C. Finally, the THF was removed in vacuo. To the crude product water (50 ml) and diethyl ether (50 ml) were added and the mixture was neutralized with HCl. The phases were separated and the aqueous phase was extracted with diethyl ether (2 × 50 ml). The residue of the combined, dried and concentrated organic phases was purified by chromatography on silica gel in case of **2a**, **2b**, and **2e** (15 cm, Ø = 6 cm). Concentrating the fractions eluted by a mixture of petroleum ether (40/60)/diethyl ether (17:1; TLC control: R_f = 0.4 for **2a** and **2b**/29:1; TLC control: R_f = 0.45 for **2e**) gave the pure products **2a**, **2b** and **2e**. **2c** and **2d** were purified by recrystallization from petroleum ether (40/60) (20 ml). Completion of the crystallization was achieved by cooling the mixture down to −40°C for 1 h.

1a (1.6 g, 3.6 mmol) and Li (50 mg, 7.2 mmol) yielded 1.2 g (95%) of **2a** as a pasty, colorless oil. – $C_{19}H_{25}PS_2$ (348.5): calcd. C 65.48, H 7.23; P 8.89; S 18.40; found C 65.77, H 7.30, P 8.89, S 17.68. – MS (EI); *m/z* (%): 349 (50) [M^+ + 1], 319 (100) [$M^+ - C_2H_5$]. – $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = −26.9 (s).

1b (2.3 g, 5.0 mmol) and Li (69 mg, 10.0 mmol) yielded 1.7 g (93%) of **2b** as a pasty, colorless oil (even after prolonged drying, **2b** tenaciously withheld some solvent resulting in somewhat to high carbon values). – $C_{20}H_{27}PS_2$ (362.5): calcd. C 66.26, H 7.51; found C 67.11, H 7.48. – MS (FAB); *m/z* (%): 363 (70) [M^+ + 1], 319 (100) [$M^+ - C_3H_7$]. – $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = −26.8 (s).

1c (2.5 g, 5.0 mmol) and Li (138 mg, 10 mmol) yielded 1.4 g (85%) of **2c** as a colorless microcrsystalline solid. – MS (EI); *m/z* (%): 319 (100) [M^+ − 1]. – $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = −27.3 (s).

1d (2.6 g, 5.0 mmol) and Li (138 mg, 20.0 mmol) yielded 1.6 g (90%) of **2d** as a colorless microcrystalline solid. – $C_{18}H_{23}OPS_2$ (350.5): calcd. C 61.69, H 6.61, P 8.84, S 18.30; found C 61.63, H 6.77, P 8.84 S 18.58. – MS (FAB); *m/z* (%): 349 (100) [M^+]. – $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = −26.8 (s).

1e (1.9 g, 4.0 mmol) and Li (112 mg, 16.0 mmol) yielded 980 mg (85%) of **3** as a colorless, microcrystalline solid. – $C_{17}H_{21}PS$ (288.4): calcd. C 70.80, H 7.34; found C 71.26, H 7.64. – MS (FAB); *m/z* (%): 287 (100) [M^+ − 1]. – $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = −23.2 (s).

For ^{1}H- and ^{13}C-NMR data see Tables 1 and 2.

Preparation of **5**: Compound **2a** (349 mg, 1 mmol) was dissolved in CH_2Cl_2 (30 ml), solid $[(MeCN)_3(CO)_3Mo]$ was added (302 mg; 1 mmol) and the mixture was stirred for 1 h at room temperature. During the reaction the $[(MeCN)_3(CO)_3Mo]$ slowly dissolved and the color of the solution turned from light-yellow to yellow-brown.

The solvent was removed and the brown residue was chromagraphed on silica gel (15 cm, Ø = 6 cm). Concentrating the fractions eluted by a mixture of petroleum ether (40/60)/CH_2Cl_2 (1:3; TLC control: R_f = 0.75) gave 250 mg (45%) of **5** as a yellow microcrystalline solid, m.p. 150°C (dec.). – $C_{23}H_{35}MoO_4PS_2$ (556.5): calcd. C 49.64, H 4.53, P 5.57, found C 49.88, H 4.85, P 5.55. – MS (EI); *m/z* (%): 558 (8) [M^+], 530 (14) [M^+ – CO], 501 (10) [M^+ – CO – C_2H_5], 473 (6) [M^+ – 2 CO – C_2H_5], 444 (16) [M^+ – 3 CO – C_2H_5 – H]. – $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 20.0 (s).

For IR -, ^1H- and ^{13}C-NMR data see Tables 1–3.

Preparation of **6**: 1 mmol of **2d** or **4** (vide infra) was dissolved in 30 ml of THF, the solution was cooled to 0°C and treated with NaH or *n*-butyllithium (vide infra). After stirring for 30 min, solid [$(MeCN)_3(CO)_3Mo$] (302 mg, 1 mmol) was added. During the reaction the color of the mixture turned light-brown. After stirring for another 30 min, the reaction mixture was concentrated to 3–5 ml and 30 ml of petroleum ether (40/60) was added. If oily products were obtained the mixtures were treated twice with 30 ml of petroleum ether (40/60) in an ultrasonic bath. The pure yellow microcrystalline products were obtained in quantitative yields by removing the solvent in vacuo. In all cases the products contained two molecules of THF per formula unit. When compounds **6** were prepared for a consecutive reaction the purification step did not need to be applied e.g. preparation of **7** or **8**.

4 (472 mg, 1 mmol) and *n*-butyllithium (2.5 M, 0.4 ml, 1 mmol) yielded 800 mg of **6a** · 2 THF. – $C_{32}H_{29}LiMoO_3P_2S \cdot 2\ C_4H_8O$ (800.5): calcd. C 59.85, H 5.65, P 7.72; found C 58.51, H 6.13, P 7.30. – $^{31}P\{^1H\}$ NMR ([D_8]THF): δ = 21.6 (s). – ^7Li NMR ([D_8]THF): δ = –0.33.

4 (472 mg, 1 mmol) and NaH (24 mg, 1 mmol) yielded 820 mg of **6b** · 2 THF. – $^{31}P\{^1H\}$ NMR ([D_8]THF): δ = 19.8 (s).

2d (350 mg, 1 mmol) and NaH (48 mg, 2 mmol) yielded 720 mg of **6c** · 2 THF. – $^{31}P\{^1H\}$ NMR ([D_8]THF): δ = 14.9 (s).

For IR, ^1H- and ^{13}C-NMR data see Tables 1–3.

Preparation of **7**: To a solution of 1 mmol of **6a** · 2 THF or **6b** · 2 THF (vide infra) in THF (30 ml) the given cryptand (vide infra) was added. While stirring the mixtures for 30 min, yellow precipitates formed. The precipitates were separated from the solvent and washed with petroleum ether (40/60). Drying in vacuo gave the pure yellow microcrystalline products in quantitative yields.

6a · 2 THF (800 mg, 1 mmol) and [2,1,1]cryptand (288 mg, 1 mmol) yielded 946 mg of **7a**. – $C_{46}H_{57}LiMoN_2O_7P_2S$ (946.9): calcd. C 58.35, H 6.07, N 2.96, P 6.54; found C 58.04, H 6.43, N 2.76, P 6.32. – MS (FAB negative); *m/z* (%): 653 (100) [M^-]. – $^{31}P\{^1H\}$ NMR (CD_3NO_2): δ = –20.4 (s). – ^7Li NMR ([D_8]THF): δ = –1.37.

6b · 2 THF (820 mg, 1 mmol) and [2,2,2]cryptand (376 mg, 1 mmol) yielded 1050 mg of **7b**. – $C_{50}H_{65}MoN_2NaO_9PS_2$ (1049.9): calcd. C 57.19, H 6.24, N 2.67; found C 58.51, H 6.31, N 2.48. – MS (FAB negative); *m/z* (%): 653 (60) [M^-]. – $^{31}P\{^1H\}$ NMR ([D_8]THF): δ = –19.8 (s).

For IR, ^1H- and ^{13}C-NMR data see Tables 1–3.

Preparation of **8**: To a solution of **6a** · 2 THF (800 mg, 1 mmol) in THF (30 ml) the given alkylation reagent (vide infra) was added and the mixture was stirred for 2 h. The solvent was removed and the brown residue was chromagraphed on silica gel (15 cm, Ø = 6 cm). Concentrating the fractions eluted by a mixture of petroleum ether (40/60)/CH_2Cl_2 (1:3; TLC control: R_f = 0.71–0.75) gave the pure compounds **8** as yellow microcrystalline solids. While **8a** and **8b** were obtained solvent-free, **8c** crystallized with 0.5 equivalents of CH_2Cl_2 per formula unit. The obtained yields were: **8a**: 488 mg (73%), m.p. 195°C (dec.); **8b**: 409 mg (60%), m.p. 188°C (dec.); **7c**: 493 mg (70%), m.p. 205°C (dec.).

8a: MeI (426 mg, 3 mmol). – $C_{33}H_{32}MoO_3P_2S$ (666.6): calcd. C 59.28, H 4.83, P 9.27; found C 58.31, H 4.87, P 9.09. – MS (EI); *m/z* (%): 668 (28) [M^+], 640 (40) [M^+ – CO], 612 (30) [M^+ – 2 CO], 584 (100) [M^+ – 3 CO]. – $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = –18.1 (s).

8b: $Et_3O{\cdot}BF_4$ (513 mg, 3 mmol). – $C_{34}H_{34}MoO_3P_2S$ (680.6): calcd. C 59.82, H 5.02, P 9.08; found C 59.12, H 5.30, P 8.97. – MS (EI); *m/z* (%):682 (32) [M^+], 654 (46) [M^+ – CO], 626 (20) [M^+ – 2 CO], 596 (100) [M^+ – 3 CO]. – $^{31}P\{^1H\}$ NMR ([D_8]THF): δ = –22.5 (s).

8c: BzlBr (380 mg, 3 mmol). – $C_{39}H_{36}MoO_3P_2S \cdot 0.5\ CH_2Cl_2$ (785.2): calcd. C 60.42, H 4.75; found C 60.01, H 4.62. – MS (FAB); *m/z* (%): 744 (28) [M^+], 660 (46) [M^+ – 3 CO], 569 (14) [M^+ – 3 CO – Bzl], 471 (5) [M^+ – 3 CO – Bzl – Mo]. – $^{31}P\{^1H\}$ NMR (CH_2Cl_2): δ = –18.0 (s).

For IR, ^1H- and ^{13}C-NMR data see Tables 1–3.

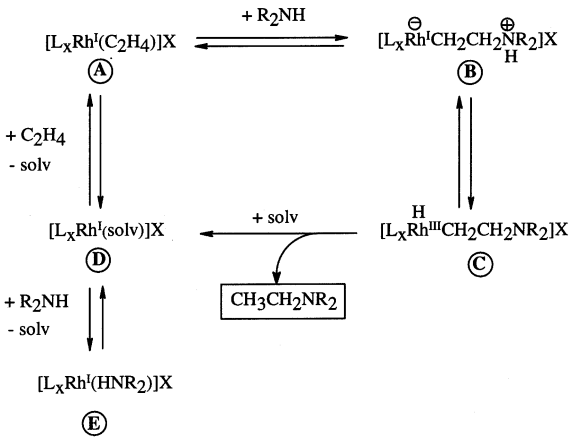
Keywords: Organorhodium(I) complexes / Tridentate ligand / Protolysis / Reductive elimination / C–H coupling

The organorhodium(I) complexes [Rh(PNP)R] [PNP = 2,6-bis(diphenylphosphanylmethyl)pyridine, R = CH_3 (**3a**), C_6H_5 (**3b**)] were synthesized from [Rh(PNP)(C_2H_4)]BF_4 (**1a**) and LiR and characterized by ^{31}P-, ^{1}H-, and ^{13}C-NMR spectroscopy and EI mass spectrometry. In a THF solution saturated with ethylene **3a** and **3b** form the five-coordinate ethylene organorhodium(I) complexes [Rh(PNP)R(C_2H_4)] (**5a**, **b**). The stable monohydridorhodium(III) complex [Rh(PNP)ClH(CH_3CN)]SO_3CF_3 (**7**) was obtained by the reaction of [Rh(PNP)Cl] with HSO_3CF_3 in a solution of THF/acetonitrile and characterized by X-ray crystallography. In a THF solution the organorhodium(I) complexes **3a**, **b** react upon the addition of either HSO_3CF_3 or $HNMe_3Cl$ with the immediate release of the respective hydrocarbon HR.

The hydroamination of ethylene was first achieved at room temp. and normal pressure by a cationic ethylenerhodium(I) complex [Rh(PPh_3)$_2$(Me_2CO)(C_2H_4)]PF_6[1]. However, the low productivity of this rhodium complex catalyst could not be improved by variation of the ligand sphere[2]. Therefore we started upon a series of model studies to investigate the reaction mechanism of the rhodium complex catalyzed hydroamination of olefins, trying to trace systematically those reaction steps considered crucial for the catalytic cycle by the use of the [2,6-bis(diphenylphosphanylmethyl)pyridine]rhodium(I) complex fragment [Rh(PNP)]$^+$ as a stable structural moiety for the respective model compounds. The hypothetical reaction mechanism of the catalyses is formulated in Scheme 1.

It was recently found that model complexes of the type **A** [Rh(PNP)(olefin)]X (olefin = ethylene, styrene; X = BF_4, PF_6, SO_3CF_3) are only in a thermodynamic equilibrium with the corresponding amine complex **E**. In this case no indication of a nucleophilic attack of the secondary amine at the C−C double bond could be detected[3]. On the other hand the nucleophilic attack of secondary amines (HNR_2) was succesful with related dicationic olefin palladium(II) complexes [Pd(PNP)(olefin)]BF_4 (olefin = ethylene, styrene), however the Pd−C σ-bond in the formed (β-aminoethyl)palladium(II) complexes [Pd(PNP)($CHR'CH_2NR_2$)]-

Scheme 1



BF_4 (R′ = H, Ph) is so stable that it can not be cleaved protolytically under the reaction conditions[4].

It is known from other rhodium-catalyzed reactions, such as the hydrogenation of olefins[5][6], that the cleavage of the Rh−C σ-bond and the formation of the C−H bond can be realized by intramolecular reductive elimination, which is proposed as the product-forming step, cf. the formation of the ethylamine, shown as the step **C**→**D** in Scheme 1.

In this paper we report on the synthesis of related organorhodium(I) model complexes [Rh(PNP)R] (R = CH_3, C_6H_5) which were used to characterize the stability of the

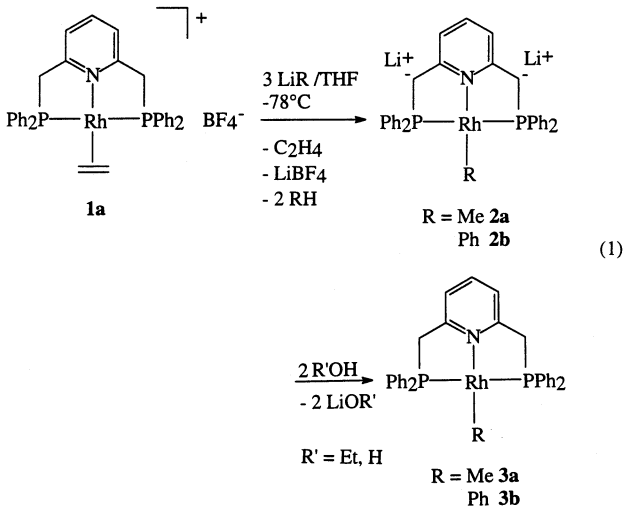
Rh−C σ-bond. For this purpose their reactivities toward ethylene and protic acids were investigated, and these results are presented here.

Results and Discussion

Synthesis and Characterization of [Rh(PNP)R]

The organorhodium(I) complexes [Rh(PNP)R] [R = CH_3 (**3a**), C_6H_5 (**3b**)] were synthesized from the cationic ethylenerhodium(I) complex [Rh(PNP)(C_2H_4)]BF_4 (**1a**)[3] with slightly more than three equiv. of the corresponding organyllithium compound, cf. Eq. 1.



(1)

The intermediates **2a**, **b** formed were characterized in situ by NMR spectroscopy. The ^{31}P-NMR spectrum of the reaction solution of **1a** with 3.1 equiv. of $LiCH_3$ in [D_8]THF shows one doublet at δ = 17.2 (J_{P-Rh} = 148 Hz) which is shifted upfield by about 11 ppm compared to the starting complex **1a**. In the ^{1}H-NMR spectrum of this solution a signal is found at δ = 0.30 (td, J_{H-P} = 4.9 Hz, $J_{H-Rh} \approx 1$ Hz, CH_3) for the methyl group coordinated at the rhodium centre. The corresponding ^{13}C signal for the methyl group appears at δ = −15.4 (dt, J_{C-P} = 10.3 Hz, J_{C-Rh} = 27.5 Hz).

A virtual triplet in the ^{1}H-NMR spectrum at δ = 3.34 has an intensity of 2 H, consistent with deprotonated methylene groups of the PNP ligand in **2a**, while the corresponding ^{13}C signal is observed at δ = 58.0 (vt, N = 24.6 Hz), which is shifted downfield in comparison to that of **1a** (δ = 43.9, vt, N = 10.9 Hz). Thus, the NMR data suggests the formation of **2a**.

The formation of the analogous phenyl compound **2b** is suggested by the ^{31}P-NMR-spectroscopic investigation of a reaction solution of **1a** and 3.2 equiv. of LiC_6H_5 in THF, where again one doublet is observed, at δ = 16.7, showing the same phosphorus-rhodium coupling constant (J_{P-Rh} = 148 Hz) as that found for **2a**.

Upon reprotonation with ethanol or water these intermediates **2a**, **b** are converted into the neutral organorhodium(I) complexes **3a**, **b**. The methyl and the phenyl complexes which are obtained in good yields are reddish/brown air-sensitive solids which are soluble in THF and toluene, moderately soluble in ethanol, and insoluble in diethyl ether. In contrast to the structurally analogous organorhodium(I) complexes [Rh(PPh_3)$_3$R], which form spontaneously the *ortho*-metallated product [Rh(*o*-$C_6H_4PPh_2$)(PPh_3)$_2$] by release of the respective hydrocarbon HR[7], the complexes **3a**, **b** are quite stable as solid compounds under an inert gas, as well as in solution at room temp.

However, only a few stable square-planar alkyl- and arylrhodium(I) complexes of the type [Rh{R′P(CH_2CH_2-CH_2PPh_2)$_2$}R] (R′ = *t*Bu, Ph) are known[8]. The *ortho*-metallation of a PPh group in these complexes as well as in **3a**, **b** is obviously prevented by the chelating structure of the tridentate ligand.

The complexes **3a**, **b** were characterized by ^{31}P-, ^{1}H-, and ^{13}C-NMR spectroscopy and by EI mass spectrometry. In the ^{31}P-NMR spectra a doublet was found at δ = 28.9 (J_{P-Rh} = 177 Hz) for **3a**, and at δ = 20.6 (J_{P-Rh} = 180 Hz) for **3b**. These signals are shifted upfield and have a larger phosphorus-rhodium coupling constant compared to those of the related cationic (PNP)rhodium(I) complexes [Rh(PNP)L]X (L = HNR_2, py, CH_3CN, DMSO, olefin; X = BF_4, PF_6, SO_3CF_3) which are found in the region of δ = 31−41 with coupling constants of 126−157 Hz[3][9].

The ^{1}H-NMR signal for the methyl group of **3a** at δ = 0.19 (J_{H-P} = 6.2 Hz; J_{H-Rh} = 1.7 Hz), as well as the corresponding ^{13}C-NMR signal at δ = −20.8 (J_{C-P} = 11.7 Hz; J_{C-Rh} = 24.6 Hz), is shifted upfield in comparison to that found for the intermediate **2a**. The characteristic virtual triplet for the methylene group of the PNP ligand appears at δ = 3.88 in the ^{1}H-NMR spectrum, and at δ = 46.8 in the ^{13}C-NMR spectrum.

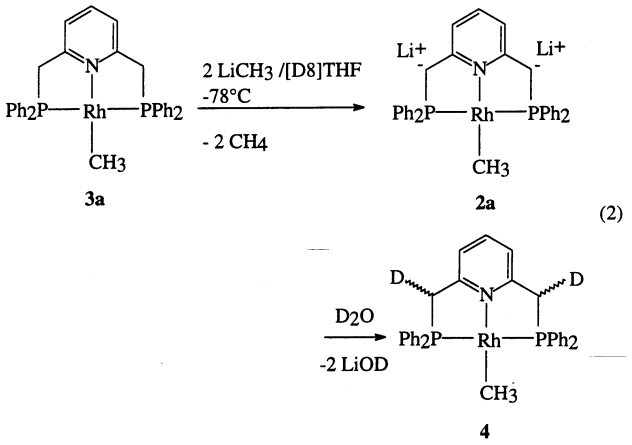
The ^{1}H-NMR signals for the phenyl moiety of **3b** are found at δ = 6.45, 6.57, and 7.36, and in the ^{13}C-NMR spectrum the corresponding signals are observed at δ = 119.0, 125.2, 140.9. While in the ^{1}H-NMR spectrum of **3b** the characteristic virtual triplet for the methylene group at δ = 4.02 is shifted slightly downfield compared to that of **3a**, the corresponding ^{13}C-NMR signal appears at the same chemical shift (δ = 46.8) as is found for **3a**.

In the EI mass spectra of **3a** and **3b** the respective peaks $[M]^+$ and $[M - R]^+$ could be observed.

A further piece of evidence for the formation of the twofold deprotonated intermediate **2a** is given by the reaction of **3a** with two equiv. of CH_3Li, cf. Eq. 2.

By the reaction of **2a** with D_2O the corresponding twofold deuterated methyl complex **4** is obtained and characterized by ^{1}H-NMR spectroscopy, where the signal for the methylene group is observed at δ = 3.87 with half the intensity found in the spectrum of **3a**. Accordingly, in the mass spectrum of **4**, the peaks for $[M]^+$ and $[M - CH_3]^+$ appear at the corresponding *m/z* values which are higher by two units than those found for **3a**.

This deprotonation reaction was also described for the structurally related [2,6-bis(diphenylphosphanylmethyl)-phenyl](methyl)platinum(II) complex, where an analogous

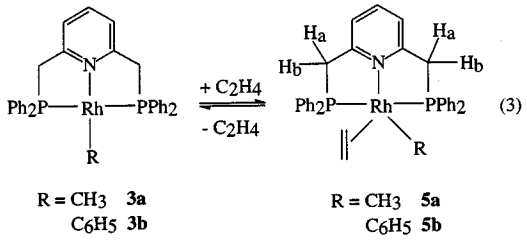


twofold deprotonated complex is obtained by the reaction with two equiv. of CH_3Li[10].

Reactivity of [Rh(PNP)R] toward Ethylene

Since the possibility of an insertion of an ethylene molecule into the Rh−C bond (cf. Scheme 1: e.g. in **B**) has to be taken into consideration as a side reaction during the hydroamination of ethylene, the investigation of the reactivity of the organorhodium(I) complexes **3a**, **b** toward ethylene was included in the model studies.

When a solution of **3a** or **3b** in THF saturated with ethylene was cooled down its colour changed reversibly from red (at room temp.) to orange-red (at −78°C). The formation of the corresponding five-coordinate ethylene organorhodium(I) complexes **5a**, **b** (cf. Eq. 3) is suggested by ^{1}H-NMR spectroscopy at room temp.: In addition to the slightly shifted signals for the coordinated PNP ligand and the organo moiety (see Experimental Section), relatively broad average signals at δ = 5.08 and δ = 4.36 are found for the methyl and phenyl complexes respectively, indicating an exchange between free and coordinated ethylene (the chemical shift of the average signal depends on the concentration of free ethylene).



In the ^{31}P-NMR spectra of these solutions the doublets at δ = 39.0 (J_{P-Rh} = 152 Hz) and 27.5 (J_{P-Rh} = 171 Hz) are observed at room temp. for the methyl and phenyl complexes **5a**, **b** respectively; these are show a remarkable downfield shift compared to those found for **3a**, **b**. These features are in agreement with the coordination of an ethylene molecule. As a consequence of the increased coordination number the phosphorus−rhodium bond becomes weaker, as reflected by the decreased phosphorus-rhodium coupling constants.

The behaviour of the solution of **3b** (under ethylene in [D_8]THF and during the cooling) was monitored by a dynamic proton-NMR experiment. The chemical shifts of the spectra run in the temperature range room temp. to −80°C are summarized in Table 1.

By cooling the sample the average signal for the ethylene becomes very broad. The coalescence temp. lies between −20°C and −40°C. At −60°C a broad signal at δ = 5.36 for the free ethylene, and two broad signals at δ = 2.48 and 1.85 for the coordinated ethylene, are visible and the signal for the methylene protons of the PNP ligand at δ ≈ 4.1 begins to split into two signals. By cooling to −80°C the signals for free and coordinated ethylene become sharper, which indicates a slow exchange relative to the NMR time scale. At this temperature the five-coordinate complex **5b** has a relatively stable coordination geometry which is no longer of C_{2v} symmetry, consequently the signals for the methylene protons become inequivalent and there is a split into two doublets at δ = 4.16 and 4.06 (J_{H-H} = 14.8 Hz).

When the solvent was removed under vacuum from a solution of **5a** or **5b** a red solid remained, identified as **3a** or **3b**, respectively. This indicates a weak coordination of the ethylene at the organorhodium(I) complexes. No indication of an insertion of the ethylene into the Rh−C σ-bond could be observed, under these conditions, for either **3a** or **3b**.

Synthesis and Structure of [Rh(PNP)ClH(CH$_3$CN)]SO$_3$CF$_3$

In the proposed catalytic cycle of the hydroamination of ethylene (cf. Scheme 1) the liberation of the ethylamine from the (β-ammonioethyl)rhodium(I) complex **B** is assumed to be achieved by oxidative addition of the proton of the β-ammonio group at the rhodium centre, forming the (β-aminoethyl)(hydrido)rhodium(III) complex **C** from which the product is reductively eliminated in an irreversible reaction step.

As is known (monohydrido)rhodium(III) complexes can be obtained by the oxidative addition of protic acids to rhodium(I) complexes[11][12], which is demonstrated here by the reaction of [Rh(PNP)Cl] (**6**)[13] with HSO_3CF_3, cf. Eq. 4.

The (chloro)(hydrido)rhodium(III) complex [Rh(PNP)-ClH(CH$_3$CN)]SO$_3$CF$_3$ (**7**) obtained was isolated as an air-stable pale yellow solid and characterized by IR and ^{1}H-NMR spectroscopy. In the IR spectrum the band at 2138 cm^{-1} is assigned to the Rh−H vibration, the two bands at 2293 and 2366 cm^{-1} are observed for the end-on coordinated acetonitrile[14], and the corresponding bands for the triflate anion (see Experimental Section) suggest its non-coordination[15]. The ^{1}H-NMR signal of the hydrido ligand appears at δ = −15.99 as a broad triplet, while for the coordinated acetonitrile a singlet is observed at δ = 1.48. For the inequivalent methylene protons of the PNP ligand the corresponding two doublets of virtual triplets appear at δ = 4.22 and 4.83.

Table 1. Dynamic ^{1}H-NMR experiment of the solution of [Rh(PNP)(C_6H_5)] (**3a**) in [D_8]THF under ethylene (500 MHz)

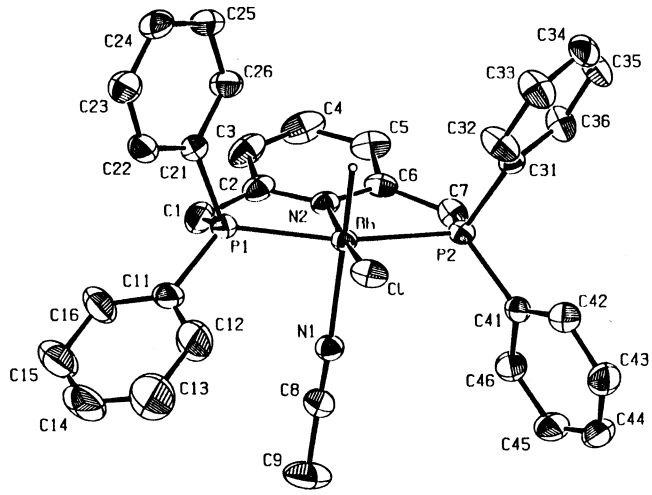
Single crystals of complex **7** were obtained from the mother liquor (THF/CH_3CN/diethyl ether) which stood three days at room temp. The molecular structure of the complex cation $[Rh(PNP)ClH(CH_3CN)]^+$ is shown in Figure 1. The Rh−Cl distance [2.3480(7) Å] is identical with that found for the chlororhodium(I) complex [Rh(PNP)Cl] [2.344(2) Å], while the Rh−N(1) distance [2.1451(19) Å] is significantly longer than the corresponding Rh−N bond length [1.984(3) Å] found in the (acetonitrile)rhodium(I) complex $[Rh(PNP)(CH_3CN)]BF_4$[9] due to the strong *trans* influence of the hydrido ligand. The Rh^{III}(PNP) fragment in **7** exhibits practically the same features of the bonding parameters as found in the Rh^{I}(PNP) fragment in **6** and in other Rh^{I}(PNP) complexes[3][9].

Figure 1. Platon[16] drawing of the complex cation $[Rh(PNP)ClH(CH_3CN)]^+$ of **7**



Reactivity of [Rh(PNP)R] toward Protic Acids

Analogous to the formation of the hydridorhodium(III) complex **7**, the reaction of the organorhodium(I) complexes **3a**, **b** with protic acids can be used as a simplified reaction model for the product-forming steps (**B** → **C** → **D** in Scheme 1). It is of interest to investigate the protolysis of [Rh(PNP)R], in one case in the presence of a weak coordinating anion X^- such as $CF_3SO_3^-$, and in another case with a stronger coordinating anion such as Cl^-. Thus, the proposed hydrido organorhodium(III) intermediates, either five-coordinate **I** or six-coordinate **II** (cf. Scheme 2), might show different reactivities concerning the reductive elimination of the hydrocarbon HR (discussed in detail by Milstein[6]).

First HSO_3CF_3 was added to a solution of **3a** or **3b** in THF. In the case of the methyl complex **3a** the release of the methane was observed immediately, visible as an evolution of gas, whereas from the phenyl complex **3b** the corresponding benzene was detected by gas chromatography of the reaction solution. However, no defined Rh^{I} complex could be isolated from the reaction solution. Obviously, the remaining $[Rh(PNP)]^+$ fragment (analogous to **D**, Scheme 1) cannot be stabilized either by the solvent (THF) or by the triflate anion. Decomposition of the reaction solution occurred and the formation of the dinuclear complex $[Rh_2(PNP)_3](SO_3CF_3)_2$ (**8**)[3] was detected by ^{31}P NMR.

However, when some acetonitrile was added to the reaction solution after the protolysis the corresponding cationic acetonitrile complex **9**[9] could be isolated, cf. Eq. 5.

According to the last step of the catalytic cycle (**D** → **A**, Scheme 1) the remaining $[Rh(PNP)]^+$ fragment can also be trapped with ethylene by formation of the cationic ethylene complex **1b**[3], cf. Eq. 6.

When cyclooctadiene was added after the protolyses of **3b** a dinuclear COD complex **10** was obtained, cf. Eq. 7, which was fully characterized by ^{31}P-, ^{1}H-, and ^{13}C-NMR

In another experiment trimethylammonium chloride was added to a solution of **3a** or **3b**. In both cases the respective hydrocarbon was also released immediately while the chlororhodium(I) complex **6** formed, which is poorly soluble in THF, began to precipitate and was filtered off after 4 h with a yield of 80−90%, cf. Eq. 8.

$$[Rh(PNP)R] + [HNMe3]Cl \xrightarrow{THF} [Rh(PNP)Cl] + HR + NMe3 \quad (8)$$

R = Me **3a**, Ph **3b** — **6**

Since a (hydrido)(phenyl)rhodium(III) complex $[Rh(PMe_3)_2(CO)(C_6H_5)HCl]$ could be detected upon the reaction of $[Rh(PMe_3)_2(CO)(C_6H_5)]$ with HCl, although only in solution at −40°C by NMR spectroscopy[17], the formation of a hydrido organo-PNP−rhodium(III) intermediate during the protolysis reaction described above might be postulated. Furthermore, the reductive elimination step from this complex seems to proceed without any kinetic inhibition, independent of the coordinating ability of the anion in the Brönsted acid used for protolysis.

Conclusions

The synthesis of the new organorhodium(I) complexes [Rh(PNP)R] (R = CH_3, C_6H_5) succeeded by the reaction of the cationic ethylene complex $[Rh(PNP)(C_2H_4)]BF_4$ with three equiv. of LiR. Organorhodium complexes containing deprotonated methylene groups of the PNP ligand occur as intermediates, which can be reprotonated with ethanol or water.

The square-planar coordination geometry of the organorhodium complexes is stabilized by the chelating structure of the tridentate PNP ligand, which avoids the release of the hydrocarbon HR by *ortho*-metallation of a PPh moiety.

The organorhodium(I) complexes [Rh(PNP)R] react with ethylene by the formation of five-coordinate complexes $[Rh(PNP)R(C_2H_4)]$ in which the ethylene is weakly coordinated and can be removed under vacuum. No indication of an insertion of the ethylene in the Rh−C σ-bond could be observed, which may be important to exclude the oligomerization of ethylene as a side reaction of the hydroamination.

As was shown a stable (monohydrido)rhodium(III) complex $[Rh(PNP)ClH(CH_3CN)]SO_3CF_3$ can be obtained by oxidative addition of HSO_3CF_3 to the chlororhodium(I) complex [Rh(PNP)Cl]. Upon protolysis with HSO_3CF_3 of the organorhodium(I) complexes [Rh(PNP)R] the hydrocarbons RH are liberated, and it is possible to trap the remaining Rh^I complex fragment with olefins, so the cationic olefin complex can be regenerated, which is as expected for the starting complex in the catalytic cycle of the hydroamination of olefins.

Independently, if a protic acid with a weakly coordinating (HSO_3CF_3) or a stronger coordinating anion ($HNMe_3Cl$) is used, the protolytic reaction of the organorhodium(I) complexes [RhPNP)R] [proceeding by intermediate formation of corresponding hydrido-organorhodium(III) complex] leads immediately in each case to the reductive elimination of the hydrocarbon HR. These results also suggest that the reductive elimination of the ethylamine (cf. Scheme 1) may proceed irreversibly and without kinetic inhibition, which is essential for a product-forming step closing the catalytic cycle. The proposed reaction mechanism for the hydroamination of olefins finds strong chemical support from these model reactions.

We thank Dr. *A. Porzel* of the *Institut für Pflanzenbiochemie* of the University of Halle for the measurement of the dynamic proton-resonance experiment and the *Deutsche Forschungsgemeinschaft* (*Sonderforschungsbereich 347* of the University of Würzburg) for financial support.

Experimental Section

General: All reactions were carried out under dry and oxygen-free argon or ethylene. Ethanol, acetone, $CDCl_3$ and [D_6]acetone were refluxed over 4-Å molecular sieves and made oxygen-free by bubbling argon through the liquid. THF and diethyl ether were refluxed in the presence of Na/benzophenone and [D_8]THF in the presence of K/Na alloy. Acetonitrile and DMSO were dried over 4-Å molecular sieves and distilled before use. HSO_3CF_3, $LiCH_3$ and LiC_6H_5 were obtained from Fluka. − IR: KBr pellets with a Perkin-Elmer FT-IR 16 spectrometer. − ^1H, $^{13}C\{^1H\}$, and $^{31}P\{^1H\}$ NMR: Varian Gemini 300 NMR spectrometer (300, 75, and 121 MHz respectively), ^1H- and ^{13}C-NMR shifts were referenced to the resonance of the residual protons of the solvents, the ^{31}P-NMR shifts were referenced to external 85% H_3PO_4. − Dynamic proton NMR: Varian Unity 500 NMR spectrometer (500 MHz). − EI MS: AMD 402 spectrometer (AMD Intectra) at 70 eV. − (C, H, and N): LECO CHN 932 analyzer. Rh elemental analysis was determined using a photometric method[18]. The Chrompack gas-chromatograph CP 9000 was used for the identification of liquid organic compounds.

Syntheses: [Rh(PNP)(C_2H_4)]BF_4 (**1a**) was prepared according to the procedure described in ref.[3].

[Rh(PNP)(CH_3)] (**3a**): 10.5 ml of a 1.6 M $LiCH_3$ solution in diethyl ether (3.2 equiv.) was added slowly at −78°C to a suspension of 3.6 g (5.2 mmol) of [Rh(PNP)(C_2H_4)]BF_4 (**1a**) in 20 ml of THF. The mixture was warmed up to room temp. and stirred for a further 10 min to give a red solution. The solvent was removed under reduced pressure. 20 ml of ethanol was added dropwise slowly at −78°C to the remaining red crystalline solid with rigorous stirring. After stirring for another 20 min at room temp., the reddish/brown solid was filtered off, washed with ethanol (2 ×), then with diethyl ether and dried under vacuum. After recrystallization of the crude product in hot THF, 2.2 g of **3a** (3.7 mmol, 71%), reddish/brown solid was isolated, temp. of decomposition 220−230°C. − ^{31}P NMR ([D_8]THF): δ = 28.89 (d, J_{P-Rh} = 177 Hz). − ^1H NMR([D_8]THF): δ = 0.19 (td, $^3J_{H-P}$ = 6.2 Hz, J_{H-Rh} = 1.7 Hz, 3 H, CH_3), 3.88 (vt, N_{H-P} = 3.9 Hz, 4 H, CH_2), 7.07 (d, J_{H-H} = 7.6 Hz, 2 H, *3,5*-py), 7.30 (m, 12 H, PPh), 7.49 (t, J_{H-H} = 7.6 Hz, 1 H, *4*-py), 7.78 (m, 8 H, PPh). − ^{13}C NMR([D_8]THF): δ = −20.8 (dt, $^2J_{C-P}$ = 11.7 Hz, J_{C-Rh} = 24.6 Hz, *C*H_3), 46.8 (vt, N_{C-P} = 9.7 Hz, *C*H_2), 120.8 (vt, N_{C-P} = 5.1 Hz, $C_{3,5\text{-py}}$), 128.6 (vt, N_{C-P} = 4.4 Hz, PC_{meta}), 129.3 (s, PC_{para}), 131.4 (s, $C_{4\text{-py}}$), 133.6 (vt, N_{C-P} = 7.5 Hz, PC_{ortho}), 138.3 (vt, N_{C-P} = 14.9 Hz, PC_{ipso}), 159.9 (vt, N_{C-P} < 3 Hz, $C_{2,6\text{-py}}$). − EI MS; *m/z* (%): 593 (100) $[M]^+$, 578 (62) $[M - CH_3]^+$. − $C_{32}H_{30}NP_2Rh$ (593.45): calcd. C 64.77, H 5.10, N 2.36, Rh 17.34; found C 64.26, H 5.04, N 2.63, Rh 17.88.

[Rh(PNP)(C_6H_5)] (**3b**): The complex **3b** was prepared in the same manner as described for **3a** from 3 g (4.3 mmol) of **1a** in 20 ml of THF and 7.5 ml of a ca. 1.8 M Et_2O/cyclohexane solution of LiC_6H_5 (13.4 mmol, 3.1 equiv.). When the solvent was removed from the red solution, a red oil remained which was treated with 20 ml of ethanol at −78°C by rigorously stirring, giving a reddish/brown suspension. After stirring for another 20 min, the solid was filtered off washed with ethanol (3 ×)and then with diethyl ether and dried under vacuum. The crude product was recrystallized in hot THF giving 2.1 g of **3b** (3.2 mmol, 75%), reddish/brown solid, temp. of decomposition 215−220°C. − ^{31}P NMR ([D_8]THF): δ = 20.6 (d, J_{P-Rh} = 180 Hz). − ^1H NMR ([D_8]THF): δ = 4.02 (vt, N_{H-P} = 3.8 Hz, 4 H, CH_2), 6.45 (t, J_{H-H} = 7.0 Hz, 1 H, H_{para}), 6.57 (t, J_{H-H} = 7.2 Hz, 2 H, H_{meta}), 7.21 (m, 14 H, PPh, *3,5*-py), 7.36 (d, J_{H-H} = 7.3 Hz, 2 H, H_{ortho}), 7.50 (m, 8 H, PPh), 7.60 (t, J_{H-H} = 7.6 Hz, 1 H, *4*-py). − ^{13}C NMR ([D_8]THF): δ = 46.8 (vt, N_{C-P} = 9.9 Hz, *C*H_2), 119.0 (s, C_{para}), 120.9 (vt, N_{C-P} = 5.2 Hz, $C_{3,5\text{-py}}$), 125.24 (s, C_{meta}), 128.5 (vt, N_{C-P} = 4.6 Hz, PC_{meta}), 129.3 (s, PC_{para}), 133.5 (s, $C_{4\text{-py}}$), 133.6 (vt, N_{C-P} = 6.9 Hz, PC_{ortho}), 137.9 (vt, N_{C-P} = 16.1 Hz, PC_{ipso}), 140.9 (vt, N_{C-P} = 3.8 Hz, C_{ortho}), 160.9 (vt, N_{C-P} < 3 Hz, $C_{2,6\text{-py}}$). − EI MS; *m/z* (100): 655 (6.7) $[M]^+$, 578 (0.1) $[M - C_6H_5]^+$. − $C_{37}H_{32}NP_2Rh$ (655.52): calcd. C 67.79, H 4.92, N 2.14, Rh 15.70; found C 63.92 (premature decomposition of the sample), H 5.03, N 1.91, Rh 15.58.

Alternatively the complexes could be obtained by reprotonation with 5 equiv. of H_2O which were added directly to the red reaction solution (**2a** or **2b**). The crude products **3a**, **b** precipitated after a few minutes from the THF solution and were isolated in yields of about 65%.

NMR-Spectroscopic Characterization of [Rh{2,6-($Ph_2PCHLi)_2$-(NC_5H_3)}(R)] [R = CH_3 (**2a**)*, C_6H_5* (**2b**)*]*

2a: (a) [Rh(PNP)(C_2H_4)]BF_4 (148 mg, 0.21 mmol, **1a**) was dissolved in 1 ml of [D_8]THF and 3.1 equiv. of solid $LiCH_3$ (0.66 mmol, obtained from 0.41 ml of a 1.6 M Et_2O solution by removing the solvent) were added at −78°C and warmed up to room temp. The NMR spectra, which were measured instantly from the red solution obtained are consistent with **2a**. − ^{31}P NMR ([D_8]THF): δ = 17.2 (d, J_{P-Rh} = 148 Hz). − ^1H NMR ([D_8]THF): δ = 0.30 (td, $^3J_{H-P}$ = 4.9 Hz, $J_{H-Rh} \approx$ 1 Hz, 3 H, CH_3), 3.34 (vt, N_{H-P} = 3.8 Hz, 2 H, C*H*), 5.10 (d, J_{H-H} = 7.6 Hz, 2 H, *3,5*-py), 6.06 (t, J_{H-H} = 7.6 Hz, 1 H, *4*-py), 6.92−7.05 (m, 12 H, PPh), 7.72 (m, 8 H, PPh). − ^{13}C NMR ([D_8]THF): δ = −15.4 (dt, $^2J_{C-P}$ = 10.3 Hz, J_{C-Rh} = 27.5 Hz, *C*H_3), 58.0 (vt, N_{C-P} = 24.6 Hz, *C*H), 92.3 (vt, N_{C-P} = 8.0 Hz, $C_{3,5\text{-py}}$), 126.1 (s, PC_{para}), 127.2 (vt, N_{C-P} = 4.2 Hz, PC_{meta}), 131.0 (s, $C_{4\text{-py}}$), 132.5 (vt, N_{C-P} = 6.6 Hz, PC_{ortho}), 148.6 (vt, N_{C-P} = 14.4 Hz, PC_{ipso}), 171.6 (vt, N_{C-P} < 3 Hz, $C_{2,6\text{-py}}$).

(b) [Rh(PNP)(CH_3)] (197 mg, 0.33 mmol, **3a**) was dissolved in 1 ml of [D_8]THF and 2.2 equiv. of solid CH_3Li (0.73 mmol, obtained from 0.46 ml of a 1.6 M Et_2O solution by removing the solvent) were added at −78°C and warmed up to room temp. The obtained red solution was instantly characterized by NMR spectroscopy. The ^{31}P-, ^1H-, and ^{13}C-NMR spectra are identical with those found for the reaction solution of **1a** and 3.1 equiv. of CH_3Li described in (a).

2b: The reaction solution of **1a** and 3.2 equiv. of C_6H_5Li (1.8 M solution in Et_2O/cyclohexane) in THF prepared in the same manner as described for **2a** was characterized by ^{31}P NMR (with external ref. C_6D_6): δ = 16.7 (d, J_{P-Rh} = 148 Hz).

Reaction of **2a** *with D_2O:* 5 equiv. of D_2O were added to a solution of **2a** in THF, which was prepared from **3a** and 2.2 equiv. of CH_3Li as described above. The reddish/brown crystalline solid which was precipitated was filtered off washed with ethanol and diethyl ether and dried under vacuum. The ^1H-NMR spectrum of the solid is consistent with [Rh{2,6-($Ph_2PCHD)_2$(NC_5H_3)}(CH_3)] (**4**). For the deuterated methylene group a multiplet at δ = 3.87 was found with an intensity of 2 H. All other signals of **4** agree with those of **3a**. − EI MS of **4**; *m/z* (%): 595 $[M]^+$ (81), 580 $[M - CH_3]^+$ (53).

Reaction of **3a**, **b** *with Ethylene:* The complexes **3a**, **b** were dissolved in [D_8]THF. The solutions were saturated with ethylene at −78°C. The five-coordinate complexes [Rh(PNP)R(C_2H_4)] [R = CH_3 (**5a**), C_6H_5 (**5b**)] were identified by ^{31}P- and ^{1}H-NMR spectroscopy.

5a: ^{31}P NMR ([D_8]THF): δ = 39.0 (d, J_{P-Rh} = 152 Hz). − ^{1}H NMR ([D_8]THF): δ = −0.54 (td, $^3J_{H-P}$ = 7.3 Hz, J_{H-Rh} = 1.5 Hz, 3 H, CH_3), 4.04 (vt, N_{H-P} = 3.0 Hz, 4 H, CH_2), 5.08 (br., average signal for free and coord. C_2H_4), 7.12−7.62 (m, 23 H, PPh, py).

5b: ^{31}P NMR ([D_8]THF): δ = 27.5 (d, J_{P-Rh} = 171 Hz). − ^{1}H NMR ([D_8]THF): δ = 4.05 (vt, N_{H-P} = 3.0 Hz, 4 H, CH_2), 4.36 (br., average signal for free and coord. C_2H_4), 6.45 (t, J_{H-H} = 7.3 Hz, 1 H, H_{para}), 6.55 (t, J_{H-H} = 7.3 Hz, 2 H, H_{meta}), 7.07−7.40 (m, 23 H, PPh, *3,5*-py, H_{ortho}), 7.54 (t, J_{H-H} = 7.9 Hz, 1 H, *4*-py).

[Rh(PNP)ClH(CH$_3$CN)]SO$_3$CF$_3$ (**7**): 0.2 ml of HSO_3CF_3 was added to a suspension of 345 mg (0.56 mmol) of [Rh(PNP)Cl][9][13] in 5 ml of THF and 1 ml of acetonitrile. The mixture changed its colour to pale yellow. After filtration of the solution, diethyl ether was added dropwise and a yellow/brown oil precipitated which crystallized to a pale yellow solid. The crude product was filtered off, washed with diethyl ether (2 ×), and recrystallized in acetone/diethyl ether to give 290 mg of **7** (0.38 mmol, 67%), temp. of decomposition 160−170°C. − IR (KBr): $\tilde{\nu}$ = 2366 cm^{-1}, 2293 (CH_3CN); 2138 (Rh−H); 1602, 1568 (py); 1261, 1223, 1159, 1030, 638, 572 (SO_3CF_3). − ^{1}H NMR ($CDCl_3$): δ = −15.9 (t, $^2J_{H-P}$ = 9.5 Hz, 1 H, Rh*H*), 1.49 (s, 3 H, NCH_3) 4.22 (dvt, J_{Ha-Hb} = 17.8 Hz, N_{H-P} = 4.6 Hz, 2 H, CH_a), 4.83 (dvt, J_{Ha-Hb} = 17.8 Hz, N_{H-P} = 4.6 Hz, 2 H, CH_b), 7.41−7.94 (m, 23 H, PPh, py).

Reactivity of **3a**, **b** *toward HSO$_3$CF$_3$:* (a) 1 equiv. of HSO_3CF_3 was added to a solution of 1 mmol of **3a** or **3b** in 8 ml of THF. In the case of the reaction with **3a** the evolution of methane was immediately visible. In the reaction solution of **3b** benzene was correspondingly detected by gas chromatography. By addition of diethyl ether to the respective reaction solutions dark red oil precipitated giving reddish/brown solids upon removal of the solvent in vacuum. The solids obtained from both reaction solutions contain the dinuclear complex [Rh_2(PNP)$_3$](SO_3CF_3)$_2$ (**8**) among decomposition products; detected by ^{31}P-NMR spectroscopy (δ = 43.9 dd, $J_{P(a)-Rh}$ = 139 Hz, $J_{P(a)-P(b)}$ = 39 Hz; δ = 26.4, dt $J_{P(b)-Rh}$ = 169 Hz)[3].

(b) In presence of CH_3CN: After the protolysis of **3a** or **3b** with HSO_3CF_3 (see above), 1 ml of acetonitrile was added to the reaction solution and stirred for 20 min at room temp. Upon dropwise addition of diethyl ether an orange/brown oil precipitated which crystallized after 1 d to give a brown/yellow solid which was filtered off washed with diethyl ether and dried under vacuum. In each case the solid was analyzed by ^{1}H-NMR spectroscopy as the pure acetonitrile complex [Rh(PNP)(CH_3CN)]SO_3CF_3 (**9**) when compared to the spectrum of an authentic sample prepared according to the procedure in the literature[9] (yield: 50−60%).

(c) In presence of ethylene: After the protolysis of **3a** or **3b** with HSO_3CF_3 (see above), the reaction solution was stirred for 20 min under ethylene at −78°C. The mixture was warmed up to room temp. Upon addition of diethyl ether to the solution an orange yellow crystalline solid precipitated which was filtered off, washed with diethyl ether and dried under vacuum. The solid was identified as the pure ethylene complex [Rh(PNP)(C_2H_4)]SO_3CF_3 (**1b**) by ^{1}H-NMR spectroscopy when compared to an authentic sample[3] (yield: 60−80%).

(d) In the presence of COD: 114 μl of HSO_3CF_3 was added to a solution of 830 mg (1.26 mmol) of [Rh(PNP)(C_6H_5)] (**3b**) in 8 ml of THF. After 5 min, 1.6 ml (12.6 mmol) of cyclooctadiene (COD) was added and stirred for 30 min while an orange yellow solid crystallized slowly from the solution. The solid was filtered off the next day. For recrystallization the solid was dissolved in acetone and precipitated after addition of diethyl ether to the solution. The crystalline solid was filtered off, washed with diethyl ether and dried under vacuum. The solid was characterized as [Rh_2(PNP)$_2$(COD)](SO_3CF_3)$_2$ (**10**) which was isolated in a yield of 520 mg (0.66 mmol, 53%), temp. of decomposition 232°C. − ^{31}P NMR ([D_6]acetone): δ = 41.2 (d, J_{P-Rh} = 142 Hz). − ^{1}H NMR ([D_6]acetone): δ = 1.18 (m, 4 H, COD), 2.25 (m, 4 H, COD), 4.09 (m, 4 H, COD), 4.36 (vt, N_{H-P} = 3.6 Hz, 4 H, CH_2), 7.37−7.81 (m, 23 H, PPh, py). − ^{13}C NMR ([D_6]acetone): δ = 44.7 (vt, N_{C-P} = 11.5 Hz, *C*H$_2$), 77.8 (d, J_{C-Rh} = 12 Hz), 122.7 (vt, N_{C-P} < 3 Hz, $C_{3,5\text{-py}}$), 129.9 (vt, N_{C-P} = 4.2 Hz, PC_{meta}), 131.0 (vt, N_{C-P} = 15.8 Hz, PC_{ipso}), 132.2 (s, PC_{para}), 134.5 (vt, N_{C-P} = 6.6 Hz, PC_{ortho}), 141.7 (s, $C_{4\text{-py}}$), 161.9 (vt, N_{C-P} < 3 Hz, $C_{2,6\text{-py}}$). − $C_{72}H_{66}F_6N_2O_6P_4Rh_2S_2$ (1563.15): calcd. C 55.31, H 4.26, N 1.79, Rh 13.17; found C 54.91, H 4.26, N 1.65, Rh 13.07.

Reactivity of **3a**, **b** *toward HNMe$_3$Cl:* 48 mg (0.5 mmol) of $HNMe_3Cl$, dissolved in 2 ml of THF, was added to a solution of 0.5 mmol of **3a** or **3b**, dissolved in 8 ml of THF. A red crystalline solid precipitated and, in the case of the methyl complex **3a**, an evolution of gas was observed immediately. In the reaction solution of **3b** benzene was detected by gas chromatography. After 4 h, the red solid was filtered off, washed with THF and diethyl ether and dried under vacuum. The solid was identified in each case as [Rh(PNP)Cl][9][13] (**6**) by ^{31}P-NMR and IR spectroscopy (yield: 80−90%).

Crystal-Structure Determination of **7**: A single crystal of approximate dimensions 0.64 × 0.28 × 0.08 mm was mounted inside a Lindemann glass capillary. Crystal data and structure refinement details are given in Table 3.

Reflections, collected	10392
Independent reflections	5972
Data/restraints/parameters	5972/0/548
Goodness-of-fit on F^2	0.948
Final *R* indices [$I > 2\sigma(I)$]	$R1$ = 0.0249, $wR2$ = 0.0571
R indices (all data)	$R1$ = 0.0337, $wR2$ = 0.0588
Largest diff peak and hole [e Å^{-3}]	+0.53; −0.62

The data were measured with a STOE IPDS[18] using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). A decay correction using the program DECAY[19] was applied. The structure was solved by direct methods[20], completed by subsequent difference Fourier syntheses, and refined by full-matrix least-squares procedures[21]. Final cycles of refinement converged at $R1 = \Sigma(\|F_o| -$

$||F_c||)/\Sigma|F_o| = 0.0249$ and $wR2 = [\Sigma w(F_o^2 - F_c^2)^2/\Sigma w(F_o^2)^2]^{1/2} = 0.0571$ for 4931 observed reflections [$I > 2\sigma(I)$]. All non-hydrogen atoms were refined with anisotropic displacement coefficients. All hydrogen atom positions were found in the difference map calculated from the model containing all non-hydrogen atoms. The hydrogen positions were refined with individual isotropic temperature parameters. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre (CCDC-101416). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033, E-mail: deposit@ccdc.cam.ac.uk].

Keywords: Mass spectrometry / Clusters / Germanium / Tin / Lead

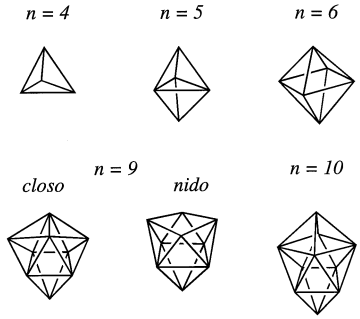
Time-of-flight mass-spectrometric investigations show that laser desorption leads to anionic, large clusters of the elements (E) Ge, Sn, and Pb without special gas-phase clustering conditions and additional ionization processes. Ion formation strongly depends on the nature of the starting materials used during desorption experiments. Cluster anions from pure elements E were observed with a maximum of 6 atoms and their relative intensities decreased exponentially with increasing cluster size. Larger clusters are observed if alkali metals (K, Rb, and Cs) are present. Binary phases of nominal composition K_4E_9, ethylenediamine solutions of these phases, and crystalline compounds containing well-defined cluster anions as in $[K([2.2.2]\text{-crypt})]_3E_9$ are used as sources for desorption experiments. The latter results in the formation of clusters of 11 (Ge), 15 (Sn), and 13 (Pb) E atoms. Under similar conditions cations are observed at much lower intensities and the maximum cluster size is 6. For E = Ge anions containing two different kinds of atoms KGe_n^- are observed with relatively high abundance for n = 5, 9, and 10; KGe_{11}^- and KGe_{13}^- are also detected. The results are compared to the formation of clusters in binary alloys. Analogies to structurally characterized Zintl ions E_n^{x-} (x = 2, 3, 4) are given. The enhanced formation of cluster anions during the laser desorption process in the presence of electropositive metals indicates a more general application for anion formation in the gas phase.

Introduction

The relationship between the stability of gas-phase clusters and Zintl ions is of considerable interest[1][2]. The remarkable feature of anions of group-14 elements E (E = Ge, Sn, Pb) is their distinct tendency towards *cluster* formation in the solid state, in solution, and in the gas phase. The earliest studies on soluble E_n clusters were reported more than 100 years ago[3]. The systematic work of Kraus, Smyth, and Zintl[4][5] proved the existence of polyanions, such as Pb_9^{4-} and Pb_7^{4-}. Since then, several homoatomic cluster anions − so-called *Zintl ions* − have been structurally characterized, most of them as their $[K([2.2.2]\text{crypt})]^+$ and $[Na([2.2.2]\text{crypt})]^+$ salts[6]: E_5^{2-}, E_9^{x-} (x = 3, 4), and Ge_{10}^{2-}. Sn_9^{4-} and Pb_9^{4-} clusters stabilized by $Cr(CO)_3$ have also been isolated (Figure 1)[7]. Interestingly, there is only one structural report of an octahedral group-14 species $[SnCr(CO)_5]_6^{2-}$ characterized as $[K([2.2.2]\text{crypt})]^+$ salt[8].

The enhanced stability of these anions can be understood using Wade's electron counting rules for clusters[9]. Deltahedral n-vertex clusters are stable with $2n + 2$, $2n + 4$ and $2n + 6$ skeletal electrons and form *closo*-, *nido*-, and *arachno*-type clusters, respectively. As a result, E_n^{x-} clusters which are build up from group-14 elements should be especially favored independent of cluster size with the same relatively low charges of −2, −4, and −6. Deltahedral *closo* structures were predicted for $n \leq 24$[10] and are known for boranes and caboranes for $4 \leq n \leq 12$.

Figure 1. Structurally characterized homoatomic deltahedra E_n with n = 4, 5, 6, 9, 10 vertices; nine-atom clusters occur with different electron counts and structures between the *closo* and *nido* type; octahedral clusters are only known with stabilizing organometallic ligands (for further details see text)



Several homoatomic clusters of the heavier group-14 elements were characterized by mass spectrometry. Under equilibrium conditions in Knudsen cell effusion, the abundance of tetrameric molecules is independent of the composition of the condensed starting material. Such precursors include binary to quaternary systems of group-14 to -16 elements, some of which also contain alkali metals[11]. The stability of these molecules correlates with their electron numbers (20 and 22 electrons) and hence with their possible structures (planar and tetrahedral)[12]. Cooling hot metal vapors using different techniques enables the production of larger cluster species and ultrasmall particles[1][13][14][15]. In

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1434−1948/98/1010−1433 $ 17.50+.50/0

many cases electron bombardment or laser ionization generates positive cluster ions from neutral cluster beams. Positively and negatively charged cluster ions can be obtained by laser desorption[13] or injecting electrons from a biased filament[16]. Several mass-spectrometric investigations of larger group-13 to -16 clusters use the corresponding elements as ion sources. Gas-phase reaction and gas-aggregation techniques used for the binary systems Cs/Sn and Cs/Pb show intensity maxima for the molecules $Cs_3Sn_5^+$, $Cs_3Sn_9^+$, $Cs_5Sn_9^+$, and $Cs_3Pb_5^+$. Sn_{10}^+ is observed at low intensity. Larger clusters were not observed due to the limitation of the mass spectrometer[1].

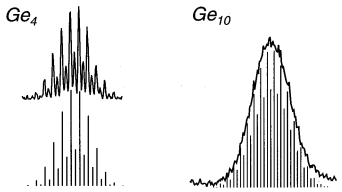
The facile synthesis and isolation of molecular paramagnetic clusters E_9^{3-} in good yields[17] prompted us to investigate the gas-phase ion formation from samples that contain discrete cluster units. Here we report our time-of-flight (TOF) mass-spectrometric studies of $E_n^{+/-}$ ions (E = Ge, Sn, and Pb) generated by laser desorption in a commercially available TOF mass spectrometer. The generation of large, anionic clusters is achieved by laser desorption without gas-phase aggregation techniques.

In order to evaluate the dependency of the gas-phase cluster-ion formation on the ability of electron transfer and thus ion formation in the precursors, we investigated the following series of samples: pure elements (Ge, Pb); mixtures of the elements K and E = Ge, Pb; binary phases K_4E_9 (E = Ge, Sn, and Pb); ethylenediamine solutions of A_4E_9 (A = alkali metal, E = Ge, Sn, and Pb); $[K([2.2.2]crypt)]_3E_9$ salts containing isolated Zintl ions E_9^{3-} (E = Ge, Sn, and Pb).

Results

The resolution of the TOF spectrometer allows the identification of the isotopic distribution in the clusters up to a maximum cluster size of six atoms. As an example, the observed and simulated spectrum of Ge_4 is shown in Figure 2a, left where the five most abundant isotopes are used for the calculation (isotope mass, relative abundance: 69.9, 0.56; 71.9, 0.75; 72.9 ,0.21; 73.9, 1.00; 75.9, 0.21). Larger clusters appear as broader signals (Figure 2b, right). Typical mass spectra of the investigations are shown in Figures 3−5. The inserts show the mass spectra of delayed extraction. In Figures 3c and 4a higher mass regions are shown on enlarged intensity scales.

Figure 2. Comparison of the measured and simulated (lines) mass spectra of Ge_4 and Ge_{10}



Pure Elements E = Ge, Pb

A typical spectrum of negatively charged Ge clusters generated by laser desorption from elemental germanium is shown in Figure 3a. All ion signals have the expected mass distribution due to the abundance of the different isotopes of Ge. The largest detected ion is a six-atom cluster. The relative intensities of the ion signals decrease exponentially with increasing cluster size. The relative intensities differ clearly from those recorded using vapor-phase condensation techniques. In these experiments cluster-size "magic numbers"[15][16][18] appear and a dependency of the cluster size distribution on the gas-aggregation technique is observed[14][19]. The size distribution for Ge and Pb cations are very similar, however, in the case of Pb also oxide formation Pb_3O_y with $y = 1-4$ is found.

Mixtures of K and E = Ge, Pb

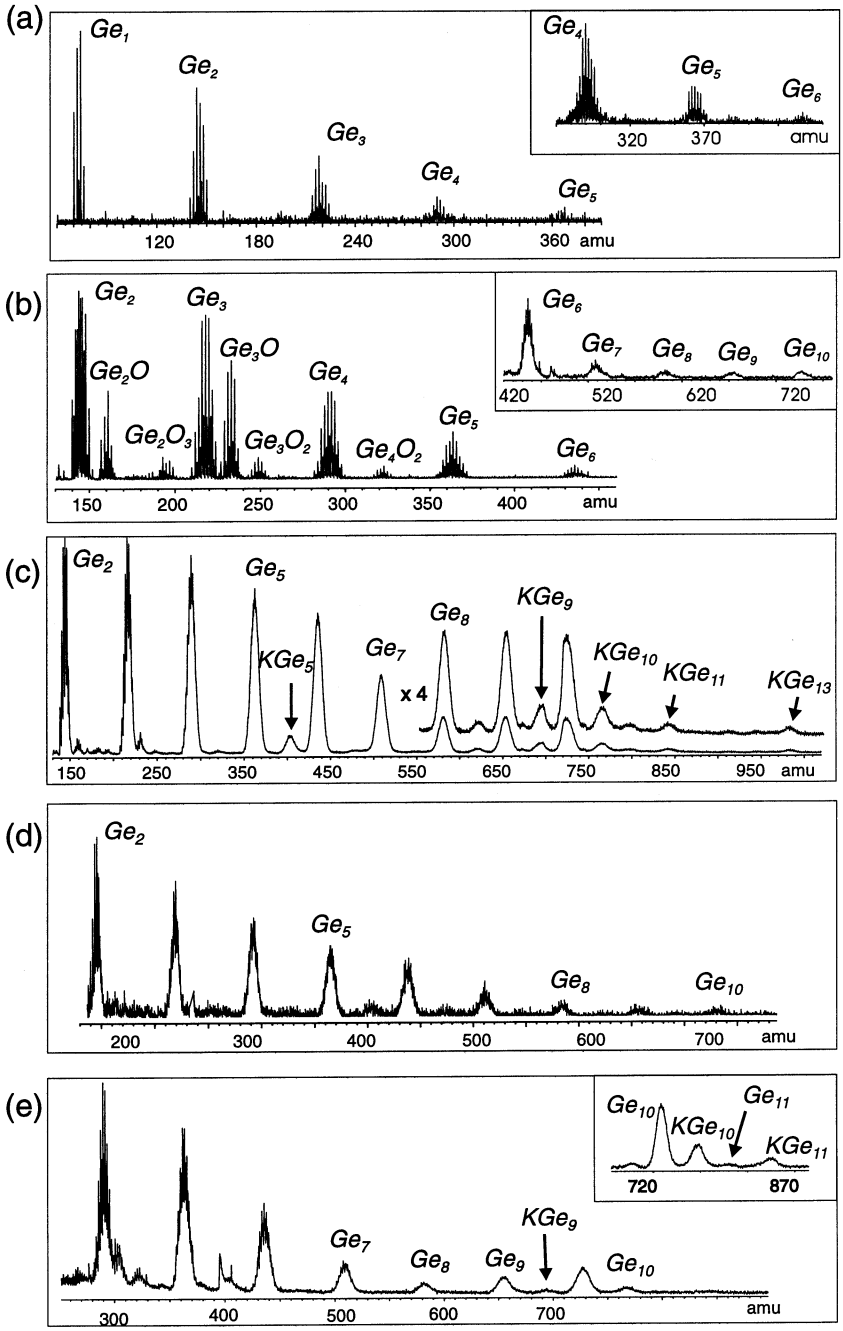
If potassium is present during the laser evaporation process, the formation of larger anionic clusters occurs. The mass spectrum in Figure 3b reveals an exponential decay of the anion intensities from $n = 1$ to 6 for Ge. After a drop of relative intensity, larger clusters ($n = 7-10$) appear with similar intensities. An analogous spectrum is obtained with E = Pb (not shown). No mixed atom clusters KE_n^- are present. For E = Ge and Pb several oxide-containing anions are observed: Ge_2O^-, $Ge_2O_2^-$, $Ge_2O_3^-$, Ge_3O^-, $Ge_3O_2^-$, $Ge_3O_3^-$, $Ge_4O_2^-$ and the series $Pb_nO_{n+1}^-$ as well as $KPb_nO_{n+1}^-$ ($n = 2-6$) are predominant. The enhanced formation of oxides is probably caused by oxygen impurities in elemental potassium or partial oxidation of the surface of the samples during sample transfer to the mass spectrometer. Certainly, the alkali metal acts as an electron donor, and thus promotes the anion cluster formation in the plasma. Lead cation abundance using the mixture as source is similar to the mass distributions from pure metal sources.

Binary Phases of Nominal Composition "K_4E_9" (E = Ge, Sn, and Pb)

Recently, binary A/E = 4:9 phases have been structurally characterized for E = Ge and Sn and A = K, Rb, Cs[20]. They contain discrete E_9^{4-} cluster ions. In the case of E = Pb the existence of a 4:9 phase was discussed earlier[5]. The results of the desorption experiments are shown in Figure 3c for E = Ge. Clusters with maximum size $n = 13$ are observed. The ion signals of the homoatomic clusters Ge_n^- show a decay in intensity up to cluster size $n = 8$. The nine- and ten-atom clusters occur with similar intensities as the eight-atom cluster. Species containing 11 to 13 atoms are detected at lower relative intensities. The formation of mixed metal clusters KGe_n^- for $n = 5$, 9, and 10 is favored, accompained by ions with $n = 8$, 11, and 13 at lower intensities.

In the case of E = Sn and Pb, the anionic clusters occur with a stronger decay in relative intensity in the higher mass

Figure 3. Mass spectra of Ge_n^- clusters obtained from a) elemental Ge, b) mixture of K and Ge, c) K_4Ge_9, d) ethylenediamine extract of K_4Ge_9, and e) $[K([2.2.2]crypt)]_3Ge_9$, containing discrete Ge_9^{3-} clusters; inserts show spectra optimized for the higher mass regions (delayed extractions)



region and reach a maximum cluster size of 10 atoms. Mixed metal clusters KSn_n^- or KPb_n^- are absent but the anions $KSn_2O_3^-$, $KSn_3O_4^-$, KPb_9O^-, and $KPb_{10}O^-$ are present.

Ethylenediamine (en) Solutions of Phases of Nominal Composition "A_4E_9" (E = Ge, A = Na, K, Rb; E = Sn, Pb, A = K)

If phases of nominal composition Na_4E_9 (E = Ge, Sn) are dissolved in en, the crystalline product $[Na_4 \cdot x\ en]\ E_9$ ($x = 0-7$) can be isolated after slow evaporation of the solvent[21]. Using K instead of Na leads to products with similar compositions. The mass spectra of residues of en solutions of K_4Ge_9, K_4Sn_9, and K_4Pb_9 are shown in Figures 3d, 4a, and 5a, respectively. The spectra of the en solutions of Na_4Ge_9 (not shown), K_4Ge_9, Rb_4Ge_9 (not shown), and K_4Pb_9 reveal very similar mass distributions and relative intensities. E_n^- clusters are observed with an exponential decay of their intensities with increasing mass for $n \leq 10$. $NaGe_5^-$, KGe_5^-, KGe_6^-, $RbGe_5^-$, and $RbGe_{10}^-$ are also observed. In the lead system several oxides as dis-

cussed earlier are present. In K_4Sn_9 the occurrence of ion pairs Sn_n^- and Sn_n^- + 56 (±1) amu, corresponding to the mass of Sn_n and KSn_nO, respectively, is prominent. These peaks are present for $7 \leq n \leq 12$ (Figure 4a). Notice the high abundance of the $KSn_{11}O^-$ anion. For larger n the ternary ions show higher abundance than Sn_n^- anions.

Figure 4. Mass spectra of Sn_n^- clusters obtained from a) ethylenediamine extract of a solidified melt of nominal composition K_4Sn_9, and b) $[K([2.2.2]crypt)]_3Sn_9$, containing discrete Sn_9^{3-} clusters; for insert cf. caption of Figure 3

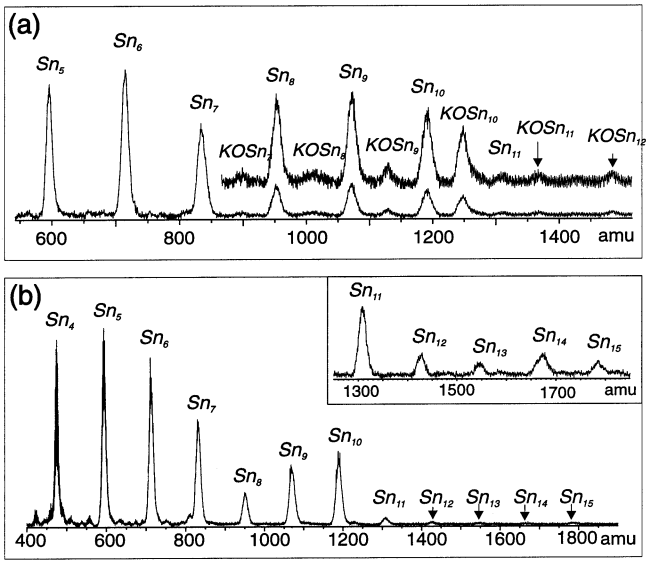


Figure 5. Mass spectra of Pb_n^- clusters obtained from a) ethylenediamine extract of a solidified melt of nominal composition K_4Pb_9, and b) $[K([2.2.2]crypt)]_3Pb_9$, containing discrete Pb_9^{3-} clusters; for inserts cf. caption of Figure 3

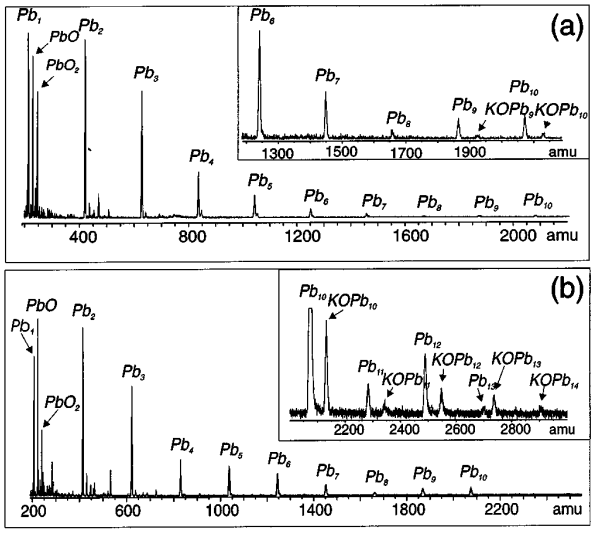

Compounds Containing E_9^{3-} Zintl Ions Separated by K-[2.2.2]crypt Units (E = Ge, Sn, Pb)

On use of the alkali-metal-sequestering reagent [2.2.2]crypt[6] crystalline compounds $[K-[2.2.2]crypt)]_3E_9$ containing discrete polyanions can be isolated from the en solutions of the A_4E_9 alloys[7][17]. Photodesorption and photoionization of these Ge, Sn, and Pb compounds leads to the formation of ions of size $1 \leq n \leq 11$ (Figure 3e), $1 \leq n \leq 15$ (Figure 4b), and $1 \leq n \leq 13$ (Figure 5b), respectively. An exceptional increase of abundance with respect to smaller clusters of cluster size $8 \leq n \leq 10$ is observed. The intriguing difference to the other experiments is the occurrence of larger clusters. For E = Ge the spectrum is very similar to that of "K_4Ge_9" (Figure 3c); however, mixed metal anions are less frequent. The same holds for E = Sn, where a very high abundance of E_{10} and the occurrence of a cluster series with $11 \leq n \leq 15$ at lower intensities is visible (Figure 4b). Desorption of the lead compound leads to a series of clusters $1 \leq n \leq 10$ with exponential decay of intensity (Figure 5b). The maximum size of Pb_n clusters is limited to $n = 13$. The higher mass region shows predominant peaks of ion pairs [Pb_n + 56 (±1) amu] as found in the case of Sn (Figure 4a), corresponding to the series KPb_nO^- with $n = 10-14$.

Discussion

We found that the relative abundance of ions depends strongly on the nature of the starting material used for the desorption process. The desorption conditions used in this investigation generate *cluster anions* from pure elements E with a maximum size of 6 atoms and display an exponential and monotone decrease of their relative intensities with increasing cluster size. In the case of E = Sn the results are consistent with a recent investigation using direct laser ablation of tin metal in an ICR cell[22]. We observe larger anionic clusters in the presence of alkali metals, e.g. from mixtures of the elements K/E, from phases of nominal composition K_4E_9, and from residues of ethylenediamine solutions of these phases. Clusters E_n with maximum size of 13, 12, and 10 atoms are found for E = Ge, Sn, and Pb, respectively. On use of compounds containing preformed E_9^{3-} clusters separated by large counterions $(K-[2.2.2]crypt)^+$, gas phase species with maximum sizes up to 15 E atoms are found (KGe_{11}^-, Sn_{15}^-, and $KOPb_{14}^-$). The general feature of the spectra is a decay of intensity as the number of constituent cluster atoms increases from one to seven and a minimum in intensity for clusters of eight atoms. Nine- and ten-atom clusters are found with similar or increased intensity relative to the abundance of eight-atom clusters. The increase of intensity of clusters with $n = 9$ and 10 are most pronounced in $[K-([2.2.2]crypt)]_3E_9$ as source. The maximum cluster size for *cations* is 6 atoms, however, much smaller intensities are measured.

The ion distributions do not correlate to photoelectron threshold energies and thus electron affinities of the E_n clusters, generated by other techniques. Higher values are ob-

served for $n = 5$ and 9 for Ge[23], 5 and 8 for Sn, and 5, 10, and 11 for Pb[18]. This is in contrast to the relative intensities observed in our experiments, where exponential decays with increasing size or intensity minima for $n = 8$ are found. Also, if electron affinity would dominate the occurrence of specific mass peaks in the spectra, a similar abundance of clusters should be found, independent of the sample used as starting material.

Conclusions and Comparison to Solid-State Analogues

Naked polyatomic ions of the type E_n^{x-} belong to the class of Zintl ions. Many of these ions cannot be described using classical electron counting rules such as the octet rule; thus, bonding models with electron delocalization (e.g. molecular orbital theory and related electron counting rules for clusters) are used for their electronic description. According to electron-counting rules for deltahedral clusters an *n*-vertex *closo*-deltahedron is stable if $n + 1$ skeletal orbitals are filled. As cluster size increases, a deviation from the expected number of electrons (or structures) is possible. Variable electron counts are especially observed for clusters of the heavier elements E, which have smaller HOMO-LUMO gaps[24]. Interestingly, ligand-free polyhedral clusters E_9 occur more frequently with additional electrons. E_9^{3-} and E_9^{4-} clusters with 21 and 22 skeletal electrons, respectively, possess deltahedral structures, albeit distorted and a compromise between tricapped trigonal prismatic (*closo*) and monocapped quadratic antiprismatic (*nido*)[7]. The E_n^- anions investigated here in the gas phase might correspond to $2n + 1$ skeletal electron clusters and might therefore also adopt to deltahedral structures. In other words the single-charged gas-phase anions might be regarded as *closo*-type clusters with a deficiency of one electron. Indeed, density functional studies on anionic Sn_n^- clusters confirm that the species adopt *closo* structures at the optimized minimum energies for $n = 5$, 6, and 7[22].

It has been pointed out earlier that clusters with one negative charge (e.g. E_n^-) are probably not stable in the solid state due to an inherent insufficient cation presence for anion separation[25]. Although no E_9^- species has been hitherto isolated from solution, the variability of electron numbers for these clusters makes the existence of singly charged ions with deltahedral structures more likely. Recent electrochemical investigations show that Ge_9^{3-} undergoes two pseudo reversible oxidative electron processes and therefore Ge_9^- might be a stable cluster. Oxidation of Sn_9^{3-} and Pb_9^{3-} in solution is possible, but is accompanied by an adsorption process making the interpretation more difficult[26]. Even more intriguing is the high abundance of KE_n^- ions. The formation of the mixed element clusters KGe_n^- for $n = 5$, 9, and 10 is predominant beside $n = 8$, 11, and 13 at lower intensities. Applying the *Zintl-Klemm-Busmann*[27] concept applicable to binary phases also to the KGe_n^- ions[1] – in other words transferring the valence electron from the more electropositive K atom to the element cluster – the doubly charged and according to Wades rules electron-precise Ge_n^{2-} Zintl ions result.

The exceptional occurrence of KGe_{13}^- and Sn_{15}^- anions attests to the possible existence of large Zintl ions. Remarkable is the fact that the counterion [K-[2.2.2]crypt]$^+$ is capable of good crystal packing also with very large anions such as C_{60}^{2-}[28]. However, large *n*-vertex polyhedra with $n > 10$ of the elements Ge and Sn are known only as structural units in three-dimensional anionic networks of Zintl phases. Pentagonal dodecahedra E_{20} which are centered by A atoms are found as linked building blocks in the Zintl phases A_4E_{22}[29] and $A_{6+x}E_{25}$[30].

In summary, we see a tendency for the formation of larger clusters, especially if preformed cluster units or electropositive elements are already present in the precursor. The latter point indicates a more general application for anion formation in plasmas. Owing to the possible variable electron counts of polyhedral clusters, the gas-phase monoanionic Zintl ions are in close relation to polyanions found in solution and in the solid state. Therefore these results suggest the possibility that large, discrete main-group clusters of Ge, Sn, and Pb may also exist in solution or in the solid state.

The authors like to thank Dr. *W. Amrein* for the use of the TOF mass spectrometer and the *Eidgenössische Technische Hochschule Zürich* for financial support.

Experimental Section

The elements Ge, Sn, Pb, and K, Na, Rb were purchased from Fluka and Aldrich and used without further purification. The syntheses of the binary phases, the ethylenediamine solutions of the latter, and the compounds [K-[2.2.2]crypt]$_3E_9$ are described elsewhere[17]. The mixtures of the elements K/E were prepared in an argon-filled dry-box by stirring the corresponding group-14 element with a slight excess (by weight) of molten alkali metal at 200°C. The solid samples were pressed in a recess of a stainless steel target of 3 mm in diameter. The ethylenediamine solutions of the binary A_4E_9 phases, as well as the acetonitrile solutions of [K-[2.2.2]crypt]E_9 salts were transferred to the target in an argon-filled dry-box and the solvent was subsequently removed under vacuum. During the transfer of the targets into the mass spectrometer, the samples were briefly exposed to air (approx. 5–10 s).

The mass analysis was carried out with a reflector time-of-flight (RETOF) mass spectrometer (Bruker Reflex™). Desorption and ionization of the clusters were achieved in a single step with a pulsed N_2 laser (337 nm, 3.7 eV, pulse duration: 3 ns; pulse frequency: 3–5 Hz) operating at a maximum pulse energy of 0.1 mJ. The spectra shown here are accumulations of 20–50 laser shots at acceleration voltages ranging from 7–15 kV in the negative ion mode. For each accumulation the laser power is adjusted slightly above the threshold level for detection of ion signals by the use of a variable attenuator. In order to enhance the intensity and resolution of ions with masses greater than 600 amu, ions of lower masses, i.e. shorter flight times, are ejected by applying an electric field between the two deflection plates by a rectangular signal triggered by the pulsed laser (delayed extraction). We like to emphasize that no special clustering conditions (e.g. gas expansion) are used for the generation of the clusters.

Keywords: Layered double hydroxides / Hydrotalcite-like compounds / Magnesium / Aluminium / Intercalation

Hydrotalcite-like anionic clays of general formula $[M(II)_{1-x}M(III)_x(OH)_2]^{x+}[CO_3^{2-}{}_{x/2}]^{x-} \cdot m\ H_2O$ with M(III) = Al and M(II) = Mg, Ni, Zn have been prepared by precipitation of the hydroxycarbonates from the "homogeneous" solution after the thermally induced hydrolysis of urea. The effect of the temperature of precipitation, of the total metal cations concentration, of the molar fraction M(III)/M(III) + M(II) and of the molar fraction urea/M(II) + M(III) in solution on the composition and on the crystallinity degree of the samples has been investigated. The optimum conditions are reported to obtain micro-crystalline powders with a narrow distribution of particle size in a short time with a simple procedure. The compounds obtained have been characterised for chemical composition, thermal behaviour, particle-size distribution and BET-surface area. In addition, the crystal structure of $Mg_{0.67}Al_{0.33}(OH)_2\ (CO_3)_{0.165} \cdot 0.4\ H_2O$ has been refined by X-ray diffraction powder methods. The carbonate form has been converted into the chloride form by letting gaseous HCl flow over the hydrotalcite-like compounds, heated at 150 °C. The exchange of Cl^- anions with some alkoxide anions in the presence of the respective alkanols has been investigated. The exchange reaction was driven by the segregation of NaCl crystals poorly soluble in alkanols and led to the co-intercalation of the alkoxide ions together with the alkanol with the formation of a bi-layer of extended alkyl chain in the interlayer region of the Mg-Al hydrotalcite. The intercalation compound, washed with water, produces a hydrotalcite with Cl^- and OH^- as balancing anions.

Hydrotalcite-like compounds (HTlc) form, at present, a large class of inorganic materials, extensively studied as catalysts, precursors and supports of catalysts, anionic exchangers, sorbents, additives[1][2][3][4][5]. Furthermore, the HTlc are, practically, the only known family of layered solids with positively charged layers and interlayered charge balancing anions that may be replaced by ion-exchange processes. The structure of HTlc originates from the packing of layers built up in a manner similar to that found in brucite, the naturally occurring $Mg(OH)_2$. In this mineral, the Mg atoms are octahedrally co-ordinated by six oxygen atoms belonging to six OH groups; each OH group is, in turn, shared by three octahedral cations and points to the interlayer space[6]. When some of the Mg(II) cations are isomorphously replaced by Al(III) cations, carbonate anions are inserted between the metal hydroxide sheets to maintain the electroneutrality and the mineral hydrotalcite, with ideal formula $Mg_6Al_2(OH)_{16}CO_3 \cdot 4H_2O$, is obtained[7]. Hydrotalcite and hydrotalcite-like minerals are rare in nature but it is relatively simple and cheap to prepare these compounds on a laboratory scale.

The general formula of synthetic HTlc is often written as $[M(II)_{1-x}M(III)_x(OH)_2]^{x+}[A^{n-}{}_{x/n}]^{x-} \cdot m$ S, where M(II) may be Mg, Zn, Co, Ni, Mn, etc.; M(III) may be Al, Cr, Fe, V, Co, etc.; A^{n-} is the charged compensating anion (CO_3^{2-}, SO_4^{2-}, Cl^-, NO_3^-, organic anions, etc.); m the number of mols of co-intercalated solvent (S), generally water, per formula weight of compound. The number of mols x of M(III) cation per formula weight of compound, generally ranges between 0.2 and 0.33, and its value determines the charge density of the layer[3][4].

Most of the synthetic HTlc are prepared by co-precipitation of the chosen M(II) and M(III) hydroxides with diluted NaOH and/or $NaHCO_3$ or Na_2CO_3 solutions. Poorly crystalline samples are generally obtained, unless a low degree of supersaturation and a relatively high temperature are maintained during precipitation. However, to obtain well-crystallised samples a hydrothermal treatment, i.e. digestion of the gel at 180−200 °C under pressure, is often required[1][4]. In an attempt to prepare HTlc with a good degree of crystallinity using simpler methods, we turned our attention to methods known as precipitation from "homogeneous" solutions and found that the hydrolysis of urea in the presence of a mixture of M(II) and M(III) salts leads to the formation of HTlc with good crystallinity degree and a narrow distribution of particle size. This result is rather surprising since research papers and quantitative analysis textbooks[8][9] recommend the urea method for precipitating aluminium in the presence of magnesium.

This paper describes the preparative conditions of some HTlc anionic clays by the urea method, the physico-chemical characterisation of the products thereby obtained, and the preparation of some intercalation compounds with alkoxides. In addition, a novel method to convert the carbon-

ate form of HTlc into the chloride form, by gas-solid reaction is reported.

Results

Preparation of the Hydrotalcite-Like Compounds

Urea has a number of properties that makes its use as an agent for precipitation from "homogeneous" solution very attractive and it has long been used in gravimetric analysis to precipitate several metal ions as hydroxides or as insoluble salts when in the presence of a suitable anion[9]. Urea is a very weak Brønsted base (pK_b = 13.8), highly soluble in water, and its hydrolysis rate may be easily controlled by controlling the temperature of the reaction. According to Shaw and Bordeaux[10] the mechanism of hydrolysis consists of the formation of ammonium cyanate, as the rate-determining step, and the fast hydrolysis of the cyanate to ammoniun carbonate, i.e.:

$$CO(NH_2)_2 \rightarrow NH_4CNO$$
$$NH_4CNO + 2H_2O \rightarrow (NH_4)_2CO_3$$

The rate constant increases by about 200 times when the temperature is increased from 60 to 100°C. The hydrolysis of ammonium to ammonia and carbonate to hydrogen carbonate gives a pH of about 9, depending on the temperature. This pH is suitable for precipitating a large number of metal hydroxides.

After some preliminary positive tests, a wider investigation was undertaken to find the optimal conditions to produce, with a simple procedure, HTlc microcrystals of uniform size, well crystallised, and with the required stoichiometry. The following couples of cations, as chlorides, were considered: Mg(II)-Al(III); Zn(II)-Al(III); Ni(II)-Al(III). In the case of Zn(II), a weighed amount of ZnO was dissolved in a stoichiometric amount of 6 mol/dm^3 HCl solution.

Solid urea was added to 0.5 mol/dm^3 metal chloride solutions, having molar fraction M(III)/M(III) + M(II) equal to 0.33, until the molar ratio urea/M(II) + M(III) reached the value 3.3. The clear solutions were heated, under stirring, at temperatures between 60 and 100°C. As expected, longer precipitation times were observed for the lower temperatures. However, all the materials showed XRPD patterns typical of hydrotalcite-like compounds. A preliminary rough analysis of the variation of the crystallinity degree as a function of the precipitation temperature was made on the basis of the quality of the X-ray diffraction patterns of the samples, that is the number of reflections, their intensity and width at half-height. The results shown in Table 1 (see also Figure 1) indicate that hydrotalcite-like compounds with a good crystallinity degree were obtained in the 90−100°C temperature range after 24−36 h of precipitation.

Further characterisation was performed taking into account the preparation of the Mg-Al HTlc, maintaining the temperature at 100°C and the precipitation time at 36 h. Table 2 reports the composition, expressed as a molar fraction in the solid, X_{sol} = Al(III)/Al(III) + Mg(II), and the crystallinity degree of several samples, as a function of the total concentration of the cations, of their molar fraction in solution and of the urea/Al(III) + Mg(II) molar fraction. The data of Table 2 show that the variation of the indicated parameters does not markedly affect the crystallinity degree of the samples, even though the most crystalline samples were obtained at values of the urea/Al(III) + Mg(II) fraction close to 4 and at a value of the total metal ion concentration of 0.5 mol/dm^3. Temperature seems to be the most important parameter to control in order to produce well crystallised samples.

It is interesting to note that the molar fraction Al(III)/Al(III) + Mg(II) of the solids reaches values near to 0.32 even when the corresponding values in solution are as low as 0.2. As already discussed, the precipitation of the HTlc occurs at pH values of 8.5−9.0 (the hydrolysis pH of ammonium carbonate) and at these pH values the solubility of magnesium hydroxide is much higher than that of aluminium hydroxide. Therefore almost all the alluminium is co-precipitated with the magnesium ions to obtain a solid with the stoichiometry of two Mg(II) for each Al(III). This corresponds to an ideal disposition in the brucite-like sheet of each aluminium atom surrounded by six magnesium atoms. In general, the Al(III) molar fraction in the solid is higher than that in solution and it is possible to reach val-

ues near to 0.44 value, indicated by Pausch et al.[11] as the maximum for a pure HTlc.

However, in order to prove the absence of co-precipitated $Al(OH)_3$ in the samples, the molar ratio CO_3^{2-}/Al^{3+} in the solid was determined. In all cases the molar ratio CO_3^{2-}/Al^{3+} in the solid was found to be near to 0.5 (see Table 2), as expected for pure HTlc and we may exclude the presence of co-precipitated aluminium hydroxide.

Therefore, the urea-method is not indicated for the preparation of Mg-Al HTlc with low charge density but allows the preparation of compounds with high charge density not easily obtainable with the other proposed procedures[4]. However, if the M(II) hydroxide is much more insoluble than the $Mg(OH)_2$, the HTlc obtained has a composition very near to that predicted from the composition of the solution. This is the case, for example, for the Zn-Al and Ni-Al systems. As may be seen from the data of Table 3 the Al molar ratio in the solid was found to be very near to that of the precipitating solutions.

Table 3. Effect of the metal ion concentration on the crystallinity degree and on the composition of Zn-Al-HTlc and Ni-Al-HTlc; conditions of precipitation: total metal ion concentration 0.5 mol/dm^3, molar fraction urea/M(II) + Al(III) = 3.3, temperature and time 100°C and 36 h

[a] g = good; v = very.

At the end of this investigation, we suggest the following simple procedure to obtain HTlc with a good crystallinity degree in a relatively short time. Solid urea is dissolved in a solution 0.5 mol/dm^3 in the chosen metal chlorides, [molar ratio M(III)/M(II) + M(III) equal to 0.33 M(III) = Al; M(II) = Mg or Ni or Zn], to reach urea/metal ions molar ratio of 3.3. The clear solution is maintained at 100°C, or even at the refluxing temperature, for 36 h. If the digestion time is prolonged, the crystallinity degree of the samples is slightly improved. The solids, separated from the solution, are washed with distilled water up to a negative test for chloride ions. Finally, they are air-dried and stored in a desiccator with P_4O_{10} at room temperature.

Physico-Chemical and Structural Characterisation

Empirical formula and water content were determined by thermoanalytical methods. Specific surface-area and particle-size distributions of selected samples were also measured. The crystallographic parameters of a well-crystallised Al-Mg HTlc were obtained from X-ray powder diffraction patterns.

Table 4 collects the data of composition, interlayer distance and B.E.T. specific surface area. The XRPD patterns of these samples are reported in Figure 2.

Table 4. Composition, interlayer distance and B.E.T. specific surface area for HTlc obtained by urea hydrolysis; conditions of precipitation: total metal ion concentration 0.5 mol/dm^3, molar ratio urea/M(II) + Al(III) = 3.3, temperature and time 100°C and 36 h

M(II)-M(III)-HTlc	Composition	d [Å]	Surface area [m^2/g]
Mg-Al	$[Mg_{0.67}Al_{0.33}(OH)_2](CO_3)_{0.165}\cdot 0.48\ H_2O$	7.57	24.1
Zn-Al	$[Zn_{0.65}Al_{0.35}(OH)_2](CO_3)_{0.175}\cdot 0.48\ H_2O$	7.55	24.9
Ni-Al	$[Ni_{0.69}Al_{0.31}(OH)_2](CO_3)_{0.155}\cdot 0.76\ H_2O$	7.98	47.4

Figure 3 shows the coupled TG-DTA curves of the Al-Mg and Al-Ni HTlc. The shape of the curves reflects the good crystallinity degree of the samples and, in both cases, the curves may be divided into two well-differentiated main regions. In the first one, ranging from 80 to 250°C there is a broad endothermic peak related to the dehydration of the

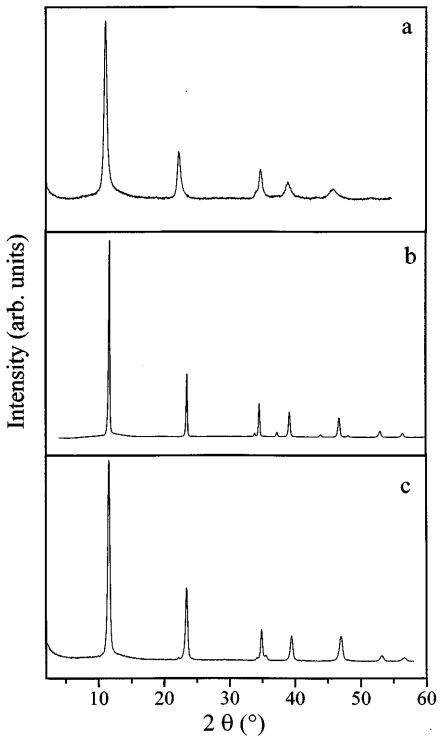

Figure 3. TG (solid line) and DTA (dashed line) curves of (a) Al-Mg-HTlc and (b) Al-Ni-HTlc previously equilibrated over P_4O_{10}; heating rate 5°C/min, air-flow 30 ml/min

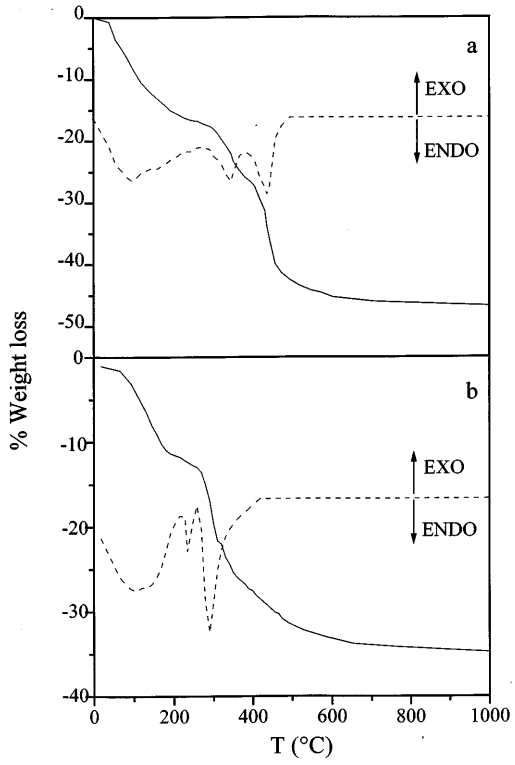
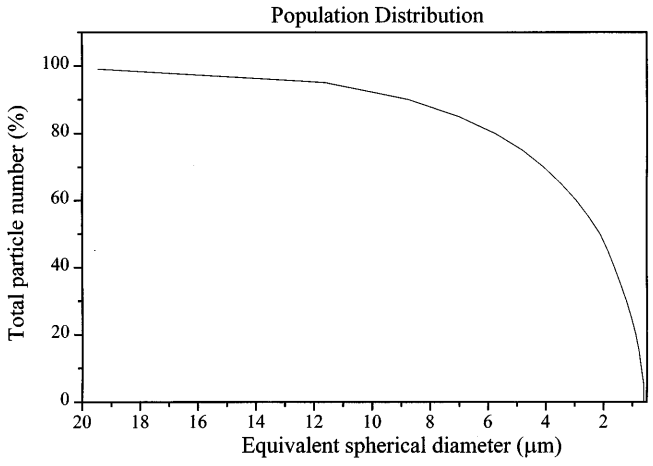


samples. The second region, corresponds to the weight loss due to the dehydroxylation and de-carbonation reactions, that, as discussed by Rey et al., overlap in this temperature range[12]. The XRD patterns of the samples heated at 1000°C show the typical reflections of MgO (or NiO) and of the $MgAlO_2$ (or $NiAlO_2$).

Figure 4 shows the cumulative particle-size distribution of the Mg-Al HTlc. It shows that more than 90% of particles have a diameter between 10 and 0.5 μm. The microcrystals are well formed and appear as hexagonal platelets, as shown in the SEM photograph (Figure 5).

Having at our disposition microcrystalline powders of good crystallinity degree, attempts were done to use the Rietveld method to refine the Al-Mg HTlc structure. Accurate positions of XRPD maxima were first determined by a peak-fitting procedure, using a pseudo Voigt function for the peak-profile description. The pattern was then indexed by the TREOR program[13] using the first 18 peaks. The parameters of the hexagonal cell found were a = 3.044 Å, c = 22.703 Å [$M(18)$ = 35] in good agreement with those already known[6]. All the reflection indexes followed the $-h + k + l = 3n$ rule, in agreement with the expected R-3m space group. The Rietveld refinement was then carried out by the GSAS program[14] using, as starting model, the structural parameters reported in ref.[7]. The refinement included a 5-terms Fourier cosine series function for the background and a modified pseudo Voigt peak-profile function. March-Dollase correction was employed to model

Figure 4. Population distribution as a function of equivalent spherical diameter for microcrystals of Al-Mg-HTlc



the preferred orientations. No corrections were made for absorption effects. The *003* reflection was not included in the refinement because of its strong asymmetry. When the refinement was stopped, the shifts in all the refined parameters were less than their estimated standard deviations, and the following residual values were reached: wRp = 8.7%; Rp = 6.6%; R_F = 4.4%. A difference Fourier map calculated at this stage, did not reveal any peak larger than 0.5 electron density units. The Rietveld plot is shown in Figure 6. The atomic parameters and main geometrical data ob-

Chemical Reactivity

A large research program, involving the ion-exchange properties, the interlayer reactivity, the storage in the interlayer region and subsequent release of species of pharmacological and biological interest has been undertaken to study the chemical reactivity of the HTlc, prepared by the urea method. Here we report new methods to convert the HTlc in the Cl^- and OH^- forms. These exchanged forms are commonly considered[4] the best precursors to intercalate other charged and neutral species even of large dimensions.

The carbonate anions fit well in the hexagonal arrangement of the hydroxy ions of the brucite-like sheets, and this accounts for their high affinity for HTlc[1]. The exchange of carbonate for others anions (Cl^-, NO_3^-, SO_4^{2-}) is then performed by treating the solid with diluted solutions of the corresponding mineral acid[15]. The exchange reaction is driven by the release of gaseous CO_2, but a concomitant slight dissolution of the solid can take place. To avoid these effects we used the gas-solid exchange reactions already employed to convert layered zirconium phosphate into some salt forms[16]. We passed a stream of water vapour and gaseous HCl through Mg-Al-CO_3 HTlc maintained at 140−160°C in a glass tube. At these temperatures Mg-Al-CO_3 HTlc has a very small CO_2 vapour pressure[17] and in the presence of hydrochloric acid the following reaction takes place:

$$Mg_{0.67}Al_{0.33}(OH)_2(CO_3)_{0.165} + 0.33\ HCl \rightarrow Mg_{0.67}Al_{0.33}(OH)_2Cl_{0.33} + 0.165\ CO_2 + 0.165\ H_2O$$

After preliminary positive tests, the procedure was optimised as follows: 1 g of Mg-Al CO_3 HTlc was heated at 150°C in a glass tube for one hour. A stream of N_2, passed through a 6 mol/dm^3 HCl solution at a flux of about 40 ml/min, was allowed to flow over the sample for 8 h. From time to time the presence of CO_2 was monitored by bubbling the escaping gas in barite solution. When the $Ba(OH)_2$ solution was clear, the heating was stopped and the sample recovered. Ion-chromatography analysis showed that the conversion was completed and the XRPD patterns (see Figure 7) showed that the material maintained a good crystallinity degree.

It is well known that Mg-Al HTlc may be obtained in the OH^- form taking advantage of the so-called "memory effect"[12]. According to this method, hydrotalcite in carbonate form is first heated to 400−450°C, the mixture of metal oxides thus obtained is then dispersed in water and reconstruction of the layered structure occurs, the positive charges being balanced by the OH^-. Alternatively, the chloride ions of Mg-Al-Cl HTlc may be replaced by hydroxide ions by equilibrating the solid with a diluted NaOH solution. A slight dissolution of the solid may also occur. However, in both cases a loss in crystallinity degree of the samples is observed.

Searching for methods that would lead to hydrotalcites in hydroxy form, in the cases in which they do not show the "memory effect" or when it is difficult to perform the ion exchange process in water, we considered the exchange of Cl^- for alkoxide ion in alkanol media. The alkoxide

form, treated with water, would immediately give rise to the hydroxide form. Furthermore, it was of interest to see whether bases stronger than the OH^-, would be stabilised in the interlayer region of the hydrotalcites.

One gram of $Mg_{0.67}Al_{0.33}(OH)_2Cl_{0.33}$, prepared as above, and dehydrated at 150°C, was equilibrated in 100 cm^3 of ROH containing 0.1 mol/dm^3 of RONa (R = nC_3H_7, nC_4H_9, nC_5H_{11}, nC_6H_{13}) for two days at room temperature. The solid was separated from the solution by centrifuging under N_2. The equilibrating solution did not contain an appreciable amount of Cl^- ions as though the ion exchange process had not taken place. The XRPD patterns of the solid samples, still wet with the alkanol solution, showed indeed a large shift of the first diffraction maxima towards low angles, indicating that an intercalation process had occurred. Figure 8 shows the XRPD patterns of the sample treated with sodium butoxide in *n*-butanol. Two sharp reflections at 2Θ = 27.25° and 31.47°, typical of cubic NaCl, are present. The exchange Cl^-/RO^- has indeed occurred, driven by the segregation of NaCl crystals, insoluble in alkanols.

Figure 8. XRPD patterns of the Mg-Al-Cl-HTlc equilibrated with 0.1 mol/dm^3 sodium butoxide in *n*-butanol; the peaks of NaCl microcrystals are marked by an asterisk

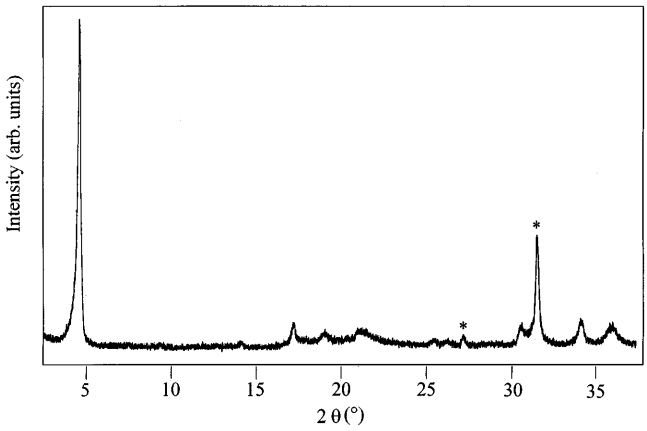

Figure 9 shows the interlayer distance of the alkoxide-exchanged HTlc as a function of the number of carbon atoms in the alkyl chain. Note that the intercept is close to the value of the interlayer distance of the compound in OH form, while the increment of the interlayer distance for each additional carbon atom, 2.3 Å/carbon atom, is consistent with the presence of a bi-layer of alkyl chain in the interlayer region. Since the cross-sectional area of a *trans-trans*-alkyl chains is estimated to be 18.6 Å[18] and the free area surrounding each positive charge on one side of the layer is 48 Å^2, the interpenetration of the alkyl chain of the alkoxide ions interacting with the two facing sides of the lamellae was expected to produce a monolayer similar to that depicted in Figure 10 and found in the intercalation of *n*-alkyl carboxylate anions[2]. The formation of the bi-layer may be explained by the fact that the Cl^-/RO^- exchange occurs in ROH media and that the alkanol molecules are co-intercalated to produce a bi-layer similar to the one shown in Figure 11. Treating the alkoxide-exchanged HTlc with water, we observed a partial washing of the NaCl crystals and a sudden increase of the pH of the washing solution. In the presence of water, the RO^- is readily transformed into the corresponding ROH and the OH^- assumes the role of bal-

ancing charge. No variation of the pH of the solution should occur. In the presence of Cl^- ions, however, some Cl^-/OH^- exchange takes place and the pH increases.

Conclusion

At present we do not know whether the urea method, proposed in this paper, to prepare HTlc has general applicability. Preliminary results indicate that the method also works well for the Mg-Fe-CO_3 and for the Al-Li-CO_3 HTlc. Some difficulties arise in the presence of cations such as Cr(III) or Cu(II). In such cases the method will require some modification and improvement. This is not surprising, if we agree with the concept already expressed by Riechle[1], that each layered double hydroxide requires its own procedure to be obtained in the best way. However, Mg-Al, Ni-Al and Zn-Al hydrotalcites have been obtained with the urea procedure and the materials have a high crystallinity degree and a narrow distribution of particle size. The high crystallinity degree has allowed the refinement of the structure with the Rietveld method.

A novel method to convert the carbonate into the chloride form, based on a gas-solid reaction has been proposed. Bases as strong as alkoxides were successfully intercalated. Further study is in progress to obtain the pure OH^- form, starting from alkoxide derivatives.

This work was supported by *M.U.R.S.T.* and *C.N.R.*

Experimental Section

Materials: All the reagents used were of analytical grade (C. Erba RPE-ACS). Alkoxides were prepared by a reaction of metallic sodium and the corresponding alkanol, previously dehydrated over CaO.

Analytical Procedures: To obtain the chemical composition of the HTlc, weighed amounts of the samples (ca. 100 mg) were dissolved in a few drops of concentrated HCl and diluted with water to 50 ml. The metal ion content of the latter solution was determined with standard EDTA titrations [Mg(II), Al(III), Ni(II), Zn(II)] and atomic absorption spectroscopy [Mg(II), Ni(II), Zn(II)]. The carbonate anion content of HTlc was obtained both with C elemental analysis and thermogravimetry. Anions, unlike carbonate, were determined by ion chromatography (DIONEX 2000 I/SP), after elution of the anion with 1 mol/dm^3 sodium carbonate solution. The water content was obtained by thermogravimetry.

Instrumentation: Coupled TG-DTG-DTA thermogravimetric curves were obtained with a Stanton-Redcroft STA 780 Analyzer at a heating rate of 5°C/min, under an air flow. − X-ray powder diffraction (XRPD) patterns were taken with a computer-controlled PW 1710 Philips diffractometer operating at 40 kV, 30 mA, using a PW 1820 goniometer, supplied with a bent graphite monochromator in the diffracted beam, and Cu-K_α radiation. XRPD patterns for indexing and structure refinement were taken with the step-scanning technique. The samples were prepared using the side-loading procedure in order to minimize preferred orientations. Diffractograms were collected from $2\Theta = 6$ to 120° using steps of 0.01° and a counting time of 20 s per step. − N_2 adsorption-desorption isotherms were taken by Sorptomatic 1800 supplied with an outgassing unit (C. Erba Strumentazione). − Particle-size distribution was obtained by means of an AccuSizer™ 770 Optical Particle Sizer, Santa Barbara, CA 93117, USA. − The scanning electron microscopy (SEM) photographs of the microcrystals were taken with a Philips XL30 apparatus.

Keywords: Layered compounds / Zirconium / Amino acids / Zirconium L-(+)-serinephosphates / Intercalation

A layered derivative of α-zirconium phosphate containing L-(+)-serine covalently attached to the inorganic layer has been prepared by allowing Zr fluoro complexes to decompose in the presence of L-(+)-phosphoserine. On the basis of thermogravimetric weight loss and C,H,N elemental analyses, the layered compound obtained has been formulated as $Zr[HOOCCH(NH_2)CH_2OPO_3]_2$. The X-ray powder diffraction pattern has been indexed with a monoclinic cell (a = 5.3737 Å, b = 9.3231 Å, c = 14.510 Å, β = 96.99°, Z = 2). FT-IR absorption spectra show that the serine groups attached to the inorganic layers are present as zwitterions. Thermal decomposition commences at ca. 250 °C and occurs in two steps: the first is due to a decarboxylation reaction, with the formation of the amino derivative $Zr(NH_2CH_2CH_2OPO_3)_2$, while the second is associated with pyrolysis of the organic moiety, leading to ZrP_2O_7. Despite the presence of the amino acid function in the interlayer region, the compound does not show intercalation ability towards cations or anions or polar species. However, compounds with a certain degree of microporosity and possessing ion-exchange and adsorption properties have been obtained by replacing some of the phosphoserine groups of the compound by HPO_4 groups, to produce the mixed layered derivatives $Zr[HOOCCH(NH_2)CH_2OPO_3]_{2-x}(HPO_4)_x$.

In 1978, Alberti and co-workers showed that it is possible to anchor organic functions to the layers of α-zirconium phosphate [α-$Zr(HOPO_3)_2$] by allowing fluorozirconium complexes to decompose in the presence of organophosphoric or -phosphonic acids[1]. As the complexing agent is slowly removed (i.e. as HF), layered zirconium organophosphates or -phosphonates of the general formulae $Zr(ROPO_3)_2$ or $Zr(RPO_3)_2$ (where R is the organic moiety) with structures similar to that of the inorganic analogue are obtained. This method has attracted the attention of many researchers since a large number of layered compounds with different properties and functionalities can be obtained simply by changing the nature of the R groups[2]. The sole limitation to synthesis is that only groups with a cross-section equal to or less than 24 $Å^2$ can be used, which corresponds to the free area around each POH group present on the surface of the layers of the parent α-$Zr(HOPO_3)_2$[3]. However, more voluminous groups may be attached to the α-layers if their dimensions are compensated for by introducing small groups R′ (e.g. H, OH, CH_3) so as to obtain compounds of the formula $Zr(RPO_3)_{2-x}(R'PO_3)_x$[4].

To date, many organic derivatives bearing different functional groups (alkyl, aryl, carboxylic acid, aldehydic, amino, etc.) and even macrocyclic ligands have been prepared and investigated[5][6][7][8][9]. However, only a few papers on layered derivatives bearing the amino acid function can be found in the literature[10][11], despite the fact this functional group is of interest with regard to its amphoteric character and in view of its ability to coordinatively bind transition metal ions.

We report herein on the results of an investigation of the layered compounds obtained by precipitating Zr^{IV} with L-(+)-phosphoserine or with a mixture of L-(+)-phosphoserine and phosphoric acid. The aim of the work was not only to prepare new derivatives incorporating the amino acid function but also to obtain new stationary phases for chiral recognition, by anchoring chiral groups to a stable and insoluble inorganic backbone.

Results

Preparation and Characterization of α-Zirconium L-(+)-Serinephosphate

Figure 1 shows a computer-generated model of the phosphoserine molecule. The cross-section, evaluated at the level of the amino acid group, is very near to 24 $Å^2$, the maximum permissible value for the preparation of stoichiometric zirconium organophosphates. However, before starting the synthetic procedures, experiments were carried out to assess the stability of the ester bond of phosphoserine in acidic media at 60°C, by recording ^{31}P-NMR spectra of such solutions at regular intervals. The hydrolysis of phosphoserine (0.2 M) in HCl (0.4 M) at this temperature was found to be a very slow process, the amount of phosphates in solution after 3 days accounting for less than 3% of the total phosphorus content (Figure 2). This result indicates that phosphoserine is sufficiently stable to be employed un-

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1434−1948/98/1010−1447 $ 17.50+.50/0

der the synthesis conditions. Nevertheless, precipitates obtained following the procedure described in the experimental section, collected after 1−3 days, were found to contain increasing amounts of phosphates (from 5 to 10% of the total phosphorus content). In order to reduce the presence of phosphates in the precipitate, the rate of precipitation was increased by bubbling wet nitrogen into the reaction vessel. Under these conditions, the solid collected after 12 h did not contain appreciable amounts of phosphates. The X-ray powder diffraction (XRPD) pattern of the wet sample was almost identical to that of a sample dried over phosphorus pentoxide and further characterization was performed on the latter sample.

Figure 1. Ball-and-stick model of L-(+)-phosphoserine

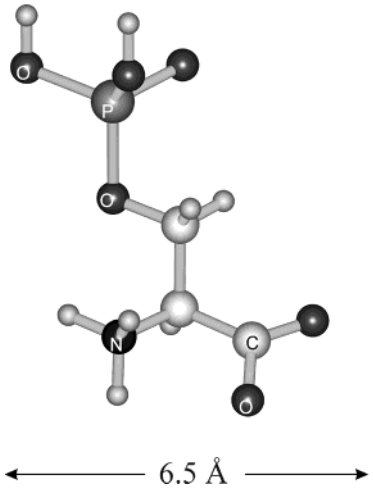

Figure 3 shows the thermogravimetric (TG) and differential thermal analysis (DTA) curves obtained at a heating rate of 5°C/min under oxygen. No appreciable loss is seen up to about 250°C, suggesting the absence of water of crystallization. Thermal decomposition starts at about 250°C and occurs in two steps. The first is very sharp and corresponds to the loss of 20% of the initial weight, while the second occurs over a much broader temperature range and leads to the formation of cubic ZrP_2O_7, as shown by the XRPD spectrum of a sample heated at 900°C. The total weight loss amounts to 42.1%, which is almost identical to that calculated (42.2%) for the following thermal decomposition:

$$Zr[HOOC-CH(NH_2)CH_2OPO_3]_2 + 5\ O_2 \rightarrow ZrP_2O_7 + 2\ NH_3 + 3\ H_2O + 6\ CO_2$$

Results of C,H,N elemental analyses were consistent to within 5% of the stoichiometry derived from TG data. Percentage weights calculated on the basis of the above formula and found values were: C 15.7, H 2.6, N 6.1, and C 15.2, H 2.8, N 5.8, respectively.

Figure 4 depicts the XRPD pattern obtained using the stepwise scanning procedure. The pattern was indexed, using the TREOR program[12], on the basis of a monoclinic cell with parameters a = 5.3737 Å, b = 9.3231 Å, c = 14.510 Å, β = 96.99°, $M(18)$ = 23, $F(18)$ = 30. Assuming

Figure 2. ^{31}P-NMR spectra of a sample of 0.2 M phosphoserine in 0.4 M HCl, using D_2O as solvent, maintained at 60°C for 30 min (spectrum a) and 3 d (spectrum b); peak labels are expressed in Hz

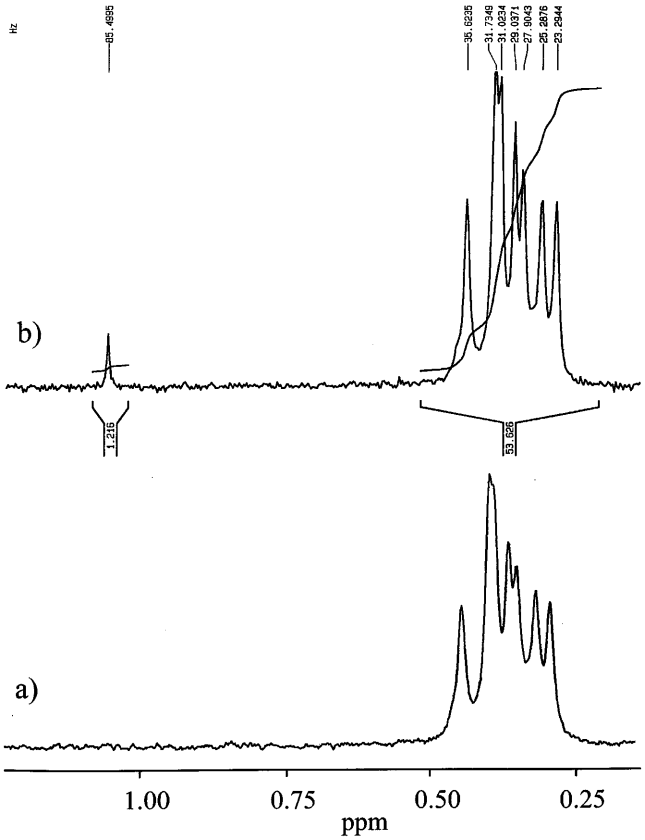

Figure 3. TG (solid line) and DTA (dotted line) curves of zirconium L-(+)-serinephosphate previously equilibrated over P_4O_{10}; heating rate 5°C/min, O_2 flow 30 ml/min

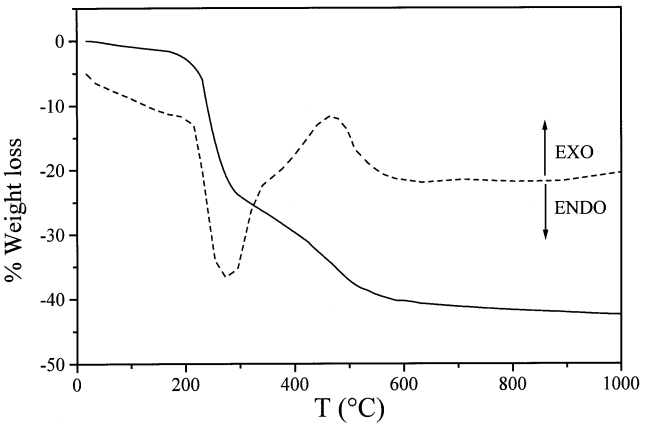

the presence of two formula weights in the unit cell volume (V = 721.5 Å^3), the calculated density (2.10 g cm^{-3}) is very near to the measured density (2.11 g cm^{-3}).

The XRPD pattern of the zirconium serinephosphate is typical of that of layered zirconium phosphate or phosphonates, with a strong first reflection (see Figure 4) corresponding to an interlayer distance (d) of 14.40 Å. Information about the type of layered structure can be obtained by determining the number (n) of moles of compound per

Figure 4. XRPD patterns of zirconium L-(+)-serinephosphate

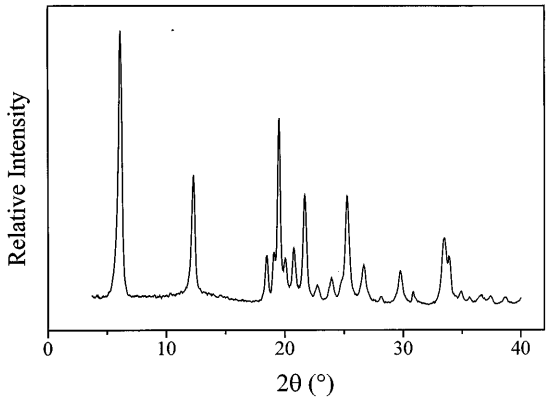

Figure 5. FT-IR absorption spectra of (a) L-(+)-phosphoserine, (b) zirconium L-(+)-serinephosphate

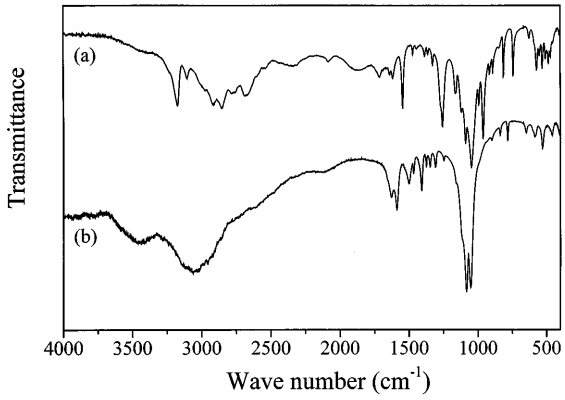
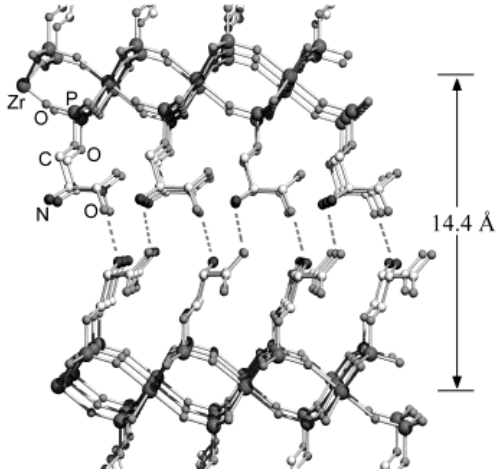


unit area of layer. This number is calculated from the ratio density × interlayer distance/formula weight, and is characteristic of the type of layer structure, being $6.8 \cdot 10^{-10}$ and $9.3 \cdot 10^{-10}$ mol cm^{-2} for the α- and γ-type compounds, respectively[13]. The *n* parameter of zirconium serinephosphate, calculated from the density of 2.11 g/cm^3, the interlayer distance of 14.40 Å, and the formula weight of 457.2 Da (from TG data), is $6.6 \cdot 10^{-10}$ mol cm^{-2}. This result is indicative of an α-type layer structure, where each layer consists of a planar arrangement of zirconium atoms bridged by the oxygen atoms of the phosphate groups, which are located alternatively above and below the zirconium plane. The *a* and *b* axes of the monoclinic cell lie in a plane parallel to the Zr atom plane and the area $a \times b/2$ corresponds to the free area around each phosphorus atom. This free area amounts to 25.1 Å^2, a value slightly higher than the 24 Å^2 typical for α-$Zr(HPO_4)_2$[3], probably because of the presence of the serine group bonded to the phosphate.

Further structural information was derived from a comparison of the IR absorption spectra of solid phosphoserine and zirconium serinephosphate (see Figure 5, spectra a and b, respectively). Both spectra show the typical bands of the protonated amino group and of the ionized carboxyl group. The region 1800−1300 cm^{-1} is particularly significant. The phosphoserine spectrum shows the typical amino acid I and II bands due to NH_3^+ deformations at 1640 and 1620 cm^{-1}, and the asymmetric stretching of the COO^- group at 1548 cm^{-1}. Furthermore, the absorption of the undissociated COOH group at 1717 cm^{-1} indicates that not all phosphoserine molecules are present as zwitterions. This absorption is absent in the zirconium serinephosphate spectrum (Figure 5, spectrum b). In addition, the I and II bands attributable to NH_3^+ deformation are split and shifted to lower wavenumbers (1628 and 1590 cm^{-1}), probably due to the hydrogen bonds being weaker in the layered compound. A similar shift is observed for the asymmetric stretching of the COO^- group (1501 cm^{-1})[14]. At higher wavenumbers (3700−3500 cm^{-1}), the zirconium serinephosphate spectrum shows a broad band, probably due to some water adsorbed on the surface microcrystals. Indeed, TG data do not show any bulk water loss. At lower wavenumbers, in the region 1300−800 cm^{-1}, the zirconium serinephosphate spectrum shows a complex system of bands attributable to the phosphate groups.

In conclusion, the data collected indicate that zirconium L-(+)-serinephosphate has a layered structure of the α-type, similar to that shown in Figure 6. This model representation was obtained by applying the Hyperchem MM+ force field (a modified version of the Allinger's original data set[15]) to a set of L-(+)-phosphoserine molecules to obtain a monolayer that fits the phosphate site distribution on each side of the inorganic matrix, which is assumed to be almost identical to that in α-$Zr(HOPO_3)_2$. It is interesting to note that when the layers are brought together, a hydrogen atom of the ammonium groups resides at such a distance from the oxygen atom of the carboxylic groups (2.6 Å) that allows the formation of hydrogen bonds. The layer −layer interactions are dominated by ionic and hydrogen bonds and the interlayer distance obtained from the model is similar to that measured from XRPD patterns.

Figure 6. Computer-generated model showing the packing of two layers of zirconium L-(+)-serinephosphate; the possible hydrogen bonds are indicated



Once the empirical formula and the structural model had been established, it seemed of interest to reconsider the thermal decomposition process, since the TG data (see Figure 3) showed that, at about 250°C, the first sharp weight

loss (20% of the initial weight) was near to that (19.3%) calculated for the following process:

$$Zr[HOOCCH(NH_2)CH_2OPO_3]_2 \rightarrow Zr(NH_2CH_2CH_2OPO_3)_2 + 2\ CO_2$$

Further evidence for this reaction was gained by collecting XRPD spectra of zirconium serinephosphate maintained at different temperatures (see Figure 7), and by performing evolution gas analysis (EGA) on a sample heated to 900°C (see Figure 8). Both these experiments gave clear evidence that a clean decarboxylation reaction occurs. It can be seen from Figure 7 that the *d* value does not change up to about 200°C, but decreases from 14.4 Å to 12.1 Å at 250°C. At higher temperatures, the XRPD patterns become more and more disordered. It is interesting to note that the phase at 250°C has an interlayer distance similar to that of zirconium 2-aminoethylphosphonate (11.3 Å)[16]. Furthermore, the EGA profile (see Figure 8) shows a marked increase of the CO_2 partial pressure in the 250−300°C temperature range.

Figure 7. XRPD patterns of zirconium L-(+)-serinephosphate maintained at the indicated temperature

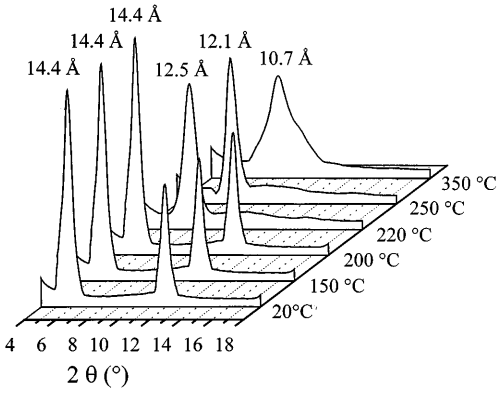


Figure 8. CO_2 partial pressure as a function of temperature in evolution gas analysis of zirconium L-(+)-serinephosphate

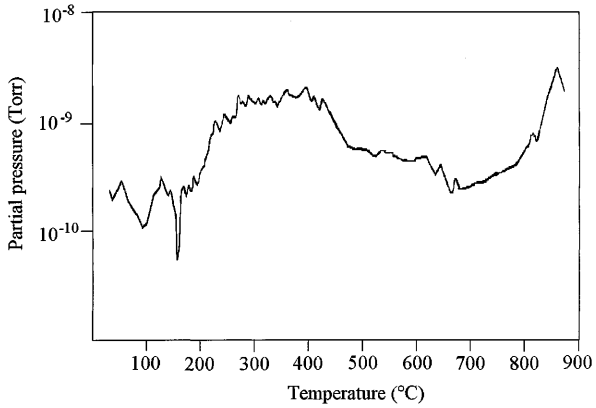


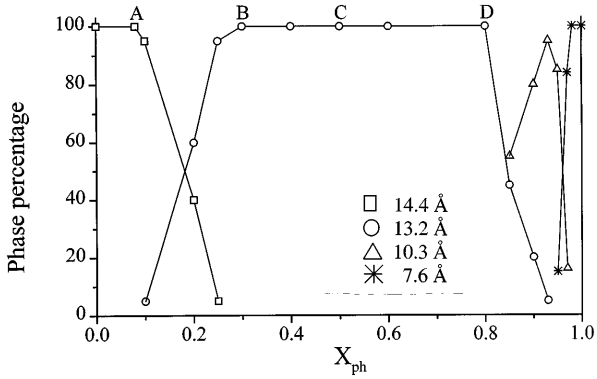
Considering the proposed structure, this new layered compound might be expected to behave as an amphoteric ion-exchange material, capable of taking up cations, anions and even neutral salts from solutions. Moreover, it could also be expected to act as an intercalating agent of polar molecules. Unfortunately, despite the numerous attempts made, the compound was found to be incapable of intercalating neutral species (alkanols, ethyleneglycol, propylamine, glycine), nor could it be titrated with NaOH or HCl solutions.

The lack of intercalation is probably due to the strong layer−layer interactions arising from the long-range ionic bonds between the zwitterions anchored to the surface of the layers, as well as from the network of interlamellar hydrogen bonds. The layer separation necessary for the insertion of the guest species seems to require a very high activation energy. However, it was observed that precipitates obtained after 3 days of precipitation time, which contained a small number of hydrogen phosphate groups, showed some exchange properties toward sodium ions. Therefore, zirconium serinephosphates in which some of the phosphoserine groups are replaced by phosphate groups were prepared, and their ion-exchange behaviour was investigated.

Preparation and Characterization of Zirconium L-(+)-Serinephosphate Phosphates

Several samples of zirconium serinephosphate phosphate, containing increasing amounts of phosphate groups, were prepared using the HF procedure[17] (see Experimental Section) starting from solutions with increasing mole fraction Xph = phosphoric acid/phosphoserine + phosphoric acid. The general trend shown by the system is summarized in Figure 9, where the approximate percentage composition of the phases obtained, identified by their interlayer distances, is plotted against the Xph in the precipitating solution. The percentage of a given phase was estimated from the intensity of the relevant first reflection in the XRPD powder pattern, which is assumed to be roughly proportional to the amount of that phase.

Figure 9. Percentage of the phases obtained in the system Zr(IV)/L-(+)-serinephosphate/phosphoric acid as a function of the molar fraction Xph (see text) in the precipitating solution



The system is discontinuous: initially, up to Xph ≈ 0.1, some phosphates replace an equivalent amount of serinephosphate groups in zirconium serinephosphate (14.4 Å) with slight modification of the XRPD patterns. When the maximum solubility of O_3POH groups in this latter phase is reached (the solid contains an average of one phosphate in every five groups), formation of a new phase with an

interlayer distance of 13.2 Å begins and the phase transition 14.4 → 13.2 Å is completed at Xph ≈ 0.3. The solids precipitated in the range 0.3 ≤ Xph ≤ 0.8 maintain about the same interlayer distance. Concomitantly, their phosphate content increases from one phosphate in every three groups to the idealized composition of two phosphates in every three groups.

A further increase in Xph produces another immiscible phase with a higher phosphate content and an interlayer distance of 10.3 Å, together with pure α-$Zr(HOPO_3)_2$ (interlayer distance 7.6 Å). It proved impossible to isolate the 10.3 Å phase in pure form. However, the spacing of 10.3 Å would be that expected for a mixed compound[18], in which a layer of serinephosphate containing phosphate groups regularly alternates with a layer containing only phosphates, i.e. (13.2 Å + 7.6 Å)/2 = 10.4 Å.

Some representative samples of the mixed compounds obtained by varying the Xph in solution (those marked with a capital letter in Figure 9) were characterized by thermal analysis, as well as by C, N elemental analysis in order to establish their empirical formulae. Figure 10 shows the weight-loss curves of the samples, previously conditioned at room temp. and 75% relative humidity, and the results of C, N elemental analyses. When heated at 1000°C, all samples show the typical XRPD pattern of cubic ZrP_2O_7. Assuming that all the zirconium and phosphorus present was transformed into zirconium pyrophosphate, and taking into account the experimental percentage weight loss, the formula weights were calculated at room temp. Furthermore, the results of C,N elemental analyses allow the determination of the number of moles of phosphoserine per formula weight, while the percentage weight losses at 150°C allow determination of the number of moles of water of hydration. The empirical formula of the mixed compounds can be written as $Zr[HOOCCH(NH_2)CH_2OPO_3]_{2-x}$-$[HOPO_3]_x \cdot n\ H_2O$. Table 1 shows the values of x and n for the samples examined, together with the interlayer distance taken from the XRPD patterns depicted in Figure 11. In addition, Table 1 includes the no. of mmol of exchangeable protons bound to the carboxylic and phosphate groups per gram of compound, calculated on the basis of the empirical formula. To assess their ion-exchange capacity, the samples were titrated with an NaOH solution in the presence of added NaCl. The potentiometric titration curves, shown in Figure 12, give experimental ion-exchange capacities very near to those that would be expected if only the protons of the P−OH groups were replaced by the sodium ions. Furthermore, the titration curves do not show any well-defined ion-exchange plateau, as though the Na^+ uptake process occurs without the phase transitions usually associated with ion-exchange processes in layered metal(IV) phosphates[19]. The XRPD patterns of the samples obtained after titration indicate that the uptake process occurs without appreciable alteration of the interlayer distance. It seems that the serinephosphate groups act as pillars, determining the interlayer distance, and that the ionogenic phosphate groups are randomly inserted between these pillars. Hence, the incoming sodium ions find sufficient space to be accommodated without an increase of the interlayer distance. In this context, it was of interest to examine the surface properties of the mixed compounds in comparison with those of the original zirconium serinephosphate.

Figure 10. Percent weight loss as a function of the temperature of the indicated samples previously equilibrated at 75% relative humidity at room temp. Heating rate 5°C/min, air flow; the C,N elemental analysis (percent by weight) of the same samples is reported in the inset

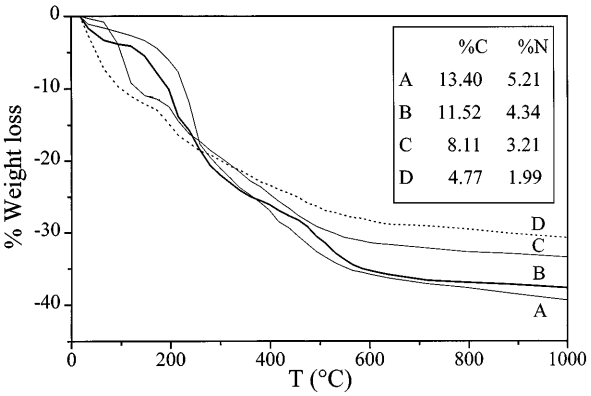


Figure 11. XRPD patterns of samples A and C (see text)

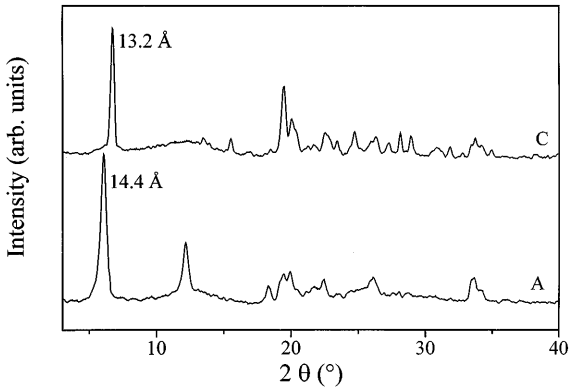

Table 1. Composition, interlayer distance, and calculated ion-exchange capacity of the two ionogenic groups of zirconium serinephosphate phosphates, obtained at the indicated values of mole fraction of phosphoric acid in solution (Xph)

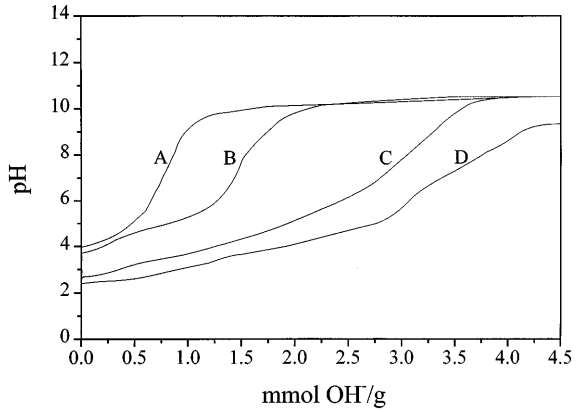
Sample	Xph	$Zr[HOOCCH(NH_2)CH_2OPO_3]_{2-x}(HPO_4)_x \cdot n\ H_2O$ x	n	d [Å]	mmol H^+ [−COOH]/g	mmol H^+ [−POH]/g
A	0.1	0.36	0.65	14.4	3.75	0.823
B	0.25	0.60	1.14	13.2	3.29	1.41
C	0.5	1.1	2.05	13.2	2.26	2.76
D	0.8	1.4	2.62	13.2	1.57	3.66

N_2 adsorption isotherms of zirconium serinephosphate and of samples A and C were recorded. B.E.T. analysis of the isotherms gives specific surface areas of 5.5, 10.6, and 54.5 m^2/g, respectively. It seems that the replacement of serinephosphate groups by phosphates produces an increase in the specific surface area of the solids and the high surface area of sample C may be attributed to the presence of some microporosity in the interlayer region.

Figure 12. Potentiometric titration curves of the indicated samples with a 0.1 M NaOH solution in the presence of 0.1 M NaCl as added salt



Conclusion

As noted by Clearfield in a recent monograph[7], one of the most exciting aspects of the chemistry of metal(IV) phosphates and phosphonates is the possibility of manipulating the inorganic layered backbone by "soft chemistry" procedures, so as to design materials with specific properties. The work reported herein shows that it is possible to anchor an amino acid function bearing a chiral centre to the α-layer. The α-zirconium serinephosphate obtained does not show the expected ion-exchange or intercalation properties. However, the interlayer region becomes accessible to sodium ions upon replacing some serinephosphate groups by phosphate groups. The zirconium serinephosphate phosphates obtained merit further study, e.g. with regard to investigation of their ion-exchange and intercalation properties with the aim of producing exfoliation of the layered microcrystals. Furthermore, new chiral stationary phases may be obtained by deposition of the exfoliated materials onto suitable supports. This may represent an alternative method to that suggested by Malluk and coworkers[20] based on the intercalation of a chiral receptor in the original α-zirconium phosphate.

Experimental Section

Materials: L-(+)-Phosphoserine (2-amino-3-phosphatylpropanoic acid) was purchased from Sigma and used as received. $ZrOCl_2 \cdot 8\ H_2O$ was a Merck product; all other chemicals were Carlo Erba RP-ACS reagents. − Zirconium serinephosphate and zirconium serinephosphate phosphates were prepared using the method of slow decomposition of zirconium fluoro complexes[3] in the presence of an aqueous solution of phosphoric acid and/or phosphoserine. The preparation conditions were as follows: molar ratio $Zr^{IV}/HF = 6$, molar ratio $P/Zr^{IV} = 3$, phosphoserine and/or phosphoric acid concentration 0.2 M, temperature of precipitation 60°C, time of precipitation 1−4 d. After precipitation, the microcrystals were separated from the solution, washed with distilled water up to pH ≈ 4, and finally dried at room temperature over a saturated NaCl solution (relative humidity ca. 75%) or over phosphorus pentoxide.

Instrumentation: The X-ray powder diffraction (XRPD) patterns of the samples were recorded by the stepwise scanning procedure (increment: $2\Theta = 0.02°$, time per step: 5 s) with a computer-controlled Philips PW 1710 diffractometer, using Ni-filtered Cu-K_α radiation. The XRPD patterns at different temperatures were obtained with an A. Paar HTK diffraction camera. − TG and DTA analyses were performed with a Stanton Redcroft thermal analyser (STA 781), with a heating rate of 5°C/min under an air or O_2 flow. This apparatus coupled with a Fisons mass spectrometer was used to obtain EGA curves. − N_2 adsorption and desorption isotherms were recorded with a Carlo Erba Sorptomatic 1800 apparatus. − C,H,N, elemental analyses were carried out with a Carlo Erba Model 1106 Analyser. Densities were determined pycnometrically at 20°C, using CCl_4 as the displacement liquid. − The molar ratios phosphate/serinephosphate in the products investigated were also estimated by liquid-state ^{31}P-NMR analysis with a Bruker AC 200 instrument, after dissolving 0.05 g of the sample in a small volume of conc. HF (ca. 0.5 ml) and D_2O as solvent. − The ion-exchange experiments were performed with a Mettler DK automatic titrator operating in equilibrium-point mode, by titrating 200 mg of the sample, suspended in 40 ml of 0.1 M NaCl solution, with 0.1 M NaOH solution under an N_2 stream.

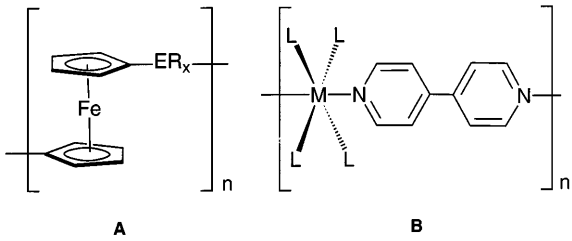
Keywords: Iron / Boron / Ferrocene / Charge-transfer complexes / Coordination polymers

Compared to parent ferrocene, the redox potential of the Fe^{II}/Fe^{III} transition is shifted to much more cathodic values in B–N adducts **1**·Do and **2**·$(Do)_2$ of borylated ferrocenes $FcBMe_2$ (**1**) and 1,1′-fc$(BMe_2)_2$ (**2**) with pyridine bases Do [Fc: $(C_5H_5)Fe(C_5H_4)$; fc: $(C_5H_4)Fe(C_5H_4)$; Do: γ-picoline, 4-(dimethylamino)pyridine, *N*-(*n*-propyl)-4-(4′-pyridyl)pyridinium hexafluorophosphate]. Electron donation by one single BMe_2·Do substituent at the cyclopentadienyl ligand is approximately equal to the positive inductive effect of the five methyl groups in a C_5Me_5 (cp^*) moiety. Using the bidentate nitrogen ligand 4,4′-bipyridine (bipy), the dark-purple dimetallic complex **1**·bipy·**1** is obtained upon reaction with 2 equiv. of **1**. **1**·bipy·**1** has been structurally characterized by X-ray crystallography. The compound tolerates loss of two electrons at the ferrocene groups, as well as two one-electron reductions at the bipy linker. Dark purple coloured coordination polymers [**2**·bipy]$_n$ are accessible from bipy and 1 equiv. of the diborylated derivative **2**. The intense colours of **1**·bipy·**1** and [**2**·bipy]$_n$ are indicative of charge-transfer interactions between the electron-rich ferrocene fragments and the viologen-like R_3B–bipy–BR_3 acceptor. Neat, solid [**2**·bipy]$_n$ is thermally stable up to 240 °C, but in the presence of toluene, polymerization is fully reversible at about 85 °C.

Introduction

Multimolecular arrays in which metal complexes are joined by rigid (electroactive) bridges represent a highly promising class of compounds, due to the potential properties of these materials such as electrical conductivity,[1] magnetism[2] and liquid-crystalline behaviour.[3] Two main lines of research that are particularly relevant in the context of this paper, concern: (a) Poly(ferrocenes) **A** derived from strained, ring-tilted *ansa*-ferrocenes by thermal[4][5] or catalytic[6] ring-opening polymerization (Figure 1). (b) Low-dimensional solids **B** comprised of coordinatively unsaturated metal complex fragments and bridging dihapto ligands. Among the latter, 4,4′-bipyridine (bipy) and 1,2-bis(4-pyridyl)ethane (pyetpy) are particularly prominent (**B**, Figure 1).[7]

Figure 1. Poly(ferrocenes) **A** and bipy-bridged coordination polymers **B**



A **B**

E : e.g. Si, Ge, P, As

ML_4 : e.g. Fe(phthalocyaninato), Co(dimethylglyoximato)$_2$

Our group is currently developing a novel synthetic approach to oligonuclear complexes and organometallic polymers, which is based on the facile formation of boron−nitrogen bonds and thus provides a convenient means of connecting mononuclear metal-containing building blocks.[8][9][10][11] This concept appeared to us to be well-suited for the generation of molecular materials combining the advantages of poly(ferrocenes) (e.g. thermal and chemical inertness of the ferrocene backbone; reversible redox processes) and bipy coordination polymers (e.g. facile synthesis; electron-accepting properties of the bipy unit). It will be shown in this paper that, starting from readily available borylated ferrocenes,[12][13][14][15][16] the addition of 4,4′-bipyridine or 1,2-bis(4-pyridyl)ethane gives dimetallic complexes and polymeric materials by B−N adduct formation (Schemes 1 and 2).

A variety of intriguing properties can be expected to result from the combination of ferrocene and pyridine bases, and the following points will be addressed:

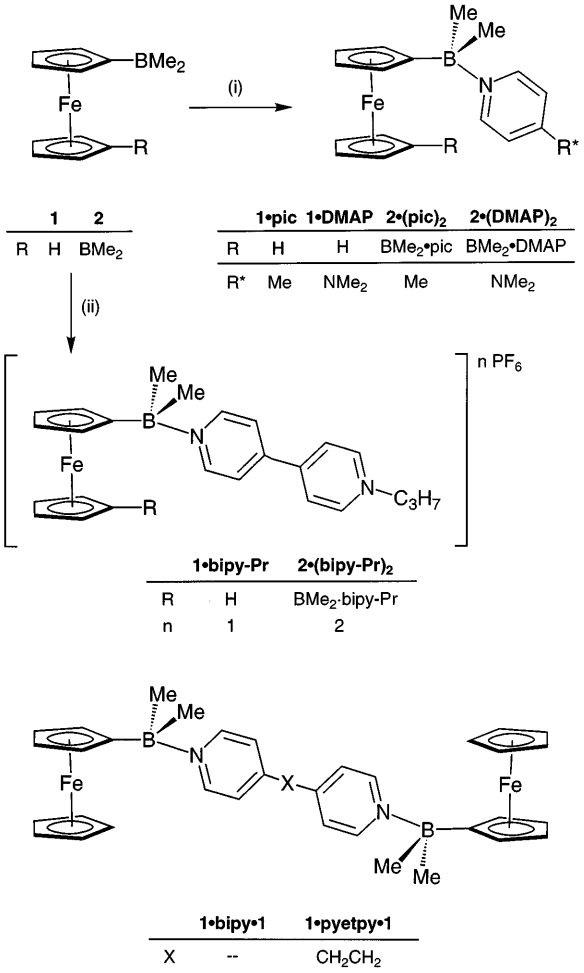
(1) The ligand 4,4′-bipyridine has two coordination sites, which may influence each other by the delocalized π-electron system. The question then arises as to what extent

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1434−1948/98/1010−1453 $ 17.50+.50/0

N→B σ bonding at one nitrogen centre lowers the Lewis basicity of the remaining free N atom, i.e. whether the formation of $R_3B{\cdot}bipy{\cdot}BR_3$ involves stable and isolable $R_3B{\cdot}bipy$ intermediates.

(2) Closely related to the aforementioned question is the problem as to whether a bipy spacer allows electronic communication between two pendant ferrocenylborane units (**1**·bipy·**1**; Scheme 1).

Scheme 1

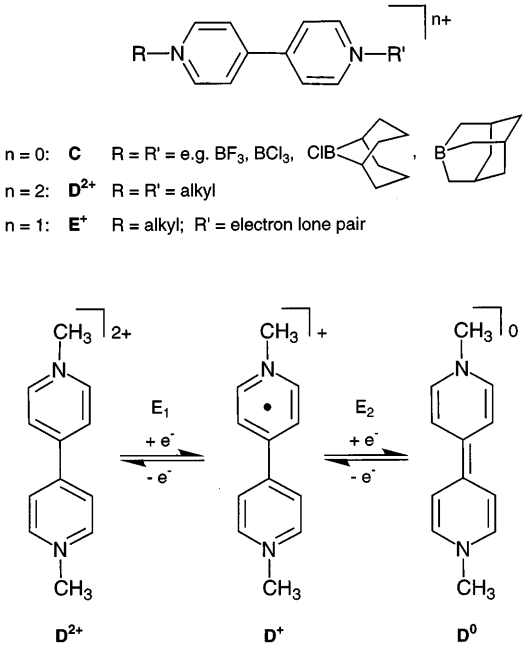


Reagents: (i) **1**·pic/**1**·DMAP: **1** + 1 pic/DMAP; toluene, ambient temp. **2**·$(pic)_2$/**2**·$(DMAP)_2$: **2** + 2 pic/DMAP; toluene, ambient temp. (ii) **1**·bipy-Pr: **1** + 1 bipy-Pr; acetonitrile, ambient temp. **2**·$(bipy\text{-}Pr)_2$: **2** + 2 bipy-Pr; acetonitrile, ambient temp.

Moreover, comparison of the electrochemical data of the Lewis acid/base complexes **1**·pic, **1**·DMAP, **2**·$(pic)_2$ and **2**·$(DMAP)_2$ (Scheme 1), featuring the moderately strong electron donor γ-picoline (pic; pK_a = 6.02; in water, 25°C)[17] on the one hand, and the more basic 4-(dimethylamino)pyridine (DMAP; pK_a = 9.71; in water, 20°C)[18] on the other, will yield information on the influence of tetracoordinate boron substituents on the redox potential of the ferrocene fragment.

(3) 4,4′-Bipyridine-1,1′-diyldiboranes **C** are analogues of the bis-quaternary salts of 4,4′-bipyridine ($\mathbf{D}^{2+}$, "viologens"), which behave as perfectly reversible two-step redox

Figure 2. B−N adducts **C** as structural and electrochemical analogues of the two-step redox system viologen $\mathbf{D}^{2+}$

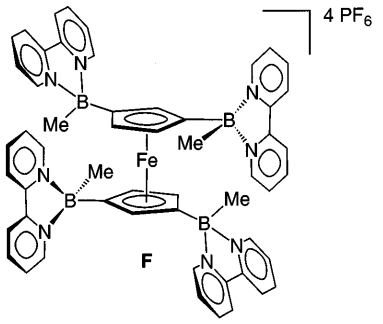


systems in polar aprotic solvents such as acetonitrile and dimethylformamide (Figure 2).[19]

Consequently, derivatives of $\mathbf{D}^{2+}$ have found widespread use as electron acceptors[20][21] and electron carriers,[22] and it is in the latter context that the incorporation of viologens into polymers has been thoroughly investigated.[23][24][25][26] To a large extent, these polymeric materials retain the chemical and electrochemical properties of the monomeric species $\mathbf{D}^{2+}$, although the first reduction (E_1) of polyviologens usually occurs at a more anodic, and the second (E_2) at a more cathodic potential, compared to the corresponding monomers. Thus, in polymeric viologens, the difference ΔE between the two potential values was found to be about twice as large as that in the monomers, and this effect is observable even in oligomers with only 2 or 3 repeating units.[25] This behaviour is indicative of a certain degree of electronic communication between the electroactive sites, which has been attributed to intramolecular interactions among neighbouring pendant viologen cation radicals. Given this background, it will be interesting to see how the electronic behaviour of polymeric viologens changes when the highly flexible backbones used to date are substituted for the more rigid 1,1′-ferrocenediyl spacer [cf. **2**·$(bipy\text{-}Pr)_2$; Scheme 1]. For a general discussion of $L_nM{\cdot}bipy{\cdot}ML_n$ adducts (ML_n: main-group Lewis acid) and the respective radicals formed upon one-electron reduction, the reader is referred to the work of Kaim et al.[27][28][29][30]

(4) The synthesis of aggregates composed of electron-donating ferrocene units and electron-accepting viologen bridges may lead to charge-transfer (CT) processes between the two components. This assumption is based on the observation of pronounced CT interactions between the ferrocene backbone and its pendant 2,2′-bipyridylboronium substituents in the case of related systems **F** (Figure 3).[31][32]

Figure 3. View of the charge-transfer complex **F**



Results and Discussion

In the following, the numbers **1** and **2** are used to denote derivatives of mono- and diborylated ferrocenes, respectively. These numbers are followed by a specification of the coordinating pyridine, i.e. pic, DMAP, bipy, pyetpy and bipy-Pr [*N*-(*n*-propyl)-4-(4′-pyridyl)pyridinium hexafluorophosphate[26]]. The term "Do" stands for all these cited pyridine donors in general.

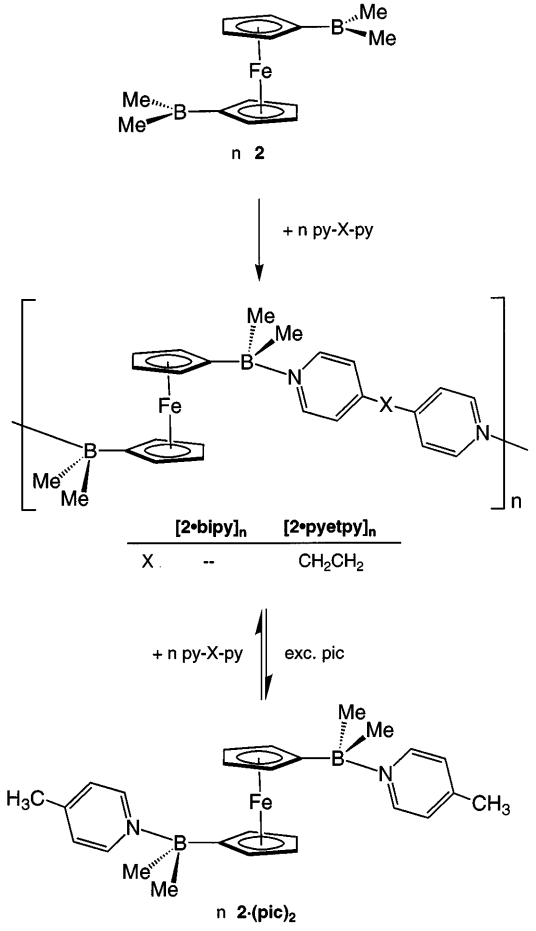
Synthesis

1·pic, **1**·DMAP and **2**·$(pic)_2$, **2**·$(DMAP)_2$ were prepared by mixing toluene solutions of the appropriate nitrogen base and **1** (molar ratio 1:1) or **2** (molar ratio 2:1) at ambient temperature (Scheme 1). Orange crystalline solids were obtained in almost quantitative yields. Even in solution, the compounds show only moderate sensitivity towards moisture, but **2**·$(pic)_2$ and **2**·$(DMAP)_2$ are rapidly oxidized on exposure to air (see below). The syntheses of the ionic adducts **1**·bipy-Pr and **2**·$(bipy\text{-}Pr)_2$ were performed in acetonitrile (Scheme 1). From the dark, purple-red reaction mixtures, the compounds were isolated as almost black crystals. The dinuclear complex **1**·bipy·**1**, which was obtained from toluene solutions of **1** and bipy (molar ratio 2:1), also forms dark-purple crystals and gives intensely red-coloured solutions in toluene as well as in chloroform. In contrast, the related compound **1**·pyetpy·**1** is orange, both in solution and in the solid state, and thus resembles the pic and DMAP adducts described above.

While alkyl bipyridinium systems $\mathbf{E}^+$ (R = alkyl; R′ = electron lone pair; n = 1) are readily accessible (Figure 2),[26] we have not been able to isolate a stable 1:1 adduct of bipy with **1**, even though this species is likely to be abundant in an equimolar solution of the two components. Communication of both nitrogen termini in bipy seems to be observable only when electrophiles of very high Lewis acidity are used for nitrogen coordination, and this condition is apparently not met with **1**.

When diborylated ferrocene **2** in $CHCl_3$ is layered with one equiv. of bipy in CH_2Cl_2, polymeric [**2**·bipy]$_n$ is obtained as a purple microcrystalline solid, which is insoluble in all common non-coordinating solvents. In an attempt to grow single crystals suitable for X-ray crystallography, we tried to slow down the reaction rate by replacing the highly Lewis acidic **2** with its corresponding picoline adduct **2**·$(pic)_2$ (Scheme 2). Using this method, black rhombic crystals of [**2**·bipy]$_n$ grew within 24 h, and it was shown that coordinated pic may be substituted for bipy, even though the former is a much stronger base [pic: pK_a = 6.02;[17] bipy: pK_a(1) = 4.82, pK_a(2) = 3.17;[33] in water, 25°C]. A driving force for this reaction clearly lies in the precipitation of [**2**·bipy]$_n$, which is thus continuously removed from the reaction mixture, thereby shifting the equilibrium towards polymer formation. Polymerization can be reversed by treating purple [**2**·bipy]$_n$ with excess picoline. From the resulting orange solutions, uncomplexed bipy and **2**·$(pic)_2$ can be recovered quantitatively. A polymeric product is also obtained from **2** or **2**·$(pic)_2$ upon reaction with one equiv. of 1,2-bis(4-pyridyl)ethane (pyetpy). Like the dinuclear species **1**·pyetpy·**1**, and unlike **1**·bipy·**1** and [**2**·bipy]$_n$, [**2**·pyetpy]$_n$ exhibits the orange colour usually observed for ferrocenes bearing tetracoordinate boron substituents.

Scheme 2. Preparation of the coordination polymers [**2**·bipy]$_n$ and [**2**·pyetpy]$_n$



NMR Spectroscopy

It is a characteristic feature of B−N donor−acceptor compounds that a dynamic equilibrium exists in solution involving the four-coordinate species and the respective free acids and bases. The chemical shifts observed in the NMR spectra are thus a weighted average between those of the adducts and those of the uncomplexed components. Obviously, the relative amount of an adduct increases when the

solution becomes more concentrated. Therefore, we have used saturated solutions for all NMR spectroscopic measurements to ensure full reproducibility of the data and to obtain chemical shift values as close as possible to the resonances of **1**·Do and **2**·$(Do)_2$. Since the B−N adducts under investigation possess different solubilities in the chosen solvents ($CDCl_3$, CD_3CN), a quantitative comparison, particularly of their ^{11}B-NMR data, is problematic. We have therefore restricted the discussion of NMR spectra to a qualitative level.

Compared to the ^{11}B-NMR spectra of **1** [$\delta(^{11}B) = 70.5$] and **2** [$\delta(^{11}B) = 72.1$], the resonances of **1**·Do and **2**·$(Do)_2$ show large upfield shifts upon addition of the pyridine bases [$\delta(^{11}B) = -3.0$ to 15.0], giving good evidence for B−N adduct structures with four-coordinate boron centres.[34] The relative base strengths of the different pyridines are nicely reflected in the ^{11}B chemical shift values of the B−N complexes, with stronger donors leading to a better shielding of the boron centre: $\delta(^{11}B) = -3.0$ (**1**·DMAP), 0.4 (**1**·pic), 7.5 (**1**·bipy-Pr); 6.2 (**1**·pyetpy·**1**), 15.1 (**1**·bipy·**1**). A similar correlation holds for the adducts of diborylated **2**, but the ^{11}B-NMR signals of the diadducts generally appear at lower field compared to those of the corresponding monoadducts, e.g. $\delta(^{11}B) = 0.4$ (**1**·pic), 15.0 [**2**·$(pic)_2$]. When a large excess (0.5 ml) of pic is added to a solution of **2**·$(pic)_2$ in $CDCl_3$, the boron resonance closely approaches that of **1**·pic [**2**·$(pic)_2$ and excess of pic: $\delta(^{11}B) = 0.0$]. This finding is in good agreement with the assumption of a dissociation equilibrium, which is shifted towards adduct formation in the presence of free base. To gain a deeper insight into this phenomenon, we have investigated the dynamic behaviour of equimolar mixtures of **2** with pic and DMAP in [D_8]toluene at various temperatures by ^{11}B-NMR spectroscopy. In the case of pic, only one extremely broad resonance is detected at ambient temperature [$\delta(^{11}B) \approx 33$]. Upon warming, the signal sharpens considerably, but no significant change of its chemical shift is observed [+60°C: $\delta(^{11}B) = 35.0$; $h_{1/2} = 720$ Hz]. The signal vanishes upon cooling to +15°C. At −10°C, two very broad humps become visible at $\delta(^{11}B) = 70$ and 0, while at −50°C the resonances appear at $\delta(^{11}B) = 73.6$ ($h_{1/2} = 1780$ Hz) and −0.6 ($h_{1/2} = 720$ Hz). In the DMAP case, two ^{11}B-NMR signals are observed even at ambient temperature [$\delta(^{11}B) = 71.0$ ($h_{1/2} = 320$ Hz), −2.8 ($h_{1/2} = 640$ Hz)]. Coalescence of these signals occurs in the temperature range between +80 and +90°C, and at +110°C only one resonance is seen at $\delta(^{11}B) = 35$ ($h_{1/2} = 1360$ Hz). These data suggest that at ambient temperature, and when the N donor is of moderate basicity (pic), the base rapidly fluctuates between the two boron atoms of **2**. The observed ^{11}B-chemical shift is thus time-averaged. In contrast, the stronger donor DMAP comes to a rest at one of the BMe_2 centres under these conditions, and the ^{11}B-NMR spectrum is indicative of the presence of one tri- and one tetracoordinate boron atom. The free activation enthalpies $\Delta G^{\neq}$ of the dynamic processes can be estimated as 45 ± 2 kJ mol^{-1} (pic) and 58 ± 2 kJ mol^{-1} {DMAP; $\Delta G^{\neq} = 19.14\ T_c\ [10.32 + \log(T_c k_c^{-1}]$; $k_c = 2.22 \cdot \Delta\nu$}[35].

In the ^{1}H- and ^{13}C-NMR spectra, one observes only minor changes of the chemical shifts of the pyridine bases upon B−N adduct formation. This finding is in contrast to what was expected, since in the case of e.g. compounds **C**, a pronounced dependence of the bipy proton ^{1}H signals on the nature of the coordinated borane has been reported, e.g. R, R′ = BF_3: $\delta(^1H) = 8.63, 9.54$; R, R′ = 1-boraadamantane: $\delta(^1H) = 8.31, 8.84$ ([D_6]DMSO).[36] For most derivatives of **C**, these values are intermediate between those of free bipy [$\delta(^1H) = 7.79, 8.63$] and those of the bis-quaternary $\mathbf{D}^{2+}$ [R, R′ = CH_3: $\delta(^1H) = 8.68, 9.21$].[36] It has thus been argued that coordination of a highly Lewis acidic borane is mirrored by a pronounced deshielding of the bipy protons in the ^{1}H-NMR spectrum.[36] Even though this correlation may serve as a useful rule of thumb, a quantitative interpretation requires more detailed scrutiny, and other factors, such as magnetic anisotropy effects, also have to be taken into account. For example, the reasons why the bipy protons in the BF_3 adduct experience a large downfield shift, even though BF_3 is a rather weak electrophile,[37][38] still remain obscure.

The ^{1}H-NMR resonances of the $FcBMe_2$ moiety are more informative, showing characteristic upfield shifts upon treatment with pyridine bases: (a) The signal of the BMe_2 fragment, which appears at $\delta(^1H) = 0.82$ in uncomplexed **1**, is found in the corresponding B−N adducts at $\delta(^1H) = 0.30$ (**1**·bipy-Pr), 0.27 (**1**·pic), 0.16 (**1**·DMAP) and at $\delta(^1H) = 0.40$ (**1**·bipy·**1**), 0.29 (**1**·pyetpy·**1**). (b) The protons of the C_5H_4 ring bearing the boryl substituent resonate at $\delta(^1H) = 4.37, 4.59$ in the case of **1**, but are significantly more shielded in **1**·bipy-Pr [$\delta(^1H) = 4.08, 4.19$], **1**·pic [$\delta(^1H) = 4.03, 4.16$], **1**·DMAP [δ⊥ft parenthesis^{1}H) = 3.97, 4.09] and in **1**·bipy·**1** [$\delta(^1H) = 4.13, 4.27$] and **1**·pyetpy·**1** [$\delta(^1H) = 4.04, 4.18$]. These data clearly indicate that not only the ^{11}B-NMR spectra, but also the cited proton shifts can be taken as a measure of the pK_a values of the coordinating pyridines. Similar effects as described for **1** are operative in the case of diborylated derivatives, cf. **2**: $\delta(^1H) = 0.84$ (BCH_3), 4.31, 4.44 (C_5H_4); **2**·$(pic)_2$: $\delta(^1H) = 0.34$ (BCH_3), 3.99, 4.13 (C_5H_4).

The ^{13}C-NMR data of **1**, **2** on the one hand, and of **1**·Do, **2**·$(Do)_2$ on the other, show similar changes and therefore do not merit further discussion.

Infrared Spectroscopy

The infrared spectrum of a pyridine base is modified when the non-bonding pair of electrons on the nitrogen atom is donated into a vacant orbital of an electron acceptor. Consequently, a comparison of the IR data (KBr disc) of **1**, **2** and of the free donors Do with **1**·Do and **2**·$(Do)_2$ reveals a number of alterations characteristic of B−N adduct formation, which will be described here in detail for the oligometallic complexes **1**·bipy·**1** and [**2**·bipy]$_n$ only (Table 1).

B−N Vibration: The values of the B−N stretching modes are of particular importance in obtaining information about the stability of the Lewis acid/base pairs under investigation. The B−N frequencies of solid (KBr disc)

BCl_3·pyridine and BF_3·pyridine have been reported to occur at $\tilde{\nu}$ = 1113 cm^{-1}[39] and $\tilde{\nu}$ = 1112 cm^{-1}[40], respectively. For a series of complexes BX_3·pyridine (X: H, F, Cl, Br) in $CHCl_3$ solution, the corresponding bands are found in the 1102−1090 cm^{-1} interval. They are shifted to lower values when pyridines bearing electron-withdrawing substituents at the 4-position are used (e.g. BCl_3·4-chloropyridine: 1076 cm^{-1}).[41]

Table 1. Infrared bands [cm^{-1}] of selected compounds **1**·Do and **2**·$(Do)_2$ (KBr disc) in the characteristic regions 1650−1450 cm^{-1} (C=C and C=N stretch) and 1100−1050 cm^{-1} (B−N vibration)

[a] *N*,*N*′-Bis(*n*-propyl)-4,4′-bipyridinium hexafluorophosphate.

1·bipy·**1** exhibits three bands in the region of interest ($\tilde{\nu}$ = 1100 cm^{-1}, 1075 cm^{-1}, 1058 cm^{-1}), while [**2**·bipy]$_n$ shows only two such absorptions at $\tilde{\nu}$ = 1075 cm^{-1} and 1061 cm^{-1} (Table 1). It can thus be concluded that the band at $\tilde{\nu}$ = 1100 cm^{-1} is probably not caused by a B−N vibration. The band at $\tilde{\nu}$ = 1075 cm^{-1} appears not only in **1**·bipy·**1** and [**2**·bipy]$_n$, but also in the IR spectra of the free Lewis acids **1** and **2**. Moreover, it does not show the isotope doublet structure ($^{10}B/^{11}B$) that would be expected for a vibration involving the motion of a boron atom. Given this background, the band at $\tilde{\nu}$ = 1058 cm^{-1} (1061 cm^{-1}) is tentatively assigned to the B−N stretching mode of **1**·bipy·**1** ([**2**·bipy]$_n$). It has to be concluded that the B−N bonds in **1**·Do and **2**·$(Do)_2$ are not very strong, which is in accord with the thermal behaviour of these compounds in solution, as well as with the NMR spectroscopic results outlined above.

C=C/C=N Vibration: The region between $\tilde{\nu}$ = 1650 cm^{-1} and $\tilde{\nu}$ = 1450 cm^{-1}, showing three bands at 1622 cm^{-1}, 1540 cm^{-1} and 1493 cm^{-1} both for **1**·bipy·**1**, and for [**2**·bipy]$_n$, also merits further discussion (Table 1). Neither **1** nor **2** exhibits significant absorptions in this region of the spectrum, and thus we may safely assume that these bands are due to C=N and C=C stretching modes of the bipy fragments. Compared to the free base, which shows bands at $\tilde{\nu}$ = 1590 cm^{-1}, 1531 cm^{-1} and 1487 cm^{-1} (KBr disc), the adduct absorptions are shifted by 32 cm^{-1}, 9 cm^{-1} and 6 cm^{-1} towards higher wavenumbers. Similar changes have previously been reported for other complexes of pyridines with main-group Lewis acids.[39][41] The pronounced shift of the highest energy band may therefore be used as a valuable diagnostic tool to investigate (a) the degree of **1**·bipy·**1** dissociation in solution on a very fast time scale, and (b) the molecular structure of solid [**2**·bipy]$_n$.

(a) All infrared frequencies exhibited by solid **1**·bipy·**1** (KBr disc) are also found in CH_2Cl_2 solution. The solution spectrum, however, reveals two additional weak bands ($\tilde{\nu}$ = 1597 cm^{-1}, 1517 cm^{-1}) in the characteristic region between $\tilde{\nu}$ = 1650 cm^{-1} and 1450 cm^{-1}, thereby indicating the presence of a second species that is not found in the solid state. Since the additional absorptions do not match those of free bipy in CH_2Cl_2 ($\tilde{\nu}$ = 1592 cm^{-1}, 1535 cm^{-1}, 1485 cm^{-1}), they are most likely caused by the monoadduct **1**·bipy. This molecule may be formed in a dynamic equilibrium by the dissociation of a small proportion of **1**·bipy·**1**, as has already been suggested from an inspection of the ^{11}B-NMR spectra.

(b) An intense band at $\tilde{\nu}$ = 1622 cm^{-1} and the absence of an absorption at $\tilde{\nu}$ = 1590 cm^{-1} in the infrared spectrum of [**2**·bipy]$_n$ provides strong evidence in favour of the proposed adduct structure. The amount of any free bipy that might have co-crystallized with [**2**·bipy]$_n$ is beyond the detection limit of the IR spectrometer. The question then remains as to whether [**2**·bipy]$_n$ consists mainly of short oligomeric fragments, or whether it is a well-organized coordination polymer. One way of distinguishing between these two structural motifs is to evaluate the amount of uncomplexed BMe_2 substituents or of terminal bipy units with one coordinating and one uncomplexed nitrogen atom. The two types of chain end should be equally abundant in [**2**·bipy]$_n$, but we will focus our attention on the latter, which is easier to detect by IR spectroscopy. Terminal bipy ligands have a less symmetrical environment than bridging bipy, which leads to the appearance of additional infrared lines. For example, monosubstituted [bipy-Pr]PF_6 exhibits (among others) four well-resolved C=C/C=N stretching frequencies at $\tilde{\nu}$ = 1597 cm^{-1}, 1548 cm^{-1}, 1526 cm^{-1} and 1496 cm^{-1}, whereas the bis-quaternary salt [Pr−bipy−Pr]$(PF_6)_2$ shows only two lines in this spectral range with intermediate values of $\tilde{\nu}$ = 1569 cm^{-1} and 1509 cm^{-1}. In the characteristic region, the frequency pattern of [**2**·bipy]$_n$ closely resembles that of [Pr−bipy−Pr]$(PF_6)_2$ and is absolutely identical with the IR spectrum of **1**·bipy·**1**. These findings suggest that there are far less terminal than internal bipy ligands present in [**2**·bipy]$_n$ and are thus consistent with the proposed polymeric structure. It should be noted, however, that on the basis of the infrared data discussed, the presence of cyclic structures *cyclo*-[**2**·bipy]$_n$ cannot be ruled out.

Solid-State Structure of 1·bipy·1

Dark-purple crystals of **1**·bipy·**1** (Figure 4, Table 2) were grown from toluene/hexane (1:1) in the triclinic space group $P\bar{1}$ with two crystallographically independent molecules in the asymmetric unit (**1**·bipy·$\mathbf{1}_A$, **1**·bipy·$\mathbf{1}_B$; 0.5 equiv. of disordered toluene in the crystal lattice). Selected bond lengths, angles and dihedral angles of both molecules are given in Table 3. The complete set of structural data of **1**·bipy·$\mathbf{1}_A$ and **1**·bipy·$\mathbf{1}_B$ is available on request.[42]

Since both molecules **1**·bipy·$\mathbf{1}_A$ and **1**·bipy·$\mathbf{1}_B$ possess rather similar structures within experimental error, only

1·bipy·$\mathbf{1}_A$ is discussed here in detail. As has already been deduced from the NMR data, the compound consists of two ferrocenylborane moieties bridged by a doubly coordinating bipy ligand. An inversion centre is located between C(33) and C(33a), and the bipy unit adopts the planar conformation required for an effective viologen-like electron acceptor. This finding is somewhat peculiar, because 4,4′-bipyridines, as well as biphenyls, tend to be twisted about their central C−C bond so as to minimize non-bonding interactions between adjacent hydrogen atoms.[43]

Compared to pyridine (py) complexes of boron Lewis acids,[43] the boron−nitrogen bonds of **1**·bipy·$\mathbf{1}_A$ are rather long [B(1)−N(1) = 1.682(5) Å; cf. BF_3·py: B−N = 1.603(5) Å, BCl_3·py: B−N = 1.592(3) Å].[38][44] Nevertheless, the boron centres are fully pyramidalized with the relevant angles C(1)−B(1)−C(2) = 113.5(3)°, C(1)−B(1)−C(11) = 112.9(3)° and C(2)−B(1)−C(11) = 114.2(3)° being only slightly larger than the value expected for an sp^3-hybridized boron atom with ideal tetrahedral geometry (109.5°). The B−N vectors of **1**·bipy·$\mathbf{1}_A$ are almost orthogonal to the C_5H_4 rings of the pendant ferrocenyl substituents with a torsion angle C(12)−C(11)−B(1)−N(1) of 90.5(4)°. The plane of the bipy bridge in **1**·bipy·$\mathbf{1}_A$ shows a dihedral angle C(11)−B(1)−N(1)−C(35) of 42.9(4)° with respect to the B(1)−C(11) bond [**1**·bipy·$\mathbf{1}_B$ shows a significantly different value of 4.3(3)°]. In summary, crystalline **1**·bipy·**1** features the desired molecular architecture: Two electropositive ferrocenyl fragments are held in close proximity to a rigid electroactive linker by means of simple B−N adduct formation.

Electrochemistry

The potential values are referred to the Saturated Calomel Electrode (S.C.E.); where necessary, literature data used for comparison have been recalculated for S.C.E. as reference. All the ferrocene adducts studied here display the typical ferrocene-centred oxidation, showing features of chemical reversibility on the cyclic voltammetric time scale. However, the electrochemical behaviour of most of the present complexes was found to be dependent on the concentrations employed. This is illustrated in Figure 5, which shows the cyclic voltammetric responses of **1**·bipy-Pr in DMF at concentrations of 2.3 × 10^{-3} mol·dm^{-3} (Figure 5a) and 0.2 × 10^{-3} mol·dm^{-3} (Figure 5b).

Following the main oxidation step, a minor but significant reversible peak system appears in the more dilute

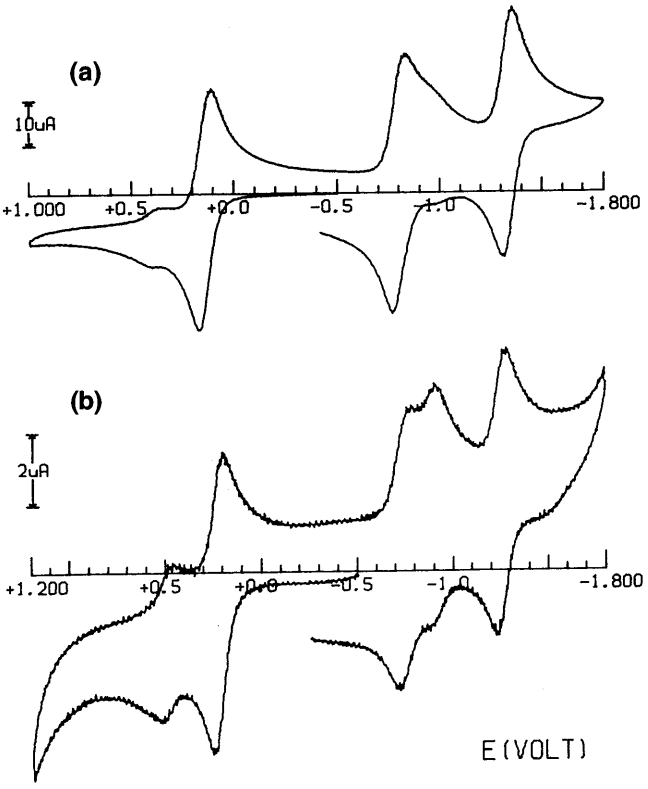
sample at about +0.5 V, which vanishes almost completely when the concentration of **1**·bipy-Pr is increased by one order of magnitude. This picture is qualitatively independent of the scan rate (0.02 Vs^{-1} to 2.00 Vs^{-1}). **1**·bipy-Pr, as well as most other bipy adducts under investigation here, also exhibits two sequential reversible reduction processes, which are most likely centred at the bipy ligand ($E^{\circ\prime}$ = −0.80 V, −1.33 V; Table 4). Again, a concentration-dependent chemical complication is readily detectable. The corresponding potential value ($E^{\circ\prime} \approx -0.9$ V) is intermediate between the formal electrode potentials of the first redox transition of bipy ($E^{\circ\prime}$ = −1.84 V; Table 4) and that of paraquat $\mathbf{D}^{2+}$ ($E^{\circ\prime}$ = −0.36 V; Table 4). Moreover, the feature occurs at a more negative electrode potential than is observed in the case of **1**·bipy-Pr and may thus be assigned to the reduction of uncomplexed $[bipy\text{-}Pr]^+$. This assumption was confirmed by investigating an authentic sample of $[bipy\text{-}Pr]PF_6$, which possesses redox potentials of $E^{\circ\prime}$ = −0.95 V and −1.66 V. Our attempts to obtain cyclic voltammograms of **1** suffered from poor reproducibility due to severe decomposition processes that accompanied the one-electron removal. The minor reversible oxidation wave at $E^{\circ\prime} \approx +0.5$ V is thus probably not attributable to a $\mathbf{1/1}^+$ transition, but may be tentatively assigned to the oxidation of parent ferrocene, formed by rapid decomposition of free **1** under the experimental conditions employed. It may be concluded, therefore, that the chemical complications observed at low concentrations of **1**·Do are indicative of a dynamic equilibrium between the B−N adducts and their constituent components, as has already been deduced from NMR and IR data.

Controlled potential coulometric tests performed on concentrated DMF solutions of **1**·bipy-Pr (E_w = +0.4 V) consume one electron per molecule. The colour of the solution turns to pale-green and the typical absorption (λ_{max} = 635 nm) of ferricinium derivatives is observed. Moreover, in confirmation of the chemical reversibility of the **1**·bipy-Pr/$[\mathbf{1}\cdot bipy\text{-}Pr]^+$ oxidation, cyclic voltammetry on the exhaustively oxidized solution gives a voltammetric profile quite complementary to that shown in Figure 5a.

Analysis[45] of the cyclic voltammetric anodic response with scan rates varying from 0.02 Vs^{-1} to 1.00 Vs^{-1} shows that (a) the current ratio i_{pc}/i_{pa} is equal to 1 throughout; (b) the current function $i_{pa}/v^{1/2}$ remains constant; (c) the peak-to-peak separation does not depart appreciably from the value of 59 mV theoretically expected for an electrochemically reversible one-electron process. The same diagnostic criteria essentially hold for both reduction steps. The electrochemical reversibility of these processes indicates that no significant structural reorganizations are involved. The relevant redox potentials are compiled in Table 4, together with the electrochemical characteristics of all other complexes under consideration.

In confirmation of the assumption that the oxidation process is centred on the ferrocene moiety and that the sequential reductions are centred on the bipy fragment, the relative peak heights of the cathodic vs. the anodic steps exactly reflect the ratio between the number of bipy and

Figure 5. Cyclic voltammetric responses recorded at a platinum electrode of DMF solutions containing $[NEt_4]PF_6$ (0.1 $mol\cdot dm^{-3}$) and **1**·bipy-Pr: (a) 2.3×10^{-3} $mol\cdot dm^{-3}$; (b) 0.2×10^{-3} $mol\cdot dm^{-3}$; scan rate 0.2 Vs^{-1}



ferrocenyl units present in each molecule [i.e. **1**·bipy·**1**: 2:1; **2**·$(bipy\text{-}Pr)_2$: 1:2]. In passing, we note that the appearance of a single two-electron oxidation in the biferrocenyl complexes **1**·bipy·**1** and **1**·pyetpy·**1** suggests that no electronic communication between the outer ferrocenyl fragments takes place.

The presence of four-coordinate boron substituents in **1**·Do and **2**·$(Do)_2$ considerably lowers the oxidation potential of the central iron atoms. The effect is apparently additive, as can be seen from the $E^{\circ\prime}$ values of the parent ferrocene (+0.49 V), **1**·pic (+0.20 V) and **2**·$(pic)_2$ (−0.01 V) in DMF solution (Table 4). Oxidation generally occurs at somewhat more cathodic values in CH_2Cl_2. Most importantly, the oxidation potentials of **1**·pic ($E^{\circ\prime}$ = +0.20 V [DMF], +0.11 V [CH_2Cl_2]) and **2**·$(pic)_2$ ($E^{\circ\prime}$ = −0.01 V [DMF], −0.12 V [CH_2Cl_2]) are very close to those of Cp* FeCp ($E^{\circ\prime}$ = +0.12 [CH_3CN])[46] and Cp*FeCp* ($E^{\circ\prime}$ = −0.12 [CH_3CN]),[46] respectively. When pic is substituted by the more nucleophilic DMAP, a cathodic shift of the Fe^{II}/Fe^{III} transition is observed: $\Delta E^{\circ\prime}$(**1**·DMAP − **1**·pic) = −0.05 V [CH_2Cl_2], $\Delta E^{\circ\prime}$[**2**·$(DMAP)_2$ − **2**·$(pic)_2$] = −0.08 V [CH_2Cl_2]. We may therefore conclude that the electron-donating ability of a BMe_2·Do substituent attached to the Cp ligand is approximately equal to the positive inductive effect of the five methyl groups in (pentamethyl)cyclopentadienyl (Cp*). In addition, some fine-tuning of the Fe^{II}/Fe^{III} redox potential is possible by choosing pyridine bases of different pK_a values for boron coordination.

Table 4. [a] Referred to the oxidized species. – [b] Not measured because of slow decomposition. – [c] Not measured. – [d] Not interpretable. – [e] Peak potential value. – [f] Ref.[6].

As expected, B−N adduct formation shifts the two reduction potentials of the bipy moiety by more than 0.6 V (DMF) towards more anodic values in the dimetallic complex **1**·bipy·**1** (bipy: $E^{\circ\prime}$ = −1.84 V, −2.38 V;[36] **1**·bipy·**1**: $E^{\circ\prime}$ = −1.20 V, −1.75 V). This effect is somewhat less pronounced than in the 9-boraadamantane adduct **C** [Figure 2; $E^{\circ\prime}$ = −1.10 V, −1.68 V (DMSO)],[36] which may be explained by the lower Lewis acidity of **1** bearing a strongly electron-donating ferrocenyl substituent. Like the Fc fragments in **1**·bipy·**1**, the two bipy-Pr substituents in **2**·$(bipy\text{-}Pr)_2$ do not show any significant degree of electronic communication.

UV/Vis Spectroscopy

In the solid state, all bipy complexes **1**·bipy·**1**, **1**·bipy-Pr, **2**·$(bipy\text{-}Pr)_2$ and [**2**·bipy]$_n$ exhibit an intense blue to purple colour, and single crystals of these compounds are almost black. We consider that these additional electronic absorptions, which cannot be attributed to internal transitions of bipy or the ferrocenylboranes **1** and **2**, are due to charge-transfer interactions between the electron-rich ferrocene donors and the electron-poor bipy diadducts. When the extended π-electron system of bipy is disrupted by inserting an ethylene spacer into its central C−C bond, the viologen-like electron acceptor is destroyed, and consequently the colour of the respective complexes changes to yellow (cf. **1**·pyetpy·**1**, [**2**·pyetpy]$_n$).

Somewhat surprisingly, the UV/Vis spectra of **1**·bipy·**1** and **1**·pyetpy·**1** are rather similar in solution (toluene, CH_2Cl_2) [λ_{max} = 447 nm (**1**·bipy·**1**); 447 nm (**1**·pyetpy·**1**)]. Several possible explanations for this phenomenon can be envisaged: (a) The Fc-to-bipy charge transfer may occur *inter*molecularly and thus require close contacts with specific spatial orientation of the individual complexes. These conditions are more likely to be met in the solid state rather than in dilute solution. (b) As has been shown by X-ray crystallography, the bipy bridge of **1**·bipy·**1** adopts a planar conformation in the crystal lattice. In solution, however, rotation about the central C(33)−C(33a) bond is to be expected, leading to a weakening of the electron acceptor due to the continuous perturbation of the π-electron system. (c) The Lambert-Beer law is only valid for highly dilute solutions. Since dilution favours dissociation of **1**·bipy·**1** and **1**·pyetpy·**1**, the UV spectra recorded under these conditions are not representative of the adduct complexes, but are most likely dominated by the bands of free **1**, bipy and pyetpy.

Thermal Analysis

To investigate the stability of solid **1**·bipy·**1** and [**2**·bipy]$_n$ more closely, differential thermal scans (DSC)[47] and thermogravimetric measurements (TG-MS)[48] were performed [heating rate: 10 $K \cdot min^{-1}$; inert gas flow (He): 16 sccm (DSC); 60 sccm (TGA)]. For comparison, the model compounds **1**·pic, **1**·DMAP and **2**·$(pic)_2$, **2**·$(DMAP)_2$ were included in this study.

All complexes show a sharp endothermic feature, followed by a broad, sometimes ill-defined, endothermic event at higher temperatures. With the exception of **2**·$(pic)_2$, the position of the first signal is independent of whether the thermal scans are run at constant pressure or at constant volume. In contrast, the second endothermic transition is markedly influenced by pressure and its onset temperature is generally shifted to higher values in a closed system (V = const.; Table 5).

These findings suggest that the first signal in each DSC plot is due to crystal melting, and this was confirmed by independent melting-point determinations, during which

Table 5. Results of DSC measurements

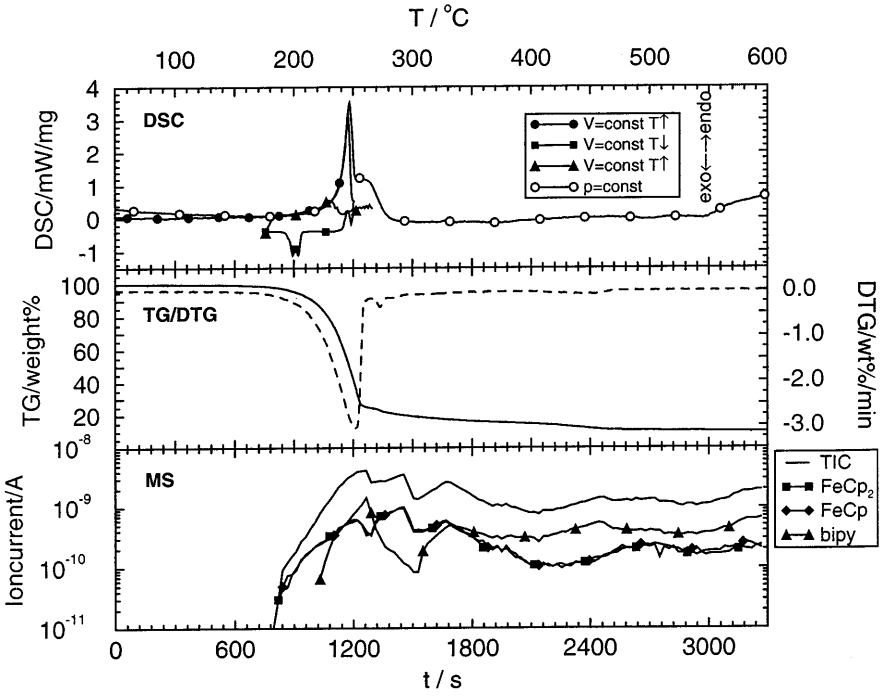
$T(2)_p$[b]	195[c]/240[d]	290[c]/320[d]	–[c]/250[d]	280[c]/310[d]	240[c]/305[d]	260[c]/–[d]

[a] Onset temperature. – [b] Peak temperature of the first (1) and second (2) endothermic events. – [c] p = constant. – [d] V = constant.

the samples were viewed under a microscope. The much broader, less regular line shape recorded in most cases for the second endotherm, as well as its pressure dependence, indicates the occurrence of chemical transformations in the respective temperature range. At this stage, B–Cp and B–N bond rupture takes place, generating more volatile components such as the free pyridine bases, ferrocene, and the $(C_5H_5)Fe$ fragment (cf. $[\mathbf{2}\cdot bipy]_n$; Figure 6). The melting process of some adducts is thus accompanied by chemical decomposition. In these cases, it is not possible to accurately determine the onset temperatures $T(2)_{on}$ and therefore only the peak values $T(2)_p$ are given in Table 5. The melting points of **1**·pic to **2**·$(DMAP)_2$ show the expected influence of base strength, dipole moment, and molecular weight of the individual compounds. On going from pic to the more basic DMAP, the decomposition temperatures increase, which provides additional support for the assumption that the B–N bonds are the weakest parts in the molecular frameworks. No significant differences are found for the decomposition temperatures $T(2)_p$ of **1**·pic, **2**·$(pic)_2$ on the one hand, and of **1**·DMAP, **2**·$(DMAP)_2$ on the other. Hence, B–N adduct formation at one BMe_2 substituent seems to have little influence on the Lewis acidity of the second boron centre.

The dimetallic complex **1**·bipy·**1** and the coordination polymer $[\mathbf{2}\cdot bipy]_n$ possess high thermal stability in the solid state (Table 5). This finding is in contrast to the ready dissociation of $[\mathbf{2}\cdot bipy]_n$, even at moderate temperatures in toluene: As outlined above, $[\mathbf{2}\cdot bipy]_n$ is virtually insoluble in all common solvents at 20°C. At elevated temperature (T > 85°C), however, a slurry of $[\mathbf{2}\cdot bipy]_n$ in toluene is turned into a clear, orange-red solution, from which purple dendritic crystals are re-formed upon cooling (T < 70°C). This process may be repeated several times without significant decomposition of the material. The thermal behaviour of $[\mathbf{2}\cdot bipy]_n$ in the presence of a low-polarity solvent indicates that a reversible rupture of the oligomer backbone can be induced. Thermolysis of a slurry of $[\mathbf{2}\cdot bipy]_n$ in anhydrous and deaerated $[D_8]$toluene was also monitored by means of ^{1}H-NMR spectroscopy. Initially (20°C), the colourless supernatant shows no signals other than those of incompletely deuterated solvent. Upon heating to 80°C, however, resonances attributable to the mononuclear building blocks **2** [$\delta(^1H)$ = 0.84, 4.31, 4.44] and bipy [$(\delta(^1H)$ = 7.51, 8.72]

Figure 6. DSC, TG/DTG plots of $[\mathbf{2}\cdot bipy]_n$ and mass spectrometric analysis of thermolysis products



are detected in a molar ratio of 1:1. Some reversibility of the thermal transformation of [**2**·bipy]$_n$ is also maintained in the solid state (Figure 6).

When heating of the sample is stopped at 250°C under isochoric conditions and then the sample is cooled down again, an exothermic event is observed with an onset temperature $T(2)_{on}$ = 207°C and a peak temperature $T(2)_p$ = 200°C. A second heating scan again reveals an endothermic transition [$T(2)_p$ = 220°C] of lower intensity compared to the first scan.

Polymer Analysis

IR spectroscopy, DSC measurements and elemental analysis of neat [**2**·bipy]$_n$ suggest that this material consists of B−N coordination polymers. A solid-state ^{13}C-NMR spectrum of [**2**·bipy]$_n$ reveals that the compound crystallizes together with a small proportion of toluene. Otherwise, only the signals expected for well-defined polymeric [**2**·bipy]$_n$ are observed [$\delta(^{13}C)$ = 13.7 (BMe), 71.5 (Fc), 90.3 (Fc-*ipso*), 121.7, 143.9 (bipy), 147.2 (bipy-*ipso*)].

When a slurry of purple [**2**·bipy]$_n$ in CH_2Cl_2 is treated with excess pic, a clear orange solution is obtained (cf. Scheme 2), from which **2**·(pic)$_2$ and free bipy can be recovered in almost quantitative yield. This finding clearly demonstrates that the integrities of the molecular frameworks of **2** and bipy are maintained in [**2**·bipy]$_n$, and that its formation is not accompanied by unwanted side reactions. Moreover, it is evident that the copolymerization of **2** and bipy can not only be reversed by thermally induced B−N bond cleavage (see above), but also with the help of Lewis basic additives.

We have attempted to gather more detailed structural information on [**2**·bipy]$_n$ by X-ray crystallography. Unfortunately, we have not yet been able to obtain single crystals of sufficiently good quality to allow a full structure refinement (polysynthetic twins), although the polymeric nature of [**2**·bipy]$_n$ has been proven by a preliminary crystal structure solution.

Conclusion

A boron−nitrogen donor−acceptor bond is highly directional and is of a reversible nature. It can be very strong (H_3B-NH_3: 31 kcal·mol^{-1}), but the energy required for heterolytic dissociation may also be tuned over a wide range by judicious choice of appropriate substituents at the boron and nitrogen atoms. We therefore suggest consideration of B−N Lewis acid/base pairing as an alternative to hydrogen bonding for the generation of reversible polymer systems. Since an individual hydrogen bond is rather weak (3−7 kcal·mol^{-1}), only the cooperative action of many of them provides a linker that is sufficiently stable to build well-defined supramolecular aggregates.[49] The efficient control of cooperative phenomena requires very careful positioning of every single binding site, and this difficult task can be circumvented by employing B−N bonds instead.

On the basis of this B−N concept, organometallic polymers [**2**·bipy]$_n$ and [**2**·pyetpy]$_n$ have been synthesized from 1,1′-fc(BMe$_2$)$_2$, **2**, 4,4′-bipyridine, and 1,2-bis(4-pyridyl)-ethane, respectively. Neat [**2**·bipy]$_n$ is stable up to 240°C in the solid state. In the presence of toluene, however, the polymer is reversibly split into its constituent monomers upon warming to 85°C.

Apart from its role in establishing the polymer backbone, B−N adduct formation substantially changes the charge distribution of the ferrocene fragments and of the bipy bridges, as is evident from an investigation of the model complexes **1**·Do, **2**·(Do)$_2$ [Do: γ-picoline, 4-(dimethylamino)pyridine, *N*-(*n*-propyl)-4-(4′-pyridyl)pyridinium hexafluorophosphate], and **1**·Do·**1** [Do: 4,4′-bipyridine, 1,2-bis(4-pyridyl)ethane]: The donor strength of one BMe$_2$·Do substituent at ferrocene is equal to the electron-releasing effect of five methyl groups and consequently leads to a large cathodic shift of the Fe^{II}/Fe^{III} redox transition {e.g. $E°'$ = +0.44 V [CpFeCp, CH_2Cl_2]; +0.11 V [**1**·pic, CH_2Cl_2], +0.12 V [Cp*FeCp, CH_3CN]; −0.12 V [**2**·(pic)$_2$, CH_2Cl_2], −0.12 V [Cp*FeCp*, CH_3CN]}. For this reason, base adducts of ferrocenylboranes are an alternative to the widely used decamethylferrocene as electron donors in organometallic redox chemistry. In contrast to Cp*FeCp*, there are still four CH groups at each Cp ring of **1**·Do and **2**·(Do)$_2$ available for further functionalization, and the Fe^{II}/Fe^{III} redox potential is, moreover, tunable by selecting the appropriate pyridine base.

The electrochemical behaviour of the bipy linker is also sensitive to its coordination state, since each of the two one-electron reductions of parent 4,4′-bipyridine ($E°'$ = −1.84 V, −2.38 V; DMF) is shifted by about 0.6 V towards less negative values as a result of FcBMe$_2$ binding ($E°'$ = −1.20 V, −1.75 V [**1**·bipy·**1**; DMF]).

Destabilization of the ferrocene HOMO parallel to the stabilization of the bipy LUMO facilitates charge-transfer interactions between the two orbitals in **1**·bipy·**1**, **1**·bipy-Pr, **2**·(bipy-Pr)$_2$ and [**2**·bipy]$_n$, as indicated by the deep-purple colour of these compounds. In contrast, the ferrocene-free B−N adducts **C** (Figure 2), as well as the metal-containing complexes **1**·pyetpy·**1** and [**2**·pyetpy]$_n$ with two separated pyridine rings, exhibit the yellow colour usually observed for ferrocene derivatives bearing tetracoordinate boron substituents. The question as to whether charge-transfer in e.g. [**2**·bipy]$_n$ occurs within the polymeric rod or between two adjacent polymer chains will be subject of future investigations. Also attendant on the investigation of [**2**·bipy]$_n$ is the screening of a variety of bidentate Lewis bases other than bipy in order to increase the extent of charge delocalization in ferrocenylborane-containing coordination polymers. Promising results have already been obtained with pyrazine, which (a) brings adjacent ferrocene units into closer proximity, (b) is more rigid than bipy, and (c) forms bis-quaternary salts that are able to accept an electron at considerably more anodic potential values compared to *N*,*N*′-dialkylbipyridinium acceptors.[50][51]

We are grateful to Prof. Dr. *W. A. Herrmann* (Technische Universität München) for his generous support, to *H. Heise* for recording the solid-state ^{13}C-NMR spectra, and to *W. Hieringer* for helpful discussions. Financial funding by the *Deutsche Forschungsgemein-*

schaft (DFG) and the *Fonds der Chemischen Industrie* is acknowledged.

Experimental Section

All reactions and manipulations were carried out in dry, oxygen-free Ar using standard Schlenk glassware or in an Ar-filled dry-box. Solvents were freshly distilled under N_2 from Na/K alloy/benzophenone (hexane, toluene, THF) or from CaH_2 (CH_2Cl_2, CH_3Cl, CH_3CN) prior to use. − UV/Vis: Hewlett-Packard 8452 A. − IR: Perkin-Elmer 1650 FT-IR. − NMR: Jeol JMN-GX 400 and Bruker DPX 400 [abbreviations: s: singlet, d: doublet, t: triplet, vt: virtual triplet, br: broad, n.r.: multiplet expected but not resolved; pic: γ-picoline, DMAP: 4-(dimethylamino)pyridine, bipy: 4,4′-bipyridine, pyetpy: 1,2-bis(4-pyridyl)ethane, bipy-Pr: *N*-(*n*-propyl)-4-(4′-pyridyl)pyridinium hexafluorophosphate]. − ^{11}B-NMR spectra were referenced to external $BF_3{\cdot}Et_2O$. − MS (FAB/CI mode): Finnigan MAT 90. − Thermal analyses: Netzsch DSC 404 high-temperature furnace, thermocouple Pt/Rh, Perkin-Elmer TGA 7 thermobalance equipped with a Balzers QMG 420 mass spectrometer. − Elemental analyses: Microanalytical laboratory of the Technische Universität München. − The compounds **1**, **2**[15] and bipy-Pr[26] were synthesized according to literature procedures.

Preparation of **1**·pic: To a solution of **1** (0.25 g, 1.11 mmol) in toluene (10 ml) at ambient temperature, was added γ-picoline (0.10 g, 1.07 mmol) in toluene (5 ml) by means of a cannula. The resultant clear orange solution was stirred for 3 h and then concentrated to half of its original volume in vacuo, whereupon **1**·pic gradually precipitated as an orange crystalline solid. The precipitate was collected on a frit (G3), treated with cold hexane (−30°C) and dried in vacuo. The mother liquor was kept in a refrigerator (−30°C) for 12 h to yield a second crop. Yield 0.32 g (93%). − IR (KBr, cm^{-1}): $\tilde{\nu}$ = 1628 (vs), 1507 (m) (pic-C−C, C−N), 1104 (m), 1068 (m), 1058 (m) (B−N). − ^{11}B NMR (128.3 MHz, $CDCl_3$): δ = 0.4 ($h_{1/2}$ = 300 Hz). − ^{1}H NMR (400 MHz, $CDCl_3$): δ = 0.27 (s, 6 H, BCH_3), 2.35 (s, 3 H, pic-CH_3), 4.03 (vt, 2 H, *J* = 1.7 Hz, C_5H_4), 4.06 (s, 5 H, C_5H_5), 4.16 (vt, 2 H, *J* = 1.7 Hz, C_5H_4), 7.16 (d, 2 H, *J* = 6.6 Hz, pic-3-H, -5-H), 8.41 (d, 2 H, *J* = 6.6 Hz, pic-2-H, -6-H). − ^{13}C NMR (100.5 MHz, $CDCl_3$): δ = 11.1 (br, BCH_3), 21.0 (pic-CH_3), 67.9 (C_5H_5), 68.4, 71.7 (C_5H_4), n.o. (C_5H_4-*ipso*), 125.4 (pic-C-3, -C-5), 144.5 (pic-C-2, -C-6), 150.7 (pic-C-4). − $C_{18}H_{22}BFeN$ (319.04): calcd. C 67.77, H 6.95, N 4.39; found C 67.86, H 6.92, N 4.31.

Preparation of **1**·DMAP: **1** (0.34 g, 1.51 mmol) in toluene (10 ml) was treated with 4-(dimethylamino)pyridine (0.18 g, 1.47 mmol) in toluene (5 ml) at ambient temperature. The cloudy orange mixture was stirred for 1 h and then concentrated to half of its original volume in vacuo, whereupon an orange precipitate gradually formed. The precipitate was removed by filtration (G3 frit), triturated with hexane, and dried in vacuo. A second crop was obtained from the mother liquor upon storage at −30°C for 12 h. Yield 0.46 g (90%). − IR (KBr, cm^{-1}): $\tilde{\nu}$ = 1636 (vs), 1544 (m) (DMAP-C−C, C−N), 1104 (m), 1076 (m), 1058 (m) (B−N). − ^{11}B NMR (128.3 MHz, $CDCl_3$): δ = −3.0 ($h_{1/2}$ = 300 Hz). − ^{1}H NMR (400 MHz, $CDCl_3$): δ = 0.16 (s, 6 H, BCH_3), 3.02 (s, 6 H, NCH_3), 3.97 (vt, 2 H, *J* = 1.5 Hz, C_5H_4), 4.05 (s, 5 H, C_5H_5), 4.09 (vt, 2 H, *J* = 1.5 Hz, C_5H_4), 6.41 (d, 2 H, *J* = 6.6 Hz, DMAP-3-H, -5-H), 8.09 (d, 2 H, *J* = 6.6 Hz, DMAP-2-H, -6-H). − ^{13}C NMR (100.5 MHz, $CDCl_3$): δ = 10.9 (br, BCH_3), 39.2 (NCH_3), 67.8 (C_5H_5), 68.0, 71.5 (C_5H_4), n.o. Preparation of **1**·bipy-Pr: **1** (0.11 g, 0.49 mmol) in CH_3CN (3 ml) was treated with *N*-(*n*-propyl)-4-(4′-pyridyl)pyridinium hexafluorophosphate (0.17 g, 0.49 mmol) in CH_3CN (2 ml) at ambient temperature. The reaction mixture, which instantaneously took on a purple colour, was stirred for 1 h and then concentrated to a volume of 1 ml. Toluene (15 ml) was added, whereupon **1**·bipy-Pr precipitated quantitatively as a dark-purple microcrystalline solid, which was triturated with toluene (3 × 5 ml) and hexane (2 × 5 ml) and dried in vacuo overnight. Yield 0.25 g (90%). − IR (KBr, cm^{-1}): $\tilde{\nu}$ = 1646 (vs), 1627 (vs), 1552 (m), 1501 (m) (bipy-C−C, C−N), 1102 (m), 1079 (m), 1061 (m) (B−N). − ^{11}B NMR (128.3 MHz, CD_3CN): δ = 7.5 ($h_{1/2}$ = 350 Hz). − ^{1}H NMR (400 MHz, CD_3CN): δ = 0.30 (s, 6 H, BCH_3), 0.97 (t, 3 H, *J* = 7.5 Hz, CH_3), 2.01 (m, 2 H, CH_2CH_3), 4.06 (s, 5 H, C_5H_5), 4.08, 4.19 (n.r., 2 × 2 H, C_5H_4), 4.53 (t, 2 H, *J* = 7.6 Hz, NCH_2), 7.91, 8.29, 8.80, 8.87 (4 × d, 4 × 2 H, *J* = 6.5 Hz, bipy). − ^{13}C NMR (100.5 MHz, CD_3CN): δ = 10.5 (CH_3), 11.0 (br, BCH_3), 25.3 (CH_2CH_3), 64.0 (NCH_2), 69.2 (C_5H_5), 70.0, 72.5 (2 × br, C_5H_4), n.o. (C_5H_4-*ipso*), 124.4, 127.7, 144.6, 146.1, 148.5, 153.5 (bipy). − $C_{25}H_{30}BF_6FeN_2P$ (570.15): calcd. C 52.67, H 5.30, N 4.91; found C 52.33, H 5.25, N 4.92.

Preparation of **1**·bipy·**1**: At ambient temperature, a colourless solution of 4,4′-bipyridine (0.25 g, 1.60 mmol) in toluene (10 ml) was added dropwise to an orange-red solution of **1** (0.73 g, 3.23 mmol) in toluene (10 ml). The reaction mixture, which instantaneously took on a dark-brown colour, was stirred for 3 h, whereupon a purple microcrystalline solid gradually precipitated. All insolubles were collected on a frit (G3), triturated with toluene (5 ml) and hexane (5 ml), and dried in vacuo. The filtrate was kept at −30°C overnight to yield a second crop. Yield 0.91 g (94%). X-ray quality crystals were obtained from toluene/hexane (1:1) at −30°C. − IR (KBr, cm^{-1}): $\tilde{\nu}$ = 1622 (vs), 1540 (m), 1493 (m) (bipy-C−C, C−N), 1100 (s), 1075 (s), 1058 (s) (B−N); IR (CH_2Cl_2, cm^{-1}): $\tilde{\nu}$ = 1622 (vs), 1597 (w), 1538 (w), 1517 (vw), 1489 (m) (bipy-C−C, C−N), 1104 (s), 1076 (s), 1058 (s) (B−N). − UV (CH_2Cl_2): λ = 239, 447 nm. − ^{11}B NMR (128.3 MHz, $CDCl_3$): δ = 15.1 ($h_{1/2}$ = 700 Hz). − ^{1}H NMR (400 MHz, $CDCl_3$): δ = 0.40 (s, 12 H, BCH_3), 4.08 (s, 10 H, C_5H_5), 4.13, 4.27 (2 × n.r., 2 × 4 H, C_5H_4), 7.53 (d, 4 H, *J* = 5.5 Hz, bipy-3-H, -5-H), 8.72 (d, 4 H, *J* = 5.5 Hz, bipy-2-H, -6-H). − ^{13}C NMR (100.5 MHz, $CDCl_3$): δ = 10.8 (br, BCH_3), 68.5 (C_5H_5), 70.3, 72.8 (C_5H_4), n.o. (C_5H_4-*ipso*), 122.2 (bipy-C-3, -C-5), 145.9 (bipy-C-4), 147.4 (bipy-C-2, -C-6). − $C_{34}H_{38}B_2Fe_2N_2$ (608.00): calcd. C 67.17, H 6.30, N 4.61; found C 66.81, H 6.54, N 4.41.

Preparation of **1**·pyetpy·**1**: **1** (0.72 g, 3.19 mmol) in toluene (20 ml) was treated dropwise with 1,2-bis(4-pyridyl)ethane (0.29 g, 1.57 mmol) in toluene (10 ml) at ambient temperature. A yellow microcrystalline solid precipitated from the orange reaction mixture. The slurry was stirred for 3 h and the solid material was isolated by filtration. After trituration with toluene (5 ml) and hexane (5 ml), the product was dried in vacuo. Yield 0.96 g (84%). − IR (KBr, cm^{-1}): $\tilde{\nu}$ = 1623 (s), 1560 (w), 1506 (m), 1496 (m) (pyetpy-C−C, C−N), 1102 (m), 1069 (s), 1061 (m) (B−N). − UV (CH_2Cl_2): λ = 239, 447 nm. − ^{11}B NMR (128.3 MHz, $CDCl_3$): δ = 6.2 ($h_{1/2}$ = 900 Hz). − ^{1}H NMR (400 MHz, $CDCl_3$): δ = 0.29 (s, 12 H, BCH_3), 2.94 (s, 4 H, -CH_2-), 4.04 (vt, 4 H, *J* = 1.5 Hz, C_5H_4), 4.06 (s, 10 H, C_5H_5), 4.18 (vt, 4 H, *J* = 1.5 Hz, C_5H_4), 7.14 (d, 4 H, *J* = 6.0 Hz, pyetpy-3-H, -5-H), 8.48 (d, 4 H, *J* = 6.0 Hz, pyetpy-2-H, -6-H). − ^{13}C NMR (100.5 MHz, $CDCl_3$): δ = 10.9 (br, BCH_3), 34.8 (−CH_2−), 68.1 (C_5H_5), 69.2, 72.1 (C_5H_4), n.o. (C_5H_4-*ipso*), 124.4 (pyetpy-C-3, -C-5), 145.8 (pyetpy-C-2, -C-6), 151.8 (pyetpy-C-4). − $C_{36}H_{42}B_2Fe_2N_2$ (636.07)·C_7H_8 (92.14): calcd. C 70.92, H 6.92, N 3.85; found C 70.97, H 6.67, N 3.79.

Preparation of **2**·$(pic)_2$: **2** (0.43 g, 1.62 mmol) in toluene (10 ml) was treated with a solution of γ-picoline (0.33 g, 3.54 mmol) in

toluene (5 ml) at ambient temperature. The resultant orange slurry was stirred for 1 h. Insoluble material was collected on a frit (G3), triturated with hexane (5 ml), and dried in vacuo. Yield 0.59 g (81%). − IR (KBr, cm^{-1}): $\tilde{\nu}$ = 1628 (s), 1508 (m) (pic-C−C, C−N), 1066 (s), 1047 (s) (B−N). − ^{11}B NMR (128.3 MHz, $CDCl_3$): δ = 15.0 ($h_{1/2}$ = 300 Hz). − ^1H NMR (400 MHz, $CDCl_3$): δ = 0.34 (s, 12 H, BCH_3), 2.37 (s, 6 H, pic-CH_3), 3.99, 4.13 (2 × n.r., 2 × 4 H, C_5H_4), 7.15 (d, 4 H, J = 6.0 Hz, pic-3-H, -5-H), 8.44 (d, 4 H, J = 6.0 Hz, pic-2-H, -6-H). − ^{13}C NMR (100.5 MHz, $CDCl_3$): δ = 10.9 (br, BCH_3), 21.1 (pic-CH_3), 71.0, 72.6 (C_5H_4), n.o. (C_5H_4-*ipso*), 125.2 (pic-C-3, -C-5), 145.6 (pic-C-2, -C-6), 149.8 (pic-C-4). − $C_{26}H_{34}B_2FeN_2$ (452.04): calcd. C 69.08, H 7.58, N 6.20; found C 68.58, H 7.38, N 6.10.

Preparation of **2**·$(DMAP)_2$: The compound was synthesized similarly to **2**·$(pic)_2$ using **2** (0.18 g, 0.68 mmol) and 4-(dimethylamino)-pyridine (0.17 g, 1.39 mmol). Yield 0.28 g (81%). − IR (KBr, cm^{-1}): $\tilde{\nu}$ = 1638 (vs), 1552 (s) (DMAP-C−C, C−N), 1077 (m), 1060 (m) (B−N). − ^{11}B NMR (128.3 MHz, $CDCl_3$): δ = −2.3 ($h_{1/2}$ = 500 Hz). − ^1H NMR (400 MHz, $CDCl_3$, 55°C): δ = 0.39 (s, 12 H, BCH_3), 3.01 (s, 12 H, NCH_3), 4.01, 4.16 (2 × n.r., 2 × 4 H, C_5H_4), 6.42 (d, 4 H, J = 6.6 Hz, DMAP-3-H, -5-H), 8.12 (d, 4 H, J = 6.6 Hz, DMAP-2-H, -6-H). − ^{13}C NMR (100.5 MHz, $CDCl_3$, 55°C): δ = 10.6 (br, BCH_3), 39.2 (NCH_3), 71.8, 73.1 (C_5H_4), n.o. (C_5H_4-*ipso*), 106.1 (DMAP-C-3, -C-5), 144.4 (DMAP-C-2, -C-6), 154.7 (DMAP-C-4). − $C_{28}H_{40}B_2FeN_4$ (510.13): calcd. C 65.93, H 7.90, N 10.98; found C 65.44, H 7.77, N 10.74.

Preparation of **2**·$(bipy\text{-}Pr)_2$: The compound was synthesized similarly to **1**·bipy-Pr from **2** (0.19 g, 0.71 mmol) and *N*-(*n*-propyl)-4-(4′-pyridyl)pyridinium hexafluorophosphate (0.49 g, 1.42 mmol). Yield 0.42 g (60%). − IR (KBr, cm^{-1}): $\tilde{\nu}$ = 1645 (vs), 1624 (s), 1550 (m), 1496 (m), 1470 (m) (bipy-C−C, C−N), 1072 (w), 1062 (m) (B−N). − ^{11}B NMR (128.3 MHz, CD_3CN): δ = 15.1 ($h_{1/2}$ = 500 Hz). − ^1H NMR (400 MHz, CD_3CN): δ = 0.42 (br, 12 H, BCH_3), 0.97 (t, 6 H, J = 7.5 Hz, CH_3), 2.01 (m, 4 H, CH_2CH_3), 4.05, 4.18 (2 × n.r., 2 × 4 H, C_5H_4), 4.52 (t, 4 H, J = 7.6 Hz, NCH_2), 7.88, 8.30, 8.76, 8.88 (4 × d, 4 × 4 H, J = 6.5 Hz, bipy). − ^{13}C NMR (100.5 MHz, CD_3CN): δ = 10.5 (CH_3), 11.0 (br, BCH_3), 25.3 (CH_2CH_3), 64.0 (NCH_2), 73.0, 74.0 (2 × br, C_5H_4), n.o. (C_5H_4-*ipso*), 124.1, 127.4, 144.1, 146.0, 149.2, 153.9 (bipy). − $C_{40}H_{50}B_2F_{12}FeN_4P_2$ (954.27)·0.4 C_7H_8 (92.14): calcd. C 51.87, H 5.41, N 5.65, Fe 5.63; found C 51.92, H 5.45, N 5.68, Fe 5.23.

Preparation of [**2**·bipy]$_n$: A red solution of **2** (0.13 g, 0.49 mmol) in $CHCl_3$ (15 ml) was layered firstly with neat CH_2Cl_2 (15 ml) and secondly with a solution of 4,4′-bipyridine (0.08 g, 0.51 mmol) in THF (10 ml). After 12 h, mixing of all three phases was complete and a purple microcrystalline precipitate had formed, which was found to be insoluble in all common solvents at ambient temperature. Yield 0.20 g (96%). − IR (KBr, cm^{-1}): $\tilde{\nu}$ = 1622 (vs), 1540 (m), 1493 (m) (bipy-C−C, C−N), 1075 (s), 1061 (s) (B−N). − $[C_{24}H_{28}B_2FeN_2]_n$ (421.97)$_n$: calcd. C 68.31, H 6.69, N 6.64; found C 67.91, H 6.62, N 6.48.

Preparation of [**2**·pyetpy]$_n$: A solution of 1,2-bis(4-pyridyl)ethane (0.13 g, 0.71 mmol) in toluene (20 ml) was added dropwise with stirring to **2** (0.19 g, 0.71 mmol) in toluene (20 ml). The resultant orange slurry was stirred for 4 h, the insoluble material was collected on a frit (G3), triturated with hexane (5 ml), and dried in vacuo. The product was found to be insoluble in all common solvents at ambient temperature. Yield 0.25 g (78%). − IR (KBr, cm^{-1}): $\tilde{\nu}$ = 1626 (vs), 1567 (w), 1506 (m) (pyetpy-C−C, C−N), 1073 (m), 1059 (s) (B−N). − $[C_{26}H_{32}B_2FeN_2]_n$ (450.03)$_n$: calcd. C 69.39, H 7.17, N 6.22; found C 69.33, H 7.27, N 6.26.

X-ray Crystal Structure Analysis of **1**·bipy·**1**:[42] A selected purple crystal of **1**·bipy·**1** was placed in perfluorinated oil and mounted in a glass capillary on an Image Plate Diffraction System (IPDS, STOE). Final lattice parameters were obtained by least-squares refinement of 2988 reflections (graphite monochromator, λ = 0.71073 Å, Mo-K_α). Empirical formula $C_{34}H_{38}B_2Fe_2N_2$, formula weight = 608.00, triclinic system, space group $P\bar{1}$ (I.T. no.: 2); a = 8.7143(5) Å, b = 13.8257(10) Å, c = 15.8214(12) Å, α = 65.820(7), β = 86.337(7), γ = 75.376(7), V = 1680.9(2) Å^3, crystal size 0.20 × 0.13 × 0.13 mm, Z = 2, F(000) = 636. Data were collected at 293 K, distance from crystal to image plate 70 mm (10.2° < Θ < 24.7°), 300 images collected, 0° < φ < 300°, Δφ = 1°, exposure time 5 min. Data were corrected for Lorentz and polarization terms.[52] A decay and absorption correction (μ = 8.9 cm^{-1}) was performed using the program DECAY;[52] 19554 data measured, 4982 independent reflections used for refinement. The structure was solved by direct methods and refined with standard difference Fourier techniques.[53] All hydrogen atoms of **1**·bipy·**1** were calculated in ideal positions (riding model). **1**·bipy·**1** crystallizes together with 0.5 equiv. of toluene (NMR spectroscopy; elemental analysis). Severe disorder of the toluene molecules precluded their structural refinement to any satisfactory level. We have therefore applied the "squeeze" routine[54] to remedy this disordered solvent problem (potential solvent accessible area: 293 Å^3). Number of parameters refined: 361, 13.8 data per parameter, weighting scheme w = 1/[$\sigma^2(F_o^2)$ + (0.0176·P)^2] where P = (F_o^2 + 2·F_c^2)/3, shift/error < 0.001 in the last cycle of refinement, residual electron density +0.15 eÅ^{-3}, −0.18 eÅ^{-3}, *R1* = 0.0319 [I > 2σ(I)], *wR2* = 0.0558 (all data), the minimized function was Σw(F_o^2 − F_c^2)^2. Neutral atom scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from the *International Tables for X-ray Crystallography.*[55] All calculations were performed with a DEC 3000 AXP workstation with the STRUX-V system,[56] incorporating the programs PLATON-92,[57] PLUTON-92,[57] SHELXS-86,[58] SIR-92,[53] and SHELXL-93.[59]

Electrochemical Measurements: Cyclic voltammetry and controlled potential coulometry were performed in deaerated dimethylformamide (DMF) and CH_2Cl_2 solutions containing [NEt_4][PF_6] (0.1 mol·dm^{-3}) and [NBu_4][ClO_4] (0.2 mol·dm^{-3}), respectively, as supporting electrolytes. All potential values are referred to the Saturated Calomel Electrode (S.C.E.). The apparatus for electrochemistry measurements is described in ref.[60].

☆ Dedicated to Professor *Heinrich Nöth* with gratitude on the occasion of his 70th birthday.

Keywords: Dimethyltin salicylaldoximates / Chiral ligands / Proton-tin HMQC NMR / X-ray structure / Trinuclear microclusters

The complex {[$(CH_3)_2Sn]_2$[$(CH_3)_2SnO$](OCH$_3$)(HONZO)(ONZO)} (**3**) [ONZOH is the oximate residue, *o*-(–ON=CH–C_6H_4–OH), HONZO the corresponding phenolate residue, *o*-(HON=CH–C_6H_4–O–), and ONZO the dibasic species *o*-(–ON=CH–C_6H_4–O–), all derived from salicylaldoxime, *o*-(HON=CH–C_6H_4–OH)] reacts with an excess of racemic (*d,l*)-2-methyl-1-butanol to afford the μ_2-substitution product **5a** {[$(CH_3)_2Sn]_2$[$(CH_3)_2SnO$][$OCH_2CH(CH_3)CH_2CH_3$](HONZO)(ONZO)]}. Crystallographic characterisation of the trinuclear microcluster **5a** shows the presence of the monobasic HONZO ligand in a tridentate μ_2-O,N mode and of the dibasic ONZO ligand in a tridentate O,N,O mode. This coordination mode leads to one seven-coordinate and two five-coordinate tin centers that are linked by a μ_3-oxo function. The coordination geometries are distorted pentagonal bipyramidal and trigonal bipyramidal, respectively. The two low-coordinate tin atoms are linked by the alkoxide ion. The corresponding chiral (*S*)-2-methyl-1-butanol reacts analogously to yield **5b**. By contrast, reaction of **3** with chiral secondary alcohols (2-butanol or 1-phenyl-1-ethanol), in various molar ratios, failed to provide the corresponding μ_2-alkoxy complex. Instead, pure crystals of {[$(CH_3)_2Sn]_2$[$(CH_3)_2SnO$](OH)(HONZO)(ONZO)} (**2a**) were isolated.

Introduction

Reaction of salicylaldoxime, *o*-(HON=CH−C_6H_4−OH), and diorganotin(IV) oxide, R_2SnO (R = Me, *n*-Bu), yields small clusters represented as [$(R_2Sn)_2(R_2SnO)$(ONZOH)(HONZO)(ONZO)] (**1b**: R = *n*-Bu; **2b**: R = Me), where ONZOH is the oximate residue *o*-(−ON=CH−C_6H_4−OH), HONZO is the phenolate *o*-(HON=CH−C_6H_4−O−), and ONZO is the dibasic species *o*-(−ON=CH−C_6H_4−O−), associated with salicylaldoxime[1]. Their general structure is displayed in Figure 1[1].

Attempts to crystallize crude **1b** or **2b** with hydroxylated solvents usually lead to substitution compounds like the μ_2-hydroxy-bridged compound **1a** (R = *n*-Bu)[1a], or a μ_2-alkoxy-bridged compound (R = Me)[1b], as e.g. **3**, the μ_2-bridged ONZOH unit being eliminated as salicylaldoxime (HONZOH).

Such compounds undergo facile reversible μ_2-nucleophilic substitutions with protonated nucleophiles, according to Scheme 1[2][3].

X-ray data on several such compounds reveal that ligand A is planar, with Sn(1), Sn(2) and Sn(3) being coplanar. By contrast, ligand B is dramatically twisted since the atom N18 is 0.3 Å away from the mean plane of the aromatic ring with which it is associated[1a][1b][2]. As a consequence, these derivatives have a chiral skeleton in the solid state.

In order to assess whether this skeleton chirality could be detected in solution, we prepared dimethyltin salicylaldoximate derivatives containing a ligand with a chiral center bridging the Sn(2) and Sn(3) tin atoms. Provided the chirality of the cluster skeleton would be maintained in solution, it should indeed be observable through the formation of the diastereoisomers necessarily obtained[4].

This paper presents solid-state and solution characterization by X-ray diffraction and 1D- and 2D-NMR spectroscopy, mainly gradient assisted[5] ^{1}H-^{13}C HMQC[6a] and HMBC[6b][6c] and ^{1}H-^{119}Sn HMQC[7], of compounds derived from the reaction of **3** with chiral alcohols. The first tris(dimethyltin) disalicylaldoximate with a chiral μ_2-bridged alkoxy ligand is reported.

Results and Discussion

Synthesis

Reaction of **3** with an excess of racemic (*d,l*)-2-methyl-1-butanol provides, after recrystallization from dichlorometh-

$$[(R_2Sn)_2(R_2SnO)(Nu)(HONZO)(ONZO)] + Nu'\text{-}H \rightleftharpoons [(R_2Sn)_2(R_2SnO)(Nu')(HONZO)(ONZO)] + Nu\text{-}H$$

ane/hexane (1:1), pure crystals of μ_2-(*d,l*)-2-methylbutoxydimethyltin salicylaldoximate (**5a**) (Figure 1). Similarly, crystals of μ_2-(*S*)-2-methylbutoxydimethyltin salicylaldoximate (**5b**) were obtained starting from (*S*)-(−)-2-methyl-1-butanol.

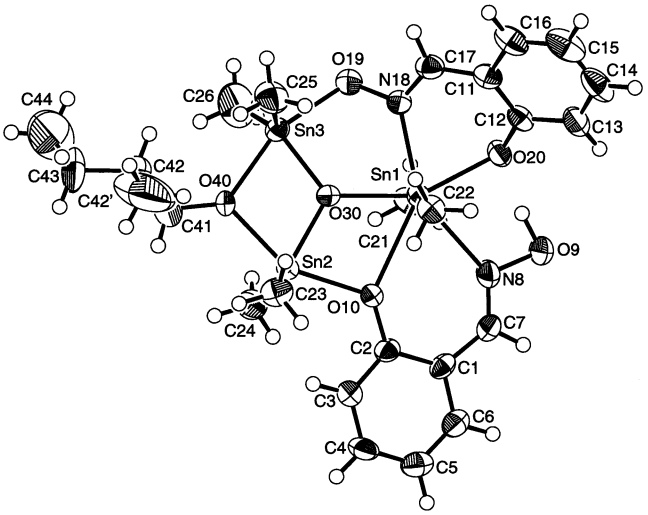
By contrast, reaction of **3** with chiral secondary alcohols (2-butanol or 1-phenyl-1-ethanol), in various molar ratios, failed to provide the corresponding crystalline μ_2-alkoxy complex. Instead, pure crystals of **2a** were isolated; the compound **2a** was observed so far only as a transient[1b][2][3], where the μ_2-methoxy moiety of **3** is substituted for a μ_2-hydroxy one.

NMR analysis of the crude product obtained by reaction of **3** with secondary alcohols revealed the presence of the desired μ_2-(*sec*)-alkoxy compound in small fractions, depending on the starting alcohol, in addition to **3** and **2b**. Monitoring the reaction of **3** with (*d,l*)-2-butanol by ^1H, ^{13}C and ^{119}Sn NMR reveals an equilibrium mixture with the μ_2-1-methylpropoxy compound as a minor species, even when the secondary alcohol is used in large excess. This result implies that a μ_2-alkoxy moiety bridging Sn(2) and Sn(3) is more stable when it originates from a primary alcohol than from a secondary one, probably due to steric hindrance of the latter.

X-ray Diffraction Analysis of Compound 5a

The molecular structure of **5a** resembles closely those found for related systems[1][2][3] and hence, only a brief description of **5a** is given (Figure 2).

Figure 2. Molecular structure and crystallographic numbering scheme employed for **5a**



There are two distinct coordination geometries about the tin atoms in the trinuclear structure. The Sn(1) atom is seven-coordinate, existing in a distorted pentagonal bipyramidal geometry with the methyl substituents occupying axial positions, C−Sn−C is 167.4(3)°. The equatorial plane is defined by the phenoxide O(10) and O(20) atoms, the oxime N(8) and N(18) atoms and an oxo O(30) atom. In this description, the Sn(1) atom lies 0.0012(4) Å out of the plane in the direction of the C(21) atom. The remaining tin atom geometries are based on trigonal bipyramidal geometries defined by the oxo O(30) atom, the alkoxide O(40) atom, two methyl substituents and for Sn(2) the phenoxide O(10) atom and for Sn(3) the oxime O(19) atom. The Sn(2) atom lies 0.0932(4) Å above the $C_2O(30)$ trigonal plane in the direction of the O(10) atom and the deviation of the Sn(3) atom from the $C_2O(30)$ plane is 0.0324(4) Å, in the direction of the O(19) atom. The geometric parameters describing **5a** (Table 1) are in essential agreement with those found in the analogous T = Me, Et, *n*Pr and *i*Pr structures[1b]. Notable features in the structure include the presence of the tri-coordinate O(30) atom, the symmetric alkoxide bridge [Sn(2)−O(40) is 2.164(4) Å and Sn(3)−O(40) is 2.174(4) Å], and an intramolecular hydrogen bond formed between the O(9)*H* and O(20) atoms such that O(9)*H*···O(20) is 1.59 Å and O(9)−H···O(20) is 166°. The crystal structure of **5a** is comprised of equal amounts of the *R* and *S* forms of the chiral alcohol, i.e. is racemic.

An investigation of the structure of the chiral *S* form of the compound, i.e. **5b**, was also undertaken[8]. The crystal

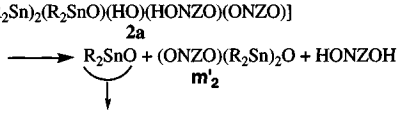
structure obtained for a crystal chosen from the recrystallisation of **5b** shows the presence of both the *S* form as well as a small amount of the *R* form. The asymmetric unit contains two pseudo-centrosymmetrically related molecules. One site contains 100% of the *S* form, while the other site contains 58.6% of the *R* form, giving a 1.414(22):0.586 ratio of the two forms in the crystal investigated. A number of crystals were examined and similar results were obtained each time, including under conditions of low temperature (200 K). Presumably, the centrosymmetric structure packing ($P2_1/c$) is thermodynamically favoured implying that the better grown crystals have a higher percentage of the minor component[8]. The geometric features determined for **5b** are as described for the racemic species.

Solution-State Structure

Dissolving dimethyltin salicylaldoximates usually gives rise to minor species involved in a complex equilibrium, among which **2b** and the dimethyl analogue of m_2[1a]. In benzene solution, **5** remains the major species. By contrast, when **2a** is dissolved in C_6D_6, it remains only as a minor species, the transient signals of m_2 dominating the ^{119}Sn NMR spectrum. This is accompanied by an important precipitation in the NMR tube. This observation is accounted for by the reaction of Scheme 2.

Scheme 2

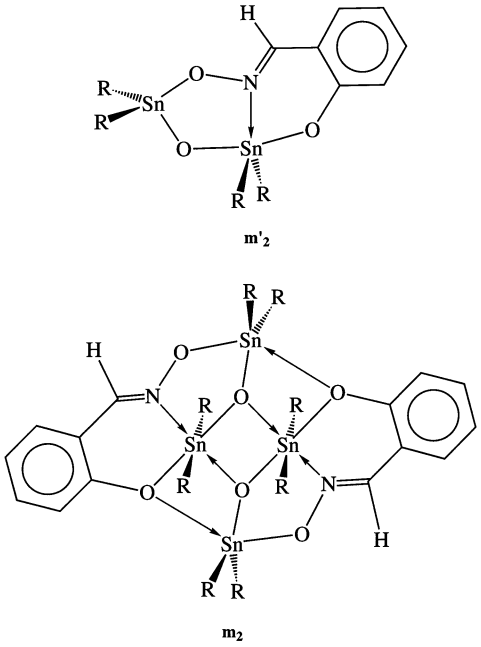


The structures of m'_2, and of its resulting dimer, m_2, proposed from comparable observations[1a] on the corresponding di-*n*-butyltin compound **1a**, are shown in Figure 3. Further evidence to the reaction of Scheme 2 is the observation of the oximic ^{1}H resonance of free salicylaldoxime.

In $CDCl_3$, the transient fractions remain low. Lowering the temperature increases the fraction of **2a** in the mixture, enabling its full NMR characterization at 270 K.

Table 2 presents an overview of the ^{1}H, ^{13}C, and ^{119}Sn chemical shifts and coupling constants associated with the dimethyltin moieties. The ^{1}H,^{13}C and ^{119}Sn resonances of **5** and **2a** were assigned with exactly the same strategy as reported previously for **2b**, **3** and **4**, using 2D gradient-enhanced ^{1}H-^{13}C HMQC and HMBC spectroscopy[5][6][7] and ^{1}H-^{119}Sn HMQC spectroscopy[1][2][3][6], evidencing the same basic tritin cluster structure for **5** and **2a** as for **2b** and

Figure 3. Transients generated from dissolving compound **2a** in C_6D_6 (see text)



of Sn(1), probably because the latter are too remote from the chiral center.

NMR spectra of **5** do not show any evidence of skeletal chirality in dimethyltin salicylaldoximate in addition to that arising from the chiral alkoxide moiety. Indeed, additional skeletal chirality observable on the NMR time scale should have provided two racemic diastereoisomers resulting in further unequal duplication of the ^{119}Sn resonances of all three Sn(1), Sn(2) and Sn(3) atoms. This expectation remained unfulfilled in spite of the very high sensitivity to the electronic environment of the ^{119}Sn nucleus evidenced by its wide chemical shift range (3000 ppm)[4][9]. Hence, it can be concluded that the observed splitting of equal intensity in the ^{1}H and ^{13}C resonances for **5** is due to a pairwise anisochrony of the two methyl groups within each of the five-coordinate tin atoms generated by their vicinity to the stereogenic carbon centre of the chiral alkoxy ligand.

Conclusion

This paper has addressed several issues unsolved so far in the chemistry of tris(dimethyltin) disalicylaldoximates. First, a chiral group could be incorporated for the first time

[a] Chemical-shift data in ppm and coupling constants in Hz. − [b] Averaged values from unresolved ^{n}J(^{119}Sn-^{119}Sn) and ^{n}J(^{119}Sn-^{117}Sn) coupling satellites in ^{119}Sn spectrum. − [c] Spectrum recorded from a C_6D_6 solution of **5** at 303 K. − [d] Invisible satellites because of broad ^{119}Sn(1) resonance feet. − [e] Spectrum recorded from a $CDCl_3$ solution of **2a** at 270 K.

3 (Figure 1). The ^{1}H-^{119}Sn HMQC cross peaks of **5** and **2a** reviewed in Table 3, similar to those of **1a**, **1b**, **2b** and **3**, support this conclusion, as do all the ^1J(^{13}C-$^{119/117}$Sn), ^{n}J(^{119}SN−O-$^{119/117}$Sn), and ^2J(^{1}H-$^{119/117}$Sn) coupling data.

Characteristically, the ^{1}H-^{119}Sn HMQC spectrum of **5** shows a cross peak between the two diastereotopic protons, H(41A) and H(41B) of the 2-methylbutoxy group, and both Sn(2) and Sn(3) atoms. In the case of **2a**, a correlation is observed between the hydroxy proton, H(40), and both Sn(2) and Sn(3) tin atoms. These correlations are in agreement with the binding site of the entering nucleophile between Sn(2) and Sn(3).

The ^{1}H and ^{13}C methyl resonances of Sn(2) and Sn(3) in compound **5** are duplicated (Table 2). This is in agreement with the pairwise diastereotopism of the Sn(2) and Sn(3) methyl groups due to the presence of the chiral carbon atom C(42) (see below). These features are observed both in **5a**, obtained from racemic (*R,S*)-2-methyl-1-butanol, and **5b** from enantiomerically enriched (*S*)-2-methyl-1-butanol. Such an anisochrony is not observed for the methyl groups

into such a complex. Second, the limits of the reactivity of these complexes towards alcohols have clearly been defined. Thus, while primary alcohols smoothly react towards the corresponding μ_2-alkoxy-substituted complex, even when the substituent on the CH_2OH moiety is rather bulky, secondary alcohols, apart from 2-propanol[1b], fail to yield the corresponding μ_2-substitution products. A steric effect from a moderately bulky group is responsible for this. Third, the first clear evidence of chirality-related anisochrony of the two methyl groups on the dimethyltin moieties demonstrates that their diastereotopism can be induced on the NMR time scale only by the introduction of a μ_2-bridged chiral group into the complex. Accordingly, this rules out that the skeletal chirality displayed by these microclusters in the crystalline state remains observable in solution on the ^{119}Sn-NMR time scale, no anisochrony being visible without chiral substituent. This suggests a fast inversion of the skeletal chirality on this time scale. Last, albeit unexpected, the μ_2-hydroxy-bridged complex could be fully isolated, having been observed only as a transient so far[1][2]. Actu-

ally, this complex appears to be the only one that can be generated from the reaction mixture when the synthesis of complexes involving chiral μ_2-bridged secondary alkoxy groups is attempted. Noteworthy is that the resulting complex reaction mixture smoothly evolves by crystallization to the single μ_2-hydroxy complex, just by taking up water present in the medium, either in the solvent and/or in the atmosphere.

Experimental Section

General: The samples were prepared by dissolving ca. 40 mg of product in 0.5 ml of solvent. NMR spectra of compounds **5a** and **5b** were recorded at 303 K in C_6D_6 and those of compound **2a** were recorded at 270 K in $CDCl_3$. ^{1}H-, ^{13}C- and ^{119}Sn-NMR spectra were recorded with a Bruker AMX500 spectrometer equipped with a digital lock and operating at 500.13, 125.77 and 186.50 MHz, respectively. Chemical shifts are in ppm, coupling constants in Hz. The ^{119}Sn reference frequency was calculated from the absolute frequency of Me_4Sn, Ξ = 37.290 665 MHz[10]. ^{13}C and ^{1}H chemical shifts were respectively referenced to the ^{13}C resonance of the solvent at δ = 128.0 (C_6D_6) or 77.0 ($CDCl_3$) and to the residual ^{1}H solvent resonance at δ = 7.15 (C_6D_5H) or 7.24 ($CHCl_3$); multiplicity patterns in ^{1}H spectra are: d: doublet; dd: doublet of doublets; ddd: doublet of doublets of doublets; s: singlet; m: complex pattern; nr: non resolved. ^nJ(^{1}H-^{1}H) coupling constants are given between parentheses. ^nJ(^{1}H-^{119}Sn), ^1J(^{13}C-$^{119/117}$Sn), and ^2J(^{119}Sn-$^{119/117}$Sn) coupling constants are given in Table 2 and not repeated here. Broad-band ^{1}H-decoupled ^{13}C and ^{119}Sn spectra were recorded using Bruker standard pulse sequences. All heteronuclear correlation-spectroscopy experiments consisted of gradient-enhanced versions of the standard ^{1}H-^{119}Sn HMQC and ^{1}H-^{13}C HMQC or HMBC pulse sequences, implemented in exactly the same way as explained elsewhere and processed in the magnitude mode[1b].

X-ray Diffraction Studies: Intensity data for a colourless crystal of **5a** were collected at 200 K with a Rigaku AFC6R diffractometer employing Mo-K_α radiation (λ = 0.71073 Å) and the ω-2θ scan technique to $2\theta_{max}$ = 50.0°. The data set was corrected for Lorentz and polarisation effects[11] as well as for absorption employing an empirical procedure (range of transmisison factors: 0.756 to 1)[12]. Data that satisfied the $I \geq 3.0\sigma(I)$ criterion of observability were used in the subsequent analysis. Crystal data and refinement details are given in Table 4.

Table 4. Crystallographic data for **5a**

Formula	$C_{25}H_{40}N_2O_6Sn_3$
Formula weight	820.7
Crystal system	monoclinic
Space group	$P2_1/c$
a [Å]	8.865(5)
b [Å]	17.64(1)
c [Å]	19.52(1)
β [°]	92.49(6)
V [Å^3]	3048(3)
Z	4
Crystal dimensions [mm]	0.11 × 0.37 × 0.47
$\rho_{calcd.}$ [g cm^{-3}]	1.788
$F(000)$	1608
No. of data collected	5970
No. of unique data	5591
No. of reflections with $I \geq 3.0\sigma(I)$	4144
No. of refined parameters	325
R	0.035
R_w	0.041
Residual ρ_{max} [e Å^{-3}]	0.73

The structure was solved by direct methods[13] and refined by a full-matrix least-squares procedure based on F[11]. Non-hydrogen atoms were refined with anisotropic displacement parameters and hydrogen atoms were included in the model at their calculated positions (C−H 0.95 Å). The refinement was continued until convergence employing sigma weights, i.e. $1/\sigma^2(F)$. Selected interatomic parameters are collected in Table 1 and the crystallographic numbering scheme employed is shown in Figure 2 which was drawn with ORTEP[14] at 50% probability ellipsoids. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-101351. Copies of the data can be obtained free of charge on application

Compound **3**: Compound **3** was synthesized as previously described[1b].

Compound **5a**: To a solution of 1.000 g (1.31 mmol) of **3** in 10 ml of dichloromethane was added a solution of 0.598 g (6.8 mmol, 5.2 equiv.) of (*d,l*)-2-methyl-1-butanol in 10 ml of dichloromethane. The mixture was stirred for 5 min and the solvent was evaporated under vacuum. Recrystallization in dichloromethane/hexane (1:1) of the precipitate obtained provided 0.942 g of pure **5a** crystals suitable for X-ray analysis (yield: 88%). The compound starts melting under decomposition at 116°C. − $C_{25}H_{40}N_2O_6Sn_3$ (820.67): calcd. C 36.6, H 4.9, N 3.4; found C 36.6, H 5.2, N 3.4. − ^{1}H NMR (C_6D_6, 500.13 MHz; for complex patterns, the centre of ^{1}H-^{13}C HMQC cross peaks is given): δ = 13.88 [s, OH(9)], 8.23 (s, 17-H), 8.14 (s, 7-H), 7.07 (mnr, 3′-H), 7.06 (mnr, 4′-H), 7.04 (mnr, 4-H), 6.847 (dd, *J* = 7.7, 1.9 Hz, 6-H), 6.823 (dd, *J* = 7.6, 1.1 Hz, 6′-H), 6.605 (ddd, *J* = 7.4, 7.4, 0.8 Hz, 5-H), 6.570 (ddd, *J* = 7.6, 6.5, 1.8 Hz, 5′-H), 6.244 (d, *J* = 8.2 Hz, 3-H), 3.074 (dd, *J* = 10.9, 6.5 Hz, 41A-H), 2.955 (dd, *J* = 10.9, 7.0 Hz, 41B-H), 1.30 (mnr, 43A-H), 1.103 [s, CH_3 (Sn-1)]; 1.06 (mnr, 42-H), 0.81 (mnr, 43B-H), 0.78 (mnr, 44-H), 0.684 (d, *J* = 6.6 Hz, 45-H), 0.517 [s, Sn(2)−CH_3], 0.511 [s, Sn(2)−CH_3], 0.493 [s, Sn(3)−CH_3], 0.491 [s, Sn(3)−CH_3]. − ^{13}C NMR (C_6D_6, 125.76 MHz): δ = 162.6 (C-2′), 161.0 (C-2), 154.6 (C-17), 149.9 (C-7), 135.6 (C-6), 132.4 (C-4′), 132.1 (C-6′), 131.0 (C-4), 120.9 (C-3′), 120.7 (C-1), 119.4 (C-1′), 117.9 (C-3), 117.2 (C-5′), 117.1 (C-5), 68.5 (C-41), 38.8 (C-42), 26.3 (C-43), 16.5 (C-45), 14.8 [C−Sn(1)], 11.4 (C-44), 2.56 [C−Sn(2)], 2.51 [C−Sn(2)], −0.16 [C−Sn(3)], −0.27 [C−Sn(3)]. − ^{119}Sn NMR (C_6D_6, 186.50 MHz): −130.6 Sn(3), −141.8 Sn(2), −458.0 Sn(1).

Compound **5b**: Synthesis is the same as for **5a**, using 0.592 g of (*S*)-(−)-2-methyl-1-butanol; yield 53%. The compound starts melting under decomposition at 109°C. − $C_{25}H_{40}O_6N_2Sn_3$ (820.67): calcd. C 36.6, H 4.9, N 3.4; found C 36.1, H 5.0, N 3.4. − NMR spectra of **5b** are identical to those of **5a**.

Compound **2a**: Same procedure as for **5a**, using 1.000 g of **3** and 0.492 g (6.6 mmol, 5.1 equiv.) of (*d,l*)-2-butanol; recrystallization from dichloromethane/hexane (1:4); yield 59%. The compound starts melting under decomposition at 99°C. − $C_{20}H_{30}O_6N_2Sn_3$ (750.54): calcd. C 32.0, H 4.0, N 3.7; found C 32.1, H 4.1, N 3.6. − ^{1}H NMR ($CDCl_3$, 500.13 MHz): δ = 13.536 [s, OH(9)], 8.133 (s, 17-H), 8.006 (s, 7-H), 7.227 (ddd, *J* = 8.6, 7.2, 1.8 Hz, 4′-H), 7.17 (mnr, 4-H), 7.15 (mnr, 6-H), 7.104 (dd, *J* = 7.7, 1.7 Hz, 6′-H), 6,824 (d, *J* = 8.0 Hz, 3′-H), 6.746 (t, *J* = 7.4 Hz, 5-H and 5′-H), 6.366 (d, *J* = 8.1 Hz, 3-H), 2.406 (s, 40-H), 0.813 [s, Sn(1)−CH_3], 0.793 [s, Sn(2)−CH_3], 0.623 [s, Sn(3)−CH_3]. − ^{13}C NMR ($CDCl_3$, 125.76 MHz): δ = 161.4 (C-2′), 160.4 (C-2), 154.1 (C-17), 149.6 (C-7), 134.9 (C-6), 131.9 (C-4′), 131.7 (C-6′), 131.1 (C-4), 120.3 (C-3′), 119.4 (C-1), 118.7 (C-1′), 117.5 (C-3), 116.9 (C-5′), 116.5 (C-5), 14.0 [Sn(1)−CH_3], 4.4 [Sn(2)−CH_3], 1.9 [Sn(3)−CH_3]. − ^{119}Sn NMR ($CDCl_3$, 186.50 MHz): δ = −130.9 [Sn(3)], −142.6 [Sn(2)], −458.5 [Sn(1)].

Keywords: Electrochemistry / Mixed-valent compounds / Alkynecobalt complexes / Through-bond interactions / Through-space interactions

The electrochemical behaviour of the $[Co_2(CO)_6]_2$(μ-R–C≡C–L–C≡C–R) and $[Co_2(CO)_4(dppm)]_2$(μ-R–C≡C–L–C≡C–R) series is reported. Qualitative evidence suggests that both through-space and through-bond interactions are operating with different relative weight depending on the spacer L.

Introduction

Organometallic polymers with unsaturated bridging units are currently the subject of much research because of their potential as non-linear optical (NLO) materials[1][2], liquid crystals[3][4], and quasi-one-dimensional conductors[5]. The properties of such materials can be tuned by varying the organic link or by adjusting the metal itself. Poly-yne segments are recognised to allow long-distance electronic interactions through π-delocalization[6][7][8][9][10][11][12]. Several studies have been performed on organometallic "rigid rod" polymers, Lapinte[13] and Gladysz[14] have demonstrated that conjugated C_2 to C_{20} σ-acetylide bridges constitute the most efficient link between organometallic redox-active termini. Recently, we have investigated the electronic communication between redox-active clusters joined with diynes in a σ/π fashion[15][16][17], although this kind of interaction is suspected to reduce the π-conjugation.

Electrochemistry represents a simple tool to evaluate the extent of the electronic interaction between two redox centres[18][19][20][21]. When there is no electronic interaction between two redox cores, the $E^{\circ\prime}$ values differ only by a small statistical factor[22] (ca. 36 mV at 298 K) and in polarography/CV a single wave/peak is observed. On the other hand, when there is charge delocalization over the two centres, the $E^{\circ\prime}$ values for the redox processes differ up to about 700 mV[23], giving two, more or less resolved, waves/peaks.

In this paper, we study a large series of complexes where the redox centres are either "$Co_2(CO)_6$" or "$Co_2(CO)_4$(dppm)" moieties and the bidentate ligand is a μ-R−C≡C−L−C≡C−R chain[15][16][24]. The "Co_2-alkyne" electrochemical reduction is reasonably well understood[24][25], although fast ECE processes complicate its behaviour. Phosphane ligand substitution in $Co_2(CO)_6$(μ-alkyne) has been extensively studied mainly by Robinson et al.[26][27][28][29][30][31] The $Co_2(CO)_{6-n}(PR_3)_n$(alkyne) series exhibits a further electrochemically and chemically reversible 1e oxidation[24] only when n = 3, 4 and R = OMe. Similar behaviour has recently been observed for $Co_2(CO)_4$(dppm)(μ-alkyne) derivatives[32].

Results and Discussion

Complexes $[Co_2(CO)_6]_2$(μ-diyne) have been synthesised by reaction of $Co_2(CO)_8$ with the appropriate ligand[33] (Figure 1).

The subsequent CO substitution was achieved by thermal reaction of the $[Co_2(CO)_6]_2$(μ-diyne) with dppm [bis(diphenylphosphanyl)methane, $Ph_2P-CH_2-PPh_2$][34] (Scheme 1).

Scheme 1

$$2\ Co_2(CO)_8 + R-C\equiv C-L-C\equiv C-R \rightarrow [Co_2(CO)_6]_2(R-C\equiv C-L-C\equiv C-R) + 4\ CO$$

$$[Co_2(CO)_6]_2(R-C\equiv C-L-C\equiv C-R) + 2\ Ph_2P-CH_2-PPh_2 \rightarrow [Co_2(CO)_4(Ph_2P-CH_2-PPh_2)]_2(R-C\equiv C-L-C\equiv C-R) + 4\ CO$$

In most cases, in order to increase the yields of the desired compounds, $Co_2(CO)_6$(dppm) was employed as starting reagent[35].

Scheme 2

$$Co_2(CO)_8 + Ph_2P-CH_2-PPh_2 \rightarrow Co_2(CO)_6(Ph_2P-CH_2-PPh_2) + 2\ CO$$

$$2\ Co_2(CO)_6(Ph_2P-CH_2-PPh_2) + (R-C\equiv C-L-C\equiv C-R) \rightarrow [Co_2(CO)_4(Ph_2P-CH_2-PPh_2)]_2(R-C\equiv C-L-C\equiv C-R) + 4\ CO$$

Some substituted complexes were not stable enough to be isolated from both the pathways, namely $[Co_2(CO)_4(dppm)]_2(H-C\equiv C-CH_2-CH_2-C\equiv C-H)$, $[Co_2(CO)_4(dppm)]_2(H_3C-C\equiv C-C\equiv C-CH_3)$, and $[Co_2(CO)_4(dppm)]_2[Me_3Si-C\equiv C-C\equiv C-SiMe_3]$.

At room temperature, all diyne complexes **1**−**10** undergo an *apparently* single two-electron reduction process in the relative CV responses. However, as the temperature is low-

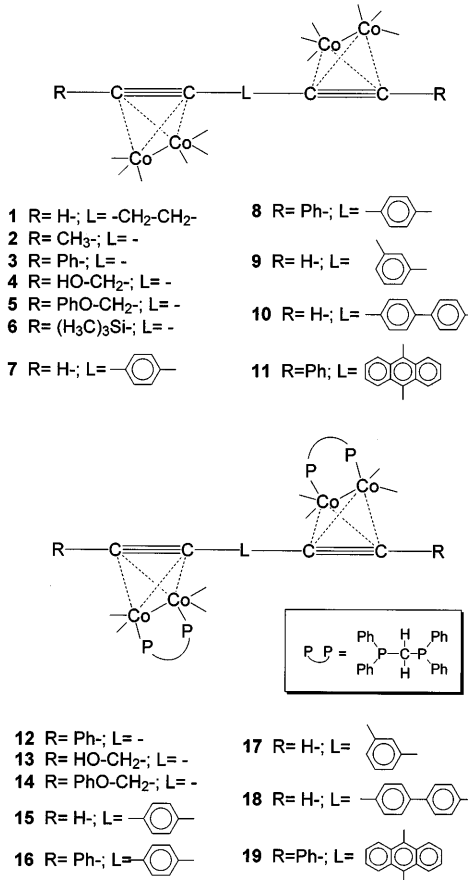
Figure 1. Sketch of structures of complexes **1**−**19**; CO ligands are omitted for clarity

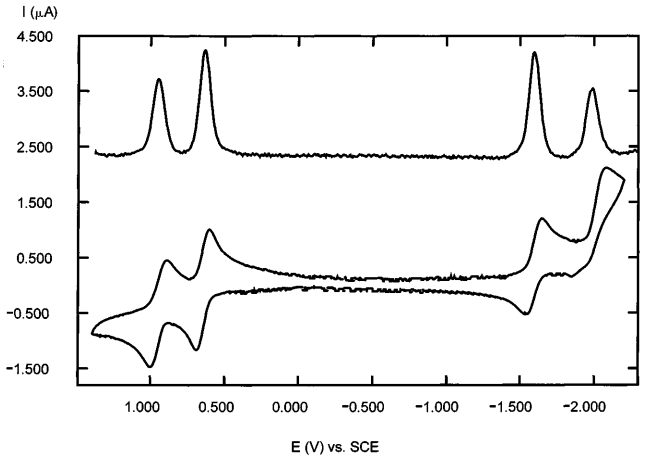


ered and/or the scan rate is increased, the chemical complications involving the primary radical anions are quenched so that two peak couples, corresponding to subsequent 1e reductions and showing full chemical reversibility, are observed[16][17].

For complexes **1**−**6**, two distinct peak couples are clearly observed in CV, at −30°C, allowing the calculation of the relevant formal electrode potentials $E^{\circ\prime}$ as $(E_p^c + E_p^a)/2$ (Table 1). Generally speaking, the external substituents R of the diyne affect the half-life of the electrogenerated monoanion; hydrogen substituents, in particular, give faster decomposition: in every case such complications can be eliminated by further raising the scan rate.

The complexes $[Co_2(CO)_4(dppm)]_2(R-C\equiv C-L-C\equiv C-R)$ (**12**−**19**) are interesting molecules as they have two identical redox centres which can undergo both reduction and oxidation processes. At ambient temperature, the cathodic scans mirror those of the parent compounds, albeit with a higher degree of chemical reversibility; the study of their $\Delta E^{\circ\prime}$ values requires low temperature. In contrast, two peak couples corresponding to Nernstian and chemically reversible 1e oxidation processes are always observed in the anodic region (Figure 2). It is worth mentioning that at low temperature (−30°C) such oxidation processes become electrochemically quasi-reversible, as testified by the increased ΔE_p values.

Figure 2. Electrochemical response of a THF solution of **12** ($1\cdot10^{-3}$ M) on a GC electrode at room temperature: SWV at 30 Hz (top) and CV at 0.2 V s^{-1}(bottom)



Certainly, the presence of dppm, which allows reversible oxidations to be observed at room temperature, facilitates the experimental work and, furthermore, permits the evaluation of the electronic communication for compounds such as **19**, where the aromatic 9,10-bis(phenylethynyl)anthracene gives reduction processes which overlap with those of the redox centres under study. In fact, no indication of electronic interaction could be obtained for **11**[17].

For complexes **7**−**10** and **15**−**19**, where the aromatic spacer is interpolated between the "Co_2C_2" moieties, the $E^{\circ\prime}$ values cannot be immediately evaluated from the CV responses at low temperature since the peaks are partially overlapped. We successfully employed a computer-assisted technique for peak resolution enhancement called *semi-derivative voltammetry*[36][37], where the CV data are first semi-integrated and then differentiated with respect to time (Figure 3). Alternatively, we used the Square Wave Voltammetry (SWV) technique[38] to resolve this overlapping. The relevant $E^{\circ\prime}$ values obtained from the above described techniques are in agreement (±10 mV) and are reported in Table 1.

For all compounds **1**−**19** the $\Delta E^{\circ\prime}$ values suggest a low to moderate electronic communication between the two bimetallic cores (formally corresponding to class-II mixed-valence systems in the Hush-Robin-Day formulation)[39][40].

Through-Bond and Through-Space Electronic Interaction

A large amount of data have been published on the metal−metal interactions in binuclear complexes M−L−M′ evaluated by electrochemistry. However, there are only rare attempts to rationalise this collection of potentials by using the distinction between through-space and through-bond interaction. Although both represent approximations, they can be distinguished via specially designed models. Through-space is the solvent-dependent coulombic interaction within the molecule and through-bond is both the so-called inductive (by successive polarisation of the bonds)

Figure 3. Cyclic voltammograms (top) and corresponding semiderivative voltammograms (bottom) of a THF solution of **16** on a GC electrode at 0.2 V s^{-1}; the cathodic scan is recorded at −30°C, the anodic scan at room temperature; Fc* = decamethylferrocene, added as an internal standard

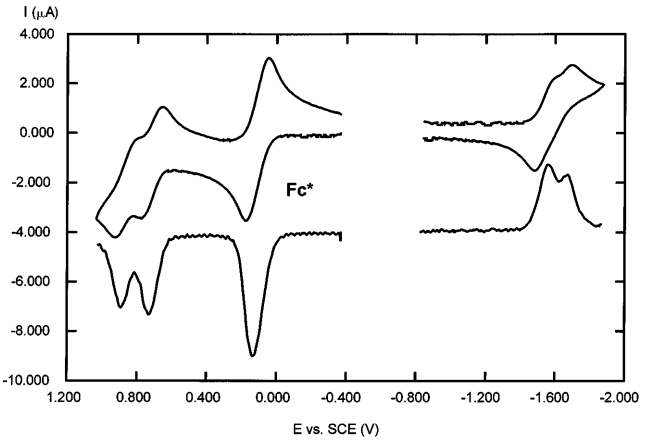


Table 1. Electrochemical data for complexes **1**−**11**, evaluated in THF containing $[Bu_4N][PF_6]$ (0.1 M) at −30°C, GC working electrode

Complex	$E^{\circ\prime}$(0,0/0,1−) [V vs. SCE]	$E^{\circ\prime}$(0,1−/1−,1−) [V vs. SCE]	$\Delta E^{\circ\prime}$ [mV]

7	−0.91	−1.02	110
8	−0.87	−1.01	140
9	−0.93	−1.07	140
10	−0.93	−1.01	80
11	[a]	[a]	[a]

[a] Not evaluated because of overlapping of the reduction of the 9,10-bis(phenylethynyl)anthracene.

and mesomeric (delocalised) effects[41]. It seems to be generally true that extensive intervening π-bond systems facilitate electron communication while σ-bond networks help less. However, a σ-bond system is strongly preferable to transmission across free space.

Complex **1**, having a $-CH_2-CH_2-$ spacer (a region of saturation), shows a $\Delta E^{\circ\prime}$ value about three times lower than those of complexes **2**−**6** but similar to those of complexes **7**−**9** where a phenylene spacer is present (Table 1). This comparison suggests that through-space interaction may be operative in complex **1**, especially if one considers that the $-CH_2-CH_2-$ chain is flexible enough to allow the two redox "Co_2C_2" centres to be in close contact.

In a simple electrostatic model the dependence of comproportionation constant K_c on the distance between the redox centres has been discussed by Reimers and Hush[42]; ln K_c, and hence $\Delta E^{\circ\prime}$[22][43][44][45], is found to be inversely related to both the distance between the redox centres and the dielectric constant (ε) of the solvent. On passing from THF (ε = 7.5) to acetone (ε = 21.0) to acetonitrile (ε = 36.6), $\Delta E^{\circ\prime}$ of compound **1** has decreasing values of 150, 90, and 50 mV, respectively. Although ion pairing effects play a role especially in the presence of supporting electrolyte in high concentration (0.1 M $[NBu_4][PF_6]$), the trend is consistent with this view[*]. The general tendency for the remaining **2**−**10** complexes is as follows: (i) compounds **2**−**6** (having a direct C−C bond between the two subunits) show a weaker dependence of $\Delta E^{\circ\prime}$ values on the solvent, suggesting that a residual through-space electronic interaction is still operative; (ii) compounds **7**−**10** (having large π-delocalised spacer) show negligible dependence of $\Delta E^{\circ\prime}$ values on the solvent indicating that the through-bond electronic coupling is dominant.

Complexes **7** and **9** (as well as **15** and **17**) are two substitutional isomers, *para* and *meta* respectively. Their $\Delta E^{\circ\prime}$ experimental values are very similar. In contrast, in a purely through-bond model, the *para* isomer is expected to show stronger electronic interaction than the *meta* isomer, due to a higher degree of mixing between aryl and acetylenic orbitals.

A closer inspection of the available solid-state structures indicates that the "Co−Co" centres (a *naive* attempt of localisation of the redox cores) are not so far apart; i.e. the distance is about 4.43 Å in $[Co_2(CO)_6]_2(PhC{\equiv}C-C{\equiv}CPh)$[46] and 4.36 Å in $[Co_2(CO)_4(dppm)]_2(PhC{\equiv}C-C{\equiv}CPh)$[32], so that the substitution of CO groups by dppm does not alter substantially the aforementioned distance. Only in $[Co_2(CO)_6]_2(HC{\equiv}C-C_6H_4-C{\equiv}CH)$[47] such a distance increases up to 8.60 Å and in $[Co_2(CO)_6]_2(Me_3SiC{\equiv}C-C_6H_4-C_6H_4-C{\equiv}CSiMe_3)$[47] is 12.8 Å.

For complexes **12**−**19** we obtained slightly different values for $\Delta E^{\circ\prime}{}_{red}$ (measured at −30°C, when complete chemical reversibility is achieved for both reductions) and $\Delta E^{\circ\prime}{}_{ox}$ (measured at the same temperature for comparison purpose) (Table 2), although the trend is clearly the same. If the electronic communication were purely through-space one should foresee identical $\Delta E^{\circ\prime}$ values for oxidation and reduction. On the contrary, for extensive π-delocalization the $\Delta E^{\circ\prime}$ values depend on the character of both HOMO (depopulated by oxidation) and LUMO (populated by reduction) and should be, in principle, different. These orbitals have been postulated to be essentially Co−Co in character (bonding and antibonding, respectively) by simple EHT calculations on the model derivative $Co_2(CO)_6(H-C{\equiv}C-C{\equiv}C-H)$[48]. EHT calculations (CACAO package)[49] on the model complex $Co_2(CO)_4(H_2P-CH_2-PH_2)(H-C{\equiv}C-C{\equiv}C-H)$[**] confirm that the HOMO's composition is mainly metal−metal bonding in character (ca. 57%) with small contributions of

[*] In the electrochemical context, $\Delta E^{\circ\prime}$ seems to be a good parameter to compare electronic interactions between redox centres in different solvents because it should be free of liquid junction potential errors, which effect each $E^{\circ\prime}$ equally.

[**] The geometry of the model complex $Co_2(CO)_4(H_2P-CH_2-PH_2)(H-C{\equiv}C-C{\equiv}C-H)$ was build up from the known structure of $Co_2(CO)_4(Ph_2P-CH_2-PPh_2)(Ph-C{\equiv}C-C{\equiv}C-Ph)$[32] by formal removal of the phenyl groups and substitution with hydrogen atoms (imposing a C−H distance of 1.10 A and a P−H distance of 1.34 A).

Table 2: Electrochemical data for complexes **12−19**, evaluated in THF containing $[Bu_4N][PF_6]$ (0.1 M), GC working electrode

[a] Not evaluated because of overlapping of the reduction of the 9,10-bis(phenylethynyl)anthracene. − [b] At −30°C. − [c] At 20°C.

the butadiyne π-orbitals (ca. 5%) and of diphosphane (ca. 4%). Similarly, the LUMO′s composition is mainly metal−metal antibonding in character (ca. 49%) with partial contribution of the diyne (ca. 11%) and negligible contribution of diphosphane. This similar but not identical composition does not allow any firm conclusion on the nature of interactions.

The bulk of results suggests that for all the compounds under investigation through-space interaction is always operative with different weight depending on the nature of the spacer L. The $\Delta E°'$ values (80−90 mV) evaluated for complexes **10** and **18**, having the larger aromatic spacer employed for the series, represent the limit of "purely" through-bond interactions.

We thank the *Ministero dell' Università e della Ricerca Scientifica e Tecnologica* (MURST, Rome), the *Centro Nazionale delle Ricerche* (CNR, Rome), and the *European Union* (EU, Brussells) (COST Chemistry Action D5/0008/93) for financial support. We are indebted to Professors *C. Amatore* (Ecole Normale Superieure, Paris) and *C. Mealli* (CNR, Florence) for useful discussions.

Experimental Section

Electrochemical Methods and Instrumentation: Electrochemical measurements were performed using EG&G PAR 273 or EG&G PAR 263 electrochemical analysers interfaced to personal computers employing PAR M270 Electrochemical Software. A standard three-electrode cell was constructed so that it allowed the tip of the reference system to approach the working electrode closely. An aqueous saturated calomel electrode (SCE) (separated from the cell solution with a Luggin probe) was the operational reference electrode at room temperature and all potentials are referred to SCE. A silver wire was used as a pseudo-reference for the low temperature measurements. The stability of the pseudo-reference electrode was verified by adding decamethylferrocene as an internal standard; the $Fc^*(0/1+)$ potential was evaluated in the same experimental conditions to be +0.11 V vs. SCE in THF[50][51]. The working electrode was a glassy carbon (GC) disk (diameter = 0.1 cm) sealed in inert resin. The voltammetric responses were recorded in THF $1\cdot10^{-3}$ M in electroactive material and 0.1 M in supporting electrolyte, $[Bu_4N][PF_6]$.

Preparation of $[Co_2(CO)_6]_2$-Diyne Complexes **1−11**: In a typical preparation stoichiometric amounts of the appropriate alkyne and $Co_2(CO)_8$ were allowed to react at room temperature, for 1 h in CH_2Cl_2 (35 ml/mmol) in a Schlenk tube under nitrogen. The reaction mixture was filtered through silica gel to remove any insoluble impurities and the filtrate taken to dryness in vacuum. The complex was then purified by recrystallisation from hexane at −20°C. Yields 70−80%. Since the spectroscopic characteristics of similar complexes have been previously discussed[52], the IR, ^{1}H- and ^{31}P-NMR spectroscopic data and elemental analyses of each new compound are simply reported as follows:

1: $C_{18}H_6Co_4O_{12}$: calcd. C 33.26, H 0.93; found C 33.20, H 0.90. − IR (CH_2Cl_2); ν_{CO}: 2091m, 2056vs, 2026vs cm^{-1}. − ^{1}H NMR ($CDCl_3$): δ = 6.09 (s, 2 H, ≡C*H*), 3.16 (s, 4 H, −CH_2−).

2: $C_{18}H_6Co_4O_{12}$: calcd. C 33.26, H 0.93; found C 33.00, H 0.92. − IR (CH_2Cl_2); ν_{CO}: 2100m, 2080s, 2057vs, 2029s, 2021s cm^{-1}. − ^{1}H NMR ($CDCl_3$): δ = 2.74 (s, 6 H, −CH_3).

4: $C_{18}H_6Co_4O_{14}$: calcd. C 31.70, H 0.89; found C 31.50, H 0.90. − IR (CH_2Cl_2); ν_{CO}: 2103m, 2083s, 2061vs, 2034sh, 2028s cm^{-1}. − ^{1}H NMR ($CDCl_3$): δ = 6.09 (d, 4 H, $^3J_{HH}$ = 5.6 Hz, −CH_2−), 2.87 (t, 2 H, $^3J_{HH}$ = 5.6 Hz, −O*H*),

5: $C_{30}H_{14}Co_4O_{14}$: calcd. C 43.20, H 1.69; found: C 43.15, H 1.72. − IR (CH_2Cl_2); ν_{CO}: 2105m, 2085s, 2063vs, 2034s, 2029s cm^{-1}. − ^{1}H NMR ($CDCl_3$): δ = 7.36−6.99 (m, 10 H, Ph), 5.24 (s, 4 H, −CH_2−).

6: $C_{22}H_{18}Co_4O_{12}Si_2$: calcd. C 34.48, H 2.37; found C 34.40, H 2.30. − IR (CH_2Cl_2); ν_{CO}: 2099m, 2078s, 2059vs, 2032s, 2020s cm^{-1}. − ^{1}H NMR ($CDCl_3$): δ = 0.42 (s, 18 H, −CH_3).

9: $C_{22}H_6Co_4O_{12}$: C 37.86, H 0.87; found: C 37.70, H 0.85. − IR (CH_2Cl_2); ν_{CO}: 2092m, 2060vs, 2028vs cm^{-1}. − ^{1}H NMR ($CDCl_3$): δ = 7.70−7.30 (m, 4 H, C_6H_4), 6.39 (s, 2 H, ≡C*H*).

10: $C_{28}H_{10}Co_4O_{12}$: calcd. C 43.44, H 1.30; found C 43.39, H 1.32. − IR (CH_2Cl_2); ν_{CO}: 2093m, 2057vs, 2028vs cm^{-1}. − ^{1}H NMR ($CDCl_3$): δ = 7.60 (s, 8 H, Ph), 6.43 (s, 2 H, ≡C*H*).

Preparation of $[Co_2(CO)_4(dppm)]_2$-Diyne Complexes **12−19**: Stoichiometric amounts of the appropriate alkyne and $Co_2(CO)_6$(dppm), prepared according to a literature procedure[35], were heated at reflux in benzene for 2 h, under nitrogen. The hot reaction mixture was filtered through silica gel to remove any insoluble impurities and the filtrate taken to dryness in vacuum. The complex was then purified by recrystallisation from hexane/CH_2Cl_2 at −20°C. Yields 60−70%. Noteworthy, the co-ordination of two dppm ligands to the available Co−Co units is inferred by the presence of two complex multiplets in the region δ = 4.3−3.2, as expected for an ABX_2 pattern (X = ^{31}P) in the ^{1}H-NMR spectra[53] and by a single resonance in the region δ = 36−43 in the ^{31}P-NMR spectra.

13: $C_{64}H_{50}Co_4O_{10}P_4$: calcd. C 57.42, H 3.76; found C 57.382, H 3.7. − IR (CH_2Cl_2); ν_{CO}: 2033 (w), 2002vs, 1968m cm^{-1}. − ^{1}H NMR ($CDCl_3$): δ = 7.56−7.04 (m, 40 H, Ph), 5.31 (s, br., 4 H, −CH_2−), 4.17, 3.22 (m, 4 H, P−CH_2−P), 2.20 (s, br., 2 H, −O*H*). − ^{31}P NMR ($CDCl_3$): δ = 39.8 (s).

14: $C_{76}H_{58}Co_4O_{10}P_4$: calcd. C 61.23, H 3.92; found C 61.19, H 3.89. – IR (CH_2Cl_2); ν_{CO}: 2034 (w), 2005vs, 1971m cm^{-1}. – ^1H NMR ($CDCl_3$): δ = 7.50–6.40 (m, 50 H, Ph), 5.63 (s, 4 H, $-CH_2-$), 4.30, 3.26 (m, 4 H, $P-CH_2-P$). – ^{31}P NMR ($CDCl_3$): δ = 39.5 (s).

15: $C_{68}H_{50}Co_4O_8P_4$: calcd. C 60.29, H 3.72; found: C 60.25, H 3.70. – IR (CH_2Cl_2); ν_{CO}: 2021s, 1995vs, 1970s cm^{-1}. – ^1H NMR ($CDCl_3$): δ = 7.78–6.92 (m, 44 H, Ph and C_6H_4), 5.82 (t, $^3J_{HP}$ = 3.1 Hz, 2 H, $\equiv CH$), 4.31, 3.20 (m, 4 H, $P-CH_2-P$). – ^{31}P NMR ($CDCl_3$): δ = 43.2 (s).

16: $C_{80}H_{58}Co_4O_8P_4$: calcd. C 63.76, H 3.88; found C 63.70, H 3.80. – IR (CH_2Cl_2); ν_{CO}: 2021s, 1997vs, 1971s cm^{-1}. – ^1H NMR ($CDCl_3$): δ = 7.80–6.92 (m, 54 H, Ph and C_6H_4), 4.27, 3.25 (m, 4 H, $P-CH_2-P$). – ^{31}P NMR ($CDCl_3$): δ = 35.6 (s).

17: $C_{68}H_{50}Co_4O_8P_4$: calcd. C 60.29, H 3.72; found C 60.19, H 3.69. – IR (CH_2Cl_2); ν_{CO}: 2021s, 1997vs, 1969s cm^{-1}. – ^1H NMR ($CDCl_3$): δ = 7.88–6.80 (m, 44 H, Ph and C_6H_4), 5.82 (t, $^3J_{HP}$ = 3.2 Hz, 2 H, $\equiv CH$), 3.62, 3.11 (m, 4 H, $P-CH_2-P$). – ^{31}P NMR ($CDCl_3$): δ = 43.1 (s).

18: $C_{74}H_{54}Co_4O_8P_4$: calcd. C 62.12, H 3.80; found C 62.00, H 3.60. – IR (CH_2Cl_2); ν_{CO}: 2021s, 1995vs, 1970s cm^{-1}. – ^1H NMR ($CDCl_3$): δ = 8.00–6.80 (m, 48 H, Ph and C_6H_4), 5.81 (t, $^3J_{HP}$ = 3.1 Hz, 2 H, $\equiv CH$), 3.61, 3.18 (m, 4 H, $P-CH_2-P$). – ^{31}P NMR ($CDCl_3$): δ = 43.2 (s).

19: $C_{88}H_{62}Co_4O_8P_4$: calcd. C 65.77, H 3.89; found C 65.69, H 3.80. – IR (CH_2Cl_2); ν_{CO}: 2022s, 1997vs, 1973s cm^{-1}. – ^1H NMR ($CDCl_3$): δ = 8.88–6.82 (m, 58 H, Ph and $C_{14}H_8$), 3.45, 3.23 (m, 4 H, $P-CH_2-P$). – ^{31}P NMR ($CDCl_3$): δ = 36.5 (s).

Keywords: Photochemistry / Ruthenium / Osmium / Clusters / Nitrogen heterocycles

The photochemistry of $M_3(CO)_{12}$ [M = Ru (**1a**), Os (**1b**)] with pyrazole, 3,5-dimethylpyrazole, and 3,5-diphenylpyrazole is documented. With **1a**, photolysis with pyrazole leads to the substitution product $HRu_3(CO)_{10}(C_3H_3N_2)$ (**2a**). In the case of **1b**, the initial product is the *ortho*-metallated species $HOs_3(CO)_{10}(C_3H_3N_2)$ (**3b**), heating of which yields $HOs_3(CO)_{10}(C_3H_3N_2)$ (**2b**). Photolysis of **1a** and **1b** with 3,5-dimethylpyrazole yields $HRu_3(CO)_{10}(C_3HMe_2N_2)$ (**4a**) and $HOs_3(CO)_{10}(C_3HMe_2N_2)$ (**4b**), respectively. The molecular structure of **4b** has been determined by X-ray crystallography. There is no reaction on photolysis of **1a** and **1b** with 3,5-diphenylpyrazole.

The reaction chemistry of cluster carbonyl complexes with nitrogen-heterocyclic ligands has received little attention as compared to that of other ligands such as phosphanes[1].This may be attributed in part to the harsh conditions frequently required to prepare N-heterocycle complexes, reactions often resulting in cluster degradation or the formation of complex products[2]. Our research has led us to investigate the photochemistry of ruthenium and osmium complexes with a number of ligand systems[3][4]. Photochemistry offers a simple, and often highly selective, route to organometallic compounds, overcoming large enthalpy barriers. As a consequence, it is often possible to prepare complexes that are otherwise inaccessible by conventional thermochemical routes[3][4][5].

The trinuclear cluster $Ru_3(CO)_{12}$ (**1a**) serves as a prototype for the photoreactivity of more complex examples. Our studies have shown that, by broad-band UV irradiation of a dichloromethane solution of **1a** in the presence of a two-electron donor ligand, high yields of photofragmentation products can be obtained[6]. This opens a route to substituted mononuclear ruthenium and osmium complexes. Although there has been much work on the synthetic potential of the reactive intermediates generated by photofragmentation of **1a**, the corresponding photosubstitution pathway is still relatively unexplored[7]. Our research has shown that, simply by changing the solvent from dichloromethane to ethyl acetate, ether, or acetonitrile, it is possible to prepare photosubstitution products from **1a** this enabling the synthesis of substituted cluster products[8].

A range of trinuclear complexes can be formed on photolysis of **1a** and its osmium analogue $Os_3(CO)_{12}$ (**1b**) with pyridine and bipyridine[9]. The work documented here focuses on the photochemistry of **1a** and **1b** with pyrazole and its substituted derivatives. The aim of the investigation was to prepare photochemically a number of trinuclear carbonyl complexes containing nitrogen heterocycles as ligands since these compounds may well have the ability to act as efficient catalysts for key industrial synthetic transformations[10].

Results and Discussion

The results from the investigations are summarised in Scheme 1 and all spectroscopic data are shown in Table 1.

Photoreactions with Pyrazole

Broad-band UV photolysis of an ethyl acetate solution of **1a** in the presence of an excess of pyrazole leads, within 30 min, to the formation of the substitution product $HRu_3(CO)_{10}(\mu_N{:}\mu_N\text{-}C_3H_3N_2)$ (**2a**). The ^{1}H-NMR spectrum of **2a** shows a symmetrical arrangement of the pyrazolide group and, in the IR spectrum, the complex does not show any bands assignable to μ-CO groups.

The formation of **2a** from **1a** is a relatively inefficient process, the photoreactions taking some considerable time. To explain this, the mechanism for photosubstitution needs to be considered. By using matrix-isolation and flash-photolysis techniques key intermediates involved in the photosubstitution pathway of **1a** have been generated[11]. The primary photoreaction is the dissociation of CO to form the coordinatively unsaturated fragment $[Ru_3(CO)_{11}]$. This fragment is highly selective in its chemistry, reaction with photoejected CO is eight times faster than with added PPh_3[11]. Therefore, in the case of an added ligand, L, photosubstitution of CO by L is in competition with recombination of the unsaturated triruthenium fragment with photoejected CO.

Due to the increased stability of trinuclear osmium complexes over their ruthenium analogues, different products are often formed. Broad-band UV photolysis of an ethyl acetate solution of **1b** in the presence of an excess of pyrazole leads, within 45 min, to the relatively insoluble *ortho*-

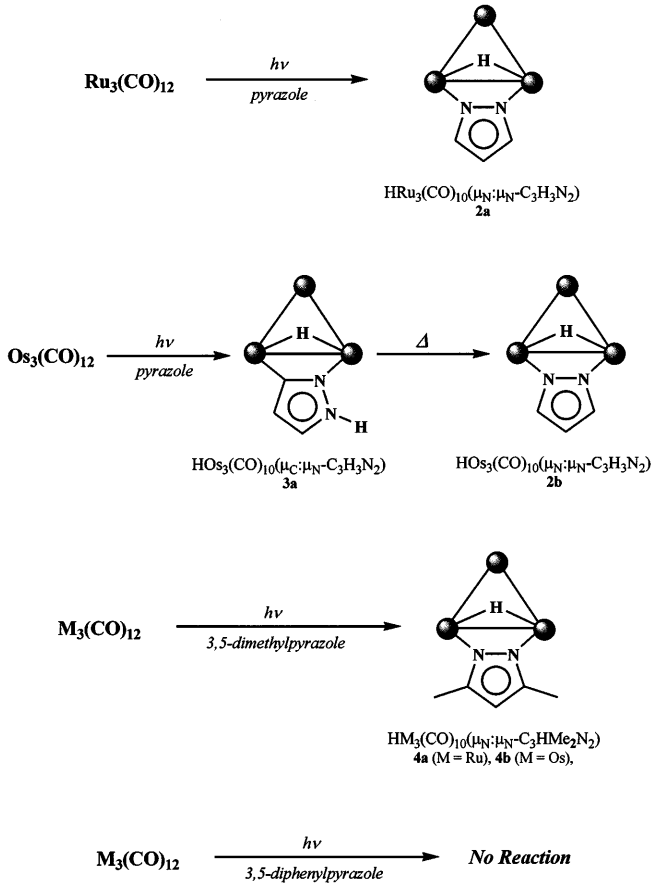
Scheme 1. A summary of the results reported



metallated complex $HOs_3(CO)_{10}(\mu_C{:}\mu_N\text{-}C_3H_3N_2)$ (**3b**). Retention of the N−H bond is evident from the spectral data and, because of this and the solubility problem, separation by chromatography is difficult since the acidic amine group interacts with the silica gel surface. Heating **3b** in boiling xylene in the absence of light yields the osmium analogue of **2a**, $HOs_3(CO)_{10}(\mu_N{:}\mu_N\text{-}C_3H_3N_2)$ (**2b**). The *ortho*-metallated complex **3b**, has been reported previously, as a minor product in the reaction of the lightly ligated complex $Os_3(CO)_{10}(MeCN)_2$ with pyrazole under reflux in benzene, the major product being **2b**[12]. This shows clearly one of the benefits of photochemistry over conventional thermolytic routes; the reaction conditions being mild and less stable complexes often being formed. This has also been shown in the reaction of **1a** and **1b** with pyridine, photolysis leading initially to the relatively unstable complex $Os_3(CO)_{11}(C_5H_5N)$ before orthometallating to form the more stable $HOs_3(CO)_{10}(C_5H_4N)$, the latter being the only thermolytic product[9].

Of note is that there is no evidence for the formation of the *ortho*-metallated analogue of **3b**, $HRu_3(CO)_{10}(\mu_C{:}\mu_N\text{-}C_3H_3N_2)$ (**3a**) in the photochemical reaction of **1a** with pyrazole or in the case of reaction of $Ru_3(CO)_{10}(MeCN)$ with the heterocycle, both routes leading to **2a**.

Photolysis of **2b** and **3b** over a longer time period 1−2 h results in the formation of a black precipitate, this being uncharacterised at present. It is, however, proposed that the black products are charged in nature, due to their insolubility in common organic solvents. This is not wholly unexpected since the photochemistry of $Ru(CO)_5$ with polydentate heterocycles has been show to result in Ru^{III} complexes as a result of a proposed photooxidation process[13]. This occurs regardless of the temperature at which the photolysis is undertaken.

Photoreactions with 3,5-Dimethylpyrazole

With 3,5-dimethylpyrazole, there is no scope for the formation of orthometallated products. Photolysis leads to the $\mu_N{:}\mu_N$ substitution products $HRu_3(CO)_{10}(\mu_N{:}\mu_N\text{-}C_3HMe_2N_2)$ (**4a**) and $HOs_3(CO)_{10}(\mu_N{:}\mu_N\text{-}C_3HMe_2N_2)$ (**4b**) in the cases of **1a** and **1b**, respectively. Again, prolonged photolysis of the reaction products leads to decomposition and photooxidation.

Photoreactions with 3,5-Diphenylpyrazole

When ethyl acetate solutions of **1a** and **1b** containing 3,5-diphenylpyrazole are irradiated, no net photoreaction is observed. This is attributed to the considerable steric shielding of the nitrogen atom of the pyrazole ring in 3,5-diphenylpyrazole and the concomitant steric hindrance to formation of complexes with the clusters.

The Molecular Structure of $HOs_3(CO)_{10}(\mu_N{:}\mu_N\text{-}C_3HMe_2N_2)$ (4b)

The molecular structure of $HOs_3(CO)_{10}(\mu_N{:}\mu_N\text{-}C_3HMe_2N_2)$ (**4b**) has been determined by single-crystal X-ray diffraction studies and is shown in Figure 1. Selected bond lengths and angles are reported in Table 2.

Figure 1. The molecular structure of $HOs_3(CO)_{10}(\mu_N{:}\mu_N\text{-}C_3HMe_2N_2)$ (**4b**)

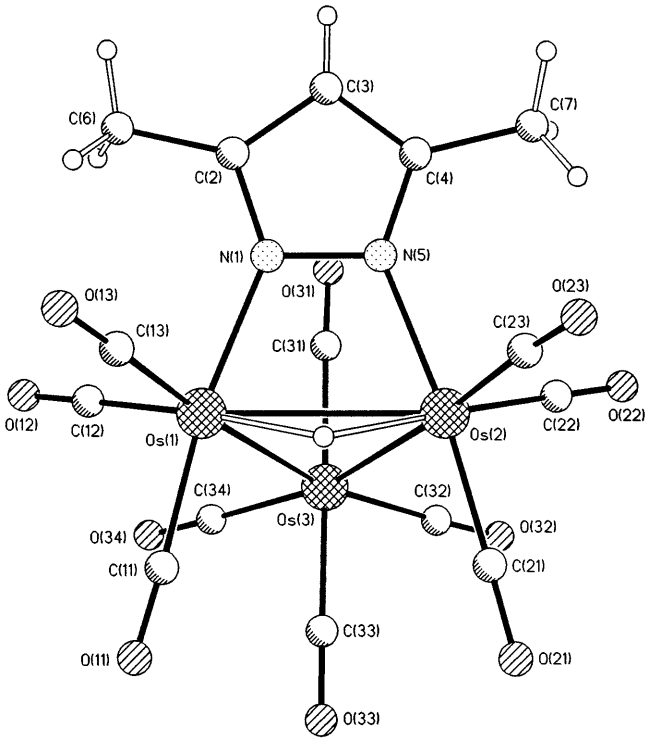


Table 2. Selected bond lengths [Å] and angles [°] for **4b**

Os(3)−Os(1)−Os(2)	59.26(2)	C(22)−Os(2)−Os(3)	85.1(5)
Os(3)−Os(2)−Os(1)	59.43(3)	C(23)−Os(2)−Os(3)	175.3(4)
Os(2)−Os(3)−Os(1)	61.31(3)	C(22)−Os(2)−Os(1)	139.4(5)
N(1)−Os(1)−Os(3)	87.3(3)	C(23)−Os(2)−Os(1)	116.1(4)
N(1)−Os(1)−Os(2)	68.6(3)	C(32)−Os(3)−Os(2)	98.6(5)
N(5)−Os(2)−Os(3)	88.0(3)	C(34)−Os(3)−Os(1)	97.9(5)
N(5)−Os(2)−Os(1)	68.6(3)	N(5)−N(1)−Os(1)	111.3(8)
C(12)−Os(1)−Os(3)	85.9(4)	N(1)−N(5)−Os(2)	111.5(8)
C(13)−Os(1)−Os(3)	175.9(5)	C(2)−N(1)−N(5)	108.4(11)
C(12)−Os(1)−Os(2)	141.0(4)	C(4)−N(5)−N(1)	108.8(11)
C(13)−Os(1)−Os(2)	117.2(5)		

The solid-state structure of **4b** is consistent with that in solution, the heterocyclic unit bridging one of the Os−Os bonds. The two unbridged Os−Os bond lengths (mean 2.875 Å) in **4b** are very similar to those in $Os_3(CO)_{12}$ **1b** (mean 2.867 Å)[14]. The bridged Os−Os bond is significantly longer at 2.9243 Å. The hydride was not located directly in the Fourier difference map but its position was determined using the program HYDEX[15]. The pyrazolate unit, which is inclined at an angle of 102.4° to the Os_3 plane, coordinates with one nitrogen atom axially bonded to Os(1) and one nitrogen atom axially bonded to Os(2) [Os(1)−N(1) = 2.116(11) Å; Os(1)−N(5) = 2.114(10) Å]. The complex possesses a similar molecular architecture to that of the related complexes $HOs_3(CO)_{10}[\mu_2\text{-}2,3\text{-}\eta^2\text{-}NNN(O)C_6H_4]$[16] (**5b**) and $HOs_3(CO)_{10}(\mu\text{-}\eta^2\text{-}N{=}NPh)$[17] (**6b**) prepared from the reactions of $Os_3(CO)_{10}(MeCN)_2$ and 1-hydroxybenzotriazole and phenyldiazonium tetrafluoroborate, respectively. In both **5b** and **6b**, there is extension of the Os−Os bond bridged by the heterocycle and hydride ligand, as in **4b**. The heterocyclic unit is inclined at an angle of 102.5° in **5b** and at 103.25° in **6b**. In all three structures, a survey of the *cis*-diequatorial angles around the triosmium framework shows that the angles are larger than the remaining *cis*-diequatorial OC−Os−Os angles [for **4b**: C(23)−Os(2)−Os(1) = 116.1(4), C(13)−Os(1)−Os(2) = 117.2(5), C(34)−Os(3)−Os(1) = 97.9(5), C(32)−Os(3)−Os(2) = 98.6(5)]. Compared to the free pyrazole ligand, coordination to **4b** has remarkable little effect, the bond lengths being almost unchanged within the remit of statistical significance[18].

Conclusions

The photolysis of ethyl acetate solutions of $M_3(CO)_{12}$ [M = Ru (**1a**), Os (**1b**)] with pyrazole and 3,5-dimethylpyrazole leads to photosubstitution products. With pyrazole, **1a** forms the substitution product $HRu_3(CO)_{10}(\mu_N{:}\mu_N\text{-}C_3H_3N_2)$ (**2a**) but, in the case of osmium, the *ortho*-metallated complex $HOs_3(CO)_{10}(\mu_C{:}\mu_N\text{-}C_3H_3N_2)$ (**3b**) can be isolated. Heating **3b** yields the osmium analogue of **2a**, $HOs_3(CO)_{10}(\mu_N{:}\mu_N\text{-}C_3H_3N_2)$ (**2b**). Photolysis of **1a** and **1b** with 3,5-dimethylpyrazole yields the substitution products $HRu_3(CO)_{10}(\mu_N{:}\mu_N\text{-}C_3HMe_2N_2)$ (**4a**) and $HOs_3(CO)_{10}(\mu_N{:}\mu_N\text{-}C_3HMe_2N_2)$ (**4b**), respectively. With 2,6-diphenylpyrazole no net photoreaction is observed.

Girton College Cambridge is thanked for a Research Fellowship. This work was funded in part by the *UK Engineering and Physical Sciences Research Council* and *Johnson-Matthey plc* is acknowledged for the generous loan of ruthenium chloride. Advice and assistance from *G.P. Shields* is greatly appreciated.

Experimental Section

General Experimental: Unless stated otherwise, all syntheses were performed under dry nitrogen using standard Schlenk techniques. All photochemical reactions were performed in a specially designed glass reaction vessel fitted with a nitrogen bubbler, reflux condenser and dry-ice cooling finger. A 125-W mercury arc broad-band UV lamp was used as the irradiation source and reflectors placed around the reaction vessel to maximise efficiency. All reagents were purchased from commercial sources and used as received unless noted otherwise. Literature methods were used to prepare the starting material compounds $Ru_3(CO)_{12}$ (**1a**)[19] and $Os_3(CO)_{12}$ (**1b**)[20]. Purification of the reaction products was by thin layer chromatography (laboratory prepared glass plates coated to a thickness of 1.0 mm with Merck Kieselgel 60 F_{254}) using light petroleum ether as eluent.

Physical Measurements: Infrared (IR) spectra were recorded in NaCl solution cells (path length 0.5 mm) using a Perkin-Elmer PE 1710 Fourier transform infrared spectrometer. All values quoted are in wavenumbers (cm^{-1}). – The ^1H-NMR spectra were recorded using a Bruker AM400, WM250, or WP80SY Fourier transform NMR spectrometer and data reported using the chemical shift scale in units of ppm relative to the solvent resonance. – Fast atom bombardment (FAB) mass spectra were recorded using a KRATOS MS-50 spectrometer, with either 3-nitrobenzyl alcohol or thioglycerol as a matrix and CsI as calibrant. – IR, NMR, and mass spectral data are collected in Table 1.

Photolyses

An Ethyl Acetate Solution of $Ru_3(CO)_{12}$ (**1a**) *with Pyrazole:* An ethyl acetate solution of **1a** (30 mg in 150 ml) containing excess pyrazole (9.6 g) was irradiated using the broad-band UV source. The reaction was deemed complete when there was no further change in the IR spectrum (30 min). From comparison with literature data it was proposed that the yellow-orange cluster formed in 60% yield was $HRu_3(CO)_{10}(\mu_N{:}\mu_N\text{-}C_3H_3N_2)$ (**2a**)[21]. Prolonged photolysis of the reaction mixture (1 h) led to decomposition.

An Ethyl Acetate Solution of $Os_3(CO)_{12}$ (**1b**) *with Pyrazole:* The photolysis was performed as with **1a** but using **1b** (40 mg in 150 ml) and 16 mg of the heterocycle. The yellow-green *ortho*-metallated cluster $HOs_3(CO)_{10}(\mu_C{:}\mu_N\text{-}C_3H_3N_2)$ (**3b**) was formed in 60% yield after 45 min, as characterised by comparison with literature data[12]. The product is not particularly soluble and sticks to the silica gel surface of TLC plates. As a result, an eluent of 2:1 petroleum ether/dichloromethane was used for purification. Prolonged photolysis of the reaction mixture (1 h) led to decomposition. Heating a solution of **3b** in refluxing xylene for 1 h led to the formation of $HOs_3(CO)_{10}(\mu_N{:}\mu_N\text{-}C_3H_3N_2)$ (**2b**) in 70% yield.

An Ethyl Acetate Solution of $Ru_3(CO)_{12}$ (**1a**) *with 3,5-Dimethylpyrazole:* The photolysis was performed as with pyrazole but using 3,5-dimethylpyrazole (16 mg) as the heterocycle. The yellow cluster $HRu_3(CO)_{10}(\mu_N{:}\mu_N\text{-}C_3HMe_2N_2)$ (**4a**) was formed in 60% yield after 30 min. Prolonged photolysis of the reaction mixture (1 h) led to decomposition.

An Ethyl Acetate Solution of $Os_3(CO)_{12}$ (**1b**) *with 3,5-Dimethylpyrazole:* The photolysis was performed as with **1a** but using $Os_3(CO)_{12}$ (**1b**) (40 mg in 150 ml) and 24 mg of the heterocycle. The yellow cluster $HOs_3(CO)_{10}(\mu_N{:}\mu_N\text{-}C_3HMe_2N_2)$ (**4b**) was formed in 50% yield after 45 min. Prolonged photolysis of the reaction mixture (1 h) led to decomposition.

An Ethyl Acetate Solution of $Ru_3(CO)_{12}$ (**1a**) *and $Os_3(CO)_{12}$* (**1b**) *with 3,5-Diphenylpyrazole:* The photolyses were performed as with pyrazole but using 3,5-diphenylpyrazole (26 mg for **1a**, 35 mg for **1b**) as the heterocycle. No net photoreaction was observed in each case.

Determination of the Molecular Structure of $HOs_3(CO)_{10}(\mu_N{:}\mu_N\text{-}C_3HMe_2N_2)$ (**4b**) *by Single-Crystal X-ray Diffraction*

Crystal Data: $C_{15}H_8N_2O_{10}Os_3$, M = 946.83, monoclinic, space group $P2_1/c$ (no. 14), a = 16.392(3), b = 7.636(2), c = 18.536(4) Å, β = 115.53(3), U = 2093.6(8) Å^3 (from refinement of 2θ values of 25 independent reflections), Z = 4, D_c = 3.004 gcm^{-3}, T = 293 K, yellow-orange rectangular plate 0.50 × 0.40 × 0.40 mm, μ(Mo-K_α) = 18.216 mm^{-1}, F(000) = 1680.

Data Collection and Processing: All X-ray measurements were made with graphite monochromated Mo-K_α radiation (λ = 0.71073 Å) with a Stoe-Siemens diffractometer using the ω-θ scan mode, 4994 reflections collected, 3681 independent (R_{int} = 0.0454) ($-19 \le h \le 19$, $-8 \le k \le 9$, $-22 \le l \le 22$; $5.5° \le 2\theta \le 50°$). Semi-empirical absorption correction based on ψ-scan data was applied (minimum and maximum transmission factors 0.153 and 0.288, respectively)[22].

Structure Solution and Refinement: The osmium atom positions were determined by direct methods (SHELXTL-PLUS)[23] and all non-hydrogen atoms located by subsequent Fourier difference syntheses. Full-matrix least-squares refinement on F^2 (SHELXL-93)[24] was performed with anisotropic displacement parameters for all non-hydrogen atoms. Hydrogen atoms were placed in idealised positions and allowed to ride on the relevant carbon atom. The hydride ligand was located using the program HYDEX. In the final cycles of refinement, a weighting scheme of the form $w^{-1} = [\sigma(F_o^2) + 0.053P^2 + 10.46P]$ [where $P = (F_o^2 + 2F_c^2)/3$] was introduced which produced a flat analysis of variance. At final convergence (max Δ/σ = 0.001), $wR(F^2)$ = 0.1025 for all data, $R(F)$ = 0.0865 for 2801 observed reflections [$I > 2\sigma(I)$] and 188 parameters. The final difference synthesis showed no Δρ above 2.882 or below −1.390 eÅ^{-3}, the major features lying near the osmium atoms.

Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data centre as supplementary publication no. CCDC-101356. Copies of the data can be obtained free of charge on application to the CCDC, 12 Union Road, Cambridge, CB2 1EZ [Fax: int. code + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Keywords: Titanium / Vanadium / Polymerizations / Diimine / Dialkylmetal compounds

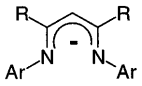
(Mono-β-diiminato)titanium(III) and -vanadium(III) dichlorides $LMCl_2$ [L = ArNC(R)CHC(R)NAr$^-$] are easily accessible from the metal trichlorides and LLi in THF. The crystal structures of $LVCl_2$ (Ar = 2,6-*i*$Pr_2C_6H_3$, R = Me) and $LTiCl_2$ (Ar = 2,4,6-$Me_3C_6H_2$, R = Me and Ar = 2,4,6-$Me_3C_6H_2$, R = *t*Bu) reveal tetrahedral metal environments. Treatment of $LVCl_2$ with alkyllithium reagents affords surprisingly stable dialkylvanadium(III) compounds; the structure of $LV(n\text{Bu})_2$ (Ar = 2,6-*i*$Pr_2C_6H_3$, R = Me) is similar to that of the dichloride. The corresponding dialkyltitanium(III) compounds are less stable; only the dimethyl derivatives could be obtained in pure form (from $LTiCl_2$ and MeMgI), and only for ligands bearing 2,6-disubstituted aryl groups. The structure of $LTiMe_2$ (Ar = 2,4,6-$Me_3C_6H_2$, R = Me) is also similar to that of the dichloride. Reaction of $LTiMe_2$ with $B(C_6F_5)_3$ produces a catalyst for α-olefin polymerization, but the corresponding V^{III} derivatives are inactive.

Introduction

The development of metallocene catalysis has led to intense interest in the generation and reactivity of early transition alkylmetal compounds. Neutral dialkylmetal compounds, in particular, are of great importance as precursors of catalytically active cationic monoalkyl species. Most of the work in this area has concentrated on diamagnetic d^0 complexes of group-III and -IV metals. It is still unclear whether d^1 or d^2 complexes can be as efficient in olefin polymerization as their d^0 analogues, and this lack of insight is at least partly due to the unavailability of suitable catalyst precursors. However, work by Theopold on d^3 chromium systems demonstrates that well-defined paramagnetic homogeneous polymerization catalysts are certainly possible.[1]

We report herein on the preparation of Ti^{III} (d^1) and V^{III} (d^2) complexes containing a β-diiminato ancillary ligand. The β-diimine ligand has not been widely used in organometallic chemistry. Some Pd^{II} and Ni^{II} complexes have been prepared recently; in comparison with related α-diimine complexes they showed a much lower activity in Brookhart-type olefin polymerization.[2] Collins has recently reported the synthesis of several Zr^{IV} complexes of β-diimines.[3]

One advantage of β-diimines is that ligand variation, in both the ligand backbone and the substituent at the nitrogen atom, is relatively easy. This has allowed us to probe the consequences of steric effects in the present study (Scheme 1 shows the ligands studied and the abbreviations used here). We have concentrated on the $\mathbf{L^1}$ and $\mathbf{L^2}$ ligands, because the Ti and V dichloride and dimethyl derivatives were found to crystallize well, and only examined the use of the other ligands in selected cases.[4]



Ligand Syntheses

The two main routes for the synthesis of β-diimines are summarized in Scheme 1. The most convenient route (**A**) is condensation of a β-diketone with an (aromatic) amine.[5] The second route (**B**) is especially useful for very bulky diimines,[6] where the route **A** condensation is very sluggish. Route **B** is also applicable to the synthesis of asymmetrically substituted diimines (different Ar groups). The ligands used in the present work were all prepared by one of these two methods. Lappert has reported a more exotic synthesis of silyl-substituted diiminates from bis(trimethylsilyl)methyllithium and nitriles.[7]

Dichloride Complexes

Complexes $LMCl_2$ (M = Ti^{III}, V^{III}; L ≠ $\mathbf{L^4}$ or $\mathbf{L^6}$) are conveniently prepared by reaction in THF of $MCl_3(THF)_3$ with the lithium salt of the β-diimine (prepared in situ from the free diimine and *n*BuLi). After evaporation of the solvent, the complex is extracted with toluene and purified by

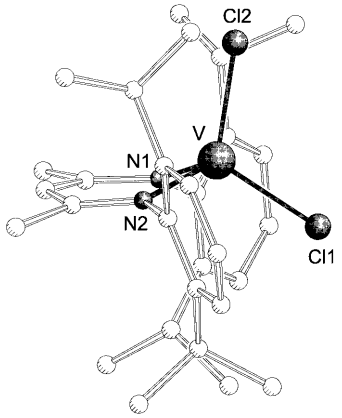
crystallization from toluene or hexane. In several instances, we initially observed formation of a THF complex; repeated distillation of toluene (at 1 bar) from a solution of the complex was found to be a convenient method for removal of this THF.

The $\mathbf{L^4}$ complexes tenaciously retain 2 molecules of complexed THF. Treatment of $VCl_3(THF)_3$ with $\mathbf{L^4}$Li in THF results in precipitation of dark-green needles of poorly soluble $\mathbf{L^4}VCl_2(THF)_2$. Most of the coordinated THF can be removed by the above-mentioned toluene distillation, but the resulting product is an ill-defined black substance. $\mathbf{L^4}TiCl_2(THF)_2$ is poorly soluble even in hot THF or toluene/THF mixtures; small amounts can be crystallized from THF as dark-brown needles. Reaction of the THF complex with Me_3SiI[8] removes the coordinated THF but also exchanges the chlorides for iodides, giving dark-red $\mathbf{L^4}TiI_2$, which is fairly soluble in toluene and diethyl ether.

All the dichlorides are stable at room temperature, but are highly sensitive to air and moisture. They are paramagnetic and exhibit strongly broadened NMR spectra that could not be fully interpreted. Complexes $\mathbf{L^2}VCl_2$ (Figure 1), $\mathbf{L^1}TiCl_2$ (Figure 2), and $\mathbf{L^5}TiCl_2$ (Figure 3) were characterized by X-ray diffraction. They are monomeric and show the expected distorted tetrahedral surrounding of the metal center. In the case of the bulky $\mathbf{L^2}$ ligand, the metal atom has moved out of the NCCCN plane of the ligand. This allows the aryl groups at the nitrogen atoms to tilt, thus relieving steric repulsion between the chlorides and the isopropyl substituents. Movement of the metal atom out of the NCCCN plane has also been observed in the sterically hindered zirconium complex [$Me_3SiNC(t\text{Bu})CHC(t\text{Bu})NSiMe_3$]$ZrCl_3$[7] and in the tin derivative [$Me_3SiNC(t\text{Bu})CHC(t\text{Bu})NSiMe_3$]$SnMe_2Cl$,[7] whereas the unhindered tin complex [$HNC(t\text{Bu})CHC(t\text{Bu})NH$]$SnMe_2Cl$[7] and the lanthanide complex [$PhNC(Me)CHC(Me)NPh$]$GdBr_2(THF)_2$[9] have essentially planar skeletons. The *neutral* β-diimine complex ($H\mathbf{L^2}$)$NiBr_2$ and the *C*-metallated [$Pd(NCMe)_3$][μ-C:N,N′-$\mathbf{L^2}$][$Pd(NCMe)_2$]$^{3+}$ also have non-planar diimine skeletons.[2] The strongly non-planar structure recently reported for ($\mathbf{L^4}$)(indenyl)$ZrCl_2$ by Collins was described as partially η^5;[3] the nonplanarity of our $\mathbf{L^2}VCl_2$ complex is clearly not pronounced enough to warrant such a description.

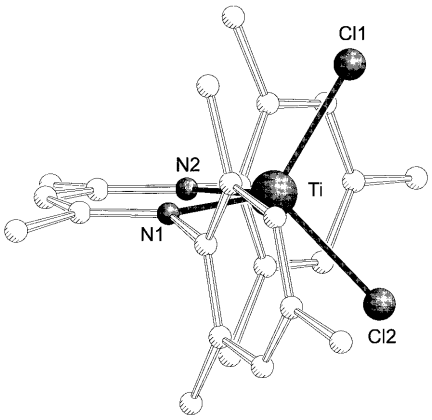
Figure 1. X-ray structure of L^2VCl_2[a]



[a] Selected structure data: V−N1 1.940(2), V−N2 1.963(2), V−Cl1 2.242(1), V−Cl2 2.234(1) Å; N1−V−N2 94.0(1), Cl1−V−Cl2 114.3(1)°.

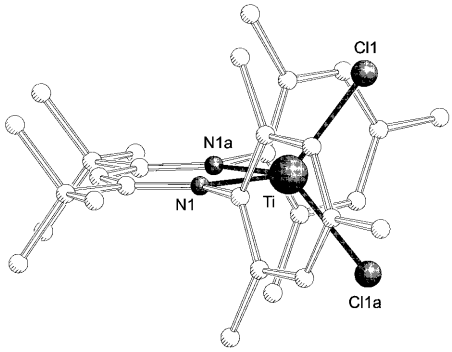
Surprisingly, we were unable to prepare transition metal complexes of the bulkiest ligand ($\mathbf{L^6}$). Neither the lithium salt nor the potassium salt reacted with $TiCl_3$ in refluxing THF, despite the fact that in the less hindered systems ligand transfer occurs even at room temperature. With VCl_3, some kind of reaction took place, but no vanadium diiminate was formed. It occurred to us that the steric repulsion between the backbone *t*Bu groups and the substituents at the nitrogen atoms might destabilize the geometry needed

Figure 2. X-ray structure of L^1TiCl_2[a]



[a] Selected structure data: Ti−N1 1.983(3), Ti−N2 1.964(3), Ti−Cl1 2.294(1), Ti−Cl2 2.295(1) Å; N1−Ti−N2 84.2(1), Cl1−Ti−Cl2 106.34(5)°.

Figure 3. X-ray structure of L^5TiCl_2[a]



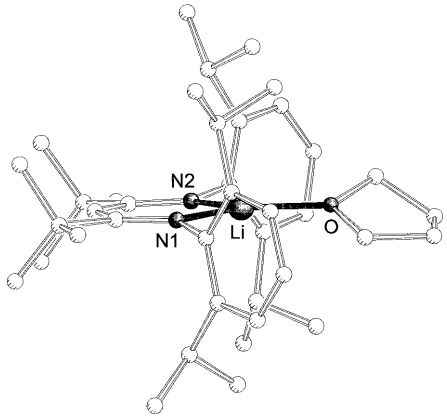
[a] Selected structure data: Ti−N1 1.986(1), Ti−Cl1 2.2966(6) Å; N1−Ti−N1a 83.88(8), Cl1−Ti−Cl1a 104.57(3)°.

for chelation, for example by enforcing a *trans* arrangement of the *t*Bu and diisopropylphenyl groups around the C=N bonds. However, the X-ray structure of the salt $\mathbf{L^6}$Li(THF) (Figure 4) shows a normal chelate structure. The most likely explanation for the failure to form Ti and V complexes is still a steric one. The *t*Bu groups enforce a larger C−N−C angle [compare the values of 119 and 120° in $\mathbf{L^2}VCl_2$ and 121 and 122° in $\mathbf{L^1}TiCl_2$ to 128° in $\mathbf{L^5}TiCl_2$ and 127 and 129° in $\mathbf{L^6}$Li(THF)], thus restricting the amount of space in the open "wedge" between the aryl groups. Also, the possibility of strain relief by aryl group tilting as found in $\mathbf{L^2}VCl_2$ is probably limited by the *t*Bu groups. Thus, there is still enough space in the center of the open wedge for the single THF molecule in $\mathbf{L^6}$Li(THF), but the isopropyl groups might cause severe repulsion at the two tetrahedral positions of the chlorides in a hypothetical $\mathbf{L^6}MCl_2$ molecule.

Dialkylvanadium(III) Compounds

Treatment of complexes $LVCl_2$ with alkyllithium compounds (MeLi, *n*BuLi) in diethyl ether affords easy access to dialkylmetal compounds LVR_2. These complexes were found to be unexpectedly stable. For example, $\mathbf{L^2}V(n\text{Bu})_2$,

Figure 4. X-ray structure of L^6Li(THF)[a]



[a] Selected structure data: Li−N1 1.927(6), Li−N2 1.927(6), Li−O 1.910(6) Å; N1−Li−N2 100.2(3), N1−Li−O 130.9(3), N2−Li−O 128.8(3)°.

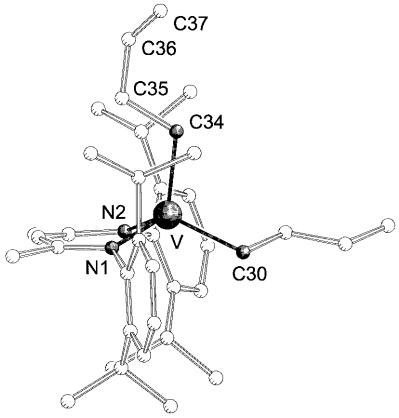
which is formally a 10-*e* complex (or at most a 14-*e* complex, if π-donation from both nitrogen atoms is included in the count) and contains 4 β-hydrogen atomss, could be crystallized from warm (50°C) hexane without significant decomposition. The X-ray structure of this complex (Figure 5) shows a tetrahedral environment of the metal centre, similar to that in the dichloride. There is some disorder in one of the *n*-butyl groups, but the structure is otherwise unremarkable. There is no evidence for significant agostic interactions or short intermolecular contacts.

Not many dialkylvanadium(III) compounds are known. Two examples bearing tridentate amido ligands have been reported: Edwards obtained a compound formulated as $[(Me_2PCH_2CH_2)_2N]VMe_2$ as an oil from the reaction of the dichloride with MeLi;[10] he also obtained the crystalline complex $[(Et_2NCH_2CH_2)_2N]VMe_2$ in a similar manner.[11] $CpVMe_2(PMe_3)_2$[12] and $CpVR_2(PMe_3)$ (R = CH_2CMe_3, CH_2CMe_2Ph, CH_2SiMe_3)[13] have been reported by the group of Teuben. None of these complexes have been characterized by X-ray diffraction, but the crystal structure of the metallated alkyl-aryl complex $CpV(CH_2CMe_2\text{-}o\text{-}C_6H_4)(PMe_3)_2$ has been determined and shows a rather long V−C(alkyl) distance of 2.194(3) Å.[13] The *tri*alkyl complex $[(Me_3CCH_2)_3V]_2(\mu\text{-}N_2)$ has much shorter V−C bonds [2.026(2) Å];[14] those in our complex $\mathbf{L^2}V(n\text{Bu})_2$ are intermediate [2.062(5) Å].

Dialkyltitanium(III) Compounds

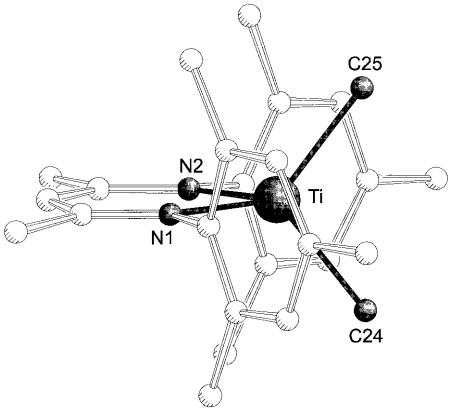
The related dialkyltitanium(III) compounds were found to be less stable. For ligands bearing 2,6-disubstituted aryl groups, $LTiMe_2$ complexes are best prepared from $LTiCl_2$ and MeMgI in diethyl ether. Addition of 1 equiv. of dioxane, evaporation of the solvent, and extraction with hexane gave an impure product, which could be purified further by crystallization from hexane. The $LTiMe_2$ complexes all have an intense dark-blue colour. The structure of $\mathbf{L^1}TiMe_2$ (Figure 6) shows the expected tetrahedral environment of the metal centre and is very similar to that of

Figure 5. X-ray structure of $L^2V(n\text{Bu})_2$[a]



[a] Selected structure data: V–N1 1.997(4), V–N2 1.991(4), V–C30 2.062(5), V–C34 2.062(5) Å; N1–V–N2 94.5(2), C30–V–C34 109.6(2)°; the apparent near-eclipsed confirmation of the C34–C37 butyl chain is caused by a disorder in the positions of C35 and C36, probably between two possible *gauche* conformations.

Figure 6. X-ray structure of L^1TiMe_2[a]



[a] Selected structure data: Ti–N1 1.989(2), Ti–N2 1.989(2), Ti–C24 2.131(3), Ti–C25 2.123(3) A; N1–Ti–N2 85.33(7), C24–Ti–C25 104.5(1)°.

the dichloride. Paramagnetic alkyltitanium compounds are relatively rare, and only a few examples not bearing cyclopentadienyl substituents have been described. Arnold has reported the synthesis of a *mono*methyltitanium(III) benzamidinate complex, $[PhC(NSiMe_3)_2]_2TiMe$,[15] and suggested that the unusually short Ti–C bond in this complex, 2.120(5) Å, was due to the low coordination number (5) of the Ti atom. The coordination number of Ti in $\mathbf{L^1}TiMe_2$ is even lower (4), but the Ti–C bond lengths [2.123(3) and 2.131(3) Å] are not shorter than those in the benzamidinate compound. However, the benzamidinato ligand should be "harder" than the diiminato ligand, and this is reflected in much longer Ti–N bonds [2.104(3), 2.164(3), 2.095(3), and 2.160(3) Å, vs. 1.989(2) Å in $\mathbf{L^1}TiMe_2$], which might compensate for the difference in coordination number. Cummins has reported the X-ray structure of $[\eta^1\text{-}(t\text{Bu})(\text{Ar})\text{N}][\eta^3\text{-}(t\text{Bu})(\text{Ar})\text{N}]\text{TiCH}(SiMe_3)_2$ (Ar = 3,5-$Me_2C_6H_3$), which has a Ti–C distance of 2.137(7) Å.[16] Edwards has reported the preparation of $[(Et_2NCH_2CH_2)_2N]TiMe_2$, which was characterized by elemental analysis and ESR; no further details of its stability and reactivity were given.[11] Gambarotta has prepared several anionic dialkyltitanium(III) compounds $(R_2N)_2Ti(\mu\text{-}R')_2Li(TMEDA)$ and $[(R_2N)_2Ti(R')_2]^-[Li(TMEDA)_2]^+$.[17]

The presence of sufficient steric shielding appears to be essential for the stability of the product. Whereas $LTiMe_2$ complexes bearing *2,6-disubstituted* aryl groupss were found to be reasonably stable at room temperature, the bis(*o-tolyl*) ($\mathbf{L^3}$) derivative decomposes within 1 h (an impure product could be obtained by carrying out the reaction and isolation at −10°C). The di*phenyl* ($\mathbf{L^4}$) derivative was initially formed upon addition of MeMgI to $LTiCl_2$ (as indicated by the deep-blue colour), but within ca. 10 seconds the colour had changed to green-brown, indicating rapid decomposition. We could not find any conditions under which the rate of formation was sufficiently high and the decomposition slow enough to allow isolation of $\mathbf{L^4}TiMe_2$.

Higher alkyl derivatives are less stable than the methyl complexes. A few large, dark-blue crystals of what appeared to be $\mathbf{L^1}TiEt_2$ were obtained by rapid work-up of the reaction product from $\mathbf{L^1}TiCl_2$ and EtMgBr in Et_2O, but even during crystallization at −20°C the initially blue hexane solution turned green, indicating partial decomposition. The crystals themselves were fully decomposed after 1 night at room temperature. No further attempts were made to prepare higher alkyl compounds.

Polymerization Experiments

Even though they are coordinatively unsaturated, the dialkylmetal compounds themselves were found to be unreactive towards olefins. Treatment with MAO or $EtAlCl_2$ resulted in transfer of the β-diimine ligand to Al, and no significant polymerization activity was observed. The reaction of $LVMe_2$ complexes with 1 equiv. of $B(C_6F_5)_3$ produced a brown solution, possibly containing the ionic species, but no polymerization activity was observed with propene, and only a very low activity with ethene.

The corresponding Ti complexes proved to be significantly more active. Reaction of $\mathbf{L^1}TiMe_2$ with $B(C_6F_5)_3$ in benzene produced a red-brown solution, possibly containing $\mathbf{L^1}TiMe^+MeB(C_6F_5)_3^-$. This solution was found to be active in the polymerization of propene and 1-hexene, producing atactic materials, although activities in propene polymerization (see Table 1) are not very high compared to those of metallocene catalysts. The molecular weight distribution is rather narrow ($M_w/M_n \approx 1.58-1.78$) indicating relatively slow chain transfer. The polymerization is not "living", since propene absorption almost stopped after 15 min. The stoichiometry of the reaction indicates the formation of ca. 1 chain per metal atom. NMR analysis of the product did not reveal any unsaturated end groups. These facts suggest that the polymerization does *not* terminate by β-elimination, but by a different mechanism which prevents initiation of a new chain. One possibility is reaction with impurities in the feed (since there is no scavenger present

Table 1. Propene polymerization experiments[a]

[a] 0.1 mmol of cat. and co-cat., 25 ml of solvent, 5–6 bar propene, room temperature. – [b] (g olefin)/(mol Ti)·h. – [c] Multiple entries are results from separate experiments.

in this system), but alkyl transfer to the ligand cannot be excluded: Floriani observed transfer of alkyl groups from Zr^{IV} to the imine carbon atoms of the macrocyclic bis(diiminato) ligand tmtaa.[18] Reproducibility of the activities is poor (see the different activities given for entries 1, 3, 7, 8, 9 in the table). We found that the time taken to prepare the catalyst mixture and the laboratory temperature had a significant influence, indicating that the catalyst is not very stable.

Curiously, polymerization activity is virtually zero if toluene is used as the solvent instead of benzene (entries 1 and 3). Inhibition of polymerization by toluene has been noted for a closely related Ti^{IV} di*amide* catalyst by McConville,[19] but he did not report on the effect of benzene in the same system. McConville attributed the effect of toluene to the formation of a toluene complex. Our observed difference between benzene and toluene might have a similar cause, since toluene is a somewhat stronger donor than benzene. However, we do not consider this very likely since some activity was observed when the reaction was carried out at a lower temperature in toluene. Chemical reaction with toluene (e.g. benzylic C–H activation) could be an alternative explanation.

The catalyst system used here allows only a limited amount of "tuning". Increasing the steric hindrance at the metal centre was found to have a deleterious effect on activity (compare entries 1 and 10). *Reduction* of steric hindrance was not possible since the required $LTiMe_2$ precursors are unstable (see above). Use of the less coordinating anion $B(C_6F_5)_4^-$ also decreased activity (entries 1 and 6), possibly because of faster catalyst decomposition. Activity is also lower at higher temperature (entries 1 and 3), again indicating catalyst decomposition. Thus, the scope of this Ti^{III} catalyst appears to be rather limited.

Conclusions

β-Diimine complexes $LMCl_2$ of Ti^{III} and V^{III} are easily prepared. The corresponding dialkylmetal compounds are unexpectedly stable when M = V, but they do not seem to give rise to active polymerization catalysts. The corresponding dialkyltitanium(III) compounds are much less stable, but catalysts generated from $LTiMe_2$ and $B(C_6F_5)_3$ show activity in α-olefin polymerization. The reasons for these differences are unclear and point out the need for a more detailed understanding of the reactivity of paramagnetic non-d^0 systems

Experimental Section

General: All manipulations involving lithium, potassium, and transition metal compounds were performed in standard Schlenk glassware under an inert atmosphere. Reagents were used as received. Solvents were dried by distillation from sodium under argon prior to use. – ^{1}H- and ^{13}C-NMR spectra were recorded using Varian XL-200 and Varian VXR-300 instruments, respectively. – The metal chlorides $TiCl_3(THF)_3$ and $VCl_3(THF)_3$[20], the ligands $\mathbf{L^2}H$[2] and $\mathbf{L^4}H$[5] and the borane $B(C_6F_5)_3$[21] were prepared according to literature methods. For some syntheses of vanadium compounds, $VCl_3(THF)_3$ was prepared in situ by refluxing anhydrous VCl_3 in THF prior to reaction with a lithium β-diiminate.

L²Li: 76 g of $\mathbf{L^2}H$ was dissolved in 200 ml of THF. To a cooled solution of 10.2 g of *n*BuLi in 250 ml of hexane was added 25 ml of diisopropylamine, and this solution was slowly added to the cooled solution of $\mathbf{L^2}H$. The mixture was warmed to room temperature and the solvents were removed in vacuo. The crude product was crystallized from hexane (+65°C/–20°C) to give light-yellow crystals of the composition $\mathbf{L^2}Li(THF)$ (by NMR) (ca. 70 g, 80%). – ^{1}H NMR (C_6D_6): δ = 7.28 (*m*-H), 7.20 (*p*-H), 5.14 (C*H*C=N), 2.03 (CH_3C=N), 1.30, 1.40, 3.55 (*i*Pr), 1.02, 2.83 (THF). – ^{13}C NMR ([D_8]THF): δ = 150.3 (*i*-C), 141.4 (*o*-C), 123.4 (*m*-C), 123.1 (*p*-C), 163.4 (*C*=N), 92.7 (*C*HC=N), 28.4 (*C*H_3C=N), 24.8, 24.0 (*C*H_3CH), 23.3 (*C*HCH$_3$).

L¹H was prepared by a similar route to that used for $\mathbf{L^2}H$:[2] A mixture of 25.03 g of acetylacetone (0.25 mol), 67.6 g of 2,4,6-trimethylaniline (0.5 mol), and 20.8 ml of 12 N hydrochloric acid (0.25 mol) was heated to 120°C for 4 h. Water was allowed to distil from the reaction mixture and heating was continued at 140°C overnight. Thereafter, the solids produced were crystallized from refluxing ethanol. Two fractions were collected, the second fraction after treatment with diethyl ether. Yield of crude $\mathbf{L^1}H$·HCl: 87.6 g (94%). – ^{1}H NMR ($CDCl_3$): δ = 2.65 (1-H), 4.29 (3-H), 6.74 (*m*-H), 1.94 (α*o*-H), 2.23 (α*p*-H), 4.88 (NH). – ^{13}C NMR ($CDCl_3$): δ = 21.1 (C-1), 171.5 (C-2), 90.5 (C-3), 139.7 (*i*-C), 135.5 (*o*-C), 130.0 (*m*-C), 132.7 (*p*-C), 17.5 (α*o*-C), 21.2 (α*p*-C). A mixture of 60.2 g of crude $\mathbf{L^1}H$·HCl (162 mmol), 30 ml of triethylamine (218 mmol), 200 ml of dichloromethane, and 100 ml of water was stirred

for 1 h until all solids had dissolved and a clear separation of the two layers had occurred. The organic phase was removed, dried with magnesium sulfate, filtered, and the solvent was removed in vacuo. The resulting thick oil was dried in vacuo at 100°C for 4 h (to remove small amounts of 2,4,6-trimethylaniline). The crude product **L[1]H** was isolated as a brown solid, yield 46.2 g (85%), and was used as such, without further purification, for reaction with transition metal chlorides. – ^{1}H NMR ($CDCl_3$): δ = 1.68 (1-H), 4.85 (3-H), 6.85 (*m*-H), 2.25 (α*o*-H), 2.11 (α*p*-H). – ^{13}C NMR ($CDCl_3$): δ = 20.3 (C-1), 160.9 (C-2), 93.3 (C-3), 141.1 (*i*-C), 131.8 (*o*-C), 128.4 (*m*-C), 133.4 (*p*-C), 18.2 (α*o*-C), 20.8 (α*p*-C).

L[5]H was prepared by procedures similar to those used by Knorr and Weiss for bulky diimines.[6] – (a) To a mixture of 67.6 g of 2,4,6-trimethylaniline (0.5 mol) and 50.6 g of triethylamine (0.5 mol) in 800 ml of dichloromethane was slowly added a solution of 60.3 g of pivaloyl chloride (0.5 mol) in 200 ml of dichloromethane. After the addition was completed, the reaction mixture was refluxed for 1 h and then extracted with 2 × 250 ml water. The organic fraction was dried with magnesium sulfate, filtered, and the solvent was removed in vacuo. The resulting yellow oil was treated with diethyl ether, yielding a white, microcrystalline powder. This powder was filtered off and dried. Yield: 96 g (88%) of crude 2,2-dimethyl-*N*-(2,4,6-trimethylphenyl)propionamide. – ^{1}H NMR ($CDCl_3$): δ = 1.32 (3-H), 6.86 (*m*-H), 2.14 (α*o*-H), 2.25 (α*p*-H). – ^{13}C NMR ($CDCl_3$): δ = 176.5 (C-1), 39.2 (C-2), 27.8 (C-3), 136.6 (*i*-C), 135.1 (*o*-C), 128.8 (*m*-C), 131.3 (*p*-C), 18.1 (α*o*-C), 20.9 (α*p*-C).

(b) To a slurry of 96 g (438 mmol) of the crude amide in 1 l of toluene, 91.15 g of phosphorus pentachloride (438 mmol) was added in small portions. During the course of the addition, HCl gas was liberated and the reaction mixture became a clear yellow solution. After the addition was completed, the reaction mixture was stirred overnight. The solvent was distilled off, first toluene followed by the formed $POCl_3$. Finally, the product was distilled at 85°C (4 mbar oil pump). Yield: 88.8 g (85%) of 1-chloro-2,2-dimethyl-1-(2,4,6-trimethylphenylimino)propane. – ^{1}H NMR ($CDCl_3$): δ = 1.43 (3-H), 6.88 (*m*-H), 2.03 (α*o*-H), 2.29 (α*p*-H). – ^{13}C NMR ($CDCl_3$): δ = 155.3 (C-1), 43.8 (C-2), 28.5 (C-3), 143.1 (*i*-C), 125.9 (*o*-C), 128.4 (*m*-C), 133.1 (*p*-C), 17.5 (α*o*-C), 20.8 (α*p*-C).

(c) To 32.5 g of 1-chloro-2,2-dimethyl-1-(2,4,6-trimethylphenylimino)propane (137 mmol) in 200 ml of diethyl ether was added 170 ml of 1.6 M methyllithium in diethyl ether (274 mmol). The solution became warm and methane gas was evolved. The reaction mixture was stirred for 1 h at room temperature. After careful hydrolysis with water and subsequent extraction, the organic fraction was dried with magnesium sulfate, filtered, and distilled at 106–108°C (3 mbar oil pump). Yield: 27.6 g (93%) of 3,3-dimethyl-2-(2,4,6-trimethylphenylimino)butane. – ^{1}H NMR ($CDCl_3$): δ = 1.61 (1-H), 1.27 (4-H), 6.81 (m-H), 1.93 (α*o*-H), 2.25 (α*p*-H). – ^{13}C NMR ($CDCl_3$): δ = 15.2 (C-1), 177.0 (C-2), 40.3 (C-3), 28.0 (C-4), 146.3 (*i*-C), 125.1 (*o*-C), 128.4 (*m*-C), 131.2 (*p*-C), 17.5 (α*o*-C), 20.7 (α*p*-C).

(d) To a cooled (–78°C) mixture of 10.85 g of 3,3-dimethyl-2-(2,4,6-trimethylphenylimino)butane (50 mmol) and 5.8 g of *N,N,N′N′*-tetramethylethylenediamine (TMEDA) (50 mmol) in 100 ml of hexane was added 31.25 ml of 1.6 M *n*-butyllithium in hexane (50 mmol). The reaction mixture was allowed to warm to room temperature and was then stirred overnight, resulting in a cloudy, slightly yellow slurry. To this was added dropwise 11.875 g of 1-chloro-2,2-dimethyl-1-(2,4,6-trimethylphenylimino)propane (50 mmol) in 75 ml of hexane. The reaction temperature was maintained below reflux temperature with water-bath cooling. After the addition was completed, the mixture was refluxed for 1 h. Then, 100 ml of water and 100 ml of diethyl ether were added and the product was extracted. The aqueous layer was extracted once with 100 ml of diethyl ether. The combined organic fractions were dried with magnesium sulfate, filtered, and the solvent was evaporated in vacuo. The product was crystallized from refluxing ethanol. Yield: 15.88 g (76%). The NMR spectra show separate peaks due to the imine-enamine and bis(imine) (minor component) forms. – ^{1}H NMR ($CDCl_3$) of imine-enamine form: δ = 1.14 (1-H), 5.43 (4-H), 6.71 (*m*-H), 2.20 (α*o*-H), 2.14 (α*p*-H), 13 (NH); of bis(imine) form (all peaks broad): δ = 0.8–1.4 (1-H), 3.2 (4-H), 1.9 (α*o*-H), 2.23 (α*p*-H), 6.75 (*m*-H). – ^{13}C NMR ($CDCl_3$) of imine-enamine form: δ = 30.4 (C-1), 40.3 (C-2), 170 (C-3), 91 (C-4), 143 (*i*-C), 131.3 (*o*-C), 128.7 (*m*-C), 132.7 (*p*-C), 19.2 (α*o*-C), 20.9 (α*p*-C).

L[6]H was prepared by a route similar to that used for **L[5]H**. – (a) To a mixture of 44.3 g of 2,6-diisopropylaniline (0.25 mol) and 25.3 g of triethylamine (0.25 mol) in 400 ml of dichloromethane was slowly added a solution of 30.145 g of pivaloyl chloride (0.25 mol) in 100 ml of dichloromethane. After the addition was completed, the reaction mixture was refluxed for 1.5 h. It was then diluted with 500 ml of dichloromethane and extracted with water (3 × 100 ml). The organic fraction was dried with magnesium sulfate, filtered, and the solvent was removed in vacuo. The resulting yellow oil was treated with diethyl ether to yield a white microcrystalline powder. This powder was filtered off and dried. Yield: 65.5 g (100%) of crude *N*-(2,6-diisopropylphenyl)-2,2-dimethylpropionamide. – ^{1}H NMR ($CDCl_3$): δ = 1.36 (3-H), 7.15–7.25 (*m*-, *p*-H), 3.00 (α-H), 1.19 (β-H), 6.8 (NH). – ^{13}C NMR ($CDCl_3$): δ = 177.1 (C-1), 39.2 (C-2), 28.7 (C-3), 131.4 (*i*-C), 146.1 (*o*-C), 123.3 (*m*-C), 128.0 (*p*-C), 23.5 (α-C), 27.8 (β-C).

(b) To a slurry of 65.5 g of *N*-(2,6-diisopropylphenyl)-2,2-dimethylpropionamide (0.25 mol) in 500 ml of benzene, 52 g of phosphorus pentachloride (0.25 mol) was added in small portions. During the course of the addition, HCl gas was liberated and the reaction mixture became a clear yellow solution. After the addition was completed, the reaction mixture was stirred for 1 h. The solvent was then distilled off, first benzene followed by the formed $POCl_3$. Finally, the product was distilled at 85°C (4 mbar oil pump). Yield: 54.4 g (78%) of 1-chloro-1-(2,6-diisopropylphenylimino)-2,2-dimethylpropane.[22] – ^{1}H NMR ($CDCl_3$): δ = 1.44 (3-H), 7.14 (*m*-, *p*-H), 2.75 (α-H), 1.2 (β-H). – ^{13}C NMR ($CDCl_3$): δ = 154.6 (C-1), 43.9 (C-2), 28.4 (C-3), 143.1 (*i*-C), 136.4 (*o*-C), 122.9 (*m*-C), 124.4 (*p*-C), 23 (α-, β-C).

(c) To 32.76 g of 1-chloro-1-(2,6-diisopropylphenylimino)-2,2-dimethylpropane (117 mmol) in 100 ml of diethyl ether was added a large excess of 200 ml of 1.6 M methyllithium in diethyl ether (320 mmol). The solution became warm and methane gas was evolved. The reaction mixture was stirred for 3 h at room temperature and then carefully (!) hydrolysed with water. After extraction, the organic fraction was dried with magnesium sulfate, filtered, and distilled at 75°C (2 mbar oil pump). Yield: 27.9 g (92%) of 2-(2,6-diisopropylphenylimino)-3,3-dimethylbutane. – ^{1}H NMR ($CDCl_3$): δ = 1.7 (1-H), 1.3 (4-H), 7.0–7.3 (*m*-, *p*-H), 2.71 (α-H), 1.15, 1.18 (β-H). – ^{13}C NMR ($CDCl_3$): δ = 15.9 (C-1), 176.4 (C-2), 40.4 (C-3), 28.0 (C-4), 146.6 (*i*-C), 135.7 (*o*-C), 122.7 (*m*-C), 122.6 (*p*-C), 27.8 (α-C), 22.8, 23.0 (β-C).

(d) To a cooled (–78°C) mixture of 27.9 g 2-(2,6-diisopropylphenylimino)-3,3-dimethylbutane (107.5 mmol) and 12.5 g of *N,N,N′N′*-tetramethylethylenediamine TMEDA (107.5 mmol) in 100 ml of hexane was added 67.5 ml of 1.6 M *n*-butyllithium in hexane (107.5 mmol). The reaction mixture was allowed to warm

to room temperature and then stirred overnight. A sticky white slurry was obtained, which was treated dropwise with 30.1 g of 1-chloro-1-(2,6-diisopropylphenylimino)-2,2-dimethylpropane (107.5 mmol) in 75 ml of hexane. The reaction temperature was maintained below reflux temperature with water-bath cooling. After the addition was completed, the mixture was refluxed for 1 h. Then, 100 ml of water and 100 ml of diethyl ether were added and the product was extracted. The aqueous layer was extracted once with 100 ml of diethyl ether. The combined organic fractions were dried with magnesium sulfate, filtered, and the solvent was evaporated in vacuo. The product was crystallized from refluxing hexane. Two fractions of white crystals (35.86 and 7.47 g) were collected; combined yield 43.33 g (80%) of **L⁶**H. The NMR spectra show separate peaks due to the imine-enamine and bis(imine) (minor component) forms. – ^{1}H NMR ($CDCl_3$) of imine-enamine form: δ = 1.08 (1-H), 5.42 (4-H), 6.94 (*m*-, *p*-H), 3.26 (α-H), 1.02, 1.22 (β-H), 4.9 (NH); of bis(imine) (all peaks broad): δ = 0.8−1.4 (1-H, β-H), 2.4−2.8 (α-H), 6.9−7.2 (*m*-, *p*-H). – ^{13}C NMR ($CDCl_3$) of imine-enamine form: δ = 31.3 (C-1), 41.3 (C-2), 169.3 (C-3), 94.7 (C-4), 142.7 (*i*-C), 141.3 (*o*-C), 123.1 (*m*-C), 122.9 (*p*-C), 28.9 (α-C), 22.5, 25.8 (β-C).

L⁶Li: To a cooled (−78°C) mixture of 1.0 g of **L⁶**H (2 mmol) and 202 mg of diisopropylamine in 15 ml of THF was added 1.25 ml 1.6 of M *n*BuLi in hexane. The reaction mixture was allowed to warm to room temperature and then refluxed for a short time (10 min). The solvent was evaporated in vacuo and the product was crystallized from refluxing hexane, yielding beautiful yellow crystals of **L⁶**Li·THF. – ^{1}H NMR (C_7D_8): δ = 1.26 (1-H), 5.11 (4-H), 6.8−7.0 (*m*-, *p*-H), 3.36 (α-H), 1.03, 1.29 (β-H). – ^{13}C NMR (C_7D_8): δ = 33.3 (C-1), 44.1 (C-2), 170.1 (C-3), 92.2 (C-4), 150.9 (*i*-C), 139.5 (*o*-C), 122.9 (*m*-C), 121.6 (*p*-C), 27.9 (α-C), 23.1, 25.3 (β-C).

L⁶K: To a stirred suspension of 0.16 g (4 mmol) of KH (dispersion in mineral oil, washed with hexane to remove the oil) in 25 ml of THF, 1.0 g (2 mmol) of **L⁶**H was added in small portions. The yellowish solution was stirred at 65°C for 1 h and then filtered. The THF was removed in vacuo, and the product was washed with hexane to give off-white **L⁶**K (0.9 g, 90%). – ^{1}H NMR ([D_8]THF): δ = 1.16−1.19 (1-H, β-H), 3.85 (4-H), 6.84 (*m*-H), 6.51 (*p*-H), 3.35 (α-H). – ^{13}C NMR ([D_8]THF): δ = 31.4 (C-1), 42.2 (C-2), 168 (br., C-3), 88.4 (C-4), 153.7 (*i*-C), 137.8 (*o*-C), 122.3 (*m*-C), 117.0 (*p*-C), 28.1 (α-C), 23.8, 25.4 (β-C).

L³H: (a) A mixture of 46.9 g of *o*-toluidine (438 mmol) and 48.2 g of acetylacetone (481 mmol) in 500 ml of toluene, plus a few drops of H_2SO_4, was heated under reflux in a Dean-Stark apparatus for the azeotropic removal of water. After 16 h, the reaction mixture was cooled to room temperature and the solvent was removed in vacuo. The product was distilled at 118°C (5 mbar) to give 4-*o*-tolylamino-3-penten-2-one as a light-yellow oil (75.3 g, 91%). – ^{1}H NMR ($CDCl_3$): δ = 1.86 (CH_3C=N), 2.10 (CH_3C=O), 2.27 (*o*-CH_3), 5.19 (C*H*), 7.0−7.3 (Ar-H), 12.3 (NH). – ^{13}C NMR ($CDCl_3$): δ = 29.0 (CH_3C=O), 196.0 (CH_3C=O), 97.0 (*C*H), 161.1 (CH_3C=N), 19.5 (CH_3C=N), 137.4 (arom. C-1), 133.8 (arom. C-2), 130.7 (arom. C-3), 126.2 (arom. C-4), 126.3 (arom. C-5). 126.2 (arom. C-6), 18.0 (*o*-CH_3).

(b) A mixture of 47.3 g of 4-*o*-tolylamino-3-penten-2-one (250 mmol) and 35.9 g of *o*-toluidine hydrochloride (250 mmol) was refluxed in the minimum volume of ethanol for dissolution of both components. Cooling the reaction mixture to room temperature yielded yellow crystals of the monohydrochloride of 2,4-di-*o*-tolyliminopentane (63.1 g, 80%). – ^{1}H NMR (CD_3OD): δ = 2.68 (CH_3C=N), 2.06 (*o*-CH_3), 4.64 (CH), 4.89 (NH), 6.8−7.3 (Ar-H). – ^{13}C NMR (CD_3OD): δ = 22.0 (CH_3C=N), 171.5 (CH_3C=N), 92.4 (*C*H), 136.5 (arom. C-1), 135.6 (arom. C-2), 132.2 (arom. C-3), 127.7 (arom. C-4), 129.8 (arom. C-5), 128.2 (arom. C-6), 17.4 (*o*-CH_3).

(c) A mixture of 7.87 g of 2,4-di-*o*-tolyliminopentane·HCl (25 mmol), 7 ml of triethylamine (50 mmol), 100 ml of dichloromethane, and 100 ml of water was stirred for 1 h until all solids had dissolved and a clear separation of the two layers had occurred. The organic phase was removed, dried with magnesium sulfate, filtered, and the solvent was removed in vacuo. The resulting thick yellow oil was dried in vacuo for 16 h. The product was isolated as a yellow oil (6.36 g, 91%). – ^{1}H NMR ($CDCl_3$): δ = 1.97 (CH_3C=N), 2.27 (*o*-CH_3), 4.98 (CH), 12.6 (NH), 6.9−7.3 (Ar-H). – ^{13}C NMR ($CDCl_3$): δ = 20.7 (CH_3C=N), 159.8 (CH_3C=N), 96.5 (*C*H), 144.6 (arom. C-1), 130.7 (arom. C-2), 130.2 (arom. C-3), 123.6 (arom. C-4), 126.1 (arom. C-5), 123.0 (arom. C-6), 16.3 (*o*-CH_3).

L¹VCl₂: Vanadium trichloride (7.865 g, 50 mmol) was refluxed for 3 h in 100 ml of THF to form $VCl_3(THF)_3$. A solution of 16.725 g (50 mmol) of **L¹**H in 100 ml of THF was cooled to −78°C. To this was added 31.4 ml (50 mmol) of 1.6 M *n*-butyllithium in hexane, and the mixture was allowed to warm to room temperature. The orange/yellow solution thus obtained was added to the pink/red slurry of $VCl_3(THF)_3$ resulting in an immediate colour change to an intense dark brown-red. The reaction mixture was refluxed for an additional 1 h. The solvent was then removed in vacuo, and the residue was dried at 80°C in vacuo. It was then washed with 50 ml of hexane, dried, and extracted with 200 ml of toluene. The product was crystallized from toluene as red crystals. Two fractions were obtained (7.425 g and 5.4 g). Yield: 12.825 g (56%). – $C_{23}H_{29}Cl_2N_2V$ (455.34): calcd. C 60.67, H 6.42, Cl 15.57, N 6.15, V 11.19; found C 60.39, H 6.26, Cl 15.45, N 6.00, V 10.95.

L¹VMe₂: To a suspension of 9.3 g of **L¹**VCl_2 (20.4 mmol) in 150 ml of diethyl ether, cooled to −78°C, was slowly added 25.65 ml of a solution of methyllithium in diethyl ether (1.6 M, 40.8 mmol). The mixture was allowed to warm to room temperature and the solvent was removed in vacuo. Crystallization from hexane (+40°C/−20°C) gave dark-brown crystals. Yield: 5.42 g (64%). – $C_{25}H_{35}N_2V$ (414.51): calcd. C 72.44, H 8.51, N 6.76, V 12.29; found C 72.18, H 8.33, N 6.71, V 12.10, Cl < 0.1.

L¹TiCl₂: To a solution of 6.69 g of **L1**H (20 mmol) in 50 ml of THF, cooled to −78°C, was added 6.3 ml (20 mmol) 1.6 of M *n*BuLi in hexane, and the mixture was allowed to warm to room temperature. Then, 3.7 g of solid $TiCl_3(THF)_3$ (20 mmol) was added and the reaction mixture was refluxed overnight. A colour change from green to dark brown took place. The solvent was then removed in vacuo and 100 ml of toluene was added. The resulting solution was reduced in volume by 20 ml by distillation of toluene along with residual THF and/or hexane. The warm, deep-red solution was filtered and the filtrate was concentrated, at reflux temperature, until crystals appeared. After leaving the solution to stand overnight, deep-red crystals were collected. Yield: 7.32 g (81%). – $C_{23}H_{29}Cl_2N_2Ti$ (452.30): calcd. C 61.08, H 6.46, Cl 15.68, N 6.19, Ti 10.59; found C 60.90, H 6.62, Cl 15.76, N 6.03, Ti 10.45.

L¹TiMe₂: 1. *Using MeLi:* To a stirred suspension of 1.0 g (2.2 mmol) of **L¹**$TiCl_2$ in 20 ml of diethyl ether, cooled to −80°C, was slowly added 2.8 ml (4.4 mmol) of a 1.6 M solution of MeLi in diethyl ether. The mixture was allowed to warm to 0°C, whereupon a deep-blue colour appeared. The solvent was then removed in vacuo, and the residue was quickly extracted with two 15-ml portions of hexane. The combined hexane fractions were concentrated in vacuo to a volume of ca. 2.5 ml and after storage overnight at

−20°C, a dark-blue crystalline solid was isolated. The yield of this synthesis was rather variable, but was usually in the range 10−50%. The isolated product was found to be stable at room temperature, both in solution and in the solid state. Crystals for X-ray diffraction were obtained by recrystallization from pentane (+25°C/−20°C).

2. *Using MeMgI:* To a stirred suspension of 1.0 g (2.2 mmol) of $\mathbf{L^1}TiCl_2$ in 20 ml of diethyl ether was slowly added a solution of 1.06 g (4.4 mmol) of $MeMgI(Et_2O)$ in 15 ml of diethyl ether. The mixture immediately turned deep-blue. The solvent was removed in vacuo, and the residue was extracted with two 15-ml portions of hexane. Concentration of the solution and cooling to −20°C gave dark-blue crystals of the product (0.64 g, 70%).

Attempted Synthesis of $\boldsymbol{L^1TiEt_2}$*:* To a stirred suspension of 1.0 g (2.2 mmol) of $\mathbf{L^1}$TiCl2 in 20 ml of diethyl ether, cooled to −20°C, was slowly added a solution of 0.92 g (4.4 mmol) of $EtMgBr(Et_2O)$ in 15 ml of diethyl ether. The mixture immediately turned deep-blue. It was allowed to warm to 5°C and then cooled once more to −20°C. The solvent was then removed in vacuo, and the residue was quickly extracted with two 15-ml portions of hexane. Concentration of the combined extracts at −20°C and storage at this temperature overnight gave a few very large, dark-blue crystals of the product. These decomposed within a day at room temperature, both in solution and in the solid state, leading to unidentified brown products with liberation of ethane.

$\boldsymbol{L^2VCl_2}$*:* Vanadium trichloride (7.865 g, 50 mmol) was refluxed for 2 h in 150 ml of THF to form $VCl_3(THF)_3$. To this was added a solution of 24.84 g of $\mathbf{L^2}$Li(THF) (50 mmol) in 50 ml of THF and the reaction mixture was refluxed for 30 min resulting in a deep brown-red colouration. The solvent was then removed in vacuo and the residue was dried at 100°C, whereupon it slowly turned dark green. It was then washed with 25 ml hexane, dried, and crystallized from toluene as very dark-green crystals. Yield: 22.15 g (82%). − $C_{29}H_{41}Cl_2N_2V$ (539.50): calcd. C 64.56, H 7.66, Cl 13.14, N 5.19, V 9.44; found C 64.30, H 7.52, Cl 13.00, N 5.03, V 9.55.

$\boldsymbol{L^2VMe_2}$: To a solution of 2.7 g of $\mathbf{L^2}VCl_2$ (5 mmol) in 25 ml of diethyl ether, cooled to −80°C, was slowly added 6.28 ml of methyllithium in diethyl ether (1.6 M, 10 mmol). The stirred mixture was allowed to warm to room temperature and then refluxed for 1.5 h. The resulting solution was filtered through a fine frit and the solvent was removed in vacuo. Crystallization from hexane gave dark-brown crystals. Yield: 1.12 g, second crop 0.4 g, total yield: 1.52 g (61%).

$\boldsymbol{L^2V(nBu)_2}$*:* To a suspension of 1.0 g of $\mathbf{L^2}VCl_2$ (1.7 mmol) in 10 ml of toluene, cooled to −80°C, was slowly added 2.1 ml of a solution of *n*BuLi (1.6 M in hexane). The stirred mixture was allowed to warm to room temperature. The solvents were then removed in vacuo, and the product was extracted with a small amount of warm hexane. After leaving the resulting solution to stand for 1 week at −20°C, large, dark-brown crystals were deposited.

$\boldsymbol{L^2TiCl_2}$*:* A solution of 4.967 g of $\mathbf{L^2}$Li(THF) (20 mmol) and 3.7 g of $TiCl_3(THF)_3$ in 50 ml of THF was refluxed overnight. The colour of the reaction mixture changed from light green to dark green. The solvent was then removed in vacuo and 75 ml of toluene was added. The resulting solution was reduced in volume by 20 ml by distillation of toluene along with residual THF and/or hexane. A further 20 ml of fresh toluene was added and distilled off once more. The warm, deep-red/brown solution was filtered and the filtrate was concentrated, at reflux temperature, until crystals appeared. After storage overnight, deep-red/brown crystals were deposited. Yield: 2.85 g (53%).

$\boldsymbol{L^2TiMe_2}$*:* This was prepared in the same manner as $\mathbf{L^1}$TiMe2 (Grignard route). The residue after the reaction was sticky, and extraction with hexane was far from complete; from 1.0 g of $\mathbf{L^2}TiCl_2$, we obtained only 0.09 g (10%) of $\mathbf{L^2}TiMe_2$ as dark-blue needles from hexane.

$\boldsymbol{L^5VCl_2}$*:* Vanadium trichloride (1.57 g, 10 mmol) was refluxed for 2 h in 25 ml of THF to form $VCl_3(THF)_3$. A solution of 4.19 g (10 mmol) of $\mathbf{L^5}$H in 25 ml of hexane was cooled to −78°C. To this was added 6.25 ml (10 mmol) of 1.6 M *n*-butyllithium solution in hexane and the mixture was allowed to warm to room temperature. The reaction mixture slurry was stirred overnight and then a small amount of THF was added until a clear yellow solution was obtained. This yellow solution was added to the pink/red slurry of $VCl_3(THF)_3$ and the mixture was refluxed for 1 d. The solvent was then removed in vacuo and the residue was crystallized from toluene (30 ml) to afford dark-red crystals. Yield: 2.07 g (38%). − $C_{29}H_{41}Cl_2N_2V$ (539.50): calcd. C 64.56, H 7.66, Cl 13.14, N 5.19, V 9.44; found C 64.81, H 7.72, Cl 12.93, N 5.18, V 9.55.

$\boldsymbol{L^5TiCl_2}$*:* To a mixture of 5.66 g of $\mathbf{L^5}$H (13.5 mmol) in 30 ml of hexane was added 8.5 ml (13.5 mmol) of 1.6 M *n*BuLi in hexane. The reaction mixture was allowed to warm to room temperature and then stirred overnight. The initially clear yellow solution became a yellow slurry. To this, 5.0 g of $TiCl_3(THF)_3$ (13.5 mmol) and 30 ml of THF were added and the mixture was refluxed overnight. The solvent was then removed in vacuo and 75 ml of toluene was added. The resulting solution was reduced in volume by 10 ml by distillation of toluene along with residual THF and/or hexane. The warm, deep-red solution was filtered and the filtrate was concentrated, at reflux temperature, until crystals appeared. After storage overnight, deep-red crystals separated. Yield: 4.36 g (74%). − $C_{29}H_{41}Cl_2N_2Ti$ (536.46): calcd. C 64.93, H 7.70, Cl 13.22, N 5.22, Ti 8.93; found C 64.89, H 7.56, Cl 13.32, N 5.18, Ti 8.79.

$\boldsymbol{L^5TiMe_2}$*:* This was prepared in the same manner as $\mathbf{L^1}TiMe_2$ (MeLi route) but crystallized more easily and was typically obtained in 70% yield as dark-blue crystals.

Attempted Synthesis of $\boldsymbol{L^3TiMe_2}$*:* $\mathbf{L^3}TiCl_2$ was prepared in the same manner as $\mathbf{L^1}TiCl_2$. However, the compound did not crystallize well from toluene, and so an excess of hexane was added to the dark-brown toluene solution to precipitate the product as a brown-green powder. To a stirred suspension of 1.0 g (2.5 mmol) of crude $\mathbf{L^3}TiCl_2$ in 20 ml of diethyl ether, cooled to −10°C, was slowly added a cooled solution of 1.21 g (5.1 mmol) of $MeMgI(Et_2O)$ in 15 ml of diethyl ether. The solution turned deep-blue. After 1 min, 0.43 ml of 1,4-dioxane was added, the solvent was removed in vacuo, and the residue was extracted with two cold (−10°C) 15-ml portions of hexane. Evaporation of the solvent left a dark-blue solid, which upon hydrolysis produced variable amounts of methane (but always less than 2 equivalents based on $\mathbf{L^3}TiMe_2$). All attempts at purification or crystallization resulted in the disappearance of the blue color, indicating decomposition.

$\boldsymbol{L^4VCl_2(THF)_2}$*:* Vanadium trichloride (7.9 g, 50 mmol) was refluxed for 3 h in 100 ml of THF to form $VCl_3(THF)_3$. A slurry of 14.3 g (50 mmol) of $\mathbf{L^4}H \cdot HCl$ in 100 ml of THF was cooled to −78°C. To this was added 63 ml (100 mmol) of 1.6 M *n*-butyllithium in hexane, and the mixture was allowed to warm to room temperature. The resulting orange/yellow solution was added to the cooled, pink/red slurry of $VCl_3(THF)_3$. An immediate colour change to very dark green was observed and small crystals were formed. After leaving the mixture to stand overnight, the supernatant was decanted, the crystals were washed with 50 ml of THF, and dried in vacuo. Yield: 20.8 g (81%). − $C_{25}H_{33}N_2VO_2Cl_2$

(515.40): calcd. C 58.26, H 6.45, Cl 13.76, N 5.44, V 9.88; found C 57.93, H 6.23, Cl 14.01, N 5.60, V 10.10.

L^4VMe_2: To a slurry of 1.03 g (2 mmol) of **L^4**VCl2(THF)$_2$ in 30 ml of THF, cooled to −78°C, was added 2.5 ml (4 mmol) of 1.6 M methyllithium in diethyl ether. The reaction mixture was allowed to warm to room temperature, whereupon the colour changed from dark green/blue to dark red. The solvent was then removed in vacuo, and the product was redissolved in diethyl ether. Filtration of the resulting solution and evaporation of the solvent yielded the product as a solid foam. Because of its high solubility, we were unable to purify the product further; the number of methyl groups still present in the complex was determined by controlled hydrolysis. A 430-mg (1.3 mmol) portion of the solid foam was dissolved in the minimum volume of dichloromethane and the complex was deliberately decomposed with 1 ml of methanol. The volume of evolved gas was measured as 58 cm^3 (2.6 mmol).

$L^4TiCl_2(THF)_2$: To a solution of *n*BuLi (2.6 ml of a 1.6 M solution in hexane; 4.2 mmol) in 15 ml of THF, cooled to −40°C, was added 0.7 ml (4.8 mmol) of diisopropylamine. The resulting mixture was added to a solution of 1.0 g (4.0 mmol) of **L^4**H in 15 ml of THF and the solvent was removed in vacuo (50°C, 1 h). The residue was taken up in 10 ml of THF, and the resulting solution was slowly added to a suspension of 1.48 g (4.0 mmol) of $TiCl_3(THF)_3$ in 25 ml of THF. The mixture was heated to 50°C and after 10 min the solvent was removed in vacuo. The residue was quickly[23] extracted with two 25-ml portions of toluene. After the addition of 1 ml of THF to the combined extracts and leaving the solution to stand, brown crystals of **L^4**$TiCl_2(THF)_2$ were deposited (1.4 g, 70%). The product could be recrystallized from toluene/THF mixtures, but its solubility is low even in hot solvent mixtures.

L^4TiI_2: To a suspension of **L^4**$TiCl_2(THF)_2$ (0.5 g, 1 mmol) in 25 ml of benzene was added 0.78 g (0.56 mmol) of Me_3SiI. The mixture was stirred for 4 h at 70°C, during which it turned violet. The solvent was then removed in vacuo, the residue was washed with hexane, and crystallized from toluene/hexane to give red-purple crystals of **L^4**TiI_2 (0.43 g, 80%).

Polymerization Experiments: Under argon, a glass Büchi miniclave was charged with benzene (21 ml) followed by 41 mg of tris(pentafluorophenyl)borane (0.1 mmol) in 2 ml of benzene. The solvent was then saturated with propene and the dimethyltitanium compound (0.1 mmol) in 2 ml of benzene was introduced. The dark blue/green colour of the diminatodimethyltitanium compound immediately disappeared and a clear, red solution was formed. The propene pressure was maintained at 5−6 bar for 30 min. The propene pressure was then released and the solution was poured into 200 ml of methanol. The polymer produced was filtered off and dried in vacuo at 100°C.

X-ray Structure Determinations: All crystals were mounted in thin-walled glass capillaries under N_2 and held in place with silicone grease. Diffraction measurements were made with a Siemens P3m diffractometer fitted with an LT-1 crystal cooling device, using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). Unit cell dimensions were determined from carefully centered reflections in the range 15.0° < 2θ < 40.0°. Diffracted intensities were measured in a unique volume of reciprocal space for 4.0° < 2θ < 50.0° by Wyckoff ω scans. Three check reflections were measured again after every 100 ordinary data over the period of data collection in order to monitor and correct for crystal decay and long term intensity fluctuations. Duplicate and equivalent measurements were averaged and systematic absences were deleted. Absorption corrections were applied based on azimuthal scan data and Lorentz and polarization corrections were applied. The structures were solved by Patterson and Fourier methods. All non-hydrogen atoms were assigned anisotropic displacement parameters and all hydrogen atoms were given fixed isotropic displacement parameters and constrained to idealized geometries (C−H 0.96 Å, methyl H−C−H 109.5°). Full-matrix least-squares refinements were against F_o or F_o^2. Weights, *w*, were adjusted to minimize the variation in *S* as a function of F_o. Final difference electron density maps showed no

chemically significant features (with one exception noted below). All calculations were carried out using programs of the SHELXTL-PLUS and SHELXL-93 packages.[24] Complex neutral-atom scattering factors were used. Table 2 gives further details of the individual structure determinations. The γ and δ carbon atoms of one of the butyl chains of $\mathbf{L^2}V(n\mathrm{Bu})_2$ showed large thermal parameters, and significant electron density features were found close to these atoms. This clearly implies some kind of disorder in the chain, but no satisfactory multisite model was derived.

Crystallographic data (excluding structure factors) have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-101413. Copies of the data can be obtained free of charge on application to CCCD, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) + 44-1223/336033; E-mail: deposit@ccdc.cam.ac.uk].

[23] The crystalline product is rather insoluble, but we usually found that the crude product first dissolves and only starts to crystallize after a period of a few hours or days. If, for some reason, crystallization starts *before* extraction is complete, the best way to proceed is to extract the residue with a fairly large volume of hot toluene containing a few drops of THF.

Keywords: Alkyne complexes / Titanium / *ansa*-Metallocenes / Carbon dioxide fixation / C–C coupling / Metallacycles / Regioselectivity

The reaction of [*meso*-(ebthi)$TiCl_2$] [ebthi = 1,2-ethylene-1,1′-bis(η^5-tetrahydroindenyl)] with magnesium in the presence of the alkynes $Me_3SiC{\equiv}CSiMe_3$ and $PhC{\equiv}CSiMe_3$ resulted in the formation of the complexes [*meso*-(ebthi)Ti(η^2-$Me_3SiC_2SiMe_3$)] (**1**) and [*meso*-(ebthi)Ti(η^2-PhC_2SiMe_3)] (**2a** and **2b**), which were isolated and then characterized by their NMR spectra. Due to incomplete reduction the Ti^{III} complex [*meso*-(ebthi)Ti(THF)Cl] (**3**) was also obtained as a by-product of these reactions. By insertion into the Ti–CPh bond carbon dioxide reacted with the titanacyclopropene structure of the alkyne complex [*meso*-(ebthi)Ti(η^2-PhC_2SiMe_3)] (**2a**), with untypical regioselectivity to yield the α-silyl-substituted *meso*-(ebthi)titanafuranone **6a**. In the analogous reactions of the complexes [(thi)$_2$Ti(η^2-PhC_2SiMe_3)] (thi = η^5-tetrahydroindenyl), [*rac*-(ebthi)Ti(η^2-PhC_2SiMe_3)], and [$Cp^*{}_2$Ti(η^2-PhC_2SiMe_3)] with carbon dioxide typical regioselectivity (insertion into the M–CSi bond of the titanacyclopropene) was observed, yielding the β-silyl-substituted titanafuranones **7**, **8a**, and **9**. These results show that insertion of carbon dioxide into the M–C bond of the titanacyclopropene structure of the alkynemetallocene complexes is governed by the substitution pattern of the alkyne and the steric enviroment around the metal center. The complexes **3**, **6a**, and **7** were investigated by X-ray crystal structure analysis.

A large number of reviews concerning the cooordination chemistry, the stoichiometric reactions, and the catalytic activation of carbon dioxide have been published.[1] In this series of publications little has been reported concerning insertion reactions of carbon dioxide into the metallacyclopropene structure of alkynetitanocene and -zirconocene complexes, although the nature of the observed products shows a strong dependence on the different Cp substituents, the alkynes, and the metals used. To the best of our knowledge Scheme 1 summarizes all the different types of reaction products previously described.

The first results of this chemistry came from Vol′pin et al.[2] who trapped the benzyne complex [Cp_2Ti(η^2-*o*-C_6H_4)] during the thermal decomposition of Cp_2TiPh_2 by a reaction with CO_2 to give the titanabenzofuranone complex **I**. The titanafuranone **VI** as well as the dimeric carboxylate complex **XI** (not isolated or characterized) were said to be the result of the interaction of a solution of [CpCp*Ti(η^2-PhC_2CPh)] with CO_2.[3] Recently, we have shown that dimeric compounds such as **VIII** and **X** are the primary products in the reactions of alkynetitanocene complexes [Cp_2Ti(η^2-RC_2R)] (R = Ph, Me_3Si) with CO_2[4] and that only after subsequent interaction with oxygen the titanafuranone complexes **II** and **III**[4] are formed. In the first step a coupling of only half the amount of the alkynes with CO_2 occurs, and not the direct coupling of all the alkyne to metallafuranones. Other complexes of this type **IV** and **V** were also described.[5]

The chemoselectivity for coupling of the alkyne and CO_2, as well as the structures of the products obtained, depends strongly on the substituents of the Cp ligands and the alkynes. In the reaction of CO_2 with the permethyltitanocene complex [$Cp^*{}_2$Ti(η^2-$Me_3SiC_2SiMe_3$)] the alkyne is not coupled and the carbonate-bridged complex **XII**[6a][6b] was obtained. When [$Cp^*{}_2$Ti(Me)Ph] was thermolyzed in the presence of CO_2 the benzyne complex [$Cp^*{}_2$Ti(η^2-*o*-C_6H_4)] was trapped, and the complex **VII** formed.[6c] In the reaction of [Cp_2Ti(η^2-Me_3SiC_2tBu)] and CO_2[4d] the products obtained are another carbonate-bridged complex **XIII**, the carbon monoxide complex [$Cp_2Ti(CO)_2$], and the free alkyne.

In the reaction of the alkynezirconocene complex [Cp_2Zr(THF)(η^2-$Me_3SiC_2SiMe_3$)] with CO_2 only the zirconafuranone **XIV** was obtained, which has a dimeric structure.[7]

Whereas, e.g. for nickel(0) complexes with unsymmetrically substituted alkynes, the regioselectivity of the carbon dioxide coupling reaction was studied both theoretically[1r] and experimentally[1s][1t], fewer results have been reported on the regioselectivity of these reactions with titanocene

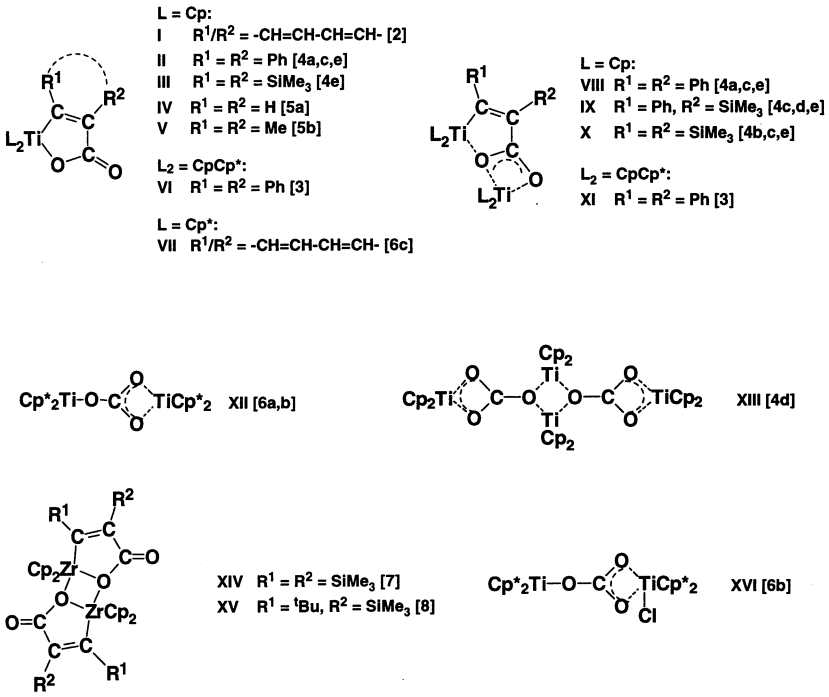
Scheme 1



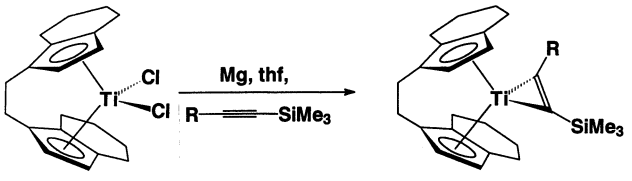
and zirconocene complexes. Using the unsymmetrically disubstituted alkynes $PhC{\equiv}CSiMe_3$ and $tBuC{\equiv}CSiMe_3$, an insertion of carbon dioxide at the silicon-substituted carbon atom is typical for titanocene as well as zirconocene, yielding the (vinylcarboxylato)titanium complex **IX**[4d] and the dimeric zirconocene compound **XV**,[8] respectively (see explanation below).

Here we report on a strategy to change the regioselectivity of the insertion of carbon dioxide into titanocene complexes, using $PhC{\equiv}CSiMe_3$, by the use of different ligand systems.

Results

Complex Syntheses

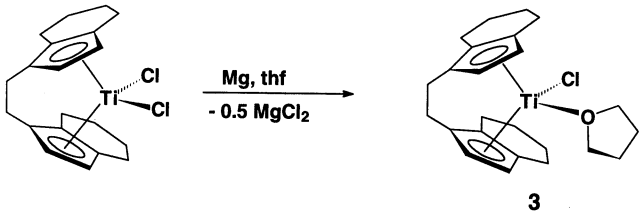
Starting Materials: The preparation of the complexes $[Cp_2Ti(\eta^2\text{-}PhC_2SiMe_3)]$,[4c][11] $[(thi)_2Ti(\eta^2\text{-}PhC_2SiMe_3)]$ (thi = tetrahydroindenyl),[12] and [*rac*-(ebthi)Ti(η^2-$Me_3SiC_2SiMe_3$)][13] has been described recently. In order to investigate the influence of the ligand system on the regiochemistry of insertion reactions we prepared the alkyne complexes [*meso*-(ebthi)Ti(η^2-$Me_3SiC_2SiMe_3$)] (**1**) and [*meso*-(ebthi)Ti(η^2-PhC_2SiMe_3)] (**2**) by the same procedure (Eq. 1).



1 R= SiMe3
2a R= Ph

As a consequence of the *meso*-ebthi ligand we obtained the complex **2** as a mixture (3:1) of the two diastereomeric products **2a** (major isomer) and **2b** (minor isomer), which could not be seperated by crystallization. The ratio in which the two diastereomers are formed can be explained if one considers the different steric requirements of the alkyne substituents. In the major isomer the bulky trimethylsilyl group could be located at the less hindered side of the molecule, while the flat phenyl group could be situated between the two saturated rings. This assumption was proven by ^{1}H-NOESY NMR investigations (see below).

One by-product in the reaction of [*meso*-(ebthi)$TiCl_2$] with magnesium in THF in the presence of $Me_3SiC{\equiv}CSiMe_3$ is the Ti^{III} complex **3**, as the result of an incomplete reduction (Eq. 2).



3

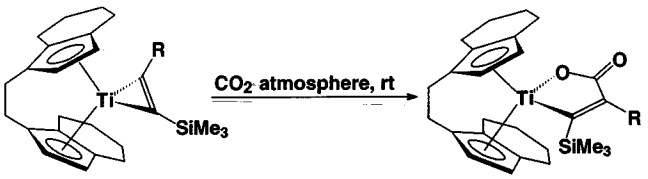
Regioselectivity: Three general questions must be kept in mind when determining the regioselectivity of the coupling of carbon dioxide with phenyl(trimethylsilyl)acetylene:

(i) What is the overall regioselectivity in the raw material (before the workup)?

(ii) Is the regioisomer identified by the X-ray crystal structure determination identical with the bulk product, as determined by NMR investigations?

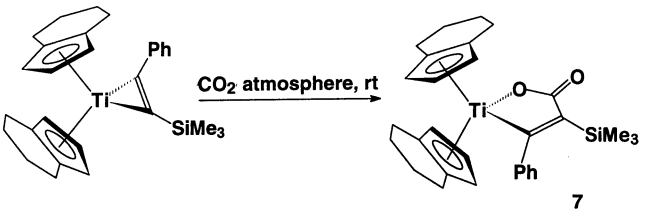
(iii) Is there any cycloreversion of one regioisomer leading to the "opposite" product?

Complex **1** with the symmetrically substituted bis(trimethylsilyl)acetylene reacts with CO_2 to give the titanafuranone **5**, where the bulky Me_3Si groups are located at the sterically less hindered side of the complex, while the CO_2 is situated between the two saturated rings, as verified by NOE experiments. For **2a** an unusual insertion reaction was observed at the phenyl-substituted carbon atom and the complex **6a** was isolated in a high yield of 87% (Eq. 3). No other isomers were detected by NMR investigation of the raw material. The structure of the unexpected product **6a,** with the Me_3Si group in α-position, was proven by NMR investigations (NOE experiments) and confirmed by an X-ray crystal structure analysis (see below).



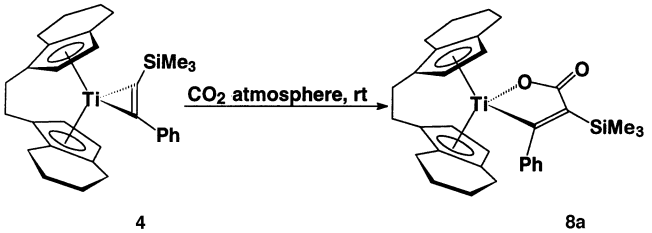
1 R = $SiMe_3$ **5 R = $SiMe_3$**
2a R = Ph **6a R = Ph**

The opposite regioselectivity was observed in the reaction of the corresponding alkyne complex [$(thi)_2Ti(\eta^2$-$PhC_2SiMe_3)$] with CO_2. The titanafuranone **7** was formed by insertion of CO_2 at the silicon-substituted carbon atom (Eq. 4). A by-product, detected by NMR and in a very low yield (5%), is presumed to be the titanafuranone resulting from CO_2 insertion at the Ti−CPh bond.



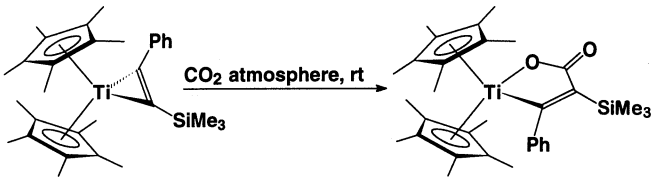
7

The opposite regioselectivity, compared to the reaction course from complex **2a** to **6a**, was also found in the reaction of the bridged alkyne complex [*rac*-(ebthi)Ti(η^2-Me_3SiC_2Ph)] **4** with carbon dioxide to yield the complex **8a** (Eq. 5).



4 **8a**

This regioselectivity is identical to that obtained in the reaction of the (alkyne)permethyltitanocene complex [$Cp^*_2Ti(\eta^2$-$Me_3SiC_2Ph)$][4c] with carbon dioxide, which gives the complex **9** as the sole product (Eq. 6).



9

NMR and Structural Investigations: The regio- and stereochemistry of the reactions were investigated by ^{1}H- and ^{13}C-NMR methods. The ^{1}H-NOESY spectra of the isomer **2a** feature NOE cross peaks from the CH protons of ebthi (^{1}H: δ = 4.88, d, ^3J = 3.0 Hz, 2 H, CH ebthi; δ = 7.28, d, ^3J = 3.0 Hz, 2 H, CH ebthi) to the trimethylsilyl group. This clearly indicates that the Me_3Si group is located at the sterically less hindered side of the complex. For the minor isomer **2b** the analogous NOE signals could not be observed. Similarly, a strong NOE is found at the cyclopentadienyl doublets for titanafuranone **6a** upon irradiation of the $SiMe_3$ protons, proving a close proximity, and hence silyl substitution, at C_α relative to Ti.

The position of the silyl group at the metallafuranone (α or β) can also be determined from proton-coupled ^{13}C-NMR spectra, where characteristic and clearly distinguishable patterns occur for the trimethylsilyl- and phenyl-substituted carbon atoms. The C_α signal appears at very low field (δ > 230); the C_β and the carbonyl signals are found at δ ≈ 160 (see Experimental Section). Surprisingly, there is no clear influence of the substituents on the chemical shifts, and the C_α signal of the product with the "opposite" regiochemistry (**6a**) exhibits a very similar shift compared to that of the other titanafuranones (**6a**: C_α-$SiMe_3$: δ = 237.4; **7**: C_α-Ph: δ = 239.2; **8a**: C_α-Ph: δ = 236.2), and the same observation is made for the shifts of C_β. This is not understood because Me_3Si groups very often give a more extended low-field shift for signals of C atoms in the β position to the silicon atom (see also complex **5**: C_α: δ = 264.9).[8] Complex **3** was investigated by X-ray crystal-structure analysis (see Figure 1). To clarify the regioselectivity and to understand it from the perspective of the structures of the products obtained, the complexes **6a** and **7** were investigated by X-ray crystal-structure analysis (see Figures 2 and 3).

Discussion

Preparation of Starting Complexes

The complex [*rac*-(ebthi)Ti(η^2-$Me_3SiC_2SiMe_3$)] was recently prepared in high yield by the reduction of [*rac*-(ebthi)$TiCl_2$] with magnesium in THF at room temp. in the presence of bis(trimethylsilyl)acetylene.[13] Using the same procedure to prepare [*meso*-(ebthi)Ti(η^2-$Me_3SiC_2SiMe_3$)] (**1**), the titanium(III) complex **3** is obtained as a by-product. The incomplete reduction seems to be the consequence of

the steric situation in the *meso*-ebthi isomer, where the ligand shields one face of the molecule. Detailed investigations concerning the reduction of $[Cp_2TiCl_2]$ by magnesium in THF without the alkyne had shown the chlorine-bridged $Ti-(\mu\text{-}Cl)_2-Mg$ species to be formed in one of the first steps of the reactions.[14] It seems reasonable to assume that steric reasons influence the reaction pathway and lead to the formation of Ti^{III} complexes such as **3**. A similar complex $[Cp^*_2Ti(THF)Cl]$ was also indicated as a by-product during the preparation of $[Cp^*_2Ti(\eta^2\text{-}Me_3SiC_2SiMe_3)]$. The reaction of the mother liquor with CO_2 gave not only **XII** but also **XVI** (see Scheme 1), apparently formed due to the presence of incompletely reduced Ti^{III} complex in the solution.[6b] Interestingly, **3** is a monomer and coordinates a THF ligand. In a series of well-known complexes $[(C_5H_{5-n}Me_n)TiX]$ (n = 0, 1, 3−5; X = Cl, Br, I) it was shown that an increase in n in the range n = 3−5 is connected with an increasing tendency to monomerize and to coordinate THF. This was explained primarily by considering the electron-donating properties of the Me groups.[15] Additionally, in **3** the threefold substituted Cp ligand is fixed in such a position that a dimerization seems to be unfavourable. The complexes with an unsymmetrically substituted alkyne, $[$*meso*-(ebthi)$Ti(\eta^2\text{-}PhSiC_2SiMe_3)]$ (**2**), and the corresponding racemic compound **4** were prepared by the same procedure.

Regioselectivity

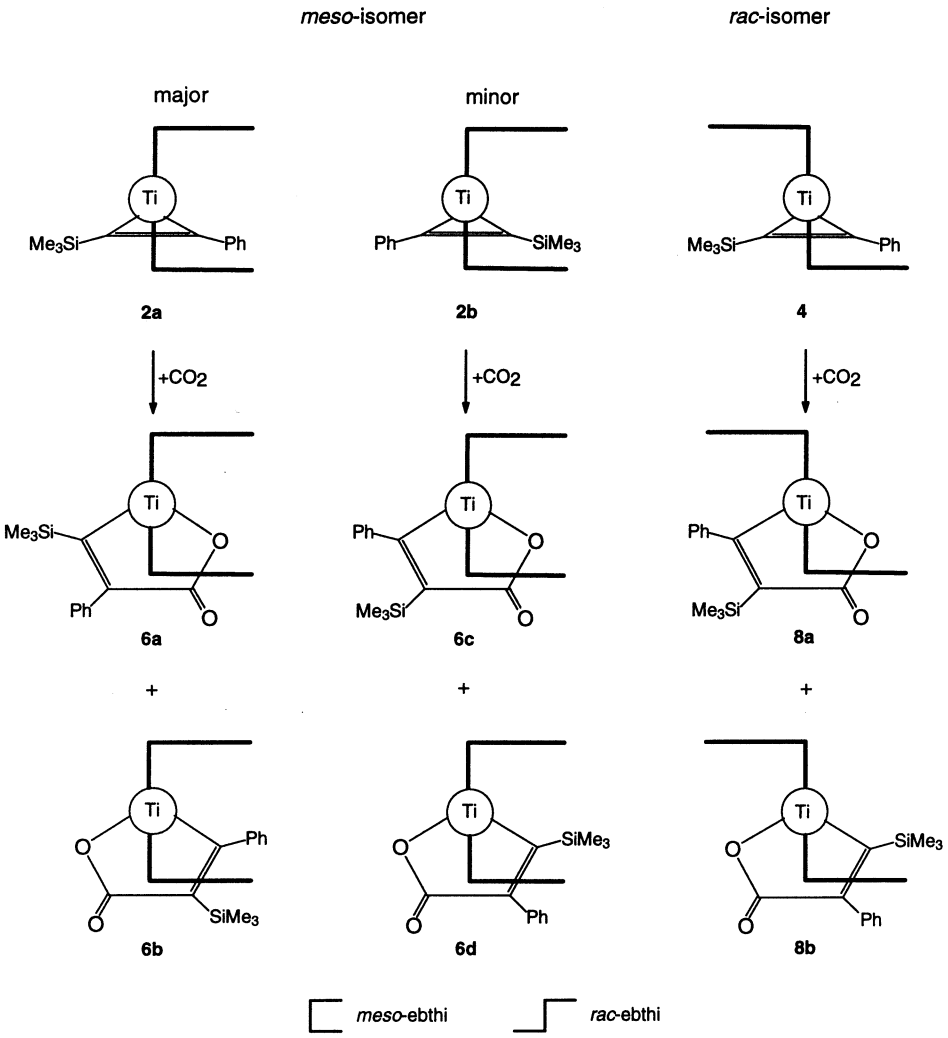
All titanocene and zirconocene complexes with unsymmetrically disubstituted alkynes of the type $[Cp_2Ti(\eta^2\text{-}RC_2SiMe_3)]$ or $[Cp_2Zr(thf)(\eta^2\text{-}RC_2SiMe_3)]$ are characterized by longer M−CSi than M−CR distances.[4d][8] This is explained electronically by assuming a (d-p)-π interaction of silyl groups, which reduces the electron density from the alkyne resulting in a positive charge on the CR group and a shorter M−CR bond, or by steric reasons resulting from the bulky $SiMe_3$ groups. The result of these effects is a kinetically favored reaction at the M−CSi bond to give the β-silyl-substituted metallacycles. In some cases a subsequent cycloreversion in solution to the thermodynamically more stable α-silyl product[4d][8] was observed.

The regioselectivity of the CO_2 insertion, influenced by the alkyne substituents, is characterized by insertions into the M−CSi bond (e.g as found. in **IX** and **XV**). For these complexes no cycloreversion could be observed. In this respect, the regioselectivity found in **6a** is unexpected and opposite: insertion into the M−CPh bond.

Regarding the stereochemical possibilities for the CO_2 insertion into the metallacyclopropene structure of the diastereomers **2a** and **2b,** in total four reaction products were expected, as indicated in Scheme 2.

For the major complex **2a** the attack of CO_2 occurs at the M−C−Ph bond to give the complex **6a**, and the other regioisomer, **6b,** was not found. There are three different explanations for the observed regioselectivity shown by the product obtained:

Scheme 2



(i) In the starting complex [*meso*-(ebthi)Ti(η^2-PhC_2SiMe_3)] the larger $SiMe_3$ groups are preferentially located at the nonsubstituted sides of the Cp′s, whereas the flat phenyl groups are between the cyclohexanediyl substituents (a similar situation is verified in complex **3** with the smaller chlorine atom and larger THF molecule). The insertion of CO_2 occurs in the M−CPh bond in order to minimize the steric restrictions between the saturated ring units and the phenyl group.

(ii) The Me_3Si group comes into the α position to the metal center which is in many metallacycles thermodynamically favoured (after cycloreversion) as shown by a number of coupling reactions of silylalkynes.[4d][8]

(iii) It seems possible that in the starting complex **2a** the M−CPh distances become nearly identical or longer, compared to the M−CSi bonds, due to the steric interactions of the phenyl groups and the cyclohexanediyl substituents. This could be the reason for the other regioselectivity, since all Cp complexes show longer M−CSi than M−CPh bonds.

Complex **2b** seems to form two insertion products, **6c** and **6d**. This is surprising because the steric repulsion between the bulky Me_3Si group and the tetramethylene unit should lead to a uniform reaction and only one product (**6c**). So far the separation and unambiguous characterization of the insertion products formed has failed and a stereochemical statement is not possible.

Compared to this "unusual" regioselectivity, the "normal" insertion of carbon dioxide into the complexes [$(thi)_2$Ti(η^2-PhC_2SiMe_3)], [*rac*-(ebthi)Ti(η^2-Me_3SiC_2Ph)], and [Cp^*_2Ti(η^2-Me_3SiC_2Ph)] follows the rules discussed above, with insertions at the M−CSi bond to the β-silyl-substituted metallacycles.

The reaction product **9** of the (alkyne)permethyltitanocene complex [Cp^*_2Ti(η^2-Me_3SiC_2Ph)] with carbon dioxide, differs from the dinuclear complex **IX**[4c][4d][4e] (Scheme 1) which was observed in the reaction of the corresponding titanocene complex [Cp_2Ti(η^2-Me_3SiC_2Ph)] with carbon dioxide. Interestingly, in the reaction of the corresponding permethylzirconocene complex [Cp^*_2Zr(η^2-Me_3SiC_2Ph)][16] with carbon dioxide a 1:1 mixture of the two possible regioisomers was obtained.[17]

Conclusion

The regioselectivity of the carbon dioxide insertion into titanocene complexes with unsymmetrically disubstituted alkynes of the type [$L_2Ti(\eta^2$-PhC_2SiMe_3)] is influenced by the nature of the ligands L used. With L_2 = Cp_2, Cp^*_2, thi_2 or *rac*-ebthi the "normal" reaction at the M−CSi bond to give the β-silyl-substituted titanafuranones was observed. With L_2 = *meso*-ebthi the opposite regioselectivity gives, after insertion into the M−CPh bond, the α-silyl-substituted titanacycle.

In all reactions investigated, the regioselectivity identified by X-ray crystal structure determination is consistent with the results of NMR investigations. In most reactions only one regioisomer was obtained. There are no hints of any cycloreversion leading to the "opposite" regioisomeric titanafuranone, as e.g. found in corresponding metallacyclic compounds.[4d][8]

Steric interactions seem to be the reason for the different regioselectivity and, after these considerations, the fixation of the tetrahydroindenyl units in a certain position by the *ansa* bridge is the most important feature in understanding the unusual regioselectivity for carbon dioxide insertion.

Experimental Section

General Remarks: All operations were carried out under argon with standard Schlenk techniques. Prior to use, solvents were freshly distilled from sodium tetraethylaluminate under argon. Deuterated solvents were treated with sodium or sodium tetraethylaluminate, distilled and stored under argon. − NMR: Bruker ARX 400 at 9.4 T (chemical shifts given in ppm relative to TMS; the signals of the aliphatic ebthi protons have not been analyzed). − Melting points: Sealed capillaries with a Büchi 535 apparatus. − Elemental analyses: Leco CHNS-932 elemental analyzer.

Preparation of [meso-(ebthi)Ti(η^2-$Me_3SiC_2SiMe_3$)] (**1**): 0.03 g (1.5 mmol) of magnesium cuttings and 0.34 ml (1.5 mmol) of bis(trimethylsilyl)acetylene were added to a suspension of 0.53 g (1.4 mmol) of [*meso*-(ebthi)$TiCl_2$] in 15 ml of THF. The mixture was stirred at 45°C until the color changed from red to black/brown. After that, the solution was stirred at room temp. for 2 h, the solvent removed in vacuo and the brown solid residue dissolved in 15 ml of *n*-hexane. After filtration and repeated removal of the solvent, brown/yellow needles of **1** crystallized from the oil at −78°C. The crystals were collected by filtration after washing with *n*-hexane at −78°C. Yield: 0.42 g (62%); m.p. 142−145°C. − ^{1}H NMR ([D_6]benzene): δ = −0.20 (s, 9 H, $SiMe_3$), 0.09 (s, 9 H, $SiMe_3$), 4.32 (d, ^3J = 3.0 Hz, 2 H, CH ebthi), 7.83 (d, ^3J = 3.0 Hz, 2 H, CH ebthi). − ^{13}C NMR ([D_6]benzene): δ = 1.1, 4.4 ($SiMe_3$), 23.5, 23.6, 24.4, 26.3, 26.7 (CH_2 ebthi), 113.8, 114.3 (CH ebthi), 122.7, 126.0, 129.0 (C ebthi), 242.1, 254.3 (C alkyne). − $C_{28}H_{42}Si_2Ti$ (482.7): calcd. C 69.67, H 8.77; found C 68.69, H 8.56. − IR (Nujol): $\tilde{\nu}$ = 1589 cm^{-1}.

Preparation of the Complexes [meso-(ebthi)Ti(η^2-Me_3SiC_2Ph)] (**2a** and **2b**): As described above for **1**, 0.37 g (0.96 mmol) of [*meso*-(ebthi)$TiCl_2$], 24 mg (1.0 mmol) of magnesium cuttings, and 0.20 ml (1.0 mmol) of phenyl(trimethylsilyl)acetylene yielded the red/brown alkynemetallocene complexes **2a** and **2b**, as indicated by both NMR and IR. The product was isolated in the same manner as described for **1**, but only a red brown oil was obtained which was a mixture (3:1) of the diastereomeric products **2a** (major) and **2b** (minor). Yield: 0.21 g of **2a** and **2b** (45%). − ^{1}H NMR ([D_6]benzene) of major isomer **2a**: δ = −0.02 (s, 9 H, $SiMe_3$), 4.88 (d, ^3J = 3.0 Hz, 2 H, CH ebthi), 6.6−7.5 (m, 5 H, Ph), 7.29 (d, ^3J = 3.0 Hz, 2 H, CH ebthi). − ^{1}H NMR ([D_6]benzene) of minor isomer **2b**: δ = 0.19 (s, 9 H, $SiMe_3$), 4.38 (d, ^3J = 3.0 Hz, 2 H, CH ebthi), 6.6−7.5 (m, 5 H, Ph), 7.44 (d, ^3J = 3.0 Hz, 2 H, CH ebthi). − ^{13}C NMR ([D_6]benzene) of major isomer **2a**: δ = 0.6 ($SiMe_3$), 23.4, 23.4, 23.7, 25.5, 27.3 (CH_2 ebthi), 112.1, 114.5 (CH ebthi), 122.5, 123.5, 125.2 (C ebthi), 127.6, 131.2 (CH Ph, *para* not found), 139.7 (C Ph), 220.1, 224.9 C(alkyne). − ^{13}C NMR([D_6]benzene) of minor isomer **2b**: δ = 3.9 ($SiMe_3$), 23.4, 23.8, 24.3, 25.9, 27.2 (CH_2 ebthi), 112.5, 113.2 (CH ebthi), 145.7 (C Ph, further ebthi and Ph signals not unambiguously identified), 210.3, 227.9 C(alkyne). − $C_{31}H_{38}SiTi$ (486.6): calcd. C 76.52, H 7.87; found C 76.04; H 7.72.

Preparation of [meso-(ebthi)Ti(THF)Cl] (**3**): The method used was as described above for **1** {starting with 0.31 g of [*meso*-(ebthi)$TiCl_2$]} but after the reaction a second extraction of the brown solid with 20 ml of THF yielded a dark blue solution, which was reduced to ca. 5 ml and stored at −30°C. After 72 h at −30°C, blue crystals (57 mg, 17%) formed, which were washed with cold *n*-hexane and isolated by filtration. M.p. decomposition, loss of THF in vacuo. − $C_{24}H_{32}ClOTi$ (419.9): calcd.C 68.66, H 7.68; found: C 68.02; H 7.63.

Preparation of [rac-(ebthi)Ti(η^2-Me_3SiC_2Ph)] (**4**): The method used was as described above for **1**. 0.32 g (0.84 mmol) of [*rac*-(ebthi)$TiCl_2$], 21 mg (0.86 mmol) of magnesium cuttings, and 0.17 ml (0.86 mmol) of phenyl(trimethylsilyl)acetylene yielded the alkynemetallocene complex **4**, which was isolated as a black oil. After standing for one week, the oil solidified as black crystals (0.29 g, 90%), which were washed with cold *n*-hexane (−30°C) to obtain analytical pure material, m.p. 156°C. − ^{1}H NMR ([D_6]benzene): δ = 0.15 (s, 9 H, $SiMe_3$), 4.23 (d, ^3J = 3.0 Hz, 1 H, CH ebthi), 4.54 (d, ^3J = 3.2 Hz, 1 H, CH ebthi), 6.66 (2 H, Ph *ortho*), 6.92 (1 H, Ph *para*), 7.07 (2 H, Ph *meta*), 8.10 (d, ^3J = 3.2 Hz, 1 H, CH ebthi), 8.50 (d, J = 3.0 Hz, 1 H, CH ebthi). − ^{13}C NMR ([D_6]benzene): δ = 2.1 ($SiMe_3$), 22.9, 23.2, 23.4, 23.7, 23.7, 23.9, 25.3, 25.3, 26.5, 26.6 (CH_2 ebthi), 111.7, 112.8, 113.8, 114.0 (CH ebthi), 128.0, 130.2 (CH Ph, *para* not found), 124.6, 124.8, 124.8, 126.0, 126.1, 127.5 (C ebthi), 141.2 (C Ph), 213.8, 220.8 C(alkyne). − $C_{31}H_{38}SiTi$ (486.6): calcd. C 76.52, H 7.87; found C 75.97, H 7.81. − IR (Nujol): $\tilde{\nu}$ = 1638 cm^{-1}.

Preparation of **5**: 0.48 g (1.0 mmol) of [*meso*-(ebthi)Ti(η^2-$Me_3SiC_2SiMe_3$)] was dissolved in a mixture of THF/*n*-hexane (3:1) (ca. 10 ml) which was exposed to CO_2. The color of the solution changed from red/brown to orange. After standing 24 h at −78°C, 0.37g (0.70 mmol, 70%) of red needles of complex **5** precipitated from the solution; m.p. > 240°C. − ^{1}H NMR ([D_8]THF): δ = 0.05 (s, 9 H, α-$SiMe_3$), 0.17 (s, 9 H, β-$SiMe_3$), 5.83 (d, ^3J = 3.1 Hz, 2 H, CH ebthi), 6.54 (d, ^3J = 3.1 Hz, 2 H, CH ebthi). − ^{13}C NMR ([D_8]THF): δ = 3.0, 3.6 ($SiMe_3$), 22.1, 22.9, 23.6, 24.7, 29.3 (CH_2 ebthi), 113.0, 115.3 (CH ebthi), 129.9, 132.5, 133.8 (C ebthi), 161.5, 171.7 (C_β titanacycle), 264.9 (C_α titanacycle). − $C_{29}H_{42}O_2Si_2Ti$ (526.7): calcd. C 66.13, H 8.03. found C 66.32, H 7.98. − IR (Nujol): $\tilde{\nu}$ = 1610 cm^{-1}.

Preparation of **6a**: 200 mg (0.41 mmol) of [*meso*-(ebthi)Ti(η^2-Me_3SiC_2Ph)] was dissolved in 10 ml of a mixture of THF/*n*-hexane (3:1) which was exposed to CO_2. The color of the solution changed from red/brown to orange. After standing 36 h at −30°C, light red crystals of **6a** crystallized from the solution which were then isolated by filtration to yield 137 mg (63%); m.p. >240°C. − ^{1}H NMR ([D_8]THF): δ = −0.25 (s, 9 H, $SiMe_3$), 5.86 (d, ^3J = 3.0 Hz, 2 H,

CH ebthi), 6.66 (d, ^3J = 3.0 Hz, 2 H, CH ebthi), 7.08 (2 H, Ph *ortho*), 7.15 (3 H, Ph *meta*/*para*). − ^{13}C NMR ([D$_8$]THF): δ = 2.4 ($SiMe_3$), 22.1, 22.8, 23.8, 24.6, 29.4 (CH_2 ebthi), 112.8, 115.7 (CH ebthi), 130.0, 132.3, 133.4 (C ebthi), 126.5 (*p*-Ph), 127.3, 130.5 (CH Ph), 144.4 (*i*-Ph), 158.1 (*C*-Ph), 162.6 (CO), 237.4 (*C*-$SiMe_3$). − $C_{32}H_{38}O_2TiSi$ (530.62): calcd. C 72.43, H 7.22. found C 71.95, H 7.29. − IR (Nujol): $\tilde{\nu}$ = 1240 cm^{-1}.

Preparation of **7**: 200 mg (0.43 mmol) of [(thi)$_2$Ti(η^2-Me_3Si-C_2Ph)][12] was dissolved in 5 ml of a mixture of THF/*n*-hexane (3:1) which was exposed to CO_2. The color of the solution changed from dark red to orange. After standing 24 h at 0°C, light red crystals crystallized from the solution. Filtration yielded 188 mg of **7** (87%); m.p. 185°C. − ^{1}H NMR ([D$_8$]THF): δ = −0.16 (s, 9 H, $SiMe_3$), 1.58 (m, 4 H, thi), 1.74 (m, 2 H, thi), 1.88 (m, 2 H, thi), 1.98 (ddd, ^2J = 16 Hz, ^3J = 5 and 7 Hz, 2 H, α-CH_2 thi), 2.47 (dt, ^2J = 16 Hz, ^3J = 6 Hz, 2 H, α-CH_2 thi), 2.77 (dt, ^2J = 17 Hz, ^3J = 6 Hz, 2 H, α-CH_2 thi), 2.92 (dt, ^2J = 17 Hz, ^3J = 6 Hz, 2 H, α-CH_2 thi), 5.20 (t, J = 3 Hz, 2 H, β-CH thi), 6.44 (dd, J = 2 and 3 Hz, 2 H, α-CH thi), 6.57 (dd, J = 2 and 3 Hz, 2 H, α-CH thi), 6.92 (2 H, Ph *ortho*), 6.97 (1 H, Ph *para*), 7.16 (2 H; Ph *meta*). − ^{13}C NMR ([D$_8$]THF): δ = 1.0 ($SiMe_3$) 22.8, 22.8, 25.3, 25.4 (CH_2 thi), 110.2, 111.8, 119.9 (CH thi), 124.9 (*o*-Ph), 125.5 (*p*-Ph), 128.2 (*m*-Ph), 131.4, 134.7 (C thi), 150.5 (*i*-Ph) 155.5 (*C*-$SiMe_3$), 164.8 (CO), 239.2 (*C*-Ph). − MS (70eV); *m*/*z* (%): 504.6 [M$^+$], 286 [(thi)$_2$Ti$^+$]. $C_{30}H_{36}O_2SiTi$ (504.6): calcd. C 71.41, H 7.19; found C 71.45, H 7.04.

Preparation of **8a**: As described above for **6a**, 143 mg [*rac*-(ebthi)$_2$Ti(η^2-Me_3SiC_2Ph)] yielded, after exposure to CO_2 and recrystallization from THF/*n*-hexane (1:1) (ca. 3 ml), 112 mg (72%) of **8a** as orange needles, m.p. 268°C (decomposition). − ^{1}H NMR ([D$_8$]THF) δ = −0.10 (s, 9 H, $SiMe_3$), 5.35 (d, ^3J = 2.8 Hz, 1 H, CH ebthi), 5.57 (d, ^3J = 3.2 Hz, 1 H, CH ebthi), 6.40 (d, ^3J = 3.2 Hz, 1 H, CH ebthi), 6.89 (2 H, Ph *ortho*), 7.07 (1 H, Ph *para*), 7.18 (2 H, Ph *meta*), 7.55 (d, ^3J = 2.8 Hz, 1 H, CH ebthi). − ^{13}C NMR ([D$_8$]THF): δ = 1.8 ($SiMe_3$), 21.6, 22.2, 22.3, 22.7, 23.9, 24.3, 24.3, 24.6, 28.7, 28.9 (CH_2 ebthi), 111.4, 114.7, 117.0, 123.3 (CH ebthi), 126.1, 129.7, 133.0, 133.8, 134.6, 136.2 (C ebthi), 126.9 (*p*-Ph), 127.9, 128.2 (CH Ph), 147.7 (*i*-Ph), 156.4 (*C*−$SiMe_3$), 164.6 (CO), 236.2 (*C*−Ph). − $C_{32}H_{38}O_2TiSi$ (530.62): calcd. C: 72.43, H: 7.22; found C: 72.04, H: 7.04.

Preparation of **9**: 344 mg (0.70 mmol) of [Cp*$_2$Ti(η^2-Me_3Si-C_2Ph)][4c] was dissolved in 15 ml of *n*-hexane under argon and the resulting solution filtered. Argon was then carefully removed in vacuo, and the flask with the solution filled with CO_2 at 20°C. After standing 24 h at 20°C, dark red crystals had formed, which were filtered, washed with cold *n*-hexane and dried in vacuo. Yield 266 mg of **9** (71%); m.p. 173−174°C. − ^{1}H NMR ([D$_8$]THF): δ = 0.01 (s, 9 H, $SiMe_3$), 1.86 (s, 30 H, C_5Me_5), 6.58 (m, 2 H, *o*-Ph), 7.04 (m, 1 H, *p*-Ph), 7.15 (m, 2 H, *m*-Ph). − ^{13}C NMR ([D$_8$]THF): δ = 2.0 ($SiMe_3$), 12.3 ($C_5\mathit{Me}_5$), 126.9 (C_5Me_5), 126.6 (*p*-Ph), 127.8 (*m*-Ph), 129.8 (*o*-Ph), 146.5 (*i*-Ph), 154.7 (*C*−$SiMe_3$), 166.1 (CO), 244.1 (*C*−Ph). − IR (Nujol): $\tilde{\nu}$ = 1620 (CO), 1237 ($SiMe_3$) cm^{-1}. − MS (70eV); *m*/*z* (%): 537 [M$^+$]. − $C_{32}H_{44}O_2SiTi$ (536.7): calcd. C 71.62, H 8.62; found C 71.76, H 8.63.

X-ray Crystallographic Study of Complexes **3**, **6a**, *and* **7**: Data were collected with a STOE-IPDS diffractometer using graphite-monochromated Mo-K_α radiation. The structures were solved by direct methods (SHELXS-86)[9] and refined by full-matrix least-squares techniques against F^2 (SHELXL-93)[10]. The hydrogen atoms were included at calculated positions. All other nonhydrogen atoms were refined anisotropically. Cell constants and other experimental details were collected and are recorded in Table 1. XP (SIEMENS Analytical X-ray Instruments, Inc.) was used for structure representations. Further details of the crystal-structure investigations are available on request from the Cambridge Crystallographic Data Centre, on quoting the depository number CCDC-101470.

Keywords: Pyrazolato ligands / Rhenium / Carbonylmetal complexes / Crystal structure / Hydrogen bonds

The mononuclear complexes $[Re(CO)_3(Hpz)_2Br]$ (**1**) and $[Re(CO)_3(Hdmpz)_2Br]$ (**2**) were obtained by treating $[Re(CO)_5Br]$ with pyrazole (Hpz) or 3,5-dimethylpyrazole (Hdmpz). Complex **1** reacted with triethylamine affording a mixture of the ionic dinuclear derivative $(Et_3NH)[Re_2(CO)_6(pz)_2Br]$ (**3**) and of the mononuclear species $[Re(CO)_3(Hpz)_2(pz)]$ (**4**). Complex **4** was obtained in a pure form by carrying out the reaction in the presence of excess free pyrazole. Treatment of **4** with pyridine afforded the $[Re(CO)_3(py)(Hpz)(pz)]$ species (**6**). The analogues of **4** and **6** with Hdmpz, i.e. $[Re(CO)_3(Hdmpz)_2(dmpz)]$ (**7**) and $[Re(CO)_3(py)(Hdmpz)(dmpz)]$ (**8**) were also synthesized. All species were characterized in solution by ^{1}H-NMR spectroscopy, while the crystal structures of complexes **1**, **3**, **4** and **6** were determined by single-crystal X-ray diffraction analysis. The $[(CO)_3Re(\mu\text{-}pz)_2(\mu\text{-}Br)Re(CO)_3]^-$ anion represents the first structurally characterized species containing rhenium(I) atoms bridged by μ-pyrazolate ligands.

Introduction

The rapid development of the coordination and organometallic chemistry of the pyrazolate anion and its derivatives has been witnessed in recent years[1]. Thanks to the possibility of modifying the steric and electronic properties of the pyrazole ligand by the action of the substituents of the heterocyclic ring, pyrazolates, which possess two adjacent nucleophilic sites, give rise to a versatile and varied chemistry. For example, it is well known that pyrazolates (i) can act as monodentate, *exo*- or even *endo*-bidentate anionic ligands[1], (ii) can afford, for the same stoichiometry, oligomers of different nuclearities (and polymers) depending on the synthetic methods used[2] and (iii) have been shown to possess a rather wide conformational variability,[2c][3] despite possessing a stiff heterocyclic ring.

In the recent past we have been active in the field of metal pyrazolates and have reported extensively on copper, silver and palladium species, demonstrating the structural versatility caused by the pyrazolate ligand and the catalytic activity of some of its complexes[2c][4]. Our continual interest in evaluating the coordination properties of this class of ligands led us to explore the synthesis and reactivity of rhenium(I) pyrazolate derivatives, a field so far scarcely investigated.

The easily accessible mononuclear carbonylrhenium(I) complex $[Re(CO)_5Br]$ was found to be an excellent starting material for the synthesis of pyrazole- and pyrazolatorhenium(I) derivatives. In this paper we report the synthesis, spectroscopic and structural characterization of a series of rhenium(I) species derived by direct reaction of $[Re(CO)_5Br]$ with pyrazole (Hpz) and 3,5-dimethylpyrazole (Hdmpz).

Results and Discussion

The reaction of $[Re(CO)_5Br]$ with pyrazole in toluene at 80°C afforded quantitatively a white product, revealed by analysis as $[Re(CO)_3(Hpz)_2Br]$ (**1**), produced by the substitution of two carbonyl groups with two pyrazole molecules (eq. 1).

$$[Re(CO)_5Br] + 2\ Hpz \rightarrow [Re(CO)_3(Hpz)_2Br]\ (\mathbf{1}) + 2\ CO \qquad (1)$$

The IR spectrum of **1**, recorded in toluene, shows three strong $\tilde{\nu}$(CO) bands at 2031, 1929 and 1897 cm^{-1} typical for a *fac* structure [the spectrum of the alternative *mer* geometry would show two strong and one weak $\tilde{\nu}$(CO) bands][5]. Evidence for a similar geometry, the most plausible taking in account the *trans* effect of the carbonyl groups, was also found in earlier substitution studies on $[Re(CO)_5Br]$ with nitrogen[6] or phosphorous[7] ligands. An X-ray crystal-structure determination provided an unambiguous confirmation of the assigned geometry (see later).

It is noteworthy that the monosubstituted product, i.e. $[Re(CO)_4(Hpz)Br]$, could not be isolated (even by carrying out the reaction with a Hpz/Re ratio < 2 and employing a decarbonylating agent such as Me_3NO), nor did the IR spectra of the reaction mixture show any indication of a spectroscopically detectable monosubstituted intermediate. On the contrary, in earlier studies on the substitution of CO with PPh_3 in $[Re(CO)_5Br]$, the intermediate formation of

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1434−1948/98/1010−1503 $ 17.50+.50/0

monosubstitution derivatives was proved by means of IR spectroscopy[7a].

The ^{1}H-NMR spectrum of **1** recorded in CD_2Cl_2 at 20°C shows three sharp signals at δ = 6.29 [C(4)−*H*], 7.53 [C(3)−*H*] and 7.66 [C(5)−*H*][8], and a broader signal at δ = 11.7 assignable to N−*H* protons. The presence of only one set of signals for each pyrazole hydrogen atom reveals the equivalence of the two pyrazole molecules coordinated to the rhenium centre. The scrambling process which equalizes the 3 and 5 sites, frequently found in complexes containing anionic *mono*dentate pyrazolate ligands[9], is in this case absent. Indeed, in complexes containing neutral pyrazoles, the interchange of the nitrogen sites requires simultaneous proton transfer and metal hopping, and is, therefore, expected to be more difficult. Accordingly, the dynamic behaviour observed for [Ir(CO)(PPh$_3$)(dmpz)] disappears upon protonation to the corresponding Hdmpz derivative[9a]. The NMR characterization of various pyrazole complexes revealed both static[10] and dynamic[11] behaviour. On lowering the temperature to −80°C, all signals split as a result of the coupling C(3)−*H*/C(4)−*H*, C(5)−*H*/C(4)−*H* and of N−*H* with the three heterocyclic C−*H* protons, leading to a very complex spectrum because of partial overlapping of the signals. N−*H* irradiation allows a simplification of the ^{1}H-NMR spectrum of **1** to three resonances, a doublet [δ = 7.65, $J_{5,4}$ = 2.2 Hz, C(5)−*H*], a second doublet [δ = 7.53, $J_{3,4}$ = 1.8 Hz, C(3)−*H*] and a pseudotriplet centred at δ = 6.29 [C(4)−*H*]. Similar features were previously reported for the pyrazoleplatinum(II) derivative [(C$_6$Cl$_5$)$_2$Pt(Hpz)$_2$][10a].

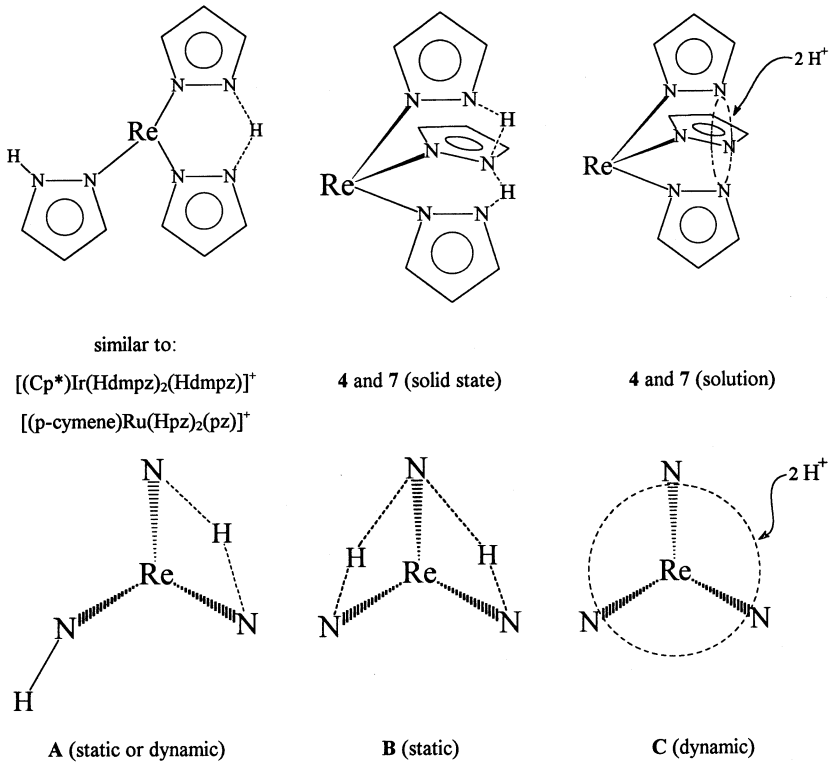
Scheme 1



When $[Re(CO)_5Br]$ was treated with Hdmpz, the $[Re(CO)_3(Hdmpz)_2Br]$ species (**2**) was similarly obtained. Its IR spectrum (toluene solution) shows three strong $\tilde{\nu}$(CO) bands at 2028, 1925, and 1893 cm^{-1}. On the basis of a comparison between the IR and ^{1}H-NMR spectra of **1** and **2** (see Table 1) we assign to the latter species a structure identical to **1**. Note, however, the significant red-shift of all resonances, ca. 4 cm^{-1}, caused by the higher basicity of Hdmpz compared to Hpz.

A closely related rhenium(I) species, $[Re(CO)_3(Hdmpz)_2Cl]$, derived by the breakdown of the tridentate pyrazolylborate ligand into pyrazole fragments, was fortuitously obtained by reaction of $[Re(CO)_4Cl]_2$ with $K[HB(dmpz)_3]$[12].

Reaction of 1 with Triethylamine

When monitoring the treatment of $[Re(CO)_3(Hpz)_2Br]$ with Et_3N in toluene at 60°C using IR spectroscopy, the $\tilde{\nu}$(CO) absorptions of the starting complex were observed to disappear along with the simultaneous appearance of a complex pattern of CO bands. The changes in the IR spectrum were accompanied by the formation of a white precipitate. The work-up of the reaction mixture (see Experimental Section) led to the isolation of two rhenium(I) complexes, both exhibiting $\tilde{\nu}$(CO) bands in their IR spectra (eq. 2).

$$[Re(CO)_3(Hpz)_2Br] + Et_3N \rightarrow \mathbf{3} + \mathbf{4} + (Et_3NH)Br \quad (2)$$

Complex **3**, sparingly soluble in toluene, was isolated in an analytically pure form, whereas the second species, **4**, soluble in the reaction medium, was always recovered contaminated by variable amounts of **3**; only by employing an alternative synthetic route was it possible to isolate **4** in a pure form (see later).

Complex **3** shows two strong bands at 2008 and 1899 cm^{-1}, the latter, broader, is probably due to the superposition of two different bands. Additionally, a broad absorption attributable to the $\tilde{\nu}$(N−H) of the triethylammonium cation is also observed. On the basis of elemental analysis and spectroscopic data, the ionic dinuclear formulation $(Et_3NH)[Re_2(CO)_6(pz)_2Br]$ was assigned to complex **3**. As later shown by an X-ray crystal structure analysis, the two rhenium centres are held together by one bromide and two pyrazolate bridges.

Care must be paid in order to exclude moisture from the reaction medium because the presence of adventitious water in solvents or reactants caused the formation of the hydroxo-bridged $(Et_3NH)[Re_2(CO)_6(pz)_2(OH)]$ species (**5**), formally derived by hydrolysis of the bromide bridge in complex **3**, and characterized by an ancillary X-ray diffraction study[13].

Reaction of 1 with Triethylamine in the Presence of Pyrazole

When reaction 2 was carried out in the presence of excess pyrazole, complex **4** could be obtained in analytically pure form as the unique reaction product. On the basis of elemental analysis and spectroscopic data, it was formulated as monomeric $[Re(CO)_3(Hpz)_2(pz)]$ species (**4**) (eq. 3).

$$[Re(CO)_3(Hpz)_2Br] + Et_3N + Hpz \rightarrow [Re(CO)_3(Hpz)_2(pz)]\ (\mathbf{4}) + (Et_3NH)Br \quad (3)$$

The IR spectrum of **4**, recorded in toluene, shows three strong $\tilde{\nu}$(CO) bands at 2024, 1916, and 1902 cm^{-1}, suggesting a *fac* geometry in this case too. An additional broad band centred at about 2850 cm^{-1} (nujol mull) indicates the presence of hydrogen bonds between the pyrazole and pyrazolate groups. The proposed formulation was confirmed by an X-ray diffraction study (see later).

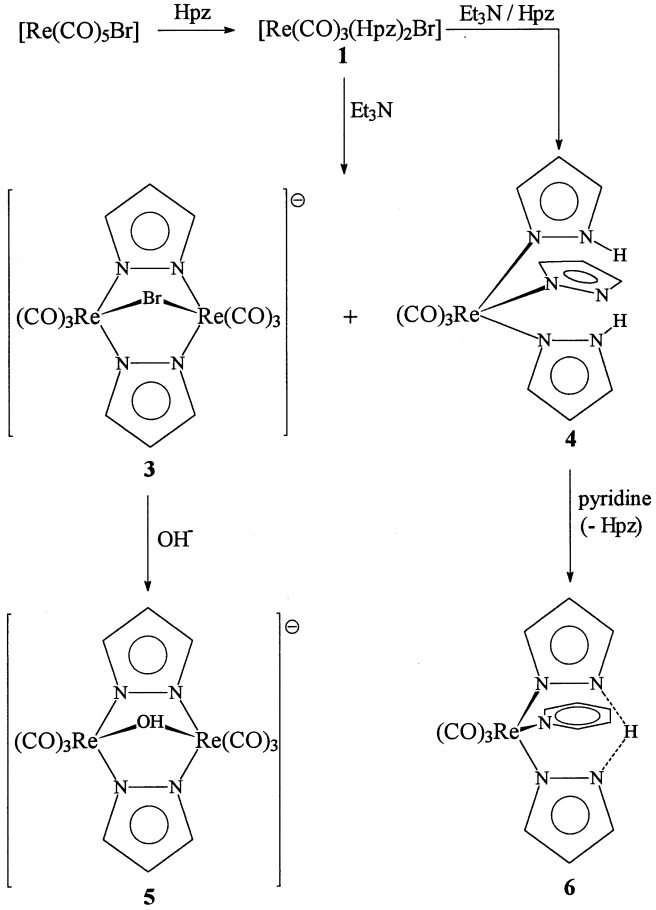
The simultaneous formation of complexes **3** and **4** in reaction 2 can therefore be rationalized by taking into account the stoichiometries of formation of **3** and **4** (eq. 4a and b).

$$2\,[Re(CO)_3(Hpz)_2Br] + 2\,Et_3N \rightarrow (Et_3NH)[Re_2(CO)_6(pz)_2Br]\ (\mathbf{3}) + 2\,Hpz + (Et_3NH)Br \quad (4a)$$

$$[Re(CO)_3(Hpz)_2Br] + Hpz + Et_3N \rightarrow [Re(CO)_3(Hpz)_2(pz)]\ (\mathbf{4}) + (Et_3NH)Br \quad (4b)$$

The pyrazole released in eq. 4a, as a result of the presence of Et_3N, is deprotonated to the pyrazolate anion, which is

Scheme 2



responsible for the nucleophilic substitution of the bromide anion on the starting $[Re(CO)_3(Hpz)_2Br]$ derivative. In the light of these observations, it is reasonable to exclude the intermediacy of **3** in the formation of complex **4** in eq. 3, the more probable reaction pathway being a direct substitution of the terminal bromide anion by the pyrazolate anion generated in situ in the reaction medium.

The ^{1}H-NMR spectrum of **4**, recorded in CD_2Cl_2 at 298 K, shows three resonances: a doublet centred at $\delta = 7.80$ ($J_{4,5} = 2.37$ Hz), a second doublet centred at $\delta = 7.67$ ($J_{3,4} = 1.75$ Hz) and a pseudotriplet (due to partial overlapping of two doublets) at $\delta = 6.35$. In addition, a broad peak at $\delta \approx 13$, due to N−*H*, is found. The spectral features do not change appreciably on lowering the temperature down to 198 K. The first two doublets can easily be assigned to the 3,5 protons of the heterocyclic ring, and, taking into account that $J_{4,5}$ is usually larger than $J_{3,4}$[14], the doublet downfield can likely be assigned to the C(5)−*H* protons. The pseudotriplet is due to the C(4)−*H* coupled to the 3 and 5 protons. As a matter of fact, the ^{1}H-NMR spectrum of **4** clearly shows that both (neutral) pyrazoles and the pyrazolate ligand appear identical on the NMR time scale. Although a static conformation with the two pyrazole *N*-hydrogen atoms sharing the same uncoordinated pyrazolate nitrogen atom cannot be completely ruled out, an (N)−H intramolecular exchange, producing a dynamic hydrogen bonding between the three pyrazole/pyrazolate ligands is probably more realistic. Indeed, of the three conformations which can be envisaged for a $(CO)_3Re(Hpz)_2(pz)$ molecule (see Scheme 1), only a dynamic proton exchange as depicted in C is in full agreement with our spectroscopic observations. It is useful to compare the chemical shift of the N−*H* protons for complex **4** [$\delta = 12.8$ (298 K); 14.6 (198 K)] to that found in the palladium(II) derivative $[Pd(dmpz)_2(Hdmpz)_2]_2$[15] ($\delta = 18.1$, 198 K). In the latter, the presence of very strong hydrogen bonds, shown also by IR bands at 2400 and 1900 cm^{-1}, caused the dramatic downfield shift of the N−*H* signals [free Hdmpz: $\delta = 13.1$ (CD_2Cl_2, 0.5 M)], and the total rigidity of the molecular framework. In contrast, the chemical shift of the N−*H* protons in **4** is close to that of free pyrazole [$\delta = 12.6$ (CD_2Cl_2, 0.5 M)], thus suggesting a rather flexible $(Hpz)_2(pz)$ system with dynamic exchange of the H atoms.

When complex **4** is treated with pyridine, the substitution of only one pyrazole molecule takes place, giving the mononuclear $[Re(CO)_3(py)(Hpz)(pz)]$ (**6**) derivative, (eq. 5).

$$[Re(CO)_3(Hpz)_2(pz)] + py \rightarrow [Re(CO)_3(Hpz)(pz)(py)]\ (\mathbf{6}) + Hpz \quad (5)$$

The IR spectrum of **6** shows, in the carbonyl region, three strong bands at 2023, 1915 and 1898 cm^{-1}. Furthermore, a broad band in the region 3300−3400 cm^{-1}, attributable to hydrogen bonds, is also observed. Significantly, the ^{1}H-NMR spectrum of **6** (toluene, 298 K) shows the N−*H* resonance as a very sharp peak at $\delta = 18.2$, indicating the presence of a strong hydrogen bond equalizing the pyrazole and pyrazolate ligands (as revealed by the signals of the carbon protons of the heterocyclic rings, see Table 1), stabilizing the complex and hampering, in our opinion, the substitution of the second pyrazole molecule, even when reaction 5 is performed with excess pyridine.

*Intra*molecular hydrogen bonds between pyrazole and pyrazolate ligands have been previously observed by ^{1}H-NMR spectroscopy in rhenium(V)[16], iridium(III)[17], palladium(II)[10] and platinum(II)[10] derivatives, and confirmed by means of X-ray crystallography[10][17], but in no case was the chemical shift of the N−*H* protons found so downfield shifted as in **6**.

Employing 3,5-dimethylpyrazole in place of pyrazole, the related $[Re(CO)_3(Hdmpz)_2(dmpz)]$ (**7**) and $[Re(CO)_3(py)(Hdmpz)(dmpz)]$ (**8**) derivatives have been obtained. As revealed by ^{1}H-NMR spectroscopy (see Table 1), the solution behaviour of complexes **7** and **8** is quite similar to that of the related derivatives **4** and **6**, indicating that the steric hindrance of the methyl substituents on the pyrazole ring plays a minor role. A different situation was found for the iridium(III) couple $[(Cp^*)Ir(Hpz)(pz)_2]$ and $[(Cp^*)Ir(Hdmpz)(dmpz)_2]$, where the presence of the more sterically demanding Hdmpz ligand prevented the formation of a (dynamic) *bifurcated* hydrogen bond, such as that observed in the Hpz analogue[17a]. The larger ionic radius is probably responsible for these differences.

A synopsis of the spectroscopic data for complexes **1**−**8** is collected in Table 1, and Scheme 2 summarizes the reactions discussed above.

Crystal Structures of 1, 4 and 6

All these compounds are mononuclear species, packed in space by normal van der Waals contacts. Their ORTEP drawings are shown in Figures 1−3, together with a partial labelling scheme.

Table 2 reports the significant bond lengths and angles for **1**, **4** and **6**. These three compounds belong to the class of octahedral rhenium(I) species, bearing three carbonyl ligands in a *fac* disposition. The remaining coordination sites are occupied by one negatively charged ligand (pyrazolate or bromide) and two neutral fragments, such as pyrazole and/or pyridine. Despite this formal distinction, when both Hpz and pz fragments are present in the same molecule, such as in **4** and **6**, one might suspect that assignment of the Hpz/pz nature could be dubious. This is indeed the case for the hydrogen-bonded ligands of **6**, which, sharing a common H atom [N2−H 1.36(5) and N4−H 1.28(4) Å], show a very short N···N distance of 2.561(8) Å {in agreement with the ^{1}H-NMR spectrum and with other pyrazole/pyrazolato complexes such as $[M(C_6F_5)(Hpz)(pz)]$, (M = Pd, Pt)[10a], $[Zn_2(Hdmpz)_2(dmpz)_4]$[18], $[Co(Hdmpz)_2(dmpz)_4]$[19], $[(\eta^5\text{-}C_5Me_5)Ir(dmpz)_2(Hdmpz)]$[17a] and $[(\eta^6\text{-p-cymene})Ru(Hpz)_2(pz)]^+$[20]}.

In contrast, the situation in **4** is much clearer: Two H atoms are bound to two (different) neutral ligands, with both N−H vectors pointing toward the bare nitrogen atom of the

Figure 1. ORTEP drawing of the $[Re(CO)_3(Hpz)_2Br]$ species with partial labelling scheme; thermal ellipsoids drawn at the 30% probability level; hydrogen atoms are omitted for clarity; primed atoms are generated by the $-x, y, -z - 1/2$ symmetry operation

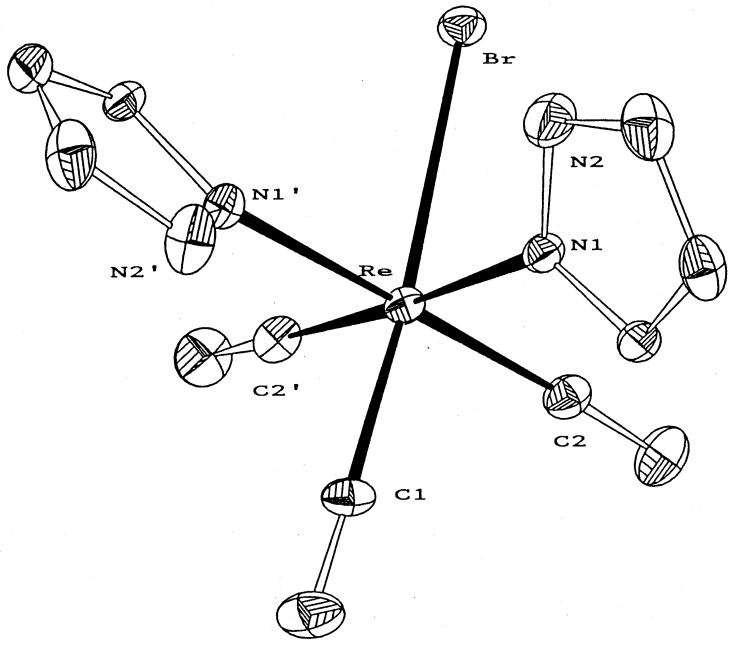


Figure 2. ORTEP drawing of the $[Re(CO)_3(Hpz)_2(pz)]$ species with partial labelling scheme; thermal ellipsoids drawn at the 30% probability level; hydrogen atoms connected to carbon vatoms are omitted for clarity; at the drawing resolution, the other independent molecule looks similar

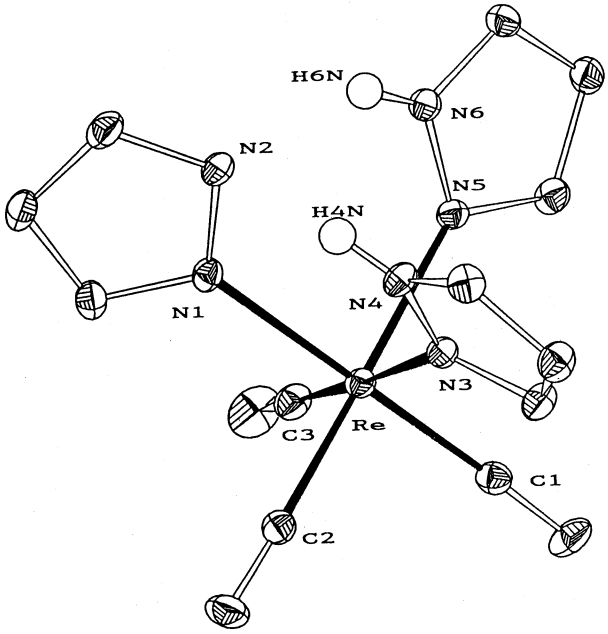

Figure 3. ORTEP drawing of the $[Re(CO)_3(Hpz)(pz)(py)]$ species with partial labelling scheme; thermal ellipsoids drawn at the 30% probability level; hydrogen atoms connected to carbon atoms are omitted for clarity

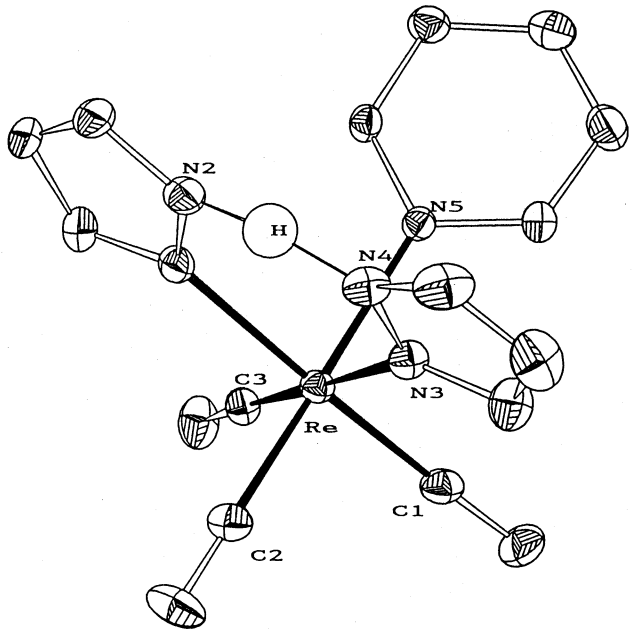

remaining pz fragment [four N−H···N interactions in the range 2.749(7)−2.883(6) Å]. This is indeed observed in both crystallographically independent molecules and confirmed by an ancillary successful crystal-structure determination of **7**[21], with a (crystallographically unique) N−H···N contact of 2.751 Å, clearly demonstrating the N−H···N···H−N nature of this interaction. Therefore, *in the solid state*, molecules of **4** and **7** are better represented by the static picture B (see Scheme 1). When no pyrazolates are present, such as in **1**, the nitrogen atoms of the neutral Hpz ligands in A are found to lie far apart from each other (ca. 5.27 Å). However, a short N−H···Br *inter*molecular hydrogen bond is present in

[a] Two independent molecules in the asymmetric unit.

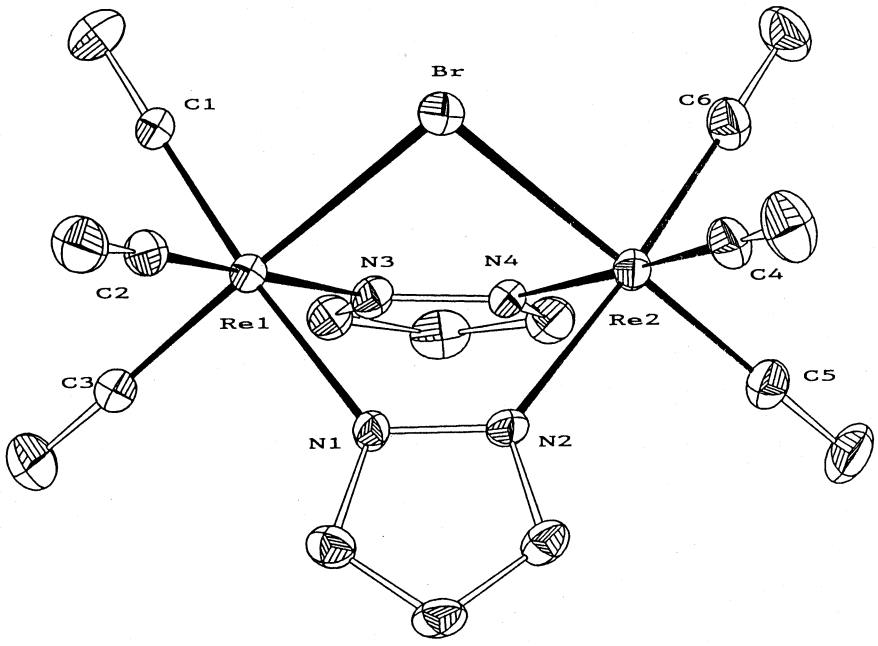
the solid state, with an estimated length of 2.645(8) Å for H2···Br.

In the absence of strained cyclic rings, such as that observed in $Re(CO)_3Cl(died)$ (died = *N*,*N*′-diisopropylethylenediimine), where the N−Re−N angle is as low as 72.72°[22], the *cis* octahedral angles about the rhenium atoms are fairly regular and range from 83.4(2) to 95.7(3)°. Analogously, the digonal geometry of the CO carbon atoms is also maintained [Re−C−O in the range 176.4(4)−179.0(5)°]. In all three compounds the Re−C distances are similar [1.881(6)−1.94(4) Å] and fall close to the mean value observed for the 28 ReC_3N_2X structures (X = F, Cl, Br) deposited in the CCDC file (1.907 Å). If a minor chemical effect is sought, one can envisage that the presence of a more basic[23] ligand (py) in **6** than in **4** (Hpz) slightly shortens the Re−C interactions [from 1.913 (**4**) to 1.888 Å (**6**), typical e.s.d.'s of 0.005 Å]; this effect, i.e. the presence of a stronger π back-donation in **6** than in **4**, can also be seen in the C−O values [1.152 (**4**) vs. 1.171 Å in **6**]. Re−N bond lengths lie in the range 2.183(4)−2.227(4) Å (CCDC avg. value, 2.208 Å).

Crystal Structure of 3

Crystals of **3** contain anionic, dinuclear $[(CO)_3Re(\mu\text{-}pz)_2(\mu\text{-}Br)Re(CO)_3]^-$ species and triethylammonium cations, packed in space by Coulombic forces and weak(er) van der Waals contacts. An ORTEP drawing of the anion is shown in Figure 4, together with a partial labelling scheme and a list of chemically relevant bond lengths and angles. The rhenium atoms in **3** exhibit an octahedral geometry, with *fac*-carbonyl ligands, and fulfil the 18-electron rule without the need for a

Figure 4. ORTEP drawing of the $[Re_2(CO)_6(pz)_2(Br)]^-$ anion with partial labelling scheme; thermal ellipsoids drawn at the 30% probability level[a]



[a] Selected bond lengths [Å] and angles [°]: Re···Re 3.825(1), Re(1)−Br 2.654(1), Re(2)−Br 2.641(1), Re−C avg. 1.895, C−O avg. 1.16; Re(1)−Br−Re(2) 92.51(4), Re−C−O 177(1)−180(1); hydrogen atoms are omitted for clarity.

direct metal−metal bond. The $[(CO)_3Re(\mu\text{-}pz)_2(\mu\text{-}Br)Re(CO)_3]^-$ anion represents the first structurally characterized species containing rhenium(I) atoms bridged by μ-pyrazolate ligands.

A similar rhenium(V) species $[ReO\{\eta^2\text{-}B(pz)_4\}(\mu\text{-}pz)]_2(\mu\text{-}O)$, has been recently reported[16], and showed a nonbonding Re···Re interaction of 3.425 Å. In addition, the synthesis and spectroscopic properties of an oxorhenium(VII) species, possibly a dimer containing two pz bridges, $[ReO_3(\mu\text{-}pz)]_2$, have long been known[24], but, in the absence of single crystals of suitable quality, this species could not be characterized any further. Therefore, the observed nonbonding Re−Re separation, 3.825(1) Å, cannot usefully be compared to other cases. However, it appears, among pyrazolato-bridged complexes, to be rather long, even though rare examples with exceptionally distant metals (up to 4.56 Å) have been reported for polydentate complex pyrazolates[25]. In spite of the presence of a triple (pz, pz, Br) bridge which, avoiding overcrowding of ligands at the metal centres, should shorten the Re···Re distance, such a long Re···Re contact is certainly determined by the simultaneous presence of large metals (leading to Re−N distances of about 2.17 Å) and a rather bulky bridging anion, the bromide, with Re−Br interactions of about 2.65 Å. The above observations agree well with the coordination versatility of pz groups (which are known to form single- to quadruple-bridged[26] systems), capable of bridging metal atoms which are as close as 2.353 Å or even acting as *endo*bidentate η^2 ligands[9b][27]. Also in this case, *inter*molecular hydrogen bonds are found. Indeed, if the nitrogen-bonded proton is added to the triethylammonium cation in the ideal position, one can devise an N−H···Br contact with a Br···H distance of, say, 2.90 Å. During our studies of the crystal structure of **3**, a crystal which eventually was characterized as the product of bromine hydrolysis, containing hydroxo, rather than bromide, bridges[13] came fortuitously to our attention. In order to maintain the hydrogen-bond network, which properly stabilizes the crystal, an extra water molecule was found in its asymmetric unit, leading to a $\mu\text{-}OH\cdots(H_2O)\cdots H-N(Et)_3$ fragment replacing the $Br\cdots H-N(Et)_3$ contact of **3**. In **5**, as expected, replacement of Br by a smaller hydroxo group lowers the intermetallic distance to 3.659(1) Å.

Conclusion

The synthesis and structural properties of a series of mononuclear and dinuclear pyrazolate complexes of rhenium(I) have been described. In particular, we foresee that the mononuclear derivatives $[Re(CO)_3(Hpz)_2(pz)]$ (**4**) and $[Re(CO)_3(Hdmpz)_2(dmpz)]$ (**6**) may act as useful synthetic precursors in building heteropolynuclear metal complexes.

In fact, **4** and **6** belong to a limited class of complexes that, from a coordination point of view, are comparable to the protonated tris(pyrazolyl)borate molecules[28]. The other members of this class, $[(\eta^5\text{-}C_5Me_5)Ir(Hpz)(pz)_2]$[17a], $[(\eta^6\text{-}p\text{-cymene})Ru(Hpz)(pz)_2]$[20] and $[(\eta^6\text{-mesitylene})Ru(Hpz)(pz)_2]$[29] when deprotonated to the anionic fragments $[(\eta^5\text{-}C_5Me_5)Ir(pz)_3]^-$, $[(\eta^6\text{-}p\text{-cymene})Ru(pz)_3]^-$ and $[(\eta^6\text{-mesitylene})Ru(pz)_3]^-$, have been shown to behave in some respect as the tris(pyrazolyl)borate anion, acting as organometallic ligands toward a variety of metal ions[29][30].

Accordingly, preliminary results[31] with group-7 and -11 metals show that, in the presence of appropriate deprotonating agents, complex **4** results in the dianionic species $[Re(CO)_3(pz)_3]^{2-}$, capable of coordination through the lone pairs of the three monodentate pyrazolate groups on a single or on two different metal centres, leading to bi- and trimetallic species. In this way, an analogy with the Kläui tripod-like metallorganic ligands such as $[(\eta^5\text{-}C_5H_5)M\{P(O)R_2\}_3]^-$ (M = Co, Rh) can be drawn[32]. Finally, the use of complexes **4** and **6** in the synthesis of bimetallic derivatives with potential catalytic applications is currently under investigation and will be the subject of a forthcoming paper.

Experimental Section

General: Solvents were dried and purified by standard methods. Pyrazole and 3,5-dimethylpyrazole (Aldrich Chemical Co.) were used as supplied. $[Re(CO)_5Br]$ was prepared according to literature procedures[33]. − Infrared spectra were taken with a BIO RAD FTIR 7 instrument. − ^{1}H-NMR spectra were acquired with a Bruker AC-200 FT spectrometer operating at 200.13 MHz. − Elemental analyses (C, H, N) were performed at the Microanalytical Laboratory of this University. All reactions were carried out under dry nitrogen using standard Schlenk techniques.

[Re(CO)$_3$(Hpz)$_2$Br] (**1**): $[Re(CO)_5Br]$ (400 mg, 0.98 mmol) was dissolved in 10 ml of toluene and solid pyrazole (200 mg, 2.94 mmol) was added under stirring. The solution was kept at 80°C until no change in the IR spectrum was observed (about 4 h) and then concentrated to dryness. The white residue was treated with 3 ml of water, filtered off and dried under vacuum (414 mg, 87%). − $C_9H_8BrN_4O_3Re$ (486): calcd. C 22.23, H 1.66, N 11.53; found C 22.22, H 1.67, N 11.52. − Crystals suitable for X-ray structure analysis were obtained by slow diffusion of *n*-hexane into a dichloromethane solution of **1**.

[Re(CO)$_3$(Hdmpz)$_2$Br] (**2**): Prepared in a similar way, employing 3,5-dimethylpyrazole in place of pyrazole (yield 85%). − $C_{13}H_{16}BrN_4O_3Re$ (542): calcd. C 28.78, H 2.98, N 10.33; found C 28.85, H 2.84, N 10.34.

(Et$_3$NH)[Re$_2$(CO)$_6$(pz)$_2$(Br)] (**3**): To a toluene solution of **1** (400 mg, 0.823 mmol) maintained at 50°C, triethylamine (0.5 ml) was added under stirring. In a few minutes a white precipitate formed. After 6 h, the solid was separated by filtration, washed with water (2 ml), and dried under vacuum (yield about 30%). − $C_{18}H_{22}BrN_5O_6Re_2$ (857): calcd. C 25.20, H 2.59, N 8.17; found C 25.28, H 2.65, N 8.21. − The mother liquors were concentrated to dryness and the residue treated with water. A mixture of variable amounts of **3** and **4** (on the basis of the IR spectrum) was always obtained (see text).

[Re(CO)$_3$(Hpz)$_2$(pz)] (**4**): $[Re(CO)_5Br]$ (1.03 g, 2.54 mmol) was added to a solution of pyrazole (0.920 g, 13.5 mmol) in toluene (20 ml) containing 0.5 ml of triethylamine. The solution was maintained

[a] Frame width and exposure time per frame. − [b] $GOF = [\Sigma w(F_o^2 - F_c^2)^2/(n-p)]^{1/2}$ (where *n* is the number of reflections and *p* is the number of refined parameters). − [c] $R1 = \Sigma\|F_o| - |F_c\| / \Sigma|F_o|$, $wR2 = [\Sigma w(F_o^2 - F_c^2)^2 / \Sigma wF_o^4]^{1/2}$. − [d] $w = 1/[\sigma(F_o^2) + (a\,P)^2]$ where $P = (F_o^2 + 2F_c^2)/3$.

under stirring at 80°C for 6 h, the formation of $(Et_3NH)Br$, insoluble in the reaction medium, being observed. The solvent was then evaporated to dryness and the residue dissolved in the minimum amount of ethanol (2 ml). The addition of water caused the precipitation of **4** as a white product. The product was filtered, washed with water and dried under vacuum (yield 1.08 g, 90%). − $C_{12}H_{11}N_6O_3Re$ (474): calcd. C 30.38, H 2.34, N 17.72; found C 30.50, H 2.24, N 17.34.

[Re(CO)$_3$(Hdmpz)$_2$(dmpz)] (**7**): Obtained in a similar way employing Hdmpz (yield 90%). − $C_{18}H_{23}N_6O_3Re$ (558): calcd. C 38.70, H 4.15, N 15.05; found C 38.52, H 4.01, N 14.91. − Crystals suitable for X-ray structure analysis were obtained by slow concentration of toluene solutions of **4** or **7**.

[Re(CO)$_3$(py)(Hpz)(pz)] (**6**): Pyridine (1 ml) was added to a solution of **4** (300 mg, 0.634 mmol) in toluene. The clear solution was maintained under stirring at 50°C for 3 h. The solvent was then evaporated to dryness and the residue was dissolved in ethanol (1 ml). Addition of water caused the precipitation of **6** as a white product. The complex was filtered, washed with water and dried under vacuum (yield 240 mg, 78%). − $C_{14}H_{12}N_5O_3Re$ (485): calcd. C 34.64, H 2.49, N 14.43; found C 34.64, H 2.52, N 14.37. −Crystals suitable for X-ray structure analysis were obtained from an *n*-hexane solution of complex **6** kept at −25°C.

[Re(CO)$_3$(Hdmpz)(dmpz)(py)] (**8**): Obtained similarly starting from complex **7** (yield 80%). − $C_{18}H_{20}N_6O_3Re$ (555): calcd. C 38.91, H 3.63, N 15.14; found C 39.40, H 3.57, N 15.53.

Crystallography[34]: Crystals of **1**, **3**, **4** and **6** were studied by conventional single-crystal X-ray methods; an overview of the methodology used can be found in ref.[35]. A list of crystal data, refinement parameters and final agreement factors is reported in Table 3.

Keywords: Arene complexes / Ab initio calculations / Polymeric clathrates / Host-guest chemistry

A systematic ab initio investigation of the complexes benzene/halogen molecules is presented. For the whole halogen series, the T-shaped geometry is clearly favored relative to the sandwich geometry. This preference is rationalized in terms of the electrostatic fields generated by the interacting molcules. Higher binding energies have been calculated on going from /F_2 to /I_2 molecular complexes.

Introduction

Van der Waals interactions of aromatic systems are of considerable interest because they often play an important structure-determining role. These interactions control such diverse phenomena as porphyrin aggregation, the packing of aromatic molecules, and the base-base interactions in DNA. For this reason, a large number of experimental as well as theoretical papers have been devoted to the study of the weak interactions in prototype systems of the type benzene/benzene, benzene/H_2O, benzene/NH_3, benzene/N_2, benzene/alkane, and benzene/hydrogen halide.[1][2]

Another phenomenon of considerable interest that is often controlled by these interactions is the sorption of small molecules in polymers,[3][4] the economic importance of which, e.g. in the packaging industry and in the field of membrane separation processes, is well known. For instance, systematic studies of the sorption of various molecules in amorphous polymeric materials based on atactic polystyrene have allowed correlations to be made between the structures of the small molecules and the relevant sorption parameters.[3] Moreover, studies of the sorption of halogenated aliphatic molecules have led to molecular models of absorption that involve interactions of the halogen atoms with the phenyl groups of the polymeric absorbents.[5] However, experimental and theoretical studies of the molecular interactions responsible for the sorption phenomena are made difficult by the dynamic intramolecular and intermolecular disorder that is characteristic of the swollen polymeric phases.

Recently, semicrystalline polymeric materials based on syndiotactic polystyrene that are able to absorb small molecules, not only in the amorphous phase but also in the cavities of suitable crystalline phases, have been described.[6][7][8][9] It has also been found that the same classes of molecules that are suitable for sorption into atactic polystyrene based samples,[3] are absorbed both into amorphous and crystalline phases of syndiotactic polystyrene samples.[6][7][8][9] Furthermore, it is remarkable that at low activities these small molecules are preferentially (or exclusively) absorbed as guests in the crystalline phase to form clathrates.[9] This suggests that the host-guest interactions in clathrate structures are similar to the interactions between the polymer and small molecules in the amorphous phase.

X-ray diffraction[10][11] and FT-IR-spectroscopic[9] studies on these clathrate samples can give detailed experimental information regarding the molecular interactions that occur between the guest molecules and the host polymer in the crystalline cavities. In particular, the number and distances of the intermolecular interactions, the preferred relative orientations of the guest and host, as well as possible preferential guest conformations can be established. Finally, it is worth noting that the study of host-guest interactions in these polymeric clathrates is also relevant due to the potential applications of nanoporous materials based on syndiotactic polystyrene for water and air purification and, more generally, for chemical separations.[6]

The clathrate structure of syndiotactic polystyrene incorporating two I_2 molecules per cavity has been well characterized by X-ray diffraction study.[7] The I_2 molecule interacts significantly with only two phenyl rings, and the I_2 molecular axis is almost perpendicular to the planes of the phenyl rings. Moreover, X-ray studies of the benzene/Cl_2[12] and benzene/Br_2[13] systems have shown that a T-shaped geometry (see Figure 1), with the halogen molecule almost aligned along the C_{6v} symmetry axis of the benzene, is preferred. Furthermore, IR-spectroscopic studies indicate that an axial or slightly bent structure is also adopted in nitrogen matrices.[14][15] However, despite the great interest in these complexes, a systematic theoretical description of

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1434–1948/98/1010–1513 $ 17.50+.50/0

the benzene/X_2 (X = F, Cl, Br, I) series is still lacking. To the best of our knowledge, of this series only the benzene/I_2 complex has been studied in detail from a theoretical point of view.[16][17][18] For this reason, we have carried out a systematic study of the interactions occurring in the ground state of the model systems benzene/X_2 (X = F, Cl, Br, I) using the second-order Møller-Plesset (MP2) theory.

Methods

The interaction energy, ΔE, of the complexes was evaluated as the sum of the self-consistent field interaction energy, ΔE_{SCF},[19] and the correlation interaction energy, ΔE_{COR},[19] where ΔE_{COR} was calculated using MP2 theory.[19] We applied the supermolecule approach.[1] Thus, the interaction energy was obtained as the difference between the energy of the complex and the energies of the free benzene and halogen molecules. All the calculated interaction energies were basis set superposition error (BSSE) free.[19] For the BSSE evaluation, the counterpoise method of Boys and Bernardi was used.[20] All the calculations were performed using the GAMESS package.[21]

The geometries of the benzene (R_{C-C} = 1.406 and R_{C-H} = 1.08 Å) and halogen molecules (R_{F-F} = 1.34, R_{Cl-Cl} = 1.99, R_{Br-Br} = 2.28, R_{I-I} = 2.68 Å) were kept rigid, and only the distance between the centres of mass of the benzene and halogen molecules, R, was varied. To locate the BSSE-free minimum energy geometries, the potential energy surface was scanned simply by varying the distance R. To save computer time, we used the 6-31G basis set for the C and H atoms,[22] augmented with single d and p polarization functions,[22] respectively, and the SBK effective core potential (ECP) and valence basis set, augmented with a d polarization function, for the halogens.[23] To assess the dependence of the interaction energy on the particular basis set used, single-point energy calculations were performed on the minimum energy geometries obtained from the potential energy surface scan. In these cases, a double-ζ basis set, DZ, augmented with two d polarization functions on the C atoms, was adopted for the benzene.[24] Finally, test calculations were performed using the SBK ECP basis set on the C atoms of the benzene as well. Due to the fact that envisaged extensions of this work will focus on systems of considerably larger size (polymer cavities containing guest molecules), we decided to use basis sets of moderate size only.

Results

As already suggested by other authors,[1] for benzene-containing molecular complexes the total interaction energy is mainly determined by the electrostatic (quadrupole-quadrupole) interaction, essentially included in the ΔE_{SCF} contribution, and by the dispersion energy, essentially included in the ΔE_{COR} contribution. For this reason, the selection of suitable basis sets requires that one-electron properties, in particular the quadrupole moment, Q_{zz}, be reproduced with good accuracy.

Table 1 shows the Hartree-Fock quadrupole moments of the molecules considered in the present study. As reported previously,[1] for the benzene molecule the 6-31G basis set, even augmented by two polarization functions on the carbon atoms, underestimates the quadrupole moment. On the other hand, with the DZ basis set reasonable values for the quadrupole moment are obtained, even in the absence of polarization functions.

Table 1. Quadrupole moments of the benzene and halogen molecules at the Hartree-Fock level

On the contrary, for the halogen molecules, both with DZ (for F_2 and Cl_2) and ECP (for the whole series) basis sets, the quadrupole moments are clearly underestimated in the absence of polarization functions. For F_2 and Cl_2, the DZ and ECP basis sets augmented with two polarization functions provide reasonable values of Q_{zz}, whereas for the heavier Br_2 and I_2 halogen molecules Q_{zz} is overestimated.

Table 2 shows the calculated minimum energy distances, BSSE-free, and the interaction energy contributions for the benzene/X_2 molecular complexes. Clearly, the T-shaped geometry is preferred for each of the halogens. This result is in

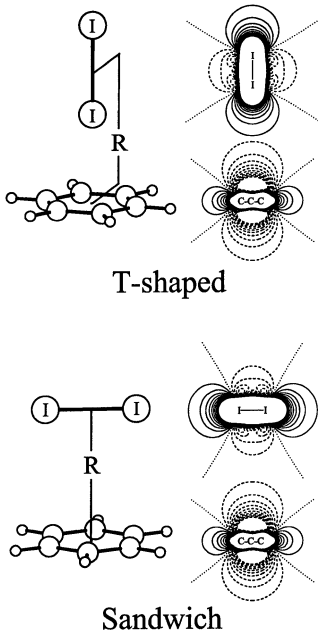
[a] Optimized intermolecular distance, BSSE-free.

agreement with X-ray structural investigations of benzene/Cl_2[12] and benzene/Br_2[13] complexes, which have shown that the T-shaped geometry is the most probable. The minimum energy distances R, between the centres of mass of the benzene and halogen molecules for the T-shaped structures are 3.9, 4.6, 4.7, and 4.9 Å for F_2, Cl_2, Br_2, and I_2, respectively. The calculated values of R are overestimated by roughly 0.3 Å (4.27 and 4.34 Å in the crystalline structures of the benzene/Cl_2 and benzene/Br_2 complexes, respectively). The T-shaped geometry for the benzene/X_2 complexes is also in agreement with the structures indicated by infrared absorption spectra of the Cl_2, Br_2 and I_2 complexes with benzene in nitrogen matrices,[14][15] and with previous ab initio studies on the benzene/I_2 complex.[16][17][18]

As already outlined,[1] the rationalization of the preferred geometry in molecular complexes with benzene is essentially related to the electrostatic interaction (quadrupole-quadrupole) between the two molecules. In order to rationalize the preferred geometry in terms of electrostatic interactions, the electrostatic fields generated by the two interacting molecules are depicted in Figure 1. In the T-shaped geometry, negative and positive regions of the electrostatic potential of the benzene and halogen molecules face each other, whereas in the sandwich geometry regions of electrostatic potential of the same sign face each other. As a consequence, the electrostatic interactions clearly favour the T-shaped geometry relative to the sandwich geometry.

Our analysis is in agreement with the previously reported rationalization based on the quadrupole-quadrupole electrostatic interaction. In order to optimize this interaction, and depending on the sign of the quadrupole moment of

Figure 1. Schematic representation of the T-shaped and sandwich geometries for the benzene/I_2 complex; the distance R between the centres of mass of the two molecules, which was varied during the potential energy surface scan, is indicated; the electrostatic fields generated by the two molecules are also indicated; starting from the 0.0 contours (dotted lines), positive and negative contours of the electrostatic field (continuous and dashed lines, respectively) are shown; the isopotential curves are spaced by 1 kcal/mol



the two molecules that form the molecular complex, either T-shaped (benzene/benzene and benzene/I_2) or sandwich (benzene/N_2) geometries are adopted. Considering that all

the halogen molecules have quadrupole moments of the same sign, it is reasonable to assume that the T-shaped structure is the preferred geometry throughout the benzene/X_2 series.

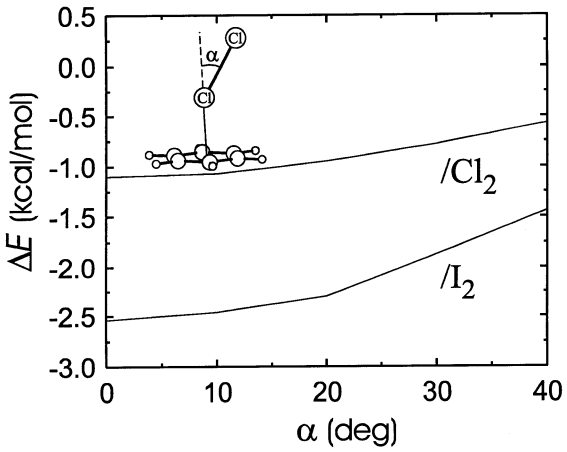
This rationalization is also supported by the fact that the ΔE_{SCF} contribution always favours the T-shaped geometry. Moreover, the repulsive electrostatic interaction in the sandwich geometry pushes the two molecules far apart, and this reduces the strength of the attractive dispersion interactions. As a consequence, the ΔE_{COR} energy contribution also favours the T-shaped geometry.

As regards the total binding energy, more stable complexes are observed on going from the very weakly bound F_2 to I_2, both for T-shaped and sandwich geometries. The calculated value for the T-shaped benzene/I_2 complex, 2.54 kcal/mol, is in fair agreement with the heat of formation of this complex in the gas phase, as determined by spectrometric methods (2.0−2.6 kcal/mol).[25] Previous ab initio calculations led to binding energies of 1.91[16] and 2.07[18] kcal/mol. By using the DZ basis set for benzene and the SBK ECP set for the halogens, and augmenting these basis sets with two standard polarization functions on the C and halogen atoms, the same trend is observed, i.e. higher binding energies on going from F_2 to I_2. With this basis set, which should be of better quality, the binding energies are probably overestimated. In fact, for the T-shaped benzene/I_2 complex this basis set gives a binding energy of 4.23 kcal/mol. Finally, by using the SBK ECP basis set for the C atoms of benzene as well, results fairly similar to those obtained using the 6-31G basis set are obtained. However, there is a decrease in the energy difference between the sandwich and the more stable T-shaped geometry [ΔE(sandwich − T-shaped) = 0.46, 0.89, 1.76, and 2.11 kcal/mol using the 6-31G basis set for the benzene, and 0.21, 0.52, 1.20, and 1.28 kcal/mol using the SBK ECP basis set for the benzene, for F_2, Cl_2, Br_2, and I_2, respectively].

The results shown in Table 2 clearly indicate that the ΔE_{SCF} contribution is virtually independent of the basis set used, and that the increase in the binding energy is essentially due to the dispersion term, ΔE_{COR}. It is also apparent that the ΔE_{COR} contribution is not yet converged. Due to the fact that we have mixed a DZ basis set with a split-valence ECP basis set, we checked the reasonability of this mixing by using, for the Cl_2 complex only, a DZ all-electron basis set. The results obtained with the ECP were in very good agreement with the all-electron results. Thus, we believe that the basis set mixing that we have used represents a reasonable approximation.

In the last part of our study, we investigated the feasibility of oblique structures. In Figure 2, the BSSE-free interaction energies of the oblique geometries of the benzene/Cl_2 and benzene/I_2 complexes are plotted as a function of the angle α between the halogen−halogen bond and the C_{6v} symmetry axis of the benzene. Since in the bent structures the distance R is not re-optimized, we confined our analysis to structures close to the T-shaped geometry, that is, to values of $\alpha \leq 40°$. The geometries at $\alpha = 0°$ correspond to the minimum energy T-shaped geometries of the Cl_2 and I_2 complexes. It is clear that the T-shaped geometries of the two complexes represent only shallow minima, and that large oscillations might easily be achieved. In fact, α deformations of 20−30° require less than 0.5 kcal/mol. Our results support the hypothesis that in photoexcitation experiments the excitation process occurs in bent conformations, i.e. the conformations with the largest transition moment.[18]

Figure 2. MP2 BSSE-free interaction energy as a function of α for the benzene/Cl_2 and benzene/I_2 complexes; the 6-31G d,p and ECP SBK 2d basis sets were used for the benzene and halogen molecules, respectively



Conclusions

A systematic investigation of benzene/halogen molecule complexes in the ground state has indicated that the T-shaped geometry is preferred relative to the sandwich geometry for each of the halogens. The calculated minimum energy distances for the benzene/Cl_2 and benzene/Br_2 complexes (for which X-ray structures are available) overestimate the experimental values by roughly 0.3 Å. Moreover, irrespective of the particular basis set used, higher binding energies have been calculated on going from benzene/F_2 to benzene/I_2 molecular complexes. The relative stability of the T-shaped and sandwich geometries is essentially determined by the electrostatic quadrupole-quadrupole interaction. This can clearly be visualized in terms of the electrostatic potential generated by the interacting molecules. Finally, we note that the T-shaped geometry represents only a shallow minimum, and that environmental effects (i.e. crystal packing or inert matrices) can reasonably force the adoption of oblique geometries.

Keywords: *B*,*B*′-Dimesityldiborane(4) dihalides / *B*,*B*′-Diamino-*B*,*B*′-dimesityldiboranes(4) / *B*,*B*′-Di-*tert*-butyloxy-*B*,*B*′-dimesityldiborane(4) / *B*,*B*′-Dimesityl-*B*,*B*′-di(organylthio)diborane(4) / NMR spectroscopy / X-ray structures

An efficient route to *B*,*B*′-dihalo-*B*,*B*′-dimesityldiboranes(4) is reported, as well as the conversion of these and of *B*,*B*′-dimesityl-*B*,*B*′-dimethoxydiborane(4) into other *B*,*B*′-dimesityldiboranes $B_2mes_2X_2$ (X = OR, SR, NR_2, NHR). The substituents X influence the shielding of the ^{11}B nucleus in the expected manner. Hindered rotation about the B–N bond is observed for X = pyrrolyl, while in solution there is free rotation about the B–C bond. However, X-ray structural results reveal that the mesityl group is almost orthogonal to the B(B)CY plane in the solid state. The shortest B–B bond is observed in $mes_2B_2I_2$, indicating that the iodide is the strongest Lewis acid in the reported series of $mes_2B_2Y_2$ compounds. This is also reflected in short B–C bonds. Moreover, the two mes(Y)B units also approach orthogonality in these diborane(4) compounds, and thus enforce this as a typical structural feature of diborane(4) derivatives. For this reason, the planar C(N)B–B(N)C unit of *B*,*B*′-di(benzylamino)-*B*,*B*′-dimesityldiborane(4) is regarded as exceptional for aminodiboranes(4).

Introduction

Although B_2Cl_4, the first diborane(4) compound, was synthesized as long ago as 1925[2], the intensive study of diborane(4) derivatives only began in the early 1960s, when an easy access to $B_2(NMe_2)_4$ was found[3][4]. Because $B_2(NMe_2)_4$ can be converted into $B_2(NMe_2)_3X$ or *sym*-$B_2(NMe_2)_2X_2$ (X = Cl, Br) by reaction with BX_3, a very useful synthon for the synthesis of amino-substituted diborane(4) derivatives was available on a preparative scale[4]. It was soon recognized that the stability of diborane(4) compounds B_2X_4 could be enhanced by increasing the electronic and steric shielding at the boron centers, so as to suppress decomposition into BX_3 and $(BX)_n$[5]. Thus, $B_2(NMe_2)_4$ is the most stable derivative due to N−B π-bonding in addition to the steric effect of the Me_2N groups, while B_2Me_4 remains unknown. Nevertheless, the first stable tetraorganyldiborane(4) derivatives, such as $(t\mathrm{Bu})_2\mathrm{B}-\mathrm{B}(t\mathrm{Bu})\mathrm{Me}$[6] and $(t\mathrm{Bu})_2\mathrm{B}-\mathrm{B}(t\mathrm{Bu})(\mathrm{CH}_2t\mathrm{Bu})$[7], were reported in 1980, demonstrating that only steric hindrance is required for the stabilization of diborane(4) species of this type. Although the *tert*-butyl groups are able to prevent redox disproportionation of these tetraalkyldiborane(4) derivatives, the halogenated species $t\mathrm{Bu}_2\mathrm{B}_2\mathrm{X}_2$ (X = Cl, Br) decompose readily[8].

While in alkyl-substituted diborane(4) derivatives the boron−carbon bonds can be described purely as σ-bonds, a B−C π-interaction can be expected in cases where aryl substituents are attached at the boron atoms, as the π-electrons of the aryl ligand can interact with the empty p-orbital of the boron atom. This has been documented in several examples[9][10]. Therefore, aryl-substituted diborane(4) derivatives might be expected to show an enhanced stability in comparison with their alkyl counterparts due to B−C π-bonding in B_2R_4. Indeed, some aryl-substituted diborane(4) derivatives such as $mes_2B-B(mes)Ph$ and $mes_2B-B(mes)CH_2SiMe_3$ are thermally stable, although little evidence for π-bonding or hyperconjugation was found[11].

We now report on the synthesis and crystallographic characterization of a variety of mesityl-substituted diborane(4) derivatives. These studies were undertaken in order to gain further insight into the stabilities, electronic properties, and conformations of such species.

Synthesis

As mentioned above, $B_2(NMe_2)_4$ and $B_2(NMe_2)_2X_2$ (X = Cl, Br) are key species in diborane(4) chemistry. The reaction of bis(dimethylamino)diborane(4) dichloride with mesityllithium, mesLi, for example, leads to $mes_2B_2(NMe_2)_2$[12][13] (Eq. 1a), which can be converted into $mes_2B_2(OMe)_2$ in very good yield according to Eq. 1b[11][13].

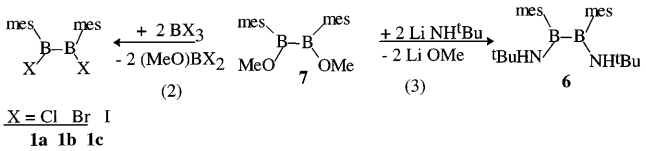
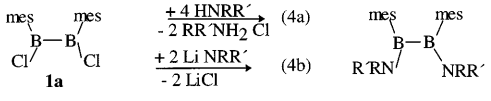
 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1434−1948/98/1010−1519 $ 17.50+.50/0

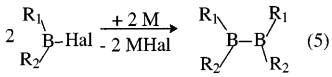
As shown in Eqs. 2 and 3, $mes_2B_2(OMe)_2$ itself can be further used as a starting material for the synthesis of various mesityl-substituted diboranes(4), e.g. the dihalides $mes_2B_2X_2$. In particular, the iodide **1c** is readily available under mild conditions and is obtained in good yield. Additionally, several diaminodimesityldiboranes(4) **2**–**6** were synthesized by allowing $mes_2B_2(OMe)_2$ to react with LiNH*t*Bu or $mes_2B_2Cl_2$ to react with amines or lithium amides (Eqs. 3, 4a, and 4b).



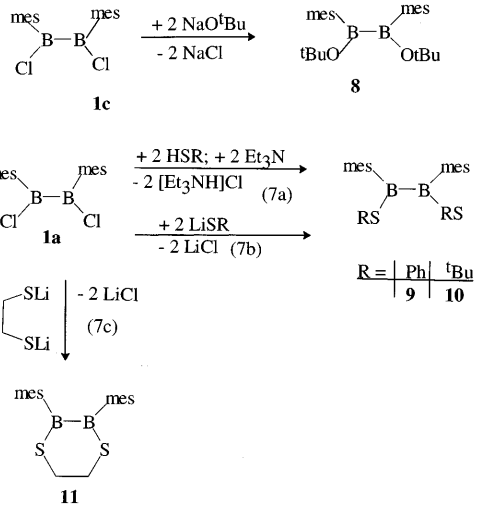


amine		Li NRR´		
$MeNH_2$	**2**	Li NH*i*Pr	**4**	bzl = benzyl
$bzlNH_2$	**3**	Li pyr	**5**	pyr = pyrrolyl

Although all these reactions provided the diaminodimesityldiboranes(4) in yields > 70%, better results were obtained when lithium amides were allowed to react with $mes_2B_2Cl_2$ rather than $mes_2B_2(OMe)_2$. This is due to the enhanced reactivity of the halogenated species. Moreover, the reactions can be carried out at lower temperatures and in less time. Furthermore, compared to the preparation of di(benzylamino)dimesityldiborane(4) (**3**) by the amine route, where a voluminous precipitate of benzylammonium chloride is formed, the by-product LiCl precipitates as a fine powder, and the reaction mixture can be stirred more readily. On the other hand, the method using amines as auxiliary bases can be advantageous when gaseous amines such as $MeNH_2$ are employed. $mes_2B_2(NHtBu)_2$ is also obtained in good yield by ligand exchange from $mes_2B_2(OMe)_2$ according to Eq. 3, but not by dehalogenation of haloboranes to diboranes(4), as shown in Eq. 5. The latter method fails when bulky substituents are attached to the boron atom.



Earlier attempts to synthesize dialkyldialkoxydiboranes(4) as well as dialkyldialkylthiodiboranes(4) were unsuccessful, and compounds of the type $R_2B_2X_2$ (X = OR, SR) were regarded as unstable as only borane(III) derivatives could be isolated[5]. Thus, only a few dialkyldiborane(4) derivatives with elements of the sixth main group are known[8]. In order to avoid redox disproportionation of these derivatives into R_2BX and "BX", one *t*Bu group was attached at each boron atom in order to stabilize the diborane(4) compounds. However, most of these dialkyldiborane(4) compounds are liquids and structural characterization by X-ray diffraction has as yet been impossible[8]. In order to gain further structural insight into the conformation of dialkoxydimesityldiborane(4) derivatives and to compare them with the structure of $mes_2B_2(OMe)_2$ (**7**)[11] (see Eq. 1b), we synthesized $mes_2B_2(OtBu)_2$ (**8**) (Eq. 6), as well as several mercapto derivatives $mes_2B_2(SR)_2$. The latter were prepared from $mes_2B_2Cl_2$ with either a mixture of the respective thiol and Et_3N as auxiliary base, or with lithium mercaptides, as shown in Eqs. 7a, 7b, and 7c. The best results were obtained using the latter method.



Efforts were also made to synthesize phosphanyl-substituted dimesityldiborane(4) derivatives. However, the reactions of $mes_2B_2Cl_2$ and LiPH*t*Bu in a 1:1 and in a 1:2 stoichiometry, as well as the reaction with one equivalent of Li_2PtBu, led only to ill-defined, multicomponent mixtures, as was evident from the many signals in the ^{11}B-NMR spectra, which ranged from $\delta = 90$ to -25. On the other hand, when $mes_2B_2Cl_2$ was allowed to react with lithiated 1,2-bis(isopropylphosphanyl)benzene, a planar heteroaromatic B–P–C cyclic product was formed in quantitative yield[14].

NMR Spectra

The ^{11}B-NMR shifts of the amino derivatives **2**–**6** are found in the range $\delta = 45-60$, which is typical for diaminodiorganyldiboranes(4)[15]. The signals for $B_2mes_2(NHR)_2$ compounds (R = Me, *i*Pr, *t*Bu) are shifted to higher field compared to those of $(Me_2N)mesB-Bmes(NMe_2)$ [$\delta^{11}B$ ($CDCl_3$) = 55]. The magnitude of the shift difference increases in the order NHMe < NHBz < NH*i*Pr < NH*t*Bu ($\delta^{11}B$ = 48.3, 47.9, 46.3, and 45.3, respectively) as the branching of R at the nitrogen atom increases. On the contrary, the ^{11}B resonance shows a deshielding ($\delta = 60.5$ for **5**) when an aromatic amine ligand is attached to the boron atoms, because the electrons of the p_z orbital at the nitrogen atom contribute to the aromaticity of the pyrrole heterocycle. Consequently, the B–N bonds possess less π-bond character. Nevertheless, the ^1H- and ^{13}C-NMR spectra show a discrete signal for each H and C atom of the pyrrole ligand, indicating hindered rotation of this subunit at ambient temperature, and therefore N–B back bonding (vide infra).

In analogy to borane(3) derivatives, the replacement of an amino group by an alkoxy group leads to a deshielding of the ^{11}B nucleus due to the higher electronegativity of the substituent. The resonance signals of the two alkoxy compounds **7** and **8** are found at $\delta^{11}B \approx 60$ (±5) depending on the solvent. In the ^{13}C-NMR spectra, the signals of the oxygen-bonded carbon atoms of the alkoxy ligands are shifted to lower field by about 5−7 ppm compared to those of the free alcohol[16]. This effect can be explained in terms of an O−B π-back donation, reducing the electron deficiency at the boron atom, leading to a deshielding of the respective C atom.

Within the dimercaptodimesityldiborane(4) series, the ^{11}B-NMR signals span a range from $\delta = 69-81$. The thiophenolate derivative **9** shows the least shielded boron atom ($\delta^{11}B = 80.6$), while those of the cyclic dithiadiborinane **11** ($\delta^{11}B = 69.4$) are the best shielded among these compounds. Furthermore, the signal of the latter compound shows a relatively narrow half-width of ca. 210 Hz, while the signals of the acyclic derivatives exhibit half-widths of 1000−1550 Hz. In analogy to the alkoxydiboranes(4) **7** and **8**, the signals of the sulfur-bonded carbon atoms of the mercapto ligands are shifted to lower field compared with those of the free thiol[16], indicating partial π-character of the S−B bond (vide infra). The magnitude of shift difference is about 4−8 ppm, as is observed for the alkoxy analogues.

Molecular Structures

In order to obtain information on the preferred conformations, and to gain further insight into steric and/or electronic effects of the ligands in the solid state of dimesityldiboranes(4), X-ray structure determinations of some representative derivatives were carried out.

Table 1 shows that the B−B bond lengths span a range from 1.709(5) Å in **5** to 1.735(7) Å in **8**. These can be compared with the B−B bond lengths in tetraaminodiboranes(4) **12**[17] and **13**[18] [1.693(9) Å and 1.750(8) Å, respectively]. Within the amino-substituted dimesityldiborane(4) series, compounds **6** and **3** show B−N bond lengths between 1.388(5) Å and 1.394(2) Å. These are slightly shorter than those in **12** and **13** (average of 1.415 and 1.426 Å)[17][18] and correspond, within the limits of significance, to the values determined for mes(Me$_2$N)B−B(NMe$_2$)mes (1.40 Å)[12]. It is interesting to note that the B−N bond lengths to the aromatic pyrrole ligands in compound **5** are significantly longer [1.434(4) and 1.438(4) Å] compared to those in the non-aromatic analogues mes$_2$B$_2$(NMe$_2$)$_2$[12] and mes$_2$B$_2$(NH*t*Bu)$_2$ **6**.

As expected, the boron atoms reside in planar environments (sum of bond angles = 360°). Nevertheless, although the NBC$_{mes}$ bond angles of the bis(dimethylamino)- as well as the dimesityldipyrrolyldiborane(4) are all 120 ± 2.5°, in compound **6** this angle is widened to 126.7° due to the steric repulsion between the mesityl and *tert*-butylamino groups. Consequently, the B−B−N bond angle in **6** is reduced to 114.9°. It is quite interesting that compounds **3** and **6** exhibit point group symmetry C_i in the solid state and thus possess planar $C_2B_2N_2$ skeletons. Normally, diborane(4) derivatives show a dihedral angle between the two planes at the boron atoms in the range 60−80°. It seems that only packing effects are responsible for the conformation in the solid state, because no intermolecular interactions between the molecules other than van der Waals contacts are detectable.

A comparison of the crystal structures of mes$_2$B$_2$(OMe)$_2$ (**7**)[11] and mes$_2$B$_2$(O*t*Bu)$_2$ (**8**) reveals no significant differences in the B−B, B−O, and B−C bond lengths. The B−B bonds are only marginally longer than in the tetraalkoxy-substituted diborane(4) **14** [1.711(6) Å][19], but are significantly longer compared to those in compounds **15a** and **15b**, where the B−B bond lengths are 1.687(3) and 1.684(3), respectively[20]. The B−O bonds of **8** [1.348(6) and 1.366(7) Å] are intermediate between single and double bond lengths (1.46 and 1.26 Å)[21], indicating partial B−O π-bonding[22][23]. In comparison, the B−O bonds in mes$_2$B(OMe) (1.352 Å)[23] and compound **16** (average 1.367 Å)[24] are equally long, while in the triborane(5) derivative **17** a value of 1.396(5) Å is observed[25]. Due to enhanced steric repulsion between the *tert*-butyloxy group and the mesityl ligand, the OBC$_{mes}$ angles in **8** are widened to 128° compared with the corresponding bond angles in the methoxy derivative **7** [121.9(5)° and 123.2(5)°][11]. B−B−O and B−B−C$_{mes}$ bond angles are smaller (114.8−116.9°) as the sum of the bond angles around each boron atom is 360°. Most probably as a result of the aforementioned steric repulsion, the B−O−C$_{t\mathrm{Bu}}$ angles in **8** are even wider (131°) than the B−O−C$_{Me}$ angles in **7** (121° and 123.4°) and mes(OMe)B−Bmes$_2$ [125.0(9)°][11], but are very similar to that in compound **17** [130.7(4)°][25].

The mercaptodiborane(4) mes(*t*BuS)B−B(S*t*Bu)mes (**10**) exhibits a B−B bond length of 1.712(6) Å, which is intermediate between the corresponding bond lengths of the amino-substituted B−S heterocycles **18** [1.72(1) Å] and **19** [1.66(1) and 1.69(1) Å][26]. The B−S distance in **10** was found to be 1.771(4) Å, which is intermediate between a

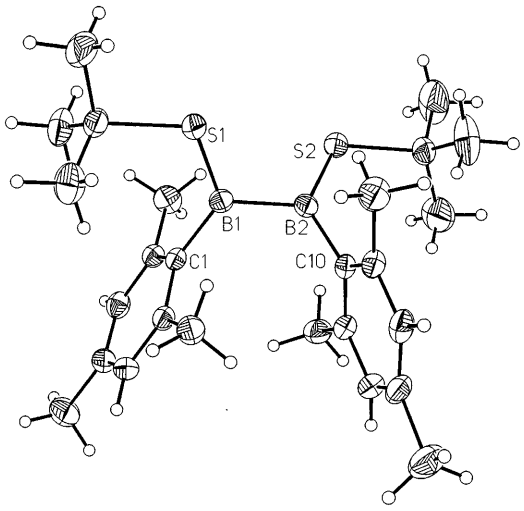
[a] Selected bond angles [°]: O1−B1−C1 128.1(4), O1−B1−B2 116.9(4), C1−B1−B2 114.9(4), O2−B2−C10 128.2(4), O2−B2−B1 114.8(5), C10−B2−B1 116.9(4), B1−O1−C19 130.7(3), B2−O2−C23 131.0(4).

B−S single bond (1.89 Å) and a B−S double bond (1.69 Å)[21]. Similar B−S bond lengths were observed in the trithiadiborolanes $(MeB)_2S_3$ (1.803 Å)[27a] and $(ClB)_2S_3$ (1.794 Å)[27b], as well as in the tris(methylthio)borane $B(SMe)_3$ (1.805 Å)[28], where partial S−B π-bonding is discussed. Furthermore, the B−S bond length in **10** matches very well those found in the acyclic derivatives mes_2BSMe [1.787(6) Å][23] and mes_2BSPh [1.790(6) Å][29], as well as in compounds **20** [1.799(6) and 1.802(6) Å][30] and **21** (average 1.80 Å)[30]. In molecules with less B−S π-bond character, such as the triborane(5) **22**, the B−S bonds are noticeably longer [1.864(2) and 1.849(2) Å][25].

The $S-B-C_{mes}$ angles are on average 128.5° and are thus of the same order as those in the *tert*-butyloxy analogue **8**,

Figure 5. ORTEP representation of the molecular structure of **10**; esd′s in parentheses; thermal ellipsoids are represented at a 25% probability level[a]



[a] Selected bond angles [°]: C1−B1−B2 118.0(3), C1−B1−S1 127.6(3), B2−B1−S1 114.4(3), C10−B2−B1 115.5(3), C10−B2−S2 129.4(3), B1−B2−S2 115.1(3), B1−S1−C19 114.0(2), B2−S2−C23 114.1(2).

but the B−B−S and $B-B-C_{mes}$ angles are smaller (114.4° and 118.0°, respectively). Owing to the steric repulsion between the mesityl ligand and the *tert*-butyl group, the $B-S-C_{tBu}$ angles in **10** are larger (114°) than those in $mes_2B(SMe)$ (109.8°)[23] or in the derivatives **20**−**23**, where B−S−R angles in the range 104.8−107.3° were measured[25][29][30].

The mesityl rings adopt an orientation almost perpendicular to the plane around the boron centers. This is a common feature of all the newly studied compounds.

The crystal structures of the dihalogenodimesityldiborane(4) compounds reveal some interesting characteristics. Among all studied diborane(4) compounds, they exhibit the shortest B−B bonds. With an average of 1.67 Å, they are at the lower end of the range for B−B single bonds and, within the series, an interesting trend is observed (Table 2). Surprisingly, the bond lengths vary in a manner opposite to what might have been expected. As the covalent radius of the halogen atom increases on going from chlorine to iodine, the

Figure 6. ORTEP representation of the molecular structure of **1a**; esd's in parentheses; thermal ellipsoids are represented at a 25% probability level

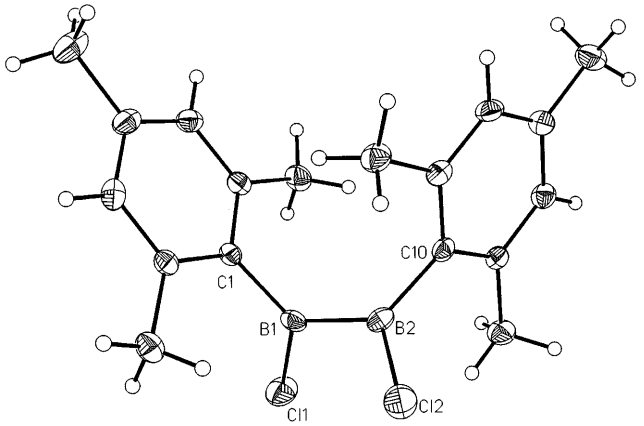

Figure 7. ORTEP representation of the molecular structure of **1b**; esd's in parentheses; thermal ellipsoids are represented at a 25% probability level

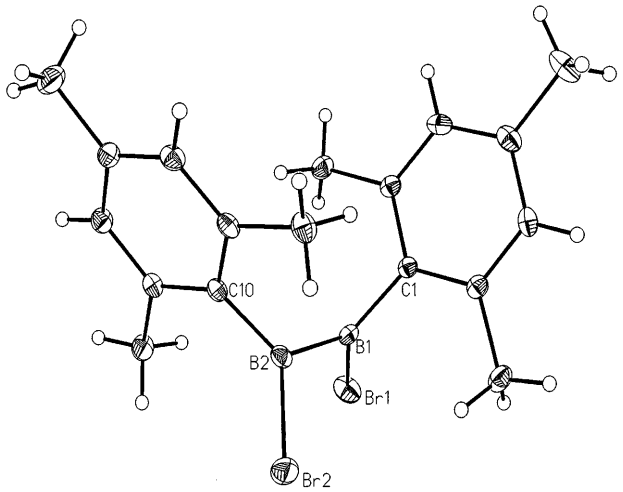

Figure 8. ORTEP representation of the molecular structure of **1c**; esd's in parentheses; thermal ellipsoids are represented at a 25% probability level

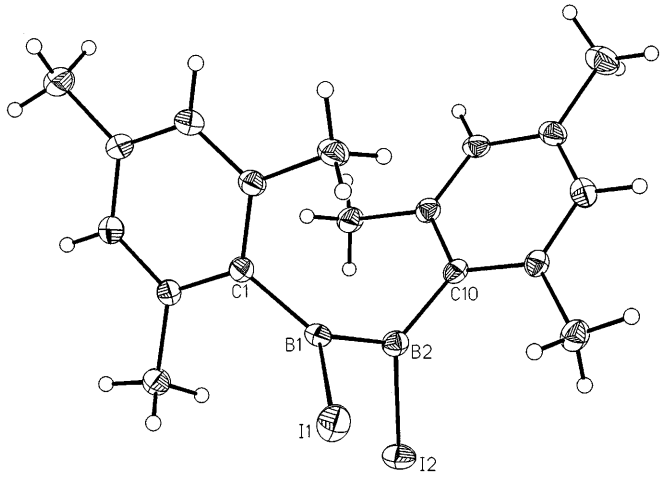

B−B distances *decrease*. This shrinkage is contrary to expectation in terms of the *−I* effect of the halogen atoms, but fits the Lewis acidity scale of the boron halides. We regard this as further experimental evidence that π-bonding at boron halides decreases on ascending the series F > Cl > Br > I, with the consequence that in most cases the iodides are the most Lewis acidic compounds among such species. Moreover, electron diffraction experiments on the tetrahalodiboranes(4) B_2Cl_4[31] and B_2Br_4[32] show the same trend and lengths 1.70(7) Å and 1.69(2) Å], although these distances have large standard errors associated with them and do not differ significantly. At 1.68(2) Å[12], the B−B bond length in $(Me_2N)_2B_2Br_2$ fits very well into this series. The B−Cl bond lengths in **1a** (see Table 2) are significantly shorter than those observed for compounds **23**[33] [1.790(4) Å, 1.805(4) Å] and **24**[33] [1.814(5) Å]. This implies partial π-bond character. In comparison, the B−Cl bond lengths in the tetraborane(6) derivative **25**[25] are 1.809(5) Å for the terminal boron atom of the tetraborane chain and 1.870(4) Å for the di(aminoboryl) subunit. The same trend, i.e. a short B−Hal bond length, is also observed in B_2Br_4. The B−Br bond lengths in **1b** [1.928(4) Å, 1.932(4) Å] are obviously short, since a single bond would be expected to have a length of 1.99 Å [atomic radii of boron (0.85 Å) and bromine (1.14 Å)[21]], as observed in $(Me_2N)_2B_2Br_2$[12] [1.97(1) Å and 1.99(1) Å] and in compound **26**[25] [1.99(1) Å and 2.00(1) Å]. Even $mes_2B_2I_2$ exhibits a B−I bond length (average 2.16 Å) that is slightly smaller than the sum of the atomic radii[21] (0.85 Å and 1.33 Å, giving 2.18 Å). In this respect, it is interesting to note that the diiodotriborane(5) derivative **27** has longer B−I bonds [2.224(6) and 2.237(6) Å][25], which seems to be due to the presence of the amino groups.

However, all the halogen derivatives **1a**−**1c** show the common feature of shorter $B-C_{mes}$ bonds compared to the compounds listed in Table 1. In all cases, the mesityl rings are almost orthogonally orientated with respect to the plane at the boron atom. Furthermore, irrespective of the nature of the halogen atom, compounds **1a**−**1c** exhibit an X−B−B−X dihedral angle of 71°.

Conclusions

A comparison of the chemistry of *B*,*B'*-di-*tert*-butyldiboranes(4) with that of *B*,*B'*-dimesityldiboranes(4) reveals the higher stability of the latter compounds. This is particularly evident for the dihalides $mes_2B_2X_2$ (X = Cl, Br, I) and $tBu_2B_2X_2$. Because there is *no* significant electronic contribution to stabilize the B−B bond by decreasing the electron deficiency at the boron atoms by X by B−C π-bonding, it is evident that the stability of $R_2B_2Y_2$ compounds with respect to dismutation into B^I and B^{III} species is kinetically but not thermodynamically controlled. This is also supported by the geometry of the structure of *B*,*B'*-dimesityldiborane(4) in the solid state, because possible π-overlap as in 1,4-butadienes is prevented by an almost orthogonal arrangement of the CB(B)Y planes and the C_3B plane to the B(C)B(Y) plane. All the structural and chemical evidence collected for diborane(4) derivatives indicates that the B−B bond lengths are primarily determined by the character of the group Y. Thus, it appears that kinetically stable tetraorganyldiboranes B_2R_4 can be prepared with bulky groups R,

as verified for $B_2(tBu)_3SiMe_3$[6] and similar compounds. The former may be used to generate $B_2H_2(tBu)SiMe_3$, an unstable molecule that may be used to determine whether hydroboration or diboration prevails in kinetic experiments.

We are grateful to the *Fonds der Chemischen Industrie* and the *Chemetall GmbH* for support of our research, and to the technical staff at the *Institute of Inorganic Chemistry* for recording NMR, IR and mass spectra, as well as for performing elemental analyses.

Experimental Section

Schlenk techniques were used in all experiments with nitrogen gas as a blanket. Solvents were dried by standard procedures. Commercial chemicals were purified before use as necessary. Literature procedures were employed for the preparation of $B_2(NMe_2)_4$[3][4], $(Me_2N)_2B_2Cl_2$[4], $mes_2B_2(NMe_2)_2$[13], $mes_2B_2(OMe)_2$[13], and $mes_2B_2Cl_2$[13]. − NMR: Bruker AC-P 200 (^{11}B), Jeol GSX 270 (^1H, ^{13}C); standards: int. TMS, ext. $BF_3{\cdot}OEt_2$. − IR: Perkin-Elmer 325. − MS: Varian CH7 (70 eV). − X-ray analyses: Siemens P4 and Nicolet R3m diffractometer, Mo-K_α radiation, graphite monochromator.

B,B′-Dibromo-B,B′-dimesityldiborane(4) (**1b**): To a stirred suspension of $mes_2B_2(OMe)_2$ (510 mg, 1.6 mmol) in 60 ml of hexane at −30°C was added BBr_3 (1.00 g, 3.99 mmol, 0.38 ml). The reaction mixture was allowed to warm to 0°C and was kept at this temperature for at least 1 h. A clear, light-yellow solution resulted. The solution was stored at −20°C overnight, and then concentrated to a volume of about 20 ml. At −20°C, yellow crystals of $mes_2B_2Br_2$ (**1b**) separated (450 mg, 1.1 mmol). A second crop of **1b** was isolated by reducing the volume of the solution still further. Total yield: 0.53 g (80%); m.p. 98−101°C. **1b** can be stored under an inert atmosphere at low temperatures (< −20°C) for several months without decomposition. Even in solution at −20°C, **1b** is stable for weeks, while at ambient temperature it decomposes readily into $mesBBr_2$ ($\delta^{11}B$ = 62.8) and other boron-containing compounds [$\delta^{11}B$ = 42.5, 30 (br.), −6]. − NMR (C_6D_6): δ^1H = 2.05 (s, 6 H, *p*-CH_3), 2.18 (s, 12 H, *o*-CH_3), 6.58 (s, 4 H, *m*-H). − $\delta^{11}B$ = 86 ($h_{1/2} \approx$ 1000 Hz). − $\delta^{13}C$ = 21.1 (*p*-CH_3), 22.3 (*o*-CH_3), 127.8 (*m*-C), 135.7 (*o*-C), 139.3 (*p*-C), *ipso*-C signal not obsd. − $C_{18}H_{22}B_2Br_2$ (419.80): calcd. C 51.50, H 5.28; found C 51.20, H 5.13.

B,B′-Diiodo-B,B′-dimesityldiborane(4) (**1c**): To a stirred solution of $mes_2B_2(OMe)_2$ (1.21 g, 3.76 mmol) in 40 ml of hexane, a solution of BI_3 (3.51 g, 8.94 mmol, 19% excess) in hexane (60 ml) was added at 0°C with the exclusion of light. After stirring for 2 h at this temperature, an ^{11}B-NMR spectrum showed the signals of excess BI_3 ($\delta^{11}B$ = −7.5), of $(MeO)BI_2$ ($\delta^{11}B$ = 6.5), and of $mes_2B_2I_2$ ($\delta^{11}B$ = 89). Insoluble material was then removed by filtration and the filtrate was stored at −20°C overnight. A small amount of $mes_2B_2I_2$ (**1c**) was obtained in the form of yellow crystals, suitable for X-ray diffraction. Fractional crystallization by reducing the volume of the solution in a stepwise manner to about 30 ml, provided additional **1c**. Yield: 1.32 g (2.57 mmol, 68%); m.p. ca. 89°C (decomp.). − NMR (C_6D_6): δ^1H = 2.08 (s, 6 H, *p*-CH_3), 2.21 (s, 12 H, *o*-CH_3), 6.59 (s, 4 H, *m*-H). − $\delta^{11}B$ = 89. − $\delta^{13}C$ = 21.1 (*p*-CH_3), 23.0 (*o*-CH_3), 128.5 (*m*-C), 134.1 (*o*-C), 139.3 (*p*-C), *ipso*-C signal not obsd. − $C_{18}H_{22}B_2I_2$ (513.78): calcd. C 42.08, H 4.32; found C 40.20, H 4.36.

B,B′-Dimesityl-B,B′-bis(methylamino)diborane(4) (**2**): At −30°C, methylamine (3.0 ml, 68 mmol) was condensed into a stirred solution of $mes_2B_2Cl_2$ (1.80 g, 5.44 mmol) in 50 ml of hexane, resulting in the immediate precipitation of methylammonium chloride. The reaction mixture was allowed to warm to ambient temp. while stirring overnight. After separation of the solid (0.88 g, 119% "$[MeNH_3]Cl$"), the solvent and all volatile materials were removed in vacuo. The residue was treated with 50 ml of hexane, and insoluble material was removed by centrifugation for 10 min (1200 rpm). The clear solution was then stored at −78°C, whereupon **2** precipitated as a white solid. Yield: 1.55 g (4.84 mmol, 89%). Within 2 d, **2** crystallized in the form of colorless cubes in an NMR tube, m.p. 190°C. − NMR ($CDCl_3$): δ^1H = 2.17 (s, 12 H, *o*-CH_3), 2.30 (s, 6 H, *p*-CH_3), 2.49 (d, 6 H, NMe, $^3J_{HH}$ = 8 Hz), 4.7 (br., 2 H, NH), 6.81 (s, 4 H, *m*-H). − $\delta^{11}B$ = 48.3. − $\delta^{13}C$ = 21.2 (*p*-CH_3), 21.7 (*o*-CH_3), 31.4 (NMe), 127.0 (*m*-C), 135.7 (*p*-C), 138.4 (*o*-C), *ipso*-C signal not obsd. − $C_{20}H_{30}B_2N_2$ (320.10): calcd. C 75.05, H 9.45, N 8.75; found C 74.66, H 9.31, N 8.22.

B,B′-Di(benzylamino)-B,B′-dimesityldiborane(4) (**3**): $mes_2B_2Cl_2$ (1.77 g, 5.35 mmol) was dissolved in 60 ml of pentane and the flask was placed in an ice bath. Under stirring, benzylamine (2.50 ml, 2.46 g, 22.9 mmol) was added, resulting in the immediate precipitation of benzylammonium chloride. The suspension was allowed to warm to ambient temp., and then stirring was continued for a further 4 h. The insoluble material was then removed by filtration (1.98 g), and the filtrate was concentrated to dryness in vacuo. Since the residue was found to be moderately soluble in pentane and hexane, it was treated with a few mls of pentane and the solid was recovered by filtration. After drying in vacuo, **3** was obtained as a white powder (1.20 g, 2.54 mmol, 47%), essentially pure on the basis of its NMR spectra. Recrystallization from 5 ml of diethyl ether gave colorless crystals, suitable for X-ray diffraction; m.p. 115−117°C. − NMR ($CDCl_3$): δ^1H = 2.26 (s, 12 H, *o*-CH_3), 2.30 (s, 6 H, *p*-CH_3), 4.08 (d, 4 H, CH_2, $^3J_{HH}$ = 7.3 Hz), 5.16 (t, 2 H, NH), 6.82 (s, 4 H, *m*-H), 7.14−7.27 (m, 10 H, Ph). − $\delta^{11}B$ = 47.9 ($h1/2 \approx$ 980 Hz). − $\delta^{13}C$ = 21.1 (*p*-CH_3), 22.0 (*o*-CH_3), 49.0 (CH_2), 126.5 (*m*-mes), 126.8 (*p*-Ph), 127.0 (*o*-Ph), 128.2 (*m*-Ph), 135.7 (*p*-mes), 138.2 (*o*-mes), 141.2 (*ipso*-Ph), *ipso*-mes signal not obsd. − $C_{32}H_{38}B_2N_2$ (472.29): calcd. C 81.38, H 8.11, N 5.93; found C 80.98, H 8.00, N 5.84.

B,B′-Di(isopropylamino)-B,B′-dimesityldiborane(4) (**4**): $mes_2B_2Cl_2$ (1.37 g, 4.14 mmol) was dissolved in 30 ml of hexane and the solution was cooled to −35°C. To the stirred solution, a suspension of iPr_2NLi (0.54 g, 8.27 mmol) in 20 ml of hexane was added. After allowing the mixture to warm to ambient temp. overnight, the insoluble material (LiCl) was removed by filtration. The filtrate was then concentrated in vacuo to a volume of about 20 ml. Compound **4** separated as a white solid at −50°C. Yield: 1.34 g (3.56 mmol, 86%); m.p. 185°C. − NMR ($CDCl_3$): δ^1H = 0.91 (d, 12 H, CH*Me*, $^3J_{HH}$ = 8 Hz), 2.18 (s, 12 H, *o*-CH_3), 2.31 (s, 6 H, *p*-CH_3), 3.12 (sept, 2 H, C*H*Me), 4.55 (d, 2 H, NH), 6.80 (s, 4 H, *m*-H). − $\delta^{11}B$ = 46.3. − $\delta^{13}C$ = 21.2 (*p*-CH_3), 22.0 (*o*-CH_3), 25.5 (CH*Me*), 46.1 (*C*HMe), 126.8 (*m*-C), 135.2 (*p*-C), 138.4 (*o*-C), 141.0 (*ipso*-C, low intensity). − $C_{24}H_{38}B_2N_2$ (376.20): calcd. C 76.63, H 10.18, N 7.45; found C 76.77, H 10.50, N 7.23.

B,B′-Dimesityl-B,B′-dipyrrolyldiborane(4) (**5**): To a solution of $mes_2B_2(OMe)_2$ (2.04 g, 6.17 mmol) in 50 ml of toluene at 0°C, was added a suspension of pyrLi (0.90 g, 12.3 mmol) in 20 ml of hexane. The reaction mixture was stirred overnight at ambient temp. All solid material was then removed by filtration (0.58 g), the filtrate was concentrated to a volume of 15 ml in vacuo, and cooled to −20°C. Colorless crystals, suitable for X-ray diffraction were obtained after recrystallization from *n*-hexane. Yield: 5.1 g, (2.0 mmol, (82%); m.p. 148−150°C. − NMR ($CDCl_3$): δ^1H = 1.90 (s, 12 H, *o*-CH_3), 2.30 (s, 6 H, *p*-CH_3), 6.41, 6.53 (each m, 4 H, $H_{2,3}$-

$_{pyr}$), 6.74 (s, 4 H, *m*-H), 6.81, 7.25 (each m, 4 H, $H_{1,4\text{-pyr}}$). − $\delta^{11}B$ = 60 ($h_{1/2} \approx 1500$ Hz). − $\delta^{13}C$ = 21.1 (*o*-CH_3), 21.7 (*p*-CH_3), 114.8, 115.6 (pyr-C-3, -C-4), 126.9, 127.1 (pyr-C-2, -C-5), 129.6 (*m*-C_{mes}), 137.2 (*o*-C_{mes}), 137.6 (*p*-C_{mes}), 138.2 (*ipso*-C_{mes}, br. low intensity). − $C_{26}H_{30}B_2N_2$ (392.16): calcd. C 79.63, H 7.71, N 7.14; found C 79.39, H 7.68, N 7.00.

B,B′-Di(tert-butylamino)-B,B′-dimesityldiborane(4) (**6**): $mes_2B_2(OMe)_2$ (0.86 g, 2.7 mmol) was dissolved in 25 ml of hexane and 15 ml of diethyl ether. A suspension of *t*BuNHLi (0.42 g, 5.3 mmol) was added at 0°C, and the resulting mixture was stirred at ambient temp. for 2 d. The reaction was completed by heating the suspension for 4 h. The insoluble material (0.25 g) was removed by filtration and the filtrate was concentrated to a volume of 25−30 ml. After 5 d, colorless crystals separated. A second crop of **6** was isolated after storage of the mother liquor at −20°C for 2 weeks. Total yield: 0.75 g (1.9 mmol, 70%); m.p. 194−195°C. − NMR (C_6D_6): δ^1H = 0.91 (s, 18 H, CMe_3), 2.25 (s, 6 H, *p*-CH_3), 2.40 (s, 12 H, *o*-CH_3), 4.99 (s, 2 H, NH), 6.88 (s, 4 H, *m*-H). − $\delta^{11}B$ ($CDCl_3$) = 45.3. − $\delta^{13}C$ (C_6D_6) = 21.3 (*o*-CH_3), 22.9 (*p*-CH_3), 31.6 (CMe_3), 52.9 (CMe_3), 127.7 (*m*-C), 135.4 (*p*-C), 137.3 (*o*-C), *ipso*-C signal not obsd. − $C_{26}H_{42}B_2N_2$ (404.26): calcd. C 77.25, H 10.47, N 6.93; found C 77.08, H 10.40, N 6.92.

B,B′-Di(tert-butyloxy)-B,B′-dimesityldiborane(4) (**8**): Dichlorodimesityldiborane(4) (0.90 g, 2.7 mmol) was dissolved in 40 ml of hexane. At −35°C, a suspension of NaO*t*Bu (0.52 g, 5.4 mmol) in 30 ml hexane was added to the stirred solution. Stirring was continued overnight, while the mixture was allowed to reach ambient temp. The insoluble material (0.34 g) was removed by filtration and the filtrate was kept at −20°C, resulting in the deposition of 0.83 g of **8** (2.05 mmol, 75%) in the form of cubic crystals within 1 d; m.p. 158−162°C. − NMR (C_6D_6): δ^1H = 1.27 (s, 18 H, $OCMe_3$), 2.00 (s, 12 H, *o*-CH_3), 2.23 (s, 6 H, *p*-CH_3), 6.63 (s, 4 H, *m*-H). − $\delta^{11}B$ = 57.0. − $\delta^{13}C$ = 21.1 (*p*-CH_3), 22.1 (*o*-CH_3), 30.8 ($OCMe_3$), 77.4 ($OCMe_3$), 126.8 (*m*-C), 135.6 (*p*-C), 136.8 (*o*-C), *ipso*-C signal not obsd. − MS (70 eV); *m/z* (%): 406 (2) [$M^{\bullet+}$], 349 (100) [$M^{\bullet+}$ − *t*Bu], 333 (27) [$M^{\bullet+}$ − O*t*Bu], 173 (90) [$M^{\bullet+}$ − *t*Bu − C_4H_8 − mesH], 147 (85) [$M^{\bullet+}$ − *t*Bu − C_4H_8 − OBmes]. − $C_{26}H_{40}B_2O_2$ (406.23): calcd. C 76.88, H 9.93; found C 75.06, H 9.52.

B,B′-Dimesityl-B,B′-di(phenylthio)diborane(4) (**9**): (a) To a stirred solution of $mes_2B_2Cl_2$ (1.20 g, 3.66 mmol) in 35 ml of hexane at −30°C, was added a mixture of thiophenol (0.81 g, 7.3 mmol) and triethylamine (0.74 g, 7.3 mmol, 1.01 ml), dissolved in 10 ml of hexane. A voluminous white precipitate of [Et_3N·HCl] formed immediately. To allow better stirring, the reaction mixture was quickly warmed to 0°C and 20 ml of benzene was added. After stirring overnight, the solid was removed by filtration (0.96 g, 95% [Et_3NH]Cl), and the filtrate was concentrated to dryness in vacuo. After adding 20 ml of hexane to the residue, insoluble material was removed by filtration. Cooling the clear filtrate to −20°C yielded 0.70 g of **9** (1.46 mmol, 40%).

(b) To a stirred solution of $mes_2B_2Cl_2$ (0.89g, 2.96 mmol) in 30 ml of hexane at −35°C was added a suspension of LiSPh (0.69 g, 5.9 mmol) in 20 ml of hexane. The reaction mixture was allowed to warm to ambient temp. and then stirred overnight. The white precipitate (0.30 g, 120% "LiCl") was removed by filtration and the filtrate was concentrated to a volume of approximately 30 ml. Storing this solution at −50°C yielded a colorless crystalline mass within 3 d, which was collected and dried in vacuo. The crystals turned slightly yellowish, but no decomposition was detectable. Yield 0.96 g (2.01 mmol, 68%); m.p. 58−62°C. − NMR ($CDCl_3$): δ^1H = 1.95 (s, 12 H, *o*-CH_3), 2.13 (s, 6 H, *p*-CH_3), 6.54 (s, 4 H, *m*-H), 7.0−7.12 (m, 10 H, Ph). − $\delta^{11}B$ = 80.6. − $\delta^{13}C$ = 21.0 (*p*-CH_3), 22.0 (*o*-CH_3), 126.9 (*m*-C_{mes}), 127.3 (*p*-C_{Ph}), 128.3 (*o*-C_{Ph}), 131.2 (*m*-C_{Ph}), 134.0 (*i*-C_{Ph}), 135.6 (*o*-C_{mes}), 136.6 (*p*-C_{mes}), 137.8

(*i*-C_{mes}). – $C_{30}H_{32}B_2S_2$ (478.34): calcd. C 75.33, H 6.74, S 13.41; found C 75.04, H 6.74, S 13.45.

B,B′-Di(tert-butylthio)-B,B′-dimesityldiborane(4) (**10**): To a solution of $mes_2B_2Cl_2$ (1.62 g, 4.89 mmol) in 70 ml of hexane at −40°C was added a suspension of Li*S*t*B*u (0.94 g, 9.8 mmol) in 30 ml of hexane. The reaction mixture was stirred overnight while it warmed to ambient temp. The insoluble material (0.49 g, 118% "LiCl") was filtered off, and the light-yellow filtrate was stored at −20°C. Colorless, rectangular crystals of **10** separated. On concentrating the solution still further to less than half of its original volume, a second crop of **10** was obtained. Total yield: 1.80 g (84%); m.p. 183−185°C. – NMR ($CDCl_3$): δ^1H = 1.24 (s, 18 H, CMe_3), 1.91 (s, 12 H, *o*-CH_3), 2.23 (s, 6 H, *p*-CH_3), 6.65 (s, 4 H, *m*-H). – $\delta^{11}B$ = 77.0. – $\delta^{13}C$ = 21.0 (*p*-CH_3), 22.3 (*o*-CH_3), 32.0 (CMe_3), 49.2 (CMe_3), 127.1 (*m*-C), 135.7 (*o*-C), 136.3 (*p*-C), *ipso*-C signal not obsd. – MS (70 eV); *m/z* (%): 438 (11) [$M^{\bullet+}$], 381 (26) [$M^{\bullet+}$ − *t*Bu], 324 (100) [$M^{\bullet+}$ − 2 *t*Bu], 219 (10) [mesBS*t*Bu$^+$], 162 (100) [mesBS$^{\bullet+}$]. – $C_{26}H_{40}B_2S_2$ (438.36): calcd. C 71.24, H 9.42, S 14.63; found C 71.08, H 8.92, S 13.70.

2,3-Dimesityl-1,4,2,3-dithiadiborinane (**11**): To a solution of $mes_2B_2Cl_2$ (1.00 g, 3.02 mmol) in 40 ml of hexane at −35°C was added a suspension of dilithium ethanedithiolate (0.32 g, 3.0 mmol) in 30 ml of hexane. The reaction mixture was allowed to warm to ambient temp. and stirring was continued overnight. The white precipitate (0.28 g, 109% "LiCl") was separated, and the filtrate was concentrated to dryness in vacuo. The yellow residue was treated with 30 ml of hexane, centrifuged for 10 min (1200 rpm), and the clear solution was stored at −20°C. Within 3 d, a yellow crystalline mass had formed, which was separated and dried in vacuo. Yield: 0.43 g of **11** (1.2 mmol, 40%), m.p. 115−118 °C. – NMR ($CDCl_3$): δ^1H = 2.17 (s, 6 H, *p*-CH_3), 2.20 (s, 12 H, *o*-CH_3), 2.55 (s, 4 H, CH_2), 6.71 (s, 4 H, *m*-H). – $\delta^{11}B$ = 69.4. – $\delta^{13}C$ = 21.1 (*p*-CH_3), 22.5 (*o*-CH_3), 30.5 (CH_2), 127.8 (*m*-C), 136.6 (*p*-C), 137.0 (*o*-C), *ipso*-C signal not obsd. – $C_{20}H_{26}B_2S_2$ (352.18): calcd. C 68.21, H 7.44, S 18.21; found C 68.33, H 7.78, S 17.26.

X-ray Structure Determinations: Single crystals were either sealed in glass capillaries under argon or were covered and mounted with perfluoroether oil on glass fibres. The setting angles of 15−20 well-centered reflections were used for the determination of the dimensions of the unit cells (Siemens P4) or the data on 60 frames collected with a Siemens P4 instrument equipped with a CCD detector. Data collection was performed by using a graphite monochromator and Mo-K_α radiation, either in the ω/2θ scan mode with variable scan speed, or in the hemisphere mode with 10 s exposures per frame and Δω = 0.3. Data reduction was performed by applying Lorentz and polarization corrections or with the SAINT routine. The structures were solved by direct methods; non-hydrogen atoms were refined anisotropically and, unless stated otherwise, H atoms were refined in calculated positions using a riding model. Programs used: SHELXTL-PC plus[34] and SHELXL-93/97[35]. A summary of the data is given in Table 3. Crystallographic data have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-102212 (**5**), -102213 (**6**), -102214 (**3**), -102211 (**8**), -102210 (**10**), -102209 (**1a**), -102208 (**1b**), -102207 (**1c**). Copies of the data can be obtained free of charge on application to CCCD, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) +44-1223/336033; E-mail: deposit@ccdc.cam.ac.uk].

Keywords: Ab initio calculations / Mass spectrometry / Gas-phase chemistry / Ammonia oxide / Hydroxylamine

Mass-spectrometric experiments were combined with ab initio calculations to explore the cationic and neutral $[H_3,N,O]^{\bullet+/0}$ potential energy surfaces and relevant anionic species. The calculations predict the existence of three stable cationic and neutral $[H_3,N,O]^{\bullet+/0}$ isomers, i.e. ammonia oxide $H_3NO^{\bullet+/0}$ ($\mathbf{1}^{\bullet+/0}$), hydroxylamine $H_2NOH^{\bullet+/0}$ ($\mathbf{2}^{\bullet+/0}$) and the imine-water complex $HNOH_2^{\bullet+/0}$ ($\mathbf{3}^{\bullet+/0}$). Hydroxylamine **2** represents the most stable isomer on the neutral surface (E_{rel} = 0), and the metastable isomers **1** (E_{rel} = 24.8 kcal mol^{-1}) and **3** (E_{rel} = 61.4 kcal mol^{-1}) are separated by barriers of 49.5 kcal mol^{-1} and 64.2 kcal mol^{-1}, respectively. Adiabatic ionization of **2** (IE_a = 9.15 eV) yields $\mathbf{2}^{\bullet+}$, which is 21.4 kcal mol^{-1} more stable than $\mathbf{1}^{\bullet+}$ and 36.4 kcal mol^{-1} more stable than $\mathbf{3}^{\bullet+}$. The barriers associated with the isomerizations of the cations are 58.6 kcal mol^{-1} for $\mathbf{2}^{\bullet+} \rightarrow \mathbf{1}^{\bullet+}$ and 71.4 kcal mol^{-1} for $\mathbf{2}^{\bullet+} \rightarrow \mathbf{3}^{\bullet+}$. Collisional activation (CA) and unimolecular decomposition (MI) experiments allow for a clear distinction of $\mathbf{1}^{\bullet+}$ from $\mathbf{2}^{\bullet+}$. Besides, neutralization/reionization (NR) experiments strongly support the gas-phase existence of the long-sought neutral ammonia oxide.

Introduction

The generation of ammonia oxide (**1**) represents a major challenge to experimentalists working in the field of elusive molecules, as there is a striking discrepancy between the numerous quantum chemical studies,[1] which predict a distinct stability of the molecule, and the still scarce experimental evidence.[2] Moreover, it has recently been stated that "the *possible* characterization of two metastable isomers of hydroxylamine ... would be a significant step forward towards the understanding of important aspects of N/O/H chemistry."[2a]

The fact that homologs of **1** like trialkylamine oxides are well-known, storable compounds indicates that the atom connectivity R_3N-O is not inherently unstable. Therefore, for R = H the main problem is to prevent the isomerization of **1** to the more stable hydroxylamine (**2**). This can occur in two ways, i.e. either a unimolecular [1,2]-H shift or a bi- or termolecular acid/base-catalyzed path, of which we presume the latter to be energetically favorable. Such an acid/base-catalyzed isomerization can be circumvented by generating the species of interest in the diluted gas phase of a mass spectrometer. The generation and characterization of several elusive ionic and neutral molecules has been achieved during the last decade by combining advanced mass-spectrometric techniques, like collisional activation (CA) and neutralization/reionization (NR), with appropriate theoretical means.[3][4]

Nowadays, theoretical calculations of small systems, like $[H_3,N,O]$, can achieve an accuracy such that they do complement the experimental results. Therefore, we have performed a series of mass-spectrometric experiments and calculated all relevant structures of the cationic and neutral $[H_3,N,O]$ surfaces with a G2-like ab initio method; also the anionic species are briefly discussed (see below). The neutral surface was reexamined using the same level of theory, as previous theoretical studies did not include the relevant exit channels. For the sake of simplicity and readability, the potential energy surfaces (PES) of the different charge states are calibrated to the respective global minima, which are set to zero (E_{rel} = 0). As all the experiments start from cationic states, the cationic PES will be discussed first.

Theoretical Results

The relative energies of all relevant species of the $[H_3,N,O]^{\bullet+}$ surface are displayed in Table 1. Ionized hydroxylamine ($\mathbf{2}^{\bullet+}$) represents the global minimum (E_{rel} = 0) and possesses a planar structure. Mulliken analysis reveals that the spin density is distributed between the nitrogen (0.80) and the oxygen atom (0.20). This indicates that the unpaired electron is mainly located on the nitrogen atom, but that there is also exchange with the adjacent oxygen lone pairs. As a consequence, the N−O bond length is significantly shortened compared to neutral hydroxylamine (128 pm vs. 144 pm, see below). A [1,2]-H shift from the nitrogen to the oxygen atom requires an energy of 58.6 kcal mol^{-1} and leads to the ammonia oxide cation ($\mathbf{1}^{\bullet+}$), which

[+] Present address: The Skaggs Institute for Chemical Biology, The Scripps Research Institute, 10550 North Torrey Pines Road, La Jolla, CA, 92037, USA.

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1434−1948/98/1010−1529 $ 17.50+.50/0

is a minimum with E_{rel} = 21.4 kcal mol^{-1}. Thus, the calculations suggest that the ammonia oxide cation (**1**$^{\bullet+}$) is trapped in a potential well which may be deep enough to capture **1**$^{\bullet+}$ without facile isomerization to **2**$^{\bullet+}$ or dissociation. With respect to the lowest lying direct exit channel for the dissociation of $[H_3,N,O]^{\bullet+}$, i.e. loss of H$^{\bullet}$ (E_{rel} = 69.7 kcal mol^{-1}), unimolecular isomerization **1**$^{\bullet+}$ ⇌ **2**$^{\bullet+}$ is, however, conceivable. The ammonia oxide cation (**1**$^{\bullet+}$) has C_s symmetry due to a small Jahn-Teller distortion of the C_{3v}-symmetric molecule. The unpaired electron is located on the oxygen atom (spin density = 1.05). In contrast to hydroxylamine, the N−O bond is not shortened, but slightly elongated upon ionization of the neutral **1** (138 pm vs. 135 pm, see below); this can be explained in terms of a diminished electrostatic interaction compared to the neutral $H_3N^+-O^-$ zwitterion. Another minimum structure of $[H_3,N,O]^{\bullet+}$ is obtained by a [1,2]-H shift from the nitrogen to the oxygen atom starting from hydroxylamine. The resulting distonic ion **3**$^{\bullet+}$ (E_{rel} = 36.4 kcal mol^{-1}) can be regarded as an ion-dipole complex between the imine fragment (*IE* = 13.49 eV) and the water cation (*IE* = 12.612 eV).[5] The barrier associated with this [1,2]-H shift (E_{rel} = 71.4 kcal mol^{-1}) implies that the $NH_2OH^{\bullet+}$/$NHOH_2^{\bullet+}$ isomerization is disfavored compared to the $NH_2OH^{\bullet+}$/$NH_3O^{\bullet+}$ equilibrium. Moreover, the exit channel for loss of H$^{\bullet}$ to yield H_2NO^+ **4**$^+$ is lower in energy (E_{rel} = 69.7 kcal mol^{-1}) and has much smaller entropical restrictions than the rearrangement **2**$^{\bullet+}$ → **3**$^{\bullet+}$. Therefore, we expect that $NHOH_2^{\bullet+}$ (**3**$^{\bullet+}$), can hardly be generated by isomerization starting from **1**$^{\bullet+}$ and **2**$^{\bullet+}$ when the $[H_3,N,O]^{\bullet+}$ surface is accessed experimentally. A further proton shift from the nitrogen to the oxygen atom and consecutive fragmentation yields H_3O^+ and N (^4S) as the lowest lying exit channel of the cationic PES (E_{rel} = 49.3 kcal mol^{-1}). However, as H_3O^+ and N (^4S) can only be produced after spin crossing and extensive isomerization, severe kinetic restrictions are imposed on this otherwise thermochemically favorable exit channel.

Cleavage of one of the N−H bonds in ionized hydroxylamine (**2**$^{\bullet+}$) gives H$^{\bullet}$ and *cis*- or *trans*-$HNOH^+$ (**5**$^+$) with E_{rel} = 87.0 kcal mol^{-1} (*trans*) and 93.6 kcal mol^{-1} (*cis*), respectively (Table 2).[6] Further exit channels of $[H_3,N,O]^{\bullet+}$ yield $HNO^{\bullet+}$ (**6**$^{\bullet+}$) and H_2 (E_{rel} = 58.4 kcal mol^{-1}), $NOH^{\bullet+}$ (**7**$^{\bullet+}$) and H_2 (E_{rel} = 73.2 kcal mol^{-1}), or NO^+, **8**$^+$, H_2, and H$^{\bullet}$ (E_{rel} = 77 kcal mol^{-1}). Although these exit channels are low in energy, they are associated with significant activation barriers. Thus, the transition state **TS 1**$^{\bullet+}$**/6**$^{\bullet+}$ for 1,1-elimination of H_2 from **1**$^{\bullet+}$ has a relative energy of 89.5 kcal mol^{-1}, and the transition state **TS 2**$^{\bullet+}$**/7**$^{\bullet+}$ for the analogous 1,1-elimination of H_2 from **2**$^{\bullet+}$ has a relative energy of 92.3 kcal mol^{-1}. Despite an intensive search from several starting geometries, a transition state for a formal 1,2-elimination from **2**$^{\bullet+}$ could not be located. Instead, optimization leads to two transition structures **TS 5**$^+$**/6**$^{\bullet+}$ and **TS 4**$^+$**/6**$^{\bullet+}$, which are featured by linear O−H−H (**TS 5**$^+$**/6**$^{\bullet+}$) and N−H−H (**TS 4**$^+$**/6**$^{\bullet+}$) arrangements. An analysis of the internal reaction coordinate (IRC) reveals that the respective reaction pathways correspond to an attack of a hydrogen atom at H_2NO^+ (**4**$^+$) and at $HNOH^+$ (**5**$^+$), respectively, to yield $HNO^{\bullet+}$ (**6**$^{\bullet+}$) and H_2. Although the barriers associated with these transition structures are comparable to those for **TS 1**$^{\bullet+}$**/6**$^{\bullet+}$ and **TS 2**$^{\bullet+}$**/7**$^{\bullet+}$, it is hard to imagine that **TS 4**$^+$**/6**$^{\bullet+}$ or **TS 5**$^+$**/6**$^{\bullet+}$ can be reached, because instead of a long-range H migration starting from **1**$^{\bullet+}$ or **2**$^{\bullet+}$, an irreversible loss of the migrating hydrogen atom appears to be favored. Therefore, it is suggested that the only ways to produce $HNO^{\bullet+}$/H_2 from $[H_3,N,O]^{\bullet+}$ proceed by 1,1-eliminations (**TS 1**$^{\bullet+}$**/6**$^{\bullet+}$ and **TS 2**$^{\bullet+}$**/7**$^{\bullet+}$). Two different pathways of NO^+ generation from $[H_3,N,O]^{\bullet+}$ are conceivable: Either H_2 elimination to yield $[H,N,O]^{\bullet+}$ precedes H$^{\bullet}$ abstraction, or H$^{\bullet}$ is lost first to yield **4**$^+$ and/or **5**$^+$, which can subsequently be dehydrogenated to NO^+. The calculations predict that the initial H_2 eliminations either from **1**$^{\bullet+}$ or from **2**$^{\bullet+}$ are strongly favored by at least 66.1 kcal mol^{-1} compared to the dehydrogenations of **4**$^+$ and **5**$^+$ (Figure 1). Therefore, it can be concluded that only the pathway involving loss of H_2 followed by loss of H$^{\bullet}$ is relevant for NO^+ production in the present context.

Losses of one or several hydrogen atoms do not reveal information about the connectivity of the $[H_3,N,O]^{\bullet+}$ precursors. For a structural elucidation, fragments arising from cleavage of the N−O bond are decisive: Cleavage of N−O in **2**$^{\bullet+}$ into NH_2^+ ($^3B_1$) and OH$^{\bullet}$ has an energy demand of E_{rel} = 104.0 kcal mol^{-1}, whereas the N−O cleavage of **1**$^{\bullet+}$ to yield O (^3P) and $NH_3^{\bullet+}$ requires E_{rel} = 79.4 kcal mol^{-1}. For **2**$^{\bullet+}$, the calculations predict a competition of two processes: The direct bond cleavage into NH_2^+ ($^3B_1$) and OH$^{\bullet}$ is energetically disfavored, but has probably no kinetic restriction. In contrast, while the production of $NH_3^{\bullet+}$ + O

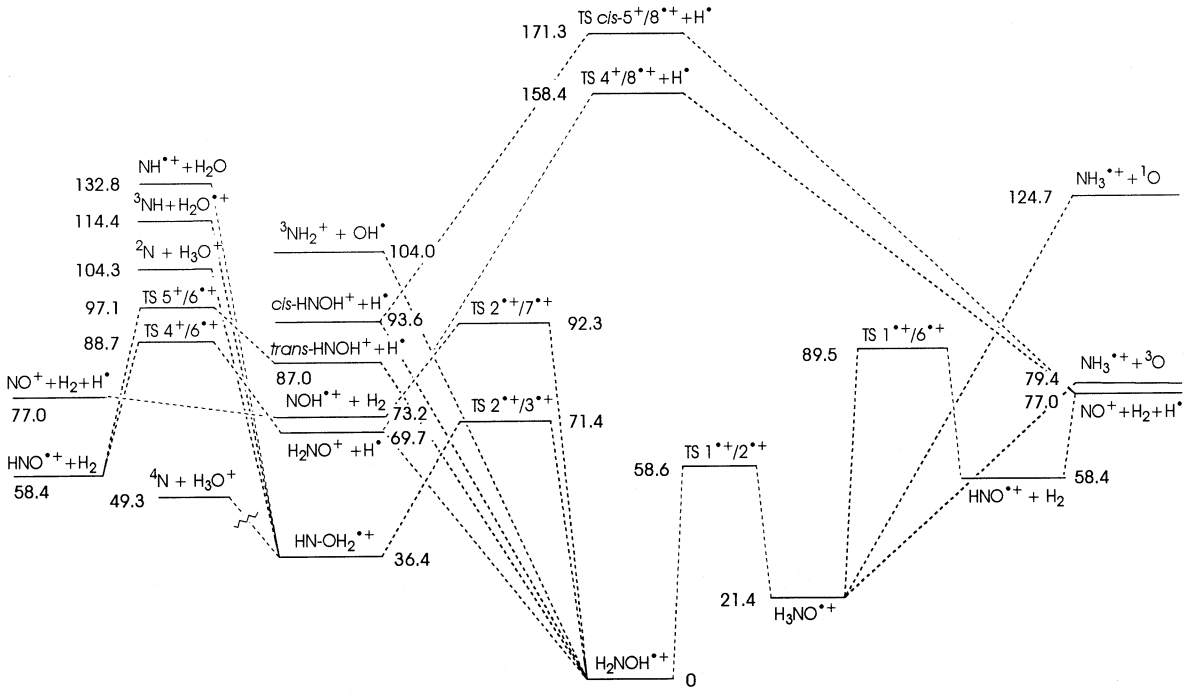
and $NH_3^{\bullet+}$ is favored due to thermochemical *and* kinetic reasons.

The profile of the neutral $[H_3,N,O]$ surface resembles its cationic counterpart as far as the hydroxylamine/ammonia oxide region is concerned. Hydroxylamine (**2**) again represents the global minimum and has two C_s-symmetrical conformers which differ in energy by 4.1 kcal mol^{-1} (E_{rel} = 0 for θ_{HNOH} = 125.1°, E_{rel} = 4.1 kcal mol^{-1} for θ_{HNOH} = 57.4°). Hydroxylamine (**2**) can isomerize to ammonia oxide (**1**) by a [1,2]-H shift with an energy barrier of 49.5 kcal mol^{-1}. **1** lies 24.8 kcal mol^{-1} higher in energy than **2**, but may be captured as a metastable molecule due to the reverse barrier of 24.7 kcal mol^{-1} towards isomerization to **2** and a barrier of 48.9 kcal mol^{-1} associated with fragmentation into HNO and H_2. The N−O bond in **1** is significantly shorter than in **2** (135 pm vs. 144 pm), which can be rationalized with an electrostatic attraction of the zwitterionic **1** and the repulsion of lone pairs in **2**. The two molecules are predicted to differ also in other physical properties such as dipole moments[7] (μ = 5.63 D for **1** and 0.788 D for **2**) or vertical ionization energies[8][9] (IE_v = 9.1 eV for **1** and 10.72 eV for **2**). Two factors are mainly responsible for the fact that vertically ionized hydroxylamine is 36.1 kcal mol^{-1} above the minimum geometry of the cation. First, the minimum-energy conformation of **2**$^{\bullet+}$ is planar, while C_s-symmetrical, neutral **2** has a dihedral HNOH angle of 125°. Secondly, the N−O bond lengths in **2** and **2**$^{\bullet+}$ differ significantly (Figures 3 and 4). In contrast, the geometry changes upon adiabatic ionization of **1** are negligible, and IE_a and

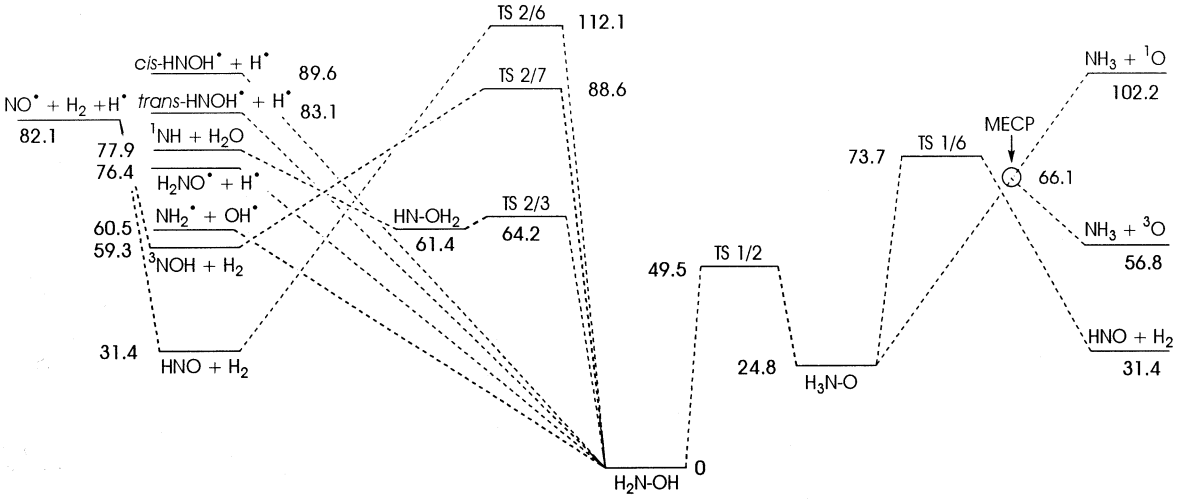
Figure 1. Potential energy surface of cationic $[H_3,N,O]^{\bullet+}$; zero-point corrected energies given in kcal mol^{-1} relative to $H_2NOH^{\bullet+}$ (**2**$^{\bullet+}$)



is lower in energy, it is kinetically hampered due to the entropic restrictions associated with **TS 1**$^{\bullet+}$**/2**$^{\bullet+}$. For ionized ammonia oxide, however, the direct fragmentation into O

IE_v differ by no more than 0.29 kcal mol^{-1}. As a result, the vertical ionization energies of hydroxylamine (IE_v = 10.72 eV) and ammonia oxide (IE_v = 9.1 eV) differ by as much

Figure 2. Potential energy surface of neutral $[H_3,N,O]$; zero-point corrected energies given in kcal mol^{-1} relative to H_2NOH (**2**)



as 1.6 eV, although IE_a is comparable for both isomers.[8][9] A similar difference can be discerned for the recombination processes of an electron with the cations to the neutral molecules. In fact, these pronounced differences in physical properties may enable an experimental distinction of these two isomers.

The stability of the third neutral isomer, the imine-water complex **3**, has very much decreased compared to the cationic surface. The minimum structure is hardly more stable than the transition state of the [1,2]-H shift **TS 2/3**, and a further internal energy of 16.5 kcal mol^{-1} is sufficient to dissociate the molecule into ^{1}NH and H_2O. Dissociation into ^{3}NH and H_2O is exothermic by 25.5 kcal mol^{-1}, but a spin-forbidden process for **^{1}3**.

The relative heights of the exit channels are also different from the cationic surface, especially as far as the structure-indicative channels involving N−O bond cleavage are concerned. In this respect, dissociation of $[H_3,N,O]$ into $H_2N^•$ and $OH^•$ represents the lowest lying, barrier-free exit channel with a relative energy of 60.5 kcal mol^{-1}, whereas the spin-allowed dissociation into O (^1D) and NH_3 becomes quite unfavorable with a relative energy of 102.2 kcal mol^{-1}. Therefore, the dissociation behaviour of the neutral isomers is expected to be quite different from that of the cations, in that for $[H_3,N,O]$ formation of $H_2N^•$ and $OH^•$ should be more pronounced than $NH_2^+ + OH^•$ for $[H_3,N,O]^{•+}$. The relative stability of the closed-shell pair HNO + H_2 (31.4 kcal mol^{-1}) is much higher than $H^•$ losses to yield the open-shell pairs $H_2NO^• + H^•$ (76.4 kcal mol^{-1}), *trans*-$HNOH^• + H^•$ (83.1 kcal mol^{-1}) and *cis*-$HNOH^• + H^•$ (89.6 kcal mol^{-1}). However, HNO + H_2 formation is again hampered by significant activation barriers of 73.7 kcal mol^{-1} for 1,1-elimination from H_3NO and of 112.1 kcal mol^{-1} for 1,2-elimination from H_2NOH. Besides, NOH (^{3}A″) and H_2 (E_{rel} = 59.3 kcal mol^{-1}) are obtained by 1,1-elimination of H_2 from H_2NOH, which is associated with a barrier of 88.6 kcal mol^{-1}.

Figure 3. Calculated bond lengths in pm and angles in degrees of relevant cationic $[H_3,N,O]^{•+}$ species; for geometries of $[H_2,N,O]^+$ species pertinent to the present work, see ref.[6]

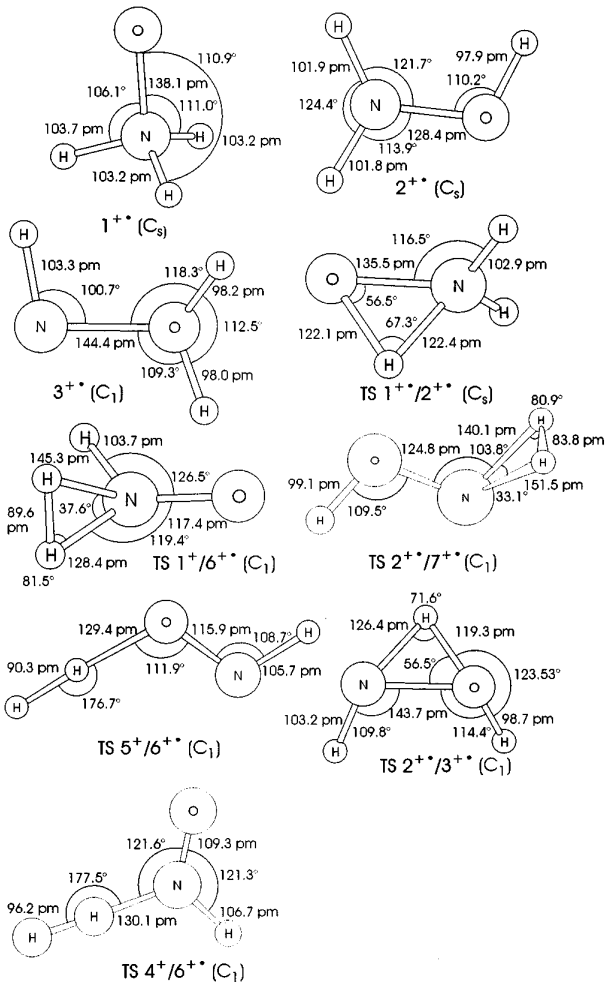


Figure 4. Calculated bond lengths in pm and angles in degrees of relevant neutral $[H_3,N,O]$ species

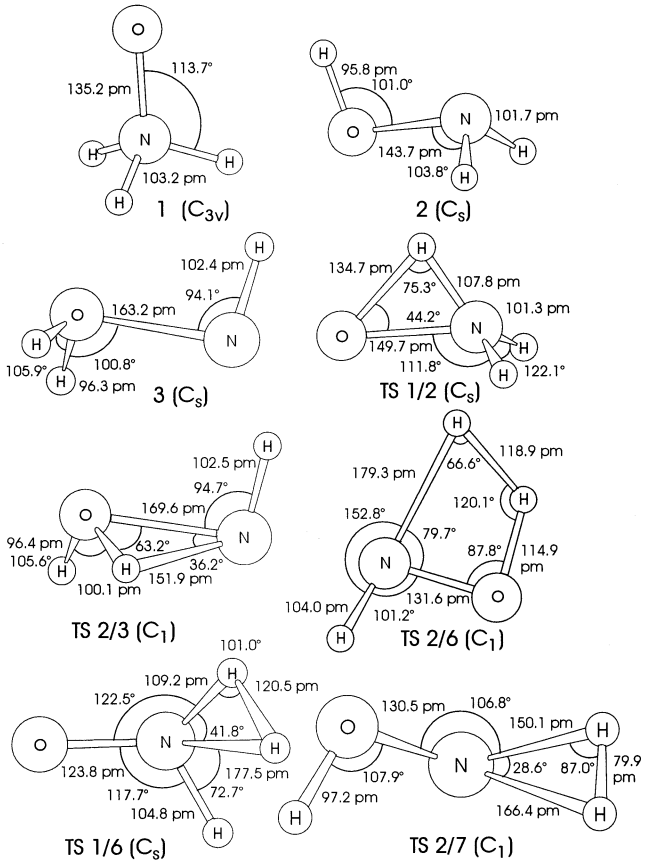

The $NH_3 + O$ (^3P) exit channel has a comparatively low relative energy of 56.8 kcal mol^{-1}, but cannot be entered from the singlet surface in a spin-allowed manner. However, two processes that eventually yield $^3O + NH_3$ should be mentioned briefly: (i) The dissociation of ^3H_3NO (^{3}**1**), which has an energy of 56 kcal mol^{-1} relative to **2** and 31.2 kcal mol^{-1} relative to $^1NH_3O$ (^{1}**1**), is spin-allowed. However, the N−O distance in geometry-optimized ^{3}**1** is 296 pm, revealing that the structure actually corresponds to a $^3O\cdots NH_3$ van der Waals complex with a binding energy of only 0.8 kcal mol^{-1}. A triplet structure for H_2NOH could not be located, but a second minimum on the triplet surface corresponding to $H_2N^{\bullet}\cdots H-O^{\bullet}$ with r_{N-H} = 200 pm was found with an energy of 58.7 kcal mol^{-1} relative to ^{1}**2**, only 1.9 kcal mol^{-1} below the separated species $H_2N^{\bullet}$ and $HO^{\bullet}$. (ii) In addition, the $NH_3 + O$ (^3P) exit channel might be accessed by spin crossing of ^{1}**1** en route to oxygen dissociation. The highest spin crossing probability is achieved at geometries where both spin states possess the same energy. Therefore, the minimum energy crossing point (MECP) for the H_3N-O dissociation was located with a recently developed method.[10] Most efficient crossing is expected at N−O distances of 192 pm, where the molecule has an energy of 66.1 kcal mol^{-1} relative to **1**.

As far as $[H_3,N,O]^{\bullet-}$ anions are concerned, three minimum structures could be located that all correspond to weakly bound ion-dipole complexes.[4][11] The respective relative energies are E_{rel} = 0 for $HNH^{\bullet}\cdots OH^-$, E_{rel} = 3.1 kcal mol^{-1} for $HOH\cdots NH^{\bullet-}$ and E_{rel} = 7.7 kcal mol^{-1} for $H_2NH\cdots O^{\bullet-}$. None of the complexes possesses an intact N−O bond, and dissociations into $H_2N^{\bullet}$ and OH^- (E_{rel} = 15.3 kcal mol^{-1}), NH_3 and $O^{\bullet-}$ (E_{rel} = 23.3 kcal mol^{-1}) or into $HN^{\bullet-}$ and H_2O (E_{rel} = 27.3 kcal mol^{-1}) can occur easily. We would like to point out that both neutral isomers **1** and **2** possess negative vertical electron affinities, i.e. EA_v = −22.8 kcal mol^{-1} for **1** and EA_v = −47.4 kcal mol^{-1} for **2**. Thus, theory strongly suggests that a distinction of neutral **1** and **2** by electron attachment experiments, which have been applied successfully to the generation and identification of the neutral singlet water oxide molecule,[4][11] is not feasible for the $[H_3,N,O]$ system.

In conclusion, the quantum chemical calculations predict the existence of three $[H_3,N,O]^{\bullet+/0}$ isomers. Whereas the shapes of the neutral and cationic PES are similar concerning the hydroxylamine/ammonia oxide tautomerism, distinct differences exist with respect to the energetics of the fragmentation channels.

Experimental Results

The analysis of the hydroxylamine/ammonia oxide system based on dissociation products is hampered by an analytical problem, because the structure-indicative cleavages of the N−O bonds lead to fragments of equal masses, i.e. $NH_2^{\bullet}$ and O (both 16 amu) as well as NH_3 and $OH^{\bullet}$ (both 17 amu). Therefore, we decided to carry out additional experiments with the fully deuterated analogs $[D_3,N,O]$, such that the combination of the two sets of data allows for a deconvolution of the overlapping fragments, i.e. ND_2 and OD (both 18 amu) as well as ND_3 and D_2O (both 20 amu). In order to produce the three different isomers $\mathbf{1}^{\bullet+}$, $\mathbf{2}^{\bullet+}$, and $\mathbf{3}^{\bullet+}$, the following precursors were chosen. (i) A mixture of NH_3 and N_2O was subjected to chemical ionization in which one may envision N_2O as a donor for atomic oxygen to afford ammonia oxide cation $\mathbf{1}^{\bullet+}$. (ii) Pure hydroxylamine was ionized to (predominantly) yield $\mathbf{2}^{\bullet+}$. (iii) Surprisingly, electron ionization of an aqueous N_3H solution also yields reasonable amounts of $[H_3,N,O]^{\bullet+}$, and high mass-resolution and labeling experiments assured that the selected beam actually had the desired elemental composition. The mechanism of $[H_3,N,O]^{\bullet+}$ formation could not be established and seems particularly obscure for N_3H/H_2O. Although we cannot exclude rigorously ion-molecule reactions, the fact that the highest yields of $[H_3,N,O]^{\bullet+}$ are obtained under electron ionization conditions suggests that a volatile, hitherto uncharacterized N,H,O compound is liberated from an aqueous mixture of NaN_3 and H_2SO_4. Methods (i) and (iii) gave similar spectra (Table 3), but the $[H_3,N,O]^{\bullet+}$ intensities obtained from N_3H/H_2O were much higher than those from NH_3/N_2O. Thus, in the following discussion, the fragmentation patterns obtained for ionized

NH_2OH are compared with those for N_3H/H_2O and their deuterated analogues.

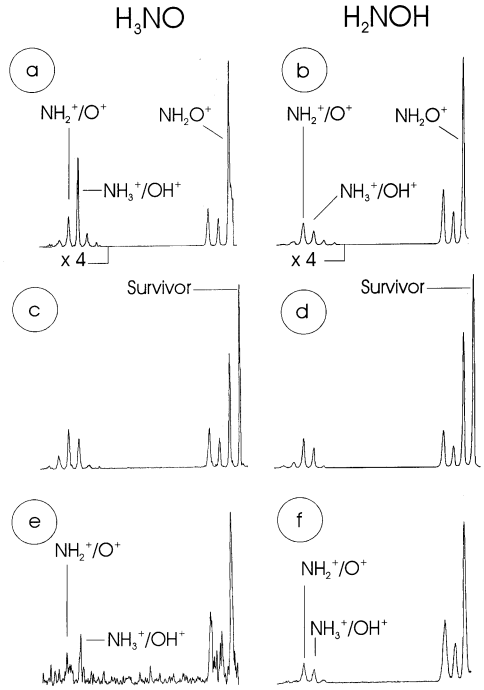
The intensities of the metastable ion (MI) spectra are low, consistent with the fact that $[H_3,N,O]$ has only few degrees of freedom for the storage of internal energy. In all spectra, the by far dominant process corresponds to $H^\bullet$ loss to yield $[H_2,N,O]^+$, which is the lowest lying barrier-free exit channel of the system. However, as already mentioned neither this nor the other hydrogen loss channels are indicative as far as structural aspects are concerned. Thus, the following discussion is primarily based on the structurally indicative signals due to N−O bond cleavage. Unimolecular dissociation of ionized hydroxylamine yields fragments of masses 16 and 17 in a 1.3:1 ratio, while only mass 17 is observed in the MI experiment using the HN_3/H_2O mixture as precursor. Accordingly, the MI spectrum of $[D_3,N,O]^{\bullet+}$ obtained from DN_3/D_2O gives rise to a single signal at mass 20, which demonstrates that exclusively $ND_3^{\bullet+}$ is formed. In comparison, the MI spectrum of $ND_2OD^{\bullet+}$ is featured by two peaks at $m = 18$ and $m = 20$ in a 1.2:1 ratio, indicating that ND_2^+ as well as $ND_3^{\bullet+}$ are produced with ND_2^+ slightly dominating. Further, the combined analysis of the results obtained for the unlabeled and the labeled ions suggests that contributions of oxygen-containing fragments are minor in the MI mass spectra. This is consistent with the order of the *IE*s of the complementary fragments arising from $[H_3,N,O]$, i.e. $IE(NH_2) = 11.4$ eV vs. $IE(OH) = 13.0$ eV and $IE(NH_3) = 10.2$ eV vs. $IE(O) = 13.6$ eV.[5]

An increase of the internal energy of the molecules by collisional activation leads to much more abundant fragmentations. In addition, a fraction of "hot" molecules possesses lifetimes long enough to allow for extensive rearrangements preceding decomposition, which is indicated by fragments like $H_2O^{\bullet+}$ and H_3O^+ (or $D_2O^{\bullet+}$ and D_3O^+, respectively). Nonetheless, collisional activation with ions having keV energies promotes characteristic direct bond cleavages which are valuable for a structural characterization.

Due to collision-induced isomerization, the differences in the CA spectra of the two precursors are less pronounced compared to the metastable ion decay patterns. However, whereas ionized hydroxylamine shows an *m*/*z* 16/17 ratio of 1.3:1, this ratio amounts to 1:2.7 for the ion observed from the HN_3/H_2O mixture (Figures 5a and 5b). Analogous results are obtained with the deuterated compounds, in that the 18/20 ratio for ND_2OD is 1.4:1, as compared to 1:1.9 for the DN_3/D_2O mixture. In order to probe whether an alteration of the ion internal energy has any effect, CA spectra of $\mathbf{2}^{\bullet+}$ were also recorded at various ionization energies ranging from 10 to 100 V under EI conditions; in addition, **2** was ionized under CI conditions at higher source pressures. Except for the $HNO^{\bullet+}/NO^+$ ratio (see below), both variations, however, did not lead to significant changes of fragmentation patterns, suggesting that internal energy effects can be neglected to a first approximation.

The differences in the MI and CA spectra of the two precursors prove that the ion beam produced via HN_3/H_2O cannot consist of $\mathbf{2}^{\bullet+}$ alone. In fact, the absence of the signal at 16 amu in the MI spectra suggests that rather a pure beam of ammonia oxide ($\mathbf{1}^{\bullet+}$) is produced. The dominant

Figure 5. Mass spectra of $[H_3,N,O]^{\bullet+}$ ions generated from HN_3/H_2O and NH_2OH, respectively, as neutral precursors; CA spectra for HN_3/H_2O (a) and NH_2OH (b), $^{+}NR^{+}$ spectra for HN_3/H_2O (c) and NH_2OH (d), and $^{+}NR^{+}$/CA spectra for HN_3/H_2O (e) and NH_2OH (f)

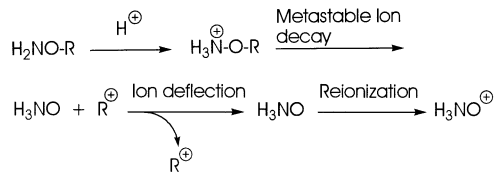


signal corresponds to $NH_3^{\bullet+}$, which is in line with an NH_3-O connectivity, whereas the dominant fragment of the NH_2OH precursor is NH_2^+, as expected for the NH_2-OH connectivity. In both MI and CA experiments, the HN_3/H_2O couple gives rise to a much more distinct and characteristic 16/17 ratio compared to NH_2OH. An explanation can be derived from the cationic potential energy surface. The $NH_3^{\bullet+}$ + O (^3P) exit channel is much lower in energy compared to NH_2^+ + $OH^{\bullet}$ (58 kcal mol^{-1} vs. 104 kcal mol^{-1}). Starting from $\mathbf{2}^{\bullet+}$, two decomposition paths compete. Compared to the direct bond cleavage to yield NH_2^+ + OH, the $NH_3^{\bullet+}$ + O exit channel is energetically favored, but entropically severely disfavored due to the necessity of a hydrogen migration. Especially in the MI experiment, the ions can store only a relatively low amount of internal energy; therefore, a fraction of molecules does not possess enough energy to access direct bond cleavage, but undergoes isomerization instead. Another indication for the formation of $\mathbf{1}^{\bullet+}$ from HN_3/H_2O is the fact that the intensity of the N–O cleavage relative to the base peak is much smaller for NH_2OH compared to HN_3/N_2O. A common feature of the CA spectra of both precursors is that NO^+ formation is more pronounced than $[H,N,O]^{\bullet+}$ formation, although the $NO^+/H_2/H^{\bullet}$ exit channel is 18.6 kcal mol^{-1} higher in energy than $HNO^{\bullet+}/H_2$ and 3.8 kcal mol^{-1} higher than $NOH^{\bullet+}/H_2$. The theoretical results show that for $[H,N,O]^{\bullet+}$ production, barriers of 89.5 kcal mol^{-1} for 1,1-elimination from $\mathbf{1}^{\bullet+}$ and of 92.3 kcal mol^{-1} for 1,1-elimination from $\mathbf{2}^{\bullet+}$ have to be overcome. Therefore, *every* generated $[H,N,O]^{\bullet+}$ + H_2 unit has an internal excess energy of at least 19.1 kcal mol^{-1}. This excess energy is sufficient to convert a considerable fraction of $[H,N,O]^{\bullet+}$ immediately to NO^+ and $H^{\bullet}$. It was found that the $NO^+/[H,N,O]^{\bullet+}$ ratio varies easily with experimental conditions, pointing to a high sensitivity of this particular ratio towards the internal energy. Unimolecular decomposition of both precursors yields, next to dominant $H^{\bullet}$ loss, small amounts of $[H,N,O]^{\bullet+}$ and NO^+, the $[H,N,O]^{\bullet+}$ signal being higher in each case. In contrast to that, unimolecular decomposition of $\mathbf{4}^+$ and $\mathbf{5}^+$ produces mainly NO^+ and only minor amounts of $HNO^{\bullet+}$ cation.[6] Therefore, it can be concluded that at least in the low-energy regime, $[H,N,O]^{\bullet+}$ and NO^+ fragments in $[H_3,N,O]^{\bullet+}$ are not generated via $[H_2,N,O]^+$ as an intermediate, but produced on a different way, probably by H_2 elimination; this conjecture is completely in line with the theoretical predictions. Finally, it should be noted that signals due to H_3O^+ ions are minor in CA spectra and not observed at all in MI spectra of both precursors, although fragmentation into H_3O^+ and N (^4S) is predicted to be the thermodynamically most favorable exit channel of $[H_3,N,O]^{\bullet+}$. Obviously, access to this fragmentation is severely hampered by the kinetic restrictions associated with extensive isomerization and spin crossing.

After having shown that two different cationic $[H_3,N,O]^{\bullet+}$ precursors can be distinguished, an experimental differentiation of the corresponding neutral counterparts **1** and **2** is attempted. One approach to neutral ammonia oxide is based on the strategy shown in Scheme 1. Thus, a precursor molecule H_2N-OR is protonated with a suitable CI gas. If the preferred protonation site is nitrogen, and if the group R can form a stable cation, metastable ion decay of H_3N^+-O-R may lead to R^+ and neutral ammonia oxide (H_3NO). This route can be followed by performing CIDI (collision induced dissociative ionization) experiments in which after deflection of all charged species from the beam, the neutrals are subsequently reionized and detected.[12] CIDI experiments were performed with $H_2NOSiMe_3$ (**9**), $H_2NOSiMe_2Ph$, and $H_2NOSi\mathit{t}BuPh_2$ as precursors.[13] Although the stabilities of the cationic leaving groups should increase in the order $SiMe_3^+ < SiMe_2Ph^+ < Si\mathit{t}BuPh_2^+$, meaningful CIDI spectra could only be obtained for **9**. This is probably a consequence of the fact that the effective kinetic energies of the neutral $[H_3,N,O]$ fragments decrease with increasing size of the precursor, which lowers the reionization yields of $[H_3,N,O]$. The MI spectrum of $H_3NOSiMe_3^+$, which was generated by protonation of **9** with methane as CI gas,[14] is featured by losses of 15 amu (30%), 16 amu (100%), and 33 amu (50%), demonstrating that the heaviest neutral fragment lost is actually $[H_3,N,O]$. The most important feature of the CIDI spectrum is that reionized neutral $[H_3,N,O]$ constitutes the base peak in the spectrum. According to the MI spectrum, no peaks with masses higher than 33 should be present in a pure CIDI spectrum. Small signals between 40 and 47 amu indicate, however, that few NR processes occur due to diffusion of the reionization gas through the deflector region of the mass spectrometer.[12] The key issue is, however,

whether the peak at *m*/*z* 33 can be assigned unambiguously to reionized ammonia oxide. Mainly two concerns discard the CIDI experiment as a proof. Although theory predicts that *N*-protonation of **9** is favored over *O*-protonation by 16 kcal mol^{-1}, it cannot be excluded that a fraction of molecules is protonated at the oxygen atom, because the protonation with methane as CI gas is strongly exothermic at either side, i. e. 86.4 kcal mol^{-1} and 70.4 kcal mol^{-1}, respectively.[15] Thus, one might argue that the observed reionized [H_3,N,O] stems from the *O*-protonated species, which produces hydroxylamine concomitantly with the generation of $SiMe_3^+$. Moreover, even if exclusive initial *N*-protonation is assumed, one cannot rule out a possible [1,2]-H shift from the nitrogen to the oxygen atom prior to or concerted with $SiMe_3^+$ loss. Both objectives would be disprovable if it was possible to examine *N*-protonated $Me_3SiNHOH$, but this compound has not been synthesized yet. Due to the concerns mentioned, for the time being the CIDI experiments should be regarded as an experimental hint for neutral ammonia oxide rather than a proof.

Scheme 1



In a different approach to generate the neutral [H_3,N,O] molecule, the cationic beam was neutralized with xenon, and after removal of all ionic species from the beam, the neutrals were reionized with oxygen, subsequently mass-analyzed and detected.[3] The base peak of all neutralization-reionization spectra belongs to intact [H_3,N,O], which demonstrates the distinct stability of neutral [H_3,N,O] (Figures 5c and 5d). As low-mass fragments represent a superposition of decompositions of the projectile ion, the neutral transient, and the reionized species, structural information of the neutrals is difficult to achieve from fragment ion analysis. However, we note that the most intense peak in the lower mass region corresponds to $NH_2^\bullet$ ($ND_2^\bullet$) for both precursors, in line with the theoretical predictions for this exit channel.

The mere observation of an NR survivor ion arising from cationic ammonia oxide does, however, not prove the existence of neutral ammonia oxide, as the structural integrity might have been lost by isomerization at the neutral stage. Therefore, the structure of reionized [H_3,N,O] survivor ions was examined by a collisional activation experiment (Figures 5e and 5f). For H_2NOH and its deuterated analog, CA and NR/CA spectra are practically indistinguishable, which proves that no significant isomerization occurs at the neutral stage. The corresponding NR/CA experiment with the ammonia oxide precursor was conducted close to the detection limit of the instrument. Although the signal-to-noise ratio is poor, it can be seen that the fragmentation pattern in the structurally indicative region again resembles the observed CA pattern for the ammonia oxide cation rather than that of ionized NH_2OH (Fig. 5e and 5f). Thus, at least a complete isomerization **1** → **2** at the neutral stage seems improbable. Further, the intense survivor ion in NR spectra indicates favorable Franck-Condon factors for single-electron reduction to neutral **1**, being in line with the fact that the geometries of neutral and cationic ammonia oxide are very similar. The $NH_2^+/NH_3^{\bullet+}$ ratio in the NR/CA spectrum of $\mathbf{2}^{\bullet+}$ (Figure 5f) also implies that hydroxylamine does not isomerize during the NR experiment, in spite of the much less favorable Franck-Condon overlap of cation and neutral.

In conclusion, relevant points of the cationic and neutral $[H_3,N,O]^{\bullet+/0}$ surface have been calculated on a high theoretical level, predicting the existence of three different [H_3,N,O] isomers. Information obtained from the experiments, combined with the theoretical results, show that two cationic $[H_3,N,O]^{\bullet+}$ species can be distinguished in the gas phase. Furthermore, the experiments strongly suggest the existence of neutral ammonia oxide, although a definitive proof cannot be provided yet. This ambiguity is probably due to (i) the fact that the differences of the NR spectra of $\mathbf{1}^{\bullet+}$ and $\mathbf{2}^{\bullet+}$ are minor suggesting a compensation of Franck-Condon effects in conjunction with the different fragmentation channels accessible and (ii) the failure to perform $^-CR^+$ and/or $^-NR^+$ experiments as far as meaningful information about connectivity is concerned. Nonetheless, the NR/CA experiments presented here are very much in favor of the generation of $\mathbf{1}^{\bullet+}$ upon ionization of HN_3/H_2O as well as the generation of neutral ammonia oxide **1**.

K. acknowledge the *Stiftung Stipendien-Fonds des Verbandes der Chemischen Industrie* for Ph. D. scholarships. We thank Dr. *J. N. Harvey* for helpful discussions concerning the quantum chemical calculations.

Experimental Section

The experiments were performed with a modified VG/ZAB/HF/AMD four-sector mass spectrometer of *BEBE* configuration (*B* stands for magnetic and *E* for electric sector), which has been described in detail elsewhere.[16] NH_2OH and N_3H/H_2O were ionized by a beam of electrons (100 eV) in an electron ionization source (repeller voltage ca. 30 V). NH_3/N_2O mixtures were ionized under chemical ionization conditions. The ions of interest were accelerated to 8 keV and mass-selected by means of *B*(1)/*E*(1) at a resolution of $m/\Delta m \geq 3000$; isobaric impurities, i.e. O_2H^+ and $N_2H_5^+$ for [H_3,N,O] or $N_2D_4^{\bullet+}$ and $D_2O_2^{\bullet+}$ for [D_3,N,O] were either absent or baseline-resolved. Unimolecular fragmentations occurring in the field-free region preceding the second magnet are referred to as metastable ion spectra. For collisional activation experiments, helium (80% transmission, T) was admitted to a collision cell located between *E*(1) and *B*(2). In these MI and CA experiments, the ionic fragments were recorded by scanning *B*(2). For comparison with the NR/CA spectra (see below), MI and CA experiments were also performed with *B*(1)/*E*(1)/*B*(2)-mass-selected ions, scanning products with *E*(2). For NR experiments, cations were neutralized

by collisions with xenon (80% T); unreacted ions were removed from the beam. Subsequent reionization of the neutrals was achieved by collision with oxygen (80% T), and the resulting cationic fragments were recorded by scanning *B*(2). For NR/CA experiments, the survivor ions of the NR experiment were mass-selected with *B*(2), collided with helium (80% T), and the produced fragments were recorded by scanning *E*(2). In order to improve the signal-to-noise ratio, 5−100 spectra were accumulated and online-processed with the AMD-Intectra data system.

ND_2OD was obtained by repeated recrystallization of pure NH_2OH in CH_3CH_2OD. Pure NH_2OH was deliberated from $NH_2OH \cdot HCl$ with NaOEt.[17] ND_3 was produced by deuterolysis of Mg_3N_2 with D_2O. Aqueous HN_3 was produced by dropping concentrated sulfuric acid into a solution of NaN_3 in water. The concentration of HN_3 solutions was about 1−5%. $H_2NOSiMe_3$, $H_2NOSiMe_2Ph$, and $H_2NOSitBuPh_2$ were synthesized by treating hydroxylamine with the corresponding chlorosilanes $ClSiR_3$ in dichloromethane.[18] All chemicals were introduced in the ion source via the metal-free teflon/glass inlet system.[19]

Ab initio quantum-mechanical calculations were performed with IBM RS/6000 workstations and Pentium PCs using Gaussian 94.[20] For trimethylsilyl-substituted species, geometries were fully optimized at the HF/6-31G* level, and single-point energies were calculated at the MP2/6-31G* level. For all other species, full geometry optimizations and frequency calculations were carried out at the MP2/6-311G(d,p) level. The effect of using larger basis sets and a better correlation treatment was examined by performing single-point MP2/6-311+G(3df,2p) and CCSD(T)/6-311G(d,p) calculations at the previously optimized geometries. These results were further used to determine extrapolated[21] CCSD(T)/6-311+G(3df,2p) energies in an approach similar to the well-known G2 method.[23] All data in Tables 1 and 2 include the unscaled MP2/6-311G** zero-point energy corrections. The relative energy of ^1O was determined by adding the experimental value for the $^3P \rightarrow {}^1D$ excitation (1.967 eV)[24] to the calculated total energy of ^3O. Analogously, the relative energy of ^2N was determined by adding the experimental value for the $^4S \rightarrow {}^2D$ excitation (2.383 eV)[24] to the calculated total energy of ^4N. The minimum energy crossing point (MECP) of H_3NO was located by employing a recently developed hybrid method[10] which calculates energy gradients at the MP2/6-311G(d,p) level and energies of stationary points at the CCSD(T)/6-311G(d,p) level. The geometries of both spin states were adjusted until the energy difference between them was smaller than 0.06 kcal mol^{-1}.

[7] Our calculated dipole moments agree fairly well with the experimentally determined values of 0.59 D for hydroxylamine (taken from *Selected Values of Electric Moments for Molecules in the Gas Phase*, U.S. Department of Commerce, National Bureau of Standards, **1967**) and of 5.0 D for Me_3NO (taken from: N. Hacket, R. J. W. Fevre, *J. Chem. Soc.* **1961**, 1612).

[8] The discrepancy between our calculated value for $IE_a(\mathbf{2}) = 9.15$ eV and the literature values (9.6 eV[9a] and 10.0 eV[9b]) derived from photoelectron spectra is quite high. We ascribe it to the absence of the 0-0 transition in the experiment, yielding an overestimation of IE_a. The calculated value for $IE_v(\mathbf{2}) = 10.72$ eV and the experimental values (10.6 eV[9a] and 10.56 eV[9b]) agree much better.

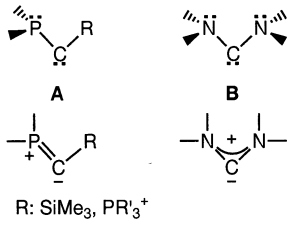
Bis(diisopropylamino)(trimethylstannyl)phosphane (**2**) reacts with the (chloromethylene)diisopropylammonium salt **1** affording the *C*-phosphanyl-substituted iminium salt **3** (67 % yield), which features a short C–N (1.284 Å) and a long P–C bond (1.850 Å), a planar iminium nitrogen atom and a pyramidalized phosphorus atom. Deprotonation of **3** leads to the enamine **8** (92 % yield), while addition of sodium methoxide followed by thermolysis of the resulting hemiaminal **9** (90 % yield) gives rise to the azaphosphetane **10** (85 % yield), by intramolecular CH insertion of the transiently formed (amino)(phosphanyl)carbene **6**.

Introduction

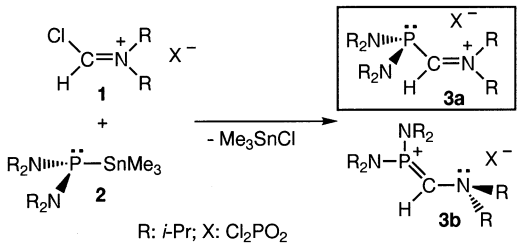
The genuine carbene nature of stable phosphanylcarbenes **A**[1] and diaminocarbenes **B**[2] is still a debatable topic.[3] Part of the debate relates to the role of the heteroatom substituents. Indeed, in the ground state, both **A** and **B** feature a heteroatom−carbon multiple-bond character.[4] In a recent paper, Schleyer et al[5] mentioned that "the *inherent* p donor capabilities of the heavier elements are as large as or larger than their second row counterparts" but add that "the superior ability of nitrogen compared to phosphorus to act as a p donor is due to the ease in achieving the optimum planar configurations with sp^2 hybridization". Here we report our preliminary results concerning the synthesis of an "(amino)(phosphanyl)carbenium salt",[6][7] and the generation of an (amino)(phosphanyl)carbene.



Results and Discussion

The "[bis(diisopropylamino)phosphanyl](diisopropylamino)carbenium salt" **3** was obtained in 67% yield, along with chlorotrimethylstannane, on reaction of the (chloromethylene)ammonium salt **1**[8a] with the stannylphosphane **2**[9] (Scheme 1). Only one signal is observed in the ^{1}H- and ^{13}C-NMR spectra for the four CH groups of the amino substituents bonded to the phosphorus atom, while two signals are detected for the two CH groups of the amino group directly bonded to the carbon atom. Thus, in solution, derivative **3** has to be regarded as *C*-phosphanyl-substituted iminium salt **3a**. Single crystals of **3** suitable for an X-ray diffraction study were grown from a dichloromethane/ether solution at −20°C. The molecular structure of **3** along with pertinent geometric parameters are shown on Figure 1. The C(1) and N(1) atoms are planar (sum of the angles: 359.9 and 359.8°, respectively) while the phosphorus atom is strongly pyramidalized (sum of the angles: 308.48°). The C(1)−P (1.850 Å) and the C(1)−N(1) (1.284 Å) bond lengths are in the range expected for C−P single and C=N double bonds, respectively. Therefore, in solution and in the solid state, derivative **3** has to be regarded as *C*-phosphanyl-substituted iminium salt **3a**, and not as (*C*-aminomethylene)phosphonium salt **3b**,[10] clearly demonstrating the superior p donor ability of the nitrogen compared to the phosphorus atom toward carbenium centers.

Scheme 1



Recently, the bis(diisopropylamino)carbene **5** has been obtained by a reaction of the corresponding formamidinium chloride **4** with LDA.[8a] However, this synthetic method appeared inappropriate to generate the (amino)-

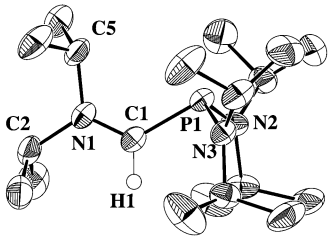
Figure 1. Molecular structure of **3**[a]



[a] Selected bond lengths [Å] and angles [°]: C(1)−N(1) 1.284(4), C(1)−P(1) 1.850(3), C(1)−H(1) 0.99(4); N(2)−P(1)−N(3) 113.90(12), N(3)−P(1)−C(1) 97.93(13), N(2)−P(1)−C(1) 96.65(13), N(1)−C(1)−P(1) 124.6(2), N(1)−C(1)−H(1) 115.6(2.2), P(1)−C(1)−H(1) 119.7(2.2), C(1)−N(1)−C(2) 121.3(3), C(1)−N(1)−C(5) 120.2(7), C(2)−N(1)−C(5) 118.3(7), N(1)−C(2)−C(3) 110.3(3), N(1)−C(2)−C(4) 110.3(3).

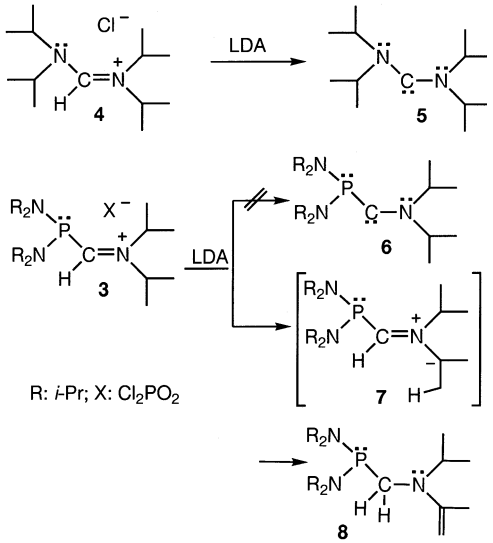
(phosphanyl)carbene **6**. Indeed, LDA reacts with **3**, but leads to the enamine **8** (92% yield), probably through the transient formation of the azomethine ylide **7**, followed by a prototropic rearrangement (Scheme 2).

In order to generate the (amino)(phosphanyl)carbene **6**, the synthetic method developed by Enders et al. was used.[11] Compound **3** was first treated with sodium methoxide affording the hemiaminal **9** in 90% yield, which was subsequently thermolyzed at 160°C under vacuum. Instead of the desired carbene **6**, the azaphosphetane **10** was obtained in 85% yield. The formation of heterocycle **10** clearly results from a regio- and stereoselective intramolecular insertion of the transient carbene **6** into a methine C−H bond of an isopropylamino group bonded to P. The same regio- and stereoselectivity have already been observed with the diphosphanylcarbene **11**.[12] Note that CH insertions are typical reactions for transient singlet carbenes, but have never been observed with diaminocarbenes[13] (Scheme 3).

Conclusion

For cationic species, the experimental results reported here clearly corroborate the theory:[5] an amino substituent has a better p-donor ability than a phosphanyl substituent. For carbenes with comparable steric hindrance, it was already known that the diaminocarbenes are stable,[8b] while the diphosphanylcarbenes are only transient intermediates;[12] the (amino)(phosphanyl)carbenes seem also to be unstable. Therefore, from these results and those previously

Scheme 2



reported in the literature, it seems clear that the stabilization of singlet[14] carbenes can at least be achieved by two strong p-donor substituents *which can easily adopt a planar configuration*, and by the combination of a weak p donor with a p-acceptor substituent,[15] such as in **A**.

We thank the *CNRS* for financial support of this work, and the *Alexander von Humboldt Foundation* for a grant to H. G.

Experimental Section

General: All experiments were performed under dry argon. Melting points are uncorrected. ^{1}H-, ^{13}C-, and ^{31}P-NMR spectra were recorded with Brucker AC80, AC200, WM250, or AMX400 spectrometers. ^{1}H- and ^{13}C-chemical shifts are reported in ppm relative to Me_4Si as external standard. ^{31}P-NMR downfield chemical shifts are expressed with a positive sign, in ppm, relative to external 85% H_3PO_4. Mass spectra were obtained with a Ribermag R10 10E instrument. Conventional glassware was used.

3: To a CH_2Cl_2 solution (5 ml) of (chloromethylene)ammonium salt **1** (0.28 g, 1 mmol) was added at −78°C one equivalent of [bis(diisopropylamino)]trimethylstannylphosphane (**2**) (0.39 g, 1 mmol). The solution was allowed to warm to room temperature (r.t.) and stirred for a further 30 min. After evaporation of the solvent under vacuum, the residue was dissolved in a minimum of CH_2Cl_2. Compound **3** was precipitated as a yellow solid (0.32 g, 67%) by adding Et_2O. M.p. 153°C. − ^{31}P NMR (32 MHz, $CDCl_3$):

Keywords: High-spin molecule / 3d-4f complex / Heterodinuclear complex / Fe–Gd complex / Ferromagnetism

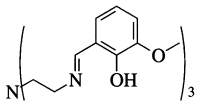
The tripodal ligand tris[4-(2-hydroxy-3-methoxyphenyl)-3-aza-3-buten]amine (H_3vantren) offers two coordination sites, an inner N_4O_3 one and an outer O_6 one. Therefore, it can successively encapsulate two different metal ions, a 3d(III) ion in the N_4O_3 site, and a 4f(III) ion in the O_6 site. This general route to homo- and heterodinuclear complexes has been exploited for the preparation of the vantrenFeGd$(NO_3)_3 \cdot 2\ H_2O$ complex (**2**), featuring a high-spin iron centre. This compound has been characterized by chemical analysis and mass spectrometry (FAB^+). Its magnetic properties have been investigated and show that the (Fe,Gd) pair (**2**) exhibits a ferromagnetic interaction of low intensity [$J = 0.50(5)$ cm^{-1}]. The resulting $S = 12/2$ ground state is, most probably, the highest spin ground state that can be expected for a dinuclear complex.

Introduction

In recent years, there has been increasing interest in the magnetic properties of dinuclear complexes composed of either 4f and 3d ions or of identical 4f ions.[1][2][3][4][5][6][7] This interest has been largely focused on the Cu−Gd couple, but one of our aims is to extend this work to other M−Gd couples (M being a 3d cation such as Ni^{2+},[8] Co^{2+},[9] or VO^{2+}[10]). As for the strategies used to prepare these polynuclear complexes, tripodal ligands derived from tris(2-aminoethyl)amine have so far been employed as hosts for 3d or 4f ions, leading to mononuclear (3d or 4f) and homodinuclear (4f, 4f) complexes.[11][12][13][14][15][16][17][18][19][20][21][22][23][24][25][26][27] Very recently, it has been shown that a mononuclear (4f) complex prepared from a novel tripodal ligand can be deprotonated to incorporate an Ni^{2+} ion.[28] Also relevant to the present paper is the use of 3d-block tripods in obtaining self-assembled triple-stranded heterodinuclear (3d, 4f) complexes.[29][30] The structural determination of an $Fe^{II}-La^{III}$ complex has been carried out.[30]

We have also demonstrated the effectiveness of the potentially decadentate tripodal Schiff base H_3vantren[31] {tris[4-(2-hydroxy-3-methoxyphenyl)-3-aza-3-buten]amine} in generating hetero- (4f, 4f′) as well as homo-dimetallic (4f, 4f) species. A schematic representation of the ligand H_3vantren is given in Figure 1. The aim of the present contribution is to demonstrate the ability of this tripodal ligand to successively incorporate 3d and 4f ions, thereby affording vantrenFe (**1**) and vantrenFeGd$(NO_3)_3 \cdot 2\ H_2O$ (**2**), and to report the magnetic properties of these complexes. At this point we should mention an $Fe^{III}-La$ complex prepared with a compartmental Schiff base ligand, for which neither a structural determination nor magnetic properties were reported.[24]

Figure 1. Schematic representation of the H_3vantren ligand



Results and Discussion

The tripodal H_3saltren ligand, obtained by reaction of salicylaldehyde with tris(2-aminoethyl)amine (tren), and its 5-chloro- ($H_3$5-Clsaltren) and 3-methoxy-substituted (H_3vantren) analogues, react with 3d(III) ions and particularly with Fe^{III} to yield neutral complexes formulated as saltrenFe.[18][19][20][24] The iron centre in 5-ClsaltrenFe[19] resides in an N_3O_3 environment, with the bridgehead nitrogen atom not being involved in coordination. A similar situation is found in vantrenMn.[20][24]

H_3vantren is a potentially decadentate tripodal ligand with two different complexation sites: an inner N_4O_3 site and an outer O_6 site. These differ in their size and nature, thus making easier the stepwise complexation of different metal ions. The marked preference of iron(III) for the inner site has been clearly demonstrated,[18][19] but we have recently shown that 4f metal ions can also be complexed in this deprotonated coordination site.[31] The bridgehead nitrogen atom that caps the structure is "tucked in", with its lone pair of electrons directed towards the Yb^{3+} ion.[31] The same disposition has been observed in mononuclear (Gd, Dy, or Yb) complexes of tripodal ligands.[12][32][33] However, in our case, the bonding interaction is expected to be

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1434−1948/98/1010−1543 $ 17.50+.50/0

weak, as indicated by the N(2)−Yb separation of 2.626(4) Å, which is significantly larger than the related distances involving the imino nitrogen atoms [2.448(5) to 2.494(4) Å].[31] Furthermore, the difference in ionic radii between 3d(III) and 4f(III) centres induces a large difference in bond lengths between the Fe−N(imine), Fe−O(phenolato) and the Ln−N(imine), Ln−O(phenolato) bonds, respectively, [Fe−N: 2.185(7) Å; Yb−N: 2.448(5)−2.494(4) Å and Fe−O: 1.953(6) Å; Yb−O: 2.259(3)−2.329(3) Å]. This large difference is not expected to be a stabilizing factor for the desired 3d(III)−4f(III) pairs.

Infrared spectra of vantrenFe (**1**) and vantrenFeGd$(NO_3)_3\cdot 2\ H_2O$ (**2**) mainly serve to reveal the presence of water and nitrate ions in **2**. Bands attributable to bidentate nitrates are observed at 1462 and 1335 cm^{-1}. A splitting of the 1620 cm^{-1} band for **1** into two bands at 1615 and 1641 cm^{-1} for **2** is also observed.

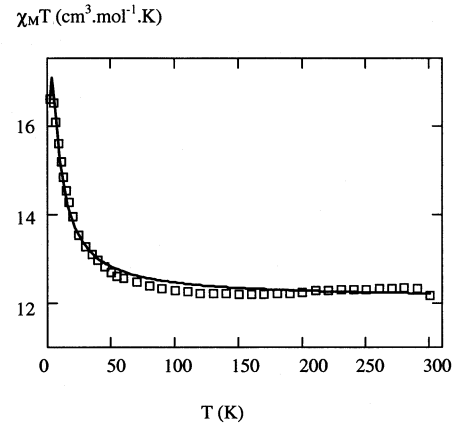
In addition to the analytical results, important information is provided by positive-ion FAB mass spectrometry. The main peak appears at m/z = 602 (100%) for the vantrenFe compound. This value together with the isotopic feature is attributable to the $[vantrenFe + 1]^+$ ion. In the case of vantrenFeGd$(NO_3)_3\cdot 2\ H_2O$, the signal corresponding to $[vantrenFeGd(NO_3)_2]^+$ is not observed. However, a signal appears at m/z = 821. This corresponds to the $[vantrenFeGd(NO_3)]^+$ ion, suggesting a change in the oxidation state of a metal centre (Fe or Gd). A similar observation has been made in previous reports.[1][3][8][9][10] The existence of a species such as [vantrenFeGd$(NO_3)_2]_2\cdot Gd(NO_3)_5$ is ruled out by the analytical results and the absence of a signal attributable to the $[Gd(NO_3)_5]^-$ anion in the FAB^- spectrum.[31]

The temperature dependence of the magnetic susceptibility over the range 5−300 K for vantrenFeGd$(NO_3)_3\cdot 2\ H_2O$ is shown in Figure 2 in the $\chi_M T$ vs. T form, the applied magnetic field being equal to 0.05 T. At 300 K, $\chi_M T$ is equal to 12.17 cm^3 K mol^{-1}, which roughly corresponds to the value expected for two uncoupled metal ions (12.25 cm^3 K mol^{-1}). On lowering the temperature, $\chi_M T$ remains practically constant until 80 K and then increases, reaching a maximum of 16.55 cm^3 K mol^{-1} at 5 K. The behaviour observed in the 300−5 K range is indicative of a ferromagnetic interaction between the Gd^{III} and Fe^{III} ions. The maximum value of 16.55 is lower than the value of 21 cm^3 K mol^{-1} that would be expected for the spin state S = 6 resulting from ferromagnetic coupling between Gd^{III} (S = 7/2) and Fe^{III} (S = 5/2), both ions having g values of 2.0. The decrease of $\chi_M T$ observed below 5 K is most likely attributable to saturation effects or to zero-field splitting. In this instance, the experimental results obtained between 5 and 300 K can be analysed on the basis of a spin-only Hamiltonian for isotropic exchange $H = -JS_{Fe}\cdot S_{Gd}$. The six low-lying spin levels, $E(6) = 0$, $E(5) = 6J$, $E(4) = 11J$, $E(3) = 15J$, $E(2) = 18J$ and $E(1) = 20J$ are characterized by different g values[34], $g_6 = (7g_{Gd} + 5g_{Fe})/12$, $g_5 = (37g_{Gd} + 23g_{Fe})/60$, $g_4 = (27g_{Gd} + 13g_{Fe})/40$, $g_3 = (19g_{Gd} + 5g_{Fe})/24$, $g_2 = (13g_{Gd} - g_{Fe})/12$, $g_1 = (9g_{Gd} - 5g_{Fe})/4$. Finally, the experimental data may be fitted to the following expression:

$$\chi_M T = \frac{N\beta^2}{k}\,\frac{91g_6^2 + 55g_5^2 e(\frac{-6J}{kT}) + 30g_4^2 e(\frac{-11J}{kT}) + 14g_3^2 e(\frac{-15J}{kT}) + 5g_2^2 e(\frac{-18J}{kT}) + g_1^2 e(\frac{-20J}{kT})}{13 + 11e(\frac{-6J}{kT}) + 9e(\frac{-11J}{kT}) + 7e(\frac{-15J}{kT}) + 5e(\frac{-18J}{kT}) + 3e(\frac{-20J}{kT})}$$

In the 5−300 K temperature range, a satisfactory fit [$R = \Sigma(\chi_{obs.}T - \chi_{calcd.}T)^2/\Sigma(\chi_{obs.}T)^2 = 2.4\cdot 10^{-4}$] is obtained for the following set of parameters: g_{Fe} = 1.96, g_{Gd} = 2.00, J = 0.50(5) cm^{-1}. In order to account for the decrease of the product below 5 K, a θ parameter has been introduced to gauge second-order effects. Then, the best fit over the 2−300 K temperature range yields g_{Fe} = 1.96, g_{Gd} = 2.00, J = 0.66(5) cm^{-1} and θ = −0.46 K, with $R = 1.0\cdot 10^{-4}$.

Figure 2. Thermal dependence of $\chi_M T$ for LFeGd$(NO_3)_3\cdot 2\ H_2O$ **2** at 0.05 T; the solid line corresponds to the best data fit



The sign of the magnetic interaction between the Fe^{3+} and Gd^{3+} ions is definitively supported by the field dependence of the magnetization M at 5 K. In Figure 3, the experimental values of M have been fitted to the Brillouin function, yielding g = 1.94 and S = 5.6 with $R = \Sigma[M_{calcd.} - M_{obsd.}]^2/\Sigma[M_{obsd.}]^2 = 2.5\cdot 10^{-3}$. The S value differs little from the value (S = 12/2) expected for a ferromagnetic ground state. Although the agreement cannot be considered as perfect, we can state that the experimental magnetization is larger than that for isolated Gd^{III} and Fe^{III} metal ions. In spite of the lack of a structural determination, the ferromagnetic behaviour confirms the existence of a genuine strictly dinuclear Fe−Gd complex.

Based on the structural determination of $[vantrenYbLa(NO_3)_2]^+$,[31] a possible structure for **2** has been obtained using CAChe molecular modelling software. It is shown in Figure 4. This view indicates that the bridgehead nitrogen atom is not involved in coordination to the iron centre, in full agreement with structural determinations of complexes of $3d^{III}$ elements with H_3vantren[24] or similar ligands.[19][20][22]

Finally, the main purpose of this paper is to report the first example of a discrete heterodinuclear $Fe^{III}-Gd^{III}$ complex that displays ferromagnetic behaviour. In this respect, the $Fe^{3+}-Gd^{3+}$ pair resembles the $Cu^{2+}-Gd^{3+}$,[1][3] $Ni^{2+}-Gd^{3+}$,[8] $Co^{2+}-Gd^{3+}$,[9] and $VO^{2+}-Gd^{3+}$[10] pairs

Figure 3. Field dependence of the magnetization; the solid line corresponds to the best data fit (cf. text)

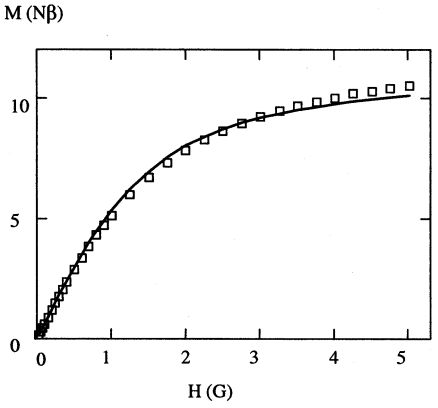


Figure 4. Possible structure of **2** based on CAChe molecular modelling software; the H atoms are not shown

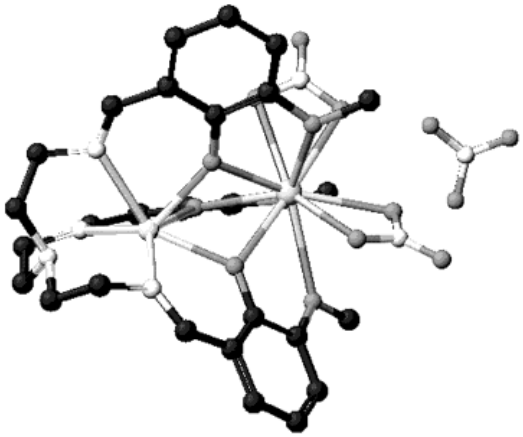

described previously. In the case of the $Cu^{2+}-Gd^{3+}$ couple, it has been proposed[35][36] that the stabilization of the parallel spin state arises from coupling between the $Cu^{II}-Gd^{III}$ ground configuration and the $Cu^{III}-Gd^{II}$ charge-transfer excited configuration, in which an electron is transferred from the singly occupied 3d-type copper orbital to an empty 5d-type gadolinium orbital. There is no obvious reason why this mechanism could not be operative in the case of the $Fe^{3+}-Gd^{3+}$ couple as well. Indeed, although the ligands involved in these different complexes are not identical, they all give rise to phenolato bridges, two with 3d(II) and three with 3d(III) metal ions. We emphasize that the value $S = 12/2$ is most probably the highest spin ground state that can be expected for a dinuclear complex. Theoretically, a higher value ($S = 14/2$) could result from a ferromagnetic coupling between two Gd^{3+} ions, but the available data[5][7] show that such a magnetic state is unlikely.

We thank Dr. *A. Mari* for his contribution to the magnetic measurements and Mrs. *S. Richelme* (Service Commun de Spectrométrie de Masse) for her contribution to the mass-spectral data.

Experimental Section

Materials and Methods: All starting materials were purchased from Aldrich and were used without further purification. Elemental analyses were carried out by the Service de Microanalyse du Laboratoire de Chimie de Coordination, Toulouse (C, H, N). Magnetic susceptibility data were collected from a powdered sample of the compound using a SQUID-based sample magnetometer with a QUANTUM Design Model MPMS instrument. All data were corrected for diamagnetism of the ligand, as estimated from Pascal's constants[38] ($-381\cdot10^{-6}$ emu mol^{-1} for **2**). Positive-ion FAB mass spectra were recorded in DMF as solvent with 3-nitrobenzyl alcohol as the matrix with a Nermag R10-10 spectrometer.

Tris[4-(2-hydroxy-3-methoxyphenyl)-3-aza-3-buten]amine: This ligand was obtained as described previously.[37]

Tris[4-(2-hydroxy-3-methoxyphenyl)-3-aza-3-buten]aminato-(3−)iron(III) (**1**): To a mixture of H_3vantren (0.55 g, 1 mmol) and anhydrous $FeCl_3$ (0.16 g, 1 mmol) in methanol (25 ml) was added triethylamine (0.3 g, 3 mmol). The mixture was heated under stirring for 20 min and, after cooling, the black precipitate produced was filtered off and washed with methanol and diethyl ether. Yield: 0.5 g (85%). − $C_{30}H_{33}FeN_4O_6$ (601.4): calcd. C 59.9, H 5.5, N 9.3; found C 59.6, H 5.3, N 9.1. − MS (FAB^+, 3-nitrobenzyl alcohol matrix): $m/z = 602$ $[LFe + 1]^+$.

Tris[4-(2-hydroxy-3-methoxyphenyl)-3-aza-3-buten]aminato-(3−)iron(III)gadolinium(III)·2 H_2O (**2**): A mixture of vantrenFe (0.5 g, $8.3\cdot10^{-4}$ mol) and $Gd(NO_3)_3\cdot6\,H_2O$ (0.37 g, $8.3\cdot10^{-4}$ mol) in acetone (20 ml) was heated under stirring for 15 min. After cooling, the resulting precipitate was filtered off and washed with acetone and diethyl ether. Yield: 0.8 g (97%). − $C_{30}H_{37}FeGdN_7O_{17}$ (980.7): calcd. C 36.7, H 3.8, Fe 5.7, Gd 16.0, N 10.0; found C 36.4, H 3.6, Fe 5.6, Gd 15.2, N 9.7. − MS (FAB^+, 3-nitrobenzyl alcohol matrix): $m/z = 821$ $[LFeGd(NO_3)]^+$.

Keywords: Imidazaboles / Carbene–borane adducts / Azole–borane adducts

The preparation and characterization of five new imidazabole derivatives is reported: 1,5-dibenzyl-4,4,8,8-tetrahydroimidazabole (**2**), 4,4,8,8-tetrafluoro-1,5-dimethylimidazabole (**3**), 4,4-difluoro-8,8-dihydro-1,5-dimethylimidazabole (**4**), 4,4,8,8-tetrachloro-1,5-dimethylimidazabole (**5**), and 4,4,8,8-tetraethyl-1,5-dimethylimidazabole (**6**). The structures of compounds **2**–**6** as dimeric carbene–borane adducts rather than dimeric *N*-borane adducts are discussed on the basis of NMR (**2**–**6**) and X-ray diffraction data (**2**, **3**, **5** and **6**).

Introduction

Heterocyclic boron hydrides have found broad application in catalysis[1]. Examples of an important class of these compounds named pyrazaboles were first synthesized in 1966 and since then they have been exhaustively studied[2]. This class of compounds features two $-BR_2-$ moieties bridging two pyrazole rings through their nitrogen atoms. Recently, two series of related compounds have been synthesized, one incorporating pyridine derivatives[3] and the other five-membered azole rings with an N−C−X moiety (X = N, S)[4]. The common, distinguishing feature of both series is that the $-BR_2-$ moiety links the two heterocyclic rings via nitrogen and carbon atoms that are both highly nucleophilic, and hence the question arises as to whether they should be considered as aza- or carbene−borane adducts. The former compounds may be compared with pyridine derivatives[5], which are very stable, but there have been virtually no studies on the azole derivatives. In this paper, the synthesis of five new imidazabole derivatives **2**−**6** is reported with a view to delineating factors that might allow a distinction to be made between C−B and N−B donation. The molecular structures of these compounds based on NMR and X-ray diffraction data are strongly indicative that compounds **1**−**6** are dimers of carbene−borane adducts rather than dimers of *N*-borane adducts (Scheme 1)[*].

3 $R^1 = CH_3$, $R^2 = R^3 = F$; **4** $R^1 = CH_3$, $R^2 = F$, $R^3 = H$
5 $R^1 = CH_3$, $R^2 = R^3 = Cl$; **6** $R^1 = CH_3$, $R^2 = R^3 = CH_2CH_3$

Results and Discussion

Synthesis

We have previously reported the synthesis of 4,4,8,8-tetrahydroimidazabole (**1**) from its *N*-methylimidazole−*N*-borane adduct[4]. The imidazabole **2** has been prepared from the 1-benzylimidazole−*N*-borane adduct in an analogous manner (Scheme 2). In order to examine the chemical stability and the molecular structures of imidazaboles (N−B−C fragment) and to compare them with pyrazaboles (N−B−N fragment), some derivatives of the parent imidazabole **1** have been synthesized (Scheme 3).

The chemical stabilities and reactivities of imidazaboles have been found to be very similar to those of pyrazaboles[2b][6]. Compounds **1**−**6** are very stable, even under the strongly acidic and oxidizing conditions of the reaction medium. Fluorination of **1** was performed with $BF_3 \cdot OEt_2$; formation of 4,4,8,8-tetrafluoro-1,5-dimethylimidazabole (**3**)

[*] Note added in proof (July 30, 1998): Other examples of carbene−boranes derived from imidazole have been recently reported: A. Wacker, H. Pritzkow, W. Siebert, *Eur. J. Inorg. Chem.* **1998**, 843−849.

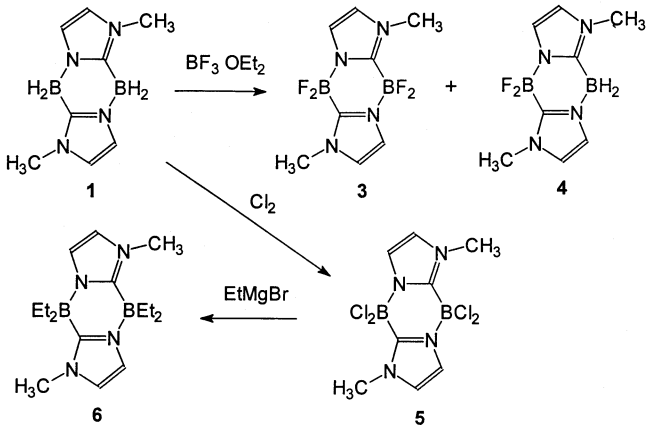
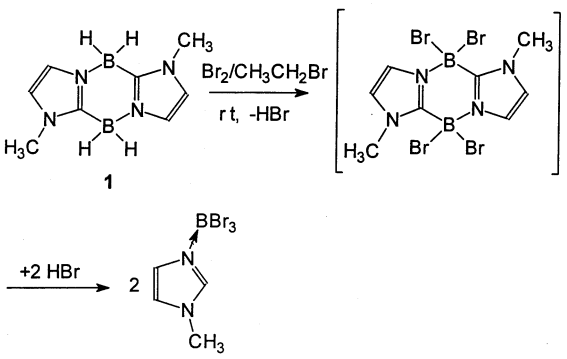
Scheme 3



and of the mixed compound 4,4-difluoro-8,8-dihydro-1,5-dimethylimidazabole (**4**) reveals that the reaction proceeds with opening of the central $C_2B_2N_2$ ring in a similar manner as in pyrazaboles[7]. Chlorination of **1** with molecular chlorine gave compound **5**, whereas bromination with Br_2 (Scheme 4) proceeded with central ring rupture via the 4,4,8,8-tetrabromo-1,5-dimethylimidazabole (observed by NMR) to give the 1-methylimidazole−tribromoborane adduct ($\delta^{11}B = -2.2$) by HBr addition. Reaction of compound **5** with MgEtBr in diethyl ether afforded **6** in good yield. The aforementioned reactions demonstrate the similar reactivity and stability of imidazabole compounds compared to pyrazabole compounds.

Scheme 4



Molecular Structures

The molecular structures of compounds **1**−**6** can be viewed as dimers of imidazole *N*-borane adducts with a simple N→B dative bond (structure **A**) or as dimers of a 2-ylidene−borane adduct (carbene adduct) with a C−B dative bond (structure **B**) (Scheme 1), similar to that described by Arduengo[8]. In order to establish the structures of the imidazaboles **2**−**6**, comparisons were made with the reported stable monomeric carbene−borane adducts 2-borane−1,2,3,4-tetramethylimidazoline (**7**) and 2-trifluoroborane−1,2,3,4-tetramethylimidazoline (**8**)[9], as well as with the N→B adducts *N*-borane−1-methylimidazole (**9**)[10] and indolylborane−*N*-methylimidazole (**10**)[11] (Scheme 5).

NMR Studies

Compounds **2**−**6** have been characterized by their ^1H-, ^{11}B- and ^{13}C-NMR data (Table 1). The ^{11}B chemical-shift values are at lower frequencies relative to those of the pyrazabole analogues [$\delta^{11}B(H_2B$-μpz-$BH_2) = -8.8$, $\delta^{11}B(F_2B$-μpz-$BF_2) = 0.2$, $\delta^{11}B(Cl_2B$-μpz-$BCl_2) = 2.1$, $\delta^{11}B(Et_2B$-μpz-$BEt_2) = 2.2$, pz = pyrazabole][7a][12], in accordance with the change from the NBN to the NBC fragment. However, ^{11}B chemical shifts do not allow a distinction to be made between N→B coordination **A** and N−B covalent bonding **B** in tetracoordinated compounds (Scheme 1). If $\delta^{11}B$ values of similar N→B coordinated adducts and of N−B covalently-bonded borates are compared {$\delta^{11}B(Me_2HN{\rightarrow}BH_3) = -13.5$ vs. $\delta^{11}B(Me_2N{-}BH_3^-) = -14.7$; $\delta^{11}B(H_3N{\rightarrow}BMe_3) = -8.7$ vs. $\delta^{11}B(H_2N{-}BEt_3^-) = -9.8$; and $\delta^{11}B$[(*N*-methylimidazole)→BH_2−pyrrole] = −7.8 vs. $\delta^{11}B(pz_2{-}BH_2^-) = -7.4$}[11][12], no significant differences are apparent. On the other hand, coupling constants ^1J(B−X, X = F, C) appear to be more characteristic and do allow a distinction between N→B adducts and N−B covalently-bonded compounds. Coupling constants ^1J(B−F) for **3** and **4** are larger (43 and 54 Hz, respectively)

Table 1. $\delta^{11}B$, $\delta^{13}C$ and $\delta^{1}H$ in ppm, [^{1}J(B−X)], [^{1}J(C−H)] and [^{3}J(H−H)]] in Hz of imidazabole derivatives **2**−**6**[a], 2-borane−1,2,3,4-tetramethylimidazoline (**7**), 2-trifluoroborane−1,2,3,4-tetramethylimidazoline (**8**) and *N*-borane−1-methylimidazole (**9**)

than in the pyrazabole analogues (23 and 22 Hz)[7a] and are intermediate between that in the adduct $Me_3N{\rightarrow}BEtF_2$ (65 Hz)[7a] and the reported value (37.6 Hz) for the carbene adduct 2-trifluoroborane−1,2,3,4-tetramethylimidazoline (**8**)[9]. Moreover, the value of the coupling constant ^{1}J(B−C) found for **6** (54 Hz) is close to that of the 2-ylidene adduct 2-borane−1,2,3,4-tetramethylimidazoline (**7**) (51.5 Hz)[9].

^{13}C chemical-shift values have proved to be a useful tool in establishing the nature of the N→B coordinative bond and to distinguish it from N−B covalent bonding[10]. The ^{13}C signal of C4 of 1-methyl imidazole (δ = 129.2) is shifted upon coordination to δ = 127.1 in the $N{\rightarrow}BH_3$ adduct **9** and to δ = 122.4 in the 1,3-dimethylimidazolium cation[10]. The ^{13}C signal of C3 (C4 in imidazoles) in compounds **2**−**6** is shifted to lower frequencies (Δδ ≈ 7−10 ppm), which is clearly indicative of N−B covalent bond formation. $\delta^{13}C$ values for C3 of **2**−**6** are in agreement with $\delta^{13}C$ values reported for C4 and C5 of the carbene adducts **7** and **8**. $\delta^{13}C$ signals for C8a of **2**−**6** are either extremely broad or are not observed at all as a result of the partially relaxed scalar $^{13}C-^{11}B$ spin-spin coupling[12]. When present, these are found in the range reported for **7**. On the other hand, $^{1}J(^{13}C,1H)$ values of C2 and C3 lie in the typical range for a neutral imidazole ring[10], in spite of the development of a positive charge delocalized over the whole ring. The C−H coupling pattern helped to unequivocally assign the ^{13}C signals for C2 and C3 in **3**, **5** and **6**. The signal for C2 appears as a double multiplet due to coupling with the 2-H, 3-H and CH_3 hydrogen atoms. These findings confirm that the canonical form with N−B covalent bonding makes the principal contribution to the structures of compounds **2**−**6**.

X-ray Structure Analysis

The molecular structure of the imidazabole **1** found by X-ray diffraction analysis was previously reported to have the space group $P2_1$ (monoclinic)[4]. However, the structure has since been resolved in space group $P2_1/n$ and this resulted in better parameters. The corrected molecular structure of imidazabole **1** is shown in Figure 1. Molecular structures of the imidazaboles **2**, **3**, **5** and **6** are shown in Figures 2−5 and selected bond lengths and angles are summarized in Table 2 (those pertaining to the central ring $C_2B_2N_2$) and Table 3 (those of the imidazole ring). Compounds **1**−**3**, **5** and **6** have a crystallographic centre of inversion. Thus, only one half of the "dimeric" molecule occupies the asymmetric unit.

The geometry around the boron atoms in **1**−**3** and **5** is of a slightly distorted tetrahedron (92% tetrahedron character, THC)[13], whereas in compound **6** it is a highly distorted tetrahedron (41% THC), probably due to steric effects. The central $C_2B_2N_2$ ring is almost planar, in contrast with the pyrazabole analogues, which are observed in chair, boat or planar conformations. The mean B−N(4) length in compounds **1**−**3** and **5** is intermediate between that of a coordinate bond $N(sp^2)-B(sp^3)$ [157.8(8) pm][11] and a covalent bond $N(sp^2)-B(sp^3)$ [151.3(2) pm][11]. This bond is significantly elongated [158.6(5) pm] in **6**, probably due to steric

effects, but it is shorter than that in the analogous pyrazabole [167(6)−172(6) pm][14]. The B−C(5) bonds lie in the typical range for a B(sp^3)−C(Ar) linkage of 160.3(8) pm[15]. The B−C(5) bond length in **3** [161.1(5) pm] is slightly longer than in 2-trifluoroborane−1,2,3,4-tetramethylimidazoline (**8**) [160.3(3) pm]. These figures suggest that the molecular structures of imidazaboles **1**−**6** should be considered as carbene−borane dimers.

[a] The numbering scheme is as that used for imidazaboles **1**−**3** and **6**.

The most categorical evidence for this conclusion comes from a comparison of the molecular structures of **1**−**3** and **5** with that of 4,4,8,8-tetramesityl-1,5-dimethylimidazabole **11**[16], the latter being characteristic of an imidazole *N*-borane adduct dimer. This compound exhibits a boat conformation of the central $C_2B_2N_2$ ring, with an angle between the two imidazole rings of 128°, in contrast with the fully planar structure found in imidazaboles **1**−**6**. The B−N bond length [163.8(4) pm] is larger than the corresponding bond lengths in imidazaboles **1**−**3**, **5** and **6**, which lie in the typical range for weak N→B adducts[17]. The marked contrast between these structures confirms that compounds **1**−**6** have to be considered as 2-ylidene−borane adducts (carbene−boranes).

The geometry of the imidazole ring is strongly modified when 2-ylidene adducts are formed. Table 3 shows bond lengths and angles related to the imidazole ring for compounds **1**−**3**, **5** and **6**, 2-trifluoroborane−1,3,4,5-tetramethylimidazoline (C−B coordination) (**8**)[9], and indolylborane−*N*-methylimidazole adduct (N→B coordination) (**10**)[11]. The main difference between the latter two lies in the N−C−N fragment. The bond length N(4)−C(5) [130.1(5) pm] is shorter than C(5)−N(1) [132.0(6) pm] in the N→B adduct **10**, whereas both have the same large value [135.2 (2) pm] in the C−B adduct **8**. These bonds in **1**−**3**, **5** and **6** are practically equivalent and have the same value as that in the C−B adduct **8**. The angle N(1)−C(5)−N(4) is wider in the C−B adduct **8** [104.7(1)°] than in the N−B adduct **10** [111.2(4)°]. In the opposite sense, the angles C(3)−N(4)−C(5) and C(2)−N(1)−C(5) become equal and are wider in the C−B adduct **8** [111.2(1)°] than in the N−B adduct **10** [106.2(4)° and 106.3(4)°, respectively]. Both these angles in **1**−**3**, **5** and **6** have a value intermediate between those found in the N−B and C−B adducts. These findings and the planarity found for all the structures reported here strongly support a significant contribution from the C−B adduct to the resonance structure and indicate that the positive charge is delocalized over the fragment N−C−N according to structure **C**, instead of over the fully delocalized resonance structure **D** (Scheme 6).

It follows from the aforementioned changes that as the groups attached to boron become bulkier, the resulting structure resembles more the N→B adduct. On the other hand, the B−C(5) length becomes longer (Table 2) as the electronegativity of the boron substituent increases (Pauling values: H 2.20, C 2.55, Cl 3.16, F 3.98)[18]. These observations demonstrate that both steric and electronic effects on the boron atom determine the degree of carbene−borane or *N*-borane dimer character of the structure.

Conclusion

NMR and X-ray diffraction experiments confirm that compounds **1**−**6** are dimers of carbene−borane adducts rather than *N*-borane adducts. The main differences between these structures are most clearly apparent in the imidazole

Table 3. Selected bond lengths [pm] and bond angles [°] of the imidazole ring in imidazaboles **1**−**3**, **5** and **6**, 2-trifluoroborane−1,2,3,4-tetramethylimidazoline (**8**) (C−B adduct)[9], and pyrrolylborane−*N*-methylimidazole adduct (**10**) (N−B adduct)[11]; the numbering scheme is as that used in Table 2

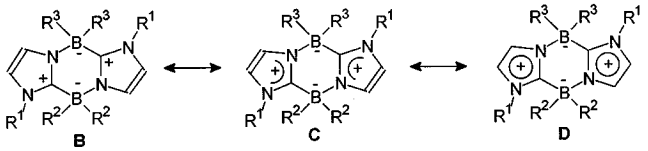
[a] For comparison purposes, the numbering scheme has been changed to the ring numbering followed in imidazaboles.

Scheme 6



N−C−N fragment bond lengths and angles and in the N−B bond lengths. The $C_2B_2N_2$ ring in compounds **1**−**6** is quite stable, even under the strongly acidic and oxidizing conditions used for the synthesis of such species. Imidazabole compounds **1**−**6** are the first examples of cyclic dimers of carbene−borane adducts to be reported.

We thank Professor *M. J. Rosalez-Hoz*, Mr. *F. Roberts* and Mr. *M. A. Leyva-Ramírez* for performing the X-ray diffraction studies

Experimental Section

General Remarks: All solvents were freshly distilled and dried before use according to established procedures. *N*-Methylimidazole, $BF_3 \cdot OEt_2$, Cl_2, Br_2 and Mg (granules) were commercial products. $BH_3 \cdot THF$ solution was prepared according to reported methods[19]. − Melting points (uncorrected): Gallenkamp apparatus. − IR (KBr): Perkin-Elmer 16F, PC spectrometer. − $^1H/^{13}C$ NMR: Jeol GXS 270 (270.67/67.94 MHz), TMS as external standard. − ^{11}B NMR: Jeol GXS 270 (86.84 MHz), $Et_2O \cdot BF_3$ as external standard ($\Xi^{11}B$ = 32.083971 MHz). − Elemental analyses were performed by Oneida Research Services, Whitesboro, N.Y. − The X-ray diffraction studies were performed with an Enraf-Nonius CAD4 diffractometer [λ(Mo-K_α) = 71.069 pm, monochromator: graphite, T = 293 K, ω-2θ scan]. Cell parameters were determined by least-squares refinement on diffractometer angles for 24 automatically centered reflections. Absorption corrections were not necessary; corrections were made for Lorentz and polarization effects. Solution and refinement: direct methods (SHELXS-86) for

[a] Program for structure solution and refinement: SHELXL-93[20]. − [b] Program for structure solution and refinement: CRYSTALS[21].

structure solution. The SHELXL[20] and CRYSTALS (version 9, **1994**)[21] software packages were used for refinement and data output. All hydrogen atoms in structures **1**, **3**, **5** and **6** were refined as riding atoms. Experimental parameters are listed in Table 4. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-101913 (**1**), -101909 (**2**), -101910 (**3**), -101912 (**5**), -101911 (**6**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: int. code +44(1223)336-033; E-mail: deposit@ccdc.cam.ac.uk].

1,5-Dibenzyl-4,4,8,8-tetrahydroimidazabole (**2**): 2.00 g (11.6 mmol) of 2-borane−1-benzylimidazole, prepared as described previously[11], was left to stand overnight at 0 °C in the presence of a solution of one small I_2 crystal in 1 ml of dry benzene. The mixture was then heated in a sand bath at 290 °C until hydrogen evolution had ceased. Crystallization from a saturated solution in toluene at −20 °C gave 0.637 g of **2** (32%) as a white, crystalline powder, m.p. 204−205 °C. Crystals suitable for X-ray structure analysis were obtained from a CH_2Cl_2 solution at −17 °C. − IR (KBr): $\tilde{\nu}_{max}$ = 2354 cm^{-1} (B−H), 1636 (C=N), 1206 (B−N). − $C_{20}H_{22}N_4B_2$ (340.04): calcd. C 70.64, H 6.52, N 16.49; found C 70.92, H 6.88, N 16.67.

4,4,8,8-Tetrafluoro-1,5-dimethylimidazabole (**3**) *and 4,4-Difluoro-8,8-dihydro-1,5-dimethylimidazabole* (**4**): To 10 ml of $BF_3 \cdot OEt_2$ was added 1.0 g of **1** and the mixture was stirred for a week. Excess $BF_3 \cdot OEt_2$ was then distilled off in vacuo, and the residual solid was washed with CH_2Cl_2 and then with THF to give 262 mg of a white solid composed of 95 parts of **3** (36% overall yield) and 5 parts of **4** (2.2% overall yield). Suitable crystals of **3** for X-ray structure analysis were obtained from acetone solution; m.p. 277 °C. − IR (KBr): $\tilde{\nu}_{max}$ = 1684 cm^{-1} (C=N), 1162 (B−N), 842 (B−F). − $C_8H_{10}N_4B_2F_4$ (259.81): calcd. C 36.98, H 3.88, N 21.56; found C 37.69, H 4.13, N 21.39. − The THF solution was found to contain a 1:1 mixture of **3** and **4**, from which the NMR spectra of **4** were obtained.

4,4,8,8-Tetrachloro-1,5-dimethylimidazabole (**5**): 2.00 g (10.6 mmol) of imidazabole **1** was dissolved in 30 ml of CH_2Cl_2. Molecular chlorine was bubbled through this solution until a yellow-green color persisted. After stirring for 1 h, the product formed was filtered off to afford 2.8 g (81%) of **5** as a white, crystalline solid, m.p. > 310 °C. − IR (KBr): $\tilde{\nu}_{max}$ = 1628 cm^{-1} (C=N), 1096 (B−N), 770 (B−Cl). − $C_8H_{10}N_4B_2Cl_4$ (325.63): calcd. C 29.51, H 3.10, N 17.21; found C 29.41, H 3.15, N 17.32.

4,4,8,8-Tetraethyl-1,5-dimethylimidazabole (**6**): A suspension of 124 mg of magnesium and a small amount of iodine in 10 ml of diethyl ether was stirred for 2 h. Then, 0.40 ml (5.1 mmol) of ethyl bromide was added and, after 1 h, a solution of 331 mg (1.02 mmol) of **5** in 100 ml of diethyl ether. The resulting mixture was refluxed under nitrogen for 4 h. After cooling overnight, 295 mg (96%) of crystals suitable for X-ray structure analysis were obtained; m.p. 200 °C. − IR (KBr): υ_{max} = 1684 cm^{-1} (C=N), 1074 (B−N). − $C_{16}H_{30}N_4B_2$ (300.06): calcd. C 64.05, H 10.08, N 18.67; found C 64.64, H 9.72, N 18.83.

Keywords: Schiff-bases / Helical structures / Structure elucidation / NMR spectroscopy / Ab initio calculations

Cadmium(II) complexes of two Schiff bases, 1,3-di(pyridine-2-carboxaldimino)propane ($C_{15}H_{16}N_4$, **L1**)[1] and tris[4-(2′-pyridyl)-3-aza-3-butenyl]amine ($C_{24}H_{27}N_7$, **L2**)[2] are described. An efficient route utilising molecular sieves for the synthesis of Schiff bases is presented. The ligands **L1** and **L2** can be described as linear and three-armed podands, respectively, **L1** being conformationally flexible and **L2** preorganised. Cadmium perchlorate in methanol with **L1** yields a crystalline complex $[Cd(\mathbf{L1})_2](ClO_4)_2$ (**1**), the structure of which was determined by X-ray structure analysis. The complex **1** has an unusual nonsymmetrical 8-coordinated helical structure and crystallizes in an acentric space group (*Cc*, no. 9) as a pure enantiomer due to spontaneous resolution. Solution studies of **1** in $CHCl_3$/DMSO (10:1) and pure DMSO were performed using ^{1}H-, ^{13}C-, ^{113}Cd-NMR and ^{1}H,^{15}N z-GS HMBC spectroscopy and they suggest a reorientation of **1** into the more symmetrical 4-coordinate complex due to the flexible nature of **L1**. The preorganised, potentially tetra-, hexa- or heptadentate, three-armed podand **L2** and its in situ complexation with the Cd^{2+} cation were investigated by ^{1}H-, ^{13}C-, ^{113}Cd-NMR and ^{1}H,^{15}N z-GS HMBC spectroscopy. The results support the formation of a highly symmetrical helical 6-coordinate podate $[Cd\mathbf{L2}](NO_3)_2$ (**2**). The structure of **2** has also been verified by ab initio HF-MO calculations using a standard 3-21G* basis set (Lan2DZ for Cd).

There is a growing interest in finding alternative approaches for the design of new inexpensive and easy-to-prepare ligand/podand systems. Hannon and coworkers have described a simple and inexpensive way to prepare imine-based rigid ligands that can form a triple-helicate structure with proper metal ions.[3a] Schiff-base complexes are considered to be among the most important stereochemical models in main-group and transition-metal coordination chemistry due to their preparative accessibility and structural variety.[4] The Schiff-base ligands and podands are not so well studied as their macrocyclic and macrobicyclic counterparts. In particular, the macrocyclic Schiff bases have been synthesized, as their metal complexes, through the [1+1] or [2+2] condensation of proper bis-amines and bis-aldehydes, using metal ions as templates.[5] In the absence of templating metal ions the reactions give poor yields and oligomeric/polymeric products. On the other hand, by using metal ions, it is often very difficult or impossible to remove the template from the macrocycle. Schiff-base helical structures are still rare[3a] and only a few examples exist for similar Schiff-base cryptates[3b]. Earlier we reported the synthesis and some metal complexes of the podand **L1**[1]. **L1** has a short flexible spacer between the two metal-binding sites, thus giving a tweezer-like bite to a single transition-metal ion. As an alternative approach to prepare Schiff-base compounds we used activated molecular sieves to increase yields in the nontemplated synthesis for a known podand **L2**[2]. **L2** offers a chemically similar complexation site, but now preorganised for *endohedral* 4-, 6- or 7-coordination. We selected the Cd^{2+} ion as a probe for a study of the solution complexation, since it has very versatile coordination behaviour and ^{113}Cd NMR has proved to be an excellent tool to monitor complex formation.[6] In this work we report the preparation of Cd^{II} complex from **L1** (Scheme 1) and the definitive characterization of the complex in the solid state by X-ray diffraction together with the synthesis of three-armed podand **L2** derived from tris(2-aminoethyl)-amine (TREN) and 2-pyridylcarbaldehyde and its in situ complexation with Cd^{2+} (Scheme 2). The Cd^{II} complexes **1** and **2** were investigated by ^{1}H-, ^{13}C-, ^{113}Cd-NMR and 2-D (two-dimensional) ^{1}H,^{15}N z-GS HMBC (z-gradient selected heteronuclear multiple-bond coherence) spectroscopy and the complex **2** also by an ab initio HF-MO calculation.

Results and Discussion

Although **L1** itself is a liquid its complexation with Cd^{II} perchlorate in methanol produced crystals suitable for X-ray diffraction study (Table 1 in Experimental Section). The

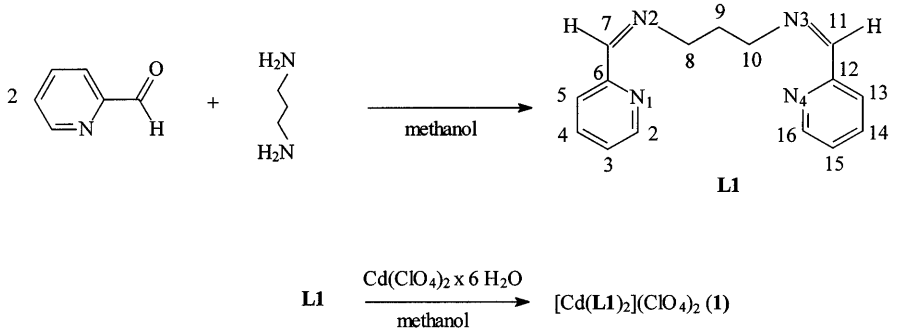
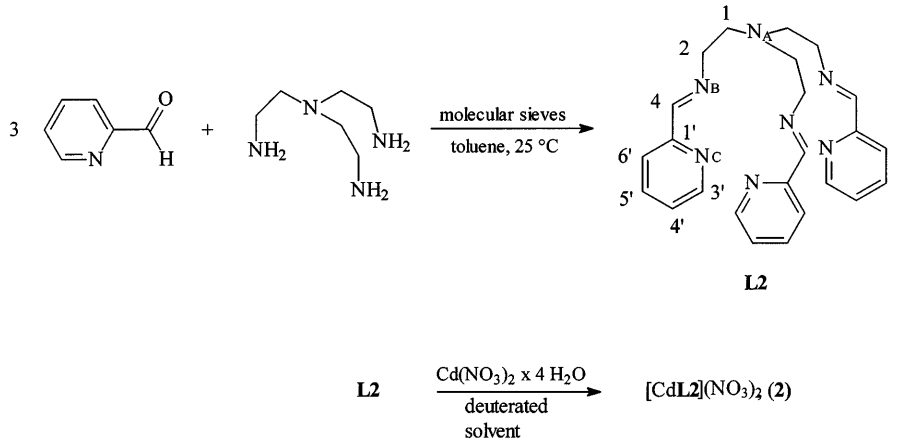
Scheme 1



Scheme 2

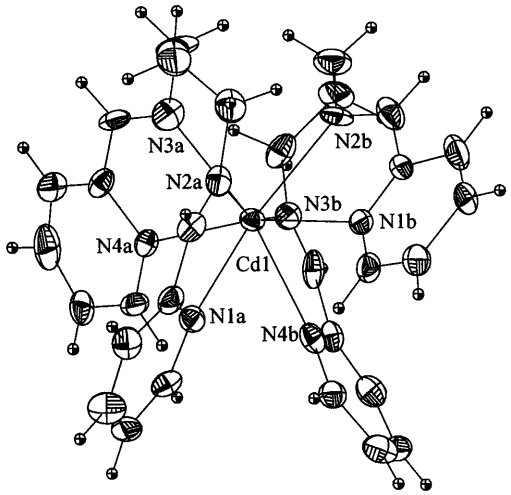


molecular structure of Cd^{II} complex **1** is displayed in Figure 1. The complex **1** is formed by coordination of two **L1** podands into a single cadmium ion. Due to its flexible nature **L1** acts as a pseudo-macrocyclic tetradentate ligand, thus resulting in a sandwich-type of 8-coordinated 1:2 complex.

Similar 8-coordination for Cd^{II} has been observed in some macrocyclic complexes.[7] The observed bond lengths and angles are consistent with the literature.[8][9] Selected bond lengths and angles for complex **1** of the Cd^{2+} ion are presented in Figure 1. To our great surprise complex **1** crystallized in an acentric space group and a detailed inspection of the structure revealed a helical arrangement of **L1** [in pseudo-macrocyclic conformation, the nonbonded intramolecular contact distances between the *ortho*-H atoms (H2, H16) are 223 pm (**L1**A) and 246 pm (**L1**B)] around the Cd^{II} ion. In some cases crystallization from a racemic solution of helical molecules can induce spontaneous resolution of the enantiomers and a mixture of enantiomerically pure crystals can be obtained[10]. The helical arrangement of the ligands results from the sterical factors around the Cd^{II} ion. The covalent radius of Cd^{II} ion is too small to bind all eight spatially neighbouring N atoms in a symmetrical cubic coordination, thus creating a twist of approximately 64° between the lower and upper ligand (Figure 2).

The four N atoms in a single **L1** ligand form a nearly symmetrical square plane (torsion angles for N1a−N2a−N3a−N4a and N1b−N2b−N3b−N4b are −4.63 and −3.69°, respectively) with almost equal nonbonded contact distances between the N atoms (N1a···N2a = 270.9 pm, N2a···N3a = 287.2 pm, N3a···N4a = 272.4 pm and N1a···N4a = 324.2 pm; N1b···N2b = 277.4 pm, N2b···N3b = 280.3 pm, N3b···N4b = 273.6 and N1b···N4b = 328.2 pm). The conformation of **L1** in the complex **1** is very close to an aza-crown conformation with all N atom lone pairs pointing in the same direction. The least-squares planes for the pyridine−imine (N1, C2−C7, N2 and N3, C11−C16, N4) parts show that they are nearly planar and the angles between the planes within the coordinated **L1** are quite similar: (N1a → N2a) and (N3a → N4a) 86.02°; (N1b → N2b) and (N3b → N4b) 75.80° The packing of the molecules in the unit cell along the *b* axis is shown in Figure 3. The weak π-stacking interactions between the two adjacent and co-planar pyridine rings along the *c* axis stabilise the packing. The distance between the co-planar pyridine rings is 416 pm.

Figure 1. The molecular structure of compound **1** [DIAMOND drawing with 20% (size reduced to improve clarity) probability ellipsoids (all non-hydrogen atoms), the uncoordinated perchlorate anions have been omitted for clarity][a]



[a] Selected bond lengths [pm] and angles [°]: Cd1−N1a (−N1b) 256.3(14) [251.8(18)], Cd1−N2a (−N2b) 247.7(17) [251.8(14)], Cd1−N3a (−N3b) 250.9(20) [250.9(20)], Cd1−N4a (−N4b) 246.9(15) [259.5(19)]; N4a−Cd1−N3b 71.6(6), N4a−Cd1−N1b 169.0(2), N3b−Cd1−N2a 161.6(3), N4a−Cd1−N3a 65.9(6), N3b−Cd1−N3a 95.7(6), N2a−Cd1−N3a 70.3(6), N3b−Cd1−N1b 109.8(5), N3a−Cd1−N1b 124.0(6), N4a−Cd1−N2b 122.5(5), N1b−Cd1−N2b 66.9(5), N1b−Cd1−N1a 91.5(5), N3b−Cd1−N1a 32.0(6), N1a−Cd1−N4b 77.6(2), N2b−Cd1−N1a 156.0(5), N2a−Cd1−N4b 131.4(6), N4a−Cd1−N1a 80.2(5), N4a−Cd1−N4b 91.2(5).

In order to obtain some information about the structure of the metal complex **1** in solution we also carried out ^{113}Cd-NMR and 2-D ^{1}H,^{15}N z-GS HMBC measurements in [D$_6$]DMSO. The metal complex shows only one strong ^{113}Cd signal at δ = 84.4 measured from external 0.1 M aqueous Cd(ClO$_4$)$_2$ (δ = 0.0). This result can be regarded as good evidence for the reorientation of the unsymmetrical complex **1** into a more symmetrical tetracoordinate complex. This result is also in good agreement with the value for the tetracoordinate Cd^{2+} complex (δ = 95) reported by Munataka et al.[6b]

The ^{15}N chemical shift of the imine nitrogen atoms changes from δ = −35.8 for the free ligand to δ = −62.2 for the cadmium complex **1**. The signal of the pyridine nitrogen atoms at δ = −62.6 of the free ligand, is not visible in the ^{1}H,^{15}N z-GS HMBC correlation map of the cadmium complex of **L1** in solution, although the delay for evolution of long-range couplings was increased to 200 ms. The ^{15}N-NMR chemical shifts of the ligand itself are in agreement with those reported for (*Z*)-*N*-benzylidenecyclohexylamine (δ = −36.4[11]) and 2-methylpyridine (δ = −62.6[12]). The absence of the ^{1}H,^{15}N z-GS HMBC correlation can be due to (i) too small a scalar coupling constant $J(^{1}H,^{15}N)$ to allow magnetization transfer between proton and ^{15}N or (ii) a dynamic process taking place inside the complex at room temperature.

We have also investigated the complexation properties of tris[4-(2′-pyridyl)-3-aza-3-butenyl]amine (**L2**) in solution

with Cd^{2+} using ^{1}H-, ^{13}C-, ^{113}Cd-NMR and 2-D $^{1}H,^{15}N$ z-GS HMBC spectroscopy. The measurements show that Cd^{2+} [added as $Cd(NO_3)_2 \cdot 4\ H_2O$] is efficiently complexed with the ligand **L2** forming tris[4-(2′-pyridyl)-3-aza-3-butenyl]aminecadmium(II) (**2**).

The metal complex **2** exhibits a strong ^{113}Cd signal at $\delta = 188.1$ in $CDCl_3$/[D_6]DMSO (10:1). From the fact that only one ^{113}Cd signal is observed it can be concluded that the potentially heptadentate Schiff-base ligand **L2** provides a highly symmetrical time-averaged complexation site for the Cd^{2+} cation. Furthermore, the more deshielded chemical shift value of **2** in comparison with **1** suggests that the coordination number must be larger in **2** than in **1**, as shown by Munataka et al.[6b]

A comparison of the $^{1}H,^{15}N$ z-GS HMBC correlation map of the free ligand **L2** with that of the cadmium complex **2** reveals that both pyridyl- and Schiff-base nitrogen atoms coordinate towards the cadmium cation. Due to the interaction with the metal centre the ^{15}N-NMR chemical shifts are moved upfield by approximately 50 ppm for each N atom compared with the free ligand **L2**. In [D_6]DMSO the ^{15}N-NMR chemical shift of the Schiff-base nitrogen atoms changes from $\delta = -38.9$ of **L2** to $\delta = -90.0$ in **2**. The pyridine nitrogen atoms show a shift from $\delta = -62.2$ to $\delta = -113.0$, respectively. The $^{1}H,^{15}N$ z-GS HMBC correlation map does not show any cross peak at room temperature due to the tertiary nitrogen atom N_A.

From the X-ray studies of related tris[4-(2′-pyridyl)-3-aza-3-butenyl]aminemetal complexes[2] it is already known that the bridging tertiary nitrogen atom N_A should also be coordinating. This assumption is further supported by the present ab initio calculation carried out on tris[4-(2′-pyridyl)-3-aza-3-butenyl]aminecadmium(II) (**2**) with a full geometry optimization at the HF/3-21G* (using Lan2DZ

[a] For the definition of the model, see ref.[2a]. − [b] See ref.[2a].

basis set for Cd) level of theory. Calculated Cartesian atomic coordinates of **2** are collected in Table 2.

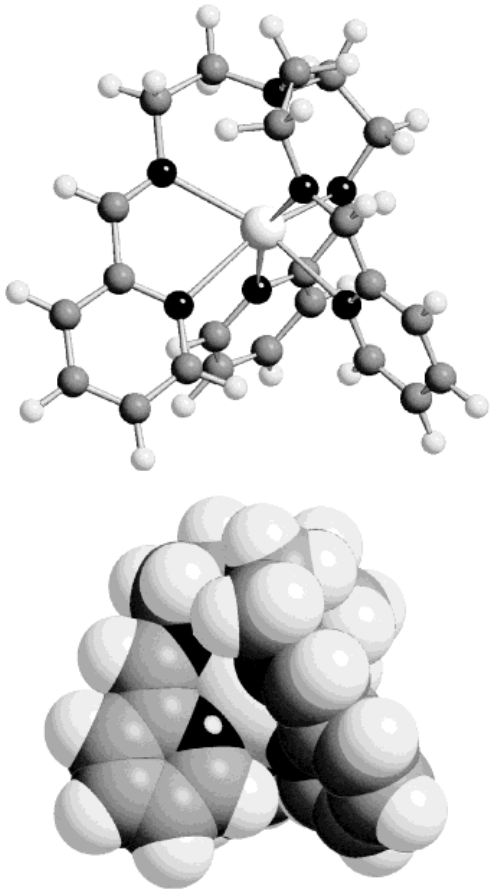
The calculated Cd^{2+} ($4d^{10}$) complex **2** and the analogous Zn^{2+} ($3d^{10}$) complex[2a] have a similar distorted trigonal antiprism (TAP) 6-coordinated structure, as might be expected. Selected bond lengths and bond angles of **2**, together with some TAP structural model parameters,[2a] are given in Table 3.

The six Cd−N distances are calculated to be between 232 pm and 250 pm as shown in Table 3 and are in agreement with the experimental range from 246.9 pm to 259.5 pm found for complex **1** (see Figure 1). The size of the coordination polyhedron in **2**, given by $M-N_6$ (the weighted mean of all M−N bond length, $M-N_A$ not included)[2a] is calculated to be 241.2 pm (weighted by δ = 2.0 pm for each bond length). The model parameters are in fair agreement when the larger size of Cd^{II} ion compared to Zn^{II} ion is taken into account. The distance between the bridgehead nitrogen atom N_A and the metal centre is calculated as 278 pm. This distance is long for an actual bond but is clearly less than 295 pm which is the sum of the covalent radius of Cd (141 pm) and the van der Waals radius of N (154 pm),[13] indicating a moderate non-bonding interaction. It is also clearly shorter than found in the Zn analogue, see Table 3. Consequently, the calculated structure of **2** allows more flexibility in that part of complex where N_A is located than for the other nitrogen atoms coordinated to Cd^{2+}. These results also can explain the fact that in $^1H,^{15}N$ z-GS HMBC experiments, nitrogen atom N_A did not give any cross peak. An ab initio optimized structure of the cation $[Cd\mathbf{L2}]^{2+}$ is shown in Figure 4.

Such an indicated dynamic process, involving the protons at C2 close to the bridgehead nitrogen atom N_A is indeed observed and can easily be studied by ^1H NMR.

At 303 K the ^1H-NMR spectrum of **2** in $CDCl_3$/$[D_6]$DMSO (10:1) shows one broad singlet for the methylene protons of C2 at δ = 3.51. This signal broadens even further when the sample is cooled down to 287 K. Further cooling leads to a splitting of this singlet into two separate signals with a multiplet splitting. At 253 K the dynamics of the diastereotopic protons 2-H and 2′-H are frozen out completely and then their separation is 86.6 Hz. Using now

Figure 4. An ab initio optimized structure and a van der Waals representation of the cation $[Cd\mathbf{L2}]^{2+}$



the Guttowsky−Holm equation[14] modified by Green[15] the activation barrier of the proton topomerization can be calculated as $\Delta G^{\neq}(287\ K) = 56.1 \pm 2.1$ kJ/mol. In contrast to above, the ^{1}H-NMR signals of the aromatic protons do not show significant temperature dependency. This finding also points to a well-defined geometry of the complexation site with strong binding interactions between the Cd^{2+}cation and the pyridine and Schiff-base nitrogen atoms.

This work was carried out with the financial support of *The Finnish Academy* (E. K.), The *Ministry of the Education of Finland* (A. J.) and *Deutsche Akademische Austauschdienst* (M. W.). Part of this work was done in the Organisch-Chemisches Institut, Westfälische Wilhelms-Universität Münster, Germany, for which the financial support of *The Finnish Academy* (A. J.) is gratefully acknowledged. Mr. *Reijo Kauppinen* is thanked for his help with NMR measurements.

Experimental Section

General: Metal salts, 2-pyridylcarbaldehyde and 1,3-diaminopropane were purchased from Merck, tris(2-aminoethyl)amine from Aldrich, powdered molecular sieves (3 Å) from Acros and used as received without further purification. Condensation reactions with molecular sieves were carried out under N_2, using a modified Schlenk technique. NMR spectra were recorded with either a Bruker Avance DRX 500 or a Bruker Avance DPX 250 FT NMR spectrometer. The ^{113}Cd-NMR chemical shift scale was fixed to the signal of a 1-mm diameter capillary tube containing 0.1 M aqueous or ethanolic (in low temperature runs) solutions of $Cd(ClO_4)_2$ inserted coaxially inside the 5-mm NMR tube as an external standard ($\delta = 0.0$). External neat nitromethane was used for the calibration in the case of ^{15}N-NMR experiments. The mass spectrum of **L1** was run with a VG AutoSpec HRMS spectrometer and the HRMS measurement of **L2** was recorded at 70 eV with a MAT 312 Finnigan mass spectrometer. IR spectra of **L2** were recorded with a Nicolet 5DXC FT-IR spectrometer, using KBr pellets.

Crystal-Structure Determinations: A specimen of suitable quality and size of compound **1** was mounted on top of a glass fibre and used for measurements of precise cell constants and intensity data collection with an Enraf Nonius CAD4 diffractometer [Mo-K_α radiation, λ(Mo-K_α) = 0.71073 Å]. During data collection three standard reflections were measured periodically as a general check of crystal and instrument stability. No significant changes were observed for compound **1**, where the data was corrected for decay (−1.4%). Lp correction was applied and intensity data were corrected for absorption effects (max $T = 0.99$, min $T = 0.84$). The atomic scattering factors and anomalous dispersion factors were taken from the International Tables for X-ray Crystallography.[16] The structure was solved by direct methods (SHELXS-86[17]) and completed by full-matrix least-squares techniques against F^2 (SHELXL-93[18]). All non-hydrogen atoms were refined anisotropically. Geometrical restraints were used to prevent anomalous bond lengths for the perchlorate anions. Calculations were performed with the hydrogen atoms in their idealized calculated positions (C−H distance 0.93 Å for aromatic CH and 0.97 Å for CH_2) and allowed to ride on their corresponding carbon atoms with fixed isotropic temperature factors ($U_{iso(fix)} = 1.2 \times U_{eq}$ of the attached C atom). Further information on crystal data, data collection and structure refinement are summarized in Table 1. Selected interatomic distances and angles are shown in the caption to Figure 1. The plots were generated with the program DIAMOND[19] and SCHAKAL92[20]. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-101258. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: int. code +44(1223)336033; E-mail: deposit@ccdc.cam.ac.uk].

Ab Initio Molecular-Orbital Calculations: A full optimization of the structure of tris[4-(2′-pyridyl)-3-aza-3-butenyl]aminecadmium-(II) (**2**) was performed at the ab initio HF level of theory using gradient techniques with the Gaussian 94 set of programs.[21] The effective core potential (ECP) standard basis set Lan2DZ[22] was utilized for cadmium. The full-electron standard basis set 3-21G*[23] was used for all other atoms. A starting MM^+ structure for the ab initio calculations was optimized using the HyperChem 4.5 program.[24]

1,3-Bis(pyridine-2-carboxaldimino)propane (**L1**): We have earlier reported the synthesis of **L1**.[1] The structure of **L1** was further characterized by elemental analysis, ^{1}H/^{13}C NMR, ^{1}H,^{13}C HMQC and ^{1}H,X (X = ^{13}C,^{15}N) HMBC as well as mass spectrometry. All attempts to crystallize **L1** failed. − ^{1}H NMR (CD_3OD, 250.13 MHz, 303 K): δ = 2.15 (m, 9-H), 3.80 (m, 8-H, 10-H), 7.46 (t, 3-H), 7.88 (d, 4-H), 8.00 (m, 5-H), 8.41 (s, 7-H, 11-H), 8.59 (m, 2-H). − ^{13}C NMR (CD_3OD, 62.90 MHz, 303 K): δ = 32.5 (C-9), 59.8 (C-8, C-10), 122.8 (C-5), 126.6 (C-3), 138.6 (C-4), 150.2 (C-2), 155.1 (C-6), 163.5 (C-7, C-11). − ^{1}H,^{15}N z-GS HMBC

([D$_6$]DMSO, 250.13 MHz/25.35 MHz, 303 K): δ = −35.8/7.46 (N-4/3-H), −62.6/8.41 (N-3/7-H and 11-H). − MS (75 eV); *m/z* (%): 252 [M$^+$]. − $C_{15}H_{16}N_4$ (252.32): calcd. C 71.40, H 6.39, N 22.20; found C 68.82, H 6.32, N 21.49. Owing to the difficulties in purifying **L1**, satisfactory elemental analysis could not be obtained.

Bis{1,3-bis(pyridine-2-carboxaldimino)propane}cadmium(II) Perchlorate {[Cd(**L1**$_2$)](ClO$_4$)$_2$ (**1**)}: To 2.00 mmol of **L1** in 10 ml of methanol was added dropwise methanolic Cd(ClO$_4$)$_2$·6 H$_2$O (1.00 mmol in 10 ml of MeOH) until precipitation was observed. The solution was allowed to stand overnight during which time yellowish crystals of the complex formed. Yield 54%. The crystals were separated by filtration and washed with acetone and a suitable crystal was selected for the X-ray diffraction study.− ^{1}H NMR ([D$_6$]DMSO, 250.13 MHz, 303 K): δ = 1.86 (m, 9-H), 3.73 (m, 8-H, 10-H), 7.68 (m, 3-H), 7.91 (m, 5-H), 8.11 (m, 4-H), 8.57 (s, 7-H, 11-H), 8.75 (m, 2-H). − ^{13}C NMR ([D$_6$]DMSO, 125.75 MHz, 303 K): δ = 31.8 (C-9), 57.8 (C-8, C-10), 125.6 (C-5), 127.4 (C-3), 139.4 (C-4), 149.5 (C-6), 149.9 (C-2), 161.2 (C-7, C-11). − $^{1\,H,13}$C z-GS HMQC ([D$_6$]DMSO, 250.13 MHz/62.90 MHz, 303 K): δ = 125.6/7.91 (C-5, 5-H), 127.4/7.68 (C-3, 3-H), 139.4/7.91 (C-4, 5-H), 139.4/8.11 (C-4, 4-H), 149.9/8.75 (C-2, 2-H), 161.2/8.57 (C-7, C-11, 7-H, 11-H). − ^{1}H,^{15}N z-GS HMBC ([D$_6$]DMSO, 250.13 MHz/25.35 MHz, 303 K): δ = −62.2/8.57 (N-3/7-H and 11-H). − ^{113}Cd NMR {[D$_6$]DMSO, 110.94 MHz, 348 K, calibration with 0.1 M aqueous Cd(ClO$_4$)$_2$}: δ = 84.4.

Tris[4-(2′-pyridyl)-3-aza-3-butenyl]amine (**L2**): 10.0 g of molecular sieves (3 Å, powdered) was thoroughly activated at 500°C in vacuo (oil pump). After addition of 90 ml of toluene, 0.51 ml (500 mg, 3.42 mmol) of tris(2-aminoethyl)amine and 0.98 ml (1.10 g, 10.3 mmol) of 2-pyridylcarbaldehyde, the resulting suspension was stirred under nitrogen at room temperature (23°C) for 12 h. The molecular sieves were then removed by filtration. After evaporation of the solvent, the slightly yellowish oil was dried under vacuum (oil pump). The yield of **L2** was 1.23 g (87%). − IR (NaCl): $\tilde{\nu}$ = 3053 (m) cm^{-1}, 3007 (m), 2940 (vs), 2906 (vs), 2886 (vs), 2850 (vs), 1648 (vs), 1587 (vs), 1567 (vs), 1468 (vs), 1436 (vs), 1352 (m), 1292 (m), 1146 (m), 1066 (s), 1045 (s), 992 (s), 773 (vs), 754 (s), 617 (m). − ^{1}H NMR (CDCl$_3$, 500.13 MHz, 303 K): δ = 2.97 (t, ^3J = 6.8 Hz, 6 H, 1-H), 3.75 (t, ^3J = 6.8 Hz, 6 H, 2-H), 7.22 (m, 3 H, 4′-H), 7.64 (m, 3 H, 5′-H), 7.87 (m, 3 H, 6′-H), 8.30 (s, 3 H, 4-H), 8.56 (m, 3 H, 3′-H). − ^{1}H NMR(CD$_3$CN, 500.13 MHz, 303 K): δ = 2.93 (t, ^3J = 6.5 Hz, 6 H, 1-H), 3.72 (dt, ^3J = 6.5 Hz, ^4J = 1.3 Hz, 6 H, 2-H), 7.32 (m, 3 H, 4′-H), 7.72 (m, 3 H, 5′-H), 7.89 (m, 3 H, 6′-H), 8.28 (s, 3 H, 4-H), 8.56 (m, 3 H, 3′-H). − ^{1}H NMR ([D$_6$]DMSO, 250.13 MHz, 303 K): δ = 2.88 (t, ^3J = 6.3 Hz, 6 H, 1-H), 3.69 (t, ^3J = 6.3 Hz, 6 H, 2-H), 7.36 (m, 3 H, 4′-H), 7.73 (m, 3 H, 5′-H), 7.86 (m, 3 H, 6′-H), 8.30 (s, 3 H, 4-H), 8.56 (m, 3 H, 3′-H) . − ^{13}C NMR (CDCl$_3$, 125.75 MHz, 303 K): δ = 55.3 (C-1), 59.8 (C-2), 121.2 (C-6′), 124.5 (C-4′), 136.4 (C-5′), 149.3 (C-3′), 154.5 (C-1′), 162.2 (C-4). − ^{13}C NMR (CD$_3$CN, 125.75 MHz, 303 K): δ = 56.1 (C-1), 60.5 (C-2), 121.4 (C-6′), 125.6 (C-4′), 137.5 (C-5′), 150.3 (C-3′), 155.8 (C-1′), 163.5 (C-4) . − ^{1}H,^{13}C HMQC (CD$_3$CN, 500.13/125.75 MHz, 303 K): δ = 56.1/2.93 (C-1, 1-H), 60.5/3.72 (C-2, 2-H), 121.4/7.89 (C-6′, 6′-H), 125.6/7.32 (C-4′, 4′-H), 137.5/7.72 (C-5′, 5′-H), 150.3/8.56 (C-3′, 3′-H), 163.5/8.28 (C-4, 4-H). − ^{1}H,^{13}C HMBC (CDCl$_3$, 500.13 MHz/125.75MHz, 303 K): δ = 55.3/3.75 (C-1/2-H), 59.8/2.97 (C-2/1-H), 59.8/8.30 (C-2/4-H), 121.2/7.22 (C-6′/4′-H), 121.2/8.30 (C-6′/4-H), 124.5/7.87 (C-4′/6′-H), 136.4/8.56 (C-5′/3′-H), 149.3/7.22 (C-3′/4′-H), 149.3/7.64 (C-3′/5′-H), 154.5/7.64 (C-1′/5′-H), 154.5/8.30 (C-1′/4-H), 154.5/8.56 (C-1′/3′-H), 162.2/3.75 (C-4/2-H). − ^{1}H,^{15}N z-GS HMBC (CDCl$_3$, 25.35 MHz/250.13 MHz, 303 K): δ = −42.0/2.97 (N$_B$/1-H), −42.0/8.30 (N$_B$/4-H), −66.8/7.22 (N$_C$/4′-H), −347.0/3.75 (N$_A$/2-H). − ^{1}H,^{15}N z-GS HMBC ([D$_6$]DMSO, 25.35 MHz/250.13 MHz, 303 K): δ = −38.9/2.88 (N$_B$/1-H), −38.9/8.30 (N$_B$/4-H), −62.2/7.36 (N$_C$/4′-H), −62.2/7.73 (N$_C$/5′-H), −62.2/8.56 (N$_C$/3′-H), −347.1/3.69 (N$_A$/2-H). − HR MS (75 eV) (C$_{24}$H$_{27}$N$_7$): calcd. 413.23279, found 413.23191.

In Situ Preparation of Tris[4-(2′-pyridyl)-3-aza-3-butenyl]aminecadmium(II) Nitrate {[Cd**L2**](NO$_3$)$_2$ (**2**)}: 31 mg (74.5 μmol) of tris[4-(2′-pyridyl)-3-aza-3-butenyl]amine (**L2**) was dissolved in 0.5 ml of CDCl$_3$. The solution was mixed with a portion of 8.0 mg (25.9 μmol) of Cd(NO$_3$)$_2$·4H$_2$O. To this mixture [D$_6$]DMSO was added dropwise until the precipitate was dissolved. The ^{1}H-NMR chemical-shift changes unambiguously revealing the complex formation between Cd^{2+}cation and **L2**, the molar ratio **2**/**L2** being 1:3 at this stage. After another addition of 15.0 mg (48.6 μmol) of the Cd salt the Schiff base **2** was completely complexed with Cd^{2+} cation. The same procedure was also carried out in pure [D$_6$]DMSO. − ^{1}H NMR (CDCl$_3$/[D$_6$]DMSO = 10:1, 500.13 MHz, 303 K): δ = 2.70 (m, 6 H, 1-H), 2.79 (br. s, 8 H, H$_2$O), 3.51 (br. s, 6 H, 2-H and 2-H′), 7.29 (m, 6 H, 3′-H and 4′-H), 7.68 (m, 3 H, 6′-H), 7.80 (m, 3 H, 5′-H), 8.58 (s, 3 H, 4-H). − ^{1}H NMR (CDCl$_3$/[D$_6$]DMSO = 10:1, 500.13 MHz, 253 K): δ = 2.65 (m, 6 H, 1-H), 3.27 (br. s, 8 H, H$_2$O), 3.38 (m, 3 H, 2-H or 2-H′), 3.55 (m, 3 H, 2-H′ or 2-H), 7.25 (m, 6 H, 3′-H and 4′-H), 7.67 (m, 3 H, 6′-H), 7.79 (m, 3 H, 5′-H), 8.56 (s, 3 H, 4-H). − ^{1}H NMR([D$_6$]DMSO, 250.13 MHz, 303 K): δ = 3.01 (br. s, 6 H, 1-H), 3.77 (br. s, 8 H, H$_2$O), 3.83 (br. s, 6 H, 2-H), 7.72 (m, 6 H, 3′-H and 4′-H), 8.08 (m, 3 H, 6′-H), 8.28 (m, 3 H, 5′-H), 8.94 (s, 3 H, 4-H) . − Variable-temperature ^{1}H NMR: $\Delta G^{\neq}(T_C)$ = R·T_C ln [(R·T_C·21/2)/(2π·N$_A$·h·Δν)], $\Delta G^{\neq}$(287 K) = 56.1 kJ mol^{-1} ± 2.1 kJ mol^{-1}, T_C = 287 K (coalescense temperature), Δν (253 K) = 86.6 Hz [difference of the baseline-separated signals of the observed protons (dynamics frozen out)], R = 8.3144 J K^{-1} mol^{-1} (gas constant), N$_A$ = 6.0220 × 10^{23} mol^{-1} (Avogadro's number), h = 6.6262 × 10^{-34} J s (Planck constant). − ^{13}C NMR (CDCl$_3$/[D$_6$]DMSO = 10:1, 125.75 MHz, 303 K): δ = 53.9 (C-1), 54.2 (C-2), 128.5 (C-3′ or C-4′), 129.0 (C-6′), 140.4 (C-5′), 146.3 (C-1′), 148.3 (C-4′ or C-3′), 162.2 (C-4). − ^{13}C NMR (CDCl$_3$/[D$_6$]DMSO = 10:1, 125.75 MHz, 253 K): δ = 53.3 (C-1), 53.9 (C-2), 128.0 (C-3′ or C-4′), 128.4 (C-6′), 140.3 (C-5′), 145.8 (C-1′), 148.0 (C-4′ or C-3′), 161.8 (C-4). − ^{1}H,13C HMQC (CDCl$_3$/[D$_6$]DMSO = 10:1, 500.13 MHz/125.75MHz, 303 K): δ = 53.9/2.70 (C-1/1-H), 54.2/3.51 (C-2/2-H), 128.5/7.29 (C-4′andC-3′/4′-H and 3′-H), 129.0/7.68 (C-6′/6′-H), 140.4/7.80 (C-5′/5′-H), 148.3/7.29 (C-3′ and C-4′/3′-H and 4′-H), 162.2/8.58 (C-4/4-H). − ^{1}H,^{13}C z-GS HMBC (CDCl$_3$/[D$_6$]DMSO = 10:1, 250.13 MHz/62.90MHz, 303 K): δ = 54.2/8.58 (C-2/4-H), 128.5/7.29 (C-3′ and C-4′/4′-H and 3′-H), 128.5/7.68 (C-3′ and C-4′/6′-H), 128.5/7.80 (C-3′ and C-4′/5′-H), 129.0/8.58 (C-6′/4-H), 140.4/7.29 (C-5′/3′-H and 4′-H), 146.3/7.29 (C-1′/3′-H and 4′-H), 146.3/7.68 (C-1′/6′-H), 146.3/7.80 (C-1′/5′-H), 146.3/8.58 (C-1′/4-H), 148.3/7.80 (C-3′/5′-H), 162.2/7.68 (C-4/6′-H). − ^{1}H,^{15}N z-GS HMBC (CDCl$_3$/[D$_6$]DMSO = 10:1, 250.13 MHz/25.35 MHz, 303 K): δ = −91.6/2.70 (N$_B$/1-H), −91.6/8.58 (N$_B$/4-H), −113.7/7.29 (N$_C$/3′-H and 4′-H),-113.7/7.68 (N$_C$/6′-H), −113.7/7.80 (N$_C$/5′-H), −113.7/8.58 (N$_C$/4-H). Keywords: *ortho*-Alkenylpyridines / C–H Activation / Palladium / Pyridine-allyl coupling / Indolizinium derivatives

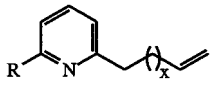
In the presence of stoichiometric amounts of bis(acetonitrile)dichloropalladium(II) the *ortho*-alkenylpyridines 2-but-3′-en-1′-ylpyridine (**1**), 2-pent-5′-en-1′-ylpyridine (**2**), 2-hex-5′-en-1′-ylpyridine (**3**), 2-hept-6′-en-1′-ylpyridine (**4**) and 2-methyl-6-pent-4′-en-1′-ylpyridine (**5**) led to a mixture of coordination compounds such as 2-alken-1′-ylpyridine-κN:$\kappa^2 C$-dichloropalladium(II) and bis(2-alken-1′-ylpyridine-κN)-dichloropalladium(II) together with 2-pent-4-ene-1′,3′-diylpyridine-κN:$\kappa^3 C$-chloropalladium(II) and 2-hex-4-en-1′,3′-diylpyridine-κN:$\kappa^3 C$-chloropalladium(II) in the case of **2** and **3** respectively. The latter were quantitatively demetallated in the presence of an excess of triphenylphosphane to yield tris(triphenylphosphane)palladium(0), 2-vinyl-2,3-dihydroindolizinium chloride and 2-prop-1′-en-1′-yl-2,3-dihydroindolizinium chloride, respectively, by a regioselective addition of the pyridine unit onto the more congested terminal carbon atom of the allyl fragment.

Introduction

The formation of an intramolecular C−N bond between an amine and an olefin activated in the presence of palladium complexes, has been extensively studied. Indeed, Hegedus and co-workers[1] have shown that for primary and secondary amines this amine-olefin coupling reaction, yielding a new C−N bond, results mainly from the addition of the amine to the alkene which has been activated towards nucleophilic addition through coordination to the palladium center. Moreover, recent studies from our group revealed that tertiary amines could also be used as nucleophiles in a different type of C−N coupling reaction to afford cationic and neutral heterocyclic compounds[2]. Here the key step is the formation of an (η^3-allyl)Pd^{II} intermediate by a palladium-assisted C−H activation process. We deemed it of great importance to check whether this coupling reaction could be extended to other nitrogen-containing systems such as those containing an sp^2-hybridised nitrogen atom. We were especially interested in nitrogen nucleophiles in pyridinic systems in these heterocyclisation reactions. It is noteworthy that prior to the work described herein the intramolecular C−N coupling of a nitrogen atom at an allylic position was limited mainly to primary or secondary amines as nitrogen-containing nucleophiles[3]. We can note that heterocycles obtained in this novel way [i.e. by intramolecular addition of a pyridine unit onto a (allyl)Pd derivative] would furnish N-bridgehead heterocycles, many of which display interesting biological properties[4].

The substrates we have chosen for this study are *ortho*-alkenylpyridine derivatives bearing a terminal olefin separated by a chain of carbon atoms of variable length, in the *ortho* position of the pyridine (Scheme 1).

Scheme 1. *ortho*-Alkenyl pyridines (*o*-AlkPy)



1: x = 1; R = H
2: x = 2; R = H
3: x = 3; R = H
4: x = 4; R = H
5: x = 2; R = Me

We report herein the reactivity of the pyridine derivatives **1**−**5** (they are called *o*-AlkPy from now on) in the presence of a palladium(II) complex and base, and we compare this to the reactions observed previously for tertiary amines. We will also describe the interactions between the nitrogen atom and/or the alkene unit and the Pd^{II} center, define under which structural conditions an allylic C−H activation can take place, and, finally study the depalladation of the thus formed organopalladium species affording the anticipated heterocyclic compounds.

Results

Synthesis of the *ortho*-Alkenylpyridines

The *o*-AlkPy ligands **1**−**5** are synthesised according to a known procedure[5]. It is based principally on a C−C coupling reaction between a 2-methylpyridyllithium derivative (prepared in situ) and an alkenyl bromide (Scheme 2).

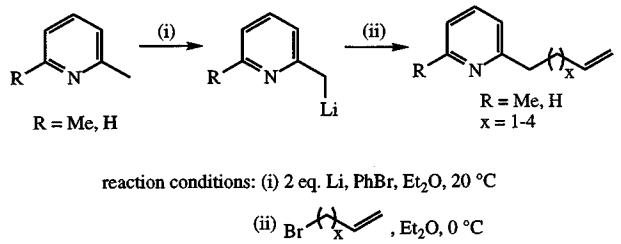
Scheme 2. Synthesis of *ortho*-alkenylpyridines

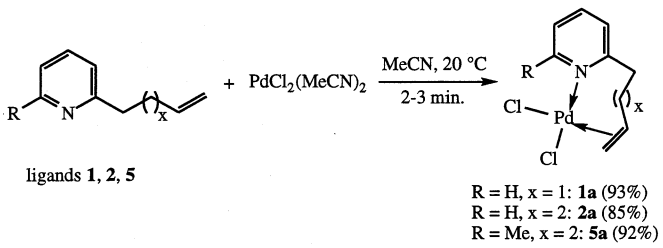


Ligand-Pd^{II} Interaction

The reaction of the *ortho*-alkenylpyridines **1**−**5** with stoichiometric amounts of $PdCl_2(MeCN)_2$ (1:1) leads to the formation of new coordination chelate complexes (Scheme 3). The stability of these compounds (**1a**, **2a** and **5a**) enabled their characterisation both in the solid state and in solution. This is in marked contrast to the corresponding derivatives obtained previously with *ortho*-alkenylaniline or -benzylamine which were only characterised in solution as they were too unstable to be isolated in the solid state.[2a] The structure of compound **2a** was determined by ^{1}H-NMR and IR spectroscopy, microanalysis and mass spectrometry while compounds **1a** and **5a** were identified by comparison of their ^{1}H-NMR spectra with that of **2a** and confirmed by their combustion analyses.

The downfield shift of the *ortho* proton of the pyridine ring in the proton-NMR spectrum of **2a** indicates that the nitrogen atom is coordinated to the Pd atom. The coordination of the olefinic double bond is evidenced by the shielding of all the protons in the lateral chain. Moreover, this is confirmed by the fact that when the chelate complexes are treated with one equivalent of PPh_3 or NEt_3, used to displace the alkene-Pd interaction, the chemical shifts of the latter protons are indeed almost identical to the values observed for the free ligand. In addition, the elemental analysis of **2a** gave a ratio of 1:2:1 with respect to palladium, chlorine and the *o*-AlkPy ligand **2**; the mass spectrum is in agreement with a monomeric species which was expected due to its solubility. Finally, two absorptions with mean intensities corresponding to the frequencies of two Pd−Cl vibrations are seen in the far-IR spectrum: the higher value is assigned to the vibration frequency of the Pd−Cl bond *trans* to N, and the lower one, to the Pd−Cl bond *trans* to the olefin[6][7].

Scheme 3. Chelate-type interaction between the *o*-AlkPy ligands and Pd^{II}



In order to check whether it would be possible to generate an (η^3-allyl)Pd^{II} complex by deprotonation at the allylic position, as it was observed in the case of tertiary amines[2a][2b], the chelate adduct **2a** was treated with a base. Indeed, the corresponding (η^3-allyl)Pd^{II} analogue was formed. Nevertheless, its poor yield (less than 10%) due to the formation of a secondary product of the type $PdCl_2(\mathbf{2})_2$ (see below), incited us to investigate optimum conditions to generate the (allyl)Pd complex.

Ligand-Pd^{II}-Base Interaction: Formation of (η^3-Allyl)Pd^{II} Complexes

The products of the one-pot reaction of the *o*-AlkPy ligands **1**−**5** with one equivalent of $PdCl_2(MeCN)_2$ and a base were studied. The reaction conditions and the products formed are indicated in Table 1 below. Several important remarks can be made concerning these results. Firstly, the nature of the final products seems to depend not only on the number of carbon atoms (*n*) between the nitrogen atom and the terminal olefin but also on the nature of R (R = Me, H). In fact, the formation of an (η^3-allyl)palladium(II) complex, analogous to that obtained in the case of tertiary amines, is limited to the cases where R = H and *n* = 4, 5. In other terms, no allylpalladium complex is observed for *n* larger than 5: the same observation was made in the case of tertiary amines where a different reactivity was noticed for the same length of the carbon chain separating the terminal olefin and the sp^3-hybridised nitrogen atom[2a][2b]. Given that the number of carbon atoms between the nitrogen atom and the allylic fragment in these two (η^3-allyl)Pd^{II} complexes (**2d** and **3d** in Table 1) is the same, we are inclined to believe that in the case of pyridinoolefins, the formation of the allyl complex is under thermodynamic control. However, the formation, in all cases and whatever the reaction conditions, of an important quantity of a secondary product (existing as two isomers except for **5c**) consisting of two *o*-AlkPy ligands and two chlorine atoms coordinated to the same palladium center, limits the yield of the allyl complex for *n* = 4, 5 and R = H. The latter organopalladium compounds **2d** and **3d** are indeed the minor products obtained during this reaction. All attempts (use of different reaction conditions, solvents or bases) to optimise its yield were unsuccessful: 18% was the maximum yield obtained for **2d** [the $PdCl_2(\mathbf{2})_2$ adduct remained the major product of the reaction] when heating a mixture of **2**, 1 equivalent of $PdCl_2(MeCN)_2$ and 2.5 equivalents of NaOAc in MeCN at 65°C for 3 h.

It is worth noting that the stability of these $PdCl_2$(ligand)$_2$ adducts depends on the value of *n*. For *n* < 4 (i.e for **1**), this adduct was not stable and was not isolated although a proton-NMR spectrum of the reaction mixture revealed unambiguously its presence in solution. When *n* increases, a higher yield of the adducts reflects an increase in their stability. A plausible explanation, based on observations from L. D. Pettit's group[5], is the increase in the basicity of the nitrogen atom as it moves further away from the olefinic

double bond with a negative inductive effect. Consequently, the donor ability of the nitrogen atom, via its lone pair of electrons, increases. This is confirmed by the chemioselective formation of this adduct in the case $n = 6$ (compounds **4b** and **4c**). In addition, for longer aliphatic chains ($n = 5$ and 6) this adduct is obtained with an isomerisation of the double bond in the lateral carbon chain of the pyridino-olefin ligand. The latter reaction is rationalised by a classical 1,3-hydrogen shift as described by Sen[8] and others[9]. Finally, the simplicity of the ^{1}H- and ^{13}C-NMR spectra (compared to those obtained for a mixture of the two isomers) suggests the formation of only one isomer of the $PdCl_2$(*o*-AlkPy)$_2$ adduct for ligand **5**. An increase in the steric bulk around the nitrogen atom resulting from the presence of a methyl group in the second *ortho* position of the pyridine ring would most probably favour the formation of the *anti* isomer **5c** rather than the *syn* isomer.

As shown in Scheme 4, ligand **2** is metallated by the palladium salt $PdCl_2(MeCN)_2$ in the presence of 2 equivalents of K_2CO_3 in MeCN to afford the (η^3-allyl)Pd^{II} complex **2d** and the two isomers **2b** and **2c** of the adduct $PdCl_2$(**2**)$_2$ as the main products, along with some palladium black and traces of unidentified products. After Celite filtration, **2d** (15%) and a mixture of isomers **2b** and **2c** (30%) were isolated by column chromatography on silica gel using ethyl acetate as eluant.

The (η^3-allyl)Pd^{II} complex **2d** was structurally characterised by microanalysis and ^{1}H- and ^{13}C-NMR spectroscopy. The ^{1}H-NMR spectrum shows the presence of the expected signals for an η^3-allyl fragment: a multiplet at $\delta \approx 5.5$ corresponding to H_b, coupled to H_a, H_c and H_d (Scheme 4); the terminal CH_2 group with the characteristic *syn* ($^3J_{HbHc}$ = 6.68 Hz), *anti* ($^3J_{HbHd}$ = 11.87 Hz) and *gem* ($^2J_{HcHd}$ = 1.1 Hz) couplings. The intramolecular coordination of the ni-

Table 1. Ligand-Pd^{II}-base interaction

Entry	Ligands (o-AlkPy)	Products formed	Conditions / yield [a]
1	 **1** (n = 3)	$PdCl_2$(**1**)$_2$ (**1b**, **1c**)	1,5 eq.K_2CO_3, MeCN, 65°C, 2h / [b]

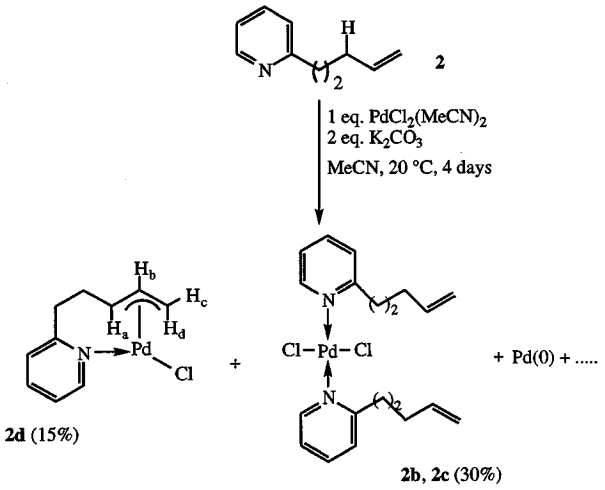
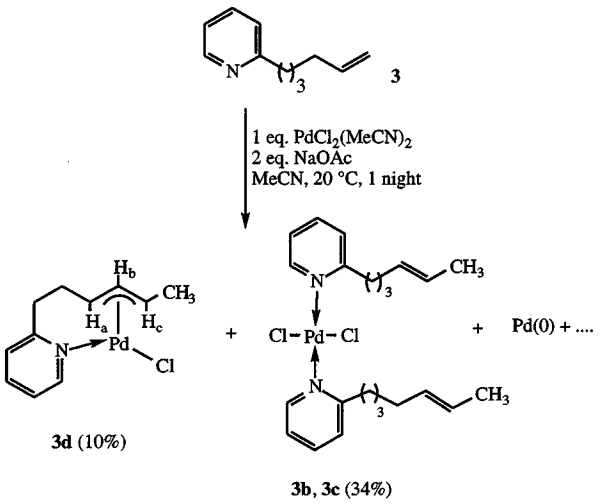
Scheme 4



trogen atom is evidenced by the deshielding of the *ortho* proton (δ = 9.4 compared to 8.4 for the free ligand). The ^{1}H-NMR spectrum of **2d** indicates the presence of only one isomer in which the coupling constant between H_b and H_a is characteristic for two protons in an *anti* position ($^3J_{HaHb}$ = 11.5 Hz) suggesting that the carbon chain is in a *syn* position to H_b.

The $PdCl_2(\mathbf{2})_2$ adduct results from the higher affinity of a palladium(II) center for an sp^2-nitrogen atom. This compound was characterised by ^{1}H and ^{13}C NMR, elemental analysis and IR. The ^{1}H-NMR spectrum shows two distinct doublets of doublets in a 1:1 ratio at $\delta \approx 9$. In the presence of a drop of deuterated pyridine this spectrum remained unchanged but with a larger excess, the free *o*-AlkPy ligand **2** and the yellow adduct $PdCl_2(pyr\text{-}D_5)_2$ were formed. All these observations seem to indicate that the terminal olefin of the lateral chain is not coordinated and that a simple adduct is formed by the coordination of *o*-AlkPy ligand **2** on the palladium(II) center. The combustion analysis is in agreement with the presence of two chlorine atoms and two ligands around one atom of palladium. The far-IR spectrum of this compound shows only one large and intense band at 347 cm^{-1}: this vibration frequency is characteristic of a Pd−Cl bond *trans* to a chlorine atom[6][7]. Thus these data indicate that the $PdCl_2(\mathbf{2})_2$ adduct is a mixture of two isomers, in a 1:1 ratio. For one of these isomers, the two lateral carbon chains are on the same side of the coordination plane of the palladium center (*syn* isomer) and in the other isomer, they are opposite each other with respect to this plane (*anti* isomer). The (η^3-allyl)Pd^{II} complex **3d** and the mixture of isomers **3b** and **3c** (Scheme 5) were isolated in an analogous way to that described for **2d**, **2b** and **2c**. Their structures were determined mainly by ^{1}H and ^{13}C NMR. The proton NMR of **3d** shows the presence of only one compound where the multiplet at δ = 5.5 characteristic of H_b, the central proton of the allylic unit is no longer observed. Instead a triplet at δ = 5.3 was found, indicating that H_b is coupled with H_a and H_c, two magnetically equivalent protons. This suggests that the (η^3-allyl)Pd^{II} complex has the *syn* configuration. The presence of the methyl group is confirmed by a doublet integrating for three protons at δ = 1.55 and with a coupling constant $^3J_{HHc}$ of 6.3 Hz. Finally, evidence for the intramolecular coordination of the nitrogen atom comes from the shielding of the *ortho* proton (δ = 9.41 compared to 8.47 for the free ligand). The structure of the *syn*-(η^3-allyl)Pd^{II} complex **3d** was confimed by ^{13}C-DEPT NMR.

Scheme 5



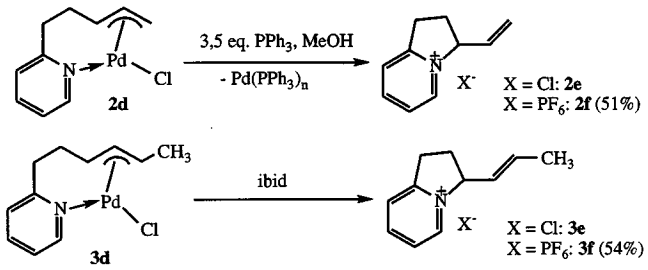
The aspect of the ^{1}H-NMR spectrum of the mixture **3b** and **3c** is also markedly different from that observed for the mixture of isomers **2b** and **2c**: the integration of the multiplets in the olefinic region indicates the presence of fewer olefinic protons (8 instead of 12). On the other hand, we noticed the appearence of a new multiplet integrating for 12 protons at δ = 1.7 and corresponding to the methyl groups. In addition, the ^{13}C-DEPT NMR spectrum shows a signal for methyl groups, thereby confirming the isomerisation of the olefinic double bond in ligand **3** during the course of the reaction and prior to the allylic deprotonation leading to the allyl complex. The same isomerisation process was observed in the case of ligand **4** and the analogous mixture of isomers **4b** and **4c** was isolated and characterised (see Table 1).

Formation of Cationic N-Bridgehead Heterocycles

The (η^3-allyl)Pd^{II} complexes **2d** and **3d** are stable in air and in solution. However, in the presence of an excess (3.5−4 equivalents) of triphenylphosphane in MeOH or MeCN at room temperature, they can be easily demetallated[10]. An orange-yellow solution was obtained together with the precipitation of a pale yellow solid. A proton NMR of the reaction mixture indicated the presence of only one organic compound and the characteristic signals of the phosphane ligands in a Pd^0 complex, $Pd(PPh_3)_n$. After filtration through Celite and anion exchange using KPF_6 in MeOH, the cationic N-heterocycles **2f** and **3f** (Scheme 6) were obtained as pure beige solids. These heterocyclic com-

pounds are indolizinium derivatives incorporating an sp^2-hybridised nitrogen atom shared between a pyridine ring and a 5-membered ring.

Scheme 6



The structures of compounds **2f** and **3f** were deduced from ^1H and ^{13}C NMR, mass spectrometry and combustion analysis. The proton-NMR spectrum of **2f** is rather simple and shows not only that all the protons are different but also that the protons of the lateral carbon chain resonate at lower frequencies compared to those observed for compound **2d**: this general shielding is best explained by the presence of a positive charge on the nitrogen atom. The diastereotopicity of the protons of both CH_2 groups in **2f** is due to the presence of a stereogenic center α to the nitrogen atom. The structure of compound **3f** was deduced by comparaison of its ^1H- and ^{13}C-NMR spectra with those of **2f**.

Discussion

This study was aimed at defining the reactivity of *ortho*-alkenylpyridine ligands with a Pd^{II} center in the presence of a base. We intended to extend the scope of the unusual reactions that were observed for the related *ortho*-alkenylanilines or -benzylamines under similar conditions, i.e. the palladium-mediated heterocyclisation of these ligands which occured via the formation of C−N bonds at the allylic position[2].

We have noticed one major similarity between tertiary amines and pyridine derivatives concerning the above-mentioned heterocyclisation process: the addition of the nucleophile (amine or pyridine) always takes place at an allylic terminal (i.e. after an allylic deprotonation in the presence of a base) instead of a direct nucleophilic addition on the activated olefin due to its coordination to a Pd^{II} center, as observed in the case of primary and secondary amines[1]. Indeed, the results we have obtained clearly demonstrate that there is very little similarity between these types of nitrogen ligands and the corresponding pyridine derivatives, since in the present work we have mainly observed the formation of stable pyridine−palladium adducts. This result is not surprising as it is well known that Pd^{II} has a much larger affinity to a pyridine nitrogen atom as compared to an sp^3-hybridised tertiary amine nitrogen atom[11].

However, in two cases we could observe the formation of some (η^3-allyl)Pd-containing complexes by a C−H activation reaction. It is interesting to note that (i) this moiety has only been observed for two ligands and (ii) that both compounds do have the same geometry around the (Py-allyl)Pd unit: in both cases a CH_2-CH_2 chain is found between the pyridine ring and one extremity of the allylic unit. This is due to the stabilisation of the π-allyl fragment by an intramolecular coordination of the pyridine, thereby confering an ideal coordination geometry for the palladium atom in an analogous manner to that observed for a Pd(benzylamine-allyl) derivative[2a].

Moreover, for ligand **3** a prior C−H migration is essential in order to obtain the same type of stabilised (Py-allyl)Pd compound observed for ligand **2** (see Table 1). However, this C−H migration occurs only once since for ligand **4**, we observed only the formation of the bis(*ortho*-alkenylpyridine)palladium adduct. This behaviour is in marked contrast to that of the corresponding ligands bearing an sp^3-hybridised tertiary amine unit[2a][2b], for which the formation of the (η^3-allyl)Pd moiety was always possible (although it could not be isolated in each case studied) regardless of the number of carbon atoms between the olefin and the N atom. We interpret this as a consequence of the strong coordination of the sp^2-hybridised nitrogen atom of the pyridine moiety to the Pd center prior to the C−H activation at the allylic position by this metal, whereas for the tertiary amine alkene derivatives the interaction of the alkene to the palladium center seems to be the key step of the metallation process, yielding the (π-allyl)Pd derivatives in a quantitative way.

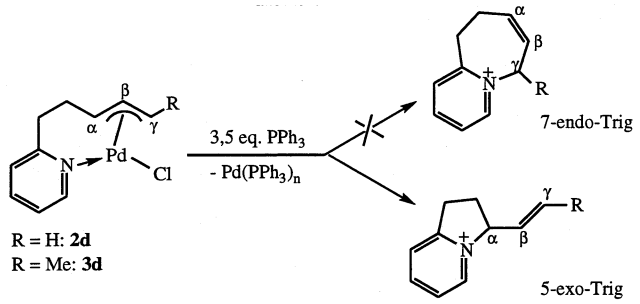
Although the corresponding (η^3-allyl)Pd^{II} complexes have been observed for pyridine derivatives, their yields are low (less than 20%) compared to those for tertiary amine analogues. These compounds are most likely formed by the intermediacy of the monomeric chelate adduct where both the nitrogen atom and the olefin are coordinated to the palladium atom (its presence in solution was unambiguously identified by ^1H NMR of the reaction mixture at the beginning of the reaction). However, the C−H activation process takes place only partially since the compounds with two ligands per palladium, $PdCl_2$(*o*-AlkPy)$_2$, are the major products of the reaction. Nevertheless, once they are formed no reverse reaction could be envisaged to transfer one species into the other; this result seems to indicate clearly the absence of any type of equilibrium between these two Pd^{II} compounds. One may anticipate, from our failed attempts to increase the yields of the allylic compounds starting from **2a** for instance, that the formations of these two classes of compounds are in competition with each other; however, in the absence of any reliable kinetic data we cannot conclude about this important mechanistic point.

It is, however, interesting to note the ease with which the allylic compounds can be demetallated to yield quantitatively heterocyclic compounds with a stable C−N bond even in the presence of Pd^0 formed. Indeed, even if some rare examples of (allyl)Pd^{II} complexes analogous to that observed for the pyridino-olefins are known for quinoline derivatives[12], the cyclisation reaction by the addition of an sp^2-nitrogen atom on an allylic fragment has never been

studied until now. One of the reasons is, most probably, a reversible reaction implying a C−N bond rupture, between the pyridinium ion formed and the simultaneous obtention of Pd^0 during the demetallation reaction. Indeed, allylpyridinium moities synthesised by other methods are used to generate in the presence of Pd^0 an (η^3-allyl)Pd^{II} complex and a trisubstituted pyridine (playing the role of a neutral leaving group) by an oxidative addition of the C−N bond on the Pd^{II} center[13]. Moreover, another reason which may justify that hitherto only few studies have been carried out concerning pyridine-allyl coupling reactions yielding new C−N bonds, is the result of the recent study carried out on the reversible intermolecular addition of a pyridine on an allylic unit[14]. Thus, this reversibility reflects the instability of the C−N^+ bond formed during this study.

The demetallation of the (η^3-allyl)Pd^{II} compounds is induced by an intramolecular attack of the sp^2-hybridised nitrogen atom on the allylic fragment and this can occur either as an endo- or exocyclisation yielding different cyclic products. In the case of substrate **2d** or **3d**, only one heterocycle is obtained by the formation of a new C−N bond between the sp^2-nitrogen and the more substituted carbon atom C_α to give a 5-membered heterocycle (Scheme 7). We have, therefore, a remarkably high regioselectivity when taking into account the two possible electrophilic centers on the allylic fragment.

Scheme 7



According to Baldwin rules governing the formation of cyclic products[15], both the formation of the 5-membered heterocycle and that of the 7-membered one are favoured processes. It is, however, accepted that the formation of 5-membered rings is more frequent than that of 7-membered derivatives[16]. An important observation is the fact that in the case of tertiary amines, for the closely related (π-allyl)Pd compounds (i.e. those having 3 carbon atoms between the N atom and the allylic fragment) the endocyclisation process was exclusively observed[2a]. This highlights the difference of the strength of the N−Pd bond in the latter case as compared to the pyridine compounds: the endocyclisation could only take place via an intermediate in which the NR_2 unit was not coordinated to the palladium atom. On the other hand, for the pyridine-containing compounds the exocyclisation could be achieved without dissociation of the Py−Pd bond by a *cis* migration of the N atom to the more substituted allylic carbon atom; however, this assumption merits a more substantial mechanistic study.

Moreover, in the case of substrate **3d**, the exocyclisation should be even more favorable owing to the steric effect of the methyl group at the external (C_γ) allylic carbon atom. Consequently, the nucleophilic attack at this position becomes more difficult[17].

Conclusion

The present study shows that even if there is a remarkable difference in affinity to a palladium(II) center between a pyridinic sp^2-nitrogen and a tertiary amino sp^3-nitrogen atom, it is possible to generate the (η^3-allyl)Pd^{II} analogue of the pyridino-olefin derivative. The demetallation of the latter complex yields, regioselectively and in mild conditions, a stable cationic N-heterocycle by the intramolecular formation of a C−N bond between the pyridinic nitrogen atom and the allylic C_3 unit. Nevertheless, the low yield of the allylpalladium complex associated with the fact that it is observed in only a few cases, considerably limits the scope of this elegant cyclisation reaction for the formation of cationic N-bridgehead heterocycles. Consequently, new methods to generate selectively and quantitatively the key (η^3-allyl)Pd^{II} intermediate are under investigation.

Experimental Section

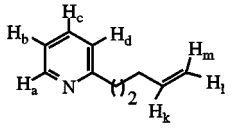
General: All the reactions described herein were carried out without any particular precaution unless otherwise stated. All the solvents used were dried beforehand and distilled under nitrogen. The other commercial starting materials were utilised without further purification. Filtrations to remove the black deposit of metallic palladium formed during the depalladation reactions, were performed using Celite pads. Column chromatography was carried out either on silica gel (Geduran SI 60; 0.063−0.200 mm) or on alumina 90 (Activity II−III mesh; 0.063−0.200 mm) from Merck. ^{1}H- (300.13 or 200.13 MHz), ^{13}C- (75.47 or 50.32 MHz) and ^{31}P-NMR spectra (81 MHz) were recorded with AC 300 and AC 200 Bruker instruments and externally referenced to TMS. Coupling constants (J) are given in Hertz. All deuterated solvants were dried with molecular sieves (4 Å) and stored under nitrogen. Combustion analyses were performed by the Service Central de Microanalyses du CNRS, Université Louis Pasteur, Strasbourg, France or by that of Vernaison, France. All Mass spectra were performed by the Laboratoire de Spectroscopie de Masse de l'Université Louis Pasteur, Strasbourg. IR spectra were recorded with an IRFT Bruker instrument and the absorption bands are given in cm^{-1}.

Ligands Synthesis: Ligands **1** and **2** were prepared according to published procedures[5]. Ligands **3**, **4** and **5** were synthesised in an analogous manner. The analytical data for these ligands are listed below.

Ligand **1**: Yellow oil (83%). − ^{1}H NMR ($CDCl_3$): δ = 8.45−8.43 (m, 1 H, H_o), 7.48 (td, 1 H, H_m, ^3J = 8.4 Hz, ^4J = 1.9 Hz), 7.09 (d, 1 H, H_m, ^3J = 19.2 Hz), 7.04−6.97 (m, 1 H, Ar, H_p), 5.86−5.73 (m, 1 H, HC=C), 5.01−4.87 (m, 2 H, C=CH_2, $^3J_{trans}$ = 17.1 Hz, $^3J_{cis}$ = 10.2 Hz), 2.83−2.78 (m, 2 H, Ar-CH_2), 2.47−2.39 (m, 2 H, CH_2). − ^{13}C NMR ($CDCl_3$): δ = 161.4, 149.2, 137.7, 136.2, 123.0, 121.0, 115.1 (aromatic and olefinic), 37.7, 33.7 (CH_2).

Ligand **2**: Pale yellow oil (78%). − The indices allocated to certain protons are given in Figure 1. − ^{1}H-NMR ($CDCl_3$): δ = 8.45 (d, 1 H, H_a, $^3J_{HaHb}$ = 3.4 Hz), 7.52 (m, 1 H, H_c), 7.03 (m, 2 H, H_b + H_d), 5.80 (m, 1 H, H_k, $^3J_{HkHm}$ = 18.8 Hz, $^3J_{HkHl}$ = 9.3 Hz), 4.92 (m, 2 H, H_l + H_m, $^2J_{HlHm}$ = 1.8 Hz), 2.74 (t, 2 H, Ar-CH_2), 2.06 (m, 2 H, CH_2−CH=), 1.80 (m, 2 H, CH_2-CH_2-CH=).

Figure 1. Numbering scheme for the protons of ligand **2**



Ligand **3**: Orange yellow oil (94%). − ^{1}H NMR ($CDCl_3$): δ = 8.47 (d, 1 H, H_o, ^3J = 4.8 Hz); 7.54 (td, 1 H, H_m, ^3J = 7.7, Hz, ^4J = 1.8 Hz), 7.10 (d, 1 H, H_m, ^3J = 7.8 Hz); 7.07−7.02 (m, 1 H, H_p), 5.82−5.71 (m, 1 H, HC=C), 5.01−4.88 (m, 2 H, H_2C=C), 2.76 (t, 2 H, Ar-CH_2, ^3J = 7.7 Hz), 2.11−2.03, 1.78−1.67, 1.49−1.38 (3 m, 6 H, CH_2). − ^{13}C NMR ($CDCl_3$): δ = 162.3, 149.2, 138.8, 136.3, 122.7, 120.9 (aromatic and olefinic), 38.3, 33.6, 29.4, 28.7 (CH_2). − MS; *m/z*: 162 (M^+ + H), 120 (M^+ − C_3H_5), 106 (M^+ − C_4H_7), 93 (M^+ − C_5H_8).

Ligand **4**: Yellow oil (93%). − ^{1}H NMR ($CDCl_3$): δ = 8.52−8.50 (m, 1 H, Ar, H_o), 7.56 (td, 1 H, Ar, ^3J = 7.7 Hz, ^4J = 1.9 Hz), 7.12 (d, 1 H, Ar, ^3J = 7.8 Hz), 7.09−7.05 (m, 1 H, Ar), 5.86−5.72 (m, 1 H, HC=C), 5.01−4.89 (m, 2 H, C=CH_2), 2.77 (t, 2 H, Ar−CH_2, ^3J = 7.6 Hz), 2.09−2.01, 1.78−1.68, 1.48−1.32 (3 m, 8 H, CH_2). − ^{13}C NMR ($CDCl_3$): δ = 162.3, 149.1, 138.9, 136.1, 122.6, 120.8 (aromatic and olefinic CH), 114.2 (olefinic CH_2), 38.3, 33.6, 29.7, 28.8, 28.7 (CH_2).

Ligand **5**: Pale yellow oil (80%). − ^{1}H NMR ($CDCl_3$): δ = 7.45 (t, 1 H, Ar, ^3J = 7.7 Hz), 6.94−6.90 (m, 2 H, Ar), 5.87−5.75 (m, 1 H, HC=C), 5.04−4.92 (m, 2 H, C=CH_2), 2.74 (t, 2 H, Ar-CH_2, ^3J = 7.7), 2.51 (s, 3 H, CH_3), 2.14−2.07, 1.84−1.74 (2 m, 4 H, CH_2). − ^{13}C NMR ($CDCl_3$): δ = 161.5, 157.7, 138.5, 136.4, 120.4, 119.5, 114.8 (aromatic and olefinic), 37.9, 33.5, 29.3 (CH_2), 24.6 (CH_3). − MS; *m/z*: 161 (M^+), 160 (M^+ − H), 120 (M^+ − C_3H_5), 107 (M^+ − C_4H_6).

Synthesis of the Chelate Adducts

Compound **2a**: To a suspension of $PdCl_2(MeCN)_2$ (0.93 g; 3.6 mmol) in acetonitrile (40 ml) was added dropwise a solution of ligand **2** (0.525 g; 3.6 mmol). The yellow suspension became gradually homogeneous with increasing amounts of the ligand. The reaction mixture was stirred for 10 min at room temperature. After removal of the solvent by evaporation, drying, washing with ether (2 × 40 ml), compound **2a** was obtained as a fine, orange-coloured powder (0.985 g; yield 85%). − ^{1}H NMR ($CDCl_3$): δ = 8.63 (d, 1 H, H_{ortho}, ^3J = 5.5 Hz), 7.83 (t, 1 H, H_{para}, ^3J = 7.7 Hz), 7.38−7.34 (m, 2 H, H_{meta}), 6.43−6.31 (m, 1 H, CH_2=C*H*), 5.78 (dd , 1 H, CH_2=CH, ^3J = 7.7 Hz, ^2J = 2.1 Hz), 4.95−4.83 (m, 1 H, Ar−CH_2), 4.68 (d, 1 H, CH_2=CH, ^3J = 14.7 Hz), 3.39−3.32 (m, 1 H, Ar−CH_2), 2.61−2.48, 2.34−2.16, 2.07−1.89, 0.95−0.88 (4 m, 4 H, CH_2). − IR (polyethylene pellet): 341 (br, m, νPd−Cl *trans* to N); 308 (br, m, νPd−Cl *trans* to the olefin). − MS (FAB); *m/z*: 328 (M^+ + 3H), 254 [M^+ − 2 Cl)]. − $C_{10}H_{13}Cl_2NPd$ (324.5): calcd. C 37.01, H 4.04, N 4.32; found C 37.10, H 4.12, N 4.38.

Compounds **1a** and **5a** were synthesised in the same way as described for compound **2a** above.

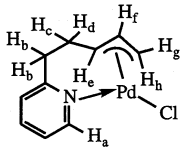
Compound **1a**: Dark yellow solid (93%). − ^{1}H NMR ($CDCl_3$): δ = 8.93 (d, 1 H, H_o, ^3J = 5.6 Hz), 7.85 (t, 1 H, H_m, ^3J = 7.5 Hz), 7.40−7.26 (m, 2 H, H_p + H_m), 6.91−6.78 (m, 1 H, C=CH), 5.85 (d, 1 H, C=CH_2, $^3J_{cis}$ = 8.2 Hz), 4.41 (d, 1 H, C=CH_2, $^3J_{trans}$ = 14.1 Hz), 3.92 (td, 1 H, CH_2, ^3J = 12.6 Hz), 3.34−3.27, 2.80−2.77, 1.70−1.54 (3 m, 3 H, CH_2). − $C_9H_{11}Cl_2NPd$ (310.5): calcd. C 34.79, H 3.54, N 4.51; found C 34.65, H 3.36, N 4.71.

Compound **5a**: Orange yellow solid (92%). − ^{1}H NMR ($CDCl_3$): δ = 7.71 (t, 1 H, Ar, ^3J = 7.5 Hz), 7.24 (d, 1 H, Ar, ^3J = 8.3 Hz), 7.17 (d, 1 H, Ar, ^3J = 7.7 Hz), 6.55−6.35 (m, 1 H, C=CH), 5.65 (d, 1 H, C=CH_2, ^3J = 7.1 Hz), 5.18−5.07 (m, 1 H, CH_2), 4.57 (d, 1 H, C=CH_2, ^3J = 14.5 Hz), 3.40−3.32 (m, 1 H, CH_2), 3.28 (s, 3 H, CH_3), 2.63−2.43, 2.25−2.10, 2.05−1.85, 1.05−0.82 (4 m, 4 H, CH_2). − $C_{11.6}H_{16.4}Cl_2NPd$ (**5a** + 0.1 C_6H_{14}) (the solvent was detected in the ^{1}H-NMR spectrum) (347.2): calcd. C 40.11, H 4.70, N 4.03; found C 40.14, H 4.45, N 4.11.

Synthesis of the (η^3-Allyl)palladium Complex **2d** *and of the Mixture* **2b** + **2c**: A suspension containing ligand **2** (1.3 g, 8.8 mmol), $PdCl_2(MeCN)_2$ (2.3 g, 8.8 mmol) and 2 equiv. of NaOAc (1.45 g, 17.6 mmol) in acetonitrile (50 ml) was heated at 65°C for 3 h. A red solution with a considerable deposit of metallic palladium was thus obtained. After filtration of the Pd^0 so formed through Celite, the clear solution was concentrated to dryness. The brown oily residue was then extracted with CH_2Cl_2 (ca. 5 ml). A column chromatography using silica gel and ethyl acetate as eluant allowed the migration of a first yellow band corresponding to the mixture **2b** + **2c**. After solvent evaporation, a yellow solid was obtained (1.25 g; yield 30%). Then a second yellow fraction containing compound **2d** was collected (0.412 g; yield 16%).

Compound **2d**: Figure 2 indicates the indices attributed to certain protons.

Figure 2. Numbering scheme for the protons of ligand **2d**



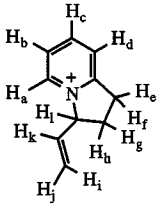
^{1}H NMR ($CDCl_3$): δ = 9.36 (d, 1 H, H_a, $^3J_{HaH}$ = 5.2 Hz), 7.73, 7.30 (2 m, 3 H, *meta* and *para* protons), 5.45 (m, 1 H, H_f, $^3J_{HfHh}$ = 11.87 Hz, $^3J_{HfHg}$ = 6.68 Hz, $^3J_{HfHe}$ = 11.5 Hz), 3.94 (d, 1 H, H_g), 3.72 (m, 1 H, H_e, $^3J_{HeHc}$ = 5.6 Hz), 3.12 (m, 2 H, H_b, $^3J_{HbHc}$ = 6.74 Hz, $^3J_{HbHd}$ = 3.15 Hz), 2.88 (d, 1 H, H_h), 2.05 (m, 1 H, H_c), 1.85 (m, 1 H, H_d). − ^{13}C NMR ($CDCl_3$): δ = 158.2, 152.2, 138.7, 124.9, 122.9 (aromatic), 111.7, 81.4, 55.9 (allylic), 41.6, 26.4 (CH_2). − $C_{12}H_{16}ClNOPd$ (**2d** + 0.5 $C_4H_8O_2$) (the solvent was detected in the ^{1}H-NMR spectrum) (332.1): calcd. C 43.37, H 4.82, N 4.22; found C 43.74, H 4.81, N 4.42.

Compounds **2b** + **2c**: ^{1}H NMR ($CDCl_3$): δ = 9.02 (d, 2 H, H_o, ^3J = 5.0 Hz), 8.90 (d, 2 H, H_o, ^3J = 4.9 Hz), 7.68 (td, 4 H, H_m, ^3J = 7.5 Hz, ^4J = 1.6 Hz), 7.30−7.18 (m, 8 H, H_m + H_p), 6.05−5.93 (m, 4 H, C=CH), 5.29−5.05 (m, 8 H, C=CH_2), 3.96−3.92 (m, 8 H, CH_2), 2.42−2.18 (m, 16 H, CH_2). − ^{13}C NMR ($CDCl_3$): δ = 164.0, 152.7, 152.2, 138.2, 138.0, 125.4, 124.5, 122.6 (aromatic carbon atoms and olefinic CH), 115.7 (olefinic CH_2), 39.5, 38.9, 33.8, 33.4, 28.2 (CH_2). − IR (polyethylene pellet): 347 (br, s, νPd−Cl *trans* to Cl). − $C_{20}H_{26}Cl_2N_2Pd$ (471.7): calcd. C 50.91, H 5.52, N 5.94; found C 51.62, H 5.52, N 5.63.

Synthesis of Indolizinium Derivatives **2e** *and* **2f**: The reaction of the allylpalladium complex **2d** (220 mg, 0.76 mmol) with 3.5 equivalents of triphenylphosphane (700 mg, 2.66 mmol) in methanol (20 ml), at room temperature and under nitrogen, gave an orange solu-

tion together with a yellow solid that precipitated after only a few minutes of reaction. The reaction mixture was allowed to stir for 1 h. Then after filtration of the fine yellow solid, the filtrate was concentrated to dryness to give an orange oily residue. Column chromatography on alumina using a mixture of ether and methanol (80:20) as eluant, enabled the migration of a yellow band corresponding to the cationic heterocycle **2e** (100 mg, crude yield 72%). Compound **2f** (PF_6^- as conter anion) was obtained pure as a beige solid by treating **2e** with KPF_6 in methanol (112 mg, yield 51%). The indices attributed to the different protons in compounds **2e** and **2f** are indicated in Figure 3.

Figure 3. Numbering scheme for the protons of ligand **2e**



Compound **2e**: ^{1}H NMR ($CDCl_3$): δ = 8.97 (d, 1 H, H_a, ^3J = 5.9 Hz), 8.42 (t, 1 H, H_c, ^3J = 7.7 Hz), 8.09 (d, 1 H, H_d, ^3J = 7.9 Hz), 7.93 (t, 1 H, H_b, ^3J = 6.7 Hz), 6.13 (dd, 1 H, H_l, ^3J = 15.2, 7.6 Hz), 6.00−5.88 (m, 1 H, H_k), 5.68 (d, 1 H, H_i, $^3J_{trans}$ = 16.8 Hz), 5.54 (d, 1 H, H_j, $^3J_{cis}$ = 10.0 Hz), 3.70−3.59, 2.83−2.77, 2.31−2.24 (4 m, 4 H, H_e + H_f + H_g + H_h). − ^{13}C NMR ($CDCl_3$): δ = 158.1, 145.7, 140.7, 132.8, 126.3, 125.3 (aromatic and olefinic CH), 124.6 (olefinic CH_2), 73.4 (N−CH), 31.6, 28.6 (CH_2). − MS (without Cl^-); *m/z*: 146 (M^+), 117 [M^+ − (vinyl + 2H)].

Compound **2f**: ^{1}H NMR ([D_6]acetone): δ = 8.89 (d, 1 H, H_a, ^3J = 6.4 Hz), 8.64 (t, 1 H, H_c, ^3J = 8.6 Hz), 8.24 (d, 1 H, H_d, ^3J = 7.8 Hz), 8.11 (t, 1 H, H_b, ^3J = 6.8 Hz), 6.28−6.17 (m, 1 H, H_k), 5.81−5.68 (m, 1 H, H_l), 5.75 (d, 1 H, H_i, $^3J_{trans}$ = 17.0 Hz), 5.69 (d, 1 H, H_j, $^3J_{cis}$ = 10.2 Hz), 3.83−3.58, 3.05−2.85, 2.62−2.42 (3 m, 4 H, H_e + H_f + H_g + H_h). − $C_{10}H_{12}F_6NP$ (291.2): calcd. C 41.24, H 4.12, N 4.81; found C 40.76, H 4.01, N 4.58.

Synthesis of the (η^3-Allyl)palladium Complex **3d** *and of the Mixture* **3b** + **3c**: To a mixture containing ligand **3** (0.76 g, 4.7 mmol) and $PdCl_2(MeCN)_2$ (1.22 g, 4.7 mmol) in acetonitrile (50 ml) were added 2 equiv. of NaOAc (0.77 g, 9.4 mmol). The reaction mixture was stirred overnight at room temperature. A red solution along with a deposit of black metallic palladium was obtained. After filtration through Celite and concentration of the filtrate to dryness, the brown oily residue was extracted with a minimum amount of CH_2Cl_2. Column chromatography on silica gel using a mixture of ether and acetone (85:15) as eluant, allowed the migration of a first yellow band containing a mixture of isomers **3b** + **3c** (0.473 g, yield 34%), followed by the migration of a second yellow fraction corresponding to the allylpalladium complex **3d** (0.142 g, yield 10%).

Compound **3d**: ^{1}H NMR ($CDCl_3$): δ = 9.41 (d, 1 H, Ar, H_o, ^3J = 5.3 Hz), 7.73 (td, 1 H, Ar, ^3J = 7.7 Hz, ^4J = 1.8 Hz), 7.34−7.27 (m, 2 H, Ar), 5.30 (t, 1 H, $H_{central\ allylic}$, ^3J = 10.8 Hz), 3.83−3.65 (m, 1 H, $H_{allylic}$), 3.53−3.43 (m, 1 H, $H_{allylic}$), 3.19−3.01 (m, 2 H, CH_2), 2.13−1.98 (m, 1 H, CH_2), 1.91−1.71 (m, 1 H, CH_2), 1,55 (d, 3 H, CH_3, ^3J = 6.3 Hz). − ^{13}C NMR ($CDCl_3$): δ = 158.4, 152.7, 138.5, 124.9, 122.8 (aromatic), 112.6, 76.9, 73.7 (allylic), 41.3, 26.4 (CH_2), 17.9 (CH_3).

Compounds **3b** + **3c**: ^{1}H NMR ($CDCl_3$): δ = 9.13−8.80 (m, 4 H, Ar, H_o), 7.67 (t, 4 H, Ar, H_m, ^3J = 6.4 Hz), 7.40−7.08 (m, 8 H, Ar, H_p),, 5.75−5.40 (m, 8 H, C=CH), 3.90 (br s, 8 H, H_2C−C=), 2.60−2.03 (m, 16 H, CH_2), 1.85−1.58 (m, 12 H, CH_3). − ^{13}C NMR ($CDCl_3$): δ = 164.3, 160.6, 152.5, 152.1, 138.2, 130.4, 126.3, 126.1, 125.3, 122.4, 121.4 (aromatic and olefinic), 39.6, 39.1, 32.6, 28.9, 26.6, 23.0, 22.5 (CH_2), 18.1,14.1 (CH_3). − $C_{22.6}H_{31.2}Cl_{3.2}N_2Pd$ (**3b**, **3c** + 0.6 CH_2Cl_2) (the solvent was detected in the ^{1}H-NMR spectrum) (550.8): calcd. C 49.27, H 5.67, N 5.09; found C 49.18, H 5.35, N 5.28.

Synthesis of the Indolizinium Derivatives **3e** *and* **3f** : Compound **3e** was prepared by a similar procedure to that described for **2e**, starting from **3d** (70 mg; 0.23 mmol) and yielding **3e** (36 mg). Compound **3f**, with PF_6^- as counterion instead of Cl^-, was obtained pure as a pale yellow solid (38 mg; yield 54%), by treating a methanol solution of **3e** with KPF_6, followed by a column chromatography on alumina using the same system of eluant as for **2e**.

Compound **3e**: ^{1}H NMR ($CDCl_3$): δ = 8.95 (d, 1 H, H_o, ^3J = 6.1 Hz), 8.37 (td, 1 H, H_m, ^3J = 6.5 Hz, ^4J = 2.0 Hz), 7.99 (d, 1 H, H_m, ^3J = 7.9 Hz), 7.93 (t, 1 H, H_p, ^3J = 6.8 Hz), 6.49−6.37 (m, 1 H, C=C*H*Me, ^3J = 6.5 Hz), 6.23 (dd, 1 H, N−C*H*, ^3J = 8.4, 16.6 Hz), 5.59−5.50 (m, 1 H, *H*C=C), 3.87−3.73, 3.61−3.51, 2.92−2.82, 2.33−2.20 (4 m, 4 H, CH_2), 1.85 (dd, 3 H, CH_3, ^3J = 6.6 Hz, ^4J = 1.6 Hz). − MS (without Cl^-); *m/z*: 160 (M^+), 132 (M^+ − C_2H_4), 106 (M^+ − C_4H_6), 95 (M^+ − C_5H_7).

Compound **3f**: ^{1}H NMR ([D_6]acetone): δ = 8.86 (d, 1 H, H_o, ^3J = 6.2 Hz), 8.60 (t, 1 H, H_m, ^3J = 7.7 Hz), 8.19 (d, 1 H, H_m, ^3J = 7.7 Hz), 8.06 (t, 1 H, H_p, ^3J = 6.6 Hz), 6.37−6.26 (m, 1 H, C=C*H*Me), 5.86−5.77 (m, 1 H, *H*C=C), 5.69 (dd, 1 H, N−C*H*, ^3J = 8.1, 16.3 Hz), 3.78−3.61, 2.95−2.70, 2.51−2.38 (3 m, 4 H, CH_2),1.87 (dd, 3 H, CH_3, ^3J = 6.6 Hz, ^4J = 1.6 Hz). − ^{13}C NMR (CD_3OD): δ = 160.5, 146.5, 141.0, 138.9, 127.4, 127.0 (aromatic and olefinic CH), 126.0 (CH_2 olefinic), 75.2 (N−CH), 32.1, 30.0 (CH_2), 18.1 (CH_3). − $C_{11}H_{14}F_6NP$ (305.2): calcd. C 43.28, H 4.59, N 4.59; found: C 43.02, H 4.41, N 4.37.

Synthesis of the Mixture of Isomers **4b** *and* **4c**: To a solution containing $PdCl_2(MeCN)_2$ (0.78 g, 3.0 mmol) and ligand **4** (0.528 g, 3.0 mmol) in acetonitrile (40 ml) were added 1.5 equiv. of NaOAC (0.37 g, 4.5 mmol). The reaction mixture was heated at 65°C overnight. The black deposit of palladium(0) thereby formed was filtered off using a Celite pad. Then, after evaporation of the solvent, the brown oily residue obtained was extracted using a minimum of CH_2Cl_2. Column chromatography on silica gel with ethyl acetate as eluant allowed the migration of a yellow band containing the mixture **4b** + **4c** (0.335 g, yield 42%). − ^{1}H NMR ($CDCl_3$): δ = 9.00 (d, 2 H, H_o, ^3J = 4.5 Hz), 8.89 (d, 2 H, H_o, ^3J = 5.0 Hz), 7.67 (t, 4 H, Ar, ^3J = 3.7 Hz), 7.26 (br t, 4 H, Ar), 7.19 (t, 4 H, Ar, ^3J = 6.5 Hz), 5.40−5.60 (m, 8 H, HC=CH), 3.92 (t, 8 H, H_2C−C=, ^3J = 7.6 Hz), 2.43−1.95 (m, 24 H, CH_2), 1.80−1.55 (m, 12 H, CH_3). − ^{13}C NMR ($CDCl_3$): δ = 159.5, 147.7, 147.3, 133.2, 126.2, 126.1, 120.5, 120.1, 117.6 (aromatic and olefinic), 35.2, 34.6, 27.6, 24.9,24.7, 24.0, 23.4 (CH_2), 13.1 (CH_3). − $C_{24}H_{34}Cl_2N_2Pd$ (527.9): calcd. C 54.61, H 6.45, N 5.31; found C 53.58, H 5.97, N 4.76.

Synthesis of Compound **5c**: A mixture containing ligand **5** (0.72 g, 4.5 mmol), $PdCl_2(MeCN)_2$ (1.17 g, 4.5 mmol) and 1.5 equiv. of NaOAc (0.55 g, 6.8 mmol) in 50 ml of acetonitrile was heated at 65°C for 3 h. An orange solution containing some black palladium was observed. After filtration through a Celite pad, the solvent was evaporated and the brown oily residue formed was extracted using a minimum of CH_2Cl_2. Column chromatography on silica gel with a mixture of CH_2Cl_2 and hexane (90:10) as eluant allowed the migration of a yellow band. After evaporation of the solvents, compound **5c** was obtained as a beige solid (0.93 g, yield 41%). − ^{1}H

NMR ($CDCl_3$): δ = 7.56 (td, 2 H, Ar, ^3J = 7.7 Hz, ^4J = 3.4 Hz), 7.10 (d, 4 H, Ar, ^3J = 7.6 Hz), 6.03−5.90 (m, 2 H, HC=C), 5.21−5.06 (m, 4 H, C=CH_2), 4.30−4.23 (m, 4 H, CH_2), 3.63 (s, 6 H, CH_3), 2.37−2.44, 2.21−2.11 (2 m, 8 H, CH_2). − ^{13}C NMR ([D_6]acetone): δ = 165.0, 161.2, 139.8, 139.1, 124.3, 123.1, 115.7 (aromatic and olefinic), 40.1, 34.3, 29.1 (CH_2), 27.9 (CH_3). − $C_{25}H_{37}Cl_2N_2Pd$ (**5c** + 0.5 C_6H_{14}) (the solvent was detected in the ^{1}H-NMR spectrum) (542.9): calcd. C 55.31, H 6.82, N 5.16; found C 55.32, H 6.39, N 5.22.

Keywords: Selenium / Spiro compounds / Phosphazene heterocycles / Chelates

The Bis[*N*-(diphenylphosphanylselenoyl)-*P*,*P*-diphenylphosphanylselenoic amidato-*Se*,*Se'*]selenium(II) (**1**) was prepared by treating [K{N($SePPh_2$)$_2$}] with [Se{S_2P(O-*i*Pr)$_2$}$_2$] in THF. The title compound was characterized by means of IR and ^{31}P-NMR spectroscopy and positive-ion FAB mass spectrometry and elemental analysis. The molecular structure was determined using single-crystal X-ray diffraction. The Se(Se_4) core exhibited a quasi perfect square planar geometry. Two selenide ligands are coordinated symmetrically to the central atom forming a spiro complex.

Introduction

The extraordinary ability of the anions $[R_2P(X)NP(X)R_2]^-$ (R = Me, Ph; X = O, S, Se) to form very unusual carbon-free chelate complexes is well known. Some examples are the tetrahedral [M{N($SPMe_2$)$_2$-*S*,*S'*}$_2$] (M = Ni, Fe)[1], the six-coordinated lanthanide complexes [Ln{N($OPPh_2$)$_2$-*O*,*O'*}$_2$][2], the true square planar tellurium(II) complex [Te{N($SPPh_2$)$_2$-*S*,*S'*}$_2$][3] and recently the square planar tin(II) complex [Sn{N($SePPh_2$)$_2$-*Se*,*Se'*}$_2$][4] with the first example of such a geometry for Sn^{II}. The great flexibility of these chelate rings with wide variations in the ring angles (P−N−P, M−X−P, X−P−N) and large bites X···X enables the central atom to "reveal" its preference for a particular geometry, since there is no restrictions imposed by the presence of rigid organic rings, e. g. the β-diketonates, or small rings, with great stereochemical restrictions, like the dithiophosphates or dithiophosphinates.

Twenty years ago, Husebye et al. classified five types of geometries for divalent sulphur, selenium and tellurium complexes with bidentate dithio and related ligands[5]. Complexes of class I are trapezoid planar tetracoordinated with all intramolecular ligand bonds. Class-II compounds are also trapezoid planar, however two of the ligand bonds are intramolecular and the other two intermolecular. Class-III compounds are mainly represented by the bis(4-morpholinethiocarbonyl) trisulfide with a "zigzag" framework; *trans* square planar complexes with monodentate ligands correspond to class IV and bidentate square planar molecules to class V. In 1982, Husebye et al. used the imidotetraphenyldithiodiphosphinate anion as a chelating ligand with a very large bite, in order to synthesis true square planar complexes (class V) with Te^{II} and Se^{II}. They obtained [Te{N($SPPh_2$)$_2$-*S*,*S'*}$_2$][3] which was a true square planar Te^{II} compound (a class-V complex), while the structure of the selenium analogous compound, [Se{N($SPPh_2$)$_2$-*S*,*S'*}$_2$], was intermediate between class I and class II, yet much closer to a class-II complex[6].

The number of compounds where the selenium atom is surrounded by four selenium atoms [Se(Se_4) core] are quite scarce. The bis(*N*,*N*-diethyldiselenocarbamate)Se^{II} is a class-I trapezoid planar complex[7]. The bis(diethyldiselenophosphinate)Se^{II} is a class-II complex[8]. The low-temperature ^{77}Se-NMR solution data of the analogous bis(diisobutildiselenocarbamate) of Se^{II} suggests a four-coordinated structure[9]. Another example with bidentate ligands corresponds to the dianionic complex [(Bu_4N)$_2${Se[Se_2C=$C(CN)_2$]$_2$}], with intrachelating Se−Se−Se angles of 75° and an $SeSe_4E_2$ (E = lone pair) distorted octahedral geometry[10]. Several examples of polyselenide derivatives containing the anion $[Se\{Se_5\}_2]^{-2}$ are known. This anion exhibits a geometry close to the square planar one[11]. The square planar Se_5 moiety with monodentate ligands was observed in tetrakis[*N*-methylbenzothiazole)-3*H*-selenone]selenium(II) tetrafluoroborate (class-IV complex)[12]. However, there are no examples of neutral true square planar neutral complexes containing the Se(Se_4) core and bidentate ligands (a class-V complexes) in the literature.

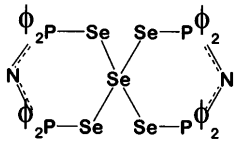
We decided to synthesise the compound [Se{N($SePPh_2$)$_2$-*Se*,*Se'*}$_2$] to determine whether it is a class-V complex, or

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1434−1948/98/1010−1573 $ 17.50+.50/0

isotructural with [Se{N(SPPh$_2$)$_2$-*S,S′*}$_2$] (a class-II compound).

Results and Discussion

Treatment of [K{N(SePPh$_2$)$_2$}] with [Se{S$_2$P(O-*i*Pr)$_2$}$_2$] in THF at room temperature, yielded [Se{N(SePPh$_2$)$_2$-*Se,Se′*}$_2$] (**1**). The compound was purified by thin layer chromatography. Attempts of purification by normal recrystallization methods were unsuccessful because the compound tends to decompose giving red selenium, free ligand, and other compounds. Derivative **1** was characterized on the basis of its elemental analysis and its ^{31}P-NMR, IR and positive-ion FAB MS data and by X-ray crystallography. It is a yellow-orange, air-stable solid, that tends to decompose in solution, soluble in polar organic solvents such as $CHCl_3$, yet insoluble in ethanol or hexane.



1

^{31}P-NMR spectra show that all phosphorus atoms are equivalent. As with other main-group complexes with this ligand, in the IR spectrum the assignments of the phosphazene bands were relatively easy, after identification of the usual phenyl group bands common to the [(PPh$_2$X)$_2$N]$^-$ ligands[13] . Individual assignments of the ν(PSe) bands is not fully possible because of the overlap with the corresponding PNP vibrations.

To date, few P−Se vibrations have been clearly assigned[14]. The FAB mass spectrum of the compound exhibits a low-intensity signal for the corresponding molecular ion, but rather intense peaks resulting from the expected first fragmentations. The most intense peak containing selenium corresponds to [Se(PPh$_2$)$_2$N$^+$]. Since the FAB mass spectrum was obtained in solution, it also shows some fragments due to a decomposition product, e.g. [{Ph$_2$P(Se)NP(Ph$_2$)}$_2$O; *m/z*: 944 and 864]. All the observed signals exhibit the expected isotopic pattern.

Description of the Structure

The structure is built of discrete neutral [Se{N(SePPh$_2$)$_2$-*Se,Se′*}$_2$] molecules, the central selenium atom is coordinated to four other selenium atoms, forming two six-membered carbon-free chelate rings, in a typical spiro arrangement. There are two crystallographically independent molecules in the cell (**1a** and **1b**). According to the cell parameters, **1** is isomorphic with the yellow [Sn{N(SePPh$_2$)$_2$-*Se,Se′*}$_2$] [*a* = 10.124(5), *b* = 13.085(4), *c* = 18.260 Å, α = 89.42(2), β = 82.75(2) , γ = 77.62(2)°] [4] and [Te{N(SPPh$_2$)$_2$-*S,S′*}$_2$] [*a* = 10.187(1), *b* = 12.929(5), *c* = 18.282(3) Å, α = 89.04(2) , β = 82.98(1) , γ = 77.40(2)°][3]. Figure 1 presents the inner coordination sphere, with angles and distances for molecules **1a** and **1b**, whereas Figure 2

Figure 1. The inner coordination sphere in **1a** and **1b**

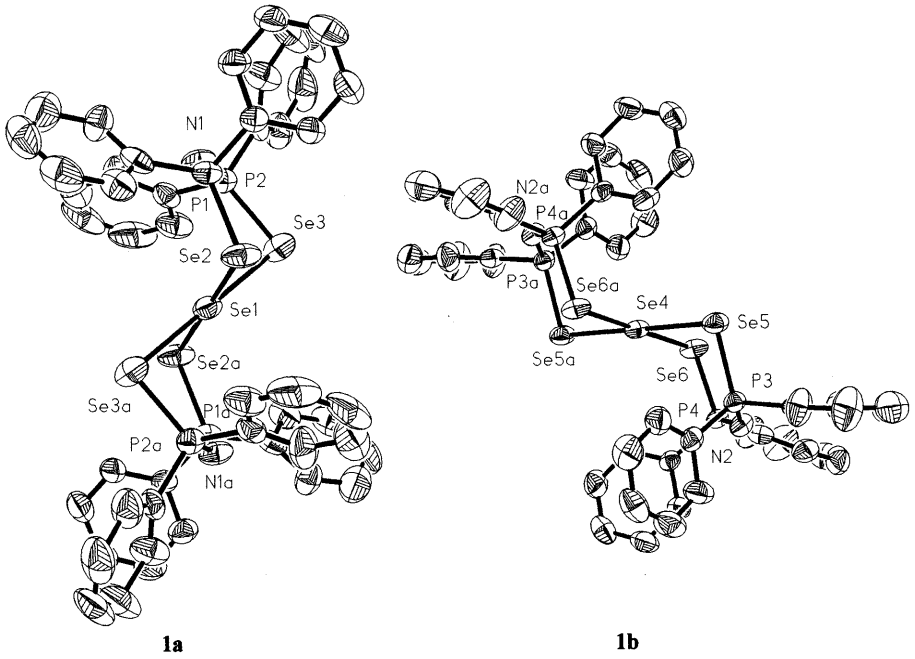
Figure 2. ORTEP plot of **1a** and **1b**, independent molecules of [Se{N(SePPh$_2$)$_2$-*Se,Se′*}$_2$]



1a **1b**

shows the molecular structures and atomic labelling scheme of compound **1**.

The most remarkable feature of the structure is the square planar character of the selenium coordination sphere. The $SeSe_4$ core is coplanar [$\Sigma\{Se-Se-Se\} = 360°$] with *trans*-Se−Se−Se angles of 180.0(1)°. There is a slight asymmetry in the Se−Se bond lengths in both molecules [long ones of 2.678(1) and 2.663(1) Å and short ones of 2.646(1) and 2.643(1) for **1a** and **1b**, respectively]. These values are similar with those found in polyselenide anions[14]. The Se···Se bite of 3.708(2) Å is intermediate between the values of 3.667(4) and 3.771(3) Å found in [Te{N(SPPh$_2$)$_2$-*S,S′*}$_2$]. As in [Sn{N(SePPh$_2$)$_2$-*Se,Se′*}$_2$], the main difference between molecules **1a** and **1b** lies in the Se−Se−P angle [96.3(1) and 88.7(1)° for **1a**, and 97.1(1) and 96.9(1)° for **1b**]. The values of the P−N−P angles for **1a** and **1b**, [139.5(5) and 136.4(5)°] are also extraordinary large − larger than that found in the free ligand [132.3(2)°][14]. Since it is expected that the coordination of the donor atoms should contract the angle, the opening is indicative of the high flexibility of the P−N−P system and explains the ability of this ligand to form unusual structures. The endocyclic Se−Se−Se angles [88.31(4) and 88.67(3)°] are smaller than the corresponding exocyciclic ones [91.69(4) and 90.46(3)°].

The existence of this new neutral square planar structure for a Se^{II} compounds, demonstrates the ability of the $[Ph_2P(Se)NP(Se)Ph_2]^-$ anion to fulfill the preferences imposed by the central atom, in function of the great flexibility of the phosphazenic system and the soft character of the donor atoms.

We thank the *Mexican National Council of Science and Technology*, CONACYT (Grant 109P-E) for financial support and Prof. Dr. *Husebye* for his comments and suggestions.

Experimental Section

The experiments were carried out with the exclusion of air and moisture, under argon.The solvents were purified and dried by the usual methods. Se{S$_2$P(O*i*Pr)$_2$}$_2$][17] and bis[*N*-diphenylphosphanylselenoyl)-*P,P*-diphenylphosphanylselenoyl)amide[15] were prepared by literature methods. The latter was converted to its potassium salt by the reaction with KO*t*Bu according to a previously described procedure[16]. − ^{31}P NMR: Varian VXS 300S (121 MHz, external standard 85% H_3PO_4). − FAB MS (3-nitrobenzyl alcohol support): Jeol JMS-SX102A, positive-ion mode. − IR (KBr): Perkin-Elmer 283B. − Elemental analysis : Galbraith Laboratories.

Bis(imidotetraphenyldiselenodiphosphanyl-Se,Se′)selenium(II) (**1**): A solution of 3.0 g (5.1 mmol) of [K{N(SePPh$_2$)$_2$}], in 50 ml of THF was added to a stirred solution of bis(diisopropyldithiophosphato)selenium(II) (1.30 g, 2.5 mmol) in 50 ml of THF. An orange solution was formed, the solvent was evaporated at low pressure and the obtained solid was washed with ethanol and filtered. 10% of the solid was subjected to a thin layer chromatographic separation using hexane/ethyl acetate as eluent (90:10). The less polar layer was separated and extracted with CH_2Cl_2 to obtain the desired compound (m. p. 210°C). Yield 62% (based on of the chromatographic separated portion). Crystals suitable for X-ray crystallography were obtained by solvent diffusion in a chloroform/*n*-hexane mixture at room temperature. − ^{31}P NMR ($CDCl_3$): δ = 34.35 (s). − IR (KBr): $\tilde{\nu}$ = 3053 cm^{-1} w [νCH)], 1211 s [νP−N)], 1177 s [ν(P−N)/δ(CH)], 744 m [ν(P−N)], 689 vs [ϕ(CC), Ph], 532 vs [γ(PNP)/ν(P−Se)]. − MS (FAB$^+$, $CHCl_3$, for ^{80}Se); *m/z*: 1164 [M$^+$], 1087 [M − Ph$^+$], 622 [Se{N(SePPh$_2$)$_2$}$^+$], 544 [(SePPh$_2$)$_2$-N$^+$], 464 [Se(PPh$_2$)$_2$N$^+$], 384 [(PPh$_2$)$_2$N$^+$], 307 [(Ph$_2$PNPPh$^+$]. − $C_{48}H_{40}N_2P_4Se_5$ (1163.5): calcd. C 49.55, H 3.46; found C 49.11, H 3.36. − Mol. mass 1164 (FAB MS; CH_3Cl for ^{80}Se).

Crystal-Structure Analysis: Data collection was performed at room temperature with a Siemens P4 four-circle diffractometer by using graphite-monochromated Mo-K_α radiation ((= 0.71073 Å). Crystal Data: $C_{48}H_{40}N_2P_4Se_5$, M = 1163.5, orange prisms, 0.24 × 0.20 × 0.12 mm; triclinic, space group $P\bar{1}$ (No. 2), a = 10.158(2), b = 13.090(2), c = 18.239(5) Å, α = 89.42(2), β = 82.56(2), γ = 77.72(2)°, V = 2349.4(1) Å^3, Z = 2, D_x = 1.645 Mg m^{-3}, μ(Mo-K_α) = 4.070 mm^{-1}, T = 293 K, F(000) = 1144, number of reflections: 8742 (8231 independent, R_{int} = 0.048), $R(F)$ = 0.041, $wR(F)$ = 0.034 (536 parameters). Structure Solution and Refinement: The structure was solved by direct methods and refined by full-matrix least-squares calculations using the program system SHELXTL-Plus (PC-version)[18]. Absorption effects were corrected by face-index numerical methods. H atoms were refined using a riding model (U = 0.06), while non-hydrogen atoms were refined anisotropically. The crystal structure data (excluding structure factors) have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-101279. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: int code + 44(1223)336-033; E-mail: deposit@ccdc.cam.ac.uk].

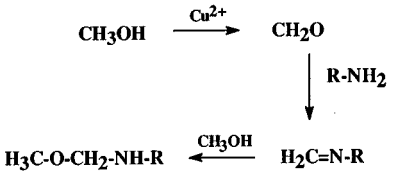
Keywords: Copper / Methoxo-bridged complexes / Crystal structure

A novel chelating ligand, synthesized in situ within the coordination sphere of Cu^{II} from 2-amino-3-methylpyridine, MeOH, and dioxygen from the air, is found to form a strongly coupled, dinuclear methoxo-bridged Cu^{II} compound with the formula $[Cu(L)(CH_3O)(NO_3)]_2$ (L = 2-methoxymethylamino-3-methylpyridine). The geometry around the copper atom is square pyramidal and the Cu–Cu distance within the dinuclear unit is 3.011(2) Å with an Cu–O–Cu angle of 103.13(8)°. Synthesis, X-ray crystal structure, and magnetism are reported.

In situ ligand formations in the presence of metal ions are not uncommon[1][2][3], and several cases are known of such reactions, like Schiff-base couplings and the formation of phthalocyanins[1][2][3]. The metal ion in these cases acts as a template, to facilitate the ring closure or the addition. Cases where a multi-step ligand reaction occurs are relatively rare. Our recent studies towards the formation of formamidines[4] have prompted us to further investigations of such reactions with aminopyridine ligands. We now wish to report a most unusual case of a three-step reaction (see Scheme 1) in which 2-amino-3-methylpyridine first forms a Schiff base with formaldehyde − in situ formed gradually by MeOH oxidation − which subsequently reacts with Cu-coordinated methanol to a 2-methoxymethylamino-3-methylpyridine chelating ligand. Copper(II) is known to be a catalyst for the air oxidation of methanol to formaldehyde[5]. The Schiff-base reaction is followed by the third step in which a methanol molecule inserts into the imine double bond[6a], resulting in the dinuclear compound: $[Cu(L)(CH_3O)(NO_3)]_2$ (in which L = 2-methoxymethylamino-3-methylpyridine). The first oxidation must originate from dioxygen from the air, as the reaction does not occur under argon. In fact deliberate addition of CH_2O accelerates the reaction. Under argon only a methoxo-bridged dinuclear Cu^{II} compound with the starting ligand, 2-amino-3-methyl-pyridine, is formed (see Experimental Section).

Scheme 1. Proposed reaction scheme (R = 3-methylpyridin-2-yl)



Structural analysis of the title compound reveals a dinuclear methoxo-bridged dinuclear unit with a centre of symmetry located between two copper ions (see Figure 1). The Cu atom has a square-pyramidal geometry with a basal plane formed by a nitrogen atom of the ligand, two oxygen atoms of the bridging methoxo molecules and an oxygen atom of the coordinating nitrate anion. The Cu−N distance and the Cu−O distances are in the normal range of ca. 2.00 Å[7]. The angles of the basal plane are almost linear [O1a−Cu1−O11 168.71(6), O1−Cu1−N11 170.61(7)°]. The apical site is occupied by the ether oxygen atom (O20) of the ligand with a distance of 2.318(2) Å and with the angle O20−Cu1−N11 of 93.09(9)°. The most striking feature of the structure is the presence of the newly synthesized ligand 2-methoxymethylamino-3-methylpyridine. Synthesis of methoxomethylamino compounds is known[6], however, in some cases they are unstable[6c]. In fact the present ligand might quite well be stabilized by the Cu chelation.

The Cu−Cu distance within the dinuclear unit is 3.011(2) Å with an Cu−O−Cu angle of 103.13(8)°. These distances and angles can be compared with some methoxo-bridged Cu^{II} dinuclear compounds which have also distances of ca. 3.0 Å and an angle of about 103°[8]. The lattice structure is stabilized by stacking between the pyridine rings of different units (ring−ring distance of 3.613 Å) and by a relatively strong hydrogen-bonding of an amino-nitrogen atom and an oxygen atom of the nitrate anion [N17···O13 = 2.939(9) Å].

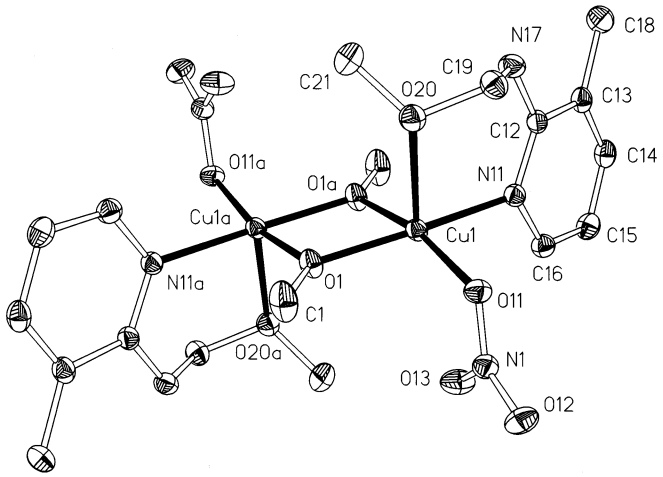
Figure 1. Plot of the structure with atom-labelling scheme; H atoms are omitted for clarity[a]



[a] Selected bond lengths [Å] and angles [°]: Cu1−O1 1.917(2), Cu1−O1a 1.9270(17), Cu1−N11 1.998(2), Cu1−O11 2.0267(18), Cu1−O20 2.318(2), Cu1−Cu1a 3.011(2); O1−Cu1−O1a 76.87(8), O1−Cu1−N11 170.61(7), O1a−Cu1−N11 94.22(8), O1−Cu1−O11 96.50(8), O1a−Cu1−O11 168.71(6), N11−Cu1−O11 91.81(8), O1−Cu1−O20 91.85(9), O1a−Cu1−O20 103.27(9), N11−Cu1−O20 93.09(9), O11−Cu1−O20 85.91(8), Cu1−O1−Cu1a 103.13(8) ($a = -x, -y, -z$).

The ligand-field spectrum reveals a broad band with a centre around $14.6 \cdot 10^3$ cm^{-1}, which is common for a square pyramidal geometry[9]. A typical infrared vibration is found at 3349 cm^{-1} as a strong sharp peak, attributed to the N−H vibration. The anion vibrations of the nitrate are found at 1453 and 1299 cm^{-1} (a splitting of 154 cm^{-1}) which is in the range for didentate coordinating nitrate[10]. In the present case one of the oxygen atoms of the nitrate anion has a strong bonding to the Cu^{II} ion and the second oxygen atom (O13) is involved in a strong intermolecular hydrogen bonding (see above).

The powder EPR spectrum at 77 K only shows a very weak signal with a $g_{\perp}$ of 2.06, a resolved $g_{||}$ of 2.32, with $A_{||}$ of 14.2 mT, typical for a $CuNO_3(O)$ chromophore[9]. Given the dinuclear nature, this weak signal must originate from a mononuclear impurity. Even a nitrogen superhyperfine structure is observed with 3 lines, which also agrees with one nitrogen donor atom per Cu. In frozen solution (DMF) at 77 K a similar spectrum is obtained, indicative of monomerisation in solution. Low-temperature solid-state powder magnetic susceptibility recorded in the region 250−5 K, shows an almost diamagnetic species below 200 K. A preliminary fit with $g = 2.10$ results in a $-2J$ value over 500 cm^{-1}.

Summarizing, it is concluded that an MeOH oxidation reaction occurs initiated by the Cu^{II} ion. However, other factors, like the strength of the anion, must contribute as well, since weaker coordinating anions like perchlorate and triflate under identical conditions, do not yield such a reaction product.

Further work will deal with related ligands yielding this structure and with oxidation reaction studies to obtain more information about the reaction process.

Haasnoot* and Dr. *W. L. Driessen* are thanked for their helpful suggestions.

Experimental Section

General: Ligand-field spectra were recorded with a Perkin-Elmer Lambda 900 spectrophotometer using the diffuse-reflectance technique, with MgO as a reference. X-band powder EPR spectra were obtained with a Jeol RE2x electron spin resonance spectrometer using DPPH ($g = 2.0036$) as a standard. Magnetic susceptibilities were measured in the temperature range 5−300 K with a Manics DSM-8 susceptometer. Data were corrected for magnetization of the sample holder and for diamagnetic contributions, which were estimated from the Pascal constants[11].

Synthesis: 2-Amino-3-methylpyridine was obtained from Acros Organics; 0.6 mmol of $Cu(NO_3)_2 \cdot 3\,H_2O$ and 1.2 mmol of 2-amino-3-methylpyridine were each dissolved in ca. 10 ml of methanol. The copper solution was added carefully to the ligand solution and filtered to remove any undissolved material. The blue solution was kept at room temp., and after a few days blue crystalline material was obtained from the solution which turned green. The product was filtered and air-dried. Adding a little sodium hydroxide or heating the solution yields the same blue compound. Yield ca. 80%. − $C_{18}H_{30}Cu_2N_6O_{10}$ (617.56): calcd. C 35.01, H 4.90, Cu 20.50, N 13.61; found 35.07 C, 5.12 H, 20.12 Cu, 13.85 N.

Using a higher L/M ratio (L/M = 4:1 or 6:1) a violet methoxo-bridged dinuclear Cu^{II} compound with the formula $[Cu_2(2\text{-amino-3-methylpyridine})_4(CH_3O)_2](NO_3)_2$ was obtained. This structure is confirmed by elemental and X-ray crystal structure analysis[13]. The same compound is derived when the present reaction (L/M ratio 2:1) is carried out under argon.

X-ray Crystal Structure Analysis: Crystal data for $[Cu(C_8H_{12}N_2O)(CH_3O)(NO_3)]_2$: $C_{18}H_{30}Cu_2N_6O_{10}$, $M = 617.56$, triclinic, space group $P\bar{1}$ (no.2), $a = 8.336(5)$, $b = 8.734(5)$, $c = 10.357(5)$ Å, $\alpha = 109.24(5)$, $\beta = 91.99(5)$, $\gamma = 113.13(4)°$, $V = 642.9(6)$ $Å^3$, $Z = 1$, $D_c = 1.595$ g cm^{-3}, $T = 193$ K, $\mu(\text{Mo-}K_\alpha) = 1.715$ mm^{-1}, $F(000) = 318$, $R1 = 0.0299$, $wR2 = 0.0804$ with $I > 2\sigma(I)$, $S = 1.084$, 3982 data collected, 2627 data used, 163 parameters. A blue crystal with dimensions of $0.48 \times 0.45 \times 0.27$ mm was selected, mounted to the glass fiber using the oil-drop method[12a]. Rigaku AFC-7S diffractometer, graphite-monochromated Mo-K_α radiation ($\lambda = 0.71073$ Å), ω-2θ scans. Data reduction using the TEXSAN[12b] package. The intensity data were corrected for Lorentz and polarization effects and for absorption and extinction. All non-H atoms were refined anisotropically. H atoms were situated from difference Fourier map and refined isotropically. The structure was solved using direct methods (SHELXS-86)[12c]. The weighting scheme $w = 1/[\sigma^2(F_o^2) + (0.0457 \cdot P)^2 + 0.3867 \cdot P]$, where $P = (F_o^2 + 2 \cdot F_c^2)/3$ was adopted. Full-matrix least-squares refinement method on F^2 was applied, using the SHELXL-93[12d] package.

Crystallographic data (excluding structure factors) for the structure in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-102597. Copies of the data can be obtained free of charge on appli-

cation to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44(1223)336-033, E-mail: deposit@ccdc.cam.ac.uk].

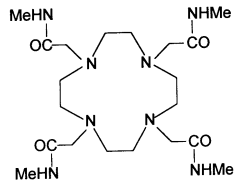
Equilibrium data on the interaction of DTMA [(DTMA = DOTA tetrakis(methylammide)] with Gd^{3+} in aqueous solution, properties of the complexes formed in the pH range 0.6–11.8, water proton relaxation rate enhancement, and the crystal structure analysis of the $[Gd(DTMA)H_2O]^{3+}$ complex are reported. In the crystal structure the metal ion is bound to the nitrogen atoms of the tetraazamacrocyclic moiety, to the amidic oxygen atoms, and to an oxygen atom of a water molecule. The nine donors are located at the vertices of a distorted square antiprism, which is capped by the coordinated water oxygen atom in the axial position. In solution $[Gd(DTMA)]^{3+}$ is not very stable [$\log K_{ML}$ = 12.8(1)] and gives rise to the formation of $[Gd(DTMA)OH]^{2+}$ [pK_a = 7.9(1)] and $[Gd(HDTMA)]^{4+}$ [$\log K_{(ML+H)}$ = 3.4(1)]. The proton solvent relaxivity of aqueous complex solutions assumes a constant value in the pH range 3–8, increasing at higher and lower pH. For pH > 3 the data are in good agreement with a previous study on the same compound. For pH < 3 a new interpretation is presented, based on the formation of $[Gd(HDTMA)]^{4+}$ and the release of Gd^{3+}.

A recent communication by Aime et al.[1] reported the interesting observations of the enhancement of the nuclear relaxation rate of water protons brought about by the $[Gd(DTMA)]^{3+}$ complex [(DTMA = DOTA tetrakis-(methylammide)] in aqueous solution. This presented for the first time a distinct evaluation of the water and prototropic exchange rates for a Gd^{3+}-coordinated solvent molecule. The uncharged DTMA ligand was selected in order to assess the contribution of prototropic exchange to the overall water exchange between the complex and the bulk solvent, as it had been observed that the exchange lifetime of Gd^{3+}-coordinated water molecules increases with decreasing negative charge of the Gd^{3+} complex. Actually, the nuclear transverse relaxation rate of ^{17}O nuclei of the solvent observed for the $[Gd(DTMA)]^{3+}$ complex is the slowest water exchange rate so far reported for a lanthanide(III) complex[1].

Aqueous solutions containing the triflate salt of $[Gd(DTMA)]^{3+}$ revealed a peculiar pH dependence of the longitudinal solvent relaxivity[2] (R_{1p}): R_{1p} assumes a constant value (ca. 2.6 $mM^{-1}s^{-1}$) in the pH range 2−8, increasing at higher and lower pH ($R_{1p} \approx 5.8$ $mM^{-1}s^{-1}$ at pH = 11−12 and $R_{1p} \approx 5.4$ $mM^{-1}s^{-1}$ at pH = 0.5). In the pH range 2−8 the low relaxivity values are consistent with a purely outer-sphere contribution[3]. ^{19}F-NMR measurements performed in this pH range were indicative of strong ion pairing between the complex $[Gd(DTMA)]^{3+}$ and the counterions $CF_3SO_3^-$[1]. The increase in relaxivity for pH > 8 was attributed to the additional contribution to ^1H-R_{1p} deriving from a prototropic exchange caused by the presence of the hydroxo species $[Gd(DTMA)OH]^{2+}$, while the increase in relaxivity in very acidic solutions was attributed to the acid-catalyzed dissociation of the ion pairs formed by $[Gd(DTMA)]^{3+}$ with the counterions[1]. The interpretation of the relaxivity behavior in acidic solutions was



DTMA

based on the assumption that the complex $[Gd(DTMA)]^{3+}$ is the only species present in such media, as suggested by the ^1H- and ^{13}C-NMR spectra of the analogous $[Eu(DTMA)]^{3+}$ complex.

Results and Discussion

A parallel but independent study performed in our laboratories on the same compound led to the determination of the crystal structure[4][5][6][7][8] of the $[Gd(DTMA)H_2O]^{3+}$ cation, to the identification of the Gd^{3+} complexes formed in solution by DTMA in the pH range 2.5−10, and to the determination of equilibrium constants of these complexes[9]. This elucidated some aspects of the system and completed the picture outlined by the previous work[1].

DTMA actually acts as an octadentate ligand toward Gd^{3+}, forming a tight structure where a water molecule is accommodated in the ninth position. Crystals of $[Gd(DTMA)H_2O](ClO_4)_3 \cdot NaClO_4 \cdot 3\ H_2O$[10] are composed of $[Gd(DTMA)H_2O]^{3+}$ cations, sodium ions, perchlorate counterions and water of crystallization. The metal ion is bound to the nitrogen atoms of the tetraazamacrocyclic moiety and to the amidic oxygen atoms provided by the four side arms, and finally to an oxygen atom of a water molecule (Figure 1).

The nine donors are located at the vertices of a distorted square antiprism, capped by the coordinated water oxygen atom in the axial position. Similar coordination spheres were found for other Gd^{3+} complexes with analogous ligands derived from the 1,4,7,10-tetraazacyclododecane macrocycle[12]. The four nitrogen atoms supplied by the macrocyclic ligand are in a well-defined plane, while the maximum deviation from the mean plane formed by the four amidic oxygen atoms is 0.025(5) Å. The oxygen atom of the water molecule is ca. 1.7 Å away from the mean O1−O2−O3−O4 plane, with the Gd−O5 bond direction almost perpendicular to this plane (87°). The metal ion is significantly shifted towards the mean plane of the oxygen donors with respect to the plane described by the four nitrogen atoms (0.74 vs. 1.59 Å, respectively). The Gd−N bond lengths [2.621(5)−2.649(6) Å], the Gd−O amidic bond lengths [2.351(5)−2.455(5) Å], as well as the Gd−O water distance [2.461(5) Å, see Figure 1] compare well with those previously reported for analogous gadolinium(III) complexes[12]. Concerning the ligand, the tetraaza ring adopts the [3333] C corners conformation[13], with the four side arms, which are folded towards the macrocyclic cavity, in a head-to-tail arrangement. The four amidic nitrogen atoms have a significant sp^2 character, thus the usual π conjugation takes place in each amidic functional group enhancing the donor capability of the carbonylic oxygen atoms.

The molecular packing reveals a large number of H-bond contacts (< 3.0 Å) involving the water of crystallization, the oxygen atoms of the perchlorate anions and various hydrogen and nitrogen atoms of the ligand, while the sodium ion is six-coordinated [Na−O bond lengths range from 2.413(9) to 2.80(1) Å] by four perchlorate oxygen atoms and two water molecules of crystallization. It is worth noting that the oxygen atom O5 of the Gd^{3+}-coordinated water molecule is very close [2.92(1) Å] to an oxygen atom of a perchlorate ion. This suggests the presence of a strong hydrogen bond between $[Gd(DTMA)H_2O]^{3+}$ and a counterion, offering a model for the ion pairing occurring in solution[1] between the complex and $CF_3SO_3^-$.

Gd^{3+} complexation by DTMA is very slow; solutions containing the metal ion and the ligand in the pH range 2.5−8 require several days to equilibrate at 298.1 K. For this reason the speciation of the system was performed by using an out-of-cell batch technique in which 40 solutions corresponding to different points in a conventional potentiometric titration were allowed to equilibrate at 298.1 K[9]. The same procedure was adopted to study the Eu^{3+}/DTMA system. The formation constants[9] determined for the complexes formed at equilibrium (0.1 mol dm^{-3} Me_4NNO_3, 298.1 ± 0.1 K) are listed in Table 1, which also contains the ligand protonation constants determined under the same experimental conditions.

The $[Gd(DTMA)]^{3+}$ complex is not very stable [$\log K$ = 12.8(1)] if compared with the analogous complex with DOTA ($\log K = 24.67$)[14], demonstrating the lower coordinating ability toward Gd^{3+} of amidic groups with respect to carboxylate groups[15]. Starting from neutral pH the metal-bound water molecules in $[Gd(DTMA)H_2O]^{3+}$ dissociate

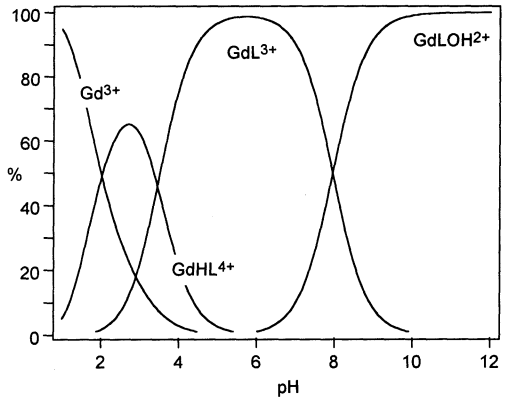
Table 1. Logarithms of the equilibrium constants of the Gd^{3+} and Eu^{3+} complexation reactions with DTMA, determined in 0.1 mol dm^{-3} Me_4NNO_3 at 298.1 ± 0.1 K[a]

reaction	log *K*
$DTMA + H^+ \rightleftharpoons HDTMA^+$	9.27(1)
$HDTMA^+ + H^+ \rightleftharpoons H_2DTMA^{2+}$	5.55(2)
$H_2DTMA^{2+} + H^+ \rightleftharpoons H_3DTMA^{3+}$	1.56(7)
$Gd^{3+} + DTMA \rightleftharpoons [Gd(DTMA)]^{3+}$	12.8(1)
$[Gd(DTMA)]^{3+} + H^+ \rightleftharpoons [Gd(HDTMA)]^{4+}$	3.4(1)
$[Gd(DTMA)]^{3+} + OH^- \rightleftharpoons [Gd(DTMA)OH]^{2+}$	5.8(1)
$Eu^{3+} + DTMA \rightleftharpoons [Eu(DTMA)]^{3+}$	13.17(4)
$[Eu(DTMA)]^{3+} + OH^- \rightleftharpoons [Eu(DTMA)OH]^{2+}$	6.83(5)

[a] Values in parentheses are standard deviations on the last significant figure

[pK_a = 7.9(1)] giving rise to the hydroxo complex $[Gd(DTMA)OH]^{2+}$, while for pH < 5 $[Gd(DTMA)]^{3+}$ undergoes protonation to produce the species $[Gd(HDTMA)]^{4+}$. Due to the reduced coordinating ability of DTMA toward Gd^{3+}, the uncoordinated metal ion is present in acidic media at pH < 4 (Figure 2).

Figure 2. Distribution diagram of the complexed species formed by DTMA with Gd^{3+} as a function of pH in 0.1 mol dm^{-3} Me_4NNO_3 solution at 298.1 K; [DTMA] = $[Gd^{3+}] = 1 \times 10^{-3}$ mol dm^{-3}



As can be seen in Table 1, DTMA displays almost the same tendency to bind Gd^{3+} and Eu^{3+}, but $[Eu(DTMA)H_2O]^{3+}$ demonstrates a higher propensity than $[Gd(DTMA)H_2O]^{3+}$ to form the hydroxylated complex [pK_a = 7.0(1)], and does not form protonated species.

Hence, the use of the Eu^{3+} complex with DTMA as a model for the Gd^{3+}/DTMA system led Aime et al. to ignore the formation of $[Gd(HDTMA)]^{4+}$ in their interpretation of the relaxivity properties in acidic media.

Measurement of water relaxation times in the presence of the gadolinium complex, performed with 0.1 mol dm^{-3} Me_4NNO_3 solutions after equilibration in the pH range 0.6−11.8, confirmed the pH dependence of relaxivity found by Aime et al.[1] in the presence of $CF_3SO_3^-$ at pH > 3. This accounts for similar properties of NO_3^- and $CF_3SO_3^-$ in the formation of ion pairs with the complex. However for pH values < 3 the relaxivity increases with decreasing pH more rapidly than previously reported[1] for measurements performed shortly after solution acidification. The equilibrium data obtained for the Gd^{3+}/DTMA system (Table 1) confirm the role played by $[Gd(DTMA)]^{3+}$ and $[Gd(DTMA)OH]^{2+}$ in determining the relaxivity properties of solutions at pH > 3 containing the complex, offering a new interpretation of the relaxivity behavior observed at pH < 3. Actually, in acidic solutions at equilibrium the relaxivity increases with increasing concentration of free Gd^{3+} (released by the complex upon acid-catalyzed dissociation), and at pH ≈ 0.5, where complete complex dissociation occurs (Figure 2), approaches the value expected (ca. 11 $mM^{-1}s^{-1}$) at such pH for a solution of Gd^{3+} in the ionic medium employed.

On the other hand, potentiometric measurements performed on $[Gd(DTMA)]^{3+}$ in acidic solutions indicate that the monoprotonated complex is formed after rather short equilibration times (2−3 h), while complex dissociation is expected[1] to produce significant concentrations of uncoordinated Gd^{3+} only after many hours.

Complex protonation produces a more open structure around Gd^{3+}, which means either an increase in the metal-ion hydration number or a wider diffusion of water molecules in proximity of the paramagnetic centre; both phenomena are expected[3] to imply an enhancement of the relaxation rate of water protons.

Therefore, the Gd^{3+}/DTMA system gives different relaxivity responses in acidic media, depending on the equilibration times of the complex; relaxivity increases with decreasing pH due to: i) the formation of the monoprotonated $[Gd(HDTMA)]^{4+}$ complex, after short equilibration times, ii) the presence of uncoordinated Gd^{3+} ion after long equilibration times. Both effects can be present simultaneously.

We believe that the relaxation properties of $[Gd(DTMA)]^{3+}$ observed by Aime et al. in acidic solutions are principally connected with the first factor.

Indeed, the results on the Gd^{3+}/DTMA system have a direct impact in the research about paramagnetic contrast agents for magnetic resonance imaging, suggesting that modulation of water proton relaxivity can be achieved by tuning the solution pH under kinetic control of the Gd^{3+}/ligand complexation reaction. Furthermore, the results described here demonstrate the necessity to be very prudent in the use of Eu^{3+} complexes as models for the corresponding Gd^{3+} systems.

Keywords: Metallodisilanes / Oxofunctionalization / Metallodisilandiols / Silanetriols / Metallosiloxanes

Reaction of the ferriodisilanes $C_5R_5(OC)_2Fe–Si_2H_5$ [R = H (**1a**), Me (**1b**)] with dimethyldioxirane leads to selective insertion of oxygen into the α-Si–H bonds to yield the ferriodihydroxydisilanes $C_5R_5(OC)_2Fe–Si(OH)_2–SiH_3$ [R = H (**2a**), Me (**2b**)]. Another access to yield **2a** is opened by hydrolysis of the dichloro(ferrio)disilane $Cp(OC)_2Fe–SiCl_2–SiH_3$ (**3a**). Treatment of the pentachloro(metallo)disilanes $C_5H_5(OC)_2Fe–Si_2Cl_5$ (**4a**) and $C_5Me_5(OC)_2Ru–Si_2Cl_5$ (**4b**) with water results in regiospecific hydroxylation of the β-silicon atom to generate metallodisilanetriols $C_5R_5(OC)_2M–SiCl_2–Si(OH)_3$ [M = Fe, R = H (**5a**); M = Ru, R = Me (**5b**)]. Controlled condensation of **5b** with $Me_2Si(H)Cl$ leads to the novel rutheniosiloxane $C_5Me_5(OC)_2Ru–SiCl_2–Si(OSiMe_2H)_3$ (**6**).

Introduction

Due to their important role as intermediates in the technical synthesis of silicones[1] organosilanoles have been the subject of extensive studies over several decades[2]. Recently, in context with our studies on the reactivity of functionalized silicon transition metal complexes we have established a new type of silanol containing an Si-bonded transition metal fragment. Access to these metallosilanols is opened by the hydrolysis of halo(metallo)silanes[3] and by the oxygenation of metallosilanes with dimethyldioxirane[4]. Especially the second approach which even allows transformation of metal-bound SiH_3 groups to $Si(OH)_3$ moieties is favored by the strong electron donor capacity of the transition metal fragment which in addition guarantees high stability with respect to condensation. We now focused our interest on metallodisilanes and pentachloro(metallo)disilanes $L_nM–SiX_2–SiX_3$ (X = H, Cl) where two extremely different types of Si–X units are present and which can be regarded as attractive model compounds for the demonstration of the directing effect of transition metal fragments. We have examined this possibility using the metallodisilanes of the iron group [$L_nM = C_5R_5(OC)_2Fe/Ru$ (R = H, Me)] accessible by simple routes[5]. We now report that the transition metal effect can create novel types of disilanyl ligands in which either the α- or the β-silicon atom is fully substituted by hydroxy groups.

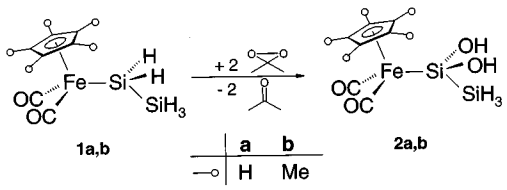
Results and Discussion

Treatment of the ferriodisilanes **1a–b** with a solution of dimethyldioxirane in acetone at −78°C results in the formation of the ferriodihydroxydisilanes **2a**, **b**, the first complexes with an $H_3Si–Si(OH)_2$ ligand (Eq. 1).



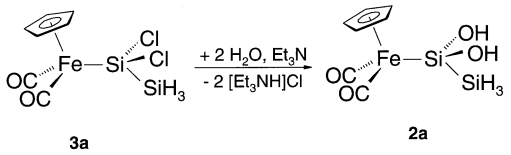
(1)

The dihydroxydisilanes **2a**, **b** are isolated as pale yellow solids in excellent yields [89% (**2a**), 83% (**2b**)] within hours and are barely soluble in aliphatic or aromatic solvents. The solubility in THF or acetone is reasonable but light-induced decomposition occurs in these solutions within 12–16 h. However, unlimited storage under nitrogen at −20°C is possible. Further hydroxylation of **2a**, **b** with a large excess of dimethyldioxirane does not lead to the expected metallopentahydroxydisilane due to extensive decomposition.

Another approach to **2a**, **b** starting from the ferriodisilanes applies in the first step the regiospecific transformation of **1a**, **b** into the corresponding dichloro(ferrio)disilanes **3a**, **b** by H/Cl exchange with CCl_4 as described recently[6], followed by treatment with water. Hydrolysis of **3a**, **b** in the presence of Et_3N as an auxiliary base takes place only in

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1434–1948/98/1111–1585 $ 17.50+.50/0

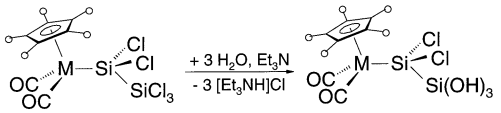
the case of **3a** (Eq. 2). Generated **2a** is isolated after 14 hours in 81% yield.



3a 2a (2)

The dichloro(ferrio)disilane **3b** does not show an analogous tendency for Cl/OH exchange according to Eq. (2), indicating that the electron-releasing capability of the Cp* $(OC)_2Fe$ fragment, which exceeds that of the $Cp(OC)_2Fe$ fragment, too strongly reduces the electrophilicity of the α-silicon atom.

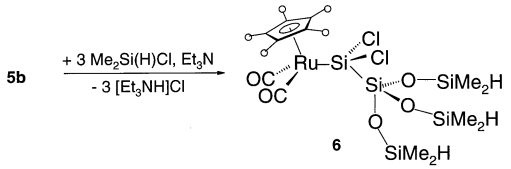
In contrast to the reactions of Eq. (1) in which the metal fragment activates the α-silicon atom with respect to electrophilic attack, nucleophilic exchange activity of this silicon atom is extremely reduced. This fact allows regiospecific hydroxylation in the β-position of the pentachloro(metallo)disilanes **4a**, **b** by base-assisted hydrolysis. Cl/OH exchange is complete within 12 hours at room temperature yielding the dichloro(metallo)trihydroxydisilanes **5a**, **b** as beige, rather air-stable solids (Eq. 3).



4a,b 5a,b (3)

	a	b
—	H	Me
M	Fe	Ru

Remarkable is the stability of the metallodisilanetrioles **5a**, **b** with respect to self-condensation. Apparently, the Si−OH group stabilization by the "transition metal effect" is working even at the β-silicon atom. This property renders **5a**, **b** useful as precursors for selective formation of unusual siloxane arrangements at the β-silicon atom. A first example is realized by base-assisted condensation of **5b** with chlorodimethylsilane to give the novel (ruthenio-silyl)(siloxy)trisiloxane **6** as a deep yellow solid after recrystallization from *n*-pentane at −78°C (yield: 74%) (Eq. 4).



(4)

The ruthenio complex **6** is characterized by a high number of Si functionalities which can be used for further hydroxylation or introduction of transition metal fragments by oxidative addition.

In forthcoming publications we will report on these transformations and further regiospecific reactions of metallodisilanes using the "transition metal effect".

Keywords: (Phosphane)iron complexes / P–H function / Insertion / Diazoacetic ester / Iron / P ligands

Treatment of the cationic secondary (phosphane)iron complexes $[Cp(OC)_2Fe–P(Ph)(R)H]BF_4$ (R = Ph, Me) (**1a**, **b**) with diazoacetic ester (**2**) yields the novel complex salts $\{Cp(OC)_2Fe–P(Ph)(R)[N(H)–N=C(H)CO_2Et]\}BF_4$ (R = Ph, Me) (**3a**, **b**) by insertion of the terminal nitrogen atom of **2** into the P–H bond of **1a**, **b**. Reaction of the primary (phosphane)iron complexes $[(R'C_5H_4)(OC)_2Fe–P(R)H_2]BF_4$ [R = *t*Bu, Ph, Mes; R′ = H, neomenthyl (NM)] (**4a–e**) with **2** affords the complex salts $\{(R'C_5H_4)(OC)_2Fe–P(R)(H)[N(H)–N=C(H)CO_2Et]\}BF_4$ (**5a–d**) or $\{(R'C_5H_4)(OC)_2Fe–P(R)[N(H)–N=C(H)CO_2Et]_2\}BF_4$ (**6a–d**), depending on the molar ratio. The structures of **5c** and **6b** are proved by X-ray analysis.

Introduction

Our investigations into the reactivity of primary phosphane-substituted iron complexes of the type $[Cp(OC)_2Fe–P(R)H_2]BF_4$ (R = alkyl, aryl) towards organoisothiocyanates have revealed that in the presence of Et_3N the corresponding ferriophosphanes $Cp(CO)_2Fe–P(H)R$ are formed as intermediates. This will subsequently lead to the product of a P–H insertion[2] or a combination of P–H insertion and [2+3] cycloaddition[1]. This result clearly contrasts with the reactivity of ferriodiorganophosphanes $Cp(OC)_2Fe–PR_2$ which in all cases were found to form the [2+3] cycloadducts $Cp(OC)Fe–PR_2–C(S)–N(R')–C^a(=O)(Fe–C^a)$[3a] with the heterocumulenes. A comparable reaction was observed with electron-deficient alkynes[3b][3c][3d][3e].

Now we have utilized this synthetic strategy for functionalization of phosphane ligands by transformation of metal-coordinated primary and secondary phosphanes with diazoacetic ester.

Results

Preferentially, the complex salts $\{Cp(OC)_2[H(R)(R')P]Fe\}BF_4$ (R = H, Me, Ph; R′ = *t*Bu, Ph, Mes) were used, which feature a simple structure and are easily accessible by thermal carbon monoxide/phosphane exchange from the cation $[Cp(OC)_3Fe]^+$.

Reaction of **1a**, **b** with diazoacetic ester (**2**) in dichloromethane at room temperature yields the insertion products **3a**, **b** after 24 h which are obtained as yellow, microcrystalline powders in high yields (87%) after precipitation with ether [Eq. (1)].

The cation of **3a**, **b** bears a functional phosphane ligand characterized by a hydrazone unit formed by insertion of the terminal nitrogen atom of **2** into the P–H bond of **1a**, **b**. The constitution of **3a**, **b** is deduced from the NMR spectroscopic data that show a doublet resonance for the N–H proton [δ = 8.61 (**3a**)/8.43 (**3b**); ^2J(PNH) = 16.7 (**3a**)/22.0 Hz (**3b**)] and a singlet resonance for the CH(=N) proton [δ = 7.35 (**3a**)/7.31 (**3b**)] in the ^{1}H-NMR spectra. The insertion of **2** causes a significant low-field shift of the ^{31}P-NMR resonance from δ = 31.8/10.8 for the secondary phosphane in the starting material **1a**, **b** to δ = 114.1/108.0 for the phosphanylhydrazone in the product **3a**, **b**. The IR spectra show the expected $\nu(CO)_{sym}$ and $\nu(CO)_{asym}$ absorptions at approximately 2050 and 2020 cm^{-1}.

In contrast to the insertion reaction of the metal-coordinated secondary phosphanes $\{Cp(OC)_2Fe–PR_2H\}^+$ (R = alkyl, aryl) with isothiocyanates which requires a base (e.g. Et_3N)[3a] the insertion of diazoacetic ester according to Eq. (1) proceeds without an auxiliary base. Since metallodiorganophosphanes, formed by deprotonation of secondary cationic phosphane complexes, have been shown to be essential intermediates for the insertion process, diazoacetic ester itself must act as the base. In accordance with this experience a reaction sequence for the formation of **3a**, **b** appears reasonable in which primarily the cation of **1a**, **b** is

[◇] Part LXI: Ref.[1].

deprotonated by diazoacetic ester to generate the phosphido species **A** followed by coupling between the terminal nitrogen atom and the phosphido phosphorus atom leading to intermediate **B** (Scheme 1). Protonation at the *P*-bound nitrogen atom gives **3a**, **b** under release of diazoacetic ester.

An insertion into one or both of the P−H bonds can be expected in the reaction of **2** with coordinated primary phosphanes. Especially the monoinsertion is of interest as it generates a stereogenic functionalized phosphorus atom. From this point of view it appears attractive to study the possibility of its asymmetrically induced formation using a chirally modified Cp ligand. In a first approach we introduced the easily accessible neomenthyl cyclopentadienyl unit[4][5].

Reaction of the primary (phosphane)iron complexes **4a−d** with **2** in acetonitrile at room temperature in a molar ratio of 1:1 yields the phosphanylhydrazone complexes **5a−d** within 2 d [Eq. (2a)]. The analogous reaction of **4a−c**, **e** with two equivalents of **2** leads to the formation of the metallophosphanyldihydrazone species **6a−d** by insertion of **2** into both the P−H bonds [Eq. (2b)]. Complexes **5a−d** and **6a−d** are obtained in good yields as yellow, microcrystalline powders after precipitation with ether from the concentrated reaction mixture.

The monoinsertion products **5a−d** are of particular interest, since they do not only contain a chiral phosphorus atom but also offer the possibility of further derivatization of the R_2P-H moiety. The NMC_5H_4 substituted compound **5d** is obtained as a 1:1 mixture of two epimers, which means that the chiral ring ligand has no effect on the stereochemical course of the coupling process[6]. Compound **5d**, however, should offer the possibility of separating the stereoisomers with (*R*) and (*S*) configuration at the phosphorus atom by chromatography[6][7].

In accordance with the postulated constitution the ^{1}H-NMR spectra of **5a−d/6a−d** show the resonances of the NH and CH protons in the typical ranges of δ = 8.20−8.98 (N−H) and 7.02−8.47 (C−H). The resonance of the *P*-bonded hydrogen atom in **5a−d** at δ = 7.68−8.59 shows a doublet splitting with a P−H coupling constant of about 400 Hz. The ^{31}P-NMR resonances of the secondary phosphane ligands in **5a−d** at δ = 64.9−113.8 exhibit a significant shift of about 120 ppm to lower field in relation to the starting materials **4a−d**. Relative to the secondary phosphane in **5a−c**, the tertiary phosphane in **6a−c** displays an additional shift of about 50 ppm (**5/6a**) or 80 ppm (**5/6b**, **c**).

The structures of the insertion products **5a−d/6a−d** deduced from the spectroscopic data are confirmed by X-ray analysis of **5c** und **6b**, demonstrating an exclusive formation of the (*E*) isomer at to the C=N double bond.

Molecular Structures of 5c and 6b

The complex salts **5c** (Figure 1) and **6b** (Figure 2) have an octahedral arrangement of the ligands CO, Cp, and P(H)(Mes)[N(H)−N=C(H)−C(O)OEt] or P(Ph)[N(H)−N=C(H)−C(O)OEt]$_2$, respectively, indicated by the bond angles of C1−Fe−C2 92.0(5)° (**5c**)/93.4(3)° (**6b**), C1−Fe−P 93.9(5)° (**5c**)/91.4(2)° (**6b**), and C2−Fe−P 95.0(8)° (**5c**)/95.0(2)° (**6b**). The Fe−C(O) distances of 1.757(12) Å (Fe−C1)/1.769(11) Å (Fe−C2) (**5c**), 1.753(7) Å (Fe−C1)/1.785(6) Å (Fe−C2) (**6b**) as well as the Fe−P distances [*d*(Fe−P) = 2.208(17) Å (**5c**)/2.1909(15) Å (**6b**)] are in good agreement with known values[1][2]. The substituents at the phosphorus atom show a nearly perfectly staggered conformation of ligands at the iron atom. In **5c** the bulky mesityl unit adopts the *anti* position to the Cp ligand [Cp(Z)−Fe−P−C10 173.47°], while in compound **6b** this position is occupied by a hydrazone unit [Cp(Z)−Fe−P−N1 167.64°]. As a consequence the other two substituents in both molecules are oriented *trans* to the CO ligands [**5c**: H−P−Fe−C2 165.0(8)°, N1−P−Fe−C1−173.1(5)°; **6b**: C10−P−Fe−C2 175.7(3)°, N3−P−Fe−C1 −159.4(3)°].

The phosphorus atoms exhibit a distorted tetrahedral conformation with the largest bond angles including the metal center [**5c**: N1−P−Fe 112.2(3)°, H−P−Fe 116.3(35)°, C10−P−Fe 118.7(2)°; **6b** N3−P−Fe 112.9(2)°, N1−P−Fe 113.8(2)°, C10−P−Fe 115.5(2)°]. The P−H distance of 1.39(8) Å is in good agreement with the expected values {[Cp(OC)(Me$_3$P)Fe−P(H)(*t*Bu)Me]I: 1.40(5) Å[8]; PH_3: 1.439 Å[9]}. The hydrazone units are characterized by N−N single bonds for N1−N2[10] [1.374(9) Å (**5c**)/1.368(6)

Å (**6b**)] and N3−N4 (**6b**) [1.367(5) Å], and values typical of a C=N double bond[11] for N2−C8 (**5c**) [1.254(11) Å], N2−C20 (**6b**) [1.263(6) Å] and N4−C30 (**6b**) [1.256(6) Å]. The structural units N(H)−N=C(H)C−(O)OEt are nearly planar [N−N−C−C: −178.5(8)° (**5c**), −174.5(4)° and 176.7(5)° (**6b**)] and exhibit (*E*) configuration; the *P*-bound nitrogen atoms N1 (**5c**, **6b**) and N3 (**6b**) as well as the sp^2-hybridized C=N carbon atoms C8 (**5c**) and C20, C30 (**6c**) show nearly ideal planarity (sum of angles: 358.8°−360.0°).

We have demonstrated that diazoacetic ester is a reagent which easily inserts into P−H bonds of metal-coordinated primary and secondary phosphanes. This procedure can be used to build up novel phosphane ligands at the metal center. Controlled monoinsertion in the case of primary

phosphanes leads to chiral secondary phosphane ligands which possess a high synthetic potential because of the P−H moiety which is useful for further derivatization.

Support of this research by the *Deutsche Forschungsgemeinschaft* (Sonderforschungsbereich 347, "*Selektive Reaktionen Metall-aktivierter Moleküle*") and the *Fonds der Chemischen Industrie* is gratefully acknowledged.

Experimental Section

General: All manipulations were performed under purified nitrogen with standard Schlenk techniques. Solvents were rigorously dried with an appropiate drying agent and distilled under nitrogen prior to use. − ^{1}H-, ^{13}C-, and ^{31}P-NMR spectra were obtained with a Bruker AMX 400 spectrometer. − Infrared spectra were recorded in solution with a Perkin-Elmer 283 grating spectrometer in NaCl cells with 0.1 mm path lengths. − Melting points were determined by Differential Thermo Analysis (DTA) with a Du Pont Thermal Analysis System 9000. − Elemental analyses were performed in the laboratories of the *Institut für Anorganische Chemie*. − $[Cp(OC)_3Fe]BF_4$[12] and $[(NMC_5H_4)(OC)_3Fe]BF_4$[6] were prepared according to literature procedures. $N_2C(H)CO_2Et$ was obtained commercially and used without further purification.

1) *General Procedure for the Preparation of {Cp(OC)$_2$[H(R)(Ph)P]Fe}BF$_4$ [R = Ph, Me (**1a**, **b**)], {Cp(OC)$_2$[H$_2$(R)P]Fe}BF$_4$ [R = tBu, Ph, Mes (**4a**−**c**)] and {(NMC$_5$H$_4$)(OC)$_2$[H$_2$(R)P]Fe}BF$_4$ [R = Mes, Ph (**4d**, **e**)]:* A cooled (0°C) solution of 3.50 mmol of $[Cp(OC)_3Fe]BF_4$ or $[(NMC_5H_4)(OC)_3Fe]BF_4$ in 20 ml of acetonitrile was combined with an equimolar amount of the appropriate phosphanes R(Ph)PH (R = Me, Ph) or RPH_2 (R = *t*Bu, Ph, Mes). The mixture was stirred for 10 h at 60°C and then reduced in vacuo to a volume of 8 ml. Precipitation of the product was achieved by addition of 10 ml of ether. The product was separated by filtration, washed with 10 ml of ether and dried in vacuo. − Yield > 85%. − Yellow to orange microcrystalline powders. − M.p.: **1a**: 123°C; **1b**: 143°C; **4a**: 177−179°C (dec.); **4b**: 178°C (dec.); **4c**: 137°C (dec.); **4d**: 76°C; **4e**: 78°C.

Keywords: Phosphaalkynes / Cooligomerization / Phosphaalkyne cyclooligomers / Cage compounds, phosphorus-carbon-aluminum / Cage compounds, phosphorus-carbon-gallium

When trialkylaluminum reagents **2** bearing sterically demanding substituents are allowed to react with phosphaalkynes **1** a highly selective phosphaalkyne cyclotrimerization with incorporation of one organometal unit occurs (→ **5a–d**). The resulting triphosphaalatricycloheptenes **5** are able to function as ligands in transition metal complexes (→ **6a**,**b**), as illustrated by the reactions of **5a** with nonacarbonyldiiron or the pentacarbonyltungsten tetrahydrofuran complex. When triethylgallium (**7**) is allowed to react with phosphaalkynes **1**, tricyclic phosphorus-carbon-gallium compounds are generated (→ **8a**,**b**).

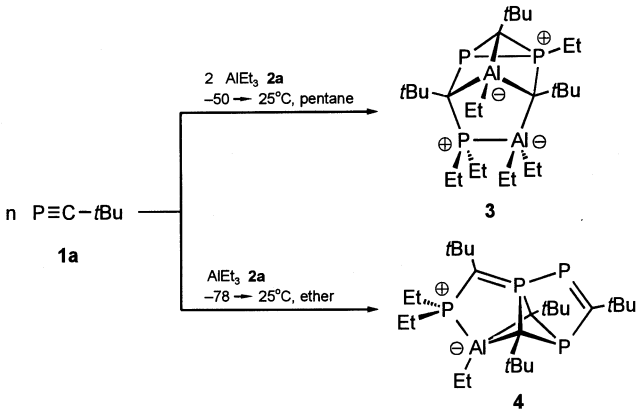
Introduction

Phosphorus-carbon cage compounds have attained increasing importance in the chemistry of low-coordinated phosphorus over the past few years. Even complicated polycyclic systems can be obtained specifically by means of various synthetic strategies[2]. One versatile concept involves the initiation of a phosphaalkyne cyclooligomerization with the help of a Lewis acid[3]. Thus, for example, the tetracyclic product **3** is obtained in high selectivity from the reaction of *tert*-butylphosphaalkyne (**1a**) with triethylaluminum (**2a**)[4][5]. A phosphaalkyne cyclooligomerization with incorporation of the Lewis acid **2a** is also observed when diethyl ether is used in place of pentane as solvent; however, in this case the cyclooligomerization process of **1a** with **2a** ends at the stage of the polycyclic betaine **4**[4][6].

The results described here represent an extension of the investigations on the preparation of the cage compounds **3** and **4** and concern the use of triorganoaluminum reagents bearing sterically demanding substituents as well as triorganogallium reagents as reaction partners for the phosphaalkynes **1**. Furthermore, the reaction behavior of a selected phosphorus-carbon-aluminum cage compound towards transition metal carbonyl complexes is discussed.

[+] Present address: Fachbereich Chemie der Universität Kaiserslautern, Erwin-Schrödinger-Straße, D-67663 Kaiserslautern, Germany; Fax: (internat.) + 49(0)631/205-3921.

Scheme 1



Results and Discussion

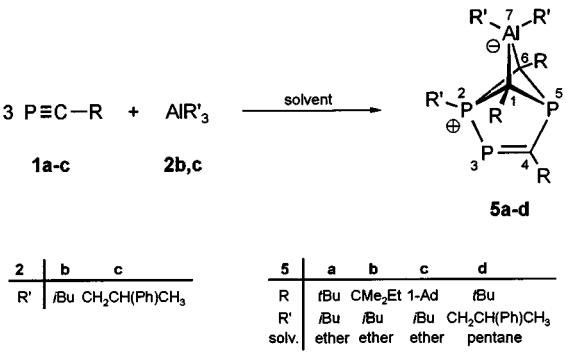
Generation of the Triphosphaalatricycloheptenes (1 → 5)

Neither the cage compound **3** nor the polycyclic system **4** are formed in the reactions of the phosphaalkynes **1a–c** with the triorganoaluminum reagents **2b**,**c** bearing voluminous substituents. Instead a cyclotrimerization of the organophosphorus compounds **1** with incorporation of one trialkylaluminum unit occurs[7]. The triphosphaalatricycloheptenes **5a–d** formed in this way can be isolated by bulb-to-bulb distillation or recrystallization from non-polar

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1434–1948/98/1111–1597 $ 17.50+.50/0

solvents and are obtained in moderate to good yields (36−82%) as yellow oils (**5a**−**c**) or a yellow solid (**5d**).

Scheme 2



Elemental analyses and mass-spectrometric data clearly show that the polycyclic compounds **5** have the constitutions of 3:1 adducts of the respective phosphaalkyne **1** with the triorganoaluminum reagent **2**. The NMR spectra of products **5** also provide valuable diagnostic information which is discussed in detail below for the example of product **5a** (R = *t*Bu; R′ = *i*Bu).

Relevant information about the degree of oligomerization is provided by the ^{31}P-NMR spectrum which contains three signals which must result from a single molecule on account of the observed ABX spin system. The signal at low field (δ = 223.3) may unequivocally be assigned to the $\lambda^3\sigma^2$ phosphorus atom P-3[8] and its large $^1J_{P,P}$ coupling constant of 299.2 Hz confirms the adjacency to the onium phosphorus atom P-2 (δ = 53.9). The remaining signal at δ = 36.5 (P-5) is split into a double doublet by two $^2J_{P,P}$ couplings (32.2 and 19.0 Hz).

The ^{1}H-NMR spectrum of compound **5a** shows two signals for the *tert*-butyl groups (integration ratio 2:1) and a total of nine signals for the three, chemically non-equivalent isobutyl groups. A two-dimensional NMR spectrum was needed to clarify the spatial relationships between the protons (^{1}H,^{1}H-COSY-45 experiment). The signal at lowest field (δ = 2.36) is assigned to the protons of the α-methylene group at the onium phosphorus atom P-2. It is split by one H,H and two H,P couplings (7.3 and 2.0 Hz). The methyl hydrogen atoms of the isobutyl group at P-2 furnish the signal at δ = 0.96; the methine hydrogen signal occurs at δ = 2.08−2.22. The signal group at δ = 0.46, 2.08−2.22 and 1.24 as well as that at δ = 0.64, 2.22−2.32 and 1.25 can each be assigned to one of the two isobutyl groups at the aluminum atom. However, a distinction between these two alkyl groups is not possible.

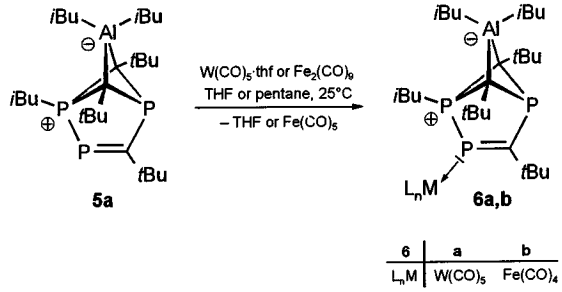
The ^{13}C-NMR-spectral data are also in harmony with the proposed structure for the polycyclic product **5a**. The signal of the phosphaalkene carbon atom C-4 is especially characteristic: it appears at relatively high field (δ = 104.4) and is split into a double doublet (50.2 and 13.4 Hz)[9]. A signal with a chemical shift of δ = 44.7 is observed for the two skeletal sp^3-carbon atoms C-1 and C-6. The signal for the methylene carbon atom at the $\lambda^4\sigma^4$-phosphorus atom (P-2) appears at relatively low field (δ = 47.2) and is split into a double doublet by two C,P couplings (24.6 and 10.5 Hz)[10].

A conclusive mechanism for the formation of the polycyclic system **5** cannot be given at present since it has not been possible to isolate or even to detect any of the occurring intermediates by NMR spectroscopy. Even so it is plausible to assume that the first step in the sequence is an attack of the Lewis acid **2** at the carbon atom of the phosphaalkyne **1**.

Metalation Reaction of the Triphosphaalatricycloheptene (5 → 6)

It has been shown elsewhere that phosphorus-carbon-aluminum cage compounds are able to act as ligands in transition metal complexes[5][6]. Complexation of the triphosphaalatricycloheptene **5a** with a carbonylmetal fragment can be realized in an analogous manner. Thus, reactions of compound **5a** with nonacarbonyldiiron[11] or the in situ generated pentacarbonyltungsten tetrahydrofuran complex[12] proceed at room temperature to furnish the transition metal complexes **6a**,**b** in practically quantitative yields (^{31}P-NMR monitoring). After recrystallization from appropriate solvents, compound **6a** is obtained as a dark-red solid (84% yield) and compound **6b** as an orange solid (76% yield).

Scheme 3



The success of the metalation reaction is immediately apparent from the IR spectra of the reaction products **6a**,**b**. Three carbonyl bands appear in each spectrum in the expected wavenumber ranges (**6a**: $\tilde{\nu}$ = 2064, 1992, 1970 cm^{-1}; **6b**: $\tilde{\nu}$ = 2076, 1960, 1948 cm^{-1}). The mass spectra of the compounds **6a**,**b** show that in both cases only one 16-valence-electron fragment has been coordinated to the polycyclic system of **5a**. The $\lambda^3\sigma^2$-phosphorus atom of the P−C double bond functions as two-electron donor to the metal center as is confirmed by the ^{31}P-NMR spectra. Accordingly, the chemical shift of the phosphorus atom P-3 is only marginally influenced by addition of the metal fragment (**5a**: δ = 223.3; **6a**: δ = 232.2; **6b**: δ = 191.0); however, the P-2/P-3 coupling constant is markedly reduced by almost 100 Hz. Furthermore, in the case of the polycyclic compound **6b** the signal at lowest field exhibits a characteristic $^1J_{P,W}$ coupling constant of 234.1 Hz[13].

Both the ^{1}H- and the ^{13}C-NMR spectra are in accord with the proposed structures: they confirm retention of the tricyclic skeleton in the course of the transformations **5a**

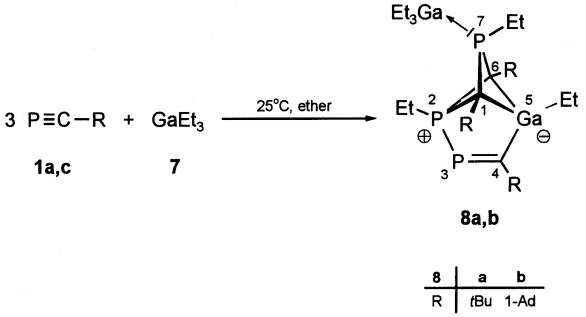
→ **6a**,**b**. In addition, the ^{13}C-NMR spectra proved relevant information about the hapticity of the polycyclic ligands. In the cases of **6a**,**b** the signals of the double-bond carbon atom C-4 experience only slight shifts to higher field in comparison to that of C-4 in the uncomplexed tricyclic compound **5a**. This finding supports the formulation of the transition metal complexes **6a**,**b** as end-on complexes and eliminates the possibility of the existence of a metallophosphacyclopropane structural unit[14].

Although the simple complexation of the tricyclic compound **5a** can easily be achieved under mild reaction conditions, it was not possible to effect complexation of a second 16-valence-electron species. Even in the presence of a large excess of the complexing reagent, the phosphorus atom P-5 remained unchanged. It is probable that the $\lambda^3\sigma^3$-phosphorus atom is sterically so strongly shielded by the three neighboring *tert*-butyl groups and by one of the isobutyl groups on the aluminum atom that an attack of the electrophilic carbonylmetal is not possible.

Generation of the Triphosphagallatricycloheptenes (1 → 8)

In many cases the chemistry of triorganogallium reagents **7** resembles that of the corresponding aluminum compounds **2**[15]. The Lewis acid **7** should thus also be able to initiate a phosphaalkyne cyclooligomerization. Indeed, when a mixture of a phosphaalkyne **1** and triethylgallium (**7**) in diethyl ether is stirred at room temperature for several days its color changes from colorless to orange-brown. Monitoring of the course of reaction by ^{31}P-NMR spectroscopy is indicative of a cyclotrimerization of the organophosphorus compound **1**. After removal of volatile materials under vacuum, recrystallization of the residue from a non-polar solvent furnishes the compounds **8a**,**b** in the

Scheme 4



form of yellow crystals in yields of 49 and 43%, respectively.

The structural relationships between the polycyclic compounds **8** and **5** are clear: both cage compounds have a tricyclo[3.2.0.0^{2,6}]hept-3-ene skeleton. In the case of **8** however, an additional, exocyclic triethylgallium unit is coordinated at a phosphorus atom of the polycyclic system. In addition, the positions of a phosphorus atom and a gallium atom are exchanged in comparison to the polycyclic skeleton of **5**.

Elemental analytical data confirm that compound **8** is composed of three molecules of phosphaalkyne **1** and two molecules of triethylgallium (**7**). The molecular ion peak is not present in the mass spectra of **8** although the fragment ions ($M^+ - Et_3Ga$) are observed in each case.

The NMR spectra provide diagnostic information about the constitutions of compounds **8**. In the case of **8a** the degree of oligomerization is apparent from the three signals appearing in the ^{31}P-NMR spectrum as an ABX spin system. The signal with the chemical shift δ = 253.6 is assigned to the $\lambda^3\sigma^2$-phosphorus atom[8]; the onium phosphorus atom P-2 produces the signal at δ = 41.6. The direct connection between these two phosphorus atoms is reflected in the coupling constant of 336.8 Hz. The signal at δ = 38.2 (P-7) is less characteristic and is split into a double doublet by two $J_{P,P}$ couplings (40.2 Hz and 25.0 Hz).

Information on the constitution of **8a** is also provided by the ^{1}H-NMR spectrum. The signals were assigned with the help of a two-dimensional NMR spectrum (^{1}H,^{1}H-COSY-45 experiment). In addition to two signals for the *tert*-butyl groups (integration ratio 2:1) there is a total of eight signals resulting from the six ethyl substituents. The two multiplets at low field (δ = 2.30−2.37 and δ = 2.05−2.10) are assigned to the α-methylene groups at the phosphorus atoms P-2 and P-7. Furthermore, the ethyl groups of the exocyclic triethylgallium unit give rise to a triplet at δ = 1.52 and a quadruplet at δ = 0.80 in the ^{1}H-NMR spectrum.

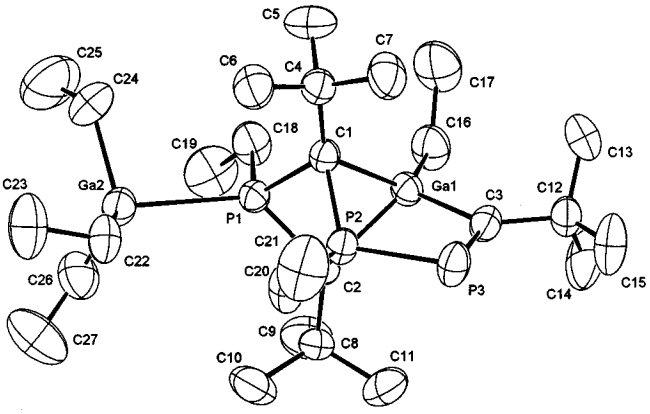
The ^{13}C-NMR spectrum is also in accord with the proposed structure for the polycyclic compound **8a**. The signal for the phosphaalkene carbon atom C-4 appears at relatively high field (δ = 79.0) while the two sp^3-skeletal carbon atoms C-1 and C-6 give rise to a double doublet (J = 23.2 and 16.7 Hz) at δ = 46.5.

The constitutions of the cyclooligomerization products were finally confirmed by an X-ray crystallographic analysis of **8a**. Crystals of the tricyclic compound **8a** are monoclinic, space group $P2_1/n$ (no. 14). A plot of the crystal structure is shown in Figure 1.

The central structural element of compound **8a** is a tricyclo[3.2.0.0^{2,6}]hept-3-ene system bearing an exocyclic triethylgallium unit. The double-bond carbon atom, all phosphorus atoms as well as the gallium atoms lie in the same plane. The sp^3-carbon atoms C-1 and C-2 are arranged in mirror symmetry around this plane.

The bond lengths and angles for compound **8a** are all of the expected magnitude; this holds especially for the P-2−P-3 linkage [2.203(2) Å; ref.[16]: 2.249 Å] and the P−C double bond [1.682(5) Å; ref.[17]: 1.670 Å]. A further characteristic feature, already observed in the structures of the polycyclic compounds **3** and **4**, is the shortening of the P−C single bonds to a $\lambda^4\sigma^4$-phosphorus atom [P-2−C-1: 1.818(4) Å; P-2−C-2: 1.811(5) Å; ref.[16]: 1.80 Å]. In contrast, the distances between the neighboring carbon atoms and the phosphorus atom P-1 are in the typical range for $\lambda^3\sigma^3$-P−C bonds [P-1−C-1: 1.869(4) Å; P-1−C-2: 1.879(4) Å; ref.[16]: 1.86 Å]. These observations, together with the P-1−Ga-2-separation of 2.581(1) Å [ref.[18]: 2.553(2)], support

Figure 1. Molecular structure of **8a**[a]



[a] Selected bond lengths [Å] and angles [°]: P1−C1 1.869(4), P1−C2 1.879(4), P2−C1 1.818(4), P2−C2 1.811(5), C2−Ga1 2.145(4), C1−Ga1 2.180(4), P2−P3 2.203(2), P3−C3 1.682(5), C3−Ga1 2.037(5), P1−P2 2.544(2), P1−Ga1 2.872(1), P2−Ga1 2.584(1), P1−Ga2 2.581(1); C3−Ga1−C1 101.6(2), C2−P1−C1 78.6(2), C3−Ga1−C2 102.6(2), C2−Ga1−C1 66.6(2), C2−P2−C1 81.7(2), C2−P2−P3 113.7(2), C1−P2−P3 113.9(2), C3−P3−P2 92.1(2), P2−C1−P1 87.3(2), P3−C3−Ga1 113.1(3), P1−C2−Ga1 90.8(2), P2−C2−Ga1 81.1(2), P2−C2−P1 87.2(2).

the existence of a donor-acceptor bond between the exocyclic triethylgallium unit and the polycyclic skeleton.

Again in this case of a cyclooligomerization of a kinetically stabilized phosphaalkyne **1** with triethylgallium (**7**), the question of the mechanism of formation of the polycyclic system **8** cannot be answered unambiguously. However, it is still reasonable to assume that the first step also involves an attack of the Lewis acid **7** at the carbon atom of the phosphaalkyne **1**.

We thank the *Fonds der Chemischen Industrie* for generous financial support and for post-graduate grants (to A. H. and A. M.).

Experimental Section

General Remarks: The reactions were carried out under argon (purity > 99.998%) in a previously oven-dried and evacuated apparatus (Schlenk techniques). The solvents were dried by standard procedures (*n*-pentane, diethyl ether and THF: Na/K alloy), distilled and stored under argon. Melting points: Mettler FP 61 (heating rate: 3°C/min). − FT-IR spectra: Perkin-Elmer infrared spectrometer 16PC. − Mass spectra: Finnigan MAT 90 spectrometer. − NMR spectra: Bruker AMX 400 (^{1}H: 400 MHz, ^{13}C: 101 MHz, ^{31}P: 162 MHz) and Bruker AC 200 (^{31}P: 81 MHz) spectrometers, solvent as internal standard (^{1}H and ^{13}C); the chemical shifts for ^{31}P are relative to external 85% orthophosphoric acid. Compounds **1a**[19], **1b**[20], **1c**[19], **2c**[15] were prepared by published methods. Compounds **2b**, **7** were purchased from Aldrich and used without further purification.

1,4,6-Tri-tert-butyl-2,7,7-triisobutyl-3,5-diphospha-2-phosphonia-7-aluminatotricyclo[3.2.0.0^{2,6}]hept-3-ene (**5a**): To a magnetically stirred solution of 0.94 g (4.75 mmol) of triisobutylaluminum (**2b**) in diethyl ether (10 ml) was added 1.67 g (16.68 mmol) of phosphaalkyne **1a**. After the reaction mixture had been heated to 100°C for 10 h in a Schlenk pressure tube, all volatile components were removed at 25°C/10^{-3} mbar. The remaining crude product was purified by bulb-to-bulb distillation (150°C/10^{-3} mbar): 1.56 g, 66% yield, yellow oil. − IR (pentane, cm^{-1}): $\tilde{\nu}$ = 1210 (s), 1200 (s), 1090 (s), 810 (s), 790 (s), 680 (s). − ^{31}P NMR (C_6D_6): δ = 36.5 (dd, $^2J_{P,P}$ = 32.2 Hz, $^2J_{P,P}$ = 19.0 Hz, P-5), 53.9 (dd, $^1J_{P,P}$ = 299.2 Hz, $^2J_{P,P}$ = 32.2 Hz, P-2), 223.3 (dd, $^1J_{P,P}$ = 299.2 Hz, $^2J_{P,P}$ = 19.0 Hz, P-3). − ^{1}H NMR (C_6D_6): δ = 0.46 [d, $^3J_{H,H}$ = 7.2 Hz, 2 H, AlCH_2CH(CH$_3$)$_2$], 0.64 [dd, $^4J_{H,P}$ = 2.3 Hz, $^3J_{H,H}$ = 7.1 Hz, 2 H, AlCH_2CH(CH$_3$)$_2$], 0.96 [d, $^3J_{H,H}$ = 6.7 Hz, 6 H, P-2-CH$_2$CH(CH_3)$_2$], 1.05 [s, 18 H, 2 C(CH_3)$_3$], 1.24 [d, $^3J_{H,H}$ = 6.5 Hz, 6 H, AlCH$_2$CH(CH_3)$_2$], 1.25 [d, $^3J_{H,H}$ = 6.5 Hz, 6 H, AlCH$_2$CH(CH_3)$_2$], 1.37 [s, 9 H, C(CH_3)$_3$], 2.08−2.22 [m, 2 H, AlCH$_2$CH(CH$_3$)$_2$ and P-2-CH$_2$CH(CH$_3$)$_2$], 2.22−2.32 [m, 1 H, AlCH$_2$CH(CH$_3$)$_2$], 2.36 [d-pseudo-t, $^2J_{H,P}$ = 7.3 Hz, $J_{H,P}$ = 2.0 Hz, $^3J_{H,H}$ = 7.3 Hz, 2 H, P-2-CH_2CH(CH$_3$)$_2$]. − ^{13}C NMR (C_6D_6): δ = 24.7 [pseudo-t, $J_{C,P}$ = 4.9 Hz, $J_{C,P}$ = 4.9 Hz, P-2-CH$_2$CH(*C*H$_3$)$_2$], 26.3 [s, broad, 2 Al*C*H$_2$CH(CH$_3$)$_2$], 26.8 [s, broad, CH$_2$*C*H(CH$_3$)$_2$], 27.8 [d, $J_{C,P}$ = 3.1 Hz, CH$_2$*C*H(CH$_3$)$_2$], 27.9 [s, CH$_2$*C*H(CH$_3$)$_2$], 29.1 [s, AlCH$_2$CH(*C*H$_3$)$_2$], 29.3 [s, AlCH$_2$CH(*C*H$_3$)$_2$], 32.1 [pseudo-t, $J_{C,P}$ = 9.0 Hz, $J_{C,P}$ = 9.0 Hz, C-4-C(*C*H$_3$)$_3$], 34.6 [dd, $J_{C,P}$ = 7.5 Hz, $J_{C,P}$ = 5.5 Hz, C-1/6-C(*C*H$_3$)$_3$], 35.8 [s, broad, 3*C*(CH$_3$)$_3$], 44.7 (d-pseudo-t, $^1J_{C,P}$ = 20.8 Hz, $J_{C,P}$ = 10.4 Hz, $J_{C,P}$ = 10.4 Hz, C-1/6), 47.2 [dd, $^1J_{C,P}$ = 24.6 Hz, $J_{C,P}$ = 10.5 Hz, P-2-*C*H$_2$CH(CH$_3$)$_2$], 104.4 (dd, $^1J_{C,P}$ = 50.2 Hz, $^1J_{C,P}$ = 13.4 Hz, C-4). − MS (CI, 120 eV); *m/z* (%): 500 (5) [M$^+$ + 2 H], 499 (17) [M$^+$ + H], 442 (24) [M$^+$ − C$_4$H$_8$], 441 (100) [M$^+$ − C$_4$H$_9$], 341 (4) [M$^+$ − C$_4$H$_9$ − PC$_5$H$_9$]. − $C_{27}H_{54}AlP_3$ (498.63): calcd. Received June 9, 1998

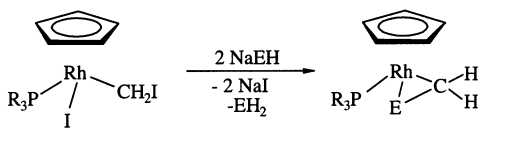
Keywords: Rhodium / Carbenoide metal complexes / Formaldehyde complexes / Thioformaldehyde complexes / Cyclopentadienyl complexes

The acetoxymethyl rhodium compounds $[(\eta^5\text{-}C_5R_5)Rh(CH_2OAc)(L)I]$ (**4**, **13**–**16**) which were prepared from the chloromethyl derivatives $[(\eta^5\text{-}C_5R_5)Rh(CH_2Cl)(L)I]$ and sodium acetate in benzene/acetic acid as solvent, reacted with $AgPF_6$ to give the chelate complexes $[(\eta^5\text{-}C_5R_5)Rh\{\kappa^2\text{-}C,O\text{-}CH_2OC(Me)O\}(L)]PF_6$ (**19**–**23**) in excellent yields. Treatment of these complexes with KOH in methanol led to the elimination of the acetyl group and to the formation of the formaldehyde compounds $[(\eta^5\text{-}C_5R_5)Rh(\eta^2\text{-}CH_2O)(L)]$ (**24**–**27**). The related thioformaldehyde complexes $[(\eta^5\text{-}C_5Me_5)Rh(\eta^2\text{-}CH_2S)(L)]$ (**46**, **47**) and $[(\eta^5\text{-}C_5H_5)Rh(\eta^2\text{-}CH_2S)(PMe_3)]$ (**50**) were obtained on a similar route. Studies on the reactivity of the formaldehyde derivatives revealed that the Rh–CH_2O bond is rather labile and the CH_2O ligand easily converted to a CO group.

In a series of papers we have recently shown[1] that cobalt and rhodium half-sandwich type complexes, which contain $MI(CH_2I)$ as a molecular unit, can be transformed to the corresponding thio-, seleno-, and telluroformaldehyde metal derivatives upon treatment with SH^-, SeH^-, and TeH^-, respectively (see Scheme 1). Due to the lone electron pairs at the chalcogen atom of the CH_2E ligand, these compounds behave as Lewis bases and react with in situ generated 16-electron fragments such as $[W(CO)_5]$ or $[(\eta^5\text{-}C_5H_5)Mn(CO)_2]$ to give dinuclear hetero-metallic complexes with the aldehyde CH_2E in a bridging position.[1d][2] First attempts to complete the series of compounds $[(\eta^5\text{-}C_5R_5)M(\eta^2\text{-}CH_2E)(L)]$ by those with E = O failed. The reaction of the respective precursor $[(\eta^5\text{-}C_5R_5)M(L)(L')]$ with monomeric formaldehyde was rather slow and in most cases led to a mixture of products among which the carbonyl complexes $[(\eta^5\text{-}C_5R_5)M(CO)(L)]$ were the dominating species. Therefore, we had to develop a different synthetic route. The present paper describes that for M = Rh the key to success was the preparation of metalated acetic acid derivatives $[Rh]CH_2OC(O)CH_3$ as intermediates which could be converted in two steps to the coordinated formaldehyde ligand. Some related results to this work were already reported.[3]

Scheme 1



Results

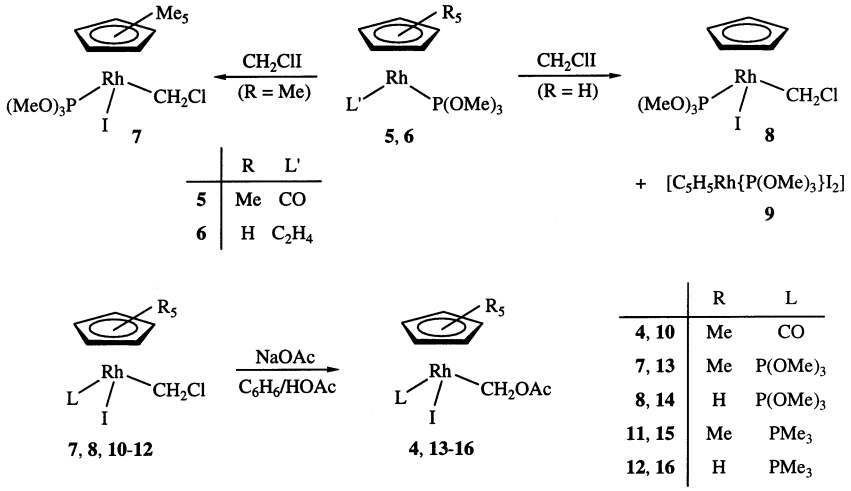
Preparation of $RhCH_2OAc$ Precursors

The carbenoide rhodium complex **1**, which can easily be prepared from $[C_5Me_5Rh(CO)_2]$ and CH_2I_2,[4] reacts quite smoothly in polar solvents with sodium acetate. While in acetone a mixture of products is formed, the reaction of **1** with excess NaOAc in methanol leads to the methoxymethyl compound **2** in good yield. In contrast, the starting material **1** and NaOAc react in ethanol to give two products **3** and **4** (see Scheme 2), which could be separated by chromatographic techniques. Although the desired acetoxy derivative **4** is the dominating species provided that an excess of sodium acetate is used, the separation of the two compounds on Al_2O_3 results in the partial conversion of **4**

Scheme 2. [Ac = CH_3CO]

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1434–1948/98/1111–1605 $ 17.50+.50/0

Scheme 3. [Ac = CH_3CO]

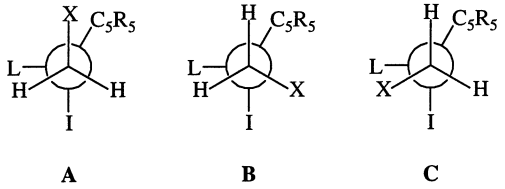


to the dinuclear complex [{(η^5-C_5Me_5)Rh(μ-CO)}$_2$]. Therefore, the isolated yield is rather low.

The method of choice for the preparation of **4** is the reaction of **7** with excess NaOAc in a mixture of benzene and glacial acetic acid as the solvent. Under these conditions, not only **4** but also the half-sandwich type Rh−CH_2OAc complexes **13**−**16** (Scheme 3) have been obtained in 80−85% yield. The synthesis of the formerly unknown chloromethyl rhodium(III) precursors **7** and **8** was achieved by oxidative addition (followed by elimination of CO or C_2H_4) of CH_2ClI to [(η^5-C_5Me_5)Rh(CO){$P(OMe)_3$}] and [(η^5-C_5H_5)Rh(C_2H_4){$P(OMe)_3$}], respectively. We note that the rate of formation of **15** from **11** is significantly higher than from [(η^5-C_5Me_5)Rh(CH_2I)(PMe_3)I][4] which can be understood by the HSAB concept: Substitution of the hard chloride by the hard nucleophile OAc^- is favoured compared to the displacement of the soft iodide by acetate.[5]

The acetoxymethyl derivatives **4** and **13**−**16** are yellow to red-brown microcrystalline solids, which are air-stable and soluble in common organic solvents. The most typical feature of the ^{1}H-NMR spectra of **4** and **13**−**16** is the appearance of two distinct signals for the methylene protons of the CH_2OAc group which due to Rh-H, H-H, and in some cases P-H coupling are split into doublets of doublets or appear as doublets of doublets of doublets. Since the size of ^3J(PH), which depends on the mutual orientation of the phosphorus and the hydrogen atoms of the $PRhCH_2$ unit,[6] differs considerably (e.g. between 0 Hz and 8.8 Hz for **15**), we assume that the rotation around the Rh−CH_2O axis is partially hindered and the conformations **A** or **B** (Figure 1) are preferred. A similar observation has already been made for compounds such as **12** and [(η^5-C_5H_5)Rh(CH_2X)-(PMe_3)X] (X = Br, I)[7] as well as for related cyclopentadienyliron derivatives [(η^5-C_5H_5)Fe(CH_2R)(CO)(PR'_3)] (R = Ph, $SiMe_3$).[8]

Figure 1. Conformations of compounds [(η^5-C_5R_5)Rh(CH_2X)(L)I] (X = Cl, OAc) viewed along the Rh−C axis. Due to the formally octahedral geometry the bond angle P−Rh−I is assumed to be 90° (see also ref.[8])

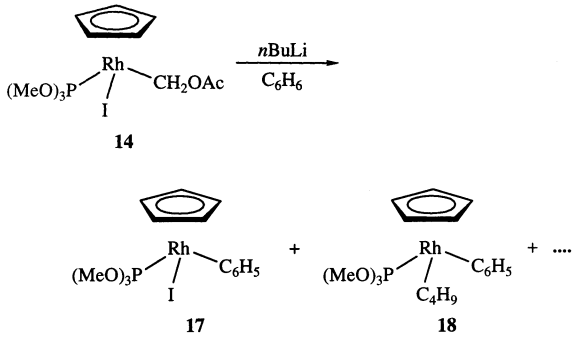


Conversion of $RhCH_2OAc$ to Rh(η^2-CH_2O) Complexes

Attempts to convert the acetoxymethyl compounds **4** and **13**−**16** to the corresponding formaldehyde complexes by using different nucleophiles failed.[9] Whereas treatment of **4** with NaOMe in methanol/benzene or with *n*BuLi in benzene led mainly to decomposition (and to the formation of small amounts of [{(η^5-C_5Me_5)Rh(μ-CO)}$_2$]), the reaction of **15** with NaOMe in methanol or with NaOH in water/benzene in the presence of [$PhCH_2NEt_3$]Cl (TEBA) as phase-transfer catalyst gave mainly the mononuclear compound [(η^5-C_5Me_5)Rh(CO)(PMe_3)].[10] Although the ^{1}H-NMR spectrum of the reaction mixture formed from **15** and NaOMe in CD_3OD showed that besides the carbonyl complex [(η^5-C_5Me_5)Rh(CO)(PMe_3)] the corresponding formaldehyde compound **26** (see Scheme 5) is probably formed, the attempts to separate the two C_5Me_5Rh species by chromatographic techniques failed. One noteworthy result is that from the mixture of products obtained upon treatment of the trimethylphosphite complex **14** with two equiv of *n*BuLi in benzene/hexane the half-sandwich type rhodium(III) derivatives **17** and **18** (Scheme 4) could be isolated in low yield. The ^{1}H NMR data as well as the mass spectra and (in the case of **17**) the elemental analysis revealed that both in **17** and **18** a Rh−C_6H_5 bond is present, the phenyl group originating either from benzene or from in situ generated LiPh, respectively.

The methodology for the successful preparation of the formaldehyde rhodium complexes **24**−**27** is outlined in Scheme 5. Instead of an attack of a nucleophile to the carbon atom of the acetoxy unit of **4** and **13**−**16** the first step involves the cleavage of the Rh−I linkage by $AgPF_6$. This is followed by the formation of a five-membered chelate

Scheme 4. [Ac = CH_3CO]



ring. Since the coordination of the carbonyl oxygen atom to the metal increases the δ+ charge at the C=O carbon atom, a subsequent nucleophilic attack at this carbon is preferred. Finally, the products **24**–**27** are obtained in moderate yield. It should be emphasized that even treatment of the highly reactive bis(trimethylphosphane) compounds $[(\eta^5\text{-}C_5H_5)Rh(PMe_3)_2]$ and $[(\eta^5\text{-}C_5Me_5)Rh(PMe_3)_2]$[11] with formaldehyde does not lead to **26** and **27** but instead gives the carbonyl derivatives $[(\eta^5\text{-}C_5H_5)Rh(CO)(PMe_3)]$ and $[(\eta^5\text{-}C_5Me_5)Rh(CO)(PMe_3)]$.

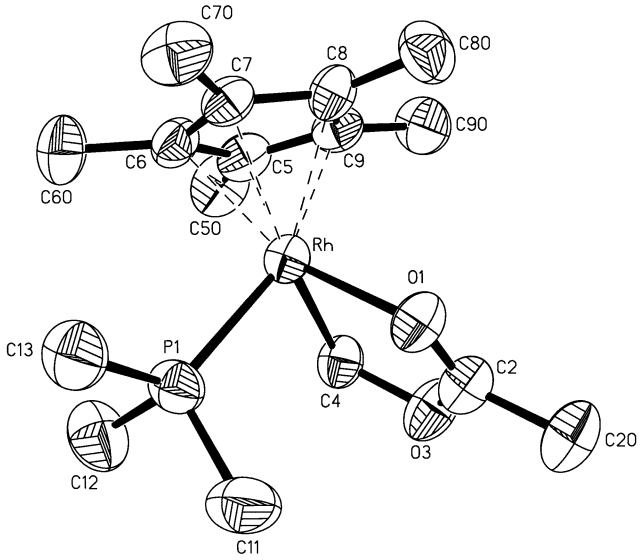
Scheme 5

	R	L
4, 19	Me	CO
13, 20, 24	Me	$P(OMe)_3$
14, 21, 25	H	$P(OMe)_3$
15, 22, 26	Me	PMe_3
16, 23, 27	H	PMe_3

The chelate complexes **19**–**23** are yellow to orange-yellow air-stable solids which in nitromethane display the conductivity expected for 1:1 electrolytes. The spectroscopic data of **19**–**23** and of the non-ionic precursors **4** and **13**–**16** differ insofar, as in the ^{13}C NMR spectra of **19**–**23** the signal of the C=O carbon atom is shifted significantly (16–20 ppm) to lower field due to the interaction of the acetyl moiety with the metal. In the IR spectra of the chelate compounds the C=O stretching frequency is also reduced and appears at 1600–1610 cm^{-1} compared with 1700–1720 cm^{-1} for **4** and **13**–**16**, respectively. For the dicyclopentadienylvanadium complexes $[(\eta^5\text{-}C_5H_5)_2V\{\eta^1\text{-}CH_2OC(O)R\}Cl]$ and $[(\eta^5\text{-}C_5H_5)_2V\{\kappa^2\text{-}C,O\text{-}CH_2OC(R)O\}]BPh_4$ an almost identical trend has been observed.[12]

The result of the X-ray crystal structure analysis of **22** is shown in Figure 2. The acetoxymethyl unit acts as a bidentate ligand and forms a nearly planar five-membered ring with the rhodium center. The distance C2–O1 [1.240(8) Å] indicates significant double bond character which is in agreement with the bonding pattern shown for **19**–**23** in Scheme 5. The corresponding C=O bond length in the vanadium complex $[(\eta^5\text{-}C_5H_5)_2V\{\kappa^2\text{-}C,O\text{-}CH_2OC(Me)O\}]^+$ is 1.236(4) Å[12] and thus almost identical to that in **22**. Compared with C2–O1, the distance C2–O3 [1.307(8) Å] is considerably longer and quite similar to the C–O(W) distance found in $[(\eta^5\text{-}C_5H_5)W(CO)_3(OAc)]$.[13] The Rh–C4 bond length [2.067(6) Å] is somewhat shorter than in related cationic cyclopentadienylrhodium compounds such as $[(\eta^5\text{-}C_5H_5)Rh(CH_2NC_5H_5)(PMe_3)I]^+$ [14] and $[(\eta^5\text{-}C_5H_5)\text{-}RhCH_3(CO)(PPh_2R)]^+$ [R = NHCH(Me)Ph][15] which could be due to the electronic effect caused by the OAc group. The Rh–C4–O3 bond angle is 109.7(4)° which is consistent with the sp^3 hybridization of the CH_2 carbon atom. The distances between rhodium and the carbon atoms of the C_5Me_5 ring are in the usual range for complexes containing the $C_5Me_5Rh(PMe_3)$ unit.[16] However, as has previously been observed for those half-sandwich type compounds with π-donating ligand,[7][17] the metal–carbon bond lengths [Rh–C5 and Rh–C6] *trans* to this ligand are shorter than the other Rh–C(ring) distances.

Figure 2. Molecular structure of **22**[a] (thermal elipsoids with 50% probability)



[a] Selected bond lengths [Å] and angles [°]: Rh–P1 2.300(2), Rh–O1 2.112(4), Rh–C4 2.067(6), Rh–C5 2.170(6), Rh–C6 2.179(6), Rh–C7 2.254(6), Rh–C8 2.230(7), Rh–C9 2.198(6), O1–C2 1.240(8), C2–O3 1.307(8), C2–C20 1.501(9), O3–C4 1.471(7); P1–Rh–O1 91.3(1), P1–Rh–C4 87.7(2), O1–Rh–C4 77.9(2), Rh–O1–C2 113.9(4), O1–C2–O3 122.2(6), O1–C2–C20 122.6(6), O3–C2–C20 115.2(6), C2–O3–C4 116.0(5), Rh–C4–O3 109.7(4).

The second step of the synthesis of compounds **24**–**27** (see Scheme 5) proved to be difficult. Treatment of the acetoxymethyl complexes **20**–**23** with NaOMe or KOH in methanol at room temperature gave in each case a mixture of products with the carbonyl and the formaldehyde compounds $[(\eta^5\text{-}C_5R_5)Rh(CO)(L)]$ and $[(\eta^5\text{-}C_5R_5)Rh(\eta^2\text{-}CH_2O)(L)]$ as the dominating species. Attempts to separate

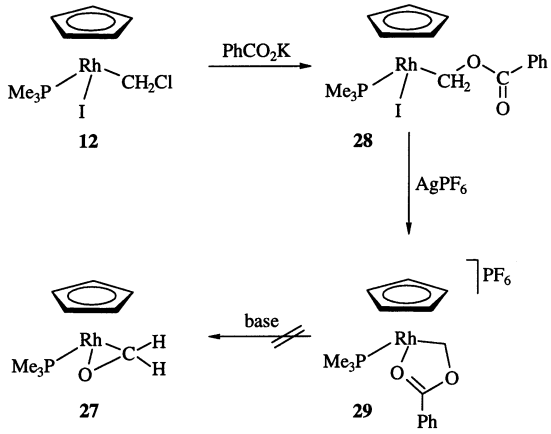
these mixtures by chromatographic techniques led mainly to the isolation of the Rh−CO complexes. However, the rate of the decomposition of the formaldehyde derivatives to $[(\eta^5\text{-}C_5R_5)Rh(CO)(L)]$ could be considerably reduced if the reaction of **20**−**23** with base was carried out at low temperature. After the reaction mixture was worked up at 0°C, oily products were obtained which could partly be converted to yellow-brown microcrystalline solids. Since the formaldehyde compounds **24**−**27** are not only labile (and air-sensitive) but also readily soluble in pentane, the yield of the isolated solids did not exceed 30%.

Even more labile than the trimethylphosphite and trimethylphosphane complexes **24**−**27** is the corresponding carbonyl derivative $[(\eta^5\text{-}C_5Me_5)Rh(\eta^2\text{-}CH_2O)(CO)]$. Addition of excess NaOMe to a solution of **19** in methanol at −78°C led initially to the formation of a clear yellow solution which rapidly turned blue if the same work-up procedure was used as applied for **24**−**27**. The isolated product consisted of both $[(\eta^5\text{-}C_5Me_5)Rh(CO)_2]$ and the dinuclear compound $[\{(\eta^5\text{-}C_5Me_5)Rh(\mu\text{-}CO)\}_2]$. However, the ^{1}H-NMR spectrum of the reaction mixture in CD_3OD at −40°C displayed two doublets of doublets at δ 5.67 [J(RhH) = 4.4, J(HH) = 6.1 Hz] and 5.46 [J(RhH) = 0.6, J(HH) = 6.1 Hz] and one doublet at δ 1.66 [J(RhH) = 0.4 Hz] which can be assigned to the CH_2 and C_5Me_5 protons of $[(\eta^5\text{-}C_5Me_5)Rh(\eta^2\text{-}CH_2O)(CO)]$, respectively.

With regard to the spectroscopic data of the isolated formaldehyde complexes, we note that at least in the case of **25**, **26**, and **27** for the methylene protons of the coordinated CH_2O ligand two distinct signals (both doublets of doublets of doublets) have been observed. The ^2J(HH) coupling of 18.2−21.5 Hz lies between that of free formaldehyde (42.2 Hz) and ethylenoxide (5.5 Hz)[18] and indicates some double bond character for the C−O bond. The H-H coupling constant of **25**−**27** is quite similar to that of the cationic rhenium compound $[(\eta^5\text{-}C_5H_5)Re(\eta^2\text{-}CH_2O)(NO)(PPh_3)]^+$ (16.6 Hz)[19] for which according to the structural data also a partial C−O double bond character has been postulated. We note that a three-membered MCO ring as shown in Scheme 6 dominates the structural chemistry of formaldehyde complexes containing the $Zr(C_5H_5)_2$ unit which is probably due to the higher oxophilicity of electron-poor transition-metal centres.[12][20]

To find out whether complexes that are structurally related to **19**−**23** are also suitable starting materials for the generation of formaldehyde rhodium derivatives, compounds **28** and **29** (Scheme 6) have been prepared. Both were obtained via the same route as **16** and **23** and characterized by elemental analysis and spectroscopic means. However, treatment of **29** with various bases led to a mixture of products among which **27** could not be exactly identified.

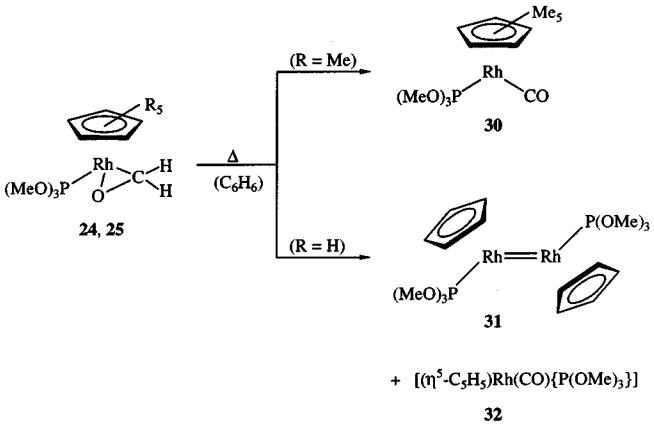
Scheme 6



Reactions of Rh(η^2-CH_2O) Complexes

The striking lability of the formaldehyde rhodium complexes $[(\eta^5\text{-}C_5R_5)Rh(\eta^2\text{-}CH_2O)(L)]$ initiated a series of experiments aimed to find out whether during the decomposition besides the carbonyl derivatives other compounds are formed too. If the course of the thermal decomposition of **24**, **26**, and **27** in C_6D_6 is studied in an NMR tube at room temperature, the complexes $[(\eta^5\text{-}C_5R_5)Rh(CO)(L)]$ indeed are the most dominating species among the observed products. After completion of the reaction the spectroscopically determined yield of the carbonyl compounds is 80−90%. Hydrido complexes such as $[(\eta^5\text{-}C_5Me_5)RhH_2(PMe_3)]$[21] could not be detected. The most surprising discovery was that in contrast to the thermolysis of **24** which gave almost quantitatively $[(\eta^5\text{-}C_5Me_5)Rh(CO)\{P(OMe)_3\}]$,[22] the corresponding reaction of **25** led to a mixture of **31** and **32** (Scheme 7) in the ratio of ca. 70:30 under the same conditions (benzene, 25°C). If a somewhat higher concentration of **25** is used, the relative amount of the dinuclear complex increases and, after fractional crystallization, the isolated yield of **31** (which is a green moderately air-sensitive solid) is about 40%.

Scheme 7



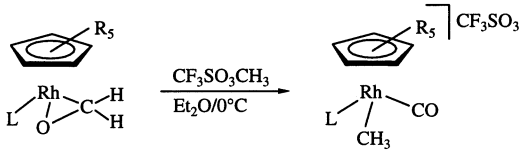
The structural proposal for **31** is mainly supported by the mass spectrum and the NMR spectroscopic data. In the mass spectrum peaks for M^+, $M^+ - P(OMe)_3$, and $M/2^+$ are observed, which is in agreement with the presence of a dinuclear framework. The ^{1}H-NMR spectrum displays two signals for the protons of the C_5H_5 and $P(OMe)_3$ ligands,

while the ^{31}P-NMR spectrum displays only a single resonance, its splitting being consistent with a spectrum of an AA′XX′ type (A,A′ = ^{31}P; X, X′ = ^{103}Rh). Since compound **31** is formally an analogue of the well-known carbonyl complex [{(η^5-C_5Me_5)Rh(μ-CO)}$_2$] (the structural data of which indicate the presence of a metal−metal double bond),[23] we tentatively assign a similar bonding pattern also to **31**. The spectroscopic data are of course not conclusive as to the *cis* or *trans* disposition of the two cyclopentadienyl (and equally the two phosphite) ligands.

The question of why compound **25** but not the related complexes **24**, **26**, and **27** decomposes by loss of formaldehyde and formation of a dinuclear product can not be answered definitively. It should be noted, however, that only in the mass spectra of **24**, **26**, and **27** the peak of the molecular ion M^+ appears, while the corresponding peak (m/z = 322) is missing in the mass spectrum of **25**. On the other hand, only in the latter the ion CH_2O^+ is observed with relatively high intensity. A plausible explanation of these results is that due to the less pronounced donor character of C_5H_5 compared to C_5Me_5 and of $P(OMe)_3$ compared to PMe_3, the metal-to-formaldehyde bond of compound **25** is the weaker and can be cleaved more easily than in the C_5Me_5Rh and $Rh(PMe_3)$ counterparts. The loss of formaldehyde from **25** would generate the 16-electron species [(η^5-C_5H_5)Rh{$P(OMe)_3$}] which dimerizes preferentially and does not react with CH_2O or benzene. The carbonyl complexes [(η^5-C_5R_5)Rh(CO)(L)] as the preferred products of the thermal decomposition of **24**, **26**, and **27** (and in part also of **25**) are probably formed via the formyl(hydrido)metal intermediates [(η^5-C_5R_5)RhH(CHO)(L)] which eliminate H_2 to give the final products. There is ample evidence for this pathway, particular due to the work by Thorn[24] and Roper et al.[25]

The reactions of **24**, **26**, and **27** with methyltriflate follow an unexpected course. In contrast to several other formaldehyde metal complexes which react with HX or RX by attack of the electrophile to the CH_2O oxygen atom,[12][25b][26] on treatment of **24**, **26**, or **27** with $CF_3SO_3CH_3$ no $RhCH_2OCH_3$ species could be detected. Instead the triflates of the cationic complexes **33**−**35** were formed. While the isolated yield of **33** and **34** was high, that of **35** was rather low which could be due to the lability of the Rh−CO bond in the rhodium(III) species. The PF_6 salts of the cations [(η^5-C_5R_5)Rh(CH_3)(CO)(PMe_3)]$^+$ (R = H, Me) were previously prepared in our laboratory either from the acyl derivative [(η^5-C_5Me_5)Rh{$C(O)CH_3$}(PMe_3)I] and $AgPF_6$[10] or by salt metathesis from [(η^5-C_5H_5)Rh(CH_3)(CO)(PMe_3)]I and NH_4PF_6[27]. We assume that compounds **33**−**35** are formed via the carbonyl complexes [(η^5-C_5R_5)Rh(CO)(L)] and that the electrophile $CF_3SO_3CH_3$ strongly facilitates the conversion of **24**, **26**, and **27** to [(η^5-C_5R_5)RhH(CHO)(L)] and subsequently to [(η^5-C_5R_5)Rh(CO)(L)]. This mechanistic proposal is supported by the observation that upon addition of methyltriflate to solutions of the starting material a rapid evolution of gas (H_2) is observed.

Scheme 8



24, 26, 27 **33-35**

	R	L
33	Me	$P(OMe)_3$
34	Me	PMe_3
35	H	PMe_3

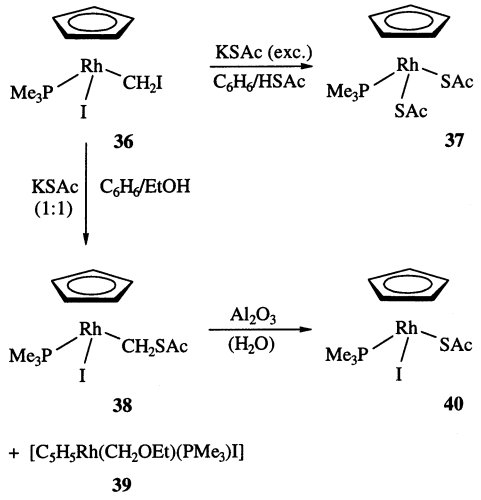
The formaldehyde complexes **26** and **27** react with CF_3SO_3H in a less straightforward manner and afford a mixture of products. Among those the cations [(η^5-C_5R_5)RhH(CO)(PMe_3)]$^+$ could be identified by ^{1}H-NMR spectroscopy.[10][27] Treatment of **26** and **27** with CH_2I_2 leads to the fast displacement of CH_2O (detected by ^{1}H NMR) and to the formation of [(η^5-C_5Me_5)Rh(CH_2I)(PMe_3)I][4] and [(η^5-C_5H_5)Rh(CH_2I)(PMe_3)I],[7] respectively. Compounds **26** and **27** behave thus analogously to the carbonyl and ethene derivatives [(η^5-C_5Me_5)Rh(CO)(PMe_3)] and [(η^5-C_5H_5)Rh(C_2H_4)(PMe_3)]. The noteworthy difference is, however, that the reactions of **26** and **27** with CH_2I_2 proceed much faster than those of the corresponding carbonyl and ethene complexes which is probably due to the weaker Rh−CH_2O compared to the Rh−CO and Rh−C_2H_4 bond.

Thioacetate− and Thioformaldehyde−Rhodium Complexes

The methodology used for the preparation of [(η^5-C_5R_5)Rh(η^2-CH_2O)(L)] (**24**−**27**) could also be applied for the synthesis of the corresponding thioformaldehyde complexes [(η^5-C_5R_5)Rh(η^2-CH_2S)(L)]. The investigations, which were carried out to obtain the respective precursors, are summarized in Schemes 9 and 10. Reaction of the starting material **36** with excess CH_3COSK in benzene/thioacetic acid led not only to cleavage of the CH_2−I but also to that of the Rh−I and Rh−C bonds and gave the bis(thioacetato)rhodium(III) compound **37** in nearly 80% yield. In contrast, treatment of **36** with one equiv of CH_3COSK in benzene/ethanol afforded a mixture of **38** and the known ethoxymethyl complex **39**,[3] which could be separated by fractional crystallization from pentane. The isolated yield of **38** was about 60%. If the separation of **38** and **39** was attempted by column chromatography using deactivated Al_2O_3, loss of the CH_2 fragment of the CH_2SAc ligand of **38** occurred and the half-sandwich rhodium(III) compound **40** was obtained. Both **37** and **38** as well as **40** were characterized by elemental analyses, mass spectra and IR and NMR spectroscopic techniques.

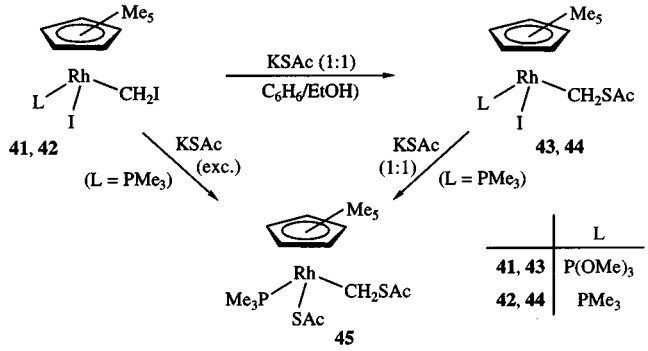
The preparation of the pentamethylcyclopentadienyl complexes **43** and **44** from the $RhCH_2I$ precursors **41** and **42** and CH_3COSK in benzene/ethanol proceeded in a clear manner and gave the expected products almost quantita-

Scheme 9. [Ac = CH_3CO]



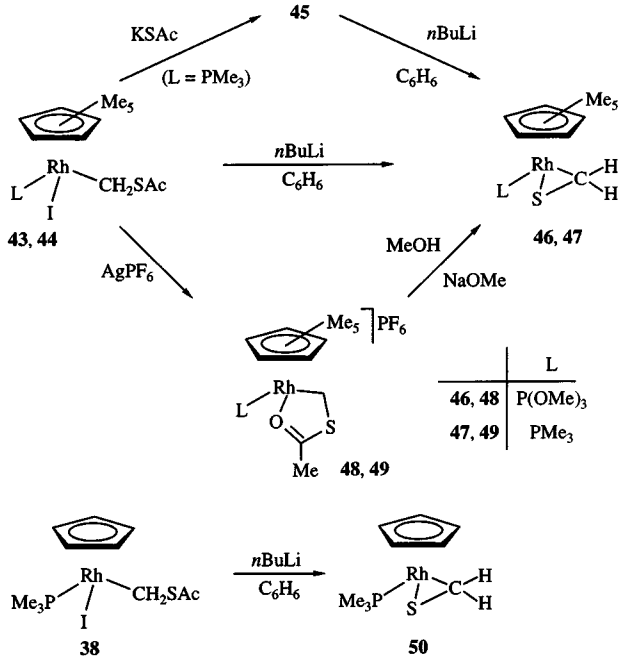
tively. In this case, no byproducts such as [(η^5-C_5Me_5)Rh(CH_2OEt)(L)I] [L = $P(OMe)_3$, PMe_3] were observed. The reaction of **42** with an excess of potassium thioacetate led both to the cleavage of the CH_2-I and the Rh−I bond and produced the thioacetatorhodium(III) derivative **45**. The same compound was obtained from **44** and an equimolar amount of CH_3COSK. The ^{1}H-NMR spectra of complexes **38**, **43**, and **44**, each containing a $RhCH_2SAc$ unit, display two distinct signals for the diastereotopic CH_2 protons which are well separated (by 0.2 to 0.7 ppm) and due to Rh-H, P-H, and H-H coupling appear as doublets of doublets of doublets.

Scheme 10. [Ac = CH_3CO]



The thioformaldehyde complexes **46** and **47** can be prepared in two different ways (see Scheme 11) using either the neutral derivatives **43** and **44** or the cationic compounds **48** and **49** as starting materials. The latter were prepared similar to the above mentioned chelate complexes **19**−**23** from **43** or **44** and $AgPF_6$ in acetone. The conversion of **48** and **49** to the thioformaldehyde compounds **46** and **47** proceeded then analogously as described for the Rh(η^2-CH_2O) counterparts.

Scheme 11. [Ac = CH_3CO]



However, in contrast to **24**−**27** the Rh(η^2-CH_2S) complexes **46** and **47** can also be prepared directly from **43** and **44** upon treatment with *n*BuLi in benzene/hexane. After the reaction mixture was worked up by column chromatography using Al_2O_3, the isolated yield of **46** and **47** was 75%. The (η^5-C_5H_5)Rh derivative **50**, which had previously been prepared from **36** and two molar equivalents of NaSH,[1a][1d] was obtained on the same route. In this context it should be reminded that treatment of **14** (a related species to **38** with a $RhCH_2OAc$ linkage) did not yield the corresponding formaldehyde complex **25**, probably due to the lability of the Rh−CH_2O bond toward the organolithium reagent. We note that the ^{1}H-, ^{13}C-, and ^{31}P-NMR spectra of **46** and **47** are quite similar to those of the cyclopentadienyl complexes [(η^5-C_5H_5)Rh(η^2-CH_2E)(L)] (E = S, Se, Te; L = PMe_3, PMe_2Ph, P*i*Pr_3)[1d] and thus deserve no further comment.

Discussion

The present investigation has shown that carbenoide rhodium compounds containing $Rh(CH_2X)I$ as a molecular fragment are not only useful starting materials for the synthesis of thio-, seleno-, and telluroformaldehyde complexes[1] but also open up a preparative route to corresponding formaldehyde metal derivatives. Although several examples are known which prove that compounds of the general composition [M(η^2-CH_2O)L_n] can be obtained from an appropriate precursor and free formaldehyde,[12][25][28] this method of synthesis failed for complexes such as [(η^5-C_5R_5)Rh(η^2-CH_2O)(L)]. The main reason for this is the lability of the Rh−CH_2O bond which is

illustrated by our studies concerned to the reactivity of the isolated compounds **24**−**27**. The preferred pathway of decomposition seems to be the conversion of [Rh](CH_2O) to [Rh](CO) and H_2 ([Rh] = [(η^5-C_5R_5)Rh(L)]) which is noteworthy insofar as the reverse reaction, i.e. the formation of [M](CH_2O) from [M](CO) and hydrogen, is described as an important step in the metal-assisted hydrogenation of carbon monoxide.[29] Presently the state of the art is that electron-poor transition metal centers are more suitable to stabilize the M−CH_2O bond than electron-rich counterparts which is probably due to the well-known oxophilicity of d^o-d^4 systems.[30] Electron-rich transition metal centers prefer to coordinate thio- and selenoformaldehyde instead of CH_2O, which has first been shown by Roper et al.[31] and has also been confirmed by this work as well as by previous studies from our laboratory.[1]

We acknowledge the support for this work by the *Deutsche Forschungsgemeinschaft* and the *Fonds der Chemischen Industrie*. Moreover, we are also grateful to Mrs. *R. Schedl* and Mr. *C. P. Kneis* for elemental analyses and DTA measurements as well as to Mrs. *M. L. Schäfer* and Dr. *W. Buchner* for recording the NMR spectra.

Experimental Section

All operations were carried out in an inert gas atmosphere with the Schlenk technique. The starting materials **1**,[4] **5**,[22] **6**,[32] **10**−**12**,[4][7] **36**,[32] and **41**, **42**[4] were prepared as described in the literature. CH_3COSK (KSAc) was prepared as a white microcrystalline solid from equimolar amounts of KOH and thioacetic acid in ethanol and used without further purification. − MS: Varian MAT CH7. − IR: Perkin-Elmer 397. − NMR: Varian EM 360 L, Bruker WH 90, AC 200, and WM 400. − Melting points: DTA. − Conductivity measurements (in CH_3NO_2) with conductometer Schott CG 851; Λ in $cm^2\Omega^{-1}mol^{-1}$.

1. Preparation of [(η^5-C_5Me_5)Rh(CH_2OMe)(CO)I] (**2**): A suspension of 85.1 mg (0.16 mmol) of **1** in 5 ml of methanol was treated with 13.5 mg (0.25 mmol) of CH_3CO_2Na and stirred for 3 h at room temp. The solvent was removed and the residue was extracted with 10 ml of ether. The extract was brought to dryness in vacuo and the residue was dissolved in 1 ml of pentane. After the solution was stored for 12 h at −78°C, a red-brown microcrystalline solid precipitated which was filtered, washed with small portions of pentane (−20°C) and dried; yield 45 mg (64%); m. p. 77°C (dec.). − IR (C_6H_6): $\tilde{\nu}$ = 2007 cm^{-1} [ν(CO)]. − ^{1}H NMR (200 MHz, C_6D_6): δ = 5.30 [dd, *J*(RhH) = 2.0, *J*(HH) = 3.8 Hz, 1 H, one H of C*H*$_2$OMe], 5.15 [dd, *J*(RhH) = 5.1, *J*(HH) = 3.8 Hz, 1 H, one H of C*H*$_2$OMe], 3.03 (s, 3 H, OCH_3), 1.68 [d, *J*(RhH) = 0.5 Hz, 15 H, C_5Me_5]. MS (70 eV); *m/z* (%) = 438 (10) [M^+], 393 (10) [M^+ − CH_2OMe], 365 (100) [$C_5Me_5RhI^+$], 266 (2) [$C_5Me_5Rh(CO)^+$], 238 (10) [$C_5Me_5Rh^+$]. − $C_{13}H_{20}IO_2Rh$ (438.1): calcd. C 35.64, H 4.60; found C 34.97, H 4.88.

2. Reaction of **1** *with CH_3CO_2Na in Ethanol:* A solution of 135.3 mg (0.25 mmol) of **1** in 5 ml of ethanol was treated with 20.9 mg (0.26 mmol) of CH_3CO_2Na and stirred for 15 h at room temp. The solvent was removed, the residue was extracted with 10 ml of benzene and after the extract was concentrated to ca. 2 ml in vacuo, it was chromatographed on Al_2O_3 (neutral, activity grade IV, height of column 5 cm). With benzene/pentane (1:1), a brown-yellow fraction was eluted which after removal of the solvent and recrystallization of the residue from ether/pentane gave red-brown crystals of **3**; yield 68 mg (60%). Subsequently with benzene, first a deep blue fraction containing [(η^5-$C_5Me_5Rh)_2$(μ-CO)$_2$] and then a yellow fraction was eluted. The latter was brought to dryness in vacuo, the residue was washed with pentane (0°C) and dried. A yellow solid of **4** was obtained; yield 19 mg (16%). − **3**: m. p. 96°C (dec.). − IR (C_6H_6): $\tilde{\nu}$ = 2010 cm^{-1} [ν(CO)]. − ^{1}H NMR (200 MHz, $CDCl_3$): δ = 5.26 [dd, *J*(RhH) = 2.0, *J*(HH) = 3.7 Hz, 1 H, one H of C*H*$_2$OEt], 5.06 [dd, *J*(RhH) = 5.0, *J*(HH) = 3.7 Hz, 1 H, one H of C*H*$_2$OEt], 3.44, 3.22, 1.20 [ABX_3 spin system, $J(H_AH_X)$ = 7.2, $J(H_BH_X)$ = −7.2, $J(H_AH_B)$ = 9.5 Hz, 5 H, $OCH_AH_BC(H_X)_3$], 1.96 [d, *J*(RhH) = 0.5 Hz, 15 H, C_5Me_5]. − MS (70 eV); *m/z* (%) = 452 (10) [M^+], 393 (9) [M^+ − CH_2OEt], 365 (100) [$C_5Me_5RhI^+$], 266 (3) [$C_5Me_5Rh(CO)^+$], 238 (14) [$C_5Me_5Rh^+$]. − $C_{14}H_{22}IO_2Rh$ (452.1): calcd. C 37.19, H 4.90; found C 37.45, H 5.03.

3. Preparation of [(η^5-C_5Me_5)Rh(CH_2OAc)(CO)I] (**4**): A solution of 152.3 mg (0.34 mmol) of **10** in 2 ml of benzene was treated with a solution of 258 mg (3.16 mmol) of CH_3CO_2Na in 2 ml of acetic acid (100%) and stirred for 3 h at 50°C. After cooling to room temp., the solvent was removed, the oily residue was extracted with 15 ml of benzene and the extract was brought to dryness in vacuo. A yellow solid was obtained which was washed with small portions of pentane (0°C) and dried; yield 103 mg (65%); m. p. 116°C (dec.). − IR (KBr): $\tilde{\nu}$ = 2020 cm^{-1} [ν(CO)], 1715 cm^{-1} [ν(C=O)]. − ^{1}H NMR (200 MHz, C_6D_6): δ = 6.20 [dd, *J*(RhH) = *J*(HH) = 2.2 Hz, 1 H, one H of C*H*$_2$OAc], 4.93 [dd, *J*(RhH) = 4.4, *J*(HH) = 2.2 Hz, 1 H, one H of C*H*$_2$OAc], 1.70 (s, 3 H, OCH_3), 1.53 [d, *J*(RhH) = 0.5 Hz, 15 H, C_5Me_5]. − ^{13}C NMR (22.5 MHz, $CDCl_3$): δ = 188.7 [d, *J*(RhC) = 78.0 Hz, Rh(CO)], 170.3 [s, *C*(O)CH_3], 104.5 [d, *J*(RhC) = 4.4 Hz, *C*$_5$Me$_5$], 55.6 [d, *J*(RhC) = 22.8 Hz, $RhCH_2$], 21.3 [s, C(O)*C*H_3], 10.1 [br. s, C_5(*C*H_3)$_5$]. − $C_{14}H_{20}IO_3Rh$ (465.1): calcd. C 36.06, H 4.32, Rh 22.09; found C 36.01, H 4.24, Rh 21.80.

4. Preparation of [(η^5-C_5Me_5)Rh(CH_2Cl){P($OMe)_3$}I] (**7**): A solution of 236.1 mg (0.61 mmol) of **5** in 8 ml of ether was treated under continuous stirring dropwise with 80 μl (1.10 mmol) of CH_2ClI. Evolution of gas (CO) was observed. The solution was stirred for 2 h at room temp. and then concentrated to ca. 2 ml in vacuo. After pentane (ca. 5 ml) was added, the solution was stored for 12 h at −78°C. Orange-red crystals precipitated which were filtered, washed with small quantities of pentane (−20°C) and dried; yield 203 mg (62%); m. p. 106°C (dec.). − ^{1}H NMR (200 MHz, C_6D_6): δ = 5.17 [ddd, *J*(RhH) = 8.0, *J*(PH) = 1.9, *J*(HH) = 6.0 Hz, 1 H, one H of C*H*$_2$OAc], 4.49 [ddd, *J*(RhH) = 1.6, *J*(PH) = 4.4, *J*(HH) = 6.0 Hz, 1 H, one H of C*H*$_2$OAc], 3.64 [d, *J*(PH) = 11.5 Hz, 9 H, P$(OMe)_3$], 1.79 [dd, *J*(RhH) = 0.3, *J*(PH) = 4.3 Hz, 15 H, C_5Me_5]. − ^{13}C NMR (22.5 MHz, C_6D_6): δ = 101.5 [dd, *J*(RhC) = *J*(PC) = 4.4 Hz, *C*$_5$Me$_5$], 54.2 [d, *J*(PC) = 6.6 Hz, P$(OMe)_3$], 35.5 [dd, *J*(RhC) = 30.2, *J*(PC) = 19.1 Hz, $RhCH_2$], 9.6 [d, *J*(RhC) = 2.2 Hz, C_5(*C*H_3)$_5$]. − ^{31}P NMR (36.2 MHz, C_6D_6): δ = 133.1 [d, *J*(RhP) = 253.1 Hz]. − MS (70 eV); *m/z* (%) = 538 (2) [M^+], 489 (66) [M^+ − CH_2Cl], 365 (100) [$C_5Me_5RhI^+$], 362 (2) [$C_5Me_5RhP(OMe)_3^+$], 238 (8) [$C_5Me_5Rh^+$]. − $C_{14}H_{26}ClIO_3PRh$ (538.6): calcd. C 31.22, H 4.87; found C 31.21, H 4.92.

5. Preparation of [(η^5-C_5H_5)Rh(CH_2Cl){P($OMe)_3$}I] (**8**) *and [(η^5-C_5H_5)Rh{P($OMe)_3$}I_2]* (**9**): A solution of 219.5 mg (0.69 mmol) of **6** in 3 ml of benzene was treated dropwise with 85 μl (1.17 mmol) of CH_2ClI and stirred for 28 h at room temp. A red-violet solid **9** precipitated. After addition of 10 ml of benzene to the reaction mixture, the solid was separated from the mother liquor, washed with acetone and ether, and dried; yield 38 mg (10%). The mother liquor was concentrated to 2−3 ml in vacuo and treated dropwise with 15 ml of pentane. A red-brown solid **8**

was formed which was filtered, repeatedly washed with small portions of ether (0°C), and dried; yield 188 mg (58%).

8: m. p. 89°C (dec.). – ^{1}H NMR (200 MHz, C_6D_6): δ = 5.47 [ddd, *J*(RhH) = 4.0, *J*(PH) = 1.4, *J*(HH) = 5.6 Hz, 1 H, one H of CH_2Cl], 5.27 [dd, *J*(RhH) = 0.3, *J*(PH) = 3.2 Hz, 5 H, C_5H_5], 4.73 [ddd, *J*(RhH) = 1.8, *J*(PH) = 9.8, *J*(HH) = 5.6 Hz, 1 H, one H of CH_2Cl], 3.53 [d, *J*(PH) = 11.8 Hz, 9 H, $P(OMe)_3$]. – ^{13}C NMR (22.5 MHz, C_6D_6): δ = 92.4 [dd, *J*(RhC) = *J*(PC) = 3.7 Hz, C_5H_5], 54.0 [d, *J*(PC) = 5.9 Hz, $P(OMe)_3$], 27.3 [dd, *J*(RhC) = 26.5, *J*(PC) = 17.2 Hz, $RhCH_2$]. – ^{31}P NMR (36.2 MHz, C_6D_6): δ = 133.4 [d, *J*(RhP) = 245.6 Hz]. – MS (70 eV); *m/z* (%) = 468 (2) [M^+], 419 (31) [$M^+ - CH_2Cl$], 341 (8) [$M^+ - I$], 295 (26) [$C_5H_5RhI^+$], 292 (9) [$C_5H_5RhP(OMe)_3^+$], 168 (28) [$C_5H_5Rh^+$]. – $C_9H_{16}ClIO_3PRh$ (468.5): calcd. C 23.08, H 3.44, Rh 21.97; found C 23.33, H 3.57, Rh 22.15.

9: m. p. 96°C (dec.). – ^{1}H NMR (60 MHz, CD_3NO_2): δ = 5.97 [dd, *J*(RhH) = 0.4, *J*(PH) = 1.3 Hz, 5 H, C_5H_5], 4.34 [d, *J*(PH) = 10.8 Hz, 9 H, $P(OMe)_3$]. – ^{31}P NMR (36.2 MHz, $CDCl_3$): δ = 116.0 [d, *J*(RhP) = 211.4 Hz]. – MS (70 eV); *m/z* (%) = 546 (21) [M^+], 419 (100) [$M^+ - I$], 295 (83) [$C_5H_5RhI^+$], 168 (60) [$C_5H_5Rh^+$]. – $C_8H_{14}I_2O_3PRh$ (545.9): calcd. C 17.60, H 2.58; found C 17.82, H 2.62.
