anism is the decrease of the spin-spin relaxation times brought about by $^{29}Si/^{27}Al$ dipolar interactions.[88] In order to assess this possibility the spin-spin relaxation times of an ETAS-10 sample with Si/Al = 0.24 has been measured. The two resonances at high frequency have short T_2 times (about 5 ms), confirming their assignment to silicons with aluminium neighbours and, thus, providing further evidence for framework substitution. The peaks attributed to Si(3Si, 1Ti) and Si(4Si) environments have similar, much longer relaxation times (35–49 ms). Therefore, the broadening of the Si(4Si) resonance cannot be explained by the dipolar mechanism discussed above. This effect is most likely caused by the distortion of the lattice upon aluminium incorporation.[86]

It is too early to say whether Al (Ga), Ti avoidance is a general phenomenon in titanoalumino(gallo)silicates. However, it seems logical that, wherever possible, Al (Ga) and Ti will not be neighbours. We have found that at relatively high Al and Ga framework concentrations slight deviations from the Al (Ga), Ti avoidance rule are observed.

The insertion of boron into ETS-10, yielding ETBS-10, has also been reported.[89] As the amount of boron in ETBS-10 increases, a new ^{29}Si MAS-NMR peak, attributed to Si–O–B environments, grows at $\delta \approx -99$ and (as in ETAS-10 and ETGS-10) all the resonances broaden considerably (not shown). On the other hand, the ^{11}B MAS-NMR spectra (not shown) of ETBS-10 samples with different boron contents are similar and contain two groups of very sharp peaks (FWHM ca. 78 Hz) at $\delta \approx -1.4$ and -2.9. This implies that any electric field gradients created by the electronic cloud at the ^{11}B nuclei are very small (quadrupole coupling constant estimated at 40–80 kHz) and shows that boron is in a tetrahedral, rather than a trigonal, coordination and replaces silicon in the framework of ETBS-10. Indeed, it has been reported that hydrated boron-substituted H-ZSM-5 zeolite gives a single sharp ^{11}B-NMR peak at $\delta = -3$.[90] On the other hand, the local environment of any extra-framework boron would, in principle, be more distorted or, at least, a dispersion of boron sites would occur leading to significantly broader ^{11}B MAS-NMR resonances.[89]

The insertion of niobium into the framework of ETS-10, replacing titanium, has been reported to pose particular problems because NMR does not provide strong evidence for it.[91] Indeed, only a relatively small broadening of the ^{29}Si MAS-NMR resonances is observed. In addition, the ^{93}Nb MAS-NMR spectrum recorded with a very fast (32 kHz) spinning rate displays a broad peak at $\delta = 100$ relative to solid Nb_2O_5, suggesting the presence of niobium in a distorted octahedral coordination. However, Raman and FTIR spectroscopies provide strong evidence for this framework substitution. ETS-10 gives a strong and sharp main Raman band at ca. 735 cm^{-1}, assigned to the TiO_6 octahedra (not shown).[91] As the niobium content of the samples increases, this peak shifts slightly and broadens and, simultaneously, a band grows at ca. 664 cm^{-1}. The latter band is typical of NbO_6 octahedra in microporous niobosilicates. The FTIR spectrum of ETS-10 (not shown) displays bands at 446, 550, and 746 cm^{-1}, associated with the TiO_6 octahedra. As the niobium content of the samples increases the intensity of these bands decreases, while a new band at 918 cm^{-1} is seen. This is a further indication that niobium replaces titanium in the ETS-10 framework.

The great (largely overlooked) potential presented by Raman spectroscopy for studying the isomorphous framework substitutions in zeolite-type materials is particularly well illustrated by the synthetic titano-niobosilicate nenadkevichite system.[44,45] The Raman spectra of a sample with Ti/Nb = 0.8 (Figure 13) displays two main bands at 668 and 226 cm^{-1} associated with the NbO_6 octahedra. With increasing titanium content the intensity of these bands decreases (particularly of the former) while simultaneously two other strong bands grow at 764 and 290 cm^{-1}. These bands are attributed to NbO_6 octahedra.

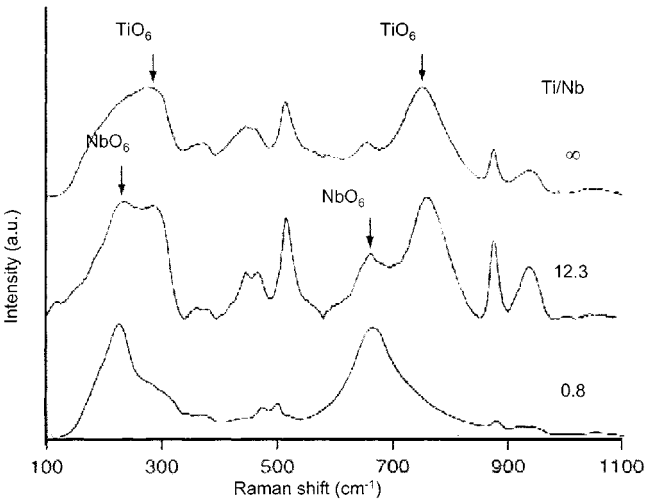

Figure 13. Raman spectra of synthetic nenadkevichite materials; the Ti/Nb ratios are indicated

The titanium for zirconium substitution in synthetic umbite has been studied in detail by powder X-ray diffraction.[31] It has been found that with increasing titanium content the unit cell shrinks in the three directions and its volume decreases systematically from ca. 985 (purely zirconeous sample) to 919 $Å^3$ (titaneous sample). This is not unexpected because Ti^{IV} is smaller than Zr^{IV}. ^{29}Si MAS-NMR spectroscopy provides further evidence for this framework substitution.[31] In the structure of umbite there are three types of Si(2Si, 2Zr) sites with populations 1:1:1.[50] The spectrum of purely zirconeous AM-2 displays a single broad peak at $\delta = -86.5$. In contrast, the spectrum of the purely titaneous sample contains a resonance at $\delta = -87.3$ and two overlapping peaks at about $\delta = -86.2$ and -85.9 in an approximate 1:1:1 intensity ratio, in accord with the crystal structure of umbite. Along the series, it is observed that as the zirconium content of the samples increases, the peak at about $\delta = -86.5$ broadens while the resonance at $\delta = -87.3$ broadens and eventually disappears from the spectrum.

Cation Location (Multiple-Quantum NMR and Computer Modelling)

The framework of these novel microporous materials is anionic and the charge density can be very high. Consider ETS-10, which has a basic formula unit of $Si_{40}Ti_8O_{104}^{16-}$. In other words there are 16 unit charges per 48 metal centres, which would be equivalent to a zeolite with a Si/Al ratio of 2 (which for zeolites is close to the Lowensteinian limit of Si/Al = 1). Moreover, the framework charge centres (at the octahedral Ti^{IV} site) carry an overall two-minus charge. Consequently, the charge distribution is quite different to the monovalent sites in the aluminosilicate zeolites. This will potentially make titanosilicates in this new class particularly attractive for exchanging divalent cations and are indeed particularly selective for some divalent heavy metals such as Pb^{2+} and Cd^{2+}.[9,92] Other materials reported above have an even higher charge density than the theoretical limit for zeolites, e.g. nenadkevichite with a composition $(Na,Ca)(Nb,Ti)Si_2O_7 \cdot H_2O$ is equivalent to a zeolite with Si/Al = 0.5.

It is desirable to characterise the cation site both in terms of crystallographic location and interaction with adsorbed molecules. For quadrupolar cations, such as sodium, the new technique of multiple-quantum MAS NMR is particularly powerful. Historically the NMR study of quadrupolar nuclei has been plagued by the inability to remove the quadrupole interaction, thereby gaining sufficient resolution to observe all possible sites. Two experimentally demanding techniques, dynamic angle spinning (DAS)[93] and double rotation (DOR),[94] were invented to overcome this problem but neither is easily implemented. Recently the technique of multiple-quantum (MQ) MAS NMR has provided a relatively straightforward solution to the problem.

The basic theory behind MQ MAS NMR is now well documented[95–98] and, thus, the following is a brief general overview. Consider the observation of a half-integer ($I > {}^1/_2$) spin nucleus. For a powdered sample, under fast spinning conditions, the frequency for symmetrical (m, $-m$) multiple-quantum transitions involves second- and fourth-rank angular dependent terms. The Legendre polynomials, P_2 and P_4, describing these angular dependencies are (Equation 3 and Equation 4)

$$P_2(\cos\theta) = \left(3\cos^2\theta - 1\right)/2 \quad (3)$$

$$P_4(\cos\theta) = \left(35\cos^4\theta - 30\cos^2\theta + 3\right)/8 \quad (4)$$

where θ is the angle between the spinning axis and the magnetic field B_0. As there is no common root to these polynomials, there is no single spinning axis that can completely remove the second-order quadrupolar broadening.

In the MQ MAS-NMR experiment the sample is spun at the magic angle and the magnetisation evolves sequentially under the triple (or quintuple) quantum Hamiltonian in the first part of time t_1 and under the single-quantum Hamiltonian during the second part. Judicious choice of the length of these evolution periods generates an isotropic echo. The simplest two-dimensional experiment is a two-pulse sequence whereby the pulse phases are cycled in an appropriate manner to select the desired quantum coherence. The projection of the (sheared) MQ MAS NMR spectrum onto axis F1 yields an isotropic, highly resolved spectrum, while the F2 projection is essentially the "conventional" MAS NMR spectrum. The position and profile of a peak in this two-dimensional spectrum immediately yields the isotropic chemical shift for the signal as well as the quadrupole coupling constant, C_Q, and the asymmetry parameter, η. These last two parameters define the quadrupole interaction, which is determined by the local environment of the nucleus. Conversely, if the environment is known then C_Q and η can be determined and compared with the NMR experiment.

Experimentally the technique is straightforward to implement. The hardware required is a conventional MAS NMR probe with smaller coil widths preferred in order to generate large radio-frequency fields. 4 mm rotors or even 2.5 mm rotors are preferable although there is a balance between sensitivity loss and gaining a high radio-frequency field. If the radio-frequency field is insufficient it will not be possible to excite nuclei experiencing a large quadrupolar interaction. These are generally highly coordinated nuclei in a very asymmetric environment.

A combination of MQ MAS NMR and computer modelling has been used to determine the sodium cation siting in ETS-10.[99–101] The ^{23}Na triple-quantum (3Q) MAS NMR spectrum of as-prepared ETS-10 is shown in Figure 14a and comprises two signals. Deconvolution of the isotropic sum projection onto F1 shows them to be in the ratio 2.6:1. The stronger signal comprises two sites, as evidenced by the shoulder in the isotropic F1 projection, with estimated δ_{iso}s and second-order quadrupole effects (SOQEs), $\sqrt{[C_Q^2(1 + (\eta^2/3)]}$ of –7.6 and 1.1 MHz and –7.5 and 1.3 MHz. The weaker signal is equally as broad in F1 and is also likely to comprise more than one site having δ_{iso}s of ca. –1.6 and a SOQEs of ca. 1.7 MHz.

Upon dehydration the weaker of the two signals in the spectrum of the hydrated material has now shifts to a lower F2 frequency (Figure 14b). This is due to an important change in δ_{iso} and SOQE from –1.6 and 1.7 MHz in hydrated ETS-10 to –3.7 and 2.4 MHz, in dehydrated ETS-10. Any sites responsible for this signal are thus strongly affected by dehydration. Although the shape of the stronger signal is slightly altered, it remains unshifted. The two sites largely unaffected by sample dehydration are assigned to sites I and II, which are tucked away on either side of the 12-ring pore (see Figure 5). The change in the position of the weaker signal upon dehydration suggests that any sites that give rise to this signal must be in the vicinity of water molecules and are thus likely to be situated in the pore void. This signal is therefore attributed to sites III and V, which are located at the top of the 12-ring pore near a titanate chain and loosely bound somewhere within the pore, respectively. A number of similar MQ MAS NMR studies have been carried out on a whole range of these novel microporous phases and the results will be published shortly.

Applications

Catalysis

For catalytic applications these novel framework materials present interesting new challenges. Apart from the possibilities for shape-selectivity and high activity through high surface area (similar to zeolites) these new materials possess a number of characteristics that make them particularly interesting as prospective heterogeneous catalysts. To date, only a moderate amount of work has been carried out on catalytic applications of the more stable wide-pore ETS-10 materials. However, this initial work is very encouraging and will no doubt be expanded greatly in the near future. For ETS-10 the catalytic applications have focused on the following attributes: high cation exchange capacity, which leads to many possibilities particularly in base catalysis; facile metal loading for bifuncionality; very low acidity; possible chiral activity; photocatalytic opportunities. It should be pointed out that the titanosilicates with octahedrally-coordinated titanium do not show good properties for oxidation catalysis in comparison to four-coordinate titanium. This is due to the ligand saturation, which prevents further attachment by oxidising agents such as hydrogen peroxide.

A number of papers by Bianchi, Ragaini, and co-workers detail Fischer–Tropsch chemistry over Co and Ru exchanged ETS-10.[102–105] The titanium silicate ETS-10 was found to be a suitable support for metal catalysts, due to its high surface area, high ion-exchange capability and the absence of an acidic function. The importance of alpha-olefin readsorption within the catalyst is discussed and the nature of this readsorption is tailored by effective control of the metal distribution inside the pores of ETS-10. The CO conversion and selectivity obtained also varies depending upon whether the active metal is introduced in the ETS-10 cages by ion-exchange or simply by impregnation.

Two groups, those of Anderson, Rocha, and co-workers[106] and Sivasanker and co-workers,[107–109] have studied the bifunctional reforming reaction of hexane to benzene over Pt-supported basic ETS-10. The basicity of the titanosilicate can be controlled by using samples exchanged with different alkali metals (M = Li, Na, K, Rb, or Cs). A distinct relationship between the intermediate electronegativity (S-int) of the different metal-exchanged ETS-10 samples and the yield of benzene is reported, suggesting the activation of Pt by the basicity of the exchanged metal. Typically ETS-10 samples exhibit greater aromatization activities than related Pt/Al_2O_3 catalysts. The very high basicity of ETS-10 in comparison with, for example zeolite X, is illustrated by Anderson and co-workers in a paper that discusses the relative conversion of 2-propanol to acetone.[110] The same group has also demonstrated how these same properties are effective in aldol chemistry[111] and dehydration of *tert*-butyl alcohol.[112,113] In this latter reaction conversions and selectivities close to 100% are observed at relatively modest temperatures.

One area of possible catalytic activity that has not yet been properly explored is the potential for photo-catalysis. In this respect, the activity of ETS-10 for the photocatalytic degradation of cyclohexanol, cyclododecanol, 2-hexanol, and benzyl alcohol is compared, by Fox and co-workers, with TiO_2 particles included within small and large pore zeolitic supports suspended in acetonitrile.[114] Although the activity was less than that displayed by the titanium-doped silicate TS-1 this work was reported before very much was known about the structure of ETS-10 and how it can be modified. Consequently, this field of research is ripe for exploration, particularly in terms of the optical properties of these novel materials.

Finally, ETS-10 offers the potential for chiral catalysis or asymmetric synthesis if the pure chiral polymorph of ETS-

10 can be synthesised. Along with zeolite β, ETS-10 is currently the only known wide-pore microporous material that possesses a chiral polymorph with a spiral channel. The structures of these as-prepared materials contain an equal proportion of intimately intergrown enantiomorphs and are consequently achiral. The task of synthesising a pure chiral polymorph is, of course, immense. However, with some of the recently developed molecular modelling techniques for designing suitable organic templates to direct the structure, it may well be possible to solve this problem in the next decade.[115]

Optical Properties

Owing to the presence of stoichiometric quantities of transition metals in the framework of these novel microporous materials, they have potential for interesting optical properties.[83,116–119] Most attention to date has again focussed on the microporous material ETS-10. The structure of ETS-10 contains –O–Ti–O–Ti–O– chains, with alternating long and short bonds, which are effectively isolated from each other by a silicate sheath. In effect, therefore, ETS-10 contains monoatomic –O–Ti–O–Ti–O– wires embedded in an insulating SiO_2 environment, a situation that leads to a one-dimensional quantum confinement of electrons or holes within this wire. A blue bandgap shift is associated with this charge carrier confinement within this unprecedented geometrical structure. The effective reduced mass, μ, of electrons and holes within this wire is calculated to be $1.66\ M(e) < \mu < 1.97\ M(e)$, which is consistent with a band gap of 4.03 eV and is quite different to that of bulk TiO_2. This work underlines the possible future role that these microporous materials may play in optoelectronic and nonlinear optical applications. The titanium within the chains can be readily reduced using Na vapour, which effects the following redox couple,[120]

$$Ti^{IV} + Na \rightarrow Ti^{III} + Na^+$$

thereby generating unpaired electrons within the titanate chain and also generating extra cation sites. After such reduction the material is not air stable and is easily reoxidised, generating additional Na_2O within the channels. Such redox couples also give strong indications of possible applications in battery technology.

Recently, Rocha et al. doped ETS-10 with Eu^{3+} and Er^{3+} by ion-exchange techniques and studied the luminescence properties of the resultant materials.[121–122] It has been found that only Eu^{3+}-doped ETS-10 is optically active. Upon calcination at temperatures in excess of 700 °C both materials transform into dense titanosilicate analogues of the mineral narsarsukite [$(Na, K)_2TiSi_4O_{11}$], which is made up of Si_4O_{10} chains that form tubes of rings consisting of four SiO_4 tetrahedra.[123] These tubes are linked by chains of corner-sharing TiO_6 octahedra. The cavities between the Si_4O_{10} tubes and octahedral chains contain Na^+, Eu^{3+} and Er^{3+} cations. Eu^{3+} and Er^{3+}-doped narsarsukite display very interesting luminescence properties. The latter, in particular, exhibits a high and stable room-temperature emission in the visible and in the infrared spectral regions. An efficient energy transfer between the narsarsukite skeleton and the optically active Er^{3+} centres seems to occur.[122]

Adsorption Properties

Dihydrogen, dinitrogen, carbon monoxide, and nitric oxide have all been adsorbed, at nominally liquid nitrogen temperature, on Na^+- and K^+- exchanged ETS-10.[124] IR spectroscopy indicates the formation of $M^+(H_2)$, $M^+(N_2)(n)$, $M^+(CO)(n)$ and $M^+(NO)$ (n = 1, 2, ...; M^+ = Na, K) adducts that prevalently involve alkali-metal cations located in the 12- membered channels. These adducts give main IR absorption bands in the range 4050–4150 cm^{-1} for H_2, 2331–2333 cm^{-1} for N_2, 2148–2176 cm^{-1} for CO, and 1820–1900 cm^{-1} for NO, which are assigned to the fundamental stretching mode of the diatomic molecules polarized by the electric field created by the metal ions. On Na-exchanged samples, the $Na^+(N_2)$ and $Na^+(CO)$ species, formed at the lowest dosage, evolve into $Na^+(N_2)(n)$ and $Na^+(CO)(n)$ (n = 2, 3) species upon increasing the gas phase pressure. This reversible "solvation" process is not observed for K-exchanged samples. There is no comparable precedent for this result for CO adsorbed on zeolites and it is indicative of the unique adsorption characteristics that can be expected with these highly charged, high cation capacity microporous materials.

Cation Exchange

To date there has been very little work on the cation exchange properties of this novel class of material. However, the cation exchange capacity is very high and, in addition, the framework anionic sites are typically divalent, which should be particularly useful for the exchange of divalent cations. Indeed ETS-10 has been shown to be particularly selective for Pb^{2+} [125] and Cd^{2+} [126] ions. Furthermore the penkvilksite structure has been shown to be particularly selective for Li^+ cations,[127] which again may indicate possible applications in battery technology.

Conclusions

In this review it has been shown that a new and exciting field of research into microporous zeotype solids is emerging. These stable silicate materials possess mixed octahedral-tetrahedral frameworks and display entirely new molecular architectures. Although much of the work performed to date has concentrated on titanosilicates, it is clear that the novel porous frameworks may contain many other elements, particularly transition metals such as Zr, Nb, Sn, V, and Y. We anticipate that some of the new materials will find applications in areas usually associated with zeolites. Others, however, may have potential applications in fields such as optoelectronics and nonlinear optics, batteries, magnetic materials and sensors.

Acknowledgments

We thank EC JOULE II (J. R. and M. W. A.), EPSRC (M. W. A.), FCT, PRAXIS XXI, and FEDER (J. R.) for financial support.

We are very grateful to Dr. O. Terasaki for helping to solve the structure of ETS-10 and for the fruitful collaboration between both our groups.

An SiO_2-Embedded Nanoscopic Pd/Au Alloy Colloid

Helmut Bönnemann,*[a] Uwe Endruschat,[a] Bernd Tesche,[a] Anna Rufínska,[a] Christian W. Lehmann,[a] Friedrich E. Wagner,[a] George Filoti,[b] Viorica Pârvulescu,[c] and Vasile I. Pârvulescu*[c]

Keywords: Colloids / Sol–gel processes / Immobilization / Heterogeneous catalysts / Hydrogenations

A bimetallic, fully alloyed Pd/Au colloid of 3.0 nm particle size, obtained by the co-reduction of Pd and Au salts with tetraalkylammonium triethylhydroborate, was embedded in a silica matrix employing a modified sol–gel procedure with THF as the solvent. The removal of the protecting tenside led to a mesoporous texture with a comparatively narrow pore distribution. The physical characterisation by a combination of several techniques has shown that the SiO_2-embedded Pd/Au colloid preserves the size and the structural characteristics of the colloidal metal precursor. The new material exhibits catalytic properties in selective hydrogenation.

The incorporation of preformed ligand-stabilized metal clusters and colloids is currently of interest both in basic research[1] and for applications in heterogeneous catalysis.[2a][2b] Bimetallic heterogeneous Pd catalysts have elicited a large interest because of their superior selectivity and their resistance to deactivation which has been observed in several processes of practical importance.[3,4,5] Gold by itself, supported on SiO_2, Al_2O_3 or MgO, shows a rather low catalytic activity,[6] but its addition to Pd was found to lead to an enhanced catalytic activity which has been interpreted in terms of geometric or electronic effects.[7,8]

Most reports on bimetallic Pd catalysts refer to systems prepared via the coimpregnation of the metal salts on solid supports using the incipient wetness technique, followed by calcination.[9,10] However, a vigorous debate is still going on as to whether the resulting Pd–Au particles on the support are fully alloyed.[11] Recent data from a combined XANES and EXAFS study made by Couves and Meeham[12] have emphasized these doubts. Another problem lies in the metal dispersion. There is strong evidence that the addition of Au to Pd salts results in a marked decrease of the dispersion of the bimetallic catalyst systems.[10,13]

Pre-prepared colloidal alloy particles, covered by various protecting shells, offer a different means of access to highly dispersed bimetallic catalyst precursors.[14–19] Following the so called "precursor concept",[20] these pre-prepared nanometals, for which the particle size distribution, composition and structure are rather well defined, may be deposited on various supports to give a new type of heterogeneous bimetallic catalyst.[18–21] Here we report the preparation of a heterogeneous Pd/Au catalyst formed by the embedding of pre-prepared tetraalkylammonium-stabilized Pd/Au alloy particles in a solid SiO_2 matrix following a modified sol–gel process.

The colloidal Pd/Au precursor was prepared in analogy to ref.[18] by the co-reduction of Pd and gold salts with $NOct_4[BEt_3H]$ (= Tetraoctylammonium triethylhydroborate) in dry THF under argon. A solution of palladium acetate (786 mg, 3.5 mmol) and gold chloride (1061 mg, 3.5 mmol) in 300 mL THF was added over the course of 2 h to a vigorously stirred solution of 0.38 M $NOct_4[BET_3H]$ in THF (46.1 mL) at ambient temperature. This process went to completion over the next 16 h and was accompanied by a colour change to black, indicating the formation of colloidal noble metal in solution. The excess of the reducing agent was removed by adding 5 mL acetone to the reaction mixture, which was stirred for another 30 min. The precipitate was removed by filtration and the solvent was evaporated under vacuum (10^{-3} mbar, room temperature, 16 h.). The isolated raw colloidal powder was redispersed in 40 mL diethyl ether and then precipitated by adding 330 mL of an ethanol/methanol mixture, which dissolves any excess protective surfactant. The mixture was allowed to stand for 24 h before the colourless supernatant was removed by decantation. The colloid was precipitated and dried in vacuo. The resulting colloid powder is fully redispersible in THF and has a metal content of 5.28 wt-% Pd and 8.96 wt-% Au (atomic ratio Pd/Au = 53:47). Monometallic Pd and Au colloids were prepared for comparison applying an analogous procedure.[19]

The embedding of the Pd/Au colloid was carried out with tetraethoxysilicate (TEOS) as the precursor for the silica support. However, since the NR_4-stabilized Pd/Au colloids are completely insoluble and even decompose at elevated temperatures in alcoholic solutions, the normal sol–gel procedure has to be modified by using THF as the solvent. molar composition of the sol was TEOS/THF/H_2O/HCl = 1:3.5:4:0.05. The colloid was added as a 4.5 wt-% THF solution at room temperature, after refluxing. The sol was stirred vigorously at 70 °C (under reflux) until the gelification was complete (after 2 days). To avoid any decomposition in the presence of air, all steps were carried out under argon. The resulting gel was dried at 110 °C using a ramp of 0.12 °C min^{-1} then calcined in air at 450 °C with a ramp of 0.3 °C min^{-1}. After cooling, the samples were reduced in flowing hydrogen at 450 °C using the same ramp. For comparison, dried samples were subjected directly to reduction without an intermediate calcination. These samples contained 1 wt-% of metal. Thermal activation (450 °C) of such hybrid materials resulted in a porous texture having a rather narrow pore diameter in the region of the mesoporous materials.

The characterisation of the Pd/Au colloids both in the free and in the embedded state was first performed by transmission electron microscopy (TEM), energy dispersive X-ray analysis (EDX), and atomic absorption spectroscopy (AAS). In addition, nitrogen adsorption-desorption curves at 77 K, H_2 chemisorption measurements, solid state ^{29}Si NMR, XRD, SAXS, XPS, and ^{197}Au Mössbauer spectroscopy were applied.

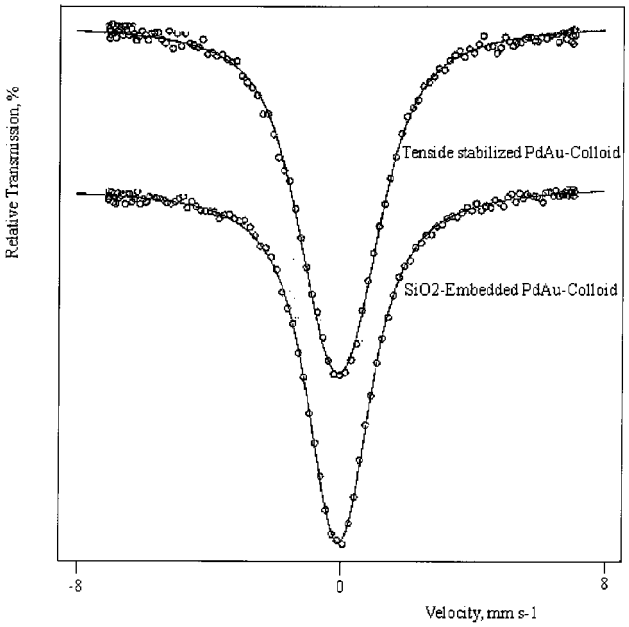

Figure 1. ^{197}Au Mössbauer spectra of tenside-stabilized pure and SiO_2-embedded Pd/Au colloid

Both Mössbauer (see Figure 1) and XRD analyses of the free Pd/Au colloid showed a fully alloyed material consisting of 52% Pd and 48% Au. These values correspond closely to those found by the chemical and EDX analysis. The embedding of the Pd–Au colloids in the sol–gel matrix does not alter the Mössbauer spectrum. There is no difference between the isomer shifts in the free Pd/Au colloid and in the embedded sample, confirming that the colloid structure had not changed during the sol–gel process. The integrity of the incorporated Pd/Au alloy particles remained virtually untouched.

The intensity distributions of XRD patterns of the embedded Au, Pd and Pd/Au colloids correspond to silica and to metallic or bimetallic species. An intense diffraction peak at 22° 2-Θ originates from calcined SiO_2, showing that the support is not totally amorphous. All peaks in the pattern recorded for the bimetallic system containing 1.0 wt-% Pd/Au in SiO_2 correspond to a bimetallic Pd/Au alloy, and no peaks assignable to single Au or Pd species are present. A peak broadening analysis was performed on the basis of FWHM values obtained from peak fitting using a pseudo-Voigt peak shape function. The instrument line broadening was obtained using a standard Si sample. The result indicates a particle size of ca. 3.0 nm both for the Pd/Au and the Au system, whereas the particles in the pure Pd system appear to be larger (ca. 5.6 nm). The composition of the bimetallic Pd/Au alloy was determined from lattice parameter calculations (52 wt-% Au, 48 wt-% Pd; a = 3.976 Å).

Table 1 summarises the textural characteristics of the embedded colloids and the H_2-chemisorption data. The results indicate that in all cases a mesoporous material was present with a rather sharp pore diameter distribution. However, SAXS has shown that the channels are randomly distributed and no tubes (such as those found in MCM materials) are present here. The same information resulted from the TEM analysis. The pore diameter and the mesoporous texture are related to characteristics of the surfactant used. The dispersion of the monometallic Pd colloid in the silica gel matrix was found to be lower than in the case of the bimetallic Pd–Au colloid in the same matrix. For the same metal loading, the Au-containing silica gel matrix exhibited the lowest dispersion. The large differences found between the amounts of physically adsorbed hydrogen and chemisorbed hydrogen, especially for Au, may account for the contribution of the support. TEM measurements (Figure 2) have confirmed a narrow size distribution of the incorporated bimetallic colloid (about 3.0 nm), another proof of the conservation of the characteristics of the colloidal precursor in the incorporated state.

The ^{29}Si CP/MAS NMR spectrum of a Pd/Au SiO_2 sample (1.0 wt-%, preactivated in hydrogen) shows the characteristic structure for Si–O bonds. A ^{29}Si MAS analysis using the "Block decay" procedure indicated that the population of Q^3 species is about 18 %, whereas almost no Q^2 species were found. These data confirm a good polymerisation grade of the silica. The Q^3-to-Q^4 ratio, when compared with published data, was proved to be consistent with the incorporation of the colloids in the silica network.[22] On the basis of the same ^{29}Si MAS analysis it was concluded that the so-called "T surrounding species" are absent.

To test the catalytic properties of the incorporated Pd/Au colloid, we examined the selective semi-hydrogenation of 3-hexyn-1-ol, which gives the corresponding *cis*-hexenol derivative. This is a valuable perfume ingredient.[18] Under standard test conditions, 6.1 mL of 3-hexyn-1-ol were converted without solvent in a stirred 50 mL stainless steel autoclave using 50 mg of catalyst (1 wt-% metal incorporated) at 20 bar hydrogen and 20 °C. The reaction products

Table 1. BET surface area, average pore diameter, hydrogen uptake, metal dispersion, and metallic surface area for the sol–gel-embedded catalysts

Catalyst	BET surface area [$m^2\ g^{-1}$]	Average pore diameter [Å]	Chemisorbed hydrogen			
			H_2 uptake [$cm^3\ g^{-1}$]	Metal dispersion [%]	Metal surface area [$m^2\ g^{-1}_{sample}$]	Metal surface area [$m^2\ g^{-1}_{metal}$]
Pd–SiO_2	319	34	0.30	14.25	0.63	63.2
Au–SiO_2	281	34	0.08	7.38	0.18	17.8
Pd/Au–SiO_2	292	35	0.48	27.60	1.01	101.2

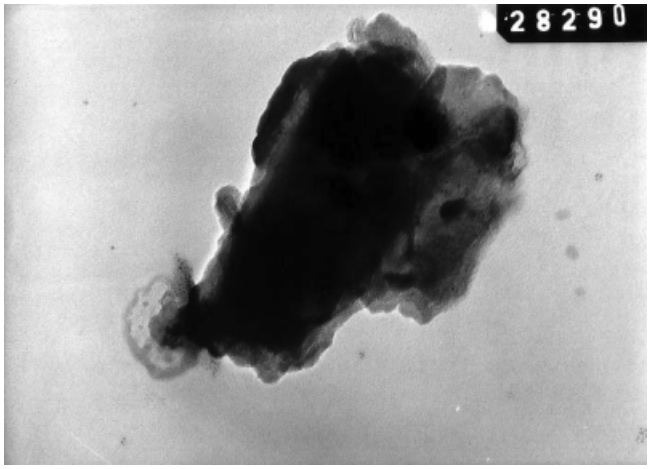

Figure 2. TEM of SiO_2-embedded Pd/Au colloid

were analysed by GC using a Varian 3700–519 chromatograph equipped with a 50 m CW-20M column. The reaction products were identified using the same GC coupled with a Finnigan MAT SSQ7000 mass spectrometer on the basis of pure standards. The results are shown in Figure 3.

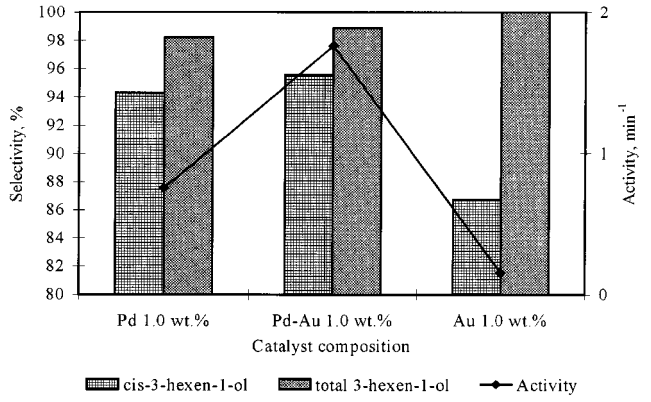

Figure 3. Catalytic activity and selectivity of the embedded colloids in the hydrogenation of 3-hexyn-1-ol

An inspection of Figure 3 shows that the catalytic activity is lowest for the embedded-Au-catalyst sample. As we expected, the catalytic activity of incorporated Pd/Au particles in SiO_2 proved to be superior to monometallic samples. Hexenol and hexanol were the only reaction products. The chemoselectivity towards hexenol reached 100% in the case of embedded Au colloids. Both the other catalysts yielded hexenol and hexanol, the chemoselectivity to hexenol still exceeding 95 %. Both the monometallic Pd and the bimetallic Pd/Au catalysts exhibit a high *cis* selectivity (> 95 %). The performances of the bimetallic Pd/Au catalyst are similar to the highest level reported in the literature.[18] Figure 4 shows the time evolution of the conversion. The selectivity in all the recorded points accounts for the values presented in Figure 3.

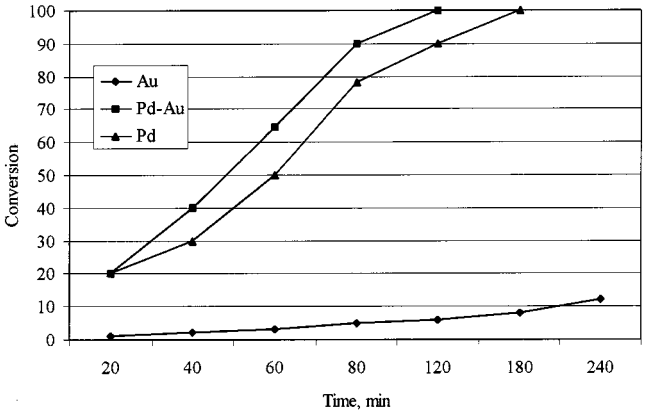

Figure 4. Time evolution of the conversion

Furthermore, we have found that bimetallic Pd–Au colloids incorporated in SiO_2 by sol–gel techniques are active catalysts for selective C,C hydrogenations of unsaturated substrates, e.g. of cinnamaldehyde and styrene. In addition SiO_2-embedded nanoscopic Pd/Au catalysts under these conditions are remarkably resistant to deactivation.

Linear, Divergent Molecular Receptors – Subtle Effects of Transition Metal Coordination Geometry

Alexander Bilyk,[a] Annegret K. Hall,[a] Jack M. Harrowfield,*[a] Mir Wais Hosseini,[b] Gilles Mislin,[b] Brian W. Skelton,[c] Christopher Taylor,[d] and Allan H. White[c]

Keywords: Thiacalixarene / Trimetallic sandwich / Cobalt / Zinc / Divergent receptors

Reaction between deprotonated *p-tert*-butyltetrathiacalix[4]-arene and Co^{II} or Zn^{II} under strictly defined conditions leads to the formation of sandwich species in which a trimetallic unit is held between two opposed, divergently oriented, staggered *O*- and *S*-bound calixarene ligands in the cone conformation. Despite the isomorphous nature of the crystalline compounds, there is a subtle difference in the coordination of Co^{II} and Zn^{II}, presumably related to the differences in metal radius and electron configuration combined with structural restrictions imposed by the calixarene framework, in that whereas all three Co atoms may be considered six-coordinate (and approximately octahedral), only two of the Zn atoms appear so, the third being five-coordinate and more nearly trigonal bipyramidal in its coordination geometry.

Introduction

The pursuit of the rational design of solid state structure, with the ultimate aim of producing new materials with properties of true utility, can be based upon the exploitation of various chemical forces.[1,2] We have previously demonstrated the feasibility of using (presumably) weak CH_3-π interactions to form one-dimensional "koilates" in which binuclear calix[4]arene metal complexes provide opposed-divergent, double-cavity receptors.[2] A difficulty in this approach arises because of the relatively limited range and possibly the limited stability of appropriate binuclear calix[4]arene derivatives.[2–4] The initial report[5] of the superior transition metal binding properties of *p-tert*-butyltetrathiacalix[4]arene therefore aroused our interest and we have recently characterised[6] an antiferromagnetically coupled dicopper(II) derivative of this calixarene which proved to have a dimeric form in the solid state in which a tetracopper square is sandwiched between opposed, eclipsed calixarene cones, thus justifying our optimism that compounds useful in koilate construction might be obtained. The coordination geometry of the copper atoms in this compound is, however, considerably distorted from any regular form of six-coordination and, in attempting to extend our studies of coordination of the tetrathiacalixarene to the elements adjacent to copper, we have found that this may be an important factor determining the metal/ligand stoichiometry, though not necessarily the opposed double-cavity form of the resultant complex. Thus, we have found that for cobalt(II) and zinc(II), compounds of the stoichiometry $M_3(calH)_2$ (where $calH^{3-}$ is the three-times deprotonated tetrathiacalixarene, $calH_4$) may be isolated. Subsequent structure determinations[7] have shown that the isomorphous cobalt and zinc compounds can indeed be regarded as containing molecular units of this stoichiometry (Figure 1) with, as in the case of the Cu^{II} compound, a small cluster of metal ions sandwiched between two opposed, quasi-staggered calixarene cones. The differences from the copper system may be associated with a stronger tendency to retain a regular octahedral coordination geometry around Co and Zn, with the incompatibility of structural demands being more readily accommodated by the Jahn–Teller accessible Cu^{II} adduct, though this can at best be considered only a partial rationalisation of the detailed differences between these three complexes.

For the preparation of these complexes it is important to adhere closely to a particular procedure to obtain a particular product and to convert it to a crystalline form suitable for X-ray diffraction. With a variety of other metals we have experienced considerable complications due to either polymorphism or alternate stoichiometries. In our initial efforts to obtain the Co and Zn complexes described herein we obtained heterogeneous materials showing only partial solubility in CH_2Cl_2. Interestingly, the ^1H NMR spectrum reported for a Zn^{II} complex[5] isolated from a solvent extraction experiment, is identical to that for the Zn species reported here after recrystallisation. The NMR spectra are consistent with a similar trinuclear species that exists in the solid state (Figure 1) persisting in solution, and where all the protons within each calixarene are chemically inequiva-

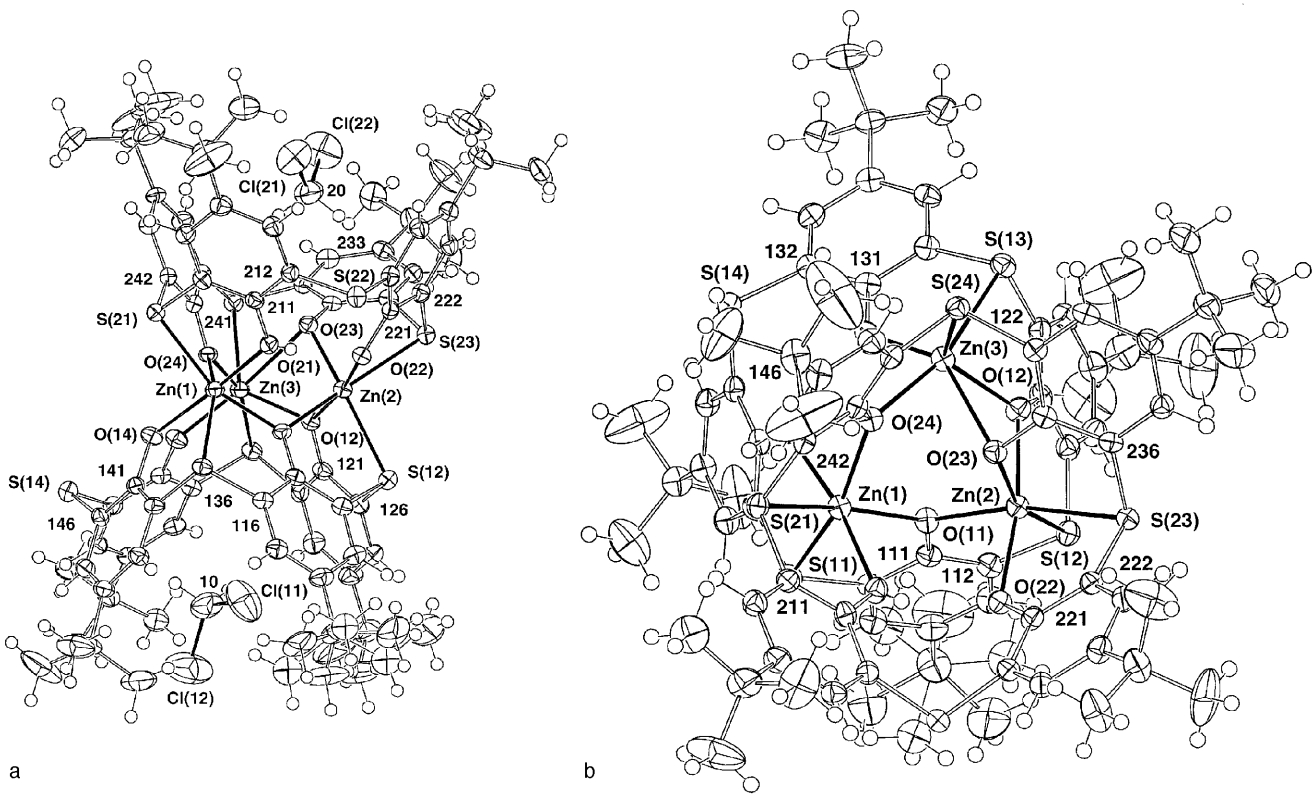

Figure 1. Projections of the zinc complex (a) through and (b) normal to the Zn_3 plane [included CH_2Cl_2 (x2) omitted in the latter]; thermal ellipsoids (50%) are shown for the non-hydrogen atoms, hydrogen atoms having arbitrary radii of 0.1 Å; the chirality of the molecule is most readily appreciated from the relative dispositions of the oxygen pairs O(13,14) and O(21,22) which do not chelate a metal atom, and/or the sulfur atoms S(14,22) which do not bind a metal; note that Zn(2,3) are bridged by a pair of μ-oxo species [O(12,23)] whereas Zn(1,2), (1,3) are bridged by single oxygen atoms O(11), O(24), respectively; note also in (b) that whereas rings 12, 23 are eclipsed at the $M(\mu\text{–}O)_2M$ linkage, the other pairs do not superimpose in this manner. M(1)–M(2,3), M(2)–M(3) are 3.606(1), 3.649(1), 3.144(1) (M = Co) and 3.5092(7), 3.5623(8), 3.2648(7) Å (M = Zn); in (a) H(14) is hidden behind O(14)

lent. We have also found it possible to reproducibly obtain the same $Zn_3(calH)_2$ species by recrystallisation of a solvent extraction product from CH_2Cl_2. However the earlier report of a significantly different Zn complex with the stoichiometry, $Zn_4(cal)(calH_2)_2$,[8] prepared under similar conditions but recrystallised from toluene, highlights the ease with which different forms of the thiacalixarene complexes may be interconverted.

In our isomorphous Co and Zn compounds, the repeating molecular unit in the solid (Figure 1) is a sandwich made up of three metal atoms between two calixarene cones arranged divergently about the metal cluster, each cone containing a dichloromethane molecule. In the case of the Co compound, each metal atom is in an approximately octahedral *cis*-MO_4S_2 environment (Figure 2), though with deviations of up to 20° from the ideal *cis* and *trans* bond angles of 90 and 180°, respectively. This is true for two of the metal atoms in the Zn compound but the third is perhaps better described as having a trigonal bipyramidal coordination environment (Figure 2), a potential sixth (O-donor) ligand atom, which in the Co compound is close enough [2.276(4) Å] to be considered bound, here lying at a distance of 2.652(3) Å. In addition, the Zn–S distances are very disparate for this atom [2.406(1), 2.674(1) Å], perhaps even indicating an approach to 4-coordination, and this disparity in M–S distances is also evident for the corresponding Co atom [Co–S 2.445(1), 2.729(2) Å]. As in the Cu^{II} compound, all donor atoms are derived from the calixarene units, one sulfur atom on each not being involved in coordination and solvent (dichloromethane) molecules only being included within the calixarene cavities and elsewhere within the lattice. The cluster sandwiches are chiral, the only approximate symmetry element being a near two-fold axis passing through one metal atom and bisecting the line joining the other two, true two-fold symmetry seemingly being lost as a result of the coordination sphere irregularities of M(3). The metal atom on the near-C_2 axis has the two phenoxide units bearing residual protons (detected and refined in the structure solution) coordinated to it in a *trans* arrangement [O–M–O 171.0(1)° (Zn), 173.8(1)° (Co)] and interacts with only two phenoxide oxygen atoms

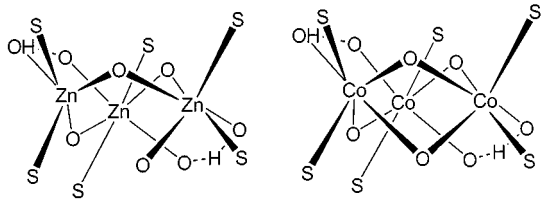

Figure 2. Representation of the coordination environments about the Zn and Co clusters; two of the Zn ions are six-coordinate, the other is five-coordinate, whilst the three Co atoms can be described as six-coordinate

which bridge to the other metal atoms. In the Co compound, each of these has three bridging phenoxide donor atoms, although with Zn, again, only two phenoxide bridging atoms are bound to each. The residual protons on the ligand are probably involved in hydrogen bonding to adjacent phenoxide oxygen atoms [O···O 2.48, 2.49 Å (Zn), 2.44, 2.46 Å (Co)].

Magnetic susceptibility measurements by SQUID magnetometry 4–300 K do not indicate any strong magnetic interactions within the Co compound, with Curie-Weiss behaviour ($\theta = -30°$) being observed, though the room temperature magnetic moment of 8.2 BM is significantly lower than expected for three independent high-spin Co^{II} centres. The possibility exists, however, for the use of connector units in koilate structures which may allow extended interactions within such solids, and we are actively pursuing this hypothesis. The residual phenolic calixarene protons present in the Co and Zn compounds should be removable by base, generating anionic species capable of stronger, electrostatically-assisted association with linker molecules. Many other paramagnetic metal ions may also be readily substituted for Co^{II} in these complexes and we have already isolated rare earth derivatives, for example. It is clear that the strong coordinating properties of tetrathiacalix[4]arene provide a prospect for the far readier development of novel applications in metal ion chemistry than is true of the parent calix[4]arene, though it may be that development of this chemistry will provide insights into further uses of the more extensive class of calixarenes in general.

Experimental Section

General Remarks: All solvents were distilled prior to use except for AR grade DMF which was used as supplied. – ^{1}H NMR spectra were measured in $CDCl_3$ and calibrated to the residual solvent peak on a Bruker ARX500 spectrometer. – FAB mass spectra were recorded on a VG-Analytical ZAB HF spectrometer with 3-nitrobenzyl alcohol as the matrix and the electronic absorption spectra in CH_2Cl_2 solution on a Hewlett–Packard 8452A diode-array spectrometer. – Microanalyses were performed by the Microanalytical Unit at the Australian National University.

$[Zn_3(calH)_2(CH_2Cl_2)_2]\cdot 3CH_2Cl_2$: $CalH_4\cdot CHCl_3$ (200 mg, 240 mmol) was dissolved in DMSO (5 mL) containing NEt_3 (0.1 mL). A solution of $[Zn(DMSO)_6](ClO_4)_2$ (350 mg, 480 mmol) in DMSO (5 mL) was added. The clear solution was left overnight, filtered, and the resulting white powder (90 mg) washed with EtOH (5 mL) and dried in air. The solid was dissolved in CH_2Cl_2, filtered and an equal volume of ethanol carefully added to form a layer above the original solution. After 3 weeks of standing, colourless crystals suitable for structural determination were obtained. The remaining crystals were collected by vacuum filtration, washed with ethanol and dried under reduced pressure to give a white powder (65 mg, 40 μmol). – ^{1}H NMR (500 MHz): δ = 1.22 (s, 36 H, *tert*-butyl), 1.24 (s, 18 H, *tert*-butyl), 1.28(s, 18 H, *tert*-butyl), 7.568 (d, ^1J = 2.5 Hz, 2 H, ArH), 7.569 (d, ^1J = 2.5 Hz, 2 H, ArH), 7.59 (d, ^1J = 2.5 Hz, 2 H, ArH), 7.61 (d, ^1J = 2.5 Hz, 2 H, ArH), 7.65 (d, ^1J = 2.5 Hz, 2 H, ArH), 7.70 (d, ^1J = 2.5 Hz, 2 H, ArH), 7.77 (d, ^1J = 2.5 Hz, 2 H, ArH). – ^{13}C NMR (125.77 MHz): δ = 31.30, 31.36, 31.44, 31.47, 34.06, 34.14, 34.2, 117.8, 118.6, 120.7, 120.76, 120.87, 120.91, 122.2, 122.5, 132.4, 133.4, 134.0, 135.1, 135.26, 135.35, 136.6, 139.1, 140.4, 141.4, 142.5, 156.8, 158.9, 160.0, 161.8. – MS (FAB); *m/z*: 1631 (M^+). – $C_{80}H_{90}O_8S_8Zn_3$ (1632): calcd. C 58.87, H 5.56, S 15.2; found C 58.48, H 5.50, S 15.68. – Electronic spectrum: λ/nm (ε_{max}/M^{-1} cm^{-1}) = 314 (39100).

$[Co_3(calH)_2(CH_2Cl_2)_2]\cdot 3CH_2Cl_2$: $CalH_4\cdot CHCl_3$ (1.0 g, 1.19 mmol) was dissolved in DMF (8 mL) containing NEt_3 (0.5 mL). A solution of $[Co(DMF)_6](ClO_4)_2$ (2.12 g, 3.04 mmol) in DMF (5 mL) was added quickly and a light green precipitate formed immediately. After 2 hours the solid was collected by vacuum filtration, washed with ethanol (5 mL) and dried in air to give a light green powder (0.37 g). This solid was recrystallised by liquid diffusion of EtOH into a CH_2Cl_2 solution to give pale green crystals suitable for structural determination. The remaining crystals were collected by vacuum filtration and dried under reduced pressure to give a light green powder (0.26 g, 150 μmol). – MS (FAB); *m/z*: 1612 (M^+). – $C_{80}H_{90}Co_3O_8S_8$ (1613): calcd. C 55.25, H 5.31, S 14.39; found C 55.67, H 5.30, S 14.30. – Electronic spectrum: λ/nm (ε_{max}/M^{-1} cm^{-1}) = 316 (37400), 380 (sh.; 200), 574 (112), 602 (114).

X-ray Crystallographic Study

Co Compound: $[(CH_2Cl_2)_2(C_{40}H_{45}O_4S_4)_2Co_3]\cdot 3CH_2Cl_2$, $C_{85}H_{100}Cl_{10}Co_3O_8S_8$, M = 2037.6. monoclinic, space group $P2_1/n$, a = 13.294(2), b = 45.401(6), c = 17.510(2) Å, β = 111.034(3)°, V = 9863(4) Å^3, Z = 4, D_c = 1.372 g·cm^{-3}, T = 293(2) K, 109219 ($2\theta_{max}$ = 58° sphere) SAINT/SADABS processed CCD reflections ($T_{min,max}$ = 0.68, 0.89) merged to 24944 unique (R_{int} = 0.048), 11937 with $|F| > 4\sigma|F|$ refining to conventional R, R_w on $|F|$ 0.064, 0.064.

Zn Compound: $[(CH_2Cl_2)_2(C_{40}H_{45}O_4S_4)_2Zn_3]\cdot 2.8CH_2Cl_2$, $C_{84.8}H_{99.6}Cl_{9.6}O_8S_8Zn_3$, M 2040. monoclinic, space group $P2_1/n$, a = 13.085(1), b = 44.800(4), c = 17.503(2) Å, β = 111.934(2)°, V = 9517(3) Å^3, Z = 4, D_c = 1.423 g·cm^{-3}, T 153 K, 106685 ($2\theta_{max}$ = 55° sphere) SAINT/SADABS processed CCD reflections ($T_{min,max}$ = 0.78, 0.96) merged to 21818 unique (R_{int} = 0.048), 17210 with $|F| > 4\sigma|F|$ refining to conventional R, R_w on $|F|$ 0.062, 0.071.

Disorder was more widespread in the cobalt compound, involving *tert*-butyl groups 114, 214, 244 [rotated over two sets of sites, major component occupancies 0.662(7), 0.775(7), 0.743(7), 114 only being disordered in the zinc (0.701(5)], and the lattice dichloromethane molecules 4 (both) and 5 (Zn only). Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Data Centre as supplementary publication no CCDC-137200 (Co compound), CCDC-137201 (Zn compound). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1 EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Ammonolysis of Trichlorosilanes

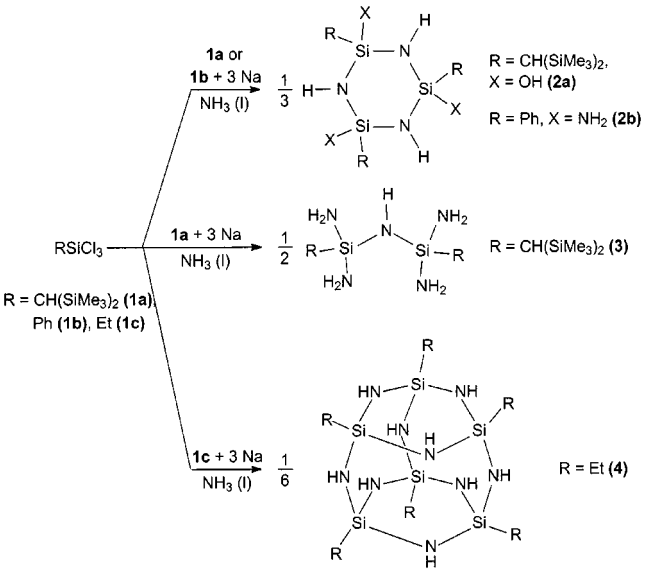
Carsten Ackerhans,[a] Bodo Räke,[a] Ralph Krätzner,[a] Peter Müller,[a] Herbert W. Roesky,*[a] and Isabel Usón[a]

Dedicated to Professor Willi Keim on the occasion of his 65th birthday

Keywords: Ammonolysis / Chlorine / Nitrogen / Silicon / Silsesquiazane

The ammonolysis of trichlorosilanes $RSiCl_3$ [R = $CH(SiMe_3)_2$ **(1a)**, Ph **(1b)**, Et **(1c)**] leads to a series of condensed products such as six-membered rings $[(Me_3Si)_2CHSi(OH)NH]_3$ **(2a)** and $[PhSi(NH_2)NH]_3$ **(2b)**, disilazane $[(Me_3Si)_2CHSi(NH_2)_2]_2NH$ **(3)** and the cage compound $(EtSi)_6(NH)_9$ **(4)**. The mixed Si–N–O compound **2a** was obtained when liquid ammonia was not dried over sodium prior to use. The reaction with sodium gives NaCl instead of NH_4Cl as a by-product which is easily removed by filtration.

Introduction



In recent years silicon−nitrogen compounds have gained more and more industrial importance due to the technical use of silicon nitride as a material which is mechanically stable and has a high resistance against heat.[1,2] Moreover, Schnick et al. reported on nitridosilicates, a class of compounds containing a highly polymeric three-dimensional silicon−nitrogen framework with incorporated cations.[3]

In 1993 Power et al. synthesized the first stable product with three NH_2 groups on one silicon atom by ammonolysis of the corresponding trichlorosilane. They used the 2,4,6-$Ph_3C_6H_2$ group as a bulky ligand for this reaction.[4] The chemistry of $RSi(NH_2)_3$ compounds was previously unknown. Consequently we became interested in this class of compounds after studying the isoelectronic compounds $RSi(OH)_3$.[5,6] In these systems R has to be a bulky ligand otherwise the formation of condensation products is observed.[7] Trichlorosilanes with ligands of medium size lead to cyclosilazanes, and trichlorosilanes with small ligands give condensed cage-like products from the reaction with ammonia.[8] Recently we reported the cage-like compound $(MeSi)_6(NH)_9$ using $MeSiCl_3$ in the presence of sodium in liquid ammonia.[9] The advantage of this method is the formation of NaCl instead of NH_4Cl which can be easily removed from the reaction mixture. Our experience has shown that NH_4Cl hinders to some extent the growth of X-ray quality single crystals. In a continuation of our work in liquid ammonia in the presence of sodium we report herein on the reaction using $RSiCl_3$ [R = $CH(SiMe_3)_2$ **(1a)**, Ph **(1b)**, Et **(1c)**] as starting material.

Results and Discussion

Synthesis and Spectra

We investigated the ammonolysis of $RSiCl_3$ compounds with and without sodium following two different routes. In the first approach the trichlorosilane $(Me_3Si)_2CHSiCl_3$ **(1a)** was stirred in liquid ammonia without sodium at −30 °C leading to a six-membered ring system with alternating silicon and nitrogen atoms and a hydroxy group at each ring-silicon atom $[RSi(OH)NH]_3$ [R = $(Me_3Si)_2CH$ **(2a)**] (Scheme 1).

Scheme 1. Reactions of $RSiCl_3$ compounds with ammonia in the presence of sodium

Single crystals suitable for an X-ray crystallographic measurement were isolated from an *n*-hexane solution. In the second route the trichlorosilane $RSiCl_3$ [R = $(Me_3Si)_2CH$ **(1a)**, Ph **(1b)**, Et **(1c)**] was dissolved in toluene

and added to a solution of sodium in predried liquid ammonia to give various different types of condensation products (Scheme 1). From the reaction of **1b** we obtained the six-membered Si−N ring **2b**, similar to that of **2a**; however the OH groups at silicon are replaced by the isoelectronic NH_2 groups. In marked contrast is the reaction product using **1a** and liquid ammonia in the presence of sodium. Under these conditions the acyclic disilazane $[(Me_3Si)_2CHSi(NH_2)_2]_2NH$ **(3)** is formed. The reaction of $EtSiCl_3$ **(1c)** in liquid ammonia and sodium resulted in the formation of the cage compound $(EtSi)_6(NH)_9$ **(4)**. We assume that in all of the reactions employing liquid ammonia/sodium, sodium amide is initially formed in situ, and then reacts with the trichlorosilane with formation of sodium chloride. However, probably due to its low solubility, solid $NaNH_2$ in liquid ammonia does not react with the trichlorosilane. All ^1H NMR signals of the NH and NH_2 groups are in the range 0.25−1.80 ppm. The silicon atoms which are bonded to the nitrogen atoms give ^{29}Si NMR signals between −22.0 and −30.8 ppm. In the NMR spectra of product **3** the number of signals for the organic ligands, but not for the two central silicon atoms, are doubled. A possible explanation for this is, that there are two sterically different conformers of the molecule. In the IR spectra we see the typical signals of the NH vibrations between 3350 and 3500 cm^{-1}, and 1535 and 1545 cm^{-1}. The signals of the vibration of the Si−N−Si groups are in the range between 930 and 970 cm^{-1} for the cyclic products **2a**, **2b** and **4**, and at 1162 and 1014 cm^{-1} for the acyclic disilazane (**3**). The mass spectra show the molecular ion peak $[M^+]$ or fragment peaks after elimination of one or two small groups such as Me, NH_2 or OH.

X-ray Structural Analysis

Compound **2a** crystallizes in the trigonal space group $P\bar{3}$ with one third of a molecule in the asymmetric unit. The rest of the molecule is generated by the $\bar{3}$ axis. The core of the structure is a six-membered Si_3N_3 ring showing 41% chair conformation[10] with N and Si atoms occupying alternating sites. To complete the tetrahedral coordination sphere each Si atom in the ring is connected to a hydroxy group and a bis(trimethylsilyl)methyl moiety. All OH groups are oriented in the same direction with respect to the ring plane (Figure 1). The endocyclic N−Si distance is 1.704(2) Å, the angles are 104.6(1)° for N−Si−N and 131.3(1)° for Si−N−Si. The distance between the Si in the ring and the connecting oxygen is 1.673(3) Å; the O−Si−C angle between the hydroxy group and the organic ligand is 106.9(1)°. In the crystal packing two molecules are always bridged by six hydrogen bonds (Figure 2). The distance between the connecting hydroxy groups was calculated to be 1.952 Å between the hydrogen and the accepting oxygen atom. The O−H−O arrangement is nearly linear with an angle of 173.6°.

The single-crystal X-ray structure shows **4** to crystallize in the triclinic space group $P\bar{1}$ with one molecule in the asymmetric unit. The core of **4** consists of two six-membered Si_3N_3 rings in the chair conformation with alternating silicon and nitrogen atoms. The rings are linked by bridging NH groups connected to the Si centers. Thus, a prismatic cage-like structure results (Figure 3). One ethyl group is bonded to each of the silicon atoms. Two groups of nitrogen centers can be differentiated: six are part of the two six-membered rings (av. Si−N distance 1.714 Å) and three are located between the two rings in a bridging posi-

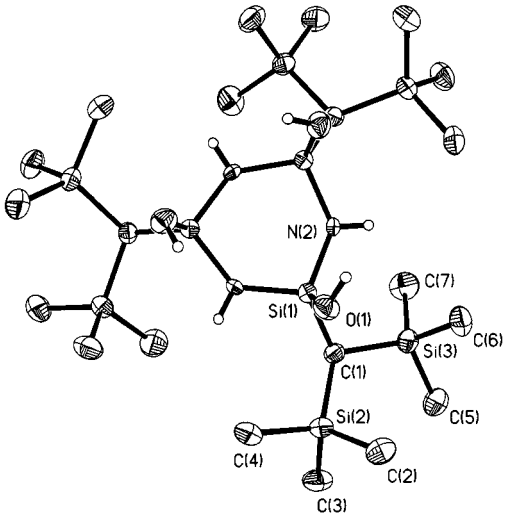

Figure 1. Molecule structure of **2a** in the crystal

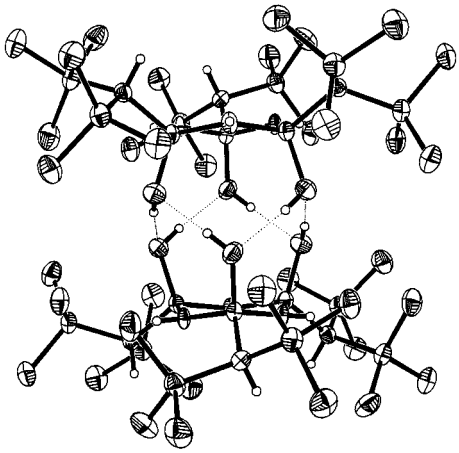

Figure 2. Molecule structure of **2a** with intermolecular hydrogen oxygen bridges

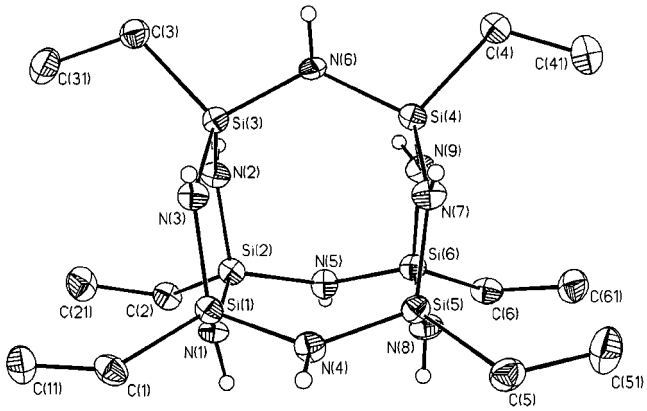

Figure 3. Molecule structure of **4** in the crystal

tion (av. Si−N distance 1.734 Å), which are slightly longer. The silicon centers are all slightly distorted from an ideal tetrahedron. Three groups of angles can be distinguished: the endocyclic N−Si−N angle (av. 131.5°); the somewhat smaller angle between a nitrogen center of one of the rings and a bridging nitrogen center (av. 126.3°); and the C−Si−N angles (av. 109.8°). The nitrogen atoms in the six-membered rings show an almost planar coordination (av. sum of angles 356°). Within the experimental error the bridging N atoms are perfectly planar coordinated (av. sum of angles 360°). The average Si−C bond length of 1.865 Å lies in the range typical for Si−C single bonds.

Conclusion

The grade of condensation and thereby the structure of the aminosilanes is dependent on the size of the ligands. Triaminosilanes with bulky ligands are stable against condensation.[4,7] Small ligands such as methyl and ethyl lead to the formation of a cage.[9] When the ligands are of medium size, then six-membered rings or other low-condensed products are the most favorable configuration. The ammonolysis with sodium in ammonia is superior in handling due to the production of NaCl, rather than NH_4Cl, which can be easily removed from the reaction mixture. It is interesting to note that the ammonolysis of **1a** with ammonia which was not predried with sodium yielded the trihydroxycyclotrisilazane **2a** while the reaction with sodium in predried ammonia gave the acyclic tetraaminodisilazane **3**.

Experimental Section

General: All reactions were performed under dry nitrogen conditions using standard Schlenk and syringe techniques. − The solvents were dried according to literature methods[11] and freshly distilled and saturated with nitrogen prior to use. − Melting points were measured on a Bühler SPA-1 melting point apparatus (uncorrected). − IR spectra were recorded using a BIO-RAD FTS 7 spectrophotometer. − Mass spectra (MS) were obtained with a Finnigan MAT 8200 or a Finnigan MAT 95 spectrometer using the EI technique. − NMR spectra were recorded with a Bruker AM 200 or a Bruker AC 250 spectrometer, δ in ppm relative to external $SiMe_4$. − Elemental analyses were performed at the Analytical Laboratory of the Institute of Inorganic Chemistry at the University of Göttingen.

Trichlorobis(trimethylsilyl)methylsilane (1a): To a suspension of $(SiMe_3)_2CHLi$ (7.4 g, 45 mmol) in toluene (100 mL) was added dropwise tetrachlorosilane (5.7 mL, 8.5 g, 50 mmol). The mixture was refluxed for 3 h, the generated LiCl was removed by filtration and the solvent was removed under vacuum. After distillation at 0.05 mbar, **1a** (10.9 g, 37 mmol, 83%) was obtained as a colorless liquid. − B.p. 45 °C (0.05 mbar). − ^{1}H NMR (C_6D_6): δ = 0.15 [s, $Si(CH_3)_3$]. (The signal from the C*H*-proton was not observed.) − ^{13}C NMR (C_6D_6): δ = 2.45 [$Si(CH_3)_3$], 15.75 ($CSiCl_3$). − ^{29}Si NMR (C_6D_6): δ = 0.37 ($SiMe_3$), 7.95 ($SiCl_3$). − IR (KBr): $\tilde{\nu}$ = 2976, 2955, 2901, 1406, 1269, 1257, 840, 772, 573, 561 cm^{-1}. − MS (EI): *m*/*z* (%) = 279 (100) [M^+ − Me]. − $C_7H_{19}Cl_3Si_3$ (293.8): calcd. C 28.6, H 6.5, Cl 36.2, Si 28.7; found C 28.8, H 6.5, Cl 35.7, Si 28.2.

1,3,5-Tris[bis(trimethylsilyl)methyl]-1,3,5-trihydroxycyclotrisilazane (2a): Ammonia (20 mL) was condensed at −78 °C onto **1a** (5.9 g, 20 mmol) and this mixture was stirred for 2 h under reflux. After warming to room temperature over 3 h, whereby the ammonia vaporized, *n*-hexane (50 mL) was added, the insoluble NH_4Cl was removed by filtration and the filtrate was concentrated in vacuo. A residue of **2a** (2.3 g, 3.5 mmol, 53%) was obtained as a white solid. Slow recrystallization from *n*-hexane (20 mL) resulted in colorless needles of **2a**. − M.p. 110 °C. − ^{1}H NMR (C_6D_6): δ = −0.39 [m, C*H*($SiMe_3$)$_2$, 3 H], 0.29 [m, Si(C*H*$_3$)$_3$, 54 H], 0.50−1.00 (m, N*H*, 3 H), 1.25−1.40 (m, O*H*, 3 H). − ^{29}Si NMR (C_6D_6): δ = −25.1 [*Si*(NH)], −1.5 (*Si*Me_3). − IR (KBr): $\tilde{\nu}$ = 3398, 1541, 1262, 1250, 1204, 1015, 955, 854, 723, 678 cm^{-1}. − MS (EI): *m*/*z* (%) = 624 (100) [M^+ − 2 OH], 607 (81) [M^+ − 3 OH]. − $C_{21}H_{63}N_3O_3Si_9$ (658.6): calcd. C 38.3, H 9.6; found C 36.9, H 9.8.

1,3,5-Triamino-1,3,5-triphenylcyclotrisilazane (2b): To a solution of sodium (3.4 g, 147 mmol) in ammonia (20 mL) was added a solution of $PhSiCl_3$ (10.4 g, 49 mmol) in toluene (100 mL) at −78 °C. After warming to room temperature the mixture was stirred for 1 h. The white precipitate was filtered off and the solvent was removed under vacuum. The residue was washed with *n*-hexane (50 mL) to give **2b** (4.7 g, 11 mmol, 70%) as a white solid. − M.p. 64−68 °C. − ^{1}H NMR (C_6D_6): δ = 0.40−1.80 (m, N*H*, NH_2, 9 H), 7.15 (m, C_6H_5, 10 H), 7.75 (m, C_6H_5, 5 H). − ^{29}Si NMR (C_6D_6): δ = −30.80 [*Si*(NH)] − IR (KBr): $\tilde{\nu}$ = 3468, 3064, 1662, 1620, 1588, 1538, 1427, 1305, 1261, 1198, 1168, 1113, 1028, 936, 918, 892, 845, 727, 699, 611, 478 cm^{-1}. − MS (EI): *m*/*z* (%) = 408 (2) [M^+], 392 (3) [M^+ − NH_2], 376 (4) [M^+ − 2 NH_2]. − $C_{18}H_{24}N_6Si_3$ (408.7): calcd. C 52.9, H 5.92, Si 20.6; found C 52.0, H 5.9, Si 20.6.

1,1,3,3-Tetraamino-1,3-bis[bis(trimethylsilyl)methyl]disilazane (3): Sodium (1.2 g, 52 mmol) was dissolved at −78 °C in liquid ammonia (20 mL). A solution of **1a** (4.6 g, 16 mmol) in toluene (100 mL) was then added dropwise over 30 min. The mixture was stirred for 2 h at −78 °C and, after heating to room temperature within 3 h, whereby the ammonia vaporized, the toluene was removed under vacuum, *n*-hexane (70 mL) was added and the insoluble solid was removed by filtration. After removing the *n*-hexane in vacuo, **3** (3.0 g, 6.6 mmol, 83%) was obtained as a colorless oil. − M.p. 10−15 °C. − ^{1}H NMR (C_6D_6): δ = −0.70 [s, C*H*($SiMe_3$)$_2$, 1 H], −0.62 [s, C*H*($SiMe_3$)$_2$, 1 H], 0.16 [s, Si(C*H*$_3$)$_3$, 18 H], 0.21 [s, Si(C*H*$_3$)$_3$, 18 H], 0.25−1.0 (br. m, N*H*, NH_2, 9 H). − ^{29}Si NMR (C_6D_6): δ = −23.20 [*Si*(NH_2)$_2$], −1.80 (*Si*Me_3), −1.68 (*Si*Me_3). − IR (KBr): $\tilde{\nu}$ = 3482, 3404, 2951, 2891, 1542, 1430, 1401, 1262, 1250, 1162, 1014, 837, 765, 678 cm^{-1}. − MS (EI): *m*/*z* (%) = 437 (40) [M^+ − NH_2], 405 (100) [M^+ − 3 NH_2]. − $C_{14}H_{47}N_5Si_6$ (454.0): calcd. C 37.0, H 10.4; found C 37.0, H 10.4. The osmometric molecular mass determination in toluene gave a molecular weight of 449 Dalton.

Hexaethylsilsesquiazane (4): To a solution of sodium (1.4 g, 60 mmol) in ammonia (20 mL) was added a solution of $EtSiCl_3$ (3.7 g, 20 mmol) in toluene (40 mL) at −78 °C. After warming to room temperature the mixture was stirred for an additional 2 h. The crude product was extracted with *n*-hexane (100 mL). After removing the solvent under vacuum **4** (1.3 g, 78%) was obtained. Recrystallization from diethyl ether (10 mL) gave colorless crystals of **4**. − M.p. 130 °C. − ^{1}H NMR (C_6D_6): δ = 0.58 (m, CH_2, 12 H), 1.05 (m, CH_3, 18 H), 0.58−1.05 (m, N*H*, 9 H). − ^{29}Si NMR (C_6D_6): δ = −22.0 (Me*Si*). − IR (KBr): $\tilde{\nu}$ = 3388, 1304, 1260, 1238, 1196, 1160, 1081, 1011, 964, 935, 841, 794, 769, 722, 685, 640 cm^{-1}. − MS (EI): *m*/*z* (%) = 477 [M^+]. − $C_{12}H_{39}N_9Si_6$ (478.1): calcd. C 30.2, H 8.2; found C 29.6, H 8.2.

[a] $R1 = \Sigma|F_o - F_c| / \Sigma|F_o|$; $wR2 = [\Sigma w(F_o^2 - F_c^2)^2 / \Sigma wF_o^4]^{1/2}$. – [b] Goodness of fit $S = [\Sigma w(F_o^2 - F_c^2)^2 / \Sigma (n\text{-}p)]^{1/2}$.

X-ray Crystal Structure Analysis:[12] The crystals were mounted on a glass fiber in a rapidly cooled perfluoropolyether.[13] Diffraction data (see Table 1) were collected on a Stoe-Siemens-Huber four-circle diffractometer coupled to a Siemens CCD area detector at 133(2) K, with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å), performing φ- and ω scans. The structures were solved by direct methods using SHELXS-97[14] and refined against F^2 on all data by full-matrix least-squares with SHELXL-97.[15] All non-hydrogen atoms were refined anisotropically. All hydrogen atoms bonded to carbon were included in the model at geometrically calculated positions and refined using a riding model. The hydrogen atoms bonded to nitrogen were localized in the difference Fourier synthesis and refined with the help of distance restraints and anisotropic displacement parameter restraints. The position of the hydrogen atom bonded to oxygen in **2a** was freely refined.

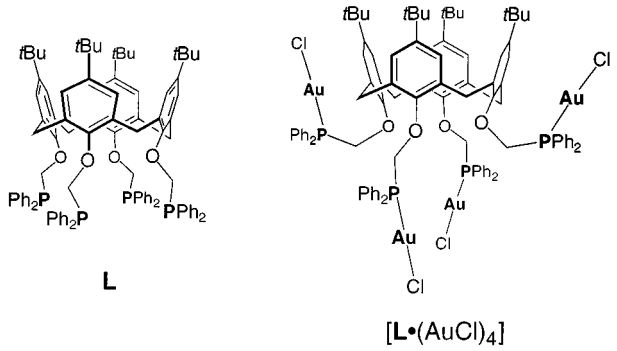
Coordination Chemistry of Calix-Phosphanes: Cooperativity in the Assembly of a Tetragold Calixarene Complex



Cedric B. Dieleman,[a] Dominique Matt,*[a] and Anthony Harriman*[b]

Keywords: Metallo-calixarenes / Gold complexes / Tetraphosphane / Stability constants

Assemblage of the tetragold complex [L·(AuCl)$_4$] from *p-tert*-butyl-calix[4]-(OCH$_2$PPh$_2$)$_4$ (L) and [AuCl(tetrahydrothiophene)] was investigated by NMR and UV/Visible spectroscopic titrations. Three steps could be resolved and are assigned, respectively, to addition of one, two and four AuCl units to the macrocyclic ligand. At each stage of metallation, symmetrical species persist on the NMR time scale since the bound AuCl fragments migrate between the different phosphorus centers via both intra- and intermolecular processes. The derived stability constants (logβ_1 = 4.4 ± 0.2, logβ_2 = 7.0 ± 0.7, and logβ_4 = 14.5 ± 2.0) indicate both positive and negative cooperativity during build-up of the tetranuclear species. An X-ray diffraction study made with crystals obtained from an L:Au (1:2) mixture revealed the formation of an unusual binuclear complex whose solid state structure comprises a polymeric chain of [L·AuCl] units linked by pseudo-tetrahedral Au$^+$ ions, each generic unit containing a pendant linear PAuCl fragment. This polymeric species, with its two distinct binding modes, provides a simple rationale by which to explain the role of cooperativity in the overall assembly process.

Introduction

Calixarene-based polytopic ligands are attractive building blocks for the construction of molecules maintaining several *discrete* transition metal centers in close proximity.[1–8] Such intricate architectures provide important opportunities to study metal–metal cooperativity in polynuclear complexes and, inter alia, to extend our understanding of the mechanism of heavy-metal transport in biological systems.[9] As reported recently, the tetra-substituted calix[4]arene **L** possesses the necessary functionality to bind up to four metal centers at the lower rim. This ligand is also known to form bimetallic gold and silver complexes displaying unusual kinetic behavior in solution,[10] although the manner in which such metallo-calixarenes are assembled remains poorly understood. Following a recent study in which we reported the synthesis of the tetranuclear gold complex [**L**·(AuCl)$_4$][10] (Scheme 1) we now describe the stepwise formation of this complex by reaction of **L** with [AuCl(THT)] (THT = tetrahydrothiophene) under conditions that allow the mechanism to be resolved. During this study an unprecedented calixarene polymer could be isolated whose structure is detailed below.

Scheme 1. Drawing of **L** and [**L**·(AuCl)$_4$]

Results and Discussion

As pointed out in a previous study, ^{31}P and ^{1}H NMR spectroscopy suggests that addition of sub-stoichiometric amounts of [AuCl(THT)] to **L** in $CDCl_3$ forms a mono-gold species[11] that co-exists with the free ligand. In fact, careful examination of the NMR spectra shows that excess **L** exchanges with coordinated ligand, since the broad signal due to the mono-gold complex moves upfield with increasing ligand concentration. Furthermore, the NMR spectra show the mono-gold complex to be symmetrical such that, in addition to bimolecular ligand exchange, it appears that the bound AuCl fragment migrates between the four P atoms attached to the calixarene platform. ^{31}P NMR spectra recorded at higher concentrations of [AuCl(THT)] (Au:**L** = 1–4; ligand concentration = 5×10^{-3} M) comprise a singlet whose chemical shift varies over the range 22–33 ppm,[12] while the corresponding ^{1}H NMR spectra confirm the presence of symmetrical species throughout the titration.[13]

X-ray diffraction studies made with crystals isolated from a concentrated **L**:Au (1:2) mixture (CH_2Cl_2, 0.025 M) indicate formation of a binuclear complex whose solid-state structure[14] consists of a polymeric chain of [**L**·AuCl] units linked by trigonal Au$^+$ ions (Figure 1). The basic motif contains a pendant P–Au–Cl fragment while each linking Au cation is bound to three phosphorus atoms, two of which originate from the same calixarene. A chloride anion is ap-

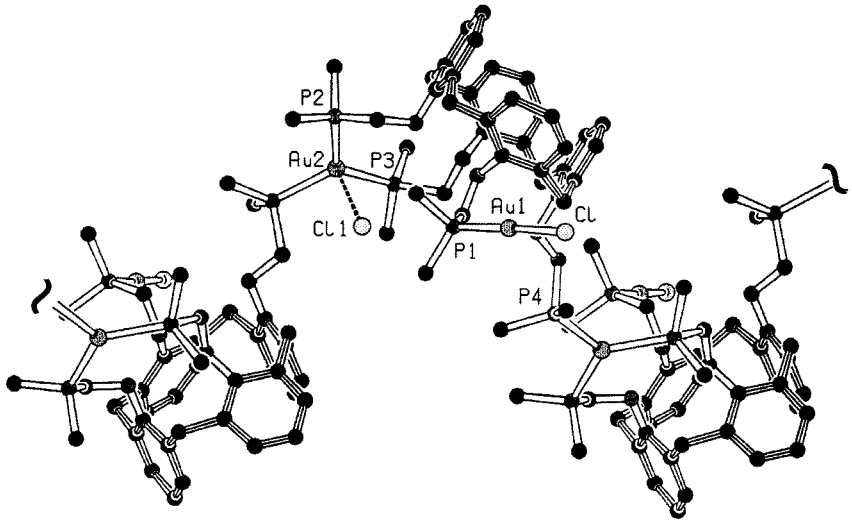

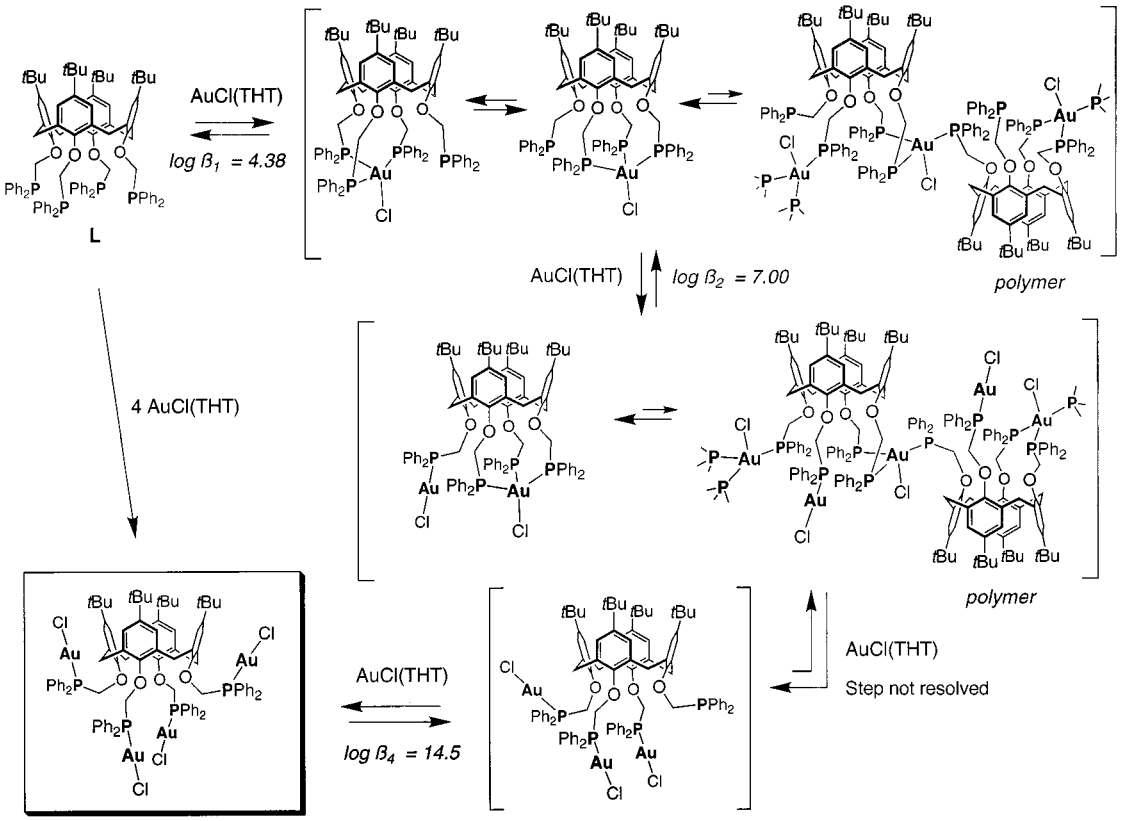

Figure 1. PLATON view of polymeric $[\mathbf{L}\cdot Au_2Cl_2]_\infty$; for clarity the *t*Bu groups have been omitted and only the *ipso* carbon atoms of the PPh_2 aryl rings are shown; selected bond distances (Å) (standard deviations in parentheses): Au(1)–Cl 2.283(7), Au(1)–P(1) 2.254(7), Au(2)–P(2) 2.371(6), Au(2)–P(3) 2.379(6), Au(2)–P′(4) 2.384(6), Au(2)–Cl(1) 3.012(6); dihedral angles between the facing aryl rings of the calixarene matrix: 80.3(7)° and 1.6(7)°

ically sited on each AuP_3 plane, the Au–Cl contact being 3.012(6) Å.[15] This structure differs markedly from known arrangements where AuCl units bound to three P^{III} atoms involve tetrahedral gold atoms.[16–19] It is also noteworthy that this structure contrasts with the numerous gold-linked inorganic polymers for which the gold(I) connector has a coordination number two.[20] The present X-ray structure, which provides a rationale for the bimolecular ligand exchange processes inferred from the NMR studies, is the first indication that gold(I) centers of coordination number two and four co-exist in a single molecule.

The processes leading to formation of $[\mathbf{L}\cdot(AuCl)_4]$ were examined by spectrophotometric titrations with progressive addition of [AuCl(THT)] to **L** (5×10^{-5} M) in acetonitrile at 25 °C. Global analysis of the titration data exposed three discrete steps in the overall assembly. The first step, which corresponds to formation of $[\mathbf{L}\cdot(AuCl)]$, involves a stability constant of $\log\beta_1 = 4.4 \pm 0.2$ while addition of a second AuCl fragment is characterized by $\log\beta_2 = 7.0 \pm 0.7$. Remarkably, addition of further AuCl fragments to $[\mathbf{L}\cdot(AuCl)_2]$ proceeds easily and, in fact, the individual steps leading to attachment of the third and fourth metallic centers could not be resolved. The tetranuclear species $[\mathbf{L}\cdot(AuCl)_4]$, which dominates the equilibrium mixture at high molar ratios of [AuCl(THT)] regardless of total concentration, is formed with $\log\beta_4 = 14.5 \pm 2.0$.

The observed trend in stability constants is best explained by reference to the X-ray structure where two different types of bound AuCl fragments can be seen. Thus, at low molar ratios of Au:**L** the incoming AuCl fragment binds to the calixarene platform with a *pseudo*-tetrahedral geometry by coordinating to three phosphane groups.[21] These phosphanes might be provided by one or two molecules of **L**, according to the total concentration, while the NMR results require that the structure is labile with facile exchange between the various phosphane groups (Scheme 2). This *pseudo*-tetrahedral arrangement is more stable than the corresponding linear P–Au–Cl geometry by ca. 10 kJ mol^{-1}.[22] Attachment of a second AuCl fragment to $[\mathbf{L}\cdot(AuCl)]$ must produce a species having both linear and *pseudo*-tetrahedral P–Au–Cl units, which equilibrate on the NMR timescale, with both monomeric and oligomeric species being possible (Scheme 2).[23] In order to accommodate a third AuCl fragment the more stable *pseudo*-tetrahedral complex must dissociate to allow the formation of two linear P–Au–Cl units. This process involves a small decrease in the Gibbs free energy ($\Delta G° \approx -4$ kJ mol^{-1}) whilst facilitating attachment of the fourth AuCl fragment by providing a vacant phosphane ligand. Therefore, formation of $[\mathbf{L}\cdot(AuCl)_4]$,[10] which is known to possess four linear P–Au–Cl units, proceeds smoothly (Scheme 2).

The present study reveals that formation of $[\mathbf{L}\cdot(AuCl)_4]$ is a stepwise process where both negative and positive cooperativity between the metal centers can take place. The key feature of the overall assembly mechanism involves the interplay between *pseudo*-tetrahedral and linear P–Au–Cl geometries, with the former being more stable but more demanding in the number of phosphane groups. Consequently, the reaction is driven towards the less-stable linear geometry as more metal centers become attached to the platform. This mechanism explains all the known aspects of the reaction, including why $[\mathbf{L}\cdot(AuCl)_2]$ crystallizes and why $[\mathbf{L}\cdot(AuCl)_3]$ is not detected, and is made possible by having X-ray structural data for both $[\mathbf{L}\cdot(AuCl)_2]$ and $[\mathbf{L}\cdot(AuCl)_4]$. Clearly, such switching between different binding geometries within the same molecule is highly unusual and it should be stressed that interconversion is uniquely controlled by the molar ratio. Complexes possessing either of the extreme *pseudo*-tetrahedral or linear geometries can be generated and it will be interesting to determine whether

Scheme 2. Proposed stepwise formation of [**L**·$(AuCl)_4$]; intramolecular migrations of the bound AuCl fragments have not been fully detailed

the exchange processes that occur during the formation of [**L**·$(AuCl)_4$] involve gold–gold interactions.

Experimental Section

Synthesis of Polymeric [L·$(AuCl)_2$]: To a solution of **L** (0.361 g, 0.25 mmol) in CH_2Cl_2 (5 mL) was added a solution of [AuCl(tetrahydrothiophene)] (0.160 g, 0.50 mmol) in CH_2Cl_2 (5 mL). The solution was filtered through Celite. Crystals of $[\mathbf{L}\cdot Au_2Cl_2]_\infty$ were obtained by slow diffusion of hexane into this solution. Yield: 0.290 g, 60%. – ^{31}P NMR (81 MHz, 293 K, CD_2Cl_2): δ = 31.4 (br s). – ^{1}H NMR (200 MHz, 293 K, $CDCl_3$): δ = 7.90–7.28 (40 H, PPh_2), 6.61 (br s, 8 H, *m*-ArH), 4.97 (br s, 8 H, PCH_2O), 4.53 and 2.92 (AB q, ^2J = 12 Hz, 2 × 4 H, $ArCH_2$), 1.04 (s, 36 H, *t*Bu). – $C_{96}H_{100}Au_2Cl_2O_4P_4\cdot 2H_2O$ (1943): calcd. C 59.36, H 5.40; found C 59.30, H 5.20.

Crystal Data for Polymeric [LAu_2Cl_2]·$2H_2O$: $C_{96}H_{100}Au_2Cl_2O_4P_4\cdot 2H_2O$, M = 1943, orthorhombic, space group $P2_12_12_1$, colorless crystals, a = 17.0365(5), b = 23.3634(8), c = 29.038(1) Å, V = 11558(1) Å^3, Z = 4, D_c = 1.12 g·cm^{-3}, μ = 2.670 mm^{-1}, $F(000)$ = 3920. Data were collected on a Nonius KappaCCD diffractometer (graphite Mo-K_α radiation, 0.71073 Å) at –100 °C. 59120 reflections collected ($2.5 \le \varphi \le 26.3°$), 5916 data with $I > 3\sigma(I)$. The structure was solved using the Nonius OpenMoleN[14] package and refined by full-matrix least-squares methods with anisotropic thermal parameters for all non-hydrogen atoms except for one water molecule. The absolute structure was determined by refining Flack's x parameter. Final results: $R(F)$ = 0.058, $wR(F)$ = 0.084, GOF = 1.653, 981 parameters, largest difference peak = 1.084 eÅ^{-3}. Structure graphics were performed with the program PLATON.[24] Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-137702. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Determination of the Binding Constants: The global binding constants log β_n were determined by UV/Visible spectrophotometric titration in acetonitrile (spectroscopic grade). For these measurements, 50 flasks were filled under N_2 atmosphere with a solution of tetraphosphane **L** in acetonitrile (3 mL, 5×10^{-5} M) to which were added variable amounts of [AuCl(THT)] as multiples of 10 μL of a 3×10^{-4} M acetonitrile solution. The Au:L ratios ranged from 0 to 7. The solutions were left for 12 h before measurement. The spectra were recorded between 190 and 310 nm using a quartz cell (1 cm path length) that was thermoregulated at 25 ± 0.5 °C. The absorbance changes monitored were significant enough to be exploited by multiwavelength numerical treatment based on a Benesi–Hildebrandt type equation (program SPECFIT©[25]), which yielded the desired global binding constants log β_n.

[11] For Au:L ≈ 0.5, the ^{31}P NMR spectrum displays a very broad peak at δ ≈ 10 corresponding to the "mono-gold" species and a sharper peak at δ = – 21 due to the free ligand.
[12] The chemical shift of the ^{31}P NMR signal varies with Au:L ratio: δ = 16.6 (1:1 ratio); 31.4 (2:1 ratio); 25.2 (3:1 ratio); 22.7 (4:1 ratio). For the free ligand, δ = –20.4.
[13] All room-temperature ^{31}P NMR spectra display a single peak. On cooling the 2Au:1L solution, the phosphorus signal broadens before splitting into several signals (202 MHz, 183 K). These observations indicate that dynamic processes occur in solution, but the exact nature of the interconverting species could not be inferred from these data. Note, there is no indication of exchange reactions occurring with [L·$(AuCl)_4$] over the temperature range –80 °C/+25 °C.

[21] P_3-coordination of **L** to a single metal center has been established recently. See: C. B. Dieleman, C. Marsol, D. Matt, A. Harriman, N. Kyritsakas, J.-P. Kintzinger, *J. Chem. Soc., Dalton Trans.* **1999**, 4139–4148. Molecular mechanics computer simulations confirm that intramolecular pseudo-tetrahedral binding is possible.
[22] We assume that β_2 corresponds to formation of the binuclear species possessing both pseudo-tetrahedral and linear AuCl fragments, whereas β_1 refers to formation of the pseudo-tetrahedral geometry. Consequently, ignoring statistical factors, free-energy changes for formation of pseudo-tetrahedral [$\Delta G^\circ = -RT\ln(\beta_1) = -24.5$ kJ mol^{-1}] and linear [$\Delta G^\circ = -RT\ln(\beta_2-\beta_1) = -14.4$ kJ mol^{-1}] sites can be estimated from the titration data. Attaching a third AuCl fragment, assumed to give three linear appendages, corresponds to a crude free-energy change of {$\Delta G^\circ \approx -RT\ln[3(\beta_2-\beta_1)-\beta_2]$} of –4.4 kJ mol^{-1}. Finally, the free energy change for attachment of four linear AuCl fragments {$\Delta G^\circ \approx -RT\ln[4(\beta_2-\beta_1) \approx -58$ kJ mol^{-1}} can be compared to the experimental value ($\Delta G^\circ = -RT\ln(\beta_4) = -80 \pm 12$ kJ mol^{-1}).
[23] Linear P–Au–P coordination occurs in $[LAu_2](PF_6)_2$ but it is most unlikely that such species are formed in the present study. Indeed, $[LAu_2]^{2+}$ does not react with "AuCl" fragments to afford compounds of higher nuclearity.

A New Approach to Well-Ordered Quantum Dots

Günter Schmid*[a] and Norbert Beyer[a]

Dedicated to Professor Dr. Heinrich Vahrenkamp on the occasion of his 60th birthday

Keywords: Gold / Clusters / Quantum dots / Monolayers / Amphiphiles

Extended ordered monolayers of ligand stabilized Au_{55} clusters are formed at the phase boundary between water and dichloromethane. The water phase, containing amphiphilic molecules like per-6-deoxy-6-thio-α-cyclodextrin **(1)** or poly(vinylpyrrolidone) **(2)**, is covered by a thin film of a solution of $[Au_{55}(PPh_3)_{12}Cl_6]$ in dichloromethane. The interaction of the cluster molecules with the thiol functions of **1** or the polymer chains of **2** form perfect cluster orders of hexagonal and cubic structure. The monolayers can be transferred onto solid substrates by a simple dipping process. The use of carbon coated copper grids allows the investigation of the monolayers by transmission electron microscopy (TEM). Electron diffraction experiments under a microscope prove the hexagonal and cubic arrangements. The reason for the formation of the one or the other modification is still unknown.

Introduction

Metal particles of the size of Au_{55} clusters (1.4 nm) show quantum size effects (QSE) even at room temperature,[1a−1e] making them promising candidates for future nanoelectronic applications. The first and most important step on this way is to order the clusters in a two-dimensional lattice to become individually addressable. Recently we described the preparation of ordered monolayers of Au_{55} clusters on modified solid surfaces by a simple dip-coating process.[2] In this paper we report the first results on a more generally applicable method to generate highly ordered and extended Au_{55} monolayers at the phase boundary between two liquids.

We believe that two facts are most important for the formation of ordered monolayers. First, an absolutely flat surface is essential. Polymers like PEI as a modifier are believed to form very thin layers that can smooth small roughnesses. Second, the surface should exhibit a large number of sites that are helpful to let the clusters settle down. In the ideal case the interaction between the clusters (or their ligand shell) and the surface should show the same strength everywhere − only a small amount of energy would then be necessary to let the clusters move around to form dense packings. On the other hand, the interaction between the clusters and the anchor groups must be strong enough to adsorb the clusters from solution and to hold them during the preparation process. This very sensitive balance between mobility and fixation determines the success of the self-assembly process.

Keeping these facts in mind we found that a solid surface needs very special conditions to fulfil all these demands. As an alternative we changed from the solid support to the interface between two liquids, exhibiting atomic flatness and isotropic behaviour all over the surface except near the beaker's wall. The long known Langmuir−Blodgett (LB) technique is based on these conditions. However, previous attempts to generate ordered monolayers of clusters by using original LB techniques didn't result in high degrees of order.[1d] Our actual aim was now to find appropriate molecules to provide amphiphilic interfaces between two liquids including useful functions to trap the clusters irreversibly.

Results and Discussion

We selected the CH_2Cl_2 soluble $[Au_{55}(PPh_3)_{12}Cl_6]$ cluster and various water-soluble amphiphilic compounds. Two of them turned out to work best as modifying agents at the phase boundary: per-6-deoxy-6-thio-α-cyclodextrin **(1)** and poly(vinylpyrrolidone) PVP **(2)**. Others like cysteine, cysteamine and poly(1,4-phenylene sulfide) showed similar behaviour; however, the results were not as promising as those with **1** and **2**.

It is to be assumed that the 12 hydroxy groups in **1** function as the hydrophilic part of the basket-like molecule, whereas the six thiol groups are oriented towards the dichloromethane phase to interact with the clusters as shown in Figure 1.

The function of PVP (**2**) is not as easy to understand as that of **1**. We believe that the polyvinyl backbones form hydrophobic−hydrophobic interactions with the PPh_3 ligands of the clusters.

The experiments were carried out by generating a thin film of a dichloromethane solution of $[Au_{55}(PPh_3)_{12}Cl_6]$ clusters on the aqueous phase containing the amphiphilic compound. Because transmission electron microscopy (TEM) is the most suitable method for examining the success of the experiments, the self-assembled cluster monolayers were transferred onto a carbon-coated copper grid. For good results it is important that the two-phase system does not invert, which may easily happen due to the higher density of the CH_2Cl_2 solution than that of water. This fact presently limits the extension of the monolayers to no more than a few square centimetres. If the CH_2Cl_2 layer becomes too large, it can drop down to the bottom of the flask. If the cluster layer is fished out through the organic phase only a thin, volatile film is covering the surface. If water covers the monolayer it is destroyed during drying.

Following this procedure we were able to generate highly ordered cluster areas in two different structures. A hexagonal and a cubic structure were found beside one another in a sample independent of the surfactant used in the water phase; however, usually the hexagonal structure dominated. The structures were formed in an approximate ratio of 1 to 20 in a number of areas although the cubic arrangements were usually twice as large in extension as the hexagonal ones. Hexagonally structured cluster monolayers, combined with the cyclodextrin **1** and PVP **2**, are shown in Figure 2 and Figure 3, respectively. The insert in Figure 3 shows the electron diffraction pattern, proving the predominately perfect hexagonal architecture.

Figure 4 shows a cut-out of a cubically organized surface, consisting of more than 20,000 clusters. Compound **2** was used as a modifier, as in Figure 3. Here the inserted diffraction pattern was calculated afterwards from the recorded image. The total area is slightly tilted so that the cubic structure is not that easily recognized. This can also be deduced from the diffraction pattern, where the spots show two different distances perpendicular to each other.

It can be assumed that the original areas of ordered clusters at the phase boundary are much larger than those observed under the microscope due to the not yet well developed transfer process from the liquid onto a solid surface. However, we started experiments to improve the procedure by automation.

As reference experiments we tested pure water and, in addition, a water phase containing sodium dodecyl sulfate (SDS). There was absolutely no evidence of cluster assembly in either case. Neither the alkyl chains of the SDS nor the water surface itself showed any attraction for the clusters.

The TEM images of the hexagonal and of the cubic structures showed cluster−cluster distances of 2.3 ± 0.1 nm. This agrees fully with the observed distances in three-dimensional cluster crystals.[3] The value of 2.3 nm seems to be completely independent of the surfactant used. Obviously there is no influence on the clusters if a 40,000 g/mol polymer like **2** or a small molecule like cysteine is used, indicating that the model of the phase boundary as a perfect flat, dense packed support with appropriate anchor groups works pretty well.

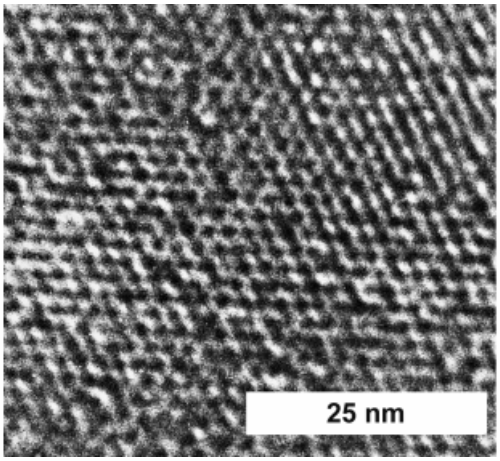

Figure 2. TEM image of a hexagonally ordered area of Au_{55} clusters with a thiol-modified cyclodextrin **1** as amphiphile

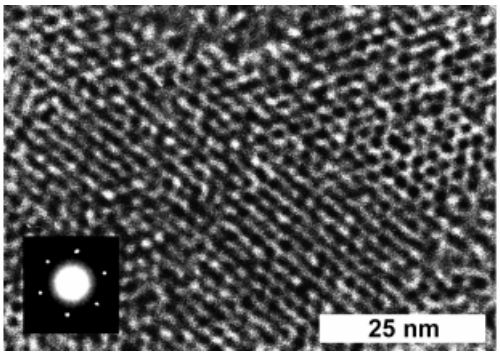

Figure 3. TEM image of a PVP **(2)** supported Au_{55} monolayer; the insert shows the electron diffraction pattern, recorded at a camera length of 4700 mm, proving the hexagonal structure

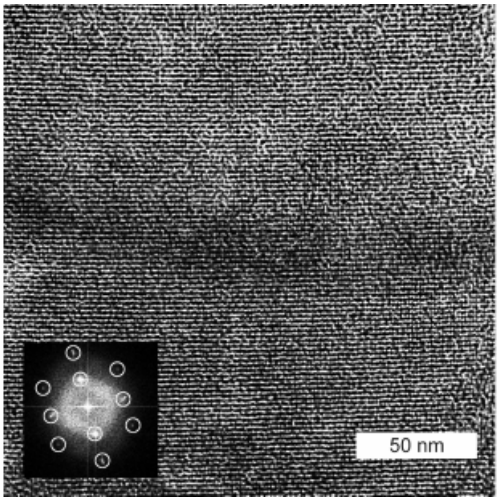

Figure 4. TEM image of a large cubic cluster arrangement; the insert shows the diffraction pattern calculated from the recorded image; the faint spots are marked with circles; the two different distances indicate that the total area was somewhat tilted

Further investigations are still in process. The formation of densely packed cluster layers should have an effect on the surface tension which could be revealed by rheological measurements. There must be strong interactions between the clusters, otherwise these nanometre-thick layers at the phase boundary would not survive under the rough conditions of the sample preparation for the TEM. We also plan to image the interface in situ by means of cryo-TEM. This technique needs very special conditions; however, it will allow snapshots of the formation process itself. Finally we have to use solid supports other than carbon-coated copper grids. First experiments with thin films of silicon carbide gave very promising results which will be reported elsewhere together with further results.

Experimental Section

The synthesis of $[Au_{55}(PPh_3)_{12}Cl_6]$ has been described elsewhere.[4a,4b] Per-6-deoxy-α-cyclodextrin (**1**) was synthezised by G. von Kiedrowski et al., University of Bochum, following published procedures.[5a,5b]. Poly(vinylpyrrolidone) (**2**) K30 (Fluka 81420) was used as received. The ordered $[Au_{55}(PPh_3)_{12}Cl_6]$ monolayers were prepared by adding a small droplet (0.5 mL) of a solution of 0.1 mg/L $[Au_{55}(PPh_3)_{12}Cl_6]$ in CH_2Cl_2 onto the aqueous phase (10 mL) in a tube of 1 cm in diameter, containing 1 mg/L of the amphiphilic compound. This has to be done very carefully to avoid the organic phase falling to the bottom of the tube. After 5−10 minutes the monolayer was formed between the two phases. This film was transferred onto a carbon-coated copper grid (Plano) by dipping it carefully under the surface and then pulling it back slowly, followed by drying in air. The characterization of the samples was carried out by transmission electron microscopy, using a Philips CM 200 FEG at 200 kV.

Acknowledgments

This work was supported by the Deutsche Forschungsgemeinschaft (SFB 452) and the Fonds der Chemischen Industrie. The authors acknowledge financial support by the MSWWF, Nordrhein-Westfalen. We also thank Prof. G. von Kiedrowski and Dipl. Chem. M. Pankau, both Ruhr-Universität Bochum, for providing us with the thiol-modified cyclodextrin.

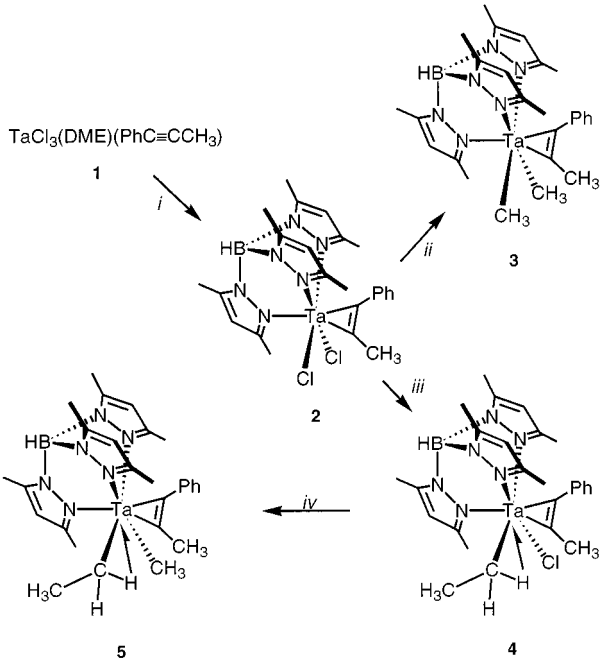
Alkyne[hydrotris(pyrazolyl)borato]tantalum Complexes – An Ethyl Group is a Better α-Agostic Donor Than a Methyl Group

Jean-Cyrille Hierso[a] and Michel Etienne*[a]



Keywords: Tris(pyrazolyl)borate / Tantalum / Agostic interactions / Alkyne complexes

The synthesis of unprecedented alkyne hydrotris(3,5-dimethylpyrazolyl)borato (Tp^{Me2}) tantalum(III) complexes is reported. The parent dichloro complex $Tp^{Me2}TaCl_2(PhC{\equiv}CCH_3)$ (**2**) is obtained from $TaCl_3(DME)(PhC{\equiv}CCH_3)$ and KTp^{Me2}. **2** reacts with methyllithium to give the dimethyl complex $Tp^{Me2}Ta(CH_3)_2(PhC{\equiv}CCH_3)$ (**3**) and with ethylmagnesium chloride to give the X-ray characterized α-agostic ethyl complex $Tp^{Me2}Ta(Cl)(\mu\text{-}H\text{–}CHCH_3)(PhC{\equiv}CCH_3)$ (**4**). Reaction of **4** with methyllithium generates the mixed methyl ethyl complex $Tp^{Me2}Ta(CH_3)(\mu\text{-}H\text{–}CHCH_3)(PhC{\equiv}CCH_3)$ (**5**) in solution. Spectroscopic data indicate that **5** is α-agostic at the ethyl group only.

Whereas β-agostic interactions in alkyl complexes are electronically favored,[1] steric constraints may induce a preference for an α-agostic interaction even though β-hydrogen atoms are available.[2] Competition between the two effects allowed us to observe the only example of an equilibrium between α- and β-agostic rotamers of an isopropyl group in $Tp^{Me2}Nb(Cl)(i\text{Pr})(PhC{\equiv}CCH_3)$ [Tp^{Me2} = hydrotris(3,5-dimethylpyrazolyl)borate].[3] The steric pressure that causes α-agostic interaction is obviously weaker when the alkyl group is methyl and ascertaining the presence of these interactions then remains a challenge.[4] Together with the synthesis of unprecedented trivalent $Tp^{Me2}Ta$ complexes,[5] we herein provide evidence that the mixed ethyl methyl complex $Tp^{Me2}Ta(CH_3)(\mu\text{-}H\text{–}CHCH_3)(PhC{\equiv}CCH_3)$ is α-agostic at the ethyl group selectively. This unprecedented situation is brought about by the efficient steric control exerted by Tp^{Me2}.

The chemistry we report is summarized in Scheme 1. Addition of one equivalent of KTp^{Me2} to in situ generated[6a][6b] $TaCl_3(DME)(PhC{\equiv}CCH_3)$ (**1**) (DME = 1,2-dimethoxyethane) affords orange crystals of $Tp^{Me2}TaCl_2(PhC{\equiv}CCH_3)$ (**2**) in 40% yield. Just like during the synthesis of $Tp^{Me2}TaCl_2(=N\text{–}t\text{Bu})$,[7] the formation of the by-product $[HB(C_3N_2Me_2H)_3BH][TaCl_6]$ lowers the yield. Addition of KTp^{Me2} to successfully isolated[6c] **1** only improves the yield slightly. $Tp^{Me2}SnCl_3$ does not react with **1**, although this reagent is efficient in the synthesis of tetra- and pentavalent $Tp^{Me2}Ta$ derivatives.[8] **2** has spectroscopic and structural properties akin to those of $Tp^{Me2}NbCl_2(PhC{\equiv}CCH_3)$.[9] Thus, the 4e-alkyne sits in the molecular mirror plane, and two discrete alkyne rotamers, depending on the orientation of the alkyne with respect to Tp^{Me2} are observed up to 373 K (^{1}H NMR, [D$_8$]toluene). The X-ray structure will be described elsewhere.

Both mono- and dialkyl derivatives have been synthesized. Treatment of **1** with two equivalents of methyllithium gives $Tp^{Me2}Ta(CH_3)_2(PhC{\equiv}CCH_3)$ (**3**) in 70% yield. Here the yield is only limited by the high solubility of **3** in alkanes. The equivalent Ta-bound methyl groups of **3** give a singlet at $\delta = 0.76$ in the ^{1}H-NMR spectrum, and a quadruplet centered at $\delta = 59.9$ ($^1J_{CH} = 114$ Hz) in the ^{13}C-NMR spectrum. These data are similar to those for $Tp^{Me2}Nb(CH_3)_2(PhC{\equiv}CCH_3)$[9] and $CpTa(CH_3)_2(ArC{\equiv}CAr)$,[10] and suggest the lack of any significant agostic interaction. The thermally stable $Tp^{Me2}Ta(Cl)(\mu\text{-}H\text{–}CHCH_3)(PhC{\equiv}CCH_3)$ (**4**) is obtained in 80% yield from the reaction between **1** and one equivalent of CH_3CH_2MgCl. A crystal structure analysis (Figure 1) reveals the α-agostic interaction through the distortion of the ethyl group with a very obtuse Ta–Cα–Cβ angle [Ta(1)–C(1)–C(2)= 123.5(3)°]. The Ta–Cα bond [Ta(1)–C(1) =

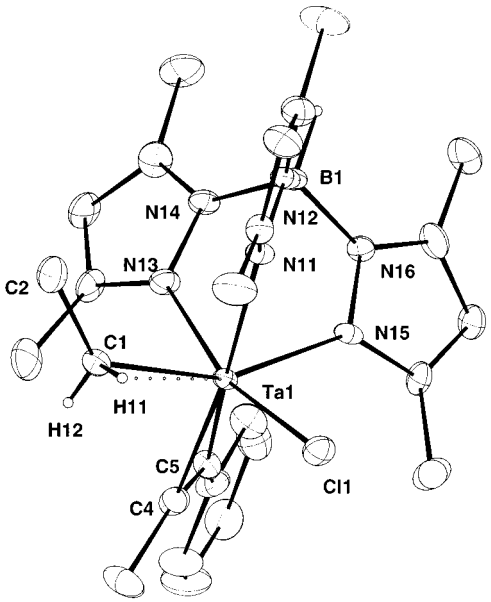

Figure 1. Plot of the molecular structure of $Tp^{Me2}Ta(Cl)(\mu\text{-}H\text{–}CHCH_3)(PhC{\equiv}CCH_3)$ (**4**); selected bond lengths [Å] and angles [°]: Ta(1)–Cl(1) 2.407(1), Ta(1)–C(1) 2.234(5), Ta(1)–C(4) 2.061(5), Ta(1)–C(5) 2.063(5), Ta(1)–H(11) 2.37(6), C(4)–C(5) 1.322(7); Cl(1)–Ta(1)–C(1) 104.4(2), Ta(1)–C(1)–C(2) 123.5(3), Ta(1)–C(1)–H(1) 88.6(43)

2.234(5) Å] remains normal. X-ray data collected at 160 K with an image plate detector combined with absorption corrections allowed the location of the methylene hydrogen atoms. The α-agostic interaction with H(11) is thus further substantiated by the observation of a short Ta···H contact [Ta(1)–H(11) = 2.37(6)°, Ta(1)–C(1)–H(11) = 88.6(43)°]. This interaction is the result of the steric locking of the ethyl group between two adjacent pyrazolyl groups which directs the methylene hydrogen atom in the appropriate location. ^{1}H- and ^{13}C-NMR-spectroscopies also give evidence for the α-agostic interaction in solution. In the room temperature ^{1}H-NMR spectrum, the entire ethyl group yields an AM_3X pattern with one shielded proton [δ = 0.59 (dq, J = 14.6, 6.6 Hz, 1 H, Ta(μ-*H*)CHCH$_3$), 1.40 (dd, J = 7.2, 6.7 Hz, 3 H, TaCH$_2$C*H*$_3$), 3.02 (dq, J = 14.6, 7.5 Hz, 1 H, Ta(μ-H)C*H*CH$_3$]. In the ^{13}C-NMR spectrum, the signal of the Ta-bound carbon atom appears as a doublet of doublets with one low and one high $^1J_{CH}$ [δ = 78.4 (dd, $^1J_{CH}$ = 102, 122 Hz)]. Similar X-ray and spectroscopic data characterize the analogous α-agostic ethyl- and related *n*-alkylniobium derivatives.[2a][2c]

Owing to the increased kinetic stability brought about by tantalum, **4** is thermally stable (373 K, toluene, 24 h) when the niobium analog readily rearranges to $Tp^{Me2}Nb(Cl)(CH_3)(PhC{\equiv}CCH_2CH_3)$ at 343 K (k = 3.0 10^{-5} s^{-1}).[2a] However, this kinetic stability allows the generation of the *unsymmetrical* dialkyl complex $Tp^{Me2}Ta(CH_3)(\mu\text{-}H\text{–}CHCH_3)(PhC{\equiv}CCH_3)$ (**5**) in quantitative yield from **4** and methyllithium in diethyl ether. Although **5** is thermally stable, it slowly decomposes upon attempted isolation. Attempts to synthesize such unsymmetrical niobium complexes lead to alkyl exchange and only dimethyl- and dibenzylniobium complexes have been obtained.[9] ^{1}H- and ^{13}C-NMR data obtained at room temperature on the crude reaction mixture are in favor of a single α-agostic interaction occurring exclusively with the ethyl group. The Ta-bound methyl group of **5** gives a ^{1}H-NMR singlet at δ = 0.68 and a ^{13}C-NMR quadruplet at δ = 55.2 ($^1J_{CH}$ = 116 Hz). In the ^{1}H-NMR spectrum, the diastereotopic methylene protons give a shielded and deshielded doublet of quadruplets at δ = –0.25 (J = 7.4, 15.0 Hz) and 2.46 (J = 7.2, 14.8 Hz). In the ^{13}C-NMR spectrum, the tantalum-bound carbon atom of the ethyl group is characterized by a doublet of doublets centered at δ = 78.0 ($^1J_{CH}$ = 105, 116 Hz). These data, compared to those for the dimethyl complex **3** and for the chloro(ethyl) complex **4**, indicate an α-agostic interaction with the ethyl group selectively. The strength of this interaction cannot be traced from the data: The ^{1}H-NMR chemical shift difference between the signals of the agostic and non-agostic methylene protons is slightly smaller in **4** (2.40 ppm) than in **5** (2.70 ppm) whereas the $^1J_{CH}$ differences are smaller for **5** (10 Hz) than for **4** (20 Hz). The agostic proton is also slightly more shielded in **5**. The ^{1}H-NMR data for **4** do not vary in the temperature range 193–363 K.

Whereas multiple agostic interactions are known, either from a single alkyl group[11a] or from two identical alkyl groups,[11b] it is the first time to our knowledge that two different alkyl groups compete for an agostic bonding. Here, the situation is dominated by the steric demand and directing properties of Tp^{Me2} both of which have little effect, if any, on a methyl group as compared to an ethyl group. The exclusive preference for agostic interaction with the ethyl group is a direct consequence of these properties. This is the main conclusion of this work in addition to the syntheses of the first trivalent $Tp^{Me2}Ta$ complexes.

Experimental Section

All reactions and workup procedures were performed under dry dinitrogen using conventional vacuum-line and Schlenk tube techniques. Toluene, DME, dichloromethane, pentane and *n*-hexane were dried and distilled by refluxing over calcium dihydride under dinitrogen. Diethyl ether was dried and distilled by refluxing over sodium benzophenone under dinitrogen. Tantalum pentachloride, zinc powder, 1-phenyl-1-propyne, methyllithium (1.6 M in diethyl ether) and ethylmagnesium chloride (2.0 M in diethyl ether) were used as received from commercial sources. [D$_6$]Benzene (degassed and stored over molecular sieves under dinitrogen) was used for NMR studies unless stated otherwise. ^{1}H- and ^{13}C-NMR data were acquired with Bruker AC 200, AM 250 or DPX 300. Elemental analyses were performed in the Analytical Service of our laboratory.

$Tp^{Me2}TaCl_2(PhC{\equiv}CCH_3)$ (2): A toluene/DME solution of $TaCl_3(DME)(PhC{\equiv}CCH_3)$, generated from $TaCl_5$ (2.15 g, 6.0 mmol), zinc powder (0.60 g, 9.0 mmol) and $PhC{\equiv}CCH_3$ (0.70 g, 6.0 mmol),[6] was filtered into a suspension of degassed KTp^{Me2} (2.02 g, 6.0 mmol) in DME (10 mL). The slurry was stirred for 5 h and then filtered through Celite to give a bright orange solution. The volatiles were removed under vacuum. The residue was extracted with toluene, filtered and dried under vacuum. This

process was repeated three times to separate the less soluble $[HB(C_3N_2Me_2H)_3BH][TaCl_6]$. $Tp^{Me2}TaCl_2(PhC{\equiv}CCH_3)$ was then obtained as an orange powder (1.60 g, 2.4 mmol, 40% yield). It can be recrystallized from a dichloromethane/hexane (1:1) mixture to give an analytical sample. $C_{24}H_{30}BCl_2N_6Ta$ (665.2): calcd. C 43.4, H 4.4, N 12.7; found C 43.1, H 4.1, N 12.7. – ^{1}H NMR: major isomer: δ = 1.82, 1.96, 2.08, 2.98 (all s, 6, 6, 3, 3 H, $Tp^{Me2}CH_3$), 4.22 (s, 3 H, ≡CCH_3), 5.35, 5.62 (both s, 2, 1 H, Tp^{Me2}CH), 6.83–7.00 (m, 5 H, C_6H_5); minor isomer (some resonances obscured): δ = 1.93, 2.71, 3.00 (all s, 6, 3, 3 H, $Tp^{Me2}CH_3$), 5.44, 5.68 (both s, 2, 1 H, Tp^{Me2}CH), 7.19 (t, J = 7.4 Hz, 1 H, p-C_6H_5), 7.5 (t, J = 7.7 Hz, 2 H, m-C_6H_5), 8.37 (d, J = 7.7 Hz, 2 H, o-C_6H_5); isomer ratio 7:1. – ^{13}C{^{1}H} NMR ($CDCl_3$): major isomer: δ = 12.6, 13.0, 15.3, 15.9 ($Tp^{Me2}CH_3$), 25.7 (≡CCH_3), 108.2, 108.6 ($Tp^{Me2}CH$), 128.6, 128.9, 130.5, 142.4 (C_6H_5), 144.2, 144.5, 153.4, 154.0 ($Tp^{Me2}CCH_3$), 226.8, 269.3 ($CH_3C{\equiv}C$Ph).

$[HB(C_3N_2Me_2H)_3BH][TaCl_6]$: $C_{15}H_{23}B_2Cl_6N_6Ta$ (702.7): calcd. C 25.6, H 3.3, N 11.9; found C 25.6, H 3.8, N 11.3. – ^{1}H NMR (CD_2Cl_2): δ = 2.42 (s, 6 H, CH_3), 6.07 (s, 1 H, CH).

$Tp^{Me2}Ta(CH_3)_2(PhC{\equiv}CCH_3)$ (3): Methyllithium (3.7 mmol, 2.3 mL of a 1.6 M ethereal solution) was added dropwise via syringe at –70 °C to a vigorously stirred suspension of $Tp^{Me2}TaCl_2$-$(PhC{\equiv}CCH_3)$ (1.00 g, 1.4 mmol) in diethyl ether (40 mL). The cooling bath was then removed and the orange suspension slowly turned to pale yellow. The mixture was stirred for 4 h and a white precipitate formed. The solvent was stripped off under vacuum and the residue was extracted three time in a mixture of pentane/diethyl ether (5:1). $Tp^{Me2}Ta(CH_3)_2(PhC{\equiv}CCH_3)$ was obtained as a spectroscopically pure yellow powder after the volatiles were removed. Crystallization from a minimum of pentane gave bright yellow needles (0.66 g, 1.0 mmol, 71% yield). $C_{26}H_{36}BN_6Ta$ (624.4): calcd. C 50.0, H 5.8, N 13.5; found C 50.2, H 5.8, N 13.6. – ^{1}H NMR: major isomer: δ = 0.76 (s, 6 H, TaCH_3), 1.71, 2.05, 2.21, 2.52 (all s, 6, 6, 3, 3 H, $Tp^{Me2}CH_3$), 3.86 (s, 3 H, ≡CCH_3), 5.48, 5.79 (both s, 2, 1 H, Tp^{Me2}CH), 7.05–8.13 (m, 5 H, C_6H_5); minor isomer (some resonances obscured): δ = 0.83 (s, 6 H, TaCH_3), 1.92, 2.04, 2.20, 2.53 (all s, 6, 6, 3, 3 H, $Tp^{Me2}CH_3$), 5.51, 5.78 (both s, 2, 1 H, Tp^{Me2}CH), 7.50 (t, J = 7.7 Hz, 2 H, C_6H_5), 8.10 (d, J = 7.7 Hz, 2 H, C_6H_5); isomer ratio 5:1. – ^{13}C NMR: major isomer: δ = 12.8, 12.7, 15.0, 15.4 ($Tp^{Me2}CH_3$), 25.2 (≡CCH_3), 59.9 (q, J = 114 Hz, TaCH_3), 107.5, 108.6 ($Tp^{Me2}CH$), 143.5, 143.8, 151.7, 151.9 ($Tp^{Me2}CCH_3$), 234.7, 262.3 ($CH_3C{\equiv}C$Ph); minor isomer: δ = 60.7 (TaCH_3).

$Tp^{Me2}Ta(Cl)(CH_2CH_3)(PhC{\equiv}CCH_3)$ (4): An ethereal solution of ethylmagnesium chloride (1.0 mmol, 0.5 mL of a 2.0 M solution) was added via syringe to a vigorously stirred suspension of Tp^{Me2}-$TaCl_2(PhC{\equiv}CCH_3)$ (0.53 g, 0.8 mmol) in diethyl ether (30 mL). The orange suspension slowly turned to a brownish yellow slurry. After filtration, the solution was concentrated to dryness and the residue was extracted with toluene and filtered through a pad of Celite. Concentration of the bright yellow solution to an oil (ca 2 mL) and addition of pentane (10 mL) led to immediate precipitation of golden yellow plates. $Tp^{Me2}Ta(Cl)(CH_2CH_3)(PhC{\equiv}CCH_3)$ (0.26 g, 0.4 mmol, 80% yield) was recovered after filtration and drying under vacuum. – $C_{26}H_{35}BClN_6Ta$ (658.8): calcd. C 47.4, H 5.4, N 12.8; found C 47.4, H, 5.3, N 12.7. – ^{1}H NMR: major isomer: δ = 0.59 [dq, J = 14.6, 6.6 Hz, 1 H, Ta(μ-H)CHCH_3], 1.40 (dd, J= 7.2, 6.7 Hz, 3 H, $TaCH_2CH_3$), 1.62, 1.90, 2.02, 2.03, 2.15, 2.77 (all s, 3 H each, $Tp^{Me2}CH_3$), 3.02 [dq, J = 14.6, 7.5 Hz, 1 H, Ta(μ-H)CHCH_3], 3.91 (s, 3 H, ≡CCH_3), 5.41, 5.52, 5.70 (all s, 1 H each, Tp^{Me2}CH), 6.93–7.09 (m, 5 H, C_6H_5); minor isomer (some resonances obscured): δ = 0.92 [m, 1 H, Ta(μ-H)CHCH_3], 1.81, 1.99, 2.07, 2.13, 2.75, 2.79 (3 H each $Tp^{Me2}CH_3$), 3.15 [m, 1 H, Ta(μ-H)CHCH_3], 5.49, 5.57, 5.69 (all s, 1 H each, Tp^{Me2}CH), 7.17 (t, J= 7.7 Hz, 1 H, p-C_6H_5), 7.49 (t, J= 7.7 Hz, 2 H, m-C_6H_5), 8.24 (dd, J = 8.0, 1.1 Hz, 2 H, o-C_6H_5); isomer ratio 4:1. – ^{13}C NMR: major isomer: δ = 12.7, 12.9, 13.2, 14.8, 15.7, 15.9, 16.0 ($TaCH_2CH_3$, $Tp^{Me2}CH_3$), 25.2 (≡CCH_3), 78.4 (dd, $w_{1/2}$ = 12 Hz, J = 122, 103 Hz, TaCH_2CH_3), 108.0, 108.1, 108.8 ($Tp^{Me2}CH$), 129.1, 130.9, 132.5 (C_6H_5), 144.0, 144.2, 144.3, 151.2, 153.6, 153.9 ($Tp^{Me2}CCH_3$), 227.3, 261.9 ($CH_3C{\equiv}C$Ph); minor isomer: δ = 79.9 ($TaCH_2CH_3$).

$Tp^{Me2}Ta(CH_3)(CH_2CH_3)(PhC{\equiv}CCH_3)$ (5): To an ice/water-cooled (5 °C) suspension of $Tp^{Me2}Ta(Cl)(CH_2CH_3)(PhC{\equiv}CCH_3)$ (0.15 g, 0.23 mmol) in diethyl ether (80 mL) was added via syringe an excess of methyllithium (0.4 mmol, 0.25 mL). The pale yellow mixture turned into a golden yellow solution after ca 15 min. The solution was then stirred for 1 h at room temperature. Various attempts to extract the product using toluene and/or pentane led to rapid decomposition. NMR data were obtained after removing the volatiles under vacuum. – ^{1}H NMR: major isomer: δ = –0.25 [dq, J = 7.2, 14.8 Hz, 1 H, Ta(μ-H)CHCH_3], 0.68 (s, 3 H, TaCH_3) 1.42 (t, J = 7.2 Hz, 3 H, $TaCH_2CH_3$), 1.71, 1.72, 2.04, 2.07, 2.21, 2.51 (all s, 3 H each, $Tp^{Me2}CH_3$), 2.46 [dq, J = 15.0, 7.4 Hz, 1 H, Ta(μ-H)CHCH_3], 3.79 (s, 3 H, ≡CCH_3), 5.47, 5.58, 5.80 (all s, 1 H each, Tp^{Me2}CH), 6.94–7.24 (m, C_6H_5); minor isomer (some resonances obscured): δ = 0.74 (s, 3 H, TaCH_3), 1.91, 1.92, 2.03, 2.06, 2.19, 2.53 (all s, 3 H, $Tp^{Me2}CH_3$), 5.53, 5.62, 5.78 (all s, 1 H, Tp^{Me2}CH), 7.52 (t, J = 7.0 Hz, 2 H, m-C_6H_5), 8.08 (dd, J = 1.5, 8.0 Hz, 2 H, o-C_6H_5); isomer ratio 5:1. – ^{13}C NMR: major isomer: δ = 12.9, 13.0, 13.1, 14.7, 15.2, 15.3, 15.7 ($TaCH_2CH_3$, $Tp^{Me2}CH_3$), 25.0 (≡CCH_3), 55.2 (q, J = 116 Hz, TaCH_3), 78.0 (dd, $w_{1/2}$ = 12 Hz, J = 116, 105 Hz, TaCH_2CH_3), 107.5, 107.6, 108.7 ($Tp^{Me2}CH$), 129.1, 130.9, 132.5 (C_6H_5), 143.9 (*ipso*-C_6H_5), 143.8, 144.0, 144.7, 151.5, 152.1, 152.2 ($Tp^{Me2}CCH_3$), 231.8, 260.2 ($CH_3C{\equiv}$CPh); minor isomer: δ = 55.4 (TaCH_3), 79.3 ($TaCH_2CH_3$).

Crystallographic Study: Single crystals of **4** were obtained from a toluene/pentane solution. Crystal data: $C_{26}H_{35}TaClN_6B$ (571.8), orthorhombic, *Pbca*, a = 15.995(4), b = 19.458(4), c = 17.259(4) Å, V = 5371(1) Å^3, Z = 8, T = 160 K, D = 1.63 Mg m^{-3}, μ = 4.21 mm^{-1}. Data collection was performed with a STOE IPDS diffractometer (Imaging Plate Device) using a graphite- monochromatized Mo-K_α radiation. The structure was solved by direct methods using SIR92.[12] Absorption corrections were applied (min/max trans. 0.5395/0.8161).[13] The refinement was carried out with the CRYSTALS package.[14] 36121 reflections were collected and 5225 found unique (R_{int} = 0.0605). All non-hydrogen atoms were anisotropically refined. Several hydrogen atoms were located from a difference Fourier map but only H(1), H(11) and H(12) were refined with an isotropic thermal parameter [equivalent parameter for H(11) and H(12)]. All the others were included in the calculations in idealized positions (C–H = 0.96 Å) with an isotropic thermal parameter 1.2 times that of the atom to which they were attached. Full-matrix least-square refinements were carried out by minimizing the function $\Sigma w(||F_o| - |F_c||)^2$, where F_o and F_c are the observed and calculated structure factors. A weighting scheme was introduced[15] with $w = w'\{1 - [\Delta F/6\sigma(F)]^2\}^2$. Final $R = \Sigma(||F_o| - |F_c||)/\Sigma|F_o|$, $Rw = [\Sigma w(||F_o| - |F_c||)^2/\Sigma w(|F_o|)^2]^{1/2}$ were 0.0196 and 0.0190, respectively [2820 reflections with $I > 2\sigma(I)$, 328 parameters, *gof* = 1.099, Δρ(min/max) = –0.73/0.54, max ls/esd shift 0.0051]. The plot of the molecular structure was performed with the software CAMERON.[16] Crystallographic data (excluding structure factors) have been deposited with the Cambridge Crystallographic Data Center as supplementary publication number No. CCDC-138605.

Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: int. code + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

Thanks are due to Dr. B. Donnadieu for the X-ray data acquisition, and to Drs. J. Jaffart and R. Mathieu for helpful discussions.

Unprecedented Coordination of 4,4′,5,5′-Tetramethyl-2,2′-biphosphinine Doubly Bridging over an Open Triosmium Core

Maarten J. Bakker,[a] Frank W. Vergeer,[a] František Hartl,*[a] Kees Goubitz,[b] Jan Fraanje,[b] Patrick Rosa,[c] and Pascal Le Floch[c]

Keywords: Triosmium cluster / Biphosphinine / Crystal structure / Cyclic voltammetry

The crystal structure of the novel cluster $[Os_3(CO)_{10}$(4,4′,5,5′-tetramethyl-2,2′-biphosphinine)] reveals an unprecedented coordination mode of the biphosphinine ligand that occupies a doubly-bridging position spanning the open osmium triangle. The cluster is photostable, pointing to a localization of the lowest-energy electronic transition largely on the negatively charged biphosphinine ligand.

Introduction

Clusters of the type $[Os_3(CO)_{10}$(α-diimine)] exhibit a very diversified photochemical and redox behaviour which is controlled by the tuneable electronic and steric properties of the α-diimine ligand. Such ligands include 4,4′-di-R-2,2′-bipyridine and pyridine-2-carbaldehyde-*N*′-R-imine (R = alkyl).[1–3] In comparison with σ*N*,σ*N*′-chelated 2,2′-bipyridine, its aromatic phosphorus derivative 4,4′,5,5′-tetramethyl-2,2′-biphosphinine (tmbp) binds as a fairly strong π-acceptor ligand in a variety of mononuclear complexes, and better stabilizes low oxidation states of the metal in the M(σ*P*,σ*P*′-tmbp) chelate ring.[4,5] In addition, it may bind as a cyclophosphahexatriene with localized double bonds, for example in $[Mn_2(CO)_6$(tmbp)] where it chelates to one $Mn(CO)_3$ moiety through the P lone pairs and to the other metal centre through the internal P=C bonds.[6]

The growing interest in biphosphinine complexes prompted us to attempt the synthesis of the cluster $[Os_3(CO)_{10}$(σ*P*,σ*P*′-tmbp)], with the aim of performing a comparative study of its spectroscopic, photochemical and redox properties. Nevertheless, as often encountered in cluster chemistry, our synthetic efforts instead yielded a structural isomer of the intended product, which presents the first example of the biphosphinine coordinated to three transition metal centres as a doubly bridging ligand. Herein we report the synthesis, X-ray crystal structure and brief characterization of this unusual triosmium cluster.

Results and Discussion

The precursor cluster $[Os_3(CO)_{10}(MeCN)_2]$ reacts with tmbp in THF at room temperature to give purple $[Os_3(CO)_{10}(\mu_2P,\mu_2P'$-tmbp)] (**1**, Figure 1). The cluster **1** was isolated and spectroscopically characterized. The X-ray crystal structure is shown in Figure 2. Similarly to the four-electron donor 2,2′-bipyridine in $[Os_3(CO)_{10}$(bpy)], the biphosphinine ligand is chelated at Os(1). In addition, each phosphorus atom forms a bridge between Os(1) and one of the other two osmium centres. The double μ_2-P bridging of tmbp causes cleavage of the Os(1)–Os(2) bond and opening of the osmium triangle [Os(1)–Os(3)–Os(2) = 85.93(2)°]. Secondly, the tmbp ligand becomes strongly distorted and its aromaticity is lifted. In all known mononuclear complexes of tmbp this ligand is perfectly planar, with C–C bond lengths in the rings between 1.38 and 1.41 Å, thus displaying a high degree of aromaticity.[4,5] In contrast, the C–C bond lengths of **1** range from 1.33(2) Å, typical for isolated C=C bonds, to 1.47(2) Å (length of a single C–C bond ≈ 1.53 Å). Importantly, the inter-ring C–C bond length in **1** is rather short [1.41(2) Å] when compared to the characteristic values for the nonreduced uncoordinated ligand (1.49 Å, average of two isomers)[7] and for mononuclear complexes of tmbp (ca. 1.47 Å).[4,5] Also the C–P bonds are rather long [1.77(2)–1.80(2) Å] compared to the C–P bond lengths of "aromatic" tmbp (1.71–1.74 Å).[4,5] These data point to partial reduction of the tmbp ligand by electron transfer from the triosmium core, causing cleavage

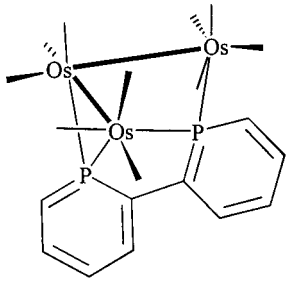

Figure 1. Schematic molecular structure of cluster **1**

of the Os–Os bond.[8] Another remarkable feature is the enormous difference between the two Os–P–Os bridge angles: 75.2(1)° [P(2)] spanning the intact Os(1)–Os(3) bond, but 110.0(1)° [P(1)] spanning the nonbonded Os(1) and Os(2) centres.

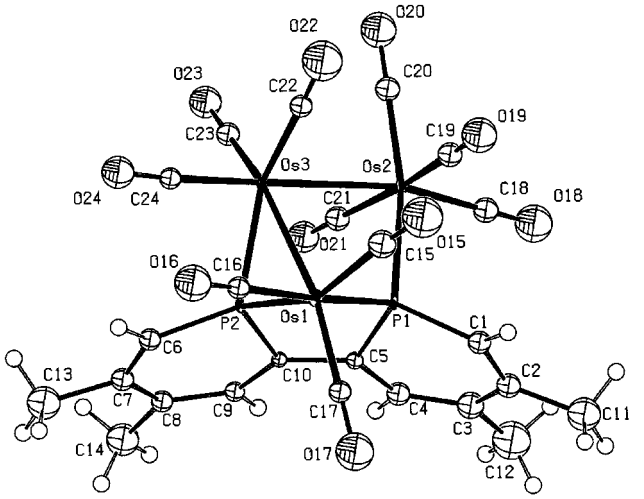

Figure 2. X-ray crystal structure of cluster **1**; selected bond lengths (Å) and angles (°) with standard deviations in parentheses: Os(1)–Os(3) 2.8856(9), Os(2)–Os(3) 2.9567(9), Os(1)–P(1) 2.395(4), Os(2)–P(1) 2.441(4), Os(1)–P(2) 2.351(3), Os(3)–P(2) 2.376(4), P(1)–C(1) 1.77(2), P(1)–C(5) 1.80(2), C(1)–C(2) 1.37(2), C(2)–C(3) 1.46(3), C(3)–C(4) 1.38(2), C(4)–C(5) 1.39(2), P(2)–C(6) 1.78(2), P(2)–C(10) 1.80(1), C(6)–C(7) 1.33(2), C(7)–C(8) 1.47(2), C(8)–C(9) 1.37(2), C(9)–C(10) 1.44(2), C(5)–C(10) 1.41(2); Os(1)–Os(3)–Os(2) 85.93(2), Os(1)–P(1)–Os(2) 110.9(1), Os(1)–P(2)–Os(3) 75.2(1), P(1)–Os(1)–P(2) 75.1(1), C(1)–P(1)–C(5) 100.1(6), C(6)–P(2)–C(10) 101.6(7)

The very different environments of both phosphorus atoms are reflected in their ^{31}P NMR chemical shifts (δ = 26.2 and –146.2). Both values significantly deviate from the strongly positive ^{31}P chemical shifts for "aromatic tmbp" complexes (δ = 178–250).[4,5] The loss of aromaticity is also reflected in the shift of the proton signals to smaller ppm values (ca. 1.5 ppm) compared to those of the noncoordinated tmbp ligand.

Cluster **1** is deep-purple coloured due to a broad absorption band at 540 nm. The corresponding electronic transition exhibits negligible solvatochromism,[9] in contrast to the lowest-energy electronic transition of $[Os_3(CO)_{10}(bpy)]$, which possesses a dominant metal(core)-to-ligand charge transfer character.[1,10] The involved frontier orbitals of **1** probably have a dominant contribution from the tmbp ligand.[8] This may explain the observed inherent photostability of **1**, as no specific metal–ligand or metal–metal bonds are significantly weakened upon visible excitation.[11]

The different electronic structure with regard to that of $[Os_3(CO)_{10}(bpy)]$ is also indicated by the electrochemical behaviour of **1** which, in the first instance, was studied by cyclic voltammetry. At room temperature and at v = 20 mV/s the reduction of **1** is a chemically irreversible two-electron process ($E_{p,c}$ = –1.73 V *vs.* Fc/Fc$^+$), resulting in loss of CO. At v = 100 V/s the reduction becomes a chemically reversible one-electron process ($E_{1/2}$ = –1.74 V *vs.* Fc/Fc$^+$). The reduction potential is more negative than would be expected for a dominantly tmbp-localized reduction of isomeric $[Os_3(CO)_{10}(\sigma P,\sigma P'\text{-tmbp})]$ with a molecular and electronic structure resembling that of $[Os_3(CO)_{10}(\alpha\text{-diimine})]$.[12] On the other hand, the higher stability of the radical anion **1**$^{-\bullet}$ does not correspond to the reduction being localized significantly on the cluster core.[3] We assume that the higher LUMO energy of **1** reflects the partial negative charge on the tmbp ligand, as deduced from the crystallographic data.

A detailed (spectro)electrochemical and quantum chemical investigation of **1** is currently being carried out.[8]

Experimental Section

General: UV/Vis: Varian Cary 4E. – IR: Bio-Rad FTS 60A – NMR: Bruker AMX 300. – MS (FAB): JEOL JMS SX/SX102A four-sector mass spectrometer, coupled to a JEOL MS-MP 7000 data system. – Elemental analyses were performed at H. Kolbe Mikroanalytisches Laboratorium in Mülheim an der Ruhr.

$[Os_3(CO)_{10}(tmbp)]$ (1): $[Os_3(CO)_{10}(MeCN)_2]$[12] (190 mg) and tmbp (45 mg, 0.9 equiv.) were dissolved in freshly distilled THF (50 mL) under an atmosphere of dry N_2. The yellow solution quickly turned red and finally deep purple. After 1.5 h the solvent was evaporated in vacuo, and the crude purple product was purified by column chromatography over silica, eluting with hexane/dichloromethane (20:1). Single crystals suitable for a crystal structure determination were grown from hexane at 293 K.

1: IR (hexane): ν(CO) = 2104 m, 2057 s, 2036 m, 2025 sh, 2022 vs, 2007 w, 1991 m, 1976 m, 1959 w, 1952 w cm^{-1} – ^{1}H NMR (300 MHz, 293 K, $CDCl_3$): δ = 1.90 (s, Me), 2.04 (s, Me), 2.15 (s, Me), 2.20 (s, Me), 6.36 (d, $^2J(P_a–H)$ = 32.1 Hz, 1 H), 6.39 (d, $^2J(P_b–H)$ = 28.5 Hz, 1 H), 6.75 (d, $^3J(P_a–H)$ = 17.4 Hz, 1 H), 6.93 (d, $^3J(P_b–H)$ = 19.2 Hz, 1 H). – ^{31}P{H} NMR (300 MHz, 293 K, $CDCl_3$): δ = –146.2 (d, P_a), 26.2 (d, P_b), $J(P_a–P_b)$ = 108 Hz. – UV/Vis (*n*-hexane): λ = 340 sh, 436 sh, 540 nm. – $C_{24}H_{16}O_{10}Os_3P_2$ (1097): calcd. C 26.28, H 1.47, P 5.65; found C 26.39, H 1.54, P 5.74. – MS (FAB): *m/z* = 1097 [M$^+$].

X-ray Structure of 1: $C_{24}H_{16}O_{10}Os_3P_2$, M = 1097, monoclinic, space group $P2_1/a$, a = 9.8115(8), b = 16.359(1), c = 18.276(1) Å, β = 98.693(6)°, U = 2899.7(3) Å^3, Z = 4, D_x = 2.51 gcm^{-3}, λ(Cu-K_α) = 1.5418 Å, μ(Cu-K_α) = 257.9 cm^{-1}, T = 253 K, F(000) = 1992, 5954 unique reflections measured, final R = 0.060 for 5264 observed reflections. During the measurement the two reference reflections that were measured hourly showed an increase in intensity which could not be explained. This may be the reason why only the heavy atoms (Os and P) could be refined anisotropically. The results of the structure refinement with respect to the geometry of the molecule were, however, satisfactory.

Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-136584. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44–1223/336–033; E-mail: deposit@ccdc.cam.ac.uk).

Cyclic Voltammetry: Cyclic voltammograms of **1** in freshly distilled THF (with 0.1 M Bu_4NPF_6 as electrolyte) were recorded under argon in a gas-tight single-compartment cell equipped with a Pt-disk

working microelectrode (r = 0.4 mm), a Pt-gauze auxiliary electrode and an Ag-coil pseudoreference electrode. Potential control was achieved with a PAR Model 283 potentiostat.

Photochemistry: Continuous-wave irradiation was performed with a Spectra Physics 2025 argon-ion laser. Nanosecond time-resolved UV/Vis experiments were carried out with 7 ns pulses (fwhm) of a 532 nm line obtained by frequency doubling of the 1064 nm fundamental of a Spectra Physics GCR-3 Nd:YAG laser. Details of the data collection system have been described elsewhere.[2]

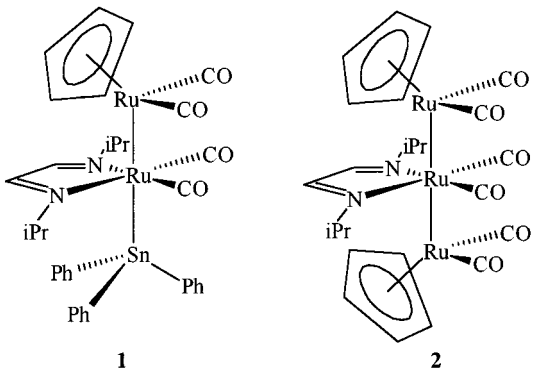
Keywords: Photochemistry / Electrochemistry / Ruthenium compounds / α-Diimine complexes

The photophysical, photochemical and redox properties of the title complexes were investigated. Resonance Raman measurements revealed the lowest-energy electronic transition to possess σ→π* character. At low temperatures, long-lived near-IR emission was observed. Irradiation in solution results in homolytic splitting of a Ru–Ru bond as the primary step, followed by secondary reactions of the radical fragments depending on the experimental conditions. (Spectro)-electrochemical investigations of the title species proved that the axial [$RuCp(CO)_2$] groups exert a stabilising influence on the corresponding radical cations, while destabilising the corresponding radical anions, compared to the redox behaviour of other ruthenium complexes of this type.

Introduction

The photochemical, photophysical and redox properties of the complexes *trans,cis*-[$Ru(L^1)(L^2)(CO)_2$(*i*-Pr–DAB)] (*i*-Pr–DAB = *N,N′*-diisopropyl-1,4-diaza-1,3-butadiene) have been studied extensively in our laboratory.[1–5] In this general formula L^1 and L^2 represent electron donating ligands such as alkyl or metal-containing groups. It was shown that in the lowest excited state of these complexes electron density was transferred from the L^1–Ru–L^2 σ system to the π* orbital of *i*-Pr–DAB, which contrasts with the lowest MLCT state of [$Ru(Cl)(Me)(CO)_2$(*i*-Pr–DAB)] and the XLCT (X = I) state of [$Ru(I)(Me)(CO)_2$(*i*-Pr–DAB)].[6–8] One of the consequences of this σπ* or Sigma-Bond-to-Ligand Charge Transfer (SBLCT) excited state character is a dramatic increase in excited state lifetime.[2] On the other hand, since the L^1–Ru–L^2 σ orbital is high in energy (and hence the corresponding σ* orbital lies relatively low) the dissociative σσ* state is thermally accessible. This imparts all members of the series [$Ru(L^1)(L^2)(CO)_2$(*i*-Pr–DAB)] with a certain degree of photoreactivity.



The present study was undertaken to investigate the influence of strongly electron releasing axial ligands on photophysical and photochemical behaviour. Two novel complexes bearing one or two [$RuCp(CO)_2$] groups as axial ligands were therefore synthesized. It was expected that incorporation of these ligands would shift the electronic absorption maximum to lower energy, hence giving rise to near-infrared emission. This is very interesting in view of the challenging application of such compounds as luminescent labels e.g. in biochemical separations, since background luminescence is negligible in the near infrared spectral region. A long luminescence lifetime is also desirable in order to make time-gated detection viable. In order to understand the influence of the electron releasing [$RuCp(CO)_2$] axial ligand(s) on the electronic properties and reactivity of the title complexes in more detail, a (spectro)electrochemical study was also undertaken.

Results and Discussion

Spectroscopic Properties

The novel title compounds, purple [$Ru(SnPh_3)\{RuCp(CO)_2\}(CO)_2$(*i*-Pr–DAB)] (**1**) and green [$Ru\{RuCp(CO)_2\}_2(CO)_2$(*i*-Pr–DAB)] (**2**) were prepared by addition of $K[RuCp(CO)_2]$ to [$Ru(Cl)(SnPh_3)(CO)_2$(*i*-Pr–DAB)] and [$RuI_2(CO)_2$(*i*-Pr–DAB)], respectively, according to the procedure used for the synthesis of [$Ru\{Re(CO)_5\}_2(CO)_2$(*i*-Pr–DAB)].[9] Both complexes are highly photoreactive in solution, but virtually photostable in the solid state. The ^1H and ^{13}C NMR chemical shifts for the coordinated *i*-Pr–DAB ligand are similar to those found for other *trans,cis*-[$Ru(L^1)(L^2)(CO)_2$(*i*-Pr–DAB)] complexes, pointing to axial positions of the [$RuCp(CO)_2$] groups (See Figure 1). Both **1** and **2** may exist as a mixture of several rotamers in solution.

The electronic absorption data are collected in Table 1. Due to the electron-releasing character of the $[RuCp(CO)_2]$ group, the lowest-energy absorption bands of both **1** and **2** are red-shifted compared to those of other complexes of this series such as $[Ru(SnPh_3)_2(CO)_2(i\text{-Pr–DAB})]$.[9,10] In the case of **1** this absorption band is considerably less solvatochromic than the metal-to-ligand charge transfer (MLCT) band of the structurally related complex $[Ru(Cl)(Me)(CO)_2(i\text{-Pr–DAB})]$,[6] and even less than is found for all presently known non-halide complexes of the $[Ru(L^1)(L^2)(CO)_2(i\text{-Pr–DAB})]$ series.[9,10] For **2** the solvatochromism is negligible. This is indicative of an electronic transition possessing a limited charge transfer character. Upon cooling a 2-MeTHF solution of **1** or **2** to a glassy solid at 80 K, the lowest-energy band shifts to higher energy by ca. 350 cm^{-1}.

In order to characterize the lowest-energy electronic transition, resonance Raman (rR) spectra were recorded for both complexes by irradiation into the corresponding absorption band. This technique relies on the resonance enhancement of Raman intensity for those vibrations which are coupled to the allowed electronic transition, activated by laser excitation. The wavenumbers of the observed Raman bands are collected in Table 1. The rR spectra of **1** and **2** (Figure 2) are significantly different. That of **1** shows resonantly enhanced Raman bands at 1460 cm^{-1} and 1281 cm^{-1}, which belong to ν(CN) and ν(CC) of the coordinated *i*-Pr–DAB ligand, respectively.[2] Their resonance enhancement indicates that the electronic transition involves some degree of charge transfer to the lowest π^*-orbital of the *i*-Pr–DAB ligand. Its occupation gives rise to a lengthening of the C=N bond, a shortening of the central C–C bond, and appearance of the corresponding stretching modes in the rR spectrum. The absence of a resonantly enhanced ν_s(CO) band implies that the π-back-bonding from the central Ru atom to the CO ligands is similar in the ground and excited states, which agrees with a delocalized Ru–Ru(*i*-Pr–DAB)–Sn system and a small charge transfer character of the transition. In contrast, Raman spectra obtained by excitation into predominantly MLCT transitions, for example in the case of $[Ru(Cl)(Me)(CO)_2(i\text{-Pr–DAB})]$, show a pronounced rR effect for ν_s(CO).[6] In the case of **2** the lowest-energy transition has virtually no charge-transfer character since the bands due to the internal stretching vibrations of the *i*-Pr–DAB ligand are absent in the rR spectrum. This observation is in line with the negligible solvatochromism of this absorption band. This effect of the variable charge transfer character on the resonance Raman spectrum is not a particular property of a $\sigma\rightarrow\pi^*$ transition; it has also been found for the ML(CT) transitions of $W(CO)_4(\alpha\text{-diimine})$.[11]

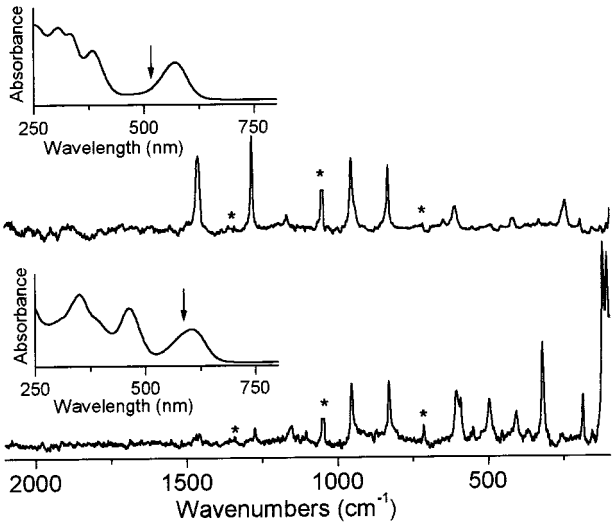

Figure 2. Resonance Raman spectra of **1** (top) and **2** (bottom) recorded by excitation (λ_{exc} = 514.5 and 590 nm, respectively) into the lowest-energy transition of the complexes dispersed in KNO_3 pellets; KNO_3 bands denoted by asterisk; UV/Vis spectra in inserts; λ_{exc} indicated by arrows

Based on the rR data, the lowest-energy absorption band of **1** is assigned to an electronic transition, qualitatively described as σ(Sn–Ru–Ru)$\rightarrow\pi^*$(*i*-Pr–DAB) with some mixing between the σ- and π^*-orbitals. In the case of **2**, this transition occurs between frontier orbitals possessing a strongly mixed σ(Ru–Ru–Ru)–π^*(*i*-Pr–DAB) character. A similar mixing between σ- and π^*-orbitals was revealed by density function calculations on the related model compound $[Ru(SnH_3)_2(CO)_2(H\text{–DAB})]$.[1] These calculations described the HOMO and LUMO as mixed contributions of a Ru p orbital, the sp^3–sp^3 combination of the SnH_3 ligands, and the π^*(H–DAB) orbital. The contribution of the π^*(*i*-Pr–DAB) orbital to the HOMO and LUMO is expected to vary from one complex to another, with a concomitant effect on the charge transfer character and the solvatochromism of the HOMO$\rightarrow$LUMO ($\sigma\rightarrow\pi^*$) transition. Going from **1** to **2**, i.e. replacing the axial $SnPh_3$-ligand by the more electron releasing $[RuCp(CO)_2]$ group, the mixing between the σ and π^* orbitals in both the HOMO and the LUMO increases. As a result the HOMO$\rightarrow$LUMO transition loses most of its charge transfer character, which is reflected in the absence of bands due to the *i*-Pr–DAB stretching vibrations

in the rR spectrum of **2**. In the 1000–100 cm^{-1} region of the rR spectrum of **1**, resonantly enhanced bands can be observed at 951 and 829 cm^{-1} (Ru–*i*-Pr–DAB metallacycle deformations) and at 609, 416, 242, and 192 cm^{-1} (metal–ligand stretching modes). These bands were also observed in the rR spectra of $[Ru(SnPh_3)_2(CO)_2(i\text{-Pr–DAB})]$ and $[Ru(SnPh_3)\{Mn(CO)_5\}(CO)_2(i\text{-Pr–DAB})]$.[2,4] In addition to these vibrations, the rR spectrum of **2** shows extra bands at 499, 320, 119 and 104 cm^{-1}, while the peak at 242 cm^{-1} is missing. The latter two bands are very intense and may belong to a ν(Ru–Ru) or a ν(Ru–Ru–Ru) mode.

Emission Properties

In a 2-MeTHF glass at 80 K, both **1** and **2** show luminescence with a much longer lifetime than that of $[Ru(Cl)(Me)(CO)_2(i\text{-Pr–DAB})]$ (Table 2).[7] This is remarkable, since **1** and **2** emit in the near infrared region, whereas the latter compound emits at much higher energy. At first, this observation seems to be in contradiction with the energy gap law. However, it can be explained by the fact that the lowest excited state has a different character. As mentioned in the introduction, the use of two σ-bound axial donor ligands results in a special type of lowest excited state. In this excited state, some electron density has been transferred from the σ-system, formed by the axial ligands and the central metal atom, to the lowest π* orbital of the α-diimine ligand, hence being called a σπ* state.[1] The long lifetime is a general property of this type of excited state, and can be rationalized as follows: In the σπ* excited state the complexes are less distorted, which is reflected in a smaller Stokes shift

Table 2. Emission properties of compounds **1** and **2** in a 2-MeTHF glass at 80 K (λ_{exc} = 532 nm).

Compound	λ_{abs} (nm)	λ_{em} (nm)	Stokes shift (cm^{-1})	τ (μs)
1	559	830	5841	16
2	593	855	5168	9
$[Ru(Cl)(Me)(CO)_2(i\text{-Pr–DAB})]$[a]	387	650	10455	0.3

[a] From ref.[7].

of their emission (Table 2). This feature originates in the delocalised nature of the electronic system, causing slight distortion of many bonds in the excited state, while the distortion along any normal coordinate is very small. Consequently, the excited state lifetime increases due to the reduction of vibrational overlap between ground and excited state wavefunctions. This situation also applies to related $[Ru(L^1)(L^2)(CO)_2(i\text{-Pr–DAB})]$ complexes, as judged from time-resolved emission and infrared data and from MO calculations.[1,2]

Photochemistry

Complexes **1** and **2** are photoreactive in solution upon irradiation into their lowest (σπ*) absorption band. The photoreactions were monitored with UV/Vis, IR, and EPR spectroscopies. The spectroscopic data of the parent complexes, photoproducts and reference compounds, are collected in Table 3 and the photoreaction pathways are summarized in Scheme 1.

First of all, solutions of **1** and **2** were irradiated in situ in an EPR spectrometer in the presence of a radical trap. The EPR spectrum recorded after irradiation of a THF solution of **1** in the presence of an excess of triphenylphosphane with a high-pressure mercury lamp ($\lambda > 455$ nm) was identical to that of the radical $[Ru(SnPh_3)(PPh_3)(CO)_2(i\text{-Pr–DAB})]^{\bullet}$, obtained by irradiation of $[Ru(SnPh_3)_2(CO)_2(i\text{-Pr–DAB})]$ in the presence of triphenylphosphane.[3] The other radical fragment, $[RuCp(CO)_2]^{\bullet}$, which was also formed by the homolysis of the Ru–Ru bond, was not observed. However, on irriadiation of **1** in toluene containing an excess of nitrosodurene, a different radical species was formed, which was identified as the nitrosodurene-trapped $[RuCp(CO)_2]^{\bullet}$ radical.[12] Exactly the same spectrum was recorded upon irradiation of **2** under the same conditions, proving that in both cases homolytic Ru–Ru bond splitting is the primary photochemical process.

In situ laser irradiation (λ_{exc} = 514.5 nm) of **1** in dichloromethane in an IR spectrometer at room temperature caused the appearance of several new bands in the CO stretching region, while those of the starting compound decreased in intensity. Initially, two bands appeared at 2056 and 2005 cm^{-1}, accompanied by three other bands at 1991, 1965 and 1936 cm^{-1}. The former two bands are assigned to $[RuCp(Cl)(CO)_2]$, in good agreement with the literature values of 2057 and 2009 cm^{-1} in CCl_4.[13] The latter three bands are attributed to $[Ru(SnPh_3)(CO)_2(i\text{-Pr–DAB})]_2$, a product which also results from photolysis of $[Ru(SnPh_3)_2(CO)_2(i\text{-Pr–DAB})]$.[3] In addition, a small peak was detected at 1773 cm^{-1}. It has been assigned to $[RuCp(CO)_2]_2$, its other ν(CO) bands being obscured by the previously mentioned bands.

On prolonged irradiation of the dichloromethane solution of **1**, new bands appeared at 2033 and 1974 cm^{-1} at the expense of the peaks belonging to $[Ru(SnPh_3)(CO)_2(i\text{-Pr–DAB})]_2$. These IR peaks and an absorption band at ca. 440 nm reveal the formation of $[Ru(Cl)(SnPh_3)(CO)_2(i\text{-Pr–DAB})]$, in agreement with literature data for this complex.[3] The dichloromethane solvent apparently does not act as an efficient radical scavenger, allowing the $[Ru(SnPh_3)(CO)_2(i\text{-Pr–DAB})]^{\bullet}$ and $[RuCp(CO)_2]^{\bullet}$ radicals to dimerise before chlorine abstraction from the solvent takes place. This applies particularly to the former radical. The photochemical quantum yield of this reaction was determined, and appeared to be rather high (0.71). These data show that σ→π* excitation of **1** causes homolysis of the Ru–Ru bond, followed by dimerisation or reaction with the solvent (Scheme 1). The Ru–Sn bond remains unaffected.

Irradiation (λ_{exc} = 514.5 nm) of **2** in spin trapping CCl_4 at 263 K gave rise to several new ν(CO) bands belonging to two chlorinated products (Scheme 1). The bands at 2058 and 2009 cm^{-1} belong to $[RuCp(Cl)(CO)_2]$, in agreement with literature data.[13] The second product [ν(CO) at 1974, 1953, 1923 and 1767 cm^{-1}] is assigned to

[a] The other ν(CO) bands are obscured by those of the other photoproducts. – [b] Ref.[3] – [c] Ref.[17] – [d] Ref.[13] – [e] With added NBu_4PF_6 electrolyte. – [f] Ref.[5]

$[Ru(Cl)\{RuCp(CO)_2\}(CO)_2(i\text{-Pr–DAB})]$. The interesting feature of this product is the ν(CO) band due to a bridging carbonyl group (1767 cm^{-1}). We assume that one carbonyl group occupies a Ru–Ru bridging position. The quantum yield of the photochemical reaction of **2** was determined to be 1.16 in CH_2Cl_2. This quantum yield, as well as that for **1** (see above), is much higher than that for $[Ru(SnPh_3)_2(CO)_2(i\text{-Pr–DAB})]$ (0.23), [3] which implies that the Ru–Ru bond is weaker than the Ru–Sn bond. A quantum efficiency higher than 1 may indicate that the radicals formed upon homolytic Ru–Ru bond splitting react with the starting compound in an electron transfer chain reaction. Similar observations were made for several related rhenium, manganese and ruthenium complexes.[14–16]

For comparison, the photochemistry of **1** and **2** was also studied in THF in the absence of radical traps (Scheme 1). In this case the major photoproduct of **1** was clearly $[Ru(SnPh_3)(CO)_2(i\text{-Pr–DAB})]_2$ [ν(CO) = 1991, 1961, 1935 cm^{-1}, λ_{max} = 385, 690 nm]. The other expected dimeric product $[RuCp(CO)_2]_2$ was only formed in a minor amount. In addition, some other bands were observed at 2037, 2022 and 2010 cm^{-1}. These peaks increased in intensity on pro-

Scheme 1. Photochemical pathways of **1** and **2** in various solvents

longed irradiation, at the expense of those belonging to $[RuCp(CO)_2]_2$. The band at 2022 cm^{-1}, together with a band at 1960 cm^{-1} (hidden under the 1961 cm^{-1} band), is assigned to $[RuCp(H)(CO)_2]$, formed by the hydrogen abstraction from the solvent by $[RuCp(CO)_2]^{\bullet}$. The same ν(CO) values were found for $[RuCp(H)(CO)_2]$ synthesized from $Ru_3(CO)_{12}$ and cyclopentadiene.[17] Similar reactions of $[RuCp(CO)_2]^{\bullet}$ were reported recently.[18] The assignment of the 2037 and 2010 cm^{-1} bands is not entirely clear, but they must also belong to a species containing the $[RuCp(CO)_2]$ moiety. On irradiation at 213 K in THF the major products were the same. However, the 2037 and 2010 cm^{-1} bands were absent, whereas a new product was observed with bands at 2045 and 1991 cm^{-1}, fitting nicely with data for the $[RuCp(THF)(CO)_2]^+$ cation (Table 3).

Irradiation of a THF solution of **2** also yielded a mixture of products. Clearly visible are ν(CO) peaks at 2023 and 1960 cm^{-1} due to $[RuCp(H)(CO)_2]$. In addition, there is a series of peaks at 1967, 1943, 1924, and 1766 cm^{-1}, which probably belong to $[Ru\{RuCp(CO)_2\}(THF)(CO)_2(i\text{-Pr–DAB})]^+$, in close correspondence with the ν(CO) values for the chlorinated derivative formed in CCl_4 (vide supra). A third product with ν(CO) bands at 1988, 1960, and 1940 cm^{-1} is proposed to be $[Ru\{RuCp(CO)_2\}(CO)_2(i\text{-Pr–DAB})]_2$. This assignment is not only in agreement with the behaviour of **1**, but is also supported by the investigation of this reaction with UV/Vis spectroscopy. The product spectrum exhibits a low energy absorption band at 703 nm which is characteristic for such a dimer (Figure 3).[3] At low temperatures (213 K) no dimeric products were observed, but only the cationic species $[Ru\{RuCp(CO)_2\}(THF)(CO)_2(i\text{-Pr–DAB})]^+$ and $[RuCp(THF)(CO)_2]^+$. Apparently, the increased viscosity of the solvent at low temperatures hampers the dimerisation of the radical fragments.

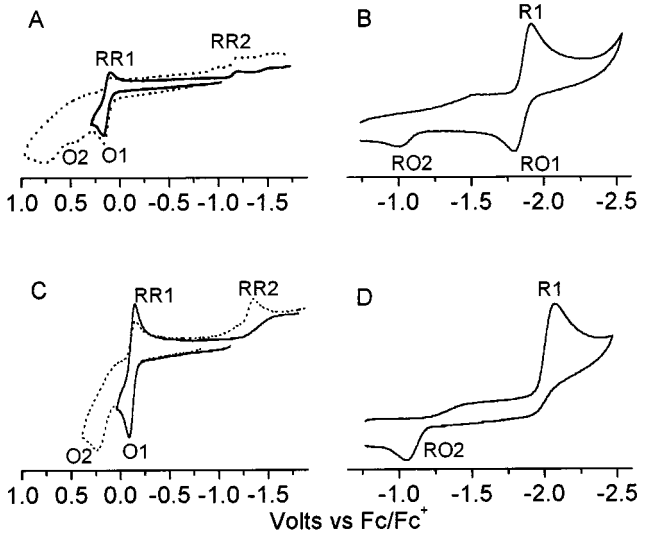

Figure 4. Cyclic voltammograms showing the oxidation of **1** (A) and **2** (C), and the reduction of **1** (B) and **2** (D) in butyronitrile solutions at 213 K

Redox Properties and Reactivity

The complexes **1** and **2** were subjected to a (spectro)electrochemical study. Cyclic voltammograms were recorded at variable temperatures to determine the electrode potentials and to study the reversibility of the corresponding redox processes (Figure 4, Table 4). The nature of the redox products was investigated by IR spectroelectrochemistry. The spectroscopic data are collected in Table 5.

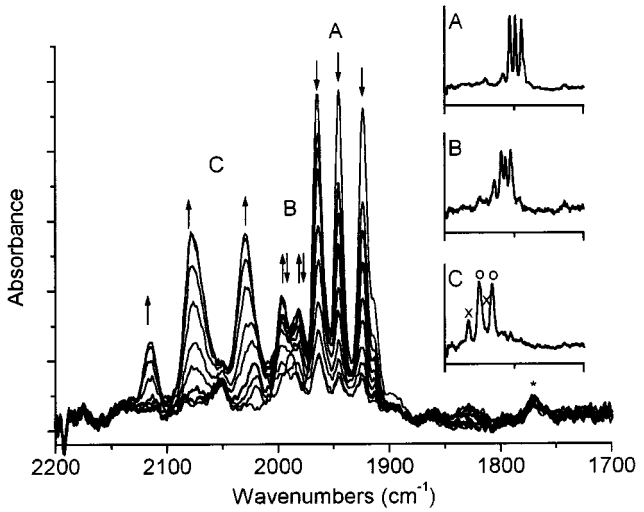
At room temperature, the oxidation of **1** is chemically completely irreversible in THF. However, at 213 K in butyronitrile two oxidation waves became apparent, with the first oxidation process (O1) being partly reversible (I_c/I_a = 0.7) on the voltammetric timescale at the scan rate of 100 mV/s (Figure 4, A). The following anodic step (O2) is completely irreversible. The fact that step O1 was found to be more than 150 mV more negatively than that of $[Ru(SnPh_3)_2(CO)_2(i\text{-Pr–DAB})]$[5] indicates that the oxidation of **1** is significantly located on the $[RuCp(CO)_2]$ moiety. Oxidising **1** at O1 led to the appearance of four bands in the IR carbonyl-stretching region. The product formation was independent of the temperature employed. The primary one-electron oxidised product detected at RR1 (Figure 4, A) at 213 K by cyclic voltammetry, is not detectable on the spectroelectrochemical timescale of seconds to minutes. Of the four bands, those at 2079 and 2031 cm^{-1} are attributed to $[RuCp(n\text{-PrCN})(CO)_2]^+$, in accordance with both the literature values of 2090 and 2044 cm^{-1} for $[RuCp(MeCN)(CO)_2]^+$ in CH_2Cl_2[19] and the observation that upon electrochemical oxidation of $[RuCp(CO)_2]_2$ in *n*-PrCN a product with identical ν(CO) wavenumbers was formed (Table 4). The two remaining bands (2042 and 1987 cm^{-1}) must be due to $[Ru(SnPh_3)(n\text{-PrCN})(CO)_2(i\text{-Pr–DAB})]^+$, as their wavenumbers are close to the values found for $[Ru(OTf)(SnPh_3)(CO)_2(i\text{-Pr–DAB})]$ (2041 and 1981 cm^{-1} in THF).[10] Taking these data into account, we propose the following oxidation path for **1**: initially, the unstable radical cation ($\mathbf{1}^{+\bullet}$) is formed, which rapidly splits to give the $[Ru(SnPh_3)(n\text{-PrCN})(CO)_2(i\text{-Pr–DAB})]^+$ cation and the $[RuCp(CO)_2]^\bullet$ radical. The latter species also binds a solvent molecule and converts to the corresponding cation in a second oxidation step. On the reverse scan, small cathodic peaks were observed (RR2, Figure 4, A), but the corresponding processes were not investigated in detail.

The oxidation of **2** is completely irreversible in THF at room temperature. However, at 213 K in butyronitrile at a v = 100 mV/s the first oxidation process (O1) is completely reversible, as indicated by ΔE_p = 61 mV and I_c/I_a = 1 (Figure 4, C). For equimolar solutions of **1** and **2** virtually the same anodic current was observed at E_a(O1) at 213 K. Considering similar values for the diffusion coefficients of **1** and **2,** this reveals that also the oxidation of **2** at low temperatures is a one-electron process. Indeed, the initial oxidation product of **2** observed in the corresponding IR-spectroelectrochemical experiment in *n*-PrCN at 193 K, exhibits a ν(CO) pattern very close to that of the parent compound **2**, but shifted by ca. 35 cm^{-1} to larger wavenumbers [ν(CO) at



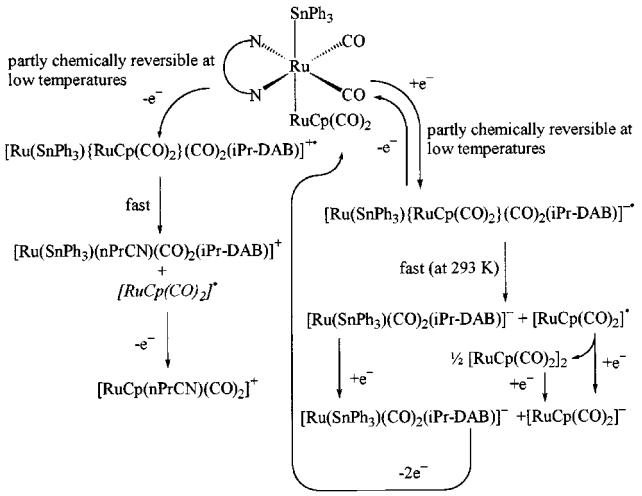


Figure 5. IR spectral changes upon oxidation of **2** in butyronitrile at 193 K. The insets are the parent compound (A), the corresponding radical cation (B), and the secondary oxidation products $[Ru(n\text{-}PrCN)_2(CO)_2(i\text{-}PrDAB)]^{2+}$ and $[RuCp(n\text{-}PrCN)(CO)_2]^+$, indicated by × and o, respectively (C). The asterisk denotes a small $[RuCp(CO)_2]_2$ impurity in the starting compound

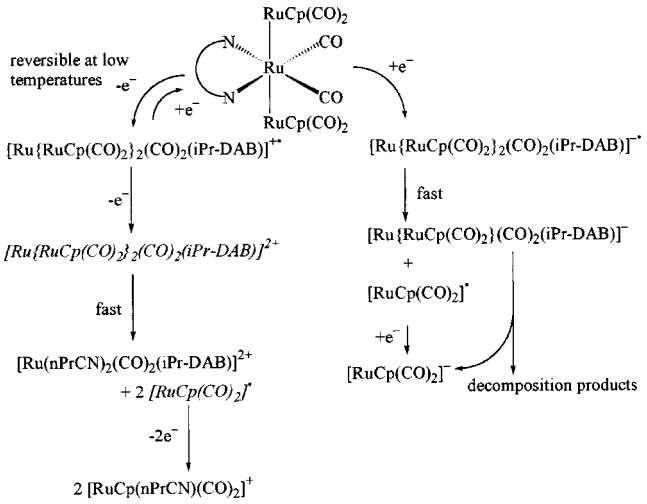
2021, 1997, 1981, 1962 and 1930 cm^{-1}, Figure 5]. This points to a similar molecular structure of the one-electron-oxidised product compared to that of neutral **2**. We therefore concluded that at low temperatures the one-electron-oxidised product $[Ru\{RuCp(CO)_2\}_2(CO)_2(i\text{-}Pr\text{–}DAB)]^{+\bullet}$ is stable both on the voltammetric and the spectro-electrochemical time scales. This is the first time that a stable radical cation has been spectroscopically characterised for complexes $[Ru(L^1)(L^2)(CO)_2(\alpha\text{-diimine})]$, albeit at low temperatures.

The second anodic step of **2** (O2) became separated from the reversible O1 step at 213 K, but remained completely irreversible (Figure 4, C). The corresponding oxidation of $\mathbf{2}^{+\bullet}$, followed in situ by IR-spectroscopy at 193 K, produced species with ν(CO) at 2116, 2060 and 2079, 2031 cm^{-1}. The latter two bands are again attributable to $[RuCp(n\text{-}PrCN)(CO)_2]^+$, while the former two bands must be due to a highly positively charged species, e.g. $[Ru(n\text{-}PrCN)_2(CO)_2(i\text{-}Pr\text{–}DAB)]^{2+}$. The secondary oxidation products of $\mathbf{2}^{+\bullet}$ were reduced back at RR2, resulting in a mixture of the parent complex **2** and $[RuCp(CO)_2]_2$.



In THF at room temperature, the irreversible reduction of **1** at R1 (see Table 4) produced the IR-detectable anions $[Ru(SnPh_3)(CO)_2(i\text{-}Pr\text{–}DAB)]^-$ [ν(CO) at 1924 and 1855 cm^{-1}][5] and $[RuCp(CO)_2]^-$ [ν(CO) at 1887 and 1801 cm^{-1}, close to the literature data[20]]. In addition to these main bands a smaller ν(CO) peak arose at 1782 cm^{-1}. This peak can be assigned to the dimer $[RuCp(CO)_2]_2$, its remaining peaks being hidden under the other ν(CO) bands (see Table 4). The reduction path of **1** is therefore proposed to involve initially an unstable radical anion, which rapidly falls apart into the stable $[Ru(SnPh_3)(CO)_2(i\text{-}Pr\text{–}DAB]^-$ anion and the $[RuCp(CO)_2]^\bullet$ radical (see Scheme 1). The latter species partly dimerises, but the majority is reduced to the $[RuCp(CO)_2]^-$ anion at the reduction potential of **1**. The fact that the latter reduction potential is similar to that of $[Ru(SnPh_3)_2(CO)_2(i\text{-}Pr\text{–}DAB)]$[5] indicates that reduction takes place primarily on the Ru(*i*-Pr–DAB) moiety.

The radical anion $\mathbf{1}^{-\bullet}$ could only be detected by cyclic voltammetry in butyronitrile at sufficiently low temperatures (Figure 4, B). At 213 K the reduction of **1** is a chemically partly reversible one-electron process with I_a/I_c = 0.78 at v = 100 mV/s (see Figure 4, B). The final reduction products $[Ru(SnPh_3)(CO)_2(i\text{-}Pr\text{–}DAB]^-$ and $[RuCp(CO)_2]^-$ are oxidised at similar electrode potentials (Table 4). Therefore, on the reverse anodic scan the oxidation of the two anions cannot be distinguished and appears as a single anodic peak (RO2) at –1.18 V (THF, room temperature) and –1.00 V vs Fc/Fc^+ (butyronitrile, 213 K, Figure 4, B). IR spectroelectrochemistry revealed that reoxidation of both anions at room temperature at RO2 mainly regenerates the parent complex **1**. In addition, a minor amount of the dimer $[Ru(SnPh_3)(CO)_2(i\text{-}Pr\text{–}DAB]_2$ was produced at the end of the reoxidation. Obviously, $[Ru(SnPh_3)(CO)_2(i\text{-}Pr\text{–}DAB]^-$ was present in a small excess in the thin solution layer after the reduction, and therefore, once all $[RuCp(CO)_2]^-$ had been consumed in the course of the parallel reoxidation, the remaining $[Ru(SnPh_3)(CO)_2(i\text{-}Pr\text{–}DAB]^-$ was oxidised to give the dimer by a previously reported ECEC path.[5]

Scheme 2. Reduction and oxidation pathways of **1** in *n*-PrCN

The reduction of **2** at R1 (Figure 4, D, Table 4) is completely chemically irreversible at moderate voltammetric scan rates, independent of temperatures between 293 and 193 K. Corresponding IR spectroelectrochemical experiments again showed the formation of the $[RuCp(CO)_2]^-$ anion [ν(CO) at 1887 and 1801 cm^{-1}]. Two other ν(CO) bands observed at 1927 and 1847 cm^{-1} are tentatively ascribed to the thermally unstable $[Ru\{RuCp(CO)_2\}(CO)_2(i\text{-}Pr\text{–}DAB]^-$ anion. Attempts to prevent its decomposition by carrying out the reduction of **2** in butyronitrile at 193 K were not successful. Considering the combined voltammetric and spectroelectrochemical results, we conclude that the reduction of **2** initially yields the radical anion $[Ru\{RuCp(CO)_2\}_2(CO)_2(i\text{-}Pr\text{–}DAB)]^{-\bullet}$, which rapidly dissociates into $[Ru\{RuCp(CO)_2\}(CO)_2(i\text{-}Pr\text{–}DAB]^-$ and $[RuCp(CO)_2]^\bullet$. The latter radical further reduces to the cor-

Scheme 3. Reduction and oxidation pathways of **2** in *n*-PrCN

responding anion. No dimerisation of the latter radical was observed in this case, probably due to the more negative reduction potential of **2** (see Table 4). The former anion is thermally unstable and dissociates into another equivalent of $[RuCp(CO)_2]^-$ and unidentified carbonyl products. This decomposition also explains the fact that the reverse oxidation at the anodic peak RO2 at –1.27 V (THF, room temperature) and –1.06 V vs Fc/Fc^+ (butyronitrile, 213 K, Figure 4, D) only concerns the $[RuCp(CO)_2]^-$ anion, yielding mainly the $[RuCp(CO)_2]_2$ dimer instead of recovering the parent complex **2**.

The redox behaviour of the complexes **1** (Scheme 2) and **2** (Scheme 3) differ considerably from that of the complexes $[Ru(L^1)(L^2)(CO)_2(i\text{-Pr–DAB})]$ (L^1, L^2 = $GePh_3$, $SnPh_3$, $PbPh_3$; not all combinations were investigated) previously studied in our laboratory.[5] The latter complexes are reduced reversibly, even at room temperature, producing fairly stable radical anions. In contrast, their oxidation is completely irreversible in the temperature range available. Apparently, coordination of the $SnPh_3$ axial ligands contributes significantly to the stability of the radical anion, mainly due to the strong delocalisation of the SOMO over the $(Ph_3Sn)_2Ru(i\text{-Pr–DAB})$ moiety and also due to the strong Ru–Sn bond.[1] On the other hand, the $[RuCp(CO)_2]$ units exert a stabilising influence on the radical cation, where the π-donor Cp-rings compensate for the reduced electron density on the axial ruthenium atom(s), compared to the neutral precursors. This property of Cp-rings has been recognised e.g. in the complexes $[RuCpX(i\text{-Pr–DAB})]$ (X = Cl, OTf).[21]

Concluding Remarks

The incorporation of one or two strongly donating $[RuCp(CO)_2]$ groups as axial ligands in $[Ru(L^1)(L^2)(CO)_2(i\text{-Pr–DAB})]$ yields complexes with a relatively high-lying $\sigma(L^1\text{–Ru–}L^2)$ HOMO. This is reflected in relatively negative oxidation potentials of **1** and **2** compared to other $[Ru(L^1)(L^2)(CO)_2(i\text{-Pr–DAB})]$ complexes.[1,2] As a further consequence, the emission shifts to the near infrared (NIR) spectral region, with lifetimes in the order of 10 μs at 80 K. This property is very interesting from the viewpoint of the potential use of this type of complexes as NIR emitting labels.[22–25] However, the photochemical reactivity of the studied complexes, which involves homolytic cleavage of a Ru–Ru bond as the primary photoprocess, presents a serious obstacle for such applications. The $[RuCp(CO)_2]$ group(s) also split off upon electrochemical reduction and oxidation of the complexes. The most remarkable difference between the redox behaviour of **1** and **2** and that of the previously studied $[Ru(L^1)(L^2)(CO)_2(i\text{-Pr–DAB})]$ complexes[5], is the stabilising influence of the $[RuCp(CO)_2]$ groups on the one-electron-oxidised products.

Experimental Section

General: $[Ru_3(CO)_{12}]$ (ABCR), I_2 (Merck), $SnClPh_3$ (Aldrich) and $[Ru(CO)_2Cp]_2$ (Strem) were used as received. *N,N′*-diisopropyl-1,4-diaza-1,3-butadiene (*i*-Pr–DAB),[26] $[RuCp(H)(CO)_2]$,[17] $[RuCp(CO)_2]_2$,[17] $[Ru(Cl)(SnPh_3)(CO)_2(i\text{-Pr–DAB})]$,[10] and $[Ru(I)_2(CO)_2(i\text{-Pr–DAB})]$[27] were prepared according to literature procedures. Solvents purchased from Acros (THF, 2-MeTHF, hexanes, dichloromethane) and Merck (heptane) were dried on and distilled from the appropriate drying agent. Silica gel (kieselgel 60, Merck, 70–230 mesh) for column chromatography was dried and activated by heating in vacuo at 160°C overnight. All syntheses and measurements were performed under a nitrogen atmosphere using standard Schlenk techniques. – UV/Vis: Varian Cary 4E and Hewlett-Packard 8453. – IR: Bio-Rad FTS 7 and FTS 60A, the latter equipped with a liquid nitrogen-cooled MCT detector. – NMR: Bruker AMX300 (^1H and ^{13}C) and DRX300 (^{119}Sn). – Resonance Raman: Dilor XY spectrometer, with an SP2040E Ar^+-laser as excitation source and a Wright Instruments CCD-detector. – EPR: Varian E-104A. – FAB-MS: JEOL JMS SX/SX102A four-sector mass spectrometer, coupled to a JEOL MS-MP7000 data system. Elemental analyses were performed at H. Kolbe Mikroanalytisches Laboratorium in Mülheim an der Ruhr.

Time-resolved emission spectra were recorded at 80 K in an Oxford Instruments cryostat. A Spectra Physics GCR-3 Nd:YAG laser, operating at 10 Hz was used as the excitation source. The desired wavelength (532 nm) was obtained by frequency doubling of the 1064 nm fundamental. The setup has been described elsewhere.[16]

Quantum yields of the photoreactions were determined from the disappearance of the parent complexes, following the decay of their lowest-energy absorption band. For this purpose the sample was irradiated within the UV/Vis spectrophotometer with one of the laser lines of an SP2025 Ar^+-ion laser through an optical fiber in a previously described setup.[16]

Cyclic voltammograms (CV) of approximately 10^{-3} M solutions of the parent complexes were recorded with added NBu_4PF_6 (0.1–0.3 M) as supporting electrolyte in a gas-tight, single-compartment, three-electrode cell equipped with platinum disk working (apparent surface area 0.42 mm^2), platinum gauze auxiliary and silver wire pseudoreference electrodes. The cell was connected to a computer-controlled PAR Model 283 potentiostat. Redox potentials are reported relative to $E_{1/2}(Fc/Fc^+)$ ($E_{1/2}$ = 0.575 and 0.43 V vs. SCE in THF and CH_3CN, respectively). Ferrocene was added as internal standard.[28] The scan speed was 100 mV/s. IR-spectroelectrochem-

ical measurements at variable temperatures were performed with ca. 10^{-2} M solutions in previously described optically transparent thin-layer electrochemical (OTTLE) cells.[29,30] The potential was controlled during these measurements by a PA4 (EKOM, Czech Republic) potentiostat.

[Ru(SnPh$_3$)[RuCp(CO)$_2$](CO)$_2$(*i*-Pr–DAB)] (1): [RuCp(CO)$_2$]$_2$ (215.5 mg, 0.48 mmol) was dissolved in 30 mL THF. An excess of 0.6 mL $NaK_{2.8}$ was added through a syringe under stirring. The yellow colour of the reaction mixture changed to brown yellow during the next 45 min, after which IR spectra showed virtually complete conversion into [RuCp(CO)$_2$]$^-$.[20] The resulting solution was added gradually through a syringe to a solution of [Ru(Cl)(SnPh$_3$)(CO)$_2$(*i*-Pr–DAB)] (181.7 mg, 0.24 mmol) in 30 mL THF under the exclusion of light. The reaction mixture turned purple immediately. The solvent was evaporated and the product was purified by column chromatography on activated silica, using a CH_2Cl_2/hexane eluent (1:3 v/v). The product elutes prior to the [RuCp(CO)$_2$]$_2$ main impurity. It was obtained as a purple microcrystalline solid in approximately 50% yield. – ^{1}H NMR ($CDCl_3$): δ = 0.99 {d, 6 H, ^3J = 6.5 Hz, CH(C*H*$_3$)$_2$ pointing toward SnPh$_3$, assignment based on comparison with the ^{1}H NMR spectra of [Ru(SnPh$_3$)$_2$(CO)$_2$(*i*-Pr–DAB)] (δ = 0.97)[1] and **2** (vide infra)}; 1.19 [d, 6 H, ^3J = 6.5 Hz, CH(C*H*$_3$)$_2$ pointing toward RuCp(CO)$_2$], 4.40 [sept, 2 H, ^3J = 6.6 Hz, C*H*(CH$_3$)$_2$], 5.22 (s, 5 H, C_5H_5), 7.27 (m, 9 H, *o*/*p*-SnC_6H_5); 7.38 (m, 6 H, *m*-SnC_6H_5); 7.87 (85% s, 15% d, 2 H, $^4J_{Sn-H}$ = 21 Hz, imine CH). – ^{13}C NMR APT (C_6D_6): δ = 25.1, 24.5 [CH(*C*H$_3$)$_2$], 63.0 [*C*H(CH$_3$)$_2$], 86.4 (C_5H_5), 128.0, 127.7 (s, *m*/*p*-SnC_6H_5), 137.8 (85% s, 15%d, J_{Sn-C} = 34 Hz, *o*-SnC_6H_5), 144.5 (s, *ipso*-SnC_6H_5), 145.4 (s, C=N), 205.7 (s, Ru$_{axial}$–CO), 209.7 (s, Ru$_{central}$–CO). – ^{119}Sn NMR ([D$_6$]acetone): δ = –45.6. – IR (THF): See Table 1. – UV/Vis: See Table 1. – FAB-MS; *m*/*z*: [M$^+$] not detected, 813 [M$^+$ – 2 CO], 764 [M$^+$ – Ph – CO], 649 [M$^+$ – RuCp(CO)$_2$].

[Ru[RuCp(CO)$_2$]$_2$(CO)$_2$(*i*-Pr–DAB)] (2): This compound was synthesized from [Ru(I)$_2$(CO)$_2$(*i*-Pr–DAB)] (103.8 mg, 0.19 mmol) following the same procedure as for **1**. It was obtained as a dark green microcrystalline solid in approximately 50% yield. – ^{1}H NMR ($CDCl_3$): δ = 1.21 [d, 12 H, ^3J = 6.6 Hz, CH(C*H*$_3$)$_2$], 4.36 [sept, 2 H, ^3J = 6.6 Hz, C*H*(CH$_3$)$_2$], 5.24 (s, 10 H, C_5H_5), 7.99 (s, 2 H, imine CH). – ^{13}C NMR APT (C_6D_6): δ = 24.8 [CH(*C*H$_3$)$_2$], 61.6 [*C*H(CH$_3$)$_2$], 86.4 (C_5H_5), 143.7 (C=N), 205.7 (Ru$_{axial}$–CO), 214.6 (Ru$_{central}$–CO). – IR (THF): See Table 1. UV/Vis: See Table 1. – FAB-MS; *m*/*z*: 743 [M$^+$], 521 [M$^+$ – RuCp(CO)$_2$]. – $C_{24}H_{26}N_2O_6Ru_3$ (869.52): calcd. C 38.87, H 3.53, N 3.78; found C 38.69, H 3.36, N 3.70.

How to Find Correlations Between Molecular Shape and Packing in a Molecular Crystal: Application of a Novel Strategy to Recognize *n*-Point Polyhedra in Three-Dimensional Space

Stefan Reichling[a] and Gottfried Huttner*[a]

Dedicated to Kurt Mislow, Princeton

Keywords: Crystal packing / Neural networks / Pattern recognition / Organometallic compounds / Close packing

The crystal structures of hundreds of thousands of molecular compounds have now been determined with the quantitative information being stored in large databases. Chemists are generally interested in that specific part of this information which refers to individual molecules. The packing of molecules and their spatial relation to each other is not the focus of interest, even though the material properties of a molecular crystal are determined by both the packing arrangement of the molecules and their specific properties. The lack of interest in packing has at least one obvious reason. It is difficult for the non-expert to find the appropriate packing categories when looking at a principally infinite lattice. A tool performing this search for individual categories of packing in an automatic manner would therefore be of general importance. The development and application of such a tool is described in this paper. Novel strategies to extract a set of n points forming a specific n-point polyhedron from a set of p points ($p > n$) is at its basis. Neural networks and second moment analysis are used as the methods of pattern recognition. In order to correlate packing and shape, second moment analysis of molecular shape is also used. This novel method is applied to three classes of organometallic compounds to determine whether the crystals formed by these compounds belong to any of the three classes *fcc*, *bcc*, or *hcp* in an idealized sense. A strong correlation is found between molecular shape and the membership or nonmembership of these classes. The corresponding program, including appropriate tools for visual representation, is available from the authors.

Introduction

The molecular concept is the basis of chemical reasoning. Even though it is quite complicated to define what a molecule really is, a well-trained chemist will immediately associate a structural representation with this idea and he or she may even take this representation as the idea itself. This kind of reduction has been, and still is, the basis of much of the development of the science of chemistry.

While in earlier days the structures of molecules had generally to be inferred from indirect reasoning, today there is an abundant wealth of structural information available, well-encoded in databases. As this information comes from three-dimensional diffraction analysis, the three-dimensional structures of all the molecules contained in such databases i.e. the coordinates of individual atoms are readily available, as is the mutual arrangement of these molecules within a crystal. While it is evident that such databases add much to the convenience with which a specific structure and even a specific substructure can be found, it is also clear that a collection of very many structures holds a lot of additional information. This additional information is encrypted in the database and one has to ask the proper questions and to apply the proper tools to extract it.

Perhaps the best known example for the validity of this statement is the mapping of a reaction pathway in the early and seminal work of Buergi and Dunitz.[1] The experimental basis for this elegant type of analysis is that the structures of many individual compounds are available within the class of compounds which are relevant to the problem. In another type of application, the conformations adopted by the many individual molecules within one class of compound may be used to find a mechanical model which correctly reproduces and also predicts the conformation of the members of this class.[2] In principle this type of database use builds on the existence or development of intelligent filters that are able to extract the desired information from the wealth of data available. The structure of these filters may be quite different, depending on whether one is looking for reaction pathways[1] or trying to develop a mechanical model.[2] Still, the basic logic is the same: look at the individual structures as snapshots of the geometry of a class of molecules and try to correlate the observed variations with some set of parameters.

It is clear from the above that extracting the hidden information calls for the appropriate tools. As far as molecular structures themselves are concerned, retrieval systems, such as the one built into the most abundant database, the Cambridge Structural Database[3] (hereafter named CSD), are well suited to select classes of compounds, specific kinds of interactions and also specific geometrical arrangements. The situation is much worse if the packing of individual molecules within a crystal is the focus of attention. Although plenty of graphical tools are available to visualize the arrangement of molecules within a three-dimensional

lattice, it is very difficult for the non-expert to understand such packing diagrams. "Understanding" in this context means that one would be able to delineate the observed pattern into some archetypal arrangement and thus recognize the basic principles. Projecting this situation onto molecular chemistry: imagine someone who looks at the structure of hexacarbonylchromium and is not able to extract the archetypal octahedron, which is of course apparent to an educated chemist at first glance. The archetypes of arrangements within infinite lattices are more complicated to recognize, one reason being the translational symmetry, and the other being the lack of appropriate training. While solid-state chemists and crystallographers are well trained to reduce a given repetitive architecture to some standard pattern, molecular chemists are generally not so. Looking at any introduction to solid-state chemistry,[4] one will be aware of the power of categorizing compounds by idealizing their geometry such that they may be understood as derivatives of a few basic patterns. Closest packing, hexagonal close packing (*hcp*), cubic close packing (*fcc*) and body-centered packing (*bcc*), are at the basis of the most proliferate idealizations of this type. Referring to the packing of molecules within crystals it has been shown by Kitaigorodskii[5,6] that the idea of closest packing helps to rationalize the individual arrangements.

Definition of the Problem

With the development of what is called supramolecular chemistry,[7–9] i.e. with the increasing awareness of the importance of secondary interactions between molecules, any information about these secondary interactions is more important to the development of chemistry than ever. Structural databases[3] contain an as yet scarcely used and abundant source of information about secondary interactions. It is these secondary interactions which govern the arrangement of molecules within a crystal.

One way to extract part of this information relies upon reconstruction of the observed patterns of packing by making the appropriate choice for the individual terms of the intermolecular potential.[10,11] By doing this for a series of related structures the potential terms may be optimized.[12,13]

Choosing a good starting point for this kind of optimization is guaranteed by yet another method of systematic exploration of aspects of molecular packing: it is found that the centers of gravity of molecules tend to be close to specific compartments of a unit cell.[14] Helpful as this analysis is, it has no direct bearing on the packing of molecules since the position of points in space depends on their coordinates as well as on the metric system to which these coordinates refer. There are – not including translation – an infinite number of three-dimensional possibilities for a set of points if the fractional coordinates are all that is known, since the real position of a point in space is dependent on the lengths of the crystal axes and the angles between them.

Another way would entail the search for specific patterns of packing (c.f. *bcc*, *fcc*, ...) of the molecules as represented by their centers of gravity. Correlation of the appearance of these patterns with parameters describing the shape of the molecules may then be attempted. Basically, this type of approach has been taken by Kitaigorodskii,[6] albeit at a time where computer retrievable databases were not yet common. To make this approach feasible and efficient, tools have to be developed which recognize a specific three-dimensional repetitive pattern automatically. Such tools are still not available, and although it may appear a simple task to use today's pattern recognition techniques to develop such a tool, the problem is quite complicated.

While, given the metric system, the coordinates of n points completely define an n-point pattern, the values of these coordinates depend on translation as well as rotation. A direct search for a specific n-point pattern in three-dimensional space would hence be quite cumbersome. A solution to this problem is to transform the observed patterns into some representation that is independent of rotation and translation, i.e. a representation in internal coordinates. Since the choice of internal reference frame is intentional, this representation of a pattern formed by an ensemble of n points is again not unique and is thus not immediately accessible to analysis by pattern recognition techniques. To make the representations independent of the specific assignment of internal coordinates – i.e. independent of the $n!$ possible choices of labeling n individual points, each by a unique label – instead of analyzing the individual values, which the internal coordinates adopt for a specific arrangement of points, the distribution of these values may be analyzed. Such a distribution may immediately serve as an input to pattern recognition tools. While representing an ensemble of n points in three-dimensional space by a few histographic data does not in general allow reconstruction of the body represented by these points, it is a very efficient way to classify arrangements of n points with respect to symmetry. Different realizations of this type of analysis are described in this paper, i.e. different types of histographic mapping are used as an input to pattern recognition tools. Neural networks[15–18] are trained to differentiate between different types of bodies based on this histographic input.

The problem of analyzing for a specific type of packing within a repetitive pattern, i.e. crystal space, is dealt with in two steps: first the m next neighbors of a given point are determined; this subset of points is then analyzed for the presence of specific polyhedra which are a characteristic consequence of the kind of packing. Thus for instance octahedra are characteristic constituents in a close-packed situation.[19–21] In looking for octahedra, all six-point combinations out of the ensemble of $m + 1$ points (a good value of m being 16 in the search for octahedra in a close packed situation) are formed and automatically analyzed with respect to their potential octahedral arrangement. The few octahedra sorted out from the $\binom{k}{6}$ (read k over six; with $k = m + 1$) point combinations are then further analyzed with respect to their connectivity. From the type of connectivity found, the type of packing (*fcc*, *hcp*, *bcc*) which best approximates the given distribution of points in crystal space is derived.[19–21]

The procedure is applied to a subset of compounds crystallizing in space group *R*3 as well as to a family of tripod–metal complexes $RCH_2C(CH_2X)(CH_2Y)(CH_2Z)ML_n$ (R = H, alkyl, aryl; X, Y, Z = NR_2, OR, SR, PR_2, PRR′) and a selection of $Cr(CO)_5L$ compounds as registered in the CSD[3] (see Experimental Section). Packings which are close to *fcc*, *hcp*, *bcc* drop out automatically by this procedure. Attempts are made to correlate the shape of the molecules with the specific packing observed. It is found that describing the shape in terms of the eigenvalues of the tensor of inertia,[22] i.e. second moment analysis[23] of the molecular shape, produces some insight into the correlation between packing and shape. Second moment analysis is also used as a tool to differentiate different types of arrangements of *n* points in space, i.e. to recognize specific types of polyhedra. It is found to be efficient in this aspect as well and its use combined with neural network analysis produces an efficient filter for sorting out specific *n*-point polyhedra from a given ensemble of *p* points ($p > n$).

Results and Discussion

In this first attempt at automatic pattern recognition in crystal space, the search was limited to the three basic close packing motifs *fcc*, *hcp*, *bcc*. On the other hand, the pattern recognition machinery was designed such that it might also deal with any other type of packing motif.

From the two alternatives of searching in direct or reciprocal space, the first was preferred. If the only goal of analysis of packing motifs was the search for approximate close packed arrangements then search in reciprocal space might be quite effective. Replacing the molecules by atoms at their centers and calculating the diffraction pattern produced by these atoms would map the packing onto reciprocal space. A search for the approximate symmetry of the diffraction pattern and approximate rules of systematic extinction would then reveal the atomic packing pattern in direct space. This kind of analysis, while presumably efficient in the search for close packing motifs, would not easily adapt itself to the search of less specialized packing motifs. Searching for patterns in direct space was therefore preferred.

It might appear that with only three close-packed motifs in mind, a search for characteristic polyhedra such as the cube octahedron (*fcc*) or the anti-cube octahedron (*hcp*) might be the topic of focus. It is however found, as may be understood by imagining these polyhedra,[19–21] that differentiation between these two bodies as a whole is relatively poor. An alternative strategy has therefore been adopted, to search for octahedra and their connectivity from which the packings may be delineated.

Search for Polyhedra

Distance Histogram

An *n*-point polyhedron may be represented by *n*-coordinate triples in three-dimensional space. Since the values of these coordinates are dependent on translation and rotation, a representation in internal coordinates is preferred for pattern recognition purposes. An especially simple representation of this type consists of a vector for the $[n(n-1)/2]$ distances between all pairs of points of the *n*-point ensemble. This vector contains a full description of the polyhedron and may be back-transformed to a corresponding set of coordinates in three-dimensional space which represent the polyhedron. This fact is made use of in distance geometry calculations.[25,26] That the vector holds all the information necessary to reconstruct the body is immediately apparent from the observation that there are $[n(n-1)/2]$ distances and $3n-6$ degrees of freedom for a body with $n > 2$ points. The number of distances will be equal to the degrees of freedom for $n = 3$ and 4, and larger for $n > 4$, meaning that in these cases ($n > 4$) not all of the distances are independent. In each case, the number of independent distances is sufficient to reconstruct the polyhedron. Such a vector containing all $[n(n-1)/2]$ distances is, however, not suited for presentation to a simple pattern recognition algorithm since it may occur in *n*! different forms corresponding to the *n*! permutations of the *n* components in this vector. Only if the labeling scheme to which the vector refers is known, i.e. when the specific connectivity to which it refers to is known, will back-transformation to the coordinates of the *n* points be possible. To create a description of the polyhedron, which is independent of the specific numbering scheme, a histographic representation of

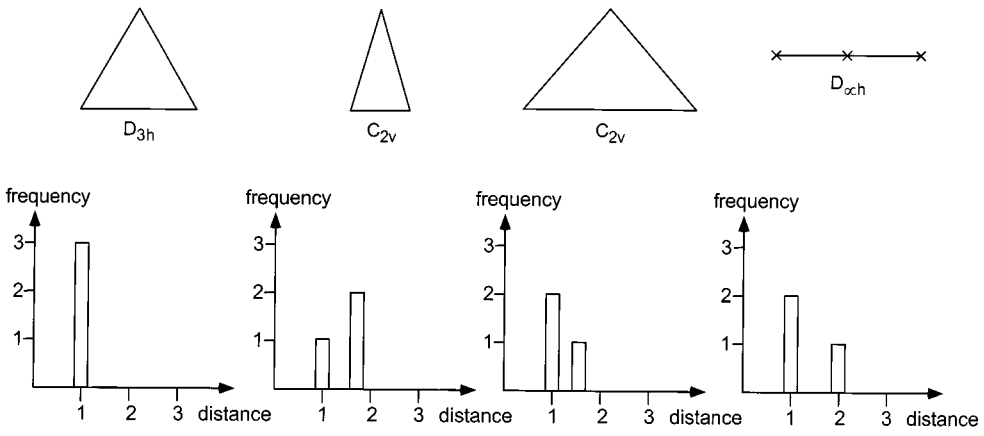

Figure 1. Histographic representation of the effects of symmetry on distance histograms for a set of three points

the vector may be chosen. That is, a histogram showing the frequency with which distances in a specific range occur may be used as input for pattern recognition machinery.

This type of histogram, even though it cannot in general be back-transformed to a three-dimensional representation of the body, is quite characteristic of the individual types of polyhedra. The reason for this is that the symmetry of the polyhedra is encoded in this type of histogram. As an example think of three points in space.

Any pattern formed by three such points is completely characterized by the three distances between these points. While in general these distances may map onto the histogram at any three positions, an arrangement of the points

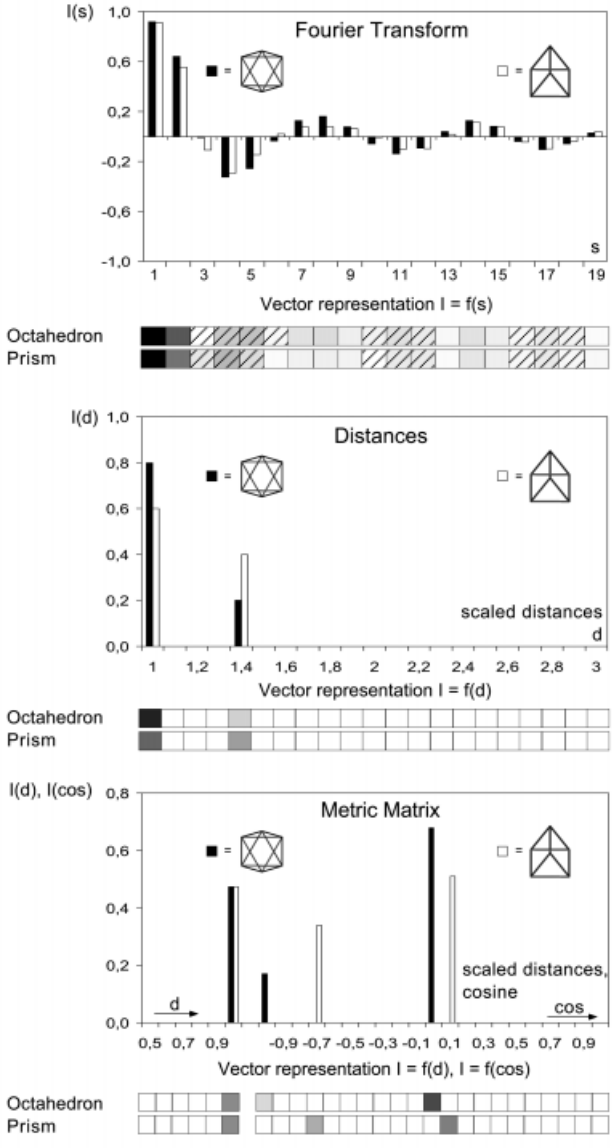

Figure 2. Three methods to represent three-dimensional bodies as a discrete function of just one independent variable. The procedures of obtaining the functions are described in the text. The functions are shown for the examples of a regular octahedron and a regular trigonal prism. The boxes below each function represent the individual components of the vector onto which the functions are mapped. The relative magnitude of the coefficients is indicated by gray shading with black being largest and white being smallest. Negative values of coefficients are indicated by dashed lines.

with any symmetry higher than C_1 will show a specific pattern. If the points conform to an equilateral triangle, the C_3 symmetry of this D_{3h} symmetric body will map itself into the histogram such that the shortest distance is observed three times and there is just one bar in the histogram (Figure 1 left). An isosceles triangle will be represented by two bars, the one corresponding to the two equal distances being twice as high as the one representing the third distance (Figure 1 middle). In the linear arrangement of the $D_{\infty h}$ borderline case of an isosceles triangle, the distance occurring only once will be twice as large as the shortest distance which occurs twice (Figure 1 right). This simple example shows how symmetry mirrors itself in the histographic representation. In this specific case of three points in space, the histographic representation is an unambiguous representation of the body itself. This is because the number of distances is equal to the number of degrees of freedom in this case. The same applies to four points in space, while with $n > 4$ the number of distances exceeds the number of degrees of freedom. In these cases ($n > 4$) the histogram is no longer unambiguous although it still responds in very specific ways to the symmetry of the arrangement of points in space. An example of this type of mapping is represented in Figure 2 (middle) for an octahedron and a trigonal prism.

Histogram for Encoding Distances and Angles: The Metric Matrix Approach

As has already been discussed, a complete set of [$n(n - 1)/2$] distances is a full representation of a body composed of n points in three-dimensional space if the connectivity is also known. It is a representation independent of translation and rotation. Another representation, which is also free of the ambiguities of translation and rotation, consists in the so-called metric matrix of the body (Figure 3 top). To construct this matrix the center of mass of the n points is taken as the origin. The scalar products of all the n vectors radiating from the origin to the n points may then be represented as a symmetric matrix that contains the squares of the distances on the diagonal, and the cosines of the angles sustained by each pair of vectors – each cosine multiplied by the product of the relevant distances – as the off-diagonal terms (Figure 3 top). The appearance of this matrix is also dependent on the scheme used to label the n points and the lines and columns of this matrix may be shuffled around by the $n!$ permutations of the labeling scheme. The matrix itself is thus not immediately suitable for input to a pattern recognition algorithm but the histogram derived from it is. The histogram now consists of two parts, one referring to the distances and the other one to the cosines of the angles (Figure 3 middle). The distances d are mapped onto the interval $0 < d \leq 1$ with the largest distance scaled to 1. Scaling of the cosines is unnecessary since their values are between –1 and +1. The frequencies are scaled such that the values fit in the range $0 \leq$ frequency ≤ 1 (see Experimental Section). The two parts of the histogram (distance, cosine) may be encoded as a vector once the resolution of its two parts (distance, cosine) is defined (Figure 3

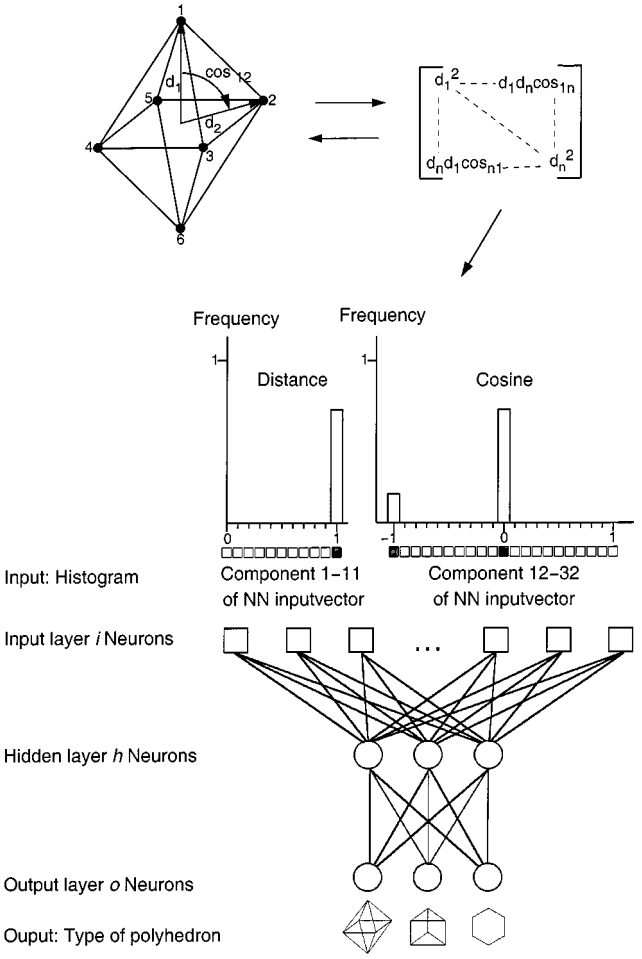

Figure 3. Sorting of *n*-point polyhedra into specific categories by neural networks. The top half of the diagram gives a shorthand illustration of how a vectorial representation of an ensemble of *n* points in space is obtained. An octahedron is deliberately selected as an example. The bottom half illustrates the type of network used. The input layer consists of $i = 32$ neurons to present the vector to the network. A hidden layer of $h = 3$ neurons connects this input layer to the output layer with $o = 3$ neurons. The network is trained to sort the bodies with respect to the class to which they have been assigned to (octahedron, trigonal prism, hexagon).

middle, Figure 2 bottom) and the vector may then be used as the input for a pattern recognition algorithm.

The histograms discussed are a projection of three-dimensional data onto a histographic function with just one independent variable. The advantage of this type of representation is that it is independent of translation and rotation of the body as well as of any permutation of the labeling scheme used to designate the points. Although much information is lost by projecting three-dimensional data this way, the patterns obtained do characterize the symmetry properties of the three-dimensional object (see above).

Fourier Transformation

A different type of projection from three-dimensional space onto a function with just one independent variable consists of a Fourier transformation of the distances spanned by the *n* points of the body. This type of transformation has a long-standing application in electron diffraction[27] and has recently been applied to the condensed description of molecular shape and constitution.[28,29] Application of this procedure is simple as it means to compute the sum

$$I(s) = \sum_{i=1}^{n-1} \sum_{j=i+1}^{n} A_i A_j \frac{\sin sd_{ij}}{sd_{ij}}$$

where *s* refers to the "scattering angle". If the distances *d* are measured in Angstroms its dimension is $Å^{-1}$. Computing this sum for $1 \leq s \leq 50$ produces values of this function at each of these 50 points in *s* space. The function itself is a weighted sum of sine functions of different periodicity. It is found, that for the problems analyzed, as little as the first 19 values of this function are sufficient due to the almost exponential decay of $I(s)$ versus *s*. A vector containing these 19 values of $I(s)$ at $s = 1,2,..,19$ may serve as input to a pattern recognition algorithm (Figure 2 top, $A_i = A_j = 1$ for $i,j = 1...n$).

A comparison of the three methods described, which are able to create specific one-dimensional projections of a set of *n* points in three-dimensional space, is shown in Figure 2. The bodies compared in this example are a regular octahedron and a trigonal prism with all edges of equal length. It can be seen that all three methods are able to differentiate these two types of body. Using the distances only, the discriminative power of the histogram in direct space and its Fourier transform equivalent in reciprocal space do not appear to be very different (Figure 2 top and middle). In fact, it has been found that the simple histographic representation of the distances in direct space is already an efficient tool, so the Fourier transform version of the distance-based code has not been used to a large extent in this work. In addition to the fact that the discriminative power of the Fourier transform representation is not significantly superior to the representation by the distances themselves, it lacks the immediate interpretability of the histogram of distances. In a sense the histogram of distances corresponds to the radial distribution curve to which diffraction data are transformed in order to extract structural information, while the Fourier transform[27] representation corresponds to the diffraction pattern itself. As is seen in Figure 2 a histographic representation of the metric matrix encoding for distances and angles has the highest power of discrimination of the three methods analyzed and is by far preferred.

All the above one-dimensional projections may be seen as kind of spectral representation of the three-dimensional bodies they represent. Specific signatures of these spectra may be interpreted as a kind of fingerprint indicating that some specific body, say an octahedron, trigonal prism, hexagon, tetrahedron, etc. is the origin of this fingerprint. While it is easy to correctly interpret these spectra if the ideal symmetry-defined bodies are at their origin, it is not so simple to extract this type of information by mere inspection if a distorted polyhedron is the origin of the spectra. In fact, if we draw away from the scalar differences for the moment, there is only one octahedron, an ideal body defined by symmetry alone. In the real world, however, there are many arrangements of six points in space which are

close to an octahedral arrangement. Any set of rules defining the extent to which a body may be distorted and still be categorized as belonging to the octahedral class is artificial, and the rules may well change in response to the questions asked. Instead of defining a set of rules in mathematically expressed restrictions of angles and distances, we adopt a different philosophy. It is argued that no arrangement of six points not completely defined by octahedral symmetry is a true octahedron.[30] Nature confronts us with all kinds of six point arrangements but we are still intuitively able to classify these arrangements as say octahedral, trigonal prismatic, and hexagonal by mere inspection of the bodies. Instead of using artificial mathematical rules for the purpose of classification of these bodies we may well rely upon our intuitive interpretation: We look at a body and see it is octahedral. We look at another one and see it is close to a plane hexagon and so on. We then classify the bodies according to what we see. It may be argued that this way of classification lacks any objectivity. However, there is no objectivity in mathematically formulated and artificial classification rules. Adopting the totally subjective view mentioned above introduces the unconventional consideration of personal judgment in science. However, if "truth" is only in the symmetry-defined ideal objects, anything outside this is a matter of taste and purpose. One might like to introduce some kind of objectivity in the manner of social science or psychology: one might present the bodies to be categorized to as many people as time allows and then base classification on a common sense evaluation. Strange as this point of view may appear when uttered in a scientific paper, the thorough logical evaluation of the situation will show that it is completely appropriate to the purpose.[30] The purpose of classification described in this paper is to classify the packing of molecules with respect to categories, which again, not considering scale, are ideals, defined by symmetry alone. Any classification of an observed packing as a distorted version of the ideal is not objective in a scientific sense and is very much biased by our desire to find this relation to one or the other of the ideal patterns.[31]

Neural Network Analysis

Instead of defining a mathematical set of rules to explicitly sort the bodies into different categories, neural networks[15–18] have been trained to choose these categories on the basis of the input vectors of the spectra described above. To train the networks a training set has to be constructed which contains not only the ideal symmetry determined bodies, but also bodies derived from these by random perturbation. To this end, the points defining the ideal body were allowed to occupy positions at random within a perturbation sphere located at the corresponding point of the ideal body. The bodies thus generated where inspected by examining different orientations of their representations on a computer screen and then categorized by inspection. The perturbation spheres were enlarged in a stepwise manner until the chance of finding a perturbed structure showing an apparent relation to the ideal structure was impracticably low e.g. no chance in ten trials. In this way, a training set of 281 polyhedra altogether was produced. The training set comprised the following classes, $n = 4$ square planar, tetrahedral, $n = 5$ pentagon, square pyramidal, trigonal bipyramidal, $n = 6$ hexagon, octahedron, trigonal prism. To analyze the whole set of data with a single network, the vectorial representation of the histograms referring to distance (Figure 2 middle) was augmented by a single coefficient which presented the number of points n underlying the pattern to the network. $1/n$ was used to represent this number. These vectors were then fed into the neural network, which was trained to sort the input into the correct output categories. To validate the trained network function an independent set of 64 distorted polyhedra, comprising all categories to which the network had been trained, was generated as above. It was observed that the categories found by the network were equal to those defined by inspection in 78% of the cases. Some of the "faults" committed by the network are easily explained: A square pyramid may be interpreted as an octahedron due to the fact that neural networks are capable of reconstructing patterns when some of the input data is missing or at error.[17,18] The $1/n$ term (see above) in the input vector did not adequately counter this tendency to pattern reconstitution. Therefore it was decided to use specific pattern recognition machines for every number n of points analyzed and it appeared reasonable to also use the spectral input derived from the metric matrix (Figure 2 bottom). Due to its greater discriminative power, this might not only improve the quality of predictions of the trained network, but it should also abbreviate the time necessary for training the network. The procedure adopted is schematically shown in Figure 3.

For any given arrangement of six points in the data set the metric matrix is calculated. The distances obtained from the diagonal terms of the matrix and the cosines derived from the off-diagonal terms are projected onto histograms, one for the distances and a second for the cosines. A vector representation of these histograms is obtained by discretisation of the distance part (the distances are scaled between zero and one) into 11 intervals and the cosine part into 21 intervals (Figure 3 middle). The vector of these 32 components is used to feed the input layer of a neural network that contains 32 input units. The network consists of this input layer, one hidden layer and one output layer. Whenever an input vector representing a body in the training set is fed into the network, it is simultaneously informed which of the three categories the body belongs to, and how far it is from the ideal. The corresponding qualifier between zero and one (zero no fit, one ideal fit) was obtained by visual inspection (Figure 4) of the body.

Training the network requires feeding the network with the input data and the expected results over and over again until there is no more change between the expected output and the output generated by the network in successive training cycles. At this point of convergence the strength of the connections between the individual neurons (lines in the diagram Figure 3) has been optimized such that the network as a whole automatically sorts the bodies into the cat-

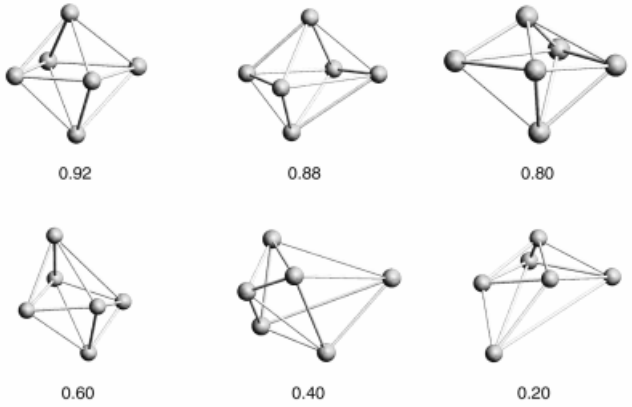

Figure 4. Distorted octahedra and their qualifiers. A few selected examples are shown. The qualifiers q were allotted by visual inspection. For the purpose of training the network only octahedra with qualifiers q greater than or equal to 0.8 were used.

egories in the best way it can. If the network is able to reproduce the artificial categorization of the bodies contained in the training set in an almost quantitative manner, it may be said that the network – with respect to the training bodies – "sees" what a human inspector would see when looking at the bodies themselves. The network is then able to reproduce the categories and qualifiers a human being would allocate by inspection, even for bodies it has never "seen" before. This means the machinery is capable of categorizing bodies in the same manner a human inspection of the bodies would. That is, the time-consuming task of inspecting a three-dimensional body by eye may be transferred to the neural network that produces the same result a human inspector would produce. This protocol was used for the subset of the polyhedra with $n = 6$. Not only was it found to lead to rapid convergence but it also led to a high quality of prediction. Based on a training set of 153 input vectors distributed over the three categories to be identified (octahedron, trigonal prism, hexagon) the square root of the mean standard error (see Experimental Section) after convergence of the training phase was only 0.017. To validate the trained network function, an independent set of 16 distorted polyhedra was generated as above, comprising all categories for which the network had been trained. It was observed that the categories found by the network were equal to those defined by inspection with a deviation between the predetermined and the calculated qualifiers of only 4.5%. Neural networks are thus found to be a sufficient filter to recognize the specific shape of an n-point body from a set of coordinates containing all kinds of n-point arrangements.

Second Moment Analysis

Since it had been found that the manner in which three-dimensional data is reduced to form a vector appropriate for input to the neural network had a large influence on the discriminative power of the trained network, another and a more traditional way of reducing the three-dimensional shape to just a few parameters has been analyzed. If a set of coordinate triples in three-dimensional space is considered to represent the coordinates of n points of equal mass, the tensor of inertia[32] associated with this set reflects the spatial distribution of these points. The lengths of the eigenvectors of this matrix of inertia characterize the shape of the body.[22,32–34] With respect to the bodies analyzed, both an ideal octahedron and an ideal tetrahedron will be characterized by three equal eigenvalues. The rotational symmetry of bodies such as the trigonal prism (C_3), trigonal bipyramid (C_3), and square pyramid (C_4) will produce two eigenvalues of the same size while the third may be different. A planar body such as a hexagon will give rise to one eigenvalue of zero. If the body has rotational symmetry, such as a hexagon with C_6 symmetry, the remaining two eigenvalues will be equal in size. The transformation of a set of points to the coordinate system defined by the eigenvectors of the matrix of inertia is a well established procedure in molecular crystallography, commonly used to define the "best plane" of a set of points.[22] In terms of pattern recognition this method is equivalent to describing the characteristics of a pattern defined by n points in three-dimensional space by its second moments.[23] Thus this method relates to a standard tool in the analysis of distributions which is also a type of pattern recognition technique.

If the masses of the n points of the ensemble analyzed are all taken to be one, the eigenvalues of the matrix of inertia are equal to the sum of the squares of the deviations of the points from the origin (center of mass) along the eigenvector axes. With respect to the bodies analyzed, this means that the eigenvectors will tend to increase with the number of points defining the bodies being analyzed. Thus the number of points is implicitly encoded in the size of the eigenvalues, given that the bodies are scaled such that they fit into a unit sphere and touch the sphere at at least one point. This condition is fulfilled for the training set as described above. In order to retain the information about the number of points n giving rise to a specific set of eigenvalues, and to make results comparable, the eigenvalues have to be scaled in an appropriate way. It has been found through a number of trials that with the conditions met in the training set, the discriminative power of this eigenvector analysis is optimized when each eigenvalue l is replaced by $l' = (1/3.5)\cdot l\cdot n$. To map the results onto a coordinate system defined by the eigenvectors in the interval zero to one, the coordinates are calculated as $l'^2/(l'^2 + 40)$. The results obtained for the training data set using this type of scaling are shown in Figure 5.

It can be seen that the different classes of bodies are, on average, neatly separated in this type of scaled eigenvector diagram. The eigenvalue filter has the advantage of projecting planar bodies onto the YZ plane (X representing the eigenvector axis associated with the smallest eigenvalue and Z corresponding to that with the largest eigenvalue). The only region where there is no clear separation is the one in which octahedra and trigonal prisms are projected (Figure 5). The degree of separation of trigonal bipyramids and square pyramids is also low. Since these bodies are well separated by the neural network technique (see above) it appears that a combination of the eigenvalue filter and the

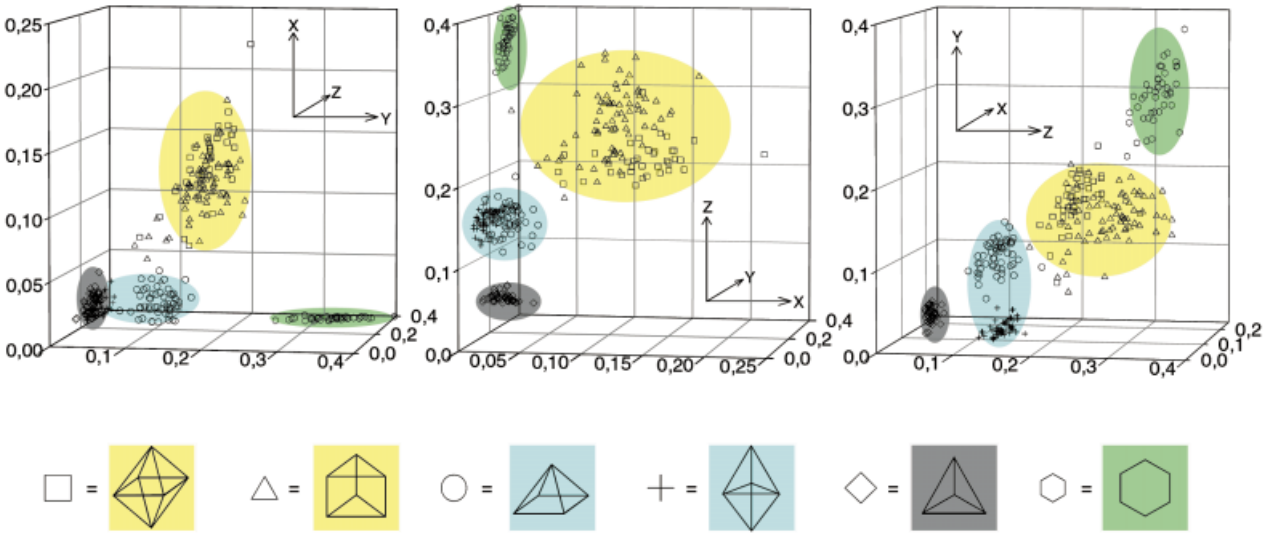

Figure 5. Sorting polyhedra in eigenvector space. The matrix of inertia of a body of n points is calculated with all points given equal weight. The eigenaxes of this matrix define the coordinate system X, Y, Z. The coordinate values are scaled in response to the eigenvalues and to the number of points comprising the body (see text). All three projections onto the eigenvector axes are shown.

neural network filter might be maximally discriminative. This method has therefore been applied as the basis of the work reported below.

Analysis of Packing

In this paper, analysis of the patterns formed by the geometric centers of the molecules within a crystal has been restricted to a search for the three basic types of closest packing. It is clear, however, that the methods developed are applicable to searching for any type of packing pattern.

The analysis has been conducted for the two patterns maximizing density (*fcc*, *hcp*) as well as for the *bcc* pattern, which maximizes the number of closest neighbors.[24] All three of these modes of packing may be described as networks of octahedra.[19–21] In the case of the two dense sphere packings, these octahedra are regular, while in the *bcc* packing mode they are tetragonally compressed. The connectivity of these octahedra, as well as the angles at which they are inclined with respect to each other, are different for the three types of packing (Figure 6; Table 1).

In the *fcc* mode the octahedra are connected via vertices and edges (Figure 6). The angles around the centers of the octahedra at the connecting points are decidedly different for these two types of connections (Table 1). In the *hcp* mode there are three types of connections, vertices, edges, faces (Figure 6) with the associated angles again being

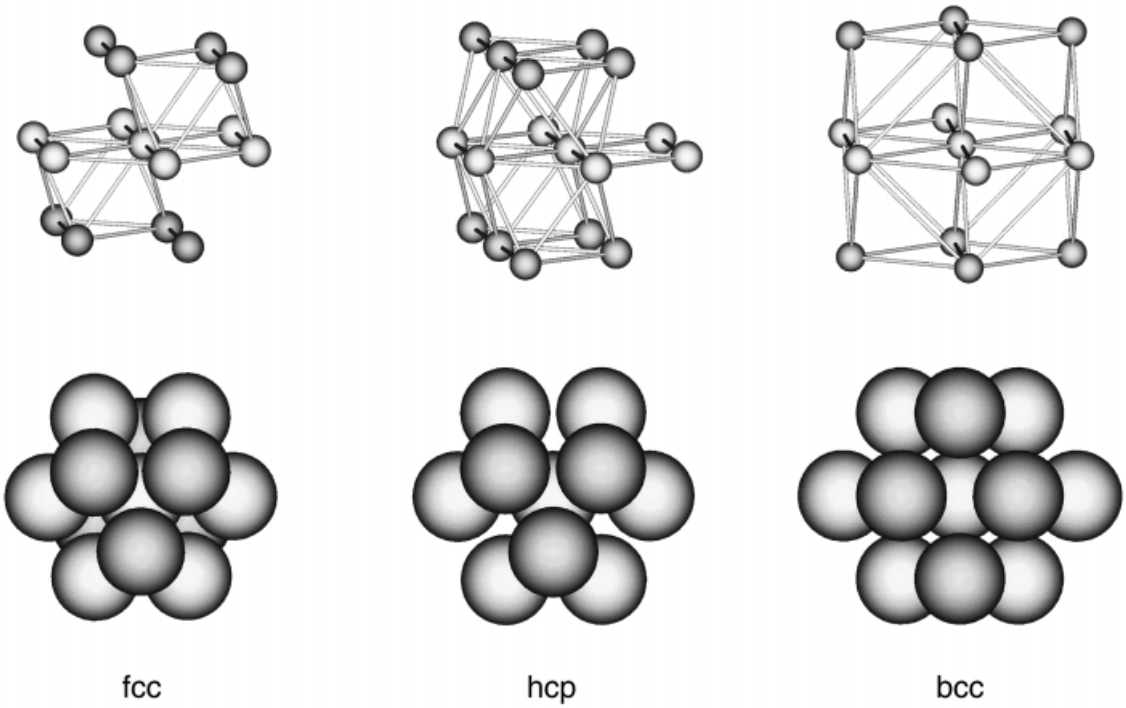

Figure 6. The three types of close packing shown as a network of octahedra (top) and as a stack of layers (bottom)

Table 1. Differentiation of octahedral networks by connection angles. The three basic packing types are described as networks made up of interconnecting octahedra. The octahedra are regular for the *fcc* and *hcp* cases but are tetragonally compressed for the *bcc* case. The values given refer to the angles subtended by the centers of the octahedra and their connecting points in the different modes of connection.

Packing type	Vertex	Edge	Face
fcc	180.0°	90.0°	–
hcp	131.8°	90.0°	70.5°
bcc	180.0°; 135.0°	90.0°	60.0°

within specific ranges (Table 1). The distorted octahedra making up a *bcc* packing also show vertex, edge and face bridging (Figure 6). The angles relevant to these bridging modes are again characteristic for the respective mode (Table 1). A similar type of description may be made with tetrahedra seen as the basic constituents.[19] It was felt that a description based on a network of octahedra[20] might be of higher discriminative power with respect to the problem at hand, since given a random repetitive pattern it is less probable to find six points making up an approximately octahedral shape than it is to find four points conforming to an approximately tetrahedral shape.

Examples

Compounds Crystallizing in Space Group R3

The procedure described above has been applied to a few classes of examples selected either by space group symmetry or by chemical composition. To start, an especially informative example was chosen. When analyzing the packing of a series of compounds which crystallize in the space group *R*3 and which have themselves crystallographic C_3 symmetry, some *bcc* and *fcc* packings should be found within the sample by applying the above methods. In this space group points lying at the C_3 axis will form ideal face-centered and body-centered cubic patterns at specific ratios of the lengths of the a and c axes of their hexagonal cells. A ratio of $a/c = 0.408$ results in an *fcc* packing and a ratio of $a/c = 1.633$ produces a *bcc* pattern.[35] Since the geometric centers of C_3 symmetric molecules necessarily lie on the crystallographic threefold axis, these ratios should also indicate ranges around which the corresponding type of packing will be observed. This means that an a priori assessment of the packing type is possible on the basis of this ratio.

On the other hand, the packing can be analyzed by the pattern recognition techniques described and the relevant packing modes can be delineated from this analysis in each case. If the pattern recognition techniques work well, it is expected that all structures for which the lattice constant ratio predicts a specific type of close packing are independently identified as the same kind of packing. It is in fact found that the predictions by the algorithm are in close agreement with predictions made on the basis of lattice constants (Table 2). This result is highly satisfying since it means that all distorted *fcc* and *bcc* patterns which are a consequence of only the actual axial ratio are found. As shown in Table 2, *bcc* and *fcc* packing modes are also found in ranges which are well outside the exact numbers of $a/c = 0.408$ and 1.633 respectively. The reason for choosing to analyze patterns of packing in space group *R*3 as the first example is also motivated by the idea that perhaps packing and molecular shape are correlated. In space group *R*3, with the centers of gravity of the C_3 symmetric molecules occupying positions at the crystallographic C_3 axis, layers are generated by the very symmetry of the space group. The stacking of these layers, which have the C_3 axis as the normal, is ABC, again solely by virtue of crystallographic symmetry.[35] Whether this kind of stacking of the densely packed layers will approximately correspond to a basic lattice type such as *fcc* depends on the dimensions of the lattice, which are again a consequence of the shape of the molecules.

Table 2. Data set analyzed for compounds crystallizing in space group *R*3. REFCODE refers to the name under which the compound is stored in the CSD. The numbers refer to the numbering scheme used in Figure 7. *a*/*c* gives the corresponding axial ratio with respect to hexagonal setting. The few cases for which a rhombohedral setting is stored in the database have been transformed to the corresponding hexagonal setting (see ref. [35]). Where no value for the *a*/*c* ratio is given the molecules do not occupy positions on a crystallographic C_3 axis. The designators in the columns "packing" refer to the idealized packing type as found by pattern analysis.

By using the eigenvalues of the tensor of inertia corresponding to the molecules, we can construct a graph which has the ratio of the length of the eigenaxis of intermediate size, *m*, to the largest one, *l*, (*m*/*l*) on one axis (horizontal axis in Figure 7) and the ratio of the smallest eigenvalue, *s*, to the intermediate one (*s*/*m*) on the other axis (vertical axis in Figure 7). This graph gives an idea of the overall shape of the molecules concerned.

Molecules projected close to the point (1,1) on this diagram are close to spherical in shape. Starting from this point (1,1) along the line $s/m = 1$, the molecular shape is

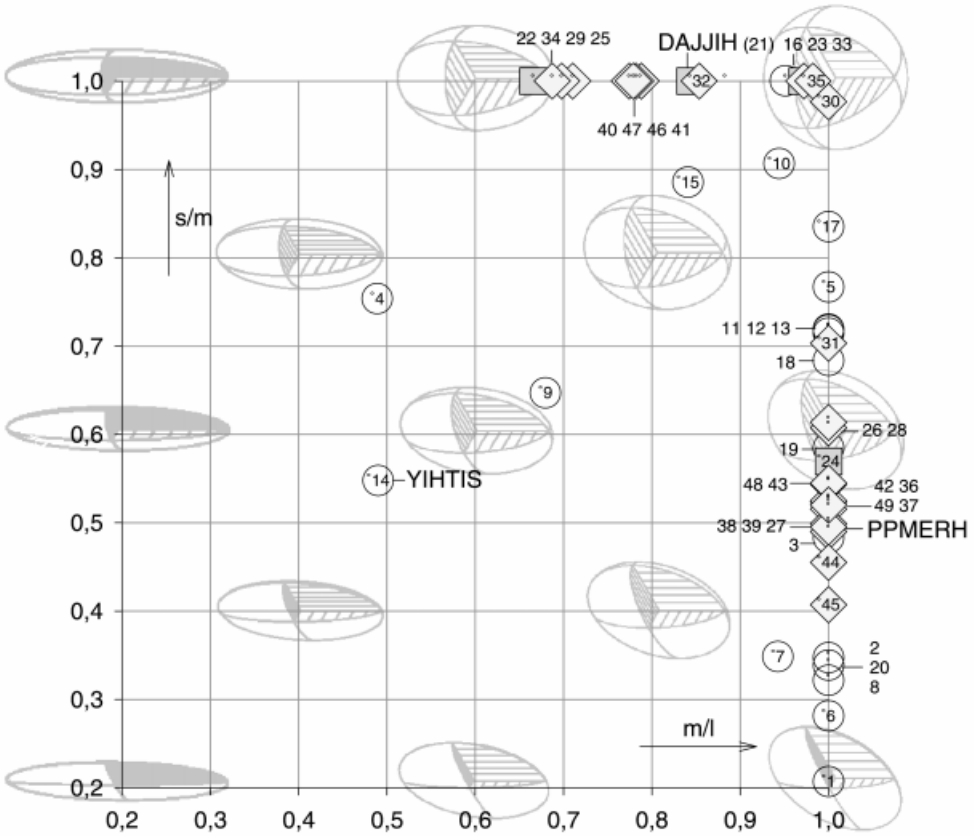

Figure 7. Molecular shape and packing of compounds crystallizing in space group *R*3. The diagram refers to the shape of the ellipsoid of inertia pertaining to each molecule analyzed. The vertical axis gives the ratio of the smallest eigenvalue of this ellipsoid to the intermediate one (*s*/*m*). The horizontal axis refers to the ratio of the intermediate eigenvalue to the largest one (*m*/*l*). The shape of the corresponding ellipsoids is shown in the background of the diagram. The numbers refer to the numbering scheme given in Table 2. In addition, three compounds are named by their REFCODE. The symbols have the following meanings: square *fcc*, diamond *bcc*, circle neither.

increasingly elongated along the C_3 axis. The smaller the value of *m*/*l* the more elongated the ellipsoid. Along the axis *m*/*l* = 1, again starting from the point (1,1), the molecules are increasingly compressed along the C_3 axes the smaller these *s*/*m* values are (Figure 7). Molecules which are not projected onto the axes (*s*/*m* = 1, *m*/*l* = 1) do not have rotational symmetry and all three eigenvalues of the ellipsoids are different. In space group *R*3 this means that these molecules (no 4, 7, 9, 10, 14, 15 see Figure 7, Table 2) are not located at special positions of the unit cell and are not necessarily C_3 symmetric.

The relation of the shape of the ellipsoid of inertia to the true molecular shape is a very reduced one. To present an idea of what this relation looks like Figure 8 shows three selected examples.

Compound no 21 (DAJJIH[36] Figure 7, Figure 8, left) is represented by an elongated ellipsoid. Compound no 39 (PPMERH[36] Figure 7, Figure 8, right) gives rise to a compressed ellipsoid. Both compounds are C_3 symmetric and the ellipsoids therefore show rotational symmetry. The third compound no 14 (YIHTIS[36] Figure 7, Figure 8, middle) gives rise to an ellipsoid with three different axial lengths. Even though the description of the true molecular shapes by their associated ellipsoids of inertia is a very simplified one this method has been used with success to classify the shape of compounds in a general way[33,34] and is also found to be useful in the present context.

When the algorithm described above is applied to the data set, a number of structures are sorted into either one of the two packings *bcc* (diamonds in Figure 7) or *fcc* (squares in Figure 7). Approximate *bcc* packing occurs more often than *fcc* arrangements in the data set analyzed (Figure 7, Table 2). It is to be noted that only structures containing C_3 symmetric molecules fall into these packing categories (*fcc*, *bcc*) and it may be argued that it is the rotational symmetry which allows for the formation of the closely packed layers.

Compounds $Cr(CO)_5L$

To further test the pattern recognition capabilities of the algorithms, a sample of $Cr(CO)_5L$ compounds, showing a wide structural variability and with no space group restrictions were selected for analysis. Among the 99 structures analyzed (Table 3) only 13 were found to fit into either one of the three search patterns *fcc*, *hcp*, *bcc*.

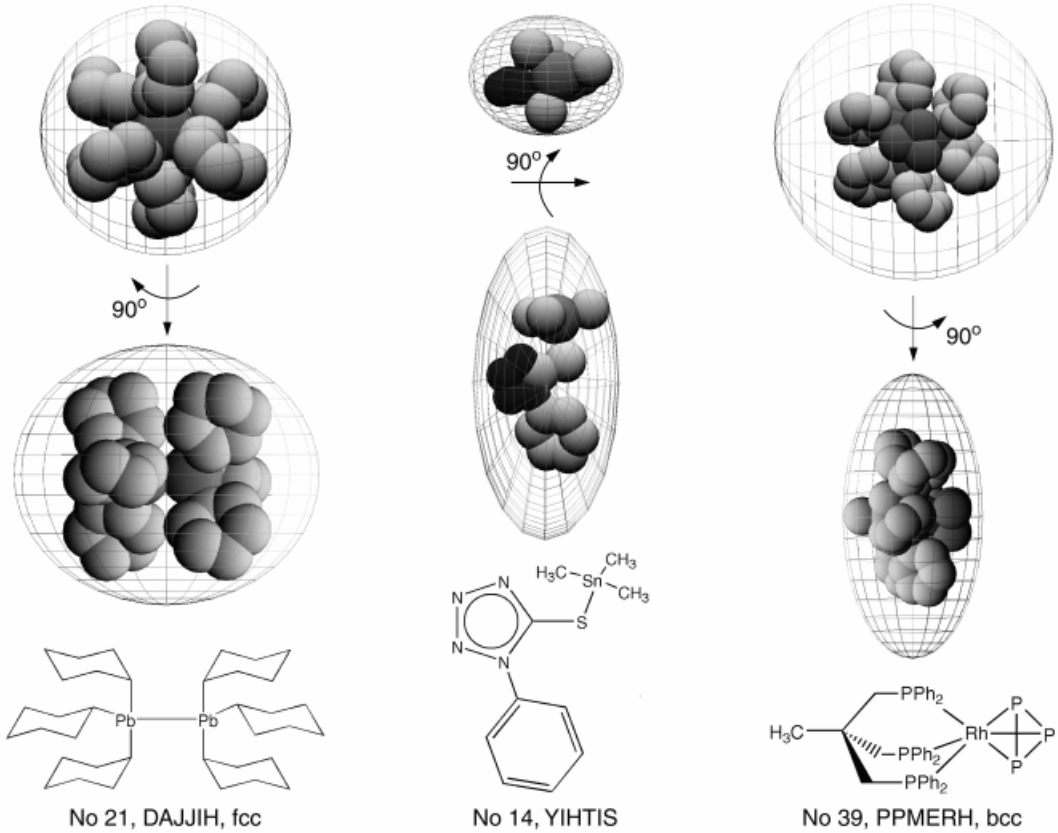

Figure 8. Description of molecular shape by ellipsoids of inertia. The numbers and designators refer to Figure 7 and Table 2. The ellipsoids are scaled such that the molecules fit into their envelope. The labels *fcc* and *bcc* refer to the idealized packing motif of the molecules.

The parent compound $Cr(CO)_6$, being octahedral in shape and thus being represented by a spherical envelope (no 99, coordinates 1,1 in diagram Figure 9) shows almost ideal hexagonal close packing. This has been previously noted by an appropriate visual inspection of the structure[37]. Close to the line $s/m = 1$, i.e. for ellipsoids which have two smaller eigenvalues of equal size, two additional *hcp* patterns are observed (no 90, 95 Figure 9). Close to this line *fcc* and *bcc* patterns are also found (no 83, 85, 89, 92 Figure 9). Out of the 99 structures only 13 are close to one of the idealized packing models, with *fcc* occurring more often than *hcp*, and *bcc* being observed only twice (no 83, 92 Figure 9). It is apparent from Figure 9 that the three basic packing motifs are only found in a range where either s/m or m/l, or both, are greater than 0.8, i.e. in a range where the ellipsoids are not distorted too far from rotational symmetry.

Figure 10 illustrates the relation between molecular shape and ellipsoidal envelope for three selected compounds (no 94, ZUKSED,[36] *fcc*; no 89, YIKSAM,[36] *fcc*; no 92, VOZMUS,[36] *bcc* in Figure 9) which pack in one of the modes analyzed.

Compound 94 gives an impression of how large the deviation from spherical symmetry may be to still allow for an approximate *fcc* type of packing. Compounds 89 and 92 are closer to spherical symmetry (see also diagram Figure 9) and their corresponding ellipsoids are closer to rotational symmetry than the one describing the shape of 94.

Compounds Containing a Tripod-Metal Entity

Due to the interest in the coordination chemistry of tripod metal templates, tripod transition metal compounds were selected as the next class for analysis. All compounds in the set are of the type $RCH_2C(CH_2X)(CH_2Y)(CH_2Z)ML_n$ (R = H, Alkyl, Aryl; X, Y, Z = NR_2, OR, SR, PR_2, PRR′). The constitutional C_3 symmetry of the tripod metal templates, which is exact when X = Y = Z, and may be still approximately so when X and Y and Z are similar, mirrors itself into the diagram Figure 11.

Obviously this constitutional C_3 symmetry is still dominant also in the structure of many of the tripod-ML_n compounds since they project close to the axes $s/m = 1$ and $m/l = 1$. As observed in the two previous examples, structures projecting close to these lines have a high probability of falling into one of the three idealized categories (*fcc*, *hcp*, *bcc*) which define the search pattern of this work. Out of the 44 examples (Table 4) 31 could be categorized this way. Only a few patterns of the *hcp* (no 38, 39, 40 in Figure 11) and *fcc* (no 36, 37 in Figure 11) types are observed. The

Table 3. Data set comprising compounds $Cr(CO)_5L$. REFCODE refers to the name under which the compound is stored in the CSD. The numbers refer to the numbering scheme used in Figure 9. The designators in the columns "packing" refer to the idealized packing type as found by pattern analysis. The designator *hl* assigned to structures 96, 97, and 98 means that the packing of the relevant compounds is characterized by layers of centered hexagons. This side result has been obtained by analyzing the data set on the basis of a filter searching for regular centered hexagons (see text).

greater majority of the patterns correspond to the *bcc* type of packing. By comparing Figure 11 with Figure 7, it appears that *bcc* forms the predominant type of packing in compounds whose inertial tensors give rise to compressed ellipsoids of rotational symmetry with the ratio of eigenvalues *s*/*m* around 0.55.

An illustration of the relation between the molecular shape of tripod metal compounds and the ellipsoids representing them is given in Figure 12.

The two molecules (no 43, NAXHID[36] Figure 12 left; no 42, DUMSUZ[36] Figure 12 middle; see also Figure 11) give rise to ellipsoids with close to rotational symmetry and to a packing which can be classified as idealized *bcc*, while the one showing less apparent symmetry (no 4, LEMFUE[36] Figure 12 right; see also Figure 11) does not fall into one of the three categories with respect to packing.

Correlation Between Packing and Molecular Shape

By comparing the results obtained from trying to correlate the shape of molecules with their mode of packing within a molecular crystal it appears that there is a definitive correlation between the shape and the tendency to pack in one of the three basic packing types, *fcc*, *hcp*, *bcc*. An overlay of Figures 7, 9, 11 is shown in Figure 13.

The results described above for each set of compounds separately are collectively presented in Figure 13. It is apparent that the examples studied map into a range of around $0.3 \leq s/m \leq 1.0$, $0.3 \leq m/l \leq 1.0$. The data tend to accumulate along the lines $s/m = 1$ and especially $m/l = 1$ while the rest of the area $s/m \geq 0.4$, $m/l \geq 0.5$ is almost randomly populated. A total of 193 compounds is represented in Figure 13. The compounds whose packings do not conform to one of the three search patterns are marked by crosses, while the ones that fit are labeled by the appropriate symbols. The area to which the compounds are mapped, and for which assignment to one of the three packing modes is possible, is shaded in yellow in the diagram. Assignment is possible for 73 compounds out of 193. This area is characterized by the symmetry of the ellipsoids describing the shape of the molecules being not too far from rotational. The deviation from rotational symmetry which still allows for one of the three basic packing types may be up to 20% ($s/m = 0.8$, $m/l > 0.8$). When the deviation is larger than this, no *fcc*, *hcp*, or *bcc* packing is found in the sample of 193 compounds (Figure 13). This is a pleasing result as it correlates molecular shape and symmetry with the probability of forming one of the sphere packing modes within a crystal. A possible explanation may be that close packing

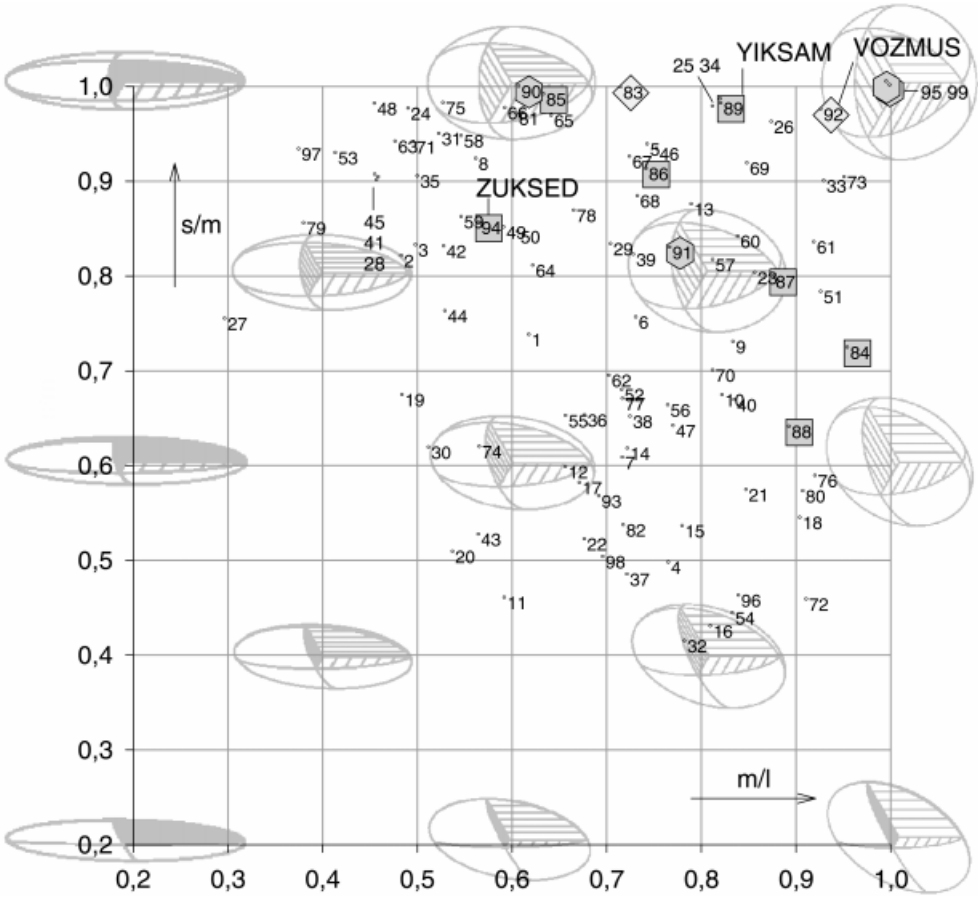

Figure 9. Molecular shape and packing of compounds $Cr(CO)_5L$. The diagram refers to the shape of the ellipsoid of inertia pertaining to each molecule analyzed. The vertical axis gives the ratio of the smallest eigenvalue of this ellipsoid to the intermediate one (*s*/*m*). The horizontal axis refers to the ratio of the intermediate eigenvalue to the largest one (*m*/*l*). The shape of the corresponding ellipsoids is shown in the background of the diagram. The numbers refer to the numbering scheme given in Table 3. In addition, three compounds are named by their REFCODE. within layers is optimal when the perimeter of the molecule within the layer is close to circular. The ratios in which the three types of packing *fcc*, *hcp*, *bcc* are observed in the sample shown in Figure 13 is 13:7:53. Even if the sample may be too small to derive any general rule from this finding, one of the reasons which might favor a *bcc* type of

packing over the other two packing modes is that, with respect to packing spheres, the *fcc* and *hcp* modes are the optimal solutions as far as efficient use of the available space is concerned. Body centered cubic packing, on the other hand, is the optimal solution with respect to maximizing the number of short direct contacts between neighboring spheres.[24] It may well be that maximizing the number of contacts does more to stabilize a molecular crystal than does the optimal use of space.

Conclusion

1. Pattern recognition techniques have been developed which allow for classification of a given set of *n* points in three-dimensional space as being similar to a predefined pattern of the same number of points. The predefined pattern may be any type of chemically interesting polyhedron or may be some other type of pattern that might be of interest. The techniques are such that the quality of fit between a given arrangement of points with one or the other of the predefined categories is quantified as a number between zero and one. Predefinition of patterns relies upon training a neural network to "see" what a human observer would see. Whenever a specific category has to be predefined, a set of training data has to be produced by randomly distorting the ideal pattern. The distorted patterns are inspected and ranked from zero to one according to similarity to and recognizability of the ideal pattern.

2. Several methods to encode three-dimensional structural data into a vector suitable as input to neural networks are reported and it is found that projecting the distance and angle data of the metric matrix of a structure in histographic form onto the vector is a highly efficient strategy.

In addition to this novel pattern recognition technique, the more traditional second moment analysis based upon the matrix of inertia and its eigenvalues is also used.

3. The packing of molecules within a crystal is analyzed with respect to whether the pattern observed might be described as a derivative of one of the three basic types of sphere packing *fcc*, *hcp*, *bcc*. To this end, the molecules are represented by the coordinates of their geometric centers. By symmetry expansion, a minimum number of *m* nearest neighbors within a sphere is generated and all six-point combinations for this set of points are analyzed for octahedral geometry. The octahedral arrangements found are evaluated with respect to their connectivity and to the angles that describe this connectivity. From the type of connectivity found, discrimination between the classes – *fcc*, *hcp*, *bcc*, none of these – is possible.

4. Three sets of compounds – containing a total of 193 organometallic structures – are analyzed with respect to whether the packing modes adopted within the crystals may be described as a variation of one of the three basic types

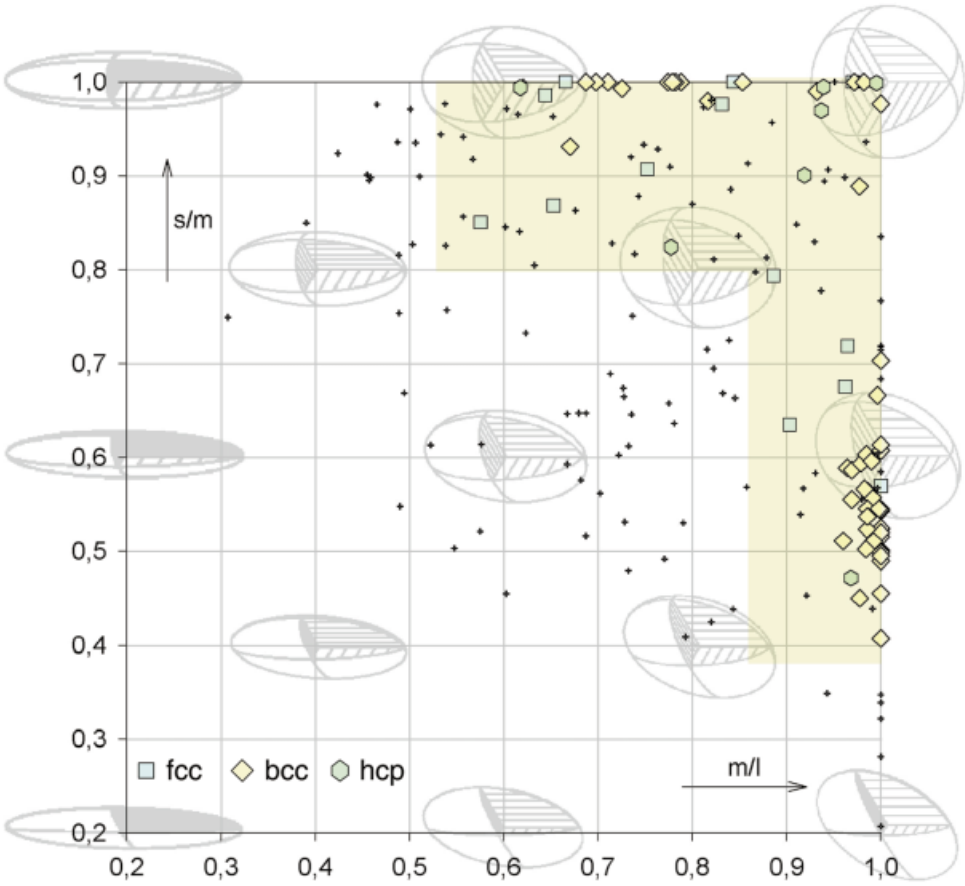

Figure 13. Relation between molecular shape and molecular packing over all data sets analyzed. The diagram refers to the shape of the ellipsoid of inertia pertaining to each molecule analyzed. The vertical axis gives the ratio of the smallest eigenvalue of this ellipsoid to the intermediate one (*s*/*m*). The horizontal axis refers to the ratio of the intermediate eigenvalue to the largest one (*m*/*l*). The shape of the corresponding ellipsoids is shown in the background of the diagram. Only molecules whose shape ellipsoids fall into the area shaded in yellow fall into one of the specified packing categories. Molecules whose shape indicators are shown as a cross do not fall into any of the packing categories analyzed.

of sphere packing. The relevant crystal data are taken from the CSD. One set comprises all organometallic compounds crystallizing in the space group *R*3. The second set contains compounds $Cr(CO)_5L$ and the third one all tripod metal derivatives $RCH_2C(CH_2X)(CH_2Y)(CH_2Z)ML_n$ (R = H, Alkyl, Aryl; X, Y, Z = NR_2, OR, SR, PR_2, PRR′). It is found that the probability of a structure falling into one of the three classes is connected with the shape of the molecules. If the shape is described by the proportions of the eigenvalues of the matrix of inertia corresponding to the molecule, the appropriate diagrams reveal that a packing mode close to one of the three types of sphere packing is most probable when the ellipsoid of inertia has rotational symmetry, i.e. if the compound has approximate C_3 or higher rotational symmetry. Compounds represented by ellipsoids devoid of rotational symmetry may still adopt one of the basic sphere packing types if the relevant eigenvalues do not differ by more than 20% from the mean. At greater ellipticities no match with the search pattern was found.

Experimental Section

Construction of a Data Set Comprising Specified Polyhedra: The data set for training the neural network and calibration of the second moment analysis was generated using a program that allows for the random distortion of ideal polyhedra. From the vertices of an ideal polyhedron, each new vertex of the distorted polyhedron is chosen by randomly selecting a point within a sphere around the vertex of the ideal polyhedron. The degree of distortion can be controlled by the radius of this sphere. As distortion of an ideal polyhedron performed in this way leads rapidly to geometries far from the ideal, a second parameter was introduced to control the distance between the vertices. For each distortion process of a given type of polyhedron, one selects the radius of the distortion sphere (see above), the percentage the distances are allowed to deviate from the ideal polyhedron and the number of distorted polyhedra to be generated. Using this procedure a data set of 381 polyhedra consisting of 37 squares, 43 tetrahedra, 36 pentagons, 55 square pyramids, 54 trigonal bipyramids, 50 hexagons, 73 trigonal prisms, and 38 octahedra including the ideal polyhedra was generated. The degree of distortion was evaluated by visual inspection of each polyhedron. The polyhedron was visualized on a computer screen in any desired orientation. The quality of fit of each polyhedron to the ideal was judged by inspection and a qualifier between $q = 0$ (no fit at all) and $q = 1$ (perfect fit) was allotted. Figure 4 gives an idea of how this subjective assignment of the quality of fit was done. With the specific pattern analysis problem in mind, only those polyhedra for which the qualifier was above 0.8 were incorporated into the training set, giving a total of 381 polyhedra together with the qualifiers (see above). Figure 14 shows six octahedra together with their qualifiers as an example.[38]

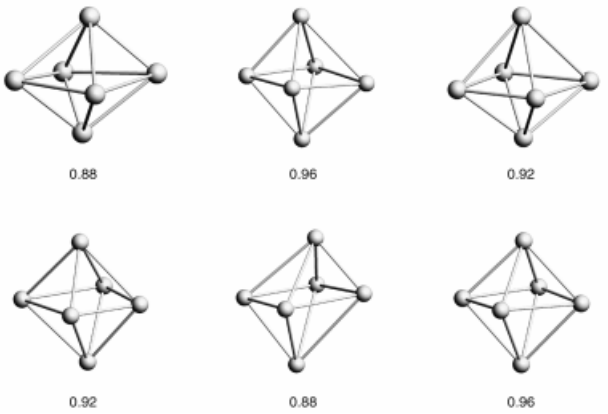

Figure 14. Example of six octahedra with qualifiers above 0.8. The octahedra were generated by randomly distorting an ideal octahedron. The qualifiers indicated by the numbers were allotted by inspection (see text).

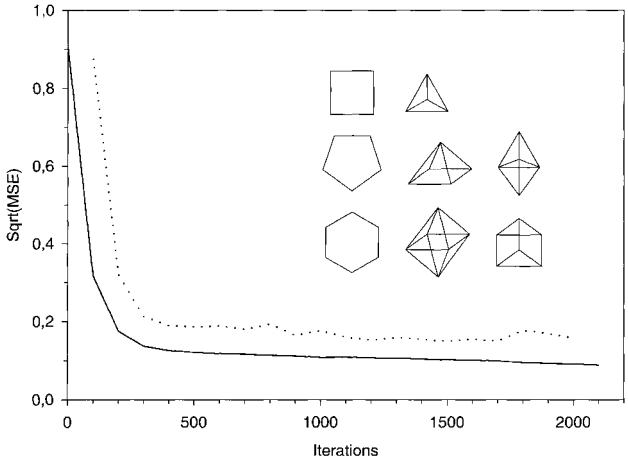

Figure 15. Training of a neural network. The network is designed (see text) to sort the types of polyhedra shown in the inset into their appropriate categories. It was trained on the basis of 281 reference polyhedra. The quality by which the learning pattern is reproduced is represented by the solid line. The quality of prediction for bodies not contained in the training data set is shown by the dashed line.

Sorting of Polyhedra With $4 \leq n \leq 6$ Vertices: The neural network simulator program SNNS,[39] version 4.1 was used. In this work only neural networks of the *feed forward* type were used.[40,41] Such a network consists of an input layer with the number of i input neurons depending on the dimension of the input vector; one or more hidden layers with a number of h hidden neurons and an output layer with the number of o output neurons depending on the dimension of the output vector (see Figure 3). The neurons between each layer are connected and each connection has a specific weight. During the learning process the individual patterns are presented to the network and the weights are adjusted such that the error between the given output vector and the calculated one is minimized.

Figure 15 (solid line) shows the progress of the learning procedure for a network with 27 input neurons, three hidden neurons and nine output neurons, which was trained with a data set containing a total of 281 polyhedra of the types shown in this figure. The shapes of these polyhedra were encoded into a vector based on the method outlined as described in Figure 3 (see above). In contrast to the example shown in Figure 3, the distance part of this vector was limited to only six components, since distances shorter than one half of the maximum distance did not occur in the data set as a consequence of the qualifier being set to q 0.8 (see above). The number of points comprising the individual types of polyhedra was implicitly encoded. Instead of normalizing the ordinate values (''frequency'' in Figure 3) in the histographic representations (for instance by setting the maximal frequency value to one in each case) the frequencies f were mapped onto an ordinate range $0 \leq$ ordinate < 1 by using $f^2/(f^2 + 40)$ as the ordinate value. This means that ordinate values will tend to be larger with larger numbers of points.

As far as convergence of the learning procedure is concerned, the dashed line in Figure 15 shows the root mean square error for a validation data set of 100 patterns containing the same kind of polyhedra as the training set. The root mean square error is defined as the square root of the mean standard error. The mean standard error (MSE) is the sum of the squared deviations between the calculated and the given components of the output vector for all training patterns divided by the number of training patterns. The root mean square error thus indicates the deviation of the output vector as a whole. The deviation of one component of the output vector is calculated as the sum of the squared distances between the calculated and the given output vectors for all training patterns, divided by the number of training patterns and by the number of vector components. The scale of the vertical axis in Figure 15 would then be reduced by a factor of nine (nine output neurons, eight for the bodies shown in Figure 15, a specific one for each body and one extra neuron introduced as a test. This ninth output neuron should only have large numbers $0 \leq q \leq 1$ allotted to it if the body analyzed has no relation to any of the types presented in the training set). The deviation of the individual components is on the order of 0.02 on a scale $0 \leq q \leq 1$. It can be seen that there is no large difference between the straight and the dashed lines. This means that the trained network cannot only recognize the patterns included in the training set but also recognizes patterns which have not been part of the training set.

Sorting of Polyhedra With $n = 6$ Vertices With Respect to Crystal Packing: For the particular problem of pattern recognition with respect to crystal packing, a neural network of the *feed forward* type was trained to filter hexagons, trigonal prisms, and octahedra from ensembles of six points in three-dimensional space. The data set comprised 153 patterns, 43 hexagons, 38 octahedra, and 73 trigonal prisms. This data set was split by random selection into a training set of 137 patterns (35 hexagons, 34 octahedra, 68 prisms) and a validation set of 16 patterns (7 hexagons, 4 octahedra, 5 prisms). The manner in which the data set is separated into different training and validation sets has no great influence on the result. The neural network contained 27 input neurons, six hidden neurons and three output neurons as is schematically shown in Figure 3 where only three hidden neurons are shown. Experiments with different modifications of this type of network suggested that six hidden neurons – as was finally used – is close to the optimum. Each output neuron represents one of the three trained classes (hexagon, octahedron, trigonal prism). The training parameters used with SNNS[39] were as follows:

Learning func: *Backprop Momentum*; Update func: *Topological Order*; Init func: *Randomize Weights*; Learning parameters: *0.6 0.1 0.05 0.05*; Iterations: *500*

Validation of the trained network with the validation data set resulted in a prediction capability of 95.5% with respect to the qualifiers q allocating the polyhedra to their corresponding categories.

The question of practical interest is whether any polyhedron was allocated to an incorrect class. It was found that the classification by the network was 100% correct in this respect, i.e. all polyhedra were correctly assigned to their corresponding class.

Second Moment Analysis: As described above, second moment analysis is another, more traditional method of pattern analysis. The method was used in this case to classify the polyhedra of the data set described at the beginning of the experimental section. For each polyhedron with p vertices one has to calculate the center of mass. The coordinates for each vertex are translated such that the center of mass is at the origin of an orthogonal coordinate system. The new orthogonal coordinates (x_i, y_i, z_i) of the p vertices build up a $3 \times p$ matrix **A**

$$\boldsymbol{A} = \begin{bmatrix} x_1 & x_2 & \cdots & \cdots & x_p \\ y_1 & y_2 & \cdots & \cdots & y_p \\ z_1 & z_2 & \cdots & \cdots & z_p \end{bmatrix}$$

which is multiplied with the transposed matrix $\mathbf{A}^T$ to give a new 3×3 matrix $\mathbf{B} = \mathbf{A}\mathbf{A}^T$. The matrix **B** can be expressed as $\mathbf{B} = \mathbf{X}\Lambda\mathbf{X}^T$, where Λ is the eigenvalue matrix holding the eigenvalues λ_1, λ_2, λ_3 as diagonal elements and **X** is the eigenvector matrix which holds the eigenvectors. The eigenvalues describe the shape of the ellipsoid of inertia which has some relation to the shape of the polyhedron. In order to retain information about the number of points giving rise to a specific set of eigenvalues and at the same time to make results comparable, the eigenvalues have to be scaled in an appropriate way. It has been found through a number of trials that, with the conditions met in the training set, the discriminative power of this eigenvector analysis with respect to separate bodies with n different vertices into individual categories is optimized when each eigenvalue λ_i is replaced by

$$r_i = \lambda_i \cdot \frac{n}{3.5} \quad i = 1,2,3$$

with the scaling function being

$$e_i = \frac{r_i^2}{r_i^2 + 40}$$

The results obtained for the training data set using this type of scaling are shown in Figure 5. The axes X, Y, Z represent the scaled eigenvalues e_i (i = 1, 2, 3). It can be seen that there is a fair separation for some kinds of polyhedra but also that octahedra and trigonal prisms as well as square pyramids and trigonal bipyramids are not well separated. The regions to which the different kinds of polyhedra are mapped to in this diagram are numerically shown in Table 5.

Table 5. Classification of polyhedra by their inertial tensors. The table refers to Figure 5. The coordinates X, Y, Z relate to the eigenvalues of their inertial tensor with a scaling function applied as described in the text. The following abbreviations are used: sq. py square pyramid; trigbpy trigonal bipyramid; oct octahedron; trig pr trigonal prism

Packing Analysis: Figure 16 illustrates the general strategy adopted. Given the coordinates of the atoms of the independent molecules within a unit cell and the dimensions and symmetry of the cell, the centers of gravity of all molecules contained in the volume of the unit cell are generated (Figure 16 I→II). The pattern thus obtained is expanded by translational symmetry (Figure 16 II→III). A point in the center of this expanded pattern is selected and its nearest neighbors (16 to start with) are found. Using the pattern recognition tools described above, all octahedra formed by any six of these 16+1 points which are above a certain quality threshold q are found. This qualifier is used to select those six point arrangements which most probably fit together to describe the packing by sharing vertices, edges and faces. In a first attempt, the value of the qualifier $q = 0.9$ is set as the lower limit and from the subgroup of octahedra transgressing this border, pairs of octahedra are selected according to the additional restriction that their qualifiers should be numerically as close together as possible. The connectivity between these pairs of octahedra is then analyzed. The process is repeated with all possible combinations. Based on the entire set of connectivities and their corresponding angles, the packing is classified as belonging to one of the three classes. If no octahedra that fulfill the above conditions are found the thresholds are reduced and the process is repeated. If no fit is found with the qualifiers still having values above $q = 0.8$, the number of points selected in the starting set is increased by one and the procedure is repeated. If no fit is found for up to 24 points in the starting set the packing is considered to not be one of the three types analyzed. In successful cases, this procedure is illustrated as step III→IV in Figure 16. While the thresholds and limits as defined do not have a theoretical foundation, they have been found to be practically sufficient to find any type of packing which has some apparent relation to the three basic packing types analyzed.

Since it is well-known that many patterns of packing involve densely packed layers of molecules, even though these layers are not stacked in such a way as to give rise to one of the three special packing modes discussed above (*fcc*, *hcp*, *bcc*), the search for densely packed layers appears especially worthwhile since the appropriate filters are available (see above). The search may be done by filtering for regular hexagons, independent whether they are centered or not. These hexagons will be filtered out as already described. As an alternative, centered hexagons may be filtered out solely by the application of second moment analysis. This search is done by momentum analysis (see second moment analysis) in order to qualify the seven point arrangements with respect to their planarity (length of the smallest eigenvector). This qualifier *eval* is later used as a parameter in the final filtering function. As a second parameter for this filter-function, the geometric center X of the seven points p_i (i = 1 ... 7) is calculated. The distances d_i from X to all seven points p_i are determined. The smallest of these, d_m, is discarded (the point p_m leading to the smallest distance d_m should be the idealized center of the hexagon). The mean, d_{mean}, of the six distances d_i ($i \neq m$) is calculated. The sum of the differences between the individual distances d_i ($i \neq m$) and their mean value, d_{mean}, is used as the parameter *ldiff*. For a close to regular centered hexagon *ldiff* should be as small as possible. In order to find the hexagons of minimum size the sum of the distances d_i ($i \neq m$) is chosen as the third parameter *lsum*. The filter function *over* is defined as

$$over_i = 1.5 \cdot \left(\frac{eval_i}{eval_{max}}\right) + \left(\frac{ldiff_i}{ldiff_{max}}\right) + \left(\frac{lsum_i}{lsum_{max}}\right)$$

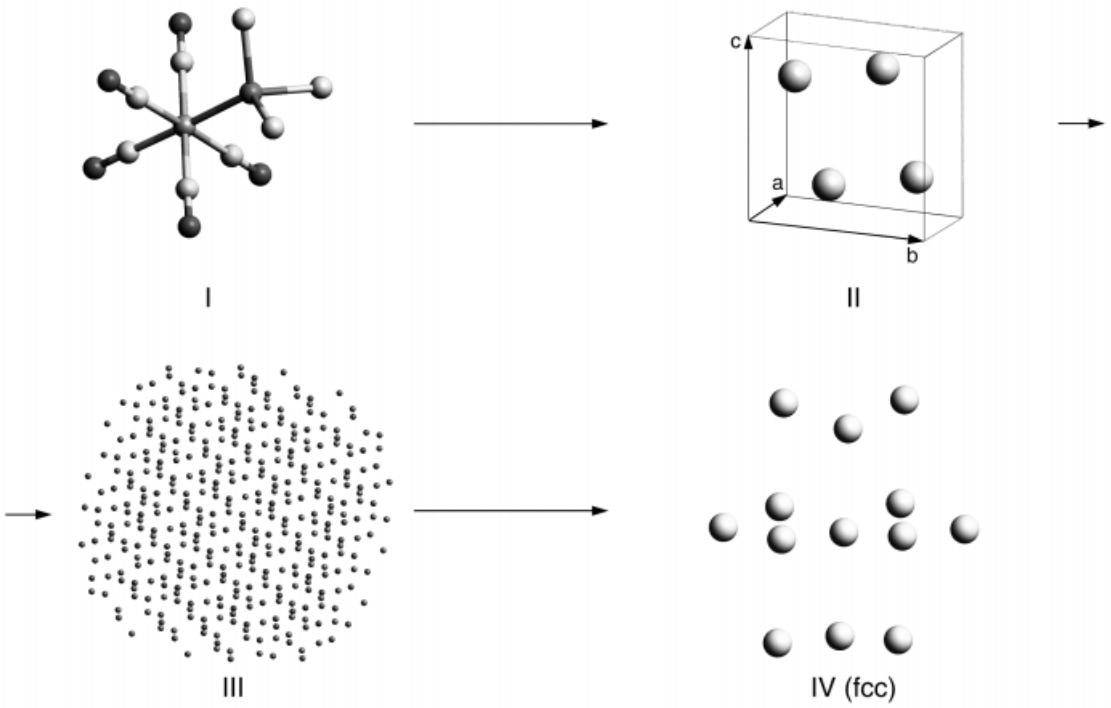

Figure 16. Schematic illustration of the strategy. Molecules within a crystal are replaced by their centers of geometry. The packing of these centers is analyzed by pattern search methods for its similarity to some predefined pattern.

$eval_{max}$ is the largest value of *eval* within the set of seven point arrangements analyzed, comprising a total of 16+1 over 7 individual arrangements. Correspondingly, $ldiff_{max}$ and $lsum_{max}$ are the maximum values found for any seven point combination within the set. Weighting the first term by 1.5 against a weight of 1 for the other terms means that planarity is taken as the most important criterion. The coefficients as well as the type of functions suitable for a filter function have been determined by trial an error. In this manner, any close packed layers are automatically found for any structure analyzed. The centered hexagon with the smallest value *over* is taken as the best plane in the search of an idealized unit cell.

Construction of a Unit Cell: The information about close packed layers obtained by the procedure described above is useful in several aspects. It may be used to project the structure – be it reduced to one central point per molecule or the complete structure – onto this densely packed plane. If the molecules are represented by points, the kind of pattern seen in this projection immediately illustrates the type of packing (see Figure 6). Layer structures with different types of stacking of the individual layers are also immediately identified (see Table 3).

In a second application, the information about layers containing centered hexagons may be used to construct an idealized unit cell. The hexagon is part of a (1,1,1) layer in the *fcc* case (layer stacking ABC) or a (1,1,0) layer in the *bcc* case (layer stacking ABA). In the latter case, even ideal hexagons do not have the full D_{6h} symmetry– which characterizes an *fcc* or *hcp* packing – but are elongated and have maximally D_{2h} symmetry. To find an idealized cube with the appropriate centering with the experimental points as its vertices and centers, the connectivity between the points of such a cube is automatically determined on the basis of the known connectivity of the ideal bodies and of their orientation with respect to the layers.

Figure 17 represents an example of such a body (data from YIKSAM,[36] no. 89 Table 3, Figure 10). In the center of this figure, the body is shown in a projection usually used for illustrating a face-centered cubic cell. At the sides of this figure, projections along the four space diagonals of this body are shown, illustrating that the packing and stacking of close packed planes is very similar in these four directions, as it should be for an *fcc* type packing, where four projections would be identical in the ideal case. The body shown in Figure 17, in addition to not being an exact cube, is not even a parallelepiped and will therefore not be suitable to

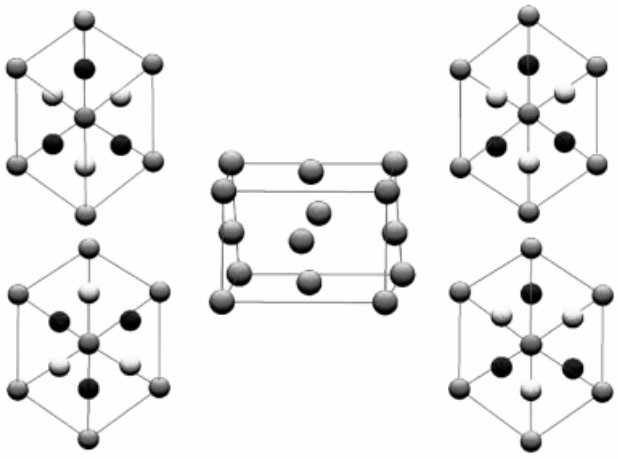

Figure 17. Idealized *fcc* arrangement of one of the specimens analyzed. The figure refers to YIKSAM (Table 3, Figure 10). A projection illustrating the approximate face-centering is shown in the middle. The four independent views of the packing along the four space diagonals of the body shown in the middle are shown at the sides.

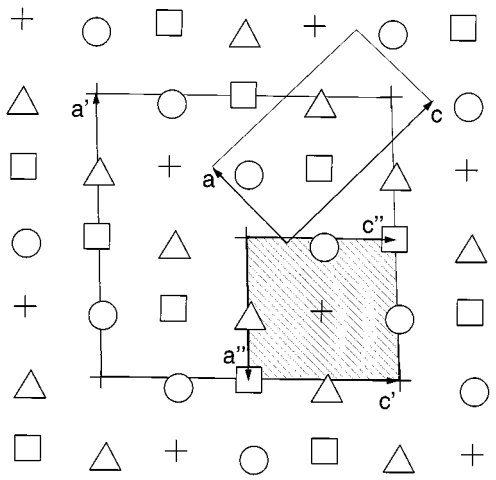
describe a crystal, which is an object characterized by translational symmetry. The specific simple example (YIKSAM) is shown in Figure 18 in a two-dimensional projection.



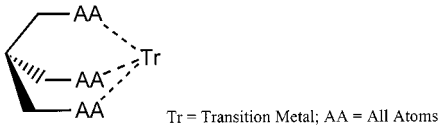


Figure 18. Relation between packing motif and unit cell. The data refer to YIKSAM (Table 3, Figure 10). The packing motif already shown in the middle of Figure 17 is projected onto one of its approximately square faces (shaded area). The axes defining this area are designated a′′, c′′. The axes of the original unit cell are indicated by a and c with the third axis b being perpendicular to a and c. While the shaded area is not yet a repeating unit, a unit cell defined by a′ and c′ is. The length of the axis b has to be doubled.

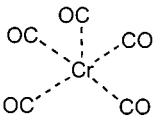
The crystallographic unit cell is indicated by the vectors a and c. The four points within this unit cell are designated by four different symbols relating to the different coordinates with respect to the third axis b, which is perpendicular to the projection. The idealized face-centered pattern is indicated by an approximately square shaded area. Since the points symbolized by squares and crosses are at approximately the same elevation, they may together form the face of a cube. The points symbolized by circles and triangles again have rather similar coordinates along the b axis but the elevation along this axis is different from that of the points forming the face of the cube. These points (circles, triangles) are the ones centering the faces parallel to the direction of projection. It can be seen that the shaded square is not yet a repetitive unit but that doubling the lengths of its axes a′′, c′′ will give a true repetitive unit, designated by a′ and c′ in the diagram. Once the packing is characterized as belonging to one of the cubic pattern modes, it is possible to construct a body with eight vertices and the respective centering with the experimental points. To find the corresponding repetitive unit the edges of this body, which are close to perpendicular with each other, are used to define a parallelepiped. The axes of this parallelepiped are then expressed in terms of the axes of the original unit cell and based on the restriction that only integer multiples of the original axes are capable of constructing a repetitive pattern, a new unit cell which is a true unit cell and contains the centered bodies as constituents is constructed. This cell may be several times larger than the basic crystallographic unit cell (Figure 18).



The algebraic details of this transformation are the following: Let a′′, b′′, c′′ be the three vectors which approximately correspond to a description of the body and let a, b, c be the base vectors of the crystallographic unit cell (Figure 18). We then search for a matrix **R**, which transforms the matrix **A** formed by the rows a, b, c into the matrix **B** composed of the rows a′′, b′′, c′′. Since both matrices are nonsingular by definition, the matrix **R** is equal to the product of **B** and the inverse of **A** ($\mathbf{R} = \mathbf{B}\cdot\mathbf{A}^{-1}$; $\mathbf{R}\cdot\mathbf{A} = \mathbf{B}$). The matrix **R** may have non-integer coefficients. Within one row of this matrix, the multipliers that make the coefficients integer, or at least close to integer, are determined and the row is multiplied by the product of these multipliers. Multiplying **A** by this modified matrix results in the best approximation to a cell that is at the same time a true repetitive unit and has the closest relation to the packing type.

Data Sets: All structures were retrieved from the August 1998 version of the CSD.[3] For all searches the parameters NRES = 1 and $Z' \leq 1$ were used. In the case of the structures in the space group *R*3, the parameters SPGN = 146 and atom type Tr were used.

For the molecules with tripodal ligands the search fragment was the following:

For the $Cr(CO)_5L$ structures the search fragment was:

Programs and Equipment: All calculations were carried out on a Silicon Graphics Indigo^2 R4400 workstation, 200 MHz, 128 MB RAM, operating under IRIX 5.3.

The described algorithm was implemented in the new program *crystpack* written in C (≈ 20,000 lines source code) using Motif[42] as graphical user interface and OpenGL[43] for rendering. The program is designed for use under Unix and Linux platforms and is available as source code via www.rzuser.uni-heidelberg.de/~il1/crystpack.html. The program makes use of the SGInfo[44] package. For the purpose of illustration the ZORTEP[45] version of ORTEP[46] and the program package InsightII[47] were used.

Acknowledgments

Fruitful discussions with the late Dr. Laszlo Zsolnai about crystallographic details are gratefully acknowledged, as are the helpful, and at times even enlightening discussions with colleagues Dr. J. Hunger, Dr. S. Beyreuther, and V. Schulz.

Synthesis of the Germanium(I) Compounds $[Ge_2Hal_4]^{2-}$ and Their Reductive Condensation to Octahedral $[Ge_6]^{2-}$ Clusters in an Organometallic Environment

Gerd Renner,[a] Peter Kircher,[a] Gottfried Huttner,*[a] Peter Rutsch,[a] and Katja Heinze[a]

Dedicated to Professor Jürgen Felsche on the occasion of his 60th birthday

Keywords: Germanium(I) / Tetrahalgenodigermanate(2–) / Octahedral $[Ge_6]^{2-}$ clusters / Organometallic derivatives / Carbonyl complexes / Chromium / Tungsten

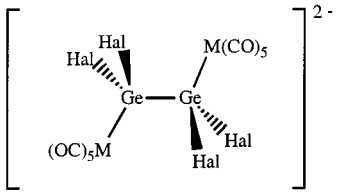
GeI_2 reacts with $[M_2(CO)_{10}]^{2-}$ (M = Cr, W) leading to reductive coupling of two GeI_2 units to produce the $[Ge_2I_4]^{2-}$ ligands of $[\{(OC)_5M\}I_2Ge–GeI_2\{M(CO)_5\}]^{2-}$ (**1a** and **2a**). The $[Ph_4P]$ salts of these anions have been characterised by X-ray structure analyses as have the $[Ph_4P]$ salts of $[\{(OC)_5M\}Cl_2Ge–GeCl_2\{M(CO)_5\}]^{2-}$ (**1b** and **2b**) obtained from the iodo derivatives **1a** and **2a** by halide metathesis with $[Ph_4P]Cl$. Treatment of GeI_2 with $[W_2(CO)_{10}]^{2-}$ in the presence of 2,2′-bipyridine leads to $[\{(OC)_5W\}I_2Ge–Ge(bipy)\{W(CO)_5\}]$ (**3**). The digermanium ligands in **1**–**3** contain germanium in the unconventional formal oxidation state +I. Reductive condensation of $[\{(OC)_5Cr\}I_2Ge–GeI_2\{Cr(CO)_5\}]^{2-}$ (**1a**) by addition of $[Cr_2(CO)_{10}]^{2-}$ leads to the octahedral cluster $[\{(OC)_5Cr\}_6Ge_6]^{2-}$ (**4**) in a yield of 40%. The sequence of reactions as reported describes the first systematic approach to the synthesis of $[E_6]^{2-}$ clusters.

Introduction

It has recently been shown that mononuclear Sn^{II} or Ge^{II} species may be transformed by group-16 carbonylmetallates to produce the octahedral $[E_6]^{2-}$ clusters (E = Ge, Sn) at the core of the well-characterised compounds $[\{(OC)_5Cr\}_6E_6]^{2-}$.[1] By statistical reasoning, the selective formation of such six-atom aggregates $[E_6]^{2-}$ from six individual constituents – each of which contains only one single element E – is a highly improbable process. Thermodynamic and kinetic control along the reaction pathway must play an important role if, as observed, six mononuclear entities aggregate to form an octahedral species. Because of the high number of oligonuclear intermediates that necessarily line out the pathway of such a process, these thermodynamic and kinetic factors are difficult to control. An extended series of experiments is needed to find the proper conditions for such selective aggregation procedures.

The number of potential steps involved in this type of reaction might be considerably reduced if oligonuclear precursors could be used in the condensation process. With this in mind we have tried to prepare dinuclear precursors that, when appropriately functionalised, would allow better control of the condensation process and a suitable procedure has in fact been developed in the case of germanium.

With germanium as the main-group centre it is known that dinuclear species Ge_2R_6 are intrinsically stable entities.[2] Such organically substituted digermanes do, however, lack the reactive functionalisation necessary to produce dielement E_2 building blocks for the formation of E_6 clusters. Ge_2H_6 might be a potential candidate as it is known that Ge–H bonds may be broken in the presence of organometallic entities,[3] although Ge_2H_6 is not easy to handle and is thus perhaps not the best choice.[4] Moreover, the established procedures for the syntheses of $[\{(OC)_5M\}_6E_6]^{2-}$ clusters all start from mononuclear $EHal_2$ compounds with the anionic pentacarbonylmetal entities $[Cr_2(CO)_{10}]^{2-}$ [5] or $[Cr(CO)_5]^{2-}$ [6] acting as halide abstractors and reducing agents at the same time.[1] The ideal precursors in this respect would therefore be the compounds Ge_2Cl_2 or Ge_2Cl_6; the former compound is still unknown while the latter has been characterised as a rather unstable species.[7] Since these precursors are not available or not suitable as such, one might try to produce them in an organometallically protected form. Since base-stabilised germylene compounds $[(OC)_5M–GeHal_2base]$ (M = Cr, W) are known,[8] a conceptual approach would consist of the reductive coupling of two such entities to give $[\{(OC)_5M\}Hal_2Ge–GeHal_2\{M(CO)_5\}]^{2-}$. This approach receives some additional credit from the observation that $PhPCl_2$ as well as PCl_3 undergo reductive coupling with $[Cr_2(CO)_{10}]^{2-}$ to produce the corresponding diphosphane coordination compounds $[\{(OC)_5Cr\}Cl(R)P–P(R)Cl\{Cr(CO)_5\}]$ (R = Ph,[9] Cl[10]).



Compounds Containing a $[Ge_2Hal_4]^{2-}$ Ligand

It is shown in this paper that GeI_2 may be reductively coupled by its reaction with $[M_2(CO)_{10}]^{2-}$ (M = Cr, W) to produce $[\{(OC)_5M\}I_2Ge–GeI_2\{M(CO)_5\}]^{2-}$ (**1a** and **2a**, Table 1). Halide exchange by $[Ph_4P]Cl$ leads to the corresponding tetrachlorodigermanate compounds **1b** and **2b** (Table 1).

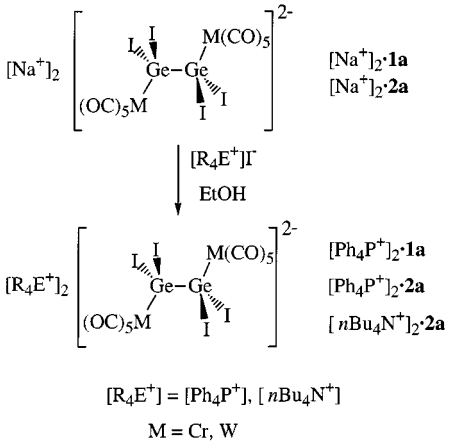
Table 1. Complexes of type **1** and **2**

	halide	metal	cation
1a	I	Cr	$[Na^+]$
1a	I	Cr	$[Ph_4P^+]$
1b	Cl	Cr	$[Ph_4P^+]$
2a	I	W	$[Na^+]$
2a	I	W	$[Ph_4P^+]$
2a	I	W	$[nBu_4N^+]$
2b	Cl	W	$[Ph_4P^+]$

These compounds contain the unconventional and hitherto unknown $[Ge_2Hal_4]^{2-}$ ligands with the formal oxidation state of Ge corresponding to +I. In assigning this oxidation state the $Cr(CO)_5$ entities are seen as neutral sixteen-electron Lewis acids with chromium in an oxidation state of zero.

In agreement with the conceptual model, it is further found that $Na_2[\{(OC)_5Cr\}I_2Ge–GeI_2\{Cr(CO)_5\}]$ ($[Na^+]_2$·**1a**) undergoes transformation to the octahedral cluster anion $[\{(OC)_5Cr\}_6Ge_6]^{2-}$ (**4**) by reaction with $[Cr_2(CO)_{10}]^{2-}$ in an overall yield of 40%.



Syntheses and Structures

When a THF solution of $Na_2[Cr_2(CO)_{10}]$ is treated with an equimolar amount of GeI_2, the solution immediately changes colour from orange to red. Chromatography gives $Na_2[\{(OC)_5Cr\}I_2Ge–GeI_2\{Cr(CO)_5\}]$ ($[Na^+]_2$·**1a**) as a red oil (Scheme 1).

Scheme 1. Reaction of $Na_2[M_2(CO)_{10}]$ (M = Cr, W) with GeI_2

The compound $[Ph_4P^+]_2$·**1a** is obtained as a crystalline derivative upon metathesis with $[Ph_4P]I$ in ethanol (Scheme 2).

Scheme 2. Salt metathesis reaction

The anionic constituent of the sodium salt $[Na^+]_2$·**1a** is the same as that of the phosphonium salt $[Ph_4P^+]_2$·**1a**, as evidenced by the $\tilde{\nu}_{CO}$-IR spectra of these compounds (Table 2). The properties of **1a** were therefore fully characterised with $[Ph_4P^+]_2$·**1a** as the example studied (Tables 5 and 6).

The constitution of **1a**, as given, is in agreement with the spectroscopic data as well as with the microanalytical data. Proof of the constitution of **1a** comes from the X-ray analysis of $[Ph_4P^+]_2$·**1a** (Figure 1, Tables 3 and 7).

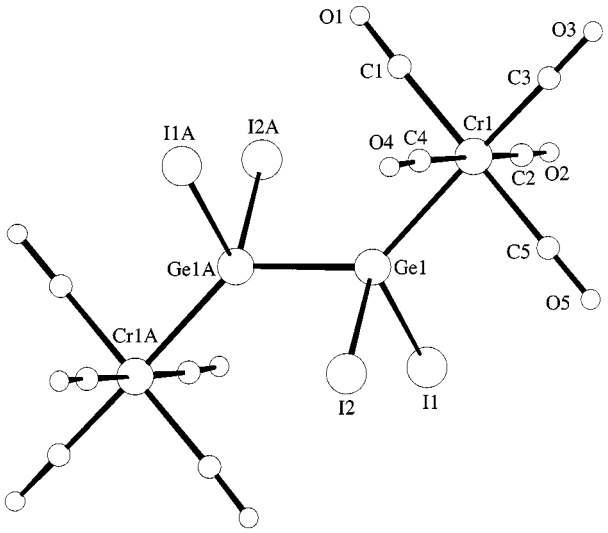

Figure 1. Structure of compound $[Ph_4P^+]_2$·**1a**

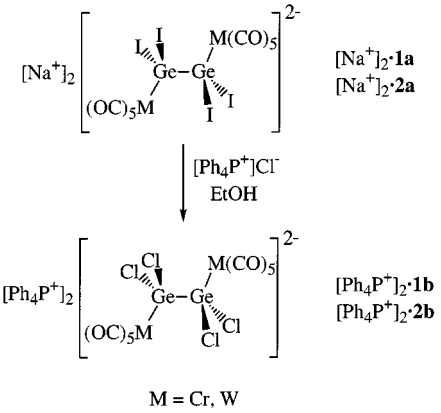
The anion has crystallographically imposed inversion symmetry (Table 7). The Ge–Ge bond length is 244.8 pm (Table 3) and is thus well within the range of Ge–Ge distances reported for Ge_2R_6 compounds and their derivatives.[2] The Ge–Cr distances (Table 3) compare favourably with the corresponding distances reported for $[\{(OC)_5Cr\}GeR_2(Donor)]$,[11] as well as with those observed for the mononuclear chelate compounds $[\{(OC)_5Cr\}_2$-Ge(bipy)] and $[\{(OC)_5Cr\}_2$Ge (phen)] (bipy = 2,2′-bipyridine; phen = 1,10-phenanthroline).[12]



The mean Ge–I bond length of 264.5 pm (Table 3) is similar to that observed for $[\{Cp'(CO)_2Mn\}GeI_3]^-$ (261.6 pm).[13] Corresponding to the inversion symmetry of the molecule, the bonds radiating from the two Ge atoms are in a perfectly staggered arrangement. The pentacarbonylchromium entities are in their conventional idealised octahedral geometry with an overall slight umbrella effect for the equatorial carbonyl groups (Table 3). The CO group C1–O1 – equivalent to C1A–O1A by symmetry – is found to bend in an obverse sense (Table 3). These latter two groups are in close proximity to the GeI_2 entity in the symmetry-related part of the molecule.

The halide functionalities in **1a** are substitutionally labile: treatment of the sodium salt of **1a** (vide supra) with $[Ph_4P]Cl$ results in an exchange of the iodine substituents of **1a** versus chlorine substituents to give **1b** (Scheme 3). Complex **1b** is obtained as a yellow microcrystalline material. The $\tilde{\nu}_{CO}$-IR pattern observed for **1b** is very similar to that shown by **1a** (Table 2). Elemental analysis indicates that halide exchange is not complete under the experimental conditions and the presence of 5 to 10% of unexchanged iodine substituents is inferred from these data (Table 5).

X-ray analysis of $[Ph_4P^+]_2$·**1b** substantiates this hypothesis. Crystals of $[Ph_4P^+]_2$·**1b** are isotypic with those of $[Ph_4P^+]_2$·**1a** (Table 7). The volume of the cell is reduced by about 4% upon substitution of iodine (**1a**) with chlorine (**1b**). The two anions **1a** and **1b** are isostructural in a qualitative sense. The Ge–Ge bond length of 245.5 pm in **1b** (Table 3) is almost equal to that observed for **1a** (244.8 pm,

Scheme 3. Salt metathesis reaction combined with an exchange of the iodine versus chlorine substituents

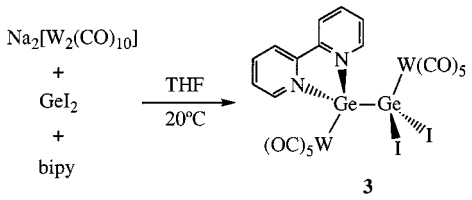

Table 3). The observed discrepancy of the Ge–Cl distances (Table 3), however, as well as the region of residual electron density of 1.6 electrons·10^{-6} pm^{-3} in the neighbourhood of the chlorine substituent Cl2 with the Ge1–Cl2 bond that is apparently too long (Table 3), have to be interpreted in terms of a partial occupancy of the chlorine position by an iodine substituent. Values of individual parameters will therefore be subject to errors and hence do not warrant a detailed discussion. The overall structure of **1b** is nevertheless unequivocally clear from the X-ray analysis.

The mass-spectrometric analyses of $[Ph_4P^+]_2$·**1a** and $[Ph_4P^+]_2$·**1b** show fragmentation patterns which that are in accordance with their assigned constitution (Table 5).

The synthetic strategy leading to the pentacarbonylchromium derivatives **1a** and **1b** works equally well for the pentacarbonyltungsten derivatives **2a** and **2b** (Schemes 1, 2, and 3; Table 1). The anions **2a** and **2b** are isolated as their respective $[Ph_4P^+]$ or $[n Bu_4N^+]$ salts. Single crystals suitable for X-ray analysis could be obtained for their $[Ph_4P^+]$ salts (Tables 3 and 7). As seen from Table 7, the phosphonium salts of **1a**, **1b**, and **2b** form a set of isotypic crystals. The corresponding salt of **2a** also crystallises in a triclinic space group. The cell parameters (Table 7) are, however, numerically quite different from those characterising the above isotypic series. The unit cell observed for $[Ph_4P^+]_2$·**2a** cannot be transformed to a unit cell showing distances and angles that would be in close numerical agreement with those for the isotypic series of the phosphonium salts **1a**, **1b**, and **2b**. Transformation of the cell data of the phosphonium salt of **2a** by {00–1, 100, 0–10} leads to a cell with dimensions (12.76, 12.06, 12.26 [Å]; 69.00, 90.39, 69.09 [°]). On using this transformed unit cell for comparison, the centres of the molecules are seen to have rather similar coordinates in all four salts. In the salt of **2a** the anionic part is, however, at a different rotational position as compared to the orientations of the anions in **1a**, **1b**, and **2b** with respect to the unit cells. By comparing the volumes of the cells (Table 7) it is clear that within the series of phosphonium salts the packing is least efficient in **2a**. This may explain the observation that crystals of $[Ph_4P^+]_2$·**2a** crack when cooled down to 200 K. A phase transition to the more closely packed pattern is in accord with this finding. Nevertheless, the structures of all four compounds (**1a**, **1b**, **2a**, and **2b**) are qualitatively identical with that shown in Figure 1, which illustrates the general arrangement with the structure of **1a** shown as the specific example. In a quantitative respect, the essential difference between the pairs of structures **1a**/**2a** and **1b**/**2b** results from the replacement of the $Cr(CO)_5$ groups in compounds **1** by $W(CO)_5$ groups in compounds **2** (Tables 1, 3, and 7). The torsion angles within the molecules are not affected to a great extent by this replacement and, in particular, the Ge–Ge bond lengths are almost identical in all four compounds within the limits of error, with an average value of 245.2 pm (Table 3). As already observed for **1b**, some of the chlorine positions in **2b** are affected by an incomplete substitution of iodine versus chlorine, with the numerical values of the distances for Ge1–Hal2 in compounds **1b** and **2b** being too large. The remaining distances and angles (Table 3) agree favourably within the set of compounds **1** and **2**. The W–Ge distances observed for **2** are also within the range of W–Ge single bond lengths known to date.[14]

[Hal_2Ge–Ge(bipy)] as a Ligand

It has been observed that formation of the cluster $[\{(OC)_5Cr\}_6Ge_6]^{2-}$ from $Na_2[Cr_2(CO)_{10}]$ and GeI_2 is promoted by the presence of bipy (2,2′-bipyridine)[1a] and so the reactions leading to **1** and **2** were repeated in the presence of bipy. It was hoped that some bipy derivative could be detected that would help to explain the role of the bipy ligand in cluster formation.[1a] However, treatment of $Na_2[Cr_2(CO)_{10}]$ in THF solution with equimolar amounts of GeI_2 and bipy did not produce any new insight into the process. The only products isolated were $[\{(OC)_5Cr\}_2$-Ge(bipy)] and $[\{(OC)_5Cr\}_6Ge_6]^{2-}$, both of which have already been reported.[1a,12] However, the use of $Na_2[W_2(CO)_{10}]$ as the starting material, under otherwise identical conditions, gave the digermanium compound **3** (Scheme 4).

Scheme 4. Reaction of $Na_2[W_2(CO)_{10}]$ with GeI_2 and 2,2′-bipyridine

Compound **3** was purified by column chromatography and the side products $[(OC)_4W(bipy)]$ and $W(CO)_6$ were separated by this procedure.[17] Compound **3** was eluted with THF as a broad red band. Some additional red material was obtained by elution with ethanol and this, by analogy, is thought to contain $[\{(OC)_5W\}_6Ge_6]^{2-}$. Compound **3** was obtained as a red oil by evaporation of the solvent from the combined THF fractions whose $\tilde{\nu}_{CO}$-IR spectra showed only the bands due to **3** (Table 2) with no indication of by-products. Compound **3** could be obtained in a crystal-

line form from its concentrated solutions by a vapour phase diffusion process (see Experimental Section). The red crystals are stable over several days when retained in the mother liquor in the dark. Handling of the crystals is nevertheless problematic since they are found to produce an amorphous material under the conditions of evaporation. It is not yet clear whether this disintegration is due to the reduced pressure – a possibility that is not highly probable since compound **3** is found to crystallise without inclusion of solvent – or whether the material is sensitive to daylight. When the amorphous material that remained after evaporation of the solvent was redissolved, red solutions were obtained and the ^{1}H-NMR spectra of these indicate the presence of a minimum of three different types of coordinated bipy ligands. By comparison with spectra of authentic samples it appears that one of these products is $[(OC)_4W(bipy)]$;[17] the identity of the two other compounds is as yet unknown. The only way to identify the nature of the primary product **3** is therefore by X-ray analysis. Single crystals of **3** were immediately transferred from the mother liquor into perfluorinated oil and then placed onto a diffractometer in as short a period of time as possible while keeping the temperature below –70 °C. This procedure ensured that the crystals survived without disintegration. The structure of **3**, as determined by crystal structure analysis, is depicted in Figure 2 (Table 4).

Crystals of **3** contain discrete molecular entities, the central part of which is the digermanium-derived constituent $[I_2Ge–Ge(bipy)]$ (Figure 2). Each of the germanium centres is coordinated to a $W(CO)_5$ group. One of the germanium centres (Ge1) has two iodine substituents, while the other germanium is coordinated to the bipy ligand (Figure 2). The germanium centres are linked by a Ge–Ge bond, the length of which (248.2 pm) is close to the Ge–Ge bond lengths observed for **1** and **2** (Tables 3 and 4).

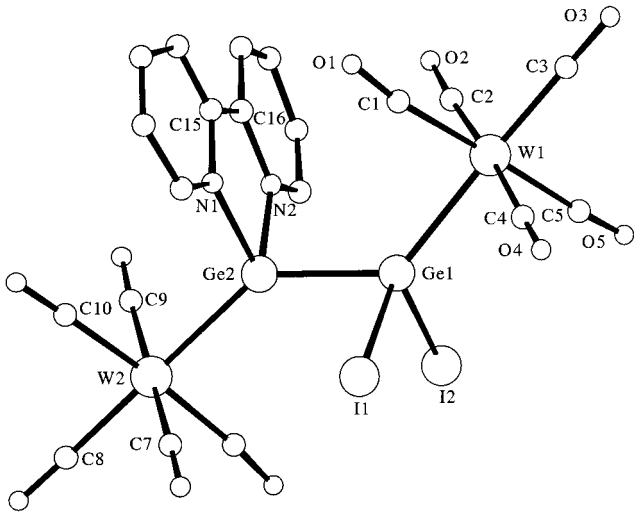

Figure 2. Structure of compound **3**

The Ge–N and Ge–I bond lengths are also within the usual range,[12,13] as are the Ge–W distances[14] (compare Tables 3 and 4). The arrangement of the substituents around the Ge–Ge axis corresponds to that observed for **1** and **2**, with the bonds radiating from the two germanium centres being staggered with respect to one another (Table 4). Even though there is no crystallographically imposed molecular symmetry for **3**, the effective molecular symmetry is close to C_S (for torsion angles, see Table 4). In contrast to the structures of **1** and **2**, the rotation of the $M(CO)_5$ groups around their respective Ge–M axis is close to an eclipsed arrangement in **3** (Table 4, Figure 2); it ap-

proximates a staggered orientation in the structures **1** and **2** (Table 3, Figure 1).

Compound **3** contains the digermanium species $[I_2Ge–Ge(bipy)]$, which is unknown in the free state and stabilised in **3** by protection with bulky $W(CO)_5$ groups. This digermanium entity may be interpreted in terms of a Lewis base/Lewis acid interaction with the organometallically protected eight electron species $L_nMGe(bipy)$ acting as the base and the equivalently protected six-electron species L_nMGeI_2 as the Lewis acid.[15] This type of interpretation is appealing since the protected six electron species $[(OC)_5M–GeR_2]$[16] are known as such and also in their base-stabilised form.[8] Lewis acid adducts of $[(OC)_5M–Ge(bipy)]$ are equally well known and are well characterised as having $[M(CO)_5]$ as the Lewis acidic group.[12] By whatever electron-counting approach the bonding situation in $[I_2Ge–Ge(bipy)]$ is analysed, it is found that it is in a formal sense isoelectronic to the $[Ge_2Hal_4]^{2–}$ entities of **1** and **2**.

The unsymmetrical substitution of the Ge–Ge entity in **3** might form the basis of its reactivity. To date, however, no attempt to transform **3** into the cluster $[\{(OC)_5W\}_6Ge_6]^{2–}$ has been successful and it may therefore be assumed that compounds of type **3** do not play a key role in the bipy-mediated[1a] synthesis of $[\{(OC)_5W\}_6Ge_6]^{2–}$.

A Straightforward Synthesis of the $[Ge_6]^{2–}$ Core

Even though **3** could not be transformed to produce a $[Ge_6]^{2–}$ cluster, an efficient synthesis of the $[Ge_6]^{2–}$ core has nevertheless been found by following a different strategy (Scheme 5). When THF solutions of $Na_2[\{(OC)_5Cr\}I_2Ge–GeI_2\{Cr(CO)_5\}]$ ($[Na^+]_2$·**1a**) (vide supra) are treated with two equivalents of $Na_2[Cr_2(CO)_{10}]$[5] dissolved in THF, a continuous change of the $\tilde{\nu}_{CO}$-IR spectra of the reaction mixture is observed. While the long-wavelength region is obscured by the bands that are characteristic of $[Cr_2(CO)_{10}]^{2–}$, in the short-wavelength range the bands characteristic of the reaction products are observed to evolve. The band pattern at 2053/2030 cm^{-1} indicates the formation of $[Cr_2(CO)_{10}H]^–$.[5,18] The assignment of this pattern to $[Cr_2(CO)_{10}H]^–$ was corroborated by the independent synthesis of $[Ph_4P][Cr_2(CO)_{10}H]$, which was characterised by single-crystal analysis and comparison with the known structure of this compound,[18] by its proton-NMR signal in CD_2Cl_2 solution at $\delta = –19.4$ and its $\tilde{\nu}_{CO}$-IR spectrum in THF solution.[5,18] A band characteristic of the cluster $[\{(OC)_5Cr\}_6Ge_6]^{2–}$ (**4**) (2043 cm^{-1})[1a] was also found to increase in intensity during the reaction. After complete addition of the two equivalents of $Na_2[Cr_2(CO)_{10}]$ during a period of three hours, the band at 2043 cm^{-1} was found not to increase any further when an additional 0.3 equivalents of $Na_2[Cr_2(CO)_{10}]$ were added. These findings indicate that the formation of the compound that gives rise to the band at 2043 cm^{-1} requires two equivalents of $Na_2[Cr_2(CO)_{10}]$ for completion. The red-brown solution was concentrated, filtered through Kieselgur, and chromatographed on silica gel. $Na_2[\{(OC)_5Cr\}_6Ge_6]$ $\{[Na^+]_2$·**4**$\}$ was obtained as a red ethanolic eluate from which **4** could be precipitated by metathesis with $[Ph_4P]Cl$ in ethanol. The salt $[Ph_4P^+]_2$·**4** was obtained as a microcrystalline red-brown material in fair yields (40%). Crystals were obtained by layering a solution of $[Ph_4P^+]_2$·**4** in DMA (*N*,*N*-dimethylacetamide) with ethanol. The identity of **4** has been inferred by comparison of the unit-cell data obtained for $[Ph_4P^+]_2$·**4** by X-ray analysis with the authentic data.[1a] X-ray analysis of these crystals proved that the sample is identical with authentic $[Ph_4P]_2[\{(OC)_5Cr\}_6Ge_6]$.[1a]

Scheme 5. Reaction of **1a** with $[Cr_2(CO)_{10}]^{2–}$ to produce **4**

Conclusions

In the presence of $M(CO)_5$ moieties (M = Cr, W) germanium(II) halides may be reductively coupled to produce $[Ge_2Hal_4]^{2–}$ ligands. In a formal sense these ligand entities contain germanium in its unconventional +I oxidation state and are formally isoelectronic to P_2R_4 ligands,[9,10] which act as bridging entities in several well-characterised organometallic derivatives. In contrast to P_2R_4, their anionic equivalents $[Ge_2R_4]^{2–}$ are not known but they are found to be stable in their $M(CO)_5$-protected form $[\{(OC)_5M\}I_2Ge–GeI_2\{M(CO)_5\}]^{2–}$ (**1** and **2**).

In the presence of bipy, the organometallically protected ligands of the type $[Hal_2Ge–Ge(bipy)]$ may be obtained under otherwise similar conditions. Here again the formal average oxidation state of germanium is +I and the ligands are not known in the free state but are stable under organometallic protection, as shown for $[\{(OC)_5W\}I_2Ge–Ge(bipy)\{W(CO)_5\}]$ (**3**).

Starting from the digermanium precursor $[\{(OC)_5Cr\}Hal_2Ge–GeHal_2\{Cr(CO)_5\}]^{2–}$ (**1**), a reductive condensation procedure produces $[\{(OC)_5Cr\}_6Ge_6]^{2–}$ (**4**), which has a $[Ge_6]^{2–}$ core. This type of process is the first straightforward approach to the selective synthesis of the $[Ge_6]^{2–}$ core.

Experimental Section

General: All manipulations were carried out under argon by means of standard Schlenk techniques at 20 °C unless mentioned otherwise. All solvents were dried by standard methods and distilled

under argon. The [D6]DMSO and [D6]acetone used for the NMR-spectroscopic measurements were degassed by three successive "freeze-pump-thaw" cycles and dried over 4-Å molecular sieves. Silica gel (Kieselgel z. A. 0.06–0.2 mm, J. T. Baker Chemicals B. V.) used for chromatography and Kieselgur (Kieselgur, gereinigt, geglüht, Erg. B.6, Riedel de Haën AG) used for filtration were degassed at 1 mbar at 130 °C for 12 h and saturated with argon. – NMR: Bruker Avance DPX 200 at 200.13 MHz (^{1}H), 50.323 MHz (^{13}C{^{1}H}), 81.015 MHz (^{31}P{^{1}H}); chemical shifts (δ) in ppm with respect to [D6]DMSO (^{1}H: δ = 2.50; ^{13}C: δ = 39.4) and [D6]acetone (^{1}H: δ = 2.05; ^{13}C: δ = 206.2), respectively, as internal standards and to 85% H_3PO_4 (^{31}P: δ = 0) as external standard. – IR: Bruker FT-IR IFS-66; CaF_2 cells. – UV/Vis/NIR: Perkin–Elmer Lambda 19; cells (0.2 cm; Hellma 110 suprasil). – MS (FAB): Finnigan MAT 8400; Nibeol matrix (4-nitrobenzyl alcohol). – Elemental analysis: Microanalytical Laboratory of the Organisch-Chemisches Institut, Universität Heidelberg. – Melting points: Gallenkamp MFB-595 010; the values are not corrected. – Chemicals: The metallates $Na_2[M_2(CO)_{10}]$[5] (M = Cr, W) and GeI_2[19] were prepared by literature methods. All other chemicals were commercially obtained and used without further purification. – Analytical and spectroscopic data are given in Table 2, Table 5, and Table 6. X-ray data are given in Tables 3, 4, and 7.

$Na_2[\{(OC)_5M\}I_2Ge–GeI_2\{M(CO)_5\}]$ ($[Na^+]_2$·1a, M = Cr; $[Na^+]_2$·2a, M = W): To a stirred orange solution of $Na_2[M_2(CO)_{10}]$ (M = Cr: 430 mg, 1 mmol; M = W: 694 mg, 1 mmol) in THF (50 mL) was added solid GeI_2 (326 mg, 1 mmol) in one portion. The orange solution turned red immediately. After stirring for 1 h, the GeI_2 had completely dissolved and a clear red solution had formed. The reaction mixture was filtered through Kieselgur (3 cm). The resulting red solution was concentrated in vacuo (5 mL) and chromatographed on silica gel (15 cm, Ø = 3 cm; THF). Elution with THF gave one yellow band that contained $[M(CO)_6]$ and $Na[M(CO)_5I]$ (M = Cr, W: identification by IR spectroscopy[20]). A red band remained on the top of the column that was eluted with ethanol. The resulting solution was taken to dryness. $[Na^+]_2$·**1a** and $[Na^+]_2$·**2a**, respectively, were obtained as deep orange oils. The identity of the sodium salts **1a** and **2a** is inferred from metathesis to the corresponding $[Ph_4P]$ salts, which may be fully characterised by various methods, including elemental analysis. The $\tilde{\nu}_{CO}$-IR patterns of the sodium salts and the phosphon-

ium salts are similar enough to leave no doubt about the nature of the organometallic anions **1a** and **2a**.

$[Ph_4P]_2[\{(OC)_5M\}I_2Ge–GeI_2\{M(CO)_5\}]$ ($[Ph_4P^+]_2$·1a, M = Cr; $[Ph_4P^+]_2$·2a, M = W): To a stirred orange solution of $[Na^+]_2$·**1a** (541 mg, 0.5 mmol) or $[Na^+]_2$·**2a** (673 mg, 0.5 mmol), respectively, in ethanol (10 mL) was added a suspension of $[Ph_4P]I$ (933 mg, 2 mmol) in ethanol (30 mL). The corresponding yellow $[Ph_4P]$ salts of **1a** or **2a** precipitated immediately. After stirring for 30 min, the solid was separated from the mother liquor by filtration and washed with ethanol (2 × 5 mL), diethyl ether (2 × 5 mL) and dried in vacuo leaving the salts of $[Ph_4P^+]_2$·**1a** and $[Ph_4P^+]_2$·**2a** as yellow powders. Yield: $[Ph_4P^+]_2$·**1a**: 394 mg, 0.23 mmol, 46%; $[Ph_4P^+]_2$·**2a**: 456 mg, 0.23 mmol, 46% (with respect to GeI_2). In order to grow single crystals of $[Ph_4P^+]_2$·**1a** and $[Ph_4P^+]_2$·**2a** the yellow powder was dissolved in DMA (5 mL) and overlayered with ethanol (20 mL). Within 5 d at 20 °C yellow single crystals suitable for X-ray analysis were obtained.

$[Ph_4P]_2[\{(OC)_5M\}Cl_2Ge–GeCl_2\{M(CO)_5\}]$ ($[Ph_4P^+]_2$·1b, M = Cr; $[Ph_4P^+]_2$·2b, M = W): To a stirred orange solution of $[Na^+]_2$·**1a** (541 mg, 0.5 mmol) or $[Na^+]_2$·**2a** (673 mg, 0.5 mmol) in ethanol (30 mL) was added solid $[Ph_4P]Cl$ (750 mg, 2 mmol). The corresponding yellow $[Ph_4P]$ salts of **1b** or **2b** precipitated immediately. Further workup and the growth of single crystals of $[Ph_4P^+]_2$·**1b** or $[Ph_4P^+]_2$·**2b** were achieved following the methods described for $[Ph_4P^+]_2$·**1a**. Yield: $[Ph_4P^+]_2$·**1b**: 310 mg, 0.23 mmol, 46%; $[Ph_4P^+]_2$·**2b**: 370 mg, 0.23 mmol, 46% (with respect to GeI_2). The exchange of iodide versus chloride is almost complete under these conditions, as shown by elemental analysis and X-ray analysis.

$[nBu_4N]_2[\{(OC)_5W\}I_2Ge–GeI_2\{W(CO)_5\}]$ ($[nBu_4N^+]_2$·2a): To a stirred orange solution of $[Na^+]_2$·**2a** (673 mg, 0.5 mmol) in ethanol (30 mL) was added solid $[nBu_4N]I$ (739 mg, 2 mmol). The corresponding yellow $[nBu_4N]$ salt of **2a** precipitated immediately. The subsequent workup followed the method described for $[Ph_4P^+]_2$·**2a**. Yield: $[nBu_4N^+]_2$·**2a**: 482 mg, 0.27 mmol, 54% (with respect to GeI_2).

$[\{(OC)_5W\}I_2Ge–Ge(bipy)\{W(CO)_5\}]$ (3): $Na_2[W_2(CO)_{10}]$ (694 mg, 1 mmol) was dissolved in THF (50 mL) and solid GeI_2 (326 mg, 1 mmol) and solid 2,2′-bipyridine (156 mg, 1 mmol) were added in one portion. The initially clear orange solution turned deep red immediately (GeI_2 dissolved in a period of minutes). After stirring for 1 h, the reaction mixture was filtered through Kieselgur (3 cm). The resulting red solution was concentrated to 5 mL in vacuo and chromatographed on silica gel (15 cm, Ø = 3 cm; diethyl ether). Elution with diethyl ether gave a red band, which was identified by IR spectroscopy to consist of $[W(CO)_6]$ and $[(OC)_4W(bipy)]$.[17,20] Elution with THF gave a second red band containing **3**. This fraction was taken to dryness to leave **3** as a red oil. Single crystals of **3** were obtained by the following procedure: A concentrated THF solution of **3** (348 mg in 5 mL of THF) was shared out between three test tubes (Ø = 1 cm), which were each placed into a Schlenk tube (250 mL). Diethyl ether (30 mL), which was in the Schlenk tube, was allowed to diffuse through the gas phase into the THF solutions (12 h at 20 °C). After this period of time the diethyl ether was replaced by petroleum ether (boiling range 40–60 °C; 50 mL). Vapour diffusion of the petroleum ether for 4 d gave red single crystals of **3** that were suitable for X-ray structure analysis. All operations were carried out in the dark. While the identity of **3** could be determined by X-ray analysis of these crystals at 200 K, dissolving these crystals in CD_2Cl_2 or $[D_6]$acetone at 20 °C resulted in red solutions that contained bipy ligands in three different coordination environments. The ^{1}H-NMR spectra show three sets of

signals that, although not individually resolved, provide evidence that compound **3** disintegrates at least in part under the given experimental conditions. In addition, a satisfactory elemental analysis could not be obtained for **3**.

$[Ph_4P]_2[\{(OC)_5Cr\}_6Ge_6]$ ($[Ph_4P^+]_2$·4): To a stirred orange solution of $[Na^+]_2$·**1a** (541 mg, 0.5 mmol) in THF (30 mL) was added a solution of $Na_2[Cr_2(CO)_{10}]$ (430 mg, 1 mmol) in THF (30 mL) in 10-mL portions during a period of 3 h. During the addition the colour of the solution turned to red-brown. The reaction mixture was filtered through Kieselgur (3 cm), concentrated to 5 mL in vacuo and chromatographed on silica gel (15 cm, Ø = 3 cm; THF). Elution with THF gave a broad yellow band containing $Na[Cr_2(CO)_{10}H]$, which was identified by IR spectroscopy.[5,18] A deep red band remained on top of the column and this was eluted with ethanol. The resulting deep red solution was taken to dryness in vacuo and redissolved in ethanol (10 mL). Addition of solid $[Ph_4P]Cl$ (375 mg, 1 mmol) led to the corresponding red-brown $[Ph_4P]$ salt of **4**, which precipitated immediately. The solid was separated from the mother liquor by filtration, washed with ethanol (2 × 5 mL), diethyl ether (2 × 5 mL) and dried in vacuo. Yield: $[Ph_4P^+]_2$·**4**: 151 mg, 0.07 mmol, 40% (with respect to GeI_2). Single crystals of $[Ph_4P^+]_2$·**4** could be obtained by layering a concentrated DMA solution of $[Ph_4P^+]_2$·**4** (3 mL) with ethanol (20 mL).

X-ray Structure Determinations: The measurements for $[Ph_4P^+]_2$·**1a**, $[Ph_4P^+]_2$·**2b**, and **3** were carried out with a Siemens P4 four-circle diffractometer, data for $[Ph_4P^+]_2$·**2a** were collected with a Nonius Kappa CCD diffractometer, all using Mo-K_α radiation. In the case of the Siemens P4 four-circle diffractometer, measurements of the intensities of three check reflections (measured every 100 reflections) remained constant throughout the data collection, thus indicating crystal and electronic stability. The data collected using a scintillation counter measuring device (Siemens P4) were corrected in the usual way including experimental absorption correction. The data from the CCD device (Nonius Kappa CCD) were processed by the standard Nonius software.[21] All calculations were performed using the SHELXT PLUS software package. Structures were solved by direct methods with the SHELXS-86 program and refined with the SHELXL-93 program.[22] The program XPMA[23] was used for graphical handling of the data. The structures were refined in fully or partially anisotropic models by full-matrix least-squares calculations. Hydrogen atoms were introduced at calculated positions. Table 7 compiles the data for the structure determinations. Crystallographic data for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-135292 ($[Ph_4P^+]_2$·**1a**), -135293 ($[Ph_4P^+]_2$·**1b**), -135291 ($[Ph_4P^+]_2$·**2a**), -135295 ($[Ph_4P^+]_2$·**2b**), -135294 (**3**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: int. code + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

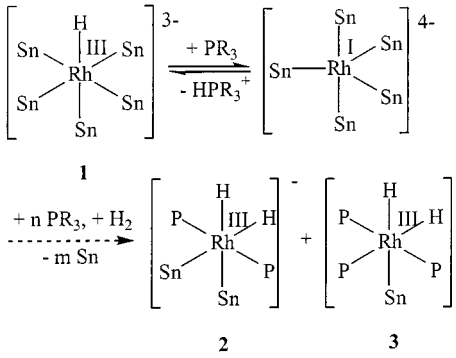
In situ NMR Detection of Dihydrides in the Systems $[RhH(SnCl_3)_5]^{3-}$/Tertiary Phosphanes/Parahydrogen

Claudia Ulrich,[a] Alexei Permin,[b] Valery Petrosyan,[b] and Joachim Bargon*[a]



Keywords: Rhodium hydride complexes / Parahydrogen / Tin ligands / Hydrogenations

The oxidative addition of dihydrogen to the $[RhH(SnCl_3)_5]^{3-}$/PR_3 system (PR_3 = PPh_3, $PEtPh_2$, PEt_3) leads to the formation of previously unknown dihydride complexes, the ^{1}H-NMR spectra of which have been studied by means of the ParaHydrogen Induced Polarization (PHIP) method. The composition of the resulting complexes crucially depends on the type of the added phosphane. With PEt_3 as the phosphane and acetonitrile as the solvent, a complex with a $SnCl_2L$ ligand (L = CD_3CN) can be detected. All systems examined catalyze the hydrogenation of phenylacetylene. During these reactions, both the ^{1}H-NMR resonances of the dihydride complexes and those of styrene, the hydrogenation product of phenylacetylene, can be detected simultaneously. In the case of $SnBr_3$ ligands, hydrogen addition in the presence of phosphanes leads to similar dihydride complexes, which were also identified via ^{1}H-NMR spectroscopy. Furthermore, a mixed complex of the structure $[Rh(SnBr_3)_nBr_{6-n}]^{3-}$ has been isolated.

Introduction

The catalytic activity of rhodium complexes containing tin trichloride ligands has been the subject of many studies ever since 1970, when their activity in the dehydrogenation of 2-propanol has first been noted.[1] This reaction and, in particular, the structure of the responsible rhodium-tin complexes have been examined before using ^{119}Sn-NMR spectroscopy.[2] Furthermore, the rhodium(III) monohydride complex **1** has previously been isolated from hydrochloric acid solutions of $RhCl_3$ and $SnCl_2$ and identified with this technique.[3] Reactions of these complexes with tertiary phosphanes have also been studied with ^{31}P- and ^{1}H-NMR spectroscopy, and upon addition of dihydrogen to these systems the formation of two dihydrido complexes **2** and **3** was detected (Scheme 1).[4]

The development of an in situ NMR technique based on ParaHydrogen Induced Polarization (PHIP) allows an extensive study of rhodium dihydride complexes, both stable and transient, via their ^{1}H-NMR spectra, which can be observed during homogeneous catalyzed hydrogenations.[5] Recently, the structure and reactivity of rhodium dihydrides relevant to both Wilkinson- and Schrock-type catalysts as well as their hydrogenation activity were extensively examined by use of PHIP-NMR spectroscopy. This method provides an extraordinary sensitivity for the detection of metal hydrides; therefore, it has been used to observe these typically unstable catalytic intermediates.[5–7] Due to the enhanced resonances, reliable information about the structure of species present in only minor quantities in reaction mixture can thus be obtained. This approach yields valuable insight into both the stereo- and regiochemistry of initial stages of the dihydrogen addition to the substrate.[8]

Scheme 1. Formation of dihydrides from $[HRh(SnCl_3)_5]^{3-}$ in presence of phosphanes and hydrogen, Sn = $SnCl_3$, P = PR_3.

Since reports on tin-containing rhodium dihydrides and the knowledge of their role in homogeneous catalysis are scarce, we have used the PHIP technique to study the reactions of two characteristic prototypes with parahydrogen, namely of the systems $[RhH(SnCl_3)_5]^{3-}$/tertiary phosphane and $RhBr_3$/$SnBr_2$/tertiary phosphane. Recently, platinum(II)-tin hydride complexes were studied in this way,[9] providing a pool of new information about the mechanism of homogeneous, platinum-tin catalyzed hydrogenations of alkynes and alkenes thanks to the identification of previously unknown intermediates. In this study here, we were interested in identifying the consequences, in particular the intermediate products, resulting from the addition of dihydrogen to a variety of tin-containing rhodium complexes. By use of PHIP-NMR spectroscopy we wanted to detect

previously elusive intermediates occurring during the stepwise tin-for-phosphane substitution as originally described in 1985,[4] in order to obtain more detailed information about the hydrogenation activity of this rhodium-tin system in particular.

Results and Discussion

Of the two rhodium-tin-systems investigated here, the first complex, $[HRh(SnCl_3)_5]^{3-}$, has been obtained and characterized earlier as an isolated rhodium monohydride,[2,3] whereas the second system, $RhBr_3/SnBr_2/HBr$, has not been investigated before.

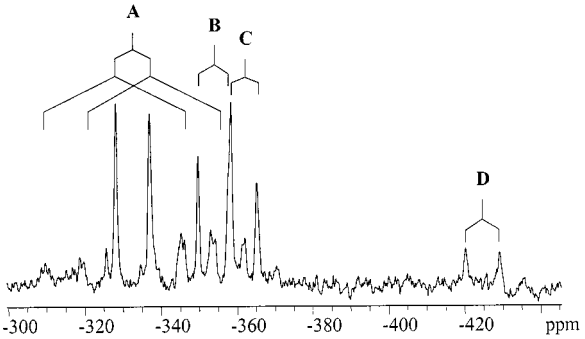

Figure 1. ^{119}Sn-NMR spectrum of the $RhBr_3/SnBr_2/HBr$ system in CD_3CN at –40° C (chemical shifts referenced to external Me_4Sn)

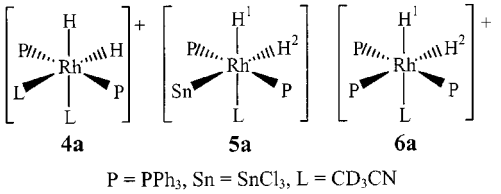

Action of NEt_4^+ onto the latter yields a solid, which was studied by means of NMR spectroscopy. The ^{119}Sn-NMR spectrum (Figure 1) exhibits four main resonances A, B, C, and D, which are due to rhodium-tin-complexes of the type $[Rh(SnBr_3)_nBr_{6-n}]^{3-}$ with typical shifts and coupling values for tin coordinated to rhodium[10] (see Experimental Section). Upon addition of parahydrogen, the ^{1}H-NMR spectrum in acetonitrile reveals no signals of any hydride, by contrast to the chloride analogue. The lack of formation of a monohydride upon addition of tetraethylammonium cations to the $RhBr_3/SnBr_2/HBr$ system seems to be due to the lower reductive ability of tin dibromide in comparison to tin dichloride, which would explain the lack of Rh^I formation and, therefore, the lack of subsequent protonation.

System $[RhH(SnCl_3)_5]^{3-}/PPh_3$

The action of parahydrogen on the $[RhH(SnCl_3)_5]^{3-}$ anion in acetonitrile does not give rise to any detectable dihydrides either. The addition of four equivalents of PPh_3 to the solution causes partial deprotonation of the hydride, since the hydride signal disappears in the ^{1}H-NMR spectrum. Furthermore, the ^{31}P-NMR spectrum reveals the presence of $HPPh_3^+$ at δ = –3 (broad), which undergoes rapid chemical exchange with PPh_3 on the NMR time scale. This behaviour is similar to that of the already described reaction with PBu_3.[4]

$$[HRh(SnCl_3)_5]^{3-} + PBu_3 \rightarrow [Rh(SnCl_3)_5]^{4-} + HPBu_3^+ \quad (1)$$

The subsequent fate of the Rh^I complex is either substitution of the tin ligands by phosphane or back-protonation to **1** as soon as a proton is liberated during the substitution. Addition of parahydrogen at room temperature gives rise to three dihydrides, two of them occurring in polarization (Figure 2).

P = PPh_3, Sn = $SnCl_3$, L = CD_3CN

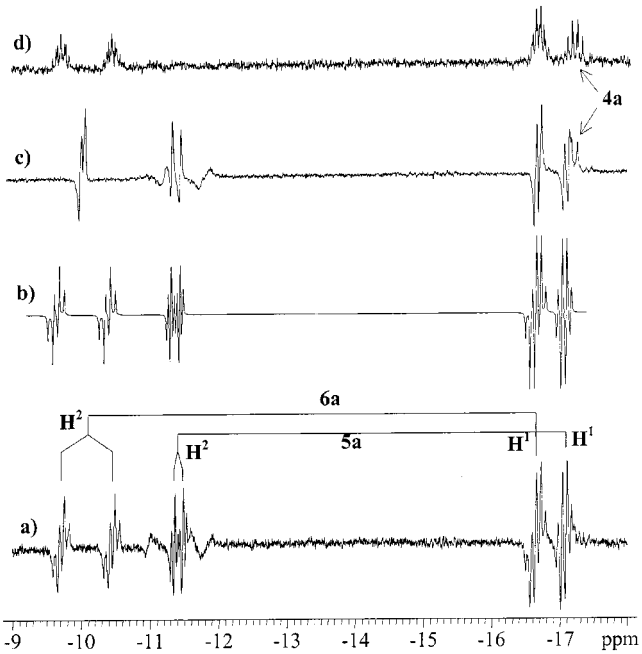

Figure 2. ^{1}H-NMR spectra of the system $[RhH(SnCl_3)_5]^{3-}/PPh_3/H_2$ in CD_3CN; a) PHIP spectrum on heating; b) PHIP++ simulation of **6a** and **5a**; c) PHIP-^{1}H{^{31}P}-NMR spectrum on heating; d) product spectrum after decay of the polarization

The unpolarized hydride resonances at δ = –17.19 are assigned to the chemically equivalent protons of the symmetric complex **4a**. This complex has already been described before.[11] These hydride resonances occur with a multiplicity consisting of doublet of triplets with ^1J(HRh) = –17.5 Hz and ^2J(HP) = 13 Hz (Table 1). The polarized resonances, however, show coupling patterns typical for a bis-phosphane and a tris-phosphane complex, respectively. The bis-phosphane complex **5a** shows one hydride resonance H^2, with a chemical shift value of δ = –11.42, which is typical for a proton in *trans* position to a trichlorostannato ligand. This resonance occurs as a doublet of triplets which are further split into doublets with "antiphase" multiplicity. (In the following the designation "antiphase multiplicity" will be used as an abbreviation universally when referring to multiplets in polarization and a splitting due to ^2J(HH′) coupling between the former two parahydrogen protons). The ^{31}P-decoupled spectrum reveals the rhodium coupling as $^1J(H^2Rh)$ = 25 Hz. The

[a] L = CD_3CN. – [b] X = Cl, Br, CD_3CN.

other hydride proton, namely H^1 *trans* to acetonitrile, occurs as a high-field pseudo-quadruplet at δ = –17.05 with a rhodium coupling of $^1J(H^1Rh)$ = 13 Hz. The presence of acetonitrile in this complex is confirmed by the fact that the same signals are not detected in the system $RhCl(PPh_3)_3$/$SnCl_2$ (1:5) in [D_6]acetone as the solvent until the addition of minor quantities of acetonitrile.

In the tris-phosphane complex **6a** the large value of $^2J(H^2P)$ = 147 Hz is typical for a *trans*-alignment of the ligands. The ^{31}P-decoupled ^{1}H-NMR spectrum approves this assignment. The high-field shift of H^1 is also due to a *trans* acetonitrile ligand, which is concluded from the observation that the $[Rh(SnBr_3)_nBr_{6-n}]^{3-}$ system gives rise to the same signals upon addition of parahydrogen. Furthermore, these signals can also be detected in the system $RhCl(PPh_3)_3/SnCl_2/PPh_3$ (1:5:7) in CD_3CN.

The complexes **4a** and **6a** are stable and can, therefore, be characterized from their resonances observed in the thermal, i.e., in the regular, "unpolarized" ^{1}H-NMR spectra. Complex **5a,** however, is a transient species which can only be observed in situ, i.e., enhanced by PHIP. The extensive incorporation of acetonitrile into the coordination sphere of the dihydrides can be rationalized by the relatively high π-acceptor properties of triphenylphosphane, which causes its competition with the tin ligands for the filled d-orbitals of rhodium. The tin trihalide ligands have been shown earlier to be relatively strong π-acceptors as well.[12] The instability of complex **5a** could be caused by the high *trans* effect of H^2; therefore, the lability of the tin ligand is enhanced, which causes its dissociation with the formation of **4a**.

System $[RhH(SnCl_3)_5]^{3-}/PEtPh_2$

Upon addition of $PEtPh_2$ to an acetonitrile solution of **1**, deprotonation becomes evident by the appearance of $HPEtPh_2^+$ in the ^{31}P-NMR spectrum at δ = – 8.5 (broad). In addition, several signals in the range of δ = 15 to 45 with typical ^1J(PRh) coupling constants of 90 to 135 Hz

Table 2. ^{31}P-NMR data of the dihydride complexes

Dihydride	Formula	Chemical shifts, δ [ppm], coupling constants J [Hz]
6a	$H_2Rh(PPh_3)_3L$[a]	42.8 (J_{PP} = 19, J_{PRh} = 111) 28.7 (J_{PRh} = 93)
6b	$H_2Rh(PEtPh_2)_3L$[a]	38.8 (J_{PP} = 20, J_{PRh} = 109) 24.3 (J_{PRh} = 96)
3c	$H_2Rh(PEt_3)_3(SnCl_3)$	28.7 (J_{PP} = 22, J_{PRh} = 96) 15.6 (J_{PRh} = 88)

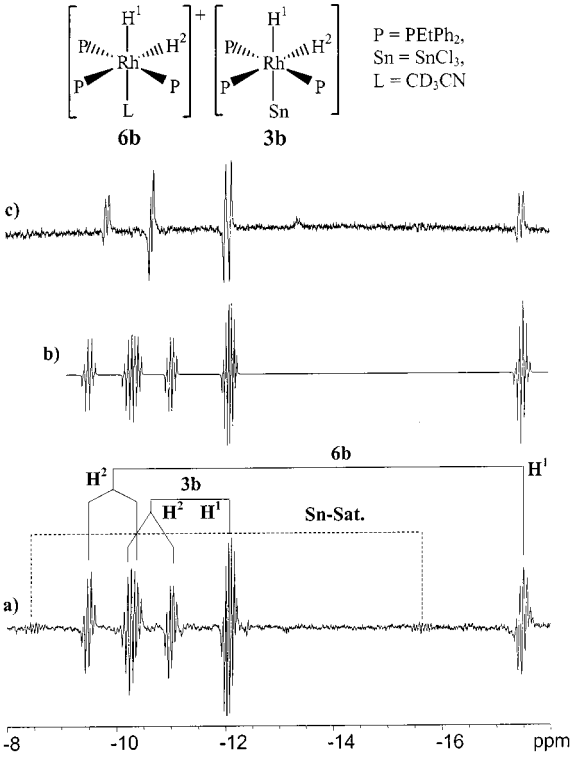
[a] L = CD_3CN

are observed (Table 2). However, the deprotonation of the monohydride does not occur completely, since it can still be detected in the ^{1}H-NMR spectrum.

The admission of parahydrogen gives rise to polarized signals of two dihydrides, **3b** and **6b**, with coupling patterns similar to those of the PPh_3 analogues (Figure 3). The presence of an acetonitrile ligand in **6b** is extrapolated from the observation of the corresponding signals in the PHIP spectra of the bromide system. The signals of **6b** are also detectable in the thermal ^{1}H-NMR spectrum, whereas **3b** is only visible when enhanced by PHIP. The higher stability of **3b** as compared to that of the PPh_3 system, can be explained by the decrease of the π-acceptor properties of $PEtPh_2$ relative to PPh_3; therefore, its competition with the tin ligand is less favourable. It should be mentioned that in this system only tris-phosphane dihydrides are observed.

System $[RhH(SnCl_3)_5]^{3-}/PEt_3$

Upon addition of PEt_3 to an acetonitrile solution of **1**, deprotonation of the monohydride becomes evident by the appearance of $HPEt_3^+$ in the ^{31}P-NMR spectrum at δ = –13.7 (broad). Furthermore, four main signals with ^1J(PRh)



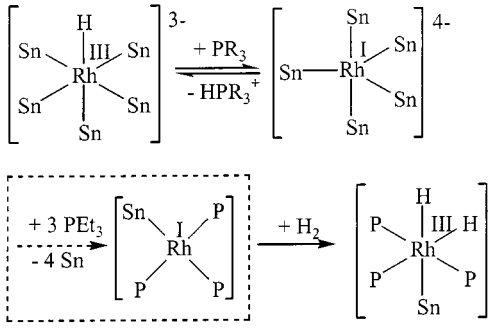


Figure 3. ^{1}H-NMR spectra of the system $[RhH(SnCl_3)_5]^{3-}$/$PEtPh_2$/H_2 in CD_3CN; a) PHIP spectrum on heating; b) PHIP++ simulation of **6b** and **3b**; c) PHIP-^{1}H{^{31}P}-NMR spectrum on heating

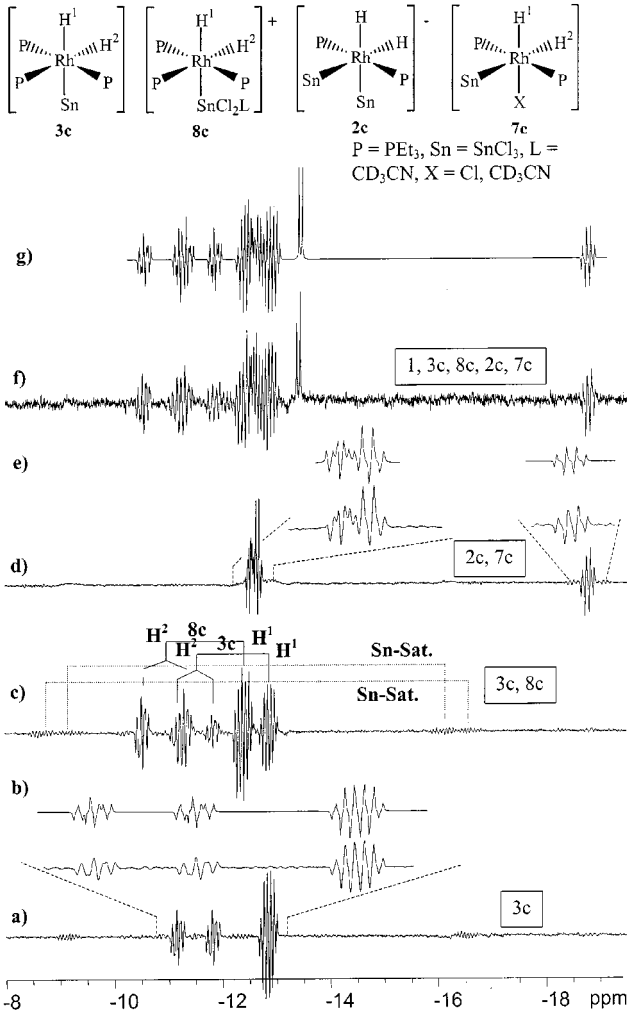
couplings of 90, 90, 116, and 137 Hz occur at δ = 7.5, 20.6, 26.4, and 42.2, respectively.

The appearance of polarized dihydrides upon parahydrogen addition depends on the initial P/Rh ratio. When an excess of phosphane (Rh/P = 1:6) is used, the resonances observed correspond to the tris-phosphane *mer*-$H_2Rh(PET_3)_3(SnCl_3)$, **3c**. This complex is also visible in the thermal spectra together with the symmetric complex **2c**, which is formed after prolonged reaction time and upon heating.

Scheme 2. Formation of a tris-phosphane rhodium dihydride at the first stage of the reaction

The dihydride **3c** is apparently the result of an oxidative addition of parahydrogen to $Rh(PET_3)_3(SnCl_3)$ formed at the very beginning of the reaction (Scheme 2). The lack of evidence for the formation of any bis-phosphane dihydrides during the first stage of the reaction can be rationalized to be the consequence of the activating *trans* effect of the first and second PET_3: If three ligands are swiftly replaced by PET_3, only the tris-phosphane is available for the oxidative addition of parahydrogen.

Likewise, at lower PET_3 concentrations (Rh/P = 1:4) the first PHIP spectrum reveals the formation of **3c** only (Figure 4, a). However, upon standing at room temperature, the addition of parahydrogen leads to the emergence of a complicated mixture of PHIP-active dihydrides, as can be concluded from the spectra shown in Figure 4, f.



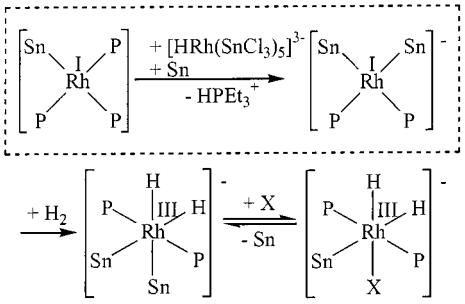


Figure 4. ^{1}H-NMR spectra of the system $[RhH(SnCl_3)_5]^{3-}$/PET_3(1:4)/H_2 in CD_3CN; a) PHIP spectrum immediately after mixing of the reagents; b) PHIP++ simulation of **3c**; c) PHIP spectrum in presence of $AgBF_4$; d) PHIP spectrum on heating; e) PHIP++ simulation of **2c** and **7c**; f) PHIP spectrum after prolonged reaction time; g) PHIP++ simulation of **1**, **2c**, **3c**, **7c**, and **8c**

Heating of the solution changes the patterns (Figure 4, d), apparently because of scrambling of the phosphane throughout the whole system (Scheme 3). Consequently, upon admission of parahydrogen two bis-phosphane dihydrides, **2c** and **7c**, are obtained. The spectral patterns observed correspond to overlapping signals of **2c** (in which the two former parahydrogen protons fail to appear in polarization, possibly due to their maintained symmetry) and the polarized multiplet of **7c**. This assignment has been confirmed by PHIP++ simulation.

Scheme 3. Formation of bis-phosphane rhodium dihydrides after prolonged reaction time

The complicated mixture of resonances observed in the PHIP spectra at room temperature after prolonged reaction times (Figure 4, f) could be analyzed to consist of the overlapping thermal and PHIP signals of **3c**, **2c**, **7c,** and of the starting complex **1,** respectively. This analysis was confirmed via PHIP++ simulation of the expected resonances for the components of this system and a subsequent weighted summation thereof (Figure 4, g).

However, in order to achieve a complete fitting of the observed patterns in the case above, the presence of another tris-phosphane dihydride has to be postulated, namely of **8c**. Its coupling patterns clearly display the *cis*-position alignment of three phosphorus ligands. The chemical shift of the H^1 proton in *cis*-position to phosphorus is characteristic for a *trans*-alignment of the tin-ligand. The difference between the two rather similar dihydrides **3c** and **8c** can only be due to variations in the structure of the tin ligand. As has already been shown before,[13,14] tin(II)chloride possesses additional coordination abilities; therefore, it can coordinate Lewis bases, leading to the formation of $SnCl_2D$ ligands (D = donor). Since this process could be strongly promoted by the abstraction of chloride, we have also recorded the spectra of this system in the presence of added $AgBF_4$ to check out the relevance of this hypothesis. The result shows a strong enhancement of the signals of **8c**, adding support to this suggestion. In addition, tin satellites are clearly visible for the resonance of H^1, exhibiting a value for ^2J(HSn), which is close to that of the related complex **3c**.

By contrast to the PPh_3 and $PEtPh_2$ chloride systems the addition of parahydrogen to the corresponding bromide systems gives rise to relatively stable, tin-containing dihydrides which appear in polarization in the PHIP-NMR spectra. Upon heating, the signals of **9c**, which is the bromide analogue of **3c**, are clearly visible. The complexes **10c** and **11c** can also be detected, which appear to be the tin-tribromide analogues of **2c** and **7c**, respectively. The high-field shift of the hydrogen in *trans*-position to the tin ligand indicates a lower *trans*-effect of $SnBr_3^-$ as compared to that of $SnCl_3^-$. Furthermore, the intensity of the PHIP signals observed in the bromide systems is generally lower than in the corresponding chloride system, apparently because of the lower concentration of Rh^I.

Hydrogenation Experiments

Upon heating, all systems studied hydrogenate added phenylacetylene in a *cis*-manner, as can be concluded from the polarization pattern of the resulting styrene. The hydrogenation activities are rather similar for all these systems.

Characteristically, in all cases investigated, the resonances of the dihydrides are present during the hydrogenation of phenylacetylene to styrene. The apparent lack of formation of any substrate-hydride complexes – similar to those detected in the previously investigated platinum-tin systems[9] – leads us to the conclusion that the observed dihydrides may not be directly included in the catalytic cycle of the hydrogenation, but might just be the precursors for related, catalytically active species. Alternatively, the rates of the individual steps for this catalytic cycle might well be rather different from those of the previously studied platinum-tin system, with the consequence that the rate-determining steps shift with the result that such intermediates, – if they are formed at all -, occur in such minute concentrations that they cannot be detected in spite of the signal enhancement associated with PHIP.

Conclusions

In comparison to PPh_3, the PEt_3 ligand has profound electron donor properties, which causes an extensive incorporation of tin ligands into the resulting dihydrides. Accordingly, when using PPh_3 as the tertiary phosphane, the formation of only one tin-containing dihydride is observed, which is thermally unstable. By contrast, in the system $[RhH(SnCl_3)_5]^{3-}/PEt_3/CD_3CN$/parahydrogen four dihydrides are detectable, which all contain tin ligands. Two of them, namely **3c** and **2c**, are rather stable species. The low stability of the tin-containing complexes with PPh_3 as the ligand is apparently due to the competition of the tin and phosphane ligands. Furthermore, this process is accompanied by more extensive incorporation of acetonitrile into the dihydrides.

In particular, the system $[RhH(SnCl_3)_5]^{3-}/PEtPh_2/CD_3CN$/parahydrogen is remarkable in the sense that it gives rise to tris-phosphane complexes only. This fact can be explained when assuming that there exists a fine balance of σ-donating and π-accepting properties of the phosphane which is apparently optimal for rhodium-phosphorus-binding here.

Experimental Section

General Remarks: All ^1H, ^1H PHIP-, ^{31}P and ^{119}Sn NMR spectra were recorded using a Bruker AC 200 spectrometer; the $^1H\{^{31}P\}$-PHIP NMR spectra were obtained with a Bruker DRX 200 spectrometer. Chemical shifts are referenced to either external TMS (^1H), 85% H_3PO_4 (^{31}P), or $Sn(CH_3)_4$ (^{119}Sn), respectively. For recording the ^{119}Sn spectrum a repetition time of 0.5 s was used, and the accumulation of 28000 scans was necessary to obtain a spectrum with a satisfactory signal-to-noise ratio. In order to obtain the PHIP spectra, excitation pulses corresponding to a flip angle of 45° were used. To record the conventional or "thermal" ^1H NMR spectra, however, the pulse width was set such that it corresponded to the conventional flip angle of 90°. The solvent CD_3CN

was purchased from Aldrich, dried and degassed prior to use, and stored under vacuum. – The simulations of the PHIP-^{1}H NMR spectra were performed using the OS/2-based PHIP++ program, developed by Greve.[15] – The complex $[RhH(SnCl_3)_5][NEt_4]_3$ was prepared as reported in the literature.[3] All starting materials were commercial products (Aldrich) which were used without additional purification.

Typical Preparation of Solutions for Hydrogenation Studies: The Rh^{III} complex, as well as PPh_3, were placed into a screw-capped NMR tube attached to a vacuum line. Then 0.7 mL of dry degassed CD_3CN was condensed into the tube. The weighted amounts of PEt_3 were vacuum-transferred to the sample. After thawing and filling with dry argon, the sample tube was disconnected from the vacuum line and fitted with a septum stopper. The necessary volumes of $PEtPh_2$ were added to the solution of the starting Rh^{III} complex using an Eppendorf micropipette. Parahydrogen was subsequently introduced into the NMR tube through a stainless steel needle through the septum at a pressure of 3 bar. After shaking of the solution in the parahydrogen atmosphere, the tube was inserted into the probe, and the ^{1}H-PHIP spectrum was recorded immediately thereafter.

Tetraethylammonium (Bromo(tribromostannato)rhodium(III) Complexes: 2 g of $SnBr_2$ (7.2 mmol) was added to a stirred solution of 0.3 g $RhBr_3$ (1 mmol) in 10 mL of 3 M HBr under argon. The mixture was heated for 1 h. After the solution had cooled down to room temperature, 0.2 M of NEt_4Br in 3 M HBr was added dropwise. A red precipitate formed which was filtered, washed three times with 3 M HBr, and dried in vacuo. The ^{119}Sn-NMR analysis revealed that the product contained several rhodium-tin complexes of the composition $[Rh(SnBr_3)_nBr_{6-n}][NEt_4]_3$. – ^{119}Sn-NMR ($CD_3CN$): δ = –332 (d, $J_{Rh,Sn}$ = 669 Hz), –354 (d, $J_{Rh,Sn}$ = 603 Hz), –361 (d, $J_{Rh,Sn}$ = 520 Hz), –425 (d, $J_{Rh,Sn}$ = 674 Hz).

A Study of the Hydration and Dehydration of Vanadyl Arsenate by X-ray Diffraction Analysis, Infrared and Raman Spectroscopy

Ludvík Beneš,*[a] Klára Melánová,[a] Vítězslav Zima,[a] Miroslava Trchová,[b] Eva Uhlířová,[b] and Pavel Matějka[c]

Keywords: Vanadyl arsenate / Hydrates / Layered compounds / Vibrational spectroscopy / X-ray scattering

The course of the intercalation and deintercalation of water molecules in vanadyl arsenate has been studied by X-ray diffraction analysis and by infrared and Raman spectroscopies. The formation of $VOAsO_4$ hydrates at ambient temperature has been found to depend on relative humidity (r.h.): $VOAsO_4 \cdot 5\,H_2O$ (basal spacing $c = 10.48$ Å) is formed at r.h. above 76%, $VOAsO_4 \cdot 3\,H_2O$ ($c = 8.03$ Å) at 43–76% r.h., $VOAsO_4 \cdot 2\,H_2O$ ($c = 7.33$ Å) at 11–43% r.h.; dehydrated $VOAsO_4$ ($c = 4.18$ Å) exists near 0% r.h. Like the thermal dehydration of $VOPO_4 \cdot 2\,H_2O$, the thermal dehydration of $VOAsO_4 \cdot 3\,H_2O$ proceeds in a stepwise manner so that the dihydrate and monohydrate are formed en route to the anhydrous compound. The arsenate monohydrate is gradually dehydrated over a broad temperature range. The broad diffraction lines observed can be explained in terms of the existence of a disordered phase containing monohydrated and anhydrous forms of vanadyl arsenate. A similar phenomenon has been observed during the dehydration of $VOAsO_4 \cdot 3\,H_2O$ over phosphorus pentoxide at ambient temperature. The hydration of $VOAsO_4$ is different from that of $VOPO_4$. The first step, i.e. the insertion of water that coordinates to the vanadium atoms, is very slow. On the contrary, the uptake of further water molecules with the formation of higher hydrates is fast. It thus seems likely that the filling of one interlayer space with water facilitates the intercalation of further water into neighboring interlayer spaces. Therefore, only higher hydrates together with the original anhydrous phase are observed. Impedance spectral measurements indicate that the conductivity of the trihydrate has a mixed ionic/electronic character.

Introduction

Compounds of the general formula $MOXO_4$ (M = V, Nb, Ta; X = P, As) constitute an isomorphic series. X-ray diffraction studies have established the structures of tetragonal forms of $MOPO_4$[1–3] and $MOAsO_4$,[4,5] which consist of chains of corner-sharing MO_6 octahedra running parallel to the *c* axis. In the *xy* plane, each MO_6 octahedron shares corners with four XO_4 tetrahedra, which link the octahedral chains to produce an $(MOXO_4)_\infty$ layer. These layers are linked along the *c* axis by the *trans*-oxygen vertices of the octahedra to form a three-dimensional lattice.

Hydrates of some of these compounds are known and their formation may be rationalized in terms of cleavage of the long M–O bonds of the respective anhydrous forms and subsequent insertion of a water molecule at the sixth coordination site of the metal in the adjacent layer. Another molecule of water, as in $VOPO_4 \cdot 2\,H_2O$, spans two layers, being simultaneously hydrogen-bonded to each. The crystal structure of this hydrate was studied by neutron powder diffraction techniques on $VOPO_4 \cdot 2\,D_2O$.[6] It confirmed the apical position of the oxygen of the first water molecule in the VO_6 octahedron. The second water molecule was found to lie between two PO_4 tetrahedra of two different $(VOPO_4)_\infty$ layers. Due to the disorder of the second water molecule, its position could not be fully determined. Isostructural hydrates of this kind have been reported for $VOPO_4$,[7,8] $VOAsO_4$,[4] $NbOPO_4$,[9] and $NbOAsO_4$.[5] Molecules other than water can also penetrate between the layers of the anhydrous hosts and can even displace water from $MOXO_4$ hydrates.[10,11]

Vanadyl arsenate forms several hydrates.[4] Vanadyl arsenate trihydrate ($a = 6.39$ Å, $c = 8.08$ Å) can be prepared by refluxing vanadium pentoxide in an excess of arsenic acid (H_3AsO_4). It was found by thermogravimetric analysis that one molecule of water is released at 50 °C forming the dihydrate ($a = 6.37$ Å, $c = 7.39$ Å). The monohydrate is formed at 80 °C and complete dehydration occurs at 105 °C resulting in anhydrous $VOAsO_4$ ($a = 6.33$ Å, $c = 4.18$ Å).

In this paper, we report on a study of these $VOAsO_4$ hydrates. The intercalation and deintercalation of water molecules has been studied by X-ray diffraction analysis and by infrared and Raman spectroscopies. The character of the hydrates has been also studied by alternating current (AC) conductivity.

Results and Discussion

In order to study the formation of various hydrates, $VOAsO_4 \cdot 3\ H_2O$ was kept in an atmosphere of controlled relative humidity (r.h.) at ambient temperature. The dependence of basal spacing and water content on relative humidity is illustrated in Figure 1. Vanadyl arsenate trihydrate was found to be stable in the r.h. range from 43% to 76%. At higher r.h., vanadyl arsenate pentahydrate with a basal spacing of 10.48 Å is formed. Vanadyl arsenate dihydrate is observed in the r.h. range from 11% to 43%. In contrast to vanadyl phosphate dihydrate, $VOAsO_4 \cdot 2\ H_2O$ loses its remaining water molecules when the r.h. is close to 0%.

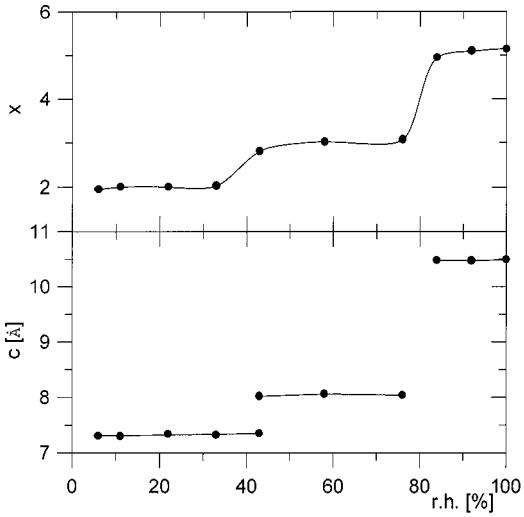

Figure 1. The dependence of the lattice parameter c and water content x of $VOAsO_4 \cdot x\ H_2O$ on relative humidity

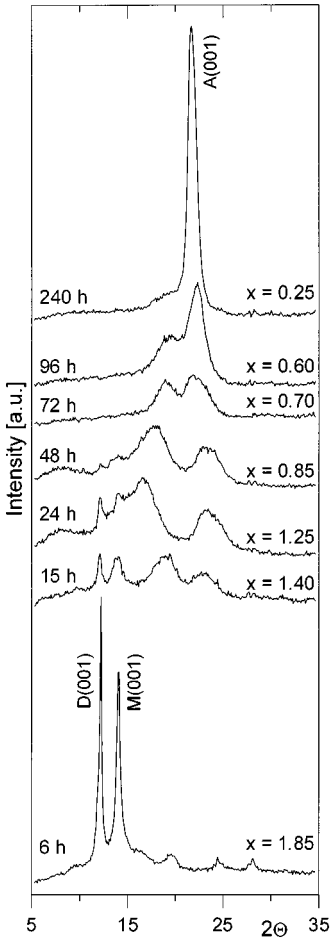

Figure 2. Diffractograms and water content x of $VOAsO_4 \cdot 3\ H_2O$ kept over P_2O_5 as a function of time; the (001) reflections of the dihydrate, monohydrate, and anhydrous compound are denoted as D, M, and A, respectively

The progressive dehydration of $VOAsO_4 \cdot 2\ H_2O$ on storage over phosphorus pentoxide at ambient temperature could be followed by XRD and TG (see Figure 2). After six hours, both the monohydrate and dihydrate were observed. Their (001) diffraction lines were sharp and the water content x became less than two. On continued dehydration, the intensities of these lines decreased, although they remained sharp. In addition, some very broad diffraction lines were seen, the positions and linewidths of which changed during the course of the dehydration. After ten days, the relatively sharp (001) line of anhydrous vanadyl arsenate had appeared. The broadening of the (00l) lines can be explained in terms of a fragmentation of the microcrystals during the dehydration, but the shift in the line positions remains unexplained. The described behavior is similar to that found for a Hendricks–Teller disordered layered lattice,[12] where layers of different types alternate randomly. However, the positions and linewidths calculated from the Hendricks–Teller functions do not correspond to those found experimentally, hence the formation of such a lattice can be excluded. As the diffractogram still shows the line due to the dihydrate after 24 h of dehydration, we presume that there is a random variation of the layers involving dihydrated, monohydrated, and anhydrous $VOAsO_4$.

In situ X-ray diffraction analysis was also employed to follow the dehydration of vanadyl arsenate trihydrate. The sample went through four diffracting phases during heating (see Figure 3). The basal spacings of these phases corresponded to the values found for $VOAsO_4 \cdot 3\ H_2O$ (c = 8.03 Å), $VOAsO_4 \cdot 2\ H_2O$ (c = 7.33 Å), $VOAsO_4 \cdot H_2O$ (c = 6.40 Å), and $VOAsO_4$ (c = 4.18 Å). The transformation of trihydrate to dihydrate was complete at 33 °C. Formation of the monohydrate was found to commence at 51 °C and this species was present up to 57 °C together with the dihydrate. In the temperature range from 63 to 111 °C, only very broad lines were observed. A Hendricks–Teller disordered structure is probably formed in this region. The temperatures of dehydration observed by XRD were lower than those determined by the thermogravimetric method. This difference can be ascribed to the fact that TG measures weight loss caused by evaporation of water released from the interlayer space of the sample.[15]

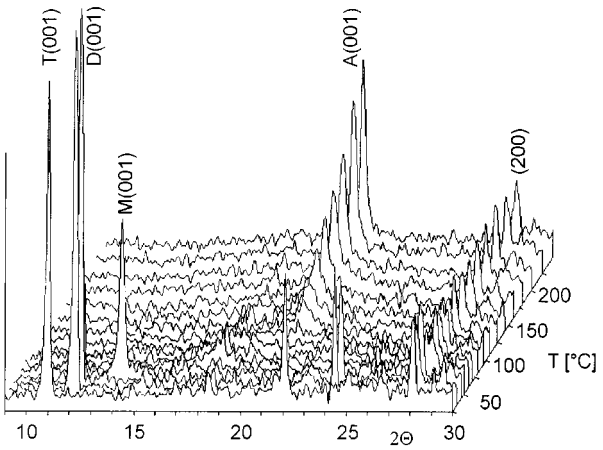

Figure 3. Temperature dependence of the X-ray diffractograms of $VOAsO_4 \cdot 3\ H_2O$

The progressive hydration of anhydrous vanadyl arsenate was studied by XRD at several relative humidities (r.h.). Even at an r.h. as high as 92%, the hydration was found to be very slow in comparison with that of $VOPO_4$.[14,16] After six hours, the intensity of the (001) diffraction line of anhydrous $VOAsO_4$ had decreased to 60% of its original value and the (001) lines of the pentahydrate and dihydrate had appeared. After one day, the intensity of the (001) line of $VOAsO_4$ had decreased to 10% and the prevailing phase was the pentahydrate. After four days, the lines due to anhydrous vanadyl arsenate had disappeared and both the pentahydrate and dihydrate were present. At an r.h. of 76%, the hydration occurred only on the surface of the crystallites of anhydrous $VOAsO_4$. The (001) reflection of the dihydrate appeared at very low intensity after one day and the diffractogram remained the same during a further five days.

Infrared Spectra

The ATR infrared spectrum of anhydrous vanadyl arsenate and the spectra of its dihydrate, trihydrate, and pentahydrate in the range 650 to 2000 cm^{-1} are shown in Figure 4. The observed bands can be fully assigned on the basis of previous studies of the $MOXO_4$ compounds.[17] The spectra have been interpreted in terms of the vibrations of the AsO_4^{3-} tetrahedron by analogy with the fundamental frequencies of the PO_4^{3-} ion in anhydrous $VOPO_4$.[16] The positions of all these bands are shifted to lower wavenumbers due to the mass effect of the As atom compared to P. Table 1 lists the spectra in the terms of the fundamental modes of AsO_4^{3-} ion, the vanadyl V=O vibration, and the O–H stretching and bending modes.

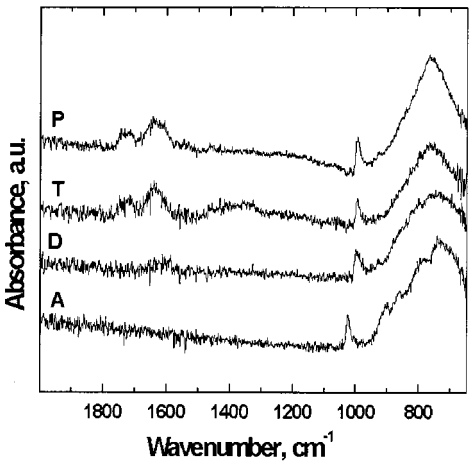

Figure 4. ATR infrared spectra of $VOAsO_4$ (A) and its dihydrate (D), trihydrate (T), and pentahydrate (P)

In the infrared spectrum of anhydrous $VOAsO_4$, the band corresponding to the degenerate antisymmetric $\nu_3(AsO_4^{3-})$ vibration is split into two bands at 905 cm^{-1} and 865 cm^{-1}. The symmetric $\nu_1(AsO_4^{3-})$ vibration at 737 cm^{-1}, which is very strong in the Raman spectrum, also appears in the infrared spectrum provided that the symmetry of the arsenate ion is perturbed from tetrahedral. It is also split in the infrared spectrum, the second band appearing at 793 cm^{-1}. The well-resolved isolated band at 1026 cm^{-1} can reasonably be attributed to the vibration of the vanadyl group V=O.

Vanadyl arsenate trihydrate is stable under ambient conditions. In the infrared spectrum of $VOAsO_4 \cdot 3\ H_2O$, in contrast to that of anhydrous $VOAsO_4$, the two bands due to the degenerate antisymmetric $\nu_3(AsO_4^{3-})$ vibration at 905 and 865 cm^{-1} are not distinguishable. They overlap with the bands of the symmetric $\nu_1(AsO_4^{3-})$ vibration in a broad maximum centred at about 740 cm^{-1}. This can be explained by the fact that there is no longer any internal stress causing

Table 1. Assignments of the observed vibration bands of $VOAsO_4$, $VOAsO_4 \cdot 2\ H_2O$, $VOAsO_4 \cdot 3\ H_2O$, and $VOAsO_4 \cdot 5\ H_2O$

Vibration	V=O	$\nu_3(AsO_4)$ + H_2O vibn.	$\nu_1(AsO_4)$ + H_2O vibn.	$\nu_2(H_2O)$ (C=O)	$\nu_1(H_2O)$	$\nu_3(H_2O)$
$VOAsO_4$	1026 cm^{-1}	905 cm^{-1} 865 cm^{-1}	793 cm^{-1} 737 cm^{-1}	not present	not present	not present
$VOAsO_4 \cdot 2\ H_2O$	1026 cm^{-1} 998 cm^{-1}	n[a]	740 cm^{-1}	1640 cm^{-1}	3500 cm^{-1}	
$VOAsO_4 \cdot 3\ H_2O$	1026 cm^{-1} 998 cm^{-1}	n[a]	740 cm^{-1}	1640 cm^{-1} (1728 cm^{-1})	3400 cm^{-1}	3580 cm^{-1}
$VOAsO_4 \cdot 5\ H_2O$	1026 cm^{-1} 997 cm^{-1}	n[a]	740 cm^{-1}	1635 cm^{-1} (1736 cm^{-1})	3400 cm^{-1}	3600 cm^{-1}

[a] Bands are overlapped or merged with the ν_1 band and cannot be distinguished.

deformation of the AsO_4^{3-} tetrahedron that leads to IR activity of this symmetric vibration. Moreover, these bands also overlap with vibration bands of H_2O molecules, which are usually observed at around 800 cm^{-1}.[16] The vanadyl group vibration band is shifted to 998 cm^{-1} in all hydrates of vanadyl arsenate. As in $VOPO_4$, this effect is caused by the coordination of a water molecule to the vanadium atom, which influences the stretching vibration of the V=O double bond. A band due to the As–O–V lattice vibrations is probably present below 400 cm^{-1}. Besides the position of the vanadyl group absorption, the spectra of all the hydrates differ from that of anhydrous vanadyl arsenate in that H_2O vibration bands are of course present. The deformation vibration of the O–H group is seen at 1640 cm^{-1}. A broad asymmetric band is observed in the region of the valence vibration of the O–H group at 3400 cm^{-1}, together with a maximum at 3580 cm^{-1} (see Table 1). The IR spectrum of the pentahydrate $VOAsO_4 \cdot 5\ H_2O$ is practically identical to that of the trihydrate $VOAsO_4 \cdot 3\ H_2O$. The spectra of these two compounds differ from that of the dihydrate in the presence of a band at about 1728 cm^{-1}, which corresponds to a small degree of contamination by the carbonyl group C=O.

Water molecules penetrated into the sample when pure, completely characterized samples of anhydrous vanadyl arsenate were briefly exposed to atmospheric moisture. The ATR infrared spectra of anhydrous $VOAsO_4$ and its progressive intercalates with water molecules under ambient conditions in the range 650 to 1150 cm^{-1} are presented in Figure 5.

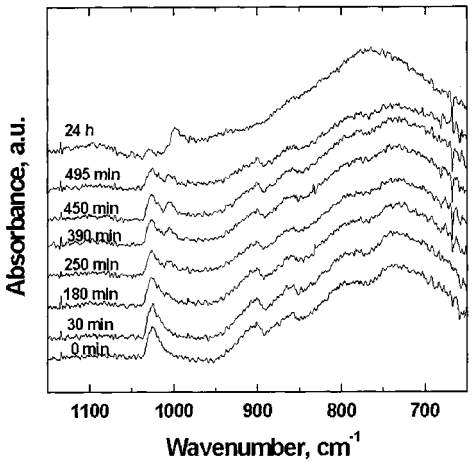

Figure 5. ATR infrared spectrum of anhydrous $VOAsO_4$ and its progressive intercalates with water molecules under ambient conditions

Analysis of these spectra led to the following conclusions:

(i) During the intercalation of water molecules, the intensity of the band at 1026 cm^{-1} due to the vanadyl V=O stretching vibration in the anhydrous form decreases, while a new band appears at 998 cm^{-1}, characteristic of the dihydrate, trihydrate, or pentahydrate.

(ii) Bands due to the symmetric stretching vibration $\nu_1(AsO_4^{3-})$ and the degenerate antisymmetric stretching vibration $\nu_3(AsO_4^{3-})$ change their profile upon hydration and become overlapped with H_2O vibration modes.

(iii) Bands due to deformation and stretching vibrations of water molecules appear at about 1640 cm^{-1} and 3400 cm^{-1} upon hydration.

(iv) The spectrum after 24 hours (Figure 5) is very similar to that of vanadyl arsenate trihydrate (or pentahydrate).

The fact that vanadyl stretching bands are present in both of the aforementioned positions in the initial stages of the intercalation indicates the simultaneous presence of anhydrous and hydrated forms. The changes in the profile of the $\nu_3(AsO_4)$ vibration bands indicate that the system of hydrogen bonds between water molecules and the oxygen of the AsO_4 tetrahedron affects its stretching and bending modes, as was observed for the hydrates of $VOPO_4$.[16]

Raman Spectroscopy

The Raman spectra strongly support the assignments of the bands observed in the infrared spectra of all the studied compounds. Unfortunately, it was not possible to study the kinetics of the hydration process by Raman spectroscopy since the laser irradiation caused a partial escape of water molecules during the measurements. The spectra corresponding to the different hydrated states of the samples between the anhydrous and hydrated forms (spectra 1, 2, and 3 in Figure 6) were obtained by regulation of the incident beam power and of the number of scans.

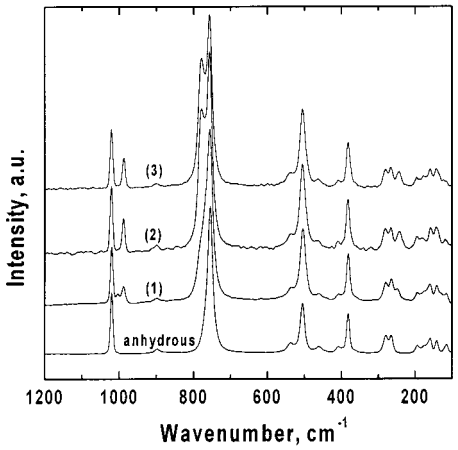

Figure 6. Raman spectra of $VOAsO_4$ and its intermediate hydrate states

The Raman spectrum of anhydrous $VOAsO_4$ (measured in a sealed ampoule) in the range 100 to 1200 cm^{-1} is shown in Figure 6. A strong symmetric $\nu_1(AsO_4^{3-})$ vibration is observed only at 756 cm^{-1}. A very small band due to the degenerate antisymmetric $\nu_3(AsO_4^{3-})$ vibration is observed only at 899 cm^{-1}. The position of the well-resolved isolated band at 1020 cm^{-1} corresponds to the vibration of the vanadyl group V=O in anhydrous vanadyl arsenate. In addition to these features, bands due to symmetric bending vibrations $\nu_4(AsO_4^{3-})$ at 535 cm^{-1} and 506 cm^{-1} and antisymmetric bending vibrations $\nu_2(AsO_4^{3-})$ at 408 and 382 cm^{-1} are also observed in the Raman spectra. The bands at about

270 cm^{-1} can probably be attributed to δ(O–As–O) deformation vibrations.

The effect of water on the spectra of vanadyl arsenate can thus be summarized as follows (see also Figure 6):

(i) In addition to the well-resolved isolated band at 1020 cm^{-1}, attributed to the vibration of the vanadyl group V=O in the anhydrous form of $VOAsO_4$, another peak at 989 cm^{-1} is observed in the Raman spectra of the hydrated forms of $VOAsO_4$.

(ii) A strong symmetric $\nu_1(AsO_4^{3-})$ vibration at 756 cm^{-1} with a strong overlapping shoulder at 780 cm^{-1} is observed.

(iii) A band due to the degenerate antisymmetric $\nu_3(AsO_4^{3-})$ vibration is observed at 899 cm^{-1} and a small shoulder is seen at 920 cm^{-1} in accordance with the infrared results.

AC Conductivity

In order to compare the electrical properties of $VOAsO_4$ with those of the previously studied $VOPO_4$,[20] its AC conductivity was determined by impedance spectroscopy. The impedance data show an arc-shaped dependence of the imaginary versus the real component, which passes through the origin in the complex impedance plot. A resistance connected in parallel with a constant phase element (CPE) was chosen as an equivalent circuit.[18] The dependence of impedance Z (where $Z = Z' - jZ''$) on frequency f for this circuit is given by Equation 1.

$$Z = \frac{R}{1 + \left(j\omega\tau_0\right)^{1-\alpha}} \quad (1)$$

Here, $\omega = 2\pi f$ is the angular frequency, R is the resistance, τ_0 is the relaxation time, and α is a parameter describing a distribution of relaxation times in frequency space. Parameters R, τ_0, and α were estimated from the experimental values by a complex nonlinear least-squares fitting.[19] The conductivity σ_m was then calculated from the estimated resistance R and the dimensions of the sample. The AC impedance curve measured at room temperature and 58% relative humidity was similar to that found for $VOPO_4 2H_2O$[20] indicating similar conductivity behavior. Indeed, the conductivities of $VOPO_4 \cdot 2\,H_2O$ and $VOAsO_4 \cdot 3\,H_2O$ are roughly the same, $\sigma_m = 1.3 \cdot 10^{-5}$ S cm^{-1}. These facts suggest that the electrical properties of $VOXO_4$ materials are not influenced by the atom X. According to these preliminary measurements, the M atom in $MOXO_4$ plays a more important role in the conductivity mechanisms. A more detailed study of the conductivities of these materials is currently underway.

Experimental Section

Materials: Vanadyl arsenate trihydrate was prepared by prolonged boiling of a mixture of vanadium pentoxide and arsenic acid (H_3AsO_4) in water[4] and was stored over a saturated aq. solution of NaBr (r.h. 58%). The samples of $VOAsO_4 \cdot 2\,H_2O$ and $VOAsO_4 \cdot 5\,H_2O$ for IR measurements were obtained by prolonged storage of the trihydrate over saturated solutions of LiCl (r.h. 11%) and KNO_3 (r.h. 92%), respectively. Anhydrous $VOAsO_4$ was prepared by dehydration of the trihydrate at about 300 °C in vacuo for 4 h. The water contents of samples were determined thermogravimetrically. The TG analyses were performed using a Derivatograph C (MOM, Budapest, Hungary). The measurements were performed in air between 20 and 500 °C at a heating rate of 5 K min^{-1}.

X-ray Diffraction: Powder data were obtained with an HZG-4 X-ray diffractometer (Freiberger Präzisionsmechanik, Germany) using Cu-K_α radiation with elimination of Cu-K_β radiation by means of an Ni filter. Diffraction angles were measured in the 2θ range 5–50°. Variable-temperature measurements in the range 20–250 °C were carried out on a thermocouple-controlled heated corundum plate.[21]

Infrared Spectroscopy: IR measurements were made with a Nicolet Impact 400 Fourier transform infrared (FTIR) spectrophotometer in an H_2O-purged environment. An ambient-temperature deuterated triglycine sulfate (DTGS) detector was used for the range from 400 to 4000 cm^{-1}. A Happ–Genzel apodization function was used in all regions and the spectral resolution was 2 cm^{-1}. Approximately 300 scans were accumulated to achieve the signal-to-noise ratio shown. The Baseline Horizontal Attenuated Total Reflection (ATR) accessory with a ZnSe crystal (n = 2.4 at 1000 cm^{-1}) was used in measuring the infrared spectra of the samples. The effective pathlength was approximately a few μm (incident angle 60°, number of reflections 7). The ATR correction was made to eliminate the dependence of the effective pathlength on the wavelength. After some trials, it was found that the best results were obtained when the sample was exposed to the external conditions for a definite time without being removed from the crystal between the subsequent spectral measurements. In this way, the water molecules are deposited on the surface of the ZnSe crystal from the volume and the adsorption of water onto the surface of the sample under investigation is avoided. The vibrational spectrum of each compound was recorded five times using five different samples of the same material. No variation of the studied spectral features was observed between the samples.

Raman Spectroscopy: FT Raman spectra were recorded using an Equinox 55/S Fourier-transform near-infrared (FT-NIR) spectrometer (Bruker) equipped with an FT Raman module FRA 106/S (Bruker). The samples were irradiated with a focused laser beam with a power of 100 mW (Nd-YAG laser, 1064 nm, coherent). The scattered light was collected in a back-scattering geometry. A quartz beamsplitter and a Ge detector (liquid N_2 cooled) were used to obtain interferograms. 128 interferograms were accumulated and subsequently Fourier-transformed using Blackman–Harris 4-term apodization and a zero-filling factor of 8 to obtain final FT Raman spectra in the range 4000–1000 cm^{-1} with 4 cm^{-1} resolution. The FT Raman spectra of pure, well-defined species ($VOAsO_4$, $VOAsO_4 \cdot 3\,H_2O$, $VOAsO_4 \cdot 5\,H_2O$) were recorded from samples in sealed glass ampoules. The ampoules were placed in the sample holder and aligned by the motorized x-y-z sample stage to achieve the optimal optical conditions for sample irradiation and the collection of the scattered light. The FT Raman spectra collected during the intercalation of water were obtained from samples placed in an aluminium cup. The aluminium cup was optically pre-aligned using sulfur as a sample and then the sulfur was replaced by the sample under investigation.

AC Conductivity: Rectangular pellets of dimensions 8 × 3 × 2 mm were prepared by compressing 15 mg of the sample at 2.5 MPa. As

a result of the applied pressure, the layers were preferentially oriented in a plane perpendicular to the direction of the pressure. The opposite sides of the pellets were coated with graphite paste, which served as electrodes, and the AC conductivity was measured along the layers. A Tesla BM 653 impedance meter working in the frequency range 20 Hz to 500 kHz was used for the measurements.

Tricarbonyl-η⁶-[(2-thiophenyl)arene]- and -η⁶-[(2-thiophenyl)carbonylarene]-chromium Complexes: Preparation and Conformational Study

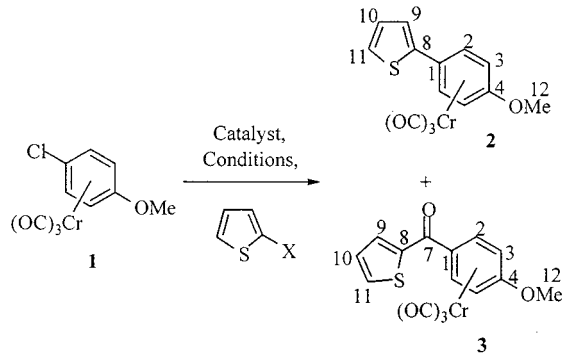
Damien Prim,[a] Jean-Philippe Tranchier,[a] Françoise Rose-Munch,[a] Eric Rose,*[a] and Jacqueline Vaissermann[b]

Keywords: Arenetricarbonyl chromium complexes / Palladium / Cross coupling reaction / Thiophenes

The cross coupling reaction of (*p*-chloroanisole)tricarbonylchromium complex (**1**) with thiophene derivatives under palladium-catalyzed conditions leads to the selective formation of tricarbonyl-η⁶-[(2-thiophenyl)arene]- or -η⁶-[(2-thiophenyl)carbonylarene]chromium complexes (**2** or **3**) depending on reaction conditions. The conformation of complexes **2** and **3** in the solid state as well as in solution are reported.

Introduction

Over the last three decades, cross-coupling reactions using Stille, Suzuki, or Negishi methodologies have attracted much attention.[1,2] The unique behaviour of organotin, boron, or zinc reagents with different halogenated aromatics (iodides, bromides, and more recently, chlorides[3]) under palladium catalysis has become one of the most powerful C_{sp2}–C_{sp2} bond formation methods.



It has been shown that the decrease of the electron density in an aromatic ring due to the presence of the $Cr(CO)_3$ moiety allows an easier oxidative addition of the carbon–halogen bond to the zero-valent palladium active species, which is the initial step of most of the palladium-catalyzed cross coupling processes. This ability allowed for the more frequent inclusion of aryl chloride among the electrophiles, thus enhancing the usefulness of these reactions.[4–6] Since then, palladium-catalyzed processes at π-bond ligands in the presence of $Cr(CO)_3$ groups have been developed.[7]

As part of our current studies on organochromium complexes[8,9] and on cross-coupling reactions,[10,11] we were interested in the preparation of tricarbonyl-η⁶-[(thiophenyl)arene- and -(thiophenyl)carbonylarene]chromium complexes by using a bimetallic activation. This paper describes how the judicious choice of reaction conditions can lead to exceptional selectivities in this class of bond-formation reactions. In particular, in taking advantage of CO insertion under a carbon monoxide atmosphere, exclusive access to carbonylation products can be achieved.

Results and Discussion

The reaction of *p*-chloroanisole tricarbonylchromium complex (**1**) with thiophene derivatives under palladium-catalyzed conditions (Scheme 1) leads to the formation of two new complexes: the expected thienyl complex **2** but also a second compound due to a carbonyl insertion into the newly formed carbon-carbon bond. We have examined the scope of this reaction with three different thienyl derivatives under several palladium-catalyzed procedures, and the results are presented in Table 1.

Scheme 1

We first tried the classical conditions: $PdCl_2(PPh_3)_2$ in refluxing THF (entry 1), complexes **2** and **3** were obtained in 54% yield in a 3:1 ratio.[12] The two complexes were easily separated by column chromatography, and their spectral data as well as their conformational study in solution and in the solid state will be discussed later (vide infra). If this reaction was performed with (2-thienyl)boronic acid (entry 2) and 2-thienyl zinc chloride[10] (entry 3) (prepared in situ from 2-thienyllithium and anhydrous zinc chloride in THF) complexes **2** and **3** were obtained in a 7:1 ratio (63% yield) and 3.5:1 ratio (19% yield), respectively after silica gel column chromatography. Under milder reaction conditions (room temperature) using Stille-coupling reaction conditions and a modified catalytic system[13] such as $Pd_2(dba)_3$

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 2000 1434–1948/00/0505–0901 $ 17.50+.50/0

Table 1. Preparation of complexes **2** and **3**

Entry	X	Catalyst	Conditions	Time [h]	2:3	Yield [%]
1	$SnBu_3$	$PdCl_2(PPh_3)_2$	THF, reflux	18	3:1	54
2	$B(OH)_2$	$Pd(PPh_3)_4$	Acetone, K_2CO_3, reflux	14	7:1	63
3	ZnCl	$Pd(PPh_3)_4$	DMF, 80°	18	3.5:1	19
4	$SnBu_3$	$Pd_2(dba)_3$, 4 $AsPh_3$	DMF, room temp.	20	1:0	82
5	$SnBu_3$	$PdCl_2(PPh_3)_2$	THF, CO, reflux	2	0:1	88

and $AsPPh_3$, where the arsane ligand has been shown to be a more effective dissociative ligand at the transmetallation stage (entry 4), we succeeded in selectively preparing complex **2** in good yield (82%). This selectivity is certainly due to the reaction conditions (room temperature) which inhibit the internal CO migration and therefore the formation of compound **3**. This reaction represents a significant improvement in the synthesis of such complexes. Indeed, the preparation of the [(2-thienyl)-η^6-benzene]tricarbonylchromium complex has already been reported[14] using thermal complexation of the $Cr(CO)_3$ entity to the six-membered ring of 2-phenylthiophene, but with a low yield of 7%. Moreover, if we carried out the coupling reaction under a CO atmosphere as reported in entry 5, we were able to isolate complex **3** as the sole product in high yield (88%).

Conformational Studies in Solution and in the Solid State of Complexes 2 and 3

Solution

The spectral data of complexes **2** and **3** were in good agreement with their respective structures. The IR spectrum of complex **3** showed one band typical for a keto group at 1635 cm^{-1}, besides the bands between 1900 and 1975 cm^{-1} due to CO ligands.

The ^{1}H-NMR data of complexes **2** and **3** are noteworthy to observe the influence by the coordination of the $Cr(CO)_3$ entity and by the conformation of the tripod in solution[15] on the chemical shifts of the protons of the arene. Indeed, protons H-2 and H-3 of complex **2** are privileged spectators vis-à-vis the $Cr(CO)_3$ conformation: they resonate at δ = 5.92 and 5.20 (Table 2, entry 1). Knowing

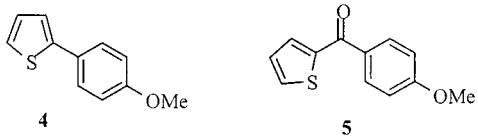

Figure 1. Free arenes

that the protons H-2 and H-3 of the free arene **4** (Figure 1) resonate at δ = 7.60 and 6.96 (Table 2, entry 2), we were able to calculate the shielding of these protons as Δδ = δ(free arene **4**) – δ(complex **2**). In this way we obtained the values of Δδ = 1.68 for H-2 and 1.76 for H-3 in complex **2** (Table 2, entry 3), a small difference of 0.08 ppm! In other words, the coordination of the tricarbonylchromium entity has the same shielding effect on the arene protons. These data are in good agreement with an almost staggered conformation of the $Cr(CO)_3$: indeed the two conformations eclipsing (**2E**, Figure 2) and *anti*-eclipsing the methoxy group (**2AE**, Figure 2), which are in equilibrium, are present in an almost 50:50 ratio.[16]

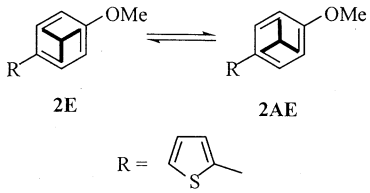

Figure 2. The two conformers of complex **2**

For complex **3**, the shielding of the two protons H-2 and H-3: Δδ = δ(free arene **5**) – δ(complex **3**) are 1.57 and 1.78 ppm, respectively, a difference of 0.21 ppm[17a]

Table 2. ^{1}H- and ^{13}C-NMR data for compounds **2**–**5**

Entry	Compound	H-2	H-3	δ(H-2) – δ(H-3)	Δδ(H-2) – Δδ(H-3)	C-2	C-3
1	2[a]	5.92	5.20	0.72	–	93.3	77.5
2	4[a]	7.60	6.96	0.64	–	127.3	114.1
3	$\Delta\delta^{[a]} = \delta(4) - \delta(2)$	1.68	1.76	–	0.08	34.0	36.6
4	2[b]	5.25	4.37	0.88	–		
5	4[b]	7.43	6.69	0.74	–		
6	$\Delta\delta^{[b]} = \delta(4) - \delta(2)$	2.18	2.32	–	0.14		
7	3[a]	6.32	5.19	1.13	–	95.8	76.6
8	5[a]	7.89	6.97	0.92	–	131.9	144.1

[a] $CDCl_3$. – [b] C_6D_6.

(Table 2, entry 9). These data are no longer consistent with a mean staggered conformation of the tripod in solution. As the proton H-2 resonates at a lower field (δ = 6.32) with respect to the proton H-3 (δ = 5.19), the population of the conformation eclipsing the methoxy group should be favoured. This can be explained by the synergic effect of the electron-withdrawing keto group which favours an *anti*-eclipsed conformation and of the electron-donating methoxy group which favours the eclipsed conformation.[17b–17f]

Some of the ^{13}C-NMR data of compounds **2–5** are reported in Table 2. First of all, the spectrum of complex **3** displayed, among others, a signal at δ = 230.7 attributed to the carbonyl keto group, whereas carbons of carbonyl ligands appeared as a signal at δ = 232.2. The shielding of the aromatic carbons of the arene ring of complexes **2–5** are, as expected, between 34 and 37 ppm, except the quaternary carbons bearing the methoxy group which are shielded only by 17.1 and 19.8 ppm for complexes **2** and **3**, respectively (Table 2, entries 3 and 9). It is worthy to note that the quaternary carbons C-8 of the thiophene residues of complexes **2** and **3** are also shielded by 17.2 and 22.0 ppm, the other carbons C-9, C-10, C-11 resonating at almost the same field for couples **2**, **4** and **3**, **5**.

Solid State

In order to know more about the conformation of complexes **2** and **3**, they were both subjected to X-ray analysis. The ORTEP views showing the most important bond distances appear in Figure 3 and Figure 4. The conformation of the $Cr(CO)_3$ entities of complexes **2** and **3** are very similar, adopting an almost staggered conformation. The

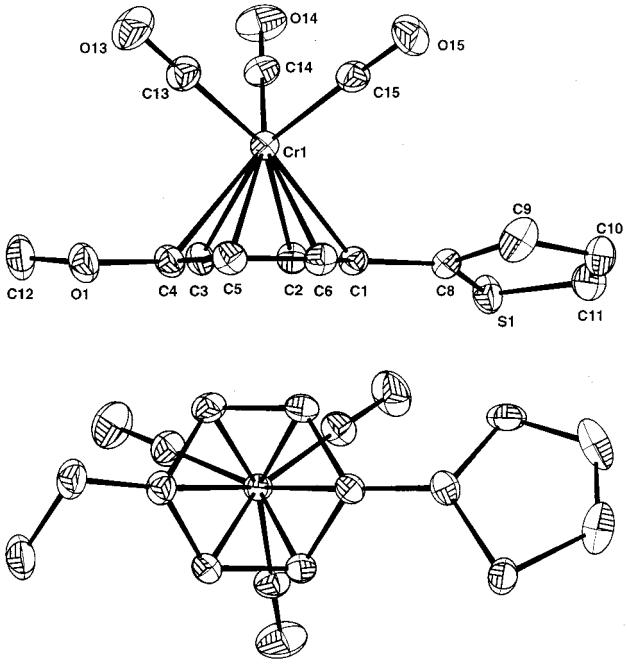

Figure 3. Two views of ORTEP diagram of complex **2**. Selected bond lengths [A]: Cr–C-1 2.233(3), Cr–C-2 2.201(3), Cr–C-3 2.251(3), Cr–C-4 2.289(3), Cr–C-5 2.221(3), Cr–C-6 2.203(3), C-8–C-9 1.46(2), C-10–C-11 1.326(2)

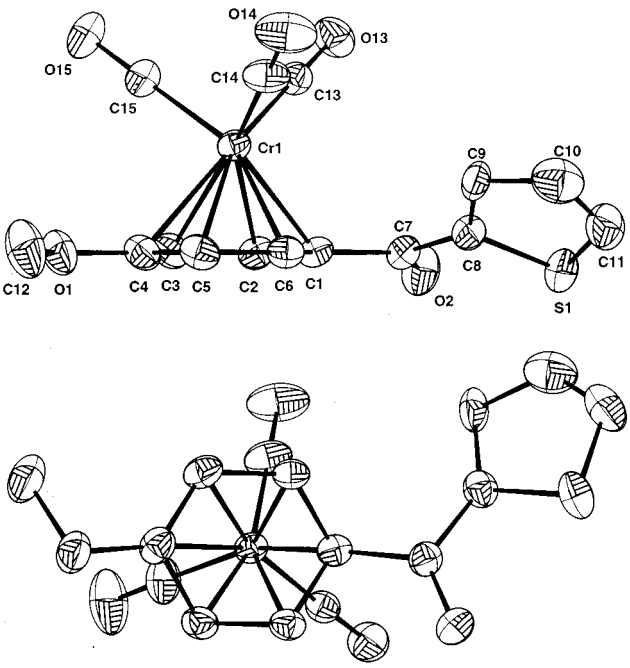

Figure 4. Two views of ORTEP diagram of complex **3**. Selected bond lengths [A]: Cr–C-1 2.181(4), Cr–C-2 2.206(4), Cr–C-3 2.238(4), Cr–C-4 2.282(4), Cr–C-5 2.242(4), Cr–C-6 2.181(4), C-8–C-9 1.52(3), C-10–C-11 1.326(7), C-7–O-2 1.216(5)

values of the torsion angles C-2–C-100–Cr–C-14, C-4–C-100–Cr–C-13, and C-6–C-100–Cr–C-15 for **2** (C-100 being the centre of the six-membered ring) are 22.73°, 22.41°, and 23.12°, respectively. The corresponding values C-2–Cr–C-100–C-13, C-6–Cr–C-100–C-14, and C-4–Cr–C-100–C-15 for **3** are 20.76°, 22.42°, and 21.76°, respectively. These data clearly show that the solid state and solution conformations of the $Cr(CO)_3$ entities are almost the same for complex **2**, but are different for complex **3**. It is interesting to point out that in the case of complex **2**, the thiophene plane is not parallel to the arene plane, the dihedral angle being 19°. In the case of complex **3**, the carbonyl function is not in the plane of the arene ring, the carbonyl pointing out in the direction opposite to the $Cr(CO)_3$ entity with dihedral angles of 14° (with the six-membered arene ring) and of 23° (with the thiophene ring). These features could partially explain why the carbonyl group does not play a complete electron-withdrawing effect in the solid state.

Conclusion

By using the same coupling reaction, we were able to selectively synthesise, in high yield, [(2-thiophenyl)-η⁶-arene]- and [(2-thiophenyl)oxo-η⁶-arene]tricarbonylchromium complexes by slightly modifying the reaction conditions. This methodology addresses the potentiality of this highly versatile bimetallic activation in the preparation of new arenechromiumtricarbonyl complexes.

Experimental Section

General: All experiments were protected at all times from exposure to light and oxygen. Workup procedures were done in air. Tetrahy-

drofuran (THF) used was distilled from sodium benzophenone ketyl under dry nitrogen. – ^{1}H- and ^{13}C-NMR spectra were obtained with Bruker 200 and ARX 400 spectrometers. – Infrared and UV/Vis spectra were recorded with Perkin–Elmer 1420 and Shimadzu 1420 spectrometers, respectively. – Elemental analyses were performed by Le Service de Microanalyses de l'Université Pierre et Marie Curie. – Melting points were measured with a Reichert apparatus. The coupling procedures using 2-thienylzinc chloride and thienylboronic acid had been reported in ref.[10] (4-Anisole)tricarbonylchromium complex was prepared according to ref.[18]

Coupling Reaction with 2-(Tributylstannyl)thiophene. – General Procedure: $Pd_2(dba)_3$ (0.025 g, 0.05 mmol) and $AsPh_3$ (0.06 g, 0.2 mmol) were added successively to complex **1** (0.280 g, 1 mmol) and 20 mL of anhydrous DMF. After 30 min at room temperature, 2-tributylstannylthiophene (0.355 g, 1 mmol) in 5 mL of DMF was added. The mixture was stirred at room temperature for 20 h, poured into 100 mL of ice cold water, and extracted twice with 50 mL of diethyl ether. The combined organic phases were dried on magnesium sulfate and evaporated under reduced pressure. The residue was then purified by flash chromatography on silica gel (petroleum ether/ethyl acetate 75:25) to afford complexes **2** (R_f = 0.36) and **3** (R_f = 0.27) as a yellow and an orange solid, respectively.

Complex 2: M.p. 189–190 °C (Et_2O/petroleum ether 1:1). – IR (CH_2Cl_2): $\tilde{\nu}$ = 1965 cm^{-1} ($Cr(CO)_3$), 1885 cm^{-1} ($Cr(CO)_3$). – UV/Vis (CH_2Cl_2): λ_{max} (ε) = 334 nm (8860), 232 (3400). – ^{1}H NMR ($CDCl_3$): δ = 3.72 (s, 3 H, OCH_3), 5.20 (d, J = 7.1 Hz, 2 H, H-3), 5.92 (d, J = 7.1 Hz, 2 H, H-2), 6.94 (m, 1 H, H-10), 7.18 (d, J = 4.7 Hz, 1 H, H-11), 7.23 (d, J = 3.8 Hz, 1 H, H-9). – ^{1}H NMR (C_6D_6): δ = 2.88 (s, 3 H, OCH_3), 4.37 (d, J = 7.0 Hz, 2 H, H-3), 5.25 (d, J = 7.0 Hz, 2 H, H-2), 6.56 (m, 1 H, H-10), 6.66 (d, J = 4.7 Hz, 1 H, H-11), 6.77 (d, J = 3.4 Hz, 1 H, H-9). – ^{13}C NMR ($CDCl_3$): δ = 56.1 (C-12), 77.5 (C-3), 93.3 (C-2), 96.7 (C-1), 124.6 (C-11), 125.9 (C-9), 127.3 (C-8), 128.0 (C-10), 142.2 (C-4), 232.7 (CO). – MS (70 eV); *m/z* (%): 327 (14) [M^{+1}], 191 (100) [M^{+1} – $Cr(CO)_3$]. – $C_{14}H_{10}CrO_4S$ (326.3): calcd. C 51.33, H 3.09; found C 51.56, H 3.10.

Complex 3: M.p. 160–161 °C (Et_2O/petroleum ether 1:1). – IR (CH_2Cl_2): 1975 cm^{-1} ($Cr(CO)_3$), 1900 cm^{-1} ($Cr(CO)_3$), 1645 (CO). – UV/Vis (CH_2Cl_2): λ_{max} (ε) = 302 nm (39300), 230 (25100). – ^{1}H NMR ($CDCl_3$): δ = 3.78 (s, 3 H, OCH_3), 5.19 (d, J = 7.0 Hz, 2 H, H-3), 6.32 (d, J = 7.1 Hz, 2 H, H-2), 7.17 (m, 1 H, H-10), 7.70 (d, J = 4.9 Hz, 1 H, H-11), 7.84 (d, J = 3.7 Hz, 1 H, H-9). – ^{1}H NMR (C_6D_6): δ = 2.85 (s, 3 H, OCH_3), 4.23 (d, J = 7.1 Hz, 2 H, H-3), 5.82 (d, J = 7.1 Hz, 2 H, H-2), 6.55 (m, 1 H, H-10), 6.81 (d, J = 4.5 Hz, 1 H, H-11), 7.60 (d, J = 3.8 Hz, 1 H, H-9). – ^{13}C NMR ($CDCl_3$): δ = 56.1 (C-12), 76.6 (C-3), 93.3 (C-1), 121.9 (C-8), 128.2 (C-10), 133.2 (C-11), 134.1 (C-9), 144.1 (C-4), 230.7 (C-7), 232.2 (CO). – MS (70 eV); *m/z* (%): 355 (18) [M^{+1}], 219 (40) [M^{+1} – $Cr(CO)_3$]. – $C_{15}H_{10}CrO_5S$ (354.3): calcd. C 50.85, H 2.85; found C 50.67, H 2.70.

Crystal Structure of 2: $[(CO)_3Cr(C_{11}H_{10}OS)]$, M = 326.3, μ = 0.972 mm^{-1}; ρ = 1.59 gcm^{-3} orthorhombic, $P2_12_12_1$, Z = 4, a = 8.111(1), b = 11.196(1), c = 15.027(2) Å, V = 1364.6(3) Å^3, from 25 reflections (34° < 2θ < 34.6°). Cell dimensions and intensities were measured at 295 K on a Nonius CAD4 diffractometer with graphite-monochromated Mo-K_α radiation (λ = 0.71069 Å). ω/20 scans, two standard reflections measured every two hours showed no significant variation 1° < θ < 30° (0 < h 11, 0 < k < 15, 14 < l < 21); 2293 measured reflections, 2268 unique reflections of which 2001 were observed {$[F_o]^2 > 3\sigma([F_o]^2)$}. Data were corrected for Lorentz and polarization effects. The structure was solved by direct methods using SHELXS,[19] all other calculations used CRYSTALS.[20] Atomic scattering factors and anomalous dispersion terms were taken from ref.[21] Full-matrix least-squares refinement based on [F] and a Chebychev weighting scheme gave final values R = 0.0383, wR = 0.0432 and s = 1.04 for 201 variables and 2001 contributing reflections. The maximum shift/esd on the last cycle was 1.71. Non-hydrogen atoms were anisotropically refined. A disorder was observed on the thiophene group between the sulfur atom S(1) and the carbon atom C(9). The best solution was obtained by a model with two positions with an occupancy of approximately 0.63/0.37. Hydrogen atoms were introduced in calculated positions (except on the thiophene group) and only an overall isotropic thermal parameter was refined. The final difference electron density map showed a maximum of 0.27 and a minimum of –0.38 eÅ^{-3}.

Crystal Structure of 3: $[(CO)_3Cr(C_{12}H_{10}O_2S)]$, M = 354.3, μ = 0.892 mm^{-1}; ρ = 1.56 g.cm^{-3} triclinic, P –1, Z = 2, a = 7.355(5), b = 10.520(3), c = 10.665(6) Å, α = 109.56(3), β = 93.65(5), γ = 101.91(4)°, V = 752.9(7) Å^3, from 25 reflections (26° < 2θ < 28°). Cell dimensions and intensities were measured at 295 K on a Nonius CAD4 diffractometer with graphite-monochromated Mo-K_α radiation (λ = 0.71069Å). ω/2θ scans, two standard reflections measured every hour showed no significant variation 1° < θ < 28° (0 < h < 9, –13 < k < 13, 14 < l < 14); 3907 measured reflections, 3628 unique reflections of which 2311 were observed ($[F_o]^2 > 3\sigma([F_o]^2)$); R_{int} = 0.04 for equivalent reflections. Data were corrected for Lorentz and polarization effects. The structure was solved by direct methods using SHELXS,[19] all other calculations used CRYSTALS.[20] Atomic scattering factors and anomalous dispersion terms were taken from ref.[21] Full-matrix least-squares refinement based on [F] and a Chebychev weighting scheme gave final values R = 0.0587, wR = 0.0711 and s = 1.04 for 245 variables and 2311 contributing reflections. The maximum shift/esd on the last cycle was 1.75. Non-hydrogen atoms were anisotropically refined. A disorder was observed on the thiophene group between the sulfur atom S(1) and the carbon atom C(9). The best solution was obtained by a model with two positions with an occupancy of approximately 0.65/0.35. Hydrogen atoms (except on the thiophene group) were located on a difference Fourier map; their coordinates were refined with an overall isotropic thermal parameter. The final difference electron density map showed a maximum of 0.47 and a minimum of –0.58 eÅ^{-3}.

Crystallographic data (excluding structure factors) have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication n° CCDC 132984 and CCDC 132985. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1 EZ, UK (Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk).

[16] We observed a similar effect during the study of the conformation of the tripod in solution of (2,6-dimethylchlorobenzene)-tricarbonylchromium, where no difference of shielding effect was detected for the aromatic protons (ref. [15b]).

[17] [17a] We also studied the conformation of the $Cr(CO)_3$ tripod in solution in another solvent. In C_6D_6 the H_2 and H_3 proton shielding are $\delta = 2.18$ and 2.32 for complex **2** (Table 2, entry 6). These shielding effects are $\delta = 1.98$ and 2.56 for complex **3**. – [17b] W. R. Preparation and Properties of Carbonyliron Complexes of 1-Aza-4-oxa-1,3-butadiene (α-Imino Ketone) – X-ray Crystal Structures of $Fe(CO)_3$[MeN=C(Ph)C(Ph)=O] and $Fe_2(CO)_4$[*t*BuN=C(H)(Me)C(O)(O)C(Me)C(H)=N*t*Bu]

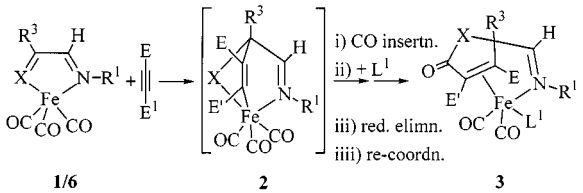
Ron Siebenlist,[a] Hans-Werner Frühauf,*[a] Kees Vrieze,[a] Wilberth J. J. Smeets,[b] and Anthony L. Spek[b]

Keywords: Coordination chemistry / α-Imino ketones / CO complexes / Iron complexes

The reaction of $Fe_2(CO)_9$ at room temperature in THF or toluene with the α-imino ketones $R^1N=C(R^2)–C(R^3)=O$ (L) (R^1 = alkyl, R^2 = H, Me, Ph, R^3 = Me, Ph) (**a–k**), initially results in the formation of the mononuclear chelate $Fe(CO)_3$(α-imino ketone) complexes **6** which can be isolated in moderate (**6h**) to high (**6e–g**) yield. Under these reaction conditions, complexes **6** subsequently react with [$Fe(CO)_4$] fragments or dimerise, to form the dinuclear complexes $Fe_2(CO)_6$(α-imino ketone) (**7a–j**) or $Fe_2(CO)_4$(L–L) (**8a,b,k**), respectively. The complexes **8** contain two α-imino ketone ligands C–C coupled at the ketone carbon atoms. Complexes **8a,b** react with CO at elevated temperatures to quantitatively yield $Fe(CO)_3$(α-imino ketone) (**6a,b**). This reaction can be reversed photochemically. Irradiation of a solution of **6a,b** in the low-energy band results in the reformation of **8a,b** in almost quantitative yield. The extremely air-sensitive complexes **6** and the dinuclear complexes **7** and **8** have been characterised spectroscopically (IR, UV/Vis, ^1H and ^{13}C NMR) and by elemental analysis. The solid state structures of complexes **6g** and **8a** have been determined by single-crystal X-ray diffraction. The molecular structure of **6g** confirms the flat σ-*O*,σ-*N* chelate coordination of the α-imino ketone. The structure of **8a** consists of two metal–metal-bonded $Fe(CO)_2$ units, bridged by a formally 10e-donating dianionic C–C coupled (*t*Bu-ADO) ligand. A mechanism for the formation of complexes **8** is discussed.



Introduction

The reaction of α-diimine ligands $R^1N=C(H)–C(H)=NR^1$ (R-DAB) (cf. Table 1) and C_5H_4N-2-$C(H)=NR^1$ (R-Pyca) (cf. Table 1) with carbonylmetal compounds of the iron triad leads to the formation of several mono-, di-, and polynuclear complexes.[1–5] The ability to donate the nitrogen lone pairs and the (C=N) imine π-bonds results in a flexible coordination behaviour in which the α-diimine ligand can donate from 2 to 8 electrons to one or more metal centres. An interesting aspect of this versatile coordination behaviour is the activation of the imine bond towards C–C, C–H, C–N, and N–H coupling reactions of R-DAB ligands in the coordination sphere of transition metals with a variety of unsaturated molecules, such as α-diimines[6–10] carbodiimides[11] sulfines,[11] and alkynes.[12–18]

Table 1. Abbreviations used throughout this text

Abbreviation	Explanation
R-DAB	1,4-Diaza-1,3-butadienes of formula $R^1N=C(H)–C(H)=NR^1$
R-Pyca	1,4-Diaza-1,3-dienes of formula C_5H_4N-2-$C(H)=NR^1$
DMAD	Dimethyl acetylenedicarboxylate
MP	Methyl propynoate
*t*Am	2-Methyl-2-butyl
R-ADO	1,6-Di-R-1,6-diazahexa-1,5-diene-3,4-dimethyl-3,4-diolato, $R^1N=C(H)(Me)C(O)HC(O)C(Me)=NR^1$
OPB	2,3-Diolato-2,3-bis(2-pyridyl)butane, [C_5H_4N-2]CMe(O)CMe(O)[2-C_5H_4N]
R-ADA	1,6-Di-R-1,6-diazahexa-1,5-diene-3,4-di-R-aminato, the reductively C–C coupled dimer of R-DAB; $R^1N=C(H)(H)C(NR^1)(H)C(NR^1)C(H)=NR^1$
R-APE	1,2-Di-R-aminato-1,2-bis(2-pyridyl)ethane, the reductively C–C coupled dimer of R-Pyca; [C_5H_4N-2]$CH(NR^1)CH(NR^1)$[2-C_5H_4N]

In a series of previous papers[19–24] we have reported in detail on the C–C coupling reaction of the [(R-DAB)$Fe(CO)_3$] complexes **1** (cf. Scheme 1; X = NR^1, R^3 = H) with the electron-deficient alkynes dimethyl acetylenedicarboxylate (DMAD) (cf. Table 1) and methyl propynoate (MP) (cf. Table 1). The initial step in this reaction can be described as an oxidative 1,3-dipolar [3+2] cycloaddition,

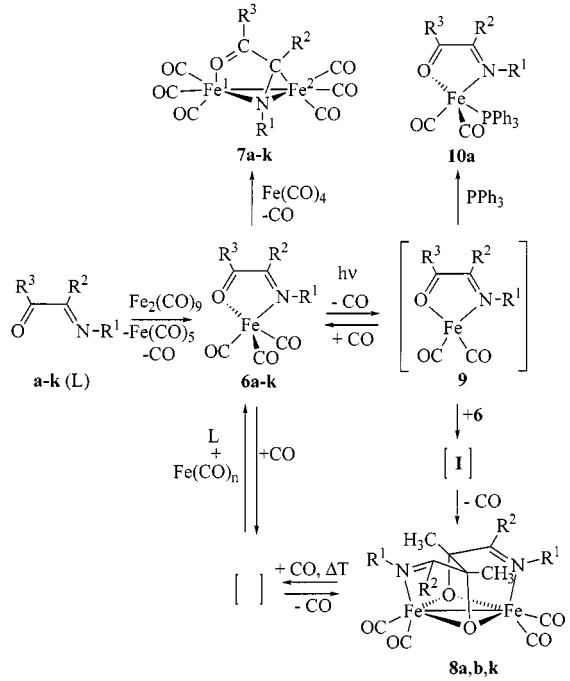
in which the electron-deficient alkyne (dipolarophile) adds across the Fe–N=C fragment (1,3-dipole) to give the bicyclo[2.2.1] intermediate **2**. Subsequent insertion of CO and uptake of an additional ligand (L′), followed by reductive elimination and recoordination of the double bond, results in the formation of the [(1,5-dihydropyrrol-2-one)$Fe(CO)_3$] complexes **3**.

In order to broaden the synthetic potential of this reaction we have investigated the closely related [$Fe(CO)_3$(1-aza-4-oxa-1,3-butadiene)] complexes **6** (cf. Scheme 1; X = O, R^3 = Me, Ph), in order to probe their reactivity towards electron-deficient alkynes.[25,26] To this end we studied the coordination behaviour of α-imino ketones towards carbonyliron compounds.

In contrast to the α-diimine chemistry little is known about the coordination behaviour of α-imino ketones towards d^8-metals. α-Imino ketones have been shown to form monodentate *trans*-[$PtCl_2(PR_3)(R^1N{=}C(R^2){-}C(R^3){=}O$][27] and bidentate [$(AlMe_3)_2$(σ,σ-*N,O*–MeN=C(Ph)–C(Ph)=O)] complexes.[28] In these complexes, as well as in the free ligand, the N=C–C=O moiety has a *gauche* conformation with a torsion angle of approximately 90° around the central C–C bond, which is attributed to a minimising of the steric repulsion between the skeleton substituents. The reaction of $Fe_2(CO)_9$ with the closely related α-imino ester PhCH(Me)N=C(H)C(OEt)=O (L*), as described by Weiss et al.,[29] resulted in the formation of two dinuclear products, $Fe_2(CO)_6$(L*) (**4**) and the C–C coupled complex $Fe_2(CO)_6$(L*–L*) (**5**) (cf. Scheme 2).



Scheme 2. Reaction of [$Fe_2(CO)_9$] with PhCH(Me)N=C(H)–C(OEt)=O (L*)

In complex **5**, a C–C coupling reaction occurs between the imine C atoms of two α-imino ester ligands. This type of C–C coupling has also been observed in the reaction of R-DAB and R-Pyca with carbonylruthenium compounds,[7] leading to [$Ru_2(CO)_{4,5}$(R-ADA)] (cf. Table 1) and [$Ru_2(CO)_{4,5}$(R-APE)] (cf. Table 1), respectively, but has never been observed for iron.

In this paper we report on the reactions of α-imino ketones (L) with $Fe_2(CO)_9$, which results in the formation of the mononuclear chelate complexes [$Fe(CO)_3$(α-imino ketone)] (**6**) and the dinuclear complexes [$Fe_2(CO)_6$(α-imino ketone)] (**7**) and [$Fe_2(CO)_4$(L–L)] (**8**). Complexes **8** contain two α-imino ketone ligands which are C–C-coupled at the ketone carbon atoms. The influence of the substitution pattern of the α-imino ketone on the formation of the complexes is discussed. The X-ray crystal structures of [$Fe(CO)_3${σ-*N*,σ-*O*-(MeN=C(Ph)–C(Ph)=O)}] (**6g**) and of the newly formed dimeric complex [$Fe_2(CO)_4$(*t*BuN=(H)C(Me)C(O)(O)C(Me)C(H)=N*t*Bu)] (**8a**) are described.

Results and Discussion

The α-imino ketones $R^1N{=}C(R^2){-}C(R^3){=}O$ (L) and the complexes discussed in this investigation are schematically presented in Scheme 3. The type of complex is identified by Arabic numbers. The different α-imino ketones are indicated by the letters **a–k**.

	a	b	c	d	e	f	g	h	i	j	k
R^1	*t*Bu	*t*Am	CH(*i*Pr)$_2$	*p*Tol	*i*Pr	*t*Bu	Me	*p*Tol	*i*Pr	$PhCH_2$	R_1–R_2 =
R^2	H	H	H	H	H	H	Ph	Ph	Ph	Me	-$(CH)_4$-
R^3	Me	Me	Me	Ph	Ph	Ph	Ph	Ph	Ph	Me	Me

Scheme 3. Observed reaction sequence for [$Fe_2(CO)_9$] with the α-imino ketones **a–k**

The reaction of [$Fe_2(CO)_9$] with the α-imino ketones **a–k** at room temperature results in the formation of the mononuclear chelate complexes [$Fe(CO)_3$(α-imino ketone)] (**6e–h**), the new dinuclear complexes [$Fe_2(CO)_6$(α-imino ketone)] (**7a–j**), and the C–C-coupled dimers [$Fe_2(CO)_4$(R-ADO)] (**8a**,**b**) (cf. Table 1) and [$Fe_2(CO)_4$(R-OPB)] (**8k**) (cf. Table 1). Throughout the text [$Fe_2(CO)_4$(L–L)] (**8a,b,k**) is used for these C–C-coupled dimers. The product formation and distribution depends strongly on the substitution pattern of the α-imino ketone and on the solvent.

In all cases the mononuclear chelate complexes [$Fe(CO)_3$(α-imino ketone)] (**6**) are initially formed. However, only when the ligands **e–h** are used are complexes **6** stable enough to be isolated, giving **6h** in moderate yield

and **6e–g** in good to high yields. The complexes **6** react with $[Fe(CO)_4]$ fragments forming $[Fe_2(CO)_6$(α-imino ketone)] (**7a–j**) in moderate to good yield depending on the α-imino ketone used. In complexes **7** the α-imino ketone is σ-*O*,μ_2-*N*,η^2-C=N-coordinated, donating six electrons to the two iron centres. When R^3 = Me, complexes **6** can also react with another equivalent of the α-imino ketone and the carbonyliron compound leading to the new complexes $[Fe_2(CO)_4$(L–L)] in moderate (**8a,b**) or low (**8k**) yield. In complexes **8**, the two α-imino ketones are reductively coupled through the ketone carbon atoms. The resulting bridging ligand is formally dianionic and donates 10 electrons to the two iron centres. Complexes **8a,b** react readily with carbon monoxide (1 atm) at 80 °C to quantitatively regenerate **6a,b**, which under these conditions are stable. Irradiation of a solution of **6a,b** in the low-energy band results in the reformation of complexes **8a–b** in almost quantitative yield. Irradiation of **6a** in the presence of PPh_3 results in the formation of complex **10a** and complex **8a** is not formed. The formed complexes have been characterised by IR, UV/Vis, ^{1}H- and ^{13}C-NMR spectroscopy, elemental analysis, and X-ray crystal structure determinations for complexes **6g** and **8a**. In the following section we will first discuss the structural data and spectroscopic properties of the relevant complexes and subsequently deal with the aspects of their formation, their stability and their reactivity. A mechanism for the formation of complexes **8** is proposed.

Molecular Structure of σ-*N*,σ-*O*-Fe(CO)$_3$[MeN=C(Ph)C(Ph)=O] (6g)

An ORTEP drawing of the molecular structure of **6g** together with the atomic numbering scheme is shown in Figure 1. Selected bond lengths and angles are given in Table 4 (see Supporting Information). The asymmetric unit of the unit cell contains two crystallographically independent molecules. Since these molecules are nearly identical, only one is discussed here.

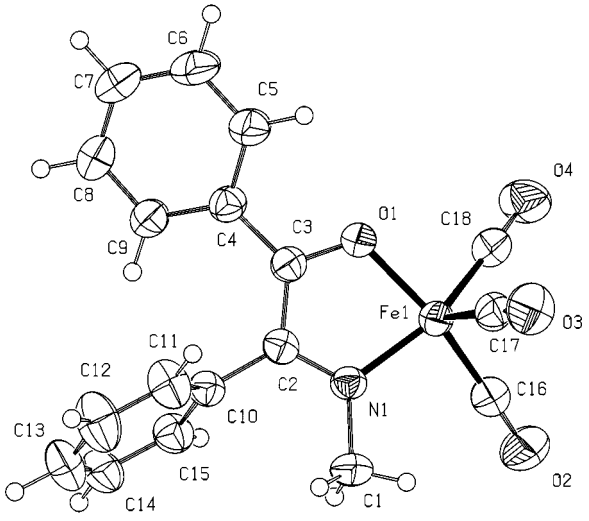


Figure 1. ORTEP drawing (50% probability level) of the molecular structure of **6g**

For a regular five-coordinate d^8 complex, a trigonal-bipyramidal (tbp) or square-pyramidal (sqp) structure might be expected.[40,41] Judging from the angles around the iron atom (cf. Table 4) the coordination around the central iron atom in **6g** more closely resembles a distorted square-pyramidal geometry (89% along the Berry pseudorotation coordinate[42]) with the basal plane defined by N(1), C(16–18), and with Fe(1) 0.353(1) Å above that plane. An ideal tbp or sqp geometry is not possible for these chelate complexes because of the small bite angle of the α-imino ketone (81 ± 1°), a feature also observed in many R-DAB complexes.[40,41,43,44]

The geometries of several five-coordinated [Fe(1,4-dihetero-1,3-butadiene)] complexes, determined by X-ray structures, change from approximately tbp to sqp with increasing π-acceptor properties of the 1,4-dihetero-1,3-butadiene ligand.[44–47] The observed sqp geometry in **6g**, in which the α-imino ketone exhibits good π-acceptor properties, is in agreement with this observation.

The N=C–C=O skeleton is planar within 0.010(3) Å, with the iron atom located 0.03(4) Å above this plane. A similar planar conformation has been found in $[Fe(CO)_2$(*t*-BuNC)(*p*Tol-DAB)],[48] and $[Fe(CO)_3$(MeN=N–N=NMe)].[45] The present example is the first structure showing an intact flat chelate N=C–C=O skeleton, i.e. a conformation with maximum orbital overlap of the C=N and C=O chromophores. From the crystal structure of the free α-imino ketone PhH(Me)CN=C(Ph)–C(Ph)=O, it is known that the N=C–C=O moiety has a torsion angle of 97.7(2)° [46] around the central C–C bond. In monodentate σ-*N*-coordinated *trans*-$[PtCl_2(Et_3)$(*t*BuN=C(H)C(Me)=O)][27] and in the bidentate bridging $[Al(Me_3)_2$-σ,σ′-*N,O*-{MeN=C(Ph)–C(Ph)=O}][28] the torsion angles are 89.0(4)° and 85.9(3)°, respectively (cf. Figure 2). On the basis of these data van Vliet et al.[28] concluded that in the case of α-imino ketones a minimising of the steric repulsion between the ligand substituents is predominant. In $[Fe_2(CO)_6$(PhCH(Me)N=C(H)C(OEt)=O)][29] (**5**) (cf. Scheme 2) an almost flat coordination of the N=C–C=O has been reported; however, in this complex, the N=C imine bond has lost its double-bond character because of the μ_2-*N*,η^2-C=N coordination.

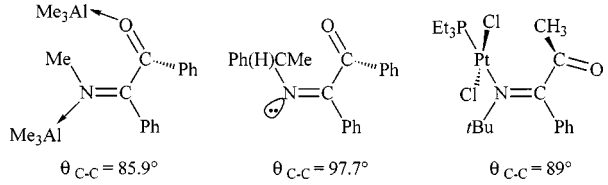

Figure 2. Torsion angles around the central C–C bond of coordinated and free α-imino ketones

The observed planar conformation in **6g** suggests that in the present case the orbital overlap of the imine and ketone moieties, i.e. the formation of a delocalised, low-lying π orbital, prevails over a minimising of the steric interactions between the skeleton substituents. The π*-orbital of the N=C–C=O system, which is antibonding in the C=N and C=O bond and bonding in the central C–C bond, plays an important role for the π-back donation from the electron-rich iron thus allowing the formation of a stable chelate.

Consequently, the coordination of the α-imino ketone to the iron centre in **6g** leads to a significant lengthening of both the imine [C(2)–N(1) = 1.336(3) Å] and the ketone [C(3)–O(1) = 1.295(3) Å] bonds while the central [C(2)–C(3) = 1.410(3) Å] bond is significantly shortened when compared to the C=N, C=O and the central C–C bonds in the free α-imino ketone PhH(Me)CN=C(Ph)C(Ph)=O [1.286(2) Å, 1.209(2) Å and 1.530(2) Å, respectively].[46] The C=O bond is significantly more elongated than the C=N bond (0.086 vs. 0.054 Å), indicating that the chelate coordination exerts a larger effect on the electron density of the C=O than of the C=N bond. This effect is also observed in the ^{13}C-NMR spectra of complexes **8** and might explain the chemoselectivity for C–C coupling at the ketone carbon atom leading to complexes **3** and **8**. Comparable changes in bond lengths, although less pronounced, have been found in [Fe(CO)$_2$(*t*BuNC)(*p*Tol-DAB)][47] and [Fe(CO)$_3$(2,6-*i*Pr$_2$C$_6$H$_3$-DAB)].[40] The Fe–C(16), Fe–C(17) and Fe–C(18) distances of 1.771(3) Å, 1.799(3) Å and 1.802(3) Å, respectively, are within the range of normally observed Fe–CO bond lengths.

Molecular Structure of [Fe$_2$(CO)$_4${*t*BuN=C(H)(Me)C(O)(O)C(Me)(H)C=N*t*Bu}] (8a)

An ORTEP drawing of the molecular structure of [Fe$_2$(CO)$_4$(*t*Bu-ADO)] (**8a**) (cf. Table 1) together with the atomic numbering scheme is shown in Figure 3. Table 5 (see Supporting Information) gives selected bond lengths and bond angles.The molecule consists of two identical Fe(CO)$_2$ units connected by a metal–metal bond and bridged by the newly formed, formally dianionic 10-electron-donating *t*Bu-ADO ligand. The *t*Bu-ADO ligand has been formed by a reductive C–C coupling of two *t*BuN=C(H)–C(Me)=O ligands through the ketone carbon atoms. As a result of this C–C coupling between C(6)–C(8), the former keto groups C(6)–O(1) and C(8)–O(2) have been reduced to anionic olato groups. The molecule exhibits noncrystallographic pseudo C_2 symmetry with the C_2 axis running through the centres of the C(6)–C(8) and the Fe(1)–Fe(2) bonds.

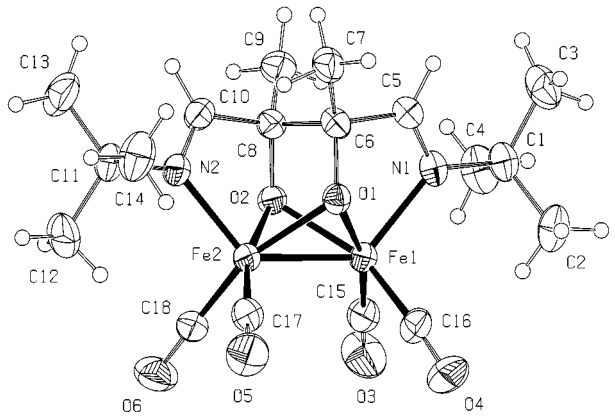

Figure 3. ORTEP drawing (50% probability level) of the molecular structure of **8a**

The Fe(1)–Fe(2) bond length in **8a** is 2.372(2) Å, i.e. a short Fe–Fe bond, since distances in the range of 2.50–2.70 Å are normally observed for single Fe–Fe bonds.[49] The Fe(1)–O(1)–Fe(2) and Fe(1)–O(2)–Fe(2) bond angles are 74.14(14) and 73.78(14)°, respectively, and the Fe–O(carboxylato) bond lengths vary between 1.944(4) and 2.002(4) Å. These bond angles and lengths are comparable to the Fe–X–Fe (X = C, N, O) bond angles and Fe–X (X = C, N, O) bond lengths found in complexes with similar (N,N′), (N,S) and (C,O) bridging ligands.[29,48,50,51] In these complexes comparably short Fe–Fe distances have also been found. The two intact imine moieties are bonded to the iron centre by normal Fe–N=C σ-donor bonds [Fe(1)–N(1) = 2.043(5) Å and Fe(2)–N(2) = 2.030(5) Å]. The angles around the C–C connective bond [C(8)–C(6)–C(5) 107.9(4)° and C(6)–C(8)–C(10) 107.3(4)°] differ only slightly from the optimum value of 109.7° for sp^3-hybridised atoms. In the related complex [Ru$_2$(CO)$_5$(*i*Pr-ADA)], it was concluded from several structural features that the *i*Pr-ADA ligand is forced to coordinate to the ruthenium centres which might explain the facile thermal rupture of the central C–C bond in this complex.[7] From the observed bond angles and lengths in **8a** it appears that the *t*Bu-ADO ligand exhibits no geometrical constraints that could explain the facile fission of the C(6)–C(8) bond under carbon monoxide. The newly formed C–C connective bond C(6)–C(8) in **8a** of 1.587(8) Å is, however, significantly longer than a normal C(sp^3)–C(sp^3) bond. Comparatively long bond lengths have been reported earlier in complexes containing two C–C-coupled R-DAB or α-imino ester ligands[8,29,52–55] and seem to be characteristic for C–C bonds in N–C–C–N moieties in which both nitrogen atoms are covalently coordinated to the metal centres. On dissolution, the dimer [EtZn(*t*Bu-Pyca)]$_2$ [53,54] dissociates to a very small extent into monomers, thus forming an equilibrium mixture showing the weakness of the C–C connective bond. However, [Mo$_2$(CO)$_6$(R-ADA)][55] complexes do not split under carbon monoxide.

In conclusion, we can say that the *t*Bu-ADO ligand in **8a** exhibits no geometrical constraint upon coordination to the iron centres, the newly formed central C(6)–C(8) bond [1.587(8) Å] is longer than normal C–C bonds. Whether or not the facile breaking of the central C(6)–C(8) bond, which is an experimental fact, may be explained by the elongation of C(6)–C(8) remains an open question.

IR, UV/Vis Spectroscopy and Elemental Analysis

The IR, UV/Vis and analytical data of the complexes **6**, **7**, **8** and **10a** are listed in Table 6 (see Supporting Information). The IR spectra of complexes **6** show three strong terminal carbonyl absorptions of equal intensity in the ν(CO) region of 2100–1900 cm^{-1}. The CO absorptions of **6e–g**, and even more so of **6h**, are found at higher frequencies than those of **6a,b** indicating that π-back bonding to the terminal carbonyl ligands decreases on going from **6a** to **6h**. This is a result of the better π-accepting capacity of the α-imino ketones going from ligands **a,b** to **e,f** to **g** and **h**, which bear none, one, two or three electron-withdrawing aromatic groups, respectively.

The six terminal carbonyl ligands of $[Fe_2(CO)_6L]$ (**7a–j**) give rise to six medium to strong absorptions in the ν(CO) region. The pattern of the absorptions is identical to that of $[M_2(CO)_6$(R-DAB/R-Pyca)] (M = Fe, Ru, Os and FeRu).[6,56–59] This strongly suggests that these complexes are isostructural, which is corroborated by the ^{1}H- and ^{13}C-NMR- spectroscopic data. The substituents on the α-imino ketone show only a marginal influence on the frequency of the CO absorption bands of complexes **7**.

The IR spectra of complexes **8** show three terminal carbonyl absorptions, two of high and one of medium intensity. The pattern of the CO absorption bands strongly resembles that of the closely related complex $[Ru_2(CO)_4$(R-ADA)],[6,7] which contains a similarly coupled dimer of R-DAB. The absorption bands are shifted to a higher frequency (approximately 10–20 cm^{-1}) than those of $[Ru_2(CO)_4$(R-ADA)]. Similar shifts to higher frequency are observed for $[M(CO)_3$(R-DAB)] and $[M_2(CO)_6$(R-DAB)] on going from iron to ruthenium.

Electronic Absorption Spectra of Complexes 6 and 8

All complexes **6** show an intense band at about 530 nm. A second band is located at about 410 nm and for complexes **6e–h** a third band is present at approximately 348 nm. The pattern of the bands in the UV/Vis spectra of complexes **6** closely resembles those found for the isostructural complex $[Fe(CO)_3$(R-DAB)],[60] except for the shift of approximately 20 nm to lower energy. The polarity of the solvent has almost no influence on the positions of the absorption bands [λ_{max} **6a**; 524 nm (pentane), 526 nm (toluene), 527 nm (THF)]. This lack of solvatochromic behaviour is also found for $[Fe(CO)_3$(R-DAB)][40,60,61] and $[W(CO)_4$(R-DAB)][61] and is attributed to a strong mixing of the metal d-(HOMO) and α-diimine π*-(LUMO) orbitals. As a result these transitions hardly possess any charge-transfer character, and therefore do not show solvatochromic behaviour. On the basis of these similarities, the band at 530 nm is assigned to several electronic transitions within the metallacycle[40,61] rather than to a charge transfer transition from the metal to the α-imino ketone ligand (MLCT). The band at 410 nm is assigned to a LF transition as for $[Fe(CO)_3$(R-DAB)]. The third band at 348 nm observed in **6e–h** is due to an intra-ligand transition.

Complexes **8a,b** possess a weak band at approximately 640 nm (MLCT) and a strong absorption band at 367 nm. The latter is assigned to the σ–σ* transition of the metal–metal bond. This is corroborated by the increase in intensity of this band upon lowering the temperature, an effect which has been observed before for σ–σ* transitions of metal–metal bonds.[62,63]

Elemental Analyses

Except for **6g**, complexes **6** have not been analysed due to their instability and the fact that they cannot be crystallised. No satisfactory elemental analyses could be obtained for complex **7d** because the isolated oil was not analytically pure and no crystals could be obtained. Complex **8k** has not been analysed because the isolated powder was not analytically pure and the complex decomposes on crystallisation.

NMR Spectroscopy

Tables 6 and 7 with the complete ^{1}H- and ^{13}C-NMR-spectroscopic data of complexes **6**, **7** and **8** are available as Supporting Information.

The ^{1}H- and ^{13}C-NMR spectra of **6a–b** were obtained by splitting **8a–b** under carbon monoxide pressure because, due to the instability of **6a–b**, it was not possible to prepare a suitable NMR sample from the reaction mixture (see Experimental Section). The imine proton resonances (**6a**,**b**,**e**,**f**) are observed between δ = 8.74 and δ = 7.61, whereas in the uncoordinated α-imino ketones the imine proton (**a–f**) resonances are observed between δ = 8.1 and δ = 7.2. The imine and ketone carbon atom resonances are shifted by approximately 12–15 and 20–28 ppm to lower frequency, relative to those of the free ligands, as a result of π-back donation into the low-lying delocalised LUMO of the α-imino ketone. Comparable shifts have been observed for $[Fe(CO)_3$(R-DAB)].[64] The large low-frequency shift of the ketone carbon atom in comparison with the imine carbon atom suggests that the chelate coordination exerts a larger effect on the electron density of the ketone carbon atom. This might be the reason for the observed chemoselectivity in the C–C-coupling reactions, i.e. only coupling at the ketone carbon atom is observed resulting in the formation of complexes **8** and **3** (cf. Scheme 1). Furthermore, it is evident from the X-ray crystal structure of **6g** that the C=O bond is significantly more elongated than the C=N bond, which also suggests a larger effect on the C=O bond upon chelate coordination.

In all complexes **6** the three terminal carbonyl ligands give rise to a single resonance between δ = 212.0 and δ = 214.1, indicating that they rapidly interchange on the NMR time scale at 263 K.

The imine proton and carbon atom resonances of complexes **7** are observed between δ = 4.78–3.77 and δ = 65–90, respectively. These large shifts to lower frequency of approximately 4 ppm and 80 ppm are typical for a μ^2-*N*,η^2-C=N coordination of the C=N moiety of the α-imino ketone and have also been observed in $[M_2(CO)_6$(R-DAB)] (M = Fe, Ru, Os and FeRu) complexes.[6,57–59] The resonances of the ketone carbon atoms are only marginally shifted relative to those of the free ligand.

Because of the asymmetric coordination of the α-imino ketone ligand, the six terminal carbonyl ligands in complexes **7** are inequivalent. In a rigid carbonylmetal skeleton this should result in six independent resonances for the carbonyl groups. However, at 263 K complexes **7** show four resonances with relative intensities of 1:3:1:1 going from high to low frequency. This indicates a local scrambling of the carbonyl groups on one metal centre, which has also been observed in $[Fe_2(CO)_6$(R-DAB)] complexes.[65] This exchange process has been demonstrated for complex **7f** in CD_2Cl_2. At 183 K the six carbonyl ligands give rise to six separate signals, showing that at this temperature the ter-

minal carbonyl ligands on both metal centres are at the limit of slow exchange. The individual assignment of the CO resonances to either one of the two $Fe(CO)_3$ moieties is not clear from this dynamic behaviour but can reasonably be deduced from the ^{13}CO-NMR-spectroscopic data of $[FeRu(CO)_6$(R-Pyca)] complexes. From the crystal structure of $[FeRu(CO)_6$(*i*Pr-Pyca)],[59] it is known that the μ_2-*N*,η^2-C=N coordination of the C=N moiety is directed towards the iron centre. In the ^{13}CO-NMR spectra of these complexes recorded at 263 K the Fe–CO signals appeared as one sharp resonance and the Ru–CO signals as three separate resonances. Consequently, in our case, the three signals of equal intensity (263 K) correspond to the μ_2-*N*,σ-*O*-coordinated $Fe^1(CO)_3$ moiety and the broad resonance corresponds to the three carbonyl groups of the $Fe^2(CO)_3$ moiety, which is μ_2-*N*,η^2-C=N-coordinated through the C=N bond of the α-imino ketone (cf. Scheme 3).

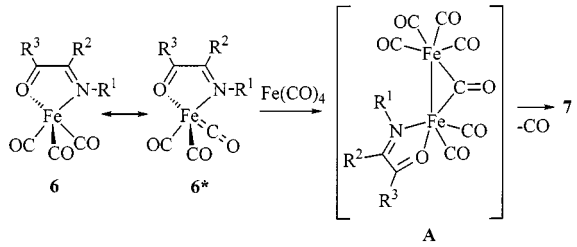
In complexes **8a**,**b** the imine-proton and carbon-atom resonances are observed between δ = 7.55–7.80 and δ = 169.5–174.0, respectively, indicating that the imine moiety is σ-*N*-coordinated to the iron centre. The signals of the reductively coupled ketone carbon atoms in **8** accordingly show a pronounced coordination shift (ca. 120 ppm) to lower frequency and are observed around δ = 80. The four terminal carbonyl ligands give rise to two resonances between δ = 217 and δ = 218, indicating pairwise exchange at each iron centre.

Reactions of α-Imino Ketones with Carbonyliron

Complex Formation

The formation, stability and yield of complexes **6**, **7** and **8** strongly depends on the R^1, R^2, and R^3 substituents attached to the imine nitrogen atom, the imine carbon, and the ketone carbon atom, respectively. In the following sections we will first discuss the formation of complexes **6** and **7** and the factors that influence their stability. Subsequently, the formation of complex **8** is discussed and a mechanism is proposed.

Formation and Reactivity of $[Fe(CO)_3$(α-imino ketone)] (6)



The reaction of $[Fe_2(CO)_9]$ with the α-imino ketones **a–k** at room temperature in THF or toluene results in the initial formation of the deep purple chelate $[Fe(CO)_3$(α-imino ketone)] complexes **6**, probably via a monodenate *N*-coordinated $[Fe(CO)_4$(α-imino ketone)] intermediate, as a result of the better σ-coordinating properties of the C=N moiety than the C=O moiety,[27,66] according to Equation 1.

$$[Fe_2(CO)_9] + \text{α-imino ketone} \rightarrow [Fe(CO)_3(\text{α-imino ketone})]\ (\mathbf{6}) + [Fe(CO)_5] + CO \quad (1)$$

In THF no formation of **6i** was observed. In toluene, however, low concentrations of **6i** were formed which, under the reaction conditions, rapidly reacts further to **7i**. Analogous to $[Fe(CO)_3$(R-DAB)], complexes **6** are intensely coloured, highly air-sensitive and could not be isolated pure in the solid state except for **6g**. Complexes **6** are soluble and stable in common solvents as hexane, Et_2O, toluene and THF, but decompose in chlorinated solvents like $CHCl_3$, as is the case for $[M(CO)_3$(R-DAB)] (M = Fe, Ru).[7] Complexes **6a,b** react photochemically to form the corresponding complexes **8a,b**. Irradiation of **6e–g**, however, does not lead to the corresponding C–C coupled complexes **8** but results in slow decomposition of **6e–g**.

Formation and Reactivity of $[Fe_2(CO)_6$(α-Imino Ketone)] (7)

The $[Fe_2(CO)_6$(α-imino ketone)] complexes **7** are formed in THF and toluene by reaction of $[Fe(CO)_3$(α-imino ketone)] (**6**) with $Fe(CO)_4$ (cf. Scheme 4). Complexes **7** are probably formed via the CO-bridged intermediate **A**, similar to the proposed intermediate for the formation of $[Fe_2(CO)_6$(R-DAB)].[67] The formation of **A** can be described as an isolobal analogue[68,69] of the addition of an olefin to a carbene giving a cyclopropane ring system. In the present case, $Fe(CO)_4$ is isolobal with a carbene and the Fe–C bond of a terminal CO ligand in **6** is, in its resonance structure (**6***), isolobal with an olefin. Addition results in the formation of intermediate **A**, and subsequent coordination of the C=N π-bond with concomitant loss of CO completes the structure of complex **7**.

Scheme 4. Proposed reaction mechanism for the formation of **7**

Complexes **7** are isolated as red-brown crystalline solids, except for **7d**, and are air-stable in crystalline form. The stoichiometry of complexes **7** has been established by elemental analyses. The α-imino ketone in complexes **7** is σ-*O*,μ_2-*N*,η^2-C=N-coordinated to the two iron centres and donates six electrons, as can be concluded from the IR, ^{1}H-NMR, and ^{13}C-NMR spectra. An analogous coordination has been found for the closely related α-imino ester complex $[Fe_2(CO)_6\{PhCH(Me)N{=}C(H)C(OEt){=}O\}]$[29] (**5**) (cf. Scheme 2). No formation of the alternative possible six-electron coordination mode, i.e. σ-*N*,μ_2-*O*,η^2-C=O, has been observed. In the α-imino ketone 2-acetylpyridine (**k**), the C=N π-bond is not available for η^2 coordination because it is part of an aromatic pyridine system. Therefore, σ-*N*,μ_2-*O*,η^2-C=O is the only accessible six-electron coordination mode. However, with ketone **k** only complex **8k** is formed and the formation of a complex with a σ-*N*,μ_2-*O*,η^2-C=O coordination mode is not observed. With the closely related α-imino ketones 2-benzoylpyridine and pyridine-2-carboxaldehyde (i.e. bearing a phenyl group and a proton on the ketone carbon atom, respectively) no isolable complexes are formed. Since initially the mononuclear chelate $[Fe(CO)_3\{C_5H_4N$-2-$C(R^3){=}NR^1\}]$ complexes are formed, indicated by the deep blue colour of the reaction mixture,

this means that either complexes with a σ-*N*,μ_2-*O*,η^2-C=O coordination of the α-imino ketone are not formed, or they decompose under the reaction conditions.

The yields of complexes **7** depend strongly on the ligand used. Generally the yields are higher for the ligands with a phenyl substituent on the ketone carbon atom than for those bearing a methyl group. In the latter case the lowest yields are found for ligands **a** and **b** (ca. 17%). With these ligands, however, complexes **8a,b** are formed in ca. 25% yield leading to a total yield of binuclear complexes of 40 to 45%. Furthermore, it is apparent that when R^1 (the imine nitrogen substituent) is an aryl group the yield is much lower than for R^1 = alkyl. This observation can be accounted for in terms of the lower basicity of the imine donor site for aryl vs. alkyl; if R^1 is aryl, this will lead to a less-efficient μ_2-*N*,η^2-C=N interaction. As a consequence, under these conditions complexes **7d**,**h** react with $Fe(CO)_n$ fragments to give unknown products, which lowers the yields. This has also been found in $[Fe_2(CO)_6$(Aryl-Pyca)] complexes.[70]

Reaction With Free Ligand

Complexes **7** do not react thermally or photochemically with an excess of free ligand. Consequently, **7** is not an intermediate in the formation of **8**.

Reaction With CO

Treatment of $[Fe_2(CO)_6$(R-DAB)] with carbon monoxide (40–50 bar) at elevated temperatures yielded the monomeric complexes $[Fe(CO)_3$(R-DAB)] and $[Fe(CO)_5]$.[43,70] This route should also be convenient for the formation of the monomeric $[Fe(CO)_3$(α-imino ketone)] complexes **6**. However, reaction of $[Fe_2(CO)_6$(α-imino ketone)] (**7**) with CO leads only to decomposition, and the monomeric complexes **6** are not detected. The η^2-C=N coordination is probably stronger than the σ-*O* coordination and, consequently, the coordinated keto oxygen atom is substituted by CO, which triggers the decomposition of **7**.

Factors that Influence the Formation and Stability of Complexes 6 and 7

It has been mentioned before that the N=C–C=O skeleton has a conformational preference for a near orthogonality of the N=C and C=O groups (cf. Figure 2), caused by steric interactions of the ligand substituents, especially on the 1,3-and 2,4-positions.[27,28,46]

The crystal structure of **6g** confirms that the α-imino ketone is σ-*N*,σ-*O* chelating in a flat planar *cis* conformation. This planar coordination of an intact N=C–C=O moiety shown in **6g** has never been observed before. So, the primary factor that influences the formation and stability of complexes **6** is whether the α-imino ketone can sterically easily adopt a planar or near planar *cis* conformation. Furthermore, the stability of complexes **6** depends on the σ-donor and π-accepting properties of the α-imino ketone ligand upon coordination. Because the energy of the n-electrons at the oxygen is much lower than at the nitrogen atom, α-imino ketones are weaker donors than diazabutadienes. The unoccupied orbitals of the iron centre are at still higher energy than the n-electrons at the nitrogen atom.[66,71] Consequently, reinforcement of the dative bond by significant π-back donation is required for the formation of stable chelate complexes **6**.[66] The extent of π-back donation depends on the energy level of the π*-LUMO, which in turn can be tuned with the ligand substituents, especially the substituent on the ketone carbon atom. As a consequence, electron-donating groups (like methyl) disfavour chelate coordination, while electron-withdrawing groups (like phenyl) will lead to more stable complexes. It should be noted that when the level of the π*-LUMO is lowered too far in energy this can lead to a redox reaction in which the metal centre is oxidised, leading to decomposition of the formed complexes.[66]

Thirdly, the stability of complexes **6** depends on the propensity of η^2-C=N coordination to a second metal fragment, giving rise to the formation of complexes **7**. The propensity of the analogous R-DAB towards η^2-C=N coordination has been studied by Staal et al.[17] and decreases on going from RCH_2 to R_2CH to R_3C for the imine nitrogen substituent on R-DAB. The propensity towards η^2-C=N coordination will also depend on the substituent on the imine carbon atom and decreases in the order H > Me >> Ph, as has been found in the reactivity of complexes $[\{C_5H_4N$-2-$C(R^3)=NR^1\}Fe(CO)_3]$ (R^3= H, Me, Ph) towards $Fe(CO)_4$ fragments.[70]

Considering these factors it is understandable that for the α-imino ketones **e–g**, and less so for **h**, the stable complexes **6e–h** are formed. All three have an electron-withdrawing phenyl substituent on the ketone carbon atom which favours the formation of a stable chelate. The α-imino ketones **g** and **h** have relatively small substituents on the imine nitrogen atom and a bulky phenyl substituent on the imine carbon atom, while the α-imino ketones **e,f** have relatively bulky *i*Pr and *t*Bu groups on the nitrogen but only a proton on the imine carbon atom. This means that these α-imino ketones can easily adopt a planar *cis* conformation and subsequently form the stable complexes **6e–h**. The reaction of **6e** → **7e** is more favourable than the reaction **6f** → **7f** because of the greater propensity for η^2-C=N coordination (R_2CH vs. R_3C) of ligand **e**, which is corroborated by the higher yields of **7e**. For the α-imino ketone **h**, the steric influence of the *p*Tol group is similar to that of a cyclohexyl, but electronic influences also play an important role as can be seen from the instability of **7d**,**h** (see above). Complex **6h** slowly decomposes in solution, which could be due to the inferior σ-donating capacity of the nitrogen or to an internal redox reaction because of the low-lying π*-LUMO.

When relatively bulky substituents are attached to both the imine nitrogen and carbon atoms (**c**,**i**) it is difficult for these ligands to adopt the planar *cis* conformation. This is confirmed by the observation that only very low concentrations of **6c**,**i** are formed during the reaction, i.e. no intensive colouring of the reaction mixture is observed. The reaction of α-imino ketone **i** in THF resulted only in the formation of $[Fe(CO)_4$(THF)] and free ligand. Performing the same

reaction in toluene, a less coordinating solvent, resulted in the formation of **7i** in good yield by a fast reaction of **6i** with $Fe(CO)_4$. This demonstrates particularly well the poor chelating properties of α-imino ketones when they cannot easily adopt a planar *cis* geometry.

The ligands **a–c** have a methyl substituent on the ketone carbon, a proton on the imine carbon, and a big aliphatic substituent on the imine nitrogen atom. In principle this set of substituents appears sterically suitable for the formation of complexes **6**. However, complexes **6a–c** cannot be isolated in high yield. With ligand **c**, complex **6c** is formed in very low concentrations, i.e. no intense colouring of the reaction mixture is observed. Apparently, the 2,4-dimethyl-3-pentyl substituent on the imine nitrogen atom in ligand **c** is so bulky that the planar *cis* conformation is strongly disfavoured, i.e **6c** is formed in low concentrations and quickly reacts further to form complex **7c** in 38% yield. The reduced yields of **7a**,**b** (ca. 17%) have to be ascribed to the formation of **8a,b** and the sterically disfavoured η^2-C=N coordination due to the tertiary (CR_3) substituent on the imine nitrogen in **a**,**b** as opposed to the secondary substituent (CHR_2) in **c**. The methyl substituent on the ketone carbon atom also contributes to the overall low yields because it restricts the coordination of the oxygen atom through reduced π-back donation. Under the reaction conditions this probably leads to a slow chelate formation and consequently decomposition of the initially formed $[Fe(CO)_4\{R^1N{=}C(R^2){-}C(R^3){=}O\}]$ complexes which are known to be very labile.[68,69]

Formation and Reactivity of $Fe_2(CO)_4$(L-L) (8a,b,k)

Complexes **8a**,**b**,**k** are synthesised in moderate (**8a,b**) or low (**8k**) yield by reaction of the ligands **a,b,k** with $[Fe_2(CO)_9]$, according to Equation 2.

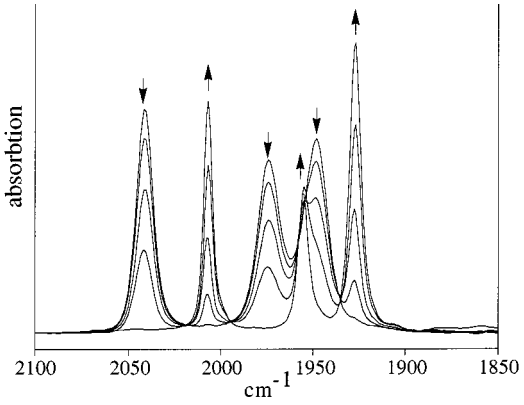
$$2\,[Fe_2(CO)_9] + 2\,\alpha\text{-imino ketone} \rightarrow [Fe_2(CO)_4(L{-}L)]\,(\mathbf{8}) + 2\,[Fe(CO)_5] + 4\,CO \quad (2)$$

They are isolated as dark green powders and are air-stable (**8a,b**) in their crystalline form. They are readily soluble in toluene, acetone, CH_2Cl_2 and THF. In solution **8a,b** are slightly light-sensitive whereas **8k** is very light-sensitive, especially in chlorinated solvents. Irradiation of the isostructural $[Mo_2(CO)_6(t\text{Bu-ADA})]$ at the Mo–Mo-σ,σ* transition results in the formation of $[Mo_2(CO)_6(t\text{Bu-DAB})_2]$,[63] i.e. fission of the C–C bond. Irradiation of **8a,b** at the high-energy slope (λ = 350 nm) of the metal–metal bond σ,σ* transition (**8a**; λ_{max} = 362 nm), however, leads to a fast (CH_2Cl_2) or slow (THF) decomposition of the starting complexes, and formation of $[Fe_2(CO)_4(\alpha\text{-imino ketone})_2]$ is not observed.

Heating a solution of **8a,b** (0.21 mmol, 50 mL) in toluene under CO at 80 °C for ca. 40 min causes fission of the central C–C bond between the two α-imino ketone ligands and of the metal–metal bond giving the mononuclear complexes **6a,b** in quantitative yield, according to Equation 3.

$$[Fe_2(CO)_4(L{-}L)] + 2\,CO \rightarrow 2\,[Fe(CO)_3(\alpha\text{-imino ketone})] \quad (3)$$

Irradiation of a toluene or THF solution of **6a,b** at the low-energy band (**6a**; λ_{max} = 526 nm) with the 514.5-nm line of an argon ion laser at room temperature leads to reformation of **8a,b** in high yield (cf. Figure 4).



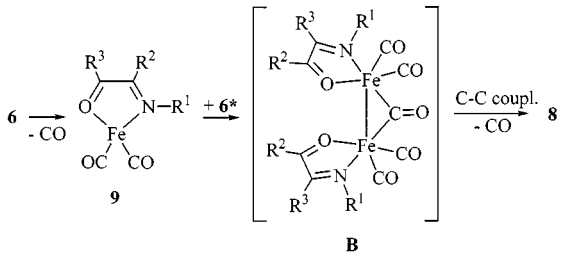


Figure 4. IR-spectral changes in the terminal carbonyl region during the irradiation of $[Fe(CO)_3\{t\text{BuN}{=}C(H){-}C(Me){=}O\}]$ (**6a**) in toluene at 293 K (514.5 nm); formation of **8a**

The irradiation times in THF are longer than those in toluene. The reaction time can be shortened in both cases by purging the solution with nitrogen gas, or degassing the solution under vacuum during irradiation. This observation can be explained by assuming the occurrence of an intermediate (**I** in Scheme 3) with the composition $[Fe_2(CO)_5(\alpha\text{-imino ketone})_2]$, which is formed by the loss of CO from **6a** and subsequent reaction of the highly reactive $[Fe(CO)_2(\alpha\text{-imino ketone})]$ (**9**) with the parent complex **6a**. For intermediate **I**, a metal–metal-bonded structure **B**, containing a bridging CO and two chelating α-imino ketone ligands, can be envisaged. A similar intermediate has been proposed for the formation of $[Ru_2(CO)_{4,5}(\text{R-IAE})]$.[7] The formation of **B**, like the formation of **A**, can be seen as an isolobal analogue to the reaction between a carbene and an olefin (cf. Scheme 5). In the present case, $[Fe(CO)_2(\alpha\text{-imino ketone})]$ (**9**) is a d^8-ML_4 fragment, like $Fe(CO)_4$, and is thus isolobal with a carbene. Subsequent addition to the Fe=C bond in **6*** (isolobal with an olefin, Scheme 4) leads to the formation of **B** which contains, as opposed to intermediate **A**, two chelating α-imino ketones. Reductive C–C coupling of the ketone carbon atoms with concomitant extrusion of CO results in the formation of **8a,b,k**. Further support for structure **B** stems from the formation of the isostructural complexes $[Fe_2(CO)_5(c\text{Hex-DAB})_2]$[60] and $[Ru_2(CO)_5\{CH(i\text{Pr})_2\text{-DAB}\}_2]$[72] upon irradiation of $[Fe(CO)_3(c\text{Hex-DAB})]$ and $[Ru(CO)_3\{CH(i\text{Pr})_2\text{-DAB}\}]$ in hexane at 150 K. However, in these cases no C–C bond formation was observed even upon warming the solution.

In order to obtain spectroscopic proof for the proposed mechanism, low-temperature IR and UV/Vis experiments were carried out. Irradiation of **6a** in 2-MeTHF at –120 °C leads initially to the formation of a single photoproduct and upon longer irradiation in the formation of **8a**. The new photoproduct has two CO stretching frequencies at 1962 and 1881 cm^{-1}, a shift of approximately 75 cm^{-1} to lower frequency with respect to those of **6a**, which points to the

Scheme 5. Proposed reaction mechanism for the formation of **8**

formation of $[Fe(CO)_2(2\text{-MeTHF})\{t\text{BuN}{=}C(H)\text{–}C(Me){=}O\}]$ (**9a**·2-MeTHF), i.e. loss of CO. The low-frequency shift is due to the good σ-donor capacity of 2-MeTHF at low temperature. In the UV/Vis spectrum, a new intense band is observed at 496 nm, which means that the ML band is shifted somewhat to higher energy on substitution of CO for 2-MeTHF. Irradiation in the presence of PPh_3 results, under the same conditions (–120 °C) or at room temperature, in the formation of the stable complex $[Fe(CO)_2(PPh_3)\{t\text{BuN}{=}C(H)\text{–}C(Me){=}O\}]$ (**10a**) [IR: 1967, 1903 cm^{-1}; UV: 560 nm (cf. Scheme 3)], and complex **8a** is not observed. Thermally (–120 °C), **9a** reacts back to form the parent complex **6a** (95%) and, to a small extent, to **8a** (5%). Irradiation of **6a** in toluene at –80 °C leads, as at room temperature, to the formation of **8a** accompanied by some decomposition; no intermediates are observed. These observations firmly support the proposal that the first step in the photochemical reaction is loss of CO. Depending on the stabilising effect of the σ-donor ligand present in solution, the initially formed labile 16e-$[Fe(CO)_2\{t\text{BuN}{=}C(H)\text{–}C(Me){=}O\}]$ intermediate (**9a**) can be trapped and isolated (PPh_3), stabilised at low temperature (2-MeTHF) or allowed to react further to form **8a** (toluene).

Irradiation of **6a** in hexane at –100 °C leads predominantly to **8a** together with a new photoproduct in approximately 10% yield. Due to the limited solubility of **8a** in hexane at –100 °C, and probably also of the new photoproduct, they both precipitate from the solution, thus giving rise to rather weak and broad absorptions. However, it can still be seen that the new photoproduct has a bridging CO ligand (1780 cm^{-1}) and three or four absorptions in the terminal region. This supports the formation of the CO-bridged structure **B**, which is furthermore corroborated by the absorption band at 797 nm in the UV/Vis spectrum. Similarly, $[Fe_2(CO)_5(c\text{Hex-DAB})_2]$ has an absorption band at 740 nm. It must be emphasised, however, that the conclusion that **B** is the only intermediate in the C–C-coupling reaction is not justified, since it was only observed at low concentrations. Extended photochemical studies are needed to obtain more detailed information about the reaction pathway **6** → **8**.

The question as to whether or not structure **B** is also an intermediate in the thermal C–C-coupling (**6** → **8**) or -decoupling (**8** → **6**) reaction is difficult to answer. It was mentioned earlier that complexes **6a,b** are stable in the pure form, i.e. they do not react back to their corresponding complexes **8**. As a consequence, under the reaction conditions, complexes other than **6** must play a role in the reaction pathway **6** → **8**. The decoupling reaction of **8a,b** → **6a,b** has been followed by means of high-pressure ^{1}H-NMR spectroscopy (see Experimental Section). However, an intermediate has not been observed during the conversion from **6** → **8**. It seems likely, however, that an intermediate like structure **B** should also be present in the thermal reaction.

As shown earlier, the C–C-coupled complexes **8** are only formed with ligands **a,b** and **k** which all bear a methyl substituent on the ketone carbon atom, whereas for the corresponding phenyl-substituted ligands **e** and **f** C–C coupling is not observed. Apparently, the methyl substituent is of decisive importance for the formation of **8**. This effect is most probably due to electronic factors (see below), although steric reasons cannot be excluded. The exclusive coupling at the ketone carbon atom is in line with the 1,3-dipolar reactivity, i.e. exclusive addition at the Fe–O=C fragment is observed (cf. Scheme 1). From this it might be concluded that the factors which determine the reactivity for 1,3-dipolar cycloadditions and the C–C coupling reactions discussed here are possibly similar. It has been shown that the 1,3-dipolar reactivity[26,73–75] decreases upon exchange of an electron-donating substituent for an electron-withdrawing substituent (Me → Ph). So analogously, the reactivity for C–C coupling to form **8** might decrease in this order. With ligand **j** the corresponding C–C-coupling product **8j** is not observed which is probably due to steric interactions of the methyl groups on both the ketone and the imine carbon atoms.

The yields of **8a,b** in the thermal reaction are almost identical in THF and toluene. On first sight, lower yields are expected in THF due to its better σ-donor capacity, thus stabilising $[Fe(CO)_2(\alpha\text{-imino ketone})]$, i.e. less-effective formation of intermediate **B** and accordingly **8**. However, in THF higher concentrations of $[Fe(CO)_3(\alpha\text{-imino ketone})]$ are present which results in a more effective formation of intermediate **B**. This is in agreement with the observation that $[Fe_2(CO)_5(c\text{Hex-DAB})_2]$ is only formed at rather high concentrations of $[Fe(CO)_3(c\text{Hex-DAB})]$. Furthermore, this is in line with the observation that **8c** is not formed as **6c** is present in very low concentration. Interestingly, the reaction of ligand **k** with $[Fe_2(CO)_9]$ in THF does not lead to **8k**, while in toluene it is formed in low yield. Obviously, in this case, THF inhibits the formation of **8k**.

Experimental Section

General Remarks: ^{1}H- and ^{13}C-NMR spectra were recorded with a Bruker AMX-300 spectrometer. Chemical shifts are reported relative to TMS (δ = 0) in the deuterated solvents indicated. – The IR spectra were recorded with a BioRad FTS-7 FTIR spectrophotometer or with a Perkin–Elmer 283 IR spectrophotometer. – Electronic absorption spectra were measured with a Perkin–Elmer Lambda 5 UV/Vis spectrophotometer or with a Varian Cary 4E spectrophotometer. – For low-temperature IR and UV/Vis measurements an Oxford Instruments DN 1704/54 liquid-nitrogen cryostat was used. The irradiations were carried out using the 514.5-nm line of an SP 2025 argon ion laser or a Philips HPK 125-W

high pressure mercury lamp equipped with the appropriate interference (λ = 500 nm) filter. – Elemental analyses were carried out by Dornis und Kolbe, Microanalytisches Laboratorium, Mülheim a. d. Ruhr, Germany. All solvents were carefully dried and distilled under nitrogen before use. All preparations were carried out under dry nitrogen by conventional Schlenk techniques. – Silica gel for column chromatography (Kieselgel 60, 70–230 mesh, E. Merck, Darmstadt, Germany) was dried and activated prior to use by heating to 180 °C under vacuum for 16 h. $Fe_2(CO)_9$[30] and the α-imino ketones **a**,**b**,**d–j**[31,33] were prepared according to published procedures. $Fe(CO)_5$ (Strem Chemicals) and 2-acetylpyridine (**k**) (Janssen) were used as commercially obtained.

The new α-imino ketone **c**, having R^1 = 2,4-dimethyl-3-pentyl [$CH(iPr)_2$] (cf. Table 1), R^2 = H, R^3 = Me, was synthesised according to the literature procedure for ligands **a**,**b**.[33] Yield 65%. – IR (pentane, cm^{-1}): $\tilde{\nu}$ = 1708 (vs) ν(C=O), 1650 (m) ν(C=N). – ^1H NMR ($CDCl_3$, room temp.): δ = 7.46 (s, 1 H, N=C*H*), 2.51 (t, *J* = 6.0 Hz, 1 H, N–C*H*), 2.39 (s, 3 H, CH_3), 2.06 (dsept, *J* = 6.0 Hz, 6.9 Hz, 1 H, C*H*), 0.83, 0.82 [d, *J* = 6.9 Hz, 2 × 6 H, $CH(CH_3)_2$]. – ^{13}C NMR ($CDCl_3$, room temp.): δ = 199.1 (*C*=O), 159.5 (*C*=N), 83.2 (N–CH), 29.6 (C–CH), 25.03 (CH_3), 20.5, 18.4 [$CH(CH_3)_2$].

The explanations for the acronyms used in this paper are given in Table 1.

The general procedures for the preparation of complexes **6e–h**, **7a–j** and **8a,b,k** are given below, details are listed in Table 2.

Synthesis of [Fe(CO)$_3$(α-imino ketone)] (6e–h): To a stirred suspension of [$Fe_2(CO)_9$] in 40 mL of THF was added 0.5 g of the respective α-imino ketone (cf. Table 2), whereupon the solution immediately turned dark purple. After all the free ligand had been consumed [monitored by the decrease of the ν(C=O) band of the ligand], the solution was filtered to remove the unchanged [$Fe_2(CO)_9$]. The solution was concentrated to dryness and the residue was redissolved in 60 mL of pentane (**6e–g**) or 30 mL of pentane/5 mL Et_2O (**6h**) and filtered again. For **6e,f** the solution was concentrated to dryness, yielding **6e,f** as deep purple oils in 80% (**6e**) or 90% (**6f**) yield. Due to their instability these complexes are best used directly after preparation or stored in pentane solution at –30 °C. Cooling a pentane solution of **6g** to –20 °C resulted in dark purple lustrous crystals in about 35% yield, which were suitable for X-ray diffraction. Subsequent crystallisation from a concentrated mother liquor at –30 °C led to a second batch of crystals of **6g** (35%), giving a total yield of 70%. The second batch of crystals often contained small amounts of [$Fe_2(CO)_6$(L)] (**7g**, < 5%), also formed under these reaction conditions. Cooling the pentane/Et_2O solution of **6h** to –30 °C resulted in a red voluminous precipitate, and **6h** was isolated as a pink-red powder in about 30% yield containing small amounts of [$Fe_2(CO)_6$(L)] (**9h,** <5%). Complex **6h** decomposes within 1 d at room temperature and should be stored at temperatures below –20 °C. Due to the instability of **6e,f,h**, and the fact that they cannot be crystallised, no elemental analyses could be obtained.

Synthesis of [Fe(CO)$_3${*t*AmN=C(H)–C(Me)=O}] (6b): Solutions of **6b** to be used in situ for further reactions were synthesised according to the literature procedure for **6a** (cf. Table 1).[25,26]

Synthesis of [Fe$_2$(CO)$_6$(L)] (7a–j) and [Fe$_2$(CO)$_4$(L–L)] (8a,b,k): To a stirred suspension of [$Fe_2(CO)_9$] in 40 mL of THF or toluene was added 0.5 g of the respective α-imino ketone (cf. Table 2), whereupon the solution turned dark purple (**a,b**) or blue (**k**). The reaction mixture was stirred for 3 h (THF) or 16 h (toluene) during which time the colour of the reaction mixture changed from dark purple/blue to red-brown. After evaporation of the solvent, the residue was redissolved in a minimum of CH_2Cl_2 and the products were purified by column chromatography on silica gel (column 1 × 15 cm). Elution with pentane afforded a green fraction, containing [$Fe_3(CO)_{12}$]. Further elution with pentane/Et_2O (ratio cf. Table 2) afforded a red-brown fraction which, after evaporation of the solvent, gave [$Fe_2(CO)_6$(L)] (**7a–j**) as a red-brown oil or powder. Crystallisation from pentane at –60 °C resulted in most cases in red-brown crystalline products, the yields varied between 15 and 75% (isolated product) depending on the ligand. Subsequent elution with Et_2O/CH_2Cl_2 (ratio cf. Table 2) afforded a dark green fraction which, after evaporation of the solvent, yielded [$Fe_2(CO)_4$(L–L)]

Table 2. Syntheses of complexes **6e–h**, **7a–j** and **8a**,**b**,**k**

	Ligand substituents			Ligand (mmol)[a]	$Fe_2(CO)_9$ [g, (mmol)]	Solvent (reaction time)[b]	Elution ratio[c]	Yield (%)[d]

(**8a,b,k**) as a green powder. Crystallisation from pentane/CH_2Cl_2 (2:3) resulted in dark green needles of **8a,b**, in 25 and 27% yield, respectively. Crystals of **8a** were suitable for X-ray diffraction. Complex **8k** was formed in only 4% yield and decomposed on crystallisation.

Preparation of Solutions of 6b for ^{1}H- and ^{13}C-NMR Spectroscopy: A solution of ca. 80 mg **8b** in 2.5 mL of [D$_6$]acetone was placed in a high-pressure NMR tube and kept at 313 K for 5 h under 35 bar carbon monoxide. This resulted in a complete conversion into **6b**.

Reaction of [Fe$_2$(CO)$_4$(L–L)] (8a,b) with Carbon Monoxide. – Formation of 6a,b: Compound **8a** (0.100 g, 0.21 mmol) or **8b** (0.106 g, 0.21 mmol) was dissolved in 50 mL of toluene and stirred under carbon monoxide for 40 min at 80 °C. During this time the colour of the solution turned from green to intense purple. The reaction was followed by IR spectroscopy and showed that **8a,b** had been quantitatively converted into **6a–b**.

Photochemical conversion of [Fe(CO)$_3$(L)] (6a,b) in [Fe$_2$(CO)$_4$(L–L)] (8a,b): A toluene solution containing **6a,b** (0.21 mmol, 50 mL) was irradiated into the high-energy slope of the low-energy band (λ_{max} = 526 nm) with the 514.5-nm line of an argon ion laser at room temperature. The reaction was followed by IR spectroscopy. Complete conversion of **6** to **8** took approximately 1 h, during which time the colour of the solution gradually changed from intense purple to green/brown. Due to some decomposition of **6a,b**, the formed products **8a,b** had to be purified by column chromatography. Elution with CH_2Cl_2 afforded a dark green fraction which, after evaporation of the solvent, yielded [Fe$_2$(CO)$_4$(L–L)] (**8a,b**) as a green powder in 90% yield.

X-ray Crystal Structure Determination of 6g and 8a: Dark opaque crystals were mounted under nitrogen in a Lindemann glass capillary (**6g**) or glued on a glass fibre (**8a**) and transferred to an Enraf–Nonius CAD-4T rotating-anode diffractometer for data collection. Unit-cell parameters were determined from least-squares treatment of the SET4 setting angles of 25 reflections and were checked for the presence of higher lattice symmetry.[34] The crystals of **6g** and **8a** show broad reflection profiles. All data were collected with ω/2θ scan mode, and were corrected for Lp and for the observed linear decay of the intensity control reflections; redundant data were merged into a unique data set. An empirical absorption correction was applied for both compounds with the DIFABS[34] method (correction range 0.646–1.440 for **6g** and 0.614–1.180 for **8a**). The structures were solved with either standard Patterson methods (**8a**) or direct methods (**6g**) (SHELXS86)[35] and subsequent difference Fourier syntheses. Refinement on *F* was carried out by full-matrix least-squares techniques. A small cavity at 0,0,1/2 of 49 Å^3 was found in the unit cell of **8a**. However, no significant residual density could be detected in that area (PLATON).[36] Hydrogen atoms were introduced at calculated positions [C–H = 0.98 Å] and included in the refinement riding on their carrier atoms. All non-H atoms were refined with anisotropic thermal parameters, H atoms were refined with common isotropic thermal parameters. Weights were introduced in the final refinement cycles. Neutral atom scattering factors were taken from[37] and corrected for anom-

alous dispersion.[38] All calculations were performed with SHELX76[39] and the PLATON package[36] (geometrical calculations and illustrations) on a DEC-5000 cluster. Crystal data and numerical details of the structure determinations are given in Table 3.

Supporting information for this article (Tables 4 and 5 with selected bond lengths and angles for **6g** and **8a**, Table 6 with IR, UV/Vis, and analytical data, and Tables 7 and 8 with ^{1}H- and ^{13}C-NMR-spectroscopic data for compounds **6**, **7**, and **8**) is available on the WWW under http://www.wiley-vch.de/home/eurjic or from the author. Crystallographic data (excluding structure factors) for the structures of **6g** and **8a** have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-137484 (**8a**), and -137485 (**6g**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

This investigation was in part supported (W. J. J. S., A. L. S.) by the Netherlands Foundation for Chemical Research (SON) with financial aid from the Netherlands Organisation for Scientific Research (NWO). We are indebted to J.-M. Ernsting for practical assistance with recording NMR data and to B. D. Rossenaar for practical assistance with recording LT-IR and UV/Vis data.

[30] $[Fe_2(CO)_9]$ was prepared by a slightly modified literature procedure (E. H. Braye, W. Hübel, *Inorg. Synth.* **1966**, *8*, 178) using a quartz Schlenk tube and starting with 25 mL of $Fe(CO)_5$, 150 mL of glacial acetic acid and 10 mL of acetic anhydride (the latter was added to prevent the mixture containing too much water). A rayonet RS photochemical reactor (λ_{max} = 2500 Å) was used for irradiation and a continuous stream of air was used to cool the reaction mixture. Filtration, washing with water, ethanol, ether, and subsequently drying in vacuo gave $[Fe_2(CO)_9]$ usually in more than 90% yield.

Sulfur Compounds, 212[‡]

Preparation of Organic Polysulfanes R_2S_n (n = 5, 7, 8, 9) from Sulfenyl Chlorides, RSCl, and Transition Metal Polysulfido Complexes

Ralf Steudel,*[a] Karin Hassenberg,[a] Vera Münchow,[a] Oliver Schumann,[a] and Joachim Pickardt[a]

Keywords: Sulfur / Titanium / Zinc / Polysulfido complexes / Sulfur heterocycles / Polysulfides / Polysulfanes / Sulfenyl chlorides

The preparation of seven novel organic polysulfanes is reported. Bis(n-octyl)heptasulfane R_2S_7 **1** is formed upon reaction of RSCl with $[Cp_2TiS_5]$, while the corresponding nonasulfane R_2S_9 **2** is obtained by reaction of RSSCl with $[Cp_2TiS_5]$. The bis(n-octyl)pentasulfane R_2S_5 **3** is obtained from RSCl and $[(Cp'_2TiCl)_2S_3]$ by transfer of the S_3 ligand at 20 °C. The new alkyl polysulfanes **1**–**3** have been obtained in quantitative yields. They are liquids at 20 °C, having freezing points below –50 °C, but do not form mesogenic phases. Reactions of $[Cp_2TiS_5]$ with 2-naphthyl- and 4-chlorophenyl sulfenyl chloride furnish the corresponding heptasulfanes **4** and **5**, respectively, which are solids at 20 °C. 1,2-Benzodisulfenyl chloride $C_6H_4(SCl)_2$ reacts with $[(Cp'_2TiCl)_2S_3]$ to give the known 1,2,3,4,5-benzopentathiepin $C_6H_4S_5$ **6**, with $[Cp_2TiS_5]$ to give the novel 1,2,3,4,5,6,7-benzoheptathionin $C_6H_4S_7$ **7**, and with $[(TMEDA)ZnS_6]$ to give the novel 1,2,3,4,5,6,7,8-benzooctathiecin $C_6H_4S_8$ **8**. The cyclic polysulfanes **6**–**8** are solids at 20 °C and have been recovered in yields of 60–83%. The orthorhombic structure of 1,2-$C_6H_4S_7$ has been investigated by single-crystal X-ray diffraction analysis. The molecules are found to be located at sites of C_s symmetry and the motif of the C_2S_7 heterocycle is +–+–+–+–, with the torsion angle of zero at the carbon–carbon bond. The three internuclear SS distances measure 205.0(1), 203.7(1), and 205.7(1) pm.

Introduction

Sulfur-rich organic polysulfanes R_2S_n ($n > 2$) may be synthesized by a variety of methods starting from either thiols, sulfenyl chlorides, elemental sulfur, sulfanes (H_2S_n), chlorosulfanes (S_nCl_2), ionic polysulfides (e.g. Na_2S_n), or other sulfur compounds.[1] In most cases, mixtures of polysulfanes of varying chain length n are obtained, which have to be separated by repeated crystallization or by chromatography. Such separations have to be conducted under mild conditions owing to the thermal and thermodynamic instability of the longer-chain polysulfanes, which tend to equilibrate with species of other chain lengths or to split off S_8, S_7, or S_6 (Equation 1 and 2):[2]

$$2\ R_2S_n \rightarrow R_2S_{n+x} + R_2S_{n-x} \quad (1)$$

$$R_2S_n \rightarrow R_2S_{n-8} + S_8\ (n > 8) \quad (2)$$

In recent years, the enormous potential of titanocene polysulfide complexes for the synthesis of novel homocyclic and heterocyclic organic and inorganic sulfur compounds has been demonstrated.[3,4,5,6] Using these reagents, a large number of interesting sulfur-rich species have been prepared, for which no synthetic route had hitherto been available. When organic sulfenyl chlorides or related SCl compounds are allowed to react with titanocene pentasulfide, chain-like polysulfanes with up to nine sulfur atoms may be generated (Equation 3 and 4; Cp = η^5-C_5H_5):[7,8]

$$2\ CCl_3SCl + [Cp_2TiS_5] \rightarrow (CCl_3)_2S_7 + [Cp_2TiCl_2] \quad (3)$$

$$2\ i\text{PrOSSCl} + [Cp_2TiS_5] \rightarrow (i\text{PrO})_2S_9 + [Cp_2TiCl_2] \quad (4)$$

In a similar fashion, bifunctional organic sulfenyl chlorides and chlorodisulfanes have been treated with titanocene pentasulfide or similar complexes, thereby generating cyclic sulfur-rich polysulfanes with up to 11 sulfur atoms (Equation 5 and 6):[9,10,11]

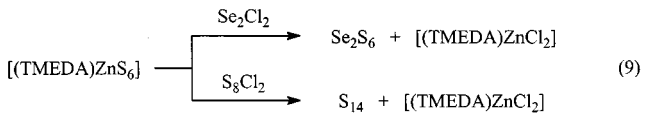
$$1,2\text{-}C_2H_4(SCl)_2 + [Cp_2TiS_5] \rightarrow C_2H_4S_7 + [Cp_2TiCl_2] \quad (5)$$

$$1,2\text{-}C_7H_{10}(SCl)(SSCl) + [Cp_2TiS_5] \rightarrow C_7H_{10}S_8 + [Cp_2TiCl_2] \quad (6)$$

A relatively new titanocene polysulfide complex is $[Cp'_2Ti(Cl)–S_3–(Cl)TiCp'_2]$,[12] which reacts with sulfenyl chlorides as an S_3 group transfer reagent (Equation 7 and 8; Cp′ = $CH_3C_5H_4$):[13]

$$C_{10}H_{12}(SCl)_2 + [(Cp'_2TiCl)_2S_3] \rightarrow C_{10}H_{12}S_5 + 2\ [Cp'_2TiCl_2] \quad (7)$$

$$C_{10}H_{12}(SCl)(SSCl) + [(Cp'_2TiCl)_2S_3] \rightarrow C_{10}H_{12}S_6 + 2\ [Cp'_2TiCl_2] \quad (8)$$



In this work, we report the synthesis of five chain-like and three cyclic organic polysulfanes with between 5 and 9 sulfur atoms. In the case of the chain-like species, we used alkyl as well as aryl substituents. The n-octyl substituent was employed in the hope that the rather long chains of (n-

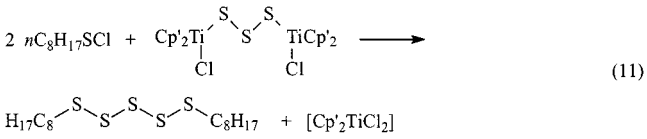
octyl)$_2S_n$ would result in a high degree of anisotropy and consequently in mesogenic properties. The aryl groups 4-chlorophenyl and 2-naphthyl were used in the expectation that readily crystallizable products suitable for X-ray crystallographic analysis would be obtained. In the case of the cyclic species, 1,2-substituted benzene was used for the same reason. A further aim of this work was to study the utility of the zinc polysulfide chelate complex [(TMEDA)ZnS_6] in the preparation of sulfur-rich organic heterocycles. This compound has previously been used to prepare inorganic rings such as 1,2-Se_2S_6 [14] and S_{14} (Equation 9).[15]

(9)



Results and Discussion

Aliphatic Polysulfanes[16]

Octylsulfenyl chloride was prepared by chlorination of *n*-octanethiol. Titanocene pentasulfide was found to react with this sulfenyl chloride at temperatures below 0 °C in carbon disulfide to quantitatively afford bis(*n*-octyl)heptasulfane **1** (Equation 10; $x = 1$). This compound is a viscous red liquid at ambient temperature and has a freezing point of –60 °C.

$$2\ n C_8H_{17}S_xCl + [Cp_2TiS_5] \rightarrow (nC_8H_{17})_2S_{5+2x} + [Cp_2TiCl_2] \quad (10)$$

Reaction of *n*-octanethiol with dichlorosulfane gives *n*-octylchlorodisulfane, which reacts with titanocene pentasulfide under the same experimental conditions as above to yield the orange bis(*n*-octyl)nonasulfane **2** (Equation 10; $x = 2$). This product freezes to a glass at –52 °C. Bis(*n*-octyl)pentasulfane **3**, a yellow liquid with freezing point –67 °C, was prepared by the reaction of *n*-octylsulfenyl chloride with bis[bis(methylcyclopentadienyl)chlorotitanium]trisulfide [(Cp′$_2$TiCl)$_2S_3$] in carbon disulfide at low temperatures (Equation 11; Cp′ = $CH_3C_5H_4$).

(11)

Analyses by ^{1}H-NMR and HPLC showed that the unusual red color of the heptasulfane 1 is not due to traces of titanocene pentasulfide or titanocene dichloride as might be suspected. Bis(*n*-octyl)nonasulfane **2** is the most sulfur-rich of all selectively available diorganylpolysulfanes that is *liquid* at ambient temperature.

The lengths of the sulfur chains in these novel compounds have been assessed not only by microanalysis, but also by reversed-phase HPLC. A linear relationship exists between the number of sulfur atoms in the chain (n_S) and the natural logarithm of the capacity factor (ln k'), which is calculated from the retention time. This has previously been demonstrated for other polysulfanes bearing alkyl and aryl substituents.[10,11,13,17] On heating of the nonasulfane **2** at 80 °C for 30 min., decomposition occurred resulting in a mixture of polysulfanes with up to 15 sulfur atoms. A plot of ln k' versus the number of sulfur atoms n_S for the bis(*n*-octyl)polysulfanes formed in this reaction is shown in Figure 1.

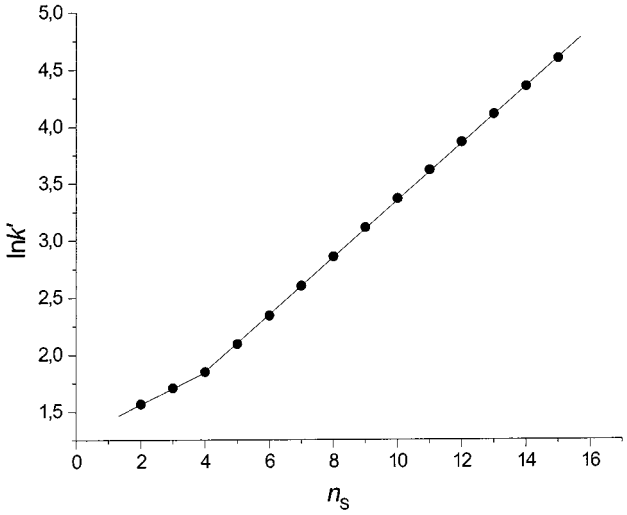


Figure 1. Dependence of the chromatographic retention times of the bis(*n*-octyl)polysulfanes $(C_8H_{17})_2S_n$ (n = 2–15) on the number of sulfur atoms n_S; here, ln k' is plotted against n_S [$k' = (t_r - t_0)/t_0$; t_0 = dead time, t_r = retention time]

Table 1. Retention data (retention times t_R, capacity factors k', and retention index values *RS*) of the homologous series $(C_8H_{17})_2S_n$ (n = 2–15)

n_S	t_R [min]	ln k'	*RS*	n_S	t_R [min]	ln k'	*RS*
2	8.10	1.565	941	9	32.83	3.111	1384
3	9.11	1.706	982	10	41.92	3.365	1457
4	10.28	1.847	1022	11	53.41	3.615	1529
5	12.47	2.092	1092	12	67.93	3.861	1599
6	15.96	2.342	1164	13	86.19	4.104	1669
7	20.23	2.600	1238	14	109.89	4.350	1740
8	25.69	2.854	1311	15	139.91	4.595	1810

The chromatographic data and the retention indices *RS* [18] derived therefrom are given in Table 1. The retention indices are independent of the chromatographic system used and can therefore be used for the identification of these species in a similar manner as spectroscopic data.

The chromatograms of the pure products **1**–**3** showed neither traces of other polysulfanes nor of sulfur homocycles, the other products of the disproportionation of polysulfanes according to Equations 1 and 2. The three liquid bis(*n*-octyl)polysulfanes can be stored at –25 °C for several months without decomposition. After storage at ambient temperatures for three days, HPLC analysis showed that about 10% of the products had undergone disproportionation. The ^{1}H- and ^{13}C-NMR spectra of **1**–**3** did not reveal any unusual features. The proton signals exhibit a very slight downfield shift with increasing number of sulfur

atoms, reflecting the increase in acidity of the sulfanes H_2S_n with increasing chain length n.[19]

The infrared spectra of **1**–**3**, recorded at ambient temperatures, are almost identical. They show mainly the absorptions of the *n*-octyl substituents, i.e. strong signals due to the CH stretching modes in the range 2850–2960 cm^{-1} and the CH_2 bending modes between 1200 and 1470 cm^{-1}. More interesting are the SS stretching modes, which can best be detected by Raman spectroscopy. The low-temperature (–135 °C) Raman spectra exhibit, besides weak to strong lines in the ranges 2700–3000 cm^{-1} and 1300–1500 cm^{-1} attributable to the *n*-octyl substituents, several lines between 420 and 510 cm^{-1}, which are characteristic of catenated sulfur. In this region, the spectrum of $(nC_8H_{17})_2S_5$ is characterized by three peaks at 435, 459, and 493 cm^{-1}, and a shoulder at 505 cm^{-1}. The heptasulfane spectrum features four lines at 429, 445, 470, and 495 cm^{-1}, and a shoulder at 463 cm^{-1}. The Raman spectrum of $(nC_8H_{17})_2S_9$ features medium to strong lines at 423, 437, 463, and 494 cm^{-1}, with shoulders at 452 and 472 cm^{-1}. All these lines must stem from SS stretching modes as the Raman spectrum of *n*-octanethiol does not feature any lines in this region (see Figure 2). The number of lines in the region 400–510 cm^{-1} is smaller than the expected number of SS stretching modes of **1**–**3**, indicating that there must be some coincidental degeneracies.

In view of the low freezing points of these liquid polysulfanes, no mesogenic properties were to be expected near room temperature. All three compounds solidify as glasses on rapid cooling to –70 °C.

Aromatic Polysulfanes

Chain-Like Heptasulfanes[20]

The 2-naphthyl and 4-chlorophenyl groups have previously been used in the preparation of relatively stable sulfur-rich derivatives, from which it can be concluded that these residues stabilize either sterically or electronically the thermodynamically unstable sulfur compounds. Since the corresponding sulfenyl chlorides are readily available,[21] we have prepared bis(2-naphthyl)heptasulfane **4** and bis(4-chlorophenyl)heptasulfane **5** by reaction with titanocene pentasulfide (Equation 12).

$$2\ RSCl + [Cp_2TiS_5] \rightarrow R_2S_7 + [Cp_2TiCl_2] \quad (12)$$

These reactions were carried out at 20 °C in carbon disulfide solution; **4** was obtained as a pale-yellow powder in 51% yield, while **5** formed lemon-yellow microcrystals (44% yield). Despite the bulky substituents, these compounds are characterized by relatively low melting points of 55 °C (**4**) and 40 °C (**5**). Reversed-phase HPLC analyses of the rapidly quenched melts did not reveal the presence of any decomposition products. However, when the heptasulfanes were heated to twice the melting temperatures (110 °C and 80 °C, respectively) for 5 min., the naphthyl derivative decomposed to give a mixture of polysulfanes R_2S_n with up to 11 sulfur atoms, while the chlorophenyl derivative produced a similar series of homologous sulfanes with 3–12 sulfur atoms. As mentioned above, such homologous series can be analysed by the systematic increase of the retention

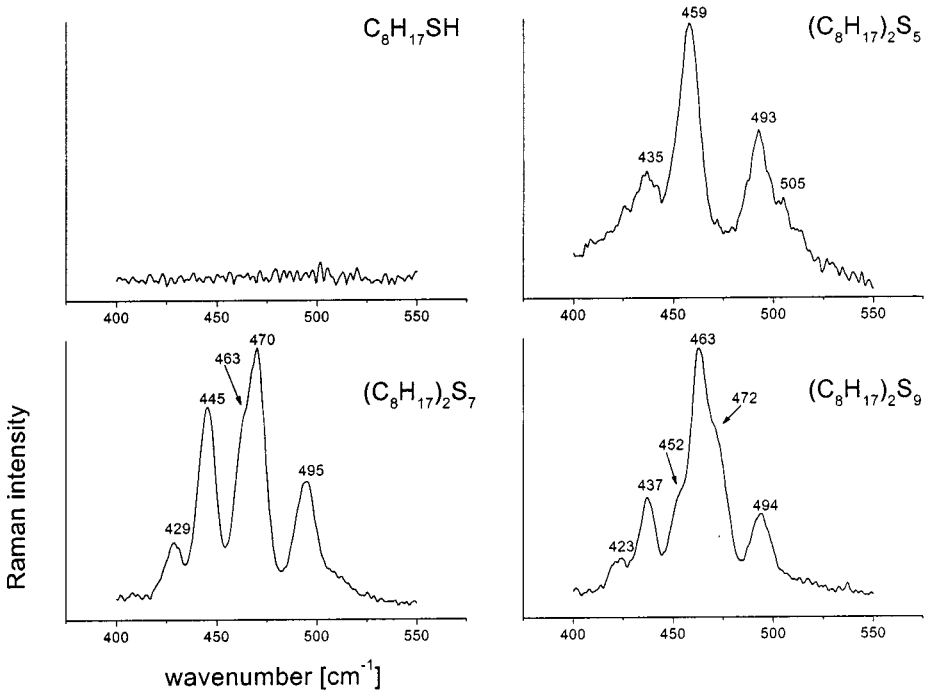

Figure 2. Raman spectra of *n*-octanethiol and of the bis(*n*-octyl)polysulfanes $(nC_8H_{17})_2S_n$ (n = 5, 7, 9) in the range 400–550 cm^{-1}

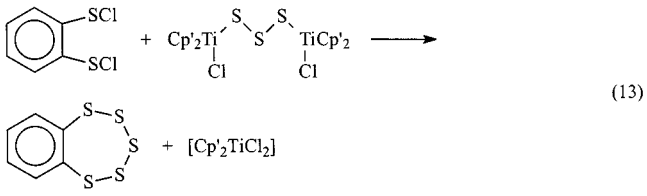
time with increasing number n_S of sulfur atoms. The retention index *RS* is a linear function of n_S and the following data were determined using methanol as an eluent:



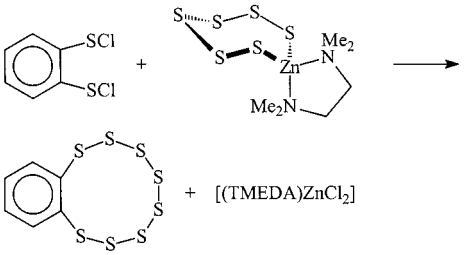
$RS = a + bn_S$
4: n_S = 2–11, a = 517, b = 69
5: n_S = 2–12, a = 382, b = 67

The linear correlation coefficients were better than 0.999.

Both heptasulfanes were found to be well-soluble in carbon disulfide and in chlorinated aliphatic hydrocarbons. They may be stored for long periods at 4 °C without decomposition, but slow decomposition occurs at 20 °C. HPLC analysis, mass spectrometry, as well as infrared, Raman, ^{1}H- and ^{13}C-NMR spectroscopic data confirmed the identities and purities of **4** and **5**. Their low melting points can be explained as follows. The torsion angle at SS bonds is usually about 90°, but may be positive or negative (enantiomeric forms). A chain with six SS bonds can therefore theoretically exist as $2^6 = 64$ conformational isomers. It has previously been shown that many of these conformers will be of almost identical energy.[22] However, in crystals of polysulfanes usually only one conformer is found.[1] It therefore seems reasonable to assume that only a single conformation of the CSSSSSSSC chain is present in solid **4** and **5**, while several conformations will be present in their melts, thus resulting in a strong increase in entropy. The melting temperature T_m and the melting entropy ΔS_m are inversely related to each other, with the melting enthalpy as an additional factor: $T_m = \Delta H_m/\Delta S_m$. Therefore, long chain-like polysulfanes are either liquid at 20 °C or have melting points only slightly above ambient temperature.

Cyclic Polysulfanes

The titanocene complex $[(Cp'_2TiCl)_2S_3]$ reacts with 1,2-benzenebis(sulfenyl chloride), prepared by chlorination of 1,2-benzenedithiol, at low temperatures in carbon disulfide solution to yield the known yellow 1,2,3,4,5-benzopentathiepin **6** (Equation 13).



(13)

Compound **6** was first synthesized by Fehér and Langer[23] by condensation of 1,2-benzenedithiol $C_6H_4(SH)_2$ with dichlorotrisulfane S_3Cl_2. It was obtained in a yield of just 50% and was seemingly not very pure since the reported melting point of 65–66 °C differs substantially from our measurements. Our product was analytically, chromatographically, and spectroscopically pure and was found to melt at 58 °C. It was recovered in 73% yield. In 1979, Fehér and Engelen determined the molecular and crystal structure of **6**,[24] and in 1984 Chenard and Miller reported a new synthesis of **6** from 1,2-benzothiadiazole and elemental sulfur in the presence of DABCO at 160–185 °C (yield 54%).[25] The melting point of **6** measured by these authors was 58–60 °C, which agrees well with our findings.

Under similar conditions as those used to generate **6**, 1,2-benzenebis(sulfenyl chloride) was found to react with titanocene pentasulfide to yield the novel 1,2,3,4,5,6,7-benzoheptathionin **7**, which was obtained in 83% yield as a yellow solid with m.p. 107 °C (Equation 14).

$$1,2\text{-}C_6H_4(SCl)_2 + [Cp_2TiS_5] \rightarrow 1,2\text{-}C_6H_4S_7 + [Cp_2TiCl_2] \qquad (14)$$

The new octasulfane 1,2,3,4,5,6,7,8-benzooctathiecin **8**, a yellow solid with m.p. 73 °C, was obtained in 60% yield following reaction of the zinc hexasulfido chelate complex $[(TMEDA)ZnS_6]$ [26] with 1,2-benzenebis(sulfenyl chloride) in carbon disulfide at ambient temperature (Equation 15; TMEDA = tetramethylethylenediamine).

(15)

The number of sulfur atoms in these cyclic polysulfides can again be assessed by reversed-phase HPLC, since there is a linear relationship between the number of sulfur atoms in the ring and the logarithm of the capacity factor (not shown). The ^{1}H-NMR spectra of **6**–**8** each feature an AA′BB′ system, which is centered at δ = 7.61 for the C_2S_5 ring, at δ = 7.63 for the C_2S_7 ring, and at δ = 7.59 for the C_2S_8 ring. The ^{13}C-NMR spectra feature only three signals in the expected region. The infrared spectra are all very similar, in line with expectation. They are dominated by a very strong absorption near 750 cm^{-1}, which is typical for 1,2-substituted benzene rings. More interesting are the Raman spectra, which show the SS stretching modes between 400 and 520 cm^{-1} (see Figure 3). The three heterocycles each exhibit a distinct pattern of SS stretching modes. In the relevant region, the spectrum of the benzopentathiepin features four lines at 418, 429, 467, and 490 cm^{-1}, that of the benzoheptathionine features five lines at 436, 451, 471, 495, and 518 cm^{-1} and a shoulder at 480 cm^{-1}, while that of the benzooctathiocene is characterized by six lines at 416, 428, 438, 460, 467, and 512 cm^{-1} with shoulders at 476 and 515 cm^{-1}.

The crystal structure of $C_6H_4S_7$ was determined by single-crystal X-ray diffraction analysis. The crystals were found to be orthorhombic with four molecules in the unit cell and a density of 1.765 g cm^{-3} at 20 °C. The molecules have C_s symmetry (Figure 4). The crystallographic mirror plane passes through the center of the C3–C3′ bond and contains S4.

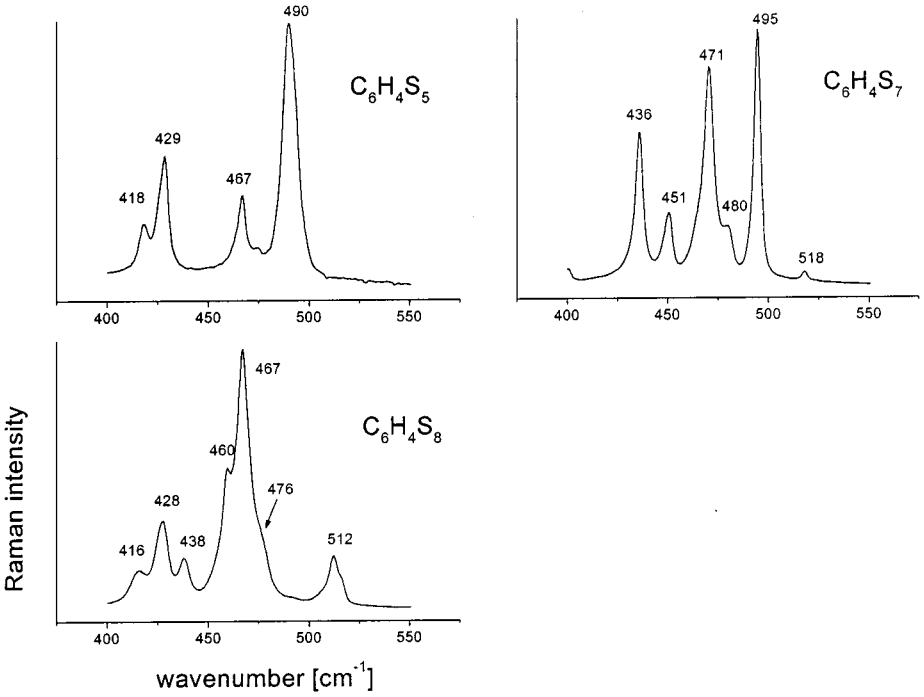


Figure 3. Raman spectra of the solid 1,2-benzenepolysulfanes $C_6H_4S_n$ (n = 5, 7, and 8) at 20 °C in the range 400–550 cm^{-1}

S(2)–S(1)–C(1)–C(1′)	–115.57(7)	C(1)–C(2)–C(3)–C(3′)	–2.0(4)

Selected internuclear distances, bond angles, and torsion angles are listed in Table 2.

The geometrical parameters show the expected values with an arithmetic mean of 138.1 pm for the CC bonds and an average of 204.8 pm for the SS bonds. The latter value is identical to the average bond length in S_8. There is a slight alternation in the SS bond lengths in **7**: d(S1−S2) = 205.0(1), d(S2−S3) = 203.7(1), and d(S3−S4) = 205.7(1) pm. The conformations of sulfur homocycles and sulfur-rich heterocycles can best be characterized by the *motif*, which describes the order of the signs of the torsion angles around the ring. The motif for the C_2S_7 heterocycle is +-+-0+-+-, with a value of zero at the carbon–carbon bond. Such a motif has not previously been observed for any nine-membered heterocycle of the type C_xS_y. The absolute values of the torsion angles at the SS bonds lie between 85° and 110° (see Table 2).

Conclusions

We have shown that sulfur-rich organic polysulfanes can be prepared in good yield not only from titanocene polysulfido complexes, but also from the relatively new zinc hexasulfido complex, despite the presence of the amine TMEDA. Normally, amines catalyze the decomposition of thermodynamically unstable polysulfur compounds. The novel bis(*n*-octyl)polysulfanes described here, which consist of chains of more than 20 non-hydrogen atoms, do not form mesogenic phases at ambient temperature since their freezing temperatures are quite low. These chains most probably have a random coil conformation rather than a straight chain structure in the liquid phase and therefore the materials solidify as glasses. The chain-like polysulfanes bearing aromatic substituents are solids at 20 °C, even when the sulfur chain is quite long. Most probably, they exist as *a single* conformer in the solid state, but as many rotational isomers in the liquid state, leading to a high melting entropy and hence to a depression of the melting temperature. Once

again, we have observed that the homologous members of the series R_2S_n with n = 2–12 exhibit a systematic increase in their reversed-phase HPLC retention times with increasing number of sulfur atoms.

Experimental Section

General: The reactions were carried out under exclusion of moisture using carefully dried solvents. The chromatographic system used has been described previously.[11] Octadecylsilane (C18) was used as a stationary phase throughout. The following spectrometers were used: Nicolet Magna 750 FT-IR spectrometer (using KBr or CsCl sample discs); Bruker RFS 100 FT Raman spectrometer, equipped with an Nd-YAG laser (1064 nm); Bruker ARX 200 and ARX 400 NMR spectrometers.

Synthesis of Bis(*n*-octyl)pentasulfane (1): *n*-Octylsulfenyl chloride was first prepared by chlorination of the corresponding thiol with one equivalent of sulfuryl chloride in dichloromethane at 0 °C according to standard procedures. At –70 °C, a solution of the sulfenyl chloride (0.181 g, 1 mmol) in CS_2 (25 mL) was added dropwise over a period of 1 h to a solution of $[(Cp'_2TiCl)_2S_3]$ (0.290 g, 0.5 mmol) in CS_2 (25 mL), which resulted in a color change from dark-green to light-red. The reaction mixture was allowed to warm to 20 °C, the volume was reduced to one-half of the original, and then the concentrated solution was cooled to –50 °C for several hours. The precipitated $[Cp'_2TiCl_2]$ was filtered off. This procedure (partial evaporation of the solvent and subsequent cooling) was repeated until no more titanocene dichloride was precipitated. The remaining solvent was then completely removed under reduced pressure yielding the liquid product. Yield: 0.193 g (quantitative); freezing temp. –66 to –68 °C. – $C_{16}H_{34}S_5$ (386.8): calcd. C 49.7, H 8.9, S 41.5; found C 50.8, H 8.2, S 40.4. – UV/Vis (methanol): λ_{max} (%) = 216 nm (100), 292 (sh). – MS (120 °C): *m*/*z* (%) = 386 (23) [M^+], 322 (100). – ^{1}H NMR (200 MHz, $CDCl_3$): δ = 2.99 (t, 4 H), 1.78 (tt, 4 H), 1.45–1.29 (br. s, 20 H), 0.89 (t, 6 H). – $^{13}C\{^1H\}$ NMR (50 MHz, $CDCl_3$): δ = 39.9, 31.8, 29.1, 29.1, 28.8, 28.4, 22.6, 14.1. – Raman (80 mW, 20 °C): $\tilde{\nu}$ = 505 cm^{-1} (SS), 493 (SS), 459 (SS), 435 (SS).

Synthesis of Bis(*n*-octyl)heptasulfane (2) and -nonasulfane (3): To a stirred solution of $[Cp_2TiS_5]$ (0.846 g, 2.5 mmol) in CS_2 (30 mL) at –20 °C (**2**) or at –70 °C (**3**), a solution of *n*-octylsulfenyl chloride (0.904 g, 5 mmol) or *n*-octylchlorodisulfane (1.064 g, 5 mmol) in CS_2 (40 mL) was added dropwise. [The chlorodisulfane, a yellow viscous liquid, had been prepared from the thiol (10 mmol) and SCl_2 (12 mmol) in CH_3OtBu at –70 to +20 °C]. The color turned from dark-red to light-red. The precipitated $[Cp_2TiCl_2]$ was removed by filtration at 20 °C in the case of **2** and at –20 °C in the case of **3** and the filtrate was concentrated to one-half of its original volume. After cooling to –50 °C for several hours, the precipitated $[Cp_2TiCl_2]$ was filtered off. On complete removal of the solvent under reduced pressure, the liquid polysulfane was obtained. Yield: 1.127 g of the heptasulfane or 1.290 g of the nonasulfane (both quantitative). – **2:** freezing temp. –61 °C. – $C_{16}H_{34}S_7$ (450.9): calcd. C 42.6, H 7.6, S 49.8; found C 43.3, H 7.8, S 48.0. – UV/Vis (methanol): λ_{max} (%) = 226 nm (100), 300 (sh). – MS (160 °C): *m*/*z* (%) = 450 (1) [M^+], 418 (7) [M^+ – S], 386 (10) [M^+ – 2S], 322 (100) [M^+ – 4S]. – ^{1}H NMR (200 MHz, $CDCl_3$): δ = 3.00 (t, 4 H), 179 (tt, 4 H), 1.46–1.29 (br. s, 20 H), 0.90 (t, 6 H). – ^{13}C NMR (50 MHz, $CDCl_3$): δ = 39.8, 31.8, 29.1, 29.1, 28.9, 28.4, 22.6, 14.1. – Raman (40 mW, –135 °C): $\tilde{\nu}$ = 429 cm^{-1} (SS), 445 (SS), 463 (SS), 470 (SS), 495 (SS). – **3:** freezing temp. –53 °C. – $C_{16}H_{34}S_9$ (515.1): calcd. C 37.3, H 6.7, S 56.0; found C 37.7, H 6.4, S 56.3. – UV/Vis (methanol): λ_{max} (%) = 228 nm (100), 284 (sh). – MS (160 °C): *m*/*z* (%) = 450 (0.2) [M^+ – 2S], 418 (2) [M^+ – 3S], 386 (4) [M^+ – 4S], 145 (100) [$C_8H_{17}S$]. – ^{1}H NMR (200 MHz, $CDCl_3$): δ = 3.01 (t, 4 H), 1.79 (tt, 4 H), 1.47–1.29 (br. s, 20 H), 0.90 (t, 6 H). – ^{13}C NMR (50 MHz, $CDCl_3$): δ = 39.8, 31.8, 29.1, 28.9, 28.4, 22.6, 14.1. – Raman (40 mW, –135 °C): $\tilde{\nu}$ = 423 cm^{-1} (SS), 437 (SS), 452 (SS), 463 (SS), 472 (SS), 494 (SS).

Synthesis of Bis(2-naphthyl)heptasulfane (4): To a stirred solution of $C_{10}H_7SCl$ (0.29 g, 1.49 mmol) in CS_2 (40 mL), $[Cp_2TiS_5]$ (0.25 g, 0.74 mmol) was added at 20 °C under an N_2 atmosphere. After the color had changed to orange-red, the precipitated $[Cp_2TiCl_2]$ was filtered off and the filtrate was stirred with a few mg of silica gel to bind residual titanocene dichloride. After filtration, the solvent was evaporated to leave a yellow oil, which was dissolved in a small volume of CH_2Cl_2. A little *n*-hexane was added and the mixture was concentrated until some turbidity appeared. It was then cooled to –50 °C, which led to the deposition of crystals of **4**. The collected crystals were washed with *n*-hexane and dried to give **4** as a yellow powder, m.p. 55–58 °C; yield 0.18 g (51%). – $C_{20}H_{14}S_7$ (478.8): calcd. C 50.2, H 3.0, S 46.9; found C 50.1, H 3.1, S 45.3. – UV/Vis (methanol): λ_{max} (%) = 222 nm (92), 233 (97), 236 (100), 240 (98), 281 (34), 334 (14). – MS (210 °C): *m*/*z* (%) = 446 (0.3) [M^+ – S], 115 (100) [C_9H_7]. – ^{1}H NMR (200 MHz, CD_2Cl_2): δ = 8.09 (d), 7.83 (m), 7.68 (dd), 7.53 (m). – ^{13}C NMR (50 MHz, CD_2Cl_2): δ = 127.0, 127.5, 127.8, 127.8, 129.3, 129.9, 133.0, 133.1, 133.4. – Raman (40 mW; 20 °C): $\tilde{\nu}$ = 394 cm^{-1} (m), 417 (sh), 430 (vs), 441 (s), 473 (vs), 505 (sh), 511 (s), 521 (m).

Synthesis of Bis(4-chlorophenyl)heptasulfane (5): To a stirred solution of $[Cp_2TiS_5]$ (1.00 g, 2.96 mmol) in CS_2 (70 mL), ClC_6H_4SCl (1.06 g, 5.91 mmol) was added at 20 °C. After 5 min., the color had changed to orange and the precipitated $[Cp_2TiCl_2]$ was filtered off. A few mg of silica gel was added to the filtrate to bind residual titanocene dichloride. After stirring for a few min., the solution was filtered, the filtrate was concentrated to a volume of 5 mL, and then *n*-pentane (10 mL), MTB ether (15 mL), and ethanol (15 mL) were added. The solvents were then evaporated until the solution became turbid. Cooling of the solution to –78 °C led to the deposition of crystals of **5** (m.p. 40 °C), which were filtered off, washed with *n*-pentane, and dried in air; yield 0.58 g (44%). – $C_{12}H_8Cl_2S_7$ (447.6): calcd. C 32.2, H 1.8, S 50.2; found C 32.3, H 1.7, S 50.2. – UV/Vis (methanol): λ_{max} (%) = 211 nm (93), 240 (100), 292 (30), 327 (23). – MS (160 °C): *m*/*z* (%) = 418 (0.2), 414 (0.4) [M^+ – S], 382 (2) [M^+ – 2S], 175 (100) [$C_6H_4ClS_2$]. – ^{1}H NMR (200 MHz, CD_2Cl_2): δ = 7.57 (dm, 4 H), 7.36 (dm, 4 H). – ^{13}C NMR (50 MHz, CD_2Cl_2): δ = 129.5, 132.0, 134.4, 135.0. – Raman (40 mW; 20 °C): $\tilde{\nu}$ = 376 cm^{-1} (m), 419 (w), 435 (vs), 456 (vw), 473 (vs), 509 (m), 541 (m).

Synthesis of 1,2,3,4,5-Benzopentathiepin (6): To a stirred solution of $[(Cp'_2TiCl)_2S_3]$ (0.150 g, 0.259 mmol) in CS_2 (40 mL) at –78 °C, a solution of 1,2-benzenebis(sulfenyl chloride) (0.055 g, 0.259 mmol) in CS_2 (40 mL) was added dropwise over a period of 20 min. [The bis(sulfenyl chloride) had been prepared by chlorination of the corresponding dithiol using elemental chlorine in CCl_4 at 0 °C]. On warming the reaction mixture to ambient temperature, the color changed from dark-green to light-red. After filtering off the precipitated $[Cp'_2TiCl_2]$, the filtrate was concentrated to one-quarter of its original volume and the mixture was cooled to –55 °C for several hours. After another filtration, the solvent was completely removed under reduced pressure. The yellow crude product was recrystallized from a mixture of CS_2 and CH_3OtBu (1:1). Yield: 0.045 g (73%); m.p. 58 °C. – $C_6H_4S_5$ (236.4): calcd. C

30.4, H 1.7, S 67.7; found C 30.3, H 1.4, S 66.1. – UV/Vis (methanol): λ_{max} (%) = 223 nm (100), 272 (sh), 314 (sh). – MS (88 °C): *m/z* (%) = 236 (16) [M^+], 172 (100) [$M^+ - S_2$]. – ^{1}H NMR (200 MHz, CD_2Cl_2): δ = 7.85 (m, 2 H), 7.36 (m, 2 H). – ^{13}C NMR (50 MHz, $CDCl_3$): δ = 143.8, 135.8, 129.6. – Raman (150 mW, 20 °C): $\tilde{\nu}$ = 418 cm^{-1} (SS), 428 (SS), 467 (SS), 490 (SS).

Synthesis of 1,2,3,4,5,6,7-Benzoheptathionin (7): The synthesis was carried out in analogy to the preparation of **4** starting from [Cp_2TiS_5] (0.8 g, 2.37 mmol) in CS_2 (150 mL) and 1,2-benzenebis(sulfenyl chloride) (0.5 g, 2.37 mmol) in CS_2 (50 mL). Yield: 0.59 g (83%); m.p. 107 °C. – $C_6H_4S_7$ (300.6): calcd. C 24.0, H 1.3; found C 24.2, H 1.1. – UV/Vis (methanol): λ_{max} (%) = 218 nm (100), 295 (sh). – MS (149 °C): *m/z* (%) = 300 (2) [M^+], 172 (100) [$C_6H_4S_3$]. – ^{1}H NMR (200 MHz, CD_2Cl_2): δ = 7.77 (m, 2 H), 7.48 (m, 2 H). – ^{13}C NMR (50 MHz, $CDCl_3$): δ = 137.9, 135.2, 131.3. – Raman (150 mW, 20 °C): $\tilde{\nu}$ = 436 cm^{-1} (SS), 451 (SS), 471 (SS), 495 (SS), 518 (SS).

Synthesis of 1,2,3,4,5,6,7,8-Benzooctathiecin (8): To a stirred solution of [(TMEDA)ZnS_6] (0.326 g, 0.94 mmol) in CS_2 (30 mL), a solution of 1,2-benzenebis(sulfenyl chloride) (0.2 g, 0.94 mmol) in CS_2 (20 mL) was added dropwise over a period of 30 min. After stirring for 1 h, the precipitated [(TMEDA)$ZnCl_2$] was filtered off and the solvent was removed completely from the filtrate. The crude yellow oil was crystallized from a mixture of CS_2 and MTB ether (1:1). Yield: 0.19 g (60%); m.p. 73 °C. – $C_6H_4S_8$ (332.6): calcd. C 21.7, H 1.2; found C 21.2, H 0.9. – UV/Vis (methanol): λ_{max} (%) = 213 nm (100), 235 (sh), 318 (sh). – MS (120 °C): *m/z* (%) = 332 (1) [M^+], 172 (100) [$C_6H_4S_3$]. – ^{1}H NMR (200 MHz, CD_2Cl_2): δ = 7.74 (m, 2 H), 7.43 (m, 2 H). – ^{13}C NMR (50 MHz, $CDCl_3$): δ = 139.4, 133.9, 129.8. – Raman (150 mW, 20°C): $\tilde{\nu}$ = 416 cm^{-1} (SS), 428 (SS), 438 (SS), 460 (SS), 467 (SS), 512 (SS).

Table 3. Crystal data and structure refinement for $C_6H_4S_7$

Empirical formula	$C_6H_4S_7$
Formula weight	300.51
Temperature [K]	293(2)
Wavelength [Å]	0.71073
Crystal system	orthorhombic
Space group	*Pnma*
Z	4
a [Å]	17.7990(7)
b [Å]	13.2422(6)
c [Å]	4.7990(2)
V [Å^3]	1131.11(8)
D (calcd.) [g cm^{-3}]	1.765
μ [mm^{-1}]	1.342
Crystal size [mm]	0.3 × 0.08 × 0.08
2θ range [°]	4.58–55.00
Index ranges	*h* ±22, *k* +17, *l* ±6
Collected reflections	7947
Independent reflections	1358 (R_{int} = 0.0625)
Obsd. with $I > 2\sigma(I)$	916
Data/restraints/parameters	1358/0/61
Goodness-of-fit on F^2	1.119
R_1 [$I > 2\sigma(I)$]	0.0507
R_1 (all data)	0.0889
Largest diff. peak/hole [eÅ^{-3}]	0.425/–0.229

Crystallography: Crystals were obtained by dissolving **7** in carbon disulfide and adding *n*-hexane until the mixture became turbid. On cooling this mixture to 4 °C, crystals separated. Diffraction measurements were made at room temperature using a Siemens SMART CCD diffractometer (Mo-K_α radiation, 10 s per frame, 0.3° ω-scan increments, specimen–detector distance 3 cm). Preliminary lattice constants were obtained from 45 orientation frames and final unit cell dimensions by refinement of the reflections obtained from all frames. The compound crystallizes in the space group *Pnma* (no. 62). An empirical absorption correction (SADABS[27]) was performed. Structure solution and refinement were performed using SHELXTL.[28] H atom positions were calculated assuming trigonal-planar coordination of C atoms with C–H distances of 93 pm and were refined as riding on the C atoms with isotropic temperature factors 1.2$U_{equiv.}$ of the corresponding C atoms. A summary of data collection and refinement is given in Table 3. Crystallographic data (excluding structure factors) have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-136074. Copies of the data can be obtained free of charge on application to the CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax.: (internat.) +44 (0)1223 336033; E-mail: deposit@ccdc.cam.ac.uk].

Cationic *ansa*-(η^5-Cyclopentadienyl)(η^6-arene) Complexes of Titanium[+]

Patrick J. W. Deckers,[a] Arjan J. van der Linden,[b] Auke Meetsma,[a] and Bart Hessen*[a]

Keywords: Titanium / Cyclopentadienes / Arene complexes / Cations / Bridging ligands

The half-sandwich titanium trimethyl complex (η^5-$C_5H_4CMe_2Ar$)$TiMe_3$ (Ar = 3,5-$Me_2C_6H_3$) reacts with the Lewis acid $B(C_6F_5)_3$ to give the ionic Ti^{IV} *ansa*-cyclopentadienyl-arene complex [(η^5,η^6-$C_5H_4CMe_2Ar$)$TiMe_2$]-[$MeB(C_6F_5)_3$]. In bromobenzene solvent, addition of more $B(C_6F_5)_3$ leads to C_6F_5/Me exchange and, subsequently, to formation of an unusual dimeric Ti^{III} dicationic species, {[(η^5,η^6-$C_5H_4CMe_2Ar$)Ti(μ-Br)]$_2$}[$B(C_6F_5)_4$]$_2$, which was structurally characterized. Its formation involves reduction of the transition-metal center, solvent C–Br cleavage and perfluoroaryl-group scrambling.

Introduction

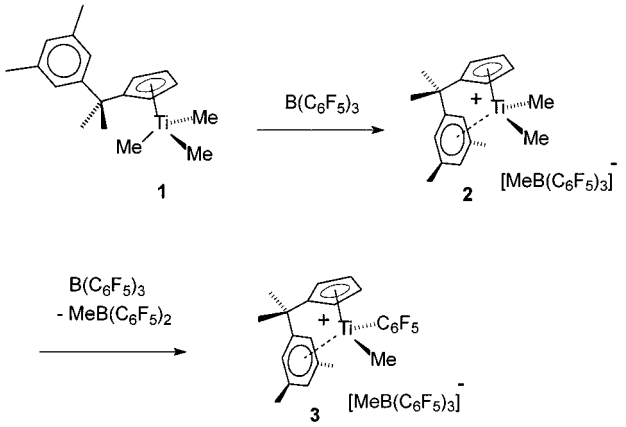
Cationic titanium half-sandwich (mono-cyclopentadienyl) species show interesting catalytic activity, especially in the syndiotactic polymerization of styrene[1] and the polymerization of propene to high molecular weight atactic polypropene.[2] There has been some debate in the literature about the nature of the actual active species in these systems, e.g. whether Ti^{IV} or Ti^{III} species are involved, or both.[3] As the cationic species [(η^5-C_5R_5)$TiMe_2$]$^+$ are highly electron-deficient we sought ways of stabilizing these, without resorting to strong heteroatom-based Lewis basic moieties, in order to study their reactive properties. Baird et al. found that [(η^5-C_5Me_5)MMe_2]$^+$ cations (M = Ti, Zr, Hf) can bind arenes reversibly,[4] and that this interaction is significantly stronger for Zr and Hf (for which a related crystal structure has been reported[5]) than for Ti. We thus set out to prepare half-sandwich titanium complexes with benzyl-substituted Cp-ligands to use these interactions in an intramolecular fashion. The feasibility of this was suggested by observations of Chien, Rausch et al. on the [η^5-$C_5Me_4(CH_2CH_2Ph)$]$TiMe_3$ + [Ph_3C][$B(C_6F_5)_4$] system, where NMR evidence was obtained for η^6-coordination of the arene moiety in the thermally labile cationic dimethyl species.[6] In this contribution we describe the synthesis of neutral and cationic titanium complexes with the benzyl-substituted cyclopentadienyl ligand [$C_5H_4CMe_2Ar$]$^-$ (Ar = 3,5-dimethylphenyl).

The cationic *ansa*-cyclopentadienyl-arene complex [(η^5,η^6-$C_5H_4CMe_2Ar$)$TiMe_2$][$MeB(C_6F_5)_3$] was found to be quite stable in bromobenzene solution at ambient temperature, but it reacts with the Lewis acid $B(C_6F_5)_3$ via Me/C_6F_5 scrambling. This species subsequently undergoes a highly unusual transformation, resulting in a dicationic dimeric Ti^{III} complex. The crystal structure of this product represents the first structural characterization of an *ansa*-cyclopentadienyl-arene early transition-metal compound.

Results and Discussion

The synthesis of the benzyl-cyclopentadienyl salt Li[$C_5H_4CMe_2Ar$] (Ar = 3,5-dimethylphenyl) is straightforward, proceeding through addition of ArLi (obtained from ArBr and *n*BuLi) to 6,6-dimethylfulvene, analogous to the preparation of Li[$C_5H_4CMe_2Ph$].[7] The 3,5-(dimethyl)-phenyl group was chosen initially to provide a stronger donor interaction (in [Cp*MMe_2(arene)]$^+$ toluene is more strongly bound than benzene[4]) and to make arene cyclometallation[8] less favorable. Reaction of this Li salt with $TiCl_4$ in dichloromethane afforded ($C_5H_4CMe_2Ar$)$TiCl_3$, which was methylated in benzene solvent using Me_2Mg(dioxane) to give the trimethyl derivative ($C_5H_4CMe_2Ar$)$TiMe_3$ (**1**).

In [D_2]-1,1,2,2-tetrachloroethane or [D_5]bromobenzene solvent, **1** reacts with 1 equiv. of the Lewis acid $B(C_6F_5)_3$ to give deep red solutions of a species that was identified by 1D and 2D NMR techniques as the ionic *ansa*-cyclopentadienyl-arene complex [(η^5,η^6-$C_5H_4CMe_2Ar$)$TiMe_2$][$MeB(C_6F_5)_3$] (**2**, Scheme 1).



The resonances for the [$MeB(C_6F_5)_3$]$^-$ anion are consistent with those for a noncoordinated anion,[9] and the resonances for the arene moiety show substantial coordination chemical shifts (downfield for *o*-C and *p*-C, upfield for *m*-C; the *o*-H proton resonances are found upfield shifted at δ = 5.91). The chemical shift difference between the two sets of Cp protons also increases strongly ($\Delta\delta$ = 1.59 in **2** and 0.14 in **1**). Compound **2** is a 16-electron complex and does not readily react with propene or styrene at ambient temperature (as seen from NMR-tube-scale experiments). This suggests that the arene moiety is fairly strongly bound. Addition of a drop of [D_8]THF to a C_6D_5Br solution of **2** shows a shift of the Cp and aryl proton resonances back to

Scheme 1. Generation of the cationic species **2** and **3**

"normal" chemical shift ranges, indicating release of the arene moiety in the presence of a hard Lewis base to give a $[(\eta^5\text{-}C_5H_4CMe_2Ar)TiMe_2(THF)_x][MeB(C_6F_5)_3]$ species. Compound **2** is reasonably stable in $C_2D_2Cl_4$ or $[D_5]$bromobenzene and only very gradually decomposes at ambient temperature. Solutions of **2**, prepared in situ in $[D_5]$bromobenzene, produced a few deep brown-green crystals upon standing at ambient temperatures for several days (vide infra).

The presence of one equivalent of excess $B(C_6F_5)_3$ in bromobenzene solutions of **2** resulted in a reaction (complete in about 20–24 h at ambient temperature) forming $MeB(C_6F_5)_2$[10] and an organometallic species that, based on NMR spectroscopy, was identified as the mixed methyl/perfluoroaryl species $[(\eta^5,\eta^6\text{-}C_5H_4CMe_2Ar)Ti(C_6F_5)Me][MeB(C_6F_5)_3]$ (**3**, Scheme 1). The ^{19}F NMR spectrum shows a C_6F_5 group with a downfield shifted *o*-F resonance, and the ^{13}C NMR spectrum a triplet with $^3J_{CF} = 7.3$ Hz at $\delta = 102.7$ for the Ti–Me group. These features are consistent with a $Ti(Me)(C_6F_5)$ species.[11] The ^1H NMR resonances of **3** are broad at ambient temperature, but at –30 °C they reveal an asymmetric structure, and the retention of the η^5,η^6-coordination mode of the ancillary ligand. Thus the addition of an extra equivalent of the Lewis acid induces a scrambling of Ti-bound and B-bound hydrocarbyl groups. Upon standing at ambient temperature the solution produces brown-green crystals that (based on lattice parameters) are identical to those that are (more slowly) formed in solutions of **2**.

An X-ray structure determination showed that these crystals are of the salt $\{[(\eta^5,\eta^6\text{-}C_5H_4CMe_2Ar)Ti(\mu\text{-}Br)]_2\}[B(C_6F_5)_4]_2$ (**4**, Figure 1).

In this compound a dicationic dimeric Ti^{III} *ansa*-cyclopentadienyl-arene bromide complex is complemented by two tetrakis(pentafluorophenyl)borate anions. The dication is centrosymmetric, with nearly equivalent Ti–Br bond lengths in the $Ti(\mu\text{-}Br)_2Ti$ bridge. The Ti–Br distances are, on average, 0.085 Å shorter than in the isoelectronic neutral $[(C_5H_4Me)_2Ti(\mu\text{-}Br)]_2$ complex[12] and this, combined with the wider Br–Ti–Br' angle, results in a Ti···Ti distance of 3.7858(9) Å in **4** that is 0.34 Å shorter than in the latter compound. The bend angle of the Cp-arene ligand backbone, C(5)–C(6)–C(7), is quite acute at 95.8(3)°, and the Cp(centroid)–Ti–Ar(centroid) angle is 125.0°. The arene ring does not deviate significantly from planarity, but the bonding to the Ti atom is highly asymmetric, with Ti–C(7), Ti–C(8) and Ti–C(12) being much shorter than the Ti–C(9), –C(10) and –C(11) distances. This results in a slight lengthening of the C(7)–C(8) and C(7)–C(12) bonds relative to the other arene C–C bonds.

The formation of compound **4** is remarkable for at least two reasons: a) the reaction of a Ti^{IV} cation with a Lewis acid in a halogenated solvent yields a Ti^{III} halide species, and b) starting from a cation with the $[MeB(C_6F_5)_3]^-$ counterion, a product is formed with $[B(C_6F_5)_4]^-$ counterions. This indicates that the reaction involves a reduction of the

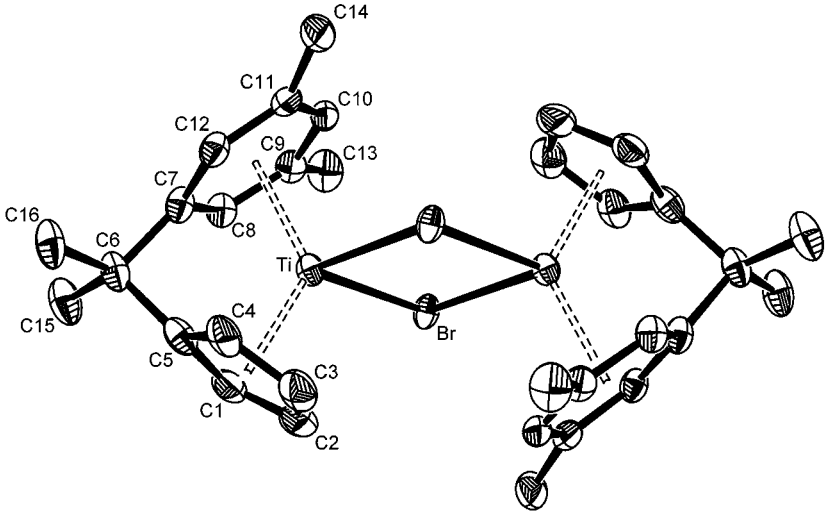

Figure 1. ORTEP diagram of the molecular structure of the cationic part of **4**; hydrogen atoms are omitted for clarity; selected interatomic distances [Å] and angles [°]: Ti–Br 2.6250(7), Ti–Br' 2.6334(7), Ti–C(1) 2.341(4), Ti–C(2) 2.410(5), Ti–C(3) 2.383(5), Ti–C(4) 2.313(4), Ti–C(5) 2.323(3), Ti–C(7) 2.379(3), Ti–C(8) 2.473(4), Ti–C(9) 2.674(4), Ti–C(10) 2.725(3), Ti–C(11) 2.713(4), Ti–C(12) 2.470(4), C(7)–C(8) 1.419(6), C(8)–C(9) 1.393(5), C(9)–C(10) 1.393(6), C(10)–C(11) 1.394(6), C(11)–C(12) 1.395(5), C(7)–C(12) 1.410(6); Br–Ti–Br' 87.90(2), Ti–Br–Ti' 92.10(2), C(5)–C(6)–C(7) 95.8(3), C(15)–C(6)–C(16) 107.6(3)

metal center, cleavage of the solvent C–Br bond, and a scrambling of the substituents on the borane/borate species. In C_6D_5Br solvent, formation of $CH_3C_6D_5$ is seen (GC/MS). The isolated yield of **4** is rather low (18%) and precise reactive pathways in this transformation are, as yet, unclear, but the observations made so far are of interest. For instance, they may shed some light on the way in which Ti^{III} centers can be generated by the reaction of Ti^{IV} alkyls with an excess of Lewis acid activator (note that Grassi et al. use chlorobenzene as solvent for their ESR experiments with Cp^*TiMe_3 and Lewis acids[3b]). It also demonstrates the dynamic nature of perfluoroarylborate "weakly coordinating" anions, in which tetraarylborates may be formed from alkyltriarylborates (an interesting contrast to the aryl abstraction from the $[B(C_6F_5)_4]^-$ anion, recently reported by Bochmann et al.[13]).

In conclusion, we have observed the formation of a cationic *ansa*-Cp-arene titanium dimethyl species, hydrocarbyl ligand scrambling on this species induced by the presence of excess Lewis acid, and a highly unusual degradation of a cationic Ti^{IV} species in bromobenzene to produce a Ti^{III} complex, the first structurally characterized *ansa*-Cp-arene early transition-metal derivative. These observations provide an interesting insight into the possible activation and degradation processes in titanium-based half-sandwich olefin polymerization catalysts, and we are presently studying related hemilabile monocyclopentadienyl Ti^{IV} species to increase our understanding of this chemistry.

Experimental Section

General: All experiments were performed under a nitrogen atmosphere with standard Schlenk and glove-box techniques. Deuterated solvents (Aldrich, Acros) were either degassed and dried over molecular sieves ($C_2D_2Cl_4$, C_6D_5Br, CD_2Cl_2) or dried over Na/K alloy and vacuum transferred before use. Dichloromethane was distilled from P_2O_5, C_6H_5Br from Ca chips, other solvents were distilled from Na/K alloy or Na (toluene) before use. – NMR spectra were recorded on Varian Gemini 200/300, Inova 400 and Unity 500 spectrometers. The ^{1}H-NMR spectra were referenced to resonances of residual protons in the deuterated solvents. Chemical shifts (δ) are given relative to tetramethylsilane (downfield shifts are positive). Li[$C_5H_4CMe_2Ar$] (Ar = 3,5-dimethylphenyl) was prepared analogously to the derivative with Ar = Ph[7] using 3,5-dimethylphenyllithium prepared in hexane from the corresponding aryl bromide and *n*BuLi. 6,6-Dimethylfulvene and 5-bromo-3-methyltoluene (Aldrich) were used as purchased.

Preparation of (η^5-$C_5H_4CMe_2Ar$)$TiCl_3$: To a stirred solution of $TiCl_4$ (1.0 g, 5.3 mmol) in 20 mL of dichloromethane, cooled at –40 °C, was added solid Li[$C_5H_4CMe_2Ar$] (1.16 g, 5.3 mmol). The red suspension was warmed to room temperature and stirred for 16 h. The salts were separated by centrifugation and subsequent decanting. The solvent was removed in vacuo from the supernatant, and the resulting red-brown oil was extracted with pentane. Cooling the extract to –40 °C yielded orange crystals of the title compound. Yield: 1.28 g (3.50 mmol, 66%). – ^{1}H NMR ([D_6]benzene): δ = 6.69 (s, 2 H, *o-H*), 6.66 (s, 1 H, *p-H*), 6.37 (ps. t, 2 H, Cp), 6.03 (ps. t, 2 H, Cp), 2.10 (s, 6 H, Ar–CH_3), 1.63 [s, 6 H, C(CH_3)$_2$]. – ^{13}C{^{1}H} NMR (CD_2Cl_2): δ = 158.0 (Ar C_{ipso}), 149.8 (Cp C_{ipso}), 140.2 (Ar *m-C*), 130.3 (Ar *p-C*H), 126.5 (Cp *C*H), 126.0 (Ar *o-C*H), 124.5 (Cp *C*H), 43.1 (*C*Me$_2$), 30.8 [C(*C*H$_3$)$_2$], 23.4 (Ar–CH$_3$). – $C_{16}H_{19}Cl_3Ti$ (365.6): calcd. C 52.57, H 5.24, Cl 29.09, Ti 13.10; found C 52.42, H 5.32, Cl 28.91, Ti 12.85.

Preparation of (η^5-$C_5H_4CMe_2Ar$)$TiMe_3$ (1): To a solution of ($C_5H_4CMe_2Ar$)$TiCl_3$ (0.95 g, 2.6 mmol) in 15 mL of benzene was added $Me_2Mg(dioxane)_{0.5}$ (1.86 g, 4.0 mmol). The suspension was stirred at ambient temperature while the color changed gradually from red to yellow. The mixture was centrifuged and the salts were separated by decantation. The solvent was removed in vacuo, and the residue extracted with pentane. Evaporation of the solvent yielded **1** as a yellow oil that solidified on standing. The compound is very soluble in pentane, but may be crystallized from this solvent at low temperature to yield analytically pure material. – ^{1}H NMR ([D_6]benzene): δ = 6.94 (s, 2 H, *o-H*), 6.69 (s, 1 H, *p-H*), 5.95 (ps. t, 2 H, Cp), 5.81 (ps. t, 2 H, Cp), 2.15 (s, 6 H, Ar–CH_3), 1.45 [s, 6 H, C(CH_3)$_2$], 1.31 (s, 9 H, Ti–CH_3) . – ^{13}C NMR ([D_6]benzene): δ = 150.3 (s, Ar C_{ipso}), 144.7 (s, Cp C_{ipso}), 137.4 (s, Ar *m-C*), 129 (Ar *p-C*H, part. overlapped by solvent), 124.3 (d, J_{CH} = 149 Hz, Ar *o-C*H), 114.0 (d, J_{CH} = 167 Hz, Cp *C*H), 109.5 (d, J_{CH} = 171 Hz, Cp *C*H), 63.0 (q, J_{CH} = 120 Hz, Ti-*C*H$_3$), 39.7 (s, *C*Me$_2$), 29.6 [q, J_{CH} = 132 Hz, C(*C*H$_3$)$_2$], 21.6 (q, J_{CH} = 121 Hz, Ar–CH$_3$). – $C_{19}H_{28}Ti$ (304.3): calcd. C 74.99, H 9.27, Ti 15.73; found C 74.80, H 9.29, Ti 15.50.

Generation of [(η^5,η^6-$C_5H_4CMe_2Ar$)$TiMe_2$][$MeB(C_6F_5)_3$] (2): A solution of **1** (13.5 mg, 44.3 μmol) in 0.25 mL of $C_2D_2Cl_4$ was added to a solution of $B(C_6F_5)_3$ (22.7 mg, 44.3 μmol) in 0.25 mL of $C_2D_2Cl_4$ to give a deep red solution of **2**. The reaction proceeds in a similar fashion in C_6D_5Br solvent. – ^{1}H NMR (C_6D_5Br): δ = 7.02 (s, 1 H, *p-H*), 6.74 (ps. t, 2 H, Cp), 5.91 (s, 2 H, *o-H*), 5.15 (ps. t, 2 H, Cp), 2.10 (s, 6 H, Ar–CH_3), 1.07 [6 H, C(CH_3)$_2$, + 3 H B–CH_3], 0.34 (s, 6 H, Ti–CH_3). – ^{13}C NMR ($C_2D_2Cl_4$, –40 °C): δ = 155.2 (s, Ar C_{ipso}), 151.2 (d, J_{CF} = 236 Hz, *o-C*F), 140.3 (d, J_{CF} = 236 Hz, *p-C*F), 139.2 (d, J_{CF} = 236 Hz, *m-C*F), 138.0 (s, Cp C_{ipso}), 135.3 (d, J_{CH} = 166 Hz, Ar *p-C*H), 131.4 (br, C_6F_5 C_{ipso}), 128.2 (d, J_{CH} = 186 Hz, Ar *o-C*H), 125.3 (d, J_{CH} = 166 Hz, Cp *C*H), 123.4 (s, Ar *m-C*), 115.9 (d, J_{CH} = 172 Hz, Cp *C*H), 74.4 (q, J_{CH} = 126 Hz, Ti–CH$_3$), 43.9 (s, *C*Me$_2$), 25.8 [q, J_{CH} = 130 Hz, C(*C*H$_3$)$_2$], 21.6 (q, J_{CH} = 126 Hz, Ar–CH$_3$), 13.5 (br, B–CH$_3$). – ^{19}F NMR ($C_2D_2Cl_4$): δ = –132.8 (*o-F*), –164.1 (*p-F*), –166.7 (*m-F*).

Reaction of 2 with [D_8]THF: To a deep red solution of **2** in C_6D_5Br, prepared as described above, was added a drop of [D_8]THF, resulting in a red solution of [(η^5-$C_5H_4CMe_2Ar$)Ti-Me_2(THF)$_n$][$MeB(C_6F_5)_3$]. – ^{1}H NMR (C_6D_5Br/[D_8]THF): δ = 6.72 (s, 2 H, *o-H*), 6.66 (s, 1 H, *p-H*), 6.14 (ps. t, 2 H, Cp), 6.04 (ps. t, 2 H, Cp), 2.14 (s, 6 H, Ar–CH_3), 1.37 [6 H, C(CH_3)$_2$ + 6 H, Ti–CH_3], 1.04 (br, 3 H, B–CH_3).

Reaction of 2 with $B(C_6F_5)_3$: In an NMR tube with a Teflon (Young) valve, a solution of **2** was prepared as described above, but using two equivalents of $B(C_6F_5)_3$ per Ti. The tube was allowed to stand at ambient temperature, and was monitored at regular intervals by ^{1}H and ^{19}F NMR. After 24 h all of **2** had disappeared, giving **3** and $MeB(C_6F_5)_2$.

3: ^{1}H NMR (C_6D_5Br, –30 °C): δ = 6.85 and 6.80 (br, 1 H each, Cp), 6.71 (s, 1 H, *p*-H), 5.96 and 5.74 (s, 1 H each, *o-H*), 5.66 and 5.53 (br, 1 H each, Cp), 2.11 and 1.38 (s, 3 H each, Ar–CH_3), 1.13–1.09 [total 9 H, C(CH_3)$_2$ + Ti–CH_3]. – ^{13}C{^{1}H} NMR (C_6D_5Br, –30 °C): δ = 102.7 (t, $^3J_{CF}$ = 7.3 Hz, Ti–CH$_3$), 40.5 [*C*(CH$_3$)$_2$], 22.2 [C(*C*H$_3$)$_2$], 20.2, 21.0 (Ar–CH$_3$), aromatic resonances poorly resolved. – ^{19}F NMR (C_6D_5Br, –30 °C): δ = –114.3 (*o*-F, Ti–Ar), –

132.9 (*o*-F, B–Ar), –149.9 (*p*-F, Ti–Ar), –159.5 (*m*-F, Ti–Ar), –164.7 (*p*-F, B–Ar), –167.3 (*m*-F, B–Ar).

$MeB(C_6F_5)_2$: ^{1}H NMR (C_6D_5Br, 20 °C): δ = 1.52 (quint., $^5J_{HF}$ = 2 Hz, B–Me). – ^{19}F NMR (C_6D_5Br, –30 °C): δ = –129.9 (*o*-F), –147.5 (*p*-F), –161.5 (*m*-F).

Formation of $\{[(\eta^5,\eta^6\text{-}C_5H_4CMe_2Ar)Ti(\mu\text{-}Br)]_2\}[B(C_6F_5)_4]_2$ (4): A solution of **1** (0.120 g, 0.39 mmol) in 5 mL of bromobenzene was added to $B(C_6F_5)_3$ (0.40 g, 0.78 mmol). Over a period of 3 weeks at ambient temperature green-brown crystals separated from the solution. The supernatant was decanted and the crystals rinsed twice with 10 mL of pentane. Yield: 0.070 g (34 μmol, 18%) of analytically pure **4**. – $C_{80}H_{38}B_2Br_2F_{40}Ti_2$ (2036.3): calcd. C 47.19, H 1.88, Ti 4.70; found C 47.03, H 2.22, Ti 4.58.

Crystal Structure Analysis of 4: Enraf–Nonius CAD4-F diffractometer, Mo-K_α radiation (λ = 0.71073 Å), T = 130 K; monoclinic, $P2_1/n$, a = 13.616(2), b = 16.014(1), c = 17.702(2) Å, β = 109.01(1), V = 3649.4(7) Å^3, Z = 2, D_x = 1.853 g cm^{-3}, μ = 14.7 cm^{-1}. The structure was solved by direct methods. A final refinement on F^2 converged at $wR(F^2)$ = 0.1143 for 7118 reflections with $F_o^2 \geq 0$ and $R(F)$ = 0.0415 for 5390 reflections with $F_o \geq 4\sigma(F_o)$ and 644 parameters.

Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-135683. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Note Added in Proof (February 28, 2000): During the processing of this contribution a paper was published describing the generation and NMR-spectroscopic characterization (in CD_2Cl_2 solvent at –60 °C) of the cation $[\eta^5,\eta^6\text{-}C_5H_4CMe_2Ph)TiMe_2]^+$.[14]

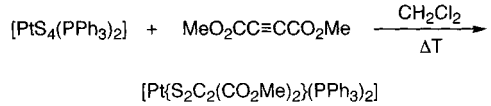
Reaction of the Tetrachalcogenides [ME_4(dppe)] (M = Pd, E = S; M = Pt, E = S, Se) with Activated Alkynes to Form Dithiolenes and Diselenolenes

Susan Ford,[a] Mark R. Lewtas,[a] Christopher P. Morley,*[a] and Massimo Di Vaira[b]



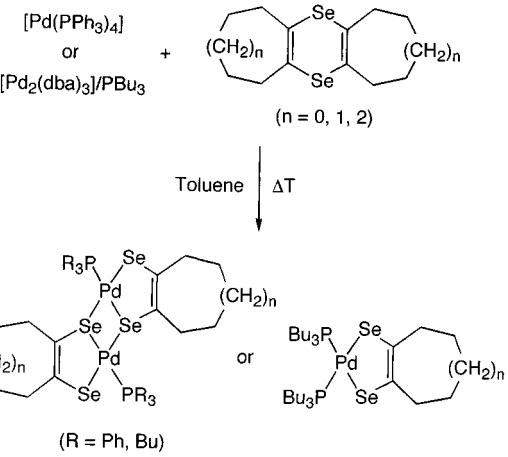
Keywords: Palladium / Platinum / Dithiolenes / Diselenolenes / Sulfur / Selenium

The tetrachalcogenides [ME_4(dppe)] (M = Pd, E = S; M = Pt, E = S, Se) react with the activated alkynes $RO_2CC{\equiv}CCO_2R$ (R = Me, Et) to form the dithiolenes and diselenolenes [M{$E_2C_2(CO_2R)_2$}(dppe)]; the structures of the compounds with E = S, R = Et have been determined by X-ray crystallography; [PdS_4(dppe)] also reacts with the carbene complex [$W(CO)_5${C(OEt)C≡CPh}] to yield the bimetallic dithiolene [Pd{S_2C_2[C(OEt)$W(CO)_5$]Ph}(dppe)].

Introduction

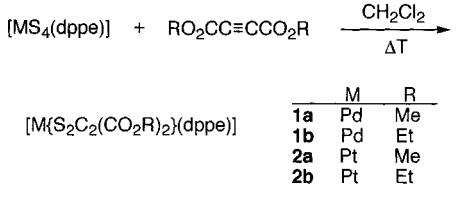
For many years, the potentially useful electrochemical and optical properties of transition metal dithiolenes have attracted the attention of chemists, physicists, and materials scientists.[1] Possible areas of application include molecular electronics, infrared dyes, liquid crystals, and catalysis.[2–4] By contrast, the selenium analogues of dithiolenes (diselenolenes) have been little studied,[5–10] largely because of the lack of generally applicable preparative methods. These complexes are, however, attractive synthetic targets since the incorporation of selenium should lead to a smaller HOMO–LUMO gap and an increase in the strength of intermolecular interactions in the solid state.

We are interested in the potential reactivity of metal polychalcogenides towards activated alkynes to yield dithiolenes and diselenolenes. Treatment of [$PtS_4(PPh_3)_2$][11] with dimethyl acetylenedicarboxylate (DMAD) has already been shown to lead to the dithiolene [Pt{$S_2C_2(CO_2Me)_2$}-$(PPh_3)_2$] (Scheme 1).[12]



Scheme 1

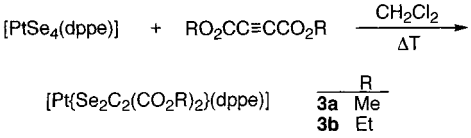
In a parallel study, we have recently prepared palladium diselenolenes bearing hydrocarbon substituents from Pd^0 complexes and 1,4-diselenines (Scheme 2).[13,14]



We now report the preparation of a number of dithiolenes and diselenolenes starting from the tetrachalcogenides [PdS_4(dppe)], [PtS_4(dppe)], and [$PtSe_4$(dppe)][15] [dppe = 1,2-bis(diphenylphosphanyl)ethane].

Results and Discussion

The polychalcogenides [PdS_4(dppe)], [PtS_4(dppe)], and [$PtSe_4$(dppe)] are readily prepared from appropriate M^0 precursors and the elemental chalcogen. In an extension of the work of Dudis et al.[12] stirring [MS_4(dppe)] (M = Pd, Pt) with an activated alkyne (dimethyl or diethyl acetylenedicarboxylate) in dichloromethane at reflux leads to formation of the dithiolenes **1a**,**b** (M = Pd) and **2a**,**b** (M = Pt) (Scheme 3).



Scheme 2

Scheme 3

The tetraselenide [$PtSe_4$(dppe)] reacts in an analogous fashion to yield the diselenolenes **3a**,**b** (Scheme 4). A similar reaction of the MSe_4 fragment has previously been observed for the anionic tungsten complex $[WSe(Se_4)_2]^{2-}$.[16]

Scheme 4

The reactivity within this system of the three tetrachalcogenides is noticeably different, with [PdS_4(dppe)] being the most reactive, followed by [$PtSe_4$(dppe)] and then [PtS_4(dppe)].

The reaction of [$PtSe_4$(dppe)] with a large excess of DMAD was monitored by ^{31}P-NMR spectroscopy. An intermediate is formed in the early stages of the reaction that has inequivalent phosphorus nuclei [**4a**: P_A, δ = 49.5, $J(^{195}Pt\text{-}^{31}P)$ = 1906 Hz; P_B, δ = 48.5, $J(^{195}Pt\text{-}^{31}P)$ = 3166 Hz; $J(^{31}P_A\text{-}^{31}P_B)$ = 10.8 Hz]. This intermediate is not present once the starting material has been consumed. The final phosphorus-containing product is predominantly the diselenolene **3a**, but there is also a second species present in low concentration [**5a**: P_A, δ = 45.6, $J(^{195}Pt\text{-}^{31}P)$ = 3223 Hz; P_B, δ = 43.9, $J(^{195}Pt\text{-}^{31}P)$ = 2054 Hz; $J(^{31}P_A\text{-}^{31}P_B)$ = 7.4 Hz]. The coupling constants in the ^{31}P-NMR spectra of **4a** and **5a** are comparable with those in the selenaketocarbene complex [$Pt(SeC_8H_{12})(PPh_3)_2$],[17] which has one phosphorus atom *trans* to selenium and one *trans* to carbon.

The reaction of [$Ti(\eta^5\text{-}C_5H_5)_2Se_5$] with DMAD to yield [$Ti(\eta^5\text{-}C_5H_5)_2\{Se_2C_2(CO_2Me)_2\}$] has been studied by Bollinger and Rauchfuss.[8] They showed that the mechanism involves binding of the alkyne to the chalcogenide chelate ring in the rate-determining step. The structure of an adduct between DMAD and the dithiolene [$Rh(\eta^5\text{-}C_5H_5)\{S_2C_2(CO_2Me)_2\}$] has been reported.[18] In this compound a new metal–carbon bond has been generated by insertion of the alkyne into the metal–chalcogen bond. We therefore tentatively assign the structures shown in Figure 1 to **4a** and **5a**.

4a **5a**

Figure 1. Proposed structures of **4a** and **5a**

Compounds **1a**, **2a**, and **3a** could not be obtained in a pure state due to the formation of polymeric material derived from DMAD, although the NMR-spectroscopic and mass-spectrometric data confirm their formulation as [$M\{E_2C_2(CO_2Me)_2\}$(dppe)] (**1a**: M = Pd, E = S; **2a**: M = Pt, E = S; **3a**: M = Pt, E = Se). No such problems were, however, encountered with the ethyl derivatives **1b**, **2b**, and **3b**, which were characterised by standard analytical and spectroscopic methods. It seems likely that the greater size of the ethyl substituents in DEAD inhibits the formation of a species analogous to **5a**, which might function as an intermediate in the polymerisation process.

The crystal structures of the isomorphous compounds **1b** and **2b** were determined by X-ray diffraction (Figure 2, Table 1). There are only very small differences between them, with the bonding in the dithiolene unit being slightly asymmetric in each case: One M–S bond is ca. 0.02 Å longer than the other, and one P–M–S angle is significantly expanded [**1b**: 96.51(5)° vs. 89.83(4)°; **2b**: 96.16(5)° vs. 90.26(5)°]. This feature does not appear to have been observed before in the structures of palladium and platinum dithiolenes, and is probably to be attributed to packing effects.

The structures of relatively few palladium mono-dithiolenes have been reported. The Pd–S distances in **1b** (2.284, 2.310 Å) are in the range of those previously observed (2.274–2.324 Å),[19] and are comparable with those in [Pd{$S_2C_2(CH_2CH_2\text{-}N\text{-}$2-pyridinium)}(dppe)][$BPh_4$] (2.297, 2.303 Å).[20] Platinum mono-dithiolenes are more numerous, in part because of interest in their luminescent properties. The Pt–P distances in **2b** (2.268, 2.265 Å) may be compared with those in [Pt{$S_2C_2S_2CS$}(dppe)] (2.258, 2.250 Å)[21] and [Pt{$S_2C_2(CN)_2$}(dppe)] (2.262, 2.252 Å).[22] Comparable Pt–S distances to those in **2b** (2.297, 2.318 Å) are found in [Pt{$S_2C_2(CO_2Me)_2$}{$P(OMe)_3$}$_2$] (2.300, 2.302 Å)[23] and [Pt{$S_2C_2(CO_2Me)_2$}(PPh_3)$_2$] (2.304 Å).[12]

Crystals of **3b** suitable for study by X-ray diffraction could not be obtained. The spectroscopic data are, however, entirely in accord with a structure for **3b** analogous to those of **1b** and **2b**. The NMR data for all three compounds are strikingly similar. There are small, but significant differences between the palladium and platinum derivatives [particularly in the value of $\delta(^{31}P)$], which we have observed in other dppe complexes of these metals. Replacement of the sulfur in **2b** by selenium (**3b**) leads to a slight upfield shift in $\delta(^{13}C)$ for the dichalcogenolene carbons. This is accompanied by a slight downfield shift in $\delta(^{31}P)$ and an increase in the platinum-phosphorus coupling constant [$J(^{31}P\text{-}^{195}Pt)$]. These changes may imply that the diselenolene ring in **3b** has a marginally greater electron density than the dithiolene ring in **2b**. A similar increase in $J(^{31}P\text{-}^{195}Pt)$ was observed by Rauchfuss et al. for the analogous triphenylphosphane derivatives [Pt{$E_2C_2(CO_2Me)_2$}(PPh_3)$_2$] (E = S, Se).[8]

The ^{77}Se-NMR spectrum of **3b** is shown in Figure 3, together with the satellite structure of the ^{31}P resonance. Analysis of the data allows evaluation of the three coupling constants in this system: $J(^{31}P_{trans}\text{-}^{77}Se)$ = 64.3 Hz; $J(^{31}P_{cis}\text{-}^{77}Se)$ = 31.8 Hz; $J(^{31}P\text{-}^{31}P)$ = 13.9 Hz. The values of $J(^{31}P\text{-}^{77}Se)$ are significantly higher than those previously determined in platinum selenolate complexes,[24] but are comparable with that reported for the diselenolene [Pt{Se_2C_2-$(CO_2Me)_2$}(PPh_3)$_2$] (52 Hz, presumably an average value).[8]

In the IR spectra of **1b**, **2b**, and **3b** four bands corresponding to C=O stretching are observed and these are at lower frequencies (by ca. 10–100 cm^{-1}) than $\nu_{C=O}$ in DEAD (1724 cm^{-1}). There is an accompanying small decrease (by ca. 20 cm^{-1}) of the C–O stretching frequency from its value in DEAD, which is 1255 cm^{-1}. These changes are reflected in a substantial increase (by ca. 16 ppm) in the ^{13}C-NMR chemical shift of the carbonyl carbon atoms [in DEAD $\delta(CO)$ = 151.7]. All the compounds give intense molecular ions in their FAB mass spectra. Ions corresponding to the expected fragmentation patterns are also observed, of which

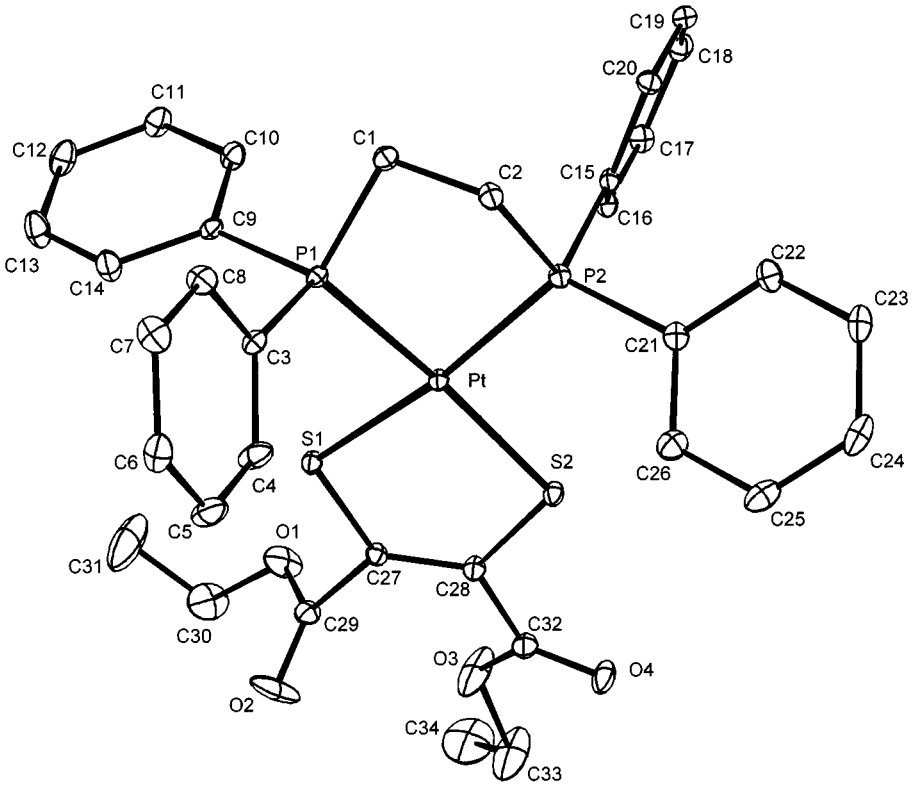

Figure 2. Molecular stuctures of [M{$S_2C_2(CO_2R)_2$}(dppe)] [M = Pd, **1b**; M = Pt, **2b** (shown)]

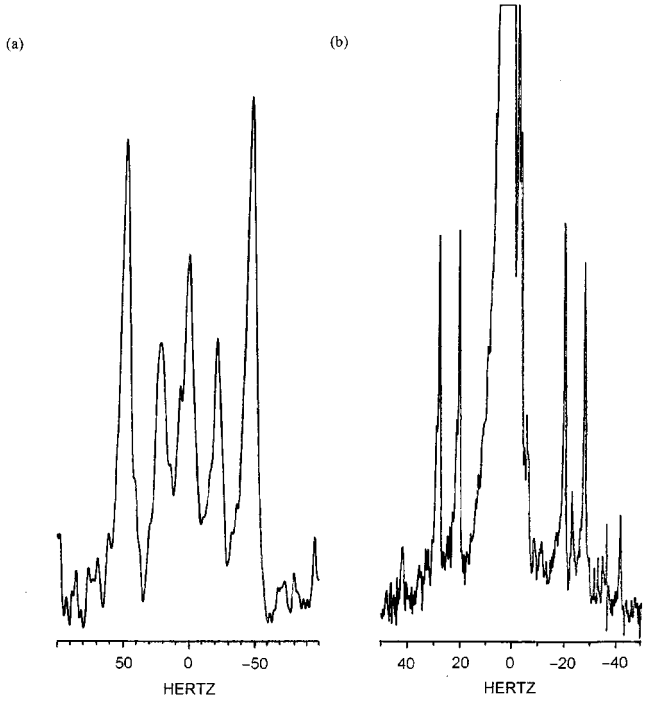
those arising from loss of DEAD {i.e. $[ME_2(dppe)]^+$} are particularly prominent.

No products could be isolated from the reactions of $[ME_4(dppe)]$ (M = Pd, E = S; M = Pt, E = S, Se) with less activated alkynes, such as PhC≡CH, PhC≡CPh, HC≡CCO_2Et, or PhC≡CCO_2Et. In the case of the most reactive of the tetrachalcogenides ($[PdS_4(dppe)]$), treatment with PhC≡CCO_2Et did lead to the observation of a new AB pattern in the ^{31}P-NMR spectrum, analysis of which yielded δ = 50.5, 50.2, J = 41.0 Hz. This is presumed to arise from the unsymmetrical dithiolene [Pd{S_2C_2-



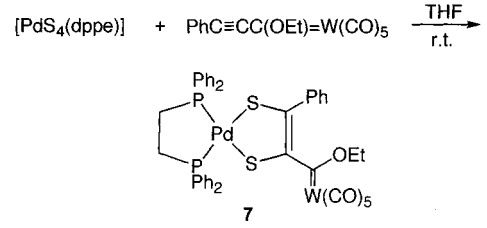


Figure 3. NMR spectra of **3b**: (a) structure of ^{77}Se resonance, (b) satellite structure of ^{31}P resonance; analysis of the data gives J(^{31}P-^{77}Se) = 64.3 Hz, 31.8 Hz; J(^{31}P-^{31}P) = 13.9 Hz

$(CO_2Et)Ph$}(dppe)] (**6**), as the molecular ion for this species was observed in the mass spectrum of the reaction mixture. The NMR data are also strikingly similar to those for

[Pd{S_2C_2[C(OEt)$W(CO)_5$]Ph}(dppe)] (**7**) (vide infra). The extent of conversion into product was, however, very low, and separation of compound **6** was not achieved.

The carbene complex [$W(CO)_5${C(OEt)C≡CPh}][25] is an alkyne bearing a highly electron-withdrawing substituent. It reacts with [PdS_4(dppe)] {but not with the platinum tetrachalcogenides [PtE_4(dppe)] (E = S, Se)} at room temperature in tetrahydrofuran solution to yield the unsymmetrical dithiolene [Pd{S_2C_2[C(OEt)$W(CO)_5$]Ph}(dppe)] (**7**) in moderate yield (Scheme 5). The reaction could not be performed in dichloromethane, as decomposition occurs in this solvent. Some starting material remains unchanged and must be separated from the product by column chromatography. There are also a number of unidentified by-products. Compound **7** could not be obtained as a crystalline solid, but its composition is assured on the basis of NMR, UV/Vis, and IR spectroscopy and mass spectrometry.

Scheme 5

The ^{31}P-NMR spectrum of **7** contains the expected AB pattern for the inequivalent phosphorus atoms. Analysis of the data gives δ(^{31}P) = 50.0, 49.1; ^2J(^{31}P-^{31}P) = 40.9 Hz. The chemical shifts are similar to those observed for the symmetrical palladium dithiolenes **1a,b**. The coupling constant is comparable with that for the palladium diselenolene [Pd{$Se_2C_7H_{10}$}(PBu_3)$_2$] (44 Hz),[14] and is significantly greater than that for the platinum analogue **3b** (13.9 Hz).

The ^{13}C-NMR spectrum of **7** has many similarities to that of **1b**. Each of the carbon atoms in the phenyl rings and the CH_2 group of dppe forms the X part of an AA′X system, and should therefore give rise to five lines in the spectrum. The outermost lines are often weak and were not observed in **1b**. In **7** the phenyl rings bound to the two inequivalent phosphorus atoms are themselves inequivalent, so we expect to see a doubling of the number of lines. This is essentially what is observed, although overlapping occurs in some cases. The greatest discrimination occurs for the carbon atoms in the dithiolene. These have chemical shifts of δ = 145.0 and δ = 138.5 in **7**. Although the equivalent single resonance was too weak to be observed in **1b**, in **2b** and **3b** it is at δ = 139.5 and 137.3, respectively. We assign the resonance at δ = 145.0 to the carbon bearing the highly electron-withdrawing carbene substituent.

Bands corresponding to C≡O stretching are not observed in the IR spectrum of **7**. This is surprising, given their prominence in the spectrum of the carbene starting material. Convincing evidence for the presence of the carbonyl ligands is, however, provided by the FAB mass spectrum. In addition to an intense molecular ion centred on *m/z* = 1051, there are clusters of peaks around *m/z* = 967 (M^+ – 3 CO) and *m/z* = 911 (M^+ – 5 CO), as well as several other fragments resulting from carbonyl loss.

Overall, it can be seen that the reactions of palladium and platinum tetrachalcogenides with activated alkynes provide an effective route to dithiolenes and diselenolenes bearing highly electron-withdrawing groups. This preparative method is thus complementary to the use of 1,2,3-selenadiazoles or 1,4-diselenines, which enables the synthesis of hydrocarbyl-substituted derivatives. We are now proceeding to examine in more detail the photophysical and electrochemical properties of this class of compound.

Experimental Section

General: All reactions were performed using standard Schlenk techniques and pre-dried solvents under dinitrogen. – ^{1}H- and ^{13}C-NMR spectra: Bruker AC400; tetramethylsilane as internal standard. ^{31}P-, ^{77}Se-, and ^{195}Pt-NMR spectra: Bruker WM250; 85% phosphoric acid, dimethyl selenide, or sodium hexachloroplatinate as external standard. – IR spectra: Perkin–Elmer 1725X. – UV/Vis spectra: Perkin–Elmer Lambda 9. – Mass spectra were recorded by the EPSRC Mass Spectrometry Centre, using Fast Atom Bombardment (FAB). Values of *m/z* quoted are for isotopomers containing ^{80}Se, ^{106}Pd, or ^{195}Pt as appropriate; expected isotope distribution patterns were observed. – Elemental analyses were performed by the analytical service of the University of Wales, Cardiff.

Bis(diphenylphosphanyl)ethane(tetrasulfido-*S*,*S*)palladium and -platinum,[12] bis(diphenylphosphanyl)ethane(tetraselenido-*Se*,*Se*)-platinum[14], and pentacarbonyl[phenylethynyl(ethoxy)carbene]-tungsten[25] were prepared by literature procedures.

Palladium Dithiolenes (1a,b), Platinum Dithiolenes (2a,b) and Platinum Diselenolenes (3a,b): The same general procedure was used for all three types of compound. A mixture of [ME_4(dppe)] [0.063 g (M = Pd, E = S), 0.072 g (M = Pt, E = S) or 0.091 g (M = Pt, E = Se), 0.1 mmol] and dimethyl or diethyl acetylenedicarboxylate (0.43 g or 0.48 g, 3.0 mmol) in dichloromethane (50 mL) was heated under reflux for a prolonged period (**1a**,**b**: 18 h; **2a**,**b**: 6 d; **3a**,**b**: 4 d). After this time, a brown or red solid had precipitated. The mixture was filtered, and the solvent removed from the filtrate by evaporation under reduced pressure to leave an oily yellow to orange solid. This was purified by recrystallisation from a mixture of dichloromethane and petroleum ether (b.p. 30–40 °C). The products of the reaction with DMAD (**1a**, **2a**, **3a**) could not be obtained free of a polymeric impurity. Compounds **1b**, **2b**, **3b** are air-stable crystalline solids (**1b**, pale orange; **2b**, cream; **3b**, yellow) that are soluble in a wide range of organic solvents.

Palladium Complex 7: A mixture of [PdS_4(dppe)] (0.063 g, 0.1 mmol) and [$W(CO)_5${=C(OEt)C≡CPh}] (0.048 g, 0.1 mmol) in THF (100 mL) was stirred at room temperature for 4 h. During this time the solution became cloudy and some of the [PdS_4(dppe)] remained undissolved. The solvent was removed from the mixture by evaporation under reduced pressure to give a dark red oily solid, which was chromatographed on a short column of silica, using toluene as eluent. A band was collected that was yellow on the column. On changing the eluent to dichloromethane, four bands were collected that were light brown, yellow, orange and pink in order of elution. The third of these contained the product, which was isolated as a dark red-brown oily solid after removal of the solvent. The others yielded dppe disulfide, [PdS_4(dppe)], and small amounts of unidentified compounds.

7: Yield: 0.036 g, 34%. – ^{1}H NMR: δ = 7.80 (m, 7 H), 7.42 (m, 15 H), 7.16 (m, 3 H), 4.18 (q, J = 7 Hz, 2 H), 2.48 (m, 4 H), 0.66 (t, J = 7 Hz, 3 H). – ^{13}C NMR: (*C*=O, *C*=W not observed), δ = 145.0 [*C*=C, J(^{13}C-^{31}P) not resolved], 138.5 [C=*C*, J(^{13}C-^{31}P) not resolved], 133.5 [four peaks], 131.4, 129.9 [P*C*$_{Ar}$, average J(^{13}C-^{31}P) = 22 Hz], 129.0 [four peaks], 128.4, 127.3, 126.2, C*C*$_{Ar}$ not observed, 67.4 [O*C*H$_2$], 27.9 [*C*H$_2$P, seven peaks], 12.7 [*C*H$_3$]. – ^{31}P NMR: δ = 50.0, 49.1 [AB: J(^{31}P-^{31}P) = 40.9 Hz]. – IR (KBr): $\tilde{\nu}$ = 2920 vs, 2850 s, 1635 m, 1465 w, 1435 m, 1384 w, 1234 m, 1102 s, 801 w, 745 w, 692 m, 529 m, 480 w cm^{-1}. – UV/Vis (CH_2Cl_2), λ_{max} (ε [dm^3 cm^{-1} mol^{-1}]) = 230 (90000), 270 (73000), 420 (16000), 480 (7300) nm. – MS; *m*/*z*: 1051 [M$^+$].

X-ray Crystallography: Details of the crystal structure determinations are given in Table 2. Measurements were carried out at room temperature with an Enraf–Nonius CAD4 diffractometer for **1b**, using graphite-monochromated Mo-K_α radiation, and with a Bruker-AXS CCD platform mounted on a rotating anode generator equipped with Göbel mirrors for **2b**, using Cu-K_α radiation. No crystal decay was observed during data collections, although **2b** was found to decompose if Mo-K_α radiation was used. Empirical corrections for absorption were applied, based on ψ scans (**1b**) or SADABS[26] (**2b**) [min., max. transmission factors: 0.93, 0.98 (**1b**);

0.412, 1.000 (**2b**)]. Structure solution was by direct methods, with SIR97,[27] and Fourier cycles with SHELXL-93,[28] which was also used for structure refinements. The final refinement cycles were performed against F^2 with all nonhydrogen atoms anisotropic and hydrogen atoms in calculated positions. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publications CCDC-136286 (**1b**) and -136287 (**2b**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

On the Hydrolysis of tBu$_2$Ge(OEt)$_2$: Supramolecular Self Assembly in the Solid State of 2 tBu$_2$Ge(OH)$_2$, (tBu$_2$GeOH)$_2$O, and H$_2$O

Jens Beckmann,[a][+] Klaus Jurkschat,*[a] and Markus Schürmann[a]

Dedicated to Professor Stanislaw Pasynkiewicz on the occasion of his 70th birthday

Keywords: Germanium / Germanol / Hydrogen bonds / X-ray structure

The hydrolysis of tBu$_2$Ge(OEt)$_2$ is described. Depending on the amount of water used either tBu$_2$Ge(OH)$_2$ (**1**) or a mixture of the latter and (tBu$_2$GeOH)$_2$O (**2**) were obtained. A cocrystallate consisting of 2tBu$_2$Ge(OH)$_2$, (tBu$_2$GeOH)$_2$O and water was the subject of a single crystal X-ray diffraction study. In the solid state the individual molecules are connected by hydrogen bonds giving rise to the formation of a polymeric double chain ribbon.

Introduction

Organosilanols represent a well established class of compounds. In the solid state they are connected through hydrogen bonds and adopt various secondary structural motifs.[1] Organosilanols find applications as building blocks for the synthesis of molecular metallasiloxanes and related materials.[2] In contrast, only a very few examples of organogermanols are known, presumably because of their higher sensitivity toward self-condensation than organosilanols. For organogermanols, hydrogen bonding is also observed in the solid state.[3] As part of our ongoing studies on metallastannoxanes we prepared tBu$_2$Ge(OH)$_2$ by hydrolysis of tBu$_2$Ge(OEt)$_2$, and used this product for further investigations. Despite the mild reaction conditions applied, in one case a mixture of tBu$_2$Ge(OH)$_2$ and (tBu$_2$GeOH)$_2$O was obtained. Attempts to separate this mixture by fractional crystallization afforded a cocrystallate of 2tBu$_2$Ge(OH)$_2$, (tBu$_2$GeOH)$_2$O, and water, the structure of which is reported in this paper.

Results and Discussion

The hydrolysis of tBu$_2$Ge(OEt)$_2$ with a slight excess of water provided a mixture of the germanols tBu$_2$Ge(OH)$_2$ (**1**) and (tBu$_2$GeOH)$_2$O (**2**) whereas the use of a large excess of water exclusively gave tBu$_2$Ge(OH)$_2$ (**1**) (Equation 1).

$$3\,t\mathrm{Bu_2Ge(OEt)_2} \xrightarrow[-\ \mathrm{EtOH}]{\mathrm{H_2O}} \underset{\mathbf{1}}{t\mathrm{Bu_2Ge(OH)_2}} + \underset{\mathbf{2}}{(t\mathrm{Bu_2GeOH})_2\mathrm{O}} \qquad (1)$$

Compound **2** is the first example of a 1,1,3,3-tetraorganogermanoxane-1,3-diol. Recently, Puff et al. reported the low-yield synthesis of tBu$_2$Ge(OH)$_2$ (**1**) by the hydrolysis of tBu$_2$GeCl$_2$.[3a,4] Moreover, the authors used tBu$_2$Ge(OH)$_2$ (**1**) for the preparation of the diorganogermanium oxide *cyclo*-(tBu$_2$GeO)$_3$ which was obtained in moderate yield.[3a,4] However, no information was given on the identity of by-products such as **2**, or higher oligomers, from these reactions.

After the first crop of **1** had been isolated attempts to separate the above-mentioned mixture of **1** and **2** by fractional crystallisation failed. Instead, we obtained a single crystalline material which, according to ^{1}H NMR spectroscopy, consisted of a mixture of **1** and **2** in the ratio of 2:1. In this context it is worth mentioning that Weidenbruch et al., by the same method, succeeded in the separation of the silicon analogues tBu$_2$Si(OH)$_2$ and (tBu$_2$SiOH)$_2$O.[5]

The molecular structure of the cocrystallate is shown in Figure 1. Crystallographic data are given in Table 1 and selected bond lengths and angles are listed in Table 2.

The asymmetric unit indeed contains two molecules of **1**, a molecule of **2** and, in addition, a molecule of water; these three components are connected by a framework of hydrogen bonds (Figure 1). The mean Ge–O and Ge–C bond lengths amount to 1.77 and 1.96 Å, respectively, and are comparable with those of other organogermanols.[3] The germanium atoms of **1** and **2** show distorted tetrahedral configurations with the greatest deviations of 121.8(2) and 119.6(2)°, respectively, found for the C–Ge–C bond angles, due to the steric demand of the bulky *tert*-butyl groups. The Ge–O–Ge bond angle in **2** amounts to 143.9(2)° which is by 10.9 and 8.7° greater than the corresponding angles in (tBu$_2$GeO)$_3$[3a] and (Ph$_3$Ge)$_2$O,[6] respectively. Bearing in mind the variety of different hydrogen bonding frameworks in solid organosilanols, it is quite remarkable that the secondary structural motifs within this cocrystallate, and individual tBu$_2$Ge(OH)$_2$ (**1**)[3a] and tBu$_2$Si(OH)$_2$,[7] are virtually the same and adopt polymeric double chain ribbons (Figure 2). Selected hydrogen bond lengths and angles are listed

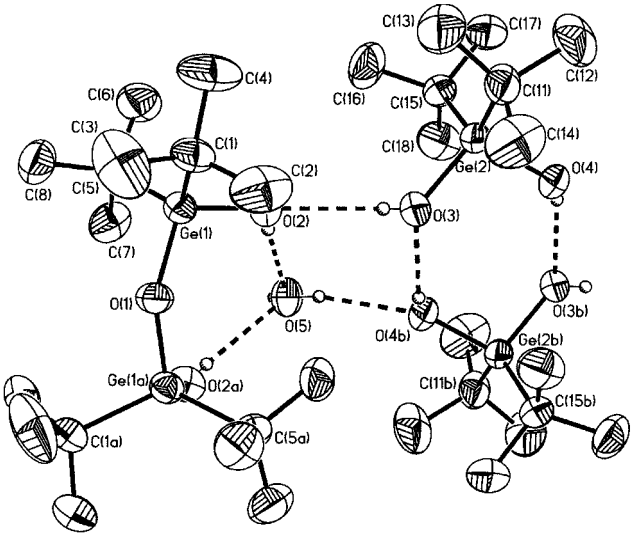

Figure 1. General view (SHELXTL-PLUS) of the cocrystallate showing 30% probability displacement ellipsoids and the atom numbering scheme

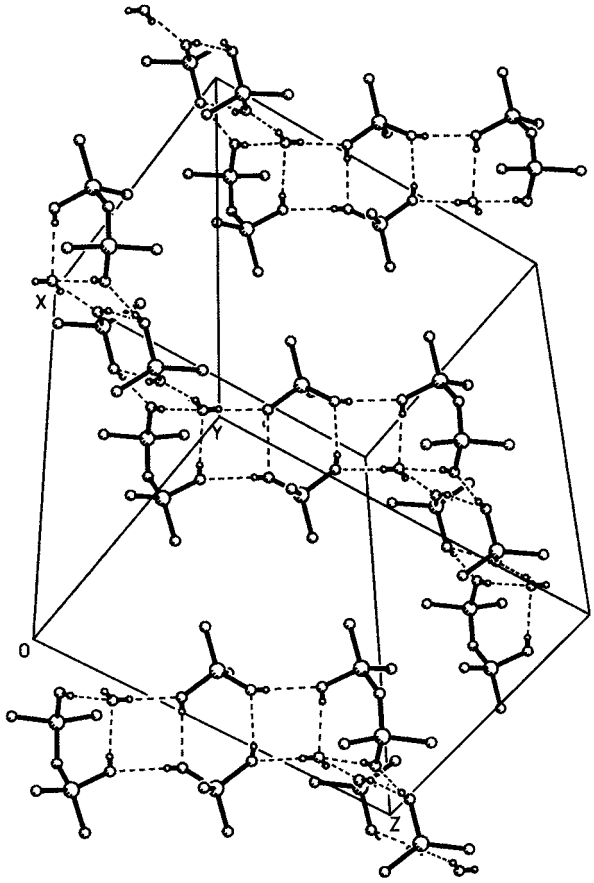

Figure 2. Perspective view (SHELXTL-PLUS) of the hydrogen bonding in the crystal lattice

in Table 3. The observed O···O distances in the cocrystallate are within the range of related compounds, e.g. organosilanols, and show no particularities.[1]

With the view that the crystals can be regarded as supramolecular entities, a comprehensive knowledge of the parameters which control the solid state structures is very welcome.[8] In this context it is obvious that the bulky *tert*-butyl groups dominate the structures of the above-mentioned compounds. This assumption is further supported by the isotypic di-*tert*-butyl element oxides (tBu$_2$MO)$_3$ (M = Si, Ge, Sn)[3a,9a,9b] and di-*tert*-butyl element imides (tBu$_2$MNH)$_3$ (M = Si, Sn).[10a,10b]

Experimental Section

General Remarks: tBu$_2$Ge(OEt)$_2$ was synthesized by the reaction of tBuLi with Ge(OEt)$_4$.[11] – NMR spectra were recorded on a Bruker DRX 400 spectrometer operating at 400.13 MHz (^{1}H) and 100.62 MHz (^{13}C). Chemical shifts (δ) are given in ppm relative to SiMe$_4$. – Mass spectra were obtained on a Finnigan MAT 8230 spectrometer. – IR spectra were recorded on a Bruker FTIR IFS 113v spectrometer. – The elemental analyses were performed on an instrument from Carlo Erba Strumentazione (Modell 1106). – The density of single crystals was determined using a Micromeritics Accu Pyc 1330.

Synthesis of Di-*tert*-butylgermane Diol (1) and 1,1,3,3-Tetra-*tert*-butyldigermanoxane-1,3-diol (2): A solution of tBu$_2$Ge(OEt)$_2$ (5.54 g, 20.0 mmol) in ethanol (50 mL) was treated with water (900 mg, 50.0 mmol) and heated for 15 h at 40 °C. The solvent was then removed in vacuo. The residue was recrystallized several times from chloroform at –10 °C affording colorless crystals of **1** as the first fraction (1.4 g, 6.3 mmol, 32%, m.p. 146 °C). – ^{1}H NMR (400.13 MHz, $CDCl_3$): δ = 1.49 (s, 2 H, GeO*H*) 1.70 (s, 18 H, GeC*Me$_3$*). – ^{13}C{^{1}H} NMR (100.62 MHz, $CDCl_3$): δ = 29.1 (Ge*C*Me$_3$) 27.4 (GeC*Me$_3$*). – IR (KBr): ν_{OH} = 3248 (bs) cm^{-1}. – $C_8H_{20}GeO_2$ (220.9): C 43.50, H 9.13; found C 44.00, H 9.43. – From the residue a second crystalline fraction was obtained (2.8 g)

which, according to ^{1}H NMR spectroscopy, still contained a mixture of **1** and **2** in a ratio of about 2:1. From the second fraction a single crystal was taken for the X-ray diffraction studies. From the remainder, compound **2** (850 mg, 2.0 mmol, 20%, m.p. 87 °C) was isolated by size-exclusion chromatography (Sephadex-G20, CH_2Cl_2). – ^{1}H NMR (400.13 MHz, $CDCl_3$): δ = 1.85 (s, 2 H, GeOH) 1.11 (s, 36 H, GeC*Me*$_3$). – ^{13}C{^{1}H} NMR (100.62 MHz, $CDCl_3$): δ = 29.8 (GeC*Me*$_3$), 27.9 (GeC*Me*$_3$). – IR (KBr) ν_{OH}: 3314 (bm) cm^{-1}. – MS; *m/z* (%): 367 (50) [$M^+ - C_4H_9$], 349 (28) [$M^+ - C_4H_{11}O$], 293 (72) [$M^+ - C_8H_{19}O$], 277 (22) [$M^+ - C_8H_{19}O_2$]. – $C_{16}H_{38}Ge_2O_3$ (423.7): C 45.35, H 9.04; found C 45.83, H 9.90. – Using the same procedure with a large excess of water (25 mL), the diorganogermane diol **1** was formed almost quantitatively.

X-ray Crystallography: Intensity data for the colorless crystals grown from chloroform were collected on a Nonius Kappa CCD diffractometer with graphite-monochromated Mo-K_α (0.71069 Å) radiation at 291 K. The data collection covered almost the whole sphere of reciprocal space with 360 frames via ω-rotation (Δ/ω = 1°) at two times 20s per frame. The crystal-to-detector distance was 3.0 cm. Crystal decay was monitored by repeating the initial frames at the end of data collection. Analyzing the duplicate reflections there was no indication for any decay. The data were not corrected for absorption effects. The structure was solved by direct methods SHELXS97[12a] and successive difference-Fourier syntheses. Refinement applied full-matrix least-squares methods SHELXL97.[12b] – The H atoms of the hydroxy groups and the water molecule were located in the difference Fourier map and refined isotropically. The other H atoms were placed in geometrically calculated positions using a riding model (including free rotation about C–C) and refined with a common isotropic temperature factor [C–$H_{prim.}$ 0.96 Å; U_{iso} 0.160(4) Å^2]. – Atomic scattering factors for neutral atoms and real and imaginary dispersion terms were taken from the International Tables for X-ray Crystallography.[12c] The figures were created by SHELXTL-Plus.[12d] Crystallographic data are given in Table 1, selected bond distances and angles in Table 2, and hydrogen bond distances and angles in Table 3. – Crystallographic data for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-136796. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

New Di- and Trinuclear Complexes with Pyrazolato Bridges. Crystal Structures of $[\{(C_6F_5)_2Pd(\mu\text{-}pz)(\mu\text{-}Cl)\}_2Pd]^{2-}$ and $[(C_6F_5)_2Pd(\mu\text{-}pz)_2Pd(\eta^3\text{-}C_4H_7)]$ (pz = pyrazolate)

José Ruiz,*[a] Félix Florenciano,[a] Miguel A. Sánchez,[a] Gregorio López,[a] M. Carmen Ramírez de Arellano,[b] and José Pérez[a]

Keywords: Pyrazolate complexes / Palladium / Platinum / N ligands / Bridging ligands

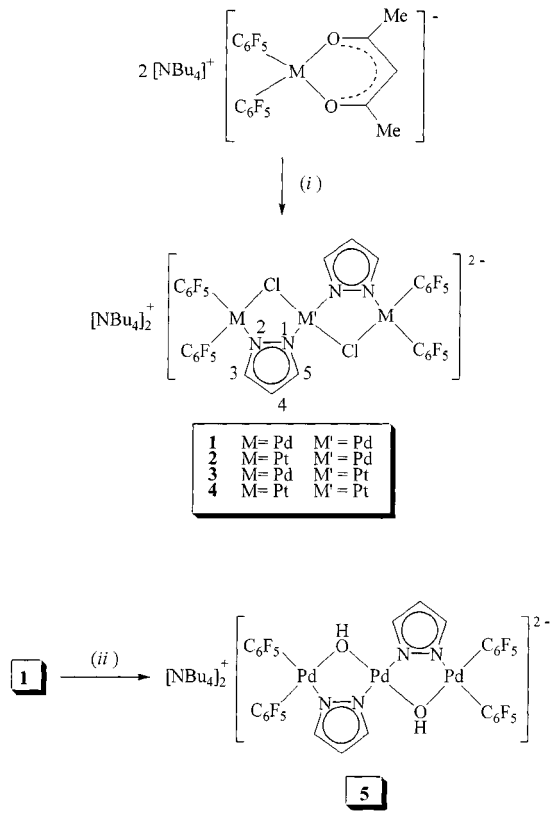
Trinuclear complexes containing pyrazolate bridging ligands of the type $[NBu_4]_2[\{(C_6F_5)_2\ M(\mu\text{-}pz)(\mu\text{-}X)\}_2M']$ (M, M′= Pd or Pt; X= Cl, OH, or pz) (Hpz = pyrazole) have been prepared using $[NBu_4][M(C_6F_5)_2(acac)]$ (acac = acetylacetonate) or $[NBu_4]_2[M_2(C_6F_5)_4(\mu\text{-}OH)_2]$ and $[M'Cl_2(Hpz)_2]$ or $[M'(Hpz)_4]^{2+}$ as starting materials. Asymmetric homo- and heterobimetallic complexes of the types $[NBu_4][R_2M(\mu\text{-}pz)_2Pd(\eta^3\text{-allyl})]$ and $[R_2M(\mu\text{-}pz)_2M'L_2]$ (allyl = C_3H_5 or C_4H_7; L_2 = 2 PEt_3 or bipy; R = C_6F_5 or C_6Cl_5; M, M′ = Pd or Pt) have been obtained starting from $[NBu_4][MR_2(pzHpz)]$ and $[Pd(\eta^3\text{-allyl})(acac)]$ or $[M'L_2Cl_2]$, respectively. The identity of the new complexes has been established by NMR (^1H, ^{19}F and ^{31}P) spectroscopy. The crystal structure of $[\{(C_6F_5)_2Pd(\mu\text{-}pz)(\mu\text{-}Cl)\}_2Pd]^{2-}$ has an inversion centre, with a bent appearance of the $Pd_3(\mu\text{-}pz)_2(\mu\text{-}Cl)_2$ moiety. The crystal structure of $[(C_6F_5)_2Pd(\mu\text{-}pz)_2Pd(\eta^3\text{-}C_4H_7)]$ has also been determined by single-crystal X-ray diffraction, where a boat conformation of the central "Pd_2N_4" six-membered rings is observed.

Introduction

Metal pyrazolate (pz) complexes have attracted considerable interest in recent years due to their versatile coordination chemistry,[1–10] and to a number of potential properties of these compounds such as catalytic activity [11] and bioactivity.[12] Pyrazolate exobidentate ligands can firmly hold two metal atoms in close proximity, thereby allowing extensive electron delocalization between the two centres. Homobimetallic pyrazolate-bridged nickel,[7,13] palladium,[14] and platinum[15] complexes $[\{M(C_6F_5)_2(\mu\text{-}pz)\}_2]^{2-}$ have previously been prepared in our laboratory by reaction between the basic $[\{M(C_6F_5)_2(\mu\text{-}OH)\}_2]^{2-}$ and the acidic pyrazole. We have also recently described[16] the preparation and characterization of mononuclear pyrazole-pyrazolate complexes of palladium(II) and platinum(II) $[NBu_4][R_2M(pzHpz)]$ (M = Pd, Pt; R = C_6F_5, C_6Cl_5; Hpz = pyrazole), which contain an acidic pyrazole ligand and which could act as metalloligands towards a variety of metallic fragments showing η^2 coordination mode, a synthetic strategy widely and successfully applied by Oro et al. to rhodium, ruthenium and iridium chemistry.[4–6,17,18] Studies of the reactivity of some palladium and platinum pyrazolate complexes towards Lewis acid metal complexes have been very recently reported.[9,10]

Oligomeric compounds of the type $[\{R_nM(\mu\text{-}pz)(\mu\text{-}X)\}_2M']^{m-}$ (M, M′ = Pd or Pt) are rare and only $[\{RM(\mu\text{-}pz)(\mu\text{-}X)\}_2M']$ (R = η^3-C_3H_5, η^3-C_4H_7) have been described.[19] In this paper we report the synthesis and characterization of trinuclear complexes of the type $[\{(C_6F_5)_2M(\mu\text{-}pz)(\mu\text{-}X)\}_2M']^{2-}$ (M, M′ = Pd or Pt; X = Cl, OH, or pz) as well as the preparation of asymmetric homo- and heterobimetallic complexes MM′ (M = Pd, Pt; M′ = Pd or Pt) with pyrazolato bridging ligands by using $[R_2M(pzHpz)]^-$ as a building block. The X-ray crystal structures of $[\{(C_6F_5)_2Pd(\mu\text{-}pz)(\mu\text{-}Cl)\}_2Pd]^{2-}$ (which is so far the first complex of this kind to be structurally characterized) and $[(C_6F_5)_2Pd(\mu\text{-}pz)_2Pd(\eta^3\text{-}C_4H_7)]$ are also reported.

The complexes $[NBu_4][M(C_6F_5)_2(acac)]$, $[NBu_4]_2[M_2(C_6F_5)_4(\mu\text{-}OH)_2]$, $[NBu_4][MR_2(pzHpz)]$ (M = Pd, Pt) and $[Pd(\eta^3\text{-allyl})(acac)]$ have shown to be useful precursors for the synthesis of the polynuclear compounds reported herein.



Results and Discussion

The reaction (2:1) between the mononuclear complex $[NBu_4][M(C_6F_5)_2(acac)]$ (M′ Pd or Pt) and *trans*-$[M'(pzH)_2Cl_2]$ (M′ Pd or Pt) in acetone or methanol leads to the corresponding trinuclear complex $[NBu_4]_2[\{(C_6F_5)_2M(\mu\text{-}pz)(\mu\text{-}Cl)\}_2M']$ (M, M′ = Pd or Pt) (Scheme 1) with the concomitant release of Hacac.

Elemental analyses of these complexes are satisfactory and the complexes have been characterized by IR, ^1H and $^{19}F\{^1H\}$ NMR spectroscopy. Measurements of the molar conductivity in acetone indicate that they behave as 2:1 electrolytes.[20] The IR spectra of complexes **1–4** show the characteristic absorptions of the C_6F_5 group[21] at 1630, 1490, 1450, 1050, 950 cm^{-1} and a split band at ca. 800 cm^{-1}, derived from the so-called X-sensitive mode in C_6F_5-halogen

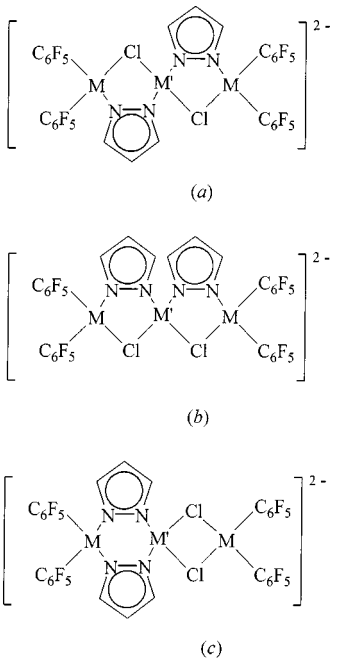

Scheme 1. (i) $M'Cl_2(pzH)_2$; (ii) 2 NBu_4OH

molecules, which is characteristic of the *cis*-$Pd(C_6F_5)_2$ fragment [16,22] and behaves like a ν(M–C) band.[23] The ^1H NMR spectra exhibit a set of three resonances for the pyrazolate rings which indicates that only one of the three possible geometrical isomers (Scheme 2) is present in solution. Taking into account the *trans* geometry of the complexes $[M'(pzH)_2Cl_2]$, (M′ = Pd[19] or Pt[24]) an *anti* arrangement (Scheme 2a) should be the most probable structure for these trinuclear complexes, and this is confirmed by an X-ray diffraction study of complex **1** (vide infra).

In all cases the resonance at δ = 5.8 or 5.9 is assigned to the 4-H. The resonance at δ = 6.84 or 6.87 in complexes **2** or **4**, respectively, appears flanked by ^{195}Pt satellites which suggests that it should be assigned to 3-H (with the numbering given in Scheme 1). The observed values for $J(^{195}Pt-^1H)$ (ca. 15 Hz) agree with the values found in the literature.[9,16,25] The ^{19}F NMR spectroscopy patterns are consistent with the presence of two nonequivalent C_6F_5 groups, one trans to Cl and one trans to pz. As expected, the *ortho* F signals of complexes **2** and **4** are flanked by the satellites due to coupling to ^{195}Pt.

The structure of **1** is shown in Figure 1 and selected bond lengths and angles in Table 1. Insofar as we know this is the first tripalladium species of this kind to be structurally characterized. Since Pd(2) lies on an inversion centre, the "central" PdN_2Cl_2 unit is square planar. The geometry around the Pd(1) is essentially square-planar as well, the deviation of Pd(1) from the best plane through the atoms defining the coordination plane is 0.005(1) Å. The Pd_2(μ-pz)(μ-Cl) unit has an envelope conformation at Cl. The "central" PdN_2Cl_2 unit makes dihedral angles of 124.70(7)° to the "terminal" PdNCl planes, giving a bent appearance to the $Pd_3(\mu\text{-pz})_2(\mu\text{-Cl})_2$ moiety. The bridging chlorine to Pd(2) distances are significantly shorter than those to Pd(1). The Pd(2)Cl distance, 2.313(1) Å, is in the range found for chlorine trans to chlorine on Pd^{II}.[26] In a similar way the Pd(2)N distances are shorter than those of Pd(1)N. The distances between the central Pd(2) and the two Pd(1) atoms are 3.484 Å and show no significant metal–metal interactions. The pyrazolato rings are planar with the atoms defining the plane all being coplanar within 0.002(2) Å. The two pentafluorophenyl rings bonded to Pd(1) are planar and rotated 81.9(1)° with respect to each other. The rings present distortions as indicated by the values of the C–C–C angles which range from 113.7 to 124.3 °. This type of distortion has already been observed in other fluorophenyl rings.[27]

Scheme 2. Geometrical isomers of complexes **1**–**4**

The addition of [NBu_4]OH (aq) to a dichloromethane solution of **1** gives rise to the yellow hydroxo- homotrinuclear $[NBu_4]_2[\{(C_6F_5)_2Pd(\mu\text{-pz})(\mu\text{-OH})\}_2Pd]$ (**5**). The presence of the hydroxo- ligand is manifested by the observation of the characteristic IR absorption in the vicinity of 3600 cm^{-1} and of a high-field proton resonance at δ –1.82.[14] The X-ray crystal structure of the related binuclear hydroxo pyrazolate platinum complex $[NBu_4]_2[\{(C_6F_5)_2Pt\}_2(\mu\text{-pz})(\mu\text{-OH})]$ has previously been reported.[15]

The reaction (1:2:1) between $[NBu_4]_2[M_2(C_6F_5)_4(\mu\text{-OH})_2]$ (M′ = Pd or Pt), [NBu_4]OH (aq) and $[M'(pzH)_4]Cl_2$ (M = Pd or Pt) leads to the formation of the white trimeric complexes $[NBu_4]_2[\{(C_6F_5)_2M(\mu\text{-pz})_2)\}_2M']$ (M, M′ = Pd or Pt) **6–8** (Scheme 3) containing four pyrazolate anions as bridging ligands. The ^1H NMR spectra exhibit a unique set of three resonances with relative intensities of 4:4:4 for the pyrazolato rings. The ^{19}F NMR spectra of compounds **6–8**

14	M = Pt,	R = C_6F_5,	R' = H

Scheme 4. Synthesis of allyl complexes **9**–**14**

The mononuclear palladium or platinum complexes *cis*-$[MR_2(pzHpz)]^-$ (R = C_6F_5 or C_6Cl_5) react with [Pd(acac)(η^3-allyl)] (allyl = C_3H_5 or C_4H_7) to give [$R_2M(\mu$-$pz)_2Pd(\eta^3$-allyl)] complexes (Scheme 4) with the concomitant release of Hacac. The related metal complexes [Ir(η^5-C_5Me_5)$(pz)_2$(Hpz)] or [Ru(η^6-*p*-cymene)$(pz)_2$(Hpz)] give similar reactions.[5,6,17,18]

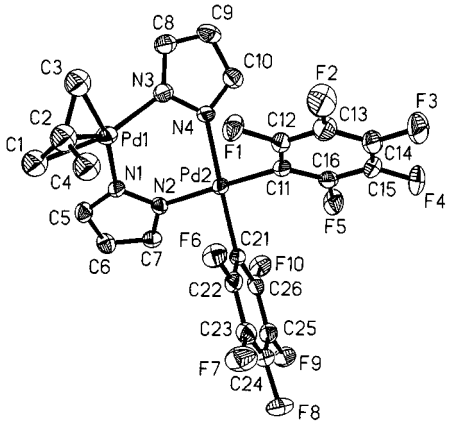
The new complexes **9–14** have been characterized on the basis of partial elemental analysis and spectroscopic data. The IR spectra show the bands assigned to the C_6F_5 (1630, 1490, 1460, 1050 and 950 cm^{-1})[20] or the C_6Cl_5 (1315, 1285, 1220 and 670 cm^{-1})[28] groups. Morever, a split absorption located at ca. 800 cm^{-1} in the spectra of the bis(pentahalophenyl) derivatives [22,29] is observed. Complexes **9–14** be-

have in acetone as 1:1 electrolytes,[19] in accordance with the formulae given.

The two signals observed in the *ortho*-F region of the ^{19}F NMR spectra of compounds **13** and **14** indicate that rotation of the C_6F_5 groups around the carbon–metal bond is hindered.

The ^1H NMR spectra consist of three resonances with relative intensities of 2:2:2 for the heterocyclic rings. The resonance at $\delta = 5.9–5.4$ in the spectra of complexes **9–14** are unambiguously assigned to the 4-H atom (the numbering given in Scheme 4). The high-field pyrazolyl resonance at ca. $\delta = 7.3–7.1$ should be assigned to 3-H because this signal is flanked by ^{195}Pt satellites in the spectra of compounds **13** and **14**.

The ^1H NMR spectra of complexes **10, 12** and **14** also show three resonances with an intensity ratio of 1: 2: 2 in the allylic group region, whereas the spectra of complexes **9**, **11** and **13** show three singlets for the methylallyl group with the expected intensity ratio of 2:2:3.



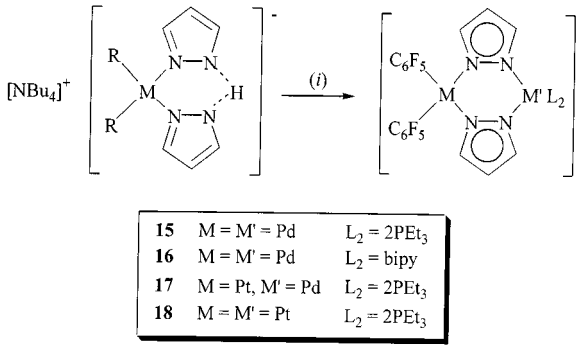


Figure 2. Structure of the anion of **9** showing the atom numbering scheme; hydrogen atoms have been omitted for clarity

The crystal structure of the anion of complex **9** is shown in Figure 2 and selected bond lengths and angles in Table 2. The structure shows an asymmetric dinuclear complex in which the Pd(η^3-allyl) and the Pd(C_6F_5)$_2$ units are bridged by two pyrazolate ligands. The Pd(1)–Pd(2) vector is coplanar with both pyrazolate ligands (mean deviations 0.035 and 0.048 Å). The Pd(1)–N(1)–N(2)–Pd(2)–N(4)–N(3) ring exhibits a typical boat conformation with a dihedral angle Pd(1)–Pd(2)–N(1)–N(2) and Pd(1)–Pd(2)–N(3)–N(4) of 65.3°. The allyl ligand is bonded to the Pd(1) atom in an asymmetric η^3-mode [Pd(1)–C(1) 2.172(9) and Pd(1)–C(3) 2.110(9) Å]. The vector joining the centre of the C(1)–C(2)–C(3) fragment and the Pd(1) atom makes an angle of 65.2° with the allyl plane. The Pd(2) centre shows a square planar geometry.

Although the hydrogen of the (pyrazole)(pyrazolato) complexes [MR_2(pz)(Hpz)]$^-$ (M = Pd or Pt) cannot be abstracted by reaction with an additional mol of NBu_4OH, in the presence of chloro complexes of the type [$M'Cl_2L_2$] (M' = Pd or Pt; L_2 = 2 PEt_3 or bipy), both metal complexes allow the preparation, in acetone, of the new heterodinuclear complexes [$(C_6F_5)_2M(\mu\text{-pz})_2M'L_2$] (**15–18**; Scheme 5), which were recrystallized from dichloromethane/hexane.

18	M = M' = Pt	$L_2 = 2PEt_3$

Scheme 5. (i) $NBu_4OH/[M'Cl_2L_2]$

All complexes give satisfactory analytical data. The ^1H NMR spectrum of complex **17** exhibits a resonance at $\delta = 7.41$, flanked by ^{195}Pt satellites. The ^{19}F NMR spectra of complexes **15, 17** and **18** show a broad resonance for the *ortho* F atoms, but a unique resonance for the *para* F atom, indicating partial restriction in the rotation around the M–C bond. Two multiplets for the methylene and methyl groups of the PEt_3 ligands are observed in the ^1H NMR spectra, in agreement with previous results.[30,31]

The presence of two resonances in the ^{19}F NMR spectrum of **16** for the *ortho* F atoms together with a resonance for the *para* F atom suggest again that rotation around the Pd–C bond is restricted even at room temperature.

The ^{31}P NMR spectra of **15** and **17** show a unique resonance whereas complex **18** exhibits a singlet with ^{195}Pt satellites (J_{Pt-P} = 3060 Hz). Several heteropolymetallic systems involving platinum(II) and palladium(II) of general formula [(L–L)M(μ-az)$_2$M'X$_2$] (where L–L is a chelating ligand, M = Pt or Pd, M' = Zn, Cd or Ni) have recently been reported.[9,25]

Experimental Section

General Methods: C, H and N analyses were performed with a Carlo Erba model EA 1108 microanalyzer. – Decomposition temperatures were determined with a Mettler TG-50 thermobalance

with a heating rate of 10°C min^{-1}. – Molar conductivities were measured in an acetone solution ($c \approx 5 \times 10^{-4}$ mol dm^{-3}) with a Crison 525 conductimeter. – The NMR spectra were recorded on a Bruker AC 200E (^{1}H) or Varian Unity 300 (^{19}F, ^{31}P) spectrometer. – Infrared spectra were recorded on a Perkin–Elmer 16F PC FT-IR spectrophotometer using nujol mulls between polyethylene sheets. – The starting complexes $[NBu_4]_2[M_2(C_6F_5)_4(\mu\text{-}OH)_2]$ (M = Pd[14] or Pt[32]), [Pd(acac)(allyl)] (allyl = C_3H_5 or C_4H_7),[23] $[NBu_4][MR_2(pzHpz)]$ (M = Pd or Pt, R = C_6F_5 or C_6Cl_5),[16] $[NBu_4][M(C_6F_5)_2(acac)]$ (M = Pd or Pt),[14,32] $[ML_2Cl_2]$ (L_2 = PEt_3, M = Pd,[33] Pt;[34] L_2 = bipy, M′ Pd;[35] L = Hpz, M = Pd,[23] Pt[24]) and $[M(pzH)_4]Cl_2$ (M = Pd or Pt)[24] were prepared as described in the literature.

$[NBu_4]_2[\{(C_6F_5)_2Pd(\mu\text{-}pz)(\mu\text{-}Cl)\}_2M]$ M = Pd (1) or Pt (3): *trans*-$M(pzH)_2Cl_2$ (M = Pd, Pt) (0.064 mmol) was added to a solution of $[NBu_4][Pd(C_6F_5)_2(acac)]$ (100 mg, 0.13 mmol) in acetone (15 cm^3), the solution was stirred at room temperature for 30 min and the solvent was then partially evaporated under reduced pressure. On addition of ether and hexane the yellow complexes **1** and **3** precipitated and were filtered off and air-dried.

1: Yield 85%. – $C_{62}H_{78}Cl_2F_{20}N_6Pd_3$ (1677): calcd. C 44.4, H 4.7, N 5.0; found C 44.1, H 4.5, N 4.9. – M.p. 219 °C (dec.). – Λ_M = 171 S cm^2 mol^{-1}. – IR (nujol): $\tilde{\nu}$ = 796, 782 cm^{-1} (Pd-C_6F_5). – ^{1}H NMR ([D$_6$]acetone, TMS): δ = 7.47 (d, $J_{4,5}$ = 2.1 Hz, 2 H, H^5), 6.64 (d, $J_{3,4}$ = 1.7 Hz, 2 H, H^3), 5.83 (pseudo-t, 2 H, H^4). – ^{19}F NMR ([D$_6$]acetone, $CFCl_3$): δ = –112.9 (d, $J_{o,m}$ = 28.7 Hz, 4 F_o), –113.5 (d, $J_{o,m}$ = 27.6 Hz, 4 F_o), –163.7 (t, $J_{m,p}$ = 20.3 Hz, 2 F_p), –164.2 (t, $J_{m,p}$ = 19.1 Hz, 2 F_p), –165.2 (m, 4 F_m), –165.9 (m, 4 F_m).

3: Yield 74%. – $C_{62}H_{78}Cl_2F_{20}N_6Pd_2Pt$ (1766): calcd. C 42.2, H 4.5, N 4.8; found C 42.4, H 4.5, N 4.9. – M.p. = 211 °C (dec.). – Λ_M = 165 S cm^2 mol^{-1}. – IR (nujol): $\tilde{\nu}$ = 796, 784 cm^{-1} (Pd-C_6F_5). – ^{1}H NMR ([D$_6$]acetone, TMS): δ = 7.58 (d, $J_{4,5}$ = 1.9 Hz, 2 H, H^5), 6.84 (br, 2 H, H^3), 5.88 (pseudo-t, 2 H, H^4). – ^{19}F NMR ([D$_6$]acetone, $CFCl_3$): δ = –112.8 (d, $J_{o,m}$ = 25.6 Hz, 4 F_o), –113.4 (d, $J_{o,m}$ = 26.2 Hz, 4 F_o), –163.6 (t, $J_{m,p}$ = 19.5 Hz, 2 F_p), –164.1 (t, $J_{m,p}$ = 19.2 Hz, 2 F_p), –165.3 (m, 4 F_m), –165.8 (m, 4 F_m).

$[NBu_4]_2[\{(C_6F_5)_2Pt(\mu\text{-}pz)(\mu\text{-}Cl)\}_2M]$ M = Pd (2) or Pt (4): *trans*-$M(pzH)_2Cl_2$ (M= Pd, Pt) (0.046 mmol) was added to a solution of $[NBu_4][(C_6F_5)_2Pt(acac)]$ (80.0 mg, 0.1 mmol) in methanol (15 cm^3), the solution was stirred at room temperature for 6 h and the solvent was then partially evaporated under reduced pressure. The precipitate was collected by filtration and air-dried. Both compounds were recrystallized from dichloromethane/hexane.

2: Yield 75%. – $C_{62}H_{78}Cl_2F_{20}N_6PdPt_2$ (1855): calcd. C 40.2, H 4.2, N 4.5; found C 40.1, H 4.2, N 4.4. – M.p. = 225 °C (dec.). – Λ_M = 165 S cm^2 mol^{-1}. – IR (nujol): $\tilde{\nu}$ = 796, 782 cm^{-1} (Pt-C_6F_5). – ^{1}H NMR ([D$_6$]acetone, TMS): δ = 7.47 (br, 2 H, H^5), 6.84 (br, J_{HPt} = 15 Hz, 2 H, H^3), 5.87 (br pseudo-t, 2 H, H^4). – ^{19}F NMR ([D$_6$]acetone, $CFCl_3$): δ = –117.5 (d, $J_{o,m}$ = 23.1, J_{PtFo} = 446.6, J_{PtFo} = 550.2 Hz, 8F_o), –166.4 (t, $J_{m,p}$ = 19.7 Hz, 2 F_p), –166.7 (t, $J_{m,p}$ = 19.7 Hz, 2 F_p), –167.4 (m, 4 F_m), –167.8 (m, 4 F_m).

4: Yield 70%. – $C_{62}H_{78}Cl_2F_{20}N_6Pt_3$ (1943): calcd. C 38.1, H 4.1, N 4.3; found C 38.3, H 4.1, N 4.4. – M.p. = 246 °C (dec.). – Λ_M = 169 S cm^2 mol^{-1}. – IR (nujol): $\tilde{\nu}$ = 808, 798 cm^{-1} (Pt-C_6F_5). – ^{1}H NMR ([D$_6$]acetone, TMS): δ = 7.62 (d, $J_{4,5}$ = 1.7 Hz, 2 H, H^5), 6.87 (d, $J_{3,4}$ = 1.8, J_{HPt}= 15.1 Hz, 2 H, H^3), 5.94 (pseudo-t, 2 H, H^4). – ^{19}F NMR ([D$_6$]acetone, $CFCl_3$): δ = –117.6 (d, $J_{o,m}$ = 29.0, J_{PtFo} = 442.2, J_{PtFo} = 556.7 Hz, 8F_o), –166.2 (t, $J_{m,p}$ = 19.7 Hz, 2 F_p), –166.4 (t, $J_{m,p}$ = 20.0 Hz, 2 F_p), –167.3 (m, 4 F_m), –167.7 (m, 4 F_m).

$[NBu_4]_2[\{(C_6F_5)_2Pd(\mu\text{-}pz)(\mu\text{-}OH)\}_2Pd]$ (5): A 20% solution of $[NBu_4]OH$ (0.055 cm^3, 0.072 mmol) was added to a solution of **1** (60.0 mg, 0.036 mmol) in dichloromethane (10 cm^3). The solution was stirred at room temperature for 30 min and then concentrated to dryness. Addition of methanol and water followed by vigorous stirring rendered a yellow suspension, from which a yellow solid was filtered off and air-dried. – Yield 70%. – $C_{62}H_{80}F_{20}N_6O_2Pd_3$ (1641): calcd. C 45.4, H 4.9, N 5.1; found C 45.2, H 4.7, N 5.0. – M.p. = 185 °C (dec.). – Λ_M = 193 S cm^2 mol^{-1}. – IR (nujol): $\tilde{\nu}$ = 3606 cm^{-1} (OH str), 794, 780 cm^{-1} (Pd-C_6F_5). – ^{1}H NMR ([D$_6$]acetone, TMS): δ = 7.0 (d, $J_{4,5}$ = 1.7 Hz, 2 H, H^5), 6.56 (br, 2 H, H^3), 5.82 (pseudo-t, 2 H, H^4), –1.82 (s, 2 H, OH). – ^{19}F NMR ([D$_6$]acetone, $CFCl_3$): δ = –112.9 (d, $J_{o,m}$ = 27.1 Hz, 4 F_o), –113.6 (d, $J_{o,m}$ = 25.6 Hz, 4 F_o), –164.9 (t, $J_{m,p}$ = 19.7 Hz, 2 F_p), –165.0 (t, $J_{m,p}$ = 20.0 Hz, 2 F_p), –166.1 (m, 8 F_m).

$[NBu_4]_2[\{(C_6F_5)_2Pd(\mu\text{-}pz)_2)\}_2M]$ M = Pd (6) or Pt (7): A 20% solution of $[NBu_4]OH$ (0.18 cm^3, 0.142 mmol), followed by $M(pzH)_4Cl_2$ (M′Pd, Pt) (0.071 mmol) were added to a solution of $[NBu_4]_2[(C_6F_5)_2Pd(\mu\text{-}OH)_2Pd(C_6F_5)_2]$ (100 mg, 0.071 mmol) in *N,N*-dimethylformamide (5 cm^3). The solution was stirred at room temperature for 1 h and on addition of water complexes **6** and **7** precipitated as white solids which were collected by filtration, washed with diethyl ether and air-dried.

6: Yield 85%. – $C_{68}H_{84}F_{20}N_{10}Pd_3$ (1747): calcd. C 46.9, H 4.9, N 8.0; found C 46.9, H 4.9, N 7.7. – M.p. = 272 °C (dec.). – Λ_M = 176 S cm^2 mol^{-1}. – IR (nujol): $\tilde{\nu}$ = 792, 778 cm^{-1} (Pd-C_6F_5). – ^{1}H NMR ([D$_6$]acetone, TMS): δ = 7.08 (d, $J_{4,5}$ = 1.6 Hz, 4 H, H^5), 6.89 (d, $J_{3,4}$ = 1.7 Hz, 4 H, H^3), 5.80 (pseudo-t, 4 H, H^4). – ^{19}F NMR ([D$_6$]acetone, $CFCl_3$): δ = –113.0 (d, $J_{o,m}$ = 30.7 Hz, 4 F_o), –114.9 (d, $J_{o,m}$ = 20.7 Hz, 4 F_o), –165.9 (t, J = 19.7 Hz, 4 F_p), –166.8 (br, 8 F_m).

7: Yield 82%. – $C_{68}H_{84}F_{20}N_{10}Pd_2Pt$ (1829): calcd. C 44.7, H 4.6, N 7.7; found C 44.4, H 4.3, N 7.5. – M.p. = 304 °C (dec.). – Λ_M = 199 S cm^2 mol^{-1}. – IR (nujol): $\tilde{\nu}$ = 792, 778 cm^{-1} (Pd-C_6F_5). – ^{1}H NMR ([D$_6$]acetone, TMS): δ = 7.08 (d, $J_{4,5}$ = 2.1 Hz, 4 H, H^5), 6.93 (d, $J_{3,4}$ = 1.8 Hz, 4 H, H^3), 5.83 (pseudo-t, 4 H, H^4). – ^{19}F NMR ([D$_6$]acetone, $CFCl_3$): δ = –113.1 (d, $J_{o,m}$ = 28.9 Hz, 4 F_o), –114.7 (d, $J_{o,m}$ = 27.5 Hz, 4 F_o), –166.0 (t, $J_{m,p}$ 19.1 Hz, 4 F_p), –166.8 (br, 8F_m).

$[NBu_4]_2[\{(C_6F_5)_2Pt(\mu\text{-}pz)_2)\}_2Pt]$ (8): A 20% solution of $[NBu_4]OH$ (0.13 cm^3, 0.10 mmol), followed by $Pt(pzH)_4Cl_2$ (26.32 mg, 0.10 mmol) were added to a solution of $[[NBu_4]_2[(C_6F_5)_2Pt(\mu\text{-}OH)_2Pt(C_6F_5)_2]$ (80.0 mg, 0.05 mmol) in methanol (10 cm^3). The solution was stirred at room temperature for 4 h and the solvent was then partially evaporated under reduced pressure. On addition of water the white complex **8** precipitated and was filtered off and air-dried. – Yield 72%. – $C_{68}H_{84}F_{20}N_{10}PdPt_2$ (1918): calcd. C 42.6, H 4.4, N 7.3; found C 42.7, H 4.2, N 7.1. – M.p. = 295 °C (dec.). – Λ_M = 180 S cm^2 mol^{-1}. – IR (nujol): $\tilde{\nu}$ = 804, 792 cm^{-1} (Pt-C_6F_5). – ^{1}H NMR ([D$_6$]acetone, TMS): δ = 7.17 (d, $J_{3,4}$ = 1.7 Hz, J_{HPt} = 15.6 Hz, 4 H, H^3), 6.97 (d, $J_{4,5}$ = 1.7 Hz, 4 H, H^5), 5.87 (pt, J = 2.0 Hz, 4 H, H^4). – ^{19}F NMR ([D$_6$]acetone, $CFCl_3$): δ = –116.2 (br, J_{PtFo} = 465 Hz, 4 F_o), –117.3 (br, J_{PtFo} = 506 Hz, 4 F_o), –166.7 (m, 4 F_p+ 8 F_m).

$[NBu_4][R_2M(\mu\text{-}pz)_2Pd(\eta^3\text{-}allyl)]$ (9–14): [Pd (allyl)(acac)] (allyl = C_3H_5 or C_4H_7) (0.122 mmol) was added to a solution of $[NBu_4][R_2M(pzHpz)]$ (M = Pd or Pt, R = C_6F_5 or C_6Cl_5) (0.122 mmol) in dichloromethane (8 cm^3). The solution was stirred at room temperature for 30 min and the solvent was then partially evaporated under reduced pressure. On addition of hexane the

white complexes **9–14** precipitated and were filtered off and air-dried (see Scheme 4).

9: Yield 70%. – $C_{38}H_{43}F_{10}N_5Pd_2$ (972.6): calcd. C 46.9, H 4.5, N 7.2; found C 46.6, H 4.8, N 7.2. – M.p. = 247 °C (dec.). – Λ_M = 102 S cm^2 mol^{-1}. – IR (nujol): $\tilde{\nu}$ = 785, 775 cm^{-1} (Pd-C_6F_5). – ^{1}H NMR ([D$_6$]acetone, TMS): δ = 7.30 (d, $J_{4,5}$ = 1.8 Hz, 2 H, H^5), 7.10 (d, $J_{3,4}$ = 1.8 Hz, 2 H, H^3), 5.88 (pt, 2 H, H^4), 3.49 (s, 2 H, H_{syn}), 2.86 (s, 2 H, H_{anti}), 2.30 (s, 3 H, CH_3). – ^{19}F NMR ([D$_6$]acetone, $CFCl_3$): δ = –113.4 (d, $J_{o,m}$ = 32.2 Hz, 2 F_o), –114.2 (d, $J_{o,m}$ = 32.2 Hz, 2 F_o), –166.1 (t, $J_{m,p}$ 19.8 Hz, 2 F_P), –166.7 (m, 4 F_m).

10: Yield 75%. – $C_{37}H_{41}F_{10}N_5Pd_2$ (958.6): calcd. C 46.4, H 4.3, N 7.3; found C 46.1, H 4.6, N 7.2. – M.p. = 284 °C (dec.). – Λ_M = 91 S cm^2 mol^{-1}. – IR (nujol): $\tilde{\nu}$ = 785, 775 cm^{-1} (Pd-C_6F_5). – ^{1}H NMR ([D$_6$]acetone, TMS): δ = 7.30 (d, $J_{4,5}$ = 1.9 Hz, 2 H, H^5), 7.13 (d, $J_{3,4}$ = 1.9 Hz, 2 H, H^3), 5.91 (pt, 2 H, H^4), 5.74 (m, 1 H, H^2), 3.75 (d, J = 6.9 Hz, 2 H, H_{syn}), 3.05 (d, J = 12.3 Hz, 2 H, H_{anti}). – ^{19}F NMR ([D$_6$]acetone, $CFCl_3$): δ = –113.9 (d, $J_{o,m}$ = 31.6 Hz Hz, 4 F_o), –166.0 (t, $J_{m,p}$ = 20.0 Hz, 2 F_p), –166.7 (m, 4 F_m).

11: Yield 75%. – $C_{38}H_{43}Cl_{10}N_5Pd_2$ (1137): calcd. C 40.1, H 3.8, N 6.2; found C 39.9, H 4.0, N 5.9. – M.p. = 234 °C (dec.). – Λ_M = 100 S cm^2 mol^{-1}. – IR (nujol): $\tilde{\nu}$ = 830, 825 cm^{-1} (Pd-C_6Cl_5). – ^{1}H NMR ([D$_6$]acetone, TMS): δ = 7.33 (d, $J_{4,5}$ = 1.7 Hz, 2 H, H^5), 7.29 (d, $J_{3,4}$ = 1.7 Hz, 2 H, H^3), 5.84 (pt, 2 H, H^4), 3.48 (s, 2 H, H_{syn}), 2.87 (s, 2 H, H_{anti}), 2.23 (s, 3 H, CH_3).

12: Yield 70%. – $C_{37}H_{41}Cl_{10}N_5Pd_2$ (1123): calcd. C 39.6, H 3.7, N 6.2; found C 39.6, H 3.9, N 6.2. – M.p. = 230 °C (dec.). – Λ_M = 101 S cm^2 mol^{-1}. – IR (nujol): $\tilde{\nu}$ = 835, 825 cm^{-1} (Pd-C_6Cl_5). – ^{1}H NMR ([D$_6$]acetone, TMS): δ = 7.32 (d, $J_{4,5}$ = 1.9 Hz, 2 H, H^5), 7.30 (d, $J_{3,4}$ = 1.9 Hz 2 H, H^3), 5.84 (pt, 2 H, H^4), 5.69 (m, 1 H, H^2), 3.69 (d, J = 6.9 Hz, 2 H, H_{syn}), 3.00 (d, J = 12.4 Hz, 2 H, H_{anti}).

13: Yield 84%. – $C_{38}H_{43}F_{10}N_5PdPt$ (1061): calcd. C 43.0, H 4.1, N 6.6; found C 43.1, H 4.0, N 6.3. – M.p. = 324 °C (dec.). – Λ_M = 97 S cm^2 mol^{-1}. – IR (nujol): $\tilde{\nu}$ = 800, 790 cm^{-1} (Pt-C_6F_5). – ^{1}H NMR ([D$_6$]acetone, TMS): δ = 7.30 (d, $J_{4,5}$ = 1.8 Hz, 2 H, H^5), 7.20 (d, $J_{3,4}$ = 1.8, J_{HPt} = 14.5 Hz, 2 H, H^3), 5.92 (pt, 2 H, H^4), 3.50 (s, 2 H, H_{syn}), 2.80 (s, 2 H, H_{anti}), 2.28 (s, 3 H, CH_3). – ^{19}F NMR ([D$_6$]acetone, $CFCl_3$): δ = –117.2 (br, J_{PtFo} = 507.6 Hz, 2 F_o), –117.7 (br, J_{PtFo} = 505.8 Hz, 2 F_o), –168.0 (m, 2 F_p + 4 F_m).

14: Yield 90%. – $C_{37}H_{41}F_{10}N_5PdPt$ (1047): calcd. C 42.4, H 4.0, N 6.7; found C 42.3, H 4.3, N 6.6. – M.p. = 328 °C (dec.). – Λ_M = 99 S cm^2 mol^{-1}. – IR (nujol): $\tilde{\nu}$ = 800, 790 cm^{-1} (Pt-C_6F_5). – ^{1}H NMR ([D$_6$]acetone, TMS): δ = 7.28 (d, $J_{4,5}$ = 1.8 Hz, 2 H, H^5), 7.24 (d, J = 1.8, J_{HPt} = 13.5 Hz, 2 H, H^3), 5.93 (pt, 2 H, H^4), 5.70 (m, 1 H, H^2), 3.75 (d, J = 6.9 Hz, 2 H, H_{syn}), 3.04 (d, J = 12.3 Hz, 2 H, H_{anti}). – ^{19}F NMR ([D$_6$]acetone, $CFCl_3$): δ = –117.5 (br, J_{PtFo} = 507.9 Hz, 4 F_o), –167.8 (m, 2 F_p + 4 F_m).

[$R_2M(\mu\text{-pz})_2M'L_2$] (15–18): A 20% solution of [NBu$_4$]OH (0.122 mmol) was added to a solution of [NBu$_4$]-[M(C_6F_5)$_2$(pz)(Hpz)] (M = Pd or Pt) (0.122 mmol) in acetone (5 cm^3). After stirring for 5 min, [M′L_2Cl_2] (M′ = Pd, Pt; L_2 = 2 PEt_3, bipy) (0.122 mmol) was added to initially yield a suspension, that slowly changed to a solution that was stirred for 2 h (5 h for **18**) and then partially evaporated under reduced pressure. On addition of methanol/water the white complexes **15–18** precipitated. They were filtered off, washed with water and air-dried. Complexes **15–18** were recrystallized from dichloromethane/hexane (see Scheme 5).

15: Yield 53%. – $C_{30}H_{36}F_{10}N_4P_2Pd_2$ (917.4): calcd. C 39.3, H 4.0, N 6.1; found C 39.3, H 4.0, N 5.8. – M.p. = 289 °C (dec.). – IR (nujol): $\tilde{\nu}$ = 790, 780 cm^{-1} (Pd-C_6F_5). – ^{1}H NMR ([D$_6$]acetone, TMS): δ = 7.34 (br, 4 H), 6.01 (br, 2 H, H^4), 1.91 (m, 12 H, CH_2), 1.20 (dt, J_{HH} = 7.2 Hz, J_{PH} = 17.8, 18 H, CH_3). – ^{19}F NMR ([D$_6$]acetone, $CFCl_3$): δ = –113.1 (br, 4 F_o), –164.6 (t, 2 F_p, $J_{m,p}$ 19.7 Hz), –166.1 (m, 4 F_m). – ^{31}P NMR ([D$_6$]acetone, H_3PO_4): δ = 25.0 (s).

16: Yield 55%. – $C_{28}H_{14}F_{10}N_6Pd_2$ (837.3): calcd. and transferred to the diffractometer (Siemens P4) as summarised in Table 3.

Cell constants were refined from 31 (compound **1**) or 62 (compound **9**) reflections in the 2θ range 10–25°. Crystal data were corrected for absorption using ψ-scans. The structures were solved by the heavy atom method and refined anisotropically on F^2 (program SHELXL-93).[36] Hydrogen atoms were included using a riding model. For compound **9** the allyl ligand is disordered over two sites (68 and 32% refined occupancy).

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-137011 (for complex **9**) and CCDC-137012 (for complex **1**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Keywords: Copper / Nickel / Amides / Polynuclear complexes / Magnetic properties

New homo- and heterometallic hexanuclear complexes of formula $\{[Cu(tmen)(H_2O)]_2[Cu(tmen)]_2[Cu_2L](H_2O)\}(ClO_4)_4 \cdot 2\,H_2O$ **[Cu_6-tmen]** $\{[Cu(pmdien)]_4[Cu_2L]\}(ClO_4)_4 \cdot 4\,H_2O$ **[Cu_6-pmdien]** and $\{[Ni(cyclam)]_4[Cu_2L]\}(ClO_4)_4 \cdot 4\,H_2O$ **[Cu_2Ni_4-cyclam]** [H_8L = tetrakis(aminomethylene)methanetetrakis(oxamic acid), tmen = *N,N,N′,N′*-tetramethylethylenediamine, pmdien = *N,N,N′,N′,N″*-pentamethyldiethylenetriamine, and cyclam = 1,4,8,11-tetraazacyclotetradecane] have been synthesized. The crystal structure of **[Cu_6-tmen]** has been determined by single-crystal X-ray diffraction. The structure consists of cationic $\{[Cu(tmen)(H_2O)]_2[Cu(tmen)]_2[Cu_2L](H_2O)\}^{4+}$ hexanuclear units. The hexanuclear cation is made up of two symmetry-related oxamato-bridged trinuclear units connected through the central carbon atom C(6) of the L^{8-} ligand. Variable-temperature magnetic susceptibility measurements (1.8–300 K) have been performed for these series of complexes including the dinuclear precursors of formula $Na_4[Cu_2L] \cdot 10.5\,H_2O$ **[Cu_2-Na]**, $(NMe_4)_4[Cu_2L] \cdot 4\,H_2O$ **[Cu_2-NMe_4]** and $(PPh_4)_4[Cu_2L] \cdot 6\,H_2O$ **[Cu_2-PPh_4]**. The magnetic data have been interpreted. Evidence of a weak intramolecular ferromagnetic interaction between the two Cu^{II} ions in $[Cu_2L]^{4-}$ has been observed. For the hexanuclear species, the interaction through the oxamato bridge was found to be equal to –6790, –2650, and –1643 yJ (–342, –133, and –82 cm^{-1}) for **[Cu_6-tmen]**, **[Cu_6-pmdien]**, and **[Cu_2Ni_4-cyclam]**, respectively. In these complexes, the weak intramolecular ferromagnetic coupling between the two Cu^{II} ions within the dinuclear synthon was masked by intermolecular interactions or local anisotropy.

Introduction

One of the current challenges for inorganic chemists is the design and synthesis of high nuclearity complexes of the first row transition metal ions in a controlled fashion.[1–2] The pathways used to obtain these intriguing species are based, essentially, on the following synthetic schemes: i) the self-assembly method,[3–10] ii) the use of polynucleating ligands,[11–12] or iii) the use of complexes as ligands.[13–18] In the former case, the nature of the final products cannot be determined a priori. In contrast, the latter two methods proceed step by step. Hence they provide an alternative route to gain control of both the nuclearity and the dimensionality of the polymetallic edifice and, furthermore, allow the preparation of species containing metal ions of different natures, i.e. heterometallic complexes.

In a previous paper,[19] we described the synthesis of a new dinuclear copper(II) complex $[Cu_2L]^{4-}$ (Figure 1), where L^{8-} is the bis-tetradentate chelating ligand *N,N′,N″,N‴*-tetramethylenemethanetetrakis(oxamato). This dinuclear complex can be used as a building block for the synthesis of high nuclearity complexes or extended networks, following the strategy of "complexes as ligands". The design of this molecular synthon fulfils several important criteria. Firstly, $[Cu_2L]^{4-}$ is potentially a tetrakis-bidentate ligand that can coordinate to four other metal ions through the external oxygen atoms. The use of ancillary ligands on these metal ions avoids polymerisation, and leads to polynuclear species instead of extended networks. Also, the chelating nature of the oxamate groups ensures high values for the stability constants of the polynuclear complexes. Secondly, from a topological point of view, the connectivity number of four of this ligand is favourable for the construction of high-spin dendrimer-like molecules, and also for the synthesis of molecular-based magnets, since the critical temperature T_C is related to the number of neighbours of each magnetic centre.[20] Furthermore, the geometry of the ligand with non-coplanarity between the two planes containing the copper ions, as shown in Figure 1, has been designed with the aim of inducing a ferromagnetic coupling between the two Cu^{II} ions.[21] Such a coupling should, therefore, lead to a molecular synthon with an $S = 1$ ground state. Polynuclear complexes or extended networks built with this dinuclear complex are expected to have attractive magnetic properties.

This "complexes as ligands" strategy has been successfully applied in the preparation of the homometallic hexanuclear complexes $\{[Cu(tmen)(H_2O)]_2[Cu(tmen)]_2[Cu_2L]\}$-

$(H_2O)\}(ClO_4)_4 \cdot 2\,H_2O$ **[Cu_6-tmen]** (tmen = *N,N,N′,N′*-tetramethylethylenediamine) and $\{[Cu(pmdien)]_4[Cu_2L]\}(ClO_4)_4 \cdot 4\,H_2O$ **[Cu_6-pmdien]** (pmdien = *N,N,N′,N′,N″*-pentamethyldiethylenetriamine), and a heterometallic hexanuclear complex $\{[Ni(cyclam)]_4[Cu_2L]\}(ClO_4)_4 \cdot 4\,H_2O$ **[Cu_2Ni_4-cyclam]**. We report herein their synthesis and magnetic characterisations as well as the magnetic properties of their dinuclear precursors $Na_4[Cu_2L] \cdot 10.5\,H_2O$ **[Cu_2-Na]**, $(NMe_4)_4[Cu_2L] \cdot 4\,H_2O$ **[Cu_2-NMe_4]** and $(PPh_4)_4[Cu_2L] \cdot 6\,H_2O$ **[Cu_2-PPh_4]**, and the X-ray structural determination of **[Cu_6-tmen]**.

Results and Discussion

Synthesis of the Complexes

The dinuclear precursors were obtained by reaction of the tetraethyl ester derivative of the ligand (Et_4H_4L) with NaOH or NMe_4OH, for **[Cu_2-Na]** and **[Cu_2-NMe_4]** respectively, followed by addition of Cu^{2+}. The tetraphenylphosphonium derivative **[Cu_2-PPh_4]** was then obtained by successive metatheses with Ag^+ and PPh_4^+. The hexanuclear compounds were synthesised by adding four equivalents of an external complex to the dinuclear **[Cu_2-Na]** precursor and isolated as microcrystalline powders after slow evaporation of the solvent. External complexes were Ni(cyclam)$(ClO_4)_2(H_2O)_2$, or in situ generated Cu(tmen)$(ClO_4)_2$ or Cu(pmdien)$(ClO_4)_2$.

Crystal Structure Analysis

The structure of **[Cu_6-tmen]** consists of hexameric copper(II) complex cations, $\{[Cu(tmen)(H_2O)]_2[Cu(tmen)]_2[Cu_2L](H_2O)\}^{4+}$ (Figure 2), perchlorate anions and crystallisation water molecules. The hexanuclear cation is made up of two symmetry-related oxamato-bridged trinuclear units (I = 1 – *x*, *y*, –*z*) connected through the central carbon atom C(6) which lies on a crystallographic twofold axis, in accordance with the C_2 space group.

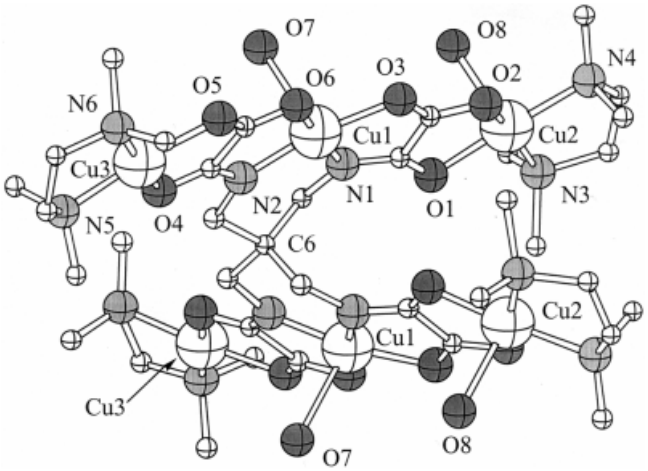

Figure 2. Perspective view of the cationic hexanuclear unit $\{[Cu(tmen)(H_2O)]_2[Cu(tmen)]_2Cu_2L(H_2O)\}^{4+}$ of **[Cu_6-tmen]** with the atom-numbering scheme (hydrogen atoms have been omitted for clarity); selected bond lengths [pm] and angles [°] with standard deviations in parentheses: Cu(1)–N(1) 192.6(5), Cu(1)–N(2) 191.7(5), Cu(1)–O(3) 196.1(4), Cu(1)–O(6) 196.3(4), Cu(2)–N(3) 192.9(5), Cu(2)–N(4) 191.9(5), Cu(2)–O(9) 196.6(4), Cu(2)–O(12) 198.2(4); N(2)–Cu(1)–N(1) 96.7(2), O(3)–Cu(1)–N(1) 84.3(2), O(6)–Cu(1)–N(1) 173.4(2), N(2)–Cu(1)–O(3) 176.8(2), N(2)–Cu(1)–O(6) 84.2(2), O(6)–Cu(1)–O(3) 95.1(2), N(3)–Cu(2)–N(4) 95.2(2), O(9)–Cu(2)–N(3) 84.4(2), O(12)–Cu(2)–N(3) 179.0(2), N(4)–Cu(2)–O(9) 172.4(2), N(4)–Cu(2)–O(12) 83.9(2), O(12)–Cu(2)–O(9) 96.4(2)

Within each trinuclear fragment, the terminal Cu(2) and Cu(3) atoms are (4 + 1) and (4 + 2) coordinated, respectively. Their basal planes are formed by two amino nitrogen atoms from the tmen ligand and two oxygen atoms from the oxamato bridge. The apical positions are filled by the oxygen atom O(8) from the water molecule (234 pm) in the former, and the O(10) and O(13) atoms from two weakly bound perchlorate anions (272 pm) in the latter. The central Cu(1) atom has a (4 + 1) coordination environment, with an equatorial plane occupied by two deprotonated amido nitrogen atoms and two carboxylate oxygen atoms from the oxamato groups. The fifth axial position is occupied by the water oxygen atom O(7) (250 pm). The metal atoms Cu(1) and Cu(2) are displaced from the least-square basal plane toward the apical water molecule by 15 and 20 pm, respectively, while the Cu(3) atom shows no deviation from the mean plane. The basal planes of the three copper(II) ions in the trinuclear unit are almost coplanar [dihedral angles of 7(2), 6(2), and 5(2)° for Cu(1)–Cu(2), Cu(1)–Cu(3), and Cu(2)–Cu(3), respectively], in contrast to those of the central copper(II) ions from the $[Cu_2L]$ fragment [43.2(8)° for $Cu(1)–Cu^{I}(1)$].

In the crystal, two neighbouring hexanuclear entities (II = 1 – *x*, *y*, 1 – *z*) are linked through the oxygen atom O(7) from apical water which acts as a bridge between the central copper(II) ions, thus leading to a chain along the *c* axis (Figure 3). The $Cu(1)–O(7)–Cu^{II}(1)$ angle is 124(2)°. The intramolecular metal–metal separations Cu(1)···Cu(2), Cu(1)···Cu(3), Cu(2)···Cu(3), and $Cu(1)\cdots Cu^{I}(1)$ are 514,

513, 1024, and 591 pm, respectively, whereas the intermolecular one Cu(1)···Cu^{II}(1) is 442 pm.

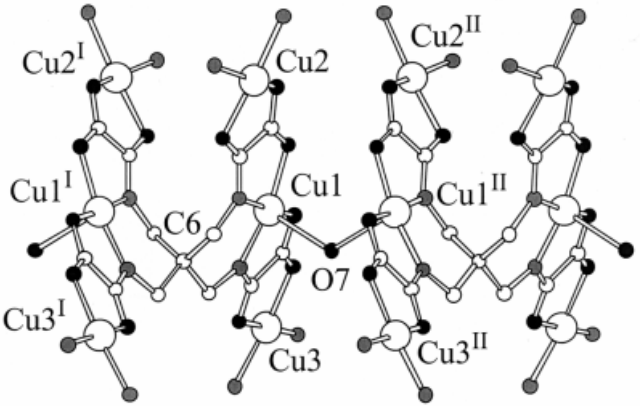

Figure 3. View of two symmetry-related hexanuclear complexes (II: $1-x$, y, $1-z$) belonging to the chain which runs along the c axis; the carbon atoms of the tmen ligands and the oxygen atoms of coordinated water and perchlorate molecules have been omitted for clarity

Magnetic Properties of Dinuclear Precursors

The magnetic properties of **[Cu$_2$-Na]**, **[Cu$_2$-NMe$_4$]** and **[Cu$_2$-PPh$_4$]** (SQUID, 1.8–300 K) are depicted in Figure 4. The magnetic properties of the dinuclear copper(II) complexes strongly depend on the nature of the counter-cation. As can be seen for **[Cu$_2$-Na]**, the $\chi_M T$ curve smoothly decreases upon cooling below 5 K, showing that the dominant interaction between Cu^{II} ions is antiferromagnetic. On the contrary, upon cooling **[Cu$_2$-NMe$_4$]** and **[Cu$_2$-PPh$_4$]**, the increase of the $\chi_M T$ product indicates that the coupling between the Cu^{II} ions is ferromagnetic. The best fits are obtained using the following parameters J = –4.6 yJ (–0.23 cm^{-1}), g = 2.10, 5.4 yJ (0.27 cm^{-1}), g = 2.05 and 23.8 yJ (1.2 cm^{-1}), g = 2.02 for **[Cu$_2$-Na]**, **[Cu$_2$-NMe$_4$]** and **[Cu$_2$-PPh$_4$]**, respectively ($H = -JS_1 \cdot S_2$).[22] The agreement factors R defined as $\Sigma(\chi_M T_{exp}-\chi_M T_{theo})^2/\Sigma(\chi_M T_{exp})^2$ are then equal to $4.6\cdot10^{-5}$, $7\cdot10^{-6}$, and $4\cdot10^{-5}$ for **[Cu$_2$-Na]**, **[Cu$_2$-NMe$_4$]**, and **[Cu$_2$-PPh$_4$]**, respectively.

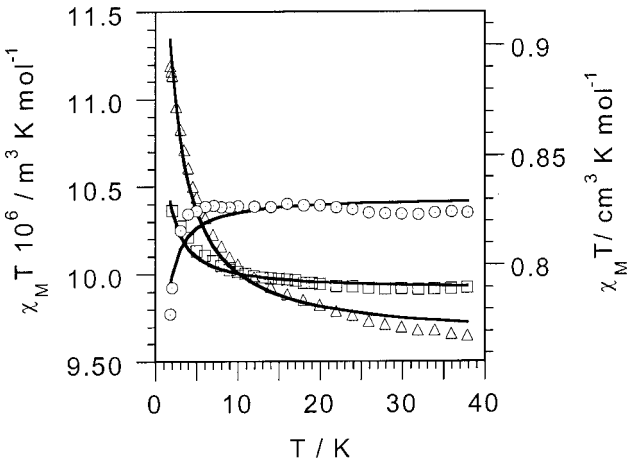

Figure 4. Thermal variation of the magnetic susceptibility of **[Cu$_2$Na]** (⊙), **[Cu$_2$NMe$_4$]** (□) and **[Cu$_2$PPh$_4$]** (Δ) in the form of $\chi_M T$ versus T plot; the lines are the calculated curves

The antiferromagnetic interaction obtained for [Cu$_2$Na] can be explained in light of its crystal structure. The dinuclear units are not isolated within the crystal, as the oxygen atoms of oxamato groups of [Cu$_2$L]$^{4-}$ are coordinated to the Na^{I} ions leading to an extended 3D network.[19] The antiferromagnetic coupling between the Cu^{II} ions is probably due to the interaction through the Na^{I} ions and not from the interaction through the carbon atoms linking the two Cu^{II} ions. This analysis is reinforced by the magnetic behaviour of **[Cu$_2$-NMe$_4$]** and **[Cu$_2$-PPh$_4$]**. For these two compounds, where organic cations are present and cannot be coordinated to the external oxygen atoms of the oxamato group, the coupling is, as expected, ferromagnetic. Moreover, the magnitude of the coupling seems to be related to the size of the counter-cation, i.e. the bulkier the counter-cation, the more pronounced the coupling. Even though no crystallographic structures of these compounds are yet available, the stronger ferromagnetic interaction is observed for the PPh_4^+ salt where the intermolecular interactions are expected to be the smallest.

Magnetic Properties of Hexanuclear Species

The magnetic properties of the hexanuclear complexes **[Cu$_6$-tmen]** and **[Cu$_6$-pmdien]** are shown in Figure 5. At room temperature, $\chi_M T$ is equal to 14.9 μm^3 K mol^{-1} (1.19 cm^3 K mol^{-1}) and 24.6 μm^3 K mol^{-1} (1.96 cm^3 K mol^{-1}) for **[Cu$_6$-tmen]** and **[Cu$_6$-pmdien]**, respectively. These values are lower than expected for six noninteracting copper(II) ions (31.2 μm^3 K mol^{-1}). For both compounds, $\chi_M T$ decreases upon cooling to reach a constant value of 10.0 μm^3 K mol^{-1} (0.798 cm^3 K mol^{-1}) around 100 K for **[Cu$_6$-tmen]** and 10.2 μm^3 K mol^{-1} (0.811 cm^3 K mol^{-1}) around 20 K for **[Cu$_6$-pmdien]**. Upon further cooling, $\chi_M T$ decreases abruptly below 20 K for **[Cu$_6$-tmen]** and 8 K for **[Cu$_6$-pmdien]**. At 1.8 K, $\chi_M T$ values are equal to 6.36 μm^3 K mol^{-1} (0.506 cm^3 K mol^{-1}) and 9.31 μm^3 K mol^{-1} (0.741 cm^3 K mol^{-1}) for **[Cu$_6$-tmen]** and **[Cu$_6$-pmdien]**, respectively. In the high temperature region, these observed trends are typical of strongly coupled trinuclear Cu^{II} complexes and the plateaux correspond to temperature ranges where the $S = {}^1/_2$ ground states of the trinuclear units are the only populated states.

The rapid decrease in the $\chi_M T$ products at low temperature is interpreted as arising from a weak interaction between the trinuclear units. To take this into account, the effective spin Hamiltonian shown in Equation 1 has been used where $S_A = S_B = {}^1/_2$ correspond to the two ground-state doublets of the Cu$_3^{II}$ trimeric units, defined as A and B in this perturbational treatment.[23]

$$H = -J(S_{A1}S_{A2} + S_{A1}S_{A3} + S_{B1}S_{B2} + S_{B1}S_{B3}) - j_{eff}S_AS_B + g\beta(S_{A1} + S_{A2} + S_{A3} + S_{B1} + S_{B2} + S_{B3})\cdot B \quad (1)$$

Over the whole temperature range, the theoretical curves derived from the above Hamiltonian closely follow the experimental data for both compounds. The best fits are obtained using the following parameters J = –6790 yJ (–342 cm^{-1}), j_{eff} = –31.8 yJ (–1.6 cm^{-1}), g = 2.07 and J = –2650 yJ (–133 cm^{-1}), j_{eff} = –10.7 yJ (–0.54 cm^{-1}), g =

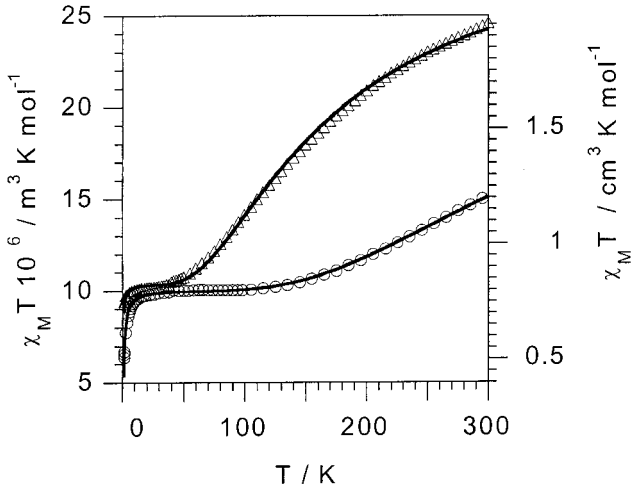

Figure 5. Thermal variation of the magnetic susceptibility of **[Cu$_6$-tmen]** (Δ) and **[Cu$_6$-pmdien]** (O) in the form of $\chi_M T$ versus T plot; the lines are the calculated curves

2.10 for **[Cu$_6$-tmen]** and **[Cu$_6$-pmdien]**, respectively (solid lines in Figure 5). The agreement factors R are then equal to $1.91 \cdot 10^{-4}$ and $7.4 \cdot 10^{-5}$, respectively. In **[Cu$_6$-tmen]**, the exchange interaction parameter J between Cu(1) and Cu(2) or equivalently, Cu(1) and Cu(3) ($J = J_{12} = J_{13}$) through the oxamato bridge is in excellent agreement with that of the related trinuclear complex {[Cu(tmen)]$_2$Cu(pba)}-(ClO$_4$)$_2$,[24] where J is equal to –7530 yJ (–379 cm^{-1}). As for the effective interaction parameter j_{eff} between the two trinuclear units, it may be related to the exchange parameter J_{Cu-Cu} between the two central Cu^{II} ions by the expression $j_{eff} = 1/9 \cdot J_{Cu-Cu}$, i.e. J_{Cu-Cu} = –278 yJ (–14 cm^{-1}).[25] This value may be associated with two different pathways for the interaction between the trinuclear units. The first is an intramolecular coupling between the two trinuclear units of the same molecule, through the N–C–C–C–N σ-bond moiety. The other takes place between units of two different molecules, due to the Cu(1) ions which are connected by the apical O(7) oxygen (Figure 3). The latter pathway takes preference as coupling occurs through only one atom. This preference is also supported by a comparison between the value of –278 yJ for this interaction and those of the dinuclear units **[Cu$_2$-NMe$_4$]** and **[Cu$_2$-PPh$_4$]** (+5.4 and +23.8 yJ). It is noteworthy that there is no improvement in the quality of the fit for the low temperature data by using an alternating $S = {}^1/_2$ chain model. In other words, it is not possible to determine from the magnetic data the respective contribution of the intra- and intermolecular interactions.

The lack of crystallographic structure renders the thorough analysis of the magnetic behaviour of **[Cu$_6$-pmdien]** difficult. Nevertheless, the J value through the oxamato bridge (–2650 yJ) is also in very good agreement with that of the related trinuclear complex {[Cu(pmdien)]$_2$Cu(pba)}-(PPh$_4$)$_2$,[24] where J is equal to –3020 yJ (–152 cm^{-1}). In **[Cu$_6$-pmdien]**, the j_{eff} value of –10.7 yJ is likewise associated to intermolecular interaction. The weaker interaction through the oxamato bridge for **[Cu$_6$-pmdien]** than for **[Cu$_6$-tmen]** stems from the relative orientation of the magnetic orbitals in these complexes. In the latter compound, all magnetic orbitals lie almost in the same plane, ensuring a maximum overlap between them. On the contrary, in **[Cu$_6$-pmdien]** the magnetic orbitals of the Cu^{II} ions are not coplanar, and hence leads to a decrease in the orbital overlapping.[24][26][27]

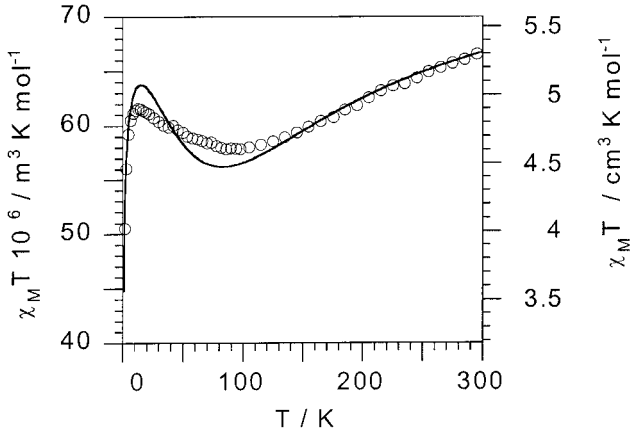

Figure 6. Thermal variation of the magnetic susceptibility **[Cu$_2$Ni$_4$-cyclam]** in the form of $\chi_M T$ versus T plot: (O) experimental data, calculated curve (line)

The magnetic properties of **[Cu$_2$Ni$_4$-cyclam]** are depicted in Figure 6. At room temperature $\chi_M T$ is equal to 66.6 μm^3 K mol^{-1} (5.3 cm^3 K mol^{-1}) which is close to 71.3 μm^3 K mol^{-1}, the expected value for noninteracting ions (for g_{Cu} = 2.1 and g_{Ni} = 2.2). The $\chi_M T$ product first decreases upon cooling, reaches a minimum around 80 K, then increases to a maximum at about 15 K with $\chi_M T$ equal to 66.6 μm^3 K mol^{-1}, and finally decreases again upon cooling to 2 K.

The expected behaviour of **[Cu$_2$Ni$_4$-cyclam]** is that of [NiCuNi] heterotrinuclear species, with a weak interaction between the trinuclear units in the low temperature region. In fact, the experimental curve can be fitted using the theoretical law of a trinuclear [NiCuNi] complex.[13][28] In this model, the decrease of $\chi_M T$ at low temperature is attributed to the zero field splitting in the $S = {}^3/_2$ ground state of the [NiCuNi] trinuclear unit. The best fit of the experimental data is obtained using the following parameters J = –1704 yJ (–85 cm^{-1}), D = –69.6 yJ (–3.5 cm^{-1}), g_{Ni} = 2.30 and g_{Cu} = 2.15. The agreement factor R is then equal to $5.2 \cdot 10^{-4}$. On the other hand, the experimental data can also be fitted to a hexanuclear model using the effective spin Hamiltonian (1) with $S_A = S_B = {}^3/_2$ being the two quadruplets ground states of the [NiCuNi] trimeric units, defined as A and B. For this model, the best fit of the data is obtained with the following parameters J = –1643 yJ (–82 cm^{-1}), j_{eff} = –1.4 yJ (–0.068 cm^{-1}), g_{Ni} = 2.30 and g_{Cu} = 2.15. The agreement factor R is then equal to $4.5 \cdot 10^{-4}$. The effective interaction parameter j_{eff} between the two trinuclear units may be related to the exchange parameter J_{Cu-Cu} between the two central Cu^{II} ions by the expression $j_{eff} = 1/25 \cdot J_{Cu-Cu}$

i.e. J_{Cu-Cu} = –34 yJ (–1.7 cm^{-1}). For both models, the interaction through the oxamato bridge is smaller than that of the related [NiCuNi] trinuclear complexes. Recently, the role of peripheral ligand on the coupling constant has been studied in oxalato-bridged nickel(II) complexes.[29] With four nitrogens as donor atoms, the peripheral cyclam ligand is expected to induce a coupling close to that of the cth ligand (cth = 2,4,4,9,9,11-hexamathyl-1,5,8,12-tetraazacyclotetradacane), that is –2470 yJ (–124.5 cm^{-1}).[13] This is not observed experimentally, but in the absence of an X-ray analysis of the compound, it is not possible to give a satisfactory explanation to this relatively small value of the exchange interaction through the oxamato bridge.

It should be noted that the theoretical curves for the two alternative models are almost indistinguishable, showing that the D and j_{eff} parameters are strongly correlated. This renders impossible an unambiguous determination of D and j_{eff} by a fit of the magnetic data with a theoretical model including the two parameters. Nevertheless, **[Cu_2Ni_4-cyclam]** is EPR silent indicating that both effects are not negligible. First, the weak interaction j_{eff} between two trinuclear subunits leads to integer spin values for the hexanuclear species. Second, the large value for the Ni^{II} single ions zero field splitting makes the low lying integer spin states EPR silent. Unfortunately, neither the magnetic data nor the EPR spectra are able to give the relative values of D and j_{eff}. Hence, we cannot rule out the possibility of the weak ferromagnetic coupling between the trinuclear subunits associated with large values of the zero field splitting in the low lying states in **[Cu_2Ni_4-cyclam]**.

Conclusion

We have obtained three new hexanuclear species with a new dinuclear Cu^{II} molecular synthon. The non-coplanarity of the Cu^{II}'s coordination environment favours a ferromagnetic coupling between the two ions as shown by the magnetic properties of **[Cu_2-NMe_4]** and **[Cu_2-PPh_4]**. However, the ferromagnetic coupling between the two Cu^{II} ions within the dinuclear synthon is weak and often masked by intermolecular interactions, as in **[Cu_2-Na]** and **[Cu_6-tmen]**, or local anisotropy as in **[Cu_2Ni_4-cyclam]**. To overcome this problem, we are presently working on new polynuclear synthons with different spacers that should induce larger ferromagnetic couplings. To the best of our knowledge, only ligands allowing the synthesis of homo-hexanuclear[12] or hetero-tetranuclear species have been described in the literature.[30][31] The tetrakis-bidentate molecular synthon $[Cu_2L]^{4-}$ reported here, is a unique example of a building block allowing the synthesis of homo- and heterometallic hexanuclear complexes in a rational fashion. Taking advantage of the design of $[Cu_2L]^{4-}$, high-spin (S = 9) heterometallic hexanuclear species with Mn^{II} or Fe^{III} ions are in the process of being synthesised. We are also using this tetrakis-bidentate complex as a ligand to obtain extended networks. The non-coplanar connectivity of four should lead to both a graphite-like hexagonal 2D array and a diamond like 3D network, and possibly to high-temperature molecular-based magnets.

Experimental Section

General: All reagents were obtained from commercial sources and used as received. The tetraethyl ester derivative Et_4H_4L of the ligand was synthesed following a literature procedure.[19] – Elemental analyses were performed by the Microanalytical Service of ICNS (CNRS). – IR spectra were carried out on a Spectrum 1000 FT-IR spectrophotometer (Perkin–Elmer). – Magnetic measurements in the 1.8–300 K temperature range were carried out with a MPMS5 SQUID susceptometer (Quantum Design Inc). – EPR measurements were performed at 100 K on a Bruker ER 200 E at X-band on solid samples.

Syntheses and General Physical Properties of the Dinuclear Complex: The dicopper(II) complex was obtained by reaction of the tetraethyl ester derivative of the ligand (Et_4H_4L) with Cu^{2+} in basic aqueous media and isolated as its sodium, tetramethylammonium, and tetraphenylphosphonium salts.

[Cu_2-Na]: The synthesis and characterisation of the sodium salt $Na_4[Cu_2L] \cdot 10.5\ H_2O$ have previously been described.[19]

[Cu_2-NMe_4]: The tetramethylammonium derivative $(NMe_4)_4[Cu_2L] \cdot 4\ H_2O$ was synthesised and isolated in a similar manner to that of **[Cu_2-Na]**: To a suspension of the tetraethyl ester derivative Et_4H_4L (1.33 g, 2.5 mmol) in water (50 mL) was added NMe_4OH (8.9 mL of a 25% methanolic solution, 22 mmol). After stirring for 5 min at room temperature, an aqueous solution (25 mL) of $Cu(NO_3)_2 \cdot 3\ H_2O$ (1.20 g, 5 mmol) was added dropwise. The deep-blue solution was then filtered and the solvent volume was reduced to 10 mL on a rotary evaporator. Slow addition of absolute ethanol to the mother liquor gave a hygroscopic purple solid which was collected by filtration, washed with ethanol and ether, and dried under vacuum (74%). – $C_{13}H_8Cu_2N_4O_{12}[N(C_4H_{12})_4]_4 \cdot 4\ H_2O$ (1629.7): calcd. C 38.36, H 7.10, Cu 13.9, N 12.34; found C 37.88, H 6.79, Cu 13.6, N 12.26. – IR (KBr): $\tilde{\nu}$ = 1635 and 1602 cm^{-1} (C=O).

[Cu_2-PPh_4]: The tetraphenylphosphonium derivative $(PPh_4)_4[Cu_2L] \cdot 6\ H_2O$ was synthesised from **[Cu_2-Na]** by successive metatheses with Ag^+ and PPh_4^+: To a solution of **[Cu_2-Na]** (140 mg, 0.17 mmol) in water (10 mL) was added solid silver nitrate (31 mg, 0.18 mmol). After stirring for 5 min, the purple precipitate that formed in a quantitative yield was collected by filtration, washed successively with water, ethanol and ether, and then dried under vacuum. To a suspension of this solid (152 mg, 0.16 mmol) in water (5 mL) was added an aqueous solution (10 mL) of tetraphenylphosphonium chloride (235 mg, 0.63 mmol). Silver chloride appeared as a white solid. After stirring for 15 min, the purple blue solution was filtered and evaporated to dryness. The solid residue was dissolved in the minimum amount of acetonitrile and 5 mL of acetone was added. Addition of ether allowed the isolation of a hygroscopic purple precipitate which was collected by filtration, washed with ether and kept in a dessicator (94%). – $C_{13}H_8Cu_2N_4O_{12}[P(C_6H_5)_4]_4 \cdot 6\ H_2O$ (2005): calcd. C 65.30, H 5.03, Cu 6.34, N 2.79; found C 65.54, H 5.04, Cu 6.26, N 2.87. – IR (KBr): $\tilde{\nu}$ = 1634 and 1603 cm^{-1} (C=O).

Syntheses and General Physical Properties of the Hexanuclear Complexes: These compounds were synthesised in a straightforward

manner from the dinuclear copper(II) complex **[Cu_2-Na]** and the appropriate external complex.

[Cu_6-tmen]: The hexacopper complex $\{[Cu(tmen)(H_2O)]_2[Cu(tmen)]_2[Cu_2L](H_2O)\}(ClO_4)_4 \cdot 2\,H_2O$ was synthesed in the following way with $[Cu(tmen)]^{2+}$ prepared in situ from a 1:1 mixture of Cu^{2+} and the corresponding diamine: To a solution of copper(II) perchlorate (0.74 g, 2.0 mmol) and *N,N,N′,N′*-tetramethylethylenediamine (302 μL, 2 mmol) in water (20 mL) was added under stirring an aqueous solution (10 mL) of **[Cu_2-Na]** (0.39 g, 0.5 mmol). Slow evaporation at room temperature of the deep-blue filtered solution gave, after a few days, a microcrystalline deep-blue powder which was filtered off and air-dried. – $C_{37}H_{82}Cl_4Cu_6N_{12}O_{33}$ (1746.2): calcd. C 25.45, H 4.73, N 9.63; found C 25.72, H 4.83, N 9.58. – IR (KBr): $\tilde{\nu}$ = 1634 and 1600 cm^{-1} (C=O), 1120 and 1086 cm^{-1} (Cl–O; ClO_4^-). A single crystal of **[Cu_6-tmen]** of low quality but good enough for a complete structure determination was selected. Up to now, attempts to obtain single crystals of higher quality by recrystallization from various solvents (water, methanol, acetonitrile) have been unsuccessful.

[Cu_6-pmdien]: The other hexacopper complex $\{[Cu(pmdien)]_4[Cu_2L]\}(ClO_4)_4 \cdot 4\,H_2O$ was formed by the same procedure with *N,N,N′,N′,N″*-pentamethyldiethylenetriamine (418 μL, 2 mmol) in place of *N,N,N′,N′*-tetramethylethylenediamine. After slow evaporation, a deep-blue microcrystalline powder formed, but no well-shaped crystals of a sufficient quality for X-ray analysis were obtained. – $C_{49}H_{100}Cl_4Cu_6N_{16}O_{28} \cdot 4\,H_2O$ (1956.6): calcd. C 30.08, H 5.56, Cl 7.25, N 11.45; found C 29.92, H 5.58, Cl 7.33, N 11.41. – IR (KBr): $\tilde{\nu}$ = 1620 cm^{-1} (C=O), 1121 and 1089 cm^{-1} (Cl–O; ClO_4^-).

[Cu_2Ni_4-cyclam]: The polymetallic complex $\{[Ni(cyclam)]_4[Cu_2L]\}(ClO_4)_4 \cdot 4\,H_2O$ was obtained as follows: To a solution of Ni(cyclam)$(H_2O)_2(ClO_4)_2$ (198 mg, 0.4 mmol) in 1:1 water/acetonitrile (6 mL) was added solid **[Cu_2-Na]** (82 mg, 0.1 mmol). After stirring for 30 min at 40 °C all the solid had dissolved to give a purple-red solution. Slow evaporation at room temperature afforded crystalline material of very low quality for X-ray analysis. All attempts at isolating crystals of good quality by recrystallisation were unsuccessful. – $C_{53}H_{104}Cl_4Cu_2N_{20}Ni_4O_{28} \cdot 4\,H_2O$ (2045.3): calcd. C 31.12, H 5.52, Cl 6.93, N 13.70; found C 30.98, H 5.51, Cl 7.06, N 13.73. – IR (KBr): $\tilde{\nu}$ = 1614 cm^{-1} (C=O), 1114 and 1086 (Cl–O; ClO_4^-), 2925 and 2869 (N–H; cyclam).

X-ray Crystallographic Study: Crystal structure analysis of the selected crystal of **[Cu_6-tmen]**: Enraf–Nonius CAD-4 diffractometer, Mo-K_α radiation, λ = 71.069 pm, graphite monochromator, 293 K. Data collection solution and refinement: *w*-2θ, Lorentz and polarisation effects and absorption correction, standard Patterson methods with subsequent full-matrix least-squares method refinement SHELX86, SHELX93.[32,33] $C_{37}H_{82}Cl_4Cu_6N_{12}O_{33}$, monoclinic, space group C_2, a = 2807.1(10), b = 1430.4(6), c = 872.1(7) pm, β = 95.28(2)°, V = 3.487(3) nm^3, Z = 4, r_{calcd} = 1.65 g cm^{-3}, m = 2.04 mm^{-1}, $1 \le \theta \le 25°$, crystal size 0.10 × 0.10 × 0.10 mm. 2395 Unique reflections, and 2344 assumed as observed with $I > 2\sigma(I)$. The hydrogen atoms were not found or calculated. Refinement of 363 variables with anisotropic thermal parameters for all atoms except for the O(5) atom which was refined with an overall isotropic thermal parameter gave R = 0.105 and R_w = 0.251 with Σ = 1.09. The crystal drawings were carried out with the CRYSTAL MAKER[34] program. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-101561. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB21EZ, UK [fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

[22] This paper uses the SI units. The molar magnetic susceptibility χ_M is expressed in $m^3\ mol^{-1}$. The conversion factor to the irrational emu quantity $\chi_M^{(ir)}$ is $10^6/4\pi$. The energies are expressed in 10^{-24} Joule. The submultiple prefix for 10^{-24} is yocto, its symbol is y. Therefore 1 yJ means 10^{-24} Joule. The conversion factor to cm^{-1} is 5.034 10^{-2} (1 $cm^{-1} \approx$ 20 yJ).

Preparation, Properties, and Reactions of Metal-Containing Heterocycles, 101[‡]

Inclusion of Copper(I) into a Novel Bipyridine-Containing Tetraphosphadiplatinacyclophane

Ekkehard Lindner,*[a] Robert Veigel,[a] Kirstin Ortner,[a] Christiane Nachtigal,[a] and Manfred Steimann[a]

Dedicated to Professor Heinrich Vahrenkamp on the occasion of his 60th birthday

Keywords: Bipyridyldiphosphane ligands / Macrocycles / Metallacyclophanes / Platinum / Supramolecular chemistry

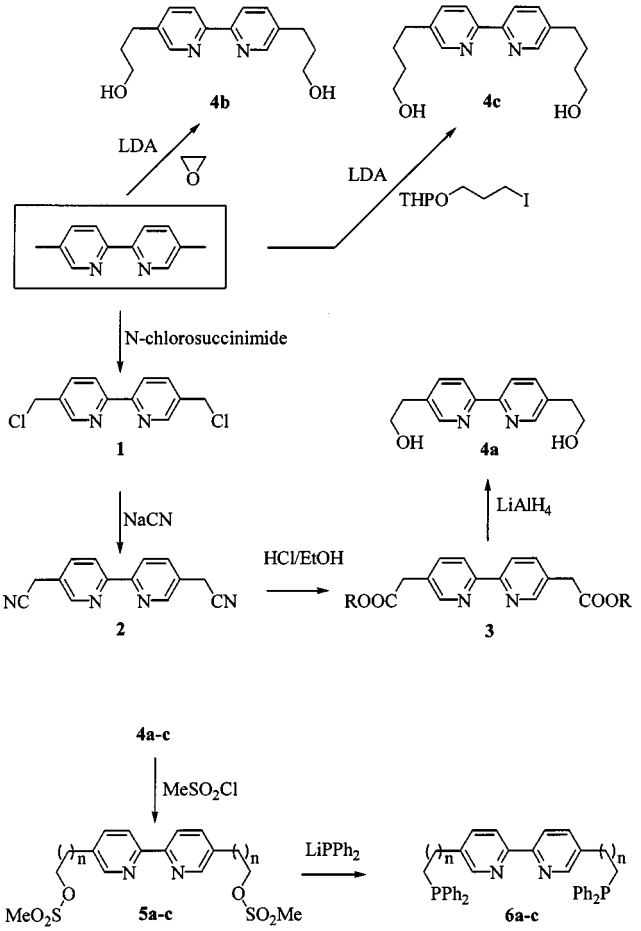
The 5,5′-bis(hydroxyalkyl)-2,2′-bipyridines **4a–c** (Scheme 1) were prepared either in one step (**4b**, **4c**) or in four steps (**4a**) starting with 5,5′-dimethyl-2,2′-bipyridine in each case. Reaction of **4a–c** with mesyl chloride afforded the bis(mesylates) $[–C_5H_3N–(CH_2)_n–CH_2–OSO_2Me]_2$ **5a–c** [n = 1 (**a**), 2 (**b**), 3 (**c**)], which could easily be transformed into the diphosphanes **6a–c** by reaction with $LiPPh_2$. Treatment of **6c**, **6b** with $Cl_2Pt(NCPh)_2$ and $(RC_6H_4)_2Pt(COD)$ according to the high-dilution method resulted in the formation of the tetraphosphadiplatinacyclophanes $[–C_5H_3N–(CH_2)_4–PPh_2PtCl_2PPh_2–(CH_2)_4–C_5H_3N–]_2$ (**7c**) and $[–C_5H_3N–(CH_2)_3–PPh_2Pt(C_6H_4R)_2–PPh_2–(CH_2)_3–C_5H_3N–]_2$ (**8b**, **9b**) (**8b**: R = H, **9b**: R = *t*Bu), respectively (Scheme 2). The molecular structures of **8b** and **9b** were elucidated by X-ray structural analyses. The noncoordinated bipyridine moieties in **8b** were employed to encapsulate copper(I) to give the host/guest complex **10b** (Scheme 3), which was investigated by FAB-MS, NMR spectroscopy, and cyclovoltammetry. **10b** exhibited a quasi-reversible oxidation at $E_{1/2}$ = –0.31 V and an electrodeposition-redissolution redox system at $E_{1/2}$ = –0.79 V, owing to the formation of copper at the surface of the working electrode.

Introduction

Since the systematic investigations of metal-containing macrocycles by Fujita et al.,[1] great interest emerged in the synthesis and design of such systems.[2] A couple of years later, the first synthesis of typical metallacyclophanes was published in the literature.[3] This kind of macrocycle presents the classically bridged cyclophane structure with aromatic units at the bottom and the top of the molecule, whereas the metals are located in the center of the aliphatic chain.[4] The introduction of transition metal fragments leads to a remarkable influence on the structure of the cyclophane framework.[3,5] Furthermore, a new potential reactive center is obtained, which can, for example, be used for the insertion of carbon monoxide into M–C σ bonds[3,5] or for catalysis.[6] Meanwhile several methods for the incorporation of transition metals into the cyclophane framework are known.[5,7,8] Most of these metallacyclophanes were obtained by reaction of metal-containing precursors with tertiary phosphanes or aliphatic and aromatic amines, in particular bipyridine.[9] Surprisingly, little attention has been paid to hybrid bipyridylphosphane ligands,[10] which combine the coordination chemistry of a remarkable chelator with that of a tertiary phosphane. Recently, Ziessel et al. described the generation of such a ligand and its employment in the formation of an interesting ruthenium(II)- and copper(I)-containing macrocycle.[10c,10d] In this case, the bipyridine core was provided with only one phosphane. Therefore, both donor types were needed to accomplish cyclization.

The present work deals with the construction of bipyridyldiphosphane ligands, which allows for the formation of metallacyclophanes by using only the P donors. Consequently, the resulting metallacyclophanes should have the capability to encapsulate metal ions by the formation of metal–nitrogen bonds, thus representing an important step in the design of organometallic analogues of the tris(bipyridine) cages published by Vögtle et al.[11] In this context, it was necessary to provide the macrocycle with sufficient flexibility. To achieve this goal, three novel PNNP ligands with methylene spacer units of different length between the phosphane and the bipyridine were made accessible. To prevent the formation of mononuclear species, less common 5,5′-substituted bipyridines were introduced.

Results and Discussion



Synthesis of Ligands

For the diols **4a–c** which are important intermediates in the synthesis of the bipyridyldiphosphane ligands **6a–c** (Scheme 1), three different approaches had to be investigated. The diol **4a** was obtained in a conventional four-step process, starting with 5,5′-dimethyl-2,2′-bipyridine.[11a] Chlorination with *N*-chlorosuccinimide afforded compound **1** in which both chlorides were subsequently exchanged by

Scheme 2. Tetraphosphadiplatinacyclophanes **7c**, **8b**, and **9b** [R = H (**8b**), *t*Bu (**9b**)]

cyanides to achieve chain propagation. Acid catalyzed ethanolysis of **2** led to the bifunctionalized ester **3**, which was finally reduced with $LiAlH_4$ to form the target molecule **4a**. In contrast, the diols **4b**[12] and **4c** were made accessible in a one pot reaction. In both cases, 5,5′-dimethyl-2,2′-bipyridine was consecutively deprotonated with lithium diisopropylamide and reacted with oxirane and 1-tetrahydropyranyloxy-3-iodopropane,[13] respectively.

Treatment of the diols **4a–c** with mesyl chloride resulted in the formation of the corresponding dimesylates **5a–c**. This excellent leaving group was then replaced for phosphanes by the reaction of **5a–c** with $LiPPh_2$ to give the bipyridyldiphosphanes **6a–c**. The compounds **6a–c** were obtained as colorless, slightly air-sensitive solids, which were soluble in all common organic solvents with the exception of hydrocarbons and alcohols. Their molecular composition was corroborated by FAB mass spectra displaying in each case the expected molecular peak. Both phosphorus donors in **6a–c** are chemically equivalent, giving rise to a singlet each between δ = –15.1 and –15.5 in the $^{31}P\{^1H\}$-NMR spectra ($CDCl_3$).

Platinacyclophanes

Under high-dilution conditions, the bipyridyldiphosphane ligand **6c** reacted with bis(benzonitrile)dichloroplatinum(II)[14] in CH_2Cl_2 to give the 38-membered macrocycle **7c** in remarkably good yields (Scheme 2). An ES mass spectrum confirmed the dinuclear assembly of this molecule. Owing to the 5,5′-substitution pattern in **6c**, the formation of the undesired mononuclear cyclophane was successfully prevented. From a dichloromethane solution **7c** precipitated as a colorless, thermally stable solid when this solvent was removed in vacuo. It is only slightly soluble in dichloromethane and hot chloroform.

The $^{31}P\{^1H\}$-NMR spectrum of **7c** (in CD_2Cl_2) displayed a singlet at δ = 8.4 which was assigned to the four chemically equivalent phosphorus atoms, and a doublet for the ^{195}Pt satellites. The coupling constant of 3646 Hz is typical for a *cis*-$PtCl_2$ arrangement.[15] In the downfield part of the $^{13}C\{^1H\}$-NMR spectrum of **7c** (in CD_2Cl_2), six singlets and three complex multiplets resulting from AXX′ spin systems were assigned to the five bipyridine- and *para*-substituted carbon atoms of the $P(C_6H_5)_2$ units and to the *ipso*-, *ortho*-, and *meta*-carbon atoms of the phosphorus-bound phenyl groups, respectively.[15] Two further AXX′ patterns at δ = 30.0 and 25.4 were ascribed to the α- and β-carbon atoms of the alkyl chain adjacent to the phosphorus atom.[15] Finally, a multiplet at δ = 32.5 consisted of overlapping peaks of the aliphatic γ- and δ-carbon atoms.

Analogous reactions of the bipyridyldiphosphanes **6a**,**b** with bis(benzonitrile) dichloroplatinum(II) afforded poorly soluble products of either polymers or platinacyclophanes, and hence no distinction or separation was possible. Since the solubility of platinacyclophanes of the above-mentioned type is strongly dependent on the kind of the ligands attached to platinum, for further reactions cyclooctadienediphenylplatinum(II)[16] was employed as a starting material. When (COD)Pt(C_6H_5)$_2$ was allowed to react with the ligands **6a**–**c** under high-dilution conditions, soluble products could be obtained. However, only the tetraphosphadiplatinacyclophane **8b** was isolated in acceptable yields (Scheme 2). In the case of **8a**,**c** not only were the yields very low, but several by-products were also formed. The reasons for this behavior can be summarized as follows: (i) owing to the chelate effect of cyclooctadiene and the strengthening of the metal–carbon π back bond caused by the *trans*-positioned phenyl ligands which are strong σ donors, cyclooctadienediphenylplatinum(II) does not react as fast as bis(benzonitrile)dichloroplatinum(II).[16] This decrease in reaction rate exerts a negative impact on the effectiveness of the high dilution method.[17] (ii) In the case of the employment of cyclooctadienediphenylplatinum, the coordination of the bipyridine moiety in the ligands **6a**–**c** to platinum occurs as a side reaction. Although the ratio of coordinated bipyridine to phosphane is very low, this phenomenon upsets the exact stoichiometry of the starting compounds and favours an undesired polymerization. Nevertheless, the tetraphosphadiplatinacyclophane **8b** was obtained in more than 20% yield, while the isolation of the corresponding tetraphosphadiplatinacyclophanes **8a** and **8c** with shorter and longer alkyl chains failed. This suggested that the size of the 34-membered macrocycle **8b** represents an entropic maximum or enthalpic minimum with regard to the cyclization.[18]

By slow evaporation of the solvent, **8b** crystallized from a mixture of dichloromethane and methanol in the form of pale yellow plates, which were temperature-sensitive and dissolved readily in halogenated hydrocarbons and hot benzene. An FAB mass spectrum of **8b** displayed the expected molecular peak at *m*/*z* = 1915. The $^{31}P\{^1H\}$-NMR spectrum (in CD_2Cl_2) consisted of a singlet at δ = 8.8 along with a doublet for the ^{195}Pt satellites with a coupling constant of 1773 Hz, typical for the *cis*-diphenyldiphosphaneplatinum(II) fragment.[19] The downfield part of the $^{13}C\{^1H\}$-NMR spectrum of **8b** revealed six singlets and three AXX′ spin systems[20] which could be assigned in the same way as in the corresponding spectrum of **7b**. Additionally, three singlets and one AXX′ pattern with platinum satellites were ascribed to the carbon atoms of the Pt(C_6H_5)$_2$ unit.[19] In the upfield part of the spectrum, three AXX′ patterns were found, which were assigned to the three methylene groups of the alkyl chain.

The introduction of diareneplatinum(II) in the synthesis of metallacyclophanes creates a new possibility for tuning the properties of such compounds by varying the aromatic core. In the last years, a plethora of diareneplatinum(II) compounds with different properties with regard to crystallization, solubility, reactivity, and steric demand of the organometallic fragment was reported.[21] To investigate the practicability of these variations a bulky *tert*-butyl group was introduced in the *para*-position of the phenyl ligand. To achieve this goal, bis(*tert*-butylphenyl)cyclooctadieneplatinum(II)[19] was treated with the bipyridyldiphosphane **6b** under high-dilution conditions in CH_2Cl_2. The resulting macrocycle **9b** was obtained in a comparable yield to **8b**, but crystallized even better, which simplified the isolation of the compound. The $^{31}P\{^1H\}$- and $^{13}C\{^1H\}$-NMR spectra of **9b** were similar to those of **8b**, but revealed two additional singlets, related to the *tert*-butyl group in the former case. The FAB mass spectrum displayed the expected molecular peak at *m*/*z* = 2138.

X-ray Crystal Structures of 8b and 9b

Crystals of the tetraphosphadiplatinacyclophanes **8b** and **9b**, suitable for X-ray crystallography were obtained by slow concentration of a solution of **8b**, **9b** in dichloromethane/methanol. ORTEP diagrams of the molecular structures of **8b**, **9b** with atomic labeling are depicted in Figure 1 and Figure 2, respectively. Because of disordered solvent molecules, the diffraction data are of somewhat restricted quality which, however, is not unusual for macrocycles of the size presented in this investigation.[8,9,10b,22] Surprisingly, both structures are rather similar, despite the steric congestion of the bulky *tert*-butyl groups in **9b**. In both cases, the cavity has the shape of a parallelogram, with edges of lengths of 10.00(2)/11.83(2) Å and 9.92(4)/11.77(3) Å (C16–C3A/C16–C3) for **8b** and **9b**, respectively. The vertices of these parallelograms are occupied by the atoms C3, C3A and C16, C16A with distances of 15.84(3)/15.14(3) Å (**8b**) and 14.58(3)/16.18(6) Å (**9b**). The Pt1–Pt1A distances are 9.782(2) Å (**8b**) and 9.645(3) Å (**9b**). Owing to the center of inversion, the opposite pyridyl units are arranged face to face. The normals of the adjacent pyridyl rings form angles of 15.6(9)° (**8b**) and 14.8(9)° (**9b**). Also very similar are the distances of the bridging atoms of the opposite bipyridine groups (C7–C10A) with 12.08(2) Å (**8b**) and 12.07(3) Å (**9b**). In **8b** and **9b**, one P–phenyl and both Pt–phenyl substituents point to the interior of the macrocycle and exert a shielding effect on the access to the cavity. Nevertheless, a water molecule is encapsulated in **8b** which is not the case in **9b** containing additional bulky and hydrophobic *tert*-butyl groups. Remarkably, the water molecules in **8b** are located in the center of the macrocycle and simultaneously at the vertices of the triclinic unit cell (Figure 3). The two platinum atoms of each macrocycle and the encapsulated water molecule are arranged on an axis, which is indicated by dotted lines. Figure 3 demonstrates the appearance of tubes formed by the macrocycles along the *b* axis.

Encapsulation of Copper(I)

The tetraphosphadimetallacyclophanes **7c**, **8b**, and **9b** are provided with bipyridine units, which are available to coordinate transition metals which prefer a tetrahedral envir-

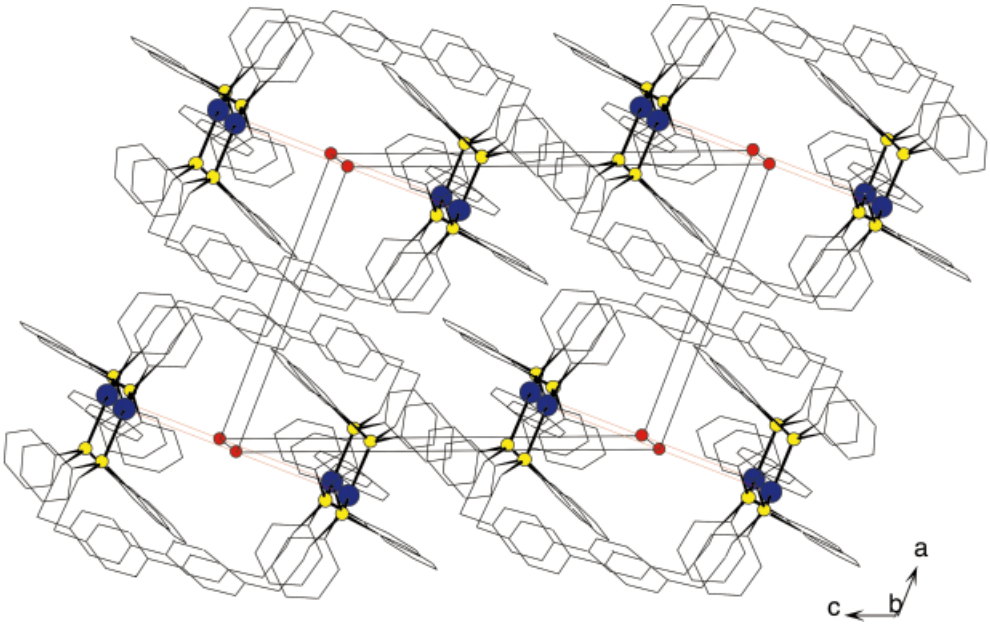
Figure 1. Figure 2. Molecular structure of **9b** · 2 CH_2Cl_2 in the crystal; ORTEP plot with thermal ellipsoids at 20% probability; hydrogen atoms are omitted for clarity; selected distances [A]: Pt1–CA1 = Pt1A–CA1A = 2.03(2), Pt1–CB1 = Pt1A–CB1A = 2.08(2), Pt1–P1 = Pt1A–P1A = 2.310(6), Pt1–P2 = Pt1A–P2A = 2.315(5)

onment. The incorporation of the bipyridine ligands into a macrocyclic framework should enhance the stability of such a complex. This phenomenon is known as the macrocyclic effect.[23] Owing to its better solubility, the macrocycle **8b** was chosen for encapsulation studies. Upon treatment of a solution of **8b** in dichloromethane with $[Cu(NCMe)_4][BF_4]$,[24] its color immediately turned from pale yellow to deep red, indicating the formation of a bis(bipyridine)copper(I) complex. Indeed, after purification the host/guest compound **10b** (Scheme 3) was obtained as a red–brown solid, which was air- and temperature-sensitive. An FAB mass spectrum confirmed the composition of **10b**. The $^{31}P\{^1H\}$-NMR spectrum of **10b** was still characterized by a singlet (δ = 9.8) along with two platinum satellites ($^1J_{PtP}$ = 1778 Hz). Only the ^{13}C-NMR signals of the bipyridine framework show a difference in chemical shifts of up to



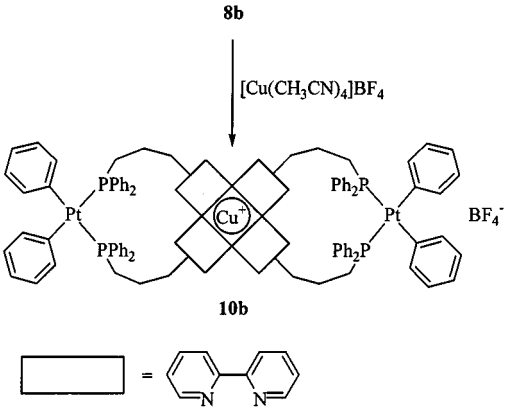


Figure 3. A view of the tubes formed by the macrocycle **8b** along the *b* axis of the crystal

Scheme 3. Encapsulation of copper(I) into the macrocycle **8b**

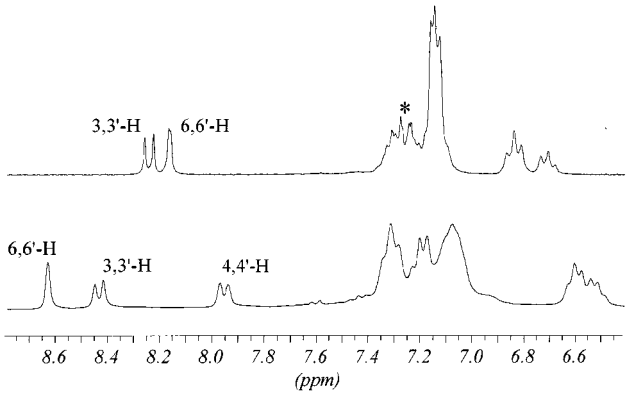

Figure 4. Comparison of the aromatic part of the ^{1}H-NMR spectra of **8b** (top) and **10b** (bottom); resonances of protons of the bipyridine units are labeled; the asterisk marks the position of the 4,4′-H resonances of the bipyridine units in **8b** as determined by a 2D COSY NMR experiment

4.5 ppm, which was traced back to the coordination of copper(I); all other ^{13}C resonances were similar to those of **8b**. A comparison of the downfield part of the ^{1}H-NMR spectra of **10b** and **8b** showed that the resonances of the bipyridine protons also underwent remarkable shifts (Figure 4). The tetrahedral coordination of copper(I)[25] is responsible for a lowering of the symmetry causing a prochirality of the protons of the alkyl chain in **10b**.[26] Because of this prochirality, their ^{1}H-NMR signals are broadened, which is rationalized by an ABCDEFXX′ spin system. In particular, the ^{1}H-NMR signals of the γ-methylene groups adjacent to the bipyridine backbone were examined by a comparison of the HMQC spectra of **10b** and **8b**. As a result, the change of the splitting pattern from a triplet (**8b**) to *two* multiplets (**10b**) is observed, which is explained by the magnetic nonequivalence of the two protons, caused by their prochirality. Apart from a slight broadening of the ^{1}H and ^{13}C resonances, no chemical exchange effects[27] were observed, which is in agreement with the use of the non-coordinating counterion[27b,28] and solvent,[29] the chelate effect of the macrocyclic ligand,[23,30] the shielding of the copper center by the bulky organometallic units, and the rigidity of the host/guest complex **10b**. In the ^{19}F-NMR spectrum of **10b**, the presence of the counterion BF_4^- is confirmed by a singlet at $\delta = -153.0$. An intensive absorption at 1056 cm^{-1} in the IR spectrum is assigned to the triply degenerate BF_3 vibration.

The electrochemical behavior of the host/guest complex **10b** was investigated by cyclic voltammetry. A quasi-reversible wave at $E_{1/2} = -0.31$ V vs. fc/fc$^+$ in CH_2Cl_2/CH_3CN was attributed to the Cu^I/Cu^{II} redox system. The $E_{1/2}$ value was similar to that of $[Cu(bipy)_2]^+$ [31] and its derivatives which are not substituted at the 6-position.[32] Typical of the low $E_{1/2}$ value was the easy and fast oxidation of copper(I) to copper(II) when a solution of **10b** was exposed to air. This was accompanied by a change in color from deep red to green.[33] Obviously, the above-mentioned stabilization of the bis(bipyridine)copper(I) complex does not include inertness toward oxygen, which can only be achieved by the introduction of substituents at the 6-position.[34,35]

On the other hand, such air-sensitive bis(bipyridine)copper(I) systems have applications in the field of redox catalysis.[36,37]

A electrodeposition–redissolution peak system at $E_{1/2}$ = –0.79 V is traced back to the formation of copper(0) at the surface of the working electrode.[31] Finally, an irreversible peak was found at 0.92 V caused by the oxidation of the diphenyldiphosphaneplatinum(II) fragment.

Conclusion

The incorporation of transition metals into the framework of cyclophanes has opened new perspectives in the field of macrocyclic chemistry.[5–9] Most of these systems were constructed using phosphorus or nitrogen donor functions and in particular they were provided with diphenylphosphane or bipyridine units.[9] However, surprisingly little attention has been paid to systems which combine both types of these ligand systems.[10] In the present investigation, the synthesis of new hybrid bipyridylphosphane ligands was introduced, enabling the formation of metallacyclophanes by the employment of P donors only. Major problems that had to be overcome to achieve the desired binuclear macrocycles were the formation of polymers, the premature complexation of bipyridine as a side reaction, and the poor solubility of the products. These drawbacks could largely be eliminated by variation of both the organometallic fragment and the length of the alkyl chain between the bipyridine and the phosphane units. As a result of these examinations, the tetraphosphadiplatinacyclophanes **8b** and **9b** were obtained, which exhibit satisfactory solubility and crystallization properties. At least two methylene groups between bipyridine and the phosphane were a prerequisite for sufficient flexibility to include tetrahedrally coordinated transition metals. The occurrence of undesirable mononuclear products was successfully prevented by the 5,5′-substitution pattern at the bipyridine cores. Owing to the presence of bipyridines which were still uncoordinated and the solubility of the macrocycle **8b** in solvents of medium polarity, it was possible to encapsulate copper(I) in **8b**. The resulting host/guest complex **10b** has three metal atoms with different coordination environments. The macrocycles described in this publication also represent an important step in the design of organometallic analogues of the tris(bipyridine) cages published by Vögtle et al.[11]

Experimental Section

General: All reactions were carried out under dry argon. Solvents were dried with appropriate reagents and stored under dry argon. – Column chromatography was performed using activated silica gel, 0.063–0.200 mm (Merck); column dimensions are reported in the specific sections describing the synthesis of the respective compounds. – Elemental analyses were carried out with a Carlo Erba 1106 and an Elementar Vario EL analyzer. Cl and S analyses were carried out according to Schöniger.[38] Chlorine and sulphur were determined as described by Dirscherl and Erne[39] according to Brunisholz and Michot,[40] and Wagner,[41] respectively. Copper and platinum were quantitatively analyzed with a Varian AA20 spectrometer. – Mass spectra: EI-MS Finnigan TSQ 70 (200 °C). FD- and FAB-MS: Finnigan 711A (8 kV), modified by AMD. ESI spectra were recorded with a triple-quadrupole mass spectrometer API III (Sciex, Thornhill, Canada) equipped with a nebulizer-assisted electrospray source. – FT-IR: Bruker IFS 48. – ^{1}H, ^{13}C{^{1}H}, ^{31}P{^{1}H}, and ^{19}F{^{1}H} NMR: Bruker DRX 250 spectrometer operating at 250.13, 62.90, 101.26, and 235.33 MHz, respectively. ^{1}H chemical shifts were referenced to the residual proton peaks of the solvent and are quoted in ppm downfield from TMS. ^{13}C chemical shifts were calibrated against the deuterated solvent multiplets and referenced to TMS. ^{31}P chemical shifts were measured relative to external 85% H_3PO_4 with downfield values being taken as positive. ^{19}F chemical shifts were measured relative to external 0.05% 1,3,5-trifluorotoluene. The assignment of the signals has been supported by DEPT-135 (Distortionless Enhancement by Polarization Transfer), homonuclear, and heteronuclear correlation spectra, when necessary. – The electrochemical experiments were performed with a Bioanalytical Systems (BAS, West Lafayette, IN) CV-50 W electrochemical workstation controlled by a standard 80486 personal computer (control program version 2.0). For electroanalytical experiments a Metrohm Pt electrode tip (Filderstadt, Germany) was used as working electrode. The counter electrode was a Pt wire of 1 mm diameter. A single-unit Habber–Luggin double reference-electrode[42] was used. The resulting potential values refer to Ag/Ag^+ (0.01 M in CH_3CN/0.1 M NBu_4PF_6). Ferrocene was used as an external standard. Its potential was determined by separate cyclic voltammetric experiments in the respective solvent, and all potentials were rescaled to $E°$(fc/fc^+) (0.145 V in CH_2Cl_2/CH_3CN vs Ag/Ag^+). All potentials in the present paper are reported relative to the fc/fc^+ standard.[43] For cyclic voltammetry, a gas-tight full-glass three-electrode cell was used: its assembly for the experiments has been described.[44] The cell was purged with argon before it was filled with the electrolyte. Background curves were recorded before adding the substrate to the solution. These were later subtracted from the experimental data with substrate. The automatic BAS CV-50 W *iR*-drop compensation facility was used for all experiments. – *N*-Chlorosuccinimide, lithium aluminum hydride, oxirane, ferrocene, and methanesulfonyl chloride were of commercial grade and used without further purification; the latter was stored under argon. 5,5′-Dimethyl-2,2′-bipyridine,[11] 1-tetrahydropyranyloxy-3-iodopropane,[13] lithium diphenylphosphide,[45] bis(benzonitrile)-dichloroplatinum(II),[14] cyclooctadienediphenylplatinum(II),[16] and bis(*tert*-butylphenyl)cyclooctadieneplatinum(II)[19] were synthesized according to literature methods.

5,5′-Bis(chloromethyl)-2,2′-bipyridine (1): 5,5′-Dimethyl-2,2′-bipyridine (30.0 g, 163.0 mmol), *N*-chlorosuccinimide (52.2 g, 391.2 mmol), and benzoyl peroxide (500 mg, 1.74 mmol) were suspended in CCl_4 (1300 mL). The suspension was heated at reflux for 48 h, and filtered hot (P3). The filtrate was concentrated to 200 mL under reduced pressure and the precipitated product was collected on a filter (P3). The crude product was purified by recrystallization from benzene. Yield 20.9 g (50.6%), colorless solid, m.p. 165 °C. – ^{1}H NMR ($CDCl_3$): δ = 8.67 (d, $^4J_{HH}$ = 2.0 Hz, 2 H, 6,6′-H, bipy), 8.40 (d, $^3J_{HH}$ = 8.2 Hz, 2 H, 3,3′-H, bipy), 7.86 (dd, $^3J_{HH}$ = 8.2 Hz, $^4J_{HH}$ = 2.0 Hz, 2 H, 4,4′-H, bipy), 4.64 (s, 4 H, CH_2Cl). – ^{13}C{^{1}H} NMR ($CDCl_3$): δ = 155.7 (s, C, bipy), 149.2 (s, CH, bipy), 137.4 (s, CH, bipy), 133.6 (s, C, bipy), 121.3 (s, CH, bipy), 43.2 (s, CH_2Cl). – MS (EI); *m/z*: 252.0 [M^+]. – $C_{12}H_{10}Cl_2N_2$ (253.1): calcd. C 56.94, H 3.98, Cl 28.01, N 11.07; found C 57.10, H 3.83, Cl 27.91, N 10.95.

5,5′-Bis(cyanomethyl)-2,2′-bipyridine (2): Compound **1** (15.0 g, 59.3 mmol) was dissolved in a mixture of ethanol (400 mL) and concentrated hydrochloric acid (7 mL). This solution was added dropwise over a period of 30 min to a refluxing solution of sodium cyanide (23.6 g, 480.6 mmol) in 500 mL of water and 500 mL of ethanol (***Caution: Generation of hydrogen cyanide!***). The solution was then heated at reflux for further 2 h and concentrated to a volume of 200 mL under reduced pressure. The remaining solution was diluted with 800 mL of water and the solution was stirred for 30 min. The precipitated product was filtered (P3) and washed with water (2 × 100 mL). The residue was dissolved in 300 mL of acetone and filtered (P3). The solvent of the filtrate was evaporated to dryness to give the crude product, which was used without further purification. Yield 8.3 g (59.3%), brown solid. For analytical data **2** was purified by sublimation and a colorless solid was obtained, m.p. 197 °C. – IR (KBr): $\tilde{\nu}$ = 2256 cm^{-1} (CN). – ^1H NMR ([D$_6$]acetone): δ = 8.72 (d, $^4J_{HH}$ = 1.9 Hz, 2 H, 6,6′-H, bipy), 8.51 (d, $^3J_{HH}$ = 8.2 Hz, 2 H, 3,3′-H, bipy), 7.99 (dd, $^3J_{HH}$ = 8.2 Hz, $^4J_{HH}$ = 1.9 Hz, 2 H, 4,4′-H, bipy), 4.14 (s, 4 H, CH_2CN). – $^{13}C\{^1H\}$ NMR ([D$_6$]acetone): δ = 155.9 (s, C, bipy), 149.8 (s, CH, bipy), 137.7 (s, CH, bipy), 129.0 (s, C, bipy), 121.6 (s, CH, bipy), 118.6 (s, CH_2CN), 21.0 (s, CH_2CN). – MS (EI); *m*/*z*: 234.0 [M$^+$]. – $C_{14}H_{10}N_4$ (234.3): calcd. C 71.78, H 4.30, N 23.92; found C 71.80, H 4.14, N 23.37.

Diester 3: To a suspension of **2** (7.7 g, 32.9 mmol) in 500 mL of ethanol, at 0 °C dry hydrogen chloride was added until saturation was achieved. The solution was heated at reflux for 18 h and concentrated to dryness under reduced pressure. The residue was suspended in 200 mL of water, neutralized with $NaHCO_3$, and extracted with ethyl acetate (2 × 300 mL). The combined organic layers were dried with Na_2SO_4, filtered (P3), and the solution was concentrated to dryness under reduced pressure. The product was purified by column chromatography (ethyl acetate, diameter/length of column 7/50 cm). Yield 5.3 g (48.8%), colorless solid. – M.p. 76 °C. – IR (KBr): $\tilde{\nu}$ = 1736 cm^{-1} (CO). – ^1H NMR ($CDCl_3$): δ = 8.52 (d, $^4J_{HH}$ = 2.0 Hz, 2 H, 6,6′-H, bipy), 8.30 (d, $^3J_{HH}$ = 8.1 Hz, 2 H, 3,3′-H, bipy), 7.69 (dd, $^3J_{HH}$ = 8.1 Hz, $^4J_{HH}$ = 2.0 Hz, 2 H, 4,4′-H, bipy), 4.10 (q, $^3J_{HH}$ = 7.1 Hz, 4 H, $COOCH_2CH_3$), 3.61 (s, 4 H, $CH_2COOC_2H_5$), 1.18 (t, $^3J_{HH}$ = 7.1 Hz, 6 H, $COOCH_2CH_3$). – $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 154.6 (s, C, bipy), 149.6 (s, CH, bipy), 137.6 (s, CH, bipy), 129.8 (s, C, bipy), 120.5 (s, CH, bipy) 61.0 (s, $COOCH_2CH_3$), 38.2 (s, $CH_2COOC_2H_5$), 14.0 (s, $COOCH_2CH_3$). – MS (EI); *m*/*z*: 328.1 [M$^+$]. – $C_{18}H_{20}N_2O_4$ (328.4): calcd. C 65.84, H 6.14, N 8.53; found C 65.52, H 6.14, N 8.56.

Diol 4a: Lithium aluminum hydride (1.18 g, 31.03 mmol) was suspended in 100 mL of THF and the suspension was added dropwise to an ice-cold solution of **3** (5.09 g, 15.50 mmol) in 200 mL of THF. The resulting suspension was stirred for 4 h at room temperature, then cautiously quenched with water and concentrated to dryness. The residue was dissolved in 120 mL of water and extracted continuously with diethyl ether for 48 h. The organic layer was dried with Na_2SO_4, filtered (P3), and concentrated. The crude product was purified using column chromatography (dichloromethane/methanol, 7:1, diameter/length of column 7/50). Yield 2.15 g (56.8%), colorless solid, m.p 146 °C. – ^1H NMR (CD_3OD): δ = 8.49 (d, $^4J_{HH}$ = 2.0 Hz, 2 H, 6,6′-H, bipy), 8.14 (d, $^3J_{HH}$ = 8.2 Hz, 2 H, 3,3′-H, bipy), 7.79 (dd, $^3J_{HH}$ = 8.2 Hz, $^4J_{HH}$ = 2.0 Hz, 2 H, 4,4′-H, bipy), 3.82 (t, $^3J_{HH}$ = 6.7 Hz, 4 H, CH_2CH_2OH), 2.90 (t, $^3J_{HH}$ = 6.7 Hz, 4 H, CH_2CH_2OH). – $^{13}C\{^1H\}$ NMR (CD_3OD): δ = 154.7 (s, C, bipy), 150.3 (s, CH, bipy), 139.1 (s, CH, bipy), 136.4 (s, C, bipy), 122.1 (s, CH, bipy), 63.1 (s, CH_2CH_2OH), 36.7 (s, CH_2CH_2OH). – MS (EI); *m*/*z*: 244.1 [M$^+$]. – $C_{14}H_{16}N_2O_2$ (244.3): calcd. C 68.83, H 6.60, N 11.47; found C 68.31, H 6.11, N 11.27.

Diol 4b: A freshly prepared solution of 100.0 mmol of lithium diisopropylamide in 375 mL of a 1:2 mixture of *n*-hexane and THF was added dropwise to a solution of 5,5′-dimethyl-2,2′-bipyridine (18.4 g, 100.0 mmol) in 700 mL of THF at –50 °C. The solution was then allowed to warm to room temperature and stirred for 1 h. Then it was cooled to –50 °C and oxirane (4.9 g, 111.4 mmol) was added. Subsequently the solution was heated to 40 °C for 4 h, while the condenser was kept at –30 °C. The complete procedure had to be repeated. The solution was then quenched with a saturated aqueous NH_4Cl solution until pH = 7 was achieved. THF was removed under reduced pressure and the resulting suspension was extracted seven times with a 2:1 mixture of dichloromethane and ethyl acetate. The combined organic layers were dried with Na_2SO_4, filtered (P3), and concentrated. The crude product was purified by column chromatography (dichloromethane/methanol, 10:1, diameter/length of column 7/50). Yield 6.32 g (23.2%), colorless solid, m.p. 119 °C. – ^1H NMR (CD_3OD): δ = 8.47 (d, $^4J_{HH}$ = 2.0 Hz, 2 H, 6,6′-H, bipy), 8.14 (d, $^3J_{HH}$ = 8.2 Hz, 2 H, 3,3′-H, bipy), 7.75 (dd, $^3J_{HH}$ = 8.2 Hz, $^4J_{HH}$ = 2.0 Hz, 2 H, 4,4′-H, bipy), 3.59 (t, $^3J_{HH}$ = 6.3 Hz, 4 H, $CH_2CH_2CH_2OH$), 2.76 (t, $^3J_{HH}$ = 7.8 Hz, 4 H, $CH_2CH_2CH_2OH$) 1.86 (m, 4 H, $CH_2CH_2CH_2OH$). – $^{13}C\{^1H\}$ NMR (CD_3OD): δ = 155.0 (s, C, bipy), 150.3 (s, CH, bipy), 139.5 (s, CH, bipy), 138.7 (s, C, bipy), 122.3 (s, CH, bipy), 61.9 (s, $CH_2CH_2CH_2OH$), 35.0 (s, $CH_2CH_2CH_2OH$), 30.0 (s, $CH_2CH_2CH_2OH$). – MS (EI); *m*/*z*: 272.1 [M$^+$]. – $C_{16}H_{20}N_2O_2$ (272.3): calcd. C 70.56, H 7.40, N 10.29; found C 70.40, H 7.35, N 10.34.

Diol 4c: A freshly prepared solution of 100.0 mmol of lithium diisopropylamide in 375 mL of a 1:2 mixture of *n*-hexane and THF was added dropwise to a solution of 5,5′-dimethyl-2,2′-bipyridine (18.4 g, 100.0 mmol) in 700 mL of THF at –50 °C. The solution was allowed to warm to room temperature and stirred for 1 h. Then it was cooled to –78 °C and 1-iodo-3-(tetrahydropyranyloxy)propane (28.4 g, 105.2 mmol) was added dropwise. The solution was allowed to warm to room temperature and stirred for 30 min. The complete procedure was repeated. The solution was then quenched with 1 M hydrochloric acid until pH = 0 was achieved, stirred for an additional hour and neutralized with $NaHCO_3$. THF was removed under reduced pressure and the resulting suspension was extracted seven times with a 2:1 mixture of dichloromethane and ethyl acetate. The combined organic layers were dried with Na_2SO_4, filtered (P3), and concentrated. The crude product was purified by column chromatography (dichloromethane/methanol, 10:1, diameter/length of column 7/50). Yield 6.11 g (20.4%), colorless solid, m.p. 109 °C. – ^1H NMR (CD_3OD): δ = 8.48 (d, $^4J_{HH}$ = 2.1 Hz, 2 H, 6,6′-H, bipy), 8.17 (d, $^3J_{HH}$ = 8.1 Hz, 2 H, 3,3′-H, bipy), 7.80 (dd, $^3J_{HH}$ = 8.1 Hz, $^4J_{HH}$ = 2.1 Hz, 2 H, 4,4′-H, bipy), 3.57 (t, $^3J_{HH}$ = 6.3 Hz, 4 H, $CH_2CH_2CH_2CH_2OH$), 2.73 (t, $^3J_{HH}$ = 7.5 Hz, 4 H, $CH_2CH_2CH_2CH_2OH$) 1.74 (m, 4 H, CH_2), 1.59 (m, 4 H, CH_2). – $^{13}C\{^1H\}$ NMR (CD_3OD): δ = 155.1 (s, C, bipy), 150.4 (s, CH, bipy), 140.0 (s, CH, bipy), 138.8 (s, C, bipy), 122.4 (s, CH, bipy), 62.8 (s, $CH_2CH_2CH_2CH_2OH$), 33.6 (s, CH_2), 33.3 (s, CH_2), 28.8 (s, CH_2). – MS (EI); *m*/*z*: 300.1 [M$^+$]. – $C_{18}H_{24}N_2O_2$ (300.4): calcd. C 71.96, H 8.06, N 9.32; found C 72.33, H 8.01, N 9.48.

General Procedure for the Preparation of the Dimesylates 5a–c: Methanesulfonyl chloride (2.50 g, 22.0 mmol) in 20 mL of dichloromethane was added dropwise to a suspension of **5a–c** (10.0 mmol) and triethylamine (2.22 g, 22.0 mmol) in 200 mL of dichloromethane at 0 °C. The reaction mixture was allowed to

warm to room temperature, stirred for 1 h, and washed with 100 mL of a diluted aqueous $NaHCO_3$ solution. The aqueous layer was reextracted with 100 mL of dichloromethane and the combined organic layers were dried with Na_2SO_4, filtered (P3), and concentrated to dryness. The products were washed with 20 mL of cold methanol (0 °C) and dried in vacuo.

Dimesylate 5a: Yield 3.61 g (90.3%), colorless solid, m.p. >130 °C (dec.). – ^{1}H NMR ($CDCl_3$): δ = 8.56 (d, $^4J_{HH}$ = 1.9 Hz, 2 H, 6,6′-H, bipy), 8.35 (d, $^3J_{HH}$ = 8.2 Hz, 2 H, 3,3′-H, bipy), 7.72 (dd, $^3J_{HH}$ = 8.2 Hz, $^4J_{HH}$ = 1.9 Hz, 2 H, 4,4′-H, bipy), 3.13 (t, $^3J_{HH}$ = 6.6 Hz, 4 H, $CH_2CH_2OSO_2CH_3$), 3.13 (t, $^3J_{HH}$ = 6.6 Hz, 4 H, $CH_2CH_2OSO_2CH_3$), 2.93 (s, 6 H, $CH_2CH_2OSO_2CH_3$). – ^{13}C{^{1}H} NMR ($CDCl_3$): δ = 154.8 (s, C, bipy), 149.7 (s, CH, bipy), 137.7 (s, CH, bipy), 132.4 (s, C, bipy), 121.1 (s, CH, bipy), 69.3 (s, $CH_2CH_2OSO_2CH_3$), 37.7 (s, $CH_2CH_2OSO_2CH_3$), 32.9 (s, $CH_2CH_2OSO_2CH_3$). – MS (FD, 30 °C); *m/z*: 400.1 [M$^+$]. – $C_{16}H_{20}N_2O_6S_2$ (400.6): calcd. C 47.99, H 5.03, N 7.00, S 16.01; found C 47.98, H 5.08, N 6.93, S 15.73.

Dimesylate 5b: Yield 3.60 g (84.2%), colorless solid, m.p. >130 °C (dec.). – ^{1}H NMR ($CDCl_3$): δ = 8.54 (d, $^4J_{HH}$ = 2.0 Hz, 2 H, 6,6′-H, bipy), 8.32 (d, $^3J_{HH}$ = 8.1 Hz, 2 H, 3,3′-H, bipy), 7.67 (dd, $^3J_{HH}$ = 8.1 Hz, $^4J_{HH}$ = 2.0 Hz, 2 H, 4,4′-H, bipy), 4.27 (t, $^3J_{HH}$ = 6.2 Hz, 4 H, $CH_2CH_2CH_2OSO_2CH_3$), 3.00 (s, 6 H, $CH_2CH_2CH_2OSO_2CH_3$), 2.84 (t, $^3J_{HH}$ = 7.6 Hz, 4 H, $CH_2CH_2CH_2OSO_2CH_3$), 2.13 (m, 4 H, $CH_2CH_2CH_2OSO_2CH_3$). – ^{13}C{^{1}H} NMR ($CDCl_3$): δ = 154.1 (s, C, bipy), 149.2 (s, CH, bipy), 137.4 (s, CH, bipy), 136.1 (s, C, bipy), 121.1 (s, CH, bipy), 68.8 (s, $CH_2CH_2CH_2OSO_2CH_3$), 37.6 (s, $CH_2CH_2CH_2OSO_2CH_3$), 30.5 (s, $CH_2CH_2CH_2OSO_2CH_3$), 28.8 (s, $CH_2CH_2CH_2OSO_2CH_3$). – MS (FD, 30 °C); *m/z*: 428.0 [M$^+$]. – $C_{18}H_{24}N_2O_6S_2$ (428.6): calcd. General Procedure for the Preparation of the Diphosphanes 6a–c: A freshly prepared solution of lithium diphenylphosphide (1.69 g, 8.8 mmol) in 50 mL of THF was added dropwise to a solution of 8.0 mmol of **6a–c** in 200 mL of THF at –78 °C. The solution was allowed to warm to room temperature, stirred for 30 min and quenched with degassed water. The solvent was completly removed under reduced pressure and the residue was washed two times with 10 mL of cold methanol (0 °C). The remainder was dissolved in 50 mL of dichloromethane, and the solution was filtered (P4), and then concentrated in vacuo.

Diphosphane 6a: Yield 4.23 g (91.1%), colorless, slightly air-sensitive solid, m.p. 156 °C. – ^{1}H NMR ($CDCl_3$): δ = 8.45 (d, $^4J_{HH}$ = 1.9 Hz, 2 H, 6,6′-H, bipy), 8.26 (d, $^3J_{HH}$ = 8.2 Hz, 2 H, 3,3′-H, bipy), 7.59 (dd, $^3J_{HH}$ = 8.2 Hz, $^4J_{HH}$ = 1.9 Hz, 2 H, 4,4′-H, bipy), 7.47–7.27 (m, 20 H, Ph), 2.75 (m, 4 H, $CH_2CH_2PPh_2$), 2.36 (m, 4 H, $CH_2CH_2PPh_2$). – ^{13}C{^{1}H} NMR ($CDCl_3$): δ = 153.8 (s, C, bipy), 149.0 (s, CH, bipy), 138.3–138.0 (m, *ipso*-Ph and C, bipy), 136.9 (s, CH, bipy), 132.8 (d, $^2J_{PC}$ = 18.6 Hz, *ortho*-Ph), 128.9 (s, *para*-Ph), 128.7 (d, $^3J_{PC}$ = 6.4 Hz, *meta*-Ph), 121.1 (s, CH, bipy), 29.9 (d, CH_2), 29.3 (d, CH_2). – ^{31}P{^{1}H} NMR ($CDCl_3$): δ = –15.1 (s). – MS (FAB, 30 °C); *m/z*: 581.3 [M$^+$ + H]. – $C_{38}H_{34}N_2P_2$ (580.6): calcd. C 78.61, H 5.90, N 4.82; found C 78.29, H 5.51, N 4.69.

Diphosphane 6b: Yield 4.30 g (88.4%), colorless, slightly air sensitive solid, m.p. 163 °C. – ^{1}H NMR ($CDCl_3$): δ = 8.45 (d, $^4J_{HH}$ = 2.0 Hz, 2 H, 6,6′-H, bipy), 8.23 (d, $^3J_{HH}$ = 8.1 Hz, 2 H, 3,3′-H, bipy), 7.55 (dd, $^3J_{HH}$ = 8.1 Hz, $^4J_{HH}$ = 2.0 Hz, 2 H, 4,4′-H, bipy), 7.42–7.28 (m, 20 H, Ph) 2.78 (t, $^3J_{HH}$ = 7.2 Hz, 4 H, $CH_2CH_2CH_2PPh_2$), 2.06 (m, 4 H, $CH_2CH_2CH_2PPh_2$), 1.73 (m, 4 H, $CH_2CH_2CH_2PPh_2$). – ^{13}C{^{1}H} NMR ($CDCl_3$): δ = 154.3 (s, C, bipy), 149.6 (s, CH, bipy), 138.6 (d, $^1J_{PC}$ = 12.8 Hz, *ipso*-Ph), 137.1 (s, C, bipy), 137.0 (s, CH, bipy), 132.8 (d, $^2J_{PC}$ = 18.5 Hz, *ortho*-Ph), 128.8–128.5 (m, *meta*- and *para*-Ph), 120.6 (s, CH, bipy), 34.1 (d, $^3J_{PC}$ = 13.8 Hz, $CH_2CH_2CH_2PPh_2$), 27.7–27.3 (m, 8 H, $CH_2CH_2CH_2PPh_2$). – ^{31}P{^{1}H} NMR ($CDCl_3$): δ = –15.5 (s). – MS (FAB, 50 °C); *m/z*: 609.0 [M$^+$ + H]. – $C_{40}H_{38}N_2P_2$ (608.7): calcd. C 78.93, H 6.29, N 4.60; found C 79.06, H 6.44, N 4.45.

Diphosphane 6c: Yield 4.51 g (88.6%), colorless, slightly air sensitive solid, m.p. 132 °C. – ^{1}H NMR ($CDCl_3$): δ = 8.41 (d, $^4J_{HH}$ = 2.0 Hz, 2 H, 6,6′-H, bipy), 8.20 (d, $^3J_{HH}$ = 8.2 Hz, 2 H, 3,3′-H, bipy), 7.50 (dd, $^3J_{HH}$ = 8.2 Hz, $^4J_{HH}$ = 2.0 Hz, 2 H, 4,4′-H, bipy), 7.43–7.25 (m, 20 H, PPh_2), 2.60 (t, $^3J_{HH}$ = 7.6 Hz, 4 H, $CH_2CH_2CH_2CH_2PPh_2$), 2.06 (m, 4 H, $CH_2CH_2CH_2CH_2PPh_2$), 1.87–1.68 (m, 8 H, $CH_2CH_2CH_2CH_2PPh_2$). – ^{13}C{^{1}H} NMR ($CDCl_3$): δ = 154.1 (s, C, bipy), 149.3 (s, CH, bipy), 138.8 (d, $^1J_{PC}$ = 13.0 Hz, *ipso*-Ph), 137.5 (s, C, bipy), 136.7 (s, CH, bipy), 132.8 (d, $^2J_{PC}$ = 18.5 Hz, *ortho*-Ph), 128.6 (s, *para*-Ph), 128.5 (d, $^3J_{PC}$ = 6.5 Hz, *meta*-Ph), 120.5 (s, CH, bipy), 32.5–32.2 (m, $CH_2CH_2CH_2CH_2PPh_2$ and $CH_2CH_2CH_2CH_2PPh_2$) 28.0 (d, $^1J_{PC}$ = 11.5 Hz, $CH_2CH_2CH_2CH_2PPh_2$), 25.7 (d, $^2J_{PC}$ = 16.2 Hz, $CH_2CH_2CH_2CH_2PPh_2$). – ^{31}P{^{1}H} NMR ($CDCl_3$): δ = –15.3 (s). – MS (FAB, 30 °C); *m/z*: 637.3 [M$^+$ + H]. – $C_{42}H_{42}N_2P_2$ (636.8): calcd. C 79.22, H 6.65, N 4.40; found C 78.83, H 6.70, N 4.21.

Tetrachlorodiplatinacyclophane 7c: Solutions of bis(benzonitrile)-dichloroplatinum(II) (1.35 g, 2.858 mmol) and of **6c** (1.82 g, 2.860 mmol) in 200 mL of dichloromethane each were simultaneously added dropwise within 2 h into 200 mL of dichloromethane. After the solution was stirred for 30 min and concentrated to 10 mL in vacuo, polymeric fractions precipitated. These were removed by filtration (P4) and the filtrate was concentrated to dryness. The residue was washed intensively with *n*-pentane, dissolved in 100 mL of hot chloroform, and the resulting solution was cooled to room temperature, filtered (P4), and concentrated to dryness. Yield: 1.52 g (58.9%), colorless solid, m.p. >290 °C (dec.). – ^{1}H NMR (CD_2Cl_2): δ = 8.35 (d, 4 H, 6,6′-H, bipy), 8.24 (d, $^3J_{HH}$ = 8.1 Hz, 4 H, 3,3′-H, bipy), 7.53–7.18 (m, 44 H, PPh_2 and 4,4′-H, bipy), 2.54 (t, $^3J_{HH}$ = 7.6 Hz, 8 H, $CH_2CH_2CH_2CH_2PPh_2$), 2.12 (m, 8 H, $CH_2CH_2CH_2CH_2PPh_2$), 1.75–1.48 (m, 16 H, $CH_2CH_2CH_2CH_2PPh_2$). – ^{13}C{^{1}H} NMR (CD_2Cl_2): δ = 154.6 (s, C, bipy), 149.8 (s, CH, bipy), 137.9 (s, C, bipy), 137.1 (s, CH, bipy), 134.0 (m,[46] *N* = 9.5 Hz, *ortho*-Ph), 131.7 (s, *para*-Ph), 130.1 (m,[46] *N* = 58.8 Hz, *ipso*-Ph), 129.0 (m,[46] *N* = 10.2 Hz, *meta*-Ph), 120.8 (s, CH, bipy), 32.9–32.1 (m, $CH_2CH_2CH_2CH_2PPh_2$), 30.0 (m,[46] *N* = 39.5 Hz, $CH_2CH_2CH_2CH_2PPh_2$), 25.4 (s br,[14,46] $CH_2CH_2CH_2CH_2PPh_2$). – ^{31}P{^{1}H} NMR (CD_2Cl_2): δ = 8.4 (s, d, $^1J_{PtP}$ = 3646 Hz). – MS (ES); *m/z*: 1769.4 [M$^+$ – Cl]. –

$C_{84}H_{84}Cl_4N_4P_4Pt_2$ (1805.5): calcd. C 55.88, H 4.69, Cl 7.85, N 3.10, Pt 21.61; found C 55.65, H 4.73, Cl 7.70, N 3.41, Pt 20.96.

General Procedure for the Tetraaryldiplatinacyclophanes 8b and 9b: Solutions of cyclooctadienediphenylplatinum(II) or bis(*tert*-butylphenyl)cyclooctadieneplatinum(II) (3.38 mmol) and of **6b** (2.06 g, 3.39 mmol) in 400 mL of dichloromethane each were simultaneously added dropwise during 5 h into 500 mL of dichloromethane. The solution was stirred overnight and concentrated. The residue was purified by column chromatography (dichloromethane/methanol, 50:1, diameter/length of column 7/50) and recrystallized twice from dichloromethane/methanol.

Tetraphenyldiplatinacyclophane 8b: Yield: 670 mg (20.7%), pale yellow plates, m.p. >150 °C (dec.). – ^{1}H NMR (CD_2Cl_2): δ = 8.26 (d, $^3J_{HH}$ = 8.2 Hz, 4 H, 3,3′-H, bipy), 8.18 (d, $^4J_{HH}$ = 2.0 Hz, 4 H, 6,6′-H, bipy), 7.37–7.10 (m, 52 H, Ph_2P, Ph_2Pt and 4,4′-H, bipy), 6.92–6.67 (m, 12 H, Ph_2Pt), 2.19 (t, $^3J_{HH}$ = 6.3 Hz, 8 H, $CH_2CH_2CH_2PPh_2$), 1.65–1.25 (m, 16 H, $CH_2CH_2CH_2PPh_2$). – ^{13}C{^{1}H} NMR (CD_2Cl_2): δ = 161.5 (m,[46] $^1J_{PtC}$ = 840.8 Hz, *ipso*-Ph_2Pt), 154.5 (s, C, bipy), 149.8 (s, CH, bipy), 137.7–136.8 (m, C, bipy, CH, bipy, *ortho*-Ph_2Pt), 133.5 (m,[46] *N* = 10.0 Hz, *ortho*-Ph_2P), 132.9 (m,[46] *N* = 41.3 Hz, *ipso*-Ph_2P), 130.1 (s, *para*-Ph_2P), 128.4 (m,[46] *N* = 8.5 Hz, *meta*-Ph_2P), 127.5 (s, d, $^3J_{PtC}$ = 65.5 Hz, *meta*-Ph_2Pt), 121.6 (s, *para*-Ph_2Pt), 120.4 (s, CH, bipy), 34.2 (m,[46] *N* = 13.5 Hz, $CH_2CH_2CH_2PPh_2$), 27.8 (m,[46] *N* = 33.4 Hz, $CH_2CH_2CH_2PPh_2$), 26.6 (s, br,[14,46] $CH_2CH_2CH_2PPh_2$). – ^{31}P{^{1}H} NMR (CD_2Cl_2): δ = 8.8 (s, d, $^1J_{PtP}$ = 1773 Hz). – MS (FAB, 30 °C); *m/z*: 1915.6 [M^+], 1761.0 [M^+– 2 Ph], 1684.4 [M^+– 3 Ph], 1607.3 [M^+– 4 Ph]. – $C_{104}H_{96}N_4P_4Pt_2$ (1916.0): calcd. C 65.20, H 5.05, N 2.92, Pt 20.36; found C 65.16, H 5.28, N 2.97, Pt 19.95.

Tetrakis(*tert*-butylphenyl)diplatinacyclophane 9b: Yield: 840 mg (23.2%), pale yellow plates, m.p. >145 °C (dec.). – ^{1}H NMR (CD_2Cl_2): δ = 8.25 (d, $^3J_{HH}$ = 8.2 Hz, 4 H, 3,3′-H, bipy), 8.15 (d, $^4J_{HH}$ = 2.0 Hz, 4 H, 6,6′-H, bipy), 7.36–7.12 (m, 52 H, Ph_2P, Ph_2Pt and 4,4′-H, bipy), 6.98–6.89 (m, 8 H, $PtPh_2$), 2.14 (t, $^3J_{HH}$ = 6.3 Hz, 8 H, $CH_2CH_2CH_2PPh_2$), 1.58–1.22 [m, 52 H, $CH_2CH_2CH_2PPh_2$, and $C(CH_3)_3$]. – ^{13}C{^{1}H} NMR (CD_2Cl_2): δ = 157.4 [m,[46] *ipso*-(*tert*-butylPh)$_2$Pt], 154.5 (s, C, bipy), 149.8 (s, CH, bipy), 144.0 [s, *para*-(*tert*-butylPh)$_2$Pt], 137.2 (s, C, bipy) 137.1 (s, CH, bipy), 136.6 [s, d, $^2J_{PtC}$ = 34.8 Hz, *ortho*-(*tert*-butylPh)$_2$Pt], 133.5 (m,[46] *N* = 10.7 Hz, *ortho*-Ph_2P), 133.0 (m,[46] *N* = 41.3 Hz, *ipso*-Ph_2P), 130.0 (s, *para*-Ph_2P), 128.4 (m,[46] *N* = 9.3 Hz, *meta*–Ph_2P), 124.4 [s, d, $^3J_{PtC}$ = 64.0 Hz, *meta*-(*tert*-butylPh)$_2$Pt], 120.6 (s, CH, bipy), 34.3–34.0 [m, $CH_2CH_2CH_2PPh_2$ and $C(CH_3)_3$],

Table 1. Crystal data, data collection and structure refinement for compounds **8b** and **9b**

	8b	**9b**
Crystal data

31.9 [s, C(CH_3)$_3$], 27.7 (m,[46] N = 32.7 Hz, $CH_2CH_2CH_2PPh_2$), 26.5 (s, br,[14,46] $CH_2CH_2CH_2PPh_2$). – $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = 9.1 (s, d, $^1J_{PtP}$ = 1763 Hz). – MS (FAB, 30 °C); *m/z*: 2138.8 [M^+ – H], 1873.5 [M^+ – 2 *tert*-butylPh], 1740.2 [M^+ – 3 *tert*-butylPh], 1607.2 [M^+ – 4 *tert*-butylPh]. – $C_{120}H_{128}N_4P_4Pt_2$ (2140.4): calcd. C 67.34, H 6.03, N 2.62, Pt 18.23; found C 67.11, H 6.06, N 2.44, Pt 17.88.

Copper Complex 10b: $[Cu(CH_3CN)_4][BF_4]$ (47.2 mg, 0.15 mmol) in 4 mL of acetonitrile was added to a solution of **8b** (287.4 mg, 0.15 mmol) in 10 mL of dichloromethane. The solution was stirred for 15 min and concentrated. The residue was dissolved in 10 mL of dichloromethane, precipitated with 40 mL of *n*-pentane, filtered (P4), and washed with benzene/dichlormethane (1:1). Yield: 257.6 mg (83.1%), red-brown, air-sensitive solid. – IR (KBr): $\tilde{\nu}$ = 1056 cm^{-1} (BF_4). – UV/Vis (CD_2Cl_2): χ_{max} = 300.9, 314.2, 433.0 nm. – ^1H NMR (CD_2Cl_2): δ = 8.64 (s, 4 H, 6,6′-H, bipy), 8.44 (d, $^3J_{HH}$ = 8.1 Hz, 4 H, 3,3′-H, bipy), 7.96 (d, $^3J_{HH}$ = 8.1 Hz, 4 H, 4,4′-H, bipy), 7.39–6.98 (m, 48 H, Ph_2P and Ph_2Pt), 6.66–6.47 (m, 12 H, Ph_2Pt), 3.02–1.08 (m, 24 H, $CH_2CH_2CH_2PPh_2$). – $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 161.0 (m,[46] *ipso*-Ph_2Pt), 151.0 (s, C, bipy), 148.4 (s, CH, bipy), 141.7 (s, C, bipy), 139.1 (s, CH, bipy), 137.0 (s, d, $^2J_{PtC}$ = 29.9 Hz, *ortho*-Ph_2Pt), 134.2–132.3 (m, *ipso*- and *ortho*-Ph_2P), 130.0 (s, *para*-Ph_2P), 128.5 (m,[46] N = 8.8 Hz, *meta*-Ph_2P), 127.3 (s, d, $^3J_{PtC}$ = 64.0 Hz, *meta*-Ph_2Pt), 122.3 (s, CH, bipy), 121.5 (s, *para*-Ph_2Pt), 35.0 (m,[46] N = 16.8 Hz, $CH_2CH_2CH_2PPh_2$), 28.6 (s, br,[14,46] $CH_2CH_2CH_2PPh_2$), 26.3 (m,[46] N = 34.9 Hz $CH_2CH_2CH_2PPh_2$). – $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = 9.8 (s, d, $^1J_{PtP}$ = 1778 Hz). – $^{19}F\{^1H\}$ NMR (CD_2Cl_2): δ = –153.0 (s, br). – MS (FAB, 30 °C); *m/z*: 1979.4 [M^+ – BF_4], 1670.4 [M^+ – BF_4 – 4 Ph]. – $C_{104}H_{96}BCuF_4N_4P_4Pt_2 \cdot 2\ CH_2Cl_2$ (2236.2): calcd. C 56.93, H 4.51, Cu 2.84, N 2.51, Pt 17.45; found C 56.59, H 4.32, Cu 2.32, N 2.44, Pt 16.67.

X-ray Structural Determination of the Diplatinacyclophanes 8b · 3 H_2O · 2 CH_2Cl_2 and 9b · 2 CH_2Cl_2: Crystallographic data for both compounds are summarized in Table 1. Single crystals of **8b** and **9b** were obtained from a dichloromethane/methanol solution. Each crystal was mounted on a goniometer head and transferred to a Siemens P4 diffractometer (Mo-K_α radiation, graphite monochromator) and to an Enraf Nonius CAD4 diffractometer (Cu-K_α, graphite monochromator), respectively. Accurate unit cell parameters and orientation matrices were determined by least-squares refinement of setting angles of a set of well-centered reflections. Reduced cell calculations did not indicate higher lattice symmetry for **8b** than $P\bar{1}$, while **9b** crystallizes in the orthorhombic space group *Pbcn*. Data were corrected for LP effects and for observed linear decay. An empirical absorption correction via Ψ-scan was applied for **8b**. The structures were solved by direct methods (SHELXS)[47] and refined by least-squares methods based on F^2 using SHELXL 97.[48] All non-hydrogen atoms except the solvent molecules were refined anisotropically. All hydrogen atoms were located in calculated positions, with the exception of those of the solvent molecules in **8b**. Crystallographic data for both structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-131421 for **8b** and CCDC-131420 for **9b**. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (int. code) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

R. V. wishes to thank the Land Baden-Württemberg for the award of a Ph.D. fellowship (Landesgraduiertenförderungsgesetz). Support of this research by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie is gratefully acknowledged. Degussa AG is thanked for supplying starting materials. We are also indebted to Priv.-Doz. Dr. H. A. Mayer, Institut für Anorganische Chemie, University of Tübingen and Prof. Dr. B. Speiser, Institut für Organische Chemie, University of Tübingen, for helpful discussions regarding the interpretation of the NMR spectra and CV measurements, respectively.

Experimental Evidence for a Second Coordination Sphere Water Molecule in the Hydration Structure of YbDTPA – Insights for a Re-Assessment of the Relaxivity Data of GdDTPA

Kenneth Irvin Hardcastle,*[a] Mauro Botta,*[b] Mauro Fasano,[c] and Giuseppe Digilio[d]

Keywords: Lanthanides / Ytterbium / MRI contrast agents / Solid-state structures / Hydration

The low temperature (–100 °C) X-ray structure of the complex $K_2[Yb(DTPA)(H_2O)]$ has been determined. The metal ion is at the center of a tricapped trigonal prism and is nine-coordinate, binding to the three nitrogens and five oxygens of the ligand and one water molecule. From the structure obtained, three well-defined hydration shells can be observed consisting of: i) one coordinated water molecule; ii) several water molecules in the outer coordination sphere of the Yb^{III} ion and iii) one water molecule surprisingly close to the metal center and hydrogen-bonded to proximate carboxylate groups. A variable-field and temperature NMRD study of the corresponding Gd complex has been performed and the data interpreted by taking into account the presence of second-sphere water molecule(s). The results of the analysis are in excellent agreement with the X-ray structural data.

Introduction

The use of paramagnetic metal complexes to alter the nuclear magnetic relaxation times of water protons in tissues is a well established procedure in clinical diagnosis for enhancing the contrast between healthy and diseased regions in MRI (**M**agnetic **R**esonance **I**maging) images.[1] Currently, about 35% of the MRI examinations are performed with the use of contrast enhancing agents (CA). The most common class of these compounds are neutral or negatively charged polyaminocarboxylate complexes of Gd^{III}, both linear and macrocyclic, which are extracellular, nonspecific CA which rapidly diffuse throughout the body after injection and are excreted via the renal route.[2–4] The first of these complexes to be considered as a CA and to be tested on humans was $[Gd(DTPA)(H_2O)]^{2-}$ ($DTPA^{5-}$ = diethylenetriamine-*N*,*N*′,*N*′′-pentaacetate).[5] Much is known about this compound; the ligand is octadentate and fully exploits its chelating ability towards lanthanide(III) ions to form thermodynamically stable tricapped trigonal structures where one of the capping positions is occupied by a water molecule. In solution the complexes are stereochemically non-rigid and the fluxional process involves conformational inversion of the ethylenediamine rings and rotation of the acetate arms which corresponds to the interconversion between two enantiomeric forms;[6,7] isostructurality across the lanthanide series has been suggested by the analysis of NMR data.[8] The coordination sphere of the Gd^{III} complex is completed by a water molecule that has a mean residence lifetime of about 300 ns at 298 K, as assessed by Merbach et al. by ^{17}O NMR.[9] It is common practice to evaluate the efficacy of a given Gd complex as a CA in terms of the relaxivity parameter, r_{1p} ($mM^{-1}\ s^{-1}$), the net increment in the water proton longitudinal relaxation rate per millimolar concentration of the paramagnetic compound.[1,2] The relaxivity reflects the efficiency of the nuclear-electron dipolar coupling between the nuclear magnetic moment of the water protons and the electronic magnetic moment of the metal ion and is traditionally described on the basis of a model that considers two distinct contributions: *inner sphere*, related to the exchange of the bound water molecule(s) from the coordination site to the bulk, and *outer sphere*, which involves the water molecules diffusing near the paramagnetic center during their translational diffusion.[10] The relaxivity has a strong dependence upon the applied magnetic field strength and from the analysis of this dependence (NMRD, **N**uclear **M**agnetic **R**elaxation **D**ispersion profiles) several important structural and dynamic parameters may be obtained.[11] However, the polar nature of these complexes, featuring negative charges localized on the carboxylate groups, has recently suggested the presence of structured, hydrogen-bonded water molecules in the second coordination sphere of Gd^{III} and thus a possible inadequacy in the physical model used for the interpretation of the relaxation data and the analysis of the NMRD profiles.[1,12–14] The contribution

of second sphere water molecules to r_{1p} has been suggested in a few special cases over the last few years by some indirect evidence, but the possibility of its more general role and its influence on the correct evaluation of the relaxation parameters has not yet been discussed.[15] Here we report on a low temperature single crystal X-ray structural determination of K_2[Yb(DTPA)(H_2O)] where the hydration structure of the complex is clearly detectable and provides firm evidence of a water molecule adjacent to the carboxylate oxygens at a distance sufficiently close to the metal ion to be able to influence significantly the relaxivity of the corresponding Gd^{III} complex. On the basis of these findings, the NMRD data are reinterpreted and the new set of relaxation parameters are found to be in a better agreement with the available structural data.

Results and Discussion

Solid State Structural Characterization

Table 1 lists some selected interatomic distances for K_2[Yb(DTPA)(H_2O)]; the molecular geometry of the anion, [Yb(DTPA)(H_2O)]$^{2-}$, along with associated water molecules is shown in Figure 1. The Yb^{III} ion is surrounded by nine coordinating atoms: three nitrogen atoms, N1, N2, N3, five carboxylato oxygen atoms, O1, O3, O5, O7 and O9 and a bound water molecule, O1 W, which form a tri-capped trigonal prism (TTP) geometry around the central ytterbium ion. The capping atoms are the bound water, O1 W, and N1 and N3 (crystallographic data see Table 2).

Table 1. Selected interatomic distances [Å] for K_2[Yb(DTPA)-(H_2O)]

Yb(1)–N(1)	2.553(5)	Yb(1)–O(5)	2.291(4)
Yb(1)–N(2)	2.553(5)	Yb(1)–O(7)	2.320(4)
Yb(1)–N(3)	2.742(5)	Yb(1)–O(9)	2.303(4)
Yb(1)–O(1)	2.295(4)	Yb(1)–O(1 W)	2.423(4)
Yb(1)–O(3)	2.324(4)	Yb(1)–O(7 W)	4.178(4)
Yb(1)–H(7WA)	3.280(7)	Yb(1)–H(7WB)	4.539(7)

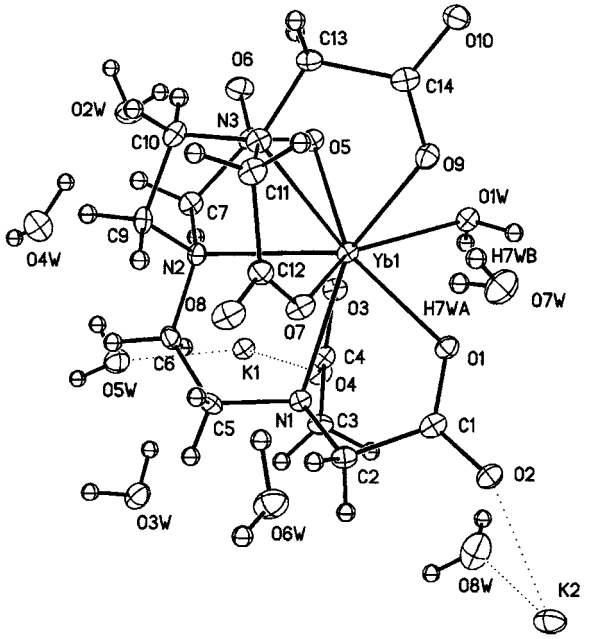

Figure 1. Solid state structure of K_2[Yb(DTPA)(H_2O)]

The geometry of the ligand can also be described as a monocapped square antiprism (CSAP); however, the distortions from a regular geometry are much greater in this configuration than in the trigonal prism geometry. For example, in the trigonal prismatic geometry, only the Yb–N2 distance is significantly longer, 2.553(5) Å, than the Yb–O1, O3, O6, O7, O10 distances, 2.307(4) Å (ave); whereas with the square antiprism geometry, the N1, N2, N3, O7 atom deviations from a regular plane are +0.24, –0.21, +0.25 and –0.28 Å, respectively. The geometry of the anion, [Yb(DTPA)(H_2O)]$^{2-}$ is very similar to that of other lanthanide DTPA complexes of gadolinium[16,17] and neodymium.[18] The bound water molecule to ytterbium ion distance, Yb–O1 W, is 2.423(4) Å, which is significantly shorter than the corresponding distance in the analogous Gd^{III} complex of 2.490 Å. Interestingly, unlike the few structures of lanthanide complexes with DTPA previously reported, in this low temperature X-ray diffraction study we were able to observe the hydration structure of the complex. The structure of K_2[Yb(DTPA)(H_2O)] has eight associated water molecules, one bound water, O1 W, and six water molecules in the outer coordination sphere surrounding the anionic ytterbium complex, at an average distance of 5.8 Å from the Yb to the oxygen atoms of the water molecules. One additional water molecule, O7 W, was located 4.18 Å from the ytterbium atom and strongly hydrogen-bonded to the carboxylate oxygen atoms O1, O7 and O9 at distances of 2.38–2.54 Å, respectively, which are significantly shorter than the van der Waals distance and within the accepted range for hydrogen bonds .

Relaxometry

The water proton longitudinal relaxation rate is strongly enhanced in a solution containing a paramagnetic Gd^{III} complex and the measured value, R_1^{obs} (s^{-1}), is normally resolved into three contributions:

$$R_1^{obs} = R_{1p}^{is} + R_{1p}^{os} + R_1^{w} \quad (1)$$

where R_1^w is the background diamagnetic term, corresponding to the water relaxation rate in a solution of a related diamagnetic derivative, R_{1p}^{is} the represents the contribution arising from exchange ($k_{ex} = 1/\tau_M$) of the metal-bound water molecule(s) from the coordination site to the bulk solvent and R_{1p}^{os} is the contribution associated with the solvent molecules diffusing near the paramagnetic center in the outer coordination sphere. The inner sphere relaxation rate arises from the modulation of the dipolar electron-nucleus interaction by chemical exchange (τ_M), electron spin relaxation (τ_S) and reorientation of the Gd–O_w vector (τ_R) and is described in terms of the following set of Equations:[2,10]

Table 2. Crystal data and structure refinement for $K_2[Yb(DTPA)(H_2O)]$

Identification code	$K_2[YbDTPA(H_2O)]$	
Empirical formula	$C_{14}H_{34}K_2N_3O_{18}Yb$	
Formula weight	783.68	
Temperature	173(2) K

R indices (all data)	$R1$ = 0.0418, $wR2$ = 0.1150	
Largest diff. peak and hole	2.250 and –1.404 e.Å^{-3}	

$$R_{1p}^{is} = \frac{[M]\times q}{55.6} \times \frac{1}{T_{1M} + \tau_M} \quad (2)$$

$$\frac{1}{T_{1M}} = \frac{2}{15}\left(\frac{\mu_0}{4\pi}\right)^2 \frac{\hbar^2\gamma_S^2\gamma_I^2}{r_{GdH}^6} S(S+1)\left[\frac{3\tau_{c1}}{1+\omega_I^2\tau_{c1}^2} + \frac{7\tau_{c2}}{1+\omega_S^2\tau_{c2}^2}\right] \quad (3)$$

$$\frac{1}{\tau_{ci}} = \frac{1}{\tau_M} + \frac{1}{\tau_R} + \frac{1}{\tau_{Si}} \qquad i = 1, 2 \quad (4)$$

$$\left(\frac{1}{\tau_{S1}}\right)^{ZFS} = \Delta^2\tau_v\left(\frac{2.4}{1+\omega_S^2\tau_v^2} + \frac{9.6}{1+4\omega_S^2\tau_v^2}\right) \quad (5)$$

$$\left(\frac{1}{\tau_{S2}}\right)^{ZFS} = \Delta^2\tau_v\left[\frac{5.26}{1+0.372\omega_S^2\tau_v^2} + \frac{7.18}{1+1.24\omega_S\tau_v}\right] \quad (6)$$

In Equations 2–6 [M] is the molar concentration of the paramagnetic complex; q is the number of water molecules coordinated to the metal ion; τ_M is their mean residence lifetime; T_{1M} is their longitudinal relaxation time; S is the electron spin quantum number; γ_H is the proton nuclear magnetogyric ratio; g and β are the electronic g factor and Bohr magneton, respectively; r_{Gd-H} is the distance between the metal ion and the protons of the coordinated water molecules; ω_H and ω_S are the proton and electron Larmor frequencies, respectively; τ_R is the reorientational correlation time; and τ_{S1} and τ_{S2} are the longitudinal and transverse electron spin relaxation times. These latter terms, in analogy with the nuclear magnetic relaxation times, have a frequency dependence which is normally represented by Equations 5 and 6 where τ_v is the correlation time associated with the modulation of the electron-lattice interaction and Δ is the square root of the average quadratic (transient) zero-field splitting tensor. This latter term is often expressed in terms of τ_{S0}, the limiting value of the electronic relaxation time at zero magnetic field, according to the expression:

$$\Delta^2 = \frac{1}{12\tau_{S0}\tau_v} \quad (7)$$

The outer-sphere relaxivity has a dependence on the electronic relaxation times, τ_{S1} and τ_{S2} of the metal ion, on the distance of closest approach of solute and solvent (d), on the sum of solvent and solute diffusion constants (D) and on the magnetic field strength. This term is well described by the Freed equation modified in a form suitable for small paramagnetic metal chelates:

$$R_{1p}^{os} = C^{os}\left(\frac{1}{aD}\right)\left[7J(\omega_S) + 3J(\omega_H)\right] \quad (8)$$

where C^{os} is a constant ($5.8\cdot10^{-13}$ s^{-2}M^{-1}) and the dependence on the electronic relaxation times is expressed in the non-Lorentzian spectral density functions $J(\omega_i)$.[19] Thus the paramagnetic contribution to the water protons' relaxation rate implicitly contains very useful information for a series of important structural and dynamic parameters which would allow for a complete characterization of the solute and its interaction with the solvent. In order to obtain reliable values for these parameters the magnetic field dependence of r_{1p} through Equations 3–6 is exploited by measuring the paramagnetic relaxation rate as a function of the applied magnetic field strength. This is best done by

using specialized instrumentation, the field-cycling relaxometer, which switches magnetic field strength very rapidly over the desired range (typically corresponding to proton Larmor frequencies of 0.01 to 50 MHz), thus allowing a complete and accurate dataset to be recorded in about 0.5 h. The $1/T_1$ dataset, otherwise known as a NMRD profile, represents the sum of the spectral density functions of the active relaxation mechanisms and can be fitted to the inner- and outer-sphere equations to yield the values of the relaxation parameters.[11]

For small, rapidly tumbling Gd^{III} chelates the NMRD profile near room temperature is flat, ie. r_{1p} assumes a constant value for frequency values up to about 1–2 MHz, then it decreases because of the dispersion of the $\omega_S\ \tau_{c2}$ term in Equation 3 and tends to level off in the high field region. For polyaminocarboxylate complexes with $q = 1$, inner- and outer sphere terms at the imaging fields (10–60 MHz) make a similar contribution to the relaxivity, the contribution being determined primarily by the terms τ_R/r^6_{Gd-H} (r^{is}_{1p}) and d^2/D (r^{os}_{1p}).[2,11] For this reason, complexes of similar size and molecular weight are expected to have similar relaxivity at these magnetic fields. Normally, the NMRD profiles are not sensitive to the value of τ_M, which at 25 °C is of the order of a few hundred nanoseconds for enneacoordinate Gd^{III} chelates and thus makes a negligible contribution to τ_{ci} (Equation 4). In the low field region r_{1p} is affected by the value of the electronic relaxation time which varies from one complex to another as a result of their different symmetries, rigidities and donor atoms.[20,21] In Figure 2, the experimental NMRD data of $[Gd(DTPA)(H_2O)]^{2-}$ are reported as measured at 25 °C and pH = 7.2. Because of the particularly important role played by this complex in the field of MRI contrast agents, where it has been considered as a reference in the development of new compounds, its profile is well-known and has been analyzed and discussed in considerable detail, primarily by S. H. Koenig and R. D. Brown III.[11]

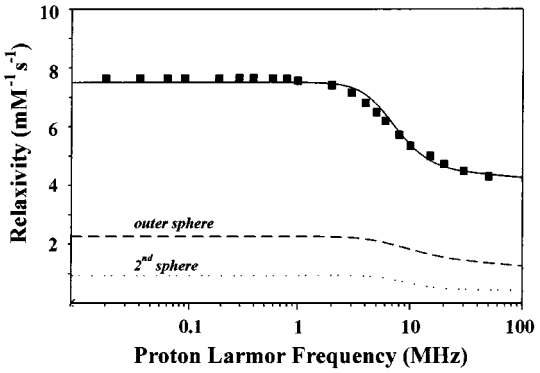

Figure 2. NMRD profile at 25 °C and pH = 7.2 of $Na_2[Gd(DTPA)(H_2O)]$. The curve through the data points has been calculated with the parameters of Table 3, obtained through a best-fitting procedure to equations for paramagnetic relaxation, as described in the text. The lower dashed and dotted curves represent the outer- and 2nd sphere contributions, respectively.

An excellent fit of the data to both inner and outer sphere theory was obtained by considering as adjustable parameters τ_{S0} (85 ps), τ_v (20 ps), τ_R (80 ps) and r_{Gd-H} (3.05 Å), whereas reasonable assumptions were made with regard to d (3.6 Å), D (the diffusion constant of the complex is assumed to be about 25% that of water), q (= 1) and τ_M (1 ns). This interpretation, based on resolution of the data into inner and outer sphere contributions, has proven to be very useful for comparing the data of different complexes, understanding the relaxometric behavior as a function of viscosity, temperature and pH and provides a good basis for rational design of new CA.

However, when one compares the parameters of the fitting procedure with the available structural data on a series of related Gd^{III} complexes several discrepancies are found. The solid state X-ray structures of numerous Gd^{III} chelates reveal that the $Gd–O_w$ distance does not show significant variation from a value of about 2.45 Å, which corresponds to a r_{Gd-H} value of about 2.9 Å.[16,17,22] When compared to the fitted value of 3.05 Å, this represents a significant difference, considering that the relaxivity has a dependence on the inverse of the 6th power of this parameter. On the other hand, the value of 3.6 Å for the closest distance of approach of the outer sphere water molecules to the paramagnetic center is far too short, even shorter than metal-ligand proton distances found in Ln^{III} complexes with DTPA. The X-ray structural determination presented here clearly indicates for this parameter an average value of 4.5 Å, which implies a contribution of the outer sphere relaxivity which is markedly lower than normally calculated. The reorientational correlation time, τ_R = 80 ps, is sensibly longer than the value, about 70 ps, calculated from ^{13}C NMR data on diamagnetic derivatives (La^{III}, Y^{III} or Lu^{III} complexes), probably a consequence of its strong correlation with the value of r_{Gd-H} . On the other hand, when we try to fit the NMRD profile by fixing the parameters r_{Gd-H}, d, D and τ_R to more realistic values (and by using $q = 1$ and τ_M = 360 ns, as calculated by Merbach et al.),[9] a very poor result is obtained. The much larger value of d reduces by almost 50% the contribution of r^{os}_{1p} and is not compensated by the shorter value of the distance r_{Gd-H} . We tried to account for the remaining contribution to the relaxivity by including into the fitting model a term which considers the dipolar interaction of second sphere water molecules with the paramagnetic Gd^{III} ion (r^{2s}_{1p}). Over the last 15 years this contribution has seldom been taken into account for the interpretation of relaxometric data and, in the case of MRI contrast agents, only in studies involving small Gd^{III} chelates with $q = 0$.[12,15] The X-ray crystal structure of $[Yb(DTPA)(H_2O)]^{2-}$ provides clear evidence of the presence of a water molecule hydrogen-bonded to oxygen atoms of adjacent carboxylate groups and at a distance significantly closer than that of the outer sphere solvent molecules. In fact, the orientation of this water molecule, directed towards the metal ion, is such that a hydrogen atom is located only 3.28 Å from Gd^{III}. A contribution to relaxivity is thus expected provided that the mean residence lifetime of the molecule is longer than the diffusional correlation time, i.e. the time necessary for the solvent and the metal complex to diffuse apart from each other (proportional to d^2/D, about 50 ps). Under this condition,

Table 3. Best fitting parameters derived from the variable temperature NMRD data of $Na_2[Gd(DTPA)(H_2O)]$

Parameter	4 °C	10 °C	18 °C	25 °C	32 °C	39 °C
τ_{SO} (ps)	85	82	74	72	73	65
τ_V (ps)	35	31	27	22	19	17
τ_M (ns)	1270	864	531	363	241	166
τ_R (ps)	126	106	86	65	61	52
D (10^5 cm^2s^{-1})	1.62	1.92	2.38	2.84	3.38	3.99
τ_{M_1} (ps)	156	129	101	94	67	56

the second sphere water molecule experiences rotation of the complex and its effect to the measured solvent relaxation rate can be evaluated by using the inner sphere approach. We then fitted the experimental NMRD data at 25 °C with a model that includes the second sphere term and thus 3 more parameters: the number of the second sphere water molecules, q_{2S}, their distance from Gd^{III}, r_{2S} and their mean residence lifetime τ_{M2S}. The total number of relaxation parameters is 11, but several of them can be fixed by using structural data or can be estimated by using values obtained with other techniques. An accurate value of τ_M has been obtained by Merbach and co-workers by ^{17}O NMR ($\tau_M \cong 360$ ns at 25 °C); τ_R has been calculated by ^{13}C NMR relaxation data to be about 70 ps; r_{Gd-H} is allowed to vary slightly about the value of 2.93 Å estimated from X-ray data; the D value has been previously assessed by the analysis of NMRD profiles for complexes whose relaxivity is exclusively controlled by the outer sphere term ($q = 0$); to d we may assign the value of 4.50 Å as estimated before. The adjustable parameters are then the electronic relaxation time (τ_{S0} and τ_v), τ_{M2S} and q_{2S}/r_{2S}, whereas τ_R and τ_M were allowed to vary a little from the initial estimates in order to optimize the fitting. The results of the fitting procedure of the data measured at 4, 10, 18, 25, 32 and 39 °C to this model are reported in Table 3. In Figure 2 the experimental and calculated profiles at 25 °C, along with the calculated contributions of the outer- and second sphere components are shown. The experimental data for all temperatures are fit nicely with a set of structural parameters that match the crystallographic data, reproduce very well previous estimates on the electronic relaxation times and water exchange lifetime and account for a second sphere water contribution of about 13% of the observed relaxivity at low fields. The calculated (20 MHz; 25 °C) temperature dependence of the second sphere contribution is reported in Figure 3 and shows an exponential decrease with increasing temperature, in accord with the fitting results, indicating that the residence lifetime of the hydrogen-bonded water molecules represents the dominant correlation time of the dipolar interaction. This behavior is in agreement with the expectation that at high temperatures the lifetime of the hydrogen-bonding interaction becomes so short as to approach the diffusion limit, where this contribution vanishes.

The best fit value of q_{2S}/r_{2S} is $1.5 \cdot 10^7$ cm^{-1} which could be assigned to a water molecule with a proton at 3.28 Å from the Gd^{III} ion by analogy with the crystal structure of the Yb complex. Clearly, this is only an approximation, as

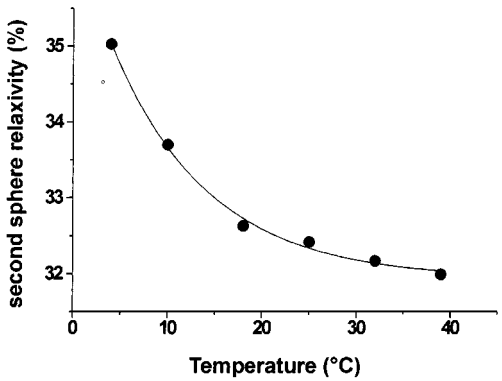

Figure 3. Temperature dependence of the second sphere contribution (%) to the overall relaxivity of $[Gd(DTPA)(H_2O)]^{2-}$ at 20 MHz and 25 °C.

the number of water molecules hydrogen-bonded to the carboxylate groups is surely higher than one. On the other hand, it must be stressed that the technique is only capable of detecting the effects associated with those solvent molecules whose mean residence lifetime is sufficiently long. Thus, it cannot be excluded that the second sphere contribution evidenced in this work is attributable to a single water molecule located in a well-defined position, as revealed by the X-ray crystal structure. The estimated residence lifetime of this water is 94 ps at 25 °C, in good agreement with previous estimates on related systems.

It is generally assumed that the temperature dependence of the correlation time τ_v (and of Δ^2) follows

$$\frac{1}{\tau_v} = \frac{RT}{Nh} exp\left(\Delta S^{\#} / R - \Delta H^{\#} / RT\right) \quad (9)$$

an Eyring behavior (Equation 9) and the plot of data versus temperature, reported in a linear form in Figure 4, represents a good check of the reliability and accuracy of the fitting procedure. The two straight lines in Figure 4 have R factors > 0.99 indicating that the assumptions made for deriving the parameters listed in Table 3 are reasonable and provide correct estimates of the electronic relaxation times of Gd^{III}.

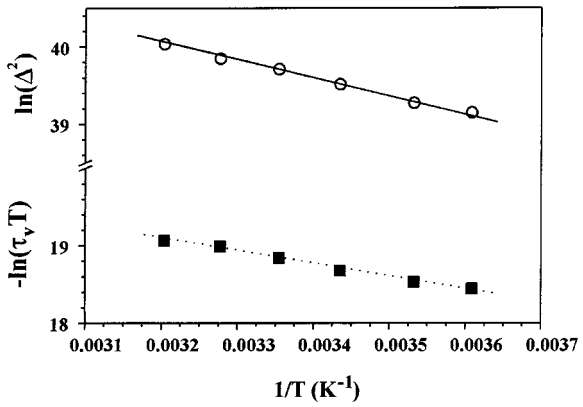

Figure 4. Temperature dependence of the relaxation parameters Δ^2 and $\tau_V T$, calculated from the best-fitting procedure of the NMRD profiles measured at 4, 10, 18, 25, 32 and 39 °C.

Conclusion

The X-ray crystal structure of K_2[Yb(DTPA)(H_2O)] shows that the coordination polyhedron around the metal ion is very similar to that previously found for the Gd^{III} complex, with a nine-coordinate ligand environment composed of the three amine nitrogens, five carboxylate oxygens and one water molecule. The coordination geometry is best described as a tricapped trigonal prism. Additional water molecules have been localized and described as belonging to the outer- and second hydration spheres of the metal ion. In particular, the second sphere water molecule is involved in an hydrogen bond network with the bound water and the uncoordinated carboxylate oxygens and is located very close to the metal ion. From the X-ray results we have reconsidered the NMRD relaxivity profiles of the MRI contrast agent [Gd(DTPA)(H_2O)]$^{2-}$, based on a model comprising contributions from the water molecules in the three different environments: inner-, outer- and second sphere. An excellent fit of the experimental data to this model has been obtained with a set of the relaxation parameters which is in much better agreement with the available structural data. The contribution of the second sphere term is about 10% of the total relaxivity but is very important for a correct and more realistic interpretation of the experimental data. Furthermore, its contribution could be optimized and the relaxivity enhanced through suitable ligand design.[23]

Experimental Section

General Remarks: $GdCl_3 \cdot 6H_2O$, $YbCl_3 \cdot 6H_2O$ and H_5DTPA were purchased from Aldrich. The metal complexes were prepared by mixing stoichiometric amounts of the ligand and of the metal chloride and by adjusting the pH to 7 with KOH. The solutions were kept at room temperature under vigorous stirring for one hour until the pH stabilized. The compounds were then purified by precipitation by addition of acetone. In the case of K_2[Gd(DTPA)(H_2O)], the absence of free metal ion was assessed by the constant value of the water proton relaxation rate, measured at 298 K and 20 MHz, after successive additions of a small excess of the free ligand. The paramagnetic solutions of the Gd^{III} complex for the ^{1}H low resolution NMR study were prepared by weight of the solid compound and their concentrations (1–2 mM) measured by relaxometry from the known value of the relaxivity at 312 K. A 0.15 M solution of the Yb^{III} complex was prepared in D_2O and the purity of the compound was ascertained by recording the ^{1}H NMR spectrum. Crystals suitable for the X-ray diffraction study were obtained after very slow evaporation at room temperature of a concentrated aqueous solution of the complex.

^{1}H NMR Measurements: Water proton relaxation measurements (20 MHz, 25 °C) were carried out with a Stelar Spinmaster Spectrometer (Mede, Pv, Italy) on 0.5–2 mM solutions of K_2[Gd(DTPA)(H_2O)] at pH = 7.2, I = 0.1. Spin-lattice relaxation times T_1 were measured by the standard inversion recovery method with typical 90° pulse width of 3.5 ms, 16 experiments of 4 scans. The reproducibility of the data is ±1%. The $1/T_1$ nuclear magnetic relaxation dispersion profiles of water protons were measured at 4, 10, 18, 25 and 39 °C using 1.5 mM solutions of the complex on the field-cycling Koenig–Brown relaxometer of the University of Torino (Italy). The temperature was controlled by circulating a freon from an external bath and measured by a thermometer inserted into the freon close to the sample. The reproducibilities of the measured T_1 values were estimated to be ±2%.

X-ray Crystallographic Study

A suitable crystal of K_2[Yb(DTPA)(H_2O)] was coated with Paratone oil, placed on the end of a silica fiber and mounted in a goniometer head on the Nonius CAD4 diffractometer in a stream of cold nitrogen gas. The crystal was centered optically and unit cell parameters and an orientation matrix for data collection were obtained at –100 °C by using the centering program in the CAD4 system. Details of the crystal data are given in Table 2 The actual scan range was calculated by scan width = scan range + 0.35 tanθ and backgrounds were measured by using the moving-crystal – moving-counter technique at the beginning and end of each scan. Two representative reflections were monitored every 2 h as a check on instrument and crystal stability. Lorentz, polarization, and decay corrections were applied to the data as well as an absorption correction based on a series of ψ scans. The weighting scheme used during refinement was $1/\sigma^2$, based on counting statistics.

The structure was solved by Direct Methods using SHELXTL/PC V5.03[24] which revealed the positions of most of the non-hydrogen atoms. All other non-hydrogen atoms were found by successive difference Fourier syntheses including the ytterbium-bound water, O(1 W), the second sphere water molecule, O(7 W) and the outer sphere water molecules, O(2,3,4,5,6,8 W). Hydrogen atoms were placed their expected chemical positions using the HFIX command for all ligand hydrogens, but hydrogens attached to oxygen-water molecules were identified from a difference Fourier; all hydrogens were included in the final cycles of least squares with isotropic U_{ij} 's related to the atoms on which they rode. All other non-hydrogen atoms were refined anisotropically.

Neutral atom scattering factors and values of $\Delta f'$ and $\Delta f''$ were taken from Volume C of the *International Tables for X-ray Crystallography.*[25] Structure refinement and preparation of figures and tables for publication were carried out on PCs by using SHELXTL/PC V5.03.[24] Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC- 133337. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44–1223/336–033; E-mail: deposit@ccdc.cam.ac.uk].

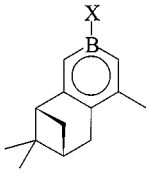
Borabenzene Derivatives, 31[‡]

Enantiomerically Pure Complexes of Manganese, Iron, and Zirconium with Pinene-Fused Boratabenzene Ligands – Structures of *exo*-FeCp*($C_{13}H_{17}BNMe_2$) and *exo*,*exo*-$ZrCl_2(C_{13}H_{17}BNMe_2)_2$



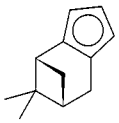
Gerhard E. Herberich,*[a] Ulli Englert,[a] Beate Ganter,[a] and Mario Pons[a]

Keywords: Boron / Transition metals / Sandwich complexes / Boratabenzene / Pinene

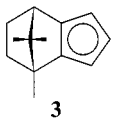
Complexes of pinene-fused boratabenzene ligands [(1*R*,9*R*)-6,10,10-trimethyl-4-boratatricyclo[7.1.1.$0^{2,7}$]undeca-2,4,6-trienes] $C_{13}H_{17}BX$ (with **a**: X = NMe_2; **b**: X = OMe; **c**: X = Me) are described. The lithium salt Li($C_{13}H_{17}BNMe_2$) [Li(**1a**)] reacts with [Cp*Fe(NCMe)$_3$]PF_6 and with $Mn(CO)_3Br(py)_2$ to give diastereomeric mixtures FeCp*($C_{13}H_{17}BNMe_2$) (**4a**) and $Mn(CO)_3(C_{13}H_{17}BNMe_2)$ (**7**). The mixture **4a** undergoes solvolysis in methanol to produce methoxy compounds **4b**, which in turn react with LiMe in Et_2O to give methyl derivatives **4c**. The lithium salts Li($C_{13}H_{17}BX$) [Li(**1a**–**c**)] react with $ZrCl_4$ in toluene or Et_2O to give *exo*,*exo*-$ZrCl_2(C_{13}H_{17}BX)_2$ complexes (**8a**–**c**). The dimethyl derivative *exo*,*exo*-$ZrMe_2(C_{13}H_{17}BNMe_2)_2$ (**9**) can also be prepared from **8a**/LiMe in Et_2O. NOE difference spectra have been analyzed to determine the configurations of the diastereomers and to establish a chemical shift criterion for assessing the configuration of the metal–ligand coordination. An independent confirmation of the product stereochemistries has been obtained by single-crystal X-ray structure determinations of *exo*-**4a** and **8a**.

Introduction

In previous work, we developed a synthetic route to enantiomerically pure, pinene-fused lithium boratabenzenes Li(**1a**–**c**).[1] In this paper, we describe the first transition metal complexes of the ligands **1a**–**c**.



1



a: X = NMe_2
b: X = OMe
c: X = Me

The motivation for this research stems from analogous cyclopentadienyl chemistry. Chiral metallocenes[2] have been employed as catalyst precursors in stereoregular olefin polymerization,[3] in enantioselective synthesis,[4] and as auxiliary ligands in asymmetric catalysis.[5,6]

The chirality of a metallocene may have different origins.[7] Annulated chiral cyclopentadienyl ligands derived from the chiral pool are of particular interest. They promise well-defined asymmetry and stereocontrol. Using enantiomerically pure starting materials, enantiomerically pure complexes are obtained. Early and important examples are the camphor-derived CamCp ligand (**2**)[8] and the pinene-derived PinCp (**3**).[9] Finally, it should be noted that the ligands **2** and **3** as well as **1a**–**c** possess diastereotopic faces, the more crowded *endo* face with the dimethylmethylene bridge, and the less crowded *exo* face with an ethylene bridge in the case of **2** and a methylene bridge in the case of **1** and **3**. As a consequence, complex formation with these ligands will usually produce mixtures of *exo* and *endo* diastereomers.

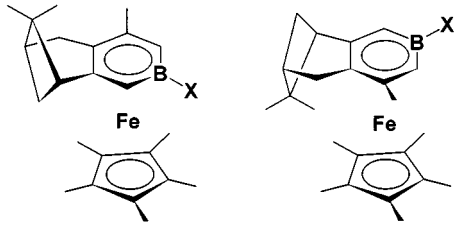
Results and Discussion



(Pentamethylcyclopentadienyl)iron Complexes

First we describe complexes of the ligands **1a**–**c** with the FeCp* fragment. The simpler 1-methylboratabenzene derivative Fe(C_5H_5BMe)Cp*[10] has previously been synthesized in near quantitative yield from [Cp*Fe(NCMe)$_3$]PF_6[11] and Li(C_5H_5BMe).[12] Using the same general method,[13] [Cp*Fe(NCMe)$_3$]PF_6 was treated with the 4-dimethylamino compound Li(**1a**) in the form of its TMEDA adduct[1b] to give a mixture of the two diastereomers *exo*-FeCp*(**1a**) [≡ *exo*-**4a**] and *endo*-FeCp*(**1a**) [≡ *endo*-**4a**] as a deep-red crystalline solid in near quantitative yield (97%). The *exo* isomer was invariably formed preferentially, along with 10–25% of the *endo* isomer. Pure *exo* isomer *exo*-**4a** could be obtained by fractional crystallization from hexane in acceptable yield (50%). In methanol solution, the diastereomeric mixture **4a** slowly underwent solvolysis (60 °C, 24 h) to give, after workup, a corresponding mixture of the methoxy compounds **4b** as a red oil (100%). Treatment of **4b** with

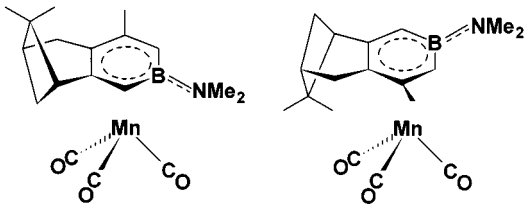
exo - 4 endo - 4

a: X = NMe_2, b: X = OMe, c: X = Me

LiMe in Et_2O led to a smooth substitution to afford a mixture of the methyl compounds **4c** as a slowly solidifying deep-red oil (97%).



Careful analysis of the NMR spectra in combination with NOE difference spectra led to the conclusion that the major isomer in these mixtures **4a**–**c** was the *exo* diastereomer. This assignment was later confirmed by an X-ray structure determination of *exo*-**4a** (see below).

A fully satisfying preparative-scale separation of the diastereomers could not be achieved in any of the three cases. However, in the case of **4c**, which has an unreactive substituent at boron, a catalyzed isomerization could be observed. In an NMR tube, the diastereomeric mixture **4c** was dissolved in [D_6]acetone and treated with a catalytic amount of [Cp*Fe(NCMe)$_3$]PF_6 at ambient temperature; within a few hours complete isomerization to the clearly more stable *exo*-**4c** isomer had occurred. This observation can readily be explained. The sterically less crowded Fe(C_5H_5BMe)Cp* reacts with [Cp*Fe(NCMe)$_3$]PF_6 in dichloromethane with reversible formation of the triple-decker complex [Cp*Fe(μ-C_5H_5BMe)FeCp*]PF_6 [≡ (**5**)PF_6].[10] With the bulkier pinene-fused boratabenzene ligand **1c**, the corresponding triple-decker species $\mathbf{6}^+$ should be highly destabilized. The equilibrium of the triple-decker formation will be shifted to the left and the concentration of the triple-decker cation will be too low for its detection by NMR. On the other hand, we may assume that $\mathbf{6}^+$ is still energetically accessible, thus providing a low-energy isomerization pathway. This type of equilibration of diastereomers was first established by ourselves in the case of the diastereomeric isodicyclopentadienyl (Idcp) complexes *endo*- and *exo*-Ru(Icdp)Cp*.[14]

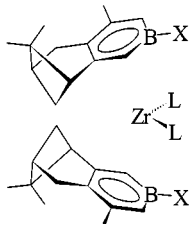
A Tricarbonylmanganese Complex

The tricarbonylmanganese complex Mn(CO)$_3$(**1a**) [≡ **7**] was chosen as a further example of a late transition metal complex. In reactions with *C*-unsubstituted lithium 1-aminoboratabenzenes, the complex [Mn(CO)$_3$(NCMe)$_3$]PF_6[15] has been successfully used as a source of the Mn(CO)$_3$ fragment.[16] However, treatment of the presumably much more basic[17] Li(TMEDA)(**1a**) with [Mn(CO)$_3$(NCMe)$_3$]PF_6 in THF led to protonation of $\mathbf{1a}^-$ and the pinene-fused dihydroborinine H(**1a**) (with the proton added at C-5)[1b] was isolated in near quantitative yield. We then used MnBr(CO)$_3$(py)$_2$[18] (see Experimental Section for an improved preparation); reaction with Li(**1a**) gave mixtures of the two diastereomers *exo*-**7** and *endo*-**7** as orange, light-sensitive oils.

exo - 7 endo - 7

A systematic variation of the reaction conditions[19] showed that nonpolar solvents favor the formation of *exo*-**7** (in hexane, 65 °C, 72 h; diastereomeric ratio *exo*/*endo* = 76:24), whereas in THF *endo*-**7** is obtained preferentially (65 °C, 2 h; *exo*/*endo* = 36:64). Pure *exo*-**7** could readily be obtained from mixtures **7** with high *exo*/*endo* ratios as a yellow, light-sensitive solid by two fractional crystallizations from hexane. In contrast, pure isomer *endo*-**7** could not be isolated.

Zirconium Complexes



The synthesis of enantiomerically pure bis(ligand) complexes of zirconium seemed to be a particularly interesting goal. A number of simple achiral bis(boratabenzene)dichlorozirconium complexes,[20,21,22a] achiral *ansa*-,[22a] as well as some chiral *ansa*-compounds[22b] have been described. In combination with MAO, these complexes are active catalysts for olefin polymerization.[21,22]

The reaction of freshly sublimed $ZrCl_4$ with the lithium boratabenzene Li(**1a**) in toluene or diethyl ether produces the bis(ligand) complex **8a** as a blue to purple solid in a crude yield of 55%. The main by-product (20–30%) results from protonation of $\mathbf{1a}^-$ and is in fact the pinene-fused dihydroborinine H(**1a**) mentioned above. In THF, the protonation of $\mathbf{1a}^-$ becomes almost entirely predominant.

For a bis(ligand) complex, three diastereomers with *exo*,*exo*, *exo*,*endo*, and *endo*,*endo* coordination may be expected, but only the *exo*,*exo* diastereomer is found experimentally. This result is in accord with similar findings made for the analogous reaction with Paquette's pinene-fused lithium cyclopentadienide.[23]

The methoxy compound Li(**1b**) and the methyl compound Li(**1c**) also give bis(ligand) complexes, i.e. the orange compounds **8b** and **8c**, both of which also have the *exo*,*exo* configuration according to their spectral data. Loss of starting material by protonation is less significant in these cases [ca. 10% of Li(**1b**), negligible in the synthesis of **8c**], presumably because of the lower basicities of the corresponding anions.

The bis(boratabenzene)zirconium complex $ZrCl_2(C_5H_5BNiPr_2)_2$ can readily be methylated with LiMe in Et_2O to give the corresponding dimethyl derivative $ZrMe_2(C_5H_5BNiPr_2)_2$.[21a] Analogously, a solution of **8a** can be titrated with LiMe in Et_2O. The end of the titration is indicated by a color change from purple to deep-red; the dimethyl derivative **9** thus obtained can be crystallized from toluene to give small red crystals.

NMR Spectroscopic Distinction of Diastereomers

In the preceding paper on pinene-fused boratabenzenes, we discussed the characteristic spectroscopic features of these compounds and the assignment techniques used.[1a] In the present work, the only additional point of interest with regard to the NMR characterization is the distinction of the diastereomers and the assignment of *exo* and *endo* configurations, respectively. Selected ^{1}H-NMR data are presented in Table 1. In the case of the diastereomeric FeCp* complexes *exo*-**4a**–**c** and *endo*-**4a**–**c**, NOE difference spectra for the proton signals of the Cp* ligand and for the protons 10-Me_{endo}, and 11-H_{endo} (and to a lesser extent also 8-H_{endo} and 8-H_{exo}), respectively, can be used to assign these signals and to determine the configuration of the complex in question.

For the pairs of diastereomers of **4a**–**c**, chemical shift patterns emerge that show an unambiguous correlation with the configuration of the metal–ligand bond. The pair of manganese complexes *exo*-**7** and *endo*-**7** (for which the NOE assignment technique is not applicable) also conform to this pattern. In the case of the zirconium complexes **8a**–**c** and **9**, where only one diastereomer is found, the data (especially for the pair of methyl groups 10-Me_{exo}/10-Me_{endo} and the relatively high chemical shift values for 11-H_{endo}) indicate an *exo* configuration of the metal–ligand bond, and hence an *exo*,*exo* configuration of the complexes. These conclusions are in agreement with the results of the structure determinations described below.

[a] Measured in C_6D_6 for the Fe and Mn complexes and in CD_2Cl_2 for the Zr compounds. – [b] Assignments are not confirmed by NOE difference spectra. – [c] Signal obscured.

Structure of the Iron Complex *exo*-4a

A sample of pure *exo*-**4a** was recrystallized from hexane at –30 °C to give deep-red crystals of good quality. Complex *exo*-**4a** crystallizes in the chiral orthorhombic space group $P2_12_12_1$. The structure determination confirmed the *exo* configuration of *exo*-**4a** (Figure 1).

The molecule shows a typical sandwich structure. The atoms C1C5 are essentially coplanar [maximum vertical displacement of 0.021(4) Å for C3], but the aminoboranediyl group is bent away from the metal and the boron atom resides 0.191(5) Å above the C1C5 plane. There are several indications of transannular repulsive interactions. The ring–ring conformation places the methylene group between two methyl groups of the Cp* ligand and the same is true for the B–NMe_2 group. There is a marked bending of the sandwich, which results in an increased distance between the Cp* ligand and the *endo*-methylene bridge; the angle between the best Cp* plane and the best C_5B plane amounts to 5.0(1)°. The slip distortion[25] of the boratabenzene ring amounts to 0.11 Å and is smaller than that in Fe(C_5H_5BMe)Cp* (0.15 Å).[10] This detail may seem surprising, but an increase in the slip distortion would be counteracted by an increase in the transannular repulsion of the *endo*-methylene bridge. Finally, we note the relatively long Fe–B distance of 2.352(6) Å and the relatively short B–N distance of 1.438(7) Å. These features demonstrate the often documented π-interaction between the boron p_z orbital and the nitrogen lone pair.

Structure of the Bis(ligand) Zirconium Complex 8a

Crystals suitable for X-ray crystallographic analysis were obtained by crystallization of **8a** from toluene at –30 °C. Complex **8a** crystallizes in the chiral orthorhombic space group $P2_12_12_1$ and displays a bent-sandwich structure with a bending angle of 131.65(14)° (Figure 2 and 3). The front view illustrates the approximate C_2-symmetry of this complex.

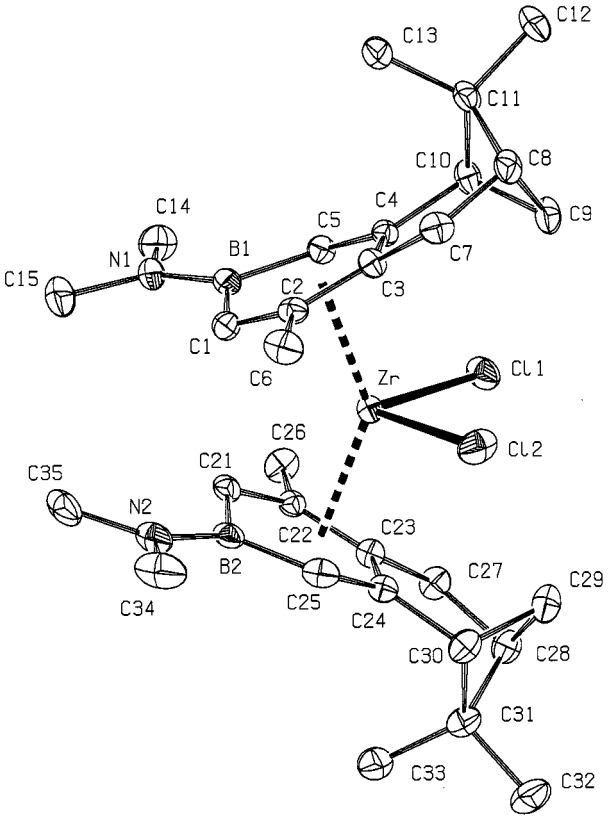

Figure 2. Side view of the molecular structure (PLATON plot, see ref.[25]) of **8a** in the crystal; selected bond lengths [A] and angles [°] for **8a**: Zr–Cl1 2.437(1), Zr–Cl2 2.428(1), Zr–C1 2.642(3), Zr–C2 2.615(3), Zr–C3 2.628(3), Zr–C4 2.627(3), Zr–C5 2.622(3), Zr–B1 2.901(4), Zr–C21 2.593(3), Zr–C22 2.599(3), Zr–C23 2.641(3), Zr–C24 2.685(3), Zr–C25 2.656(3), Zr–B2 2.860(4); Cl1–Zr–Cl2 94.85(3)

The planes C1C5 and C21C25 of the boratabenzene ligands are good planes [with a maximum vertical displacement of 0.017(3) Å]; the aminoboranediyl groups are bent away from the metal with vertical displacements of 0.271(4) Å for B1 and 0.229(4) Å for B2. The average Zr–B distance of 2.88 Å is comparable with the corresponding distances in $ZrCl_2(C_5H_5BMe)_2$ (2.81 Å),[20] $ZrCl_2$(4-Bu*t*$C_5H_4BPh)_2$ (2.80 Å),[21a] $ZrCl_2(C_5H_5BOEt)_2$ (2.83 Å),[21c] and $ZrCl_2(C_5H_5BNiPr_2)_2$ [2.98 Å; B–N 1.396(6) Å].[21a] The average B–N bond length amounts to 1.419 Å and indicates considerable π-interaction between the boron and the exocyclic substituent. This weakens the Zr–B interaction and as a consequence markedly lengthened Zr–B distances are found. A more subtle question is why this situation results in a shorter Zr–B distance and a longer B–N bond length in **8a** as compared to the values in $ZrCl_2(C_5H_5BNiPr_2)_2$.[21a] We suggest that this difference is due to steric effects. The

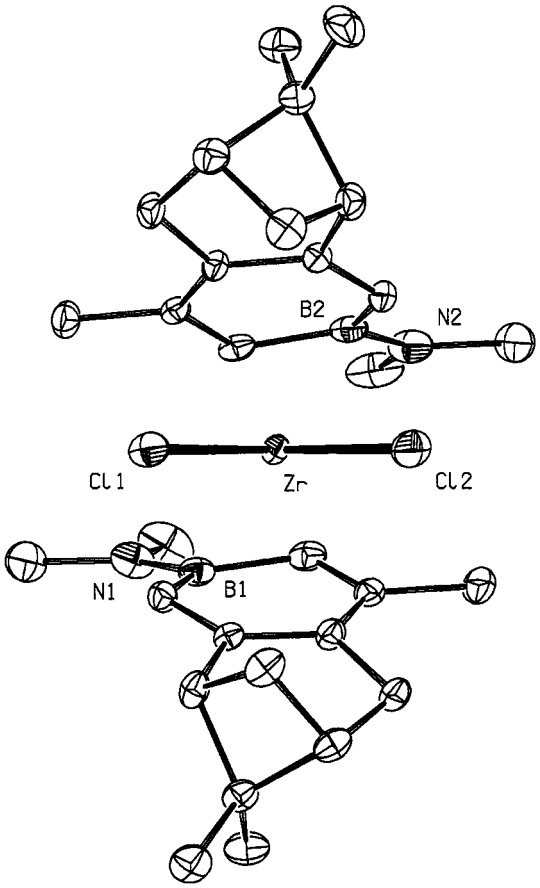

Figure 3. Front view of the molecular structure (PLATON plot, see ref.[25]) of **8a** in the crystal

bulky pinene part of the ligand in **8a** shifts the Zr atom towards the boron (as explained above in the case of *exo*-**4a**) and this results in shorter Zr–B distances and remarkably small slip distortions of just 0.12 and 0.15 Å for the two ligands. The bulky N*i*Pr$_2$ group in ZrCl$_2$(C$_5$H$_5$BN*i*Pr$_2$)$_2$ can be expected to have the opposite effect, resulting in particularly long Zr–B distances and particularly short B–N bond lengths.

Concluding Remarks

In this paper we have described the first transition metal complexes of pinene-fused boratabenzene ligands. With complex fragments incorporating late d-metals, complex formation gives diastereomeric mixtures in most cases, with a marked preference for the the sterically less congested *exo* diastereomers. In contrast, the bis(ligand)zirconium complexes are formed exclusively as *exo*,*exo* isomeric products. Parallels with earlier work by Paquette's group on complexes of the pinene-fused cyclopentadienyl ligand are evident. The pinene-fused Cp also shows a pronounced preference for coordination of the metal at the less hindered *exo* face.[9] Considering the data presented here, this preference seems to be less strong for the pinene-fused boratabenzenes.

Experimental Section

General Remarks: Reactions were carried out under an atmosphere of dinitrogen by employing conventional Schlenk techniques. Hexane was distilled from potassium, toluene from sodium, THF and Et$_2$O from sodium benzophenone ketyl, and CH$_2$Cl$_2$ from CaH$_2$. Electron-impact mass spectra were recorded on a Finnigan MAT-95 spectrometer with a nominal electron energy of 70 eV. Elemental analyses were performed by the Analytische Laboratorien Prof. Dr. H. Malissa und G. Reuter GmbH, D-51789 Lindlar. Melting points were determined in sealed capillaries on a Büchi 510 melting point apparatus and are uncorrected. NMR spectra were recorded on a Varian Unity 500 (^{1}H, 500 MHz; ^{13}C{^{1}H}, 125.7 MHz; ^{11}B{^{1}H}, 160.4 MHz), a Varian VXR 300 (^{1}H, 300 MHz; ^{13}C{^{1}H}, 75.4 MHz), or a Rototec/Picinotti Mini-FID spectrometer (^{11}B{^{1}H}, 29 MHz). Chemical shifts, measured at ambient temperature, are quoted relative to internal TMS for ^{1}H and ^{13}C, and relative to external BF$_3$·Et$_2$O for ^{11}B.

FeCp*(C$_{13}$H$_{17}$BNMe$_2$) (4a): A solution of Li(TMEDA)(**1a**) (1.23 g, 3.50 mmol) in THF (20 mL) was added to [Cp*Fe(NCMe)$_3$]PF$_6$ (1.56 g, 3.40 mmol) in acetonitrile (20 mL). The mixture immediately turned red and was left at ambient temperature for 12 h. After careful removal of the volatiles, the resulting residue was triturated with hexane. Filtration through a frit covered with kieselguhr and concentration of the filtrate in vacuo left a red oil, which was purified by chromatography on alumina (deactivated with 5% H$_2$O, 5 cm layer) using pentane containing 1% triethylamine as eluent. Removal of the solvents gave **4a** (1.38 g, 97%) as a red oil; the diastereomeric ratio *exo*/*endo* was found to vary between 3:1 and 9:1. Pure *exo* isomer *exo*-**4a** could be obtained from hexane at –30 °C as deep-red crystals in 50% yield; barely air-sensitive, soluble in hexane, benzene, THF, and CH$_2$Cl$_2$; m.p. 116 °C.

***exo*-4a**: ^{1}H NMR (500 MHz, C$_6$D$_6$): δ = 3.10 (d, *J* = 2.1 Hz, 5-H), 2.98 (d, *J* = 2.1 Hz, 3-H), 2.98 (br. s, NMe), 2.96 (br. s, NMe), 2.63 (dd, *J* = 15.7, 2.4 Hz, 8-H$_{exo}$), 2.58 (dddd, *J* = 9.2, 5.8, 5.8, 1.5 Hz, 11-H$_{exo}$), 2.25 (ddd, *J* = 15.7, 2.5, 1.5 Hz, 8-H$_{endo}$), 2.18 (dd, *J* = 5.8, 5.5 Hz, 1-H), 2.17 (dddd, *J* = 5.8, 5.5, 2.5, 2.4 Hz, 9-H), 2.10 (d, *J* = 9.2 Hz, 11-H$_{endo}$), 1.81 (s, 6-Me), 1.59 (s, Cp*), 1.32 (s, 10-Me$_{exo}$), 0.60 (s, 10-Me$_{endo}$). – ^{13}C{^{1}H} NMR (126 MHz, C$_6$D$_6$): δ = 113.7 (C-2), 98.3 (C-6), 80.8 (*C*$_5$Me$_5$), 79.5 (C-7), 66.3 (br., C-5), 64.8 (br., C-3), 48.4 (C-1), 41.3 (C-9), 39.9 (br., NMe$_2$), 39.4 (C-10), 33.7 (C-11), 29.4 (C-8), 26.8 (10-Me$_{exo}$), 21.3 (10-Me$_{endo}$), 20.9 (6-Me), 10.5 (C$_5$*Me*$_5$). – ^{11}B{^{1}H} NMR (160 MHz, C$_6$D$_6$): δ = 20. – MS: *m*/*z* (%) = 419 (100) [M$^+$], 364 (13) [M$^+$ – NMe$_2$]. – C$_{25}$H$_{38}$BFeN (419.3): calcd. ***endo*-4c**: ^{1}H NMR (500 MHz, C_6D_6): δ = 3.80 (d, *J* = 1.2 Hz, 5-H), 3.68 (d, *J* = 1.2 Hz, 3-H), 2.53 (m, 8-H$_{endo}$), 2.35 (m, 2 H, 1-H and 11-H$_{exo}$), 2.01 (m, 9-H), 1.84 (s, 6-Me), 1.60 (s, 10-Me$_{endo}$), 1.54 (s, Cp*), 1.26 (s, 10-Me$_{exo}$), 1.20 (s, BMe), 0.66 (d, *J* = 8.2 Hz, 11-H$_{endo}$). – ^{13}C{^{1}H} NMR (126 MHz, C_6D_6): δ = 79.9 (C_5Me_5), 49.5 (C-1), 40.9 (C-9), 38.4 (C-10), 34.8 (C-11), 28.9 (C-8), 27.2 (10-Me$_{exo}$), 23.8 (10-Me$_{endo}$), 20.9 (6-Me), 10.6 (C_5Me_5). – ^{11}B{^{1}H} NMR (160 MHz, C_6D_6): δ = 20. – Signals due to 8-H$_{exo}$, C-2, C-3, BMe, C-5, C-6, and C-7 could not be located; note that many signals are almost superimposed by those of the *exo* isomer.

MnBr(CO)$_3$(py)$_2$: Pyridine (20 mL) was added with stirring to MnBr(CO)$_5$,[18b] which resulted in rapid gas evolution (CO). As far as possible, light was excluded during the subsequent steps. When the gas evolution had subsided, the mixture was warmed to 80 °C for 1 h, then slowly allowed to cool to ambient temperature. Hexane (60 mL) was added and the deposited orange solid was collected on a frit. It was then washed through the frit by dissolving it in CH_2Cl_2. Removal of the solvent in vacuo left the orange-red crystalline product (9.65 g, 98%); light-sensitive, insoluble in hexane and toluene, soluble in pyridine, THF, and CH_2Cl_2. – ^{1}H NMR (250 MHz, CD_2Cl_2): δ = 8.74 (m, 2-/6-H), 7.61 (m, 4-H), 7.31 (m, 3-/5-H). – IR (CD_2Cl_2): $\tilde{\nu}$ = 2030 (s), 1944 (s), 1910 cm^{-1} (m).

Mn(CO)$_3$($C_{13}H_{17}$BNMe$_2$) (7): A solution of Li(**1a**) (873 mg, containing a known amount of THF, 3.10 mmol) in hexane (20 mL) was added to a suspension of MnBr(CO)$_3$(C_5H_5N)$_2$ (1.13 g, 3.00 mmol) in hexane (75 mL) at 65 °C by means of a cannula. The mixture was kept at 65 °C for 72 h and then filtered through a frit covered with kieselguhr. Removal of the volatiles left **7** (1.00 g, 91%) as an orange oil; the diastereomeric ratio *exo*/*endo* was found to be 3:1. The pure *exo* isomer was isolated as a yellow-orange shiny solid by fractional crystallization from hexane at –30 °C; m.p. 87 °C; soluble in hexane, benzene, THF, and diethyl ether; light-sensitive. When the same reaction was carried out in THF for 2 h at 65 °C, an orange oil with a diastereomeric ratio *exo*/*endo* of 1:2 in favour of the *endo* isomer was obtained.

***exo*-7**: ^{1}H NMR (500 MHz, C_6D_6): δ = 3.54 (d, *J* = 2.5 Hz, 5-H), 3.32 (d, *J* = 2.5 Hz, 3-H), 2.69 (br. s, NMe), 2.62 (br. s, NMe), 2.48 (dd, *J* = 16.3, 3.1 Hz, 8-H$_{exo}$), 2.39 (dddd, *J* = 9.8, 6.1, 5.5, 1.5 Hz, 11-H$_{exo}$), 2.24 (ddd, *J* = 16.3, 2.8, 1.5 Hz, 8-H$_{endo}$), 2.08 (dd, *J* = 5.5, 5.5 Hz, 1-H), 1.87 (dddd, *J* = 6.1, 5.5, 3.1, 2.8 Hz, 9-H), 1.84 (d, *J* = 9.8 Hz, 11-H$_{endo}$), 1.74 (s, 6-Me), 1.11 (s, 10-Me$_{exo}$), 0.56 (s, 10-Me$_{endo}$). – ^{13}C{^{1}H} NMR (126 MHz, C_6D_6): δ = 223.2 (CO), 134.7 (C-2), 120.0 (C-6), 91.0 (C-7), 78.6 (br., C-5), 72.4 (br., C-3), 49.6 (C-1), 40.9 (C-9), 38.8 (C-10), 38.5 (NMe$_2$), 33.2 (C-11), 30.1 (C-8), 26.3 (10-Me$_{exo}$), 21.3 (6-Me), 21.1 (10-Me$_{endo}$). – ^{11}B{^{1}H} NMR (160 MHz, C_6D_6): δ = 23. – MS: *m*/*z* (%) = 367 (14) [M^+], 311 (9) [M^+ – 2 CO], 283 (100) [M^+ – 3 CO], 228 (2) [M^+ – Mn(CO)$_3$], 55 (5) [Mn^+]. – $C_{18}H_{23}BMnNO_3$ (367.1): calcd. X-ray Structure Determination of *exo*-4a: $C_{25}H_{38}BFeN$; formula mass 419.25 g·mol^{-1}, orthorhombic space group $P2_12_12_1$ (no. 19); *a* = 7.974(4), *b* = 16.783(4), *c* = 17.128(7) Å, *V* = 2292(3) Å^3, *Z* = 4, $d_{calcd.}$ = 1.21 g·cm^{-3}, μ_{lin} = 0.67 mm^{-1}. Enraf–Nonius CAD4 diffractometer; Mo-K_α radiation (λ = 0.71073 Å); graphite monochromator. Data collection at 223 K on a red crystal of dimensions ca. 0.50 × 0.40 × 0.35 mm^3 using ω/2θ scans in the diffraction range 3 < θ < 26° yielded 4798 reflections, which were corrected for Lorentz and polarization effects; no absorption correction was applied. After merging symmetry-equivalent data, 4478 unique reflections remained for structure solution by direct methods[26] and subsequent Fourier difference syntheses. Least-squares refinement on structure factors[27] was performed with anisotropic displacement parameters for all non-hydrogen atoms and with isotropic displacement parameters for all hydrogen atoms. Convergence was obtained for 405 variables, 3811 unique observations with $I > 1.0\ \sigma(I)$ at $R = 0.058$, $R_w = 0.050$, GoF = 1.079. A final difference Fourier map showed fluctuations of less than 0.50 e·Å^{-3}.[28]

X-ray Structure Determination of 8a: $C_{30}H_{46}B_2Cl_2N_2Zr$; formula mass 618.46 g·mol^{-1}, orthorhombic space group $P2_12_12_1$ (no. 19); *a* = 9.162(3), *b* = 17.777(3), *c* = 18.841(5) Å, *V* = 3069(1) Å^3, *Z* = 4, $d_{calcd.}$ = 1.34 g·cm^{-3}, μ_{lin} = 0.55 mm^{-1}. Enraf–Nonius CAD4 diffractometer; Mo-K_α radiation (λ = 0.71073 Å); graphite monochromator. Data collection at 203 K on a blue translucent platelet of dimensions ca. 0.50 × 0.50 × 0.20 mm^3 using ω/2θ scans in the diffraction range 2 < θ < 28° yielded 9358 reflections. The data were corrected for Lorentz and polarization effects, and an empirical absorption correction based on azimuthal scans[29] (min. rel. trans. 0.861, max. rel. trans. 1.000) was applied. After merging symmetry-equivalent data, 6869 unique reflections remained for structure solution by direct methods[26] and subsequent Fourier difference syntheses. Least-squares refinement on structure factors[27] was performed with anisotropic displacement parameters for all non-hydrogen atoms and with hydrogen atoms in calculated positions [C–H = 0.98 Å, U_{iso}(H) = 1.3 U_{eq}(C)]. Convergence was obtained for 334 variables, 6228 unique observations with $I > 1.0\ \sigma(I)$ at $R = 0.040$, $R_w = 0.041$, GoF = 1.095. A final difference Fourier map showed fluctuations of less than 0.62 eÅ^{-3}.[28]

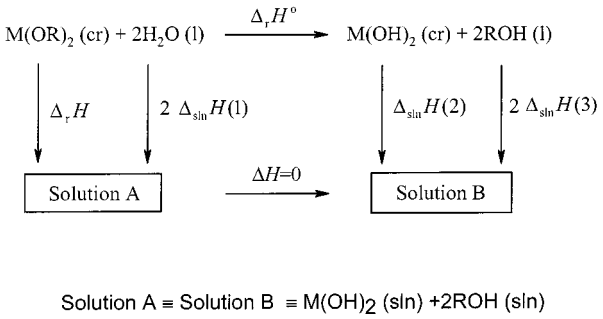
Standard Molar Enthalpies of Formation of Mg and Ca Alkoxides

Teresa Barreira[a] and João Paulo Leal*[a]

Keywords: Thermochemistry / Alkaline-Earth Alkoxides / Enthalpy of Formation / Calcium / Magnesium

The enthalpies of formation of some alkaline-earth alkoxides were determined by reaction-solution calorimetry (Δ_fH^o[Mg(OMe)$_2$] = –792.6±1.2 kJ/mol; Δ_fH^o[Mg(OEt)$_2$] = –847.9±2.7 kJ/mol; Δ_fH^o[Ca(OMe)$_2$] = –890.8±6.4 kJ/mol; Δ_fH^o[Ca(OEt)$_2$] = –924.5±2.6 kJ/mol; Δ_fH^o[Ca(OBu)$_2$] = –989.8±5.4 kJ/mol) and allowed us to extend a previously developed model for predicting the enthalpies of formation of Be, Sr and Ba alkoxides.



Introduction

Alkaline and alkaline-earth metal alkoxide compounds are of major importance in synthetic chemistry.[1] However, thermochemical data for these substances is rather scarce. Previous results obtained for sodium and lithium alkoxides[2,3] show that there exists a linear relation between the enthalpies of formation of the alkoxides and those of the corresponding alcohols for short-chain unbranched alkoxides. A model based on the alkoxide energy calculations and a simple electrostatic model was also developed, which enabled us to predict unknown alkali metal alkoxide enthalpies of formation.

In this paper we extend the previously developed model to alkaline-earth alkoxides and use it for the prediction of some unmeasured Be, Sr and Ba alkoxides.

Results and Discussion

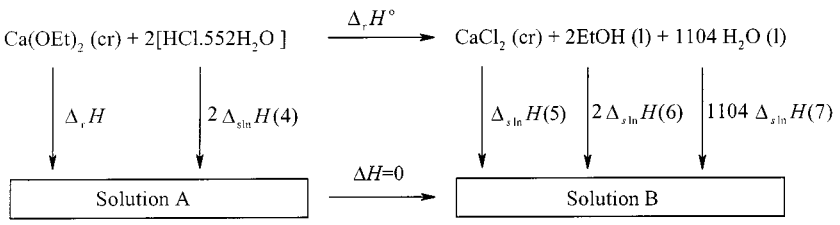
The enthalpies of formation of magnesium and calcium alkoxides were calculated according to Scheme 1 (reaction with water, used for all the compounds studied in this paper) or Scheme 2 [reaction with 0.1 M HCl, used for Ca(OEt)$_2$]. In these schemes, Δ_rH^o represents the reaction enthalpy with all the compounds in their standard state, Δ_rH the experimentally measured reaction enthalpy, $\Delta_{sln}H(2)$ the dissolution enthalpy for stoichiometric amounts of M(OH)$_2$ in H_2O, $\Delta_{sln}H(3)$ the dissolution enthalpy of the alcohol in H_2O + M(OH)$_2$, $\Delta_{sln}H(5)$ the dissolution of $CaCl_2$ in 0.1 M HCl, $\Delta_{sln}H(6)$ the dissolution of ethanol in a 0.1 M HCl + $CaCl_2$ solution, and $\Delta_{sln}H(7)$ the dissolution of water in 0.1 M HCl solution. $\Delta_{sln}H(1)$ (dissolution of water in water) and $\Delta_{sln}H(4)$ (dissolution of 0.1 M HCl in 0.1 M HCl) are obviously zero.

Scheme 1. Reaction with water

As the concentrations of M(OH)$_2$ in solution were always very small [about 1 mol M(OH)$_2$ in 4 × 10^5 mol water] an infinite dilution can be assumed and $\Delta_{sln}H(2)$ can be calculated as –2.30 kJ/mol for magnesium hydroxide and –16.73 kJ/mol for the calcium analogue using the data in Table 1.[4,5] In the cases of ethanol and methanol, $\Delta_{sln}H(3)$ values were calculated from the differences between the enthalpies of formation of the pure alcohols and the respective enthalpies of formation at infinite dilution in water (Table 2 and Equation 1 and 2). $\Delta_{sln}H(3)$ for butanol was taken as −7.39 ± 0.59 kJ/mol.[3]

$$\Delta_{sln}H(3)\ (MeOH) = \Delta_fH^o\ (CH_3OH,\infty\ H_2O) - \Delta_fH^o\ (CH_3OH,l) = -7.3 \pm 0.4\ kJ/mol \quad (1)$$

$$\Delta_{sln}H(3)\ (EtOH) = \Delta_fH^o\ (C_2H_5OH,\infty\ H_2O) - \Delta_fH^o\ (C_2H_5OH,\ l) = -10.7 \pm 0.6\ kJ/mol \quad (2)$$



The fact that the above $\Delta_{sln}H(3)$ values were obtained in water and not in H_2O + M(OH)$_2$ solutions should not be relevant due to the low concentrations of M(OH)$_2$ in solution. This is in keeping with the values in a previous publication[3] where the dissolution of butanol in water, H_2O + LiOH and H_2O + NaOH was measured, and showed no difference within experimental error.

The enthalpies of formation of aqueous 0.1 M HCl and crystalline calcium chloride are known (Table 1). The dissolution of calcium chloride in 0.1 M HCl and of ethanol in $CaCl_2$ + 0.1 M HCl solution was measured (Table 2). The dissolution of water in the solvent is negligible (smaller than the detection limit of the apparatus) and even when multiplied by 1104 yields a minor contribution to the final Δ_rH^o value (smaller than the experimental error). Therefore, $\Delta_{sln}H(7)$ was neglected.

Schemes 1 and 2 lead to Equations 3 and 4, that allow the calculation of the enthalpies of formation of the metal alkoxides shown in Table 3.

[a] Reaction with water unless stated otherwise. – [b] Reaction with 0.1 M HCl.

$$\Delta_f H^o [M(OR)_2] = \Delta_f H^o [M(OH)_2,cr] + 2\Delta_f H^o [ROH, l] - 2\Delta_f H^o [H_2O, l] - \Delta_r H + \Delta_{sln} H(2) + 2\Delta_{sln} H(3) \quad (3)$$

$$\Delta_f H^o [Ca(OEt)_2, cr] = \Delta_f H^o [CaCl_2,cr] + 2\Delta_f H^o [EtOH, 1] - 2\Delta_f H^o [HCl \cdot 552H_2O] - \Delta_r H + \Delta_{sln} H(5) + 2\Delta_{sln} H(6) + 1104\ \Delta_{sln} H(7) \quad (4)$$

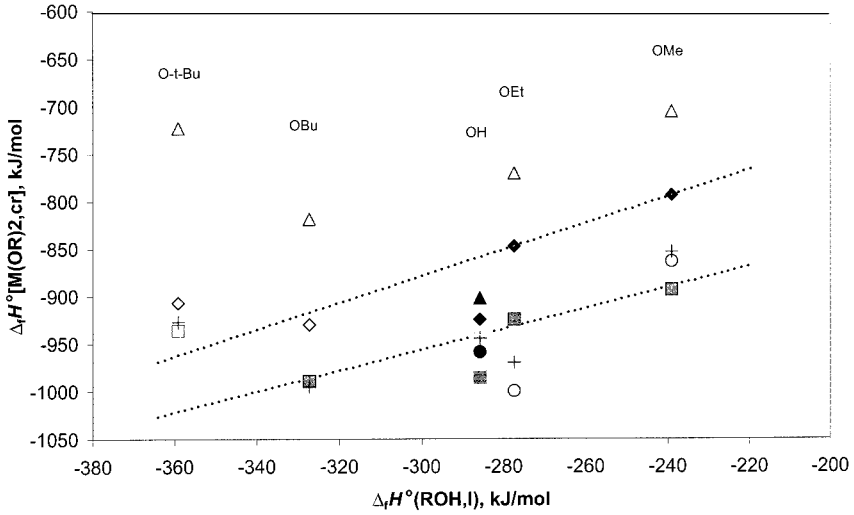
As a first comment we note the good agreement between the values for the enthalpy of formation of $Ca(OEt)_2$ obtained by the two different methods referred to above. Since the reaction with HCl was studied mainly to test the consistency of the results, in all subsequent calculations the values derived from the reactions with water will be used.

A plot of the enthalpies of formation of the crystalline alkoxides against the enthalpies of formation of the corresponding alcohols in their standard reference states is shown in Figure 1. This type of plot has been used before for many compound families,[6] including sodium[2] and lithium alkoxides,[3] and it is useful to assess the reliability of the data. For calcium alkoxides, and using the three points for R = Me, Et and Bu, a fairly linear correlation (r = 0.9922; uncertainty intervals are standard deviations) (Equation 5) is obtained. The slope defined by the two points for Mg alkoxides (R = Me and Et) is 1.44.

$$\Delta_f H^o (Ca(OR)_2) = (1.13 \pm 0.14)\ \Delta_f H^o (ROH, l) - (617 \pm 39) \quad (5)$$

To understand the plot of Figure 1 (or Equation 5) we can use Equation 6, where $\Delta_r H^o$ is simply defined in terms of the standard enthalpies of formation of reactants and products. If a linear correlation between $\Delta_f H^o$ [$M(OR)_2$,cr] and $\Delta_f H^o$ (ROH,l) is observed, this means that $\Delta_r H^o$ is constant for several R. On the other hand, as evidenced by Equation 6, the slope of the line should be close to 2 (the number of alkoxide ligands bound to M). However, this is not observed either for Mg or Ca compounds, nor is $\Delta_r H^o$ constant (Table 3) in Equation 5. Similar behaviour had been noticed for some K, Rb and Cs alkoxides.[7] This type of plot should work well only if the crystal structure has little effect on the energetics. Since none of the crystal structures are known, and since changing the anions and/or the cations is very likely to change the crystal structure, Figure 1 should be used mainly as a visual aid to find trends in the values.

$$\Delta_f H^o [M(OR)_2, cr] = 2\Delta_f H^o [ROH, l] + \Delta_f H^o [M(OH)_2, cr] - 2\Delta_f H^o [H_2O, l] - \Delta_r H^o \quad (6)$$



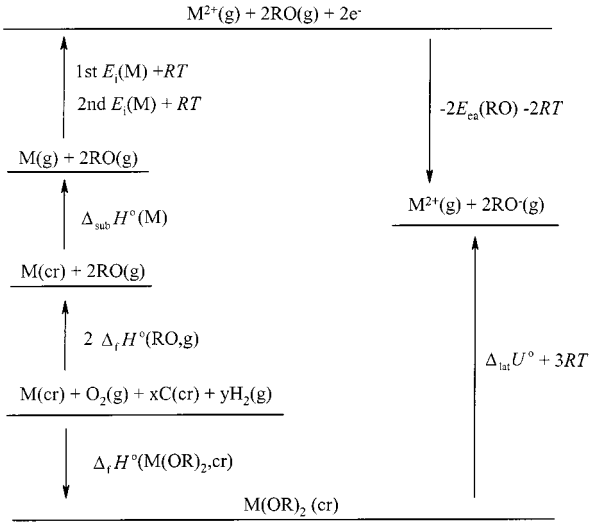


Figure 1. Enthalpies of formation of alkaline-earth metal alkoxides versus the enthalpies of formation of the corresponding alcohols (experimental data: filled symbols; estimated data: empty symbols; Be: triangle; Mg: diamond; Ca: square; Sr: circle; Ba: cross); the lower line is a linear regression using the three experimental values for Ca, and the upper line is simply a line passing through the two experimental Mg values, which are included mainly as a visual guide

Scheme 3

Another way of discussing the data in Table 4 involves the calculation of lattice energies ($\Delta_{lat}U°$) of magnesium and calcium alkoxides.

These values, displayed in Table 4, were obtained from the standard enthalpies of formation of the alkoxides and from literature data, according to Scheme 3. The high ionic character of the alkoxides is indicated by their lattice energies, which are under 200 kJ/mol lower than the lattice energies of the corresponding hydroxides.

Let us assume a simple ionic model and the Kapustinskii approximation represented by Equation 7.[8] In this expression, v represents the number of ions in the molecule, Z_+ and Z_- the charges of the cation and anion and r_+ and r_- the respective radii in pm. As the ionic radii of Mg^{2+} and Ca^{2+} are known,[9] the ionic radii of the alkoxide anions can be derived from the data in Table 4. The results are shown in Table 5, which also includes early data for alkaline-earth and alkali metal alkoxides [2,3,7] and estimates of the radii of the alkoxide ions in some alkaline-earth metal alkoxides not studied in this work.

$$\Delta_{lat}U° = \frac{1.079\times10^5 . v . Z_+ Z_-}{r_+ + r_-} \quad (7)$$

The radii calculated by the above procedure are called "thermochemical radii" and have no special physical meaning, apart from reproducing lattice energies when introduced in Equation 7. It is to be noted that the values of the *n*-butoxy anion always have a greater error than the others. This is mainly due to the huge error in the electroaffinity of the butoxy ion.

Using these estimated radii and Scheme 3, it is possible to calculate the enthalpies of formation for some unknown alkaline-earth metal alkoxides (Table 6). The error bars are

Table 5. Thermochemical radii[a] calculated or estimated[b] for the alkoxide ions in alkali and alkaline-earth metal alkoxides[c]

[a] Thermochemical radii studied in the present paper are in bold. – [b] Estimated thermochemical radii in parentheses[c] $r_+(Li^+)$ = 90 ±1 pm, $r_+(Na^+)$ = 116 ±1 pm, $r_+(K^+)$ = 152 ±1 pm, $r_+(Rb^+)$ = 166 ±1 pm, $r_+(Cs^+)$ = 181 ±1 pm, $r_+(Be^{2+})$ = 59 ±1 pm, $r_+(Mg^{2+})$ = 86 ±1 pm, $r_+(Ca^{2+})$ = 114 ±1 pm, $r_+(Sr^{2+})$ = 132±1 pm, $r_+(Ba^{2+})$ = 149±1 pm.[9] – [d] Δ_fH^o[Be(OH)$_2$,cr] = –902.5 kJ/mol, Δ_fH^o[Sr(OH)$_2$,cr] = –959.0 kJ/mol, Δ_fH^o[Ba(OH)$_2$,cr] = –944.7 kJ/mol, $\Delta_fH^o(Be^{2+},g)$ = 2993.23 kJ/mol, $\Delta_fH^o(Sr^{2+},g)$ = 1790.54 kJ/mol, $\Delta_fH^o(Ba^{2+},g)$ = 1660.38 kJ/mol.[4] – [e] Calculated from data in ref.[3] – [f] Calculated from data in ref.[2] – [g] From ref.[7]

large (50 kJ/mol excluding the butoxides and 90 kJ/mol for the butoxides) when compared with those for the alkoxides measured on this paper (2–6 kJ/mol). The main reason is that a small error in the radii will be amplified in the lattice energy values (since $\Delta_{lat}U^o$ is a big value) and therefore in the values of the enthalpy of formation.

$Ba(Ot Bu)_2$[a]	(2029±51)	(–927±53)

[a] $\Delta_fH^o(Ot Bu)$ = –91±5 kJ/mol from D. F. McMillen, D. M. Golden, *Ann. Rev. Phys. Chem.* **1982**, *33*, 493; $E_{ea}(Ot Bu)$ = 184.4±5.2 from S. G. Lias, J. E. Bartmess, J. F. Liebman, J. L. Holmes, R. D. Levin, W. G. Mallard, *J. Phys. Chem.* **1988**, *17*, Suppl. no. 1.

Nevertheless, if no other values exist, those can be quite useful. In the future we intend to extend this study to other alkaline-earth metal alkoxides to achieve better data for these compounds.

Knowing the structures would give deep insight into in these kinds of compounds. Despite all efforts, it has not yet been possible to obtain single crystals, and powder studies have yet to be undertaken.

Experimental Section

Materials: Methanol (Merck, 99.8%) and ethanol (Merck, 99.8%) were pre-dried over calcium sulfate, refluxed over activated magnesium and iodine, and finally distilled. Butanol (Sigma, 99.0%) was dried over calcium hydride and distilled. Magnesium (turnings, Sigma) and calcium (granules, Sigma) were used as supplied and stored in an oxygen- and water-free glovebox. Iodine was sublimed twice before use. Pentane was distilled over P_2O_5 and stored in the glovebox over 4 Å molecular sieves.

Physical Measurements: Infrared spectra were determined using a Perkin–Elmer 577 spectrophotometer with samples mounted as Nujol mulls between KBr plates. Elemental analyses were performed on a Perkin–Elmer 240 C (C, H) automatic analyzer or by gravimetric analyses (Mg as magnesium oxide,[10] Ca as calcium oxalate[11]). Iodine was qualitatively analyzed by an energy-dispersive X-ray spectrometer with a primary photon beam produced by a high power rhodium anode X-ray tube (Kevex Delta XRF Analyst System).

Alkoxide Syntheses: The studied alkoxides are moisture sensitive. Therefore, all syntheses were performed inside an oxygen- and water-free (<5 ppm) glovebox. Alcohols were degassed before use. Magnesium alkoxides were prepared by addition of the metal to an excess of alcohol (methanol or ethanol) containing a small amount of sublimed iodine (acting as a catalyst) and stirred for several days inside the glovebox at room temperature. The solution was taken to dryness, washed twice with pentane and dried under high vacuum (10^{-4}–10^{-5} Torr). The calcium alkoxides (methoxy, ethoxy and butoxy) were synthesized in a similar way without adding the catalyst. One of the problems that may occur is the formation of metal hydroxides due to the presence of water, and which are virtually impossible to separate from the alkoxides. Another problem is ensuring that the alkoxides are completely dry, i.e. all the excess alcohol must be removed. IR spectra showed that all the alkoxides used in

Table 7. Elemental analysis of magnesium and calcium alkoxides

Alkoxide	Found %C	%H	%M	Theoretical %C	%H	%M
$Mg(OMe)_2$	27.95	6.77	–	27.90	7.03	–

$Ca(OMe)_2$	23.21	5.97	–	23.52	5.92	–
$Ca(OEt)_2$	38.23	7.82	31.0	36.90	7.74	30.78
$Ca(OBu)_2$	51.03	9.65	–	51.57	9.74	–

this work were alcohol- and hydroxide-free. Elemental analysis of the alkoxides (C, H, metal) was also performed (metal analysis on only some of them) to assess the purity (Table 7). For the magnesium compounds energy-dispersive X-ray spectrometry was conducted to check if any iodine was incorporated, the result always being negative.

Reaction-Solution Calorimetry: The calorimeter used was specially built for the study of oxygen- and water-sensitive compounds, and the experimental procedure was described in a previous paper.[2] All measurements were made near 298.15 K, and the results are averages of at least four runs. The errors presented are twice the standard deviation of the mean in each case. To determine the enthalpies of formation of the alkoxides, their reactions with water were studied in the calorimeter. As a test for consistency, the reaction of $Ca(OEt)_2$ with a 0.1 M aqueous solution of HCl was also studied.

Acknowledgments

The authors thank Dr. Fátima Araújo (ITN) for energy-dispersive X-ray spectrometry analysis. Financial support from FCT (PRAXIS/2/2.1/QUI/51/94) is gratefully acknowledged.

[8] Kapustinskii noticed that, in the formula for the lattice energy in an ionic model, dividing the Madelung constants by the number of ions in the molecule gives a new constant, which is almost independent of the structure of the lattice. He also assumed the repulsive part of the energy to be 1/9 the attractive part and split the internuclear equilibrium distance in a sum of two radii (r+ and r-). This equation is a simplification of the Born-Lande equation and thus works on the assumption of spherical particles, but if the thermochemical radii is not given a physical meaning but used as a parameter for calculation, as we have done here, the equation can be used for non-spherical particles (e.g. *n*-butoxy). Protonation of [tpmRu(PPh$_3$)$_2$H]BF$_4$ [tpm = Tris(pyrazolyl)methane] – Formation of Unusual Hydrogen-Bonded Species

Hei Shing Chu,[a] Zhitao Xu,[b] Siu Man Ng,[a] Chak Po Lau,*[a] and Zhenyang Lin*[b]

Keywords: Ruthenium / Dihydrogen complexes / Dihydrogen bonding / Hydride protonation

Protonation of [tpmRu(PPh$_3$)$_2$H](BF$_4$) with excess HBF$_4$Et$_2$O in CD$_2$Cl$_2$ yielded, in a straightforward manner, the dicationic η^2-dihydrogen complex [tpmRu(PPh$_3$)$_2$(H$_2$)](BF$_4$)$_2$, which, as expected, is more acidic than its monocationic Tp [Tp = hydrotris(pyrazolyl)borate] analog [TpRu(PPh$_3$)$_2$(H$_2$)]BF$_4$ (pK_a: 2.8 vs. 7.6). The complex [tpmRu(PPh$_3$)$_2$(H$_2$)](BF$_4$)$_2$ is unstable towards H$_2$ loss at ambient temperature. However, acidification of [tpmRu(PPh$_3$)$_2$H]BF$_4$ with excess aqueous HBF$_4$ or aqueous triflic acid in [D$_8$]THF gave very interesting results. Variable-temperature ^{1}H- and ^{31}P-NMR studies revealed that the aqueous acid did not fully protonate the metal hydride to form the dihydrogen complex, but a hydrogen-bonded species was obtained. The feature of this species is that the strength of its Ru–H···H–(H$_2$O)$_m$ interaction decreases with temperature; this phenomenon is unusual because other complexes containing dihydrogen bonds show enhanced M–H···H–X interaction as the temperature is lowered. Decrease of the dihydrogen-bond strength with temperature in the present case can be attributed to the decline of acidity that results from the formation of larger H$^+$(H$_2$O)$_n$ ($n > m$) clusters at lower temperatures; steric hindrance of these large clusters also contribute to the weakening of the dihydrogen bonding interactions. At higher temperatures, facile H/H exchange occurs in Ru–H···H–(H$_2$O)$_m$ via the intermediacy of a "hydrogen-bonded dihydrogen complex" Ru–(H$_2$)···(H$_2$O)$_m$. To investigate the effect of the H$^+$(H$_2$O)$_m$ cluster size on the strength of the dihydrogen bonding in [tpmRu(PPh$_3$)$_2$H]$^+$, molecular orbital calculations at the B3LYP level have been performed on model systems, [tpmRu(PH$_3$)$_2$H]$^+$ + H$^+$(H$_2$O) and [tpmRu(PH$_3$)$_2$H]$^+$ + H$^+$(H$_2$O)$_2$. The results provide further support to the notion that the formation of larger H$^+$(H$_2$O)$_n$ clusters weakens the Ru–H····H(H$_2$O)$_n$ dihydrogen bonding interaction.

Introduction

The recent discovery of intramolecular[1] and intermolecular[2] M–H···H–A dihydrogen bonding between a transition-metal hydride and a hydrogen-bond donor containing an O–H or an N–H group has attracted much attention. It has been shown that such hydride–proton interactions may significantly contribute to the stabilization of organometallic structures in mononuclear complexes[3] and cluster hydride derivatives.[1h,4] They may also be very important in the elucidation of reaction pathways occurring on the surface of transition-metal clusters bearing hydride ligands.[1h,4] Furthermore, complexes containing dihydrogen bonding have been proposed as intermediates for the formation of η^2-dihydrogen complexes or heterolytic cleavage of η^2-H$_2$ ligand.[5] This proposal has been vividly demonstrated by our recent work on intramolecularly hydrogen-bonded ruthenium complexes containing [2-(dimethylamino)ethyl]cyclopentadienyl and [3-(dimethylamino)propyl]cyclopentadienyl ligands (Scheme 1). The intramolecularly hydrogen-bonded complexes were unequivocally characterized by relaxation time T_1 measurements and spin saturation transfer study; the dihydrogen complexes in Scheme 1 were unstable toward H$_2$ loss.[6]

Scheme 1

Chaudret et al.[7] have recently reported the first direct observation of an intermolecular dynamic proton transfer equilibrium: *trans*-(dppm)$_2$HRuH···HOPh ⇌ *trans*-[(dppm)$_2$HRu(H$_2$)]$^+$(OPh)$^-$, when excess PhOH was added to a C$_6$D$_6$ or C$_7$D$_8$ solution of (dppm)$_2$RuH$_2$. The use of 10 equiv. of the more acidic alcohol, hexafluoroisopropyl alcohol (HFP) in place of PhOH resulted in complete proton transfer to give the η^2-dihydrogen complex *trans*-[(dppm)$_2$HRu(H$_2$)]$^+$[OCH(CF$_3$)$_2$]$^-$ immediately. Therefore, it seems that isolation of the hydrogen-bonded complex

L_nM–H···HA is very dependent on the acid strength of HA. We report here that protonation of the monocationic ruthenium hydride complex $[tpmRu(PPh_3)_2H]^+$ [tpm = tris(pyrazolyl)methane] with $HBF_4{\cdot}Et_2O$ in CD_2Cl_2 readily yields the dicationic η^2-dihydrogen complex $[tpmRu(PPh_3)_2(H_2)]^{2+}$, while on the other hand, acidification of the hydride precursor with aqueous HBF_4 or aqueous CF_3SO_3H in [D$_8$]THF generates a hydrogen-bonded species $[tpmRu(PPh_3)_2H{\cdots}H(H_2O)_m]^{2+}$, which displays some unusual and interesting behaviors in variable temperature ^{1}H- and ^{31}P-NMR spectroscopy.

Results and Discussion

Synthesis, Characterization, and Acidity Measurement of $[tpmRu(PPh_3)_2(H_2)](BF_4)_2$ (2)

The dihydrogen complex $[tpmRu(PPh_3)_2(H_2)](BF_4)_2$ (**2**) was synthesized according to the sequence shown in Scheme 2. Reaction of $RuHCl(PPh_3)_3$ with tpm and $NaBF_4$ in THF gave $[tpmRu(PPh_3)_2H]BF_4$ (**1**); adoption of the synthetic route of the analogous Tp complex $TpRu(PPh_3)_2H$ [Tp = hydrotris(pyrazolyl)borate][8] to **1** was not successful. The Tp hydride complex was prepared by sodium borohydride reduction of the chloro precursor $TpRu(PPh_3)_2Cl$, which in turn was synthesized by reaction of $RuCl_2(PPh_3)_3$ with KTp.[9] An analogous reaction of $RuCl_2(PPh_3)_3$ with tpm in the presence of $NaBF_4$ did not, however, yield $[tpmRu(PPh_3)_2Cl]BF_4$ in a pure form, instead it was contaminated with some reddish brown solids. We have learned that the reaction of the neutral facial ligand 1,4,7-trimethyl-1,4,7-triazacyclononane (^{Me}Cn) with $RuCl_2(PPh_3)_3$ and $NaBF_4$ is always plagued by impurities too.[10]

Scheme 2

The ^{1}H-NMR spectrum of **1** shows the hydride signal as a triplet at $\delta = -13.98$ ($J_{HP} = 27.6$ Hz). The coupling constant is similar to those reported for analogous complexes with three-legged piano-stool structures. For example, J = 34.0 Hz for $CpRu(PPh_3)_2H$,[11] and 26.4 Hz for $TpRu(PPh_3)_2H$.[8] The presence of the hydride ligand is also confirmed by IR spectroscopy, which shows the ν(Ru–H) at 2054 cm^{-1} (KBr). That the net positive charge in **1** improves the Ru–H binding is evidenced by comparison of its ν(Ru–H) with that of $TpRu(PPh_3)_2H$ [ν(Ru–H) = 2008 cm^{-1}, KBr].[8] The ^{31}P{^{1}H}-NMR spectrum of **1** shows one resonance at $\delta = 68.3$, indicative of the chemical equivalence of the phosphorous atoms. The molecular dihydrogen complex **2** was prepared in situ by protonation of **1** with $HBF_4{\cdot}Et_2O$ in [D$_2$]dichloromethane at –50 °C.

The presence of the η^2-H_2 moiety in **2** was confirmed by variable-temperature relaxation time T_1 measurements and the observation of a large $^1J_{HD}$ value for the corresponding isotopomer $[tpmRu(PPh_3)_2(HD)](BF_4)_2$. The ^{1}H-NMR spectrum of **2** showed a broad signal at $\delta = -8.04$, integrating for two hydrogen atoms. A minimum T_1 value of 24 ms was recorded at 241 K and 400 MHz. Acidification of **1** with excess DBF_4 gave the η^2-HD isotopomer, which showed a 1:1:1 triplet ($^1J_{HD}$ = 31.1 Hz) of a 1:2:1 triplet ($^2J_{HP}$ = 5.7 Hz) centered at $\delta = -8.06$ in the ^{1}H-NMR spectrum.

The pseudo aqueous pK_a of **2** was estimated by studying the equilibrium shown in Equation 1 with ^{1}H NMR in CD_2Cl_2, using the hydride complex $[^{Me}CnRu(dppe)H]^+$ (^{Me}Cn = 1,4,7-trimethyl-1,4,7-triazacyclononane) as the base.

$$[tpmRu(PPh_3)_2(H_2)]^{2+} + [^{Me}CnRu(dppe)H]^+ \rightleftharpoons [tpmRu(PPh_3)_2H]^+ + [^{Me}CnRu(dppe)(H_2)]^{2+} \quad (1)$$

The pseudo aqueous pK_a value of $[^{Me}CnRu(dppe)(H_2)]^{2+}$ has been determined previously in CD_2Cl_2 using a similar method.[12a] The equilibrium mixture could be conveniently obtained by protonating a mixture of $[tpmRu(PPh_3)_2H]^+$ and $[^{Me}CnRu(dppe)H]^+$ with a limited amount of $HBF_4{\cdot}Et_2O$. The equilibrium was obtained at –60 °C because the η^2-dihydrogen complex **2** is unstable towards H_2 loss at higher temperatures. The relative concentrations of the dihydrogen complexes and metal hydrides in the equilibrium were estimated from integration of the upfield hydride signals in the ^{1}H-NMR spectrum. The pK_a of **2** was estimated to be 3 according to Equation 2. K_{eq} in Equation 2 is the equilibrium constant of Equation 1.

$$pK_a(\mathbf{2}) = pK_{eq} + pK_a([^{Me}CnRu(dppe)(H_2)]^{2+}) \quad (2)$$

The dihydrogen complex **2** is a new entry into the relatively small family of dicationic η^2-dihydrogen complexes.[12] In contrast to the abundance of monocationic dihydrogen complexes, the number of well-characterized dicationic dihydrogen complexes is still limited. The double positive charge of the metal center in these complexes lowers the effectiveness of $d\sigma(M)\rightarrow\sigma^*(H_2)$ back bonding, and increases the $\sigma(H_2)\rightarrow d\sigma(M)$ interaction. It is therefore expected that depletion of electron density in the η^2-H_2 ligand renders the dicationic dihydrogen complexes very

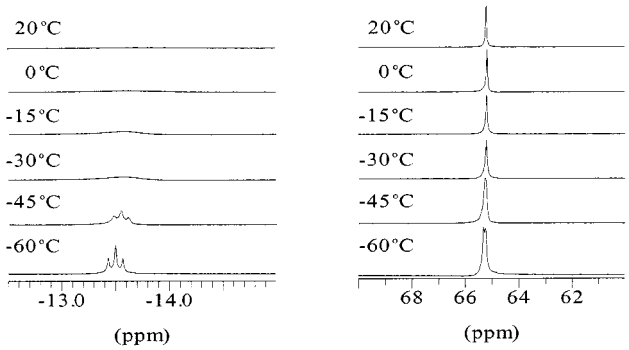
acidic. Dicationic dihydrogen complexes, which demonstrate high reactivity toward heterolysis of η^2-H_2 ($pK_a < -2$) and high room-temperature stability with respect to loss of H_2, both in solid state and in solution, have recently been reported, including $[Os(bpy)(PR_3)_2(CO)(H_2)]^{2+}$ (PR_3 = PPh_3, $PMePh_2$; bpy = 2,2′-bipyridine),[12b][12c] $[Os(phen)(PPh_3)_2(CO)(H_2)]^{2+}$ (phen = 1,10-phenanthroline),[12c] $[Os(dppp)_2(CO)(H_2)]^{2+}$,[12d] *trans*-$[Os(dppe)_2(CH_3CN)(H_2)]^{2+}$,[12e] and *trans*-$[Fe(dppe)_2(L)(H_2)]^{2+}$ (L = CO, CNH).[12f] A strong $\sigma(H_2)\rightarrow d\sigma(M)$ interaction is believed to be dominant in these complexes.

Less stable (H_2 loss at room temperature), but acidic dicationic dihydrogen complexes are exemplified by $[Os(P\mathit{i}Pr_3)_2(CH_3CN)_3(H_2)]^{2+}$,[12g] $[Ru(bpy)(PPh_3)_2(CO)(H_2)]^{2+}$,[12c] and $[Ru(dppp)_2(CO)(H_2)]^{2+}$.[12d] We have recently reported the synthesis and acidity of some dicationic dihydrogen complexes containing the facial triazacyclononane ligands $[^{R}CnRu(L)(L')(H_2)]^{2+}$ [^{H}Cn = 1,4,7-triazacyclononane, ^{Me}Cn = 1,4,7-trimethyl-1,4,7-triazacyclononane; L,L′ = $(PPh_3)_2$, dppe, and CO, PPh_3]; the acidity of the complexes $[^{H}CnRu(PPh_3)_2(H_2)]^{2+}$ (pK_a = 4.5) and $[^{Me}CnRu(dppe)(H_2)]^{2+}$ (pK_a = 3.8), although low in comparison to those of the aforementioned dicationic dihydrogen complexes, are nevertheless significantly higher than those of their monocationic hydrotris(pyrazolyl)borato (Tp) and Cp analogoues (by 3–4 pK_a units). The carbonyl-containing complexes $[^{H}CnRu(PPh_3)(CO)(H_2)]^{2+}$ (pK_a = –1.3) and $[^{Me}CnRu(PPh_3)(CO)(H_2)]^{2+}$ (pK_a = –2.6) are also more acidic than their monocationic Tp counterpart $[TpRu(PPh_3)(CO)(H_2)]^{+}$ (pK_a = –0.6), but to a smaller extent. The non-carbonyl-containing ^{R}Cn dihydrogen complexes are stable in the solid state at room temperature, but in solution the η^2-H_2 ligand is displaced by strongly coordinating solvent such as acetonitrile.[12a] It should be mentioned that dicationic dihydrogen complexes are not necessarily acidic, for example, $[Os(NH_3)_4(L)(H_2)]^{2+}$ [12h,12i] and $[Os(en)_2(L)(H_2)]^{2+}$,[12j] reported by Taube and co-workers, which tightly bind H_2, are not acidic, probably due to the strong electron-donating effect of the NH_3 and en ligands.

The fact that complex **2** is more acidic than the analogous dicationic ^{R}Cn dihydrogen complexes $[^{H}CnRu(PPh_3)_2(H_2)]^{2+}$ [12a] and $[^{Me}CnRu(PPh_3)_2(H_2)]^{2+}$ [12a] seems to indicate that the tpm ligand is less electron donating than ^{R}Cn. As expected, **2** is significantly more acidic than the analogous monocationic Tp and Cp complexes. On the other hand, the stability of **2** is lower than that of the ^{R}Cn, Tp, and Cp counterparts. The η^2-H_2 of **2** is labile at –15 °C. In fact, addition of $HBF_4{\cdot}Et_2O$ to **1** in CD_2Cl_2 at room temperature resulted in immediate evolution of H_2, which gave a signal at δ = 4.62 in the ^{1}H-NMR spectrum. The major product of the reaction was the aquo complex $[tpmRu(PPh_3)_2(H_2O)](BF_4)_2$ (**3**),[13] which was formed by displacement of η^2-H_2 by residual H_2O in the solvent, only a trace amount of **2** was detected (vide infra). It is noteworthy that the T_1(min) of **2** is larger than that of the monocationic analog $[TpRu(PPh_3)_2(H_2)]BF_4$,[8] and its $^1J_{HD}$ value is smaller than that of the latter. The weaker H–H interaction of the η^2-H_2 ligand in **2** relative to that of the η^2-H_2 in $[TpRu(PPh_3)_2(H_2)]BF_4$ may be due the fact that the tpm ruthenium fragment $[tpmRu(PPh_3)_2]^{2+}$ is a stronger σ-acceptor than the Tp counterpart. Morris has pointed out that the lower H–H bond strength of the η^2-H_2 in $[Os(pys)(PPh_3)_2(CO)(H_2)]BF_4$ (pys = 2-pyridinethiolate) is a result of the strong $\sigma(H_2)\rightarrow d\sigma(M)$ interaction.[14]

Acidification of [tpmRu(PPh$_3$)$_2$H](BF$_4$) (1) with Aqueous HBF$_4$ or Aqueous CF$_3$SO$_3$H

While protonation of **1** with excess $HBF_4{\cdot}Et_2O$ in CD_2Cl_2 generated **2** in a straightforward manner, acidification of **1** in [D$_8$]THF with excess aqueous HBF_4 or aqueous CF_3SO_3H gave quite different results. No dihydrogen gas evolution was detected, even when the acidification was carried out at room temperature; and no signal seemed to be observable in the upfield region of the ^{1}H-NMR spectrum (Figure 1, left). However, a very broad signal became detectable at –15°C; and it gradually evolved into a broad triplet as the temperature was lowered to –45°C; the broad triplet sharpened when the temperature was further decreased to –60°C . The spectral change with temperature was found to be reversible, i.e. the triplet gradually broadened into the baseline again with increasing temperature. Concurrent off-resonance decoupled ^{31}P-NMR spectra are also shown in Figure 1 (right). It can be seen that as the triplet hydride peak starts broadening out at –45 °C, H–P coupling in the ^{31}P-NMR spectrum disappears. The phosphorus peak also sharpens as the hydride signal broadens into the baseline. Like the VT ^{1}H-NMR study, the spectral changes with temperature in the ^{31}P-NMR measurements are also reversible. In fact, if the protonation reaction was carried out at –60°C, and the temperature gradually raised to 20°C, the sets of ^{1}H- and ^{31}P-NMR spectra collected at various temperatures were identical to those depicted in Figure 1. It is interesting to note that throughout the whole variable-temperature NMR study, signals pertaining to η^2-H_2 ligand and free H_2 were not observed.



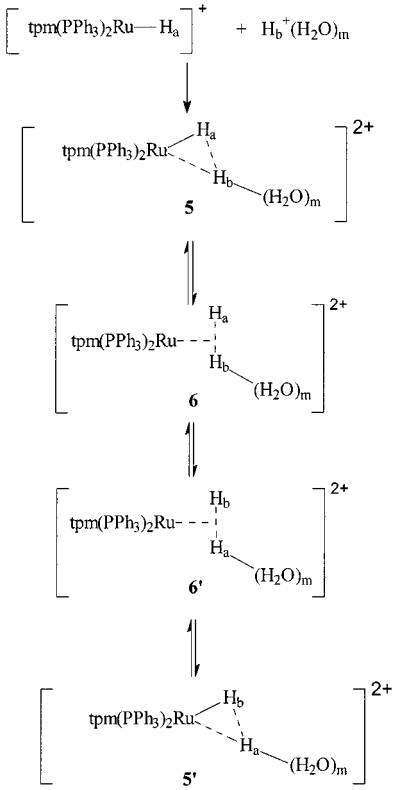


Figure 1. Variable-temperature (left) ^{1}H-NMR spectra (upfield region) and (right) ^{31}P-NMR spectra of $[tpmRu(PPh_3)_2H]^+$ + aq HBF_4 in [D$_8$]THF

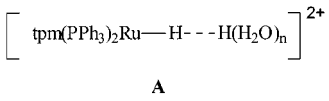
The fact that acidification of **1** with aqueous HBF_4 or aqueous CF_3SO_3H in [D$_8$]THF gave identical result, as revealed by VT ^{1}H- and ^{31}P-NMR studies, seemed to indicate that the two acids were leveled to the same species in the



two systems. We assume that the acids were both leveled to $H^+(H_2O)_m$, and have to admit that the precise state of solvation of H^+ was unknown.[15] It seems, however, that the pK_a value (–1.74)[16] commonly assigned to H_3O^+ does not reflect the actual acidity of the aqueous HBF_4 or aqueous CF_3SO_3H in our case. Failure to generate the dihydrogen complex **2** with aqueous HBF_4 or aqueous CF_3SO_3H implies that acidity of either acid might only be close to or even lower than that of $[tpmRu(PPh_3)_2(H_2)]^{2+}$, and therefore is not able to effect complete proton transfer to **1**. In our recent work, we have attributed deprotonation of the η^2-H_2 ligands in $[TpRu(L_2)(H_2)]^+$ [L_2 = $(PPh_3)_2$, dppe][8][12a] and $[^RCnRu(L_2)(H_2)]^{2+}$ [^RCn = 1,4,7-triazacyclononane, 1,4,7-trimethyl-1,4,7-triazacyclononane; L_2 = $(PPh_3)_2$, dppe][12a] by H_2O in THF/H_2O or organic/aqueous mixed solvents to strong solvation of H^+ by H_2O; all these complexes have pK_a values higher than 3.

Scheme 3

Spectral changes of the hydride signal in the VT ^{1}H-NMR study of the acidification reaction of **1** with aqueous acid are contrary to the behaviors of the hydride signals of complexes containing dihydrogen bonding. The hydride signals of these complexes usually broaden as the temperature goes down, due to strengthening of the M–H···H–X interaction, and they sharpen as the temperature is increased because of weakening of the dihydrogen bonding. The unusual spectral behavior displayed by the hydride ligand of **1** in the acidification process can be reconciled by the sequence depicted in Scheme 3. Acidification of **1** with aqueous acid generates the hydrogen-bonded species **5**; at higher temperature, rapid H/H exchange between Ru–H and $H^+(H_2O)_m$ (**5** ⇌ **5′**) via the intermediacies of a pair of transient η^2-dihydrogen complexes (**6** and **6′**) leads to broadening-out of the hydride signal. The feature of this pair (**6** and **6′**) is that the η^2-H_2 ligand, which is hydrogen-bonded to the $(H_2O)_m$, does not dissociate readily from the metal center, and that might be the reason for not observing free H_2 in the course of the VT ^{1}H-NMR study. Analogously, Crabtree et al. have very recently reported that hydrogen-bonding provided by a pendant amine group is the key factor that allows stabilization of an Ir–(HF) complex.[17] Species similar to **5** (or **5′**) and **6** (or **6′**) have been proposed as intermediates in the protonation of *cis*-$[FeH_2\{PCH_2CH_2PPh_2)_3\}]$ to form the η^2-dihydrogen complex.[18]

At low temperature (–60° C), acidity decreases due to higher degree of solvation of H^+, i.e. formation of larger cluster $H^+(H_2O)_n$; Ru–H···H$(H_2O)_n$, dihydrogen bonding in **A** weakens and therefore results in sharpening of the hydride signal.

A

Weakening of the dihydrogen bonding in **A** at low temperature can also be rationalized in terms of steric effect of the large cluster $H^+(H_2O)_n$.

Another possible scenario for the protonation of **1** with aqueous acid is the occurrence of a rapid proton transfer between **1** and H_2O (Equation 3); lowering the temperature would slow down this proton exchange and the low temperature spectrum closely resembles that of complex **1**. But the equilibrium depicted in Equation 3 does not seem to be in congruence with the VT NMR spectra shown Figure 1.

$$[tpmRu(PPh_3)_2H]^+ + H_3O^+ \rightleftharpoons [tpmRu(PPh_3)_2(H_2)]^{2+} + H_2O \quad (3)$$

1 **2**

If such a rapid proton transfer occurs, it is most likely that a weighted average of hydride signals of **1** and **2** is observed, and the phosphorus signal is also an average of those of **1** and **2**. However, careful examination of the VT ^{1}H- and ^{31}P-NMR spectra does not reveal the existence of these average signals. It is also noteworthy that no H_2 loss was observed when the system was allowed to stand at room temperature. Had the equilibrium depicted in Equation 3 existed, the equilibrating **2** should have evolved H_2 while standing at room temperature. We have learned that **2** is unstable with respect to H_2 loss at –15 °C.

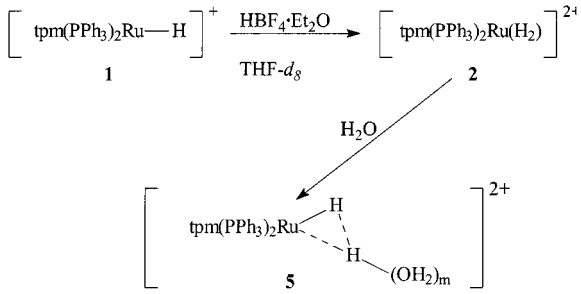
Dihydrogen bonding between the protonated water cluster $H(H_2O)_m^+$ and the hydride in **5** (or **5′**) was characterized by IR spectroscopy in THF at room temperature. A THF solution of **2** showed the ν(RuH) band at 2040 cm^{-1}, upon addition of 10 equiv. of aqueous HBF_4, this band was shifted to a lower wavenumber at 1967 cm^{-1}. Berke, Epstein, and co-workers have characterized intermolecular hydrogen bonding of acidic alcohols to the hydride ligand of $WH(CO)_2(NO)L_2$ by IR spectroscopy in hexane at 200 K. The IR spectrum of the tungsten hydride complex showed

a low-wavenumber shoulder in the ν(WH) band, in the presence of 3 equiv. of hexafluoro-2-propanol (HFIP).[2e] Unfortunately, it is not possible to characterize the dihydrogen bonding between **2** and protonated water cluster by measurement of T_1(min) because the strength of the Ru–H···H(H$_2$O)$_{m\ or\ n}$ dihydrogen bond in the system varies with temperature. Furthermore, it is not possible to measure T_1 at –30 °C or above since the hydride signal broadens into the baseline at these temperatures. Acidification of **1** with HBF$_4$·Et$_2$O in CD$_3$OD/[D$_8$]THF gave practically identical results as the protonation of **1** with aqueous HBF$_4$ in [D$_8$]THF. This is not surprising since it is expected that methanol behaves very similarly to H$_2$O in this process. Quantum chemical calculations described in the following section also seem to support our proposal of Scheme 3.

At this point, we would like to comment on the formation of aquo complex [tpmRu(PPh$_3$)$_2$(H$_2$O)](BF$_4$)$_2$ (**3**) in the room-temperature protonation reaction of **1** with HBF$_4$·Et$_2$O in CD$_2$Cl$_2$. The predominant form of acid in this system is Et$_2$OH$^+$, which is strong enough to fully protonate **1** to form **2**. The trace amount of water present in the system does not form the hydrogen-bonded species **5** (or **5′**) with **2** because it is protonated by Et$_2$OH$^+$ (Equation 4), which is a stronger acid than **2**. At –15°C or above, the η^2-H$_2$ ligand in **2** becomes labile, and the coordinatively unsaturated species generated upon dissociation of H$_2$ from **2** abstracts H$_2$O from the equilibrium (Equation 4) to form the thermodynamically stable aquo complex **3**.

$$Et_2OH^+ + H_2O \rightleftharpoons Et_2O + H_3O^+ \quad (4)$$

The H/H exchange proposed in Scheme 3 was further supported by H/D exchange, which occurred in the acidification of a [D$_8$]THF solution of **1** with CF$_3$SO$_3$D/D$_2$O. It was found that addition of CF$_3$SO$_3$D/D$_2$O (v/v, 1:1) to a [D$_8$]THF solution of **1** at room temperature led to immediate broadening of the hydride signal into the baseline. The upfield triplet signal, which re-appeared as the temperature was lowered to –60 °C, diminished considerably due to H/D exchange.



Structure **5** (or **5′**) can be viewed as an intermediate on the reaction path that leads to transient **6** (or **6′**), and then to the product of complete proton transfer from an acid to the metal hydride precursor. Gusev and Reinhart have very recently proposed that reactions of anionic ruthenium and rhenium hydrides with phenylacetylene first generate the hydrogen-bonded species [L$_n$M–H···H–C≡CPh]$^-$, which equilibrates with the transient [L$_n$M(μ-H$_2$)(CCPh)]$^-$ (Equation 5). The latter, which is analogous to **6** (or **6′**), then undergoes hydride transfer to the C$_\alpha$ atom of phenylacetylene to form the [L$_n$M–C(Ph)=CH$_2$]$^-$ vinyl intermediate.[19]

(5)

Generation of the Hydrogen-Bonded Complex from 2

We have been able to generate the hydrogen-bonded complex **5** from the η^2-dihydrogen complex **2**, and have monitored this transformation by using ^{1}H-NMR spectroscopy. Complex **2** was first formed in a 5-mm NMR tube by acidification of a [D$_8$]THF solution of **1** (0.4 mL) with 1 equiv. of HBF$_4$·Et$_2$O at –30 °C, subsequent addition of 50 μL of H$_2$O to the solution led to the disappearance of the η^2-H$_2$ signal of **2** and concomitant appearance of the very broad peak of the hydrogen-bonded hydride of **5** (Scheme 4).

Scheme 4

Quantum Chemical Study

The broadening/sharpening changes of the hydride signal for the dihydrogen-bonded species **5** observed in the variable-temperature NMR experiments show unusual behavior when compared to other dihydrogen bonded systems.[2e,7] In order to provide an insight into the understanding of the unusual behavior, quantum mechanical calculations at the density-functional B3LYP level of theory have been undertaken to investigate the structural details for the following model systems: [tpmRu(PH$_3$)$_2$H]$^+$, [tpmRu(PH$_3$)$_2$(H$_2$)]$^{2+}$, [tpmRu(PH$_3$)$_2$H]$^+$ + H$^+$(H$_2$O), and [tpmRu(PH$_3$)$_2$H]$^+$ + H$^+$(H$_2$O)$_2$. The [tpmRu(PH$_3$)$_2$(H$_2$)]$^{2+}$ system represents the complete proton transfer product in organic solvent. The latter two model systems represent the corresponding situation in aqueous/THF solution, and the relevant calculations allow us to study the effect of water aggregation on the dihydrogen bonding. They can also provide information on the structural details of protonated products under different acidity because one can consider that HBF$_4$·Et$_2$O is more acidic than H$^+$(H$_2$O), which in turn, is more acidic than H$^+$(H$_2$O)$_2$. It should be noted that the model systems cannot be directly related to the experimental systems because the actual degree of water aggregation in each experimental system cannot be well-defined. Therefore, the calculated H···H distances for different numbers of water molecules in the model systems are only useful in considering the trend, which qualitatively accounts for the effect of water aggregation on the dihydrogen bonding.

The optimized structures for the four model systems are shown in Figure 2. Consistent with the experimental finding that the direct protonation of [tmpRu(PPh$_3$)$_2$H]$^+$ with HBF$_4$·Et$_2$O in an organic solvent gives a non-classical dihydrogen complex, [tpmRu(PH$_3$)$_2$(H$_2$)]$^{2+}$. The H–H distance in this dihydrogen complex is calculated to be 0.81 Å with a symmetrical coordination of the η^2-H$_2$ unit (Ru–H: 1.82 Å).[20]

The calculations for the [tpmRu(PH$_3$)$_2$H]$^+$ + H$^+$(H$_2$O) system give a similar result. The system can be described as [tpmRu(PH$_3$)$_2$(H$_2$)···OH$_2$]$^{2+}$, again a non-classical dihydro-

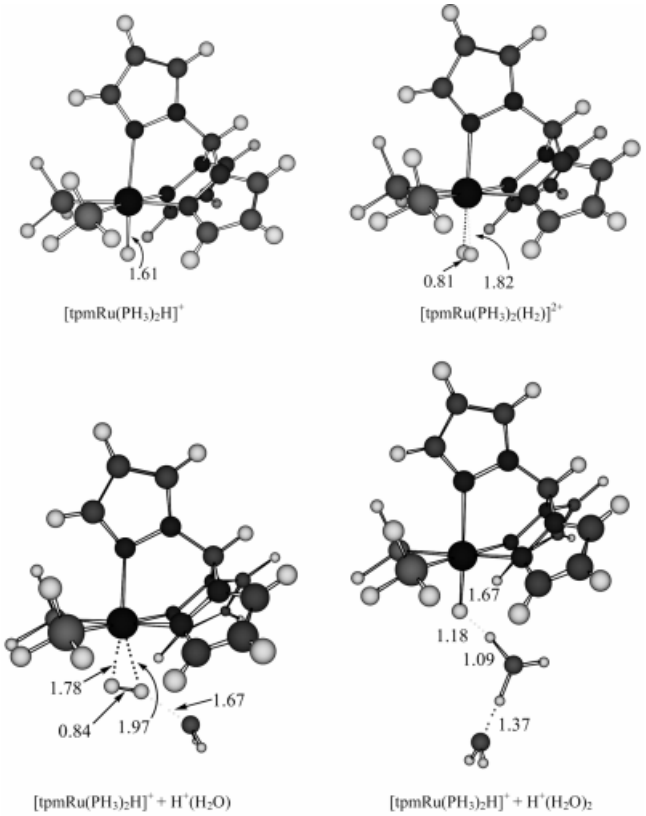


Figure 2. Optimized structures for model systems: $[tpmRu(PH_3)_2H]^+$, $[tpmRu(PH_3)_2(\eta^2\text{-}H_2)]^{2+}$, $[tpmRu(PH_3)_2H]^+ + H^+(H_2O)$, and $[tpmRu(PH_3)_2H]^+ + H^+(H_2O)_2$

gen complex, a weak hydrogen bond exists between one of the two hydrogen atoms and the oxygen atom of H_2O (H···O: 1.67 Å). The H–H distance (0.84 Å) in the η^2-H_2 unit lengthens only slightly, although the coordination of the η^2-H_2 ligand becomes unsymmetrical. The Ru–H distance on the side of the O···H hydrogen bonding is lengthened (1.97 Å) while the other is shortened (1.78 Å). The results of these calculations for the mono-water system suggest that $H^+(H_2O)$ is still very acidic, resulting in the formation of non-classical structure upon protonation.

Surprisingly, further association with one more water molecule, which gives the $[tpmRu(PH_3)_2H]^+ + H^+(H_2O)_2$ system, leads to a species that is close to a classical hydride. The metal-hydride distance, calculated to be 1.67 Å, is within the range of classical M–H distance[20g,21] {1.61 Å in $[tpmRu(PH_3)_2H]^+$}. In this system, the hydride ligand was also found to have a significant interaction with the proton from the $H^+(H_2O)_2$ unit. The H···H distance was calculated to be 1.18 Å. The typical H···H distance in other M–H···H–X systems is around 1.8 Å.[5] Apparently, in the current system, the hydride acceptor [H^+ in $H^+(H_2O)_2$] is very protonic when compared to other systems studied previously.[2e,7] In the structure of $[tpmRu(PH_3)_2H]^+ \cdots H^+(H_2O)_2$, one can clearly see the aggregate of $H^+(H_2O)_2$, which can be formulated as $H^+(H_2O)\cdots OH_2$. The additional H_2O is only weakly bounded through normal hydrogen bonding.

These calculations indicate that the mono-water system prefers a dihydrogen non-classical structure, while the di-water system adopts a structure close to a classical hydride. Though weakly bound, the presence of an additional water molecule surprisingly switches the non-classical structure to a classical one with M–H···H–X dihydrogen bonding. This result suggests that a fast exchange can occur between classical and non-classical structures, as proposed in Scheme 3, when temperature increases. The association and dissociation of the weakly bound water molecule can be strongly influenced by temperature.

The current work deals with the effect of water aggregation on the H···H dihydrogen bonding. The stability of these dicationic hydrogen-bonded systems is another important topic that requires further attention. Theoretically, the evaluation of the H···H bonding strengths in the studied systems involves the charge-separation processes. Therefore, much higher levels of theory are necessary in order to produce some meaningful results. Clearly, the stability of these systems should be further studied both theoretically and experimentally.

Conclusion

We have shown in this study, the species that are proposed as intermediates along the reaction pathway of protonation of metal hydrides to form η^2-dihydrogen complexes. One of these species is a hydrogen-bonded metal hydride, $[tpmRu(PPh_3)_2H\cdots H(H_2O)_n]^{2+}$ (**A**), which is formed by acidification of $[tpmRu(PPh_3)_2H]^+$ with aqueous HBF_4 in [D_8]THF at –60 °C. The comparatively weak Ru–H···$H(H_2O)_n$ dihydrogen interaction is attributable to lower acidity and larger steric hindrance of the bulky $H^+(H_2O)_n$ clusters, which are the major forms of acid at low temperature. At higher temperatures, the degree of aquation of H^+ decreases and the smaller clusters $H^+(H_2O)_m$ ($m < n$) exhibit relatively higher acidity, therefore the species **5** (or **5′**) with stronger dihydrogen bonding become the major species in solution. Finally, a full-fledged η^2-dihydrogen complex $[tpmRu(PPh_3)_2(H_2)]^{2+}$ is generated when $tpmRu(PPh_3)_2H$ is protonated with $HBF_4{\cdot}Et_2O$ in CD_2Cl_2. The results of our quantum chemical calculations at B3LYP level on model systems, $[tpmRu(PH_3)_2H]^+ + H^+(H_2O)$ and $[tpmRu(PH_3)_2H]^+ + H^+(H_2O)_2$, indeed suggest that the Ru–H···$H(H_2O)_m$ dihydrogen bonding interaction greatly depends on the size of the water cluster. For the mono-water model system, a non-classical dihydrogen complex is preferred. The di-water system, however, gives a Ru–H···$H(H_2O)_2$ dihydrogen bonded species.

The acidification of metal hydrides normally leads to either non-classical η^2-H_2 dihydrogen complexes or formation of species with the M–H···H–X interaction (dihydrogen bonding). Strongly acidic conditions give non-classical complexes, while weakly acidic conditions result in dihydrogen bonding. Here, we demonstrate that the strength of hydride-proton interaction can be tuned through the association of water molecules to H^+.

Experimental Section

All reactions were performed under dry nitrogen using standard Schlenk techniques. Solvents were distilled under nitrogen from appropriate drying agents[22] (solvent/drying agent): methanol/Mg/I$_2$, ethanol/Mg/I$_2$, acetonitrile/CaH$_2$, dichloromethane/CaH$_2$, tetrahydrofuran/Na/benzophenone, diethyl ether/Na, *n*-hexane/Na. Ruthenium trichloride, RuCl$_3$·3H$_2$O, pyrazole, sodium tetrafluoroborate, and [D$_1$]trifluoromethanesulfonic acid were purchased from Aldrich. Tetrafluoroboric acid in ethereal solution and aqueous solution were obtained from Fluka. Triphenylphosphane was obtained from Merck and was recrystallized from ethanol before use. The complexes RuHCl(PPh$_3$)$_3$ [23] and [^{Me}CnRu(dppe)H]BF$_4$ (^{Me}Cn = 1,4,7-trimethyl-1,4,7-triazacyclononane)[12a] were synthesized according to literature methods. – Infrared spectra were obtained from a Nicolet Magna 750 Ft-IR spectrophotometer. ^{1}H-NMR spectra were recorded with a Bruker DPX-400 spectrometer; chemical shifts were reported relative to residual protons of the deuterated solvents. ^{31}P-NMR spectrum were measured at 161.7 MHz with a Bruker DPX-400 spectrometer; chemical shifts of these spectra were externally referenced to 85% H$_3$PO$_4$ in D$_2$O (δ = 0). Relaxation-time T_1 measurements were carried out at 400 MHz by the inversion-recovery method using the standard 180°–τ–90° pulse sequences. Elemental analyses were performed by M–H–W laboratories, Phoenix, AZ.

Trispyrazolylmethane (tpm): The ligand tpm was prepared by following a literature method,[24] with some modifications. A solution of pyrazole (10.00 g, 0.15 mmol) in 30 mL of THF was added to a vigorously stirred suspension of potassium (1.9 g, 50 mmol) in 200 mL of THF. After the potassium had completely reacted, chloroform (6.0 mL, 6.5 mmol) was slowly added over a period of 2 h, and the colloidal mixture was stirred under reflux for 36 h. The mixture was filtered at room temperature to remove the KCl, and the solvent of the filtrate was removed by using a rotary evaporator to yield a dark brown sludge. Pure trispyrazolylmethane was obtained by sublimation of the dark brown sludge. Yield: 3.1 g (9.5% based on pyrazole used).

[tpmRu(PPh$_3$)$_2$H]BF$_4$ (1): Samples of RuHCl(PPh$_3$)$_3$ (0.60 g, 0.60 mmol), tpm (0.15 g, 0.70 mmol), and NaBF$_4$ (0.072 g 0.66 mmol) were dissolved is 20 mL of THF and the solution was stirred at room temperature for 1 h. The solution was then concentrated to dryness under vacuum, and the residue was washed with methanol. Pure product was obtained by recrystallization of the residue with dichloromethane/hexane. Yield: 0.48 g (87%). – C$_{46}$H$_{41}$BF$_4$N$_6$P$_2$Ru: calcd. C 59.55, H 4.45, N 9.06; found C 59.48, H 4.48, N 8.94. – IR (KBr, cm^{-1}): ν(Ru–H) = 2054 (m). – ^{1}H NMR ([D$_6$]acetone, 400 MHz, 25 °C): δ = –13.82 (t, 1 H, $^3J_{HP}$ = 27.8 Hz), 5.99 (t, 2 H, pz, $^3J_{HH}$ = 2.36 Hz), 6.31 (t, 1 H, pz, $^3J_{HH}$ = 2.35 Hz), 6.83 (d, 1 H, pz, $^3J_{HH}$ = 1.70 Hz), 6.88 (d, 2 H, pz, $^3J_{HH}$ = 1.82 Hz), 7.13–7.37 (m, 30 H of PPh$_3$), 8.21 (d, 2 H, pz, $^3J_{HH}$ = 2.59 Hz), 8.48 (d, 1 H, pz, $^3J_{HH}$ = 2.57 Hz), 9.33 (s, 1 H, pz$_3$C*H*). – ^{31}P{^{1}H} NMR (CD$_2$Cl$_2$, 161.70 MHz, 25 °C): δ = 70.6 (s).

In Situ Preparation of [tpmRu(PPh$_3$)$_2$(H$_2$)](BF$_4$)$_2$ (2): A sample of **1** (10 mg, 11 μmol) was dissolved in 0.4 mL of [D$_2$]dichloromethane, the solution was cooled to –50 °C inside the NMR probe, 1.3 μL of HBF$_4$ (13 μmol, 54% solution in diethyl ether) was then added. A period of 15 min was allowed for completion of the reaction before NMR spectra were recorded. – ^{1}H NMR (CD$_2$Cl$_2$, 400 MHz, –50 °C): δ = –8.04 [br. s, 2 H, Ru–(H$_2$)], 5.34 (s, 1 H, pz), 5.76 (s, 1 H, pz), 5.93 (s, 2 H, pz), 6.32 (s, 2 H, pz), 6.98–7.50 (m, 30 H of PPh$_3$), 7.98 (s, 2 H, pz), 8.41 (s, 1 H, pz), 9.33 (s, 1 H, pz$_3$C*H*). – ^{31}P{^{1}H} NMR (CD$_2$CL$_2$, 161.70 MHz, –50 °C): δ = 48.2 (s). Variable- temperature T_1 measurements on the H$_2$ signal were carried out by the inversion-recovery method using standard 180°–τ–90° pulse sequence. – T_1 (400 MHz, ms): 41.3 (203 K), 32.9 (213 K), 28.2 (223 K), 25.2 (233 K), 23.9 (243 K), 28.7 (253 K). T_1(min) (400 MHz, 241 K): 24.0 ms.

In Situ Preparation of [tpmRu(PPh$_3$)$_2$(HD)](BF$_4$)$_2$ ([D$_1$]-2): A sample of **1** (18 mg, 20 μmol) was dissolved in 0.4 mL of [D$_2$]dichloromethane. After cooling the solution to –50 °C, 2.1 μL of DBF$_4$ solution was added. – ^{1}H NMR (CD$_2$Cl$_2$, 400 MHz, –50 °C): δ = –8.06 (tt, J_{HD} = 31.1 Hz, J_{HP} = 5.8 Hz).

[tpmRu(PPh$_3$)$_2$(H$_2$O)](BF$_4$)$_2$ (3): A sample of **1** (300 mg, 0.3 mmol) was dissolved in 20 mL of CH$_2$Cl$_2$, excess HBF$_4$·Et$_2$O (100 μL, 54% solution in diethyl ether) was added, followed by addition of 5 μL of H$_2$O. The solution was stirred at room temperature for 30 min, and was then concentrated to dryness under vacuum to yield a pale yellow solid, which was washed with 20 mL of diethyl ether. Yield: 270 mg (88%). – C$_{46}$H$_{42}$B$_2$F$_8$N$_6$OP$_2$Ru: calcd. C 53.55, H 4.10, N 8.15; found C 53.36, H 3.93, N 8.07. – ^{1}H NMR (CD$_2$Cl$_2$, 400 MHz, 20 °C): δ = 9.91 (s, 1 H, pz$_3$C*H*), 8.79 (d, 1 H, pz, $^3J_{HH}$ = 2.90 Hz), 8.55 (d, 2 H, pz, $^3J_{HH}$ = 2.78 Hz), 7.60–7.34 (m, 30H of PPh$_3$), 6.90 (d, 1 H, pz, $^3J_{HH}$ = 1.98 Hz), 6.43 (t, 2 H, pz, $^3J_{HH}$ = 2.48 Hz), 5.86 (t, 1 H, pz, $^3J_{HH}$ = 2.68 Hz), 5.52 (d, 1 H, pz, $^3J_{HH}$ = 2.31 Hz), 3.71 (s, 2 H, *H*$_2$O). – ^{31}P{^{1}H} NMR (CD$_2$Cl$_2$, 162 MHz, 20 °C): δ = 44.1 (s).

Acidity Measurement: The pK_a value of [tpmRu(PPh$_3$)$_2$(H$_2$)](BF$_4$)$_2$ was estimated by studying the equilibrium shown in Equation 1. In the experiment, appropriate amounts of [tpmRu(PPh$_3$)$_2$H]BF$_4$ and [^{Me}CnRu(dppe)H]BF$_4$ were dissolved in CD$_2$Cl$_2$ in an NMR tube, and a limited amount of HBF$_4$·Et$_2$O was then added. The ^{1}H-NMR spectrum was immediately taken at –60 °C. Relative molar concentrations of the equilibrated species were derived from the ^{1}H-NMR integrations of the hydride signals.

Protonation of [tpmRu(PPh$_3$)$_2$H]BF$_4$ (1) with Aqueous HBF$_4$: A sample of [tpmRu(PPh$_3$)$_2$H]BF$_4$ (**1**) (10 mg, 0.011 mmol) was dissolved in 0.4 mL of [D$_8$]THF in a 5-mm NMR tube, and 10 μL of aqueous HBF$_4$ (8 M) was added. The VT ^{1}H-NMR spectra were immediately taken.

Computational Details: The quantum mechanical calculations at the density-functional B3LYP level of theory used the effective core potentials of Wadt and Hay with double-ζ valence functions[25] for the Ru and P atoms. The standard 3–21G basis sets were applied to the first-row elements H, C, and N, with those hydrogens directly involved in hydrogen bonding (and dihydrogen bonding) augmented by single-ζ polarization functions (i.e. 3–21 g**).[26] The use of the 3–21G basis set in the calculations allows us to keep the computational expense reasonable due to the large size of the tmp ligand. All structures were fully optimized with the Gaussian98 package.[27]

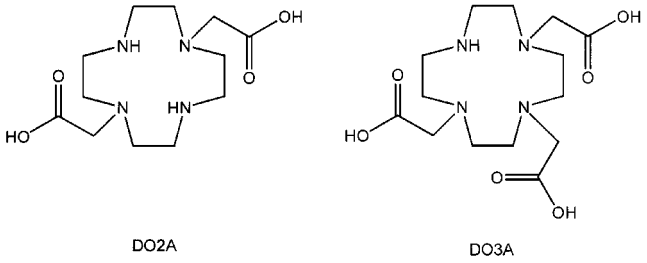
Keywords: Imaging agents / Lanthanides / NMR spectroscopy / DNA cleavage

The hydration state of a series of $[Ln(DO2A)(H_2O)_n]^+$ complexes in aqueous solution at pH = 6.4–7.0 was studied by measuring the lanthanide-induced ^{17}O shifts (LIS) of water [Ln includes elements from Ce to Yb; DO2A = 1,7-bis(carboxymethyl)-1,4,7,10-tetraazacyclododecane]. Their contact contribution, obtained from Reilley plots, indicated a decrease in the inner-sphere water coordination number of the $[Ln(DO2A)(H_2O)_n]^+$ complexes from $n = 3$ (Ce–Eu), to $n = 2$ (Tb–Yb). A temperature-dependent UV/Vis absorption study of the 578–582 nm $^7F_0 \rightarrow {}^5D_0$ transition band of $[Eu(DO2A)(H_2O)_n]^+$ in aqueous solution showed that this complex is present in an equilibrium between eight- and nine-coordinate species with $n = 2$ and $n = 3$, respectively. The hydration equilibrium parameters ($2 \rightleftarrows 3$), $K_{2-3}^{298} = 4.0 \pm 0.2$, $\Delta H_{2-3}^0 = -12.1 \pm 1$ kJ mol^{-1} and $\Delta S_{2-3}^0 = -28.9 \pm 3$ J mol^{-1} K^{-1},correspond to an average hydration number of 2.65–2.85 in the temperature range 273–363 K. A variable temperature, multiple field ^{17}O NMR study combined with direct EPR measurements of the transverse electronic relaxation rates has been used to obtain the parameters characterizing water exchange, rotation and electronic relaxation, all influencing the proton relaxivity of $[Gd(DO2A)(H_2O)_{2-3}]^+$. The small increase in the water exchange rate of $[Gd(DO2A)(H_2O)_{2-3}]^+$ ($k_{ex}^{298} = (10 \pm 5) \times 10^6 s^{-1}$) relative to that of$[Gd(DOTA)(H_2O)]^-$ (4.8×10^6 s^{-1}) is a consequence of an unfavorable interplay of charge and hydration equilibria. The value of $\tau_R^{298} = 40 \pm 1$ ps is short, and the electronic relaxation rate ($1/T_{2e} \approx 1.2 \times 10^{10}$ s^{-1}) is fast relative to $[Gd(DOTA)(H_2O)]^-$ ($1.3–2.4 \times 10^9$ s^{-1} for $B = 0.34$ T). These parameters negate to some extent the expected increase in proton relaxivity of the $[Gd(DO2A)(H_2O)_{2-3}]^+$ complex.



Introduction

There is a continued strong interest in the synthesis and characterization of trivalent lanthanide complexes, largely driven by biological and medical applications in magnetic resonance imaging (MRI),[1] NMR shift reagents,[2] luminescence probes[3] and DNA/RNA cleavage agents.[4] Macrocyclic ligands are often targeted because they form thermodynamically and kinetically stable complexes with Ln^{3+} ions, thereby making them particularly attractive for these types of biomedical applications. A classic example is the $[Gd(DOTA)(H_2O)]^-$ complex, a widely used MRI contrast agent [DOTA = 1,4,7,10-tetrakis(carboxymethyl)-1,4,7,10-tetraazacyclododecane]. One feature of $[Gd(DOTA)(H_2O)]^-$ that is common to most other commercially available contrast agents is its lack of tissue specificity. One approach to obtain tissue-specific MRI contrast agents has been the synthesis of positively charged Gd^{III} complexes which target bone tissue.[5] It has been proposed that the mechanism of bone uptake is related to the ability of positively charged complexes to mimic biological cations (Ca^{2+}, K^+, etc.) in their interactions with anionic bone surfaces.[5b] Cationic complexes also serve as candidates for DNA/RNA ribonuclease mimics, provided they have free coordination sites (inner-sphere waters) available to coordinate with nucleotides.[6] Removal of one or two carboxylates from the ligand DOTA results in a decrease in complex stability and an increase in the number of inner-sphere water molecules [see structures of DO3A = 1,4,7-tris(carboxymethyl)-1,4,7,10-tetraazacyclododecane and DO2A = 1,7-bis(carboxymethyl)-1,4,7,10-tetraazacyclododecane in Scheme 1].

A recent UV/Vis study of $[Eu(DO3A)(H_2O)_n]$ has shown that in aqueous solution this complex is present in an equilibrium between eight- and nine-coordinate species having one and two inner-sphere water molecules, respectively.[7] Among other parameters, including the rate of molecular tumbling and electronic relaxation, the exchange rate of these coordinated water molecules is an important factor in

Scheme 1. Structure of the ligands DO2A and DO3A

determining the proton relaxivity, hence the efficiency of the Gd^{III} complex as an MRI contrast agent.

The objective of this work was to study the hydration state of several $[Ln(DO2A)(H_2O)_n]^+$ complexes and to evaluate the factors that influence the proton relaxivity of $[Gd(DO2A)(H_2O)_n]^+$. Although the low stability constant recently reported for $[Gd(DO2A)(H_2O)_n]^+$,[8] much lower than the value reported previously,[5c] indicates that this complex may not be suitable for biomedical applications, it serves as a useful model of a complex having more than a single inner-sphere water molecule, and the influence of this on water relaxivity. To get information on structural similarities or changes along the Ln^{III} series, lanthanide induced ^{17}O shifts (LIS) of water have been measured for the whole series of lanthanide(III) DO2A complexes and analyzed in terms of Reilley plots.[9] The UV/Vis spectra of $[Eu(DO2A)(H_2O)_n]^+$ gave unambiguous evidence for the existence of a hydration equilibrium for this complex. A variable temperature, multiple field ^{17}O NMR study combined with direct measurements of the transverse electronic relaxation rates has been used to determine the water exchange rate of $[Gd(DO2A)(H_2O)_n]^+$.

Results and Discussion

Lanthanide Induced ^{17}O NMR Shift Measurements

To obtain the number of inner-sphere water molecules, n, in the $[Ln(DO2A)(H_2O)_n]^+$ complexes, ^{17}O NMR chemical shifts were measured on 0.020 M solutions of those complexes in 2% ^{17}O-enriched water (Ln = La, Ce, Pr, Nd, Eu, Dy, Ho, Er, Yb and Lu), at pH 7–8, 346 K and 9.4 T. To ensure that the complexes are fully formed (for 0.020 M solutions, at pH > 7.8 for the La^{III} complex, at pH > 6.8 for the Gd^{III} complex, and at pH > 6.5 for the Lu^{III} complex),[8] complexation was verified by ^1H NMR spectroscopy. As there are two conflicting reports on the thermodynamic stability constant for $[Gd(DO2A)(H_2O)_n]^+$,[5c,8] the lower stability constant value was assumed when preparing the complexes so as to ensure that all metal was complexed. Although some complexes may have one partially hydrolyzed, inner-sphere water molecule under the conditions used here (the value of the hydrolysis constant obtained for the $[Eu(DO2A)(H_2O)_n]^+$ complex has been reported to be $pK_a^{Eu} = 8.1 \pm 0.3$),[8] such ionization would not affect the measured ^{17}O shift values of bulk water.[1b]

The ^{17}O shift (Δ) of water in the presence of a paramagnetic complex has diamagnetic (Δ_d), contact (Δ_c) and pseudocontact contributions (Δ_p).[1b] The value of Δ_d was taken as the average shift observed in the La^{3+} and Lu^{3+} complexes. The remaining sum, $\Delta_c + \Delta_p$, can be expressed as a product of terms, one characteristic of the Ln^{3+} ion but independent of the structure of the complex ($<S_z>$ and C^D, respectively) and another characteristic of the complex but independent of the Ln^{3+} ion (F and G, respectively). Thus, the paramagnetic shift induced by the lanthanide (LIS) Δ' is given by Equation 1:[1b,10,11]

$$\Delta' = \Delta - \Delta_d = \Delta_c + \Delta_p = <S_z> F + C^D G \quad (1)$$

Values of $<S_z>$ and C^D were taken from the literature[10,11] and Equation 1 was rearranged into a linear form to give Equation 2:[9,12]

$$\Delta'/C^D = <S_z> F/C^D + G \quad (2)$$

For an isostructural series of Ln^{3+} complexes, a plot of Δ'/C^D vs. $<S_z>/C^D$ should be linear. Deviations from linearity have been taken as evidence for a change in structure along the Ln^{III} series.[1b,9,12]

The observed ^{17}O LIS values of water at 346 K were extrapolated to $\rho_W = [Ln]/[H_2O] = 1$. Since water exchange between the bulk and the inner coordination sphere of the $[Ln(DO2A)(H_2O)_n]^+$ complexes is fast,[5c] the extrapolated ^{17}O shift values correspond to nΔ.[13] A plot of ^{17}O shifts according to Equation 2 does not follow a single linear correlation but rather divides into two groups (Ce–Eu and Dy–Yb) with a "break" near the middle of the lanthanide series (see Figure 1).

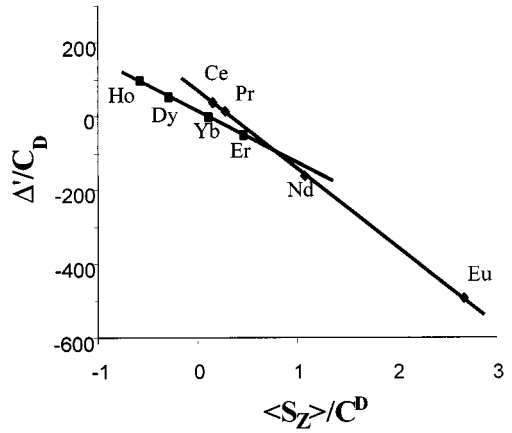

Figure 1. Plot of Δ'/C^D versus $<S_z>/C^D$ for the ^{17}O resonance of the $[Ln(DO2A)(H_2O)_n]$ complexes at 346 K

Such a break could reflect a change in the water coordination number of the complexes along the lanthanide series. A linear regression analysis[9] of the two sets of data gives nF = –211 ± 1 and nG = 72.5 ± 2.1 for Ln = Ce–Eu, and nF = –140 ± 4 and nG = 12.2 ± 1.7 for Ln = Dy–Yb. The ^{17}O LIS of the coordinated water molecules is dominated by the contact contribution[1b] as shown by the large F values. The values of F for Ln^{3+}-bound ^{17}O nuclei are known to be rather constant at –70 ± 11 at 346 K.[1b,13] Using this constant and the values of nF obtained from the plot, values of $n = 3 \pm 0.3$ and $n = 2 \pm 0.3$ were estimated

for the Ce–Eu and Dy–Yb series, respectively. The value of $n = 2$ for the heavier Ln ion complexes agrees with the previously published value for $[Dy(DO2A)(H_2O)_n]^+$ derived from a ^{17}O shift titration.[5c] The calculated values of nG and n also led us to values of $G = 21.2 \pm 0.7$ for Ce–Eu and $G = 6.1 \pm 0.8$ for Dy–Yb. This decrease in the average geometric term G for the ^{17}O nuclei of the coordinated water molecules from the first to the second half of the Ln series is also in agreement with the proposed decrease in the water coordination number. In fact, the change of $n = 3$, with a possible monocapped square antiprismatic coordination geometry of the Ln ion in $[Ln(DO2A)(H_2O)_3]^+$, to $n = 2$, with a possible square antiprismatic coordination geometry of the Ln ion in $[Ln(DO2A)(H_2O)_2]^+$, would correspond to a loss of the water molecule in the capping position. This coordination position makes the largest contribution to the G value.

UV/Vis Measurements

The ^{17}O LIS measurements indicated that a structural change occurs in the middle of the Ln^{III} series near Eu^{III}. Eu^{III} has a transition band in the visible spectrum at 578–582 nm ($^7F_0 \rightarrow {}^5D_0$) which is very sensitive to changes in the coordination environment and has been previously used to characterize coordination equilibria for Eu^{III} complexes.[7,14,15] In accordance with the ^{17}O LIS measurements, the UV/Vis spectrum of a $[Eu(DO2A)(H_2O)_n]^+$ solution clearly shows the presence of two coordination species (a representative spectrum is given in Figure 2).

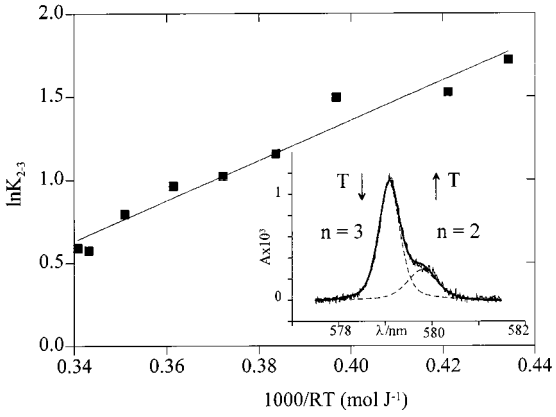

Figure 2. Ratio of the integrals of the two transition bands ($n = 2$ and $n = 3$) in the UV/Vis spectrum of $[Eu(DO2A)(H_2O)_n]^+$ as a function of the inverse temperature; the line represents a linear least-squares fit to the data points; the resulting parameters are $\Delta H^0 = -12.1 \pm 1$ kJ mol^{-1}, $\Delta S^0 = -28.9 \pm 3$ J mol^{-1} K^{-1}; the inserted figure shows a typical UV/Vis spectrum of the Eu^{3+} $^7F_0 \rightarrow {}^5D_0$ transition in a $[Eu(DO2A)(H_2O)_n]^+$ solution ($T = 323.0$ K; $c_{Eu} = 0.01$ M); the dashed lines represent the fitted contributions of the two peaks to the overall spectrum, itself given by the solid line

Chang et al. recently published a pH-dependent luminescence study of $[Eu(DO2A)(H_2O)_n]^+$ in the pH range 5.2–9.6 (ambient temperature).[8] The luminescence spectra present two bands of varying intensity as a function of pH, assigned to the $[Eu(DO2A)(H_2O)_3]^+$ and $[Eu(DO2A)(H_2O)_2(OH)]$ species. Based on the relative peak intensities, they estimated a hydrolysis constant of 8.1 ± 0.3 (pK_a). Since the pH of our $[Eu(DO2A)(H_2O)_n]^+$ sample was 6.4, the amount of any deprotonated complex would be negligible and hence this cannot explain the second absorption band in the spectrum. Moreover, the intensity of one band increases while that of the other decreases with increasing temperature, a feature characteristic of hydration equilibria. Since $DO2A^{2-}$ has 6 donor atoms and coordination numbers of 8 or 9 are generally observed for Eu^{III} complexes, the equilibrium can be depicted as shown in Equation 3:

$$[Eu(DO2A)(H_2O)_2]^+ + H_2O \rightleftarrows [Eu(DO2A)(H_2O)_3]^+ \quad (3)$$

A comparison of the position of the two transition bands with those of previously studied 8- and 9-coordinate Eu^{III} poly(aminocarboxylate) complexes[7,15] is consistent with this assignment. The band at $\lambda_{max} \approx 579.8$ nm, which gains intensity with increasing temperature, is assigned to the complex of lower coordination number, $[Eu(DO2A)(H_2O)_2]^+$, while the band at $\lambda_{max} \approx 579.0$ nm can be assigned to $[Eu(DO2A)(H_2O)_3]^+$.

The hydration equilibrium constant is defined by Equation 4:

$$K_{2-3} = \frac{[Eu(DO2A)(H_2O)_3]^+}{[Eu(DO2A)(H_2O)_2]^+} \quad (4)$$

The reaction enthalpy, $\Delta H_{2-3}°$, and the reaction entropy, $\Delta S_{2-3}°$, for the equilibrium can be obtained from the temperature dependence of K_{2-3} (Equation 5):

$$\ln K_{2-3} = \frac{\Delta S^0_{2-3}}{R} - \frac{\Delta H^0_{2-3}}{RT} \quad (5)$$

The spectra were analyzed with a program developed in our laboratory,[15] which relates the ratio of the integrals of the two bands to the equilibrium constant. The temperature dependence of the ratio of the band integrals is presented in Figure 2. A fitting of the data to Equation 5 gave values for $\Delta H^0_{2-3} = -12.1 \pm 1$ kJ mol^{-1}, $\Delta S^0_{2-3} = -28.9 \pm 3$ J mol^{-1} K^{-1} and $K^{298}_{2-3} = 4.0 \pm 0.2$. This corresponds to an average hydration number of 2.65–2.85 for $[Eu(DO2A)(H_2O)_{2-3}]^+$ in the temperature range 273–363 K.

It should also be noted that in the spectra reported by Chang et al., a small shoulder on one of the bands was present. Though not interpreted by the authors, it could represent differently hydrated species. In their study, the number of inner-sphere water molecules as determined by differences in excited-state lifetimes in H_2O and D_2O[16] was found to be $n = 3.0$ for the fully protonated species. However, it does not preclude the existence of a hydration equilibrium since the usual error in the value of n determined by this method is approximately ± 0.2.

^{17}O NMR and EPR Measurements

Transverse and longitudinal ^{17}O relaxation rates and chemical shifts were measured for $[Gd(DO2A)(H_2O)_n]^+$ at

1.41, 9.4 and 14.1 T as a function of temperature. The UV/Vis measurements performed on the corresponding $[Eu(DO2A)(H_2O)_n]^+$ complex indicated that this complex is present in two hydrated forms. There is no direct method to study hydration equilibrium for a Gd^{III} complex, so one can only rely on the results obtained for the nearest neighbor, Eu^{III}. In the case of $[Ln(DO3A)(H_2O)_n]$, a luminescence study of the Tb^{III} complex and the UV/Vis measurements on the corresponding Eu^{III} chelate both resulted in similar values for the water coordination number (n = 1.8 and 1.9, respectively), indicating that it is reasonable to assume the same hydration equilibria for the Gd^{III} and Eu^{III} complexes. This means that in a solution of $[Gd(DO2A)(H_2O)_n]^+$ there are two species (the bis- and tris-hydrated complex) both of which can, in principle, exchange with bulk water. Consequently, any analysis of the transverse relaxation rates in this system should be treated as a three-site exchange problem.

We recently compared the analyses of ^{17}O NMR data of $[Gd(DO3A)(H_2O)_n]$ (n = 1 and 2) performed with the rigorous three-site exchange approach using Kubo–Sack matrices versus the more typical Swift–Connick treatment by assuming a temperature-dependent value for the mole fraction of bound water.[7] The two approaches gave the same results for parameters derived from the ^{17}O NMR data. This led us to conclude that, in such cases, where the equilibrium between the two differently hydrated species is strongly shifted towards one complex (for both $[Gd(DO2A)(H_2O)_n]^+$ and $[Gd(DO3A)(H_2O)_n]$ it was the nine-coordinate complex), the simpler Swift–Connick treatment provides sufficiently precise results, and application of the more complicated Kubo–Sack formalism is not necessary. Therefore the present ^{17}O NMR data for $[Gd(DO2A)(H_2O)_n]^+$ have been analyzed by means of the Swift–Connick equations, according to the method previously described.[7,17,18] For the mole fraction of bound water (P_m), we used a temperature-dependent value calculated on the basis of ΔH^0_{2-3} and ΔS^0_{2-3} obtained for $[Eu(DO2A)(H_2O)_{2-3}]^+$ in the UV/Vis study. In the calculations, the electronic relaxation rates measured by EPR at 0.34 T (X-band) have been fitted simultaneously with the ^{17}O NMR data. The transverse electronic relaxation rate ($1.2 \pm 0.1 \times 10^{10}$ s^{-1}) measured at 0.34 T was independent of temperature over the range T = 274 – 356 K. The transverse ^{17}O relaxation rates and chemical shifts as well as the fitted curves are presented in Figure 3.

The fit resulted in the following parameters: $k_{ex}^{298} = 10 \pm 5 \times 10^6$ s^{-1}, $\Delta H^{\neq} = 21.3 \pm 4$ kJ/mol, $\Delta S^{\neq} = -39 \pm 11$ kJ/mol $\tau_R^{298} = 40 \pm 1$ ps, $E_R = 16.4 \pm 0.7$ kJ/mol, $\tau_v^{298} = 16 \pm 1$ ps, $E_v = 1.0$ kJ/mol, $\Delta^2 = 1.06 \pm 0.02 \times 10^{20}$ s^{-2} and $A/\hbar = -3.4 \pm 0.2 \times 10^6$ rad s^{-1}.

Previous ^{17}O NMR studies on numerous Gd^{III} complexes have shown that the rate and mechanism of water exchange is strongly related to the inner-sphere structure of the chelate. These findings suggested that, for complexes with a hydration equilibrium, less energy is needed to pass from the reactant to the transition state since both are already present in solution. Thus, one might expect an increased

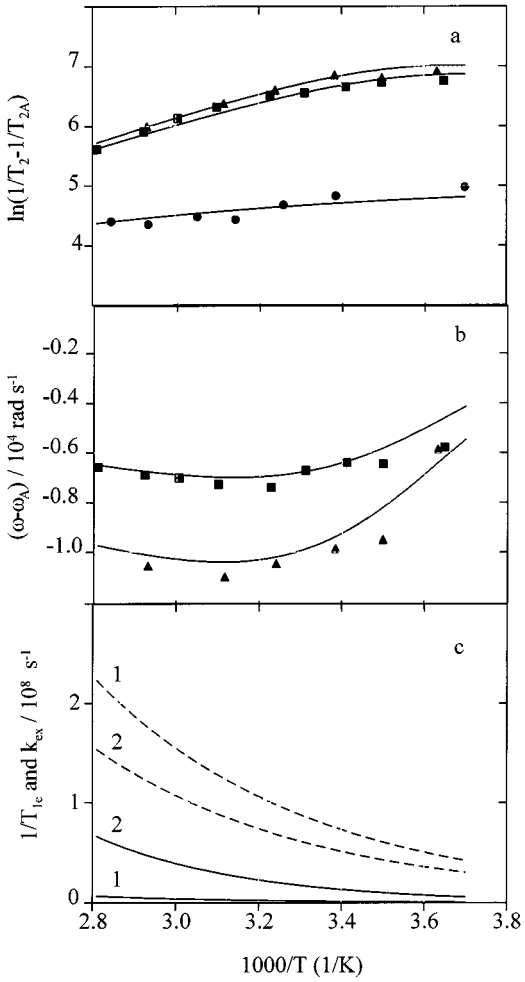

Figure 3. Temperature dependence of the transverse ^{17}O relaxation enhancements (a) and chemical shifts (b) at B = 14.1 T (σ), 9.4 T (n) and 1.41 T (l); the solid lines correspond to the simultaneous least-squares fit to all data points according to the Swift and Connick equations using a temperature dependent P_m value; the lower part of the figure (c) represents k_{ex} (solid lines) and $1/T_{1e}$ (dashed lines), the two contributions to the overall correlation time that governs the transverse ^{17}O relaxation, as computed for the two limiting cases of $k_{ex}^{298} = 5 \times 10^6$ (1) and 15×10^6 s^{-1} (2) (see text)

water exchange rate for $[Gd(DO2A)(H_2O)_{2-3}]^+$ than for a system like $[Gd(DOTA)(H_2O)]^-$ having a single hydrated species. Contrary to expectations for both $[Gd(DO2A)(H_2O)_{2-3}]^+$ and $[Gd(DO3A)(H_2O)_{1-2}]$, only a limited gain in the water exchange rate was observed {about two-fold compared with $[Gd(DOTA)(H_2O)]^-$ ($k_{ex}^{298} = 10 \times 10^6$ s^{-1} and 11×10^6 s^{-1} for the DO2A and DO3A complexes, respectively, versus 4.8×10^6 s^{-1} for the DOTA complex)}.[7] However, a second confounding factor that one must consider in these complexes is the increase in overall positive charge on the DO3A and DO2A complexes. A previous study on the Gd^{III} complex of the pentacarboxylate $DOTASA^{5-}$ has clearly shown that a higher negative charge favors fast water exchange, as k_{ex}^{298} of $[Gd(DOTASA)(H_2O)]^{2-}$ was about 50% higher than that of $[Gd(DOTA)(H_2O)]^-$ ($H_5DOTASA$ = 1,4,7,10-tetraazacyclododecane-1-succinic acid-4,7,10-triacetic acid).[19] A similar effect was observed upon substitution of one carboxylate of

$DOTA^{4-}$ or $DTPA^{5-}$ by noncharged amide groups. In both systems, the water exchange rate diminished by a factor of 3–4. Thus, the limited increase in the water exchange rate of $[Gd(DO2A)(H_2O)_{2-3}]^+$ or $[Gd(DO3A)(H_2O)_{1-2}]$ relative to that of $[Gd(DOTA)(H_2O)]^-$ must reflect two opposing effects: the favorable hydration equilibrium effect partially cancelled by the unfavorable charge effects.

The k_{ex} values as cited above correspond to the exchange of one water molecule, hence the overall water exchange rate is about twice the k_{ex} of $[Gd(DO3A)(H_2O)_{1-2}]$ (the average hydration number close to 2) and three times the k_{ex} of $[Gd(DO2A)(H_2O)_{2-3}]^+$ (the average hydration number close to 3). Consequently, the overall water-exchange rates of $[Gd(DO3A)(H_2O)_{1-2}]$ and $[Gd(DO2A)(H_2O)_{2-3}]^+$ relative to that of $[Gd(DOTA)(H_2O)]^-$ were greater by a factor 4 and 6, respectively.

It should be noted that the error in k_{ex}^{298} determined in this study is exceptionally high. The reason lies in the unfavorable interplay of water exchange and electronic relaxation for this system. For $[Gd(DO2A)(H_2O)_{2-3}]^+$, a slow exchange region, where the $1/T_2$ values are directly proportional to the water exchange rate, does not exist over the temperature range examined (the transverse relaxation rate enhancement never increases with temperature; see Figure 3). In the fast and intermediate exchange regions, the relaxation rate of the Gd^{III} electron spin also contributes to the measured $1/T_2$ values. Thus, one needs information on the electronic relaxation rate to extract an accurate value for k_{ex}. We have performed further measurements of the transverse electronic relaxation rates by EPR (unfortunately the magnetic field is quite different from that used in the ^{17}O study) and ^{17}O transverse relaxation rates at three different magnetic fields, in order to achieve this goal. The latter information usually allows better definition of the electronic relaxation contribution, which is the field-dependent term in $1/T_2$. Despite these efforts, the uncertainty in the water exchange rate remained unusually high. Figure 3(c) summarizes the contribution of k_{ex} and the longitudinal electronic relaxation rate, $1/T_{1e}$, to the overall correlation time that governs the ^{17}O transverse relaxation ($1/\tau_{s1,2} = k_{ex} + 1/T_{1e}$). The plots clearly show that, at all temperatures, the contribution of $1/T_{1e}$ is larger than that of k_{ex}. The relatively fast electronic relaxation is directly evidenced by the $1/T_{2e}$ values measured by EPR (ca. 1.2×10^{10} s^{-1}) and independent of temperature for $[Gd(DO2A)(H_2O)_{2-3}]^+$, but in the range $1.3–2.4\times10^9$ s^{-1} for $[Gd(DOTA)(H_2O)]^-$ ($B = 0.34$ T). Interestingly, the electronic-relaxation times obtained from NMRD profiles for positively charged pyridine containing DO2A-like Gd^{III} complexes have also been reported to be shorter than for $[Gd(DOTA)(H_2O)]^-$.[5b]

Implications for Water Proton Relaxivity

The relaxivity of $[Gd(DO2A)(H_2O)_n]^+$ in the pH region where the complex is fully formed is proportional to its hydration state (n).[20] However, deprotonation of one of the inner-sphere water molecules in the $[Gd(DO2A)(H_2O)_n]^+$ complexes, leading to the $[Gd(DO2A)(H_2O)_{n-1}(OH)]$ species could modify the relaxivity at high pH. It has been reported in several systems that at high pH values, OH^- catalyzed proton exchange becomes important and the proton-exchange rate determining the proton relaxivity cannot be simply given by the water-exchange rate. The hydration and hydrolysis equilibria have been studied for the Eu^{III} complex,[8] where the tris-aqua form predominates, $K_{2-3}^{298} = 4.0 \pm 0.2$. Therefore the value of the hydrolysis constant, $pK_a^{Eu} = 8.1 \pm 0.3$,[8] which is an average of the hydrolysis constants for the two species with $n = 2$ and 3 weighted by their concentrations, corresponds almost exclusively to the deprotonation of the trihydrated complex, $[Eu(DO2A)(H_2O)_3]^+$. Assuming that the hydration and hydrolysis equilibria of the Gd^{III} and Eu^{III} complexes are similar, their ionization pK_a values should also be similar and no changes in relaxivity of $[Gd(DO2A)(H_2O)_n]^+$ due to hydrolysis are expected below pH $\approx$ 7.1.

A relaxivity of 6.49 $mM^{-1}s^{-1}$ has been reported previously[5b] for $[Gd(DO2A)(H_2O)_n]^+$ at pH 7.0, 298 K and 40 MHz. A simulation using an average n of 2.8 and the parameters obtained from the ^{17}O NMR and EPR study estimated a relaxivity of 6.18 $mM^{-1}s^{-1}$ at the same frequency and temperature, consistent with the measured value.

As discussed in the introduction, the Gd^{III} complexes with hydration equilibrium were expected to have higher water-exchange rates than chelates with a single hydration state. Such accelerated water exchange could result in a significant increase in proton relaxivity for macromolecular derivatives of such systems where the relaxivity is limited by slow water exchange. For $[Gd(DO2A)(H_2O)_{2-3}]^+$ itself, water exchange has no observable effect on the proton relaxivity since it is exclusively limited by fast rotation (and perhaps by fast electronic relaxation). However, in a macromolecular agent the substitution of $DOTA^{4-}$ with $DO2A^{2-}$ could result in a significant increase in proton relaxivity, since the water exchange rate would be increased by a factor of 6.

Conclusion

The hydration equilibrium and dynamics of a series of $[Ln(DO2A)(H_2O)_n]^+$ complexes in aqueous solution at pH = 6.4 – 7.0 was studied by several spectroscopic techniques. An analysis of the lanthanide induced ^{17}O shifts (LIS) of bulk water provided evidence for a decrease in the number of inner-sphere coordinated water molecules in the $[Ln(DO2A)(H_2O)_n]^+$ complexes, changing from $n = 3$ to $n = 2$ near Eu^{III}. A temperature-dependent UV/Vis study of $[Eu(DO2A)(H_2O)_n]^+$ in aqueous solution provided further evidence for an equilibrium between eight- and nine-coordinate species (n = 2,3), with the nine-coordinate $[Eu(DO2A)(H_2O)_3]^+$ species predominating.

A variable temperature, multiple field ^{17}O NMR study combined with direct EPR measurements has been used to calculate the parameters characterizing water exchange, rotation and electronic relaxation, all of which influence the proton relaxivity of $[Gd(DO2A)(H_2O)_{2-3}]^+$. The limited in-

crease in water exchange rate, $k_{ex}^{298} = 10 \pm 5 \times 10^6$ s^{-1}, compared with $[Gd(DOTA)(H_2O)]^-$ (4.8×10^6 s^{-1}) is a consequence of the opposite influence of the charge and of the hydration equilibrium. However, as there are 2.8 times as many water molecules on average in the $[Gd(DO2A)(H_2O)_{2-3}]^+$ complex compared with $[Gd(DOTA)(H_2O)]^-$ (298 K), the overall gain in water exchange is significant. The proton relaxivity of $[Gd(DO2A)(H_2O)_{2-3}]^+$ is lower than expected, despite the favorable water coordination number of this complex. This reflects a combination of favorable and unfavorable parameters that contribute to its relaxivity, in particular a relatively slow water exchange rate, a short τ_R, and a fast electronic relaxation rate.

Experimental Section

Sample Preparation: The $DO2A^{2-}$ ligand was synthesized by a previously published method.[21] The $[Ln(DO2A)(H_2O)_n]$ complexes were prepared by mixing equimolar quantities of the ligand and metal solutions, followed by heating (353 K) for two hours. The pH was regularly adjusted to 6 – 7. The ^{17}O NMR shift measurements for the series of Ln^{III} complexes (different from Gd^{III}) were performed on 0.020 mM $[Ln(DO2A)(H_2O)_n]^+$ solutions (pH = 7.0). The ^{17}O NMR measurements for the Gd^{III} complex were performed on a 0.0119 mol/kg $[Gd(DO2A)(H_2O)_n]^+$ solution (pH = 6.53); a $[Y(DO2A)(H_2O)_n]^+$ solution of the same pH and concentration was used as an external reference. To improve sensitivity, ^{17}O-enriched water (10% $H_2^{17}O$, Yeda R&D Co.) was added to the solutions resulting in a 2% ^{17}O enrichment. The absence of free Ln^{III} ion was verified with xylenol orange indicator.[22]

UV/Visible Spectrophotometry: UV/Visible spectra of a $[Eu(DO2A)(H_2O)_n]^+$ solution (c_{Eu} = 0.01 M; pH = 6.5) were recorded in the temperature range 277–350 K on a Perkin–Elmer Lambda 19 spectrometer, using thermostated cells with a 10 cm optical length (λ = 577.5 – 581.5 nm).

^{17}O NMR Measurements: The ^{17}O NMR shift study of the $[Ln(DO2A)(H_2O)_n]^+$ series of complexes was performed using a Bruker AM-400 spectrometer (9.4 T; 54.2 MHz) at 346 K. The samples were introduced in spherical glass bulbs inside 10 mm NMR tubes, with a drop of nitromethane as an internal shift reference. The spectra were run unlocked. Downfield-induced shifts were taken as positive. A variable temperature ^{17}O NMR study of $[Gd(DO2A)(H_2O)_n]^+$ was performed at 3 different magnetic fields using Bruker spectrometers: AMX2–600 (14.1 T, 81.4 MHz), AM-400 (9.4 T; 54.2 MHz) and a 1.41 T, 8.14 MHz electromagnet were connected to an AC-200 console. Bruker VT-1000 temperature control units were used to stabilize the temperature, which was measured by a substitution technique.[23] Bulk water longitudinal relaxation rates, $1/T_1$, were obtained by the inversion recovery method,[24] and transverse relaxation rates, $1/T_2$, by the Carr–Purcell–Meiboom–Gill spin echo technique.[25]

Data Analysis: The least-squares fitting was performed by the program Scientist® for Windows® by Micromath®, version 2.0 The reported errors correspond to one standard deviation obtained by the statistical analysis.

Linkage Isomerization in Pt^{II}–9-Methyladenine Complexes

Jorma Arpalahti,*[a] Karel D. Klika,[a] and Satu Molander[a]

Keywords: Linkage isomerization / NMR spectroscopy / Nucleobases / Platinum / Structure elucidation

Bis(9-methyladenine) complexes of *cis*-$Pt^{II}(NH_3)_2$ undergo slow linkage isomerization from the N7 to the N1 site in aqueous solution at elevated temperatures. The ratio of the isomeric complexes during the isomerization process indicates that whilst Pt^{II} prefers the N(7) site in the adenine moiety kinetically, it is the N(1) coordination mode which is thermodynamically more stable. The crystal structures of the isomers do not reveal any unusual features; the few apparently structurally significant differences in the bond angles in the N(1)-bound bis(complex) merely reflect the poor quality of the crystal and/or crystal packing effects rather than a direct result emanating from the coordination mode of the ligand.

Introduction

Of the naturally occurring nucleobases, the adenine moiety exhibits the most flexible binding-site behavior with metal ions. In 9-substituted adenine derivatives, the ring nitrogens N(1) and N(7) are the predominant binding sites;[1] in aqueous solution the distribution of the metal ion between these sites depends on the pH, the metal, and the other ligands coordinated to the metal.[2] When coordination to both of these sites is blocked binding may then occur at N(3).[3] In exceptional cases, various metal ions may also bind to the exocyclic amino group with a concomitant loss of a proton.[4–6]

The site distribution of the metal ion is pH-dependent due to the different basicities of the adenine nitrogen atoms and in this respect, the N(1),N(7) dichotomy of 9-substituted adenines has received considerable attention. Whilst hard 3d transition metal ions slightly favor the N(7) site over the N(1) site,[7] softer metal species such as Pd^{II} appear to prefer the N(1) site.[1a] With inert cations like Pt^{II}, however, care must be taken to distinguish the kinetically preferred binding site from the thermodynamically more stable one. Recently, we have shown that monofunctional, aquated Pt^{II}(dien) kinetically favors the N(7) site in adenosine, although it is the N(1) binding mode which is thermodynamically more stable.[8] (The slow isomerization process takes several days at 65 °C in aqueous solution.) With bifunctional Pt^{II} compounds, such as the biologically important Pt^{II} diamines, the majority of studies reveal only N(7) coordination,[2,9] with only rare instances of the Pt^{II} binding to other sites in the adenine moiety such as N(1),[10–12] or N(6)[6b]. Although the Pt^{II}–N bond is generally considered inert, the relatively easy bond rearrangement found in platinated oligonucleotides[11b,13] have led to this dogma being questioned.[12] Together with the novel S→N migration of coordinated Pt in sulfur containing biomolecules,[14] this has led to tremendous interest in the linkage isomerization in Pt-nucleobase complexes.[6,12] In this work we report the isomerization of bis(9-methyladenine) complexes of *cis*-$Pt^{II}(NH_3)_2$ in aqueous solution. The isomeric complexes exhibiting the N(1),N(1); N(1),N(7); and N(7),N(7) binding modes of Pt^{II} in the adenine moiety have been structurally characterized by X-ray crystallography and by ^{1}H-, ^{13}C-, and ^{195}Pt-NMR spectroscopy. To our knowledge, the former two complexes represent the first examples of mononuclear Pt^{II} bis(complexes) in which the adenine moiety displays the N(1) binding mode.

Results and Discussion

The isomerization of the bis(complexes) of 9-methyladenine (9-made), *cis*-$[Pt(NH_3)_2$(9-made-*N*7)$_2]^{2+}$ (**1**), *cis*-$[Pt(NH_3)_2$(9-made–*N*1)(9-made-*N*7)$]^{2+}$ (**2**) *cis*-$[Pt(NH_3)_2$(9-made-*N*1)$_2]^{2+}$ (**3**), can be conveniently followed by HPLC (see Figure 1).

When compared to free nucleobase, the bis(complexes) have longer retention times and the complexes follow an elution order of **1** < **2** < **3**. In a solution containing a slight excess of the ligand ($[Pt]_T/[L]_T$ = 1:2.5), the N(7) coordination mode predominates at the beginning of complexation

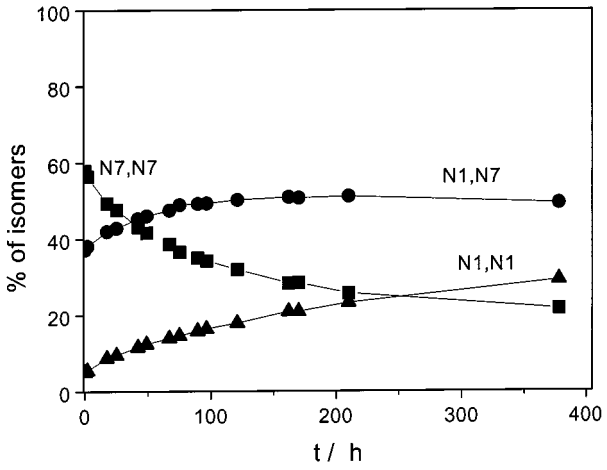

Figure 2. The relative percentage of different complexes (based on peak areas at 260 nm) during the isomerization process in aqueous solution at 80–85 °C

(Figure 2). However, when kept at ca. 85 °C for several days a slow N(7)→N(1) isomerization takes place, as shown by the diminution of the N(7),N(7)-bound species and an increase in the N(1),N(7)- and the N(1),N(1)-bound species. The time-dependent concentrations of the different complexes indicate that it is the N(7) binding mode which is kinetically preferred, whereas it is the N(1) site which forms the thermodynamically more stable complexes; this is in line with findings for monofunctional Pt^{II}.[8] Interestingly, the amount of the bis(complex) with the mixed N(1),N(7) coordination mode first increases and then only very slowly decreases indicating stepwise N(7)→N(1) isomerization. The slowness of the reaction, as compared to intramolecular bond rearrangements,[6] suggests that in this case the isomerization results from the breaking and reformation of Pt-nucleobase bonds. Unfortunately, the data do not allow definitive conclusion about the reaction path, i.e. solvent path and/or direct nucleophilic attack of the free nucleobase on the complex for both are expected to be very slow.[1b]

The kinetic preference of Pt^{II} for the adenine N(7) site may be attributed to steric hindrance by the exocyclic amino group that limits the platination of the N(1) site[7,10] despite its stronger basicity.[15] Because the N(7)→N(1) isomerization is slow even at elevated temperatures, reflecting the high thermodynamic stability of the Pt–N bond,[15] it is not surprising therefore that the formation of bis(complexes) exhibiting only the N(1) binding mode has been previously overlooked.[11a]

The ^1H, ^{13}C, and ^{195}Pt spectral data for the dications **1**, **2**, and **3** are listed in Table 1. All three complexes in aqueous solutions show evidence of dynamic processes, as indicated by the splitting and/or broadening of the ^1H, ^{13}C, and ^{195}Pt signals. In all likelihood, the dynamic process in effect is the restricted rotation of the nucleobase(s) about the Pt–N bond resulting from the close spatial proximity of the Pt^{II} atom and the exocyclic amino group of the adenine moiety. This spatial proximity is particularly close for the N(1)-bound species[6a,8] and consistent with this, **3** displays the strongest effects. Nevertheless, the observed ^1H chemical shifts corroborate the assignment of the Pt binding modes showing significant downfield shifts by those signals near the proposed coordination site. The δ_{Pt} values of all three isomeric complexes are close to –2500 ppm, typical for a PtN_4 coordination sphere.[16]

Crystal Stuctures

The crystal structure analyses confirmed the Pt^{II} binding modes of the isomeric complexes and the thermal ellipsoids of the dications of **1a – 3a** are shown in Figures 3, 4, and 5, respectively; selected interatomic distances and angles are listed in Table 2.

The crystallographic data, experimental details and results of structure refinements are listed in Table 3. In all complexes, the Pt^{II} coordination sphere is nearly square-planar with normal and very similar Pt–N bond lengths and angles, except in **1**, where the Pt–N(7a) distance of 2.021(6) Å seems to be significantly shorter (3.8σ[17]) than the Pt–N(11) distance of 2.056(7) Å. Otherwise the cation of **1a** is very similar to the corresponding one of the nitrate salt.[9] The complexed nucleobases are orientated in a head-to-tail fashion in **1** and **2**, whereas in **3** their orientation is head-to-head. The latter is of particular interest, as it brings the exocyclic C(6)–NH_2 groups onto the same side of the PtN_4 plane. The N(6)···Pt distance of 3.21(1) Å in **3** is close to that found in **2** for the N(1)-bound 9-made, viz. 3.149(8) Å, and comparable to those reported earlier for other N(1) platinated adenine derivatives.[6a,8] With the N(1) binding mode, the exocyclic amino group is significantly closer to the Pt^{II} atom than it is in N(7)-bound species; the N(6)···Pt distance is 3.446(8) Å in the N(7)-bound 9-made of **2,** and 3.430(7) Å (unit A) and 3.515(7) Å (unit B) in **1**. The close proximity of the Pt^{II} and N(6) atoms may indicate a hydrogen bond type of interaction between these two atoms. The calculated values for the N(6)H···Pt distances and the N(6)–H(6)···Pt angles of 2.76 Å and 114° [H(6B)] in **3**, 2.67 Å and 116° [H(6A1)], and 2.75 Å and 139° [H(6B2)] in **2**, 2.73 Å and 139° [H(6A2)], and 2.82 Å and 139° [H(6B2)] in **1** are, at least for the N(7)-bound species, close to the values given in the literature for this type of interaction, viz. 2.2–3.5 Å and >120°, respectively.[18] Irrespective of this interaction being present, the Pt^{II} atom lies virtually in the plane defined by the four coordinating nitrogen atoms and deviates by less than 0.02 Å from this plane in all three complexes.

The corresponding bond lengths and angles of the base moieties in **1** and **2** are very similar and they do not significantly deviate from the values given for uncomplexed 9-methyladenine.[19] The same holds true also for the bond lengths in **3**, where the several seemingly large differences become insignificant when the large e.s.d.s are taken into account, e.g. the C(4)–C(5) bond. However, some of the ring angles in **3** display significant changes when compared

to isomers **1** and **2** and to the uncomplexed ligand. The most significant difference can be seen in the N(3)–C(4)–N(9) angle of 103(4)°, which differs by 6.2σ[17] from that in the N(1)-bound 9-made of **2**, viz.128.1(8)°. Other significant differences include the angles C(4)–N(9)–C(8) (5.2σ from that in **1**, unit B), C(4)–N(9)–C(9) (5.2σ from that in **1**, unit A), C(5)–C(4)–N(9) (5.1σ) and C(4)–C(5)–N(7) (4.1σ) from that in **2** [N(1)-bound 9-made]. It seems to us that these differences merely reflect the poor quality of the crystal and/or crystal packing effects rather than a direct result emanating from the coordination mode of the ligand,[20] since the majority of the significant differences are seen relative to the N(1)-bound ligand in **2**.

The packing of the isomeric complexes is predominantly stabilized by hydrogen bonding involving primarily the am(m)ine hydrogens and anions and/or lattice water (Table 4). Additional H-bonds may be formed between the exocyclic amino groups and endocyclic nitrogens in **2a**, and between water molecules in **1a** and **3a**. By contrast, stacking of the base moieties seems to be relative unimportant in stabilizing the crystal lattice. In **1a**, the neighboring bases are orientated in a head-to-tail fashion with a distance of 3.64 Å between the centers of the 5- and 6-membered rings, which may indicate a weak stacking interaction. With **2a** and **3a**, the distances between the neighboring heteroaromatic rings are > 4 Å.

Conclusions

The isomerization of the bis(9-methyladenine) complexes of *cis*-$Pt^{II}(NH_3)_2$ in aqueous solution is a very slow process. The ratio of the isomeric complexes as a function of time indicates that Pt^{II} kinetically prefers the N(7) site in the adenine moiety, whilst it is the N(1) coordination mode which is thermodynamically more stable. The slowness of the reaction, as compared to the intramolecular Pt^{II}–N bond rearrangement,[6b] suggests that the isomerization of the bis(complexes) results from the breaking and reformation of Pt-nucleobase bonds, although no definitive conclusion about the reaction path can be made. In this respect, the relative easy bond rearrangements in platinated oligonucleotides (single stranded or double stranded)[11b,13] are strongly suggestive for an intramolecular migration mechanism. The crystal structures of the isomers do not reveal any unusual features, except for those few apparently significant differences in the bond angles in the N(1)-bound bis(complex), which merely reflect the poor quality of the crystal and/or crystal packing effects rather than a direct result emanating from the coordination mode of the ligand. The packing of the isomeric complexes is predominantly stabilized by hydrogen bonding, whilst stacking of the base moieties seems to be relative unimportant in stabilizing the crystal lattice.

Experimental Section

General Remarks: The NMR measurements were carried out in D_2O (^1H) or in H_2O/D_2O (^{13}C and ^{195}Pt) at ambient temperature. Spectra were acquired on a JEOL Alpha 500 spectrometer equipped with a 5 mm tunable probe operating at 500.16 MHz for ^1H, 125.78 MHz for ^{13}C, and 107.21 MHz for ^{195}Pt.[8] The ^1H and ^{13}C spectra were referenced internally to sodium 4,4-dimethyl-4-silapentanesulfonate (DSS), assigned as $\delta = 0.015$ ppm for proton and 0 ppm for carbon; the ^{195}Pt spectra were referenced externally to $[PtCl_4]^{2-}$ (δ_{Pt} –1625 ppm from $[PtCl_6]^{2-}$). The assignments of the ^1H and ^{13}C resonances were based on HMQC, DEPT, and HMBC spectra and by comparison to the assignments of the Pt^{II}(dien) complexes of adenosine.[8] – The HPLC measurements were carried out on a Merck-Hitachi chromatograph using an end-capped RP-18 column (5 μm, E. Merck AG) and a water/methanol (85:15) mixture (0.05 M $NaClO_4$, pH 3) as eluent. – Adenine was purchased from Sigma, $NaClO_4 \cdot H_2O$ and DMF from E. Merck AG, and $NaPF_6$ (98%) from Ventron; all were used as received.

Isomerization Procedure: Treatment of *cis*-$[PtI_2(NH_3)_2]$[21] (970 mg, 2.0 mmol) with two equivalents of $AgNO_3$ in 10 mL of water for two hours at 60 °C gave a clear solution of the diaqua species upon removing the AgI precipitate by filtration. After the addition of 9-methyladenine[22] (9-made, 550 mg, 3.7 mmol) into 7.4 mL of the Pt^{II} solution, the mixture was stirred at 80–85 °C and the progress of the isomerization was intermittantly followed by HPLC. After 15 days, the reaction was stopped (the mixture began to turn yellow together with the formation of some black solid), the mixture was filtered, and the filtrate was left to evaporate to dryness at ambient temperature. The solid residue was treated with 30 mL of boiling methanol to remove most of the unchanged 9-made. According to HPLC analysis the remaining solid residue (620 mg) contained ca. 20% of 9-made and ca. 75% of the desired isomers. The isomeric complexes were isolated and purified by fractional crystallization with different anions, as described below.

***cis*-[Pt(NH$_3$)$_2$(9-made-*N*7)$_2$](ClO$_4$)$_2$ · 2 H$_2$O (1a):** The crude product obtained above was dissolved in 2 mL of water with gentle warming. Slow cooling to +4 °C afforded a crystalline product with a composition of [**2**] ≈ [**1**] > [**3**] as deduced by HPLC analysis. Repeated recrystallizations from a minimal amount of water finally gave ca. 50 mg of chromatographically pure crystals of **1** with NO_3^- as the counter ion. Alternatively, and more conveniently, **1** was prepared by dissolving 9-made (120 mg, 0.8 mmol) in 2 mL of 1 M HNO_3 [to prevent N(1) platination], followed by the addition of 0.38 equiv. of *cis*-$[Pt(NH_3)_2(H_2O)_2]^{2+}$ in 5 mL of water. After stirring for 48 h at ca. 35 °C, the filtered solution was neutralized with 1 M NaOH, which afforded 125 mg of pale yellow crystals (50% from Pt) upon cooling to +4 °C. The isomeric purity of the product (>99%) was ascertained by HPLC analysis. Finally, **1** was crystallized as a perchlorate (**1a**) by dissolving the dinitrate in 1 M $NaClO_4$. – $C_{12}H_{24}Cl_2N_{12}O_{10}Pt$ (762.42): calcd. C 18.90, H 3.17, N 22.05; found C 18.80, H 3.02, N 21.82.

***cis*-[Pt(NH$_3$)$_2$(9-made-*N*1)(9-made-*N*7)](ClO$_4$)$_2$ (2a):** All of the solutions obtained from the above fractional crystallizations were pooled, which gave a mixture with a relative composition of [**2**] > [**3**] > [**1**]. This solution was concentrated to ca. 1 mL; after the addition of 1 mL of 1 M $NaClO_4$ to the mixture, crystals (ca. 320 mg) were obtained at +4 °C. The filtered crystalline product was then dissolved in 1.5 mL of DMF.[23] Crude **2a**, obtained at –20 °C after the addition of 0.2 mL of water and 6 mL of ethanol to the solution, was filtered off and washed with cold water. Recrystallization from a minimal amount water gave 120 mg of chromatographically pure **2a**. – $C_{12}H_{20}Cl_2N_{12}O_8Pt$ (726.39): calcd. C 19.84, H 2.78, N 23.14; found C 19.91, H 2.91, N 22.72.

***cis*-[Pt(NH$_3$)$_2$(9-made-*N*1)$_2$](PF$_6$)$_2$ · 3 H$_2$O (3a):** The DMF solution and washings of **2a** were evaporated to dryness at ambient temperature. The solid residue was washed with cold 0.1 M $HClO_4$ to remove most of the remaining **2a**. Dissolving the residue in 1 mL of water yielded 50 mg of chromatographically pure **3a** at +4 °C after the addition of 1 mL of 1 M $NaPF_6$ (pH 5, adjusted with 1 M NaOH) to the solution. – $C_{12}H_{26}F_{12}N_{12}O_3P_2Pt$ (871.48): calcd. C 16.54, H 3.01, N 19.29; found C 16.41, H 2.81, N 18.98.

X-ray Diffraction Studies: All X-ray data were collected on a Rigaku AFC5S diffractometer at ambient temperature with Mo-K_α radiation (λ = 0.71069 Å). Unit cell parameters were obtained from a least-squares fit of 25 reflections [41.60 < 2θ < 45.48° (**1a**), 40.82 < 2θ < 46.60° (**2a**), and 20.95 < 2θ < 31.61° (**3a**)]. Intensity data were collected by the ω/2θ scan technique to a maximum 2θ value of 50° (55° for **3a**). The intensities of three standard reflections were measured every 150 data points in all cases, and they showed no intensity decay. The intensities of the reflections were corrected for Lorenz, polarisation and absorption (empirical) effects.[24] The structures were solved by standard Patterson and difference Fourier methods and refined by full-matrix least-squares calculations employing SHELXL-97.[25] All atoms except hydrogen were refined with anisotropic temperature factors. In all complexes the hydrogen atoms are at the calculated positions. The final cycle of refinement gave for the structure **1a**, R_1 = 0.0401 and $wR2$ = 0.0991 for the observed data [$I > 2\sigma(I)$] and 334 parameters and R_1 = 0.0532 and $wR2$ = 0.1047 for all data. For **2a**, refinement converged at R_1 = 0.0387 and $wR2$ = 0.0890 for the observed data and 311 parameters and R_1 = 0.0654 and $wR2$ = 0.1004 for all data. For **3a** the final refinement cycle gave R_1 = 0.0422 and $wR2$ = 0.0785 for the observed data and 200 parameters and R_1 = 0.1021 and $wR2$ = 0.0926 for all data. Crystallographic data and experimental details are given in Table 2, selected bond lengths and angles are given in Table 3, and possible hydrogen bonds in Table 4. Data reduction and subsequent calculations were performed with *teXsan for Windows*.[26] Figures were drawn with *Ortep-3 for Windows*.[27] Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-135162 (**1a**), CCDC-135163 (**2a**), and CCDC-135164 (**3a**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road Cambridge, CB2 1EZ, UK [Fax: +44 (0)1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis and Characterization of Some Metal Complexes with New Nitrogen–Oxygen Donor Macrocyclic Ligands – X-ray Crystal Structures of a 26-Membered Reduced Monoprotonated Macrocycle and a 20-Membered Pendant-Arm Schiff-Base Macrocyclic Cadmium(II) Complex

Manuel Vicente,[a] Carlos Lodeiro,[a] Harry Adams,[b] Rufina Bastida,*[a] Andrés de Blas,[c] David E. Fenton,[b] Alejandro Macías,[a] Adolfo Rodríguez,[a] and Teresa Rodríguez-Blas[c]

Keywords: Metal complexes / Template synthesis / Schiff bases / Oxaazamacrocycles

New series of macrocyclic Schiff-base lanthanide(III), yttrium(III), and cadmium(II) complexes, $[M(\mathbf{1})]X_n$ (X = NO_3^-, M = Y, Ln = La–Yb except Pm and Dy; X = ClO_4^-, M = Cd, La, Ce, Pr, Sm, Gd, or Er) and $[M(\mathbf{3})]X_n$ (X = NO_3^-, M = Dy; X = ClO_4^-, M = Er and Cd), have been prepared by cyclocondensation of O^1,O^7-bis(2-formylphenyl)-1,4,7-trioxaheptane with O^1,O^7-bis(2-aninyl)-1,4,7-trioxaheptane (**1**) or tris(2-aminoethyl)amine (**3**) in the presence of the appropriate metal salt as a template agent. The Schiff-base macrocycles **1** and **3** are also formed in the absence of a metal ion. Treatment of **1** with $NaBH_4$ in methanol gives the diamine macrocycle **2**. The reactions of Ln^{III}, Cd^{II}, and Y^{III} ions with **2** have also been investigated. The crystal structures of the monoprotonated ligand **2** and of the complex $[Cd(\mathbf{3})](ClO_4)_2$ have been determined by X-ray diffraction analysis.

Introduction

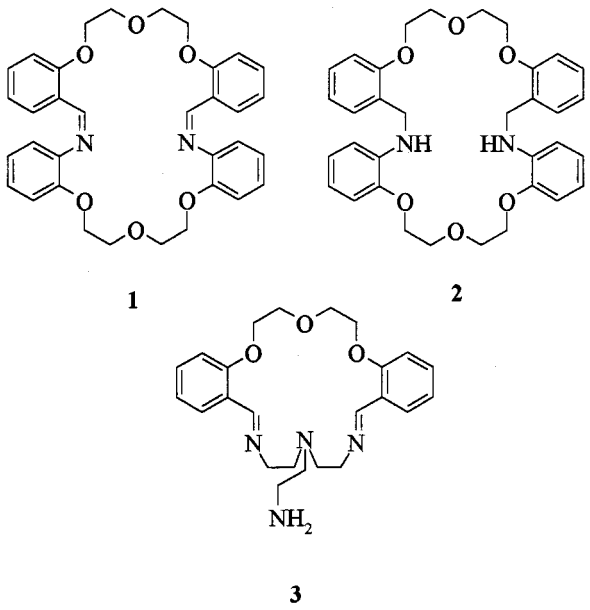
Enormous progress in macrocyclic chemistry has been made in the past decade.[1–4] The number of new macrocyclic ligand molecules designed and synthesized has increased significantly and their structures have become much more complex. One reason for the interest in this field is that it offers exciting possibilities for creative minds to construct novel supramolecular assemblies that are capable of performing highly specific molecular functions. The precise molecular recognition between macrocyclic ligands and their guests provides a good opportunity for studying key aspects of supramolecular chemistry, which are also significant in a variety of disciplines including chemistry, biology, physics, medicine, and related science and technology.

In the course of our research programme on the synthesis and characterization of new coordination complexes of lanthanides, we have reported the synthesis of lanthanide(III) complexes with several N_xO_y-donor macrocyclic ligands containing aromatic, head, and lateral units.[5–10] The compound O^1,O^7-bis(2-formylphenyl)-1,4,7-trioxaheptane has been used as a dicarbonyl precursor in the design of macrocyclic ligands incorporating mixed donor atoms. Most efforts to date have focused on its use in the synthesis of oxaazapolyamine macrocycles as complexing agents for transition metal or heavy metal ions.[11–14] In contrast, little has been reported on its use in the synthesis of Schiff-base macrocycles and their metal complexes.[15–17]

An important aspect of the present work has been the synthesis of two novel dibenzo-substituted Schiff-base macrocycles derived from O^1,O^7-bis(2-formylphenyl)-1,4,7-trioxaheptane, specifically the 26-membered N_2O_6-donor macrocycle **1** and the 20-membered N_4O_3-donor pendant-arm macrocycle **3** (Scheme 1).

The coordination abilities of **1** and **3** towards lanthanide(III) ions have been investigated and, as an extension of these studies, a comparative investigation of the interactions of Y^{III} and Cd^{II} with these ligands has also been carried out. In macrocycle **3**, the role of the amine moiety as an axial coordinating pendant arm has been confirmed by X-ray structural analysis of the complex $[Cd(\mathbf{3})](ClO_4)_2$. The Schiff-base ligand **1** has been reduced to the corresponding saturated macrocycle **2** in order to increase its flexibility and the complexation behaviour of **2** towards the aforementioned metal ions has also been investigated. We also report the X-ray crystal structure of the monoprotonated macrocycle **2**.

Results and Discussion



Macrocycle 1 and Its Metal Complexes

The non-template reaction of O^1,O^7-bis(2-formylphenyl)-1,4,7-trioxaheptane and O^1,O^7-bis(2-aninyl)-1,4,7-trioxa-

Scheme 1. Macrocycle **1**: 12,13,15,16,29,30,32,33-octahydrotetrabenzo[*h*,*l*,*u*,*y*][1,4,7,14,17,20,10,24]hexaoxadiazacyclohexacosine; macrocycle **2**: 5,6,12,13,15,16,22,23,29,30,32,33-dodecahydrotetrabenzo[*h*,*l*,*u*,*y*][1,4,7,14,17,20,10,24]hexaoxadiazacyclohexacosine, macrocycle **3**: 2-(8,9,10,11,19,20,22,23-octahydro-7*H*-dibenzo[*h*,*s*][1,4,7,11,14, 17]trioxatriazacycloicosin-9-yl)-1-ethylamine

heptane in methanol yields the Schiff-base macrocycle **1**. It was not found necessary to carry out this ring-closure under high-dilution conditions. The product was isolated as an air-stable orange-yellow solid in 75% yield and was characterized by elemental analysis, FAB MS, IR, and ^{1}H-NMR spectroscopy. The FAB mass spectrum shows the parent-ion peak at m/z = 567, confirming the [1+1] cyclic nature of the Schiff-base ligand. The IR spectrum features a strong band at 1620 cm^{-1} attributable to the azomethine group. The ^{1}H-NMR spectrum in CD_3CN solution is complicated and shows more than the expected number of signals; a signal at δ = 8.91 can be attributed to the CH=N- proton. The complexity may be due to hydration and hydrolysis of imine bonds leading to carbinolamine formation and reversal of the Schiff base reaction.[18]

Cyclocondensation reactions carried out in the presence of metal salts (M = Y, Ln, Cd) yielded solids, which were characterized as the metal complexes $[M(\mathbf{1})]X_n \cdot x\,H_2O$ (X = NO_3^-, M = Y, La–Yb except Pm and Dy; X = ClO_4^-, M = Cd, La, Ce, Pr, Sm, Gd, or Er). Their analytical and conductivity data are presented in Table 1. The molar conductivities of the nitrate complexes in acetonitrile fall within the range reported for 2:1 electrolytes in this solvent.[19] This implies that one anion must be coordinated, at least in MeCN solution, and most probably in the solid state as well. The perchlorate complexes of La, Ce, Pr, Sm, and Er have conductivities between those for 2:1 and 3:1 electrolytes and the Gd and Cd complexes have values corresponding to 2:1 electrolytes, reflecting the weak coordination ability of the perchlorate anion. The FAB mass spectral results confirm the monomeric [1+1] (dicarbonyl + diamine) nature of the complexes, the most intense peak corresponding to $[\mathbf{1} + H]^+$. The spectra of the complexes frequently show peaks due to $[Ln(\mathbf{1})X_2]^+$ and for the cadmium complex peaks corresponding to $[Cd(\mathbf{1})(ClO_4)]^+$ at m/z = 779 and $[Cd(\mathbf{1})]^+$ at m/z = 680 are seen.

The complexes have similar IR spectra and the data are again consistent with the presence of imine bonds, each complex exhibiting the ν(C=N) mode at ca. 1644 cm^{-1},[20] while no bands attributable to C=O or NH_2 groups are detected. The shift of the imine band to higher wavenumbers upon complexation suggests coordination through the imine nitrogen atoms.[21,22] In the complexes derived from La^{III} nitrate and Cd^{II} and Sm^{III} perchlorates, a ν(C=N) band at ca. 1624 cm^{-1} is also seen, suggesting that in these cases only one imine N atom may be bound to the metal. The water present in the majority of the complexes (giving broad absorption bands at ca. 3450 cm^{-1}) is probably lattice and/or coordinated water.[23] All nitrate complexes exhibit absorption bands characteristic of both coordinated [ca. 1450 (ν_5), 1300 (ν_1), and 1030 (ν_2) cm^{-1}] and ionic (ca. 1380 cm^{-1}) nitrate.[24–26] The magnitude of the separation of the nitrate stretching vibrations ($\nu_5 - \nu_1$) of ca. 160 cm^{-1} is indicative of bidentate coordination.[27]

The IR spectra of the perchlorate complexes feature split bands attributable to the asymmetric Cl–O stretching mode at ca. 1080 cm^{-1} (ν_3) and the asymmetric Cl–O bending mode (ν_4) at ca. 620 cm^{-1}, suggesting that both bound and free anions are present.[28,29] The highest-energy band comprises three well-resolved maxima at ca. 1140, 1120, and 1080 cm^{-1}. However, as ν_{as}(C–O–C) for the polyether chains of the ligand also falls in this region it is not possible to precisely define the coordination mode.

The UV/visible spectra of macrocycle **1** and the corresponding metal complexes were recorded using 10^{-3}–10^{-6} M solutions in acetonitrile. For the complexes, the spectra were recorded immediately after preparation of the solutions and again after these solution had been set aside for periods of one day and one week. The spectra were found to be reproducible and no loss of the metal ion in solution could be detected. The positions of the absorption maxima, the extinction coefficients, and the linear correlation coefficients are available as Supporting Information. The free macrocycle exhibits two strong, broad absorption bands at ca. 251 and 320 nm, corresponding to the π-π* transitions of benzene rings and azomethine groups.[30] In the spectra of the metal complexes, the π-π* absorption bands are red-shifted with respect to their positions in the spectrum of **1**. The perchlorate complexes of La^{III} and Ce^{III} exhibit three strong absorptions at around 274, 317, and 391 nm; the spectra of the other complexes are similar, featuring four absorptions around 246, 291, 315, and 391 nm; the band around 246 nm may arise from charge-transfer transitions.[31,32]

Room temperature emission spectra were recorded using 10^{-6} M acetonitrile solutions of the free ligand **1** and of the $[Ln(\mathbf{1})]X_3$ (Ln = La, Nd, Eu, Gd, Tb, Lu; X = NO_3^-) and $[Cd(\mathbf{1})](ClO_4)_2$ complexes. The spectrum of the free ligand was recorded following excitation at 265 nm, which resulted

in a low fluorescent emission. It was not possible to observe an antenna effect[33] and the luminescent quantum yield could not be calculated because of the low residual intensity of the emission.

Macrocycle 2 and Its Metal Complexes

It has previously been reported that diamine-containing oxaazamacrocyclic ligands derived from O^1,O^7-bis(2-formylphenyl)-1,4,7-trioxaheptane can be prepared by a non-template cyclocondensation of the precursor dialdehyde and the appropriate diamine, followed by in situ reduction with sodium borohydride.[12] We have found that a similar procedure may successfully be employed for the preparation of the reduced macrocycle **2**. The FAB mass spectrum shows a highest molecular weight peak at m/z = 571, corresponding to $[\mathbf{2} + H]^+$, while the IR spectrum features a secondary amine N–H stretching band at ca. 3410 cm^{-1} and no imine band at ca. 1620 cm^{-1}. Comparison of the ^{1}H-NMR spectra of macrocycles **1** and **2** reveals the disappearance of the signal at δ = ca. 8.91 due to the imine proton and the appearance of a new broad singlet signal at δ = 3.65 corresponding to the N*H*CH_2 amine protons.

Complexation reactions of macrocycle **2** with hydrated metal salts ($X = NO_3^-$, M = Y, La, Ce, Pr, Sm, Gd, Er, or Lu; $X = ClO_4^-$, M = Cd, La, Pr, Gd, or Er) were carried out in order to investigate the coordination capability of this more flexible and hydrolytically stable ligand towards the Ln^{III}, Y^{III}, and Cd^{II} ions. In most cases, the microana-

[a] $[M_m(\mathbf{2})]X_n \cdot 1.5\,CHCl_3$. – [b] $[M_m(\mathbf{2})]X_n \cdot 2\,CHCl_3$. – [c] $[M_m(\mathbf{2})]X_n \cdot 3\,CHCl_3$. – [d] $[M_m(\mathbf{2})]X_n \cdot 3\,CH_3OH$. – [e] $[M_m(\mathbf{2})]X_n \cdot CH_3OH$.

lytical data (Table 2) were in accord with the formation of mononuclear complexes of the type $[M(\mathbf{2})]X_n \cdot x\,H_2O$ (X = NO_3^-, M = Y, La, Ce, Pr, Sm; X = ClO_4^-, M = Cd, La, Pr). However, in contrast to the complexes of macrocycle **1**, elemental analyses of complexes of the heavier lanthanides Gd, Er (NO_3^-, ClO_4^-), and Lu (NO_3^-) were indicative of dinuclear complexes of the general formula $[Ln_2(\mathbf{2})]X_6$. These may arise from the increased flexibility of the reduced macrocycle, allowing the accommodation of the smaller cations; attempts to obtain the corresponding mononuclear complexes were unsuccessful. The molar conductivities of the complexes $[M(\mathbf{2})]X_n \cdot x\,H_2O$ in acetonitrile were found to fall in the range reported for 2:1 electrolytes in this solvent.[19]

The FAB mass spectra of the complexes invariably show the peak corresponding to the free macrocycle. The spectra of the yttrium, cerium, and cadmium complexes also show peaks corresponding to $[Y(\mathbf{2})(NO_3)]^+$ (m/z = 721), $[Ce(\mathbf{2})(NO_3)_2]^+$ (m/z = 834) and $[Cd(\mathbf{2})(ClO_4)]^+$ (m/z = 783).

The IR spectra of the nitrate complexes feature several bands in the region associated with nitrate vibrations, from which it is evident that these species contain both coordinated and ionic nitrate groups.[24,25] The two most intense nitrate absorptions, associated with $\nu(N{=}O)$ and $\nu_a(NO_2)$, appear at ca. 1450 and 1300 cm^{-1}. The $\Delta\nu$ separations between the two highest frequency bands fall in the range 154–213 cm^{-1}, suggesting bidentate coordination of the nitrate anions.[27] In the spectra of the perchlorate complexes, the higher-energy band (ν_3) consists of three maxima at ca. 1137, 1120, and 1080 cm^{-1}. The ν_4 band also shows splitting with maxima at ca. 636 and 624 cm^{-1}. The splitting of these bands is indicative of coordination of at least one of the perchlorate anions to the metal,[28,29] but as with the complexes of macrocycle **1** a full assignment is hindered by the presence of ligand bands.

The UV/visible spectra of macrocycle **2** and the corresponding metal complexes were recorded using 10^{-3}–10^{-6} M acetonitrile solutions. The free macrocycle exhibits three broad absorption bands at ca. 250, 277, and 293 nm, corresponding to the π-π* transitions of benzene rings and azomethine groups.[30] In the spectra of the metal complexes, the π-π* absorption bands are red-shifted with respect to their positions in the spectrum of macrocycle **2**. Emission spectra of the free ligand **2** and some of its metal complexes were recorded using 10^{-6} M acetonitrile solutions. Low fluorescent emissions were observed, similar to those seen with macrocycle **1** and its metal complexes.

Crystal Structure of $[(\mathbf{2})H](ClO_4) \cdot CHCl_3$

Single crystals of $[(\mathbf{2})H](ClO_4) \cdot CHCl_3$ suitable for X-ray analysis were obtained by slow crystallization from a solution of the complex $[Cd(\mathbf{2})](ClO_4)_2 \cdot 2\,H_2O$ in diethyl ether/chloroform open to the atmosphere. The crystal structure of the cation is shown in Figure 1. There are two $[(\mathbf{2})H](ClO_4) \cdot CHCl_3$ groups in the asymmetric unit. Only one of the two amine nitrogen atoms in the ligand is protonated and the flexibility of the macrocycle allows it to adopt a folded conformation. This is reinforced by intramolecular hydrogen-bond interactions. The perchlorate ions and the solvent molecules are not involved in hydrogen-bond interactions with macrocycle **2**. The bond lengths and angles fall within the expected ranges.

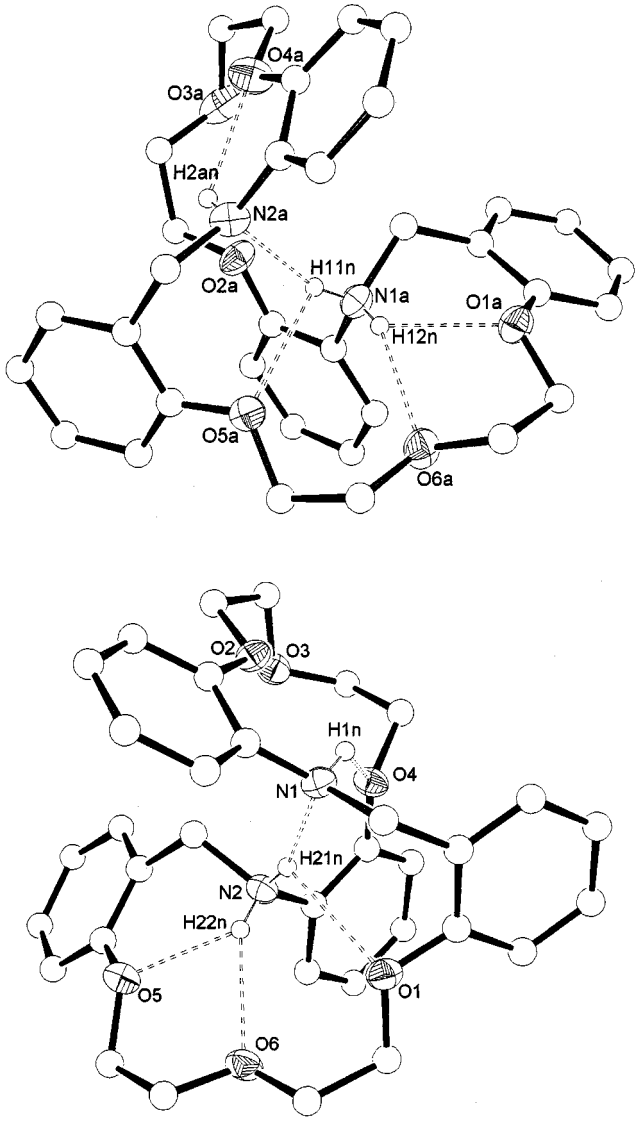

Figure 1. Molecules 1 and 2 of the protonated macrocycle **2** in the asymmetric unit of $[(\mathbf{2})H](ClO_4) \cdot CHCl_3$

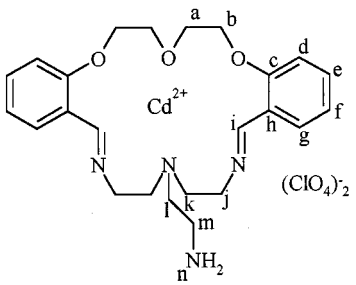
Macrocycle 3 and Its Metal Complexes

Reactions of heterocyclic dialdehydes with tris(2-aminoethyl)amine give cryptands,[34–36] while the reaction of 2,6-diacetylpyridine with tris(2-aminoethyl)amine in the presence of metal templates gives a [2+2] pendant-armed Schiff-base macrocycle resulting from the condensation of two molecules of each precursor.[37] It was therefore extremely interesting to find that the non-template reaction of O^1,O^7-bis(2-formylphenyl)-1,4,7-trioxaheptane and tris(2-aminoethyl)amine in acetonitrile produced a rare example of an amino pendant-armed [1+1] Schiff-base macrocycle, i.e. **3**.



The compound was isolated as a yellow solid, and was found to be stable in air and moderately soluble in most common organic solvents. The IR spectrum features a strong peak at 1636 cm^{-1} due to C=N while no bands attributable to C=O groups are detectable. The primary amine stretching modes of the *pendant-arm* NH_2 group cannot be assigned owing to the presence of an intense broad band centred at ca. 3400 cm^{-1}. The latter is consistent with the presence of water, as is also suggested by the microanalytical data. The FAB mass spectrum shows the parent peak at m/z = 425, confirming the [1+1] cyclic nature of the Schiff base. The ^{1}H-NMR spectrum recorded in $CDCl_3$ solution features two imine proton singlets at δ = 8.79 and δ = 8.77, suggesting the possible presence of conformers in solution. The C_6H_4 protons give rise to a multiplet at δ = 7.96–6.84, while the CH_2CH_2 chains give rise to four multiplets in the aliphatic region. The complex nature of these signals could stem from the presence of related conformers in solution or from the magnetic inequivalence of the geminal hydrogen pairs caused by restricted rotation about the C–C bond.[38,39] In the pendant arm, this restriction could possibly be due to hydrogen-bonding effects. The broad singlet at δ = 1.84–1.95 may be assigned to the NH_2 group, as was confirmed by deuterium exchange when D_2O was added to the $CDCl_3$ solution. No change in the spectrum of the macrocycle was observed after 24 h, demonstrating a greater stability of this ligand compared with macrocycle **1**.

Metal-template reactions between equimolar amounts of O^1,O^7-bis(2-formylphenyl)-1,4,7-trioxaheptane and tris(2-aminoethyl)amine in the presence of hydrated lanthanide nitrates or perchlorates gave analytically pure products formulated as $[Ln(\mathbf{3})]X_3 \cdot x\,H_2O$ only for Er (X = ClO_4^-) and Dy (X = NO_3^-). Attempts to obtain other Ln^{III} complexes by changing the experimental conditions were unsuccessful and it was possible to identify complexes derived from the precursor amine as the major components of the products. The complexes cannot be prepared by a two-step procedure involving preparation of the free macrocycle followed by a complexation reaction with the requisite lanthanide salt.

The IR spectra of $[Er(\mathbf{3})](ClO_4)_3 \cdot 2\,H_2O$ and $[Dy(\mathbf{3})](NO_3)_3 \cdot H_2O$ show the imine band at ca. 1638 cm^{-1}. This band is slightly shifted in comparison to its position in the spectrum of the free ligand. The ν(NH_2) band is masked by a broad band at ca. 3400 cm^{-1} due to the water present in the complexes. Bands attributable to the perchlorate groups are present in the spectrum of the Er complex at ca. 1120, 1109, and 1088 cm^{-1} (ν_3) and at 627 and 637 cm^{-1} (ν_4), suggesting the presence of coordinated perchlorate groups. The spectrum of the Dy complex features bands at ca. 1458 (ν_5), 1298 (ν_1), and 1030 (ν_2) cm^{-1}, indicative of bidentate nitrate groups, as well as a band at 1383 cm^{-1} due to ionic nitrate. The molar conductance of the Dy complex in dimethylformamide (71 $\Omega^{-1}cm^2mol^{-1}$) is in the range reported for 1:1 electrolytes in this solvent,[19] indicating strong coordination of the nitrate ions. The very limited solubility of the Er complex in various solvents prohibited the measurement of conductivity. The FAB mass spectra of the complexes feature a peak corresponding to the free macrocycle **3** at m/z = 425; in neither case was the molecular ion observed.

When the template reaction was carried out in the presence of hydrated cadmium perchlorate, $[Cd(\mathbf{3})](ClO_4)_2$ was isolated as a white solid. It was found that direct reaction of macrocycle **3** with the metal salt could also be exploited for the synthesis of the complex. The molar conductivity in acetonitrile (307 $\Omega^{-1}cm^2mol^{-1}$) indicates that the complex is

Table 3. ^{1}H- and ^{13}C-NMR data (250 MHz) for $[Cd(\mathbf{3})](ClO_4)_2$ in CD_3CN

Assignment	Shift (δ value)	Integration	*J*/Hz	Assignment	Shift (δ value)
H_i	8.37 (s)	2 H	^3J (^{1}H,^{111,113}Cd) 43	C_a	66.7

a 2:1 electrolyte, hence the ClO_4^- anion is not coordinated in solution. In the IR spectrum of the complex, the strong absorption at 1642 cm^{-1} corresponds to the expected C=N vibration of the Schiff base; this band is shifted to higher wavenumber than in the free ligand. Two strong peaks at 3354 and 3274 cm^{-1} can be attributed to the vibration of the primary amine, and the spectrum also features single bands attributable to ionic ClO_4^- anions at 1080 cm^{-1} (ν_3) and 620 cm^{-1} (ν_4). The FAB mass spectrum shows peaks attributable to $[Cd(\mathbf{3})ClO_4]^+$ at m/z = 637 and $[Cd(\mathbf{3})]^+$ at m/z = 537. The ^{1}H-NMR spectrum (Table 3), recorded immediately after dissolution in CD_3CN, features only a single imine proton peak at δ = 8.37, along with two cadmium satellites [$^3J(^1H,^{111,113}Cd) \approx 43$ Hz]. A broad signal is observed at δ = ca. 3.39, corresponding to the pendant-amine protons. A spectrum recorded after 24 h showed no significant changes, demonstrating the stability of the cadmium perchlorate complex in solution. Recrystallization of the complex from acetonitrile resulted in the formation of crystals suitable for an X-ray crystallographic study.

Description of the Structure of $[Cd(3)](ClO_4)_2$

The X-ray crystal structure of complex $[Cd(\mathbf{3})](ClO_4)_2$ is shown in Figure 2, together with selected bond lengths and angles at the metal, and confirms that a single cadmium cation is coordinated by macrocycle **3**. The perchlorate anions do not interact with the metal. The flexibility of the macrocycle allows it to adopt a folded cleft-like conformation that encapsulates the metal, giving an irregular 7-coordinated N_4O_3 complex in which the Cd ion interacts with all heteroatoms of the ligand. Similar 7-coordination of Cd^{II} has been observed in other macrocyclic complexes.[40,41] The cadmium–nitrogen bond lengths range from 2.254(4) Å [Cd–pendant amine nitrogen N(4)] to 2.492(4) Å [Cd–tertiary amine nitrogen N(2)], with the distances between the metal and the two imino nitrogens and the pendant amino nitrogen N(4) being shorter than the standard Cd–N bond length of 2.33 ± 0.005 Å,[42] thus indicating strong coordinative bonds between these N atoms and the metal. The three Cd–ether oxygen bonds appear to be somewhat elongated, although they fall within the range of 2.36–2.84 Å reported for similar bonds in other cadmium(II) complexes.[43–45] The distances and angles in the ligand are normal. The folding of the macrocycle to achieve the hepta-coordination results in an almost coplanar arrangement of the two phenyl rings [interplanar angle 19.9(2)°].

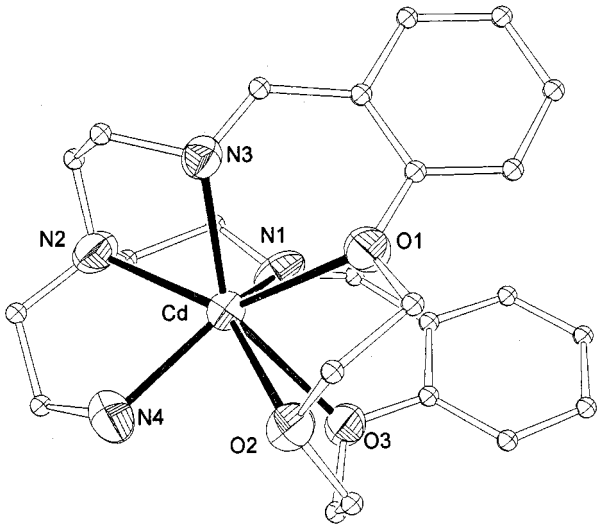

Figure 2. Crystal structure of the cation in $[Cd(\mathbf{3})](ClO_4)_2$: selected bond lengths (Å) and angles (°) at the metal: Cd–N4, 2.254(4), Cd–N1 2.268(4), Cd–N3 2.309(3), Cd–N2 2.492(4), Cd–O1 2.558(3), Cd–O3 2.581(3), Cd–O2 2.605(3); N4–Cd–N1 123.73(18), N4–Cd–N3 119.48(17), N1–Cd–N3 93.73(12), N4–Cd–N2 74.42(16), N1–Cd–N2 75.57(14), N3–Cd–N2 71.56(12), N4–Cd–O1 135.57(15), N1–Cd–O1 96.73(13), N3–Cd–O1 69.55(11), N2–Cd–O1 139.71(11), N4–Cd–O3 95.23(16), N1–Cd–O3 70.56(118), N3–Cd–O3 144.46(10), N2–Cd–O3 130.12(11), O1–Cd–O3 80.58(10), N4–Cd–O2 75.00(15), N1–Cd–O2 132.22(11), N3–Cd–O2 115.41(10), N2–Cd–O2 147.45(12), O1–Cd–O2 63.44(9), O3–Cd–O2 63.76(9)

Conclusions

The cyclocondensation of O^1,O^7-bis(2-formylphenyl)-1,4,7-trioxaheptane with O^1,O^7-bis(2-aninyl)-1,4,7-trioxaheptane gives the oxa-aza Schiff-base macrocycle **1**, which, on reaction with $NaBH_4$, is readily reduced to macrocycle **2**. Mononuclear lanthanide complexes have been prepared from both macrocycles, with dinuclear complexes being formed only by the more flexible ligand **2** and the smaller lanthanide ions. Most interestingly, the reaction of O^1,O^7-bis(2-formylphenyl)-1,4,7-trioxaheptane with tris(2-aminoethyl)amine has been found to give a rare example of an amino pendant-armed [1+1] Schiff-base macrocycle **3** rather than a cryptand or a [2+2] macrocycle. The integrity of the macrocycle **3** has been confirmed by a crystal structure determination of the complex $[Cd(\mathbf{3})](ClO_4)_2$. This type of functionalized macrocycle should provide opportunities for the synthesis of a wide range of derivatives suitable as precursors for polynuclear complexation.

Experimental Section

Measurements: Elemental analyses were carried out by the University of Santiago de Compostela Microanalytical Service on Carlo Erba 1108 and Leco CNHS-932 microanalysers. – Infrared spectra were recorded with samples between KBr discs using a Mattson Cygnus 100 spectrophotometer. – Proton NMR spectra were recorded on a Bruker WM-300 spectrometer. – Positive-ion FAB mass spectra were recorded on a Kratos MS50TC spectrometer using a 3-nitrobenzyl alcohol (*m*NBA) matrix. Conductivity measurements were carried out on 10^{-3} mol dm^{-3} acetonitrile solutions at 20 °C using a WTW LF-3 conductivimeter. The electronic absorption spectra of the complexes (10^{-3}–10^{-6} M acetonitrile solutions) were measured in the range 300–900 nm using Hitachi U-3200 and Perkin–Elmer Lambda 6 spectrophotometers. Emission spectra were recorded on a SPEX F111 Fluorolog spectrofluorimeter.

Chemicals and Starting Materials: O^1,O^7-Bis(2-formylphenyl)-1,4,7-trioxaheptane was prepared according to a literature method;[17] O^1,O^7-bis(2-aninyl)-1,4,7-trioxaheptane was prepared by reduction of the corresponding dinitro precursor using a proced-

ure similar to that described previously.[46–49] Tris(2-aminoethyl)-amine and the metal salts were commercial products (from Alfa and Aldrich) and were used without further purification. Solvents were of reagent grade and were purified by the usual methods. ***Caution:*** Perchlorate salts are potentially explosive! Only small amounts of material should be prepared and handled with great care; particular caution must be exercised when they are heated in vacuo.

Condensation of O^1,O^7-Bis(2-formylphenyl)-1,4,7-trioxaheptane with O^1,O^7-Bis(2-aninyl)-1,4,7-trioxaheptane in the Absence of Metal Ions: A solution of O^1,O^7-bis(2-aninyl)-1,4,7-trioxaheptane (0.28 g, 1 mmol) in hot methanol (50 mL) was added dropwise to a refluxing solution of O^1,O^7-bis(2-formylphenyl)-1,4,7-trioxaheptane (0.31 g, 1 mmol) in hot methanol (50 mL). The resulting solution was gently refluxed with magnetic stirring for ca. 5 h. The colour changed to yellow and an orange-brown powder precipitated, which was filtered off. The solution was then concentrated using a rotary evaporator; on leaving the concentrated filtrate to stand, an orange-yellow powder precipitated, which was filtered off, washed with diethyl ether, and dried in vacuo. This product was characterized as the macrocyclic ligand. Yield 75%; m.p. 160 °C. – IR (KBr): $\tilde{\nu}$ = 1620 cm^{-1} $(C{=}N)_{imi}$, 1590 (C=C). – MS (FAB; *m*NBA): *m*/z = 567 [**1** + H]$^+$.– HR MS: *m*/*z* = 566 (100%) $C_{34}H_{34}N_2O_6$. – ^{1}H NMR (CD_3CN): δ = 8.9 (s, 2 H, $HC{=}N_{imi}$). – $C_{34}H_{34}N_2O_6 \cdot 0.5\,H_2O$: calcd. C 70.95, H 6.15, N 4.90; found C 70.80, H 6.10, N 5.25.

Reaction of O^1,O^7-Bis(2-formylphenyl)-1,4,7-trioxaheptane and O^1,O^7-Bis(2-aninyl)-1,4,7-trioxaheptane in the Presence of Metal Ions: General Procedure for [M(1)][X]$_n$: To a refluxing solution of O^1,O^7-bis(2-formylphenyl)-1,4,7-trioxaheptane (1 mmol) in hot methanol (25 mL) was added a solution of the hydrated metal salt (1 mmol) (M = Y, Cd, Ln = La–Yb except Pm and Dy) in methanol (15 mL). The resulting solution was magnetically stirred and heated while a methanolic solution of O^1,O^7-bis(2-aninyl)-1,4,7-trioxaheptane (1 mmol) was slowly added. Following the addition, refluxing was continued for ca. 4–5 h. The solution was then concentrated in a rotary evaporator to a volume of ca. 10–15 mL. An equal volume of acetonitrile/diethyl ether was slowly infused into the solution, which led to the deposition of a powdery precipitate. The product was filtered off, washed with absolute ethanol, and dried in vacuo. Microanalytical data are given in Table 1. The compounds were found to be air-stable, soluble in methanol, dimethylformamide, dimethyl sulfoxide, acetonitrile, pyridine, dichloromethane, nitrobenzene, and nitromethane, moderately soluble in absolute ethanol, and insoluble in diethyl ether, water, chloroform, and cyclohexane.

Synthesis of Macrocycle 2: The reduction was carried out according to a modification of a literature method.[49,50] O^1,O^7-Bis(2-aninyl)-1,4,7-trioxaheptane (4.0 mmol) in warm methanol (150 mL) was slowly added to a solution of O^1,O^7-bis(2-formylphenyl)-1,4,7-trioxaheptane (4.0 mmol) in warm methanol (300 mL). The resulting mixture was refluxed for 1 h, cooled, and then solid $NaBH_4$ (65 mmol) was carefully added portionwise with stirring. When effervescence had ceased, a white precipitate was observed, which was collected by filtration. This product was washed with water and characterized as the macrocycle. The filtrate was concentrated to dryness in a rotary evaporator and the residue was taken up in dichloromethane (150 mL). The resulting solution was stirred for ca. 72 h. A grey precipitate was removed by filtration and the solution was dried over anhydrous sodium sulfate. It was then concentrated to a volume of ca. 10–15 mL in a rotary evaporator whereupon diethyl ether was added, which led to the deposition of a white product. This was filtered off, washed with absolute ethanol, and dried in vacuo to give a second crop of the macrocyclic product. The compound was found to be air-stable, soluble in warm chloroform/benzene (1:1); moderately soluble in hot methanol and chloroform, and insoluble in acetonitrile, absolute ethanol, diethyl ether, dimethylformamide, dimethyl sulfoxide, pyridine, and water. Yield 40%; m.p. 179–181 °C. – IR (KBr): $\tilde{\nu}$ = 3364 cm^{-1} (NH), 1601 (C=C). – MS (FAB; *m*NBA): *m*/*z* = 571 [**2** + H]$^+$. – HR MS: *m*/*z* = 570 (100%) $C_{34}H_{38}N_2O_6$.– ^{1}H NMR ($CDCl_3$): δ = 7.42–6.67 (m, 16 H, C_6H_4), 4.75 (s, 4 H, CH_2NH), 4.23–3.87 (m, 16 H, OCH_2CH_2), 3.65 (br. s, 2 H, NH). – $C_{34}H_{38}N_2O_6 \cdot H_2O$: calcd. C 69.40, H 6.50, N 8.10; found C 69.50, H 6.75, N 7.95.

Crystal Structure of [(2)H](ClO$_4$) · CHCl$_3$: A yellow plate-like crystal of $[C_{34}H_{39}N_2O_6](ClO_4) \cdot CHCl_3$ (790.48), dimensions 0.5 × 0.5 × 0.2 mm, crystallized from diethyl ether/chloroform, was used for the structure determination. The chosen crystal was mounted on a glass fibre using an epoxy resin. Data were collected by means of a Bruker Smart CCD area detector with an Oxford Cryosystems low-temperature system held at 150 K. Cell parameters were refined from the setting angles of 140 reflections (θ range 1.35–28.48). Reflections were measured from a hemisphere of data composed of frames each covering 0.3° in ω. Of the 24613 reflections measured, all of which were corrected for Lorentz and polarization effects and for absorption (maximum and minimum transmission coefficients of 0.893 and 0.223), 9824 independent reflections exceeded the significance level $F/\sigma(F) > 4.0$. The structure was solved by direct methods and refined by full-matrix least-squares methods on F^2. Hydrogen atoms were placed in geometrically idealized positions and refined with a riding model (including torsional freedom for methyl groups) with U_{iso} restrained as 1.2 (or 1.5 for methyl groups) times U_{eq} of the carrier atom. Refinement converged at a final $R = 0.0745$ ($wR2 = 0.2321$ for all 16888 unique data, 943 parameters, mean and maximum Δ/σ 0.000, 0.0001) with allowance for the thermal anisotropy of all non-hydrogen atoms. Minimum and maximum final electron density –0.816 and 0.987 eÅ^{-3}. A weighting scheme $w = 1/[\sigma^2(F_o^2) + (0.1408P)^2 + 0.0000P]$, where $P = (F_o^2 + 2F_c^2)/3$, was used in the latter stages of refinement. Complex scattering factors were taken from the SHELXTL program package[51] as implemented on a Viglen Pentium computer, while molecular graphics were derived from ORTEP-3.[52] A summary of the experimental and structure solution procedure is given in Table 4.

Metal Complexes of Macrocycle 2. – General Procedure: The appropriate metal salt (0.15 mmol) was dissolved in methanol (10 mL) and added to a stirred solution of the ligand **2** (0.15 mmol) in chloroform/benzene (20 mL + 20 mL). An immediate colour change was usually observed and a precipitate began to deposit. The mixture was then stirred for 3 days at room temperature. The product was subsequently filtered off and dried in vacuo. The filtrate was concentrated in a rotary evaporator to leave an oil. On treatment with diethyl ether, a solid was obtained, which was filtered off and dried in vacuo. This reaction was attempted with $Cd(ClO_4)_2 \cdot x\,H_2O$ and $Y(NO_3)_3 \cdot x\,H_2O$, the nitrates of La, Ce, Pr, Sm, Gd, Er, and Lu, and the perchlorates of La, Pr, Gd, and Er. Microanalytical data of the relevant products are given in Table 2. The complexes were found to be air-stable, soluble in acetonitrile, chloroform, dimethylformamide, and dimethyl sulfoxide, moderately soluble in methanol and dichloromethane, and insoluble in absolute ethanol, cyclohexane, diethyl ether, and water.

Reaction of O^1,O^7-Bis(2-formylphenyl)-1,4,7-trioxaheptane and Tris(2-aminoethyl)amine in the Absence of Metal Ions: A solution of O^1,O^7-bis(2-formylphenyl)-1,4,7-trioxaheptane (0.31 g, 1 mmol)

Table 4. Crystal data and structure refinement for $[C_{34}H_{39}N_2O_6](ClO_4) \cdot CHCl_3$

Empirical formula	$C_{35}H_{40}Cl_4N_2O_{10}$
Formula weight	790.48
Temperature [K]	423(2)
Wavelength [Å]	0.71073
Crystal system, space group	triclinic, *P*-1

a [Å]	10.4438(11)
b [Å]	11.9470(12)
c [Å]	30.724(3) Å
α [°]	90.619(2)
β [°]	99.485(2)
γ [°]	102.441(2)
Volume [Å^3]	3688.1(7)
Z	4
Calculated density [Mg/m^3]	1.328
Absorption coefficient [mm^{-1}]	0.243
F(000)	1528
Crystal size [mm]	0.5 × 0.5 × 0.2
θ range for data collection [°]	1.35 to 28.48
Index ranges	$-13 \le h \le 9$ $-14 \le k \le 15$ $-40 \le l \le 40$
Reflections collected/unique	24613/16888 [*R*(int) = 0.0464]
Completeness to 2θ	28.48°; 90.7%
Absorption correction	None
Refinement method	Full-matrix least-squares on F^2
Data/restraints/parameters	16888/0/943
Goodness-of-fit on F^2	0.990
Final *R* indices [$I > 2\sigma(I)$]	*R*1 = 0.0745, *wR*2 = 0.1982
R indices (all data)	*R*1 = 0.1200, *wR*2 = 0.2321
Largest diff. peak and hole	0.987 and –0.816 e · Å^{-3}

in hot acetonitrile (100 mL) was added dropwise to a refluxing solution of tris(2-aminoethyl)amine (0.15 mL, 1 mmol) in hot acetonitrile (300 mL). The resulting solution was gently refluxed with magnetic stirring for ca. 3 h. The colour of the reaction mixture changed to yellow and first an unidentified precipitate was deposited, which was removed by filtration. The filtrate was then concentrated to a volume of ca. 10 mL and a yellow product was obtained. This was collected by filtration, washed with diethyl ether, and dried in vacuo to give macrocycle **3** in 25% yield; m.p. 115 °C (dec.) – IR (KBr): $\tilde{\nu}$ = 1636 cm^{-1} (C=N)$_{imi}$. – ^{1}H NMR ($CDCl_3$): δ = 8.79–8.77 (s, 2 H, HC=N$_{imi}$), 7.96–6.84 (m, 8 H, C_6H_4), 4.24–4.14 (m, 4 H, CH_2O), 4.00–3.84 (m, 4 H, CH_2O-aryl), 3.71–3.62 (m, 4 H, C*H*$_2$N=CH), 2.92–2.60 (m, 8 H, CH_2-N$_{ternary}$), 1.94–1.85 (br. s, 2 H, NH_2). – MS (FAB; *m*NBA): *m*/*z* = 425 [**3** + H]$^+$. – MS(EI): P$^+$ = 394 [**3** – CH_2NH_2]$^+$. – $C_{24}H_{32}N_4O_3 \cdot 1.5\ H_2O$: calcd. C 63.85, H 7.75, N 12.45; found C 64.40, H 7.50, N 12.40.

Reaction of *O*^{1},*O*^{7}-Bis(2-formylphenyl)-1,4,7-trioxaheptane and Tris(2-aminoethyl)amine in the Presence of Metal Ions: General Procedure for [M(3)][X]$_n$: To a refluxing solution of tris(2-aminoethyl)-amine (1 mmol) in either hot methanol, acetonitrile, or absolute ethanol (50 mL) was added a solution of the hydrated lanthanide salt (1 mmol) (X = ClO_4^-, Ln = La, Ce, Gd, Er or Ho; X = NO_3^-, Ln = La, Pr, Sm, Eu, Gd, Tb, Dy, Ho, Er, Tm, Yb, or Lu) in the same solvent (50 mL). The resulting mixture was magnetically stirred and heated for 1 h, during which a methanolic or ethanolic solution (50 mL) of *O*^{1},*O*^{7}-bis(2-formylphenyl)-1,4,7-trioxaheptane (1 mmol) was slowly added. Refluxing was continued for ca. 3–4 h. The solution was then concentrated in a rotary evaporator to a volume of ca. 10–15 mL. An equal volume of diethyl ether was slowly infused into the concentrated solution, which led to the deposition of a yellow powdery precipitate. The product was filtered off and dried in vacuo. The products thus obtained gave unsatisfactory analytical results. When the methanol/diethyl ether or ethanol/diethyl ether solution was concentrated to dryness once more and further diethyl ether was added, a second product was isolated by filtration and identified as the metal complex only in the cases of the reactions with erbium perchlorate and dysprosium nitrate. In the reactions with the other Ln^{III} nitrates or perchlorates, no analytically pure products could be isolated. The compounds were found to be air-sensitive. When the same reaction was carried out with Cd^{II} perchlorate in absolute ethanol, the product isolated was characterized as the [Cd(**3**)]$(ClO_4)_2$ complex; recrystallization from acetonitrile resulted in the formation of crystals suitable for X-ray crystallographic analysis.

[Er(3)](ClO$_4$)$_3$ · 2 H$_2$O: Solvent: Methanol. Yield: 16%. – IR (KBr): $\tilde{\nu}$ = 1637 cm^{-1} (C=N)$_{imi}$, 1600 (C=C), 1120, 1109, 1088, 627, and 636 (ClO_4^-). – MS (FAB; *m*NBA): *m*/*z* = 425 [**3** + H]$^+$. – $C_{24}H_{36}N_4O_{17}Cl_3Er$: calcd. C 31.10, H 3.90, N 6.05; found C 30.60, H 3.75, N 6.80. The yellow complex was found to be moderately soluble in acetonitrile, dimethylformamide, and acetone, but insoluble in methanol, chloroform, absolute ethanol, dimethyl sulfoxide, diethyl ether, and water.

[Dy(3)](NO$_3$)$_3$ · H$_2$O: Solvent: Acetonitrile. Yield: 63%. – IR (KBr): $\tilde{\nu}$ = 1638 cm^{-1} (C=N)$_{imi}$, 1600 (C=C), 1458, 1383, 1298, 1046, and 1030 (NO_3^-). – MS (FAB; *m*NBA): *m*/*z* = 425 [**3** + H]$^+$. – Λ_M (DMF): 71 Ω^{-1}cm^{2}mol^{-1}. – $C_{24}H_{34}N_7O_{13}Dy$: calcd. C 37.55, H 4.50, N 12.75; found C 37.50, H 4.80, N 12.55. The yellow complex was found to be soluble in dimethylformamide and dimethyl sulfoxide, moderately soluble in acetonitrile, methanol, chloroform, absolute ethanol, and acetone, and insoluble in diethyl ether and water.

[Cd(3)](ClO$_4$)$_2$: Solvent: Absolute ethanol; the order of addition of tris(2-aminoethyl)amine and *O*^{1},*O*^{7}-bis(2-formylphenyl)-1,4,7-trioxaheptane was reversed. The white precipitate obtained directly from the reaction mixture was filtered off and dried in vacuo. Yield: 36%. – IR (KBr): 1642 cm^{-1} (C=N)$_{imi}$, 1116, 1083, 1039, and 620 (ClO_4^-). – ^{1}H- and ^{13}C-NMR spectra; see Table 3. – MS (FAB; *m*NBA): *m*/*z* = 637 [Cd(**3**)(ClO_4)]$^+$, 537 [Cd(**3**)]$^+$. – $C_{24}H_{32}N_4O_{11}Cl_2Cd$: calcd. C 39.20, H 4.40, N 7.60; found C 39.35,

Largest diff. peak and hole	1.151 and -0.749 eÅ^{-3}

H 4.40, N 7.30. The complex was found to be air-stable, soluble in acetonitrile, dimethylformamide, and dimethyl sulfoxide, but insoluble in methanol, chloroform, absolute ethanol, acetone, diethyl ether, and water. Recrystallization from acetonitrile resulted in the formation of crystals suitable for an X-ray crystallographic study.

Crystal Structure of [Cd(3)](ClO$_4$)$_2$: A colorless, plate-like crystal of $[Cd(C_{24}H_{32}N_4O_3)](ClO_4)_2$ (735.84), crystallized from acetonitrile solution, with dimensions 0.55 × 0.30 × 0.05 mm, was used for the structure determination. The chosen crystal was mounted on a glass fibre using an epoxy resin. Data were collected using a Siemens SMART CCD area detector single-crystal diffractometer with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). Preliminary unit cell constants were determined from a set of 45 narrow-frame scans (0.3 in ω). A total of 1420 frames of intensity data were collected with a width of 0.3° per frame and a counting time of 20 s/frame at a crystal-to-detector distance of 4.5 cm. The collected frames were integrated using an orientation matrix determined from the narrow-frame scans and refined using Siemens SAINT[53] software on all observed reflections. Absorption corrections were applied by means of the SADABS[54] program (maximum and minimum transmission coefficients, 1.0000 and 0.7650). The integration process yielded 20796 reflections, of which 7078 were independent. The structure was solved using SHELX-97[55] by the heavy atom method (Cd atom) and subsequent Fourier difference synthesis, and refined by full-matrix least-squares methods on F^2. The amine hydrogen atoms were located on a Fourier map. All other hydrogen atoms were included in calculated positions and refined in riding mode with U(H) equal to 1.2 times U_{eq} of the parent atom. Molecular graphics were generated using ORTEP-3.[52] A summary of the experimental and structure solution procedure is given in Table 5.

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-135465 for [(2)H](ClO$_4$) · CHCl$_3$ and CCDC-135464 for [Cd(**3**)](ClO$_4$)$_2$. Copies of the data can be obtained free of charge on application to the CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) +44 (0)1223 336033; E-mail: deposit@ccdc.cam.ac.uk].

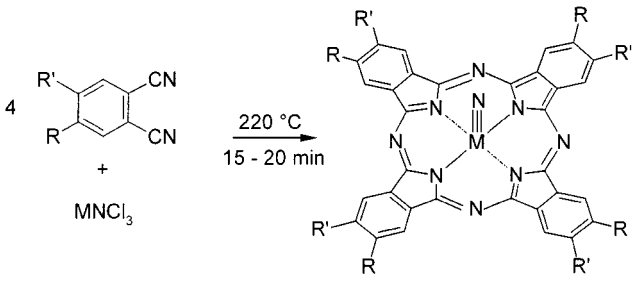
Novel Nitrido- and Oxo(phthalocyaninato) Complexes of Molybdenum, Tungsten and Rhenium

Karsten Frick,[a] Sanjiv Verma,[a] Jörg Sundermeyer,[b] and Michael Hanack*[a]

Keywords: Phthalocyanines / Nitrides / Oxo complexes / Rhenium / Molybdenum / Tungsten



The synthesis of new nitrido(phthalocyaninato)molybdenum (**1**–**4**) and -tungsten complexes (**5**–**7**) starting from the corresponding phthalonitriles and $MNCl_3$ (M = Mo, W) is reported. In addition, the reaction of (tBu$_4$Pc)WN (**6**) with PPh_3 leading, after several steps, to the diamagnetic compound (tBu$_4$Pc)WO (**7**) is described. The reaction of (tBu$_4$Pc)ReN (**9**) with PPh_3 leads to [(tBu$_4$Pc)ReO]$_2$ (**12**), and of [(C$_5$H$_{11}$)$_8$Pc]ReN (**10**) with PPh_3 leads, under different conditions, to {[(C$_5$H$_{11}$)$_8$Pc]ReO}$_2$O (**11**).

Introduction

Continuing with our work on nitrido(phthalocyaninato)-metal compounds[1] we report here on the synthesis and properties of novel nitrido(phthalocyaninato)metal complexes of molybdenum and tungsten, as well as two other oxo(phthalocyaninato)rhenium dimers. The aim of our work on the paramagnetic PcMN complexes (M = Mo, W) is to reduce them to the anionic phthalocyaninato complexes PcMN$^-$ and to investigate their subsequent reaction with electrophiles to obtain new nitrido-bridged phthalocyaninato complexes. These complexes should be more reactive in their nitrido functionality than the nitrido-bridged rhenium phthalocyanines which we have reported recently.[1]

Until now, the few publications concerning molybdenum phthalocyanines mostly concentrate on oxophthalocyaninatomolybdenum(IV), PcMoO.[2] Some porphyrinato complexes of molybdenum are known.[3] The most interesting are (TMP)MoN (TMP = tetramesitylporphyrinato), (TTP)MoN (TTP = tetratolylporphyrinato) and (TPP)MoN (TPP = tetraphenylporphyrinato) because the molybdenum is in the +5 oxidation state and in a planar arrangement with the porphyrinato ligand.[4]

The preparation of unsubstituted[5] and substituted PcMoN is successful starting from the appropriate phthalonitriles and $MoNCl_3$[6,7], by melting them at 220 °C for 15 to 20 minutes (Scheme 1). The dark green PcMoN (**1**) can be separated from its impurities by Soxhlet extraction with acetone and toluene. The substituted complexes (R$_8$Pc)MoN [R = C$_3$H$_7$ (**2**), C$_4$H$_9$ (**3**), C$_5$H$_{11}$ (**4**)] are purified by column chromatography on Al_2O_3 with toluene and by washing with methanol. The yield is 65% in the case of **1**. The yields are higher for the substituted PcMoN complexes [**2** (11%), **3** (8%), **4** (10%)] than for the corresponding nitrido(phthalocyaninato)rhenium complexes.[1] We assume that either the excess dinitrile is responsible for the Cl radical abstraction from $MNCl_3$, or that Cl$^-$ is oxidized to Cl_2 with reduction of the metal center.

	1	2	3	4	5	6	7
M	Mo	Mo	Mo	Mo	W	W	W
R	H	C$_3$H$_7$	C$_4$H$_9$	C$_5$H$_{11}$	H	H	C$_5$H$_{11}$
R'	H	C$_3$H$_7$	C$_4$H$_9$	C$_5$H$_{11}$	H	*t*Bu	C$_5$H$_{11}$

Scheme 1. Synthesis and structure of nitrido(phthalocyaninato)metal complexes

The M$^+$ peak for PcMoN (**1**) in the FAB-MS is observed at m/z = 623.1 (calcd. 622.5). The complexes (R$_8$Pc)MoN [R = C$_3$H$_7$ (**2**), C$_4$H$_9$ (**3**), C$_5$H$_{11}$ (**4**)] show their M$^+$ peak in the FD-MS with the expected isotopic pattern. The infrared spectra of **1**–**4** are difficult to interpret. Usually the Mo≡N stretching vibration[6] is observed higher than 1000 cm^{-1} and the Mo=O vibration in phthalocyanines appears at $\tilde{\nu}$ =

Table 1. EPR, IR and UV data of the new phthalocyanines

	EPR g	IR [cm^{-1}] $\nu_{M\equiv N}$	UV [nm] λ (Q)
PcMoN (**1**)	1.97	953	703.5 (ClN)[a]
[$(C_3H_7)_8$Pc]MoN (**2**)	1.97	974	709.0 (toluene)
[$(C_4H_9)_8$Pc]MoN (**3**)	1.97	962	711.5 (toluene)
[$(C_5H_{11})_8$Pc]MoN (**4**)	1.97	974	716.0 (toluene)
PcWN (**5**)	1.88	953	751.0 (ClN)[a]
(tBu$_4$Pc)WN (**6**)	1.89	959	745.0 (toluene)
[$(C_5H_{11})_8$Pc]WN (**7**)	1.89	957	770.5 (toluene)
PcWO (**8**)	–	$\nu_{W=O}$ = 1047[b]	674.5 (toluene)
[(tBu$_4$Pc)Re(O)]$_2$ (**12**)	–	$\nu_{Re=O}$ = 960[b]	652.5 (chloroform)
{[$(C_5H_{11})_8$Pc]Re(O)}$_2$O (**11**)	–	–	701.5 (chloroform)

[a] ClN = 1-chloronaphthalene. – [b] Tentative assignment.

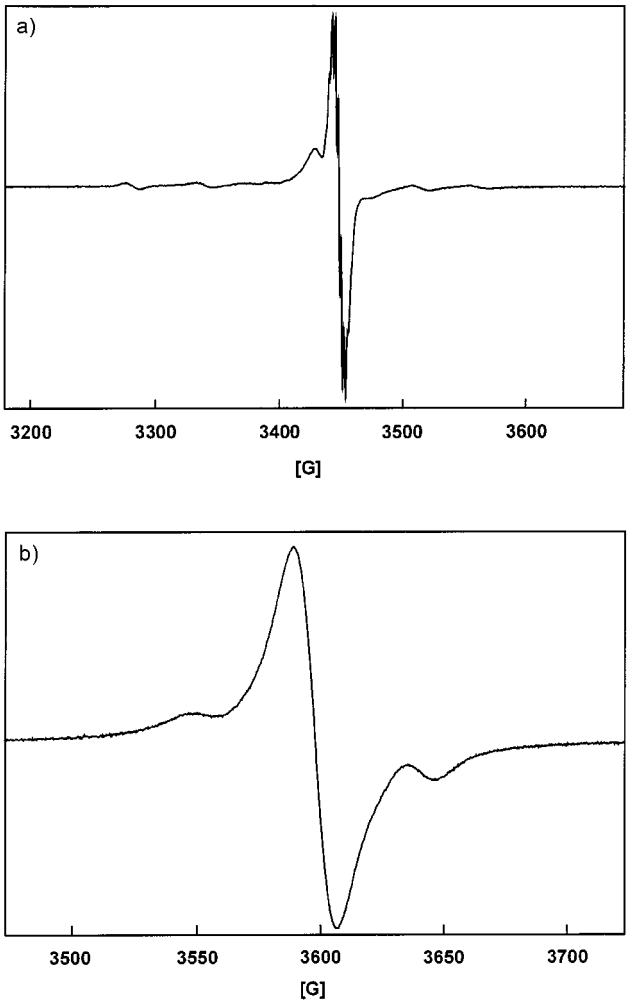

Figure 1. EPR spectra of a) PcMoN (**1**) and b) $(C_5H_{11})_8$PcWN (**7**)

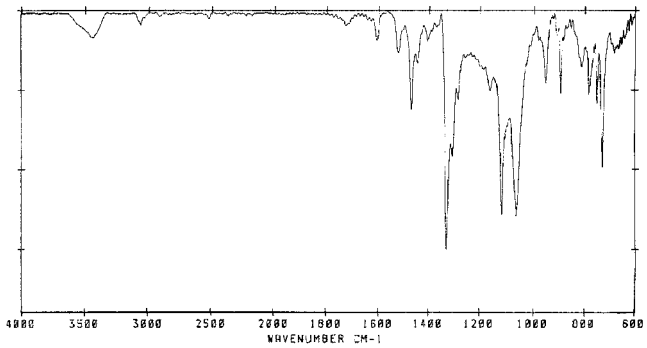
950–980 cm^{-1}.[2a] For PcMoN (**1**) and (R_8Pc)MoN **2**–**4** the Mo≡N stretching vibration is observed below 1000 cm^{-1} (Table 1). The lowered value of the stretching vibration can be explained by interaction of the nitrogen lone pair with the following Lewis acidic Mo center within the same stack, which reduces the bond order of MoN. In PcReN the Re≡N stretching vibration is located at $\tilde{\nu}$ = 978 cm^{-1} due to the same effect.[1b,1c] This lowering is not unusual, e.g. in $MoNF_4^-$ the band for MoN is located at $\tilde{\nu}$ = 969 cm^{-1}.[8] The UV/Vis spectrum of **1** in solution and as a KBr pellet indicates the presence of dimers: the maximum of the Q-band in solution (chloroform) is seen at λ = 703.5 nm (satellites are located at λ = 639.5 and 602.5 nm) and a shoulder is seen at λ = 777.0 nm in the solution spectrum and at λ = 791.5 nm in the solid state. Under the assumption of a Davidov–Kasha exciton interaction,[9] the shoulders at λ = 649.5 and 791.5 nm are due to dimers with an interaction of ΔE = 2750 cm^{-1}. In contrast to **1** the UV/Vis spectra of **2**–**4** show the usual Q- and B-bands of monomeric phthalocyanines. As an element of group six, molybdenum in the oxidation state +5 has a d^1 configuration with one unpaired electron. An EPR spectrum of PcMoN (**1**) in 1-chloronaphthalene shows intense central lines (g = 1.97) due to the coupling of the electron with the five nitrogens. Six weaker lines seen symmetrically on both the right and the left side of the central signal are due to the electron–Mo^{95}/Mo^{97} coupling (Figure 1a). The simulated spectrum corresponds to the measured spectrum. The spectra of the more soluble compounds **2**–**4** show the same patterns (Table 1). The g factor for the complexes **1**–**4** is 1.97.

Some phthalocyaninato complexes of tungsten have been synthesized,[10] but only in $PcWCl_3$[10a] and (ClPc)W(O)OH[11] is the metal in the +5 oxidation state. These examples indicate that nitrido(phthalocyaninato)-tungsten complexes should also exist. With the same synthetic strategy as for the PcMoN compounds, unsubstituted, tetra- and octasubstituted nitrido(phthalocyaninato)-tungsten complexes **5**–**7** are obtained (Scheme 1). Their stability against moisture is greater than that observed for the molybdenum phthalocyanines **1**–**4**. PcWN (**5**) is separated from its impurities by Soxhlet extraction with ethanol, acetone and toluene and isolated as a dark green powder in high yield (70%). The M^+ peak of **5** in the FAB-MS appears at m/z = 709.9 (calcd. 710.1). Purification of (tBu$_4$Pc)WN (**6**) and [$(C_5H_{11})_8$Pc]WN (**7**) is not possible by column chromatography. The excess of phthalonitrile in the substituted complexes **6** and **7** is separated by Soxhlet extraction (hexane), further impurities are precipitated with dichloromethane/hexane. The synthesis of $(C_5H_{11})_8$PcWN (**7**) can be carried out in a higher yield using $W(NTos)_2Cl_2$[12] instead of $WNCl_3$. Impurities are separated by washing the crude product with methanol and precipitated with dichloromethane/hexane. The molecular ions of compounds **6** and **7** can be seen in the FD-MS with the expected isotopic pattern. The IR spectrum of **5** is quite similar to that of PcReN[1b,1c] and almost the same as that of PcMoN (**1**). All phthalocyanine vibrations are in the usual regions. The W≡N vibration is expected between 1000 and 950 cm^{-1}. A band of medium intensity at $\tilde{\nu}$ = 953 cm^{-1} is assigned to this vibration (Figure 2). The W=O vibration in (ClPc)W(O)OH[11] is also found around $\tilde{\nu}$ = 953 cm^{-1}. This indicates that the W≡N vibration appears at lower wavelength due to the interaction with the next metal center within a stack as explained for PcMoN



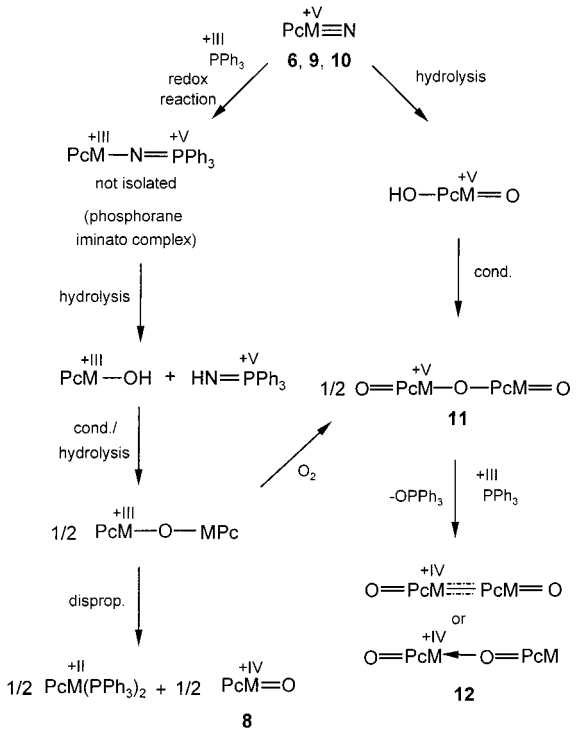


Figure 2. IR spectrum of PcWN (**5**)

(**1**). The W≡N vibration in the soluble complexes **6** and **7** is observed at $\tilde{\nu}$ = 959 (**6**) and 957 cm^{-1} (**7**) (Table 1).

In (ClPc)W(O)OH the maximum of the Q-band is at λ = 730 nm.[11] PcWN (**5**) shows a red shift in the Q-band maximum at λ = 751.0 nm (Table 1); the Q-band is broadened and shows two shoulders at λ = 699.5 and 673.5 nm. A shoulder at higher wavelength cannot be found, which indicates that only monomeric units of **5** are present in solution. (tBu$_4$Pc)WN (**6**) and [$(C_5H_{11})_8$Pc]WN (**7**) show broadened Q-bands at λ = 745.0 (**6**) and 770.5 nm (**7**). The d^1-electron configuration of tungsten in PcWN (**5**), (tBu$_4$Pc)WN (**6**) and [$(C_5H_{11})_8$Pc]WN (**7**) allows the recording of their EPR spectra. Compound **6** exhibits a broad intense signal at g = 1.88 without hyperfine structure due to the electron–nitrogen or electron–tungsten coupling (Table 1). This is quite normal for powder spectra even at 77 K.[11] However, **6** and **7** show an electron–W^{183} coupling in toluene solution (Figure 1b). Two signals, besides the main resonance, with an intensity of about 7% appear [g = 1.89 (**6**, **7**)] (Table 1).

Reactions of PcReN[13] and PcMoO[2f] complexes with phosphanes have been the focus of recent studies. To date, the exact mechanism of the reaction of the PcMN complexes **6**, (tBu$_4$Pc)ReN (**9**), [$(C_5H_{11})_8$Pc]ReN (**10**) with PPh_3 is unknown but we suggest two pathways (Scheme 2). The first possible mechanism involves nucleophilic attack of the phosphane at the LUMO of the nitrido complex having mainly the character of an MN–π*-orbital.[6] This redox reaction would lead to a phosphorane iminato complex that could undergo hydrolysis to finally yield PcWO (**8**) as described in Scheme 2. The second pathway begins with hydrolysis of **6**, **9** and **10**. After condensation **11** is obtained which can be reduced with PPh_3 to the phthalocyaninatometal complex **12**.

As a first attempt the reaction of (tBu$_4$Pc)WN (**6**) with PPh_3 was investigated. After column chromatography only (tBu$_4$Pc)WO (**8**) was isolated in 50% yield. The FD-MS spectrum of **8** shows the expected molecular peak at m/z = 936.5 (calcd. 936.3) in accordance with the calculated isotopic pattern. An interesting result is indicated in the IR spectrum of **8** in which the W≡N stretching vibration disappears. All other vibrations show very little or no difference in intensity or wave number. The assignment of the W=O vibration is difficult, however a shoulder at $\tilde{\nu}$ = 1047 cm^{-1} could correspond to this vibration (Table 1). In the UV/Vis spectrum of **8** the Q-band shows a heavy blue shift relative to (tBu$_4$Pc)WN (**6**), with a maximum at λ = 674.5 nm and shoulders at λ = 725.0 and 611.0 nm (Table 1). In the same way the B-band is shifted to lower wavelength. The ^{1}H NMR spectrum of diamagnetic (tBu$_4$Pc)WO (**8**) shows the signals of the tBu groups between δ = 1.60–2.26 due to the structural isomers present in tetrasubstituted phthalocyanines. The signals of the aromatic protons are found between δ = 7.5–8.6.

Scheme 2. Mechanism leading to PcWO (**8**), [tBu$_4$PcRe(O)]$_2$ (**12**) and [$(C_5H_{11})_8$PcRe(O)]$_2$O (**11**)

The reaction of PcMN with PPh_3 is studied further with the nitridophthalocyaninatorhenium complexes (tBu$_4$Pc)ReN (**9**) and [$(C_5H_{11})_8$Pc]ReN (**10**). Recently the reaction of Re_2O_7 and phthalonitrile with PPh_3 leading to the formation of $(PcRe)_2$ was reported.[14] In the first step of this reaction $(PPh_3)_2$PcRe was formed, after heating to 350 °C $(PcRe)_2$ was obtained. $(PPh_3)_2$PcRe was also successfully prepared starting from "PcReO" and PPh_3.[13] The reaction of **9** and **10** with PPh_3 at different reaction temperatures gives different products (Scheme 2). At lower temperatures μ-oxo[oxoocta(n-pentyl)phthalocyaninato]rhenium {[$(C_5H_{11})_8$Pc]Re(O)}$_2$O (**11**) is obtained, while at higher temperatures (350 °C) rhenium is reduced to the +4 oxidation state. After column chromatography on Al_2O_3 with toluene and dichloromethane as eluents, [(tBu$_4$Pc)Re(O)]$_2$ (**12**) is isolated. There are two possible structures for **12**: first, the stacking of a second molecule in trans-position to form a μ-oxo bridged dimer, and second a dimer with a rhenium-rhenium bond. From the UV/Vis spectra we assume that the dimeric complex [(tBu$_4$Pc)Re(O)]$_2$ (**12**) with a rhenium–rhenium bond is obtained. In the FD-MS the

molecular peak for **12** is found at *m/z* = 1876.6 (calcd. 1876.4) and the signal of the monomeric fragment (tBu$_4$Pc)Re(O)$^+$ appears at *m/z* = 938.2. The IR spectrum of **12** shows differences from that of the starting material (tBu$_4$Pc)ReN (**9**). The Re≡N vibration disappears; however, the Re=O vibration is not seen due to strong new ligand vibrations in that region. In the UV/Vis spectrum of **12** in chloroform the dimerization is proved by the blue shift of the Q-band to λ = 652.5 nm relative to (tBu$_4$Pc)ReN (**9**) [λ_{max} (Q) = 698 nm (CH_2Cl_2)] and the appearance of the forbidden Q$^-$-band at λ = 801.5 nm (Figure 3a, Table 1). The exciton interaction is calculated to be ΔE = 2850 cm^{-1}, while for (PcRe)$_2$ the calculated value is lower than 2400 cm^{-1}.[14] The interaction caused by the distance of the macrocycles is dependent on the radius of the metal ions. In (PcRe)$_2$ the oxidation state of rhenium is +2, but in **12** it is +4. The effect of the sterically demanding tBu groups on the distance of the macrocycles is low.[15] With the UV/Vis spectrum as KBr pellet the exciton interaction in the solid state is ascertained to be ΔE = 2000 cm^{-1}. A higher distance of the macrocycles is concluded from these results and may be explained by an eclipsed conformation in the solid state. In solution, **12** rotates to the staggered conformation. A change of conformation was also established for (PcRe)$_2$.[14] In the presence of light, a chloroform solution of **12** decomposes as seen by the appearance of a greater absorbance of the monomer band at λ = 692.0 nm.

In the ^{1}H NMR spectrum of [(tBu$_4$Pc)Re(O)]$_2$ (**12**) a broadening of the signals due to the interaction of two macrocycles and the structural isomers is seen. The signals of the aromatic protons are between δ = 9.58–9.49 and δ = 8.50–8.39, while the tBu groups are shifted to lower field (δ = 2.15–1.81) than for (tBu$_4$Pc)ReN (**9**).

The reaction of [(C$_5$H$_{11}$)$_8$Pc]ReN (**10**) with PPh$_3$ at 250 °C for 30 minutes leads to the μ-oxo dimer [{(C$_5$H$_{11}$)$_8$Pc}Re(O)]$_2$O (**11**) as a product of hydrolysis (Scheme 2). Compound **11** is separated from its impurities by column chromatography on Al$_2$O$_3$. Unchanged **10** is first obtained with toluene and **11** is then eluted with dichloromethane in 18% yield. The shorter reaction time at lower temperature does not reduce the rhenium. The mechanism of the reaction is still unknown but a suggested mechanism can be seen in Scheme 2. The calculated and observed isotopic pattern of the molecular peak at *m/z* = 2568.2 in the FD-MS are in agreement.

In the IR spectrum **11** shows two new intense bands at $\tilde{\nu}$ = 685 and 658 cm^{-1}. The Re≡N vibration disappears with the formation of a new band at $\tilde{\nu}$ = 802 cm^{-1}. There are different possibilities of a $M_2O_3^{4+}$ unit, e.g. (TTP)Nb$_2$O$_3$ has three μ-oxo-bridges.[16] This is not the case for **11** because in (tBu$_4$Pc)Re(O)OEt the Re=O vibration is assigned to $\tilde{\nu}$ = 949 cm^{-1}.[15] The O=PcRe–O–PcRe=O units in phthalocyanines are in a linear arrangement due to steric reasons. In linear complexes the Re–O–Re vibration is located between 650–700 cm^{-1}. In [(OEP)ReO]$_2$O (OEP = octaethylporphyrinato) this vibration is observed at $\tilde{\nu}$ = 675 cm^{-1}.[17] Consequently the new band at 802 cm^{-1} is assigned to a ligand vibration. The Re=O vibration is not found in the expected region due to strong bands at $\tilde{\nu}$ = 685 and 658 cm^{-1}. Another possible explanation for the new bands is that in a linear arrangement of O=PcRe–O–PcRe=O, vibrational coupling of the $\nu_{Re=O}$ and ν_{Re-O} modes may occur shifting $\nu_{Re=O}$ to lower (802 cm^{-1}) and ν_{Re-O} to higher frequencies (685/658 cm^{-1}). Dimerization is again confirmed by the UV/Vis spectrum of **11** in chloroform (Figure 3c). A red shift in the Q-band to λ = 701.5 nm is seen and the forbidden Q$^-$-band is located at λ = 778.5 nm (Table 1). From these data the exciton interaction is estimated to be ΔE = 1410 cm^{-1}, in the solid state it is calculated to be ΔE = 1450 cm^{-1}. The appearance of the Q$^-$-band may be explained by a lowering of symmetry. These results indicate that the conformation of **11** has not changed. In the ^{1}H NMR and the ^{13}C-DEPT-135 NMR spectra all expected signals are observed. The 16 equivalent aromatic protons show a singlet at δ = 8.80. The signals of the different methylene groups appear separate and are easily assigned. The methyl group shows its resonance as a triplet at δ = 1.20. In the ^{13}C-DEPT-135 spectrum all CH-signals occur in the expected region.

Experimental Section

$W(NTos)_2Cl_2$,[12] $MoNCl_3$,[7] $WNCl_3$,[7] 4-*tert*-butylphthalonitrile,[18] 4,5-di-*n*-alkylphthalonitriles[19] (alkyl = propyl, butyl, pentyl), nitrido(tetra-*tert*-butyl-phthalocyaninato)rhenium[1,15] and nitrido[octa(*n*-pentyl)phthalocyaninato)rhenium[1] were prepared according to known procedures.

FT-IR: Bruker IFS 48. – UV/Vis: Shimadzu UV−365. – MS: Varian Mat 711 (EI, FD). – ^1H, ^{13}C, ^{11}B NMR: Bruker AC 250 (^1H: 250.133, ^{13}C: 62.902, ^{11}B: 80.251 MHz). – Elemental Analyses: Carlo Erba Elemental Analyser 1104, 1106. – EPR: Bruker ESP 300 (X-band).

Nitrido(phthalocyaninato)molybdenum (1): Phthalonitrile (393 mg, 3.08 mmol) was heated with $MoNCl_3$ (147.9 mg, 0.68 mmol) at 220 °C. The temperature was held constant for 20 minutes. After cooling the reaction to room temperature the solid was crushed in a mortar and Soxhlet extracted with acetone and toluene to remove impurities. Yield: PcMoN (**1**) (275 mg, 65%) as a dark green powder. – IR (KBr): $\tilde{\nu}$ = 1605 cm^{-1}, 1549, 1470, 1414, 1331, 1304, 1163, 1119, 1090, 1066, 953 (Mo≡N), 906, 895, 804, 781, 750, 729. – UV/Vis (1-chloronaphthalene): λ = 396.5 nm, 602.5, 639.5, 664.5, 703.5, 777.0. – UV/Vis (KBr): λ = 365.0 nm, 509.5, 609.5, 649.5, 732.0, 791.5. – MS (FAB): *m*/*z* = 623.1 (M^+), 514.7 (M^+ – MoN). – EPR (1-chloronaphthalene, room temp.): *g* = 1.97.

Nitrido[octa(*n*-alkyl)phthalocyaninato]molybdenum [alkyl = propyl (2), butyl (3), pentyl (4)]: The appropriate 4,5-di-*n*-alkylphthalonitrile (2.08 mmol) was melted with $MoNCl_3$ (100 mg, 0.46 mmol) at 220 °C for 15 minutes. Most of the impurities were removed by column chromatography in the dark on Al_2O_3 with toluene (two or three times). The solid was then washed several times with methanol. Yield: $[(C_3H_7)_8Pc]MoN$ (**2**) (58 mg, 11%), $[(C_4H_9)_8Pc]MoN$ (**3**) (33 mg, 8%) and $[(C_5H_{11})_8Pc]MoN$ (**4**) (48 mg, 10%) as green powders.

2: IR (KBr): $\tilde{\nu}$ = 2959 cm^{-1}, 2932, 1618, 1501, 1454, 1402, 1377, 1325, 1261, 1105, 1013, 974 (Mo≡N), 905, 802, 756, 702. – UV/Vis (toluene): λ = 348.5 nm, 647.5, 672.5, 709.0. – MS (FD) (toluene): *m*/*z* = 959.8 (M^+). – EPR (toluene, room temp.): *g* = 1.97.

3: IR (KBr): $\tilde{\nu}$ = 3423 cm^{-1}, 3290, 3036, 2957, 2870, 1715, 1643, 1620, 1460, 1377, 1337, 1321, 1211, 1173, 1103, 1013, 962 (Mo≡N), 901, 754, 704. – UV/Vis (toluene): λ = 351.5 nm, 614.5, 647.5, 673.0, 711.5. – MS (FD) (toluene): *m*/*z* = 1072.3 (M^+), 962.4 (M^+ – MoN). – EPR (toluene, room temp.): *g* = 1.97.

4: IR (KBr): $\tilde{\nu}$ = 2957 cm^{-1}, 2928, 1684, 1645, 1618, 1566, 1520, 1456, 1377, 1330, 1261, 1103, 1015, 974 (Mo≡N), 899, 802, 754, 733. – UV/Vis (toluene): λ = 353.5 nm, 649.5, 679.0, 716.0. – MS (FD) (toluene): *m*/*z* = 1184.8 (M^+). – EPR (toluene, room temp.): *g* = 1.97.

Nitrido(phthalocyaninato)tungsten (5): Phthalonitrile (260 mg, 2.04 mmol) was mixed with $WNCl_3$ (138 mg, 0.45 mmol) and melted at 220 °C for 20 minutes. The crude product was then extracted with EtOH, acetone and toluene. Yield: PcWN (**5**) (230 mg, 72%) as a dark green solid. – IR (KBr): $\tilde{\nu}$ = 1604 cm^{-1}, 1470, 1445, 1331, 1308, 1159, 1119, 1064, 953 (W≡N), 895, 812, 783, 750, 729. – UV/Vis (1-chloronaphthalene): λ = 359.5 nm, 673.5, 699.5, 751.0. – UV/Vis (KBr): λ = 355.0 nm, 622.5, 674.5, 704.0, 753.0. – MS (FAB): *m*/*z* = 709.9 (M^+). – EPR (solid state, 77 K): *g* = 1.88.

Nitrido[tetra(*tert*-butyl)phthalocyaninato]tungsten (6): A mixture of 4-*tert*-butylphthalonitrile (700 mg, 3.8 mmol) and $WNCl_3$ (255 mg, 0.84 mmol) was heated to 220 °C for 15 minutes. The solid was crushed in a mortar and Soxhlet extracted with hexane to remove the unreacted phthalonitrile. Further impurities were precipitated with CH_2Cl_2/hexane. The solvent was then removed to give (tBu$_4$Pc)WN (**6**) (110 mg, 14%) as a green solid. – IR (KBr): $\tilde{\nu}$ = 3443 cm^{-1}, 3069, 2963, 2905, 1612, 1516, 1483, 1394, 1366, 1323, 1258, 1200, 1150, 1072, 959 (W≡N), 930, 833, 762, 748. – UV/Vis (toluene): λ = 365.0 nm, 677.0, 745.0. – MS (IS) (MeOH): *m*/*z* = 934.5 (M^+). – MS (FAB): *m*/*z* = 934.3 (M^+). – EPR (toluene, room temp.): *g* = 1.89.

Nitrido[octa(*n*-pentyl)phthalocyaninato]tungsten (7). Method a): 4,5-Di-*n*-pentylphthalonitrile (500 mg, 1.87 mmol) was melted with $WNCl_3$ (114 mg, 0.37 mmol) at 220 °C for 15 minutes. After extraction of the excess of phthalonitrile with hexane, further impurities were precipitated three times with CH_2Cl_2/hexane. Removal of the solvent under vacuum gave $[(C_5H_{11})_8Pc]WN$ (**7**) (43 mg, 9%) as a green solid. **Method b):** 4,5-Di-*n*-pentylphthalonitrile (800 mg, 3.0 mmol) was reacted with $W(NTos)_2Cl_2$ (413 mg, 0.66 mmol) at 220 °C for 10 min. The crude product was first washed with three times methanol and further impurities were then precipitated from CH_2Cl_2/hexane (5×). The solution was separated from solid impurities and the solvent was removed yielding **7** (107 mg, 13%). – IR (KBr): $\tilde{\nu}$ = 3437 cm^{-1}, 3024, 2957, 2928, 2870, 1614, 1483, 1454, 1396, 1325, 1157, 1076, 1011, 957 (W≡N), 893, 814, 746, 733, 685. – UV/Vis (toluene): λ = 376.0 nm, 695.5, 770.5. – MS (FD) (toluene): *m*/*z* = 1270.7 (M^+). – EPR (toluene, room temp.): *g* = 1.89.

Oxo[tetra(*tert*-butyl)phthalocyaninato]tungsten (8): (tBu$_4$Pc)WN (31 mg, 0.033 mmol) (**6**) was slowly heated with PPh_3 (31 mg, 0.33 mmol) to 250 °C. The temperature was held for 1 h. After cooling to room temperature the solid was chromatographed on Al_2O_3 (10% H_2O) with chloroform as the eluent. The product was then eluted with THF. Finally, further impurities were extracted with hexane to give 15 mg (49%) (tBu$_4$Pc)WO (**8**). – IR (KBr): $\tilde{\nu}$ = 3165 cm^{-1}, 3076, 2963, 2907, 1734, 1722, 1614, 1483, 1464, 1394, 1366, 1327, 1281, 1255, 1200, 1146, 1080, 928, 893, 831, 748, 685, 665. – UV/Vis (toluene): λ = 356.5 nm, 611.0, 674.5, 725.0. – MS (FD) (CH_2Cl_2): *m*/*z* = 936.5 (M^+). – ^1H NMR ($CDCl_3$): δ = 1.60–2.26 (36 H, *t*Bu). – ^{13}C NMR ($CDCl_3$): δ = 31.0 (CCH_3), 32.1 (CCH_3).

μ-Oxo[oxo{octa(*n*-pentyl)}phthalocyaninato]rhenium (11): (tBu$_4$Pc)-ReN (22.0 mg, 0.0235 mmol) was slowly heated with PPh_3 (61.7 mg, 0.235 mmol) to 220 °C at 6 × 10^{-2} mbar. The temperature was held for 30 minutes. The crude product was then chromatographed on Al_2O_3 with toluene to remove the impurities. Compound **11** was eluted with CH_2Cl_2. Yield: $[\{(C_5H_{11})_8Pc\}Re(O)]_2O$ (**11**) (11 mg, 18%). – IR (KBr): $\tilde{\nu}$ = 2957 cm^{-1}, 2928, 1620, 1485, 1456, 1398, 1377, 1340, 1261, 1138, 1116, 1032, 891, 802, 723, 685, 658. – UV/Vis ($CHCl_3$): λ = 363.5 nm, 380.5, 637.0, 701.5, 778.5. – UV/Vis (KBr): λ = 383.0 nm, 691.0, 768.0, 818.5. – MS (FD) (toluene): *m*/*z* = 2568.2 (M^+). – ^1H NMR ($CDCl_3$): δ = 1.17–1.23 (t, 24 H, CH_3), 1.72–1.80 (m, 16 H, CH_3CH_2), 1.91–1.99 (m, 16 H, $CH_3CH_2CH_2$), 2.24–2.30 (m, 16 H, $ArCH_2CH_2$), 3.41–3.48 (m, 16 H, $ArCH_2$), 8.80 (8 H, H-b). – ^{13}C NMR ($CDCl_3$): δ = 14.5 (CH_3), 23.1 (CH_3CH_2), 32.4 ($CH_3CH_2CH_2$), 32.7 ($ArCH_2CH_2$), 34.8 ($ArCH_2$), 123.9 (C-b), 135.8 (C-c), 143.4 (C-a), 145.4 (C-d). – ^{13}C NMR (DEPT 135, $CDCl_3$): δ = 14.5 (CH_3), 23.1 (CH_3CH_2), 32.4 ($CH_3CH_2CH_2$), 32.7 ($ArCH_2CH_2$), 34.8 ($ArCH_2$), 123.9 (C-b). – $C_{144}H_{192}N_{16}O_3Re$ (2567.6): calcd. Structure and Dynamic Behavior of (η^3-Allyl)bromodicarbonylmolybdenum(II) Complexes Containing Polydentate 2-Pyridylphosphanes or Their Oxides as Chelating Ligands: Occurrence of Three Fluxional Processes

Pablo Espinet,*[a] Rosa Hernando,[a] Gonzalo Iturbe,[a] Fernando Villafañe,[a] A. Guy Orpen,[b] and Isabel Pascual[b]

Keywords: Molybdenum / Fluxionality / Pyridylphosphanes / Phosphane oxides / Polydentate ligands

The pseudo-octahedral complexes [Mo(η^3-allyl)Br(CO)$_2$(P-Py$_n$Ph$_{3-n}$-*P,N*)] (Py = 2-pyridyl; n = 2, 3) and [Mo(η^3-allyl)Br(CO)$_2$(OPPy$_m$Ph$_{3-m}$-*O,N*)] (m = 1, 2, 3) undergo three different dynamic processes in solution, depending on the chelating ligand. The complexes containing PPhPy$_2$ and PPy$_3$ as chelating *P,N*-donors undergo a novel "pivoted double switch" mechanism which scrambles two *equatorial* coordination sites with racemization, while maintaining the identity of the phosphorus atom *trans* to the allyl ligand. The complexes containing 2-pyridylphosphane oxides as chelating *O,N*-donors undergo a nondissociative intramolecular trigonal-twist (or turnstile) rearrangement which maintains the identity of the phosphane oxide oxygen atom coordinated in an *equatorial* position. All the complexes containing uncoordinated pyridyls undergo a slow dissociative exchange of pyridyls without coordination site scrambling. The structure of the complex [Mo(η^3-allyl)Br(CO)$_2$(OPPy$_3$-*O,N*)] has been determined by X-ray diffraction.

Introduction

The coordination of 2-pyridylphosphanes or their P-substituted derivatives has allowed the elucidation of many dynamic processes in solution. Our group is currently carrying out a study of their behavior with different metals, such as palladium, platinum[1] and molybdenum.[2] In the course of these studies, we decided to explore the behavior of 2-pyridylphosphanes[3] or their oxides towards (η^3-allyl)bromodicarbonylmolybdenum(II), with the aim of understanding how the ligands coordinate to this metal moiety (there are very few reports on hybrid chelating or tripodal ligands coordinated to this system), and examine possible dynamic processes in solution.

The complexes [Mo(η^3-allyl)X(CO)$_2$(L^1)(L^2)] (X = anionic ligand; L^1, L^2 = two monodentate neutral ligands, or one bidentate neutral ligand), show two possible solid state structures, as depicted in Figure 1 (**A** and **B**). Both are pseudo-octahedral complexes if the η^3-allyl ligand is considered as occupying one coordination site with its terminal atoms oriented over the carbonyl groups, which has been demonstrated to be the most energetically favorable arrangement.[4] In structure **A** the anionic ligand occupies the *axial* position, *trans* to the allyl group, giving rise to C_s symmetry with a σ plane which bisects the allyl group and contains the metal atom, whereas in structure **B** the anionic ligand X occupies one of the *equatorial* positions leading to a C_1 geometry. The adoption of one of these two possible arrangements in the solid state does not seem to follow clear rules. Structure A is usually observed when X is a halogen or a pseudohalogen and L–L is a bidentate nitrogen donor ligand, such as bipy.[5] However, structure B has been found for trifluoroacetate as the anionic ligand and 1,10-phenanthroline as the chelate,[6] or when the neutral ligands are two pyrazols and bromide is the anionic ligand.[7]

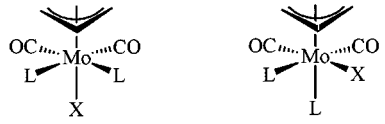

Figure 1. Two possible structures, **A** and **B**, for [Mo(η^3-allyl)X(CO)$_2$(L^1)(L^2)]

Several solution dynamic processes have been detected for this type of complex: the nondissociative trigonal-twist rearrangement[8] or turnstile mechanism,[1c,9] in which there is an intramolecular rotation of the "XL$_2$" face, was first established for L$_2$ = diphosphane and X = halogen. This process has since then been observed for a variety of "XL$_2$" systems, including cationic complexes with XL$_2$ = neutral tridentate nitrogen donor ligand.[10] Other solution processes detected for these complexes are the substitution of the neutral ligands (usually nitrogen donors) by solvents such as MeCN or water,[10b,11] and the η^3–η^1–η^3 rearrangement of the allyl ligand, which has been proposed for tridentate nitrogen donor ligands such as trispyrazolylborate or bispyrazolylaminomethane.[12]

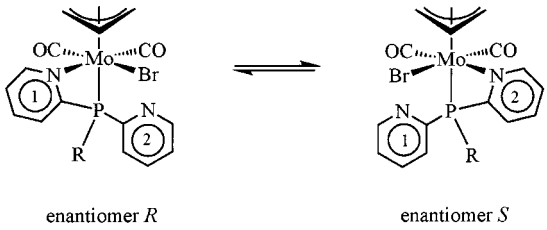
Results and Discussion

[Mo(η³-allyl)Br(CO)$_2$(PPy$_n$Ph$_{3-n}$-*P,N*)] (*n* = 2, 3)

The complexes [Mo(η³-allyl)Br(CO)$_2$(PPy$_n$Ph$_{3-n}$-*P,N*)] [*n* = 2 (**1**), 3 (**2**)] were obtained by displacement of the nitrile ligands in [Mo(η³-allyl)Br(CO)$_2$(MeCN)$_2$] with PPy$_2$Ph or PPy$_3$.[13] All attempts to obtain a similar complex with PPyPh$_2$ were unsuccessful. This may be due to electronic factors since PPyPh$_2$ is a weaker donor than the other pyridylphosphanes.[14] The IR spectra of **1** and **2** in the C–O stretching region show two bands, as expected for *cis* dicarbonyl complexes. Their low electrical conductivity in solution indicates that the complexes are neutral, supporting coordination of the bromo ligand to the molybdenum atom.



Characterization of [Mo(η³-allyl)Br(CO)$_2$(PPy$_2$Ph-*P,N*)] (1)

The low temperature ^{1}H NMR spectrum (–60 °C) corresponds to an asymmetric complex, the signals of the allyl group displaying the expected ABCDX pattern. Two doublets are observed for the H^6 protons of the pyridyls: one at very low field (9.60 ppm) typical of a pyridyl ligand coordinated *cis* to a halogen ligand, as has been clearly established for square planar geometries;[15] and the second (9.12 ppm) in the typical range of H^6 for uncoordinated pyridyls. Thus, for complex **1** at low temperature, these data support the *P,N*-coordination of the PPy$_2$Ph ligand.

However, a symmetrically averaged spectrum (revealing a racemization process) is observed at high temperature (+55 °C): the allyl group displays an A$_2$M$_2$X pattern where both H^{anti} are equivalent, as well as both H^{syn}, and only one doublet (9.46 ppm) is detected for both pyridyl H^6 atoms. Therefore, the dynamic process detected results in simultaneous equivalence of the two pyridyl groups and both ends of the allyl group. The phosphorus atom of PPy$_2$Ph is not directly involved in the dynamic process, and its chemical shift remains practically unchanged from –60 °C to +55 °C (–8.7 ppm in the ^{31}P{^{1}H} NMR spectra). This implies it coordinates in the *axial* position *trans* to the allyl group in a structure of type B (Figure 1).

The only process consistent with this NMR behavior is the racemization shown in Scheme 1 (R = Ph for **1**). In this exchange process, the pyridyl groups always occupy the same position when coordinated, and the Br ligand switches between two *equatorial* positions. We will refer to this process as a "pivoted double switch" mechanism.

Both the geometry of the molecule and the dynamic process in complex **1** were confirmed by a phase sensitive 2-D ^{1}H NOESY spectrum recorded at –50 °C, shown in Figure 2. At this temperature, the significant signals have split and the interchange process is slow. In Figure 2 a (positive peaks), cross-peaks due to chemical exchange of magnetization are detected between both H^{syn}, and also between both H^{anti} of the allyl group (the latter are difficult to observe because their signals almost overlap); whereas for the aromatic protons, cross-peaks relate the H^6 protons of the coordinated and uncoordinated pyridyls at this temperature. Figure 2b shows negative cross peaks due to NOEs between both H^6–H^{central}, H^{syn}–H^{anti}, and H^6–other aromatic protons. The latter two are expected NOEs, and do not provide structural information, but the first correlation indicates a close spatial proximity of the H^{central} of the allyl ligand and both H^6 atoms. A similar NOE has been reported for a complex containing a phenanthroline coordinated in the

Scheme 1. "Pivoted double switch" mechanism in complexes **1** (R = Ph) and **2** (R = Py)

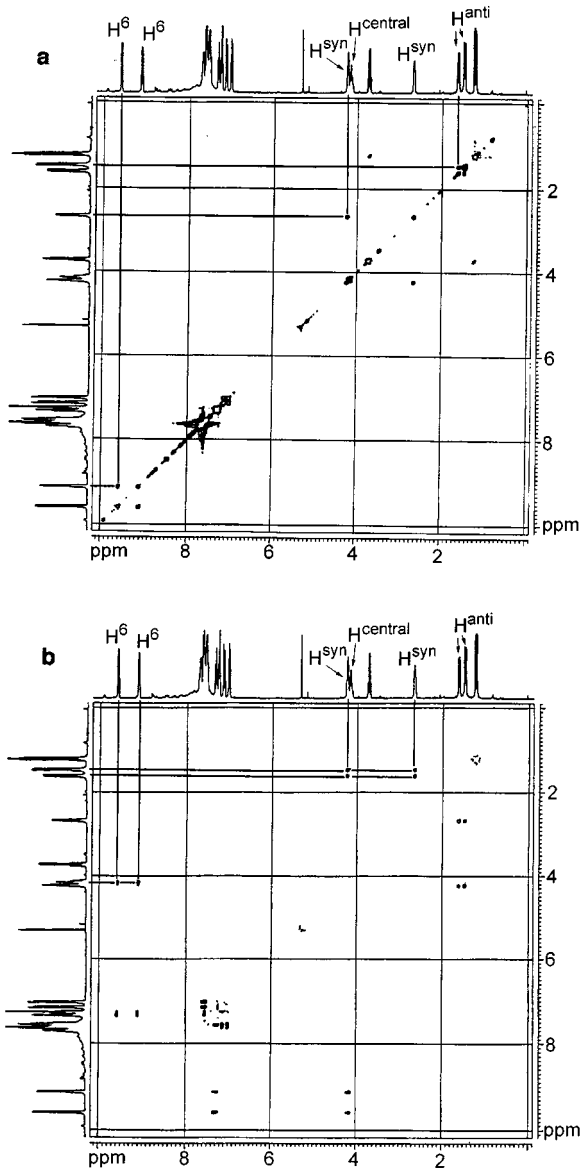


Figure 2. Phase sensitive 2-D NOESY experiment carried out for **1** at –50 °C. (a) Positive peaks due to chemical exchange of magnetization. (b) Negative peaks due to NOEs

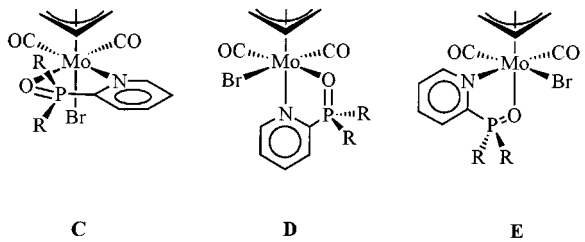
same position as the pyridyl in our system.[6] The observation of two intense cross-peaks between $H^{central}$ and the two H^6 at lower field in complex **1** must presumably be related to the dynamic process shown in Scheme 1.

Characterization of [Mo(η^3-allyl)Br(CO)$_2$(PPy$_3$-*P,N*)] (2)

All the main features observed for **1** are also detected for **2**. The $^{31}P\{^1H\}$ NMR spectra at different temperatures (from +55 °C to –60 °C) show only one invariant singlet at –10.0 ppm. The ^1H NMR spectrum at –60 °C supports the existence of only one asymmetric complex in solution (which is a racemic mixture, as before), where three doublets are observed for the H^6 protons of the three pyridyls present: one at very low field (9.56 ppm) for the pyridyl coordinated *cis* to the bromo ligand,[15] and two more for the H^6 of the uncoordinated pyridyls (9.11 and 8.98 ppm). The ^1H NMR spectra at room temperature and above correspond to a symmetric averaged species where the allyl group displays the expected A_2M_2X pattern, and the signals of two H^6 (one coordinated and one uncoordinated) have coalesced to one broad signal, whereas the H^6 of the third pyridyl (that at higher field) remains nonequivalent. This indicates that the exchange process depicted in Scheme 1 (with R = Py in **2**) affects only one of the two uncoordinated pyridyls, the one which is able to coordinate by virtue of its geometry.

The ^1H NMR spectrum at 55 °C shows a slight broadening of all the signals, which is not observed in the spectrum of **1** at this temperature, suggesting that the third pyridyl begins to become involved in a second, and slower, exchange process. This second process interchanging the third pyridyl with the other two is too slow to be detected by variable temperature NMR (decomposition of the sample is observed upon further heating), but could be confirmed by a phase sensitive 2-D ^1H NOESY experiment. Chemical exchange is detected between both H^{syn}, between both H^{anti}, and between two H^6 (as for **1**), but in addition less intense cross peaks relating these two H^6 with the third H^6 (8.98 ppm) are also observed, supporting the involvement of the third pyridyl (R in Scheme 1) in a slower exchange equilibrium.

Discussion of the Dynamic Process of Complexes 1 and 2



The dynamic process shown in Scheme 1 for complexes **1** and **2** seems not to have precedent in the literature for the (η^3-allyl)bromodicarbonylmolybdenum(II) system, so the mechanism of interconversion deserves further discussion. All dissociative mechanisms can be discarded. An η^3–η^1–η^3 rearrangement of the allyl ligand would render H^{anti} and H^{syn} equivalent giving an A_4X pattern for the allyl group in the ^1H NMR spectra, which is not observed. A mechanism involving dissociation of the coordinated pyridyl ligand with concomitant rotation about the Mo–P may also be discounted, as the second slow process detected for **2**, which exchanges the three pyridyls, in fact requires decoordination of the pyridyl to allow for rotation around the Mo–P bond and hence coordination of the third pyridyl (Scheme 1). Hence, if decoordination of the coordinated pyridyl was occurring for the process in Scheme 1, the exchange of the third pyridyl should take place at the same rate (assuming rotation about the Mo–P bond is rapid), which is not observed. Dissociation of the bromo ligand may also be discounted since addition of excess bromide [5:1 as NBu_4Br in $(CD_3)_2CO$ solution of **2**][16] did not reduce the exchange rate.

To ascertain whether the dynamic process was associative, $\Delta S^{\ddagger}$ was determined by line shape analysis using the DNMR6 program for complex **2** (data taken from –40 to +40 °C). The value obtained, -2 ± 4 J mol^{-1} K^{-1}, is too low to unequivocally support an associative mechanism for this process, although values close to zero have been found for processes which have been finally identified as associative.[1b] Therefore, either an associative or a concerted mechanism may be proposed for this dynamic process, as the dissociative path can be definitely discarded.

[Mo(η^3-allyl)Br(CO)$_2$(OPPy$_n$Ph$_{3-n}$-*O,N*)] (*n* = 1, 2, 3)

The complexes [Mo(η^3-allyl)Br(CO)$_2$(OPPy$_n$Ph$_{3-n}$-*O,N*)] [*n* = 1 (**3**), 2 (**4**), 3 (**5**)] were obtained by displacement of the nitrile ligands in [Mo(η^3-allyl)Br(CO)$_2$(MeCN)$_2$] with the ligands $OPPyPh_2$, $OPPy_2Ph$, and $OPPy_3$ to obtain **3**, **4**, and **5**, respectively. Complex **4** could also be obtained by oxidative addition of allyl bromide to [Mo(CO)$_3$(OPPy$_2$Ph-*O,N*$_2$)].

The three complexes show two C–O stretching bands in the solid state, as expected for *cis* dicarbonyl complexes. Complexes **3** and **5** also display two C–O stretching bands in solution, whereas **4** shows four. According to the isomer equilibria discussed below, four bands should be expected (at least when all the isomers are noticeably abundant). However, the bands for each pair of isomers **C** and **D** are almost coincident (Figure 3). In fact careful examination of the IR C–O bands reveals that they are asymmetric and show shoulders, but the presence of **C** and **D** isomers only becomes clear in the NMR spectra. The IR spectra of the solid complexes **3–5** do not show bands in the 1300–1200 cm^{-1} region, where the P–O stretching absorptions of the free ligands are found. This implies coordination of the ligands as oxygen donors, although the assignment of the band due to P–O stretching is very difficult, due to the pres-

C(1)–C(2)–C(3)	115.1(6)		

The low electrical conductivities in solution indicate that the complexes **3–5** are neutral, with the bromo ligand coordinated to the molybdenum atom. Only the three isomers **C**, **D**, and **E**, shown in Figure 3, can be proposed in accordance with the IR and conductivity data. The molecules are chiral, and Figure 3 shows the *R* enantiomers only.

The $^{31}P\{^{1}H\}$ NMR spectra of complexes **3** and **5** show two singlets of different intensity at low temperature, which coalesce on heating. This implies that a dynamic process interchanging two of the three possible isomers in Figure 3 is occurring. Twice as many signals are observed in the $^{31}P\{^{1}H\}$ NMR spectra of **4**, that is, four singlets at –60 °C which coalesce to two singlets of different intensity at 50 °C. In this complex the R groups are different (Ph and Py), thus the isomers, which are enantiomers in **3** and **5** (and which therefore have indistinguishable NMR spectra) become diastereoisomers for **4**, doubling the number of signals; but again only two of the three structures **C**, **D**, or **E** are involved. The exchange process observed corresponds exactly to the trigonal-twist mechanism described in the literature for the complex [Mo(η³-allyl)I(CO)$_2$(arphos)],[8] and needs no further discussion except for identification of the two isomers involved. This was achieved as described below.

Scheme 2. Dynamic processes in complexes **3**, **4**, and **5**: fast nondissociative intramolecular trigonal-twist (or turnstile) rearrangement in complexes **3**, **4**, and **5** and slow pyridyl-exchange equilibria in complexes **4** and **5**

Structure of [Mo(η³-allyl)Br(CO)$_2$(OPPy$_3$-*O,N*)] (5)

An X-ray structural determination was carried out for [Mo(η³-allyl)Br(CO)$_2$(OPPy$_3$-*O,N*)] (**5**). The structure is shown in Figure 4, and Table 1 lists relevant distances and angles. The molybdenum atom is *pseudo*-octahedrally coordinated, assuming that the allyl group occupies one site. The two carbonyls and the allyl are mutually *cis*, with the terminal carbon atoms of the allyl moiety oriented over the carbonyls, as usually found for this class of complex.[4] The observed structure is of the form labeled **C** in Figure 3. The P–O distance is slightly elongated compared to those found in palladium(II) complexes containing the OPPy$_2$Ph ligand, where the oxygen atom is not coordinated to the metal: P–O = 1.480(2) and 1.482(2) Å in [Pd(C$_6$F$_5$)X(OPPy$_2$Ph-*N$_2$*)] (X = Br and C$_6$F$_5$, respectively)[1b] *cf.* 1.501(4) Å in **5**. The donor atoms of the OPPy$_3$ ligand coordinated in the *equatorial* positions have different donor properties, but this seems to induce very little asymmetry in the *trans* carbonyl groups: the Mo–C distances are equal [1.934(7) and 1.934(8) Å] and the C–O distances show insignificant differences [1.149(8) and 1.130(8) Å]. The allyl group is also essentially symmetrical [C–C = 1.380(9) and 1.415(9) Å; Mo–C^{terminal} = 2.314(6) and 2.301(7) Å]. This indicates that the different donor properties of the atoms in the *equatorial* sites do not induce observable asymmetry in the allyl ligand, as has been previously reported.[10a] The distances

and angles of the allyl group found in **5** are very similar to those reported for [Mo(η^3-allyl)(acac)(CO)$_2$(py)],[18] which also contains an oxygen donor ligand and a nitrogen donor ligand in the *equatorial* positions.

Discussion of the Dynamic Process of Complexes 3–5

When an NMR sample of **5** in $CDCl_3$ was prepared in a liquid nitrogen bath, and then allowed to melt and simultaneously dissolve at –60 °C in the NMR probe, only one isomer was found, which is logically assigned to structure **C**. The solution was then warmed to room temperature to establish the equilibrium between the isomers, and a phase sensitive 2-D ^{1}H NOESY spectrum was recorded at –50 °C. Negative peaks associated to NOE are not observed, which disfavors structure **E** for which an NOE between the coordinated pyridyl and some of the allyl protons would be expected (H^6–$H^{central}$ correlations were observed for **1** and **2**). Consequently, we assign structure **D** to the second isomer. Positive peaks were observed between $H^{central}$, and each H^{syn} and H^{anti} of the two isomers **C** and **D**, but not between the two H^{syn} or between the two H^{anti} atoms of each isomer. In other words, there was no racemization of the molecule and the two halves of the allyl group remained inequivalent during the fluxional processes. Finally, there were also weak cross peaks showing exchange of the coordinated and the free pyridyl groups.

Thus two types of exchange are operative in these systems, which are depicted in the general Scheme 2. The faster movement is a nondissociative intramolecular trigonal-twist (or turnstile) rearrangement, converting diastereoisomers **C** and **D**. This is the only mechanism operating for $R^1 = R^2 =$ Ph (in **3**). The second and slower movement (it is barely observed in the one dimensional spectrum of **5** at 55 °C as a broadening of the signals) is an exchange of pyridyls without racemization. In this respect, it is very different from the "pivoted double switch" as seen in **1** and **2**. The conservation of the asymmetry allows decoordination of the oxygen to give a *N,N*-bonded intermediate to be discounted, as this would create a symmetry plane. In fact, in conjunction with the observation of pyridyl exchange of **1** and **2**, a dissociative mechanism is more plausible, with the incoming pyridyl group taking the site left vacant by dissociation. This, as shown in Scheme 2, converts $\mathbf{C_1}$ to $\mathbf{C_2}$, these being identical for **5**, but diastereoisomers for **4**. The slowness of this mechanism is also consistent with a dissociative process.

Conclusion

The systems studied here reveal the existence of three mechanisms, depending on the chelating ligand. The slowest mechanism is common to both ligands that have uncoordinated pyridyls, which is a dissociative exchange of pyridyls without scrambling of coordination sites. The second, shown by the pyridylphosphane oxides, is the well-known nondissociative intramolecular trigonal-twist (or turnstile) mechanism, which produces scrambling of the coordination sites but retaining the elements of chirality (i.e. without racemization). Finally, for bis- or trispyridylphosphane, the pendant pyridyl triggers a novel "pivoted double switch" mechanism scrambling two coordination sites with racemization. A different but somewhat related case has been discussed in detail elsewhere.[19]

Experimental Section

General Remarks: All reactions were carried out under an atmosphere of pre-purified dinitrogen. Solvents were purified according to standard procedures.[20] [Mo(η^3-allyl)Br(CO)$_2$(MeCN)$_2$],[21] [Mo(CO)$_3$(OPPy$_2$Ph-*O,N*$_2$)],[2b] and 2-pyridylphosphanes were prepared as previously described,[22] and their oxides were synthesized by standard methods.[23] The synthesis of [Mo(η^3-allyl)Br(CO)$_2$(PPy$_2$Ph-*P,N*)] has been previously reported.[2a]

The progress of the reactions involving carbonyl complexes was monitored by solution IR spectra in the 2100–1700 cm^{-1} region. Filtrations were carried out on dry Celite without exclusion of air. The products are air-stable solids which were recrystallized at –20 °C.

Infrared spectra were recorded on Perkin–Elmer 883 or 1720X apparatus in NaCl cells for solutions, and as Nujol mulls or KBr pellets for solids. NMR spectra were recorded on Bruker AC-300 or ARX-300 instruments in $CDCl_3$. NMR spectra were referred to TMS or 85% aqueous H_3PO_4. Elemental analyses were performed on a Perkin–Elmer 2400B microanalyzer. The electrical conductivity measurements were carried out at room temperature with a Crison 522 conductivity meter using $5\cdot10^{-4}$ M solutions; the range of molar conductivity for 1:1 electrolytes is 75–95 S·cm^2·mol^{-1} in nitromethane solutions.[24]

General Method for the Preparation of the Complexes: A 100 mL Schlenk flask was successively charged with equimolar amounts (0.2–0.5 mmol) of [Mo(η^3-allyl)Br(CO)$_2$(MeCN)$_2$], the respective ligand, and CH_2Cl_2 (10–25 mL). The solution was stirred at room temperature for 15 min., and then EtOH or hexane was added (5–15 mL). Concentration of the solution in vacuo and cooling to –20 °C gave microcrystalline solids, which were filtered, washed with Et_2O (3 × 3 mL approximately), and dried in vacuo. The yields, color, and spectroscopic data of the products obtained are given below.

X-ray Crystallographic Analysis of 5: Crystal data and other details of the structure analysis are presented in Table 2. Red crystals of **5** were recrystallized from dichloromethane/diethyl ether and showed a block-like habit. One of these crystals was mounted on a glass fiber with epoxy resin. All diffraction measurements were made at room temperature with a Siemens SMART[25] diffractometer using graphite monochromated Mo-K_α radiation. A full hemisphere of reciprocal space was scanned by 0.3° ω steps with the area detector center held at 2θ = –27°. A total of 1321 data frames were collected for 10 seconds exposure per frame. The reflections were integrated using the SAINT program.[26] No crystal decay over the period of data collection was observed. A total of 10001 diffracted intensities were measured, 3685 unique observations remained after averaging of duplicate and equivalent measurements (R_{int} = 0.0579) and deletion of the systematic absences. Of these 2587 had $I > 2\sigma(I)$. An empirical absorption and detector correction was applied, effective transmission coefficients were in the range 0.878 to 0.634. Lorentz and polarization corrections were applied. The structure was solved by direct and Fourier methods, and refined using full-matrix least-squares refinement on F^2.[27] All non-hydrogen atoms were assigned anisotropic displacement parameters and refined without positional constraints. All hydrogen atoms were constrained to idealized geometries and assigned isotropic displacement parameters 1.2 times the U_{iso} value of their attached carbon for aromatic hydrogens. Final residuals and other details are given in Table 1.[28] Weights, w, were set to minimize the variation in S as a function of $|F_o|$. Final difference electron density maps showed no significant features. Complex neutral-atom scattering factors were taken from ref.[29].

Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-134122. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

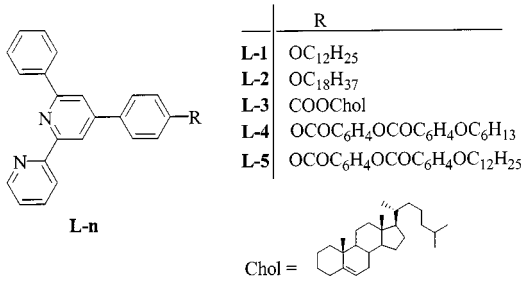
Metal-Containing Amphiphiles: Orthometallated Iridium(III) Complexes with Substituted 6′-Phenyl-2,2′-bipyridines

Francesco Neve*[a] and Alessandra Crispini[a]



Keywords: Iridium / Amphiphiles / N ligands / Structure elucidation

The reaction of 4′-functionalized 6′-phenyl-2,2′-bipyridine ligands (**L-*n***) with the dimer $[(ppy)_2IrCl]_2$ (ppy = 2-phenylpyridine anion) and subsequent counterion exchange affords a new series of cationic orthometallated iridium(III) complexes, $[(ppy)_2Ir(L\text{-}n)][PF_6]$ (**1**–**5**), which have been characterized by spectroscopic methods. These complexes have a large shape anisotropy and significant amphiphilic character. The crystal structure of **4** has been determined by X-ray diffraction.

Introduction

The coexistence of distinct hydrophobic and hydrophilic moieties in the same structure is the key factor inducing segregation of dissimilar parts thus generating supramolecular anisotropic assemblies. In this light amphiphilic molecules, either neutral or ionic, are known to self-organise into a great variety of supramolecular structures both in solution and in the solid state.[1,2] On the other hand, since the incorporation of a transition metal ion into the polar part may impart additional features to the resulting amphiphile, metal coordination has been considered a simple way of preparing novel classes of amphiphiles. Recently, redox-active,[3,4] photo-active[3] or simply surface-active[5] amphiphilic complexes have been prepared. In addition, liquid-crystal behaviour has also been described for both thermotropic (temperature-active)[6,7] and lyotropic (concentration-active)[8] metal-containing amphiphiles.

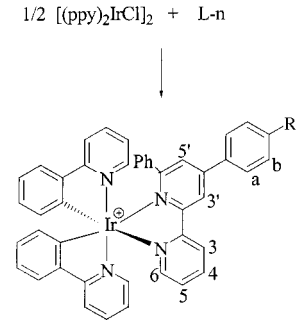
We recently reported the synthesis of new 6′-phenyl-2,2′-bipyridines bearing promesogenic substituents in the 4′-position.[9] Our investigation showed that strongly anisometric, photoactive complexes with square-planar geometry could be obtained with these ligands,[9,10] which eventually exhibited liquid-crystalline properties.[11] In order to prepare new amphiphilic complexes, we have focused our attention on 6′-phenyl-2,2′-bipyridine ligands that bear highly hydrophobic substituents (**L-*n*** in Scheme 1) and which, at the same time, may afford species with a high aspect ratio (i.e. width-to-length ratio). Here we report on the synthesis and structural characterization of the series of Ir^{III} cationic complexes $[(ppy)_2Ir(\mathbf{L}\text{-}n)][PF_6]$ (**1**–**5**) which are based on the ligands **L-*n*** (n = 1–5) and which also contain the orthometallated $\{(ppy)_2Ir\}$ fragment (ppy = orthometallated 2-phenylpyridine). The synthesis of ligands **L-2** and **L-3** is also reported here for the first time.

Scheme 1

Anisometric Ligands

The functionalized **L-*n*** ligands present either alkoxy (–OR) or ester (–COOR or –OCOR) functions in the periphery of the *N*,*N*-chelating site (Scheme 1). Such an arrangement leads to the formation of ligands with a large anisometry (i.e. shape anisotropy) provided a terminal group ensures the right content of aliphatic carbon atoms.

Derivatization of the 6′-phenyl-2,2′-bipyridine moiety can be accomplished following two different synthetic strategies. The build-up of the 2,2′-bipyridine skeleton through a Kröhnke-type[12] synthesis may follow (see the preparation of **L-2**) or precede the introduction of the peripheral substituent usually through condensation reactions (as for **L-3**). The latter strategy seems to be more valuable since it potentially allows a wide variety of derivatives to be prepared.[11]



Orthometallated Iridium(III) Complexes

Bridge-splitting reactions of $[(ppy)_2IrCl]_2$ with *N*,*N*-chelating ligands are commonplace when the incorporation of the orthometallated $\{(ppy)_2Ir\}$ fragment into a mononuclear[13] or multinuclear[14] species is desired. Likewise, the cationic complexes **1**–**5** were obtained in good yield upon reaction of the dimer $[(ppy)_2IrCl]_2$ with the **L-*n*** ligands under reflux conditions in a dichloromethane/methanol mixture (Scheme 2). Metathesis of the chloride counterion with excess NH_4PF_6 gave the final products $[(ppy)_2Ir(L\text{-}n)][PF_6]$.

The ^1H NMR spectroscopic characterization of **1**–**5** showed that only a single isomer resulted from the reaction. From the NMR evidence it follows that both the pyridine

rings of **L** are involved in the coordination and no metallation has occurred. Although no attempt was made to assign all the resonances of the spectra (e.g. the proton spectrum of **3** shows some 19 distinct signals or groups of signals in the aromatic region), it is apparent that all the complexes belong to an isostructural series, where the two metallated ppy ligands for each complex experience through-space shielding effects different from each other.

Complexes **1**–**5** are insoluble in water, but reasonably soluble in dichloromethane or chloroform (with **1** and **2** showing the best solubility) affording air-stable solutions. All complexes are also very soluble in acetonitrile and solutions of **1**–**5** in this solvent were used to measure the electronic absorption spectra. The absorption spectra of all the complexes are dominated by a broad band peaking in the UV region and extending to the visible. The maximum of this band is around 270 nm, and receives its main contribution from ligand-centred LC transitions involving the metallated phenylpyridine ligands.[15] The absorptions which appear as shoulders of the main band probably arise from spin-allowed MLCT transitions. In particular spin-allowed Ir→(**L-*n***) CT transitions probably dominate the lowest energy portion of the spectra.[13,16,17] Finally, the very weak features reaching into the visible region may correspond to formally spin-forbidden MLCT transitions. A more detailed assignment of the electronic absorption spectra of **1**–**5** is, however, beyond the scope of the present work.

Crystal Structure of 4

Despite the poor tendency to crystallize of the remaining members of the series **1**–**5**, single crystals of **4** were easily obtained at ambient temperature by slow diffusion of methanol into chloroform solutions of the complex. An X-ray analysis showed the presence in the unit cell of two crystallographically independent molecules with similar metric parameters and the same configuration at the metal (Table 1). Figure 1 shows a perspective drawing of one of the cations (cation **1**).

Although the study revealed several causes of disorder which affected the general accuracy, the molecular and crystal features are well established. The metal centre displays a slightly distorted octahedral geometry with *trans* angles at the Ir^{III} centre spanning the range 167–176°. The C-donor atoms of the metallated ppy ligands adopt a *cis* configuration as in the parent dimer,[18] showing a remarkable *trans*-influence which is in good agreement with similar observations on related complexes[13b,17,19,20]. The pyridine rings of the **L-4** ligand are almost coplanar (dihedral angle between the two mean planes of 10°), whereas the rotationally free 6′-phenyl ring is found to be nearly orthogonal to the mean plane of the coordinated **L-4** ligand (tilt angle of 82°). The hexyloxy chain of cation **1** deviates from a fully *trans*-planar conformation with the C(59)–C(60) and C(62)–C(63) bonds in a *gauche* conformation (66 and 69°, respectively). The corresponding chain of cation **2** shows a slightly different sequence of conformations (i.e. *tttgg*).

The mutual orientation between the two molecules in the asymmetric unit is such that the central pyridine ring of the **L-4** ligand of one cation faces the 4′-phenyl ring of the second cation thus resulting in a slipped *head*-to-*tail* arrangement. The packing diagram shows a layered structure with layers stacking along the *b* axis (Figure 2). In particular, the alternating tilt of the hydrocarbon chain axes along *b* generates a herringbone motif.

Thermal Behaviour of Complexes 1–5

Since some of the free **L-*n*** ligands are thermotropic liquid crystals,[11] we tried to ascertain whether complexes **1**–**5** displayed a thermotropic phase behaviour using thermal polarizing optical microscopy and differential scanning calorimetry (DSC) techniques. Although some notable differ-

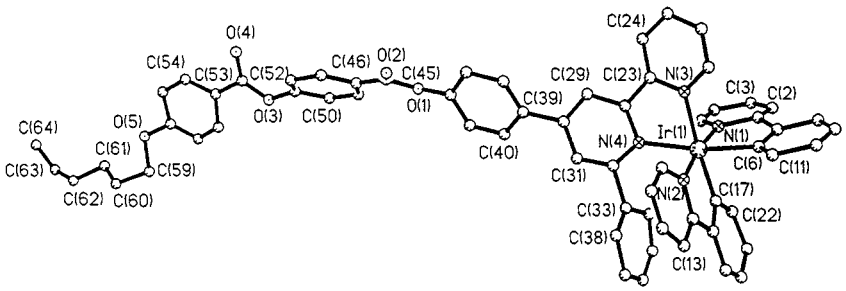

Figure 1. A perspective view and numbering scheme of cation **1** of complex **4**; all atoms are shown as arbitrarily sized circles; H atoms omitted for clarity

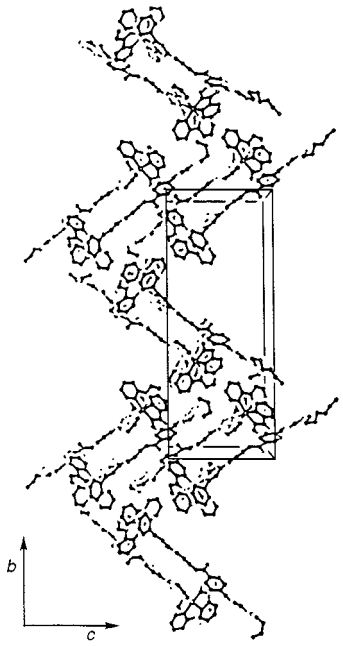

Figure 2. Packing diagram of **4** viewed down the *a* axis

ences were observed, both techniques confirmed the absence of liquid-crystalline behaviour along the whole series of complexes. Thus, while **1** and **4** clearly melt to an isotropic liquid, compounds **2** and **5** very smoothly become plastic solids on heating (above 140 and 170 °C, respectively) with fading birefringence. No clearing (or decomposition) is then observed till ca. 300°C, and cooling affords only glassy solids. The behaviour of **3** is even less clear, roughly matching that of **2**.

The above observations show that, whereas the cations $[(ppy)_2Ir(L\text{-}n)]^+$ possess a suitable polar/apolar ratio of their molecular parts which may guarantee phase separation, the bulkiness of the six-coordinate head-group in **1**–**5** somewhat reduces the structural anisotropy of the **L-*n*** ligands and no compensation for such a reduction is available from dipolar and/or dispersive interactions in the melt. In conclusion, we have prepared ionic metal-containing amphiphiles which failed to display mesogenic properties as pure species. Other properties are more predictable (e.g. photoluminescence) although unexplored. Attempts are in progress to design materials with improved properties.

Experimental Section

Materials and Methods: Ammonium acetate (Lancaster), 1-[2-oxo-2-(phenyl)ethyl]pyridinium bromide [hereafter *N*-(phenacyl)pyridinium bromide] (Lancaster), cholesterol (Lancaster), 1,3-dicyclohexylcarbodiimide (Aldrich) and 4-(pyrrolidino)pyridine (Aldrich) were used as received. The complex $[(ppy)_2IrCl]_2$ was prepared as described in the literature.[16a] The diester ligands 4′-{4-[4-(hexyloxybenzoyloxy)benzoyloxy]phenyl}-6′-phenyl-2,2′-bipyridine (**L-4**) and 4′-{4-[4-(dodecyloxybenzoyloxy)benzoyloxy]-phenyl}-6′-phenyl-2,2′-bipyridine (**L-5**) were obtained according to a method recently devised in our laboratory.[11] The synthesis of 4′-(4′′-carboxyphenyl)-6′-phenyl-2,2′-bipyridine to be used as starting material in the preparation of the ligand **L-3** has been reported elsewhere.[20] All reactions and manipulations of the complexes were performed in air. – ^{1}H NMR spectra were recorded at room temperature on a 300-MHz Bruker AC300 spectrometer. Chemical shifts are reported relative to internal TMS. – IR spectra were obtained as nujol mulls or KBr pellets on a Perkin–Elmer System-2000 FT-IR spectrophotometer. – Optical observations were carried out with a Zeiss Axioskop polarizing microscope equipped with a Linkam CO 600 heating stage and a temperature control unit. – Melting temperatures were measured by differential scanning calorimetry (DSC) with a Perkin–Elmer DSC-7. – Elemental analyses of the new complexes were performed by the Microanalytical Service of our department.

4′-(4′′-Octadecyloxyphenyl)-6′-phenyl-2,2′-bipyridine (L-2): The ligand **L-2** was prepared in a way similar to that for the previously reported **L-1**.[10] A solution of *N*-(phenacyl)pyridinium bromide (0.52 g, 1.88 mmol), 1-(2-pyridyl)-3-[4-(octadecyloxy)phenyl]propen-1-one (0.90 g, 1.88 mmol), and ammonium acetate (1.45 g, 18.8 mmol) in methanol (25 mL) was heated to reflux for 8 h. A brown precipitate was obtained after cooling the reaction mixture to 0 °C. Purification of the crude solid by column chromatography on SiO_2 (CH_2Cl_2 and diethyl ether as consecutive eluents) yielded the product after workup as a pinkish-brown flaky solid in low yield (18%). M.p. 92 °C. – ^{1}H NMR (300 MHz, $CDCl_3$): δ = 8.72 (br d, 1 H), 8.69 (d, J = 8.1 Hz, 1 H), 8.62 (d, J = 1.4 Hz, 1 H), 8.20 (m, 2 H), 7.96 (d, J = 1.4 Hz, 1 H), 7.86 (t d, J = 7.6 Hz, J = 5.0 Hz, J = 1.7 Hz, 1 H), 7.79 (d, J = 8.6 Hz, 2 H), 7.52 (m, 3 H), 7.34 (m, 1 H), 4.03 (t, 2 H, OCH_2), 1.80 (m, 2 H, OCH_2CH_2), 1.49–1.20 [m, 30 H, $(CH_2)_{15}$], 0.88 (t, 3 H, CH_3).

4′-[(Cholesteryloxycarbonyl)phenyl]-6′-phenyl-2,2′-bipyridine (L-3): Cholesterol (0.08 g, 0.2 mmol), 4′-(4′′-carboxyphenyl)-6′-phenyl-2,2′-bipyridine (0.07 g, 0.2 mmol), 1,3-dicyclohexylcarbodiimide (0.04 g, 0.2 mmol) and 4-(pyrrolidino)pyridine (0.004 g, 0.03 mmol) were suspended in degassed CH_2Cl_2 (30 mL) and stirred under a dry nitrogen atmosphere for 24 h. A white precipitate was removed

by filtration, and the colourless filtrate was consecutively washed with 5% acetic acid (20 mL) and water (2 × 20 mL). The organic phase was dried over sodium sulfate and rotary-evaporated to dryness. The desired product was obtained as a white solid after purification of the solid residue by column chromatography (SiO_2, CH_2Cl_2/3% MeOH). Yield: 31%. – IR (KBr): $\tilde{\nu}$ = 1716 cm^{-1} (CO). – ^1H NMR (300 MHz, $CDCl_3$): δ = 8.74–8.69 (m, 2 H), 8.66 (br s, 1 H), 8.23–8.17 (m, 4 H), 8.00 (br s, 1 H), 7.90–7.86 (m, 3 H), 7.57–7.45 (m, 3 H), 7.36 (m, 1 H), 5.44 (br d, 1 H, chol.), 4.92 (m, 1 H, chol.), 2.53–0.68 (m, 43 H, chol.).

General Procedure for the Synthesis of the Complexes 1–5: A stirred suspension of the appropriate ligand (0.06 mmol) and $[(ppy)_2IrCl]_2$ (0.03 mmol) in CH_2Cl_2/MeOH (10 ml; 6:4) was heated to reflux. Clear orange or brown solutions were observed within 10 min. After 2 h, the solution was allowed to cool to ambient temperature. Then, a saturated solution of a five-fold excess (based on the ligand) of NH_4PF_6 in MeOH was added and stirring was continued for a further 30 min. The products were isolated after partial evaporation of the solvents under reduced pressure, washed with methanol and diethyl ether, and dried in vacuo.

[(ppy)$_2$Ir(L-1)][PF$_6$] (1): Yield: 65%, brown powder. – M.p. (DSC) 187 °C. – IR (KBr): $\tilde{\nu}$ = 842 cm^{-1} (PF) cm^{-1}. – UV/Vis (acetonitrile): λ_{max} (log ε) = 271 nm (4.64), 315sh (4.52), 383sh (4.02). – ^1H NMR (300 MHz, CD_3CN): δ = 8.88 (d, *J* = 8.2 Hz, 1 H, 3-H), 8.83 (br s, 1 H, 3′-H), 8.19 (br t, 1 H, 4-H), 7.92 (d, *J* = 8.6 Hz, 2 H, a-H), 7.81–7.69 (m, 6 H), 7.54 (br s, 1 H, 5′-H), 7.48 (d, *J* = 7.5 Hz, 1 H), 7.31 (br m, 1 H, 5-H), 7.20 (d, *J* = 7.6 Hz, 1 H), 7.10–7.05 (m, 3 H), 6.95–6.88 (m, 2 H), 6.81–6.70 (m, 3 H), 6.59–6.54 (m, 2 H), 6.36 (br t, 1 H), 5.93 (d, *J* = 7.5 Hz, 1 H), 5.57 (d, *J* = 7.5 Hz, 1 H), 4.03 (t, 2 H, OCH_2), 1.80 (m, 2 H, OCH_2CH_2), 1.46–1.27 (m, 18 H, $(CH_2)_9$), 0.88 (t, 3 H, CH_3). – $C_{56}H_{56}F_6IrN_4OP$ (1138): calcd. C 59.09, H 4.92, N 4.92; found C 58.72, H 5.23, N 5.10.

[(ppy)$_2$Ir(L-2)][PF$_6$] (2): Yield (after chromatography on silica gel with CH_2Cl_2/5% MeOH as eluent): 24%, orange-brown powder. – IR (KBr): $\tilde{\nu}$ = 843 cm^{-1} (PF). – UV/Vis (acetonitrile): λ_{max} (log ε) = 272 nm (4.63), 314sh (4.49), 377sh (4.01). – ^1H NMR ($CDCl_3$): δ = 8.86 (d, *J* = 7.9 Hz, 1 H, 3-H), 8.81 (d, *J* = 2.0 Hz, 1 H, 3′-H), 8.17 (br t, 1 H, 4-H), 7.91 (d, *J* = 8.8 Hz, 2 H, a-H), 7.85–7.67 (m, 6 H), 7.54 (br s, 1 H, 5′-H), 7.47 (d, *J* = 7.0 Hz, 1 H), 7.30 (br m, 1 H, 5-H), 7.19 (d, *J* = 7.0 Hz, 1 H), 7.07–7.04 (m, 3 H), 6.94–6.87 (m, 2 H), 6.80–6.70 (m, 3 H), 6.58–6.53 (m, 2 H), 6.35 (br t, 1 H), 5.92 (d, *J* = 7.9 Hz, 1 H), 5.57 (d, *J* = 7.9 Hz, 1 H), 4.01 (t, 2 H, OCH_2), 1.79 (m, 2 H, OCH_2CH_2), 1.45–1.25 [m, 30 H, $(CH_2)_{15}$], 0.87 (t, 3 H, CH_3). – $C_{62}H_{68}F_6IrN_4OP$ (1222): calcd. C 60.92, H 5.61, N 4.58; found C 61.08, H 5.78, N 4.34.

[(ppy)$_2$Ir(L-3)][PF$_6$] (3): Yield: 81%, orange powder. – IR (KBr): $\tilde{\nu}$ = 1716 cm^{-1} (CO), 842 (PF). – UV/Vis (acetonitrile): λ_{max} (log ε) = 270 nm (4.44), 317sh (4.08), 386sh (3.57). – ^1H NMR (300 MHz, CD_3CN): δ = 8.82 (d, *J* = 2.0 Hz, 1 H, 3′-H), 8.74 (d, *J* = 7.8 Hz, 1 H, 3-H), 8.20 (d, *J* = 8.9 Hz, 2 H, b-H), 8.16 (t, *J* = 7.8 Hz, 1 H, 4-H), 8.08 (d, *J* = 8.9 Hz, 2 H, a-H), 7.96–7.89 (m, 4 H), 7.84 (d, *J* = 6.0 Hz, 2 H), 7.79 (d, *J* = 2.0 Hz, 1 H, 5′-H), 7.69 (d, *J* = 5.9 Hz, 1 H), 7.61 (d, *J* = 7.8 Hz, 1 H), 7.13–7.07 (m, 2 H), 6.98–6.92 (m, 2 H), 6.82 (t, *J* = 7.0 Hz, 1 H), 6.77 (t, *J* = 7.8 Hz, 2 H), 6.65 (br s, 2 H), 6.57 (t, *J* = 7.0 Hz, 1 H), 6.37 (d, *J* = 7.4 Hz, 1 H), 5.96 (d, *J* = 7.0 Hz, 1 H), 5.57 (d, *J* = 7.0 Hz, 1 H), 5.45 (d, *J* = 4.9 Hz, 1 H, chol.), 4.81 (m, 1 H, chol.), 2.5–0.7 (m, 43 H, chol.). – $C_{72}H_{76}F_6IrN_4O_2P$ (1366): calcd. C 63.28, H 5.61, N 4.10; found C 63.02, H 5.62, N 4.12.

[(ppy)$_2$Ir(L-4)][PF$_6$] (4): Yield: 80%, bright yellow powder. – M.p. (DSC) 288 °C. – IR (KBr): $\tilde{\nu}$ = 1740, 1733 cm^{-1} (CO), 840 (PF). – UV/Vis (acetonitrile): λ_{max} (log ε) = 270 nm (4.61), 320sh (4.14), 380sh (3.60). – ^1H NMR (300 MHz, CD_3CN): δ = 8.83 (br s, 1 H, 3′-H), 8.74 (d, *J* = 8.2 Hz, 1 H, 3-H), 8.31 (d, *J* = 8.5 Hz, 2 H), 8.22–8.02 (m, 5 H), 7.98–7.83 (m, 6 H), 7.80 (br s, 1 H, 5-H), 7.68 (d, *J* = 5.7 Hz, 1 H), 7.61 (d, *J* = 7.6 Hz, 1 H), 7.54–7.44 (m, 5 H), 7.31 (d, *J* = 7.8 Hz, 1 H), 7.17–7.06 (m, 4 H), 6.95 (m, 2 H), 6.83 (br t, 1 H), 6.77 (t, *J* = 7.8 Hz, 2 H), 6.66 (v br s, 2 H), 6.58 (t, *J* = 7.4 Hz, 1 H), 6.38 (t, *J* = 7.4 Hz, 1 H), 5.97 (d, *J* = 7.7 Hz, 1 H), 5.58 (d, *J* = 7.7 Hz, 1 H), 4.12 (t, 2 H, OCH_2), 1.80 (m, 2 H, OCH_2CH_2), 1.41–1.36 [m, 6 H, $(CH_2)_3$], 0.94 (t, 3 H, CH_3). – $C_{64}H_{52}F_6IrN_4O_5P$ (1294): calcd. C 59.39, H 4.05, N 4.33; found C 59.30, H 4.17, N 4.21.

[(ppy)$_2$Ir(L-5)][PF$_6$] (5): Yield: 75%, brownish orange powder. – IR (KBr): $\tilde{\nu}$ = 1736 cm^{-1} (CO), 842 (PF). – UV/Vis (acetonitrile): λ_{max} (log ε) = 270 nm (4.71), 321sh (4.27), 381sh (3.72). – ^1H NMR (300 MHz, CD_3CN): δ = 8.83 (br s, 1 H, 3′-H), 8.74 (d, *J* = 8.2 Hz, 1 H, 3-H), 8.31 (d, *J* = 8.5 Hz, 2 H), 8.18–8.02 (m, 5 H), 7.98–7.83 (m, 6 H), 7.80 (d, *J* = 1.8 Hz, 1 H, 5′-H), 7.66 (d, *J* = 5.8 Hz, 1 H), 7.63 (d, *J* = 8.0 Hz, 1 H), 7.53–7.43 (m, 5 H), 7.30 (d, *J* = 8.0 Hz, 1 H), 7.17–7.06 (m, 4 H), 6.95 (m, 2 H), 6.83 (t, *J* = 7.7 Hz, 1 H), 6.76 (t, *J* = 7.8 Hz, 2 H), 6.65 (v br s, 2 H), 6.57 (t, *J* = 7.6 Hz, 1 H), 6.37 (t, *J* = 7.4 Hz, 1 H), 5.96 (d, *J* = 7.7 Hz, 1 H), 5.58 (d, *J* = 7.5 Hz, 1 H), 4.07 (t, 2 H, OCH_2), 1.81 (m, 2 H, OCH_2CH_2), 1.45–1.28 [m, 18 H, $(CH_2)_9$], 0.89 (t, 3 H, CH_3). – $C_{70}H_{64}F_6IrN_4O_5P$ (1378): calcd. C 60.99, H 4.68, N 4.06; found C 60.56, H 4.57, N 4.27.

Crystal Structure Determination: Diffraction data for complex **4** were collected on a Siemens (Bruker) SMART area detector diffractometer by using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) with the ω-2θ method (*T* = 163 K). Data were corrected for absorption (SADABS)[21] and Lorentz-polarization effects. The structure was solved by direct methods using SHELXS-97[22] and refined by full-matrix least-squares on F^2 (SHELXL-97).[22] Crystal data and structure refinements parameters are given in Table 2. All nonhydrogen atoms were refined anisotropically. Hydrogen atoms were placed in calculated positions with fixed contri-

Keywords: Palladium / Dithiadiazole / Radicals

Two new 1,2,3,5-dithiadiazoles, [4-(4′-C_5H_4N)CN_2S_2] (**L¹**) and [4-(3′-C_5H_4N)CN_2S_2] (**L²**), with different pyridyl groups at the 4-position were prepared. As Lewis bases, the dithiadiazoles reacted with Lewis acids via their pyridyl groups to form acid-base adducts with retention of the five-membered dithiadiazole ring. Ligands **L¹** and **L²** reacted with excess triethylborane to give **L¹**BEt_3 and **L²**BEt_3 (**1a** and **1b**) and with $Mn(CO)_5Br$ to give the *fac*-$Mn(CO)_3Br(L^1)_2$ (**2a**) and *fac*-$Mn(CO)_3Br(L^2)_2$ (**2b**) complexes. When reacted with Pd^0 complexes, namely, $Pd(PPh_3)_4$ and a mixture of $[Pd_2(dba)_3]$ and dppf, the dithiadiazoles underwent ring-opening reaction by reductive cleavage of the S–S bond of the dithiadiazole ring. The resulting formation of Pd–S bonds gave the corresponding trinuclear complexes [Pd_3{μ-SNC(4′-C_5H_4N)NS-*S*,*S*′}$_2$(PPh_3)$_4$] (**3a**), [Pd_3{μ-SNC(3′-C_5H_4N)NS-*S*,*S*′}$_2$(PPh_3)$_4$] (**3b**), and [Pd_3{μ-SNC(4′-C_5H_4N)NS-*S*,*S*′}$_2$(dppf)$_2$] (**4**) [dba = dibenzylideneacetone, dppf = 1,1′-bis(diphenylphosphanyl)-ferrocene]. Complexes **3a** and **3b** reacted with excess triethylborane to give the corresponding acid-base adducts [Pd_3{μ-SNC(4′-$C_5H_4NBEt_3$)NS-*S*,*S*′}$_2$(PPh_3)$_4$] (**5a**) and [Pd_3{μ-SNC(3′-$C_5H_4NBEt_3$)NS-*S*,*S*′}$_2$(PPh_3)$_4$] (**5b**.) Complex **3a** reacted with $Mn(CO)_5Br$ to give {[Pd_3{μ-SNC(4′-C_5H_4N)NS-*S*,*S*′}$_2$(PPh_3)$_4$][$MnBr(CO)_3$]}$_n$ (**6**). The structures of **3a**, **5a**, and **5b** were established by X-ray crystallography.

Introduction

1,2,3,5-Dithiadiazoles belong to a remarkable and new class of stable free radicals which exist as a monomer–dimer equilibrium in the solid state and in solution.[1–10] These radicals have attracted special attention because they can act as molecular building blocks in the preparation of both conducting materials and "organic" magnets. Another interesting property is their ability to act as chelating or bridging ligands for transition metals. When reacted with low-valent transition metal complexes, the radical species underwent reductive cleavage of the S–S bond of the dithiadiazolyl ring with the formation of metal–sulfur bonds. However, so far only the reactivity of the phenyl derivative $(PhCNSSN)_2$ toward low-valent transition metal complexes has been studied.[11–15]

In this paper, we report the syntheses of two new 1,2,3,5-dithiadiazoles with different pyridyl groups at the 4-position and their reactivities toward low-valent transition metal complexes. These ligands have two different reactive sites, namely, the pyridyl group and the dithiadiazolyl ring. When reacted via the pyridyl group, these ligands simply act as Lewis bases with ring-retention. When reacted via the dithiadiazolyl group, these ligands undergo ring-opening reaction with the cleavage of the S–S bond and the formation of metal–sulfur bonds.

Results and Discussion

Preparation of L^1 and L^2

The compounds [4-(4′-NC_5H_4)CN_2S_2] (**L¹**) and [4-(3′-NC_5H_4)CN_2S_2] (**L²**) were prepared according to the synthetic routes shown in Scheme 1, in low to moderate yields (33% for **L¹**; 50% for **L²**) as black solids after sublimation. Both compounds are only slightly soluble in common organic solvents and are sensitive to air and moisture. The IR spectra (KBr) of ligands **L¹** and **L²** showed the characteristic absorption peaks for substituted dithiadiazole ring at 1140 (m), 810 (s), 656 (s), 510 (m), and 1146 (m), 809 (s), 667 (s), 511 (m) cm^{-1}, respectively.[1] The low-resolution mass spectra (LRMS) of **L¹** and **L²** operated in EI mode exhibited the highest mass peak at *m*/*z* 364 with the most abundant peak at *m*/*z* 182 corresponding to the dimer $[(NC_5H_4)CN_2S_2]_2$ and the monomer $[(NC_5H_4)CN_2S_2]$, respectively. The solid-state EPR spectra of **L¹** and **L²** both displayed a broad peak compared with the diphenyl picrylhydrazyl (DPPH) standard. The *g*-value was determined to be 2.014 which is characteristic of a single unpaired electron. It is likely that dissociation of $(RCN_2S_2)_2$ (R = 4-pyridyl and 3-pyridyl) to the monomer, similar to that observed in $(PhCN_2S_2)_2$[16] and $[S_6N_4]^{2+}$ salts,[17,18] takes place in the solid state.

Both **L¹** and **L²** exhibited concentration- and temperature-dependent solution EPR spectra. At their saturated concentration in toluene, the room temperature solution EPR spectra of both **L¹** and **L²** showed a broad peak at $g = 2.014$. However, when the solution was diluted ten-fold, the EPR spectra exhibited a simple 1:2:3:2:1 quintuplet pattern. These observations are indicative of the occurrence of

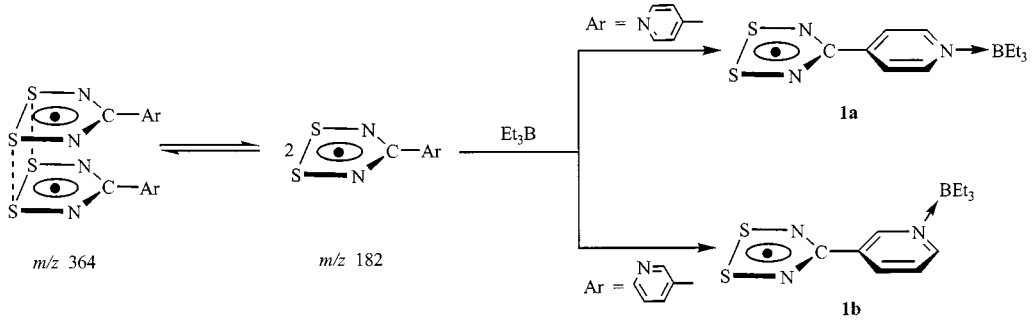
Scheme 1

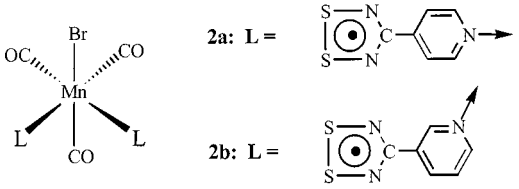
an electron spin exchange process, commonly observed in free radical systems in solution, where two radicals collide and exchange electrons. At saturated concentration, the rate of this bi-molecular process is very high, resulting in a severe broadening of the EPR resonances. With a ten-fold dilution, the rate of this bi-molecular exchange became sufficiently slow that the intrinsic EPR resonances of the free radicals were not significantly affected and the hyperfine splitting pattern became observable. The 1:2:3:2:1 hyperfine splitting pattern of **L¹** and **L²** suggested that the unpaired electron was delocalized over the five-membered ring and coupled to the two equivalent ^{14}N nuclei. The observation of a *g*-factor of 2.014 together with a hyperfine coupling constant *A* of ca. 0.50 mT indicates that the pyridyl group does not exert any significant effect on the single unpaired electron on the dithiadiazole ring. The solution became EPR-silent when cooled down to liquid-nitrogen temperature (i.e., –196°C), suggesting that **L¹** and **L²** no longer exist as monomers at this temperature. Since an eclipsed dimeric structure has been found for the analogous 4-phenyl-1,2-dithia-3,5-diazole in its crystalline state,[19] the formation of such a dimeric structure for both **L¹** and **L²** at –196°C, which will allow for an antiferromagnetic coupling between the two unpaired electrons on the two 5-membered rings, could well explain the quenching of the EPR signals observed at this temperature.



Reaction with Triethylborane

When a suspension of **L¹** or **L²** was allowed to react with excess triethylborane in dichloromethane or toluene at ambient temperature, a dark-red clear solution was immediately obtained. The EPR behaviour of the resultant solution was very similar to that of **L¹** or **L²**. The EPR spectra exhibited a single peak at $g = 2.014$ and after dilution with a relevant solvent, a quintet signal with an intensity pattern of 1:2:3:2:1 and a *g* value of 2.014 ($A = 0.50$ mT). Attempts to isolate the products in pure crystalline form only led to the isolation of an air-sensitive dark-red viscous oil. The EPR data showed that the products retained the characteristics of the dithiadiazolyl ring. This suggested that the products were probably the acid-base adducts **L¹** · BEt_3 (**1a**) and **L²** · BEt_3 (**1b**), which were formed by the interaction of the pyridyl group of **L¹** and **L²** with triethylborane as shown in Scheme 2. However, this could not preclude the possibility that triethylborane also formed acid-base adducts with the dimers of **L¹** and **L²**.

Reaction with $Mn(CO)_5Br$

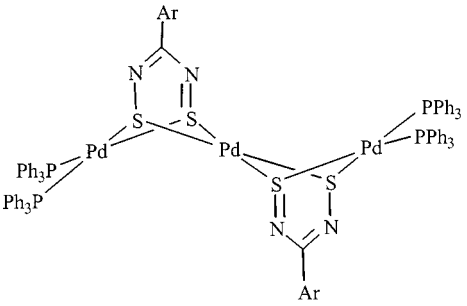


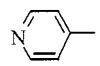
When ligand **L¹** was allowed to react with an excess of $Mn(CO)_5Br$ in tetrahydrofuran at 55 °C for 4 h, workup gave the stoichiometric product $C_{15}H_8BrMnN_6O_3S_4 \cdot 2.5\ H_2O$ (**2a** · 2.5 H_2O), as reddish-brown tiny crystals, in moderate yield (56%). In the carbonyl region of its IR spectrum (KBr), **2a** exhibited three very strong absorptions at 2030, 1942, and 1909 cm^{-1}, characteristic of a *fac*-$Mn(CO)_3$ configuration. Complex **2a** exhibited a broad peak and a quintuplet with a relative intensity pattern of 1:2:3:2:1 in its solid state and tetrahydrofuran solution EPR spectra, respectively. The measured *g* value of 2.014 indicates the presence of a single electron and the five-line pattern ($A = 0.50$ mT) observed was due to the coupling of the single electron with two equivalent ^{14}N nuclei in the dithiadiazolyl ring. The EPR spectra of **2a** were similar to those of **L¹**, indicating retention of the dithiadiazolyl ring. LRMS (EI mode) of **2a** exhibited a peak at *m/z* 182 for **L¹** while the parent peak of **2a** was not observed. Based on the above spectroscopic and analytical data, compound **2a** could be formulated as *fac*-$Mn(CO)_3Br(\mathbf{L^1})_2$.

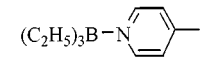
Similarly, when **L²** was allowed to react with $Mn(CO)_5Br$, work up gave the reddish-brown stoichiometric solid $C_{15}H_8BrMnN_6O_3S_4 \cdot H_2O$ (**2b** · H_2O) in good yield (75%).

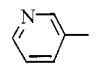
Scheme 2

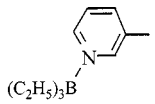
The spectroscopic data of **2b** were very similar to those of **2a**. In the carbonyl region of its IR spectrum (KBr), **2b** showed three very strong absorptions at 2028, 1947, and 1912 cm^{-1}, characteristic of a *fac*-$Mn(CO)_3$ configuration. Compound **2b** also exhibited a broad peak and a quintet with an intensity pattern of 1:2:3:2:1 in its solid state and tetrahydrofuran solution EPR spectra, respectively. The measured *g*-value was 2.014 with the hyperfine coupling constant $A = 0.51$ mT. Compound **2b** was also formulated as *fac*-$Mn(CO)_3Br(\mathbf{L^2})_2$.











Preparation of $[Pd_3\{\mu\text{-SNC(Ar}')\text{NS–}S,S'\}_2(PPh_3)_4]$

Ar′ = 4′-C_5H_4N

When $\mathbf{L^1}$ was allowed to react with 4 equivalents of $Pd(PPh_3)_4$ in toluene for 4 h at ambient temperature, workup gave red crystals of $(Ph_3P)_4Pd_3(C_{12}H_8N_6S_4) \cdot 0.25\,CH_2Cl_2$, **3a** · $0.25\,CH_2Cl_2$, in good yield (70%) after recrystallization from a dichloromethane solution. In the IR spectrum of **3a**, absorption corresponding to $\mathbf{L^1}$ (characterized by strong absorptions at 1140, 810, 656, and 510 cm^{-1}) were not observed. Instead three strong absorptions at 1434, 691, and 527 cm^{-1} were detected. This IR spectrum was indicative of a ring opening reaction between the two sulfur-sulfur atoms. In addition to the pyridyl and phenyl carbons, the $^{13}C\text{-}\{^1H\}$ NMR spectrum of **3a** gave a singlet at $\delta = 174.0$ for the C=N carbon of the amidine group. The ^1H-NMR spectrum of **3a** showed resonances at $\delta = 8.52$ (dd, 4 H, $J = 4.6$, 1.6 Hz) and 8.11 (dd, 4 H, $J = 4.6$, 1.6 Hz) for the pyridyl α- and β-protons, respectively, and at $\delta = 7.12$ (t, 12 H, $J = 7.3$ Hz), 6.97 (t, 24 H, $J = 7.3$ Hz), and 6.83 (m, 24 H) for the phenyl protons. The $^{31}P\text{-}\{^1H\}$ NMR spectrum of **3a** in $CDCl_3$ exhibited only a singlet at $\delta = 27.5$ for the PPh_3 groups, indicating that all the triphenylphosphane groups were equivalent. LRMS (positive FAB) of **3a** exhibited a parent peak at *m/z* 1731 [(M + 1) for ^{106}Pd]. Based on the above spectroscopic data, compound **3a** could be formulated as $[Pd_3\{\mu\text{-SNC(4}'\text{-}C_5H_4N)\text{NS-}S,S'\}_2(PPh_3)_4]$ with a structure similar to that of $[Pd_3\{\mu\text{-SNC(Ph)NS-}S,S'\}_2(PPh_3)_4]$ as shown below.[15] This was confirmed by an X-ray crystallographic study.

Crystals of **3a** · 2 $(C_2H_5)_2O$ suitable for X-ray diffraction study were grown from a dichloromethane/diethyl ether mixture. A perspective drawing of **3a** is shown in Figure 1 and selected bond lengths and angles are given in Table 1. The solid state structure of **3a** is consistent with its spectroscopic data. The structure of **3a** is composed of a linear Pd_3 chain bridged by two SNC(4-C_5H_4N)NS ligands in which the terminal Pd atoms are related through a crystallographic inversion center at Pd(2). Both Pd(1) and Pd(2)

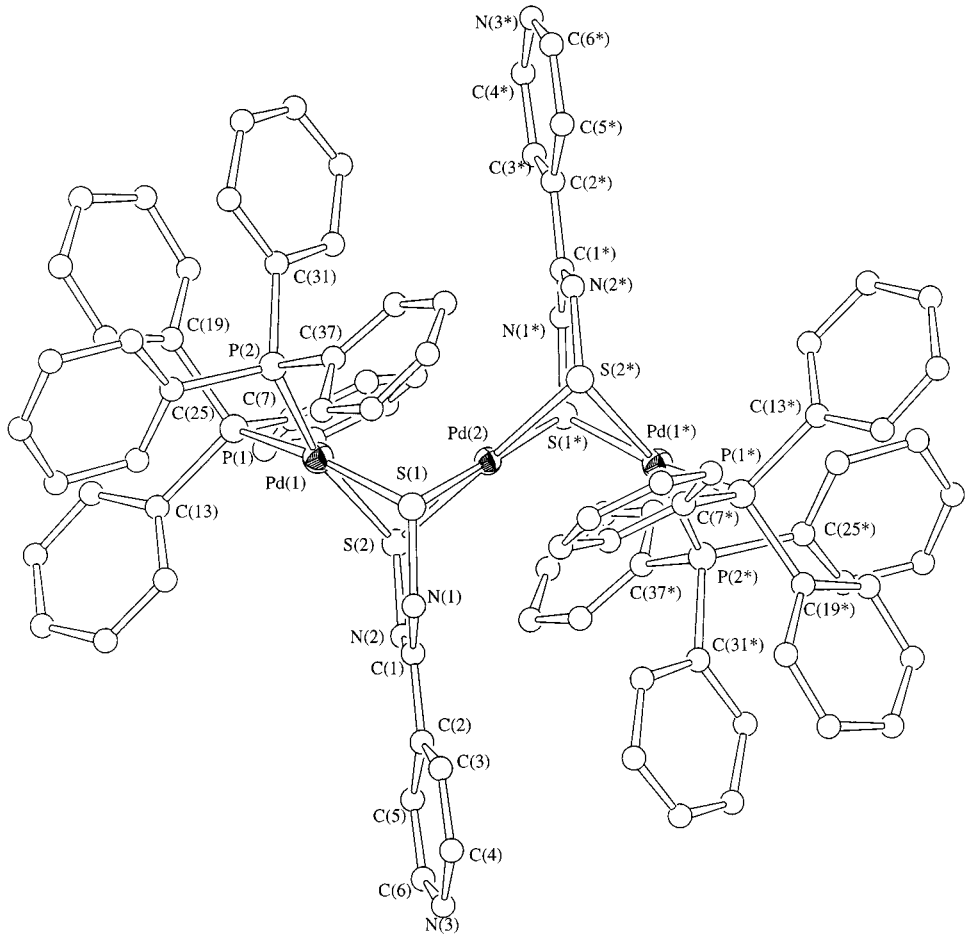
3a: Ar = 
5a: Ar = 
3b: Ar = 
5b: Ar = 

atoms possess a square planar geometry. The terminal Pd atoms have a PdP_2S_2 environment whereas the central Pd is bound only to the dithiadiazolyl S atoms, thus producing a PdS_4 coordination geometry. This structure is analogous to those of $[Pt_3\{\mu\text{-SNC(Ph)NS-}S,S'\}_2(PPh_3)_4]$ and $[Pd_3\{\mu\text{-SNC(Ph)NS-}S,S'\}_2(PPh_3)_4]$ reported previously.[15] In **3a**, the dithiadiazolyl ligands take up a bridging mode between Pd(1) and Pd(2) with a Pd···Pd distance of 2.852(1) Å. Such metal–metal distance is slightly longer than the sum of the metallic radii (2.76 Å for Pd), suggesting that no metal-metal bond exists.

As a bridging ligand, the S–S bond in the dithiadiazolyl ring has been broken. The S(1)–N(1) and S(2)–N(2) distances are 1.64(1) and 1.65(1) Å, respectively. The N(1)–C(1) and N(2)–C(1) distances of 1.34(1) and 1.331(1) Å, respectively, are also intermediate between those expected for carbon-nitrogen single (1.46 Å) and double (1.26 Å) bonds. All these indicate some degree of electron delocalization about the SNCNS framework. This delocalization is also reflected in the S(1)–N(1)–C(1) and S(2)–N(2)–C(1) bond angles of 125.6(9) and 124.2(9)°, respectively, which deviate significantly from that expected for a tetrahedral sp^3 nitrogen atom and are closer to a sp^2 nitrogen atom.

Ar′ = 3′-C_5H_4N

When two equivalents of $\mathbf{L^2}$ were allowed to react with 3 equivalents of $Pd(PPh_3)_4$ in toluene for 4 h at ambient temperature, workup gave a stoichiometric red solid, $(Ph_3P)_4Pd_3(C_{12}H_8N_6S_4)1.7CH_2Cl_2$ (**3b** · $1.7\,CH_2Cl_2$) in good yield (60%) after recrystallization from dichloromethane. The spectroscopic data of **3b** were very similar to those of **3a**. Compound **3b** exhibited a similar IR spectrum to that of **3a** with three strong absorptions at 1433, 692, and 526 cm^{-1}. In addition to the pyridyl and phenyl carbons, the $^{13}C\text{-}\{^1H\}$ NMR spectrum of **3a** exhibited a singlet at $\delta = 173.9$ for the C=N carbon of the amidine group. The $^{31}P\text{-}\{^1H\}$ NMR spectrum of **3b** in $CDCl_3$ gave only a singlet at $\delta = 27.5$ for the PPh_3 groups. The ^1H-NMR spectrum of **3b** exhibited resonances at $\delta = 9.46$ (d, 2 H, $J = 1.6$ Hz), 8.50 (dd, 4 H, $J = 4.6$, 1.6 Hz), and 8.39 (dt, 2 H, $J = 8.4$, 1.6 Hz) for the pyridyl protons, and at $\delta = 7.25$–6.82 (60



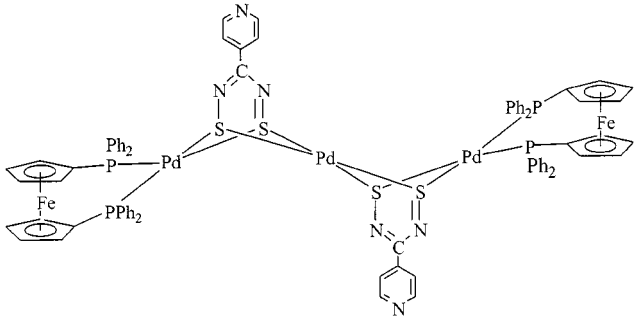


Figure 1. A perspective drawing of the molecular structure of **3a**

H, m) for the phenyl protons. LRMS (positive FAB) of **3b** exhibited a parent peak at *m/z* 1731 [(M + 1) for ^{106}Pd]. Based on the above spectroscopic and analytical data, a centrosymmetric trinuclear complex with a structure similar to that of **3a** was proposed for **3b**.

Preparation of [Pd_3{μ-SNC(4′-NC_5H_4)NS–*S,S′*}$_2$(dppf)$_2$] (4)

When one equivalent of $\mathbf{L^1}$ was allowed to react with a mixture of two equivalents of 1,1′-bis(diphenylphosphanyl)ferrocene (dppf) and one equivalent of tris(dibenzylideneacetone)dipalladium [$Pd_2(dba)_3$] in toluene for one day at room temperature, workup gave a stoichiometric red solid of $(dppf)_2Pd_3(C_{12}H_8N_6S_4) \cdot 0.5\,CH_2Cl_2$ (**4** · 0.25 CH_2Cl_2) in a moderate yield (50%). In addition to the pyridyl and phenyl carbon signals, the ^{13}C-{^1H} NMR spectrum of **4** exhibited three broad singlets at δ = 73.3, 72.3, and 72.0 for the cyclopentadienyl carbon atoms. The ^{31}P-{^1H} NMR spectrum of **4** in $CDCl_3$ exhibited only a singlet at δ = 25.5 for the phosphanyl groups. The ^1H-NMR spectrum of **4** exhibited two doublets at δ = 8.56 (d, 4 H, *J* = 6.2 Hz) and 8.22 (d, 4 H, *J* = 6.2 Hz) for the pyridyl protons, a complex multiplet at δ = 7.52–7.08 (m, 48 H) for the phenyl protons, and four singlets at δ = 3.92 (s, 4 H), 3.68 (s, 4 H), 3.65 (s, 4 H), and 3.61 (s, 4 H) for the cyclopentadienyl protons. LRMS (positive FAB) of **4** exhibited a parent ion peak at *m/z* 1791 [(M + 1) for ^{106}Pd]. Based on the spectroscopic and analytical data, compound **4** could be formulated as [Pd_3{μ-SNC(4′-NC_5H_4)NS-*S,S′*}$_2$(dppf)$_2$] with the structure as shown below.

4

Reaction of Triethylborane with 3a and 3b

When an excess amount of triethylborane was allowed to react with **3a** and **3b** in CH_2Cl_2/hexane mixture for one day at ambient temperature, workup gave red crystals of **5a** and **5b** of the same stoichiometry $(Ph_3P)_4Pd_3(C_{12}H_8N_6S_4)$-$(BEt_3)_2$ in 74 and 71% yield, respectively. Compound **5a** exhibited a spectroscopic pattern similar to that of **3a**. In

the IR spectrum (KBr), other than the three strong absorptions at 1435, 692, and 520 cm^{-1}, the observation of *v*(Py, CN) at 1619 cm^{-1}, a shift of ca. 34 cm^{-1} from that of **3a** (1585 cm^{-1}), indicated B–N bond formation. In addition to the ethyl resonance, the ^{1}H-NMR spectrum of **5a** also exhibited two resonances at δ = 8.47 (d, 4 H, *J* = 6.6 Hz) and 8.35 (d, 4 H, *J* = 6.6 Hz) for the α-H and β-H of the pyridyl group, respectively. The slight upfield shift of ca. 0.05 ppm for the α-H signal from that of **3a** (δ = 8.52) and downfield shift of ca. 0.24 ppm for the β-H signal from that of **3a** (δ = 8.11) were also characteristic of the formation of B–N dative bond. The ^{31}P-{^{1}H} NMR spectrum of **5a** in $CDCl_3$ exhibited a singlet at δ = 27.5 for the PPh_3 groups. LRMS (positive FAB) of **5a** exhibited an ion peak at *m*/*z* 1731 [(M – 2 BEt_3 + 1) for ^{106}Pd]. Based on the above spectroscopic data, compound **5a** could be envisaged as an acid-base adduct of the triethylborane and the pyridyl groups of **3a**, and formulated as [Pd_3{μ-SNC(4′-$C_5H_4NBEt_3$)NS-*S,S′*}$_2$(PPh_3)$_4$].

Other than the phenyl protons, the ^{1}H-NMR spectrum of **5b** showed resonances of the triethylborane protons at δ = 0.60 (m, 18 H) and 0.51 (m, 12 H), and the pyridyl protons at δ = 9.47 (2 H, br s), 8.47 (m, 4 H), and 7.85 (s, 2 H). The ^{31}P-{^{1}H} NMR spectrum of **5b** in $CDCl_3$ exhibited only a singlet at δ = 26.9 for the PPh_3 groups. LRMS (positive FAB) of **5b** exhibited an ion peak at *m*/*z* 1731 [(M – 2 BEt_3 + 1) for ^{106}Pd]. Thus, compound **5b** could also be formulated as [Pd_3{μ-SNC(3′-$C_5H_4N \cdot BEt_3$)NS-*S,S′*}$_2$(PPh_3)$_4$]. The structures of both compounds **5a** and **5b** were ascertained by X-ray crystallography.

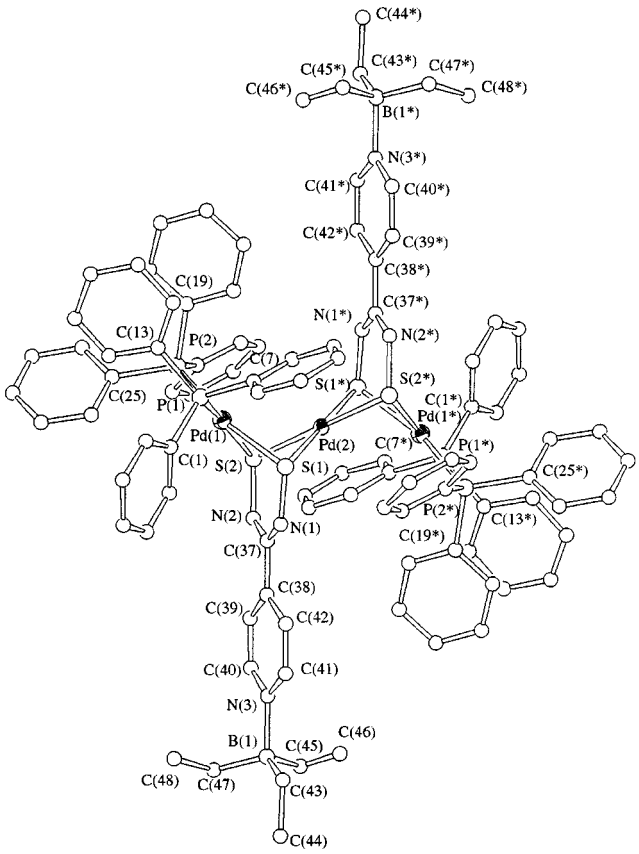

Figure 2. A perspective drawing of the molecular structure of **5a**

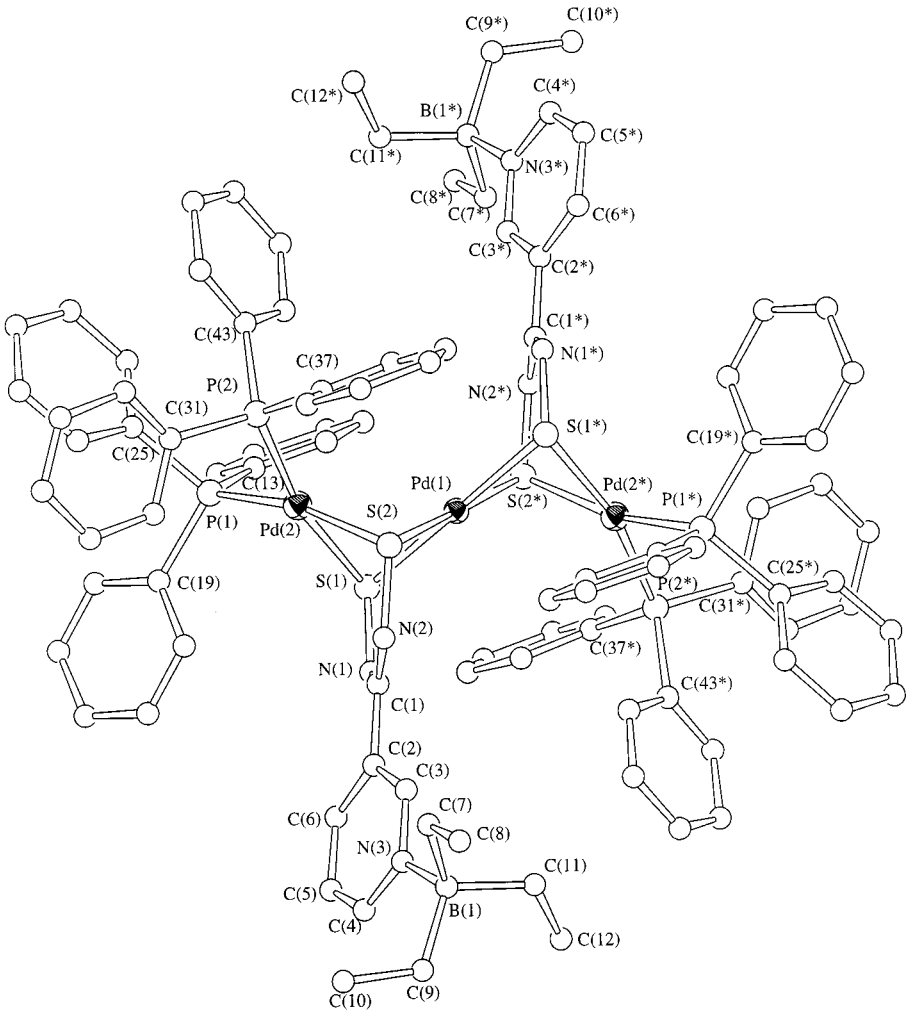
Crystals of **5a** · 4 CH_2Cl_2 and **5b** · 4 CH_2Cl_2 suitable for X-ray diffraction studies were grown from a solution of the respective compound in a dichloromethane/hexane mixture. Perspective drawings of the compounds are shown in Figure 2 and Figure 3, respectively. Selected bond lengths and angles are given in Table 1. The solid state structures of **5a** and **5b** are consistent with their spectroscopic data. Crystal structure analyses revealed that the triethylborane groups interact with the pyridyl groups of **3a** and **3b** forming acid-base adducts with a B–N distance of 1.69(1) and 1.66(1) Å, respectively. Other than the presence of triethylborane groups at the pyridyl groups, the structures of **5a** and **5b** are very similar to that of **3a** and **3b**.

Preparation of {[Pd_3{μ-SNC(4′-C_5H_4N)NS–*S,S′*}$_2$-(PPh_3)$_4$][$Mn(CO)_3Br$]}$_n$ (6)

When **3a** was allowed to react with 2 equivalents of $Mn(CO)_5Br$ in dichloromethane for one day at ambient tem-



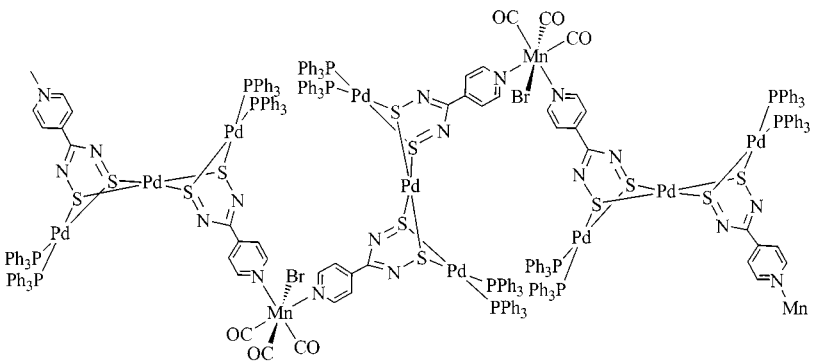


Figure 3. A perspective drawing of the molecular structure of **5b**

6

perature, workup gave a stoichiometric red solid of $(Ph_3P)_4Pd_3(C_{12}H_8N_6S_4)[Mn(CO)_3Br] \cdot 1.5\ CH_2Cl_2$ (**6** · 1.5 CH_2Cl_2) in a moderate yield of 55%. In the IR spectrum (KBr), compound **6** exhibited three very strong absorptions in the terminal carbonyl region at 2024, 1935, and 1905 cm^{-1}, which were indicative of a *fac*-$Mn(CO)_3$ configuration; and ν(Py, CN) at 1606 cm^{-1}, a shift of ca. 21 cm^{-1} from that of **3a** (1585 cm^{-1}), indicating the formation of Mn–N bonds. The Mn–N bond formation was also reflected in the chemical shifts of the pyridyl protons in the ^{1}H-NMR spectrum ($CDCl_3$), in which the α-H and β-H signals were shifted downfield from δ = 8.52 and 8.11 for **3a** to δ = 8.71 and 8.14 for **6**. The ^{1}H-NMR spectrum of **6** exhibited two resonances of relative intensity 4:30 for the pyridyl and phenyl protons, respectively. The ^{31}P-{^{1}H} NMR spectrum of **6** in $CDCl_3$ gave only a singlet at δ = 27.4 for the PPh_3 groups. LRMS (positive FAB) of **6** exhibited an ion peak at *m*/*z* 1730 {[M – $MnBr(CO)_3$] for ^{106}Pd}. Based on the spectroscopic and analytical data, compound **6** could be formulated as $\{[Pd_3\{\mu\text{-}SNC(4'\text{-}C_5H_4N)NS\text{-}S,S'\}_2(PPh_3)_4][Mn(CO)_3Br]\}_n$ with a possible structure shown below. In **6**, complex **3a** and $Mn(CO)_3Br$ were linked alternately together in a linear manner, in which the central metal Mn possesses an octahedral geometry with the three carbonyl ligands in a *fac* configuration, while the two nitrogen atoms adopt a *cis* configuration. The two nitrogen atoms coordinated to the same metal Mn came from two different molecules of **3a**. Thus, **6** could also be described as two $Mn(CO)_3Br$ and one bridging **3a** ligand alternately linking together in a linear geometry.

Experimental Section

General Procedures: Unless otherwise stated, manipulations were performed under oxygen-free nitrogen using standard techniques in a glovebox. Solvents were dried by standard procedures, distilled and de-aerated prior to use. All chemicals used were of reagent grade, obtained from the Aldrich Chemical Company and, where appropriate, degassed before use. The compounds $Pd(PPh_3)_4$,[20] dppf,[21] and $Pd_2(dba)_3$[22] were prepared according to literature methods. – Microanalyses were performed by the Shanghai Institute of Organic Chemistry, Chinese Academy of Sciences, China. – The melting points were obtained in glass capillaries and were uncorrected. – Infrared spectra were recorded with a Nicolet Nagna-IR 550 spectrometer and NMR spectra with a JEOL EX270 spectrometer. Chemical shifts of ^{1}H and ^{13}C-{^{1}H} NMR spectra were referenced to internal deuteriated solvents and then recalculated to $SiMe_4$ (δ = 0.00), those of ^{31}P-{^{1}H} NMR spectra were referenced to external 85% H_3PO_4 (δ = 0.00). The EPR spectra were obtained with an X-band JEOL JES TE-100 spectrometer at room temperature, low-resolution mass spectra with a Finnigan MAT SSQ-710 or MAT 95 spectrometer either in EI or FAB (positive ion) mode.

[4-(4′-NC_5H_4)CN_2S_2] L^1: A solution of $Li[N(SiMe_3)_2]$, generated in situ by treating $(Me_3Si)_2NH$ (32.94 g, 200 mmol) in diethyl ether (100 mL) with *n*BuLi (122 mL of 1.6 M, 200 mmol) in hexane, was slowly added to a solution of 4-cyanopyridine (20.8 g, 200 mmol) in tetrahydrofuran (70 mL) at 0 °C. The resulting dark-red solution was warmed to room temperature and allowed to react overnight. The solvent was removed in vacuo to give a dark red residue that was then suspended in toluene (400 mL). A solution of Me_3SiCl (22.4 g, 200 mmol) in toluene (100 mL) was then slowly added to the suspension at room temperature. Upon complete addition, the solution mixture was stirred under reflux for 7 h, then at room temperature overnight. The resultant reaction mixture was then filtered to afford a red filtrate, which was pumped dry before acetonitrile (200 mL) was added. A solution of sulfur dichloride (42 g, 400 mmol) in acetonitrile (50 mL) was then slowly added. The mixture was stirred at room temperature for 24 h and then filtered to afford crude 4-(4′-pyridyl)dithiadiazolylium chloride as a yellow solid, which was washed once with a 1:1 mixture of acetonitrile/toluene (200 mL) and then suspended in acetonitrile (200 mL). A solution of triphenylantimony (72 g, 200 mmol) in acetonitrile (100 mL) was slowly added to the suspension at room temperature to give a dark purple precipitate. The reaction mixture was allowed to stir at room temperature for 2 h before the solvent was removed in vacuo to give a dark purple residue. Sublimation of the residual solid at 110°C/0.05 Torr afforded a dark red solid of [4-(4′-NC_5H_4)CN_2S_2]. Yield: 12.1 g, 33.3%; m. p. 252–254°C (dec.). – $C_6H_4N_3S_2 \cdot H_2O$ (200.25): calcd. C 36.0, H 3.0, N 21.0, S 32.0; found C 36.0, H 2.9, N 20.8, S 31.0. – IR (cm^{-1}, in KBr): $\tilde{\nu}$ = 3388 vs, 3332 s, 3266 s, 3120 m, 3028 m, 1945 w, 1693 m, 1649 m, 1599 s, 1560 w, 1417 vs, 1377 s, 1230 m, 1140 m, 1062 m, 1018 m, 1000 m, 913 w, 828 s, 810 s, 785 vs, 747 w, 736 w, 667 m, 656 vs, 618 w, 510 m, 464 w. – LRMS (EI mode); *m*/*z*: 364 [M_2 for ^{32}S] and 182 [M for ^{32}S]. – EPR (in toluene): g = 2.014, A = 0.52 mT (five lines with relative intensity 1:2:3:2:1).

[4-(3′-NC_5H_4)CN_2S_2] L^2: The compound was prepared as described for L^1. $LiN(SiMe_3)_2$ (2.7 g, 164 mmol), 3-cyanopyridine (17.4 g, 164 mmol), $SiMe_3Cl$ (17.8 g, 164 mmol), sulfur dichloride (51.7 g, 492 mmol), and triphenylantimony (29.2 g, 82 mmol) were used. A dark red powder was obtained after sublimation (100°C/0.03 Torr). Yield: 14.9 g, 50%; m. p. 215–217°C (dec.). – $C_6H_4N_3S_2 \cdot 0.25\ H_2O$ (186.74): calcd. C 38.6, H 2.4, N 22.5, S 34.3; found C 38.4, H 2.4, N 21.9, S 33.7. – IR (cm^{-1}, KBr): $\tilde{\nu}$ = 3608 w, 3423 m, 3067 m, 3038 m, 2964 w, 1686 m, 1589 m, 1480 w, 1429 m, 1375 vs, 1325 m, 1244 m, 1189 m, 1146 m, 1116 w, 1091 w, 1040 m, 1026 s, 905 w, 834 m, 809 vs, 782 vs, 698 vs, 667 s, 627 m, 511 m, 459 m. – LRMS (EI mode); *m*/*z*: 364 [M_2 for ^{32}S] and 182 [M for ^{32}S]. – EPR (in toluene): g = 2.013, A = 0.51 mT (five lines with relative intensity 1:2:3:2:1).

***fac*-$MnBr(CO)_3(L^1)_2$ (2a):** $Mn(CO)_5Br$ (0.58 g, 2.1 mmol) and L^1 (0.19 g, 1.04 mmol) were stirred in tetrahydrofuran (20 mL) at 55°C for 4 h to yield a reddish-brown solution and a small amount of yellow precipitate. After cooling to room temperature, the solution was filtered. The red-brown filtrate was cooled to –5°C to give tiny reddish-brown needle crystals, which were filtered and dried in vacuo. Yield: 0.18 g, 56%; m. p. 167–169°C (dec.). – $C_{15}H_8BrMnN_6O_3S_4 \cdot 2.5\ H_2O$ (628.37): calcd. X-ray Crystallography: Suitable crystals of **3a**, **5a**, and **5b** were mounted and sealed in Lindemann capillaries. All pertinent crystallographic data and other experimental details are summarised in Table 2. Intensity data of **3a** and **5b** were collected with a Rigaku AFC7R diffractometer, and that for **5a** with an MAR research image plate scanner using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) at room temperature. All intensity data were corrected for Lorentz polarisation effects. Empirical absorption corrections based on the ψ-scan method were employed for **3a** and **5b**, whereas an approximation of absorption corrections by inter-image scaling was applied for **5a**. For **5a**, 60 3° frames with an exposure time of 5 min per frame were used. The structures were solved by a combination of direct methods (SIR 92) [23] and Fourier difference techniques, and refined by full-matrix least-squares analysis on *F* until convergence was reached. However, in compound **3a**, attempts to refine all non-hydrogen atoms anisotropically gave unreasonably high displacement parameters for the atoms. Therefore, only the heavy atoms (Pd, S, and P) were included in subsequent refinement cycles. The atoms of the ether solvent molecule in **3a** were fixed throughout in the refinement processes. Hydrogen atoms on the organic moieties were generated at their ideal positions (C–H 0.95 Å) and allowed to ride on their respective parent carbon atoms. All calculations were performed with a Silicon-Graphics computer using the program package TEXSAN.[24] Crystallographic data (excluding structure factors) for the structure(s) reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-135684 to -135686. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: int. code + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Fixation of Carbon Dioxide by Oxalic Amidinato Magnesium Complexes: Structures and Reactions of Trimetallic Magnesium Carbamato and Related Complexes

Mario Ruben,[c] Dirk Walther,*[a] René Knake,[a] Helmar Görls,[a] and Rainer Beckert[b]

Dedicated to Professor Heinrich Vahrenkamp on the occasion of his 60th birthday

Keywords: Carbon dioxide fixation / Magnesium / N ligands / C–C coupling

The reaction of oxalic amidines R^1–N=C(NHR^2)–C(NHR^2)=N–R^1 with CH_3MgX followed by uptake of CO_2 results in the formation of the trimeric carbamato complexes [R^1–N=C(NR^2–COO)–C(NR^{2}COO)=N–R^1]$_3$Mg$_3$(THF)$_6$ (**2a**: R^1 = R^2 = Ph; **2b**: R^1 = R^2 = *p*-tolyl) as the thermodynamically stable final products of the reaction. Their X-ray crystal structures show that the three metal centres are in a linear arrangement. The central magnesium ion is octahedrally surrounded by six O-donor atoms of the μ_2-carbamato bridges, while both peripheral magnesium ions are facially coordinated by three O-donor atoms of the carbamato groups and three THF molecules. This coordination sphere can be considered as a structural model for the active centre in the ribulose-1,5-bisphosphate carboxylase/oxygenase enzyme. Compound **2a** reacts with $ZnCl_2$ or $CoBr_2$, with CO_2 elimination, to form dimeric complexes of the type [X$_2$M(oxalamidinato)MX$_2$][Mg(DMF)$_6$] (M = Zn, Co; X = Cl, Br). X-ray crystal structure analyses show that the d-metals are tetrahedrally coordinated. The magnesium-bromide-containing intermediates in the formation of **2a** and **2b** are able to transfer CO_2 to acetophenone, thus simulating the CO_2 activation step in enzymatic biotin-dependent carboxylation reactions.

Introduction

Biological transformation reactions of carbon dioxide into organic material by C–C linkage are either activated by biotin-depending enzymes (Acetyl CoA carboxylase) in the fatty acids synthesis, or catalysed by Rubisco in the dark reaction of natural photosynthesis. In both enzymes carbamato magnesium complexes seems to play an essential role. In biotin-containing systems the carbamato magnesium complexes are carriers of "active CO_2" which can be transferred to C–H bonds to form the C–COOH group. However, neither the structure of the carbamato complex nor the mechanism of the CO_2 activation reaction have yet been established.[1–8]

In contrast, in Rubisco the carbamato group does not act as a CO_2 source, but is proposed to serve as proton relay which abstracts the C3 proton from ribulose-1,5-bisphosphate. The resulting enol reacts with carbon dioxide in the coordination sphere of the magnesium centre to form a new C–C bond (for reviews see refs.[9–11]). The structure of various forms of Rubisco have been elucidated by X-ray crystallography.[9] In the substrate-free complex the Mg^{II} centre is octahedrally surrounded by a monodentate carbamato group, two carboxylato ligands and three water molecules.[12]

It is noteworthy that, so far, the chemistry of abiotic carbamato magnesium complexes is poorly developed, especially with respect to the understanding of their reactivity as CO_2-transfer reagents.[13–19] Furthermore, structurally elucidated complexes which might act as structural or functional models for the above-mentioned enzymes are very rare. Only one organometallic mixed Al–Mg alkyl compound has been structurally characterised.[20a] Recently the X-ray structure of an oligomer consisting of six diethylcarbamato–Mg units has also been reported.[20b]

We describe here the synthesis, structure, and reactivity of a variety of new magnesium carbamato complexes which may act as models for the above-mentioned CO_2-transforming systems. The complexes were synthesised from magnesium oxalic amidinates or from the di(isopropyl)amido magnesium complex and carbon dioxide.

Results and Discussion

Synthesis and Structure of Carbamato Mg Complexes

The reaction of tetraphenyloxalic amidine **H_2A** (2.56 mmol, Figure 1) with two equivalents of CH_3MgBr in 50 mL of THF resulted in the deprotonation of the ligand and formation of methane. Subsequent reaction with CO_2 at –20 °C afforded a white precipitate (**1a**, 60%). According to the elemental analyses it was contaminated with ca. 10% of complex **2a** which was formed by elimination of $MgBr_2$

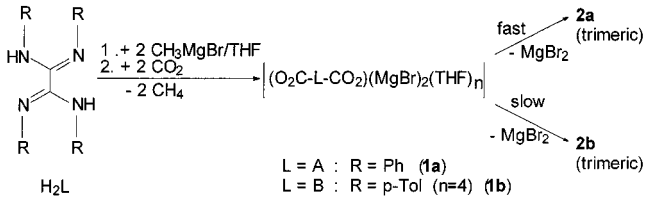

Figure 1. Pathway of the formation of **2a** and **2b**

from **1a**. Colourless crystals of pure **2a** could be obtained from the filtrate in 30% yield.

When the synthesis was carried out in dilute solution (90 mL of THF) only pure **2a** was isolated in 80% yield. In contrast, the product of the analogous reaction with tetra-*p*-tolyloxalic amidine was analytically pure **1b** (Figure 1).

The IR spectrum of **2a** exhibits two bands in the region of the C=O and C=N valence frequencies at 1630 (less intense) and 1656 cm^{-1} (more intense). This suggests that both C=N and carbamato groups are present in the molecule.

Elemental analysis of **2a** showed that there was no bromide in the CO_2 insertion product and pointed to the analytical composition of $[Mg(CO_2)_2(\mathbf{A})(THF)_2]_n$. A spectroscopically identical product was obtained by using dried air for the CO_2 insertion.

Single crystals of **2a** were grown from a dilute THF solution. The X-ray crystal structure revealed a trimeric structure of the product in which three magnesium centres are connected by six μ_2-carbamato bridges according to the above-mentioned analytical composition $[Mg(CO_2)_2(\mathbf{A})(THF)_2]_3$. Figure 2 shows the molecular structure of the

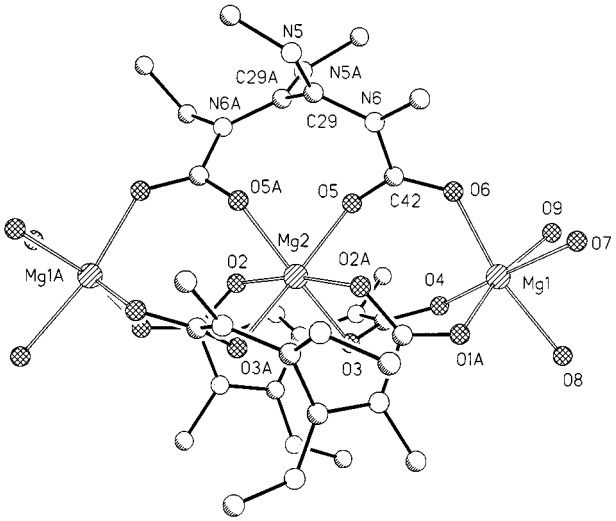

Figure 2. View of the inner sphere of complex **2a** with selected bond lengths [Å] and bond angles [°]: Mg1–O1A 2.021(6), Mg1–O4 2.026(5), Mg1–O6 2.016(6), Mg1–O7 2.169(6), Mg1–O8 2.144(6), Mg1–O9 2.110(7), Mg2–O2 2.075(4), Mg2–O3 2.089(6), Mg2–O5 2.076(6), C42–O5 1.239(8), C42–O6 1.263(9), N6–C29 1.377(10), N6–C42 1.420(10), N5–C29 1.271(10), C29–C29A 1.54(2); O1A–Mg1–O4 97.0(2), O1A–Mg1–O6 98.7(3), O1A–Mg1–O7 89.5(2), O1A–Mg1–O8 85.7(3), O1A–Mg1–O9 168.4(3), O2–Mg2–O2A 170.6(3), O2–Mg2–O3 84.9(2), O2–Mg2–O3A 88.8(2), O2–Mg2–O5 96.3(2), O2–Mg2–O5A 90.6(2), O5–C42–O6 127.6(7), N5–C29–N6 120.3(7); symmetry transformation used to generate equivalent atoms A: $-x - 1, -y, z$

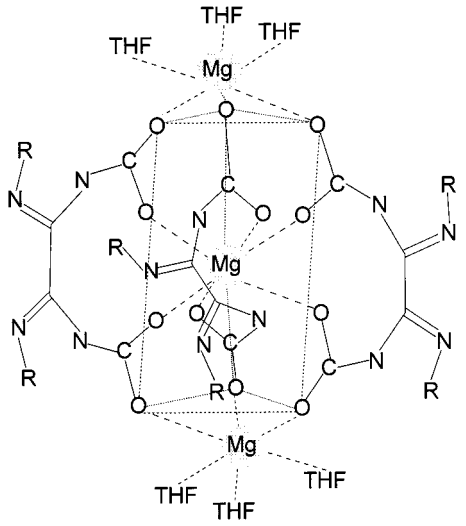

Figure 3. Coordination of the three carbamato strains in **2a** around the Mg centres

molecule and Figure 3 the inner part of **2a**. Relevant bond lengths and angles are also summarised in Figure 2.

The shape of the molecule resembles a straight prism (h = 6.4 Å) with two eclipsed (by 17°) triangles (3 × 3 × 3 Å) (Figure 3). The three magnesium atoms are exactly linear (the Mg–Mg–Mg angle is 180°) and lie within a distance of d_{Mg} = 4.211(6) Å. The central magnesium ion is surrounded by six O-donor atoms of the μ_2-carbamato bridges in an octahedral fashion, while the two peripheral magnesium ions are facially coordinated by three O-donor atoms of the carbamato groups and three THF molecules. The six negatively charged carbamato groups in **2a** have almost identical C–O distances [1.25(1) Å] and O–C–O angles [127.0(4) –127.6(4)°]. Three strongly twisted oxalamidine groups are located above the edges of the prism, with the 1,2-diimine units directed outwards, with a torsion angle for the N=C–C=N groups of 122.3°.

Thus, the molecule exhibits three soft Lewis base centres (the uncoordinated 1,2-diimine units) above the edges of the prism and two (potentially hard) Lewis centres (the peripheral magnesium atoms) above the basic triangles of the same prism. Because of the energetically unfavourable "hard-soft" combination the Lewis acid and base centres do not proceed to polymers. However, the free 1,2-diimine units can react with further metal centres (vide infra).

The ^{13}C-NMR spectrum of **2a** in [D$_6$]DMSO has only twelve resonances which correspond to the carboxylated oxalic amidinato ligands. The very strong carbamate signal appears at δ = 159.5 and the signals for THF at δ = 67.9 and 26.3. This simple pattern clearly shows that the highly symmetrical trimeric structure found by X-ray diffraction remains intact in solution.

The coordination of the peripheral magnesium atoms resembles the coordination of the magnesium ion in the substrate-free Rubisco enzyme[4] in which the magnesium centre also has an octahedral environment formed by three facially coordinated COO groups (one from a carbamato ligand and two from carboxylato groups) and three coord-

inated solvent molecules (water). However, the Mg–O(carbamato) distances in **2a** [d_{Mg-O} = 2.016(6)–2.169(6) Å] are significantly shorter than in the enzyme crystal (d_{Mg-O} = 2.31 Å).

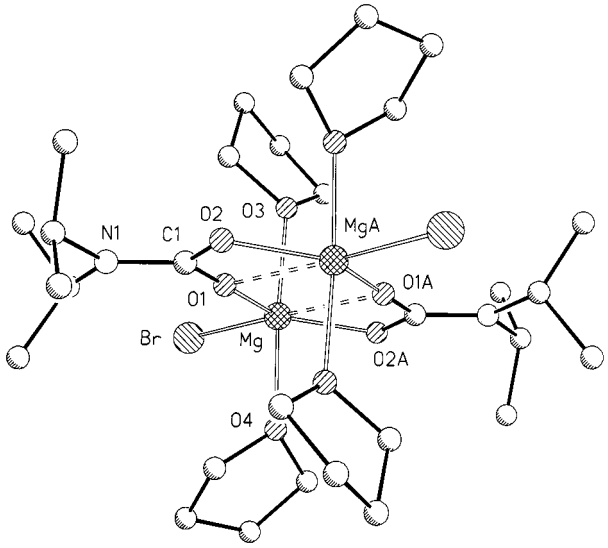
In contrast to the above-described reaction with tetraphenyloxalic amidine, the reaction of tetra-*p*-tolyloxalic amidine **H_2B** with CH_3MgBr, followed by treatment with carbon dioxide, resulted in the pure bromo magnesium complex **1b** with the analytical composition $[(MgBr)_2(CO_2)_2$-(**B**)$(THF)_4]_n$ which was isolated as a microcrystalline solid. In this reaction the subsequent elimination of $MgBr_2$ proceeded very slowly (Figure 1). Nevertheless, some crystals of bromide-free carbamato complex **2b** could be obtained from the reaction mixture after some weeks. Compound **2b** was found to be isostructural with **2a** by an X-ray structural analysis.

The ^{13}C-NMR investigations of **1b** pointed to a molecule with only low symmetry; the signal of the carbamato group was found at δ = 161.7. The IR spectrum showed a strong band at 1639 cm^{-1} which may be assigned to the carbonyl group of the carbamato ligand. Since single crystals of **1b** could not be isolated, the structure of this compound remains unknown.

To gain further insight into the coordination sphere in MgBr-containing carbamato complexes, we have also synthesised complex **3** by deprotonation of $(isopropyl)_2NH$ with one equivalent MeMgBr and subsequent reaction with CO_2 to form a white, crystalline product with the analytical composition $[(iPr)_2–N–CO_2–MgBr(THF)_2]_2$ in high yield (95%) (Equation 1).

$$\begin{aligned} &2\,(i\mathrm{Pr})_2\mathrm{NH} + 2\,\mathrm{CH_3MgBr} + n\,\mathrm{THF} \rightarrow \\ &2\,(i\mathrm{Pr})_2\mathrm{N–MgBr(THF)_n} + 2\,\mathrm{CH_4} \\ &2\,(i\mathrm{Pr})_2\mathrm{N–MgBr(THF)}_n + 2\,\mathrm{CO_2} \rightarrow \\ &[(i\mathrm{Pr})_2\mathrm{N–CO_2)(MgBr(THF)_2]_2} + n - 2\,\mathrm{THF} \end{aligned} \quad (1)$$

The ^{1}H-NMR spectrum of **3** ([D_6]DMSO, 20 °C) shows only the resonances for the protons of the isopropyl group (δ = 1.17, 1.20, and 3.28) and the protons of THF (δ = 1.73, 3.57). However, no signal for the N–H proton was found. Furthermore, the ^{13}C-NMR spectrum exhibits only one, weak carbamate signal at δ = 166.39 in [D_7]DMF. In addition, the IR spectrum showed no band for the N–H stretching frequency in the 3300 cm^{-1} region. An X-ray crystal structure determination showed the dimeric structure of **3**, which is shown in Figure 4 along with relevant bond lengths and angles. The coordination sphere around the magnesium ions consists of three oxygen donor atoms of the bridging carbamato groups, two axially coordinated THF molecules and one monodentate bromide anion, and can be described as a distorted octahedron. Two of the carbamato oxygens are bonded at a distance of 1.963(2) Å, while the third one is more weakly bound with a bond length of 2.358(2) Å. Both carbamato groups act as tridentate bridging ligands and form, together with the two Mg ions, a planar eight-membered ring with a Mg–Mg distance of 3.277(2) Å.



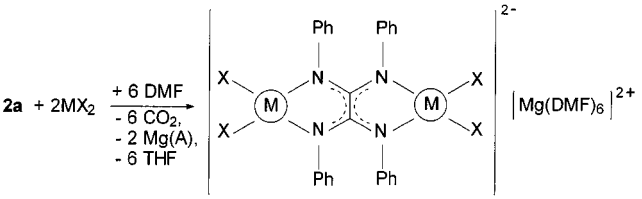


Figure 4. Molecular structure of the dimeric complex **3** with selected bond lengths [Å] and bond angles [°]: Mg–Br 2.572(1), Mg–O1 1.963(2), Mg–O2A 2.042(2), Mg–O1A 2.358(2), Mg–O3 2.117(2), Mg–O4 2.119(2), C1–O1 1.286(3), C1–O2 1.262(4), C1–N1 1.348(4); Br–Mg–O1 108.88(7), Br–Mg–O1A 168.95(7), Br–Mg–O2A 110.06(7), Br–Mg–O3 89.92(7), Br–Mg–O4 91.49(7), O1–C1–O2 118.8(3), N1–C1–O1 120.5(3), N1–C1–O2 120.7(3); symmetry transformation used to generate equivalent atoms A: $-x + 2, -y + 2, -z + 2$

Reactions of the Carbamato Complexes With Metal Halides

The reaction of **2a** with $ZnCl_2$ in DMF gave the yellow, sparingly soluble complex $[Cl_2Zn(A)ZnCl_2][Mg(DMF)_6]$ (**4**) in 80% yield (with respect to $ZnCl_2$) even when the starting materials were reacted in the molar ratio 1:1. Using an excess of $ZnCl_2$ (6:1) resulted in higher yields of **4** (Figure 5)

4 : M = Zn, X = Cl
5 : M = Co, X = Br

Figure 5. Formation reaction of the dimeric complexes **4** and **5**

An X-ray crystal structure determination (Figure 6) and FAB-MS showed a complex anion with two tetrahedrally coordinated zinc ions bridged by the deprotonated oxalamidine ligand. The electrostatic charge is counterbalanced by a magnesium ion which is surrounded by six DMF molecules. No CO_2 is present in the complex. This structure seems to indicate that coordination of metal fragments at the peripheral 1,2-diimine units of the trimeric complex **2a** causes steric strain in the inner part of the trimer leading to a complete rearrangement of the molecule with elimination of CO_2 and formation of the dimer **4**.

The same reaction was observed when $CoBr_2$ was treated with **2a** (Figure 5). Single crystals of the resulting green Co complex **5** were obtained from THF. According to the X-

ray structural analysis, compound **5** exhibits the same dimeric structure as found for the Zn complex **4**. The bond lengths and angles in the bridging oxalic amidinate, and between the tetrahedral Co^{II} centres and the nitrogen donor atoms, are also similar (Figure 7).

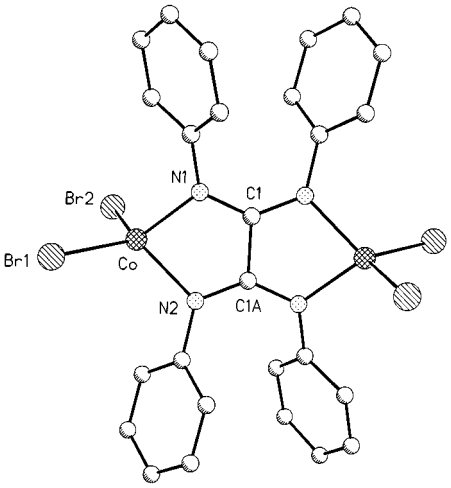

Figure 7. Molecular structure of **5** with selected bond lengths [Å] and bond angles [°] (the cation $[Mg(DMF)_6]^{2+}$ is omitted for clarity): Co–Br1 2.375(1), Co–Br2 2.375(1), Co–N1 1.986(6), Co–N2 1.999(6), N1–C1 1.340(9), N2–C1A 1.328(9), C1–C1A 1.555(13); Br1–Co–Br2 112.30(6), Br1–Co–N1 115.6(1), Br1–Co–N2 115.0(1), N1–C1–N2A 132.7(6), N1–C1–C1A 113.2(8); symmetry transformation used to generate equivalent atoms A: $-x + 1$, $-y + 1$, $-z + 2$

Carboxylation of Acetophenone

Acetophenone was used as the substrate for CO_2 transfer reactions because it contains the CH_3CO–R group which is carboxylated in biotion-dependent reactions as well. The reaction of acetophenone with the carbamato complexes **1b** or **1a** (contaminated with ca. 10% of the inactive trimer **2a**) either in THF at 70 °C or in DMF at room temperature, followed by hydrolysis, resulted in the formation of the carboxylation product benzoylic acid. The free carboxylic acid could either be determined by NMR spectroscopy or by HPLC determination. Although the yields of this C–C-linkage reaction were low (10%), the reaction may be considered as a model step for the CO_2 transfer reaction of carboxybiotin in biological reactions which proceed with acetylCoA to form the carboxylated product HOOC–CH_2–CO–CoA. In contrast, **2a**, **2b**, and **3** do not contain "activated" CO_2. This suggests that the coordination environment of the metal centre essentially influences the reactivity of the carbamato–Mg group.

Conclusions

In the present paper we have shown that carbamato magnesium complexes can be synthesised by treating oxalic amidines or di(isopropyl)amine with CH_3MgBr, followed by uptake of CO_2. The complexes **2a**, **2b**, and **3** represent structurally elucidated carbamato magnesium complexes which are of interest with respect to the magnesium containing active centres of biotin-dependent enzymes and Rubisco. The reaction of $ZnCl_2$ or $CoBr_2$ with the free diimine groups of **2a** results in the complete elimination of CO_2 and a rearrangement of the system to form the dinuclear complexes **4** and **5**.

Whereas **2a**, **2b**, and **3** are not able to transfer CO_2 to compounds with C–H-acidic bonds, both the carbamato complexes **1b** and **1a** (containing ca. 10% of the inactive trimer **2a**) react with acetophenone to form benzoylic acid upon hydrolysis, simulating the C–C linking step in biotin-dependent CO_2 transfer reactions.

Experimental Section

General: The oxalic amidine ligands were prepared according to literature procedures.[21] CH_3MgBr and CH_3MgCl (3 M in diethyl ether), purchased from Aldrich, and pure CO_2 (4.8) from Linde AG, were used without additional purification.

All reactions were carried out under argon with standard Schlenk techniques and all solvents dried and distilled before use.

^{1}H-NMR spectra were obtained with a Bruker AC 200 MHz spectrometer and all spectra were referenced to TMS or deuterated solvent as an internal standard. FAB mass spectra were obtained with a Finnigan MAT SSQ 710 spectrometer (2,4-dimethoxybenzyl alcohol as matrix). IR measurements were carried out with a Perkin–Elmer System 2000 FT-IR. Analytical HPLC experiments were carried out using a water HPLC system, consisting of a Knauer HPLC pump 64, a Rheodyne 7125 5 μL injector loop, a Merck Li Chrophor RP 18 (5μm) column and a Knauer variable wavelength detector at $\lambda = 295$ nm. The system was controlled by Knauer HPLC 2.21a software. The mobile phase used was 50:50 CH_3CN/H_2O containing 0.01 M KH_2PO_4 and adjusted to pH = 2. Elemental analyses were carried out at the Microanalytical Laboratory of the Friedrich Schiller University, Jena. Metals were determined by complexometric titration of an aqueous solution, obtained by reaction of the complex with dilute H_2SO_4, followed by extraction

of the organic products with diethyl ether and subsequent addition of ammonia. Halogen was determined by titration with silver nitrate.

$[Mg(CO_2)_2(A)(THF)_2]_3$ (2a): One equivalent (per N–H group) of CH_3MgBr (3 M in diethyl ether) was added slowly to a stirred solution of ligand H_2A (1 g, 2.56 mmol) in 50 mL of anhydrous THF until the gas evolution was finished. Then the yellowish solution was cooled to –20 °C and CO_2 was bubbled through the solution for some minutes. The resulting solution was shaken at room temperature for 1 h. After 24 h, a white precipitate of product **1a** (containing ca. 10% **2a** as calculated from the elemental analysis) was isolated by filtration, washed three times with diethyl ether and subsequently dried in vacuo. Yield: 60%. Additionally, pure complex **2a** crystallised from the mother liquor after standing overnight. Yield: 30% of pure **2a**.

When the reaction was carried out in 90 mL of THF as solvent and a CH_3MgBr solution in toluene was used, only pure crystalline **2a** was isolated in 80% yield.

Single crystals of **2a** were obtained by reducing the remaining THF solution to half volume and allowing to crystallise at room temperature, or by recrystallisation of the isolated crude product **1a** from THF. Longer reaction times and higher temperatures resulted in the formation of **2a** in higher yields by accomplished $MgBr_2$ extrusion.

2a: $C_{108}H_{108}Mg_3N_{12}O_{18}$ (1935.03): calcd. C 67.0, H 5.6, Mg 3.8, N 8.7; found C 66.3, H 5.8, Mg 3.7, N 8.7. – ^{1}H NMR ([D$_6$]DMSO, 20 °C): δ = 6.63–7.28 (m, arom.). – ^{13}C NMR ([D$_6$]DMSO, 20 °C): δ = 25.2, 67.1 (THF), 120.4, 121.6, 122.0, 124.4, 127.2, 128.2, (arom., phenyl), 143.3 (*ipso*-C-amine), 149.3 (N=C–N), 150.4 (*ipso*-C-imine), 159.5 (carbamate). – IR (nujol): $\tilde{\nu}$ = 1592 (C=C_{arom}), 1630, 1656, (N–COO, C=N) cm^{-1}.

$[Mg_2Br_2(CO_2)_2(B)(THF)_4]_n$ (1b): The reaction was carried out as described above for **2a**. The main product in this reaction was **1b**. Yield 92%. – $C_{48}H_{60}Br_2Mg_2N_4O_8$ (1029.5): calcd. C 56.0, H 5.9, Br 15.4, Mg 4,7, N 5.4; found C 55.0, H 6.1, Br 14.1, Mg 4.5, N 5.3. – ^{1}H NMR ([D$_6$]DMSO, 20 °C): δ = 1.73 (dd, 16 H, CH_2), 2.13, 2.26 (2 × s, 12 H, CH_3), 3.57 (dd, 16 H, CH_2), 7.27–6.62 (m, 20 H, arom.). – ^{13}C NMR ([D$_6$]DMSO, 20 °C): δ = 20.8, 20.9, (CH_3), 25.2, 67.0 (CH_2, THF), 120.0, 121.7, 122.3, 128.8, 129.2, 130.8, 131.7, 134.9 (arom. tolyl), 141.6 (*ipso*-C-amine), 148.1 (N=C–N), 151.0 (*ipso*-C-imine), 161.7 (carbamate). – IR (Nujol): $\tilde{\nu}$ = 1592 (C=C_{arom}), 1630, 1639 (N–COO, C=N) cm^{-1}.

Single crystals of **2b** were isolated from the mother liquor after storage at –20 °C for some weeks. Yield: 5%. Characterization by X-ray analysis.

$[(iPr)_2NCO_2MgBr(THF)_2]_2$ (3): The reaction was analogously carried out as described for **2a.** Yield 95%. – $C_{30}H_{60}Br_2Mg_2N_2O_8$ (785.2): calcd. C 45.9, H 7.7, Br 20.4, N 3.6; found: C 44.6, H 8.2, Br 24.1, N 3.6. – ^{1}H NMR ([D$_6$]DMSO, 20 °C): δ = 1.17 (s, 6 H, CH_3), 1.20 (s, 6 H, CH_3), 1.73 (dd, 8 H, CH_2, THF), 3.28 (m, 2 H, CH), 3.57 (dd, 8 H, O–CH_2, THF). – ^{13}C NMR ([D$_6$]DMSO, 20 °C): δ = 19.9 (CH_3), 28.8 (CH_2, THF), 34.2 (C–H), 67.8 (O–CH_2, THF), 166.3 (carbamate). – IR (Nujol): $\tilde{\nu}$ = 1578 cm^{-1} (carbamate).

$[Mg(DMF)_6][Zn_2(A)Cl_4]$ (4): Compound **2a** (100 mg, 5.2·10^{-5} mol) was dissolved in 1 mL of anhydrous DMF and $ZnCl_2$ (42 mg, 31.2·10^{-5} mol), dissolved in 1 mL of DMF, was added. After a few minutes of stirring, a yellow solid precipitated. The solid was filtered off, washed with THF and dried in vacuo. Single crystals were grown from the mother liquor at room temperature. Yield: 152 mg (87%). – $C_{44}H_{62}Cl_2MgN_{10}O_6Zn_2$ (1123.9): calcd. C 47.0, H 5.5, Cl 12.6, N 12.5; found C 42.7, H 5.1, Cl 12.6, N 11.2. – ^{1}H NMR ([D$_6$]DMSO, 20 °C) δ = 2.72 (s, CH_3, 18 H, DMF), 2.88 (s, CH_3, 18 H, DMF), 6.55–6.82 (m, 20 H, arom.), 7.94 (s, 6 H, CH, DMF). – IR (nujol): $\tilde{\nu}$ = 1591 (C=C_{arom}), 1659 (C=O, DMF) cm^{-1}. – FAB-MS [DMBA]: *m*/*z* = 945 [M$^+$ – 2 DMF – Cl + 2 H], 622 [M$^+$ – 6 DMF – Mg – Cl + 2 H].

$[Mg(DMF)_6][Co_2(A)Br_4]$ (5): This compound was prepared in a similar manner to **4**. Single crystals of the green compound were grown from a solution of the redissolved product in DMF at –20 °C. IR (nujol): $\tilde{\nu}$ = 1659 (C=O, DMF), 1591 (C=C_{arom}) cm^{-1}. – FAB-MS [DMBA]: *m*/*z* = 1288 [M$^+$], 838 [M$^+$ – 2 DMF – Cl + 2 H – 2 DMF + 2 H$^+$], 602 [**A**CoBr(DMF) + 2 H$^+$], 528 [**A**CoBr + 2 H$^+$].

Carboxylation of Acetophenone: Compound **1b** (1.35 mol), dissolved in 70 mL, of anhydrous DMF was treated with 1.2 mL of acetophenone and the resulting solution was stirred for 12 h at room temperature. The resulting benzoyl acetic acid was determined either by aqueous work up or by HPLC.

By Wet Workup: After removal of the DMF in vacuo, the remaining residue was hydrolysed with 50 mL of 25% HCl and the water phase extracted three times with diethyl ether. The organic phase was washed with a 10% solution of Na_2CO_3 and the separated water phase was acidified carefully until pH = 5 and subsequently extracted with diethyl ether. The diethyl ether phase was dried with solid Na_2SO_4 and the solvent removed in vacuo to give benzoyl acetic acid as a white solid. Yield 5–10%. – ^{1}H NMR ([D$_6$]acetone, 20 °C): δ = 4.02 (–CH_2–).

By HPLC: Benzoyl acetic acid was determined by comparison with an authentic sample of benzoylic acid. Yield: 6–10%.

The reaction product **1a/2a** (90:10) reacts analogously to form 6–10% benzoylic acid.

Crystal Structure Determinations: The intensity data for the compounds **2a** and **3** were collected with a Nonius CAD4 diffractometer and for the other compounds with a Nonius Kappa CCD diffractometer, using graphite-monochromated Mo-K_α radiation. Data were corrected for Lorentz and polarization effects. Only the compounds **3** and **5** were corrected for absorption effects.[22,23]

The structures were solved by direct methods (SHELXS[24]) and refined by full-matrix least-squares techniques against F_o^2 (SHELXL-97[25]). For compound **4** the hydrogen atoms were located by difference Fourier synthesis and refined isotropically; the hydrogen atoms of the other compounds were included at calculated positions with fixed thermal parameters. All non-hydrogen atoms were refined anisotropically.[25] XP (SIEMENS Analytical X-ray Instruments, Inc.) was used for structure representations.

Crystal Data for 2a:[26] $C_{108}H_{108}Mg_3N_{12}O_{18} \cdot 1.5\,C_4H_8O$, M_r = 2043.15 gmol^{-1}, colourless prism, size 0.40 × 0.38 × 0.36 mm, orthorhombic, space group *Aba*2, crystal is a racemic twin, *a* = 17.978(2), *b* = 23.753(3), *c* = 28.248(3) Å, *V* = 12063 (1) Å^3, *T* = –90 °C, *Z* = 4, $\rho_{calcd.}$ = 1.125 gcm^{-3}, μ (Mo-K_α) = 0.91 cm^{-1}, *F*(000) = 4320, 6269 reflections in *h*(0/22), *k*(0/29), *l*(0/35), measured in the range 2.27° ≤ Θ ≤ 26.33°, 6269 independent reflections, 3659 reflections with $F_o > 4\,\sigma(F_o)$, 620 parameters, 1 restraint, $R1_{obs}$ = 0.086, $wR2_{obs}$ = 0.218, $R1_{all}$ = 0.177, $wR2_{all}$ = 0.274,

GOOF = 1.765, largest difference peak and hole: 0.862/–0.332 e Å^{-3}.

Crystal Data for 2b: $C_{146}H_{180}Mg_3N_{12}O_{24}$, M_r = 2559.95 gmol^{-1}, colourless prism, size 0.40 × 0.35 × 0.30 mm, monoclinic, space group $P2_1/c$, a = 24.085(2), b = 18.1640(10), c = 30.297(3) Å, β = 91.274(4) °, V = 13251.1(19) Å^3, T = –90 °C, Z = 4, $\rho_{calcd.}$ = 1.283 gcm^{-3}, μ (Mo-K_α) = 1 cm^{-1}, F(000) = 5472, 30541 reflections in h(–25/25), k(0/20), l(–30/32), measured in the range 2.44° ≤ Θ ≤ 23.28°, completeness Θ_{max} = 97.2%, 17884 independent reflections, R_{int} = 0.099, 10749 reflections with $F_o > 4\,\sigma(F_o)$, 1438 parameters, 0 restraints, $R1_{obs}$ = 0.225, wR^2_{obs} = 0.542, $R1_{all}$ = 0.281, wR^2_{all} = 0.580, GOOF = 1.255, largest difference peak and hole: 1.063/–0.694 e Å^{-3}.

Crystal Data for 3:[26] $C_{30}H_{60}Br_2Mg_2N_2O_8$, M_r = 785.24 gmol^{-1}, colourless prism, size 0.40 × 0.35 × 0.35 mm, monoclinic, space group $P2_1/n$, a = 11.062(3), b = 11.743(2), c = 15.184(3) Å, β = 101.38(2)°, V = 1933.6(7) Å^3, T = –90 °C, Z = 2, $\rho_{calcd.}$ = 1.349 gcm^{-3}, μ (Mo-K_α) = 21.73 cm^{-1}, ψ scan, $trans_{min.}$: 0.117, $trans_{max.}$: 0.279, F(000) = 824, 3762 reflections in h(0/13), k(–14/0), l(–18/17), measured in the range 2.21° ≤ Θ ≤ 26.30°, 3579 independent reflections, R_{int} = 0.028, 2440 reflections with $F_o > 4\,\sigma(F_o)$, 319 parameters, 0 restraints, $R1_{obs}$ = 0.035, wR^2_{obs} = 0.075, $R1_{all}$ = 0.084, wR^2_{all} = 0.091, GOOF = 1.080, largest difference peak and hole: 0.305/–0.504 e Å^{-3}.

Crystal Data for 4:[26] $[C_{18}H_{42}MgN_6O_6]^+[C_{26}H_{20}Cl_4N_4Zn_2]^-$, M_r = 1123.9 gmol^{-1}, colourless prism, size 0.32 × 0.30 × 0.28 mm, triclinic, space group P–1, a = 9.6879(4), b = 10.9384(4), c = 13.9082(4) Å, α = 78.401(2), β = 71.791(2), γ = 78.934(2) °, V = 1358.19(8) Å^3, T = –90 °C, Z = 1, $\rho_{calcd.}$ = 1.367 gcm^{-3}, μ (Mo-K_α) = 11.43 cm^{-1}, F(000) = 578, 12317 reflections in h(0/12), k(–13/13), l(–16/17), measured in the range 3.12° ≤ Θ ≤ 26.35°, completeness Θ_{max} = 99.2%, 5496 independent reflections, R_{int} = 0.036, 4374 reflections with $F_o > 4\sigma(F_o)$, 304 parameters, 0 restraints, $R1_{obs}$ = 0.083, wR^2_{obs} = 0.210, $R1_{all}$ = 0.104, wR^2_{all} = 0.228, GOOF = 1.004, largest difference peak and hole: 1.419/–1.350 e Å^{-3}.

Crystal Data for 5:[26] $[C_{18}H_{42}MgN_6O_6]^+[C_{26}H_{20}Co_2Br_4N_4]^-$, M_r = 1282.80 gmol^{-1}, colourless prism, size 0.28 × 0.22 × 0.11 mm, triclinic, space group P–1, a = 9.8104(6), b = 11.0742(5), c = 14.0020(9) Å, α = 76.997(3), β = 71.602(2), γ = 78.400(3) °, V = 1392.46(14) Å^3, T = –90 °C, Z = 1, $\rho_{calcd.}$ = 1.530 gcm^{-3}, μ (Mo-K_α) = 35.27 cm^{-1}, semi-empirical, $trans_{min.}$: 0.432, $trans_{max.}$: 0.776, F(000) = 644, 9237 reflections in h(0/12), k(–13/13), l(–16/17), measured in the range 3.04° ≤ Θ ≤ 26.49°, completeness Θ_{max} = 98.5%, 5693 independent reflections, R_{int} = 0.085, 3271 reflections with $F_o > 4\sigma(F_o)$, 304 parameters, 0 restraints, $R1_{obs}$ = 0.078, wR^2_{obs} = 0.178, $R1_{all}$ = 0.1527, wR^2_{all} = 0.2164, GOOF = 0.986, largest difference peak and hole: 0.706/–1.020 e Å^{-3}.

Acknowledgments

Financial support for this work from the Deutsche Forschungsgemeinschaft (SFB 436), the VW-Stiftung and the Fonds der Chemischen Industrie is gratefully acknowledged. M. R. wishes to thank the Studienstiftung des Deutschen Volkes for a grant.

Organolanthanoids, 24[‡] Organoamido- and Aryloxo-Lanthanoids, 21[‡]

Syntheses and Structures of Bis(aryloxo)fluoroytterbium(III) Complexes, $[Yb(OAr)_2F(THF)]_2$ (OAr = OC_6H_2-2,6-*t*Bu_2-4-R; R = H, Me, *t*Bu), and Bis(cyclopentadienyl)fluoroytterbium(III) Complexes, $[YbCp_2F]_3$, $[Yb(MeCp)_2F]_4$, $[YbCp_2F(OPPh_3)]_2$, and $[Yb(MeCp)_2F(THF)]_2$

Glen B. Deacon,*[a] Gerd Meyer,[b] and Dirk Stellfeldt[b]

Dedicated to Prof. Dr. Othmar Stelzer on the occasion of his 60th birthday

Keywords: Lanthanide(III) / Ytterbium / Aryloxides / Fluorine / C–F Activation

Reaction of $[Yb(OAr)_2(THF)_3]$ (OAr = OC_6H_2-2,6-*t*Bu_2-4-R; R = H, Me, *t*Bu) with perfluorodecalin in THF at room temperature results in C–F activation and formation of the first heteroleptic aryloxofluorolanthanoid complexes, $[Yb(OAr)_2F(THF)]_2$. Oxidation of bis(cyclopentadienyl)ytterbium(II) with perfluoro(methylcyclohexane) or perfluorodecalin in DME surprisingly gives unsolvated $[YbCp_2F]_3$. The analogous reaction of bis(methylcyclopentadienyl)ytterbium(II) yields unsolvated $[Yb(MeCp)_2F]_4$, whilst in THF, the oxidation provides $[Yb(MeCp)_2F(THF)]_2$. Treatment of $[YbCp_2F(THF)]_2$ with triphenylphosphane oxide gives $[YbCp_2F(OPPh_3)]_2$. X-ray structure determinations revealed $[Yb(OAr)_2F(THF)]_2$ (R = H or *t*Bu) to be centrosymmetric fluoride-bridged dimers with five-coordination for ytterbium. Examination of the structures of the cyclopentadienyl complexes showed that $[YbCp_2F]_3$ is trimeric with formal eight-coordination for ytterbium and a planar $(YbF)_3$ ring, whereas $[Yb(MeCp)_2F]_4$ is an eight-coordinate tetramer having a puckered $(YbF)_4$ ring with F–Yb–F angles of ca. 90° and Yb–F–Yb angles close to 180° [178.9(4), 168.4(3)°]. Both $[Yb(MeCp)_2F(THF)]_2$ and $[YbCp_2F(OPPh_3)]_2$ are nine-coordinate fluoride-bridged dimers.

Introduction

Heteroleptic lanthanoid fluorides $[LnF_nL_{3-n}]$ [L = cyclopentadienyl (Cp), OAr, OR, NR_2 etc.] provide a synthetic challenge since the high stability of lanthanoid fluorides[3] may favour rearrangement into LnF_3 and LnL_3. {A tendency in this direction is shown by the isolation of the fluoride-rich, multiple-fluoride-bridged cage $[Yb_5(C_5Me_5)_6F_9]$ from the reaction of $[Yb(C_5Me_5)_2(OEt_2)]$ with C_9F_{18} in toluene.[3]} They are also of interest as potential olefin polymerisation catalysts, especially in view of the success of cyclopentadienylzirconium fluorides[4] in this role.[5] Complexes of this type are extremely rare,[6–14] there being no reported aryloxofluorolanthanoid complexes[9–12] and few examples of cyclopentadienylfluorolanthanoids.[3,6–8,12–21] We now report the syntheses and structures of the first aryloxofluorolanthanoid complexes, $[Yb(OAr)_2F(THF)]_2$ (OAr = OC_6H_2-2,6-*t*Bu_2-4-R; R = H, Me, *t*Bu), and some new bis(cyclopentadienyl)fluorolanthanoid(III) complexes, $[YbCp_2F]_3$, $[Yb(MeCp)_2F]_4$, and $[YbCp_2F(OPPh_3)]_2$, as well as a new synthesis and the structure of the previously reported,[3] but structurally uncharacterized, $[Yb(MeCp)_2F(THF)]_2$.

Results and Discussion

Syntheses

Reaction of the ytterbium(II) aryloxides $[Yb(OAr)_2(THF)_3]$ (OAr = OC_6H_2-2,6-*t*Bu_2-4-R; R = H, Me, *t*Bu) with perfluorodecalin gives the corresponding heteroleptic bis(aryloxo)fluorolanthanoid(III) complexes, shown (below) to be the dimers $[Yb(OAr)_2F(THF)]_2$.

$$2\,[Yb(OAr)_2(THF)_3] + C_{10}F_{18} \rightarrow [Yb(OAr)_2F(THF)]_2 + \text{unsaturated fluorocarbons} \quad (1)$$

Pefluorodecalin was recently introduced as an oxidant in lanthanoid chemistry in the synthesis of $[YbCp_2F(THF)]_2$.[21] This provided the first example of C–F activation of a saturated fluorocarbon by a lanthanoid complex. The compound has also been used to give Group 4 organometallic fluorides.[22]

The versatility of perfluorocycloalkanes in the preparation of heteroleptic lanthanoid fluorides is also illustrated

by syntheses of new bis(cyclopentadienyl)fluoroytterbium(III) complexes. Thus, reaction of $[YbCp_2(DME)]$ with perfluorodecalin or perfluoro(methylcyclohexane) in 1,2-dimethoxyethane surprisingly yields *unsolvated* bis(cyclopentadienyl)fluoroytterbium(III), shown to be trimeric (Equation 2).

$$3\ [YbCp_2(DME)] + C_{10}F_{18}\ (C_7F_{14}) \rightarrow [YbCp_2F]_3 + \text{unsaturated fluorocarbons} \quad (2)$$

This contrasts isolation of the solvated complex $[YbCp_2F(THF)]_2$ from the synthesis in tetrahydrofuran.[21] A similar reaction of $[Yb(MeCp)_2(THF)]$ with perfluorodecalin in DME also gives an *unsolvated* complex, revealed to be the novel and unexpected tetramer, $[Yb(MeCp)_2F]_4$, by X-ray crystallography.

$$4\ [Yb(MeCp)_2(THF)] + C_{10}F_{18} \rightarrow [Yb(MeCp)_2F]_4 + \text{unsaturated fluorocarbons} \quad (3)$$

The use of THF as a solvent for this reaction provides $Yb(MeCp)_2F(THF)$, which has been previously prepared by C–F activation of the more reactive perfluoro-2,3-dimethylpent-2-ene in THF.[3] These syntheses (1)–(3) establish oxidation of ytterbium(II) compounds by perfluorodecalin to be a general route to heteroleptic ytterbium(III) fluorides. However, perfluoro(methylcyclohexane) was an unsatisfactory oxidant for $[Yb(MeCp)_2(THF)]$ in THF [cf. $YbCp_2(DME)$[21]] and hence is a less widely applicable reagent. The low-moderate yields are probably due to incomplete deposition of the products, which have appreciable solubility in the reaction media, rather than competing reactions. Any LnF_3 formed by rearrangement (see Introduction) would have coprecipitated with the heteroleptic fluoro complexes, precluding the observed satisfactory analyses (below). In the present syntheses, the reduction products were not examined, but it has been shown that the oxidation of $[YbCp_2(DME)]$ by perfluoro(methylcyclohexane) yields perfluorotoluene and *p*-, *m*-, and *o*-$HC_6F_4CF_3$,[21] and that reduction of perfluorodecalin by low oxidation state group 4 metallocenes gives perfluoronaphthalene and specific hydropolyfluoronaphthalenes.[23]

The first complex of a bis(cyclopentadienyl)fluorolanthanoid with a ligand other than an ether has been obtained by displacement of coordinated THF by triphenylphosphane oxide.

$$[YbCp_2F(THF)]_2 + 2\ Ph_3PO \rightarrow [YbCp_2F(OPPh_3)]_2 + 2\ THF \quad (4)$$

It is of interest that this could be achieved without incurring rearrangement into the strongly-bonded phosphane oxide complex $[YbCp_3(OPPh_3)]$[1] and the highly stable[3] YbF_3.

Characterization

The composition of the complexes was established by lanthanoid metal and fluorine analyses. The latter were very valuable, particularly for the highly hydrolytically labile $[Yb(OAr)_2F(THF)]_2$ complexes, in view of the similarity in molecular weights between the fluoro and the corresponding hydroxo complexes. Further, the presence of fluorine in single crystals of $[Yb(OC_6H_2\text{-}2,4,6\text{-}t\text{Bu}_3)_2F(THF)]_2 \cdot 3\ THF$ was established by EDAX-measurements. The THF of solvation was lost on drying under vacuum in isolation of the bulk product. By contrast, for OAr = $OC_6H_3\text{-}2,6\text{-}t\text{Bu}_2$, both bulk product and single crystals have the same composition. The extreme sensitivity of $[Yb(OAr)_2F(THF)]_2$ compounds to hydrolysis was illustrated by the invariable observation of weak bands at ca. 3600 cm^{-1} in their infrared spectra, near to reported ν(OH) absorptions [3685, 3651m(sp)] of $[Yb(OC_6H_2\text{-}2,4,6\text{-}t\text{Bu}_3)_2(OH)(THF)]_2$,[24] and these bands intensified rapidly on brief deliberate exposure of the mulls/disk to the atmosphere. (The plate protected Nujol mulls or the KBr disks were briefly in air on transfer to the chamber of the IR spectrometer). Extreme sensitivity is not observed for the cyclopentadienylfluoroytterbium(III) complexes, which showed no analogous absorption in similarly recorded spectra. When solutions of the complexes were stored for several days to grow single crystals (see Experimental Section), there was no evidence of decomposition into LnF_3.

For the tetrahydrofuran complexes, absorption bands at 1050–1020 cm^{-1} and 880–860 cm^{-1} can be attributed to ring stretching modes of coordinated THF, shifted from the free ligand values (1070, 912 cm^{-1}) as expected on coordination[25] {e.g. compare $[Yb(MeCp)_2F(THF)]_2$ and $[Yb(MeCp)_2F]_4$; Experimental Section}, though phenolate absorption also occurs in the latter region.[26] By contrast the spectra of $[YbCp_2F]_3$ and $[Yb(MeCp)_2F]_4$, isolated from DME, do not show any absorption at 900–840 cm^{-1} corresponding to the intense absorption of free DME at 858 cm^{-1},[27] expected at higher energy on coordination.[28] In the spectrum of $[YbCp_2F(OPPh_3)]_2$, ν(PO) is observed at 1179 cm^{-1}, lowered from the free ligand value (1195 cm^{-1}) as expected on coordination.[29] The relatively small shift is consistent with observations for other $Ln(OPPh_3)$ complexes, which show a decrease in the shift of ν(PO) from La to Lu.[1,30]

Comparison of the far infrared spectra of $[Yb(OAr)_2F(THF)]_2$ and $[Yb(OAr)_2(THF)_3]$ complexes (Experimental section) suggests an intense ν(YbF) absorption is located at 390–375 cm^{-1} (Table 1) with the possibility of a second absorption (expected for a halogen-bridged dimeric structure[31]) near 300 cm^{-1} at least for OAr = $OC_6H_2\text{-}2,6\text{-}t\text{Bu}_2\text{-}4\text{-R}$, R = Me, or *t*Bu. The former are at higher frequencies than reported ν(YbF) values (330–298 cm^{-1})[3,21] for formally eight and nine-coordinate bis(cyclopentadienyl)fluorolanthanoid(III) complexes (Table 1), consistent with the lower coordination number, and are expectedly lower than ν(YbF) (569, 546 cm^{-1}) of matrix isolated, three-coordinate YbF_3.[32] No infrared absorption band was observed for $[YbCp_2F]_3$ at 350–275 cm^{-1}, where ν(YbF) is expected, but the Raman spectrum showed a ν(YbF) line at 336 cm^{-1}. Thus, ν(YbF) for the highly symmetrical structure (see below), is infrared inactive. For the less symmet-

rical $[Yb(MeCp)_2F]_4$, ν(YbF) was observed in the infrared spectrum, and the assignment for $[Yb(MeCp)_2F(THF)]_2$ is in agreement with that reported[3] (Table 1). There is some uncertainty over ν(YbF) of $[YbCp_2F(OPPh_3)]_2$ as Ph_3PO has weak absorption in the relevant region,[33] but the higher frequency band of two near 300 cm^{-1} seems the more likely. Overall, it is not possible to distinguish between eight- and nine-coordinate bis(cyclopentadienyl)fluorolanthanoid(III) complexes on the basis of ν(YbF) frequencies (Table 1).

[a] From far infrared spectra, except where indicated otherwise. – [b] This work.

No metal containing ions were observed in the mass spectra of $[Yb(OAr)_2F(THF)]_2$ complexes, but trinuclear and dinuclear ions were observed for $[YbCp_2F]_3$, $[Yb(MeCp)_2F]_4$, $[YbCp_2F(OPPh_3)]_2$ and $[Yb(MeCp)_2F(THF)]_2$. In each case the highest observed ion was $[Yb_3L_5F_3]^+$ (L = Cp or MeCp) or this ion ±H. (For the methylcyclopentadienyl complexes, this ion was close to the instrument limit, hence the possibility of formation of tetranuclear ions cannot be ruled out.) An analogous ion was the highest observed in the spectra of $[YbCp_2F(THF)]_2$,[21] $[ScCp_2F]_3$,[15] and $[Sm(t\text{BuCp})_2F]_3$.[20] Formation of trinuclear ions for the dimeric complexes $[YbCp_2F(OPPh_3)]_2$ and $[Yb(MeCp)_2F(THF)]_2$ evidently involves thermally induced dissociation of the neutral ligand and further association, as observed for $[YbCp_2F(THF)]_2$.[21] Because of such reactions, the mass spectra are an uncertain guide as to solid state structures. In general the fragmentation patterns of the Cp complexes were similar to those of $[YbCp_2F(THF)]_2$ [21] and $[ScCp_2F]_3$,[15] whilst those of the MeCp complexes showed features (loss of $MeCp^•$, $Me^•$, and, for the THF complex, $H^•$) similar to those of $[Ln(MeCp)_3]$.[34] However there was no evidence of the electron impact-induced ring expansions shown by $[Ln(MeCp)_3]$.[34] For the phosphane oxide complex, no ions with coordinated Ph_3PO were observed, although such ions, notably $LnCp_2(OPPh_3)^+$, have been observed with low intensity in the mass spectra of some $[LnCp_3(OPR_3)]$ complexes.[1]

X-ray Crystal Structures

1. $[Yb(OC_6H_2\text{-}2,6\text{-}t\text{Bu}_2\text{-}4\text{-}X)_2F(THF)]_2$ (X = H or *t*Bu): X-ray crystallography has shown that the complexes $[Yb(OC_6H_2\text{-}2,6\text{-}t\text{Bu}_2\text{-}4\text{-}X)_2F(THF)]_2$ (X = H or *t*Bu) are dimeric with bridging fluorides and five-coordinate ytterbium. In each case the fluoride bridging is somewhat unsymmetrical (0.04–0.07 Å), the differences being significant on consideration of the errors in bond lengths. Selected bond lengths and angles for the X = H complex and for the two crystallographically independent X = *t*Bu molecules are listed in Table 2, whilst the structure of $[Yb(OC_6H_3\text{-}2,6\text{-}t\text{Bu}_2)_2F(THF)]_2$ is displayed in Figure 1, and that of molecule 1 of $[Yb(OC_6H_2\text{-}2,4,6\text{-}t\text{Bu}_3)_2F(THF)]_2$ in Figure 2. The stereochemistry is very irregular, but can be regarded as distorted trigonal bipyramidal with an aryloxide oxygen and a fluorine apical (ArO–Yb–F 150–153°), and the other aryloxide oxygen, O(THF), and the other fluorine equatorial. A similar arrangement is observed in $[Yb(OC_6H_2\text{-}2,4,6\text{-}t\text{Bu}_3)_2OH(THF)]_2$ [24] where the apical ArO–Yb–OH angle is somewhat larger [156.2(3)°] than the ArO–Yb–F angles (Table 2). A similar arrangement of Cp ring centres, THF oxygen, and bridging fluorides is observed in $[YbCp_2F(THF)]_2$,[21] $[Yb(MeCp)_2F(THF)]_2$, and $[YbCp_2F(OPPh_3)]_2$, (below), but the largest (transoid) angle, O(THF)–Yb–F, is only ca. 140°. Moreover, $[Yb(OAr)_2F(THF)]_2$ complexes have one of the bulky ligands in an apical position, whereas neither of the larger groups (Cp/MeCp) is apical in the cyclopentadienyl complexes. At first sight, the Yb–(μ-F) distances (Table 2) are surprisingly long for a five-coordinate complex, since they are comparable with those of the nine-coordinate dimers, $[YbCp_2F(THF)]_2$,[21] $[Yb(MeCp)_2F(THF)]_2$, and $[YbCp_2F(OPPh_3)]_2$ (see below), as well as those [2.206(5), 2.196(5) Å] of the two sets of Yb–(μ–F) bonds in eight-coordinate $[Yb_5(C_5Me_5)_6(\mu_4\text{-}F)(\mu_3\text{-}F)_2(\mu\text{-}F)_6]$.[3] On the basis of the data for the cyclopentadienyl compounds[3,21] and the variation of ionic radius with coordination number,[35] a Yb–(μ-F) distance of ca. 2.0 Å might be expected in $[Yb(OAr)_2F(THF)]_2$ complexes. This would be near terminal Yb–F distances [2.015(4), 2.026(2) Å] in monomeric eight-coordinate $[Yb(C_5Me_5)_2F(L)]$ (L = THF or Et_2O) complexes.[3] However there is actually quite wide variation in the limited range of bridging Yb–F distances reported[3,16,17,21]. Thus, Yb–(μ_3-F) distances for eight-coordinate Yb^{III} in $[Yb_5(C_5Me_5)_6(\mu_4\text{-}F)(\mu_3\text{-}F)_2(\mu\text{-}F)_6]$ are much longer [2.319(6)–2.468(6) Å] than Yb–(μ-F) above, and Yb–(μ_4-F) lenghts cover a narrower range (2.365–2.387 Å).[3] By contrast, Yb^{III}–(μ-F) distances for fluoride ions bridging Yb^{III} and Yb^{II} in seven-coordinate $[Yb_2(C_5Me_5)_4(\mu\text{-}F)]$[17] and eight-coordinate (for Yb^{III}) $[Yb_4(C_5Me_5)_6(\mu\text{-}F)_4]$[16] are very short at 2.084(2) and 2.129 ± 0.002 Å respectively. Even Sm–(μ-F) of eight-coordinate $[Sm(C_5H_4\text{-}t\text{Bu})_2F]_3$ [20] and $[Sm\{C_5H_3\text{–}1,3\text{-}(SiMe_3)_2\}_2F]_2$ [19] differ by ca. 0.06 Å. In the present complexes, the relatively long (for coordination number 5) Yb–(μ-F) distances are attributed to steric crowding around ytterbium. The sum of the steric coordination numbers[36] of the ligands for the $[Yb(OAr)_2F(THF)]_2$ complexes is 8.0, whereas the values for the topologically related $[YbCp_2F(THF)]_2$ [21] and $[Yb(MeCp)_2F(THF)]_2$ are 7.3–7.5, indicative of less steric hindrance. Thus long Yb–(μ-F) bonds in the $[Yb(OAr)_2F(THF)]_2$ complexes are reasonable because of

crowding, and there are also relatively long Yb–O(THF) bonds (see below).

The average Yb–O(THF) distance (2.32 Å) is somewhat shorter than that [2.363(8) Å] of five-coordinate $[Yb(OC_6H_2\text{-}2,6\text{-}tBu)_2OH(THF)]_2$.[24] Subtraction of an extrapolated radius (from the data of Shannon[35]) for five-coordinate Yb^{3+} from Yb–O(THF) gives 1.51 Å, typical of values (1.48–1.59 Å) derived from Ln–O(THF) of low coordinate complexes with bulky aryloxides.[24,26,37] This is larger than subtraction values of 1.34 ± 0.05 Å derived from Ln–O(THF) of cyclopentadienyllanthanoid complexes[38] and specifically 1.37 Å from Yb–O(THF) of $[YbCp_2F(THF)]_2$ [21] and reflects bond lenghtening induced by steric crowding as noted for Yb–(μ-F) above. The Yb–OAr distances are comparable with those of both five-coordinate $[Yb(OC_6H_2\text{–}2,4,6\text{-}tBu_3)_2OH(THF)]_2$ [24] and $[Yb(OC_6H_3\text{-}2,6\text{-}Ph_2)_3(THF)_2]$,[37a] and subtraction of the 5-coordinate Yb^{3+} radius from <Yb–OAr> gives 1.25 Å, quite typical of values derived from data for low coordinate Yb^{II} and Yb^{III} aryloxides.[24,26,37]

Further evidence of considerable steric crowding in the $[Yb(OAr)_2F(THF)]_2$ complexes is provided by the existence of short Yb···C(Me) and C(Me)···C(Me) separations (Table 3) and the former are displayed for molecule 1 of $[Yb(OC_6H_2\text{-}2,4,6\text{-}tBu_3)_2F(THF)]_2$ in Figure 2. The listed Yb···C(Me) distances are less than the sum (3.94 Å) of the metallic radius of ytterbium[39] (which can be viewed as a pseudo van der Waals radius) and the van der Waals radius of a methyl group.[40] However these contacts are significantly longer than can be attributed to agostic Yb···C(alkyl) contacts (ca. 2.9–3.2 Å)[16,41] and are thus approaches induced by ligand congestion. The close C(Me)···C(Me) contacts that also reflect congestion are between methyls of *different tert*-butyl groups on the same or different Yb atoms. Their separations are less than two methyl van der Waals

Table 3. Non bonding close Yb···C and C(Me)···C(Me) contacts (Å) in $[Yb(OC_6H_2\text{-}2,6\text{-}t\text{Bu-}4\text{-}X]_2$ complexes

radii. In addition to these contacts there are also a number just above the sum of the van der Waals radii.

2. $[YbCp_2F]_3$: Unsolvated bis(cyclopentadienyl)fluoroytterbium(III) crystallizes as a trimer with eight-coordinate ytterbium ions, and is the first *unsolvated unsubstituted* cyclopentadienyllanthanoid fluoride to be structurally characterized, though similar trimers have been observed for $[ScCp_2F]_3$,[15] $[Sm(C_5H_4\text{-}t\text{Bu})_2F]_3$,[20] and $[Sm(C_5Me_5)_2Cl]_3$.[42] Selected bond lengths and angles are given in Table 4 and the structure is shown in Figure 3. The structure features a planar Yb_3F_3 ring with near equal Yb–F bond lengths, but with one Yb–F–Yb and one F–Yb–F angle slightly different from the other two. However, these slight variations are of little consequence and the structure is sufficiently symmetrical for ν(Yb–F) to be infrared inactive and observed only in the Raman spectrum (Table 1). There is little variation in <Ln–C> bond lengths between $[YbCp_2F]_3$ (Figure 3) and $[ScCp_2F]_3$,[15] $[Sm(C_5H_4\text{-}t\text{Bu})_2F]_3$ [20] and $[Sm(C_5Me_5)Cl]_3$ [42] and in <Ln–F> between the three fluorides, when allowance is made for variation in Ln^{3+} radii. Thus subtraction of the ionic radius for eight-coordinate Ln^{3+} from <Ln–C> gives 1.61, 1.60, 1.63, and 1.65 Å for the respective compounds. These values are in the normal range[43] and compare with 1.60 Å similarly derived from <Yb–C> of $[YbCp_2F(THF)]_2$.[21] A similar subtraction from <Ln–F> of the first three compounds gives 1.17, 1.18, and 1.17 Å, respectively. Values from <Ln–F> of $[YbCp_2F(THF)]_2$ [21] (1.15 Å) and $[Sm\{C_5H_3\text{-}1,3\text{-}(SiMe_3)_2\}_2F]_2$ [19] (1.22 Å) lie either side of the values for the trimers, and all are well below similarly derived values (1.36 and 1.41 Å) for the two different Yb–F bonds of the bulky $[Yb(OAr)_2F(THF)]_2$ complexes (above). Of the four trimeric bis(cyclopentadienyl)lanthanoid(III) halide structures (Figure 3 and refs.[15,20,42]), the present complex has the largest X–Ln–X (X = Cl or F) angle and the smallest Ln–X–Ln angle, a result that is unexpected since the group contains the complex of the much smaller Sc^{3+}. Although the cen–Yb–cen (cen = centroid of a Cp ring) angle is in

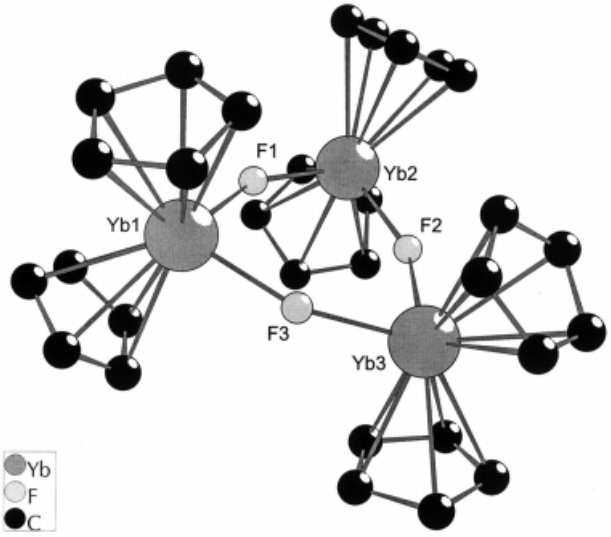

Figure 3. The molecular structure of $[YbCp_2F]_3$

the range (127–140°) for 8-coordinate complexes, it is close to the overlap with the range (113–129°) for 9-coordinate complexes (see literature cited in ref.[21]). The sum of the steric coordination numbers of the ligands[36] is quite low at 6.1, especially compared with 7.3 for $[YbCp_2F(THF)]_2$, and highlights the surprising failure to obtain a solvate from DME. A dimer with chelating DME and 10-coordinate ytterbium would have a sum of steric coordination numbers of 7.9. Whilst comparable with the value 8.0 for $[Yb(OAr)_2F(THF)]_2$ complexes, it may be too large when other alternatives are available. A monomer with chelating DME would have a reasonable value of 6.85, but the molecule would have only one stable Yb–F bond per Yb compared with two in dimers and trimers. However, a dimer with unidentate DME (known refs.[28,44] in lanthanoid chemistry) would allow two Yb–F bonds/Yb and a reasonable steric coordination number sum of 7.0. Despite this, the sterically unsaturated $[YbCp_2F]_3$ is preferred. With this structure, the non bonding Yb(n)···Yb(m) separations [(1)/(2) 4.186; (1)/(3) 4.185; (2)/(3) 4.196 Å] and F(n)···F(m) separations [(1)/(2) 2.885; (1)/(3) 2.975; (2)/(3) 2.981 Å] exceed those for the solvated dimer $[Yb(MeCp)_2F(THF)]_2$ (Yb···Yb 3.666 Å; F···F 2.465 Å). From the structural data for $[Sm(C_5H_3\text{-}1,3\text{-}(SiMe_3)_2)_2F]_2$,[19] a Yb···Yb separation of ca. 3.60 Å in the unsolvated dimer "$[YbCp_2F]_2$" can be estimated. This reinforces the lack of crowding revealed by steric coordination numbers.

3. $[Yb(MeCp)_2F]_4$: Crystallization of this heteroleptic fluoride from DME as a tetramer with eight-coordinate Yb^{III} is particularly surprising. Not only is the complex not solvated, but it is the first tetrameric bis(cyclopentadienyl)lanthanoid(III) fluoride. Previously only an unsolvated dimer,[19] trimers,[15,20] and a solvated dimer[21] have been isolated. The nearest similar structure is the mixed oxidation state ($Yb^{II,III}$) $[Yb_4(C_5Me_5)_6(\mu\text{-}F)_4]$,[16] which has eight-coordinate Yb^{III} and five-coordinate Yb^{II}. Selected bond lengths and angles for $[Yb(MeCp)_2F]_4$ are given in Table 4.

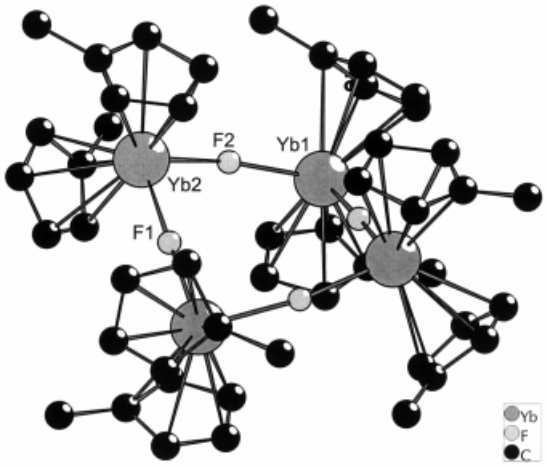

Figure 4. The molecular structure of $[Yb(MeCp)_2F]_4$

The structure is displayed in Figure 4. The eight-membered Yb_4F_4 ring is puckered with Yb–F–Yb angles near linear and F–Yb–F angles near 90° (Table 4). Similar F–Yb–F angles are observed in $[Yb_4(C_5Me_5)_6(\mu\text{-}F)_4]$,[16] but the Yb–F–Yb angles [160.0(2), 157.3(2)°] show much greater deviation from linearity than in $[Yb(MeCp)_2F]_4$. The four fluorine atoms are near coplanar (max. deviation 0.007 Å) with the plane parallel to the [101] plane, but the two different ytterbium atoms are very substantially displaced [Yb(1) +0.605 Å; Yb(2) −0.575 Å] from the F_4 plane. In $[Yb_4(C_5Me_5)_6(\mu\text{-}F)_4]$ the Yb^{III} atoms are similarly displaced from the F_4 plane, but the Yb^{II} atoms are only slightly displaced.[16] The average Yb–C and Yb–F distances are virtually identical with those of $[YbCp_2F]_3$, and subtraction of the ionic radius[35] for eight-coordinate Yb^{3+} gives 1.60 and 1.17 Å respectively. Although the methylcyclopentadienyl ligand is somewhat bulkier than Cp, the cen–Yb–cen angles are marginally smaller for the MeCp complex and are approaching the limit for eight-coordinate complexes (see literature cited in ref.[21]). As with $[YbCp_2F]_3$, the sum of the steric coordination numbers for the ligands[36] is small at 6.3, and contrasts 7.5 for the solvated dimer $[Yb(MeCp)_2F(THF)]_2$ (below). Again, a solvated monomer "$[Yb(MeCp)_2F(DME)]$" with chelating DME or a dimer solvated with unidentate DME are sterically viable. Formation of a tetramer leads to even longer Yb···Yb and F···F separations (4.296/4.299 and 3.088/3.106 Å, respectively) than in the trimer with the *less bulky* ligand. Whilst this should minimise non-bonding interactions, several molecules with closer Ln···Ln and F···F separations are isolable. In particular, the highly crowded $[Yb(OAr)_2F(THF)]_2$ dimers have average Yb···Yb separations of 3.635 Å and average F···F separations of 2.49 Å.

4. $[YbCp_2F(OPPh_3)]_2$ and $[Yb(MeCp)_2F(THF)]_2$: Both complexes were established as fluoride-bridged dimers with nine-coordinate ytterbium. The structures are displayed in Figure 5 and Figure 6, and bond length and angle data are compared with those of $[YbCp_2F(THF)]_2$ in Table 5. Two independent molecules are observed for the phosphane oxide complex, but data are listed for only one owing to the low precision of the determination. A structure was needed for the previously reported[3] $[Yb(MeCp)_2F(THF)]$, since both monomeric $[Yb(C_5Me_5)_2F(THF)]$[3] and dimeric $[YbCp_2F(THF)]_2$[21] structural analogues exist.

The arrangement of centroids of the cyclopentadienyl rings, the fluorines, and the oxygen donor atom can be viewed as distorted trigonal bipyramidal with oxygen and one bridging fluoride in the apical positions. For the phosphane oxide complex, within the error limits, the Yb–C, Yb–F, and Yb–O distances show no unexpected features. The bond lengths of $[Yb(MeCp)_2F(THF)]_2$ show interesting trends, when compared with those of $[YbCp_2F(THF)]_2$.[21] From <Yb–C> and <Yb–F> values, there is a hint of bond lengthening in the methylcyclopentadienyl compound, but the size of the estimated standard deviations in the earlier determination[21] makes the comparison uncertain. However Yb–O(THF) is clearly larger for $[Yb(MeCp)_2F(THF)]_2$. Subtraction of the ionic radius for nine-coordinate Yb^{3+} gives 1.45 Å, which is higher than usual (1.34 ± 0.05 Å)[38] for THF complexes of

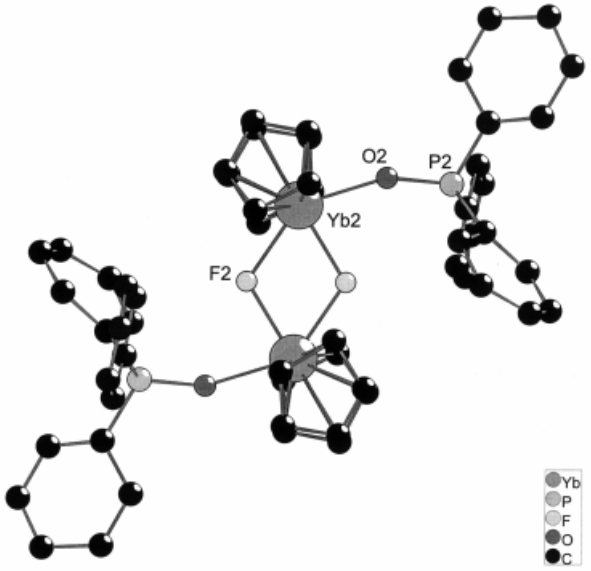

Figure 5. The molecular structure of molecule 2 of $[YbCp_2F(OPPh_3)]_2$

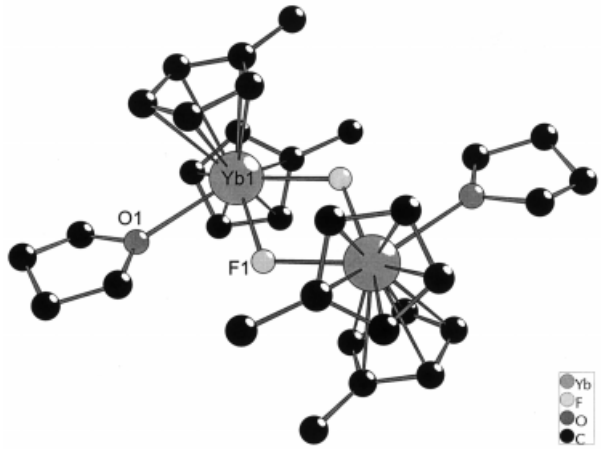

Figure 6. The molecular structure of $[Yb(MeCp)_2F(THF)]_2$

cyclopentadienyllanthanoids, e.g. 1.37 Å for $[YbCp_2F(THF)]_2$ [21] and 1.34 Å for monomeric $[Yb(C_5Me_5)_2F(THF)]$, and approaching values (1.49–1.59 Å)[24,26,37] derived from Yb-O(THF) of THF complexes of bulky lanthanoid aryloxides (see e.g. $[Yb(OAr)_2F(THF)]_2$ above). Thus the small increase in cyclopentadienyl ligand bulkiness from $[YbCp_2F(THF)]_2$ to $[Yb(MeCp)_2F(THF)]_2$ (sum of ligand steric coordination numbers 7.3 and 7.5 respectively) is sufficient to weaken the Yb–O bond significantly. It also becomes apparent why $[Yb(C_5Me_5)_2F(THF)]$[3] is monomeric, not dimeric. The dimer would have a ligand steric coordination number sum of 8.2, higher even than for $[Yb(OAr)_2F(THF)]_2$ (8.0), and THF would plausibily be dissociated, whereas the steric coordination number sum for the monomer is 7.2, comparable with $[YbCp_2F(THF)]_2$, permitting an uncrowded Yb–O bond.

From the packing diagrams, it is evident that the molecules of the above dimers, trimer, and tetramer are well separated and non interacting. In $[YbCp_2F]_3$, the trimeric molecules are parallel to one another in alternating layers, whilst in $[Yb(MeCp)_2F]_4$ the planes of the four fluorines of the tetramers align parallel to the [101] plane. The two independent molecules of $[Yb(OC_6H_2\text{-}2,4,6\text{-}t\text{Bu}_3)_2F(THF)]_2$ are perpendicular to each other.

Conclusions

The present study establishes that a range of heteroleptic lanthanoid fluorides can be prepared, including aryloxides, and that considerable structural variety is exhibited. A heteroleptic aryloxide chloride analogous to the

$[Yb(OAr)_2F(THF)]_2$ complexes is known, viz. $[Sm(OC_6H_2$-2,6-tBu_2-4-Me$)_2Cl(THF)]_2$,[45] but the larger iodide gives a slightly more crowded monomer $[Ln(OAr)_2I(THF)_2]$ (Ln = Sm[45] or Yb[46]). There are both chloride and hydride analogues of $[Ln(Cp$ or MeCp$)_2FL]_2$ where L = THF (see ref.[21] and literature cited therein), but not for L = Ph_3PO, and $[Sm(C_5Me_5)_2Cl]_3$ [42] is related to $[YbCp_2F]_3$. However there is no homocyclic chloride tetramer structurally similar to $[Yb(MeCp)_2F]_4$.[12–14] Although the tetramer $[GdCp_2Cl]_4$ is known, the structure is a dimer of dimers with a ladder arrangement[13]. Isolation of $[YbCp_2F]_3$ and $[Yb($-$MeCp)_2F]_4$ unsolvated from DME is striking, and contrasts the formation of $[Yb(Cp$ or MeCp$)_2F(THF)]_2$. The corresponding DME complexes would have the more unusual[28,44] unidentate DME and appear unable to compete with the very uncrowded unsolvated trimer and tetramer.

Experimental Section

General: The lanthanoid(II) reactants and lanthanoid(III) products are extremely air- and moisture-sensitive, hence all operations were carried out under purified Ar or N_2. Unless indicated otherwise, handling methods and solvent purification were as described previously.[47] – Infrared spectra (4000–600 cm^{-1}) were obtained for Nujol mulls between NaCl plates with a Nicolet 5PC-FTIR-spectrometer or as KBr disks with a Bruker 66V/S instrument. Far infrared spectra (600–50 cm^{-1}) were recorded for polyethylene disks with a Bruker IFS 66V/S spectrometer. – The Raman spectrum was obtained for a solid sample in a sealed capillary with a Bruker FRA 106/S instrument. – Mass spectra were recorded with a Varian MAT CH5-DF mass spectrometer. The aryloxofluoroytterbium(III) complexes showed only ligand ions and the data are not listed. For the cyclopentadienylfluoroytterbium(III) compounds, clusters with the correct isotope pattern for the assignments given were observed. – The Energy Dispersive Analysis through X-ray (EDAX) measurement was carried out with an ECON IV PV 9900–26 instrument, II. Physikalische Institut, Universität zu Köln. – Metal analysis were effected as described previously.[47] Fluorine analyses for samples sealed under Ar in gelatin capsules were carried out by the method of Campbell.[48] Perfluorodecalin and perfluoro(methylcyclohexane), from Avocado Chemicals, were dried over molecular sieves (4 Å), degassed, and vacuum transferred to storage vessels. Ytterbium(II) aryloxides were prepared as described previously[26] and had IR spectra in agreement with those reported. Far IR spectra – for comparison with trivalent complexes (below): $[Yb(OC_6H_3$-2,6-$tBu_2)_2(THF)_3]$: $\tilde{\nu}$ = 590 w cm^{-1}, 534 m (br), 490 w, 459 w, 441 m, 383 w, 333 s, 309 m, 270 w, 184 w, 143 w (br). $[Yb(OC_6H_2$-2,6-tBu_2-4-Me$)_2(THF)_3]$: $\tilde{\nu}$ = 577 m cm^{-1}, 564 w, 527 s (br), 501 s, 353 s, 302 s, 223 w, 180 w, 149 w, 116 w. $[Yb(OC_6H_2$-2,4,6-$tBu_3)_2(THF)_3]$: $\tilde{\nu}$ = 578 vw cm^{-1}, 537 m, 519 s, 491 vw, 447 m, 358 s (br), 263 w (br), 170 w, 144 m, 87 w. The divalent ytterbocenes $[YbCp_2(DME)]$ and $[Yb(MeCp)_2(THF)]$ were also prepared by reported methods.[49]

Bis(aryloxo)fluorolanthanoid(III) Complexes $[Yb(OAr)_2F(THF)]_2$: The appropriate $[Yb(OC_6H_2$-2,6-tBu_2-4-R$)_2(THF)_3]$ (R = H, Me, *t*Bu) complex (ca. 0.30–0.40 mmol) and perfluorodecalin (mol ratio 4:1) were stirred in THF (2.5 mL) at room temperature for 48 h. The resulting suspension was heated to 50 °C and then cooled to room temperature, when the deposited solid was filtered off and washed twice with THF (0.5 mL) and dried for at least 3 h under vacuum. The products were obtained as bright orange microcrystalline powders in 25–30% yield.

Di{bis(2,6-di-*tert*-butylphenolato)(μ-fluoro)(tetrahydrofuran)ytterbium(III)}: IR (Nujol): $\tilde{\nu}$ = 3077 w cm^{-1}, 3063 w, 1584 w, 1410 s, 1358 m, 1316 w, 1260 s, 1246 s, 1200 m, 1130 w, 1105 m, 1036 w, 1003 m, 953 w, 924 w, 914 w, 870 s, 821 w, 750 s, 662 m. – Far-IR: $\tilde{\nu}$ = 589 w cm^{-1}, 573 w, 562 w, 547 s, 526 w, 494 m, 451 m, 387 s (br), 338 vs, 304 m, 279 m, 207 s, 140 w, 125 w. – $C_{64}H_{100}F_2O_6Yb_2$ (1349.52): calcd. F 2.82, Yb 25.64; found F 2.59, Yb 25.41. Single crystals were obtained by storage of a THF solution in a dry box for 4 weeks.

Di{bis(2,6-di-*tert*-butyl-4-methylphenolato)(μ-fluoro)(tetrahydrofuran)ytterbium(III)}: IR (KBr disk): $\tilde{\nu}$ = 3059 w cm^{-1}, 2955 s, 2913 s, 2869 m, 1459 m, 1419 s, 1386 m, 1356 w, 1260 s (br), 1219 m, 1202 w, 1149 w, 1122 w, 1067 w, 1020 m, 915 w, 887 w, 861 m, 830 m, 807 w, 780 w. – Far-IR: $\tilde{\nu}$ = 577 w cm^{-1}, 563 w, 537 vs, 401 w (sh), 381 s (br), 356 m, 325 w (sh), 314 m, 302 m, 219 w, 190w. – $C_{68}H_{108}F_2O_6Yb_2$ (1408.70): calcd. F 2.70, Yb 24.62; found F 2.50, Yb 24.53.

Di{(μ-fluoro)(tetrahydrofuran)bis(2,4,6-tri-*tert*-butylphenolato)ytterbium(III)}: IR (Nujol): $\tilde{\nu}$ = 3067 w cm^{-1}, 1584 w, 1408 s, 1360 m (sh), 1260 s, 1246 s, 1200 w, 1130 w, 1105 w, 1036 w, 1003 w, 953 w, 914 w, 870 m, 822 w, 797 w, 750 s, 662 w. – Far-IR: $\tilde{\nu}$ = 539 s cm^{-1}, 475 w (sh), 461 m, 375 s (br), 359 s (sh), 304 m, 273 w, 206 m, 183 w. – $C_{80}H_{132}F_2O_6Yb_2$ (1574.00): calcd. F 2.41, Yb 21.99; found F 2.42, Yb 22.18. Single crystals of the complex as a tris(tetrahydrofuran) solvate were obtained by storage of a saturated THF solution at –20 °C for 2 d, and were shown to contain fluorine by EDAX measurements.

Bis(cyclopentadienyl)fluoroytterbium(III) Complexes. – Tri{bis(cyclopentadienyl)(μ-fluoro)ytterbium(III)}: To a solution of $[YbCp_2(DME)]$ (1.0 g, 2.5 mmol) in DME (10 mL), perfluoro(methylcyclohexane) (0.23 g, 0.51 mmol) was added. The biphasic system was stirred for 48 h at room temperature. The resulting yellow precipitate was filtered off and washed twice with DME (3 mL). The product was dried for 3 h under vacuum (yield 45%). – IR (Nujol): $\tilde{\nu}$ = 3077 w cm^{-1}, 2708 w, 1653 w, 1576 w, 1152 w, 1067 w, 1011 s, 774 vs, 667 w, 621 w. – Far IR: $\tilde{\nu}$ = 480 s (br) cm^{-1}, 265 m, 230 w, 194 m, 114 w. – Raman Spectrum: $\tilde{\nu}$ = 938 w cm^{-1}, 629 s, 336 m, 119 m. – MS (20 eV, 260 °C), *m/z* (%): 901 (100) $[Yb_3Cp_5F_3]^+$, 836 (2.5) $[Yb_3Cp_4F_3]^+$, 644 (10) $[Yb_2Cp_4F_3]^+$, 625 (5.4) $[Yb_2Cp_4F_2]^+$, 579 (38) $[Yb_2Cp_3F_2]^+$, 533 (2.6) $[Yb_2Cp_2F_2]^+$, 369 (18) $[YbCp_3]^+$, 304 (76) $[YbCp_2]^+$, 239 (31) $[YbCp]^+$, 173 (1.6) $[Yb]^+$, 66 (41) $[CpH]^+$, 65 (27) $[Cp]^+$, 39 (24) $[HF_2]^+$, 19 (57) $[F]^+$. – $C_{30}H_{30}F_3Yb_3$ (966.69): calcd. F 5.90, Yb 53.70; found F 5.66 Yb 53.36. – A saturated DME solution was stored for 3 weeks at –20 °C giving yellow crystals of the title compound suitable for X-ray crystallography. An analogous preparation using perfluorodecalin gave the compound in 49% yield.

Tetra{(μ-fluoro)bis(methylcyclopentadienyl)ytterbium(III)}: To $[Yb($-$MeCp)_2(THF)]$ (1.06 g, 2.6 mmol) and perfluorodecalin (0.30 g, 0.66 mmol), DME (2.5 mL) was added. The solution became emerald green and the biphasic system was stirred for 24 h at room temperature. An orange solid was precipitated after 2 h. This was filtered off and washed twice with DME (0.5 mL) and dried for 3 h under vacuum (yield 25%). – IR (KBr): $\tilde{\nu}$ = 3083 w cm^{-1}, 2927 m, 2864 m, 1703 w, 1634 w, 1534 w, 1486 w, 1454 m, 1381 w, 1350 w, 1237 w, 1038 s, 933 m, 830 s, 768 vs, 623 w. – Far IR: $\tilde{\nu}$ = 470 vs (br) cm^{-1}, 328 s, 260 s, 230 m, 197 m, 164 w, 144 w. – MS (20 eV, 205 °C), *m/z* (%): 971 (44) $[Yb_3(MeCp)_5F_3]^+$, 957 (29)

$[Yb_3(MeCp)_4(Cp)F_3]^+$, 942 (7.2) $[Yb_3(MeCp)_3(Cp)(C_5H_4)F_3]^+$, 700 (18) $[Yb_2(MeCp)_4F_2]^+$, 686 (5.4) $[Yb_2(MeCp)_3(Cp)F_2]^+$, 621 (82) $[Yb_2(MeCp)_3F_2]^+$, 607 (21) $[Yb_2(MeCp)_2(Cp)F_2]^+$, 594 (1.1) $[Yb_2(MeCp)(Cp)(C_5H_6)F_2]^+$, 542 (10) $[Yb_2(MeCp)_2F_2]^+$, 528 (1.4) $[Yb_2(MeCp)_2(Cp)F_2]^+$, 463 (3.3) $[Yb_2(MeCp)F_2]^+$, 411 (16) $[Yb_3(MeCp)_3]^+$, 397 (4.1) $[Yb(MeCp)_2(Cp)]^+$, 332 (100) $[Yb(MeCp)_2]^+$, 318 (14) $[Yb(MeCp)(Cp)]^+$, 253 (39) $[Yb(MeCp)]^+$, 239 (3.6) $[Yb(Cp)]^+$, 174 (2.2) $[Yb]^+$, 79 (57) $[MeCp]^+$, 67 (10.3) $[CpH]^+$. – $C_{48}H_{56}F_4Yb_4$ (1401.09): calcd. F 5.42, Yb 49.40; found F 5.27, Yb 49.61. Single crystals for X-ray analysis were obtained by isothermal evaporation of DME in a U-tube, with the solution in one arm at room temperature, and the other arm cooled in liquid nitrogen.

Di{bis(cyclopentadienyl)(μ-fluoro)(triphenylphosphane oxide)-ytterbium(III)}: $[YbCp_2(DME)]$ (0.59 g, 1.5 mmol) and perfluorodecalin (0.17 g, 3.8 mmol) were stirred in THF (4 mL) at room temperature for 24 h. The colour of the solution changed to dark brown and a yellow solid precipitated. To this mixture, THF (4 mL) and $OPPh_3$ (0.42 g, 1.5 mmol) were added. After stirring for 24 h at room temperature and 3 d at 50 °C, the resulting yellow precipitate was filtered off. The pale yellow solid was washed twice with

THF (2 mL) and dried for 3 h under vacuum (yield 34%). – IR (KBr): $\tilde{\nu}$ = 3084 m cm^{-1}, 3059 m, 1650 w, 1591 w, 1486 w, 1438 s, 1179 s (br), 1124 s, 1098 m, 1071 w, 1012 s, 926 w, 873 w, 846 w, 779 s (br), 747 s, 726 s, 692 s. – Far IR: $\tilde{\nu}$ = 540 s cm^{-1}, 514 w, 476 s, 458 s (br), 421 w, 389 w, 306 m, 292 m, 254 m, 225 w, 203 m (sh), 195 s, 141 w, 117 w. – MS (20 eV, 280 °C), *m/z* (%): 902 (1.7) $[Yb_3Cp_5F_3H]^+$, 643 (0.7) $[Yb_2Cp_3F_2(C_5H_4)]^+$, 578 (1.4) $[Yb_2Cp_2F_2(C_5H_4)]^+$, 513 (0.3) $[Yb_2CpF_2(C_5H_4)]^+$, 369 (8.8) $[YbCp_3]^+$, 304 (18) $[YbCp_2]^+$, 278 (57) $[OPPh_3]^+$, 277 (100) $[OPPh_2(C_6H_4)]^+$, 239 (15) $[CpYb]^+$, 201 (17) $[OPPh_2]^+$, 185 (8.6) $[PPh_2]^+$, 154 (3.6) $[Ph_2]^+$, 77 (4.3) $[Ph]^+$, 65 (2.9) $[Cp]^+$, 39 (3.5) $[HF_2]^+$. – $C_{56}H_{50}F_2O_2P_2Yb_2$ (1200.98): calcd. F 3.16; found F 3.22. Slow evaporation of the THF filtrate in a U-tube yielded yellow needles of $[YbCp_2F(OPPh_3)]_2$ suitable for X-ray crystallography.

Di{(μ-fluoro)bis(methylcyclopentadienyl)(tetrahydrofuran)ytterbium-(III)}: $[Yb(MeCp)_2(THF)]$ (0.76 g, 1.8 mmol) and perfluorodecalin (0.21 g, 4.5 mmol) were stirred for 48 h in THF (2.5 mL) at room temperature. The mixture was warmed up to 50 °C for 2 h and then slowly cooled. The microcrystalline precipitate was filtered off and washed twice with 0.5 mL of THF (yield 24%). – IR (Nujol): $\tilde{\nu}$ = 3079 w cm^{-1}, 1239 w, 1067 w, 1049 m, 1034 m, 932 m, 835 s, 766 vs, 616 w. – Far IR: $\tilde{\nu}$ = 468 vs (br) cm^{-1}, 331 s, 268 s, 229 m, 197 m, 116 w. – MS (20 eV, 215 °C), *m/z* (%): 970 (47) $[Yb_3(MeCp)_4(CpCH_2)F_3]^+$, 956 (29) $[Yb_3(MeCp)_4(C_5H_4)F_3]^+$, 943 (7.7) $[Yb_3(MeCp)_3(Cp)_2F_3]^+$, 700 (12) $[Yb_2(MeCp)_4F_2]^+$, 684 (3.4) $[Yb_2(MeCp)_3(Cp)F_2]^+$, 621 (38) $[Yb_2(MeCp)_3F_2]^+$, 609 (8.6) $[Yb_2(MeCp)_2(C_5H_7)F_2]^+$, 542 (4.9) $[Yb_2(MeCp)_2F_2]^+$, 528 (1.1) $[Yb_2(MeCp)(Cp)F_2]^+$, 411 (29) $[Yb(MeCp)_3]^+$, 397 (7.3) $[Yb(MeCp)_2(Cp)]^+$, 332 (100) $[Yb(MeCp)_2]^+$, 318 (17) $[Yb(MeCp)(Cp)]^+$, 253 (51) $[Yb(MeCp)]^+$, 239 (6.6) $[Yb(Cp)]^+$, 174 (2.2) $[Yb]^+$, 79 (66) $[MeCp]^+$, 39 (12) $[HF_2]^+$. – $C_{32}H_{44}F_2O_2Yb_2$ (844.75): calcd. F 4.50, Yb 41.00; found F 4.29, Yb 41.38. – Single crystals were obtained by isothermal evaporation of the filtrate in a U-tube. An attempt to effect a similar synthesis with perfluoro(methylcyclohexane) at room temperature for 7 d showed the reaction to be very slow.

X-ray Structure Determination: Crystals were mounted in 0.2/0.3 mm diameter glass capillaries under dry argon in a glove box. Data sets were measured with an IPDS diffractometer (imaging plate system STOE) using Mo-K_α radiation and a graphite monochromator (Table 6 and Table 7). Structure determinations were carried out with the programs SHELX-96 and SHELX-97.[50] Numerical absorption corrections for $[YbCp_2F]_3$, $[Yb(MeCp)_2F]_4$, $[Yb(MeCp)_2F(THF)]_2$, and $[Yb(OC_6H_2\text{-}2,6\text{-}tBu_2\text{-}4\text{-}X)_2F(THF)]_2$ were run after crystal face optimisation (X-Shape[51] and X-RED[52]). Neutral atom scattering factors were from International Tables, vol. C.[53] Complete lists of atomic coordinates, bond lengths and angles, thermal parameters, and hydrogen atom coordinates are available from the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-136401–136406. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB121EZ (UK) [Fax: (int. code) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Density Functional Study of Possible Intermediates in the Mechanism of Olefin Cyclopropanation Catalyzed by Metal Carboxylates

Cristóbal Rodríguez-García,[a] Òscar González-Blanco,[a] Antonio Oliva,[a] Rosa M. Ortuño,[a] and Vicenç Branchadell*[a]

Keywords: Carbene complexes / Carboxylato complexes / Density functional calculations / Palladium / Rhodium

The structures of several complexes arising from the interaction between methylene and palladium and rhodium diformates were optimized through density functional calculations. For palladium, mono-, di-, and trimeric complexes were considered. The results obtained show that in all cases the most stable structures correspond to complexes in which methylene has inserted in one of the M–O bonds, while metal–carbene complexes are energy minima only for monomeric palladium diformate and for rhodium diformate. Trimeric palladium formate is thermodynamically stable upon fragmentation. However, when it reacts with methylene, fragmentation becomes favorable. The role of the resulting monomeric complex in the olefin cyclopropanation mechanism catalyzed by palladium dicarboxylates is discussed.

Introduction

The reaction of olefins with diazomethane catalyzed by transition metal complexes is one of the methods for obtaining cyclopropane derivatives.[1–2] The generally accepted mechanism for this reaction involves the formation of a metal–carbene complex as intermediate. Pfeiffer and Dötz[3] have recently reported the first direct spectroscopic observation of such an intermediate for cyclopropanation reactions of enol ethers catalyzed by Cr^0 complexes.

Rhodium and palladium diacetates are among the most efficient catalysts for the cyclopropanation of olefins by diazo compounds. Because their ability to coordinate olefins differs, different mechanisms for these two catalysts have been postulated.[4] For rhodium, the first step would be the formation of the metal–carbene complex that would then react with the olefin, whereas for palladium a metal–olefin complex would be formed before the attack at diazomethane.

Ortuño et al.[5] have reported that in the reaction between diazomethane and chiral cyclohexenones catalyzed by palladium diacetate, the methylenation can take place both at the C–C double bond and at the carbonyl group, the site-selectivity of the process depending on the nature of the substituents in cyclohexenone. The knowledge of the structure of the intermediate arising from the interaction between diazomethane and palladium diacetate seems crucial for understanding the origin of this selectivity.

Metal–carbene complexes have also been studied from a theoretical point of view.[6–13] Vyboishchikov and Frenking[13] have recently studied a series of tungsten–carbene complexes and have analyzed the nature of the bonding. For low-valent complexes, such as $(CO)_5WCH_2$, the bonding can be analyzed in terms of an electron donation from the HOMO of singlet methylene to the corresponding empty d orbital of the metal and a back-donation from one of the doubly occupied dπ orbitals of the metal to the virtual $1b_1$ orbital of singlet methylene. On the other hand, for high-valent complexes, such as Cl_4WCH_2, the bonding is better described as a covalent double bond arising from the interaction between metal and methylene open-shell fragments. In this case, the metal–carbene bond is stronger (larger bond dissociation energy and shorter bond length).

In this paper we present a theoretical study of complexes arising from the reaction between diazomethane and palladium dicarboxylates, which can be relevant in the olefin cyclopropanation mechanism. The alkyl groups have been modeled by hydrogen atoms to simplify the calculations.

Computational Details

Molecular geometries were fully optimized at the generalized gradient approximation (GGA) level of calculation with Becke's[14] exchange potential and the correlation potential of Perdew and Wang[15] (BPW91) implemented in the ADF program.[16–18] The inner electrons of the metal (up to the 3d shell), C, and O were treated within the frozen-core approximation.[17] For the valence space, a basis set of uncontracted Slater-type orbitals was used.[19] The basis set for the metal is triple-ξ. The valence basis set for C, O, and H is of the double-ξ type, supplemented with a set of 3d (C and O) and 2p (H) polarization functions. At this level of calculation the computed bonding energy of $PdCH_2$ is 49.4 kcal mol^{-1}, in excellent agreement with the value obtained by Siegbahn,[20] using the MCPF method (51.0 kcal mol^{-1}).

Relativistic effects were considered in all atoms through the so-called quasi-relativistic method,[21] in which the first-order scalar relativistic Pauli Hamiltonian is diagonalized in the space of the nonrelativistic solutions. These effects were included in the geometry optimization.

Molecular geometries were also optimized at the local density approximation[22] (LDA) level of calculation with the Gaussian-98 program.[23] These geometries were used to calculate harmonic vibrational frequencies. In these calculations we used the effective core potentials of Hay and Wadt[24] for the metal atoms. For the remaining atoms we used the D95 basis set[25] supplemented with a set of 3d polarization functions for C and O.

Results and Discussion

Palladium diacetate has a trimeric structure in the solid state.[26] We optimized the geometry of trimeric palladium diformate as well as those corresponding to the dimer and the monomer. For comparison, we also studied dimeric rhodium diformate.[27] The optimized geometries of these complexes are shown in Figure 1 and selected geometry parameters are presented in Table 1.

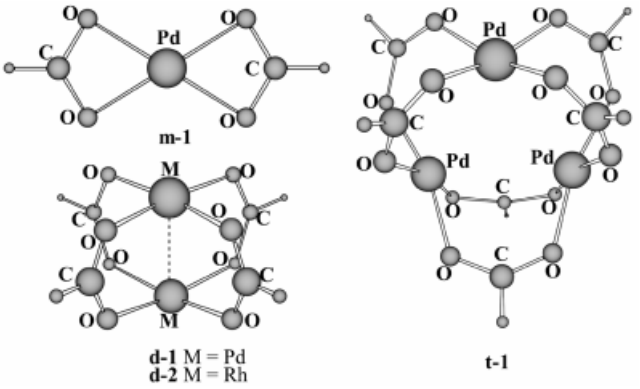

Figure 1. Structures of palladium and rhodium diformates

Table 1. Selected geometry parameters obtained for palladium and rhodium diformate

Structure[a]	M–O[b]	O–C	M–O–C	O–C–O	O–M–O	M–M
m-1	2.082	1.278	89.2	118.2	63.5	
d-1	2.07	1.271	118.1	131.1	89.8	2.581
d-2	2.059	1.270	116.8	128.9	90.0	2.380
t-1[c]	2.049	1.262	127.5	131.5	92.5	3.242
	(1.989)	(1.237)	(130.9)	(125.6)		(3.131)

[a] See Figure 1. – [b] Distances in Å, angles in degrees. – [c] Experimental values corresponding to the crystal structure of palladium diacetate are given in parentheses (ref.[26a]).

Monomeric palladium diformate, **m-1**, has D_{2h} symmetry with the two formate ligands in a bidentate coordination mode, in such a way that Pd is in a square-planar environment, as expected for d^8 ML_4 complexes.

Dimeric palladium diformate, **d-1**, and rhodium diformate, **d-2**, have D_{4h} symmetry. Both metal atoms are linked to each other through four bridging formate ligands, so that each metal atom is also in a square-planar environment. In this environment, Rh^{II} has a d^7 electron configuration. The d orbital pointing to the four oxygen atoms of the coordination plane is empty, while the d_{z^2} orbital, which is perpendicular to the coordination plane, is singly occupied. The interaction between the d_{z^2} orbitals of both Rh atoms leads to a single Rh–Rh bond in **d-2**. The geometry parameters obtained for this complex are very similar to those reported by Cotton and Feng.[28] On the other hand, for the palladium dimeric complex, **d-1**, there is no metal–metal bond, since the dz^2 orbitals of both Pd atoms are doubly occupied. The relatively short value of the Pd–Pd distance is due to the bridging ligands and it is similar to values observed for other Pd^{II} dinuclear complexes.[28]

The trimeric palladium diformate, **t-1**, has D_{3h} symmetry, with the three Pd atoms forming an equilateral triangle (see Figure 1). Two formate bridges link each pair of Pd atoms, leading to a square-planar environment for all metal centers. The optimized geometry parameters obtained for **t-1** (see Table 1) are in very good agreement with the crystal structure determined for palladium diacetate.[26]

Even though palladium diacetate has a trimeric structure in the solid state, in solution it could also exist as a monomer or a dimer. Fragmentation of **t-1** could take place according to the following steps:

t-1 → **d-1** + **m-1** (1)

d-1 → **m-1** + **m-1** (2)

Table 2. Variation of energy and of thermodynamic functions; computed for palladium diformate fragmentation

Step	ΔE[a]	$\Delta H°_{298}$ [a]	$\Delta S°_{298}$[b]	$\Delta G°_{298}$[a]
1	30.9	29.3	43.3	16.4
2	28.1	26.2	48.9	11.6

[a] In kcal mol^{-1}. – [b] In cal K^{-1} mol^{-1}.

Table 2 presents the computed values for energies and thermodynamic functions associated with these steps. Fragmentation of **t-1** is energetically and thermodynamically unfavorable in the gas phase. However, we cannot exclude the possibility that the solvent effect or the coordination of an additional ligand make this process feasible. For this reason, we will consider the formation of carbene complexes from the three forms of palladium diformate.

For comparison, we also considered the fragmentation of **d-2**, which would lead to planar monomeric rhodium diformate in a ^2A_g state. This process is energetically more unfavorable than the fragmentation of **d-1**, the computed fragmentation energy being 80.3 kcal mol^{-1}, since it would involve the cleavage of a Rh–Rh bond, whereas for the palladium complex the metal–metal interaction is repulsive.

For the interaction of methylene with **m-1**, we obtained two different structures (see Figure 2): a Pd–CH_2 complex with C_2 symmetry (**m-3**) and a structure in which methylene has inserted into one of the Pd–O bonds (**m-4**). Both structures are energy minima, since all their vibrational frequencies are real. The **m-3** structure can be considered as a distorted trigonal bipyramid in which O1 and O2 are in the axial positions. The inserted structure **m-4** is 35.3 kcal mol^{-1} more stable than **m-3** and the coordination is square planar.

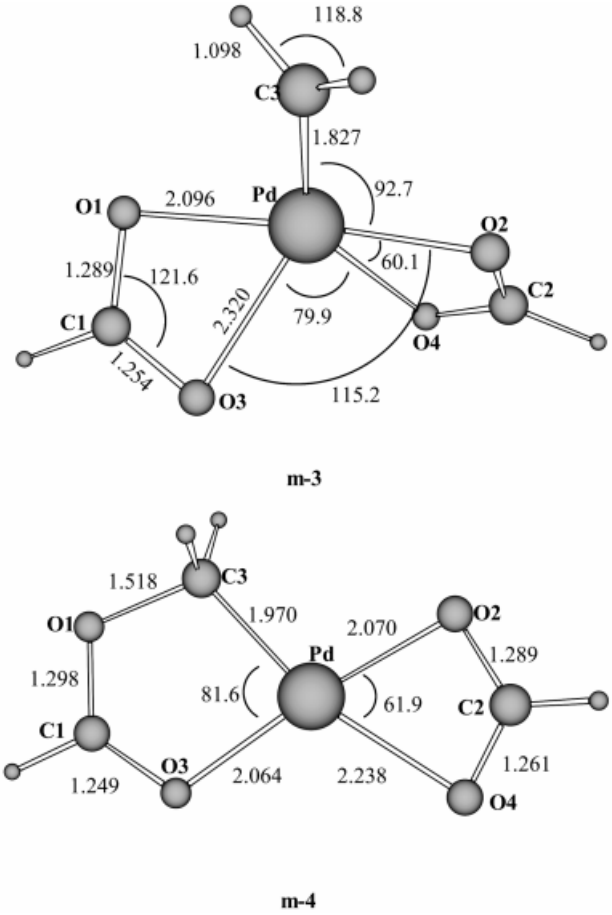

Figure 2. Structures of complexes arising from the interaction between methylene and monomeric palladium diformate; distances are in Å and angles in degrees

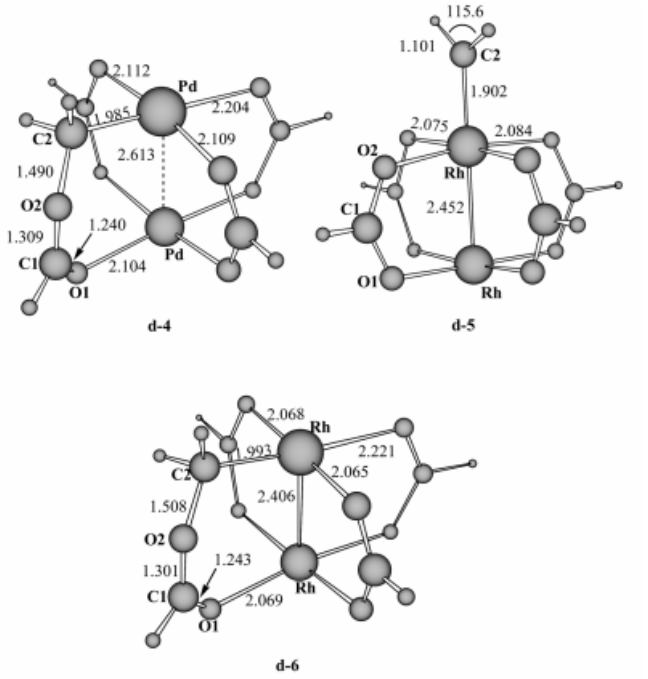

Figure 3. Structures of complexes arising from the interaction between methylene and dimeric rhodium and palladium diformates; distances are in Å and angles in degrees

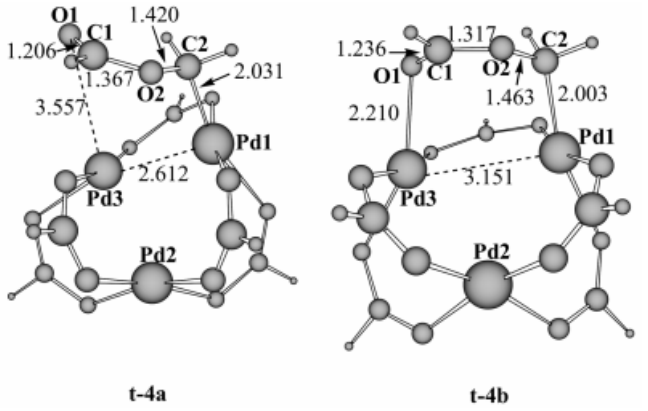

Figure 4. Structures of complexes arising from the interaction between methylene and trimeric palladium diformate; distances are in Å and angles in degrees

Figure 3 represents the structures obtained for the interaction of methylene with dimeric complexes **d-1** and **d-2**. For rhodium diformate, we obtained a metal–carbene complex with C_{2v} symmetry (**d-5**). A similar structure was optimized for palladium diformate, but it has three imaginary frequencies, of symmetries a_2, b_1, and b_2. By lowering the symmetry to C_2, a structure with one imaginary frequency of b symmetry is obtained. Relaxation of all symmetry constraints leads to a structure in which the CH_2 group has inserted into one of the Pd–O bonds (**d-4**). This structure is 35.4 kcal mol^{-1} lower in energy than the C_{2v} Pd–CH_2 structure. A similar CH_2-inserted structure was also obtained for Rh (**d-6**), this structure being 16.6 kcal mol^{-1} lower in energy than **d-5**.

For the interaction between **t-1** and methylene, we obtained a Pd–CH_2 structure with C_2 symmetry. However, this structure is not an energy minimum, since it has an imaginary frequency of b symmetry. When symmetry restrictions are removed, this structure evolves to the CH_2-inserted complex **t-4a** represented in Figure 4. This structure is 32.3 kcal mol^{-1} lower in energy than the C_2 one. Figure 4 shows that in **t-4a** one of the Pd atoms is surrounded by only three oxygen atoms, and that the C1–O1 carbonyl group is not interacting with any of the Pd atoms. We also optimized the geometry of a CH_2-inserted structure in which all Pd atoms are linked through bidentate ligands, as in dimeric complexes **d-4** and **d-6**. The obtained structure, **t-4b**, which is also shown in Figure 4, is 6.0 kcal higher in energy than **t-4a**.

The value of the Pd1–Pd3 distance in **t-4a** (see Figure 4) and the fact that Pd3 is only coordinated to three oxygen atoms seem to indicate that some kind of bonding interaction exists between Pd1 and Pd3. This interaction could be viewed as the electron donation from an occupied dz^2-type orbital perpendicular to the Pd1 coordination plane to an empty d orbital of Pd3. In this way, Pd3 would be in a square-planar tetracoordinated environment, while Pd1 would be in a square-pyramidal pentacoordinated environment.

Structure **t-4b** would be more similar to the CH_2-inserted structures obtained for the monomer and the dimer. However, it is destabilized with respect to **t-4a**. The reason is that the Pd1–Pd3 distance is too large for a bridging ligand such as CH_2OCHO. In the monomeric complex **m-4**, all the C and O atoms of the CH_2OCHO bidentate ligand are in the same plane as Pd, so that the C1–O1–C3–Pd dihedral angle is 0°. In the dimeric complexes, the CH_2OCHO bridging ligand is not coplanar with the metal atoms and the C1–O2–C2–M dihedral angle is –59.4° for **d-4** (M = Pd) and –57.8° for **d-6** (M = Rh). Finally, in **t-4b**, the C1–O2–C2–Pd1 dihedral angle is –80.1°. This large deviation from planarity makes **t-4b** unstable with respect to **t-4a**.

These results suggest that a metal–carbene complex does not exist for dimeric and trimeric palladium dicarboxylates. This kind of structure would exist for monomeric palladium dicarboxylates and for dimeric rhodium dicarboxylates, but, in both cases, the metal–carbene complex would be unstable with respect to methylene insertion in one of the M–O bonds. To rationalize these results, we will analyze the metal–carbene bond in complexes **m-3** and **d-5**.

For comparison, we also optimized the geometries of $(CO)_5WCH_2$ and Cl_4WCH_2 as representative examples of different kinds of metal–carbene complexes. The results obtained, which are summarized in Table 3, are very similar to those reported by Vyboishchikov and Frenking.[13] If we compare the values of the M–CH_2 bond length and of the internal geometry parameters of the methylene group corresponding to **m-3** (Figure 2) and **d-5** (Figure 3) with those

Table 3. Selected geometry parameters of $(CO)_5WCH_2$ and Cl_4WCH_2

Complex	Geometry parameter[a]	
$(CO)_5WCH_2$	W–C[b]	2.070
	C–H	1.101
	H–C–H	108.9
Cl_4WCH_2	W–C	1.881
	C–H	1.097
	H–C–H	115.6

[a] Bond lengths in Å and bond angles in degrees. – [b] Methylene C atom.

presented in Table 3, we observe that Pd and Rh complexes are more similar to Cl_4WCH_2 than to $(CO)_5WCH_2$. So, **m-3** and **d-5** complexes would be better viewed as arising from the interaction of the $^3B_1$ ground state of methylene with the corresponding metal fragment also in a triplet state, as shown in Figure 5.

According to the extended transition state method,[30] the M–CH_2 bonding energy (*BE*) can be formally partitioned into the following terms

$$BE = -(\Delta E_{prep} + \Delta E_{st} + \Delta E_{orb})$$

The preparation energy term, ΔE_{prep}, is the energy difference between the ground state equilibrium geometry of each fragment and the geometry and electronic state they have in the complex. ΔE_{st}, is the steric energy term and represents the interaction energy between both prepared fragments with the geometries corresponding to the final complex, but with the densities that each fragment would have if the other fragment was absent. Finally, the orbital interaction term, ΔE_{orb}, takes into account the stabilization produced when the densities of both fragments are allowed to relax.

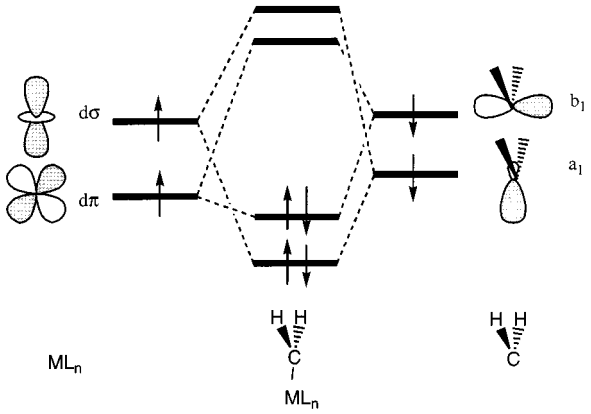

Figure 5. Schematic orbital interaction diagram for triplet methylene and a metal fragment

The formation of the M–CH_2 bond requires monooccupied dσ and dπ orbitals in the metal. These orbitals are doubly occupied in the ground state structure of **m-1**, where the only vacant metal d orbital is the one pointing to the four oxygen atoms (d_{xy}). In the prepared fragment, this orbital is doubly occupied, so that the interaction with the formate ligands becomes repulsive. Geometry distortion relieves this repulsion, leading to the structure shown in Figure 3.

For the metal fragment of **d-5**, the dσ orbital is the unoccupied antibonding combination of the Rh dz^2 orbitals, while dπ is the doubly occupied antibonding combination of the corresponding Rh d orbitals. The preparation of the metal fragment involves a promotion from dπ to dσ. Since dσ is a Rh–Rh antibonding orbital, the Rh–Rh bond becomes weaker upon complex formation (see Table 1 and Figure 3).

We separated the orbital interaction term into two contributions:

$$\Delta E_{orb} = \Delta E_{\sigma+\pi} + \Delta E_{pol}$$

The first term arises from a calculation in which all virtual orbitals of both fragments were removed, so that the energy stabilization is due only to the metal–carbene double bond formation. σ and π contributions can be separated, since the corresponding orbitals belong to different symmetry species, both in **m-3** (*a* and *b*) and in **d-5** (a_1 and b_1). The second term (ΔE_{pol}) is the additional stabilization produced when all virtual orbitals are included in the calculation and can be attributed to the polarization of the densities of both fragments.

Table 4 shows that the M–CH_2 bonds in **m-3** and **d-5** are weaker than in Cl_4WCH_2. The energy partition analysis shows that the dominant factor is the strength of σ and π interactions. The M–CH_2 bond is polarized towards

methylene. The Mulliken population analysis shows that the charge in the CH_2 fragment is –0.33 for **m-3** and –0.39 for **d-5**. The value obtained for Cl_4WCH_2 is –0.45, so that the donor ability of the metal fragments in **m-3** and **d-5** is lower than that of WCl_4.

Table 4. Components of the M–CH_2 bonding energy of metal–carbene complexes. See text for definitions; energies in kcal mol^{-1}

	Cl_4WCH_2	m-3	d-5
ΔE_{prep}	36.3	30.8	23.2
ΔE_{Pauli}	261.1	215.6	190.8
ΔE_{elstat}	–186.5	–150.2	–126.8
ΔE_{st}	74.6	65.4	64.0
ΔE_{σ}	–113.3	–95.0	–91.7
ΔE_{π}	–48.7	–34.0	–22.3
$\Delta E_{\sigma+\pi}$	–160.0	–129.0	–114.0
ΔE_{pol}	–36.6	–22.9	–26.5
BE	85.7	55.7	53.3

Since the M–CH_2 bond in **m-3** and **d-5** is not strong enough, these complexes are unstable with respect to methylene insertion in one of the M–O bonds. This process, which restores the square-planar coordination arrangement around the metal, involves the cleavage of a M–O bond and the formation of a σ M–C bond. For dimeric and trimeric palladium diformate, metal–carbene complexes are much more destabilized and do not correspond to stable structures. In these cases, the preparation energy of the metal fragment would be notably larger than for **m-3** and **d-5** and the rigidity of the structures does not allow a similar geometry relaxation as the one observed for the monomer.

We have seen that trimeric palladium diformate is thermodynamically stable with respect to fragmentation. Let us now consider the fragmentation of the methylene-inserted structure **t-4a**. This fragmentation can take place through the following steps:

t-4a → **d-1** + **m-4** (3)

t-4a → **d-4** + **m-1** (4)

d-4 → **m-4** + **m-1** (5)

Table 5. Variation of energy and thermodynamic functions for the fragmentation of **t-4a**

Step	ΔE[a]	$\Delta H°_{298}$[a]	$\Delta S°_{298}$[b]	$\Delta G°_{298}$[a]
3	4.3	2.6	39.2	–9.1
4	17.9	17.0	42.3	4.4
5	14.5	12.8	45.8	–0.9

[a] In kcal mol^{-1}. – [b] In cal K^{-1} mol^{-1}.

Table 5 contains the energies and variation of thermodynamic functions associated with these processes. Fragmentation is energetically unfavorable, but the inclusion of the entropy contribution makes step 3 thermodynamically favorable. These results can be compared with those corresponding to the fragmentation of **t-1** (Table 2), which was unfavorable even when the entropy contribution was considered.

Thus, **t-4a** is unstable with respect to fragmentation even in the gas phase and the monomeric **m-4** complex, which would be the product of such a process, could be envisaged as an intermediate in the cyclopropanation mechanism. A possible mechanistic scheme for the reaction between diazomethane and ethylene catalyzed by palladium dicarboxylates is presented in Figure 6. In the first step, the reaction between diazomethane and **t-1** leads to the formation of **t-4a**. Then, the fragmentation of this complex leads to **m-4**. Reaction between this complex and ethylene would lead to the formation of the corresponding cyclopropane derivative and **m-1**, which could also react with diazomethane to regenerate **m-4**. The reaction between **m-4** and the olefin is expected to involve several steps, such as the coordination of the olefin to Pd and the formation of a metalacyclobutane intermediate. The detailed study of this process, including the location of transition states, is currently in progress. The computed Gibbs energies presented in Figure 6 show that the overall mechanism is thermodynamically feasible for the cyclopropanation of ethylene.

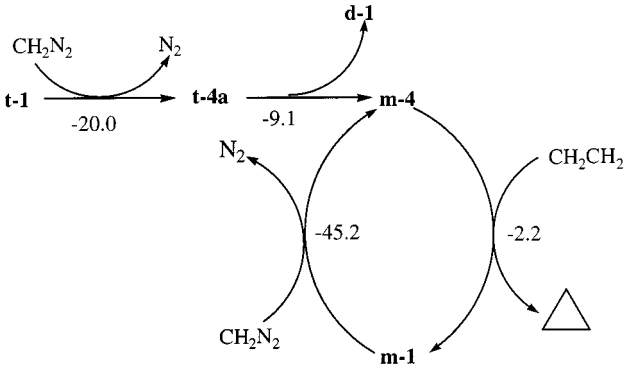

Figure 6. Possible mechanism for cyclopropanation of ethylene by diazomethane catalyzed by palladium diformate; values of reaction Gibbs energies are given in kcal mol^{-1}

As we mentioned in the introduction, other mechanisms involving the prior coordination of the olefin to palladium diacetate had also been postulated.[4] Our results showed that the coordination of an additional ligand in a tetracoordinated Pd^{II} complex requires an important rearrangement of the ligands to minimize metal–ligand repulsion. We saw that this rearrangement is not possible for the coordination of methylene in dimeric and trimeric palladium complexes. Similar behavior is expected for other ligands such as ethylene. So, a palladium–ethylene complex would only be formed from the monomeric structure **m-1**. We optimized the geometry of this complex and the obtained structure is shown in Figure 7. This structure can be consid-

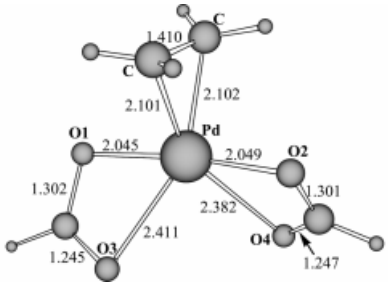

Figure 7. Structure of complexes arising from the interaction between ethylene and monomeric palladium diformate; distances are in Å

ered to be trigonal bipyramidal with ethylene in one of the equatorial positions. Compared to **m-4** (Figure 2), the Pd–O3 and Pd–O4 distances are notably larger in the ethylene complex, while Pd–O1 and Pd–O2 distances are slightly shorter. The computed Pd–ethylene bond dissociation energy is 16.8 kcal mol^{-1}. We also optimized the geometry of a complex in which ethylene inserts in one of the Pd–O bonds, but it is 2.7 kcal mol^{-1} higher in energy than the ethylene-coordinated complex.

The reaction between **m-1** and diazomethane to yield **m-4** and N_2 has a reaction energy of –47.2 kcal mol^{-1}, so that it is energetically much more favorable than the formation of the ethylene-coordinated complex. Cui et al.[31] studied the reaction between Cu and diazomethane to form $CuCH_2$ and N_2 theoretically, and observed that the reaction proceeds without an energy barrier and with a reaction energy of –34.9 kcal mol^{-1}. The formation of **m-4** from **m-1** and diazomethane involves an important rearrangement of the formate ligands, so that an energy barrier is expected for this process. Since this rearrangement is also necessary for ethylene coordination, the corresponding energy barriers are expected to be similar.

These results suggest that the mechanism for the cyclopropanation of olefins by diazomethane catalyzed by palladium dicarboxylates does not involve the prior formation of a metal–olefin complex. On the other hand, metal–carbene complexes are unstable with respect to methylene insertion in one of the Pd–O bonds, so that these CH_2-inserted species could be intermediates in the cyclopropanation mechanism.

Concluding Remarks

We optimized the geometries of several complexes arising from the interaction between methylene and palladium and rhodium diformates. In all cases, the most stable structures correspond to complexes in which methylene has inserted into one of the M–O bonds, while metal–carbene complexes correspond to energy minima only for monomeric palladium diformate and for dimeric rhodium diformate. In these cases, the analysis of the metal–carbene bonding shows that the bond is weaker than for other complexes, such as Cl_4WCH_2, due to a lower σ and π donor ability of the metal fragment.

Trimeric palladium formate (**t-1**) is thermodynamically stable upon fragmentation. However, when it forms a complex with methylene (**t-4a)**, fragmentation becomes favorable. The resulting monomeric complex **m-4** can be envisaged as an intermediate in the olefin cyclopropanation mechanism catalyzed by palladium dicarboxylates.

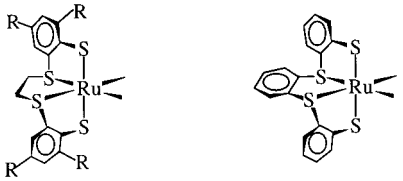
Transition Metal Complexes with Sulfur Ligands, 143[‡]

Coordination of CO, NO, N_2H_2, and Other Nitrogenase Relevant Small Molecules to Sulfur-Rich Ruthenium Complexes with the New Ligand 'tpS_4'$^{2-}$ = 1,2-Bis(2-mercaptophenylthio)phenylene(2–)

Dieter Sellmann,*[a] Klaus Engl,[a] Frank W. Heinemann,[a] and Joachim Sieler[b]

Dedicated to Professor Heinrich Vahrenkamp on the occasion of his 60th birthday



Keywords: Ruthenium / S ligands / Hydrazine / Diazene

In the search for ruthenium complexes with sulfur-dominated coordination spheres that bind, activate, or stabilize nitrogenase relevant molecules, complexes containing the new and robust tetradentate ligand 'tpS_4'–H_2 were synthesized. Treatment of $[RuCl_2(PPh_3)_3]$ with 'tpS_4'$^{2-}$ gives $[Ru(PPh_3)_2('tpS_4')]$ (**1**), which contains two labile PPh_3 ligands. The reaction of **1** with PEt_3 or DMSO led to substitution of both PPh_3 ligands, yielding $[Ru(PEt_3)_2('tpS_4')]$ (**2**) and $[Ru(DMSO)_2('tpS_4')]$ (**3**), respectively. When treated with nitrogenous ligands, complex **1** lost only one PPh_3 ligand to yield $[Ru(L)(PPh_3)('tpS_4')]$ complexes where L = py (**7**), NH_3 (**8**), N_2H_4 (**9**), NH_2NHMe (**10**), and CH_3CN (**12**), all of which are labile. The labile acetonitrile complex $[Ru(CH_3CN)(PPh_3)('tpS_4')]$ (**12**) proved to be particularly suited as a precursor for the syntheses of other $[Ru(L)(PPh_3)('tpS_4')]$ complexes. The 18 and 19 valence electron NO complexes $[Ru(NO)(PPh_3)('tpS_4')]BF_4$ (**13**) and $[Ru(NO)(PPh_3)('tpS_4')]$ (**14**), $(NEt_4)[Ru(N_3)(PPh_3)('tpS_4')]$ (**15**), $[Ru(I)(PPh_3)('tpS_4')]$ (**16**), and $[Ru(N_3)(PPh_3)('tpS_4')]$ (**17**) were obtained starting from complex **12**. The labile mononuclear hydrazine complex $[Ru(N_2H_4)(PPh_3)('tpS_4')]$ (**9**) gave the dinuclear complex $[\mu\text{-}N_2H_4\{Ru(PPh_3)('tpS_4')\}_2]$ (**18**) by dissociation of hydrazine. The dinuclear diazene complex $[\mu\text{-}N_2H_2\{Ru(PPh_3)('tpS_4')\}_2]$ (**19**) was obtained by oxidation of **9** and more readily from $[Ru(CH_3CN)(PPh_3)('tpS_4')]$ (**12**) and N_2H_2, which was generated in situ from $K_2N_2(CO_2)_2$ and acetic acid. The molecular structures of **7**, **13**, **16**, **18**, and **19** were determined by X-ray structure analyses. The complexes **18** and **19** represent the first complexes containing the hydrazine/diazene couple, which enables us to compare both the bonding features and the formation of N–H···S bridges when hydrazine and diazene bind to transition metal sulfur sites.

Introduction

The stabilization, or coordination and activation of small molecules such as CO, N_2, H_2, NO, N_3^-, N_2H_2, N_2H_4, and NH_3 by transition metal sulfur complexes is of pivotal interest for understanding the molecular mechanisms of nitrogenases.[1] It can be assumed that these molecules interact with the FeMo, FeV, or FeFe cofactors that are the active sites of nitrogenases. The FeMo cofactors of FeMo nitrogenase in the resting state have been shown by X-ray crystallography to contain $[Fe_7MoS_9]$ clusters.[2] Similar structures are assumed for the FeV or FeFe cofactors of the alternative FeV and FeFe nitrogenases.[3] However, the functioning of these clusters has remained unexplained, not least because a compound that models basic structural *and* functional principles of the cofactors has yet to be found. In particular, these principles are metal sulfur sites *and* the mild catalytic reduction of N_2 with biologically compatible redox potentials.[4]

In our search for such compounds we have found that both the [Ru('S_4')] fragments and their tertiary butyl derivatives [Ru('$^{bu}S_4$')] coordinate the complete series of above mentioned molecules, with the exception of N_2 (Scheme 1).[5]

Scheme 1. [Ru('$^{R}S_4$')] and [Ru('tpS_4')]

Another shortcoming of the [Ru('$^{R}S_4$')] complexes are ligand C–S cleavage reactions. In most cases, the [Ru('$^{R}S_4$')] fragments prove to be robust and the '$^{R}S_4$'$^{2-}$ ligands stay intact, behaving as spectator ligands. However, under strongly reducing or photolytic conditions, in reactions with

electron-rich metal complexes, and in reactions involving 19 valence electron complexes, C(alkyl)–S cleavage reactions take place yielding, among other products, 1,2-benzenedithiolate, or vinylthio(2-mercapto)benzene(1–) ligands and ethylene.[6] Since aromatic C–S bonds are more stable towards cleavage than C(alkyl)–S bonds, we synthesized the new dithioether–dithiolate ligand 'tpS_4'$^{2-}$ = 1,2-bis(2-mercaptophenylthio)phenylene(2–), which contains exclusively aromatic C–S bonds. In a previous paper we described the syntheses of 'tpS_4'$^{2-}$ and a few Ru, Os, and Ni complexes containing [M('tpS_4')] fragments, demonstrating that the 'tpS_4'$^{2-}$ ligand coordinates metals in the same helical manner as the '$^{R}S_4$'$^{2-}$ ligands and is indeed stable toward C–S cleavage.[7] Preliminary tests also indicated that analogous [Ru('$^{R}S_4$')] and [Ru('tpS_4')] complexes can have quite different substitution reactivity. This prompted us to systematically investigate the synthesis and reactivity of [Ru('tpS_4')] complexes, focusing on hydrazine, nitrosyl, and azido derivatives as potential N_2 complex precursors,[8] because subtle differences in the [Ru('$^{R}S_4$')] and [Ru('tpS_4')] fragments may be decisive in the binding or nonbinding of N_2.[9]

Results

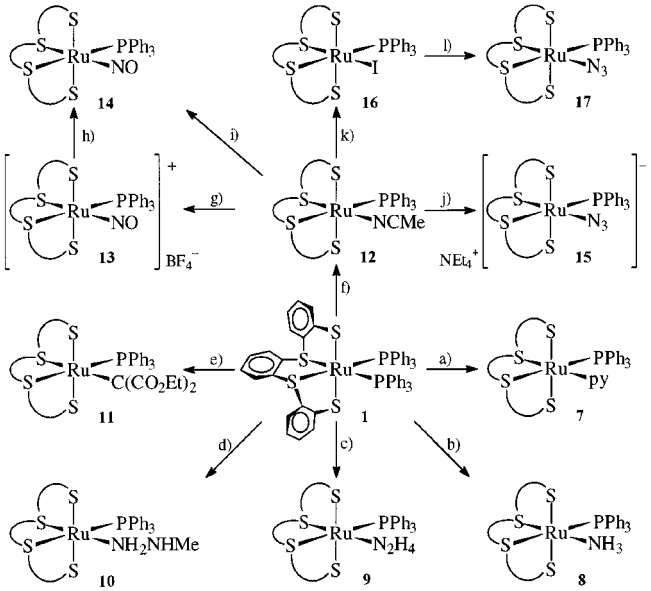
Syntheses of [Ru('tpS_4')] Complexes with DMSO, Phosphanes, and Nitrogenous Coligands

In the search for labile [Ru(L)(L')('tpS_4')] complexes we probed the exchange of PPh_3 in the readily accessible [Ru(PPh_3)$_2$('tpS_4')] (**1**) (Scheme 2).[7]

Scheme 2. Phosphane and DMSO exchange reactions of [Ru(PPh_3)$_2$('tpS_4')]: a) + [$RuCl_2(PPh_3)_3$], THF, 4 h, room temperature (room temp.); b) + exc. PEt_3, THF, 3 min, reflux; c) DMSO, 5 min, reflux; d) + [$RuCl_2(DMSO)_4$], THF, 2.5 d, room temp.; e) + CH_3I, 2 h, room temp.; f) + exc. PMe_3, THF, 3 h, room temp.; g) + CO (1bar), THF, 4 d, room temp.; h) + [$RuCl_2(PMe_3)_4$], MeOH, 4 h, reflux

When **1** was treated with PEt_3, [Ru(PEt_3)$_2$('tpS_4')] (**2**) formed. Formation of the mixed phosphane complex [Ru(PEt_3)(PPh_3)('tpS_4')] was not observed. Brief heating of **1** in DMSO yielded [Ru(DMSO)$_2$('tpS_4')] (**3**) which could be readily obtained directly from [$RuCl_2(DMSO)_4$] and 'tpS_4'$^{2-}$. With regard to the PEt_3 and DMSO reactions, the reactivity of **1** is in contrast to that of the parent complex [Ru(PPh_3)$_2$('S_4')] which exchanges only one or none of its PPh_3 ligands under comparable conditions. An analogous behavior of **1** and the parent complex [Ru(PPh_3)$_2$('S_4')] was found in the reactions with MeI and PMe_3. Treatment of **1** in CH_2Cl_2 with excess MeI afforded the doubly methylated derivative [Ru(I)(PPh_3)('tpS_4–Me_2')]I (**4**) in isomerically pure form. PMe_3 was able to substitute only one PPh_3 ligand in **1** to give [Ru(PMe_3)(PPh_3)('tpS_4')] (**5**), even when an excess of PMe_3 was applied and the temperature was raised. The bis(PMe_3) complex [Ru(PMe_3)$_2$('tpS_4')] (**6**) formed from [$RuCl_2(PMe_3)_4$] and Li_2–'tpS_4' in boiling MeOH.

In order to probe the lability of PMe_3 versus that of PPh_3 in [Ru(PMe_3)(PPh_3)('tpS_4')] (**5**), complex **5** was treated with CO under standard conditions. Monitoring the reaction by IR and NMR spectroscopy as well as mass spectrometry showed the formation of [Ru(CO)(PMe_3)('tpS_4')], indicating that in **5** the large PPh_3 is more labile than the small PMe_3 ligand.



The complexes **2**–**6** proved to be less labile than the PPh_3 complex **1** and were not suited for exchange reactions with nitrogenous ligands. Attempts to exchange directly one PPh_3 in **1** for such ligands succeeded with pyridine, hydrazine(s), ammonia, and even diazomalonic ethyl ester, but failed for NO, NO^+, or N_3^-. In order to achieve their coordination it was necessary to proceed via the acetonitrile complex [Ru(MeCN)(PPh_3)('tpS_4')] (**12**). Scheme 3 summarizes these reactions and complexes.

Brief heating of **1** in pyridine gave [Ru(py)(PPh_3)('tpS_4')] (**7**). Treatment of **1** in THF with an excess of NH_3 gas, N_2H_4, or N_2H_3Me likewise afforded [Ru(NH_3)(PPh_3)('tpS_4')] (**8**), [Ru(N_2H_4)(PPh_3)('tpS_4')] (**9**), and [Ru(N_2H_3Me)(PPh_3)('tpS_4')] (**10**). In order to drive the reactions to completion, the solutions were usually heated to boiling for a short time. The conversion of **9** into a dinuclear hydrazine complex is described below.

A reaction was also observed between **1** and diethyl diazomalonate [$N_2C(CO_2Et)_2$)] in boiling THF. Monitoring the reaction by ^1H NMR spectroscopy showed that the primary product is presumably [Ru{$N_2C(CO_2Et)_2$}(PPh_3)('tpS_4')], which rapidly transforms into the carbene complex [Ru{$C(CO_2Et)_2$}(PPh_3)('tpS_4')] (**11**).

These results indicate that nitrogenous ligands are able to selectively substitute one PPh_3 in [Ru(PPh_3)$_2$('tpS_4')] (**1**). In the quest for labile solvent complex derivatives of **1**, which had so far remained inaccessible, we now tried to obtain the acetonitrile complex [Ru(MeCN)(PPh_3)('tpS_4')] (**12**). The yellow complex **12** formed from boiling acetonitrile solutions of **1**, could be isolated in solid state, completely characterized, and proved an excellent starting material for further complexes.

The reaction of **12** with CO at ambient conditions established the lability of the MeCN ligand. The CO complex

Scheme 3. Coordination of nitrogenous ligands to the [Ru(PPh$_3$)('tpS$_4$')] fragment: a) pyridine, 10 min, reflux; b) + NH$_3$ (gaseous), THF, 5 min, reflux; c) + exc. N$_2$C(CO$_2$Et)$_2$, THF, 4 h, reflux; f) MeCN, 3 h, reflux; g) + NOBF$_4$, CH$_2$Cl$_2$, 3 h, room temp.; h) + LiBEt$_3$ H, THF, 30 min, room temp.; i) NO (gaseous), CH$_2$Cl$_2$, 20 h, room temp.; j) + NEt$_4$N$_3$, acetone, 3 h, room temp.; k) + 0.5 I$_2$, THF 12 h, room temp.; l) + exc. NEt$_4$N$_3$, acetone, 3 d, room temp.

[Ru(CO)(PPh$_3$)('tpS$_4$')] [ν(CO) = 1964 cm^{-1}] formed nearly instantly. [Ru(CO)(PPh$_3$)('tpS$_4$')] also formed directly from **1** and CO. However, this reaction needed ca. 12 h to go to completion.[7]

Treatment of **12** with one equivalent of NOBF$_4$ yielded [Ru(NO)(PPh$_3$)('tpS$_4$')]BF$_4$ (**13**). Complex **13** is the first 18 valence electron nitrosyl complex with an [RuPS$_4$] core characterized by X-ray structure determination. It was of particular interest as a test complex for probing the stability of the 'tpS$_4$'$^{2-}$ ligand towards reduction.

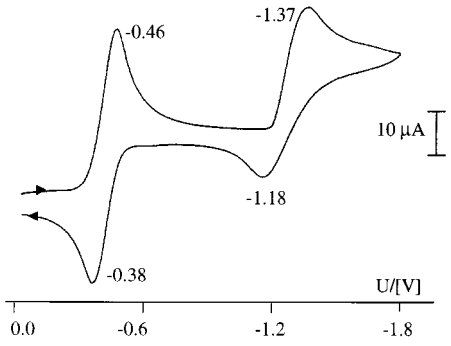


Figure 1. Cyclic voltammogram of [Ru(NO)(PPh$_3$)('tpS$_4$')]BF$_4$ (**13**) in CH$_2$Cl$_2$ (10^{-3} M, 10^{-1} M NBu$_4$PF$_6$, v = 0.05Vs^{-1})

The cyclic voltammogram (CV) of **13** in CH$_2$Cl$_2$ (Figure 1) exhibited two redox waves in the cathodic region. The redox wave at $E_{1/2}$ = –0.42 V could be assigned to the reversible reduction [Ru(NO)(PPh$_3$)('tpS$_4$')]$^+$/[Ru(NO)(PPh$_3$)('tpS$_4$')]^0 and indicated the viability of the neutral 19 valence electron nitrosyl complex [Ru(NO)(PPh$_3$)('tpS$_4$')] (**14**).

This result was corroborated by chemical reduction of **13** and the reaction of the acetonitrile complex **12** with NO gas. Monitoring the reaction of **13** with LiBEt$_3$H in THF by IR spectroscopy showed that the ν(NO) band of **13** at 1850 cm^{-1} was replaced by a new band at 1602 cm^{-1}. No gas was evolved, and the intensity and frequency of the 1602 cm^{-1} band was found to be compatible with the formation of **14**.[10] Treating **12** with NO gas in CH$_2$Cl$_2$ led to a strong ν(NO) band appearing in the same region at 1605 cm^{-1}. Complex **14** could be precipitated from this solution as red-brown solid by the addition of *n*-hexane. Complex **14** is highly reactive and almost instantly oxidized by traces of air to give the [Ru(NO)(PPh$_3$)('tpS$_4$')]$^+$ cation, as indicated by the ν(NO) band at 1842 cm^{-1} (KBr). Complex **14** is paramagnetic and was only characterized by elemental analyses, IR spectroscopy, and mass spectrometry, which confirmed that the 'tpS$_4$'$^{2-}$ ligand remained intact.

Attempts to convert the nitrosyl ligands of either cationic **13** or neutral **14** into dinitrogen ligands by reactions with azide or ammonia have so far been unsuccessful. For the alternate route, in which the ligating azide is converted into N$_2$ by attack with NO$^+$, azido complexes were needed. Treatment of **12** in acetone with one equivalent of NEt$_4$N$_3$ yielded the azido complex (NEt$_4$)[Ru(N$_3$)(PPh$_3$)('tpS$_4$')] (**15**) whose formation could be established by IR and ^{1}H NMR spectroscopy. However, **15** proved to be too labile to obtain ^{13}C and ^{31}P NMR spectra and rapidly decomposed, even in the solid state, to give a brown mixture of intractable products. Repeated attempts to purify **15** by recrystallization were unsuccessful. For these reasons, we tried to obtain a potentially more stable Ru^{III} azide complex via the Ru^{III} iodide complex [Ru(I)(PPh$_3$)('tpS$_4$')] (**16**). Complex **16** formed from the reaction of the acetonitrile complex **12** with half an equivalent of iodine, and could be characterized by X-ray crystallography. The subsequent reaction of **16** with NEt$_4$N$_3$ yielded [Ru(N$_3$)(PPh$_3$)('tpS$_4$')] (**17**) which was isolated in pure state and characterized by IR spectroscopy and mass spectrometry. As expected, and confirmed from the ^{1}H NMR spectra showing broad and unresolved peaks, **16** and **17** are both paramagnetic. Complex **17** was further characterized by its cyclic voltammogram (Figure 2).

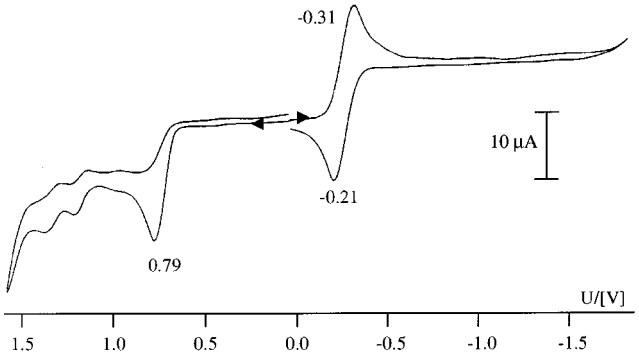

Figure 2. Cyclic voltammogram of [Ru(N$_3$)(PPh$_3$)('tpS$_4$')]BF$_4$ (**17**) in CH$_2$Cl$_2$ (10^{-3} M, 10^{-1} M NBu$_4$PF$_6$, v = 0.02Vs^{-1})

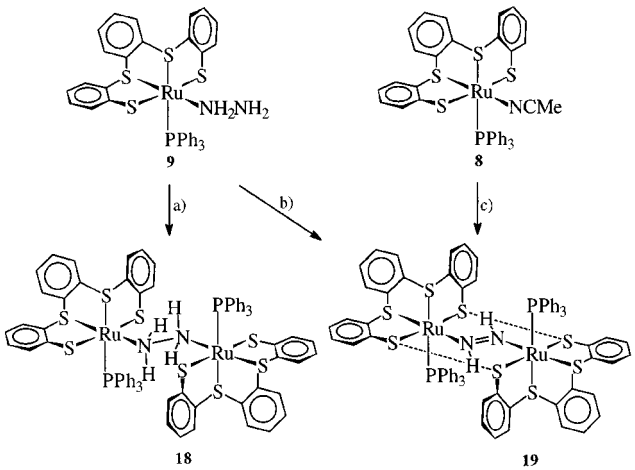

In the cathodic region, **17** showed a reversible redox wave at $E_{1/2}$ = –0.26 V. It is compatible with the reversible reduc-

tion of **17** to give the anion of the Ru^{II} complex **15**. Attempts to convert **17** photolytically, thermally, or by treatment with HBF_4 in CH_2Cl_2 into a dinitrogen complex remained unsuccessful.

Dinuclear Hydrazine and Diazene Complexes with [Ru(PPh$_3$)('tpS$_4$')] Fragments

The unsuccessful attempts to obtain a [Ru(PPh_3)('tpS_4')] dinitrogen complex via nitrosyl or azide precursors prompted us to return to the hydrazine complex [Ru(N_2H_4)(PPh_3)('tpS_4')] (**9**). As mentioned above, the N_2H_4 ligand is labile. In this respect **9** resembles the other [Ru(L)(PPh_3)('tpS_4')] complexes in which L is a σ-N donor ligand.

The complex [Ru(N_2H_4)(PPh_3)('tpS_4')] (**9**) did not yield a dinitrogen complex either. However, further investigation led to the characterization of [μ-N_2H_4{Ru(PPh_3)('tpS_4')}$_2$] (**18**) and [μ-N_2H_2{Ru(PPh_3)('tpS_4')}$_2$] (**19**) which represent the first hydrazine and diazene couple characterized by X-ray structure determination (Scheme 4).

Scheme 4. Formation of dinuclear hydrazine and diazene complexes with [Ru(PPh_3)('tpS_4')] fragments: a) CH_2Cl_2, 7 d, room temp.; b) + O_2, CH_2Cl_2, 36 h, room temp.; c) + exc. $K_2N_2(CO_2)_2$, + exc. CH_3CO_2H, THF, 3 h, room temp.

Attempts to recrystallize **9** from CH_2Cl_2/MeOH mixtures afforded yellow microcrystals that proved so sparingly soluble that no NMR spectra could be recorded. The elemental analyses and IR spectra indicated that two molecules of mononuclear **9** had formed the dinuclear hydrazine complex **18** by dissociation of hydrazine. Carrying out the same experiment in THF/Et_2O mixtures afforded single crystals of **18**·4THF, which could be structurally characterized. When the CH_2Cl_2 solutions of the hydrazine complex **9** were treated with atmospheric oxygen, their color turned from yellow to dark green and green crystals precipitated. They were also sparingly soluble, but we were able to record a ^1H NMR spectrum which exhibited a signal at δ = 14.59, indicative of an N_2H_2 ligand in a centrosymmetric dinuclear diazene complex of the type [μ-N_2H_2{Ru(PPh_3)('tpS_4')}$_2$] (**19**). Intense absorptions at 307 and 463 nm in the UV/Vis spectrum also suggested the formation of **19**, which was finally and unambiguously characterized by an X-ray crystal structure determination of **19**·4CH_2Cl_2.

The aerial oxidation of **9** afforded **19** in yields of 25%. A potential reason for the low yield is that the dinuclear hydrazine complex **18** must form before subsequent oxidation occurs to give **19**. Therefore we sought a better synthesis of **19** and found that much higher yields (> 80%) were obtained from the reaction of the labile acetonitrile complex **12** with N_2H_2, which was generated in situ by acidolysis of $K_2N_2(CO_2)_2$ with dilute acetic acid in THF. This trapping of the unstable diazene in solution is possible with particular metal sulfur complex fragments and was first discovered with the synthesis of [μ-N_2H_2{Fe(PPr_3)('S_4')}$_2$].[11]

General Properties and Spectroscopic Characterization of [Ru(L)(L')('tpS$_4$')] Complexes

As far as possible, all [Ru(L)(L')('tpS_4')] complexes have been characterized by the common spectroscopic methods and elemental analyses. The molecular structures of **7**, **13**, **16**, **18**, and **19** have been determined by X-ray structure analysis. All Ru^{II} complexes are diamagnetic, while the two Ru^{III} complexes are paramagnetic as indicated by their ^1H NMR spectra. The colors of the complexes range from yellow or orange (**1**–**12**), to green (**17**, **19**) and brown (**13**, **14**, **16**). All complexes, except the dinuclear species **18** and **19**, show moderate to good solubilities in CH_2Cl_2. The IR spectra of all complexes in KBr exhibit the typical absorptions of the [Ru('tpS_4')] fragment. A strong ν(CO) absorption at 1968 cm^{-1} and a strong δ(PCH) at 953 cm^{-1} characterize [Ru(CO)(PMe_3)('tpS_4')]. A ν(SO) band at 1015 cm^{-1} indicates sulfur coordination of DMSO in [Ru$(DMSO)_2$('tpS_4')] (**3**). Weak ν(NH) (3334, 3292, 3245, 3164 cm^{-1}) and ν(CN) (2271 cm^{-1}) bands readily identify [Ru(N_2H_4)(PPh_3)('tpS_4')] (**9**) and [Ru(MeCN)(PPh_3)('tpS_4')] (**12**) respectively. Strong ν(NO) bands at 1852 and 1598 cm^{-1} characterize the nitrosyl complexes **13** and **14**. The azide complexes **15** and **17** show characteristic ν(N_3) absorptions at 2029 and 2036 cm^{-1}. The ^1H NMR spectra of C_2-symmetric [Ru$(L)_2$('tpS_4')] complexes exhibit a typical set of six multiplets for the aromatic 'tpS_4' protons. This multiplet changes when the symmetry is lowered to C_1 in [Ru(L)(L')('tpS_4')] complexes. In all [Ru(L)(PPh_3)('tpS_4')] complexes, the 'tpS_4' multiplets are superimposed on the PPh_3 multiplets. Thus, the [Ru(L)(PPh_3)('tpS_4')] complexes usually are more readily identified by their ^{13}C and ^{31}P NMR spectra.

However, the ^1H NMR spectrum of [Ru(I)(PPh_3)('tpS_4–Me_2')]I (**4**) showed two singlets for the methyl groups, establishing that only one of several possible isomers had formed. The ^1H NMR spectra of **8** and **12** exhibited characteristic singlets at δ = 1.70 and 1.75, indicating the coordination of ammonia and acetonitrile. The hydrazine complex **9** gave rise to two multiplets at δ = 4.2 and 4.1 which are attributed to the Ru-bound NH_2 group, and a broad singlet at δ = 3.4 which is assigned to the terminal NH_2 group. The N_2H_2 singlet at δ = 14.59 is characteristic of the diazene complex [μ-N_2H_2{Ru(PPh_3)('tpS_4')}$_2$] (**19**). Complex **19** was further characterized by its UV/Vis spectrum, showing a strong absorption at 463 nm (ε = 8162 L

mol^{-1} cm^{-1}) which is characteristic of the 4c-6 e^- π bond system of [M=NH=NH=M] fragments (Figure 3).[12]

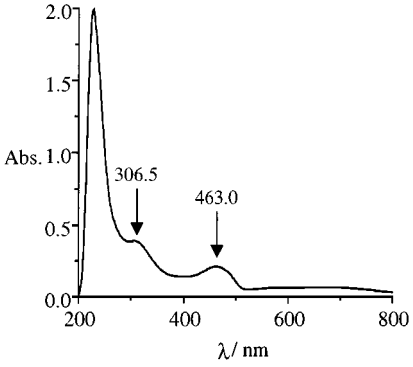

Figure 3. UV/Vis spectrum of $[\mu\text{–}N_2H_2\{Ru(PPh_3)(\text{'}tpS_4\text{'})\}_2]$ in CH_2Cl_2

X-ray Structure Analysis

The molecular structures of [Ru(py)(PPh_3)('tpS_4')] (**7**), [Ru(NO)(PPh_3)('tpS_4')]BF_4·CH_2Cl_2 (**13**·CH_2Cl_2), [Ru(I)(PPh_3)('tpS_4')]·CH_2Cl_2 (**16**·CH_2Cl_2), [μ-N_2H_4\{Ru(PPh_3)('tpS_4')\}$_2$]·4THF (**18**·4THF), and [μ-N_2H_2\{Ru(PPh_3)('tpS_4')\}$_2$]·4CH_2Cl_2 (**19**·4CH_2Cl_2) were determined by X-ray crystallography and are shown in Figure 4. Table 1 lists selected distances and angles.

In all cases the crystal lattices contain discrete molecules or ions. All compounds exhibit six-coordinate Ru centers, helical coordination of the 'tpS_4'$^{2-}$ ligands with *trans*-thiolate and *cis*-thioether S donors, and *cis* coordination of the ligands PPh_3 and L = py, NO, I, N_2H_4, N_2H_2.

Distances and angles lie in the range observed for related [Ru('S_4')] complexes. For example, in both the [Ru('tpS_4')] and [Ru('S_4')] complexes, the average Ru–S distances are found to be in the narrow range of 233–238 pm. This is worthy of note, in light of the different properties of the coligands which coordinate to the [RuS_4] cores, such as the σ-π ligands CO, NO^+ or N_2H_2, or the σ ligands N_2H_4 and pyridine. Even in the Ru^{III} complex [Ru(I)(PPh_3)('tpS_4')]·CH_2Cl_2 (**16**·CH_2Cl_2), the average Ru–S distance (234 pm) does not significantly differ from that of Ru^{II} complexes. This invariance of averaged M–S distances in low-spin complexes having no electrons in antibonding orbitals has been previously discussed and can be traced back to the bonding properties of sulfur ligands, which can function as σ-donor, σ-donor–π-acceptor, and σ-donor–π-donor ligands.[13–15]

The diazene and hydrazine complexes **19**·4CH_2Cl_2 and **18**·4THF deserve special consideration. They represent the first structurally characterized complexes containing the N_2H_2/N_2H_4 couple, and enable comparison of both the differing bonding situations and the formation of N–H···S bridges when hydrazine or diazene bind to transition metal

sulfur sites. Both complexes possess a crystallographically imposed inversion symmetry. The N_2H_2 and N_2H_4 ligands bridge two enantiomeric [Ru(PPh_3)('tpS_4')] fragments, and the centers of the N–N bonds represent the inversion centers. The average Ru–S distances in the hydrazine complex **18**·4THF (235.1 pm) and the diazene complex **19**·4CH_2Cl_2 (236.6 pm) are also similar. The difference of 1.5 pm is a result of different Ru–S2 distances *trans* to the N_2H_4 and N_2H_2 ligands, which are 227.5(4) pm (**18**·4THF) vs. 232.9(2) pm (**19**·4CH_2Cl_2). All other Ru–S distances are identical within the 3σ criterion in both **18**·4THF and **19**·4CH_2Cl_2.

The Ru–S2 distance of **19**·4CH_2Cl_2 [232.9(2) pm] indicates the *trans* bond lengthening influence of the σ-π ligand N_2H_2, since the corresponding Ru–S2 distances of the σ ligand N_2H_4 and pyridine complexes **18**·4THF [227.5(4) pm] and **7** [227.7(1) pm] are shorter. The Ru–S distances *trans* to N_2H_2 in the closely related complexes [μ-N_2H_2{Ru(PPh_3)('S_4')$}_2$] [228.2(2) pm] and [μ-N_2H_2{Ru(PPh_3)('$^{bu}S_4$')$}_2$] [230.7(3) pm][12] are slightly shorter than in **19**·4CH_2Cl_2. Nonetheless, as in **19**·4CH_2Cl_2, the Ru–S bonds *trans* to the N_2H_2 ligand always represent the shortest Ru–S bonds in [μ-N_2H_2{RuS_4}$_2$] complexes so far characterized.

The different bonding properties of N_2H_2 and N_2H_4 are also illustrated by the Ru–N distances of **18**·4THF [214.4(9) pm] and **19**·4CH_2Cl_2 [203.0(7) pm], indicating Ru–N single and partial Ru–N double bonds. The Ru–N distance in **18**·4THF is comparable with that of the pyridine complex **7** [215.5(3) pm], while the Ru–N distance in **19**·4CH_2Cl_2 is rationalized by the [M=NH=NH=M] 4c-6e$^-$ π bonding system, which is characteristic of this type of [μ-N_2H_2{M}$_2$] complex.[12] The N–N distances in **18**·4THF [149(2) pm] and in **19**·4CH_2Cl_2 [129(1) pm] correspond with N–N single and slightly elongated N–N double bonds.

In both **18**·4THF and **19**·4CH_2Cl_2, the Ru centers and the thiolate donors form approximated planes. When least-squares planes are calculated through the six atoms Ru1, S1, S4, Ru1A, S1A, and S4A, the largest deviations from these planes are observed for the Ru centers, being 11.0(2) pm (**18**·4THF) and 10.8(1) pm (**19**·4CH_2Cl_2), respectively. In the diazene complex **19**·4CH_2Cl_2, the diazene N atoms are also coplanar, deviating by only 5.5(6) pm. In the hydrazine complex **18**·4THF, the hydrazine N atoms show a large deviation of 25.9(9) pm from the respective plane. This deviation gives rise to a step-like arrangement of the two enantiomeric [Ru(NH_2)(PPh_3)('tpS_4')] halves of **18**·4THF. The step height, calculated as distance between the two least-squares planes [Ru1, S1, S2, S4, N1] and [Ru1A, S1A, S2A, S4A, N1A], is 52.8 pm. The step-like arrangement of the two [$RuNPS_4$] cores in **18**·4THF is also reflected by the [S4–Ru1–N1–N1A] torsion angle of –151.9(1)°. [In the diazene complex, in which the Ru, the thiolate S and diazene N atoms form a nearly perfect plane, the corresponding angle is 173.9(9)°, close to the ideal of 180°.]

The arrangement of Ru, thiolate S, diazene N, or hydrazine N atoms enables the formation of stabilizing N–H···S hydrogen bonds in both **18**·4THF and **19**·4CH_2Cl_2. The N–H···S bonds are indicated by both the N–H···S vectors and the distances, which are shorter than the sum of the corresponding van der Waals radii (r_H = 120 pm, r_S = 185 pm) (Figure 5).

In the diazene complex **19**·4CH_2Cl_2, two bifurcated and nearly planar N–H···S_2 (thiolate) bridges exist [*d*(H1···S1A) = 258 pm, *d*(H1···S4) = 289 pm]. In the hydrazine complex **18**·4THF, two similar but nonplanar bifurcated hydrogen bonds are indicated by the H1···S1A (258 pm) and H1···S4 (298 pm) distances. It is significant that in the hydrazine complex the H2···S3A and the corresponding H2A···S3 distances of 288 pm indicate two additional hydrogen bonds between the thioether S atoms S3 and S3A and the NH_2 group atoms H2, and H2A. (Assuming sp^3 hybridization of the thioether S donors, the lone pairs at S3 and S3A indeed point directly at the positions of H2 and H2A respectively.)

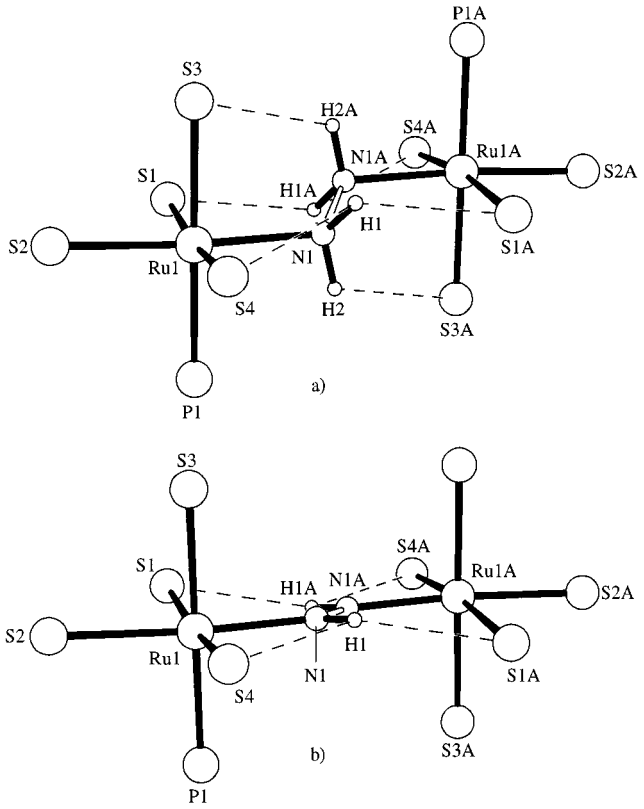

Figure 5. The [μ-N_2H_x{$RuPS_4$}$_2$] cores of a) **18**·4THF (x = 4) and b) **19**·4CH_2Cl_2 (x = 2) illustrating the [μ-N_2H_x{RuS_2(thiolate)}$_2$] planes and NH···S bridges

Due to the inversion center, the two NH_2 groups in **18**·4THF assume a staggered conformation, in contrast to the conformation in free hydrazine which exhibits a dihedral angle of about 95°.[16]

Discussion and Conclusion

The [Ru('tpS_4')] fragment exhibits a similarly versatile coordination chemistry as the [Ru('$^RS_4$')] fragments and binds a large number of coligands ranging from CO, NO, CR_2, PR_3 to N_3^-, N_2H_2, N_2H_4, and NH_3. In addition, [Ru('tpS_4')] complexes undergo reactions and yield species not yet observed with [Ru('$^RS_4$')] fragments. For example, [Ru(PPh_3)$_2$('tpS_4')] (**1**) exchanges both of its PPh_3 ligands with DMSO or PEt_3. When the [Ru(NO)(PPh_3)('tpS_4')]$^+$ (**13**) cation is reduced to give the neutral 19 valence electron species [Ru(NO)(PPh_3)('tpS_4')] (**14**), the 'tpS_4'$^{2-}$ ligand stays intact, in contrast to the '$^RS_4$'$^{2-}$ ligands, which undergo C–S cleavage reactions.[6]

In the search for labile [Ru('tpS_4')] precursor complexes, [Ru(PPh_3)$_2$('tpS_4')] (**1**) was found to exclusively exchange one PPh_3 for nitrogenous ligands. This enabled the synthesis of N_2H_4 and NH_3 complexes and, in particular, of the acetonitrile complex [Ru(MeCN)(PPh_3)('tpS_4')] (**12**). Complex **12** made feasible the synthesis of the azido, iodo, and nitrosyl complexes. All attempts to obtain dinitrogen complexes have so far remained unsuccessful also with the [Ru('tpS_4')] fragment. However, structurally characterized transition metal sulfur complexes containing the hydrazine and diazene couple could be obtained for the first time. The complexes [μ-N_2H_4{Ru(PPh_3)('tpS_4')}$_2$] (**18**) and [μ-N_2H_2{Ru(PPh_3)('tpS_4')}$_2$] (**19**) permitted a detailed analysis of the structural and bonding properties of hydrazine versus diazene complexes. The structural parameters indicate bifurcated N–H···S_2(thiolate) hydrogen bonds in both **18** and **19** and additional N–H···S(thioether) bridges in the hydrazine complex **18**. The increased number of N–H···S hydrogen bonds formed when going from the diazene to hydrazine complexes is significant with regard to the "open-side" model of the FeMoco function in nitrogenases.[4a], [13a] According to this model, N_2 is activated through binding to two low-spin Fe^{II} centers in [S, N, O] coordination spheres. Over the course of three subsequent [2 H^+, 2 e^-] reduction steps yielding NH_3 via N_2H_2 and N_2H_4 intermediates, an increased number of N–H···S(O) hydrogen bonds is instrumental in keeping the redox potential in the range –280 mV to ca. –500 mV, which are the both the thermodynamic limiting and biologically compatible values of enzymatic N_2 reduction.

Experimental Section

General Methods: Unless otherwise noted, all reactions and operations were carried out at room temperature under nitrogen using standard Schlenk techniques. Solvents were dried and distilled before use. As far as possible, reactions were monitored by IR or NMR spectroscopy. – Spectra were recorded with the following instruments: IR (KBr disks or CaF_2 cuvettes, solvent bands were compensated): Perkin–Elmer 983, 1620 FT IR, and 16PC FT-IR. – NMR: Jeol FT-JNM-GX 270, EX 270, and Lambda LA 400 with the protio solvent signals used as a reference. Chemical shifts are quoted on the δ scale (downfield shifts are positive) relative to tetramethylsilane (^{1}H, ^{13}C{^{1}H} NMR) or 85% H_3PO_4 (^{31}P{^{1}H} NMR). Spectra were recorded at 25 °C. – Mass spectra: Jeol MSTATION 700 spectrometer. – UV/Vis: Shimadzu UV-3101 – Elemental analysis: Carlo Erba EA 1106 or 1108 analyzer. – Cyclic voltammetry was performed with a PAR 264A potentiostat using a three-electrode cell with glassy carbon ROTEL A working, Pt reference and Pt counter electrodes. Solutions were 10^{-3} M in complex. TBA[PF_6] (10^{-1} M) was used as conducting electrolyte. Potentials were referenced to the normal hydrogen electrode via Fc/Fc$^+$ as internal standard (E_{Fc/Fc^+} = +0.4 V versus normal hydrogen electrode).[17] – $N_2C(CO_2Et_2)_2$,[18] $K_2C_2N_2O_4$,[19] [$RuCl_2$-$(DMSO)_4$],[20] [$RuCl_2(PMe_3)_4$],[21] NEt_4N_3,[22] [Ru(PPh_3)$_2$-('tpS_4')] (**1**),[7] and 'tpS_4'–H_2,[7] were prepared as described in the literature, LiOMe, MeI, $NOBF_4$, $LiBEt_3H$, NH_2NHMe, and N_2H_4 were purchased from Aldrich.

[Ru(PEt_3)$_2$('tpS_4')] (2): PEt_3 (0.5 mL, 3.4 mmol) was added to a yellow-orange suspension of [Ru(PPh_3)$_2$('tpS_4')] (**1**) (190 mg, 0.19 mmol) in THF (10 mL) and heated at reflux for 3 min. The resultant yellow solution was cooled to room temperature, and concentrated to dryness. The yellow residue was dissolved in THF (5 mL), the resulting solution was filtered, layered with *n*-hexane (50 mL) and cooled to –30 °C. Yellow microcrystals precipitated, which were separated after 1 d, washed with *n*-hexane (40 mL) and dried in vacuo. Yield: 70 mg of **2**·0.5THF (50%). – $C_{32}H_{46}O_{0.5}P_2RuS_4$ (**2**·0.5THF) (730.0): calcd. C 52.65, H 6.35, S

17.57; found C 52.90, H 6.56, S 17.21. – MS (FD, CH_2Cl_2, ^{102}Ru); *m/z*: 694 [Ru(PEt_3)$_2$('tpS_4')]$^+$. – ^1H NMR (CD_2Cl_2, 269.6 MHz): δ = 7.95–7.85 (m, 2 H, C_6H_4), 7.75 (d, 2 H, C_6H_4), 7.35 (d, 2 H, C_6H_4), 7.25–7.18 (m, 2 H, C_6H_4), 6.90–6.75 (m, 4 H, C_6H_4), 1.95–1.75 (m, 12 H, P–CH_2CH$_3$), 1.10–0.97 (m, 15 H, P–CH$_2$CH_3). – $^{13}C\{^1H\}$ NMR (100.40 MHz, CD_2Cl_2): δ = 158.9, 138.6, 136.8, 132.0, 131.5, 130.2, 129.7, 128.8, 121.1 [*C*(aryl)], 19.2 (t, P–*C*H$_2$CH$_3$), 8.5 (P–CH$_2$*C*H$_3$). – $^{31}P\{^1H\}$ NMR (109.38 MHz, CD_2Cl_2): δ = 18.0 (s).

[Ru(DMSO)$_2$('tpS$_4$')] (3): A yellow-orange suspension of [Ru(PPh_3)$_2$('tpS_4')] (**1**) (196 mg, 0.20 mmol) in DMSO (15 mL) was heated at reflux for 5 min, yielding a yellow-green solution. The solution was cooled to room temperature, combined with MeOH (75 mL), and stirred for 12 h. A yellow solid precipitated, which was separated, washed with MeOH (30 mL), Et_2O (20 mL), and dried in vacuo. Despite several recrystallizations from CH_2Cl_2/MeOH, satisfactory elemental analyses could not be obtained. However, the NMR spectra of the yellow solid showed the absence of any PPh_3 resulting from the precursor complex **1**. Yield: 50 mg of **3** (41%). – $C_{22}H_{24}O_2RuS_6$ (**3**) (613.9): calcd. C 43.05, H 3.94; found C 44.42, H 4.13. – IR (KBr): $\tilde{\nu}$ = 1015 cm^{-1}, s, ν(SO). – MS (FD, CH_2Cl_2, ^{102}Ru); *m/z*: 614 [Ru(DMSO)$_2$('tpS_4')]$^+$. – ^1H NMR (269.6 MHz, CD_2Cl_2): δ = 7.85–7.80 (m, 2 H, C_6H_4), 7.65 (d, 2 H, C_6H_4), 7.50 (d, 2 H, C_6H_4), 7.33–7.28 (m, 2 H, C_6H_4), 7.00 (t, 2 H, C_6H_4), 6.87 (t, 2 H, C_6H_4), 3.25 (s, 3 H, S–CH_3), 3.05 (s, 3 H, S–CH_3). – $^{13}C\{^1H\}$ NMR (100.40 MHz, CD_2Cl_2): δ = 153.9, 137.1, 136.9, 132.5, 131.8, 130.7, 130.6, 130.0, 122.8, (C_6H_4), 46.3, 44.9 (S–*C*H$_3$).

[Ru(I)(PPh$_3$)('tpS$_4$–Me$_2$')]I (4): MeI (0.5 mL, 8.0 mmol) was added while stirring to a yellow-orange solution of [Ru(PPh_3)$_2$('tpS_4')] (**1**) (140 mg, 0.14 mmol) in CH_2Cl_2 (30 mL) which changed its color to yellow over the course of 2 h. After addition of *n*-hexane (40 mL), a yellow solid precipitated, which was separated, washed with MeOH (10 mL), *n*-hexane (20 mL), and dried in vacuo. Recrystallization from CH_2Cl_2/Et_2O (20 mL/ 40 mL) yielded yellow crystals, which were separated, washed with Et_2O (20 mL), and dried in vacuo. Yield: 100 mg of **4** (71%). – $C_{38}H_{33}I_2PRuS_4$ (**4**) (1004): calcd. C 45.47, H 3.31, S 12.78; found C 45.25, H 3.50, S 12.59. – ^1H NMR (CD_2Cl_2, 269.6 MHz): δ = 8.30 (t, 2 H, C_6H_4), 8.00 (d, 1 H, C_6H_4), 7.90–7.80 (m, 1 H, C_6H_4), 7.75–7.60 [m, 8 H, C_6H_4 and P(C_6H_5)$_3$], 7.60–7.30 [m, 15 H, C_6H_4 and P(C_6H_5)$_3$], 2.85 (s, 3 H, S–CH_3), 2.05 (s, 3 H, S–CH_3). – $^{31}P\{^1H\}$ NMR (109.38 MHz, CD_2Cl_2): δ = 23.5 (s).

[Ru(PMe$_3$)(PPh$_3$)('tpS$_4$')] (5): PMe_3 (0.8 mL, 7.70 mmol) was added to a yellow suspension of [Ru(PPh_3)$_2$('tpS_4')] (**1**) (400 mg, 0.41 mmol) in THF (15 mL). The suspension was stirred for 3 h, during the course of which a yellow solution resulted, which was filtered and concentrated to dryness to give a yellow residue. The residue was digested with *n*-hexane (40 mL) for 1 h, separated, washed with *n*-hexane (40 mL), and dried in vacuo. Yield 180 mg of **5** (55%). – $C_{39}H_{36}P_2RuS_4$ (**5**) (796.0): calcd. C 58.85, H 4.56, S 16.11; found C 59.10, H 4.57, S 15.52. – IR (KBr): $\tilde{\nu}$ = 953 cm^{-1}, δ(PCH). – MS (FD, CH_2Cl_2, ^{102} Ru); *m/z*: 796 [Ru(PMe_3)(PPh_3)('tpS_4')]$^+$. – ^1H NMR (269.6 MHz, CD_2Cl_2): δ = 7.86–7.74 (m, 3 H, C_6H_4), 7.59–7.46 [m, 7 H, C_6H_4 and P(C_6H_5)$_3$], 7.26–7.23 [m, 11 H, C_6H_4 and P(C_6H_5)$_3$], 7.09 (d, 1 H, C_6H_4), 6.96–6.94 (m, 2 H, C_6H_4), 6.85 (t, 1 H, C_6H_4), 6.65 (t, 1 H, C_6H_4), 6.56 (t, 1 H, C_6H_4), 1.16 [d, *J* = 4.32 Hz, 9 H, P(CH_3)]. – $^{13}C\{^1H\}$ NMR (67.8 MHz, CD_2Cl_2): δ = 159.0 (d, J_{PC} = 5.96 Hz), 156.2 (d, J_{PC} = 7.95 Hz), 138.9, 138.7, 138.2, 138.0, 136.6, 136.1, 135.9, 135.3, 134.6 (d, J_{PC} = 9.93 Hz), 132.2, 131.4, 130.5, 129.8 (d, J_{PC} = 3.48 Hz), 129.7, 129.5, 129.2, 128.5, 127.4 (d, J_{PC} = 8.94 Hz), 121.2, 121.1 [*C*(aryl)], 18.3 [d, J_{PC} = 9.94 Hz, (P(*C*H$_3$)], 17.9 [d, J_{PC} = 9.94, (P(*C*H$_3$)]. – $^{31}P\{^1H\}$ NMR (109.38 MHz, CD_2Cl_2): δ = –6.5 (d, *P*Me$_3$), +37 (d, *P*Ph$_3$).

[Ru(PMe$_3$)$_2$('tpS$_4$')] (6): Solid Li_2–'tpS_4' (159 mg, 0.43 mmol) was added to a stirred suspension of [RuCl_2(PMe_3)$_4$] (205 mg, 0.43 mmol) in MeOH (10 mL), which was heated at reflux for 4 h, yielding a yellow solution from which yellow microcrystals started precipitating. Cooling to room temperature completed the precipitation. The resulting yellow microcrystals were separated, washed with MeOH (15 mL) and *n*-hexane (20 mL), and dried in vacuo. Yield: 120 mg of **6** (46%). – $C_{24}H_{30}P_2RuS_4$ (**6**) (609.8): calcd. C 47.27, H 4.96, S 21.03; found C 47.20, H 4.88, S 21.11. – IR (KBr, cm^{-1}): $\tilde{\nu}$ = 958, 943 vs, δ(PCH). – MS (FD, CH_2Cl_2, ^{102}Ru); *m/z*: 610 [Ru(PMe_3)$_2$('tpS_4')]$^+$. – ^1H NMR ([D$_8$]THF, 399.65 MHz): δ = 7.97–7.93 (m, 2 H, C_6H_4), 7.77 (d, 2 H, C_6H_4), 7.29 (d, 2 H, C_6H_4), 7.20–7.16 (m, 2 H, C_6H_4), 6.80–6.76 (m, 2 H, C_6H_4), 6.72–6.68 (m, 2 H, C_6H_4), 1.41 (d, *J* = 4.28 Hz, 18 H, P–CH_3). – $^{13}C\{^1H\}$ NMR (100.40 MHz, [D$_8$]THF): δ = 159.8 (t), 139.7 (t), 137.3, 132.7–132.5 (m), 132.5, 130.9, 130.0, 128.8, 121.0 [*C*(aryl)], 18.9–18.0 (m, P–*C*H$_3$). – $^{31}P\{^1H\}$ NMR (161.70 MHz, [D$_8$]THF): δ = 7.7 (s).

[Ru(py)(PPh$_3$)('tpS$_4$')] (7): A yellow-orange suspension of [Ru(PPh_3)$_2$('tpS_4')] (**1**) (235 mg, 0.24 mmol) in pyridine (7 mL) was heated at reflux for 10 min to give an orange-red solution. The solution was cooled to room temperature, combined with MeOH (70 mL), and stirred for 1 h. A yellow solid precipitated, which was separated, washed with MeOH (40 mL) and Et_2O (40 mL), and dried in vacuo. Yield 125 mg of **7** (65%). – $C_{41}H_{32}NPRuS_4$ (**7**) (799.0): calcd. C 61.63, H 4.04, N 1.75, S 16.05; found C 61.41, H 3.89, N 1.99, S 16.15. – MS (FD,CH_2Cl_2, ^{102}Ru); *m/z*: 799 [Ru(py)(PPh_3)('tpS_4')]$^+$. – ^1H NMR (269.6 MHz, CD_2Cl_2): δ = 8.50 [d, 2 H, *o*-*H*(py)], 7.95 (d, 1 H, C_6H_4), 7.70 (d, 1 H, C_6H_4), 7.65–7.60 (m, 1 H, C_6H_4), 7.53–7.48 (m, 1 H, C_6H_4), 7.40–7.30 [m, 6 H, C_6H_4 and P(C_6H_5)$_3$], 7.25–7.10 [m, 12 H, C_6H_4, P(C_6H_5)$_3$ and py], 7.05–6.90 (m, 3 H, C_6H_4), 6.80–6.75 (m, 3 H, C_6H_4), 6.65 (t, 1 H, C_6H_4), 6.55 (t, 1 H, C_6H_4). – $^{31}P\{^1H\}$ NMR (109.38 MHz, CD_2Cl_2): δ = 41.50 (s).

[Ru(NH$_3$)(PPh$_3$)('tpS$_4$')] (8): NH_3 gas was bubbled through a refluxing yellow-orange suspension of [Ru(PPh_3)$_2$('tpS_4')] (**1**) (200 mg, 0.20 mmol) in THF (25 mL) for 5 min. A yellow-orange solution resulted which was cooled to room temperature, combined with *n*-hexane (100 mL), and stirred for 2 h. A yellow solid precipitated, which was separated, washed with *n*-hexane (40 mL), and dried in vacuo. Yield 100 mg of **8**·THF (65%). – $C_{38}H_{34}NO_{0.5}PRuS_4$ (**8**·0.5THF) (773.0): calcd. C 59.04, H 4.43, N 1.81, S 16.59; found C 59.03, H 4.21, N 1.67, S 16.33. – IR (KBr, cm^{-1}): $\tilde{\nu}$ = 3348, 3245, ν(NH). – ^1H NMR (399.65 MHz, CD_2Cl_2) δ = 7.95 (d, 1 H, C_6H_4), 7.86 (d, 2 H, C_6H_4), 7.69–7.64 [m, 6 H, C_6H_4 and P(C_6H_5)$_3$], 7.46 (d, 1 H, C_6H_4), 7.36–7.26 [m, 12 H, C_6H_4 and P(C_6H_5)$_3$], 6.97 (t, 1 H, C_6H_4), 6.90–6.86 (m, 2 H, C_6H_4), 6.57–6.52 (m, 2 H, C_6H_4), 1.70 (s, 3 H, NH_3). – $^{31}P\{^1H\}$ NMR (109.38 MHz, CD_2Cl_2): δ = 47.5 (s).

[Ru(N$_2$H$_4$)(PPh$_3$)('tpS$_4$')] (9): N_2H_4 (0.25 mL, 8.00 mmol) was added to a stirred yellow-orange suspension of [Ru(PPh_3)$_2$('tpS_4')] (**1**) (250 mg, 0.25 mmol) in THF (20 mL), which was heated at reflux for 10 min to give a yellow-orange solution. The solution was cooled to room temperature, filtered, combined with *n*-hexane (80 mL), and stirred for 1 h. A yellow solid precipitated, which was separated, washed with MeOH (10 mL) and *n*-hexane (40 mL), and dried in vacuo. Yield: 100 mg of **9** (53%). – $C_{36}H_{31}N_2PRuS_4$ (**9**) (752.0): calcd. vacuo. Yield: 85 mg of **17**·0.5Me$_2$CO. – $C_{37.5}H_{30}N_3O_{0.5}PRuS_4$ (**17**·0.5Me$_2$CO) (791.0): calcd. C 56.94, H 3.82, N 5.31, S 16.22; found C 56.58, H 3.82, N 5.10, S 16.02. – IR (KBr, cm^{-1}): $\tilde{\nu}$ = 2036 ν (N_3). – MS (FD, CH_2Cl_2, ^{102}Ru); *m*/*z*: 762 [Ru(N_3)-(PPh$_3$)$_2$('tpS$_4$')]$^+$.

[μ-N$_2$H$_4${Ru(PPh$_3$)('tpS$_4$')}$_2$] (18): [Ru(N_2H_4)(PPh$_3$)('tpS$_4$')] (**9**) (120 mg, 0.16 mmol) was dissolved in CH_2Cl_2 (7 mL) and the solution was stirred for 7 d. After addition of MeOH (10 mL), yellow microcrystals precipitated, which were separated, washed with MeOH (10 mL), Et_2O (15 mL), and dried in vacuo. Yield: 20 mg of **17**·0.75CH_2Cl_2 (16%). – $C_{72.75}H_{59.5}Cl_{1.5}N_2P_2Ru_2S_8$ (**18**·0.75CH_2Cl_2) (1536): calcd. C 56.90, H 3.91, N 1.82, S 16.71; found C 56.72, H 4.03, N 2.01, S 16.30

[μ-N$_2$H$_2${Ru(PPh$_3$)('tpS$_4$')}$_2$] (19). – a) From [Ru(N_2H_4)-(PPh$_3$)('tpS$_4$')] (9) and O$_2$: [Ru(N_2H_4)(PPh$_3$)('tpS$_4$')] (**9**) (145 mg, 0.19 mmol) was dissolved in CH_2Cl_2 (20 mL) in a Schlenk tube that was closed by a septum. Air (20 mL, 0.19 mmol O_2) was injected into the solution by means of a syringe. Over the course of 36 h, the solution changed color from yellow to green, and green microcrystals precipitated. They were separated, washed with CH_2Cl_2 (5 mL), MeOH (15 mL), H_2O (10 mL) and Et_2O (20 mL), and dried in vacuo. Yield: 35 mg of **19**·CH_2Cl_2 (24%). – $C_{73}H_{58}Cl_2N_2P_2Ru_2S_8$ (**19**·CH_2Cl_2) (1555): calcd. C 56.40, H 3.76, N 1.80, S 16.50; found C 56.27, H 3.73, N 1.99, S 16.55. – UV/Vis (CH_2Cl_2): λ_{max} (nm) = 306.5 (ε = 15159 L mol^{-1} cm^{-1}), 463 (ε = 8162 L mol^{-1} cm^{-1}). – **b) From [Ru(MeCN)(PPh$_3$)('tpS$_4$')] (12), K$_2$N$_2$(CO$_2$)$_2$ and HAc:** 0.2 M acetic acid (3.45 mL, 0.69 mmol) was added dropwise to a stirred suspension of [Ru(-MeCN)(PPh$_3$)('tpS$_4$')] (**12**) (175 mg, 0.23 mmol) and $K_2N_2(CO_2)_2$ (134 mg, 0.69 mmol)in THF (25 mL). A dark green solution resulted with evolution of gas. Over the course of 5 min a green solid precipitated, which was separated after 3 h, washed with H_2O (15 mL), THF (25 mL), Et_2O (25 mL), and dried in vacuo. Yield: 153 mg of **19**·2H_2O (88%). – $C_{72}H_{60}N_2O_2P_2Ru_2S_8$ (**19**·2H_2O) (1506): calcd. C 57.43, H 4.02, N 1.86, S 17.03; found C 57.26, H 3.95, N 1.77, S 16.67.

X-ray Structure Analyses of [Ru(py)(PPh$_3$)('tpS$_4$')] (7), [Ru(NO)(PPh$_3$)('tpS$_4$')]BF$_4$·CH$_2$Cl$_2$ (13·CH$_2$Cl$_2$), [Ru(I)(PPh$_3$)-('tpS$_4$')]·CH$_2$Cl$_2$ (16·CH$_2$Cl$_2$), [μ-N$_2$H$_4${Ru(PPh$_3$)('tpS$_4$')}$_2$]·4THF (18·4THF), and [μ-N$_2$H$_2${Ru(PPh$_3$)('tpS$_4$')}$_2$]·4CH$_2$Cl$_2$ (19·4CH$_2$Cl$_2$): Orange crystals of **7** were grown by layering a hot pyridine solution of **7** with MeOH. Dark-brown platelets of **13**·CH_2Cl_2 formed when a saturated CH_2Cl_2 solution of **13** was layered with *n*-hexane. Black rhombohedra of [Ru(I)(PPh$_3$)('tpS$_4$')]·CH_2Cl_2 (**16**·CH_2Cl_2) were obtained when a saturated CH_2Cl_2 solution of **16** was layered with MeOH. Yellow platelets of [μ-N_2H_4{Ru(PPh$_3$)('tpS$_4$')}$_2$]·4THF (**18**·4THF) crystallized from a THF solution of **18** layered with Et_2O. Green platelets of **19**·4CH_2Cl_2 formed when air was injected into a yellow solution of [Ru(N_2H_4)(PPh$_3$)('tpS$_4$')] (**9**) in CH_2Cl_2. – Suitable single crystals were mounted by using the oil-drop mounting technique.[23] For all data sets Lorentz and polarization corrections were applied. For **18**·4THF absorption effects have been neglected. A ψ-scan absorption correction has been applied for **7** (T_{min} = 0.4357, T_{max} = 0.4699), **13**·CH_2Cl_2 (T_{min} = 0.4254, T_{max} = 0.4680), and **16**·CH_2Cl_2 (T_{min} = 0.2677, T_{max} = 0.3412). An empirical correction was used for **19**·4CH_2Cl_2 (SADABS, T_{min} = 0.8294, T_{max} = 0.9923).[24] All structures were solved by direct methods and were refined using full-matrix least-squares procedures on F^2 (SHELXTL 5.03).[25] – All non-hydrogen atoms were refined anisotropically. The positions of the hydrogen atoms were taken from a difference Fourier map and were either refined isotropically (**7**), refined with a common isotropic displacement parameter (**13**·CH_2Cl_2 and **16**·CH_2Cl_2) or were kept fixed with a common isotropic displacement parameter

(**18**·4THF, **19**·4CH_2Cl_2). The BF_4 anion in the structure of **13**·CH_2Cl_2 is disordered around the B1-F11 vector, where two possible sites have been refined such that they are both equally occupied (50%). Furthermore, the solvate CH_2Cl_2 molecule is disordered with two different sites having occupancies of 74(4)% and 26(4)% respectively. In **16**·CH_2Cl_2, one Cl atom of the solvate molecule is disordered. Two possible sites have been refined with occupancies of 61(5)% and 39(5)%. In **19**·4CH_2Cl_2 two of the solvate molecules are disordered with site occupancies of the two possible sites being refined to 77(1)% and 29(1)%. The hydrogen atoms of the solvate molecules in all structures are geometrically positioned. Selected crystallographic data are summarized in Table 2.[26]

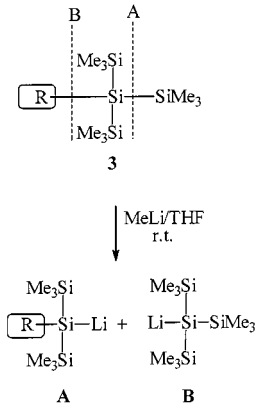
The Syntheses and Molecular Structure of a Branched Oligosilyl Anion with a Record of Nine Silicon Atoms and of the First Branched Oligosilyl Dianion

Yitzhak Apeloig,*[a] Gady Korogodsky,[a] Dmitry Bravo-Zhivotovskii,*[a] Dieter Bläser,[b] and Roland Boese[b]

Keywords: Silicon / Silyl anions / Lithium / Silanes / Polysilyl dianions / α,ω-Dilithiooligosilanes

$(Me_3Si)_3Si(Me_2Si)_2(Me_3Si)_2SiLi$ (**1**) and $LiSi(Me_3Si)_2(Me_2Si)_2Si(Me_3Si)_2Li$ (**2**) were synthesized by the reaction of $(Me_3Si)_3Si(Me_2Si)_2Si(Me_3Si)_3$ in THF with one or two mol-equivalents, respectively, of MeLi. Both **1** and **2** were characterized spectroscopically and by trapping reactions, and **1** also by X-ray crystallography.

Introduction



Silyl anions are potentially important reagents in synthesis[1] and they are probably involved in the formation and degradation of polysilanes.[2] However, the number and variety of synthetically useful silyl anions and the information on their structures is very limited,[1] especially in comparison to carbanions; e.g., $CH_3(CH_2)_nCH_2Li$ reagents are widely used in synthesis, while the analogous $Me_3Si(SiMe_2)_nSiMe_2Li$ are unknown, except for $Me_3SiSiMe_2Li$.[3] Of contemporary interest is the branched "hypersilyl" anion, $(Me_3Si)_3Si^-$, first prepared in situ[4] and later isolated as stable THF[5a,5b] or DME[5c] complexes of the lithium salt, e.g., $(Me_3Si)_3SiLi{\cdot}3THF$. The large steric requirements,[6] the interesting electronic properties[7] and the solubility of its derivatives in organic solvents has made the $(Me_3Si)_3Si$ group a popular ligand in main-group[8] and in transition-metal chemistry.[9] Recently, several new branched polysilyl anions have been synthesized by us[10a] (and were used to prepare novel stable silenes[10b]), as well as by other groups.[11] However, these anions have a relatively small number of silicon atoms, and in anions which were structurally characterized the maximum number of silicon atoms is only four.[10a,11a]

We report here[12] the synthesis and the full structural characterization of a new branched polysilyl anion $(Me_3Si)_3SiMe_2SiMe_2Si(Me_3Si)_2SiLi{\cdot}3THF$ (**1**) holding two records for silyl anions: (a) It has nine silicon atoms – the highest known; and (b) it has a chain of 5 silicon atoms (including the anionic center) – the longest known. We also report on the synthesis of the first known branched oligosilyl dianion, the corresponding nTHF·$LiSi(Me_3Si)_2Me_2SiMe_2Si(Me_3Si)_2SiLi{\cdot}n$THF (**2**).

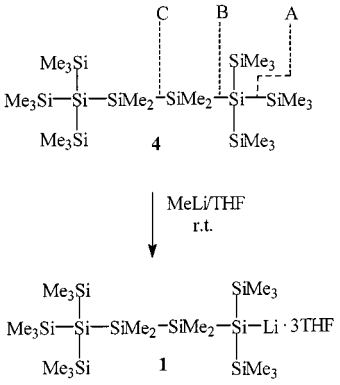
Results and Discussion

Recently we found[10a] that the products obtained from the reaction of branched polysilanes **3** with methyllithium (Scheme 1) depend on the substituent R as follows: when R has one or two silicon atoms (series 1) CH_3Li attacks preferentially at the sterically less-hindered Si atom, yielding the silyllithium **A** (bond A is cleaved). However, when R is a branched polysilane fragment (series 2) only $(Me_3Si)_3SiLi$ (**B**) was obtained (bond B is cleaved).



Series 1: R = $SiMe_2tBu$, $SiMe_2SiMe_3$; $SiMe_2SiMe_2tBu$.
Series 2: R = $SiMe(SiMe_3)_2$; $Si(SiMe_3)_3$; $SiMe_2Si(SiMe_3)_3$; $SiMeHSi(SiMe_3)_3$.

Scheme 1

To gain a better understanding of the reaction in Scheme 1 we also studied the cleavage of the doubly branched polysilane **4**.[13] Reaction of **4** with one equivalent of MeLi leads to cleavage of bond A [i.e., **4** behaves as a member of series 1, even though it possesses a $(Me_3Si)_3Si$ fragment], producing the novel branched polysilyl anion **1** (Scheme 2). The structure of **1** was first assigned by isolating the expected trapping products $(Me_3Si)_3SiMe_2SiMe_2Si(Me_3Si)_2SiR$ (R = tBuMe$_2$Si, PhMe$_2$Si, CH_3OCH_2) when treated with tBuMe$_2$SiCl, PhMe$_2$SiCl and CH_3OCH_2Cl, respectively (see Experimental Section). These compounds were characterized by their ^1H, ^{13}C and ^{29}Si NMR spectra

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 2000 1434–1948/00/0505–1091 $ 17.50+.50/0

and finally by X-ray crystallography. To the best of our knowledge, **1** is *the isolated silyl anion with the highest number of silicon atoms* (i.e., nine) *and with the longest polysilicon chain* (5 silicon atoms), of any other known silyl anion.

Scheme 2

Our results contrast with those of Pannell et al.[13] who reported that the reaction of **4** with CH_3Li followed by reaction with CH_3I yields $(Me_3Si)_4Si$, implying the presence of $(Me_3Si)_3SiMe_2SiLi$ and thus cleavage of bond C in **4**. Preliminary experiments aimed at the resolving this discrepancy, which we have carried out, suggest that Pannell's observation may result from the presence of impurities in the precursor which was used. Thus, when **4** was purified by crystallization (according to Pannell's procedure[13]) reaction with CH_3Li followed by addition of water led exclusively to $(Me_3Si)_4Si$ (as observed by Pannell et al.[13] who, however, used CH_3I). No traces of $(Me_3Si)_3SiSiMe_2H$ (expected if bond C in **4** is cleaved) were detected. On the other hand, **4** (which was carefully purified by liquid chromatography) produced only **1**.[14] HPLC chromatography of **4** purified by crystallization, showed 10% of two additional compounds, yet unidentified. We therefore speculate that these impurities catalyze the production of $(Me_3Si)_4Si$ which was observed by Pannell et al.[13]

The structure of **1**·3THF, as determined by X-ray crystallography, is shown in Figure 1. Except for $(Me_3Si)_3SiLi$[5] and the closely related *t*$BuMe_2Si(Me_3Si)_2SiLi$·3THF[10a] this is the only other reported X-ray structure of a solvated[15] branched silyllithium compound.

Table 1 summarizes the most important structural parameters of the four known solvated[15] branched silyl lithium compounds: **1**·3THF, $(Me_3Si)_3SiLi$·3THF (**5**·3THF), *t*$BuMe_2Si(Me_3Si)_2SiLi$·3THF (**6**·3THF)[10a] and $(Me_3SiMe_2Si)_3SiLi$·3THF (**7**·3THF) – recently synthesized by our group.[16] In general the four structures are quite similar, but some differences can be noted;[17] *r*(Si–Li) in **1**·3THF (2.657 Å) is similar to that in **5**·3THF (2.644 Å),[5a] and in **6**·3THF (2.684 Å)[10a] but it is 0.11 Å shorter than in **7**·3THF (2.767 Å). We refrain from interpreting these differences because quantum-mechanical calculations show that the force-constant for the Si–Li bond stretching is very small,[16] so that even small effects (including crystal packing forces), can cause significant changes in *r*(Si–Li). The

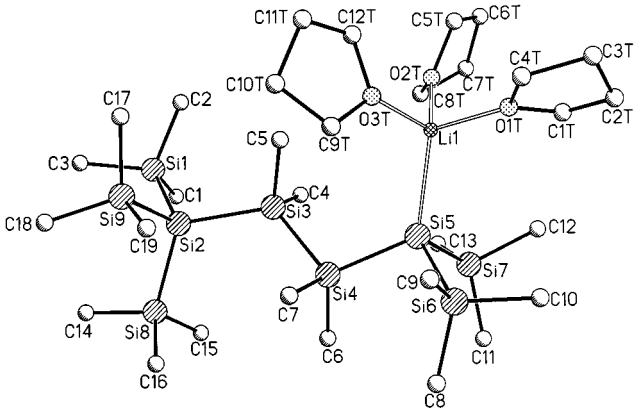


Figure 1. Molecular structure of **1**; hydrogen atoms have been omitted for clarity; selected bond lengths (Å) and bond angles (°): Si(1)–Si(2) 2.361(1), Si(2)–Si(9) 2.355(2), Si(2)–Si(8) 2.348(1), Si(2)–Si(3) 2.378(1), Si(3)–Si(4) 2.355(1), Si(4)–Si(5) 2.363(1), Si(7)–Si(5) 2.352(1), Si(6)–Si(5) 2.348(1), Si(5)–Li, 2.657(6); Si(1)–Si(2)–Si(9) 105.9(1), Si(1)–Si(2)–Si(8) 107.3(1), Si(2)–Si(3)–Si(4) 118.2(1), Si(3)–Si(4)–Si(5) 109.9(1), Si(4)–Si(5)–Si(6) 101.0(1), Si(4)–Si(5)–Si(7) 104.2(1), Si(6)–Si(5)–Si(7) 100.2(1)

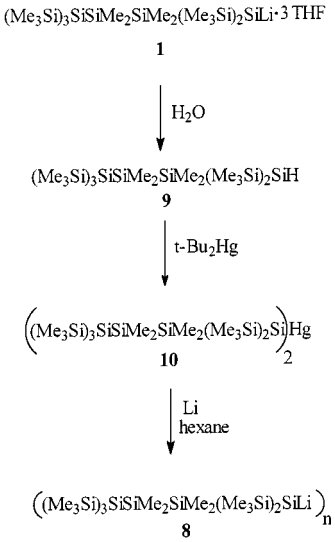
Table 1. Selected bond lengths [Å] and bond angles [°] for solvated branched silyllithium compounds and silanes



Compound	*r*(Si–Li)	*r*(Si–Si)[a]		α(Si–Si–Si)[b]

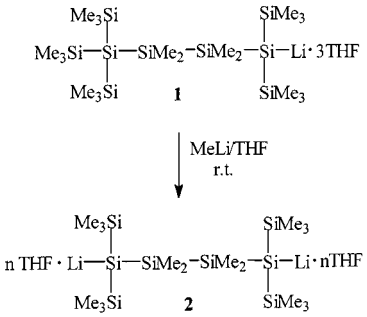
$(Me_3Si)_4Si$[5a]		2.346[c]	2.346[c]	109.5[c]	109.5[c]
4[13]		2.361, 2.355, 2.345, 2.375	2.359	107.0, 109.0, 115.3	110.3

[a] Between the central silicon atom (the anionic center) and an α-silicon atom. – [b] Around the central silicon atom (the anionic center). – [c] All values are identical by symmetry.

Si–Si bonds around the anionic center [Si(5)] are slightly longer in **1**·3THF, **6**·3THF and **7**·3THF than in **5**·3THF, (average bond lengths: 2.355 Å, 2.347 Å, 2.361 Å and 2.334 Å, respectively), probably reflecting repulsions between the bulky branched silicon chains. The average Si–Si–Si angles around Si(5) are similar in all compounds. Comparison with the neutral silane **4**[13] reveals distortions in the polysilicon backbone of **1**·3THF; the Si(2)–Si(3) and Si(4)–Si(5) bonds in **1**·3THF are slightly elongated, while *r*[Si(3)–Si(4)] is slightly shortened relative to **4**. The Si(3)–Si(4)–Si(5) angle in **1**·3THF is contracted to 109.9° (117.1° in **4**), while the Si(2)–Si(3)–Si(4) angles in **1**·3THF and **4** are similar.

The ^{29}Si NMR chemical shift of the anionic center Si(5) in **1** is at δ = –181.5, strongly shielded, as expected, compared to the corresponding silane **4** (δ = –119.6). This shift is similar to that observed on going from $(Me_3Si)_4Si$ (δ = –135.5) to $(Me_3Si)_3SiLi$·3THF (δ = –189.0). A comparison



with other silyl anions shows that the ^{29}Si chemical shift of the anionic center in **1** is shifted slightly downfield compared to that in $(Me_3Si)_3SiLi{\cdot}3THF$ (δ = –189.0) and slightly upfield compared with that in **7**·3THF (δ = –176.8). These changes probably reflect a combination of steric and electronic effects. Interestingly, in **1** the chemical shifts of Si(4) (δ = –22.2) and of the more remote Si(3) (δ = –33.5) are shifted in opposite directions (by 7 ppm downfield and by 4 ppm upfield, respectively) relative to their positions in **4** (δ = –29.5). The chemical shift of Si(2) in **1** (δ = –129.9) is shifted upfield by 10.3 ppm relative to **4** (δ = –119.6).

Scheme 3

We have also prepared, according to Scheme 3, the unsolvated analogue of **1**, i.e. **8**. Compound **1** was first hydrolyzed to the corresponding oligosilane **9** which was then reacted with tBu$_2$Hg to give the corresponding disilylmercury compound **10**. Compound **10** was then reacted with Li in hexane to give unsolvated **8**. Compound **8** was characterized by ^1H, ^{13}C, and ^{29}Si NMR spectroscopy and by its reaction products with tBuMe$_2$SiCl, HMe$_2$SiCl and CH_3OCH_2Cl (see Experimental Section), but we have not yet been able to obtain suitable crystals of **8** for an X-ray analysis. In analogy with other similar silyl lithium compounds[1,2] we assume that **8** is a dimer (i.e. n = 2).

Compound **1** reacts (in THF) with an additional equivalent of CH_3Li to give the corresponding dianion **2** (Scheme 4) which has a total of 8 silicon atoms and a chain

Scheme 4

of 4 silicon atoms. The proposed structure of **2** is supported by ^1H, ^{13}C and ^{29}Si NMR spectroscopy and by the isolation of the expected trapping products: R(Me$_3$Si)$_2$SiMe$_2$SiMe$_2$-SiSi(SiMe$_3$)$_2$R (R = SiMe$_2$$t$Bu, SiMe$_2H, CH_2OCH_3$) in the reactions with tBuMe$_2$SiCl, ClSiMe$_2$H and ClCH$_2$OCH$_3$, respectively (see Experimental Section). Recently we have also isolated the unsolvated **2**.[16] Attempts to crystallize **2** in order to determine its molecular structure by X-ray crystallography are in progress. Several linear α,ω-dilithium oligosilanes were reported previously.[11b,18] However, **2** is the first isolated and spectroscopically characterized branched silyldilithium compound.

Conclusion

We have synthesized, isolated and determined using X-ray crystallography the molecular structure of a new branched polysilyllithium compound $(Me_3Si)_3SiMe_2$-$SiMe_2Si(Me_3Si)_2SiLi{\cdot}3THF$ (**1**) holding two records for silyl anions: (a) it has nine silicon atoms – the highest known; and (b) it has a chain of 5 silicon atoms (including the anionic center) – the longest known. We have also synthesized the first branched oligosilyldilithium compound, the corresponding nTHF·LiSi(Me$_3$Si)$_2$Me$_2$SiMe$_2$Si(Me$_3$Si)$_2$SiLi·nTHF (**2**). Compounds **1** and **2** are expected to have a variety of synthetic applications; e.g., most recently Lambert et al. have applied **1** (prepared according to our procedure[12]) for synthesizing a nanometer-scale dendritic polysilane.

We are continuing our efforts to synthesize even longer branched polysilyl anions and to study their properties and their potential applications.

Experimental Section

General Remarks: Standard Schlenk techniques were used for all syntheses and all sample manipulations. – NMR spectra were recorded at room temperature in C_6D_6 solution using a Bruker EM-200 or Bruker-400 instruments. – Mass spectroscopy (MS) data were obtained with a Finnigan MAT TSQ 45 triplestage quadrupole mass spectrometer.

(Me$_3$Si)$_3$SiMe$_2$SiMe$_2$Si(Me$_3$Si)$_2$SiLi·3THF (1): Compound **4**[13] (7.0 g, 11.3 mmol) in dry THF (30 mL) was placed in a Schlenk flask under vacuum, and 9 mL of a 1.4 M solution of CH_3Li in diethyl ether was added in 10 portions over 72 h (conversion was followed by NMR spectroscopy). The THF solvent was removed and **1** was crystallized from hexane to give 6.5 g of colorless crystals of **1**·3THF (75% yield), suitable for X-ray analysis. – ^1H NMR (C_6D_6): δ = 0.42 [s, 27 H, Si(SiMe$_3$)$_3$], 0.55 [s, 18 H, SiLi(SiMe$_3$)$_2$], 0.60 (s, 6 H, SiMe$_2$), 0.73 (s, 6 H, SiMe$_2$), 1.37 (m, 12 H, CH$_2$ of THF), 3.50 (m, 12 H, OCH$_2$ of THF). – ^{13}C NMR (C_6D_6): δ = 3.7 [Si(SiMe$_3$)$_3$], 1.6 (SiMe$_2$), 6.9 (SiMe$_2$), 7.5 [SiLi(SiMe$_3$)$_2$], 25.3 (CH$_2$ of THF), 68.5 (OCH$_2$ of THF). – ^{29}Si NMR (C_6D_6): δ = –181.5 [*Si*Li(SiMe$_3$)$_2$], –129.9 [*Si*(SiMe$_3$)$_3$], –33.5 (SiMe$_2$), –22.2 (SiMe$_2$), –9.4 [Si(*Si*Me$_3$)$_3$], –5.0 [SiLi(*Si*Me$_3$)$_2$].

***n*THF·LiSi(Me$_3$Si)$_2$Me$_2$SiMe$_2$Si(Me$_3$Si)$_2$SiLi·*n*THF (2):** Compound **1** (6.5 g, 8.5 mmol) in dry THF (30 mL) was placed in a Schlenk flask under vacuum, and 9 mL of a 1.4 M solution of CH_3Li in ether was added in 10 portions over 72 h (conversion was

followed by NMR spectroscopy). Removal of the solvent gave 4.7 g of **2**·*n*THF (60% yield). – ^{1}H NMR (C_6D_6): δ = 0.49 [s, 36 H, $SiLi(SiMe_3)_2$], 0.64 (s, 12 H, $SiMe_2$), 1.37 (m, 12 H, CH_2 of THF), 3.50 (m, 12 H, OCH_2 of THF). – ^{29}Si NMR (C_6D_6): δ = –187.6 [*Si*$Li(SiMe_3)_2$], –25.6 ($SiMe_2$), –4.3 [$SiLi(SiMe_3)_2$].

Trapping Reactions. – General Procedure: The trapping reagent (15 mmol) in 50 mL of toluene was added to a solution of **1** (10 mmol) or **2** (5 mmol) in 40 mL of toluene cooled to –78 °C. All operations were carried out under vacuum using Schlenk techniques. The reaction mixture was stirred at room temperature for 10 h. The pure products were isolated after filtration of the reaction mixture and evaporation of the solvent, in yields which generally exceeded 90%.

Reaction of 1 with $PhMe_2SiCl$. – $(Me_3Si)_3SiMe_2SiMe_2Si(Me_3Si)_2SiSiMe_2Ph$: ^{1}H NMR ($C_6D_6$): δ = 0.31 [s, 27 H, $Si(SiMe_3)_3$], 0.33 [s, 18 H, $Si(Si\mathit{Me}_3)_2SiMe_2Ph$], 0.40 [s, 6 H, $Si(SiMe_3)_2Si\mathit{Me}_2Ph$], 0.50 (s, 6 H, $SiMe_2$), 0.59 (s, 6 H, $SiMe_2$), 7.19 [m, 3 H, $Si(SiMe_3)_2SiMe_2\mathit{Ph}$], 7.56 [m, 2 H, $Si(SiMe_3)_2SiMe_2\mathit{Ph}$]. – ^{13}C NMR ($C_6D_6$): δ = 1.4 ($SiMe_2$), 1.7 ($SiMe_2$), 2.4 [$Si(SiMe_3)_2Si\mathit{Me}_2Ph$], 3.8 [$Si(SiMe_3)_3$], 3.9 [$Si(Si\mathit{Me}_3)_2SiMe_2Ph$], 127.9, 129.6, 133.3, 134.7 [$Si(SiMe_3)_2SiMe_2\mathit{Ph}$]. – ^{29}Si NMR ($C_6D_6$): δ = –127.3 [*Si*$(SiMe_3)_3$], –125.8 [*Si*$(SiMe_3)_2SiMe_2Ph$], –29.0 ($SiMe_2$), –28.8 ($SiMe_2$), –9.4 [$Si(\mathit{Si}Me_3)_3$], –9.0 [$Si(\mathit{Si}Me_3)_2SiMe_2Ph$], –2.1 [$Si(SiMe_3)_2\mathit{Si}Me_2Ph$]. – MS (CI); *m*/*z*: 674 [M^+ + 2], 657 [M^+ – Me], 595 [M^+ – Ph].

Reaction of 1 with tBuMe$_2$SiCl. – $(Me_3Si)_3SiMe_2SiMe_2Si(Me_3Si)_2SiSiMe_2tBu$: ^{1}H NMR ($C_6D_6$): δ = 0.28 [s, 6 H, $Si(SiMe_3)_2Si\mathit{Me}_2t$Bu], 0.34 [s,27 H, $Si(SiMe_3)_3$], 0.37 [s, 18 H, $Si(Si\mathit{Me}_3)_2SiMe_2t$Bu], 0.57 (s, 6 H, $SiMe_2$), 0.60 (s, 6 H, $SiMe_2$), 1.02 [m, 3 H, $Si(SiMe_3)_2SiMe_2t$Bu]. – ^{13}C NMR (C_6D_6): δ = 0.2 [$Si(SiMe_3)_2Si\mathit{Me}_2t$Bu], 2.0 ($SiMe_2$), 2.7 ($SiMe_2$), 3.9 [$Si(SiMe_3)_3$], 5.0 [$Si(Si\mathit{Me}_3)_2SiMe_2t$Bu], 19.1 [$Si(SiMe_3)_2SiMe_2C\mathit{CH}_3$], 28.6 [$Si(SiMe_3)_2SiMe_2\mathbf{C}CH_3$]. – ^{29}Si NMR ($C_6D_6$): δ = –127.7 [*Si*$(SiMe_3)_3$], –126.6 [*Si*$(SiMe_3)_2SiMe_2t$Bu], –29.3 ($SiMe_2$), –27.0 ($SiMe_2$), –9.4 [$Si(\mathit{Si}Me_3)_3$], –9.0 [$Si(\mathit{Si}Me_3)_2SiMe_2t$Bu], 5.7 [$Si(SiMe_3)_2\mathit{Si}Me_2t$Bu]. – MS (CI); *m*/*z*: 652 [M^+ + 2], 637 [M^+ + 2 – Me], 595 [M^+ + 2 – tBu].

Reaction of 1 with H_2O. – $(Me_3Si)_3SiMe_2SiMe_2Si(Me_3Si)_2SiH$ (9): ^{1}H NMR (C_6D_6): δ = 0.28 [s, 18 H, $Si(Si\mathit{Me}_3)_2H$], 0.32 [s, 27 H, $Si(SiMe_3)_3$], 0.45 (s, 6 H, $SiMe_2$), 0.46 (s, 6 H, $SiMe_2$), 2.7 [s, 1 H, $Si(SiMe_3)_2\mathit{H}$]. – MS (EI); *m*/*z*: 449 [M^+ – $HSi(SiMe_3)$], 375 [M^+ – $HSi(SiMe_3)_2$].

Reaction of 1 with $ClCH_2OCH_3$. – $(Me_3Si)_3SiMe_2SiMe_2Si(Me_3Si)_2SiCH_2OCH_3$: ^{1}H NMR ($C_6D_6$): δ = 0.32 [s, 18 H, $Si(Si\mathit{Me}_3)_2CH_2OCH_3$], 0.33 [s, 27 H, $Si(SiMe_3)_3$], 0.51 (s, 6 H, $SiMe_2$), 0.54 (s, 6 H, $SiMe_2$), 3.13 [s, 3 H, $Si(SiMe_3)_2CH_2O\mathit{CH}_3$], 3.48 [s, 2 H, $Si(SiMe_3)_2\mathit{CH}_2OCH_3$]. – ^{13}C NMR ($C_6D_6$): δ = –0.4 ($SiMe_2$), 0.9 ($SiMe_2$), 1.8 [$Si(Si\mathit{Me}_3)_2CH_2OCH_3$], 3.6 [$Si(SiMe_3)_3$], 62.9 [$Si(SiMe_3)_2\mathit{CH}_2OCH_3$], 63.1 [$Si(SiMe_3)_2CH_2O\mathit{CH}_3$]. – ^{29}Si NMR ($C_6D_6$): δ = –128.3 [*Si*$(SiMe_3)_3$], –76.2 [*Si*$(SiMe_3)_2CH_2OCH_3$], –32.8 ($SiMe_2$), –31.0 ($SiMe_2$), –11.7 [$Si(\mathit{Si}Me_3)_2CH_2OCH_3$], –9.5 [$Si(\mathit{Si}Me_3)_3$]. – MS (EI); *m*/*z*: 567 [M^+ – Me], 637 [M^+ – Si $SiMe_3)_3$].

Reaction of 2 with $PhMe_2SiCl$. – $PhMe_2SiSi(Me_3Si)_2Me_2SiMe_2Si(Me_3Si)_2SiSiMe_2Ph$: ^{1}H NMR ($C_6D_6$): δ = 0.29 [s, 36 H, $Si(Si\mathit{Me}_3)_2SiMe_2Ph$], 0.38 [s, 12 H, $Si(SiMe_3)_2Si\mathit{Me}_2Ph$)], 0.57 (s, 12 H, $SiMe_2$), 7.57 [m, 5 H, $Si(SiMe_3)_2SiMe_2\mathit{Ph}$]. – ^{13}C NMR ($C_6D_6$): δ = 1.5 ($SiMe_2$), 2.5 [$Si(SiMe_3)_2Si\mathit{Me}_2Ph$], 4.0 [$Si(Si\mathit{Me}_3)_2SiMe_2Ph$], 129.6, 134.7, 141.5 [$Si(SiMe_3)_2SiMe_2\mathit{Ph}$]. – ^{29}Si NMR ($C_6D_6$): δ = –126.2 [*Si*$(SiMe_3)_2SiMe_2Ph$], –28.6 ($SiMe_2$), –12.1 [$Si(SiMe_3)_2\mathit{Si}Me_2Ph$], –9.0 [$Si(\mathit{Si}Me_3)_2SiMe_2Ph$]. – MS (CI); *m*/*z*: 703 [M^+ – 2Me], 657 [M^+ – Ph].

Reaction of 2 with tBuMe$_2$SiCl. – $tBuMe_2SiSi(Me_3Si)_2Me_2SiMe_2Si(Me_3Si)_2SiSiMe_2tBu$: ^{1}H NMR ($C_6D_6$): δ = 0.27 [s, 12 H, $Si(SiMe_3)_2Si\mathit{Me}_2t$Bu], 0.31 [s, 36 H, $Si(SiMe_3)_2$], 0.63 (s, 12 H, $SiMe_2$), 1.03 [s, 18 H, $Si(SiMe_3)_2SiMe_2t$Bu].

Reaction of 2 with H_2O. – $HSi(Me_3Si)_2Me_2SiMe_2Si(Me_3Si)_2SiH$: ^{1}H NMR ($C_6D_6$): δ = 0.28 [s, 36 H, $Si(SiMe_3)_2$], 0.44 (s, 12 H, $SiMe_2$), 2.70 [s, 1 H, $Si(SiMe_3)_2H$].

Synthesis of 8. – 1. Synthesis of the Precursor $[(Me_3Si)_3SiMe_2Si-Me_2Si(Me_3Si)_2Si]_2Hg$ (10): (tBu)$_2$Hg (0.99 g, 3.15 mmol) and **9** (6.5 mmol) (see above) were heated under argon to 120 °C. The reaction mixture was stirred for 4 h, during which time 5.25 mmol of 2-methylpropane was formed. Evaporation of the volatile compounds and crystallization of the reaction mixture from pentane gave **10** (3.40 g, 85% yield). – ^{1}H NMR (C_6D_6): δ = 0.44 [s, 18 H, $Si(SiMe_3)_2$], 0.54 [s, 27 H, $Si(SiMe_3)_3$], 0.63 (s, 6 H, $SiMe_2$), 0.64 (s, 6 H, $SiMe_2$). – ^{13}C NMR (C_6D_6): δ = 3.6 [$Si(SiMe_3)_3$], 5.5 [$Si(SiMe_3)_2$], 25.8 ($SiMe_2$), 67.8 ($SiMe_2$). – ^{29}Si NMR (C_6D_6): δ = –128.9 [*Si*$(SiMe_3)_3$], –53.1 [*Si*$(SiMe_3)_2$], –33.0 ($SiMe_2$), –19.2 ($SiMe_2$), –9.4 [$Si(\mathit{Si}Me_3)_3$], –2.7 [$Si(\mathit{Si}Me_3)_2$].

2. Synthesis of $(Me_3Si)_3SiMe_2SiMe_2Si(Me_3Si)_2SiLi$ (8): A hexane solution of **10** (3.4 g, 2.67 mmol) was sonicated with an excess of Li. After Hg precipitation the solvent was separated from the metallic residue. Evaporation of hexane gave **8** (2.5 g, 85% yield). – ^{1}H NMR (C_6D_6): δ = 0.42 [s, 27 H, $Si(SiMe_3)_3$], 0.55 [s, 18 H, $SiLi(SiMe_3)_2$], 0.60 (s, 6 H, $SiMe_2$), 0.73 (s, 6 H, $SiMe_2$). – ^{13}C NMR (C_6D_6): δ = 1.4 ($SiMe_2$), 3.8 [$Si(SiMe_3)_3$], 6.5 ($SiMe_2$), 7.6 [$SiLi(SiMe_3)_2$]. – ^{29}Si NMR (C_6D_6): δ = –181.5 [*Si*$Li(SiMe_3)_2$], –129.9 [*Si*$(SiMe_3)_3$], –33.0 ($SiMe_2$), –22.6 ($SiMe_2$), –9.4 [$Si(\mathit{Si}Me_3)_3$], –5.0 [$SiLi(\mathit{Si}Me_3)_2$].

X-ray Crystallographic Study: Crystal data of **1**·3THF: $C_{19}H_{57}LiSi_9{\cdot}3C_4H_8O$, crystal dimensions 0.37 × 0.29 × 0.24 mm, measured on a Nicolet R3 diffractometer with Mo-K_α radiation at T = 128 K. Cell dimensions: a = 19.071(3), b = 15.113(2), c = 17.379(3) Å, V = 5009(1) Å^3, orthorhombic crystal system, Z = 4, $d_{calcd.}$ = 1.010 g·cm^{-3}, μ = 0.263 mm^{-1}, space group $Pca2_1$, data collection of 10872 intensities ($2\Theta_{max}$ = 50°), 8347 independent (R_{merg} = 0.0190), 7531 observed [$F_o > 4\sigma(F)$], structure solution with direct methods (Siemens-SHELXS) and refinement on F^2 (Siemens-SHELXTL 5.03) (397 parameters). The hydrogen atom positions were calculated and refined as rigid groups with the 1.2-fold (1.5 for methyl groups) U_{iso} values of the corresponding C atoms. The absolute structure was confirmed by refinement of the x parameter resulting in –0.27(13). $R1$ = 0.0460, $wR2$ (all data) = 0.1255, $w^{-1} = \sigma^2(F_o^2) + (0.0839\ P)^2 + 2.0556\ P$, where $P = [(\max F_o^2) + (2F_c^2)]/3$, GoF ($F^2$) = 1.04, maximum residual electron density 0.780 eÅ^{-3}. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-1994140. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

[15] The structures of the unsolvated dimeric $[Me(PhMe_2Si)_2SiLi]_2$ and $[Ph(Me_3Si)_2SiLi]_2$ were reported recently,[11a] but these compounds, being nonsolvated, have different structural characteristics from the solvated silyl lithium compounds and therefore they are not discussed here.

[16] D. Bravo-Zhivotovskii, Y. Apeloig et al., to be published.

[17] In the structural discussion we use the structure of **5**·3THF reported by Sheldrick et al.,[5a] who reported the structures of both pure **5**·3THF and of **5**·3THF cocrystallized with $Si(SiMe_3)_4$. The structural data of Power et al.[5b] is very similar to that reported by Sheldrick for **5**·3THF cocrystalized with $Si(SiMe_3)_4$ [5a] but the presence or absence of $Si(SiMe_3)_4$ was not mentioned.[5b] We therefore assumed that the most reliable data for pure **5**·3THF is that reported in ref.[5a]

(β-Octafluoro-*meso*-tetraarylporphyrin)manganese Complexes: Synthesis, Characterization and Catalytic Behaviour in Monooxygenation Reactions

Emmanuel Porhiel,[a] Arnaud Bondon,*[a] and Jacques Leroy[b]

Keywords: Fluorinated porphyrins / Electrochemistry / Manganese / Oxidation catalysis

The synthesis and characterization of manganese complexes of β-octafluoro-*meso*-tetraarylporphyrins are reported. The presence of the electron-withdrawing β-fluorine atoms induces a very large shift of the redox potential for the oxidation of the manganese(II) derivatives. With the *meso*-aryl group bearing two *ortho*-chlorine atoms (2,6-dichlorophenyl) or five fluorine atoms (pentafluorophenyl), metal complexation leads to the isolation of pure manganese(II) compounds. The stability and catalytic activity of these new derivatives have been studied using hydrogen peroxide and iodosylbenzene as oxidants, and standard substrates for epoxidation and hydroxylation reactions. The results are compared to those obtained with the β-hydrogenated analogs under the same conditions. In the case of hydrogen peroxide, the high level of porphyrin degradation prevents efficient catalytic activity. With iodosylbenzene as oxidant, both stability and epoxidation are similar to those of the β-hydrogenated porphyrins, however, a substantial improvement in the efficiency of the hydroxylation of cyclohexane is observed with up to 33 turnovers with (perfluorotetraphenylporphyrin)manganese(II).

Introduction

Metalloporphyrins have long been known to catalyze the oxidation of various substrates. These catalytic reactions can be performed with a large variety of oxygen donors such as iodosylbenzene (PhIO), peroxides (hydrogen or alkyl), hypochlorites, potassium peroxysulfate, *N*-oxides or molecular oxygen.[1–4] Although various metalloporphyrins have been shown to be catalytically efficient,[5] the most studied ones are those containing iron and manganese. Despite substantial progress towards the use of metalloporphyrins as catalysts to perform cytochrome-P450-like oxidative reactions, especially in the hydroxylation of alkanes, synthesis of new porphyrins with electron-withdrawing substituents is still a challenge. The objective is to prepare porphyrins characterized by very high redox potentials which should resist oxidative decomposition and exhibit a very high efficiency in oxidation catalysis. Three generations of metalloporphyrins have been successively studied: i) the unsubstituted core-planar tetraphenylporphyrin (TPP),[6–9] ii) the porphyrins bearing substituents on the *meso*-aryl groups[10–13] and iii) the porphyrins β-octahalogenated or β-substituted with other electron-withdrawing groups.[14–18] In the latter group, the chloro and the bromo derivatives have been extensively studied whereas the fluorinated compounds have only recently been reported.[19,20]

In a misleading paper published in 1989, the ferric "Teflon" porphyrin [2,3,7,8,12,13,17,18-octafluoro-5,10,15,20-tetrakis(pentafluorophenyl)porphyrin] was reported to be very stable and very efficient for epoxidation and hydroxylation with hydrogen peroxide.[21] Not only was the characterization of the β-fluorinated porphyrins shown to be erroneous,[19,20] but the purported catalytic activities have been invalidated.[22] With the exception of the hydroxylation of aromatic compounds involving the use of a large excess of the substrate anisole[23] or toluene,[24] β-octahalogenation of metalloporphyrins leads to catalysts relatively unstable towards hydrogen peroxide[22,25,26] or hypochlorites.[27] Nevertheless, a great improvement in catalytic activity occurs through β-octahalogenation of *meso*-tetrakis(2,6-dichlorophenyl)porphyrin when using $KHSO_5$,[15] PhIO[22,28] or molecular oxygen[17] as oxidants. Surprisingly, the β-octahalogenation of the *meso*-tetrakis(pentafluorophenyl)porphyrin does not improve the efficiency of the epoxidation or hydroxylation with PhIO,[22,28] but does so for the hydroxylation of alkanes with molecular oxygen.[17]

The origin of the increased activity associated with the presence of electron-withdrawing substituents at the β-pyrrolic position is mainly related to a large anodic shift in the first oxidation potential[20,29–39] and to distortion of the macrocycle.[33,40–42]

Our previous work has shown that the β-fluorination of porphyriniron complexes leads to an increased catalytic activity with regard to the hydroxylation of alkanes.[22] However, with H_2O_2, the expected higher stability of the porphyriniron derivatives was not observed.[22] In the present study, we have prepared and characterized the manganese complexes of 2,3,7,8,12,13,17,18-octafluoro-5,10,15,20-tetraphenylporphyrin (β-F_8TPP), 2,3,7,8,12,13,17,18-octafluoro-5,10,15,20-tetrakis(2,6-dichlorophenyl)porphyrin (β-F_8TDCPP) and 2,3,7,8,12,13,17,18-octafluoro-5,10,15,20-tetrakis(pentafluorophenyl)porphyrin (β-F_8TPFPP,

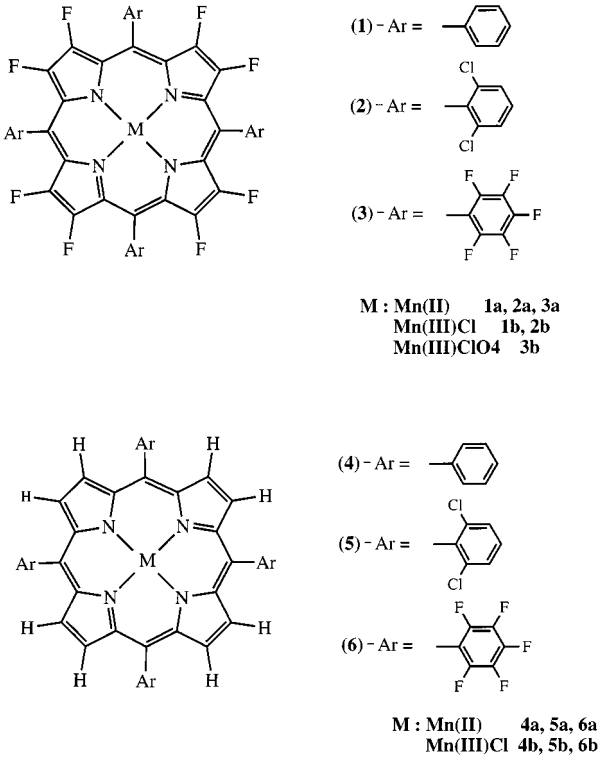
also called perfluorotetraphenylporphyrin). Their stability in the presence of PhIO and H_2O_2 has been measured, as well as their catalytic behaviour in the epoxidation of cyclooctene and the hydroxylation of cyclohexane.

Results



Synthesis of Metalloporphyrins

Preparation of the (β-octafluoro-*meso*-tetraarylporphyrin)manganese complexes (Scheme 1) was carried out under standard conditions,[43] from free-base porphyrins using a ten-fold excess of $Mn(OAc)_2{\cdot}4H_2O$ in DMF under an inert gas. Metallation was achieved after refluxing for a few minutes. Pure Mn^{II}(β-F_8TPP) complex (**1a**) could be obtained if the reaction was performed under anaerobic conditions, whereas pure manganese(II) complexes were always isolated, even after refluxing for several hours, under aerobic conditions, with the β-F_8TDCPP and β-F_8TPFPP porphyrins. These complexes, (β-F_8TDCPP)Mn^{II} (**2a**) and (β-F_8TPFPP)Mn^{II} (**3a**), obtained in high yield (>90%) after purification by column chromatography, are perfectly stable in air. In contrast, the complex (β-F_8TPP)Mn^{II} (**1a**) must be stored as an acetonitrile solution because slow oxidation occurs in air even in the solid state. A second step to prepare the manganese(III) derivatives is necessary, the protocol depending on the nature of the aryl groups. The complex (β-F_8TPP)Mn^{III}Cl (**1b**) was obtained from **1a** by autooxidation during column chromatography on silica gel. The compound (β-F_8TDCPP)Mn^{III}Cl (**2b**) can be prepared from **2a** by oxidation with iron perchlorate or ferricinium salt in dichloromethane solution. Attempts to isolate pure (β-F_8TPFPP)Mn^{III}Cl were unsuccessful because the manganese(III) complex is readily reduced to the Mn^{II} complex **3a**, but the perchloratomanganese(III) complex **3b** could be obtained in dichloromethane by addition of solid iron perchlorate.

Characterization of Metalloporphyrins

UV/Visible Spectroscopy

The electronic absorption spectra of the β-fluorinated manganese complexes in $CHCl_3$ are summarized in Table 1. The manganese(II) complexes display a hypsochromic shift of 13–16 nm compared to the β-hydrogenated analogs. The Soret bands of both (β-F_8TPP)Mn (**1a**) or (β-F_8TPFPP)Mn (**3a**) are found at 419 nm and that of the complex (β-F_8TDCPP)Mn (**2a**) at 422 nm. As for the β-hydrogenated analogs, two Q bands (551 and 588 nm) are observed for complex **1a** and only one near 550 nm for complexes **2a** and **3a**. The corresponding manganese(III) derivatives exhibit a Soret absorption at 474 nm for **1b** and **2b**, with a blue shift of only 3–4 nm as compared to **4b** and **5b**, respectively. However, the (perfluorotetraphenyl)porphyrin complex **3b** displays a shift of 14 nm (Soret band at 458 nm) relative to the hydrogenated complex **6b**.

Electrochemistry

The redox potential data for the manganese compounds were obtained by cyclic voltammetry in dichloromethane containing 0.1 M Bu_4NPF_6 as supporting electrolyte. Results are referenced to the SCE and summarized in Table 2. All complexes undergo a reversible Mn^{II}/Mn^{III} process with $E^{1/2}$ ranging from –0.34 V for **4** to 0.70 V for **3**. Similar values have already been reported for the hydrogenated complexes **4**–**6**.[24,44,45] The potentials of the β-fluorinated porphyrinmanganese complexes are significantly higher than those of their hydrogenated analogs. The most important anodic shift is +0.82 V for (β-F_8TPFPP)Mn (**3**), compared to (TPFPP)Mn (**6**). Smaller shifts are observed be-

tween **2** and **5** (+0.58 V) and between **1** and **4** (+0.5 V). Furthermore, the amplitude of the redox potential values, which follows the order **1** < **2** < **3**, is larger than that of the hydrogenated complexes, which follows the order **4** < **5** < **6**. With the exception of the complex **1**, which shows a second oxidation wave at 1.51 V, there are no accessible oxidation waves, up to 1.8 V, for the complexes **2** and **3**. Two reversible reductions are often observed with manganese complexes.[46] The presence of the eight fluorine atoms induces small shifts at lower potentials for the complexes **1** and **2**, whereas a much larger influence is observed in the case of **3** with differences of 0.62 V and 0.47 V for the first and the second reduction waves, respectively.

Nuclear Magnetic Resonance

The fluorine chemical shifts of the new β-fluorinated porphyrinmanganese complexes are reported in the Experimental Section. To the best of our knowledge, only one report has been dedicated to fluorine-NMR study of (pentafluorophenyl)porphyrin derivatives complexed by zinc, iron or ruthenium.[47] With the paramagnetic manganese complexes, the resonances of the β-fluorine atoms are broadened beyond detection in the case of manganese(II) derivatives, whereas for the manganese(III) complexes broad signals are detected at δ = –4.9, –4.2 and –2.8 for complexes **1b**, **2b** and **3b**, respectively. The chemical shifts seem to correlate with the redox potential for the reduction of the manganese complexes [δ (ppm) = –5.44 + 3.8 $E^{1/2}$ (V); correlation coefficient: 0.993], but additional compounds would be needed to confirm this relationship.

Oxidation with Iodosylbenzene

Stability in the Absence of Substrate

The robustness of porphyrinmanganese complexes towards PhIO as oxidant has been studied at room temperature under aerobic conditions, both in the absence and presence of a co-catalyst such as 1-methylimidazole or ammonium acetate, and in the absence of substrate. The ratio catalyst/oxidant/co-catalyst employed was 1:100:10. An excess of cyclooctene was added to the cuvette prior to measurement to convert high-valent manganese species into Mn^{III} derivatives, allowing us to estimate the decrease of the Soret band of the Mn^{III} complexes (Table 3). Addition of cyclooctene was necessary since manganese complexes react with iodosylbenzene to generate, in the absence of substrate, (porphyrin)Mn^{IV} complexes.[48,49] A dimeric complex [(PhIO)TPPMn^{IV}Cl]$_2$O has been characterized by a broad Soret band at 421 nm in chlorobenzene.[48] Under similar conditions, but in dichloromethane, a Soret band was observed at 426 nm for the new complexes obtained from **4b** and **5b**, and at 417 nm from **6b**. With the β-fluorinated porphyrinmanganese complexes, the addition of PhIO to **1**(**a** or **b**), **2**(**a** or **b**) and **3a** produces new intermediates, characterized by Soret bands at 412, 410 and 404 nm, respectively, irrespective of the oxidation state of the starting complexes Mn^{II} or Mn^{III} (Table 4). Once again, β-fluorination leads to a blue-shift of 13–16 nm when compared with the β-hydrogenated analogs.

The results obtained show that with 1-methylimidazole or without co-catalyst, the β-fluorinated porphyrinmanganese(II) or -manganese(III) complexes show a similar robustness comparable with the β-hydrogenated analogs. It must be emphasized that the sterically protected porphyrins **2a**, **2b** and **5b** are very stable (loss <5%) even under the drastic conditions employed. On the other hand, the decomposition of complexes **3a** and **6b** is around 50%. In the absence of co-catalyst, complexes **1a**, **1b** and **4b** are quite stable, exhibiting only a 15 to 19% decrease in the intensity of Soret band. With a co-catalyst this decrease is ca. 55%. The stability depends on the nature of the aryl groups and increases in the order $C_6H_5 < C_6F_5 < C_6H_3Cl_2$, which applies both for the β-hydrogenated and the β-fluorinated porphyrins. With ammonium acetate as co-catalyst the stabilities of the catalysts were close to those observed with imidazole. However, with this co-catalyst, the reaction of PhIO with **2a**,**b** and **3a** leads to new complexes characterized by Soret peaks at 407 and 401 nm, respectively. These species still remain after addition of cyclooctene and have not been further characterized.

Epoxidation

The catalytic activity of the porphyrinmanganese complexes in cyclooctene epoxidation has been evaluated using unusually drastic catalytic conditions with a cyclooctene/PhIO/co-catalyst/catalyst ratio of 100:100:10:1 (Table 5). Thus, the epoxide yields, calculated relative to the substrate and the oxidant, which are in equal amounts, correspond directly to the turnover numbers.

Table 3. Stability of various porphyrinmanganese complexes towards PhIO

Catalyst	Decrease in Soret absorbance (%)[a]		Catalyst
(β-F_8TPP)Mn (**1a** or **1b**)[b]	55 (15)[c]	56 (19)[c]	(TPP)Mn^{III}Cl (**4b**)

Table 5. Cyclooctene epoxidation by PhIO catalyzed by porphyrinmanganese complexes

Catalyst	Epoxide yield (%)[a] Cyclooctene/PhIO		Catalyst
(β-F_8TPP)Mn (**1a** or **1b**)[b]	43 (42)[c]	42 (43)[c]	(TPP)Mn^{III}Cl (**4b**)
(β-F_8TDCPP)Mn (**2a** or **2b**)[b]	73 (71)[c]	73 (74)[c]	(TDCPP)Mn^{III}Cl (**5b**)
(β-F_8TPFPP)Mn^{II} (**3a**)	63 (60)[c]	59 (60)[c]	(TPFPP)Mn^{III}Cl (**6b**)

[a] Cyclooctene/PhIO/1-MeIm/catalyst = 100:100:10:1 in CH_2Cl_2 (catalyst at 2 mM), at room temperature. Yields were determined by GC after 1 h and based on starting cyclooctene. – [b] Reduced and oxidized manganese complexes give identical values. – [c] In parentheses, $CH_3CO_2NH_4$ used as co-catalyst with same ratio.

With 1-methylimidazole or ammonium acetate as co-catalyst, the activities of β-fluorinated (porphyrin)Mn^{II} or -Mn^{III} catalysts are very similar. Surprisingly, the results are also comparable to those obtained with the β-hydrogenated analogs. The epoxide yield was found to be about 43% for catalysts **1a**,**b** or **4b** and 60% for **3a** or **6b**. The best yields, of ca. 73%, were observed with the protected manganese complexes **2a**,**b** and **5b**. Therefore the activity is dependant on the nature of the aryl groups and increases in the order $C_6H_5 < C_6F_5 < C_6H_3Cl_2$.

Hydroxylation

The hydroxylation of cyclohexane was chosen to evaluate the catalytic activity of the porphyrinmanganese complexes. We used the same ratio as for epoxidation, namely a cyclohexane/PhIO/co-catalyst/catalyst ratio equal to 100:100:10:1, and the results are reported in Table 6. Again, we noticed similar activities for both β-fluorinated Mn^{II} and Mn^{III} catalysts. However, in this case, the presence of β-fluorine atoms improves the cyclohexane hydroxylation. In particular, with 1-methylimidazole, a two-fold increase in yield was observed with the catalyst **2**, as compared with **5b**. The best hydroxylation yield is obtained with the (perfluorotetraphenyl)porphyrin complex **3a**, with a 33% yield of cyclohexanol in the presence of 1-methylimidazole as co-catalyst. The activity depends also on the nature of the aryl groups, increasing in the order: $C_6H_5 < C_6H_3Cl_2 < C_6F_5$, in contrast to that observed for epoxidation. Finally, the co-catalyst clearly has an effect on the yields, 1-methylimidazole being more effective than ammonium acetate.

Oxidation with Hydrogen Peroxide

Stability in the Absence of Substrate

The stability of the manganese porphyrins was studied with a H_2O_2/co-catalyst/porphyrin ratio of 100:10:1, under aerobic conditions at room temperature (Table 7). Usually, acetonitrile is used for diluting hydrogen peroxide, but in this solvent complexes **2a** and **3a** remain in the reduced state, even in the presence of H_2O_2. Coordination of acetonitrile prevents reaction with H_2O_2. Moreover, the addition of acetonitrile to a dichloromethane solution of complex **2b** induces its reduction to the Mn^{II} complex **2a**. Therefore, we used methanol as co-solvent to assess the stability and catalytic activities of complexes **2a** and **2b**. However, the most electron-deficient catalyst **3a** was found to be unreactive towards H_2O_2 in methanol.

The effect of the co-solvent on the reactivity of the porphyrin complexes **2a** and **2b** was shown to be crucial, but the nature of the co-solvent is also important when measuring the stability of the β-hydrogenated complexes **4–6**. The complex **6b** is stable with acetonitrile as co-solvent and partially decomposed in the presence of methanol, whereas complex **5b** shows the opposite behaviour. The introduction of fluorine at the β-position of (TPP)Mn seems to stabilize the complex in acetonitrile but not in methanol. Degrada-

Table 6. Cyclohexane hydroxylation by PhIO, catalyzed by porphyrinmanganese complexes

Catalyst	Cyclohexane/PhIO with $CH_3CO_2NH_4$	Product yield (%)[a] Cyclohexanol + -one	Cyclohexane/PhIO with 1-MeIm

			3	37	(TPFPP)Mn^{III}Cl (**6b**)

[a] H_2O_2 was added at once (100 equiv., 3% in CH_3CN or CH_3OH) to the porphyrinmanganese complex (2 mM) in CH_2Cl_2/CH_3CN (1:1) or CH_2Cl_2/CH_3OH (1:1) and the decrease was measured after 15 min at 25 °C. – [b] The complex remains as Mn^{II}. – [c] The complex is reduced to Mn^{II}.

tion of ca. 53% was measured for both Mn^{II} and Mn^{III} complexes **2a**, **2b**, much more important than that observed for the hydrogenated analog. Finally, the oxidized and reduced complexes **2a**, **2b** show the same decrease in intensity of the Soret band whereas the stability of complex **1** depends on the oxidation state. Bleaching of the reduced form **1a** is very rapid with both co-solvents even though the oxidized form **1b** decays more slowly and is sensitive to the nature of the co-solvent.9

Epoxidation and Hydroxylation

The olefin epoxidation activity of the porphyrinmanganese complexes was investigated by epoxidation of cyclooctene, with a cyclooctene/H_2O_2/$CH_3CO_2NH_4$/catalyst ratio of 100:200:10:1, in CH_2Cl_2/CH_3CN and CH_2Cl_2/CH_3OH mixtures (Table 8). As suggested by the stability test, the complex **3a** is inactive in these solvent mixtures. Both oxidation states of (β-F_8TDCPP)manganese complexes **2a** and **2b** are also inactive in acetonitrile. However, in methanol, a similar efficiency was observed for the two complexes. With a 15% yield of cyclooctene epoxide, these

(β-F_8TPFPP)Mn^{II} (**3a**)	n. d.[b]	n. d.[b]	69	41	(TPFPP)Mn^{III}Cl (**6b**)

[a] Cyclooctene/H_2O_2/$CH_3CO_2NH_4$/catalyst = 100:200:10:1 (catalyst at 2 mM), at room temperature. Yields were determined by GC after 1 h and based on starting cyclooctene. Mn(P), substrate and co-catalyst were dissolved in CH_2Cl_2/CH_3CN or CH_3OH (1:1); concentrated aqueous H_2O_2 diluted to 3% in the indicated solvent, was added by 2 additions of 1 molar equivalent relative to cyclooctene, at 0 and 20 min. – [b] Not detected.

β-fluorinated porphyrinmanganese complexes were less efficient than the analog (TDCPP)MnCl (**5b**). The same applies for the complexes of β-F_8TPP, **1a** and **1b**, which exhibit poor activities that are even inferior to the hydrogen equivalent **4b**.

In order to gain some insight into the catalytic activities of (perfluorotetraphenylporphyrin)manganese, a co-solvent which permits oxidations with H_2O_2 was required. With acetone as co-solvent instead of acetonitrile or methanol, we found that the perfluorotetraphenylporphyrin complex **3a** reacts with hydrogen peroxide.[50] A decrease in the Soret absorption of the (β-F_8TPFPP)Mn band was observed by UV/Vis spectroscopy, but without appearance of the Mn^{III} band, presumably due to a rapid return to the reduced form. In this system, even in the presence of the substrate, part of the hydrogen peroxide was consumed and reduced to water by the continual oxidation of Mn^{II} to Mn^{III}, to the detriment of substrate oxidation. Consequently, the use of a larger amount of H_2O_2 (8 equivalents relative to the substrate) led to a yield of epoxide of 32% (Table 9).

Hydroxylation reactions were only performed with the perfluorotetraphenylporphyrin complex **3a** and its β-hydrogenated analog **6b** (Table 9) based on their reasonable yields obtained for epoxidation. The yields of hydroxylation with these two porphyrinmanganese complexes are low although a slight increase is observed through β-fluorination.

Discussion

In some cases, β-octachlorinated or β-octabrominated porphyrins display higher activities, especially in hydroxylation catalysis. However, due to the strong electron-withdrawing character of the fluorine atoms, recent calculations have predicted that β-octafluorination should exert an electronic effect significantly larger than that of β-octachlorination or β-octabromination.[51] Furthermore, the effect on the energy level of the HOMO should be even more pronounced because the core distortion induced by steric hindrance between the aryl groups and the β-chlorine or -bromine is absent with the smaller fluorine atoms. This saddle distortion is responsible for some destabilization of the HOMO, resulting in a decrease in the first oxidation potential.[33,39,52] In a sense, the erroneous paper by Tsuchiya and Seno[21] corresponded to the expected improvement in stability and efficiency in hydroxylation catalysis. We recently unambiguously demonstrated the erroneous character of these results using authentic iron complexes of β-octafluorinated porphyrins. On the other hand, an increase in the efficiency of the catalyst for alkane hydroxylation is associated with β-octafluorination.[22]

Synthesis and Characterization

Manganese complexation results in the formation of stable Mn^{II} derivatives. Oxidation of manganese is not observed for complexes **2** and **3**, even during prolonged reflux in air, in contrast with β-octachlorinated or β-octabrominated porphyrins,[15] but in agreement with electrochemical data. The presence of the β-fluorine atoms induces a blue-shift in the Mn^{II} and Mn^{III} UV/Vis spectra as compared to the hydrogenated compounds. The amplitude of these blue-shifts varies in the range 5–20 nm depending on the oxidation state of the metal and the aryl substituents. This range is very close to the observed variation for the free-base porphyrins[19,20] or iron complexes.[53] This result, consistent with the planar structure of the β-octafluorinated porphyrins,[20,54] contrasts with the strong red-shifts observed for other β-octahalogenated derivatives which are associated with a large macrocycle distortion. However, the crystallographic structure of the pentacoordinated (H_2O)β-F_8TPPZn complex shows a pronounced saddle shape,[19] which is more likely attributable to crystal packing. Also surprising, but possibly related to the same variations between the solution and the solid state, is the near-planar structure of the hexacoordinated zinc complex of the β-heptanitrotetraphenylporphyrin,[18] whereas strong red-shifts of the Soret band are observed for the β-(nitro)$_{1-7}$porphyrins.[18,28,30,38]

The data for one-electron redox potentials are also in agreement with the strong electron-withdrawing character of the fluorine atoms. β-Octafluorinated porphyrinmanganese(III) complexes are more easily reduced to manganese(II) complexes than the hydrogenated analogs. Redox potentials of 0.16 V and 0.30 V are found for the derivatives **1** and **2**, respectively, whereas complex **3** exhibits a value of 0.70 V which corresponds to the highest redox potential for a halogenated porphyrin. Only the (β-heptanitrotetraphenylporphyrin)manganese complex was reported to have a higher potential (0.94 V).[38] Similarly, positive shifts of the potentials are observed, but to a lesser extent, for the first and the second ring reduction. These data explain why the complexes are isolated as reduced manganese derivatives as well as their extreme stability of the reduced state. For example, the complexes **2** and **3** remain as Mn^{II} under reflux in air, whereas the (β-octabromotetramesitylporphyrin)Mn^{II} is converted into the Mn^{III} complex.[15]

Oxidation Reactions

Over the last few years, the main objective in the search for new metalloporphyrins as oxidation catalysts has been the preparation of very stable and efficient molecules. In accordance with this aim, we have performed all tests of stability and catalytic activity under severe conditions, with equimolar proportions of oxidant and substrate. The catalyst was used at 1% relative to the oxidant, even for the measures of stability. These conditions allowed us to obtain directly the turnover number without any protection by excess substrate. Consequently, most of our results correspond to relatively modest yields. Furthermore, analysis of the influence of the β-octafluorination required us to carry out the experiments on the nonfluorinated porphyrinmanganese complexes under the same conditions.

Iodosylbenzene

This oxidant is not a good one in terms of the environment, but has been extensively used in order to assess the

catalytic properties of metalloporphyrins. It has been used as oxygen donor with porphyrinmanganese complexes for some time.[8,9] Beside porphyrin modifications, an improvement is associated with the use of imidazole as co-catalyst, corresponding to an enhancement of the reaction rate.[55] In this study, we used 1-methylimidazole or ammonium acetate as co-catalysts, the latter known to be a good co-catalyst in oxidation reactions with hydrogen peroxide.[56]

The study of the stability of the new β-octafluorinated porphyrinmanganese derivatives towards iodosylbenzene, in the absence of substrate, gave unexpected results. The decrease in the intensity of the Soret band is the same for both the β-octafluorinated complexes **1–3** and the β-octahydrogenated analogs **4–6**. The amount of decomposition is also independent of the manganese oxidation state in the starting compounds, the reduced state being available in the complexes **1–3**. The addition of 1-methylimidazole as co-catalyst induces a difference in the case of the tetraphenyl derivatives **1** and **4** only, with a larger (or at least faster) decomposition of these catalysts. The extent of the decrease in intensity of the Soret band was measured after addition of cyclooctene because an intermediate was formed during the reaction of the manganese complexes with iodosylbenzene. These intermediates are converted into Mn^{III} by adding the substrate with concomitant formation of epoxide, characteristic of a higher oxidation state of manganese. Mn^{IV} complexes have been extensively studied,[1,48,49,57–60] and the formation of a dimeric (μ-oxo)porphyrinmanganese complex that contains one iodosylbenzene per manganese has been reported.[48] This product was characterized by a Soret band at 421 nm. Compared to the non-β-halogenated derivatives **4–6**, a blue-shift of the Soret bands of 13–16 nm is also observed for the β-fluorinated complexes **1–3**. This analogous result suggests the formation of Mn^{IV} derivatives.

As far as the epoxidation catalysis is concerned, the absence of any significant difference in the yields of epoxidation between the β-fluorinated and the β-hydrogenated complexes is surprising. The best systems contain *meso*-2,6-dichlorophenyl as the aryl group, independent of the substitution at the β-positions. According to the results of the stability study, the use of catalysts with reduced or oxidized manganese leads to a very similar outcome suggesting the same reactive intermediates. Finally, the use of co-catalysts increases the rate of the reactions as previously observed,[55] without any difference in the turnover numbers obtained with 1-methylimidazole or ammonium acetate.

In contrast to epoxidation, large variations in the yields of hydroxylation of cyclohexane are observed, depending on: i) the presence of β-fluorine atoms, ii) the absence or the nature of co-catalyst and iii) the nature of the aryl group of the tetraarylporphyrins. 1-Methylimidazole has been shown to be an efficient co-catalyst favoring a high-valent (oxo)Mn intermediate.[61] With this co-catalyst, conversion of cyclohexane lies in the range 5–25% for the β-hydrogenated complexes **4–6** and 8–33% for the β-fluorinated porphyrinmanganese complexes **1–3**. The increase in the turnover number is close to 100% for Ar = phenyl (**1** and **4**) and dichlorophenyl (**2** and **5**) and 30% for Ar = pentafluorophenyl (**3** and **6**), with up to 33 turnovers for the perfluorotetraphenylporphyrin catalyst. It should also be emphasized that, in contrast with the epoxidation reaction, the best yields are obtained with Ar = pentafluorophenyl (**3** and **6**) rather than Ar = dichlorophenyl (**2** and **5**). Similarly, the efficiency for the hydroxylation of linear alkane by PhIO by tetraarylporphyriniron complexes is larger for Ar = pentafluorophenyl than for Ar = dichlorophenyl.[62]

Hydrogen Peroxide

The conditions employed correspond to two bulk additions of equimolar hydrogen peroxide (relative to the substrate) rather than dropwise addition. We used ammonium acetate as co-catalyst which has been shown to be more efficient than imidazole and carboxylic acids.[56] However, the studies have been complicated by the high metal oxidation potentials of the β-fluoroporphyrin complexes, corresponding to a very easy reduction of the manganese. Acetonitrile, the most common solvent for homogeneous reaction with H_2O_2, binds and stabilizes Mn^{II} complexes. Even methanol is able to prevent the reaction of hydrogen peroxide with (perfluorotetraphenylporphyrin)manganese. For this last porphyrin derivative, we have found a way to perform catalytic studies using acetone as solvent.

Under the conditions employed, the main finding is the instability of the β-fluoroporphyrinmanganese complexes towards hydrogen peroxide. Similar results have already been reported for β-chloro- or β-bromoporphyrinmanganese complexes.[25,26] However, good yields of hydroxylation have been reported, but in the presence of very large excess of substrate and very small oxidant/catalyst ratios.[23,24] The large amount of decomposition of the β-fluoroporphyrins, previously encountered with the iron complexes, has been associated with the high reactivity of the β-fluorinated positions towards homolytic cleavage, or nucleophilic attack of H_2O_2.[22] We have observed that β-fluoroporphyrinzinc complexes exhibit good stability towards H_2O_2, while extensive protection of β-halogenated porphyrins can be achieved with the use of radical scavengers.[26] Overall, these data are more in favor of the homolytic cleavage of hydrogen peroxide.

Conclusion

Many factors are involved in the catalytic activity of metalloporphyrins. Among these are the reactivity of the oxometal intermediate, the steric protection due to the substituents on the aryl groups, the distortion of the macrocycle, the resistance towards oxidation of the porphyrin and also the nature of the co-catalyst, the oxidant and the effect of solvent. It is still difficult to rationalize why the *meso*-tetraarylmetalloporphyrins are so efficient when the aryl groups are 2,6-dichlorophenyl or pentafluorophenyl. However, the olefin requires a less reactive oxometal intermediate for epoxidation than alkane hydroxylation. In the for-

mer reaction, steric protection due to the chlorine atoms of the dichlorophenyl group could be considered an important factor in efficient epoxidation. With alkane hydroxylation, more electron-deficient metalloporphyrins are responsible for an increase in the reactivity of the oxometal species, which favors a higher yield in hydroxylation. This view is consistent with the very small differences in the results obtained with iodosylbenzene, associated with the β-fluorination of the porphyrin in epoxidation, whereas larger effects are observed in the hydroxylation of cyclohexane. With hydrogen peroxide, the high level of decomposition prevents any improvement in epoxidation from being detected, as was previously observed with iron β-chloro- or -bromoporphyrins[26] and β-fluoroporphyrins.[22] However, a small increase in hydroxylation is observed with the (perfluorotetraphenylporphyrin)manganese as compared to the β-hydrogenated analog.

In conclusion, these results, as well as those obtained with β-fluoroporphyriniron complexes,[22] show an improvement in the reactivity of the oxometal intermediate leading to better yields in reactions of hydroxylation.

Experimental Section

General: All solvents were distilled prior to use. Chemical reagents were obtained from commercial sources. PhIO was prepared according to a literature procedure.[63] – UV/Vis spectra were recorded with a Uvikon 941 spectrometer. – NMR spectra were recorded with a Bruker 200 DPX spectrometer in $CDCl_3$ (^1H: 200 MHz, ^{19}F: 188 MHz). – Cyclic voltammograms were measured with a PAR M 263, the $E^{1/2}$ values (V) are reported versus SCE. – FAB mass spectrometry was performed, at the CRMPO, with a ZabSepc TOF Micromass. – Gas chromatography analyses were performed with a GC 121 DFL Delsi instrument. – Analytical thin layer chromatography was performed on commercial aluminium sheets coated with silica gel 60 F_{254} (Merck).

General Complexation Procedure for β-Octafluoroporphyrins: The porphyrins were prepared as previously reported using the Lindsey procedure[64] by condensation of the desired aldehyde and 3,4-difluoropyrrole.[19,65,66] To a suspension of the porphyrin (10 mmol) in DMF (5 mL), under argon, $Mn(OAc)_2{\cdot}4H_2O$ (10 equiv.) was added, and then the mixture was heated to reflux.[43] The complexation was completed within 5 min and after cooling the solvent was removed under vacuum. The complexes **2a** and **3a** were dissolved in dichloromethane and the solutions were filtered through a short silica gel column and concentrated. The complex **1a** was dissolved in dichloromethane/*n*-hexane (1:1 in volume) and the solution filtered and concentrated. **1a** was stored in acetonitrile to prevent oxidation.

Oxidation of Mn^{II} Complexes to $Mn^{III}Cl$: The complex **1a** obtained after evaporation of DMF, was chromatographed on a silica gel column (CH_2Cl_2/CH_3OH, 90:10). The solvents were removed and the residue was dissolved in CH_2Cl_2, washed with 3 M HCl, dried with NaCl and concentrated to give the complex **1b**. An excess of solid $FeClO_4$ was added to the complex **2a** in dichloromethane, and the oxidation monitored by UV/Vis spectroscopy. After filtration, the solution was washed with 3 M HCl, dried with NaCl and concentrated to give the complex **2b**.

The complex **3b** was prepared in situ by addition of a small excess of iron perchlorate to **3a** in dichloromethane.

[2,3,7,8,12,13,17,18-Octafluoro-5,10,15,20-tetraphenylporphyrin]-manganese(II) (1a): MS (FAB HRMS); *m/z* (%): 811.0923 (100) [M^+]; calcd. for $C_{44}H_{20}F_8MnN_4$: 811.0941. – UV/Vis (CH_2Cl_2): λ_{max} (log ε) = 419 (5.08), 549 (3.95), 586 nm (3.87). – CV (CH_2Cl_2/Bu_4NPF_6): E = 1.51 V, 0.16 V, –1.28 V, –1.53 V.

Oxidation Procedure: All reactions were carried out, in duplicate, at room temperature, under aerobic conditions in a tube stirred by a Vortex.

Oxidation with Iodosylbenzene: To the desired porphyrinmanganese complex (0.4 μmol), substrate (cyclooctene or cyclohexane, 40 μmol), and co-catalyst (4 μmol when present), in 200 μL of CH_2Cl_2, PhIO (40 μmol, 8.8 mg) was added in a single aliquot. The reaction mixtures were analyzed by gas chromatography and UV/Vis at 20 min and 60 min by taking 10-μL aliquots.

Oxidation with Hydrogen Peroxide: To the desired porphyrinmanganese complex (0.4 μmol), substrate (cyclooctene or cyclohexane, 40 μmol), and $AcONH_4$ as co-catalyst (4 μmol) in 200 μL of CH_2Cl_2/CH_3OH or CH_2Cl_2/CH_3CN (1:1 in volume), two additions of 50 μL (one molar equivalent, relative to the substrate) of H_2O_2, diluted to 3% in CH_3OH or CH_3CN, were performed at 0 min and 20 min. The reaction mixtures were analyzed by gas chromatography at 20 min and 60 min by taking 10-μL aliquots.

Oxidation in Acetone with Hydrogen Peroxide: To the desired manganese porphyrin (0.4 μmol), substrate (cyclooctene or cyclohexane, 40 μmol), and $AcONH_4$ as co-catalyst (4 μmol) in 200 μL of CH_2Cl_2/CH_3COCH_3 (80:20), concentrated (35%) aqueous solution of H_2O_2 (5 μL, two equivalents relative to the substrate) was added

at 0, 10, 20 and 30 min. The reaction mixtures were analyzed by gas chromatography at 20 min and 60 min by taking 10-μL aliquots.

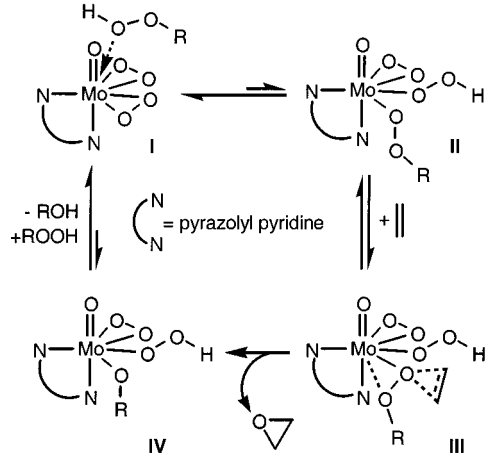
New Insights into the Mechanism of Hydroperoxide Activation by Investigation of Dynamic Processes in the Coordination Sphere of Seven-Coordinated Molybdenum Peroxo Complexes

Angelika Hroch,[a] Gerd Gemmecker,[a] and Werner R. Thiel*[b]

Dedicated to Prof. O. Nuyken on the occasion of his 60th birthday



Keywords: Catalysis / Densitiy functional theory / Epoxidation / Reaction mechanisms

Seven-coordinated molybdenum oxobisperoxo complexes with chelate nitrogen donors like pyrazolylpyridines are catalysts for the epoxidation of olefins. An NMR spectroscopic and quantumchemical study on the fluxionality of the chelate ligand proves that during this process partial ligand dissociation takes place. This gave rise to a detailed theoretical study on the activation of CH_3OOH at the model complex $(NH_3)_2MoO(O_2)_2$ including dissociation of one of the ammonia ligands and proton transfer from the hydroperoxide to one of the peroxo ligands.

Introduction

During the last decades, a series of mechanistic studies on the olefin epoxidation with hydroperoxides catalyzed by high-valent transition metal complexes was carried out to get a deeper insight into the elementary steps of the activation of the oxidising agent,[2–5] but also to understand the transfer of chirality in the synthetically important enantio- and diastereoselective epoxidation of allylic alcohols.[6] As a result of these investigations, it is more and more accepted that the activation of alkyl hydroperoxides (ROOH) is performed by an intermediate η^2-coordination of the peroxidic agent to the Lewis acidic metal centre.[7–12] This is considered to be an "umpolung" of the electron rich alkyl peroxide allowing an electrophilic attack to the olefin. The intermediate alkyl peroxo complexes are usually generated by ligand exchange from suitable precursor complexes, but some transition metal alkyl peroxo complexes have been isolated[13–21] and a few exhibiting η^2-coordination of ROOH have been structurally characterised.[9,10,22] An analogous sequence may be postulated when hydrogen peroxide is used as the oxidising agent, but the final prove of a M–OOH structural motive is still lacking.

We investigated the mechanism of the olefin epoxidation with seven-coordinated molybdenum peroxo complexes of the type $MoO(O_2)_2(L–L)$ (L–L = pyrazolylpyridine ligand) during the last years[23–28] and were able to show that these complexes do not transfer oxygen from one of the η^2-O_2 ligands to the olefin, neither via a spirocyclic transition state nor by precoordination of the olefin to molybdenum as it was postulated in the literature. Instead, they act as activators of the oxidising agent ROOH as it is known from other high valent transition metal complexes. Based upon these results, a new mechanism for the olefin epoxidation with molybdenum peroxo complexes could be proposed (Scheme 1), wherein the oxidising agent coordinates to the Mo^{VI} centre (**I**), undergoes a proton transfer to one of the peroxo ligands (**II**) and is activated for oxygen transfer by η^2-coordination (**III**). This mechanistic idea was supported by a series of experiments especially concerning the proton transfer and kinetic aspects.[25,26]

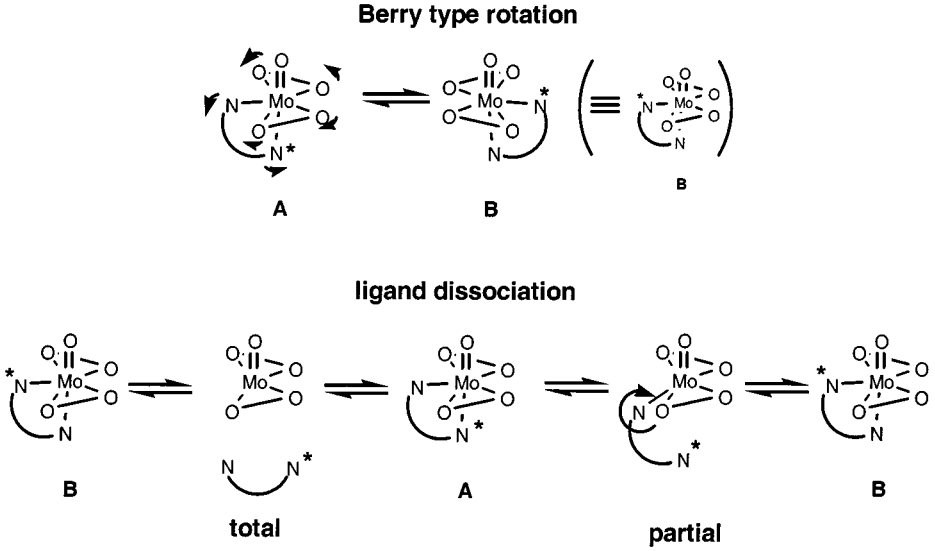
Owing to the asymmetric nature of the ligand bearing two different nitrogen donor centres, these peroxo complexes exist in two isomeric forms **A** and **B**, which differ in the orientation of the aromatic rings relative to the axial oxo ligand and which are in equilibrium in solution (Scheme 2, R = alkyl, $-CH_2COOEt$). This special feature gave us insight into the role of the Lewis acidity of the metal centre which can be tuned by the donor properties of the chelate ligands and allowed for the first time to establish a quantitative relationship between the structure of an epoxidation catalyst and its activity.[27]

Scheme 2

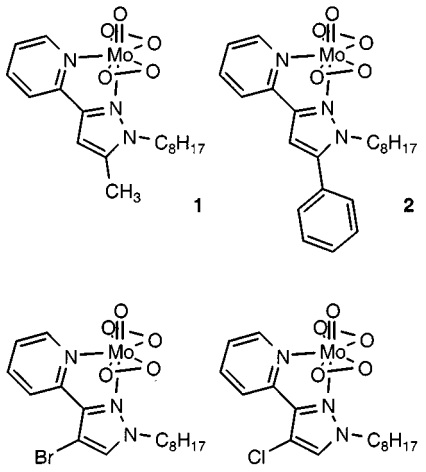
In the present paper, we report on the NMR spectroscopic investigation of the isomerisation process (**A** $\rightleftarrows$ **B**). In addition to the kinetic and thermodynamic data obtained herein, this investigation opens up the door to the activation of ROOH at peroxo complexes, which we elucidated by means of computational methods.



Results and Discussion

For long, the existence of the two isomers **A** and **B** was discussed as a more or less static phenomenon, since simple temperature dependent NMR experiments did not show any significant change in the spectra of the pyrazolylpyridine complexes up to a temperature of 100 °C. This simple image had to be improved when the fluxionality of these systems was preliminarily examined[29] by one dimensional spin transfer experiments, which allow the determination of slow dynamic processes.[30,31]

From a formal point of view, the isomer equilibration (**A** $\rightleftarrows$ **B**) can be achieved either by a Berry-type process of ligand fluxionality (Scheme 3, top) or by ligand dissociation (either complete or partial dissociation; Scheme 3, bottom).



While a Berry-type rotation may be considered unfavourable due to the chelating ligands (pyrazolylpyridine, η^2-O_2-), ligand dissociation from the high valent transition metal centre Mo^{VI} will also be an endothermic process. For a more accurate and extended determination of these processes and the related kinetic and thermodynamic data, the oxobisperoxo molybdenum complexes **1–4**, bearing pyrazolylpyridine ligands with different substituents at the pyrazole moiety, were investigated by temperature-dependent two dimensional NOESY[32] experiments. A common feature of the peroxo complexes investigated are positive entropies of activation (ca. 42–76 $JK^{-1}mol^{-1}$), which prove a dissociation to take place in the rate determining step of the equilibration and therefore rule out a Berry-type rotation. The energies of activation derived from the kinetic data are found in a range of ca. 89–110 $kJmol^{-1}$ (Table 1).

Since these NMR experiments do not allow to distinguish between a partial and a complete ligand dissociation, we investigated the dissociation process by quantum chemical calculations on the model complex $MoO(\eta^2\text{-}O_2)_2(NH_3)_2$ using density functional theory (B3LYP-method[33–35] with LanL2DZ* basis set[36–39]) . The complex geometries resulting from these calculations are in good agreement with the bond parameters obtained from X-ray structure analysis of analogous molybdenum peroxo complexes.[23,24,28,40–42] Figure 1 shows a comparison between the calculated structural parameters and those of oxodiperoxo[3-(2-pyridyl)-1-pyrazolylacetic acid ethyl ester]molybdenum(VI).[23] All calculated bond lengths are found slightly too long, which is due to the applied method.[43] Only the distance between the apical NH_3 ligand and the

$\Delta H^{\ddagger}$	108.4	105.6	94.6	86.6
$\Delta S^{\ddagger}$	76.2	77.0	71.0	42.7

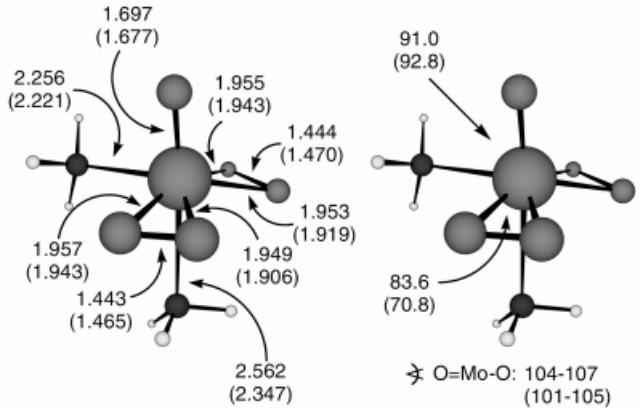

Figure 1. Calculated (DFT) bond lengths (left side) and bond angles (right side) of $MoO(\eta^2\text{-}O_2)_2(NH_3)_2$ compared with values obtained by X-ray structure analysis (in parentheses)[23]

molybdenum centre is calculated much too long, implicating a flat PES (potential energy surface). The same feature has already been described for the ligated water molecule in the rhenium peroxo complex $ReO(\eta^2\text{-}O_2)_2(CH_3)(H_2O)$ by Rösch et al.[44]

Ligand dissociation obviously is an endothermic process: we calculated 56.2 kJmol^{-1} for the dissociation of the axial NH_3 ligand, about 165 kJmol^{-1} for the dissociation of the equatorial NH_3 ligand, and 241.9 kJmol^{-1} for the dissociation of both NH_3 ligands (Figure 2, Table 2). While calculation of $MoO(\eta^2\text{-}O_2)_2(ax\text{-}NH_3)(eq\text{-}NH_3)$ (**a**), $MoO(\eta^2\text{-}O_2)_2(eq\text{-}NH_3)$ (**c**), and $MoO(\eta^2\text{-}O_2)_2$ (**d**), resulted in stable geometries, geometry optimisation of the axially-coordinated isomer **b** lead to **c**. Therefore, the dissociation energy

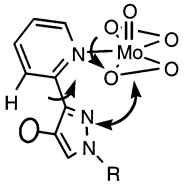
related to isomer **b** could just be obtained by a single point calculation.

As the geometry of the $MoO(\eta^2\text{-}O_2)_2$ centre does not change dramatically by addition of one or two NH_3 ligands (Table 2), the energies of activation obtained from the NMR experiments should be somehow related to one of the calculated dissociation energies. Since 242 kJmol^{-1} for the complete ligand dissociation is far from the experimentally found value of about 100 kJmol^{-1}, we propose a partial ligand dissociation as the key step in the isomerisation process. This agrees with the observation that peroxo complexes of this type undergo a relatively slow decomposition in the presence of excess trifluoroacetic acid (after 15 min about 10–15% of decomp.) in $CHCl_3$ solution.[45] A complete dissociation of the chelate ligand would give rise to a rapid protonation of the liberated ligand and precipitation of a polymeric molybdenum peroxide. Additionally the



catalytic activity of the complexes strongly depends on the substituent pattern of the donor ligand, which also makes a complete ligand dissociation unfavourable. Based on the quantum chemical calculations, spectroscopic investigations and reactivity studies, the isomerisation process depicted in Scheme 4 is proposed.

Scheme 4

Since we could not find a stable axially coordinated intermediate $MoO(\eta^2\text{-}O_2)_2(ax\text{-}NH_3)$ in our calculations, the compounds ***ax*-A** and ***ax*-B** may be discussed as transition states in the isomerisation sequence. The species ***eq*-A** and ***eq*-B** represent flat minima or saddle points of the PES, which correlates with the dissociative nature of the rate determining step.

While the activation energies obtained from the NOESY kinetics qualitatively reflect the strengths of the Mo–N bonds to be broken and therefore the donor potencies of the appropriate chelate ligands, the entropies of activation give an idea about the increase of ligand fluxionality after partial dissociation. They should depend on the substitution pattern of the pyrazolyl fragment: bulky substituents in 4-position (Br) as well as substituents forming H interactions with the proton in the 3-position of the pyridine ring (Cl) will hinder the free rotation around the pyrazole–pyridine bond (Scheme 5) and decrease the entropy of activation (Table 1).

Scheme 5

Beside the clarification of the equilibration process, these investigations may open up a new insight into mechanistic details of the olefin epoxidation with seven-coordinated molybdenum peroxo catalysts. The intermediate $16e^-$ complex **II** of the postulated epoxidation mechanism (Scheme 1) still may undergo a η^2-coordination of the alkyl hydroperoxide to give the activated species **III** ($18e^-$). However, its Lewis acidity should be rather moderate and the derived eight-coordinated species **III** can be considered as sterically overcrowded, which makes the activation process unfavourable. In contrast, partial ligand dissociation would open a coordination site at the molybdenum centre for coordination/activation of the alkyl hydroperoxide, and additionally enhance its Lewis acidity. For that reason, we investigated by quantum chemical calculations the interaction of methyl hydroperoxide (CH_3OOH) with both, the seven-coordinated model system $MoO(\eta^2\text{-}O_2)_2(NH_3)_2$ (**a**) and its six-coordinated congener $MoO(\eta^2\text{-}O_2)_2(eq\text{-}NH_3)$ (**c**), which has been calculated to be just about 56 $kJmol^{-1}$ higher in energy.

A first interaction of a hydroperoxide with a seven-coordinated peroxo species of the type **I** (Scheme 1) may result either from a hydrogen bond between one or both of the peroxo ligands, an attack of one of the Lewis basic oxygen atoms of the hydroperoxide at the molybdenum center, or by a combination of both. For the first mode as a series of stable geometries were found by computational calculations ($\mathbf{e_1}$, $\mathbf{e_2}$, $\mathbf{e_3}$). Despite the well-known fact that density functional theory is not the best method for the calculation of weak interactions like hydrogen bonds,[46] we believe that the geometries and energies we found may give an impression about the first approach of a hydroperoxide to the peroxo complex. The hydrogen bonded system is stabilised by 46.6 to 67.7 $kJmol^{-1}$ compared to free $MoO(\eta^2\text{-}O_2)_2(NH_3)_2/CH_3OOH$ (Figure 3, Table 3). Taking into account that one of the ammonia ligands also forms hydrogen bonds to the hydroperoxide in all the calculated structures and that the calculations do not include any solvent effect, the calculated energies reflect quite well the energy of an intermolecular hydrogen bond in complex **5** (Scheme 6, S = solvent), which was estimated to 8–20 $kJmol^{-1}$ by NMR spectroscopic investigations.[28] **5** forms intramolecular H-bonds to an $\eta^2\text{-}O_2$ ligand in nonpolar solvents like chloroform, intermolecular H-bonds to the solvent in polar solvents like acetone and intermolecular H-bonds to an $\eta^2\text{-}O_2$ ligand of another peroxo complex in the solid state structure.[28]

[a] Compared to free $MoO(\eta^2\text{-}O_2)_2(NH_3)_2$ + CH_3OOH.

Up to now it was not possible to find a local minimum on the PES representing a Lewis acid/base interaction between $MoO(\eta^2\text{-}O_2)_2(NH_3)_2$ (**a**) and CH_3OOH or a combination of the latter feature with hydrogen bonding.

Proton transfer from the hydroperoxide to either the rear or the front oxygen atom of one of the peroxo ligands results in the formation isomeric species of the type **II** $MoO(\eta^2\text{-}O_2)(OOH)(OOCH_3)(NH_3)_2$ ($\mathbf{f_1}$, $\mathbf{f_2}$, $\mathbf{f_3}$), all lower in energy than the starting materials (Figure 4, Table 4).

They are stabilised by intramolecular hydrogen bonding ($\mathbf{f_1}$, $\mathbf{f_2}$) between the proton of the hydroperoxo ligand and the α-oxygen atom of the alkyl peroxo ligand, forming a five-membered ring system and hydrogen bonds to one or both of the ammonia ligands. Along with these theoretical studies we investigated the behaviour of oxobisperoxo(pyrazolylpyridine)molybdenum complexes in the presence of excess *t*BuOOH by NMR. NMR spectroscopy did not prove any interaction between the hydroperoxide and the molybdenum complex, which may either be explained by the different steric demand of *t*BuOOH and CH_3OOH or by a certain error related to the computational method due to the simplification of the donor ligand by NH_3 and by neglect of solvent effects. However, it is indisputable that the energies assigned to the proton transfer and the opening of one $\eta^2\text{-}O_2$ ligand to form a $Mo(OOH)(OOCH_3)$ fragment are low, which makes the existence of species of the type **II** (Scheme 1) in equilibrium with **I** feasible.

Parallel to the seven-coordinated system $MoO(\eta^2\text{-}O_2)_2(NH_3)_2$ (**a**) the interaction of CH_3OOH with the six-coordinated complex $MoO(\eta^2\text{-}O_2)_2(eq\text{-}NH_3)$ (**c**) was investigated. As shown before, dissociation of the axial donor was found to be low in energy. Although unproductive in the

[a] Related to the reaction: **a** + $CH_3OOH \rightarrow$ **g** + NH_3.

isomerisation process of the pyrazolylpyridine complexes (Scheme 4), it may be considered as the key step in the activation of the alkyl hydroperoxide.

We therefore investigated structures of the type $MoO(\eta^2\text{-}O_2)_2(eq\text{-}NH_3)(ax\text{-}CH_3OOH)$ (**g**) by means of computational methods and found three minima on the PES (there may even be more). The energies of these compounds (Table 5), wherein the hydroperoxide can be bound to the molybdenum centre by either the protonated ($\mathbf{g_1}$, $\mathbf{g_2}$) or the alkylated ($\mathbf{g_3}$) oxygen atom, are related to the reaction $MoO(\eta^2\text{-}O_2)_2(NH_3)_2 + CH_3OOH \rightarrow MoO(\eta^2\text{-}O_2)_2(eq\text{-}NH_3)(ax\text{-}CH_3OOH) + NH_3$. The data prove that methyl hydroperoxide is able to stabilise the molybdenum centre in the same manner as ammonia does it. This is promoted by interactions between the proton of the hydroperoxide and one or two of the oxygen atoms of an η^2-peroxo ligand and one of the NH_3 protons with the coordinating oxygen atom of the hydroperoxide, reflecting the basicity of CH_3OOH (Figure 5, Table 5).

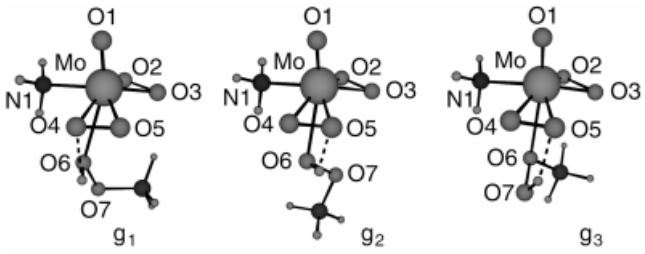

Figure 5. Structures of CH_3OOH adducts to $MoO(\eta^2\text{-}O_2)_2(eq\text{-}NH_3)$

The weak hydrogen bond between OOH and (η^2-O_2) can again be considered as the first step of a proton transfer from the hydroperoxide to the peroxo ligand as discussed before. Proton transfer leads to a series of isomeric molybdenum complexes of the type $MoO(\eta^2\text{-}O_2)(eq\text{-}NH_3)(OOH)(OOCH_3)$ (**h**) showing different ligand conformations (Figure 6 shows three examples, there may be more). The energies given in Table 6 are related to the reaction $MoO(\eta^2\text{-}O_2)_2(NH_3)_2 + CH_3OOH \rightarrow MoO(\eta^2\text{-}O_2)(\eta^1\text{-}O_2H)(eq\text{-}NH_3)(\eta^1\text{-}OOCH_3) + NH_3$.

The intramolecular proton transfer should be a rapid process with a low barrier of activation, it is only slightly endothermic. In all cases we observed, the complexes are stabilised by hydrogen bonds and by η^2-coordination of the methyl hydroperoxo and/or the hydroperoxo ligand, a feature which was not found in the complexes $MoO(\eta^2\text{-}O_2)(OOH)(OOCH_3)(NH_3)_2$ ($\mathbf{f_1}$–$\mathbf{f_3}$, Figure 4). This shows that previous partial dissociation of one donor ligand from a seven-coordinated peroxo complex is energetically feasible and that the activation of the hydroperoxide for oxygen transfer may start with such a dissociative process.

The calculated Mo–O–O angles lie between the data of complexes bearing η^1-coordinated (112–118°[13–21]) and η^2-coordinated alkyl peroxo ligands (59–65°[9,10,20]).

[a]Related to the reaction: **a** + CH_3OOH → **h** + NH_3.

Scheme 7

The overall mechanistic idea resulting from the NMR investigations and the computational calculations is shown in Scheme 7, wherein the seven-coordinated oxobisperoxo complex represents a kind of resting state in the catalytic cycle.

Thus, seven-coordinated molybdenum peroxo complexes bearing chelate pyrazolylpyridine ligands do not undergo a direct oxygen transfer from an η^2-coordinated peroxo ligand to an olefin but activate a potential oxidising agent for oxygen transfer, similar to other high valent and highly Lewis acidic transition metal centres. This includes the requirement of basic ligands to undergo a proton transfer reaction prior to the activation of the hydroperoxide. η^2-Coordinated peroxo ligands are ideal for this purpose since they are weak π donors, which preserves the Lewis acidity of the metal centre. They remain ligated to the metal in a η^1-coordination mode allowing rapid intramolecular proton transfer after the oxygen transfer to regenerate the catalyst.

Conclusion

As shown by NMR spectroscopy and quantum chemical calculations, ligand fluxionality may play an important role in the activation of the hydroperoxide. We were able to show, that the energies related with a partial ligand dissociation and intra- and intermolecular proton transfer reactions are low and that η^2-coordination of an alkylperoxo ligand stabilises six-coordinated molybdenum species.

Experimental Section

NMR spectra were recorded with a Bruker DMX 600 spectrometer and processed by Silicon Graphics workstations with the X-WIN-NMR software package. The 1D spectra and the 2D NOESY spectra were measured at different temperatures/mixing times: **1** (297.3 K/2s, 306.8 K/2 s, 316.3 K/2 s, 325.8 K/2 s), **2** (297.3 K/1 s, 306.8 K/1 s, 316.3 K/1 s), **3** (287.9 K/1 s, 297.3 K/0.5 s, 306.8 K/0.3 s, 316.3 K/0.2 s), **4** (290.0 K/1 s, 300.0 K/0.5 s, 310.0 K/0.2 s, 320 K/0.1 s). – Quantum chemical calculations were performed with the program Gaussian98W using the B3LYP gradient-corrected exchange-correlation functional[33–35] in combination with the Los Alamos effective core potentials on molybdenum atoms together with a gaussian valence basis set of double zeta quality (LanL2DZ).[36–39] The orbital basis sets of carbon, nitrogen and oxygen atoms were augmented by a single set of polarisation functions.[47] Full geometry optimisations were carried out in C_1 symmetry using analytical gradient techniques and the resulting structures were confirmed to be true minima by diagonalisation of the analytical Hessian Matrix.

Acknowledgments

We wish to thank the Deutsche Forschungsgemeinschaft (Schwerpunktprogramm "Peroxidchemie"), the Fonds der Chemischen Industrie for financial support and Prof. W. A. Herrmann and Prof. H. Kessler for logistic support of this work.

Reaction of Organolithium Compounds with Alkali Metal Alkoxides – A Route to Superbases

Lubomír Lochmann[a]

Keywords: Alkali metals / Organolithium compounds / Alkali metal alkoxides / Metal exchange / Metallation

Organolithium compounds and lithium alkoxides form adducts, the reactivities of which are similar to those of the parent organolithium compounds. On the other hand, with heavy alkali metal alkoxides a metal interchange takes place, which gives rise to heavy alkali metal organic compounds. This is accompanied by a dramatic increase in the reactivity of the system, hence the name "Superbase" (SB) may be applied. This metal interchange is a general reaction and proceeds not only with organolithium compounds but also with lithium amides and lithium enolates of ketones and esters. SBs readily react with organic substrates to give heavy alkali metal derivatives of the substrate. Such reactions, followed by conversion with an electrophile, find wide application in organic synthesis. The properties of SBs may be further enhanced by using a greater than equimolar amount of a highly-branched heavy alkali metal alkoxide (R^2OM). In this review, the mechanism of SB reactions with substrates is discussed and the stoichiometric participation rather than catalytic effect of R^2OM is documented. Although various routes for the reaction of SBs with substrates may be envisaged, a heavy alkali metal organic compound is involved in all cases.

Introduction

Organolithium compounds react with alkali metal alkoxides in different ways depending on the metal of the alkoxide. Lithium alkoxides and organolithium compounds form adducts, the reactivities of which approach those of the parent organolithium compounds. On the other hand, heavy alkali metal alkoxides undergo a metal interchange with organolithium species, giving rise to heavy alkali metal organic compounds and lithium alkoxides. The reactivities of these systems are dramatically enhanced and this phenomenon warrants the name Superbase (SB). SBs are extremely strong bases; they readily react with many organic compounds and thus represent useful tools in organic synthesis.

The very first reference to the system prepared from butyllithium and sodium or potassium *tert*-butoxide can be found in a U.S. patent[1] [applied for on Nov. 14, 1963 by Wofford (Phillips Petroleum Co.)], where its use as a polymerization catalyst is described. A paper on this topic appeared much later.[2] The next account of this system appeared in a Czech patent[3] (applied for on Dec. 30, 1964, by Lochmann et al.), which was followed by a lecture[4] and a paper by the same authors[5] (submitted on Nov. 24, 1965). These communications and the following papers[6,7] described the metal interchange leading to the generation of heavy alkali metal organic compounds, as well as the formation of the latter through reaction of SBs with organic

Lubomír Lochmann was born in Prague, Czech Republic, in 1926. He studied chemistry at the Faculty of Chemical Technology, Czech Technical University, Prague, and obtained his M.Sc. degree in 1949. Between 1955 and 1960 he worked in industry and was engaged in the synthesis of fine organic chemicals. He joined the Institute of Macromolecular Chemistry, Academy of Sciences of the Czech Republic, Prague, in 1961 and has been active there up to the present time as a leading scientist. He obtained his Ph.D. degree in 1968 and D.Sc. degree in 1998 from the same Institute. In 1992 and 1993 he was a Visiting Scientist at Cornell University, Ithaca, N.Y., USA, with Prof. J. M. J. Fréchet. His main scientific interests are organic compounds of alkali metals (alkali metal carbanions, amides, and alkoxides; their interactions, formation, and reactions of Superbases) and anionic polymerization, in particular that of (meth)acrylate esters (mechanism, growth centre properties, block copolymers). He is an author of 80 scientific papers, 25 patents, and 3 reviews. For the discovery of the lithium–heavy alkali metal interchange and of Superbases, he received an Award of the Czechoslovak Bureau of Patents and Discoveries (1991).

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

substrates. Subsequently, the general nature of this metal interchange was established and more effective SBs were discovered.[7–11] Eventually, Schlosser submitted a paper (on Aug. 4, 1966) describing an increased reactivity of butyllithium (BuLi) in the presence of potassium *tert*-butoxide and explained this phenomenon in terms of solvation of the BuLi by the oxygen atom of the alkoxide, akin to the solvation of organometallics by ethers. Metallations of several substrates and their subsequent conversions into derivatives through in situ reactions with electrophiles were also described in this paper.[12] This author went on to investigate reactions of SBs with many organic substrates and contributed substantially to the use of SBs in organic synthesis; the relevant results have been summarized in two reviews.[13,14] The properties of SBs have also been investigated in other laboratories. Some salient accounts can be found in refs.[15–23]

The bulk of this review is focussed on the formation and properties of SBs based on results obtained by the author. As SBs find such widespread application in synthetic chemistry, a complete listing of their uses is beyond the scope of this survey (see other reports[13,14,24,25]). Some reactions with specific substrates are described here in greater detail merely in the context of elucidating the reaction mechanism. Throughout this paper, the term "organolithium compounds" is used to denote compounds having a carbon–lithium, a nitrogen–lithium, or an enolate group–lithium bond.

Interaction of Organolithium Compounds with Lithium Alkoxides

Preparation and Properties of $[R^1Li{\cdot}R^2OLi]_x$ Adducts

In mixtures of organolithium compounds and lithium alkoxides, adducts are formed according to Scheme 1.[26–29] This interaction is complex in nature, which stems from the ability of these compounds to form supermolecular aggregates.[30–32] The degree and strength of alkali metal alkoxide aggregation is controlled by the steric requirement of the alkoxy group and the properties of the metal.

$$1/x\,[R^1Li]_x + n\;1/y\,[R^2OLi]_y \rightleftharpoons 1/z\,[R^1Li \cdot n\,R^2OLi]_z$$

Scheme 1

In terms of increasing adduct stability, such systems may be ordered as shown in Scheme 2. Bulky organolithium compounds form adducts less readily than simple ones, whereas the opposite is true for the alkoxides. This is probably due to the fact that the stability of supermolecular aggregates of alkoxides decreases with increased branching, and that this no longer disfavours adduct formation. In accordance with these conclusions, the adduct composed of butyllithium (BuLi) and lithium *tert*-butoxide (*t*BuOLi) is easily formed, whereas lithium methoxide is unable to form such adducts.

Increasing bulkiness of RLi ↓	C_4H_9Li	+	$(CH_3)_3COLi$	↑ Increasing bulkiness of the alkoxide	**Increasing adduct stability**
	$(CH_3)_2CHLi$	+	$(CH_3)_3COLi$		
	$(CH_3)_3CLi$	+	$(CH_3)_3COLi$		
	C_4H_9Li	+	C_4H_9OLi		
	C_4H_9Li	+	CH_3OLi		

Scheme 2

Structure of the $[C_4H_9Li{\cdot}(CH_3)_3COLi]_x$ Adduct

The structure of this adduct, which is isolable in crystalline form, was investigated by Boche et al. by means of X-ray diffraction analysis.[33] It was found to consist of tetrameric aggregates containing two kinds of Li atoms, some being bound to two C atoms and one O atom, the others to one C atom and two O atoms. The degree of aggregation of this adduct in benzene solution is also equal to four,[28,34] hence a solution structure similar to that in the crystalline state may be anticipated.

Reactivity of $[R^1Li{\cdot}R^2OLi]_x$ Adducts

The interaction of organolithium compounds with lithium alkoxides is also manifested in a change in the reactivity of the former,[35–38] although the effect is not so pronounced in this case. The addition of BuLi to 1,1-diphenylethene was chosen for a systematic investigation of the effect of lithium alkoxides on the reaction rate.[35] The ratios of the respective rate constants obtained in the absence and presence of various Li alkoxides at two different concentrations are given in Table 1. The effects of the lithium alkoxides on the rate of addition of BuLi are seen to be negligible, apart from in the case of lithium (–)-(1*R*)-menthoxide. At the lower concentration used, even this effect became very slight.

Table 1. Rate constants for the addition of butyllithium (BuLi) to 1,1-diphenylethene (DPE) in the presence of lithium alkoxides (ROLi)

R	ROLi[a] [10^{-2} mol/L]	BuLi [10^{-2} mol/L]	DPE [10^{-2} mol/L]	k_m/k[b]
(–)-(1*R*)-Menthyl	15.0	15.0	0.1010	4.65
(–)-(1*R*)-Menthyl	1.5	1.5	0.0101	1.20
tert-Butyl	15.0	15.0	0.1010	1.70
tert-Butyl	1.5	1.5	0.0101	0.93
Butyl	12.3[c]	15.0	0.1010	1.43
Butyl	1.1[c]	1.5	0.0101	0.82

[a] In benzene at 29 °C. [b] k_m and k are the rate constants for the addition of butyllithium to DPE in the presence and absence of ROLi, respectively. [c] Saturated solution of lithium butoxide in the corresponding butyllithium solution.

Thus, in summary, it can be stated that lithium alkoxides influence the reactivity of BuLi only to a small extent.

Reaction of Organolithium Compounds with Heavy Alkali Metal Alkoxides – Formation of Superbases

Exchange of Li by Na, K, Rb, Cs

In continuation of the above investigation, it was found that heavy alkali metal alkoxides, in contrast to lithium alkoxides, increase the reactivity of organolithium compounds to a great extent, by a factor of more than 10^6. This is due to another reaction, which occurs in such systems after formation of an initial adduct (similar to the adducts with lithium alkoxides), namely a lithium–heavy alkali metal interchange as generalized in Scheme 3.[3–7,39–43] This interchange gives rise to organic compounds of heavy alkali metals and lithium alkoxides. It was first observed with organolithium compounds containing a C–Li bond, as that in BuLi.[3–6] Subsequently, it was also verified for compounds with an N–Li bond, as that in lithium diisopropylamide,[40] and finally it was found to occur with lithium enolates of esters[42] or ketones, such as lithiated pinacoline.[43] The structure of the starting heavy alkali metal alkoxide may also be varied, tertiary alkoxides being most suited for practical applications, while methoxides are unsuitable. Hence, the validity of this metal interchange scheme is quite general. The systems ($R^1Li + R^2OM$) are often called Superbases due to their increased reactivities.

$$R^1Li + R^2OM \rightarrow R^1M + R^2OLi \qquad (M = Na, K, Rb, Cs)$$

R^1Li represents compounds with C–Li, or N–Li, as well as enolate group $-Li\left(\left[>C{=}C(Y){-}O\right]-Li\right.$, where Y = OR or R) bonds. R^2OM is a tertiary, secondary or primary alkoxide (methoxides excluded).

Scheme 3

Thus, the reactions according to Scheme 4 may proceed.

$$C_4H_9Li + (CH_3)_2(C_2H_5)CONa \text{ (or K)} \rightarrow C_4H_9Na \text{ (or K)} + (CH_3)_2(C_2H_5)COLi$$

$$(iso\text{-}C_3H_7)_2NLi + (CH_3)_3CONa \text{ (or K)} \rightarrow (iso\text{-}C_3H_7)_2NNa \text{ (or K)} + (CH_3)_3COLi$$

$$(CH_3)_2CLiCOOC_2H_5 + (CH_3)_3CONa \text{ (or K)} \rightarrow (CH_3)_2CNa(\text{or K})COOC_2H_5 + (CH_3)_3COLi$$

Scheme 4

This metal interchange takes place not only in hydrocarbon media, from which the reaction product is precipitated, but also in media in which the product remains in solution, as has been verified either by EPR[16] or NMR[15,44] spectroscopy. These results indicate that separation of the reaction product is not the only driving force for the metal interchange.

An SB based on 2-ethylhexyllithium has recently been developed, which exhibits good solubility even in aliphatic hydrocarbons in the absence of any additive[41] (2-ethylhexylsodium is known to be soluble in hexane[45]). This modification is very convenient for reactions of SBs with organic substrates, particularly with those that are insoluble in hydrocarbons. Alternative solvent systems (e.g. with electron-donating solvents at low temperatures) are not compatible with all compounds.

Synthesis of Heavy Alkali Metal Organic Compounds Through Metal Interchange

Organic compounds of heavy alkali metals formed by metal interchange (Scheme 3) can in some cases be isolated in high yield and in a high state of purity,[5–7,39–43] making this a method of choice for their preparation. The procedure is extremely simple: hydrocarbon solutions of the organolithium compound and the heavy alkali metal alkoxide (both ca. 1 M) are mixed under stirring at room temperature; the insoluble product typically separates within a few minutes and can be collected by filtration. It should be noted that the purities of the starting compounds and solvents are of critical importance with regard to the quality of the product. Heavy alkali metal alkoxides soluble in hydrocarbons, such as potassium 2-methyl-2-butoxide (*tert*-pentoxide) (*t*PeOK) or menthoxide (rather than *t*BuOK) are best suited for the metal interchange and give rise to pure organopotassium compounds.

A number of pure heavy alkali metal organic compounds have been prepared through such metal interchange: compounds with a C–heavy alkali metal bond may be obtained from *n*-alkyl or aryllithium compounds in good yields (see Table 2). Their heavy alkali metal contents are close to the calculated values and the Li contents are generally less than 0.5%. For further details concerning this reaction, see refs.[47–53] Some organolithium compounds are barely soluble in aliphatic hydrocarbons, such as methyl- or phenyllithium. In these cases, the use of diethyl ether as a solvent or cosolvent has been proposed by Weiss.[54]

Several heavy alkali metal substituted amides have been prepared in benzene solution according to Scheme 3 (Table 3). Metal interchange with lithium amides that are well-soluble in benzene, e.g. lithium diisopropylamide, gives rise to heavy alkali metal amides of high purity in appreciable yields.[40]

Heavy alkali metal enolates of esters and ketones may also be prepared from the corresponding lithium enolates according to Scheme 3 (cf. Table 3 in ref.[7]). However, these compounds are more conveniently prepared by direct metallation of the parent carbonyl compounds with sodium or potassium hexamethyldisilazanes.[42,43]

Interaction of Organopotassium Compounds with Alkali Metal Alkoxides

The behaviour of organopotassium compounds towards alkali metal alkoxides seems to be very variable. Simple alkylpotassium compounds do not form adducts with potassium *tert*-pentoxide (*t*PeOK) or menthoxide, even in an excess of the alkoxide[55] (Scheme 5, Table 2), but do so with a three molar amount of lithium *tert*-pentoxide (*t*PeOLi), as is illustrated in the case of butylpotassium (formed by metal interchange)[56] (Scheme 6).

Table 2. Preparation of alkyl(aryl)sodium and potassium compounds by metal interchange

BuLi + (1–3) *t*PeOK → *t*PeOLi + (0–2) *t*PeOK + BuK
(no adducts formation)

Scheme 5

BuLi + *t*PeOK + 2 *t*PeOLi → (Bu, *t*PeO)(Li, K) (mixed adduct)

Scheme 6

This mixed aggregate was isolated and was found to have an Li/K molar ratio of ca. 1.4 and a Bu/*t*PeO group ratio of ca. 1.2.

Benzyl- and phenylpotassium (formed by arene metallation by SB) behave in just the opposite manner: they do not react with *t*PeOLi (even in excess), but do form adducts with excess *t*PeOK[41,57] (Scheme 7).

BuLi + *t*PeOK + $PhCH_3$ → BuH + *t*PeOLi + $PhCH_2K$

but: BuLi + 3 *t*PeOK + $PhCH_3$ →
BuH + *t*PeOLi + [$PhCH_2K \cdot n$ *t*PeOK]

PhK + *t*PeOK → [PhK · *n* *t*PeOK]

Scheme 7

The mixed benzylpotassium + *t*PeOK adduct was isolated as a microcrystalline solid; after hydrolysis a $PhCH_3$/*t*PeOH ratio of ca. 1.6 and an Li content of 0.4% were found.

Reaction of Superbases with Substrates

General Aspects and Synthesis of Heavy Alkali Metal Derivatives of the Substrates

It is well-known that heavy alkali metal organic compounds are much more reactive than the corresponding lithium derivatives. The formation of such a compound in the system organolithium compound + heavy alkali metal alkoxide is the predominant reason for the high reactivity of SBs towards organic substrates.[5,44,56]

These reactions may be very different in nature (Scheme 8). Some examples, not covering all the potential applications, are hydrogen–metal exchange (metallation), addition to multiple C=C or other bonds, Wurtz-type coupling with organic halides (even with non-activated halides such as BuBr), and the initiation of anionic polymerization.

$R^1Li + R^2OM + R^3H \rightarrow R^1H + R^2OLi + R^3M$ [$pK(R^1H) > pK(R^3H)$]

$R^1Li + R^2OM + (C_6H_4)_2C{=}CH_2 \rightarrow (C_6H_4)_2CM{-}CH_2{-}R^1 + R^2OLi$

$R^1Li + R^2OM + R^3X \rightarrow R^1{-}R^3 + MX + R^2OLi$ + side-products (X = Br, I)

$R^1Li + R^2OM + n\ CH_2{=}C(CH_3)COOCH_3 \rightarrow R^1{-}[{-}CH_2{-}(CH_3)COOCH_3){-}]_{n-1}{-}CH_2{-}(CH_3)COOCH_3)M + R^2OLi$ (M = Na, K, Rb, Cs)

Scheme 8

A common feature of all the reactions shown in Scheme 8 is that the resulting derivative of the substrate contains predominantly the heavy alkali metal.[5–7,41] This was confirmed by determining the individual alkali metals in the organometallic products isolated prior to protolysis. Hence, metal interchange must also be involved in reactions of SBs with organic substrates. These reactions can thus be used for the preparation of heavy alkali metal derivatives of the substrates. Some examples are shown in Table 4, where the isolated yields of the organometallic products are good, their heavy alkali metal contents are in good agreement with the calculated values, and the Li contents are below

Table 4. Reaction of organic compounds of lithium (R^1Li), heavy alkali metal alkoxides (R^2OM), and organic substrates

Reactants			Product	Yield	Metal content[a] [%]

0.5%. For other examples of the preparation of heavy alkali metal organic compounds, see refs.[58,59] Conversely, there are also cases where the product composition does not match the calculated values and depends rather strongly on the reaction conditions, as will be shown below.

The substrate metallated with the SB may alternatively be reacted with an electrophile without isolation, and this is the way in which SBs are most often used in organic synthesis (see refs.[13,14,24,25]).

In principle, reactions of SBs with substrates can be carried out in one of two different ways. In Method A, the organolithium compound and heavy alkali metal alkoxide are mixed in an appropriate solvent prior to addition of the substrate. In Method B, one component of the SB is mixed with the substrate first, and only then is the other component of the SB added. In the latter case, the SB acts in statu nascendi[56,60] and shows slightly higher reaction rates; however, the conditions in the course of the reaction are neither constant nor well defined.

Typical procedures for the reaction of substrates with SBs are as follows: the substrate (in excess relative to R^1Li, if possible) is mixed with the SB components (according to Method A or B), the ratio R^2OM/R^1Li being 1.1–1.3 (for synthesis of the organometallic compound) or 2–3 (for use in organic synthesis; see below), in an appropriate solvent (typically an aliphatic hydrocarbon) at room temperature and the resulting mixture is stirred for 0.5–3 h under an inert gas. Potassium *tert*-pentoxide is preferred to *t*BuOK. Prolonged stirring and/or an increase in the temperature do not generally increase the yield but lead only to more side reactions. Ethereal solvents may be used at lower reaction temperatures and with substrates having a higher C–H acidity. Generally speaking, better yields of the desired metallated compounds are obtained with substrates having less sterically hindered and more acidic reaction sites and under conditions that favour the metallation (e.g. with an excess of the substrate in cases, where only monometalation is attempted).

Reactions of Superbases with Aromatic Hydrocarbons

The metallation of aromatic hydrocarbons has been studied in detail in order to elucidate the mechanism of SB reactions. This investigation involved the isolation of metallated substrates prior to their hydrolysis and analysis.

Metallation of toluene with the SB derived from 2-ethylhexyllithium (EtHexLi) and *t*PeOK was investigated first.[41] Table 5 highlights the key finding that under all conditions used for these experiments, relatively pure benzylpotassium with a low Li content was formed. The quality of the benzylpotassium was not affected even at ratios of *t*PeOK/EtHexLi below unity, e.g. at a ratio of 0.3. In this case, however, the yield of benzylpotassium was lower and corresponded exactly to the amount of potassium alkoxide present. This shows that potassium alkoxide actually participates in the metallation in a stoichiometric amount and is not merely a catalyst. As soon as all the potassium alkoxide is consumed, no further metallation takes place in spite of the presence of some remaining organolithium compound. Thus, metal interchange is substantial for reactions of SBs with organic substrates.

The reduced concentration of potassium alkoxide in an SB is also reflected in an extraordinarily decreased rate of metallation. Using equimolar amounts of the alkoxide and EtHexLi, the metallation of toluene is complete within ca. 10 min. However, with an SB containing only 0.3 equivalents of the alkoxide, the limiting yield of benzylpotassium was only obtained after more than 20 h.

The product of toluene metallation using an SB containing an excess of *t*PeOK was analyzed in a similar manner. With a small excess of this alkoxide, e.g. 1.3 molar, the quality of benzylpotassium formed remained virtually unchanged. On the other hand, with a large excess, e.g. 3

molar, an adduct of benzylpotassium with the excess of potassium alkoxide was isolated following toluene metallation. This excess of *t*PeOK in the SB causes an approximately 10-fold increase in the rate of toluene metallation in comparison with the SB composed of equimolar amounts of the components.

Further, the effect of lithium alkoxide concentration on the rate of toluene metallation with the SB prepared from BuLi and *t*PeOK was investigated.[56] The molar ratio of lithium *tert*-pentoxide (*t*PeOLi) to butylpotassium in the SB was varied in the range 7:1 to 0:1, either through the addition of an excess of the lithium alkoxide or by removing the lithium alkoxide from the SB reaction mixture by repeated washing prior to toluene addition. It would appear (Table 6) that the toluene metallation rate is influenced only slightly by the lithium alkoxide, and that the metallation rate in the presence of excess of the lithium alkoxide is decreased rather than increased. It should be stressed that the reactivity of neat butylpotassium, as obtained by complete removal of the *t*PeOLi after the metal interchange by washing, is of the same order of magnitude as that of the equimolar butylpotassium + *t*PeOLi mixture formed according to Scheme 3. Thus, in contrast to the potassium alkoxide, lithium alkoxide does not play a substantial role for the high reactivity of the SB.

Metallations of other aromatic hydrocarbons were investigated by employing the same procedure. Table 7 shows that the metallation of benzene is much more dependent on the reaction conditions than that of toluene.[57,61] In the case of benzene, the concentration of the substrate plays a most important role. Phenylpotassium was obtained in good yield and in a highly pure state at the highest benzene concentrations, e.g. if benzene was used as a solvent. With decreasing benzene concentration, the amounts of lithium and alkoxides in the product increased. These parameters could be somewhat improved by using a higher concentration of the potassium alkoxide; however, other conditions did not affect the product quality to any significant extent. Metallations of other aromatic hydrocarbons, such as cumene[62] or naphthalene,[55] with SBs were found to be even less straightforward (Table 8). Thus, optimal conditions for the metallation of aromatic hydrocarbons have to be assessed in each individual case.

[a] After reaction according to Scheme 3. – [b] Method A: [BuLi + *t*PeOK] + toluene; Method B: [BuLi + toluene] + *t*PeOK; solution or insoluble; both in heptane at 20 °C. – [c] Toluene conversion after 30 min. – [d] $F = t_{1/2}$ (standard)/$t_{1/2}$. – [e] Reaction mixture quenched with methyl iodide 30 min. after toluene addition. – [f] 100 – (unchanged toluene + ethylbenzene + xylenes). – [g] *t*PeOLi removed before toluene addition by washing with heptane under strictly inert conditions.

A marked improvement in the product quality was observed when a small amount of diethyl ether was present during the metallation (Table 8).[55,57] In this way, the amounts of Li and other impurities present in the product could be halved or reduced even further.

The described dependence of the product composition on the substrate structure and reaction conditions may be re-

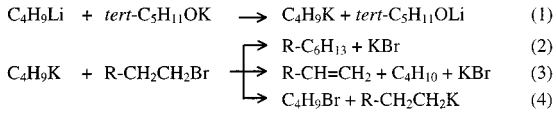
lated to the ability of organometallic compounds to form supermolecular aggregates. The course of metallation is controlled predominantly by kinetic effects. In those cases where the substrate is metallated slowly, either due to its structure or a low concentration, the concentration of the resulting organometallic product is also low. In this situation, other alkali metal compounds, such as alkoxides or Li compounds, are co-aggregated or co-precipitated with the product to a significant extent, yielding a low-purity product. Solvation of the organic alkali metal compounds with electron-donor solvents such as diethyl ether stabilizes the organometallics at lower degrees of aggregation and increases the metallation rate, which leads to higher product concentrations. Accordingly, the presence of diethyl ether during the metallation of aromatic hydrocarbons has been shown to have a favourable effect on the product purity.

Reactions of Superbases with Olefins

SBs can react with olefins in two different ways: by substitution of an olefinic hydrogen by the alkali metal (see for instance[21,22,25]) or by the addition of SB across the olefinic double bond.

Olefins with polarized double bonds add organometallics across this double bond, giving rise to new organometallic compounds. In some cases, addition of the new organometallic to the olefin may be repeated many times, ultimately leading to polymers (anionic polymerization).



Following reactions of 1,1-diphenylethene (1,1-DPE, anionic polymerization of which is difficult) with SBs prepared from BuLi and *t*PeOK or *t*PeONa, the organometallic products were isolated and analyzed.[55] The results indicated that addition of SB across the double bond was the major reaction rather than hydrogen–metal exchange. The reactivity of the 1,1-diphenylhexylpotassium formed in this reaction was so high that addition to another 1,1-DPE molecule was possible. Thus, reaction of a three-fold molar amount of 1,1-DPE relative to the SB resulted in the predominant formation of 1,1,3,3-tetraphenyloctylpotassium. The lithium content in all isolated products was < 0.4%.

Another example of SB addition across an activated C=C double bond is seen in the anionic polymerization of methyl methacrylate, which is readily initiated by the SBs generated from a lithium ester enolate and sodium or potassium *tert*-butoxides.[7,63,64] The microstructure of the obtained poly(methyl methacrylate) revealed that metal interchange occurred even in this system and that the heavy alkali metal enolate was the active species in this polymerization.

Thus, lithium–potassium (sodium) interchange according to Scheme 3 takes place even in the case of additions of SBs to the C=C double bonds.

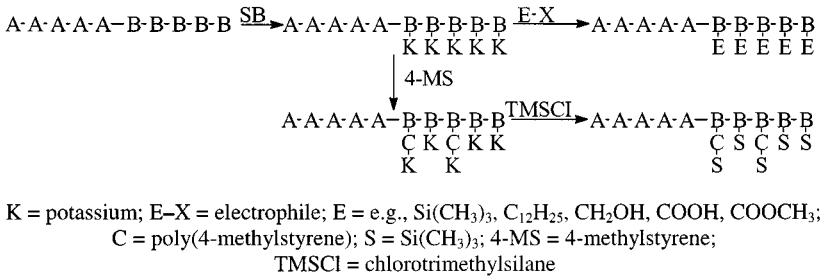
Reaction of Superbases with Organic Halides

Non-activated organic halides, such as butyl or octyl bromides, react with BuLi in hydrocarbons only to a negligible extent. If, however, a heavy alkali metal alkoxide is added to such a mixture, a fast or even vigorous reaction commences, in which products of C–C coupling are formed

Scheme 9

(e.g. reaction 2 in Scheme 9), or β-elimination of hydrogen halide (e.g. reaction 3 in Scheme 9) and halogen–metal exchange (e.g. reaction 4 in Scheme 9) take place.[65] Besides these main products, only lithium alkoxide and heavy alkali metal halide are detected in the mixtures prior to hydrolysis. Obviously, at some stage of the reaction the lithium–heavy alkali metal exchange must have occurred (e.g. reaction 1 in Scheme 9).

Under favourable conditions, i.e. with primary or aromatic bromides or iodides, the reaction can be conducted in such a way that a high yield of the C–C coupling product is obtained, e.g. over 80%. Hence, the reaction between SBs and organic halides may be regarded as an improvement of the Wurtz hydrocarbon synthesis.



Use of Superbases in Polymer Chemistry

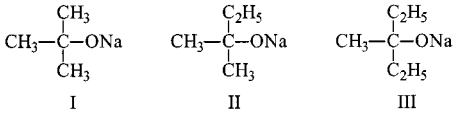
It emerged that SBs are also useful in polymer chemistry as initiators of anionic polymerization.[1,66–68] Another, even more promising use of SBs in polymer chemistry lies in the chemical modification of some polymers.

A suitable reagent for the metallation of some non-polar polymers was found about two decades ago, namely a mixture of BuLi and *N,N,N,N*-tetramethylethylenediamine (TMEDA).[69–71] SBs prepared from organolithium compounds and potassium alkoxides, however, seem to be superior to the TMEDA reagent because of higher reactivity, efficiency,[23,55] and regioselectivity.[72]

The procedure for multi-site functionalization of polymers using SBs involves two steps: (i) metallation of the polymer with the SB, which results in a multi-site potassium-metallated polymer, and (ii) in situ reaction of the metallated intermediate with an electrophile, giving rise to the multi-site functionalized polymer.[62] A similar procedure was suggested independently by Nemes.[73] Due to the high reactivity of the carbon–potassium bond in the metallated intermediate, the choice of electrophiles for step (ii) is wide and polymers with diverse functional groups are easily accessible. The procedure has been applied to various polymers, such as polystyrene,[62] polybutadiene,[74] poly(4-methylstyrene),[55] and polyether dendrimers.[75,76] In this way, polymers randomly substituted to various degrees with diverse functional groups are obtained in a simple one-pot process.

Non-polar copolymers, both random and block (e.g. A–B), can likewise be multi-site-functionalized employing a method similar to that described for homopolymers. If the difference in C–H acidities of various units (blocks) is sufficiently high ($pK_A - pK_B > 2$), it is possible to selectively metallate the more acidic units in the copolymer by appropriate choice of the SB.[72] For instance, the methyl groups in the block copolymer polystyrene-*block*-poly(4-methylstyrene) are selectively substituted, as illustrated in Scheme 10.

K = potassium; E–X = electrophile; E = e.g., $Si(CH_3)_3$, $C_{12}H_{25}$, CH_2OH, COOH, $COOCH_3$;
C = poly(4-methylstyrene); S = $Si(CH_3)_3$; 4-MS = 4-methylstyrene;
TMSCl = chlorotrimethylsilane



Scheme 10

The metallated (co)polymer intermediate is also effective as a multifunctional initiator of anionic polymerization, giving rise to grafted (co)polymers. In Scheme 10, this is shown for the case of grafting a block copolymer.[77]

By virtue of the great flexibility of the method, an appreciable number of novel random or block copolymers or diverse structures made up of selectively grafted (co)polymers can be prepared.

More Effective Modifications of Superbases (Second-Generation SBs)

The reactivity of an SB not only depends on the structure of the parent organolithium compound, it is also influenced by the alkoxide component. The effect of the structure and concentration of the heavy alkali metal alkoxide on SB properties has been investigated[8–11,56] using sodium alkoxides of structures I, II, and III (Scheme 11).

Scheme 11

In order to assess the SB reactivity, the time–conversion dependence in the reaction of modified SBs with organic halides was monitored. Some results are shown in Figure 1,

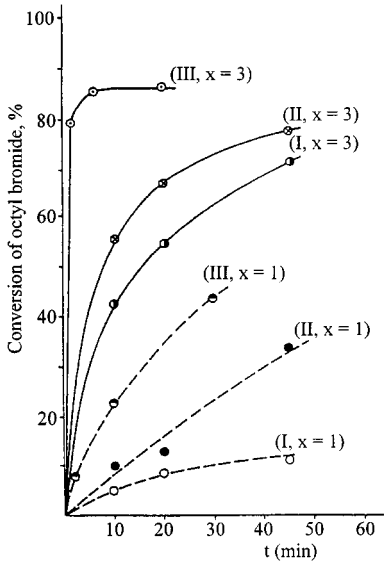


Figure 1. Conversion of octyl bromide in the reaction with various Superbases [C_4H_9Li + *x* RONa] in heptane at –30 °C (by Br ion determination); R = *tert*-butyl (I), *tert*-pentyl (II), 3-methylpentan-3-yl (III) (see Scheme 11); *x* = 1 or 3

in which the time–conversion curves for the reaction of octyl bromide with SBs of various compositions are plotted. It can clearly be seen that the reaction rate increases with the alkoxide concentration in the SB and with the degree of branching of the alkoxide.[9] The corresponding acceleration factors are summarized in Table 9. Rate accelerations caused by a similar modification of the SB could also be observed in metallations of aromatic hydrocarbons.

The effect of the alkoxide structure on SB properties is evidently associated with the degree of substitution on the alkoxide in the vicinity of the OM group. It was mentioned above that the strength of the alkoxide aggregation decreases with increasing substitution. The alkoxide autoaggregation competes with its other interactions and, there-

Table 9. Rates of reaction of octyl bromide with various Superbases [C_4H_9Li + *x* RONa] and yields of dodecane (coupling product) in heptane at –30 °C

RONa R	[RONa]/ [C_4H_9Li] [*x*]	Reaction half-time [min]	Total acceleration factor	Yield of dodecane [%]
tert-butyl	1	> 1000	1	35
tert-pentyl	1	74	> 13	47
3-methylpentan-3-yl	1	40	> 25	55
tert-butyl	3	16	> 60	75
tert-pentyl	3	8	> 125	81
3-methylpentan-3-yl	3	0.8	> 1250	53[a]

[a] An appreciable amount of another reaction product was formed.

fore, these interactions can be expected to be favoured with more substituted alkoxides. The effects and structures of alkoxides I, II, and III (Scheme 11) are in accord with this statement. From a practical point of view, SBs prepared from *tert*-pentoxides appear to be much more suited for metallations than those prepared from *tert*-butoxides.

The structure and concentration of the heavy alkali metal alkoxide also affect the regioselectivity in reactions of SBs with substrates. For instance, in the reaction of an SB with octyl bromide, the yield of dodecane (the expected product of the C–C coupling) increased from 47 to 81% when the alkoxide to BuLi ratio was increased from 1 to 3 (Table 9).[9] Another striking example is the metallation of ethylbenzene (Figure 2).[11] Metallation of this substrate with various SBs followed by quenching with methyl iodide should give rise to cumene. In the reaction using the standard SB derived from BuLi and one equivalent of *t*BuOK, only 30% of cumene was obtained and the limiting conversion of ethylbenzene reached just 65% (curves 1a and 2a). On the other hand, use of a modified SB prepared from BuLi and three equivalents of potassium 3-methyl-3-pentoxide (a more branched alkoxide, akin to structure III in Scheme 11) (*t*MePeOK) under the same conditions resulted in 88% of cumene and a 100% conversion of ethylbenzene (curves 1b and 2b). Moreover, the metallation rate was about 10 times higher using the modified SB compared to that with the standard one.

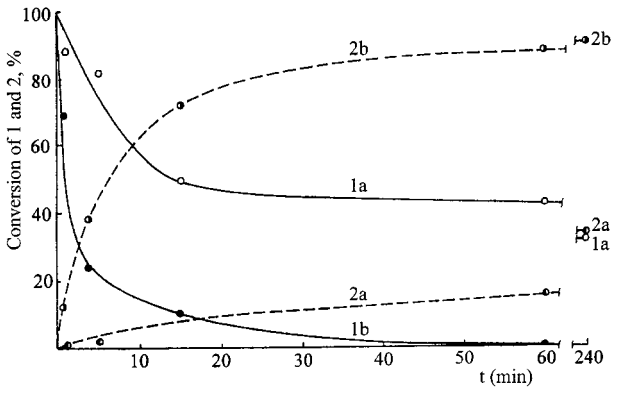

Figure 2. Metallation of ethylbenzene with various Superbases; $[BuLi]_0$ = 0.27 mol/L, heptane, 20 °C, metallation quenched with methyl iodide; curves: 1 (a,b) = ethylbenzene, 2 (a,b) = cumene; curves a: [ethylbenzene]/[BuLi]/[*t*BuOK] = 1:1:1; curves b: [ethylbenzene]/[BuLi]/[potassium 3-methyl-3-pentoxide] = 1:1:3

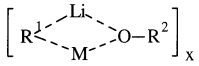
Consequently, the properties of the first-generation Superbases, prepared using one equivalent of heavy alkali metal *tert*-butoxide, have been considerably improved by using larger amounts of a more branched alkoxide of the same metal. Therefore, the latter can be designated as second-generation Superbases. They are more advantageous in organic and polymer chemistry in that they give higher yields of the desired products in a more straightforward process.



The origins of the novel properties of second-generation Superbases are probably complex. The described effect of heavy alkali metal alkoxides may be due to the formation of new SB supermolecular aggregate species possessing increased reactivities. More probably, however, the reasons may merely be physicochemical in origin, such as a change in the metal interchange equilibrium and/or rate, or a change in the solubilities or degrees of aggregation of the reaction components.

Reaction Mechanism

Mechanism of the Metal Interchange in the System R^1Li + R^2OM

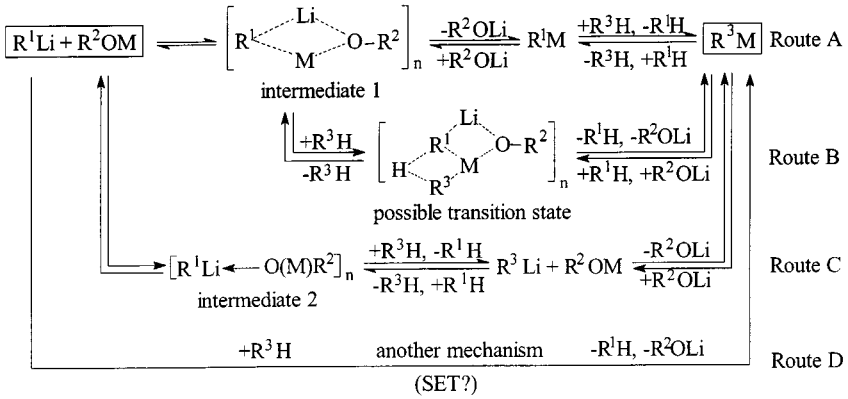
Only limited information is available on the mechanism of the reaction between organolithium compounds and heavy alkali metal alkoxides. The situation is complicated by the autoaggregation of these compounds.

When organolithium compounds interact with heavy alkali metal alkoxides, an intermediate adduct is formed first, which is similar to the adducts of lithium alkoxides (see above) with the simplified structural units shown in Scheme 12. The adduct formation is obviously a dynamic equilibrium reaction.[28] An ab initio computational study of the model system R^1Li + R^2OM (M = Na to Cs) showed that an adduct of the type depicted in Scheme 12 is the most stable in the system.[78] Further transformation of this adduct was not predicted in this study, obviously due to the simplified model structures and conditions (gas phase). Another computational study dealt with the system CH_3Li–CH_3OK, from which it was concluded that an intermediate 1:3 adduct was the most reactive.[79] The X-ray structure of a compound with intramolecular bridging similar to that in Scheme 12 has also been described.[80]

Scheme 12

In the next step, transformation of the [$R^1Li{\cdot}R^2OM$] intermediate according to Scheme 3 takes place. With the assumption that this intermediate has a structure similar to that of the BuLi + *t*BuOLi adduct,[33] the metal atoms bound to two oxygen atoms and one carbon atom could be lithium, while those bound to two carbon atoms and one oxygen atom could be the heavy alkali metal. If this were the case, splitting of the intermediate adduct to an organic heavy alkali metal compound and lithium alkoxide in the following reaction step may easily be envisaged.

The lithium–heavy alkali metal interchange proceeds in the direction opposite to the assumed one because it leads to a product containing a more electropositive heavy alkali metal bound to a less electronegative atom than the oxygen of the alkoxide, i.e. to a carbon or nitrogen atom, or to an enolate group. Therefore, the question of the driving force for this interchange is of great importance. The exchange process is certainly supported by a shift in the reaction equilibria due to the precipitation of the least soluble component in hydrocarbon solvents, which is most often the heavy alkali metal organic compound. However, the metal interchange also takes place in solution[15,16,44] and, therefore, some other effects must also be operative. The formation of an oxygen–lithium bond in the lithium alkoxide could be one of these effects. According to the HSAB principle, this alkoxide would seem to be thermodynamically more stable than the heavy alkali metal alkoxides. Moreover, lithium alkoxides appear as products in all kinds of metal interchange reactions, such as those reported above (Scheme 3). Another factor could be the different stabilities of supermolecular aggregates of various alkali metal alkoxides. The greater stability of lithium alkoxides compared with the corresponding heavy alkali metal alkoxides is reflected in the fact that various aprotic donor solvents have a less pronounced effect on the degree of aggregation of the former.[32]



Mechanism of Reactions of Superbases with Organic Substrates

As mentioned above, two procedures can be used for the reaction of an organic substrate with an SB prepared from R^1Li and R^2OM. In Method A, the SB components are mixed first and only then is the substrate added. In this case, the heavy alkali metal organic compound is precipitated following metal interchange prior to addition of the substrate. There are then two possible modes of reaction of the substrate: (i) either the substrate is adsorbed onto the surface of the precipitate and the reaction takes place there, or (ii) the substrate reacts in solution with a very low concentration of the precipitated compound. In neither case can participation of alkali metal alkoxides present in the system be completely ruled out as, for instance, they may change the solubility or adsorption. Indeed, it follows from Table 6 that to some extent these alkoxides influence the behaviour of the organopotassium precipitate in the reaction with toluene: the reaction rate is increased in the presence of an excess of potassium alkoxide and decreased when the lithium alkoxide is in excess. Moreover, a change in the product distribution as a result of the presence of the alkoxides has also been observed,[56] in agreement with an earlier finding.[60] Nevertheless, in all these cases, the organopotassium compound in any form should remain the principal reagent (cf. below).

In the second commonly used procedure, Method B, the organic substrate is mixed with one component of the SB first and only then is the other SB component added. In this case, various routes can be suggested for the transition from the initial to the final stages, the structures of both of which are well established.

In the case of metallation of hydrocarbon R^3H, some of these pathways can be defined as shown in Scheme 13. According to Route A, the intermediate adduct 1 is first decomposed to the lithium alkoxide and the heavy alkali metal compound, which in a further step metallates the hydrocarbon R^3H to give a heavy alkali metal derivative. On the other hand, the intermediate adduct of type 1 (precursor of the C–heavy alkali metal compound) may also react directly with the substrate, yielding the heavy alkali metal derivative of the substrate through a transition state with a structure as that depicted in Scheme 13. This pathway is designated as Route B.

In the intermediate type 2, proposed in ref.,[12] activation of the organolithium compound is assumed to occur through solvation of the heavy alkali metal alkoxide, akin to that by electron-donor solvents (Route C). In this case, metallation should produce a lithium derivative of the substrate. In order to obtain the heavy alkali metal substituted substrate (as is isolated), an additional lithium–heavy alkali metal interchange must be assumed. The reason for this interchange is not clear within this hypothesis. Moreover, this idea does not explain why *t*BuOK increases the reactivity of BuLi through "solvation" to such an enormous extent ($>> 10^6$ times, ref.[56]), whereas *t*BuOLi is almost inactive in this respect (see above). It is questionable as to whether the difference in polarities of the O–Li and O–M bonds (M = Na, K, Rb, Cs) could cause such a change in the

Scheme 13

BuLi behaviour. Consequently, the mechanism of Route C is difficult to rationalize.

Finally, other mechanisms, e.g. those involving single-electron transfer (SET mechanism) cannot be ruled out either and are summarized in Route D.

The isolation of the heavy alkali metal derivative as the final product as well as the stoichiometric participation of the heavy alkali metal alkoxide in the reactions of SBs with organic substrates (see above) would seem to favour Routes A and B.

Structure of the "Active" Species in Reactions of Superbases

Let us summarize principal information on the R^1Li + R^2OM system: (i) After mixing of these components of the SB, metal interchange gives rise to the heavy alkali metal organic compound R^1M, which may be isolated in a pure state by washing. (ii) The organometallic products obtained from reactions of SBs with substrates isolated prior to hydrolysis contain predominantly the heavy alkali metal and only traces of lithium. This is found in reactions of SBs with substrates of different types, i.e. in metallations, in additions to double bonds, and in reactions with organic halides or polymers. (iii) Potassium alkoxide participates in reactions of SBs with substrates in a stoichiometric amount and does not merely act as a catalyst or as an activator of R^1Li. SBs having an R^2OM/R^1Li ratio below unity no longer metallate the substrate once all the R^2OM has been consumed, in spite of some unchanged R^1Li still being present. (iv) The reactivity of R^1Li + R^2OM mixtures is only slightly influenced by the concentration of the lithium alkoxide formed in the metal interchange. For instance, after complete removal of *t*PeOLi, BuK shows approximately the same reactivity as an equimolar mixture of the SB components. Mixtures of BuK with excess *t*PeOLi exhibit a decreased reactivity and, therefore, the formation of such an adduct cannot be responsible for the high SB reactivity. (v) The reactivities of SBs prepared from R^1Li and various R^2OM species increase with increasing concentration and bulkiness of R^2OM. (vi) A detailed NMR investigation of the system generated from triphenylmethyllithium and caesium 3-ethylhept-3-oxide in THF solution has shown that triphenylmethylcaesium and lithium 3-ethyl-3-heptoxide are formed through metal interchange and that they exist as separate species rather than as an adduct.[44]

Considering the points (i) to (vi), it can be concluded that in the reaction of a substrate with the R^1Li + R^2OM system, the metal interchange is the essential step and that the "active" species should be the heavy alkali metal organic compound or a derivative thereof.

When trying to decide which of the possible mechanisms proposed for the reactions of SBs with substrates is in fact correct, it should be borne in mind that the system involves a number of partial reactions, including coordination and aggregation equilibria. This makes the system very flexible. The rate and equilibrium constants may specifically depend on the properties of a given system, i.e. the structures of the reactants, the reaction conditions, and the reaction type. For instance, the extent of participation of Routes A and B in a reaction of an SB with a particular substrate depends primarily on the ratio of the rate constants for cleavage of the intermediate 1 according to Route A and those for direct metallation of the substrate by this intermediate. This ratio may be different in specific cases; thus, a substrate that is metallated more slowly would prefer Route A, while a more readily metallated substrate would be subject to a greater contribution from Route B.

Hence, it is questionable as to whether the reactions of SBs with substrates invariably proceed in exactly the same way. It could also be the case that one mechanism may predominate under certain conditions while another may become more important under other circumstances. Thus, any search for a "single universal active species" in SB reactions is irrelevant. Nevertheless, regardless of the actual path taken by the SB reactions with substrates, the metal interchange must take place at some stage in all cases and is an integral part of the reaction.

The Formation of a Solid from the Reaction $SiCl_4(g) + O_2(g) \rightarrow SiO_2(s) + 2Cl_2(g)$

Michael Binnewies*[a] and Karl Jug[b]

Dedicated to Prof. Dr. Heinrich Vahrenkamp on the occasion of his 60th birthday

Keywords: Growth pattern / Chemical vapor deposition / Silicon / Chlorine / Oxygen / Thermochemistry

The formation of a solid by the reaction of small gaseous molecules during a CVD or CVT experiment is a highly complicated process. In the case of the combustion of silicon(IV) chloride in oxygen, which leads to solid silicon dioxide, hundreds of intermediate chlorosiloxanes have been detected. On the basis of their compositions, structures, and stabilities, growth mechanisms of Si–O networks can be derived. The stepwise formation of solid SiO_2 can be described in terms of three basic reactions: (i) formation of highly reactive $O{=}SiCl_2$, (ii) insertion of $O{=}SiCl_2$ into an Si–Cl bond, and (iii) thermally induced elimination of $SiCl_4$ from the resulting chlorosiloxanes.

1. Introduction

Although solid-state chemistry has been largely concerned with the structures, physical and chemical properties, and broad applications of solids, over the past 30 years solid-state chemists have become increasingly interested in their formation and in the intermediates involved during the formation process. Nowadays, cluster compounds are considered and discussed as connecting links between molecules and solids. Whereas these were considered as rare exceptions in the 1960s,[1] more and more examples have been found, in particular as a result of the impressive development in the area of X-ray analysis, of substances that can be classified as cluster compounds. The principle of condensed clusters[2] accounts for their role as links between molecules and solids. Colloids, as examples of giant clusters with 10^3 to 10^9 atoms, are also included in the discussion.[3] In general, clusters represent small fragments of the structures of solids. From the present viewpoint, it can be stated that the traditional separation between molecules and solids is nei-

Michael Binnewies studied chemistry in Münster/Westfalen, where he received his Diploma in 1971 and his Dr. rer. nat. in 1973. He worked on solid-gas equilibria in metal halide systems under the direction of Harald Schäfer. Further work involved the mass spectrometric characterization of highly reactive molecules containing main group elements. In 1988, he took up a professorship in Freiburg/Br. Since 1992, he has been Professor of Inorganic Chemistry at the University of Hannover. His current research interests lie in the fields of chemical vapour transport reactions and main group chemistry.

Karl Jug studied physics in Frankfurt/Main, where he received his Diploma in physics in 1964 and his Dr. phil. nat. in physical chemistry in 1965. His research work, under the direction of Hermann Hartmann, was on quantum chemical modelling of the spectra of inorganic and organic compounds. From 1965 to 1967, he was head of staff of Theoretica Chimica Acta in Frankfurt/M., before he moved to the IIT in Chicago to work with Peter Lykos. He was Assistant Professor in 1969 and Associate Professor in 1971 at St. Louis University. He returned to Germany in 1975 to take up a position as Professor of Theoretical Chemistry at the University of Hannover. His research interests have focussed on semiempirical methods and the theoretical basis of chemical concepts (charge, bonding, diradicals, aromaticity). In applied work, he has been concerned with thermal and photochemical reactions of organic compounds, the structures and reactivities of organic and inorganic compounds and clusters, the cluster simulation of solid-state surfaces, and heterogeneous catalysis.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

ther up to date nor scientifically substantiated. While the structural borderline between molecules and solids has become largely indistinct, the physical properties of compounds in this transition range are becoming increasingly interesting. Typical co-operative phenomena, such as electrical conductivity, do not appear abruptly, but change continuously over a certain range.

Whereas solid compounds have generally been characterized after their formation, in the transition range between molecules and solids the relevant formation pathways and mechanisms have not been so well investigated. In the case of the title reaction, i.e. the formation of solid SiO_2 from $SiCl_4$ and oxygen, this chemically – from the viewpoint of substance change – interesting question has now been investigated and is largely understood. This subject is reviewed here.

2. Thermodynamic Aspects

Reactions of chlorides of elements with oxygen to give the corresponding oxides and chlorine are found to be exothermic for almost all elements. The Gibbs energy ΔG^0_R is almost always negative. The reaction equilibrium generally lies on the side of the oxide, as is the case with silicon. At 298 K, a reaction enthalpy of –248.2 kJ/mol and a reaction entropy of 48.3 J/(Kmol)[4,5] are calculated for the title reaction and consequently ΔG^0_R (298) = –233 kJ/mol. The equilibrium at 298 K therefore lies close to the product SiO_2. This also holds true for temperatures of 1000 or 2000 K, although the equilibrium constant decreases with increasing temperature. In spite of this extreme equilibrium situation, if an oxygen flow containing $SiCl_4$ is passed through a heated tube about 30 cm in length, noticeable reaction only occurs at temperatures above 700–800 °C. In the temperature range 800–1000 °C, the resulting product is, however, not the SiO_2 that would be expected from a thermodynamic point of view. Instead, a multitude of chlorosiloxanes $Si_xO_yCl_z$ are formed. In these compounds, the chlorine atoms of the starting $SiCl_4$ are only partially replaced by oxygen atoms. The compounds are considered as intermediates that are formed in the course of the reaction. Their investigation allows an insight into the mode of formation of the solid silicon dioxide and the individual steps involved. If the reaction temperature is increased to above 1000 °C, the reaction rate becomes considerably enhanced. The title reaction proceeds very quickly without noticeable by-product formation to give the final products SiO_2 and Cl_2. Under these conditions, the experimental possibility of trapping the intermediates in order to learn more about the reaction process is lost. For a better understanding of the reaction process, the temperature range between 700 and 1000 °C, in which the chlorosiloxanes are formed, is therefore of special interest.

3. Chlorosiloxanes

3.1 Literature Survey

3.1.1 Experimental Facts

In the following, a tabular survey of the literature on perchlorosiloxanes[6–34] with up to 10 silicon atoms per molecule and their mode of formation is given (Table 1).

Beyond the listed compounds, the title reaction leads to the formation of numerous other higher chlorosiloxanes with molar weights up to 7000 D. These contain between 11 and about 70 silicon atoms per molecule, and have quite different oxygen and chlorine contents. The formulae of about 250 other chlorosiloxanes with molar weights up to 5000 D have been reported following mass spectrometric investigations, which are listed below. Details can be found in the literature.[34]

$Si_{11}O_{12}Cl_{20}$, $Si_{11}O_{13}Cl_{18}$, $Si_{11}O_{14}Cl_{16}$, $Si_{11}O_{15}Cl_{14}$, $Si_{12}O_{13}Cl_{22}$, $Si_{12}O_{14}Cl_{20}$, $Si_{12}O_{15}Cl_{18}$, $Si_{12}O_{16}Cl_{16}$, $Si_{12}O_{17}Cl_{14}$, $Si_{13}O_{14}Cl_{24}$, $Si_{13}O_{15}Cl_{22}$, $Si_{13}O_{16}Cl_{20}$, $Si_{13}O_{17}Cl_{18}$, $Si_{13}O_{18}Cl_{16}$, $Si_{13}O_{19}Cl_{14}$, $Si_{13}O_{20}Cl_{12}$, To give a complete survey of chlorosiloxanes, we have also listed in Table 1 such compounds that are not formed by the title reaction. In the following, however, only the thermally formed chlorosiloxanes are discussed. The present compounds can be classified as belonging to a homologous series of the general formula $Si_nO_{n+x}Cl_{2(n-x)}$ ($x = -1$ to 24). We observe that particularly oxygen-rich chlorosiloxanes (large x) are favoured in the case of large molecules (large n). This is to be expected, because x cannot exceed n. For $x = n$, the limit of Si_nO_{2n}, i.e. SiO_2 is obtained. The composition of a chlorosiloxane closely corresponds to its structure. This will be demonstrated in Section 3.2.

As can be seen, the reaction of $SiCl_4$ with oxygen results in the formation of an unusual multitude of chlorosiloxanes. The number of Si atoms ranges from 1 up to about 70 per molecule. With just a few exceptions, all of the aforementioned chlorosiloxanes can be prepared in significant amounts, although often not in pure form. In particular, the higher molecular weight siloxanes [$n(Si) > 10$] can only be characterized in mixtures owing to separation difficult-

ies. Whereas the lower homologues can be separated by distillation[13] and the medium weight homologues by gas chromatography,[32] separation of the high molecular weight compounds has proved insurmountable. The sensitivity of chlorosiloxanes to hydrolysis makes separation even more difficult, although it should also be noted that this is reduced with increasing oxygen content. However, with increasing oxygen content the molar weight increases accordingly. Adjacent compounds become more and more similar with respect to their physical and chemical properties and hence separation becomes more difficult.

3.1.2 Theoretical Methods

A difficulty in evaluating the experimental results is the structural characterization of the chlorosiloxanes described by the general molecular formula $Si_nO_{n+x}Cl_{2(n-x)}$. Whereas for a few Si atoms it is possible to obtain an appropriate structure by application of simple valence rules, this is no longer the case for larger systems due to the sharp increase in the number of possible isomers. Moreover, structural data such as bond lengths and bond angles, as well as the relative stabilities of the isomers, cannot be experimentally determined in a simple way. Here, quantum chemical methods can offer additional information to complement that obtained in the experimental investigations. So-called ab initio methods are mainly based on the Hartree–Fock method in the self-consistent field (SCF) approximation. Here, the electrons are described by one-electron functions, the molecular orbitals (MOs), where each MO for an electron is calculated in the field of the nuclei and the average field of all the other electrons. This one-electron approximation can be improved by the inclusion of the correlation between the electrons. This is achieved by applying configuration interaction (CI) or perturbation theory (MP2). Since ab initio calculations are very demanding in terms of computer time due to the increased basis sets and the inclusion of correlation, their application is restricted to systems with a few dozen atoms.

For comparative studies, which are necessary in the case of siloxanes because of the multitude of compounds, semiempirical methods are more appropriate. Here, one also starts from the SCF method and tries to considerably reduce the computer time by applying approximations. In this way, the differential overlaps of the atomic orbitals are neglected (ZDO approximation) and the remaining integrals are in part empirically adjusted. The first procedure can be justified by the orthogonalization of the atomic orbitals. The second leads to an implicit inclusion of correlation and therefore often to substantial improvements in the prediction of structures and stabilities. As a result of the continuous improvements of semiempirical methods, large systems with more than a hundred atoms can now be reliably calculated, once smaller systems have been tested by making comparisons with experimental data or highly accurate ab initio calculations. Semiempirical methods suitable for the calculation of larger molecules with first and second row atoms are AM1,[35] PM3,[36] MNDO/d,[37] and SINDO1[38] or its improved version MSINDO.[39]

Siloxanes were at first studied only sporadically.[40] Here, the basic system $SiOCl_2$ played a special role. As a single molecule it is undoubtedly stable, but is extremely reactive. It is possible that it is formed from Si_2OCl_6, which is easily accessible experimentally. Relevant calculations were performed ab initio with large basis sets and correlation.[41] SINDO1 calculations were first performed for small systems with up to eight Si atoms. The emphasis was on structure and stability with the aim of deriving rules for predicting the preferred formation of isomers.[42] These selected systems were $Si_nO_{n-1}Cl_{2(n+1)}$ (n = 2–4), $Si_nO_nCl_{2n}$ (n = 2–5), $Si_nO_{n+1}Cl_{2(n-1)}$ (n = 4, 5), and $Si_nO_{n+3}Cl_{2(n-3)}$ (n = 8). In order to gain insight into the growth mechanism, the palette of these small systems was extended to $Si_nO_{n-1}Cl_{2(n+1)}$ (n = 5), $Si_nO_nCl_{2n}$ (n = 6), $Si_nO_{n+1}Cl_{2(n-1)}$ (n = 6, 7), $Si_nO_{n+2}Cl_{2(n-2)}$ (n = 5–8, 10), and $Si_nO_{n+3}Cl_{2(n-3)}$ (n = 10, 12).[43] In order to understand the growth mechanism, additional calculations were needed, which introduced interesting new aspects, in particular with regard to the silsesquioxanes $Si_{2n}O_{3n}Cl_{2n}$ (n = 2–8, 10, 12, 18, 24, 30) and polycycles $Si_{2n}O_{3n-3}Cl_{2(n+3)}$ (n = 9, 15).

3.2 Structures of Chlorosiloxanes

Mainly on the basis of ^{29}Si NMR studies, but also by crystal structure analyses, the structures of a substantial number of chlorosiloxanes have been determined.[13,14,27,28,31,44–46] For the characterization of such species, the chlorosiloxanes have first been prepared and then derivatized (esterified) with retention of the Si–O backbone, and the derivatives have been structurally characterized. In the following, only the siloxanes formed by the title reaction will be discussed. A compilation of the experimentally determined connection patterns is presented in Table 2 in the form of structure diagrams. For completeness, the atomic connections of chlorosiloxanes prepared in a different way are additionally listed in Table 3.

From the survey, the relationship between the structures of the molecules and their compositions can be seen. The chlorosiloxanes $Si_nO_{n+x}Cl_{2(n-x)}$ with $x = -1$ form chains and both unbranched and branched catenated structures are found.[13] For $x = 0$, Si–O monocyclic rings are observed, which often bear side groups[31] of the same composition. It should be mentioned that among the prepared chlorosiloxanes there are no four-membered rings of the Si_2O_2 type. This is in agreement with the structural chemistry of silicon dioxide and silicates, as well as with the results of quantum chemical calculations.[42] Three-dimensional polycyclic Si–O structures are formed when $x \geq 1$. Increasing oxygen content leads to an increase in the three-dimensional character of the Si–O framework. The largest chlorosilsesquioxane with an experimentally determined structure is $Si_8O_{12}Cl_8$,[46] which has a cubane-like cage structure. The compound $Si_8O_{12}(OCH_3)_8$ has in fact been studied previously.[47] However, this structure was obtained in a different way and will not be discussed here.

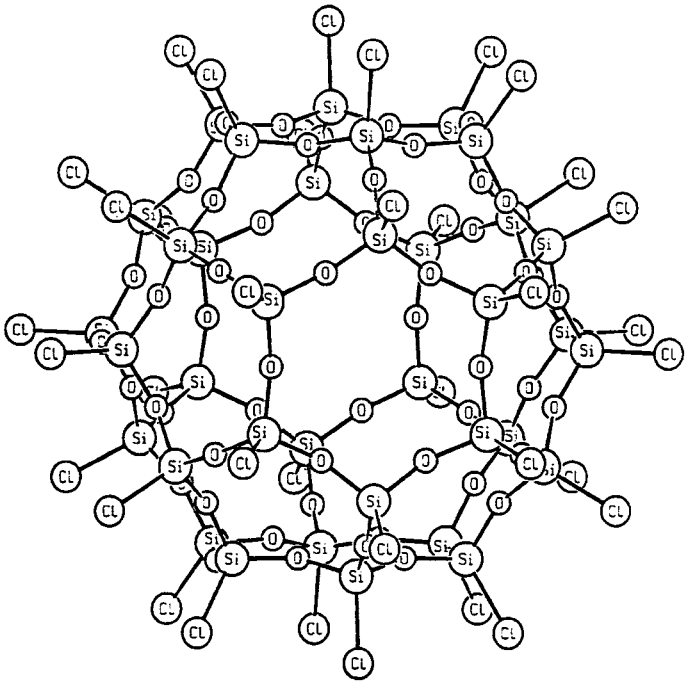
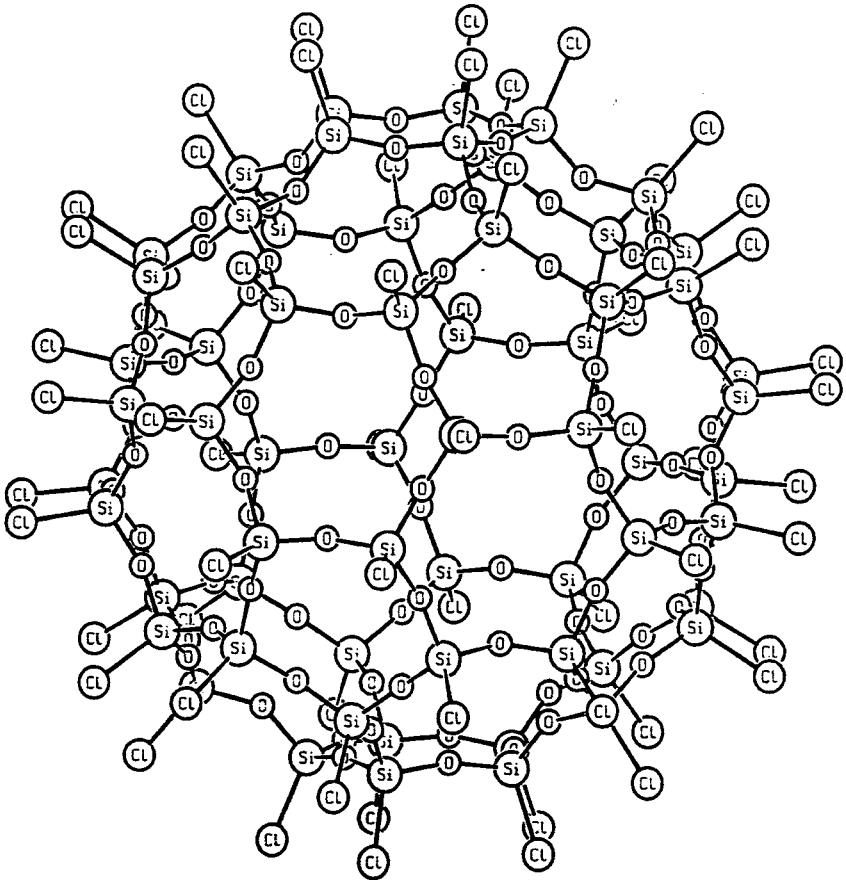
Table 3. Survey of structures of other chlorosiloxanes not thermally formed



Larger molecules have to date eluded experimental structure determination for the aforementioned reasons, but the results of quantum chemical calculations are available, on the basis of which cage-like structures can be expected for siloxanes with up to 40 Si atoms.[43,48] Particularly comprehensive information is available for hydridosilsesquioxanes $Si_{2n}O_{3n}H_{2n}$,[48] which are built up analogously to the chlorosilsesquioxanes $Si_{2n}O_{3n}Cl_{2n}$. In Figure 1, the expected structures of a few representative compounds are presented.



A common feature of all the structures, determined both experimentally and theoretically, is that they contain differently connected six-, eight-, ten-, and twelve-membered rings. The preferred ring size can be established from stabilization curves and the growth patterns.[43,48] The findings

$Si_{16}O_{24}Cl_{16}$ (D_{4d})

$Si_{36}O_{54}Cl_{36}$ (D_{6h})

$Si_{60}O_{90}Cl_{60}$ (I_h)

Figure 1. Quantum chemically calculated structures of some silsesquioxanes

are in agreement with studies on the stabilities of monocyclic chlorosiloxanes, which led us to expect very similar stabilities for rings of different sizes,[43] although with larger rings being somewhat more stabilized. However, with a further increase in ring size, the energy decreases once more so that a saturation is reached for twelve-membered rings. A balanced combination of rings (ten- and twelve-membered) is more stable than a combination of small (six- and eight-membered) and large (twelve- and higher-membered) rings.

3.3 Stability of Chlorosiloxanes

For none of the chlorosiloxanes discussed here have heats of formation or entropies been experimentally determined, hence a discussion of their thermodynamic stabilities has to rely on quantum chemical calculations, estimates, and practical experience.

The fact that these compounds are formed at temperatures slightly less than 1000 °C seems to suggest that they are thermodynamically stable. However, there are also literature reports pertaining to their thermal decomposition at similar temperatures.[7,30] Considering the rather complicated decomposition reaction of a chlorosiloxane, it is apparent that silicon tetrachloride and a variety of oxygen-rich chlorosiloxanes will invariably be formed. In the resultant product(s) of the thermolysis, the number of silicon atoms can be either smaller (a), equally large (b), or both larger and smaller (c). Let us now consider these three possible decomposition reactions and formulate for each case one of the many possible reaction equations in a general form. In the following, we choose one example of each case and discuss its likelihood.

(a) Decomposition of a gaseous chlorosiloxane under cleavage of $SiCl_4$: [30]

$$Si_nO_{n+x}Cl_{2(n-x)} \rightarrow SiCl_4 + Si_{n-1}O_{n+x}Cl_{2(n-x-2)} \quad (1)$$

$$Si_4O_3Cl_{10} \rightarrow SiCl_4 + Si_3O_3Cl_6 \; (n = 4, x = -1) \quad (2)$$

(b) Decomposition of a chlorosiloxane with n Si atoms with formation of an oxygen-richer and an oxygen-poorer chlorosiloxane with n Si atoms in each:

$$2Si_nO_{n+x}Cl_{2(n-x)} \rightarrow Si_nO_{n+x+1}Cl_{2(n-x-1)} + Si_nO_{n+x-1}Cl_{2(n-x+1)} \quad (3)$$

$$2Si_4O_4Cl_8 \rightarrow Si_4O_5Cl_6 + Si_4O_3Cl_{10} \quad (4)$$

(c) Decomposition of a chlorosiloxane with n Si atoms with formation of a larger (n + 1 Si atoms) and a smaller (n – 1 Si atoms) siloxane:

$$2Si_nO_{n+x}Cl_{2(n-x)} \rightarrow Si_{n+1}O_{n+x+1}Cl_{2(n-x+1)} + Si_{n-1}O_{n+x-1}Cl_{2(n-x-1)} \quad (5)$$

$$2Si_4O_4Cl_8 \rightarrow Si_5O_5Cl_{10} + Si_3O_3Cl_6 \quad (6)$$

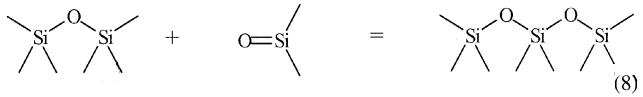
In all such cases, the total number of Si–O and Si–Cl bonds remains unchanged in the course of the reaction. Since one can assume that the bond energies in such chemically similar systems will have similar values, heats of reaction close to 0 kJ/mol are to be expected. The entropies of the reactions of types (a)–(c) are, however, more significant, at least in case (a). If a chlorosiloxane decomposes into several smaller molecules [reaction type (a)], the increase in the number of molecules means that such a process will invariably proceed under entropy gain (considering the homogeneous gas-phase reaction). This reaction entropy can be expected to be of the order of 120–160 J/(Kmol) for a change in the number of molecules (Δv) of +1. If a chlorosiloxane decomposes into two comparatively equal siloxanes, distinguished only by their oxygen content [reaction type (b)], such a reaction occurs without a change in the number of molecules and hence its associated entropy will be close to 0 J/(Kmol). The same holds for a reaction of type (c). Of course, mixed forms of reactions (a)–(c) are conceivable. For case (a), a temperature-independent ($\Delta H = 0$) equilibrium constant of $e^{120/R}$ to $e^{160/R} \approx 10^6$ to 10^8 is obtained from the above considerations. Almost complete decomposition is thus to be expected from a thermodynamic point of view. For cases (b) and (c), equilibrium constants of about $e^0 = 1$ are to be expected. The decomposition products should thus be present in similar concentrations as the reactant. For each of the resulting decomposition products (other than $SiCl_4$), analogous considerations can be made. In summary, we can state from a thermodynamic point of view that each chlorosiloxane should undergo decomposition. The most favoured decomposition reaction is the cleavage of $SiCl_4$, which should eventually lead to SiO_2 and $SiCl_4$. Consideration of the discussed decomposition reactions from a molecular point of view (kinetic aspect) also leads to a clear preference for decomposition reaction (a). To bring about reaction (a), only the necessary activation energy from a collision with an energy-rich molecule or the (hot) wall of the reaction vessel has to be supplied. For reactions (b) and (c), however, a collision of two molecules of equal composition is necessary. This is rather improbable in the complex reaction mixture. Unimolecular reactions leading to the products of reactions (b) and (c) are inconceivable.

The results of these considerations clearly show that from both thermodynamic and kinetic points of view, all chlorosiloxanes must be unstable. They decompose to give $SiCl_4$ along with oxygen-richer siloxanes. This is consistent with all the experimental evidence.[7,30,49,50]

4. Build-Up and Decomposition Reactions: Growth of Si–O Frameworks

In Section 3.1, it was shown that an impressive number of descendants, i.e. chlorosiloxanes of quite different composition with molar weights up to 7000 D, can be generated. We suspect that further chlorosiloxanes with even higher molar weights are formed, which remain undetected.[50] The formation of such a wealth of reaction products in this seemingly simple reaction leads to the conjecture that a highly reactive intermediate is involved, which reacts with numerous reaction partners in a non-specific manner, thereby generating the broad spectrum of products. Recent matrix-spectroscopic studies have shown that in both the

reaction of $SiCl_4$ with O_2 and the thermolysis of Si_2OCl_6, the initial step at about 1000 °C leads to the formation of $O{=}SiCl_2$.[51] Although silaphosgene has long been known as a molecule that can be isolated in a matrix,[6] its presence in high-temperature vapours has now been demonstrated for the first time. Thermodynamic calculations [without consideration of SiO_2(s) and subsequent reactions of $O{=}SiCl_2$] lead us to expect that $O{=}SiCl_2$ should appear in the temperature range from about 1100 K to 1700 K, in concentrations peaking at 1400 K.[51] The performed experiments support this expectation. The temperature at which $O{=}SiCl_2$ first appears in appreciable concentrations (about 1100 K) is identical to that at which the reaction of $SiCl_4$ with O_2 commences and chlorosiloxanes are formed. This can be taken as strong evidence that $O{=}SiCl_2$ is involved in the formation of chlorosiloxanes. The initial step in the thermolysis of Si_2OCl_6 also leads to silaphosgene,[51] as well as to a build-up of higher chlorosiloxanes.[7,30,49] Here, the key role of silaphosgene in the build-up of catena-siloxanes has been demonstrated.[49] The chemical properties of $O{=}SiCl_2$ are not known. In view of the unusual coordination number of three at silicon and the presence of an Si–O double bond, it can be expected to be a highly reactive molecule. Although the value of its standard heat of formation is highly negative at –702.1 kJ/mol,[40] decomposition into solid SiO_2 and $SiCl_4$ can be expected on the basis of literature data concerning the stabilities of other silicon compounds.[4] In the case of the reaction of $SiCl_4$ with O_2, a great excess of $SiCl_4$ is available as a potential reaction partner. Silaphosgene could react with it by inserting into an Si–Cl bond with the formation of Si_2OCl_6:



(7)

In fact, Si_2OCl_6 is also the main product when $SiCl_4$ and O_2 are reacted in the temperature range 700–950 °C. If Si_2OCl_6 is indeed formed, it is also available as a reaction partner for silaphosgene.

For catena-siloxanes with 4 or more silicon atoms, several isomers are formed, which can be separated, to some extent, by gas chromatography.[50] This growth of unbranched and branched chains is terminated for chain lengths of about 10 Si atoms.[32] Larger catena-siloxanes have not hitherto been observed.

This mechanism allows some understanding of the growth of the chains. However, it does not provide an explanation for the formation of mono- and oligocyclic siloxanes (see Table 1). In a growth reaction, $O{=}SiCl_2$ will invariably introduce Si and O atoms into the newly formed

(8)

siloxanes in a 1:1 ratio. In this way, no chlorosiloxanes with more oxygen than silicon atoms can be formed. Since these are, however, undoubtedly formed, the insertion of $O{=}SiCl_2$ cannot be the only reaction responsible for the build-up of the Si–O frameworks of oxygen-rich siloxanes and eventually therefore of solid SiO_2. In Section 3.2, it was explained that all chlorosiloxanes must decompose for entropy reasons, preferably according to the following decomposition reaction:

$$Si_nO_{n+x}Cl_{2(n-x)} \rightarrow SiCl_4 + Si_{n-1}O_{n+x}Cl_{2(n-x-2)} \quad (9)$$

For each such decomposition step, the stepwise built-up chlorosiloxane is decomposed once more, but in a stoichiometrically different way than for the build-up. Whereas in a growth reaction, the Si and O atoms are invariably introduced in equal numbers, only Si and Cl are cleaved in the decomposition process (eq. 9). All oxygen atoms are retained by the decomposing molecule. In this way, the molecules becomes smaller after each decomposition step, but concurrently oxygen-richer. Step by step, siloxanes with three-dimensional, cage-like Si–O frameworks are generated.

In Figure 2, we attempt to represent graphically the interplay between growth and decomposition. For chlorosiloxanes $Si_nO_{n+x}Cl_{2(n-x)}$, the ratio $(n+x)/n$ of the number of mol of oxygen and silicon is plotted against the number n of Si atoms per molecule for a series of x values.

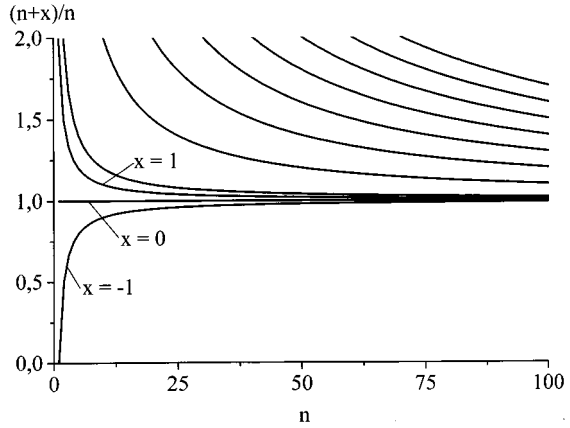


Figure 2. Dependence of the composition of homologous chlorosiloxanes on the number of silicon atoms

The generated sequences of points can be connected with hyperbola-like curves. Each of these curves corresponds to a homologous series of chlorosiloxanes; the lowest to the catena-siloxanes ($x = -1$), the next to the cyclosiloxanes ($x = 0$), etc. If growth and decomposition steps are introduced (in the form of arrows) into this diagram, Figure 3 is obtained.

Starting from $SiCl_4$, first Si_2OCl_6 is formed, then a further increase in the chain length occurs, for example up to $Si_5O_4Cl_{12}$. If this decomposes with formation of $SiCl_4$, $Si_4O_4Cl_8$ is formed, which can grow for example up to $Si_7O_7Cl_{14}$, before this in turn decomposes into the bicyclic

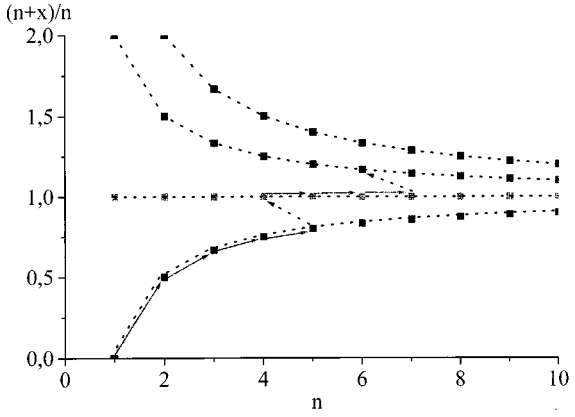

Figure 3. Growth pathways of chlorosiloxanes

$Si_6O_7Cl_7$. In this way, the stepwise transformation of $SiCl_4$ to SiO_2 can be followed almost continuously.

For thermolysis of Si_2OCl_6 in a closed vessel, it has been shown[49] that the rate of the growth reaction [v(growth)] is greater than that of the decomposition reaction [v(decomposition)]. Therefore, at a constant temperature, more and more chlorosiloxanes are formed. In studies of the influence of temperature on the formation of chlorosiloxanes it is found that the relative amount of increasingly oxygen-rich siloxanes increases.[30,49] This means that the rate of decomposition reaction, which leads to the formation of oxygen-rich compounds, has a higher temperature coefficient than that of the growth reaction. The following inequalities hold:

$$v(\text{growth}) > v(\text{decomposition}),$$
$$dv(\text{growth})/dT < dv(\text{decomposition})/dT$$

This means that with increasing temperature a point must be reached where the overall decomposition reaction proceeds more rapidly than the overall growth reaction. The two curves intersect at a temperature T_s. This is schematically represented in Figure 4.

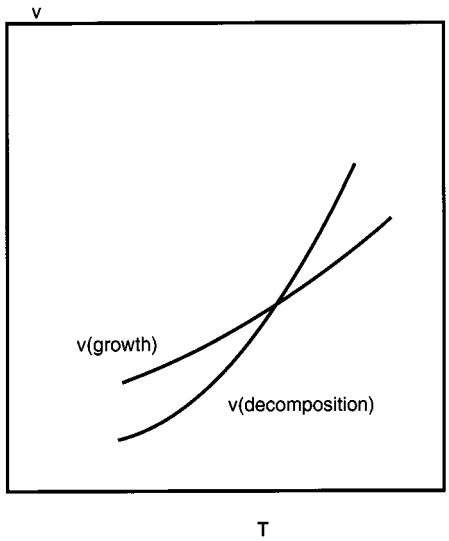

Figure 4. Temperature-dependence of the growth and decomposition rates of chlorosiloxanes

This temperature is at first unknown. Also unknown is to what (average) molar weight the molecules have grown at this point. It is certain that the reaction process discussed on the basis of the experimental results takes place below T_s.

In summary, we can say that $O{=}SiCl_2$ is formed in a first step of the reaction between $SiCl_4$ and O_2. This is a highly reactive molecule, which reacts with all reaction partners possessing an Si–Cl bond with formation of an Si–O–Si group. This is a typical growth reaction and leads to a variety of catena-siloxanes starting from $SiCl_4$. However, siloxanes with a ratio n(O)/n(Si) greater than one cannot originate in this way. They are formed from chlorosiloxanes by entropy-driven cleavage of $SiCl_4$. In this way, the molecules become smaller once more, but oxygen-richer. Their compositions approach that of the final product SiO_2. Species with up to about 70 Si atoms and molar weights of 7000 D could be followed experimentally. As regards the further reaction, we can only speculate. However, it is unlikely that there will be any change in the fundamental reaction pattern, which is governed by the decomposition of chlorosiloxanes. If we extrapolate on the basis of the described findings, two alternative possibilities arise depending on the reaction conditions.

(a) The reaction temperature is always below T_s: As long as the formed siloxanes are at the reaction temperature and $O{=}SiCl_2$ is available as a reaction partner, the molecules will keep growing and become increasingly oxygen-rich. This growth cannot proceed indefinitely as the volatility of the siloxanes decreases with increasing molar weight. Eventually, condensed phases must arise. In particular, this will occur if the residence period of the siloxanes in the reaction zone, and consequently the time for molecular growth, is long. As an alternative to the condensation of high molecular weight chlorosiloxanes, the formation of aerosols, small suspended particles with diameters of 10^{-7} to 10^{-3} cm, appears likely. The formation of such an aerosol, which shows no tendency to undergo condensation, is not unusual. Indeed, in the technological processing of light-wave conductors, such aerosols present an exhaust air problem. Here, an oxygen flow loaded with $SiCl_4$, $GeCl_4$, BCl_3, $POCl_3$ and other compounds is passed through a heated tube of very pure quartz glass so that the oxides of the aforementioned elements are deposited on the interior of the quartz tube. From this so-called "preform", light-wave guides for optical data transfer are manufactured. This reaction, which is very similar to the one discussed, does not proceed to completion either. A portion of the introduced halogen compounds leaves the reaction tube as smoke, which is difficult to condense or filter. Whether such a suspended particle follows the same growth and decomposition mechanisms as a large siloxane molecule is not clear, but is nevertheless conceivable.

(b) The reaction temperature exceeds T_s: The decomposition reactions (in particular $SiCl_4$ cleavage) proceed more rapidly than the formation reactions. However, such molecules cannot completely decompose in this way. If $SiCl_4$ is cleaved, Si and Cl atoms are lost in a ratio of 1:4. If, in

the limiting situation, all Cl atoms are eliminated, we can formulate the following equation:

$$Si_nO_{n+x}Cl_{2(n-x)} = 0.5(n-x)SiCl_4 + Si_{(n+x)/2}O_{(n+x)} \quad (10)$$

An $(SiO_2)_{(n+x)/2}$ "molecule" would have to be formed, an oligomer of the monomer SiO_2,[6] i.e. an SiO_2 cluster with a molar weight not much lower than that of the chlorosiloxane from which it originated.

Since a fundamental change of the whole Si–O framework is unlikely in this process, a structural relationship between the formed SiO_2 and the high molecular weight chlorosiloxanes can be expected. Quantum chemical calculations on the structures and stabilities of SiO_2 clusters seem quite interesting this context.

It is found experimentally that the reaction of $SiCl_4$ with oxygen leads to larger and larger amounts of increasingly oxygen-rich chlorosiloxanes with increasing temperature. Depending on the experimental conditions, a point just below 1000 °C is reached at which the reaction behaviour changes abruptly within a temperature interval of just a few degrees.[50] This sudden change in the reaction behaviour could be connected with the marked intersection point T_s. No more chlorosiloxanes with typically molecular properties (relatively high fugacity, solubility in non-polar organic solvents) are formed, but rather a white, X-ray-amorphous solid, which mainly consists of "SiO_2" with variable but low chlorine content (< 5%). The globular particles have diameters of about 0.1 μm and are reminiscent of the industrial product "Aerosil" (Degussa–Hüls). This is formed in a similar way, under similar conditions. Thus, gaseous $SiCl_4$ is blown into an oxyhydrogen flame at temperatures of about 1000 °C. Depending on the reaction conditions, SiO_2 particles with diameters between 7 and 50 nm are formed. The reactions occurring in the flame are unknown. In principle, three reaction partners are initially available for the $SiCl_4$: H_2, O_2, and H_2O. If H_2 and O_2 are introduced in the ratio 2:1, they should react primarily as in the oxyhydrogen reaction and water will be the primary reaction partner for $SiCl_4$. In a first step, trichlorosilanol $SiCl_3OH$ will thus be generated with elimination of HCl.[17] This can then react in a similar manner as $O{=}SiCl_2$ with $SiCl_4$ or chlorosiloxanes with formation of Si–O–Si bonds.[52] The interplay between growth and decomposition should be analogous to the situation discussed above. If a globular Aerosil particle with a diameter of 7 nm and densely packed oxygen atoms is considered, we can estimate that such a particle contains 10^5 O atoms. This corresponds to a formula of $Si_{50000}O_{100000}$ in molecular language. Such a giant molecule is thus separated from the chlorosiloxane with about 50 Si atoms by three orders of magnitude. Nevertheless, a continuous transition from the high molecular weight chlorosiloxanes to these solid-state particles is not unlikely. The properties and uses of Aerosil and related products are described in company reports.[53–55]

Finally, two questions will be addressed:

(a) Why is X-ray amorphous SiO_2 formed?

(b) Does the situation described for the system Si/O/Cl apply to elements other than silicon?

Let us start with (a): It is obvious that SiO_2 formed in fractions of a second in an oxyhydrogen flame cannot be well-ordered and crystalline. An equally amorphous product is formed if an oxygen stream loaded with $SiCl_4$ is passed through a heating section of about 40 cm[50] at a relatively low flow velocity. The thermolysis of Si_2OCl_6 in a closed system for an extended time of several weeks also leads to amorphous products.[50] This latter observation would suggest that the reaction time is of lesser importance. Although as a typical glass-forming substance, SiO_2 is a material that is normally solidified from a melt, it can be obtained in crystalline form from media of low viscosity, such as supercritical water (hydrothermolysis of α-quartz). An intrinsic property of SiO_2 is therefore probably not the reason. Thus, this phenomenon is seemingly related to the discussed reaction course. In the discussion of the structures of the initially formed chlorosiloxanes, it was pointed out that rings of different sizes arise in the monocyclic and oligocyclic siloxanes. In the course of the reaction, these rings become linked to form increasingly complicated three-dimensional structures. For the silsesquioxanes in particular, quantum chemical calculations were performed to gain insight into the stabilities of isomeric siloxanes. These showed that beyond molecular sizes of about 48 silicon atoms, structures with skeletons akin to that in crystalline SiO_2 become favoured.[43,56] In the example shown in Figure 5, two isomers of $Si_{48}O_{72}Cl_{48}$ are depicted; the upper one is an Si–O framework corresponding to the so-called α-cage, while the lower one corresponds to the structure of β-tridymite.

The latter isomer is more stable according to new MSINDO calculations.[56] The stability of such a bulk-like structure is also greater than that of a fullerene-like cage structure with 12 ten-membered and 14 twelve-membered rings.[48] The growth of fullerene-like structures can occur in two steps in the presence of water and is accompanied by the elimination of HCl. The insertion mechanism has been described previously.[48] In cases where the intermediately formed chlorosiloxanes show bulk-like structures even at the beginning of their growth, we would, of course, expect crystalline SiO_2. However, this is not the case, as was made clear in Section 3.2. If the growth of Si–O frameworks starts in a different way than the formation and condensation of Si–O twelve-membered rings (as in crystalline SiO_2) and molecules of the type depicted in the upper portion of Figure 5 are initially formed, it is difficult to conceive that a rearrangement to a bulk-like, albeit more stable structure (Figure 5, below), would occur. It seems, therefore, that the initial growth of chlorosiloxane molecules with a few dozen Si atoms is responsible for the non-occurrence of bulk-like crystalline SiO_2.

(b) The question arises as to whether the discussed mechanisms are also applicable to other material systems, and whether intermediates analogous to those of the present reaction are also observable for other elements. There are relatively few examples in the literature of elements that

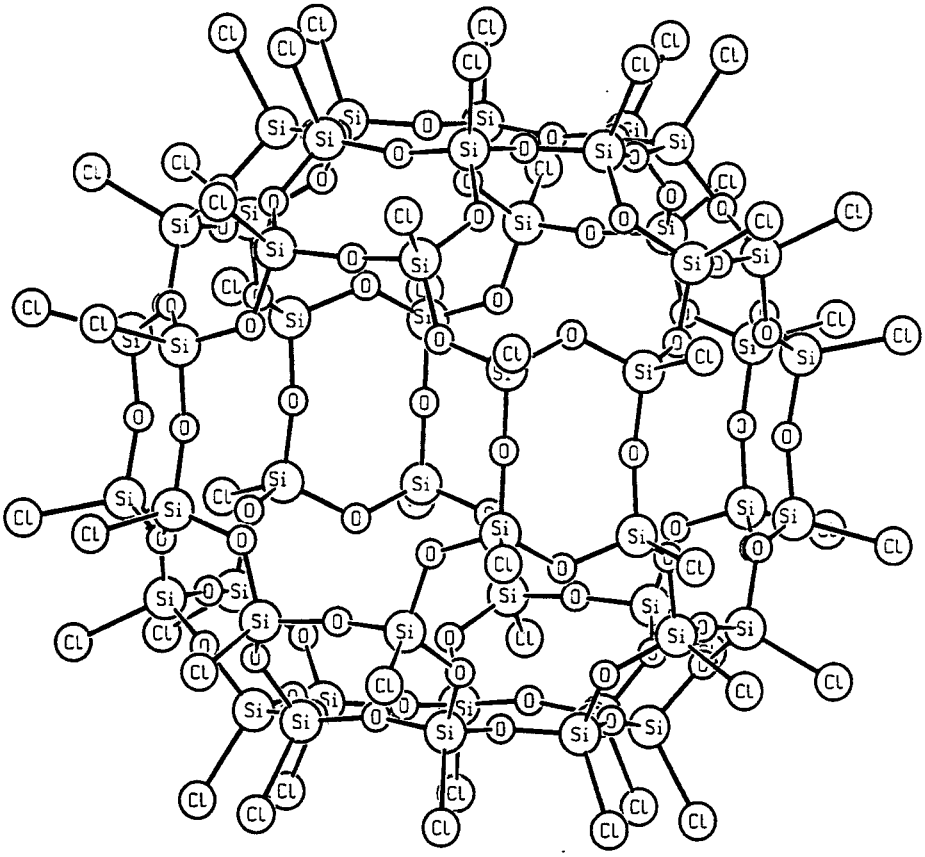

Figure 5. Quantum chemically calculated structures of two isomeric silsesquioxanes (Si_{48}); top: α-cage; bottom: tridymite structure

form molecular oxyhalides that can be discussed as intermediates of the reactions of halides with oxygen. These are mainly the metalloids and non-metals, as well as a few transition elements (fifth, sixth, and seventh subgroups). Oxyhalides of germanium, which correspond to those of silicon, but are thermally more labile, are known in somewhat larger numbers.[57] No other element shows the variety of molecular oxyhalides as silicon. In the group of one of the authors (M.B.), analogous experiments on other systems have been attempted, most notably on the reaction of $TiCl_4$ with oxygen. Despite extensive efforts, the search for corresponding intermediates was in this and many other cases fruitless. Clearly, silicon represents a special situation. If we consider the similarities and differences of the material systems Si/O/Cl and Ti/O/Cl, we can say the structural chemistry of silicon is characterized by the coordination number 4 and tetrahedral coordination, whereas for titanium oxides the coordination number 6 dominates. In contrast to titanium, for silicon the transition from chloride to oxide proceeds without a change in the coordination number or geometry. Therefore, a stepwise substitution of Cl by O atoms is possible for silicon, without destruction of the short-range order. This is not possible for the transition of molecular chloride to oxide in the case of titanium. The reaction of $TiCl_4$ with oxygen also leads also to the oxide and may conceivably pass through similar intermediates. However, even if these are indeed formed, they are so unstable and have such a short lifetime that they cannot be isolated or observed experimentally. This argument holds true not only for titanium, but also for almost all metals.

Selective C−H Bond Activation with Na_2PtCl_4 in Inverted Micelles

S. Gaemers,[a] K. Keune,[a] A. M. Kluwer,[a] and C. J. Elsevier*[a]

Keywords: Platinum / Micelles / C−H activation / NMR spectroscopy / Inverted micelles

The selective C–H activation of *n*-heptane and methylcyclohexane with Na_2PtCl_4 under mild conditions in water in inverted micelles is described.

Introduction

The selective activation and functionalisation of aliphatic hydrocarbons is of great interest.[1,2] In particular, the transformation of aliphatic hydrocarbons under mild reaction conditions to, for example, alcohols and aldehydes presents a problem. The activation of C−H bonds is thermodynamically not a difficult process, but the selective activation of C−H bonds of specific sp^3 carbon atoms is troublesome.[3,4] The use of appropriate transition metal catalysts may alleviate this problem.[5] To date several (catalytic) reactions are known for the conversion of hydrocarbons to functionalised hydrocarbons.[1,4−7] The activation of C−H bonds has been achieved by using $[PtCl_4]^{2-}$ as the catalyst with various substrates.[8,9] Such reactions are often performed under highly acidic conditions in aqueous solutions containing CF_3COOH or H_2SO_4.[2,6,8,9] For the selective C−H activation of hydrocarbons with platinum(II), we decided to introduce a water-soluble platinum salt in an aliphatic reaction medium by means of inverted micelles. The reaction rates in water[10−13] and in biphasic systems[14] (water in oil micro-emulsions) can be increased by using inverted micelles as this increases the surface contact area between catalyst and substrate. We decided to use inverted micelles of AOT[15] as this surfactant has been well studied and is commercially available.

The incubation of inverted micelles of AOT containing a 0.20 M solution of Na_2PtCl_4 in D_2O during several hours at 353 K resulted in the selective C−H activation of the CH_3 moieties of *n*-heptane and methylcyclohexane, as witnessed by the observed H-D exchange. The use of D_2O enables a stable ^2H lock during ^{195}Pt NMR experiments and allows for the observation of the exchange of protons for deuterons in the Pt^{II}-mediated C−H activation, see below.

Water and Platinum Loading

The size and shape of inverted micelles is determined (apart from the type of surfactant, solvent, concentration) by the amount of water present in inverted micelles. The water/AOT ratio is expressed as W_0 (W_0 = [H_2O]/[AOT]). Variations of W_0 cause changes in the size and structure of the inverted micelles,[16] the volume of the micro-droplets, the rotational correlation time (τ_c) of the inverted micelles[17] and the water-structure in the inverted micelles.[18] Therefore, it is of vital importance to control the W_0 parameter. When performing catalysis or spectroscopy in inverted micelles, the concentration of the compound(s) of interest (catalyst and/or substrates) is an important parameter as well; it is closely related to W_0 and may influence the size and shape of inverted micelles in a similar manner. The concentration of Na_2PtCl_4 in inverted micelles may influence the maximum water loading of the inverted micelles. Therefore, the maximum platinum concentration that can be reached in a solution of inverted AOT micelles in *n*-heptane has been determined by titration,[19,20] the results of which are shown in Figure 1.

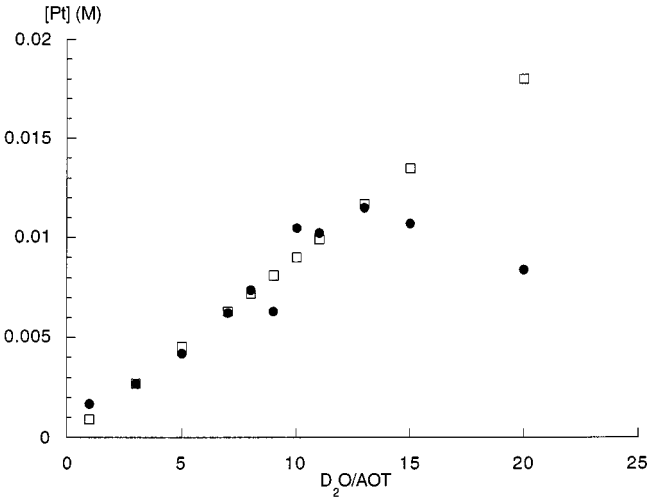

Figure 1. Titration of a solution of 0.25 M AOT in *n*-heptane with a 0.2 M solution of Na_2PtCl_4 in D_2O; filled circles are the measured platinum concentrations, open squares are the calculated concentrations

At the W_0 value where the measured concentration starts to deviate from the calculated concentration, the maximum platinum loading for the inverted micelles is reached.[21] Up to W_0 = 13 the concentration of platinum *in* the inverted micelle is 0.2 M. No precipitation of the platinum salt or exclusion of water was observed below this value. The ex-

periments in micellar solutions have been performed at $W_0 = 10$. The orange/brown colour of the micellar solutions clearly indicates that the platinum salt is indeed dissolved in the inverted micelles. No coloration of the aliphatic solvents occurs in the absence of AOT.

^{195}Pt NMR Spectroscopy

In order to assess putative interactions between the surface of the inverted micelles and the Na_2PtCl_4, we performed a ^{195}Pt NMR study (see Table 1). As the ^{195}Pt chemical shift is very sensitive to small changes in the chemical environment of the salt, interactions between the inverted micelle and Na_2PtCl_4 are expected to appear as variations in the ^{195}Pt chemical shift. Note that a decrease of the ^{195}Pt chemical shift by 11 ppm is observed when varying the Na_2PtCl_4 concentration from 0.05 M to 0.2 M in D_2O. As we did not observe any changes of the ^{195}Pt chemical shift in inverted micelles of AOT (where the concentration is 0.2 M) relative to the chemical shift in a 0.2 M D_2O solution of Na_2PtCl_4, it can be concluded that the environment of the platinum(II) species in inverted micelles is comparable to that in D_2O solution.

Table 1. ^{195}Pt chemical shift data of Na_2PtCl_4 in inverted micelles in various solvents, $[Na_2PtCl_4] = 0.2$ M

	Solvent	[AOT][a]	$\delta(^{195}Pt)$[b]
1	D_2O[c]	–	−1614
2	D_2O	–	−1625
3	heptane	0.25	−1626
4	hexane	0.25	−1626
5	pentane	0.25	−1624

[a] AOT concentration in mols/L. – [b] $\delta(^{195}Pt)$ in ppm. – [c] 0.05 M solution.

H-D Exchange

We observe that H-D exchange of the methyl protons of *n*-heptane with deuterons from D_2O readily proceeds at 353 K in inverted micelles of AOT, as indicated by ^{2}H NMR spectroscopy and GC-MS. Stacked plots of the ^{2}H NMR spectra of 0.25 M AOT in *n*-heptane or methylcyclohexane containing 0.2 M Na_2PtCl_4 in D_2O are shown in Figure 2. Monitoring the ^{2}H NMR intensity of *n*-heptane of a micellar solution of AOT containing Na_2PtCl_4 at 353 K as a function of time, showed an increase of the integral of the methyl resonance by a factor of 2.5. Similarly, an increase of the deuterium content was observed for the methyl group of methylcyclohexane. GC-MS spectra of methylcyclohexane after H-D exchange showed a deuteration level in the isotope pattern three times higher than the natural abundance. No concomitant increase of the integral of the ^{2}H NMR resonance of the methylene protons was observed in either case. This observation is proof of the selective enrichment of the methyl groups with ^{2}H due to exchange of protons with deuterons from D_2O. Comparison with a blank experiment showed that no enrichment in deuterium of the terminal methyl groups takes place in the absence of the platinum salt. Hence, this enrichment must

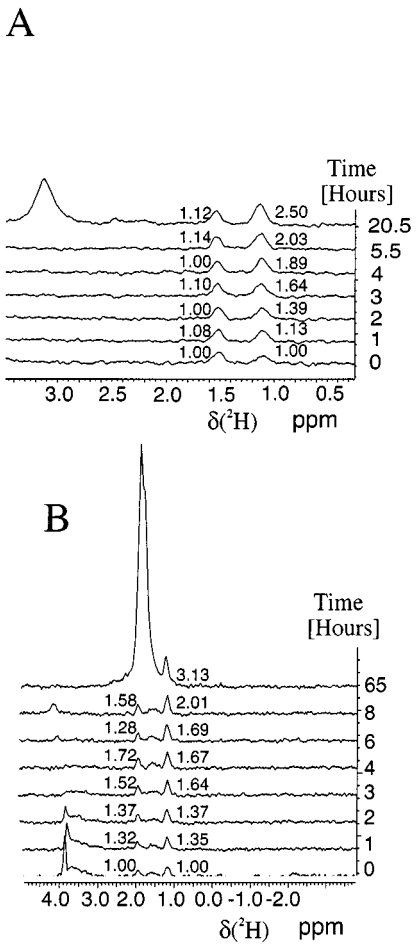

Figure 2. Stacked plots of ^{2}H NMR spectra recorded at 353 K of a micellar solution of AOT containing a 0.2 M D_2O solution of Na_2PtCl_4, demonstrating the H-D exchange in the methyl groups of *n*-heptane (A) and methylcyclohexane (B); an increase of the ^{2}H intensity of the *methyl* resonances is observed exclusively; the intensities at t = 0 have been arbitrarily calibrated at 1.00

stem from selective C−H activation by platinum(II) followed by exchange of the proton by a deuteron from D_2O.

This finding exemplifies the selective activation of the terminal methyl groups of aliphatic hydrocarbons in inverted micelles. Based on the total amount of platinum present in solution, we calculated that a sub-stoichiometric conversion (minimum value 10%) has been obtained so far.

After the H-D exchange had ceased, a colourless two phase system containing metallic platinum was obtained. The reason for the formation of metallic platinum is presently unknown. The signal observed at 1.5 ppm in Figure 2b might be the result of the hydrolysis of AOT, resulting in 2-ethyl-1-hexanol.

Conclusions and Outlook

The use of inverted micelles of AOT in a biphasic system of water-solubilised platinum salts in aliphatic solvents offers a very mild and selective route for the C−H bond activation of CH_3 groups in hydrocarbons. This may have in-

teresting implications for new routes towards terminally substituted (linear) alkane derivatives.

We now aim at employing a more stable surfactant, which may increase the lifetime of the micro-emulsion. The intrinsic features of inverted micelles in biphasic systems, such as a high contact area and ease of separation of the catalyst from products, deserve further attention in connection with the activation of C−element bonds.

Experimental Section

The surfactant sodium bis(2-ethylhexyl)sulfosuccinate (AOT) was dried by azeotropically distilling the salt three times with benzene followed by drying overnight in vacuo. Solutions of inverted micelles containing Na_2PtCl_4 were prepared by the addition of 135 μL of a 0.2 M stock solution of the appropriate platinum salt in D_2O to a 0.25 M AOT stock solution in *n*-heptane or methylcyclohexane. Stirring for at least two hours resulted in yellow or brown optically transparent solutions, which are stable for several days at room temperature. The solutions of inverted micelles containing Na_2PtCl_4 (0.2 M) thus obtained were heated to 353 K in a closed NMR tube, preferably a 10 mm od, 8 mm id sapphire HP NMR tube to prevent evaporation of the solvent. The HP NMR tube has been described in detail elsewhere.[22,23] For every ^2H NMR spectrum 512 scans were acquired at 353 K using the broad band channel of a 10 mm broad band 10 MHz-121 MHz-{^1H} probe (^1H at 300 MHz). The pulse duration was 5 μs (≈30° pulse), a 1.0 s preaquisition delay was used, during which the HOD resonance was saturated by CW irradiation.

[19] A solution of 0.25 M AOT in *n*-heptane was titrated with a stock solution of 0.2 M Na_2PtCl_4 in D_2O. The concentration of the AOT solution used (0.25 M) is well above the critical micelle concentration of AOT, which is 0.4 mM in aliphatic solvents.[20] The platinum concentration of the solutions of inverted micelles were determined by UV/Vis absorption spectrometry at 375 nm for a number of W_0 values. A blank solution of 0.25 M AOT devoid of platinum showed no absorption at 375 nm. The extinction coefficient of the micellar solutions was calculated from the known concentration where $W_0 = 3$ and was 132 M^{-1} cm^{-1} for Na_2PtCl_4.

[20] [20a] M. Ueno, H. Kishimoto , Y. Kyogoku, *Chem. Lett.* **1977**, 599. − [20b] F. Heatly, *J. Chem. Soc., Faraday Trans.* **1987**, *83*, 517.

[21] The concentration as determined by UV/Vis deviates from the calculated concentration Na_2PtCl_4 for $W_0 > 13$. Above this value, the micelles either only take up water and exclude platinum, or exclude both water and platinum from the interior of the inverted micelles.

New Silyl-Substituted Tin-Nitrogen Heterocubanes: Fourfold Metal-Coordinated Nitrogen and Exceptional Chemical and NMR Properties

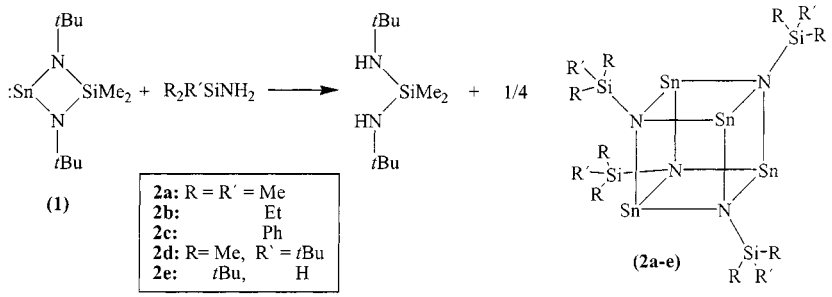
Michael Veith,*[a] Michael Opsölder,[a] Michael Zimmer,[a] and Volker Huch[a]

Dedicated to Prof. Schmutzler on the occasion of his 65th birthday

Keywords: Tin / Nitrogen / Cage compounds / Cluster compounds / Fourfold metal-coordinated nitrogen

The synthesis of new silyl-substituted tin-nitrogen heterocubanes and the structural analysis of $[Me_3SiNSn]_4$ is described. A sharp signal in the ^{14}N NMR spectrum and a septet in the ^{119}Sn NMR spectrum are among the interesting properties of this new type of compound with nitrogen surrounded by four (hemi)metals.

Introduction



Iminostannylenes of the type $[SnNR]_4$ have been known for about twenty years and were prepared and examined with varying substituents (e.g. R = *t*Bu,[1] *i*Pr, NMe_2,[2] 2,6-$iPr_2C_6H_3$, $BMes_2$,[3] C_6H_{11}, 2-$CH_2C_5H_4N$,[4] Ph[5]).[6] The main structural feature of these compounds is a Sn_4N_4 cage which represents a distorted heterocubane or two interpenetrating tetrahedrons (Sn_4 or N_4), with the R ligands at the nitrogen atoms.

Results and Discussion

From the reaction of the cyclic diazastannylene **1** with primary silylamines (Scheme 1) it was possible to extend the spectrum of substituents to give a new class with silicon, which is the most electropositive element bonded to the nitrogen atom up to now. In addition, the nitrogen carries four electropositive ligands (three metals, one hemimetal) which is unusual for this element. To the best of our knowledge, only three compounds have been characterized by crystal structure analysis where nitrogen is surrounded by four tin(IV) atoms[7] or two silicon and two germanium(II) atoms.[8]

Because of the high condensation tendency of trimethylsilylamine,[9] it had to be synthesised and reacted in situ with **1** to obtain directly **2a**. With other silylamines, we obtained a seconorcubane-like cage $Sn_3H_2(NSiRR'_2)_4$ as an intermediate in the synthesis of **2b–e**, which is analogous to the reaction observed with *tert*-butylamine.[1a] At high temperatures and with reduced pressure (240 °C, 0.01 Torr) it can be transformed to the corresponding cubane-like cage.

The X-ray structure analysis of **2a** reveals, to a good approximation, a $\bar{4}3m$ (T_d) molecular symmetry, but the molecule has only one crystallographic mirror plane passing through Sn(1)−Sn(2)−N(1)−N(2). At the four corners of the distorted Sn_4N_4 cube the Me_3Si groups are located in a staggered form towards the divalent tin atoms (Figure 1). Compound **2a** is the first compound known to us where a nitrogen atom is surrounded by three tin atoms and one silicon atom. The Sn−N bonds in **2a** are slightly shorter than those in the *tert*-butyl-derivative $[tBuNSn]_4$, whereas the Si−N bonds are exceptionally short. The average distance is only about 173 pm whereas 179−183 pm is expected for quaternary nitrogen; only a few exceptions are known.[10]

Scheme 1. General synthesis for $[R'R_2Si–NSu]_4$ (**2a**–**2e**)

Because of this special coordination environment the nitrogen shows unusual NMR properties which are not usually found for (metal)organic compounds. The four electropositive elements surround the ^{14}N nucleus so symmetric-

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 2000 1434−1948/00/0606−1143 $ 17.50+.50/0

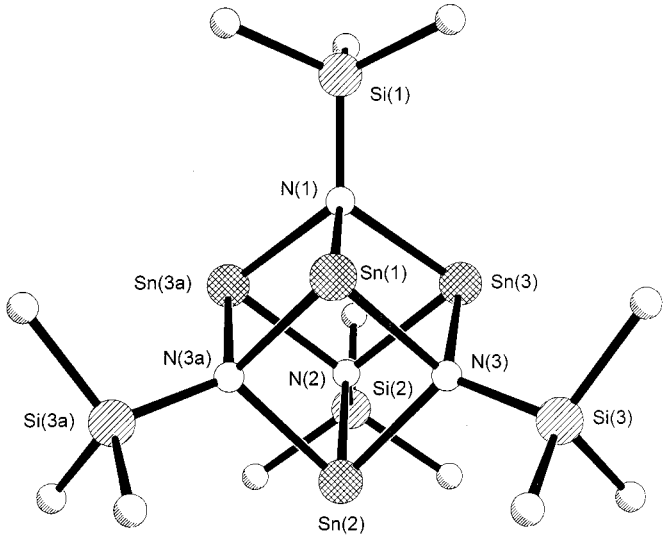

Figure 1. X-ray structure of **2a**; carbon atoms are not labelled; selected distances (average) [pm] and angles [°]: Sn−N 219.6(4), Sn−Sn 329.5(1), Si−N 172.7(4); N−Sn−N 82.3(2), Sn−N−Sn 97.2(2)

ally that its quadrupole moment does not affect the measurability of a ^{14}N NMR spectrum in a negative way. It is possible to get good ^{14}N signals with a half-height width of 8 Hz for the compounds **2a−e**; these signals are accompanied by Sn satellites (integration: approximately 35% of the signal, as expected[11] for three Sn atoms).[12] In addition to that the three ^{14}N nuclei ($I = 1$) around each ^{119}Sn atom split the tin resonance into a septet with an intensity ratio of 1:3:6:7:6:3:1 (Figure 2). The small satellite signals marked with stars are ^{117}Sn satellites with $^2J(^{117}Sn,^{119}Sn) = 57$ Hz, as proved by simulation[13] of the spectrum.

The tests on the reactivity of **2b** showed a remarkable stability of the Sn−N and Si−N bonds. No reaction could be observed with $AlCl_3$, $SnCl_4$, $ZnCl_2$, CuCl, Me_3SnCl, Ph_3SnCl, Me_3SiN_3, LiOMe, NaO*t*Bu, *t*BuOH, LiOH or NH_3, even under drastic conditions with some of them. This is probably due to the special bonding situation of the nitrogen with the neighbouring atoms.

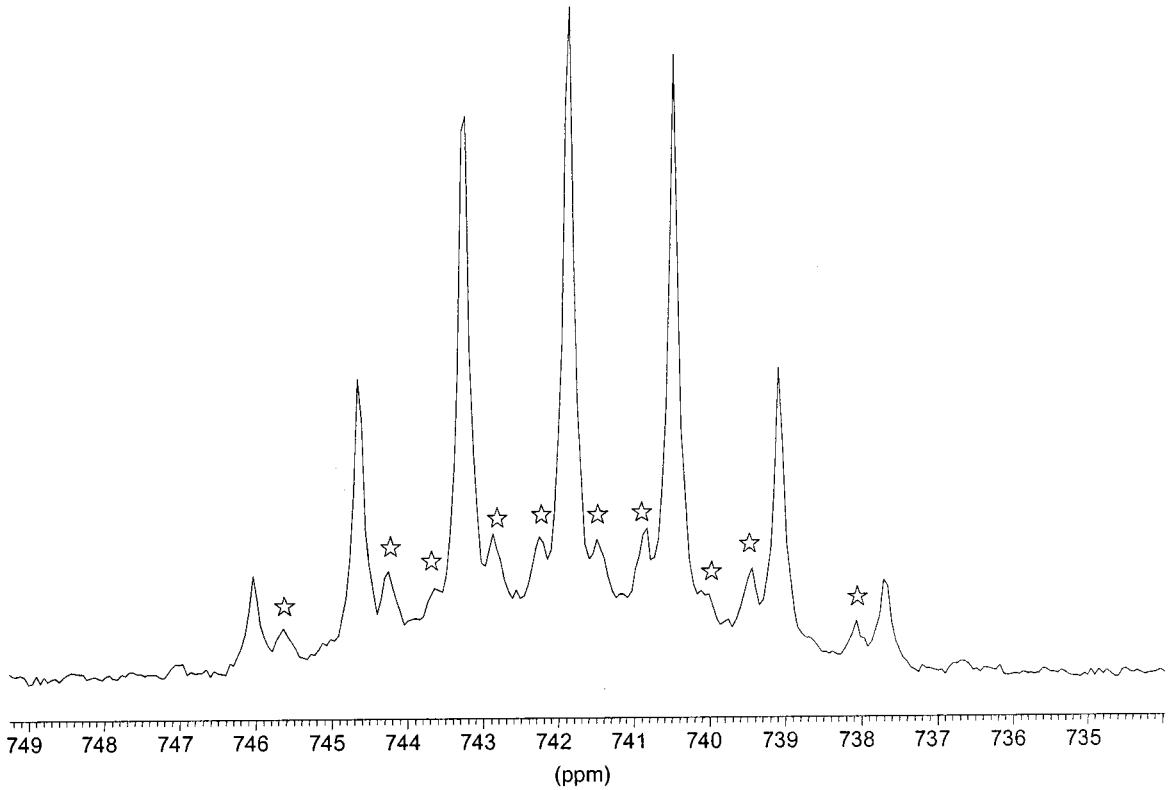

Figure 2. ^{119}Sn NMR spectrum of **2d**; couplings to three ^{14}N nuclei ($I = 1$) are responsible for the extraordinary splitting of the ^{119}Sn signal into a septet with a coupling constant of $^1J(^{14}N,^{119}Sn) = 103.8$ Hz, the signal intensities are in the ratio 1:3:6:7:6:3:1; the peaks marked with stars are ^{117}Sn satellite signals with $^2J(^{117}Sn, ^{119}Sn) = 57$ Hz

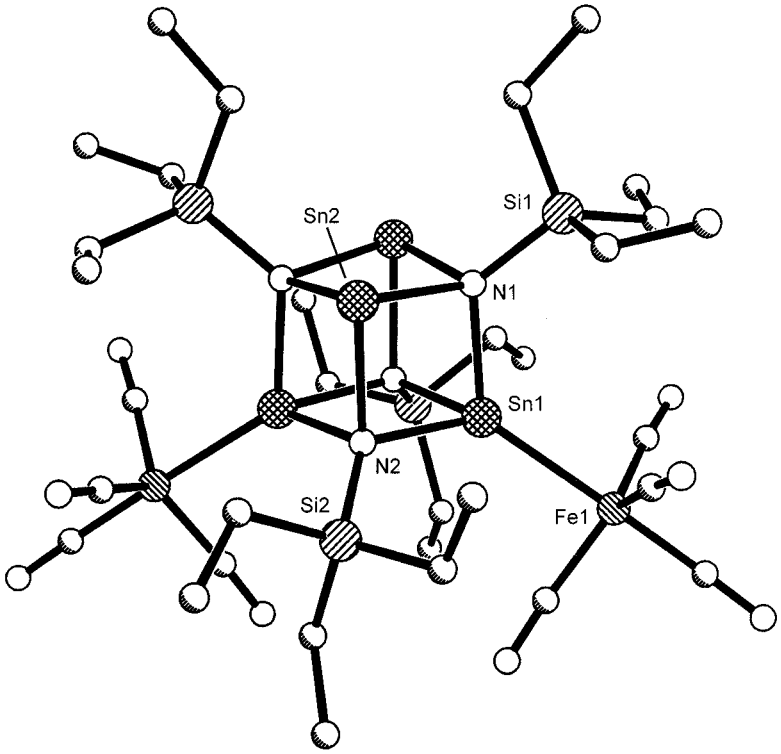

Figure 3. X-ray structure of **3**; carbon and oxygen atoms are not labelled; selected distances [pm] and angles [°]: Sn(1)−N (av.) 215.2(3), Sn(2)−N 224.4(3), Sn(1)−Sn(1a) 321.5(1), Sn(1/1a)−Sn(2/2a) (av.) 327.4(1), Sn(2)−Sn(2a) 332.6(1), Sn(1)−Fe(1) 248.4(1); N−Sn(1)−N (av.) 85.2(1), N−Sn(2)−N (av.) 81.5(1), Sn−N(1)−Sn (av.) 97.1(1), Sn−N(2)−Sn (av.) 95.4(1)

However, it was possible to make use of the Lewis base properties of two of the tin atoms. The reaction of $Fe_2(CO)_9$ with **2b** gave the molecule $[Et_3SiNSn]_4[Fe(CO)_4]_2$ **(3)**. A similar molecule, $[t\text{BuNSn}]_4[Cr(CO)_5]_2$,[14] is known. The structure of **3** (Figure 3) shows a crystallographic twofold axis (C_2) orthogonal to the cube faces Sn(1)−N(2)−Sn(1a)−N(2a) and Sn(2)−N(1)−Sn(2a)−N(1a). The Sn_4N_4 core is close to a C_{2v} (mm2) symmetry. The Sn(1)−N and Sn(1)−Sn(1a) contacts are considerably shorter than in **2a**. The reason for this is the shift of electron density from tin to iron and with that the Et_3Si groups make way for the iron carbonyls, as shown by the larger angles at Sn(1) and the different Si−N−Sn angles.

Experimental Section

General: All substances were handled under an atmosphere of dry nitrogen and solvents were dried and stored over sodium.

$[Me_3SiNSn]_4$ (2a): Me_3SiCl (11 g, 0.1 mol) in 50 mL hexane was added dropwise at −50 °C to liquid ammonia (50 mL). The ammonia was then removed in vacuo at the same temperature. The cold solution was decanted from the NH_4Cl precipitate, added to a solution of **1**[15] (3.2 g, 10 mmol) in hexane (10 mL) and was then allowed to warm to room temperature. After removing all volatile substances the crude product was purified by sublimation (0.01 Torr, 200 °C). m.p. 238 °C, 72% yield. − ^{1}H NMR (200.13 MHz, C_6D_6): δ = 0.26 (s).

$[R_2R'SiNSn]$ (2b−e): A solution of **1** (2.4 g, 7.5 mmol) was added dropwise to a solution of the silylamine (10 mmol; **b**: Et_3SiNH_2, **c**: Ph_3SiNH_2, **d**: $Me_2t\text{BuNH}_2$,[17] **e**: $t\text{Bu}_2\text{HSiNH}_2$[16]) in 10 mL toluene. After stirring for two hours it was refluxed for one hour. The volatile substances were removed in vacuum and the seconorcubane-like intermediate was pyrolysed in vacuo at 0.01 Torr and 250 °C. The formed silylamine was cold trapped and the product sublimed. − ^{1}H NMR (200.13 MHz, C_6D_6/C_7D_8) **2b**: δ = 0.86 (q), 1.15 (t); **2c**: δ = 7.05−7.25 (m), 7.58−7.63 (m); **2d**: δ = 0.26 (s), 1.10 (s); **2e**: δ = 1.24 (s), 4.30 [s, $^3J(^1H, ^{117/119}Sn)$ = 18 Hz].

$[Et_3SiNSn]_4[Fe(CO)_4]_2$ (3): $Fe_2(CO)_9$ (0.76 g, 2.1 mmol) and **2b** (0.40 g, 0.40 mmol) were heated to 65 °C in toluene (10 mL) for 2 hours (the colour changed from orange to green) and then to 100 °C for 6 hours. Toluene and $Fe(CO)_5$ were then removed in vacuum. The mixture of crude product and $Fe_3(CO)_{12}$ was diluted with hexane, filtered and concentrated to obtain crystals of the product (82% yield) which were recrystallized from toluene. − ^{1}H NMR (200.13 MHz, C_6D_6): δ = 1.09/1.86 (broad signals).

All compounds gave correct elemental analyses. A molecular weight determination of **2b** in benzene (cryoscopy) gave a mass of 997.8 g·mol^{-1} (calcd. 992.0 g·mol^{-1}).

X-ray Crystallography

The First Ru^{II} Bipyridyl-Capped Cyclodextrin: Evidence of Electron-Transfer Through the Cavity

Dominique Armspach,*[a] Dominique Matt,*[a] and Anthony Harriman[b]

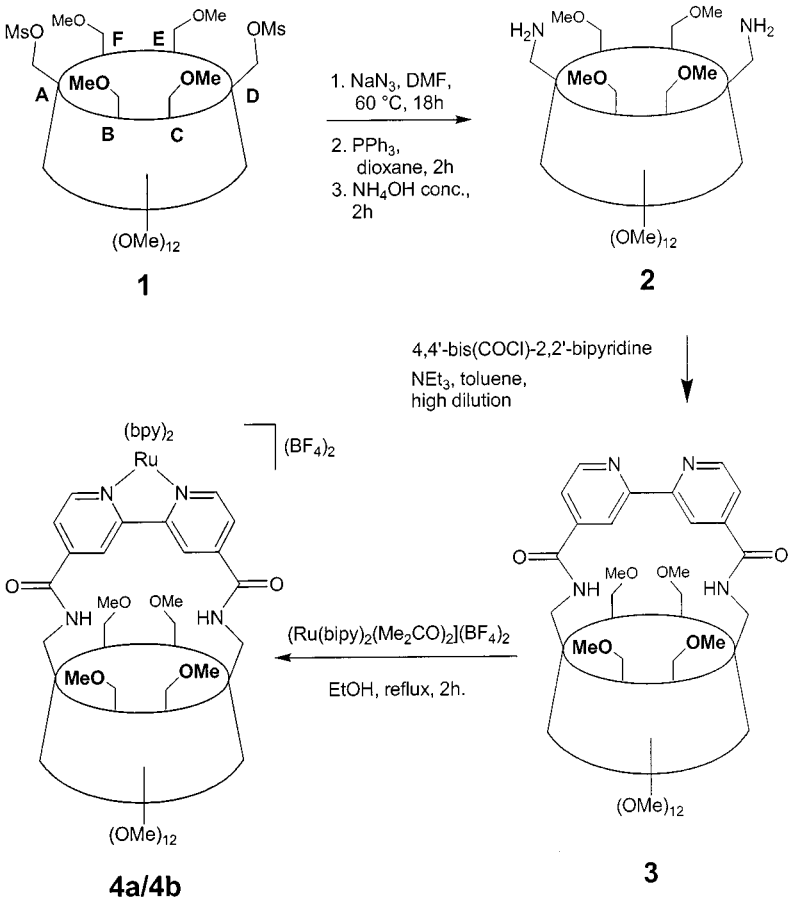
Keywords: Cyclodextrins / Ruthenium / N ligands / Electron transfer / Inclusion compounds

The narrow rim of an α-cyclodextrin has been AD-capped with a photoactive ruthenium(II) tris(2,2′-bipyridyl) fragment giving a diastereomeric mixture of complexes that bind 1,4-benzoquinone in water. Steady-state and time-resolved emission studies have been used to probe electron-transfer processes occurring inside and outside the cavity.

Introduction

Supramolecular assemblies displaying *vectorial* photoinduced electron-transfer (ET) reactions have attracted much attention in recent years from the view point of designing efficient artificial photosynthetic systems and light-driven molecular machines.[1−5] In order to gain a better understanding of through-space ET processes, it is necessary to closely position the reactants in a *rigid* manner but to avoid either direct orbital contact or a connecting organic framework. Here, we describe the synthesis and photophysical properties of a water-soluble α-cyclodextrin (α-CD) host for which a photoactive ruthenium(II) centre is held, for the first time, at a *fixed* distance above the receptor. Our approach involves capping the α-CD with a difunctionalized 2,2′-pyridyl ligand before subsequent metallation. The resulting complex is expected to behave as a metallo-receptor which, upon illumination, will transfer an electron between the excited metal centre and a redox-active substrate trapped in the cavity. Photoactive Ru^{II}(bipy) centres appended to cyclodextrin receptors have been reported previously, but these systems contain *flexible* Ru−CD connectors, thus preventing full geometrical control of the ET process.[6]

Results and Discussion



The key precursor for our study is 6A,6D-diamino-6A,6D-dideoxy-hexadeca-*O*-methyl-α-CD (**2**) which allows effective capping with diacid chlorides and good solubility in organic solvents. Compound **2** was synthesised in two steps from the dimesylate **1**[7] according to Scheme 1. Macrocyclisation of **2** under high dilution with 4,4′-bis(chlorocarbonyl)-2,2′-bipyridine in the presence of triethylamine afforded the "exo"-bipy ligand **3** in ca. 50% yield which, on treatment with the solvent complex $[Ru(bipy)_2(Me_2CO)_2][BF_4]_2$, gave an equimolar mixture of the diastereomeric complexes **4a/4b**[8] which was not resolved (see Experimental Section). Unlike ligand **3**, these complexes are soluble in water as well as in organic solvents.

Both ^1H NMR and ^{13}C NMR spectroscopy revealed the diastereomeric nature of the ruthenium complexes **4a/4b**. Each individual compound retains the C_2 symmetry of the ligand. Complexes **4a/4b** undergo chemical shift changes in D_2O upon addition of varying amounts of 1,4-benzoquinone (BQ) indicative of bimolecular association (Figure 1). A titration procedure involving the measurement of chemicals shifts for aqueous solutions containing excess BQ confirmed the 1:1 stoichiometry of the resultant supramolecular assembly and indicated an association constant (K_a) of $9 \pm 3\ M^{-1}$.[9] The CIS[10] (complexation-induced shift on 100% complexation) values obtained from these ^1H NMR spectra are listed in Table 1 for nonoverlapping probes and provide clear indication for the inclusion of BQ into the CD cavity. Amongst the most significant changes are those experienced by the H-3,3′ protons ($\Delta\delta_{max} = +0.22$, vs. +0.05 for H-5,5′ and +0.03 ppm for H-6,6′) of the 4,4′-dicarbonyl-2,2′-bipyridyl fragment, the only 2,2′-bipyridyl (bipy) protons that point towards the cavity interior. Interestingly, some of the CD MeO-3 protons[10] which also point towards the interior of the cavity are strongly upfield shifted ($\Delta\delta_{max} = -0.20$ and −0.23) whereas others are slightly downfield shifted or remain unchanged ($\Delta\delta_{max} = +0.05$ and −0.01) (Figure 1), suggesting that a particular guest orientation within the CD cavity is favoured, perhaps because of some structural distortion imposed by the bipy cap. Furthermore, the chemical shift change found for the H_{CD}-5 protons[11] ($\Delta\delta_{max} = +0.13$) is consistent with medium immersion of BQ.[10]

Luminescence from the metal complex in **4** is quenched upon addition of BQ but Stern-Volmer plots show *pronounced* positive deviations from linearity without reaching a plateau at high quinone concentrations (Figure 2). This situation arises from a combination of both diffusional and static emission quenching processes, as confirmed by time-

resolved luminescence studies. Fitting the titration data collected over a wide variation in BQ concentration, however, requires a second diffusional process which becomes important only at high BQ concentrations. These results are readily accommodated within a model for which BQ quenches emission from **4** via a diffusional process having a bimolecular rate constant of 3×10^9 M^{-1} s^{-1} and that competes with inclusion of BQ into the cavity. The second diffusional step, which also occurs with a bimolecular rate constant of 3×10^9 M^{-1} s^{-1}, can now be assigned to quenching of residual emission from the BQ·**4** complex. The best fit to the luminescence data gives $K_a = 45$ M^{-1} and indicates that the encapsulated quinone quenches the excited state of the metal complex with a first-order rate constant of 3.0×10^7 s^{-1}. Insisting on $K_a = 10$ M^{-1}, as indicated by the NMR studies, raises this latter rate constant to 4.7×10^7 s^{-1}. Each quenching step is attributed to ET from the triplet excited metal complex to BQ, although the radical ion products could not be detected by transient absorption spectroscopy.

The NMR studies indicate that the BQ guest is located at an edge-to-edge separation distance (R) of ca. 7 Å[12] from the bipy capping unit. Since the rate of electron transfer usually decreases exponentially with increasing R according to $k = A \exp(-\beta R)$, where the pre-exponential factor A has a value of ca. 10^{13} s^{-1}, we can approximate the attenuation factor β as being ca. 1.8 Å^{-1}. This means that the cavity exerts a serious damping effect on the rate of ET, being comparable to that of a solvent molecule. In the present study, the preferential 3D orientation of an electron-accepting guest takes place within an AD-capped α-CD and, for the first time, photoinduced ET within a Ru(bipy)−cyclodextrin receptor that guests a benzoquinone is shown to occur. Although the rigidified metalloreceptor **4** facilitates study of through-space, light-induced electron transfer in which a variety of redox-active substrates could

[a] The $\Delta\delta$ values relate to the chemical shift changes experienced by nonoverlapping probe protons in the host on 100% 1:1 complexation (CIS values). They were obtained after treatment of the binding data by an iterative nonlinear curve fitting program. All measurements were carried out using external $Me_4Si/CDCl_3$ as reference. The H_{CD}-3, H_{CD}-4, and H_{CD}-6 protons could not be identified. – [b] H-n,n′ stands for bipy protons while H_{CD}-n corresponds to cyclodextrin signals. For some probes two distinct signals were observed either because of diastereomer distinction, or because of the presence of two nonequivalent H atoms belonging to the same diastereomer.

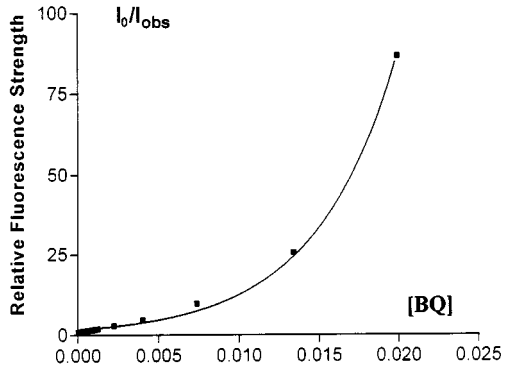

Figure 2. Stern-Volmer plot for the Ru-quinone system derived from **4a/4b**; [Ru] = 1.94×10^{-5} M in H_2O, at 25 °C; [Q] in mol/L

be used, it is necessary to optimise the binding process. This is most easily accomplished by enlarging the cavity and such studies are now underway.

Experimental Section

General: All manipulations were performed under dry nitrogen using purified solvents. A COSY experiment on complexes **4a/4b** allowed precise assignment of the bipy protons. The luminescence experiments were performed using a Perkin−Elmer LS 50B spectrofluorometer at room temperature. Full details for the synthesis of compounds **2** and **3** will be described elsewhere. For the atom numbering of α-cyclodextrin, see ref.[13].

Compound 2: yield 88% (starting from **1**). M.p. 184−186 °C. − ^1H NMR (200.13 MHz, $CDCl_3$): δ = 1.40 (br s, 4 H, NH_2), 3.38 (s, 6 H, CH_3O-6), 3.39 (s, 6 H, CH_3O-6), 3.49 (s, 18 H, CH_3O), 3.63 (s, 6 H, CH_3O), 3.64 (s, 6 H, CH_3O), 3.65 (s, 6 H, CH_3O), 2.99−3.94 (m, 36 H, H_{CD}-2, H_{CD}-3, H_{CD}-4, H_{CD}-5 and H_{CD}-6), 5.02 (d, ^3J = 3 Hz, 2 H, H_{CD}-1), 5.06 (d, ^3J = 3.5 Hz, 4 H, H_{CD}-1). − $^{13}C\{^1H\}$ NMR (50.32 MHz, $CDCl_3$): δ = 42.7 (CH_2N), 57.8 (×2) and 58.0 (CH_3O), 59.0 and 59.1 (CH_3O-6), 61.7 and 61.8 (×2) (CH_3O), 71.1, 71.2, and 72.4 (C_{CD}-5), 71.1 (×2) (C_{CD}-$6^{B,C,E,F}$), 81.3 (×3), 82.2 (×4), 82.5, 83.2 (C_{CD}-2, C_{CD}-3, and C_{CD}-4), 99.8, 100.0, and 100.3 (C_{CD}-1). − $C_{52}H_{94}N_2O_{28}$ (1195): calcd. C 52.25, H 7.93, N 2.34; found C 52.19, H 8.00, N 2.22.

Ligand 3: yield 50%. M.p. 195−197 °C. − IR (KBr): $\tilde{\nu}$ = 1655 (CO) cm^{-1}. − ^1H NMR (200.13 MHz, $CDCl_3$): δ = 3.02 (s, 6 H, CH_3O-6), 3.12 (s, 6 H, CH_3O-6), 3.45 (s, 6 H, CH_3O), 3.47 (s, 12 H, CH_3O), 3.60 (s, 6 H, CH_3O), 3.63 (s, 6 H, CH_3O), 3.65 (s, 6 H, CH_3O), 3.13−4.14 (m, 36 H, H_{CD}-2, H_{CD}-3, H_{CD}-4, H_{CD}-5 and H_{CD}-6), 4.94 (d, ^3J = 3 Hz, 2 H, H_{CD}-1), 5.00 (d, ^3J = 3.5 Hz, 2 H, H_{CD}-1), 5.03 (d, ^3J = 3.1 Hz, 2 H, H_{CD}-1), 7.57 (br. t, 2 H, CONH), 7.89 (d, ^3J = 5 Hz, 2 H, H_{pyr}-5,5′), 8.28 (s, 2 H, H_{pyr}-3,3′), 8.96 (d, ^3J = 5 Hz, 2 H, H_{pyr}-6,6′). − $^{13}C\{^1H\}$ NMR (50.32 MHz, $CDCl_3$): δ = 43.2 (CH_2NH), 57.8 and 58.1 (×2) (CH_3O), 58.8 and 59.1 (CH_3O-6), 61.6 and 61.7 (×2) (CH_3O), 70.7, 71.4, and 72.9 (C_{CD}-5), 70.9 and 72.3 (C_{CD}-$6^{B,C,E,F}$), 80.6, 81.3, 81.4, 81.8 (×3), 82.1 (×2), 82.3, and 85.8 (C_{CD}-2, C_{CD}-3, and C_{CD}-4), 99.5, 99.6, and 100.1 (C_{CD}-1), 118.7 (C_{pyr}-5,5′), 121.7(C_{pyr}-3,3′), 142.3 (C_{pyr}-4,4′), 151.8 (C_{pyr}-6,6′), 157.1 (C_{pyr}-2,2′), 164.5 (CONH). − $C_{64}H_{98}N_4O_{30}$ (1404): calcd. C 54.77, H 7.04, N 3.99; found C 54.70, H 7.09, N 3.84.

Complexes 4a + 4b (mixture): A mixture of *cis*-$RuCl_2(bipy)_2$ (0.074 g, 0.14 mmol) and $AgBF_4$ (0.064 g, 0.32 mmol) in acetone (20 mL) was refluxed for 2 h. After cooling, the filtered solution was added to a solution of **3** (0.200 g, 0.14 mmol) in ethanol (10 mL). Acetone was removed under reduced pressure and the ethanolic solution was stirred under reflux for 2 h. A solution of $NaBF_4$ in water (1 M, ca. 20 mL) was then added to the mixture. Extraction with CH_2Cl_2 (3 × 50 mL) and drying over $MgSO_4$ afforded **4** as a mixture of two diastereomers.[8] Yield: 0.270 g, 95%. − IR (KBr): $\tilde{\nu}$ = 1655 (CO) cm^{-1} − UV/Vis (H_2O): λ_{max} (ε) = 485 (11000), 421 (10400). − ^1H NMR (500.14 MHz, D_2O, ext. ref.: $SiMe_4$ in $CDCl_3$): δ = 2.60 (s, 6 H, CH_3O-6), 2.92 (s, 6 H, CH_3O-6), 3.05 (s, 6 H, CH_3O-6), 3.21 (s, 6 H, CH_3O-6), 3.23−3.37 (6dd, ^3J = 2.8 and 9.7 Hz, 12 H, H_{CD}-2), 3.48 (s, 12 H, CH_3O-2), 3.49 (s, 6 H, CH_3O-2), 3.50 (s, 6 H, CH_3O-2), 3.52 (s, 6 H, CH_3O-2), 3.54 (s, 6 H, CH_3O-2), 3.55−4.22 (m, 48 H, H_{CD}-3, H_{CD}-4, and H_{CD}-6), 3.96−4.20 (m, 6 H, H_{CD}-5), 5.11 (d, ^3J = 3.7 Hz, 2 H, H_{CD}-1), 5.12 (d, ^3J = 3.7 Hz, 2 H, H_{CD}-1), 5.16 (d, ^3J = 2.8 Hz, 2 H, H_{CD}-1), 5.20 (d, ^3J = 2.8 Hz, 2 H, H_{CD}-1), 5.27 (d, ^3J = 3.4 Hz, 2 H, H_{CD}-1), 5.29 (d, ^3J = 3.4 Hz, 2 H, H_{CD}-1), 7.35−7.43 (m, 8 H, H_{pyr}-5,5′), 7.68 (d, ^3J = 5.4 Hz, 2 H, H_{pyr}-6,6′), 7.72 (d, ^3J = 5.4 Hz, 2 H, H_{pyr}-6,6′), 7.80 (dd, ^3J = 5.5 Hz and ^4J = 1.8 Hz, 4 H, H_{pyr}-5,5′ connected to CD), 7.82 (d, ^3J = 5.4 Hz, 2 H, H_{pyr}-6,6′), 7.86 (d, ^3J = 5.4 Hz, 2 H, H_{pyr}-6,6′), 8.04−8.13 (m, 12 H, H_{pyr}-4.4′ of bipy and H_{pyr}-6,6′ connected to CD), 8.57−8.59 (m, 8 H, H_{pyr}-3,3′), 9.07 (d, ^4J = 1.8 Hz, 2 H, H_{pyr}-3,3′ connected to CD), 9.12 (d, ^4J = 1.8 Hz, 2 H, H_{pyr}-3,3′ connected to CD). − $^{13}C\{^1H\}$ NMR (50.32 MHz, $CDCl_3$): δ = 44.3 (×2) (CH_2NH), 57.4 (×2), 57.7 (×2) and 57.6 (×2) (CH_3O), 58.5 (×2), 58.7 and 58.9 (CH_3O-6), 61.5 (×2), 61.7 (×2) and 62.0 (×2) (CH_3O), 70.1(×2), 70.4 (×2), and 70.5 (×2) (C_{CD}-5), 70.7 (×2) and 71.3 (×2) (C_{CD}-$6^{B,C,E,F}$), 80.3 (×2), 81.9 (×4), 82.1 (×2), 82.3 (×4), 82.4 (×2), 82.6 (×2), and 84.2 (×2) (C_{CD}-2, C_{CD}-3, and C_{CD}-4), 99.9 (×2), 100.2 (×2), and 100.4 (×2) (C_{CD}-1), 120.1 (×2), 124.6

(×4) (C_{pyr}-3,3′), 127.7 (×2), 127.9 (×2), and 128.5 (×2) (C_{pyr}-5,5′), 138.4 (×2), 138.6 (×2), 143.3 and 143.4 (C_{pyr}-4,4′), 150.5 (×2), 151.2 (×2), 152.1 (×2) (C_{pyr}-6,6′), 156.0 (×2), 156.7 (×2), 157.3 (×2) (C_{pyr}-2,2′), 162.2 (×2) (CONH). − FAB-MS: *m/z* (%) = 1903 (15) $(M - BF_4)^+$, 1816 (100) $(M - 2BF_4)^+$. − $C_{84}H_{114}B_2F_8N_8O_{30}Ru$ (1991): calcd. C 50.69, H 5.77, N 5.63; found C 50.62, H 5.90, N 5.41.

The determination of the association constants is based on the chemical shift variation of certain nonoverlapping H-signals upon addition of an excess (3−40 equiv.) of BQ to a 2.7×10^{-3} M solution of **4** in D_2O. The data were treated by a nonlinear regression analysis program in order to extract K_a and CIS values. A similar procedure was used to evaluate the K_a value ($K_a = 8 \pm 3\ M^{-1}$) for the complex formed between [hexakis(2,3,6-tri-*O*-methyl-α-cyclodextrin] (TM-α-CD) and BQ. Comparison of the two K_a values suggests that the [$Ru(bipy)_2$(4,4′-biscarbonylbipy)] cap has little influence on the complexation process.

Emission spectra (room temperature, $\lambda_{exc} = 460$ nm) in air-saturated water were obtained for a concentration of complex **4** that was maintained constant throughout the titration (1.94×10^{-5} M). The quinone concentration ranges from 1.94×10^{-5} M to 2.00×10^{-2} M.

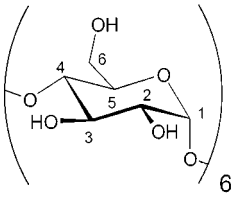
[8] Molecule **4** combines an enantiomerically pure cyclodextrin fragment with the dissymetric ruthenium centre. This combination results in the formation of two diastereomers.



[9] Both diastereomers **4a/4b** were found to undergo similar chemical shift changes upon complexation with BQ and therefore identical K_a values for the 1:1 complexes were obtained. Probes giving the maximum chemical shift changes were used to evaluate the K_a values, namely H-3,3′ protons of the 4,4′-dicarbonyl-2,2′-bipyridyl moiety and one of the CD MeO-3 signals.

[10] H.-J. Schneider, F. Hacket, V. Rüdiger, H. Ikeda, *Chem. Rev.* **1998**, *98,* 1755−1785.

[11] Unfortunately, the H_{CD}-3 signals which are usually strongly upfield-shifted, even for a shallow complexation process, could not be identified as a result of signal overlap. However, the H_{CD}-3 signal of the (TM-α-CD)·BQ complex could be clearly seen and undergoes a significant upfield-shift on complexation (CIS = −0.42 ppm on 100% complexation). Based on this probe, an association constant of $8 \pm 3\ M^{-1}$ was determined; this value is in agreement with that obtained for BQ complexation with **4a/4b** ($9 \pm 3\ M^{-1}$).

[12] This value was estimated on the basis of the NMR CIS values found for protons located in the CD cavity together with molecular models. Clearly, the large chemical shift changes on BQ-complexation experienced by some of the MeO-3 protons indicate a shallow guest inclusion of the guest at the cavity entrance. For steric reasons the *OO*-axis of included BQ was assumed to be oriented along the CD C_2 axis. The estimated edge-to-edge separation stands for the distance between an N atom of the substituted bipy and the nearest BQ-oxygen atom.

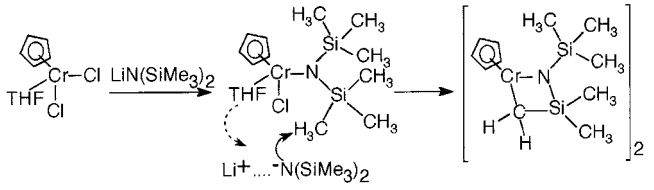
Preparation, Characterization and Crystal Structure of the Dinuclear Chromium Complex $\{(C_5H_5)Cr[\mu\text{-}CH_2SiMe_2{-}N(SiMe_3)]\}_2$

Rino Messere,[a] Marie-Rose Spirlet,[b] Dominique Jan,[c] Albert Demonceau,[c] and Alfred F. Noels*[c]

Keywords: Chromium / Cyclopentadienes / Si ligands / Metallacycles



The complex $\{(C_5H_5)Cr[\mu\text{-}CH_2SiMe_2{-}N(SiMe_3)]\}_2$ (**1**) was obtained by reacting lithium bis(trimethylsilyl)amide (**2**) with $CpCrCl_2{\cdot}THF$. A single crystal X-ray diffraction study revealed that the complex is dimeric with two [μ-CH_2SiMe_2–$N(SiMe_3)$] bridging units and a *cis* configuration of the two cyclopentadienyl ligands. Bond distances and angles are compared with those observed in $[(C_5Me_5)Cr^{I}Me]_2$ and $[(C_5H_5)Cr^{III}Me_2]_2$.

Introduction

Chromium-based heterogeneous catalysts have a long-standing use in the commercial polymerization of small olefins. The search for soluble analogues has led Theopold et al. to synthesize a variety of low valent chromium complexes.[1] In this context, different permethylated cyclopentadienyl complexes of Cr^{II} and Cr^{III} have been fully identified as monomeric and/or dimeric species,[2] revealing new structures and reactivities towards olefins.[3]

We now report the first example of a cyclopentadienyl complex of chromium(III) containing a bidentate alkyl-amido ligand. Although amido derivatives of Si, Ti, V, Fe and Cr have been reported,[4] amide complexes of chromium are rare and, to date, never simultaneously ligated to a Cp ligand.

The new complex was readily obtained from $CpCrCl_2{\cdot}THF$ (or $[CpCrCl_2]_n$) and $LiN(SiMe_3)_2$, (**2**). Reaction of $CpCrCl_2{\cdot}THF$ with three equivalents of $LiN(SiMe_3)_2$ in THF produced a dark violet solution from which, instead of the expected complex $[(C_5H_5)Cr(NSiMe_3)_2]$, an unprecedented dimeric complex $\{(C_5H_5)Cr[\mu\text{-}CH_2SiMe_2{-}N(SiMe_3)]\}_2$ **(1)** (Scheme 1) was isolated as a crystalline material in 55% yield after purification.

Scheme 1. Synthesis of di-Cr^{III} complex **1**

At this preliminary stage, complex **1** appears to result from a C–H σ bond metathesis similar to that described by Berno et al. for a similar vanadium complex,[5] the deprotonation being performed by $LiN(SiMe_3)_2$ which acts as a base rather than as a nucleophile.

The ^1H NMR spectrum of paramagnetic **1** displays broadened, intense absorptions which are characteristic of the CH_3 groups [δ = 0.62 (*C20, C21* and *C22*, 9 H); δ = 2.28 (s, 3 H), −1.79 (s, 3 H), *C 19, C 18*; δ = 27.2 (μ-CH_2)]. The ^{13}C NMR spectrum displays three broad absorptions at 46.3, 35.1 and 2.7 ppm and a doublet at 89 ppm. The FTIR spectrum shows the characteristic absorptions of the Si–N and Si–CH_3 stretching at 850 and 1250 cm^{-1}.

The molecular structure of **1** has been unambiguously established by an X-ray structure analysis.

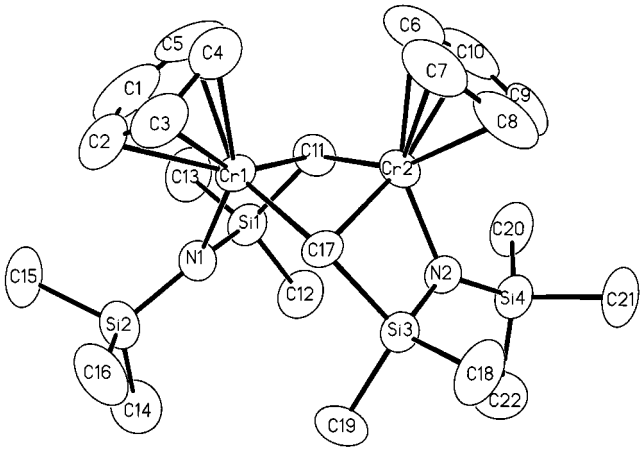


Figure 1. X-ray structure of **1** with atom labelling scheme

Figure 1 shows the geometry and the atom labelling scheme for the molecule. It appears indeed that **1** is a dimer consisting of two $[(C_5H_5)Cr]$ moieties bridged by two [μ-$CH_2SiMe_2{-}N(SiMe_3)$] units. The two Cp ligands are unexpectedly in a *cis* arrangement. Selected bond lengths and

angles are reported hereafter. The two bridging units form two almost p1anar (within 0.10 Å) four-membered metallaazasilacyclobutane rings (an example where a cyclobutane ring is made up of four different elements!), and form the dimeric unit by sharing the CH_2 groups with the two Cr atoms. The two bridging carbon atoms are almost symmetrically placed between the two Cr atoms [Cr1−C11 = 2.163(5), Cr1−C17 = 2.221(5), Cr2−C11 = 2.217(5), Cr2−C17 = 2.172(5) Å] but are significantly longer than typical Cr^{III}−C alkyl σ-bonds (2.09 Å).[6] The coordination about each chromium has approximate C_{3v} symmetry with the center of the Cp ring at the apex and the bridging methyl carbons and the nitrogen at the base of a distorted tetrahedron. The two tetrahedrons are joined by sharing a C−C edge. The Cr−C bond lengths of C_5H_5Cr are in the range expected for η^5-coordinated cyclopentadienyl rings. The distortion of the coordination polyhedrons is reflected by the angles subtended at the chromium atoms. While the C−Cr−C and N−Cr−C angles are less than 109°, the Cp−Cr−C and Cp−Cr−N angles are nearly identical but greater than 109°. The Cr−C (bridging) mean distance of 2.193(5) Å is in agreement with the mean value of 2.186 Å observed in $[(C_5Me_5)Cr^{II}Me]]_2$ [1b] and 2.188 Å observed in $[(C_5H_5)(CH_3)Cr^{III}Me]_2$.[2b] The chromium−chromium distance of 2.662(2) Å is fairly short and close to the value (2.606 Å) reported for the dimeric complex $\{(C_5H_5)(CH_3)Cr^{III}Me\}_2$.[2b] In light of the theoretical MO-analysis of metal−metal bonding in related paramagnetic chromium(III) complexes by Janiak et al.,[6] such short distances are consistent with metal−metal interactions, although we do not care to speculate about the exact bond order or bond strength of this interaction. This Cr−Cr bond remains, however, considerably longer than that of a Cr^{III} bis(μ-alkylidene) complex (2.262 Å) recently described by Theopold et al., the shortest metal−metal distance found so far in Cr^{III} alkyls.[7]

Complex **1** alone is inactive in the polymerization of ethylene and addition of an alkylaluminium is required to initiate ethylene polymerization. Polymerization results will be reported in due course.

Experimental Section

All reactions were carried out under an atmosphere of purified nitrogen. Solvents were distilled, dried and kept under nitrogen before use.

$(C_5H_5)CrCl_2\cdot THF$: Finely divided $CrCl_3\cdot THF_3$ (10 g) was poured into 200 mL of dry deoxygenated THF. A solution of CpNa in THF (1 M, 20 mL) at 0° C was added to this suspension and the resulting green solution stirred for 1 hour at 0 °C. The solution was then warmed to 20 °C and kept for one hour at that temperature. The green solution turned blue. The solution was then taken to dryness under low pressure to yield a blue product. This dark solid was washed with pentane (100 mL) at 20 °C to yield a blue, hygroscopic powder after drying under vacuum at 30 °C. Yield 95%.

$\{(C_5H_5)Cr[\mu\text{-}CH_2SiMe_2\text{−}N(SiMe_3)]\}_2$ (1): $(C_5H_5)CrCl_2\cdot THF$ (0.1 g) was dissolved in 50 mL of purified THF under an inert atmosphere. To this solution was added a solution of $LiN(SiMe_3)_2$ (1 M, 2.7 mL) in THF at 10 °C. The reaction mixture was then stirred at 20° C for 4 hours after which the solution was taken to dryness under low pressure, yielding a black solid. This dark product was extracted with pentane (20 mL) and then with toluene (2 × 30 mL). The combined toluene filtrate was kept at −20 °C for 2 days to yield a dark-violet solid. Yield 55%.

X-ray Crystallographic Study:[8] Crystal data for $C_{22}Cr_2N_2Si_4$ (M_r = 508.6): monoclinic system with cell dimensions at 20 °C of a = 14.847(3)Å, b = 11.172(2) Å, c = 17.889(3) Å, β = 93.43(3)°; V = 2962(1) Å^3; μ(Mo-K_α) = 0.904 mm^{-1}; F(000) = 1000; space group $P2_1/c$ with Z = 4 and $D_{calcd.}$ = 1.141 g/cm^3. A selected specimen (0.45 × 0.35 × 0.35 mm.) was sealed in a thin-walled glass capillary under argon. The X-ray diffraction data were obtained with a Siemens R3m/V four-circle computer-controlled X-ray diffractometer (graphite-monochromated Mo-K_α radiation: λ = 0.71073 Å) at 293 K. The unit cell parameters and standard deviations were calculated for the setting angles of 25 reflections with 10° < 2θ < 35°. The space group $P2_1/c$ was unequivocally established from systematic absences. The intensities of 7519 reflections corresponding to 3823 independent reflections ($R_{int.}$ = 0.038) were measured by the ω scan technique in the range 3.5° < 2θ < 45.0° (h: −15 → 15, k: −12 → 12, l: −19 → 19). Three standard reflections were monitored every 97 reflections to check crystal stability. No decrease of intensity during data collection was observed. Data were corrected for Lorentz polarization and absorption effects, the latter with a semi-empirical method. The transmission factors range from 0.765 to 0.967. The structure was solved by direct methods and Fourier techniques. Full-matrix least-squares refinement was carried out against F^2. The thermal behavior of the nonhydrogen atoms was treated anisotropically. Riding H atoms, with C−H bond lengths of 0.95 Å and a fixed isotropic U of 0.08 Å were included in the refinement. The final agreement factors were 0.056 for 2914 reflections with $F_o^2 > 2\sigma(F_o^2)$ and 271 parameters. The maximum shift/e.s.d. in the final cycle was less than 0.001. The highest peak in the final difference Fourier map was 0.703 eÅ^{-3}. Calculations were performed with Siemens SHELXTL PLUS package programs.[9]

Synthesis and Structure of Cyclotrigermenium Salts of Tetrakis{3,5-bis(trifluoromethyl)phenyl}borate, Tetrakis(pentafluorophenyl)borate and Tetrakis{4-[*tert*-butyl(dimethyl)silyl]-2,3,5,6-tetrafluorophenyl}borate: A Stable Free Germyl Cation in the Condensed Phase

Akira Sekiguchi,*[a] Norihisa Fukaya,[a] Masaaki Ichinohe,[a] and Yutaka Ishida[a]

Keywords: Cations / Electron transfer / Germanium / Small ring systems

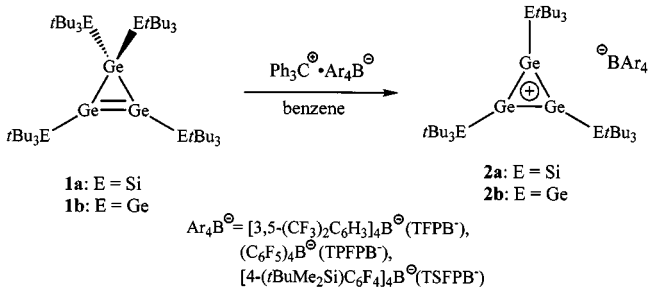
The reaction of tetrakis(tri-*tert*-butylsilyl)cyclotrigermene (**1a**) with $Ph_3C^+[3,5\text{-}(CF_3)_2C_6H_3]_4B^-$ ($TFPB^-$), $Ph_3C^+(C_6F_5)_4B^-$ ($TPFPB^-$), and $Ph_3C^+[4\text{-}(t\text{BuMe}_2\text{Si})C_6F_4]_4B^-$ ($TSFPB^-$) in benzene produced the stable free tris(tri-*tert*-butylsilyl)cyclotrigermenium ion ($\mathbf{2a}^+$) with the corresponding tetraarylborate as the counterion. The crystal structures of $\mathbf{2a}^+TFPB^-$ and $\mathbf{2a}^+TSFPB^-$ reveal a free germyl cation with a two π-electron system. The three-membered ring of germanium atoms constitutes an almost equilateral triangle. The cyclotrigermenium tetraarylborates, $\mathbf{2a}^+TFPB^-$, $\mathbf{2a}^+TPFPB^-$, and $\mathbf{2a}^+TSFPB^-$, are stable in solution. The spectroscopic data show that $\mathbf{2a}^+$ is a free germyl cation, does not coordinate to either the solvent molecules (dichloromethane, chloroform, toluene, or diethyl ether) or the counter anions ($TFPB^-$, $TPFPB^-$, or $TSFPB^-$). The tris(tri-*tert*-butylgermyl)cyclotrigermenium ion ($\mathbf{2b}^+$) was also characterized.

Introduction

The chemistry of tricoordinated germyl and silyl cations in the condensed phase has developed rapidly in recent years.[1] Their study is, however, at an early stage compared to that of the carbocations.[2] Over the years, many efforts have been directed towards the synthesis and characterization of free germyl and silyl cations in the condensed phase.[3] In 1997, Lambert and Zhao successfully synthesized the trimesitylsilyl cation, which was a long-sought free silyl cation.[4] Although they did not perform an X-ray study, convincing evidence of its existence was given by its ^{29}Si NMR chemical shift in aromatic solvents.[4,5] The presence of the free silyl cation has been strongly supported by ab initio calculations, demonstrating good agreement between the calculated and experimental ^{29}Si NMR chemical shifts.[6]

In contrast to the silyl cations, very little experimental work has been reported on the germyl cation in the condensed phase.[5,7] Recently, we isolated and characterized $[(t\text{Bu}_3\text{SiGe})_3^+BPh_4^-]$ ($\mathbf{2a}^+TPB^-$, TPB^- = tetraphenylborate) by the reaction of tetrakis(tri-*tert*-butylsilyl)cyclotrigermene with $Ph_3C^+TPB^-$, which was the first example of a free germyl cation with a two π-electron system.[8,9] However, a problem of the TPB anion is its chemical instability.[10] $\mathbf{2a}^+TPB^-$ can survive in a solution of dichloromethane only at temperatures below −78 °C.

$[3,5\text{-}(CF_3)_2C_6H_3]_4B^-$ ($TFPB^-$, tetrakis{3,5-bis(trifluoromethyl)phenyl}borate),[11] $(C_6F_5)_4B^-$ ($TPFPB^-$, tetrakis(pentafluorophenyl)borate),[12] and $[4\text{-}(t\text{BuMe}_2\text{Si})C_6F_4]_4B^-$ ($TSFPB^-$, tetrakis{4-[*tert*-butyl(dimethyl)silyl]-2,3,5,6-tetrafluorophenyl}borate)[13] are known to be stable borate anions. These counter anions should increase the stability of the resulting cyclotrigermenium ion. This prompted us to examine the reaction of $t\text{Bu}_3\text{E}$- substituted cyclotrigermenes **1a** (E = Si)[14] and **1b** (E = Ge)[14] with $Ph_3C^+TFPB^-$, $Ph_3C^+TPFPB^-$, and $Ph_3C^+TSFPB^-$, producing $[(t\text{Bu}_3\text{EGe})_3^+TFPB^-]$, $[(t\text{Bu}_3\text{EGe})_3^+TPFPB^-]$, and $[(t\text{Bu}_3\text{EGe})_3^+TSFPB^-]$ (E = Si, Ge). These germyl cations can survive for extensive periods without decomposition both in solution and the solid state. We report here spectroscopic and structural evidence that $\mathbf{2}^+TFPB^-$, $\mathbf{2}^+TPFPB^-$, and $\mathbf{2}^+TSFPB^-$ incorporate free germyl cations, which do not coordinate to either the solvent molecules dichloromethane, chloroform, toluene or diethyl ether, or the counter anions $TFPB^-$, $TPFPB^-$, or $TSFPB^-$.



Results and Discussion

Synthesis of $\mathbf{2}^+TFPB^-$, $\mathbf{2}^+TPFPB^-$, and $\mathbf{2}^+TSFPB^-$

Synthesis was carried out under an inert atmosphere by standard Schlenk and high-vacuum line techniques. Dry oxygen-free benzene was introduced by vacuum transfer to a mixture of $(t\text{Bu}_3\text{Si})_4Ge_3$ (**1a**) and $Ph_3C^+TFPB^-$, and the mixture was stirred at room temperature. The solution immediately changed from the dark red color of **1a** to yellow, and a brown powder formed. The solvent was removed under vacuum and the resulting solid was washed with hexane in a glove box to afford $\mathbf{2a}^+TFPB^-$ as a yellow powder in 81% yield (Scheme 1). Despite the large steric congestion, the reaction is very rapid and is complete within 5 min. The reaction is possibly initiated by electron transfer from **1a** to the trityl cation followed by elimination of a $t\text{Bu}_3\text{Si}$ radical through cleavage of the weak exocyclic Si-Ge bond to produce $\mathbf{2a}^+TFPB^-$.[15] The reaction of **1b** with $Ph_3C^+TFPB^-$

Scheme 1

in benzene also proceeded to give **2b**$^+$TFPB$^-$ in 76% yield. Both **2a**$^+$TFPB$^-$ and **2b**$^+$TFPB$^-$ are soluble in dichloromethane, but only slightly soluble in toluene. Similarly to the reaction with Ph_3C^+TFPB$^-$, the reaction of **1a** and **1b** with Ph_3C^+TPFPB$^-$ in benzene produced **2a**$^+$TPFPB$^-$ (80%) and **2b**$^+$TPFPB$^-$ (80%), respectively. However, several attempts to obtain crystals of these complexes failed. The reaction of **1a** with Ph_3C^+TSFPB$^-$ in benzene produced **2a**$^+$TSFPB$^-$ as orange crystals in 88% yield. The tetraarylborate derivatives of the cyclotrigermenium ion are extremely air- and moisture-sensitive, and the yellow color disappeared immediately when solutions were exposed to the air.

Crystal Structures of 2a$^+$TFPB$^-$ and 2a$^+$TSFPB$^-$

Recrystallization of **2a**$^+$TFPB$^-$ from toluene yielded yellow-orange crystals suitable for X-ray crystallography; its molecular structure is shown in Figure 1. The three-membered ring consisting of germanium atoms forms an almost equilateral triangle, as determined by the internal bond angles of 59.79(3) to 60.28(3) °. The Ge−Ge distances of the three-membered ring are almost equal, ranging from 2.3284(8) to 2.3398(8) Å (av. 2.3333(8) Å). The Ge−Ge bond lengths observed for **2a**$^+$TFPB$^-$ (Figure 1) are intermediate between the Ge=Ge double bond (2.239(4) Å) and

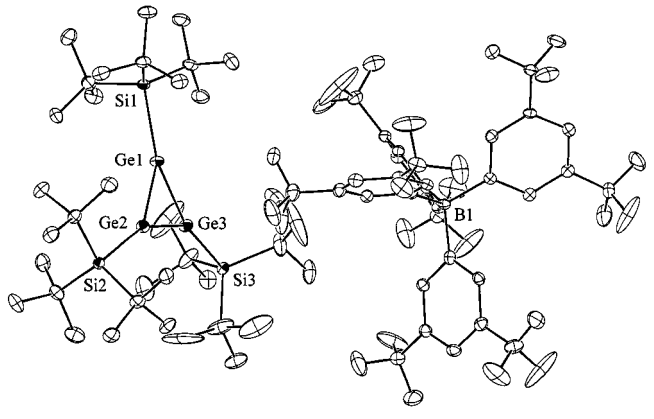

Figure 1. Perspective view of **2a**$^+$TFPB$^-$ in the crystal at the 30% probability level (hydrogen atoms are omitted for the clarity). Selected bond lengths (Å): Ge1−Ge2, 2.3316(9); Ge1−Ge3, 2.3284(8); Ge2−Ge3, 2.3398(8); Ge1−Si1, 2.425(1); Ge2−Si2, 2.442(1); Ge3−Si3, 2.444(1). Selected bond angles (deg): Ge2−Ge1−Ge3, 60.28(3); Ge2−Ge1−Si1, 150.58(5); Ge3−Ge1−Si1, 148.55(5); Ge1−Ge2−Ge3, 59.79(3); Ge1−Ge2−Si2, 145.94(5); Ge3−Ge2−Si2, 152.75(5); Ge1−Ge3−Ge2, 59.93(3); Ge1−Ge3−Si3, 152.36(5); Ge2−Ge3−Si3, 146.70(5).

the Ge−Ge single bond (2.522(4) Å) of the precursor **1a**.[14] The three silicon atoms are nearly coplanar with the central three-membered ring. The bond lengths of the Ge−Si bonds (Ge1−Si1, 2.425(1) Å; Ge2−Si2, 2.442(1) Å; Ge3−Si3, 2.444(1) Å) of **2a**$^+$TFPB$^-$ are shorter than those of **1a**[14] (2.629(7) Å for the Ge−Si bond length of sp^3 Ge atom and 2.448(7) Å for the Ge−Si bond length of sp^2 Ge atoms).

The perspective view appears to show a weak electrostatic interaction between the germanium and fluorine atoms. The three closest distances range from 3.823 to 5.097 Å, as depicted in Figure 2. However, these distances are longer than the sum (3.57 Å) of the van der Waals radii for germanium and fluorine atoms.[16] Undoubtedly, CF_3 groups of the counter anion are sufficiently remote from the germanium center to preclude any covalent interaction.

We have also obtained X-ray diffraction data for **2a**$^+$TSFPB$^-$, which was obtained by recrystallization from toluene. Due to the steric bulkiness of the *t*BuMe$_2$Si group attached to the *para* positions of the phenyl rings of borate anion, no interaction between the cation moiety and the counter anion can be found (Figure 3). As a consequence, the skeleton of the three-membered framework forms an equilateral triangle; the Ge−Ge bond lengths are 2.3310(8) Å for Ge1−Ge2, 2.3315(7) Å for Ge1−Ge3, and 2.3349(8) Å for Ge2−Ge3, and the Ge−Ge−Ge bond angles are 60.10(2)° for Ge2−Ge1−Ge3, 59.96(2)° for Ge1−Ge2−Ge3, 59.94(2)° for Ge1−Ge3−Ge2. In addition, the silicon atoms of the *t*Bu$_3$Si groups attached to the germanium atoms are in approximately the same plane as the three-membered ring, as determined by the sum of the respective bond angles around the germanium atoms (e.g. 359.99(4)° for Ge1, 359.96(4)° for Ge2, and 359.86(5)° for Ge3).

These structural features for **2a**$^+$TFPB$^-$ and **2a**$^+$TSFPB$^-$ are practically the same as those of **2a**$^+$TPB$^-$,[8a] i.e. the counter anion does not affect the framework of the cyclotrigermenium ion. Thus, the crystal structure of the cyclotrigermenium ion reveals a free germyl cation with a two π-electron system. The three germanium atoms form an equilateral triangle similar to its carbon analog, the cyclopropenium ion.[17]

The structures of **2a**$^+$TFPB$^-$ and **2a**$^+$TSFPB$^-$ presented here are very close to those predicted by a calculation on the corresponding D_{3h} $(HGe)_3^+$ isomer.[7d] The observed average Ge−Ge distances for **2a**$^+$TFPB$^-$ and **2a**$^+$TSFPB$^-$ are 2.3333(8) Å and 2.3325(8) Å, compared with the calculated value of 2.361 Å for a $(HGe)_3^+$ ion with D_{3h} symmetry. The theoretical calculations also predict a hydrogen-bridged nonplanar structure with C_{3v} symmetry that has a lower energy than that of a planar one with D_{3h} symmetry.[7d] However, the more stable hydrogen-bridged $(HGe)_3^+$ isomer cannot be expected when the hydrogens are replaced by other groups. Due to the steric hindrance and electronic properties of the *t*Bu$_3$Si group,[18] the cyclotrigermenium ion favors a planar structure similar to that of the cyclopropenium ion. A cyclotrigallane dianion, Na_2[(2,6-$Mes_2C_6H_3$)Ga]$_3$ (Mes = 2,4,6-trimethylphenyl), has been

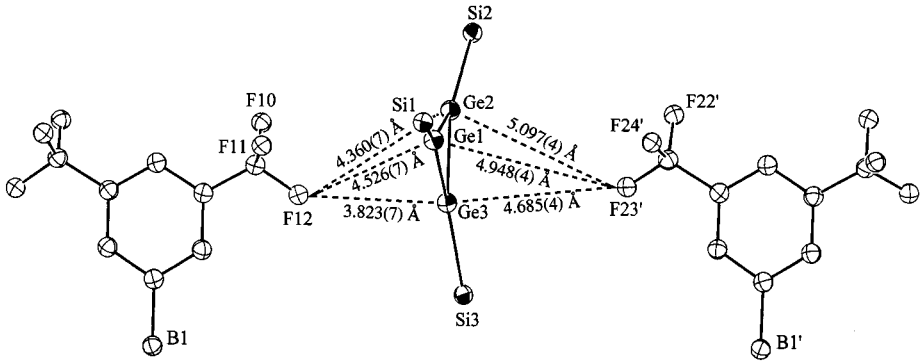

Figure 2. Section from the structure of $\mathbf{2a}^{+}$TFPB^{-} with the closest atomic distances between Ge and F.

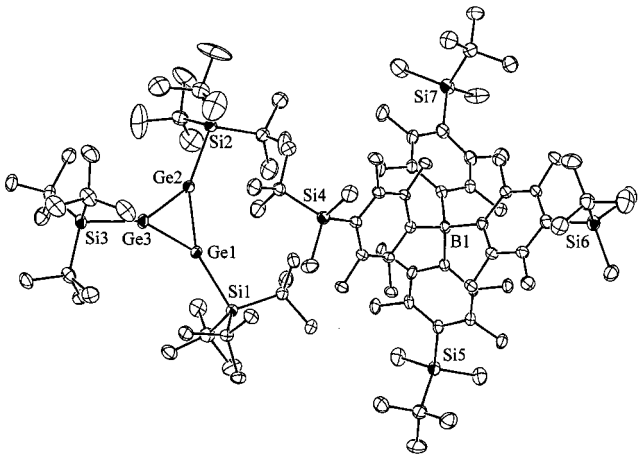

Figure 3. Perspective view of $\mathbf{2a}^{+}$TSFPB^{-} in the crystal at the 30% probability level (hydrogen atoms are omitted for the clarity). Selected bond lengths (Å): Ge1−Ge2, 2.3310(8); Ge1−Ge3, 2.3315(7); Ge2−Ge3, 2.3349(8); Ge1−Si1, 2.420(1); Ge2−Si2, 2.460 (1); Ge3−Si3, 2.434(1). Selected bond angles (deg): Ge2−Ge1−Ge3, 60.10(2); Ge2−Ge1−Si1, 151.17(4); Ge3−Ge1−Si1, 148.72 (4); Ge1−Ge2−Ge3, 59.96(2); Ge1−Ge2−Si2, 150.86(4); Ge3−Ge2−Si2, 149.14(4); Ge1−Ge3−Ge2, 59.94(2); Ge1−Ge3−Si3, 151.94(5); Ge2−Ge3−Si3, 147.98(5).

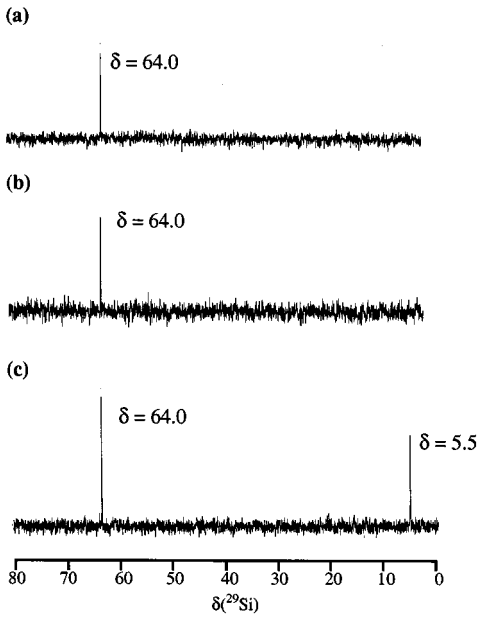

Figure 4. ^{29}Si NMR spectra of $\mathbf{2a}^{+}$TFPB^{-} (a), $\mathbf{2a}^{+}$TPFPB^{-} (b), $\mathbf{2a}^{+}$TSFPB^{-} (c) in CD_2Cl_2 at 298 K.

synthesized as a metallic ring system possessing aromatic character.[19]

Free Cyclotrigermenium Ion in Solution

The evidence for the free cyclotrigermenium ion is supported by the NMR spectroscopic data. The ^{1}H, ^{13}C, and ^{29}Si NMR chemical shifts for the cyclotrigermenium moiety of $\mathbf{2a}^{+}$TFPB^{-}, $\mathbf{2a}^{+}$TPFPB^{-}, and $\mathbf{2a}^{+}$TSFPB^{-} in CD_2Cl_2 are practically the same (see the Experimental Section). For example, ^{29}Si NMR chemical shifts of $\mathbf{2a}^{+}$TFPB^{-}, $\mathbf{2a}^{+}$TPFPB^{-}, and $\mathbf{2a}^{+}$TSFPB^{-}, as shown in Figure 4, are independent of the counter anion. The ^{29}Si NMR chemical shift of $\mathbf{2a}^{+}$TFPB^{-} is also essentially the same in the different solvents, appearing at $\delta = 64.0$ in CD_2Cl_2, $\delta = 64.2$ in $CDCl_3$, $\delta = 64.4$ in [D$_8$]toluene, and $\delta = 64.5$ in Et_2O. This independence from the both counter anion and solvent clearly indicates that $\mathbf{2a}^{+}$ is a free germyl cation in solution.

The large downfield shift of the ^{29}Si NMR resonance of $\mathbf{2a}^{+}$, relative to that of **1** ($\delta = 37.2$ for tBu$_3$Si attached to the saturated Ge atom and 50.1 for tBu$_3$Si attached to the Ge=Ge double bond), is due to the positive charge on the cyclotrigermenium ion. The positive charge is not localized on the germanium atoms, but is significantly transferred to the silicon centers. According to the Mulliken charges, most of the positive charge is distributed on the silicon atoms of the substituents rather than on the ring germanium atoms. It has been reported that the positive charge on the ring carbon atoms of cyclopropenium cations $(RC)_3^{+}$ decreases with decreasing electronegativity of the substituent: +0.200 (R = CH$_3$), +0.026 (R = H), −0.243 (R = SiH$_3$).[20] The atomic (Mulliken) charges on $(H_3SiGe)_3^{+}$, according to the HF/6−31G* level calculations, indicate a similar delocalization of the positive charge: −0.07 for the ring germanium

atoms, +0.64 for the silicon atoms of the SiH_3 substituents.[21]

Conclusion

Treatment of tetrakis(tri-*tert*-butylsilyl)cyclotrigermene (**1a**) with the trityl cation in benzene produces the stable free tris(tri-*tert*-butylsilyl)cyclotrigermenium ion (**2a**$^+$) with three different counter anions. The crystal structures and the spectroscopic data show that **2a**$^+$ is a free germyl cation, which does not coordinate to either the counter anions or the solvent molecules.

Experimental Section

All manipulations were carried out under an inert atmosphere in a MBRAUN MB 150B-G gas-replacement type glove box or by standard Schlenk and high-vacuum line techniques. − ^{1}H NMR spectra were recorded at 300.1 MHz on a Bruker AC-300 FT NMR spectrometer. ^{13}C and ^{29}Si NMR spectra were collected on a Bruker AC-300 at 75.5, 59.6 MHz, respectively. − All solvents were dried and degassed over potassium mirror in vacuo prior to use in the preparation of cyclotrigermenium ion. The cyclotrigermenes **1a**,[14] **1b**,[14] and trityl cations Ph_3C^+ $[3,5\text{-}(CF_3)_2C_6H_3]_4B^-$ (TFPB$^-$),[11] $Ph_3C^+(C_6F_5)_4B^-$ (TPFPB$^-$),[12] and Ph_3C^+[4-(*t*Bu-Me_2Si) $C_6F_4]_4B^-$ (TSFPB$^-$)[13] were prepared according to literature procedures. On account of the inclusion of solvent molecules, no satisfactory elemental analyses data for the cyclotrigermenium salts could be obtained.

Tris(tri-*tert*-butylsilyl)cyclotrigermenium Tetrakis[3,5-bis(trifluoromethyl)phenyl]borate (2a$^+$TFPB$^-$): Dry oxygen-free benzene was introduced by vacuum transfer to a mixture of **1a** (60 mg, 0.06 mmol) and Ph_3C^+TFPB$^-$ (65 mg, 0.06 mmol), and the mixture was stirred at room temperature for 10 min. The dark red solution of **1a** became yellow, and brown powder was formed. The solvent was removed under vacuum and the resulting solid was washed with hexane in a glove box to afford a yellow powder of **2a**$^+$TFPB$^-$ (80 mg, 81%). M.p. 132−134 °C (dec). − ^{1}H NMR (CD_2Cl_2): δ = 1.40 (s, 81 H), 7.56 (s, 4 H), 7.73 (s, 8 H). − ^{13}C{^{1}H} NMR (CD_2Cl_2): δ = 27.2, 31.8, 117.8, 125.0 [q, $^1J(^{13}C\text{-}^{19}F)$ = 270 Hz], 129.1−129.9 (m), 135.2, 162.2 [q, $^1J(^{13}C\text{-}^{11}B)$ = 50 Hz]. − ^{29}Si{^{1}H} NMR (CD_2Cl_2): δ = 64.0.

Tris(tri-*tert*-butylsilyl)cyclotrigermenium Tetrakis(pentafluorophenyl)borate (2a$^+$TPFPB$^-$): By the procedure described above, the reaction of **1a** (60 mg, 0.06 mmol) and Ph_3C^+TPFPB$^-$ (55 mg, 0.06 mmol) provided **2a**$^+$TPFPB$^-$ (ca. 80%) as a yellow waxy solid. − ^{1}H NMR (CD_2Cl_2): δ = 1.40 (s, 81 H). − ^{13}C{^{1}H} NMR (CD_2Cl_2): δ = 27.2, 31.8, 124.0−125.5 (m), 136.7 [d, $^1J(^{13}C\text{-}^{19}F)$ = 240 Hz], 138.6 [d, $^1J(^{13}C\text{-}^{19}F)$ = 240 Hz], 148.5 [d, $^1J(^{13}C\text{-}^{19}F)$ = 240 Hz]. − ^{29}Si{^{1}H} NMR (CD_2Cl_2): δ = 64.0.

Tris(tri-*tert*-butylgermyl)cyclotrigermenium Tetrakis[3,5-bis(trifluoromethyl)phenyl]borate (2b$^+$TFPB$^-$): By the procedure described above, the reaction of **2b** (30 mg, 0.03 mmol) and Ph_3C^+TFPB$^-$ (30 mg, 0.03 mmol) provided **2b**$^+$TPFPB$^-$ (34 mg, 76%) as yellow crystals. M.p. 112−114 °C (dec). − ^{1}H NMR (CD_2Cl_2): δ = 1.48 (s, 81 H), 7.56 (s, 4 H), 7.73 (s, 8 H). − ^{13}C{^{1}H} NMR (CD_2Cl_2): δ = 32.4, 37.1, 117.8, 125.0 [q, $^1J(^{13}C\text{-}^{19}F)$ = 270 Hz], 129.1−129.9 (m), 135.2, 162.2 [q, $^1J(^{13}C\text{-}^{11}B)$ = 50 Hz].

Tris(tri-*tert*-butylgermyl)cyclotrigermenium Tetrakis(pentafluorophenyl)borate (2b$^+$TPFPB$^-$): By the procedure described above, the reaction of **2b** (30 mg, 0.03 mmol) and Ph_3C^+TPFPB$^-$ (25 mg, 0.03 mmol) provided **2b**$^+$TPFPB$^-$ (ca. 80%) as a yellow waxy solid. − ^{1}H NMR (CD_2Cl_2): δ = 1.48 (s, 81 H). − ^{13}C{^{1}H} NMR (CD_2Cl_2): δ = 32.4, 37.1, 124.0−125.5 (m), 136.7 [d, $^1J(^{13}C\text{-}^{19}F)$ = 240 Hz], 138.6 [d, $^1J(^{13}C\text{-}^{19}F)$ = 240 Hz], 148.5 [d, $^1J(^{13}C\text{-}^{19}F)$ = 240 Hz].

Tris(tri-*tert*-butylsilyl)cyclotrigermenium Tetrakis{4-[*tert*-butyl(dimethyl)silyl]-2,3,5,6-tetrafluorophenyl}borate) (2a$^+$TSFPB$^-$): By the procedure described above, the reaction of **2a** (200 mg, 0.20 mmol) and Ph_3C^+TSFPB$^-$ (258 mg, 0.20 mmol) provided **2a**$^+$TSFPB$^-$ (326 mg, 88%) as orange crystals. M.p. 154−156 °C (dec). − ^{1}H NMR (CD_2Cl_2): δ = 0.33 (s, 24 H), 0.90 (s, 36 H), 1.41 (s, 81 H). − ^{13}C{^{1}H} NMR (CD_2Cl_2): δ = −3.2, 18.3, 27.0, 27.7, 32.3, 108.8 [t, $^2J(^{13}C\text{-}^{19}F)$ = 33 Hz], 134.3−135.8 (m), 149.2 [d, $^1J(^{13}C\text{-}^{19}F)$ = 262 Hz]. − ^{29}Si{^{1}H} NMR (CD_2Cl_2): δ = 5.47, 64.0.

X-ray Crystal Structure Determination of 2a$^+$TFPB$^-$ and 2a$^+$TSFPB$^-$: Single crystals of **2a**$^+$TFPB$^-$ and **2a**$^+$TSFPB$^-$ suitable for X-ray diffraction were grown from toluene solutions. The X-ray crystallographic experiments were performed on a MacScience DIP2020 or DIP2030 image plate diffractometer equipped with graphite-monochromatized Mo-K_α radiation (λ = 0.71073). Crystal data for **2a**$^+$TFPB$^-$ at 120 K: $M_F = C_{68}H_{93}BF_{24}Ge_3Si_3$, Mr = 1679.27, monoclinic, a = 16.912(1) Å, b = 20.919(1) Å, c = 23.399(1) Å, β = 108.147(4)°, V = 7866.4(7) Å^3, space group = $P2_1/n$, Z = 4, $D_{calcd.}$ = 1.418 g/cm^3, R = 0.0849 (R_w = 0.2153 for all data). Crystal data for **2a**$^+$TSFPB$^-$(C_7H_8)$_2$ at 120 K: $M_F = C_{98}H_{157}BF_{16}Ge_3Si_7$, Mr = 2064.54, orthorhombic, a = 13.3320(5) Å, b = 20.5110(3) Å, c = 40.638(1) Å, V = 11112.6(5)Å ^{3}, space group = $Pc2_1n$, Z = 4, $D_{calcd.}$ = 1.234 g/cm^3, R = 0.0523 (R_w = 0.1512 for all data). Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-137540 and 137541. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44(1223)336−033; E-mail:deposit@ccdc.cam.ac.uk].

Computational Details: Calculations at the Hartree−Fock (HF) level were performed by using the Gaussian 94 computer program.[21] The 6−31G* basis set was used for all geometry optimizations.

Dedicated to Hedda Meyer on the occasion of her 60th birthday

Keywords: Sesquifulvalene / Manganese / Chromium / Heterobimetallic complexes / Nonlinear optics

The synthesis of monometallic manganese and bimetallic manganese–chromium complexes incorporating the sesquifulvalene derivatives 2-(2,4,6-cycloheptatrien-1-ylidene)indene (**VI**) and [(2,4,6-cycloheptatrien-1-ylidene)ethenylidene]cyclopentadiene (**VII**) is reported. Charge separation is observed upon complexation and stabilization of **VI** and **VII** by metal centers, and the spectroscopic and structural properties of [(**VI**)$Mn(CO)_3$]BF_4 (**6**), [$(OC)_3$Mn(μ-**VI**)$Cr(CO)_3$]BF_4 (**8**), [(**VII**)$Mn(CO)_3$]BF_4 (**13**), and [$(OC)_3$Mn(μ-**VII**)$Mn(CO)_3$]BF_4 (**15**) are clearly indicative of sesquifulvalene ligands coordinated in a dipolar η^5 or μ-η^5:η^7 fashion, respectively. The coplanar cyclopentadienyl and cycloheptatrienyl fragments act as strongly coupled electron-donating and -accepting groups and strong negative solvatochromism is observed for complexes **6**, **8**, **13**, and **15**. Accordingly, exceptionally large first molecular hyperpolarizabilities β have been determined by means of hyper Raleigh scattering for the bimetallic species **8** and **15**, as well as for some related compounds. The X-ray crystal structures of *anti*-[$(OC)_3$Mn(μ-η^5:η^7-**VI**)$Cr(CO)_3$] (**8**) and *syn*-[$(OC)_3$Mn(μ-η^5:η^7-**VII**)$Cr(CO)_3$] (**15**) are reported.

Introduction

In recent years, considerable effort has been devoted to exploring the organometallic chemistry of η-cycloheptatrienyl ligands and significant progress has been made in the development of new synthetic routes to their metal complexes.[1] However, η-cycloheptatrienyl transition metal complexes, M(η-C_7H_7), still remain poorly explored in comparison with the analogous η-cyclopentadienyl, M(η-C_5H_5), and benzene systems, M(η-C_6H_6). This also holds true in the area of bimetallic complexes with conjugated hydrocarbon-bridged transition metal fragments, which is dominated by ligands containing five- and six-membered rings,[2] e.g. bicyclopentadienyl (**I**)[3,4] and biphenyl (**II**)[5] (Scheme 1). On the other hand, related complexes with the iso-π-electronic hydrocarbon bicycloheptatrienyl (**III**) have been reported only recently by Whiteley and co-workers.[6] Direct linkage of an anionic cyclopentadienyl unit and a cationic cycloheptatrienylium unit gives the cross-conjugated hydrocarbon sesquifulvalene (**IV**), which constitutes a dipolar structural isomer of biphenyl (**II**). Despite the fact that **IV** can be described by resonance structure **IVB** containing two aromatic subunits, it is quite unstable and behaves like a polyene with alternating bond lengths;[7] its ground state electronic structure is best represented by the apolar canonical form **IVA**.

Scheme 1

In contrast, charge separation is observed upon complexation and stabilization of **I** and its derivatives by transition metal fragments,[8−10] and heterobimetallic iron−chromium[9] and manganese−chromium[10] complexes of type **V** have been obtained. The spectroscopic and structural properties of the latter are clearly indicative of sesquifulvalene ligands coordinated in a dipolar μ-η^5:η^7 fashion (resonance structure **VA**, Scheme 1). In these complexes, the cyclopentadienyl and cycloheptatrienyl frag-

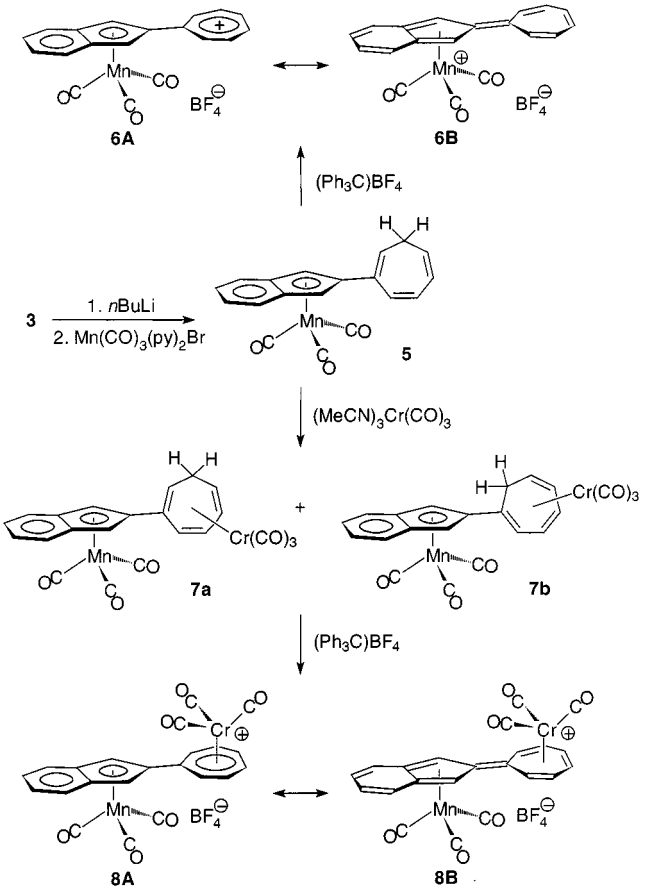
ments act as strongly coupled electron-donating and -accepting groups, respectively, and thus together meet the requirements for the classical construction of compounds with large SHG (second harmonic generation) efficiencies.[11] Accordingly, it has been observed that sesquifulvalene complexes exhibit unusually pronounced nonlinear optical (NLO) properties, and their first molecular hyperpolarizabilities β are among the highest ever measured for organometallic NLO chromophores.[12]

In continuation of our work on transition metal complexes with dipolar cycloheptatrienyl ligands,[8−10,13] we report herein on the syntheses and properties of mono- and bimetallic complexes incorporating either the benzanellated sesquifulvalene derivative 2-(2,4,6-cycloheptatrien-1-ylidene)indene (**VI**) (complexes **6**, **8**) or the "cumulogous" sesquifulvalene [(2,4,6-cycloheptatrien-1-ylidene)ethenylidene]-cyclopentadiene (**VII**) (complexes **13**, **15**). Furthermore, an investigation of the first molecular hyperpolarizabilities of various manganese sesquifulvalene complexes using the hyper Raleigh scattering technique is presented.

Results and Discussion

Synthesis of Complexes 6 and 8

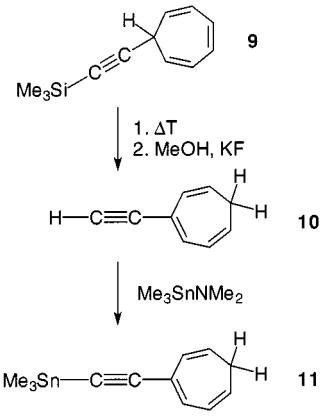
The preparation of sesquifulvalene complexes has hitherto been accomplished by template syntheses, which usually involve a C−C coupling reaction between a cyclopentadienyl complex and a cycloheptatrienyl derivative, followed by complexation of the cycloheptatrienyl unit and/or hydride abstraction.[8]−[10] This synthetic procedure is limited to cyclopentadienyl complexes that can readily be functionalized at the five-membered ring, e.g. by metallation and halogenation reactions.[14] In order to develop methods more widely applicable to the preparation of sesquifulvalene complexes, we became interested in employing dihydrosesquifulvalenes such as **3** (Scheme 2), which can be deprotonated and transferred to metal centers in the same way as ordinary cyclopentadiene derivatives.[15] In principle, dihydrosesquifulvalenes can be prepared by addition of a nucleophilic cyclopentadienyl anion to an electrophilic tropylium cation yielding 1,3,5-cycloheptatrienes bearing the Cp residue in the allylic 7-position.[16] These hydrocarbons are of limited use, however, as complexation of the seven-membered ring can lead to two different stereoisomers with *exo* and *endo* configurations, and this may hamper the ensuing hydride abstraction.[10,17] Therefore, as a suitable starting material we chose 2-trimethylstannyl-1,3,5-cycloheptatriene (**1**), which is functionalized in a vinylic rather than the allylic position, and which can be obtained directly from cycloheptatriene by metallation and subsequent reaction with Me_3SnCl.[10,18] The 1,3,5-cycloheptatrien-2-yl anion can easily be generated and used as a nucleophile by transmetallation of **1** with *n*BuLi.[13b,13c] Hence, its addition to cyclopentenones and subsequent dehydration of the resulting adducts by acidic workup should lead to appropriately substituted dihydrosesquifulvalenes.[15,19]



Scheme 2

To test the strategy outlined above, we started with 2-indanone, since the dihydrosesquifulvalene **3** was expected to be stable and isolable in isomerically pure form as a result of benzanellation in the 4,5-positions (Scheme 2). The alcohol **2**, however, could only be isolated in 26% yield from the reaction of 2-indanone with RLi (R = 1,3,5-cycloheptatrienyl-2-yl). Evidently, the lithium complex not only acts as a nucleophile towards the ketone, but the desired addition to the carbonyl group is accompanied by significant simple deprotonation.[20] As organocerium compounds generally exhibit higher nucleophilicity and reduced basicity compared to organolithium compounds,[21] the undesired formation of the enolate anion could be suppressed to some extent by employing $RCeCl_2$ (R = 1,3,5-cycloheptatrienyl-2-yl), although the yield still remained quite low (40%). Dehydration of **2** was then achieved by refluxing in benzene in the presence of a catalytic amount of *p*-toluenesulfonic acid using a water trap; subsequent chromatographic separation afforded **3** as a crystalline white solid.[22]

To improve the poor overall yield of **3** (10−20% based on 2-indanone), an alternative route involving a Stille coupling reaction[23] between the triflate **4** and the stannane **1** was used (Scheme 2).[24] Triflate **4** was prepared by deprotonation of 2-indanone with lithium diisopropylamide (LDA) and subsequent reaction of the intermediate enolate with bis(trifluoromethanesulfonato)phenylamine (Tf_2NPh).[25] Stille coupling with a catalytic amount of $Pd(PPh_3)_4$ afforded **3** in at least moderate yield (60% based on **1**, 45% based on 2-indanone). The dihydrosesquifulvalene **3** proved to be indefinitely stable at 0 °C under argon, but was found to slowly decompose in solution over a period of several hours with the deposition of a precipitate. All resonances in the ^1H and ^{13}C NMR spectra could unambiguously be assigned by means of correlated two-dimensional NMR spectroscopy ($^1H,^1H$ and $^1H,^{13}C$ COSY).



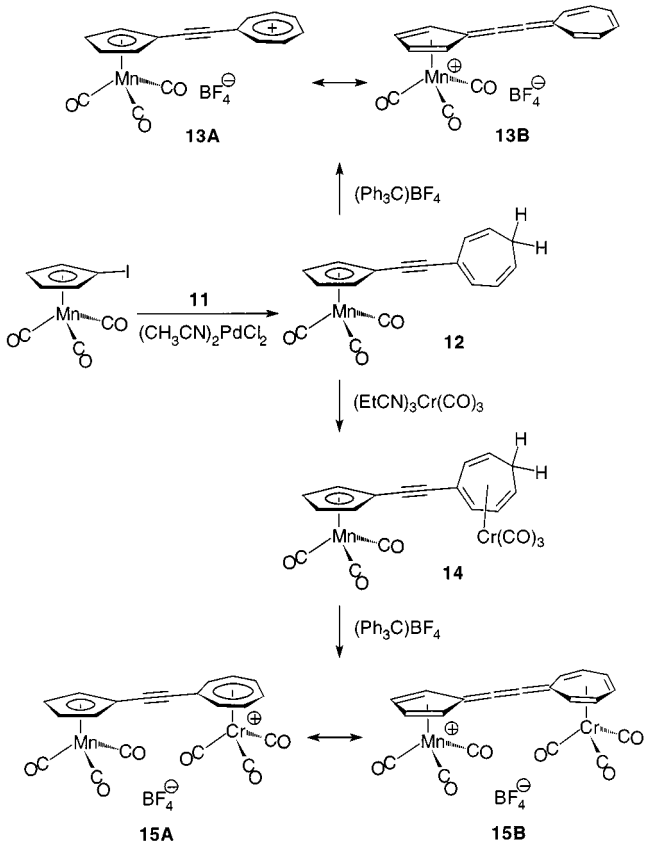
Compound **3** could then be used for the preparation of cycloheptatrienyl-substituted indenyl complexes. In order to assess the influence of benzanellation on the electronic and

Scheme 3

optical properties of sesquifulvalene complexes derived from **3**, complexes **6** and **8** were prepared and compared with the known parent compounds **16** and **17** (Figure 3, vide infra). Treatment of **3** with *n*BuLi followed by $Mn(CO)_3(pyridine)_2Br$[19b,26] produced the cymantrene derivative **5** (Scheme 3). Hydride abstraction at this stage using triphenylcarbenium tetrafluoroborate, $(Ph_3C)BF_4$, led to the monometallic benzosesquifulvalene complex **6**, which could be quantitatively isolated in the form of red-brown crystals. Alternatively, reaction of **5** with $(MeCN)_3Cr(CO)_3$ in refluxing THF gave a mixture of the two bimetallic isomers **7a** and **7b** (**7a**:**7b** ≈ 60:40, Scheme 3). Comparison with the spectroscopic data of related complexes[10] revealed that in **7a** the $Cr(CO)_3$ group is coordinated to a 1,3,5-cycloheptatrien-2-yl ring as expected, whereas **7b** contains a 1,3,5-cycloheptatrien-1-yl ring. The formation of **7b** must have resulted from thermal rearrangement of the coordinated cycloheptatrienyl ring in **7a** through a 1,5-sigmatropic hydrogen migration.[17,27] As both complexes are racemic mixtures of two enantiomers, six resonances are observed for the diastereotopic indenyl protons of each isomer.

Nevertheless, **7a** and **7b** are equally useful for the synthesis of the bimetallic sesquifulvalene complex **8** as the *exo* hydrogen atom in both isomers is easily accessible for hydride abstraction. Indeed, **8** was formed quantitatively upon treatment with $(Ph_3C)BF_4$ and could be isolated in the form of orange-brown crystals.

Scheme 4



Synthesis of Complexes 13 and 15

The monometallic complex **13** has previously been obtained from the reaction of $[\eta^5\text{-}(LiC{\equiv}CC_5H_4)Mn(CO)_3]$ with tropylium salts, followed by hydride abstraction.[8a] However, the complexation of the intermediate 1,3,5-cycloheptatrien-7-yl derivative could again lead to an isomeric mixture of *exo* and *endo* isomers, which would hamper the required reaction with the trityl cation (vide supra). In order to obtain suitably functionalized ethynylcycloheptatriene derivatives that would allow a high-yielding synthesis of **15**, we followed a route involving the stannane **11** (Scheme 4). 7-Trimethylsilylethynyl-1,3,5-cycloheptatriene (**9**) was found to undergo thermal rearrangement in DMF at 135 °C.[28] Desilylation in methanol in the presence of a catalytic amount of KF[29] followed by distillation yielded a mixture of isomeric hydrocarbons composed almost entirely of 3-ethynyl-1,3,5-cycloheptatriene (**10**) formed by just one 1,5-hydrogen shift. Further hydrogen migrations led to the formation of cycloheptatrienes substituted in the 1- and 2-positions. Treatment of **10** with Me_3SnNMe_2 gave **11**, which could then be used in Stille coupling reactions.

Thus, the Pd-catalyzed reaction of **11** with iodocymantrene, $[\eta^5\text{-}(C_5H_4I)Mn(CO)_3]$,[14a,14b] in DMF afforded a yellow oil, which crystallized on standing at 4 °C for a couple of days (Scheme 5). At this stage, the 1,3,5-cycloheptatrien-3-yl derivative **12** was the only isomer detectable by NMR spectroscopy. As expected, hydride abstraction gave the known monometallic sesquifulvalene complex **13**,[8b] whereas reaction with $(EtCN)_3Cr(CO)_3$ at room temperature produced bimetallic **14**. As the two sides of the seven-membered ring in **13** are enantiotopic, **14** forms a racemic mixture of two enantiomers and its ^{13}C NMR spectrum features five cyclopentadienyl resonances due to the diastereotopic carbon atoms. The allylic *exo* hydrogen atom in **14** is again easily accessible to the trityl cation and **15** can be isolated in quantitative yield as yellow-orange crystals following treatment with $(Ph_3C)BF_4$.

Structural Characterization of Sesquifulvalene Complexes 8 and 15

The molecular structure of the cation in **8** is depicted in Figure 1. The five- and seven-membered rings are almost

Scheme 5

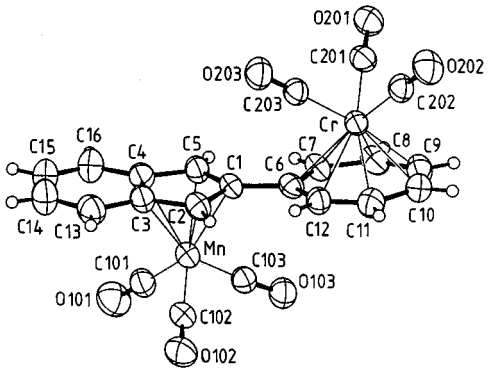


Figure 1. ORTEP drawing of the cation in **8**; selected bond lengths [Å] and angles [°]: Mn−C1 2.110(8), Mn−C2 2.125(11), Mn−C3 2.207(11), Mn−C4 2.236(10), Mn−C5 2.151(10), C1−C2 1.433(12), C2−C3 1.440(14), C3−C4 1.41(2), C4−C5 1.436(13), C5−C1 1.432(12), C1−C6 1.489(12), C6−C7 1.391(12), C7−C8 1.422(14), C8−C9 1.38(2), C9−C10 1.40(2), C10−C11 1.45(2), C11−C12 1.321(14), C12−C6 1.440(13), Cr−C6 2.277(9), Cr−C7 2.222(9), Cr−C8 2.210(10), Cr−C9 2.224(11), Cr−C10 2.206(11), Cr−C11 2.219(11), Cr−C12 2.215(10); (C1−5)(C6−12) 4.6(6)°

perfectly coplanar [dihedral angle of 4.6(6)°]. The ligand coordinates to the $Mn(CO)_3$ and $Cr(CO)_3$ fragments in η^5 and η^7 modes, respectively, and the fragments adopt an *anti*-facial arrangement. Unfortunately, due to the high absorption coefficient (see Experimental Section), the structure could only be refined with reduced accuracy, thus preventing a very detailed discussion of the bonding geometry. Nevertheless, the inter-ring bond length in **8** [C1−C6 = 1.489(12) Å] clearly corresponds to a $C(sp^2)-C(sp^2)$ single

Figure 2. bond, and hence the solid-state structure of **8** is evidently that of an indenyl-cycloheptatrienyl complex and is best described by canonical form **8A** in Scheme 4. However, a minor contribution from resonance form **8B** could be deduced from the observation that the bonding between the seven-membered ring and the $Cr(CO)_3$ moiety is slightly distorted towards a fulvene-type coordination geometry, the Cr−C6 bond length [2.277(9) Å] being significantly longer than the remaining Cr−C distances [average 2.216(10) Å].

In **15**, the asymmetric unit contains two independent molecules with both cations adopting a *syn*-facial conformation. The molecular structure of one cation is shown in Figure 2. The two cations differ slightly in the relative orientations of their *cyclo*-C_5 and *cyclo*-C_7 units, the relevant dihedral angles being 5.4(4)° and 17.2(4)°. Within experimental error, the bond lengths and angles in the two molecules are almost identical and correspond to a solid-state structure best described by canonical form **15A** in Scheme 5. For instance, the C(sp)−C(sp) bonds are clearly triple bonds [C113−C114 = 1.189(4) Å and C213−C214 = 1.186(4) Å]. Furthermore, the intra-ring bond lengths do not alternate significantly, as befits aromatic cyclopentadienyl and cycloheptatrienyl units.

Spectroscopic Properties of Sesquifulvalene Derivatives

The NMR spectroscopic data of the mono- and bimetallic complexes **6**, **8**, **13**, and **15** confirm that complexation of the sesquifulvalene derivatives leads to charge separation within the ligands and to dipolar coordination of the respective hydrocarbon. Accordingly, low-field resonances at $\delta \approx 9$ are observed for the cycloheptatrienyl protons in monometallic **6** and **13**, which fall in the expected range for tropylium cations of the type $(C_7H_6R)^+$.[30] As a result of coordination of the seven-membered rings to the $Cr(CO)_3$ moieties, these resonances are shifted to significantly higher

Table 1. UV/Vis data for complexes **6**, **8**, **13**, and **15**

Compound	λ_{max} [nm] CH_2Cl_2	CH_3CN	$\Delta\tilde{\nu}$ [cm^{-1}]
6	501	471	−1270
8	486	468	−790
13	537	491	−1740
15	449	429	−1040

field in bimetallic **8** and **15** (δ = 6.25−6.50) and are wholly consistent with the values expected for cycloheptatrienyl complexes of the type [η^7-(C_7H_6R)$Cr(CO)_3$].[17,31]

As mentioned above, the four sesquifulvalene derivatives are intensely colored compounds. They show strong solvatochromic behaviour and their UV/Vis spectra are markedly solvent-dependent, which is usually a good indication of possible NLO activity.[32] The lowest-energy band λ_{max} (Table 1) is most strongly shifted upon changing the solvent from dichloromethane to acetonitrile ($\Delta\tilde{\nu}$ ranging from −790 cm^{-1} in **8** to −1740 cm^{-1} in **13**). On the basis of these hypsochromic shifts (negative solvatochromic behaviour), the lowest-energy transition in these systems can be assigned to a π to π^* CT transition,[33] which is APPROXIMATELY (!) represented by the canonical forms **A** (ground state) and **B** (excited state) shown in Scheme 3 for **6** and **8** and in Scheme 5 for **13** and **15**.

The bimetallic derivatives **8** and **15** absorb at higher energy than the corresponding monometallic complexes **6** and **13**, and λ_{max} is hypsochromically shifted upon complexation of the seven-membered ring. This observation implies that interaction of the $Cr(CO)_3$ group with the cycloheptatrienyl unit increases the HOMO/LUMO energy gap of the relevant π to π^* CT excitation. In other words, the [(C_7H_6R)$Cr(CO)_3$] moiety has a stronger ability to effectively stabilize a positive charge than the "naked" tropylium system, which leads to an increase in the energy difference between the two limiting resonance structures **A** and **B** (Schemes 3 and 5).

Nonlinear Optical Properties of Sesquifulvalene Derivatives

It has been demonstrated that sesquifulvalene complexes are among the most promising organometallic candidates for nonlinear optical applications.[9] Consequently, we have measured the first molecular hyperpolarizabilities β of selected monometallic manganese and bimetallic manganese−chromium sesquifulvalene complexes (Figure 3) using the hyper Raleigh scattering technique (HRS), which allows determination of β in solution even for ionic compounds.[34] Here, HRS experiments were performed with an Nd:YAG laser (λ = 1064 nm). The intensity of the frequency-doubled scattered light ($\lambda/2$ = 532 nm) was measured as a function of the concentration of the NLO chromophore. The results are shown in Table 2.

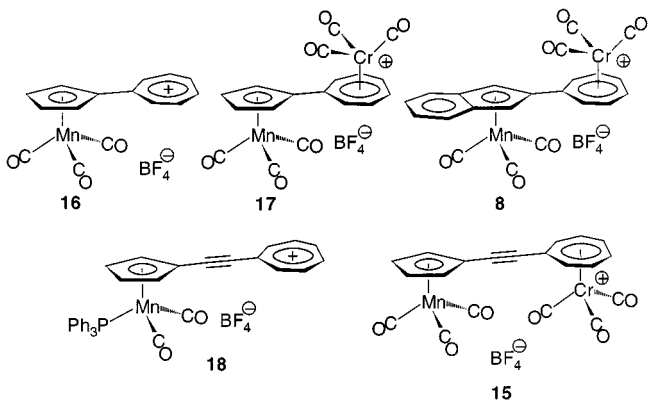

Figure 3. Sesquifulvalene complexes studied by hyper Raleigh scattering

Table 2. UV/Vis and NLO data for selected sesquifulvalene complexes

Compound	Solvent[a]	λ_{max}, nm	β, 10^{-30} esu[b]	β_0, 10^{-30} esu[b][c]
8	CH_3NO_2	435	112	31
15	CH_2Cl_2	449	244	58
16	CH_3NO_2	510	240	15
17	CH_3NO_2	445	77	19
18	CH_2Cl_2	751	226	113

[a] Solutions of *p*-nitroaniline as external reference [$\beta(CH_2Cl_2)$ = 21.6 × 10^{-30} esu, $\beta(CH_3NO_2)$ = 34.6 × 10^{-30} esu]. − [b] β-values in electrostatic units (esu) of the CGS systems (Gaussian system); [β_{CGS}] = cm^4/statV = esu; [β_{SI}] = Cm^3/V^2 = C^3m^3/J^2; β_{SI} = $(1/3)^3$ × 10^{-19} β_{CGS} (see ref.[12a]). − [c] β_0 = β [(1 − $4\lambda_{max}^2/\lambda^2$) (1 − $\lambda_{max}^2/\lambda^2$)] with λ = 1064 nm (Nd:YAG laser) (see refs.[34a,35]).

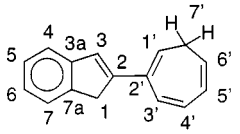
The β values in Table 2 are unusually large owing to resonance enhancement, which occurs when the frequency of the charge-transfer excitation is close to the frequency of the stimulating laser or close to the doubled frequency. Therefore, extrapolation of the dynamic hyperpolarizabilities β to their static counterparts β_0 was accomplished by means of the two-level model (Table 2).[34a,35] The first molecular hyperpolarizabilities presented here are very high compared to those of organic[11,36] or organometallic[12] compounds with chromophores of similar lengths. Comparison of the nonlinear optical efficiency of bimetallic **15** with that of the related ferrocene derivative [(C_5H_5)Fe(μ-η^5:η^7-C_5H_4−C≡C−C_7H_6)$Cr(CO)_3$]BF_4 (β_0 = 105 × 10^{-30} esu)[9] shows that the ferrocene moiety is superior to the cymantrene unit, (C_5H_4R)$Mn(CO)_3$, probably due to its stronger electron-donating ability. However, the electronic and optical properties of these manganese complexes can be easily and efficiently tuned by ligand substitution reactions,[8b] and the introduction of a phosphane ligand to give monometallic **18** results in extraordinary frequency-doubling characteristics. Furthermore, this protocol could be extended to the introduction of readily available chiral phosphanes leading to optically active compounds that can be expected to crystallize in noncentrosymmetric space groups, thereby fulfilling a crucial requirement for the observation of macroscopic NLO effects.[11,12]

Conclusion

In summary, we have presented new methods for the syntheses of sesquifulvalene complexes that can be considered

as widely applicable for the preparation of various other bimetallic complexes. In particular, use of the appropriately substituted cycloheptatrienyl derivatives **3** and **11** circumvents the *exo*/*endo* problem encountered with the 1,3,5-cycloheptatrien-7-yl derivatives and facilitates high-yielding syntheses. Finally, the first hyperpolarizabilities determined for various manganese sesquifulvalene complexes confirm the suitability of such complexes for nonlinear optical applications.

Experimental Section



General: All operations were performed under an atmosphere of dry argon by using Schlenk and vacuum techniques. Solvents were dried by standard methods and distilled prior to use. The following compounds were prepared as described in the literature: $Mn(CO)_3(pyridine)_2Br$,[26] $(C_5H_4I)Mn(CO)_3$,[14a] $(CH_3CN)_3Cr(CO)_3$,[37] $(CH_3CH_2CN)_3Cr(CO)_3$,[38] 2-trimethylstannyl-1,3,5-cycloheptatriene (**1**).[10] The synthesis of **13** has been published previously.[8a] Complete assignment of all resonances in **3** and **10** was achieved with the aid of two-dimensional NMR spectroscopy ($^1H,^1H$ and $^1H,^{13}C$ COSY experiments).

2-(1,3,5-Cycloheptatrien-2-yl)indan-2-ol (2). − Method A: A solution of **1** (1.59 g, 6.24 mmol) in THF (30 mL) was treated with *n*-butyllithium (2.5 mL of a 2.5 M solution in hexane, 6.3 mmol) at −78 °C. After stirring for 45 min, a solution of 2-indanone (0.79 g, 5.98 mmol) in THF (15 mL) was added. The reaction mixture was then allowed to warm to room temperature and stirring was continued for 12 h. Quenching with aqueous HCl (24%, 2 mL) and ice (6 g) resulted in the formation of **2**. After 30 min, the reaction mixture was made alkaline with aqueous ammonia solution (3.5%) and then diluted with brine (20 mL). It was then extracted with diethyl ether (3 × 20 mL) and the combined extracts were dried over Na_2SO_4 and concentrated. Chromatography of the residue on alumina (4% H_2O) eluting with dichloromethane gave **2** as a white solid. Yield: 0.35 g (26%).

Method B: At −78 °C, a suspension of $CeCl_3$ (2.88 g, 11.68 mmol) in THF (35 mL) was added to a solution containing the 1,3,5-cycloheptatrien-2-yl anion, which had been generated from a solution of **1** (2.54 g, 9.96 mmol) in THF (50 mL) and *n*-butyllithium (4.0 mL of a 2.5 M solution in hexane, 10.0 mmol) as described above (Method A). After stirring for 30 min, a solution of 2-indanone (1.19 g, 9.00 mmol) in THF (9 mL) was added dropwise and stirring was continued for 15 h at −74 °C. The reaction mixture was then allowed to warm to room temperature, whereupon TMEDA (ca. 2.6 mL) was added. After 30 min, the reaction mixture was quenched with aqueous $NaHCO_3$ and diluted with brine. Extraction with dichloromethane (3 × 100 mL), drying of the combined extracts with Na_2SO_4, and evaporation of the solvent afforded **2**, which could be purified chromatographically as described above. Yield: 0.81 g (40%). − ^1H NMR ($CDCl_3$, 400 MHz): δ = 7.32−7.22 (m, 4 H, C_6H_4), 6.83 (d, 1 H, C_7 ring: CH), 6.65 (dd, 1 H, C_7 ring: CH), 6.15 (dd, 1 H, C_7 ring: CH), 5.63 (t, 1 H, C_7 ring: CH), 5.54 (dt, 1 H, C_7 ring: CH), 3.36 (d, 2 H, C_5 ring: CH_2), 3.06 (d, 2 H, C_5 ring: CH_2), 2.26 (t, 2 H, C_7 ring: CH_2); no OH resonance could be observed.

2-(1,3,5-Cycloheptatrien-2-yl)indene (3). − Method A: A solution of **2** (1.75 g, 7.80 mmol) in benzene (30 mL) was treated with a catalytic amount of *p*-toluenesulfonic acid and refluxed for 12 h in an apparatus fitted with a water trap. After removal of the solvent in vacuo, the crude product was purified by chromatography on silica (4% H_2O) using petroleum ether/dichloromethane (3:1) as eluent to afford **3** as a white crystalline solid. Yield: 0.60 g (37%).

Method B: At room temperature, a suspension of lithium chloride (2.41 g, 56.85 mmol) and $Pd(PPh_3)_4$ (0.18 g, 0.16 mmol) in THF (20 mL) was treated with a solution of **4** (2.05 g, 7.76 mmol) in THF (20 mL). After stirring for 15 min, a solution of stannane **1** (1.97 g, 7.73 mmol) in THF (20 mL) was added and the resulting mixture was refluxed for 16 h. The dark-green solution thus obtained was then diluted with pentane (200 mL) and treated with aqueous ammonia solution (10%, 3 × 75 mL). The organic layer was separated, dried with Na_2SO_4, and the solvent was removed in vacuo. Crude **3** (Figure 4) could be purified chromatographically as described above. Yield: 0.98 g (61%); m.p. 92 °C. − ^1H NMR ($CDCl_3$, 400 MHz): δ = 7.37 (d, *J* = 6 Hz, 1 H, 7-H), 7.29 (d, *J* = 6 Hz, 1 H, 4-H), 7.22 (dd, *J* = 6 Hz, 6 Hz, 1 H, 6-H), 7.13 (dd, *J* = 6 Hz, 6 Hz, 1 H, 5-H), 7.07 (d, *J* = 9 Hz, 1 H, 3′-H), 6.78 (s, 1 H, 3-H), 6.69 (dd, *J* = 9 Hz, 5 Hz, 1 H, 4′-H), 6.18 (dd, *J* = 6 Hz, 5 Hz, 1 H, 5′-H), 5.74 (t, *J* = 8 Hz, 1 H, 1′-H), 5.60 (td, *J* = 8 Hz, 6 Hz, 1 H, 6′-H), 3.56 (s, 2 H, 1-H), 2.35 (t, *J* = 8 Hz, 2 H, 7′-H). − ^{13}C NMR ($CDCl_3$, 100.4 MHz): δ = 146.6 (C-7a), 145.5 (C-3a), 142.7 (C-2), 134.4 (C-2′), 131.5 (C-4′), 130.1 (C-3′), 127.0 (C-3), 126.9 (C-5′), 126.4 (C-6), 124.5 (C-5), 123.7 (C-6′), 123.4 (C-7), 120.7 (C-4), 119.7 (C-1′), 39.1 (C-1), 27.7 (C-7′). − MS (EI); *m*/*z* (%): 206 (100) [M^+], 191 (43) [$M - CH_3]^+$, 115 (26) [$M - C_7H_7]^+$, 91 (76) [$M - C_9H_7]^+$, 65 (5) [$M - C_9H_7 - C_2H_2]^+$. − $C_{16}H_{14}$ (206.3): calcd. C 93.16, H 6.84; found C 92.01, H 6.81

Figure 4. Numbering scheme for **3**

1*H*-Inden-2-yl Trifluoromethanesulfonate (4): A solution of diisopropylamine (2.1 mL, 15.0 mmol) in THF (15 mL) was treated with *n*-butyllithium (5.3 mL of a 2.5 M solution in hexane, 13.3 mmol) at −78 °C and the resulting mixture was allowed to warm to room temperature. The LDA solution thus obtained was then cooled to −78 °C once more, whereupon a solution of 2-indanone (1.39 g, 10.52 mmol) in THF (11 mL) was added. After 15 min at −78 °C, stirring was continued for 2 h at ambient temperature. The enolate solution was then treated with a solution of *N*,*N*-bis(trifluoromethanesulfonyl)aniline (4.20 g, 11.76 mmol) in THF (25 mL) at −78 °C and the resulting mixture was stirred at room temperature for 10 h. It was then diluted with aqueous NH_4Cl solution (20 mL) and extracted with diethyl ether (3 × 40 mL). After removal of the solvent from the combined extracts, the oily residue was purified by column chromatography on silica (4% H_2O) using petroleum ether/dichloromethane (5:1) as eluent to afford the sulfonate **4** as a yellow oil, which was dried in vacuo. Yield: 2.05 g (74%). − ^1H NMR ($CDCl_3$, 250 MHz): δ = 7.42−7.24 (m, 4 H, C_6H_4), 6.70 (s, 1 H, 1-H), 3.68 (s, 2 H, 3-H).

Manganese Complex 5: At −50 °C, a solution of **3** (0.98 g, 4.75 mmol) in THF (40 mL) was treated with *n*-butyllithium (2.0 mL of a 2.5 M solution in hexane, 5.0 mmol). After stirring for 60 min, a solution of $Mn(pyridine)_2(CO)_3Br$ (2.10 g, 5.57 mmol) in THF (60 mL) was added dropwise and the resulting mixture was refluxed for 3 h. Removal of the solvent in vacuo and purification of the residue by column chromatography on alumina (4% H_2O)

eluting with petroleum ether/dichloromethane (5:1) afforded **5** as a yellow crystalline solid. Yield: 1.04 g (64%); m.p. 41 °C. − ^{1}H NMR ($CDCl_3$, 400 MHz): δ = 7.44 (d, 2 H, C_6 ring: CH), 7.09−7.07 (m, 3 H, C_6 ring: CH + C_7 ring: CH), 6.74 (s, 2 H, C_5 ring: CH), 6.23−6.19 (m, 2 H, C_7 ring: CH), 5.73 (t, 1 H, C_7 ring: CH), 5.54 (dt, 1 H, C_7 ring: CH), 2.40 (t, 2 H, CH_2). − ^{13}C NMR ($CDCl_3$, 100.4 MHz): δ = 224.9 (Mn−CO), 132.7 (C_7 ring: CH), 130.5 (C_7 ring: C-2), 129.3, 127.0 (C_7 ring: CH), 126.4, 125.2 (C_6 ring: CH), 122.9, 119.1 (C_7 ring: CH), 108.9 (C_5 ring: C-1), 103.1 ($C_{5/6}$ ring: C), 69.9 (C_5 ring: CH), 27.5 (CH_2). − MS (EI); *m*/*z* (%): 344 (11) [M^+], 316 (4) [M − CO]$^+$, 288 (5) [M − 2CO]$^+$, 260 (64) [M − 3CO]$^+$, 205 (100) [M − 3CO − Mn]$^+$, 191 (28) [M − 3CO − Mn − CH_2]$^+$, 178 (7) [M − 3CO − Mn − H − C_2H_2]$^+$. − IR (KBr): ν (CO) = 2010, 1935, 1914 cm^{-1}. − $C_{19}H_{13}MnO_3$ (344.3): calcd. X-ray Crystal Structure Analysis of 8:[39] $C_{22}H_{12}BCrF_4MnO_6$, M_r = 566.1, dark brown crystal, dimensions 0.65 × 0.25 × 0.20 mm, *a* = 16.486(3) Å, *b* = 7.992(1) Å, *c* = 17.548(5) Å, β = 102.60(2)°, *V* = 2256.4(8) Å^3, $\rho_{calcd.}$ = 1.666 g cm^{-3}, *F*(000) = 1128 e, μ = 9.173 mm^{-1}, no absorption correction applied, *Z* = 4, monoclinic, space group $P2_1/a$ (No. 14), λ = 1.54176 Å, *T* = 293 K, ω scans, 2850 reflections collected in the θ range between 2.58 and 59.94° (−18 ≤ *h* ≤ 17, 0 ≤ *k* ≤ 8, 0 ≤ *l* ≤ 19), 2834 observed reflections [$I \geq 2\sigma(I)$], 320 refined parameters, R = 0.0962, wR^2 = 0.2516, max. residual electron density 0.926 (−0.463) e Å^{-3}. Data were collected with an Enraf−Nonius Turbo-CAD4 diffractometer equipped with a rotating anode generator. Structure solution with SHELXS-86, structure refinement with SHELXL-93, graphics with ORTEP.

7-(Trimethylsilylethynyl)-1,3,5-cycloheptatriene (9): A solution of trimethylsilylacetylene (3.04 g, 30.0 mmol) in THF (10 mL) was treated with *n*-butyllithium (12.4 mL, 2.5 M solution in hexane, 31.0 mmol) at −40 °C. After stirring for 30 min at ambient temperature, the acetylide solution was added to a suspension of $(C_7H_7)BF_4$ (5.0 g, 28.1 mmol) in THF (100 mL) at −40 °C. The reaction mixture was stirred for 1 h at this temperature and then allowed to warm to room temperature, whereupon saturated NH_4Cl solution (100 mL) was added. The resulting mixture was extracted with diethyl ether (3 × 50 mL) and the combined extracts were dried over $MgSO_4$. Evaporation of the solvent and distillation of the residue at 0.07 mbar and 50−52 °C afforded **9** as a clear, yellowish oil. Yield: 4.36 g (82%). − ^{1}H NMR ($CDCl_3$, 200 MHz): δ = 6.63 (m, 2 H, 3,4-H), 6.18 (m, 2 H, 2,5-H), 5.33 (dd, 2 H, 1,6-H), 2.50 (tt, 1 H, 7-H), 0.20 (s, 9 H, $SiCH_3$). − ^{13}C NMR ($CDCl_3$, 50.3 MHz): δ = 130.9 (C-3,4), 124.6 (C-2,5), 123.0 (C-1,6), 108.0 (*C*≡C−$SiMe_3$), 84.5 (C≡*C*−$SiMe_3$), 32.6 (C-7), 0.1 ($SiCH_3$).

3-Ethynyl-1,3,5-cycloheptatriene (10): A solution of **9** (4.0 g, 21.2 mmol) in DMF (40 mL) was heated to 150 °C for 3 h. After evaporation of the solvent, the dark-brown concentrated reaction mixture was taken up in methanol and treated with a catalytic amount of KF (50 mg). The resulting mixture was stirred for 3 days at room temperature, then cooled to 0 °C, whereupon the product was separated by adding saturated NH_4Cl solution (60 mL). Extraction with diethyl ether (3 × 10 mL), drying of the combined extracts over $MgSO_4$, and careful removal of the solvent in vacuo afforded crude **10**, which could be obtained as a colorless liquid by distillation at 15 mbar. Yield: 1.52 g (62%). − ^{1}H NMR ($CDCl_3$, 400 MHz): δ = 6.95 (d, *J* = 6 Hz, 1 H, 4-H), 6.19 (d, *J* = 9 Hz, 1 H, 2-H), 6.17 (dd, *J* = 9 Hz, 6 Hz, 1 H, 5-H), 5.51 (dt, *J* = 9 Hz, 7 Hz, 1 H, 6-H), 5.39 (dt, *J* = 9 Hz, 7 Hz, 1 H, 1-H), 3.02 (s, 1 H, C≡CH), 2.28 (dd, *J* = 7 Hz, 7 Hz, 2 H, CH_2). − ^{13}C NMR ($CDCl_3$, 100.4 MHz): δ = 137.1 (C-4), 128.2 (C-2), 126.3 (C-5), 124.4 (C-3), 124.0 (C-6), 121.8 (C-1), 85.4 (*C*≡CH), 77.1 (C≡*C*H), 27.6 (C-7). − MS (EI); *m*/*z* (%): 116 (41) [M^+], 115 (100) [M − H]$^+$.

3-(Trimethylstannylethynyl)-1,3,5-cycloheptatriene (11): Me_3SnNMe_2 (1.8 g, 8.6 mmol) was added to **10** (1.0 g, 8.6 mmol) and the reaction mixture was stirred without a solvent for 5 min at ambient temperature. After evaporation of the Me_2NH formed, **11** was isolated in quantitative yield as a yellow-orange oil, which was suffi-

ciently pure for use in further reactions. – ^{1}H NMR ($CDCl_3$, 200 MHz): δ = 6.91 (d, 1 H, CH), 6.16 (d + dd, 2 H, CH), 5.44 (m, 2 H, CH), 2.28 (t, 2 H, CH_2), 0.31 ($SnCH_3$). – ^{13}C NMR ($CDCl_3$, 50.3 MHz): δ = 136.3, 128.5, 126.4 (CH), 125.7 (Sn−C≡C−*C*), 123.6, 121.8 (CH), 110.6, 93.3 (C≡C), 27.6 (CH_2), −7.7 ($SnCH_3$).

Manganese Complex 12: $(C_5H_4I)Mn(CO)_3$ (2.44 g, 7.39 mmol) and **11** (1.80 g, 6.45 mmol) were dissolved in DMF (50 mL) and $Pd(CH_3CN)_2Cl_2$ (60 mg) was added. The solution turned brown and stirring was continued for 12 h at room temperature. After the addition of diethyl ether (50 mL) followed by a solution of KF (750 mg) in water (25 mL), the mixture was stirred for 1 h while argon was bubbled through it. The organic phase was then separated and washed with water (3 × 100 mL). The combined aqueous phases were extracted with diethyl ether (2 × 50 mL) and the ethereal extracts were dried over $MgSO_4$. After removal of the solvent in vacuo, the crude product was purified by chromatography on silica (4% H_2O) eluting with petroleum ether/CH_2Cl_2 (10:1). Evaporation of the solvent from the appropriate fraction afforded **12** as a yellow oil, which solidified on storage in a refrigerator at 4 °C. Yield: 2.05 g (87%). – ^{1}H NMR ($CDCl_3$, 200 MHz): δ = 6.91 (d, 1 H, C_7 ring: CH), 6.18 (m, 2 H, C_7 ring: CH), 5.46 (m, 2 H, C_7 ring: CH), 5.00 (br. s, 2 H, C_5 ring: CH), 4.69 (br. s, 2 H, C_5 ring: CH), 2.31 (t, 2 H, CH_2). – ^{13}C NMR ($CDCl_3$, 50.3 MHz): δ = 224.3 (Mn−CO), 136.7, 127.8, 126.3 (C_7 ring: CH), 124.5 (C_7 ring: C-3), 124.1, 122.0 (C_7 ring: CH), 90.5 (C_5 ring: C-1), 86.0 (C_5 ring: CH), 83.1 (C≡C), 82.0 (C_5 ring: CH), 81.4 (C≡C), 27.6 (CH_2). – MS (EI); *m*/*z* (%): 318 (84) [M^+], 262 (71) [M − 2CO]$^+$, 234 (100) [M − 3CO]$^+$, 179 (62) [M − 3CO − Mn]$^+$. – IR(KBr): $\tilde{\nu}$ = 2222 (C≡C), 2021, 1932 (CO) cm^{-1}. – $C_{17}H_{11}MnO_3$ (318.2): calcd. C 64.17, H 3.48; found C 64.10, H 3.77.

Manganese−Chromium Complex 14: To a solution of **12** (1.0 g, 3.1 mmol) in THF (20 mL) was added $(CH_3CH_2CN)_3Cr(CO)_3$ (1.1 g, 3.8 mmol) as a solid. The mixture was stirred at ambient temperature for 3 days. After removal of the solvent in vacuo, the crude product was purified by chromatography on silica (4% H_2O) eluting with petroleum ether/CH_2Cl_2 (3:1). Evaporation of the solvent afforded **14** as an orange-red crystalline solid. Yield: 770 mg (55%). – ^{1}H NMR ($CDCl_3$, 200 MHz): δ = 6.29 (d, 1 H, C_7 ring: CH), 5.09 (s, 2 H, C_5 ring: CH), 5.00 (d, 1 H, C_7 ring: CH), 4.83 (t, 1 H, C_7 ring: CH), 4.74 (s, 2 H, C_5 ring: CH), 3.39 (m, 2 H, C_7 ring: CH), 2.95 (m, 1 H, 7-*endo*-H), 1.83 (dm, 1 H, 7-*exo*-H). – ^{13}C NMR ($CDCl_3$, 50.3 MHz): δ = 231.2 (Cr−CO), 224.1 (Mn−CO), 103.9, 100.7, 99.2 (C_7 ring: CH), 94.9 (C_7 ring: C-3), 89.5 (C_5 ring: C-1), 86.8, 86.6, 82.3, 82.2 (C_5 ring: diastereotopic CH), 81.1, 78.4 (C≡C), 57.5, 56.7 (C_7 ring: CH), 23.9 (CH_2). – MS (EI): *m*/*z* (%) = 454 (3) [M^+], 398 (3) [M − 2CO]$^+$, 370 (8) [M − 3CO]$^+$, 314 (6) [M − 5CO]$^+$, 286 (19) [M − 6CO]$^+$, 234 (27) [M − 6CO − Cr]$^+$, 179 (35) [M − 6CO − Mn − Cr]$^+$, 52 (100) Cr^+. – IR (KBr): ν (CO) = 2023, 1955, 1925, 1890 cm^{-1}. – $C_{20}H_{11}CrMnO_6$ (454.2): calcd. C 52.88, H 2.44; found C 52.06, H 2.65.

Manganese−Chromium Complex 15: A solution of **14** (0.50 g, 1.10 mmol) in dichloromethane (15 mL) was added dropwise to a stirred solution of $(Ph_3C)BF_4$ (0.33 g, 1.00 mmol) in dichloromethane (5 mL) at 0 °C. The resulting mixture was allowed to warm to room temperature and stirring was continued for 2 h. The reaction mixture was then poured into rapidly stirred diethyl ether (100 mL), which led to the precipitation of **15** as a dark-yellow, crystalline solid. Crystallization from dichloromethane afforded **15**·CH_2Cl_2 as red crystals. Yield: 535 mg (90%). – ^{1}H NMR (CD_2Cl_2, 200 MHz): δ = 6.76 (m, 2 H, C_7 ring: CH), 6.64 (m, 2 H, C_7 ring: CH), 6.49 (d, 2 H, C_7 ring: CH), 5.31 (m, 2 H, C_5 ring: CH), 4.88 (m, 2 H, C_5 ring: CH). – ^{13}C NMR (CD_2Cl_2, 50.3 MHz): δ = 224.2 (Cr−CO), 219.7 (Mn−CO), 107.1 (C_7 ring: C-1), 105.2 (C_7 ring: CH), 104.8 (C_7 ring: CH), 104.2 (C_7 ring: CH), 91.8 (C_5 ring: C-1), 89.6 (C_5 ring: CH), 85.4 (C≡C), 83.8 (C_5 ring: CH), 75.6 (C≡C). – MS (ESI): *m*/*z* (%) = 453 (100) [M^+], 369 (88) [M − 3CO]$^+$, 313 (100) [M − 5CO]$^+$, 285 (24) [M − 6CO]$^+$. – IR (KBr): $\tilde{\nu}$ = 2227 (C≡C), 2061, 2022, 1935 (CO) cm^{-1}. – UV/Vis (CH_2Cl_2): λ (lg ε) = 266 (4.24), 309 (4.18), 449 (3.74) nm. – UV/Vis (CH_3CN): λ (lg ε) = 300 (4.24), 334 (4.12), 429 (3.75) nm. – $C_{20}H_{10}BCrF_4MnO_6{\cdot}CH_2Cl_2$ (625.0): calcd. C 40.36, H 1.94; found C 39.83, H 1.82.

X-ray Crystal Structure Analysis of 15·CH_2Cl_2:[39] $C_{20}H_{10}BCrF_4MnO_6{\cdot}CH_2Cl_2$, M_r = 625.0, dark-red crystal, dimensions 0.30 × 0.15 × 0.05 mm, *a* = 20.387(1) Å, *b* = 7.354(1) Å, *c* = 32.882(1) Å, β = 96.12(1)°, *V* = 4901.8(7) Å^3, $\rho_{calcd.}$ = 1.694 g cm^{-3}, *F*(000) = 2480 e, μ = 12.42 cm^{-1}, absorption correction (0.707 ≤ *T* ≤ 0.941), *Z* = 8, monoclinic, space group $P2_1/n$ (No. 14), λ = 0.71073 Å, *T* = 198 K, ω and φ scans, 30148 reflections collected (±*h*, ±*k*, ±*l*), [(sinθ)/λ] = 0.65 Å^{-1}, 11195 independent (R_{int} = 0.041) and 8158 observed reflections [$I \geq 2\sigma(I)$], 649 refined parameters, *R* = 0.052, wR^2 = 0.127, max. residual electron density 1.17 (−1.08) e Å^{-3}, hydrogens calculated and refined as riding atoms, two chemically identical molecules with different conformations in the asymmetric unit. Data were collected with a Nonius KappaCCD diffractometer equipped with a rotating anode generator. Programs used: data acquisition COLLECT, data reduction DENZO-SMN, absorption correction SORTAV, structure solution SHELXS-86, structure refinement SHELXL-97, graphics DIAMOND.

Hyper Raleigh Scattering: For the experimental set-up, see ref.[34c] As the incident light source a Nd:YAG laser with a wavelength of 1064 nm was used. All measurements were made in dry CH_2Cl_2 or CH_3NO_2 with concentrations in the range 10^{-6} to 10^{-4} M and *p*-nitroaniline (*p*-NA) as a reference [$\beta_{p\text{-NA}}(CH_2Cl_2) = 21.6 \times 10^{-30}$ esu; $\beta_{p\text{-NA}}(CH_3NO_2) = 34.6 \times 10^{-30}$ esu]. The solutions were kept in darkness to prevent decomposition by daylight and were checked by recording UV/Vis spectra. An estimate of β absorption corrections was calculated as suggested in ref.[40] All compounds were checked for nonfluorescence by using interference filters of varying peak transmittance.[41]

Acknowledgments

This work was financially supported by the Deutsche Forschungsgemeinschaft (Ta 189/1-4,5) and the Fonds der Chemischen Industrie. M. T., T. B., and K. B. are grateful to Prof. Dr. F. E. Hahn for his generous support. The excellent technical assistance of D. Beck is also gratefully acknowledged.

Dissociation Patterns of Small $Fe_mO_n^+$ (m = 1–4, $n \leq 6$) Cluster Cations Formed Upon Chemical Ionization of $Fe(CO)_5/O_2$ Mixtures

Detlef Schröder,[a] Phillip Jackson,[a] and Helmut Schwarz*[a]

Keywords: Clusters / Iron oxides / Mass spectrometry / Metal peroxides / Oxidation

The collisional activation mass spectra of cationic iron oxide clusters $Fe_mO_n^+$ (m = 1–4, $n \leq 6$) prepared by chemical ionization of $Fe(CO)_5/O_2$ mixtures show remarkable trends in the fragmentation behaviors, which can be attributed to the formal oxidation states of iron. (i) The preferential fragmentation pathways of $Fe_mO_n^+$ clusters with $m/n \geq 1$ correspond to losses of atomic oxygen as well as FeO units. (ii) For $Fe_mO_n^+$ clusters with $1 > m/n > 2/3$, losses of neutral FeO_2 begin to compete with those of O and FeO. (iii) For FeO_2^+ and the oxygen-rich clusters $Fe_2O_3^+$ and $Fe_4O_6^+$ (m/n = 2/3), losses of molecular oxygen predominate, while this channel is more or less irrelevant for the other $Fe_mO_n^+$ cations. These observations are interpreted using peroxide structures for the oxygen-rich $Fe_mO_n^+$ ions, thereby preventing the need for formal high-valent iron(IV) in these clusters.

Introduction

Ionic iron oxide clusters $Fe_mO_n^{+/-}$ can be generated by sputtering neutral iron oxide,[1,2] by seeding Smalley-type expansion sources for iron clusters with oxygen,[3–5] or by reacting cationic Fe_m^+ clusters with suitable oxidants.[6–10] As far as cations are concerned, most of these methods are restricted to metal-rich clusters with $m/n \geq 1$, i.e. clusters containing iron in formal oxidation states up to Fe^{III}. High-valent metal-oxo species that are potentially attractive as oxidants (e.g. the dinuclear Fe^{IV} oxide core of methane monooxygenase)[11,12] are usually not formed.

A viable approach for synthesizing oxygen-rich Fe/O clusters in the gas phase is by means of redox reactions, which we refer to hereafter as the chemical route to metal-oxide clusters.[6,13] Upon chemical ionization of a mixture of $Fe(CO)_5$ with an excess of oxygen, a complex sequence of reactions occurs that ultimately leads to the formation of oxygen-rich $Fe_mO_n^+$ clusters [see Equations (1) – (5)].

Ionization

$$O_2 + e \rightarrow O_2^+ + 2e \quad (1)$$

Charge transfer

$$Fe(CO)_5 + O_2^+ \rightarrow Fe(CO)_n^+ + nCO + O_2 \quad (2)$$

Clustering

$$Fe(CO)_n^+ + Fe(CO)_5 \rightarrow Fe_2(CO)_m^+ + (5 + n - m)CO \quad (3)$$

Oxidation

$$Fe_2(CO)_m^+ + O_2 \rightarrow Fe_2O(CO)_p^+ + CO_2 + (m - p - 1)CO \quad (4)$$

$$Fe_2O(CO)_p^+ + O_2 \rightarrow Fe_2O_2^+ + CO_2 + (p - 1)CO \quad (5)$$

Let us illustrate this manifold by describing a plausible route for the formation of $Fe_2O_2^+$ as an example. The sequence starts with electron ionization of O_2 as the major component of the neutral mixture [Equation (1)], followed by (dissociative) charge transfer to yield iron-carbonyl cations [Equation (2)]. These ions then undergo clustering with neutral $Fe(CO)_5$ to afford dinuclear iron-carbonyl clusters [Equation (3)],[6,14,15] followed by stepwise oxidation of the clusters by dioxygen [Equations (4) and (5)].[6,16] Side reactions lead to $Fe_2O_3^+$ and trace amounts of Fe_2O^+ (see below). Similarly, higher $Fe_mO_n^+$ clusters are accessible through this scheme, and their abundances very much depend on the $Fe(CO)_5/O_2$ mixing ratios and other ionization parameters such as overall pressure, repeller voltage etc. Under typical CI conditions, reasonably intense signals can be achieved for (i) FeO^+ and FeO_2^+, (ii) $Fe_2O_2^+$ and $Fe_2O_3^+$, (iii) $Fe_3O_3^+$ and $Fe_3O_4^+$, as well as (iv) $Fe_4O_4^+$, $Fe_4O_5^+$, and $Fe_4O_6^+$ (Table 1). More abundant Fe_2O^+ fluxes than those obtained by chemical ionization of $Fe(CO)_5/O_2$ can be achieved by electron ionization of dicyclopentadienyldinitrosyldiiron $[Cp_2Fe_2(NO)_2]$.[17]

Results and Discussion

The $Fe_mO_n^+$ cations were probed by their collisional activation (CA) mass spectra (Table 1); the results for the mononuclear species FeO^+ and FeO_2^+ are presented for comparative purposes only and are not discussed.[18] While the fragmentation patterns of the $Fe_mO_n^+$ clusters appear rather complex at the first inspection, some insightful aspects are revealed if the formal oxidation state of iron is considered as an additional parameter. In this formalism, we assume that oxygen acts as a strict two-electron acceptor, i.e. O^{2-}, count the positive charge as additional valence, and avoid split valencies of the atoms. For example, we assign Fe_2O^+ as containing one Fe^I and one Fe^{II}; it is thus denoted as Fe^I/Fe^{II}. Accordingly, $Fe_2O_2^+$ is Fe^{II}/Fe^{III},

$Fe_4O_6^+$	3.25	8	100		1	2	15			5		

[a] Formal assignments of the elemental compositions. For example, loss of FeO_3 could also correspond to FeO + O_2, FeO_2 + O, FeO + 2 O etc. – [b] Intensities given relative to the base peaks = 100%. For the sake of clarity, some minor fragments below 5% are omitted. – [c] See text for the formalism. – [d] For discussions of the structural dichotomy of $[Fe,O_2]^{0/+}$, see refs.[18,27]. – [e] Fe_2O^+ is formed in only minor amounts upon CI of $Fe(CO)_5/O_2$ mixtures; $Cp_2Fe_2(NO)_2$ was instead used as precursor.[17]

$Fe_2O_3^+$ is Fe^{III}/Fe^{IV}, $Fe_3O_3^+$ is 2 Fe^{II}/Fe^{III}, etc. The corresponding net oxidation states of the iron atoms in the clusters are 1.5 in Fe_2O^+, 2.5 in $Fe_2O_2^+$, 3.5 in $Fe_2O_3^+$, and 2.3 in $Fe_3O_3^+$.

Using this formalism, the fragmentation patterns can be categorized as follows. (i) For low-valent $Fe_mO_n^+$ clusters ($m/n \geq 1$), losses of FeO prevail, (ii) for $Fe_mO_n^+$ species with $1 > m/n > 2/3$, loss of FeO_2 begins to compete, and (iii) for $Fe_mO_n^+$ ions with $m/n = 2/3$, i.e. $Fe_2O_3^+$ and $Fe_4O_6^+$, loss of molecular oxygen is the dominant pathway. While these patterns can be deduced from Table 1, a more obvious representation is provided by Figure 1, in which only the fractional losses of FeO, FeO_2, and O_2 are considered. Loss of atomic oxygen is not regarded as structurally characteristic and, moreover, it is likely to be overestimated in collisional activation employing kilo electron-volt energies because momentum transfer in high-energy collisions and collection efficiencies favor observation of fragments due to losses of light neutrals.

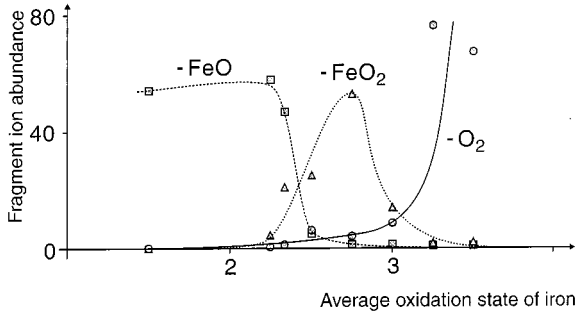

Figure 1. Normalized intensities of FeO (■), FeO_2 (▲), and O_2 (•) losses from $Fe_mO_n^+$ clusters as a function of the averaged oxidation state of the iron atoms; the lines serve just as a guide. Normalization is made to the sum of all fragments observed and the oxidation states are calculated as outlined in the text; for example, a formal oxidation state of 2.5 is attributed to $Fe_2O_2^+$, i.e. Fe^{II}/Fe^{III} that is one Fe^{II} and one Fe^{III}.

Unlike the iron-rich $Fe_mO_n^+$ clusters with $m > n$ studied by Armentrout and co-workers,[7,9] expulsion of neutral iron atoms (or Fe_n aggregates) is rarely observed for the ions under study. Expulsion of FeO units from the low-valent species is formally associated with preservation of the oxidation states of the remaining metal atoms while increasing the average, e.g. loss of the iron(II) compound FeO from $Fe_4O_4^+$ to afford $Fe_3O_3^+$ leads from $3Fe^{II}/Fe^{III}$ to $2Fe^{II}/Fe^{III}$. If we assign neutral FeO_2 to formal iron(IV),[19,20] loss of this neutral corresponds to a disproportionation of the oxidation states between ions and neutrals. In this formalism, losses of molecular oxygen correspond to four-electron reductions of the clusters.

Energetics

The fragmentations observed in the CA spectra cannot directly be related to the associated thermochemical thresholds of the respective channels because collisions occurring in the kilo electronvolt regime do not sample equilibrium. Nevertheless, some correlations can be seen for those clusters for which additional thermochemical information is available.[21]

For example, the predominance of FeO loss from Fe_2O^+ over those of O and Fe, respectively, is consistent with the thermochemistry of the fragments; expressed as sums of heats of formations these are $\Sigma\Delta_fH(Fe^+ + FeO) = 338$ kcal/mol, $\Sigma\Delta_fH(Fe_2^+ + O) = 375$ kcal/mol, and $\Sigma\Delta_fH(FeO^+ + Fe) = 360$ kcal/mol.[21] Similarly, the prevalence of FeO_2 over FeO losses from $Fe_2O_2^+$ is in keeping with the thermochemical thresholds of these channels, i.e. $\Sigma\Delta_fH(FeO^+ + FeO) = 318$ kcal/mol versus $\Sigma\Delta_fH(Fe^+ + FeO_2) = 297$ kcal/mol; note that the base peak due to loss of an O atom has an energy demand of $\Sigma\Delta_fH(Fe_2O^+ + O) = 314$ kcal/mol. Likewise, the competition of FeO and FeO_2 losses for $Fe_3O_3^+$ [Equations (6) and (7)] is consistent with the thermochemical information available. Thus, $D(OFe_2^+–O) \approx D(Fe_2^+–O)$[8] and $D(Fe_2^+–O) = 119 \pm 3$ kcal/mol[7,9] in conjunction with $\Delta_fH(FeO) = 57 \pm 3$ kcal/mol and two nicely consistent values of $\Delta_fH(FeO_2) = 18 \pm 5$ kcal/mol[22] and 15 ± 3 kcal/mol,[3,23,24] respectively, imply $\Sigma\Delta_fH(Fe_2O_2^+ + FeO) = 253$ kcal/mol and $\Sigma\Delta_fH(Fe_2O^+ + FeO_2) = 272$ kcal/mol. Even though the energetics for $Fe_3O_3^+$ are undetermined, these values suggest a difference of about 20 kcal/mol in favor of Equation (6), which is in

accord with the observed preference for this channel in the CA spectrum of $Fe_3O_3^+$.

$$Fe_3O_3^+ \rightarrow Fe_2O_2^+ + FeO \quad (6)$$

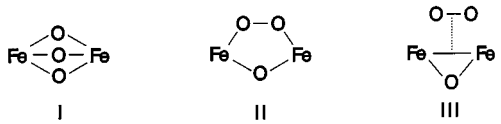
$$Fe_3O_3^+ \rightarrow Fe_2O^+ + FeO_2 \quad (7)$$

$$Fe_3O_3^+ \rightarrow Fe_3O^+ + O_2 \quad (8)$$

Interestingly, while loss of dioxygen from $Fe_3O_3^+$ according to Equation (8) has a comparable energy demand, $\Sigma\Delta_f H(Fe_3O^+ + O_2) = 269$ kcal/mol, this channel is hardly observed experimentally (Table 1). Hence, the absence (or occurrence) of O_2 loss is subject to kinetic rather than thermodynamic restrictions. Thereby, it could reflect structural motifs of the ionic species being probed. We note in passing that, although conceivable, loss of two O atoms instead of molecular oxygen in Equation (8) is much more energy demanding [$\Sigma\Delta_f H(Fe_3O^+ + 2O) = 387$ kcal/mol]. Thus, sequential oxygen-atom loss is not considered to play a major role in the experimentally observed fragmentation pattern.

Structures

Unambiguous conclusions about the geometric structures of the $Fe_mO_n^+$ clusters cannot be derived from the fragmentation patterns; for example, already eight different isomers need to be considered for the four-atomic, neutral Fe_2O_2 cluster.[25] However, it is precisely the loss of molecular oxygen that at least provides intuitive guides to the possible cluster structures generated. Specifically, intense dioxygen losses observed for oxygen-rich $Fe_2O_3^+$ and $Fe_4O_6^+$ species imply the presence of peroxide units in these clusters while this motif is less likely in the other clusters. Here, the term "peroxide unit" only refers to the presence of O–O bonds in the cluster; whether these are best described as μ^2 peroxo ligands or η^1/η^2 dioxygen complexes is a matter of spin coupling,[18,20,26] which is presently unknown for the cationic $Fe_mO_n^+$ clusters studied here.



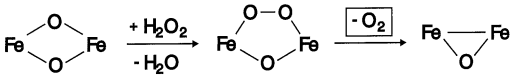
Another, indirect indication of peroxidic structures for $Fe_2O_3^+$ and $Fe_4O_6^+$ is the complete absence of $Fe_3O_5^+$ upon chemical ionization of $Fe(CO)_5/O_2$ mixtures; putative $Fe_3O_5^+$ (250 amu) turns out to be exclusively [$Fe_3O_5H_2^+$] (252 amu) containing one ^{54}Fe isotope; most probably $Fe_3O_4^+ \cdot H_2O$. A possible rationale for these observations is that, among the ions formed in the CI plasma, $Fe_2O(CO)^+$ and $Fe_4O_4(CO)^+$, but not $Fe_3O_3(CO)^+$, are observed. These iron oxide carbonyl clusters are in turn likely to serve as precursors for the formation of $Fe_2O_3^+$ and $Fe_4O_6^+$, respectively, by exchange of the CO ligand by dioxygen; a reaction that also occurs for the mononuclear species, i.e. $Fe(CO)^+ + O_2 \rightarrow FeO_2^+ + CO$.[18] Absence of $Fe_3O_3(CO)^+$ as a precursor can account for the failure to generate $Fe_3O_5^+$ in the $Fe(CO)_5/O_2$ plasma. In turn, the presence of O−O bonds in $Fe_2O_3^+$ and $Fe_4O_6^+$ is implied. Thus, we suggest that $Fe_2O_3^+$ is, for example, formed in Equation (9) from an intermediate carbonyl cluster, i.e. the ligand replacement in Equation (9) competes with the oxidation of the cluster according to Equation (5).

$$Fe_2O(CO)^+ + O_2 \rightarrow Fe_2O_3^+ + CO \quad (9)$$

Oxidation States and Fragmentation Routes

In the series of oxygen-deficient $Fe_mO_n^+$ clusters studied as transients by Armentrout and co-workers,[7,9,10] losses of Fe and Fe_2 units prevailed. In terms of the net oxidation state, these evaporations of neutral Fe units increase the formal cluster valencies, e.g. $Fe_5O_2^+ \rightarrow Fe_3O_2^+ + Fe_2$ leads from an averaged oxidation state of 1.0 in the reactant to 1.67 in the product Fe/O cluster. For the $Fe_mO_n^+$ clusters with $m = n$, our results show preferential losses of the iron(II) compound FeO, e.g. $Fe_3O_3^+ \rightarrow Fe_2O_2^+ + FeO$ corresponds to an increase of the formal valence state from 2.33 in the reactant to 2.5 in the Fe/O cluster formed while the oxidation states of the atoms remain unchanged in reactants and products, i.e. both $2Fe^{II}/Fe^{III}$.

Loss of neutral FeO_2 from the clusters with $m < n$ corresponds to a formal disproportionation of valencies, e.g. from 2.5 in $Fe_2O_2^+$ to 1.0 in the ionic product Fe^+ and 4.0 in neutral FeO_2. Consideration of formal oxidation states also provides a rationale for the switch from FeO to FeO_2 loss upon increasing oxygen content. For example, loss of FeO from $Fe_3O_4^+$ would lead to $Fe_2O_3^+$, which has a high-valent iron(IV) or bearing a peroxidic O−O bond, both features that are considered energetically demanding. Instead, disproportionation with concomitant loss of neutral FeO_2 leads to $Fe_2O_2^+$, an Fe/O cluster with reasonably strong Fe−O bonds.[7–9]



Scheme 1

The oxygen-rich $Fe_mO_n^+$ clusters with $m/n = 2/3$ show preferential losses of molecular oxygen. If these clusters were indeed oxide and not peroxide clusters, high-valent iron(IV) would be present, e.g. Fe^{III}/Fe^{IV} for structure **I** of $Fe_2O_3^+$ (Scheme 1). Involvement of peroxidic structures enables iron to adopt lower oxidation states. For example, the formal valencies in the bridged peroxide **II** are Fe^{II}/Fe^{III} and only Fe^{I}/Fe^{II} in the corresponding dioxygen complex **III**. The avoidance of high valencies is consistent with the mode of generation as well as the fragmentation behavior observed in the experiments. Hence, we suggest that oxygen-rich Fe/O clusters trade-off high oxidation states and prefer the formation of peroxo units instead.

From a conceptual point of view, the formation of peroxo units in the oxygen-rich Fe/O clusters and the associated ability to release molecular oxygen suggest a catalase activity of polynuclear Fe/O clusters. That is, instead of forming

high-valent iron-oxo species with hydrogen peroxide, Fe/O clusters can mediate the disproportionation of H_2O_2 into H_2O and 1/2 O_2 via peroxidic metal clusters as intermediates (Scheme 2). In particular, the near degeneracy of low-lying electronic states of different multiplicities in transition metal oxide clusters may counter the spin problem associated with the release of O_2 in its triplet ground state.[27,28] We will continue to address these points in the context of studies of the catalytic activation of peroxides by transition metals in the gas phase.[29,30]

Scheme 2

As demonstrated in this study, collisional activation of cationic Fe/O clusters can provide qualitative insights into structural features, i.e. the presence of O−O bonds, but definitely not more than that. In particular, no precise information about the bonding schemes, e.g. symmetric versus antisymmetric clusters, presence of Fe−Fe bonds, nature of the bridging ligands etc., not to mention spin states, can be discerned. Nevertheless, these kinds of phenomenological studies of transition metal oxide clusters will continue to be important for the time being due to inadequacies of otherwise powerful theoretical methods. While recent applications of density functional theory have proven rather promising for mononuclear iron compounds,[31] there are grave difficulties for these methods in the treatment of coordinatively unsaturated transition metal oxide clusters.[11,12,25]

Experimental Section

The experiments were performed with a modified VG ZAB/HF/AMD 604 four-sector mass spectrometer of BEBE configuration, which has been described elsewhere.[32] The $Fe_mO_n^+$ cations were generated as described above by chemical ionization (CI) of mixtures of $Fe(CO)_5$ and oxygen in ratios varying from ca. 1:5 to 1:50. We note in passing that chemical ionization of mixtures containing high concentrations of oxygen drastically reduces the lifetimes of the tungsten filaments used in the ion source from months (or even years) to a few hours. Better yields of Fe_2O^+ were obtained by electron ionization of $Cp_2Fe_2(NO)_2$.[17] After acceleration to a kinetic energy of 8 keV, the ions of interest were mass-selected using B(1) and E(1) at mass resolutions $m/\Delta m$ between 3000 and 5000. Collisional activation (CA) in the field-free region between E(1) and B(2) was affected using oxygen at 80% transmittance of the incident ion beam. The fragmentation products were scanned using B(2), detected, on-line processed, and accumulated using the AMD/Intectra data system.

An inherent interference for $Fe_mO_n^+$ cations formed upon CI of $Fe(CO)_5/O_2$ mixtures are the carbonyl clusters of the type $Fe_{m-1}(CO)_2O_n^+$, because Fe and 2CO have the same nominal mass (both 56 amu). These interferences are readily apparent as characteristic losses of carbon monoxide (28 amu) in the CA mass spectra, and such losses are not observed for pure $Fe_mO_n^+$ clusters. In practise, these interferences were minimized by appropriate adjustment of the mass resolution whilst maintaining an excess of O_2 in the mixtures, thereby favoring oxidation of all iron-containing ions to the corresponding oxide clusters. Another possible interference is due to clusters in which one ^{56}FeO unit is replaced by an ion-dipole complex with residual water containing the lighter ^{54}Fe isotope (both 72 amu); this interference is readily identified by characteristic loss of water (18 amu) in the CA spectrum of these ions. With the notable exception of formal $Fe_3O_5^+$ (see above), these hydrated iron oxide cluster ions were of negligible abundance.

Acknowledgments

Financial support by the Deutsche Forschungsgemeinschaft, the Volkswagen Stiftung, and the Fonds der Chemischen Industrie is gratefully acknowledged. We thank Prof. J. Müller for providing us with a sample of $Cp_2Fe_2(NO)_2$.

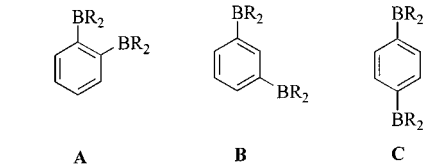
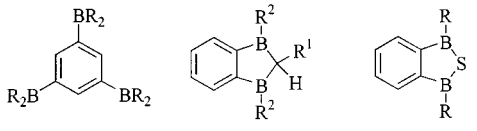
Syntheses, Structures, and Reactivity of Hexaborylbenzene Derivatives

Christian Ester,[a] Andreas Maderna,[a] Hans Pritzkow,[a] and Walter Siebert*[a]



Dedicated to Prof. Heinrich Vahrenkamp on the occasion of his 60th birthday

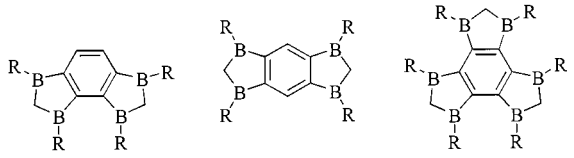
Keywords: Hexaborylbenzenes / Bis(boryl)acetylenes / Cyclooligomerization / Catalysts / Boranes / Boron



The hexaborylbenzene derivatives **2a** and **2b** have been obtained by transition metal catalyzed {[$CpCo(CO)_2$], [$Co_2(CO)_8$], [Ni(cod)$_2$]} cyclotrimerization of bis(1,3,2-benzodioxaborol-2-yl)acetylene (**1a**) and bis[1,3,2-(2,3-naphtho)-dioxaborol-2-yl]acetylene (**1b**). Reaction of [$Co_2(CO)_8$] with **1a** yielded the bis(1,3,2-dioxaborol-2-yl)dicobaltatetrahedrane derivative **3a**, which has been subjected to X-ray structure analysis. Reaction of stoichiometric amounts of **3a** and diphenylacetylene was found to give the bis(boryl)tetraphenylbenzene derivative **4**, while **3a** and mono(1,3,2-benzodioxaborol-2-yl)acetylene (**5**) reacted to yield the tetraborylbenzene derivative **6**. $AlMe_3$ and $AlEt_3$ were found to react with **2a**,**b** to furnish $C_6(BMe_2)_6$ (**7a**) and $C_6(BEt_2)_6$ (**7b**), respectively. With pyridine, the hexafunctional Lewis acid **7a** formed the crystalline bis(pyridine) adduct $C_6(BMe_2)_6{\cdot}(NC_5H_5)_2$ (**8a**). Thermolysis of $C_6(BEt_2)_6$ (**7b**) resulted in the intramolecular elimination of ethane to give the 1,2,3,4-bis(2′,3′-dihydro-1′,3′-diborole)-5,6-bis(diethylboryl)benzene compound **9b**. The molecular structure of the hexaborylbenzene pyridine adduct **8a** has been determined by X-ray structure analysis.

Introduction

Over the past two decades, borylbenzene compounds have become an area of particular interest in relation to the syntheses of boraheterocycles[1] and of polymeric graphite-like boron−carbon frameworks.[2] Several derivatives of the bis(boryl)benzene isomers **A**, **B**, and **C** are known. Kaufmann[3] obtained 1,2-bis(dichloroboryl)benzene **A** (R = Cl) by silicon−boron exchange with BCl_3, while Eisch et al.[4] synthesized the bis(diethylboryl)benzene derivatives of **A**, **B**, and **C** (R = Et) through tin−boron exchange by reacting the corresponding bis(trimethylstannyl)benzenes with Et_2BX (X = Cl, Br).



A **B** **C**

D **E** **F**

The formation and electrochemical properties of bis(boryl)benzene derivatives **C** (R = Ph, Mes) have been studied by Kaim and Schulz.[5] The synthesis of a 1,3,5-tris(boryl)-benzene derivative of **D** (R = Br, OH) was achieved by Stern and Washburn[6] by means of a Friedel−Crafts reaction. Okada, Oda, et al.[7] obtained the mesityl derivatives of **B** and **D** by treating dimesitylfluoroborane with Grignard solutions prepared from 1,3-dibromo- and 1,3,5-tribromobenzene.

G **H** **I**

The benzo-1,3-diborole heterocycle **E** (R^1 = H, Me; R^2 = Cl, Me, NMe_2) has been synthesized by tin−boron exchange of 1,2-bis(trimethylstannyl)benzene with bis(dichloroboryl)methane derivatives, and its ligand properties have been studied in the context of complex formation.[8] The redox reaction between 1,2-diiodobenzene, BI_3, and $(IBS)_3$ led to the formation of the benzo-2,5-diiodo-1,2,5-thiadiborole derivative **F** (R = I), in which the iodine could easily be substituted, thereby allowing access to a variety of derivatives.[9] Its dimethyl derivative (**F**, R = Me) formed the first stable tricarbonylironthiaborane complex.[10] Bis- and tris(2,3-dihydro-1,3-diborole)benzene compounds **G**−**I** are of interest with regard to the synthesis of doubly- and triply-stacked complexes with bridging 1,3-diborolyl ligands. Tetra- and hexaborylbenzenes are potential precursors for the preparation of boron-containing polymers. A graphite-like web $(C_3B)_n$, in which each boron atom is connected to three carbon atoms, should be feasible by polycondensation of $C_6(BR_2)_6$ with elimination of BR_3. We report herein on the synthesis of hexaborylbenzene derivatives by transition metal catalyzed cyclotrimerization of

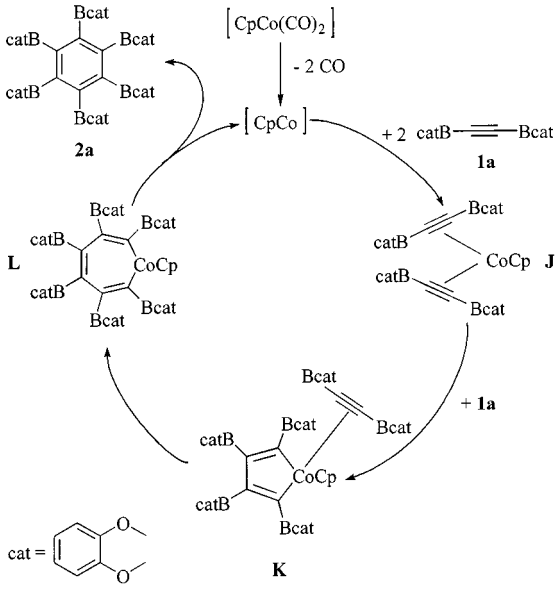
bis(boryl)acetylene derivatives and on the reactivities of these compounds. A preliminary account of our work has been reported previously.[11]

Results and Discussion



Hexakis(1,3,2-benzodioxaborolyl)benzene (2a) and Hexakis{1,3,2-naphtho[2,3-*d*]dioxaborolyl}benzene (2b)

Since the early report of thermal trimerization of acetylene to benzene by Berthelot,[12] and the first transition metal catalyzed version of this reaction by Reppe,[13] the [2+2+2] cyclotrimerization of acetylenes has been extensively studied. A large number of transition metal complexes as well as Ziegler-type catalysts[14] are known to catalyze this reaction.[15] The formation of substituted arenes by cobalt-catalyzed [2+2+2] cyclotrimerization of alkynes is well-known and has found widespread application in organic synthesis.[16] In an analogous manner, the diborylacetylene **1a**[17] (R = H) has been cyclotrimerized in the presence of (η^5-cyclopentadienyl)dicarbonyl-cobalt in refluxing toluene to give the hexaborylbenzene derivative **2a** (R = H) in 75% yield (Scheme 1).[11]

Scheme 1

Compound **2a** is only slightly soluble in most organic solvents; in methanol, a slow reaction leading to the formation of $H_4C_6O_2BOMe$ takes place. Purification of **2a** can be accomplished by repeated washing with toluene. The ^{11}B NMR spectrum in [D_4]MeOH shows a broad signal at δ = 29 due to **2a** and a sharp one at δ = 19.0 attributable to the methanolysis product $H_4C_6O_2BOCD_3$. A characteristic feature of borylbenzenes is the broad ^{13}C NMR resonance signal of the *ipso* carbon atom(s) of the central C_6 ring (δ = 130−150).[18] **2a** exhibits a resonance at δ = 143 due to the *ipso* carbon atoms, which is shifted by 50 ppm to lower field as compared to that of the bis(boryl)acetylene **1a**. This reflects the change of the hybridization of the carbon atoms from sp to sp^2. The ^{13}C NMR signals of the aromatic carbons of the catecholyl substituents appear at δ = 116.3, 120.8, and 146.2. The ^1H NMR spectrum features one multiplet at δ = 6.61−6.77 due to the aromatic protons. EI-MS data confirm the identity of **2a** through the appearance of ion peaks at *m*/*z* = 785 [M^+] and 667 [$M^+ - H_4C_6O_2B$].

Scheme 2

Similarly, the bis(boryl)acetylene **1b** ($R_2 = C_4H_4$) could be trimerized in the presence of a catalytic amount of $CpCo(CO)_2$ to give hexakis{1,3,2-naphtho[2,3-*d*]dioxaborolyl}benzene (**2b**, $R_2 = C_4H_4$) in good yield (Scheme 1). Compound **2b** was characterized by ^1H, ^{13}C, and ^{11}B NMR spectroscopy, elemental analysis, and mass spectrometry. The ^1H NMR spectrum shows the expected multiplet at δ = 7.14−7.59 due to the aromatic protons. In the ^{13}C NMR spectrum, the signals due to the naphthol substituent are seen at δ = 110.8, 124.4−131.0, and 147.8, while that due to the carbons of the benzene ring appears at δ = 144. The ^{11}B NMR shift of δ = 28.3 is comparable with that seen for **2a** (R = H). In the EI mass spectrum of **2b**, the molecular ion appears at *m*/*z* = 1085 and shows the expected isotopic pattern.

Catalytic Cycles with [CpCo(CO)$_2$], [Co$_2$(CO)$_8$], and [Ni(cod)$_2$]

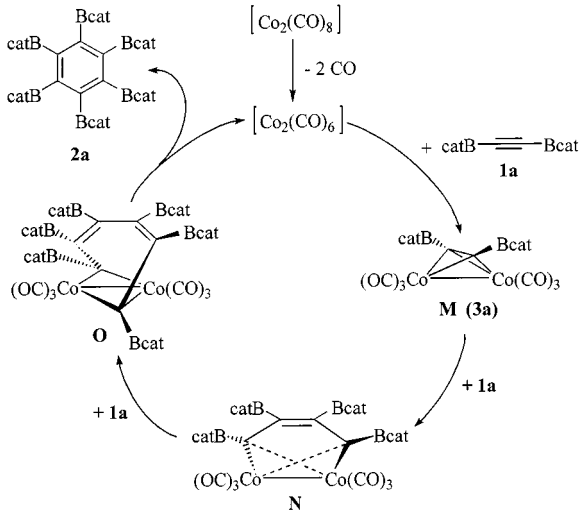
The postulated mechanism of [$CpCo(CO)_2$]-catalyzed cyclotrimerization[16] of acetylene is illustrated for diborylacetylenes in Scheme 2. It is likely that under thermal conditions two alkyne moieties displace the two CO ligands at the metal to form the diborylacetylene complex **J**. Subsequent reductive coupling of the alkynes would then give a coordinatively unsaturated cobaltacyclopentadiene complex. Complexation of a third molecule of **1a** could then lead to **K**, which would be followed by alkyne insertion to form the cobaltacycloheptatriene **L**. Finally, reductive elimination of the CpCo complex fragment would account for the formation of the observed hexaborylbenzene **2a**. Recently, Vollhardt et al.[19] succeeded in synthesizing a cobaltacyclopentadiene−alkyne complex of type **K**, thus

seemingly proving this mechanism, although no direct evidence for the intermediacy of the postulated cobaltacycloheptatriene was obtained. Indeed, theoretical investigations of the mechanism at ab initio and density functional (DFT) levels[20] indicate that a cobaltacycloheptatriene (in Scheme 2) is in fact very unlikely to occur.

Analogously, the catalytic trimerization of **1a** with octacarbonyldicobalt leads to the hexaborylbenzene derivative **2a** in 70% yield. The proposed mechanism of this catalytic cyclotrimerization is outlined in Scheme 3. In the first step of the catalytic cycle, the elimination of two CO ligands leads to the unsaturated species $[Co_2(CO)_6]$, which then reacts with **1a** to give the bis(boryl)dicobaltatetrahedrane **M** (**3a**) (Scheme 3). Insertion of one molecule of bis(boryl)acetylene **1a** leads to complex **N**, which reacts with a third acetylene molecule to give **O**. Subsequent reductive elimination yields the hexaborylbenzene **2a**. An intermediate of the type **O** obtained from the reaction of acetylene, *tert*-butylacetylene, and octacarbonyldicobalt has been characterized by X-ray structure analysis.[21]

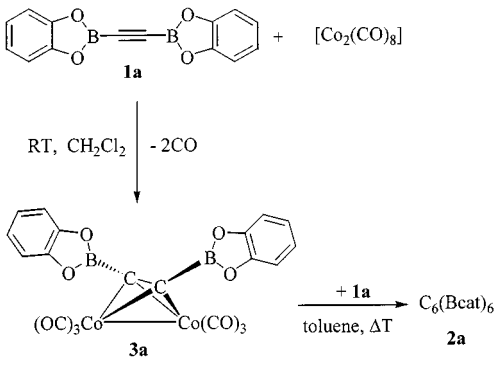
In the past, numerous compounds incorporating benzene or cyclooctatetraene derivatives have been synthesized in the presence of nickel catalysts.[22a][22b] It was found that the [2+2+2] cycloaddition of **1a** to give the hexaborylbenzene derivative **2a** was also catalyzed by $[Ni(cod)_2]$ in 80% yield. The proposed mechanism of the catalytic cyclotrimerization with $[Ni(cod)_2]$ is similar to that with $[CpCo(CO)_2]$ (Scheme 2).

Synthesis and Properties of Bis(borolyl)dicobaltatetrahedrane (3a)



In 1956, it was found that acetylene and substituted acetylenes are capable of displacing two carbonyl groups from $[Co_2(CO)_8]$ to yield dicobaltatetrahedranes.[23] To investigate the mechanism of the cyclotrimerization with $[Co_2(CO)_8]$ as catalyst, the first intermediate **M** of the catalytic cycle was synthesized. Thus, the bis(borolyl)dicobaltatetrahedrane **3a** was prepared in 45% yield by treating the bis(boryl)ethyne **1a** with one equivalent of $[Co_2(CO)_8]$ in dichloromethane at room temperature (Scheme 4). **3a** was isolated by column chromatography on Florisil® and characterized by ^1H, ^{13}C, and ^{11}B NMR, IR, mass spectrometry, as well as an X-ray structure analysis.

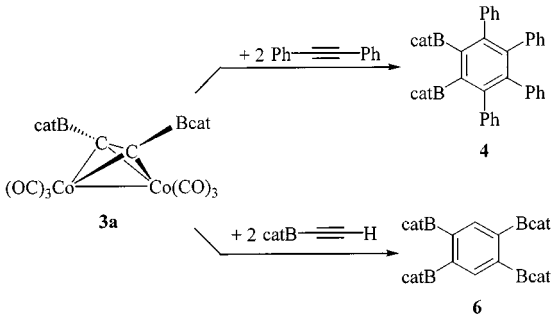
The ^1H NMR spectrum shows the signal due to the aromatic protons at $\delta = 6.85-7.29$. In the ^{13}C NMR spectrum, the arene carbon atoms give rise to signals at $\delta = 111.5$, 122.0, and 147.4. The signals of the carbon atoms bonded to boron are observed at $\delta = 96$, while those of the carbonyl ligands appear at $\delta = 197.4$. The ^{11}B NMR signal, seen at $\delta = 33.1$, is shifted to low field ($\Delta\delta = 10$ ppm) as compared to that of the bis(boryl)acetylene **1a**. The IR spectrum of **3a** features three absorption bands at $\tilde{\nu} = 2102$, 2066, and 2038 cm^{-1} attributable to the CO ligands. In the mass spectrum (EI) of **3a**, the molecular ion peak appears at $m/z = 548$ and shows the expected isotopic distribution as well as the appropriate fragmentation pattern arising from the stepwise loss of the six CO ligands.



The bis(1,3,2-benzodioxaborolyl)dicobaltatetrahedrane (**3a**) was shown to catalyze the trimerization of **1a**, thus verifying the catalytic cycle with $[Co_2(CO)_8]$. Catalytic amounts of **3a** and the diborylacetylene **1a** were allowed to react in refluxing toluene for 24 h. The resulting product was the expected hexakis(1,3,2-benzodioxaborolyl)benzene (**2a**, Scheme 4).

Bis(1,3,2-benzodioxaborolyl)tetraphenylbenzene and Tetrakis(1,3,2-benzodioxaborolyl)benzene

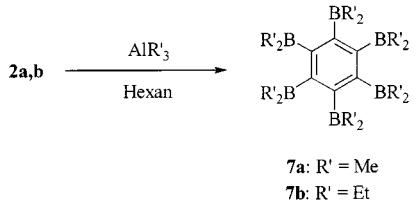
Since the syntheses of the first dicobaltatetrahedranes,[23] numerous cobalt complexes have been reported.[24] However, the use of C_2Co_2 clusters for the preparation of substituted arenes has not been studied in detail. We have explored this route and have found that heating of diphenylacetylene and a stoichiometric amount of **3a** in toluene results in the formation of bis(1,3,2-benzodioxaborolyl)tetraphenylbenzene (**4**) in good yield (Scheme 5). Compound **4** was characterized by ^1H, ^{13}C, and ^{11}B NMR spectroscopy, and by mass spectrometry. The ^1H NMR spectrum shows the expected multiplet due to the aromatic protons at $\delta = 6.60-7.30$. In the ^{13}C NMR spectrum, the signals attributable to the benzodioxaborolyl substituent appear at $\delta = 112.6$, 122.5, and 148.5, while those of the phenyl substituents are seen at $\delta = 125.8$, 127.3, 131.4, and 141.7. The ^{11}B NMR spectrum features one signal at $\delta = 32.3$. In the HR-



Scheme 3

Scheme 4

EI mass spectrum, the molecular ion peak of **4** is seen at m/z = 618 and shows the expected isotopic pattern.

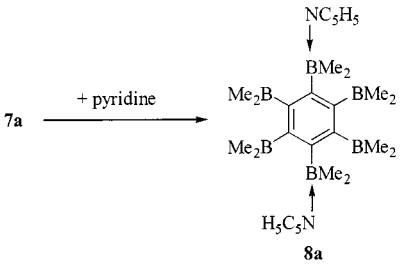


Scheme 5

Analogously, the bis(borolyl)dicobaltatetrahedrane (**3a**) reacts with the monoborylacetylene **5** to give the tetrakis(1,3,2-benzodioxaborolyl)benzene (**6**) (Scheme 5). To the best of our knowledge, this represents the first example of the synthesis of a tetraborylbenzene derivative through a stoichiometric reaction of a transition metal cluster and an acetylene.

Tetrakis(1,3,2-benzodioxaborolyl)benzene (**6**) is − in contrast to the hexaboryl derivatives **2a**,**b**, which are only slightly soluble in most organic solvents − highly soluble in toluene and chlorinated solvents. The molecular ion peak of **6** is detected in the HR-EI mass spectrum at m/z = 550. In the ^{11}B NMR spectrum, one signal is seen at δ = 22.2, while the ^{1}H NMR spectrum shows a signal at δ = 6.83−7.20 due to the protons of the catecholyl ligand. The signals of the two aromatic protons of the central benzene ring are not detected. In the ^{13}C NMR spectrum, the carbon atoms of the catecholyl ligand give rise to signals at δ = 111.6, 121.8, and 146.5. It would seem that **6** consists not only of the 1,2,4,5-isomer, but is rather a mixture of the 1,2,4,5-, 1,2,3,4-, and 1,2,3,5-isomers.

Substitution of the Catechol Groups in 2a,b

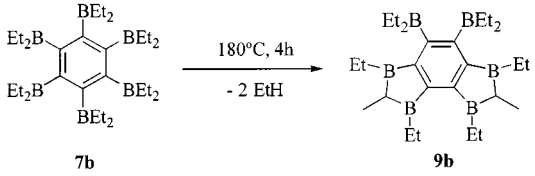


In analogy to the cleavage of the B−O bonds in 2-alkyl-1,3,2-benzodioxaborole derivatives with Grignard reagents,[25] treatment of a suspension of **2a**,**b** in hexane with trimethylaluminum furnishes hexakis(dimethylboryl)benzene (**7a**) (Scheme 6). Purification of the crude product could only be achieved by column chromatography on Florisil®, which allowed pure **7a** to be isolated in 24% yield. Compound **7a** is a low melting, colorless solid, which, in contrast to **2a**,**b**, is extremely sensitive to air and moisture. It was characterized by ^{1}H-, ^{13}C-, and ^{11}B NMR spectroscopy, and by mass spectrometry. The ^{1}H NMR spectrum shows only one signal at δ = 0.95, attributable to the B−CH_3 groups. In the ^{13}C NMR spectrum, the *ipso* carbon atoms of the benzene ring give rise to signals at δ = 149.1, while the B−CH_3 groups resonate at δ = 18.6. The ^{11}B NMR spectrum features one broad signal at δ = 85.1, which is in the range typical for alkylated boron compounds.[26] In the HR-EI mass spectrum of **8a**, the molecular ion peak is seen at m/z = 317 and shows the expected isotopic distribution.

Scheme 6

On treating **2a**,**b** with triethylaluminum, the hexakis(diethylboryl)benzene (**7b**) is formed. As in the case of the methyl analogue, purification could only be achieved by chromatography on a column of Florisil®. Compound **7b** was found to be soluble in hexane and also proved to be sensitive to air and moisture. In the ^{1}H NMR spectrum, a triplet (J = 7.1 Hz) is seen at δ = 1.07 due to the methyl groups, along with a quadruplet at δ = 1.34 due to the methylene units. The ^{13}C NMR spectrum of **7b** features two signals at δ = 9.9 and 23.9 attributable to the ethyl substituents, while the resonances of the benzene carbon atoms are seen at δ = 146.8. The ^{11}B NMR shift of δ = 83.7 is comparable with the shift of **7a** quoted above. In the HR-EI mass spectrum, the molecular ion peak appears at m/z = 485.5.

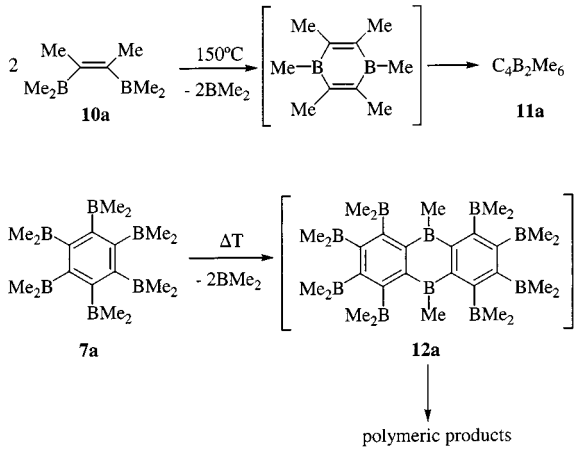
The hexaborylbenzene derivatives **7a**,**b** possess six electron-poor boryl groups and may be regarded as hexafunctional Lewis acids. Therefore, pyridine was added to a solution of **7a** in hexane (Scheme 7). At −15 °C, a white precipitate was obtained, which was found to consist of two crystalline products, a microcrystalline compound and colorless needles.



Scheme 7

NMR and mass spectral data showed this precipitate to be composed of $C_6(BMe)_6$ and pyridine. The ^{11}B NMR spectrum in [D_8]THF shows signals at δ = 55.4, 3.1, and 48.8, the latter being attributable to the protolysis product Me_2BOH. The signal at δ = 55.4 can be assigned to [$C_6(BMe_2)_6 \cdot (NC_5H_5)_2$] (**8a**), in which only two pyridines are coordinated, while the broad peak centered at δ = 3.1 corresponds to a compound in which all the boron atoms are tetracoordinated. It is likely that the boron atoms in **7a** are completely coordinated by pyridine, although we are unable to prove this. Evidently, the two pyridine ligands in **8a** are not fixed, but undergo rapid exchange with the neighboring boryl groups so that only an averaged signal

(δ = 55.4) is seen in the ^{11}B NMR spectrum. In the mass spectrum (EI) of **8a**, the molecular ion peak of **2a** (*m*/*z* = 317), without the two pyridine molecules, is observed.



Thermolysis of Hexakis(diethylboryl)benzene (7b)

In 1968, Binger reported the first synthesis of the derivative 1,3,4,5-tetraethyl-2,3-dihydro-2-methyl-1,3-diborole, which involved thermolysis of *cis*-3,4-diethyl-3,4-bis(diethylboryl)hexene[27] at 160 °C. Similarly, a sample of **7b** was heated to 180 °C for 4 h in an argon stream. The reaction was accompanied by the evolution of ethane and the color changed from white to yellow. NMR and mass spectral data indicated that 1,2,3,4-bis(1′,3′-diborole-2′,3′-dihydro)-5,6-bis(boryl)benzene (**9b**) had been formed (Scheme 8). This represents the first example of a benzo derivative with two attached 1,3-diborole rings. In the ^{11}B NMR spectrum, one broad signal is seen at δ = 77.0, which is shifted upfield by 8 ppm compared to that of $C_6(BEt_2)_6$ (**7b**). The ^{13}C NMR spectrum of **9b** features three signals at δ = 7.8, 9.8, and 10.9 due to the three different methyl groups. The resonances of the methylene carbon atoms are found at δ = 24.2 and 25.6, while the bridging methylene carbon atoms give a signal at δ = 67.8. The signal due to the arene carbon atoms is seen at δ = 154.0. In the mass spectrum (EI) of **9b**, the molecular ion peak is seen at *m*/*z* = 425 and shows the expected isotopic distribution.

Scheme 8

Binger also reported the thermolysis of the *cis*-2,3-dimethyl-2,3-bis(dimethylboryl)hexene[27] at 150 °C to give, via the 1,4-hexamethyldiboracyclohexadiene, the *nido*-tetracarbahexaborane(6) (**11a**) (Scheme 9). Analogously, methyl derivative **7a** was heated to 150 °C in the hope of isolating the condensation product **12a** (Scheme 9). However, no low molecular weight species such as **12a** could be detected; only insoluble brown products were obtained, which may have web-like structures.

Crystal Structures

The structure of **3a** was characterized by performing a single-crystal X-ray analysis (crystal data and structure refinement parameters for **3a** and **8a** are presented in Table 1). The dark-red crystals of **3a**, grown at 4 °C from a solution in toluene, belong to the monoclinic system, space group *C*2/*c* and have four formula units in the unit cell.

The molecular structure (Figure 1) shows the Co_2C_2 framework; each cobalt atom is surrounded by three CO ligands and each carbon atom bears a terminal $BO_2C_6H_4$ group. The C1–C14 distance of 1.345 Å is similar to that in other Co_2C_2 tetrahedrane compounds.[28a,28b] The

Co1−Co1 distance (2.472 Å) falls within the normal range.[28a][28b]

To elucidate the structure of **8a**, an X-ray diffraction study was carried out. A single crystal was grown from a solution in hexane at −15 °C. The determined structure is shown in Figure 2. **8a** crystallizes in the trigonal space group $R\bar{3}$ with nine formula units in the unit cell.

The crystal structure analysis reveals that in the donor−acceptor compound **8a**, two pyridines are coordinated to *para*-BMe_2 groups in *anterti* positions (Figure 2). The boron atoms of the remaining four boryl groups are coordinated in a planar fashion, the BC_2 planes being perpendicular to the central benzene plane. The distances C1−C2 (1.438 Å), C2−C3 (1.391 Å), and C3−C1 (1.422 Å) in the aromatic ring are somewhat elongated.

Experimental Section

General: All manipulations of compounds were performed with rigorous exclusion of air and moisture under an argon atmosphere using standard Schlenk techniques. Solvents were dried with the appropriate drying agents and distilled under a nitrogen atmosphere. − Column chromatography: Florisil® (Fluka), 100−200 mesh. − Elemental analyses were carried out at the Microanalytical Laboratory, Universität Heidelberg. − Melting points (uncorrected) were obtained on a Büchi apparatus using samples sealed in capillaries under argon. − ^{1}H, ^{13}C, and ^{11}B NMR: Bruker AC 200 spectrometer; ^{1}H and ^{13}C spectra were referenced to $(CH_3)_4Si$; ^{11}B spectra to $BF_3\cdot Et_2O$. − IR spectra were recorded on a Bruker IFS 28 FT spectrometer. − Mass spectra were obtained on Finnigan MAT 8230 and Jeol MStation IMS-700 spectrometers operating in EI and FD modes. − Bis(1,3,2-benzodioxaborol-2-yl)acetylene (**1a**),[17] $(Me_3Sn)_2C_2$,[29] $[Ni(cod)_2]$,[30] and $[CpCo(C_2H_4)_2]$[31] were prepared according to literature procedures. $[CpCo(CO)_2]$, $[Co_2(CO)_8]$, and 2,3-dihydroxynaphthalene were purchased from Aldrich®.

2-Chloro-[1,3,2-(2,3-naphtho)dioxaborole]: To a solution of BCl_3 (39.0 g, 0.33 mol) in CH_2Cl_2 (500 mL), 2,3-dihydroxynaphthalene (50.0 g, 0.31 mol) was added at −78 °C. The mixture was allowed to warm to room temperature and stirred for a further 12 h. It was then concentrated and the resulting crystalline precipitate was collected by filtration. Yield: 61.3 g (96%), colorless needles; m.p. 152 °C. − ^{1}H NMR (200.1 MHz, $CDCl_3$): δ = 7.84−7.44 (m, 6 H, arene H). − ^{13}C NMR (50.3 MHz, $CDCl_3$): δ = 108.8, 125.3, 127.8, 130.4, 147.3 ($C_{10}H_6$). − ^{11}B NMR (64.2 MHz, $CDCl_3$): δ = 29.9. − MS (70 eV, EI): *m*/*z* (%) = 204 (100) [M^+].

Bis[1,3,2-(2,3-naphtho)dioxaborol-2-yl]acetylene (1b): To a solution of $(Me_3Sn)_2C_2$ (4.00 g, 11.4 mmol) in toluene (50 mL), $C_{10}H_6O_2BCl$ (4.65 g, 22.8 mmol) in toluene (150 mL) was added at −78 °C. The mixture was allowed to warm to room temperature and stirred for a further 24 h. It was then concentrated and the resulting precipitate was collected by filtration. Yield: 3.73 g (91%) of **1b** as a colorless, crystalline, air-stable solid; m.p. 255 °C. − ^{1}H NMR (200.1 MHz, [D$_4$]MeOH): δ = 7.54−7.10 (m, 12 H, arene H). − ^{13}C NMR (50.3 MHz, [D$_4$]MeOH): δ = 110.2, 124.1, 126.4, 131.5, 148.3 ($C_{10}H_6$), 98 (BCCB). − ^{11}B NMR (64.2 MHz, [D$_4$]MeOH): δ = 22.1. − MS (70 eV, EI): *m*/*z* (%) = 362 (100) [M^+].

Hexakis(1,3,2-benzodioxaborolyl)benzene (2a). − Catalyst [CpCo(CO)$_2$]: To a suspension of **1a** (2.28 g, 8.7 mmol) in toluene (30 mL), (η^5-cyclopentadienyl)dicarbonylcobalt (0.09 g, 0.5 mmol) was added at room temperature. The mixture was then heated under reflux for 48 h. After cooling, the resulting precipitate was collected by filtration, washed several times with toluene, and dried in vacuo. Yield: 1.71 g (75%) of **2a** as a white, air-stable powder; m.p. > 310 °C. − ^{1}H NMR (200.1 MHz, [D$_4$]MeOH): δ = 6.61−6.77

(m, 24 H, arene H). − ^{13}C NMR (50.3 MHz, [D$_4$]MeOH): δ = 116.3, 120.8, 146.2 (C_6H_4), 143 (br., C_{ar}−B). − ^{11}B NMR (64.2 MHz, [D$_4$]MeOH): δ = 29.3. − MS (70 eV, HR-EI): *m/z* (%) = 785.1879 (100) [M$^+$; calcd. $^{12}C_{42}{}^{1}H_{24}{}^{10}B_1{}^{11}B_5{}^{16}O_{12}$: 785.1862]. − $C_{42}H_{24}B_6O_{12}$ (785.51): calcd. C 64.22, H 3.08; found C 64.06, H 3.26.

Catalyst [$Co_2(CO)_8$]: A suspension of **1a** (1.02 g, 3.9 mmol) and octacarbonyldicobalt (0.13 g, 0.4 mL) in toluene (30 mL) was heated for 24 h under reflux. Workup was carried out as above. Yield: 0.69 g (68%) of **2a**.

Catalyst [Ni(cod)$_2$]: A suspension of **1a** (1.38 g, 5.3 mmol) and [Ni(C_8H_8)$_2$] (0.08 g, 0.3 mmol) in toluene (40 mL) was heated for 20 h under reflux. Workup was carried out as above. Yield: 1.07 g (77%) of **2a**.

Catalyst 3a: A suspension of **1a** (1.12 g, 4.3 mmol) and bis(1,3,2-benzodioxaborolyl)dicobalttetrahedrane (**3a**) (0.11 g, 0.2 mmol) in toluene (30 mL) was heated for 24 h under reflux. Workup was carried out as above. Yield: 0.63 g (56%) of **2a**.

Hexakis{1,3,2-naphtho[2,3-*d*]dioxaborolyl}benzene (2b): A suspension of **1b** (2.03 g, 5.6 mmol) and (η^5-cyclopentadienyl)dicarbonylcobalt (0.08 g, 0.4 mmol) in toluene (30 mL) was heated for 48 h under reflux. Workup was carried out as for **2a**. Yield: 1.28 g (63%) of **2b** as a white, air-stable powder; m.p. > 310 °C. − ^{1}H NMR (200.1 MHz, [D$_4$]MeOH): δ = 7.14−7.59 (m, 36 H, arene H). − ^{13}C NMR (50.3 MHz, [D$_4$]MeOH): δ = 110.8, 124.4, 127.0, 131.0, 147.8 ($C_{10}H_6$), 144 (br., C_{ar}−B). − ^{11}B NMR (64.2 MHz, [D$_4$]MeOH): δ = 28.3. − MS (70 eV, EI): *m/z* (%) = 1085 (7) [M$^+$], 917 (4) [M$^+$ − $C_{10}H_6O_2B$], 749 (3) [M$^+$ − 2 $C_{10}H_6O_2B$]. − $C_{66}H_{36}B_6O_{12}$ (1086): calcd. C 73.00, H 3.34; found C 71.40, H 3.39.

Bis(borolyl)dicobaltatetrahedrane (3a): To a solution of bis(1,3,2-benzodioxaborole-2-yl)acetylene (**1a**; 1.22 g, 4.7 mmol) in CH_2Cl_2 (40 mL), a solution of octacarbonyldicobalt (1.61 g, 4.7 mmol) in CH_2Cl_2 (20 mL) was added dropwise at room temperature. An immediate reaction ensued, as indicated by the evolution of carbon monoxide. The mixture was stirred for 20 h at room temperature and thereafter for 2 h at reflux temperature. To the red-brown solution was then added Florisil® (10 g) and the solvent was removed in vacuo. The residue was separated by column chromatography (Florisil®/hexane) to give two fractions. Using hexane as eluent, [$Co_2(CO)_8$] was obtained first. The second fraction (hexane/toluene, 1:1) was found to contain **3a**. Yield: 1.17 g (45%) of **3a** as a red, air-sensitive solid; m.p. 102 °C. − ^{1}H NMR (200.1 MHz, C_6D_6): δ = 6.85−7.29 (m, 8 H, C_{ar}H). − ^{13}C NMR (50.3 MHz, C_6D_6): δ = 111.5, 122.0, and 147.4 (C_{ar}), 96 (br., C−B), 197.4 (CO). − ^{11}B NMR (64.2 MHz, C_6D_6): δ = 33.1. − IR (hexane): $\tilde{\nu}$ [cm^{-1}] = 2102 (s), 2066 (vs), 2038 (vs). − MS (70 eV, EI): *m/z* (%) = 548 (2) [M$^+$], 520 (7) [M$^+$ − CO], 492 (9) [M$^+$ − 2 CO], 464 (6) [M$^+$ − 3 CO], 436 (9) [M$^+$ − 4 CO], 408 (23) [M$^+$ − 5 CO], 380 (13) [M$^+$ − 6 CO], 321 (8) [M$^+$ − 6 CO − Co], 262 (100) [M$^+$ − 6 CO − 2 Co].

Bis(1,3,2-benzodioxaborolyl)tetraphenylbenzene (4): To a solution of **3a** (1.14 g, 2.1 mmol) in toluene (30 mL), diphenylacetylene (0.75 g, 4.2 mmol) was added at room temperature. The resulting mixture was stirred for 24 h under reflux. After cooling, the brown solution thus obtained was filtered and the filtrate was concentrated to dryness in vacuo. The residue was washed several times with hexane and dried in vacuo. Yield: 1.01 g (76%) of **4** as a white, air-stable powder. − ^{1}H NMR (200.1 MHz, $CDCl_3$): δ = 6.60−7.30 (m, 28 H, arene H). − ^{13}C NMR (50.3 MHz, $CDCl_3$): δ = 112.6, 122.5, 148.5 (C_6H_4), 125.8, 127.3, 131.4, 141.7 (C_6H_5), 145 (br., C_{ar}−B). − ^{11}B NMR (64.2 MHz, $CDCl_3$): δ = 32.3. − MS (70 eV, HR-EI): *m/z* (%) = 618.21839 (45) [M$^+$; calcd. $^{12}C_{42}{}^{1}H_{28}{}^{11}B_2{}^{16}O_4$: 618.21869].

Tetrakis(1,3,2-benzodioxaborolyl)benzene (6): To a solution of **3a** (1.06 g, 1.9 mmol) in toluene (25 mL), monoborylacetylene[32] **5** (0.56 g, 3.9 mmol) was added at room temperature. The resulting mixture was stirred for 24 h under reflux. After cooling, the brown solution thus obtained was filtered and the filtrate was concentrated to dryness in vacuo. The residue was washed several times with hexane and dried in vacuo. Yield: 0.83 g (79%) of **6** as a white, air-stable powder. − ^{1}H NMR (200.1 MHz, $CDCl_3$): δ = 6.83−7.20 (m, 16 H, arene H, catecholyl); C_{ar}−H not observed . − ^{13}C NMR (50.3 MHz, $CDCl_3$): δ = 111.6, 121.8, 146.5 (C_6H_4); C_{ar}−B and C_{ar}−H not observed. − ^{11}B NMR (64.2 MHz, $CDCl_3$): δ = 22.2. − MS (70 eV, HR-EI): *m/z* (%) = 550.1371 (83) [M$^+$; calcd. $^{12}C_{30}{}^{1}H_{18}{}^{11}B_4{}^{16}O_8$: 550.1365]; Δmmu = 0.6.

Hexakis(dimethylboryl)benzene (7a): To a suspension of **2a** (1.51 g, 1.9 mmol) [or **2b** (1.67 g, 1.5 mmol)] in hexane (40 mL), trimethylaluminum (0.56 g, 7.8 mmol) [0.45 g, 6.2 mmol] was added dropwise at −20 °C. The reaction mixture was allowed to warm to room temperature, stirred for 24 h, and then heated under reflux for 2 h. The brown-yellow solution thus obtained was filtered and the filtrate was concentrated to dryness in vacuo. The oily residue was redissolved in hexane (10 mL) and separated by column chromatography (Florisil®/hexane). Yield: 0.14 g (24%) [0.10 g (20%)] of **7a** as a colorless, air-sensitive solid; m.p. 34 °C. − ^{1}H NMR (200.1 MHz, C_6D_6): δ = 0.96 (s, 36 H, BCH_3). − ^{13}C NMR (50.3 MHz, C_6D_6): δ = 18.6 (BCH_3), 149.1 [C_{ar}−B(CH_3)$_2$]. − ^{11}B NMR (64.2 MHz, C_6D_6): δ = 85.1. − MS (70 eV, EI): *m/z* (%) = 317 (27) [M$^+$], 302 (7) [M$^+$ − CH_3], 246 (13) [M$^+$ − B(CH_3)$_2$ − 2 CH_3]; HR-EI: *m/z* (%) = 317.34155 (29) [M$^+$; calcd. $^{12}C_{18}{}^{1}H_{36}{}^{10}B_1{}^{11}B_5$: 317.34116]; Δ mmu = 0.39.

Hexakis(diethylboryl)benzene (7b): To a suspension of **2a** (1.32 g, 1.7 mmol) [or **2b** (1.53 g, 1.4 mmol)] in hexane (35 mL), triethylaluminum (0.77 g, 6.7 mmol) [0.64 g, 5.6 mmol] was added dropwise at −20 °C. Workup was carried out as for **7a**. Yield: 0.33 g (40%) [0.19 g (28%)] of **7b** as a colorless, air-sensitive solid; m.p. 48 °C. − ^{1}H NMR (200.1 MHz, C_6D_6): δ = 1.07 (t, *J* = 7.1 Hz, 36 H, CH_2CH_3), 1.34 (q, *J* = 7.3 Hz, 24 H, CH_2CH_3). − ^{13}C NMR (50.3 MHz, C_6D_6): δ = 9.9 (CH_2CH_3), 23.9 (CH_2CH_3), 146.8 [C_{ar}−B(CH_2CH_3)$_2$]. − ^{11}B NMR (64.2 MHz, C_6D_6): δ = 83.7. − MS (70 eV, EI): *m/z* (%) = 485.5 (54) [M$^+$], 456 (9) [M$^+$ − C_2H_5], 428 (5) [M$^+$ − 2 C_2H_5], 348 (22) [M$^+$ − 2 B(C_2H_5)$_2$]; HR-EI: *m/z* (%) = 485.5330 (5) [M$^+$; calcd. $^{12}C_{30}{}^{1}H_{60}{}^{10}B_1{}^{11}B_5$: 485.5290]; Δ mmu = 4.0.

Hexakis(dimethylboryl)benzene−Bipyridine Adduct (8a): Hexakis(-dimethylboryl)benzene **7a**, obtained from **2a** (1.21 g, 1.5 mmol) and trimethylaluminum (0.44 g, 6.0 mmol), was dissolved in hexane (12 mL) and then pyridine (2 mL) was added. The reaction mixture was cooled to −15 °C, whereupon a white precipitate was deposited. Yield: 0.22 g (30%) of **8a** as colorless, air-sensitive needles; m.p. 110 °C. − ^{1}H NMR (200.1 MHz, [D$_8$]THF): δ = 0.90 (s, BCH_3), 1.28 [s, B(CH_3)$_2$−NC_5H_5], 6.96 (m, C_5H_5N), 7.71 (m, C_5H_5N), 8.49 (m, C_5H_5N). − ^{13}C NMR (50.3 MHz, [D$_8$]THF): δ = 1.5 [B(CH_3)$_2$−NC_5H_5], 19.3 (BCH_3), 128.5, 134.3, 146.2 (C_5H_5N), 144.7 [$CB(CH_3)_2$]. − ^{11}B NMR (64.2 MHz, [D$_8$]THF): δ = 55.4. − MS (70 eV, EI): *m/z* (%) = 317 (35) [M$^+$ − 2 C_5H_5N], 302 (7) [M$^+$ − 2 C_5H_5N − CH_3], 246 (11) [M$^+$ − 2 C_5H_5N − B(CH_3)$_2$ − 2 CH_3], 79 (100) [C_5H_5N].

1,2,3,4-Bis(1,3-diborole)-5,6-bis(boryl)benzene (9b): Under argon, hexakis(diethylboryl)benzene (**7b**; 0.21 g, 0.4 mmol) was slowly

heated without a solvent to 180 °C and maintained at this temperature for 4 h. Yield: 0.14 g (77%) of a yellow, air-sensitive oily residue. – ^{1}H NMR (200.1 MHz, C_6D_6): δ = 1.04 (m, CH_2CH_3), 1.52 (m, CH_2CH_3), 3.5 ($CHCH_3$). – ^{13}C NMR (50.3 MHz, C_6D_6): δ = 7.8 ($CHCH_3$), 9.8 [$B(CH_2CH_3)_2$], 10.9 [$B(CH_2CH_3)$], 24.2 [$B(CH_2CH_3)_2$], 25.6 [$B(CH_2CH_3)$], 67.8 ($CHCH_3$), 154 [$C-B(CH_2CH_3)_2$]. – ^{11}B NMR (64.2 MHz, C_6D_6): δ = 77. – MS (70 eV, EI): *m/z* (%) = 425 (42) [M^+], 396 (71) [$M^+ - C_2H_5$], 327 (21) [$M^+ - C_2H_5 - B(C_2H_5)_2$], 298 (13) [$M^+ - 2\ C_2H_5 - B(C_2H_5)_2$].

Crystal Structure Determinations of 3a and 8a: Crystal data and details of the structure determinations are listed in Table 1. Unique sets of intensity data were collected at −65 °C and −70 °C on a Siemens−Stoe AED four-circle diffractometer (Mo-K_α radiation, λ = 0.7107 Å, graphite monochromator, ω-scans). Empirical absorption corrections (ψ-scans) were applied. The structures were solved by direct methods (SHELXS-86)[33] and refined by least-squares methods based on F^2 with all measured reflections (SHELXL-97).[34] All nonhydrogen atoms were refined anisotropically. Hydrogen atoms were included in calculated positions or as part of rigid groups (CH_3).

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-137769 (**3a**) and CCDC-137770 (**8a**). Copies of the data can be obtained free of charge on application to the CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) +44 (0)1223/336033; E-mail: deposit@ccdc.cam.ac.uk]

Transition-Metal Substituted Phosphaalkenes, 41[‡]

Syntheses and Structures of *C*-Monoamino-*P*-ferriophosphaalkenes $[(\eta^5\text{-}C_5Me_5)(CO)_2FeP{=}CR^1(NR^2_2)]$ (R^1 = Ph, *t*Bu, 3,4,5-$(MeO)_3C_6H_2$; NR^2_2 = NMe_2, Piperidino)

Lothar Weber,*[a] Stefan Kleinebekel,[a] Annette Rühlicke,[a] Hans-Georg Stammler,[a] and Beate Neumann[a]

Dedicated to Professor Gerd Becker on the occasion of his 60th birthday

Keywords: Phosphaalkenes / Iron / Condensation reactions

Reaction of equimolar amounts of the carbenium iodides $[Me_2N(R)CSMe]I$ [**1a**: R = Ph; **1b**: *t*Bu; **1c**: 3,4,5-$(MeO)_3C_6H_2$], [pip(Ph)CSMe]I (**1d**) (pip = piperidino), and $LiP(SiMe_3)_2 \cdot$ DME afforded phosphaalkenes $Me_2N(R)C{=}PSiMe_3$ (**2a–c**) and pip(Ph)C=$PSiMe_3$ (**2d**). Combination of **2a–d** with $[(\eta^5\text{-}C_5Me_5)(CO)_2FeCl]$ led to the formation of $[(\eta^5\text{-}C_5Me_5)(CO)_2\text{-}FeP{=}C(R)NMe_2]$ [**3a**: R = Ph; **3b**: *t*Bu; **3c**: 3,4,5-$(MeO)_3C_6H_2$] and $[(\eta^5\text{-}C_5Me_5)(CO)_2FeP{=}C(Ph)pip]$ (**3d**). Compounds **2a–d** and **3a–d** were characterized by means of spectroscopy (IR, ^1H, $^{13}C\{^1H\}$, $^{31}P\{^1H\}$ NMR). The molecular structures of **3a** and **3b** were determined by X-ray diffraction analysis. The results of an X-ray study on $[(\eta^5\text{-}C_5Me_5)(CO)_2Fe{-}P{=}C(Ph)SiMe_3]$ (**3g**) for comparison are also included. All experimental observations are rationalized by the assumption that complexes **3a**, **3c**, and **3d** are phosphaalkenes with an inverse π-electron distribution ($P^{\delta-}\,C^{\delta+}$) and are comparable to $[(\eta^5\text{-}C_5Me_5)(CO)_2FeP{=}C(NMe_2)_2]$ (**3e**), whereas **3b** is better regarded as phosphaalkene with a normal polarization ($P^{\delta+}\,C^{\delta-}$) of the P=C bond, similar to that given in **3g**.

Introduction

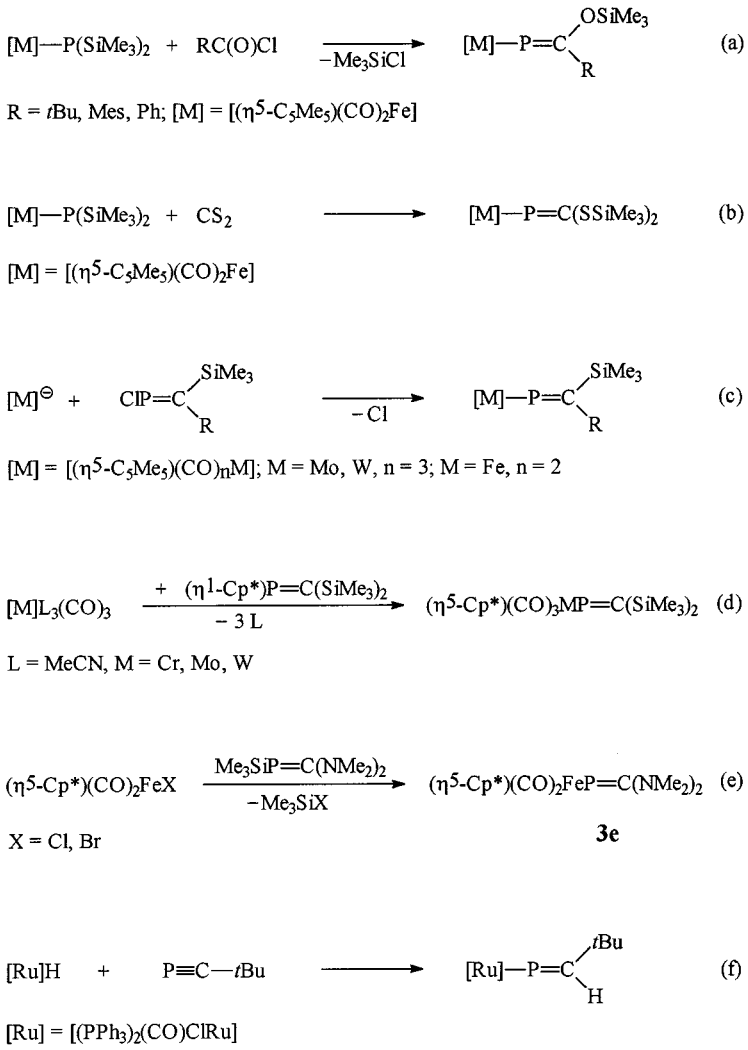
Within the last 15 years metallophosphaalkenes have emerged from being laboratory curiosities to become versatile synthons in organoelement and coordination chemistry.[1] P-metallophosphaalkenes are now accessible by a variety of different synthetic pathways (Scheme 1).

In methods (a)[2] and (b),[3] the P=C double bond was built up during a sequence of condensation and rearrangement steps, whereas in routes (c),[4] (d),[5] and (e),[6] reactants with preformed P=C bonds were involved. The organophosphorus precursor of route (f) is a phosphaalkyne, the bond order of which was reduced from 3 to 2 by hydroruthenation.[7] To date it is obvious that all the synthetic principles depicted in Scheme 1 suffer from limited generality. Thus, route (e) was limited to Fe and Ru derivatives. The ferriophosphaalkene **3e** is interesting because its P=C bond displays an inverse π-electron distribution. This leads to a highly nucleophilic phosphorus center, and consistently, to a rich and versatile chemistry with inorganic, organometallic, and organic electrophiles.[1,8]

We were now interested in experimentally determining the borderline between "classically polarized" metallophosphaalkenes such as $(\eta^5\text{-}C_5Me_5)(CO)_2FeP{=}C(SiMe_3)R$, (R = $SiMe_3$, Ph)[4] and $(\eta^5\text{-}C_5Me_5)(CO)_2FeP{=}C(O\text{-}SiMe_3)(R)$ (R = Ph, *t*Bu, Mes)[2] on the one hand, and "inversely polarized" phosphaalkenes on the other hand.

One possible experimental approach to this target was based on the replacement of one amino substituent in **3e** by an organic group that cannot participate in π-conjugation with the P=C bond.

Results and Discussion



For the preparation of ferriophosphaalkenes with only one amino group at the methylene carbon atom, a synthetic route according to reaction (e) (Scheme 1) seemed promising. The required P-silylated phosphaalkenes were formed by the reaction of equimolar amounts of the (methylthiomethylene)immonium iodides **1a–d** and $LiP(SiMe_3)_2 \cdot$ DME[9] in a mixture of *n*-pentane and 1,2-dimethoxyethane (DME, −75 °C → room temperature). Within 24 h the reaction mixtures slowly turned orange.

Orange $Me_3SiP{=}CR^1(NR^2_2)$ (**2a–d**) were isolated as oils in moderate yields (38–62%) after filtration and removal of solvents. Phosphaalkenes **2a** and **2b** were purified by vacuum distillation to afford light yellow oils. The distillates were still contaminated with some $P(SiMe_3)_3$, which was invariably formed as a by-product. Due to its inherent thermolability, the attempted distillation of **2c** and **2d** was thwarted by decomposition. This approach parallels our

Scheme 2. Synthesis of phosphaalkenes **2a−d** and **3a−d**; pip = NC_5H_{10}

previous synthesis of $Me_3SiP{=}C(NMe_2)_2$ (**2e**) from LiP(SiMe$_3$)$_2$ · DME and [(Me$_2$N)$_2$CSMe]I,[10] and constitutes a generalization of the reaction principle. The novel phosphaalkenes **2a−d** are sensitive to oxygen and moisture. Upon combination of **2a−d** with one equivalent of (η^5-C_5Me_5)(CO)$_2$FeCl[11] in a mixture of *n*-pentane and DME, a reaction occurred in the temperature range −75 to 20 °C to give the red microcrystalline ferriophosphaalkenes **3a−d** in 34 to 67% yield.

The replacement of one dimethylamino group in $Me_3SiP{=}C(NMe_2)_2$ (**2e**) ($\delta^{31}P$ = 46.5)[10] by an aryl ring resulted in slight downfield shifts to δ = 50.3 (**2c**), 54.3 (**2a**), and 59.5 (**2d**). The introduction of one *tert*-butyl group, however, was accompanied by a more pronounced deshielding in **2b** (δ = 68.7).

In the $^{13}C\{^1H\}$ NMR spectra of **2a**, **2c**, and **2d**, the doublets of the methylene carbon atoms of the P=C bond are insignificantly shifted δ ^{13}C = 204.7−205.1 when compared with **2e** (δ = 204.0). Also, the coupling constants $^1J_{P,C}$ decrease from 85.0 Hz in **2e** to 64.4−65.4 Hz. Interestingly, in the *tert*-butyl derivative **2b** the carbon atom of the P=C bonds was observed at much lower field (δ = 219.7) with an increased coupling constant ($^1J_{P,C}$ = 94.1 Hz). Two discrete singlet resonances for the methyl groups of the dimethylamino function in **2a** and **2c** are paralleled by two broad singlets, each accounting for 3-H atoms in the ^{1}H-NMR spec-

tra, and point to a hindered rotation of the amino group about the N-C_{sp^2} bond at room temperature. In **2b** only one resonance for the NMe_2 group in the $^{13}C\{^1H\}$ as well as the ^1H-NMR spectra was measured. The replacement of the trimethylsilyl group in **2a–d** by the [(η^5-C_5Me_5)-$(CO)_2Fe$] fragment caused strong downfield shifts in the $^{31}P\{^1H\}$-NMR spectra. Ferriophosphaalkenes **3a** (δ = 232.0), **3c** (δ = 225.4), and **3d** (δ = 225.4) also display more deshielded $^{31}P\{^1H\}$-NMR resonances in comparison to (η^5-C_5Me_5)$(CO)_2FeP{=}C(NMe_2)_2$ (**3e**) (δ = 135.5).[6] This observation indicates that the inverse polarity in the novel products is considerably reduced with respect to **3e**. This effect is much more evident with the *tert*-butyl-substituted ferriophosphaalkene **3b**, where a singlet at $\delta^{31}P$ = 409.0 was registered. At this point it is helpful to compare our data with the ^{31}P-NMR-resonances of the "classically" polarized ferriophosphaalkenes (η^5-C_5Me_5)$(CO)_2FeP{=}C(SiMe_3)_2$ (δ = 641.5)[4] and (η^5-C_5Me_5)$(CO)_2FeP{=}C(Ph)(SiMe_3)$ (δ = 520.7).[4] On the ground of ^{31}P-NMR spectroscopy, compound **3b** should not be considered as an inversely polarized phosphaalkene. The ^{13}C nuclei of the P=C bond in **3a–d** experience small high fields ($\Delta\delta^{13}C$ = 2.4–5.0 ppm) relative to precursors **2a–d**. The $^1J_{P,C}$ coupling constants of **2a**, **2c**, and **2d** were increased by ca. 20 Hz. An opposite trend, however, was observed with **2b** and **3b**, where the metallation was accompanied by a decrease of the coupling constant $^1J_{P,C}$ by 18.8 Hz. Again, a bonding situation in **3b** different from that in **3a**, **c**, and **d** might be anticipated. In the ^{13}C-NMR spectra of **3a–d** the carbonyl ligands give rise to singlets in the narrow range of δ = 218.0 to 218.5. The high-field shift in comparison to (η^5-C_5Me_5)$(CO)_2$-$FeP{=}C(NMe_2)_2$ (**3e**) agrees with a smaller degree of charge transfer from the organophosphorus ligand via the iron atom onto the carbonyls in **3a–d**. This is also reflected in the IR spectra of **3a–d**, where two intense ν(CO) bands at 1987–1989 cm^{-1} and 1940–1941 cm^{-1} are hypsochromically shifted when compared with **3e** (1973 and 1925 cm^{-1}). In the classically polarized phosphaalkenes (η^5-C_5Me_5)-$(CO)_2FeP{=}C(SiMe_3)_2$ (**3f**) and (η^5-C_5Me_5)$(CO)_2FeP{=}$ $C(Ph)(SiMe_3)$ (**3g**) the ^{13}C(CO) NMR signals were observed at δ = 217.6 and 216.1, respectively, and the ν(CO) bands in the IR spectra occurred at $\tilde{\nu}$ = 1988 and 1942 or 1993 and 1940 cm^{-1}, respectively.[4]

This spectroscopic evidence may be interpreted as with **3b**, as if the borderline between the inversely polarized ferriophosphaalkene **3e** and the more classically polarized compounds **3f** and **3g** has been trespassed.

To further substantiate this idea, X-ray structural analyses of **3a** and **3b** were necessary.

X-ray Structural Analysis of 3a

Single crystals of **3a** were grown from toluene at −30 °C. The molecular structure of **3a** is related to that of the metallophosphaalkene **3e**.[6] The molecule displays a distorted "piano stool" geometry [P(1)–Fe(1)–C(11) 91.8(1)°, P(1)–Fe(1)–C(12) 93.3(1)°, C(11)–Fe(1)–C(12) 96.5(2)°] (Figure 1).

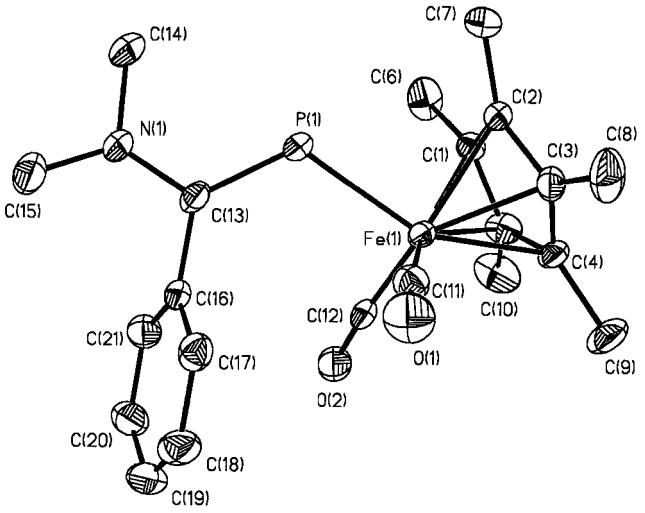

Figure 1. Molecular structure of **3a** in the crystal; selected bond lengths [Å] and angles [°]: Fe(1)–P(1) 2.316(1), Fe(1)–C(11) 1.764(4), Fe(1)–C(12) 1.766(4), P(1)–C(13) 1.717(4), N(1)–C(13) 1.399(4), N(1)–C(14) 1.452(5), N(1)–C(15) 1.449(5), C(13)–C(16) 1.495(5), O(1)–C(11) 1.138(5), O(2)–C(12) 1.137(4); P(1)–Fe(1)–C(11) 91.8(1), P(1)–Fe(1)–C(12) 93.3(1), C(11)–Fe(1)–C(12) 96.5(2), Fe(1)–C(11)–O(1) 176.2(4), Fe(1)–C(12)–O(2) 174.1(3), Fe(1)–P(1)–C(13) 118.9(1), P(1)–C(13)–N(1) 120.0(3), P(1)–C(13)–C(16) 126.1(2), N(1)–C(13)–C(16) 113.7(3), C(13)–N(1)–C(14) 118.5(3), C(13)–N(1)–C(15) 120.8(3), C(14)–N(1)–C(15) 113.3(3)

Two of the legs are represented by nearly linear terminal carbonyl ligands. The organophosphorus ligand is connected with the $(C_5Me_5)(CO)_2Fe$ fragment by a Fe–P single bond of 2.316(1) Å, which compares well with that in **3e** [2.325(2) Å]. The same holds true for the P=C bond lengths in both molecules [**3a**: 1.717(4) Å; **3e**: 1.709(5) Å], which fall in the typical region of 1.70–1.76 Å usually determined for amino-substituted phosphaalkenes.[12] The P=C bond is in an (*E*) configuration, with the iron atom and the phenyl group on the same side of the molecule. Presumably due to steric congestion, the angles Fe(1)–P(1)–C(13) [118.9(1)°] and P(1)–C(13)–C(16) [126.1(2)°] are markedly different. The phenyl ring is twisted out of the plane defined by the atoms Fe(1), P(1), and C(13) by 70.7°. The angle at the P atom in **3e** was found to be 117.9(2)°. The carbon atom C(13) in **3a** is in a trigonal-planar configuration (sum of angles = 359.8°), featuring a bond length of 1.399(4) Å to the slightly pyramidal nitrogen atom (sum of angles = 352.6°). The plane defined by the atom C(13), C(14), and C(15) encloses an angle of 16.6° with the plane through the atoms Fe(1), P(1), and C(13). This allows for effective π-conjugation of the lone-pair at the nitrogen atom with the P=C bond. In line with this, bond N(1)–C(13) is markedly shorter than the calculated value for a $C_{(sp^2)}$–$N_{(sp^2)}$ single bond (1.45 Å).[12] In **3e**, the pyramidal geometry was only observed for the N atom of the *trans*-oriented dimethylamino group [sum of angles = 350.5°, *d*(CN) = 1.410(7) Å]. The NMe_2 unit in a *cis*-disposition to the iron atom of **3e** was planar [sum of angles = 360.0°, *d*(CN) = 1.372(8) Å].

X-ray Structural Analysis of 3b

Single crystals of **3b** were grown from toluene at −30 °C. Again the molecule possesses a distorted piano stool configuration at the $(\eta^5\text{-}C_5Me_5)(CO)_2Fe$ unit (Figure 2).

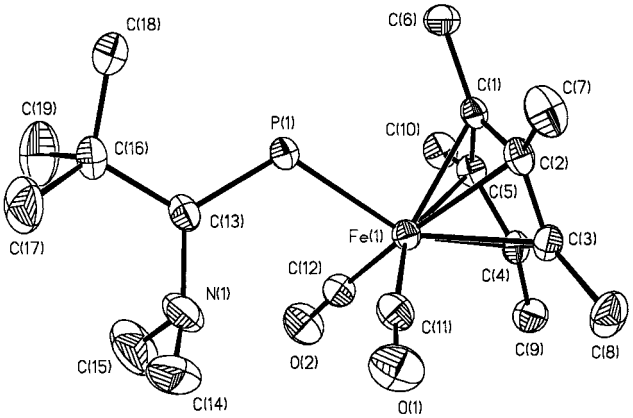

Figure 2. Molecular structure of **3b** in the crystal; selected bond lengths [Å] and angles [°]: Fe(1)−P(1) 2.276(1), Fe(1)−C(11) 1.756(3), Fe(1)−C(12) 1.756(3), P(1)−C(13) 1.697(3), N(1)−C(13) 1.448(4), N(1)−C(14) 1.447(5), N(1)−C(15) 1.449(5), C(13)−C(16) 1.551(4); P(1)−Fe(1)−C(11) 89.7(1), P(1)−Fe(1)−C(12) 90.0(1), C(11)−Fe(1)−C(12) 97.1(1), Fe(1)−C(11)−O(1) 173.8(3), Fe(1)−C(12)−O(2) 174.6(3), Fe(1)−P(1)−C(13) 117.0(1), P(1)−C(13)−N(1) 120.8(2), P(1)−C(13)−C(16) 118.8(2), N(1)−C(13)−C(16) 120.4(2), C(13)−N(1)−C(14) 118.1(3), C(13)−N(1)−C(15) 118.0(3), C(14)−N(1)−C(15) 112.1(3)

The Fe−P bond of 2.276(1) Å, however, is much shorter than in **3a**. Interestingly, the dimethylamino group at the P=C double bond [P(1)−C(13) = 1.697(3) Å] is oriented nearly perpendicular to the plane defined by the atoms Fe(1), P(1), and C(13) (= 86.7°) thus preventing any notable π-conjugation. In keeping with this, the atomic distance N(1)−C(13) of 1.448(4) Å is much longer than in **3a** and compares well with the remaining bond lengths N(1)−C(14) [1.447(5) Å], and N(1)−C(15) [1.449(5) Å]. The nitrogen atom is slightly pyramidal [sum of angles = 348.2°] with its lone pair directed towards the carbonyl ligands. The atom C(13) is trigonal-planarly ligated with a *tert*-butyl group in *trans*-disposition to the bulky $(\eta^5\text{-}C_5Me_5)(CO)_2Fe$ unit. The valence angle at the P atom [117.0(1)°] compares well with those in **2a** and **2e** (vide supra). The peculiarities in the spectroscopic data of **2b** in relation to those of **2a** and **2e** can be rationalized by a non-existent N(lone pair)−P=C π conjugation, which is the prerequisite for excess electron density to the P atom. The lack of electronic repulsion between an electron abundant phosphorus atom and the (also) electron-rich iron-complex fragment in **3b** allows for a much shorter Fe−P distance. To further support these arguments, the X-ray structural analysis of the "classically" polarized ferriophosphaalkene $[(\eta^5\text{-}C_5Me_5)(CO)_2FeP{=}C(Ph)(SiMe_3)]$ (**3g**)[4,13] is included in this paper.

X-ray Structural Analysis of 3g

Single crystals of **3g** were grown from *n*-pentane at −4 °C. The analysis shows that the molecule is bisected by a mirror plane defined by the atoms Si(1), C(10), P(1), and Fe(1) (Figure 3).

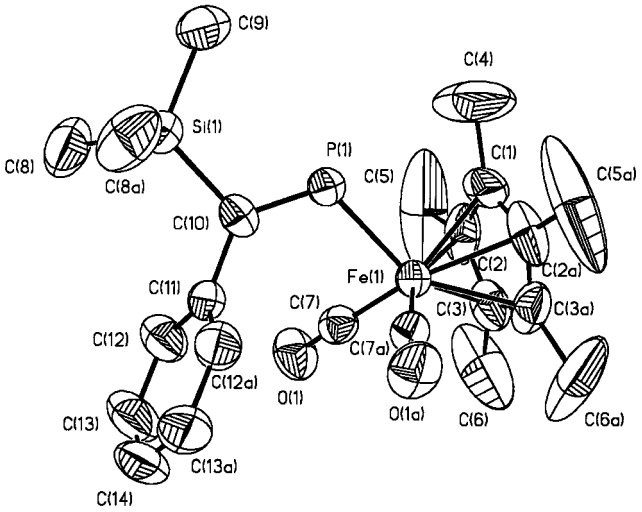

Figure 3. Molecular structure of **3g** in the crystal; selected bond lengths [Å] and angles [°]: Fe(1)−P(1) 2.269(2), Fe(1)−C(7) 1.749(5), P(1)−C(10) 1.665(6), C(10)−Si(1) 1.887(7), C(10)−C(11) 1.484(8), O(1)−C(7) 1.148(5); P(1)−Fe(1)−C(7) 90.2(2), C(7)−Fe(1)−C(7a) 99.0(3), Fe(1)−P(1)−C(10) 119.3(2), P(1)−C(10)−Si(1) 117.6(5), P(1)−C(10)−C(11) 129.4(5), Si(1)−C(10)−C(11) 112.9(4), Fe(1)−C(7)−O(1) 174.5(4)

The pentamethylcyclopentadienyl ring is disordered. The organophosphorus ligand in the "piano stool"-configured complex fragment is of primary interest for our discussion. As is observed for **3a**, an (*E*) configuration at the P=C double bond with an orthogonally directed phenyl ring in the vicinity of the $Fe(CO)_2$ unit is observed. However, in marked contrast to **3a** the bond Fe(1)−P(1) [2.269(2) Å] is shorter and compares more favorably with the bond encountered in **3b**. The P=C double bond of **3g** [1.665(6) Å] is shorter than in the inversely polarized phosphaalkenes **3a** and **3e**, and more typical for "classically polarized" phosphaalkenes without π-donating atoms at the methylene carbon atom. The valence angle Fe(1)−P(1)−C(10) of 119.3(2)° compares well with the corresponding data in **3a**, **3b**, and **3e**. The angle P(1)−C(10)−C(11) [129.5(4)°] at the trigonal planar carbon atom C(10) [sum of angles = 360.0°] is markedly more obtuse than the angle P(1)−C(10)−Si(1) [117.6(5) Å] at the side opposite to the bulky iron-complex fragment.

Conclusions

In a series of ferriophosphaalkenes of the type $[(\eta^5\text{-}C_5Me_5)(CO)_2FeP{=}CR^1(NR^2_2)]$ (R^1 = Ph, *t*Bu, 3,4,5-$(MeO)_3C_6H_2$; NR^2_2 = NMe_2, pip) it was demonstrated that the phenomenon of an inverse electron density distribution $P^{\delta-}\ C^{\delta+}$ is only realized whenever an allylic-like π-conjuga-

tion of the lone pair at the N atom with the P=C π-bond is possible. In such molecules, where the lone pair at the nitrogen atom is oriented perpendicular to the PC-π-system, a classical behavior concerning the polarity of the P=C bond ($P^{\delta+}$ $C^{\delta-}$) is observed. In an earlier paper Appel already pointed to a correlation between ^{31}P-NMR shifts of amino-substituted phosphaalkenes and the dihedral angle between the plane that includes the atoms P, C, N, and the NR_2 plane.[14]

Experimental Section

All manipulations were performed under dry nitrogen. Solvents were rigorously dried with an appropriate drying agent and freshly distilled before use. − The following compounds were prepared according to literature procedures: Thioamides $PhC(S)NMe_2$, tBuC(S)NMe_2, and {3,4,5-$(MeO)_3C_6H_2$}C(S)NMe_2 were obtained from the corresponding amides and P_4S_{10}.[15] PhC(S)pip was synthesized from benzaldehyde, piperidine, and sulfur.[16] The carbenium salts [PhC(SMe)NMe_2)I (**1a**)[17] and [PhC(SMe)pip]I (**1d**)[18] resulted from the corresponding thioamides and methyl iodide. [η^5-$Cp^*(CO)_2FeCl$],[11] $LiP(SiMe_3)_2 \cdot DME$[9] − IR spectra: Bruker FT-IR VECTOR 22. − ^{1}H-, ^{13}C-, ^{29}Si-, and ^{31}P-NMR spectra at room temp.; Bruker AC 100 (^{1}H, 100.13 MHz; ^{31}P, 40.53 MHz), Bruker Avance DRX 500 (^{1}H, 500.13 MHz; ^{13}C, 125.75 MHz; ^{29}Si, 99.53 MHz; ^{31}P, 202.46 MHz) references: $SiMe_4$ (^{1}H, ^{13}C, ^{29}Si), 85% D_3PO_4 (^{31}P).

[Me_2N(tBu)CSMe]I (1b): A solution of iodomethane (9.38 g, 66.1 mmol) in diethyl ether (60 mL) was added dropwise at ambient temp. to an ethereal solution (250 mL) of tBuC(S)NMe_2 (9.38 g, 66.1 mmol). Stirring was continued for 24 h. The precipitate was filtered, washed with diethyl ether (2 × 30 mL) and dried in vacuo to give 10.52 g (56%) of **1b** as a white powder. − ^{1}H NMR ($CDCl_3$): δ = 1.44 (s, 9 H, tBu), 2.94 (s, 3 H, SCH_3), 3.76 (s, 6 H, NCH_3). − ^{13}C{^{1}H} NMR ($CDCl_3$): δ = 23.3 (s, SCH_3), 28.7 [s, C(CH_3)$_3$], 44.3 [s, $C(CH_3)_3$], 49.4 (s, NCH_3), 53.5 (s, NCH_3), 203.7 (s, CH_3SC). − $C_8H_{18}INS$ (287.2): calcd. C 33.46, H 6.32, N 4.88; found C 33.41, H 6.05, N 4.90.

[{3,4,5-$(MeO)_3C_6H_2$}C(NMe_2)SMe]I (1c): A solution of {3,4,5-$(MeO)_3C_6H_2$}C(S)NMe_2 (9.1 g, 35.6 mmol) in diethyl ether (500 mL) was slowly combined with iodomethane (5.06 g, 35.6 mmol). After 24 h of stirring at room temp. it was filtered to afford 6.28 g (44%) of **1c** as a colorless powder. − ^{1}H NMR ($CDCl_3$): δ = 2.29 (s, 3 H, SCH_3), 3.53 (s, 3 H, NCH_3), 3.81 (s, 3 H, p-OCH_3), 3.86 (s, 6 H, m-OCH_3), 6.99 (s, 2 H, H-phenyl). − ^{13}C{^{1}H} NMR ($CDCl_3$): δ = 18.7 (s, SCH_3), 45.8 (s, NCH_3), 49.0 (s, NCH_3), 57.2 (s, m-OCH_3), 60.8 (s, p-OCH_3), 104.1 (s, C-o-phenyl), 124.2 (s, C-i-phenyl), 140.1 (s, C-p-phenyl), 154.3 (s, C-m-phenyl), 190.7 (s, $CSCH_3$). − $C_{13}H_{20}INO_3S$ (397.4): calcd. C 39.30, H 5.07, N 3.53; found C 39.02, H 5.10, N 3.53.

Me_3SiP=C(Ph)NMe_2 (2a): To a slurry of [Me_2N(Ph)CSMe]I (**1a**) (27.60 g, 89.8 mmol) in a mixture of n-pentane (100 mL) and 1,2-dimethoxyethane (DME) (100 mL) at 0 °C was slowly added a solution of $LiP(SiMe_3)_2 \cdot DME$ (24.70 g, 89.8 mmol) in a mixture of n-pentane (70 mL) and DME (70 mL). The dark yellow slurry was warmed to room temp. and stirred for another 16 h. It was filtered, and the filter cake was washed with 30 mL of DME and then with two portions of 30 mL of n-pentane. Solvents and volatile components were removed in vacuo to afford a deep orange residue. The crude product was purified by vacuum distillation (bp = 55−75 °C, 5Pa) to give 11.50 g (54%) of **2a** as a light yellow oil, which contained small amounts of $P(SiMe_3)_3$ as an impurity. − ^{1}H NMR (C_6D_6): δ = 0.10 (d, $^3J_{P,H}$ = 4.7 Hz, 9 H, $SiCH_3$), 2.20 (s, br, 3 H, NCH_3), 3.07 (s, br, 3 H, NCH_3), 6.96−7.03 (m, 5 H, Ph). − ^{13}C{^{1}H} NMR (C_6D_6): δ = 2.5 (d, $^2J_{P,C}$ = 16.6 Hz, $SiCH_3$), 42.1 (s, NCH_3), 42.3 (s, NCH_3), 127.1−128.3 (C-o-, m-, p-phenyl), 143.5 (d, $^2J_{P,C}$ = 9.0 Hz, C-i-phenyl), 204.7 (d, $^1J_{P,C}$ = 65.2 Hz, P=C). − ^{29}Si{^{1}H} NMR (C_6D_6): δ = −4.1 (d, $^1J_{P,Si}$ = 56.1 Hz). − ^{31}P{^{1}H} NMR (C_6D_6): δ = 54.3 s. Analytically samples of **2a** could not be obtained due to partial decomposition to $P(SiMe_3)_3$.

Me_3SiP=C(tBu)NMe_2 (2b): A slurry of **1b** (7.97 g, 28.0 mmol) in a mixture of 60 mL of n-pentane and 30 mL of DME was treated at −30 °C with a solution of $LiP(SiMe_3)_2 \cdot DME$ in 60 mL of a 1:1 mixture of n-pentane and DME. Stirring at room temp. was stopped after 3 h, and the slurry was filtered. From the dark yellow filtrate 2.31 g (38%) of yellow **2b** was isolated by distillation (bp: 55−60 °C, 10 Pa). − ^{1}H NMR (C_6D_6): δ = 0.31 (d, $^3J_{P,H}$ = 13.9 Hz, 9 H, $SiCH_3$), 1.35 (d, $^3J_{P,H}$ = 1.2 Hz, 9 H, tBu), 2.76 (s, 6 H, NCH_3). − ^{13}C{^{1}H} NMR (C_6D_6): δ = 2.7 (d, $^2J_{P,C}$ = 13.0 Hz, $SiCH_3$), 31.6 [s, C(CH_3)$_3$], 43.7 [d, $^2J_{P,C}$ = 25.0 Hz, $C(CH_3)_3$], 47.80 (s, NCH_3), 219.7 (d, $^1J_{P,C}$ = 94.1 Hz, P=C). − ^{29}Si{^{1}H} NMR (C_6D_6): δ = −3.1 (d, $^1J_{P,Si}$ = 74.5 Hz). − ^{31}P{^{1}H} NMR (C_6D_6: δ = 68.7 s. − Analytically pure samples of **2b** could not be obtained. Major impurity is $P(SiMe_3)_3$.

Me_3SiP=C[3,4,5-$(MeO)_3C_6H_2$]NMe_2 (2c): A slurry of **1c** (17.80 g, 45.0 mmol) in a mixture of 50 mL of n-pentane and 50 mL of DME was cooled to −70 °C, and a solution of $LiP(SiMe_3)_2 \cdot DME$ (12.40 g, 45.0 mmol) was added dropwise. It was warmed to room temp. and stirred for 4 h. Filtration and removal of volatile components in vacuo led to 8.20 g of crude orange **2c** (56%). The thermolabile oil was contaminated with $P(SiMe_3)_3$ and decomposed completely upon distillation. − ^{1}H NMR (C_6D_6): δ = 0.17 (d, $^3J_{P,H}$ = 4.5 Hz, 9 H, $SiCH_3$), 2.34 (s, br, 3 H, NCH_3), 3.15 (s, br, 3H. NCH_3), 3.38 (s, 6 H, m-OCH_3), 3.81 (s, 3 H, p-OCH_3), 6.27 (s, 2 H, Ph). − ^{13}C{^{1}H} NMR (C_6D_6): δ = 2.6 (d, $^2J_{P,C}$ = 12.6 Hz, $SiCH_3$), 42.0 (s, NCH_3), 42.2 (s, NCH_3), 55.7 (s, m-OCH_3), 60.7 (s, p-OCH_3), 105.5 (d, $^3J_{P,C}$ = 14.6 Hz, C-o-phenyl), 138.6 (d, $^2J_{P,C}$ = 9.3 Hz, C-i-phenyl), 138.8 (s, C-p-phenyl), 153.7 (s, C-m-phenyl), 204.8 (d, $^1J_{P,C}$ = 65.4 Hz, P=C). −^{29}Si{^{1}H} NMR (C_6D_6): δ = −4.1 (d, $^1J_{P,Si}$ = 56.1 Hz). − ^{31}P{^{1}H} NMR (C_6D_6): δ = 50.3 s. Analytically pure samples of **2c** could not be obtained. Major impurity is $P(SiMe_3)_3$.

Me_3SiP=C(Ph)pip (2d): Similarly, crude thermolabile **2d** (2.27 g, 62%) was obtained as an orange oil from **1d** (4.80 g, 13.2 mmol) and $LiP(SiMe_3)_2$ DME (3.79 g, 13.8 mmol) in a mixture of n-pentane and DME at −50 °C. Stirring of the resulting yellow slurry at room temp. was maintained for 16 h. − ^{1}H NMR (C_6D_6): δ = 0.11 (d, $^3J_{P,H}$ = 4.6 Hz, 9 H, $SiCH_3$), 1.17 (s, br, 6 H, CH_2), 2.70 (s, br, 2 H, NCH_2), 3.90 (s, br, 2 H, NCH_2), 6.98−7.09 (m, 5 H, Ph). − ^{13}C{^{1}H} NMR (C_6D_6): δ = 2.5 (d, $^2J_{P,C}$ = 14.3 Hz, $SiCH_3$), 24.5 (s, br, CH_2), 26.8 (s, br, CH_2), 50.9 (s, NCH_2), 127.5−128.8 (C-o-, m-, p- phenyl), 146.6 (d, $^2J_{P,C}$ = 8.6 Hz, C-i-phenyl), 205.1 (d, $^1J_{P,C}$ = 64.8 Hz, P=C). − ^{29}Si{^{1}H} NMR (C_6D_6): δ = 3.5 (d, $^1J_{P,Si}$ = 57.5 Hz). − ^{31}P{^{1}H} NMR (C_6D_6): δ = 59.5 s. Analytically pure samples of **2d** could not be obtained. Major impurity is $P(SiMe_3)_3$.

[(η^5-C_5Me_5)$(CO)_2$FeP=C(Ph)NMe_2] (3a): A solution of **2a** (4.60 g, 19.5 mmol) in DME (30 mL) was added to a slurry of [(η^5-C_5Me_5)-$(CO)_2$FeCl] (5.50 g, 19.5 mmol) in cold n-pentane (40 mL, −30 °C).

[(η^5-C_5Me_5)(CO)$_2$FeP=C(Ph)pip] (3d): Compound **3d** (0.79 g, 38%) resulted as red-brown needles from the reaction of [(η^5-C_5Me_5)-(CO)$_2$FeCl] (1.31 g, 4.6 mmol) and 1.28 g (4.6 mmol) of **2d** in an *n*-pentane/DME mixture at −78 °C. − IR (Nujol, cm^{-1}): $\tilde{\nu}$ = 1990 vs (CO), 1941 vs (CO). − ^{1}H NMR (C_6D_6): δ = 1.30−1.51 (m, 6 H, CH_2), 1.45 [s, 15 H, $C_5(CH_3)_5$], 3.44 (t, $^3J_{HH}$ = 5.4 Hz, NCH_2), 7.08−7.62 (m, 5 H, Ph). − ^{13}C{^{1}H} NMR (C_6D_6): δ = 9.0 [s, $C_5(CH_3)_5$], 24.9 (s, CH_2), 26.2 (s, CH_2), 52.7 (d, $^3J_{P,C}$ = 18.4 Hz, NCH_2), 95.8 [s, $C_5(CH_3)_5$], 127.0−130.0 (C-*o*-, *m*-, *p*-phenyl), 146.5 (d, $^2J_{P,C}$ = 7.2 Hz, C-*i*-phenyl), 201.3 (d, $^1J_{P,C}$ = 82.9 Hz, P=C), 218.0 (s, CO). − ^{31}P{^{1}H} NMR (C_6D_6): δ = 256.4 s. − $C_{24}H_{30}FeNO_2P$ (451.3): calcd. C 63.87, H 6.70, N 3.10; found C 63.77, H 6.50, N 3.07.

X-ray Crystallography: Crystallographic data were collected with a Siemens $P2_1$ four circle diffractometer with Mo-K_α (graphite monochromator, λ = 0.71073 Å). Crystallographic programs used for the structure solution and refinement were from SHELXTL PLUS and SHELXL-97. The structures were solved by Direct Methods and were refined by using full-matrix least squares on F^2 of all unique reflections with anisotropic thermal parameters for all non-hydrogen atoms. Hydrogen atoms were included at calculated positions with U(H) = 1.2 U_{eq} for groups, U(H) = 1.5 U_{eq} for CH_3 groups. Crystal data of the compounds are listed in Table 1.[19]

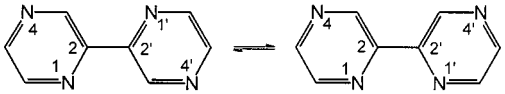
Molecular Architecture with 2,2′-Bipyrazine and Metal Ions: Infinite Loop and Molecular Square

Ralf-Dieter Schnebeck,[a] Eva Freisinger,[a] and Bernhard Lippert*[a]



Dedicated to Professor Heinrich Vahrenkamp on the occasion of his 60th birthday

Keywords: N ligands / Palladium / Platinum / Silver / Molecular architecture / Structure elucidation

The potential of $[L_2Pd(2,2'\text{-bpz-}N^1,N^{1'})]^{2+}$ [L_2 = en (**1**), L = H_2O (**4a**), 2,2′-bpz = 2,2′-bipyrazine] for use as an angular element in the generation of self-organized systems of variable molecular architecture has been studied. Ag^+ forms an infinite loop **3** with **1**, in which the metal ions function as cross-linking agents between the organic entities 2,2′-bpz. Complex **4a**, on the other hand, self-assembles as a bis(μ-OH) dinuclear species **4b**, and in the presence of 4,4′-bipyridine (4,4′-bpy) as a molecular square **6** with the heteroaromatic 4,4′-bpy ligands representing the cross-linking entities.

Introduction

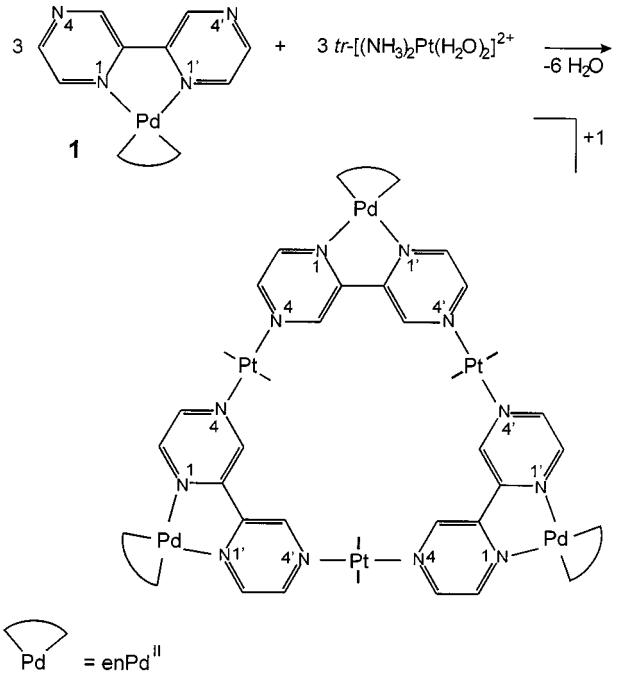
The generation of regularly shaped molecules ("molecular architecture") from organic ligands and metal entities is an area of great current interest.[1] Our own activities in this field have centered on combinations of linear (*trans*-a_2Pt^{II} with a = NH_3 or CH_3NH_2; Hg^{2+}) or *cis*-square planar (*cis*-a_2Pt^{II}, $enPt^{II}$, $enPd^{II}$) metal fragments and nucleobases or other heterocyclic ligands.[2] Among others, we have been able to isolate and characterize molecular rectangles,[3] hexagons,[4] open boxes,[4,5] triangles,[6] and barrels.[7] The use of 2,2′-bipyrazine (2,2′-bpz) proved to be particularly fortunate since it provided a large number of different metal-binding patterns due to the availability of four ring N donor atoms and its structural flexibility about the central C2−C2′ bond (Scheme 1).

Scheme 1

Interestingly, $enPd^{II}$ forms a mononuclear chelate with 2,2′-bpz, $[enPd(2,2'\text{-bpz-}N^1,N^{1'})]^{2+}$ (**1**),[6a] whereas under comparable conditions $enPt^{II}$ forms a cyclic trinuclear structure, $[\{enPt(2,2'\text{-bpz-}N^4,N^{4'})\}_3]^{6+}$,[7] which is to be considered the kinetic product of this reaction. It can be converted into the analogous chelate with $N(1),N(1')$−metal binding on prolonged heating.[7] The triangle can exist as different conformers, depending on the mutual orientation of the two pyrazine moieties of the 2,2′-bpz ligand.[7] Both the mononuclear Pd complex[6] and the Pt triangle[6a,7] can be applied as building blocks for larger aggregates by combining them with suitable metal fragments. For example, three $[enPd(2,2'\text{-bpz-}N^1,N^{1'})]^{2+}$ cations and three *trans*-$(NH_3)_2Pt^{II}$ units form a flat triangle **2** with Pd^{II} at the corners and Pt^{II} in the middle of the sides of the triangle,[6c] whereas combination of the Pt triangle $[\{enPt(2,2'\text{-bpz-}N^4,N^{4'})\}_3]^{6+}$ with three $enPd^{II}$ yields a hexanuclear molecular vase[6b] or with three Ag^+, a container compound.[7] Anion inclusion is a general phenomenon of all these compounds.

In continuation of this work we report herein the product obtained by cocrystallizing **1** with $AgClO_4$, as well as our efforts to prepare *cis*-$[(H_2O)_2M(2,2'\text{-bpz-}N^1,N^{1'})]^{2+}$ (M = Pd^{II}, Pt^{II}) instead of coordinatively saturated $[enPd(bpz\text{-}N^1,N^{1'})]^{2+}$ species and to probe their use as building blocks for regularly shaped macrocyclic compounds.

Results and Discussion



Infinite Loop Structure

As mentioned in the introduction, $[enPd(2,2'\text{-bpz-}N^1,N^{1'})]^{2+}$ (**1**) forms a triangle **2** with *trans*-$[(NH_3)_2Pt(H_2O)_2]^{2+}$, with the bpz ligands essentially coplanar with the six metal ions (Scheme 2).[6c] Although **2** forms an arrangement in the solid state that gives rise to a channel with a string of ClO_4^- anions in its center, the presence of the NH_3 ligands at Pt^{II} and their orientation essentially perpendicular to the plane of the triangle precludes any direct stacking of the cations. Rather, counter anions and water molecules are assisting formation of the channel. An obvious idea was to apply linearly coordinated metal ions such as Ag^+ instead of *trans*-$(NH_3)_2Pt^{II}$ in order to achieve neat stacking of the 2,2′-bpz entities. At the same time the use of Ag^+ instead of Pt^{2+} would somewhat reduce the high positive charge of the hexanuclear cation. However, the experiment carried out with $AgClO_4$ did not yield the anticipated closed triangular structure and neither did it generate a helical nor a polymeric open zigzag chain. Rather, as revealed by X-ray crystallography, an infinite loop is formed.

Figure 1 provides different views of the polymeric structure of $\{[enPd(2,2'\text{-bpz})Ag](ClO_4)_3\}_\infty$ (**3**). Selected bond

Scheme 2

lengths and angles of **3** are listed in Table 1. The geometry of the enPd(2,2′-bpz) moiety is normal.[6a] Ag(1) cross-links two [enPd(2,2′-bpz-N^1,$N^{1'}$)]$^{2+}$ fragments via two N(4) positions in a linear fashion, whereas there is a 160.4(3)° angle about Ag(2). It appears 1that deviation from linearity about the second silver ion is caused by the asymmetry of weak Ag(2)···$OClO_3^-$ interactions (Figure 2). The two enPd(2,2′-bpz) units bound to Ag(1) are coplanar, but those bound to Ag(2) form a dihedral angle of 30.5(2)°. As a consequence, Pd−Pd distances across Ag(1) are longer [13.930(2) Å] than those across Ag(2) [13.542(3) Å], and likewise distances between the Ag centers differ [Ag(1)···Ag(1′), 6.780(2) Å; Ag(2)···Ag(2′), 13.559(3) Å]. As evident from Figure 1, the respective metal cations are arranged in a collinear fashion along the *x* axis.

Table 1. Selected bond lengths [Å] and angles [°] of **3**

Pd(1)−N(1)	2.020(5)	N(1)−Pd(1)−N(12)	177.3(2)
Pd(1)−N(12)	2.025(5)	N(1)−Pd(1)−N(11)	98.2(2)
Pd(1)−N(11)	2.027(5)	N(12)−Pd(1)−N(11)	82.7(2)
Pd(1)−N(1′)	2.035(4)	N(1)−Pd(1)−N(1′)	80.3(2)

Ag(2)−N(4′)	2.200(4)	N(11)−Pd(1)−N(1′)	178.4(2)
		N(4)[a]−Ag(1)−N(4)	180
		N(4′)[b]−Ag(2)−N(4′)	160.4(3)

Symmetry operation: [a] $-x+1, -y, -z$. − [b] $-x+1, y, -z-1/2$.

Triangle vs. Alternatives

Reaction of **1** with Ag^+ can, in principle, lead to a triangle, an infinite helix, an infinite zigzag chain, or an infinite loop (Scheme 3). Formation of monomeric species with PdAg or $PdAg_2$ stoichiometry is not considered here. With $AgClO_4$ the loop structure is exclusively formed. Inspection of the solid state structure reveals why **3**, unlike the structurally related Pd_3Pt_3 compound **2**, does not from a triangle. At the same time it provides clues regarding the re-

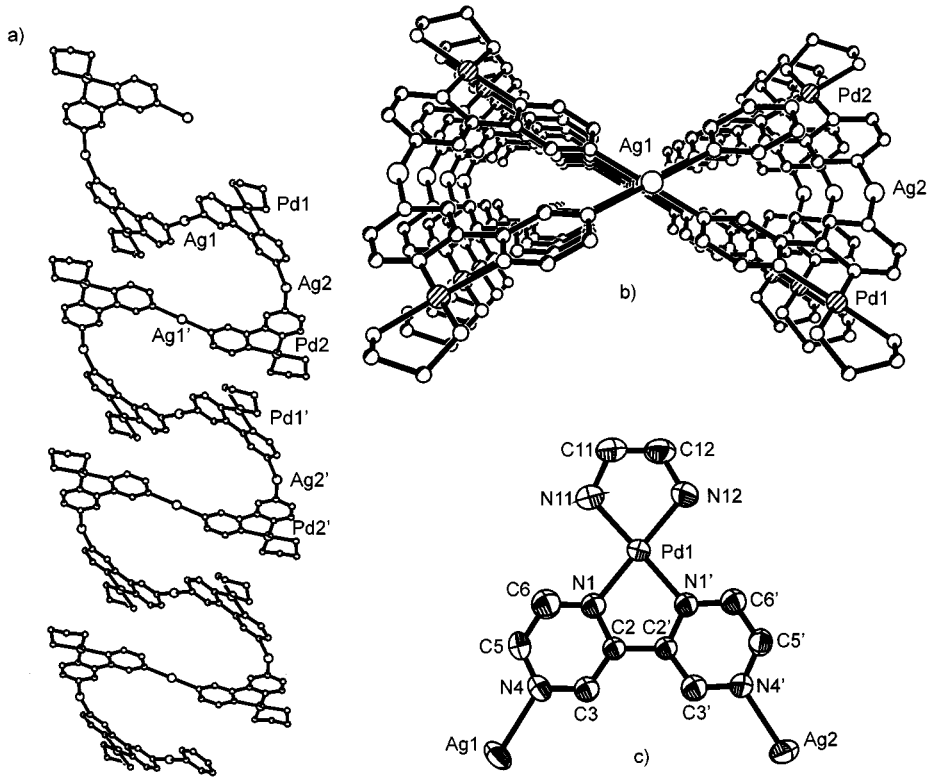

Figure 1. Side view (a), view along the *x* axis (b), and view of a section of [enPd(2,2′-bpz)Ag](ClO$_4$)$_3$ (**3**) (c); central Ag(1) ions are 6.780(2) Å apart, outer Ag(2) as well as Pd(1) ions are 13.559(3) Å apart, which correspond to the length of the crystallographic *c* axis

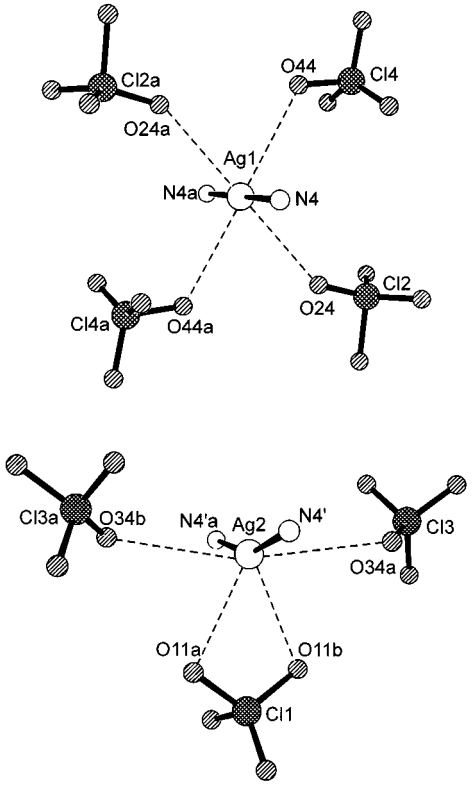

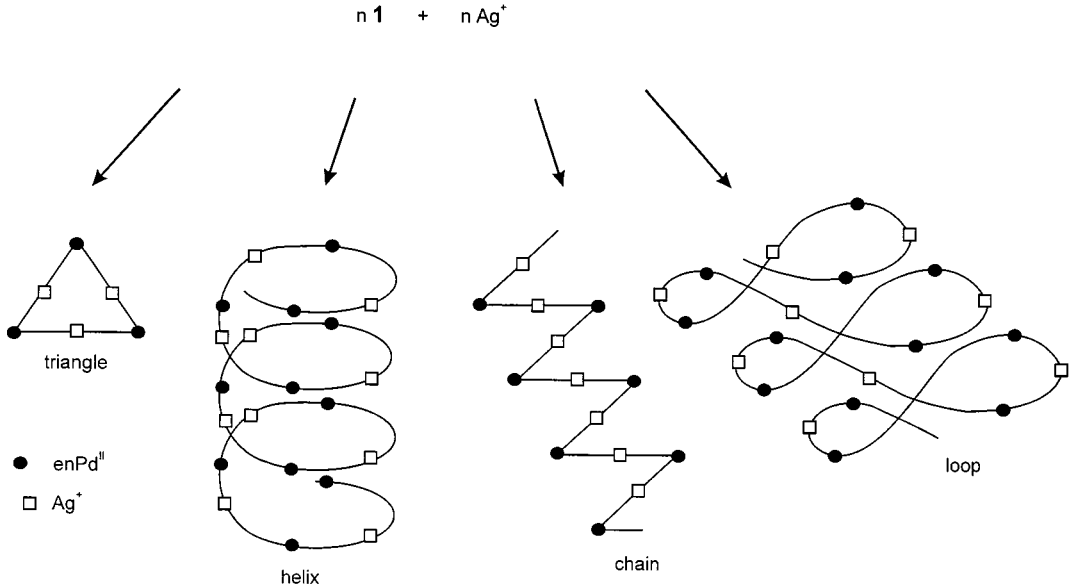

Figure 2. Different environments of Ag(1) and Ag(2) ions; Ag···O contacts are as follows: Ag(1)···O(44), 2.770(7) Å; Ag(2)···O(34a), 2.96(2) Å; Ag(2)···O(11a), 2.71(2) Å; Ag(1)···O(24), 2.71(2) Å

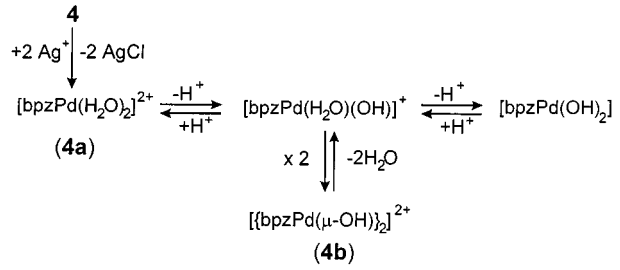
quirements for formation of all four feasible arrangements. There are two geometrical features that prevent closure of a Pd_3Ag_3 combination to form a triangle: First, the loss of coplanarity of the enPd(2,2′-bpz) entities cross-linked by Ag(2). Second, the *head-tail* orientation of the two enPd(2,2′-bpz) entities cross-linked by Ag(1). For formation of a closed triangle, mutual *head-head* orientation of all three enPd(2,2′-bpz) units is absolutely essential. It appears that the loss of collinearity about Ag(2) is of less importance, even though it might facilitate the propeller twist, hence loss of coplanarity of the two bpz ligands bound to Ag(2). The two geometrical parameters mentioned above therefore determine which of the three possible alternatives to the triangle is formed (Table 2).

Table 2. Relationship between possible structures derived from [enPd(2,2′-bpz- N^1,$N^{1'}$)]$^{2+}$ and linear metal entities from geometrical parameters

Structure	Angles [°] between three adjacent bpz ligands	Mutual orientation of adjacent bpz ligands
Triangle	ca. 0	all *head-head*
1D helix	at least 1 angle ≠ 0	all *head-head*
Loop	at least 1 angle ≠ 0	1 *head-tail*
Zigzag chain	0 or ≠ 0	all *head-tail*

We suspect that in addition to concentration effects, which should favor formation of a triangle in more dilute solution and of polymeric structures in concentrated solution, the role of the anions may be crucial in determining the solid-state structure. Although we have varied the Ag salts ($AgNO_3$, $AgPF_6$), we were unable to obtain crystals of sufficient quality for X-ray analysis with NO_3^- and PF_6^- anions. According to ^{1}H-NMR spectroscopy, **3** is labile in aqueous solution and dissociates into **1**, Ag^+, and ClO_4^-. Crystallization thus necessarily occurs from a concentrated solution, thereby favoring a polymeric structure. We note that polymeric helical structures are quite common in systems comprised of heterocyclic N-donor ligands, Ag^+ ions and poorly coordinating anions.[8] There is also an interesting parallel in the literature between our previously described Pd_3Pt_3 triangle[6c] and the polymeric PdAg structure of **3**: Kim et al.[9] have described a molecular triangle comprised of $enPt^{II}$ corners and sides that consist of pseudorotaxanes [cucurbituril entity treaded by the bifunctional



Scheme 3

N,*N*′-bis(3-pyridylmethyl)-1,4-diaminopentane], yet find formation of a 1D helix when enPt^{II} is replaced by Ag^+.[10]

Utility of *cis*-[$(H_2O)_2$M(2,2′-bpz-N^1,$N^{1'}$)]$^{2+}$ as Building Block

Our previous efforts to use 2,2′-bpz compounds had focused on coordinatively saturated enM^{II} (M = Pd or Pt) complexes with this ligand. In order to generate a molecular architecture with **1** (triangle,[6a] loop, vase[7]) bridging metal ions had to be applied. Their function was to cross-link N(4) positions. By replacing the en ligand by two Cl^- ligands, building blocks which have the potential of additional substitution of the Cl^- ligands are feasible, and hence permit an extension in two directions: Metal cross-linking through the available N(4) sites as in the case of **1** (above) and/or coordination of bridging ligands by substitution of the chloro ligands. In order to further pursue this option, we have prepared [Cl_2Pd(2,2′-bpz-N^1,$N^{1'}$)] (**4**) by reaction of K_2PdCl_4 with 2,2′-bpz and subsequently abstracted the Cl^- ligands by $AgNO_3$ to produce [$(H_2O)_2$Pd(2,2′-bpz-N^1,$N^{1'}$)]$(NO_3)_2$ (**4a**) (Scheme 4). pD-dependent ^{1}H-NMR spectra of **4a** (Figure 3) reveal formation of at least one kinetically inert (NMR time scale!) intermediate between [$(H_2O)_2$Pd(2,2′-bpz)]$^{2+}$ at low pH and the high-pH species [$(OH)_2$Pd(2,2′-bpz)]. Isolation on a preparative scale proved that this species is the dinuclear, μ-OH bridged complex [(2,2′-bpz)Pd$(OH)_2$Pd(2,2′-bpz)]$(NO_3)_2$ (**4b**). Spectra in the pD = 6−7 range indicate the presence of yet another, unidentified species. In analogy to the behavior of *cis*-[$(NH_3)_2$Pt$(H_2O)_2$]$^{2+}$,[11] [enPt$(H_2O)_2$]$^{2+}$,[12] and [enPd$(H_2O)_2$]$^{2+}$,[13] which form both μ-OH dimers, μ-OH trimers and even μ-OH tetramers,[12a] these resonances might be due to one of these higher oligomers. There is no indication of any (measurable) oligomerization of **4a** via the available N(4) sites of the 2,2′-bpz ligand.

Scheme 4

The cation of [(2,2′-bpz-N^1,$N^{1'}$)Pd$(OH)_2$Pd(2,2′-bpz-N^1,$N^{1'}$)]$(NO_3)_2$·4 H_2O (**4b**) is depicted in Figure 4. Selected interatomic distances and angles are given in Table 3.

The geometry of the central PdO_2Pd core compares very well with that of the μ-OH Pt^{II} dimer mentioned above,[11a] except that the Pd···Pd separation is somewhat shorter than that of Pt···Pt. Features of the (bpz-N^1,$N^{1'}$)Pd^{II} entity are similar to those observed in related complexes.[6,7] Dinuclear cations of **4b** are arranged like the tiles of a roof in stacks with parallel 2,2′-bpz ligands approximately 3.1 Å apart. NO_3^- anions and water molecules run in channels between individual stacks and interconnect these by hydrogen-bond formation and weak axial Pd···ONO_2 contacts. For example, NO_3^- is hydrogen-bonded to a μ-OH group [2.805(4) Å], has a contact with Pd [3.370(4) Å], and forms another hydrogen bond with a water molecule [2.807(5) Å] which in turn shows a weak contact [3.38(4) Å] with C(5)H of 2,2′-bpz in a neighboring stack.

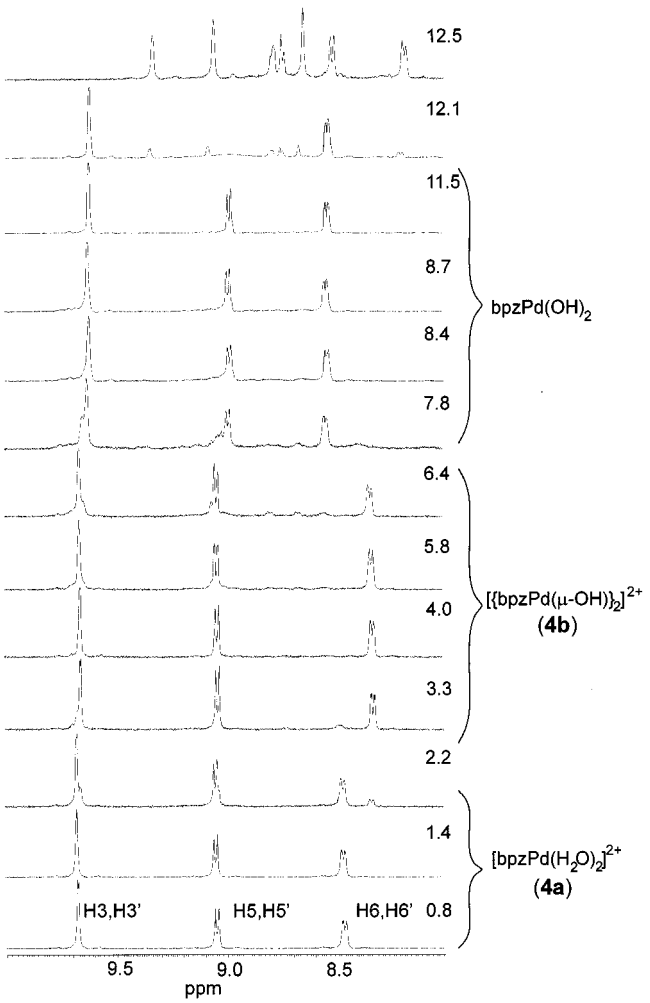


Figure 3. pD-dependent ^{1}H-NMR spectra of [(2,2′-bpz)Pd$(H_2O)_2$]$^{2+}$ in D_2O; above pD = 12 complex decomposition or rearrangement reactions take place

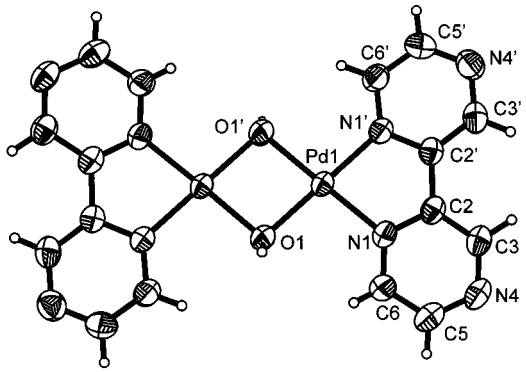

Figure 4. Molecular cation of [(2,2′-bpz-N^1,$N^{1'}$)Pd$(OH)_2$Pd(2,2′-bpz-N^1,$N^{1'}$)] $(NO_3)_2$·4 H_2O (**4b**) with atom numbering scheme; the Pt analogue **5b** is isostructural and not shown

[a] Symmetry operation: $-x, -y + 2, -z + 1$.

Similarly to **4**, the corresponding Pt complex **5** was prepared, although it was not isolated in analytically pure form. Treatment of **5** with $AgNO_3$ and crystallization at pH ≈ 3 gave the isostructural Pt analogue of **4b** [(2,2′-bpz-N^1,$N^{1'}$)Pt(OH)$_2$Pt(2,2′-bpz-N^1,$N^{1'}$)](NO$_3$)$_2$·4 H$_2$O (**5b**) in crystalline form, yet low yield. The compound is not shown, but selected structural details are listed in Table 4. The purity of **5b** was also established by ^{195}Pt- as well as ^{1}H-NMR spectroscopy in D_2O [δ = 9.64 (s, H3, H3′), 9.02 (d, J = 4 Hz, H5, H5′), 8.88 (d, H6, H6′)]. The position of the ^{195}Pt-NMR singlet at δ = −1442 agrees well with that of the μ-OH dimer derived from (*trans*-1,2-diaminocyclohexane)Pt^{II},[14] but differs from that of *cis*-[(NH$_3$)$_2$Pt(OH)$_2$Pt(NH$_3$)$_2$]$^{2+}$ (δ = −1156).[15] Addition of DNO_3 (pD = 1) converts **5b** into monomeric [(D$_2$O)$_2$Pt(2,2′-bpz)]$^{2+}$ (^{1}H-NMR resonances at δ = 9.69, 9.04, 8.84), while addition of NaOD (pD = 7) in a slow reaction gives [(OH)$_2$Pt(2,2′-bpz)] (^{1}H-NMR resonances at δ = 9.49, 9.04, 8.88).

Open Molecular Box ("Square")

Conversion of **4b** to [(H$_2$O)$_2$Pd(2,2′-bpz-N^1,$N^{1'}$)]$^{2+}$ (**4a**) and subsequent reaction with 4,4′-bipyridine (4,4′-bpy) yielded the cyclic compound [{(bpz-N^1,$N^{1'}$)Pd(4,4′-bpy)}$_4$](NO$_3$)$_8$·14.4 H$_2$O (**6**) in high yield. Figure 5 gives a view of the tetranuclear cation.

Table 5. Selected bond lengths [Å] and angles [°] of **6**

[a] Symmetry operation: $-x + 1, -y, -z + 2$.

Salient structural features are listed in Table 5. The cation bears a close resemblance to related molecular squares[16] built of 4,4′-bpy sides and segments of two-dimensional networks containing the 4,4′-bpy square motif, respect-

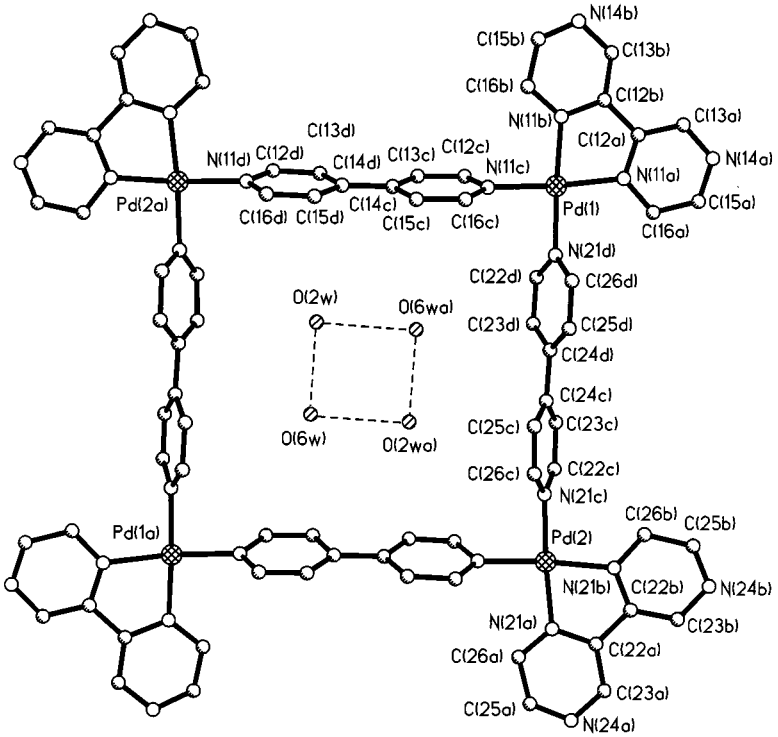

Figure 5. View of tetranuclear cation of **6** with four water molecules inserted

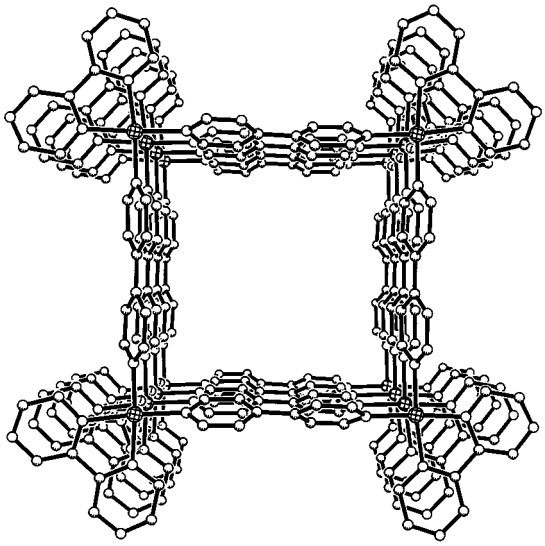
ively.[17] The four heavy-metal ions are exactly coplanar (as opposed to a strongly puckered, hence nonplanar arrangement as seen with bulky phosphane groups at the metal entities[16]), forming a square with edge-to-edge distances of ca. 11.057(3) Å and diagonal Pd···Pd distances of 15.703(4) Å [Pd(1)···Pd(1)] and 15.603(4) Å [Pd(2)···Pd(2)]. Of the 4,4′-bpy units in **6**, two are markedly twisted [41.6(3)°] about the central C−C bond, while the two others are hardly twisted [1.5(7)°]. Nevertheless, the four 4,4′-bpy ligands are approximately perpendicular to the Pd_4 square, thus making **6** in essence an "open box".[18] The coordination geometries of the Pd corner units deviate markedly from the ideal square-plane as far as angles are concerned. Four water molecules, interacting through H bonds [O(2w)···O(6w), 2.97(2) Å] and almost coplanar with the Pd_4 plane [deviations 0.26(2) Å for O(2w); 0.25(2) Å for O(6w)], reside in the center of the square. Tetranuclear cations of **6** stack, at a distance of 6.302(1) Å between Pd centers, in such a way as to produce long channels (Figure 6), which run along the *y* axis. Individual segments of the channel (Pd_4 squares) are interrupted by four NO_3^- anions, which are oriented parallel to the Pd_4 plane and sandwiched between individual squares. Pd···O distances are 3.02(1) Å [Pd(1)···O(22)] and 3.09(1) Å [Pd(2)···O(12)]. The remaining anions are distributed as follows: Pairs of NO_3^- anions (50% occupancy) are oriented perpendicular to the Pd_4 planes in the space between layers of Pd_4 squares. They show multiple hydrogen bonding interactions with additional water molecules. The remaining NO_3^- anions (three per tetranuclear cation) reside at the outside of the square, hence between individual channels.



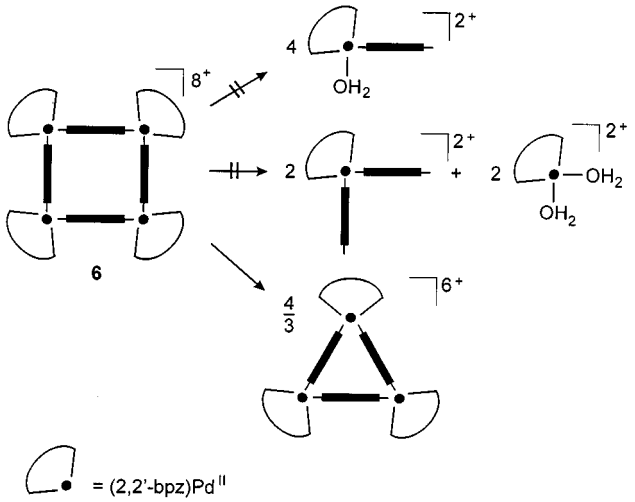


Figure 6. Packing diagram with channel formed by cations of **6**; the view is along the *y* axis; nearest intercationic Pd···Pd distances are 6.302(1) Å; water molecules and NO_3^- anions are omitted

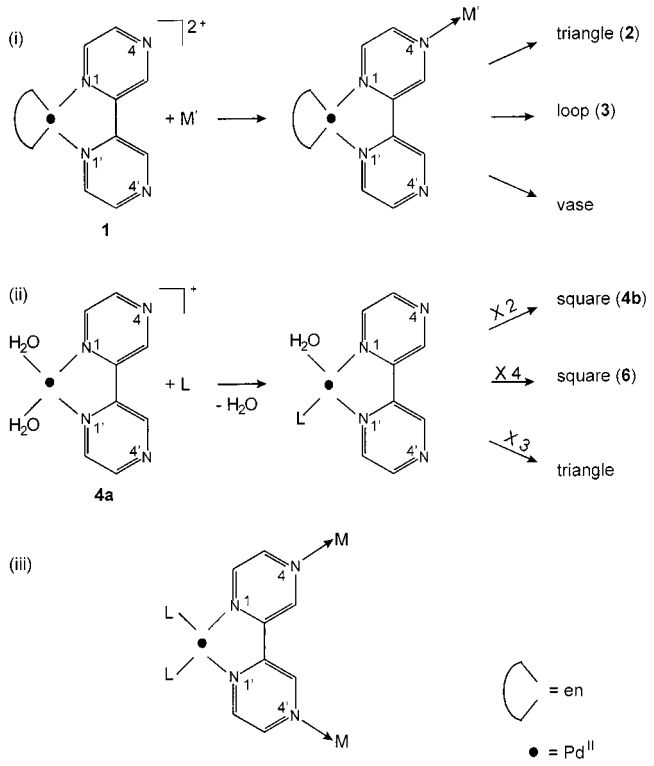
Formation of similar channels has been reported before,[16,17,19] occasionally with inclusion of strongly hydrophobic guests such as *o*-halobenzene[17] or naphthalene.[19]



In aqueous solution (pD = 2) **6** coexists with a second species. In addition to the five ^{1}H-NMR resonances due to the 2,2′-bpz ligands (H3, H3′; H5, H5′; H6, H6′) and the two protons H_α and H_β of 4,4′-bpy, a second set of resonances (ca. 30−35% of the former at a concentration of 0.016 M of dissolved tetramer **6**) is observed. The assignment of the individual resonances is straightforward on the basis of differences in H,H coupling constants and 2D-NMR experiments, respectively. The simplicity of the signal patterns of 2,2′-bpz and 4,4′-bpy resonances of both species present in solution are neither consistent with dissociation of tetranuclear **6** into monomeric $[(2,2'\text{-bpz})Pd(4,4'\text{-bpy-}N^1)(D_2O)]^{2+}$ (expected doubling of bpz and bpy resonances due to nonequivalence of two halves of these molecules) nor dissociation into $[(2,2'\text{-bpz})Pd(4,4'\text{-bpy-}N^1)_2]^{2+}$ and free $[(2,2'\text{-bpz})Pd(D_2O)_2]^{2+}$ (expected doubling of bpy resonances; two sets of bpz resonances). We tentatively favor a proposal made by Fujita et al.,[19] according to which the molecular square assembled from $(2,2'\text{-bpy})Pd^{II}$ (2,2′-bpy = 2,2′-bipyridine) and 4,4′-bpy equilibrates in solution with a cyclic trinuclear species[19] (Scheme 5). An interesting detail of the ^{1}H-NMR spectrum of dissolved **6** (c.f. Experimental Section) supporting this view refers to the chemical shift of the protons H6, H6′ of the 2,2′-bpz ligands in the two species: In the major species, which is assigned to the square, this resonance (d, $^3J_{5,6}$ = 3 Hz) occurs at δ = 7.98 while in the minor one, tentatively assigned to the cyclic trimer, this doublet is found at δ = 8.38. From model building it becomes clear that H6, H6′ of 2,2′-bpz is experiencing the ring current of the pyridine ring of the 4,4′-bpy ligands to a larger extent than is to be anticipated for a triangular structure. Therefore it is to be expected that H6, H6′ of 2,2′-bpz resonates upfield from that of the molecular triangle in the case of a molecular square.

Scheme 5

Conclusions

As outlined in Scheme 6, $[L_2Pd(2,2'\text{-bpz-}N^1,N^{1'})]^{2+}$ cations [L_2 = en (**1**), L = H_2O (**4a**)] represent useful angular units for the generation of larger cationic aggregates. There are two principal ways by which this can be achieved. (i) When additional metal ions M′ bind to the available N(4) positions of the chelating 2,2′-bpz ligand in **1** and cross-

Scheme 6

link to other cations **1**, depending on the geometry of M′, flat triangles [M′ = *trans*-$(NH_3)_2Pt^{II}$ **2**[6c]], loop structures ($M' = Ag^+$ in **3**) or hexanuclear vases (M′ = $enPd^{II}$ [7]) can form. (ii) Compound **4a** can likewise act as an angular unit upon substitution of the aqua ligands by other bridging ligands L. These may be small (OH^- in **4b**) or large (4,4′-bpy in **6**) and may themselves be angular (OH^-) or linear units (4,4′-bpy). Of course, variations of these motifs are possible, e.g. upon use of M′−L−M′ fragments in (i) or L−M′−L linear units in (ii). Finally there is, in principle, also the possibility of combining (i) and (ii) in such a way as to use **4a** as a cross element in molecular architecture [option (iii) in Scheme 6].

Experimental Section

2,2′-Bpz[20] and [enPd(2,2′-bpz-$N^1,N^{1'}$)]$(ClO_4)_2$ (**1**)[6a] were prepared as reported. 4,4′-Bipyridine was obtained commercially.

[enPd(2,2′-bpz-$N^1,N^{1'}$)Ag]$_n(ClO_4)_{3n}$ (3): [enPd(2,2′-bpz-$N^1,N^{1'}$)]$(ClO_4)_2$ (**1**) (100.00 mg, 0.191 mmol) was dissolved in water (10 mL) and stirred with $AgClO_4$ (43.00 mg, 0.191 mmol) for 1 d at room temperature. The yellow solution was then filtered, concentrated to 3 mL by rotary evaporation, and then kept at 4 °C. Yellow **3** was obtained in 79% yield (110.28 mg) within 4 d. $C_{10}H_{14}AgCl_3N_6O_{12}Pd$ (730.89): calcd. C 16.4, H 1.9, N 11.4; found C 16.2, H 1.9, N 11.3. ***Caution!*** Perchlorate salts are potentially explosive and should be used in small quantities only.

[Cl_2Pd(2,2′-bpz-$N^1,N^{1'}$)] (4): 2,2′-bpz (100.00 mg, 0.63 mmol) and K_2PdCl_4 (206.00 mg, 0.63 mmol) were suspended in water (20 mL) and stirred for 1 d at room temperature. The yellow solid was then filtered off and washed with $CHCl_3$ (10 mL) (95% yield, 200.78 mg). $C_8H_6Cl_2N_4Pd$ (335.48): calcd. C 28.6, H 1.8, N 16.7; found C 28.3, H 1.9, N 16.5.

[$(H_2O)_2$Pd(2,2′-bpz-$N^1,N^{1'}$)]$(NO_3)_2$ (4a): The complex was prepared in situ by treating **4** with 2 equiv. of $AgNO_3$ in H_2O or alternatively by acidification (HNO_3, pH < 3) of an aqueous solution of **4b**. − ^{1}H NMR (200 MHz, D_2O, TSP, pD < 3): δ = 8.47 (dd, $^3J_{5,6}$ = 3 Hz, 2 H, arom., $^5J_{3,6}$ = 1.1 Hz, 2 H, arom.), 9.05 (d, $^3J_{5,6}$ = 3 Hz, 2 H, arom.), 9.68 (d, $^5J_{3,6}$ = 1 Hz, 2 H, arom.).

[(2,2′-bpz-$N^1,N^{1'}$)Pd$(OH)_2$Pd(2,2′-bpz-$N^1,N^{1'}$)]$(NO_3)_2$·4 H_2O (4b): **4** (300.00 mg, 0.994 mmol) was suspended in water (15 mL) and stirred for 24 h at room temperature with $AgNO_3$ (338.00 mg, 1.988 mmol). After removal of AgCl by filtration, the pH value was adjusted to 3, then the reaction mixture was heated to 60 °C and filtered again. Yellow-orange crystals of **4b** were isolated in 62% yield (222.85 mg) within 1 d at 4 °C. $C_{16}H_{18}N_{10}Pd_2O_{10}$ (723.21 for dihydrate): calcd. C 26.6, H 2.5, N 19.4; found C 26.7, H 2.4, N 19.3. − ^{1}H NMR (200 MHz, D_2O, TSP, pD = 5.5): δ = 8.34 (dd, $^3J_{5,6}$ = 3 Hz, 2 H, arom., $^5J_{3,6}$ = 1.1 Hz, 2 H, arom.), 9.05 (d, $^3J_{5,6}$ = 3 Hz, 2 H, arom.), 9.66 (d, $^5J_{3,6}$ = 1 Hz, 2 H, arom.).

[Cl_2Pt(2,2′-bpz-$N^1,N^{1'}$)] (5): 2,2′-bpz (100.00 mg, 0.63 mmol) and K_2PtCl_4 (262.00 mg, 0.63 mmol) were suspended in water (15 mL) and stirred for 4 d at 80 °C. The yellow solid was then filtered off, washed with $CHCl_3$ (10 mL) and dried. **5** could not be isolated in pure form and possibly contained a compound with (2,2′-bpz-$N^4,N^{4'}$)Pt^{II} species.

[(2,2′-bpz-$N^1,N^{1'}$)Pt$(OH)_2$Pt(2,2′-bpz-$N^1,N^{1'}$)]$(NO_3)_2$·4 H_2O (5b): Crude **5** (369.00 mg, 0.87 mmol) was suspended in water (15 mL) and stirred for 24 h at 80 °C with $AgNO_3$ (338.00 mg, 1.988 mmol). After removal of AgCl by filtration, the pH value was adjusted to 3, the reaction mixture heated to 60 °C and filtered again. Yellow-orange crystals of **5b** were isolated in less than 5% yield (22.00 mg)

within 1 d at 4 °C. − ^{1}H NMR (200 MHz, D_2O, TSP, pD = 4.2): δ = 8.71 (d, $^3J_{5,6}$ = 4 Hz, 2 H, arom.), 9.02 (d, $^3J_{5,6}$ = 4 Hz, 2 H, arom.), 9.62 (s, 2 H, arom.).

[{(2,2′-bpz-N^1,$N^{1'}$)Pd(4,4′-bpy)}$_4$](NO$_3$)$_8$·14.4 H$_2$O (6): 4b (88.00 mg, 0.127 mmol) was dissolved in H_2O (15 mL) at 40 °C and the pH value of the solution was adjusted to 1.5 with 1N HNO_3. 4,4′-Bipyridine (38.00 mg, 0.243 mmol) was then added, the pH value readjusted and the mixture stirred for 12 h at 45 °C. Following cooling at 4 °C, thin yellow needles of **6** were isolated within 1 h. The needles were filtered and washed with H_2O (5 mL). After recrystallization from H_2O, the yield was 86% (132.60 mg). $C_{72}H_{84.8}N_{32}Pd_4O_{38.4}$ (2438.52): calcd. C 35.5, H 3.5, N 18.4; found C 35.9, H 3.2, N 18.8. − ^{1}H NMR (200 MHz, D_2O, TSP, pD = 2) major peaks: δ = 10.17 (s, 2 H, arom. H3-bpz), 9.60 (d, $^3J_{\alpha,\beta}$ = 6.5 Hz, 4 H, arom. Hα-bpy), 9.24 (d, $^3J_{5,6}$ = 3 Hz, 2 H, arom. H5-bpz), 8.49 (d, $^3J_{\alpha,\beta}$ = 6.5 Hz, 4 H, arom. Hβ-bpy), 7.98 (d, $^3J_{5,6}$ = 3 Hz, 2 H, arom. H6-bpz); minor peaks: δ = 9.41 (d, $^3J_{\alpha,\beta}$ = 6.5 Hz, 4 H, arom. Hα-bpy), 9.29 (d, $^3J_{5,6}$ = 3 Hz, 2 H, arom. H5-bpz), 8.38 (d, $^3J_{5,6}$ = 3 Hz, 2 H, arom. H6-bpz), 8.35 (d, $^3J_{\alpha,\beta}$ = 6.5 Hz, 4 H, arom. Hβ-bpy).

Instrumentation: ^{1}H-NMR spectra were recorded at 20 °C with a Bruker AC 200 FT NMR spectrometer in D_2O (with TSP as internal standard). pD values (for D_2O solutions) were obtained by adding 0.4 units to the pH meter reading of the electrode. − Elemental analyses were performed with a Carlo Erba Model 1106 Strumentazione Element-Analyzer.

X-ray Crystal Structure Determinations: Intensity data for **3**, **4b**, **5b**, and **6** were collected with an Enraf−Nonius Kappa CCD[21] (Mo-K_α, λ = 0.71069 Å, graphite monochromator) with sample-to-detector distances of 26.7 (**4b**, **5b**), and 30.7 mm (**3**, **6**), respectively. They covered the whole sphere of reciprocal space by measurement of 360 frames rotating about ω in steps of 1°. The exposure times were 14 (**3**), 30 (**4b**), 45 (**5b**), and 75 s (**6**) per frame. Preliminary orientation matrices and unit cell parameters were obtained from the peaks of the first ten frames, respectively, and refined using the whole data set. Frames were integrated and corrected for Lorentz and polarization effects using DENZO.[22] The scaling as well as the global refinement of crystal parameters were performed by SCALEPACK.[22] Reflections, which were partly measured on previous and following frames, are used to scale these frames with each other. Merging of redundant reflections in part eliminates absorption effects and also reveals if crystal decay occurs. The structures were solved by standard Patterson methods[23] and refined by full-matrix least squares based on F^2 using the SHELXTL-PLUS[24] and SHELXL-93 programs.[25] The scattering factors for the atoms were those given in the SHELXTL-PLUS program. Transmission factors were calculated with SHELXL-97.[26] Hydrogen atoms were included in calculated positions and refined with isotropic displacement parameters according to the riding model, except for all protons in **4b** and the hydroxy and the four water protons in **5b**, which could be localized with difference Fourier synthesis. The anions and water molecules in **3** and **6** are disordered.[27] X-ray data are provided in Table 6.

NMR Solution Structure of a DNA 12/11-*mer*: d(CTCCTGTGTCTC)·d(GAGATA−AGGAG) Containing a Transplatin Interstrand G−N7/A−N1 Cross-Link

Bjørn Andersen,[a] Eloy Bernal-Méndez,[b] Marc Leng,[b] and Einar Sletten*[a]

Keywords: Oligonucleotides / Platinum / Molecular dynamics / NMR spectroscopy

The solution structure of a double-stranded DNA oligonucleotide, d(CTCCTG*TGTCTC)·d(GAGATA*–AGGAG), containing a *trans*-diammineplatinum(II) interstrand cross-link (the asterisks indicate the two cross-linked bases) has been determined by means of two-dimensional nuclear magnetic resonance (2D NMR) and NOE-restrained molecular dynamics and energy minimization refinement. The cross-linked duplex was prepared in two steps. First, *trans*-diamminedichloroplatinum(II) was reacted with the single-stranded d(CTCCTGTGTCTC), which resulted in the formation of a stable (G1,G3)-intrastrand cross-link. Then, the platinated oligonucleotide was hybridized with the partially complementary oligonucleotide d(GAGATA–AGGAG), in which the d(AT) doublet facing the intrastrand GTG cross-link replaced the d(CAC) triplet in a regular duplex. The formation of the hybrid promoted the rearrangement of the (G1,G3)-intrastrand cross-link into an interstrand cross-link. The NMR experiments were performed in 0.5 m NaCl solution. All the exchangeable and nonexchangeable proton resonances (except some H5′/H5′′ signals) of the major species could be assigned. NOESY spectra and chemical shift data indicate that the interstrand cross-link is established between G6–N7 and A18–N1. The platinated G residue is rotated about the glycosyl bond from an *anti* conformation into a *syn* conformation. The two imino protons G8–H1 and T17–H3 forming hydrogen bonds in the mismatched base pair, G8–T17, give rise to signals (upfield as expected) at δ = 10.52 and δ = 10.82. Using all the NOESY data (215 constraints) from a 0.8 mm sample, a solution structure of the cross-linked duplex has been obtained by NOE-restrained molecular dynamics/mechanics refinements. Only the central portion of the duplex deviates significantly from regular B-form geometry. The base residue T7 in the context GTG in the top strand is located in an extrahelical position. The interstrand cross-link induces a bend of 21° in the duplex.

Introduction

Recent years have witnessed the advent of oligonucleotides as tools for the modulation of gene expression. In the so-called antisense strategy, the binding of oligonucleotides to mRNA leads to inhibition of translation or RNA metabolism by two general mechanisms, namely the degradation of the targeted RNA by RNase H or the steric blocking of the cellular machinery.[1−8] Most studies in this area have dealt with RNase H-catalyzed cleavage of mRNA by phosphodiester oligonucleotides. However, a major drawback of these oligonucleotides is their rapid degradation by nucleases. They can be replaced by phosphorothioate oligonucleotides, which retain the ability to activate RNase H and are resistant to nucleases. Unfortunately, however, these are known to have side effects because of nonspecific binding to cellular proteins. An advantage of the steric blocking of cellular machinery is that chemically modified, and thus nuclease-resistant oligonucleotides can be used. However, a major constraint is that the oligonucleotide−RNA hybrids have to be sufficiently stable to avoid dissociation by the cellular machinery. Cross-linking of the oligonucleotides to their targets[1−8] can prevent such dissociation. Recently, a convenient method has been proposed for the specific and irreversible cross-linking of oligonucleotides to their targets in both cell-free and cell media. In this approach, *trans*-DDP [DDP: diamminedichloroplatinum(II)] modified oligonucleotides are used.[9]

In the reaction between *trans*-DDP and single-stranded oligonucleotides containing the triplet GNG (N being a nucleotide residue), (G1,G3)-intrastrand cross-links are formed. These intrastrand cross-links are stable as long as the oligonucleotides are single-stranded. There is, however, one exception.[10,11] It concerns intrastrand cross-links that have an adjacent C residue on the 5′ side. In the context d(CGNG) (N being A, T, or C), the following linkage isomerization occurs: *trans*-DDP [d(CGNG)−N7−G, N7−G] ⇄ *trans*-DDP [d(CGNG)−N3−C, N7−G]. Replacement of the C residue adjacent to the adduct on the 5′ side by a G, A, or T residue prevents this reaction.

Pairing of the single-stranded oligonucleotides containing a (G1,G3)-intrastrand cross-link with their complementary strands has two consequences. Firstly, the rearrangement of the (G1,G3)-intrastrand cross-link to the

(C1,G4)-intrastrand cross-link is blocked. Secondly, another linkage isomerization reaction is triggered by the formation of the double helix, which involves rearrangement of the (G1,G3)-intrastrand cross-link into an interstrand cross-link. This rearrangement occurs irrespective of the nature of the nucleotide residues adjacent to the intrastrand cross-link.[9,12−14]

The mechanism of the rearrangement is not yet known in detail, although some points have been established.[12−14] In the interstrand cross-link, only the 5′G (and not the 3′G) of the former intrastrand cross-link is involved. The interstrand cross-linking reaction does not proceed through a solvent-associated intermediate. Cleavage of the Pt−3′G bond with formation of a monofunctional adduct can be excluded. Direct nucleophilic attack of the Pt−3′G bond by either the C residue complementary to 5′G, or the A residue if the triplet complementary to the intrastrand cross-link is replaced by the doublet d(TA) or r(UA), has been suggested. At 37 °C, the rate of the interstrand cross-linking reaction depends on several parameters, such as the shape of the double helix and the sequence of the targeted oligonucleotide. The fastest reaction (complete within a few minutes) occurs in the hybrids between platinated oligo(2′-*O*-Me)nucleotides and RNA containing the doublet UA facing the platinated triplet.

Our envisaged uses of the *trans*-DDP-modified oligonucleotides are as tools in molecular biology and as drugs for modulating gene expression. In both cases, the requisite oligonucleotides have to be designed, which implies a complete knowledge of the interstrand cross-linking reaction. Knowledge of the structures of the cross-linked duplexes is thus essential, which prompted us to undertake a systematic study of the structures of these duplexes. In this paper, we report on a structure determination of a *trans*-DDP interstrand cross-linked DNA duplex. The system investigated in detail consists of a 12/11-*mer* hybrid d(CTCCTG*TGTCTC)·d(GAGATA*−AGGAG) (the asterisks indicate the cross-linked bases), in which the lower strand differs from the regular complementary strand in that the CAC triplet complementary to the platinated GTG triplet is replaced by the doublet d(TA). The interstrand cross-linked product has been characterized by NMR spectroscopy and a combination of NOESY-restrained molecular dynamics and energy minimization refinement.

Results

Synthesis of the Cross-Linked Duplexes

A scheme showing the synthesis of a duplex incorporating an interstrand cross-link is given in Figure 1, a. The progress of the cross-linking reaction was monitored by FPLC analysis (Figure 1, b), which showed that after 9 days it had almost reached completion. The ^{1}H-NMR spectrum of the sample obtained following FPLC purification featured one set of major resonances as well as some small signals due to a minor component (< 3%) (Figure 2, a). When the spectrum was recorded a few days later, the resonances attributable to the minor component had increased to ca. 14% (Figure 2, b). The signals due to this minor species were not characterized further by NMR analysis because of a low spectral signal-to-noise ratio. Subsequently, the salt concentration was increased to 0.5 M NaCl, which led to an appreciable reduction in the amount of the minor component, its concentration returning to a level comparable to that seen in the initial spectrum (< 3%). This suggests a salt-induced shift in the conformational equilibrium in favor of the major component. The melting temperature for the cross-linked duplex in 0.150 M NaCl was found to be 62 °C, and probably a few degrees higher in 0.500 M NaCl.

NMR Assignments

Comparison of the aromatic−H1′/H5 regions of the NOESY spectra of the platinated (Figure 3) and nonplatinated duplex (Figure 4) reveals dramatic changes in the chemical shift patterns. It is difficult to directly compare the

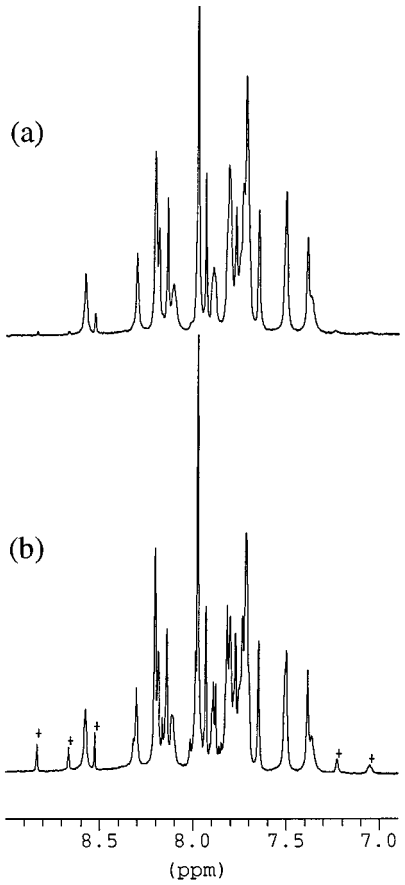

Figure 2. The downfield region of the 600 MHz ^{1}H-NMR spectrum of the *trans*-DDP cross-linked duplex d(CTCCTG* TGTCTC)·d(GAGATA*−AGGAG) (the asterisks * indicate the cross-linked bases) in D_2O at 305 K; (a) freshly prepared sample, (b) one week later; the signals attributable to the minor component are marked with +

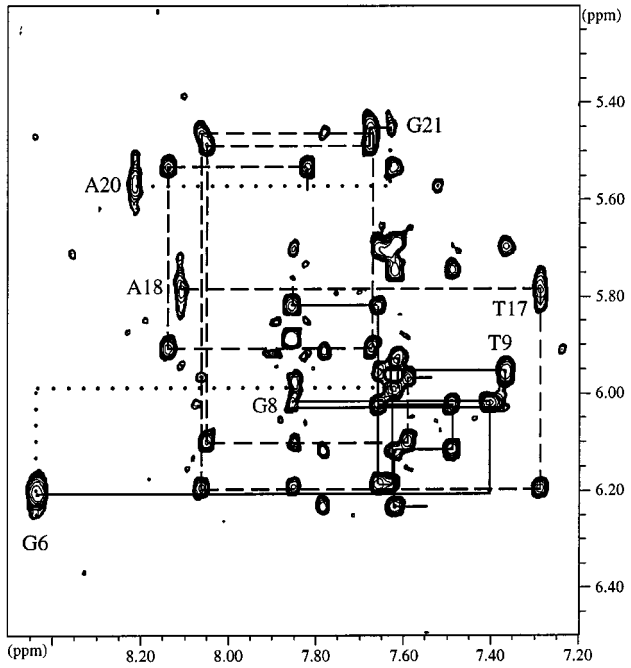

Figure 3. Contour plots of the resolution-enhanced H8/6−H1′/H5 region in the 600 MHz NOESY spectra of the *trans*-DDP cross-linked duplex d(CTCCTG*TGTCTC)·d(GAGATA*−AGGAG); the sequential connectivities are indicated with solid lines for the upper strand and broken lines for the lower strand, while absent connectivities are shown with dotted lines; the mixing time was 200 ms and the temperature 290 K

number of observed cross-peaks due to the large concentration difference, i.e. 0.8 mM and 3 mM, respectively. The non-exchangeable proton resonances were assigned following standard procedures; most of the sequential connectivities could be observed in the cross-peaks in the different spectral regions, i.e. aromatic−H1′/H3′, and aromatic−aromatic. Cross-peaks arising from traces of nonplatinated oligomers could be identified by comparison of NOESY maps of the duplex before and after platination. As expected, the 2D NOESY map of the platinated species shows a substantial downfield shift of the signal due to H8 of the cross-linked G6 residue. The chemical shift of adenine A18−H8, the cross-linked residue on the lower strand, is found in the normal range for H8 protons of nonplatinated A−N7. In the expanded portion of the downfield region of the 1D proton spectrum, two broad partially overlapping signals are observed at $\delta = 8.43$ and $\delta = 8.45$. By reference to the NOESY spectra, these resonances were assigned to the downfield shifted G6−H8 and A18−H2 protons of the platinated G and A residues, respectively. The DQF-COSY data were not of sufficient quality to yield reliable coupling constants for the sugar region due to severe overlap. The exchangeable proton resonances were assigned on the basis of the 1D spectra (Figure 5) and 2D NOESY spectra of the imino−imino and amino−aromatic regions. The chemical shifts of the assigned resonances of the platinated and non-platinated duplexes are listed in Table 1.

The NMR data for the 13/12-*mer* cross-linked duplex, which has an extra GC base pair, are almost identical to those obtained for the 12/11-*mer* (data not shown). The idea of extending the sequence was to increase the thermal stability of the duplex and thus to improve the quality of the spectral data. However, a comparison of the imino regions of the 12/11-*mer* and the 13/12-*mer* reveals only marginal improvement (data not shown).

The most prominent features in the spectra are the large downfield shifts of G6−H8 ($\delta = 8.43$) and A18−H2 ($\delta = 8.45$), which confirm that the cross-link is established between G6−N7 and A18−N1. The large intranucleotide G6−H8···H1′ crosspeak (Figure 3) corresponds to a *syn* conformation, which is probably adopted as a result of the platination. The H8/H1′ cross-peaks involving the adenine residues A18 and A20 are elongated, reflecting the rather flexible conformation at 290 K.

The connectivities involving adenine H2 protons are important in determining the global structure. The signal-to-noise level in the NOESY spectra of the nonplatinated duplex allows us to identify several H2···H1′ contacts of the type H2(n)···H1′(n), H1′(n+1), H1′(m+1), H1′(m), where n and m refer to complementary residues in a base pair. The H2(n)···H1′(m) distance in a regular Watson−Crick base pair is approximately 5.1 Å and the cross-peak correspond-

Figure 4. Figure 5. Imino proton resonances of the duplex d(CTCCTG*TGTCTC)·d(GAGATA*−AGGAG) at 290 K; (a) nonplatinated and (b) *trans*-DDP platinated

ing to such a long distance is not normally observed in NOESY maps. In the platinated form, H2(n)···H1′(m+1) cross-strand contacts are observed between A14/C12, A16/C10, and A23/C3.

The proton resonances of two of the thymine residues, T7 and T17, are of particular importance since these are involved in atypical duplex geometry. Thymine T7 may be located either in a bulged extrahelical position or stacked in the helix. Thymine T17 is partner in a GT mismatched base pair and thus might exhibit unusual chemical shifts. The methyl resonance of T7 is very weak, indicating a high degree of conformational motion. No cross-peaks in the aromatic−aromatic region involving T7−H6 are detected, suggesting that T7 is looped out of the double helix. The chemical shifts of the thymine T17 protons are, however, compatible with a regular B-DNA geometry.

The ^{1}H-NMR spectrum of the exchangeable protons in H_2O solution is rather noisy at 290 K (Figure 5). At lower temperatures, the situation is not improved due to extensive signal broadening at the relatively high salt concentration (0.5 M NaCl). The imino resonances of G8 and T17 are, however, easily recognized by virtue of their expected upfield positions at $\delta = 10.52$ and $\delta = 10.82$, characteristic for a mismatched base pair. Due to the low signal-to-noise level in the NOESY map, not all of the imino resonances could be assigned unambiguously.

^{31}P-NMR spectra of the nonplatinated and platinated duplexes are shown in Figure 6. It was not possible to assign the resonances on the basis of the available data. For the nonplatinated duplex, we had expected a downfield shifted resonance for the extrahelical thymine residue. However, the resonance patterns for both the nonplatinated and platinated duplexes, centered at about $\delta = -4.1$ and with no downfield shifted resonances, are indicative of a range of phosphate conformations consistent with regular DNA geometry.

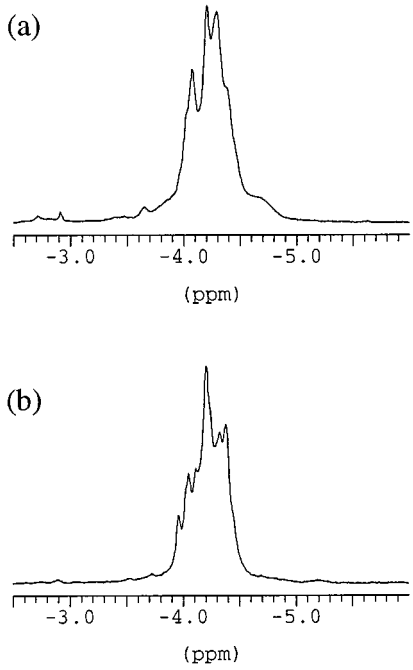

Figure 6. ^{31}P-NMR spectra of the duplex d(CTCCTG*TGTCTC)·d(GAGATA*−AGGAG) at 290 K; (a) nonplatinated and (b) *trans*-DDP platinated; shifts referenced to trimethyl phosphate

Molecular Modelling

Many cycles of subsequent interactive geometry refinements starting from regular B-DNA geometry converged at a model, the simulated NOESY spectra for which were in satisfactory agreement with the experimental spectra, as

Table 1. ^{1}H-NMR chemical shifts (ppm) for the *trans*-DDP cross-linked duplex d(CTCCTG*TGTCTC)·d(GAGATA*−AGGAG); the differences in the chemical shifts between the platinated and nonplatinated duplex are given below the chemical shifts; all shifts are referenced to the HOD resonance at δ = 4.84, T = 290 K

judged by visual inspection. Figure 7 shows a comparison between the simulated and experimental spectra for the aromatic-H1′/H5/H3′ and aromatic-aromatic regions. All the NOESY peaks in the simulated spectra are observed in the experimental spectra, except for the cross-peaks corresponding to A18-H2G8-H8 and A20-H2G6−H8. This may be explained by partial saturation of the NOE signals involving A−H2 due to the short (2 s) relaxation delay. The overall agreement is, however, quite satisfactory. Some minor residual cross-peaks are apparent, corresponding to the H-bonded amino protons that have not been completely exchanged with deuterium, as well as a few cross-peaks that are presumably attributable to the minor component. A refinement starting from A-DNA geometry also led to an excellent fit between the simulated and experimental NOESY spectra, although the global bending for this model was larger than that in the case of a refinement starting from B-DNA.

Stereoviews of the refined structure (Figure 8) and a close-up of the central section of the duplex (Figure 9) are presented. The main feature to be noticed is the G6−N7···A18−N1 cross-link, which is accommodated within the duplex with retention of the overall B-DNA geometry. The ammonia ligands are seen to form hydrogen bonds to T5−O2 (2.70 Å) and T17−O4 (3.27 Å), respectively. In addition, both ammonia ligands are located in hydrophilic pockets and show several close contacts in the range 2.4−3.3 Å. The extra residue, thymine T7, is seen to loop out of the helix, giving it added conformational flexibility. The adenine A18 platination site could, in principle, involve either N7 or N1. Both models were tested in the refinement, but only the latter gave a reasonable fit to the NOE data. Additional support in favor of A−N1 involvement is provided by a related system where the cross-linking reaction rate is retarded when UA is replaced by the UG doublet.[13]

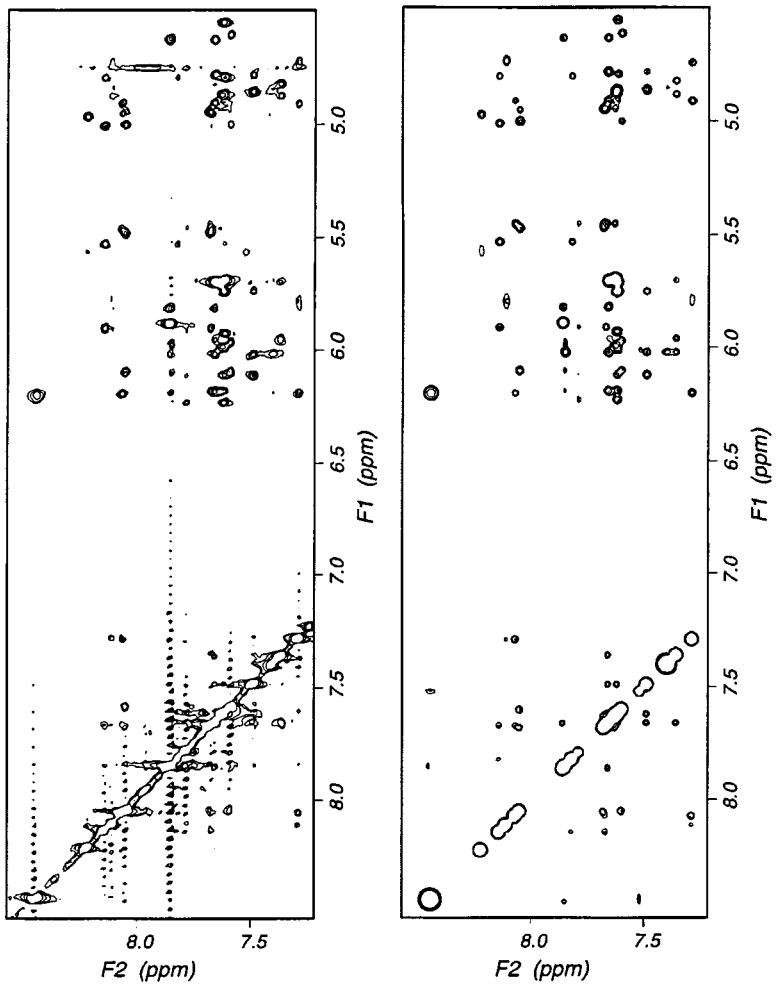

Figure 7. Expanded regions of the nonexchangeable proton 2D NOESY spectra of the *trans*-DDP cross-linked duplex d(CTCCTG*TGTCTC)·d(GAGATA*−AGGAG; left: experimental spectra: aromatic−aromatic region and aromatic−H1′/H3′ region; right: the corresponding simulated spectra

The helix is bent by 21°, as measured by the angle between the two helix axes calculated by CURVES[15] through residues 1−5 and 8−12, respectively, excluding residues G6, T7, and A18. The stacking interactions between the bases are maintained throughout the duplex except for those involving residues G6 and T7. The simulated NOESY data fit quite well with the experimental data representing the stacking region (aromatic−aromatic, Figure 7). The interplanar distances for the stacked bases were calculated by CURVES to lie in the range 2.7−3.8 Å. A complete listing of helical parameters is available as supplementary material.

Watson−Crick hydrogen-bonding is maintained for 10 of the 11 possible combinations. As expected, the platinated residues G6 and A18 are not involved in hydrogen bonding. The mismatched GT base pair, on the other hand, forms two quite regular N−H···O bonds. The chemical shifts of the two imino protons involved were observed at the expected upfield positions. The regular hydrogen-bonded base pairs have a negative propeller twist in the range −19° to −45°. Similar values have been observed in other duplex DNA oligonucleotides.[16] The mismatched base pair, G8−T17, has a positive propeller twist of 35°. The helical parameters are generally not well-defined, mainly due to a low signal-to-noise level in the 2D NOESY spectra obtained from the rather dilute (0.8 mM sample), and are not sufficiently precise for a high-quality structure determination.

Discussion

The 1,3-intrastrand cross-links between *trans*-DDP and two guanine residues separated by one base are relatively stable under single-strand conditions[10,11] and rearrange into interstrand cross-links when the platinated oligonucleotides are annealed with their complementary strands.[12−14] The different rates observed for such cross-linking reactions can be rationalized in terms of the relative positions of the attacking nucleotide residue and the platinum residue as well as the chemical nature of the attacking nucleotide residue. It is important to determine the local conformation of the double helix in these platinated species for several reasons, e.g. to establish the link between geometric factors and the rate of the interstrand cross-linking reaction.

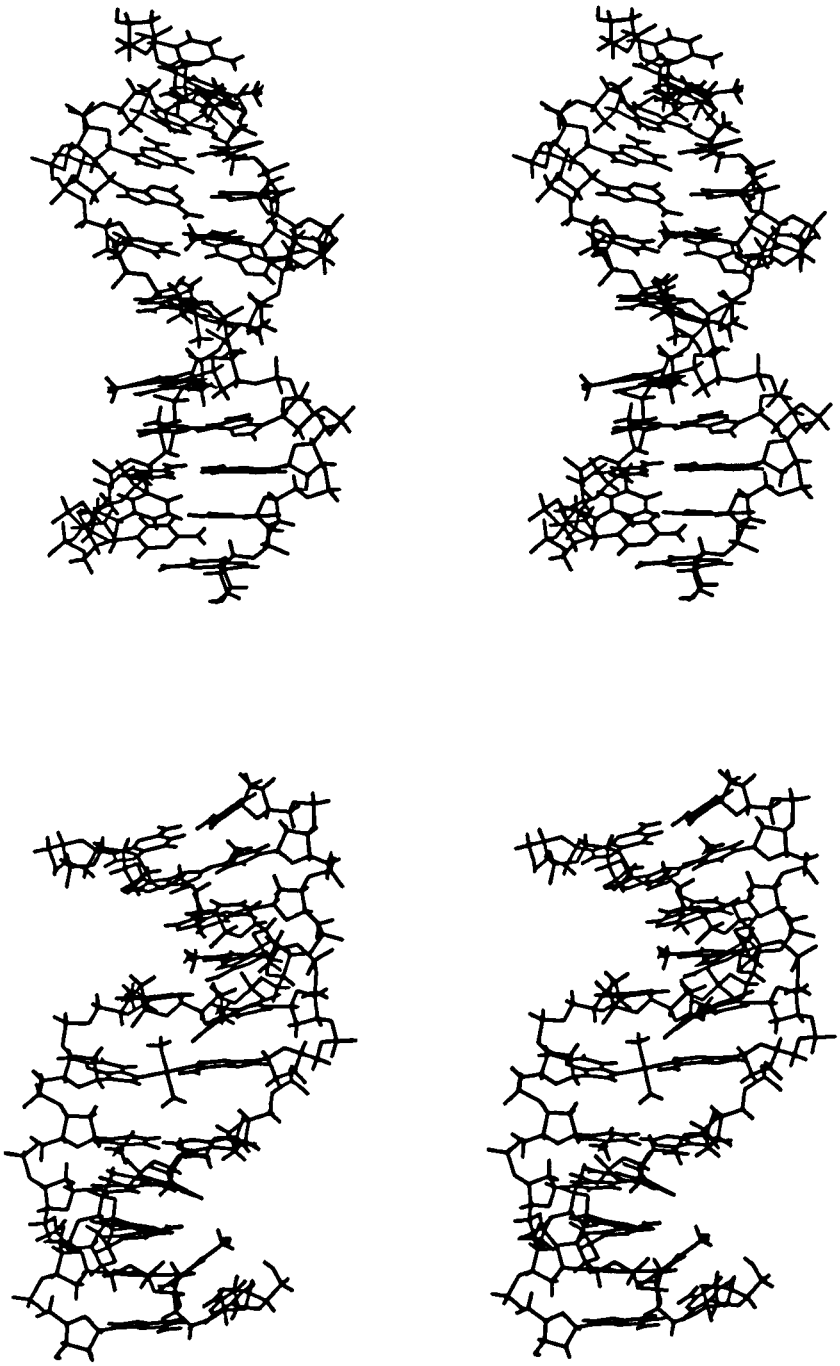

Figure 8. Stereoviews of the molecular model of the refined *trans*-DDP interstrand cross-linked duplex d(CTCCTG*TGTCTC)·d(GAGATA*−AGGAG)

The occurrence of both a major and a minor component of the cross-linked duplex, their contributions depending on time and the electrolyte concentration, indicates that a reversible conformational equilibrium is established. The minor component has not been further characterized by NMR analysis, thus the nature of these salt-induced structural changes has not been delineated. HPLC analysis and capillary electrophoretic measurements of the sample several weeks after the NMR data had been recorded revealed that the major cross-linked species was in fact accompanied by three minor constituents (3−9%).

Two broad downfield-shifted resonances at $\delta = 8.45$ and $\delta = 8.43$ were assigned to A18−H2 and G6−H8, respectively. Most of the NMR-based structural information currently available on platinum−DNA adducts pertains to *cis*-DDP, whereas only a few structural investigations of *trans*-DDP−DNA have been performed. Platination of purine N7 is predicted to induce a downfield shift of the H8 signal by ca. 0.5 ppm as a result of an inductive effect,[17] with a further contribution from conformation-dependent effects of the environment. In a study of *trans*-DDP adducts of d(GpTpG) platinated at N7, the downfield shifted G−H8

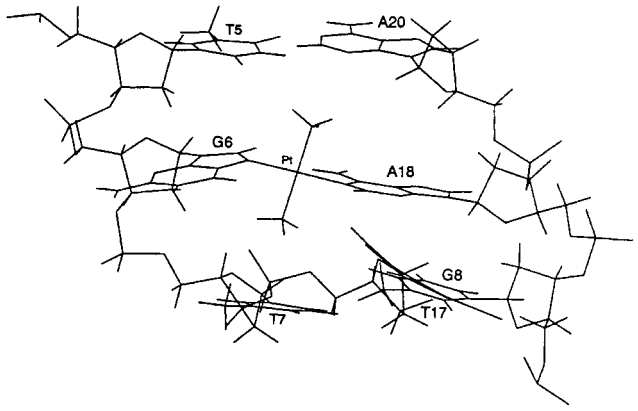

Figure 9. View of the central part of the platinated duplex

signal was observed at $\delta \approx 8.7$ (300 K).[18] In the single-stranded d(A*GG*CCT) containing the 1,3-*trans*-DDP adduct at A1−N7 and G3−N7, the signals of the aromatic protons A−H8 and G−H8 are observed at $\delta = 9.3$ and $\delta = 8.7$, respectively.[19] There is no corresponding example of an oligonucleotide *trans*-DDP-modified at A−N1, although in a study of the isomers d(GpA) and d(ApG), *cis*-DDP-modified at G−N7 and A−N1, downfield shifted A−H2 signals were observed at $\delta = 8.75$ and $\delta = 9.00$, respectively.[20]

From the NOESY spectra, it is evident that the residues adjacent to the platinated sites have a high degree of flexibility. The H8···H1′ cross-peaks involving residues A18 and A20 are especially poorly defined and provide only qualitative interatomic distance information. A sequential "walk" including *intra*- and *inter*-nucleotide connectivities in the aromatic−H1′ region can be completed for most of the residues, except for G6−H8···T7−H1′ in the upper strand and A18−H8···A20−H1′ in the lower strand. The NOESY maps for the 13/12-*mer* cross-linked duplex, which has an extra GC base pair, show essentially the same shift and connectivity pattern as for the 12/11-*mer*, thus excluding the possibility of any artifacts due to the duplex being too short.

The molecular structure of the platinated duplex shown in Figure 8 is based on NMR spectroscopy and restrained molecular dynamics and energy minimization calculations. In general, it has been observed that extrahelical pyrimidine bases tend to destack, while extrahelical purine bases stack with the nonplatinated duplexes.[21,22] However, in the NOESY spectrum of the nonplatinated duplex (Figure 4) the H6 resonance of thymine T7 in the context −GTG− is observed in an extreme upfield position, which suggests a high degree of deshielding in a base-stacked environment. In the platinated duplex, this thymine residue is looped out of the helix, although its exact location is not well-defined since T7 is involved in only a few NOE constraints. The fact that pyrimidine T7 is looped out leaves more room for the G6 residue to adopt a nonregular conformation, which may facilitate the interstrand cross-linking reaction. Kinetics experiments have shown that the rate of the interstrand cross-linking reaction is independent of the nature of the intervening base between the two cross-linked G residues in the top strand.[12−14]

The interstrand cross-link causes a local distortion of the double helix and induces a bend (21°) of its axis towards the major groove. However, it is generally accepted that the determination of global bending by NMR methods is rather inaccurate.[23] It is remarkable that the base pairs flanking the interstrand cross-links adopt a regular B-DNA conformation and that the distortion is located at the level of the cross-link. A similar conclusion has been reached in the case of duplexes containing a *cis*-DDP interstrand cross-link,[24−26] although the local distortions induced by *cis*- and *trans*-DDP are quite different.

Finally, an interesting aspect of this study is the fact that one of the amino groups of the Pt residue protrudes into the minor groove of the cross-linked duplexes (Figure 8). Both of the NH_3 ligands are seen to form hydrogen bonds to adjacent base residues (T5, T17), although one of the NH_3 ligands is less constrained and more exposed to the solvent. This suggests that the cross-linked duplexes should be able to accommodate larger nonleaving groups (L), which, in turn, may facilitate the cross-linking reaction and stabilize the platinated duplexes. Work is currently in progress with *trans* complexes of the general formula *trans*-$[Pt(NH_3)LCl_2]$.

Concluding Remarks

This work deals with structural characterization of a Pt−DNA duplex posing several nonroutine obstacles: (i) the duplex is made up of nonpalindromic sequences (giving a double set of resonances), (ii) a residue is missing from the complementary strand, (iii) the sample is dilute (0.8 mM) and furthermore contains several minor species, leading to a decreased signal-to-noise level. Thus, the task represents a real challenge to the standard NMR procedures for structure determination of oligonucleotide duplexes. In comparison with other NMR determinations of regular, platinated and nonplatinated oligonucleotides, the accuracy of the present structure is consequently expected to be lower. However, the main objective of this investigation has been achieved, i.e. to qualitatively determine the cross-linking arrangement in order to be able to suggest modifications to further speed up the cross-linking reaction rate.

Experimental Section

Sample Preparation: All the sequences were purchased from Oswell DNA Service as HPLC purified compounds. The reactions between *trans*-DDP and the pyrimidine-rich strands d(CTCCTGTGTCTC) (I) and d(CTCCTGTGCTCTC) (II) containing the GTG sites were performed as described previously.[12,14] Briefly, the single-stranded oligonucleotides ($c = 40$ μM) were incubated with 1.1 equivalents of *trans*-DDP in 10 mM $NaClO_4$/4 mM acetate buffer at pH 3.6 and

37 °C over a period of 24 h. Thereafter, the reaction mixtures were treated with thiourea (10 mM) for 10 min at 37 °C. The oligonucleotides containing a single 1,3-*trans*-{$Pt(NH_3)_2$[d(G*TG*)]} cross-link were purified by chromatography on a strongly basic anion-exchange resin on a Pharmacia FPLC system equipped with a MonoQ column, using a 0.2 to 0.7 M NaCl gradient in 10 mM NaOH. The binding of the platinum at the G residues was verified by the nonreactivity of dimethyl sulfate towards these sites.[12,14]

The platinated oligonucleotides were mixed with one equivalent of the complementary sequence, d(GAGATA−AGGAG) or d(GAGAGTA−AGGAG), respectively. Then, the duplexes (20 μM final concentration) in 500 mM NaCl, 10 mM Tris-HCl buffer (pH 7.5), and 0.5 mM EDTA were incubated at 288 K. After 9 days, the intrastrand to interstrand cross-link isomerization reactions were complete. The interstrand cross-linked duplexes were subsequently purified by chromatography on a strongly basic anion-exchange resin and then desalted on a Sep-Pak Column. The platinated 12/11-*mer* NMR sample was made up from 0.5 mL of the 0.8 mM in duplex solution in 0.5 M NaCl and 0.04 mM EDTA, and the pH was adjusted to 5.9. No buffer was added. The sample of the non-platinated duplex was dissolved in 0.55 mL of 9:1 H_2O/D_2O containing 0.520 M NaCl (pH 5.9) so that the final duplex concentration was 3.0 mM. ^{1}H-NMR spectra were recorded in H_2O solution and subsequently in D_2O after freeze-drying of the samples and redissolving them in 99.996% D_2O.

NMR Spectroscopy: The ^{1}H NMR experiments were performed on a Bruker DRX 600 instrument operating at 600 MHz for ^{1}H. In order to avoid melting of the duplexes and to obtain reasonable resolutions, all experiments were carried out at 290 K. 1D ^{1}H spectra were acquired with a total of 32 K complex points and 64 scans. For all 1D and 2D spectra, the spectral widths were 6000 Hz (in D_2O) or 13200 Hz (in H_2O) and a relaxation delay of 2 s was used. The 3-9-19 WATERGATE pulse sequence was used for water suppression.[27] The ^{1}H NOESY spectra were recorded in the pure absorption mode with quadrature detection using the States TPPI acquisition scheme.[28] A total of 2048 complex points in t_2 were collected for each of 512 t_1 increments and 80 transients were averaged for each increment. 2D NOESY spectra were acquired at four different mixing times (75, 125, 200, and 300 ms) in D_2O and in H_2O. The FIDs were processed by linear prediction routines increasing the time domain to 4 K, which significantly improves the signal-to-noise in the NOESY map.[29] DQF-COSY experiments were performed by collecting 2048 data points in t_2 and 512 data points in t_1, and the data were zero-filled to 2 K in both directions. The NMR data were processed on a Silicon Graphics INDY workstation using the program FELIX (Biosym)[30] and on a 133 MHz Pentium PC using 1D and 2D WIN-NMR (Bruker).[31] The one-dimensional ^{1}H FIDs were multiplied by an exponential window function prior to Fourier transformation. Typically, 1 Hz was added to the line widths. No baseline correction was needed. The two-dimensional NOESYs, which were used for integration, were apodized by a sinebell filter function, while assignments were made from resolution-enhanced spectra using a Gaussian function. The proton spectra were referenced to the HOD resonance at δ = 4.84 (290 K). ^{31}P-NMR spectra of the platinated and nonplatinated duplexes were acquired at 242.94 MHz. T_1 spin-lattice relaxation times were determined by the inversion recovery method.

NOE Distance-Restrained Molecular Dynamics/Mechanics Refinement: Nonexchangeable proton−proton distances were derived from initial NOE build-up rates as a function of mixing times using the cytosine H5−H6 distance of 2.46 Å as a reference. Cross-peaks were selected and integrated using WIN-NMR (Bruker). The thymine methyl (pseudo atom)−H6 distances were fixed at 3.1 Å. For all the N···H bonds, lower and upper limits of 1.7 Å and 2.0 Å, respectively, were used, while corresponding limits of 1.8 Å and 2.2 Å were used for O···H bonds. The platinum was attached to G6−N7 and A18−N1 at a fixed Pt−N distance of 2.0 Å. The square-planar coordination geometry about the metal was completed by two NH_3 ligands in *trans* positions. Charges on the metal and its NH_3 ligands were set in accordance with previous work by Kozelka et al.[32] Restrained molecular dynamics were conducted using the AMBER all-atom force field as implemented in DISCOVER (3.1) software. The calculations were carried out in vacuo with a distance-dependent dielectric constant of the form 4*r* and a force field with all 1−4 nonbonding interactions scaled by a factor of 0.5.[33]

The force constants used for the hydrogen bonds were set to 25 mol^{-1} $Å^{-2}$. For the other constraints, a force constant of 20 kcal mol^{-1} $Å^{-2}$ was applied when the relevant distances were outside of their limits. This approach is in accordance with recent work by Jourdan et al.[34] All dynamics calculations were performed on a Silicon Graphics INDY workstation using the programs INSIGHT II, DISCOVER, and NMR Refine (Biosym).[33] The calculation began with both classical A-DNA and B-DNA as modelled in INSIGHT II. The platinated guanine residue G6 was rotated into a *syn* configuration, in agreement with the derived intranucleotide G6−H8···H1′ NOE distance.

A total of 215 NOE distance constraints were used in the energy refinements of the starting models (A- and B-form DNA) using a conjugate gradient minimization algorithm. Initially, 500 cycles of energy minimization followed by 20 ps of molecular dynamics calculations at a constant temperature of 300 K were performed. The Verlet Leapfrog[35] algorithm was used to integrate the equations of motion, with an integration step of 1 fs. The average calculation frequency was 10 steps. The DISCOVER program uses Berendsens method[36] for pressure control. The molecular dynamics calculation was followed by a second run of 2000 cycles of energy refinement until an average rms gradient of 0.06 kcal mol^{-1} $Å^{-2}$ had been achieved. NMR Refine (Bruker) was used to generate the NOESY cross-peak volumes, using matrix doubling with a full relaxation matrix. T_1 leakage rates were set to 1 s^{-1}, cut-off distance to 5.5 Å, and τ_c was found to be optimal at 3.5 ns. Simulated spectra of the 200 ms NOESY experiments were calculated from these theoretical volumes using the program FELIX (Biosym). The back-calculated NOESY spectra were used to optimize the constraint file. The new constraint file was then used to create a new structure. These back-calculated refinement cycles were performed until the simulated NOESY cross-peak volumes matched the experimental data. In addition to visual matching of the cross-peak intensities, sometimes an *R*-factor, which sums the deviations between simulated and experimental cross-peaks, was calculated. However, this *R*-factor should be used with caution as a refinement parameter since intensities corresponding to short local sugar distances completely mask the intensities of weak cross-peaks that represent long-range global structure information. The program CURVES 5.3 was used to extract the helical parameters from the final structure.[15]

Acknowledgments

Financial support from the European Commission BIOMEDII program (Contract BMH4-CT97−2485) and Agence Nationale de Recherches sur le Sida is gratefully acknowledged. Thanks are ex-

tended to the Norwegian Research Council for a fellowship to B.A. We thank Dr. J. Arpalahti for carrying out additional HPLC and electrophoretic analysis.

Stability Constants and Decay of Aqua-Copper(III) – A Study by Pulse Radiolysis with Conductometric and Optical Detection

Piotr Ulanski[a] and Clemens von Sonntag*[b]

Keywords: Radicals / OH radical / Copper(III) / Copper(I) / Pulse radiolysis

Hydroxyl radicals were generated radiolytically in N_2O-saturated aqueous solutions and reacted with Cu^{2+}_{aq} ions. Pulse radiolysis with conductometric detection showed that the aqua-Cu^{III} species thus formed ($k = 3.2 \times 10^8$ dm^3 mol^{-1} s^{-1}) is uncharged at pH 5, i.e. $[Cu(OH)_3]_{aq}$, and from the changes in conductance as a function of pH it has been calculated that $Cu(OH)^{+}_{2aq}$ must have a pK value of 4.8 and $Cu(OH)^{2+}_{aq}$ a value of 3.7. At pH 2.5 there is no strong evidence for the presence of Cu^{3+}_{aq}. Aqua-$Cu(OH)_3$ decays bimolecularly to give Cu^{2+}_{aq} and H_2O_2. $Cu(OH)^{2+}_{aq}$ [and possibly also $Cu(OH)^{+}_{2aq}$] are in equilibrium with Cu^{2+}_{aq} and OH radicals [$K(Cu(OH)^{2+}_{aq}) \approx 3.7 \times 10^4$ dm^3 mol^{-1}]. Rapid electron transfer occurs from Cu^{+}_{aq} to $[Cu(OH)_3]_{aq}$ ($k = 3.5 \times 10^9$ dm^3 mol^{-1} s^{-1}).

Introduction

With the advent of pulse radiolysis in the 1960s it became possible to study the properties of transition-metal ions in unusually high oxidation states, which can be formed in aqueous solutions in reactions with the OH radical. Similarly, their lower than common oxidation states can be generated with the hydrated electron and also by the less-reducing H-atom (for a compilation of rate constants see ref.[1]; for a review see ref.[2]). In the case of Cu^{2+}_{aq} it has been shown that it is reduced at practically diffusion-controlled rates by the hydrated electron and the H-atom.[1] In the latter case a hydride is formed in the first step.[3,4] Even the less reducing superoxide radical ($E^7 = -0.3$ V)[5] is capable of reducing Cu^{2+}_{aq}.[6]

The Cu^{2+}_{aq} ion also reacts with the OH radical, although the rate of this reaction is significantly below diffusion controlled rates [Equation 1, $k_1 \approx 3 \times 10^8$ dm^3 mol^{-1} s^{-1}].[3,7–10] In neutral solution the species formed is characterized by a strong absorption at 280 nm (see Figure 8). From a high-pressure pulse-radiolysis experiment it has been concluded that in the first step a water molecule is replaced by an OH radical [Equation (1)].[10]

$$^{\bullet}OH + Cu(H_2O)^{2+}_n \rightarrow CuOH(H_2O)^{2+}_{n-1} + H_2O \quad (1)$$

Since the rate of build-up is rather slow, the primary species formed in this reaction may subsequently undergo rapid protonation/deprotonation reactions without being noticeable by changes in the UV absorption [Equations (2)–(4)].

$$Cu(H_2O)^{3+}_n \rightleftarrows CuOH(H_2O)^{2+}_{n-1} + H^+ \quad (2)$$

$$CuOH(H_2O)^{2+}_{n-1} \rightleftarrows Cu(OH)_2(H_2O)^{+}_{n-2} + H^+ \quad (3)$$

$$Cu(OH)_2(H_2O)^{+}_{n-2} \rightleftarrows Cu(OH)_3(H_2O)_{n-3} + H^+ \quad (4)$$

Thus, the species that is observed by spectrophotometry does not necessarily carry a doubly-positive charge. The absorption of the aqua-Cu^{III} intermediate varies with pH and from these data it has been deduced that it should have a pK_a value of around 3, a value that has been attributed to equilibrium (2).[3,7] Pulse radiolysis experiments with conductometric detection have indicated, however, that the intermediate observed at around pH 5 might in fact be neutral.[8,11] The rate of decay of the aqua-Cu^{III} intermediate increases with decreasing pH and decreasing Cu^{2+}_{aq} concentration, and below pH 4 no separation between the formation and disappearance was noticed. In addition, there is strong evidence that under these conditions OH radicals and the aqua-Cu^{III} intermediate must be in equilibrium.[3]

There is potentially another kind of Cu^{III} intermediate. When Cu^{+}_{aq} is reacted with H_2O_2 in the presence of methanol, a very effective chain reaction leading to the formation of formaldehyde is induced, but the fact that the chain length strongly depends on the methanol concentration has led to the conclusion that OH radicals are not the chain carrier[12,13] (for ESR experiments and a potentially different interpretation see refs.[14–17]; for the role of such intermediates in DNA cleavage see the review[18]). Because of their strong oxidative power, Cu^{III} complexes have been considered not to play a role in biological systems.[19] However, the presence of Cu^{III} has been postulated in model systems related to enzymes (refs.[20–24]). Interesting data on the properties of Cu^{III}-oligopeptide complexes have been obtained by pulse radiolysis.[25] There are also other means of generating copper(III) and this reagent is of some value in preparative organic chemistry (refs.[26,27]).

Thus there is some interest in characterising the interesting aqua-Cu^{III} intermediate in more detail. The earlier pulse radiolysis experiments using conductometric detection were carried out in Ar-saturated solutions.[8] This is not the best condition for such an experiment. In the radiolysis of water [Equation (5)] OH radicals, hydrated electrons and H atoms are formed side by side [$G(^{\bullet}OH) \approx G(e^-_{aq}) \approx 2.8 \times 10^{-7}$ mol J^{-1}, $G(H^{\bullet}) \approx 0.6 \times 10^{-7}$ mol J^{-1}, $G(H_2O_2) = 0.7 \times 10^{-7}$ mol J^{-1}, $G(H_2) = 0.5 \times 10^{-7}$ mol J^{-1}].[28] Thus, in assessing the state of charge of the intermediate in question, the observed conductance changes have to be corrected for contributions caused by the reduction processes (formation of Cu^+_{aq} and H^+). Their assignment to $[Cu(OH)_3]_{aq}$ has been supported by a more decisive experiment.[11] In fact, such a correction can be largely avoided by saturating the solutions with nitrous oxide, which converts the hydrated electron into an OH radical [Equation (6); $k_6 = 9.7 \times 10^9$ dm^3 mol^{-1} s^{-1}].[1] Under these conditions a correction for a contribution of the H atom is minor (ca. 10%), at least when the pH is not too low, [Equation (7)], $k_7 = 2.3 \times 10^{10}$ dm^3 mol^{-1} s^{-1}.

$$H_2O \xrightarrow{\text{ionizing radiation}} {}^{\bullet}OH, e^-_{aq}, H^{\bullet}, H^+, H_2O_2, H_2 \quad (5)$$

$$e^-_{aq} + N_2O \rightarrow {}^{\bullet}OH + N_2 + OH^- \quad (6)$$

$$e^-_{aq} + H^+ \rightarrow H^{\bullet} \quad (7)$$

We have again used this approach to study the pH dependence of the stability constants of the aqua-Cu^{III} intermediates over a wide pH range (pH 2.5–5). Moreover, it will be shown that differently charged aqua-Cu^{III} may decay by different routes. Indeed, at low pH reaction (1) becomes reversible.

Results and Discussion

Determination of Stability Constants

Conductometric experiments have to be carried out at pH $\leq$ 5 in order to avoid buffering effects of Cu^{2+}_{aq} [p$K(Cu^{2+}_{aq}) \approx$ 7.2].[29] Low Cu^{2+}_{aq} concentrations have to be used in order to ensure that their reaction with the hydrated electron [$k(e^-_{aq} + Cu^{2+}_{aq} \rightarrow Cu^+_{aq}) \approx 3 \times 10^{10}$ dm^3 mol^{-1} s^{-1}][1] does not compete significantly with reaction (6). At these low Cu^{2+}_{aq} concentrations the rate of the reaction of the OH radical with Cu^{2+}_{aq} is rather slow, and very low doses per pulse (e.g. 1 $\leq$ Gy, Figure 1) have to be applied for a quantitative reaction because of the fast recombination of the OH radicals [2 $^{\bullet}OH \rightarrow H_2O_2$; $2k = 5.5 \times 10^9$ dm^3 mol^{-1} s^{-1}].[1] The conductance signal is even further reduced at high doses, since proton formation will lower the pH, an effect that also leads to a decrease in the conductance signal (cf. Figure 3).

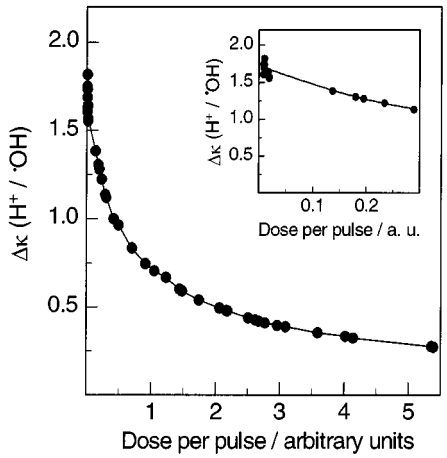

Figure 1. Pulse radiolysis of N_2O-saturated solutions of Cu^{2+}_{aq} (1×10^{-4} mol dm^{-3}), pH 5.0. The yields of conductance change (number of H^+ released per $^{\bullet}OH$ reacted) as a function of dose per pulse. One arbitrary dosimeter unit (a. u.) is approximately equivalent to 12 Gy

When the reaction of OH radicals under such conditions is followed by conductometry, the rate of increase in the conductance is proportional to the Cu^{2+}_{aq} concentration (Figure 2). From the slope of the straight line in Figure 2, a rate constant of 3.2×10^8 dm^3 mol^{-1} s^{-1} is calculated for the reaction of OH radicals with Cu^{2+}_{aq}, which compares well with the literature data obtained by optical detection (see above).

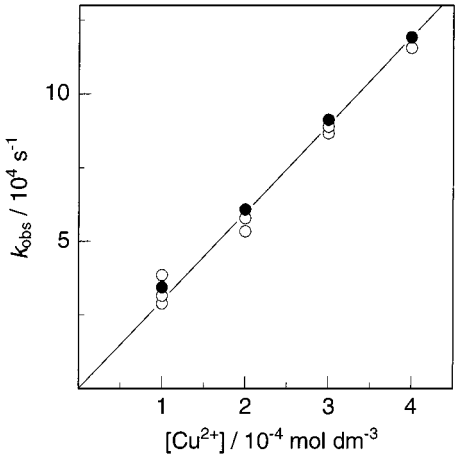

Figure 2. Pulse radiolysis of N_2O-saturated solutions of Cu^{2+}_{aq}. The rate of absorbance change at 350 nm (●; pH 5, extrapolation to zero dose) and conductance changes (○; pH 4, dose per pulse $\leq$ 1 Gy) as a function of the Cu^{2+}_{aq} concentration

In Figure 3 the proton yield per OH radical is plotted as a function of pH. These values are based upon dimethyl sulfoxide dosimetry, where one mol of OH radicals yields close to one mol of methanesulfinic acid.[30] It can be calculated from the data shown in Figure 3 that at pH 5 two mol of protons are formed per mol of OH radical reacted, i.e. the resulting aqua-Cu^{III} species must be uncharged $[Cu(OH)_3]_{aq}$, see Equation (8), which is in agreement with the earlier[8,11] conclusion.

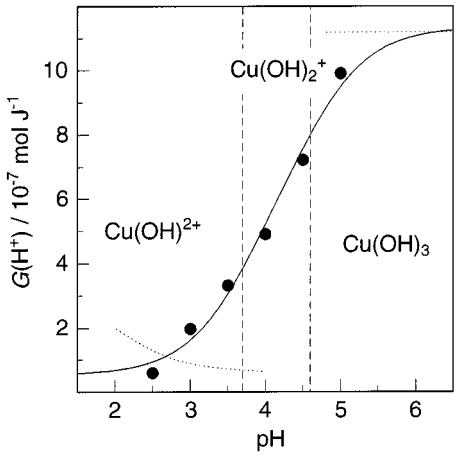

Figure 3. Pulse radiolysis of N_2O-saturated solutions of Cu^{2+}_{aq} (1×10^{-4} mol dm^{-3}). Conductance changes as a function of pH. Values extrapolated to zero dose per pulse

$$Cu^{2+}_{aq} + {}^{\bullet}OH + 2\,H_2O \rightarrow [Cu(OH)_3]_{aq} + 2\,H^+ \quad (8)$$

$$Cu^{2+}_{aq} + {}^{\bullet}OH + H_2O \rightarrow Cu(OH)^{+}_{2\,aq} + H^+ \quad (9)$$

$$Cu^{2+}_{aq} + {}^{\bullet}OH \leftrightharpoons Cu(OH)^{2+}_{aq} \quad (10)$$

Upon lowering the pH the proton yield drops, and at pH 2.5 no protons are liberated beyond those formed by the H atom with Cu^{2+}_{aq} ($Cu^{2+}_{aq} + H^{\bullet} \rightarrow Cu^{+}_{aq} + H^+$; note the dashed line in Figure 3). The experimental value at pH 2.5 is somewhat lower than this limit, which might suggest the onset of Cu^{3+}_{aq} formation. However, the relatively high background conductivity of the solution at this pH along with the low signals make the measurement conditions unfavourable. Thus, no firm conclusions can be drawn regarding the presence of the triply-charged species.

The pH range where this decrease is observed is rather narrow, although two pK values must be involved [Equations (3) and (4)].

The data can be fitted (solid line in Figure 3) using pK values at pH = 3.7 and 4.6. Our observations are in agreement with the earlier conclusion[8,11] that at pH 5 the aqua-Cu^{III} species are largely uncharged. The mono-charged species only dominates at around pH 4. In the more acidic pH range the aqua-Cu^{III} is doubly-charged and, as mentioned above, evidence for a triply-charged species at pH $\leq$ 2.5 is very weak. The difference between our results and those reported by Asmus et al.[11] only concerns the strongly acidic range. In the earlier study[11] a ten-fold higher Cu^{2+}_{aq} concentration was used and this, together with the protons, competes with N_2O for the solvated electrons. The reactions of Cu^{2+}_{aq} with the solvated electron and the H atom lead to the formation of Cu^{+}_{aq} and a proton. The reported data were corrected, but it is not stated whether the correction was only for the reduction in OH-radical yield or whether the latter effect was also corrected for in the evaluation of the conductance signals.

It is noted that the aqua-Cu^{III} species deprotonates only at much lower pH values than Cu^{2+}_{aq} (Cu^{2+}_{aq} dominates below pH 7).

A comparison can be made between the aqua-Cu^{III} and the isoelectronic aqua-Pd^{II} complex. The pK_a value of the $[Pd(H_2O)_3OH]^+$ species has been recently re-measured[31] as being close to 3.0 and the pK_a value of the neutral species must be even higher (not measurable because of the formation of polynuclear complexes). In this case the pK_a value of aqua-$Cu(OH)^{+}_{2}$ (equivalent to the neutral aqua-Pd^{II} complex) has been found at 3.7. This pK_a value is not unexpected given that the aqua-Cu^{III} ion is slightly smaller. The structure of aqua-Pd^{II} is square planar,[32] and one may therefore expect that the analogous aqua-Cu^{III} species has the same structure.

Decay of Aqua-Copper(III)

Aqua-$Cu(OH)_3$ is a highly reactive species. It decays under our experimental conditions on the millisecond time range and leads to restoration of the original conductance (Figure 4).

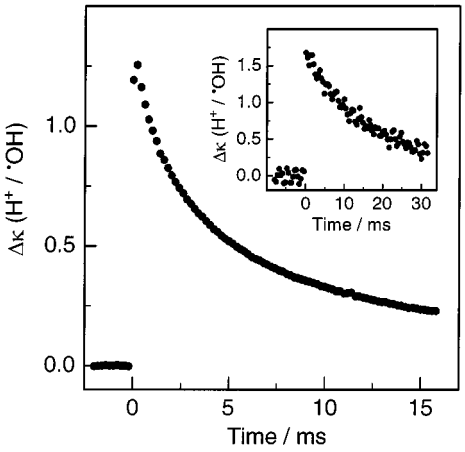

Figure 4. Pulse radiolysis of N_2O-saturated aqueous solutions of Cu^{2+}_{aq} (1×10^{-4} mol dm^{-3}) at pH 5 and a dose of 2.2 Gy (Inset: 0.1 Gy). Decay of aqua-$Cu(OH)_3$ as followed by conductance changes

At pH 5 the decay is largely bimolecular, i.e. the first half-life of decay decreases with increasing aqua-$Cu(OH)_3$ concentration. To achieve this by increasing the dose per pulse is not easy because of the slowness of the reaction of the OH radical with Cu^{2+}_{aq} (see Figure 1). However, the relevant aqua-$Cu(OH)_3$ concentration can be calculated from its maximum absorbance at 270 nm (Figure 5). These data yield a bimolecular rate constant of 1.8×10^8 dm^3 mol^{-1} s^{-1}. Similar experiments have been performed using conductometric detection. Although the dose per pulse was not known precisely in the experiments shown in the inset of Figure 5 (the estimated error is ±20%; for a possible method to determine this value exactly see ref.[33]), the approximate rate constant for the bimolecular decay of aqua-$Cu(OH)_3$ calculated from these data is $2k = 2 \times 10^8$ dm^3 mol^{-1} s^{-1}. These two sets of data agree well, but are considerably higher than the value of 4.6×10^7 dm^3 mol^{-1} s^{-1} reported earlier.[3]

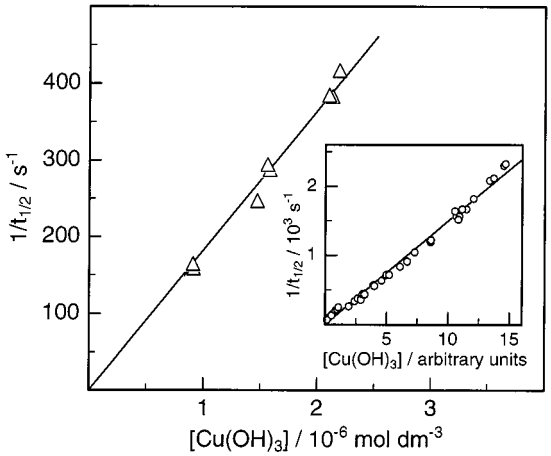

Figure 5. Pulse radiolysis of N_2O-saturated aqueous solutions of Cu^{2+}_{aq} (2×10^{-4} mol dm^{-3}) at pH 5. The reciprocal first half-lives of the decay of aqua-Cu(OH)$_3$ at 270 nm as a function of the initial $[Cu(OH)_3]_{aq}$ concentration (see text). Inset: Conductivity measurements; the initial [aqua-Cu(OH)$_3$] was taken to be proportional to the $[H^+]$ 100 μs after the pulse

It is reasonable to assume that in this bimolecular decay two Cu^{2+}_{aq} ions are reformed and one mol of H_2O_2 is thereby produced [Equation (11)].

$$2\,[Cu(OH)_3]_{aq} \rightarrow 2\,Cu^{2+}_{aq} + 4\,OH^- + H_2O_2 \quad (11)$$

This stoichiometry is indeed observed when a series of pulses of 1 Gy is given to an N_2O-saturated solution of Cu^{2+}_{aq} (2×10^{-4} mol dm^{-3}). Under these conditions the H_2O_2 concentration increases linearly with increasing dose (data not shown), and from these data a value of $G(H_2O_2) = 2.6 \times 10^{-7}$ mol J^{-1} is calculated. This value is not too far from that expected considering that Cu^{+}_{aq} [$G(Cu^{+}_{aq}) \approx 0.7 \times 10^{-7}$ mol J^{-1} under these conditions] will react rapidly with aqua-Cu(OH)$_3$ (see below) and thus will prevent the formation of H_2O_2. However, when the same experiment is carried out at the low dose rates of γ-radiolysis, only $G(H_2O_2) = 0.5 \times 10^{-7}$ mol J^{-1} is measured. Thus, reactions that consume the H_2O_2 formed must play a role in this situation and these are discussed below.

The rate of disappearance of the aqua-Cu^{III} intermediates is pH-dependent and increases as the solutions become more acidic. In addition, at low pH, build-up and decay were not clearly distinguishable.[3] It has been concluded that during this decay OH radicals are liberated [Equation (10)].[3]

A considerable drawback in the determination of equilibrium (10) by UV spectrophotometry is the fact that the reported[3,7] spectrum of the OH radical is very close to that resulting from its reaction with Cu^{2+}_{aq} at low pH. Moreover, at these low absorptions (cf. Figure 9) the signals become very noisy at the low doses required. This prevents the determination of equilibrium (10) by optical detection. However, conductometric experiments may allow some firmer conclusions to be drawn. In order to test the liberation of OH radicals, trace amounts (10^{-6} mol dm^{-3}) of dimethyl sulfoxide were added [Equation (12); $k_{12} = 7 \times 10^9$ dm^3 mol^{-1} s^{-1}].[30]

$$^{\bullet}OH + (CH_3)_2SO \rightarrow CH_3S(O)O^- + H^+ + {}^{\bullet}CH_3 \quad (12)$$

This reaction leads to the formation of methanesulfinic acid and hence contributes to a small extent to the observed conductance changes that occur immediately after the pulse, since these small amounts only scavenge ca. 9% of the primary OH radicals. However, the competition between Cu^{2+}_{aq} and dimethyl sulfoxide can become much more favourable for dimethyl sulfoxide in the long run. This is due to the fact that OH radicals liberated from the aqua-Cu^{III} intermediates will then have a chance to react with dimethyl sulfoxide in competition with a reaction with Cu^{2+}_{aq} that restores the aqua-Cu^{III} species [see Equation (10)].

This system was first tested at pH 5, where it has been shown above that very few, if any, OH radicals are liberated on the time scale of the decay of aqua-Cu(OH)$_3$, which dominates at this pH. If OH radicals had been eliminated, the conductance signal should have dropped during the bimolecular decay from two H^+ per OH radical to one H^+ per OH radical (dashed line in Figure 6). However, the former level of conductance is fully restored, confirming the above conclusions that at pH 5 no OH radicals are liberated on the pulse radiolysis time scale.

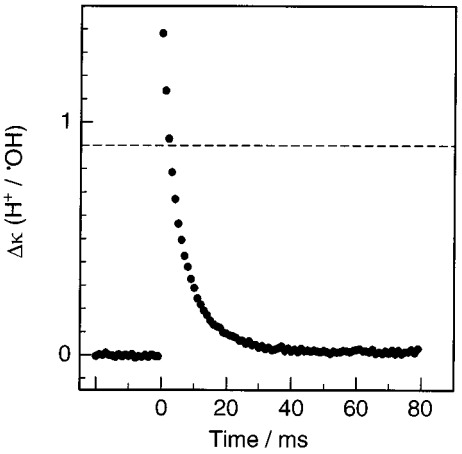

Figure 6. Pulse radiolysis of N_2O-saturated aqueous solutions of Cu^{2+}_{aq} (2×10^{-4} mol dm^{-3}) at pH 5 in the presence of dimethyl sulfoxide (10^{-6} mol dm^{-3}). The dashed line indicates the conductance change that should have been reached if aqua-Cu(OH)$_3$ had released an OH radical and the OH radicals had reacted with dimethyl sulfoxide

However, at pH 2.5, where no conductance changes are observed upon the reaction of OH radicals with Cu^{2+}_{aq}, the conductance should increase to a value of one H^+ per OH radical during the decay of the aqua-Cu^{III} intermediate when the released OH radical is scavenged by dimethyl sulfoxide. This limiting value is indicated by the dashed line in Figure 7.

From the data shown in Figure 7 it is possible to estimate the stability constant K_{10} by a simulation of the reactions that must contribute (yields of H atoms and OH radicals in N_2O-saturated solutions at this low pH [$G(H^{\bullet}) = 1.2 \times 10^{-7}$ mol J^{-1}, $G(^{\bullet}OH) = 5.0 \times 10^{-7}$ mol J^{-1}], formation of Cu^{+}_{aq}

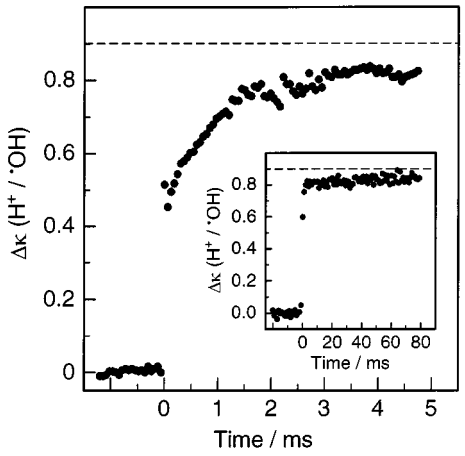

Figure 7. Pulse radiolysis of N_2O-saturated aqueous solutions of Cu^{2+}_{aq} (2×10^{-4} mol dm^{-3}) at pH 2.5 in the presence of dimethyl sulfoxide (10^{-6} mol dm^{-3}). The dashed line indicates the conductance change that should have been reached if the aqua-$Cu(OH)^{2+}$ had released an OH radical and the OH radicals had reacted with dimethyl sulfoxide

and H^+ by the H atom, bimolecular decay of Cu^+_{aq} and $Cu(OH)^{2+}_{aq}$, see below) to the observed conductivity changes, although practically no experimental variations can be made to put this value on a better footing. The experimental data are reasonably modelled by taking $k_{10} \approx 8 \times 10^3$ s^{-1}, $k_{-10} = 3 \times 10^8$ dm^3 mol^{-1} s^{-1}, i.e. $K_{10} \approx 3.7 \times 10^4$ dm^3 mol^{-1}. This value is of the same order as the values reported earlier ($K = 1.1 \times 10^4$ dm^3 mol^{-1}; at pH 3.65).[3]

The fact that OH radicals can be liberated in unimolecular reactions of aqua-Cu^{III} intermediates allows us to interpret the observation that at the low dose rates of γ-radiolysis, where reactions that are kinetically of first order will dominate, no H_2O_2 is formed at pH 2.5 and only low yields are formed at pH 5 (see above). The hydroxyl radical reacts with H_2O_2 by H-abstraction [Equation (13), $k_{13} = 2.7 \times 10^7$ dm^3 mol^{-1} s^{-1}][1] and this reaction yields the superoxide radical, which, although a peroxyl radical, is a powerful reductant[34] and readily reacts even with Cu^{2+}_{aq} [Equation (14)].[6]

$$^{\bullet}OH + H_2O_2 \rightarrow H_2O + HO^{\bullet}_2 \quad [HO^{\bullet}_2 \leftrightarrows O^{\bullet}_2{}^- + H^+;\ pK_a(HO^{\bullet}_2) = 4.8] \qquad (13)$$

$$Cu^{2+}_{aq} + O^{\bullet}_2{}^- \rightarrow Cu^+_{aq} + O_2 \qquad (14)$$

At pH 5 and with low dose rates of γ-radiolysis the yield of H_2O_2 was considerably lower than the value obtained under the high dose rate conditions of electron beam irradiation. Thus, at this pH some OH radicals must also have been liberated during the bimolecular decay of the aqua-Cu^{III} intermediates. It is hence concluded that either aqua-$Cu(OH)_3$ itself or aqua-$Cu(OH)^+_2$/aqua-$Cu(OH)^{2+}$, which are also present in lower steady-state concentrations, can liberate OH radicals [aqua-$Cu(OH)_3$ – albeit very slowly, if at all, see above].

Reaction of Aqua-$Cu(OH)_3$ with Cu^+_{aq}

In order to determine the rate of the reaction of aqua-$Cu(OH)_3$ with Cu^+_{aq} [Equation (15)] conditions were chosen where $O^{\bullet}_2{}^-$ (i.e. Cu^+_{aq}) is in a large excess in comparison with aqua-$Cu(OH)_3$. This situation can be achieved by pulse-irradiation of O_2-saturated solutions of Cu^{2+}_{aq} (1×10^{-3} mol dm^{-3}) that also contain formate ions (1×10^{-3} mol dm^{-3}). Under these conditions the OH radicals will be partially scavenged by formate [Equation (16)] and the resulting $CO^{\bullet}_2{}^-$ radicals converted by O_2 into $O^{\bullet}_2{}^-$ radicals [Equation (17)]. In addition, the solvated electrons are also converted by O_2 into $O^{\bullet}_2{}^-$ radicals, and some of the solvated electrons will also contribute to the Cu^+_{aq} yield [Equations (18) and (19)].

$$Cu^+_{aq} + [Cu(OH)_3]_{aq} \rightarrow 2\,Cu^{2+}_{aq} + 3\,OH^- \qquad (15)$$

$$^{\bullet}OH + HCO^-_3 \rightarrow H_2O + CO^{\bullet}_2{}^- \qquad (16)$$

$$CO^{\bullet}_2{}^- + O_2 \rightarrow CO_2 + O^{\bullet}_2{}^- \qquad (17)$$

$$e^-_{aq} + O_2 \rightarrow O^{\bullet}_2{}^- \qquad (18)$$

$$e^-_{aq} + Cu^{2+}_{aq} \rightarrow Cu^+_{aq} \qquad (19)$$

Under such conditions, the decay kinetics of aqua-$Cu(OH)_3$ are of (pseudo) first order. By increasing the dose per pulse, the Cu^+_{aq} concentration is raised correspondingly, and from the linear k_{obs} vs. Cu^+_{aq} concentration relationship (Figure 8) a value of $k_{15} = 3.5 \times 10^9$ dm^3 mol^{-1} s^{-1} is calculated. Thus, the expectation discussed above, namely that aqua-Cu^{III} intermediates are readily reduced by Cu^+_{aq}, has been substantiated.

In the experiments represented in Figure 8 the decay of aqua-$Cu(OH)_3$ was followed by optical detection. This required a re-determination of the absorption spectrum of aqua-$[Cu(OH)_3]_{aq}$, which is shown in Figure 9. In the present study much lower doses per pulse were used than was possible in the earlier[7] study.

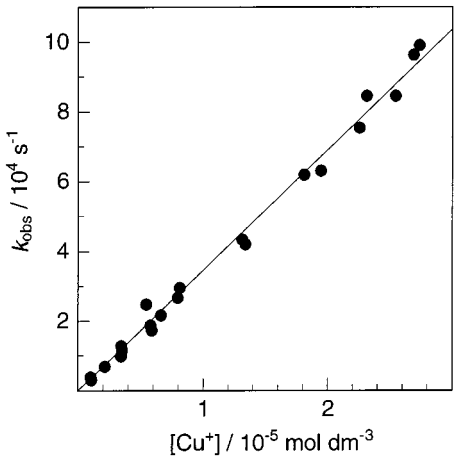

Figure 8. Pulse radiolysis of O_2-saturated aqueous solutions of Cu^{2+}_{aq} (1×10^{-3} mol dm^{-3}) containing 1×10^{-3} mol dm^{-3} of formate, pH 5.0. The observed pseudo-first-order rate constant of aqua-$Cu(OH)_3$ decay, followed as absorbance decrease at $\lambda = 300$ nm, as a function of Cu^+_{aq} concentration

It can be seen from Figure 9 that there is a considerable drop in absorbance with decreasing pH. Taking the pK

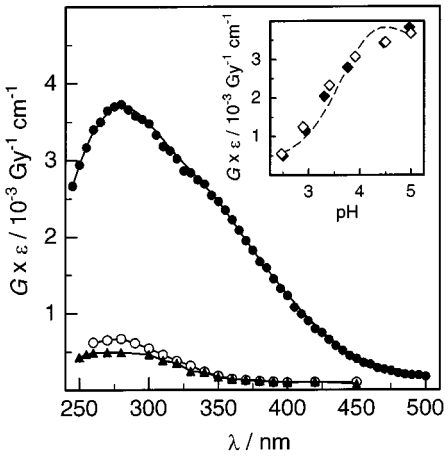

Figure 9. Pulse radiolysis of aqueous solutions of Cu^{2+}_{aq} (2×10^{-4} mol dm^{-3}). Absorption spectra (in units of $G \times \varepsilon$) recorded at 60–80 μs after a pulse of 1.8 Gy. Filled circle: N_2O-saturated solutions of pH 5.0; open circle: N_2O-saturated, pH 2.5; filled triangle: Ar-saturated, pH 2.5. Inset: Absorbance at 270 nm (in units of $G \times \varepsilon$) as a function of pH; filled square: $Cu(SO_4)/H_2SO_4$; open square: $Cu(ClO_4)_2/HClO_4$

values that were determined earlier and fixing the absorption coefficient of $Cu(OH)^{2+}_{aq}$ at 500 dm^3 mol^{-1} cm^{-1} (i.e. close to that of the OH radical),[1] the best fit (dashed line in the inset of Figure 9) is obtained with $\varepsilon[Cu(OH)^{+}_{2\,aq}]$ = 8000 dm^3 mol^{-1} cm^{-1} and ε[aqua-$Cu(OH)_3$] = 4800 dm^3 mol^{-1} cm^{-1}. The reason why the monocharged species has the highest absorption coefficient is not yet understood. In the inset in Figure 9are shown the data obtained with copper sulfate and copper perchlorate. This is a strong indication that the anion has no influence on the absorption spectra (see also ref.[3]), in particular the strong absorptions of the neutral and the monocharged species are not due to complexation by the sulfate ion.

Some experiments were also performed at pH 2.5 in Ar-saturated solutions (see filled triangle in Figure 9). Under these conditions approximately equal amounts of aqua-$Cu(OH)^{2+}$ and Cu^{+}_{aq} are formed (note the conversion of the solvated electron into an H atom at low pH). The experiments show that Cu^{+}_{aq} also absorbs in this wavelength region, but its contribution to the spectrum obtained in N_2O-saturated solutions (see open circle in Figure 9) is only small.

Experimental Section

Copper(II) sulfate pentahydrate, copper(II) perchlorate and all other chemicals were used as received. Solutions were made up in Milli-Q-filtered water (Millipore). The pH was adjusted with H_2SO_4 or with $HClO_4$. Prior to irradiation, solutions were saturated for 45 min with N_2O, which had been purified using an Oxisorb column (Messer-Griesheim), or for 20 min with O_2. γ-Irradiation was performed with a panorama ^{60}Co-γ-source (Nuclear Engineering) at a dose rate of 0.67 Gy s^{-1}. Pulse radiolysis measurements were carried out with a van de Graaff accelerator, generating 0.4 μs pulses of 2.8 MeV electrons. Details of the conductometric and optical detection systems are given elsewhere.[35,36] Dimethyl sulfoxide and thiocyanate were used as dosimeters for the conductometric and optical pulse radiolysis experiments.[30,37] In the conductometric experiments dosimetry allows the calculation of the yields (G value) of the conducting species formed, although their absolute concentrations cannot be ascertained by this method. The knowledge of the absolute concentration is only required for the evaluation of bimolecular rate constants. In principle this can be determined,[33] but for the present work it was sufficient to know the approximate valus for dose per pulse (± 20%). One dosimeter unit, as given in the figures, corresponds to approximately 12 Gy.

For the determination of H_2O_2 yields (measured spectrophotometrically with titanyl sulfate)[38] under pulse-irradiation conditions, solutions contained in a small vessel that permitted continuous N_2O-saturation were subjected to a series of electron pulses. The absorbed dose was determined using the O_2-saturated Fricke dosimeter.

Keywords: Tripodal ligands / N ligands / O ligands / Thermodynamics / EPR spectroscopy / Iron

An eight-step synthesis of a new water-soluble tripodal ligand TRENPYPOLS (tris[2-(2-hydroxy-3-(2-pyridinyl)-5-sulfobenzamido)ethyl]amine) is described. TRENPYPOLS is built by connecting the TREN spacer through a tris-amide moiety to the *ortho* phenolic position of three 2-(2-hydroxyphenyl)pyridine chelating subunits, (followed by the sulfonation of the 5-positions). The three [O,N_{pyr}] bidentate subunits of TRENPYPOLS involve six-membered coordination rings. The solution coordination chemistry of the ligand and its iron complexes have been studied by means of pH potentiometric, spectrophotometric and voltammetric methods. The stability constants, log β_{110}, are 30.1 for the ferric complex and 17.7 for the ferrous complex (pFe^{III} and pFe^{II} values are 23.6 and 11.2 respectively at pH = 7.4, $[L]_{tot} = 10^{-5}$ M, $[Fe]_{tot} = 10^{-6}$ M). Comparison with the data of O-TRENSOX (8-hydroxyquinoline subunits with a 5-membered chelate ring) corroborates the usual rules concerning the influence of the chelate ring size on complexation ability. Fe^{III}-TRENPYPOLS has been tested as a single source of iron in nutritional experiments with *Arabidopsis thaliana* plant cells. The efficiency towards growth and resistance to iron chlorosis is good, comparable to that of Fe^{III}-EDTA, the most commonly used complex for in vitro cell cultures.

Introduction

Siderophores are iron-chelating agents that are excreted by microorganisms. They render iron soluble in the environment and favour the uptake of this metal.[1,2] Iron chelation, by some natural or abiotic chelators, can be used in the study of human diseases characterized by iron overload. Water-soluble iron complexes can be used to alleviate iron deficiency in plants, preventing and even reversing iron chlorosis. Natural siderophores, and most of their synthetic models, contain three catecholate or hydroxamate groups (hard donor groups) which bind the hard ferric ions, giving stable Fe^{III} octahedral complexes (Figure 1). As there has been an intense interest in the complexation of both ferrous and ferric iron for chelation therapy (Fe^{II} is hazardous and redox recycling of iron may occur in the cells[3]), for plant nutrition, and also for the development of tools for the study of iron metabolism, we have developed a promising water-soluble chelator O-TRENSOX (Figure 1).[4−7] This ligand was synthesized by connecting the TREN spacer through a tris-amide moiety to the 7 position of 8-hydroxyquinoline-5-sulfonic acid, a bidentate ligand containing both a hard phenolate oxygen and a softer pyridine nitrogen as donor groups. O-TRENSOX exhibits strong complexing ability towards the ferric cation, of the same order of magnitude as the triscatecholate (TRENCAMS)[8] and the trishydroxamate (TRENDROX)[9] analogs (Figure 1). Moreover, O-TRENSOX exhibits strong complexing ability towards the ferrous cation: as expected, [O,N_{pyr}] instead of [O,O] donor sets may allow strong complexation of both Fe^{3+} and Fe^{2+} ions. The pFe^{III} values[10] (calculated for $[Fe^{III}] = 1$ μM, [L] = 10μM at pH =7.4) shown in Figure 1 provide a direct comparison of the affinities of the ligands for Fe^{3+}. It must be emphasized that all the bidentate subunits of the usual iron chelators (and particularly those depicted in Figure 1) involve 5-membered chelate rings but few subunits involve 6- membered chelate rings. Several 1,3,5-tris(5-substituted salicylamino)cyclohexanes, which involve the unusual 6-membered coordination ring, have been synthesized and their Fe^{III} complexes structurally characterized, but no thermodynamic or kinetic data have been reported.[11]

The new water soluble ligand TRENPYPOLS incorporates three [O,N_{pyr}] bidentate subunits involving six-membered coordination rings. The solution coordination chemistry of the ligand and its iron complexes have been studied by means of pH potentiometric, spectrophotometric and voltammetric methods. The complexing ability of TRENPYPOLS has been compared to ligands involving 5-membered chelate ring. TRENPYPOLS has been tested as a single source of iron in nutritional experiments with *Arabidopsis thaliana* plant cells.

We have synthesized the first synthetic water-soluble tris bidentate iron chelator where the [O,N_{pyr}] type chelating units have been retained and incorporate a six-membered chelate ring. The so-called TRENPYPOLS (the full name of the

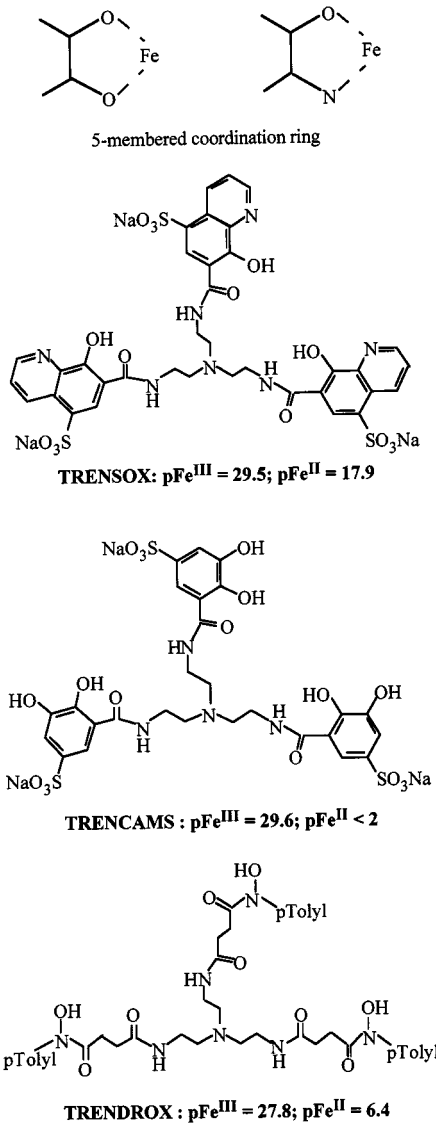

Figure 1. Iron chelators with 5-membered coordination rings

acidic form is tris[2-(2-hydroxy-3-(2-pyridinyl)-5-sulfobenzamido)ethyl]amine) is depicted in Figure 2. As in the chelators given in Figure 1, it is built by connecting the TREN spacer through a tris-amide moiety to the chelating subunits.Only a few studies of the coordination chemistry of the 2-(2-hydroxyphenyl)pyridine ligand have been reported, probably because they are difficult to prepare. Pd^{II}, Co^{III}, Ru^{II}, Ru^{III} and Cr^{III} mononuclear complexes have been described.[12−14] This ligand may be considered as an hydrolytically stable analog of salicylaldimines. It was therefore of great interest to synthesize a tripodal ligand involving three bidentate subunits of this type. This had never been realized before this work. It must be emphasized that in previous studies of the octahedral coordination involving three independent bidentate 2-(2-hydroxyphenyl)pyridine ligands, the three oxygen and the three nitrogen atoms of the coordination sphere are respectively in a *mer* arrangement, as shown in the crystal structures.[12,13] In the complex of a tripodal ligand such as TRENPYPOLS, these atoms are forced

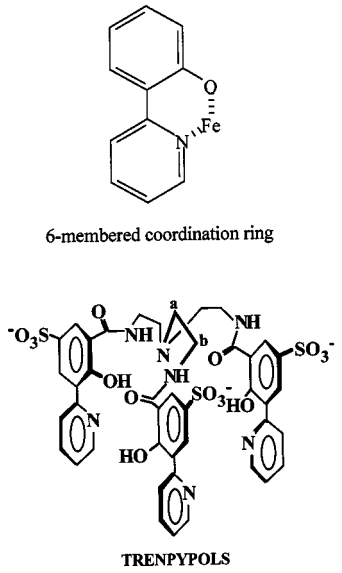

Figure 2. Structural formula of TRENPYPOLS

to be *fac*. In this paper, we report the synthesis, the iron binding properties (thermodynamic and spectroscopic studies) and the nutritional behavior for plant cells of this ligand.

Results and Discussion

Synthesis

The ligand TRENPYPOLS was prepared by sulfonation (oleum) of TRENPYPOL **9**. The methoxylated podand **8** was obtained by coupling of tris(2-aminoethylamine) (TREN) and acid chloride **7**. The key step in the preparation of **7** was the heteroaromatic coupling[15] of 2-bromopyridine and the Grignard derivative **4** of 2-bromo-6-methyl-anisole **3**. The brominated precursors **2** and **3** were prepared by slight modifications of reported procedures (Figure 3).[16,17]

Ligand Deprotonation Constants

The ligand TRENPYPOLS possesses seven deprotonation sites (three pyridinium nitrogen atoms, one tertiary ammonium nitrogen atom and three hydroxy oxygen atoms) and is denoted LH_7^+, taking into account the negative charges of the three sulfonate groups. The deprotonation constants, pK_{an}, of TRENPYPOLS were determined by potentiometric titrations of the fully protonated ligand. Analysis of the potentiometric titration curve (Figure 4a) by the SUPERQUAD program[18] yielded the pK_{an} values (σ_{fit} = 4.8) defined by Equation (1) and Equation (2) (charges omitted for clarity):

$$LH_n \rightleftarrows LH_{n-1} + H^+ \quad (1)$$

$$K_{an} = [LH_{n-1}][H^+]/[LH_n] \quad (2)$$

pK_{a1} = 10.32 ± 0.03, pK_{a2} = 10.07 ± 0.04, pK_{a3} = 9.23 ± 0.06,
pK_{a4} = 5.25 ± 0.08, pK_{a5} = 4.38 ± 0.08, pK_{a6} = 3.21 ± 0.09 and pK_{a7} = 2.77 ± 0.12

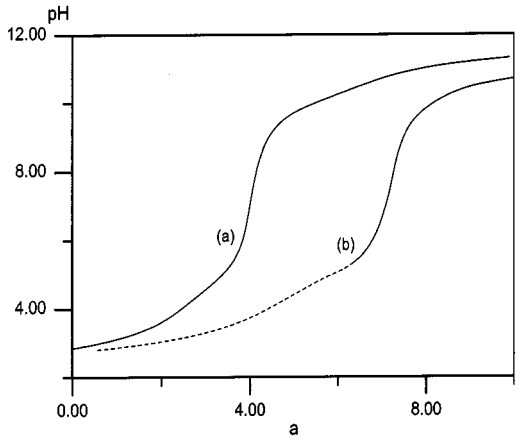

Figure 4. Potentiometric titration curves for (a) 0.5 mM ligand TRENPYPOLS; (b) TRENPYPOLS + Fe^{III} 1:1 0.5 mM (the dashed line indicates precipitation of the complex); a = mol of base added per mol of ligand. All solutions were at 25 °C and ionic strength I = 0.1 M ($NaClO_4$)

The pK_a of the tertiary ammonium nitrogen could be assigned from an ^{1}H NMR spectroscopic titration, by measuring the chemical shifts of the methylene protons H_a and H_b (see assignments in Figure 2), since they undergo a significant shift related to the deprotonation of this nitrogen. An upfield shift, as expected for a deprotonation, was observed over the pD range 4 to 6 (Figure 5) with an inflection

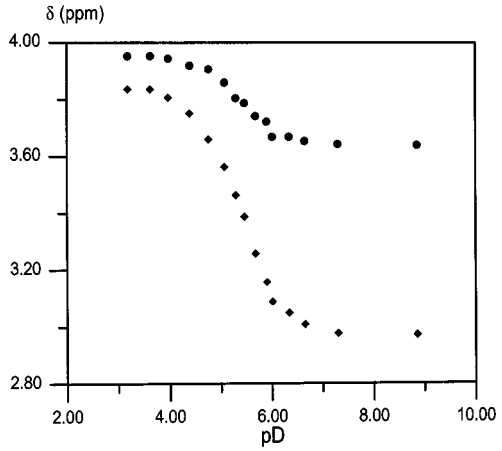

Figure 5. ^{1}H NMR chemical shifts δ (ppm) for the methylene protons H_a (◆) and H_b (●) of TRENPYPOLS in D_2O as a function of pD

point at pD 5 indicating that the value of 5.25 determined from potentiometric titration can be assigned to the tertiary amine. However, it should be noted that the pK_a values which are determined potentiometrically are macroconstants, they cannot be directly assigned to a single functional group when the pK$_a$s differ by less than 2 log units. Thus pK_{a4} is partly produced by ionization of the pyridinium nitrogens. The three lower pK_as corresponded to the pyridinium nitrogens and the three higher ones to the hydroxy groups. The range over which the determined stepwise deprotonation constants for the pyridinium nitrogens (2.77, 3.21 and 4.38) and the hydroxy groups (9.23, 10.07 and 10.32) occurs, is slightly different from the statistical factor of log 3 (0.48). This indicates that there is some cooperativity between the three arms of the tripod.

The average deprotonation constants p$K_{av(5-7)}$ for the pyridinium nitrogens is 3.4. The average deprotonation constants p$K_{av(1-3)}$ for the hydroxy groups is 9.87. In comparison with the pK_a of phenol (9.9), one would expect that the pK_a for the hydroxy groups should be less than that of phenols by about one log unit owing to the electron-withdrawing effect of the amide and sulfonate substituents. The high values for the hydroxy pK_as can be ascribed to the formation of an intramolecular hydrogen bond with the pyridyl nitrogen in each arm, which favors the protonated form and thus enhances the pK_a.

It is interesting to compare the pK_a value of 5.25 of the tertiary ammonium nitrogen with those of similar ligands based on the TREN backbone connected to the amide group and containing three bidentate units, such as 8-hydroxyquinoline (O-TRENSOX), pK_a = 6.36[7] ; 2,2′-dihydroxybiphenyl (TBPAS), pK_a = 7.1;[19] catechol (TRENCAMS), pK_a = 8.03[8]; methoxycatechol (TREN(ME)SAM), pK_a = 6.3;[20] and phenol (TRENSAM), pK_a = 8.9.[20] It has been observed that the basicity of the tertiary amine is related to its ability to form a hydrogen bond with the amide hydrogen depending on the conformation of the amide group and on the hydrogen bond networks available in the molecule. Two hydrogen bond networks may be envisaged according to Figure 6: (i) the tertiary amine deprotonates first (scheme 1) as in O-TRENSOX, TREN(ME)SAM and TRENPYPOLS, (ii) the o-hydroxy

deprotonates first as in TRENCAMS and TRENSAM (scheme 2). Scheme 1 appears more favorable for TRENPYPOLS since the hydroxy group can establish H-bonds with both the carbonyl oxygen and the second donor atom (N) leading to one five-membered ring and to two six-membered rings.

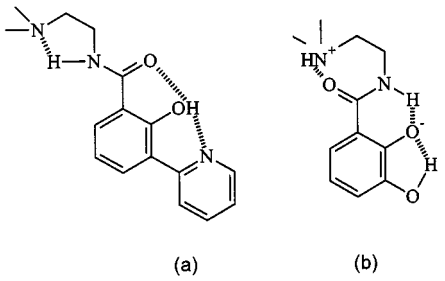

Figure 6. Deprotonation schemes of TRENPYPOLS (scheme 1) and TRENCAMS (scheme 2) showing the hydrogen bond networks

Stability Constants of the Ferric Complex

Potentiometric titrations of 1:1 solutions of ferric ion and ligand were carried out over the pH range 2.5 to 10 (Figure 4b). The titration curve has a buffer region from a (mol base per mol ligand) = 5−7 which covers a pH range of 4−5.5, indicating the formation of the FeL complex from about pH 6. However, the precipitation of the complex below pH 5 precluded the use of the titration data in the refinement program.

The spectrophotometric titration of the ferric complexes at a 1:1 metal-to-ligand molar ratio was carried out from pH 1 to 10 in order to study the Fe^{III}-TRENPYPOLS complexation equilibria as a function of pH. In addition, the equilibrium constant β_{110} was determined by spectrophotometric competition experiments. The spectra are shown in Figure 7. An increase in the pH from 1 to 3 resulted in the appearance of a charge-transfer band at λ_{max} = 470 nm (Figure 7a). The absorbance data were processed with the LETAGROP-SPEFO program.[21,22] The best fit ($\Sigma(A_{exp} - A_{calc})^2 = 2 \times 10^{-4}$) was obtained by considering the formation of the $[FeLH_5]^{2+}$ species. The values log K_{FeLH5} = 1.79 ± 0.05 and ε_{max} = 3900 M^{-1} cm^{-1} (λ_{max} = 470 nm) were obtained, where K_{FeLH5} is defined by Equation (3) and Equation (4):

$$Fe^{3+} + LH_7^+ \rightleftarrows FeLH_5^{2+} + 2\,H^+ \quad (3)$$

$$K_{FeLH5} = [FeLH_5^{2+}]\,[H^+]^2/[Fe^{3+}]\,[LH_7^+] \quad (4)$$

When the pH is raised beyond 3, the spectra exhibited one buffer region in the pH range 3.2−6 with an isosbestic point (Figure 7b), indicating the presence of only two species with different absorbance. These absorbance data were also refined with the LETAGROP-SPEFO program. The best fit [$\Sigma(A_{exp} - A_{calcd.})^2 = 3 \times 10^{-5}$] showed that deprotonation occurs via a one-proton step yielding a pK_a value of 4.50 ± 0.05 and an absorbance maximum at λ = 495 nm with ε = 2500 M^{-1} cm^{-1} for the $FeLH_{n-1}$ species according to the equilibrium shown in Equation (5):

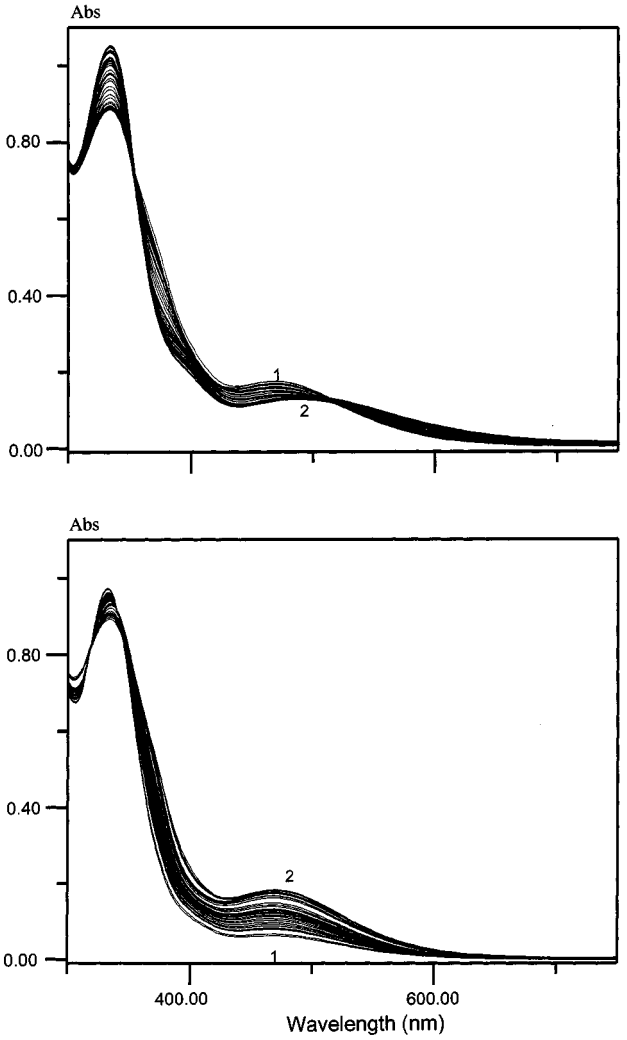

Figure 7. UV/Vis absorbance spectra of Fe^{III} -TRENPYPOLS as a function of pH; (bottom) 1: pH = 1; 2: pH = 2.5; (top) 1: pH = 3.2; 2: pH = 6; $[Fe^{3+}]_{tot}$ = $[TRENPYPOLS]_{tot}$ = 0.24 mM, I = 0.1 M ($NaClO_4$)

$$FeLH_n \rightleftarrows FeLH_{n-1} + H^+ \quad (5)$$

No spectral change was observed over the pH range 6−8.5. Beyond pH 8.5, a slight decrease in absorbance was observed suggesting the formation of hydroxo complexes.

The UV/Vis spectrum of the $[FeLH_5]^{2+}$ species exhibited features (λ_{max} = 470 nm, ε_{max} = 3900 M^{-1} cm^{-1}) that suggest a bis-salicylate coordination, involving the amide oxygen and the hydroxy oxygen atoms, as opposed to the tris-salicylate complex Fe^{III}-TRENSAM (λ_{max} = 455 nm, ε = 4800 M^{-1} cm^{-1}).[20] On raising the pH from 3 to 6, an increase of λ_{max} from 470 to 495 nm with a decrease in the molar extinction coefficient (ε = 2500 M^{-1} cm^{-1}) was observed. These parameters are consistent with a phenolato−Fe^{III} charge-transfer band. This result indicates a shift of the coordination from a salicylate to a phenolate coordination and suggests the replacement of the O(=C) → Fe^{III} bonding mode by the N_{pyr} → Fe^{III} bonding mode.

However, it should be noted that the UV/Vis absorbance dependence on the pH can only give information on the

deprotonation of the phenol group. The deprotonation constants of the $[FeLH_5]^{2+}$ complex corresponding to the ammonium nitrogen and to the three pyridinium nitrogens cannot be determined since these deprotonations do not change the phenolato−Fe^{III} charge-transfer band. It is reasonable to predict that the pK_a values for the pyridinium nitrogens are lower than that of the free ligand (i.e. < about 4). Furthermore, the potentiometric titration clearly showed that there are two deprotonation constants that are close to one another between pH 4.5 and 5. We may attribute one deprotonation to the ammonium nitrogen and the other to the phenol oxygen when compared with the value of 4.5 determined from visible spectrum.

The stability constant β_{110} of the ferric complex FeL was determined by spectrophotometric competition experiments. The constant was determined by competition against EDTA (noted Y) over the pH range 7−8. The competition equilibrium can be expressed by Equation (6) and Equation (7) (charges omitted for clarity):

$$FeL + YH + 2\,H^+ \rightleftarrows FeY + LH_3 \quad (6)$$

$$K = [FeY][LH_3]/[FeL][HY][H^+]^2 = \beta_{110}(FeY)\,K'_{a1}/\beta_{110}(FeL)\,K_{a1}\,K_{a2}\,K_{a3} \quad (7)$$

where L represents the deprotonated form of the ligand TRENPYPOLS; K_{a1}, K_{a2}, K_{a3}, the deprotonation constants of LH_3 and K'_{a1} the deprotonation constant of YH ($10^{-10.2}$).[23] The concentration of FeL was calculated from the absorbance at 500 nm where FeL is the only absorbing species. The concentrations of the other species in Equation (6) were calculated from the pH and mass balance Equations (8)−(10):

$$[Fe]_{tot} = \alpha_{FeL}\,[FeL] + \alpha_{FeY}\,[FeY] \quad (8)$$

$$[L]_{tot} = \alpha_{FeL}\,[FeL] + \alpha_{L}\,[L] \quad (9)$$

$$[Y]_{tot} = \alpha_{FeY}\,[FeY] + \alpha_{Y}\,[Y] \quad (10)$$

where α represents the usual Ringbom's coefficients.[24] Using the known formation constants of FeY (log β_{110} = 25.0),[23] the average formation constant of the Fe^{III}-TRENPYPOLS complex was determined to be log β_{110} = 30.1 ± 0.15. The pFe^{III} values have been calculated over the pH range 3−9 (or 4−9 for TRENPYPOLS and TRENCAM since the stability constants for their protonated complexes existing at pH<4 are unknown) and reported on the plot pFe = f(pH) presented in Figure 8, together with the plots calculated for other tripodal ligands based on the TREN backbone. In addition, the pFe^{III} value for TRENPYPOLS (under biologically reasonable conditions, i.e. pH = 7.4, $[L]_{tot}$ = 10^{-5} M, $[Fe]_{tot}$ = 10^{-6} M) has been calculated to be 23.6. This value is lower than those for other tripodal ligands such as TRENCAM: 27.8,[25] TRENCAMS: 29.6,[8] TRENDROX: 27.8,[9] O-TRENSOX: 29.5[7] The pFe^{III} values for the complexes involving five-membered chelate rings are significantly higher than the values for the complexes having six-membered chelate rings as in Fe^{III}-TRENPYPOLS. This result is in accordance with a general rule: an increase in the size of the chelate ring usually leads to a decrease in complex stability.[26] However, this rule had never been experimentally confirmed for octahedral complexes with tris-bidentate tripodal ligands.

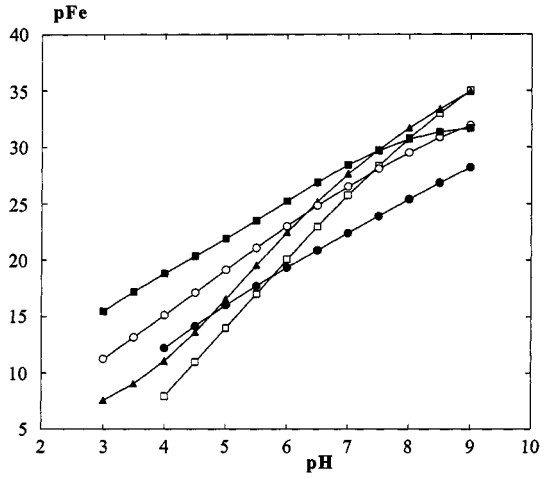

Figure 8. Plot of pFe^{III} *vs* pH for various tripodal ligands. pFe^{III} was calculated for $[L]_{tot}$ = 10^{-5} M, $[Fe^{3+}]_{tot}$ = 10^{-6} M using the known constants of TRENPYPOLS (●), O-TRENSOX[7] (■), TRENCAM[25] (□) TRENCAMS[8] (▲) and TRENDROX[9] (O).

Electron Spin Resonance

The ESR spectra of frozen aqueous solutions (with 10% glycerol) of Fe^{III}-TRENPYPOLS (Figure 9, spectra 1−5) were recorded at 100 K over the pH range 2−8. Below pH 4.8, the spectrum exhibited one single signal at g = 4.3 characteristic of a high-spin octahedral ligand field. The isotropic signal reflects a rhombic symmetry and represents a transition within the intermediate Kramer doublet (for an E/D ratio of 1/3 and a D parameter of about 0.5 cm^{-1} for this type of complex), and is large relative to the quantum of energy used in the EPR experiment. At pH above 5.8, a dissymmetric signal at g = 4.3 was observed indicating a slightly distorted rhombic geometry. The spectra resemble those of the ferric complexes with O-TRENSOX (Figure 9) in acidic (pH = 1.5, spectrum 6) and in neutral media (pH = 7.1, spectrum 7) in which the ferric ion is coordinated through a tris-salicylate mode [O(=C),O)][27] and a tris-oxinate mode $[O,N_{pyr}]^7$, respectively. These results suggest similar change of coordination for Fe^{III}-TRENPYPOLS complexes on raising the pH and are consistent with the change observed in the UV/Vis spectra.

Electrochemistry

The electrochemical behavior of the Fe^{III}-TRENPYPOLS complex, studied by cyclic voltammetry, in an aqueous electrolyte (0.1 M $NaClO_4$) buffered at pH 7 is characterized by a well-defined pair of peaks at $E^c_{1/2}$ = −0.18 V vs Ag/AgCl (0.04 V vs NHE) (ΔE_p = 0.11 V, υ = 0.1 V s^{-1}) corresponding to the quasi-reversible complexed Fe^{II}/Fe^{III} redox couple (Figure 10). Taking into account a value of $E^f_{1/2}$= 0.55 V (i.e. 0.77 V vs NHE) for the free Fe^{II}/Fe^{III} redox couple, this result shows that the complexation with TREN-

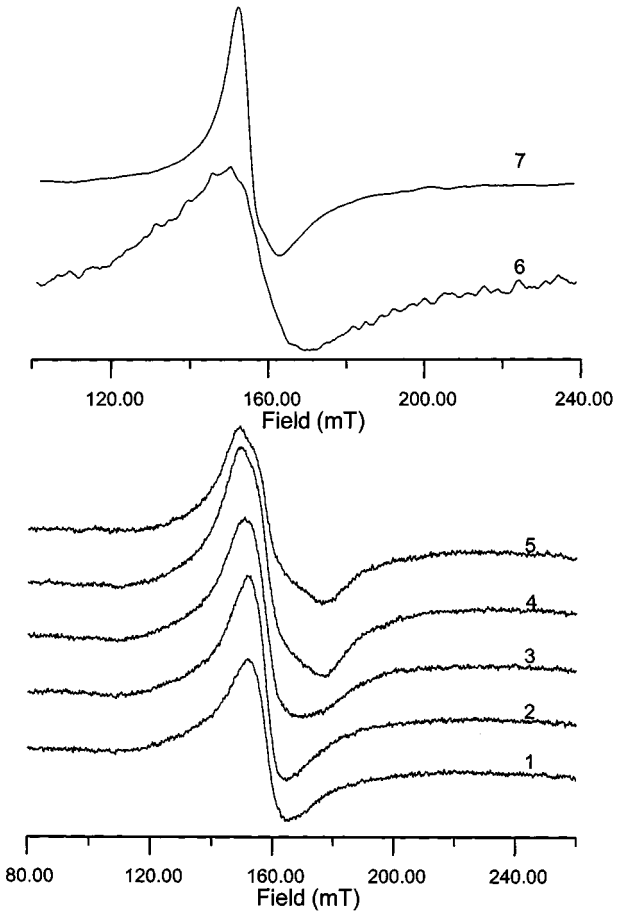

Figure 9. ESR spectra of (bottom) Fe^{III}-TRENPYPOLS (0.001 M) in frozen water-glycerol (90:10) solution at pH 4.0 (1), 4.8 (2), 5.4 (3), 5.8 (4) and 7.0 (5); (top) Fe^{III}-O-TRENSOX (0.001 M) in frozen water-glycerol (90:10) solution a pH 1.5 (6) and 7 (7).

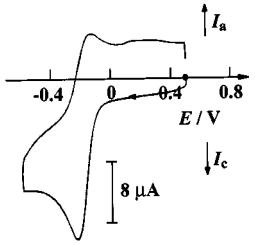

Figure 10. Cyclic voltammogram of Fe^{III}-TRENPYPOLS complex in aqueous solution (1 mM) at pH 7 with 0.1 M $NaClO_4$; v = 0.1 V s^{-1}; working electrode: glassy carbon disc (5 mm diameter).

PYPOLS leads to a strong stabilization by ca 0.73 V of the oxidized form of the redox couple. The ratio $\beta_{110}(Fe^{II}L)/\beta_{110}(Fe^{III}L)$ can be calculated from Equation (11):

$$E^c_{1/2} = E^f_{1/2} + 0.059 \log \beta_{110}(Fe^{II}L)/\beta_{110}(Fe^{III}L) \quad (11)$$

and gives $\beta_{110}(Fe^{II}L) = 17.7$ leading to a pFe^{II} value of 11.2. TRENPYPOLS appears to be a stronger ferrous ion chelator than the catecholate and hydroxamate ligands. This is a characteristic property of the $[O,N_{pyr}]$ donor set as previously observed for the ligand O-TRENSOX ($E^c_{1/2} = 0.087$ V vs NHE).[7] The difference in pFe^{II} between O-TRENSOX and

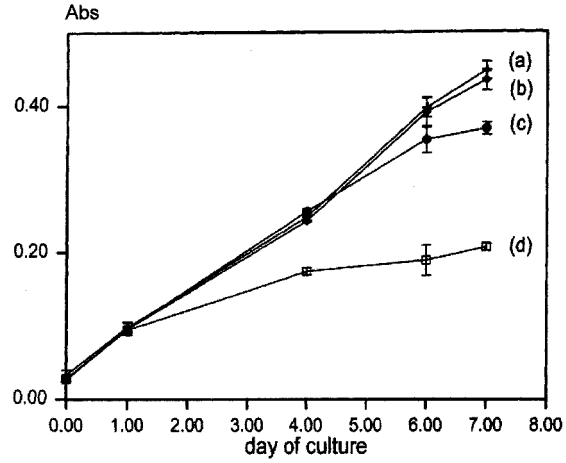

Figure 11. Growth of cells of *Arabidopsis thaliana* using Fe^{III} -TRENPYPOLS or Fe^{III} -EDTA as siderophores. A: 50 μM Fe^{III}-TRENPYPOLS; B: 50 μM Fe^{III}-EDTA; C: 5 μM Fe^{III} -TRENPYPOLS; D: without iron; 25 °C, 220 rpm, 18 hours light per day. The inoculum originated from a previous culture with 2.0 μM Fe^{III} -EDTA presenting slight symptoms of chlorosis.

TRENPYPOLS (6.7) is of the same order of magnitude as the difference between their pFe^{III} (5.9). The electrochemical behavior of the Fe^{III}-TRENPYPOLS complex has also been studied at pH 2.5 where the major species is $[FeLH_5]^{2+}$. Reduction of the complex could not be observed on the voltammograms in the accessible potential range at pH 2.5 i.e. the reduction of the complex occurs at a potential lower than −0.6 V vs Ag/AgCl (−0.38 V vs NHE). The lower reduction potential at pH 2.5 indicates that the Fe^{III} complex is more stable relative to the Fe^{II} complex at pH 2.5 than at pH 7. This suggests a change in coordination of iron as previously deduced from the UV/Vis and EPR spectra.

Plant Nutrition

TRENPYPOLS was tested as single source of iron in nutritional experiments. This was performed by comparing the growth and greening of *Arabidopdis thaliana* plant cells during cell suspension cultures. In the control experiment, iron was provided as a complex Fe^{III} -EDTA (50μM). An iron free control was cultivated in the iron free nutrient solution (MS−Fe). The assays were performed in MS−Fe supplemented with Fe^{III}-TRENPYPOLS at 5 and 50μM using 8 independent replications. The results are shown in Figure 11. Growth and resistance to chlorosis were equivalent when Fe^{III} -TRENPYPOLS was used instead of Fe^{III} -EDTA. Symptoms of chlorosis appeared when 5 μM Fe^{III} -TRENPYPOLS was used and the growth was slowed down. The efficiency of Fe^{III}-TRENPYPOLS is good, comparable to that of Fe^{III}-EDTA, the most commonly used complex for in vitro cell cultures.

Conclusion

The iron-complexing agent TRENPYPOLS is the first water-soluble tris-bidentate ligand involving three $[O,N_{pyr}]$ donor sets with 6-membered chelate rings. The solution physicochemical data (thermodynamic) of this new chelator have

been established, allowing comparisons with the usual iron chelators, with a special focus on O-TRENSOX which involves three [O,N_{pyr}] donor sets with 5-membered coordination rings. TRENPYPOLS and O-TRENSOX form a new class of Fe chelators with an affinity for both Fe^{III} and Fe^{II}. There are two important distinctions in the metal binding cavity between TRENPYPOLS and O-TRENSOX that influence the affinity of these ligands for Fe^{III} and Fe^{II}. The first, is the flexibility of the binding cavity. TRENPYPOLS provides a more flexible cavity by forming six-membered chelate rings and allowing free rotation of the pyridine ring relative to the phenol ring. O-TRENSOX forms five-membered chelate rings and prevents pyridine ring rotation through a fused ring structure. The second, is a difference in ligand pK_a values which results in a lower pFe^{III} and pFe^{II} for TRENPYPOLS. These features influence the relative Fe^{III} and Fe^{II} affinity of the two ligands as determined by their pFe values. Consequently, TRENPYPOLS has a lower Fe^{III} and Fe^{II} affinity than O-TRENSOX, but the same relative Fe^{III}/Fe^{II} selectivity ($\Delta pFe = pFe^{III} - pFe^{II}$), making it more suitable for use as a biological Fe sensor. There is always a need for biological sensors for the study of iron metabolism. They have to be able to measure the labile iron pool and the concentration of cellular free iron.[28] For this purpose, ligands with complexing abilities that are too high must be avoided since they induce perturbation in iron metabolism (uptake of iron from proteins). The pFe^{III} values of TRENPYPOLS are in a suitable range. It is envisaged that a fluorescent probe could be grafted on the ligand in order to build a new sensor, well suited to be used in conjunction with calcein, the most frequently used probe for iron to date.[28]

Experimental Section

Materials and Equipment: Solvents were distilled prior to use. The amine TREN (tris-2-aminoethyl)amine) was distilled over sodium. All other compounds were of reagent grade and were used without further purification. Fe^{III} stock solutions were prepared by dissolving appropriate amounts of ferric perchlorate hydrate (Aldrich) in standardized $HClO_4/NaClO_4$ solutions. The solutions were standardized spectrophotometrically for ferric ion by using a molar extinction coefficient of 4160 M^{-1} cm^{-1} at 240 nm.[29] − IR spectra were collected using a Perkin−Elmer 397 or Nicolet Impact 400 spectrometer. − UV/Vis absorbance spectra were recorded using 1.000 cm path length quartz cells housed in a Perkin−Elmer Lambda 2 spectrometer connected to a microcomputer. − Mass spectra were recorded on a NERMAG R 10 1 C mass spectrometer. − Microanalyses were performed by the Central Service of CNRS, Solaize (France). − Melting points were determined with a Büchi apparatus and are not corrected. − ^1H and ^{13}C NMR spectra were obtained in 5 mm tubes at 25 °C with a Bruker AM 300 or a Bruker AM 400 spectrometer. For ^1H NMR spectroscopic titrations, the ligand TRENPYPOLS was dissolved in D_2O. The pD was adjusted with DCl or NaOD solutions. pH measurements were performed with a Tacussel PHN 850 apparatus equipped with a microelectrode Radiometer XC61. pD values were calculated according to $pD = pH_{meas} + 0.4$.[30] − EPR experiments were conducted using a ESP 300E Bruker apparatus with a variable temperature unit. Spectra were treated by using the winEPR software. Each aqueous Fe^{III}-TRENPYPOLS sample (200 μL, 10^{-3} M) contained 10% glycerol. The field was scanned from 0.1 to 0.5 Tesla.

Synthesis of TRENPYPOLS (Figure 3)

2-(2-Methoxy-3-methylphenyl)pyridine (5): The Grignard reagent **4** was prepared under Argon at 0 °C, from **3** (5.05 g, 25.0 mmol) and Mg (0.65 g, 27.0 mmol) in dry THF (30 mL). It was transferred, *via* canula, to a mixture of 2-bromopyridine (3.79 g, 24.0 mmol) and $Ni(dppe)_2Cl_2$ (0.55 g, 1.00 mmol) in THF (20 mL). The mixture was then stirred overnight at room temperature. After quenching with aqueous NH_4Cl and acidification with HCl (4 M) to pH ≈ 1, THF was evaporated under vacuum. Extraction with CH_2Cl_2 (3 × 100 mL), drying on $MgSO_4$ and evaporation of the solvent gave a brown oil. Column chromatography (silica eluted with a CH_2Cl_2 + MeOH mixture (1% to 5% vol)) afforded pure **5** (3.54 g, 17.7 mmol). Yield 71%. − ^1H NMR (250 MHz, $CDCl_3$): δ = 2.35 (s, 3 H), 3.46 (s, 3 H, OCH_3), 7.12 (t, 1 H, *J* = 7.5 Hz), 7.18−7.26 (m, 2 H), 7.54 (dd, 1 H, *J* = 7.5/1.7 Hz), 7.71 (td, 1 H, *J* = 7.5 Hz, *J* = 0.7 Hz), 7.84 (broad d, 1 H, *J* = 7.5 Hz), 8.70 (ddd, 1 H, *J* = 4.9 Hz, *J* = 1.7 Hz, *J* = 0.7 Hz). − ^{13}C NMR (50 MHz, $CDCl_3$): δ = 16.1 (CH_3), 60.5 (OCH_3), 121.8 (CH), 124.2 (CH), 124.5 (CH), 128.9 (CH), 131.5 (C*q*), 131.6 (CH), 133.3 (C*q*), 136.1 (CH), 149.4 (CH), 156.3 (C*q*), 156.6 (C*q*). − MS (EI): 199 (M^+), 184, 181, 168, 154. − $C_{13}H_{13}NO$ (199.3): calcd. C 78.30, H 6.58, N 7.03; found C 77.90, H 6.57, N 6.91.

2-Methoxy-3-(2-pyridyl)benzoic Acid (6): A mixture of **5** (2 g, 10.0 mmol), $KMnO_4$ (6 g, 38.0 mmol) and $NaHCO_3$ (0.78 g, 9.3 mmol) in water (120 mL) was stirred under reflux for 3 h. MnO_2 was removed by filtration and the solution extracted with diethyl ether. The aqueous solution was acidified to pH ≈ 5 with dilute HCl and the water was evaporated under vacuum. The solid residue was treated by methanol, and inorganic salts were removed by filtration. Evaporation of methanol gave **6** as a white powder (1.77 g, 7.7 mmol), pure enough for the following step. Yield 77%. − ^1H NMR (250 MHz, CD_3OD): δ = 3.58 (s, 3 H, OCH_3), 7.22 (t, 1 H, *J* = 7.7 Hz), 7.39 (td, 1 H, *J* = 5.0 Hz, *J* = 1.6 Hz), 7.56−7.67 (m, 2 H), 7.79−7.90 (m, 2 H), 8.61 (broad d, 1 H, *J* = 4.8 Hz). − ^{13}C NMR (50 MHz, D_2O−NaOD): δ = 62.0 (OCH_3), 123.2 (CH), 124.4 (CH), 125.2 (CH), 128.8 (CH), 131.3 (CH), 133.2 (C*q*), 134.0 (C*q*), 138.0 (CH), 148.7 (CH), 153.5 (C*q*), 155.3 (C*q*), 176.3 (CO). − MS (DCI, NH_3+isobutane): 230 [M^+ + 1].

2-(3-Chloroformyl-2-methoxyphenyl)pyridinium Chloride (7): A mixture of **6** (1 g, 4.4 mmol) and distilled thionyl chloride (50 mL) was stirred under nitrogen for 4 h at room temperature. Excess $SOCl_2$ was removed under vacuum, giving **7** as a yellow powder (1.24 g, quant. yield). − ^1H NMR (200 MHz, $CDCl_3$): δ = 3.72 (s, 3 H, OCH_3), 7.56 (t, 1 H, *J* = 7.9 Hz), 8.07 (t, 1 H, *J* = 7.9 Hz), 8.25−8.35 (m, 3 H), 8.58 (t, 1 H, *J* = 7.6 Hz), 9.05 (d, 1 H, *J* = 5.1 Hz). − ^{13}C NMR (50 MHz, $CDCl_3$): δ = 63.8 (OCH_3), 125.07 (CH), 125.08 (C*q*), 125.5 (C*q*), 125.7 (CH), 128.6 (CH), 137.0 (CH), 137.7 (CH), 142.3 (CH), 145.3 (CH), 148.7 (C*q*), 157.6 (C*q*), 164.4 (CO).

Methoxylated Podand 8: A mixture of TREN (tris-2-aminoethyl)amine) (0.24 g, 16.4 mmol) and triethylamine (2.9 g, 29.0 mmol) in dry THF (10 mL) was added dropwise, under nitrogen, to a solution of acid chloride **7** (1.24 g, 4.4 mmol) in THF (50 mL). The mixture was stirred at room temperature for 12 h. Filtration and evaporation of THF afforded an orange oil which was mixed with CH_2C1_2. The solution was washed with brine then dried on Na_2SO_4. Removal of the solvent under vacuum gave a foamy material which was added to pentane. Tripodand **8** was recovered by filtration as a yellow powder (0.8 g). Yield 70%. M.p. 62−63 °C. − IR (KBr):

$\tilde{\nu}$ = 1650, 1523 cm^{-1} . − ^1H NMR (200 MHz, $CDCl_3$): δ = 2.92 (t, 6 H, *J* = 6.5 Hz, CH_2N), 3.48 (s, 9 H, OCH_3), 3.65 (td, 6 H, *J* = 6.5 Hz, $CH_2-NH-CO$), 7.26 (td, 6 H, *J* = 5.5 Hz, *J* = 3.1 Hz), 7.64−7.72 (m, 6 H), 7.75 (dd, 3 H, *J* = 7.5 Hz, *J* = 2.0 Hz), 8.03 (dd, 3 H, *J* = 7.9 Hz, *J* = 1.7 Hz), 8.16 (broad t, 3 H, NH), 8.70 (broad d, 3 H, *J* = 4.8 Hz). − ^{13}C NMR (50 MHz, $CDCl_3$): δ = 37.8 (CH_2), 53.4 ($N-CH_2$), 62.2 (OCH_3), 122.3 (CH), 124.4 (CH), 124.8 (CH), 126.9 (C*q*), 131.9 (CH), 134.1 (C*q*), 134.6 (CH), 136.3 (CH), 149.6 (CH), 155.4 (C*q*), 156.0 (C*q*), 165.6 (CO). − MS (DCI, NH_3+isobutane): 780 [M^+ + 1]. − $C_{45}H_{45}N_7O_6 \cdot 1\ H_2O$ (797.9): calcd. C 67.74, H 5.94, N 12.29; found C 67.42, H 5.83, N 12.03.

TRENPYPOL (9): Podand **8** (1.09 g, 1.4 mmol) was dissolved in dry CH_2Cl_2 (100 mL), under nitrogen at 0 °C, and BBr_3 (15 mL of a solution with 1 M CH_2Cl_2, excess) was added dropwise. The mixture was stirred for 12 h at room temperature and then concentrated under vacuum. Methanol (50 mL) was added and the mixture was stirred for 1 h and then repeatedly evaporated with methanol (5 × 100 mL). The resulting yellow precipitate was dissolved in HCl 4N and the solution was extracted with CH_2Cl_2. The aqueous solution was adjusted to pH 7−8 with $NaHCO_3$ and extracted with CH_2Cl_2. Washing with brine, drying on $MgSO_4$, evaporation of the solvent and treatment with pentane-ether gave **9**·2HCl as a yellow powder (0.964 g). Yield 85%. − IR (KBr): $\tilde{\nu}$ = 3356, 1644 cm^{-1}. − $C_{42}H_{39}N_7O_6$, $1H_2O$ (755.8): calcd. C 66.74, H 5.47, N 12.97; found C 66.68, H 5.54, N 12.66. − ^1H NMR (250 MHz, D_2O): δ = 3.77 (broad s, 6 H, CH_2N), 3.85 (broad s, 6 H, $CH_2-NH-CO$), 6.71 (t, 3 H, *J* = 7.8 Hz), 7.49 (d, 3 H, *J* = 7.6 Hz), 7.64 (m, 6 H), 7.71 (broad t, 3 H, *J* = 7.6 Hz), 8.30 (broad t, 3 H, *J* = 7.8 Hz), 8.49 (broad d, 3 H, *J* = 5.6 Hz). − ^{13}C NMR (50 MHz, DMSO): δ = 37.3 (CH_2), 52.8 ($N-CH_2$), 117.9 (CH), 119.7 (C*q*), 120.5 (C*q*), 122.3 (CH), 130.3 (CH), 131.9 (CH), 138.5 (CH), 145.2 (CH), 155.7 (C*q*), 158.9 (C*q*), 165.6 (CO). − MS (DCI, NH_3+isobutane): 738 [M^+ + 1], 567, 541, 524, 510.

TRENPYPOLS (10): Podand **9** (1 g, 1.35 mmol) was dissolved in oleum (15 mL) and the mixture was stirred for 12 h, at room temperature. The brown solution was poured onto ice and the pH was raised to 9−10 by cautious addition of 1 M NaOH. Methanol (100 mL) was added to precipitate Na_2SO_4. Filtration and concentration gave a yellow powder, containing again some Na_2SO_4; this salt was removed by repeated treatment (formation of a white precipitate, then concentration) with a mixture of methanol and diethyl ether. Evaporation of the resulting solution gave a yellow powder (tetrasodium salt, 0.74 g). Yield 52%. − IR (KBr): $\tilde{\nu}$ = 3440, 1640 cm^{-1}. − ^1H NMR (200 MHz, D_2O+NaOD): δ = 2.69 (broad s, 6 H, CH_2N), 3.36 (broad s, 6 H, $CH_2-NH-CO$), 7.06 (m, 3 H), 7.40−7.55 (m, 9 H), 8.05 (m, 3 H), 8.27 (m, 3 H). − ^{13}C NMR (50 MHz, D_2O+NaOD): δ = 36.8 (CH_2), 53.0 ($N-CH_2$), 119.0 (C*q*), 122.7 (CH), 125.9 (CH), 126.1 (C*q*), 128.8 (CH), 130.9 (CH), 132.8 (C*q*), 137.4 (CH), 148.8 (CH), 157.3 (C*q*), 170.2 (C*q*), 170.4 (CO). − MS (FAB positive mode M + 1, NBA matrix): 1066 ($C_{42}H_{35}N_7O_{15}S_3Na_4$ + 1). The molecular mass was also checked by potentiometric titration.

Potentiometric Titrations: All measurements were performed at 25 °C and the solutions were prepared with deionized and twice distilled water. The ionic strength was fixed at *I* = 0.1 M with sodium perchlorate (PROLABO puriss.). The potentiometric titrations were performed using an automatic titrator system DMS 716 Titrino (Metrohm) with a combined glass electrode (Metrohm, filled with saturated NaCl solution) and connected to an IBM Aptiva microcomputer. The electrodes were calibrated to read p[H] according to the classical method[31] (titration of 0.1 M $HClO_4$ with 0.1 M NaOH). The ligand and its Fe^{III} complex, ca 0.001 M, were titrated with standardized 0.025 M sodium hydroxide. Argon was bubbled through the solutions to exclude CO_2 and O_2. Sodium hydroxide was prepared from 0.1 M NaOH (Prolabo) and was standardized against potassium hydrogen phthalate. Carbonate content was checked by Gran's method. The titration data (108 points collected over the pH range 2.85−10.77 for the ligand solution) were refined by the nonlinear least-squares refinement program SUPERQUAD[18] to determine the deprotonation constants. The pK_{an} values were calculated from the cumulative constants determined with the program. The uncertainties in the pK_{an} values correspond to the added standard deviations (1σ) in the cumulative constants.

Spectrophotometric Experiments: The ferric complexes were studied by spectrophotometry. The UV/Vis spectrum of a solution containing equal amounts of ligand and Fe^{III} (10^{-4} M) was recorded as a function of pH over the range 1−9 (adjusted with $HClO_4$ or NaOH). An aliquot was taken from the solution after each adjustment of the pH and its spectrum was recorded. pH measurements were made with a 713 Metrohm digital pH meter equipped with a microelectrode. The ionic strength was fixed at *I* = 0.1 M with $NaClO_4$/$HClO_4$. The spectrophotometric data were analyzed using the LETAGROP-SPEFO program.[19,20]The program uses a nonlinear least-squares method to calculate the thermodynamic constants of the absorbing species and their corresponding electronic spectra. The calculations were performed using absorbance values from about 6-8 wavelengths (between 400 and 600 nm). The range of values for the residual-squares sum ($\Sigma(A_{exp}-A_{calc})^2$) of the fits was $10^{-4}-10^{-5}$.

Spectrophotometric competition experiments were carried out with Na_2H_2EDTA over the pH range 7−8. Typical solutions contained 10^{-4} M Fe^{III} ion, TRENPYPOLS and Na_2H_2EDTA. Five solutions were prepared. The samples were allowed to equilibrate for one week in the dark at 25 °C.

Electrochemical Measurements: Electrochemical experiments were carried out using a PAR model 273 potentiostat equipped with a Kipp−Zonen *x*-*y* recorder. All experiments were run at room temperature under argon in a glove-box. A standard three-electrode cell was used. An Ag/AgCl, 3M NaCl, aqueous reference electrode (+0.222 V *vs* NHE) was used. A glassy carbon disc electrode was used as the working electrode (5 mm diameter) and was polished with 1 μm diamond paste. The electrochemical behavior of the Fe^{III} -TRENPYPOLS complex was studied by cyclic voltammetry (CV) in an aqueous solution containing 0.1 M $NaClO_4$ as the supporting electrolyte and buffered with Tris-buffer for the experiments performed at pH 7 or acidified with $HClO_4$ for the experiments at pH 2. The Fe^{III} -TRENPYPOLS solutions were prepared by dissolving stochiometric amounts of ferric perchlorate and TRENPYPOLS in the electrolytic solutions.

Plant Cells Culture and Growth Measurements: Plant cells were grown in 24 well sterile cell culture plates (Nunc); each well contained an independent axenic culture (1.5 mL). Wells were inoculated at an absorbance of 0.003 (*ca* 1/12) with early stationary phase *Arabidopsis thaliana* (var. Columbia) cell suspensions. For axeny, plates were sealed with "Magic Scotch®" tape. 24 well plates were agitated at 220 rpm at 25 °C in a New Brunswik "innova" 4230 refrigerated incubator shaker. Light was supplied for 18 h a day by 2 growlux sylvania 15 W in the " photosynthesis " accessory.

The measurements of cell density were made daily as previously described.[28] The Biorad video camera system Geldoc 1000, with the "molecular analyst" software was used for quantification. Full frame images were captured in constant light conditions, i.e. white

light was adjusted so that just a few saturated pixels appeared in red in the empty optical field. In these light conditions, a reproducible relationship was found between the absorbance of wells in densitometric scanning profiles of recorded images and the amount of cells in the wells. Images of culture plates without cells were used as a baseline reference. They showed an uneven light background. This fact was compensated by the subtraction of an adapted baseline.

The medium (MS) was a modified Murashige and Skoog[32] medium; for 1 L of medium: 4.3 g macro and micro elements powder (provided by Duchefa, cat N° M0221, Haarlem Netherlands), 10 mL KH_2PO_4 (20 g/l), 0.5 mL Kinetin (0.1 g/l), 0.5 mL 2,4 D (0.2 g/l), 1 mL × 1000 vitamin solution (Duchefa M 0409) and 30 g saccharose. Iron free MS medium (MS−Fe) has the same content, made from reagent grade products, omitting the Fe^{III}-EDTA complex. The Fe^{III}-TRENPYPOLS complex was first prepared at low pH then raised to pH 5.8 with NaOH and a Tris maleate buffer, then mixed to the MS−Fe solution at the same pH. The complex was filtered using a 0.22 μm Millipore filter and sterilized. MS−Fe was autoclaved.

Acknowledgments

The authors thank Dr. Alain Deronzier (LEOPR, Grenoble, France) for the use of the laboratory facilities and Professor A. L. Crumbliss (Durham, NC) for very helpful discussions.

Binary [Hydrotris(indazol-1-yl)borato]metal Complexes, $M(Tp^{4Bo})_2$[1] with M = Fe, Co, Ni, Cu, and Zn: Electronic Properties and Solvent-Dependent Framework Structures through C−H•••π Interactions

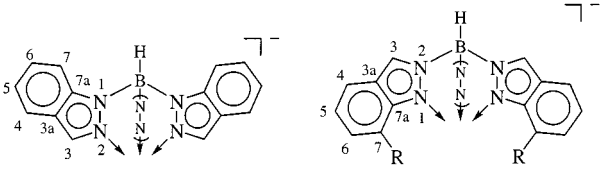
Keywords: Boron / N ligands / UV/Vis spectroscopy / Cyclic voltammetry / Mössbauer spectroscopy / π interactions



The bis[hydrotris(indazol-1-yl)borato]metal complexes $[M\{HB(C_7H_5N_2)_3\}_2]$, $M(Tp^{4Bo})_2$, with M = Fe, Co, Ni, Cu, and Zn have been synthesized and characterized by NMR, IR, UV/Vis, MS, Mössbauer spectrometry (M = Fe) and cyclic voltammetry (M = Fe, Co). The ligand field strength of the Tp^{4Bo} ligand is slightly higher than that of the normal Tp ligand. The molecular and crystal structure of the compounds with different solvents of crystallization (tetrahydrofuran, chloroform, dioxane) were elucidated by X-ray crystallography. The metal complexes exhibit the usual pseudo-octahedral D_{3d}-symmetrical geometry for two tripodal ligands with a Jahn–Teller distortion for M = Cu. The crystal packing between the molecular complexes is controlled mainly by C–H•••π interactions from the indazolyl moieties. This gives rise to large non-covalent framework structures with voids and channels ranging in volume from about 19 to 39% of the unit cell volume. The open space is filled by solvent molecules. The crystal packing and the space group depends on the type of solvent.

Introduction

The hydrotris(pyrazolyl)borate (Tp) ligand **1** was introduced into coordination chemistry by Trofimenko more than 30 years ago[2], and in various substituted forms has developed into one of the most versatile tripodal auxiliary ligands in (bio)inorganic coordination chemistry.[3−5] Particular interest is sometimes devoted to special azolyl rings, such as triazolyl,[6−9] tetrazolyl,[10] 3,5-bis(trifluoromethyl)-pyrazolyl,[11] and indazolyl.[12,13] Poly(indazolyl)borate systems are of interest because of the possible regioisomeric structures **2a** and **2b**. The latter isomer **2b** is the empirically expected form where B−N bond formation (from KBH_4 and indazole) had occurred at the least-hindered nitrogen atom N2 (by indazole numbering).[12] This isomer, however, appears only to be encountered with 7-substituted indazoles.[13−15] With unsubstituted or otherwise substituted indazoles the isomer **2a** is formed, probably because of electronic reasons. In **2a**, boron is bonded to the sterically more hindered but electronically richer nitrogen atom.[12,16,17]

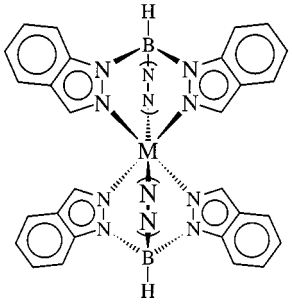
2a, Tp^{4Bo} [1] **2b, Tp^{3Bo}**

-(N-N)- denotes the third pyrazolyl or indazolyl ring which is oriented to the rear



In the extension of our work on [hydrotris(triazolyl)borato]metal complexes,[6,7,9] we were interested in the electronic ligand field effect of the anellated benzo ring on the nitrogen−metal bond.[7,18] We therefore synthesized the homoleptic bis[hydrotris(indazol-1-yl)borato]metal(II) complexes $[M(\mathbf{2a})_2]$ or $[M(Tp^{4Bo})_2]$ of iron, cobalt, nickel, copper, and zinc, to compare their electronic properties with those of the analogous bis[hydrotris(pyrazolyl)borato]-metal compounds.[19−21] Furthermore, during the course of

our studies we became interested in the crystal packing of the $M(Tp^{4Bo})_2$[1] complexes.

$[M(2a)_2]$, $[M(Tp^{4Bo})_2]$

-(N-N)- denotes the third indazolyl ring which is oriented to the rear or front, respectively

Syntheses and Properties of $[M\{HB(C_7H_5N_2)_3\}_2]$, $[M(Tp^{4Bo})_2]$ with M = Fe (4), Co (5), Ni (6), Cu (7), and Zn (8)

The hydrotris(indazol-1-yl)borato anion **2a** in the form of its potassium salt **3** reacts with transition-metal(II) salts in methanol with the formation of bis[hydrotris(indazol-1-yl)borato]metal(II) complexes [Equation (1)]. Yields were above 50%. The complexes are initially obtained as powders, but could be crystallized from tetrahydrofuran (THF), dioxane or chloroform. Crystallization proceeded either by slow solvent evaporation, cooling or overlayering of the dioxane phase with petroleum ether (30/50). The crystals of **4**−**8** quickly eliminate the incorporated $CHCl_3$ and THF solvent, when taken out of the solvent phase, with concomitant loss of crystallinity. The complexes are air-stable, but decompose in water. The tris[(indazolyl)borato]metal complexes are insoluble to slightly soluble in methanol and DMSO, and rather soluble in THF. The thermal stability of all compounds is high, their melting or decomposition point is above 300 °C (undetermined). A melting point of 446 °C had been determined for **4** by DSC.[12] The infrared spectra of the complexes are similar to each other, and to the potassium salt **3**.

NMR Spectroscopy

The ^1H- and ^{13}C-NMR chemical shifts of the borato anion **2a** and of the diamagnetic transition-metal complexes correspond roughly to the spectrum of indazole[22] and of the tetrakis(indazol-1-yl)borato anion, $[B(C_7H_5N_2)_4]^-$,[16] and the signals were assigned accordingly. Despite its paramagnetism, the cobalt compound **5** gave a well-resolved ^1H-NMR spectrum with relatively sharp signals in a chemical shift range of over 200 ppm.[12]
