Mononuclear Ruthenium and Hetero-Tetranuclear Ruthenium-Silver Complexes Containing the Unsymmetrical Bidentate Ligands $R_2P(CH_2)_nER'_2$ (n = 1, 2; E = P, As) as Chelating or Bridging Units

Guido Fries,[a] Birgit Weberndörfer,[a] Kerstin Ilg,[a] and Helmut Werner*[a]

Dedicated to Professor Gerhard Roewer on the occasion of his 60th birthday

Keywords: Arene complexes / Heteronuclear complexes / Ruthenium / Silver / Unsymmetrical chelating ligands

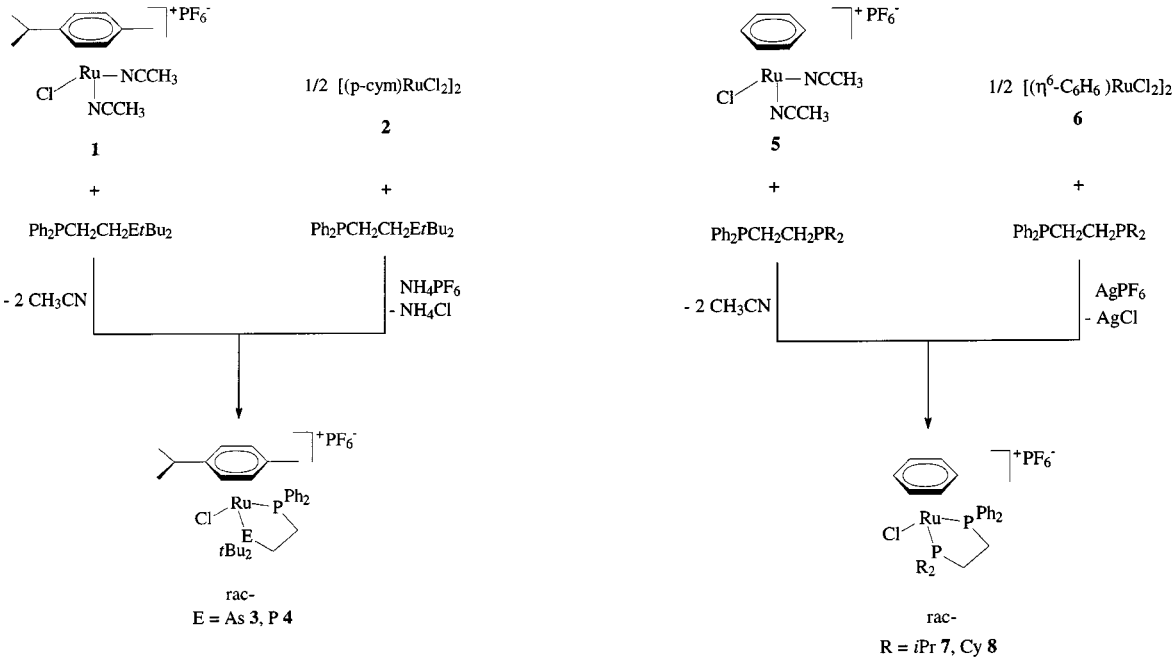
The chelate complexes [(*p*-cym)RuCl(κ²-$Ph_2PCH_2CH_2As$*t*Bu_2)]PF_6 (**3**), [(arene)RuCl(κ²-$Ph_2PCH_2CH_2PR_2$)]PF_6 (**4**, **7**, **8**) and [(*p*-cym)RuCl(κ²-*i*Pr_2PCH_2As*t*Bu_2)]PF_6 (**11**) were prepared either from [(arene)RuCl(NCMe)$_2$]PF_6 (**1**, **5**) or from [(arene)$RuCl_2$]$_2$ (**2**, **6**), in the presence of NH_4PF_6 or $AgPF_6$. The stepwise reaction of [(*p*-cym)$RuCl_2$]$_2$ (**2**) with Ph_2P-CH_2CH_2P*t*Bu_2 and $AgPF_6$ gave the hetero-tetranuclear compound [{(*p*-cym)RuAg(μ-Cl)$_2$(μ-P^1_{Ru},P^2_{Ag}-$Ph_2P^1CH_2CH_2P^2$-*t*Bu_2)}$_2$]$(PF_6)_2$ (**9**), the structure of which was determined by an X-ray crystal structure analysis. The bidentate As,O donor $Ph_2P(O)CH_2CH_2As$*t*Bu_2 also reacted with **2**, in the presence of $AgPF_6$, to afford the chelate complex [(*p*-cym)RuCl-{κ²(*As*,*O*)-$Ph_2P(O)CH_2CH_2As$*t*Bu_2}]PF_6 (**10**), which was also characterized crystallographically.

Introduction

In the search for new, possibly hemilabile, bidentate ligands, we recently described a simple and fairly general one-pot synthesis for unsymmetrical 1,2-bis(phosphanyl)-ethanes and 1-arsanyl-2-phosphanylethanes with and without a stereogenic center.[1] In an initial attempt, we tested the coordination properties of one of the new ligands, $Ph_2PCH_2CH_2P$*i*Pr_2, towards ruthenium(II) and prepared a series of octahedral complexes including [Ru{κ²(*O*,*Cl*)-OC_6Cl_5}$_2$($Ph_2PCH_2CH_2P$*i*Pr_2)] in which the pentachlorophenolate anions behave as chelating ligands.[1,2] In the last decade the chemistry of (arene)ruthenium(II) complexes has attracted a great deal of attention[3] and so we became interested in finding out whether the compounds $Ph_2PCH_2CH_2PR_2$ and $Ph_2PCH_2CH_2AsR_2$, even with bulky substituents R such as *tert*-butyl or cyclohexyl, could also bind to an [(arene)RuCl]$^+$ fragment in a chelating fashion. The present paper reports the preparation of several complexes of the general type [(arene)RuCl(L−L′)]PF_6, and describes the isolation and structural characterization of a novel dicationic tetranuclear Ru_2Ag_2 compound in which two $Ph_2PCH_2CH_2P$*t*Bu_2 ligands bridge the Ru^{II} and Ag^{I} metal centers.

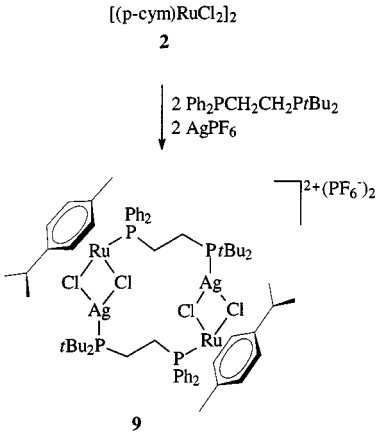
Results and Discussion

The preparation of the chelate complexes **3**, **4** and **7**, **8** (see Scheme 1) can be achieved by two different routes, using either the cationic bis(acetonitrile)ruthenium(II) compounds **1** and **5**[4] or the well-known (arene)ruthenium dichloride dimers **2** and **6** as the starting materials. While **1** and **5** react quite smoothly with the new unsymmetrical 1,2-bis(phosphanyl)- or 1-arsanyl-2-phosphanylethanes in acetonitrile at room temperature to give the half-sandwich-type complexes **3**, **4** and **7**, **8**, respectively, the dimers **2** and **6** are somewhat less reactive and only in the presence of NH_4PF_6 or $AgPF_6$, in dichloromethane as solvent, do they afford the products in good yields.



Compounds **3**, **4** and **7**, **8** are orange, air-stable solids that are soluble in polar solvents such as CH_2Cl_2, THF, methanol, or acetone, and which have been characterized both by elemental analysis and conductivity measurements. Compared to the free ligands $Ph_2PCH_2CH_2PR_2$ and $Ph_2PCH_2CH_2As$*t*Bu_2, the resonances in the ^{31}P-NMR spectra of **3**, **4**, **7**, and **8** are shifted to significantly lower fields, the difference in the chemical shifts being 50−90 ppm.

The unusual tetranuclear complex **9** (Scheme 2) is obtained if the reaction of **2** with $Ph_2PCH_2CH_2P$*t*Bu_2 is carried out in the presence of $AgPF_6$ instead of NH_4PF_6. In contrast to **4**, which also contains $Ph_2PCH_2CH_2P$*t*Bu_2 as a ligand, the ^{31}P-NMR spectrum of **9** displays, besides the signal for the PF_6^- anion, a doublet at δ = 28.0 and two doublet of doublets at δ = 68.0 and 67.9, which arise from the coupling of the ^{31}P nuclei of the P*t*Bu_2 unit with the silver isotopes ^{107}Ag and ^{109}Ag, respectively. The resulting coupling constants $J(^{31}P^{107}Ag)$ = 643.0 Hz and $J(^{31}P^{109}Ag)$ = 743.3 Hz are considerably larger than in a variety of (phosphane)silver(I) complexes.[5] Similar $J(^{31}P^{107}Ag)$ and $J(^{31}P^{109}Ag)$ values (657.5 and 758.8 Hz) have recently been observed for the tris(pyrazolyl)borato compound [{HB[3,5-$(CF_3)_2$pz]$_3$}Ag(PPh_3)] where the coordination number of Ag^{I} is four.[6]



The result of the X-ray crystal structure analysis of the cation of **9** is shown in Figure 1. The coordination sphere around the two ruthenium centers in the centrosymmetric dimer corresponds to that of a half-sandwich-type molecule

with the tridentate *p*-cymene, the phosphorus atom of the PPh_2 unit and the two chlorine atoms Cl1 and Cl2 occupying the six coordination sites. The geometry around the two silver centers is distorted trigonal-planar, one angle (Cl1−Ag2−P2A) being nearly 120° while the two others (Cl2−Ag2−P2A and Cl1−Ag2−Cl2) deviate significantly from the value expected for an sp^2-hybridized metal atom. The distance Ag2−P2A of 2.3592(1) Å is somewhat shorter than in the anionic species $[Cl(C_6Cl_5)_2Pt(\mu\text{-}Cl)Ag(PPh_3)]^-$ [2.395(2) Å][7] and in the neutral compounds $[(PPh_3)_2Ag(\mu\text{-}Cl)_2OsCl_2(\mu\text{-}Cl)_2Ag(PPh_3)_2]$ [2.452(3) and 2.455(3) Å][8] and $[(PPh_3)_2Ag(\mu\text{-}Cl)_2Co(\mu\text{-}Cl)_2Ag(PPh_3)_2]$ (2.43−2.47 Å).[9] The most remarkable feature, however, is the short bond length Ag2−Cl2 [2.4707(18) Å], which is not only much shorter than the distance Ag2−Cl1 [2.7261(19) Å] but also differs from the Ag−Cl bond lengths found in other chloride-bridged silver-metal complexes.[7,8,9] In contrast to the distances Ag2−Cl1 and Ag2−Cl2, the bond lengths Ru1−Cl1 and Ru1−Cl2 are almost identical [2.4234(17) and 2.4432(18) Å] and only slightly longer than those in the mononuclear compounds $[(arene)RuCl_2(L)]$.[10] We note that quite recently a tetranuclear Ru_2Ag_2 complex has been reported in which an $Ag(\mu\text{-}iPr_2PCH_2CH_2PiPr_2)Ag$ fragment is linked to two phenylethynyl ligands, each of which is σ-bonded to one ruthenium center.[11]

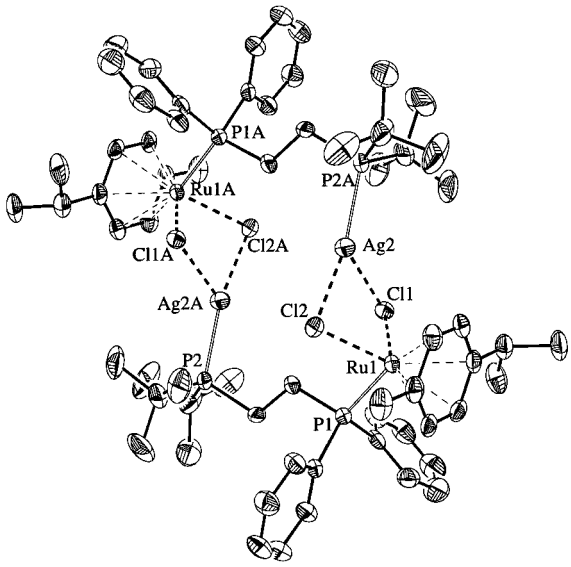

Figure 1. Molecular structure (ORTEP plot) of **9**; the PF_6^- ions are omitted for clarity; selected bond lengths [Å] and angles [°]: Ru1−P1 2.3608(17), Ru1−Cl1 2.4234(17), Ru1−Cl2 2.4432(18), Ag2−Cl1 2.7261, Ag2−Cl2 2.4707(18), Ag2−P2A 2.3592(19); P1−Ru1−Cl1 84.50(6), P1−Ru1−Cl2 88.28(6), Cl1−Ru1−Cl2 87.31(6), Ru1−Cl1−Ag2 82.70(5), Ru1−Cl2−Ag2 87.88(6), Cl1−Ag2−P2A 121.69(6), Cl2−Ag2−P2A 157.48(6), Cl1−Ag2−Cl2 80.39(5)

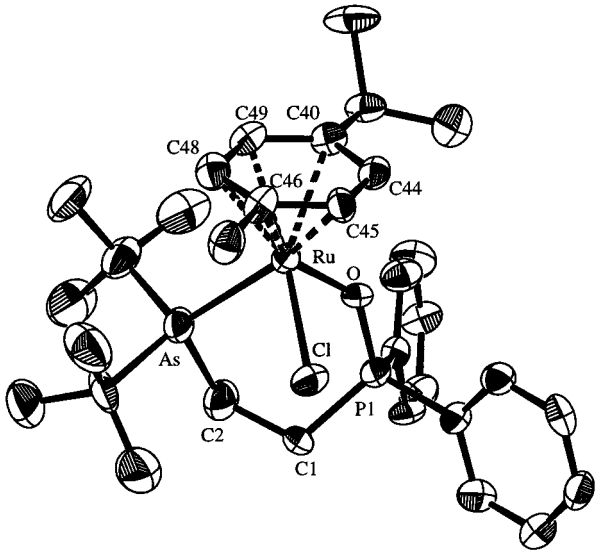
The observation that not only the 1,2-bis(phosphanyl)-ethanes $Ph_2PCH_2CH_2PR_2$ (R = *i*Pr, *t*Bu, Cy) but also the As,P counterpart $Ph_2PCH_2CH_2AstBu_2$ is easily oxidized to



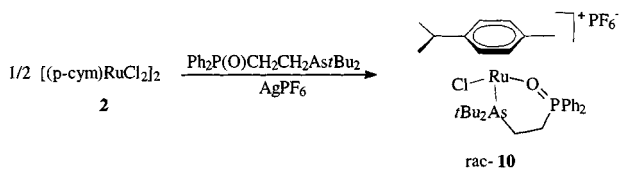


Figure 2. Molecular structure (ORTEP plot) of **10**; the PF_6^- ion is omitted for clarity; selected bond lengths [Å] and angles [°]: Ru−As 2.5490(11), Ru−O 2.141(5), Ru−Cl 2.386(2), P1−O 1.510(5), Ru−C40 2.215(7), Ru−C44 2.201(8), Ru−C45 2.198(8), Ru−C46 2.212(7), Ru−C48 2.171(8), Ru−C49 2.176(7); As−Ru−O 83.49(13), As−Ru−Cl 87.67(6), Cl−Ru−O 88.19(14), Ru−O−P1 135.7(3), Ru−As−C2 111.7(2), As−C2−C1 116.2(6), P1−C1−C2 110.0(6), O−P1−C1 113.9(3)

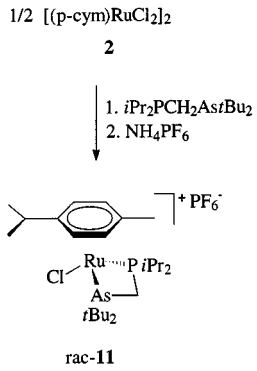

the corresponding oxide $Ph_2P(O)CH_2CH_2AstBu_2$, prompted us to use this molecule as a ligand in (arene)ruthenium(II) chemistry. Treating a solution of the oxide $Ph_2P(O)CH_2CH_2AstBu_2$, generated in situ from the precursor $Ph_2PCH_2CH_2AstBu_2$ and molecular oxygen, with a solution of **2** in CH_2Cl_2, in the presence of one equivalent of $AgPF_6$, leads to the formation of the PF_6 salt of the cationic complex **10** (Scheme 3) in which the oxophosphorane forms a six-membered chelate ring with the metal center. The dark-red solid is air-stable and readily soluble in THF, nitromethane and methanol. The resonance in the ^{31}P-NMR spectrum of **10** appears at $\delta = 53.8$ and is shifted by ca. 17 ppm upfield compared to the corresponding signal for **3**. In the latter compound the nonoxidized ligand $Ph_2PCH_2CH_2AstBu_2$ is coordinated to the ruthenium center rather than $Ph_2P(O)CH_2CH_2AstBu_2$.

The molecular structure of the cation of **10** is shown in Figure 2. The single crystals, which were grown from a solution in methanol, contained only one enantiomer of the cationic (arene)ruthenium complex in which, owing to the calculated structural parameter x of −0.025(15), the asymmetric metal center possesses the (*R*) configuration.[12] In analogy to the situation in **9**, the coordination geometry around the ruthenium center is pseudo-octahedral with the arsenic, the oxygen and the chlorine atoms bonded opposite to the tridentate *p*-cymene ligand. The distance Ru−Cl [2.386(2) Å] is ca. 0.05 Å shorter than the two Ru−Cl bond lengths in **9** but quite similar to the Ru−Cl distances found in other cationic (arene)(chloro)ruthenium(II) complexes.[13] The Ru−As bond length [2.5490(11) Å] is slightly longer than the average Ru−As distance in the neutral compounds *trans*-$[RuI_2(AsMe_2Ph)_4]$ [2.458−2.504 Å][14] and $[RuCl_2(CO)_2(AsPh_3)_2]$ [2.4927(6) Å, 2.4855(6) Å],[15] where six monodentate ligands are bonded to the ruthenium(II) ion. The distances Ru−O and P1−O are nearly the same as in the related cations $[(p\text{-cym})RuCl\{\kappa^2(P,O)\text{-}Ph_2P(O)CH_2PPh_2\}]^+$ and $[(p\text{-cym})RuCl\{\kappa^2(P,O)\text{-}Ph_2P(O)CH(CH_3)PPh_2\}]^+$, which were quite recently prepared by Faller et al. and structurally characterized as the SbF_6^- salts.[16]

Scheme 3

To compare the ligand behavior of 1-arsanyl-2-phosphanylethanes and (arsanyl)(phosphanyl)methanes, the reaction of the starting material **2** with $iPr_2PCH_2AstBu_2$ was also carried out. After heating the two substrates in ethanol, the cationic complex $[(p\text{-cym})RuCl\{\kappa^2\text{-}iPr_2PCH_2AstBu_2\}]^+$ with chloride as the counterion was formed, which upon salt metathesis with NH_4PF_6 gave **11** in 80% yield (Scheme 4). Similarly to **3**, compound **11** is a yellow air-stable solid that is soluble in polar solvents and, in nitromethane, shows the conductivity of a 1:1 electrolyte. The chemical shift of the singlet resonance in the ^{31}P-NMR spectrum of **11** indicates a chelate coordination of the unsymmetrical bidentate As,P ligand to the ruthenium center.[17] In agreement with the structural proposal, the ^{1}H-NMR spectrum of **11** displays two signals at $\delta = 3.41$ and 3.22 for the CH_2 protons of the $AsCH_2P$ unit and, due to P−H and H−H couplings, these are split into doublets of doublets.

Scheme 4

Conclusions

The work presented in this paper has shown that 1,2-bis(phosphanyl)ethanes as well as 1-arsanyl-2-phosphanylethanes, regardless of the bulk of the PR_2 or AsR_2 units, prefer to coordinate to a cationic $[(arene)RuCl]^+$ fragment in a chelating fashion. Only in the presence of silver(I) as an additional metal center was a heteronuclear Ru_2Ag_2 complex isolated and, in this case, the unsymmetrical bidentate ligand $Ph_2PCH_2CH_2PtBu_2$ binds in a bridging mode. Although four-membered chelate rings are generally less favored than five-membered rings, the methane derivat-

ive iPr$_2$PCH$_2$AstBu$_2$, like Ph$_2$PCH$_2$CH$_2$AstBu$_2$, generates a chelate complex with [(p-cym)RuCl]$^+$ as a building block.

Experimental Section

All operations were carried out under argon using Schlenk techniques. The starting materials **1**, **5**,[4] **2** and **6**[18] as well as the ligands iPr$_2$PCH$_2$AstBu$_2$,[19] Ph$_2$PCH$_2$CH$_2$AstBu$_2$ and Ph$_2$PCH$_2$CH$_2$PR$_2$ (R = iPr, tBu, Cy)[1,2] were prepared as described in the literature. − NMR: Bruker AC 200 and AMX 400. − Conductivity measurements (in nitromethane): Schott conductometer CG 851. − Melting points determined by DTA.

1. Preparation of [(p-cym)RuCl(κ^2-Ph$_2$PCH$_2$CH$_2$AstBu$_2$)]PF$_6$ (3): (a) A solution of 120 mg (0.2 mmol) of **1** in 3 mL of CH$_3$CN was treated dropwise with a solution of 97 mg (0.2 mmol) of Ph$_2$PCH$_2$CH$_2$AstBu$_2$ in 3 mL of CH$_3$CN at room temperature. A change of color from yellow to orange occurred. The solution was concentrated to dryness in vacuo, the residue was washed with 5 mL of pentane and dried. An orange microcrystalline solid was obtained; yield 128 mg (65%). − (b) A suspension of 133 mg (0.2 mmol) of **2** in 5 mL of CH$_2$Cl$_2$ was treated with 177 mg (0.4 mmol) of Ph$_2$PCH$_2$CH$_2$AstBu$_2$ and stirred for 2 h at room temperature. A solution of 72 mg (0.4 mmol) of NH$_4$PF$_6$ in 3 mL of CH$_2$Cl$_2$ was added and the resulting reaction mixture was stirred for 2 h and then filtered. The filtrate was concentrated to dryness in vacuo, the residue was washed with 10 mL of ether and dried. An orange microcrystalline solid was obtained; yield 216 mg (60%); m.p. 145 °C (dec.). − Conductivity Λ = 74.3 cm^{2}Ω^{-1}mol^{-1}. − ^{1}H NMR (400 MHz, CD$_2$Cl$_2$): δ = 7.65−7.30 (m, 10 H, C$_6$H$_5$), 6.50 [d, 1 H, J(HH) = 5.8 Hz, 1 × H of C$_6$H$_4$], 6.37, 5.85 [both d, 1 H each, J(HH) = 6.2 Hz, 2 × H of C$_6$H$_4$], 5.64 [d, 1 H, J(HH) = 5.8 Hz, 1 × H of C$_6$H$_4$], 3.28−3.23 (br m, 1 H, 1 × H of PCH$_2$CH$_2$As), 2.76 [sept, 1 H, J(HH) = 7.0 Hz, CH$_3$C$_6$H$_4$CH(CH$_3$)$_2$], 2.50−2.43, 2.31−2.22, 1.91−1.82 (each br m, 3 H, 3 × H of PCH$_2$CH$_2$As), 1.52, 1.36 (both s, 9 H each, AsCCH$_3$), 1.35, 1.30 [both d, 3 H each, J(HH) = 7.0 Hz, CH$_3$C$_6$H$_4$CH(CH_3)$_2$], 1.04 [s, 3 H, CH_3C$_6$H$_4$CH(CH$_3$)$_2$]. − ^{13}C NMR (100.6 MHz, CD$_2$Cl$_2$): δ = 135.5 [d, J(PC) = 42.9 Hz, *ipso*-C of C$_6$H$_5$], 134.0 [d, J(PC) = 8.6 Hz, C$_6$H$_5$], 133.1 [d, J(PC) = 58.2 Hz, *ipso*-C of C$_6$H$_5$], 131.8 [d, J(PC) = 8.6 Hz, C$_6$H$_5$], 131.6 [d, J(PC) = 5.7 Hz, C$_6$H$_5$], 131.6 (s, C$_6$H$_5$), 129.6 [d, J(PC) = 9.5 Hz, C$_6$H$_5$], 129.0 [d, J(PC) = 10.5 Hz, C$_6$H$_5$], 126.1 [d, J(PC) = 5.7 Hz, C$_6$H$_4$], 98.4, 92.3, 89.7, 89.0 (all s, C$_6$H$_4$), 86.2 [d, J(PC) = 8.6 Hz, C$_6$H$_4$], 46.7, 42.0 (both s, AsCCH$_3$), 32.0 (s, AsCCH$_3$), 30.6 [s, CH$_3$C$_6$H$_4$$C$H(CH$_3$)$_2$], 30.1 (s, As$CCH_3$), 29.8 [d, J(PC) = 35.3 Hz, PCH$_2$CH$_2$As], 22.8, 20.8 [both s, CH$_3$C$_6$H$_4$CH(CH$_3$)$_2$], 19.3 [d, J(PC) = 8.6 Hz, PCH$_2$$CH_2$As], 15.3 [s, CH$_3C_6H_4$CH(CH$_3$)$_2$]. − ^{31}P NMR (162.0 MHz, CD$_2$Cl$_2$): δ = 71.1 (s, Ph$_2$P), −144.3 [sept, J(FP) = 710.6 Hz, PF$_6^-$]. − C$_{32}$H$_{46}$AsClF$_6$P$_2$Ru (818.1): calcd. C 46.98, H 5.67; found C 46.43, H 5.15.

2. Preparation of [(p-cym)RuCl(κ^2-Ph$_2$PCH$_2$CH$_2$PtBu$_2$)]PF$_6$ (4): (a) In an analogous way to that described for **3** [method (a)] using 174 mg (0.4 mmol) of **1** and 127 mg (0.4 mmol) of Ph$_2$PCH$_2$CH$_2$PtBu$_2$ as starting materials. Yield 203 mg (75%). − (b) In an analogous way to that described for **3** [method (b)] using 162 mg (0.3 mmol) of **2**, 191 mg (0.5 mmol) of Ph$_2$PCH$_2$CH$_2$PtBu$_2$ and 86 mg (0.5 mmol) of NH$_4$PF$_6$ as starting materials. Orange microcrystalline solid; yield 287 mg (70%); m.p. 152 °C (dec.). − Conductivity Λ = 61.8 cm^{2}Ω^{-1}mol^{-1}. − ^{1}H NMR (400 MHz, CD$_2$Cl$_2$): δ = 7.68−7.35 (m, 10 H, C$_6$H$_5$), 6.45, 6.18, 5.95, 5.46 [all d, 1 H each, J(HH) = 6.2 Hz, C$_6$H$_4$], 3.31−3.19 (br m, 2 H, PCH_2CH$_2$P), 2.81−2.77 (br m, 1 H, PCHCH$_3$), 2.60−2.42 (br m, 3 H, PCH$_2$CH_2P and PCHCH$_3$), 2.20 [s, 3 H, CH_3C$_6$H$_4$CH(CH$_3$)$_2$], 1.60−1.10 [m, 24 H, CH$_3$C$_6$H$_4$CH(CH_3)$_2$ and PCCH$_3$]. − ^{13}C NMR (100.6 MHz, CD$_2$Cl$_2$): δ = 136.0 [d, J(PC) = 11.4 Hz, C$_6$H$_5$], 132.8 (m, C$_6$H$_5$), 131.0 [d, J(PC) = 2.9 Hz, C$_6$H$_5$], 129.8 [d, J(PC) = 41.0 Hz, C$_6$H$_5$], 128.8, 128.3 [both d, J(PC) = 10.5 Hz, C$_6$H$_5$], 125.8, 102.9 (both s, C$_6$H$_4$), 93.0 [d, J(PC) = 3.8 Hz, C$_6$H$_4$], 92.2 [d, J(PC) = 2.9 Hz, C$_6$H$_4$], 91.9, 90.3 [both d, J(PC) = 6.7 Hz, C$_6$H$_4$], 36.8 [dd, J(P^{1}C) = 25.7, J(P^{2}C) = 14.3 Hz, PCH$_2$CH$_2$P], 35.2 [dd, J(P^{1}C) = 31.9, J(P^{2}C) = 10.0 Hz, PCH$_2$$CH_2$P], 31.3 [s, CH$_3C_6H_4$$C$H(CH$_3$)$_2$], 28.5 [d, J(PC) = 25.7 Hz, PCCH$_3$], 27.7 [d, J(PC) = 20.0 Hz, PCCH$_3$], 22.4 [s, CH$_3$C$_6$H$_4$CH(CH$_3$)$_2$], 21.7 [d, J(PC) = 2.9 Hz, PCCH$_3$], 20.9 [s, CH$_3$C$_6$H$_4$CH(CH$_3$)$_2$], 20.7 [d, J(PC) = 3.9 Hz, PCCH$_3$], 20.2 [s, CH$_3$C$_6$H$_4$CH(CH$_3$)$_2$]. − ^{31}P NMR (162.0 MHz, CD$_2$Cl$_2$): δ = 85.2 [d, J(PP) = 33.1 Hz, tBu$_2$P], 78.3 [d, J(PP) = 33.1 Hz, Ph$_2$P], −144.9 [sept, J(FP) = 709.5 Hz, PF$_6^-$]. − C$_{32}$H$_{46}$ClF$_6$P$_3$Ru (774.2): calcd. C 49.65, H 5.99; found C 49.64, H 5.76.

3. Preparation of [(η^6-C$_6$H$_6$)RuCl(κ^2-Ph$_2$PCH$_2$CH$_2$PiPr$_2$)]PF$_6$ (7): (a) In an analogous way to that described for **3** [method (a)], by using 163 mg (0.4 mmol) of **5** and 129 mg (0.4 mmol) of Ph$_2$PCH$_2$CH$_2$PiPr$_2$ as starting materials. Yield 207 mg (77%). − (b) A suspension of 273 mg (0.6 mmol) of **6** in 8 mL of CH$_3$CN was treated with 361 mg (1.1 mmol) of Ph$_2$PCH$_2$CH$_2$PiPr$_2$ and 258 mg (1.1 mmol) of AgPF$_6$ and stirred for 2 h at 60 °C. Upon cooling to room temperature, the solvent was removed in vacuo and the residue was extracted with 10 mL of CH$_2$Cl$_2$. The extract was then concentrated to dryness in vacuo, the residue was washed with 10 mL of ether and dried. An orange microcrystalline solid was obtained; yield 570 mg (75%); m.p. 148 °C (dec.). − Conductivity Λ = 69.8 cm^{2}Ω^{-1}mol^{-1}. − ^{1}H NMR (400 MHz, CD$_2$Cl$_2$): δ = 7.78−7.12 (m, 10 H, C$_6$H$_5$), 5.86 (s, 6 H, C$_6$H$_6$), 2.70−1.83 (br m, 6 H, PCH$_2$CH$_2$P and PCHCH$_3$), 1.37 [dd, 6 H, J(PH) = 15.8, J(HH) = 7.9 Hz, PCHCH_3], 1.28 [dd, 3 H, J(PH) = 15.1, J(HH) = 7.2 Hz, PCHCH_3], 1.22 [dd, 3 H, J(PH) = 14.4, J(HH) = 7.0 Hz, PCHCH_3]. − ^{13}C NMR (100.6 MHz, CD$_2$Cl$_2$): δ = 135.5 [d, J(PC) = 47.8 Hz, *ipso*-C of C$_6$H$_5$], 133.9, 133.3 [both d, J(PC) = 9.2 Hz, C$_6$H$_5$], 131.6, 129.9 [both d, J(PC) = 10.2 Hz, C$_6$H$_5$], 129.2, 129.1 [both d, J(PC) = 11.1 Hz, C$_6$H$_5$], 93.4 [d, J(PC) = 2.0 Hz, C$_6$H$_6$], 31.6 [d, J(PC) = 24.4 Hz, PCHCH$_3$], 26.6 [d, J(PC) = 26.4 Hz, PCHCH$_3$], 26.6 [dd, J(P^{1}C) = 35.6, J(P^{2}C) = 8.1 Hz, PCH$_2$CH$_2$P], 21.3 [dd, J(P^{1}C) = 30.0, J(P^{2}C) = 10.7 Hz, PCH$_2$$CH_2$P], 20.6 (s, PCH$CH_3$), 19.7 [d, J(PC) = 2.0 Hz, PCHCH$_3$], 19.4 (s, PCHCH$_3$), 18.8 [d, J(PC) = 3.0 Hz, PCHCH$_3$]. − ^{31}P NMR (162.0 MHz, CD$_2$Cl$_2$): δ = 86.9 [d, J(PP) = 32.7 Hz, iPr$_2$P], 70.0 [d, J(PP) = 32.7 Hz, Ph$_2$P], −144.3 [sept, J(FP) = 710.6 Hz, PF$_6^-$]. − C$_{26}$H$_{34}$ClF$_6$P$_3$Ru (690.0): calcd. C 45.26, H 4.97; found C 44.98, H 5.06.

4. Preparation of [(η^6-C$_6$H$_6$)RuCl(κ^2-Ph$_2$PCH$_2$CH$_2$PCy$_2$)]PF$_6$ (8): (a) In an analogous way to that described for **3** [method (a)], by using 120 mg (0.3 mmol) of **5** and 119 mg (0.3 mmol) of Ph$_2$PCH$_2$CH$_2$PCy$_2$ as starting materials. Yield 270 mg (78%). − (b) In an analogous way to that described for **7** [method (b)], by using 225 mg (0.5 mmol) of **6**, 370 mg (0.9 mmol) of Ph$_2$PCH$_2$CH$_2$PCy$_2$ and 227 mg (0.9 mmol) of AgPF$_6$ as starting materials. Orange microcrystalline solid; yield 520 mg (75%); m.p. 131 °C (dec.). − Conductivity Λ = 71.6 cm^{2}Ω^{-1}mol^{-1}. − ^{1}H NMR (400 MHz, CD$_2$Cl$_2$): δ = 7.72−7.18 (m, 10 H, C$_6$H$_5$), 5.92 (s, 6 H, C$_6$H$_6$), 2.84−2.72 (m, 2 H, PCH_2CH$_2$P), 2.42−2.23 (m, 2 H, PCH$_2$CH_2P), 2.20−1.15 (br m, 22 H, CH and CH$_2$ of C$_6$H$_{11}$). − ^{13}C NMR (100.6 MHz, CD$_2$Cl$_2$): δ = 135.5 [d, J(PC) = 48.6 Hz, *ipso*-C of C$_6$H$_5$], 133.8, [d, J(PC) = 9.5 Hz, C$_6$H$_5$], 132.0, 131.9 [both d,

J(PC) = 2.9 Hz, C_6H_5], 131.7 [d, J(PC) = 9.5 Hz, C_6H_5], 130.4 [d, J(PC) = 54.3 Hz, *ipso*-C of C_6H_5], 129.9 [d, J(PC) = 9.5 Hz, C_6H_5], 129.1 [d, J(PC) = 10.5 Hz, C_6H_5], 93.3 (s, C_6H_6), 42.9 [d, J(PC) = 21.9 Hz, CH of C_6H_{11}], 37.1 [d, J(PC) = 25.7 Hz, CH of C_6H_{11}], 30.7, 30.0, 29.9, 29.8 (all s, CH_2 of C_6H_{11}), 29.4 [d, J(PC) = 4.8 Hz, CH_2 of C_6H_{11}], 28.1 [d, J(PC) = 13.4 Hz, CH_2 of C_6H_{11}], 27.4 [d, J(PC) = 9.5 Hz, CH_2 of C_6H_{11}], 27.7, 27.1 [both d, J(PC) = 10.5 Hz, CH_2 of C_6H_{11}], 26.6 [dd, $J(P^1C)$ = 35.3, $J(P^2C)$ = 6.7 Hz, P*C*$H_2$$CH_2$P], 26.2 [d, J(PC) = 10.5 Hz, CH_2 of C_6H_{11}], 20.3 [dd, $J(P^1C)$ = 30.5, $J(P^2C)$ = 10.5 Hz, PCH_2*C*H_2P]. – ^{31}P NMR (162.0 MHz, CD_2Cl_2): δ = 79.2 [d, J(PP) = 30.5 Hz, Cy_2P], 70.2 [d, J(PP) = 30.5 Hz, Ph_2P], −142.1 [sept, J(FP) = 710.6 Hz, PF_6^-]. – $C_{32}H_{42}ClF_6P_3Ru$ (770.1): calcd. C 49.91, H 5.50; found C 49.46, H 5.86.

5. Preparation of [(*p*-cym)RuAg(μ-Cl)$_2$(μ-P^1_{Ru},P^2_{Ag}-Ph$_2$P^{1}CH$_2$-CH$_2$P^2*t*Bu$_2$)]$_2$(PF$_6$)$_2$ (9): A solution of 245 mg (0.4 mmol) of **1** and 286 mg (0.8 mmol) of $Ph_2PCH_2CH_2Pt$Bu$_2$ in 5 mL of CH_2Cl_2 was stirred for 1 h and then treated dropwise with a solution of 198 mg (0.8 mmol) of $AgPF_6$ in 3 mL of CH_2Cl_2. After 1 h of stirring at room temperature, the resulting reaction mixture was filtered. The filtrate was concentrated to dryness in vacuo, the residue was washed with 10 mL of pentane and dried. A red microcrystalline solid was obtained; yield 701 mg (95%); m.p. 204 °C (dec.). – ^{1}H NMR (400 MHz, CD_2Cl_2): δ = 7.78 (m, 4 H, C_6H_5), 7.58 (m, 6 H, C_6H_5), 5.44, 5.25 [both d, 4 H, J(HH) = 5.0 Hz, C_6H_4], 2.63−2.52 (m, 2 H, PC$H_2$$CH_2$P), 2.22 [sept, 1 H, J(HH) = 7.0 Hz, $CH_3C_6H_4CH(CH_3)_2$], 1.33−1.19 (br m, 2 H, PCH_2CH_2P), 1.04 [s, 3 H, $CH_3C_6H_4CH(CH_3)_2$], 0.98 [d, 18 H, J(PH) = 15.0 Hz, $PCCH_3$], 0.77 [d, 3 H, J(HH) = 6.8 Hz, $CH_3C_6H_4CH(CH_3)_2$], 0.73 [d, 3 H, J(HH) = 7.0 Hz, $CH_3C_6H_4CH(CH_3)_2$]. – ^{13}C NMR (100.6 MHz, CD_2Cl_2): δ = 132.9 [d, J(PC) = 9.5 Hz, C_6H_5], 132.5 [d, J(PC) = 3.5 Hz, C_6H_5], 129.7 [d, J(PC) = 44.8 Hz, *ipso*-C of C_6H_5], 129.7 [d, J(PC) = 9.5 Hz, C_6H_5], 108.8, 95.6 [both s, C_6H_4], 91.4 [d, J(PC) = 3.8 Hz, C_6H_4], 86.4 [d, J(PC) = 4.8 Hz, C_6H_4], 34.2 [dd, $J(P^1C)$ = 11.0, $J(P^2C)$ = 5.2 Hz, P*C*CH_3], 31.0 [s, $CH_3C_6H_4CH(CH_3)_2$], 29.4 [d, J(PC) = 6.7 Hz, PC*C*H_3], 25.4 [dd, $J(P^1C)$ = 21.5, $J(P^2C)$ = 15.7 Hz, P*C*$H_2$$CH_2$P], 21.2, 17.8 [both s, $CH_3C_6H_4CH(CH_3)_2$ and $CH_3C_6H_4CH(CH_3)_2$], 13.9 (m, PCH_2CH_2P). – ^{31}P NMR (162 MHz, CD_2Cl_2): δ = 68.0 [dd, $^1J(^{109}AgP)$ = 743.3 Hz, J(PP) = 39.2 Hz, tBu$_2$P], 67.9 [dd, $^1J(^{107}AgP)$ = 643.0 Hz, J(PP) = 39.2 Hz, tBu$_2$P], 28.0 [d, J(PP) = 39.2 Hz, Ph_2P], −144.3 [sept, J(FP) = 710.8 Hz, PF_6^-]. – $C_{64}H_{92}Ag_2Cl_4F_{12}P_6Ru_2$ (1835): calcd. 6. Preparation of [(*p*-cym)RuCl{κ^2(As,O)-Ph$_2$P(O)CH$_2$CH$_2$-As*t*Bu$_2$}]PF$_6$ (10): A solution of 214 mg (0.5 mmol) of $Ph_2PCH_2CH_2Ast$Bu$_2$ in 10 mL of CH_2Cl_2 was treated with oxygen for ca. 10 min at room temperature and then added to a solution of 165 mg (0.3 mmol) of **1** in 4 mL of CH_2Cl_2. After 1 h of stirring, a solution of 132 mg (0.5 mmol) of $AgPF_6$ in 3 mL of CH_2Cl_2 was added dropwise. The resulting reaction mixture was stirred for 20 min and then filtered. The filtrate was concentrated to dryness in vacuo, the residue was washed twice with 4 mL of cold methanol and dried. A dark-red microcrystalline solid was obtained; yield 199 mg (45%); m.p. 131 °C (dec.). – ^{1}H NMR (200 MHz, CD_2Cl_2): δ = 7.75−7.26 (m, 10 H, C_6H_5), 6.53 [d, 1 H, J(HH) = 5.8 Hz, 1 × H of C_6H_4], 6.39, 5.89 [both d, 1 H each, J(HH) = 6.4 Hz, 2 × H of C_6H_4], 5.62 [d, 1 H, J(HH) = 6.1 Hz, 1 × H of C_6H_4], 3.30−3.20 (br m, 1 H, 1 × H of PCH_2CH_2As), 2.74 [sept, 1 H, J(HH) = 7.1 Hz, $CH_3C_6H_4CH(CH_3)_2$], 2.52−2.46, 2.35−2.21, 1.89−1.82 (all br m, 3 H, PCH_2CH_2As), 1.51, 1.34 (both s, 9 H each, $AsCCH_3$), 1.33, 1.30 [both d, 3 H each, J(HH) = 7.1 Hz, $CH_3C_6H_4CH(CH_3)_2$], 1.10 [s, 3 H, $CH_3C_6H_4CH(CH_3)_2$]. – ^{13}C NMR (50.3 MHz, CD_2Cl_2): δ = 142.5 [d, J(PC) = 43.9 Hz, *ipso*-C of C_6H_5], 135.0 [d, J(PC) = 8.4 Hz, C_6H_5], 134.3 [d, J(PC) = 52.2 Hz, *ipso*-C of C_6H_5], 132.8 [d, J(PC) = 8.4 Hz, C_6H_5], 131.6 [d, J(PC) = 5.8 Hz, C_6H_5], 131.5 (s, C_6H_5), 129.4 [d, J(PC) = 9.5 Hz, C_6H_5], 129.0 [d, J(PC) = 10.5 Hz, C_6H_5], 125.8 [d, J(PC) = 4.7 Hz, C_6H_4], 97.4, 92.6, 89.9, 89.1 (all s, C_6H_4), 87.2 [d, J(PC) = 8.7 Hz, C_6H_4], 46.5, 42.3 (both s, As*C*CH_3), 32.3 (s, AsC*C*H_3), 30.4 [s, $CH_3C_6H_4CH(CH_3)_2$], 31.8 [d, J(PC) = 30.3 Hz, P*C*$H_2$$CH_2$As], 30.1 (s, $AsCCH_3$), 22.5, 21.3 [both s, $CH_3C_6H_4CH(CH_3)_2$], 20.3 [d, J(PC) = 6.6 Hz, PCH_2CH_2As], 14.8 [s, $CH_3C_6H_4CH(CH_3)_2$]. – ^{31}P NMR (81 MHz, CD_2Cl_2): δ = 53.8 [s, Ph_2P(O)], −144.2 [sept, J(FP) = 710.8, PF_6^-]. – $C_{32}H_{46}AsClF_6OP_2Ru$ (834.1): calcd. C 46.08, H 5.56; found C 45.56, H 5.15.

7. Preparation of [(*p*-cym)RuCl(κ^2-*i*Pr$_2$PCH$_2$As*t*Bu$_2$)]PF$_6$ (11): A solution of 32 mg (0.1 mmol) of **2** in 5 mL of ethanol was treated with a solution of 67 mg (0.2 mmol) of iPr$_2$PCH$_2$AstBu$_2$ in 5 mL of ethanol and the mixture stirred under reflux for 24 h. Upon cooling to room temperature, 17 mg (0.1 mmol) of NH_4PF_6 was added to the reaction mixture. After 10 min of stirring, the solvent was removed in vacuo, the residue was washed three times with 10 mL of pentane and dried. A yellow solid was obtained; yield 75 mg (80%); m.p. 86 °C. – Conductivity Λ = 70.2 $cm^2\Omega^{-1}mol^{-1}$. – ^{1}H NMR (400 MHz, $CDCl_3$): δ = 6.34 [d, 1 H, J(HH) = 5.3 Hz, 1 × H of C_6H_4], 6.14 [d, 1 H, J(HH) = 5.8 Hz, 1 × H of C_6H_4], 6.08 [d, 1 H, J(HH) = 5.9 Hz, 1 × H of C_6H_4], 5.28 [d, 1 H, J(HH) = 5.3 Hz, 1 × H of C_6H_4], 3.41 [dd, 1 H, J(PH) = 15.0, J(HH) = 9.9 Hz, 1 × H of PCH_2As], 3.22 [dd, 1 H, J(PH) = 14.8, J(HH) = 9.9 Hz, 1 × H of PCH_2As], 2.57, 2.65, 2.77 [all m, 1 H each, P*C*HCH_3 and $CH_3C_6H_4C$*H*$(CH_3)_2$], 2.19 [s, 3 H, $CH_3C_6H_4CH(CH_3)_2$], 1.56 [dd, 3 H, J(PH) = 16.1, J(HH) = 7.3 Hz, $PCHCH_3$], 1.46, 1.40 (both s, 9 H each, $AsCCH_3$), 1.32 [dd, 3 H, J(PH) = 11.4, J(HH) = 7.2 Hz, $PCHCH_3$], 1.29 [dd, 3 H, J(PH) = 10.8, J(HH) = 6.9 Hz, $PCHCH_3$], 1.27 [dd, 3 H, J(PH) = 9.7, J(HH) = 7.3 Hz, $PCHCH_3$], 1.25 [d, 3 H, J(HH) = 7.1 Hz, $CH_3C_6H_4CHCH_3$], 1.19 [d, 3 H, J(HH) = 7.0 Hz, $CH_3C_6H_5CHCH_3$]. – ^{13}C NMR (100.6 MHz, $CDCl_3$): δ = 124.0 [d, J(PC) = 5.7 Hz, C_6H_4], 95.4, 88.3, 88.1 (all s, C_6H_4), 84.4 [d, J(PC) = 7.6 Hz, C_6H_4], 82.9 (s, C_6H_4), 45.6 [d, J(PC) = 6.7 Hz, As*C*CH_3], 39.4 (s, As*C*CH_3), 31.8 (s, $AsCCH_3$), 31.7 [d, J(PC) = 19.0 Hz, PCH_2As], 29.4 [s, $CH_3C_6H_4CH(CH_3)_2$], 28.4 (s, AsC*C*H_3), 27.0, 27.2 [both d, J(PC) = 17.9 Hz, P*C*HCH_3], 22.4 [s, $CH_3C_6H_4CH(CH_3)_2$], 18.8, 19.0, 19.8, (all s, $PCHCH_3$), 17.5 [d, J(PC) = 2.9 Hz, $PCHCH_3$], 17.3 [s, $CH_3C_6H_4CH(CH_3)_2$]. – ^{31}P NMR (162 MHz, $CDCl_3$): δ = 19.3 (s, P*i*Pr$_2$), −142.1 [sept, J(FP) = 710.6 Hz, PF_6^-]. – $C_{25}H_{48}AsClF_6P_2Ru$ (736.0): calcd. C 40.80, H 6.57; found C 40.53, H 6.29.

X-ray Structure Determination of Compounds 9 and 10:[20] Single crystals of **9** were grown from acetone/methanol at 25 °C and those of **10** from methanol at 25 °C. Crystal data collection parameters for these structures are presented in Table 1. The data were collected with an Enraf−Nonius CAD4 diffractometer (**9**) and with a Stoe IPDS diffractometer using monochromated Mo-K_α radiation (λ = 0.71073 Å). Intensity data were corrected for Lorentz and polarization effects. The structures were solved by direct methods (**10**) with SHELXS-97.[21] All structures were refined by full-matrix least-squares procedures on F^2 using SHELXL-97.[22] The positions of all hydrogen atoms were calculated according to ideal geometry and were refined by employing the riding method. For **10** the Flack parameter was refined to a value of −0.025(15)[12] and the extinction coefficient was refined to 0.00116(10).

Table 1. Crystal data for complexes **9** and **10**

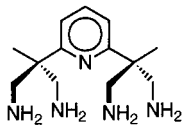
A Structurally Characterised Pair of Dicobalt(III) Peroxo/Superoxo Complexes with C_2-Symmetrical Tetrapodal Pentadentate Amine Ligands, and Some Reactivity en route

Stefan Schmidt,[a] Frank W. Heinemann,[a] and Andreas Grohmann*[a]



Dedicated to Professor Martin A. Bennett on the occasion of his retirement

Keywords: N ligands / Cobalt / Peroxo complexes / Superoxo complexes / Sulfito complexes

The tetrapodal pentaamine ligand 2,6-bis(1′,3′-diamino-2′-methylprop-2′yl)pyridine (pyN_4, **1**) provides square-pyramidal coordinated cobalt(II) building blocks, which have been used in the synthesis of the singly-bridged dicobalt(III) μ_2-η^1:η^1-peroxo and superoxo complexes $[(\mathbf{1})Co–O_2–Co(\mathbf{1})]^{4+/5+}$, isolated as the chloride, bromide, and mixed chloride/dithionate and bromide/dithionate salts. The peroxo complex is accessible by the classical route involving oxygenation of $[(pyN_4)Co^{II}]$, but has also been obtained from a cobalt(III) precursor in air, which implies that the pentaamine **1** acts as a multi-electron reductant. Oxidation of the peroxo complex with chlorine generated in situ from an HCl/H_2O_2 mixture (H_2O_2 derived from partial peroxo complex hydrolysis) generates the superoxo complex. Both cations have highly symmetrical solid state structures, locked in transoid Co–O–O–Co conformations by two pairs of intramolecular hydrogen bonds. Each involves two protons in the equatorial $Co(NH_2R)_4$ plane of one half of the molecule and the bridge oxygen atom in the other half. A significant difference between the two structures is the orientation of the O_2 bridge, which is coplanar with the pyridine rings of the coordination caps in the peroxo complex and at right angles in the superoxo complex. The reactivities of the complexes in acidic and basic media have been explored, and the mononuclear bromo complex $[(\mathbf{1})CoBr]^{2+}$ was isolated in one of the products. Dithionite, intended as an external reducing agent in the reaction of $Na_3[Co^{III}(CO_3)_3]$ with **1**, instead yields the *S*-sulfito complex cation $[(\mathbf{1})Co(SO_3)]^+$, by disproportionation of $S_2O_4^{2-}$ to give SO_3^{2-} and S^{2-}. All complexes have been characterised by ^1H, ^{13}C NMR, IR, Raman, UV/Vis, and EPR spectroscopy (as applicable), elemental analysis and X-ray structure determination, and the cyclic voltammetry parameters of the peroxo/superoxo pair of complexes have been determined.

Introduction

With a view to creating an active ligand periphery for octahedrally coordinating transition metal ions, we recently introduced a tetrapodal pentadentate amine ligand with an NN_4 donor set (pyN_4, **1**).[1] This ligand acts as a highly symmetrical square-pyramidal coordination cap,[2] and derivatisation of the equatorial NH_2 groups[3] is aimed at creating a functional environment for a monodentate "substrate" at the sixth coordination site. Judicious choice of functional groups should allow for the fine-tuning of secondary interactions between the substrate and the ligand periphery (such as hydrogen bonding, interaction with an electrochemically active centre, π,π-stacking, etc.) and thus enable the modulation of substrate reactivity.[4] An alternative approach is to link pyN_4 coordination caps through suitable bridges so as to create polynucleating ligands,[5] which can bind two or more metal centres having "labile" coordination sites in close proximity.

1

Mononuclear cobalt(III) complexes of the parent ligand **1** that have been isolated so far have a chloro,[1] an OH,[6] or a CH_3[7] ligand at the sixth coordination site. The kinetic inertness and the known reactivity of Co^{III} amine complexes with respect to Mannich-type transformations of the coordinated ligands[8,9] led us to further explore this class of complexes. Dinuclear complexes with a suitable bridge linking two $[M(pyN_4)]^{n+}$ fragments have two adjacent $M(H_2NR)_4$ planes, which opens up the possibility of connecting the two coordination caps. In the case of M = Co, a readily introduced bridge can be derived from dioxygen.

Peroxo and superoxo amine complexes of cobalt(III) have been the subject of scientific investigations for at least 150 years,[10–12] the first detailed study being that of Frémy in 1852. He noted that aqueous ammonia solutions containing cobalt(II) salts turn dark upon exposure to air. He isolated

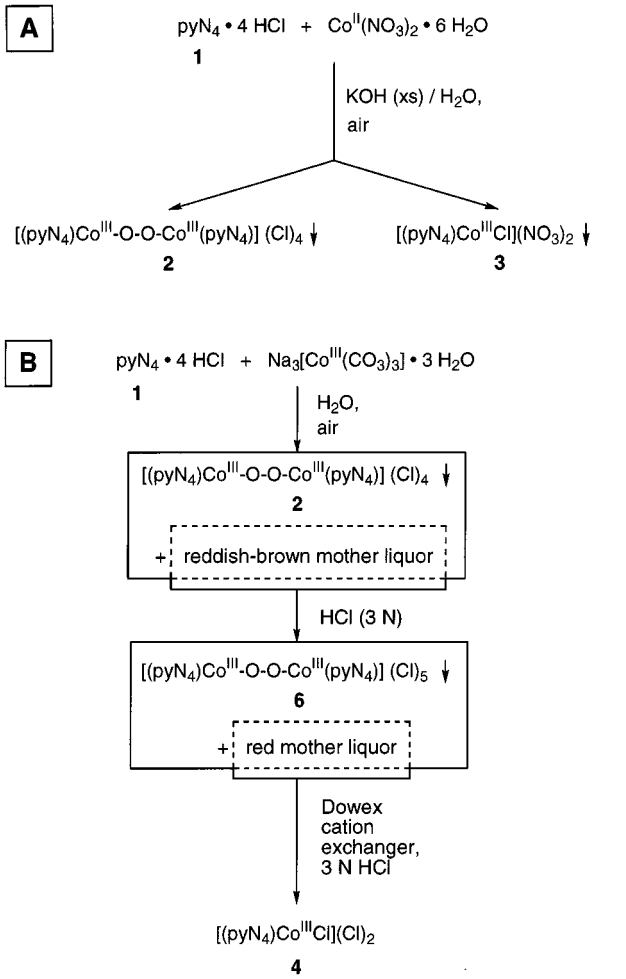
and analysed the brown compound $[Co_2(NH_3)_{10}O_2](SO_4)_2 \cdot 3H_2O$ and found that it evolved oxygen when redissolved in water.[13,14] Work by Maquenne and Vortmann followed, recording facile oxidation of the brown material, which led to a "class of dark green compounds".[15,16] Werner and Mylius were the first in 1898 to describe the brown products as ammine complexes containing two cobalt atoms linked by an O_2 bridge, $[(NH_3)_5Co-O-O-Co(NH_3)_5]^{4+}$ $(X^-)_4$, and to assign the general formula $[(NH_3)_5Co-O-O-Co(NH_3)_5]^{5+}$ $(X^-)_5$ to the green products.[17] Both assignments were confirmed after structural techniques became available.



Structural analogues of these prototypes with chelating amine ligands were subsequently prepared. The potential of these and similar complexes as oxygen carriers for a variety of applications was soon recognized[18–20] and has been actively investigated to this day.[21–23] The literature on singly-bridged dinuclear peroxo and superoxo amine complexes of cobalt(III) is extensive, and the structures of a large number of peroxo complexes have been determined. The structural characterisation of superoxo complexes has, by contrast, been accomplished much less frequently, and there is little precedent in the literature where the parameters of singly-bridged peroxo and superoxo cobalt(III) complexes with otherwise identical ligands have been compared.[24–26] For these reasons, we chose to investigate the formation and structure of dinuclear cobalt(III) complexes of **1** with a dioxygen-derived bridging group, as well as some peripheral reactions, and present results in this contribution.

Results and Discussion

Simplicio and Wilkins showed that oxygen uptake by ammoniacal cobalt(II) solutions is due mainly to the reaction of the pentakis(ammine) aqua complex $[Co(NH_3)_5(H_2O)]^{2+}$, whereas the bis(aqua) and tris(aqua) complexes $[Co(NH_3)_4(H_2O)_2]^{2+}$ and $[Co(NH_3)_3(H_2O)_3]^{2+}$ are virtually inert.[27,28] While such species do add oxygen when the nitrogen donor atoms are incorporated into chelate ligands, oxygenation is clearly enhanced as a consequence of an increasing number of ammine or amino groups coordinated to cobalt.[11] A variety of chelating pentaamines, including an early example of a tetrapodal pentadentate ligand,[29,30] have been investigated in this context, and a number of μ-peroxo complexes thus obtained have been structurally characterised. Synthesis usually involves oxygenation of aqueous solutions of cobalt(II) salts in the presence of a ligand.[31–41] As described below, this method was successful with the pentaamine ligand **1**, but we also found an alternative route which uses dioxygen from air, a cobalt(III) starting material, and no apparent reducing agent.

[(1)Co−O−O−Co(1)]Cl$_4$ (2)

Procedure A: The peroxo-bridged dinuclear tetrachloride **2** was obtained as a brown microcrystalline precipitate from a cooled aerated aqueous solution containing stoichiometric quantities of **1**·4HCl[1] and $Co(NO_3)_2 \cdot 6H_2O$ (see Scheme 1, Part **A**). An excess of potassium hydroxide was used to neutralise the acid form of the amine ligand, resulting in a basic reaction medium. No attempt was made to optimise the yield (9%), which may increase with longer reaction times. A significant amount of a red crystalline material identified as $[(\mathbf{1})CoCl](NO_3)_2$ **3**, precipitated from the filtrate upon standing for several days. Compound **2** may be recrystallised from water to give the hydrate $[(\mathbf{1})Co-O-O-Co(\mathbf{1})]Cl_4 \cdot 3H_2O$, as indicated by elemental analysis. Solubility in other polar protic solvents, such as methanol and DMSO, is also high. Contrary to the observations with other dicobalt(III) peroxo complexes,[12] **2** does not release dioxygen upon heating the solid in vacuo (145 °C, 12 h), and the material is recovered unchanged. The IR spectrum of **2** has bands characteristic of the pyN_4 coordination cap. An intense absorption in the Raman spectrum at 800 cm^{-1} is assigned to the O−O stretching vibration, in agreement with data obtained for related complexes.[21,42] Compound **2** is diamagnetic, and its ^{1}H NMR spectrum ([D$_6$]DMSO, room temp.) resembles that recorded for the mononuclear chloro complex $[(\mathbf{1})CoCl](Cl)(ClO_4) \cdot H_2O$,[1] with two signals of triplet and doublet multiplicity in the intensity ratio 1:2 for the pyridine ring protons. The Co−O−O−Co unit is not expected to be linear. Hence, ro-

Scheme 1. Preparation of dicobalt(III) peroxo and superoxo complexes of the pentaamine ligand **1**

tation around the Co−O bond must be fast on the NMR time scale as the spectrum shows all amine and methylene groups to be equivalent. The geminal protons in these groups are, however, diastereotopic, and each gives rise to a set of two well-resolved resonances. The assignment of the exocyclic CH_3 protons is straightforward. The ^{13}C NMR spectrum mirrors the diagnosis of fast rotation of the {(pyN_4)Co} fragments in solution, and supports the assumption of highly symmetrical coordination caps. The UV/Vis spectrum of **2** has an intense band at 295 nm. Such a band is due to the $\pi_\sigma^*(O_2^{2-}) \rightarrow d_z^2(Co)$ LMCT transition.[43] In solution spectra, it has been suggested to be typical of *trans*-μ_2-η^1:η^1-dicobalt(III) peroxo complexes in which the Co−O−O−Co unit is planar (dihedral angle of 180°).[34,37] Bands at ca. 325 nm and ca. 375 nm, which would indicate a nonplanar arrangement of the Co−O−O−Co unit in solution, are absent.[34,37] However, in the light of our NMR spectral data which imply conformational nonrigidity of the Co−O−O−Co unit in solution, the observed UV/Vis spectrum more likely reflects primarily the symmetrical ligand field of the pyN_4 ligand, whereas a ligand field of lower symmetry is expected to produce a two-band spectrum.[44] The cyclic voltammogram of **2** has a quasi-reversible redox wave associated with the peroxo/superoxo system at $E_{1/2} = +0.40$ V (vs. NHE; solvent: DMSO; for other conditions see Experimental Section).[45] Two irreversible one-electron waves are recorded at $E_{1/2} = -1.11$ V and $E_{1/2} = -1.67$ V, respectively, which we assign to the sequential reduction of the cobalt(III) centres to cobalt(II).[33,36]

Procedure B: We fortuitously found an alternative synthesis of **2** when we wished to repeat the preparation of the mononuclear complex [(**1**)CoCl](X)$_2$ (X = Cl: **4**). The published procedure[1] requires that all manipulations be carried out under a blanket of dinitrogen, allowing the isolation of red [(**1**)CoCl](Cl)$_2$ as the primary product. Performing the reaction between $Na_3[Co(CO_3)_3]\cdot 3H_2O$ and **1**·4HCl in air under otherwise identical conditions (including a water/methanol solvent mixture) gave a brown microcrystalline precipitate which was found to be the dinuclear peroxo-bridged tetrachloride **2** (isolated yield accounts for 18% of **1**; see Scheme 1, Part **B**). The mother liquor was basic. Compound **2** did not precipitate quantitatively, owing to its marked solubility in water. Workup of the mother liquor allowed the sequential isolation of the superoxo complex [(**1**)Co−O−O−Co(**1**)]Cl$_5$ **(6)**, and the mononuclear chloro complex [(**1**)CoCl](Cl)$_2$ **(4)** (see below). The NMR, IR, Raman and UV/Vis spectroscopic data of **2** obtained according to procedure **B** are identical to the data determined for the product prepared by route **A**. Addition of an excess of sodium dithionate to an aqueous solution of **2** gave single crystals of [(**1**)Co−O−O−Co(**1**)](S_2O_6)-$Cl_2\cdot 6H_2O$ **(5)** which were suitable for an X-ray structure analysis.

[(1)Co−O−O−Co(1)]Cl$_5$ (6)

In Procedure **B** (see above and Scheme 1, Part **B**), a reddish-brown filtrate remained after the isolation of precipitated peroxo complex **2**, still containing a sizeable amount of this complex in solution. Acidification of this filtrate with hydrochloric acid and reaction overnight produced a green crystalline precipitate and a red solution. The ESR spectrum of the isolated crystalline material (DMSO, 120 K) has a Zeeman splitting factor of $g = 2.0269$, which is in agreement with the formulation of the product as a singly-bridged dicobalt(III) superoxo complex. Hyperfine coupling with the ^{59}Co nucleus is not observed.[26,46] Elemental analysis of a recrystallised sample showed that the product was a bridged superoxo complex [(**1**)Co−O−O−Co(**1**)]Cl$_5$, **6** (isolated yield accounts for 14% of **1**). Further support comes from the Raman spectrum of a solid sample (dispersant: KBr) which shows a strong absorption at 1075 cm^{-1}, in a region typical of ν(O−O str) of other bridged superoxo complexes.[21,42] The UV/Vis spectrum has bands of varying intensity at 208, 307, 464, and 698 nm and is thus in good qualitative agreement with the spectrum reported for $[(NH_3)_5Co-O-O-Co(NH_3)_5]Cl_5\cdot 4H_2O$.[47] As expected, the cyclic voltammogram of the superoxo complex (determined for the mixed chloride hexafluorophosphate salt [(**1**)Co−O−O−Co(**1**)]Cl$_2$(PF_6)$_3$) corresponds to that of the peroxo complex **2** (above). The red filtrate of this reaction provided, upon workup, the desired mononuclear complex **4** (yield accounts for 19% of **1**). Partial anion exchange of **6** with sodium dithionate gave single crystals of [(**1**)Co−O−O−Co(**1**)](S_2O_6)$_2$Cl·10H_2O **(7)**, which were suitable for X-ray structure analysis.

The superoxo complex was also formed when sulfuric acid was used instead of hydrochloric acid for the acidification of the reaction mixture, as long as the reaction was performed on the chloride salt **2**. Alternatively, the superoxo complex formed when the perchlorate salt [(**1**)Co−O−O−Co(**1**)](ClO_4)$_4$ was reacted with HCl. The superoxo complex did not form when the perchlorate salt was treated with H_2SO_4. Instead, the colour of the solution turned orange, indicating the formation of a mononuclear species, presumably the aqua complex [(**1**)Co(OH_2)]$^{3+}$. Aqueous hydrogen peroxide alone showed no reaction with either the chloride or the perchlorate salt. When allowed to react with the chloride salt **2**, a mixture of hydrogen peroxide and hydrochloric acid produced the superoxo complex much faster (as judged by the change of colour from brown to green) than hydrochloric acid alone.

Our conclusions from these observations are as follows: (i) Unlike Procedure **A**, the reduction equivalents required for the generation of the peroxo bridge in Procedure **B** cannot originate from the metal precursor as this already contains cobalt in the +3 oxidation state. Methanol as reductant cannot be excluded at this stage (see, however, below) but we have no indications for the formation of formaldehyde which would be the likely oxidation product. Alternatively, a decomposition pathway may operate by which a certain amount of pentaamine ligand **1** is oxidised, with concomitant formation of cobalt(II), which is subsequently reoxidised upon reaction with aerial dioxygen.[48] This would explain the moderate yields of **2**, **4** and **6** obtained from

these reactions (only about 50% of **1** is accounted for in the products); (ii) The chloride ion and water are unlikely reductants for Co^{III}, on the grounds that the redox potentials of the half-reactions $2\ Cl^- \rightarrow Cl_2 + 2\ e^-$ and $2\ H_2O \rightarrow O_2 + 4\ H^+ + 4\ e^-$ are too high for Co^{III} to accomplish either oxidation and be reduced in the presence of amine ligand. While experimental evidence indicates that $Na_3[Co(CO_3)_3]\cdot 3H_2O$ reacts with aqueous HCl in the absence of other ligands to form the hexaaqua complex $[Co^{III}(H_2O)_6]^{3+}$ (which is a powerful oxidant in aqueous solution, generating O_2, H^+, and $[Co^{II}(H_2O)_6]^{2+}$), it is unlikely that in the presence of the chelating amine ligand, cobalt(II) can originate from this reaction. We have no experimental data to support the notion that in our system of peroxo and superoxo complexes, the O_2 bridge derives from dioxygen generated internally, by a Co^{III}/Co^{II} redox reaction as indicated above. In the original preparation of the mononuclear chloro complex **6** under an inert atmosphere,[1] formation of the peroxo complex was not observed. Impurities or decomposition products in the starting material, $Na_3[Co(CO_3)_3]\cdot 3H_2O$, might act as a source of cobalt(II), but batches were freshly prepared, and elemental analyses indicated the correct composition; (iii) For the transformation of **2** into **6** upon addition of hydrochloric acid, we postulate HCl-induced decomposition of **2** and liberation of hydrogen peroxide[48] (Equations 1a–c). At a critical HCl concentration, mixtures of H_2O_2 and HCl are known to form Cl_2,[49] which acts as an oxidising agent on the peroxo complex **2** and produces the superoxo complex **6** (Scheme 1, Part **B**). This assumption is supported by the fact that neither hydrogen peroxide alone nor a combination of chloride-free acid and non-halide salt of the peroxo complex will produce the superoxo complex. In a separate experiment, a brown aqueous solution of **2** reacted immediately with gaseous chlorine or its solution in water to give a green precipitate. The formation of cobalt(III) superoxo complexes by reaction of the corresponding peroxo complexes with halogens has been described in the literature.[11,26]

$$[(pyN_4)Co^{III}\text{-}O\text{-}O\text{-}Co^{III}(pyN_4)]\,(Cl)_4 + 2\ HCl \xrightarrow{\mathbf{2}} 2\ [(pyN_4)Co^{III}Cl](Cl)_2 + H_2O_2 \quad (1a)$$

[(1)Co–O–O–Co(1)]Br_4 (8) and [(1)Co–O–O–Co(1)]Br_5 (10)

For clarification of the circumstances surrounding the formation of **2** from a cobalt(III) precursor in air, some of the reactions described above were repeated in the absence of methanol with the methanol-free salt **1**·5HBr, or with the hydrobromide/methanol solvate **1**·4HBr·MeOH, and with a variation of pH. The methanol-free hydrobromide was prepared from the methanol solvate by ion exchange chromatography (Dowex 50W×2, eluent: 3 N HBr). The reaction of equimolar quantities of **1**·5HBr and $Na_3[Co(CO_3)_3]\cdot 3H_2O$ under a blanket of nitrogen in degassed water gave an orange solution, which upon exposure to air, deposited the tetrabromide salt **8** as a greenish-brown crystalline material in an isolated yield accounting for 21% of **1**. The solubility of the tetrabromide **8** in water is far lower than that of the tetrachloride **2**, making precipitation near-quantitative. The mother liquor contained the mononuclear bromo complex [(**1**)CoBr](Br)$_2$ **(9)** as the only other isolated product. Repeating the reaction with **1**·4HBr·MeOH and a water/methanol (1:1 v/v) solvent mixture under otherwise identical conditions gave essentially the same results. A further experiment combined **1**·4 HBr·MeOH (10 mmol), $Na_3[Co(CO_3)_3]\cdot 3H_2O$ (10 mmol), and HBr (10 mmol) in a water/methanol solvent mixture, the reaction being carried out in air (see Experimental Section). The tetrakis(hydrobromide) salt provides four equivalents of acid, while sodium tris(carbonato)cobaltate contains six equivalents of base. We reasoned that further addition of acid would make more cobalt(III) available for complexation. After reaction, the mixture was found to be at pH 7, and the peroxo complex **8** was isolated in the highest yield recorded in this series of experiments (accounting for 56% of **1**). Workup of the mother liquor provided the bromo complex **9** in a yield accounting for 22% of **1**. An experiment with additional HBr (pH after the reaction was 4) gave, instead of the peroxo complex, the bromo complex **9** as the exclusive product. Heating an authentic sample of **9** at reflux under a stream of air for an extended period of time (12 h), in the presence or absence of methanol, did not produce the dinuclear peroxo complex; rather, **9** was partially transformed into the aqua complex [(**1**)Co(H_2O)]Br_3, as indicated by ^1H NMR and IR spectroscopy.[50] Finally, the superoxo complex **10** was obtained as green microcrystals from a suspension of peroxo complex **8** in 3 N HBr in an isolated yield of 65% relative to **8**. From the mother liquor was isolated the bromo complex **9** as the only other product. The IR, Raman, NMR and UV/Vis spectroscopic parameters of **8** and **10** (as applicable) are similar to those determined for the corresponding chloride salts **2** and **6**. Addition of excess sodium dithionate to an aqueous solution of **8** gave single crystals of [(**1**)Co–O–O–Co(**1**)](S_2O_6)$Br_2\cdot 6H_2O$ (**11**), and partial anion exchange of **9** with NH_4PF_6 (carried out in a similar manner) gave single crystals of [(**1**)CoBr]-Br(PF_6)$\cdot H_2O$ (**12**). Both batches of crystals were suitable for X-ray structure analysis.

Our conclusions from the observed reactivity are as follows: (i) Methanol as a possible reductant may be excluded; (ii) The addition of one extra equivalent of acid increases the yield of peroxo complex **8** markedly. Products containing close to 80% of the initially employed pentamine ligand **1** were isolated, making the involvement of **1** as a *one*-electron reductant questionable; (iii) The action of bromide ion as reductant in the formation of the peroxo complex may be excluded since only the aqua complex is generated in a control experiment. Moreover, the generated bromine should induce further oxidation, leading to the superoxo complex, which is not observed; (iv) The yield of superoxo complex from the reaction of the peroxo complex with HBr corresponds exactly to the theoretical value expected on the basis of Equation 1d. This observation suggests that processes analogous to those described by Equations 1a−1c for the chloride salt operate for the bromide salt: the acid-induced decomposition of one third of the peroxo complex yields hydrogen peroxide which oxidises bromide ion to bromine, which in turn oxidises the remaining two thirds of peroxo complex.[11]

Overall, the most likely explanation for the observed reactivity is that the polyamine ligand **1** acts as a multiple-electron donor, depending on the reaction conditions. We are currently seeking to identify a specific ligand oxidation product. An amino acid ester has previously been suggested to be the electron source in the preparation of a bridging peroxo cobalt(III) dimer from a cobalt(III) precursor in air.[48]

The reactivity of the described peroxo and superoxo complexes with varying pH may be summarised as follows: Once generated, the peroxo complexes may be transformed into bridged superoxo and mononuclear species upon addition of a suitable acid. In aqueous alkaline solution (pH $\geq$ 12), the peroxo complexes are stable for hours without noticeable decomposition, while the superoxo complexes react with aqueous ammonia to reform the peroxo complexes. Similar reactivity has been documented for a number of O_2-bridged dicobalt(III) complexes with other polyamine ligands.[11]

[(1)CoSO$_3$]Br (13)

With a view to studying the effect of an external reducing agent on the generation of the peroxo complex **8** from $Na_3[Co(CO_3)_3]\cdot 3H_2O$ and **1**·4HBr·MeOH in air, we reacted two equivalents each of the cobaltate and the pentaamine ligand in the presence of one equivalent of sodium dithionite in water, which contained an excess of $NaHCO_3$ ($Na_2S_2O_4$ has been used to decompose $Co^{II}-O_2$ adducts, but the product(s) deriving from the dithionite ion have never been identified[27]). The only isolated products of this reaction were a finely divided black solid (which tested positive for S^{2-} and is presumably Co_2S_3) and an orange-brown microcrystalline precipitate identified as the *S*-sulfito complex [(**1**)CoSO$_3$]Br (**13**) by elemental and X-ray structural analysis (yield accounts for 39% of the pentaamine ligand **1**). The formation of Co_2S_3 and **13** in the presence of dithionite implies disproportionation of the latter, a reaction known to occur in basic solution,[51] particularly in the presence of heavy metal salts having a propensity to form sulfides (Equation 2). There is no indication of the intermediacy of a cobalt(II) species in the formation of **13**.[52] The observed formation of **13** contrasts with the classical synthesis of cobalt(III) *S*-sulfito amine complexes, in which the SO_3^{2-} ligand is introduced in the form of sodium disulfite ($Na_2S_2O_5$), which hydrolyses rapidly on dissolving in water to give an equilibrium mixture of $SO_2/HSO_3^-/SO_3^{2-}$.[53,54] Cobalt(III) *S*-sulfito amine complexes have been studied in detail because of the particularly strong kinetic and structural *trans* effect exerted by the SO_3^{2-} ligand,[53,55−59] a phenomenon which causes some of the compounds to have unusual catalytic[60] and redox properties.[52,60]

$$3\,S_2O_4^{2-} + 6\,OH^- \longrightarrow 5\,SO_3^{2-} + S^{2-} + 3\,H_2O \qquad (2)$$

Solid State Structures

Structural details of the square-pyramidally coordinated {(pyN_4)Co} fragment have been described elsewhere,[1,6,7] and the corresponding bond lengths and angles in compounds **5**, **7**, **12** and **13** are given in Table 1 for reference. Parameters that quantify distortions (if any) of the ligand cap are listed in Table 2. The structures of **3** and **11** have been determined and deposited with the Cambridge Structural Database but will not be discussed, as their parameters are similar to those of [(**1**)CoCl](Cl)(ClO_4)·H_2O[1] and **5**, respectively. The discussion addresses the salient structural features of the cations in **5**, **7**, **12** and **13**, especially the conformation of and intramolecular hydrogen bonding in the O_2-bridged dinuclear complexes.

[(**1**)Co−O−O−Co(**1**)](S_2O_6)$Cl_2\cdot 6H_2O$ (**5**)

The cation (Figure 1) contains two virtually undistorted octahedral cobalt(III) centres and lies on a twofold crystallographic rotation axis which passes through the midpoint of the O−O bond. The 4+ charge on the cation is consistent with the assignment of the bridging group as peroxide, and the Co−O [1.883(3) Å] and O−O bond lengths [1.467(5) Å] as well as the Co−O−O angle [110.7(3)°] are all within the range of values found for other Co(N_5) peroxo complexes.[37] The dihedral angle Co1−O1−O1A−Co1A is 177.5(2)°. The Co−O−O−Co core is virtually coplanar with the pyridine ring N11···C15, the best planes being at an angle of 4.62(3)°. As a consequence of the inherent molecular symmetry, the two CoN_4 units are parallel and adopt an eclipsed conformation with respect to each other (Figure 2a). Relevant nonbonded distances within the (N_4)Co−O−O−Co(N_4) subunit are listed in Table 3. The Co−N bond *trans* to the O_2^{2-} group (1.928(4) Å) is significantly shorter than the equatorial bonds (on average 1.950 Å), both values being similar to the corresponding bond lengths in the pentaamine peroxo complex [(trenen)-Co−O−O−Co(trenen)](ClO_4)$_4$ [trenen = *N*,*N*,*N*′-tris(2-

found in the structures of other CoN$_5$ complexes, where the Co−N(*trans*) bond can be up to 3% longer than the other Co−N bonds.[37,61]

In the solid state, the central Co−O−O−Co moiety of **5** is locked in a transoid conformation by four intramolecular hydrogen bonds indicated as dashed lines in Figure 1, defining the "triangular" arrangement N12−H12B···O1A···H13A−N13 and its symmetry-related counterpart [averaged distances and angles: d(N···O) = 2.76 Å; (N−H···O) =

126°]. Similar triangular intramolecular hydrogen bonding with planar Co−O−O−Co units has been found in the complexes [(en)(dien)Co−O−O−Co(dien)(en)]$(ClO_4)_4$,[62] [(tren)(NH_3)Co−O−O−Co(NH_3)(tren)]$(SCN)_4\cdot 2H_2O$[63] and [(papd)Co−O−O−Co(papd)]$(S_2O_6)(NO_3)_2\cdot 4H_2O$[34] (papd = 1,5,8,11,15-pentazapentadecane), and the adopted solid state conformations of bis[pentaaminecobalt(III)] peroxo cations have been discussed in terms of the balance of such intramolecular hydrogen-bonding interactions and lattice energy effects.[34] Intramolecular hydrogen bonding which significantly *distorts* the Co−O−O−Co core of a dicobalt(III) peroxo species from planarity has been described for $[(NH_3)_5Co-O-O-Co(NH_3)_5](SO_4)_2\cdot 4H_2O$,[25] and most recently also for a complex with carbohydrate-derived ligands.[64]

[(**1**)Co−O−O−Co(**1**)]$(S_2O_6)_2Cl\cdot 10H_2O$ (**7**)

Figure 3 shows the molecular structure of the cation, which formally consists of two essentially undistorted octahedral cobalt(III) centres linked by an O_2^- bridge, with an inversion centre at the midpoint of the O−O bond. The superoxo nature of the bridge is evident from the 5+ charge on the cation and the significantly shorter O−O bond length [1.325(3) Å] relative to **5**. This value and the Co−O distance [1.915(2) Å] and Co−O−O angle [116.5(2)°] are similar to the corresponding values determined for other $Co(N_5)$ superoxo complexes.[24,26,36,65] Molecular symmetry requires the Co−O−O−Co unit to be planar and, in the same way as in **5**, implies that the CoN_4 "squares" are parallel and adopt an eclipsed orientation (Figure 2b). It can be seen from Table 3 that, while the metal centres in **7** are further apart than in **5**, the other nonbonded distances within the (N_4)Co−O−O−Co(N_4) framework are similar in both structures. Also, the Co−N bond lengths in **7** are virtually identical to those in **5**. Most significantly, the bond *trans* to the *superoxo* bridge in **7** has the same length (within experimental error) as the bond *trans* to the *peroxo* bridge in **5** and is significantly shorter than the equatorial bonds. In the two previously characterised pairs of cobalt(III) peroxo/superoxo complexes with otherwise identical ligands,[24−26] the $Co-N_{trans}$ distance decreased markedly on going from peroxide to superoxide. It should be noted at this point that the coordination geometry imposed by the pyN_4 ligand does not necessarily obscure the *trans*-influence of ligands at the sixth site. A strong *trans*-influence is apparent in the structure of $[(\mathbf{1})Co(CH_3)]S_2O_6$,[7] and still discernible in the structure of **13** (below).

The most striking difference between the structures of **5** and **7** in the solid state is that, while the peroxo group is coplanar with the pyridine rings in **5**, the superoxo group in **7** is orientated at essentially right angles to them [87.0(2)°, which is the angle between the best planes defined by Co−O−O−Co and the pyridine ring N11···C15, respectively). The intramolecular hydrogen-bonding in **7** is again triangular, but this time involves nitrogen atoms on either diaminopropyl sidearm of the pyN_4 coordination cap [N12−H12B···O1A···H15A−N15 and its symmetry equivalent; averaged distances and angles: d(N···O) = 2.90 Å; (N−H···O) = 107°]. It is assumed that the different hydrogen-bonding requirements[26,66] of the bridging groups in either salt, as well as electrostatic effects due to the different sets of counterions, are responsible for the change in the solid state conformation upon oxidation. Density functional theory-based calculations are currently being performed[67] in order to gain insight into the electronic structures of the adopted geometries.[43,65]

[(**1**)CoBr]Br$(PF_6)\cdot H_2O$ (**12**) and [(**1**)Co(SO_3)]Br$\cdot 3H_2O$ (**13**)

The coordination cap of the cation in **12** (Figure 4a) is perfectly regular, owing to a crystallographic mirror plane which contains the pyridine ring. Distances and angles are similar to the values observed for **5** and **7** (Table 1), and also to those of the related chloro complex [(**1**)CoCl](Cl)$(ClO_4)\cdot H_2O$.[1] The $Co-N_{ax}$ bond in **12** is again slightly shorter [1.934(5) Å] than the four $Co-N_{eq}$ bonds [1.960(5) and 1.964(4) Å]. The Co−Br bond length at 2.422(1) Å lies in the range of values for this bond in other bromocobalt(III) complexes.[68][69] The molecular structure of the *S*-sulfito complex cation in **13** is shown in Figure 4b. The coordination cap is essentially regular (Table 1). The sulfito ligand shows rotational disorder, which may be a consequence of mismatched intra-cation hydrogen bonding between the protons on the equatorial N_4 donor set and the three trigonally disposed sulfito oxygen atoms. Two preferred orientations of the sixth ligand (with occupancy factors of 75% and 25%) have been refined. The Co−S bond length is 2.226(1) Å and thus ident-

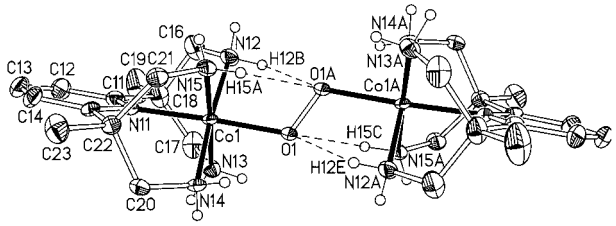

Figure 3. Molecular structure of the superoxo complex cation in **7** with thermal ellipsoids at the 50% probability level; only the hydrogen atoms in the $Co(NH_2R)_4$ planes are shown, and intramolecularhydrogen bonds are indicated by dashed lines

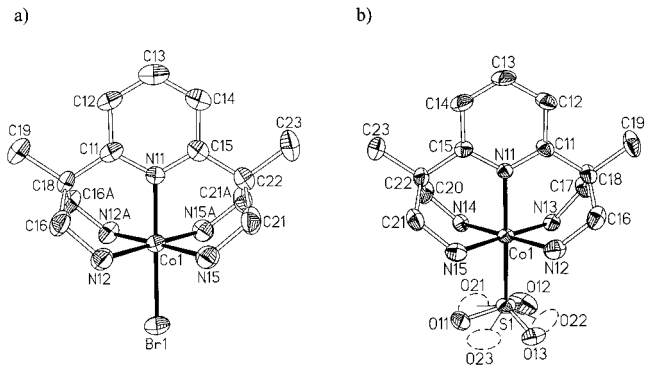

Figure 4. Molecular structures of the mononuclear cations in **12** (a) and **13** (b), with ellipsoids at the 50% probability level; hydrogen atoms have been omitted for clarity; the other resolvable orientation of the *S*-sulfito ligand in **13** is indicated by dashed ellipsoids

ical to the value in the related complex $[(en)_2(NH_3)Co(SO_3)]ClO_4$ [2.227(2) Å].[57] In contrast to the situation in complexes **5**, **7** and **12**, there is a noticeable structural *trans*-influence of the sixth ligand in **13**, as is evident from $Co-N_{ax}$ and $Co-N_{eq}$(av) bond lengths of 1.997(3) Å and 1.972(4) Å, respectively. This influence of the *S*-sulfito ligand in **13** is, however, not as pronounced as in a *trans*-ammine-bis(ethylenediamine)cobalt complex, where the difference between axial and averaged equatorial bond lengths is 0.11 Å.[57]

Conclusion

The work presented here extends the series of known cobalt(III) complexes of the type $[(\mathbf{1})CoX]^{n+}$, in which the tetrapodal pentaamine ligand **1** acts as a highly symmetrical square pyramidal coordination cap. While the preparation of mononuclear complexes with $X = Br^-$, H_2O is straightforward, it is unusual for $X = SO_3^{2-}$, which involves the disproportionation of dithionite ion to SO_3^{2-} and S^{2-}. Singly-bridged dinuclear μ_2-η^1:η^1-peroxo and -superoxo complexes $[(\mathbf{1})Co-O_2-Co(\mathbf{1})]^{4+/5+}$ are accessible by established methods [oxygenation of a cobalt(II) precursor/oxidation of the peroxo complex thus formed]. The peroxo complex may, however, be obtained in a better yield from a cobalt(III) precursor in air, which implicates the pentaamine **1** as a multi-electron reductant under the chosen conditions. The most significant solid-state structural difference between peroxo and superoxo complex is the orientation of the O_2 bridge relative to the pyridine rings of the coordination caps. Both complexes have parallel $Co(NH_2R)_4$ units in an eclipsed conformation on either side of the O_2 bridge. The peroxo complex is stable in basic aqueous solution and thus represents an attractive template for Mannich-type reactions which may, by analogy to the preparation of "sepulchrates" pioneered by Sargeson, lead to molecules with an encapsulated Co−O−O−Co spine. Work to this end is currently in progress.

Experimental Section

Materials and Instrumentation: Manipulations were performed in air unless otherwise stated. Reagents were AR grade or better and were purchased from Merck, Fluka, and Aldrich. Compounds **1**·4HCl[1] and **1**·4HBr·MeOH[70] were prepared as described previously. IR (KBr discs) and UV/Vis spectra (solvent: water) were recorded on Perkin−Elmer 16PC FT-IR and Shimadzu UV-3101 PC instruments, respectively. Cyclic voltammograms were recorded using an EG & G potentiostat PAR model 264A and a conventional three-electrode configuration consisting of a glassy carbon working electrode, a platinum auxiliary electrode and a platinum reference electrode (scan rate: 20 mV s^{-1}). NMR spectra were measured on a JEOL JNM-EX 270 spectrometer, and mass spectra were obtained on a JEOL MSTATION 700 spectrometer. Elemental analyses were performed using Carlo Erba Elemental Analysers 1106 and 1108. The ESR spectrum (DMSO glass, 120 K) was obtained on a Bruker ESP 300E instrument. Raman spectra were measured with a laser spectrophotometer (Coherent Inova 90) using argon-ion excitation at 514 nm over the region 400−3400 cm^{-1}.

X-ray Crystallography: Crystal data for compounds **5, 7**, **12** and **13** are given in Table 4, and selected distances and angles are listed in Table 1−3. The structures of the cations are presented in Figure 1, Figure 3, and Figure 4. Data for compounds **3** and **11** have been deposited (CCDC) but are not discussed. All structures were solved by direct methods and refined by full-matrix least-squares procedures on F^2 using either SHELXTL 5.03[71] (**7**, **12**) or SHELXTL 5.1.[72] The hydrogen atoms of **5** and **12** were geometrically positioned and allowed to ride on their carrier atoms during refinement; their isotropic displacement parameters were tied to those of the adjacent atoms by a factor of 1.2 or 1.5. For **7** and **13**, hydrogen atom positions were obtained from a difference Fourier synthesis and refined with a common fixed isotropic displacement parameter. Hydrogen atoms for the solvate water molecules of **5**, **12**, and **13** were not included.

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-137875 (**3**) − -137880 (**13**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk]

[(1)Co−O−O−Co(1)]Cl_4 (2). − Procedure A: The preparation was carried out in air and essentially followed the procedure given by Mori et al.[73] To a solution of **1**·4HCl (3.00 g, 7.55 mmol) in water (3 mL) was added a solution of KOH (1.70 g, 30.3 mmol) in water (2 mL). This solution was added slowly (pipette) with stirring to a filtered solution of $Co^{II}(NO_3)_2·6H_2O$ (2.20 g, 7.55 mmol) in water (5 mL). In the course of the addition, the mixture turned brown, and a turbidity appeared. The mixture was cooled to 5 °C, and reacted with a stream of compressed air from the immersed tip of a Pasteur pipette for 90 min. A solution of $NaNO_3$ (0.88 g, 10 mmol) in water (1.5 mL) was then added, and bubbling of the ice-cooled solution continued for 30 min., after which time a microcrystalline brown precipitate had formed. This was filtered over a glass frit (porosity G4), washed with cold water (2 mL), then with ethanol (3 mL) and diethyl ether (3 mL), and dried in vacuo. After recrystallization from a small amount of warm water (4 mL) the isolated yield of single crystals was 0.56 g (0.71 mmol, 9.3%). The crystals were suitable for X-ray crystallography. − IR (KBr): $\tilde{\nu}$ = 3442 cm^{-1} (s), 3194vs, 2968m, 2934m, 2880w, 1606m, 1468m, 1394m, 1384m, 1167m, 1102m, 1037m, 762m, 560m. − ^1H NMR ([D_6]DMSO, room temp.): δ = 8.19 [AB_2, 3 lines, ^3J(HH) = 8.07/8.07 Hz, 2 H, H^4], 7.72 [AB_2, 2 lines, ^3J(HH) = 8.07 Hz, 4 H, $H^{3,5}$], 5.47 [br. m, 8 H, −N*H*H−], 5.27 [br. m, 8 H, −NH*H*−], 2.93 [br. m, 8 H, −C*H*H−], 2.28 [br. m, 8 H, −CH*H*−], 1.47 (s, 12 H, $-CH_3$); (D_2O, room temp.): δ = 8.06 [AB_2, 3 lines, ^3J(HH) = 7.34/8.07 Hz, 2 H, H^4], 7.65 [AB_2, 2 lines, ^3J(HH) = 8.07 Hz, 4 H, $H^{3,5}$], 2.78 [d, ^2J(HH) = 12.47 Hz, 8 H, −C*H*H−], 2.38 [d, ^2J(HH) = 13.20 Hz, 8 H, −CH*H*−], 1.43 (s, 12 H, $-CH_3$). − ^{13}C NMR ([D_6]DMSO, room temp.): δ = 165.83 (s, C2/6), 140.39 (s, C4), 120.37 (s, C3/5), 47.09 (s, >C<), 44.96 (s, $-CH_2-$), 21.55 (s, $-CH_3$). − UV/Vis (water): λ max (ε) = 293 (19 707). − $C_{26}H_{50}Cl_4Co_2N_{10}O_2·3H_2O$ (848.5): calcd. C 36.81, H 6.65, N 16.51; found C 37.01, H 6.58, N 16.79.

Procedure B: The preparation was carried out in air. To a mixture of **1**·4HCl (3.27 g, 8.23 mmol) and $Na_3[Co(CO_3)_3]·3H_2O$[74] (2.98 g, 8.23 mmol) was added a mixture of water and methanol (1:1, 100 mL) in one portion, which resulted in immediate foaming (evolution of CO_2). The mixture was heated at reflux until CO_2 evolution ceased. Upon standing at room temperature, a microcrys-

talline green−brown material precipitated, leaving a reddish brown filtrate. The solid was collected by filtration, washed repeatedly with small volumes of methanol and dried in vacuo (0.61 g, 0.73 mmol, 17.7% relative to **1**). – IR (KBr): $\tilde{\nu}$ = 3430 cm^{-1} (s), 3186s, 3094s, 2964w, 2938w, 2878w, 1605s, 1467s, 1394w, 1276w, 1206w, 1164m, 1102m, 1040m, 816w, 763m, 560w, 482w. – $C_{26}H_{50}Cl_4Co_2N_{10}O_2{\cdot}1.5H_2O{\cdot}0.5CH_3OH$ (837.5): calcd. C 38.01, H 6.62, N 16.72; found C 38.32, H 7.03, N 17.12.

[(1)Co−O−O−Co(1)]Cl$_5$ (6): The filtrate obtained as under B above (100 mL) was acidified with hydrochloric acid (3 N, 5 mL), and stirred overnight at room temperature. A green precipitate formed which was collected by filtration, washed with small volumes of methanol, and dried in vacuo (0.69 g, 0.59 mmol, 14% relative to **1**). An anion exchange with NH_4PF_6 was carried out in order to obtain analytically pure material. – IR (KBr): $\tilde{\nu}$ = 3627 cm^{-1} (w), 3426w, 3083m, 1607m, 1472m, 1441w, 1220w, 1178w, 1112w, 1032w, 938vs, 764w, 740w, 559s. – ESR (DMSO, 120 K): *g* = 2.0269. – UV/Vis (water): λ max (ε) = 698 (1720), 464 (360), 307 (28940), 208 (42520). – $C_{26}H_{50}Cl_2Co_2F_{18}N_{10}O_2P_3{\cdot}H_2O$ ([(**1**)Co−O−O−Co(**1**)] $Cl_2(PF_6)_3{\cdot}H_2O$, 1176): calcd. C 26.55, H 4.46, N 11.91; found C 26.53, H 4.39, N 11.82.

[(1)CoCl]Cl$_2$ (4): The mother liquor obtained in the preparation of **6** (100 mL) was loaded on a Dowex 50WX2 cation exchange column (∅ 15 mm, length 250 mm). Gradient elution with HCl gave an orange−red fraction (3 N HCl, 300 mL). Reducing its volume to ca. 50 mL on a rotary evaporator induced precipitation of a microcrystalline pink solid, which was collected, washed with small volumes of an ethanol/diethyl ether mixture (1:1), and diethyl ether, and dried in vacuo (0.74 g, 1.6 mmol, 19.2% relative to **1**). – IR (KBr): $\tilde{\nu}$ = 3394 cm^{-1} (s), 3199s, 3086s, 2970w, 2882w, 1603s, 1470m, 1396w, 1289w, 1261w, 1214w, 1171m, 1104m, 1042m, 826w, 774w. – ^{1}H NMR ([D$_6$]DMSO, room temp.): δ = 8.19 [AB$_2$, 3 lines, ^3J(HH) = 7.66/7.90 Hz, 1 H, H^4], 7.69 [AB$_2$, 2 lines, ^3J(HH) = 7.90 Hz, 2 H, H^{3,5}], 6.46 [br. m, 4 H, −N*H*H−], 5.23 [br. m, 4 H, −NH*H*−], 2.74 [br. m, 4 H, −C*H*H−], 2.25 [br. m, 4 H, −CH*H*−], 1.47 (s, 6 H, $-CH_3$). – ^{13}C NMR ([D$_6$]DMSO, room temp.): δ = 165.18 (s, C2/6), 140.98 (s, C4), 121.00 (s, C3/5), 47.16 (s, >C<), 44.16 (s, $-CH_2-$), 21.33 (s, $-CH_3$). – $C_{13}H_{25}Cl_3CoN_5{\cdot}0.75C_2H_5OH{\cdot}H_2O$ (469.2): calcd. C 37.12, H 6.77, N 14.93; found C 37.49, H 7.04, N 15.27.

[(1)CoBr]Br$_2$ (9). – Procedure A: The preparation was carried out in air. To a mixture of **1**·4HBr·MeOH (6.07 g, 10.0 mmol) and $Na_3[Co(CO_3)_3]{\cdot}3H_2O$ (3.62 g, 10.0 mmol) was added a mixture of water and methanol (50:50 v/v, 180 mL) in one portion, which resulted in immediate foaming. After CO_2 evolution had subsided, hydrobromic acid (1.0 N, 10 mL) was added. The mixture was heated at reflux until CO_2 evolution ceased. The mixture (still hot) was filtered to remove unchanged $Na_3[Co(CO_3)_3]$, and a brown crystalline material precipitated on standing at room temperature, leaving a reddish brown mother liquor. The solid was removed by filtration and washed with methanol ([(**1**)−Co−O−O−Co−(**1**)]$Br_4{\cdot}3H_2O$, 2.85 g, 55.5% relative to **1**). The filtrate was loaded on a Dowex 50WX2 cation exchange column (∅ 15 mm, length 250 mm). Gradient elution with HBr gave a red−violet fraction (3 N HBr, 300 mL). Reducing its volume to ca. 50 mL on a rotary evaporator induced precipitation of a microcrystalline purple solid, which was collected, washed with small volumes of an ethanol/diethyl ether mixture (50:50 v/v), and dried in vacuo (1.23 g, 2.24 mmol, 22.4% relative to **1**).

Procedure B: [(**1**)−Co−O−O−Co−(**1**)]Br_4·3H_2O (0.30 g, 0.29 mmol) was suspended in hydrobromic acid (3 N, 25 mL) and stirred for one hour. Over this period the colour of the suspension changed from brown to green. The precipitate was collected by filtration, washed with small volumes of an ethanol/diethyl ether mixture (50:50 v/v) and dried in vacuo ([(**1**)−Co−O−O−Co−(**1**)]Br_5, 0.20 g, 65% relative to **1**), leaving a reddish violet filtrate. Reducing the volume of the filtrate to ca. 50 mL on a rotary evaporator induced precipitation of a microcrystalline reddish purple solid, which was collected, washed with a small amount of ethanol/diethyl ether (50:50 v/v) and dried in vacuo. As elemental analysis was not yet satisfactory, and in order to obtain single crystals suitable for X-ray crystallography, an anion exchange was carried out with NH_4PF_6. − IR (KBr): $\tilde{\nu}$ = 3671 cm^{-1} (m), 3596m, 3421w, 3304m, 3181m, 3088m, 2951w, 1595s, 1470m, 1400w, 1284w, 1210w, 1170m, 1104m, 1034m, 846vs, 741w, 559vs, 415w. − ^{1}H NMR ([D_6]DMSO, room temp.): δ = 8.21 [AB_2, 3 lines, ^3J(HH) = 7.90/7.66 Hz, 1 H, H^4], 7.71 [AB_2, 2 lines, ^3J(HH) = 7.93 Hz, 2 H, $H^{3,5}$], 5.40 [br. m, 8 H, −NH_2], 2.76 [br. m, 4 H, −C*H*H−], 2.26 [br. m, 4 H, −CH*H*−], 1.46 (s, 6 H, −CH_3). − ^{13}C NMR ([D_6]DMSO, room temp.): δ = 165.06 (s, C2/6), 141.11 (s, C4), 121.22 (s, C3/5), 46.77 (s, >C<), 44.12 (s, −CH_2−), 21.27 (s, −CH_3). − $C_{13}H_{25}Br_2CoF_6N_5P$·$H_2O$ ([(**1**)CoBr]$BrPF_6$·H_2O, 633.1): calcd. C 24.66, H 4.30, N 11.06; found C 24.86, H 4.00, N 11.09.

[(1)CoSO$_3$]Br (13): Manipulations were performed under nitrogen in deoxygenated solvents using standard Schlenk techniques. To a mixture of **1**·4HBr·MeOH (0.61 g, 1.0 mmol) and $Na_3[Co(CO_3)_3]$·3H_2O (0.36 g, 1.0 mmol) was added water (25 mL) in one portion (with stirring), which resulted in immediate foaming (evolution of CO_2). After CO_2 evolution had ceased, a solution of $Na_2S_2O_4$ (0.1 g, 0.5 mmol) and $NaHCO_3$ (0.17 g, 2.0 mmol) in water (10 mL) was added, and the mixture stirred overnight. Precipitated Co_2S_3 was removed by filtration, and the hydrogen sulfide which evolved after acidification identified by its smell. The volume of the mother liquor was reduced until an orange−brown precipitate appeared, and the suspension then kept at 4 °C overnight in order to complete precipitation. The microcrystalline material was collected by filtration, washed repeatedly with small volumes of ethanol and dried in vacuo (0.22 g, 39% relative to **1**). The volume of the mother liquor was reduced further, and storage at 4 °C produced a small batch of single crystals suitable for X-ray structural analysis. Anion exchange of the major fraction with NH_4PF_6 in dilute aqueous ammonia gave crystalline material which analysed correctly for C, H, and N, and was used for IR and NMR spectroscopic characterization. − IR (KBr): $\tilde{\nu}$ = 3471 cm^{-1} (s), 3329s, 3227s, 2975w, 2890w, 1670w, 1606m, 1471m, 1402w, 1283w, 1206w, 1109s, 1082s, 1025m, 984vs, 840vs, 770w, 740w, 638m, 558s, 510w. − ^{1}H NMR ([D_6]DMSO, room temp.): δ = 8.26 [AB_2, 3 lines, ^3J(HH) = 7.90/7.90 Hz, 1 H, H^4], 7.80 [AB_2, 2 lines, ^3J(HH) = 7.90 Hz, 2 H, $H^{3,5}$], 3.99 [br. m, 8 H, −NH_2], 2.65 [br. m, 4 H, −C*H*H−], 2.15 [br. m, 4 H, −CH*H*−], 1.40 [br. s, 6 H, −CH_3]. − ^{13}C NMR ([D_6]DMSO, room temp.): δ = 166.02 (s, C2/6), 140.24 (s, C4), 120.09 (s, C3/5), 45.29 (s, >C<), 44.34 (br. s, −CH_2−), 21.12 (s, −CH_3). − $C_{13}H_{25}CoF_6N_5O_3PS$·2$H_2O$ (571.4): calcd. C 27.33, H 5.12, N 12.26, S 5.61; found C 27.51, H 5.46, N 12.19, S 5.44.

Acknowledgments

We thank Professor D. Sellmann for generous support of this work and Professor S. Schneider, Dr. G. Brehm and Dr. M. Niegl for the measurement of the Raman spectra. Financial support from the Deutsche Forschungsgemeinschaft is gratefully acknowledged.

Cyclopropenylium−Borate Betaines: Opening an Organometallic Route to Neutral Carbocation-Like Compounds

Sabine Venne-Dunker,[a] Wolfgang Ahlers,[a] Gerhard Erker,*[a] and Roland Fröhlich[a][+]

Keywords: Cyclopropenylium cation / Group-4 metallocenes / Alkynyl coupling / Insertions / Zirconium / Boron

Treatment of bis(propynyl)zirconocene (**5**) with a stoichiometric quantity of $B(C_6F_5)_3$ leads to C–C coupling of the alkynyl ligands to form the zirconocene–(μ-hexadiyne)–borate betaine complex **11**. This apparently is in an endothermic equilibrium with a methylenecyclopropene-type isomer **13**, formed by intramolecular alkyne insertion into the (sp^2-carbon)–zirconium linkage, which is very effectively trapped by added scavenger reagents such as organic nitriles or isonitriles, to yield the stable unsaturated three-membered ring products **14** or **15**, respectively. Subsequent hydrolysis removes the zirconocene moiety from the product, but the newly formed (sp^2-carbon)–$B(C_6F_5)_3$ linkage remains intact. The resulting products **16** and **17** formally contain a central methylenecyclopropene framework, but their structural properties point to a substantial π-delocalization, that indicates a pronounced participation of an enamino-substituted cyclopropenylium–borate betaine resonance structure. The description of the neutral betaine compounds **16** and **17** as approaching cyclopropenylium cation-type compounds that have their counteranion covalently bonded to them, is further supported by the observation of low activation barriers of the rotation around the exocyclic C3–C4 bond [$\Delta G^{\neq}_{CCrot}$ (330 K) = 17.5 ± 0.5 kcal mol^{-1} for **17a**] and around the C5–N linkage [$\Delta G^{\neq}_{CNrot}$ (306 K) = 14.5 ± 0.5 kcal mol^{-1} for **16a**]. The neutral cyclopropenylium–betaine compound **17a** shows a carbocation-like chemical reactivity, and inserts *tert*-butyl isocyanide to yield the ring-expanded four-membered carbocyclic product **21**.

Introduction

Cyclopropenylium cations $C_3R_3^+$ (**1**) represent the smallest members of the carbocyclic arenes. The many reported examples of this class of compounds profit from the marked thermodynamic stabilization provided by aromaticity, but kinetically the reactivity features of many cyclopropenylium systems appear to be largely governed by their ionic nature, and hence by electrostatic effects.[1] It would be interesting to see how the cyclopropenylium arenes would behave in the absence of their positive charge. In principle, this could be achieved by covalently attaching a suitable anion as a

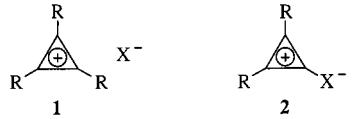
[+] X-ray crystal structure analyses

Sabine Venne-Dunker (top left) studied chemistry at the Universität Münster where she did her diplom thesis in Prof. Erker's group. Since October 1998 she has been carrying out work for her doctoral thesis on the synthesis of novel Group-4 and -5 metal complexes and their catalytic application.

Wolfgang Ahlers (top right) also studied chemistry at the Universität Münster and did his doctoral dissertation in Prof. Erker's group. He received his doctoral degree in 1997. He then joined the BASF company in Ludwigshafen, where he currently does catalysis research in the Ammoniaklaboratorium.

Gerhard Erker (bottom left) studied chemistry at the Universität Köln. In 1973 he received his doctoral degree at the Universität Bochum, where he worked with Professor Wolfgang R. Roth in physical organic chemistry. After a stay as a DFG postdoctoral fellow with Professor Maitland Jones, Jr. at Princeton University (carbene chemistry) he did his habilitation at Bochum (1981). He was a Heisenberg fellow at the Max-Planck-Institut für Kohlenforschung in Mülheim a. d. Ruhr (1984–1985), then a C3-Professor at the Institut für Organische Chemie in Würzburg, and since 1990 he has been a C4-Professor at Münster. His major research interests are in the areas of reaction mechanisms, the synthesis of unusually structured organic compounds, organometallic chemistry, and catalysis.

Roland Fröhlich (bottom right) studied chemistry at the universities of Münster and Köln and received his doctoral degree in 1982. After postdoctoral studies at the Institute for Crystallography of the Universität Karlsruhe he worked as a sales and application manager for Enraf Nonius. Since 1993 he is a senior scientist at the Universität Münster being responsible for the X-ray laboratory of the Institut für Organische Chemie. Since 1994 he is also a docent for X-ray Crystallography at the University of Jyväskylä, Finland.



MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

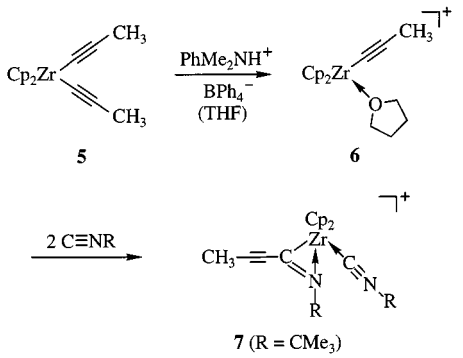
substituent to the cyclopropenylium core. Such a construction would result in the formation of a cyclopropenylium betaine **2**, a system that is neutral overall, but may be highly polarized and function chemically as a cyclopropenylium system without the electrostatic effects of the otherwise dominating positive charge, provided of course that the right combination of substituents and the internal anion moiety is used (Scheme 1).

Scheme 1. Design of a cyclopropenylium betaine **2**, a potential carbocyclic three-membered ring arene without a featured positive charge

It is well established that dialkylzirconocene complexes are easily converted into [$^{R}Cp_2ZrR^+$] cations by treatment with a variety of electrophilic reagents.[2] The reaction of $^{R}Cp_2ZrR_2$, generated in situ, with methylalumoxane is mostly used for a direct generation of the [$^{R}Cp_2ZrR^+$] species, serving as a very active homogeneous metallocene Ziegler catalyst for α-olefin polymerization.[3] Treatment of a variety of $^{R}Cp_2ZrR_2$ starting materials with either a suitable Lewis acid [e.g. $B(C_6F_5)_3$] or Brønsted acid [e.g. $PhMe_2NH^+$ BPh_4^-], or a stable carbenium ion [e.g. Ph_3C^+ BPh_4^-] has invariably resulted in the formation of stable and isolable [$^{R}Cp_2ZrR^+$] cations, albeit generally carrying σ-ligands R with sp^3-carbon atoms bonded to the transition metal center.[4] The observation of some unusual chemistry taking place with alkynyl zirconocene cations [$Cp_2Zr-C\equiv C-R^+$], generated by the Lewis acid route mentioned above, has led to the development of a simple organometallic route to a variety of examples of cyclopropenylium−betaine systems **2**, to the best of our knowledge representing the first examples of their kind. The development of this synthetic entry is reviewed in this article, along with a description of the structural features and some chemistry of the unique cyclopropenylium−borate betaines prepared by our new reaction (Scheme 2).



Scheme 2. Methods of [Cp_2ZrR^+] cation generation used in this study

Results and Discussion

(Propynyl)zirconocene Cation Prepared by a Protonation Route

Bis(propynyl)zirconocene (**5**) was synthesized by treatment of zirconocene dichloride with two molar equivalents of propynyllithium.[5] The X-ray crystal structure analysis of **5** revealed a Zr−C(sp) σ-bond length of 2.249(3) Å, which is only slightly shorter than the documented Zr−C(sp^3) bond length in $Cp_2Zr(CH_3)_2$ [2.277(5) Å], thus indicating that there is probably no extensive propargyl π-interaction of the −C≡C−R unit with the 16-electron metallocene moiety in **5**.[5] Treatment of **5** with the Brønsted acid *N*,*N*-dimethylanilinium tetraphenylborate in THF, furnished the (σ-propynyl)zirconocene cation−THF adduct **6**. This turned out to be a very reactive and sensitive complex, but we were able to characterize it chemically by means of an alkyl isocyanide insertion reaction. *tert*-Butyl isocyanide inserts into the Zr−C(sp) σ-bond of **6** to form an (η^2-iminoacyl)zirconocene cation complex, which takes up another equivalent of the isonitrile reagent to form the stable product **7** that was isolated and characterized by X-ray diffraction (see Scheme 3 and Figure 1).[6]

Scheme 3. Generation and reaction of a THF-stabilized (σ-alkynyl)zirconocene cation

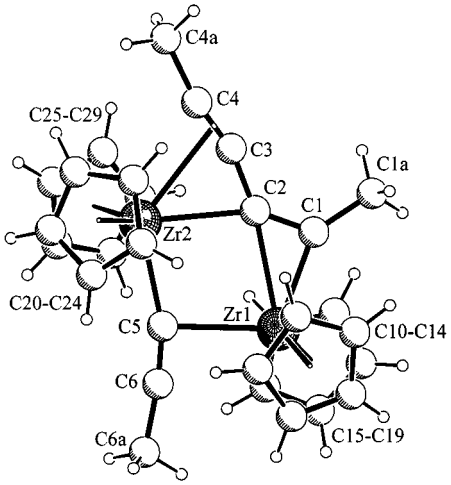
(Propynyl)zirconocene Cation Generated by the Trityl Cation Route Leads to a Stable Planar-Tetracoordinated Carbon Compound

Treatment of bis(propynyl)zirconocene (**5**) with trityl tetraphenylborate led to the abstraction of a σ-C≡C−CH_3 ligand (to yield $Ph_3C-C\equiv C-CH_3$) and generation of the donor-ligand free [$Cp_2Zr-C\equiv C-CH_3^+$] cation (**8**). In contrast with the analogous [$Cp_2Zr-CH_3^+$] cation, complex **8**

Scheme 4. Formation of a stable planar-tetracoordinated carbon compound from (propynyl)zirconocene cation

is not stable under the typical reaction conditions of its generation, but instantaneously reacts with one equivalent of the bis(propynyl)zirconocene starting material.[7] Rapid carbon−carbon coupling ensues, with formation of a μ-hexadiyne ligand. The resulting dinuclear cation complex **9** contains a bridging μ-propynyl ligand and an unsymmetrically bridging μ-hexadiyne moiety (Scheme 4). The latter contains a planar-tetracoordinated carbon atom[8] (C2 in Figure 2) that features short bonds to two adjacent carbon atoms [C1−C2 1.317(8) Å, C2−C3 1.400(8) Å] as well as to the two zirconium centers [C2−Zr1 2.530(5) Å, C2−Zr2 2.434(6) Å, the sum of the bond angles at C2 is 360.0°]. The C1−C2 bond represents a C=C double bond, and the Zr1−C2−Zr2 linkage is to be regarded as a three-center two-electron bonding situation. Thus, the bonding features at carbon atom C2 are as expected for a stable *anti*-van't Hoff/LeBel compound that contains stabilizing metal substituents. Complex **9** represents just another example of an increasing number of isolated and structurally characterized examples of such types of very stable but unusually structured carbon compounds.[8b][8c]



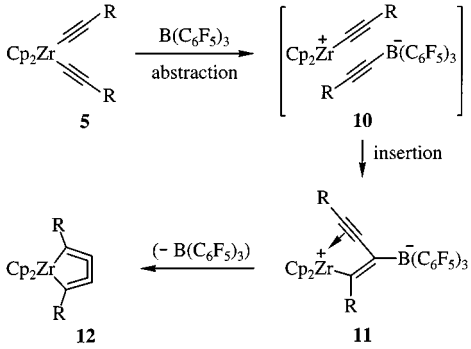


Figure 2. Molecular structure of the "*anti*-van't Hoff/LeBel compound" **9**

Reactions of Bis(alkynyl)zirconocenes with $B(C_6F_5)_3$, the Unexpected Formation of Carbocyclic Three-Membered Ring Products by Unsymmetrical Alkynyl Dimerization

We have found that a variety of bis(alkynyl)zirconocenes **5** are converted into their substituted (η-butadiyne)$ZrCp_2$ isomers **12** by treatment with catalytic amounts of the strong organometallic Lewis acid $B(C_6F_5)_3$.[9,10] The likely intermediate of the catalytic C−C coupling reaction is **11**. Several examples of such zirconocene−(μ-RC_4R)−borate betaines were isolated from the stoichiometric reaction of a

Scheme 5. Products formed in the reaction of bis(alkynyl)zirconocenes with $B(C_6F_5)_3$

variety of bis(alkynyl)zirconocenes [as well as bis(alkynyl)-hafnocenes] with $B(C_6F_5)_3$.[9,11] It is likely that the $B(C_6F_5)_3$ reagent abstracts a σ-alkynyl ligand from the metallocene to form the ion pair **10**. Subsequent rapid alkyne insertion of the $R-C\equiv C-B(C_6F_5)_3^-$ unit into the (sp-C)−Zr σ-bond of the very reactive [$Cp_2Zr-C\equiv C-R^+$] cation moiety then results in carbon−carbon coupling to directly yield the observed metallocene−(μ-diyne)−borate betaine system **11** (see Scheme 5).

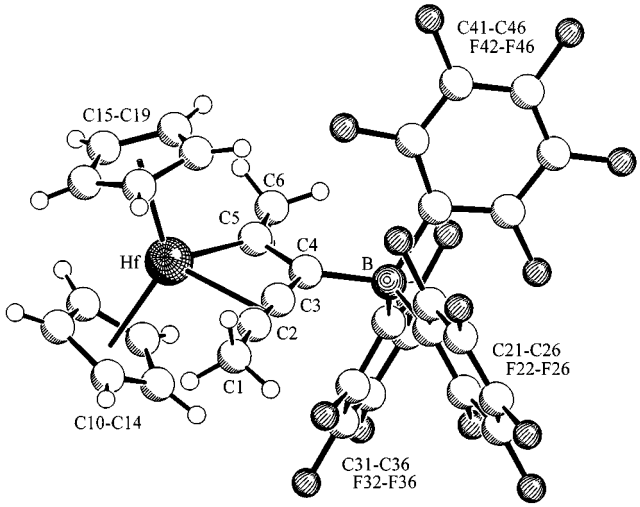

Figure 3. A view of the molecular structure of the metallocene−(μ-hexadiyne)−borate betaine **11′**

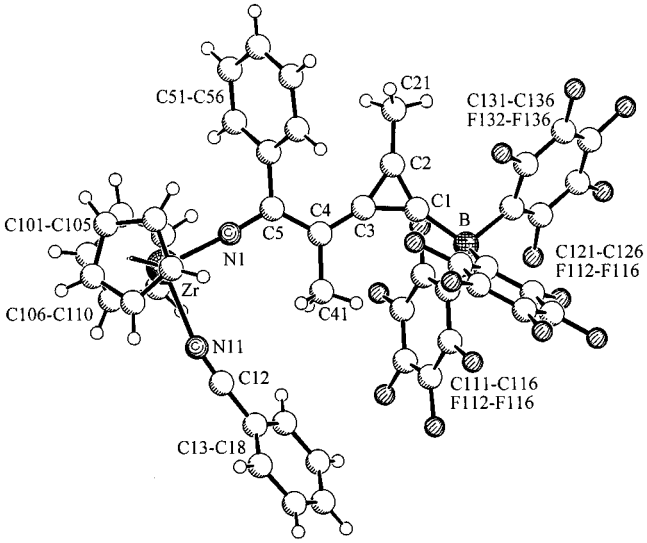
The hafnocene−(μ-hexadiyne)−borate betaine **11′** was characterized by X-ray diffraction (see Figure 3).[11,12] It shows the presence of a planar μ-C_4Me_2 ligand that bridges between hafnium and boron. The (sp^2-C)-to-hafnium σ-bond (C5−Hf in Figure 3) amounts to 2.150(10) Å. The C4−B bond length is 1.63(2) Å. The C4−C5 bond [1.412(13) Å] is in the range for a carbon−carbon double bond, whereas the adjacent C2−C3 bond is much shorter at 1.220(14) Å. The Hf−(C2≡C3) unit represents one of the rare examples of a structurally characterized (η^2-alkyne) group-4 metallocene moiety. The characteristic Hf−C2 and Hf−C3 bond lengths were found to be 2.671(11) Å and 2.310(10) Å, respectively.

In the crystal, the borate unit is chiral, exhibiting a $-B(C_6F_5)_3$ propeller geometry. This chirality element is persistent in many examples of the complexes **11** in solution



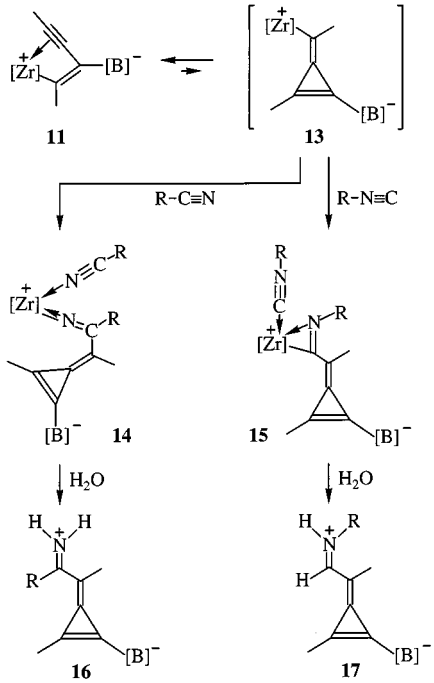


Figure 4. Molecular structure of complex **14**

on the NMR time scale. This gives rise, at sufficiently low temperature, to the observed typical NMR signals for diastereotopic pairs of Cp ligands. From the coalescence of the ^{1}H-NMR Cp resonances the Gibbs activation energies of the borate-propeller enantiomerization were obtained. The $\Delta G^{\neq}_{enant}$ values showed a marked dependence on the steric bulk of the substituents R attached at the μ-C_4 ligand (see Scheme 5) [e.g.: M = Zr, R = CH_3: $\Delta G^{\neq}_{enant}$ (292 K) = 14.3 kcal mol^{-1}; R = cyclohexyl: $\Delta G^{\neq}_{enant}$ (323 K) = 16.4 kcal mol^{-1}].[11]

A most unusual reaction took place when the zirconocene−(μ-hexadiyne)−borate betaine complex **11** was treated with benzonitrile. A rapid reaction ensued which resulted in the consumption of two molar equivalents of the nitrile reagent with formation of product **14**.[9] The X-ray crystal structure analysis (see Figure 4) showed that an unsaturated three-membered ring was formed with typical bond lengths of 1.335(3) Å (C1−C2), 1.394(3) Å (C2−C3), and 1.423(3) Å (C1−C3). The exocyclic unsaturated C3−C4 linkage features a bond length of 1.366(3) Å, and the newly formed bond (C4−C5 in Figure 4) amounts to 1.427(3) Å. The central C_4 framework of **14** in principle features a methylenecyclopropene-type structure, although a marked tendency for π-delocalization is noticed upon comparison with unperturbed methylenecyclopropene examples. The Zr−N=CR_2 unit is almost linear [Zr−N−C 173.4(2)°], and exhibits a marked heteroallene character [Zr−N 1.955(2) Å, N=C 1.299(2) Å].[13] The second benzonitrile unit is just coordinated to zirconium, and stabilizes the electron-deficient metallocene cation substructure in the dipolar arrangement of complex **14** [Zr−N≡C angle 166.5(2)°, Zr−N 2.289(2) Å, N≡C 1.142(3) Å].

The formation of a methylenecyclopropene unit from **11** can be formulated by a reaction sequence initiated by an intramolecular insertion of the coordinated alkyne moiety into the adjacent (sp^2-C)−Zr σ-bond. Compound **13**, the methylenecyclopropene isomer of **11**, is formed in situ and may be present in an equilibrium situation, although the

Scheme 6. Trapping of the in situ generated zirconium−(methylenecyclopropene)−borate betaine **13** with nitriles and isonitriles {[Zr] = Cp_2Zr; [B] = $B(C_6F_5)_3$; substituents used for **14** and **16**: R = C_6H_5 (**a**), *p*-$C_6H_4OCH_3$ (**b**), *p*-$C_6H_4N(CH_3)_2$ (**c**), *p*-$C_6H_4CO_2CH_3$ (**d**); for **15** and **17**: R = $C(CH)_3$ (**a**)}

unsaturated three-membered ring isomer formation must be quite endothermic (by > 20−30 kcal mol^{-1}). Nevertheless, it appears that the high energy isomer **13**, which is present in only a minute equilibrium concentration, being too low for direct detection, is very efficiently trapped, e.g. by the added nitrile to yield the stable product **14**. The overall stabilization of the eventually observed product comes from the C−C and N−Zr bond formation. A variety of differently substituted nitriles have successfully been used as scavengers of **13**. Other typical insertion reagents have been used as well, such as isonitriles,[14] in which case the stable (η^2-iminoacyl)Zr derivatives **15** are obtained in good yield (see Scheme 6).[15] The structure of a typical example (**15a**), derived from $Cp_2Zr(C{\equiv}C{-}C_3H_7)_2$, $B(C_6F_5)_3$, and *tert*-butyl isocyanide, is depicted in Figure 5.

Hydrolysis removes the zirconocene unit efficiently from the framework of **14** and **15**.[16,17] The borate group remains, and we have isolated the iminium−borate betaine systems **16** and **17**, respectively, in good yield (see Scheme 6) with a variety of substituent combinations. The X-ray crystal structures were determined for a number of representative examples, which revealed the remarkable structural features of this class of compounds (see Scheme 7 and Table 1). From the data compiled in Table 1 and Figure 6 it becomes apparent that compounds **16** are characterized by a very pronounced bond lengths equilibration of the C1-to-C5 core. The C1−C2 bond length is uniformly at ca. 1.35 Å. The C1−C3 bond length is ca. 1.40 Å, and the C2−C3 bond typically adopts an intermediate value of 1.37 Å. This marked bond length equilibration effect also extends to the C3−C4 linkage, which at 1.39 Å is clearly below the ex-

pected $C(sp^2)-C(sp^2)$ single bond value, almost matching the C4−C5 bond length at ca. 1.38 Å (see Table 1). These values are quite atypical for a methylenecyclopropene framework, when compared with the typical C−C distances

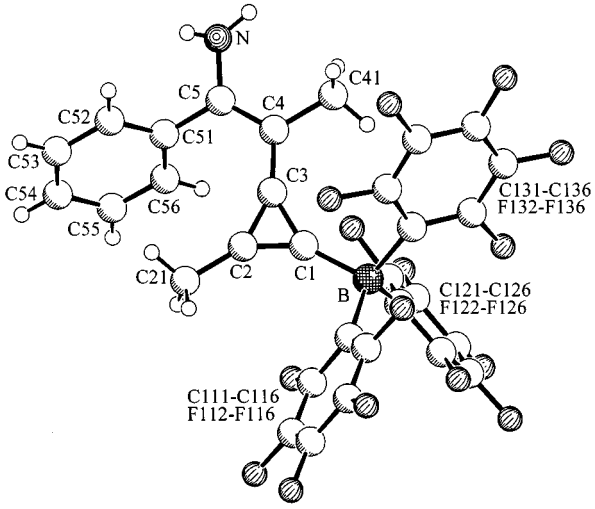

Figure 6. A view of the molecular structure of **16a**; selected bond lengths [Å] and angles [°]:C1−C2 1.341(3), C1−C3 1.399(3), C1−B 1.623(3), C2−C3 1.372(3), C2−C21 1.479(3), C3−C4 1.396(3), C4−C5 1.383(3), C4−C41 1.509(4), C5−N 1.339(3), C5−C51 1.477(4); C2−C1−C3 60.1(2), C2−C1−B 150.6(2), C3−C1−B 149.3(2), C1−C2−C3 62.1(2), C1−C2−C21 148.7(2), C3−C2−C21 149.2(2), C1−C3−C2 57.9(2), C2−C3−C4 154.2(2), C4−C3−C1 147.8(2), C3−C4−C5 118.8(2), C3−C4−C41 119.8(2), C5−C4−C41 121.4(2), C4−C5−N 121.0(3), N−C5−C51 116.0(2), C4−C5−C51 123.0(2)

in e.g. the parent hydrocarbon methylenecyclopropene itself (C1−C2 1.323 Å, C1−C3 1.441 Å, C3−C4 1.332 Å).[18]

The observed structural π-bond delocalization probably indicates a pronounced contribution of a cyclopropenylium-type structure in the framework of compounds **16** (and of **17**, see below). The triphenylcyclopropenylium cation shows a C−C bond length of 1.373 Å inside the three-membered ring,[1] a value about which the three C1-to-C3 bond lengths of compounds **16** are closely centered (see above). Thus, compounds **16** may be structurally regarded as being very closely related to cyclopropenylium betaines bearing an enamino substituent at carbon atom C3. These unique compounds, therefore, may structurally be regarded as cyclopropenylium compounds that are devoid of their +1 charge, because they carry their counter anion covalently bonded to them.

A mandatory consequence of a description of compounds **16** and **17** as substituted cyclopropenylium betaines is that the rotational barrier about the exocyclic C3−C4 partial π-bond is low, thus allowing for a rapid *cis*/*trans* isomerization of the substituents at C2 and C4 of the framework. It must be noted that none of the *cis* isomers (e.g. *cis*-**16** or *cis*-**17**) can directly result from our synthetic scheme (see Scheme 6). Consequently, any appearance of a respective product that exhibits the former alkynyl substituents −R in a relative *cis* orientation at positions C2 and C4 at the planar central carbon framework must be considered an indication of a subsequent isomerization reaction involving rotation about the C3−C4 linkage under the applied, very mild reaction conditions. Such a *cis* product, namely the *N*-*tert*-butyl-substituted cyclopropenylium betaine *cis*-**17a**, obtained by *tert*-butyl isocyanide trapping of the metallocene−borate betaine **13a** followed by hydrolysis, was

characterized structurally.[17] Compound *cis*-**17a** exhibits the typical tendency of C−C-bond length leveling in the central C_5 unit that is characteristic of the members of this larger family of compounds (see Figure 7).

Figure 7. The rotation around the C3−C4 bond in **17a** is indeed kinetically very facile in solution. Compound **17a**, dissolved in [D_5]bromobenzene, exhibits typical NMR signals of the two isomers *trans*- and *cis*-**17a** in solution (Scheme 8). The compounds are present in a ca. 80:20 ratio at 270 K. Raising the temperature results in a broadening of the signals, of e.g. the methyl substituents, and eventually to coalescence. From the dynamic NMR behavior of the complex pair, *trans*-**17a** and *cis*-**17a**, a Gibbs activation energy of $\Delta G^{\neq}_{CCrot}$ (330 K) = 17.0 ± 0.4 kcal mol^{-1} was obtained. Microscopically this value probably corresponds to the activation barrier of rotation around the C3−C4 [C(sp^2)−C(sp^2)] linkage in the compound **17a**. The observed value of 17 kcal mol^{-1} [17] is much lower than expected for a normal C=C double bond rotation, which

Scheme 8. Facile rotational *trans*/*cis* isomerization of the compound **17a**

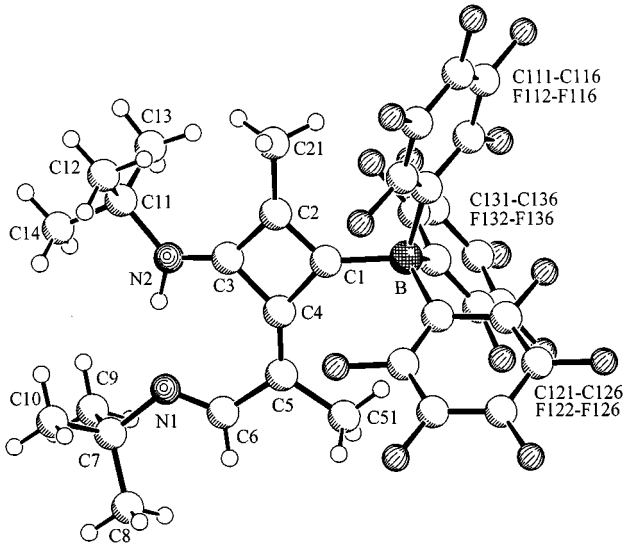
strongly supports the interpretation that these complexes behave as neutral three-membered ring aromatic cyclopropenylium betaine systems.

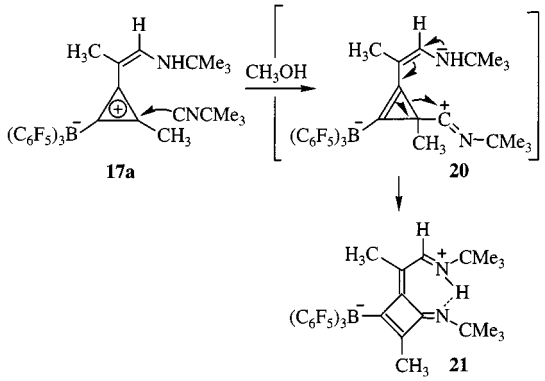
The *trans*/*cis* isomerization was observed for several other examples of this general class of compounds.[12] As a consequence of the pronounced cyclopropenylium betaine character the rotation around the enamine C5−NH_2 bond in the complexes listed in Table 1 is fast. Invariably, values close to $\Delta G^{\neq}_{CNrot}$(306 K) ≈ 14.5 ± 0.5 kcal mol^{-1} were observed, almost independent of the arene substituents X (see Scheme 7).[12][16b,17]

First Reactions of the Cyclopropenylium−Borate Betaines

Carbenium ions react with a variety of soft neutral carbon nucleophiles by carbon−carbon coupling. The reaction with isonitriles is a typical example that may ultimately lead to products derived from intermediately formed iminium ions.[19] It is expected that the neutral betaine systems **16** and **17** should typically undergo similar reactions due to the incipient carbenium ion character of their cyclopropenylium cation-type substructural unit, and this has indeed been observed when some of the cyclopropenylium betaines were treated with alkyl isocyanide reagents.

The cyclopropenylium−borate betaine **17a** reacted rapidly with one molar equivalent of *tert*-butyl isocyanide in methanol solution to selectively yield the product **21** (see Scheme 9 and Figure 8).[17] The insertion and ring expansion is likely to be initiated by nucleophilic attack of the isonitrile to the cyclopropenylium C2 position of the betaine starting material (to generate **20**). This is probably followed by C−C σ-bond migration to the in situ formed imi-





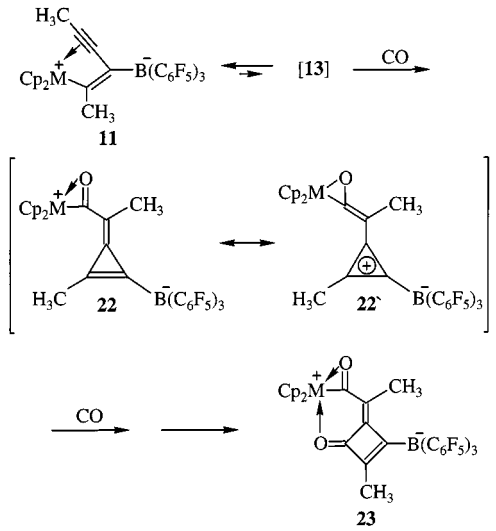


Figure 8. Molecular structure of the isonitrile insertion product **21**; selected bond lengths [Å] and angles [°]: B−C1 1.631(3), C1−C2 1.383(3), C1−C4 1.506(3), C2−C3 1.454(3), C3−N2 1.290(3), C3−C4 1.481(3), N2−C11 1.495(3), C4−C5 1.340(3), C5−C6 1.475(3), C6−N1 1.265(3), N1−C7 1.490(3); B−C1−C2 132.9(2), B−C1−C4 134.6(2), C1−C2−C3 92.2(2), C1−C4−C3 86.4(2), C2−C1−C4 91.5(2), C2−C3−C4 89.8(2), C2−C3−N2 140.6(2), C3−N2−C11 128.3(2), C1−C4−C5 138.3(2), C3−C4−C5 135.3(2), C4−C5−C6 124.4(2), C5−C6−N1 127.1(2), C6−N1−C7 121.3(2)

Scheme 9. Ring expansion reaction of **17a** upon treatment with an isonitrile

noacyl cation to give the favored expanded conjugated bis-(imine) product **21** directly.

The isonitrile insertion product was characterized by X-ray diffraction.[12,17] This has revealed the presence of the unsaturated central four-membered ring structure. One of the C=N functionalities is a part of this structure, and the other is attached to it. There is a bridging hydrogen between the two imino nitrogen atoms (^{1}H NMR: δ = 9.98), and the borate counter anion is again covalently bonded to the framework. In contrast to the markedly delocalized π-system of the cyclopropenylium betaine systems (**16** and **17**, see above), compound **21** contains clearly alternating single and double bonds around its completely unsaturated perimeter.

Scheme 10. Reaction of the betaine complex **11** with carbon monoxide

A related reaction probably takes place upon treatment of the betaine complex **11** with carbon monoxide (Scheme 10). It seems that initially the high-lying methylenecyclopropene intermediate **13** is trapped by C−C bond-forming insertion as usual, in this case giving rise to the formation of the corresponding (η^2-acyl)zirconocene product **22**. Its resonance structure **22′**, which consequently reacts rapidly by further CO uptake under the reaction conditions to eventually yield the methylenecyclobutenone complex **23**, seems to provide a favored description of the cyclopropenylium features of this neutral organometallic product. The product, **23**, was characterized spectroscopically,[12] and shows a variety of characteristic features similar to the closely related compound **21**.

Conclusions

We have found a simple way to make a number of examples of a new variety of unsaturated three-membered ring compounds.[20] Our organometallic route, which combines coupling of two acetylides at the zirconocene template [upon treatment with a stoichiometric quantity of the strong organometallic Lewis acid tris(pentafluorophenyl)-borane], with trapping of its methylenecyclopropene isomer and subsequent hydrolysis, makes compounds **16** and **17** readily available in high yield. These compounds show a pronounced cyclopropenylium−borate betaine character, with regard to their structural properties in the solid state and their typical dynamic features in solution. Thus, it seems that such compounds represent the first series of examples that may be regarded as cyclopropenylium ions bearing their counter anion covalently bonded to their three-membered ring framework. Their structural, dynamic and, as shown in first examples, chemical behavior is the same as would be expected for the smallest carbocyclic arenes, the cyclopropenylium cations, but without the dominating effects of the charge. In some respect, systems such as **16** or **17** might be suited to the study and development of some "carbenium ion chemistry without the charge". Now that first examples have become available by easily accessible organometallic pathways, the development of the chemistry of neutral variants of a variety of charged organic species as parts of such simple betaine systems may become feasible.[21]

The Structure Chemistry of Boron-Rich Solids of the Alkali Metals

Barbara Albert[a]

Keywords: Alkali metals / Boron / Borides / Carbaborides / Polyhedral frameworks

The electronic situation of boron atom frameworks in boron-rich solids is not easy to understand. Attempts to describe such compounds according to known bonding theories such as the Lipscomb or Zintl–Klemm approaches, are not completely unambiguous. To gain further insight and to create a solid experimental basis for the development of a conclusive bonding concept for non-molecular boron-rich compounds, it is essential to investigate metal borides in which the number of electrons transferred from the metal atoms to the boron atom framework appears to be well-defined. Alkali metal borides and carbaborides are such compounds, and it is the aim of this work to provide additional knowledge on their existence and crystal structures. Focussing on the crystal structures of alkali metal borides and carbaborides that are characterised by frameworks of interconnected boron atom polyhedra; it can be shown that there exist convincing geometrical similarities between boron-rich molecules and polyhedral entities in extended networks. This allows for the comparison between the bonding of boron-rich molecules with that of boron-rich solids.

Introduction

The chemistry of alkali metal borides has been covered by several reviews of Hagenmuller and Naslain and coworkers, that were published between 1967 and 1977.[1−3] At that time, it seemed likely that only three representatives of binary alkali metal borides had been synthesised in form of mono-phasic samples. These compounds were described as "NaB_6",[4] "NaB_{15}",[5,6] and "KB_6".[7,8] Unfortunately, the high-temperature synthesis conditions necessary to react boron and alkali metals usually do not lead to highly-crystalline products. The existence and crystal structures of the known boron-rich compounds of the alkali metals remained somehow unclear because in the sixties the technique of crystal structure solution and refinement based on powder diffractometry was still very young.

The lithium−boron(−carbon) system has been investigated by several groups. Boron-rich compounds like Li_3B_{14},[9−11] Li_2B_6,[9,12,13] and LiB_{13}[14] were found, as well as the lithium boride carbide LiBC.[9,15] Most of these borides were characterised by single-crystal X-ray diffraction. The formulae of these compounds were derived from the localisation and occupancies of the lithium ions in the crystal structures because it is very difficult to determine the exact composition of compounds consisting of light elements only. This was made even more difficult by certain disorder phenomena concerning the lithium atom positions. Therefore, it can be considered a real break-through, that due to the efforts of Nesper and von Schnering and coworkers we now know at least three well-defined representatives in the lithium−boron(−carbon) system. Other compounds which were described as "$LiB_{10.85}$",[16] "Li_2B",[17] "LiB",[18] "Li_5B_4", "Li_3B",[19,20] "Li_7B_6",[21] "LiB_2",

Barbara Albert studied chemistry at the Rheinische Friedrich-Wilhelms-Universität in Bonn, Germany. She received her PhD in 1995, working with solid-state chemist Professor Dr. Martin Jansen. Thanks to a Feodor-Lynen-stipend from the Alexander von Humboldt foundation, Bonn, she spent a post-doctoral year in the group of Professor Dr. A. K. Cheetham at the Materials Research Laboratory, University of California, Santa Barbara, U.S.A., where she worked on Gismondine type (P) zeolites and their structural characterisation via powder diffractometry. From 1996 to 1998, she received a Lise-Meitner-stipend from the Land Nordrhein-Westfalen. Hereby enabled to develop her own research projects, she began to synthesise, characterise, and investigate new boron-rich compounds. In 1997, her habilitation project was awarded by the Ministry of Education and Science in Nordrhein-Westfalen with the Bennigsen-Foerder-award for young scientists and artists and in 1999 with the ADUC award. Since 1998, Barbara Albert has a C1 position as a scientific assistant with Professor Dr. J. Beck at the Justus-Liebig-Universität in Giessen.

"LiB_{10}",[22] and "LiB_3"[23] (in historical order) have not proven to give reproducible results with regard to their identity and properties.

Due to their well-defined oxidation state in chemical compounds, alkali metals are especially appropriate as reaction partners of boron to investigate the electronic situation of the boron framework in the resulting boron-rich solids. Today, modern powder diffractometry and solid-state NMR spectroscopy allow us to re-address the characterisation of alkali metal boron-rich compounds. It is necessary to carefully analyse the structure and electron count of boron atom polyhedra in well-defined compounds, in order to obtain a plausible description of the chemical bonding in boron-rich solids. An investigation into the geometrical similarities between the polyhedral entities in molecules and in solids is advisable before a comparison between the bonding situation in the two types of structures can be made. In this review, the chosen experimental system is that of the alkali metal boron-rich compounds. New compounds such as Na_3B_{20},[24,25] NaB_5C,[26] Na_2B_{29},[27] and KB_5C[28] will be described and put into context with what is known from earlier work on alkali metal borides and carbaborides. The electronic situation of these compounds will be compared with that of boron-rich molecules.

One question that is of great interest is: Does a monovalent sodium or potassium hexaboride exist? "NaB_6" and "KB_6" should be discussed on a new experimental basis. This point is very important for the discussion of the bonding in boron-rich solids. It should help to decide whether Lipscomb's bonding concept[29,30] developed for boron-rich molecules is applicable for non-molecular structures.

If hexaborides of type M^IB_6 do exist, the electronic analogy between octahedral $[B_6H_6]^{2-}$ molecules and octahedral $[B_6]^{2-}$ entities in the framework of boron-rich solids like CaB_6 cannot be made. According to the traditional picture which was first introduced by Longuet-Higgins and de V. Roberts[31] and which is depicted in Figure 1, each octahedron in the framework needs twenty electrons for stabilisation. Fourteen of these are needed to fill the molecular orbitals of the B_6 unity (multicentre bonds), and six (+6 from the bonding partners) are needed for the conventional 2electron-2center bonds directed outwardly towards neighbouring octahedra (the latter are comparable to the B−H bonds in the $[B_6H_6]^{2-}$ molecular anion). Eighteen electrons are provided by the six boron atoms, the missing two electrons have to be transferred from the cation to the framework. If the cation can provide even more electrons, like for example in LaB_6, the extra electron is obviously not needed for the bonding orbitals of the boron atom framework. This is shown by the high electrical conductivity that is observed for LaB_6. However, if the cations provide fewer electrons, the polyhedral arrangement should be destabilised. So, how could this be possible if compounds such as "NaB_6" or "KB_6" with an octahedral framework existed?

The correlation between crystal structure and electron count in similar compounds containing, for example, silicon or tin instead of boron, has been discussed before .[32−34]

The Alkali Metal Borides

Moissan (1892) and Kroll (1918) were the first to find indications for the existence of alkali metal borides when investigating "impure" samples of boron.[35,36] Forty years later, Hofmann[37] and later, Lipp[38] attempted to synthesise Li-B alloys, but they did not get well-defined compounds.

The first mono-phasic sample of an alkali metal boride described in the literature is a sodium boride synthesised by Hagenmuller and Naslain in 1963.[4] The formula "NaB_6" was assigned to the crystalline powder obtained by a high-temperature reaction from the elements. Today, we know the exact composition of this compound to be Na_3B_{20}.[24,25] It can be synthesised from the elements in arc-welded tantalum tubes lined with inner crucibles made of pyrolytic boron nitride at temperatures around 1050 °C. Its crystal structure recently was solved from high-resolution X-ray powder data and will be described below.

Since 1964, different groups have investigated both the lithium−boron and the potassium−boron systems. For the latter, only one representative could be synthesised in form of a crystalline powder, "KB_6".[7,8] It was obtained only from the α-rhombohedral modification of boron and its powder diffraction pattern suggested close similarity of the

crystal structure with that of the well-known alkaline earth hexaborides (Ca, Sr, Ba).[39−44] Alkaline earth hexaborides contain a boron atom framework of three-dimensionally interconnected octahedra and divalent metal ions in 24-fold coordination spheres between the octahedra (Figure 1, top right). However, recent results concerning "KB_6" using electron energy loss spectroscopy and solid-state NMR spectroscopy suggested the presence of a third element in this compound.[45] Therefore, it seems highly probable that no binary compound in the potassium−boron system has ever been prepared until now. With regard to the lithium−boron system, in 1964 the existence of "$LiB_{3.7-4.1}$" was suggested by Lipp.[38] Since then, most other lithium borides which have been described could not be characterised to a satisfying extent. Fortunately, about fifteen years ago Nesper and von Schnering and co-workers succeeded in growing single crystals of Li_3B_{14} and Li_2B_6.[9−13] Li_3B_{14} contains a boron atom framework of interconnected B_8 and B_{10} cages. For Li_2B_6, a boron atom arrangement similar to that of the alkaline earth hexaborides was found with two cations instead of one between the slightly distorted octahedra.

The first alkali metal boride that was obtained in the form of small single crystals was described as "NaB_{16}",[4] later the formula was corrected to "NaB_{15}".[5,6] Its crystal structure was published in 1970.[5] In fact, the analysis for these crystals published in the original paper already indicated a slightly different composition. This was confirmed by a recent reinvestigation of the crystal structure, using the combined capacity of different spectroscopic and diffraction techniques. These included X-ray and neutron powder diffractometry, ^{23}Na MAS-NMR spectroscopy, single crystal investigations, and electron microscopy. The actual phase composition is Na_2B_{29} and its crystal structure is characterised by a framework consisting of interconnected boron atom icosahedra and additional interstitial boron atoms.[27]

In conclusion, we now know of at least four examples of alkali metal borides which are well-defined in terms of their composition and crystal structures, and they are Li_2B_6,[13] Li_3B_{14},[11] Na_3B_{20},[24,25] and Na_2B_{29}.[27] Rubidium or caesium borides have not been obtained yet.

Alkali Metal Carbaborides

The alkali metal−boron−carbon system has not been investigated until recently, except for one compound discovered by Nesper and von Schnering and co-workers during their search for lithium borides, LiBC.[9,15] The crystal structure of LiBC is similar to that of hexagonal boron nitride, exhibiting planar 6^3-B/C-nets. The layers are stacked along the *c* axis with lithium ions in the centres of the formed hexagonal B/C prisms. Within the sheets and in between them, a colouring scheme characterised by strictly alternating B/C ordering is observed, similar to that found recently for another layer-type compound, CaB_2C_2.[46]

Formerly unknown carbaborides with three-dimensionally extended boron/carbon frameworks were discovered recently, NaB_5C and KB_5C.[26,28] These compounds, which are the first known representatives of ternary sodium and potassium B/C compounds, were obtained by a high-temperature reaction from the elements in form of monophasic crystalline powders without a detectable phase deviation. Their crystal structures resemble those of the alkaline earth hexaborides, carbon being statistically distributed at the boron atom positions of the octahedral framework. In fact, KB_5C is isoelectronic with the well-known CaB_6 and has similar properties.

At present, three representatives of the system alkali metal−carbon−boron are known. These are LiBC, NaB_5C, and KB_5C.

Crystal Structures of the Boron-Rich Compounds of Alkali Metals

The crystal structures of NaB_5C, KB_5C, Li_2B_6,[13] Na_3B_{20}, Li_3B_{14},[11] and Na_2B_{29} are shown in Figure 2.[47]

Na_3B_{20}	[24,25]	*Cmmm*, no. 65	1869.5, 570.1, 415.1
Na_2B_{29}	[27]	*I*1*m*1, no. 7	585.9, 1039.9, 833.2, 90.4
NaB_5C	[26,28]	*Pm*-3*m*, no. 221	409.3
KB_5C	[28]	*Pm*-3*m*, no. 221	412.8

Structural data of these phases is summarised in Table 1. The crystal structures of alkali metal boron-rich compounds are characterised by non-metal frameworks consisting of different polyhedra that are three-dimensionally interconnected. Metal ions are localised in the cavities between the polyhedra. The interatomic distances are shorter than the intramolecular distances within the polyhedra. This is a well-known phenomenon and occurs due to the deficiency of electrons in the multicentre bonds in the boron atom clusters relative to the 2electron-2center bonds between them. Table 2 gives the averaged different inter- and intramolecular B-B distances for alkali metal borides.

The polyhedra observed in these compounds are as follows: octahedra in NaB_5C, KB_5C, and Li_2B_6,[13] octahedra and pentagonal bipyramids in Na_3B_{20}, dodecahedra and bicapped quadratic antiprisms in Li_3B_{14},[11] and icosahedra in Na_2B_{29}. Most of these polyhedra are slightly distorted, this will be discussed later.

In the cubic carbaborides, the B/C framework maintains the high symmetry of the hexaboride structure, whereas in Na_3B_{20} a less symmetric but otherwise very similar arrangement of polyhedra is present in which two-thirds of the octahedra are replaced by pentagonal bipyramids. Ribbons of these pentagonal bipyramids run parallel to the b axis of the unit cell. These ribbons are formed because only four of the seven boron atoms of a pentagonal bipyramid form 2electron-2centre bonds with four neighbouring polyhedra (two octahedra, two pentagonal bipyramids), similar to the hexaboride structure. Each of the remaining three boron atoms per polyhedron shows close contact to two boron atoms of neighbouring polyhedra. The boron atom coordination spheres of the sodium cations are 20-fold and 24-fold, respectively. This is shown in Figure 3.

The 24-fold coordination sphere is very similar to that of the cations in the carbaborides.

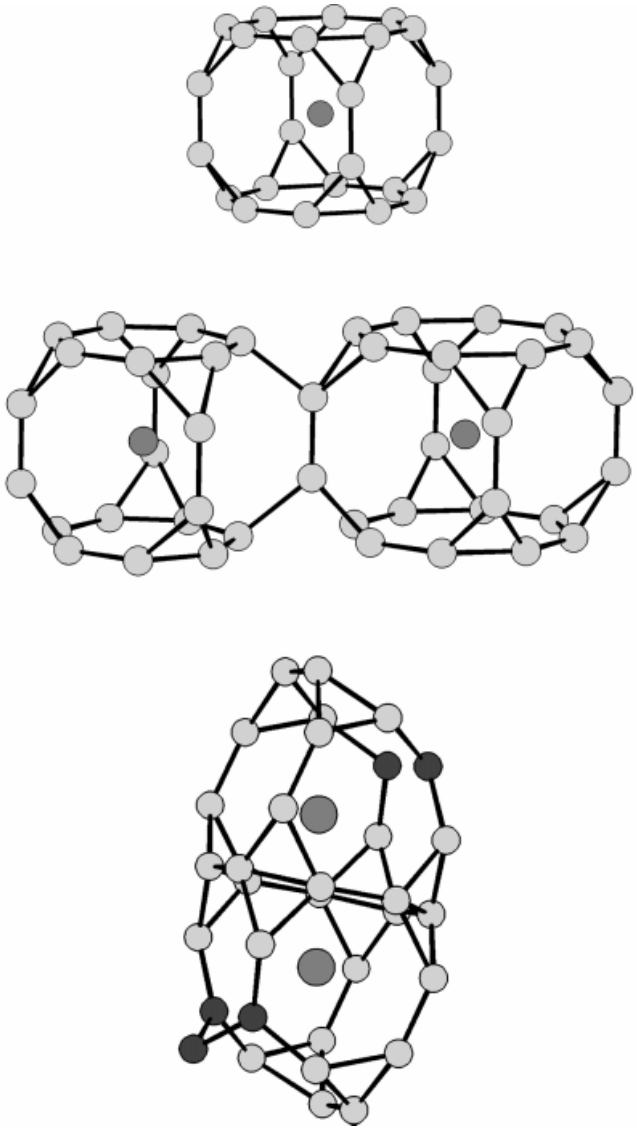

Figure 3. Sections of the structures of NaB_5C (top), Na_3B_{20} (middle), and Na_2B_{29} (bottom); sodium atoms are light grey, boron atoms are dark gray (polyhedral) and black (interstitial)

Na_2B_{29} was formerly known as "NaB_{15}", and the slight difference in the two types of sodium atoms with respect to their boron atom coordination sphere, eventually led to the proper compositional description of this compound (Figure 3, bottom). Using ^{23}Na-MAS triple quantum NMR spectroscopy the presence of two types of sodium atoms

Table 2. Inter- and intramolecular B−B distances for solids and intramolecular B−B distances for molecules

Polyhedron	Molecule: mean intrapolyhedral B−B distance [pm]	Solid: mean intrapolyhedral B−B distance [pm]	Solid: mean interpolyhedral B−B distance [pm]
$[B_6]$	$K_2[B_6H_6]$:[50] 172	Li_2B_6:[13] 176	171
	$[N(CH_3)_4]_2[B_6H_6]$:[63] 169	Na_3B_{20}: 177	172
$[B_7]$	$[(C_5H_5N)_2CH_2][B_7Br_7]$:[51] 174	Na_3B_{20}: 180	171
$[B_8]$	$[Zn(NH_3)_4][B_8H_8]$:[52] 177	Li_3B_{14}:[11] 180	174
$[B_{10}]$	$[N(C_2H_5)_3H]_2[B_{10}H_{10}]$:[53] 178.5	Li_3B_{14}:[11] 181.5	174
$[B_{12}]$	$[N(CH_3)_4]_2[B_{12}H_{12}]CH_3CN$:[54] 178.5	Na_2B_{29}: 182	177

with distinct boron atom environments was detected. The different coordination spheres of the sodium atoms are as a result of the presence of two types of interstitial boron atoms close to a single type of sodium atom in one case, and the presence of only one type of interstitial boron atom close to the second type of sodium atom in the other. The coordination sphere of Na1 includes 20 neighbouring boron atoms with a mean Na−B distance of 284 pm, whereas Na2 coordinates 21 boron atoms with a mean distance of 286 pm. Due to the loss of symmetry, the crystal structure of "NaB_{15}" = Na_2B_{29} originally described in the orthorhombic crystal system, had to be refined in the monoclinic crystal system.

Polyhedra in Boron-Rich Solids and Molecules

In order to compare the bonding situation of boron atom polyhedra in solids with that in molecules, it is first necessary to compare their geometric situations. Boron atom cages have been found in the *closo*-hydroborates $[B_nH_n]^{2-}$ with $n = 5-12$.[48] For such compounds with $n = 6$, 8, 9, 10, 11, and 12, single crystal X-ray structure determinations have been performed and the overall regularity of these polyhedra was confirmed. Homoatomic polyhedra in boron-rich systems are always isohedral containing only $n = 3$ polygons (deltahedra), as can be seen in Figure 4.

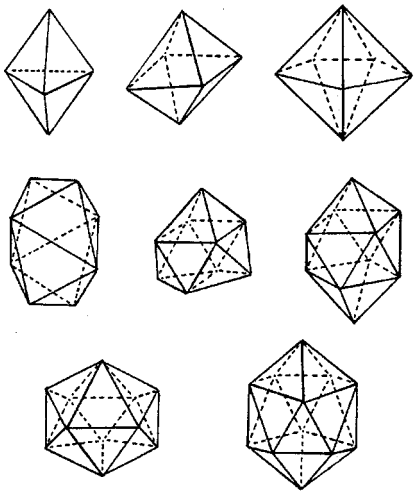

Figure 4. Polyhedra in *closo*-hydroborates according to Barton[48]

However, these polygons do not necessarily have to be regular. In principle, the octahedron and icosahedron are regular (Platonic) solids, the trigonal and pentagonal bipyramids have been described as semi-regular (Catalan) solids.[49] Less regular is the $n = 8$ cluster, which is a bisdisphenoid called a triangulated dodecahedron, the $n = 9$ and $n = 10$ cluster are monocapped and bicapped antiprisms, the $n = 11$ polyhedron is called an octadecahedron. Five of these polyhedra known from *closo*-hydroborates and their derivatives, can also be found in alkali metal boron-rich solids, the octahedron, pentagonal bipyramid, dodecahedron, bicapped antiprism, and the icosahedron. Data on the B-B bond lengths are given in Table 2 already indicate a comparability of the polyhedral entities in solids and molecules. Their similarity can be appreciated in Figure 5, where the same polyhedra extracted from the crystal structure descriptions of $K_2[B_6H_6]$,[50] $[(C_5H_5N)_2CH_2][B_7Br_7]$,[51] $[Zn(NH_3)_4][B_8H_8]$,[52] $[N(C_2H_5)_3H]_2[B_{10}H_{10}]$,[53] and [N-

$[B_{12}]$	I_h	$[N(CH_3)_4]_2[B_{12}H_{12}]CH_3CN$:[54] 0.0045	Na_2B_{29}: 0.0506

$(CH_3)_4]_2[B_{12}H_{12}]CH_3CN$[54] are compared with those extracted from alkali metal borides.

Deviations from the ideal (which in principle cannot exist: by definition, an octahedron is an ideal octahedron or it is not an octahedron[55]) are quantified using the Program SYMMOL,[56] which is based on the idea, that symmetry can be treated "as a continuous property rather than a discrete ("yes or no") one".[57] Table 3 summarises a comparison between molecular boron atom cages and cages cut out from extended boron atom frameworks, by giving the r.m.s. (root mean square) values which characterise the degree of distortion of the polyhedra. These values are always higher than zero when crystallographic symmetry is not present.

Besides the first trivial case (top, crystallographic symmetry is already O_h), it is obvious that the polyhedra are more distorted in compounds with extended frameworks than in molecules. However, the "ideal" symmetry of the polyhedra is clearly determined even for the more distorted entities and the deviations from regular polyhedra are quite small.

Conclusions

At present, the alkali metal−boron system and the alkali metal−boron−carbon system are characterised by the proven existence of seven representatives. By crystal structure analyses of these compounds, a class of well-defined boron-rich solids has been established. These compounds are especially useful in the analysis of the bonding situation in electron-deficient polyhedral *frameworks*. Lipscomb's concept is usually applicable in describing the bonding situation in electron-deficient boron-rich *molecules*. It states that for molecular B_n *closo*-cages, the electronic demand necessary to stabilise the polyhedral arrangement is $2n + 2$, according to the traditional counting scheme (Rudolph−Williams−Wade rules[58−60]). Even if we have to remind ourselves that there exist other concepts to describe boron-rich compounds (for example Mingos' rules[61]) and of known exceptions from Lipscomb's predictions (for example B_9Br_9[62] and $Li_{1.8}B_{14}$[9−11]), the conclusions which can be drawn from the experimental findings summarised in this review are as follows. The analysis of the crystal structures of alkali metal borides and carbaborides reveals geometrical similarities between polyhedra in boron-rich solids and boron-rich molecules, which suggest a comparability of their bonding situation. Consequently, each octahedral B_6 entity which is part of an extended framework should need $2n + 2$ (= 14) electrons plus six electrons for the interpolyhedral contacts, as it was suggested 45 years ago by Longuet-Higgins and de V. Roberts. Within their limitations, the evidence described above confirm the applicability of this concept, since compounds correctly described by the formulas NaB_6 and KB_6 were found not to exist. Instead, we discovered NaB_5C and KB_5C, for which the electron count is fulfilled.

Acknowledgments

I would like to thank Professor Dr. J. Beck, Bonn, for his support, and K. Schmitt and K. Hofmann, Giessen, for their enthusiastic help. Financial support from the DFG (AL536/1-1), Dr. Otto Röhm Gedächtnisstiftung, and the Fonds der Chemischen Industrie is gratefully acknowledged.

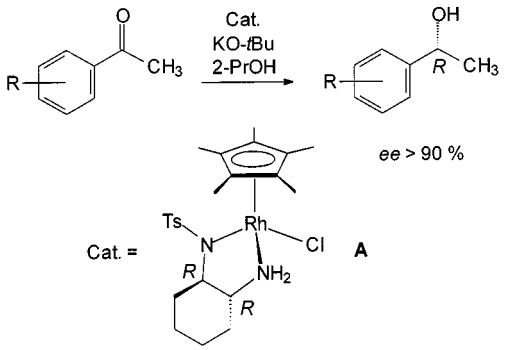
Biomimetic Catalysis with an Immobilised Chiral Rhodium(III) Complex

Kurt Polborn[a] and Kay Severin*[a]

Keywords: Heterogeneous catalysis / Molecular imprinting / Hydrogenations / Transition states / Rhodium

An organometallic transition state analogue for the asymmetric reduction of acetophenone with a Cp*Rh complex has been synthesised and structurally characterised (**3**). This complex has a chiral *N*,*N*′-chelate ligand with a styrene side chain to allow its incorporation into organic polymers. The remaining coordination site is occupied by a methylphenylphosphinato ligand. This ligand acts as a pseudosubstrate which mimics acetophenone. The conformation and configuration of **3** in the crystal are in excellent agreement with the postulated transition structure. Following the protocol of molecular imprinting, complex **3** was co-polymerised with ethylene glycol dimethacrylate in the presence of a porogen. The resulting polymer **P3** was ground and sieved and the phosphinato ligand was substituted with a chloro ligand to generate a shape-selective cavity in proximity to the catalytically active metal centre. When tested for its ability to catalyse the reduction of acetophenone and related substrates the imprinted polymer **P3** showed a significantly higher activity than a control polymer **P2** without a cavity. Excellent enantioselectivities (up to 95% *ee*) were obtained, with the catalyst **P3** being more selective than the respective control catalyst **P2** (Δee = 2–9%). Competition experiments with acetophenone and a second co-substrate have revealed that the cavity generated with the phosphinato ligand is specific for acetophenone.

Introduction



Modern organometallic catalysts display high activities, some of which can rival those of metalloenzymes.[1] Nevertheless there is a fundamental difference in how the selectivity and activity is controlled in these systems. For (homogeneous) organometallic catalysts these parameters are mainly determined by the nature of the metal ion and the first coordination sphere.[2] For metalloenzymes, on the other hand, ligands of the second coordination sphere, that is, functional groups in the vicinity of the catalytically active centre, are crucial for chemical transformations. A well-defined microenvironment allows for the molecular recognition between enzyme and substrate and/or transition state and is thus the basis for high selectivity.

In recent years several approaches for manipulating the microenvironment of synthetic organometallic catalysts in a controlled fashion have been described. For example, catalytically active metal complexes have been covalently attached to organic host molecules (e.g. cyclodextrins)[3] or embedded into porous inorganic materials (e.g. zeolites).[4] However, most of these strategies either require substantial synthetic efforts or the obtained catalysts are rather unspecific. Recently, we have reported an alternative approach which combines the technology of molecular imprinting[5] with organometallic chemistry: a transition metal catalyst, having a polymerisable side chain, is co-polymerised with an organic crosslinking monomer. During the polymerisation a pseudosubstrate is coordinated to the catalytically active centre. Selective removal of the pseudosubstrate generates a complementary, shape selective cavity. The realisation of this concept was demonstrated for the Ru^{II}-catalysed transfer hydrogenation of benzophenone.[6] Here we describe the synthesis of a highly active and selective *chiral* Rh^{III} catalyst for the asymmetric reduction of acetophenone, obtained by molecular imprinting with a defined transition-state analogue (TSA).[7,8]

Results and Discussion

The asymmetric transfer hydrogenation of ketones and imines, catalysed by chiral complexes of the late transition metals has received considerable attention in recent years.[9] In particular, chiral (arene)Ru^{II} catalysts have been shown to be highly selective. Excellent results have also been obtained with the Cp*Rh complex **A** (Scheme 1): for the reduction of acetophenone and derivatives with 2-propanol in the presence of base an enantiomeric excess of more than 90% *ee* was observed.[10]

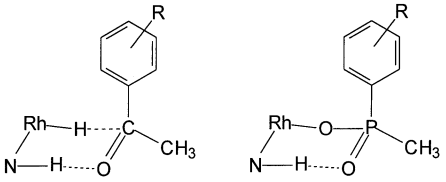
atom to the adjacent amine group. Theoretical investigations on related Ru-catalysed reactions have provided additional evidence for such a geometry (Figure 1).[11] We propose a phosphinato complex as a TSA for the asymmetric reduction of acetophenone.



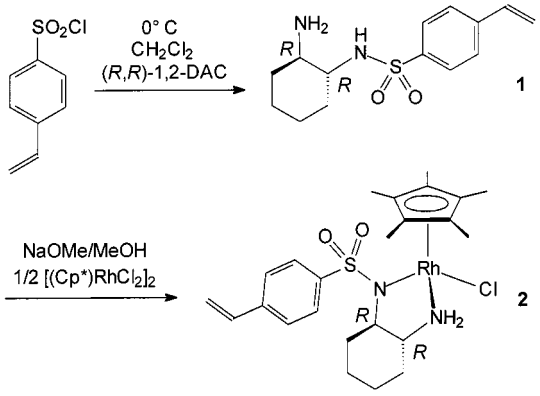


Figure 1. Postulated transition structure for the Rh^{III}-catalysed transfer hydrogenation of aromatic ketones (left); transition-state analogue with a phosphinato ligand (right)

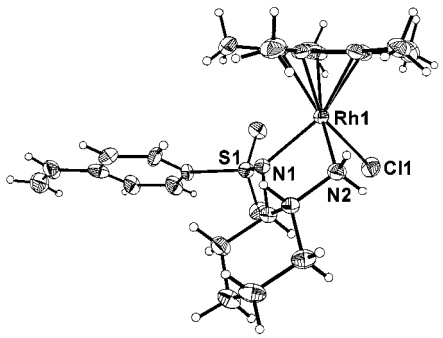
Here we describe the synthesis and the structure of a polymerisable $CpRh^{III}$ catalysts with a methylphenylposphinato ligand. To allow catalysts of this kind to be incorporated into organic polymers we have synthesised a ligand with a styrene instead of a tolyl side chain. This was accomplished by condensation of (1*R*,2*R*)-1,2-diaminocyclohexane with *p*-styrylsulfonyl chloride (**1**). The rhodium complex **2** was obtained in good yields by reaction of **1** with $[Cp^*RhCl_2]_2$ in the presence of NaOMe (Scheme 2). The ^1H NMR spectrum of **2** shows only one set of signals ($CDCl_3$). This indicates that the synthesis is completely diastereoselective.

The structure of the racemic[12] complex **2** in the crystal is depicted in Figure 2. The coordination around the rhodium

Scheme 2. Synthesis of complex **2**



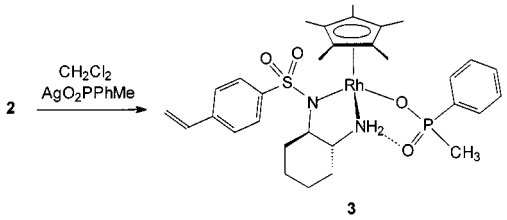


Figure 2. Structure of one enantiomer[12] of **2** in the crystal; selected bond length [Å] and angles [°]: Rh(1)−Cl(1) 2.416(2), Rh(1)−N(1) 2.152(4), Rh(1)−N(2) 2.120(4); N(2)−Rh(1)−N(1) 79.0(2), N(2)−Rh(1)−Cl(1) 82.23(13), N(1)−Rh(1)−Cl(1) 89.65(12)

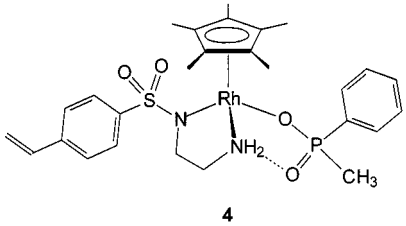


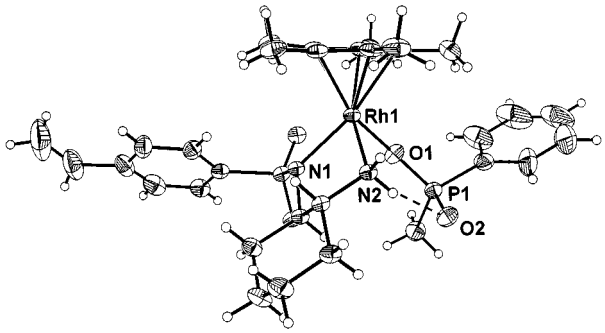
atom can be described as distorted octahedral with a bidentate, monoanionic amine ligand. The structure is similar to that found for the Cp*Rh complex **A**.[10a] Importantly, they have the same relative configuration of the rhodium atom with respect to the chiral ligand. The same relative configuration is also observed for structurally related (arene)Ru^{II} complexes.[13]

Substitution of the chloro ligand with the pseudosubstrate − the phosphinato ligand − is achieved by reaction of **2** with silver methylphenylphosphinate (Scheme 3). The resulting complex **3** has four stereogenic centres: the two carbon atoms of the amine ligand, the rhodium atom and the phosphorous atom. Four stereoisomers, which should be distinguishable by NMR spectroscopy, are thus expected. Again, however, the NMR spectra show only one set of signals ($CDCl_3$). This points to the fact that the configuration of the metal atom, as well as that of the phosphorous atom is controlled by the ligand, meaning that the chiral information is transferred with high efficiency from the ligand to the metal atom and the pseudosubstrate.

Scheme 3. Synthesis of complex **3**

It is important to note that the free phosphinato ligand is optically inactive. To determine the configurational stability of the phosphinato ligand coordinated to the rhodium atom we have synthesised complex **4** which bears an achiral chelate ligand. NMR experiments with this complex have shown that the configurational stability of the phosphinato ligand in **4** is very low. Most likely, the same is true for complex **3**.

The result of a single crystal analysis of racemic[12] **3** is shown in Figure 3. As is the case for compound **2**, the metal atom in **3** has the opposite configuration to that of the ligand. The coordination of the phosphinato ligand corresponds exactly to the postulated transition state: a monodentate coordination to the rhodium atom and a hydrogen bond to the adjacent amine group is observed. Based on quantum chemical calculations about the transition state of related (arene)Ru(aminoalcoholate) complexes Andersson et al. have predicted a strong preference for an almost planar H−Ru−N−H unit, with an energetic minimum obtained for H−Ru−N−H = 10°.[11a] Remarkably, this is exactly the value found for the corresponding angle in com-



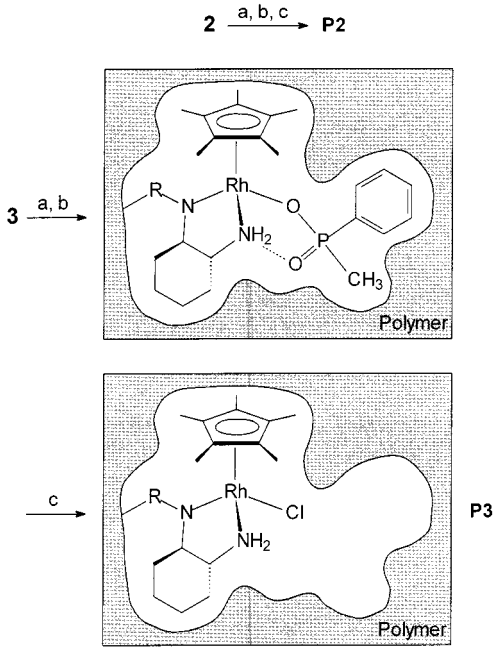


Figure 3. Structure of one enantiomer[12] of **3** in the crystal; selected bond length [Å] and angles [°]: Rh(1)−O(1) 2.131(2), Rh(1)−N(1) 2.142(4), Rh(1)−N(2) 2.120(4), P(1)−O(2) 1.489(3), P(1)−O(1) 1.504(3); N(2)−Rh(1)−N(1) 78.52(12), N(2)−Rh(1)−O(1) 88.59(12), N(1)−Rh(1)−O(1) 86.83(12)

plex **3** in the crystal (O1−Rh1−N2−H = 9.9°). From experiments with the homogeneous catalyst **A** it was observed that the reduction of acetophenone gives *R*-1-phenylethanol with high selectivity.[10a] For the transition structure a *syn*-configuration of the aryl group of the phosphinato ligand and the Cp* ring is therefore predicted. And indeed, this is the geometry which is observed for **3**. These results confirm that **3** is an excellent analogue for the transition state of the asymmetric reduction of acetophenone.

Immobilisation of the catalyst precursors **2** and **3** was achieved by co-polymerisation with ethylene glycol dimethacrylate (EGDMA) in the presence of a porogen ($CHCl_3$/MeOH, 4:1). The combination of EGDMA and $CHCl_3$ has previously been shown to be well suited for imprinting studies.[6,14] 2,2′-Azobis(4-methoxy-2,4-dimethylvaleronitrile) (V-70) was employed as the thermal initiator. The polymers **P2** and **P3** were ground and sieved to obtain a uniform particle size (25−100 μm). The orange powders were subsequently stirred in a solution of benzyltriethylammonium chloride in methanol (0.1 M), a procedure which selectively cleaves off the phosphinato ligand.[15] Therefore, both polymers have an almost identical chemical composition. Contrary to polymer **P2**, the molecularly imprinted polymer (MIP) **P3** has shape-selective cavities in proximity to the catalytically active centre of the rhodium complexes (Scheme 4).

To test the activity and enantioselectivity of the polymeric catalysts **P2** and **P3** we investigated the reduction of acetophenone with 2-propanol in the presence of KOH. For reactions with 1 mol-% **P2** after 6 h (*R*)-1-phenylethanol was obtained with 93% *ee* in 41% yield (Table 1). In the presence of the imprinted polymer **P3** the yield was increased to 81% with an optical purity of 95% *ee*. A similar increase in activity (the initial turnover frequencies differ by more than a factor of two) and selectivity (Δee = 2−8%) was observed for sterically related monohalogenated substrates. A significant difference in the enantioselectivity (Δee = 9%) was also detected in reactions with the more bulky substrate 1-acetonaphthone. These results show that the cavity generated by molecular imprinting has a pronounced effect on the activity of the immobilised catalyst. Furthermore, the expected decrease in selectivity of the heterogeneous catalyst **P2** as compared to the homogeneous version **A** is nearly abolished with the MIP catalyst **P3**. The increased enantioselectivity of **P3** (Δee = 2−9%) is most likely the result of additional space around the catalytically active rhodium complexes. The contribution of chiral cavities is less probable due to the low configurational stability of the pseudosubstrate. Overall, the imprinted catalyst **P3** displays an activity and selectivity which can compete with the homogeneous catalyst **A**[10] and which is higher than the values obtained with other homogeneous Cp*Rh catalysts.[10b,16] Compared to supported catalysts for the transfer hydrogenation of acetophenone, **P3** occupies a top position.[8a,17,18]

Scheme 4. Synthesis of the control polymer **P2** and the imprinted polymer **P3**: a) EGDMA, $CHCl_3$/CH_3OH, V-70, 24 h, 35 °C; b) 4 h, 65 °C; c) $[NEt_4]Cl$, CH_3OH

Table 1. Transfer hydrogenation of aromatic ketones in the presence of the imprinted catalyst **P3** and the control catalyst **P2**

Catalyst	Ketone	Time [h]	Yield [%]	*ee* [%][a]
P3 (**P2**)	Acetophenone	6	81 (41)	95 (93)
P3 (**P2**)	*p*-Fluoroacetophenone	6	71 (36)	93 (90)
P3 (**P2**)	*o*-Fluoroacetophenone	6	85 (52)	84 (76)
P3 (**P2**)	*m*-Fluoroacetophenone	3	98 (75)	94 (92)
P3 (**P2**)	*m*-Chloroacetophenone	3	98 (69)	94 (92)
P3 (**P2**)	1-Acetonaphthone	6	52 (24)	83 (74)

[a] In all cases the main isomer has the configuration *R*.

The substrate specificity was determined in competition experiments. The kinetics of the reduction of a mixture of acetophenone and a second substrate in the presence of **P2** or **P3** was investigated (ketone1/ketone2/catalyst = 50:50:1). Aliphatic and aromatic ketones, which differ in size and reactivity, were chosen as co-substrates. A comparison of the initial reaction rates revealed that in *all* cases the imprinted polymer **P3** displays a higher selectivity for

Table 2. Substrate selectivity of the polymeric catalysts **P2** and **P3**

Co-substrate	Selectivity[a] P3	Selectivity[a] P2
Cyclohexanone	$3.8\ 10^{-1}$	$3.1\ 10^{-1}$
2-Adamantanone	1.4	1.1
Benzophenone	$1.4\ 10^{1}$	8.9
α-Tetralone	4.2	3.7
2-Acetylnaphthalene	$8.9\ 10^{-1}$	$7.7\ 10^{-1}$

[a] The selectivity is calculated by dividing the initial rate of 1-phenylethanol formation by the initial rate of product formation for the reduction of the co-substrate.

acetophenone than the control polymer **P2** (Table 2), although the substrate selectivity is lower than that found for the immobilised ruthenium complexes previously described.[6] In accordance with the molecular structure determined for **3**, these kinetic studies prove that the methylphenylphosphinato ligand represents an excellent pseudosubstrate for acetophenone and leaves a *specific* and *shape-selective* imprint in the polymeric matrix.

Conclusions

We have shown that heterogeneous catalysts for the asymmetric transfer hydrogenation of aromatic ketones are available by immobilisation of the chiral rhodium complexes **2** and **3**, both of which were structurally characterised. The microenvironment of the polymeric catalyst **P3** was modified in a controlled fashion by molecular imprinting with the organometallic TSA **3**. As a result an enhanced activity combined with an excellent enantioselectivity was observed for the reduction of acetophenone and related substrates. Kinetic experiments have revealed that the cavity generated by imprinting is specific for acetophenone.

The concept presented in this paper for the construction of shape selective cavities in proximity to the catalytically active centre of organometallic catalysts is very simple and flexible. The results prove that this method is suitable for generating heterogeneous catalysts with a superior performance in asymmetric reactions even when optically inactive pseudosubstrates are employed. It appears likely that this methodology is applicable to other catalysts and reactions. Research along these lines may ultimately lead to tailor-made organometallic catalysts with enzyme-like characteristics.

Experimental Section

General: The synthesis of all complexes as well as the transfer hydrogenation was performed under an atmosphere of dry nitrogen, using standard Schlenk techniques. Solvents were freshly distilled over an appropriate drying agent and stored under nitrogen prior to usage. EGDMA was washed with NaOH (1 M) and saturated NaCl solution and dried with Na_2SO_4. After filtration the monomer was distilled under reduced pressure. The azo initiator V-70 was obtained from Wako Chemicals. AgO_2PPhMe was obtained as a white precipitate by reaction of KO_2PPhMe with $AgNO_3$. The synthesis of $[Cp^*Rh(NH_2CH_2CH_2NSO_2C_8H_7)Cl]$ was carried out analogously to that of **2** using the achiral ligand $NH_2CH_2CH_2NHSO_2C_8H_7$.[6b] 4-Vinyl-benzenesulfonyl chloride[18] and $[Cp^*RhCl_2]_2$[19] were prepared according to literature procedures. The ^1H, ^{13}C and ^{31}P NMR spectra were recorded on a JEOL EX 400 or a GSX 270 spectrometer with the solvent as the internal standard. All spectra were recorded at room temperature; exceptions are indicated. The GC analysis was performed with a Varian 3800 spectrometer using a CP-Cyclodextrin-B-2,3,6-M-19 column (50 m).

Synthesis of Ligand 1: A solution of *p*-styrylsulfonyl chloride (816 μL) in CH_2Cl_2 (30 mL) was added slowly (1 h) to a solution of (*R*,*R*)-1,2-diaminocyclohexane (1.84 g, 16.1 mmol) in CH_2Cl_2 (20 mL) at 0 °C. The mixture was warmed to room temperature, filtered and the solvent was removed under reduced pressure. The product was purified by flash chromatography with EtOAc/MeOH (3:2) and crystallised from CH_2Cl_2/hexane. Yield: 730 mg (16%, referred to the amine), m.p. 105−107 °C. − ^1H NMR (270 MHz, $CDCl_3$): δ = 1.04−1.26 (m, 4 H, CH_2), 1.57−1.95 (m, 4 H, CH_2), 2.37−2.46 (m, 1 H, CHN), 2.63−2.72 (m, 1 H, CHN), 3.04 (s, br, 3 H, NH_2, NH), 5.41 (d, ^3J = 11 Hz, 1 H, CH=CH_2), 5.87 (d, ^3J = 18 Hz, 1 H, CH=CH_2), 6.73 (dd, ^3J = 11 Hz, ^3J = 18 Hz, 1 H, CH=CH_2), 7.51 (d, ^3J = 8 Hz, 1 H, C_6H_4), 7.85 (d, ^3J = 8 Hz, 1 H, C_6H_4). − ^{13}C NMR (68 MHz, $CDCl_3$):δ = 24.8, 25.0, 32.7, 35.5 (CH_2), 54.8, 60.3 (NCH), 117.3, 126.8, 127.5, 135.5, 139.9, 141.7 (C_6H_4−CH=CH_2). − $C_{14}H_{20}N_2O_2S\cdot 1/3H_2O$ (286.39): calcd. C 58.72, H 7.27, N 9.78; found C 58.91, H 7.67, N 9.70.

Synthesis of Complex 2: A solution of (1*R*,2*R*)-*N*-(*p*-styrylsulfonyl)-1,2-diaminocyclohexane (280 mg, 1.0 mmol) and NaOMe (1.0 mmol, 2.37 M in MeOH) in CH_2Cl_2/MeOH (20 mL, 1:1) was added slowly to a solution of $[Cp^*RhCl_2]_2$ (309 mg, 0.5 mmol) in CH_2Cl_2 (20 mL). After stirring for 2 h the solvent was removed under reduced pressure and the product was extracted with CH_2Cl_2 (30 mL). After addition of hexane (20 mL) the solvent was removed under reduced pressure to give a yellow powder which was dried in vacuo. Yield: 451 mg (79%), m.p. 225−227 °C (dec.). − ^1H NMR (270 MHz, $CDCl_3$): δ = 0.81−1.98 (m, 7 H, CH_2), 1.74 (s, 15 H, Cp*), 2.23−2.30 (m, 3 H, NCH, CH_2), 2.99−3.02 (m, 1 H, NH), 3.38−3.42 (m, 1 H, NH), 5.27 (d, ^3J = 11 Hz, 1 H, CH=CH_2), 5.77 (d, ^3J = 18 Hz, 1 H, CH=CH_2), 6.70 (dd, ^3J = 11 Hz, ^3J = 18 Hz, 1 H, CH=CH_2), 7.39 (d, ^3J = 8 Hz, 2 H, C_6H_4), 8.02 (d, ^3J = 8 Hz, 2 H, C_6H_4). − ^{13}C NMR (101 MHz, $CDCl_3$): δ = 9.7 (CH_3, Cp*), 24.6, 24.9, 34.6, 36.3 (CH_2), 63.5, 64.4 (NCH), 94.0 (d, $^1J_{RhC}$ = 8 Hz, C, Cp*) 115.1, 125.9, 128.3, 136.4, 139.0, 145.4 (C_6H_4−CH=CH_2). − $C_{24}H_{34}ClN_2O_2RhS\cdot H_2O$ (570.97): calcd. C 50.49, H 6.36, N 4.91; found C 50.77, H 6.09, N 4.82.

Synthesis of Complex 3: A suspension of **2** (111 mg, 0.20 mmol) and AgO_2PPhMe (58 mg, 0.22 mmol) in CH_2Cl_2 (10 mL) was stirred for 96 h at room temperature. The solid products were removed by filtration and the solvent was reduced to a volume of 2 mL. After addition of hexane the solvent was removed in vacuo to give an orange powder which was dried in vacuo. Yield: 119 mg (86%), m.p. 148−150 °C (dec.). − ^1H NMR (270 MHz, $CDCl_3$): δ = 0.61−1.57 (m, 6 H, CH_2), 1.33 (d, $^2J_{PH}$ = 14 Hz, 3 H, PCH_3), 1.48 (s, 15 H, Cp*), 1.84−2.07 (m, 3 H, NCH, CH_2), 2.29−2.37 (m, 1 H, NCH), 5.20 (d, ^3J = 11 Hz, 1 H, CH=CH_2), 5.68 (d, ^3J = 17 Hz, 1 H, CH=CH_2), 6.60 (dd, ^3J = 11 Hz, ^3J = 17 Hz, 1 H, CH=CH_2), 7.26−7.30 (m, 5 H, PPh, C_6H_4), 7.66−7.77 (m, 4 H, PPh, C_6H_4). − ^{13}C NMR (101 MHz, $CDCl_3$): δ = 9.5 (CH_3, Cp*), 18.8 (d, $^1J_{PC}$ = 99 Hz, PCH_3), 24.4, 24.6, 33.9, 35.0 (CH_2), 63.3, 63.8 (NCH), 93.7 (d, $^1J_{RhC}$ = 9 Hz, C, Cp*) 115.5, 125.9,

Synthesis of Polymer P2: A freshly prepared mixture of V-70 (15 mg) and EGDMA (4.95 mmol) was added to a solution of **2** (50 μmol) in $CHCl_3$/MeOH (467 μL, 4:1) in a 4 mL screw-cap vial. The orange solution was sonicated (1 min) and degassed with nitrogen (2 min). The vial was closed and tempered at 35 °C (24 h) and then at 65 °C (3 h). The obtained polymer was ground, sieved (particle size: 25−100 μm) and stirred in a solution of benzyltriethylammonium chloride in MeOH (0.1 M). The polymer was isolated, washed with MeOH (4 × 40 mL) and dried in vacuo. The synthesis of the polymer **P3** was performed analogously to that of **P2** using complex **3** (50 μmol).

X-ray Crystallographic Investigations: An Enraf Nonius CAD 4 diffractometer was employed for data collection using Mo-K_α radiation (T = 295 K). The structures were solved by direct methods (SHELXS86) and were refined by means of the full-matrix least-squares procedures using SHELXL93 (Table 3). All non-hydrogen atoms were refined anisotropically. For the hydrogen atoms a riding model was employed. The styryl groups of **2** is disordered. Restraints were used for parts of the aromatic ring. Compound **3** crystallizes together with 0.5 molecules of dichloromethane. The solvent molecules are disordered and restraints were used for the refinement.

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-136894 (**2**) and CCDC-136895 (**3**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Transfer Hydrogenations: A suspension of **P2** (20.2 mg, this corresponds to 1.0 μmol Rh if a quantitative incorporation is assumed) in 2-propanol containing 1.2 μmol KOH were stirred for 15 min at 33 °C. The reaction was started by addition of the substrate in 2-propanol. The initial concentration of the substrate was 0.1 M (0.5 M for competition experiments) with a total volume of 1 mL. Samples were removed at the times indicated, quenched with 2-propanol/EtOAc (3:1), filtered and analysed by capillary GC (CP-cyclodextrin-B-2,3,6-M-19 column by Chrompack, 50 m). For competition experiments the course of the reaction was analysed for the first 12 min. Reactions with the imprinted polymer **P3** were performed simultaneously and under identical conditions.

Reactivity of the Anionic Carbonyltrirhenium Cluster $[Re_3(\mu\text{-}H)_3(\mu_3\text{-}ampy)(CO)_9]^-$ − Synthesis of Neutral Phosphane and Alkenyl Derivatives

Javier A. Cabeza,*[a] Fabrizia Grepioni,*[b] Angela Llamazares,[a] Víctor Riera,[a] and Rajiv Trivedi[a]

Keywords: Rhenium / Cluster compounds / Hydrido complexes / Phosphanes / Alkynes / Insertions

Protonation of the trinuclear anionic rhenium cluster $[HNEt_3][Re_3(\mu\text{-}H)_3(\mu_3\text{-}ampy)(CO)_9]$ (**1**) (Hampy = 2-amino-6-methylpyridine) with $[HOEt_2][BF_4]$ at low temperature leads to dihydrogen and the neutral unsaturated dihydride derivative $[Re_3(\mu\text{-}H)_2(\mu_3\text{-}ampy)(CO)_9]$. The low thermal stability of this compound (it undergoes decomposition above 5 °C) has prevented its isolation as a pure solid. The compound $[Re_3(\mu\text{-}H)_3(CO)_{12}]$ is the major product obtained when the protonation of **1** is carried out under CO. Protonation of **1** in the presence of phosphanes or alkynes gives the neutral derivatives $[Re_3(\mu\text{-}H)_2(\mu_3\text{-}ampy)(PR_3)(CO)_9]$ (**2**: R = Ph; **3**: R = *p*-tolyl) or $[Re_3(\mu_3\text{-}H)(\mu_3\text{-}ampy)(\mu\text{-}RC{=}CHR')(CO)_9]$ (**4**: R = R′ = Ph; **5**: R = R′ =Et; **6a**: R = Ph, R′ = H; **6b**: R = H, R′ = Ph). In **2** and **3**, the phosphane ligand is in an equatorial position on an Re atom of the NH-bridged Re–Re edge, *cis* to a hydride ligand and far away from the other hydride ion. In compounds **4**–**6**, the alkenyl ligand, which arises from the insertion of the corresponding alkyne into an Re–H bond, is attached to two metal atoms in a $\mu\text{-}\eta^1{:}\eta^2$ fashion, spanning the same Re–Re edge as the NH fragment of the ampy ligand. The hydride ligand of compounds **4**–**6** coordinates in a triply bridging fashion, capping the Re_3 triangle. Compounds **4**–**6** represent the first examples of trirhenium clusters containing alkenyl ligands.

Introduction

Until now, few carbonyl cluster compounds (three or more metal atoms connected by metal−metal bonds) of rhenium are known,[1] in comparison to those known for ruthenium and osmium.[2] This is undoubtedly due to the lack of a convenient rhenium cluster precursor. In fact, with few exceptions,[3] the cluster compounds made from $[Re_2(CO)_{10}]$, the most readily available carbonylrhenium complex, can only be isolated in medium to low yield.[4−6] For example, $[Re_3(\mu\text{-}H)_3(CO)_{12}]$, which is isoelectronic with the most important ruthenium and osmium starting clusters $[M_3(CO)_{12}]$ (M = Ru, Os), is prepared from $[Re_2(CO)_{10}]$ either by hydrogenation[4a] or treatment with $Na[BH_4]$ followed by acidification,[5d,5e] but both procedures are rather tedious and the yields are only moderate. Moreover, $[Re_3(\mu\text{-}H)_3(CO)_{12}]$ is kinetically very stable and most of its reactions require high temperatures (which promote changes in cluster and/or ligand integrity, often leading to mixtures of products)[1] or derivatization to the more reactive $[Re_3(\mu\text{-}H)_3(CO)_{10}(MeCN)_2]$.[7] Ciani, D'Alfonso and co-workers have extensively studied the derivative chemistry of the anionic unsaturated cluster $[Re_3(\mu\text{-}H)_4(CO)_{10}]^-$,[1] but its best preparation requires a high pressure hydrogenation (100 atm) of $[Re_3(\mu\text{-}H)_2(CO)_{12}]^-$,[8] which is made by deprotonation of $[Re_3(\mu\text{-}H)_3(CO)_{12}]$.[9] In addition, the unsaturated cluster $[Re_4(\mu_3\text{-}H)_4(CO)_{12}]$, which can be made by hydrogenation of $[Re_2(CO)_{10}]$,[4a] is so reactive that its reactions are generally not very selective, often leading to mixtures of many products.[10]

We have recently reported that the anionic carbonyltrirhenium cluster $[HNEt_3][Re_3(\mu\text{-}H)_3(\mu_3\text{-}ampy)(CO)_9]$ (**1**) (Hampy = 2-amino-6-methylpyridine) can be prepared in fair yield (70%) from $[Re_4(\mu_3\text{-}H)_4(CO)_{12}]$, Hampy and triethylamine.[10] It should be noted that in carbonylruthenium cluster compounds, as for example $[Ru_3(\mu\text{-}H)(\mu_3\text{-}ampy)(CO)_9]$,[11] face-bridging 2-aminopyridinato ligands help maintain the cluster integrity and provide reaction pathways of low activation energy.[12] In fact, over a hundred carbonylruthenium clusters containing μ_3-2-aminopyridinato ligands have already been prepared,[2a] including some efficient catalyst precursors for alkyne hydrogenation,[13] dimerization[14] and polymerization[14] reactions.

All the above-mentioned data prompted us to study the reactivity of compound **1**. We have already investigated the synthesis of tetranuclear Re_3Au clusters by reactions of **1** with gold complexes.[15] We now report its protonation reaction as well as the preparation of some neutral phosphane and alkenyl derivatives. The latter represent the first examples of trirhenium clusters containing alkenyl ligands.

Results and Discussion

Protonation Reaction of Compound 1

Compound **1** was found to be very stable toward nucleophilic reagents. No reaction was observed when **1** was

treated with phosphane, nitrile or alkyne reagents in THF at reflux temperature. Its anionic character and the fact that it is a saturated 48-electron trinuclear cluster may account (at least in part) for its stability toward nucleophilic reagents.

Interestingly, an instantaneous reaction was observed when compound **1** was treated with $[HOEt_2][BF_4]$: The color changed from colorless to yellow, a gas was evolved and drastic changes were observed in the IR spectrum of the solution. Unfortunately, no pure products could be isolated from this reaction, regardless of the solvent (THF, dichloromethane, acetonitrile) and the ratio of the reactants.

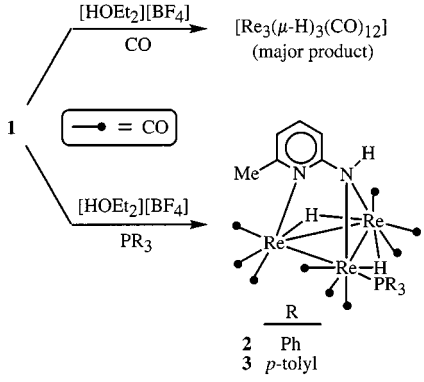
In order to obtain some insight of this reaction, the protonation was subsequently monitored by ^1H NMR spectroscopy at low temperature. A single product was observed upon mixing the reagents in CD_2Cl_2 at −78 °C, characterized by two uncoupled hydride resonances of equal intensity at $\delta = -7.85$ and -8.53, in addition to a set of resonances due to the ampy ligand. This compound remained unchanged upon warming the solution to 5 °C but, unfortunately, it decomposed to other products above this temperature.

These data suggest that the protonation of compound **1** results in the release of dihydrogen and in the formation of the neutral species $[Re_3(\mu\text{-}H)_2(\mu_3\text{-ampy})(CO)_9]$. The asymmetric structure proposed for this species in Scheme 1 is in agreement with the observation of two hydride resonances in the ^1H NMR spectrum. Its coordinative unsaturation (46-electron) may be responsible for its low thermal stability. Although the use of coordinating solvents (THF, acetonitrile) did not lead to the isolation of solvated derivatives as pure products, some phosphane and alkyne derivatives could be isolated carrying out the protonation in the presence of the appropriate ligands (vide infra). The structures of these derivatives are also in agreement with that proposed for $[Re_3(\mu\text{-}H)_2(\mu_3\text{-ampy})(CO)_9]$ in Scheme 1.

Treatment of a solution of compound **1** in dichloromethane with $[HOEt_2][BF_4]$ under carbon monoxide led to a transient color change of the initial colorless solution to pale yellow, but it returned to colorless within a few seconds. An appropriate workup of this solution allowed the isolation of $[Re_3(\mu\text{-}H)_3(CO)_{12}]$ as the major carbonyl complex of the reaction mixture. This result, which may seem of little relevance, is indeed quite interesting, since it reveals that in carbonylrhenium cluster chemistry the triply bridging ampy ligand can be removed under mild conditions and, therefore, it should not be expected to maintain the trinuclear cluster integrity as efficiently as it does in ruthenium cluster chemistry.[11−14]

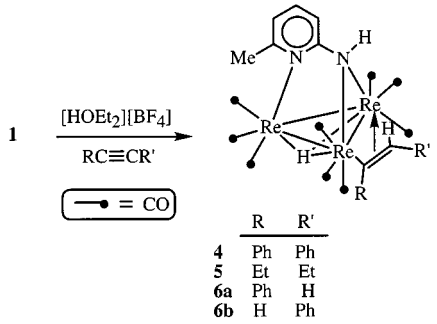
1

Scheme 1. Protonation of compound **1**



Neutral Phosphane Derivatives of Compound 1

Protonation of a dichloromethane solution of complex **1** with $[HOEt_2][BF_4]$ in the presence of triphenylphosphane (1:1:1 mol ratio) led to the immediate formation of the yellow neutral derivative $[Re_3(\mu\text{-}H)_2(\mu_3\text{-ampy})(PPh_3)(CO)_9]$ (**2**). Its formulation was clearly evidenced by its microanalysis and spectroscopic data. Its ^1H NMR spectra shows two hydride resonances, one as a doublet of doublets ($\delta = -9.50$, $J = 12.3$ and 1.6 Hz) and the other as a small doublet ($\delta = -9.92$, $J = 1.6$ Hz), indicating that the compound has two hydride ligands which couple slightly to each other (1.6 Hz) and that only one of them couples to the phosphorus atom ($J = 12.3$ Hz). As this J_{P-H} coupling value is typical of a *cis* arrangement of hydride and phosphane ligands in trinuclear metal clusters,[16] and as no coupling is observed between the other hydride ion and the phosphorus atom, we propose the structure depicted in Scheme 2 for this complex. No crystals of compound **2** suitable for an X-ray diffraction study could be obtained.



As the structure proposed for compound **2**, although reasonable, is not unambiguous, we decided to prepare an analogous derivative, containing a different phosphane ligand, in an attempt to obtain X-ray diffraction-quality crystals. The compound $[Re_3(\mu\text{-}H)_2(\mu_3\text{-ampy})\{P(p\text{-tolyl})_3\}(CO)_9]$ (**3**) was made by a similar procedure as that used for **2**. Its analytical and spectroscopic data indicate that it is isostructural with complex **2**, but, unfortunately, it could not be crystallized.

It seems clear that compounds **2** and **3** are formed upon coordination of the corresponding phosphane to the unsaturated species that results when complex **1** is protonated and dihydrogen is released.

The number of previously described phosphane derivatives of trirhenium clusters is very small, and most of them are simple phosphane-substituted derivatives of carbonyl hydrido clusters.[1,17] The anionic formimidoyl complex $[Re_3(\mu\text{-}H)_3(\mu\text{-}CH{=}NC_6H_{11})(PMe_2Ph)(CO)_9]^-$ is the only previous example of a trirhenium cluster containing both N-donor and P-donor ligands.[18]

Neutral Alkenyl Derivatives of Compound 1

Protonation of compound **1** with $[HOEt_2][BF_4]$ in the presence of diphenylacetylene, 3-hexyne or phenylacetylene led to the neutral alkenyl derivatives $[Re_3(\mu_3\text{-}H)(\mu_3\text{-ampy})(\mu\text{-RC=CHR}')(CO)_9]$ (**4**: R = R′ = Ph; **5**: R = R′ = Et; **6a**: R = Ph, R′ = H; **6b**: R = H, R = Ph) (Scheme 3). Compounds **4** and **5** were obtained as pure products, but the isomeric compounds **6a** and **6b** were obtained as an inseparable mixture. These results suggest that the reaction is quite general since it works well for internal, terminal, aryl- and alkylalkynes, giving a mixture of two isomers when the alkyne used is not symmetric. In these compounds, the alkenyl ligands arise from the coordination of the corresponding alkyne to the unsaturated species formed by protonation of compound **1**, followed by a migratory insertion of the alkyne into a Re−H bond.

The compounds were characterized by analytical and spectroscopic methods. All have similar IR and NMR spectra, indicating that they have a common structure. The most relevant features of their ^1H NMR spectra are (a) the presence of a resonance due to the vinyl hydrogen atom in the range δ = 6−3, as observed for many complexes of other metals containing bridging alkenyl ligands,[13,14] and (b) the observation of only one hydride resonance as a small doublet (J = 3.0 Hz in all cases except for **6b**, which was observed as a singlet). Decoupling experiments revealed that such a doublet arises from the coupling of the hydride with the hydrogen atom of the NH fragment of the ampy ligand (which is observed as a broad singlet in the ^1H NMR spectrum at room temperature). The fact that the hydride ligand signal of **6b** is observed as a singlet suggests that its structure may differ from that of the other alkenyl derivatives, but we have been unable to investigate this matter further because compounds **6a** and **6b** were always obtained as a mixture.

The analytical and spectroscopic data of these alkenyl derivatives were not sufficient to unequivocally assign the positions of the hydride and alkenyl ligands in the clusters. Therefore, an X-ray diffraction study was required. None of the compounds crystallized well, nonetheless, in the case of compound **4**, we managed to obtain crystals of sufficient quality for the diffraction experiment. The molecular structure of compound **4** is shown in Figure 1, together with the labeling scheme and selected bond length parameters. The ampy ligand coordinates to the Re_3 triangle in a capping mode, previously observed in many trinuclear clusters.[10−16] The alkenyl ligand spans the same Re−Re edge as the amido fragment of the ampy ligand. The carbonyl ligands are bound to the cluster in a terminal fashion, three to each Re atom. Although the hydride location could not be directly obtained from the diffraction data, calculations with the program XHYDEX[19] revealed a minimum energy position for the hydride ligand in a triply bridging site, capping the metal triangle as shown in Figure 1 and Scheme 3. Triply bridging hydrides are frequently observed in carbonylrhenium clusters.[1]

The reactions leading to compounds **4**−**6** can be regarded as pioneering processes in the so far unreported field of the reactivity of carbonyltrirhenium clusters with unsaturated hydrocarbons. In fact, compounds **4**−**6** are the first examples of trirhenium clusters containing alkenyl ligands.

Experimental Section

General: Solvents were dried with sodium diphenyl ketyl (hydrocarbons) or calcium hydride (dichloromethane) and distilled under nitrogen prior to use. The reactions were carried out under nitrogen, using Schlenk vacuum-line techniques, and were routinely monitored by solution IR spectroscopy (carbonyl stretching region) and by spot TLC (silica gel). − Compound **1** was prepared by a published procedure,[10] all other reagents were purchased as analytically pure samples. − IR spectra were recorded with a Perkin−Elmer FT 1720-X spectrophotometer, using 0.1-mm CaF_2 cells. − ^1H and $^{31}P\{^1H\}$ NMR spectra were run at room temperature with Bruker AC-200 and AC-300 instruments, being referenced to internal $SiMe_4$ (for ^1H: δ = 0) or external aqueous 85% H_3PO_4 (for ^{31}P: δ = 0). − Microanalyses were obtained from the University of Oviedo Analytical Service.

Protonation of Compound 1: A 5-mm NMR tube was charged under nitrogen with compound **1** (0.012 g) and CD_2Cl_2 (0.5 mL) and immersed in a bath kept at −78 °C. Addition of $[HOEt_2][BF_4]$ (2 μL) to the cold solution led to a color change from colorless to yellow. The tube was quickly transferred to the NMR probe, previously cooled at −80 °C. The resonances of a pure product were observed at δ = −8.53 (s, 1 H, μ-H), −7.85 (s, 1 H, μ-H), 2.78 (s, 3 H, ampy-Me), 6.44 (s, br, 1 H, ampy-N*H*), 6.76 (d, 7.6 Hz, 1 H, ampy-C*H*), 6.87 (d, 7.6 Hz, 1 H, ampy-C*H*), 7.50 (t, 7.6 Hz, 1 H, ampy-C*H*) ppm. This product could not be isolated.

Protonation of Compound 1 under Carbon Monoxide: A solution of compound **1** (0.025 g, 0.024 mmol) in dichloromethane (10 mL) was treated with $[HOEt_2][BF_4]$ (3.5 μL, 0.025 mmol) while the solution was kept under carbon monoxide. The initially colorless solution changed to pale yellow upon addition of the acid, but it soon returned to colorless. After being stirred for 3 h, the IR spectrum of the solution showed the presence of $[Re_3(\mu\text{-}H)_3(CO)_{12}]$. The solvent was removed under reduced pressure and the residue was extracted into hexane (3 × 5 mL). The extract was concentrated to dryness to give a colorless solid which was found to be $[Re_3(\mu\text{-}H)_3(CO)_{12}]$ (IR, ^{1}H NMR). The fraction insoluble in hexane contained $[HNEt_3][BF_4]$ and Hampy among other minor products (IR, ^{1}H NMR).

$[Re_3(\mu\text{-}H)_2(\mu_3\text{-ampy})(PPh_3)(CO)_9]$ (2): $[HOEt_2][BF_4]$ (3 μL, 0.021 mmol) was added to a dichloromethane solution (10 mL) of compound **1** (0.023 g, 0.022 mmol) and PPh_3 (0.006 g, 0.023 mmol). The color changed from colorless to yellow. The solution was stirred for 2 h and concentrated to dryness. The solid residue was extracted with toluene (3 × 5 mL). The extract was concentrated to dryness and the residue was crystallized from dichloromethane/hexane to give compound **2** as a yellow solid (0.015 g, 58%). − $C_{33}H_{24}N_2O_9PRe_3$ (1182.16): calcd. C 33.53, H 2.05, N 3.37; found C 33.64, H 2.13, N 3.16. − IR (CH_2Cl_2): $\tilde{\nu}$ = 2049 (m), 2017 (vs), 1949 (m), 1938 (m), 1923 (m) cm^{-1}. − ^{1}H NMR ($CDCl_3$): δ = −9.92 (d, *J* = 1.6 Hz, 1 H, μ-H), −9.50 (dd, 12.3 and 1.6 Hz, 1 H, μ-H) 2.59 (s, 3 H, ampy-Me), 4.88 (s, br, 1 H, ampy-N*H*), 5.59 (d, *J* = 7.7 Hz, 1 H, ampy-C*H*), 6.51 (d, *J* = 7.7 Hz, 1 H, ampy-C*H*), 6.87 (t, *J* = 7.7 Hz, 1 H, ampy-C*H*), 7.5−7.1 (m, 15 H, 3 Ph). − ^{31}P{^{1}H} NMR ($CDCl_3$): δ = 1.4 (s).

$[Re_3(\mu\text{-}H)_2(\mu_3\text{-ampy})\{P(p\text{-tolyl})_3\}(CO)_9]$ (3): This compound was prepared as described above for compound **2**. Reagents: **1** (0.021 g, 0.020 mmol), P(*p*-tolyl)$_3$ (0.007 g, 0.022 mmol), $[HOEt_2][BF_4]$ (3 μL, 0.021 mmol). Yellow solid (0.014 g, 57%). − $C_{36}H_{30}N_2O_9PRe_3$ (1224.24): calcd. C 35.32, H 2.47, N 2.29; found C 35.54, H 2.66, N 2.12. − IR (CH_2Cl_2): $\tilde{\nu}$ = 2049 (m), 2017 (vs), 1949 (m), 1940 (m), 1919 (m) cm^{-1}. − ^{1}H NMR ($CDCl_3$): δ = −9.93 (d, *J* = 1.3 Hz, 1 H, μ-H), −9.50 (dd, *J* = 11.0 and 1.3 Hz, 1 H, μ-H), 2.40 (s, 9 H, 3 Me), 2.57 (s, 3 H, ampy-Me), 4.87 (s, br, 1 H, ampy-N*H*), 5.63 (d, *J* = 7.7 Hz, 1 H, ampy-C*H*), 6.51 (d, *J* = 7.7 Hz, 1 H, ampy-C*H*), 6.86 (t, *J* = 7.7 Hz, 1 H, ampy-C*H*), 7.6−7.2 (m, 12 H, 3 C_6H_4). − ^{31}P{^{1}H} NMR ($CDCl_3$): δ = −0.77 (s).

$[Re_3(\mu_3\text{-}H)(\mu_3\text{-ampy})(\mu\text{-PhC=CHPh})(CO)_9]$ (4): $[HOEt_2][BF_4]$ (5 μL, 0.035 mmol) was added to a dichloromethane solution (10 mL) of compound **1** (0.035 g, 0.034 mmol) and diphenylacetylene (0.007 g, 0.039 mmol). The color changed from colorless to orange. The solution was stirred for 1 h and was concentrated to dryness. The solid residue was extracted with toluene (2 × 5 mL). The extract was concentrated to dryness and the residue was crystallized from dichloromethane/hexane to give compound **4** as an orange solid (0.024 g, 64%). − $C_{29}H_{19}N_2O_9Re_3$ (1098.10): calcd. C 31.72, H 1.74, N 2.55; found C 32.00, H 1.82, N 2.43. − IR (CH_2Cl_2): $\tilde{\nu}$ = 2055 (w), 2027 (vs), 2016 (s), 1956 (m), 1946 (sh), 1924 (sh) cm^{-1}. − ^{1}H NMR ($CDCl_3$): δ = −6.10 (d, *J* = 3.0 Hz, 1 H, μ_3-H), 2.88 (br, 1 H, ampy-N*H*), 3.06 (s, 3 H, ampy-Me), 4.86 (s, 1 H, alkenyl-C*H*), 7.6−6.5 (m, 12 H, 2 Ph + 2 ampy-C*H*).

$[Re_3(\mu_3\text{-}H)(\mu_3\text{-ampy})(\mu\text{-EtC=CHEt})(CO)_9]$ (5): This compound was prepared as described above for compound **4**. Reagents: **1** (0.060 g, 0.059 mmol), 3-hexyne (8 μL, 0.070 mmol), $[HOEt_2][BF_4]$ (9 μL, 0.063 mmol). Orange solid (0.038 g, 64%). − $C_{21}H_{19}N_2O_9Re_3$ (1002.01): calcd. C 25.17, H 1.91, N 2.80; found C 25.20, H 2.01, N 2.72. − IR (CH_2Cl_2): $\tilde{\nu}$ = 2055 (w), 2028 (vs), 2009 (s), 1958 (m), 1937 (sh), 1926 (m) cm^{-1}. − ^{1}H NMR ($CDCl_3$): δ = −8.97 (d, *J* = 3.0 Hz, 1 H, μ_3-H), 1.25 (m, 6 H of 2 Et), 2.30 (m, 2 H of Et), 2.77 (q, *J* = 6.2 Hz, 2 H of Et), 3.07 (s, 3 H, ampy-Me), 4.31 (br, 1 H, ampy-N*H*), 5.68 (t, *J* = 6.1 Hz, 1 H, alkenyl-C*H*), 6.80 (d, *J* = 7.6 Hz, 1 H, ampy-C*H*), 6.87 (d, *J* = 7.6 Hz, 1 H, ampy-C*H*), 7.46 (t, *J* = 7.6 Hz, 1 H, ampy-C*H*).

$[Re_3(\mu_3\text{-}H)(\mu_3\text{-ampy})(\mu\text{-PhC=CH}_2)(CO)_9]$ (6a) and $[Re_3(\mu_3\text{-}H)(\mu_3\text{-ampy})(\mu\text{-HC=CHPh})(CO)_9]$ (6b): These compounds were prepared as a 1:1 mixture, as described above for compound **4**. Reagents: **1** (0.025 g, 0.024 mmol), phenylacetylene (3 μL, 0.026 mmol), $[HOEt_2][BF_4]$ (4 μL, 0.028 mmol). Orange solid (0.012 g, 49%). − $C_{23}H_{15}N_2O_9Re_3$ (1022.01): calcd. C 27.03, H 1.48, N 2.74; found C 27.32, H 1.66, N 2.55. − IR (CH_2Cl_2): $\tilde{\nu}$ = 2056 (w), 2026 (vs), 2017 (s), 1957 (m), 1941 (sh), 1936 (sh) cm^{-1}. − Selected ^{1}H NMR ($CDCl_3$) data for **6a** (extracted from the spectrum of the mixture): δ = −6.36 (d, *J* = 3.0 Hz, 1 H, μ_3-H), 2.06 (s, 1 H, alkenyl-C*H*), 3.06 (s, 1 H, alkenyl-C*H*). − Selected ^{1}H NMR ($CDCl_3$) data for **6b** (extracted from the spectrum of the mixture): δ = −7.69 (s, 1 H, μ_3-H), 4.74 (d, *J* = 5.0 Hz, 1 H, alkenyl-C*H*), 7.19 (d, *J* = 5.0 Hz, 1 H, alkenyl-C*H*).

Crystal Structure of Compound 4: X-ray diffraction data was collected at room temperature with a Nonius CAD-4 diffractometer equipped with a graphite monochromator [λ(Mo-K_α) = 0.71073 Å]. Crystal data and details of measurement: $C_{29}H_{19}N_2O_9Re_3$, *M* = 1098.06, monoclinic $P2_1/n$, *a* = 11.450(4), *b* = 24.150(8), *c* = 12.344(4) Å, β = 116.89(3)°, *V* = 3044(1) Å^3, *Z* = 4, *F*(000) = 2016, D_c = 2.396 g cm^{-3}, μ = 11.954 mm^{-1}, measured refl.s 4218, unique refl.s = 4199, 209 parameters, R_1[on *F*, 2401 $I > 2\sigma(I)$] = 0.0641, R_w(on F^2, all data) = 0.1757, GoF = 0.998. The structure was solved by direct methods followed by difference Fourier syntheses and full-matrix least-squares refinement on F^2, using SHELXL97.[20a] Due to decay of the poorly diffracting crystal, the resulting data set contained a limited number of reflections with sufficient intensity; rigid constraints were applied to the phenyl groups and only rhenium and oxygen atoms were treated anisotropically. Absorption correction was applied by azimuthal scanning of high χ reflections (min.−max. absorption correction 0.67−1.00). H atoms bound to C atoms were added in calculated positions and were refined riding on their respective C atoms. The H atom bound to the N atom was directly located from a Fourier map and was not refined. The position of the hydride H atom was calculated using the program XHYDEX[19] and its coordinates were included in the Fourier calculations but not refined. Visual inspection of space filling diagrams of the molecule also allowed approximate location of the hydride H atom position, since a suitable niche was found in accordance with the calculated position. The program SCHAKAL97[20b] was used for the molecular graphical representation. Crystallographic data (excluding structure factors) for compound **4** have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-140540. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033, E-mail: deposit@ccdc.cam.ac.uk].

Calcium Ions Affect the Exchange Network but not the Structure of a Small Peptide (Melanostatin) in Solution: A ^{1}H and ^{13}C NMR Spectroscopic Study

Elena Gaggelli,*[a] Nicola D'Amelio,[a] Nicola Gaggelli,[a] and Gianni Valensin[a]

Keywords: Calcium / Melanostatin / Peptides / Exchange rates / NMR spectroscopy

The interaction of calcium ions with the peptide hormone melanostatin (Pro–Leu–Gly–NH_2) was investigated by ^{1}H and ^{13}C NMR spectroscopy in [D_6]DMSO containing H_2O (1%). Chemical shifts, spin-lattice relaxation rates, ^{1}H NOESY maps and the temperature coefficients of the amide ^{1}H NMR chemical shifts were measured at increasing concentrations of calcium. A 1:1 complex with the metal coordinated to the carbonyl moieties of Pro and Gly (K_d = 17 ± 2 mM^{-1}) was shown to be the major species in solution, although evidence was also provided for the occurrence of a minor species with the metal bound to the Leu carbonyl and with different stoichiometry. Upon metal complexation, substantial changes in the intrinsic chain flexibility of the peptide and in the exchange rates between water and amide protons were detected.

Introduction

Calcium ions are widely recognized as being central to a complex intra-cellular messenger system that mediates a wide range of biological processes. Binding selectivity, allowance for irregular bond lengths and angles and the diffusion-limited reaction on-rates make calcium a suitable binder for most biomolecules, especially peptides and proteins. The relatively high concentration of calcium in extracellular fluids (close to 1 mM) has prompted investigations of its possible role in mediating interactions of flexible peptides with their macromolecular targets.[1,2] Indeed, calcium was shown to favor the interaction of carnosine with human serum albumin,[1,2] and enhance the stability of the "active" conformation in oxytocin,[3] vasopressin,[3] and bradykinin.[4] Here we show that calcium modifies the rate of exchange of an amide proton in an intrinsically flexible small peptide (melanostatin) through the intervention of the metal hydration-sphere rather than as a consequence of exposure to water of a solvent-shielded proton.

Melanostatin (MIF, melanocyte-stimulating hormone release inhibiting factor), an important tri-peptide hormone (Pro-Leu-Gly−NH_2), was chosen because of the slow exchange rate measured for the Leu-amide proton[5−8] and its biological relevance. MIF, first discovered in rat hypothalamus,[9] is generated by the enzymatic cleavage of oxytocin, and is believed to modulate dopamine-receptors in the central nervous system[10] and to inhibit the release of the melanocyte-stimulating hormone.[11,12]

All NMR spectroscopic experiments were carried out in carefully deoxygenated [$^{2}H_6$]-dimethyl sulfoxide ([D_6]DMSO) containing 555 mM H_2O (1%). This mixture was considered because it mimics critical biochemical functions, which take place away from bulk water, where molecules with hydrophilic moieties retain solvating water.

Results and Discussion

Before the addition of calcium, the NMR spectroscopic features of melanostatin were typical of small flexible peptides showing no intramolecular structuring and motional averaging among different conformations. However, as previously observed,[5−8] the Leu-amide proton was found to exchange slowly with cosolvent water. Beyond the relatively large temperature coefficient of the amide ^{1}H NMR chemical shift (Table 1), a negative cross peak in NOESY and ROESY spectra was detected. While a NOESY negative cross peak may also arise from a true dipolar interaction, the negative sign in the ROESY spectrum demonstrates the occurrence of exchange only. The ratio of the cross peak to the Leu−NH diagonal peak intensity decreases almost linearly with increasing values of the mixing time, t_m (Figure 1). The surprisingly high temperature coefficient had been previously interpreted in terms of a solvent-shielded ("caged") but not hydrogen-bonded amide proton.[5−8] The remaining amide hydrogens display temperature coefficients typical of solvent-exposed protons. However, the negative cross peaks in the NOESY and ROESY spectra show slow exchange between the *syn* and *anti* protons of Gly−NH_2.

Table 1. ^{1}H NMR chemical shifts and temperature coefficients of amide protons measured for melanostatin 2.5 mM in [D_6]DMSO/water in the absence and in the presence of [Ca^{2+}] = 25 mM

Peak	δ (ppm)	Δδ/ΔT (ppm/K)[a] [Ca^{2+}] = 0 mM	[Ca^{2+}] = 25 mM
Gly−NH	8.21	−0.0050	−0.0048
Leu−NH	8.09	−0.0022	−0.0019
Gly−NH_2 (*anti*)	7.23	−0.0044	−0.0026
Gly−NH_2 (*syn*)	7.03	−0.0040	−0.0034

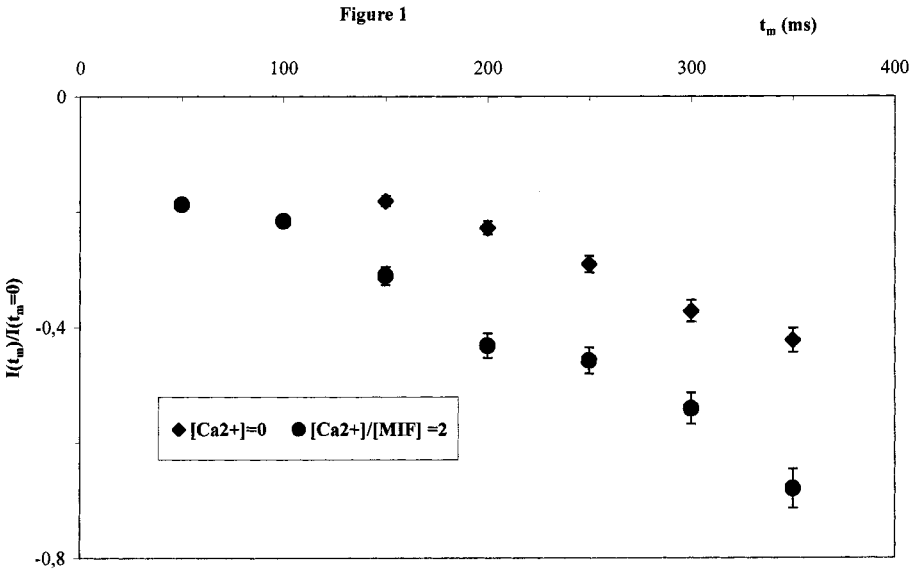

Figure 1. Intensities of the Leu−NH-water normalized exchange cross peak vs. the mixing time measured in NOESY experiments on melanostatin 2.5 mM in [D_6]DMSO/water (1%) in the absence and in the presence of Ca^{2+} 25 mM; T = 298 ± 0.1 K

Upon addition of calcium up to a ratio of [Ca^{2+}]/[MIF] = 20, several spectroscopic features were observed demonstrating formation of a 1:1 complex that substantially modifies the exchange network of the peptide with bulk water.

^{1}H and ^{13}C NMR Chemical Shifts

Both carbonyls (Figure 2 and Figure 3) and amide protons (Figure 4) were selectively affected allowing identification of the metal coordinating groups and evaluation of the dissociation constant of the complex. The Pro- and Gly-carbonyls were the most affected by the metal ion and were therefore assigned as the binding groups. It is interesting to note that two ^{13}C resonances were resolved for the Leu-carbonyl in the bound state, where the less intense of the two shifted downfield substantially. These findings seem to suggest the occurrence of a minor species, in slow chemical exchange with the major one, where the Leu-carbonyl is bound to calcium together with the Gly- or, alternatively, the Pro- carbonyls.

The titration of chemical shifts was preferably accomplished by using ^{1}H NMR spectroscopic data on amide protons that allowed several points to be obtained in a reasonable time. The exponential curves, shown in Figure 4, could be fitted to the following 1:1 binding equation [Equation (1)]with the standard regression procedure already described[13,14]

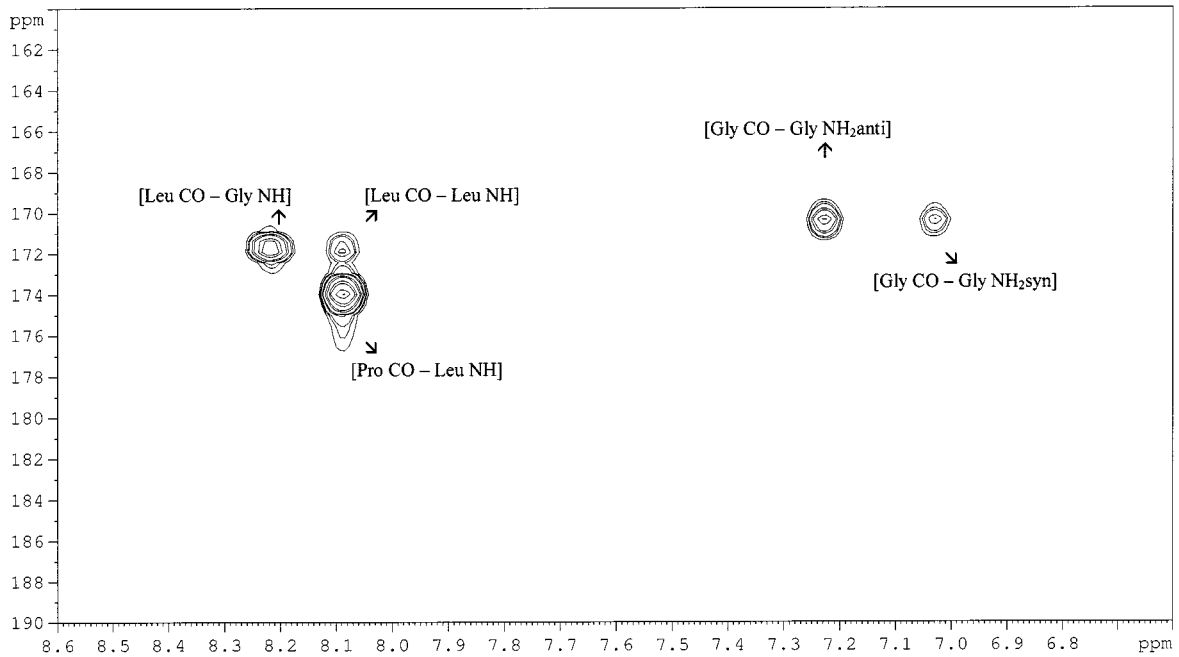

Figure 2. Low-field region of the HMBC spectrum of melanostatin 2.5 mM in [D_6]DMSO/water (1%); T = 298 ± 0.1 K

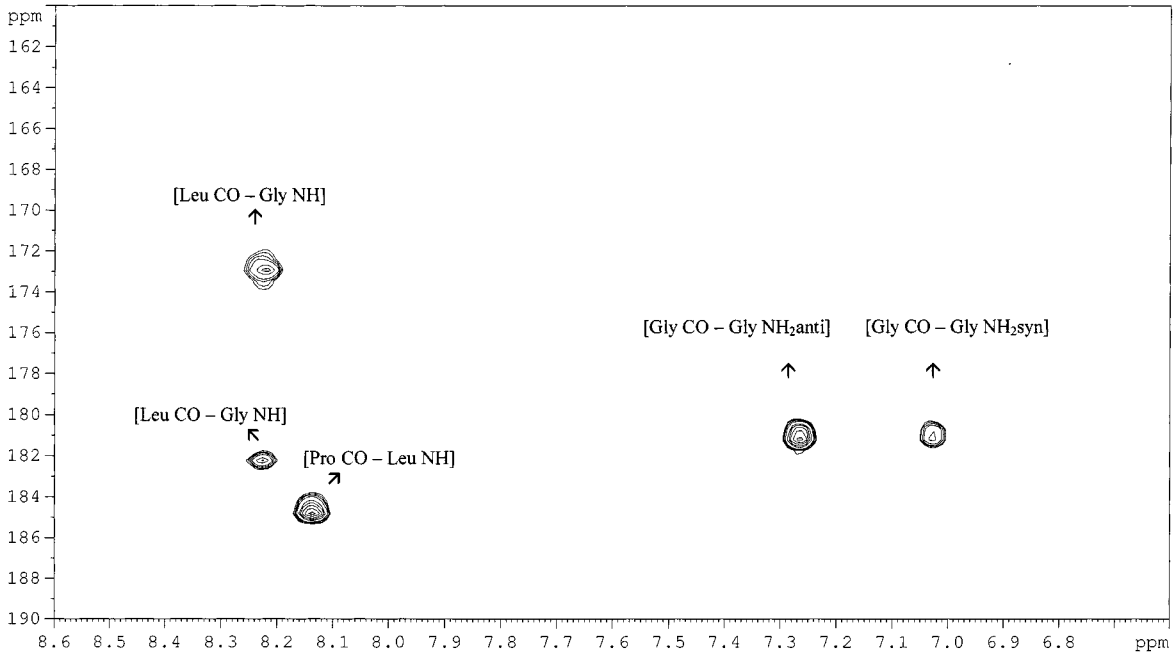

Figure 3. Low-field region of the HMBC spectrum of melanostatin 2.5 mM − Ca^{2+} 25 mM in [D_6]DMSO/water (1%); T = 298 ± 0.1 K

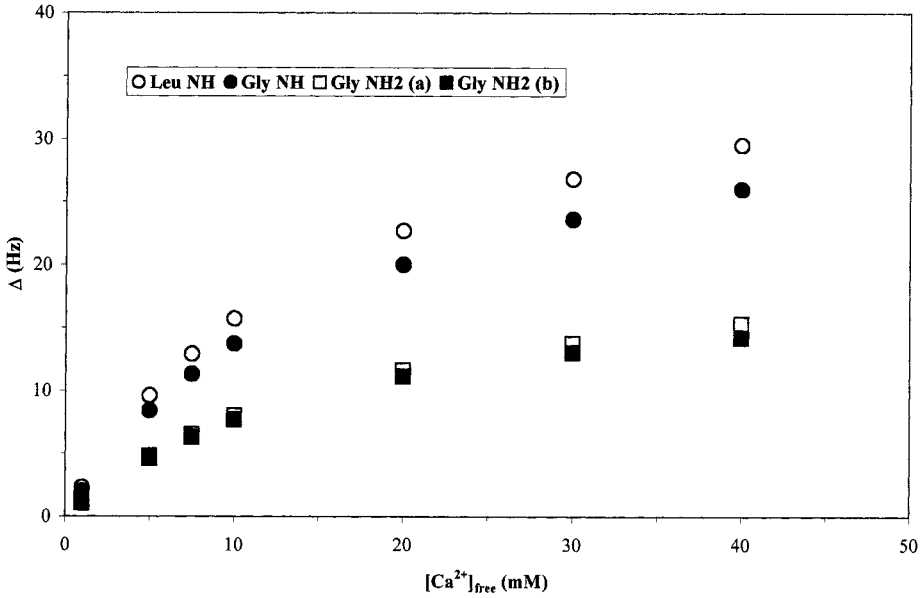

Figure 4. ^{1}H NMR downfield chemical shift changes of amide protons of melanostatin 2.5 mM in [D_6]DMSO/water (1%) vs. calcium concentration; T = 298 ± 0.1 K

$$\Delta = \Delta_0 \frac{[Ca^{2+}]_{free}}{K_d + [Ca^{2+}]_{free}} \quad (1)$$

$$\frac{\bar{\upsilon}}{[MIF]_{total}} = \frac{n}{K_d} - \frac{\bar{\upsilon}}{K_d} \quad (2)$$

where Δ is the actual change in chemical shift, Δ_0 the same change in chemical shift at the *plateau*, and K_d is the dissociation constant from the metal complex. By considering all data, K_d values in the range 0.15−0.20 mM were obtained at constant ionic strength (I = 150 mM). A Scatchard plot (not shown) was also obtained by using the experimental chemical shifts for Leu-NH and the relation shown in Equation (2)[13] where $\tilde{\upsilon}$ is the molar concentration ratio [MIF]/[Ca^{2+}] × Δ/Δ_0, $\tilde{\upsilon}/[MIF]_{total} = \Delta/(\Delta_0 - \Delta)[Ca^{2+}]_{total}$ and n is the stoichiometry of the complex. The slope and intercept from the graph of $\tilde{\upsilon}/[MIF]_{total}$ vs. $\tilde{\upsilon}$ are −5550.1 ± 11.1 and 5820.4 ± 10.6, respectively. As a consequence, the estimated values of K_d and n are ≈0.18 mM and 1, respectively. The fact that the 1:1 complex shows up as the predominant species in solution does not exclude the occurrence of different complexes in fast exchange on the NMR timescale.

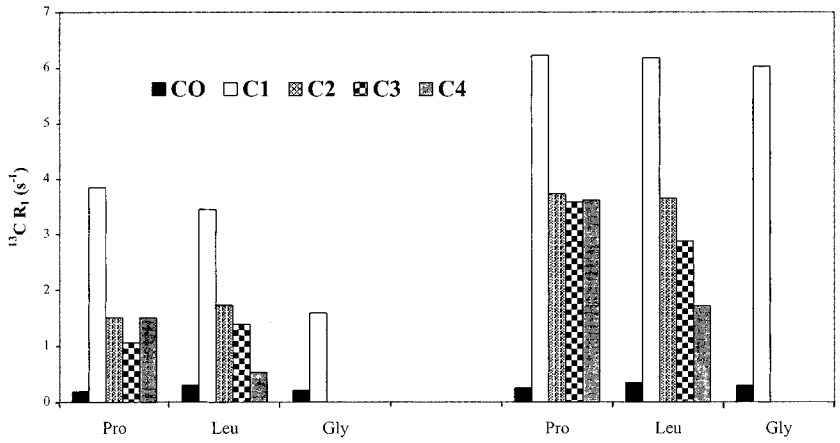

Figure 5. ^{13}C NMR spin-lattice relaxation rates of melanostatin 2.5 mM in [D$_6$]DMSO/water (1%) (left) and melanostatin 2.5 mM – Ca^{2+} 25 mM in [D$_6$]DMSO/water (1%) (right). T = 298 ± 0.1 K. Rates of protonated carbons were normalized with the number of attached protons.

^{1}H and ^{13}C NMR Spin-Lattice Relaxation Rates

Measuring ^{13}C spin-lattice relaxation rates at [Ca^{2+}]/[MIF] = 2 (Figure 5) provided the following information. In the free state, the backbone α carbons (C1 in Figure 5) display different normalized rates (R_1/n_H, where n_H is the number of protons attached to the considered carbon) and the Pro and Leu residues are characterized by the expected internal flexibility. In the calcium complex all relaxation rates are faster and, moreover, the backbone carbons are relaxed with similar rate constants and flexibility somehow reduced. The largest enhancement of relaxation rate is therefore measured for the Gly-methylene that, in the free state, was modulated by effective correlation times shorter than the other backbone carbons.

In the same manner all proton spin-lattice relaxation rates were progressively enhanced by increasing the concentration of calcium (the effect on amide protons is shown in Figure 6). In ^{13}C NMR spectroscopy the spin-lattice relaxation rates are usually determined by the dipole-dipole interaction with attached protons at a fixed distance (r_{CH} = 0.109 nm). This differs from the case of the ^{1}H nuclear spin where relaxation mainly occurs by dipole–dipole interactions with all other surrounding protons either at fixed or time-dependent distances [Equation (3)][15,16]

$$R_{1i} = \sum_{j\neq i}\rho_{ij} + \sum_{j\neq i}\sigma_{ij} + \rho_i^* \qquad (3)$$

where ρ_i* accounts for eventual mechanisms other than the dipole–dipole and ρ_{ij} and σ_{ij} are given by Equation (4)[16,17] where the interaction between any two protons i and j is averaged among all the accessible N configurations, the kth one of them being characterized by the internuclear distance r_k and the existential probability P_k. All other terms have the usual meaning: γ_H is the proton magnetogyric ratio, ω_H is the proton Larmor frequency, h is the reduced Planck constant and τ_c is the motional correlation

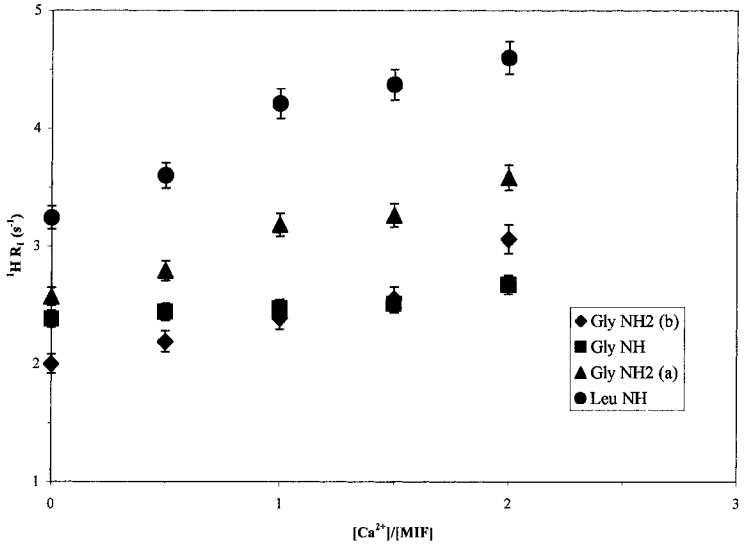

Figure 6. ^{1}H NMR spin-lattice relaxation rates of amide protons of melanostatin 2.5 mM in [D$_6$]DMSO/water (1%) vs. calcium concentration; T = 298 ± 0.1 K

$$\rho_{ij} = \frac{1}{10}\gamma_H^4\hbar^2\left\{\frac{3\tau_c}{1+\omega_H^2\tau_c^2} + \frac{6\tau_c}{1+4\omega_H^2\tau_c^2} + \tau_c\right\}\sum_{k=1}^{N}\frac{P_k}{r_k^6}$$

$$\sigma_{ij} = \frac{1}{10}\gamma_H^4\hbar^2\left\{\frac{6\tau_c}{1+4\omega_H^2\tau_c^2} - \tau_c\right\}\sum_{k=1}^{N}\frac{P_k}{r_k^6} \quad (4)$$

time. As a consequence, while the calcium-induced enhancement of ^{13}C relaxation rates can be suitably interpreted in terms of lengthened effective correlation times (vide infra), the same may not hold for protons, where changes in the number of interacting protons, internuclear distances or in ρ_i* may also be effective.

Selective (R_1^{sel}) and double selective ($R_1^{i,k}$) proton spin-lattice relaxation rates were therefore measured in order to better delineate the observed calcium induced effects. It is in fact well known that[15,18]

$$R_{1i}^{sel} = \sum_{j\neq i}\rho_{ij} + \rho_i^*$$

$$R_{1i}^{i,k} = \sum_{j\neq i}\rho_{ij} + \rho_i^* + \sigma_{ik} \quad (5)$$

Table 2. ^1H NMR relaxation rates of amide protons measured for melanostatin 2.5 mM in [D_6]DMSO/water in the absence and in the presence of [Ca^{2+}] = 25 mM

Peak	[Ca^{2+}] = 0 mM R_1/R_1^{sel}	$\sigma_{ij}\{H_j\}$ (s^{-1})	[Ca^{2+}] = 25 mM R_1/R_1^{sel}	$\sigma_{ij}\{H_j\}$ (s^{-1})
Gly−NH	1.36	----	1.09	----
Leu−NH	1.10	0.14 {Leu H_α}	1.01	−0.22 {Leu Hα}
Gly−NH_2 (*anti*)	0.59	−1.62 {Gly−NH_2}	0.62	−1.42 {Gly−NH_2}
Gly−NH_2 (*syn*)	0.64	−1.58 {Gly−NH_2}	0.66	−1.36 {Gly−NH_2}

Once measured, the new parameters (shown in Table 2) were used to delineate the effects of calcium on motional correlation times and ρ_i* through the evaluation of the ratio of nonselective to selective relaxation rates as well as on any dipole−dipole relaxation term of a proton pair σ_{ik} [Equation (6)]

$$\frac{R_{1i}}{R_{1i}^{sel}} = \frac{\sum_{j\neq i}\rho_{ij} + \sum_{j\neq i}\sigma_{ij} + \rho_i^*}{\sum_{j\neq i}\rho_{ij} + \rho_i^*} \quad (6)$$

$$\sigma_{ik} = R_{1i}^{i,k} - R_{1i}^{sel} = \sigma_{ki} = R_{1k}^{i,k} - R_{1k}^{sel}$$

The decrease of R_1/R_1^{sel} confirms that binding to calcium implies slowing down of molecular motions although different ρ_i* contributions to the relaxation pathway in the free and metal-bound states may also occur. As in the case of spin-lattice relaxation of carbons, the most affected is Gly-H_α which is thus verified to experience the largest reduction in mobility. The two obtained dipolar relaxation terms, $\sigma_{NH_2(a)-NH_2(b)}$ (−1.42 s^{-1} in the free and −1.34 s^{-1} in the metal-bound state) and $\sigma_{LeuNH-LeuH_\alpha}$, (+0.14 s^{-1} in the free and +0.05 s^{-1} in the metal-bound state), suggest that intramolecular chemical exchange provides the main relaxation mechanism for the Gly-NH_2 protons (negative σ's are obtained at each correlation time) and again that the motional correlation time in the bound state may be longer than in the free state; the dipolar relaxation rate, σ, in fact decreases and eventually becomes negative at increasing τ_c. However, any change in conformation yielding longer distances may reduce the observed rate. It is concluded that proton relaxation rates strongly suggest that binding to calcium reduces the motional flexibility of melanostatin, although other effects, namely a change in the relaxation mechanism and/or in internuclear distances, cannot be ruled out.

Temperature Dependence of Amide ^1H Chemical Shifts

The surprisingly high temperature coefficient of Leu-NH (Table 1) has been previously noticed and interpreted in terms of a solvent shielded but not hydrogen-bonded amide proton. The other three protons display coefficients typical of solvent exposed protons. However, upon addition of calcium, all coefficients are progressively enhanced, especially that of the low field Gly-NH_2 proton (from −4.4 ppb/K to −2.6 ppb/K).

^1H 2D NOESY Experiments

NOESY experiments were run for the free and calcium-bound peptide at several mixing times, t_m, in the range 50−600 ms. Beyond the positive ones, the following proton pairs displayed negative exchange cross peaks in the free state with increasing volumes at increasing t_m:

(i) the *syn* and *anti* protons within the Gly-NH_2 moiety;

(ii) Leu-NH and the residual water signal (Figure 1).

This last cross peak was analyzed by considering the following exchange matrix governing the mixing process [Equation (7)][19]

$$\hat{L} = \begin{pmatrix} \left(-R_{NH}^{sel} - \rho_{NH}^* - x_{H_2O}k\right) & -x_{MIF}\left(\sigma_{NH-H_2O} - k\right) \\ -x_{H_2O}\left(\sigma_{NH-H_2O} - k\right) & \left(-R_{H_2O}^{sel} - \rho_{H_2O}^* - x_{MIF}k\right) \end{pmatrix} \quad (7)$$

where the x are mol fractions and k is the exchange rate. By considering that $R_{NH}^{sel} >> R_{H_2O}^{sel}$, ρ_{NH}* << R_{NH}^{sel}, ρ_{H_2O}* << R_{NH}^{sel}, $x_{H_2O} >> x_{MIF}$, $\sigma_{NH-H_2O} << k$, Equations 8−10 were obtained for diagonal and cross peak coefficients as a function of the mixing time[19]

$$a_{NH}(t_m) = x_{MIF}e^{-\delta t_m}\left\{\cosh(Dt_m) - \frac{\delta}{D}\sinh(Dt_m)\right\}$$

$$a_{NH-H_2O}(t_m) = x_{MIF}\frac{k}{D}e^{-\delta t_m}\sinh(Dt_m) \quad (8)$$

with

$$\delta = \frac{1}{2}\left(R_{NH}^{sel} + k\right)$$

$$D = \frac{1}{\sqrt{2}}\left(R_{NH}^{sel} + k\right) \quad (9)$$

It follows that the ratio between the intensities of cross- and diagonal peaks is given by:

$$\frac{I_{NH-H_2O}}{I_{NH}} = \frac{k\sqrt{2}}{R_{NH}^{sel} + k} \frac{\sinh\left\{\frac{1}{\sqrt{2}}\left(R_{NH}^{sel} + k\right)t_m\right\}}{\cosh\left\{\frac{1}{\sqrt{2}}\left(R_{NH}^{sel} + k\right)t_m\right\} - \frac{\sqrt{2}}{2}\sinh\left\{\frac{1}{\sqrt{2}}\left(R_{NH}^{sel} + k\right)t_m\right\}} \quad (10)$$

which is an almost linear function of I_c/I_d vs. t_m at constant values of k and R_{NH}^{sel}. Interestingly, as shown in Figure 1, in the calcium-bound state the intensity of the water-Leu-NH cross peak at any value of t_m was rather enhanced, while that of the other exchange peak was reduced. Analysis of the reported equation allowed two inferences, (i) $k > R$ determines that the intensity ratio almost uniquely depends upon t_m; (ii) $k < R$ yields enhancements of the intensity ratio when increasing either k or R, or both. However, the effect of increasing k (at constant R) can be calculated to overwhelm that of increasing R (at constant k). This seems to suggest that the main, but not the only, cause of the observed phenomena is to be sought in a substantial change in the proton exchange rates between the involved environments.

Conclusion

Melanostatin is a small flexible molecule that, upon binding to calcium, undergoes several NMR spectroscopically detectable changes. The main species is a 1:1 complex with Pro- and Gly- carbonyls bound to the metal ion with $K_d \approx 0.16$ mM. Minor species bound through the Leu-carbonyl were also detected (Figure 7 and Figure 8). Metal chelation brings about a sizeable increase in effective motional correlation times, modulating reorientational motions of almost all carbon-proton and proton-proton dipole-dipole vectors as deduced by the enhanced ^{13}C and ^{1}H NMR relaxation rates. Moreover, the degrees of internal flexibility are reduced and the peptide is somehow forced to assume a single conformation. The most interesting feature of the complex is the change in the intensities of exchange cross peaks. It may be speculated that in the free state, reorientational motions transiently destroy the interaction with water. In the metal-bound state the Leu-amide proton enters the proton exchange network of the flexible coordination sphere of calcium. It is hydrogen-bonded to a coordinated water molecule that rapidly exchanges with bulk solvent. That this might be the case is ratified by the enhanced temperature coefficient of the involved amide proton. In the same way the large increase in the same coefficient of the low-field Gly-amide proton suggests that the same occurs for one of the NH_2 protons, thus reducing the rate of intramolecular exchange connected to damped rotation around the C−N bond. For better delineation of structure and dynamics, the motional correlation time of the calcium complex was calculated by considering the following:

(i) the ^{13}C NMR spin lattice relaxation rates ($\tau_c = 0.11 \pm 0.07$ ns at 298 K)

(ii) the proton dipolar relaxation rate $\sigma_{LeuNH-LeuH\alpha}$ at two different frequencies ($\tau_c = 0.14 \pm 0.08$ ns at 298 K).

$\tau_c = 0.12$ ns was then used to evaluate $r_{LeuNH-LeuH\alpha}$ at 0.261 ± 0.012 nm. Other constraints were not necessary to generate the models of the complexes (shown in Figure 7 and Figure 8) by using the AMBER force field within the HYPERCHEM software package. In this figure, four of the low conformational energy structures are superimposed onto the major complex, in order to show that the structure of the Leu side chain is ill-defined; whereas the rest of the molecule is structurally well defined, especially around the

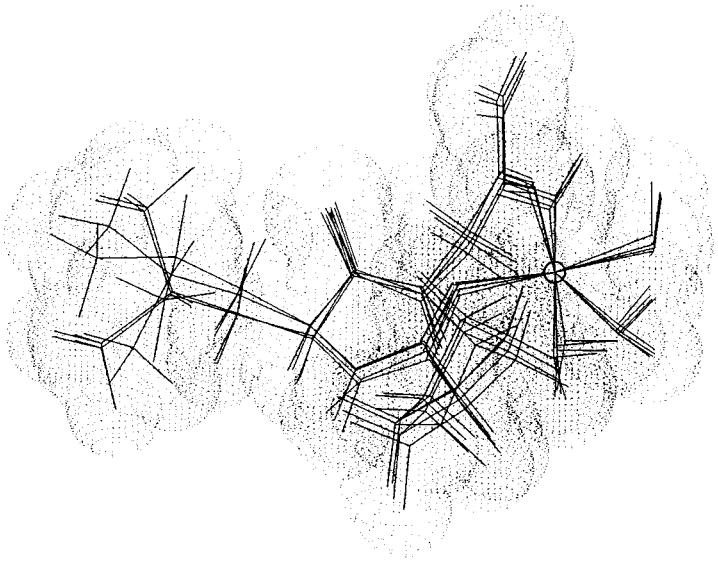

Figure 7. Superimposed stick models of four low energy structures of the main calcium-melanostatin 1:1 complex in [D_6]DMSO/water (1%); the calcium ion is circled and highlighted

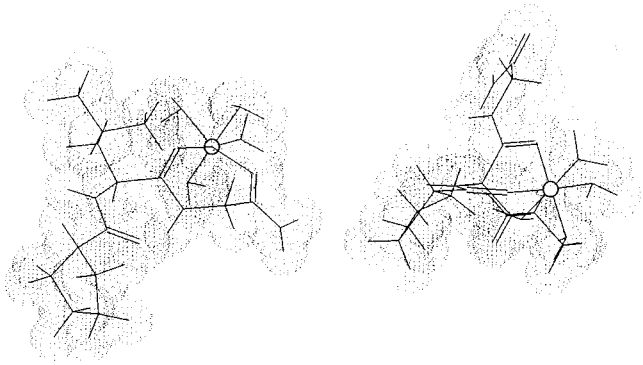

Figure 8. Stick models of low energy structures of the minor calcium-melanostatin 1:1 complexes in [D_6]DMSO/water (1%); calcium ions are circled and highlighted

metal ion (the RMSD value, calculated over the backbone atoms, was 0.06 nm).

The observed phenomena may be relevant for the biological role of calcium. Exchange of amide protons in proteins and peptides is in fact closely related to secondary and tertiary structures in solution, being the three-dimensional arrangement of any biological molecule ultimately associated with water. Backbone and side-chain hydration is a dominant factor in the stabilization of the structure, and in the process of backbone folding. It also plays an essential role in substrate binding and the mechanism of peptide and protein mediated reactions. Water diminishes charge-charge interactions and, in many proteins, has the integral role of filling cavities. Water molecules surround the molecular surface and the exchange with bulk water determines the kinetics of substrate binding or aggregation processes.

NMR 1D or 2D methods have been thoroughly exploited in discriminating solvent shielded vs. solvent exposed exchangeable protons in proteins and peptides. Exchange rates of individual amide protons in the range from reciprocal milliseconds to reciprocal months have been determined. Changes in the exchange network of backbone and side-chain protons have been consequently interpreted as demonstrating structural changes following either binding of substrates, cofactors, metal ions etc. or induced aggregation. What has been observed for melanostatin leads us to conclude that exchange rates may also be modulated by the intervention of hydration spheres of coordinated metal ions.

Experimental Section

MIF was obtained from Sigma Chemical Co. Purity of the peptide was assessed from NMR spectra and no further purification was required. Calcium perchlorate, also obtained from Sigma Chemical Co., was dried over P_2O_5 for several hours before use. Solutions were made in [D_6]DMSO containing water (1%) and were carefully deoxygenated through a freezing-sealing-thawing procedure. NMR spectroscopic experiments were carried out at 4.7 T (Varian VXR 200) and 14.1 T (Bruker Avance 600) at temperatures controlled to ± 0.1 K. Chemical shifts were referenced to internal [D_4]-trimethylsilylpropane sulfonate ([D4]TSP). NOESY experiments were carried out with standard pulse sequences at different values of the mixing time (in the range 50−600 ms). ROESY experiments were obtained at mixing times in the range 50−100 ms with the r.f. strength for the spin-lock field at values < 3.5 kHz. 2D ^{1}H-^{13}C shift correlation methods were used to detect and assign ^{13}C NMR spectra at relatively low concentration. Both ^{1}H-detected heteronuclear multiple-quantum coherence (HMQC) and ^{1}H-detected multiple-bond heteronuclear multiple-quantum coherence (HMBC) spectra were obtained with standard pulse sequences. Proton spin-lattice relaxation rates were measured with inversion recovery pulse-sequences using either non-selective, single-selective or double-selective π pulses. The rates were calculated with regression analysis of the initial decay curves of longitudinal magnetization components leading to errors in the range ±3%. Two sets of calcium titrations were performed at constant ionic strength (I = 150 mM). An approximate measure of K_d was obtained in the first set without maintaining a constant concentration of MIF.. In the second set, the peptide was added to Ca^{2+} solution to maintain a constant concentration of MIF in each NMR sample. Standard regression analysis was used to fit curves to the data by using the following equation:

$$\Delta = \Delta_0 [Ca^{2+}]_{free}/\{K_d + [Ca^{2+}]_{free}\}$$

The experimental calcium concentration was corrected thus:

$$[Ca^{2+}]_{free} = [Ca^{2+}]_{total} - [MIF]\ \Delta/\Delta_0$$

where Δ/Δ_0 is the fractional change in the chemical shift of the observed proton.[13,14]

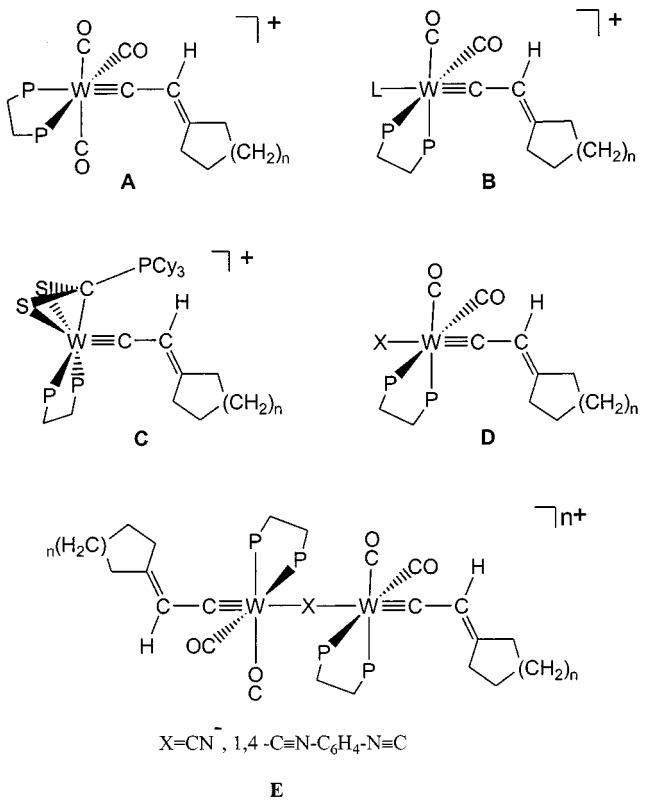
Synthesis, Structural Characterisation and Electrochemical Studies of Neutral Alkenylcarbyne Tungsten Complexes Bearing Chelating Bidentate and Tridentate Phosphanes

Lei Zhang,[a,b] M. Pilar Gamasa,[a] José Gimeno,*[a] M. Fátima C. Guedes da Silva,[b,c] Armando J. L. Pombeiro,[b] Claudia Graiff,[d] Maurizio Lanfranchi,[d] and Antonio Tiripicchio[d]

Keywords: Carbyne complexes / Alkenylcarbyne / Tungsten / Electrochemistry / Phosphanes

Neutral alkenylcarbyne complexes [X = SCN; *n* = 1 (**2a**), 4 (**2b**). X = OCN; *n* = 1 (**2c**), 4 (**2d**)] were prepared by reaction of the acetonitrile complexes [*n* = 1 (**1a**), 4 (**1b**)] with M[OCN] or M[SCN] (M = Na, K, Bu_4N), and were fully characterised. The synthesis of complex **3**, containing the tridentate phosphane triphos [triphos = $PPh(CH_2CH_2PPh_2)_2$], is also described. The structures of **2b** and **3** were determined by X-ray diffraction methods. In both complexes, the coordination of the W atom was octahedral, with the N-bonded thiocyanate (**2b**) or the chlorine (**3**) anions *trans* to the alkenylcarbyne group. The W–N and W–Cl bond lengths were significant longer than the average found in the literature; this indicates the remarkable *trans* influence of the alkenylcarbyne moiety. The electrochemical behaviour of complexes **2a**–**d** and **3**, as well as that of the related compounds **D** (**2e**: X = F, *n* = 4), (**2f**: X = Cl, *n* = 1), (**2g**: X = $S_2P(OEt)_2$, *n* = 1) and **A** (**4**: *n* = 1) was investigated by cyclic voltammetry (CV) and controlled potential electrolysis (CPE) in aprotic media and at a Pt electrode. They underwent irreversible anodic and cathodic processes, the former usually being multi-electronic in the time scale of CPE and involving anodically induced proton dissociation from the alkenylcarbynes. These ligands behave as remarkably strong π-electron acceptors and from the linear relationship between the oxidation potential of the first anodic wave and the electrochemical P_L ligand parameter, it was possible to estimate, for the first time for a carbyne-containing metal centre, that is, the site {(dppe)$(CO)_2$W≡C–R}, the values of the electrochemical electron richness (E_s) and the polarisability (β) parameters. These values indicate that this site has low electron richness and low polarisability; this is accounted for by the extensive π-electron acceptance of the alkenylcarbyne ligand. P_L was also estimated for the $S_2P(OEt)_2^-$ ligand, which was shown to act as a rather strong net electron releaser.



Introduction

We have recently reported a systematic methodology for the synthesis of Fischer-type alkenylcarbyne tungsten complexes, which has led to the preparation of a large series of cationic **A**, **B** (L = PMe_3, MeCN), and **C**, and neutral **D** [X = F, Cl, Br, I, CN, κ^1-(*S*)-$S_2P(OEt)_2$] derivatives[1−3] (Scheme 1). Furthermore, we have also studied[3] the synthesis and electrochemical behaviour of dinuclear complexes containing cyanide and diisocyanide bridging ligands **E** [X = CN, 1,4-$(CN)_2C_6H_4$], which are readily generated from the reaction of the labile cationic complexes **B** (L = MeCN) with complexes **D** (X = CN) or the bidentate diisocyanide ligand 1,4-$(CN)_2C_6H_4$. Complexes **E** are unusual examples of dimetallic species bearing long π-conjugated electronic chains involving two terminal α,β-unsaturated carbyne moieties. Molecular systems of this type, containing metallic fragments and extended organic π-systems linked by metal−carbon multiple bonds, are attracting increasing interest. Continuing our work in this field, we were interested to explore the synthesis of novel carbyne complexes displaying related conjugated electronic systems. Since electrochemical studies on metal−carbyne derivatives are rather scarce,[3−8] the synthesis of novel complexes would provide further study subjects for developing the knowledge on the electrochemical behaviour of these types of derivatives, as well as on the electron donor/acceptor character of such ligands, and on the electronic properties of their binding metal centres.

We now report the synthesis and electrochemical studies of novel neutral derivatives of type **D** [dppe = κ^2-(*P,P*)-$Ph_2P(CH_2)_2PPh_2$; X = κ-(N)-SCN; *n* = 1 (**2a**), 4 (**2b**). X =

OCN; n = 1 (**2c**), 4 (**2d**)] and **3** (Schemes 2 and 3). The molecular structures of complexes **2b** and **3** were determined by X-ray diffraction. Electrochemical studies by cyclic voltammetry and of controlled potential electrolysis of these and related alkenylcarbyne complexes are also reported.

Results and Discussion

Synthesis and Characterisation of Complexes 2a−d

Complexes **2a−d** were prepared by the reaction of the labile acetonitrile complexes **1a**,**b** with an equimolar amount of KSCN or NaOCN in MeOH (Scheme 2). Alternatively, complexes **2a**,**b** were also formed from the treatment of **1a**,**b** with [Bu_4N][SCN] in CH_2Cl_2. After the resulting solutions were worked up, the desired carbyne complexes were isolated (80−90% yield) as yellow air-stable solids (see Experimental Section) and were characterised by elemental analysis and IR spectroscopy and ^{1}H-, ^{31}P{^{1}H}-, and ^{13}C{^{1}H}-NMR spectroscopy. In addition, the structure of **2b** was determined by X ray diffraction (see below).

The IR spectra (CH_2Cl_2) of **2a−d** contained two strong ν(CO) absorptions (Table 1), as expected for the presence of the *cis*-dicarbonyl arrangement, as also observed for the analogous halide derivatives.[1] Furthermore, IR spectra of **2a**,**b** displayed a very strong absorption at 2064 cm^{-1}, assigned to the CN stretching vibration of the SCN group in accord with most of the N-bonded thiocyanato complexes.[9] This coordination mode was confirmed by the X-

	X	n
2a	SCN	1
2b	SCN	4
2c	OCN	1
2d	OCN	4

Scheme 2

ray diffraction structural determination of **2b** (vide infra). Similarly, IR spectra of **2c**,**d** showed another strong absorption at 2212 cm^{-1}, as expected for ν_a(NCO) [consisting mainly of ν(CN) vibration].[9] Since the majority of the cyanato complexes are reported to be N-bonded, we tentatively assigned this linkage to complexes **2c**,**d**. Although the ν_s(NCO) vibration for such a type of linkage is expected to appear in the 1370−1300 cm^{-1} range,[10−11] only a weak band at 1335−1338 cm^{-1} was observed. Other pseudohalide N-bonded Fischer type carbyne complexes have been reported.[12]

The ^{31}P{^{1}H}-NMR spectra (Table 1) of **2a−d** displayed single resonances at ca. δ = 40, indicating the chemical equivalence of the phosphorus atoms of dppe in accordance with the proposed *trans* pseudohalide−carbyne arrangement. J(P-W) values of ca. 228 Hz are similar to those found for the analogous halide derivatives.[1] The ^{1}H-NMR spectra (Table 1) showed a broad signal at δ 4.97−5.00 for the alkenyl proton resonance (=C$_\beta$H−) of the cyclopentenyl derivatives (n = 1, **2a**,**c**), which was shifted to a higher field (δ 4.65−4.68) in cyclooctenyl analogues (n = 4, **2b**,**d**). ^{13}C{^{1}H}-NMR spectra (Table 2) were also consistent with the expected resonances in accord with the proposed formulations. In particular, the spectra showed typical carbyne carbon resonances as triplet signals at δ = 273.0−279.0 [^2J(C−P) = 10.0−10.6 Hz], in addition to the resonances for the C$_\beta$ and C$_\gamma$ nuclei of the alkenylcarbyne chain and the *cis*-dicarbonyl ligands, which appeared as a virtual doublet of doublets. The carbon resonance of the OCN group appeared as a singlet signal at δ 145.0, while that of the SCN group was overlapped by those of the aromatic groups.

We have reported[3] that the analogous cyanide carbyne derivatives of type **D** (X= CN; n = 1, 4) (Scheme 1) reacts with complexes **1a**,**b**, affording cyanide-bridged bis(alkenylcarbyne) dinuclear complexes of type **E** (X= CN) (Scheme 1). All attempts directed to the formation of analogous dinuclear μ-NCO and μ-NCS bridging complexes from the reactions of **2a−d** with a stoichiometric amount

of **1a**,**b** or the labile acetone complex *fac*-$[W(CO)_3(dppe)(Me_2CO)]$[1a,13] were unsuccessful. In all the cases, the starting complexes were recovered unchanged.

Synthesis and Characterisation of Complex 3

The reaction of an equimolar mixture of **2f**[1a] and triphos $[PPh(CH_2CH_2PPh_2)_2]$ in refluxing toluene led to the formation of **3**, which was isolated (75% yield) as an orange air-stable solid (Scheme 3). The reaction was monitored by IR spectroscopy in the carbonyl region and was allowed to proceed until the absorptions of the starting *cis*-dicarbonyl complex disappeared. The ^{31}P-NMR spectrum of the resulting solution revealed the presence of free dppe.

Scheme 3

Analytical and spectroscopic data (IR and NMR) of **3** supported this formulation and the structure was confirmed by an X-ray diffraction study (see below). Significantly, the IR spectrum (CH_2Cl_2) (Table 1), showed a strong ν(CO) absorption at 1897 cm^{-1} and the $^{13}C\{^1H\}$-NMR spectrum (Table 2) displayed the expected resonances for the alkenylcarbyne moiety and the carbonyl group. Thus, carbon carbyne resonances appeared as a doublet of triplet signal at δ = 270.6, characteristic of the AB_2X spin system with ^2J(C–P) values of 9.7 and 8.8 Hz arising from the presence in the *cis* positions of two sets of inequivalent phosphorus atoms of the triphos ligand. Carbonyl resonances appeared at δ = 233.7 [dt, ^2J(C–P) = 88.0 and 41.0 Hz], revealing the presence of one *trans* and two *cis* phosphorus nuclei. The $^{31}P\{^1H\}$-NMR spectrum (Table 1) was consistent with the triphos arrangement around the metal centre, showing the resonances typical of an AB_2 system [δ = 84.1 (t) and 48.2 (d), *J*(P–W) = 201 and 294 Hz, respectively]. The ^1H-NMR spectrum showed aromatic and proton resonances of the triphos as well as those of the alkenylcarbyne group (see Experimental Section).

X-ray Crystal Structures of Complexes 2b and 3

The structures of complexes **2b** and **3** are shown in Figure 1 and Figure 2 together with the atom numbering scheme. Selected bond lengths and angles are given in Table 3 and Table 4, respectively.

In both complexes, the W atom was coordinated as a distorted octahedron, with the two apical positions occupied by the C atom from the alkenylcarbyne ligand and by the N atom of the isothiocyanate group (**2b**) or by the Cl atom (**3**). In **2b** the coordination was completed by two P atoms from a chelating dppe ligand and by two carbonyl

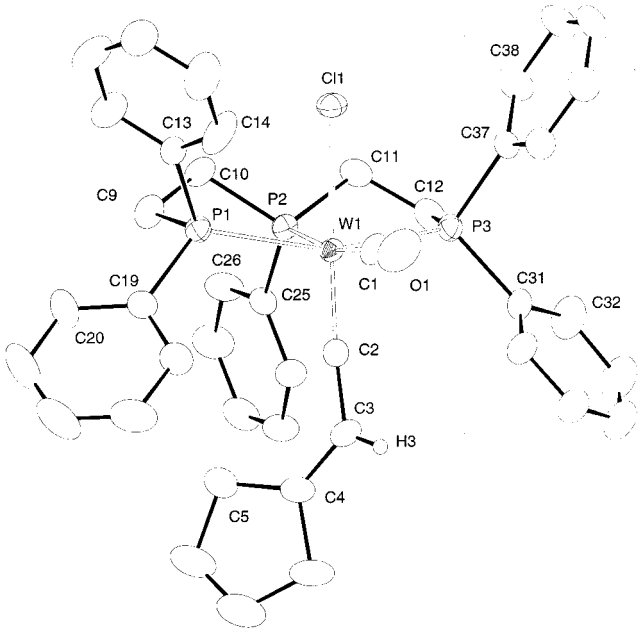

Figure 2. ORTEP view of the molecular structure of complex **3**, with the atom-numbering scheme, the thermal ellipsoids are drawn at the 30% probability level

groups, whereas in **3** the coordination was completed by three P atoms from the triphos ligand and by a carbonyl group. In **2b** the W atom was only slightly, 0.0780(4) Å, displaced from the mean plane through the four equatorial atoms pointing towards the carbyne carbon atom, whereas in **3** this deformation was much more enhanced, the W atom being displaced by 0.3535(3) Å. The W≡C bond

lengths were 1.848(5) Å in **2b** and 1.821(5) Å in **3**, comparable to those found in analogous alkenyl−carbyne complexes.[1] As expected, a remarkable alkenylcarbyne *trans* influence can be envisaged: (a) The value of the W−N bond length in **2b**, 2.200(5) Å, is longer than the average (2.148 Å) found for 12 hexacoordinate tungsten complexes with terminal N-bonded thiocyanate ligands, and (b) The W−Cl bond length in **3**, 2.572(1) Å, is much longer than the average (2.388 Å) found for 80 hexacoordinate tungsten complexes with terminal chloride ligands. (From the Cam-

bridge Crystallographic Data Base). It is noteworthy that the W−P bond lengths in **2b** with the dppe ligand, 2.533(1) and 2.538(1) Å, are significantly longer than those found in **3** with the triphos ligand, 2.488(2), 2.485(2), and 2.473(2) Å.

Electrochemical Studies

The electrochemical behaviour of the alkenylcarbyne complexes **2a**−**2d**, **3** and, for comparative purposes, of the related compounds **2e**,[2] **2f**,[1a] **2g**,[1b] and **4**,[1a] in 0.2 mol dm^{-3} [NBu_4][BF_4]/NCMe (or THF), was studied by cyclic voltammetry (CV) and controlled potential electrolysis (CPE), at a Pt (or vitreous C) disk or a Pt-gauze electrode, respectively.

Table 5. Cyclic voltammetric data for the alkenylcarbyne complexes **2a**−**d**, **2e**−**g** (Type D: Scheme 1), **3** and **4** (n = 1; Type A: Scheme 1)

[a] Potentials (peak potential E_p or half-peak potential $E_{p/2}^{ox}$ for the irreversible processes, or, in brackets, half-wave potential $E_{1/2}^{ox}$ for the reversible ones) in Volt ± 0.02 vs. SCE measured in 0.2 mol dm^{-3} [NBu_4][BF_4]/NCMe at a scan rate of 0.2 V s^{-1}, at a Pt disc (d = 0.5 mm) electrode, unless stated otherwise. [b] With a decreasing current intensity, relatively to the first anodic wave, upon increasing scan rate. [c] Included for comparison (electrochemical behavior investigated in this study): **2e**,[2] **2f**,[1a] **2g**,[1b] **4**.[1a] − [d] In THF. − [e] Broad and with a relatively low current-intensity.

Complexes **2** and **4** underwent, by CV (Table 5), one irreversible anodic wave (I) ($^{I}E_{p/2}^{ox}$ in the range 0.7−1.1 V vs. SCE for **2**, or 1.78 V for **4**), $^{I}E_{p/2}^{ox}$ which was usually followed, at a higher potential (ca. 1.0−1.3 V for **2**), by a second one (II) which was, however, not detected for **4**, conceivably being buried under the solvent/electrolyte discharge. An irreversible cathodic wave was also detected at E_p^{red} in the range −1.6 to −2.2 V (**2**) or −1.08 V (**4**).

For the triphos complex **3**, with just a single CO ligand, the first anodic wave (which corresponds to a single-electron reversible oxidation) was observed at the lowest oxidation potential ($^{I}E_{1/2}^{ox}$ = 0.32 V) when compared with those of **2** (dicarbonyl complexes) or **4** (tricarbonyl compound), in agreement with the known[14] strong π-electron acceptance of the CO ligand(s) with resulting enhancement of the oxidation potential of the corresponding complexes. In fact, the oxidation potential of the first anodic wave clearly reflects the net π-acceptor minus σ-donor character of the ligands, as measured by the electrochemical P_L ligand parameter[14] (the stronger that character, the higher the P_L).

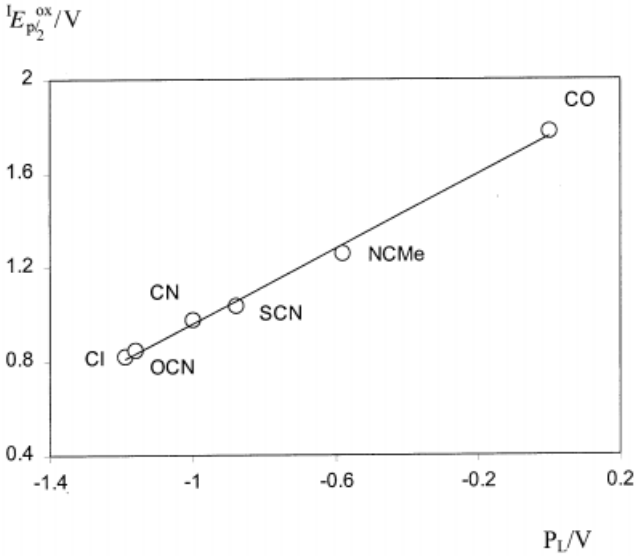

Figure 3. Plot of $^{I}E_{p/2}^{ox}$ for complexes **D** [n = 1; X = SCN (**2a**), OCN (**2c**), Cl (**2f**), or CN[3]], **A** [n = 1 (**4**)], and **1a**[3], vs. the electrochemical P_L ligand (X or L)[14] parameter. $^{I}E_{p/2}^{ox}$ = 0.80 P_L + 1.76 (correlation coefficient r = 0.998)

This is shown by the linear plot of $^{I}E_{p/2}^{ox}$ vs. P_L (Figure 3), for the series of complexes with a common alkenylcarbyne (n = 1), namely the neutral complexes [Type **D**; X = SCN (**2a**), OCN (**2c**), Cl (**2f**) or CN] and the cationic complexes **4** (Type **A**) and **1a** in which P_L refers to the variable ligand (X or L) coordinated to the common metal centre. The $^{I}E_{p/2}^{ox}$ values for the cyano- and the acetonitrile complexes were previously reported[3] and are included for comparative purposes.

A lowering of the net σ-electron-donor minus π-electron-acceptor ability of the X or L ligand (or, in other words, an increase of its net π-electron-acceptor minus σ-electron-donor character) results in stabilisation of the HOMO of the complex and therefore in an anodic shift of the oxidation potential. Hence, the values of the oxidation potential of complexes **2** with the anionic X ligand follow the order $Cl^- < OCN^- < CN^- < SCN^-$ (with corresponding P_L ligand values of −1.19, −1.16, −1.00 or −0.88 V[14]) and are significantly lower than that, $^{I}E_{p/2}^{ox}$ = 1.26 V,[3] of the acetonitrile complex, and much less anodic than that, $^{I}E_{p/2}^{ox}$ = 1.78 V, of the carbonyl analogue **4**, and are also in close agreement with the increasingly higher P_L values for ligating NCMe and CO (−0.58 and 0.0 V, respectively[14]). The tricarbonyl complex **4** with an alkenylcarbyne ligand exhibited a much higher oxidation potential than that of the related tetracarbonyl [$W(CO)_4$(dppe)] ($E_{1/2}^{ox}$ = 1.02 V),[3] indicating that the ligating alkenylcarbyne behaves as a much stronger net π-electron-acceptor minus σ-electron-donor than carbonyl. This is also the reason why the other alkenylcarbyne complexes with the strong electron-donating SCN^- ligand were still oxidized at a potential higher than that of [$W(CO)_4$(dppe)]. The carbyne ligands in *trans*-[$ReX(\equiv CCH_2R)(dppe)_2$][$BF_4$] (X = F or Cl; R = alkyl, aryl or ester) have also been shown[4] to behave as more efficient π-electron acceptors than CO.

The above linear plot corresponds to the expression [Equation (1)] proposed by C. J. Pickett et al.[14] that relates the oxidation potential of the members of a series of 18-electron octahedral complexes $[M_sL]$ (with a common $\{M_s\}$ site) with P_L for the variable L ligand. E_s is a measure of the electron richness of the metal site, and is expressed by the oxidation potential of the carbonyl complex $[M_s(CO)]$ (the higher E_s, the lower the electron richness is), and β is a measure of the polarisability of the metal site.

$$E^{ox}[M_sL] = E_s + \beta \cdot P_L(L) \quad (1)$$

Therefore, from the intercept and the slope of the plot of Figure 3, one can estimate these parameters for the common metal site of our study, $\{M_s\}$ =

$$\{(dppe)(CO)_2W{\equiv}CCH{=}\overline{CCH_2CH_2CH_2CH_2}\},$$

as E_s = 1.76 V and β = 0.80. This is the first time such parameters have been estimated for a metal site with a carbyne ligand and it is noteworthy to mention that the electron richness of this centre is rather low, even lower than that (E_s = 1.50 V) of $\{M(CO)_5\}$ (M = Cr, Mo or W),[14,15] on account of the very strong π-electron acceptor character of the alkenylcarbyne ligand and of the two carbonyls.

Moreover, the polarisability is also low [e.g., for $\{M(CO)_5\}$ (M = Cr, Mo, or W), β = 1.0−0.9[14,16]], indicating a high capacity of the alkenylcarbyne ligand to "buffer" changes in the energy of the HOMO of the complex upon replacement of the *trans* ligand, conceivably as a result of extensive delocalization of the HOMO along the carbyne ligand. Such a propensity, exhibited by strong π-electron-acceptor ligands is known for other cases such as the rhenium carbonyl centre $\{Re(CO)(dppe)_2\}^+$ with a much lower β (0.62)[17] than that of the related chloride site $\{ReCl(dppe)_2\}$ (β = 3.4).[18]

This study also provided an opportunity to investigate the electronic coordination properties of a S-bonded ligand. In spite of the relevance of S-bonded ligands in coordination chemistry, the P_L of these ligands have virtually never been determined. From the above plot, it was possible to estimate the P_L value for the ligand $S_2P(OEt)_2^-$ as −1.34 V. Hence, this ligand behaves as a slightly stronger net electron donor than Cl^- and NCO^- (P_L = −1.19 or −1.16 V, respectively),[14] and is a much more effective electron releaser than NCS^- (P_L = −0.88 V[14]).

The anodic processes of the alkenyl−carbyne complexes of this study are commonly multi-electronic on the time scale of CPE and involve anodically induced proton loss. This has also been observed[3] for the related complexes **D** (X = CN; *n* = 1 or 4) (Scheme 1), **1a** and **1b**. Hence, CPE of, for example, **2f** at the first anodic wave (I) consumes ca. 3 Faradays/mol and generates ca. 2 mol H^+/mol complex measured by potentiometric acid−base titration of the electrolysed solution, whereas a total of ca. 4 Faradays/mol and ca. 4 mol H^+/mol complex was measured upon exhaustive CPE at the peak potential of the second anodic wave (II).

As a result of the oxidation of the complex, the Brönsted acidity of the alkenylcarbyne ligand is enhanced and proton loss occurs not only from the W≡C−CH= group but also from the carbocyclic moiety. Although we could postulate the formation of, for example, vinylidene or allenylidene species, we unfortunately did not succeed in the attempted isolation and full characterisation of the products derived from CPE.

The aminocarbyne (CNH_2) and the isocyanide (CNH) ligands at *trans*-$[ReCl(CNH_n)(dppe)_2][BF_4]_{n-1}$ (*n* = 2 or 1)[6] and *trans*-$[FeH(CNH)(dppe)_2][BF_4]$,[19] as well as some aminocarbenes in complexes of Pd^{II} or Pt^{II} [20] are also anodically activated toward proton extrusion, but the less acidic carbynes CCH_2R (R = alkyl, aryl or ester) in *trans*-$[ReX(\equiv C-CH_2R)(dppe)_2][BF_4]$ (X = F or Cl)[4] do not undergo such a reaction upon single-electron oxidation of their complexes; this oxidation is fully reversible on the time scale of the CV.

The proton loss is also in agreement with the detection, by CV (cathodic sweep) of the electrolysed solution, of an irreversible and broad cathodic wave, usually at ca. −0.5 V, assigned to H^+ reduction. This cathodic wave was also observed in the cyclic voltammetric study of the complexes, upon reverse of the anodic scan (run at a sufficiently low scan rate) following the oxidation waves. When the Pt electrode was replaced with a vitreous carbon one, that cathodic wave underwent an extensive cathodic shift (e.g., to ca. −1.2 V for **2g**) in agreement with the expected overpotential required for H^+ reduction at vitreous carbon.

The involvement of more than one electron with coupled H^+ extrusion in the anodic CV processes, at sufficiently low scan rates, was also corroborated by the enhancement of their current functions $i_p^{ox}\ C^{-1}\ v^{-1/2}$ (i_p^{ox}, anodic peak current; C, concentration; *v*, scan rate) upon (i) a decrease of the scan rate (e.g., by a factor of ca. 2−2.5 for **2a**, **2b** or **2f**, from v = 10 V s^{-1} to 0.050 V s^{-1}) and (ii) addition of pyridine. (e.g., by a factor of ca. 2, for a fivefold molar excess of base, for **2f** at v = 0.2 V s^{-1}). In the absence of base and at sufficiently high scan rates, the extent of deprotonation is lowered due to the restricted duration of the assay, and the first anodic wave tends to that of a single-electron process, for example, the current function of **2f** approaches that of the one-electron oxidation of *trans*-$[ReCl(N_2)(dppe)_2]$ at scan rates above ca. 5 Vs^{-1}.

Concluding Remarks

Our studies on the chemistry of α,β-unsaturated carbyne Fischer-type tungsten complexes[1–3] were extended (Scheme 1) by the work reported here on novel mononuclear complexes of type **D** (X = NCS, NCO; *n* = 1,4) (**2a−d**) (Scheme 2) and the analogous monocarbonyl derivative **3** (Scheme 3) containing the tridentate phosphane $PPh(CH_2CH_2PPh_2)_2$ (triphos). These complexes are further examples of the synthetic potential of the acetonitrile precursor complexes **1** for the preparation of the relatively scarcely known unsaturated carbyne complexes. Special features of these complexes are the following: (a) They have a conjugated π-system of C≡N and C=C bonds, bridged by

a metal carbyne M≡C moiety. In recent years, there has been an increasing interest in metal complexes with extended π-conjugated systems, since they can be used as components of molecular materials with enhanced electrical conductivities and nonlinear (NLO) properties.[21] (b) As shown by the X-ray crystal structure determinations, the bond lengths W−Cl and W−NCS in complexes **2a** and **3**, respectively, are longer than the average values; this indicates that the alkenylcarbyne group has a *trans* influence. (c) Such an influence conceivably results from the extensive π-electron-acceptor ability of these carbyne ligands, as shown by electrochemical studies which also indicate, for the first time, that such ligands have a remarkable lowering effect on both the electron richness and polarisability of the metal sites which they belong to. These features confirm the above proposed extended π-electron delocalisation along the alkenylcarbyne−metal−*trans*-ligand framework. (d) The alkenylcarbyne ligand is susceptible to anodically-induced deprotonation; the potential synthetic use of this towards the formation of novel multiple metal−carbon bonded species should be further explored.

Experimental Section

General: The reactions were carried out under dry nitrogen by Schlenk techniques. All solvents were dried by standard methods and were distilled under nitrogen before use. The precursor complexes **1a**,**b** and **2f** as well as **2e**, **2g**, and **4** were prepared by literature methods.[1a,1b,2] NaOCN, KSCN, [NBu_4]SCN, triphos [$PhP(CH_2CH_2PPh_2)_2$] (Aldrich) were used as received. − Infrared spectra were recorded on a Perkin−Elmer 1720-XFT spectrometer. − Mass spectra (FAB) were recorded on a VG-Autospec spectrometer, operating in the positive mode; 3-nitrobenzyl alcohol (NBA) was used as the matrix. − The conductivities were measured at room temp, in ca. 10^{-3} mol dm^{-3} acetone solutions, with a Jenway PCM3 conductivimeter. − The C, H, and N analyses were carried out with a Perkin−Elmer 240-B microanalyzer. − ^{1}H-, ^{13}C-, and ^{31}P-NMR spectra were run on a Bruker AC200 spectrometer at 200 MHz (^{1}H), 81 MHz (^{31}P) or 50.3 MHz (^{13}C) and a Bruker AC300 spectrometer at 300 MHz (^{1}H), 121.5 MHz (^{31}P) or 75.5 MHz (^{13}C). The spectral references were tetramethylsilane (TMS) for ^{1}H and ^{13}C, and 85% H_3PO_4 for ^{31}P-NMR measurements. All spectra were recorded with $CDCl_3$ as solvent. − Selected IR and ^{1}H-, ^{13}C{^{1}H}-, and ^{31}P{^{1}H}-NMR spectroscopic data are collected in Table 1 and 2.

Synthesis of 2a (X = SCN; *n* = 1), 2b (X = SCN; *n* = 4), 2c (X = OCN; *n* = 1), 2d (X = OCN; *n* = 4): An equiv. of KSCN (0.019 g) or NaOCN (0.013 g) was added to an orange solution of **1a** (0.172 g) or **1b** (0.180 g) (0.2 mmol) in 40 mL of methanol. The mixture was stirred at room temperature for a few hours. The reactions were followed by IR spectroscopy. The resulting solution was evaporated to dryness when no more starting material was detected. The residue was extracted with CH_2Cl_2 and filtered. Removal of the solvent in vacuo gave the desired compounds **2a−d** as yellow solid in very high yield. **2a**,**b** were prepared similarly from [Bu_4N]SCN in CH_2Cl_2. Yield: **2a**, 0.139 g, 88%; **2b**, 0.167 g, 90%; **2c**, 0.142 g, 92%; **2d**, 0.147 g, 90%.

2a: IR [KBr, ν(SCN); ν(CO)]: 2057 (vs); 1989 (vs), 1920 (vs). − ^{1}H NMR ($CDCl_3$): δ = 1.48 (m, 4 H, 2 CH_2), 1.96 (m, 2 H, CH_2), 1.99 (m, 2 H, CH_2), 2.60 [m, 2 H, $P(CH_aH_b)_2P$], 2.80 [m, 2 H, $P(CH_aH_b)_2P$], 7.37−7.73 (m, 20 H, 2 PPh_2). − ^{13}C NMR ($CDCl_3$): δ = 25.6 (s, CH_2), 26.2 (s, CH_2), 27.6 [m, $P(CH_2)_2P$], 31.5 (s, CH_2), 34.3 (s, CH_2), 128.3−135.5 (m, $C_β$, 2 PPh_2). − $C_{36}H_{33}NO_2P_2SW$: calcd. Synthesis of 3: A yellow solution of **2f** (0.383 g, 0.5 mmol) and an equiv. amount of $PhP(CH_2CH_2PPh_2)_2$ (0.267 g) in 50 mL of toluene was stirred under reflux for 24 h. The resulting orange solution was evaporated to dryness and the residue was washed with diethyl ether (3 × 10 mL) to remove the dppe. Drying in vacuo gave the desired compound **3** as an orange solid in good yield (0.339 g, 75%). − IR [KBr, ν(CO)]: 1874 (s). − ^{1}H NMR ($CDCl_3$): δ = 1.39 (m, 4 H, 2 CH_2), 1.84 (br, 2 H, CH_2), 1.97 (br, 2 H, CH_2), 2.14 (m, 2 H, PCH_2), 2.55 (m, 4 H, 2 PCH_2), 3.39 (m, 2 H, PCH_2), 7.14−7.78 (m, 25 H, Ph, 2 PPh_2). − ^{13}C NMR ($CDCl_3$): δ = 26.4 (m, PCH_2), 27.0 (s, CH_2), 27.6 (s, CH_2), 31.8 (s, CH_2), 34.4 (m, PCH_2), 34.5 (s, CH_2), 128.3−140.4 (m, $C_β$, Ph, 2 PPh_2). − MS (FAB, *m*/*z*) [M^+ − CO] = 847, [M^+ − CO − Cl − H] = 810, [M^+ − C_5H_8] = 807, [M^+ − Cl − C_5H_{10}] = 770, [M^+ − CO − C_7H_9] = 754, [M^+ − CO − Cl − C_6H_8] = 731. − $C_{42}H_{42}ClOP_3W$: calcd. C 57.7, H 4.8; found C 58.0, H 4.8.

Crystal Structure Determination of 2b and 3: The intensity data were collected at room temp on a Philips PW 1100 (**2b**) and on a Siemens AED (**3**) single-crystal diffractometer with graphite-monochromated Mo-$K_α$ radiation and the θ/2θ scan technique. Final unit cell parameters were obtained from a least-squares refinement of 24 (**2b**) and 28 (**3**) reflections. Crystallographic and experimental details for both structures are summarised in Table 6. Data were corrected for Lorentz and polarisation effects in the usual manner. A correction for absorption was made for both complexes [maximum and minimum value for the transmission coefficient was 1.000 and 0.5754 (**2b**) and 1.000 and 0.6493 (**3**)].[22]
Both structures were solved by Patterson and Fourier methods and refined by full-matrix least-squares procedures (based on F_o^2) with

Table 6. Experimental data for the X-ray diffraction studies of complexes **2b** and **3**

anisotropic thermal parameters in the last cycles of refinement for all the non-hydrogen atoms. The hydrogen atoms were introduced into the geometrically calculated positions and were refined riding on the corresponding carbon atoms. In the final cycles of refinement a weighting scheme $w = 1/[\sigma^2F_o^2 + (0.0730\,P)^2 + 0.5625\,P]$ (**2b**) and $w = 1/[\sigma^2F_o^2 + (0.0627\,P)^2]$ (**3**) where $P = (F_o^2 + 2\,F_c^2)/3$ was used. All calculations were carried out on the DIGITAL AlphaStation 255 computers of the "Centro di Studio per la Strutturistica Diffrattometrica del CNR," Parma, with the SHELX-97 systems of crystallographic computer programs.[23]

Electrochemical Measurements: The electrochemical experiments were carried out either on an EG&G PAR 273 A potentiostat/galvanostat connected to a 386-SX personal computer through a GPIB interface, or on an EG&G PAR 173 potentiostat/galvanostat and an EG&G PARC 175 Universal programmer. Cyclic voltammetry (CV) was undertaken in a two-compartment three-electrode cell, at a platinum- or vitreous carbon disc (d = 0.5 mm) working electrode, probed by a Luggin capillary connected to a silver-wire pseudo-reference electrode; a platinum or tungsten auxiliary electrode was employed. Controlled-potential electrolyses (CPE) were carried out in a three-electrode H-type cell with a platinum-gauze working and counter electrodes in compartments separated by a glass frit; a Luggin capillary, probing the working electrode, was connected to a silver-wire pseudo-reference electrode. The oxidation potentials of the complexes were measured by cyclic voltammetry in 0.2 mol dm^{-3} [NBu$_4$][BF$_4$]/NCMe (or THF), in the presence of ferrocene as the internal standard, and the redox potential values are quoted relative to the SCE by using the [Fe(η^5-C$_5$H$_5$)$_2$]$^{0/+}$ couple ($E_{1/2}^{ox}$ = 0.42 or 0.545 V vs SCE, in 0.2 mol dm^{-3} [NBu$_4$][BF$_4$]/NCMe or THF, respectively). The use, as reference electrode, of the SCE or other electrode in aqueous medium, was avoided due to the sensitivity of the systems to water. The CPE experiments were monitored regularly by CV, thus assuring that no significant potential drift occurred along the electrolyses.

The acid−base titrations of the electrochemically oxidised solutions were carried out as indicated before,[20] with a solution of NaOH in CH$_3$OH which was standardised by titration against benzoic acid in the organic solvent (thymol blue was used as the indicator). The results presented were corrected for background effects by performing, in each case, the titration of the blank solution of 0.2 mol dm^{-3} [NBu$_4$][BF$_4$] which was electrolysed under identical conditions to those used for the corresponding complex solution.

Supplementary Material: The supplementary material for both structures includes the lists of atomic coordinates for the non-H atoms, calculated coordinates for the hydrogen atoms, and anisotropic thermal parameters. The details of the crystal structure investigations are deposited at the Cambridge Crystallographic Data Centre as supplementary publications nos. CCDC-130866 (**2b**) and CCDC-130867 (**3**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44 (0)1223/336 033, E-mail: deposit@ccdc.cam.ac.uk.

Chiral Quadridentate Ligands Derived from Amino Acids and Some Zinc Complexes Thereof

Nicole Niklas,[a] Olaf Walter,[b] and Ralf Alsfasser*[a]

Dedicated to Prof. Dr. Heinrich Vahrenkamp on the occasion of his 60th birthday

Keywords: Bioinorganic chemistry / Zinc / Amino acids / Chiral ligands / Tripodal ligands

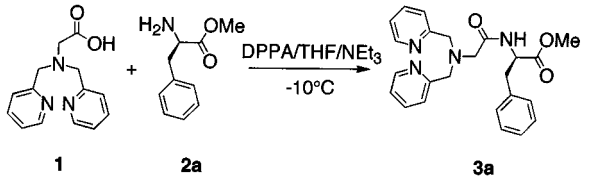
A series of three new quadridentate ligands was synthesized by reaction of the haloacetylated amino acid esters L-BrAc–Phe–OMe (**4a**), L-BrAc–Lys(Z)–OMe (**4b**), and ClAc–Gly–OEt (**4c**), respectively, with bis(picolyl)amine (bpa, **5**). The obtained products L-bpaAc–Phe–OMe (**3a**), L-bpaAc–Lys(Z)–OMe (**3b**), and bpaAc–Gly–OEt (**3c**) were treated with $Zn(OTf)_2$ (OTf = $CF_3SO_3^-$) to yield the trigonal-bipyramidal complexes [(L-bpaAc–Phe–OMe)ZnOTf](OTf) (**6a**), [(L-bpaAc–Lys(Z)–OMe)ZnOTf](OTf) (**6b**), and [(bpaAc–Gly–OEt)ZnOTf](OTf) (**6c**). Crystal structures of **6c** and the hydrolysis product [(L-bpaAc–Phe–OMe)-(H_2O)ZnOTf]$(OTf)_2$ (**7a**) are reported. The results suggest the formation of a chiral pocket at the metal center provided by the benzyl substituent in the L-phenylalanine derivative **7a**. This observation is further supported by ^{1}H-NMR and circular dichroism spectroscopic data. These methods indicate a significant ordering effect within the ligands upon metal coordination as well as interactions between the first coordination spheres and their chiral environments provided by the L-phenylalanine and L-lysine moieties of **3a** and **3b**, respectively. Our results are discussed with respect to the development of chiral building blocks for transition metal catalysts and biomimetic assemblies.

Introduction

Apart from their importance in biological systems, amino acids are versatile building blocks for a variety of fascinating synthetic molecular and supramolecular assemblies such as peptide nucleic acids (PNAs),[1] dendrimers,[2] micelles,[3] or de novo designed peptides[4] and proteins.[5,6] The scope of accessible amino acid side-chain functionalities has been tremendously broadened by organic chemists who have developed different methods for the enantioselective synthesis and processing of artificial amino acids carrying, for example, aromatic rings,[7] sugars,[8] or organic cofactors such as pyridoxamine[9] and flavine.[10] The latter two examples illustrate the potential of nonnatural amino acids as catalytically active components for the design of new materials.

Catalytically active amino acid derivatives are attractive targets not only for organic chemists but also for coordination chemistry. There is a still growing interest in metal complexes as enantioselective catalysts for organic conversions such as oxidations,[11,12] carbon−carbon bond formations,[13] or hydrolytic cleavage reactions.[14,15] Metal complexes of synthetic amino acids with covalently attached synthetic polydentate chelators are interesting building blocks for polyfunctional catalysts. They are chiral and have a powerful potential for combinatorial catalyst screening.[16,17] However, only a few examples of suitable ligands have been described in the literature. Those include bifunctional chelating reagents[18−20] developed for pharmaceutical applications, conjugates of lysine with EDTA or EDTA-related ligands,[21−23] as well as a bipyridine-modified alanine.[24] The only example of an acyclic tridentate amine ligand connected to an amino acid is a terpyridine derivative of cysteine, which has not been isolated as a monomer.[25,26]

Work in our laboratories has focused on the development and investigation of Werner-type coordination compounds with synthetic amino acids carrying well-defined metal binding sites.[27−29] In this report we present ligands derived from glycine, L-phenylalanine, and L-lysine. Zinc complexes have been prepared and investigated by X-ray crystallography, NMR, and circular dichroism spectroscopy. Characteristics of the compounds are the availability of suitable coupling positions for further derivatization, the interplay between the metal center and its chiral environment, as well as the availability of open coordination sites for metal-centered reactions.



Results

Ligand Synthesis

Our initial approach involved applying carboxylate-substituted tridentate amines in standard amide coupling reac-

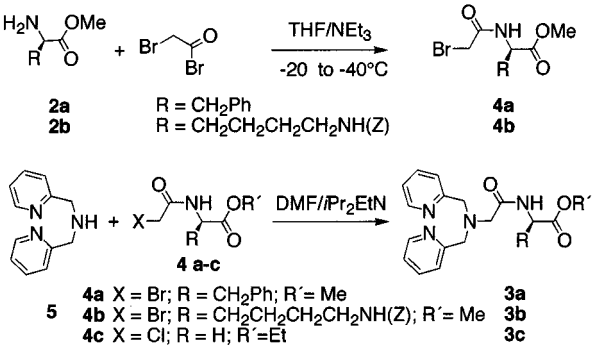


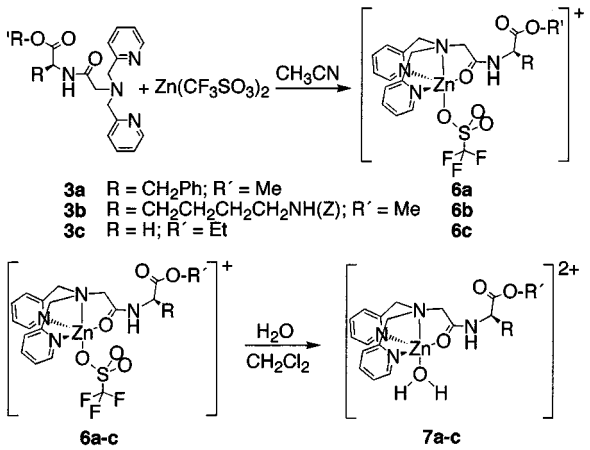
Scheme 1. Azide coupling strategy for the synthesis of the ligand **3a**

tions with the N-termini of amino acids (Scheme 1). The triamine used was the bis(picolyl)glycine **1**, which was prepared according to a procedure described by Que et al.[30] for the synthesis of iron complexes. Different methods were examined for coupling **1** to the amino group of L-phenylalanine methyl ester. Attempts to prepare the acid chloride by reaction of bis(picolyl)glycine with thionyl chloride failed. Formation of an amide bond by the intermediate formation of a mixed anhydride with isobutyl chlorofomate[31] also proved unsuccessful. The desired ligand L-bpaAc−Phe−OMe (**3a**) was finally obtained from **1** and phenylalanine methyl ester (**2a**) by the application of diphenylphosphoryl azide at low temperature in THF (Scheme 1).[31] However, purification of the product was difficult and the method afforded only poor yields (below 10%).

Since the coupling strategies described above were not satisfactory we changed our approach. The method employed involves bromoacetylation of an appropriate amino acid ester followed by nucleophilic substitution (Scheme 2). This coupling method has been shown to be very useful for the synthesis of polyfunctional chelating ligands. Typical examples include polyazamacrocycle−protein conjugates[32] for pharmaceutical applications and a phenylalanine−triazacyclononanetriamide derivative that served as a model for peptide organization at transition-metal templates.[33] Applications are not limited to metal-peptide derivatives, as exemplified by the synthesis of a hexadentate open-chain ligand by Sargeson et al.[34]

Scheme 2 illustrates our synthesis of L-bpaAc−Phe−OMe (**3a**) and the analogous ligand L-bpaAc−Lys(Z)−OMe (Z = benzyloxycarbonyl) (**3b**). L-Phe−OMe (**2a**) and L-Lys(Z)−OMe (**2b**) were treated with bromoacetyl bromide to yield the respective products L-BrAc−Phe−OMe (**4a**) and L-BrAc−Lys(Z)−OMe (**4b**). The synthesis of **4a** has been reported earlier in a communication by Fairlie et al.[33] but no experimental details were

Scheme 2. Haloacetyl strategy for the synthesis of the ligands **3a**−**c**



given. Subsequent reaction of **4a** and **4b** with bis(picolyl)-amine (bpa, **5**) resulted in the formation of the desired chiral ligands **3a** and **3b**.

We have also prepared the nonchiral glycine derivative **3c** (Scheme 2) for comparative studies concerning the role of the chiral ligand environments provided by **3a** and **3b**. The starting material for this synthesis was commercially available (chloroacetyl)glycine. It turned out that the yields of its reaction with **5** (ca. 50%) are significantly lower than those obtained after bromide substitution even if both steps of the bromoacetyl bromide route are considered (overall yield ca. 80%). All three ligands were conveniently purified by flash column chromatography and obtained as spectroscopically pure (^{1}H NMR) yellow oils, which were further characterized by FD-MS.

Complexes

The amino acid ligands **3a**−**c** readily react with nonaqueous zinc triflate [$Zn(OTf)_2$] in dry acetonitrile (Scheme 3). Single crystals suitable for X-ray crystallographic characterization were obtained for [(bpaAc−Gly−OEt)ZnOTf]OTf (**6c**) (Figure 1). The initially formed triflate complexes **6a**−**c** are extremely moisture-sensitive and hygroscopic. Their hydrolysis products **7a**−**c** are readily obtained in the presence of moisture from solvents or air. Single crystals of the aquo complex [(L-bpaAc−Phe−OMe)(H_2O)Zn](OTf)$_2$ (**7a**, Figure 2) were obtained from dichloromethane/ethyl ether solutions of **6a**, which were exposed to air. Accordingly, it is difficult to obtain samples that do not show at least trace amounts of water in their NMR spectra. C,H,N elemental analysis data are also consistent with the presence of various amounts of water. However, the monocations [LZnOTf]$^+$ are the dominant species observed by FAB mass spectrometry for all complexes.

It is interesting to note that the glycine derivative **6c** was found to be the least moisture-sensitive whereas we were not able to obtain a dry sample of the L-bpaAc−Lys(Z)−OMe complex **6b**. Purification of the latter was further complicated because the compound always separates as an oil regardless of the solvent applied, thereby

Scheme 3. Synthesis and structures of the zinc complexes **6a**−**c** and **7a**−**c**

preventing recrystallization. The oil solidified as a white foam upon drying under vacuum and this was characterized by NMR, IR, and circular dichroism spectroscopy, as well as by FAB-MS. The spectroscopic properties of this compound compare well with those of complexes **7a** and **7c** thus ensuring a correct interpretation of the data, which are consistent with the formulation **7b** given in Scheme 3.

Solid-State Structures

The mononuclear cation of [L-bpaAc−Gly−OEt)Zn-(OTf)](OTf) (**6c**) is shown in Figure 1. Selected bond lengths and angles are summarized in Table 1. A slightly distorted trigonal bipyramidal coordination environment at Zn^{2+} is observed with one triflate anion and the bridging tertiary amine nitrogen atom occupying the axial positions (N−Zn−O = 177°). The two pyridine N atoms and the amide oxygen atom of the amino acid ligands are bound in the trigonal plane. A comparison with zinc complexes of tris(picolyl)amine[35] and bis(picolyl)glycine,[36] respectively, confirms that the equatorial pyridine N−Zn bonds (204−206 pm), as well as the longer axial N−Zn bond (219 pm) are typical for tripodal quadridentate ligands derived from bis(picolyl)amine. In contrast, all Zn−N bonds are equal in trigonal-bipyramidal[37] and octahedral[38] zinc complexes of the tridentate bis(picolyl)amine ligand itself. The amide and triflate O−Zn distances in **6** (CO: 202 pm; OTf: 201 pm) are in excellent agreement with those found for carboxylate O−Zn bonds in bis(picolyl)glycine complexes.[36]

Facile exchange of a triflate ligand is an expected property of the complexes **6a**−**c**. When a sample of [(L-bpaAc−Phe−OMe)Zn(OTf)](OTf) (**6a**) in CH_2Cl_2/Et_2O was exposed to moist air overnight, crystals of the dicationic aquo complex $[(L\text{-}bpaAc-Phe-OMe)(H_2O)Zn](OTf)_2$ (**7a**, Figure 2 and Table 1) were obtained. A slight tetragonal distortion of its trigonal bipyramidal geometry is evident from the 170° angle between the coordinated water molecule, Zn^{2+}, and the tertiary amine nitrogen atom. The axial oxygen ligand is tilted towards the amide oxygen atom [**7a**: $H_2O-Zn-O$ = 92°/H_2O-Zn-N(equatorial) = 102−106° compared with **6**: OTf−Zn−O = 99° OTf−Zn−N(equatorial) = 97−102°].

As can be seen from Figure 1 and 2 the ester functions of the ligands are noncoordinating and available for further derivatization. An interesting feature of the chiral phenyl-

alanine ligand in **7a** is the orientation of its phenyl ring. The ring covers one side of the open coordination site between the amide oxygen atom and one of the pyridine rings with its center located 4.5 Å away from the metal center. The possible formation of a chiral pocket is an important difference between **3a**/**3b** and comparable ligands developed by Canary et al.[39,40] These authors have synthesized chiral derivatives of tris(picolyl)amine by derivatization of the bridging methylene groups of the ligands leading to complexes in which the bulky substituents are always pointing away from the metal center.

The solid-state IR spectra (KBr pellets) of our compounds are consistent with the X-ray crystallographic results. Binding of the amide oxygen atom is evident from a red shift of the amide IR vibrations in the complexes compared with the free ligands [1672 (**3a**) → 1641 (**7a**); 1668 (**3b**) → 1637 (**7b**); 1674 (**3c**) → 1641 (**7c**)]. The spectra of all complexes exhibit signals for the triflate anions between 1200 and 1300 cm^{-1}. These values are typical for noncoordinating $CF_3SO_3^-$ and are consistent with the formulations **7a**−**7c**. A broad OH band at 3000 cm^{-1} was always observed.

NMR Spectra

The solid-state structure of **7a** suggests that the chiral environment provided by the phenylalanine moiety may influence the accessibility of the open coordination site of the metal centers. It is important for reactivity studies to probe this structural feature in solution. We selected diamagnetic Zn^{2+} complexes as a starting point for our investigations since they allow the application of NMR spectroscopy to compare solution and solid-state structures. The assignment of the ^{1}H-NMR signals of **7a**−**c** ($CDCl_3$ solutions) is based on comparison with the free ligands, the bromoacetylated compounds, and the starting materials, as well as ^{1}H-^{1}H and ^{1}H-^{13}C COSY spectra.

As may be expected the pyridine proton resonances are shifted to lower frequencies upon coordination of the metal ion. The two rings are equivalent in the free ligands **3a**−**c**, as well as in [(bpa-Gly−OEt)(H_2O)Zn]($OTf)_2$ (**7c**). A different pattern is observed in the spectra of the chiral complexes **7a** and **7b**. These compounds show two inequivalent pyridine rings with partially overlapping signals as a consequence of the chiral carbon center. The observed splitting is a clear indication of the structural rigidity induced by metal coordination.

A very sensitive probe for changes in the environment are the methylene proton resonances, which are shown in Figure 3. Unfortunately, some of the signals overlap with those of the methyl esters and α-CH groups but they are unambiguously assignable based on ^{1}H-^{1}H and ^{1}H-^{13}C COSY experiments as well as integration. The C(O)−CH_2 groups are observed as singlets in the ligands **3a**−**3c**. Their corresponding signals of the chiral complexes **7a** and **7b** are split into two doublets. The pyridine-CH_2 protons are diastereotopic in the chiral ligands **3a** and **3b** and their signals appear as AB systems with geminal coupling constants of ca. 14 Hz. These signals are further split in the

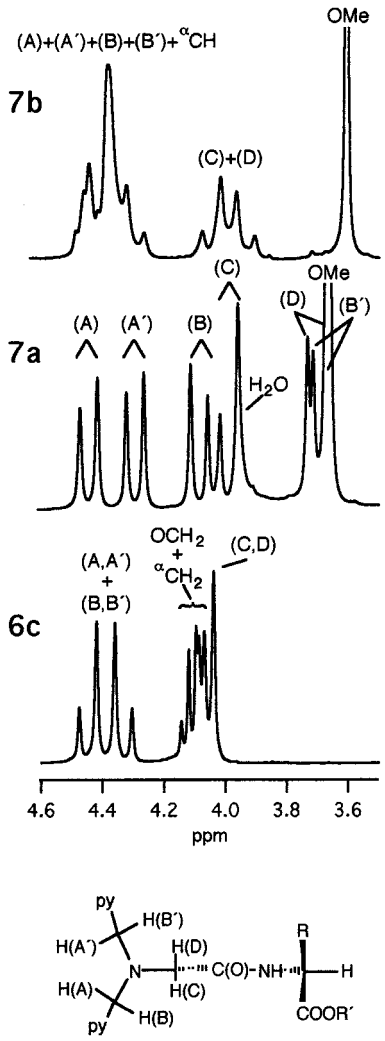

Figure 3. ^{1}H-NMR spectra of the zinc complexes **6c**, **7a**, and **7b** in $CDCl_3$

spectra of the complexes **7a** and **7b** since the two pyridine rings become inequivalent.

Most interesting is the ^{1}H-NMR spectrum of the phenylalanine derivative **7a**. Six doublets are observed for the six methylene protons. Two of them are observed at a significantly higher field (δ = 3.7) than expected if the other two complexes **7b** and **7c** are considered as a reference. The ^{1}H-^{1}H COSY spectrum confirms that one of these signals can be assigned to the C(O)−CH_2 group, whereas the other corresponds to a pyridine−methylene bridge. We interpret the observed high-field shift as an effect of the aromatic ring current of the phenyl ring, which is situated between one pyridine ring and the amide function (Figure 2). A corresponding high-field shift is also observed for the phenyl protons in **7a**, which are observed at rather unusual values of δ = 6.62 (H4) and δ = 6.92 (H3,5). The NMR spectra thus confirm the importance of specific interactions between the benzyl group of phenylalanine and the metal coordination sphere in **7a**.

Exchange of the coordinated triflate by water from air is also evident from NMR spectroscopy. For the extremely hygroscopic free ligands in $CDCl_3$ we occasionally observe

a signal at $\delta = 2$, which is assignable to H_2O. This signal is shifted to significantly lower fields in the complexes with values ranging up to $\delta = 5.6$ in the spectrum of [(L-bpa-Lys−OMe)(H_2O)Zn](OTf)$_2$ (**7b**). The position depends on the water content and moves towards $\delta = 2$ for higher H_2O concentrations. This is consistent with a fast equilibrium between coordinated and noncoordinated water molecules. It is interesting to note that the urethane H signals of the benzyloxycarbonyl protecting groups in **3b** and **7b** are sensitive to the presence of water and shift to slightly higher fields if the compounds are not rigorously dry. All other signals, including the amide H resonance, are invariant in $CDCl_3$ under all experimental conditions relevant for this work.

Circular Dichroism

Ordering phenomena of chiral molecules and supramolecules in solution are conveniently probed by circular dichroism spectroscopy.[41]–[49] A particular advantage of the method is its applicability where UV/Vis spectra are not very informative. The electronic absorption spectra of the bromoacetylated amino acids **4a** and **4b**, (chloroacetyl)glycine, the ligands **3a**−**3c**, as well as the zinc complexes **7a**−**7c** in methanol, show only a broad band at 260 nm, which is largely obscured by the slope of a strong absorption below 200 nm. In contrast, the CD spectra of [(L-bpaAc−Phe−OMe)(H_2O)Zn](OTf)$_2$ (**7a**, Figure 4a) and [(L-bpaAc−Lys−OMe)(H_2O)Zn](OTf)$_2$ (**7b**, Figure 4b) measured in methanol (10^{-3} M) have very distinct features that further support the data obtained from NMR and X-ray crystallographic studies.

The parent amino acids L-Lys−OMe and L-Phe−OMe display only one band at 210 nm (Lys) and 220 nm (Phe), respectively. The signal observed for phenylalanine is stronger and may be assigned to the π-π* transition of the phenyl ring. Bromoacetylation of ε-(benzyloxycarbonyl)lysine methyl ester results in a new signal with a negative Cotton effect at 225 nm and a positive Cotton effect at 245 nm. A shoulder at 245 nm is also well-resolved in the corresponding phenylalanine derivative. This feature disappears in the spectra of the two ligands **3a** and **3b** and a new band with a positive Cotton effect is observed at 260 nm. We assign this band to π-π* transitions of the pyridine rings in agreement with interpretations given by Canary et al.[40] Upon complexation with Zn^{2+} the sign of the pyridine signal changes and the band is shifted to slightly longer wavelengths. It is evident from Figure 4b that the intensity of the 220-nm band is significantly smaller for the ligand **3a** than for the other phenylalanine derivatives discussed in our study. This may be a consequence of the higher flexibility of L-bpaAc−Phe−OMe compared with either **2a**, **4a**, or **7a**. However, we do not have an obvious explanation for this behavior at the present stage of our investigations.

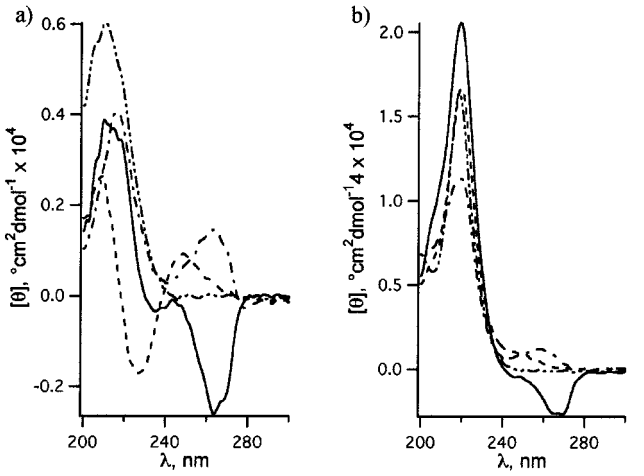

Figure 4. Circular dichroism spectra (10^{-3} M in methanol) of: (a) the L-lysine derivatives Lys(Z)−OMe (**2b**; − · · −), BrAc−Lys(Z)−OMe (**4b**; − −), bpaAc−Lys(Z)−OMe (**3b**; − · −), and [(bpaAc−Lys(Z)−OMe)(H_2O)Zn](OTf)$_2$ (**7b**, —); (b) the L-phenylalanine derivatives Phe−OMe (**2a**; − · · −), BrAc−Phe−OMe (**4a**; − −), bpaAc−Phe−OMe (**3a**; − · −), and [(bpaAc−Phe−OMe)(H_2O)Zn](OTf)$_2$ (**7a**; —)

Discussion

The ligands **3a**−**c** are quadridentate and readily bind zinc(II) to yield stable compounds that are soluble in a variety of solvents ranging from methanol to chloroform. A labile coordination site is available in the trigonal-bipyramidal triflate complexes **6a**−**c**. This is illustrated by the facile ligand exchange observed in the presence of moisture (air), which results in the formation of **7a**−**c**. We have designed our ligands with two features in mind. One is the availability of a functional group for further derivatization. This requirement is met by the presence of a noncoordinating ester function in the complexes **6a**−**c** and **7a**−**c**. No indication was found in the solid state or in solution for an interaction between this group and the metal center. Furthermore, the protected ε-amino group of lysine in bpa-Lys(Z)−OMe (**3b**) may be useful as an additional site for modifications.

Our second objective was to find a chiral noncoordinating environment provided by the ligands. The three amino acid derivatives used in the present study are well suited for comparative studies concerning interactions between the coordinated metal center and its noncoordinating environment since their side chains represent achiral and chiral, as well as aliphatic and aromatic substituents. In the solid-state structure of **7a** the phenyl ring of L-phenylalanine is oriented towards the open coordination site at Zn^{2+} (Figure 2) covering one side of the complex between a pyridine ring and the coordinated amide group. The NMR- and CD-spectroscopic studies presented in this report provide evi-

dence for a significant organization of the chiral environment upon metal complexation in **7a** and **7b** in solution. This is of particular interest for applications of the ligands and complexes in molecular recognition and reactivity studies.

Conclusions

The ligands **3a**−**c** are useful new building blocks for the synthesis of polyfunctional transition-metal complexes based on the chiral pool provided by natural amino acids. They bind tightly and in a well-defined manner to metal ions but offer sufficient flexibility and accessible open coordination sites for metal-ion reactivity. The amino acid side chains cover one side of the complexes such that the complexes **7a** and **7b** are promising candidates for enantioselective molecular recognition and hydrolysis studies. Our concept allows a facile and systematic modification of the properties of metal complexes by variation of the amino acid. The lysine derivative **7b** is particularly interesting for further modifications at the ε-amino group of the ligand. We are currently investigating this possibility in order to extend our building-block approach.

Experimental Section

General Methods: Spectra were recorded with the following instruments: UV/Vis: Cary 1G Spectrophotometer. − Circular Dichroism: Jasco J710 Spectropolarimeter. − IR: Mattson Polaris FT IR. − ^{1}H and ^{13}C NMR: Bruker Avance DPX 300. All chemical shifts are referenced to TMS as internal standard, with high-frequency shifts recorded as positive. − All reactions were carried out under dry nitrogen. The following workup was performed under ambient laboratory conditions unless stated otherwise. The bis(picolyl)glycine **1**[30] and bis(picolyl)amine **5**[52,53] were synthesized according to published procedures. L-Lys(Z)−OMe·HCl (**2b**) was purchased from Nova Biochem, L-Phe−OMe·HCl (**2a**) from Bachem. Absolute solvents (THF, CH_2Cl_2, Et_2O, DMF, CH_3CN) were purchased from Fluka and stored under nitrogen. Ethyl acetate and hexane were reagent grade (Roth). All solvents were used without further purification. Silca gel Merck type 9385 (230−400 mesh, 60 Å) from Aldrich was used for flash column chromatography. Eluents were optimized by TLC on silica gel 60 F254 sheets (0.2 mm layer) from Riedel-de Haën. All other chemicals including ClAc−Gly−OEt and deuterated solvents were obtained from Aldrich. Triethylamine was distilled under N_2 prior to use.

Diphenylphosphoryl Azide (DPPA) Coupling

bpaAc−Phe−OMe (3a): Freshly distilled NEt_3 (1.00 mL, 7.00 mmol) was added in one portion to a stirred suspension of **2a** × HCl (166 mg, 0.77 mmol) under N_2 in 10 mL of absolute THF. Stirring was continued for 30 min, the mixture filtered to remove NEt_3 × HCl and the resulting clear solution cooled to −10 °C using an ice/salt bath. This solution was added in one portion with stirring to another THF (10 mL) solution containing **1** (150 mg, 0.70 mmol) at −10 °C. DPPA (0.17 mL, 0.77 mmol) was added slowly followed by dropwise addition of NEt_3 (0.11 mL, 0.77 mmol). Care was taken to keep the temperature at or below −10 °C. The stirred reaction mixture was kept at −10 °C for another 30 min and the resulting solution was then allowed to warm up to room temperature. Stirring was continued overnight, all the solvent was removed under vacuum and the residue was treated with 10 mL of $CHCl_3$. Cooling to −20 °C afforded a solid, which was filtered off and discarded. The filtrate was concentrated to dryness and the solid obtained was redissolved in a minimum amount of AcOEt. This solution was purified by flash column chromatography on silica gel. Impurities eluted with AcOEt and the product was obtained with yields below 10% by subsequent elution with pure methanol.

Bromoacetylated Amino Acid Esters

BrAc−Phe−OMe (4a): L-Phe−OMe·HCl (10.00 g, 46.40 mmol) was suspended in 200 mL of THF. Triethylamine (12.93 mL, 92.80 mmol) was added with stirring and the mixture was cooled to −10 °C in an ice/salt bath. Bromoacetyl bromide (4.04 mL, 46.40 mmol) was dissolved in 50 mL of THF and the solution was added dropwise to the cold suspension over a period of 2 h. The mixture was stirred for another 2 h without further cooling. Insoluble $HNEt_3Br$ was filtered off and the solvent removed in a vacuum. The crude yellow solid obtained after removal of all THF was redissolved in the minimum amount of ethyl acetate. Colorless needles of the product **4a** (13.46 g, 44.86 mmol, 96.7%) were obtained after addition of hexane and storage in a refrigerator (−20 °C) overnight. The compound was collected on a sintered-glass filter, dried under vacuum, and characterized by FAB-MS, ^{1}H-NMR and ^{13}C-NMR spectroscopy. − FAB-MS (nitrobenzyl alcohol); *m/z*: 300 [M^+], 240 [M^+ − COOMe]. − ^{1}H NMR (300 MHz, $CDCl_3$): δ = 3.15 (m, 2 H, $^{\beta}CH_2$), 3.74 (s, 3 H, OCH_3), 3.84 (s, 2 H, Br−CH_2), 4.85 (m, 1 H, $^{\alpha}CH$), 6.83 (s, br, 1 H, NH), 7.12 (m, 2 H, H2-Ph + H6-Ph), 7.28 (m, 3 H, H3-Ph + H4-Ph + H5-Ph). − ^{13}C NMR (75 MHz, $CDCl_3$): δ = 28.6 (Br−C), 37.7 ($^{\beta}C$), 52.5 (OCH_3), 53.7 ($^{\alpha}C$), 127.3, 128.7, 129.3 (C2-Ph + C3-Ph + C4-Ph + C5-Ph + C6-Ph), 135.9 (C1-Ph), 165.2, 171.3 [C(O)-ester + C(O)-amide]. − IR (KBr): $\tilde{\nu}$ = 1734 cm^{-1} (COOMe), 1645 (amide I), 1537 (amide II). − Circular Dichroism (10^{-3} M in methanol): λ, nm ([θ] × 10^4 °cm^2dmol^{-1}) = 219 (+1.67), 244 (shoulder, +0.11).

BrAc−Lys(Z)−OMe (4b): L-Lys(Z)−OMe·HCl (5.02 g, 15.20 mmol) was suspended in 150 mL of THF and cooled to −30 °C in a methanol/dry ice bath. Triethylamine (4.22 mL, 30.40 mmol) was added and the mixture stirred for 30 min. Bromoacetyl bromide (1.32 mL, 15.20 mmol) was dissolved in 50 mL of THF and the solution added dropwise to the cold suspension over a period of 2.5 h. The mixture was stirred for another 1.5 h at −30 °C. Insoluble $HNEt_3Br$ was filtered off and the solvent removed by rotary evaporation. The crude brown solid obtained after removal of all THF was redissolved in 50 mL of hot ethyl acetate and the solution left at −20 °C overnight. The product precipitated as a colorless solid, which was filtered off and dried under vacuum. A second crop was obtained after addition of hexane and subsequent cooling. The fractions were combined (5.51 g, 13.27 mmol, 87.3%) and characterized by FAB-MS, ^{1}H-NMR and ^{13}C-NMR spectroscopy. − FD-MS ($CDCl_3$); *m/z*: 415 [M^+]. − ^{1}H NMR (300 MHz, $CDCl_3$): δ = 1.38 (m, 2 H, $^{\gamma}CH_2$), 1.52 (m, 2 H, $^{\delta}CH_2$), 1.81 (m, 2 H, $^{\beta}CH_2$), 3.18 (m, 2 H, $^{\varepsilon}CH_2$), 3.75 (s, 3 H, OCH_3), 3.87 (s, 2 H, Br−CH_2), 4.57 (m, 1 H, $^{\alpha}CH$), 4.89 (m, 1 H, NH-Z), 5.09 (s, 2 H, CH_2-Z), 7.35 (m, 5 H, Ph-Z), 7.02 (d, 1 H, $^3J_{HH}$ = 7.3 Hz, NH). − ^{13}C NMR (75 MHz, $CDCl_3$): δ = 22.2 ($^{\gamma}C$), 28.7 (Br−C), 29.4 ($^{\delta}C$), 31.7 ($^{\beta}C$), 40.47 ($^{\varepsilon}C$), 52.6 (OCH_3 + $^{\alpha}C$), 66.7 (CH_2-Z), 128.1, 128.1, 128.4, 128.5 (Z-C2-Ph + Z-C3-Ph + Z-C4-Ph + Z-C5-Ph + Z-C6-Ph), 136.6 (Z-C1-Ph), 156.5 [Z-C(O)], 165.6, 172.2 [C(O)-ester + amide]. − IR (KBr): $\tilde{\nu}$ = 1740 cm^{-1} (COOMe), 1698 (Z-urethane), 1646 (amide I), 1540 (amide II). − Circular Dichroism

(10^{-3} M in methanol): λ, nm ([θ] × 10^4 °cm^{2}dmol^{-1}) = 209 (+0.26), 227 (−0.17), 248 (+0.09).

Ligands

General Procedure: Equimolar amounts of bis(picolyl)amine (**5**), the respective haloacetylated amino acid ester, and ethyldiisopropylamine (DIPEA) were dissolved in DMF. The solution was stirred for 20 h at room temperature. All solvents were removed by rotary evaporation. Ethyl acetate was added, resulting in the precipitation of the ammonium halide salt, which was filtered off and discarded. The filtrate was concentrated to dryness yielding a brown oil, which was purified by silica gel column chromatography using CH_2Cl_2/MeOH (11:1) as eluent. A small yellow fraction containing some of the haloacetylated amino acid ester starting material eluted first. The product was eluted next as a broad light yellow (yellow in the case of **3a**) fraction. A third yellow fraction, which was well separated from the product, was usually not collected. The solution containing the desired product was concentrated to dryness by rotary evaporation and the resulting light yellow oil dried under vacuum.

bpaAc−Phe−OMe (3a): 9.00 g (29.98 mmol) of **4a**, 5.91 g (29.98 mmol) of bpa, 5.20 mL (29.98 mmol) of DIPEA, 100 mL of DMF, 100 mL of AcOEt. Yield: 10.17 g (24.31 mmol, 81%). − $C_{24}H_{26}N_4O_3$ (418.5 g/mol): FD-MS ($CDCl_3$); *m/z*: 418 [M^+]. − ^{1}H NMR (300 MHz, $CDCl_3$): δ = 2.00 (H_2O), 3.12−3.29 (ABX, 2 H, $^{\beta}CH_2$), 3.26 [s, 2 H, C(O)−CH_2], 3.69 (s, 3 H, OCH_3), 3.73, 3.85 (2 × d, 4 H, $^2J_{HH}$ = 14.2 Hz, 2 × py-CH_2), 4.90 (m, 1 H, $^{\alpha}CH$), 7.18 (m, 9 H, 5 × H-Ph + H3-py + H5-py), 7.56 (m, 2 H, H4-py), 8.52 (d, 2 H, $^3J_{HH}$ = 4.9 Hz, H6-py), 9.05 (d, 1 H, $^3J_{HH}$ = 8.0 Hz, NH). − ^{13}C NMR (75 MHz, $CDCl_3$): δ = 37.5 ($^{\beta}C$), 52.1 (OCH_3), 53.1 ($^{\alpha}C$), 57.6 [C(O)−CH_2], 60.1 (py-CH_2), 122.3, 122.9 (C3-py + C5-py), 126.80, 128.4, 129.2 (C2-Ph + C3-Ph + C4-Ph + C5-Ph + C6-Ph), 136.5 (3 C, 2 × C4-py + C1-Ph), 149.1 (C6-py), 158.2 (C2-py), 171.2, 172.1 [C(O)-ester + C(O)-amide]. − IR (film on NaCl): $\tilde{\nu}$ = 1745 cm^{-1} (COOMe), 1672 (amide I), 1513 (amide II). − Circular Dichroism (10^{-3} M in methanol): λ, nm ([θ] × 10^4 °cm^{2}dmol^{-1}) = 221 (+1.13), 257 (+0.05), 265 (+0.13).

bpaAc−Lys(Z)−OMe (3b): 1.83 g (4.41 mmol) of **4b**, 877 mg (4.41 mmol) of bpa, 0.77 mL (4.41 mmol) of DIPEA, 50 mL of DMF, 30 mL of AcOEt. Yield: 1.67 g (3.13 mmol, 71%). − $C_{29}H_{35}N_5O_5$ (533.6 g/mol): FD-MS ($CDCl_3$); *m/z*: 534 (M^+). − ^{1}H NMR (300 MHz, $CDCl_3$): δ = 1.39 (m, 2 H, $^{\gamma}CH_2$), 1.51 (m, 2 H, $^{\delta}CH_2$), 1.85 (m, 2 H, $^{\beta}CH_2$), 3.12 (m, 2 H, $^{\varepsilon}CH_2$), 3.35 [s, 2 H, C(O)−CH_2], 3.67 (s, 3 H, OCH_3), 3.78, 3.86 (2 × d, 4 H, $^2J_{HH}$ = 9.7 Hz, 2 × py-CH_2), 4.60 (m, 1 H, $^{\alpha}CH$), 5.06 (s, 2 H, Z-CH_2), 5.21 (m, 1 H, Z-NH), 7.14 (dd, 2 H, H5-py), 7.32 (m, 7 H, Z-Ph + H3-py), 7.60 (dd, 2 H, H4-py), 8.53 (d, 2 H, $^3J_{HH}$ = 4.56 Hz, H6-py), 9.22 (d, 1 H, $^3J_{HH}$ = 7.3 Hz, NH). − ^{13}C NMR (75 MHz, $CDCl_3$): δ = 22.7 ($^{\gamma}C$), 29.3 ($^{\delta}C$), 31.7 ($^{\beta}C$), 40.7 ($^{\varepsilon}C$), 51.7, 52.0 (OCH_3 + $^{\alpha}C$), 57.8 [C(O)−CH_2], 60.5 (py-CH_2), 66.4 (Z-CH_2), 122.4, 123.1 (C3-py + C5-py), 128.0, 128.1, 128.3, 128.4 (Z-C2-Ph + Z-C3-Ph + Z-C4-Ph + Z-C5-Ph + Z-C6-Ph), 136.6 (2 C, Z-C1-Ph + C4-py), 149.2 (C6-py), 156.4, 158.3 [C(O)-Z + C2-py], 171.5, 172.8 [C(O)-ester + C(O)-amide]. − IR (film on NaCl): $\tilde{\nu}$ = 1741 cm^{-1} (COOMe), 1718 (Z-urethane), 1668 (amide I), 1529 (amide II). − Circular Dichroism (10^{-3} M in methanol): λ, nm ([θ] × 10^4 °cm^{2}dmol^{-1}) = 216 (+0.40), 263 (+0.15).

bpaAc−Gly−OEt (3c): 7.87 g (43.81 mmol) of ClAc−Gly−OEt; 8.72 g (43.81 mmol) of dpa, 7.65 mL (43.81 mmol) of DIPEA, 100 mL of DMF, 100 mL of AcOEt. Yield: 6.04 g (17.60 mmol, 40%). − $C_{18}H_{22}N_4O_3$ (342.4 g/mol): FD-MS ($CDCl_3$); *m/z*: 342 [M^+]. − ^{1}H NMR (300 MHz, $CDCl_3$): δ = 1.24 (t, 3 H, $^3J_{HH}$ = 7.1 Hz, OCH_2CH_3), 2 (H_2O), 3.37 [s, 2 H, C(O)−CH_2], 3.90 (s, 4 H, py-CH_2), 4.08 (d, 2 H, $^3J_{HH}$ = 5.9 Hz, $^{\alpha}CH_2$), 4.18 (q, 2 H, $^3J_{HH}$ = 7.1 Hz, OCH_2CH_3), 7.16 (dd, 2 H, H5-py), 7.35 (d, 2 H, H3-py), 7.63 (m, 2 H, H4-py), 8.55 (d, 2 H, H6-py), 9.07 (m, 1 H, NH). − ^{13}C NMR (75 MHz, $CDCl_3$): δ = 14.1 (OCH_2CH_3), 41.0 ($^{\alpha}C$), 57.9 [C(O)−CH_2], 60.2 (py-CH_2), 61.1 (OCH_2CH_3), 122.4 (C3-py), 123.3 (C5-py), 136.6 (C4-py), 149.2 (C6-py), 158.3 (C2-py), 169.8, 171.8 [C(O)-ester + C(O)-amide]. − IR (film on NaCl): $\tilde{\nu}$ = 1747 cm^{-1} (COOEt), 1674 (amide I), 1525 (amide II).

Zn Complexes

General Procedure: Solid $Zn(OTf)_2$ was added in one portion to a stirred solution of 1 equiv. of the respective ligand in CH_3CN. Stirring was continued overnight at room temp. followed by removal of all solvent under vacuum. CH_2Cl_2 was added to the residue and the resulting suspension left in a refrigerator (−20 °C) overnight. Unchanged $Zn(OTf)_2$ precipitated and was filtered off. In the case of **7b** the solvent was removed by rotary evaporation and the residue dried under vacuum. Further purification was not possible since the compound did not precipitate but rather separated as an oil from common organic solvents. Accordingly, the reported yield refers to the crude product. The two other complexes (**6c** and **7a**) were purified by addition of Et_2O to the clear CH_2Cl_2 filtrate and recrystallization at −20 °C. These complexes precipitated overnight as colorless microcrystalline solids. Yields are reported for recrystallized samples. It is evident from C,H,N analysis and NMR data that the bpaAc−Gly−OEt complex **6c** was isolated without significant amounts of coordinated water whereas the same workup affords the corresponding aquo complex **7a** for bpaAc−Phe−OMe. Single crystals suitable for X-ray structure analysis of **6c** and **7a** were obtained by slow recrystallization of the pure complexes from CH_2Cl_2/Et_2O at −20 °C under dry nitrogen over a period of several weeks.

[(bpaAc−Gly−OEt)(OTf)Zn](OTf) (6c): 426 mg (1.24 mmol) of **5**, 416 mg (1.24 mmol) of $Zn(OTf)_2$, 10 mL of CH_3CN, 10 mL of CH_2Cl_2. Yield: 573 mg (0.81 mmol, 65%). − $C_{20}H_{22}F_6N_4O_9S_2Zn$ (705.9 g/mol): calcd. C 34.03, H 3.14, N 7.94; found C 33.85, H 3.25, N 7.74. − FAB-MS (nitrobenzyl alcohol); *m/z*: 555 (**3c**-ZnOTf$^+$), 407 (**3c**-Zn$^+$). − ^{1}H NMR (300 MHz, $CDCl_3$): δ = 1.21 (t, 3 H, $^3J_{HH}$ = 7.1 Hz, OCH_2CH_3), 4.04 [s, 2 H, C(O)−CH_2], 4.10 (m, 4 H, $^{\alpha}CH_2$, OCH_2CH_3), 4.34, 4.44 (2 × d, 4 H, $^2J_{HH}$ = 5.6 Hz, 2 × py-CH_2), 7.63 (m, 4 H, H5-py + H3-py), 8.05 (m, 2 H, H4-py), 8.92 (d, 2 H, H6-py), 9.03 (m, 1 H, NH). − ^{13}C NMR (75 MHz, $CDCl_3$): δ = 13.9 (OCH_2CH_3), 42.4 ($^{\alpha}C$), 56.2 [C(O)−CH_2], 57.8 (py-CH_2), 61.8 (OCH_2CH_3), 120.2 (q, $^1J_{CF}$ = 301.9 Hz, OTf^-), 125.3, 125.9 (C3-py, C5-py), 141.9 (C4-py), 149.2 (C6-py), 154.3 (C2-py), 167.5, 174.3 [C(O)-ester + C(O)-amide]. − IR (KBr): $\tilde{\nu}$ = 1747 cm^{-1} (COOEt), 1641 (amide I), 1245 (CF_3SO_3), 1218 (CF_3SO_3).

[(bpaAc−Phe−OMe)(H_2O)Zn](OTf)$_2$ (7a): 743 mg (1.77 mmol) of **3a**, 643 mg (1.77 mmol) of $Zn(OTf)_2$, 15 mL of CH_3CN, 15 mL of CH_2Cl_2. Yield: 964 mg (1.20 mmol, 68%). − $C_{26}H_{28}F_6N_4O_{10}S_2Zn$ (800.0 g/mol): calcd. C 39.03, H 3.53, N 7.00; found C 38.94, H 3.53, N 6.82. − FAB-MS (nitrobenzyl alcohol); *m/z*: 631 (**3a**-ZnOTf$^+$), 481 (**3a**-Zn$^+$). − ^{1}H NMR (300 MHz, $CDCl_3$): δ = 2.84, 3.23 (ABX, 2 H, $^{\beta}CH_2$), 3.66 (s, 3 H, OCH_3), 3.67 [d, 1 H, $^2J_{HH}$ = 16.8 Hz, py-CH(A′)*H*(B′)], 3.70 [d, 1 H, $^2J_{HH}$ = 16.8 Hz, C(O)−CH(C)*H*(D)], 3.98 [d, 3 H, $^2J_{HH}$ = 16.8 Hz, C(O)−C*H*(C)H(D) + H_2O], 4.08 [d, 1 H, $^2J_{HH}$ = 16.8 Hz, py-CH(A)*H*(B)], 4.29 [d, 1 H, $^2J_{HH}$ = 16.8 Hz, py-CH(*A′*)H(B′)], 4.44 [d, 1 H, $^2J_{HH}$ = 16.8 Hz, py-CH(*A*)H(B)], 4.99 (m, 1 H, $^{\alpha}CH$), 6.62 (dd, 1 H, H4-Ph), 6.98 (dd, 2 H, H3,5-Ph), 7.19 (d, 2 H, H2,6-Ph),

X-ray Data Collection and Structure Refinement Details: Crystal data and experimental conditions are listed in Table 2. The molecular structures are illustrated in Figures 1 and 2. Selected bond lengths and bond angles with standard deviations in parentheses are presented in Table 1. Intensity data were collected with a Siemens SMART 5000 CCD-Diffractometer with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). The exposure time was 10 s per frame collected with the ω-scan technique (Δω = 0.3°). The collected reflections were corrected for Lorentz, polarization and absorption effects. The structures were solved by direct methods and refined by full-matrix least-squares methods on F^2.[54]−[56] Non-hydrogen atoms were refined with anisotropic thermal parameters in both structures. The hydrogen atoms of the coordinated water molecule and the amide hydrogen atom of **7a** were localized from the difference electron density map and refined with isotropic thermal parameters. All other hydrogen atoms were fixed in geometrically calculated positions and isotropically refined. Details of the crystal structure determinations have been deposited at the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-140521 (**6c**) and -140522 (**7a**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

The authors gratefully acknowledge financial support from the Deutsche Forschungsgemeinschaft. We thank Prof. Rudi van Eldik who generously let us share his equipment, laboratory space, and

funding. We also thank Dr. Reiner Waibel at the Institute for Pharmacy and Food Chemistry, University of Erlangen, for his help with the circular dichroism measurements.

Reactions of UCl_4 with *t*Bu-Calix[4, 5, and 6]arenes: The First "Non-Uranyl" Calixarene Complexes of Uranium

Pascal C. Leverd*[a] and Martine Nierlich[a]

Keywords: Alkoxides / Calixarenes / Uranium

The reactions of UCl_4 with *t*Bu-calix[4, 5, and 6]arenes (*t*Bu-calix[*n*]arene = $H_nL[n]$) were used to isolate $[\{UCl(L[4])\}_3O]$ (**1**), $[\{U(L[5])\}_2O]^{2-}$ (**2**), and $[U(H_3L[6])_2]$ (**4**). The dianionic species **2** could be oxidized to its U^{VI} homologue $[\{U(L[5])\}_2O]$ (**3**). In contrast to **1**–**3** that are located around a μ-oxo bridge, **4** can be viewed as a homoleptic alkoxide. **1**–**4** are the first "non-uranyl" calixarene complexes of uranium to be reported.

Introduction

Calixarenes are made of phenolic units linked by methylene bridges into a macrocyclic arrangement.[1] For reasons linked with environmental needs and with the management of nuclear waste solutions, the actinide complexes of these potential polyalkoxide ligands have always attracted special attention from coordination chemists.[2] Research has particularly focussed on the complexes of the uranyl cation $[UO_2]^{2+}$,[3] partly because the special coordination requirements of this cation was thought to be particularly suited to the geometry of calixarenes. However, apart from the work on uranyl cations, surprisingly few complexes of the 5f-metals have been fully characterized. In fact, the thorium compound $[Th_4(HL[8])(H_2L[8])(dmso)_4(OH)_3(OH_2)]$ ($H_nL[n]$ = *t*Bu-calix[*n*]arene, dmso = Me_2SO) is the only "non-uranyl" actinide complex of this family of macrocycles whose crystal structure is available, to date, in the literature.[4] In an attempt to widen the scope of calixarene coordination chemistry to the complexes of uranium at lower oxidation states, we set out to study the reactions of UCl_4 with *t*Bu-calix[4, 5, and 6]arenes. We report herein the synthesis and the X-ray characterization of $[\{UCl(L[4])\}_3O]$ (**1**), $[\{U(L[5])\}_2O]^{2-}$ (**2**), $[\{U(L[5])\}_2O]$ (**3**), and $[U(H_3L[6])_2]$ (**4**). Complexes **1**−**4** are the first "non-uranyl" calixarene complexes of uranium to be reported.

Results and Discussion

When UCl_4 is treated with $H_4L[4]$ or $H_5L[5]$ in pyridine, the pale green solution turns slowly to red. After a few hours of heating the two components at 333 K, the dark red colour turns to black, in the case of $H_4L[4]$, and to a very dark red in the case of $H_5L[5]$. The solutions were allowed to stand, and after a few days, crystals suitable for X-ray crystallography were isolated. The structures were solved and revealed that $[\{UCl(L[4])\}_3O]$ (**1**) and $[\{U(L[5])\}_2O]^{2-}$ (**2**) had been produced by the reaction.

$$3\ UCl_4 + 3\ H_4L[4] \xrightarrow[H_2O]{\text{pyridine}} [\{UCl(L[4])\}_3O] + 12[HNC_5H_5]Cl$$

$$2\ UCl_4 + 2\ H_5L[5] \xrightarrow[H_2O]{\text{pyridine}} [HNC_5H_5]_2[\{U(L[5])\}_2O] + 8[HNC_5H_5]Cl$$

The formation of oxo-alkoxide species such as **1** and **2** is often observed in the process of synthesizing homoleptic alkoxide complexes.[5] The presence of the oxygen atom is usually explained by the hydrolysis of the intermediates by even traces of water or by a number of other possible mechanism e.g. elimination of ether. In our case, the extreme sensitivity of uranium alkoxide to moisture and the absence of any evidence for the chemical transformation of the calixarenes seems to indicate that water is present in the reaction mixture. The syntheses of **1** and **2** were nonetheless very reproducible, and starting from $H_4L[4]$ and $H_5L[5]$, we never managed not to obtain the oxo species. We are currently investigating the reaction of UCl_4 with the sodium salts of calixarenes, which should help to keep the reaction mixture rigorously dry.

Complex **1** is a trinuclear cluster organized around a μ_3-oxo bridge (Figure 1). The two-electron donor O(5) located on the C_3 axis binds the three metal cations in an almost planar fashion (±0.085 Å). This triangular geometry is often encountered in uranium chemistry, and the U(1)−O(5) bond length of 2.224(2) Å is not exceptional when compared to those of other clusters described in the literature.[6] The calixarene is fully deprotonated and all its phenolate groups form σ bonds with the metal center [U−O between 2.042(9) and 2.217(8) Å]. One of the oxygen atoms of the macrocycle [O(2)] helps to maintain the geometry of the cluster by bridging two adjacent uranium atoms [U−O 2.549(8) Å]. One unchanged chloride ligand is still present on each metal cation [U−Cl 2.645(4) Å]. All three U−Cl bonds point in a direction nearly parallel to the C_3 axis. The U−O and U−Cl bond lengths compare well with those found in the literature.[7] Large U−O−C angles of terminal

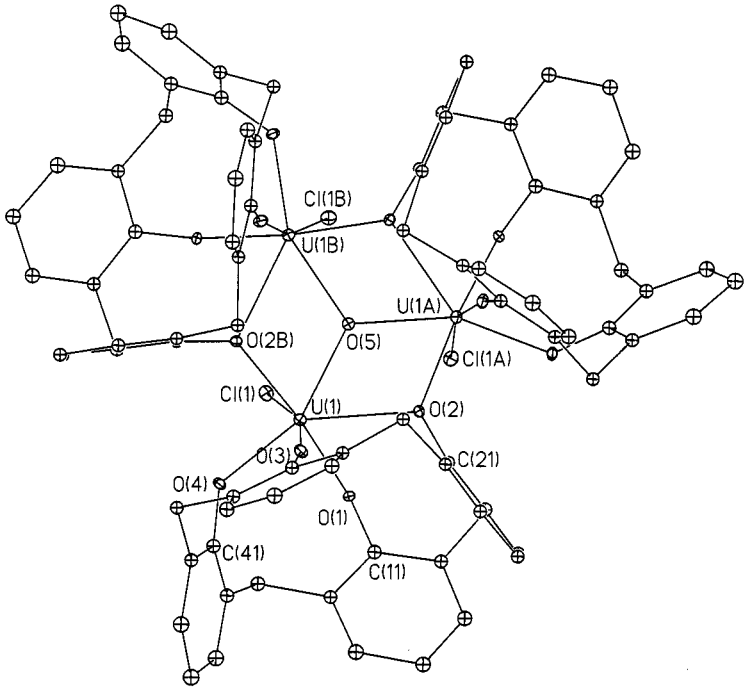

Figure 1. X-ray structure of complex **1** projected along the C_3 axis; all *t*Bu groups and hydrogen atoms or solvent molecules have been omitted for clarity; selected bond lengths [Å] and angles [°] with estimated standard deviations in parentheses: U(1)−O(1) 2.042(9), U(1)−O(2) 2.217(8), U(1)−O(3) 2.08(1), U(1)−O(4) 2.111(9), U(1)−O(5) 2.224(2), U(1)−Cl(1) 2.645(4), U(1)−U(1A) 3.831(2), U(1)−O(2B) 2.549(8); U(1)−O(5)−U(1A) 118.9(2), O(5)−U(1)−Cl(1) 80.9(4), U(1)−O(1)−C(11) 172.3(9), U(1)−O(2)−C(21) 120.4(7), U(1)−O(2A)−C(21A) 132.8(8), U(1)−O(3)−C(31) 171.0(9), U(1)−O(4)−C(41) 130.8(7)

alkoxide ligands are usually interpreted in terms of π-electron donation from the oxygen lone-pair orbitals to the metal ion.[8] These angles range between 130.8(7) and 172(3)° in **1**, which could be associated with substantial π-donation from at least two phenolate groups of the macrocycle [O(1) and O(3)]. However, in the case of bulky ligands such as calixarenes, it seems difficult to draw a line between steric requirements and electronic properties. The three cations share 17 electrons donated by the ligands, formally making **1** a mixed valence complex, with two of its metal centers in the oxidation state +VI and one in +V. Nonetheless, no difference could be observed in the environment of the three metal cations due to the presence of the C_3 axis of symmetry. The remaining electron is therefore likely to be equally shared by the three equivalent cations.[9] After $[U_2(O\mathit{t}Bu)_9]$ (+IV and +V) and $[\{(THF)U(OPh)_3(\mu_2\text{-}OPh)(\mu_3\text{-}O)(UO_2)(THF)\}_2]$ (+V and +VI), **1** is only the third mixed-valence uranium alkoxide to be described.[8][6b] Each metal cation is coordinated by seven donor atoms: The geometry around the uranium center is a distorted capped trigonal prism [O(1)−O(3)−O(2) and O(5)−Cl(1)−O(2B) define the faces of the prism, while O(4) is the cap]. The "$U_3Cl_3(\mu_3\text{-}O)(\mu_2\text{-}OR)_3$" core results from the arrangement of three such polyhedrons sharing an edge [O(5)−O(2) and its symmetry equivalents]. One molecule of pyridine is present in each calix[4]arene cavity. Whereas fused "double calixarenes" are well-known species in coordination chemistry and have been successfully used in the synthesis of metal networks,[10] **1** is the first example of a fused "triple calixarene" (Figure 2).[11] Complex **1** organizes three cone-shaped cavities and directs them in three directions of space that are separated by an angle of 120°. These three macrocycles are occupied by guest pyridine molecules in the solid state. If an adequate inclusion spacer was found to link these cavities, **1** could represent a unique paramagnetic building block for the design of new supramolecular two-dimensional networks. The other potential interest of **1** is the study of the reactivity that could take place around the remaining chloride anions. The example of $[cis\text{-}Cl_2W(L[4])]$ has already proven that a rich chemistry could be built around the displacement of the halide ligands of a metal calixarene complex.[12]

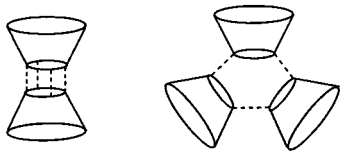

Figure 2. Schematic representation of the fused "double" and "triple" calixarenes

Complex **2** is a dinuclear complex located around a μ_2-oxo bridge (Figure 3). The two-electron donor, O(6), sits on the inversion center of the molecule and binds the two metal cations in a perfectly linear fashion. The U−O−U moiety is then sandwiched between two fully deprotonated *t*Bu-calix[5]arene units. Such a linear mode of binding [U(1)−O(6) 2.0969(9) Å] is commonplace in uranium chem-

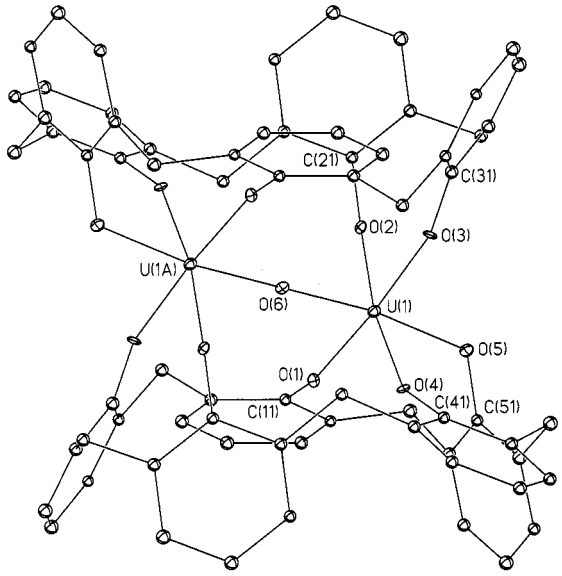

Figure 3. X-ray structure of complex **2**; all *t*Bu groups, hydrogen atoms, and solvent molecules have been omitted for clarity; respective selected bond lengths and mean bond lengths [Å] and angles [°] with estimated standard deviations in parentheses for **2** and **3**: U(1)−O(1) 2.141(9), 2.159(6); U(1)−O(2) 2.158(9), 2.112(6); U(1)−O(3) 2.110(9), 2.112(6); U(1)−O(4) 2.155(9), 2.154(6); U(1)−O(5) 2.186(9), 2.143(6); U(1)−O(6) 2.0969(9), 2.078(6); U(1)−O(1)−C(11) 152.0(8), 153.0(6); U(1)−O(2)−C(21) 142.4(8), 149.1(6); U(1)−O(3)−C(31) 160.8(8), 155.6(6); U(1)−O(4)−C(41) 156.0(7), 154.4(6); U(1)−O(5)−C(51) 120.9(7), 123.6(5)

istry.[13] The geometry around the metal center is distorted octahedral [minimum and maximum O−U−O angles equal 83.0(4) and 96.3(4)°, respectively] with each $L[5]^{5-}$ ligand binding the first uranium cation with three of its phenolate groups and the second metal cation with the other two. Of the 6 pyridine molecules found in the lattice, four were found to form pyridinium dimers (N−HN bond length of 2.98 Å). One of the pyridine molecules of the dimer is included in the cavity of the macrocycle. Such inclusion of a cation in the aromatic cavity of a calixarene is a common feature in calixarene chemistry.[14] The presence of two organic cations in the lattice implies that **2** is in fact a dianionic complex of U(+V). The broad paramagnetic signals observed in the NMR spectrum and the typical dark-red color further confirm the valency deduced from the X-ray analysis. Whereas numerous examples of U^V homoleptic alkoxides are reported in the literature,[15] it seems that mixed oxo-alkoxides such as **2** have not yet been described for this particular oxidation state. If molecules of the type $[OU(OR)_3]$ have been mentioned briefly by Bradley, they have not been well characterized by today's standards.[16] Complex **2** is also a unique example of a "double calixarene" made by the fusion of two cone-shaped calix[5]arenes. While such species are well known for the calix[4]arenes, they are more unusual for the larger macrocycles. To the best of our knowledge, the uranyl dimer $[\{UO_2(H_2L[6])\}_2]$ is the only other such compound present in the literature.[17] The closest related compound is $[Eu_2(H_2L[5])_2(dmso)_4]$, a bimetallic lanthanide complex held together by two *t*Bu-calix[5]arenes, but where the macrocycle is not in the cone conformation.[18]

As a powder or as a solution, **1** slowly decomposes to insoluble products when exposed to air. Conversely, a solution of **2** in a mixture of pyridine and acetone immediately oxidizes and turns to a light red. This solution slowly deposits beautiful single crystals among other uncharacterized decomposition products. The crystal structure was solved and revealed $[\{U(L[5])\}_2O]$ (**3**), the U^{VI} homologue of **2**.

$$[HNC_5H_5]_2[\{U(L[5])\}_2O] \xrightarrow[O_2]{\text{pyridine}} [\{U(L[5])\}_2O] + \text{decomposition products}$$

The geometry of **3** is similar to that of **2**, and no shortening of the U−O distances is observed, however the oxidation state is unambiguously confirmed by the diamagnetic NMR spectrum and by the lighter color of the complex. A pyridine molecule occupies the cavity of the calixarene in the solid state. Complex **3** is stable when exposed to air as a solid powder but slowly decomposes in the various solvents we used. The possibility of oxidizing U^V alkoxides into their U^{VI} derivatives by means of alcoholysis has been known for a long time, however the latter are strong oxidizing species that can also be used as intermediates in the synthesis of lower oxidation state complexes.[19] The oxidation of **2** to **3** does not lead to changes in the coordination geometry of the metal center and is a good example of the robustness conferred to the complex by the bridging macrocycle.

While the reactions of $H_4L[4]$ and $H_5L[5]$ with UCl_4 bear some resemblance in the kinds of oxo compounds they deliver, the reaction of $H_6L[6]$ does not follow the same pathway. When UCl_4 is treated with $H_6L[6]$ in pyridine, the pale green solution never turns to red. After hours of heating a mixture of the two reagents in pyridine under reflux, a change of color was eventually observed. Although the NMR spectrum of the mixture indicates that a reaction had possibly taken place,[20] we never managed to isolate a complex at this stage of the procedure. However, when the reaction mixture was exposed to air, the brown-green color immediately turned to a bright red. The solution was allowed to stand and after a few days, crystals suitable for X-ray crystallography were isolated. The structure was solved and revealed that $[U(H_3L[6])_2]$ (**4**) had been formed among other uncharacterized decomposition products.

$$UCl_4 + 2\,H_6L[6] \xrightarrow[O_2]{\text{pyridine}} [U(H_3L[6])_2] + \text{decomposition products}$$

Complex **4** is a U(+VI) complex, where two $H_3L[6]$ ligands coordinate the metal cation through three successive phenolate groups (Figure 4). The metal cation is the center of inversion of the complex. Its coordination geometry is thus a distorted octahedron [minimum and maximum O−U−O angles equal 85.6(3) and 94.4(3)°, respectively] with classical U−O bond lengths. Complex **4** can be viewed as an homoleptic uranium alkoxide. These are known since the early days of the Manhattan project, which started 5f-metal coordination chemistry.[21] However, only a few of

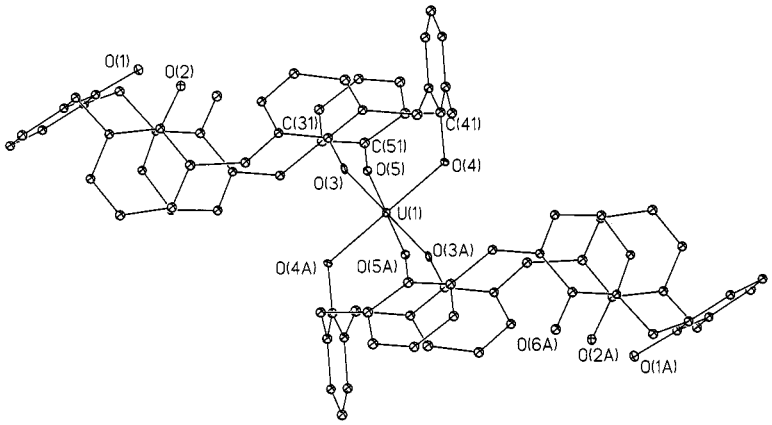

Figure 4. X-ray structure of complex **4**; all *t*Bu groups, hydrogen atoms, and solvent molecules have been omitted for clarity; selected bond length [Å] and angles [°] with estimated standard deviations in parentheses: U(1)−O(3) 2.10(1), U(1)−O(4) 2.132(8), U(1)−O(5) 2.112(9); U(1)−O(3)−C(31) 164.3(7), U(1)−O(4)−C(41) 126.(8), U(1)−O(5)−C(51) 169.1(8)

these compounds have been characterized by means of X-ray diffraction,[8,15a,15c,22] and none of them is a U^{VI} complex.[23] Complex **4** is the first "$U(OR)_6$" complex to be characterized by single-crystal X-ray diffraction. Its coordination geometry is close to the octahedral one of [$U(OTeF_5)_6$].[24] The conformation of the calixarene is 1,2,3-alternate, with the aromatic faces bearing the phenolic groups defining the first partial cone, and the three corresponding to the phenolate groups defining the second. This conformation is commonplace for the uncoordinated calix[6]arene derivatives, but had, to the best of our knowledge, never been encountered among the crystal structures of their metal complexes.[25] The fusion of two 1,2,3-alternate calix[6]arene affords a molecule with four aromatic cavities (Figure 5). In the solid state, all these half-cones are filled by pyridine molecules, thus **4** is the host to four molecular guests.

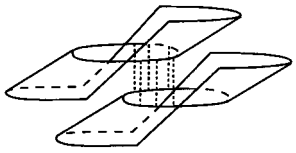

Figure 5. Schematic representation of **4** emphasizing its four half-cone cavities

In conclusion, the reactions of UCl_4 with H_4L[4], H_5L[5], and H_6L[6] enabled us to synthesize **1**, **2**, and **4**, the three first "non-uranyl" calixarene complexes of uranium. Complex **2** oxidizes to yield its U^{VI} equivalent **3** when exposed to air. The oxidation state of the metal ion in **1**−**4** is +V or +VI. If **1**−**3** contain μ-oxo bridges, **4** can be seen as a homoleptic uranium alkoxide. The isolation of **1**−**4** represents an exceptional example of the diversity of uranium compounds, and of the various molecular architectures that can be obtained from ring-size variation of a large polyalkoxide ligand. This reinforces the idea that a rich chemistry can be built at the boundary between macrocycle, supramolecular, and coordination chemistries.

Experimental Section

All NMR spectra were performed with a Bruker DPX-200. − Elemental analyses were performed at Analytische Laboratorien, D-51789 Lindlar, Germany. − Unless specified, all reactions were performed in a glove box under dry N_2. H_4L[4], H_5L[5], and H_6L[6] were dried under vacuum for 12 h at 323 K prior to use. Pyridine was dried with K (***Caution!***) and distilled prior use.

Synthesis of 1: UCl_4 (0.050 g, 0.130 mmol) was treated with H_4L[4] (0.085 g, 0.130 mmol) in pyridine (20 mL) at 333 K for 12 h. The black solution obtained was filtered and concentrated under vacuum (10 mL). It was then left standing overnight to afford a black microcrystalline powder that was filtered off, washed with cold pyridine and dried in vacuo to afford [{UCl(L[4])}$_3$O] · 2 (NC_5H_5) (0.018 g, 0.006 mmol, 14%). − ^{1}H NMR: δ = 20.12, 16.08, 11.36, 11.11, 9.60, 9.21, 9.00, 6.20, 5.63, 3.59, 3.38, 1.91, 1.87, 1.77, 1.68, 1.65, 1.61, 1.58, 1.55, 1.48, 1.23, 1.09, −0.13, −0.21, −0.34, −4.00, −14.23.[9] − $C_{142}H_{166}Cl_3N_2O_{13}U_3$ (2927.9): calcd. C 58.25, H 5.67, N 0.96; found C 58.03, H 5.75, N 0.93.

Synthesis of 2: UCl_4 (0.050 g, 0.130 mmol) was treated with H_5L[5] (0.107 g, 0.130 mmol) in pyridine (20 mL) at 333 K for 12 h. The dark red solution obtained was filtered and concentrated under vacuum (10 mL). It was then left standing overnight to afford a red microcrystalline powder that was filtered off. This powder was slowly recrystallized in pyridine to afford [HNC_5H_5]$_2$-[{U(L[5])$_2$O] · 4 (NC_5H_5) as beautiful single crystals (0.029 g, 0.011 mmol, 17%). − ^{1}H NMR: δ = 14.04 (br., 8 H, ArH), 8.81 (br., 4 H, ArH), 7.95 (br., 8 H, ArH), 6.39 (br., 8 H, Ar−CH_2−Ar), 4.68 (br., 8 H, Ar−CH_2−Ar), 1.63 (36 H, *t*Bu), 1.34 (18 H, *t*Bu), 0.97 (36 H, *t*Bu), −1.22 (br., 4 H, Ar−CH_2−Ar). − $C_{140}H_{162}N_6O_{11}U_2$ (2579.5): calcd. C 65.18, H 6.28, N 3.26; found C 65.24, H 6.49, N 3.33.

Synthesis of 3: Compound **2** (0.020 g, 0.008 mmol) was dissolved in a 50% mixture of pyridine and acetone (2 mL) at room temperature, and briefly exposed to air. The light-red solution thus obtained was left standing overnight to afford a red microcrystalline powder that was filtered off. This powder was slowly recrystallized in pyridine to afford a mixture of [{U(L[5])$_2$O] · 2.5 (NC_5H_5) as small monocrystals (0.007 g, 0.003 mmol, 37%) and microcrystalline H_5L[5]. Successive recrystallization in various solvents did not afford **3** in its elementally pure form. − ^{1}H NMR: δ = 9.11, 8.60,

8.23, 6.99, 6.74 (5 × 4 H, ArH), 6.61, 4.70 (br., 2 × 8 H, Ar−CH_2−Ar), 4.10 (br., 4 H, Ar−CH_2−Ar), 1.62 (36 H, *t*Bu), 1.26 (18 H, *t*Bu), 0.95 (36 H, *t*Bu).

Synthesis of 4: UCl_4 (0.050 g, 0.130 mmol) was treated with $H_6L[6]$ (0.256 g, 0.260 mmol) in pyridine (10 mL) at room temperature for 10 min and then briefly exposed to air. The red solution thus obtained was concentrated under vacuo (2 mL) and left standing for two weeks to deposit a red microcrystalline powder that was filtered off, washed with pentane, and dried in vacuo to afford $[U(H_3L[6])] \cdot 2\,(NC_5H_5)$ (0.030 g, 0.013 mmol, 10%). − 1H NMR: δ = 12.00 (br., 6 H, OH), 8.59, 8.45, 8.24, 7.72, 7.22, 6.88 (6 × 4 H, ArH), 6.73, 5.93, 4.31 (br., 3 × 8 H, Ar−CH_2−Ar), 1.55 (36 H, *t*Bu), 1.46 (18 H, *t*Bu), 1.17 (18 H, *t*Bu), 0.80 (36 H, *t*Bu). − $C_{142}H_{172}N_2O_{12}U$ (2335.4): calcd. C 73.02, H 7.36, N 1.20; found C 72.70, H 7.61, N 0.98.

X-ray Crystallographic Studies: Crystal data collection was performed with a Nonius Kappa CCD diffractometer equipped with a fiber glass collimator. Copies of the crystallographic data of **1**, **2**, **3**, and **4** can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44 1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Crystal Data of $1 \cdot 11.5\,(NC_5H_5)$: $C_{189.5}H_{213.5}N_{11.5}Cl_3O_{13}U_3$ (3680.7), 0.24 × 0.20 × 0.18 mm, trigonal, *P*−3*c*1, *Z* = 4, *a* = 21.576(3), *b* = 21.576(3), *c* = 45.517(9) Å, α = 90, β = 90, γ = 120°, *V* = 18350(5) Å^3, $\rho_{calcd.}$ = 1.333 g·cm^{-3}, *F*(000) = 7460, $2\theta_{max}$ = 60.58°, graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å), μ_{Mo} = 2.744 cm^{-1}, *T* = 123 K. The structure was solved by direct methods,[26] and refined on F^2.[27] Of the 26624 reflections measured, 8902 were found to be independent (R_{int} = 0.123), 4419 of which were considered as observed [$I > 2\sigma(I)$] and were used in the refinement of the 427 parameters, leading to a final R_1 of 0.0844 and a R_{all} of 0.1942. wR_{obs} and wR_2 were found to be 0.1681 and 0.2369, respectively. Hydrogen atoms were introduced in the calculation as riding on calculated positions. The goodness-of-fit parameter *S* was 1.134 and the maximum residual density 0.960 eÅ^{-3}. Crystallographic data (excluding the structure factors) have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-140041.

Crystal Data of $[HNC_5H_5]_2[2] \cdot 4\,(NC_5H_5)$: $C_{140}H_{162}N_6O_{11}U_2$ (2580.8), 0.24 × 0.18 × 0.18 mm, monoclinic, *P*2(1)/*n*, *Z* = 2, *a* = 12.580(3), *b* = 19.950(4), *c* = 25.120(5) Å, α = 90, β = 98.74(3), γ = 90°, *V* = 6231(2) Å^3, $\rho_{calcd.}$ = 1.376 g·cm^{-3}, *F*(000) = 2632, $2\theta_{max}$ = 41.48°, graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å), μ_{Mo} = 2.657 cm^{-1}, *T* = 123 K. The structure was solved by direct methods,[26] and refined on F^2.[27] Of the 35322 reflections measured, 6267 were found to be independent (R_{int} = 0.094), 3006 of which were considered as observed [$I > 2\sigma(I)$] and were used in the refinement of the 280 parameters, leading to a final R_1 of 0.0659 and a R_{all} of 0.1739. wR_{obs} and wR_2 were found to be 0.1110 and 0.1506, respectively. Solvent pyridine molecules were constrained to regular hexagons. Uranium and oxygen atoms were considered anisotropic. All the other atoms were considered as isotropic in order to keep a reasonable data/parameters ratio. Hydrogen atoms were introduced in the calculation as riding on calculated positions. The goodness-of-fit parameter *S* was 0.995 and the maximum residual density 0.705 eÅ^{-3}. Crystallographic data (excluding the structure factors) have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-140042.

Crystal Data of $[3]_2 \cdot 5\,(NC_5H_5)$: $C_{245}H_{285}N_5O_{22}U_4$ (4603.9), 0.18 × 0.18 × 0.12 mm, monoclinic, *P*2(1)/*n*, *Z* = 4, *a* = 26.907(5), *b* = 28.012(6), *c* = 31.015(6) Å, α = 90, β = 107.16(3), γ = 90°, *V* = 22336(8) Å^3, $\rho_{calcd.}$ = 1.369 g·cm^{-3}, *F*(000) = 9336, $2\theta_{max}$ = 41.64°, graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å), μ_{Mo} = 2.955 cm^{-1}, *T* = 123 K. The structure was solved by direct methods[26] and refined on F^2.[27] Of the 171260 reflections measured, 22846 were found to be independent (R_{int} = 0.0682), 15455 of which were considered as observed [$I > 2\sigma(I)$] and were used in the refinement of the 1455 parameters, leading to a final R_1 of 0.0473 and a R_{all} of 0.0889. wR_{obs} and wR_2 were found to be 0.0982 and 0.1158, respectively. Uranium and oxygen atoms were considered anisotropic. All the other atoms were considered as isotropic in order to keep the number of parameters smaller than 1500. Above this value our refinement software is unable to operate. Hydrogen atoms were introduced in the calculation as riding on calculated positions (*U* = 1.2 times that of the corresponding atom). Solvate molecules of pyridine were refined as regular hexagons. The goodness-of-fit parameter *S* was 1.084 and the maximum residual density 1.226 eÅ^{-3}. The latter was located in the center of the thermally agitated solvent molecule bearing N(5). Crystallographic data (excluding the structure factors) have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-140040.

Crystal Data of $4 \cdot [HNC_5H_5]_2Cl_2 \cdot 10\,(NC_5H_5)$: $C_{192}H_{224}Cl_2N_{12}O_{12}U$ (3200.7), 0.18 × 0.12 × 0.12 mm, triclinic, *P*−1, *Z* = 1, *a* = 15.770(3), *b* = 16.680(3), *c* = 17.380(4) Å, α = 84.24(3), β = 72.78(3), γ = 87.35(3)°, *V* = 4344(2) Å^3, $\rho_{calcd.}$ = 1.224 g·cm^{-3}, *F*(000) = 1682, $2\theta_{max}$ = 41.90°, graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å), μ_{Mo} = 1.027 cm^{-1}, *T* = 123 K. The structure was solved by direct methods,[26] and refined on F^2.[27] Of the 14651 reflections measured, 8598 were found to be independent (R_{int} = 0.156), 4672 of which were considered as observed [$I > 2\sigma(I)$] and were used in the refinement of the 482 parameters, leading to a final R_1 of 0.0918 and a R_{all} of 0.1829. wR_{obs} and wR_2 were found to be 0.1984 and 0.2613, respectively. Solvent pyridine molecules were constrained to regular hexagons. Uranium, chlorine, and oxygen atoms were considered anisotropic, as well as the carbon atoms of the non-disordered methyl of the *t*Bu groups. All the other atoms were considered as isotropic in order to keep a reasonable data/parameters ratio. Hydrogen atoms were introduced in the calculation as riding on calculated positions. The goodness-of-fit parameter *S* was 1.095 and the maximum residual density 0.848 eÅ^{-3}. Crystallographic data (excluding the structure factors) have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-140043.

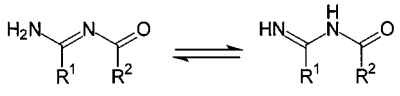
1:1- and 2:1-Copper(II) Complexes From Primary *N*-Acylamidines



Jan K. Eberhardt,[a] Roland Fröhlich,[a][++] Sabine Venne-Dunker,[a][++] and Ernst-Ulrich Würthwein*[a]

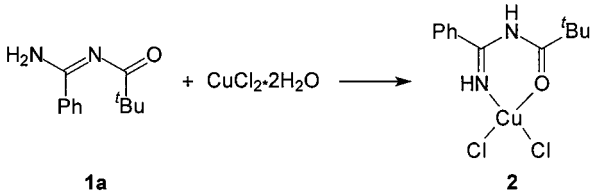
Keywords: *N*-Acylamidines / Copper(II) complexes / N ligands / O ligands

Four different types of six-membered chelate Cu^{II} complexes **2**–**5** have been synthesized from copper(II) salts and primary *N*-acylamidines ($H_2N–CR^1=N–CR^2=O$) **1**. The twofold positively charged complexes **2**–**4** contain two neutral ligands around the Cu^{II} ion. In the 1:1 compound **2** the copper(II) ion is four coordinate, leading to a distorted square coordination. The 2:1 compounds **3** and **4** show similar structural properties; the approximate square plane of the complexes is complemented by one or two loose apical contacts to the triflate counter ions. In the centrosymmetric, neutral 2:1 complex **5**, two anionic ligands interact with the central Cu^{II} ion, leading to an approximate square-planar coordination of the Cu^{II} ion. The structural versatility of these *N*-acylamidine complexes is discussed in terms of counter ion and solubility influences. All complexes have been completely characterized, including X-ray diffraction analysis.

Introduction

In order to investigate the fundamental properties of oligonitriles we initiated a thorough research program concentrating on the complex-forming ability of these new oligomers.[1] In a recent paper we reported the synthesis and structural properties of two palladium(II) complexes of differently substituted tetrameric *N*-acylated and *N*-thioacylated oligonitriles.[2] The formation of six-membered chelate rings involving either two nitrogen atoms or one nitrogen and one sulfur atom were characteristic features of these complexes. We are now focussing on the copper(II) complexes of small donor substituted model oligonitriles, the *N*-acylamidines **1**. They also offer coordination sites for the formation of six-membered chelates, namely the oxygen atom of the acyl functionality and the nitrogen atom of the amino group. In case of *N*-acylamidines **1** containing a $-NH_2$ (primary *N*-acylamidines) or a -NHR group (secondary *N*-acylamidines) tautomerism involving 1,3 proton shifts may be expected (isomers **A** and **B**).

A **B**



However, spectroscopic studies[3] as well as X-ray diffraction determinations[4] indicate the predominance of the *N*-acylamidine structures **A** in solution and in the solid phase. The second tautomer **B**, with the two protons on different nitrogen atoms, plays only a minor role in the equilibrium.

In this paper we present four different copper(II) complexes representing three different types of primary *N*-acylamidine complexes. To the best of our knowledge, there is only one report of a metal complex with a simple primary *N*-acylamidine in the literature; in 1978, the preparation and X-ray structure determination of a 2:1 nickel complex involving an anionic *N*-acylamidine ligand was reported by an Italian group.[5] *N*-Acylamidines may be considered to be aza analogues of enaminones (3-aminopropenones); several metal complexes of these ligands are known.[6]

Results

Depending on the reaction conditions, we were able to synthesize and characterize spectroscopically and by X-ray diffraction three different types of *N*-acylamidine copper(II) complexes.

If *N*-pivaloyl benzamidine (**1a**) and $Cu^{II}Cl_2 \cdot 2\,H_2O$ are dissolved in an equimolar ratio in acetonitrile, dark green crystals **2** are obtained in 67.5% yield after careful precipitation using diethyl ether.

1a **2**

The new compound **2** was studied by X-ray analysis. Crystalline **2** forms a mononuclear 1:1 complex, including 1.5 molecules of acetonitrile, with a *cis*-$CuCl_2$ unit. Complexation at the oxygen atom and nitrogen atom N(5) (crystallographic numbering) of neutral **1a** by the copper ion leads to the six-membered chelate ring of metal complex **2**

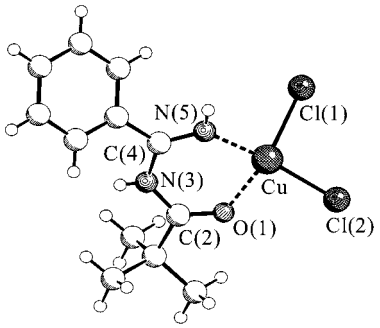

Figure 1. Molecular structure of **2**; selected bond parameters: bond lengths [Å]: Cu−Cl(1) 2.2786(7), Cu−Cl(2) 2.2167(7), Cu−O(1) 2.0245(15), Cu−N(5) 1.932(2), O(1)−C(2) 1.225(3), C(2)−N(3) 1.355(3), N(3)−C(4) 1.385(3), C(4)−N(5) 1.271(3); bond angles [°]: Cl(1)−Cu−Cl(2) 96.41(3), N(5)−Cu−O(1) 85.35(7), N(5)−Cu−Cl(1) 90.77(6), O(1)−Cu−Cl(2) 91.76(5), O(1)−C(2)−N(3) 122.3(2), C(2)−N(3)−C(4) 127.2(2), N(5)−C(4)−N(3) 120.6(2); torsional angles [°]: N(5)−Cu−O(1)−C(2) 12.22 (0.24), Cl(2)−Cu−O(1)−C(2) −176.89 (0.24), Cl(1)−Cu−O(1)−C(2) −71.69 (0.27), Cu−O(1)−C(2)−N(3) −10.17 (0.40), O(1)−C(2)−N(3)−C(4) −2.82 (0.43), C(2)−N(3)−C(4)−N(5) 9.31 (0.41), N(3)−C(4)−N(5)−Cu −2.43 (0.40), O(1)−Cu−N(5)−C(4) −5.61 (0.26)

(Figure 1). The organic section of the chelate ring is rather flat, with the copper atom well in the plane of the ligand. One of chlorides is also located in the plane; the other chloride, however, is positioned far below the plane (see Figure 1), resulting in a strongly tetrahedrally deformed square planar coordination geometry around copper(II) (sum of angles: 364.29°). Coordination bond lengths are 1.932(2) to N, 2.205(2) to O and 2.217(1) and 2.279(1) Å to chlorine. The N−Cu−O bond angle amounts to 85.35°.

Due to complexation, the amino group of the ligand is transformed into an imine moiety by a formal 1,3-shift of one of the amino hydrogen atoms to nitrogen atom N(3). The lone pair of the sp^2 hybridized imine-type nitrogen atom N(5) acts as the coordination site; thus, a conjugated 6π/5z ligand is present in the complex, carrying a central planar sp^2 amino group. This ligand may also be understood as a combination of a ketiminato and a ketono donor connected by an amino group, as can be seen from the rather similar C=N and C=O bond lengths [1.271(3) versus 1.225(3) Å]. The same applies to the C−N bonds [1.355(3) and 1.385(3) Å]. The phenyl ring is twisted out of the plane of the complex by around 40°, possibly due to packing effects rather than intramolecular steric strain. The IR spectra (KBr) show two broad absorptions at 3400 and 3200 cm^{-1}, which are assigned to the =NH and −NH stretching vibrations (isomer **B**); in contrast, the free ligand shows bands at 3320 and 3160 cm^{-1}, which are attributed to the unsymmetrical and symmetrical NH_2 stretching vibrations (isomer **A**). UV absorptions of low intensity are observed at 464 and 391 nm due to d→d transitions at the metal ion, causing the green-yellow color of solutions of **2**.

The reaction of two equivalents of either *N*-(4-methylbenzoyl) benzamidine (**1b**) or *N*-pivaloyl benzamidine (**1a**) with one equivalent of $Cu(CF_3SO_3)_2$ in acetonitrile leads to the formation of the respective copper(II) complexes **3** (Figure 2) and **4** (Figure 3). Crystallization was achieved by

adding surplus of diethyl ether, yielding metal complexes **3** (83.5% yield, from **1b**) and **4** (91.2% yield, from **1a**).

Both compounds **3** and **4** were analyzed by X-ray diffraction. Both complexes consist of two neutral *N*-acylamidines in their C=NH tautomeric form **B** (analogously to **2**) complexing a central copper(II) ion (mononuclear 2:1 complexes); the two counter ions are in close vicinity to the doubly positively charged complex (see below). As in **2**, conjugated six-membered chelate rings are formed by coordination of the oxygen atoms and terminal nitrogen atoms of the *N*-acylamidines (isomer **B**) to copper (II). In both complexes *cis* O−Cu−O and *cis* N−Cu−N coordination is observed. A fifth (and in **4**, a sixth as well) coordination

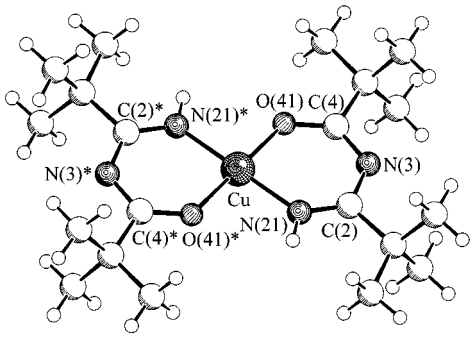
Figure 3. site of copper is loosely occupied by an oxygen atom of a $CF_3SO_3^-$ anion, although the corresponding Cu−O distances are substantially longer (see below). In compound **3**, the copper atom is five-coordinate, having an approximately flat square-pyramidal geometry, in compound **4** the central ion is six-coordinate, forming an elongated octahedral or square-bipyramidal geometry, as is known for other copper(II) complexes. Coordination bond lengths in **3** are: Cu−N: 1.930(5),1.936(5); Cu−O: 1.944(4), 1.956(4), 2.282 (4) Å (to $CF_3SO_3^-$). Coordination bond lengths in **4** are: Cu−N: 1.923(2), 1.951(2); Cu−O: 1.945(2), 1.948(2), 2.403(2), 2.560(2) Å (both to $CF_3SO_3^-$).

The IR absorptions in the NH_2 region are similar to those of **2** (3400 and 3220 cm^{-1}). Low intensity d→d transitions at 627 nm (**3**) and 626 nm (**4**) cause the blue color of the complexes.

A third type of a *N*-acylamidine copper(II) complex is obtained by treating $Cu(SO_4) \cdot 5\,H_2O$ with *N*-pivaloylpivalamidine (**1c**). $Cu(SO_4) \cdot 5\,H_2O$ and **1c** are mixed in aqueous ethanol, the solution is extracted with cyclohexane. The solvent is removed and the solid is recrystallized from acetonitrile. Metal complex **5** is obtained in 41.9% yield (calculated for **1c**) as violet needles (Figure 4).



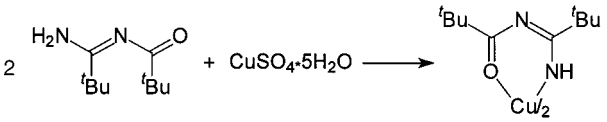


Figure 4. Molecular structure of **5**; selected bond parameters: bond lengths [Å]: Cu−N(21) 1.905(2), Cu−N(21)* 1.905(2), Cu−O(41)* 1.917(2), Cu−O(41) 1.917(2), C(2)−N(21) 1.287(4), C(2)−N(3) 1.348(4), N(3)−C(4) 1.329(4), C(4)−O(41) 1.275(4); bond angles [°]: N(21)−Cu−N(21)* 180.0(2), N(21)−Cu−O(41)* 90.5(1), N(21)*−Cu−O(41)* 89.5(1), N(21)−Cu−O(41) 89.5(1), N(21)*−Cu−O(41) 90.5(1), N(21)−C(2)−N(3) 125.1(3), C(2)−N(21)−Cu 128.2(2), C(4)−N(3)−C(2) 122.8(3), O(41)−C(4)−N(3) 127.3(3), C(4)−O(41)−Cu 126.8(2); torsion angles [°]: N(3)−C(2)−N(21)−Cu 2.30 (0.47), O(41)−Cu−N(21)−C(2) 1.53 (0.28), N(21)−C(2)−N(3)−C(4) −3.81 (0.49), C(2)−N(3)−C(4)−O(41) −0.27 (0.50), N(3)−C(4)−O(41)−Cu 5.39 (0.47), N(21)−Cu−O(41)−C(4) −5.12 (0.26)

1c **5**

In this type of 2:1 mononuclear complex two anionic *N*-acylamidines **1c** are bound to Cu^{II}, forming a neutral six-membered bis-chelate. Interestingly, the O−Cu−O and N−Cu−N units are now in a *trans* arrangement, forming the planar copper(II) complex with centric symmetry. The Cu−N [1.905(2)] and Cu−O bonds [1.917(2) Å] are rather similar in length; compared to the complexes **2**−**4** with neutral *N*-acylamidines as ligands, these bonds are shorter by about 0.05 Å as a consequence of the formally anionic ligands. As in **2**−**4** effective cyclic conjugation is indicated by the bond lengths of the ligands. However, compared to **2**−**4**, the C=O/C=N bonds in **5** are longer and the N−C−N bonds around carbon atom C(3) are shorter, resulting in a much less pronounced bond alternation.

As expected, there is only one IR signal in the NH region at 3330 cm^{-1}, occurring as a very strong, sharp absorption from the N−H stretching vibration (compare ref.[7]). The UV spectra of **5** are in sharp contrast to those of **3** and **4**; the low intensity d→d transition at 561 nm causes the purple color of the solutions and indicate stronger interactions between the ligand and the copper(II) ion than in **3** and **4**.

Discussion

As exemplified by these three types of copper(II) complexes, primary *N*-acylamidines (**1**) are rather versatile ligands for metal complexation. This is mainly due to the NH_2 groups which allow on the one hand the use of primary *N*-acylamidines as neutral ligands (isomer **B** in com-

pounds **2**−**4**), and on the other as anionic (compound **5**; see also ref.[5]) or even dianionic ligands.[8] Tautomerism between isomers **A** and **B** is important in view of the thermodynamics of the complex formation since migration of one proton to the central nitrogen atom allows the formation of a favorable cyclic conjugated six-membered chelate. Correspondingly, tertiary *N*-acylamidines carrying dialkylamino groups, which lack this possibility, are much weaker ligands compared to the primary compounds **1**.[1]

The formation of the different types of complexes obviously depends on the counter ion of the copper(II) salts employed. Independent of the stoichiometry used, ligand **1a** forms a 1:1 (**2**) and a 2:1 (**4**) complex from an acetonitrile solution if one uses copper(II) chloride and copper(II) triflate respectively. Both complexes are obtained by precipitation using diethyl ether. The solubility of the salts and complexes seems to play the important role in controlling the products. Under the conditions mentioned above, no deprotonation takes place and one obtains complexes of the neutral ligands. In contrast, reaction of the aliphatically substituted ligand **1c** in aqueous ethanol yields the neutral complex **5** containing the anionic ligand after repeated extraction with cyclohexane as nonpolar solvent. Most likely, the extraction of the highly hydrophobic complex shifts the complexation equilibrium towards the observed uncharged product, even in the absence of an additional base.

Finally, this series of closely related Cu^{II} complexes is a good demonstration of the versatility of this d^9 ion, giving *N*-acylamidine complexes with coordination numbers four, five and six, including regular square planar (**5**), tetrahedrally distorted planar (**2**), square pyramidal (**3**) and elongated octahedral (**4**) coordination; in all cases four short N−Cu/O−Cu bonds are formed. In the latter two cases, one or two long apical O−Cu contacts to the counter ions are also observed.

Experimental Section

Materials and Methods: Compounds **1a, 1b**, and **1c** were prepared as previously described.[9] Commercially available solvents (p. a. quality) were used without further purification. − CHN analyses were performed with a DiaCHN 240 (Perkin−Elmer). − IR spectra were recorded on a Perkin−Elmer PE 298 spectrophotometer as KBr pellets. − UV/Vis-spectra were recorded using a Cary 1 Bio spectrophotometer (Varian). − ^{1}H- and ^{13}C-NMR spectra were obtained using a Bruker WM 300 and a Bruker AMX 400 spectrometer. The MS (ESI) spectra were recorded using a Quattro LC-Z mass spectrometer (Micromass).

$CuCl_2$-Complex of *N*-Pivaloylbenzamidine (2): Compound **1a** (20 mg, 0.100 mmol) is treated at room temperature with $CuCl_2 \cdot 2\,H_2O$ (17 mg, 0.100 mmol) in acetonitrile (2 mL). After stirring for 5 min a clear, green solution is formed. After some time, diethyl ether (12 mL) is carefully added to form an upper layer. After five days green crystals of **2** are collected (27 mg, 0.067 mmol, 67% yield). − IR (KBr): $\tilde{\nu}$ = 3400 cm^{-1} (br, NH), 3200 (br, NH), 3050 (m, $CH_{arom.}$), 2960 (s, $CH_{aliph.}$), 2850 (w, $CH_{aliph.}$), 1650 (vs, C=O), 1570 (s, $C{=}C_{arom.}$), 1480 (s), 1390 (w), 1370 (m), 1360 (m), 1280 (w), 1220 (m), 1180 (s), 1100 (w), 1060 (m), 1020 (w), 990 (w), 960 (w), 870 (m), 840 (m), 810 (m), 780 (m), 750 (s), 700 (s). − UV/Vis (acetonitrile): λ_{max} [nm] (ε) = 464 (212), 391 (136), 273 sh (10082), 245 (13274), 197 (25444). − ^{1}H NMR (400.13 MHz, CD_3CN): δ = 2.08 (s), 3.97 (br), 6.38 (br), 6.81 (br), 9.71 (br). − MS (ESI, acetonitrile): *m/z* (%) = 506.0 (3) [$C_{24}H_{32}N_4O_2CuCl^+$], 470.1 (20) [$C_{24}H_{31}N_4O_2Cu^+$], 328.0 (2) [$C_{12}H_{15}N_2OCu^+$], 235.5 [$C_{24}H_{32}N_4O_2Cu^{2+}$], 205.0 (100) [$C_{12}H_{17}N_2O^+$]. − $C_{12}H_{16}Cl_2CuN_2O \cdot 1.5$ MeCN (400.29).

X-ray Diffraction Analysis of $2 \cdot 1.5$ MeCN: ($C_{12}H_{16}Cl_2CuN_2O \cdot 1.5$ MeCN),[10] the green single crystal was analyzed using a Nonius KappaCCD diffractometer with Mo-K_α radiation (λ=0.71073 Å) using a graphite monochromator at 293(2) K. Crystal system: monoclinic, space group *C*2/c (No. 15) with cell parameters a = 15.371(1) Å, b = 12.046(1) Å, c = 21.670(1) Å, β = 106.70(1)°, V = 3843.2(4) Å^3, $\rho_{calcd.}$ = 1.384 Mg/m^3, Z = 8. Crystal size: 0.20 × 0.10 × 0.10 mm. 18292 reflections were collected leading to 5718 independent and 4061 observed [$I > 2\sigma(I)$] reflections. Absorption coefficient μ = 1.420 mm^{-1}, absorption correction via SORTAN (0.764 ≤ T ≤ 0.871). 217 refined parameters. Non-hydrogen atoms were refined anisotropically. Coordination Compounds of *tripod*Co^{II} and *tripod*Co^{I} − Selective Substitution and Redox Behaviour

Rolf Rupp,[a] Gottfried Huttner,*[a] Peter Kircher,[a] Rainer Soltek,[a] and Michael Büchner[a]

Dedicated to Prof. Jürgen Wolfrum on the occasion of his 60th birthday

Keywords: Tripod ligands / Cobalt(I/II) / Ligand substitution / Alkyne / Redox behaviour

The five-coordinate *tripod*Cobalt(II) compound [*tripod*-$Co^{II}Cl_2$] (**2**) [*tripod* = $CH_3C(CH_2PPh_2)_3$] undergoes selective substitution of its chlorine groups on activation with KPF_6 in the first substitution step and by $TlPF_6$ in the second. Compounds of the type [*tripod*$Co^{II}LL'$]$^{2+}$ with two nitrile (**3**$^{2+}$) or isonitrile (**5**$^{2+}$) ligands are obtained by this route. Compounds [*tripod*$Co^{II}L_2$] containing two equal ligands L are also accessible from Co^{II}_{aq} as the starting material. The syntheses of [*tripod*$Co^{II}(CNR)_2$]$^{2+}$ (**5**$^{2+}$) and [*tripod*$Co^{II}X_2$] (X = CN, NCO, NCS) (**6**) are reported. Different routes to *tripod*Co^{I} derivatives are described. Depending on the nature of the co-ligands, four-coordinate − [*tripod*Co^{I}NCO] (**7**) − or five-coordinate − [*tripod*$Co^{I}(CNR)_2$]$^{+}$ (**5**$^{+}$) − compounds are obtained. Several high-yield syntheses of [*tripod*Co^{I}-alkyne]$^{+}$ (**8**$^{+}$) compounds are reported. The compounds are characterised by the usual analytical and spectroscopic techniques including X-ray analysis of selected examples.

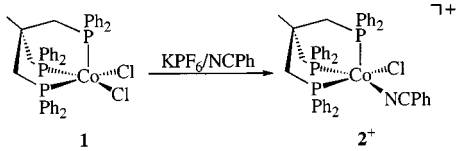
Introduction

An extensive chemistry has been described for the *tripod*cobalt template $[CH_3C(CH_2PPh_2)_3Co]^{n+}$ (n = 0−3).[1−4] Stable compounds [*tripod*CoL_m]$^{n+}$ have been characterised with cobalt in all four of its formal oxidation states of Co^0 to Co^{III}.[1−4] The standard entry into *tripod*-cobalt chemistry is by reaction of the *tripod* ligand with cobalt(II) salts in the presence of co-ligands L, which will generally produce the five-coordinate species [*tripod*$Co^{II}L_2$]. In specific cases, due to electron transfer between the co-ligand and the metal centre, *tripod*cobalt(I) derivatives e.g. [(*tripod*cobalt(I) iodide][2a] or *tripod*cobalt(III) derivatives e.g. [*tripod*cobalt(III) catecholate]$^{+}$ [4] may also be accessible by this route. While many compounds [*tripod*cobalt(II)L_2]$^{n+}$ and a number of compounds [*tripod*cobalt(I)L_2]$^{+}$ or [*tripod*cobalt(I)L] are known, almost nothing is known about the possible exchange of co-ligands in such species by selective substitution reactions.

Exchange of the η^2-acetato ligand in [*tripod*cobalt(II) acetate]$^{+}$ [3a] with an allylic ligand and the substitution of one chloride ligand in [*tripod*cobalt(II)Cl_2][2b,3b] by neutral donor ligands[2b,3c] appear to be the only examples of selective substitution reactions in *tripod*cobalt(II) chemistry. As far as *tripod*Co^{I} chemistry is concerned, the extensive work of J. Ellermann et al. has shown that the carbonyl groups in [*tripod*$Co^{I}(CO)_2$]$^{+}$ − which is obtained from $Co_2(CO)_8$ as the starting material − undergo substitution reactions under photolytic conditions.[2c−2e] The possibility of exchanging the chloride ligand in [*tripod*Co^{I}Cl] has only recently been reported as a selective entry into *tripod*Co^{I} chemistry.[2f]

It is apparent that in order to further develop the chemistry of the *tripod*cobalt template, it is necessary to develop more general methods of substitution processes. In view of the many cases where reversible reductions or oxidations of [*tripod*$Co^{II}L_2$]$^{n+}$ compounds have been documented by cyclic voltammetry, it is also necessary to find preparative methods which allow selective change in the oxidation state of the metal centre. Such methods would be especially useful with respect to *tripod*Co^{I} chemistry since *tripod*Co^{II} compounds are more easily accessible than the corresponding *tripod*Co^{I} species.

We report here on the stepwise selective subsitution of the chloro ligands in [*tripod*$CoCl_2$] (**1**) by two different donor ligands L and L′ to produce [*tripod*$Co^{II}LL'$]$^{n+}$ (n = 0, 2). Compounds of the type [*tripod*$Co^{II}L_2$]$^{n+}$, on the other hand, are easily accessible by standard methods, with the synthesis of such compounds [L = RNC, RCN (n = 2); CN^-, OCN^-, SCN^- (n = 0)] being reported. Upon reduction, these compounds [*tripod*$Co^{II}L_2$] produce [*tripod*$Co^{I}L_2$] or [*tripod*Co^{I}L] depending on the nature of L. With nitriles as co-ligands L, the cobalt(I) species [*tripod*$Co^{I}(NCR)_2$]$^{+}$ are highly reactive and react with alkynes to produce [*tripod*$Co^{I}(\eta^2$-alkyne)]$^{+}$, which may also be obtained from [*tripod*Co^{I}Cl] and alkyne upon activation with $TlPF_6$.[2f]



Results and Discussion

Stepwise Substitution Leading to [tripod$Co^{II}LL'$]

[*tripod*$CoCl_2$] (**1**)[2b,3b] undergoes selective substitution of one of its two chloro ligands by neutral two-electron donors upon activation with KPF_6[2b] or $NaBPh_4$.[3c]

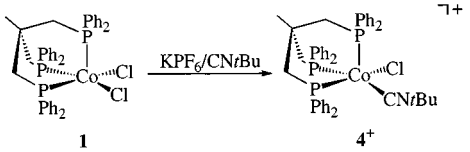
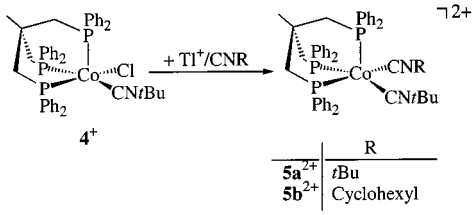
Scheme 1



The benzonitrile derivative $\mathbf{2}^+$ (Scheme 1) is obtained by a procedure analogous to the one reported for the synthesis of [*tripod*Co^{II}(Cl)(NCMe)]$^+$.[2b] Analytical and spectroscopic data (Tables 3 and 4) confirm its identity. The remaining chloride group in $\mathbf{2}^+$ may be replaced in a second substitution step upon activation with $TlPF_6$.

While compounds such as $\mathbf{3a}^{2+}$, with two identical nitrile substituents, might also be obtained by more standard methods[3d], the synthesis of compound $\mathbf{3b}^{2+}$, containing two different nitrile donors relies on the selective stepwise substitution process described (Scheme 2). Both compounds are fully characterised (Tables 3 and 4).

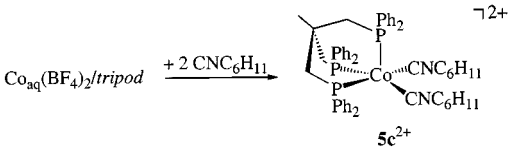


Scheme 2

It had been found by L. Sacconi et al. that **1** undergoes selective substitution of one chloro group by cyclohexyl isocyanide upon activation with $NaBPh_4$.[3c] Analogously, in the presence of KPF_6, **1** reacts with *t*BuNC to produce the monosubstituted product $\mathbf{4}^+$ (Scheme 3, for analytical and spectroscopic data see Tables 3 and 4).

Scheme 3

Only when activated with $TlPF_6$ will the remaining chloride group in $\mathbf{4}^+$ undergo substitution, producing $\mathbf{5}^{2+}$ (Scheme 4, for analytical and spectroscopic data see Tables 3 and 4).



Scheme 4

Compounds such as $\mathbf{5a}^{2+}$, containing two identical isonitrile ligands, may directly be obtained from **1** by using a 2:1 molar ratio of $TlPF_6$/**1** in the presence of two equivalents of the corresponding isonitrile. An excess of isonitrile has to be avoided since it leads to partial decoordination of the *tripod* ligand. Decomplexation is apparent from the corresponding ^{31}P-NMR spectra, which generally, even for the necessarily paramagnetic *tripod*Co^{II} compounds, show well resolved signals for the coordinated phosphorus donors around $\delta = 34$ and the signal of a decoordinated *tripod* phosphorus donor at $\delta = -27$.

One Step Formation of [tripod$Co^{II}L_2$]

Compounds such as $\mathbf{5a}^{2+}$ are easily accessible by the standard procedure of treating a mixture of $Co^{II}_{aq}(BF_4)_2$/*tripod* in $EtOH/CH_2Cl_2$ with two equivalents of an isonitrile. Since no single crystals suitable for X-ray analysis had been obtained for the PF_6^- salts of either $\mathbf{5a}^{2+}$ or $\mathbf{5b}^{2+}$, this synthetic procedure was applied with cyclohexyl isocyanide as the co-ligand to give the salt of $\mathbf{5c}^{2+}$, in the hope it would produce crystals suitable for X-ray analysis (Scheme 5).

Scheme 5

The formation of $\mathbf{5c}^{2+}$ under these reaction conditions is clear from the mass spectrum of its salt, which shows a prominent peak for [*tripod*$Co(CNC_6H_{11})_2]^+$ ($m/z = 901$) independent of the anion used. Crystals were obtained after metathesis with KPF_6 in acetone and crystallisation of the metathesis product from acetone by vapour phase diffusion of Et_2O. Structural analysis of these crystals clearly reveals the structure of $\mathbf{5c}^{2+}$ (Figure 1 and 2; Table 1 and 6).

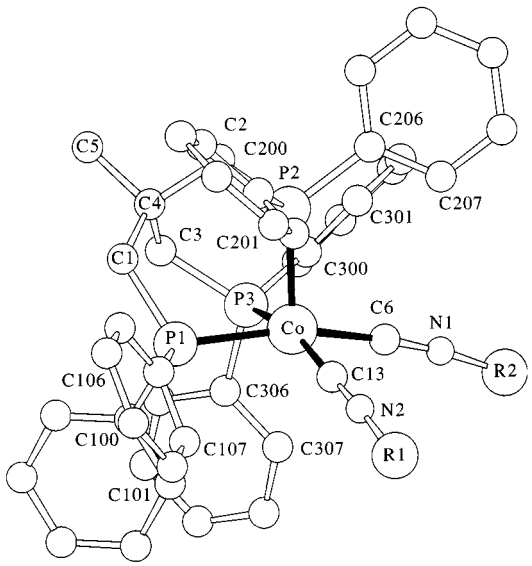


Figure 1. X-ray structure of $\mathbf{5c}^{2+}$ ($R^1 = R^2 = C_6H_{11}$)

The crystal structure was unexpectedly found to contain $PO_2F_2^-$ counterions. Formation of this type of counterion from PF_6^- has been reported in several cases.[5] The water necessary for this hydrolysis reaction may come from the cobalt(II)$_{aq}$ starting material as well as from water in the acetone solvent used for crystallisation. There are two crys-

[a] For the sake of comparison the structure was inverted with respect to the deposited data. − [b] For **5a**$^+$, **5c**$^{2+}$ the designators L1 and L2 refer to the ligands labelled by R1 and R2 respectively in Figures 2 and 3. For **6a** and **6c** L1 refers to the ligand designated by C6N6 and L2 to the one designated by C7N7 in each case (Figures 2 and 3). − [c] In order to define the rotation of the phenyl groups with respect to the idealised C_3 axis of the [*tripod*Co] entity the following procedure was adopted: a vector vertical to the P1−P2−P3 plane and pointing towards the observer with respect to the projections given in Figures 2 and 3 is fixed at the individual phosphorus atoms. Its end point is called Hz. The torsion angles given refer to this convention.

tallographically independent anions in the unit cell of **5c**$^{2+}$, both of which show disorder (see Experimental Section). In contrast to the anions, the cations of **5c**$^{2+}$ are not affected by disorder problems. The idealised square pyramidal structure of **5c**$^{2+}$ is apparent from Figure 1 and 2 and Table 1. It is assumed that **5a**$^{2+}$ and **5b**$^{2+}$ adopt the same type of geometry.

Compound **5c**$^{2+}$ can only obtained by the described route if the amount of isonitrile used does not exceed the stoichometric limit. If an excess of isonitrile is used, mixtures of compounds are obtained having at least partial replacement of the phosphorus donors by isonitrile ligands.

With cyanide as an isoelectronic anionic equivalent of RNC, the risk of replacing the phosphorus donors by cyanide ligands is even higher as it has been found that aqueous solutions of NaCN may completely replace the *tripod* and the co-ligands in [*tripod*CoL$_2$].[3e,6] Nevertheless, under controlled conditions, the cyano derivative **6a** is accessible by the standard procedure (Scheme 6).

	MX
6a	NaCN
6b	KOCN
6c	KSCN

Scheme 6

The cyanide ligands in **6a** may be viewed as isoelectronic equivalents of isonitriles analogous to compounds such as **5**$^{2+}$; they may also be seen as pseudo-halide ligands analogous to **1**. This latter classification leads to the question of whether other pseudo-halide derivatives may be accessible by the same type of procedure. It is in fact found that NCO$^-$ and NCS$^-$ form the corresponding pseudo-halide derivatives **6b** and **6c**. The compounds are isolated as microcrystalline powders (**6b**: green; **6c**: brown) with the analytical and spectroscopic data being in agreement with the assigned formulations (Table 3 and 4). The structures of **6a** and **6c** have been solved by X-ray crystallography (Figure 2 and Figure 3; Tables 1; 6 and 7).

Both compounds show an idealised square-pyramidal coordination of the cobalt centre with one of the phosphorus donors (P2, Figure 2 and 3; Table 1) occupying the apical position and with the other two phosphorus donors and the two co-ligands forming the base of the pyramid. Comparison of the three structures of the type [*tripod*Co^{II}L$_2$] reported in this paper (**5c**$^{2+}$, **6a**, **6c**; Table 1; Figure 2 and 3) shows that the apical Co−P bond is longer (229 pm) than the equatorial Co−P bonds (220−224 pm). The P−Co−P angles are, by virtue of being part of the chelate cage, close to 90° in each case. The L−Co−L angles spanned by the coordinated atoms of the co-ligands are found in the narrow range of 84−88° (Table 1). The P−Co−L angles fall into two classes. The angles referring to ligands which are in an idealised *trans* position to each other show values be-

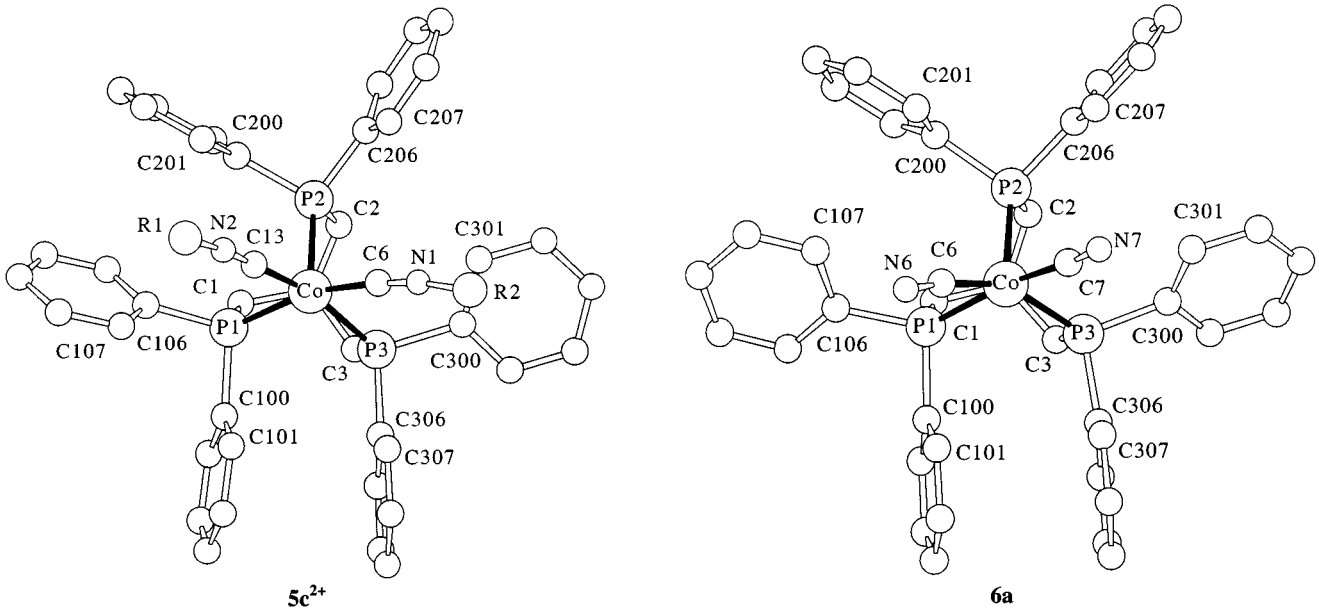

Figure 2. X-ray structure of compounds $\mathbf{5c}^{2+}$ ($R^1 = R^2 = C_6H_{11}$) and **6a**; projection onto the P1−P2−P3 plane

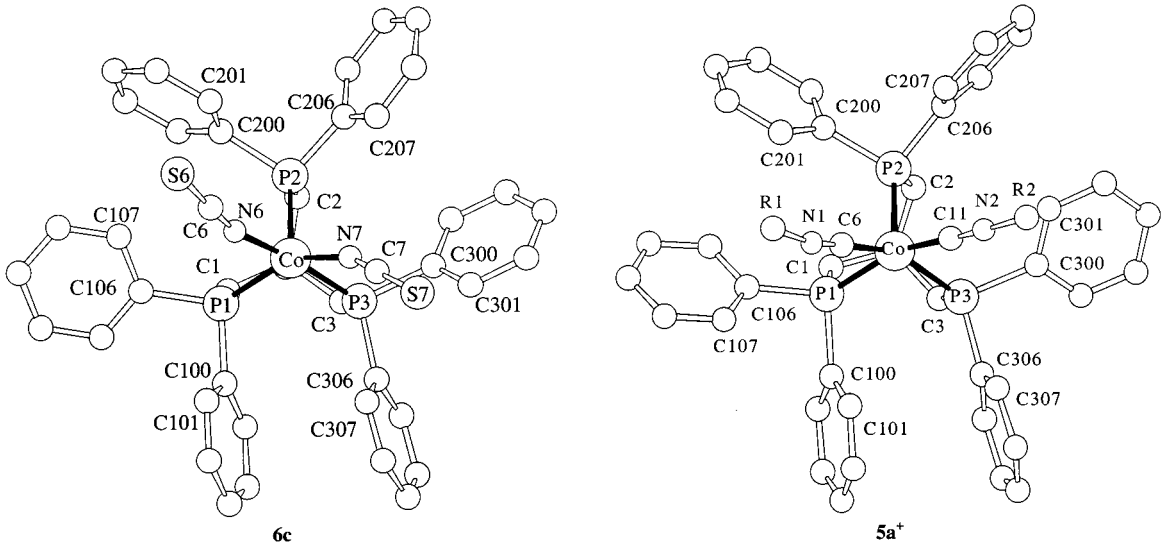

Figure 3. X-ray structure of compounds **6c** and $\mathbf{5a}^{+}$ ($R^1 = R^2 = t$Bu); projection onto the P1−P2−P3 plane.

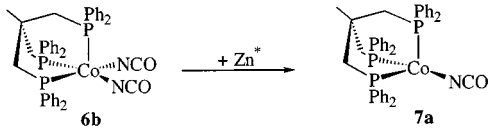
tween 151° and 169° (Table 1) while angles referring to mutual idealised *cis* positions are in a range between 86° and 116°. The deviations from the idealised square-pyramidal geometry are thus substantial. Nevertheless the Co−P bond described as axial is definitely the longest one in each case. The scheme used to label the atoms refers to the standard used in many other publications referring to the structure of *tripod*Co compounds.[7] It is such that the torsion angles of the chelate scaffolding (C4−Ci−Pi−Co; Table 1; Figure 2 and 3) are positive throughout. The rotational position of the phenyl groups (Hz−Pi−Cj−Ck; Table 1; Figure 2 and 3) shows a common trend for all three compounds $\mathbf{5c}^{2+}$, **6a**, **6c**. Two of the phenyl groups at P1 and P3 (labels C100 and C306, Figure 2 and 3, Table 1) are oriented such that they are almost parallel to the idealised C_3 axis of the *tripod*Co fragment, while the other two phenyl groups at these phosphorus atoms are tilted with respect to this axis. The phenyl groups at the axial phosphorus centre P2 tilt to a lesser degree (Figure 2 and 3; Table 1) and may well be close to being parallel to the idealised C_3 axis.

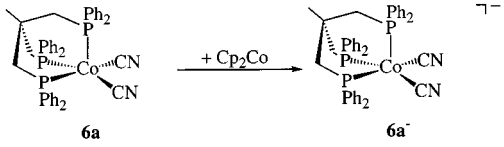


tripodCo^{I} Complexes

Starting from Co^{II} Precursors

*tripod*Co^{I} complexes should be accessible from *tripod*Co^{II} compounds, irrespective of whether their cyclovoltammetric reduction is reversible or not. In the case of a reversible reduction one would expect the reduction product to have the same composition as the Co^{II} starting material as well as a similar structure. An irreversible reduction, on the other hand, does not necessarily mean that the compound decomposes to a complex mixture of products, it only means that the product will have a structure and possibly con-

stitution which is different from the starting material. Preparative reduction has therefore been conducted for [*tripod*CoL_2] species whose cyclovoltammograms show reversible reductions, such as **5a**$^{2+}$ and **6a**, as well as those which show irreversible ones, such as **6b/c** (Tables 3 and 4).



An example of a [*tripod*$Co^{II}L_2$] compound which undergoes irreversible reduction but still selectively produces a specific *tripod*Co^{I} compound is [*tripod*$Co^{I}Cl_2$] (**1**) which is preparatively reduced to [*tripod*$Co^{I}Cl$].[2a,2b,2f] With this in mind the pseudo-halide derivatives **6b/c**, which show an irreversible reduction step in their cyclovoltammograms, may well be expected to selectively produce [*tripod*Co^{I}] derivatives upon preparative reduction. This expectation is born out by the successful synthesis of **7a** from **6b** using activated zinc powder as the reductant (Scheme 7).

Scheme 7

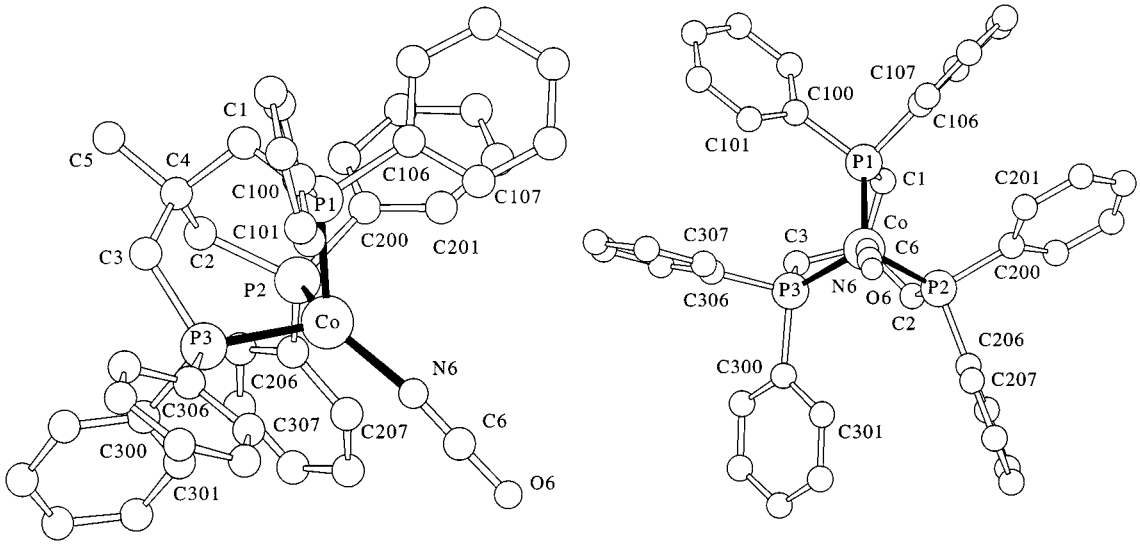
Brown **6b** produces green **7a** which is obtained as a microcrystalline powder (analytical and spectroscopic data in Tables 3 and 4). Crystals of **7a** are obtained by vapour diffusion of petroleum ether (boiling range 40−60 °C) into its CH_2Cl_2 solutions. The coordination around the Co^{I} centre of **7a** can be described as a trigonally distorted tetrahedron (Figure 4; Table 1) as is characteristic of compounds [*tripod*$Co^{I}L$].[2a,2b,2n] Compound **7a** is found to be paramagnetic with two unpaired electrons per formula unit. This is to be expected if the coordination environment around the d^8-Co^{I} centre of **7a** is an idealised tetrahedron. Two of the P−Co−P angles are about 90°; the P−Co−L angles are found to be around 120°. The rotational position of the phenyl groups closely correspond to a C_3-symmetric arrangement with three of these groups being almost parallel to the idealised C_3 axis and the three other ones (Figure 4; Table 1) being inclined in similar extents in this direction in a propeller type arrangement.

Since the five-coordinate Co^{II} compound **6b** forms the four-coordinate Co^{I} species **7a** it is clear why the cyclovoltammetric reduction is irreversible. Clearly, a rapid ligand dissociation process is initiated when **6b** undergoes one-electron reduction. With **6a** the electrochemical behaviour is the reverse of the one found for **6b**. Compound **6a** undergoes reversible reduction while its oxidation is irreversible whereas **6b** is reversibly oxidised with the reduction being irreversible. Reduction of **6a** by Cp_2Co is predicted to produce the five-coordinate compound [*tripod*$Co^{I}(CN)_2]^-$, **6a**$^-$ (Scheme 8).

Scheme 8

The salt containing **6a**$^-$ as the anion and Cp_2Co^+ as the cation is obtained as a microcrystalline red-brown material. It has not been possible to obtain it in an analytically pure form. On the other hand FAB-MS spectra clearly demonstrate its composition from [*tripod*$Co^{I}(CN)_2]^-$ (m/z = 737) and Cp_2Co^+ (m/z = 189). The presence of cyano ligands is indicated by a weak IR absorption at 2100 cm^{-1}. The corresponding broad and weak absorption is not shifted by much compared to the starting compound **6a**. The observed bands should be composed of an envelope of two vibration modes (sym. and antisym.) which are not individually resolved. The ^{31}P-NMR spectra of **6a**$^-$ show a signal characteristic for an η^3-coordinated *tripod* ligand at δ = 31.

Since the Cp_2Co^+ salt of **6a**$^-$ could not be isolated as an analytically pure compound an alternative synthesis of **6a**$^-$ was tested. [*tripod*^{I}Co$(CO)_2]^+$, which is known to undergo carbonyl substitution under photochemical activation[2c−2e] reacts with NaCN to also produce **6a**$^-$. The reaction is,



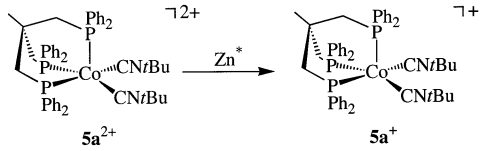


Figure 4. X-ray structure of compound **7a**

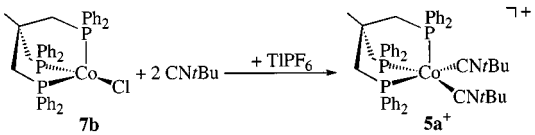
however, not as clean as the one starting from **6a**. The product obtained from [*tripod*$Co^{I}(CO)_2]^+$, while showing the FAB^- signal of $\mathbf{6a}^-$ (m/z = 737), is found to be contaminated by species in which the ligand groups of the *tripod* ligand are partially decoordinated (^{31}P NMR: $\delta = -27$).

If cyanide is viewed as a pseudo-halide species, the five-coordination of $\mathbf{6a}^-$ is in contrast to the four-coordination of **7a**. In view of the backbonding properties of the cyanide ligand the five-coordination of $\mathbf{6a}^-$ corresponds to the five-coordination of [*tripod*$Co^{I}(CO)_2]^+$. This latter view leads to the expectation that the reduction of the isonitrile derivatives $\mathbf{5}^{2+}$ might produce stable Co^{I} derivatives, since isonitrile ligands have more in common with carbonyl ligands than their isoelectronic relatives CN^-.[8] The reversible cyclovoltammetric reduction of $\mathbf{5a}^{2+}$ is mirrored by the straightforward preparative reduction of $\mathbf{5a}^{2+}$ to $\mathbf{5a}^+$ by activated zinc powder (Scheme 9).

Scheme 9



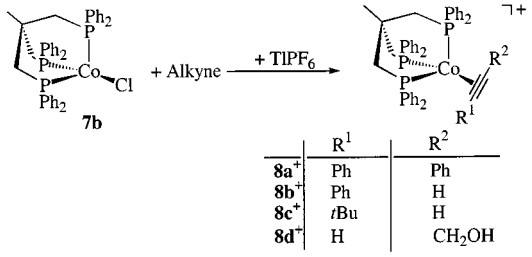
Compound $\mathbf{5a}^+$ is isolated as its PF_6^- salt after chromatography on SiO_2 as a microcrystalline powder with almost the same orange yellow colour as characteristic for starting material $\mathbf{5a}^{2+}[(PF_6)^-]_2$. The cyclovoltammogram observed for $\mathbf{5a}^+$ is the same as the one observed for $\mathbf{5a}^{2+}$ with the reduction wave of $\mathbf{5a}^{2+}$ corresponding to the oxidation wave of $\mathbf{5a}^+$ (Table 3, Experimental Section). Compound **5a**(PF_6) is a diamagnetic salt showing well-resolved NMR spectra (Experimental Section). This may be taken as a further proof of the five-coordination of its cobalt centre since four-coordination would lead to paramagnetism (see **7a**). Single crystals were grown by dissolving **5a**(PF_6) in CH_2Cl_2 and allowing Et_2O to diffuse into this solution. After several trials, a few crystals suitable for X-ray crystallography could be obtained. These crystals were found to contain a $PF_2O_2^-$ counterion instead of the PF_6^- counterion of the starting material due to hydrolysis during the crystallisation experiments. While the counterion shows disorder, in the crystal the cation $\mathbf{5a}^+$ is completely ordered (see Experimental Section).

The structure of the cation of $\mathbf{5a}^+$ is very similar to the structure of $\mathbf{5c}^{2+}$ (not taking into account the different substituents of the isonitrile ligands: $\mathbf{5c}^{2+}$: $C_6H_{11}NC$; $\mathbf{5a}^+$: C_4H_9NC), Figure 2 and 3). The idealised square-pyramidal coordination around the cobalt centres is evident from Figure 2 as well as from the data in Table 1. Co−P and Co−L bond lengths are longer in the Co^{II} compound $\mathbf{5c}^{2+}$ as compared to those in the Co^{I} species $\mathbf{5a}^+$. Arguments based on ionic radii would lead one to expect the contrary. Models based on covalent bonding characterise $\mathbf{5a}^+$ as an electron-precise 18-electron compound with the maximum number of valence electrons involved in bonding whereas $\mathbf{5c}^{2+}$ has a 17-electron configuration and thus one bonding electron less than $\mathbf{5a}^+$. The observed shortening of the bond lengths when going from the 17-electron compound $\mathbf{5c}^{2+}$ to the 18-electron species $\mathbf{5a}^+$ is thus easily understood. There is only one other pair of *tripod*Co derivatives for which the structure of the Co^{I} and the Co^{II} form is known. [*tripod*Co(η^3-allyl]$^{m+}$ (m = 0, 1) exists in the two different oxidation states Co^{I} and Co^{II}.[2n,3b] [With modified tripodal ligands such as $P(CH_2CH_2PPh_2)_3$ other structurally characterised pairs of Co^{I}/Co^{II} redox couples are known.][3l,3k] The same regularities observed for $\mathbf{5a}^+/\mathbf{5c}^{2+}$ are found for [*tripod*Co(η^3-allyl]$^{m+}$ (m = 0, 1).[2n,3b] The Co−P bonds in the Co^{II} species are some 8 pm longer than the ones in the Co^{I} derivative. The difference between the lengths of the basal and apical Co−P bonds is apparent for the cobalt(II) species (Co−P_{apical}: 230 pm; Co−P_{basal}: 221 pm) while these bonds are almost equal for the Co^{I} compound (215−217 pm).[2n,3b] A similar trend is evident when comparing the Co−P distances of $\mathbf{5c}^{2+}$ and $\mathbf{5a}^+$ (Table 1).

While isonitriles RNC are strongly backbonding ligands, nitriles RCN are far less so.[8] While the isonitrile derivative [*tripod*$Co^{II}(CNR)_2]^{2+}$ ($\mathbf{5a}^{2+}$) produces the stable five-coordinate Co^{I} reduction product $\mathbf{5a}^+$, the corresponding nitrile derivatives [*tripod*$Co^{II}(RCN)_2]^{2+}$ ($\mathbf{3}^{2+}$) are expected to produce less stable Co^{I} species since charge delocalisation into the nitrile ligand will not help to stabilise these compounds to a great extent. Nevertheless, compounds $\mathbf{3}^{2+}$ have been found to undergo reversible reduction[3d] indicating that relatively long lived five-coordinate species $\mathbf{3}^+$ are produced. One-electron reduction is not immediately followed by a ligand-dissociation step. This is in contrast to the behaviour of the five-coordinate isocyanate derivative [*tripod*$Co^{II}(NCO)_2]$ (**6b**) which produces the four-coordinate [*tripod*$Co^{I}(NCO)]$ (**7a**) upon reduction. When [*tripod*$Co^{II}(NCMe)_2](BF_4)_2$[3d] is treated with activated zinc powder, a blue solution is immediately obtained from the green solution of the starting material. When the excess zinc powder is filtered off, this solution turns brown. No single compound could be isolated from these solutions and it remains speculative whether the blue or brown colour is due to [*tripod*$Co^{I}(RCN)_2]^+$.

Starting from Co^{I} Precursors

It was felt that starting from appropriate Co^{I} compounds might solve the problem of producing nitrile derivatives of *tripod*Co^{I}. The corresponding synthetic procedure was tested with the synthesis of the isonitrile compound $\mathbf{5a}^+$ from [*tripod*$Co^{I}Cl]$ (**7b**) (Scheme 10).



Scheme 10

Since it is known that $\mathbf{5a}^+$ is a stable compound (see above) one should be able to isolate it if the procedure works. When a beige suspension of **7b** in THF is treated with $TlPF_6$, a white precipitate of TlCl forms leading to a yellow solution of [*tripod*$Co^{I}L_n]^+$ where L should be a THF

ligand. When this mixture is treated with two equivalents of *t*BuNC, an immediate colour change is observed and **5a**$^{+}$(PF$_6$)$^{-}$ is obtained in good yield. The analytical and spectroscopic data of the product correspond to those obtained when **5a**$^{+}$ is prepared from **5a**$^{2+}$ by reduction (see above). The propensity of [*tripod*CoCl] to produce compounds [*tripod*CoL$_2$]$^{+}$ when activated by Tl^{+} had already been used for the synthesis of such compounds where L$_2$ is a diene or a heterodiene ligand.[2f] The reaction principle therefore appears to be quite general and the reaction of **7b** with nitriles should produce nitrile derivatives of *tripod*Co^{I} (**3**$^{+}$). On addition of nitriles to the suspensions prepared from **7b** and TlPF$_6$ (see above), an immediate colour change from yellow to brown is observed. The brown products could, however, not be isolated and their formulation as **3**$^{+}$ may be erroneous. An argument for this formulation is the observation that such brown solutions are also obtained when **3**$^{2+}$ is reduced by activated zinc powder (see above).

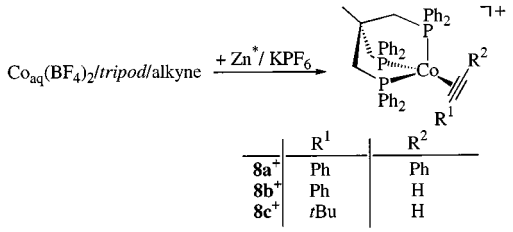
The fact that the brown compounds cannot be isolated as such shows that they are reactive species which by themselves should be able to undergo ligand substitution processes. As a test for this hypothesis the brown solutions were treated with tolane since it is known that [*tripod*Co^{I}(η^2-alkyne)] compounds are stable isolable species.[2g,2h] The salt of **8a**$^{+}$ is obtained by this procedure in yields around 90% (Table 2 and 5). Compound **8a**$^{+}$ had been obtained by L. Sacconi et al.[2g] who used the in situ reduction of Co^{II} salts by 2-propanol in the presence of *tripod* and tolane as their preparative method. The yields obtained by this procedure are not given in the literature but reproduction of these syntheses resulted in yields around 30%.[2i]

The sequence of **7b** → **3b**$^{+}$ → **8a**$^{+}$ is successful. It shows that alkynes are excellent probes for trapping kinetically

Scheme 11

labile *tripod*Co^{I} intermediates (Scheme 11). Such intermediates are of course also formed when solutions of **7b** are treated with Tl^{+} and, as expected, such solutions react with alkynes to produce the corresponding [*tripod*Co^{I}(η^2-alkyne)] complexes **8**$^{+}$ as well.

The reaction is also tolerant to terminal alkynes (**8b**$^{+}$, **8c**$^{+}$) and OH substituents on the alkyne ligand (**8d**$^{+}$).



Based on the observation made by L. Sacconi et al.[2g] that compounds **8a**$^{+}$ and **8b**$^{+}$ are obtained from a mixture of Co(ClO$_4$)$_{2aq}$/*tripod*/alkyne with 2-propanol as the reductant it is reasonable to test this type of reaction by using a more conventional reductant instead of 2-propanol. A mixture of Co$^{II}_{aq}$(BF$_4$)$_2$ and *tripod* reacts with alkynes when treated with activated zinc powder as reductant (Scheme 12).

It is found that this synthetic procedure works well, with apparently almost quantitative formation of **8**$^{+}$; yields of the isolated pure compounds are only reduced by loss during chromatographic work up. This simple reaction protocol is also tolerant to terminal alkynes (**8b**$^{+}$, **8c**$^{+}$) while alcoholic groups are not tolerated. The 18-electron compounds **8**$^{+}$ show well-resolved NMR spectra (Table 5). All groups of signals in their ^{1}H-, ^{13}C-, and ^{31}P-NMR spectra

Scheme 12

can be unequivocally assigned (Table 5). The coordination of both of the carbon atoms of the alkyne ligand is clear from the ^{13}C-NMR signals relating to these atoms. The η^2 coordination of the alkynes in compounds of the type **8**$^+$ is also indicated by comparison with a structurally analysed example.[2n] There is only one ^{31}P-NMR signal for each compound **8**$^+$. In any static structure with a C_2-symmetric alkyne, the juxtaposition of the C_3-symmetric P3−Co entity and the C_2-symmetric alkyne with the coinciding C_2 and C_3 axes give a minimum of two different phosphorus environments, and generally three different types of environment for the phosphorus atoms will exist. A single ^{31}P-NMR peak, observed for all compounds **8**$^+$, indicates that the alkynes rotate around the constitutional C_3 axis of the *tripod*Co template such that all the different environments are averaged in the time domain of the NMR experiment. Rapid rotation of the co-ligands around the idealised C_3 axis of the *tripod*Co template with only one ^{31}P-NMR signal being apparent − where a static structure would lead to at least two signals − is often observed.[2f]

Compounds **8**$^+$ are diamagnetic, which means that the alkyne acts as a 4-electron donor ligand, so that **8**$^+$ are 18-electron compounds. Oxidation of **8**$^+$ occurs at potentials above 1000 mV (vs. SCE, Table 5) and is irreversible throughout. This means that the formal oxidation products **8**$^{2+}$ are unstable. Reduction, on the other hand, is reversible or at least quasireversible for all compounds **8**$^+$ (Table 5) occurring between −600 and −800 mV (vs. SCE). The neutral reduction products **8** are formal 19-electron compounds. Their stability is thus unexpected. This may be explained by the argument that alkynes are known to act as rather flexible donor molecules, which may supply between two and four electrons.[8] In this sense the extra electron would be localised on the alkyne ligands. Any attempts to isolate the neutral compounds **8** have been unsuccessful so far.

No distinct reaction product could be obtained from Co$^{II}_{aq}$(BF$_4$)$_2$/*tripod* with HC≡C−CH$_2$OH as the alkyne and activated zinc powder as the reductant, while the reaction based on **7b** as the starting material gave the corresponding alkyne derivative **8d**$^+$ in high yield. When Me$_3$SiC≡CH is used as the alkyne, both types of reaction failed to produce an isolable η^2-alkyne compound of the type **8**$^+$. By the appropriate colour change (yellow to green with **7b** as the starting material and red-brown to green with Co$^{II}_{aq}$ as the starting compound) the production of an η^2-alkyne derivative **8**$^+$ is indicated in each case. However, on evaporation of the solvent the green-brown species decomposes to produce a grey residue from which no compounds can be extracted showing any indication (MS, ^{31}P NMR) of the presence of species of the type **8**$^+$. With TMSC≡CTMS the observations are again different. Independent of which reaction methodology is applied, no colour change is observed. With its TMS substituents, the alkyne is too bulky to enter the reaction pocket of the *tripod*cobalt template. If the alkyne substituents were to bend backwards as they do with coordinated alkynes (C≡C−R = 140°[2h]) TMSC≡CTMS might possibly fit into the pocket. However, bending will only start to occur when the coordinatively unsaturated metal and the alkyne triple bond are close enough to each other. This appears to be impossible with the small [*tripod*M]$^+$ reaction pocket and the bulky TMSC≡CTMS alkyne. If the *tripod*Co entity is seen as a protective group for protecting alkynes from undergoing standard organic transformations the observed selective response to the bulkiness of the alkyne substituents might find its application in organic synthesis.

Conclusion

The chlorine groups of [*tripod*Co^{II}(Cl)$_2$] (**1**) may be substituted in a stepwise manner by two different donor ligands to produce [*tripod*Co^{II}LL′]$^{2+}$. A broader range of preparative methods exists for the synthesis of compounds [*tripod*Co^{II}L$_2$]$^{n+}$ (n = 0, 2) with two equal donor ligands (L = RCN, RNC, CN$^-$, OCN$^-$, SCN$^-$).

Cobalt(II) derivatives [*tripod*Co^{I}L$_2$] (L = RNC) or [*tripod*Co^{I}L] (L = NCO$^-$, alkyne) are available by different routes starting from the *tripod*Co^{I} precursors [*tripod*Co^{I}(CO)$_2$]$^+$ or [*tripod*Co^{I}Cl]. They are also accessible from Co^{II} precursors using Co$^{II}_{aq}$ under reducing conditions.

Experimental Section

General Remarks: Unless otherwise noted, all manipulations were carried out under argon by means of standard Schlenk techniques. All solvents were dried by standard methods and distilled under argon (PE 40/60 = petroleum ether, boiling range 40−60 °C).[9] The zinc powder (Merck) used in some of the reactions was activated by stirring it under argon with a magnetic bar for 12 h. For ultrasonic activation of reaction mixtures an ultrasonic bath (Bender & Hobein, Laboson 200) was used. *tripod*Co^{II}Cl$_2$ was prepared in accordance with a literature procedure.[3i] All other chemicals were obtained from commercial suppliers and used without further purification. The solvents [D$_6$]acetone, CDCl$_3$, and CD$_2$Cl$_2$ used for NMR-spectroscopic measurements were degassed by three successive freeze-pump-thaw cycles and dried over 4-Å molecular sieves. − NMR: Bruker Avance DPX 200 operating at 200.12 MHz (^{1}H), 50.323 MHz (^{13}C{^{1}H}), 81.015 MHz (^{31}P{^{1}H}) T = 303 K, unless stated otherwise; chemical shifts (δ) in ppm with respect to [D$_6$]acetone (^{1}H: δ = 2.05; ^{13}C: δ = 29.8, 206.2), CDCl$_3$ (^{1}H: δ = 7.27; ^{13}C: δ = 77.0) and CD$_2$Cl$_2$ (^{1}H: δ = 5.32; ^{13}C: δ = 53.8) as internal standards. ^{31}P chemical shifts (δ) are in ppm with respect to 85% H$_3$PO$_4$ (^{31}P: δ = 0) as external standard. − IR: Bruker IFS-66, KBr disks. − EPR: Bruker ESP 300E (X-band, external standard diphenylpicrylhydrazyl). All measurements were carried

out at 20 °C in a standard cavity ER 4102St. − Magnetic measurements: Sherwood Scientific Magnetic Susceptibility Balance MSB, MK I, JM Alfa # 9997 (Sherwood Scientific Ltd.), calibration with $HgCo(SCN)_4$. All measurements were carried out at 20 °C. − UV/Vis: Perkin−Elmer Lambda 19. − Fast-atom bombardment (FAB): Finnigan MAT 8230, xenon, matrix: 4-nitrobenzyl alcohol. − HR-MS (FAB): JEOL JMS 700, matrix: 4-nitrobenzyl alcohol. − Elemental analyses: Microanalytical Laboratory of the Organisch-Chemisches Institut, Universität Heidelberg. − Melting points (not corrected): Gallenkamp MFB-595 010. − Photochemical activation: mercury high-pressure lamp (Hanau, TQ 150), Duran glass apparatus. − Cyclic voltammetry: Metrohm Universal Meß- und Titriergefäß, Metrohm GC electrode RDE 628, platinum electrode, SCE electrode, Princeton Applied Research potentiostat Model 273, 10^{-3} M in 0.1 M n-Bu_4NPF_6/CH_2Cl_2. Reactions described as reversible show a square-root dependence of current versus scan speed in the range of 50 to 800 mVs^{-1}.

General Procedure for the Synthesis of [*tripod*Co^{II}(Cl)(L)]PF_6 Complexes (L = NCPh: 2; L = CN*t*Bu: 4): [*tripod*$CoCl_2$] (**1**) (753 mg, 1 mmol) was dissolved in acetone (15 mL) to give a green-blue solution. The appropriate co-ligand (Table 2, 1 mmol) and KPF_6 (185 mg, 1 mmol) was added to the solution. While stirring the reaction mixture for 15 min, a colour change was observed − orange-brown in the case of nitriles and green in the case of isonitriles. The solvent was evaporated in vacuo and the residue dissolved in CH_2Cl_2. The solution was filtered to remove KCl. The solvent was evaporated again and the residue washed with Et_2O (5 × 5 mL). Removal of the solvent afforded **2**PF_6 and **4**PF_6. For analytical data of the compounds see Table 3 and Table 4.

General Procedure for the Synthesis of [*tripod*Co^{I}LL′]$(PF_6)_2$ Complexes from Compounds [*tripod*Co^{II}(Cl)(L)]PF_6

Method A [L = L′ = NCPh ($3a^{2+}$); L = NCPh, L′ = NCMe ($3b^{2+}$); L = CN*t*Bu ($5a^{2+}$); L = CN*t*Bu, L′ = CNCy ($5b^{2+}$)]: The appropriate [*tripod*Co^{II}(Cl)(L)]PF_6 compound (L = NCPh: **2**PF_6; L = CN*t*Bu: **4**PF_6, 1 mmol) and $TlPF_6$ (349 mg, 1 mmol) were dissolved in THF (20 mL). The appropriate co-ligand L′ (Table 2, 1 mmol) dissolved in THF (5 mL) was added to the suspension and the reaction mixture treated in an ultrasonic bath for 5 min. During this time the reaction mixture changed its colour − orange-brown to green in the case of nitriles, green to red-orange in the case of isonitriles. The solvent was evaporated in vacuo and the residue dissolved in CH_2Cl_2. The solution was filtered to remove TlCl. The solvent was evaporated again, the residue dissolved in THF (1 mL) and precipitated with Et_2O (5 × 5 mL). Removal of the solvent afforded **3a**$(PF_6)_2$, **3b**$(PF_6)_2$, **5a**$(PF_6)_2$, and **5b**$(PF_6)_2$. For analytical data of the compounds see Table 3 and 4.

Method B [L = NCPh ($3a^{2+}$); L = CN*t*Bu ($5a^{2+}$)]: 1 mmol (753 mg) of [*tripod*$Co(Cl)_2$] (**1**) and 2 mmol (700 mg) of $TlPF_6$ were dissolved in 20 mL of THF. 2 mmol of the appropriate ligand L (Table 2), dissolved in 5 mL of THF, was added to the reaction mixture which was then treated in an ultrasonic bath for 15 min. During this procedure the reaction mixture changed its colour − blue-green to green in the case of the nitrile and to red-orange in the case of the isonitrile. The solvent was evaporated in vacuo and the residue dissolved in CH_2Cl_2. The solution was filtered to remove the TlCl produced. The solvent was evaporated again, the residue dissolved in 1 mL of THF and precipitated with 5 mL of Et_2O five times. Removal of the solvent afforded **3a**$(PF_6)_2$ and **5a**$(PF_6)_2$. For analytical data of the compounds see Table 3 and 4.

Preparation of [*tripod*Co^{I}(CN*t*Bu)$_2$]PF_6 {[5a(PF_6)]}

Method C: Freshly prepared [*tripod*CoCl][2f] (**1**) (718 mg, 1 mmol) and $TlPF_6$ (349 mg, 1 mmol) were suspended in THF (20 mL) to give a yellow solution while a fine white powder precipitated. *tert*-Butyl isocyanide (168 mg, 2 mmol), dissolved in THF (5 mL), was added dropwise to the suspension and the reaction mixture treated in an ultrasonic bath for 10 min. During this time the reaction mixture changed its colour from brown-orange to red-orange. The solvent was evaporated in vacuo and the residue dissolved in CH_2Cl_2. The solution was filtered to remove $TlPF_6$. The solvent was evaporated and the residue purified by chromatography on SiO_2 (ICN 32-63, 60 Å) with a solvent mixture of Et_2O/CH_2Cl_2 (5:1) to give the PF_6 salt of [*tripod*Co(CN*t*Bu)$_2$]$^+$. − MS-FAB: 849 [*tripod*Co(CN*t*Bu)$_2$]$^+$. − ^{1}H NMR ($CDCl_3$): 1.37 (s, 18 H, *ligand*-CH_3), 1.58 (br., 4 H, *tripod*-CH_3), 2.77 (br., 6 H, CH_2), 7.16−7.74 (m, 30 H, aromatic H). − ^{13}C NMR ($CDCl_3$): 25.9 (s, *ligand*-CH_3), 30.5 (m, CH_2), 38.6 (s, *ligand*-C_q), 38.9 (m, *tripod*-CH_3), 39.3 (s,

Method D: $Co_{aq}(BF_4)_2$ (342 mg, 1 mmol) and *tripod* (624 mg, 1 mmol) were dissolved in CH_2Cl_2/ethanol (1:1, 30 mL) to give a brown-red solution. A five-fold excess of zinc powder and *tert*-butyl isocyanide (168 mg, 2 mmol), dissolved in THF (5 mL), were added dropwise. The reaction mixture was treated in an ultrasonic bath for 5 min. The solvent was removed in vacuo, the residue dissolved in CH_2Cl_2 and filtered to remove $ZnCl_2$ and excess zinc powder. The solvent was evaporated, the residue dissolved in THF and treated with a three-fold excess of KPF_6. The solvent was removed in vacuo, the residue dissolved in CH_2Cl_2 and filtered to remove excess KPF_6 and KBF_4. The solvent was evaporated and the residue purified by chromatography on SiO_2 (ICN) with a solvent mixture of Et_2O/CH_2Cl_2 (5:1) to give the PF_6 salt of [*tripod*$Co^I(CNtBu)_2]^+$ (**5a**PF_6). For analytical data see above.

Preparation of [*tripod*$Co^{II}(CN)_2$] (6a): $Co_{aq}(BF_4)_2$ (342 mg, 1 mmol) and *tripod* (624 mg, 1 mmol) were dissolved in CH_2Cl_2/EtOH (1:2, 30 mL) to give a brown-red solution. NaCN (98 mg, 2 mmol), dissolved in ethanol/water (1:1, 20 mL), was added dropwise to give a claret solution. The solvent was removed in vacuo, the residue dissolved in CH_2Cl_2 and filtered to remove $NaBF_4$. Concentration afforded **6a** as claret powder. Single crystals suitable for X-ray analysis were obtained by vapour diffusion of Et_2O into a CH_2Cl_2 solution of **6a**.

Generation of [*tripod*$Co^I(CN)_2]^-$ (6a$^-$). − Method E: Compound **6a** (739 mg, 1 mmol) and Cp_2Co (189 mg, 1 mmol) were dissolved in 20 mL of THF. The colour of the solution changed from claret to brown. The solvent was evaporated and the residue washed with Et_2O (5 × 5 mL). − MS-FAB: FAB-positive: 189 [Cp_2Cp^+]; FAB-negative: 739 [*tripod*$Co^I(CN)_2]^-$. − ^{31}P NMR (CD_2Cl_2): δ = 32.4. − IR: ṽ [cm^{-1}] = 2100 (w, CN).

Method F: [*tripod*$Co^I(CO)_2]PF_6$[2c] (885 mg, 1 mmol) and NaCN (98 mg, 2 mmol) were suspended in THF (50 mL). The suspension was irradiated for 3 h. During this time a colour change from claret to brown was observed. The solvent was removed in vacuo and the brown residue washed Et_2O (5 × 5 mL). MS-FAB: FAB-negative: 739 [*tripod*$Co(CN)_2]^-$. − ^{31}P NMR (CD_2Cl_2): δ = 32.4. − IR: ṽ [cm^{-1}] = 2100 (w, CN).

General Procedure for the Synthesis of [*tripod*$Co^{II}(NCX)_2$] Complexes [X = O (6b); X = S (6c)]: $Co_{aq}(BF_4)_2$ (342 mg, 1 mmol) and *tripod* (624 mg, 1 mmol) were dissolved in CH_2Cl_2/ethanol (1:2, 30 mL) to give a brown-red solution. The appropriate salt KX (Table 2, 2 mmol), dissolved in solvent (methanol in the case of **6b**, Et_2O in the case of **6c**, 20 mL), was added. The solvent was removed in vacuo, the residue dissolved in CH_2Cl_2 and filtered to remove KBF_4. The solvent was evaporated and the residue washed with Et_2O at 0 °C (5 × 5 mL). For analytical data of the compounds see Table 3 and 4.

Preparation of [*tripod*Co^INCO] (7a): [*tripod*$Co^{II}(NCO)_2$] (**6b**) (767 mg, 1 mmol) was dissolved in THF (20 mL) and a five-fold excess of zinc powder added. The reaction mixture was treated in an ultrasonic bath for 5 min. The solvent was removed in vacuo, the residue dissolved in CH_2Cl_2 and filtered. After concentration, **7a** was obtained as microcrystalline brown-green powder. Single

crystals suitable for X-ray analysis were obtained by vapour diffusion of Et_2O into a solution of **7a** in CH_2Cl_2. For analytical data of the compound see Table 3 and 4. The product corresponds in all its properties to the one obtained by an independent method.[2d]

General Procedure for the Synthesis of the PF_6 Salts of [*tripod*Co^{I}(η^2-alkyne)]$^+$ ($8a^+-8d^+$). – Method G: Freshly prepared [*tripod*CoCl][2f] (**1**) (718 mg, 1 mmol) and $TlPF_6$ (349 mg, 1 mmol) were suspended in THF (20 mL) to give a yellow solution while a fine white precipitate was formed. The appropriate alkyne (Table 2, 1 mmol) was added to the suspension and the reaction mixture treated in an ultrasonic bath for 10 min. During this procedure the reaction mixture changed its colour to green. The solvent was evaporated in vacuo and the residue dissolved in CH_2Cl_2. The solution was filtered to remove TlCl. The solvent was evaporated again and the residue (except $8d^+$) purified by chromatography on SiO_2 (ICN 32-63, 60 Å) with a solvent mixture of Et_2O/CH_2Cl_2 (5:1) to produce the PF_6 salts of $8a^+-8c^+$. In the case of $8d^+$ the solvent was evaporated and the residue was washed with Et_2O (5 × 5 mL). For analytical data of the compounds see Table 5.

Method H: $Co_{aq}(BF_4)_2$ (342 mg, 1 mmol) and *tripod* (624 mg, 1 mmol) were dissolved in CH_2Cl_2/EtOH (1:1, 30 mL) to give a brown-red solution. The appropriate alkyne (Table 2, 1 mmol) and a five-fold excess of zinc powder were added. The reaction mixture was treated in an ultrasonic bath for 5 min. The solvent was removed in vacuo, the residue dissolved in CH_2Cl_2 and filtered to remove $ZnCl_2$ and excess zinc powder. The solvent was evaporated, the residue dissolved in THF and treated with a three-fold excess of KPF_6. The solvent was removed in vacuo, the residue dissolved in CH_2Cl_2 and filtered to remove excess KPF_6 and KBF_4. The solvent was evaporated again and the residue purified by chromatography on SiO_2 (ICN 32-63, 60 Å) with a solvent mixture of Et_2O/CH_2Cl_2 (5:1) to produce the PF_6 salts of $8a^+-8c^+$. Analytical data of the compounds: Table 5.

X-ray Crystallographic Study: The measurements were carried out with a Siemens P4 four-circle diffractometer (**6a**) or a Nonius–Kappa CCD diffractometer ($5c^{2+}$, $5a^+$, **6b**, and **7a**), all using graphite-monochromated Mo-K_α radiation. In case of the Siemens P4 four-circle diffractometer measurements, the intensities of three reference reflections (measured every 100 reflections) remained constant throughout the data collection, thus indicating crystal and electronic stability. The data collected with the Siemens P4 diffractometer were corrected by standard methods including experimental absorption correction. The data from the Nonius–Kappa CCD device were processed by the standard Nonius software.[10] All calculations were performed using the SHELXT PLUS software package. Structures were solved by direct methods with the SHELXS-97 program and refined with the SHELXL-97 program.[11,12] Graphical handling of the structural data during solution and refinement was performed with XPMA.[13] Atomic coordinates and anisotropic thermal parameters of the non-hydrogen atoms were refined by full-matrix least-squares calculations. Table 6 and Table 7 compile the data for the structure determinations. The geometry of the counterion $PO_2F_2^-$ of $5c^{2+}[(PO_2F_2)^-]_2$ as found in this analysis is rather inaccurate due to disorder problems but is in overall agreement with the literature data.[5] This disorder could be resolved by the split-atom technique such that at one of these positions two different rotational positions were sufficient, whereas at the other position three to four rota-

tional positions had to be taken into account in order to reproduce the electron-density distribution. The $PO_2F_2^-$ counterion in $\mathbf{5a}^{+}(PO_2F_2)^{-}$ is also disordered. Refinement in a split-atom model with the phosphorus atom, the two oxygen atoms, and one fluorine atom in just one position and the second fluorine atom equally distributed over two positions gave a satisfactory agreement. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-135321 to -135325. Heterometallic Nitrido-Carbonyl Clusters − Synthesis and Characterization of $[Fe_5MN(CO)_{14}(C_5H_5)]^{2-}$, $[Fe_3M_3N(CO)_{18}]^{3-}$ (M = Mo, W) and $[HFe_5MoN(CO)_{16}]^{2-}$ and Solid-State Structures of $[Fe_5MoN(CO)_{14}(C_5H_5)]^{2-}$, $[Fe_5WN(CO)_{14}(C_5H_5)]^{2-}$, and $[Fe_3Mo_3N(CO)_{18}]^{3-}$

Roberto Della Pergola,*[a] Massimiliano Branchini,[b] Alessandro Fumagalli,[c] Luigi Garlaschelli,[b] Mario Manassero,*[d] and Mirella Sansoni[d]

Keywords: Iron / Molybdenum / Tungsten / Nitrides / Interstitial atoms / Cluster

The anionic clusters $[Fe_5MN(CO)_{14}Cp]^{2-}$ [M = Mo (**1**) or W (**2**)] were synthesized from $[Fe_4N(CO)_{12}]^-$ and $[MCp(CO)_3]^-$ in refluxing acetonitrile. The clusters $[Fe_3M_3N(CO)_{18}]^{3-}$ [M = Mo (**3**) or W (**4**)] were prepared by reaction of $[Fe_4N(CO)_{12}]^-$ with $[M_2(CO)_{10}]^{2-}$ under the same conditions. The molybdenum-containing anions **1** and **3** are obtained in higher yields than **2** and **4**. The reaction of the tetranuclear iron cluster with $[Mo(\eta^6\text{-}Me_3C_6H_3)(CO)_3]$ affords a mixture of $[Fe_3Mo_3N(CO)_{18}]^{3-}$ and $[HFe_5MoN(CO)_{16}]^{2-}$ (**5**). The solid state structures of the clusters **1**, **2** and **3** have been determined; they consist of six metal atoms, arranged in octahedral metal cages encapsulating a μ_6-N ligand. The cyclopentadienyl ligand is bound to Mo in **1** and to W in **2**; these anions have three edge-bridging carbonyl groups and eleven terminal carbonyl groups. The cluster **3** possesses three molybdenum atoms in a *fac* arrangement, and the carbonyl ligands are all terminal, or asymmetrically bridging. Inspection of the interatomic distances suggests that molybdenum interacts preferentially with the carbonyl and the nitrido ligands, whereas the iron atoms bind strongly with the other metal centres. The solid state structure of **5** could not be fully resolved owing to crystal disorder. Analytical and spectroscopic data (infrared and ^{1}H NMR) are all consistent with the proposed formula.

Introduction

The interest in heterometallic clusters is still growing, and several examples of their application in catalysis can be found in the literature.[1] In homogeneous catalysis, mixed metal species are preferred, due to the presence of polar metal−metal bonds which can tune electron density at the metal centres, thus modifying the reactivity of the coordinated ligands.[2] In the field of heterogeneous catalysis, mixed-metal species can be exploited for the formation of bimetallic particles which are extraordinarily uniform in their morphology and composition.[3] In this context, the stability of the cage due to the interstitial atoms can avoid sinterization during the absorption to the support and the decarbonylation. Heterometallic species often have unusual structures of remarkable stability due to the preference of the two elements for different chemical sites within the cluster.[4] In these compounds, the HOMO−LUMO gap can be small, and the frontier orbitals can be filled/depleted without decomposition. Therefore, heterometallic clusters with an odd number of valence electrons, and possibly displaying unusual magnetic properties, are not uncommon.[5]

For these reasons, we are studying the reactions of $[Fe_4N(CO)_{12}]^-$ with carbonyl complexes of different transition metals, aiming for the preparation of iron-based mixed-metal clusters stabilized by a nitrido ligand.[6,7] The interstitial atom plays an essential role in these syntheses, limiting the fragmentation of the starting material and directing the reconstruction of *closo* polyhedra. In order to prove the generality of this approach, and to expand this kind of chemistry as much as possible, we turned our investigations to the metals of groups 6, 7 and 10. We describe here the synthesis and characterization of several bimetallic species containing molybdenum or tungsten. These organometallic species may suggest a new approach to the preparation of transition metal nitrides,[8] which are widely investigated for their catalytic properties.[9]

Results

Syntheses

$[Fe_5MoN(CO)_{14}(C_5H_5)]^{2-}$ (1) and $[Fe_5WN(CO)_{14}(C_5H_5)]^{2-}$ (2)

The carbido dianion $[Fe_4C(CO)_{12}]^{2-}$ reacts with a large variety of metal complexes acting as Lewis acids, to give metal-cage expansion.[10] In contrast, the nitrido species $[Fe_4N(CO)_{12}]^-$, because of the low specific charge, reacts only after reduction, possibly through the labilization of a carbonyl ligand.[11] Under these conditions, the nitride reagent is partially destroyed, and the iron carbonyl fragment can contribute to the construction of larger metal cages. We have already exploited this approach to obtain $[Fe_6N(CO)_{15}]^{3-}$ [6] and $[Fe_5RhN(CO)_{15}]^{2-}$.[7] While attempting the synthesis of heterometallic species containing molybdenum or tungsten, we tested first nucleophilic anionic metal complexes, such as $[M_2(CO)_{10}]^{2-}$ or $[M(CO)_3(C_5H_5)]^-$ (M = Mo or W).[12] The reaction of $[Fe_4N(CO)_{12}]^-$ with $[Mo(CO)_3(C_5H_5)]^-$ was performed in MeCN, with both reagents as their tetraethylammonium salts in a 2:1 molar ratio. Since the process of cluster growth cannot be described by a simple balanced chemical equation, the best conditions were empirically determined to obtain the maximum yield and the simplest way of purification. Indeed, when the tetranuclear iron cluster was completely consumed (after ca. 18 h) we detected formation of the new cluster species $[Fe_5MoN(CO)_{14}(C_5H_5)]^{2-}$ (**1**), together with the known compound $[Fe_6N(CO)_{15}]^{3-}$ [6] and a large amount of unreacted $[Mo(CO)_3(C_5H_5)]^-$. The anion **1** was separated by extraction with methanol and recovered by addition of a bulky cation. The reaction with $[W(CO)_3(C_5H_5)]^-$ proceeds exactly the same way, usually requiring more time to be completed, with lower yields. Frequently, the final products **1** and **2** are slightly contaminated by traces of the $[M(CO)_3(C_5H_5)]^-$ reagents.

$[Fe_3Mo_3N(CO)_{18}]^{3-}$ (3) and $[Fe_3W_3N(CO)_{18}]^{3-}$ (4)

The reaction of $[Fe_4N(CO)_{12}]^-$ with $[Mo_2(CO)_{10}]^{2-}$ or $[W_2(CO)_{10}]^{2-}$ (both as $[NEt_4]^+$ salts in a 1:1 molar ratio) is much more rapid and selective than above, yielding mainly $[Fe_3M_3N(CO)_{18}]^{3-}$. In this case the difference of reactivity between molybdenum and tungsten is relevant: the reaction with $[Mo_2(CO)_{10}]^{2-}$ in refluxing MeCN is completed within 1 h while the tungsten derivative requires more than 5 h, even in EtCN where the boiling temperature is ca. 15 °C higher. At the end, the soluble minor impurities can be extracted in methanol, leaving behind a residue which is analytically pure according to elemental analyses. Crystals of the salt $[NEt_4]_3$**3** were grown from acetonitrile/diisopropyl ether,[13] but, unfortunately, were unsuitable for an X-ray determination; we had to prepare many different salts by cation exchange with tetraalkylammonium halides. The same metathesis proved unsuccessful for tungsten, and therefore we could only obtain the parameters of the unit cell of $[NEt_4]_3$**4**, which was isomorphous with $[NEt_4]_3$**3**, thus confirming its formula. The infrared spectra of **3** and **4** are almost superimposable, suggesting that the two compounds are also isostructural in solution.

$[HFe_5MoN(CO)_{16}]^{2-}$ (5)

The trianion **3** can be also obtained in slightly lower yields from the reaction between $[Fe_4N(CO)_{12}]^-$ and a large excess of $[Mo(CO)_3(Me_3C_6H_3)]$ in refluxing THF. In this case, the new dianion **5** is formed as a by-product; it can be separated by selective extraction with methanol, and then precipitated in a microcrystalline form by the addition of bulky organic cations. Crystals of the $[PPh_4]^+$ and $[N(PPh_3)_2]^+$ salts, both unsuitable for X-ray analysis, were obtained by this method after crystallization from THF/2-propanol. The salt $[PPh_4]_2$**5** allowed a partial structural determination, which unambiguously showed an octahedral metallic framework with a Mo:Fe ratio of 1:5.[14] Several alternative procedures have been unsuccessfully tested to selectively obtain **5** or the hypothetical Fe−W−N analogue; they include the reaction between $[Fe_4N(CO)_{12}]^-$ and the neutral complexes $[M(CO)_3(NCEt)_3]$ or the reaction between the same iron cluster and the bimetallic anions $[HFeM(CO)_9]^-$.[15]

Solid-State Structures

Molecular structures of $[Fe_5Mo(CO)_{14}(C_5H_5)]^{2-}$ and $[Fe_5W(CO)_{14}(C_5H_5)]^{2-}$

The solid-state structures of the two anions have been determined from their $[PPh_4]^+$ salts. $[PPh_4]_2$**1** and $[PPh_4]_2$**2**·C_4H_8O crystallize in different space groups, owing to the presence of one molecule of crystallization (THF) in the latter. However, the two clusters **1** and **2** have almost identical molecular geometries, with strikingly similar structural parameters. Relevant bond lengths and angles are presented in Table 1, and the structure of **1** is shown in Figure 1. The six metal atoms define an octahedron with an interstitial nitrogen atom. The cyclopentadienyl ligand is bound to molybdenum (or tungsten in **2**).

The clusters possess three edge-bridging ligands, the remainder being terminal. The disposition of the carbonyl groups strictly recalls that found in the heterometallic species $[Fe_5M'N(CO)_{15}]^{2-}$ (M′ = Rh or Ir).[7] This similarity is not unexpected considering that the "$M(C_5H_5)^-$" and the "$M'(CO)^-$" fragments are isoelectronic (12 valence electrons). As such, the four anions can be envisaged as adducts (from the stoichiometric and electronic point of view) between the well-known square pyramidal $[Fe_5N(CO)_{14}]^-$ cluster (74 valence electrons)[16] and the $[M-L]^-$ fragments, thus representing a nice example of the relationship between *nido* and *closo* cluster cages.[17]

The average bond lengths (Å) and angles (°) for the metal cage and the ligand environment are collected in Table 2. From the intermetallic distances in **1**, the covalent radii of iron and molybdenum can be estimated as $r_{Fe} = 1.32$ and $r_{Mo} = 1.52$ Å. The metal−nitrogen bond lengths also differ by 0.19 Å, suggesting that the interstitial ligand does not

interact preferentially with iron or molybdenum. However, the $Fe(CO)_3$ vertex opposite to the MoCp group shows the longest Fe(5)−N separation (1.909 Å), which could be indicative of an excess of electron density on iron [contributed by the three terminal ligands CO(9), CO(10) and CO(11)]. In agreement with this, the CO(10) and CO(11) ligands show some deviation from linearity, and short nonbonding contacts with Fe(3) and Fe(4). CO(12) and CO(13), spanning Fe−Mo edges, are asymmetric; if the different dimensions of Mo and Fe, and the M−C−O angles are taken into account, the two carbonyl groups appears to interact more strongly with the molybdenum centres.

In the Fe−W cluster the cage undergoes a small, but significant, contraction and the distances are all shorter by about 0.01 Å. As a consequence, the apparent metallic radii in **2** are r_{Fe} = 1.32 and r_w = 1.51 Å. The difference between the W−N and the Fe−N bond lengths is only 0.18 Å, slightly smaller than expected, suggesting a negligible preference of nitrogen for tungsten.

Also, the parameters for the outer ligands are very similar in the two homologous clusters, and, indeed, the only relevant difference in their ligand architecture is a more marked tilting of CO(11) in **2** toward a bridging coordination.

Molecular structure of $[Fe_3Mo_3N(CO)_{18}]^{3-}$

The molecular structure of this trianion was determined on the mixed salt $[NMe_3(CH_2Ph)]_2[NEt_4]$**3**. The anion is depicted in Figure 2, and the relevant structural parameters are listed in Table 3. Compound **3** also has an octahedral metallic framework, with the three molybdenum atom in a *fac* arrangement. The architecture of the eighteen carbonyl ligands can be viewed as a perturbation of the idealized high symmetry system having three terminal ligands for each metal atom. In the real situation, many iron-bound CO groups are tilted toward molybdenum in order to compensate the different number of valence electrons. As a result, the average M−C−O angle is much smaller for Fe than Mo (171 vs. 176°). Nevertheless, only CO(18) can be classified as a bridging, though asymmetric, ligand. This description is also in keeping with the solution infrared spectrum, which shows a high-lying band at 1820 cm^{-1} indicative of semibridging ligands, overlapping a very weak band (at 1748 cm^{-1}) attributable to "true" bridging ligands.

The octahedral metal cage of **3** is heavily distorted, showing short Fe−Fe [2.609 Å] and very long Mo−Mo [3.145 Å] separations. The Mo−Mo bond lengths in **3** are quite unusual for octahedral clusters, but are well within the range observed for Mo−Mo single bonds.[18,19] The covalent radii of the metal atoms are, therefore, r_{Fe} = 1.30 and r_{Mo} = 1.57 Å, a difference of 0.27 Å. The average Fe−Mo interaction is 2.845 Å, which matches the sum of the apparent radii. However, when examining the metal−ligand bond

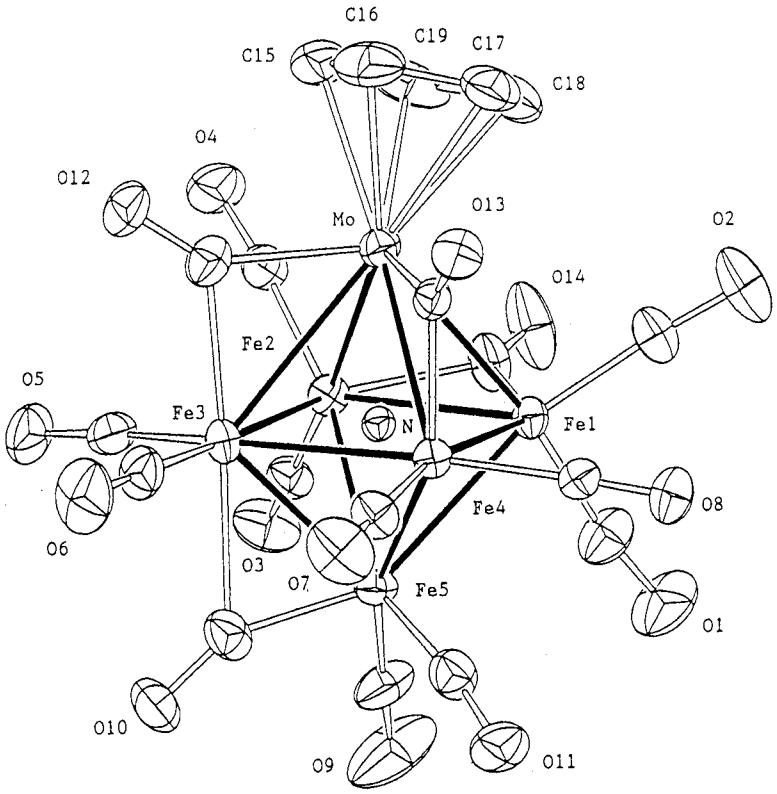

Figure 1. The solid state structure of $[Fe_5MoN(CO)_{14}(C_5H_5)]^{2-}$; ellipsoids are drawn at the 30% probability level; the carbon atoms of the carbonyl ligands are labelled as the oxygen to which they are attached

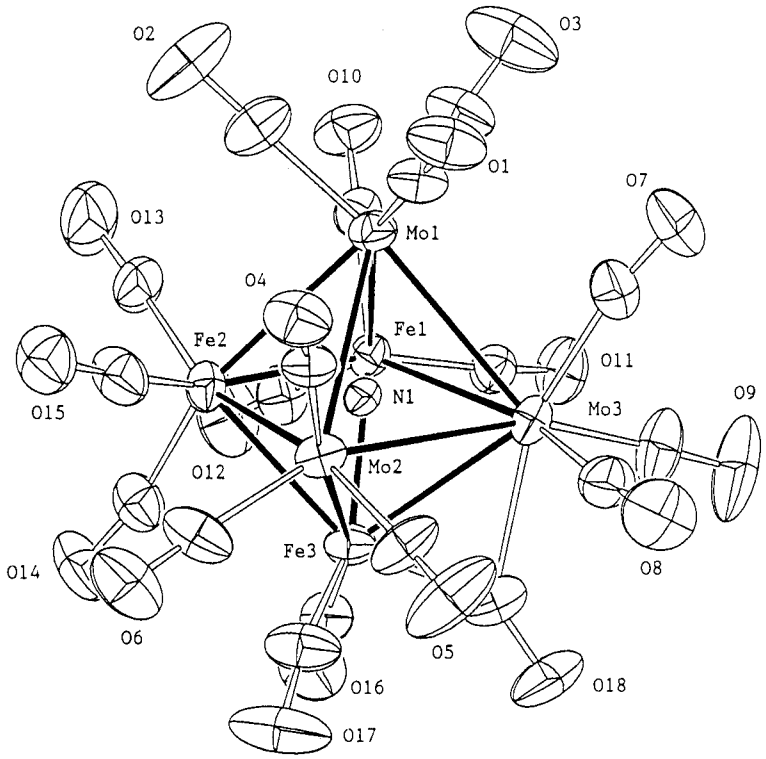

Figure 2. The solid state structure of $[Fe_3Mo_3N(CO)_{18}]^{3-}$

lengths, the difference between Mo and Fe appears much smaller: 0.14 Å for the metal−CO distances, and 0.16 Å for the metal−nitrogen separations. For example, the Mo−N bond lengths average 2.104 Å and the Fe−N 1.945 Å. On that basis, it appears that the three molybdenum atoms bind much more efficiently with the ligands (both external and interstitial), whereas iron would rather reinforce the bonds within the metal cages.

Experimental Section

All the solvents were purified and dried by conventional methods and stored under nitrogen. All the reactions were carried out under an oxygen-free nitrogen atmosphere using standard Schlenk techniques.[20] $[NEt_4][Fe_4N(CO)_{12}]$,[21] $[NEt_4][M(CO)_3(C_5H_5)]$,[22] $[NEt_4]_2[M_2(CO)_{10}]$[23] and $[Mo(CO)_3(Me_3C_6H_3)]$[24] were prepared by literature methods. Infrared spectra in solution were recorded on a Perkin−Elmer 16 PC FT-IR spectrophotometer, using calcium fluoride cells previously purged with N_2. Elemental analyses were carried out by the staff of Laboratorio di Analisi of the Dipartimento di Chimica Inorganica, Metallorganica e Analitica. ^1H NMR spectra were recorded on a Bruker AC200 spectrometer. Yields refer to the starting iron nitride.

Synthesis of $[PPh_4]_2[Fe_5MoN(CO)_{14}(C_5H_5)]$: $[NEt_4][Fe_4N(CO)_{12}]$ (0.32 g, 0.45 mmol) and $[NEt_4][Mo(CO)_3(C_5H_5)]$ (0.08 g, 0.22 mmol) were dissolved in MeCN (20 mL) and refluxed for 18 h. The solvent was evaporated in vacuum, and the residue suspended in MeOH (20 mL). The solid left undissolved (which consisted of $[NEt_4]_3[Fe_6N(CO)_{15}]$ and decomposition products) was removed by filtration, and solid $[PPh_4]Br$ (1 g) was added. The precipitate was collected by filtration, washed with 2-propanol and dried. The dark red solid was extracted from the frit with the minimum amount of THF and layered with 2-propanol to give dark crystals of $[PPh_4]_2[Fe_5MoN(CO)_{14}(C_5H_5)]$. Elemental analyses of the product material are satisfactory. Yield 0.14 g; 20%.

The salt $[PPh_4]_2$**1** is insoluble in MeOH or 2-propanol, sparingly soluble in THF, and very soluble in acetone or MeCN. − IR (MeCN): ν(CO) = 2002m, 1943vs, 1745mw cm^{-1}. − ^1H NMR (CD_3CN): δ = 4.59 (s, 5 H, C_5H_5), 7.9 (m, 40 H, $[PPh_4]^+$).

Synthesis of $[PPh_4]_2[Fe_5WN(CO)_{14}(C_5H_5)]$THF: $[NEt_4][Fe_4N(CO)_{12}]$ (0.51 g, 0.72 mmol) and $[NEt_4][W(CO)_3(C_5H_5)]$ (0.16 g, 0.35 mmol) were dissolved in MeCN (30 mL) and refluxed for 24 h. The mixture was worked-up as above. Typical yields are as low as 5−10%. − $C_{71}H_{53}Fe_5NO_{15}P_2W$ (1685.2): calcd. C 50.60, H 3.17, N 0.83; found C 51.4, H 3.0, N 0.6. Elemental analysis confirms the presence of one molecule of clathrated THF. − IR (MeCN): ν(CO) = 2020w, 2000w, 1958vs, 1946sh, 1811m, 1784mw, 1725mw cm^{-1}. − ^1H NMR (CD_3CN): δ = 4.73 (s, 5 H, C_5H_5), 7.9 (m, 40 H, $[PPh_4]^+$).

Synthesis of $[NEt_4]_3[Fe_3Mo_3N(CO)_{18}]$: $[NEt_4][Fe_4N(CO)_{12}]$ (0.24 g, 0.34 mmol) and $[NEt_4]_2[Mo_2(CO)_{10}]$ (0.22 g, 0.30 mmol) were dissolved in MeCN (20 mL) and refluxed for 1 h. The solvent was then evaporated in vacuum, and the residue suspended in MeOH (20 mL). The solid residue was collected by filtration, washed with 2-propanol and then dried. The black solid was extracted from the frit with the minimum amount of MeCN and layered with diisopropyl ether to give black crystals of $[NEt_4]_3[Fe_3Mo_3N(CO)_{18}]$. Yield 0.12 g, 26%.

Salts of **3** are usually insoluble in alcohols or THF, sparingly soluble in acetone and very soluble in MeCN. − IR (MeCN): ν(CO) = 2006 vw, 1931 vs, 1822 w,br 1748 w cm^{-1}. − $C_{42}H_{60}Fe_3Mo_3N_4O_{18}$ (1364.3): calcd. C 36.98, H 4.43, N 4.11; found C 37.2, H 4.5, N 4.3.

Crystals of the mixed salt used for X-ray analysis were obtained from an incomplete metathesis reaction between $[NEt_4]_3$**3** and $[NMe_3(CH_2Ph)]Cl$ in MeCN.

Synthesis of $[NEt_4]_3[Fe_3W_3N(CO)_{18}]$: $[NEt_4][Fe_4N(CO)_{12}]$ (0.24 g, 0.34 mmol) and $[NEt_4]_2[W_2(CO)_{10}]$ (0.31 g, 0.34 mmol) were dissolved in EtCN (20 mL) and refluxed for 4 h. The solvent was then evaporated in vacuo and the black residue treated as above. − IR (MeCN): ν(CO) = 2007 vw, 1933 vs, 1821 w,br 1759 w cm^{-1}.

Synthesis of $[PPh_4]_2[HFe_5MoN(CO)_{16}]$: $[NEt_4][Fe_4N(CO)_{12}]$ (0.55 g, 0.78 mmol) and $[Mo(CO)_3(Me_3C_6H_3)]$ (1.04 g, 3.47 mmol) were dissolved in THF (20 mL) and refluxed for 5 h. The solvent was evaporated in vacuum, and the residue washed repeatedly with toluene (4 × 10 mL). It was than suspended in MeOH (20 mL). Solid $[NEt_4]Br$ was added and the mixture was stirred for 0.5 h. Addition of water induced complete precipitation. The solid was collected by filtration, washed with water and dried. Impure $[NEt_4]_2[HFe_5MoN(CO)_{16}]$ was extracted from the frit with THF leaving the insoluble $[NEt_4]_3$**3** behind (yield 18%).

Pure $[PPh_4]_2$**5** was obtained by metathesis. The THF was evaporated in vacuo, the residue was dissolved in MeOH and $[PPh_4]Br$ was added. The microcrystalline solid was collected by filtration, washed with 2-propanol, dried and dissolved in the minimum amount of THF. Crystals were obtained by layering with 2-propanol. Yield 21%. − IR (THF): ν(CO) = 1959 vs, 1880m,br 1799 m cm^{-1}. − ^1H NMR (CD_3CN): δ = −19.77. − $C_{64}H_{41}Fe_5MoNO_{16}P_2$ (1517.2): C 50.67, H 2.72, N 0.92; found C 50.3, H 2.7, N 0.9.

X-ray Data Collection and Structure Determination: Crystal data and other experimental details are summarized in Table 4. The dif-

[a] $R = [\Sigma(|F_o - k|F_c||)/\Sigma F_o]$, $R_w = [\Sigma w(F_o - k|F_c|)^2/\Sigma wF_o^2]^{1/2}$, $w = 1/[\sigma(F_o)]^2$, $\sigma(F_o) = [\sigma^2(F_o^2) + (0.04F_o^2)^2]^{1/2}/2F_o$.

fraction experiments were carried out on a Siemens SMART CCD area-detector diffractometer at room temperature using Mo-K_α radiation (λ = 0.71073 Å) with a graphite crystal monochromator in the incident beam. Cell parameters and orientation matrices were obtained from the least-squares refinement of 150 (for $[PPh_4]_2$**1**), 278 (for $[PPh_4]_2$**2**·OC_4H_8), and 100 {for $[NMe_3(CH_2Ph)]_2[NEt_4]$**3**} reflections measured in three different sets of 15 frames each, in the range $3 < \theta < 23°$. At the end of the data collection the first 50 frames, containing 416 reflections (for $[PPh_4]_2$**1**), 894 reflections (for $[PPh_4]_2$**2**C_4H_8O), and 249 reflections (for $[NMe_3(CH_2Ph)]_2[NEt_4]$**3**) were recollected to monitor crystal decay, which was not observed, so that no time-decay correction was needed. The collected frames were processed with the software SAINT,[25] and an absorption correction was applied (SADABS)[26] to the 34144 collected reflections of $[PPh_4]_2$**1** {13768 of which are unique with $R_{int} = 0.0224$ [$R_{int} = \Sigma|F_o^2 - F_{mean}^2|/\Sigma F_o^2$]}, the 76667 collected reflections of $[PPh_4]_2$**2**·C_4H_8O (16514 of which are unique with $R_{int} = 0.0263$), and the 29939 collected reflections of $[NMe_3(CH_2Ph)]_2[NEt_4]$**3** (11983 of which are unique with $R_{int} = 0.0436$).

The calculations were performed on an AST Power Premium 486/33 computer using the Personal Structure Determination Package[27] and the physical constants tabulated therein. Scattering factors and anomalous dispersion corrections were taken from ref.[28] The structures were solved by SHELXS direct methods (contained in the Personal SDP)[27] and refined by full-matrix least-squares minimizing the function $\Sigma w(F_o - kF_c)^2$ (refinement on *F*).

In $[NMe_3(CH_2Ph)]_2[NEt_4]$**3** one of the two $[NMe_3(CH_2Ph)]^+$ cations is partially disordered, with four phenylic carbon atoms split into eight peaks, four with occupancy factors of 0.60, and four with occupancy factors of 0.40. These eight atoms were refined with isotropic thermal parameters. All the other non-hydrogen atoms were refined with anisotropic thermal parameters. The hydrogen atoms bound to the eight disordered carbon atoms were ignored. All the other hydrogen atoms were placed in their ideal positions (C−H = 0.97 Å, B = 1.15 times that of the carbon atom to which they are attached) and not refined. In the final difference Fourier maps, maximum residuals were 0.82(7) e Å^{-3} at 0.84 Å from Fe(2) in $[PPh_4]_2$**1**, 0.57(6) e Å^{-3} at 1.04 Å from C(222) (a carbon atom of a $[PPh_4]^+$ cation) in $[PPh_4]_2$**2**·C_4H_8O, and 1.36(9) e Å^{-3} at 1.08 Å from Fe(2) in $[NMe_3(CH_2Ph)]_2[NEt_4]$**3**.

Crystallographic data (excluding structure factors) for the structure(s) included in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-135691 (**1**), CCDC-135692 (**2**), and CCDC-135693 (**3**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; Email: deposit@ccdc.cam.ac.uk].

Trimeric Anions in $KTeO_2F$

Ulrich Keßler[a] and Martin Jansen*[a]

Keywords: Tellurium / Lone pair / Lewis acids / Solid-state structures / Anions

$KTeO_2F$ was prepared by solid state reaction from KF and TeO_2 at 350 °C. The structure has been determined by single crystal X-ray analysis [$P2_1/n$, $Z = 12$, $a = 1177.8(2)$ pm, $b = 1499.0(3)$ pm, $c = 619.5(2)$ pm, $\beta = 94.11(2)$ °, $R_1 = 0.0266$, $wR_2 = 0.0604$]. A characteristic feature of the structure is the presence of trimeric anions $Te_3O_6F_3^{3-}$ in which the tellurium atoms are bridged by oxygen atoms. The lone pairs are stereoactive leading to pseudotrigonal bipyramidal coordination at the tellurium atoms. Additional weak bonding interactions link these trimeric anions resulting in a layered structure.

Introduction

Acid base reactions between acidic oxides and basic (alkali) metal oxides are well-known and have lead to anions ranging from discrete *ortho* anions like sulfate to polymeric anions with chainlike (Na_3SbO_4[1]), layered (Li_3InO_3[2]) or framework ($NaGaO_2$[3]) structures. When reacting acidic oxides with basic fluorides one can generally expect the resulting fluorooxides to differ in two aspects from the pure oxo compounds. Firstly, the coordination numbers attainable should be higher, and secondly, the fluorooxo compounds should show a higher tendency to form polymeric anions.

The preparation of such fluorooxo compounds can be challenging because the desired products may tend to undergo dismutation reactions.

In the course of our investigations on reactions of fluorides with chalcogen dioxides we have solved the crystal structures of KSO_2F[4] and $KSeO_2F$.[5] Both compounds had been the subject of spectroscopic (IR, Raman)[6–8] and theoretical[8] studies leading to ambiguous results concerning the bonding situations in the complex anions. On the one hand, Seel and Boudier[7] interpreted the IR spectrum of KSO_2F in terms of discrete SO_2F^- anions containing a S–F single bond. On the other, Paetzold and Aurich[6] deduced a weakened S–F and Se–F bond with concomitant interionic bridging from the analysis of the spectra of KSO_2F and $KSeO_2F$, respectively. This weakened S–F bond was also postulated by Kornath et al.[8] who performed quantum mechanical calculations (RHF niveau). Although the crystal structures of KSO_2F and $KSeO_2F$ are closely related (they are both isopunctual) the fluorosulfite anion is discrete containing a S–F single bond, while the fluoroselenite shows weak intermolecular bonding through an asymmetric fluorine bridge, thus linking the SeO_2F^- units to chains.

We here report on the synthesis and characterization of $KTeO_2F$ representing the end member of the KEO_2F series (E = chalcogen).

Results and Discussion

Synthesis and Crystal Structure

$KTeO_2F$ has been obtained by the solid state reaction of potassium fluoride and tellurium dioxide at 350 °C in closed silver crucibles. A colourless crystalline solid that is sensitive to moist air was obtained. Its crystal structure has been solved by single crystal structure analysis (Table 1 and Table 2).

The main feature of the structure of $KTeO_2F$ is the presence of unprecedented trimeric anions $Te_3O_6F_3^{3-}$ in which the tellurium atoms are linked by oxygen atoms forming a six-membered puckered ring (Figure 1). The coordination of the crystallographically independent tellurium atoms by oxygen and fluorine atoms is pseudotrigonal bipyramidal. The terminal oxygen atoms occupy equatorial positions and the fluorine atoms axial positions. The bridging oxygen atoms link an equatorial with an axial vertex of the trigonal bipyramids. The deviations of the bond lengths and angles from perfect trigonal bipyramids can be understood on the basis of the VSEPR model.[9]

These trimeric units are linked by additional oxygen–tellurium interactions to chains running along the crystallographic *c* axis. These oxygen–tellurium contacts [282.2(3) pm] are much shorter than the sum of the van der Waals radii[10] [360 pm; r_{vdW}(Te): 210 pm, r_{vdW}(O): 150 pm] and must be considered as weakly bonding. Further interionic bridging is accomplished by fluorine–tellurium contacts [309.2(3) pm] similarly linking the trimers along the *b* axis [sum of van der Waals radii:[10] 360 pm; r_{vdW}(F): 150 pm]. Thus the anions form weakly bonded corrugated layers in the *bc* plane (Figure 2). The coordination spheres of the tellurium atoms Te1 and Te2 are extended by these intermolecular interactions to strongly distorted pseudooctahedra. The additional ligands are the terminal oxygen and fluorine atoms of Te3. The calculation of the valence

				K3−O1	322.1(3)

sums[11,12] gives support to assuming weak bonding contributions of these intermolecular Te−O/Te−F contacts since this leads to virtually equal valence sums for the three different tellurium atoms (Te1: 4.12, Te2: 4.17, Te3: 4.17).

The three potassium atoms are coordinated by six, eight and nine oxygen and fluorine atoms, respectively. K1 is situated between two layers and is coordinated by three ligands from each layer. K2 and K3 are located in voids within the layers that are formed by the anions, and are coordinated by six and seven ligands from that layer and two ligands from an adjacent layer. These electrostatic interactions of potassium with oxygen or fluorine hold together the anionic layers along the a axis.

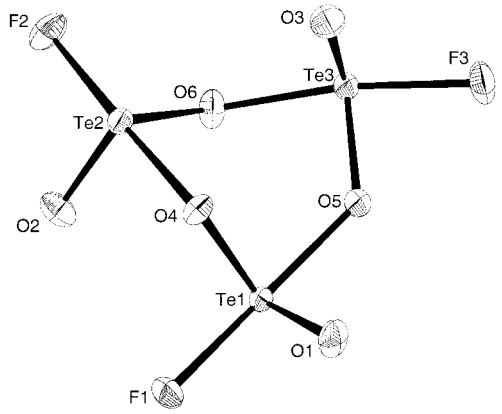

Figure 1. Trimeric cyclic anion $Te_3O_6F_3^{3-}$

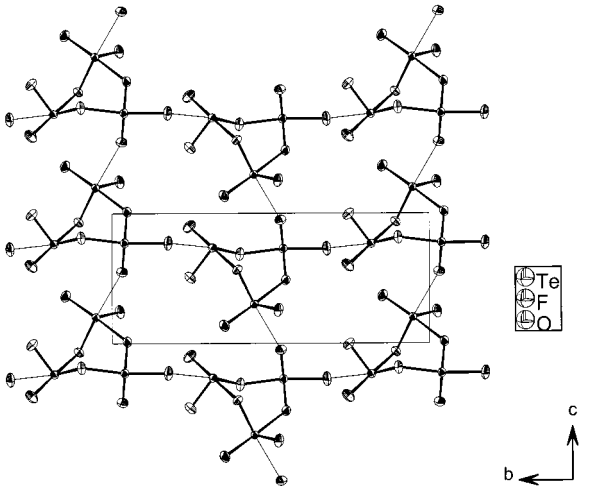

Figure 2. View along [100] showing the association of $Te_3O_6F_3^{3-}$-trimers building infinite layers

When comparing the structures of $KTeO_2F$ and its homologues one observes an increase in coordination number of the chalcogen atom as one would expect when moving from KSO_2F (C.N. 3) via $KSeO_2F$ (C.N. 3 + 1) to $KTeO_2F$ [C.N. 4 (Te3) and C.N. 4 + 1(Te1, Te2)]. However, the tendency towards intermolecular interactions through fluorine bridges, as exhibited by the selenium compound, is not continued. Instead polymerization is accomplished almost exclusively through oxygen atoms.

Since $KTeO_2F$ is the first fluorooxotellurite whose structure has been determined, it is interesting to compare it to those of pure oxotellurites. In contrast to, for example, the oxide adducts of SiO_2 or P_2O_5 in which the silicon and phosphorus atoms are fourfold coordinated, and which contain vertice-sharing tetrahedra like in the binary oxides, the tellurium-oxygen network is significantly changed when reacting TeO_2 with alkali metal oxides. The fourfold coor-

dination (pseudotrigonal bipyramidal) of the tellurium atoms is partly ($K_2Te_4O_9$, $K_2Te_2O_5$)[13] or fully (K_2TeO_3)[14] reduced to threefold pseudotetrahedral coordination. However, the structure of $KTeO_2F$ shows that, upon fluoride addition to tellurium dioxide, both the fourfold coordination of the tellurium atoms and the linkage scheme of the polyhedra (bridging oxygen atoms link equatorial and axial vertices) are preserved. It will be interesting to obtain structural information on other fluoride adducts of TeO_2 which contain more fluoride than $KTeO_2F$. Preliminary X-ray investigations on $Rb_2TeO_2F_2$[15] indicate the existence of discrete pseudotrigonal bipyramidal $TeO_2F_2^{2-}$ anions, thus confirming the preservation of the tellurium coordination when adding fluoride to TeO_2.

Vibrational Spectroscopy and Thermal Analysis

The vibrational spectra of $KTeO_2F$ are given in Table 3. For a twelve-atom molecule of C_1 symmetry, 30 absorptions are expected though additional absorptions could be present due to combination vibrations, overtones or factor group splitting. No assignment was made because of the complexity of the spectra. Theoretical studies appear to be necessary in order to reach an unambiguous assignment of the absorptions. However, the spectra do not agree with the spectra given by Milne[16] who has claimed to have synthesized $KTeO_2F$.

DTA measurements show one endothermic signal at 376 °C indicating the melting point.

Conclusion

$KTeO_2F$ can be synthesized by standard solid-state techniques from KF and TeO_2. The crystal structure represents a new structure type, the characteristic feature of which is the presence of trimeric anions $Te_3O_6F_3^{3-}$. The tellurium atoms exhibit pseudotrigonal bipyramidal coordination; they are linked by oxygen atoms forming a puckered six-membered ring. The trimeric anions are linked to layers by secondary bonding interactions.

When compared to the homologous sulfur and selenium compounds, $KTeO_2F$ shows both expected and unexpected features. While the increase in coordination number agrees with the trend known from KSO_2F and $KSeO_2F$, the bridging by oxygen atoms in $KTeO_2F$ is different from the weak bridging by fluorine atoms in $KSeO_2F$.

In contrast to the significant change of the tellurium coordination when basic oxides are reacted with TeO_2, the characteristic pseudotrigonal bipyramidal coordination of the tellurium atoms is preserved upon fluoride addition to tellurium dioxide.

Experimental Section

Synthesis: The handling of all substances was performed under carefully dried argon by standard Schlenk techniques or in an argon filled drybox (< 0.1 ppm H_2O).

KF (Merck, p. a., > 99%) was finely ground and dried in vacuum at 200 °C before use. It was then stored in sealed glass ampoules.

TeO_2 was prepared following a literature method[17] by oxidation of powdered tellurium (Merck, 99%) with nitric acid (Baker, p.a., 65%) and subsequent thermal decomposition of the basic nitrate $Te_2O_3(OH)(NO_3)$. It was stored in sealed glass ampoules.

Single-phase $KTeO_2F$ was prepared by heating a compacted stoichiometric mixture of KF and TeO_2, in a closed silver crucible encapsulated in duran glass, under argon to 350 °C for 14 days. This was then cooled to room temperature at 10 °C/h. The powder diffraction measurements of the samples were performed in sealed glass capillaries of 0.1 mm diameter. Single crystals were obtained from mixtures containing 2% KF in excess and heating for 30 days. Crystals suitable for structure determination were selected in a drybox and sealed into glass capillaries of 0.3 mm diameter.

X-ray Diffraction Analysis: Powder diffraction measurements were carried out on a powder diffractometer (STOE StadiP) with a linear position sensitive detector using Cu-$K_{\alpha 1}$ radiation (Ge monochromator). Silicon was used as an external standard. Indexing of the powder pattern yielded a monoclinic cell. Systematic absences indicated the space group $P2_1/n$ (No. 14).

Precession photographs of the single crystal used for structure determination proved the unit cell dimensions and the space group. The intensity data collection was carried out with a Smart CCD system (Bruker AXS) using Mo-K_α radiation (graphite monochromator). The data were corrected semi-empirically for absorption (SADABS[18]) improving the residual value R_{int} from 0.0866 to 0.0511. The tellurium and potassium atoms were found by the Patterson method (SHELXS-97[19]), and oxygen and fluorine atoms by a subsequent difference Fourier synthesis (SHELXL-97[20]). The distinction between oxygen and fluorine was made by chemical arguments [bond lengths, valence sums, most electronegative ligand in apical position (Bent's rule)]. Fluorine in the bridging position was tested but this assignment was rejected because the displacement parameters of the bridging atoms were larger than those of the terminal ligands. Moreover, the final difference Fourier map showed the largest peaks at the terminal apical oxygen atoms and the R-values were significantly larger (wR_2 = 0.0825). The structure refinement converged at R_1 = 0.0266, wR_2 = 0.0604. Further information on the structure determination is given in Table 1 and structural parameters are listed in Table 2.

Vibrational spectroscopy: Infrared spectra were recorded on a Bruker IFS113v with a DTGS detector using CsI pellets prepared in a drybox.

Raman spectra were recorded on a Dilor multichannel XY system (microscope technique, Kr laser, 647.1 nm, ca. 10 mW). The samples were sealed in melting point capillaries.

Thermal Analysis: Combined DTA/TG measurements were performed on a Netzsch STA 409 in an argon atmosphere using corundum crucibles.

Acknowledgments

This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank Dr. J. Nuß, MPI für Festkörperforschung, for the single crystal data collection and Prof. Dr. J. Weidlein, University of Stuttgart, for the recording of the Raman spectrum.

Synthesis, Crystal Structure and Spectral Characterization, of a New Phase of Tris(phthalocyaninato)dibismuth(III), $Bi_2(Pc)_3$

Karim Benihya,[a] Mireille Mossoyan-Déneux,*[a] Friedemann Hahn,[b] Nancy Boucharat,[a] and George Terzian[a]

Keywords: Bismuth / Phthalocyanines / Triple-decker compounds / Sandwich complexes / IR spectroscopy / UV/Vis spectroscopy

Direct-template synthesis and purification of a new phase of the triple-decker bismuth(III) phthalocyanine $Bi_2(Pc)_3$, prepared from bismuth acetate and phthalonitrile, are described. X-ray analysis shows a triple-decker molecular structure involving three phthalocyanine rings and two bismuth atoms that are 3.838(9) Å apart. The coordination polyhedron is a distorted square anti-prism. The average distances between the bismuth(III) and the isoindolic nitrogens are 2.336 Å and 2.726 Å, respectively, for the external saucer-shape ring and the more planar inner ring. The intramolecular distance between two neighbouring $4N_{iso}$ mean-planes is 3.17 Å, the inner Pc ring being rotated by 38.3° with respect to the peripheral ones. The shortest intermolecular distance between two carbon atoms in the crystal packing is 3.284 Å. This black phase is a regular stack of phthalocyanine rings that have their π system all overlapping. UV/Visible and FT-IR spectra are discussed in relation to the molecular structure and fully characterize this triple-decker compound.

Introduction

Heavy metal phthalocyanines have interesting electronic properties in the solid state. Rare-earth phthalocyanines and lead phthalocyanine Pb(Pc) have been studied intensively,[1−5] but only recently have some reports been published on phthalocyanine complexes with vicinal element: bismuth.[6,7] H. Isago and Y. Kagaya reported the synthesis, spectral characterization, and redox potential of bromo and chloro(phthalocyaninato) bismuth (III) complexes.[8,9] R. Kubiak et al. described the crystal structure of a bismuth phthalocyanine-bismuth iodide complex with formula $(Bi(Pc))_4(Bi_4I_{16})$,[10] and the synthesis and structure of an iodine-doped bismuth(III) diphthalocyanine $Bi(Pc)_2I_{1.5}$.[11] G. Ostendorp and H. Homborg described the synthesis, structure, and electrochemical and spectral properties of a bisphthalocyanine $Bi(Pc)_2,CH_2Cl_2$.[12] Bismuth(III) is very close to lanthanoids (III) in its ionic radius[13] and its ability to coordinate a large number of atoms.[14] Rare earth phthalocyanines have been investigated as monophthalocyanines,[15] bisphthalocyanines $Ln(Pc)_2$ [15−18] (double-decker compounds), or trisphthalocyanines $Ln_2(Pc)_3$ [19−21] (triple-decker compounds), because all these compounds can have many applications in electronic and display devices. Among all these complexes, the more recently studied are the triple-decker compounds, particularly the mixed ligand phthalocyanine-porphyrin lanthanide molecules.[22−25] Some homoleptic triple-decker sandwich molecules built with three phthalocyanine macrocycles have been reported: (Pc)M(Pc)M(Pc) synthetized by K. Kasuga et al.[26] with M = Y, Nd, Gd, Er, and Lu; (Pc)Lu(CRPc)Lu(Pc) with CRPc = crown-ether-substituted phthalocyanine,[27] synthesized by N. Ishikawa and Y. Kaizu who introduced the crown-ether at the periphery of the macrocycle to give these compounds greater solubility, and the $M_2(obPc)_3$ (obPc = 2,3,9,10,16,17,23,24-octabutoxyphthalocyanine, M = ytterbium, dysprosium,[28] lanthanum and lutetium[29]) synthesized by K. Takahashi et al. The only reported triple-decker phthalocyanine complexes built around a metal without any f orbitals are the indium complex[30] and, very recently, a red-violet phase of bismuth triple-decker phthalocyanine,[31] both obtained by J. Janczak et al. In this report, we present the preparation of a black phase of the same molecule $Bi_2(Pc)_3$, and discuss its crystal and molecular structures, as well as its characterization by FT-IR and UV/Visible spectroscopies.

Results and Discussion

Synthesis and Characterization

All the preparations of triple-decker rare earth phthalocyanine complexes reported in the literature are long, or include many steps.[26,27] Their purification is performed through precipitation and/or extraction with various solvents, and repeated chromatographic procedures on alumina. Janczak and Kubiak have proposed a new method[32] that allowed them to synthesize indium(III) triple-decker phthalocyanine. However, they could not obtain the $Bi_2(Pc)_3$ complex by this method since the oxidation potential of the reaction $Bi \rightarrow Bi^{3+}$ is too high. For the synthesis

of $Bi_2(Pc)_3$ they used a mixture of Bi_2Se_3 and phthalonitrile, pressed into pellets, heated at 220 °C for 24 h[31]. Our preparation method of the tris (phthalocyaninato) dibismuth(III), presented here, is very fast and simple. A mixture of bismuth acetate with a large excess of phthalonitrile was heated to 310 °C during 30 min. The obtained black powder was washed with organic solvents, and placed under reflux in an aqueous solution of NaOH for 30 min. $Bi_2(Pc)_3$ is not soluble in any of the usual solvents (water, acetone, alcohol), and is very slightly soluble in DMF or DMSO, as well as aromatic solvents like chloronaphthalene or quinoline, but not enough to recrystallize. Attempts to obtain sublimed crystals or powder by vacuum sublimation with a very slight stream of nitrogen were unsuccessful. Instead, while using the tubular oven, a very thin metallic mirror (probably metallic bismuth) was deposited on the cold wall of the quartz tube. Further away a dark blue layer, characterized as $H_2(Pc)$ by its IR spectrum, and still further needles of phthalonitrile were also found. This shows the instability of our compound, which is moreover photosensitive: slow decomposition at room temperature was observed when solutions were left in daylight whereas solid samples or dissolved samples kept in the dark at 4−10 °C, remained unchanged over several years. Contact with dilute acids led to demetallation, yielding $H_2(Pc)$. Thus $Bi_2(Pc)_3$, like Pb(Pc), appears to be a labile metallophthalocyanine.

Crystal Structure

Figure 1 shows the triple-decker structure of the molecule. We named the internal macrocycle A, and the two external macrocycles B and B′. The centre of the square formed by the four pyrrolic nitrogens of cycle A (Ct_A) form a crystallographically-imposed inversion centre of the molecule, so that the two macrocycles B and B′ are equivalent. The coordinates of each atom of the B′ ring are deduced from those of the corresponding atom of the B ring by inversion operation: $C(x, y, z) \rightarrow C'(-x, -y + 1, -z)$.

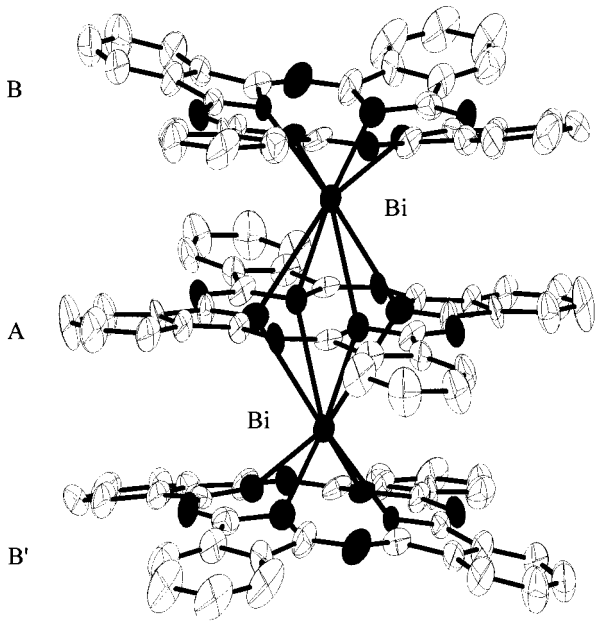

Figure 1. ORTEP drawing of $Bi_2(Pc)_3$ viewed along the *b* axis, with thermal ellipsoids shown at the 50% probability level. H atoms are omitted for clarity. The internal macrocycle is named A and the two external macrocycles B and B′

Figure 2,a is a view of the molecule along the Bi−Bi′ axis, and Figure 2,b shows this split molecule with the three macrocycles projected along the Bi−Bi′ axis, with the numbering scheme, and the staggering angles between the macrocycles. The distances between each bismuth and the centres (Ct) of the squares formed by the four pyrrolic nitrogens of the cycles A (Ct_A), B (Ct_B), and B′ (Ct_B') are indicated at the right of the scheme. As in all the other triple-decker compounds,[30,31,33] the metallic ions are not equidistant from Ct_A and Ct_B: the distance from the metallic ion is 1.918(0) Å for Ct_A and 1.247(1) Å for Ct_B or $Ct_{B'}$. The larger distance to ring A reflects the fact that the benzopyrrolic nitrogens (N_{iso}) of this macrocycle are bridging the two bismuth(III) atoms Bi and Bi′. Interestingly, these bridging nitrogens are not equivalent; selected bond lengths and angles characterizing the coordination polyhedron are given in Table 1: N11 and N9′ are closer to Bi than to Bi′, and N9 and N11′ are closer to Bi′: N11−Bi = 2.695(8) Å, N11−Bi′ = 2.774(10) Å, N9−Bi′ = 2.693(11) Å, N9−Bi = 2,740(10) Å, while the four $Bi-N_{iso}$ bonds lengths of the cycles B or B′ are equivalent (mean length = 2.34 Å). The mean rotational angles between the macrocycles A and B, and between B and B′, measured on the more external benzene carbon atoms, are 38.3° and 0.5°, respectively. The distance between the two bismuth atoms in the molecule is 3.839(0) Å, and the distance between the two centres (Ct_A) and (Ct_B) of the macrocycles is 3.17 Å. We found many distances for pyrrolic carbon atoms between neighbouring A and B planes shorter than 3.3 Å. For example: C25′−C48 = 3.275 Å, C1−C40 = 3.262 Å, C41−C8 = 3.220 Å, C48−C9 = 3.289 Å. These distances are shorter than the van der Waals distance (3.4 Å) for aromatic carbon atoms, so that adjacent phthalocyanine planes are interacting by their π orbitals. The two mean-planes $4N_{iso\ B}$ and $4N_{iso\ B'}$ are strictly parallel on account of symmetry. The angle between these two mean-planes and the $4N_{iso\ A}$ plane is approximately 3.10° (±1.94). Thus, the coordination polyhedron is a distorted square anti-prism. We note that the hole at the centre of the macrocycle B (and B′) is slightly larger than the hole at the centre of the macrocycle A (the distances between N3 and N7 and between N1 and N5 are both 3.95 Å, while the distance between N11 and N11′ is 3.90 Å and between N9 and N9′ is 3.85 Å).

The deviations from the $4N_{iso\ A}$ plane and the $4N_{iso\ B}$ mean-plane for each atom of the asymmetric unit of the molecule are shown on Figure 2,b. Benzopyrrole cycles are numbered I, II, III, IV, V, and VI. We named the 5-membered and the 6-membered ring of benzopyrrole I as I5 and I6, respectively, and the 5-membered and the 6-membered ring of benzopyrrole II as II5 and II6, and so on. The macrocycles B and B′ are slightly convex, the four mean-planes of the pyrrole rings making dihedral angles of 6.26 (I), 6.67 (II), 10.46 (III), and 8.12° (IV) with the $4N_{iso\ B}$ mean-plane

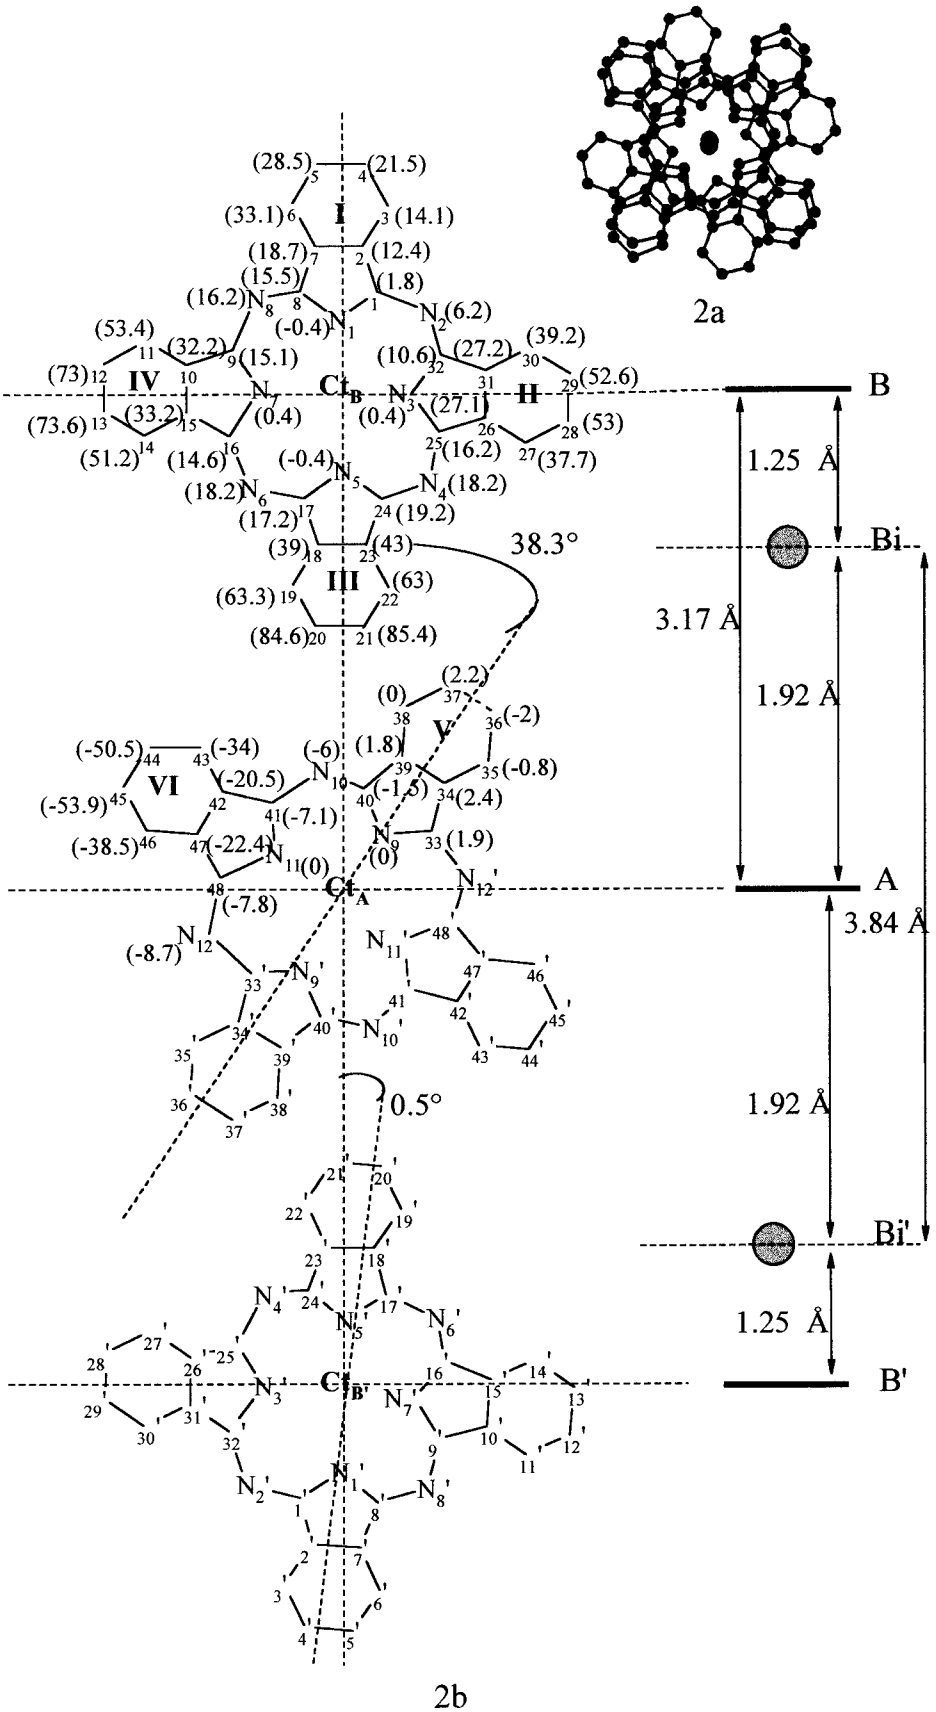

Figure 2. 2a) ORTEP drawing of $Bi_2(Pc)_3$ viewed along the Bi−Bi′ axis. − 2b) Split molecule of $Bi_2(Pc)_3$ with the three phthalocyanine rings projected along the Bi−Bi′ axis showing the numbering scheme and the staggering angles between the macrocycles. The deviation of each atom from the $4N_{iso\ A}$ and $4N_{iso\ B}$ mean-planes, respectively, are indicated in parentheses for the asymmetric unit

Table 1. Selected bond lengths (Å) and angles (deg) for $Bi_2(Pc)_3$

Bond lengths (Å)		Angles (deg)

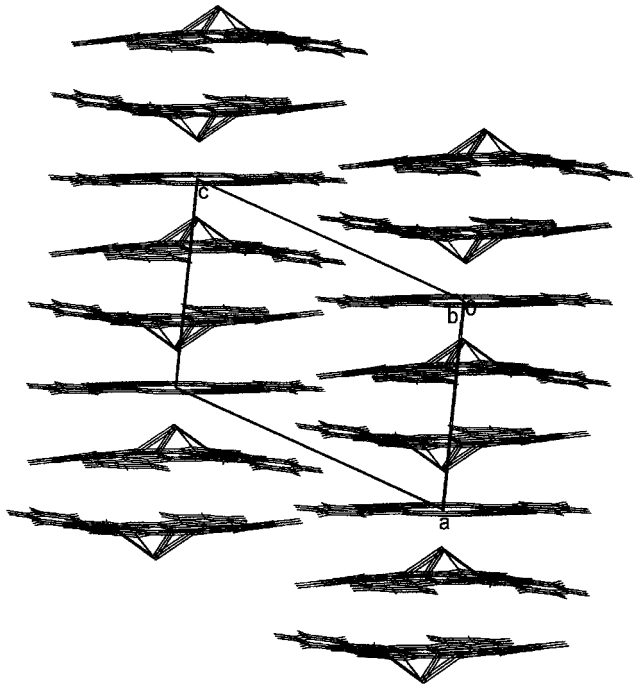

Figure 3. Projection along the *b* axis showing the columnar structure of the stacking of $Bi_2(Pc)_3$ molecules

(Table 2). Nevertheless, each benzopyrrole is nearly planar: all the angles between the pyrrole and benzene mean-planes are smaller than 1.8°. The most planar benzopyrrole (III) shows the greatest deviation from the mean-plane $4N_{iso\ B}$, and has the furthest external carbon atoms (C30 and C31) from the $4N_{iso\ B}$ mean-plane. Cycle A is nearly perfectly planar, but the benzopyrroles V and V′ are more coplanar than cycles VI and VI′, which spread slightly up and down from the $4N_{iso\ A}$ plane. The two mean-planes of the pyrrole rings make dihedral angles of 0.92 and 5.54° (±3.02) (V and VI). Dihedral angles between the pyrrole and benzene mean-planes are 1.52 (V) and 2.08° (VI).

Figure 3 shows the relative position of successive molecules in the stacking, viewed along the b axis. The stacking axis is the a axis. The closest atoms of two successive molecules in the stack lie at the distance of 3.284 Å (C4−C16). That distance is also lower than the van der Waals distance for aromatic carbon atoms. Adjacent external macrocycles of two neighbouring molecules in the stacking are also interacting by their π orbitals, so that all the phthalocyanine macrocycles are in interaction. The closest atoms in two neighbouring stacks, in the direction of the c axis, are C44 and C21, and lie at the distance of 3.497 Å apart. We have a columnar structure, in which $Bi_2(Pc)_3$ molecules are stacked segregatively, with the π orbitals of all the macrocycles interacting with each other along the column. Such a structure favours a good electrical conductivity, but since $Bi_2(Pc)_3$ is a closed-shell molecule, we think that this compound cannot be an electrical conductor without partial oxidation. Electrical properties of this triple-decker complex are currently being studied.

Similar to the comparisons made for lanthanoid phthalocyanines in the literature,[15,34,35] Table 3 compares our structure with those of double-decker compounds $Bi(Pc)_2,CH_2Cl_2$,[12] and $Bi(Pc)_2I_{1.5}$,[11] and with that of the bismuth monophthalocyanine-bismuth iodide complex.[10] The later contains a $BiPc^+$ moiety, and has the shortest distances for Bi−Ct (1.14 Å) and $Bi-N_{iso}$ (2.27 Å). In $Bi(Pc)_2,CH_2Cl_2$ the bismuth atom is nearly equidistant (1.48 and 1.50 Å) from the centres of the two $4N_{iso}$ mean-planes with a $Bi-N_{iso}$ length mean value of 2.47 Å, while in $Bi(Pc)_2I_{1.5}$, the Bi^{III} atom is not equidistant from the two Pc macrocycles (1.337 Å and 1.938 Å), and the structure shows alternating short and long $Bi-N_{iso}$ bond lengths (2.34 Å and 2.76 Å, respectively). The distance between the $4N_{iso}$ mean-planes that we observe for our triple-decker compound (3.17 Å) is intermediate between those of the two double-decker complexes $Bi(Pc)_2,CH_2Cl_2$ and $Bi(Pc)_2I_{1.5}$ (2.98 Å and 3.275 Å, respectively), in which the phthalocyanine macrocycles are oxidized. The benzopyrrole cycles of our complex have the same dimensions as those of the bisphthalocyanine, except the $N_{iso}-C_\alpha$ lengths that are longer in the triple-decker complex and the $C_\delta-C_\delta$ and $C_\beta-C_\beta$ bond lengths that are shorter.

It is very interesting to compare the structure of this black phase with the red-violet phase obtained by J. Janczak et al.[31] It is well-known that metallophthalocyanines crystallize in different phases depending of the crystallization method.[36] Generally, the molecular structure is only slightly affected but the stacking is different. In our case too, the molecular data of the two phases look very similar (Table 4), but there are some differences, principally in the stacking. The two molecules are alike with nearly the same coordination polyhedron, but the distances $Bi-N_{iso\ A}$ are slightly longer in the red-violet phase (2.747 Å) than in the black phase (2.726 Å). The staggering angle is equal to

Table 3. Comparison of the geometrical parameters for the black phase of $Bi_2(Pc)_3$ with those of other bismuth phthalocyanine complexes: the red-violet triple-decker phase,[31] the double-decker,[11−12] and monophthalocyanine[10] structures, reported in the literature

36.4° in the red-violet phase and 38.3° in the other. The major difference between the two phases is found, as we have said, in the stacking. The red-violet phase is constituted of molecules stacked back to back along the stacking axis without interaction between the π orbitals of adjacent molecules, with the shortest intermolecular distances between the overlapping phthalocyaninato ring planes being 3.56 Å. Such an alternating of short and long distances be-

tween the phthalocyanines rings along the stack does not favour good electrical conductivity. In the black phase, the shortest interatomic distances between two adjacent molecules is 3.284 Å, while there are many interatomic distances between two adjacent (Pc) rings in the same molecule shorter than 3.3 Å. So the black phase appears as a regular stack of phthalocyanines rings which have their π systems in interaction with each other, and that structure favours good conductivity.

Infrared Spectroscopy

Literature on the vibrational spectroscopy of triple-decker Pc complexes is poor. The site of one-electron oxidation in several lanthanide porphyrin-phthalocyanine triple-decker complexes was studied by resonance Raman spectroscopy[22] and some mixed phthalocyaninato-porphyrinato europium(III) triple-decker complexes were characterized by IR and Raman spectroscopies.[25] Previous studies[37–44] on monophthalocyanines have separated and assigned the frequencies of the vibrations (strongly coupled in the macrocyclic ligand). Janczak recently reported IR and far IR spectra of $In_2(Pc)_3$ compared with those of $In(Pc)_2$. [37] Figures 4 and 5 show the far and middle infrared spectra, respectively, of our complex (a), compared with the well-known spectra (b)[1,40] of lead monophthalocyanine Pb(Pc). Isago et al.[8] reported that spectra of Bi(Pc)X (X = Cl, Br) in the middle IR region, resemble those of Pb(Pc). In both spectra of $Bi_2(Pc)_3$, (middle and far infrared) we observe the same absorptions at nearly the same frequencies as in the Pb(Pc) spectra. We attribute these absorptions to the vibrations of the two parts of $Bi_2(Pc)_3$ constituted by one bismuth ion and one macrocycle B or B′, which have the same structure as Pb(Pc). We note some supplementary absorptions in each group of vibrations that we attribute to the vibrations of the moiety formed by the two bismuth atoms and the macrocycle A.

Analysis of the Far Infrared Spectra

Far and middle IR spectra of $In_2(Pc)_3$ were reported recently.[37] The far IR spectrum is slightly more complicated than that of $Bi_2(Pc)_3$, while the middle IR spectra are very similar. Due to the fact that Bi atom is heavier than In, many bands are shifted to lower frequencies for the $Bi_2(Pc)_3$ spectrum. Five bands or groups of bands are characteristic of phthalocyanine ring deformations. They lie around 625, 560–600, 490, 430–440, and 350 cm^{-1}, nearly at the same frequencies for Pb(Pc) and $Bi_2(Pc)_3$. A more thorough examination of the spectra shows that the bands for $Bi_2(Pc)_3$ are larger and less resolved than the corresponding ones in Pb(Pc). Expansions of some of these bands followed by a deconvolution are shown on Figure 5,(I) and Figure 5,(II). The group centred at 625 cm^{-1} contains only one band at 626 cm^{-1} with a shoulder at 617 cm^{-1} in the spectrum of Pb(Pc), and three bands at 626, 617, and 622 cm^{-1} in the spectrum of $Bi_2(Pc)_3$ [Figure 5,(II)]. We assigned the two first bands to the deformation of the phthalocyanine rings B and B′, and the absorption at 622 cm^{-1} to the deformation of ring A. In Figure 4, the two bands at 279 and 154 cm^{-1} for $Bi_2(Pc)_3$ have the same intensity ratio and the same wavenumber difference as the two bands at 271 and 147 cm^{-1} for Pb(Pc). We assign these two bands, respectively, to the symmetric and asymmetric stretching modes of $N_{iso}-Bi-N_{iso}$ for B and B′ rings, and to the symmetric and asymmetric stretching modes of $N_{iso}-Pb-N_{iso}$, by reference to previous work.[44,47] We equally note two supplementary bands at 223 and 94 cm^{-1} in the spectrum of

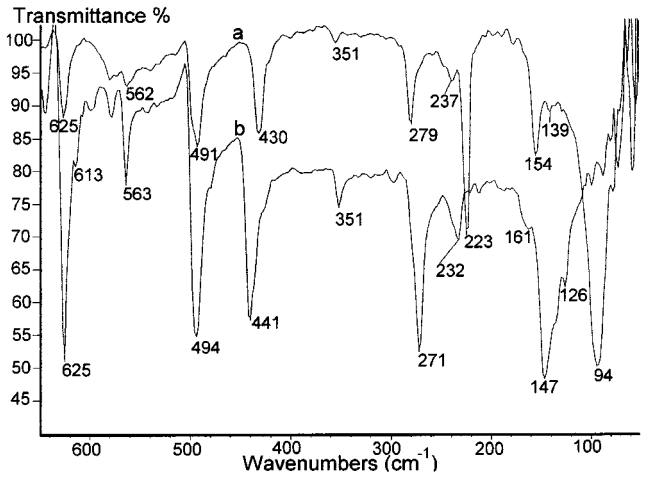

Figure 4. Far infrared spectrum of $Bi_2(Pc)_3$ (a) compared to that of Pb(Pc) (b)

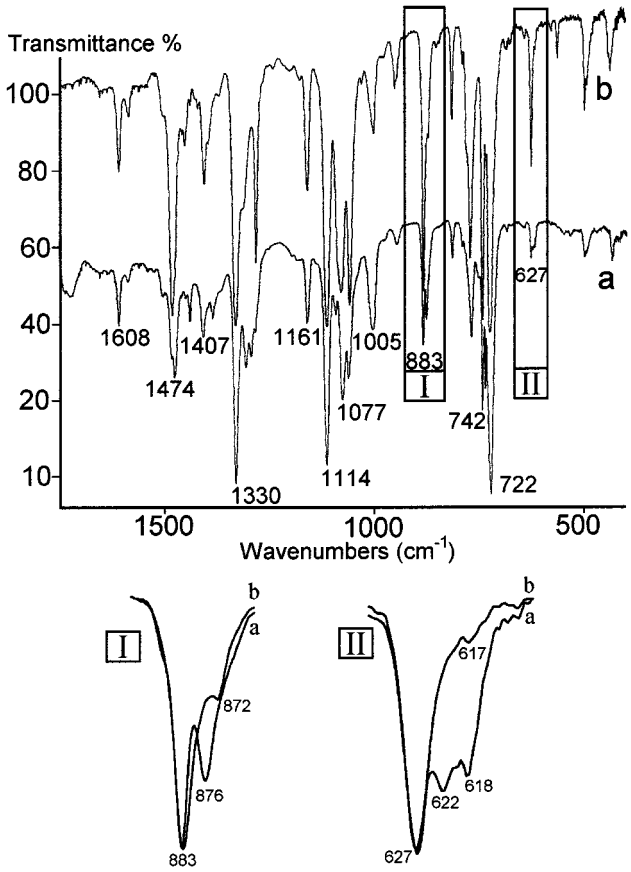

Figure 5. Middle infrared spectrum of $Bi_2(Pc)_3$ (a) compared to that of Pb(Pc) (b). I and II are expansions of the group of bands centred at 625 cm^{-1} and 883 cm^{-1}, respectively

$Bi_2(Pc)_3$. We assign these two new bands to the symmetric and asymmetric stretching modes of $N_{iso}-Bi-N_{iso}$ of macrocycle A. Their frequencies are lower than those of the same modes in the B macrocycle. This is in accordance with the bond lengths difference: 2.34 Å for the $Bi-N_{iso}$ distance of macrocycle B and B′, and 2.72 Å for the $Bi-N_{iso}$ distance of macrocycle A.

Analysis of Spectra in the Middle Infrared

The band, which lies at 883 cm^{-1} in both the spectra of Pb(Pc) and $Bi_2(Pc)_3$, is described in the literature as a metal-dependant vibration of the macrocycle.[39] This band, extended in Figure 5,(I), presents a new band at 876 cm^{-1} in the $Bi_2(Pc)_3$ spectrum, at the low wavenumbers side beyond a shoulder at 872 cm^{-1} which is evident in both spectra. We still consider this new band as a metal-dependant vibration of macrocycle A. Other supplementary bands assigned to macrocycle A are visible at 1294, 1306, and 1474 cm^{-1} in the area of the C−C stretching modes. A small band at 1385 cm^{-1} becomes very intense when the sample is allowed to age in dark at 4−10 °C for several months. The initial IR spectrum is restored when the aged sample is placed under reflux in an aqueous solution of 0.2 M NaOH.

In conclusion of this paragraph, we consider that the new bands assigned to macrocycle A, and particularly the bands related to the $Bi-N_{iso}$ vibrations, are a typical fingerprint of homoleptic triple-decker phthalocyanine complexes.

UV/Visible Spectroscopy

UV/Visible spectroscopy was largely used for the study and the characterization of rare earth triple-decker phthalocyanines. The spectra of $M_2(Pc)_3$ (M = Ln, In) are characterized by the presence of a large absorption band around 640 nm, with a shoulder or a little band more or less separated at larger wavelengths.[19,21,2,37] These two bands (Q_2 and Q_1, respectively) are due to an intramolecular π-π* interaction among the ligands, and are dependant on the distance between cycles in the triple-decker complex.[26,29] Theoretical studies[20,27] on $Lu_2(Pc)_3$ were compared with the experimental spectrum of (Pc)Lu(CRPc)Lu(Pc), which shows two major bands at 633 (Q_2) and 716 (Q_1) nm. The most intense band (633 nm) was assigned to an exciton coupling state, in which all the transitions moments in the Pc planes are in the same direction, the second (716 nm) was attributable mainly to a charge resonance state between two outer Pc′s. Two shoulder bands were observed at 580 and 550 nm. The former was assigned to a vibronic band associated with the 633 nm intense band, and the later attributed to another electronic excitation. In the B band region a broad band was observed at 330 nm.

We recorded the UV/Visible spectrum of $Bi_2(Pc)_3$ in pyridine (Figure 6, a), DMF (b), and DMSO (c). At the same concentration, spectra in pyridine and DMSO are similar. In DMF the spectrum is identical with that recorded in pyridine, but there is an hypsochromic shift of 43 nm ±3 for all the bands observable in the studied wavelength field. DMSO and pyridine are both molecules which are known

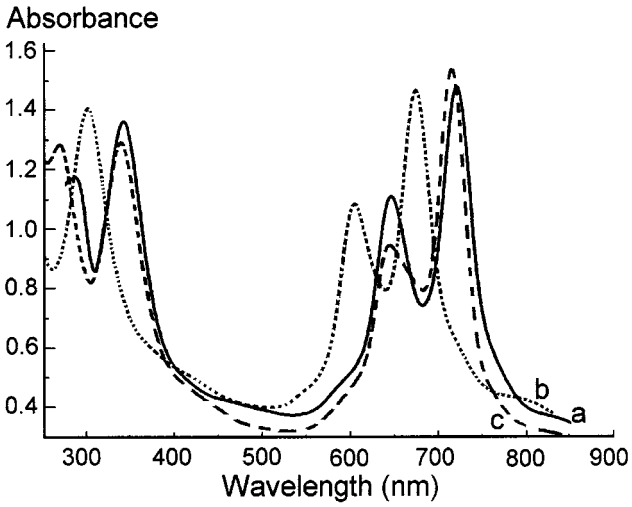

Figure 6. UV/Visible spectra of $Bi_2(Pc)_3$ in pyridine (a), DMF (b), and DMSO (c)

to coordinate strongly in apical position the metal of the monophthalocyanines. DMF has the same behaviour, but is a weaker ligand. In all our spectra, the Q band exhibits splitting in Q_1 and Q_2 bands. In pyridine Q_1 lies at 718 nm and Q_2 at 644 nm. In disagreement with the observations reported about the spectra of $Ln_2(Pc)_3$ and that of $In_2(Pc)_3$,[37] the most intense band is Q_1 at 718 nm, while Q_2 at 644 nm is smaller. Another remark refers to the value of the Q band splitting, which is reported to decrease as the interplanar distance increases.[20,28] For (Pc)Lu(CRPc)Lu(Pc) this splitting value is 83 nm with a interplanar distance fixed at 2.9 Å. As our interplanar distance is measured by the crystallographic study (3.17 Å), we expected a splitting value significantly smaller than 83 nm. The difference in the position of Q_1 and Q_2 bands is 74 nm. Nevertheless, K. Takahashi et al.[29] reported that as the interplanar distance lengthens, the intensity of Q_1 decreases, and that of Q_2 increases. One important difference with these results is the inversion of the intensities of the Q_1 and Q_2 bands. The B band region is more complicated and varies with the solvent. Some authors[48,49] have described, in addition to the B band, two other bands at lower wavelengths, the N band resulting mainly from a transition $b_{2u}(\pi) \rightarrow e_g(\pi^*)$, and the L band resulting from a combination of $a_{2u}(\pi) \rightarrow e_g(\pi^*)$ and $b_{2u}(\pi) \rightarrow e_g(\pi^*)$ transitions. In pyridine, the B and N bands are visible at 342 nm and 288 nm, respectively. In DMSO, the B band also lies at 342 nm, while the N band shifts to 272 nm, and the L band appears at 235 nm.

Conclusion

We have prepared a black phase of the tris(phthalocyaninato)dibismuth(III), $Bi_2(Pc)_3$, by a direct and fast template synthesis from bismuth acetate and phthalodinitrile. X-ray crystal analysis shows a triple-decker structure with two bismuth cations sandwiched between three phthalocyaninato ligands, the central macrocycle being rigorously planar, and the two external macrocycles convex. These latter are al-

most superimposable, while the central ligand is rotated by about 38.3° in relation to the peripheral Pc rings. The four Bi−N bond lengths involving isoindole nitrogens of the external phthalocyanines (mean: 2.34 Å) are shorter than those involving isoindole nitrogens of the central plane (mean: 2.72 Å). The distance between $4N_{iso}$ mean-planes in the molecule is 3.17 Å, and the shortest distance between two atoms belonging to two neighbouring molecules is 3.28 Å. This structure is closely related to that described by J. Janczak and R. Kubiak for a red-violet phase of $Bi_2(Pc)_3$, but the stacking is more compact and more regular in the black phase. The infrared spectra of $Bi_2(Pc)_3$ compared with that of Pb(Pc) allowed us to distinguish some deformations typical of the internal macrocycle from those of the peripheral ones. Particularly, the symmetric and asymmetric stretching modes of the $N_{iso}-Bi-N_{iso}$ groups related to the isoindole nitrogens of the central ring are identified, and differentiated from the similar groups belonging to the external rings. That differentiation is proposed as a typical fingerprint of homoleptic triple-decker phthalocyanine complexes having a similar structure. The UV/Visible spectrum of $Bi_2(Pc)_3$ is similar to all those published for $Ln_2(Pc)_3$ compounds, with the Q band split into two bands, Q_1 and Q_2. Nevertheless, we observe an inversion of the intensities of these bands, Q_1 being significantly more intense than Q_2. The presentation of these results which associates a complete crystallographic structure and the UV/Visible spectrum may be the first step for a theoretical study of the excited electronic states of $Bi_2(Pc)_3$.

Experimental Section

General Remarks: The FT-IR spectra were recorded on either a Nicolet 20 SXB spectrometer with 2 cm^{-1} resolution, or a Perkin−Elmer spectrum 1000 with 1 cm^{-1} resolution, using KBr pellets (1%) on 4000−400 cm^{-1} range and polyethylene pellets (10%) on 400−80 cm^{-1} range. UV/Visible Spectra were recorded on an Unicam UV 4 spectrometer using 10^{-4} M solution concentrations.

Synthesis and Purification: Bismuth acetate was prepared in the laboratory from bismuth nitrate·$5H_2O$ (R.P. Prolabo) using the classic method of preparation of metallic acetates,[50] by dissolving metals or metallic salts in a minimum quantity of hot concentrated nitric acid and subsequent addition of acetic anhydride (puriss. p.a. Fluka AG). Bismuth acetate (1.9 g, 5 mmol) and phthalonitrile (6.5 g, 50 mmol, puriss 99% Fluka chemica) were ground, and placed in a long glass tube, one end of which was sealed and welded with a glass rod. This reaction vessel was placed in a tubular oven at 240 °C and the extremity of the glass rod, which is out of the oven, is fixed in a chuck of a stirring shaft. The reaction mixture was rapidly heated to 310 °C during 30 min. When the reaction tube was taken out of the oven immediately after the end of the reaction and then kept at room temperature, the crude product contained many crystals. The obtained powder was washed with organic solvents in the following sequence: acetone, ethanol, benzene, acetone, dimethylformamide, chloronaphthalene, then quinoline, benzene and finally washed with ethanol and dried. The product was poured in an aqueous solution of NaOH 0.2 M and placed under reflux for 30 min. The solution was filtered and rinsed with hot distilled water until complete neutralisation of the filtrate. After washing with ethanol the product was dried at 60 °C (yield ca. 63%). This washing procedure produced a shiny black crystalline powder. Very little crystals were selected and manipulated under binocular lens at the magnifying power ×64.

Chemical Analysis: The demetallation of $Bi_2(Pc)_3$, by contact with acidic solutions was used for a chemical analysis giving the number of phthalocyanine macrocycles for one bismuth. $Bi_2(Pc)_3$ (833 mg, 0.426 mmol) was heated under reflux in 20 mL of a 35% HCl solution for two hours. The hydrolysis produced insoluble $H_2(Pc)$ and a soluble salt of bismuth (chloride or oxychlorides). Filtration, repeated washing procedures, and drying led to 665 mg (1.29 mmol) of $H_2(Pc)$ characterized by IR spectroscopy. An identical hydrolysis procedure was performed from 755.8 mg (0.38 mmol) of $Bi_2(Pc)_3$. The filtrate and the washing solutions together were made up to 500 mL with the addition of distilled water. The content of bismuth of the resulting solution, determined by AAS led to 0.76 mmol of elemental bismuth. Then we obtained 3 mol of $H_2(Pc)$ and 2 mol of bismuth for each mol of starting $Bi_2(Pc)_3$. That confirmed the high purity of our product.

X-ray Crystallographic Study:[51] One of the largest crystals (0.03×0.04×0.08 mm) obtained from the crude product after washing was picked out and stuck on a glass needle. Data collection and analysis were performed using STOE IPDS V2.78 Software on a STOE IPDS diffractometer. The crystal is a weak scatterer because of its size. By inspecting the reciprocal space with RECIPE program, reflections from three crystal domains could be detected. Reflections of all domains were integrated simultaneously with TWIN, which showed that the volume ratio of the domains was 16:11:1. All crystal systems shared a nearly common c^* axis in the reciprocal space. For the structure solution, the intensity data set of the biggest domain was employed. The structure was refined with isotropic-, then anisotropic temperature factors by full-matrix least-squares techniques using the SHELXL 97 program. The hydrogen atoms of the phenyl groups were located with geometrical correlation, and their thermal parameters were fixed. The final unweighted and weighted agreement factors converged to $R_1 = 0.0398$ and $wR_2 = 0.0617$; a goodness-of-fit calculation resulted in a value of 0.619. The drawing preparations were made by using the graphic program of the SHELXTL package. Crystal data details are given in Table 4.

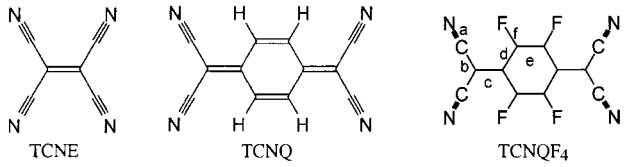
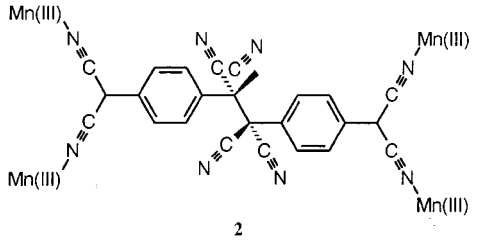
Structure and Magnetic Properties of Tetrakis(3,4,5-trimethoxyphenyl)porphinatomanganese(III) 2,3,5,6-Tetrafluoro-7,7,8,8-tetracyanoquinodimethenide: The First Example of an Isolated $[TCNQF_4]^{\bullet -}$

Mitchell T. Johnson,[a] Atta M. Arif,[a] and Joel S. Miller*[a]

Keywords: Cyanocarbon / Magnetic ordering / Crystal structure / Fluorocarbon / Electron transfer salts / Organic magnets



The crystal structure of *meso*-tetrakis(3,4,5-trimethoxyphenyl)porphinatomanganese(III) 2,3,5,6-tetrafluoro-7,7,8,8-tetracyanoquinodimethenide, $[MnT(MeO)_3PP][TCNQF_4]\cdot 3$-($o$-$C_6H_4Cl_2$), $\mathbf{1}\cdot 3C_6H_4Cl_2$, provides the first example of a non-dimeric $[TCNQF_4]^-$ that is stabilized by *trans*-μ-coordination to Mn^{III}. Compound $\mathbf{1}\cdot 3C_6H_4Cl_2$ crystallizes in the monoclinic $C2/c$ space group [a = 16.9486(10) Å, b = 25.7170(14) Å, c = 19.4009(12) Å, β = 107.091(4)°, V = 8082.8(8) Å^3, T = 200 K, Z = 4, $R(F_o)$ = 0.0547]. The $[TCNQF_4]^-$ formulation was confirmed from the crystal structure data, as well as the ν_{CN} absorption at 2196 and 2165 cm^{-1} in the IR spectrum. The $[TCNQF_4]^-$ moiety is planar with a methylene-carbon–ring-carbon distance of 1.41 Å, which is 0.038 Å longer than that for $TCNQF_4$. $\mathbf{1}\cdot 3C_6H_4Cl_2$ forms 1-D zigzag chains of alternating $\mathbf{1}^+$ and $[TCNQF_4]^-$, where the Mn^{III} atoms are bound in a *trans*-μ-fashion with Mn–N and intrachain Mn···Mn distances of 2.321(3) Å and 12.685 (4) Å, respectively. The MnNC angle and the dihedral angle between the $[TCNQF_4]^-$ and the mean MnN_4 planes are 135.9(2)° and 46.4°, respectively, with the phenyl rings rotated 80° with respect to the mean porphyrin plane. The magnetic susceptibility of $\mathbf{1}\cdot 2.3C_6H_4Cl_2$ can be calculated from the Curie–Weiss expression with θ = –37 K (T > 250 K) and θ′ = +29 K (75 < T < 200 K) with an observed minimum in $\chi T(T)$, typical of ferrimagnets, at 215 ± 10 K. At 2 T the magnetization is 14.900 emuOe/mol or 89% of 16.755 emuOe/mol expected for an S_{Tot} = 2 – 1/2 = 3/2 system. The intrachain antiferromagnetic coupling, J/k_B, is –71 K (–49 cm^{-1}; –61 meV) based on a fit to the Seiden expression for noninteracting chains comprised of alternating quantum (S = 1/2) and classical (S > 1/2) spins, and the Hamiltonian $H = -2JS_a\cdot S_b$. Compound $\mathbf{1}\cdot 2.3C_6H_4Cl_2$ ferrimagnetically orders at 7.3 K [based on the maxima in the 10 Hz χ′(T) data]. Hysteresis is observed at 2 K with coercive field, H_{cr}, of 17.1 kOe and remnant magnetization of 7.200 emuOe/mol; hysteresis is not observed at 5 K. This compound also displays metamagnetic behavior at 2 K above a critical field of 20.2 kOe. The frequency-dependent transitions observed in the χ′(T) and χ"(T) a.c. data are attributed to the transition to a spin glass or superparamagnetic state.



Introduction

Magnetically ordered molecular solids continue to attract attention worldwide, with a focus on new means of attaining a high degree of connectivity between spin-containing moieties.[1] Two classes of organic-based magnets exist; those with active and those with passive organic ligands. Passive organic ligands position the metal-ion-based spin sites to modulate the spin exchange, while active organic ligands contribute spins to the magnetic moment in addition to positioning the metal-ion-based spin sites.[1d,1e] In a few cases organic ferromagnets lacking metal ions have been prepared.[1g,1i] The magnetic ordering temperatures T_c can range up to 400 K for active-organic magnets containing metal-ion-based spins, but only up to 1.48 K for metal-ion-free systems.[1d,1e] Active ligands are rare and have been limited to strong electron acceptors, e.g. cyanocarbons [tetracyanoethylene (TCNE)],[1a–1e] chloranil,[2] and nitronyl nitroxides.[1f,1j,3] [Mn(porphyrin)][TCNE] (TCNE = tetracyanoethylene) form a family of organic-based ferrimagnets with magnetic ordering temperatures as high as 28 K.[1a,4] Several related ferrimagnets based on the antiferromagnetic coupling of S = 5/2 $Mn^{II}(hfac)_2$ (Hhfac = hexafluoroacetylacetone) and S = 1/2 nitroxides,[1f,1j] as well as S = 5/2 Mn^{II} and S = 1/2 Cu^{II} sites have been reported.[3] To date systematic approaches aimed at understanding and subsequently controlling the magnetic behavior of this class of 1-D coordination polymers has primarily focused on making the TCNE electron-transfer salts of substituted manganese(II) porphyrins.[1a,4,5] These ongoing studies have identified a correlation between a decrease of the $MnNC_{TCNE}$ angle and an increase in the intrachain magnetic coupling.[5a,6] This is attributed to increasing the magnetic coupling by increasing the σ overlap of the d_z2 and π* orbitals.[6] More recently, we have sought to alter the radical anionic bridging ligand from $[TCNE]^-$ to identify its effect on magnetic behavior. This had led to the observation that the chloranil radical anion can also stabilize magnetic ordering for this class of organic magnets.[2] Replacement of TCNE with TCNQ (TCNQ = 7,7,8,8-tetracyano-*p*-quinodimethane) is an obvious approach, but, to date, structurally characterized materials have been elusive.[7] An exception is the reaction of TCNQ with *meso*-tetrakis(2,4,6-trimethylphenyl)porphyrinatomanganese(II), which unexpectedly forms the diamagnetic μ_4-σ-$[TCNQ]_2^{2-}$ linkage, **2**.[8] In addition to TCNQ, we identified perfluoro-TCNQ, $TCNQF_4$, as a potential acceptor to stabilize magnetic ordering for this class of magnets.

2

$TCNQF_4$[9] is a very strong acceptor[10] that was sought as a component in molecule-based conductors.[10b,11] Although easily reduced to form stable $[TCNQF_4]^-$ in solution, in contrast to $[TCNQ]^-$, these solids always possessed strong diamagnetic $[TCNQF_4]_2^{2-}$ dimers which did not support the formation of segregated 1-D conducting chains. Likewise, replacement of TCNE with $TCNQF_4$ to stabilize ferromagnetic ordering for the $[Fe^{III}(C_5Me_5)_2]^+[TCNE]^-$ ferromagnet, led to the formation of diamagnetic $[TCNQF_4]_2^{2-}$ dimers that did not stabilize magnetic ordering.[12] $[TCNQF_4]^-$ could form the diamagnetic μ_4-σ-$[TCNQF_4]_2^{2-}$ linkage analogous to **2**; hence the larger substituted manganese(II) porphyrin, *meso*-tetrakis(2,4,6-trimethoxyphenyl)-porphyrinatomanganese(II), $Mn^{II}T(MeO)_3PP$ **(1)**, and herein we report the synthesis, structure and bulk magnetic properties of $[Mn^{III}T(MeO)_3PP][TCNQF_4]\cdot xC_6H_4Cl_2$, $\mathbf{1}\cdot xC_6H_4Cl_2$.

$Mn^{II}T(MeO)_3PP$

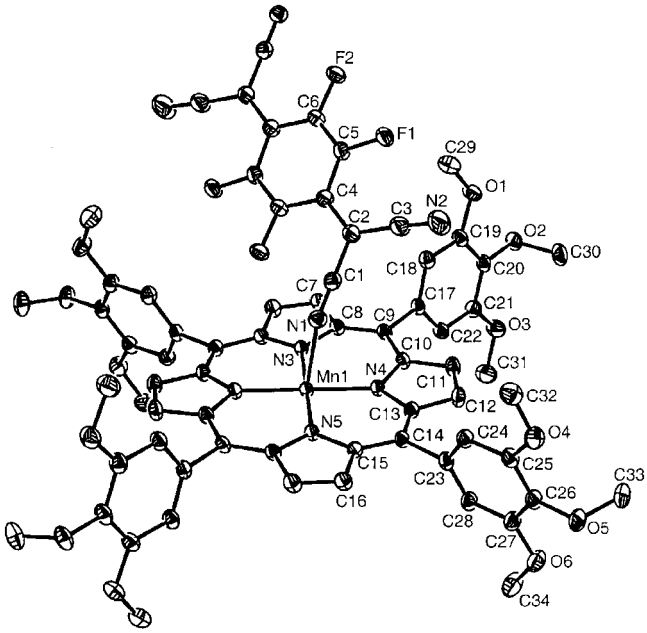
Results and Discussion

The reaction of $TCNQF_4$ and $Mn^{II}T(MeO)_3PPpy$ in 1,2-$C_6H_4Cl_2$ forms $[Mn^{III}T(MeO)_3PP][TCNQF_4]\cdot 3C_6H_4Cl_2$, $\mathbf{1}\cdot 3C_6H_4Cl_2$. The ν_{CN} IR absorptions at 2196 (m) and 2165 (s) cm^{-1} are too low in energy for $TCNQF_4$ [i.e. 2225 cm^{-1}],[12,13] and too high in energy for $[TCNQF_4]^{2-}$ [i.e. 2168 (s) and 2133 (s) cm^{-1}].[12] These values are comparable to 2195 ± 1 (s) and 2177 ± 2 (s) characteristic of $[TCNQF_4]_2^{2-}$,[12,13] but the lower value is sufficiently different to suggest a different bonding mode for $[TCNQF_4]^-$.

The solvent content of the sample used for magnetic measurements was determined to be 2.3 solvent molecules per formula unit by TGA heating at a rate of 15 °C/min starting from 38 °C. Weight loss was observed immediately and all three solvent molecules were lost by 130 °C, after which decomposition was observed as a steady weight loss to 400 °C. The mass spectra showed the effluent of the TGA contains only solvent. Other solvents were also tried, but only *o*-$C_6H_4Cl_2$ gave an identical IR spectrum to the magnetic material.

X-ray Crystal Structure

$\mathbf{1}\cdot 3C_6H_4Cl_2$ (Figure 1) is composed of alternating chains of $[MnTPP]^+$ cations and $[TCNQF_4]^-$ anions. The three 1,2-dichlorobenzene solvent molecules fill the voids of the structure and are the only source of disorder. This disorder is observed in the 1,2-$C_6H_4Cl_2$ which occupies two positions that are related by a C_2 symmetry operation.



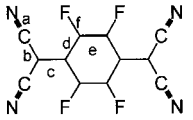


Figure 1. ORTEP drawing (50% probability level) and atom labeling diagram; the three solvent molecules are omitted for clarity

The $[MnT(MeO)_3PP]^+$ cations lie on crystallographic inversion centers with Mn at the center. The Mn^{III} atoms lie at the inversion center with $Mn–N_{por}$ distances averaging 2.004 Å, consistent with typical $[MnTPP]^+$ distances.[2,4,5a–5c,8,14] The trimethoxyphenyl-substituent plane is rotated 80° from the mean porphyrin plane.

The $TCNQF_4$ is essentially planar with a small deviation of the dicyanomethylene moiety which is twisted from the benzenoid ring plane by 5°. The $C_F–C_F$, $C_F–C_C$, and $C_C–C_{CN}$ distances are 1.352(4), 1.410(4), and 1.410(4) Å, respectively, which differ from $TCNQF_4^0$ by 0.02, 0.03, and 0.04 Å, respectively,[10b,12,15] but are comparable to the values for reduced $TCNQF_4$ as $[TCNQF_4]_2^{2-}$.[10,13,16] The bond lengths for $\mathbf{1}\cdot 3C_6H_4Cl_2$ are summarized along with other reported structures for $[TCNQF_4]^n$, Table 1. The key bond length that best describes the oxidation state of the $TCNQF_4$ is the distance *c*. This quinone-type bond in-

[a] Distances are averaged if more than one was reported. – [b] $[TCNQF_4]_2^{2-}$ – [c] $TCNQF_4$'s in dimer are offset by ca. 45°; diamagnetic. – [d] $[\sigma\text{-}TCNQF_4]_2^{2-}$. – [f] This work. – [g] Not plotted in Figure 2 as the unusual deviation of the reported bond length with respect to the other compounds in this table.

creases as the negative charge increases for $[TCNQF_4]^n$. This increase in negative charge is also evidenced by the contraction of bond d and a lengthening of bond e. When the bond length for c is plotted for each of the compounds (Figure 2) the separations of the 0, 1– and 2– species can easily be distinguished, and **1**·$3C_6H_4Cl_2$ clearly lies in the 1– regime.

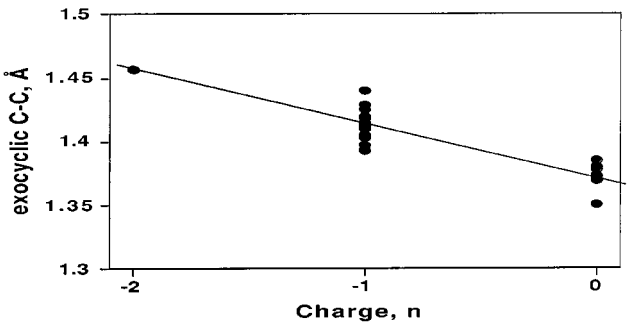

Figure 2. Bond length correlations with bond c (see Table 2) in various $[TCNQF_4]^n$ (n = 0, 1–, 2–)

This semi-quinoid-type character also causes the ring *ipso* angles to differ from the ideal 120° to 123° about F and 113° about $C(CN)_2$. The internal F angle is 118° and the external F angle is 119°. The internal C1–C2–C3 angle in 113°, while the C1–C2–C4 and C3–C2–C4 angles are 123° and 124°, respectively. Hence, in accord with the IR data (vide supra) $[TCNQF_4]^-$ must be present. $[TCNQF_4]^-$ is *trans*-μ bonded to two Mn^{III} atoms with a distance of 2.321(3) Å and an $MnNC_{TCNF4}$ angle of 135.9(2)°. The MnN_{TCNF4} distance is in the range noted for $[TCNE]^-$ analogs;[2,4,5a–5c,8,14] however, this angle is smaller than that observed for [Mn(porphyrin)][TCNE] systems, namely, the MnNC angle which range from 140° to 165°. This is presumably due to the additional space to be filled from the larger acceptor. The dihedral angle between the mean MnN_4 and the mean $[TCNQF_4]^-$ planes is 46.4°. This is in the range of those observed for the [Mn(porphyrin)][TCNE] class of compounds that range from ca. 33.4 to 89.4°.[2,4,5a–5c,8,14] The intrachain Mn···Mn separation is 12.685 Å, which, as expected due to the larger length of $[TCNQF_4]^-$ with respect to $[TCNE]^-$, exceeds the range of

intrachain Mn···Mn separations (i.e. 8.587 to 10.376 Å).[2,4,5a–5c,8,14] The interchain Mn···Mn separations of 16.959, 18.759, and 23.663 Å are also larger than those observed for the $[TCNE]^-$ electron transfer salts which is attributed to the larger spin-bearing ligand used; this is also consistent with the $[Mn^{III}TPP][chloranil]$ magnet.[2]

In the solid state $\mathbf{1}\cdot 3C_6H_4Cl_2$ forms parallel 1-D chains comprised of alternating S = 2 cations and S = 1/2 anions. All chains are identical and possess a zigzag motif (Figure 3). This is a result of the $TCNQF_4$'s aligning *cis* with respect to each other about the manganese center. These uniform chains are arranged into offset layers giving rise to two different interchain Mn···Mn distances as depicted in Figure 3. This zigzag motif is observed for the first time for this $[Mn(porphyrin)]^+$ family of magnets; however, the effect of the structural arrangement on the magnetic properties is uncertain at present.

Magnetic Behavior

The magnetic susceptibility, χ, of $\mathbf{1}\cdot 2.3C_6H_4Cl_2$ in the range 2 to 300 K can be fit to the Curie-Weiss expression, $\chi \propto 1/(T-\theta)$, with $\theta = -37$ K ($T > 250$ K), and an effective θ',[5b] of 29 K ($75 < T < 200$ K), Figure 4.

This θ'-value is markedly lower than the values observed in [Mn(porphyrin)][TCNE] uniform chain systems which range from 42 to >200 K.[1a,5] The room temperature effective moment, μ_{eff} [$\equiv(8\chi T)^{1/2}$], value is 4.81 μ_B which is slightly lower than the predicted value of 5.20 μ_B for an uncoupled S = 1/2, S = 2 system. The $\chi T(T)$ plot have a minimum at 215 ± 10 K (see Figure 4) characteristic of ferrimagnetically coupled systems.[17] The position of this minimum is responsible for the observed lower room temperature χT values. With decreasing temperature $\chi T(T)$ reaches a maximum at 9 K with a value of 10.2 emuK/mol, due to saturation, and then decreases rapidly. The $\chi T(T)$

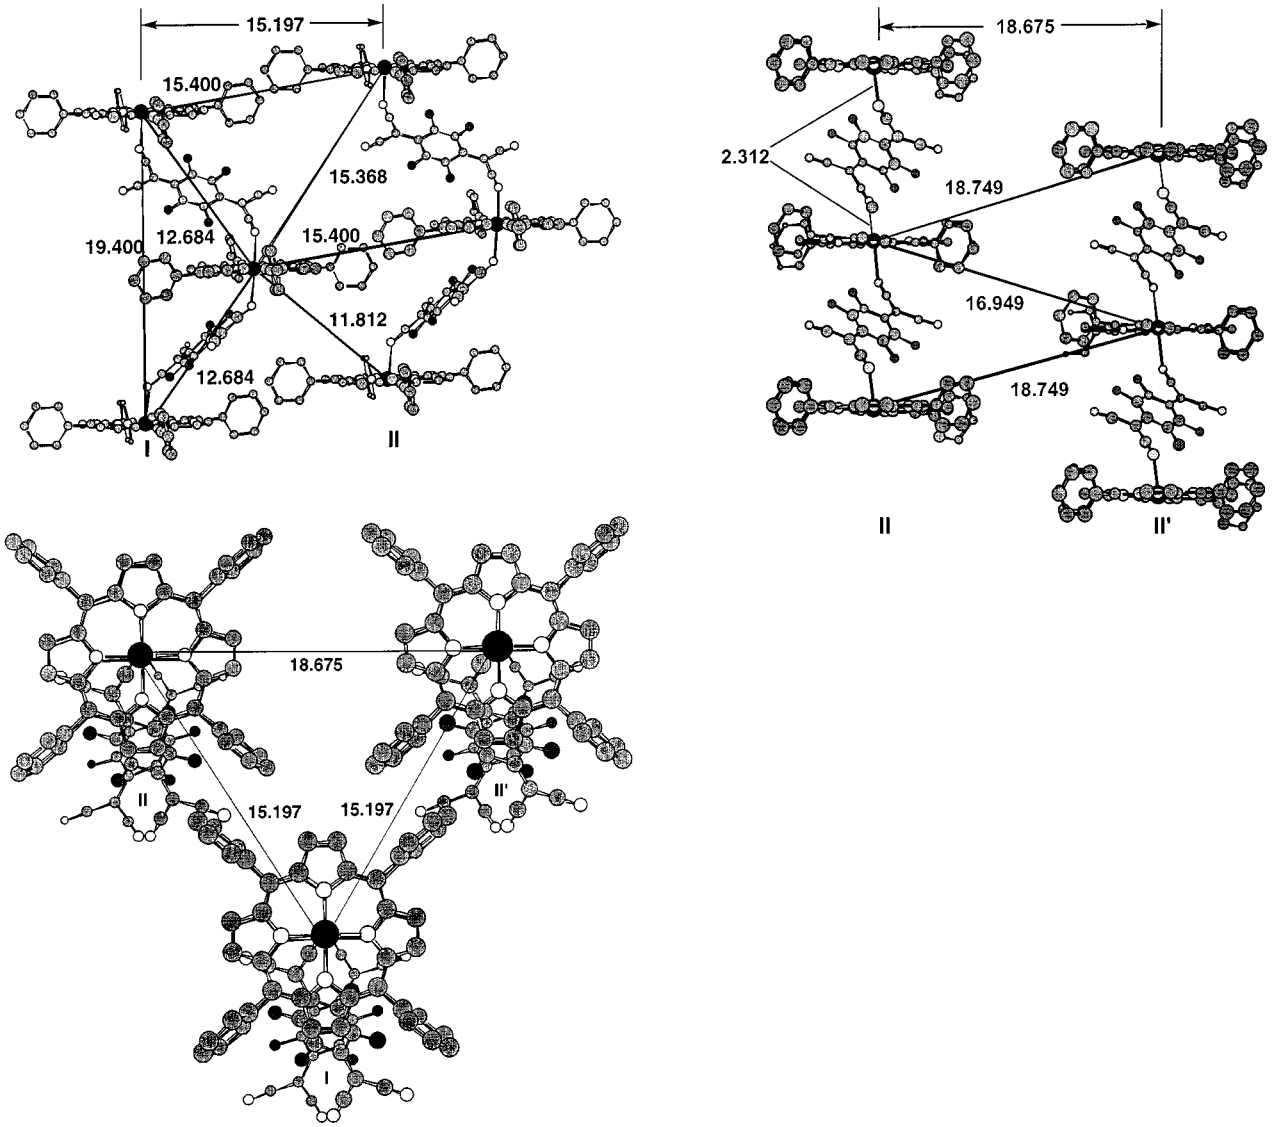

Figure 3. Views of intra- and interchain interactions among the unique chains: **I**, **II**, and **III** for $[MnT(MeO)_3PP][TCNQF_4]\cdot 3C_6H_4Cl_2$

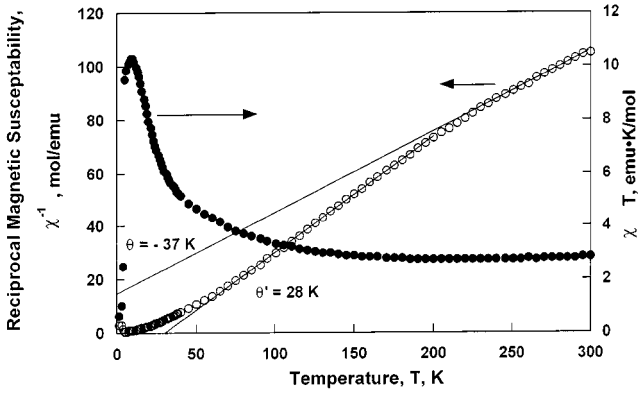

Figure 4. $\chi^{-1}(T)$ (o), and the $\chi T(T)$ (•) fit to the Seiden model (solid line) with $J/k_B = -71$ K (49 cm^{-1}) for $H = -2J\boldsymbol{S}_i\cdot\boldsymbol{S}_j$.for polycrystalline **1**·2.3$C_6H_4Cl_2$; the sample was cooled to 2 K in zero field, then the field (1000 Oe) was turned on and data was measured whilst warming to 300 K

data above 150 K can be fit to the Seiden model[18] for non-interacting chains comprised of alternating $g = 2$ quantum $S = 2$ and classical $S = 1/2$ spins, with $J/k_B = -71$ K (–49 cm^{-1}; –61 meV) for $H = -2J\mathbf{S}_i\cdot\mathbf{S}_j$, Figure 4. The deviation below 150 K is attributed to the onset of three-dimensional interactions and exceeds the values predicted by the model. Below 47 K, however, the slope of the calculated $\chi T(T)$ data begins to rise faster than the experimental data. This type of crossover has not been observed before in this family of magnets, but may be attributed to short correlation lengths. These short correlation lengths are also manifested in the lowered maximum of the $\chi T(T)$ data.

Antiferromagnetic behavior is also evident from the saturation magnetization. The isothermal magnetization at 2 K increases rapidly with the application of a small field, quickly rising to near saturation, M_s (see Figure 5). At 2 T the magnetization is 14.900 emuOe/mol or 89% of 16.755 emuOe/mol expected for an $S_{Tot} = 2 - 1/2 = 3/2$ system. This is substantially lower than that expected from ferromagnetic coupling, i.e. 27.925 emuOe/mol for an $S_{Tot} = 2 + 1/2 = 5/2$ system. At 2 K metamagnetic behavior is observed (field-induced changeover from an antiferromagnetic ground state to a ferromagnetic ground state) with a critical field of ca. 20.2 kOe, Figure 5. Similar field-dependent behavior was observed for [MnTPP][TCNE], which exhibits a

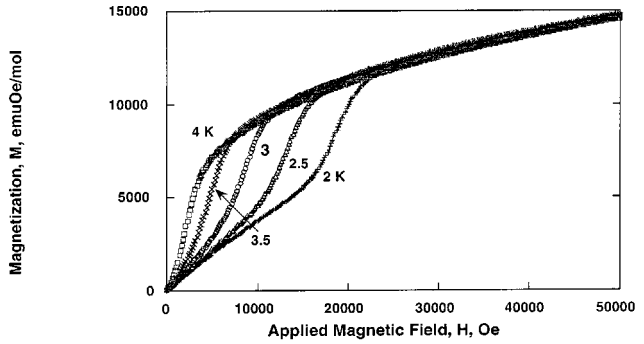

Figure 5. The magnetization curves taken at 2, 2.5, 3, 3.5, and 4 K for **1**·2.3$C_6H_4Cl_2$ displaying the disappearance of the metamagnetic behavior as the temperature is increased; the inset displays a critical field of 20.2 kOe taken from the 2 K saturation data.(solid line)

critical field of ca. 30 kOe at 2.25 K corresponding to a spin-flop transition.[19]

The field-induced crossover from an antiferromagnetic ground state to a ferromagnetic ground state is not observed above 4 K. Sample-independent hysteresis with a large coercive field of 17.1 kOe is observed at 2 K (Figure 6), but is not observed at 5 K. The 2 K remnant magnetization is 7.200 emuOe/mol. The field-cooled and zero-field-cooled data $M(T)$ data at 0.1, 1, and 10 Oe, show a bifurcation at 5.4 K (Figure 7); however, this is not a good measure of T_c since the bifurcation can begin at higher temperatures and not be observable with so few data points.

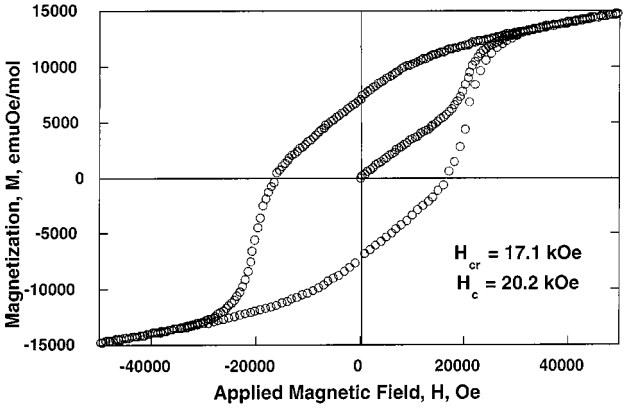

Figure 6. The observed hysteresis for **1**·2.3$C_6H_4Cl_2$ taken at 2 K; the sample was frozen in mineral oil and cooled in zero applied field

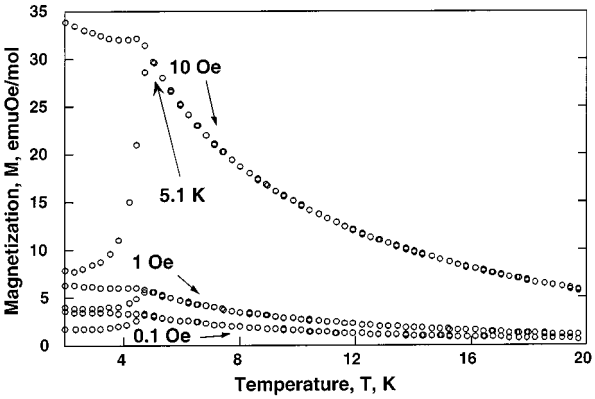

Figure 7. The field cooled and zero-field-cooled data for **1**·2.3$C_6H_4Cl_2$ displaying bifurcation at fields of 0.1, 1.0, and 10 Oe

In addition to dc measurements, the susceptibility was determined in an applied ac field of 1000 Oe (<0.05 dc field) at several frequencies and the resulting data are consistent with long-range ferromagnetic order. A peak in the real part of the 10 Hz ac susceptibility $\chi'(T)$ at 7.3 K is a better measure of T_c (Figure 8). An out-of-phase component, $\chi''(T)$, characteristic of a noncompensated moment is present with a peak at 6.3 K. There are also large frequency dependencies of both $\chi'(T)$ and $\chi''(T)$. The frequency dependence of $\chi'(T)$, ϕ [$= (T_{1000\ Hz} - T_{10\ Hz})/\{T_{10\ Hz}[\log(1000/10)]\}$], is 0.17 which is characteristic of the material being a

spin glass or superparamagnetic state.[20] The broad nature of the $\chi'(T)$ and $\chi''(T)$ peaks suggests that more than one transition is occurring.

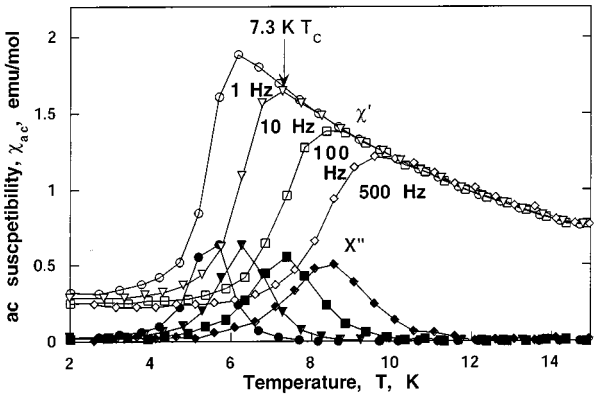

Figure 8. The dispersive, χ', and absorptive, χ'', components of the a.c. susceptibility measured at 1, 10, 100 and 500 Hz for **1**·2.3$C_6H_4Cl_2$; the 7.3 K absorption in the 10 Hz frequency data is defined as T_c; the sample was cooled to 2 K in zero field and data was taken upon warming

Experimental Section

Synthesis: All manipulations were carried out in a Vacuum Atmospheres DriLab under nitrogen. All glassware was oven dried at 110 °C and immediately pumped into the DriLab. The solvents were dried from appropriate drying agents under nitrogen. 3,4,5-Trimethoxybenzaldehyde (Acros) was used as received. $H_2T(MeO)_3PP$ was synthesized by modified literature methods,[21] The $MnT(MeO)_3PPCl$ was prepared by refluxing the free base in DMF with $Mn(OAc)_2{\cdot}4H_2O$ (Acros) and shaking with brine. $Mn^{II}T(MeO)_3PPpy$ was prepared by literature methods.[22] $TCNQF_4$, a gift from O. Webster, was recrystallized prior to use.

$[Mn^{III}T(MeO)_3PP][TCNQF_4]$·x*o*-$C_6H_4Cl_2$: This compound was prepared by adding a filtered solution of $TCNQF_4$ (12 mg, 0.043 mmol) dissolved in hot 1,2-dichlorobenzene (10 mL) to a filtered solution of $Mn^{II}T(MeO)_3PPpy$ (32 mg, 0.043 mmol) in hot 1,2-dichlorobenzene (5 mL). The resulting solution was allowed to stand for three weeks, and the black crystals (11 mg) formed were collected by vacuum filtration. Identical material can be obtained by refluxing $Mn^{II}T(MeO)_3PPpy$ and $TCNQF_4$ for 10 min and letting the solution cool to room temperature. Upon addition of hexane, a black precipitate can be collected on a fritted glass disc with a yield of approximately 70%. The black filtrate was washed with hexane (2 × 5 mL), then stored under nitrogen. – IR: ν_{CN} = 2196(m) and 2165(s) cm^{-1}.

X-ray Structure Determination: Isolation of crystals suitable for X-ray diffraction is described above. The crystal, in the mother liquor, was mounted on a glass fiber covered in oil, mounted on the goniometer and rapidly cooled in a stream of liquid nitrogen at 200 K. Data was collected at 200 K with a Nonius Kappa CCD-based X-ray diffractometer system operated at 2000 W power. The cell constants and an orientation matrix for the data collection were obtained by least-squares refinement of 6707 reflections; the key crystallographic information is given in Table 2. The crystal structure was solved by direct methods using SHELXL97.[23] Non-hydrogen atoms were refined anisotropically. Only one of the three solvent molecules is disordered, which was detected through the use of difference electron maps which illustrated a second orientation of the solvent. These two orientations were fit with the aid of a graphics workstation and the model was refined. The bonds and angles for this solvent were restrained to a standard geometry throughout the refinement.

Crystallographic data (excluding structure factors) for the structure reported herein have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-129223. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk).

Physical Methods: The magnetic susceptibility was determined as previously reported.[2] The diamagnetic correction for the 2.3 equiv. of the 1,2-$C_6H_4Cl_2$ solvate (as determined by TGA) was calculated using Pascal's constants to be -951×10^{-6} emu/mol.

The thermal properties were studied on a TA Instruments Model 2050 thermogravimetric analyzer (TGA, ambient to 1000 °C) placed in a Vacuum Atmospheres DriLab under argon, to retain the integrity of air- and water-sensitive samples. Samples were placed in an aluminum pan and heated to 450 °C at 15 °C/min under a continuous flow of nitrogen (10 mL/min).

The infrared spectra were recorded on a BioRad FTS 40 FTIR in the range of 650 to 4000 cm^{-1} on NaCl discs as a mineral oil mull.

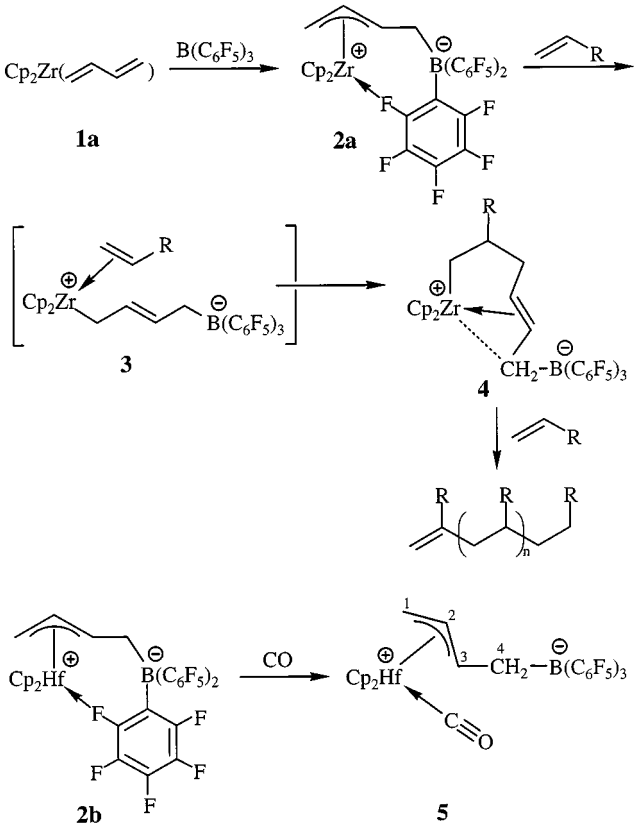
Reaction of a Zirconocene(butadiene)borate-Betaine Single-Component Ziegler Catalyst with Trimethylphosphane



Marc Dahlmann,[a] Roland Fröhlich,[a][+] and Gerhard Erker*[a]

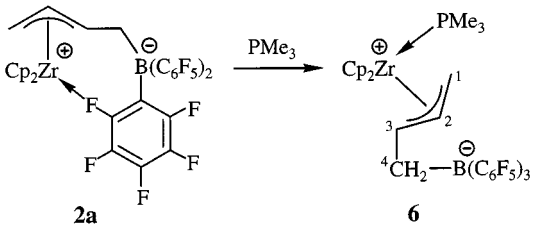
Keywords: Zirconium / Metallocenes / Borates / (Butadiene)zirconocene / Phosphanes

Trimethylphosphane adds to the zirconocene–$[C_4H_6B(C_6F_5)_3]$ betaine complex **2a** regioselectively by an overall inversion pathway, with opening of the internal ZrF–C_{Ar} bond and formation of the $Cp_2Zr(PMe_3)[C_4H_6B(C_6F_5)_3]$ adduct **6**. Complex **6** was characterized by X-ray diffraction. The betaine complex **6** contains a $-CH_2B(C_6F_5)_3$-substituted π-allyl ligand with characteristic bonding parameters of C1–C2: 1.402(8) Å, C2–C3: 1.373(7) Å, Zr–C1: 2.443(5) Å, Zr–C2: 2.526(4) Å, and Zr–C3: 2.681(4) Å.

Introduction

Tris(pentafluorophenyl)borane adds to (butadiene)zirconocene (**1**) to yield the $Cp_2Zr[C_4H_6B(C_6F_5)_3]$ betaine **2a** (Scheme 1). Complex **2** and its substituted Group-4 metallocene analogues are active single-component homogeneous Ziegler catalysts.[1] In addition, complex **2** and its congeners insert one equivalent of an α-olefin under selected reaction conditions to selectively form the primary product **4** of the initiative sequence leading into the catalytic cycle of the olefin polymerization process.[2,3] From a detailed kinetic study it is known that a reactive (η^2-alkene)(σ-allyl)metallocene-type intermediate (**3**) is formed in a preceding equilibrium step, followed by rate-determining alkene insertion into the Zr−C σ-bond.[4] The intermediate **3** cannot be observed directly because of its rapid subsequent CC-coupling reaction.[5] Therefore, we tried to model the structural chemistry of this first step by the addition of a suitable non-olefin two-electron donor ligand. THF added to **2a** with opening of the ZrF coordination, but we could not obtain crystals of the addition product that were suited for an X-ray crystal structure analysis.[1b,6,7] A carbon monoxide addition product to the hafnium homolog **2b** was characterized by X-ray diffraction, but turned out to be the wrong regioisomer (**5**) in comparison with the pathway probably followed in the alkene insertion reaction.[1a,8] We have now prepared and structurally characterized the PMe_3 adduct to the $Cp_2Zr[C_4H_6B(C_6F_5)_3]$ betaine, and found that its coordination characteristics may potentially resemble a structural situation expected at an early stage of the alkene addition reaction.

Scheme 1



Results and Discussion

The betaine complex $Cp_2Zr[C_4H_6B(C_6F_5)_3]$ (**2a**) was generated in situ by treatment of (butadiene)zirconocene (**1**)[9] with the organometallic Lewis acid tris(pentafluorophenyl)-borane[10,11] in toluene. If care is taken to ensure that the two components are employed in a 1:1 ratio, then the formation of **2a** is close to quantitative, and it is not necessary to isolate the resulting metallocene−borate betaine complex, and the toluene solution of **2a** can be used directly to carry out subsequent reactions.

The addition of a four-fold excess of trimethylphosphane resulted in an instantaneous formation of the 1:1 addition product **6**, of the phosphane to the zirconium complex

Scheme 2

(Scheme 2). The $Cp_2Zr(PMe_3)[C_4H_6B(C_6F_5)_3]$ complex (**6**) crystallized in pure form from the reaction mixture at −20 °C, and was isolated in > 90% yield as a pale yellow crystalline material. Since the product was poorly soluble once it was precipitated, solutions of **6**, generated in situ in a deuterated solvent, were used for some of the NMR spectroscopic characterization.

The ^{1}H-NMR spectrum reveals that the PMe_3 addition complex **6** is chiral. It shows the signals of a pair of diastereotopic Cp-ligands at δ = 4.88 and 4.64. Each signal is split into a doublet by coupling with the phosphorus nucleus of the coordinated PMe_3 ligand (J_{PH} = 2 Hz).[12] Consequently, a ^{31}P-NMR resonance is observed for **6** at δ = 1.25, which is markedly shifted to a higher δ value relative to free trimethylphosphane (δ = −62.1). Coordination of the PMe_3 donor ligand to zirconium has opened the ZrF interaction that was characteristic of the starting material **2a** (^{19}F NMR: δ = −213 for the ZrF−C_6H_4[B] unit).[1a] In **6**, only a set of three ^{19}F-NMR resonances is observed in the typical $RB(C_6F_5)_3^-$ range. A distorted (π-allyl)Zr moiety is retained in complex **6** as judged from the characteristic ^{1}H- and ^{13}C-NMR chemical shifts (see Table 1). The regiochemical preference of the PMe_3 addition, leading to a "$-CH_2B-$ inside" (as found in **5**) or "$-CH_2B-$ outside" structure[8a] (as formulated for **6** in Scheme 2) cannot be deduced from the NMR data of the obtained product. We were able to answer this question by an X-ray crystal structure analysis of **6**.

The single crystals obtained from the preparation of **6** (see above) were suitable for an X-ray crystal-structure analysis. The betaine complex exhibits a pseudo-tetrahedral coordination environment around the central zirconium atom. In the front sector of the bent metallocene wedge one finds the C_4H_6[B] moiety, coordinated to the metal center through its carbon atoms C1−C3, and the PMe_3 ligand.

M−X	2.423(3)[b]	2.705(1)[c]	2.246(7)[d]

[a] From ref.[1a]. − [b] Zr···F. − [c] Zr−P. − [d] Hf−CO.

The substituted allyl unit is coordinated in a η^3-fashion, but it is distorted toward a σ,π-type coordination geometry, as it is often observed for (allyl)zirconocene complexes.[13] However, this distortion in **6** is much less pronounced than it was, for instance, in the metallacyclic betaine complex **2a** (see Table 2). In **6** the *d*(Zr−C2) − *d*(Zr−C3) bond lengths difference [Δ(ZrC2/3)] amounts to only 0.155 Å, whereas Δ(ZrC2/3) = 0.216 Å was observed for complex **2a**.

The addition of the phosphane ligand has resulted in a cleavage of the ZrF−C interaction that was typical for the betaine system **2a**,[14] and has led to a conformational change of the $C_4H_6B(C_6F_5)_3$ chain. In **6**, rotation around the C3−C4 vector has oriented the C4−$B(C_6F_5)_3$ unit away from the metallocene moiety [θC2−C3−C4−B = −95.4(5)°] to minimize steric interaction between these two bulky groups.

The PMe_3 ligand was added to the bent metallocene from a position oriented as far away as possible from the bulky $-CH_2-B(C_6F_5)_3$ end of the 1-3η-$C_4H_6-B(C_6F_5)_3$ ligand (see Figure 1). It is found attached at the front side of the bent metallocene wedge in a position close to the CH_2-terminus of the $-CH_2$-borane-substituted π-allyl ligand.[15] The Zr−P bond length is 2.705(1) Å. The $Me_3P-ZrCp_2L$ unit attains a staggered-like conformational arrangement of groups along the P−Zr vector. In **6**, the bond angles at phosphorus show a systematic deviation from an ideal tetrahedron: the three H_3C-P angles are markedly smaller [101.6(3)°, 101.9(4)°, 102.6(3)°] than the adjacent C−P−Zr angles [115.7(2)°, 116.1(2)°, 116.7(2)°]. This is probably due to steric interactions, and indicates the importance of steric factors governing the regiochemistry of the adduct formation in complexes of types **6** (Figure 1) and **5** (see Scheme 1).[16]

Conclusions

The ZrF bond in the metallocene betaine complex **2a** is rather weak, estimated at ca. 8 kcal mol^{-1} bond dissociation energy from dynamic ^{19}F-NMR spectroscopy.[1b] Therefore, it is not surprising, that the zirconium−fluorine linkage in **2a** is rapidly cleaved by the addition of typical 2-electron donor ligands such as carbon monoxide or trimethylphosphane. The small CO ligand can apparently be added from the sterically less favorable side to yield the

"$-CH_2-B(C_6F_5)_3-$ inside" regioisomer **5**,[1a] but the addition of the sterically more demanding PMe_3 ligand already leads to the exclusive observation of a typical stereochemical inversion pathway. Addition of the phosphane takes place *trans* to the ZrF bond in the σ-ligand plane at the front sector of the bent metallocene wedge, leading to the selective formation of the observed regioisomer **6**, however, it is unclear whether this product formation is thermodynamically or kinetically controlled.

The involvement of a (σ-allyl)(π-olefin)metallocene betaine-type intermediate, such as **3** (see Scheme 1) in the course of the alkene insertion/polymerization sequence starting from **2**, has been indirectly demonstrated by kinetic measurements. These have shown that the typical metallocene−allyl-inversion process of **2a**, followed by dynamic NMR spectroscopy, is markedly slower in pure toluene ($\Delta G^{\ddagger}_{inv}$ = 19.8 kcal mol^{-1}) than in the presence of added propene ($\Delta G^{\ddagger}_{inv}$ = 16.5 kcal mol^{-1}).[4] The allyl inversion process must proceed through a (σ-allyl)-metallocene-type intermediate,[17] in the presence of the alkene this means by involvement of **3**. The observed allyl inversion barrier ($\Delta G^{\ddagger}_{inv}$) is lowered because the essential reactive intermediate is stabilized by π-alkene coordination, and so is the preceding transition state, according to the Hammond postulate.[18] Since the addition reactions to **2** respond very sensitively to steric interferences, it may be that an alkene adds to **2a** in a manner very similar to PMe_3, namely from the less hindered side adjacent to the unsubstituted allyl side. This potentially leads to a stereochemical inversion at the metal center upon replacing the weak F−C(Ar) coordination to zirconium. The resulting PMe_3 adduct **6**, that we obtained and structurally characterized, may therefore, potentially resemble the structural situation during the alkene addition reaction to the metallocene betaine system at an early stage on the reaction coordinate.

Experimental Section

Reactions were carried out under argon using Schlenk-type glassware or in a glove-box. Solvents were dried and distilled under argon prior to use. For additional general information, including a list of spectrometers and instruments used for physical characterization, see ref.[1b] (Butadiene)zirconocene[9] and $B(C_6F_5)_3$[10] were prepared according to literature procedures. For this study, the betaine complex **2a** (see below) was generated in situ and spectroscopically shown to be identical to the previously isolated material.

Reaction of 2a with Trimethylphosphane. − Preparation of 6. − a) NMR Experiment: For its spectroscopic characterization, complex **6** was generated in situ in [D_8]toluene. A solution of 8 mg (29.0 μmol) of (butadiene)zirconocene (**1**) in 0.4 mL of [D_8]toluene was added dropwise to a solution of 15 mg (29.3 μmol) of $B(C_6F_5)_3$ in 0.2 mL of [D_8]toluene at ambient temperature in a vial inside the glove-box. The reaction mixture was kept for 30 min at ambient temperature; during this time a small fraction of the betaine **2a** precipitated. The clear supernatant solution was transferred to an NMR tube and sealed with a septum. Trimethylphosphane (0.02 mL) was syringed into the solution. After mixing, a pale yellow solution of **6** was obtained that was used for some of the spectroscopic characterization.

b) Formation of 6 on a Preparative Scale: A solution of 54 mg (105 μmol) of $B(C_6F_5)_3$ in 3 mL of toluene was added dropwise at ambient temperature to a solution of 29 mg (105 μmol) of (butadiene)-zirconocene in 6 mL of toluene. After 30 min trimethylphosphane (0.13 mL, 420 μmol) was added and the mixture stirred for 20 min at room temperature. The pale yellow solution was kept for 1 d at −20 °C. The product crystallized as yellow needles, which were collected by filtration, washed with toluene (4 mL), and dried in vacuo to yield 85 mg (93%) of **6**, m.p. 234 °C (decomp.). The isolated product shows a low solubility in toluene. Single crystals from this preparation were used for the X-ray crystal structure analysis of **6**: formula $C_{35}H_{25}BF_{15}PZr \times 2\ C_7H_8$, M = 1047.82, light yellow crystal 0.30 × 0.20 × 0.10 mm, a = 32.936(1), b = 15.360(1), c = 21.055(1) Å, β = 113.93(1)°, V = 9736.1(8) Å^3, $\rho_{calcd.}$ = 1.430 g cm^{-3}, μ = 3.49 cm^{-1}, empirical absorption correction via SORTAV (0.903 ≤ T ≤ 0.966), Z = 8, monoclinic, space group $C2/c$ (No. 15), λ = 0.71073 Å, T = 198 K, ω and φ scans, 28280 reflections

collected ($\pm h$, $\pm k$, $\pm l$), [(sinθ)/λ] = 0.62 Å^{-1}, 9810 independent (R_{int} = 0.041) and 7840 observed reflections [$I \geq 2\,\sigma(I)$], 607 refined parameters, R = 0.076, wR^2 = 0.234, max. residual electron density 3.55 (−0.56) e Å^{-3}, beside the localized toluene molecules there is probably a further solvent molecule around 0,y,1/4. Even with strong geometrical constraints a chemical meaningful description is not possible and therefore this electron density is not taken into account in the final refinement, hydrogens calculated and refined as riding atoms.

Data set was collected with Nonius Kappa CCD diffractometer, equipped with a rotating anode generator, Nonius FR591. Programs used: data collection COLLECT (Nonius B.V., 1998), data reduction Denzo-SMN (Z. Otwinowski, W. Minor, *Methods in Enzymology*, **1997**, *276*, 307−326), absorption correction SORTAV (R. H. Blessing, *Acta Cryst.* **1995**, *A51*, 33−37; R. H. Blessing, *J. Appl. Cryst.* **1997**, *30*, 421−426), structure solution SHELXS-97 (G. M. Sheldrick, *Acta Cryst.* **1990**, *A46*, 467−473), structure refinement SHELXL-97 (G. M. Sheldrick, Universität Göttingen, 1997), graphics SCHAKAL (E. Keller, Universität Freiburg, 1997).

Crystallographic data (excluding structure factors) for the structure reported in this paper has been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. Addition and Coupling Reactions of Zirconocene Cation Complexes that Contain a Pendant η^2-Formaldiminium Side Chain

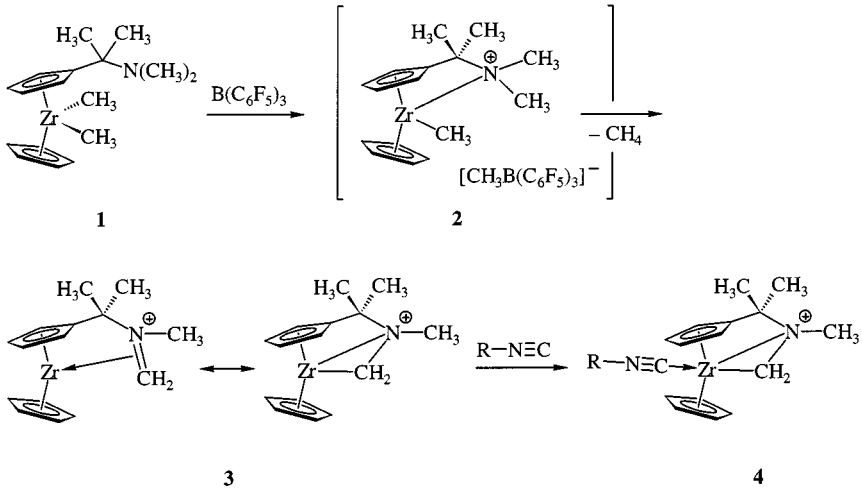
Jörg Pflug,[a] Gerhard Erker,*[a] Gerald Kehr,[a][+] and Roland Fröhlich[a][++]

Keywords: Metallocenes / Cations / Phosphanes / Alkenes / Insertions / Zirconium / C−H activation

The pendant (η^2-formaldiminium)zirconocene cation complex **3** is generated by treatment of the $(Cp–CMe_2NMe_2)CpZrMe_2$ precursor **1** with $B(C_6F_5)_3$. The formation of **3** proceeds with C–H activation and methane evolution. Addition of the phosphanes PPh_2R (R = Ph, CH_3 and cyclopropyl) leads to the stable adducts **6a–c**, in which the Zr–CH_2–N three-membered ring structure of the (η^2-formaldiminium)Zr subunit is retained. The reactive complex **3** readily inserts benzophenone into the Zr–CH_2(N) linkage to yield the carbon–carbon coupling product **7**. α-Olefins also insert into the reactive Zr–C bond of **3**. Exposure of **3** to ethene at a low temperature (–50 °C) results in the formation of the labile metallacyclic mono-alkene-insertion product **8**, that is characterized spectroscopically. Styrene and 4-*tert*-butylstyrene undergo a clean [2,1]insertion into the Zr–C bond of **3** to selectively yield the isomerically pure mono-insertion products **9a** and **9b**, respectively, that exhibit their aryl substituents in the α-position adjacent to the zirconium center. In each case a single stereoisomer is formed that contains a σ-π-structured η^3-benzylic coordination of the chain end, exhibiting the *meso*-allyl position oriented *cis* to the substituted Cp ring at the resulting metallacyclic framework. Complex **9b** was characterized by X-ray crystal-structure analysis.

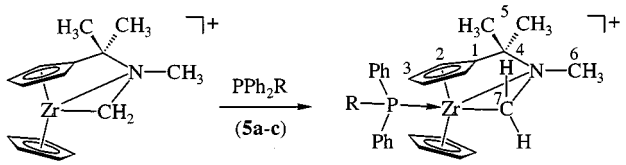
Introduction

Alkylzirconocene cations[1] are known to readily undergo alkene insertion;[2] this reaction is the basis for their action as active Ziegler polymerization catalysts.[3] However, they can also undergo C−H activation reactions if suitable reagents are brought in the vicinity of the $[Zr]^+–CH_3$ moiety.[4] Such behavior is observed when the amino-functionalized metallocene $(Cp–CMe_2NMe_2)CpZr(CH_3)_2$ (**1**)[5] is treated with the alkyl abstractor $B(C_6F_5)_3$ (Scheme 1).[6] The alkylzirconocene cation **2** which is generated in situ, is not stable under the reaction conditions but rapidly reacts further by proton abstraction from the pendant $N–CH_3$ group to form **3** with methane evolution. The product **3** probably contains a strong nitrogen−zirconium interaction and thus might be viewed as a η^2-formaldiminium complex. The three-membered ring structure is confirmed for the isonitrile adduct **4** by X-ray diffraction.[4] The Zr(η^2-CH_2=NR_2^+) moiety can also be recognized spectroscopically by a characteristically increased $^1J_{CH}$ coupling constant of the CH_2 group inside the three-membered metallacycle[7] [**4**: $^1J_{CH}$ = 153 Hz (N−CH_2−Zr), 138 Hz (N−CH_3); **3**: $^1J_{CH}$ = 152 Hz (N−CH_2−Zr), 139 Hz (N−CH_3)]. The ^{15}N-NMR chemical shift also seems to correspond to the coordinative situation at the pendant nitrogen functionality:[4,8] A ^{15}N-NMR resonance (in $[D_2]$dichloromethane) of δ = −338 is observed for the starting material **1**, whereas markedly decreased ^{15}N-NMR shift values are observed for the (η^2-formaldiminium)zirconocene cations **3** [$\delta(^{15}N) = -358$] and **4** [$\delta(^{15}N) = -375$], respectively. We have studied the behavior of the reactive complex **3**[9] towards a variety of reagents, including phosphanes, organic carbonyl compounds, and alkenes. Representative examples of the reaction of the (η^2-formaldiminium)zirconium cation system with such reagents are described in this article.



Results and Discussion

The pendant (η^2-formaldiminium)Zr cation complex **3** was generated in situ by treatment of its immediate precursor **1** with $B(C_6F_5)_3$ in $[D_2]$dichloromethane at −50 °C.[4] The phosphanes PPh_3 (**5a**), $P(Me)Ph_2$ (**5b**), and P(cyclopropyl)Ph_2 (**5c**) were added to samples of this solution. The corresponding phosphane addition products[10] (**6a−c**, respectively) were formed instantaneously (Scheme 2). Upon addition of pentane and after warming to room temperature, they separated from the reaction mixture as dark-colored oils and were each isolated in a ca. 50% yield.



The cationic (triphenylphosphane)zirconium complex **6a** shows a ^{31}P-NMR resonance signal at δ = 31.2. The phosphane coordination results in a $^3J_{PH}$ coupling (1.5 Hz) of the Cp hydrogen atoms (Table 1).[11] The chiral metallocene complex exhibits two pairs of diastereotopic C_5H_4 NMR resonances at δ = 6.19, 5.93, 5.68, 4.58 (^{1}H) and δ = 113.0, 108.8, 107.2, 96.9 (^{13}C), as well as the signals of a pair of diastereotopic methyl groups [δ = 1.61, 1.01 (^{1}H); 25.3, 17.6 (^{13}C)] bonded to carbon atom C-4 (see Scheme 2), and the methylene hydrogen atoms at C-7 (see Table 1). All three complexes **6a−c** show ^{15}N-NMR resonance signals at δ ≈ −376. This is very characteristic for a bonding situation

[a] Not determined.

where the forminium nitrogen atom retains a strong bonding contact with the central metal atom. The presence of a (Zr−N−CH_2) three-membered ring is further indicated by the rather large $^1J_{CH}$ coupling constants (155 and 146 Hz). They are much larger than the $^1J_{CH}$ value of the adjacent N(CH_3) group (138 Hz). We thus conclude that phosphane addition to the zirconium atom in **3** does not lead to the opening of the (Zr−N−CH_2) three-membered ring structure of the cationic organometallic C−H activation product. The (η^2-formaldiminium)zirconocene unit is still intact in the complexes **6a**−**c**.

We then treated **3** with benzophenone.[12] As expected, a rapid reaction takes place. The spectra of the isolated product (57% yield) indicated that carbon−carbon coupling between the *N*-methylene group and the carbonyl carbon atom had taken place − i.e. the ketone inserts into the Zr−CH_2(N) σ bond of the starting material **3**, to yield the new cation complex **7**. The former carbonyl carbon atom (C-8 in Scheme 3) now shows a ^{13}C-NMR shift of δ = 81.0,[13] and the C-7 resonance signal is at δ = 66.8. Both values indicate that carbon−carbon coupling has taken place and that the three-membered ring was opened. The most remarkable feature of the new complex **7** is that it is chiral. This is evident from the NMR-spectroscopic obser-

9 R = H (**a**), –CMe_3 (**b**) **10**

Scheme 3. Insertion reactions of **3** (all complexes with $[CH_3B(C_6F_5)_3]^-$ anion)

vation of diastereotopic methyl groups at C-4 [δ = 1.65, 1.50 (^{1}H); 25.5, 22.5 (^{13}C)], diastereotopic hydrogen atoms at C-7 (δ = 3.90, 3.57), diastereotopic phenyl groups at C-8 and diastereotopic pairs of the C-2-H and C-3-H C_5H_4-methine moieties [δ = 6.45, 6.37, 6.23, 6.17 (^{1} H); 125.9, 107.5, 106.7, 104.9 (^{13}C)]. The chirality of **7** may result from the internal coordination of the nitrogen atom to the zirconium center, or from the internal ion pairing by $CH_3B(C_6F_5)_3^-$ anion coordination to the metal center. The available spectroscopic data [^{15}N-NMR resonance signals at δ = −339 in CD_2Cl_2, −344 in C_6D_6/[D_8]THF (1:1); $CH_3B(C_6F_5)_3^-$ resonance signals at δ = 0.40 (^{1}H NMR) and 9.4 (^{13}C NMR)] are inconclusive. Without an X-ray crystal-structure analysis it was not possible to decide, with conclusive certainty, between these two possibilities. Tentatively, we assigned complex **7** a structure with a weak intramolecular metal−nitrogen interaction.

Complex **3** readily inserts a variety of reactive α-olefins, such as ethene, propene, 1-butene or 1-decene at low temperature (−50 °C). In each case a single mono-insertion product was formed regioselectively[14,15] (regular [1,2]addition was observed[3] to give the β-alkyl-substituted products in the latter cases). However, all these products rapidly decomposed upon warming to 0 °C with the formation of as yet unidentified product mixtures. Due to this thermal instability these products could not be isolated, and we have limited ourselves to briefly describing the spectroscopic characterization of the ethene-mono-insertion product **8** (for further data see the Supporting Information).

The ethene-insertion product **8** was generated by treatment of **4** with gaseous C_2H_4 at −50 °C in [D_2]dichloromethane and directly characterized by NMR spectroscopy at a low temperature. The NMR spectra show that a C_3H_6 chain connects Zr and N in **8** [^{13}C: δ = 53.4 ($^1J_{CH}$ = 144 Hz, C-7), 14.3 (124 Hz, C-8), and 46.8 (132 Hz, C-9)]. The insertion product **8** is chiral {NMR signals of diastereotopic pairs of C_5H_4 methine groups at δ = 118.4, 117.1, 110.2, 106.9 (^{13}C) and 7.40, 6.44, 6.37, 6.33 (^{1} H); of methyl substituents at C-4 [δ = 1.48, 1.28 (^{1}H); 24.9, 20.9 (^{13}C)] and of hydrogen atoms at the connecting $-CH_2-CH_2-CH_2-$ chain} (see the Experimental Section for details). We assume that the chirality of the molecular framework of complex **8** is due to a (weak) intramolecular nitrogen−zirconium interaction. The corresponding ^{15}N-NMR resonance of **8** is found at δ = −349 (in [D_2]dichloromethane at 223 K).

We then treated the cation **3** with styrene and 4-*tert*-butylstyrene, respectively. The corresponding mono-insertion products **9a**, **9b** are rather stable and can be isolated as solid materials in 70−80% yield. Single crystals of the *p*-*tert*-butylstyrene insertion product **9b** could be obtained. Complex **9b** was characterized by an X-ray crystal-structure analysis (see Figure 1).

The solid-state structure of **9b** shows that a new carbon−carbon bond has been formed between the (N)−CH_2 methylene and the styrene =CH_2 group [C7−C8: 1.514(6) Å]. The adjacent alkyl-substituted benzyl subunit is η^3-coordinated to the zirconium center through the benzylic methine carbon atom and two of the arene carbon atoms, the *ipso*-C and one of the *ortho*-arene carbon atoms.[16] The corresponding C−C bond lengths inside the π-allyl moiety are 1.430(6) Å (C9−C10) and 1.410(5) Å (C10−C11). The (π-allyl)zirconocene unit is *syn*-substituted at C9 [angle C8−C9−C10 123.5(4)°]. As expected, the η^3-benzylic moiety is rather unsymmetrically bonded to the zirconium center[17] with Zr−C9 being much shorter [2.389(4) Å] than Zr−C10 [2.604(4) Å] and Zr−C11 [2.654(4) Å]. The partial π coordination of the arene ring in **9b** results in a slight bond alternation in the remaining framework [C11−C12 1.405(6) Å, C12−C13 1.374(6) Å, C13−C12A 1.423(6) Å, C12A−C11A 1.351(6) Å, C11A−C10 1.424(5) Å].

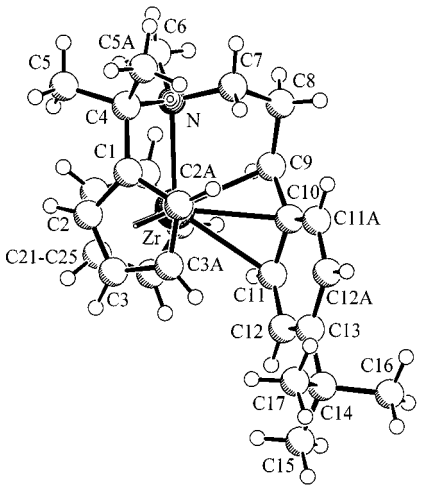

Figure 1. Molecular structure of complex **9b**; selected bond lengths [Å] and angles [°]: Zr−C1 2.461(4), Zr−C2 2.467(4), Zr−C2A 2.501(4), Zr−C3 2.541(4), Zr−C3A 2.560(4), Zr−N 2.498(3), Zr−C9 2.389(4), Zr−C10 2.604(4), Zr−C11 2.654(4), C1−C4 1.502(6), C4−N 1.554(6), N−C7 1.497(5), C7−C8 1.514(6), C8−C9 1.502(6), C9−C10 1.430(6), C10−C11 1.410(5), C10−C11A 1.424(5), C11−C12 1.405(6), C11A−C12A 1.351(6), C12−C13 1.374(6), C12A−C13 1.423(6); C1−C4−N 100.2(3), C4−N−C7 111.1(3), C4−N−Zr 98.4(2), Zr−N−C7 104.8(2), N−C7−C8 111.6(3), C7−C8−C9 111.3(4), C8−C9−Zr 115.8(3), C8−C9−C10 123.5(4), C9−C10−C11 117.6(4), C9−C10−C11A 126.3(4), C9−C10−Zr 65.3(2), C11−C10−Zr 76.4(2), C11A−C10−Zr 122.8(3), C10−C11−C12 121.8(4), C12−C11−Zr 125.4(3)

The Zr−N distance in **9b** is found at 2.498(3) Å. This is clearly within bonding distance,[18] but is substantially longer than that found in e.g. complex **4** [2.312(8) Å].[4] The nitrogen atom in **9b** is a distorted tetrahedron [bond angles C7−N−C4 111.1(3)°, C7−N−C6 107.4(3)°, C6−N−C4 113.9(3)°, Zr−N−C7 104.8(2)°, Zr−N−C6 120.7(3)°, and Zr−N−C4 98.4(2)°, sum of bond angles 656.3° vs. 656.8° of an ideal tetrahedron]. The formation of a small-ring Cp−CMe_2−N−Zr substructure introduces some strain into complex **9b**, which results in a slight distortion of the (η^5-C_5H_4R)Zr coordination [Zr−C(Cp) bond lengths ranging from 2.461(4)/2.467(4) Å through 2.501(4) Å to 2.541(4)/2.560(4) Å].

In principle, this general structural arrangement could have led to the formation of two stereoisomeric [2,1]insertion products[19] of the styrene reagents into the Zr−C(H_2) bond of **3**; however, in the crystal only the stereoisomer with the "tip" of the σ,π-benzyl unit pointing toward the substituted (η⁵-C_5H_4)−CMe_2−(N) ring (*cis* isomer) is observed.

Only a single isomer of **9b** is seen by NMR spectroscopy in solution. Complex **9b** is also chiral in solution. The NMR spectrum shows two pairs of diastereotopic C_5H_4-methine groups (^{13}C-NMR resonances at δ = 124.8, 109.0, 106.9, 101.9; ^{1}H: δ = 5.96, 5.81, 4.66, 4.07), two diastereotopic methyl groups at C-4 [δ = 25.1, 22.5 (^{13}C); δ = 1.45, 1.33 (^{1}H)], and pairs of diastereotopic CH_2 hydrogen atoms at C-7 and C-8 (see the Experimental Section for details). The ^{15}N-NMR resonance of complex **9b** occurs at δ = −352. At low temperature (233 K), the four CH carbon resonances of the arene ring in **9b** are clearly distinguished [^{13}C: δ = 88.7 (C11), 124.0 (C11′), 133.6 (C12), 133.5 (C12′); ^{1}H: δ = 5.46 (11-H), 7.06 (11′-H), 7.30 (12-H), 7.73 (12′-H)]. The $^1J_{CH}$ coupling constant of the C-11-H unit is markedly smaller (150 Hz) than the related arene C-11′/C-12/C-12′-H $^1J_{CH}$ coupling constants, which are all in the typical arene 157−159 Hz range. The ^{13}C-NMR chemical shifts of the remaining carbon atoms of the (σ,π-allyl)Zr subunit of the substituted (η³-benzyl)Zr moiety of **9b** are seen at δ = 135.6 (C-10) and 69.6 ($^1J_{CH}$ = 141 Hz, C-9). The 9-H ^{1}H-NMR signal is located at δ = 3.82.

Complex **9b** shows temperature-dependent NMR spectra of the arene methine signals originating from the substituted styrene reagent. Raising the temperature leads to the broadening of the 11-H/11′-H and 12-H/12′-H pairs of resonances and coalescence. We assume that this dynamic behavior is due to equilibration of the stable σ,π-coordinated η³-arene complex **9b** with a reactive η¹-benzyl-type intermediate[16,20] (**10b**, see Scheme 3), which allows rapid rotation around the C(sp^2)−C(sp^3) σ bond on the NMR time scale, leading to the observed averaging of the pairs of CH resonances. From the 12-H/12′-H ^{1}H-NMR coalescence a Gibbs activation energy of $\Delta G^{\neq}$(278 K) = 10.7 ± 0.4 kcal mol^{-1} is obtained for this dynamic intramolecular equilibration process of complex **9b**.[21]

Styrene insertion into the Zr−C-7 bond of **3** proceeds analogously. Only the [2,1]insertion product is formed,[19] i.e. the regioisomer **9a** that features the arene substituent at the α-carbon atom adjacent to the metal center. This regiochemistry of the insertion reaction allows for the stabilization of the product by distorted η³-benzylic arene coordination. This extra stabilization is likely to be the reason for the observed regiochemistry because there is evidence in the literature that rate-determining insertion in homogeneous metallocene Ziegler chemistry is preceded by a reversible alkene coordination/dissociation equilibrium,[22] which is a prerequisite of such a thermodynamic control of the regiochemistry. Styrene insertion also leads to a single stereoisomer **9a**. We again assume *cis* arrangement of the η³-benzyl stereogenic unit with the substituted Cp ring.

Experimental Section

The reactions were carried out under argon using Schlenk-type glassware or in a glovebox. Solvents were dried and distilled under argon prior to use. − ^{15}N-NMR spectra (60.7 MHz) were recorded with a Varian Unity Plus 600 NMR spectrometer by using a GHMBC pulse sequence (^nJ(^{15}N,^{1}H) = 5 Hz, n = 3, 4). The ^{15}N chemical shift is given with respect to a 2% [^{15}N]benzamide/0.2% $Cr(acac)_3$ sample in DMSO [δ(^{15}N) = −279.3, relative to neat CH_3NO_2, δ(^{15}N) = 0; Ξ(^{15}N) = 10.1367 MHz]. (For additional general information see ref.[4]) The preparation of **3** was described by us previously.[4] Complex **1**[5] and $B(C_6F_5)_3$[6] were prepared as described in the literature.

Reaction of 3 with Triphenylphosphane. − Preparation of 6a: A cold solution (−50 °C) containing **1** (150 mg, 0.45 mmol) in 5 mL of dichloromethane was added to a solution of $B(C_6F_5)_3$ (228 mg, 0.45 mmol) in 5 mL of dichloromethane at −50 °C. The mixture was stirred for 30 min to generate **3**. Triphenylphosphane (117 mg, 0.45 mmol) was then added. The mixture was kept at −50 °C for 15 min and then warmed to room temperature. The product was precipitated as a dark brown oil by the dropwise addition of pentane (5 mL). The supernatant organic phase was decanted. The remaining oil was washed with pentane (5 mL). Pentane (7 mL) was then added and the product stirred overnight to give a solid, which was collected to yield 266 mg of **6a** (54%), m.p. 102 °C (dec. at 212 °C). − ^{1}H NMR ([D_2]dichloromethane, 599.99 MHz): δ = 7.59 (m, 3 H, Ph-*p*-H), 7.54 (m, 6 H, Ph-*m*-H), 7.36 (m, 6 H, Ph-*o*-H), 6.19, 5.93, 5.68, 4.58 (m, each 1 H, C_5H_4), 5.88 (d, $^3J_{PH}$ = 1.5 Hz, 5 H, Cp-H), 2.56 (s, 3 H, 6-H), 1.89 (dd, $^3J_{PH}$ = 4.8 Hz, $^2J_{HH}$ = 9.4 Hz, 1 H, 7-H), 1.64 (dd, $^3J_{PH}$ = 1.9 Hz, $^2J_{HH}$ = 9.4 Hz, 1 H, 7-H), 1.61, 1.01 (s, each 3 H, 5-H, 5-H), 0.50 [br s, 3 H, $B(C_6F_5)_3$-CH_3]. − ^{13}C NMR ([D_2]dichloromethane, 150.84 MHz): δ = 134.0 (d, $^2J_{PC}$ = 19.5 Hz, C-*o*-Ph), 131.7 (C-*p*-Ph), 129.7 (d, $^3J_{PC}$ = 9.0 Hz, C-*m*-Ph), 117.0 (C-1), 113.0, 108.8, 107.2, 96.9 (C_5H_4), 108.2 (C-Cp), 58.6 (C-4), 46.8 (d, $^2J_{PC}$ = 15.5 Hz, C-7), 44.5 (C-6), 25.3, 17.6 (C-5, C-5′); 148.6 [dm, $^1J_{CF}$ = 232 Hz, *o*-$B(C_6F_5)_3$], 137.8 [dm, $^1J_{CF}$ = 241 Hz, *p*-$B(C_6F_5)_3$], 136.8 [dm, $^1J_{CF}$ = 250 Hz, *m*-$B(C_6F_5)_3$], 128.5 [br, *ipso*-$B(C_6F_5)_3$], 10.0 [$B(C_6F_5)_3$-CH_3]; C-*ipso*-Ph resonance not observed. − ^{15}N,^{1}H GHMBC ([D_2]dichloromethane, 60.72/599.99 MHz, 223 K): δ = −376.3/1.61, −376.3/1.01 (N/5-H, N/5′-H). − ^{31}P NMR ([D_2]dichloromethane, 81.02 MHz): δ = 31.2. − $C_{52}H_{38}BF_{15}NPZr$ (1095): calcd. C 57.05, H 3.50, N 1.28; found C 56.10, H 3.75, N 1.15.

Reaction of 3 with Methyldiphenylphosphane. − Preparation of 6b: Analogously as described above a sample of **1** (150 mg, 0.45 mmol) (in 5 mL of dichloromethane) was treated at −36 °C with $B(C_6F_5)_3$ (228 mg, 0.45 mmol) (in 5 mL of dichloromethane), and with methyldiphenylphosphane (89 mg, 0.45 mmol) after 15 min. After workup, as described above, the yield was 237 mg (51%) of complex **6b**, m.p. 199 °C (dec.). − ^{1}H NMR ([D_2]dichloromethane, 599.99 MHz): δ = 7.59 (m, 1 H, Ph-*p*-H), 7.56 (m, 2 H, Ph-*m*-H), 7.51 (m, 1 H, Ph-*p*-H), 7.50 (m, 2 H, Ph-*m*-H), 7.35 (m, 2 H, Ph-*o*-H), 7.21 (m, 2 H, Ph-*o*-H), 6.17, 5.97, 5.80, 4.33 (m, each 1 H, C_5H_4), 5.94 (d, $^3J_{PH}$ = 1.7 Hz, 5 H, Cp−H), 2.52 (s, 3 H, 6-H), 2.05 (d, $^2J_{PH}$ = 6.6 Hz, 3 H, PCH_3), 1.89 (dd, $^2J_{HH}$ = 9.5 Hz, $^3J_{PH}$ = 4.7 Hz, 1 H, 7-H), 1.61, 1.01 (s, each 3 H, 5-H, 5′-H), 1.43 (dd, $^2J_{HH}$ = 9.5 Hz, $^3J_{PH}$ = 2.0 Hz, 1 H, 7-H′), 0.50 [br s, 3 H, $B(C_6F_5)_3$-CH_3]. − ^{13}C {GATED} NMR ([D_2]dichloromethane, 150.84 MHz): δ = 134.9 (d, $^1J_{PC}$ = 36.0 Hz, C-*ipso*-Ph), 133.4 [C-*ipso*-Ph (from GHMBC)], 133.0 (d, $^2J_{PC}$ = 11.2 Hz, C-*o*-Ph), 131.9 (C-*p*-Ph), 131.4 (d, $^2J_{PC}$ = 10.1 Hz, C-*o*-Ph), 131.2 (C-*p*-Ph), 129.8 (d, $^3J_{PC}$ = 9.2 Hz, C-*m*-Ph), 129.5 (d, $^3J_{PC}$ = 9.2 Hz, C-*m*-Ph),

112.6 (C-1), 108.3, 107.0, 106.5, 96.7 (C_5H_4), 107.5 (C-Cp), 58.7 (C-4), 45.9 (d, $^1J_{PC}$ = 15.7 Hz, $^1J_{CH}$ = 146 Hz, $^1J_{CH}$ = 155 Hz, C-7), 44.7 ($^1J_{CH}$ = 138 Hz, C-6), 25.3 ($^1J_{CH}$ = 128 Hz), 17.3 ($^1J_{CH}$ = 128 Hz) (C-5, C-5′), 15.0 ($^1J_{PC}$ = 24.0 Hz, $^1J_{CH}$ = 132 Hz, P*C*H$_3$); 148.6 [dm, $^1J_{CF}$ = 239 Hz, *o*-B(C_6F_5)$_3$], 137.8 [dm, $^1J_{CF}$ = 240 Hz, *p*-B(C_6F_5)$_3$], 136.8 [dm, $^1J_{CF}$ = 245 Hz, *m*-B(C_6F_5)$_3$], 10.5 [B(C_6F_5)$_3$-*C*H$_3$]; *ipso*-B(C_6F_5)$_3$ signal not observed. − ^{15}N,^{1}H GHMBC ([D$_2$]dichloromethane, 60.72/599.99 MHz): δ = −376.7/1.61, −376.7/ 1.01 (N/5-H, N/5-H′). − $C_{47}H_{36}BF_{15}NPZr$ (1033): calcd. C 54.66, H 3.51; found C 54.65, H 3.71.

Reaction of 3 with Cyclopropyl(diphenyl)phosphane. − Preparation of 6c: Complex **3** was generated analogously as described above by treatment of **1** (150 mg, 0.45 mmol) with B(C_6F_5)$_3$ (228 mg, 0.45 mmol) in 3 mL of dichloromethane at −36 °C. Cyclopropyl-(diphenyl)phosphane (101 mg, 0.45 mmol) was added. The mixture was kept at −36 °C for 15 min and then warmed to room temperature. After workup, as described above, the yield was 243 mg (51%) of **6c**, m.p. 195 °C (decomp.). − ^{1}H NMR ([D$_2$]dichloromethane, 599.99 MHz): δ = 7.57 (m, 2 H, Ph-*p*-H), 7.53 (m, 4 H, Ph-*m*-H), 7.34 (m, 4 H, Ph-*o*-H), 6.11, 5.95, 5.86, 4.90 (m, each 1 H, C_5H_4), 6.02 (d, $^3J_{PH}$ = 1.4 Hz, 5 H, Cp−H), 2.47 (s, 3 H, 6-H), 1.79 (m, 1 H, 7-H), 1.61, 1.03 (s, each 3 H, 5-H, 5′-H), 1.43 (m, 1 H, PC*H*), 1.24 (m, 1 H, 7-H′), 1.14 (m, 2 H, P*c*C*H*$_2$), 0.50 [br s, 3 H, B(C_6F_5)$_3$-C*H*$_3$], 0.34 (m, 2 H, P*c*C*H*$_2$). − ^{13}C NMR ([D$_2$]dichloromethane, 150.84 MHz): δ = 133.5 (d, $^2J_{PC}$ = 10.9 Hz, C-*o*-Ph), 133.4 (d, $^2J_{PC}$ = 10.7 Hz, C-*o*-Ph), 131.8 (C-*p*-Ph), 131.6 (C-*p*-Ph), 129.5 (d, $^3J_{PC}$ = 9.0 Hz, C-*m*-Ph), 129.4 (d, $^3J_{PC}$ = 9.2 Hz, C-*m*-Ph), 112.4 (C-1), 107.9, 107.0, 106.8, 96.8 (C_5H_4), 107.5 (C-Cp), 58.7 (C-4), 46.7 (d, $^2J_{PC}$ = 15.8 Hz, C-7), 44.6 (C-6), 25.4, 17.0 (C-5, C-5′), 14.2 (s, P*C*H), 8.3 (d, $^1J_{PC}$ = 29.2 Hz, P*C*H), 5.7 (br, P*c*C*H*$_2$), 5.4 (d, $^2J_{PC}$ = 4.1 Hz, P*c*C*H*$_2$); 148.6 [dm, $^1J_{CF}$ = 239 Hz, *o*-B(C_6F_5)$_3$], 137.8 [dm, $^1J_{CF}$ = 240 Hz, *p*-B(C_6F_5)$_3$], 136.8 [dm, $^1J_{CF}$ = 245 Hz, *m*-B(C_6F_5)$_3$], 10.2 [B(C_6F_5)$_3$-*C*H$_3$]; *ipso*-B(C_6F_5)$_3$ and C-*ipso*-Ph signals not observed. − ^{15}N,^{1}H GHMBC ([D$_2$]dichloromethane, 60.72/599.99 MHz): δ = −376.2/1.61, −376.2/1.03 (N/5-H, N/5′-H). − $C_{49}H_{38}BF_{15}NPZr$ (1059): calcd. C 55.58, H 3.62, N 1.32; found C 55.70, H 3.50, N 1.31.

Reaction of 3 with Benzophenone. − Preparation of 7: A cold solution (−30 °C) containing **1** (150 mg, 0.45 mmol) in 3 mL of bromobenzene was treated with a solution of B(C_6F_5)$_3$ (228 mg, 0.45 mmol) in 6 mL of bromobenzene at −30 °C. The mixture was stirred for 15 min to generate **3**. Benzophenone (81 mg, 0.45 mmol) was then added. After 15 min at −30 °C, the red mixture was warmed to room temperature and the product was precipitated as a red oil by the addition of pentane (6 mL). The organic phase was decanted off. The residue was washed 4 times with pentane (3 mL each) and dried in vacuo to yield 265 mg (58%) of **7**, m.p. 213 °C (dec.). − ^{1}H NMR ([D$_2$]dichloromethane, 599.99 MHz, 223 K): δ = 7.71 (m, 2 H, Ph-*o*-H), 7.48 (m, 2 H, Ph-*m*-H), 7.35 (m, 1 H, Ph-*p*-H), 7.22 (m, 2 H, Ph-*o*-H), 7.11 (m, 3 H, Ph-*m*-H, Ph-*p*-H), 6.45, 6.37, 6.23, 6.17 (C_5H_4), 6.11 (s, 5 H, Cp-H), 3.90 (d, $^2J_{HH}$ = 13.8 Hz, 1 H, 7-H), 3.57 (d, $^2J_{HH}$ = 13.8 Hz, 1 H, 7-H), 2.41 (s, 3 H, 6-H), 1.65, 1.50 (s, each 3 H, 5-H, 5′-H), 0.40 [br s, 3 H, B(C_6F_5)$_3$-C*H*$_3$]. − ^{13}C NMR ([D$_2$]dichloromethane, 150.84 MHz, 223 K): δ = 147.0, 143.9 (each C-*ipso*-Ph), 128.3, 128.3 (each C-*m*-Ph), 127.3, 126.7 (C-*p*-Ph), 125.5, 124.4 (C-*o*-Ph), 125.9, 107.5, 106.7, 104.9 (C_5H_4), 125.0 (C1), 114.2 (C-Cp), 88.4 (C-8), 66.6 (C-7), 61.0 (C-4), 41.7 (C-6), 25.5, 22.5 (C-5, C-5′), 147.7 [dm, $^1J_{CF}$ = 241 Hz, *o*-B(C_6F_5)$_3$], 137.0 [dm, $^1J_{CF}$ = 250 Hz, *p*-B(C_6F_5)$_3$], 135.9 [dm, $^1J_{CF}$ = 247 Hz, *m*-B(C_6F_5)$_3$], 128.1 [br, *ipso*-B(C_6F_5)$_3$], 9.4 [B(C_6F_5)$_3$-C*H*$_3$]. − ^{15}N,^{1}H GHMBC ([D$_2$]dichloromethane, 60.72/599.99 MHz, 223 K): δ = −339.2/1.65, −339.2/1.50 (N/5-H, N/5-H). − $C_{47}H_{33}BF_{15}NOZr$ (1014.8): calcd. C 55.63, H 3.28, N 1.38; found C 55.52, H 3.47, N 1.46.

Treatment of 3 with Ethene. − Generation of 8: The insertion reaction was carried out as an NMR-spectroscopic experiment. A sample of **1** (11 mg, 29 μmol) was dissolved in 0.5 mL of [D$_2$]dichloromethane and this mixture was added at −50 °C to solid B(C_6F_5)$_3$ (15 mg, 29 μmol). The formation of **3** was monitored by NMR spectroscopy. Gaseous ethene (2 mL) was then introduced into the solution. The NMR-spectroscopic analysis at −50 °C revealed the clean formation of **8**. − ^{1}H NMR ([D$_2$]dichloromethane, 599.99 MHz, 223 K): δ = 7.40 (m, 1 H, 2′-H), 6.58 (s, 5 H, Cp-H), 6.44, 6.33 (m, each 1 H, 3-H, 3′-H), 6.37 (m, 1 H, 2-H), 3.38 (pt, 1 H, 7-H), 2.36 (m, 1 H, 9-H), 2.29 (m, 1 H, 7-H′), 2.27 (s, 3 H, 6-H), 2.02 (m, 1 H, 8-H), 1.75 (m, 1 H, 9-H′), 1.54 (m, 1 H, 8-H′), 1.48, 1.28 (s, each 3 H, 5-H, 5′-H), 0.39 [br s, 3 H, (C_6F_5)$_3$BC*H*$_3$]. − ^{13}C {GATED} NMR ([D$_2$]dichloromethane, 150.84 MHz, 223 K): δ = 121.8 (C-1), 118.4 ($^1J_{CH}$ = 177 Hz), 110.2 ($^1J_{CH}$ = 177 Hz) (C-3, C-3′), 117.1 ($^1J_{CH}$ = 175 Hz, C-2′), 115.2 ($^1J_{CH}$ = 175 Hz, C-Cp), 106.9 ($^1J_{CH}$ = 173 Hz, C-2), 63.1 (C-4), 53.4 ($^1J_{CH}$ = 144 Hz, C-7), 46.8 ($^1J_{CH}$ = 132 Hz, C-9), 41.2 ($^1J_{CH}$ = 139 Hz, C-6), 24.9 ($^1J_{CH}$ = 129 Hz), 20.9 ($^1J_{CH}$ = 129 Hz) (C-5, C-5′); 14.3 ($^1J_{CH}$ = 124 Hz, C-8), 147.7 [dm, $^1J_{CF}$ = 238 Hz, *o*-B(C_6F_5)$_3$], 137.0 [dm, $^1J_{CF}$ = 254 Hz, *p*-B(C_6F_5)$_3$], 135.9 [dm, $^1J_{CF}$ = 242 Hz, *m*-B(C_6F_5)$_3$], 127.8 [br, *ipso*-B(C_6F_5)$_3$], 9.5 [B(C_6F_5)$_3$-*C*H$_3$]. − ^{15}N,^{1}H GHMBC ([D$_2$]dichloromethane, 60.72/599.99 MHz, 223 K): δ = −348.9/1.48, −348.9/1.28 (N/5-H, N/5′-H).

Reaction of 3 with Styrene. − Preparation of 9a: A cold solution (−36 °C) containing **1** (150 mg, 0.45 mmol) in 3 mL of dichloromethane was added to solid B(C_6F_5)$_3$ (228 mg, 0.45 mmol). The mixture was stirred for 30 min to generate **3**. Styrene (47 mg, 0.45 mmol) was then added. After 45 min at −36 °C, the mixture was warmed to room temperature and the product was precipitated as a red oil by the dropwise addition of pentane (9 mL). The organic phase was carefully decanted. The remaining oil was washed with pentane (3 × 3 mL). Pentane (9 mL) was then added and the product stirred overnight to give a pale red solid, which was collected to yield 334 mg (79%) of **9a**, m.p. 211 °C (dec.). − ^{1}H NMR ([D$_2$]dichloromethane, 599.99 MHz): δ = 7.57 (m, 2 H, 12-H, 12′-H), 7.21 (t, $^3J_{HH}$ = 6.0 Hz, 13-H), 6.35 (s, 5 H, Cp-H), 5.97, 5.85, 4.71, 4.27 (m, each 1 H, C_5H_4), 3.92 (pd, 1 H, 9-H), 3.62 (m, 1 H, 7-H), 2.78 (m, 1 H, 8-H), 2.69 (m, 1 H, 7-H′), 2.42 (s, 3 H, 6-H), 2.35 (m, 1 H, 8-H′), 1.50, 1.39 (s, each 3 H, 5-H, 5-H′), 0.50 [br s, 3 H, B(C_6F_5)$_3$-C*H*$_3$]; remaining Ph-H signals not observed because of a dynamic process. − ^{1}H NMR ([D$_2$]dichloromethane, 599.99 MHz, 223 K): δ = 7.63 (t, $^3J_{HH}$ = 8.0 Hz, 1 H, 12′-H), 7.42 (t, $^3J_{HH}$ = 8.0 Hz, 1 H, 12-H), 7.15 (t, $^3J_{HH}$ = 8.0 Hz, 1 H, 13-H), 7.07 (d, $^3J_{HH}$ = 8.0 Hz, 1 H, 11′-H), 5.49 (d, $^3J_{HH}$ = 8.0 Hz, 1 H, 11-H), 6.31 (s, 5 H, Cp-H), 5.95, 5.82, 4.62, 4.19 (m, each 1 H, C_5H_4), 3.87 (m, 1 H, 9-H), 3.54 (m, 1 H, 7-H), 2.72 (m, 1 H, 8-H), 2.64 (m, 1-H, 7-H′), 2.36 (s, 3 H, 6-H), 2.29 (m, 1 H, 8-H′), 1.45, 1.33 (s, each 3 H, 5-H, 5′-H), 0.39 [br s, 3 H, B(C_6F_5)$_3$-C*H*$_3$]. − ^{13}C {GATED} NMR ([D$_2$]dichloromethane, 150.84 MHz, 223 K): δ = 138.4 (C-10), 139.3 ($^1J_{CH}$ = 162 Hz, C-12), 134.7 ($^1J_{CH}$ = 160 Hz, C-12′), 125.9, 109.3, 106.2, 102.0 (C_5H_4), 124.1 ($^1J_{CH}$ = 162 Hz, C-13), 123.6 ($^1J_{CH}$ = 160 Hz, C-11′), 118.6 (C-1), 112.1 (C-Cp), 88.2 ($^1J_{CH}$ = 150 Hz, C-11), 70.0 ($^1J_{CH}$ = 145 Hz, C-9), 63.4 (C-7), 61.5 (C-4), 40.8 (C-6), 25.1, 22.6 (C-5, C-5′), 23.8 (C-8), 147.6 [dm, $^1J_{CF}$ = 240 Hz, *o*-B(C_6F_5)$_3$], 137.2 [dm, $^1J_{CF}$ = 259 Hz *p*-B(C_6F_5)$_3$], 135.8 [dm, $^1J_{CF}$ = 240 Hz, *m*-B(C_6F_5)$_3$], 127.8 [br, *ipso*-B(C_6F_5)$_3$], 9.5 [B(C_6F_5)$_3$-*C*H$_3$]. − ^{15}N,^{1}H GHMBC ([D$_2$]dichloromethane, 60.72/599.99 MHz): δ = −352.7/1.50,

−352.7/1.39 (N/5-H, N/5′-H). − Coalescence: 12-H and 12′-H: $\Delta G^{\neq} = 10.6 \pm 0.5$ kcal/mol ($T_C = 268$ K, $\Delta\nu = 126$ Hz; $[D_2]$dichloromethane). − $C_{42}H_{31}BF_{15}NZr$ (936.7): calcd. C 53.85, H 3.34, N 1.50; found C 54.00, H 3.28, N 1.23.

Reaction of 3 with 4-*tert*-Butylstyrene. − Preparation of 9b: Analogously as described above, complex **1** (150 mg, 0.45 mmol) was treated with $B(C_6F_5)_3$ (228 mg, 0.45 mmol) in dichloromethane (−36 °C) and after 15 min with 4-*tert*-butylstyrene (72 mg, 0.45 mmol). After 30 min at −36 °C, the mixture was warmed to room temperature. After workup as described above, the yield was 321 mg (72%) of complex **9b**. Single crystals of **9b** suitable for the X-ray crystal structure analysis were obtained by allowing diethyl ether vapor to diffuse into a solution of **9b** in dichloromethane at −36 °C; m.p. 124 °C. − ^{1}H NMR ($[D_2]$dichloromethane, 599.99 MHz): δ = 7.60 (br m, 2 H, 12′-H, 12-H), 6.34 (s, 5 H, Cp-H), 5.98, 5.83, 4.73, 4.16 (m, each 1 H, C_5H_4), 3.86 (pd, 1 H, 9-H), 3.62 (m, 1 H, 7-H), 2.77 (m, 1 H, 8-H), 2.67 (m, 1 H, 7-H′), 2.40 (s, 3 H, 6-H), 2.34 (m, 1 H, 8-H′), 1.50, 1.38 (s, each 3 H, 5-H, 5′-H), 1.34 (s, 9 H, 15-H), 0.50 [br s, 3 H, $B(C_6F_5)_3$-CH_3]; remaining Ph-H signals not observed because of a dynamic process. −^{1}H NMR ($[D_2]$dichloromethane, 599.99 MHz, 233 K): δ = 7.73 (d, $^3J_{HH}$ = 7.5 Hz, 1 H, 12′-H), 7.30 (d, $^3J_{HH}$ = 8.7 Hz, 1 H, 12-H), 7.06 (d, $^3J_{HH}$ = 7.5 Hz, 1 H, 11′-H), 6.31 (s, 5 H, Cp-H), 5.96, 5.81, 4.66, 4.07 (m, each 1 H, C_5H_4), 5.46 (d, $^3J_{HH}$ = 8.7 Hz, 1 H, 11-H), 3.82 (pd, 1 H, 9-H), 3.55 (m, 1 H, 7-H), 2.72 (m, 1 H, 8-H), 2.64 (m, 1 H, 7-H′), 2.35 (s, 3 H, 6-H), 2.28 (m, 1 H, 8-H′), 1.45, 1.33 (s, each 3 H, 5-H, 5′-H), 1.29 (s, 9 H, 15-H), 0.42 [br s, 3 H, $B(C_6F_5)_3$-CH_3]. − ^{13}C {GATED} NMR ($[D_2]$dichloromethane, 150.84 MHz, 233 K): δ = 147.6 (C-13), 135.6 (C-10), 133.6 ($^1J_{CH}$ = 159 Hz, C-12), 133.5 ($^1J_{CH}$ = 157 Hz, C-12′), 124.8 ($^1J_{CH}$ = 175 Hz), 109.0 ($^1J_{CH}$ = 174 Hz), 106.9 ($^1J_{CH}$ = 175 Hz), 101.9 ($^1J_{CH}$ = 173 Hz) (C_5H_4), 124.0 ($^1J_{CH}$ = 159 Hz, C-11′), 118.9 (C-1), 112.1 ($^1J_{CH}$ = 175 Hz, C-Cp), 88.7 ($^1J_{CH}$ = 150 Hz, C-11), 69.6 ($^1J_{CH}$ = 141 Hz, C-9), 63.6 ($^1J_{CH}$ = 136 Hz, C-7), 61.5 (C-4), 40.8 ($^1J_{CH}$ = 138 Hz, C-6), 34.4 (C-14), 30.6 ($^1J_{CH}$ = 126 Hz, C-15), 25.1 ($^1J_{CH}$ = 127 Hz), 22.5 ($^1J_{CH}$ = 128 Hz) (C-5, C-5′), 24.1 ($^1J_{CH}$ = 126 Hz, C-8), 148.6 [dm, $^1J_{CF}$ = 234 Hz, *o*-$B(C_6F_5)_3$], 137.8 [dm, $^1J_{CF}$ = 239 Hz, *p*-$B(C_6F_5)_3$], 136.8 [dm, $^1J_{CF}$ = 248 Hz, *m*-$B(C_6F_5)_3$], 128.7 [br, *ipso*-$B(C_6F_5)_3$], 9.9 [$B(C_6F_5)_3$-CH_3]. − ^{15}N,^{1}H GHMBC ($[D_2]$dichloromethane, 60.72/599.99 MHz): δ = −352.4/1.45, −352.4/1.33 (N/5-H, N/5′-H). − Coalescence: 12-H and 12′-H: $\Delta G^{\neq} = 10.7 \pm 0.5$ kcal/mol ($T_C = 278$ K, $\Delta\nu = 258$ Hz; $[D_2]$dichloromethane) − $C_{46}H_{39}BF_{15}NZr$ (992.8): calcd. Carboxylation of Acetophenone with Zinc(II) Alkoxides/CO_2 Systems: A Mechanistic Study

Michael Kunert,[a] Michael Bräuer,[a] Olaf Klobes,[b] Helmar Görls,[c] Eckhard Dinjus,*[b] and Ernst Anders[a]

Dedicated to Professor Dirk Walther on the occasion of his 60th birthday

Keywords: Zinc / Carbon dioxide fixation / Carboxylato complexes / CH-acidic substrates / Ab initio calculations

The crystal structures of the homoleptic dimer zinc(II) 2,6-di-*tert*-butylphenoxide (**1b**) and of the corresponding monomer **1b/**$(DMSO)_2$ are presented. The structural motif of **1b** is a Zn–O–Zn–O four-membered ring. The bulky phenoxide ligands led to a coordination number of only three for the zinc atom. Monomer **1b/**$(DMSO)_2$ crystallized as a four-coordinated monomer with a highly distorted tetrahedral geometry around the zinc center. ^{13}C NMR investigations reveal details for the reaction of CO_2 with a series of alkoxide zinc(II)/solvent systems [2,6-dimethylphenoxide zinc(II) (**1a**), zinc(II) 2,6-di-*tert*-butylphenoxide (**1b**), zinc(II) 2,6-diphenylphenoxide (**1c**), zinc(II) 4-*tert*-butylphenoxide (**1d**), and zinc(II) 2-pyridylcarbinolato (**2**)]. The interpretation of the ^{13}C NMR signals agree with ab initio calculations of a model zinc(II) phenoxide/CO_2 system. Experimentally, the carboxylation of acetophenone as a representative for CH-acidic substrates was carried out with specific zinc(II) phenoxide/CO_2 systems. The reactions resulted in yields of ca. 40% of benzoyl acetic acid. The role of the soluble zinc(II) phenylcarbonate intermediate is discussed with respect to the subsequent CO_2 transfer reaction.

Introduction

Several investigations intermediate into the mechanism of the activation of CO_2 by Zn^{II} complexes are documented.[1,2,5] Some of the fundamental understanding was obtained from the investigation of the mechanism of the copolymerization of CO_2 and epoxides.[1,3,5] However, the number of soluble zinc(II) compounds which are amenable to mechanistic investigations is limited. A synthesis first reported by Caulton allows for the preparation of soluble homoleptic zinc(II) alkoxide compounds (Figure 2).[4] The majority of the compounds prepared by this method are monomeric zinc(II) alkoxide structures.[4,5]

Darensbourg reported on the copolymerization process of cyclohexene oxide and CO_2 using zinc(II) phenoxides at 80 °C and a pressure of 55 bar.[5] NMR investigations revealed a shift of the carbon peak of CO_2 (170 ppm). This was demonstrated for the reaction of CO_2 with zinc(II) 2,4,6-trimethylphenoxide in pyridine at room temperature. The insertion of CO_2 into only one metal phenoxide group was proposed. This is in agreement with the X-ray structure of the dimeric $[Cd(S_2CO\text{-}2,6\text{-}Ph_2C_6H_3)]_2(\mu\text{-}O\text{-}2,6\text{-}Ph_2C_6H_3)_2$ obtained from the reaction of CS_2 with the corresponding cadmium(II) phenoxide (cf. Figure 7).[6]

In this paper new results concerning the activation and the transfer of CO_2 mediated by homoleptic zinc(II) alkoxide complexes are reported. The carboxylation of acetophenone to give benzoyl acetic acid at ambient temperature is described (Figure 1). This represents a novel application of easily accessible zinc complexes.

Results and Discussion

1. Crystal Structure of Zinc(II) 2,6-Di-*tert*-butylphenoxide and Zinc(II) 2,6-Di-*tert*-butylphenoxide/$(DMSO)_2$

X-ray structures of zinc(II) phenoxides thus far reported indicate the preference of monomeric complexes which contain solvent molecules or phosphane ligands in the coordination polyhedron.[1,4,5,7] In the case of dimeric structures, there are heteroleptic compounds such as alkyl(alkyloxy) zinc(II), alkyl(aryloxy) zinc(II) compounds or $\{Zn[\mu\text{-}OCEt_3)[N(SiMe_3)_2]\}_2$.[8] For the zinc(II) 2,4,6-tris-*tert*-butylphenoxide in THF solution, an aggregation to a stereochemically rigid dimer has been reported by Caulton by means of cryoscopic molecular weight determination.[4]

We now report on the X-ray structure of a homoleptic dimeric zinc(II) 2,6-di-*tert*-butylphenoxide complex crystallized from pentane (Figure 3).[9] The synthesis was performed in THF or toluene under an argon atmosphere, as previously described (Figure 2).[4,5]

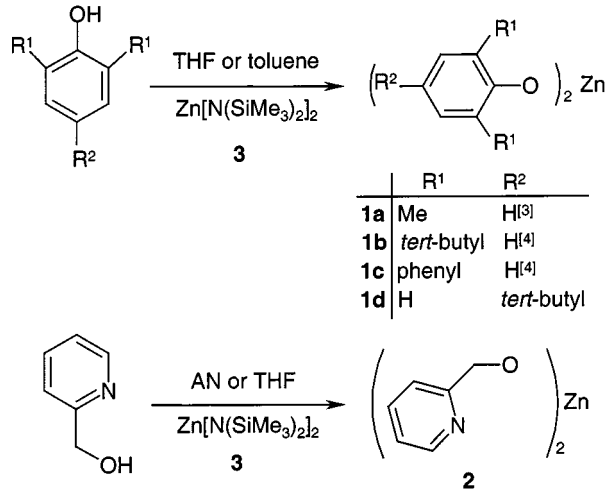

Figure 2. Synthesis of zinc(II) alkoxides

This complex contains a central four-membered Zn−O−Zn−O ring (Figure 3). The metal cation is coordinated in a distorted trigonal planar geometry. The Zn−O bond lengths of the bridging Zn−O−Zn moiety [(Zn1−O2 (1.941(1) Å, Zn1−O4(1.975(1) Å, Zn2−O2(1.980(1) Å, Zn2−O4(1.949(1) Å] are significantly larger than the terminal bonds [Zn1−O1 1.831(1) Å) and Zn2−O3 1.839(1) Å].

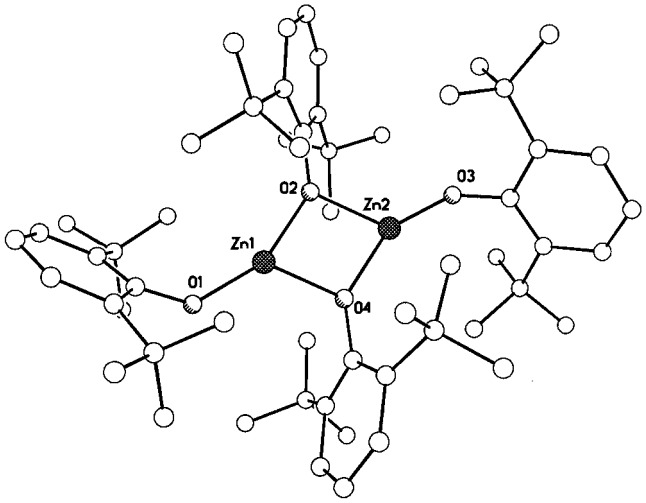

Figure 3. X-ray structure of the dimer of **1b**. Selected distances [Å] and bond angels [°]: Zn1−O1 1.831(2), Zn1−O2 1.941(2), Zn1−O4 1.975(2), Zn2−O3 1.839(2), Zn2−O2 1.980(2), Zn2−O4 1.949(2), Zn1−Zn2 2.9484(6), O1−C1 1.377(4), O3−C29 1.359(4), O2−C15 1.404(4), O4−C43 1.405(4), O1−Zn1−O2 150.5(1), O1−Zn1−O4 125.3(1), O2−Zn1−O4 82.6(1), O4−Zn2−O2 82.3(1)

The terminal zinc O(aryl) distances are equal within the experimental error to those found for the monomeric zinc complexes 2,6-di-*tert*-butylphenoxide−ZnL with L = $MePh_2$ and PCy_3 [Zn−O 1.845(4) and Zn−O 1.869 (3) Å].[7] In these complexes, the zinc atom is also coordinated in an analogous trigonal planar fashion. In the monomeric Zn^{II} phenoxide/(oxygen or nitrogen donor ligand)$_2$ structures which are reported, and also in the structure of **1b**/$(DMSO)_2$ (Figure 4), the zinc atom prefers a distorted tetrahedral coordination.[4,5,10] Also in these cases, the Zn−O bond lengths are in the range of Zn−O 1.846(11) [2,6-diisopropylphenoxide−zinc(II)/$(THF)_2$] to Zn−O 1.908(1) Å [**1b**/$(DMSO)_2$]. They are slightly longer than those of the bridged Zn−O bonds in the homoleptic dimeric structure. In heteroleptic dimeric zinc(II) compounds, the Zn−O distances [e.g. Zn−O 1.970(1) Å,[8a] 1.930(3) Å,[8b] 2.075(2) Å[8c]] are comparable to the bridging Zn−O bonds in **1b**. In general, the addition of solvent molecules to an unsolvated species leads to a ca. 0.1 Å shorter Zn−O(aryl) distance, which is easily understood in terms of electrostatic effects. In the dimeric structure, the oxygen interacts with two zinc centers.

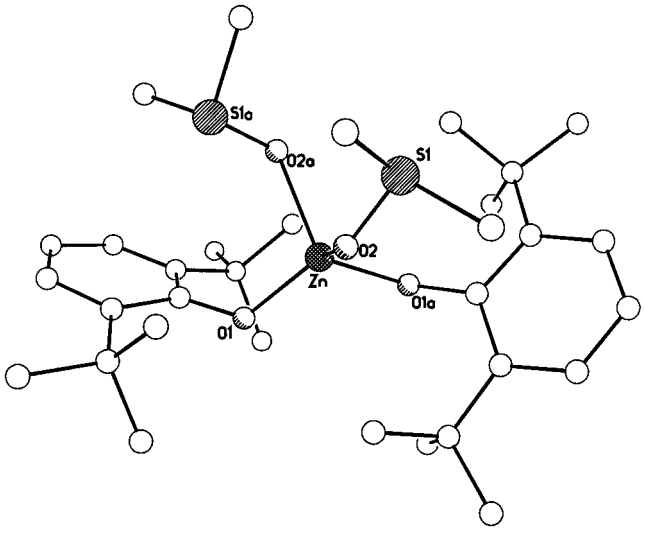

Figure 4. X-ray structure of the monomer of **1b**/$(DMSO)_2$. Selected distances [Å] and bond angels [°]: Zn−O1 1.907(1), Zn−O2 2.044(1), O1−C1 1.341(2), O1−Zn−O2 123.52(4), O1−Zn−O1a 108.77(6), O1−Zn−O2a 104.43(4), O2−Zn−O2a 93.04(7)

2. Reactivity of CO_2 with Zinc(II) Phenoxides in DMSO

The reaction of CO_2 with zinc(II) alkoxides has been studied by means of NMR spectroscopy in order to characterize the structure of a soluble phenoxide zinc(II)/CO_2 intermediate. Such an activated CO_2 is an essential prerequisite to enable the carboxylation of CH-acidic compounds at room temperature. We performed ^{13}C and ^{1}H NMR investigations in [D6]DMSO, [D7]DMF and [D5]pyridine before and after addition of CO_2. A typical NMR experiment is depicted in Figure 5 and 6 (see also Table 1).

After the addition of $^{13}CO_2$ and warming at 40 °C for 6 hours, the spectrum showed the ^{13}C chemical shifts of **1a.** Relative to these ^{13}C NMR signals, a downfield shift of the signals for the phenoxide *para*- and *ortho* carbons of 5.5 and 2.2 ppm (from δ = 113 to δ = 119 and from δ = 126 to δ = 128, respectively) was observed. This was accompanied by an upfield shift of the signal for the *ipso* carbon atom of 7.2 ppm (from δ = 163 to δ = 155). Physically dissolved $^{13}CO_2$ has a chemical shift of δ = 124. Apart from the

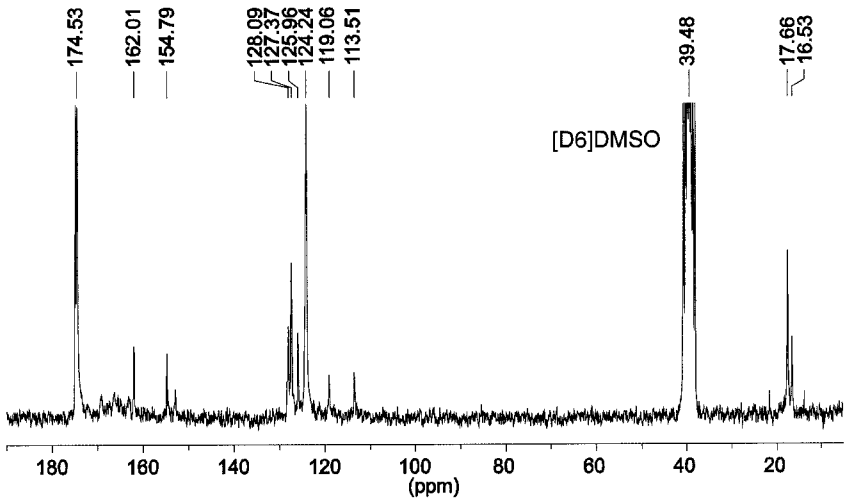

Figure 5. ^{13}C NMR spectra of **1a** in [D_6]DMSO after the addition of $^{13}CO_2$ and 6 h at 40 °C

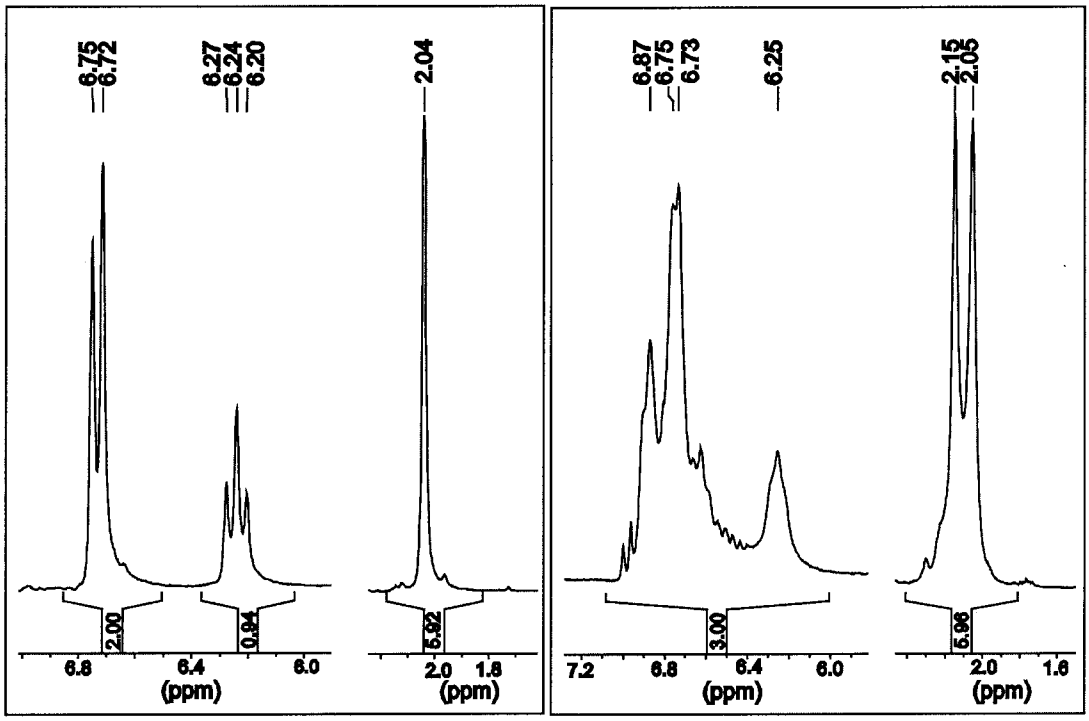

Figure 6. ^1H NMR spectra of **1a** in [D_6]DMSO and after the addition of $^{13}CO_2$ and 6 h at 40 °C

chemical shifts of the phenyl ring carbon atoms, an intense signal was detected at $\delta = 174.3$. After the addition of $^{13}CO_2$, the ^1H NMR spectrum showed a multiplet for the phenoxide hydrogen atoms and a signal at $\delta = 2.15$ in addition to the signal for the methyl hydrogen atom of **1a**. The integration of these two methyl signals suggests a 1:1 molar ratio. This is in agreement with the structure of a 2,6-diphenylphenoxide/CS_2 cadmium(II) complex and the results of the ^{13}C NMR investigations reported by Darensbourg (Figure 7).[5,6]

In contrast to Darensbourg's results, a reaction of the sterically hindered **1b** with CO_2 could be observed in DMSO.[4] The NMR spectrum is similar to that of 2,6-dimethylphenoxide zinc(II) (Table 1). Darensbourg proposed that the initiation process of the copolymer synthesis was the epoxide ring opening, because CO_2 showed no reactivity with sterically hindered zinc(II) phenoxide complexes. With our result we have found a new argument for a CO_2 insertion into the Zn−O bond as the first step of the mechanism of these reaction.

In agreement with the results of Darensbourg, **1a** and **1b** do not react with CO_2 in pyridine.[5] Also in the case of **1c** in various solvents (DMSO, DMF, pyridine, THF) and of **1d** in pyridine (**1d** is only soluble in pyridine) no such reactions were observed by ^{13}C NMR investigations. On further warming of **1d** to 60 °C, a white powder precipitated and an NMR experiment could not be performed. The product was isolated and washed with pentane. It was insoluble in

Table 1. Comparison of calculated and experimental ^{13}C chemical shifts of metal phenoxide systems

molecule	C_{CO2} δ values	C_{ipso} δ values	C_{para} δ values

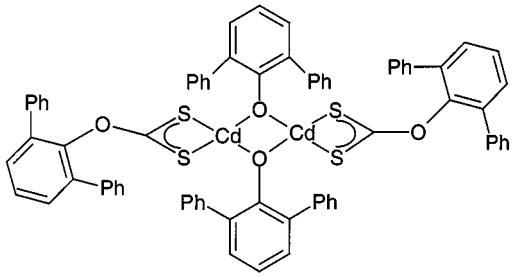

Figure 7. $[Cd(S_2CO\text{-}2,6\text{-}Ph_2C_6H_3)]_2(\mu\text{-}O\text{-}2,6\text{-}Ph_2C_6H_3)_2$ [6]

water and reacted with dilute HCl (gas evolution). In the MS measurement, both the phenol and CO_2 could be detected. We presumed that the complete reaction of CO_2 with both Zn−O(aryl) bonds of the phenoxide leads to an insoluble phenylcarbonate zinc(II). The formation of a soluble alkoxide zinc(II)/CO_2 complex is dependent on the solvent which is used and the steric demand of the phenol ligands.

In the case of the (2-pyridylcarbinolato)zinc(II) complex **2**, no signal was found in the region of δ = 170, but in pyridine a markedly broadened signal at δ = 156 was observed. Additionally, the broadened signals for the carbon atoms of the ring indicated an equilibrium reaction of the complex with CO_2. In order to get insight into the mechanism of this CO_2 insertion, quantum mechanical calculations on the model system zinc(II) phenoxide were carried out.

3. Ab initio Calculations

Darensbourg has shown a significant binding of various solvent molecules to the zinc center of phenoxide zinc(II) compounds in solution even at ambient temperature.[5] Unfortunately, computational limitations prevented us from considering the effects of microsolvation and thus explicit solvent molecules were not included in the model. However, as will be shown, our calculations agree well with the experimental data, thus verifying the validity of our approach. An analogous reaction mechanism for carbonic anhydrase was previously proposed for the activation of carbon dioxide.[11]

Due to the considerable size of the molecular geometry, optimizations were restricted to the HF/G-311+G* level of theory. All geometries were fully optimized and the nature of the stationary points characterized by harmonic frequency analysis. B3LYP/G-311+G* single point calculations were performed on the optimized geometries in order to introduce electron correlation into the energy calculation. The Gaussian94 set of programs was used.

The proposed mechanism is depicted in Figure 8. One of the electron lone pairs of the zinc-bonded oxygen interacts with the carbon of CO_2 to form the electrostatic encounter complex **II** (−2.79 kcal mol^{-1}). This facilitates the nucleophilic attack, leading to the intermediate product **III** (6.92 kcal mol^{-1}) which can rearrange to form the more stable insertion product **IV** (3.24 kcal/mol). This energy profile suggests a reversibility of the reaction.

The calculated stability of the encounter complex in solution must be questioned because electrostatic interactions in general decrease in the presence of solvent molecules.

The calculated Zn−O distance (1.78 Å) is found to be 0.15 Å shorter than the terminal Zn−O distances in the X-ray structure (cf. Figure 3). Considering the absence of dative solvent molecules in the calculated structure this fact is not surprising. In a previous study on the corresponding sodium compounds, the deviations from the experimental structures were in the range of 0.3−0.4 Å.[12] The choice of the model and the level of theory can therefore be considered to be satisfactory. The most important structural features are summarized in Figure 8. For the structures **I**−**IV**, we calculated the ^{13}C chemical shifts (Table 1). The RHF/6−311+G* level of theory on the formerly optimized geometries were used, following the guidelines reported by Chesseman et al.[13] Analogous results could be calculated in the case of the formation of the sodium phenyl carbonate.

These data allow for the verification of the ^{13}C NMR interpretation, summarized in the second part of this study. The peak at ca. 174 ppm can be assigned unambiguously to the inserted CO_2 carbon of the carbonate structure **IV**. There is also an upfield shift of the ^{13}C NMR signal of the *ipso* carbon atom and a downfield shift of the signal for the phenoxide *para* carbon, when following the reaction course from the zinc(II) phenoxide to zinc(II) phenylcarbonate.

In the case of the reaction of **2** with CO_2, the broadened signal at δ = 156 is an indicative of the existence of an equilibrium between the reactants and/or intermediate products such as **III** and **IV**.

4. Carboxylation of Acetophenone

The carboxylation of CH-acidic substrates (e.g. acetone or acetophenone) with an alkaline phenoxide solvent system was first carried out by Bottachio et al.[14] He postulated the formation of phenol and an enolate which is stabilized by the appropriate solvent in a very complex equilibrium. In a successive step, the enolate reacts with CO_2 to give the alkaline salt of the carboxylic acid. Walther et al.

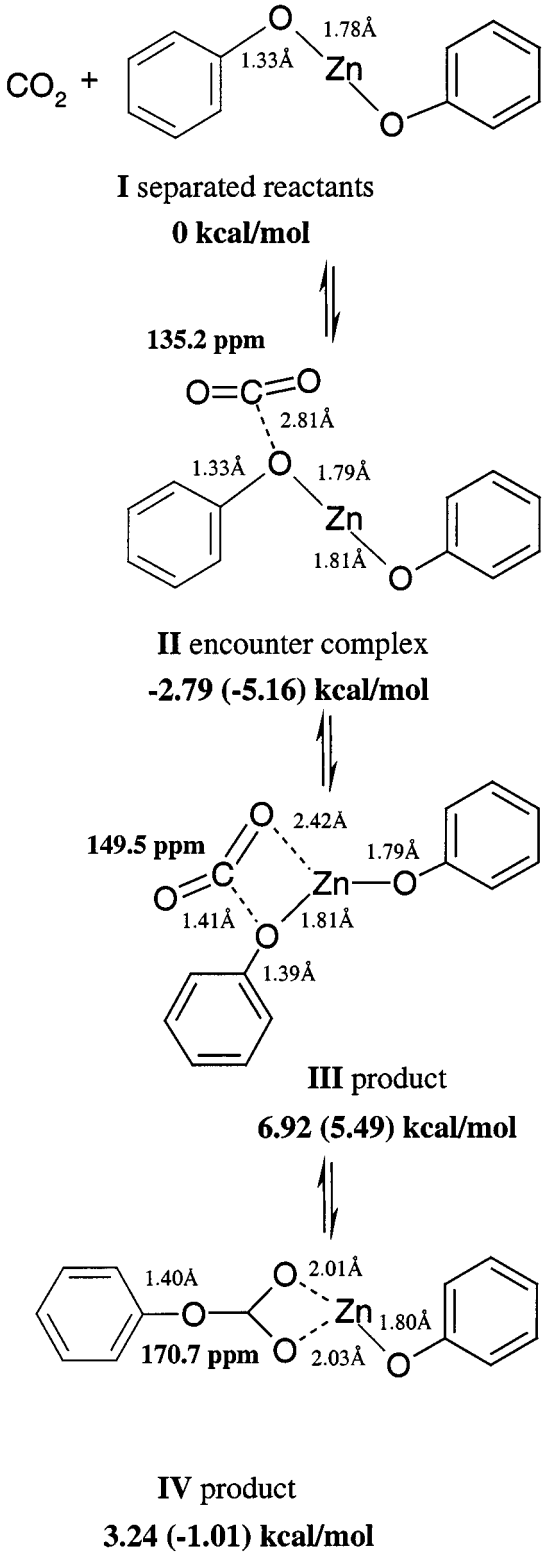

Figure 8. Quantum mechanical calculations on the model system phenoxide zinc(II)/CO_2 [geometries, relative energies, ^{13}C chemical shifts (δ, ppm relative to TMS) - B3LYP/6−311+G*//RHF/6−311+G* level of theory, HF results in parentheses]

postulated the activation of CO_2 by NaOPh/solvent complexes.[15] They obtained particularly high yields of carboxylic acids with a NaOPh/solvent ratio of 4−5:1 at room temperature. The use of magnesium enolates or carbamates had also been reported for these reactions.[16]

In our investigations, the carboxylation of acetophenone was carried out with zinc(II) alkoxide complexes (Table 2)

Table 2. Yield of the carboxylation of acetophenone in DMSO to afford benzoyl acetic acid

Complex	Yield [%]		
	25 °C	40 °C	80 °C
Zinc(II) 2,6-dimethylphenoxide (**1a**)	33	46	32
Zinc(II) 2,6-di-*tert*-butylphenylphenoxide (**1b**)	24	37	25
Zinc(II) 2,6-diphenylphenoxide (**1c**)	4	23	<1
Zinc(II) 4-*tert*-butylphenoxide (**1d**)	0	0	0
(2-Pyridylcarbinolato)zinc(II) (**2**)	<1	<1	<1
Bis(trimethylsilylamido)zinc(II) (**3**)	5	4, 16[a]	8

[a]In THF.

The ligand, the solvent and the temperature were varied. Best results were obtained using **1a** and **1b** at a temperature of 40 °C in DMSO. Comparable yields resulted in cases for which a molar ratio of 3:1 of the zinc(II) complexes to acetophenone was applied. The lower yield of benzoyl acetic acid observed at a reaction temperature of 80 °C indicates a plausible but unwanted decarboxylation. A further explanation for the decreasing yield could be the formation of an insoluble phenylcarbonate zinc(II), which would limit the transfer of the CO_2 at this temperature.

The use of **1c** in DMSO for the reaction led to a lower yield of the benzoyl acetic acid. This can be explained both by a complete reaction of CO_2 to a zinc(II) 2,6-diphenylphenylcarbonate and by a poor solubility of the insertion product. In the case of **1d** dissolved in pyridine, the addition of CO_2 led to a precipitation of the previously described "white powder". After addition of acetophenone, no benzoyl acetic was detected.

Solvent dependence: For **1a**−**1c** dissolved in pyridine, the detection of a reaction with $^{13}CO_2$ in the NMR investigations and also the carboxylation failed. It worth noting that although the starting $Zn[N(SiMe_3)]_2$ **3** does not undergo an insertion reaction with CO_2, the amide **3** also enabled the carboxylation of acetophenone. The model reaction requires a zinc(II) complex which is soluble in the presence of CO_2. Reaction of the phenoxide zinc(II) complexes with acetophenone (i.e. without CO_2) was not observed in our NMR investigations. Our experiments revealed no indication of the formation of acetophenolate zinc(II) and phenol. The charge on the carbon of the activated complexes (natural charge of **III**: q_c = 0.9974 and of **IV**: q_c = 0.9947) allows no statement about the preference of the two product structures as a potential reactant towards acetophenone. At present we presume that the reaction of the zinc(II) complex, CO_2 and acetophenone is a concerted reaction, in which one of the structures **III** or **IV** plays a dominant role (cf. Figure 8).

On the other hand, (2-pyridylcarbinolato)zinc(II), (hydroxypyridinato)zinc(II) and (2,6-di-*tert*-butylbenzoato)-zinc(II) are inactive for the carboxylation of acetophenone (20 °C, 40 °C; DMSO, pyridine). Thus, the carboxylation of CH-acidic compounds requires a well optimized zinc(II)

complex with a specific ligand design. An important property of this complex is an acceptable solubility (this requires bulky ligands). A relative low coordination number of the metal center is assumed to be decisive, too.

However, we have found a new reaction of zinc(II) alkoxides with CO_2 and acetophenone under remarkably mild conditions.

Experimental Section

The syntheses of **1a−1c** were performed under an argon atmosphere as previously described.[4,5]

Zinc(II) 2,6-Dimethylphenoxide {Zn[(OC$_6$H$_3$)(CH$_3$)$_2$]$_2$} (1a): The procedure was modified by adding Zn{N(Si(CH$_3$)$_3$)$_2$}$_2$ (7.0 g, 18 mmol) in THF (80 mL) to a solution of sublimed 2,6-dimethylphenol (4.4 g, 36 mmol) in THF (100 mL). It was heated at reflux for 4 h. After cooling to room temperature, a white powder precipitated. The THF was removed in vacuo and the resulting solid was washed twice with pentane (50 mL) and dried in vacuo to yield a colorless powder. − Yield 5.7 g (83%), $C_{16}H_{18}O_2Zn$ (307.70): calcd. C 62.5, H 5.9; found C 60.55, H 6.20 (It is not possible to remove the ether ligand completely). − IR (KBr, disk): $\tilde{\nu}$ = 3026, 2918 [ν(C−H)], 1594, 1474, 1410 [ν(C=C)], 1200 [ν(C−O)], 760 cm^{-1} [δ(C−H)]. − ^{1}H NMR ([D$_6$]DMSO, 25 °C, TMS): δ = 2.03 (s, 6 H, C*H$_3$*), 6.22 (t, 1 H, C*H$_2$ para*), 6.82 (d, 2 H, C*H$_2$ meta*). − ^{13}C NMR ([D$_6$]DMSO, 25 °C, TMS): δ = 113.6 (*C*H, *para*), 125.9 (*C*H, *ortho*), 127.6 (*C*H, *meta*), 163.5 (*C*−O, *ipso*).

Zinc(II) 2,6-Di-*tert*-butylphenoxide {Zn[(OC$_6$H$_3$)(C(CH$_3$)$_3$)$_2$]$_2$} (1b): To a solution of sublimed 2,6-di-*tert*-butylphenol (7.5 g, 36 mmol) in THF or pentane (40 mL) was added a solution of Zn{N(Si(CH$_3$)$_3$)$_2$}$_2$ (7.0 g, 18 mmol) in THF or pentane (80 mL). The solution was stirred for 4 h. The THF was then removed in vacuo and the resulting solid was washed twice with pentane (50 mL) and dried in vacuo to yield a colorless powder. After 3 days the product turned pale yellow. − Yield 6.2 (72%), $C_{28}H_{42}O_2Zn$ (476.02): calcd. C 70.65, H 8.89; found C 68.20, H 8.76. − IR (KBr, disk): $\tilde{\nu}$ = 3080, 2959 [ν(C−H)], 1468, 1426 [ν(C=C)], 1226 [ν(C−O)], 749 cm^{-1} [δ(C−H)]. − ^{1}H NMR ([D$_6$]DMSO, 25 °C, TMS): δ = 1.38, 1.40 (overlapping singlets, 19 H, C*H$_3$*), 6.27, 6.73 (t, 1 H, C*H$_2$ para*), 6.91, 7.07(d 2 H, C*H$_2$ meta*). − ^{13}C NMR ([D$_6$]DMSO, 25 °C, TMS): δ = 30.5, 31.3 (*C*H$_3$, *tert*-butyl) 34.7, 35.1 (*C*, *tert*-butyl) 112.4 (*C*H, *para*), 123.9, 124.4 (*C*H, *ortho*), 139.4 (*C*H, *meta*), 166.1 (*C*−O, *ipso*).

Zinc(II) 2,6-Diphenylphenoxide {Zn[(OC$_6$H$_3$)(C$_6$H$_5$)$_2$]$_2$} (1d): The synthesis and isolation are identical to those for the previous zinc phenoxides. Sublimed 2,6-diphenylphenol (8.9 g, 36 mmol) and Zn{N(Si(CH$_3$)$_3$)$_2$}$_2$ (7.0 g, 18 mmol) were used for the reaction. Yield 9.3 g (93%), $C_{36}H_{26}O_2Zn(THF)_2$ (700.19): calcd. C 75.48, H 6.05; found C 73.89, H 5.73. − IR (KBr, disk): $\tilde{\nu}$ = 3050, 3023 [ν(C−H)], 1594, 1496, 1459, 1429 [ν(C=C)], 1224 [ν(C−O)], 762, 746, 703 cm^{-1}[δ(C−H)]. − ^{1}H NMR ([D$_4$]THF, 25 °C, TMS): δ = 7.1 (t, 1 H, C*H*), 7.3−7.7 (m, 1 H, C*H*). − ^{13}C NMR ([D$_4$]THF, 25 °C, TMS): δ = 115.9 (*C*H, *para*), 126.4 (*C*H, *para*), 126.4, 128.5, 129.0, 130.4, 132.9, (*C*H, *ortho*, *meta*), 142.5, 161.1 (*C*−O, *ipso*).

Zinc(II) 4-*tert*-Butylphenoxide {Zn[(OC$_6$H$_3$)(C(CH$_3$)$_3$)]$_2$} (1c): The synthesis and isolation are identical to those for the previous zinc phenoxides. After addition of Zn{N(Si(CH$_3$)$_3$)$_2$}$_2$ (7.0 g, 18 mmol) in THF (30 mL) to a solution of sublimed 4-*tert*-butylphenol (5.4 g, 36 mmol) in THF (80 mL) a white powder precipitated directly. Yield 12.2 (93%), $C_{20}H_{26}O_2Zn$ (363.80): calcd. C 66.0, H 7.2; found C 64.9, H 7.3. − IR (KBr, disk): $\tilde{\nu}$ = 2964, 2870 [ν(C−H)], 1600, 1514, 1460 [ν(C=C)], 1244 [ν(C−O)], 828 cm^{-1}[δ(C−H)]. − ^{1}H NMR ([D$_6$]pyridine, 25 °C, TMS): δ = 1.2 (m, 9 H, C*H$_3$*), 7.2 (s, 4 H, C*H*). − ^{13}C NMR ([D$_6$]pyridine, 25 °C, TMS): δ = 31.9 (*C*H$_3$, *tert*-butyl) 33.7 (*C*, *tert*-butyl) 118.8 (*C*H, *para*), 126.6 (*C*H, *ortho*, *meta*), 165.7 (*C*−O, *ipso*).

(2-Pyridylcarbinolato)zinc(II) {Zn[(OCH$_2$)(C$_5$H$_4$N)]$_2$} (2): To a solution of 2-(hydroxymethyl)pyridine (2.8 g, 26 mmol) in acetonitrile (80 mL), a solution of Zn{N(Si(CH$_3$)$_3$)$_2$}$_2$ (5.0 g, 13 mmol) in acetonitrile was added. From the stirred solution a white powder precipitated. The acetonitrile was removed by decanting and the resulting product washed twice with acetonitrile (50 mL), dried in vacuo to yield a colorless powder. Yield 3.3 g (90%), $C_{12}H_{12}N_2O_2Zn$ (281.62): calcd. C 51.18.0, N 9.95, H 4.29; found C 51.24, N 10.24, H 4.50. − IR (KBr, disk): $\tilde{\nu}$ = 3057, 2809, [ν(C−H)], 1607, 1568, 1483, 1441 [ν(C=C), ν(N=C)], 1094 cm^{-1} [ν(C−O)]. − ^{1}H NMR ([D$_3$]acetonitrile, 25 °C, TMS): δ = 3.7 (s, 2 H, C*H$_2$*), 6.32 (t, 1 H, C*H*), 6.48 (d, 1 H, C*H*), 6.85 (t, 1 H, C*H*), 7.54 (d, 1 H, C*H*). − ^{13}C NMR ([D$_3$]acetonitrile, 25 °C, TMS): δ = 64.3 (*C*H$_2$) 120.7 (*C*H, *meta*) 122.4 (*C*H, *ortho*), 137.2, 148.6 (*C*H, *para*), 161.0 (*C*−*C*H$_2$, *ipso*).

Crystallization of the Dimeric 1b and Monomeric 1b/(DMSO)$_2$: A saturated solution of zinc(II) 2,6-di-*tert*-butylphenoxide in pentane or DMSO, respectively, was allowed to cool to room temperature and then filtered to separate from crystallites. Colorless crystals suitable for X-ray structure determination were grown in the filtrate after a few days. − The intensity data were collected on a Nonius KappaCCD diffractometer, using graphite-monochromated Mo-K_α radiation. Data were corrected for Lorentz and polarization effects, but not for absorption.[17] − The structures were solved by direct methods (SHELXS[18]) and refined by full-matrix least squares techniques against F_o^2 (SHELXL-97[19]). For the compounds zinc(II) 2,6-di-*tert*-butylphenoxide/(DMSO)$_2$ the hydrogen atoms were located by difference Fourier synthesis and refined isotropically. The hydrogen atoms of the compound zinc(II) 2,6-di-*tert*-butylphenoxide were included at calculated positions with fixed thermal parameters. All nonhydrogen atoms were refined anisotropically. XP (SIEMENS Analytical X-ray Instruments, Inc.) was used for structure representations.[20]

NMR Experiments: Samples of zinc(II) complexes (**1a−1c, 2, 3**) in aprotic polar solvents (0.1 M) were transferred into a NMR tube with a Young-valve system under an argon atmosphere. After measurement of both the ^{13}C NMR and the ^{1}H NMR spectrum, the solution was saturated thoroughly with CO_2 or $^{13}CO_2$ and reexamined. After this, the probe was heated for 6 h at 40 °C and the measurements were repeated at room temperature. A Bruker AC200 NMR spectrometer was used.

Carboxylation of Acetophenone: In a typical carboxylation run, {Zn[(CH$_3$)$_2$(OC$_6$H$_3$)]$_2$} (0.10 g, 0.3 mmol) was dissolved in the polar aprotic solvent (20 mL) and saturated with CO_2. Acetophenone (0.04 g, 0.3 mmol) was then added to the solution. Afterwards, CO_2 was passed through the solution for six hours at the reaction temperature. A 1:1 mixture of water/methanol (100 mL) was added to the reaction solution.

Separation and Quantitative Analysis of the Product Mixture: Phenol, acetophenone and benzoyl acetic acid were analyzed by HPLC (Gynkotec System): The method was developed by modifying a previously described procedure (Burtscher et al.).[21] Column: Nucleosil 5 C18, (Macherey−Nagel & Co.), injection volume: 20 μL, solvent A: 50% 0.01M phosphate buffer KH_2PO_4 (Merck

analytical grade), solvent B: 50% acetonitrile, flow rate: 0.8 mL min^{-1}, isothermal at 298 K, program: isocratic, wavelength: 295 nm. The retention times are 4.2 min for benzoyl acetic acid and 7.0 min for acetophenone. The quantitative analysis was carried out by an external standard method. On the basis of a stock solution of acetophenone (6.1×10^{-4} g mL^{-1}) and benzoyl acetic acid (6.2×10^{-4} g mL^{-1}), a dilution series was measured. The calibration line was determined by linear regression (acetophenone: correction factor 1.051, variation coefficient 0.30%; benzoyl acetic acid: correction factor 1.108, variation coefficient 0.22%).

The carboxylation reaction was performed three times for each solvent and was analyzed twice via HPLC. The results, shown in Table 2, are averaged values of these three reactions.

Acknowledgments

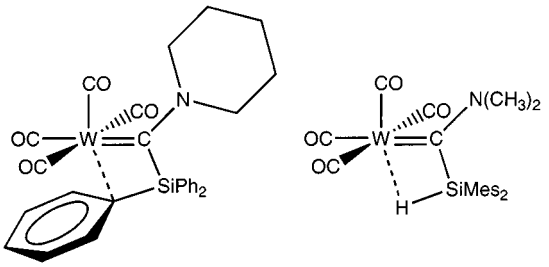
Intramolecular Stabilization of Carbene Complexes $(CO)_4W{=}C(NRR')Si(aryl)_2X$ (X = H, CMe=CHMe, NEt_2) by Interaction of the Metal Center with the Silicon Substituent X



Matthias Schwarz,[a] Guido Kickelbick,[a] and Ulrich Schubert*[a]

Keywords: Carbene complexes / Density functional calculations / Agostic interactions / Three-center bonds / Silicon / Tungsten

The degree of intramolecular stabilization by the substituent X in the carbene complexes $(CO)_4W{=}C(NRR')Si(aryl)_2X$ was investigated by density functional calculations and reactivity studies. Calculations carried out for $(CO)_4W{=}C(NH_2)SiH_2X$ (X = H, Ph, Me, CMe=CHMe) or $(CO)_4W{=}C(NH_2)OMe$ show that the agostic Si–H interaction in $(CO)_4W{=}C(NH_2)SiH_3$ transfers as much electron density to the metal as the π–interaction of the olefinic group in $(CO)_4W{=}C(NH_2)SiH_2CMe{=}CHMe$. An agostic interaction is not observed if the silicon atom is replaced by a carbon atom. Interaction of the phenyl group in $(CO)_4W{=}C(NH_2)SiH_2Ph$ is much weaker and can be described as a weak π–interaction. Owing to the agostic Si–H interaction, $(CO)_5W{=}C(NHR)SiHMes_2$ (R = Me, Et) does not eliminate $HSiR'_3$ upon thermolysis, as observed in the corresponding complexes $(CO)_5W{=}C(NHR)SiR'_3$, but instead gives the 16-electron complex $(CO)_4W{=}C(NHR)SiHMes_2$. When the complexes $(CO)_5W{=}C(NMe_2)SiPh_2CMe{=}CHMe$ or $(CO)_5W{=}C(NHMe)SiPh_2NEt_2$ are thermolyzed or photolyzed, CO is eliminated and either the olefinic or amino group coordinates intramolecularly to the empty coordination site. The corresponding reaction was not observed when the stable 16-electron complexes $(CO)_4W{=}C(NR_2)SiPh_3$ were allowed to react with olefins or tertiary amines respectively. The X-ray structure analysis of $(CO)_4W{=}C(NMe_2)SiPh_2CMe{=}CHMe$ is reported.

Introduction

Stable 16-electron carbene complexes $(CO)_4M{=}C(NR_2)SiR'_3$ (M = Cr, Mo, W) were previously obtained by thermal or photochemical CO cleavage from the corresponding 18-electron complexes $(CO)_5MC(NR_2)SiR'_3$.[1] These complexes are stabilized by intramolecular interaction of one of the silicon substituents with the metal center. In $(CO)_4W{=}C(NMe_2)SiHMes_2$ (Mes = 2,4,6-$C_6H_2Me_3$), the Si−H group interacts with the tungsten atom,[1c] and with one of the phenyl groups in $(CO)_4W{=}C(NC_5H_{10})SiPh_3$ (Scheme 1).[1a] In the $SiPh_3$ derivative, the $W-C_{phenyl}$ distances indicate that the *ipso* carbon atom is mainly involved in the interaction with the metal atom. The intramolecular interactions result in severe distortions of the bond angles at the carbene carbon atom (W−C−Si bond angle of 87.8(6)° in $(CO)_4W{=}C(NMe_2)SiHMes_2$ and of 101.2(4)° in $(CO)_4W{=}C(NC_5H_{10})SiPh_3$).

Scheme 1

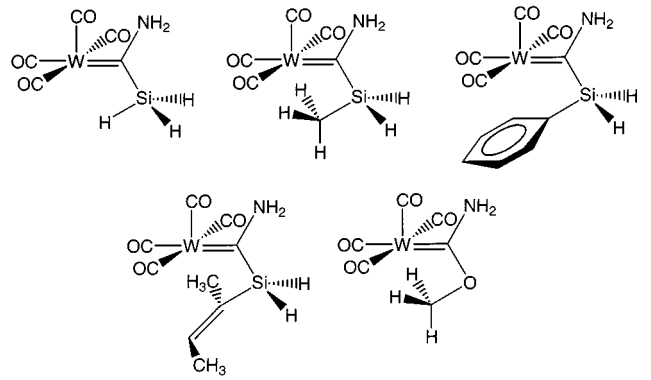
Getreidemarkt 9, A-1060 Wien, Austria

Despite the agostic interactions in the silylcarbene complexes, the coordination site is still accessible. Reaction of $(CO)_4W{=}C(NMe_2)SiR_3$ (SiR_3 = $SiPh_3$, $SiPh_2Me$) with CO, phosphanes, phosphites or isonitriles quantitatively yielded the 18-electron carbene complexes *cis*-$(CO)_4LW{=}C(NMe_2)SiR_3$ (L= CO, RNC, PR_3, $P(OR)_3$).[1b][1d] The latter complexes showed no tendency towards eliminating a ligand. However, addition of acetonitrile or pyridine to $(CO)_4W{=}C(NMe_2)SiPh_2Me$ was reversible, i.e. the complexes *cis*-$(CO)_4LW{=}C(NMe_2)SiPh_2Me$ (L = MeCN, C_5H_5N) eliminated L on evaporation of the reaction solutions, and the 16-electron complexes were re-formed. No adduct formation was observed when triethylamine, olefins or acetylenes were added to solutions of the 16-electron complex $(CO)_4W{=}C(NMe_2)SiPh_2Me$.[1d]

16-Electron carbene complexes are postulated as key intermediates in many reactions of Fischer-type carbene complexes. The stable analogues allow us to study how intramolecular interactions influence the stability and hence the reactivity of electron-deficient carbene complexes and how such interactions are controlled by electronic and steric effects. If these are properly tuned, a coordination site at the metal could be reversibly opened and protected during the reaction. In this paper, we report theoretical and experimental results of intramolecular interactions in silyl-substituted 16-electron carbene complexes.



Results and Discussion

Theoretical Calculations

To examine the nature of the intramolecular interaction and the role of steric and electronic factors in the silyl-sub-

stituted 16-electron carbene complexes $(CO)_4W{=}C(NC_5H_{10})SiPh_3$ [1a] and $(CO)_4W{=}C(NMe_2)SiMes_2H$,[1c] we carried out density functional calculations on these and related compounds, with the NR_2 replaced by NH_2 and the SiR_3 groups replaced by SiH_2R (R = H, Ph, Me, CMe=CHMe) or OMe (Scheme 2).

Scheme 2

The first question was whether steric crowding at the carbene carbon atom or the electronic interaction between the tungsten center and the substituents on silicon cause the small W−C−Si angles observed in the structurally investigated complexes. Therefore, the bulky substituents at the nitrogen and silicon atoms were substituted by hydrogen atoms. Geometrical optimization of the model structures were carried out from two starting points, the crystallographically determined structures (if known) on the one hand, and artificial structures with the bond angles around the carbene carbon atom set at 120°, on the other. In both cases, the optimizations gave very similar minimum structures, which should therefore correspond to the global minimum. This was also indicated by a frequency analysis, where no imaginary frequencies were observed. Structural parameters of the optimized structures are given in Table 1. The obtained bond lengths and angles are in good agreement with the experimental values from X-ray structure analyses. The fact that the geometry optimizations without the bulky ligands achieved the geometries of the real complexes allows us to conclude that steric reasons for the distorted arrangement around C(carbene) can be excluded. Instead, electronic reasons should be the driving force for the agostic interactions and associated structural phenomena.

The orbital responsible for the intramolecular interaction between the 16-electron tungsten carbene fragment and a donating group is the empty metal d_z^2-orbital. Stabilization of the empty coordination site can be achieved by either an agostic interaction with a suitable σ-bond or by interaction with π-orbitals of an organic substituent such as a phenyl or olefinic group.

Geometry optimization of $(CO)_4W{=}C(NH_2)SiH_3$ showed that one Si−H bond is preferentially located in the W−C−Si plane, as is observed in the solid-state structure of $(CO)_4W{=}C(NMe_2)SiMes_2H$. This conformation gives the best interaction of the Si−H bond with the empty d_z^2-orbital at the tungsten atom as shown in the electron density plot (Figure 1). The plot shows that both the H and the Si atom participate in a delocalized occupied orbital. Thus, the Si−H bond acts as an intramolecular electron donor which results in charge transfer from Si−H to the metal,

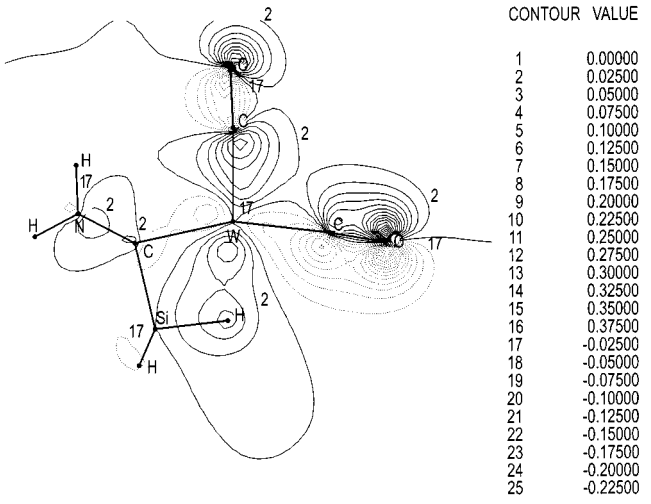

Figure 1. Contour plot of the calculated electron density for the molecular orbital participating to the greatest extent in the agostic interaction in the W=C−Si−H plane of $(CO)_4W{=}C(NH_2)SiH_3$.

Table 1. Selected parameters of the optimized structures of $(CO)_4W{=}C(NH_2)X$ (distances in pm and angles in deg; C_c = carbene carbon atom). In the $SiMeH_2$ and OMe derivative, the orientation of the methyl group was fixed (see Text)

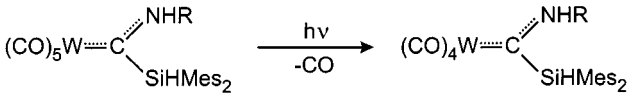
Natural charge on W	−0.54	−0.33	−0.33	−0.37	−0.46

i.e. an increase in the natural charge on the metal center (−0.54) compared to systems where no such interaction is present (Table 1).

The agostic interaction has interesting structural consequences, such as an increase in the bond length of the agostic Si−H bond (153.3 pm) as compared to the other two Si−H bonds (146.9 pm). The bending of the agostic Si−H bond ($C_{carbene}$−Si−H 96.5°, compared to 116.9° of the other two hydrogen atoms) also reflects the extraordinary bonding situation in the W−C−Si−H moiety. Furthermore, the W−$C_{carbene}$−Si angle is very small (89.2°) and the W−H distance rather short (207.7 pm). The calculated structural parameters correspond very well with the corresponding values observed in the solid-state structure of $(CO)_4W{=}C(NMe_2)SiMes_2H$ [W−$C_{carbene}$−Si 87.8(6)°, W−H 210(10) pm, Si−H 150(10) pm].[1c]



The WH interaction is restricted to the cases where the hydrogen atom is bound to silicon. This was confirmed by density functional calculations on $(CO)_4W{=}C(NH_2)SiMeH_2$ and $(CO)_4W{=}C(NH_2)OMe$ in which only the conformers with the methyl group pointing into the empty coordination site of the tungsten atom were considered (Scheme 2). In both compounds, the carbon-bonded hydrogen atoms could approach the W center with much less geometric distortion around $C_{carbene}$ than in $(CO)_4W{=}C(NH_2)SiH_3$. Nevertheless, an agostic interaction was not observed due to the fact that in the optimized structures (in which rotation of the CH_3 group was allowed) the CH_3 group was oriented in such a way that the C−H bond located in the W=C−Si plane was pointing away from the W atom.

Another possible means of stabilizing the 16-electron fragment are intramolecular π-interactions. In the investigated complexes, this was achieved either by an interaction of the *ipso* C atom of a phenyl substituent at silicon or by the coordination of the double bond of a butenyl substituent. The calculations revealed that the interaction of the SiPh substituent with the tungsten atom does not lead to a large transfer of electron density to the metal center and thus is a rather weak interaction. Interaction with the butenyl substituent is much stronger, as expected. This is also reflected in the relatively long W−C_{ipso} distance of 290.0 pm in $(CO)_4W{=}C(NH_2)SiPhH_2$ compared to the W−C_{olefin} distances of 263.3 pm and 270.8 pm in $(CO)_4W{=}C(NH_2)Si(CMe{=}CHMe)H_2$ (see also the X-ray structure analysis of **7** described below). The calculated W−C distances between the metal and the olefin in $(CO)_4W{=}C(NH_2)Si(CMe{=}CHMe)H_2$ differ by approximately 20 pm from the values in the X-ray structural analysis (W−C(81) 246.9(7) pm, W−C(82) 252.3 pm). One reason for these observations is that substitution of the bulky phenyl groups at silicon by H atoms in the calculation has a more significant effect, due to the bulkiness of the butenyl group, than in other substitution patterns. The charge on the tungsten atom in the butenyl derivative (−0.46) is close to that of the SiH_3 substituted compound with an efficient agostic interaction. The butenyl derivative corresponds to the many known alkenyl-substituted carbene complexes in which the olefinic group is connected to the carbene carbon by carbon and/or nitrogen atoms (see below).

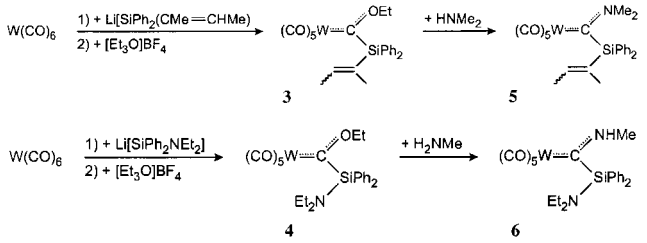
Thermal Decomposition of $(CO)_5W{=}C(NHR)SiHMes_2$

We wanted to test whether the agostic Si−H interaction affects reactions of silyl carbene complexes in which the silyl group is involved. Contrary to the corresponding NHR-substituted alkyl or arylcarbene complexes, the silylcarbene complexes $(CO)_5W{=}C(NHR)SiR_3$ (SiR_3 = $Si(aryl)_3$, $SiPh_2Me$) undergo a thermally[2] or photochemically[3] induced fragmentation reaction that quantitatively yields $HSiR_3$ and the isonitrile complexes $(CO)_5WCNR$.

When solutions of the SiR_2H-substituted complexes $(CO)_5W{=}C(NHR)SiHMes_2$ (R = Me, Et) (**1a,b**)[4] were photolyzed, this fragmentation was not observed. The spectroscopic data clearly showed that the 16-electron complexes $(CO)_4W{=}C(NHR)SiHMes_2$ (**2a,b**) were formed instead (Equation 1). The complexes **2a,b** are relatively stable. On heating, they gave **1a,b** and $W(CO)_6$, but no isonitrile complex.

1a,b **2a,b**

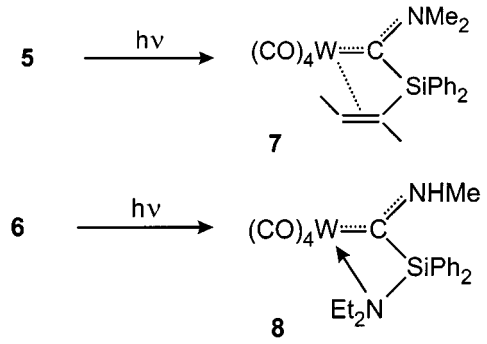
The complexes **2a,b** showed the same spectroscopic features as previously observed for NR_2-substituted 16-electron carbene complexes. The ν(CO) bands in the IR spectra were shifted to lower wavenumbers relative to **1a,b**, the ν(SiH) band was no longer observed, and the SiH signal in the ^1H NMR spectrum was shifted to higher field. The SiH coupling constants (**2a**: 104 Hz, **2b**: 105 Hz) were the same as previously observed in $(CO)_4W{=}C(NMe_2)SiHMes_2$ (106 Hz) as a result of a strong agostic W···H···Si interaction (see above). The configuration of the amino group was assigned (only the *Z* isomer is formed) on the basis of the chemical shifts of the alkyl substituents.[5]



These results show that the agostic interaction of the Si−H group with the metal center blocks the fragmentation reaction of the silylcarbene ligand (i.e. the cleavage of $HSiR_3$) that is observed in the absence of this interaction.

Intramolecular Stabilization of Silyl Carbene Complexes by Stronger Interactions

Although we did not observe the addition of amines or olefins to the empty coordination site of the stable 16-electron complexes $(CO)_4M{=}C(NR_2)SiR_3$,[1d] we anticipated that such groups could interact with the metal center when they were part of the silyl substituent.



The ethoxy(silyl)carbene complexes $(CO)_5W{=}C(OEt)SiPh_2X$ (**3**: X = CMe=CHMe; **4**: X = NEt_2) were prepared by the Fischer route starting from $W(CO)_6$ and $LiSiPh_2X$, followed by alkylation of the formed anionic acyl complex with $[Et_3O]BF_4$ (Equation 2 and 3). The 2-butenyl-substituted complex **3** was obtained with the (*Z*)- and (*E*)-butenyl groups in a 3:1 ratio. For the synthesis of **4**, an excess of

$[Et_3O]BF_4$ has to be avoided, because otherwise the amino group is cleaved.

Reaction of **3** with Me_2NH and of **4** with $MeNH_2$ resulted in the formation of the corresponding amino(silyl)-carbene complexes **5** and **6** in high yields (Equation 2 and 3). Surprisingly, the ratio of the (*Z*/*E*) isomers of **5** (different configuration of the butenyl group) changed from 3:1 in the ethoxy-substituted complex **3** to 10:1 in the amino-substituted complex **5**. The (*E*/*Z*) isomers of **6** (relative to the C(carbene)−N bond) were formed in equal portions, according to the NMR spectroscopic data.

When ether solutions of **5** or **6** were irradiated with UV light, CO was evolved, and the thermally stable tetracarbonyl complexes **7** and **8** were obtained in high yields (Equation 4 and 5). The spectroscopic data clearly showed that the olefinic group in **7** and the amino group in **8** are coordinated to the metal center.

Comparison of the NMR chemical shifts and the coupling constants of the butenyl group in **5** and **7** showed clear differences caused by π-coordination in **7**. The =CH signal in **7** is shifted to higher field by 1.2 ppm, while the signals of the CH_3 groups are shifted to lower field. Due to the weakening of the C=C bond by π-coordination, the ^4J(HCCCH) and ^5J(HCCCCH) couplings were only observed in **5**, but not in **7**. In the ^{13}C NMR spectrum of **7**, the carbon atoms of the C=C bond were strongly shifted to higher field relative to **5**, as expected. In the (aminosilyl)-carbene complex **8**, the $N-CH_2$ protons became diastereotopic upon coordination to the metal. The quadruplet observed in the ^1H NMR spectrum of the pentacarbonyl complex **6** was therefore split to a multiplet in **8**.

Only one isomer was observed for both **7** and **8**. Only the isomer with the *Z* configuration of the butenyl group was formed for **7**. The *E* isomer either gives no stable complex or is isomerized during irradiation. Comparison of the chemical shift of the NMe group and the ^3J(HNCH) coupling constant with complexes of known configuration did not allow an unequivocal determination of the geometry along the C(carbene)−N bond in **8**. Since the (*E*/*Z*) ratio in the pentacarbonyl complex was 1, and the yield of **8** was larger than 50%, isomerization must have occurred during irradiation. Photochemical isomerization of the amino group in aminocarbene complexes was previously observed for $(CO)_4W=C(NHCH_2CH=CH_2)Tol$[6] and theoretically explained for $(CO)_5Cr=C(NMe_2)Ph$.[7] The same photochemical process was found to be responsible for the isomerization of the ethoxy group in $(CO)_5W=C(OEt)SiPh_3$ and the CO elimination in $(CO)_5W=C(NC_4H_8)SiPh_3$.[8]

The ν(CO) bands in the IR spectra of **7** and **8** had the typical pattern of *cis*-$(CO)_4WLL'$ complexes with local C_{2v} symmetry. The spectra clearly showed that the electron density at the metal increases in the order **2a** < **7** < **8** (Table 2). However, the similarity of the IR spectra of **2a** and **7** indicates that intramolecular interaction of the η^2-coordinated SiH group and the π-alkenyl substituent with the tungsten atoms are electronically comparable. This is in agreement with the density functional calculations discussed above. Similar results were previously found in competition experiments between $HSiR_3$ and olefins for coordination to unsaturated metal centers.[9]

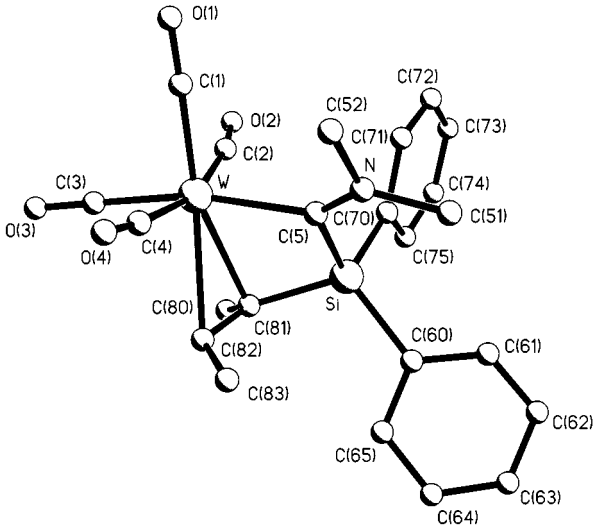
Table 2. Comparison of the ν(CO) bands of the complexes **2a**, **7** and **8** (petroleum ether or pentane solutions)

2a	2027(m)	1947(s)	1937 (vs)	1895(s)
7	2024(s)	1938(sh,s)	1928(vs)	1894(s)
8	1995(m)	1940(vs)	1915(vs)	1845(m)

The molecular structure of **7** was determined by an X-ray structure analysis (Figure 2, Table 3). The alkenyl group coordinates in a π fashion despite the relatively short spacer (C(5), Si) tethering it to the metal. In other structurally characterized alkenyl-substituted tungsten carbene complexes, such as $(CO)_4W=C(NHCH_2CH=CH_2)Tol$,[6] $(CO)_4W=C(OEt)(CH_2)_nCH=CHR$ (n = 2, 3)[10] or related cyclopentenyl derivatives,[11] the linkage between the olefinic group and the metal atom is longer, and therefore the bonding situation is less strained. That coordination of the C=C bond occurs at all is probably due to the strong distortion of the W−C(carbene)−Si (98.0(3)°) and the C(carbene)−Si−C(81) angle (93.1(3)°). Similarly large distortions have been observed in the structurally characterized 16-electron silylcarbene complexes;[1a,1c] they would hardly be possible in silicon-free systems.

Although the W−CO and W−C(carbene) bond lengths and angles around the tungsten atom in **7** are very similar to $(CO)_4W=C(NHCH_2CH=CH_2)Tol$,[6] the W−C(olefin) interaction in **7** is less optimal. The observed W−C(81)/C(82) distances [246.9(7) and 252.3(8) pm] are significantly longer and less symmetric than the corresponding distances in the known alkenyl-substituted complexes mentioned above (238−251 pm).

The geometry of *cis*-olefin carbene complexes can be characterized by the torsional angles α and β (Scheme 3). The angle α represents the dihedral angle between the car-



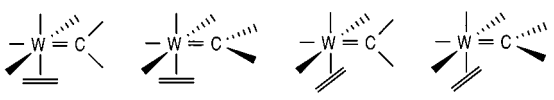


Figure 2. Molecular structure of **7**. Important distances (in pm) and angles (in deg): W−C(1) 198(1), W−C(2) 204(1), W−C(3) 199(1), W−C(4) 203(1), W−C(5) 220.4(8), W−C(81) 246.9(7), W−C(82) 252.3(8), C(5)−N 131.1(9), C(5)−Si 190.7(7), Si−C(81) 187.7(8). bene plane (plane of the carbene carbon atom and the atoms directly bonded to it) and the plane $C_{carbene}$,W,C=$C_{centroid}$, and β the dihedral angle between the olefin plane (W,C(81),C(82)) and the plane $C_{carbene}$,W,C=$C_{centroid}$.

Scheme 3

According to Extended-Hückel calculations,[12] the (90,0) conformation is the most favorable, and the (0,0) conformation the least favorable. The calculated energy difference between both conformations is 16.2 kcal/mol for $(CO)_4(C_2H_4)W{=}CH_2$. The conformation of **7** (34.4, 73.8) is clearly between the two extremes, but close to that of $(CO)_4W{=}C(NHCH_2CH{=}CH_2)Tol$ (25.7, 77.0). Thus, a similar mutual orientation of the carbene and olefin planes is reached owing to the strong angular distortions within the carbene ligand of **7**. This geometry is obviously maintained in solution. While only three signals are observed for the carbonyl ligands in the ^{13}C NMR spectra of **2** and **8**, the chemical inequivalence of all CO ligands in **7** is a consequence of the observed geometry. Contrary to the alkenyl substituent in **7**, the amino substituent in **8** has no preferred orientation in its interaction with the metal, and therefore the complex appears to be more fluxional.

Conclusions

The 16-electron carbene complexes $(CO)_4M{=}C(NR_2)SiR'_2H$ are stabilized by a strong agostic interaction of the Si−H group with the metal center. In contrast, the stabilization of $(CO)_4M{=}C(NR_2)SiPh_3$ can be traced back to a weak η^1-coordination of the phenyl group by π-interaction. Theoretical calculations indicate that electron transfer to the metal by the agostic Si−H interaction is of a similar magnitude to the π-coordination of an olefinic ligand. The agostic Si−H interaction is strong enough to inhibit the previously observed thermal elimination of $HSiR'_3$ from $(CO)_5M{=}C(NHR)SiR'_3$. Heating the complexes $(CO)_5W{=}C(NHR)SiR'_2H$ results in CO cleavage instead; the resulting 16-electron complexes $(CO)_4W{=}C(NHR)SiR'_2H$ are stabilized by the W···H···Si interaction.

When the group X in $(CO)_5W{=}C(NR_2)SiR'_2X$ is an olefinic or amino substituent, it is coordinated to the metal center once a CO ligand is eliminated. While external olefins or tertiary amines did not coordinate to the vacant coordination site of the 16-electron complexes $(CO)_4W{=}C(NR_2)SiR'_3$, *intra*molecular coordination of the same groups results in stable complexes. The interaction of the substituent X in $(CO)_4W{=}C(NR_2)SiR'_2X$ with the metal center can thus be tuned from a very weak π-type bonding for X = Ph to a rather strong agostic bond for X = H, a classic π-bond for X = $CR{=}CR_2$, or a Lewis acid/base interaction for X = NR_2.

Experimental Section

All operations were performed in an atmosphere of dry and oxygen-free N_2, using dried and nitrogen-saturated solvents. A high pressure Hg lamp (Heraeus TQ 150) was used for the photochemical reactions. − Column chromatography was performed with silica (Woelm, 0.063−0.200 mm mesh) as the stationary phase, from which oxygen was removed by heating in vacuo and storage under N_2. − IR spectra: Perkin−Elmer 283, CaF_2-cuvettes. − ^1H NMR and ^{13}C NMR spectra: Bruker AC 250.

Computational Methods: Calculations were carried out at the gradient corrected density functional level by using the local spin density approximation,[13] combined with Becke's gradient correction[14] and Lee, Yang and Parr's correlation functional (B3LYP),[15] implemented in the GAUSSIAN94[16] package. The effective core potential of Hay and Wadt[17] implemented in the GAUSSIAN94 package (LANL2DZ) was used for the tungsten atom. Silicon atoms were described by the same potential with additional polarization functions (α(Si) = 0.45). Carbon, nitrogen and oxygen atoms were described with the [6/1/1/1/4/1] basis set of Dunning.[18] The natural bond orbital formalism [19] was applied for the population analysis. The contour plots were prepared with the program MOLDEN.[20]

$(CO)_4W{=}C(NHR)SiHMes_2$ (2a,b): A solution of **1a** (330 mg) or **1b** (340 mg, 0.55 mmol)[4] in diethyl ether (120 mL) was irradiated at −20 °C with UV light. A slight stream of argon was passed through the solution to expel CO and thus to prevent the back reaction. The volume of the solution was kept at 120 mL by occasionally adding ether. The reaction was monitored by IR spectroscopy. Irradiation was stopped and the solvent removed in vacuo when the CO bands of **2** no longer increased in intensity. The oily residue was dissolved in a minimum amount of petroleum ether/ether (2:1) and chromatographed on silica at −20 °C with the same solvent mixture. Unreacted **1** was eluted first, followed by an orange red zone of **2**. After elution, the solvent was removed and the orange red product powder washed with small amounts of pentane at 0 °C.

2a: Yield 241 mg (73%). − IR (pentane): ν_{NH} = 3234(w), ν_{CO} = 2027 (m), 1947 (s), 1937 (vs), 1895 (s) cm^{-1}. − ^1H NMR (C_6D_6): δ = −2.61 [s, *J*(*Si*H) = 104 Hz, ^1J(WH) = 35 Hz, 1 H, W···H···Si], 2.01 (s, 6 H, *p*-CH_3), 2.26 (s, 12 H, *o*-CH_3), 2.64 [d, ^3J(HNCH) = 4.5 Hz, 3 H, *Z*-NCH_3], 6.58 (s, 4 H, C_6H_2), 8.37 (br s, 1 H, NH). − ^{13}C NMR (C_6D_6): δ = 20.9 (*p*-CH_3), 23.5 (*o*-CH_3), 44.6 (*Z*-NCH_3), 203.7 [^1J(WC) = 128 Hz, *eq*/*cis*-CO], 214.8, 218.4 (*eq*/*trans*- + ax/*cis*-CO), 288.7 (C_{Carben}).

2b: Yield 235 mg (69%). − IR (diethyl ether): ν_{CO} = 2020 (m), 1925 (vs, br), 1890 (s) cm^{-1}. − ^1H NMR (C_6D_6): δ = −2.54 [s, *J*(*Si*H) = 105, ^1J(WH) = 35 Hz, 1 H, W···H···Si], 0.84 [t, ^3J(HCCH) = 7.5 Hz, 3 H, CH_2-CH_3], 2.02 (s, 6 H, *p*-CH_3), 2.32 (s, 12 H, *o*-CH_3), 3.23 (m, 2 H, Z/N−CH_2), 6.58 (s, 4 H, C_6H_2), 8.76 (br s, 1 H, NH). − ^{13}C NMR (C_6D_6): δ = 12.7 (CH_2-CH_3), 21.0 (*p*-CH_3), 23.6 (*o*-CH_3), 52.9 (*Z*-NCH_2), 203.8 (eq/*cis*-CO), 214.8, 218.4 (eq/trans- + ax/*cis*-CO), 286.3 ($C_{Carbene}$).

$(CO)_5W{=}C(OEt)SiPh_2CMe{=}CHMe$ (3): To a solution of *E*/*Z*-$Ph_2ClSi-CMe{=}CHMe$ (1.97 g, 7.22 mmol) in THF (30 mL), Li (250 mg, 36.0 mmol) was added in small pieces. The solution turned dark red after 10 min and was stirred for additional 4 h at room temperature. The solution was then filtered into a dropping funnel and added dropwise over 1.5 h to a suspension of $W(CO)_6$ (2.11 g, 6.0 mmol) in diethyl ether (200 mL) at −78 °C. The solution was allowed to warm to 0 °C and stirred at this temperature for 2 h. After cooling to −50 °C, $[Et_3O]BF_4$ (5 g) was added, and the mixture was stirred at 0 °C for 1 h. All steps of the reaction were monitored by IR spectroscopy. The solution was then filtered and the solvent removed in vacuo. The product complex was extracted from the residue with several 20 mL portions of petroleum ether (until the added solvent remained colorless). The combined solutions were concentrated to 15 mL and chromatographed on silica at −15 °C with a petroleum ether/ether (50:1) mixture). Elution of the red zone and removal of the solvent resulted in a red oil. Yield 2.64 g (59%). − IR (petroleum ether): ν_{CO} 2070 (s), 1960 (sh, vs), 1950 (vs, br) cm^{-1}. − ^1H NMR (C_6D_6): δ = 1.10 [t, ^3J(HCCH) = 7.1 Hz, 3 H, *trans*-OCH_2CH_3], 1.13 [t, ^3J(HCCH) = 7.1 Hz, 3 H, *cis*-OCH_2CH_3], 1.41 [d, ^3J(HCCH) = 7.1 Hz, 3 H, *trans*-$CHCH_3$], 1.42 [d, ^{3}J(HCCH) = 7.1 Hz, 3 H, *cis*-$CHCH_3$], 1.78 [d, ^4J(HCCCH) = 11.4 Hz, 3 H, *trans*-$SiCCH_3$], 1.79 [d, ^4J(HCCCH) = 1.4 Hz, 3 H, *cis*-$SiCCH_3$], 4.74 [q, ^3J(HCCH) = 7.1 Hz, 2 H, *trans*-OCH_2], 4.77 [q, ^3J(HCCH) = 7.1 Hz, 2 H, *cis*-OCH_2], 6.23 (m, *cis*/*trans*-CH, 1 H), 7.00−7.80 (m, 10 H, Ph). − ^{13}C NMR (C_6D_6): δ = 14.3 (*cis*-OCH_2CH_3), 14.4 (*trans*-OCH_2CH_3), 14.8 (*trans*-$CHCH_3$), 20.4 (*cis*-$CHCH_3$), 25.6 (*cis*-$SiCCH_3$), 27.2 (*trans*-$SiCCH_3$), 85.0 (*cis*-OCH_2), 85.1 (*trans*-OCH_2), 127−145 (Ph and C=C), 197.7 [^1J(WC) = 127 Hz, *cis*/*cis*-CO], 197.8 (*trans*/*cis*-CO), 206.1 (*cis*/*trans*-CO), 206.2 (trans/trans-CO), 400.3 (*cis*-$C_{Carbene}$), 402.3 (*trans*-$C_{Carbene}$). − ^{29}Si NMR (C_6D_6): δ = −18.0 [^2J(WC*Si*) = 12.9 Hz].

$(CO)_5W{=}C(OEt)SiPh_2NEt_2$ (4): To a solution of $Ph_2ClSiNEt_2$[21] (1.80 g, 6.2 mmol) in THF (30 mL), Li (180 mg, 25.9 mmol) was added in small pieces at 0 °C. The solution was stirred for 4 h at 0 °C, filtered into a dropping funnel cooled to 0 °C and then added dropwise within 1 h to a suspension of $W(CO)_6$ (1.62 g, 4.6 mmol) in diethyl ether (200 mL) at −78 °C. The solution was allowed to warm to 0 °C and stirred at this temperature for 2 h. After cooling to −50 °C, $[Et_3O]BF_4$ (437 mg, 2.3 mmol) was added, and the mixture was stirred at 0 °C for 1 h. Then more $[Et_3O]BF_4$ (two portions of 50 mg, together 0.52 mmol) were added. All steps of the reaction were monitored by IR spectroscopy. The solution was then filtered and the solvent removed in vacuo. The residue was extracted with benzene (30 mL), filtered and dried in vacuo. Dark red oil; yield 1.74 g (60%). − IR (diethyl ether): ν_{CO} 2065 (s), 1970 (s), 1955 (vs), 1935 (vs, br) cm^{-1}. − ^1H NMR (C_6D_6): δ = 0.90 [t, ^3J(HCCH) = 7.1 Hz, 6 H, NCH_2CH_3], 1.14 [t, ^3J(HCCH) = 7.1 Hz, 3 H, OCH_2CH_3], 2.90 [q, ^3J(HCCH) = 7.1 Hz, 4 H, NCH_2), 4.77 [q, ^3J(HCCH) = 7.1 Hz, 2 H, OCH_2], 7.10−7.80 (m, 10 H, Ph). − ^{13}C NMR (C_6D_6): δ = 14.5 (OCH_2CH_3), 14.9 (NCH_2CH_3), 41.0 (NCH_2), 85.1 (OCH_2), 128.2, 130.2, 134.3, 136.7 (Ph), 198.0 [^1J(WC) = 128 Hz, *cis*-CO], 206.5 (*trans*-CO), 404.5 ($C_{Carbene}$). − ^{29}Si NMR (C_6D_6) δ = −22.0.

$(CO)_5W{=}C(NMe_2)SiPh_2CMe{=}CHMe$ (5): A stream of dry diethylamine was passed through a solution of **3** (1.86 g, 3.01 mmol) in diethyl ether (150 mL). Over 1 h, the dark red solution turned yellow. The progress of the reaction was monitored by IR spectroscopy. The solution was concentrated in vacuo, re-dissolved in petroleum ether/ether mixture (10 mL, 10:1) and chromatographed on silica at −15 °C. First, a small red zone containing **3** was eluted with petroleum ether, and then a yellow zone containing the product with petroleum ether/ether (20:1). A yellow solid was obtained after removal of the solvent. Yield 1.32 g (71%). M.p. 109 °C. − IR (petroleum ether): ν_{CO} 2060 (m), 1972 (w), 1933 (vs, br), 1925 (sh, vs) cm^{-1}. − ^1H NMR (C_6D_6): δ = 1.57 [dq, ^3J(HCCH) = 7.1, ^5J(HCCCH) = 1.4 Hz, 3 H, *cis*-$CHCH_3$], 1.64 [dq, ^4J(HCCCH) = 1.5, ^5J(HCCCH) = 1.4 Hz, 3 H, *cis*-$SiCCH_3$], 2.57 (s, 3 H, *trans*-*E*-NCH_3), 2.68 (s, 3 H, *cis*-*E*-NCH_3), 3.35 (s, 3 H, *trans*-*Z*-NCH_3), 3.41 (s, 3 H, *cis*-*Z*-NCH_3), 5.95 [qq, ^3J(HCCH) = 7.1 Hz, ^4J(HCCCH) = 1.5 Hz, 1 H, *cis*-CH), 7.10−7.60 (m, 10 H, Ph). − ^{13}C NMR (C_6D_6): δ = 20.7 ($CHCH_3$), 24.4 ($SiCCH_3$), 54.0 (*E*-NCH_3), 58.6 (*Z*-NCH_3), 127−145 (Ph, C=C), 199.1 [^1J(WC) = 127 Hz, *cis*-CO], 203.7 (*trans*-CO), 291.3 [^1J(WC) = 86 Hz, $C_{Carbene}$]. − ^{29}Si NMR (C_6D_6): δ = −19.6. − $C_{24}H_{23}NO_5SiW$ (617.39): calcd. $(CO)_4W{=}C(NHMe)SiPh_2NEt_2$ (8): A solution of **6** (1.40 g, 2.26 mmol) in diethyl ether (150 mL) was irradiated with UV light at −20 °C. A light stream of argon was passed through the reaction solution to expel liberated CO. The reaction was monitored by IR spectroscopy and stopped when all bands of **6** had disappeared (about 3 h). The solution was concentrated in vacuo, re-dissolved in a petroleum ether/ether mixture (10 mL, 20:1) and chromatographed on silica at −15 °C with the same solvent mixture. First, a yellow zone of **6** (re-formed by decomposition of **8**) was eluted, and then, with a 2:1 mixture of petroleum ether and ether mixture, an orange red zone containing the product. An orange red oil was obtained after removal of the solvent. Yield 0.83 g (62%). − IR (petroleum ether): ν_{CO} 1995 (m), 1940 (vs), 1915 (vs), 1845 (m) cm^{-1}. − ^1H NMR (C_6D_6): δ = 0.65 [t, ^3J(HCCH) = 7.1 Hz, 6 H, NCH_2CH_3], 1.71 [d, ^3J(HNCH) = 4.3 Hz, 3 H, NCH_3], 2.86, 3.06 (m, 4 H, NCH_2), 7.20−7.80 (m, 10 H, Ph), 8.58 (br s, 1 H, NH). − ^{13}C NMR (C_6D_6): δ = 13.8 (NCH_2CH_3), 51.4 (NCH_2), 52.3 (NCH_3), 209.9 [^1J(WC) = 130 Hz, *eq*/*cis*-CO], 217.3 [^1J(WC) = 165 Hz, *ax*/*cis*-CO], 224.1 [^1J(WC) = 128 Hz, *eq*/*trans*-CO], 302.3 (C_{Carben}). − ^{29}Si NMR (C_6D_6): δ = −6.0.

X-ray Structure Analysis of 7: (see also Table 3) Selected crystals were sealed in a glass capillary and mounted on a Siemens SMART diffractometer with a CCD area detector. Graphite-monochromated Mo-K_α radiation (71.073 pm) was used for all measurements. The crystal-to-detector distance was 5.85 cm. A hemisphere of data was collected by a combination of three sets of exposures at 293 K. Each set had a different φ angle for the crystal, and each exposure took 20 s and covered 0.3° in ω. The data were corrected for polarization and Lorentz effects, and an empirical absorption correction (SADABS) was applied. The cell dimensions were refined with all unique reflections. The structure was solved by direct methods (SHELXS86). Refinement was carried out with the full-matrix least-squares method based on F^2 (SHELXL93) with anisotropic thermal parameters for all nonhydrogen atoms. Hydrogen atoms were inserted in calculated positions and refined riding with the corresponding atom. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited at the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC 140737. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (Fax: (internat.) +44−1223/336−033; E-mail: deposit@ccdc.cam.ac.uk).

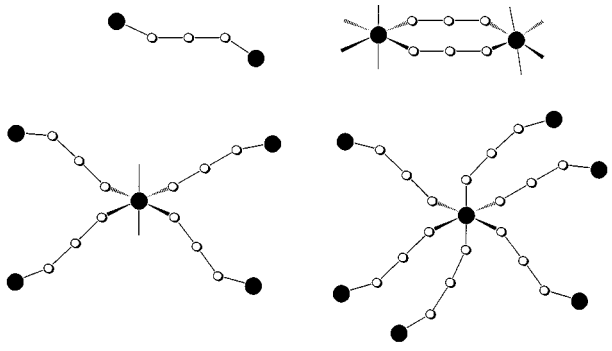
Superexchange Interactions through Quasi-Linear End-to-End Azido Bridges: Structural and Magnetic Characterisation of a New Two-Dimensional Manganese–Azido System $[Mn(DENA)_2(N_3)_2]_n$ (DENA = diethylnicotinamide)



Mohamed A. S. Goher,[a] Morsy A. M. Abu-Youssef,[a] Franz A. Mautner,[b] Ramon Vicente,[c] and Albert Escuer*[c]

Keywords: Manganese / Two-dimensional systems / Azido bridges

Reaction of sodium azide with manganese(II) and diethylnicotinamide (DENA) leads to the two-dimensional system *trans*-$[Mn(DENA)_2(N_3)_2]_n$. The compound crystallises in the *P*2/*c* (monoclinic) group. Structural determination shows layers of manganese atoms bridged by means of single $\mu_{1,3}$-azido bridges. The polymeric structure is achieved by means of two different $\mu_{1,3}$-azide bridges, one of them with Mn–N–N bond angles of 148.4(2)°, whereas the second nonequivalent azido bridge has the unusual feature of quasi-linear coordination with Mn–N–N bond angles of 171.7(2)°. Molecular orbital calculations and susceptibility data show antiferromagnetic interaction and similar constant coupling values for the two superexchange pathways, in spite of the structural differences. Susceptibility, magnetisation, and EPR properties are compared with related azido systems.

Introduction

Manganese-azide compounds in which the azide ligand acts as a bridge exclusively in the end-to-end coordination mode (EE) have recently been developed. The number of reported compounds is limited to seven, but there is an exceptional versatility of topologies and magnetic properties: one dinuclear system has a single quasi-linear EE bridge,[1] there are three chains with double EE azido bridges,[2,3] two 2-D systems[4,5] and one 3-D compound,[6] in which each of the manganese atoms is coordinated to the four neighbouring manganese atoms by means of four single EE bridges, and, finally, one 3-D system with each manganese atom octahedrally surrounded by six EE bridges. 1[7]

Scheme 1. Basic units found to date for Mn^{II}/end-to-end azide systems

Magnetically, all of them show antiferromagnetic interactions, even the quasi-linear EE bridge. The magnetic properties for the two general cases of single[6b] or double[2] EE bridge correlate with the bond structural parameters (mainly bond angles) that determine the overlap of the MO of the bridge with the adequate AO of the manganese atoms. Interest in this kind of compound was reinforced by the characterisation of long-range magnetic ordering with spontaneous magnetisation below T_C = 28 K for the 2-D $[Mn(4\text{-acpy})_2(N_3)_2]_n$ system, (4-acpy = 4-acetylpyridine).[8a]

The EE bridge has also been found in other kinds of 1-D, 2-D honeycombs, or 3-D alternating systems together with a second kind of bridge, such as the end-on azido bridge (EO)[2,6b,8] or other ligands such as 4,4'-bipyridine[9] or bipyrimidine.[10] However, in these cases, the intrinsic difficulties in determining the *J* values makes it difficult to correlate the magnitude of the coupling with structural data.[10c]

Following our research on compounds of this kind, we studied the derivative obtained from the reaction of manganese(II) with diethylnicotinamide (DENA) and sodium azide. The new two-dimensional system *trans*-$[Mn(DENA)_2(N_3)_2]_n$ was structurally characterised; this compound consists of well-isolated layers in which the manganese atoms are bridged by four azido ligands (two pairs of nonequivalent bridges) in the EE mode, showing the expected antiferromagnetic coupling. One of these nonequivalent EE bridges shows quasi-linear Mn–N–N–N–Mn coordination, with Mn–N–N bond angles of 171.7°, far from the preferred bond angles derived from the sp^2 arrangement of the terminal nitrogen atoms of the ligand. It should be emphasised that constrained linear $\mu_{1,3}$-coordination for azido bridges has been found only recently through the use of systems in which the two paramagnetic ions are placed in rigid cryptand ligands.[1]

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 2000 1434–1948/00/0808–1819 $ 17.50+.50/0

In this paper we present the synthesis, structural characterisation, magnetic behaviour (focusing our attention on the exceptional linear azido bridge), and EPR data for $[Mn(DENA)_2(N_3)_2]_n$, together with a comparison with the previously reported end-to-end manganese–azido systems.

Results and Discussion

Crystal Structure of $[Mn(DENA)_2(N_3)_2]_n$ (1)

The structure of **1** consists of 2D manganese–azido sheets. A labelled ORTEP plot of the asymmetric unit is shown in Figure 1 Manganese atoms are placed in a centrosymmetric octahed al environment. The coordination polyhedron is formed by two DENA and four azido ligands coordinated in a *trans* arrangement, elongated along the axis defined by the pyridinic ligands, Mn–N(1) = 2.291(3) and similar Mn–N azido distances Mn–N(11) = 2.210(3) and Mn–N(21) = 2.225(3) Å. Each azido ligand acts as a bridge to the next manganese atom in the end-to-end coordination mode, allowing a two-dimensional polymer in the *bc* plane (Figure 2). Whereas the bond angle Mn–N(21)–N(22) = 148.4(2)° lies in the normal range for this kind of compound,[2,7] Mn–N(11)–N(12) = 171.7(2)° shows a quasi-linear coordination which has to date only been reported for systems with strong sterical constraints, such as cryptand compounds. The Mn–azido–Mn torsion angle, defined as the Mn–N(11)–N(12)–N(11C)–Mn(1C) dihedral angle, is 180°, whereas Mn–N(21)–N(22)–N(21A)–Mn(1A) has a torsion angle value of 166.7(2)°. Due to these asymmetric bond angles and the Mn–N_3–Mn torsion angle, the planes defined by the neighbouring manganese atom and the four bonded N (azido) atoms show a low dihedral angle of 5.6°. Minimum Mn–Mn intraplane distances are 6.553(3) Å and 6.695(3) Å, whereas the shorter interplane distance is 14.153 Å (*x* axis of the cell) due to the large space occupied by the pyridine ligands which isolate the manganese–azide layers (Figure 2). The general trends of the structure of **1** is similar to that of the two-dimensional compounds with 4-acetylpyridine or methylisinicotinate ligands;[4,5] the most significant differences are the more asymmetric Mn–N–N and Mn–N···N–Mn bond angles (Table 1).

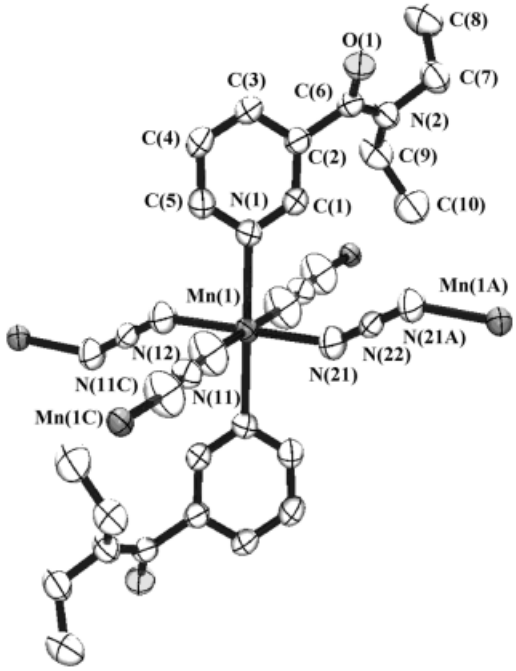

Figure 1. ORTEP drawing of $[Mn(DENA)_2(N_3)_2]_n$; ellipsoids at 50% probability level

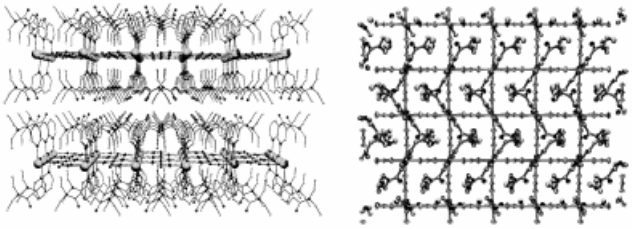

Figure 2. View of the $[Mn(DENA)_2(N_3)_2]_n$ compound along the (0 0 1) direction, to show the large interplane separation induced by the large pyridinic ligand (left); view along the (1 0 0) direction, showing the quadratic manganese–azide network

Table 1. Comparative structural and magnetic data for the three two-dimensional manganese–EE azide systems structurally characterised to date. "Angl. mean planes" refers to the angle between the MnN_4 (*N*-azide) planes; intersheet *d* is the minimum Mn–Mn interplane distance; ΔHpp is the EPR linewidth at room temperature; T_C indicates the ordering temperature, if present.

	L = DENA	L = 4-acpy	L = Me-*i*-nic

Superexchange Mechanism

Structural date enable two different superexchange pathways to be proposed, one through the azido bridge, with Mn–N–N bond angles of 148.4° (J_1), and a second through the azido bridge, with Mn–N–N bond angles of 171.7° (J_2). Previous MO calculations[6b] on the single azido bridge for manganese(II) systems (d^5 configuration) show that when the bond angle increases and approaches 180°, the interaction through the dz^2 orbitals of the paramagnetic centres and the nonbonding π orbitals of the bridge decreases, tending to zero for the 180° bond angle, whereas the overlap between the d*xz* and d*yz* atomic orbitals and the π orbitals of the bridge increases to the maximum interaction at 180°. In our case, we performed the MO calculations for the experimental bond angles, according to the molecular simulation previously proposed, and using as input parameters the experimental Mn–N(azide), N–N bond lengths and the experimental Mn–N–N and M–N–N–N–Mn bond and tor-

sion angles. The results of the calculations,[11] plotted in the Δ^2 form (Δ gap between the antibonding symmetric and antisymmetric combinations derived from each magnetically active atomic orbital of the manganese atoms, according to the Hoffmann model),[12] indicate that the superexchange through the N(11)–N(12)–N(11C) bridge occurs mainly through the two d*xz* and d*yz* interactions, whereas the dz^2 pathway contribution is negligible due to its quasi-orthogonal position with respect to the nonbonding π orbitals of the bridge (Figure 3). For the second N(21)–N(22)–N(21A) bridge, the lower bond angle enhances the overlap of the dz^2 orbitals with the π MO of the azido group, but the d*xz* interaction simultaneously decreases (Figure 3). Calculation of the $\Sigma\Delta^2$ affords the 0.104 and 0.102 eV^2 values for each bridge, indicating that the antiferromagnetic contributions for the two different bridges are accidentally similar. The main consequence is that the reported compound is assumed to be a structurally alternating 2-D system due to the two nonequivalent bridges, but magnetically the system may be studied as a homogeneous plane.

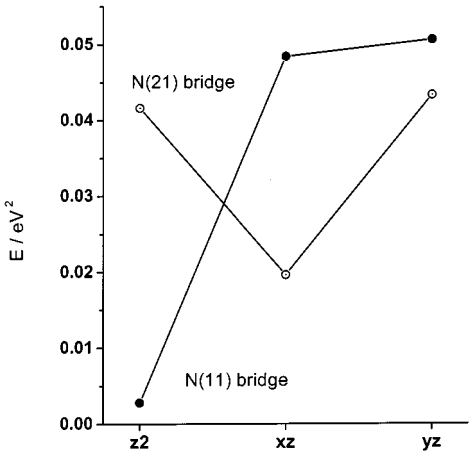

Figure 3. Contribution of each of the three active superexchange pathways for the two different EE bridges of $[Mn(DENA)_2(N_3)_2]_n$

It is remarkable that EE bridges with M–N–N bond angles close to 180° are unusual. To date the only structural and magnetic data for this kind of system was obtained from Mn–N–N–N–Mn units encapsulated in cryptand cavities to force the quasi-linear coordination of the bridge. The magnetic interaction, which was consistent with the theoretical model, was moderately antiferromagnetic.[1]

Magnetic Properties

Susceptibility measurements were performed under a 100 G field in the 300–2 K temperature range. The susceptibility plot shows a maximum placed at 44 K, whereas $\chi_M \cdot T$ decreases continuously on cooling, from 3.87 cm^3 K mol^{-1} at 300 K, and tending to zero at low temperature (Figure 4). This behaviour corresponds to moderate antiferromagnetic coupling and the low temperature shape indicates that canting-like long-range interactions are not effective even at 2 K. Magnetisation measurements at 2 K in the range ±5 T also show behaviour that is normal for an antiferromagnet (Figure 5). Structural data suggest that two *J* superexchange coupling constants are required to fit the susceptibility data, but the above MO calculations show that J_1 is roughly equal to J_2 and so the data were treated as for a homogeneous system. The susceptibility data in the 300–30 K range were fitted with the high-temperature expansion series of Lines[13] for a quadratic-layer Heisenberg antiferromagnet, derived from $H = \Sigma_{nn}(-JS_iS_j)$, where Σ_{nn} runs over all pairs of nearest spins *i* and *j*. The best-fit parameters were $J = -3.42(1)$ cm^{-1}, $g = 2.01$, $R = 9 \cdot 10^{-5}$. The *J* value and the position of the maximum agree with the value obtained from the simplified expression[13] $kT_{max}/|J| = 1.12\ S\ (S + 1) + 0.10$, from which a $J = -3.1$ cm^{-1} value is expected.

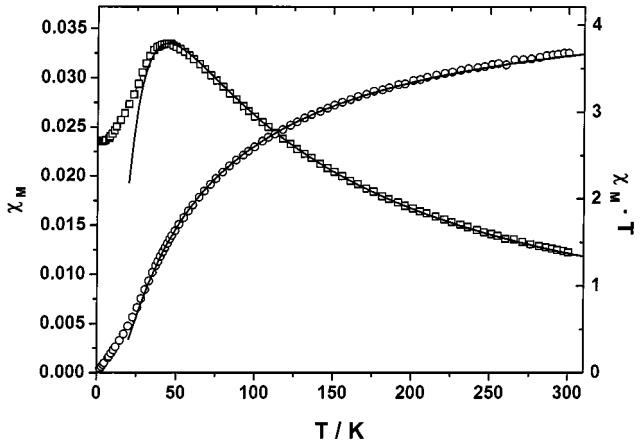

Figure 4. χ_M (dot centered circles) and $\chi_M \cdot T$ (dot centered squares) vs *T* plots for a polycrystalline sample of $[Mn(DENA)_2(N_3)_2]_n$;the solid lines show the best fit under the conditions described in the text

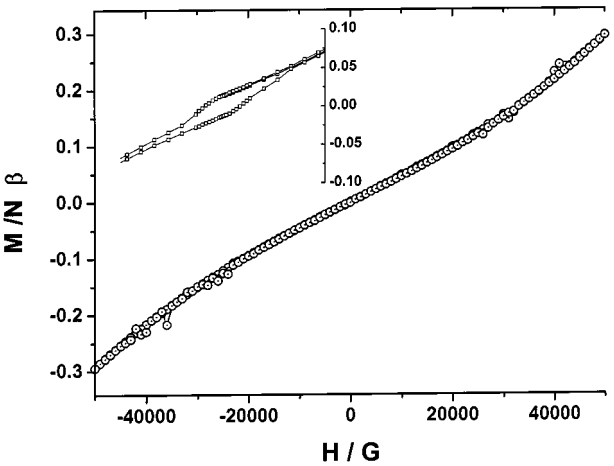

Figure 5. Magnetisation at 2.5 K vs applied field for $[Mn(DENA)_2(N_3)_2]_n$, compared with the related compound $[Mn(Meinc)_2(N_3)_2]_n$ which shows spontaneous magnetisation as a consequence of the structural differences (inset, range ±1.5 T)

This *J* value is comparable with the reported data for the two similar systems with the same topology (Table 1). The main difference between these systems is shown by $[Mn(4\text{-}acpy)_2(N_3)_2]_n$, which shows an ordered phase with a T_C of

28 K, as a consequence of the J value and the angle between the mean Mn equatorial planes, which may induce a canting phenomenon.[4][8a] $[Mn(Me\text{-}i\text{-}nic)_2(N_3)_2]_n$ has a lower J value, which should shift T_C to low temperature. Finally, for the compound reported in this paper, the quasi-parallel main axis of the coordination octahedron of the manganese atoms avoids the canting possibility.

The EPR spectrum consists of a sharp isotropic line centred at $g = 2.00$. Linewidth mainly depends on two factors: superexchange narrowing and dipolar broadening. When structural data, which show Mn···Mn intraplane distances greater than 6.5 Å are included, dipolar effects, if present, should be extremely weak, whereas the relatively high constant coupling of –3.4 cm^{-1} has a strong effect in narrowing the linewidth. The experimental spectrum shows a linewidth of 30 G, similar to the 4-acetylpyridine compounds ($J = -3.8$ cm^{-1}) and lower than the linewidth observed for the methylisonicotinate system ($J = -2.2$ cm^{-1}); this confirms the above assumptions. The dipolar broadening mechanism[14] for a two-dimensional manganese system is an anisotropic property which follows the $a + b\,(1 - \cos^2\theta)^2$ law, i.e., the maximum linewidth appears when the spectrum is measured parallel to the plane and it has the minimum linewidth at the 54.3° magic angle. The possible effects of dipolar broadening were checked in a single-crystal EPR experiment at room temperature, but for all the orientations of the crystal, the spectra were practically identical, showing a minor change in the linewidth between 28–33 G. In recent experiments[3] with the one-dimensional system $[Mn(3,5\text{-lut})_2(\mu_{1,3}\text{-}N_3)_2]_n$ (3,5-lut = 3,5-dimethylpyridine), in which the intrachain Mn···Mn distance is 5.140–5.159 Å, dipolar effects were found (linewidth variation between 40–90 G), but the greater Mn···Mn distance for the DENA compound is experimentally at the upper limit and makes this effect nondetectable.

Experimental Section

General: Infrared spectra (4000–400 cm^{-1}) were recorded in KBr pellets on a Nicolet 520 FTIR spectrophotometer. – Magnetic measurements were carried out with a Quantum Design instrument with a SQUID detector, working in the temperature range 300–2 K. The magnetic field was 100 G for the study of the low-temperature phenomena. Magnetisation measurements were recorded in the ±5 T range of external magnetic field. Diamagnetic corrections were estimated from Pascal Tables. – EPR spectra were recorded at X-band frequency with a Bruker ES200 spectrometer equipped with an Oxford liquid-helium cryostat for variable temperature work.

Synthesis of the Compound: The title complex $[Mn(DENA)_2(N_3)_2]_n$ (**1**) was synthesised by the dropwise addition of 5 mL of an aqueous solution of NaN_3 (0.42 g, 6.5 mmol) to an ethanolic solution mixture, about 30 mL, of manganese chloride trihydrate (0.59 g, 3 mmol) and 1.43 g (8 mmol) of *N*,*N*-diethylnicotinamide. The final clear solution was kept in a refrigerator for several weeks to produce well-formed crystals of the complex. Yield: 0.94 g (ca. 63%). – $C_{20}H_{28}MnN_{10}O_2$ (495.46): calcd. C, 48.4; H 5.7, Mn 11.1, N 28.3, O 6.5; found: C 48.3, H 5.6, Mn 11.2, N 28.5, O 6.4.

IR Spectra: The IR spectrum of the title complex $[Mn(DENA)_2(N_3)_2]_n$ shows bands attributable to the *N*,*N*-diethylnicotinamide ligand at normal frequencies [ν(C=O) at 1627 cm^{-1} (vs)]. In the 2000–2100 cm^{-1} region the complex shows a very strong and broad band, assigned to the asymmetric stretching azide group vibrations [$\nu_{as}(N_3)$] centred at 2092 cm^{-1} (vs). This band appears at normal frequencies; it was compared with that of the linear Mn–N_3–Mn cryptand system previously reported, (2200 cm^{-1}). In the region 1280–1360 cm^{-1} two bands could be attributed to the [$\nu_s(N_3)$] mode: 1378 cm^{-1} (ms) and 1336 cm^{-1} (m). In the far infrared region, two bands attributable to the ν(Mn–N_3) mode around 386 and 374 cm^{-1} and two bands due to the ν[Mn–N(L)] mode around 256 and 236 cm^{-1} were observed.

Crystal Structure Determination and Refinement of the Structure: Single-crystal X-ray data for $[Mn(DENA)_2(N_3)_2]_n$ were collected

with a modified STOE four-circle diffractometer. Crystal size: 0.50 × 0.34 × 0.24 mm. The crystallographic data, conditions maintained for the intensity data collection and some features of the structure refinement are listed in Table 2. Graphite-monochromated Mo-$K\alpha$ radiation (λ = 0.71069 Å) was used to collect the data set; the ω-scan technique was employed. The accurate unit-cell parameters were determined from automatic centering of 34 reflections ($8.5° < \theta < 12.9°$) and were refined by least-squares methods. 3318 reflections (2531 independent reflections, R_{int} = 0.0370) were collected in the range $2.94° < \theta < 26.50°$. An intensity decay of 6% for control reflections (–1 –2 0; 0 –2 1; 5 0 2), measured after every set of 100 reflections, was observed during data collection. Corrections were applied for Lorentz-polarization effects, for intensity decay, as well as for absorption, using the DIFABS[15] computer program. The structure was solved by direct methods with the SHELXS-86[16] computer program, and was refined by full-matrix least-squares methods on F^2 with the SHELXL-93[17] program as incorporated in the SHELXTL/PC V 5.03[18] program library, and the graphics program PLUTON.[19] All non-hydrogen atoms were refined anisotropically. The hydrogen atoms were fixed geometrically with the HFIX utility[18] (i.e., hydrogen atoms riding with idealized geometrical values on their parent carbon atoms with fixed distances: CH = 0.93 Å, CH_2 = 0.97 Å and CH_3 = 0.96 Å). Selected bond parameters are given in Table 3.

Atomic positional and thermal parameters, lists of bond lengths and angles, and F_o/F_c values are available as supplementary material from one of the authors (F. A. M.). Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication No. CCDC-127494. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, U. K. [Fax: (int.) +44–1223/336 033; E-mail: deposit@ccdc.cam.ac.uk].

Molecular orbital calculations and magnetic susceptibility properties were explored for the new two-dimensional system *trans*-$[Mn(DENA)_2(N_3)_2]_n$ (DENA = diethylnicotinamide). The compound shows an unusual alternating of the azide bridges with Mn–N–N bond angles of 171.7(2)° and 148.4(2)°. The antiferromagnetic interaction has been correlated with the structural data.

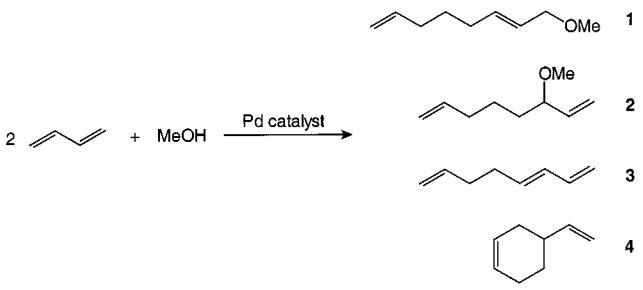
Palladium-Catalyzed Reactions for the Synthesis of Fine Chemicals, 14[+]

Control of Chemo- and Regioselectivity in the Palladium-Catalyzed Telomerization of Butadiene with Methanol − Catalysis and Mechanism

Frank Vollmüller,[a] Jochen Krause,*[b] Susanne Klein,[b] Wolfgang Mägerlein,[c] and Matthias Beller*[c]



Keywords: Palladium / Butadiene / Telomerization / Homogeneous catalysis

The palladium-catalyzed telomerization reaction of butadiene with methanol has been examined with the aim of controlling the chemoselectivity (telomerization vs. dimerization products) and regioselectivity (linear vs. branched telomerization product) of the reaction. We have shown that the reaction temperature, ligand-to-metal ratio and ratio of substrates exert a large influence on the selectivity of the reaction. Selectivities of up to 97% for the desired linear telomerization product **1** can be achieved below 50 °C by employing both low PPh_3/Pd and butadiene/methanol ratios. Mono(phosphane)palladium(0)–diallyl ether complexes, Ar_3P–Pd[$(CH_2=CHCH_2)_2O$] (**5**), serve as new catalysts for the reaction. In order to gain a mechanistic understanding of the observed selectivity effects, we synthesized the phosphane(octadienyl)palladium(II) complexes **7a** and **9a** as model compounds for key reaction intermediates and examined their stoichiometric reactions with the methoxide nucleophile. Based on our results, we propose an extension of the known telomerization mechanism that accounts for the observed selectivity effects.

Introduction

An important ecological requirement of todays chemical processes is to produce a desired compound with high selectivity whilst, as far as possible, avoiding waste or by-products. Therefore, the possibility of controlling the product selectivity in a chemical reaction is of great interest. This control can be achieved, for example, by employing an appropriate catalyst or by adjusting the crucial reaction parameters.

During the course of our studies with regard to palladium-catalyzed C−C coupling reactions we became interested in the telomerization of butadiene, since this reaction assembles simple starting materials in a 100% atom-efficient manner to give valuable functionalized octadienes. These compounds are useful as intermediates in the total synthesis of several natural products,[2] as well as in industry, as precursors for plasticizer alcohols,[3] solvents, corrosion inhibitors and nonvolatile herbicides.[4] The telomerization reaction is the dimerization of two molecules of a 1,3-diene in the presence of an appropriate nucleophile HX,[5] e.g. alcohols,[6] water,[7] amines,[8] carboxylic acids[9] and others,[10] to give substituted octadienes (1-substituted 2,7-octadiene, 3-substituted 1,7-octadiene). Of these the 1-substituted 2,7-octadiene (*n*-product) is the major isomer formed for most nucleophiles. Due to the fact that they are readily available and cheap,[11] butadiene and methanol are attractive starting materials for this reaction, reacting to yield 1-methoxyocta-2,7-diene (**1**) (Scheme 1). As previous studies have shown,[6j] the major by-products include the 3-substituted octa-1,7-diene **2** (iso product), 1,3,7-octatriene (**3**) (formed by the linear dimerization of butadiene) and, less importantly, 4-vinylcyclohexene (**4**) (formed by the Diels−Alder reaction of two molecules of butadiene).

Scheme 1

Although the mechanism of the palladium-catalyzed telomerization reaction has been carefully examined,[12] de-

tailed investigations focusing on the control of product selectivity in this process have not yet been carried out. In this paper, we describe the important factors determining the chemo- and regioselectivity, i.e. reaction temperature, ligand-to-metal ratio and butadiene-to-methanol ratio. New mono(phosphane)palladium(0) complexes **5**[13] were successfully employed as catalysts. The observed effects are rationalized mechanistically by a modified reaction mechanism for the butadiene telomerization reaction.

Results and Discussion

The examined telomerization reaction of butadiene with methanol is shown in Scheme 1.[14] Either (diallyl ether)(triphenylphosphane)palladium(0) (**5**)[13] or mixtures of palladium(II) acetate and triphenylphosphane (sometimes in combination with triethylamine) were used as the catalysts (Figure 1).

5

Figure 1

Compound **5** is representative of a new class of palladium(0) complexes in which only *one* phosphane ligand is coordinated to the palladium center. Compound **5** represents a stable analogue of an intermediate in the catalytic cycle of the reaction (vide infra, Schemes 2 and 5) and, as such, is well suited for our investigations, since it does not need to be activated (e.g. by ligand dissociation, reduction, etc.) before entering the catalytic cycle. For reasons of industrial applicability we have also included Pd^{II} precursor complexes in our studies due to the great availability of $Pd(OAc)_2$. It has already been reported that Pd^{II} precursors are rapidly reduced to the catalytically active Pd^0 species if a base, e.g. NEt_3, is present in the reaction mixture.[15] Thus, 100 equivalents NEt_3 (relative to Pd) were added to the runs in which the Pd^{II} precursor complex was used. Initial experiments showed that the content of NEt_3 in the reaction does not influence the chemo- nor the regioselectivity of the telomerization. Therefore, for the selectivity studies it was less important if the applied catalyst precursor was a Pd^0 or a Pd^{II} compound.

Selectivity Studies

The product selectivity of the palladium-catalyzed telomerization is largely influenced by temperature, ratio of starting materials and concentration of the phosphane ligands. Table 1 summarizes the influence of the reaction temperature.

The chemoselectivity, i.e. the discrimination between telomerization products (**1**, **2**) and the linear dimerization product 1,3,7-octatriene (**3**), remains excellent (95%) up to 50 °C (Entries 1−3, Table 1) but drops to 77% at 90 °C (Entry 4; Table 1). Thus, the high catalytic activity at elevated temperatures [turnover frequency (TOF) = 21000 h^{-1}: Entry 4, Table 1] is at the expense of the chemoselectivity. Above 100 °C, the Diels−Alder reaction of butadiene to yield 4-vinylcyclohexene becomes increasingly significant. On the other hand, the regioselectivity, i.e. the discrimination between both telomers **1** and **2**, remains high (≥ 95%) throughout the whole temperature range examined. Obviously, the side reaction leading to the undesired octatriene **3** becomes more important at temperatures above 50 °C, whereas the side reaction leading to the undesired iso telomer **2** is influenced by temperature to a much lesser extent. For palladium-catalyzed reactions in general, the ligand-to-metal ratio is one of the most critical reaction parameters. Typically, the variation of the ligand-to-palladium ratio influences the stability and the activity of the palladium catalyst but has a less pronounced effect on the reaction selectivity. Interestingly, in the case of the butadiene telomerization reaction the P/Pd ratio does not only influence the catalyst stability and activity but also dramatically affects the regioselectivity of the reaction. This effect was observed for both catalyst systems shown in Figure 1. The results of the catalytic runs with 1, 2, 3, 10 and 50 equivalents of phosphane (with respect to palladium) are shown in Table 2.

Firstly, the influence of the ligand-to-metal ratio on the selectivity was studied at −10 °C. The telomerization reaction was carried out using the palladium(0) complex **5** without any additional triphenylphosphane (P/Pd = 1:1: Entry 1, Table 2), as well as in the presence of 1 equiv. of triphenylphosphane (P/Pd = 2:1: Entry 2, Table 2). In both cases

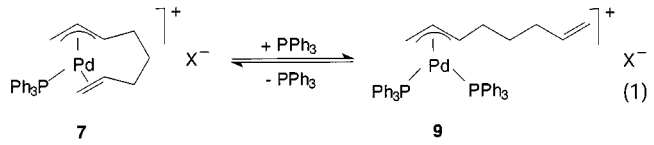
the chemoselectivity towards the telomerization products **1** and **2** was ≥ 97%; however, the *n*/iso ratio changed dramatically. With a P/Pd ratio of 1 the linear isomer **1** was produced in a 36:1 ratio relative to the branched isomer **2**. With a P/Pd ratio of 2 the ratio of **1** to **2** decreased to 12:1. Telomerization reactions using palladium(II) as the pre-catalyst do not yield any telomerization products at −10 °C. At 50 °C, in the presence of the palladium(0) complex **5** (i.e. P/Pd = 1: Entry 3, Table 2), **1** and **2** were still produced with both a high chemoselectivity of 97% and a high *n*/iso ratio of 32:1. On changing to $Pd(OAc)_2$ with 3 equiv. of triphenylphosphane (Entry 4, Table 2), the *n*/iso ratio drops slightly to 28:1, while the chemoselectivity remains excellent (97%). A further increase in the amount of triphenylphosphane at this temperature reduces the regioselectivity, thus the *n*/iso ratio decreases to 16:1 (P/Pd = 10:1: Entry 6; Table 2) and to 7:1 (P/Pd = 50:1: Entry 8, Table 2). However, the chemoselectivity (97−99%) is not affected to any significant extent by the change in the P/Pd ratio. When the telomerization reaction was carried out at 90 °C, both the chemo- and the regioselectivity were influenced by the P/Pd ratio. In the presence of 3 equiv. and 10 equiv. of triphenylphosphane (Entries 5 and 7, Table 2) the chemoselectivity decreases to 85%, and to 75% in the presence of 50 equiv. of the ligand (Entry 9, Table 2). The main side-product observed at 90 °C is 1,3,7-octatriene (**3**). In addition, the *n*/iso selectivity decreases with an increase in the reaction temperature and with an increasing P/Pd ratio. Hence, at 90 °C the linear-to-branched ratio decreases from 19:1 (3 equiv. PPh_3: Entry 5, Table 2) to 14:1 (10 equiv. PPh_3: Entry 7, Table 2). With 50 equiv. of triphenylphosphane the *n*/iso ratio was 6:1 (Entry 9, Table 2), similar to the run at 50 °C (Entry 8; Table 2).

In general, the ratio of telomerization products to dimerization products (chemoselectivity) decreases above a certain temperature (50 °C) and is not really affected by the P/Pd ratio. On the other hand, the regioselectivity is predominantly influenced by the amount of ligand present! The best regioselectivity using triphenylphosphane as the ligand is obtained with a ligand-to-palladium ratio of 1:1 below 50 °C (*n*/iso > 32:1; Entries 1 and 3, Table 2) while a *n*/iso ratio below 6:1 (Entries 8 and 9, Table 2) seems to be the borderline selectivity at high P/Pd ratios.

It is interesting to note that the established reaction mechanism ("Jolly mechanism") for the telomerization of butadiene and methanol (Scheme 2) does not explain the observed changes in regioselectivity.[12e]

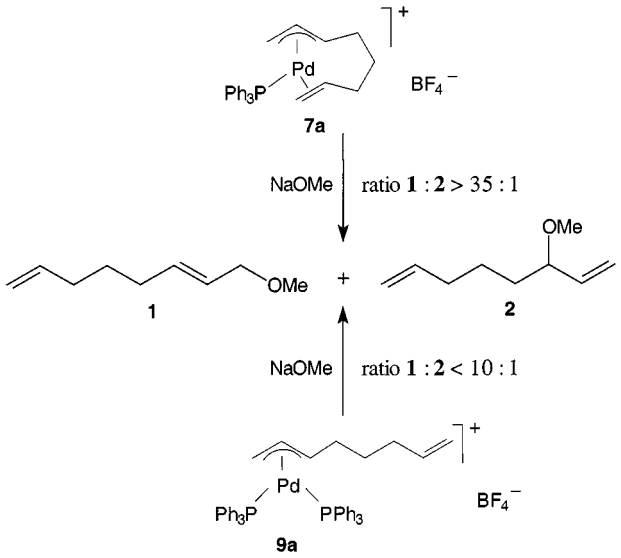
It is proposed that in the presence of palladium(0) species two molecules of butadiene couple to form the $PPh_3-Pd-(\eta^1,\eta^3$-octadiendiyl) complex **6**. Protonation by methanol at the C-6 atom of the C_8 chain leads to the $PPh_3-Pd-(\eta^2,\eta^3-C_8H_{13})$ species **7**. In the following step the methoxide ion adds to either allylic terminus C-1 or C-3 of the C_8 chain resulting in the formation of the telomers **1** (via **8**) or **2**, respectively. The formation of 1,3,7-octatriene (**3**) occurs as a side reaction by hydrogen abstraction (C-4) from **7**.



The regioselectivity-determining step of the process is the nucleophilic attack of methanol or methoxide ion on the (π-allyl)mono(phosphane)palladium complex **7**. The nucleophilic attack at the C-1 atom is favored for steric reasons, while the attack at the C-3 atom is electronically favored.[16] Moreover, the linear telomer is the thermodynamically more stable product due to the internal double bond, whereas the branched isomer with the terminal double bond is less stable. However, our control experiments with various mixtures of **1** and **2** reveal that the telomerization reaction does not proceed under thermodynamic control at the described reaction conditions, since product formation is not reversible. We propose that the major reason for the selective formation of the linear telomer **1** is the energetically favored formation of a trigonal planar (1,6-diene)palladium complex [LPd(1,6-diene)]. The branched telomer has a 1,7-diene structure which would give rise to a (1,7-diene)-palladium complex. As demonstrated by us, the stability of trigonal planar (1,6-diene)palladium complexes [LPd(1,6-

Scheme 2

diene)] is much higher than those with a 1,7-diene ligand.[13a,13c]



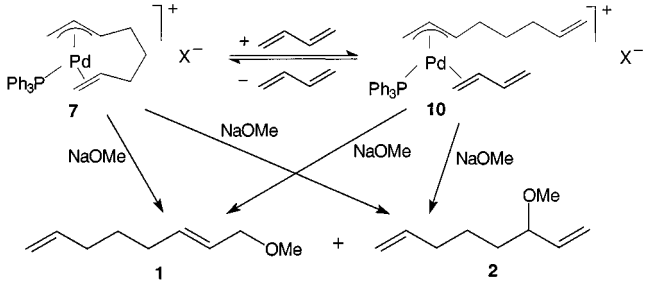
Due to the large influence of the P/Pd ratio on the regioselectivity, we postulate that (π-allyl)bis(phosphane)palladium complexes of type **9** (X = MeO^-) are involved as additional intermediates in the catalytic cycle [Equation (1)].

In complex **9**, nucleophilic attack at the C-1 allylic terminus does not give rise to an energetically favored chelating 1,6-diene coordination of the C_8 chain since coordination of both C−C double bonds is not possible at the P_2Pd^0 moiety. Hence, the greater preference for the linear telomer is less pronounced when compared with **7**. In an attempt to prove this hypothesis, we prepared the (octadienyl)palladium complex **7a** (X = BF_4^-)[12a,17] and reacted it with triphenylphosphane to obtain **9a** (X = BF_4^-). We then investigated the reactions of both **7a** and **9a** with sodium methoxide.

Proceeding from our observation that (diallyl ether)palladium complexes **5** catalyze the telomerization reaction even at low temperatures, we treated **5** with an excess of butadiene at −20 °C and obtained **6** in a quantitative yield.[17] Addition of tetrafluoroboric acid or tetrakis[3,5-bis(trifluoromethyl)phenyl]boric acid[18] in diethyl ether produced the respective cationic complexes of type **7**. The compound with the latter anion has the advantage of a high solubility in organic solvents and is therefore especially suitable for further investigations. On treatment with two equivalents of triphenylphosphane in THF, followed by the addition of pentane, the bis(phosphane)palladium complex **9a** was isolated in a quantitative yield. When excess phosphane was used, the nucleophilic attack of triphenylphosphane on the π-allyl group occurred with concomitant precipitation of tetrakis(triphenylphosphane)palladium.

In order to compare the regioselectivity of the nucleophilic attack of the methoxide anion on **7a** (X = BF_4^-) and **9a** (X = BF_4^-), each complex was treated with a threefold excess of sodium methoxide in THF/methanol (Scheme 3).

Scheme 3



In the case of **7a**, the mixture turned black after a few minutes at room temperature due to the precipitation of palladium metal. GC analysis of the product mixture showed that products **1** and **2** were formed in a ratio > 35:1. The reaction of **9a** with sodium methoxide required slight heating (30 °C) to complete the reaction. GC analysis indicated a ratio of 1:2 < 10:1. Hence, attack of the meth-

Table 3. Variation of the ratio of butadiene to methanol

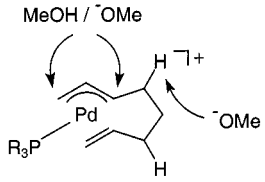
oxide ion on the C-1 allylic terminus in **9a** is less favored than in **7a**, but it is still preferred relative to the C-3 allylic terminus − probably for steric reasons.[16] From these studies it can be concluded that an excess of triphenylphosphane in the telomerization reaction mixture leads to the formation of allylbis(phosphane)palladium complexes of type **9**, which are responsible for a lower *n*/iso ratio of the telomerization products.

Additional support for our selectivity model comes from the fact that the concentration of butadiene also effects the regioselectivity of the attack of methanol on the (allyl)palladium complex. In general, experiments were carried out with a butadiene-to-methanol ratio of 1:2. Apart from this mixture, reactions with a stoichiometric ratio of starting materials and either a large excess of butadiene or methanol were studied. The results are summarized in Table 3.

Scheme 4



Indeed, we observed that variation in the ratio of starting materials significantly influences the regioselectivity. With increasing concentration of butadiene the yield of the linear telomer **1** decreases (compare Table 2 and 3). More specifically, at 50 °C with a stoichiometric butadiene to methanol ratio, the *n*/iso selectivity is only 9:1 (3 equiv. PPh_3: Entry 1, Table 3) and 7:1 (10 equiv. PPh_3: Entry 3, Table 3), respectively. In contrast, the *n*/iso selectivity totals 28:1 (3 equiv. PPh_3: Entry 4, Table 2) and 16:1 (10 equiv. PPh_3: Entry 6, Table 2) using a reaction mixture that contains a butadiene-to-methanol ratio of 1:2. The same trend holds true at a reaction temperature of 90 °C. In addition, it is shown that employing an excess of methanol, larger than 2:1, has only a small additional positive influence on the regioselectivity (compare Entry 5, Table 2 and Entry 5, Table 3). The influence of the butadiene concentration on the regioselectivity of the telomerization reaction was also observed by Beger et al.,[6b] but has not yet been explained. We suggest that the decrease in regioselectivity with increasing butadiene concentration is due to the loss of the coordination of the internal olefin in **7**. As shown in Scheme 4, the formation of a new intermediate **10** is proposed in the presence of excess butadiene. As stated before, the regioselectivity of the nucleophilic attack on **10** is no longer deter-

Scheme 5

mined by the formation of the favorable complex **8** with a chelating 1,6-diene ligand. Thus, an excess of butadiene has an analogous effect as an excess of phosphane.

The ratio of butadiene to methanol also influences the chemoselectivity of the reaction. Up to 12% of 1,3,7-octatriene (**3**) is produced when stoichiometric amounts of butadiene and methanol are combined at 90 °C (3 equiv. PPh_3: Entry 2; 10 equiv. PPh_3: Entry 4, Table 3). The chemoselectivity is much better at higher methanol concentrations (Entry 5, Table 2 and Entry 5, Table 3). This significant increase in **3** makes it likely that the telomers **1** and **2** result not only from an attack of the corresponding methoxide ion which is produced upon protonation of **6**, but also by the intermolecular reaction of methanol with **7**. While methanol is believed to react only as a nucleophile yielding the telomers, the methoxide anion can react either as a nucleophile or as a base to yield 1,3,7-octatriene (Figure 2). As a result the formation of 1,3,7-octatriene becomes more likely at lower methanol concentrations.

7

Figure 2

Conclusions

In this paper we described a detailed study of the palladium-catalyzed telomerization of butadiene with methanol concerning the control of chemo- and regioselectivity. The selective formation of the linear telomer 1-methoxyocta-2,7-diene (**1**) is influenced by the reaction temperature, the ligand-to-metal ratio and the stoichiometry of the starting materials. By careful optimization of these parameters, *n*/iso selectivities > 35:1 are realized at a low P/Pd ratio of 1:1 and high methanol-to-butadiene ratios in the absence of other coordinating species (regioselectivity up to 97%). *A second phosphane ligand bound to the palladium center dramatically reduces the regioselectivity for **1**.* With regard to chemoselectivity, the best results are obtained at low temperatures and high methanol-to-butadiene ratios (chemoselectivity up to 98%). In contrast to the regioselectivity, the chemoselectivity does not depend significantly on the P/Pd ratio.

All our results from the catalysis tests are in general agreement with the previously described mechanism proposed by Jolly. However, in order to explain the observed influences of the P/Pd ratio and the butadiene/Pd ratio on the selectivity we propose an extended mechanistic outline for telomerizations which contains two different reaction pathways (Scheme 5): pathway A going through **7** and **8** (with an energetically favored 1,6-diene C_8-ligand structure) leading to a high *n*/iso selectivity, and pathway B with **9** and **10** as intermediates which react with a lower *n*/iso selectivity as compared with **7**.

A comparison of the reactivity of the isolated complexes **7a** and **9a** with methoxide shows unequivocally that the main principle which governs the *n*/iso selectivity is the internal coordination of the olefinic side-chain. *These results appear to be of general relevance to telomerization reactions with other nucleophiles,* e.g. *this explains why the telomerization of butadiene with acetic acid yields comparably low n/iso ratios.* Thus, it is foreseeable that telomerizations with other oxygen nucleophiles or amines may be controlled by applying the same set of parameters, which we have presented here.

Another result of our work is the discovery that (diallyl ether)mono(phosphane)palladium complexes **5** react with butadiene below 0 °C to give complexes **6**. This allows extremely easy access to the catalytic intermediates of the butadiene telomerization reaction. Furthermore, (diallyl ether)mono(phosphane)palladium complexes are also efficient catalysts for the reaction of butadiene and methanol even at −10 °C. It is likely that these Pd^0 complexes will find use in other catalytic reactions.

Acknowledgments

[14] 37 mg (0.14 mmol) of triphenylphosphane and 11 mg (0.05 mmol) of palladium(II) acetate were dissolved in 56 g (1.75 mol) of methanol under argon. The mixture was transferred into a cooled (dry ice) autoclave (Parr model 4561). Subsequently, 54 g (1.00 mol) of butadiene was condensed into the autoclave and the vessel was heated to the reaction temperature. After the reaction was complete, the autoclave was cooled down and the remaining butadiene was recondensed. The conversion was determined by the mass difference of butadiene. The yields of telomerization products were determined by GC (with dodecane as an internal standard) using an HP 6869A gas chromatograph. In order to isolate the octadienyl ethers, the reaction mixture was distilled in vacuo.

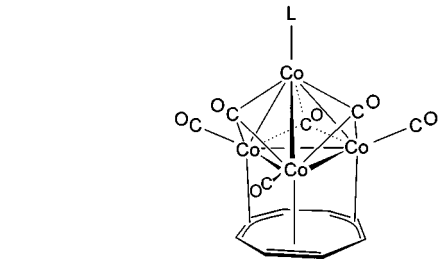
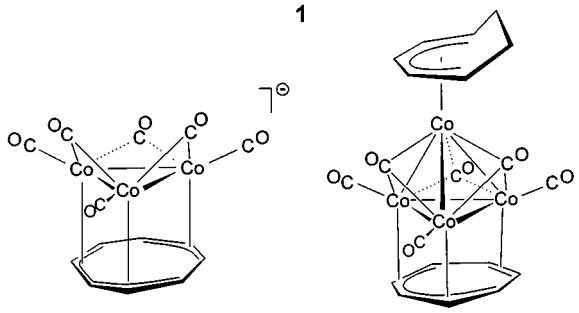
Dedicated to Professor Heinrich Vahrenkamp on the occasion of his 60th birthday



Keywords: Carbocycles / Clusters / Cobalt / Electrochemistry / Facial ligands

Chemical reduction of the tetracobalt cluster complex $[Co_4(CO)_3(\mu_3\text{-}CO)_3(\mu_3\text{-}C_7H_7)(\eta^5\text{-}C_7H_9)]$ **(3)**, followed by addition of $[PPh_4]Br$, gives the complex $[\{Co_4(CO)_3(\mu_3\text{-}CO)_3(\mu_3\text{-}C_7H_7)\}_2\{\mu\text{-}\eta^4\text{:}\eta^4\text{-}(C_7H_9)_2\}]^{2-}$ as a mixture of two diastereomers $[\mathbf{4A}]^{2-}$ and $[\mathbf{4B}]^{2-}$ in high yield. The crystal structure of $[\mathbf{4A}]^{2-}[PPh_4]_2\cdot 1.5C_7H_8$ has been determined and confirms the reductive coupling of two Co_4 cluster coordinated apical cycloheptadienyl rings to form a bridging bicycloheptyl-3,5,3′,5′-tetraene ligand. Reduction of **3** with $Li[HBEt_3]$ and subsequent treatment with aqueous $[NnBu_4]Cl$ results in the formation of $[Co_4(CO)_3(\mu_3\text{-}CO)_3(\mu_3\text{-}C_7H_7)(C_7H_{10})]^-$ $[\mathbf{5}]^-$. Addition of $[(\eta\text{-}C_6H_6)Ru(NCMe)_3][BF_4]_2$ after the borohydride reduction gives $[Ru(\eta\text{-}C_6H_6)Co_3(CO)_3(\mu_3\text{-}CO)_3(\mu_3\text{-}C_7H_7)]$ **(6)**, a product derived from reductive Co_4 cluster degradation. A detailed electrochemical and spectro-electrochemical study of the redox behaviour of **3** and $[\mathbf{4}]^{2-}$ has been carried out. The complex potential current response of **3** is rationalized in terms of the formation of the radical anion $[\mathbf{3}]^-$ as the primary intermediate, which may be reversibly reduced further to give the much more stable $[\mathbf{3}]^{2-}$ and then $[\mathbf{3}]^{3-}$. Dimerization of $[\mathbf{3}]^-$ to give $[\mathbf{4}]^{2-}$ occurs by formation of a new carbon–carbon bond between the apical C_7H_9 ligands. The two redox-active moieties in $[\mathbf{4}]^{2-}$ behave as independent, non-interacting redox centres. The oxidized form **4** is unstable and dissociates back to **3** almost quantitatively, thus completing a redox cycle characteristic of a "molecular battery". The homogeneous rate constant for dimerization has been evaluated as k_{DIM} ($2\ [\mathbf{3}]^- \rightarrow [\mathbf{4}]^{2-}$) = 0.30 ± 0.05 $mM^{-1}\ s^{-1}$.



Introduction

Two contrasting statements are frequently made concerning the consequences of an electron transfer to or from a molecular metal cluster complex:[1] (i) behaviour of the cluster as an "electron sponge", i.e. the ability to add or lose electrons without any great effect on the framework, and (ii) a rearrangement of the metal core, upon reduction typically involving cleavage of metal–metal bonds. This is usually attributed to the frontier orbitals of the cluster being generally nonbonding or antibonding with respect to the metal–metal interactions. However, as shown, for example, by the frequently observed labilization of ligands[2] at the periphery of the cluster, metal–ligand bonding may also be affected by the electron–transfer process.[3]

Recently, we have reported on the redox behaviour of a series of tetracobalt cluster complexes with a cyclooctatetraene ligand in the unusual facial (μ_3) coordination mode.[4] On chemical reduction, cluster complexes of the

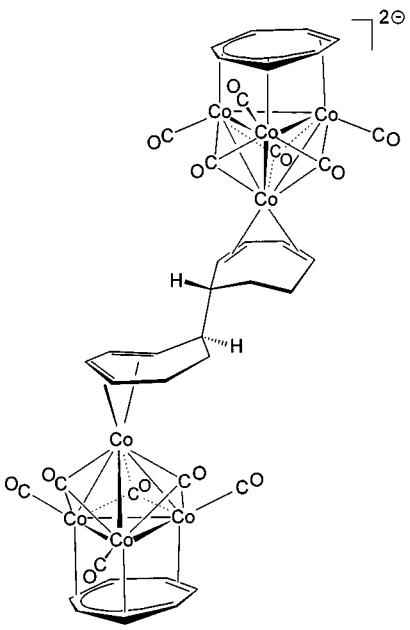
type $[Co_4(CO)_3(\mu_3\text{-}CO)_3(\mu_3\text{-}C_8H_8)(L)]$ [**1a**, L = η^4-C_8H_8; **1b**, L = η^4-C_6H_8; **1c**, L = η^4-diphenylfulvene; **1d**, L = $(CO)_2$][5] are degraded to give the trinuclear cluster anion $[Co_3(CO)_3(\mu_2\text{-}CO)_3(\mu_3\text{-}C_8H_8)]^-$ $[\mathbf{2}]^-$ in high yield. This behaviour follows the general pattern outlined above, but is nevertheless in marked contrast to that of the parent binary carbonyl cluster, $[Co_4(CO)_{12}]$. Here, reduction usually leads to a complete breakdown of the cluster.[6] The trinuclear anion $[Co_3(CO)_{10}]^-$, a close analogue of $[\mathbf{2}]^-$, is quite unstable and can only be obtained from $[Co_4(CO)_{12}]$ under very special conditions.[7]

We report herein on the reduction of $[Co_4(CO)_3(\mu_3\text{-}CO)_3(\mu_3\text{-}C_7H_7)(\eta^5\text{-}C_7H_9)]$ **(3)**,[5] a cluster complex with a facial cycloheptatrienyl ligand. It is shown that the reduction chemistry of this complex is fundamentally different from that of **1**, despite the fact that these systems are isoelectronic and structurally similar.

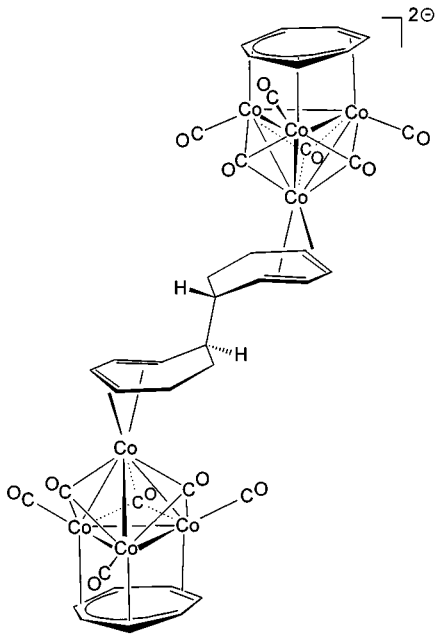
Results

Preparative and Spectroscopic Investigations



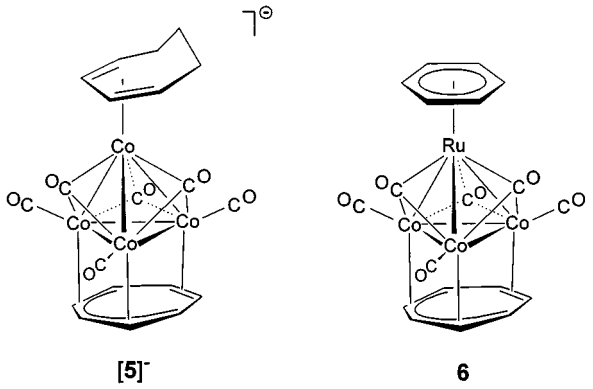
Treatment of $[Co_4(CO)_3(\mu_3\text{-}CO)_3(\mu_3\text{-}C_7H_7)(\eta^5\text{-}C_7H_9)]$ **(3)** with either $Li[HBEt_3]$, LiPh, $Na_2[Fe(CO)_4]$, or cobaltocene, followed by addition of $[PPh_4]Br$ and precipitation with methanol gave a >80% yield of the complex $[\{Co_4(CO)_3(\mu_3\text{-}CO)_3(\mu_3\text{-}C_7H_7)\}_2\{\mu\text{-}(C_7H_9)_2\}][PPh_4]_2$ as a mixture of two diastereomers, $[\mathbf{4A}]^{2-}[PPh_4]_2$ and $[\mathbf{4B}]^{2-}[PPh_4]_2$. Complete separation of the two isomers proved to be impossible on a preparative scale. Repeated crystallization from methanol/THF or nitromethane led to an enrichment in one diastereomer in the solid (up to an 86:14 ratio). This complex, $[\mathbf{4A}]^{2-}[PPh_4]_2$, was finally obtained in pure form as a small batch of single crystals by layering a CH_2Cl_2 solution of the 86:14 isomeric mixture with toluene. Isomer $[\mathbf{4B}]^{2-}[PPh_4]_2$ was only obtained about 80% pure (containing 20% $[\mathbf{4A}]^{2-}[PPh_4]_2$) from the pooled mother liquors.

Column chromatography of the supernatant solution that was left after the first precipitation with methanol gave a second anion, $[Co_4(CO)_3(\mu_3\text{-}CO)_3(\mu_3\text{-}C_7H_7)(C_7H_{10})]^-$ $[\mathbf{5}]^-$, which was obtained as the $[PPh_4]^+$ salt in very low yield (about 1%). In another experiment, where the reaction product of **3** and $Li[HBEt_3]$ was treated with aqueous $[NnBu_4]Cl$, $[\mathbf{5}]^-$ was isolated after recrystallization from ethanol as the $[NnBu_4]^+$ salt in 26% yield.



The course of the reaction of **3** with $Li[HBEt_3]$ was found to be unaffected by changing the stoichiometric ratio (1−4 equivalents of the reducing agent were used). NMR analysis of the initial reduction product (in $[D_8]$THF) showed only minor resonances in the region $-2 \leq \delta \leq 10$.

In order to trap any more highly reduced species, a THF solution of complex **3** was first treated with $Li[HBEt_3]$. The resulting material was then reacted with $[(\eta\text{-}C_6H_6)Ru(NCMe)_3][BF_4]_2$ in CH_2Cl_2. From this reaction, the dark-brown cluster complex $[Ru(\eta\text{-}C_6H_6)Co_3(CO)_3(\mu_3\text{-}CO)_3(\mu_3\text{-}C_7H_7)]$ **(6)** was isolated in 18% yield after column chromatography. On monitoring the reaction by IR spectroscopy, a rapid decrease in the ν_{CO} bands attributable to the starting material **3** was observed following the addition of the $Li[HBEt_3]$ solution, which was accompanied by a concomitant increase of new broad features at 1950 (sh), 1926 (vs), 1700 (sh), and 1675 (s) cm^{-1}. The formation of **6** was seen to be complete within a few minutes after the addition of one equivalent of the ruthenium reagent.



The cluster anions $[\mathbf{4A}]^{2-}$, $[\mathbf{4B}]^{2-}$, and $[\mathbf{5}]^-$, as well as the neutral complex **6**, were characterized by spectroscopic

$[\mathbf{4A}]^{2-}$

$[\mathbf{4B}]^{2-}$

[5]⁻ **6**

methods, and by a crystal structure analysis of $[\mathbf{4A}]^{2-}[PPh_4]_2$. The infrared ($\nu_{CO}$) spectra of all the anions are quite similar; they consist of two broad features in the characteristic regions for terminal (around 1930 cm^{-1}) and triply-bridging carbonyls (around 1680 cm^{-1}). Compared to the neutral starting material, the CO stretches are shifted by about 50−60 cm^{-1} to lower frequencies. Due to the broad absorptions, a distinction between the individual species cannot be made. The IR bands of the Co_3Ru complex **6** also appear at slightly lower wavenumbers (about 10−20 cm^{-1}) than those of the Co_4 cluster **3**. ^1H and ^{13}C NMR spectroscopic data for $[\mathbf{4A}]^{2-}$ and $[\mathbf{4B}]^{2-}$ are collected in Table 1 and Table 2, along with the corresponding data for $[\mathbf{5}]^-$.

The spectra of **6** are very simple, with just two singlets appearing in both the ^1H (δ = 3.20, 5.35) and ^{13}C NMR spectra (δ = 59.8, 95.6). Due to the low solubility and the long relaxation times of the carbonyls, no ^{13}C resonances were detected for these ligands in **6**.

Molecular Structure of $[\mathbf{4A}]^{2-}$

An X-ray crystal structure determination was carried out on a single crystal of $[\mathbf{4}]^{2-}[PPh_4]_2 \cdot 1.5C_7H_8$, containing the diastereomer $[\mathbf{4A}]^{2-}$. Details of the structure determination are given in the Experimental Section. The crystal structure arises from a packing of octanuclear cluster dianions $[\{Co_4(CO)_3(\mu_3\text{-}CO)_3(\mu_3\text{-}C_7H_7)\}_2\{\mu\text{-}\eta^4\text{:}\eta^4\text{-}(C_7H_9)_2\}]^{2-}$ and tetraphenylphosphonium cations, which are interspersed by a total of three molecules of toluene per unit cell as a solvent of crystallization. Due to the rather poor quality of the single crystals, coupled with inherent disorder in some parts of the structure, the accuracy of the structure determination is limited.

A view of the $[\mathbf{4A}]^{2-}$ molecule is presented in Figure 1. Salient bond lengths are given in Table 3. The complex di-

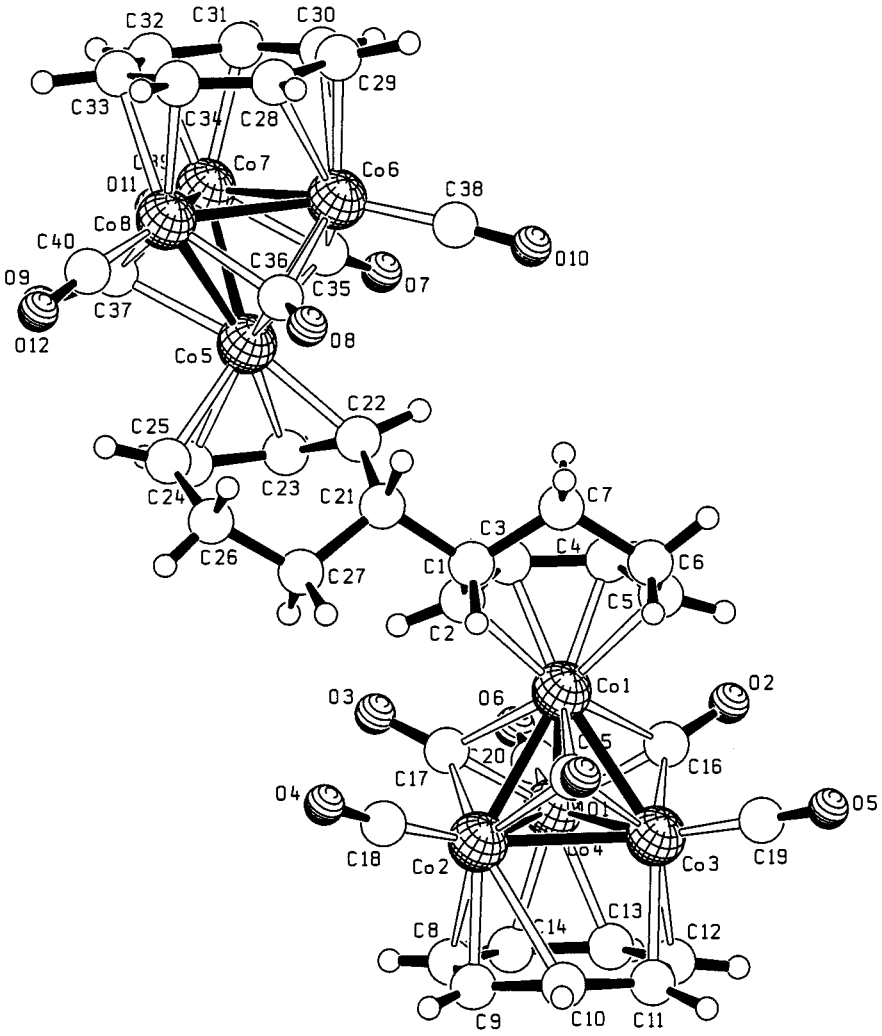

Figure 1. Molecular structure of $[\{Co_4(CO)_3(\mu_3\text{-}CO)_3(\mu_3\text{-}C_7H_7)\}_2\{\mu_2\text{-}\eta^4\text{:}\eta^4\text{-}(C_7H_9)_2\}]^{2-}$ $[\mathbf{4A}]^{2-}$ in the crystals of $[\mathbf{4A}]^{2-}[PPh_4]_2$; only one of the two disordered μ_3-C_7H_7 rings bonded to Co6, Co7, and Co8 is shown

anions $[\mathbf{4A}]^{2-}$ consist of two essentially identical subunits of the composition $[Co_4(CO)_3(\mu_3\text{-}CO)_3(\mu_3\text{-}C_7H_7)(C_7H_9)]$, which are fused together through a carbon−carbon bond involving C1 and C21 of the apical C_7H_9 ligands.[8] This results in a bridging bicyclic ring system, where both cyclohepta-1,3-diene moieties are η^4-coordinated to a $[Co_4(CO)_3(\mu_3\text{-}CO)_3(\mu_3\text{-}C_7H_7)]$ cluster unit. With respect to the bridging ligand, the two Co_4 clusters adopt an *anti* arrangement. The molecule has approximate C_2 symmetry, with the diad bisecting the bond C1−C21.

Electrochemical Investigations

The anodic cyclic voltammetric (CV) response of the cluster complex $[Co_4(CO)_3(\mu_3\text{-}CO)_3(\mu_3\text{-}C_7H_7)(\eta^5\text{-}C_7H_9)]$ **(3)** in THF solution at a glassy carbon (GC) electrode is similar to those previously reported for the butterfly structure $[Co_4(CO)_{10}(RC_2R)]$,[9] for the binary carbonyls $[Co_4(CO)_{12}]$[10] and $[Co_2(CO)_8]$,[11] and for the organometallic derivatives $[Co_3(CO)_9(CR)]$[12] and $[Co_2(CO)_6(RC_2R)]$.[13] A multi-electron oxidation peak is observed at +0.70 V, followed by an electrochemical response typical of an insoluble material adsorbed onto the electrode, and finally by anodic stripping of metallic Co from the GC electrode. This kind of oxidation process has been described in detail elsewhere[13b] and will not be considered further here. In this study, we focus on reduction processes. The relevant half-wave potentials are summarized in Table 4.

At high scan rates, the cathodic CV response of **3** in THF solution shows two subsequent one-electron processes, centred at $E_{1/2}(A/A') = -0.57$ V and $E_{1/2}(B/B') = -1.22$ V (Figure 2).

The two peak couples, which correspond to the redox processes $\mathbf{3}/[\mathbf{3}]^-$ (A/A′) and $[\mathbf{3}]^-/[\mathbf{3}]^{2-}$ (B/B′), are electrochemically and chemically reversible. The peak heights are similar to that of the peak due to an equimolar solution of decamethylferrocene (Fc*) added as an internal standard. However, as the scan rate is lowered, chemical complications arise. By switching the potential at −1.00 V, the first one-electron reduction peak couple (A/A′) remains chemically reversible [i.e. the ratio between the anodic (A′) and

cathodic (A) peak currents, i_p^a/i_p^c, is unity] only at scan rates higher than 2 V/s. At lower scan rates, a new species is produced upon reoxidation at peak C′, giving rise to a reversible peak system C/C′ centred at $E_{1/2}$(C/C′) = −0.12 V. New peak systems are seen on scanning in the available cathodic window (up to −2.4 V) at $E_{1/2}$(D/D′) = −1.69 V and $E_{1/2}$(*E*/*E*′) = −2.22 V (Figure 3).

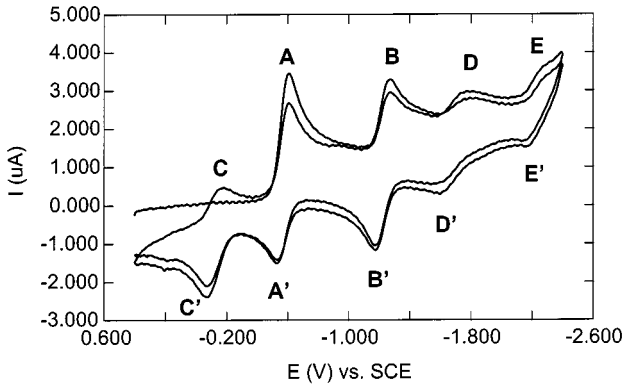

Figure 3. CV response of a THF solution of **3** at a GC electrode (scan rate 0.4 V s^{-1})

Surprisingly, the ratio $i_p^a(B')/i_p^c(B)$ is higher than unity at scan rates lower than 2 V/s. Furthermore, the heights of all the observed peaks are lower than $i_p^c(A)$. This is particularly evident at low scan rates (e.g. 100 mV/s, see Figure 4). It is interesting to note that even at very low scan rates, $i_p^a(B')$ does not disappear.

FT-IR spectroelectrochemistry (CO stretching region) performed in an OTTLE cell during the first reduction process shows a quantitative chemical conversion of **3** (νCO = 1980, 1730 cm^{-1}) to the "dimeric" dianion **[4]**$^{2-}$ (ν_{CO} = 1925, 1675 cm^{-1}), as verified by comparison with the IR spectrum of an authentic sample. Isosbestic points at 1957

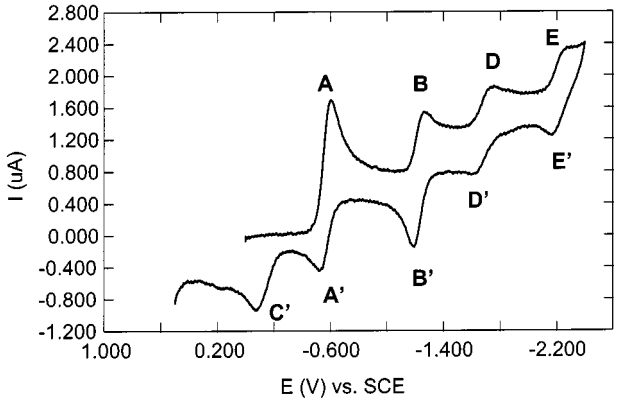

Figure 4. CV response of a THF solution of **3** at a GC electrode (scan rate 0.1 V s^{-1})

cm^{-1} and 1705 cm^{-1} are indicative of full conversion to the dimer in the course of the electrolysis (Figure 5). Reoxidation at the platinum electrode of the OTTLE cell completely restores the original spectrum of the parent compound **3**, suggesting complete chemical reversibility of the system over long-term electrolysis as well.

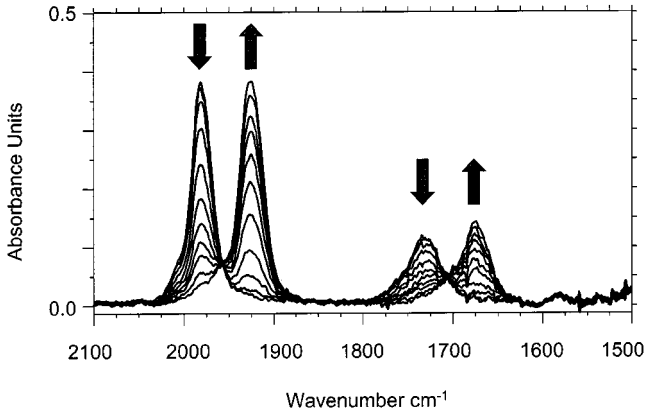

Figure 5. IR OTTLE spectra of a THF solution of **3** during the exhaustive reduction at $E_{app} \approx -0.8$ V

In analogy to CV, polarography of **3** (Figure 6, solid line) shows two reduction waves, A and B. At mercury, a further, very cathodic, reduction process is observed (wave F). Exhaustive electrolysis at a mercury-pool electrode ($E_{appl} = -0.8$ V) was followed by in situ polarography. As 1 F/mol was consumed, waves A and B completely disappeared and an apparent one-electron anodic oxidation wave C and two one-electron reduction waves D and E appeared (dotted line). Re-oxidation at potentials more positive than wave C did not fully restore the original cluster **3** as in OTTLE, probably due to interactions of the cobalt carbonyls with the mercury pool during re-oxidation. Such interactions of cobalt carbonyl derivatives with mercury have been observed several times,[14,15] and have been investigated in detail for the fragment $[Co(CO)_4]^-$.[16]

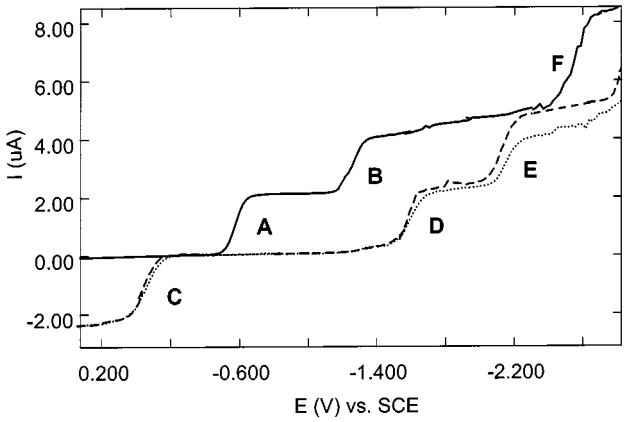

Figure 6. Polarographic responses of a THF solution of **3** recorded in situ during exhaustive electrolysis at a mercury-pool electrode; the solid line corresponds to the initial solution, while the dotted curve was recorded after 1 F/mol had been consumed at $E_{app} \approx -0.8$ V; the dashed curve is the polarographic response of a THF solution of an authentic sample of $[\mathbf{4}]^{2-}$

A pure sample of the dimer $[\mathbf{4}]^{2-}$ (the 86:14 mixture of isomers $[\mathbf{4A}]^{2-}$ and $[\mathbf{4B}]^{2-}$) (dashed line) was found to exhibit the same electrochemical behaviour. The redox waves of $[\mathbf{4}]^{2-}$ (i.e. D and E) are twice the height compared to that of an equimolar solution of Fc*, added as an internal standard. The electron stoichiometry (2 electrons) of both reduction processes was confirmed by coulometry. Furthermore, the polarographic slopes obtained from log-plot analyses and the ΔE_p values from the CV (both roughly 60 mV) are typical of a single-electron Nernstian process. Waves D and E assigned to $[\mathbf{4}]^{2-}$ (produced by exhaustive electrolysis of **3**) relate to two-electron processes, but correspond to half concentrations of the electroactive species, and therefore their heights are equal to those of waves A and B (assigned to the parent cluster **3**). Finally, $[\mathbf{4}]^{2-}$ exhibits the usual multi-electron chemical irreversible oxidation peak at +0.70 V at glassy carbon.

Discussion

A family of isoelectronic tetracobalt carbonyl cluster complexes exists where one face of the Co_4 tetrahedron is capped by a facial (μ_3) ligand. These include $[Co_4(CO)_6(\mu_2\text{-}CO)_3(\mu_3\text{-trithiane})]$ **(7)**,[17] $[Co_4(CO)_6(\mu_2\text{-}CO)_3\{\mu_3\text{-}HC(EPh_2)_3\}]$ **(8a)** (E = P), **(8b)** (E = As),[18] $[Co_4(CO)_3(\mu_3\text{-}CO)_3(\mu_3\text{-}C_8H_8)(L)]$ **(1)**,[5] and $[Co_4(CO)_3(\mu_3\text{-}CO)_3(\mu_3\text{-}C_7H_7)(L)]$ [L = η^5-C_7H_9 (**3**); η-C_5R_5, R = H, Me].[5] These derivatives of the parent binary carbonyl $[Co_4(CO)_{12}]$ are "electron precise" (60 valence electrons [VE]).[19] It has been demonstrated that the facial ligands tend to stabilize the tetrahedral Co_4 cluster core, resulting in a considerably reduced tendency to fragment during the course of chemical and electrochemical reactions. For example, $[Co_4(CO)_{12}]$ readily undergoes complete fragmentation when reduced in the absence of reactants.[6] The one-electron reduction product of **8a**, $[Co_4(CO)_9\{\mu_3\text{-}HC(PPh_2)_3\}]^-$ $[\mathbf{8a}]^-$, is more stable, but undergoes rapid ligand exchange at the apical

cobalt atom.[6b] The cyclooctatetraene-bridged clusters **1** have been shown to undergo pseudo-reversible electrochemical one-electron reductions, but are quantitatively converted to the stable trinuclear anion $[Co_3(CO)_3(\mu_2\text{-}CO)_3(\mu_3\text{-}C_8H_8)]^-$ $[\mathbf{2}]^-$ upon chemical reduction.[4]

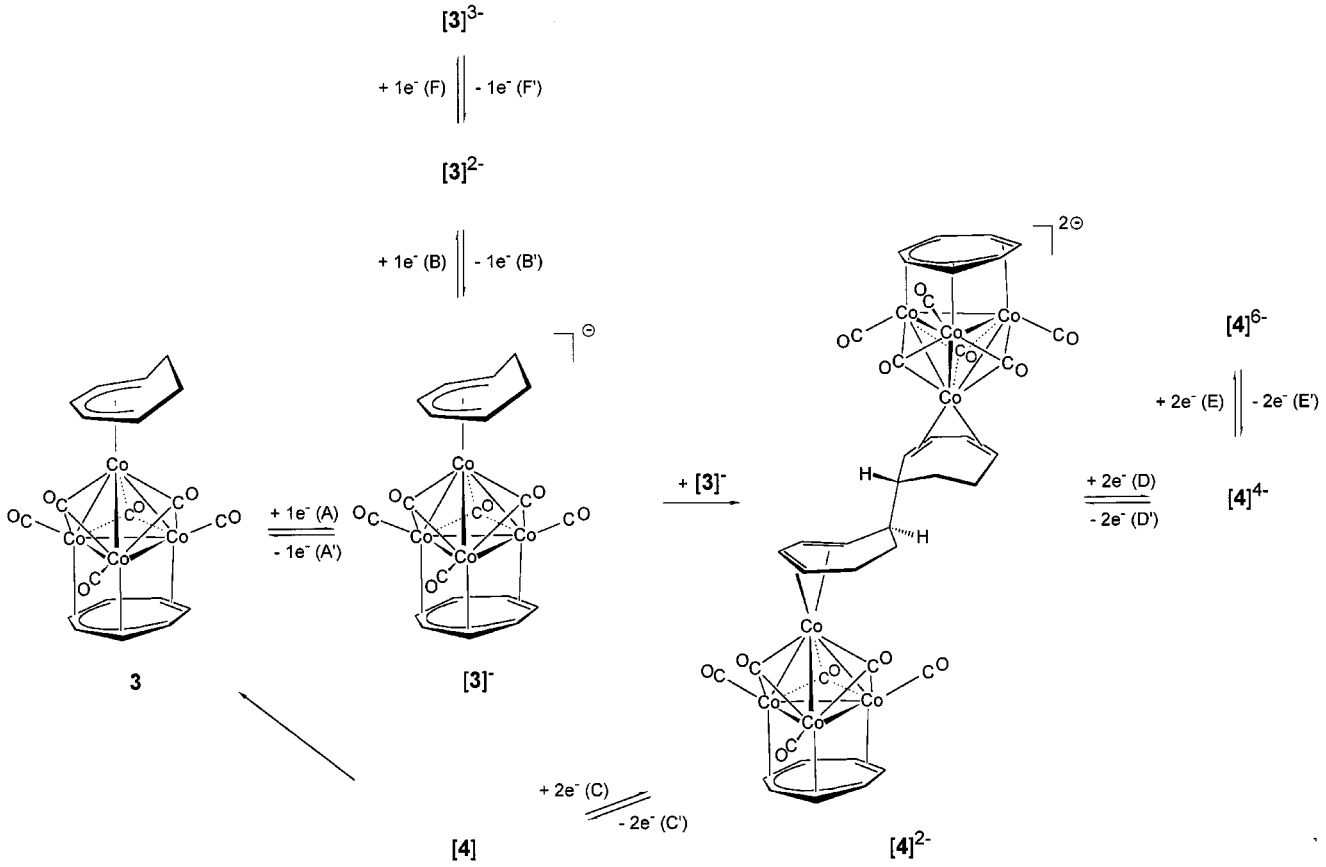
A similar behaviour was expected of the cycloheptatrienyl-bridged cluster complexes **3**, from which we hoped to generate the trinuclear dianion $[Co_3(CO)_6(\mu_3\text{-}C_7H_7)]^{2-}$ $[\mathbf{9}]^{2-}$. However, our electrochemical studies have not produced any evidence for the formation of this species. The initial reduction product $[\mathbf{3}]^-$ is indeed transient, but further reaction occurs through intermolecular ligand−ligand coupling to give $[\mathbf{4}]^{2-}$, and not by degradation of the metal framework. With some caution,[20] this can be taken as evidence that the unpaired electron in $[\mathbf{3}]^-$ is essentially centred on the apical C_7H_9 ligand, and less so on the metal cluster. This view is also consistent with the formation of minor amounts of $[\mathbf{5}]^-$, which is the electron-precise product of hydrogen abstraction from the solvent or water by $[\mathbf{3}]^-$.

The formation of $[\mathbf{4}]^{2-}$ is regiospecific [carbon−carbon bond formation occurs exclusively at the carbon atom(s) in the enylic positions, adjacent to the unsaturated π-system of the C_7H_9 ligand], but not stereospecific. The absolute configuration (*R*,*R*) [and (*S*,*S*)] can be assigned to the bridgehead carbon atoms C1 and C21 in $[\mathbf{4A}]^{2-}$ on the basis of our structure determination. It seems likely that $[\mathbf{4B}]^{2-}$ is the achiral (*R*,*S*) isomer (*meso* form).

The formation of the Co_3Ru complex **6**, another electron-precise cluster, is more difficult to explain. It could be due to a stacking reaction of the ruthenium benzene reagent with the trinuclear dianion $[\mathbf{9}]^{2-}$, akin to the reaction of $[\mathbf{2}]^-$ with $[(\eta\text{-}C_5Me_5)Ru(NCMe)_3]^+$.[4] However, this would require that $[\mathbf{9}]^{2-}$ be present, at least in minor amounts, in the mixture of reduction products of **3**. The paramagnetism of the main product, $[\mathbf{3}]^-$, could prevent the detection of $[\mathbf{9}]^{2-}$ (expected to be diamagnetic) in the reaction mixture by NMR spectroscopy. This interpretation could explain the observation that formation of **6** is complete within a few minutes, whereas the subsequent dimerization of $[\mathbf{3}]^-$ is much slower.

Alternatively, a redox condensation of the tetranuclear $[\mathbf{3}]^-$ with $[(\eta\text{-}C_6H_6)Ru(NCMe)_3]^{2+}$ could take place, which would involve extrusion of a cobalt vertex. Here, the low yield of product **6** would be accounted for by the charge balance, which requires sacrifice of two molecules of $[\mathbf{3}]^-$ for the formation of one molecule of **6**.

A 60 VE count is attained by either of the two Co_4 cluster units in $[\mathbf{4A}]^{2-}$, as well as by $[\mathbf{5}]^-$. Hence, the uptake of an electron by **3**, followed by dimerization or hydrogen abstraction, is accompanied by a decrease of hapticity of the apical seven-membered ring ligand (from η^5 to η^4). The lengths of the endocyclic carbon−carbon bonds within the bridging $(C_7H_9)_2$ ring system conform to the pattern expected for η^4-cycloheptadiene ligands: they are shorter within the η^4-diene systems (mean value 1.42 Å) and longer in the remaining rings (mean value 1.52 Å). The bond C1−C21, which joins the two seven-membered rings, is slightly longer [1.570(6) Å] than would be expected for a single bond. This value compares well with the corresponding bond lengths in the dinuclear complexes $[\{(CO)_3Fe\}_2\{\mu\text{-}\eta^4\text{:}\eta^4\text{-}(C_7H_9)_2\}]$ [1.564(4) Å][21] and $[\{(\eta\text{-}C_5H_5)Co\}_2\{\mu\text{-}\eta^4\text{:}\eta^4\text{-}(C_7H_9)_2\}]$ **(10)** [1.564(5) Å].[22]



Within the limitations of the experimental accuracy, the geometry of the $Co_4(CO)_6$ cluster units in $[\mathbf{4A}]^{2-}$ is quite similar to that seen in other complexes containing the $Co_4(CO)_6(\mu_3\text{-}C_nH_n)$ moiety.[5] The coordination mode of the facial C_7H_7 rings approaches the $\mu_3\text{-}\eta^2\text{:}\eta^2\text{:}\eta^3$ fashion and is therefore slightly different from the $\mu_3\text{-}\eta^2\text{:}\eta^3\text{:}\eta^3$ coordination found in **3**.[5] However, owing to the small actual geometric differences between the various forms of the $\mu_3\text{-}\eta^7$ coordination mode, the experimental inaccuracies, and the low barrier to rotation, no great significance should be attached to this observation.

As expected, a high mobility of the facial C_7H_7 ligands in $[\mathbf{4}]^{2-}$, $[\mathbf{5}]^-$, and **6** is evident in solution, which can be explained in terms of rapid rotation of the seven-membered rings within their coordination planes. The ^1H and ^{13}C NMR chemical shifts of these ligands compare well with those observed in **3**.[5] It appears that a ^{13}C chemical shift of about $\delta = 60$ is typical for a C_7H_7 ligand facially coordinated to a Co_3 cluster face, with a minor high-field shift of about 5 ppm when the molecule bears a negative charge. This is in contrast to the much larger coordination shifts that have been reported for $Ru_3(\mu_3\text{-}C_7H_7)$ moieties [$\delta(^{13}C) \approx 39$].[23] The proton resonance of the η^6-benzene ligand in **6** appears at a chemical shift comparable to that found for apical benzene ligands in hexa- and pentanuclear ruthenium and mixed ruthenium osmium carbonyl cluster complexes.[24] Interestingly, resonances at higher field are observed when the $(\eta\text{-}C_6H_6)Ru$ moiety is part of a penta- or hexanuclear iron carbonyl cluster {e.g. $[Ru(\eta\text{-}C_6H_6)Fe_5C(CO)_{14}]$, $\delta(^1H) = 4.37$; $[Ru(\eta\text{-}C_6H_6)Fe_4C(CO)_{12}]$, $\delta(^1H) = 4.85$}.[25]

The electrochemical data can be accounted for by the mechanism depicted in Scheme 1.

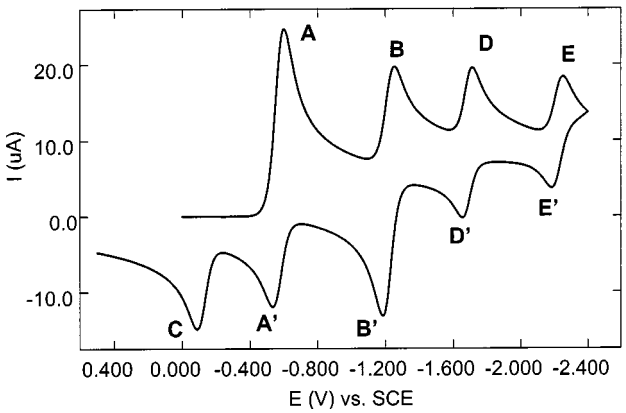
The dimerization of the radical anion $[\mathbf{3}]^-$ to form $[\mathbf{4}]^{2-}$ explains the reversible re-oxidation C′. Interestingly, the oxidized form **4** is unstable in the long-term and decomposes back to **3** almost quantitatively. The dimerization reaction $[\mathbf{3}]^- + [\mathbf{3}]^- \rightarrow [\mathbf{4}]^{2-}$ is sufficiently fast to produce peaks D/D′ and E/E′ (Figure 3), attributable to further reduction of the dimer itself, but not so fast as to lead to complete loss of peaks B and A′ (Figure 4), assigned to further reduction and re-oxidation of the monomer $[\mathbf{3}]^-$, respectively. This justifies the differences in the peak heights discussed above. Contrasting behaviour, where the anomalous peak height was rationalized in terms of a catalytic mechanism, has been observed in a study of the electron-transfer chain reaction that follows the reduction of $[H_4Ru_4(CO)_{12}]$.[26] It is noteworthy that the dianion $[\mathbf{3}]^{2-}$ is much more stable than the monoanion $[\mathbf{3}]^-$ on the CV time scale. This accounts for the fact that $i_p^a(B')$ is higher than $i_p^c(B)$.

The redox behaviour of $[\mathbf{4}]^{2-}$, as outlined above, suggests that the two redox-active moieties, $Co_4(CO)_3(\mu_3\text{-}CO)_3(\mu_3\text{-}C_7H_7)(\eta^4\text{-}C_7H_9)$, directly bonded by a single

Scheme 1. Redox processes involving complexes **3** and **4**

carbon−carbon bond, act as two independent, non-interacting redox centres. For such a case, the two one-electron reduction processes are separated by 36 mV (statistical factor) and a single, double-height wave is expected.[27]

Digital simulation[28] (Figure 7) of the overall mechanism produced a shape similar to that observed experimentally (Figure 4). The homogeneous rate constant for the dimerization was evaluated as k_{DIM} (2 [**3**]$^-$ → [**4**]$^{2-}$) = 0.30 ± 0.05



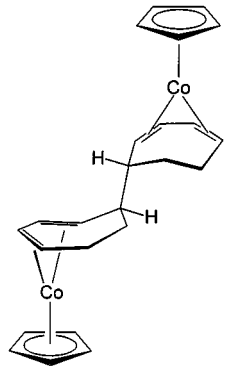


Figure 7. Digital simulation according to the mechanism in Scheme 1; scan rate 0.1 V s^{-1}; heterogeneous rate constant ($k°$) = 2 cm s^{-1}; α = 0.5; D(**3**) = 1 × 10^{-5} cm^2 s^{-1}; D(**4**) = 7 × 10^{-6} cm^2 s^{-1}; $E_{1/2}$(A/A′) = $E_{1/2}$(**3**/[**3**]$^-$) = −0.57 V; $E_{1/2}$(B/B′) = $E_{1/2}$([**3**]$^-$/[**3**]$^{2-}$) = −1.22 V; $E_{1/2}$(**4**/[**4**]$^-$) = −0.102 V; $E_{1/2}$([**4**]$^-$/[**4**]$^{2-}$) = −0.138 V; $E_{1/2}$([**4**]$^{2-}$/[**4**]$^{3-}$) = −1.672 V; $E_{1/2}$([**4**]$^{3-}$/[**4**]$^{4-}$) = −1.698 V; $E_{1/2}$([**4**]$^{4-}$/[**4**]$^{5-}$) = −2.202 V; $E_{1/2}$([**4**]$^{5-}$/[**4**]$^{6-}$) = −2.238 V; k_f (**4** → 2 **3**) = 0.2 s^{-1}; k_{DIM} (2 [**3**]$^-$ → [**4**]$^{2-}$) = 0.30 mM^{-1} s^{-1}

10

mM^{-1} s^{-1} (according to the DIM 1 mechanism proposed by Saveant et al.[29]), either by means of best-fitting of the experimental data[28] or by applying the method of Lasia[30] with different values for the scan rates (0.05−1 V/s) and concentrations of **3** (0.6−3 mM). The CV switching potential was 300 mV past the first cathodic peak potential.[30] Both methods gave a similar rate, but simulation produces an "*ad hoc*" working curve.

The redox-induced intermolecular coupling of the two cycloheptadienyl ligands has a precedent in mononuclear chemistry. Geiger et al.[22] observed that [(η-C_5H_5)Co(η^5-C_7H_9)]$^+$ undergoes two reductions, at −0.8 and −1.9 V, the latter process being irreversible. This complex generated the

"dimer" $[\{(\eta\text{-}C_5H_5)Co\}_2\{\mu\text{-}\eta^4\text{:}\eta^4\text{-}(C_7H_9)_2\}]$ **(10)** upon electrolysis at −1.0 V. The value found for the dimerization of the mononuclear cobalt complex (k_{DIM} = 1.35 mM^{-1} s^{-1})[31] is somewhat higher than that found in the present work; this is probably due to the presence of the bulkier tetracobalt unit in **3**. Whereas the dimer **10** is oxidized in two one-electron steps with limited electronic communication, the oxidation of $[\mathbf{4}]^{2-}$ occurs in a single two-electron step. Interestingly, dimer **10** is stable, whereas dimer **4** undergoes spontaneous fission of the newly formed C−C bond, thus constituting the basis of a very interesting redox cycle (see Conclusion).

For **10**, there was no indication that two stereoisomers had been formed. In the crystal used for the structure determination, the same (*R*,*R*) and (*S*,*S*) configurations of the bridgehead carbons as in $[\mathbf{4A}]^{2-}$ were found.

Conclusion

The propensity of cluster **3** to dimerize upon reduction to $[\mathbf{4}]^{2-}$ with the formation of an additional C−C bond and its reoxidation to **4**, which, in turn, is unstable and spontaneously reverts to **3** in a perfectly reversible manner by cleavage of this C−C bond, constitutes a very promising redox cycle. This system approaches the concept of a "molecular battery" proposed by Floriani,[32] i.e. a molecular device capable of storing and releasing pairs of electrons through the formation and cleavage of chemical bonds. This reservoir of electrons controlled by the reversible formation of C−C bonds may represent an interesting device for electrical energy storage.

Experimental Section

General Procedures: All operations were carried out under an atmosphere of purified nitrogen or argon (BASF R3−11 catalyst) using Schlenk techniques. Solvents were dried by conventional methods. Alumina used as a stationary phase for column chromatography was heated to 180−200 °C in vacuo for several days, deactivated with 5% water, and then stored under nitrogen. The cluster complex **3** was prepared as described previously.[5] NMR spectra were recorded on Bruker AC 200 and AVANCE DRX200 instruments (200.1 MHz for ^1H, 50.3 MHz for ^{13}C); ^1H and ^{13}C chemical shifts are reported *vs.* $SiMe_4$ and were determined by reference to internal $SiMe_4$ or residual solvent peaks. Infrared spectra were recorded from samples in CaF_2 cells on a Bruker IFS-28 Fourier-transform spectrometer (optical resolution 0.5 cm^{-1}). Elemental analyses were performed locally at the Microanalytical Laboratory of the Organisch-chemisches Institut der Universität Heidelberg and at the Mikroanalytisches Labor Beller, Göttingen.

$[PPh_4]_2[\{Co_4(CO)_3(\mu_3\text{-}CO)_3(\mu_3\text{-}C_7H_7)\}_2\{\mu_2\text{-}(C_7H_9)_2\}]$ ($[PPh_4]_2[\mathbf{4}]^{2-}$): A mixture of $[Co_4(CO)_3(\mu_3\text{-}CO)_3(\mu_3\text{-}C_7H_7)(\eta^5\text{-}C_7H_9)]$ **(3)** (1.1 g, 1.7 mmol) and $Na_2[Fe(CO)_4]\cdot 3/2$dioxane (0.64 g, 1.9 mmol) was dissolved in THF (50 mL) and the resulting solution was stirred for 30 min. at room temperature. All volatiles were then removed in vacuo, the residue was redissolved in THF (10 mL), and $[PPh_4]Br$ (3.0 g, 7.2 mmol) was added. After stirring for 1 h, the mixture was filtered and the filtrate was concentrated to a small volume. A tenfold excess of methanol was then added to precipitate the product as a mixture of diastereomers $[\mathbf{4A},\mathbf{B}]^{2-}[PPh_4]_2$ (860 mg, 54%). Partial separation of the isomers (about 86% purity for the less soluble $[\mathbf{4A}]^{2-}[PPh_4]_2$; about 80% purity for $[\mathbf{4B}]^{2-}[PPh_4]_2$) could be achieved by repeated recrystallization from THF/methanol or nitromethane. The mother liquor from the first precipitation with methanol was subsequently chromatographed on alumina (deactivated with 5% water, 2.5 × 20 cm). A red band was eluted from the column with CH_2Cl_2, from which 20 mg (1%) of $[Co_4(CO)_3(\mu_3\text{-}CO)_3(\mu_3\text{-}C_7H_7)(C_7H_{10})][PPh_4]$ ($[\mathbf{5}]^-[PPh_4]$) was isolated.

$[\mathbf{4}]^{2-}[PPh_4]_2$: IR ($CH_2Cl_2$): ν(CO) = 1955 (sh), 1926 (vs), 1702 (sh), 1675 (s) cm^{-1}. − $C_{88}H_{72}Co_8O_{12}P_2$ (1854.96): calcd. C 56.98, H 3.91; found C 56.43, H 4.10.

$[Co_4(CO)_3(\mu_3\text{-}CO)_3(\mu_3\text{-}C_7H_7)(C_7H_{10})][PPh_4]$ ($[\mathbf{5}]^-[PPh_4]$): A sample of **3** (270 mg, 0.46 mmol) in THF (30 mL) was treated with 0.5 mL of a 1 M solution of $Li[HBEt_3]$ in THF. After stirring for 30 min. at room temperature, all volatiles were removed in vacuo. The residue was redissolved in THF (5 mL) and to this solution, a solution of $[NnBu_4]Cl$ (2.4 g, 8.6 mmol) in water (40 mL) was added dropwise. After stirring for 30 min., the product was collected on a glass frit, washed with H_2O, toluene, and pentane, and dried in vacuo. Recrystallization from ethanol gave 100 mg (26%) of $[\mathbf{5}]^-[NnBu_4]$. − IR (CH_2Cl_2): ν(CO) = 1955 (sh), 1925 (vs), 1700 (sh), 1675 (s) cm^{-1}.

$[Ru(\eta\text{-}C_6H_6)Co_3(CO)_3(\mu_3\text{-}CO)_3(\mu_3\text{-}C_7H_7)]$ (6): A 1.6 mL aliquot of a 1 M solution of $Li[HBEt_3]$ in THF was added to a solution of **3** (0.92 g, 1.6 mmol) in THF (50 mL). After stirring for 1 h at room temperature, all volatiles were removed in vacuo. The residue was then treated with a solution of $[(\eta\text{-}C_6H_6)Ru(NCMe)_3][BF_4]_2$ (0.75 g, 1.6 mmol) in CH_2Cl_2 (50 mL). After 30 min., some insoluble material was removed by filtration. The filtrate was concentrated to dryness in vacuo, the black residue was washed with *n*-hexane, and then applied to the top of a column (2.5 × 20 cm) of alumina (deactivated with 5% water). Elution with toluene removed a light-brown band from the column. The product was then eluted with CH_2Cl_2 as a dark-brown band, from which 180 mg (18%) of black microcrystalline **6** was isolated. − ^1H NMR (CD_2Cl_2): δ = 3.20 (s, 7 H, C_7H_7), 5.35 (s, 6 H, C_6H_6). − $^{13}C\{^1H\}$ NMR (C_6D_6): δ = 59.8 (C_7H_7), 95.6 (C_6H_6). − IR (toluene): ν(CO) = 2000 (sh), 1973 (vs), 1715 (s) cm^{-1}. − $C_{19}H_{13}Co_3O_6Ru$ (615.18): calcd. C 37.10, H 2.13; found C 37.16, H 2.76.

Crystal Structure Determination: Single crystals of $[\mathbf{4A}][PPh_4]_2\cdot 1.5C_7H_8$ were grown from a solution of the 86:14 mixture of isomers $[\mathbf{4A}]^{2-}/[\mathbf{4B}]^{2-}$ in CH_2Cl_2 by layering with toluene at room temperature. Intensity data were collected on a Siemens-Stoe AED2 four-circle diffractometer at low temperature (Table 5). The structure was solved by direct methods and refined by full-matrix least-squares based on F^2 using all measured unique reflections. One of the $\mu_3\text{-}C_7H_7$ ligands, a phenyl ring in one of the $[PPh_4]^+$ cations, and a toluene solvate molecule were found to be disordered. Most non-hydrogen atoms were given anisotropic displacement parameters, except those of the disordered C_7H_7 and toluene rings. Some of the hydrogen atoms were localized in difference Fourier syntheses and were refined isotropically. The remaining hydrogen atoms were placed in calculated positions (except those of the disordered toluene).[33] The calculations were performed using the programs SHELXS-86 and SHELXL-97.[34] Graphical representations were produced using SCHAKAL-92.[35]

Table 5. Details of the crystal structure determination of $[\{Co_4(CO)_3(\mu_3\text{-}CO)_3(\mu_3\text{-}C_7H_7)\}_2\{\mu\text{-}\eta^4\text{:}\eta^4\text{-}(C_7H_9)_2\}][PPh_4]_2\cdot 1.5C_7H_8$ ($[4A]^{2-}$-$[PPh_4]_2$)

Electrochemistry: THF was distilled from sodium benzophenone ketyl immediately prior to use. Tetrabutylammonium hexafluorophosphate (Aldrich) was recrystallized three times from 95% ethanol and dried in a vacuum oven at 110 °C overnight. Electrochemistry was performed with an EG&G PAR 273 electrochemical analyser connected to a PC, employing the software M270. A standard three-electrode cell was designed to allow the tip of the reference electrode to closely approach the working electrode. The reference used was the Standard Calomel Electrode (SCE). The working electrode for CV was composed of glassy carbon (GC); for polarography, a dropping mercury electrode (DME) with flow rate of 1.22 mg s^{-1} at a reservoir height of 0.5 m was employed. Drop time (typically 1 s) was controlled by an electromechanical hammer. A platinum wire served as the auxiliary electrode. Positive feedback *iR* compensation was applied routinely. All measurements were carried out under Ar in anhydrous deoxygenated THF or CH_2Cl_2. Solutions were 5×10^{-4} M in the compounds under study and 1×10^{-1} M in the supporting electrolyte, $[Bu_4N][PF_6]$. Since the oxidation process of ferrocene (Fc) overlaps with those of the compounds under study, we employed decamethylferrocene (Fc*) as an internal standard; the Fc*(0/1+) potential was evaluated as +0.11 V *vs.* SCE in THF.[36,37] The number of electrons transferred (n_{app}) in a particular redox process was determined by controlled potential coulometry at a mercury pool. Each experiment was carried out in duplicate. Spectroelectrochemistry was performed in an optically transparent thin-layer electrochemical (OTTLE) cell assembled as described previously;[38] the spectra were recorded on a Bruker Equinox 55 FT-IR spectrometer.

Acknowledgments

This work was supported by the Sonderforschungsbereich 247 der Universität Heidelberg, the Fonds der Chemischen Industrie, and MURST (Rome) (COFIN-98). The award of a Heisenberg Fellowship to H.W. is gratefully acknowledged. J.F. thanks the University of Torino for a visiting grant (scambi culturali).

Self-Assembly of *meso*-Pyridylporphyrins and Zinc Phthalocyanines Through Axial Coordination

Xi-you Li[a] and Dennis K. P. Ng*[a]

Keywords: Porphyrins / Phthalocyanines / Self-assembly / Axial coordination / Zinc

Molecular assemblies of *meso*-pyridylporphyrins and zinc(II) 1,8,15,22-tetrakis(3-pentyloxy)phthalocyanine held through axial coordination are reported. Their formation has been revealed by ^{1}H NMR spectroscopy and photophysical measurements.

Introduction

Photo-induced electron- and energy-transfer in noncovalently bonded supramolecular assemblies has been studied extensively with the primary aim of harvesting solar energy and gaining a better understanding of photosynthesis, which is a marvellous but highly complex biological process.[1] Noncovalent assemblies containing porphyrins are of special importance because of their resemblance to nature, which also relies on supramolecular methods of assembly,[2] and the rich redox and photochemistry of this intriguing class of pigments.[3] Numerous porphyrin systems linked to a variety of electron acceptors, in particular quinone[4] and C_{60} derivatives,[5] have been examined. Supramolecular aggregates involving phthalocyanines, however, have received little attention despite the fact that these tetrapyrrole derivatives also exhibit fascinating physico-chemical properties.[6] Arrays of mixed porphyrin and phthalocyanine are mainly confined to the few examples of covalently linked systems,[7,8] sandwich-type complexes,[9] and face-to-face aggregates held by electrostatic interactions.[8] We describe herein the first edge-to-face arrays assembled through axial ligation of pyridyl substituents in porphyrins to zinc phthalocyanines. Although it is well-known that pyridine can relieve the extent of aggregation of zinc phthalocyanines (probably via axial coordination[10]) and that the formation of edge-to-face assemblies of the zinc(II) tribenzo(pyridino)porphyrazine has been inferred,[11] there has been a shortage of concrete experimental evidence supporting the axial coordination of zinc phthalocyanines which forms the basis of this work.[12]

Results and Discussion

The *meso*-tetra(4-pyridyl)porphyrin (**1**) and 1,8,15,22-tetrakis(3-pentyloxy)phthalocyaninatozinc(II) (**2**) were selected to construct multi(tetrapyrrole) arrays as the former is an excellent square-shaped building block[13] and the latter gives distinct and well-resolved ^{1}H NMR spectra, which facilitates the spectral analysis.[14] Figure 1 shows the ^{1}H NMR spectral changes of these macrocycles upon complexation. It can be seen that by adding one equiv. of **2** to **1** in $CDCl_3$, the three sets of aromatic signals for **2** experience a downfield shift ($\Delta\delta = 0.32$ for H_a, 0.11 for H_b, 0.10 for H_c), retaining the original multiplicity [Figure 1 (b) and (c)]. The multiplets for the 3-pentyloxy substituents (not shown) are also shifted downfield by ca. 0.1−0.2 ppm. The signals for the β-pyrrole, pyridyl and N−H protons of **1**, however, are shifted upfield and become broad [Figure 1 (a) and (c), the N−H band shifts from $\delta = -2.92$ to -3.03]. The broad signal at $\delta = 8.44$ is tentatively assigned to the β-pyrrole protons, while the broad band at $\delta = 7.70$ and the very weak tail around the solvent peak may be due to the pyridyl protons. These data are consistent with an edge-to-face dyad in which the phthalocyanine is deshielded by the ring current generated by the porphyrin macrocycle which falls into the shielding region of phthalocyanine. Similar spectral features have also been observed for related porphyrin aggregates.[13b,15] The broad nature of the porphyrin signals, in particular for the pyridyl protons, suggests that there is an extensive exchange between the coordinated and the free pyridyl groups. Due to the C_{4h} symmetry of the phthalocyanine, the resulting dyad does not possess an internal mirror plane, but a C_2 axis is present passing through two opposite pyridyl nitrogen atoms and the zinc(II) centre.[16] Therefore, some of the pyridyl protons become chemically equivalent and hence a restricted rotation of the pyridyl group along the C(*meso*)−C(pyridyl) bond may not contribute to the broadening of signals. Upon addition of four equiv. of **2** to **1** in $CDCl_3$, the NMR signals due to **2** are also shifted downfield to virtually the same extent, but the signals assigned to **1** are further broadened and shifted upfield [Figure 1 (d)]. This indicates that higher aggregates up to pentad [Figure 2 (a)] may be formed, which also exhibit relatively fast dynamic exchange processes.

The electronic absorption spectra of **1** (4×10^{-6} M), upon titration with **2** (from 4×10^{-6} to 2×10^{-5} M) in $CHCl_3$, and vice versa ([**2**] = 1×10^{-6} M, [**1**] from 1×10^{-6} to 1 ×

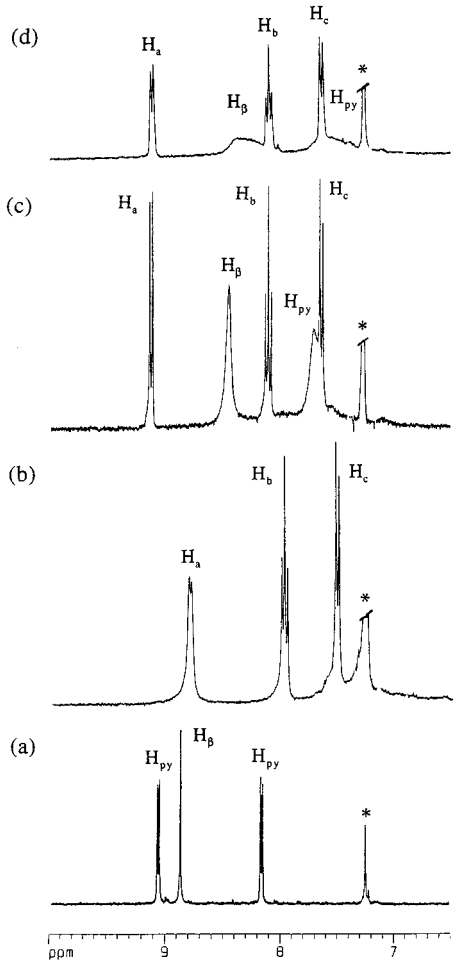

Figure 1. ^{1}H NMR spectra (aromatic region) of (a) **1**, (b) **2**, and mixtures of **1** and **2** in a (c) 1:1 and (d) 1:4 ratio in $CDCl_3$; * indicates residual solvent peak

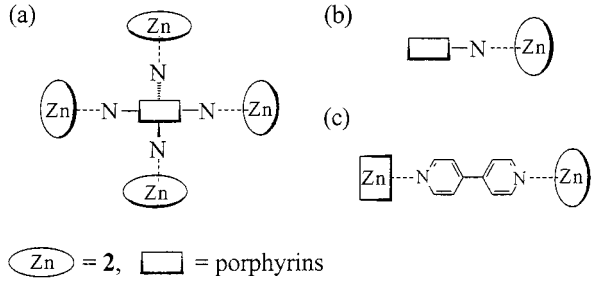

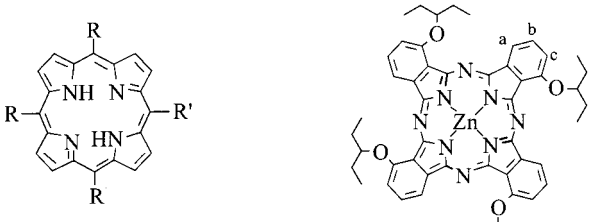

Figure 2. Schematic diagrams showing the structure of (a) **1**-(**2**)$_4$ pentad, (b) **4**−**2** dyad and (c) Zn(**5**)-bipy-**2**

10^{-5} M), remains essentially unchanged showing that the ground state π-π interactions between the perpendicularly disposed **1** and **2** are insignificant. The absence of interactions was also observed for oligoporphyrin systems linked in a similar fashion.[16] However, the fluorescence of **1** at 649 and 709 nm, upon excitation at 515 nm, diminishes gradually during titration with **2** in $CHCl_3$ (Figure 3). A similar fluorescence quenching is also observed by titrating a $CHCl_3$ solution of **2** (λ_{ex} = 615 nm, λ_{em} = 714 nm) with **1**. This mutual quenching phenomenon is likely to be due

Compound	R	R'
1	C_5H_4N	C_5H_4N
3	Ph	Ph
4	Ph	C_5H_4N
5	C_6H_4Me	C_6H_4Me

to a photo-induced electron transfer, as it is well-known that both porphyrins and phthalocyanines can act as electron donors or acceptors,[8,17] and no emission due to **2** is observed when **1** is excited which precludes an energy transfer pathway. In a control experiment, **1** was replaced with *meso*-tetraphenylporphyrin (**3**) of which the fluorescence spectra were recorded under identical conditions. There is no observable change in the fluorescence intensity of **3** upon titration with **2** which provides strong evidence for axial coordination of the pyridyl groups to the zinc(II) metal centre in **2**.

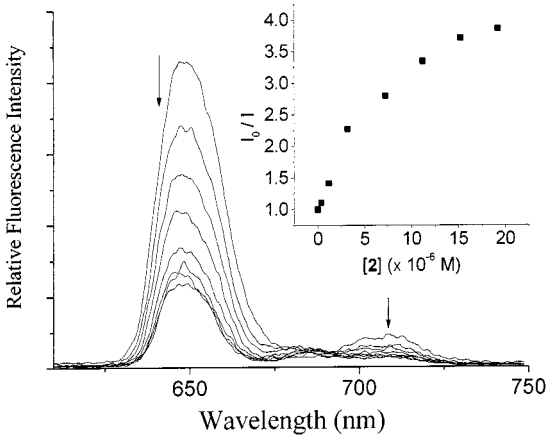

Figure 3. Fluorescence spectra of **1** (4×10^{-6} M) upon titration with **2** in $CHCl_3$. [**2**]: 0, 0.4, 1.2, 3.2, 7.2, 11.2, 15.2 and 19.2 × 10^{-6} M. The inset shows the Stern−Volmer plot for the fluorescence quenching at 649 nm

The association of *meso*-triphenyl(4-pyridyl)porphyrin (**4**) and **2** was also studied in which there is only one axial ligation [Figure 2 (b)]. Similarly, all the ^{1}H NMR signals due to **2** are shifted downfield while the signals assigned to **4** are slightly broadened and shifted upfield (see the Experimental Section). The fluorescence of **4** was also quenched by **2** and the association constant (K) for this edge-to-face dyad was determined by the Benesi−Hildebrand equation: $I_o/(I_o - I) = 1/A + 1/KA[\mathbf{2}]$, where I_o and I are the fluorescence intensity of **4** without and with the addition of **2**, respectively, and A is a constant related to the difference in the emission quantum yield of the complexed and uncomplexed **4**.[5b,18] By plotting $I_o/(I_o - I)$ vs. 1/[**2**] (Figure 4), a

perfect straight line was obtained from which the value of K was determined to be 4.2×10^4 M^{-1} which is comparable with the values reported for related porphyrin systems.[1c]

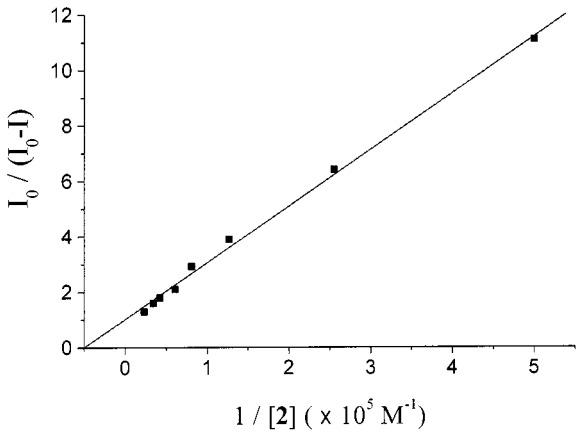

Figure 4. The Benesi−Hildebrand plot for determining the association constant between **2** and **4** (4×10^{-6} M) by fluorescence titration in $CHCl_3$

In an attempt to construct a face-to-face dyad of phthalocyanine and porphyrin linked through axial coordination, a mixture of zinc(II) *meso*-tetra(4-tolyl)porphyrin Zn(**5**), **2** and 4,4′-bipyridine (bipy) was examined. As zinc(II) tetrapyrroles normally bind to an additional ligand forming five coordinated species,[4b,13a] it was expected that apart from the hetero-dyad **2**-bipy-Zn(**5**) [Figure 2 (c)], the homo-dyads **2**-bipy-**2** and Zn(**5**)-bipy-Zn(**5**) should also be formed. Due to the presence of several dyads and the fact that some exhibit diastereomerism (those involving **2**), the ^{1}H NMR spectrum recorded in $CDCl_3$ is very complicated and cannot be unambiguously assigned. However, the formation of these face-to-face dimers is supported by the appearance of several broad bands at $\delta = 3.6-5.5$, which can be assigned to the coordinated bipy and the $OCHEt_2$ protons. The fluorescence quenching experiments provide more convincing evidence. The fluorescence intensity of Zn(**5**), when excited at 515 nm in the presence of bipy in $CHCl_3$ (both in 3.4×10^{-6} M), gradually decreases during titration with **2** (from 4.0×10^{-7} to 2.3×10^{-5} M). However, in the absence of bipy, the intensity remains relatively unchanged (Figure 5), showing that bipy plays a crucial role joining **2** and Zn(**5**) through coordination bonds.

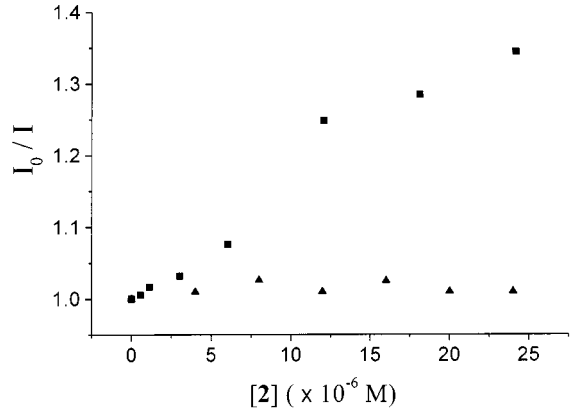

Figure 5. Stern−Volmer plots for the fluorescence quenching of Zn(**5**) by **2** with (■) or without (▲) the presence of bipy in $CHCl_3$; [Zn(**5**)] = [bipy] = 3.4×10^{-6} M

In summary, we have constructed, for the first time, assemblies of phthalocyanines and porphyrins through the relatively labile Zn(phthalocyanine)−N(pyridyl) axial ligation. Like many other supramolecules involving porphyrins, an efficient photo-induced electron transfer also occurs in these assemblies. By replacing the labile Zn^{II} ion with inert ions such as Ru^{II} and Os^{II}, it can be envisaged that more inert and diverse supramolecules based on phthalocyanines can be assembled.

Experimental Section

Compounds **2**,[14] **4**[16] and Zn(**5**)[19] were prepared by previously described methods. All other reagents and solvents were commercially available and used as received. Absorption and uncorrected fluorescence spectra were recorded on a Hitachi U-3300 spectrophotometer and a Hitachi F-4500 spectrofluorometer, respectively, both in $CHCl_3$ at ambient temperature. Phthalocyanine **2** was excited at 615 nm, while all the porphyrins were excited at 515 nm. The fluorescence intensities of porphyrins were based on the area under the fluorescence spectra in the region of 625−730 nm.

^{1}H NMR Studies: All ^{1}H NMR data were acquired on a Bruker DPX 300 (300 MHz) spectrometer at ambient temperature in $CDCl_3$, with Me_4Si as an internal standard. The concentration of **1** and **4** was kept at 0.5 mM. For a 1:1 mixture of **1** and **2**: $\delta = 9.12$ (d, $J = 7.5$ Hz, 4 H, H_a), 8.44 (br. s, 8 H, H_β), 8.09 (t, $J = 7.5$ Hz, 4 H, H_b), 7.70 (br. s, H_{py}), 7.64 (d, $J = 8.1$ Hz, 4 H, H_c), 4.88−4.94 (m, 4 H, OCH), 2.41−2.50 (m, 8 H, CH_2), 2.23−2.32 (m, 8 H, CH_2), 1.40 (t, $J = 7.5$ Hz, 24 H, CH_3), −3.03 (br. s, 2 H, NH). For a 1:4 mixture of **1** and **2**: $\delta = 9.11$ (d, $J = 7.5$ Hz, 16 H, H_a), 8.0−8.5 (br. s, H_β), 8.09 (t, $J = 7.5$ Hz, 16 H, H_b), 7.63 (d, $J = 7.8$ Hz, 16 H, H_c), 7.3−7.8 (br. s, H_{py}), 4.87−4.94 (m, 16 H, OCH), 2.40−2.47 (m, 32 H, CH_2), 2.22−2.31 (m, 32 H, CH_2), 1.40 (t, $J = 7.5$ Hz, 96 H, CH_3), −3.10 (br. s, 2 H, NH).[20] For a 1:1 mixture of **2** and **4**: δ 9.15 (d, $J = 9.0$ Hz, 4 H, H_a), 8.73−8.78 (m, 4 H, H_β), 8.60 (br. s, 2 H, H_β), 8.06−8.14 (m, 10 H, H_b & Ph), 7.63−7.74 (m, 15 H, H_c, H_β & Ph), 7.0−7.6 (br. s, 4 H, H_{py}), 4.93 (quintet, $J = 6.0$ Hz, 4 H, OCH), 2.22−2.40 (m, 8 H, CH_2), 2.42−2.56 (m, 8 H, CH_2), 1.41 (t, $J = 7.5$ Hz, 24 H, CH_3), −3.11 (br. s, 2 H, NH).

Determination of the Association Constant of the 4−2 Dyad by Fluorescence Titration: The concentration of **4** in $CHCl_3$ was kept at 4×10^{-6} M, while that for **2** was varied from 0 to 4×10^{-5} M. Upon excitation at 515 nm (where **2** has no absorption), fluorescence due to **4** was observed, and was monitored during the titration. The absorbance values at the excitation wavelength were first normalized before the fluorescence intensities were adjusted and taken. As all the absorbance values at this position were only ca. 0.1, it could be assumed that reabsorption was not significant.

1,2-Bis(trimethylsilyl)hydrazido Titanium Complexes

Brigitte Goetze,[a] Jörg Knizek,[a][+] Heinrich Nöth,[a][+] and Wolfgang Schnick*[a]

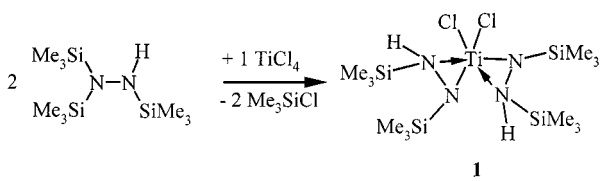
Keywords: Bis(trimethylsilyl)hydrazine / Hydrazido complexes / Nitrides / Titanium / Tris(trimethylsilyl)hydrazine

The silylhydrazido titanium complexes $[Cl_2Ti\{N_2H(SiMe_3)_2\}_2]$ (**1**), $[ClTi\{N_2H(SiMe_3)_2\}_3]$ (**2**), and $[(Cl_2Ti)_2\{N_2(SiMe_3)\}_2]$ (**3**) have been synthesized by reactions of the appropriate (trimethylsilyl)hydrazines with $TiCl_4$ in solution. The reactions are driven by the elimination of Me_3SiCl or LiCl after the dilithiation of bis(trimethylsilyl)hydrazine. According to NMR, mass spectrometry, and X-ray structure determination, products **1** and **2** are formed by the reaction of one equivalent of $TiCl_4$ with two or three equivalents of hydrazine, whereas compound **3** results from the reaction of two equivalents of $TiCl_4$ with two equivalents of hydrazine. According to the results of single-crystal X-ray diffraction investigations, complexes **1** and **3** feature an η^2-coordination of the hydrazido moiety to the titanium. In the crystals of **3**, both a chair and a twist form of the six-membered TiN_2TiN_2 rings are found, corresponding to different donor coordination modes of the hydrazido ligands to titanium. Temperature-dependent ^{29}Si NMR investigations indicate that both coordination modes co-exist in solution at low temperatures, but not at room temperature.

Introduction

In the context of the search for molecules with nitrido bridges between main group elements and transition metals, we have investigated the reactions of silazanes with various metal chlorides.[1−3] The obtained compounds have been studied with regard to their applicability as molecular precursors for the synthesis of solid-state materials of the M/Si/N system. A highly desirable property of these precursor compounds would be an ability to maintain either particular structural elements or a specific Si:M molar ratio during the transformation from the molecule to the solid-state compound. This approach has been elegantly applied for the synthesis of the nitride $SiPN_3$ starting from molecular $Cl_3SiNPCl_3$.[4]

Recently, we have extended our studies to titanium complexes of silylhydrazines. In this area, Leigh et al. have previously reported the crystal structures of the hydrazido titanium complexes $[(\eta^5\text{-}C_5H_5)(\eta^2\text{-}NHNMe_2)TiCl_2]$ and $[(\eta^5\text{-}C_5H_5)(\eta^2\text{-}NPhNH_2)TiCl_2]$ and have collected analytical data pertaining to some other titanium complexes with both cyclopentadienyl and hydrazido ligands.[5] Recently, Park et al. synthesized further cyclopentadienyl-substituted hydrazido titanium complexes with the aim of generating new Ziegler−Natta catalysts.[6]



A further class of titanium complexes has been described by Winter et al. and by Mösch-Zanetti et al. Their complexes bear η^2-pyrazolato ligands rather than hydrazido ligands and no cyclopentadienyl ligands are used to stabilize them.[7,8]

We report herein on the synthesis and characterization of novel bis(trimethylsilyl)hydrazido titanium complexes without cyclopentadienyl ligands. The silylhydrazido titanium complexes $[Cl_2Ti\{N_2H(SiMe_3)_2\}_2]$ (**1**), $[ClTi\{N_2H(SiMe_3)_2\}_3]$ (**2**), and $[(Cl_2Ti)_2\{N_2(SiMe_3)\}_2]$ (**3**) have been synthesized by reaction of the appropriate silylhydrazines with $TiCl_4$. The products show η^2-coordination of the hydrazido moiety to titanium in the solid state. For **3**, both chair and twist forms of the six-membered TiN_2TiN_2 ring have been found in the solid state, corresponding to different donor coordination modes of the hydrazido ligands to titanium.

Results and Discussion

The general synthetic approach for trimethylsilyl hydrazines is well established and some preparative methods for titanium complexes with alkyl-substituted hydrazido ligands have been described in the literature.[5,9] In order to avoid the formation of complexes with organic substituents at the metal center, we used $TiCl_4$ as the starting material. However, in several cases, we observed reduction of $TiCl_4$ by the trimethylsilylhydrazines as an unwanted side reaction. The undefined Ti^{III} species thus produced, which were deposited as green or brown precipitates, were not characterized further. Similar observations have been reported by Cotton et al., who recovered $[Ti_2Cl_9]^{3-}$ and $[Ti_3Cl_{12}]^{3-}$ from analogous precipitates.[10] In our investigations, the amorphous precipitates were carefully separated from the reaction mixtures in order to isolate the titanium hydrazido complexes without their decomposition.

Scheme 1. Synthesis of **1**

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 2000 1434−1948/00/0808−1849 $ 17.50+.50/0

Reaction of $TiCl_4$ with two equivalents of 1,1,2-tris(trimethylsilyl)hydrazine, followed by elimination of two equivalents of Me_3SiCl, yielded the hydrazido titanium dichloride **1** (Scheme 1).

The elimination of Me_3SiCl could be qualitatively observed by ^{29}Si NMR spectroscopic monitoring of the reaction mixture. After the green Ti^{III} precipitate had been removed, **1** was isolated from the solution by crystallization at 0 °C. Once isolated, the crystals proved to be stable for several weeks, even at room temperature. It would seem that no intramolecular elimination of HCl or Me_3SiCl occurs, despite the fact that the relevant substituents are in close proximity in the molecule (Figure 1).

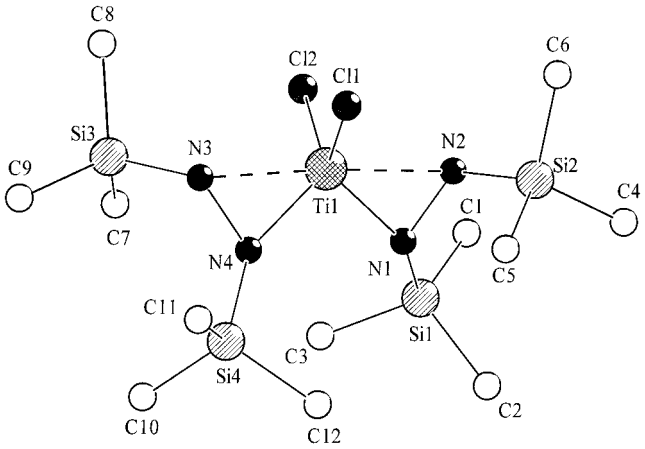

Figure 1. DIAMOND plot of the molecular structure of $Cl_2Ti[N_2H(SiMe_3)_2]_2$ (**1**)[11]

The X-ray crystal structure of **1** reveals the presence of two three-membered rings (Ti1−N1−N2 and Ti1−N4−N3) with N−N distances of 145 pm. In both cases, only one N atom (N1/N4) is actually bound to the titanium. Consequently, these N−Ti distances amount to just 189 pm, whereas the donor-coordinated N2/N3−Ti distances are about 215 pm. The corresponding bond angles are 60° at N2/N3 and 79° at N1/N4. The smallest angles are N1−Ti1−N2 and N3−Ti−N4, which measure 41° (Table 1).

The ^1H, ^{13}C, and ^{29}Si NMR spectra confirm the molecular structure of **1**. The ^{29}Si NMR spectrum shows two characteristic signals at δ = 10.15 and 23.03. The signal at δ = 10.15 can be attributed to the Si attached to the covalently bound N atom, whereas that Si bound to the NH group gives rise to a ^{29}Si NMR signal further downfield at δ = 23.03 (assigned by ^1H-coupled ^{29}Si NMR spectroscopy).

The mass spectrum clearly shows the molecular ion at m/z = 468. Mass spectrometry also revealed traces of a more volatile by-product, greater amounts of which could be generated from complex **1** and 1,1,2-tris(trimethylsilyl)hydrazine by Me_3SiCl elimination (Scheme 2). The reaction is very slow and its progress, including the elimination of Me_3SiCl, can be followed by NMR spectroscopy.

^1H, ^{13}C, and ^{29}Si NMR investigations unequivocally showed that **1** is completely transformed to **2** upon further reaction with the hydrazine. The ^{29}Si NMR spectrum of **2** features two signals at δ = 7.86 and 13.78. The signal at δ = 7.86 can be assigned to the silyl group attached to the covalently bound N atom by ^1H-coupled ^{29}Si NMR spectroscopy.

In the mass spectrum, the molecular ion of **2** (m/z = 608) could not be detected, but the fragmentation was nevertheless in accordance with the assumed composition. The calculated mass distributions of the ions at m/z = 463 and m/z = 389 correspond to the loss of two and three $SiMe_3$ groups, respectively. Unfortunately, **2** could not be obtained in crystalline form.

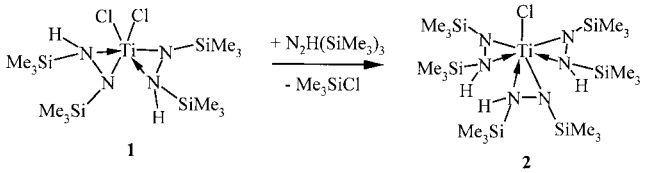
As known from the literature, the dilithiation of 1,1- and 1,2-substituted bis(trimethylsilyl)hydrazines invariably gives 1,2-substituted products.[12−14] Thus, after lithiation of a mixture of the bis(trimethylsilyl)hydrazines followed by treatment with $TiCl_4$, a titanium complex **3** with 1,2-substituted hydrazido ligands was obtained (Scheme 3).

In this reaction, a binuclear titanium complex is formed, in which the two N atoms of the hydrazido ligands are each bound to different Ti atoms. The X-ray crystal structure reveals that each covalently-bound N atom (e.g. N1) at one Ti atom (e.g. Ti2) is also involved in donor coordination to the other Ti atom (e.g. Ti1).

The X-ray crystal structure of **3** (Figure 2) also reveals that there are two different conformers **3a** and **3b** in the unit cell, which are present in a 1:2 molar ratio. Both of these are derived from the same six-membered ring system **3**, as shown in Scheme 3. The two conformers have the same composition and connectivity, but a different donor coordination of the N atoms to the Ti atoms (Scheme 4).

In the major conformer **3b**, both N atoms at Ti1 (N2 and N3) are involved in donor coordination to Ti2 on different sides of the ring, resulting in a twisted molecule with a twofold axis passing through Ti1 and Ti2. The second conformer **3a** has an inversion center and the N atoms coordinate on the same side of the six-membered ring with a parallel orientation of the hydrazido ligands, thereby leading to a chair conformation.

In both conformers, the Ti−Ti distances are very similar (271.7 and 271.8 pm). In both molecules, four TiN_2 three-membered rings with a covalent Ti−N bond measuring 194−198 pm and a weaker Ti−N donor bond measuring 214−228 pm are found.



The N−N bond lengths are 136 pm in **3a** and 138 pm in **3b**. The corresponding bonding angles at titanium are about 38° in both conformers. The Ti−N−N bonding angles at the donor-coordinated N atom are about 58−63°, while the angles at the N atom closer to Ti are in the range 77−85°.

The two conformers have comparable angles and distances in their TiN_2 rings and can thus be expected to be very similar in energy. A comparison of the coordination modes of the silylhydrazines to the titanium atoms in **1**, **3a**, and **3b** likewise reveals no significant differences (Table 1).

A comparison of the structural parameters of the Ti−N−N three-membered rings in complexes **1**, **3a**, and **3b** with those of similar structural units in hydrazido titanium complexes reported in the literature[5,6] again reveals that the bond lengths and angles are all very similar, making this a characteristic structural feature.

1 **2**

Scheme 2. Synthesis of **2**

3

Scheme 3. Synthesis of **3**

At room temperature, the ^{29}Si NMR spectrum of **3** features only one signal at $\delta = 24.87$. Low-temperature measurements in CD_2Cl_2 were then performed in order to ascertain whether the two conformations **3a** and **3b** co-exist in solution or only in the solid state (Figure 3).

The variable-temperature ^{29}Si NMR spectra confirm the existence of a six-membered ring without N donor coordination at room temperature. On lowering the temperature, increasing amounts of the two conformers **3a** and **3b** are formed in the solution. Two new signals appear in the spectra, downfield shifted by about 4 and 7 ppm. This downfield shift is due to the withdrawal of electron density from the N and Si atoms as a result of the donor coordination of the N atoms to the titanium. Spectral measurements in non-polar [D_8]toluene gave the same results, hence the formation of a donor complex with the solvent can be excluded. Low-temperature ^{1}H NMR spectra did not give useful results for further interpretation because the shift dif-

Scheme 4. The two conformers **3a** and **3b** are found to be present in the solid

ferences of the trimethylsilyl protons in the spectra at different temperatures were too small.

Conclusion

As a common structural feature, all 1,2-bis(trimethylsilyl)hydrazido titanium complexes described in this paper have a Ti−N−Si bridge with an η^2-coordinated N−N moiety at titanium. The X-ray crystal structure of **1** reveals N atoms that are either covalently bound to Ti or coordinated to Ti through a weaker donor bond. For the two conformers of **3**, N atoms with both a covalent and a donor bond to Ti are found in the solid state. These examples show that the synthesis of a variety of related transition metal hydrazides should be possible.

Experimental Section

General Remarks: All reactions were performed under an atmosphere of dry argon. The solvents were dried by standard methods. All glassware was heated to 100 °C, evacuated, and filled with dry argon several times prior to use. NMR spectra were recorded on Jeol GSX-270 and EX-400 spectrometers at 20 °C. Chemical shifts

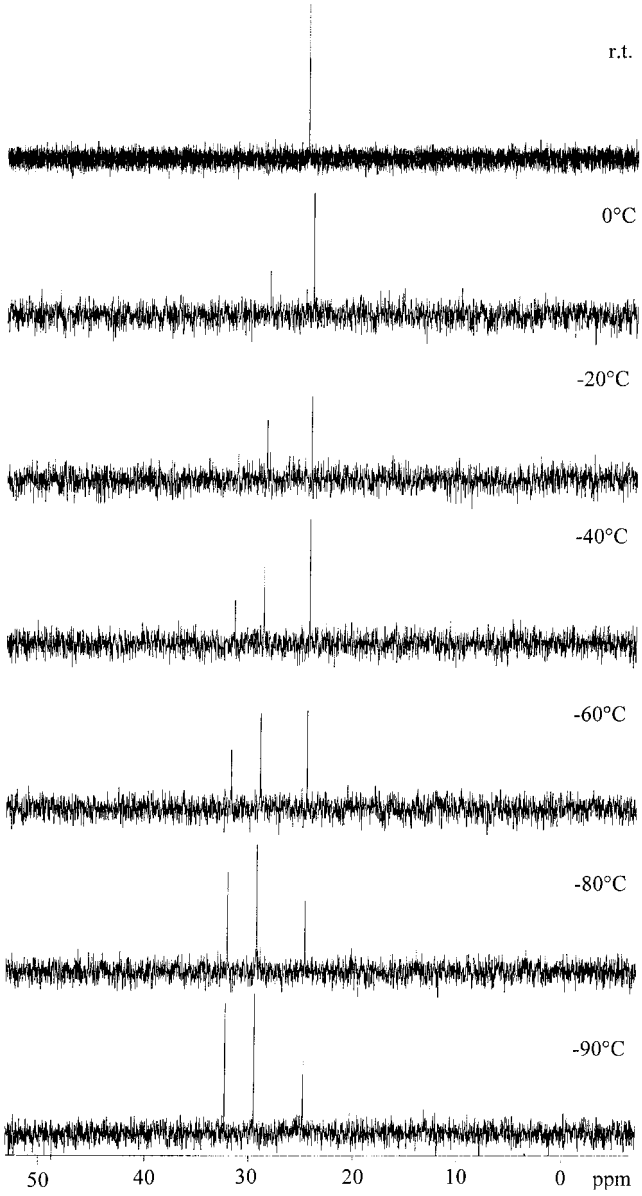

Figure 3. ^{29}Si NMR spectra of **3** at different temperatures

were determined by reference to the solvent resonances as internal standards. ^{29}Si NMR spectra were measured using the INEPT pulse sequence (TMS as external standard). Mass spectra (MS) were recorded on a Finnigan MAT spectrometer.

Elemental analysis was attempted, but due to the extreme sensitivity of the compounds the values obtained for **1** deviate from the expected composition. Likewise, it proved impossible to obtain reliable results for **2** and **3**.

Bis[*N*,*N*′-bis(trimethylsilyl)hydrazido]titanium Dichloride, $Cl_2Ti[N_2H(SiMe_3)_2]_2$ (1): 1,1,2-Tris(trimethylsilyl)hydrazine (0.70 g, 2.82 mmol) was dissolved in *n*-pentane (100 mL) at room temp. The resulting solution was cooled to −40 °C, whereupon $TiCl_4$ (0.84 mL, 0.77 mmol) was added dropwise. A green precipitate formed and the mixture was stirred at −10 °C for 2 h. The precipitate was then removed from the yellow solution by filtration and the filtrate was concentrated under reduced pressure at 0 °C. Yellowish crystals were obtained, which were recrystallized from *n*-pentane at 0 °C. The product proved to be stable under argon atmosphere at

room temp. for several weeks. Yield: 0.32 g (89%). – ^{1}H NMR ($CDCl_3$): δ = 0.23 [s, 18 H, $NSi(CH_3)_3$], 0.42 [s, 18 H, $NHSi(CH_3)_3$], 4.19 [s, 2 H, $NHSi(CH_3)_3$]. – ^{13}C NMR ($CDCl_3$): δ= –0.4 [$NSi(CH_3)_3$], 0.2 [$NHSi(CH_3)_3$]. – ^{29}Si NMR ($CDCl_3$): δ = 10.15 [$NSi(CH_3)_3$], 23.03 [$NHSi(CH_3)_3$] (assigned by ^{1}H-coupled ^{29}Si NMR spectroscopy). – MS (CI, *i*-butane): *m*/*z* (%) = 471 (9), 470 (23), 469 (12), 468 (27) [M^+], 455 (5), 453 (5) [M^+ – Me], 438 (3) [M^+ – 2 Me], 437 (8), 436 (17), 435 (47), 434 (48), 433 (91) [M^+ – Cl], 432 (32), 431 (9), 389 (6), 360 (3) [M^+ – Cl – $SiMe_3$], 228 (3), 227 (4), 192 (4), 178 (6), 177 (17), 176 (100) [$HN_2(SiMe_3)_2$ + 1], 175 (23) [$HN_2(SiMe_3)_2$], 174 (27) [$N_2(SiMe_3)_2$], 161 (5), 147 (10), 146 (60) [2$SiMe_3$], 132 (5), 130 (10). – $C_{12}H_{38}Cl_2N_4Si_4Ti$: calcd. C 30.69, H 8.16, N 11.93; found C 30.77, H 8.36, N 11.96.

Tris[*N*,*N*′-tris(trimethylsilyl)hydrazido]titanium Chloride, ClTi-[$N_2H(SiMe_3)_2$]$_3$ (2): Compound **1** (0.69 g, 1.47 mmol) and 1,1,2-tris(trimethylsilyl)hydrazine (0.75 g, 3.01 mmol) were dissolved in $CHCl_3$ (100 mL) and the mixture was refluxed for at least 16 h. The solvent and the excess tris(trimethylsilyl)hydrazine were then removed under reduced pressure to leave a brown solid. Yield: 0.77 g (86%). – ^{1}H NMR ($CDCl_3$): δ = 0.05 [s, 27 H, $NSi(CH_3)_3$], 0.11 [s, 27 H, $NHSi(CH_3)_3$], 1.24 [s, 3 H, $NHSi(CH_3)_3$]. – ^{13}C NMR ($CDCl_3$): δ = 1.8 [$NSi(CH_3)_3$], 1.9 [$NHSi(CH_3)_3$]. – ^{29}Si NMR ($CDCl_3$): δ = 7.86 [$NSi(CH_3)_3$], 13.78 [$NHSi(CH_3)_3$] (assigned by ^{1}H-coupled ^{29}Si NMR spectroscopy). – MS (CI, *i*-butane): *m*/*z* (%) = 464 (4), 463 (8) [M^+ + 1 – 2Si(Me)$_3$], 392 (9), 391 (30), 390 (40), 389 (100) [M^+ – 3$SiMe_3$], 388 (14), 387 (12), 375 (10), 374 (15), 373 (31), 358 (13), 357 (29), 341 (8), 249 (11), 248 (32) [$HN_2(SiMe_3)_3$], 233 (11), 160 (5), 147 (26), 146 (17) [2 $SiMe_3$], 145 (13), 132 (17), 130 (12).

Bis[*N*,*N*′-bis(trimethylsilyl)hydrazido]-*N*,*N*′-bis(titanium dichloride) ($Cl_2Ti)_2[N_2(SiMe_3)]_2$ (3): A mixture of 1,1-bis(trimethylsilyl)hydrazine and 1,2-bis(trimethylsilyl)hydrazine (1.39 g, 7.89 mmol) was dissolved in *n*-pentane (80 mL) at room temp. and *n*-butyllithium (9.86 mL, 15.78 mmol, 1.7 M in *n*-pentane) was added dropwise. The colorless solution rapidly became yellow and a white precipitate was deposited. After stirring for 1 h, a solution of $TiCl_4$ (0.87 mL, 7.89 mmol) in *n*-pentane (60 mL) was added dropwise at –40 °C. A green precipitate formed and the mixture was stirred at –20 °C for 2 h. The green solid was then removed from the red solution by filtration and the filtrate was concentrated under reduced pressure. Red crystals were obtained, which proved to be stable under argon atmosphere for several weeks at –20 °C. Yield: 1.64 g (71%). – ^{1}H NMR ($CDCl_3$): δ = 0.50. – ^{13}C NMR ($CDCl_3$): δ = 2.3. – ^{29}Si NMR ($CDCl_3$): δ = 24.87. – MS (CI, *i*-butane): *m*/*z* (%) = 588 (4), 586 (6) [M^+], 584 (5), 573 (3), 571 (5) [M^+ – Me], 569 (4), 551 (19) [M^+ – Cl], 549 (15), 478 (14) [M^+ – Cl – $SiMe_3$], 476 (14), 397 (13), 395 (10), 362 (13), 360 (12), 342 (76) [M^+ – 2Cl – $N_2(SiMe_3)_2$], 340 (100) [M^+ – 2 – 2Cl – $N_2(SiMe_3)_2$], 326 (14), 324 (16), 310 (9), 308 (11), 193 (5), 190 (7), 146 (16) [2 $SiMe_3$].

Reversible Formation of a Cationic Palladium(II) Hydride $[HPd(PPh_3)_2]^+$ in the Oxidative Addition of Acetic or Formic Acid to Palladium(0) in DMF

Christian Amatore,*[a] Anny Jutand,*[a] Gilbert Meyer,[a] Italo Carelli,[b] and Isabella Chiarotto[b]

Keywords: Palladium / Formic acid / Acetic acid / Oxidative addition / Hydrido complex

The oxidative addition of acetic or formic acid to $Pd^0(PPh_3)_4$ in DMF affords a cationic palladium(II) hydride, [*trans*-$HPd(PPh_3)_2(DMF)]^+$, with acetate or formate as the counter anion. The two reactions are reversible. The equilibrium and kinetic constants of the oxidative additions have been determined.

Introduction

Many palladium-catalyzed reactions are initiated by the reaction of a palladium(0) complex with an acidic derivative.[1] Such reactions include: i) cycloisomerization of enynes,[1,2] ii) hydrocarbonylation and hydrocarboxylation of alkynes,[3] iii) isomerization of alkynes to 1,3-dienes,[1][2a] iv) hydrocarbonylation of aryl halides.[4] In all these reactions, the catalytic cycle is considered to be induced by a hydridopalladium complex formed by reaction of the palladium(0) complex and the acidic derivative.[1,5] This hydridopalladium complex undergoes *syn* addition to an alkyne (hydropalladation) which generates a vinylpalladium(II) complex, a key intermediate for further reactions. This reaction has been used for the synthesis of vinylpalladium(II) intermediates as an alternative to the oxidative addition of vinyl halides to palladium(0) complexes.[6] When the acidic derivatives are strong acids (e.g. HBF_4, HCl, CF_3CO_2H, HOTs), the hydridopalladium formation may be regarded as the protonation of basic Pd^0 to afford $HPdL_n^+$ complexes ($HPdL_3^+$ [7] or $HPdL_2S^+$,[8] S = solvent) [Equation (1)].

$$H^+ + Pd^0L_{n'} \rightarrow HPdL_n^+ + (n'-n)L \quad (1)$$

The palladium may then be considered as either Pd^0 ligated by a proton or as Pd^{II} ligated by a hydride,[5] albeit that the very negative shift of the ^1H NMR signal is more indicative of a hydride linked to a palladium(II) center. This is why this reaction is also considered as an oxidative addition.[5]

When weak carboxylic acids are involved (e.g. acetic acid,[1,2,3a,3d] formic acid[3b]), the reaction is regarded as an oxidative addition, i.e., insertion of palladium(0) into the H−X bond [Equation (2)].[1,5]

$$HX + Pd^0L_{n'} \rightarrow HPd^{II}XL_n + (n'-n)L \quad (2)$$

It is not clear whether the X anion remains ligated to the palladium(II) center or not. For example, for acetic acid, the palladium hydride was initially postulated as being $HPd(OAc)L_n$[2] but more recently as $HPdL_n^+$.[1] To date, none of these complexes have been characterized.[1]

$HPdXL_2$ intermediates are also formed in palladium-catalyzed Heck reactions involving aryl halides ArX,[9,10] as the product of a β-hydride elimination of the σ-organopalladium(II) halide complex, which also generates the arylated olefin. The base-promoted recycling of $HPdXL_2$ to Pd^0L_2, which completes the catalytic cycle, is considered as a reductive elimination, i.e., the reverse of the oxidative addition of HX to a Pd(0) complex. $HPdXL_2$ complexes are key intermediates in Heck reactions since re-addition of these complexes to the double bond after arylation is the origin of double bond isomerization.[9,10] In the presence of Ag^+ [11,12] or Tl^+ [13] cations able to capture the halide, a cationic complex $HPdL_2^+$ may also be formed when aryl triflates are used[14,15] due to the triflate anion's low affinity for palladium(II) complexes.[15,16] In such cases, re-addition of $HPdL_2^+$ to the olefin after arylation may not take place.[15] This is one explanation, among others, for the better regioselectivity generally observed when Heck reactions are performed under ionic conditions.[12,13]

In our attempts to define the mechanism of the palladium-catalyzed electro-hydrocarbonylation of aryl iodides to aryl aldehydes, performed in the presence of formic acid,[4] we established that the catalytic cycle was initiated by the reversible oxidative addition of formic acid to a palladium(0) complex to afford a cationic hydride complex $HPdL_2^+$ together with formate anions.[4] We now report some more details of this reaction and on its extension to acetic acid.

Results and Discussion

Evidence for the Reversible Formation of a Cationic Palladium-Hydride $HPd(PPh_3)_2^+$ in the Oxidative Addition of Acetic or Formic Acid to $Pd^0(PPh_3)_4$ by Conductivity Measurements in DMF

The oxidative addition of acetic acid to $Pd^0(PPh_3)_4$ in DMF has been monitored at 25 °C by conductivity measurements. The conductivity κ of a solution of $Pd^0(PPh_3)_4$ (2 mM) increased after addition of n equivalents of acetic acid ($n > 1$) and reached a limit (Figure 1). This limiting value increased for values of n up to 100, but decreased in the presence of added PPh_3 (Figure 1).

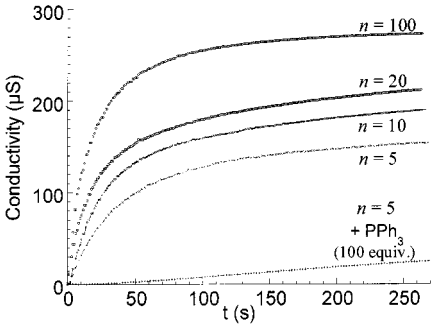

Figure 1. Conductivity measurements in DMF at 25 °C of a solution of $Pd^0(PPh_3)_4$ (2 mmol dm^{-3}) in the presence of n equivalents of acetic acid: n = 100, 20, 10, 5 in the absence of PPh_3 or in the presence of 100 equivalents of PPh_3 (when indicated)

Acetic acid is a weak acid in DMF (pK_a = 13.5).[17] Consequently, the concentration of the acetate anion and the proton is negligible compared to that of palladium(0) (2 mM). Their concentration was 8×10^{-5} mM when the acetic acid concentration reached 200 mM (n = 100). Nevertheless, the conductivity of acetic acid alone was first measured. It varied linearly with the square root of the acetic acid concentration, as expected for a weak acid. It varied from 1.7 to 6.9 μS when n was varied from 5 to 100 equivalents, respectively, so that the intrinsic conductivity of acetic acid was always negligible compared to that observed when acetic acid was added to $Pd^0(PPh_3)_4$ (Figure 1).

This series of experiments is evidence that the reaction of acetic acid and $Pd^0(PPh_3)_4$ affords ionic species which are involved in an equilibrium with the palladium(0) complex and acetic acid. PPh_3, whose overall effect is to decrease the concentration of the ionic species,[18] is then involved in the reverse reaction of this equilibrium. Since $Pd^0(PPh_3)_3$ is the major complex in solution [Equation (3)],[19] the observed overall equilibrium is described in [Equation (6)]. The inhibiting effect of PPh_3 strongly suggests that $Pd^0(PPh_3)_2$ participates in the reaction [Equations (4)−(5)], as in usual oxidative additions.[20] The mechanism of the oxidative addition of acetic acid to $Pd^0(PPh_3)_4$ may then be represented as in Equation (3) to (6) [reaction of $Pd^0(PPh_3)_4$ and acetic acid], in which the structure of the cationic complex has been established by spectroscopic techniques (vide infra).

$$Pd^0(PPh_3)_4 \rightleftharpoons Pd^0(PPh_3)_3 + PPh_3 \quad (3)$$

$$Pd^0(PPh_3)_3 \rightleftharpoons Pd^0(PPh_3)_2 + PPh_3 \quad (4)$$

$$Pd^0(PPh_3)_2 + CH_3CO_2H \rightleftharpoons HPd(PPh_3)_2^+ + CH_3CO_2^- \quad (5)$$

Overall equilibrium:

$$Pd^0(PPh_3)_3 + CH_3CO_2H \overset{K}{\rightleftharpoons} HPd(PPh_3)_2^+ + CH_3CO_2^- + PPh_3 \quad (6)$$

The reaction of $Pd^0(PPh_3)_4$ and formic acid was also monitored by conductivity measurements and led to similar results (Equation 7).[4]

However, the resulting solutions are less stable (the limiting value of the conductivity slightly increased with time) and the experiments have thus been performed at 0 °C. The equilibrium [Equation (7)] is fully displaced to the right-hand side in the presence of 70 equivalents of formic acid.

$$Pd^0(PPh_3)_3 + HCO_2H \overset{K}{\rightleftharpoons} HPd(PPh_3)_2^+ + HCO_2^- + PPh_3 \quad (7)$$

The molar conductances Λm have been calculated for the two complexes $[HPd(PPh_3)_2^+][CH_3CO_2^-]$ and $[HPd(PPh_3)_2^+][HCO_2^-]$ in DMF (Table 1). Their values are comparable to those reported for related complexes, e.g. $[HPd(PCy_3)_2(H_2O)^+][BF_4^-]$.[8]

Therefore, a cationic hydrido palladium(II) complex is formed by a reversible reaction starting from either acetic or formic acid.

Characterization of [*trans*-$HPd(PPh_3)_2(DMF)^+$][X^-] ($X^- = CH_3CO_2^-, HCO_2^-$)

Whereas neutral $HPdXL_2$ complexes have two coordinated phosphanes,[5] cationic palladium hydrides ligated by PPh_3 are usually characterized as three-coordinated complexes $HPdL_3^+$.[7e][7f] When cationic palladium hydrides are generated by the oxidative addition of acetic or formic acid to $Pd^0(PPh_3)_4$ in DMF, their ^{31}P NMR spectra exhibit a single signal for the ligated PPh_3 (Table 1) which is characteristic of a *trans* complex with two equivalent phosphorous, the fourth coordination site presumably being occupied by the solvent: *trans*-$HPd(PPh_3)_2(DMF)^+$. Despite the excess of PPh_3 from $Pd^0(PPh_3)_4$, the complex $HPd(PPh_3)_3^+$ is not formed in DMF. The solvent appears then to be a better ligand than a third PPh_3, presumably due to steric hindrance. This seems to be general since the oxidative addition of aryl triflates to $Pd^0(PPh_3)_4$ does not afford $ArPd(PPh_3)_3^+$, as is usually postulated, but *trans*-$ArPd(PPh_3)_2(DMF)^+$.[16]

The hydride has been characterized in both cases by its ^1H NMR signal, which has a negative chemical shift (Table 1).[21] The shifts of the ^1H and ^{31}P NMR signals for the two cationic complexes formed from either acetic acid or formic acid are very similar (Table 1) and do not depend significantly on the counter anion, acetate or formate, valid-

Table 1. Characterization of the cationic hydridopalladium(II) complex, $HPd(PPh_3)_2^+$ formed in the oxidative addition of $Pd^0(PPh_3)_4$ to acetic or formic acid in DMF (Equations 6 and 7)

Cyclic voltammetry, performed at a gold disk electrode, of a solution of $Pd^0(PPh_3)_4$, 2 mM in DMF (containing nBu_4NBF_4, 0.3 M) exhibits, at the gold electrode, the oxidation peak O_1 of $Pd^0(PPh_3)_3$ at + 0.057 V vs. SCE, whose peak current is proportional to the Pd^0 concentration (Figure 2a).[22]

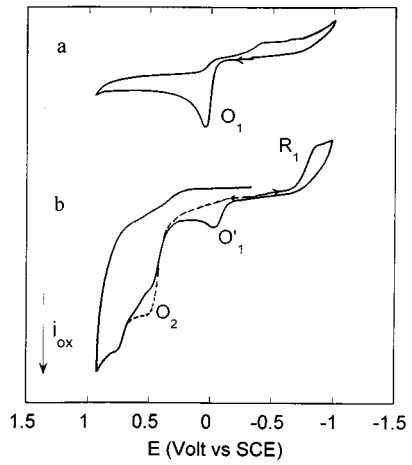

Figure 2. Cyclic voltammetry performed in DMF (containing nBu_4NBF_4, 0.3 mol dm^{-3}) at a steady gold disk electrode (0.5 mm diameter, scan rate: 0.2 V s^{-1}) at 20 °C: a) $Pd^0(PPh_3)_4$ (2 mmol dm^{-3}); b) $Pd^0(PPh_3)_4$ (2 mmol dm^{-3}) in the presence of 100 equivalents of acetic acid: (---) oxidation scan; (−) reduction scan performed first, followed by an oxidation scan

In the presence of 100 equivalents of acetic acid, the oxidation peak O_1 is no longer detected (Figure 2b, dashed voltammogram) indicating that the palladium(0) complex has undergone an oxidative addition reaction with acetic acid [Equation (6)]. The oxidation peak O_2 of the acetate anion is detected at +0.56 V. The voltammogram also exhibits a reduction peak R_1 at −0.85 V (Figure 2b, Table 1) which characterizes the reduction of the palladium(II) hydride complex formed in the oxidative addition. This reduction affords a palladium(0) complex, detected on the reverse scan by its oxidation peak O'_1 at −0.030 V (Figure 2b). Since acetate is the counter anion of the cationic palladium hydride, the reduction of $HPd(PPh_3)_2^+$ affords an anionic $Pd^0(PPh_3)_2(OAc)^-$ complex [Equation (8)].[23]

$$HPd(PPh_3)_2^+ + AcO^- + 1e \longrightarrow Pd^0(PPh_3)_2(OAc)^- + \tfrac{1}{2} H_2 \quad (8)$$

The voltammetric investigation of $Pd^0(PPh_3)_4$ in the presence of 100 equivalents of formic acid gives identical results[4] (Table 1). Whatever the precursor, acetic acid or formic acid, the same reduction peak R_1 is observed (Table 1), confirming that the same palladium hydride complex is formed in the oxidative addition of $Pd^0(PPh_3)_4$ to either acetic or formic acid [Equations (6) and (7)].

Determination of the Equilibrium and Kinetic Constants of the Oxidative Addition of $Pd^0(PPh_3)_4$ to Acetic or Formic Acid

The oxidative addition of acetic acid or formic acid to $Pd^0(PPh_3)_4$ obeys Equation (9). The equilibrium constant has been determined from the conductivity data (Figure 1).

$$Pd^0L_3 + HX \underset{}{\overset{K}{\rightleftharpoons}} HPdL_2^+ + X^- + L \quad (9)$$

L = PPh_3; HX = CH_3CO_2H, HCO_2H

Denoting x_{eq} as the equilibrium concentration ($t > 250$ s) of $HPdL_2^+$ and X^- relative to the initial concentration C_0 of $Pd^0(PPh_3)_3$, one gets [Equation (10)]:

$$K = \frac{[HPdL_2^+][X^-][L]}{[PdL_3][HX]} \qquad \frac{K}{C_0} = \frac{(x_{eq})^2(1+x_{eq})}{(1-x_{eq})(n-x_{eq})} \quad (10)$$

$x_{eq} = \kappa_{eq}/\kappa_{irrev}$; κ_{eq} = conductivity measured when the equilibrium in Equation (9) is fully established in the presence of n equivalents of HX ($t > 250$ s); κ_{irrev} = conductivity when the equilibrium in Equation (9) is totally displaced towards its right-hand side, ($n = 100$ for CH_3CO_2H and HCO_2H, $t > 250$ s). The values of K/C_0 were then calculated for acetic and formic acid from Equation (10) (Table 1).

The rate constant of the overall forward reaction [k_f in Equation (13)] has been determined in the presence of 100 equivalents of HX, so that the reverse reaction is negligible (irreversible reaction as in the uppermost curve in Figure 1).

$$Pd^0(PPh_3)_3 \underset{}{\overset{K_0}{\rightleftharpoons}} Pd^0(PPh_3)_2 + PPh_3 \quad (11)$$

$$Pd^0(PPh_3)_2 + HX \underset{k_-}{\overset{k_+}{\rightleftharpoons}} HPd(PPh_3)_2^+ + X^- \quad (12)$$

$$Pd^0(PPh_3)_3 + HX \underset{k_b}{\overset{k_f}{\rightleftharpoons}} HPd(PPh_3)_2^+ + X^- + PPh_3 \qquad K \quad (13)$$

Even under the conditions where the reaction in Equation (13) is irreversible, the PPh_3 released interferes in the mechanism through displacement of the equilibrium in Equation (11). If PPh_3 was in excess compared to $Pd^0(PPh_3)_4$, the kinetic law would simply be:

$\ln([Pd^0]_t/[Pd^0]_0) = -k_f[HX]t$

with $k_f = K_0k_+/[PPh_3]$. When starting from $Pd(PPh_3)_4$ alone, the concentration of PPh_3 is not constant [Equation (11)] and the kinetic law becomes:[22]

$2\ln([Pd^0]_t/[Pd^0]_0) - [Pd^0]_t/[Pd^0]_0 + 1 = -k_f[HX]t$

with $k_f = K_0k_+/C_0$. The value of k_f is then determined by plotting $2\ln(1 - x_t) + x_t$ *versus* time, up to 80% of conversion ($x_t = 1 - [Pd^0]_t/[Pd^0]_0$ with $x_t = \kappa_t/\kappa_\infty$; κ_t = conductivity at t; κ_∞ = final conductivity). k_f was calculated from the slope of the resulting regression line for acetic acid (Figure 3a) and formic acid (Figure 3b) (Table 1).

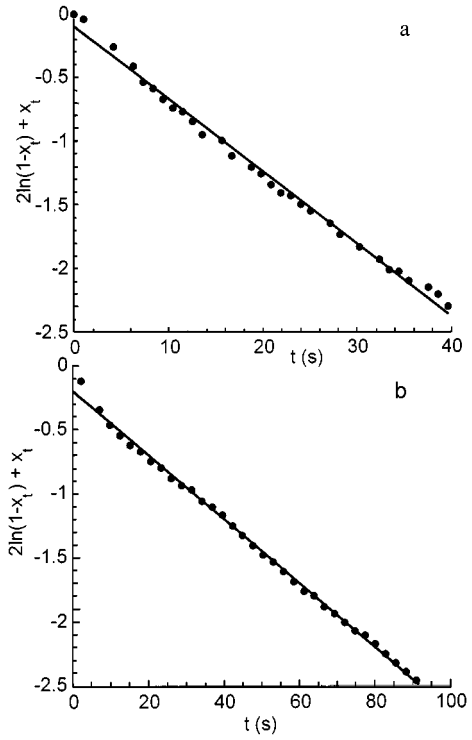

Figure 3. Kinetics of the oxidative addition of $Pd^0(PPh_3)_4$ (2 mmol dm^{-3} in DMF) under conditions where the reaction is irreversible, i.e.: a) acetic acid (0.2 mol dm^{-3}); b) formic acid (0.2 mol dm^{-3}); in both figures: plot of $2\ln(1 - x_t) + x_t$ *versus* time; $x_t = \kappa_t/\kappa_\infty$; κ_t = conductivity at t; κ_∞ = final conductivity

The value of the rate constant of the overall reverse reactions [k_b in Equation (13)] was then deduced from the equilibrium constant $K = k_f/k_b$ (Table 1).

Acetic acid is a weak acid in DMF. The concentration of the acetate anion and the proton are negligible (vide supra) compared to the palladium(0) concentration. However, this does not allow us to exclude direct protonation of $Pd^0(PPh_3)_2$. Discrimination between the two pathways: i) direct protonation of $Pd^0(PPh_3)_2$ by H^+ to form $HPdL_2^+$, or ii) oxidative addition of HX to $Pd^0(PPh_3)_2$ to form $H-Pd-XL_2$ followed by an ionization step, may be achieved by determination of the reaction order of HX under conditions where the equilibrium is totally shifted towards the cationic hydride complex (i.e. $n \geq 100$ equivalents for acetic acid, Figure 1). Indeed, a linear dependence of the observed rate constant on the acetic acid concentration would be in favor of an oxidative addition, whereas a linear dependence on the proton concentration, viz. with the square root of the acetic acid concentration, would be in favor of a protonation. The reaction of $Pd(PPh_3)_4$ with acetic acid is rather fast (Figure 1); consequently, only two concentrations of acetic acid could be tested (n = 100: k_{obs} = 0.057 s^{-1}; n = 200: k_{obs} = 0.104 s^{-1}). From these results, it ensues that the reaction order in acetic acid is close to unity, which is in favor of an oxidative addition of the H−OAc bond to palladium(0). The intermediate neutral complex, $HPdXL_2$ (X = acetate or formate) does not accumulate in the solution, thus its ionization is faster than its formation. Indeed, the kinetic curves in Figure 1, as well as those we have reported for formic acid,[4] do not exhibit any induction period which would result in a significant accumulation of such a neutral species. The degradation observed at 25 °C, when the formate anion is the counter anion, probably arises from a side reaction induced by this anion. Indeed, the intermediate neutral $HPd(OCHO)L_2$ complex is prone to undergo a well-known decarboxylation reaction[24] with formation of $HPdHL_2$, leading to H_2 and Pd^0L_2.

Conclusion

Oxidative addition of acetic acid or formic acid to a palladium(0) complex in DMF affords a cationic palladium hydride *trans*-$HPd(PPh_3)_2(DMF)^+$, with an acetate or a formate counter-anion. Both reactions are reversible and involve an unfavorable equilibrium so that a large excess of acid is required for the quantitative formation of the palladium hydride complex. This work therefore provides confirmation of the assumption made by Trost in the conclusion of one of his latest papers on this topic: "Such a species [the palladium hydride] undoubtedly is formed to some extent [from weak acids], albeit in an unfavorable equilibrium".[1]

This allows us to conclude that the catalytic reactions initiated by reaction of palladium(0) and acetic acid (or formic acid) proceed via a cationic palladium hydride *trans*-$HPd(PPh_3)_2(DMF)^+$, when they are performed in DMF.

The relative values of the kinetic constants k_f and k_b show that $HPdL_2^+$ is easily converted back to a Pd^0 complex. This reverse reaction is the step which completes the catalytic cycle of Heck reactions when they are performed under ionic conditions (from aryl triflates[14,15,25] or aryl halides in the presence of Ag^+ or Tl^+ salts[11−13,25]) with $Pd(OAc)_2$ as the palladium(0) precursor or when acetate ions are used as a base.

Experimental Section

General Remarks: ^{31}P (101 MHz) and ^{1}H (400 MHz) NMR spectra were recorded on a Bruker spectrometer. Cyclic voltammetry was performed with a home made potentiostat and wave form generator Tacussel GSTP4. The cyclic voltammograms were recorded on a Nicolet 301 oscilloscope. Conductivities were measured on a Tacussel CDM210 conductimeter (cell constant: 1 cm^{-1}).

Chemicals: DMF was distilled from calcium hydride under vacuum and kept under argon. Acetic and formic acids were obtained commercially and used as pure compounds. $Pd^0(PPh_3)_4$ was synthesized according to a reported procedure.[26]

Electrochemical Set-Up and Electrochemical Procedure for Voltammetry: Experiments were carried out in a three-electrode cell connected to a Schlenk line. The counter electrode was a platinum wire of ca. 1 cm^2 apparent surface area. The reference was a saturated calomel electrode (Tacussel) separated from the solution by a bridge filled with DMF (3 mL) containing nBu$_4$NBF$_4$ (0.3 M). DMF (12 mL) containing nBu$_4$NBF$_4$ (0.3 M) was introduced into the cell followed by $Pd(PPh_3)_4$ (28 mg, 0.024 mmol) and then 100 equivalents of acetic acid. Cyclic voltammetry was performed at a steady gold (0.5 mm diameter) or carbon (2 mm diameter) disk electrode at a scan rate of 0.2 V s^{-1}.

Acknowledgments

This work has been supported by the Centre National de la Recherche Scientifique (CNRS, UMR 8640), the Ministère de l'Education Nationale et de la Recherche et de la Technologie, and The Consiglio Nazionale delle Ricerche (CNR). Two undergraduate students T. Huy Lap and M. F. Perriot are thanked for their involvement in some of the experiments described in this work.

[21] In $CDCl_3$, two broad ^{1}H NMR signals were observed for the hydride complex formed in the oxidative addition of formic acid to $Pd^0(PPh_3)_4$, at $\delta = -6.75$ and -7.17 (ratio: 1:1.3). This shows that some $HPd(PPh_3)_3^+$ complex was formed in $CDCl_3$. The high J(H-*trans*-P) coupling (168 Hz)[7e] results in a doublet for the hydride resonance at $\delta = -6.96$. Each signal should give a triplet due to the H-*cis*-P coupling but the two signals were too broad ($\Delta\nu_{1/2} = 81$ Hz) compared to the smaller J(H-*cis*-P) coupling constant, see ref.[7e]. After addition of DMF (10% in volume) a single broad signal ($\Delta\nu_{1/2} = 150$ Hz) is observed at $\delta = -7.28$ indicating the formation of *trans*-$HPd(PPh_3)_2(DMF)^+$.

Si−NH−M Cage Compounds − Molecular Iminosilicates Containing Group 13 Metals and Their Functionalized Halogen Containing Derivatives

Carsten Rennekamp,[a] Peter Müller,[a] Jörg Prust,[a] Helge Wessel,[a] Herbert W. Roesky,*[a] and Isabel Usón[a]

Dedicated to Professor Jean-Marie Lehn on the occasion of his 60th birthday

Keywords: Aluminum / Gallium / Indium / Silicon / Cage compounds

The reaction of a kinetically stable triaminosilane $RSi(NH_2)_3$ (R = 2,6-*i*$Pr_2C_6H_3NSiMe_2$*i*Pr) (**1**) with trialkyl group 13 metal compounds MR_3 (R = Me, Et; M = Al, Ga, In) leads to Si–NH–M cage molecules, which increase in solubility from aluminum to indium in common weakly-coordinating organic solvents like toluene. These compounds may be regarded as model systems for group 13 metal containing iminosilicates. X-ray studies show a prismatic cage framework which is isostructural and isoelectronic with known heterosiloxanes. Further functionalization of these compounds without cleavage of the cage molecule was achieved by reaction with elemental bromine and iodine.

Introduction

The importance of nitrido silicates in materials science has been growing during the last years. New nitrido silicate structures with different compositions have been synthesized by Schnick et al. using silicondiimide $[Si(NH)_2]_x$ and various metals at high temperatures.[1] In these systems nitrogen has an important influence on the final properties of the materials, so that hardness and thermal stability are dramatically increased in comparison to the oxygen congeners.[2] Recently Jansen et al.[3] and Riedel et al.[4] reported on ternary and quaternary ceramics containing silicon, boron, nitrogen, and carbon. These systems may be regarded as nitridosilicates which are even more thermally stable than Si_3N_4.

The reaction of a stable triaminosilane $RSi(NH_2)_3$ with trialkyls of group 13 metals MR_3 (M = Al, Ga, In; R = Me, Et) leads to cage molecules which are isostructural and isoelectronic with the analogous heterosiloxanes. Consequently, triaminosilanes may be regarded as interesting precursors for developing nitrogen containing molecular silicate chemistry. The methyl groups of the aluminum compound are accessible for substitution reactions with elemental bromine and iodine. Compounds containing two and four halogen atoms were isolated without cleavage of the cage structure. The halogen containing compounds can serve as precursors for the synthesis of functionalized structures.

In this context we have prepared several ring and cage compounds using stable silanetriols as starting materials.[6] At present, little is known about soluble molecular nitrogen containing silicates. Therefore, we have focused on the synthesis of cage molecules starting from stable triaminosilanes which are easily prepared by ammonolysis of the corresponding trichlorosilanes[9−11] (Scheme 1).

$$RSiCl_3 + 6\,NH_3 \xrightarrow[-\,3\,NH_4Cl]{} RSi(NH_2)_3$$

R = 2,6-*i*$Pr_2C_6H_3NSiMe_2$*i*Pr

Scheme 1

The isoelectronic properties of the amino and hydroxy groups should lead to similar reactivities for silanetriols and triaminosilanes. This was first shown in the reaction using alumazene, where structurally similar products for both types of compounds were formed.[12]

Results and Discussion

Synthesis and Structural Properties of Triaminosilanes

Reaction of silanetriols with trialkyls of group 13 metals leads to different types of heterosiloxanes with alternating Si−O−M units e.g. ring, cubic or prismatic compounds, whereas the reaction of $AlMe_3$ with hitherto known triaminosilanes leads only to insoluble products.[13]

Replacing one methyl group of the $SiMe_3$ substituent in 2,6-*i*$Pr_2C_6H_3NSiMe_3Si(NH_2)_3$ by an isopropyl group increases the solubility of the triaminosilane and of the resulting products. The synthesis and the crystal structure of 2,6-*i*$Pr_2C_6H_3NSiMe_2$*i*$PrSi(NH_2)_3$ (**1**) has been reported.[11]

The X-ray structural analysis of **1** shows the interesting effect of this exchange on the degree of oligomerization in the crystal. Compound **1** is connected via hydrogen bonds as a tetramer, in contrast to 2,6-*i*$Pr_2C_6H_3NSiMe_3Si(NH_2)_3$ which is dimeric in the crystal structure.

Reaction of $AlMe_3$ with 1

Reaction of $AlMe_3$ with **1** in toluene at 0 °C leads to the formation of a white microcrystalline solid **2**, which has a

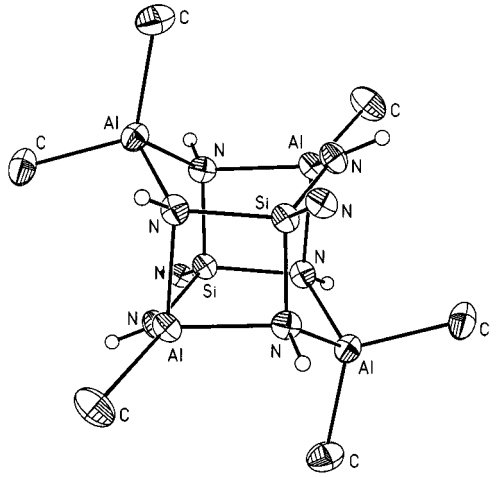
low solubility in common weakly coordinating solvents like pentane, hexane and toluene, but is soluble in coordinating solvents like tetrahydrofuran, dichloromethane or diethyl ether. Single crystals were obtained from a solution of [2,6-iPr$_2$C$_6$H$_3$NSiMe$_2$$i$PrSi(NH)$_3Al_2Me_3$]$_2$ (**2**) in a THF/hexane mixture (20:80) by evaporating the solvent over two weeks.[11]

The M_6N_6 core in the molecular structure of **2**, shown in Figure 1 can be described as a bitruncated square bipyramid. It is formed by four $SiAl_2N_3$ six-membered rings in a boat conformation, sharing the three *stern* atoms and the three *prow* atoms with each neighboring ring system. Thus, two planar four-membered $SiAlN_2$ rings are formed. In all of these rings the metal and nitrogen atoms occupy alternating sites.



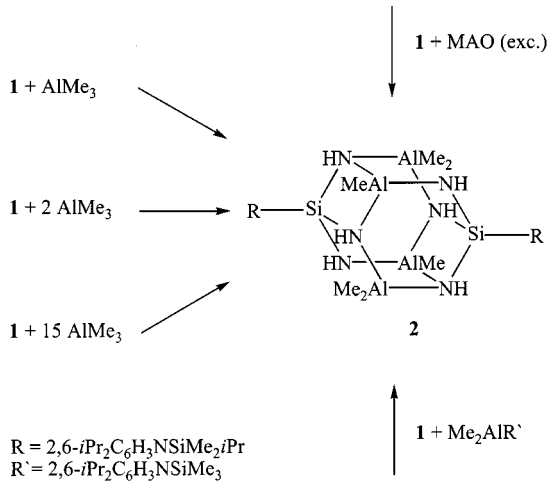


Figure 1. Central cage framework of the structure of **2** (organic substituents have been omitted for clarity)

The central framework of **2** is isostructural with the product of the reaction of diisobutyl aluminum hydride with the corresponding silanetriol.[6] In the mass spectrum the most intense peaks appear at *m*/*z* 433 (38%) and at 881 (100%) and are assigned to half of the molecular ion minus one methyl group and the molecular ion minus one methyl group respectively, which emphasizes the stability of **2** under these conditions.

Interestingly, this reaction is independent of the reaction temperature, time and the stoichiometry, but not of the solvent used. The reaction of **1** with $AlMe_3$ in different weakly coordinating solvents like hexane, pentane or toluene always gives **2**. In contrast to the corresponding silanetriol, the use of THF as solvent does not lead to a cubane but to a mixture of products, which could not be fully characterized.

The high selectivity in the formation of **2** is demonstrated in the reaction of MAO (methylaluminoxane), which contains some $AlMe_3$, and **1** to give single crystals of **2** and even the aminoalane $Me_2Al(iPr_2C_6H_3NSiMe_3)$ reacts with **1** to give **2** in high yield. The different reaction pathways are summarized in Scheme 2.

Scheme 2

Reaction of GaR_3 (R = Me, Et) and $InMe_3$ with 1

In general indiumtrialkyls show a remarkably different reaction behavior, which is due to the difference in their heats of formation and those of the corresponding aluminum and gallium compounds [$\Delta H°_f$ kJ/mol + 173 (In), −42 (Ga), −81 (Al)].[14] The comparable reaction pathways of the Al- and Ga-alkyls is indicted by the similar reaction products obtained on hydrolysis.[15]

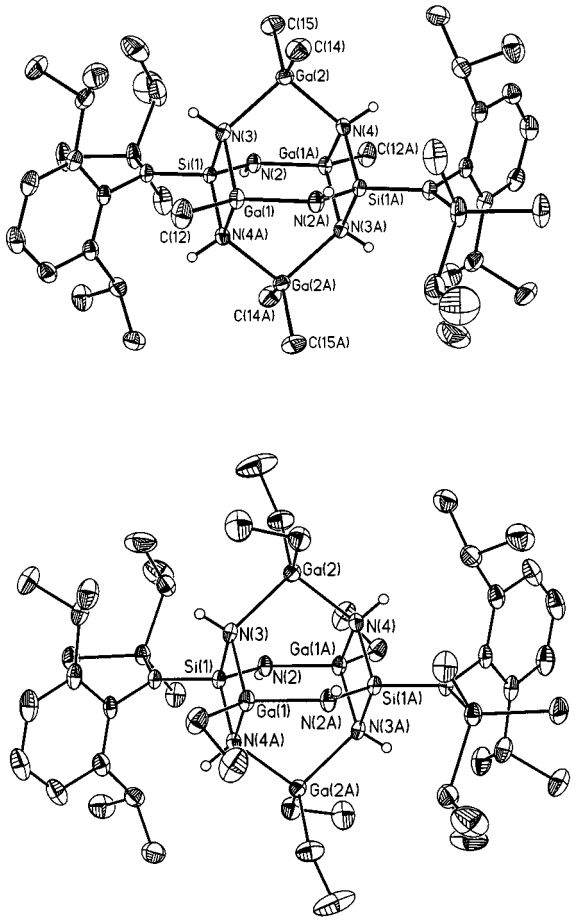

Figure 2. Crystal structures of **3** (top) and **4** (bottom) (hydrogen atoms are omitted for clarity). Selected bond lengths [pm] and angles [°] are given in Table 1. The ethyl groups in **4** are disordered

The reaction of MR_3 (M = Ga, In; R = Me, Et) with **1** in toluene at room temperature over 24 h yields a mixture of products, but heating the solutions at reflux for 1 h (in the case of the reaction of **1** with GaR_3) and 24 h (in the case of **1** with $InMe_3$) respectively leads to the formation of single crystals suitable for X-ray structural analysis. The molecular structures of $[RSi(NH)_3Ga_2Me_3]_2$ (**3**), $[RSi(NH)_3Ga_2Et_3]_2$ (**4**) and $[RSi(NH)_3In_2Me_3]_2$ (**5**) (R = 2,6-*i*$Pr_2C_6H_3$NSiMe_2*i*Pr) are shown in Figure 2 and Figure 3.

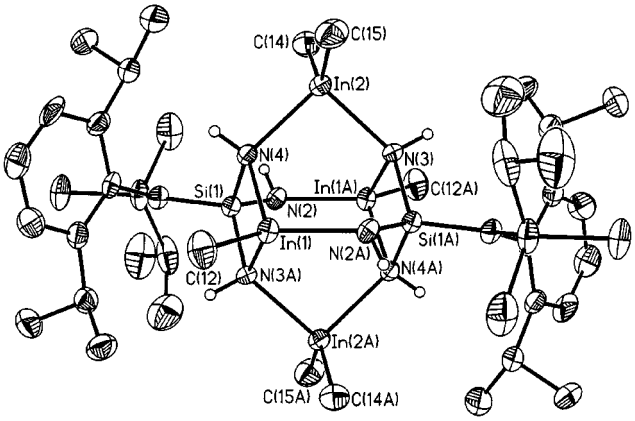

Figure 3. Crystal structure of **5** (hydrogen atoms are omitted for clarity). Selected bond lengths [pm] and angles [°] are given in Table 1

The similarity of the X-ray structures (**3**, **4**, **5**) to that of compound **2** is obvious. We preferentially describe the crystal structures of compounds **3** and **4** as representative examples for a detailed discussion of bond lengths and angles. Selected bond lengths and angles for **2**, **3, 4**, and **5** are given in Table 1. The planes described by Ga(1)Si(1)N(2)Ga(1A)-Si(1A)N(2A) and Ga(2)N(3)N(4)Ga(2A)N(3A)N(4A) form a dihedral angle of 90.7°. The N atoms can be divided into two types, having μ- and μ_3-bridging sites. The bond lengths of the μ_3-bridging N atoms are significantly longer than of the others (N(3)−Si(1) 177 pm, N(2)−Si(1) 168 pm, N(3)−Ga(1) 203 pm, N(2)−Ga(1) 189 pm). These differences and the cage constraints determine the angles in the polyhedron. Therefore the expected tetrahedral coordination spheres at N, Si and Ga are distorted. The angles within the four-membered rings vary from 80.4° to 94.6°, the angles in the six-membered rings are in the range 106.6° to 122.7°. The bond lengths and angles of **3** and **4** are equal within experimental error (Table 1). The crystallographic data of compounds **2**, **3**, **4**, and **5** are given in Table 2.

Interestingly, the mass spectral data of **3**, **4**, and **5** lead to results similar to those obtained for compound **2**, where cleavage of the cage into two monomeric species under EI-conditions is observed. However, the solution NMR spectra show a series of signals consistent with the solid state structures of **2**, **3**, **4**, and **5** respectively.

Comparison of 2, 3, 4, and 5

Trialkyls of group 13 metals react with **1** independent of stoichiometry to give the isostructural cage compounds **2**, **3, 4**, and **5**. A comparable reaction pathway for the corresponding silanetriols is not yet known, however heterosiloxanes which are isoelectronic and isostructural to **3** and **5** have been reported and underline the similar reaction behavior of **1**.

A few further observations should be briefly mentioned. All cage compounds have a remarkably high thermal stability and decompose at temperatures around 280 °C. Furthermore, their solubility increases from the aluminum to the indium compounds, which may be explained by the lower charge density at the indium centers as compared to the aluminum cage molecule. Although the reaction in coordinating solvents does not lead to the expected products, treatment of the isolated **2**, **3**, **4**, and **5** with THF, ether or dichloromethane does not result in the cleavage of the cage.

Treatment of 2 with Bromine and Iodine

A toluene solution of **2** was titrated at 0 °C with a small excess of bromine and iodine. Evaporation of the bromomethane and iodomethane, respectively, at room temperature, resulted in the formation of a mixture of products **6a/6b** and **7a/7b** (Scheme 3). Single crystals of **6a/6b** and **7a/7b** were obtained by recrystallization from warm toluene (60 °C). [16]

The solution and refinement of these structures show the presence of two different products, a mono- and a bis-halogen containing species at Al(1) and Al(1a). Molecular structures of **6a/6b** and **7a/7b** are shown in Figure 4 and Figure 5.

The halogenation has almost no influence on the prismatic core structure. Bond lengths and angles of the cages are equal within experimental error to those in **2** (see Table 1).

We observed that increasing the amount of halogen bound to the aluminum results in lower solubility, which in turn leads to preferred crystallization of the bis-halogen containing products (**6b,7b**) which have a high content in the crystal. ^{1}H NMR data and elemental analysis (of **6a/6b** and **7a/7b)** are consistent with the solid state structures,

Scheme 3

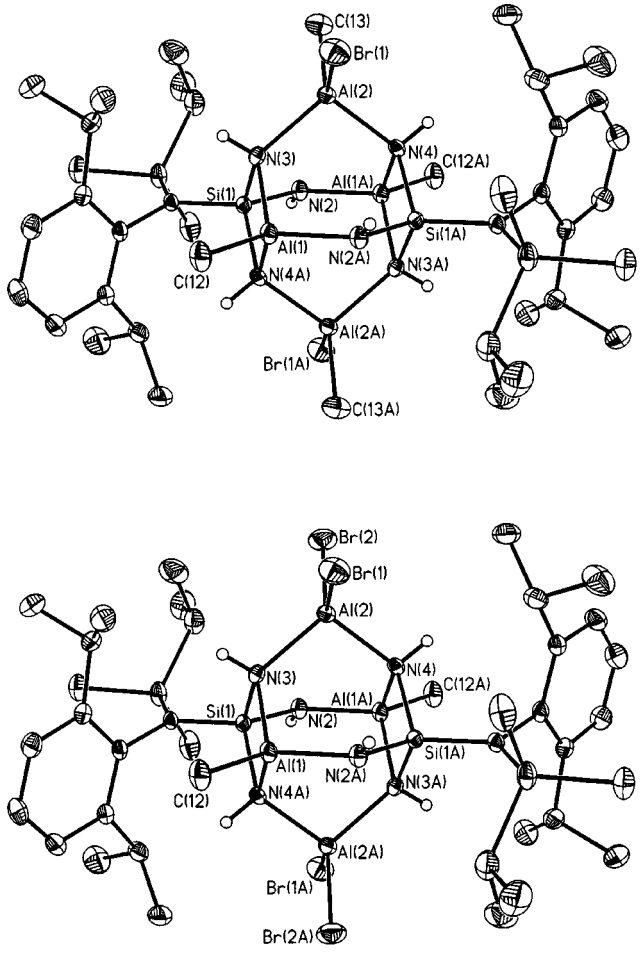

Figure 4. Crystal structures of **6a** (top) and **6b** (bottom) (hydrogen atoms are omitted for clarity). Selected bond lengths [pm] and angles [°] for **6a**: Al(2)−Br(1) 232.27(9), Al(2)−C(13) 197.1(13), C(13)−Al(2)−Br(1) 110.0(5); **6b**: Al(2)−Br(2) 220.6(5), Br(2)−Al(2)−Br(1) 113.4(2)

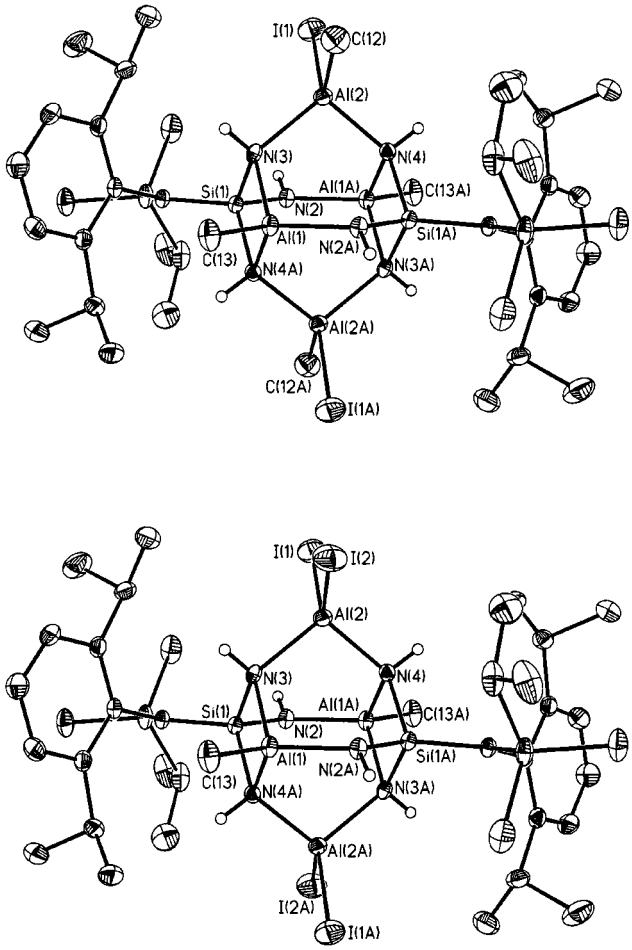

Figure 5. Crystal structures of **7a** (top) and **7b** (bottom) (hydrogen atoms are omitted for clarity). Selected bond lengths [pm] and angles [°] for **7a**: Al(2)−I(1) 257.0(1), Al(2)−C(12) 197.1(1), C(12)−Al(2)−I(1) 108.4(5); **7b:** Al(2)−I(2) 236.9(5), I(2)−Al(2)−I(1) 113.9(2)

whereas the mass spectra show several fragments which may be assigned to different halogen containing species.

The crystal structures of **6a/6b** and **7a/7b** are similar and interestingly the halogen atoms in **6a** and **7a** are located in a pseudo-trans position. At 0 °C a small excess (≈0.05 mmol) of the halogen gives the solution a characteristic color, which disappears at room temperature after 24 h. The bis-halogen containing products **6b** and **7b** are formed at higher temperatures. The second bromination step takes place at the same aluminum atom as the first, so both methyl groups at Al(1) and Al(1a) are substituted. Remarkably, only two compounds (**6a/6b**), containing two and four bromine atoms are observed, while an intermediate with three bromine atoms was not observed under these conditions.

By variation of the stoichiometry and the reaction time, we tried to synthesize the mono-, bis- and tris-bromine containing products and the related iodine compounds. X-ray structural analysis of the products showed that the crystals contain a variety of different molecules with the typical cage framework but they could not be refined, whereas under the reported reaction conditions **6a/6b** were formed several times in similar ratios.

Conclusion

By introducing a bulky substituent, we achieved to synthesize kinetically stable triaminosilanes which serve as starting materials to generate soluble iminosilicates. Based on our observations it should be possible to synthesize a variety of molecular iminosilicates and to extend this new area of chemistry. With the halogenation reaction, we present the first compounds in which there is further functionalization of the cage without cleavage of the framework. We are currently studying the use of these molecules as precursors for generating supramolecular systems under mild conditions by salt elimination reactions.

Experimental Section

General Techniques: All reactions were performed using Schlenk and dry box techniques. Solvents were appropriately dried and distilled under dinitrogen prior to use. − All NMR spectra were obtained in 5 mm tubes using dry degassed [D_8]THF as the solvent, referenced to $SiMe_4$ externally. The solubilities of the cage compounds are not sufficient for ^{13}C NMR spectroscopy. − Elemental analyses were performed by the Analytisches Chemisches Laboratorium des Instituts für Anorganische Chemie, Göttingen.

Compound **1**[11] and $GaEt_3$[17] were prepared according to literature methods. Other compounds are commercially available.

Preparation of 2 (Molar Ratio of 1 to $AlMe_3$ 1:2): A solution of $AlMe_3$ (2.3 mL, 2M in heptane) was added dropwise to a solution of **1** (0.8 g, 2.3 mmol) in toluene (20 mL) at −80 °C. As soon as gas evolution had ceased, the reaction mixture was warmed to room temperature and stirred for 12 h. The solvent was removed in vacuo and the remaining yellowish oil stirred in hexane. A white precipitate was filtered off. Compound **2** was obtained in 75% yield (0.77 g).

Preparation of 2 (Molar Ratio of 1 to $AlMe_3$ 1:1): Analogous preparation method. Yield 75%.

Preparation of 2 from 1 and $Me_2Al(iPr_2C_6H_3NSiMe_3)$: A solution of **1** (0.8 g, 2.2 mmol) in hexane (30 mL) was added dropwise to a solution of $Me_2Al(iPr_2C_6H_3NSiMe_3)$ (0.7 g, 2.2 mmol) in hexane (20 mL) at 0 °C. As soon as gas evolution had ceased, the reaction mixture was warmed to room temperature and stirred for 12 h. Finally the reaction mixture was heated to 30 °C for 1 h. The solvent was evaporated to 15 mL and the residue was filtered off. Yield 0.4 g **2** (82%).

Preparation of 2 from 1 and MAO: A solution of **1** (1.8 g, 5.1 mmol) in hexane (30 mL) was added dropwise to a solution of MAO in toluene (30.0 g, 10%, 517 mmol Al) at room temperature. The reaction mixture was stirred for 20 h. The flask was kept at room temperature for 21 d and single crystals suitable for X-ray structural analysis were formed. Yield 0.11 g **2** (5%), decomp. 280−285 °C. − ^1H NMR (200 MHz, [D_8]THF): δ = −1.37 (s, 6 H, $AlCH_3$), −0.83 [s, 12 H $Al(CH_3)_2$], 0.08 [s, 12 H, $Si(CH_3)_2iPr$], 0.89 [s, b, 6 H, $Si(NH)_3$], 1.15 [d, ^3J(H,H) = 7.1 Hz, 12 H, $CH(CH_3)_2$], 1.20 [d, ^3J(H,H) = 6.8 Hz, 12 H, $CH(CH_3)_2$], 1.32 [d, ^3J(H,H) = 6.8 Hz, 12 H, $CH(CH_3)_2$], 1.38 [sept, ^3J(H,H) = 7.1 Hz, 2 H, $CH(Me)_2$], 3.52 [sept, ^3J(H,H) = 6.8 Hz, 4 H, $CH(Me)_2$], 7.23 [s, 6 H, Ar−*H*). − IR ([cm^{-1}], KBr, Nujol): ṽ = 3407, 3345, 3328, 1383, 825, 753. − MS (EI); *m*/*z* (%): 433 (38) [1/2 M^+ − Me], 882 (100) [M^+ − Me]. − $C_{40}H_{84}Al_4N_8Si_4$ (897.43): calcd. C 52.54, H 9.44; found C 52.3, H 8.6.

Preparation of 3: A solution of $GaMe_3$ (0.53 g, 4.60 mmol) in toluene (10 mL) was added dropwise to a solution of **1** (0.80 g, 2.30 mmol) in toluene (15 mL) at room temperature. After stirring the solution for 12 h it was heated at reflux for 1 h. The reaction mixture was cooled (2 °C), and crystals suitable for X-ray structural analysis were obtained. The solvent was removed in vacuo, and the remaining solid was washed with pentane (5 mL). A colorless solid was filtered off. Yield 0.98 g (80%), decomp. 280 °C. − ^1H NMR (200 MHz, [D_8]THF): δ = −0.90 (s, 6 H, $GaCH_3$), −0.57 [s, 12 H $Ga(CH_3)_2$], 0.04 [s, 12 H, $Si(CH_3)_2iPr$], 0.82 [s, b, 2 H, Si(N*H*)GaMe], 1.05 [s, b, 4 H, $Si(NH)_2(Ga_2Me_3)_2$], 0.95 [d, ^3J(H,H) = 7.1 Hz, 12 H, $CH(CH_3)_2$], 1.05 [d, ^3J(H,H) = 6.8 Hz, 12 H, $CH(CH_3)_2$], 1.18 [d, ^3J(H,H) = 6.8 Hz, 12 H, $CH(CH_3)_2$], 1.42 [sept, ^3J(H,H) = 7.1 Hz, 2 H, $CH(Me)_2$], 3.48 [sept, ^3J(H,H) = 6.8 Hz, 4 H, $CH(Me)_2$], 7.09 (s, 6 H, Ar−*H*). − IR ([cm^{-1}], KBr, Nujol): ṽ = 3410, 3360, 3342, 1309, 827, 773. − MS (EI); *m*/*z* (%): 511 (48) [1/2 M^+ − Me], 1053 (100) [M^+ − Me]. − $C_{40}H_{84}Ga_4N_8Si_4$ (1068.39): calcd. C 44.97, H 7.92; found C 45.0, H 7.8.

Preparation of 4: A solution of $GaEt_3$ (1.07 g, 6.80 mmol) in toluene (10 mL) was added dropwise to a solution of **1** (1.20 g, 3.40 mmol) in toluene (10 mL) at room temperature, and stirred for 14 h followed by 1 h of heating at reflux. The reaction mixture was cooled to room temperature and after 24 h single crystals suitable for X-ray structural analysis were obtained. After the solvent was removed in vacuo the residue was stirred in pentane (5 mL), and a colorless solid was filtered off. Yield 1.47 g (75%), decomp. 285 °C. − ^1H NMR (200 MHz, [D_8]THF): δ = −0.05 [m, 4 H $Ga(CH_2Me)$], 0.52 [m, 8 H $Ga(CH_2Me)_2$], 0.15 [s, 12 H, $Si(CH_3)_2$-*i*Pr], 0.82 [s, b, 2 H, Si(N*H*)GaMe], 1.05 [s, b, 4 H, $Si(NH)_2(Ga_2Me_3)_2$], 1.17 [d, ^3J(H,H) = 7.1 Hz, 12 H, $CH(CH_3)_2$], 1.27 [d, ^3J(H,H) = 6.8 Hz, 12 H, $CH(CH_3)_2$], 1.41 [d, ^3J(H,H) = 6.8 Hz, 12 H, $CH(CH_3)_2$], 1.66 [sept, ^3J(H,H) = 7.1 Hz, 2 H, $CH(Me)_2$], 3.66 [sept, ^3J(H,H) = 6.8 Hz, 4 H, $CH(Me)_2$], 7.27 (s, 6 H, Ar−*H*). − IR ([cm^{-1}], KBr, Nujol): ṽ = 3411, 3360, 3342, 1363, 828, 751. − MS (EI); *m*/*z* (%): 547 (68) [1/2 M^+ − Et], 1123 (100) [M^+ − Et]. − $C_{46}H_{96}Ga_4N_8Si_4$ (1152.54): calcd. C 47.94, H 8.40; found C 48.2, H 8.20.

Preparation of 5: A solution of $InMe_3$ (0.53 g, 4.60 mmol) in toluene (10 mL) was added dropwise to a solution of **1** (0.80 g, 2.30 mmol) in toluene (15 mL) at room temperature. After stirring the solution for 1 h it was heated at reflux for 12 h. The solvent was removed in vacuo, and the remaining solid was washed with pentane (5 mL). A colorless solid was filtered off and dissolved in warm toluene (10 mL) at 60 °C. Formation of single crystals suitable for X-ray measurements was observed after 24 h. Yield 0.98 g (80%), decomp. 285 °C. − ^1H NMR (200 MHz, [D_8]THF): δ = −0.92 (s, 6 H, $InCH_3$), −0.42 [s, 12 H $In(CH_3)_2$], 0.14 [s, 12 H, $Si(CH_3)_2iPr$], 0.80 [s, b, 2 H, Si(N*H*)InMe], 1.15 [s, b, 4 H, $Si(NH)_2(In_2Me_3)_2$], 1.02 [d, ^3J(H,H) = 7.1 Hz, 12 H, $CH(CH_3)_2$], 1.05 [d, ^3J(H,H) = 6.8 Hz, 12 H, $CH(CH_3)_2$], 1.20 [d, ^3J(H,H) = 6.8 Hz, 12 H, $CH(CH_3)_2$], 1.40 [sept, ^3J(H,H) = 7.1 Hz, 2 H, $CH(Me)_2$], 3.46 [sept, ^3J(H,H) = 6.8 Hz, 4 H, $CH(Me)_2$], 7.09 (s, 6 H, Ar−*H*). − IR ([cm^{-1}], KBr, Nujol): ṽ = 3499, 3414, 3360, 1313, 802. − MS (EI); *m*/*z* (%): 609 (36) [1/2 M^+ − Me], 1233 (100) [M^+ − Me]. − $C_{40}H_{84}In_4N_8Si_4$ (1248.43): calcd. C 38.47, H 6.78; found C 38.8, H 6.8.

Preparation of 6a/6b: Bromine was added dropwise at 0 °C to a suspension of **2** (0.70 g, 0.78 mmol) in toluene (25 mL) until no color change was observed. One further drop of bromine was ad-

ded. The solution was stirred for 1 h at 0 °C. The MeBr was then removed in vacuo and the solution was allowed to warm to room temperature. Further solvent was removed (15 mL) and a white precipitate was formed, which was dissolved again by stirring the solution at 60 °C. Single crystals suitable for X-ray structural analysis were obtained after keeping the solution for 4 d at room temperature. Yield 0.39 g (43%), decomp. 295 °C. – ^{1}H NMR (200 MHz, [D$_8$]THF): (**6a**) δ = −1.07 (s, 6 H, AlCH_3), −0.83 [s, 6 H, Al(CH_3)Br], 0.10 [s, 12 H, Si(CH_3)$_2$*i*Pr], 0.76 [s, br, 6 H, Si(NH)$_3$], 1.13 [d, $^3J(H,H)$ = 7.1 Hz, 12 H, CH(CH_3)$_2$], 1.16 [d, $^3J(H,H)$ = 6.8 Hz, 12 H, CH(CH_3)$_2$], 1.32 [d, $^3J(H,H)$ = 6.8 Hz, 12 H, CH(CH_3)$_2$], 1.38 [sept, $^3J(H,H)$ = 7.1 Hz, 2 H, CH(Me)$_2$], 3.52 [sept, $^3J(H,H)$ = 6.8 Hz, 4 H, CH(Me)$_2$], 7.23 (m, 6 H, Ar−H); (**6b**) −1.17 (s, 6 H, AlCH_3), 0.08 [s, 12 H, Si(CH_3)$_2$*i*Pr], 0.89 [s, br, 6 H, Si(NH)$_3$], 1.15 [d, $^3J(H,H)$ = 7.1 Hz, 12 H, CH(CH_3)$_2$], 1.20 [d, $^3J(H,H)$ = 6.8 Hz, 12 H, CH(CH_3)$_2$], 1.40 [d, $^3J(H,H)$ = 6.8 Hz, 12 H, CH(CH_3)$_2$], 1.40 [sept, $^3J(H,H)$ = 7.1 Hz, 2 H, CH(CH$_3$)$_2$], 3.50 [sept, $^3J(H,H)$ = 6.8 Hz, 4 H, CH(CH$_3$)$_2$], 7.20 (m, 6 H, Ar−H). – IR ([cm^{-1}], KBr, Nujol): $\tilde{\nu}$ = 3408, 3348, 3330, 1381, 824, 752. – MS (EI); *m*/*z* (%): 1012 (100) [M$^+_{6a}$ − Me]; 1141 (12) [M$^+_{6b}$ − Me]. – $C_{44.56}H_{84.68}Al_4Br_{2.44}N_8Si_4$ (1101.80): calcd. Preparation of 7a/7b: A solution of iodine in toluene (0.1 M) was added dropwise at 0 °C to a suspension of **2** (0.55 g, 0.61 mmol) in toluene (25 mL) until no color change was observed. One further drop of this solution was then added. The solution was stirred for 30 min at 0 °C and 1 h at room temperature. The MeI formed, as well as 15 mL of the solvent, were removed in vacuo and a white precipitate was formed. It was dissolved again by stirring the solution at 60 °C. Single crystals suitable for X-ray structural analysis were obtained from the solution after 4 d at room temperature. Yield 0.22 g (47%), decomp. 280−285 °C. – ^{1}H NMR (200 MHz, [D$_8$]THF): (**7a**) δ = −1.07 (s, 6 H, AlCH_3), −0.83 [s, 6 H, Al(CH_3)I], 0.10 [s, 12 H, Si(CH_3)$_2$*i*Pr], 0.76 [s, br, 6 H, Si(NH)$_3$], 1.13 [d, $^3J(H,H)$ = 7.1 Hz, 12 H, CH(CH_3)$_2$], 1.16 [d, $^3J(H,H)$ = 6.8 Hz, 12 H, CH(CH_3)$_2$], 1.32 [d, $^3J(H,H)$ = 6.8 Hz, 12 H, CH(CH_3)$_2$], 1.38 [sept, $^3J(H,H)$ = 7.1 Hz, 2 H, CH(Me)$_2$], 3.52 [sept, $^3J(H,H)$ = 6.8 Hz, 4 H, CH(Me)$_2$], 7.23 (m, 6 H, Ar−H); (**7b**): δ = −1.17 (s, 6 H, AlCH_3), 0.08 [s, 12 H, Si(CH_3)$_2$*i*Pr], 0.89 [s, b, 6 H, Si(NH)$_3$], 1.15 [d, $^3J(H,H)$ = 7.1 Hz, 12 H, CH(CH_3)$_2$], 1.20 [d, $^3J(H,H)$ = 6.8 Hz, 12 H, CH(CH_3)$_2$], 1.40 [d, $^3J(H,H)$ = 6.8 Hz, 12 H, CH(CH_3)$_2$], 1.40 [sept, $^3J(H,H)$ = 7.1 Hz, 2 H, CH(Me)$_2$], 3.50 [sept, $^3J(H,H)$ = 6.8 Hz, 4 H, CH(Me)$_2$], 7.20 (m, 6 H, Ar−H). – IR ([cm^{-1}], KBr, Nujol): $\tilde{\nu}$ = 3407, 3345, 3328, 1383, 825, 753. – MS (EI); *m*/*z* (%): 1106 (100) [M$^+_{7a}$ − Me], 1329 (6) [M$^+_{7b}$ − Me]. – $C_{41.24}H_{80.64}Al_4I_{2.30}N_8Si_4$ (1200.83): calcd. C 41.25, H 6.72; found C 40.1, H 6.3.[16]

X-ray Crystallography: Crystallographic data: Crystals were mounted on a glass fiber in a rapidly cooled perfluoropolyether.[18] Diffraction data were collected on a Stoe-Siemens-Huber four-circle-diffractometer coupled to a Siemens CCD area-detector at 133(2) K, with graphite-monochromated Mo-K_α radiation (λ = 71.073 pm).

The structures were solved by direct methods using SHELXS-97[19] and refined against F^2 on all data by full-matrix least squares with SHELXL-97.[20] All nonhydrogen atoms were refined anisotropically. In all structures the hydrogen atoms bound to N(2), N(3) and N(4) were found in the difference Fourier map and refined freely, all other hydrogen atoms were included in the model at geometrically calculated positions and refined using a riding model. The disordered ethyl groups in **4** were modeled with the help of similarity restraints for 1−2 and 1−3 distances and displacement parameters as well as rigid bond restraints for anisotropic displacement parameters. The cocrystallized products in the structures of **6a/b** and **7a/b** were treated as disorders and refined with the help of similarity and rigid bond restraints. The occupancies of **6a** and **6b** refined to a ratio of 80% to 20%, the ratio of **7a** and **7b** was found to be 85% to 15%.

Atomic coordinates, thermal parameters, bond lengths and angles have been deposited at the Cambridge Crystallographic Data Centre (CCDC). Any request to the CCDC for this material should quote the full literature citation and the reference number CCDC-140493 to CCDC-140498. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

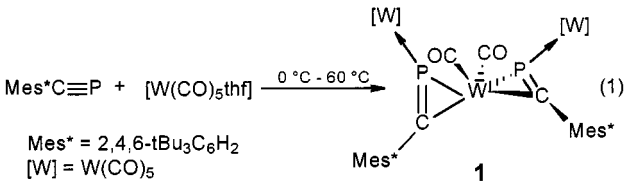
Cyclooligomerization Reactions of Different Phosphaalkynes in the Presence of [W(CO)$_5$thf] − A Route to Tungsten-Stabilised Phosphorus Heterocycles

Peter Kramkowski[a] and Manfred Scheer*[a]

Dedicated to Professor Arndt Simon in occasion of his 60th birthday

Keywords: Phosphaalkynes / Tungsten / Cyclizations / 1,3-Diphosphete ligands / Reaction mechanisms



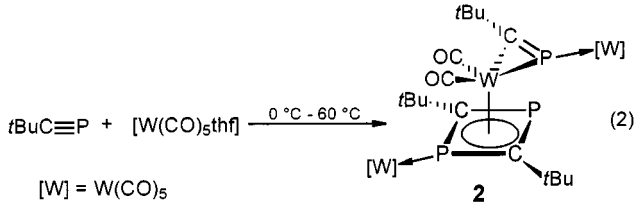
The reactivity of various phosphaalkynes versus [W(CO)$_5$thf] has been studied. The reaction with Mes*C≡P (Mes* = 2,4,6-tBu$_3$C$_6$H$_2$) exclusively leads to the low yield formation of [W(CO)$_2${(η^2-PCMes*)W(CO)$_5$}$_2$] (**1**). The reaction of the less bulky tBuC≡P with [W(CO)$_5$thf] results in high yields in [W(CO)$_2${η^4-(tBuC)$_2$P$_2$W(CO)$_5$}{η^2-(tBuCP)W(CO)$_5$}] (**2**) which possesses a 1,3-diphosphete ligand as well as a side-on coordinated tBuCP unit. Experiments employing MesC≡P (Mes = 2,4,6-Me$_3$C$_6$H$_2$) give the complexes [W(CO)$_4${η^4-(MesC)$_2$P$_2$}] (**3**), [W(CO)$_2${η^4-(MesC)$_2$P$_2$}{η^2-(MesCP)W(CO)$_5$}] (**4**) and [W(CO)$_2${η^4-(MesC)$_2$P$_2$W(CO)$_5$}⟨η^2-(MesCP)W(CO)$_5${μ-W(CO)$_4$}⟩] (**5**) which have a 1,3-diphosphete ligand in their coordination sphere and are partly substituted with an additional side-on coordinated MesC≡P unit. In **5**, two P atoms of the 1,3-diphosphete and the side-on coordinated MesC≡P are further bridged by a W(CO)$_4$ moiety. Additionally, the unusual product [{W(CO)$_3$}⟨η^6-1,2,4-(RC)$_3$P$_3${RCP→W(CO)$_5$}$_2$⟩] (R = Mes) (**6**) resulting from a pentamerization of MesC≡P initiated by [W(CO)$_5$thf], could be obtained in moderate yield. Comprehensive spectroscopical and structural investigations of all products are presented.

Introduction

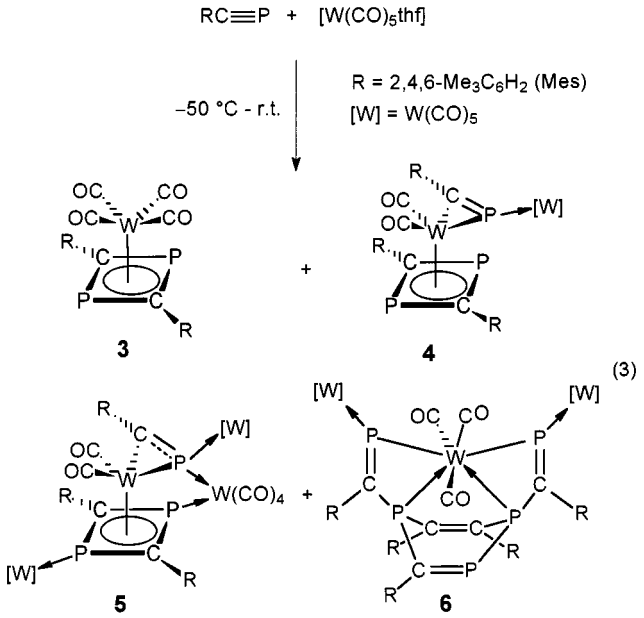
Almost twenty years ago the first kinetically stabilised phosphaalkyne tBuC≡P was designed by G. Becker and coworkers.[1] The synthesis of this compound was further improved in the groups of M. Regitz and G. Becker and has therefore become accessible to all chemists.[2] The chemistry of tBuC≡P has undergone a rapid and exciting development. Co-oligomerization and complex-chemical stabilisation of such compounds have been intensively studied and reviewed in detail.[3,4] Investigations involving phosphaalkynes with a residue R different from tBu, however, are scarce. Only a few examples of complexes derived from AdC≡P[5] (Ad = C$_{10}$H$_{15}$) and Mes*C≡P[6,7] (Mes* = 2,4,6-tBu$_3$C$_6$H$_2$) are known in the literature. Our interest is focussed on the reactivity of RC≡P towards cluster frameworks such as e.g. *nido*-[Ru$_4$(CO)$_{13}$(μ$_3$-PPh)],[6] and especially on the use of phosphaalkynes in the metathesis reaction with alkoxides of the type [(RO)$_3$W≡W(OR)$_3$].[8,9] The goal of the latter chemistry has been the development of an efficient procedure for the synthesis of phosphido complexes of the type [(RO)$_3$W≡P]. Since these compounds possess a highly reactive metal-phosphorus triple bond, it is necessary to stabilise these complexes with Lewis-acidic M(CO)$_5$-fragments to form [(RO)$_3$W≡P→M(CO)$_5$] (M = Cr, W; R = tBu; 2,6-Me$_2$C$_6$H$_3$).[10] Before one is able to explore the three component system [(RO)$_3$W≡W(OR)$_3$]/RC≡P/[M(CO)$_5$thf], one must be aware of the reaction of phosphaalkynes with [M(CO)$_5$thf] alone. We established that [Cr(CO)$_5$thf] does not react at all with RC≡P, regardless of the reaction conditions employed. However, [W(CO)$_5$thf] reveals a broad reactivity towards Mes*C≡P, tBuC≡P and MesC≡P (Mes = 2,4,6-Me$_3$C$_6$H$_2$), which we have reported herein. Furthermore, for the first time metal complexes derived from MesC≡P have been synthesised. The molecular structures and spectroscopic properties of these novel compounds will be presented.

Results and Discussion

Mes*C≡P (Mes* = 2,4,6-tBu$_3$C$_6$H$_2$) reacts with [W(CO)$_5$thf] to give [W(CO)$_2${(η^2-PCMes*)W(CO)$_5$}$_2$] (**1**) in low yield (6%) and most of the phosphaalkyne remains unchanged regardless of the reaction conditions employed [Equation (1)].[7]



(1)



If the same reaction is performed with tBuC≡P, [W(CO)$_2${η^4-(tBuC)$_2$P$_2$W(CO)$_5$}{η^2-(tBuCP)W(CO)$_5$}] (**2**) is formed almost quantitatively as the only phosphorus-containing product [Equation (2)]. The same quantities of **2** are obtained independent of whether the reaction mixture is kept at ambient temperature for 48 h or refluxed for a period of 2 h.

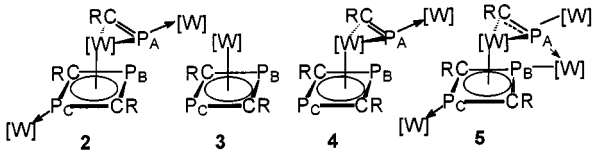
The use of MesC≡P (Mes = 2,4,6-$Me_3C_6H_2$) in the reaction with [W(CO)$_5$thf], in the temperature range from −50 °C to ambient temperature, however, leads to a variety of different products [Equation (3)].

All products are purified and separated by column chromatography. The complexes **1**, **2**, **4** are red, **3** is a yellow, **5** is a dark-red, and **6** an orange-red crystalline compound. They are sufficiently stable in the solid state to allow brief handling in air. All compounds are readily soluble in all common organic solvents such as *n*-hexane, toluene, THF, or CH_2Cl_2, apart from **3** which reveals a poor solubility in *n*-hexane.

All products are spectroscopically characterised and their molecular structures are determined by single crystal X-ray structure analysis. The crystal structure and the spectroscopic data of **1**[7] and **6**[11] were published elsewhere. Although compound **2** has been published before,[9] the X-ray structure analysis of **2** reported herein is of much higher quality, and also the spectroscopic data are completed here as well.



In **1** only side-on coordination of the large Mes*C≡P occurs which is probably due to steric reasons. The dominant feature of all other products is the occurrence of a cyclodimerization and in the case of **6** a pentamerization of RC≡P. Compounds **2**−**5** possess a 1,3-diphosphete moiety, which in **3** is the only ligand at tungsten besides 4 CO groups. In complexes **2**, **4**, and **5**, two of the CO ligands are replaced by a side-on coordinated phosphaalkyne which further coordinates to a W(CO)$_5$ group (c.f. Figures 1−4). A "head-to-tail" dimerization on 14-valence electron (VE) complexes of cobalt,[12] rhodium,[13] iron,[14] and molybdenum[15] and of 12VE fragments of zirconium and hafnium[16] have been observed in several compounds. However, additional side-on coordination of a phosphaalkyne at the capping metal fragment has not yet been found. While only a few examples exist for a trimerization,[17] and just one for a tetramerization[18] of phosphaalkyne, complex **6** is the first pentamerization product induced by a transition metal complex.[19]

Spectroscopic Properties of Compounds 2−6

The IR spectra of complexes **2**−**6** reveal bands for CO stretching frequencies in the range of 1900−2100 cm^{-1} as expected for terminal bound CO ligands. The mass spectra of **2**−**4** show the molecular ion peak and the expected fragmentation patterns.

The ^{31}P NMR data of **2**−**5** are summarised in Table 1. The signals of the ring phosphorus atoms (P_B and P_C) of the 1,3-diphosphete ligands appear in the region between δ = 13.0 (**2**) and 82.9 (**5**). These chemical shifts are in accordance with those observed for [{η^4−1,3-(*t*BuC)$_2$P$_2$}Fe(CO)$_3$] (δ = 38.1[14]) and [{η^4−1,3-(*t*BuC)$_2$P$_2$}CoCp*] (δ = 56.8[12a]) and seem to be fairly independent of whether coordination of the P atom to a W(CO)$_5$ group occurs or not. Zenneck et al. reported a chemical shift of +82.1 ppm for a 1,3-diphosphete complex of iron were both P atoms coordinate to a Cr(CO)$_5$ group.[20]

Table 1. ^{31}P NMR data for the compounds **2**−**5** in C_6D_6 at 298 K; *J* [Hz]

Compound	δ	*J*(P,P)	*J*(W,P)
2	P_A = 318.9 (d)	P_A,P_B = 38	231.5 & 61.0
	P_B = 13.1 (d)	P_B,P_A = 38	
	P_C = 14.0 (s)		235.0
3	$P_{B,C}$ = 58.1 (s)		62.2
4	P_A = 371.4 (t)	P_A,$P_{B,C}$ = 17	209.4 & 61.6
	$P_{B,C}$ = 64.9 (d)	$P_{B,C}$,P_A = 17	
5	P_A = 264.0 (s)		224.0 & 64.8
	P_B = 82.9 (s)		130.8
	P_C = 44.6 (s)		264.7

Coupling of the ring phosphorus to the tungsten carbonyl cap is only observed in the case of **3**. The signals of P_C in **2** and **5** bear one pair of tungsten satellites with coupling constants typical of an end-on coordination of a W(CO)$_5$ moiety.

The chemical shifts of the P_A atom of the side-on bound phosphaalkyne unit in **2**, **4**, and **5** are observed in the region

of δ = 264.0 (**5**) to 371.4 (**4**). The data are in good agreement with those of complex **1** (δ = 313[7]), which only possesses side-on coordinated phosphaalkynes. In **5** an unusual shift towards high field for the signal of P_A is observed which is because of the particular bonding situation in this complex due to the $W(CO)_4$ bridge between P_A and P_B. All P_A atoms in **2**, **4**, and **5** show the appropriate coupling pattern for a coordination to the end-on bound $W(CO)_5$ group and the side-on coordination to the $W(CO)_2$ cap, with coupling constants in the range of 209.0−224.0 Hz and 61.0−64.8 Hz, respectively. In the case of complexes **2** and **4**, a *J*(P,P) between the phosphorus of the side-on coordinated phosphaalkyne unit and the ring P atoms is observed. The coupling constants are within 38 and 17 Hz, a typical range for a coupling over two bonds.

Molecular Structures of 2−5

Compound **2** crystallises with two independent molecules in the unit cell. Both molecules possess essentially an identical structure. The following refers to molecule A.

The η^4-1,3-diphosphacyclobutadiene ring of **2** (Figure 1) reveals almost equidistant C−P distances and therefore is a square rather than a rectangle [*d*(P−C) = 1.768(14)−1.806(14) Å]. This is in good agreement with the bond lengths in the complexes [CpCo{η^4-(*t*BuC)$_2$P$_2$}] [*d*(P−C) = 1.79(1)−1.82(1) Å],[12b] [Cp*Co{η^4-(*t*BuC)$_2$P$_2$}] [*d*(P−C) = 1.797(3)−1.798(3) Å],[13] and [Mo{η^4-(*t*BuC)$_2$P$_2$}$_3$] [*d*(P−C) = 1.811(4)−1.860(5) Å][21]. In **2**, the ring is folded 169° along the C(13)−C(14) axis and is therefore essentially planar, since all atoms stand out of the idealised plane P(1)−P(2)−C(13)−C(14) by 0.06 Å only, on average. This 1,3-diphosphete unit coordinates to a $W(CO)_2$ cap, which is further coordinated side-on by a phosphaalkyne unit with *d*[W(1)−P(3)] = 2.369(4) and *d*[W(1)−C(23)] = 2.13(2) Å. The P−C bond length of this phosphaalkyne is elongated to 1.66(2) Å [c.f. in *t*BuC≡P: 1.54 Å[22]]. This distance is comparable to the observed bond lengths of the side-on coordinated *t*BuC≡P in [(Ph$_3$P)$_2$Pt{η^2-*t*BuCP}] [1.672(17) Å][23] or in [(Cp)$_2$Ti(PMe$_3$){η^2-*t*BuCP}] [1.634 Å].[24] This elongation is due to the back donation effects of the tungsten of the $W(CO)_2$ moiety into the π* orbitals of the C−P bond. The high degree of sp^2 hybridisation at C(23) is further reflected in the angle of 0.88° between the planes W(1)−C(23)−P(3) and P(3)−C(23)−C(24) (between the planes W(1)−C(23)−P(3) and W(3)−P(3)−C(23) the angle is 15.50°). The phosphorus atoms P(2) and P(3) further coordinate to $W(CO)_5$ fragments with bond lengths of 2.493(4) and 2.462(4) Å, respectively. This is in the range for coordinative bonds as observed e.g. in [$W(CO)_4$⟨(η^4-P_4){$W(CO)_5$}$_4$⟩] [average *d*(WP) = 2.445(7) Å].[25]

Complex **3** (Figure 2) is the first tungsten complex possessing only CO ligands, besides the 1,3-diphosphacyclobutadiene ring. The bond lengths inside the four-membered ring of **3** are slightly longer than those observed in **2** [*d*(P−C) = 1.818(3)−1.827(3) Å]. The ring system of **3** is almost planar (folding angle: 170.79°, measured along the C(3)−C(3A) axis, maximal deviation of the atoms from the idealised plane is ±0.05 Å, c.f. 0.06 Å in **2**). It is noteworthy that the mesityl ligands of the ring carbon atoms are almost in plane with the 1,3-diphosphete system. They are only twisted by 5.1°. Thus, it appears that a kind of delocalisation of three different π-systems is responsible for this effect.

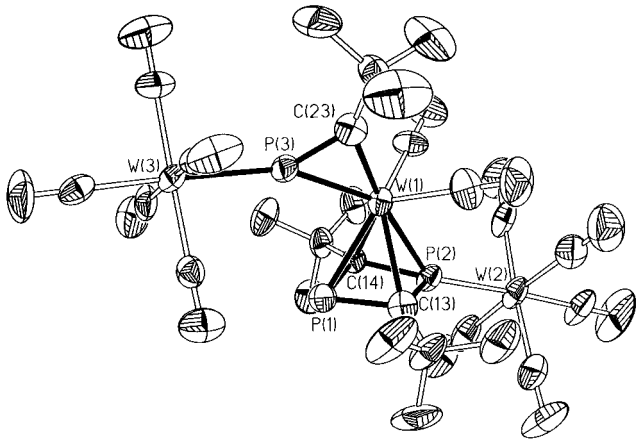


Figure 1. Molecular structure of [$W(CO)_2${η^4-(*t*BuC)$_2$P$_2$-$W(CO)_5$}{η^2-(*t*BuCP)$W(CO)_5$}] (**1**) (molecule A, ellipsoids drawn at 50% probability level). Selected bond lengths [Å] and angles [°]: P(1)−C(13) 1.806(14), P(1)−C(14) 1.791(14), P(2)−C(13) 1.768(14), P(2)−C(14) 1.778(13), P(1)−W(1) 2.495(4), P(2)−W(1) 2.551(4), C(13)−W(1) 2.33(2), C(14)−W(1) 2.368(2), P(3)−C(23) 1.66(2), P(3)−W(1) 2.369(4), C(23)−W(1) 2.13(2), P(2)−W(2) 2.493(4), P(3)−W(3) 2.462(4), C(14)−P(1)−C(13) 82.8(6), C(13)−P(2)−C(14) 84.5(6), P(1)−C(13)−P(2) 95.9(7), P(2)−C(14)−P(1) 95.7(7)

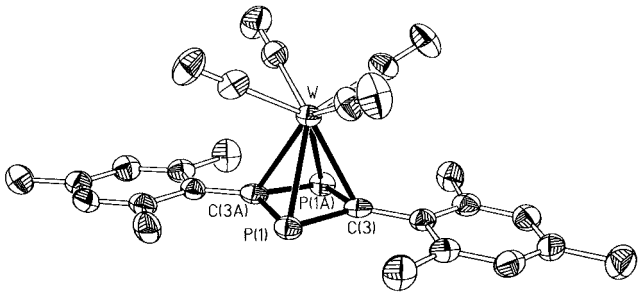

Figure 2. Molecular structure of [$W(CO)_4${η^4-(MesC)$_2$P$_2$}] (**3**) (ellipsoids drawn at 50% probability level). Selected bond lengths [Å] and angles [°]: P(1A)−C(3) 1.818(3), P(1)−C(3) 1.827(3), P(1)−W 2.5265(8), C(3)−W 2.364(3), C(3A)−P(1)−C(3) 83.92(13), P(1A)−C(3)−P(1) 95.67(13)

The molecular structure of **4** (Figure 3) is similar to the *t*Bu derivative **2**. The only difference is that in **4** none of the P atoms of the 1,3-diphosphete ligand bind to a $W(CO)_5$ group. However, the distances within the four-membered ring are slightly longer [*d*(P−C) = 1.793(4)−1.824(4) Å]. The ring system is folded along the C(18)−C(28) axis by 170.03° and is therefore in accordance with the observations for **2** and **3** (maximal deviation from the average plane in **4** is 0.06 Å). As in **2**, the side-on bound phosphaalkyne unit is coordinated to a further $W(CO)_5$ group. The bond length C(8)−P(1) of this moiety is 1.683(3) Å and is therefore only 0.023 Å longer than the corresponding bond in **2**. The degree of sp^2 hybridisation of C(8) is similar to **2** since the angles between the planes W(1)−C(8)−P(1) and P(1)−C(8)−C(9), and W(1)−C(8)−P(1) and

W(2)−P(1)−C(8) are in good agreement with **2** (**4**: 0.41 and 13.57°, respectively). In contrast to **3**, the mesityl moieties at the ring C atoms of the 1,3-diphosphete ligand are twisted by 10.7° in this complex, which is probably due to the steric influence of the side-on coordinated [MesC≡P→W(CO)$_5$] unit.

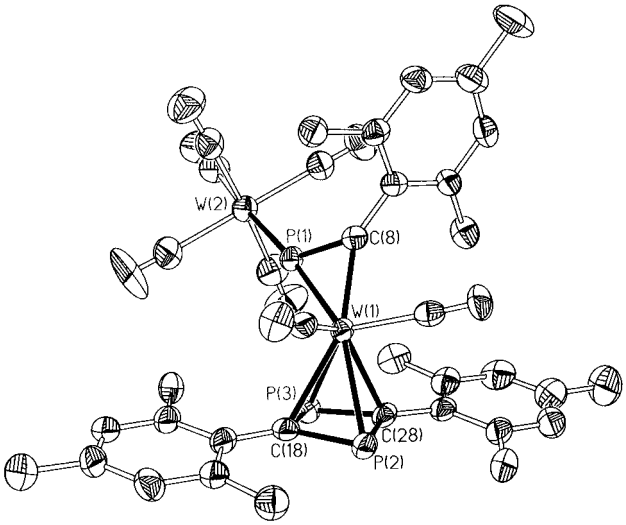

Figure 3. Molecular structure of [W(CO)$_2${η^4-(MesC)$_2$P$_2$}{η^2-(MesCP)W(CO)$_5$}] (**4**) (ellipsoids drawn at 50% probability level). Selected bond lengths [Å] and angles [°]: P(2)−C(18) 1.816(4), P(2)−C(28) 1.798(4), P(3)−C(18) 1.793(4), P(3)−C(28) 1.824(4), P(2)−W(1) 2.5518(12), P(3)−W(1) 2.5218(11), C(18)−W(1) 2.432(4), C(28)−W(1) 2.297(4), P(1)−C(8) 1.683(2), P(1)−W(1) 2.3644(11), C(8)−W(1) 2.072(3), P(1)−W(2) 2.4611(12), C(18)−P(2)−C(28) 83.7(2), C(28)−P(3)−C(18) 83.6(2), P(2)−C(18)−P(3) 96.1(2), P(2)−C(28)−P(3) 95.7(2)

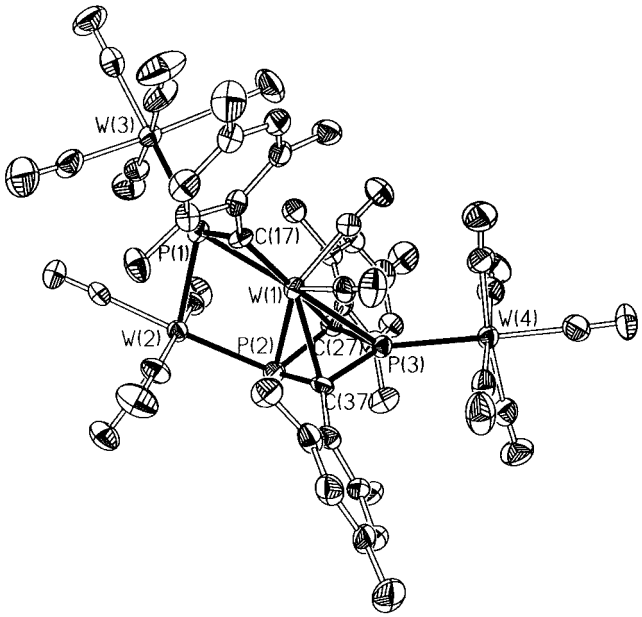
The molecular structure of **5** (Figure 4) also features a capped 1,3-diphosphete ligand. In contrast to the complexes **2**−**4**, both of the P atoms of the diphosphete ligand in **5** coordinate to tungsten carbonyl fragments. One of the P atoms is coordinated to a W(CO)$_4$ moiety, which further bridges to the side-on coordinated phosphaalkyne. While the bond lengths and the grade of folding along the C(27)−C(37) axis of the ring are still in accordance with the data of **2**−**4** [d = 1.788(9)−1.817(9) Å; maximal deviation from the average plane is ±0.06 Å], the situation of the side-on coordinated MesC≡P unit has changed considerably due to the coordination of this phosphorus atom to the bridging W(CO)$_4$ group [W(2)] and a terminal W(CO)$_5$ moiety [W(3)]. The P(1)−C(17) bond length is 1.747(9) Å and is considerably elongated in comparison to **2** and **4** and can be considered as an elongated double bond. The low degree of sp^2 hybridisation of the atom C(17) in **5** becomes obvious when the angle between the planes W(1)−C(17)−P(1) and P(1)−C(17)−C(18) is 12.2° [between W(1)−C(17)−P(1) and W(3)−P(1)−C(17) the angle is 37.7°]. The considerable difference in the bonding situation of the side-on coordinated phosphaalkyne group is further reflected in the comparably short W(1)−C(17) distance, of only 2.032(8) Å [c.f. **2**: 2.13(2) Å and **4**: 2.072(3) Å] and the elongated W(1)−P(1) bond with 2.544(2) Å [c.f. **2**: 2.369(4) Å and **4**: 2.3644(11) Å]. The bond lengths of P(1)−W(2) and P(1)−W(3) [2.562(3) Å and 2.512(3) Å, respectively] are longer than the distances observed in **2** and **4**, but are still in the range for coordinative bonds as e.g. found in [Ph$_3$P→W(CO)$_5$] [d(W−P) = 2.544 Å].[26] The special situation of this P atom is also reflected in its ^{31}P NMR resonance signal as discussed above. Due to the coordination of P(2) to the W(CO)$_4$ bridge and P(3) to a W(CO)$_5$ group, the mesityl moieties of the ring carbon atoms are much more twisted as in **3** or **4**. In **5**, the angles between the planes of the mesityl groups at the atoms C(27) and C(37) and the idealised plane C(27), C(37), P(2), and P(3) are 77.1° and 78.9°, respectively.



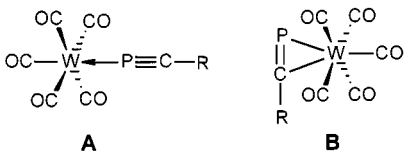


Figure 4. Molecular structure of **5** (ellipsoids drawn at 50% probability level). Selected bond lengths [Å] and angles [°]: P(2)−C(27) 1.817(9), P(2)−C(37) 1.803(9), P(3)−C(27) 1.788(9), P(3)−C(37) 1.800(9), P(2)−W(1) 2.466(3), P(3)−W(1) 2.550(3), C(27)−W(1) 2.424(8), C(37)−W(1) 2.287(9), P(1)−C(17) 1.747(9), P(1)−W(1) 2.544(2), C(17)−W(1) 2.032(8), P(1)−W(2) 2.562(3), P(1)−W(3) 2.512(3), P(2)−W(2) 2.446(3), P(3)−W(4) 2.446(2), C(27)−P(2)−C(37) 85.2(4), C(27)−P(3)−C(37) 86.2(4), P(2)−C(27)−P(3) 93.7(4), P(2)−C(37)−P(3) 93.8(4)

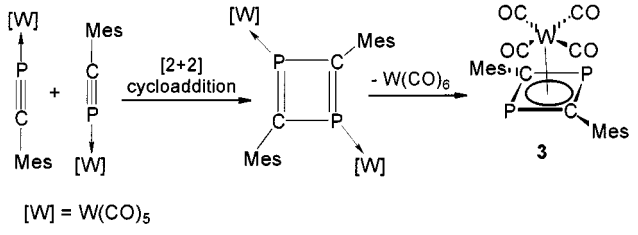
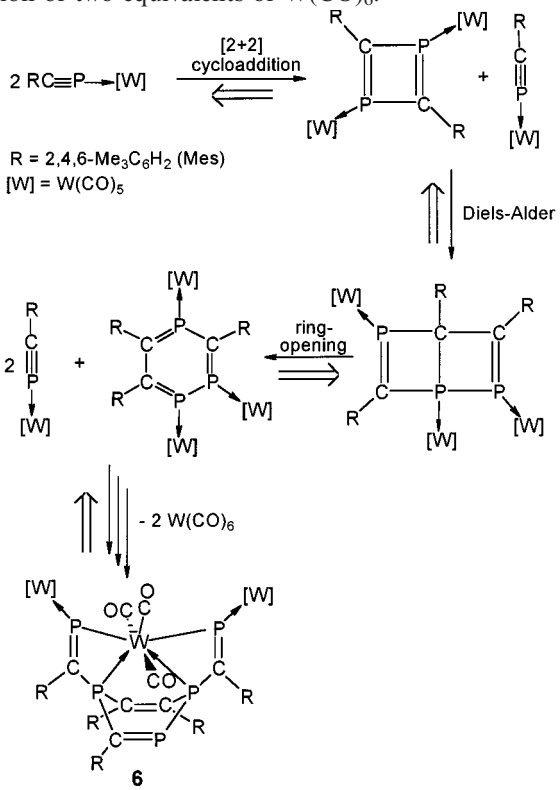
Proposal for a Reaction Pathway for the Formation of the Compounds 1−6



The nature of the products leads us to propose that the first step of these reactions must be the activation of the C≡P triple bond via the coordination of the phosphaalkyne to W(CO)$_5$. Two different coordination modes appear most likely, the end-on (**A**) or side-on (**B**) coordination.

To shed light onto this problem we followed the reaction of MesC≡P with [W(CO)$_5$thf] as a function of temperature by ^{31}P NMR spectroscopy. Indeed a singlet at δ = −74.3 ([D$_8$]toluene, 243 K; MesC≡P: δ = 2.1 (s), [D$_8$]toluene, 243 K) without any tungsten satellites is observed as an in-

termediate of this reaction. This singlet has a maximum intensity at 273 K and decreases after the signals of the products increase. For an end-on coordination of type **A** a singlet shifted into the highfield region bearing one pair of tungsten satellites is expected, revealing a coupling constant of approximately 150−280 Hz. Examples for complexes revealing an end-on coordinated phosphaalkyne are rare. In the complex $[(CO)_3W(PCy_3)_2(\eta^1\text{-}P{\equiv}CMes^*)]$, synthesised in our group, a highfield shift of 10 ppm is observed [δ = 24.4, J(W,P) = 280 Hz], in comparison to free Mes*C≡P.[27] In the group of Nixon, the compound $[FeH(\eta^1\text{-}P{\equiv}C\textit{t}Bu)(dppe)_2][BPh_4]$ could be isolated revealing a highfield shift of about 85 ppm after coordination of *t*BuC≡P (δ = −154; *t*BuC≡P: δ = −69.2).[28] A side-on coordination mode **B** requires a downfield shift as found for the P_A atoms of the side-on coordinated phosphaalkynes in **2**, **4**, and **5**. In this case only a small coupling between tungsten and phosphorus of less than 60 Hz would be expected due to the low s-character in the W−P bond. Recently Nixon et al. described a complex containing a η^2 coordinated phosphaalkyne in $[WF(C_6H_4CH_2NMeCH_2CH_2NMe_2)(CO)(\eta^2\text{-}P{\equiv}C\textit{t}Bu)]$ with a chemical shift at δ = 452.4 and a ^1J(W,P) of 82 Hz.[29] Although the high-field shift of our intermediate at δ = −74.3 seems to favour **A** as the first formed intermediate, without a resolved J(W,P) no unequivocal evidence for either of these activation modes could be achieved from the NMR spectroscopic experiment.



However, the nature of the reaction products also suggests a more end-on coordination as the first step. Firstly, this is supported by the fact that in reaction (1) Mes*C≡P does not form a 1,3-diphosphete ligand, which is likely starting from a complex of type **B**. In the case of the initially formed intermediate **A**, the bulky supermesityl group would interact sterically with the end-on coordinated $W(CO)_5$ group of the second phosphaalkyne and thus a [2+2] cycloaddition is inhibited. By contrast, for the sterically less encumbered MesC≡P the end-on intermediate **A** can undergo a cycloaddition and therefore the formation of **3** is best explained by the reaction shown in Scheme 1. Secondly, in the compounds **2**, **4**, **5**, and **6** all side-on coordinated phosphaalkynes further bear a $W(CO)_5$ group in end-on position.

Scheme 1. Proposed reaction pathway for the formation of **3**

Thus, we propose that in the first step two activated molecules of type **A** approach each other. Since a head-to-tail [2+2] cycloaddition is sterically hindered for the bulky supermesityl groups, the attack on a $W(CO)_5$ unit leads only to the spirocyclic product **1**. For *t*Bu as well as the mesityl substituents, cycloaddition is the predominant reaction pathway (Scheme 1). By elimination of $W(CO)_6$ as the driving force[30] a 1,3-diphosphete ring system capped by a $W(CO)_4$ group is generated to give compound **3**. After further elimination of CO, RC≡P→$W(CO)_5$ is coordinated side-on to give the complexes **2**, **4**, and **5**, respectively. Experiments conducted with complex **3** showed, that the phosphorus atoms of the 1,3-diphosphete ligand are still able to coordinate further $W(CO)_5$ units.

The proposed 1,3-diphosphete unit formed first can also serve as an intermediate for the formation of **6** (Scheme 2). A subsequent Diels−Alder reaction with further end-on activated phosphaalkyne leads then to a Dewar benzene like intermediate which reacts after ring opening with two more activated phosphaalkynes to give compound **6**, after elimination of two equivalents of $W(CO)_6$.

Scheme 2. Proposed reaction pathway for the formation of **6**

Conclusions

The comparison of the reactivity of different phosphaalkynes with $[W(CO)_5thf]$ reveals that MesC≡P possesses the highest potential for yielding novel complexes because its sterical and electronical properties are somewhat between those of the other phosphaalkynes used in former investigations. It is to be expected that further variations of these properties (e.g. in $R_2NC{\equiv}P$[31] and OC≡P,[32] respectively) influence the reaction behaviour dramatically and open up the approach to novel products.

Experimental Section

General Techniques: All reactions were performed under an atmosphere of dry argon using Schlenk and glove box techniques. Sol-

vents were purified and degassed by standard procedures and distilled prior to use. − NMR spectra were recorded on a Bruker AC 250 [^{1}H: 250.13 MHz; ^{31}P: 101.256 MHz; standard Me_4Si (^{1}H), 85% H_3PO_4 (^{31}P)]. − IR spectra were recorded in Nujol on a Bruker IFS 28 FT-IR-spectrometer. − MS: Finnigan MAT 711 at 70 eV. − Correct elemental analyses for the isolated products were performed by the analytical laboratory of the institute.

Reagents: Unless otherwise stated, commercial-grade chemicals were used without further purification. The silica gel was activated by removing all volatile substances at 180 °C in vacuo (10^{-3}Torr) for 48 h. [$W(CO)_5$thf] was prepared by irradiating a THF solution of $W(CO)_6$ in a UV apparatus for 2 h. *t*BuC≡P was synthesised as described in reference [2]. MesC≡P was obtained as published in ref.[33]

Crystal Structure Analysis of 2−5: Crystal structure analyses of **3** were performed on a STOE IPDS and of **2**, **4**, and **5** on a STOE STADI IV (ω-scan mode) diffractometer with Mo-K_α radiation (λ = 0.71073 Å) with empirical absorption corrections for **2**, **4**, and **5** (Psi-scans). Machine parameters, crystal data and data collection parameters are summarised in Table 2. The structures were solved by direct methods using SHELXS-86,[34a] full-matrix-least-squares refinement on F^2 in SHELXL-93[34b] with anisotropic displacement for non-H atoms. Hydrogen atoms were located in idealised positions and refined isotropically according to the riding model. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-139093 to no. CCDC-139096. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (Fax: Int. code +(44)1223/336033; E-mail: deposit@ccdc.cam.ac.uk).

$[W(CO)_2\{\eta^4\text{-}(t\text{BuC})_2P_2\text{-}W(CO)_5\}\{\eta^2\text{-}(t\text{BuCP})W(CO)_5\}]$ (2): *t*BuC≡P (100 mg, 1 mmol) dissolved in *n*-hexane (10 mL) was added to [$W(CO)_5$thf] (25 mL of a 0.04 M THF solution, 1 mmol) at ambient temperature. Subsequently the solvent was reduced to 15 mL and the mixture allowed to stir for 48 h. All volatile substances were then removed in vacuo (10^{-3} Torr). The crude product was purified by column chromatography (silica gel, 30 × 2.5 cm, Merck 60) using a *n*-hexane/toluene mixture of 1:1. After reduction of the solvent to dryness the solid was recrystallised by toluene to afford 235 mg (60%) of red crystals of **2**. Crystals suitable for X-ray analysis were grown from concentrated toluene solutions. − $C_{27}H_{27}O_{12}P_3W_3$ (1187.98): calcd. C 27.30, H 2.29; found C 27.99, H 2.84. − IR [Nujol, $\tilde{\nu}$ (CO), cm^{-1}]: 2072(m), 2018(w), 1975(sh), 1954(vs). ^{1}H NMR (25 °C, C_6D_6): δ 1.66 (s, 9 H, CH_3), 0.87 (s, 18 H, CH_3). − $^{31}P\{^1H\}$ NMR (25 °C, C_6D_6): δ = 318.9 (P3, d), *J*(P,P) = 38 Hz, *J*(W,P) = 231.5 & 61 Hz, 14 (P2, s), *J*(W,P) = 235 Hz, 13.1 (P1, d) *J*(P,P) = 38 Hz. − EI MS: *m*/*z* (%) = 1187.8 (38) [M^+], 1103.9 (14) [M^+ − 3 CO], 1076.8 (2) [M^+ − 4 CO], 1019.9 (6) [M^+ − 6 CO], 991.9 (45) [M^+ − 7 CO].

Compounds 3−6: MesC≡P (162 mg, 1 mmol) was dissolved in *n*-hexane (10 mL) and cooled to −50 °C. At this temperature the solution was added to 10 mL of a THF solution of [$W(CO)_5$thf] (1 mmol). The mixture was allowed to warm up to room temperature and stirred for further 48 h. The reaction was monitored by ^{31}P NMR spectroscopy indicating a small grade of conversion. Then all volatile substances were removed in vacuo. This reaction was repeated twice, and the combined product mixtures were worked up by column chromatography (silica gel, 30 × 2.5 cm, Merck 60). The first fraction was eluted with a mixture of *n*-hexane/toluene (5:1) giving 100 mg of **3** (10.6%). The second fraction with *n*-hexane/toluene (2:1) yielding 200 mg of red **4** (19%). The third fraction was obtained from *n*-hexane/toluene (1:1) to give orange-

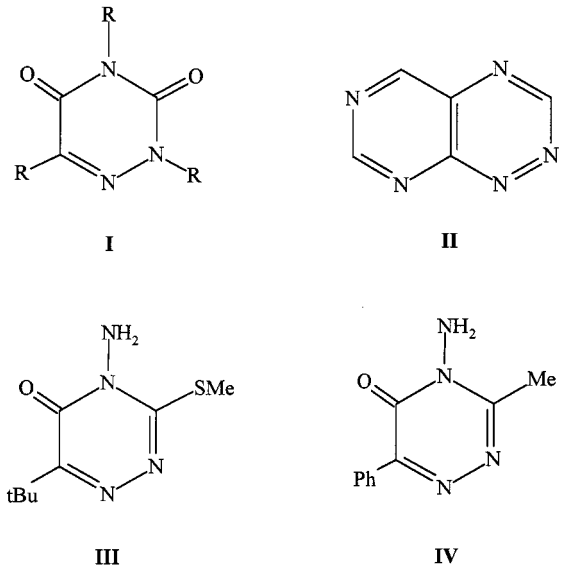
Syntheses of New Sulfur−Nitrogen Palladacycles − Crystal Structures of $[(AMTTO)PdBr_2]_2 \cdot 3.5THF$, $[(AMTTO)PdI_2]_2 \cdot 3MeOH$, $[(AMTTO)Pd(PPh_3)Br]Br \cdot MeOH$, and $[(AMTTO)Pd(PPh_3)I] \cdot 2MeOH$ (AMTTO = 4-Amino-6-methyl-1,2,4-triazine-3-thione-5-one)



Mitra Ghassemzadeh,*[a] Mohammad Bolourtchian,[a] Soheila Chitsaz,[b] Bernhard Neumüller,[b] and Majid M. Heravi[c]

Keywords: Palladium / Triazines / Metallacycles / N ligands / S ligands

Reactions of $[(AMTTO)PdCl_2] \cdot MeOH$ (**1**) with sodium bromide and sodium iodide led to the palladacycles $[(AMTTO)PdBr_2]_2 \cdot 3.5THF$ (**2**) and $[(AMTTO)PdI_2]_2 \cdot 3MeOH$ (**3**) in excellent yields. Treatment of **2** and **3** with triphenylphosphane gave the complexes $[(AMTTO)Pd(PPh_3)Br]Br \cdot MeOH$ (**4**) and $[(AMTTO)Pd(PPh_3)I] \cdot 2MeOH$ (**5**), respectively. All the complexes have been characterized by IR spectroscopy, elemental analysis, as well as by X-ray diffraction studies. In addition, **4** and **5** have been characterized by ^{31}P NMR spectroscopy. Crystal data for **2** at −80 °C: triclinic, space group $P\bar{1}$, a = 1150.8(1), b = 1234.1(1), c = 1398.1(1) pm, α = 84.01(1)°, β = 86.84(1)°, γ = 66.40(1)°, Z = 2, R_1 = 0.0366; for **3** at −50 °C: orthorhombic, space group $Pbcn$, a = 1476.2(1), b = 1333.1(1), c = 1440.1(1) pm, Z = 4, R_1 = 0.0302; for **4** at −80 °C: monoclinic, space group $P2_1/c$, a = 993.0(1), b = 993.6(1), c = 2735.5(2) pm, β = 97.64(1)°, Z = 4, R_1 = 0.0464; for **5** at −70 °C: monoclinic, space group $P2_1/c$, a = 865.7(2), b = 3760.5(3), c = 861.1(1) pm, β = 97.56(1)°, Z = 4, R_1 = 0.0613.

Introduction

1,2,4-Triazines are well-known compounds and a variety of synthetic methods for the preparation of substituted derivatives are available. Compounds containing the 1,2,4-triazine moiety are found in natural materials and some of these exhibit biological activity. A large number of synthetic 1,2,4-triazines also show biological activity and have been used for various purposes. For example, 1,2,4-triazine-3,5-diones (**I**) represent aza analogues of pyrimidine nucleic acid bases. A number of neutral antibiotics are derivatives of pyrimido[5,4-*e*]-1,2,4-triazine (**II**). 4-Amino-6-*tert*-butyl-3-methylthio-1,2,4-triazine-5-one (**III**) and 4-amino-3-methyl-6-phenyl-1,2,4-triazine-5-one (**IV**) are used as herbicides (Scheme 1).[1a] Metal complexes of ligands such as S,N-heterocycles, amino acids, and proteins often exhibit enhanced biological activities compared to the uncomplexed ligand.[1b][1c]

Scheme 1. Four important classes of N-containing heterocycles

In our investigations, we have shown that AMTTO − a representative of 4-amino-6-alkyl-1,2,4-triazine-5-one − acts as a chelating ligand in a 1+1 fashion towards $AgNO_3$ in methanol {one strong Ag−S bond and a weak Ag−N contact leading to a distortion of a ideal linear [AMTTO-Ag-AMTTO]$^+$ ion} and as a bidentate chelating ligand towards $PdCl_2$ in methanol/acetonitrile to give the air-stable complexes $[(AMTTO)_2Ag]NO_3$ [2] and $[(AMTTO)PdCl_2] \cdot MeOH$ (**1**),[3] respectively. To the best of our knowledge, the latter constitutes the first palladacycle of AMTTO.

We have already studied the reactions of **1** with triphenylphosphane and sodium thiocyanate, which led to the air-stable complexes $[(AMTTO)Pd(PPh_3)Cl]Cl \cdot MeOH$ and $[(AMTTO)Pd(SCN)_2] \cdot MeOH$, respectively.[4]

In this paper, we wish to report the halide exchange reactions of **1** using sodium bromide and sodium iodide, as well

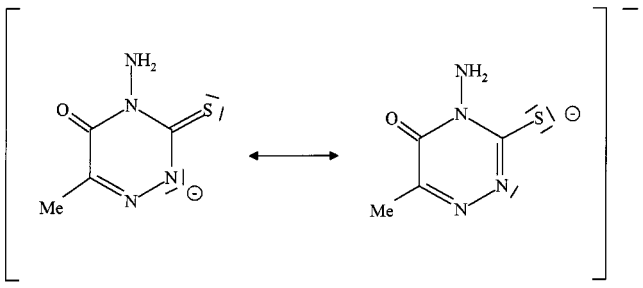
as the reactions of the bromine and iodine palladacycles with triphenylphosphane.

Results and Discussion

Syntheses and Characterization of 2, 3, 4, and 5

Treatment of **1** with sodium bromide in THF at 20 °C gave **2**; similar treatment with sodium iodide in methanol/acetonitrile gave **3** [Equation (1) and (2)].

$$2\,[(AMTTO)PdCl_2] + 4\,NaBr \xrightarrow{THF;\ 20°C} \underset{\mathbf{2}}{[(AMTTO)PdBr_2]_2 \cdot 3.5THF} + 4\,NaCl \quad (1)$$



$$2\,[(AMTTO)PdCl_2] + 4\,NaI \xrightarrow{MeOH/MeCN;\ 20°C} \underset{\mathbf{3}}{[(AMTTO)PdI_2]_2 \cdot 3MeOH} + 4\,NaCl \quad (2)$$

Further treatment of **2** and **3** with PPh_3 in methanol at 20 °C led to **4** and **5**, respectively, according to Equation (3) and (4).

$$[(AMTTO)PdBr_2] + PPh_3 \xrightarrow{MeOH;\ 20°C} \underset{\mathbf{4}}{[(AMTTO)Pd(PPh_3)Br]Br \cdot MeOH} \quad (3)$$

$$[(AMTTO)PdI_2] + PPh_3 \xrightarrow{MeOH;\ 20°C} \underset{\mathbf{5}}{[(AMTTO)Pd(PPh_3)I] \cdot 2MeOH + HI} \quad (4)$$

In contrast to Equation (3), reaction according to Equation (4) gives the complex **5** incorporating the anionic ligand $[AMTTO]^-$ (**V**). This results from an abstraction of HI owing to the relatively high acidity of this particular NH group. The coordination of the sulfur atom leads to additional acidification of the amine function (see Scheme 2).

V

Scheme 2. Mesomeric forms of the anionic AMTTO ligand

Compounds **2–5** were found to be air-stable crystalline solids. The ^{13}C NMR spectrum of the ligand AMTTO has been published for the Ag complex $[Ag(AMTTO)_2]NO_3$ [2] and the data are almost unchanged in the spectra of **2–5**. The ^{31}P NMR spectra of **4** and **5** feature only one sharp singlet at $\delta = 30.3$ and $\delta = 26.2$, respectively, in accordance with the geometries of these compounds. In the IR spectra of **2–5**, three absorptions are seen at 452, 369, and 268 cm^{-1} for **2**, at 445, 373, and 173 cm^{-1} for **3**, at 450, 382, and 259 cm^{-1} for **4**, and at 449, 374, and 198 cm^{-1} for **5**, which can be assigned to ν(PdN), ν(PdS), and ν(PdX) absorptions.[5] C=O and C=N vibrations give rise to two bands at 1703 and 1604 cm^{-1} for **2**, at 1718 and 1612 cm^{-1} for **3**, at 1719 and 1595 cm^{-1} for **4**, and at 1725 and 1625 cm^{-1} for **5**. P–C vibrations of the PPh_3 moiety are seen in the range 749–711 cm^{-1} for **4** and in the range 745–691 cm^{-1} for **5**. The N–H valence vibrations give rise to broad bands at 3254 (**2**), 3230 (**3**), 3205 (**4**), and 3250 cm^{-1} (**5**). Broad O–H absorptions, attributable to hydrogen bonding, give rise to the bands at 3620, 3554, and 3472 cm^{-1} (**3**) and at 3446 cm^{-1} (**5**). The corresponding band for **4** could not localized accurately because of the measured line width.

Crystal Structures of 2–5

The structural data of the palladacycles show that **2** (Figure 1), **3** (Figure 2), and **5** (Figure 4) are neutral molecules incorporating [(AMTTO)Pd] complex fragments. **4** is a salt consisting of $[(AMTTO)Pd(PPh_3)Br]^+$ and Br^- ions, while **5** incorporates the anionic ligand $[AMTTO]^-$. The coordination geometry about the palladium center in each of these complexes is essentially square planar. In all the complexes, the bidentate AMTTO ligand is coordinated to palladium(II) forming a five-membered chelate ring. The coordination sphere of **2** is completed by two bromide anions, while that of **3** is completed by two iodide ions. The coordination sites in **4** and **5** are occupied by one halide ion (Br^- in **4**; I^- in **5**, Figure 3 and 4) and a triphenylphosphane ligand. The Pd–S bond lengths of 225.2(2)/225.9(2) and 227.4(2) pm found in **2** and **3**, respectively, do not differ significantly from the Pd–S distances of 227.5(2) and 226.6(2) pm in **4** and **5**. On comparing the data with the lowest literature values for thioether-palladium complexes, i.e. 228–229 pm, these distances are seen to be rather short.[6,7] The Pd–N atom distances are within the range observed for related compounds.[7] The Pd–N bond lengths [211.0(5) pm in **4**; 209.2(7) pm in **5**] are longer than those in **2** and **3** [204.2(6) and 207.9(5) pm, respectively]. This lengthening reflects the *trans* influence of the phosphane ligand. The Pd–X bonds *trans* to the sulfur atom [Pd1–Br1 and Pd2–Br4, 244.7(1) and 244.1(9) pm in **2**; Pd1–I2 259.73(6) pm in **3**] are somewhat longer than the Pd–X distances *cis* to S1 [Pd1–Br2 240.75(6) pm and Pd2–Br3 242.5(1) pm in **2**; Pd1–I1 257.50(6) pm in **3**], reflecting the greater *trans* influence of the sulfur atom as compared to the nitrogen atom. The presence of an $[AMTTO]^-$ ligand in **5** leads only to marginal differences in the bonding parameters due to the delocalization of the charge in **V** (Scheme 2).

The halide atoms in **4** and **5** are oriented *cis* to the nitrogen ligands of the heterocycle, indicating the strong influence of the π-acids C=S and PPh_3. The Pd–Br and Pd–I bond lengths (Pd–Br, mean 243 pm; Pd–I, mean 259.5 pm) are shorter than the sum of the single bond radii for palladium and the halides (Pd: 131 pm, Br: 114 pm, I: 133

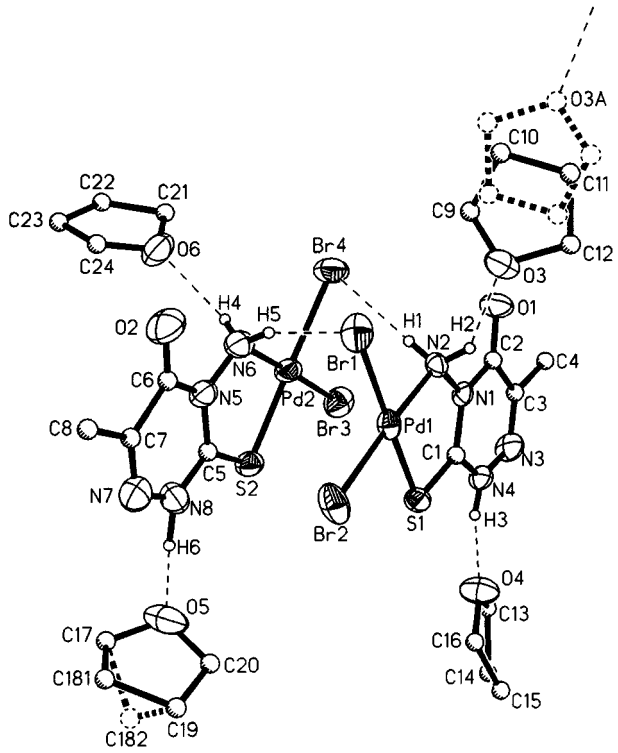


Figure 1. Molecular structure of **2** with showing disorder of the THF molecules (the C atoms are shown as spheres; most of the H atoms are omitted for the sake of clarity; 50% probability level)

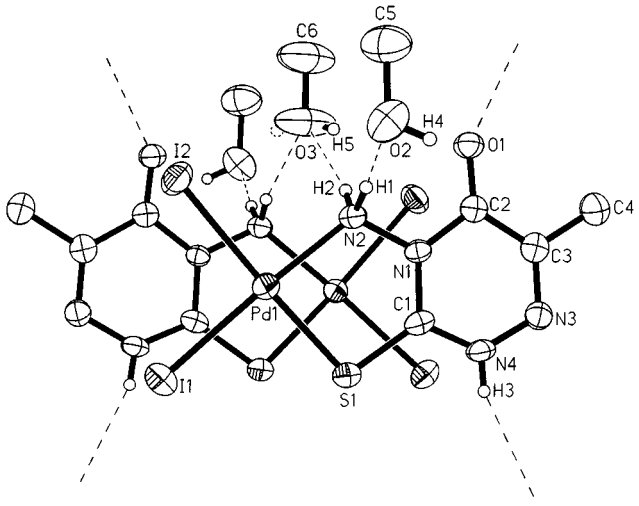

Figure 2. Molecular structure of **3** with showing disorder of the central methanol molecule (most of the H atoms are omitted for the sake of clarity)

pm),[8] but fall within the range observed for similar compounds.[9]

The Pd−P atom distances (average 225 pm) are shorter than the sum of the single bond radii for palladium and phosphorus, i.e. 241 pm,[10] are remarkably shorter than the $Pd^{II}-PPh_3$ bond reference value (230.2 pm) encountered in 248 entries,[11] and fall at the short end of a wide range (221−246 pm). The X−Pd−P angles, which measure 92.04(4)° in **4** and 92.64(7)° in **5**, are similar to values reported in the literature.[12]

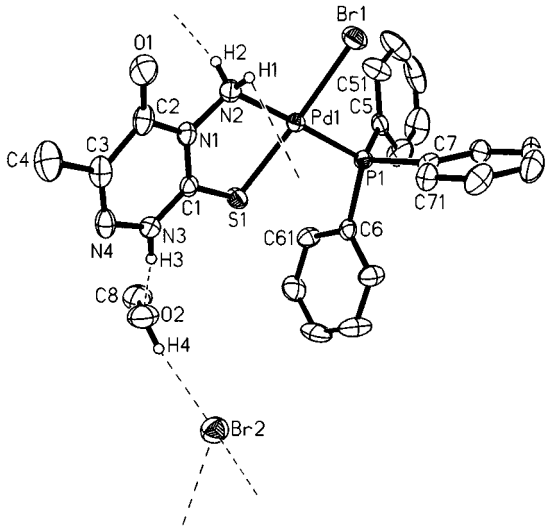

Figure 3. Molecular structure of **4** (most of the H atoms are omitted for the sake of clarity)

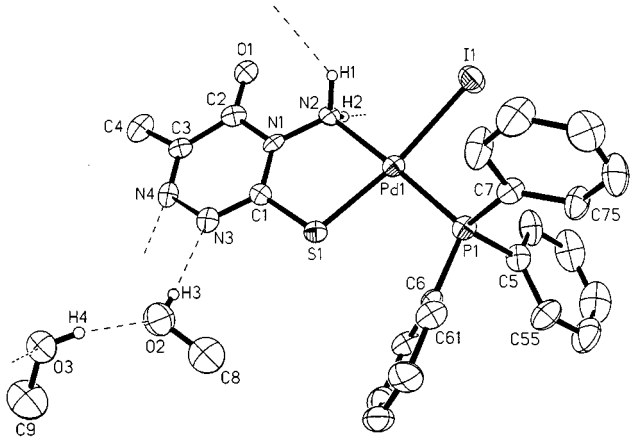

Figure 4. Molecular structure of **5** (most of the H atoms are omitted for the sake of clarity)

There are several medium to strong hydrogen bonds in the complexes. The two independent palladacycle units in **2** are held together by H···Br contacts [N2···Br4: 346.5(7); N6···Br1: 334.2(6) pm]. This leads to an angle of 7° between the "best" planes of the two complexes. THF molecules are hydrogen-bonded to H2 [N2···O3: 286.9(9) pm], H3 [N4···O4: 270.2(7) pm], H4 [N6···O6: 277.1(8) pm], and H6 [N8···O5: 265.3(9) pm]. The THF molecule O3→C12 is disordered about a center of symmetry (see Figure 1).

In **3**, two palladacycles are connected through a methanol molecule, which lies on a twofold axis. This means a disorder of the OH moiety O3−H5 over two positions [N2···O3: 287.9(8)°]. An additional methanol molecule is hydrogen-bonded to each NH_2 group [N2···O2: 282.6(7)° pm]. Each $[(AMTTO)PdI_2]_2 \cdot 3MeOH$ building block is part of a chain built up by N2−H1···O2 hydrogen bonds [N2···O2: 282.6(7)°; Figure 5] that extends along [010]. The palladacycles in **3** are slightly bent. The dihedral angle between the plane Pd1/I1/I2/N2/S2 and the ligand AMTTO amounts to 7°. In **4**, isotypical to the corresponding complex $[(AMTTO)PdCl(PPh_3)]Cl \cdot MeOH$,[4] N3 (NH function)

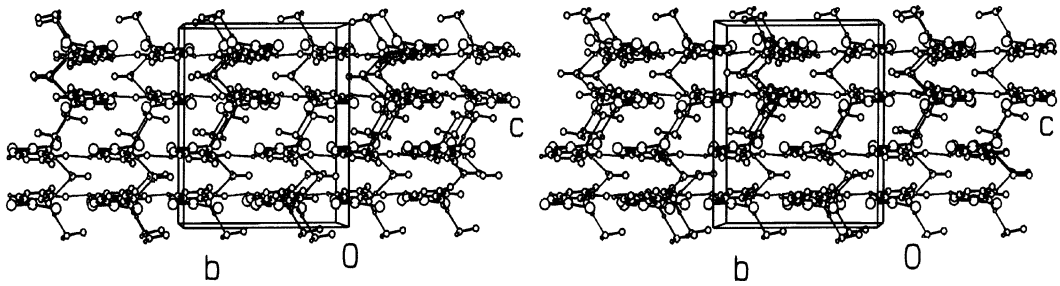

Figure 5. Stereoscopic view of the unit cell of **3**; the chains extending along [010] as a result of hydrogen bonding are also shown

is connected through the methanol molecule [N3···O2: 265.4(7) pm] to Br2 [counterion; O2···Br2: 322.3(5) pm] and then to two nitrogen atoms [N2a, N2b; NH_2 function; N2···Br2a: 338.1(5); N2···Br2b: 320.8(5) pm; Figure 3]. The packing of **4** has already been demonstrated for [(AMTTO)PdCl(PPh_3)]Cl·MeOH.[4] In **5**, medium to strong hydrogen bonds link the methanol molecules to N3 and to NH_2 groups of the adjacent AMTTO ligands, respectively (Figure 4). The contacts O3···O2 [266.7(9) pm], O2···N3 [286.9(9) pm], O3···N2a [278.7(9) pm], and N4···N2b [294.8(9) pm] give rise to a 2D-network of complex and solvate molecules that extends parallel to (010) (Figure 6).

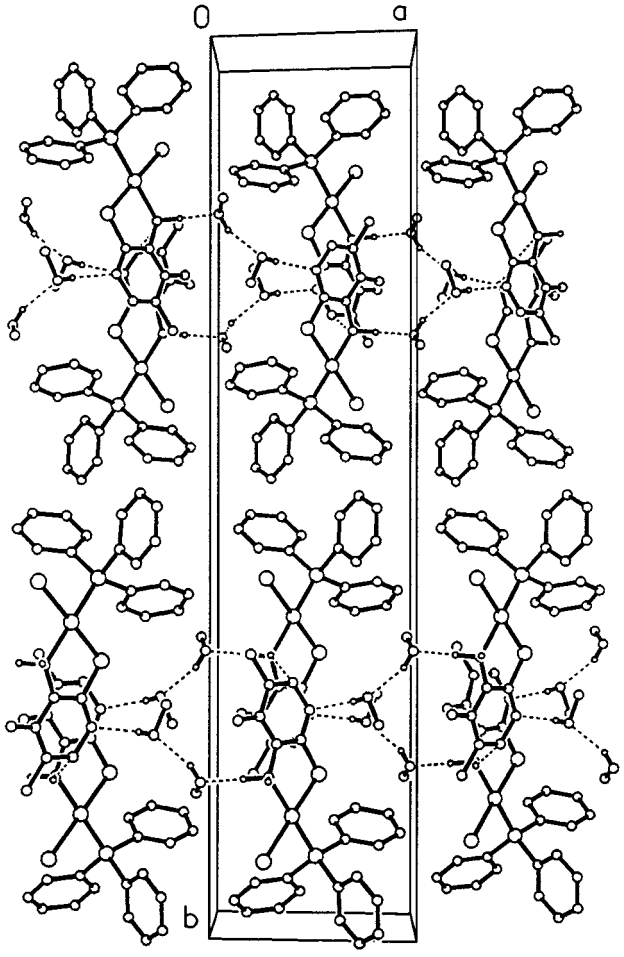

Figure 6. View of the unit cell of **5**; **5** forms layers built-up by hydrogen bonds parallel to (010)

Experimental Section

General Remarks: AMTTO[13] and **1**[3] were prepared according to literature procedures. − IR spectra were recorded on a Perkin−Elmer spectrometer 883 (KBr pellets, Nujol mulls, 4000−250 cm^{-1}) or on a Bruker IFS 88 instrument (CsBr discs, 4000−400 cm^{-1}; polyethylene discs, 500−100 cm^{-1}; Nujol mulls). − ^{31}P NMR spectra were recorded on a Bruker AC-200 spectrometer using 85% aqueous H_3PO_4 as an external standard. − Elemental analyses were performed by the following methods: C, H, N analyses: combustion method; halogen analyses: combustion and titration with $AgNO_3$; sulfur analyses: combustion and titration with $Ba(ClO_4)_2$; phosphorus: decomposition with $HClO_4$ and photometric analysis of the molybdophosphate; palladium analyses: decomposition with $HClO_4$ and analysis by atomic absorption spectroscopy. − The following chemicals were purchased from Merck and used without further purification: sodium bromide, sodium iodide, triphenylphosphane, methanol, and acetonitrile.

Synthesis of [(AMTTO)$PdBr_2$]$_2$·3.5THF (2): A solution of **1** (0.36 g, 0.98 mmol) in THF (20 mL) was treated with NaBr (0.20 g, 1.9 mmol) and the resulting mixture was stirred for 3 h at 20 °C. The white precipitate formed was filtered off and the filtrate was concentrated to a small volume (ca. 5 mL) until an orange solid separated. The crude product was filtered off and the clear solution was kept at 4 °C to give a second crop of orange crystals of **2**. − Yield: 0.96 g (95%). − $C_{22}H_{40}Br_4N_8O_{5.5}Pd_2S_2$ (1011.19): calcd. C 13.16, H 2.21, N 12.27, Br 35.01, Pd 23.31, S 7.02; found C 13.01, H 2.14, N 12.17, Br 34.90, Pd 23.35, S 6.97. − IR (Nujol): $\tilde{\nu}$ = 3254 [w, br, ν(NH)], 1703 [s, ν(C=O)], 1604 [m, ν(N=C)], 1588 (m), 1520 (m), 1321 (m), 1304 (s), 1233 (m), 1166 (m), 1036 (m), 974 (w), 930 (w), 875 (w), 802 (w), 749 (s), 675 (m), 646 (w), 606 (m), 528 (w), 506 (m), 452 [m, ν(PdN)], 409 (w), 369 [w, ν(PdS)], 310 (m), 268 [w, ν($PdBr_2$)], 246 (w), 198 (w), 165 (w).

Synthesis of [(AMTTO)PdI_2]$_2$·3MeOH (3): To a stirred solution of **1** (0.36 g, 0.98 mmol) in methanol/acetonitrile (1:1 *v*/*v*, 30 mL) at 20 °C was added NaI (0.29 g, 1.9 mmol). The reaction mixture was stirred for a further 5 h. The white solid formed was filtered off and the filtrate was concentrated to a volume of 10 mL and filtered once more. The filtrate was stored at 4 °C overnight to give orange crystals of **3**, which were collected by filtration and washed with cold methanol. − Yield: 1.05 g (93%). − $C_{11}H_{24}I_4N_8O_5Pd_2S_2$ (1133.0): calcd. C 11.66, H 2.14, N 9.89, I 44.81, Pd 18.79, S 5.66; found C 11.55, H 2.10, N 9.56, I 44.92, Pd 18.56, S 5.34. − IR (Nujol): $\tilde{\nu}$ = 3620 [vw, br, ν(OH)], 3554 [w, br, ν(OH)], 3472 [w, br, ν(OH)], 3230 [w, br, ν(NH)], 1719 [s, ν(C=O)], 1595 [m, ν(C=C)], 1538 (w), 1516 (w), 1492 (w), 1335 (m), 1301 (s), 1218 (w), 1150 (w), 1112 (w), 1048 (w), 973 (w), 926 (w), 602 (w), 512 (m), 445 [m, ν(PdN)], 409 (w), 373 [w, ν(PdS)], 325 (vw), 305 (w), 280 (vw), 253 (w), 228 (w), 201 (vw), 173 [w, ν(PdI_2)], 128 (vw) 112 (vw).

Reactions with PPh_3. − General Procedure: A solution of **2** (or **3**) (1.00 mmol) in methanol (30 mL) was treated with PPh_3 (0.26 g, 0.99 mmol) and the resulting mixture was stirred for 3 h at 20 °C. The solution was then concentrated to a small volume (ca. 10 mL) until a yellow solid separated. The crude product was filtered off and the clear filtrate was kept at 4 °C to give yellow crystals of **4** (or **5**).

Synthesis of [(AMTTO)Pd(PPh_3)Br]Br·MeOH (4): Yield: 0.64 g (90%). − $C_{23}H_{25}Br_2N_4O_2PPdS$ (718.73): calcd. C 38.44, H 3.51, N 7.80, Br 22.23, P 4.31, Pd 14.81, S 4.46; found C 38.26, H 3.46, N 7.72, Br 21.98, P 4.15, Pd 14.68, S 4.31. − IR (Nujol): $\tilde{\nu}$ = 3205 [w, br, ν(NH)], 1719 [vs, ν(C=O)], 1612 [m, ν(C=C)], 1573 (m), 1537 (m), 1435 (s), 1348 (m), 1301 (m), 1185 (w), 1146 (w), 1097 (s), 1045 (w), 1024 (w), 1000 (m), 966 (m), 936 (w), 750 (s), 712 (m), 692 (s), 655 (w), 619 (w), 601 (w), 536 (s), 507 (s), 450 [m, ν(NH)], 412 (w), 382 [m, ν(PdS)], 310 (vw), 259 [w, ν(PdBr)], 195 (m), 132 (vw). − ^{31}P NMR (CD_3OD): δ = 30.3 (s).

Synthesis of [(AMTTO)Pd(PPh_3)I]·2MeOH (5): Yield: 0.65 g (91%). − $C_{24}H_{28}IN_4O_3PPdS$ (716.87): calcd. C 40.21, H 3.94, N 7.82, I 17.78, P 4.32, Pd 14.85, S 4.47; found C 39.89, H 3.87, N 7.71, I 17.65, P 4.26, Pd 13.99, S 4.36. − IR (Nujol): $\tilde{\nu}$ = 3446 [vw, br, ν(OH)], 3250 [vw, br, ν(NH)], 1728 [vs, ν(C=O)], 1625 (m, C=

C), 1552 (m), 1500 (m), 1437 (m), 1322 (m), 1301 (m), 1228 (m), 1160 (vw), 1097 (m), 1008 (m), 968 (m), 928 (w), 847 (w), 746 (m), 691 (m), 639 (w), 602 (w), 534 (m), 506 (m), 449 [m, ν(PdN)], 409 (w), 374 [w, ν(PdS)], 308 (w), 285 (w), 227 (w), 198 [w, ν(PdI)], 139 (vw), 124 (vw). – ^{31}P NMR (CD_3OD): δ = 26.2 (s).

Crystal Structure Analyses of 2, 3, 4, and 5 (Table 1 and 2): The selected crystals of **2**–**5** were covered with a perfluorinated oil and mounted on the tip of a glass capillary under a flow of cold gaseous nitrogen. The orientation matrix and preliminary unit cell dimensions were determined from 2000 (**2**, Stoe IPDS), 2000 (**3**, Stoe IPDS), 15 (**4**, Siemens P4), and 15 (**5**, Enraf-Nonius CAD4) reflections (graphite-monochromated Mo-K_α radiation in all cases; λ = 71.073 pm). The final cell parameters were determined from 5000 reflections for **2** and **5**, and from 25 high-angle reflections for **3** and **4**. The intensities were corrected for Lorentz and polarization effects. In addition, absorption corrections were applied for **2** (numerical), **3** (empirical, 10 psi-scans), **4** (numerical), and **5** (empirical, 10 psi-scans). The structures were solved by the Patterson method for **2** and by direct methods for **3**–**5** (SHELXTL-Plus[14]) and refined against F^2 by full-matrix least-squares using the program SHELXL-97.[15] The hydrogen atoms (C–H) in **2** and **5** were calculated in ideal positions (refinement with a common displacement parameter). The hydrogen atoms of the NH groups were fixed at 85 pm (**2**) or freely refined (**5**). The positions of the H atoms in **3** were freely refined, except for the N2–H2, N3–H3, and O2–H4 distances, which were fixed at 85 pm. The hydrogen atoms in **4** were freely refined. Programs used were SHELXTL-Plus, SHELXL-97, SHELXTL,[16] ORTEP,[17] and PLATON.[18] Splitting models were applied to the following atoms: C181, C182 (and adjacent H atoms, occupancy factors: 0.7, 0.3; **2**); O3, C9, C10, C11, C12 (occupancy factor: 0.5; **2**), H5, H61, H62, H63 (occupancy factor: 0.5; **3**).[19]

Special Siloxamides: Metal Movements in a Crystalline Molecular Box

Michael Veith[a]

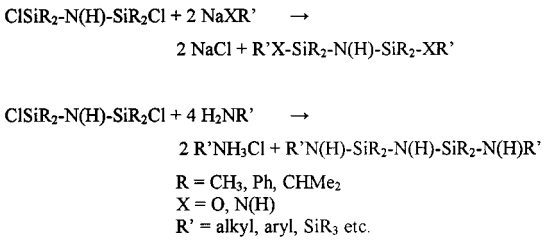
In memoriam Prof. Dr. H.-G. Unruh

Keywords: Lithium / Solid-state structures / Phase transitions / Si ligands / Dynamics in molecular solids

Metal salts of $[R–O–SiMe_2–N–SiMe_2–O–R]^-$ and $[R–N–SiR'_2–O–SiR'_2–N–R]^{2-}$ (R = *t*Bu, Me_3Si, *t*$BuMe_2Si$, Ph; R′ = Me, Et/Me, *i*Pr; Metal = Li, Na, K, Cu, Ag) have been synthesised and analysed in the crystalline state with respect to metal movements. Almost all compounds crystallize as dimers, for example $Li_2[t$BuO–$SiMe_2$–N–$SiMe_2$–O*t*$Bu]_2$ or $Li_4[t$BuN–$SiMe_2$–O–$SiMe_2$–N*t*$Bu]_2$, and form different solid-state phases. Whereas the Li atoms in the first example rotate at ambient temperature perpendicular to the NN axis of the molecule, they oscillate in the second example. The movements of the lithium atoms are coupled to ligand vibrations, and can be switched on and off by temperature changes. This switching is directly linked to phase transitions, that can be first order or second order. The other metallic atoms show no important dynamics, although phase transitions have also been found for these compounds.

Introduction

In the last ten years we have become aware of the fact that special amides of metallic elements (lithium amides being the most prominent representatives) show fluxional behaviour, mostly when dissolved in non-coordinating organic solvents.[1–3] The phenomenon is known for many amides of the main-group and transition-group metals, and the dynamics of these compounds can easily be followed by temperature-dependent NMR spectroscopy.[4] On analysing the molecules in more detail we found, compared to all other elements, the small lithium atoms in the amides have the largest amplitudes of movement, and that these amplitudes and the trajectories of the movements can be influenced by the composition of the amides. A spectacular example is the mixed metal amide $LiIn[(Me_3SiN)_2SiMe_2]_2$:[5] In this molecule the indium atom with a formal charge +3 is coordinated by the four nitrogen atoms, forming an indium-centred N_4 bisphenoid (elongated tetrahedron), pushing the lithium atom, with a formal charge +1, to the surface of the N_4 polyhedron. Because the lithium atom in this molecule is less tightly bound, it occupies several similar coordination sites, and in solution it rotates, over a certain time period, around the indium-centred N_4 core. The movement of the lithium atom can be determined experimentally, either by temperature-dependent ^{7}Li-, ^{13}C-, ^{1}H-, ^{29}Si-NMR spectroscopy, or by theoretical calculations.[6]



We were interested in finding out if similar lithium movements could be observed in crystalline solids. As the constraints of the crystal packing on the molecules and the intermolecular forces seemed to make such an attempt quite fruitless, we developed a concept which had two main ideas. The first idea was to use molecules which had a globular outer hydrogen shell to minimise the intermolecular van der Waals interactions. The second idea was to incorporate coordination holes in the molecular skeleton, so as to facilit-

Michael Veith was born in 1944 in Goerlitz, Germany. He studied chemistry at the University of Munich, where he received his Diplom-Chemiker degree in 1969. Continuing work with Prof. N. Wiberg, he received his doctoral degree in 1971. He then moved to the University of Karlsruhe, where he started his postdoctoral work with Prof. H. Bärnighausen. In 1977 he completed his Habilitation in Inorganic Chemistry. Until the end of 1978 he was Privat-Dozent at the University of Karlsruhe. In 1979 he moved to the Technische Universität Braunschweig as a Professor of Inorganic Chemistry. In 1984 he moved to the University of Saarland (Saarbrücken) and became Full Professor. Since 1984 he has been in Saarbrücken despite several offers from other universities. He has received several awards, inter alia Leibniz-Preis, 1991. In 1981, he stayed as a visiting professor at the University of Bordeaux I (France) and in 1987 at the University of Utah (Salt Lake City, USA), in 1991 at the University Paul Sabatier (Toulouse, France), and in 1993 at the University Sophia Antipolis (Nice, France). His main interests are in the field of synthetic and structural chemistry, focusing on molecular compounds containing metal elements.

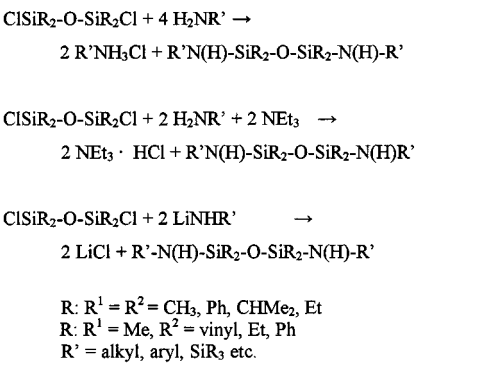
Scheme 3

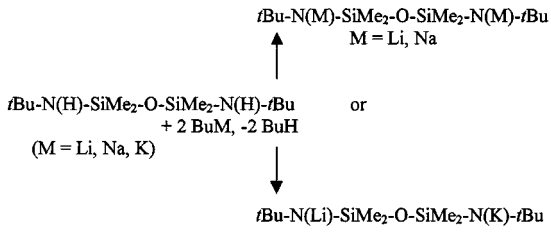


ate metal hops from an occupied non-metal coordination sphere to an unoccupied one.

The following compilation, which can be seen as an advanced report with a review-like character, is a summary of our actual knowledge on the motion of monovalent metal atoms in the molecular crystals of special metal amides. We would like to describe these dynamics as "lithium motion (or tunnelling) in a molecular box". The compounds we have investigated belong either to the series $[R'-O-SiR_2-N-SiR_2-O-R']_2M_2$ or to the series $[R'-N-SiR_2-O-SiR_2-N-R']_2M_4$ (R′ = substituent, M = monovalent metal, R = organic group). While these experiments were being conducted, several papers appeared on either lithium movements[7] or the use of the amido ligands specified above as assembling tools for different metallic elements.[8,9]

Syntheses

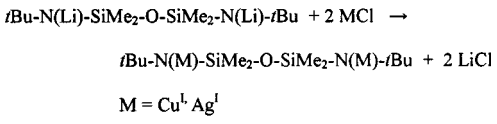
The most valuable precursor compounds for the siloxamines $R'-O-SiR_2-N(H)-SiR_2-O-R'$ and $R'-N(H)-SiR_2-O-SiR_2-N(H)-R'$ are either the bis(silyl)amine $ClSiR_2-N(H)-SiR_2Cl$[10] or the disiloxane $ClSiR_2-O-SiR_2Cl$.[11] As shown in Scheme 1 and Scheme 2, the chlorine atoms of chlorosilylamines and chlorosiloxanes can be easily substituted by amido or alkoxo groups in a straightforward way.[4]



The transformation of these siloxamines into siloxamides can be achieved by a redox/metal route (a), a transamidation (b), or by organometallic compounds (c). All three possible reactions are shown in Scheme 3.[4]

Scheme 2

The reactions are very dependent on the alkali element and the substituent R′. The higher the electropositive character of the R′ group (e.g. CMe_3 vs. $SiMe_3$) the more preferable the replacement of the hydrogen atom by the alkali metal atom. Similarly, more electropositive alkali elements will normally more easily replace the hydrogen atom attached to the nitrogen atom. Finally, the organometallic route (3c) is more generally applicable, and gives the best yields for the metal amides.



The solvents for these reactions should be completely dry and noncoordinating, such as pentane, hexane, and toluene, since adducts of the solvent with the alkali metals have to be avoided. The more electropositive alkali elements K, Rb, and Cs do not always give pure compounds, and are introduced into the amine $R'-N(H)-SiR_2-O-SiR_2-N(H)-R'$ less readily than lithium or sodium. This feature is exemplified by the reaction of tBu−N(H)−$SiMe_2$−O−$SiMe_2$−N(H)−tBu with butyllithium, -sodium,[12] and -potassium.[13] While the pure dilithium and disodium derivatives can be obtained in the first two cases, for potassium only a mixed metal derivative is obtained, which incorporates lithium as well as potassium (Scheme 4).

Scheme 4

The explanation for this unexpected reaction is the incomplete transformation of BuLi to BuK, when butyllithium is treated with potassium *tert*-butoxide prior to the reaction with the amine. Perhaps the "incomplete" BuK formation could be avoided by using potassium *tert*-pentoxide instead of potassium *tert*-butoxide.[14] Interestingly, the mixed metal derivative is isolated in high yields, which suggests that both metal atoms may be especially well accommodated in the molecule. As a matter of fact, tBu−N(Li)−$SiMe_2$−O−$SiMe_2$−N(K)−tBu is dimeric, as are most of the other derivatives, and the two alkali elements have very different coordination spheres (see below for more details of the structure). This structure cannot be achieved in a pure dilithium or dipotassium derivative.

The alkali metal derivatives shown in Scheme 3 can be transformed into other metal derivatives, using metal halides. Especially monovalent transition metals were of interest for our general study. The copper(I) and silver(I) derivatives of the $[t\text{Bu}-\text{N}-\text{SiMe}_2-\text{O}-\text{SiMe}_2-\text{N}-t\text{Bu}]^{2-}$ dianion have been obtained in high yields using this route (Scheme 5).

Scheme 5

The siloxamides of most alkali elements as well as the Cu^I and Ag^I derivatives that have been synthesised and characterised by our group are listed in Table 1.[15–19] Most of these compounds are dimeric in solution and in the crystalline state. So far there is only one exception to this rule: The compound $t\text{Bu}-\text{N(Li)}-\text{Si}(i\text{Pr})_2-\text{O}-\text{Si}(i\text{Pr})_2-\text{N(Li)}-t\text{Bu}$ is monomeric in solution as well as in the crystal (see also below).

The solution NMR spectra of the two families $[\text{R}'\text{OSiR}_2-\text{N(M)}-\text{SiR}_2\text{OR}']_2$ and $[\text{R}'\text{N(M)}-\text{SiR}_2-\text{O}-\text{SiR}_2-\text{N(M)R}']_2$ at room temperature are very simple, as all substituents R and R′ (^{1}H, ^{13}C NMR) and silicon atoms of the siloxamine backbone (^{29}Si) give resonances for only one species, the other groups being symmetry-related. This is in sharp contrast to the generally less symmetrical molecules in the crystalline solid. Consequently, many of these molecules show bond fluctuations in solution that are connected with metal movements or displacements. As we wanted to concentrate on such dynamics in the solid state, we will not discuss the solution phenomenon here in more detail.

Structural Characterisations of the Siloxamides

As the goal of our investigations was to study movements of atoms or molecular entities within a molecule, we have used different structural analysis techniques like X-ray diffraction on single crystals or powders, broad-line or MAS (magic angle spinning) NMR, differential thermal analysis (DTA), and Raman spectroscopy on single crystals. All these techniques have been used in the temperature-dependent mode, generally in the range between 120 and 350 K, using liquid nitrogen as a cooling agent or as a heated gas flow. Light microscopy on single crystals using polarised or cross-polarised light in the same temperature range was also employed. To verify our assumptions, which are based on our experimental results, we have tentatively used molecular dynamics calculations with mostly standard parameters.[20]

It became more and more evident from our experiments that phase transitions are connected with movements in the solid state. To avoid complications such as twinning, arising from symmetry reductions in single crystals, we have systematically also done X-ray diffraction experiments from phases, which have been grown as single crystals in the appropriate temperature range. Furthermore, we collected most of the X-ray diffraction data on a two-dimensional screen (IPDS system of Stoe, Darmstadt) in small angle steps, in order to obtain information about the whole reciprocal space.

High symmetries corresponding to unusual space groups for molecules can come either from dynamics or from severe static disorder of the constituent atoms. In this respect, the combination of X-ray diffraction techniques with solid-state NMR techniques is an excellent tool for deciding between these two possibilities.

Our findings are presented in several chapters which are linked in some logical sense (to follow and to verify our assumptions they have to be read together).

Rotation of Lithium Atoms within a Molecule: Siloxamides with the Skeleton O−Si−N−Si−O

The compound $\text{Li}_2[t\text{Bu}-\text{O}-\text{SiMe}_2-\text{N}-\text{SiMe}_2-\text{O}t\text{Bu}]_2$, designated in the following sections as **Li_2Z_2**, forms three different crystalline phases in the solid state.[15] At temperatures < 285 K a monoclinic phase is found, space group $P2_1/n$ with $Z = 4$. The space group with the number of molecules per cell is consistent with a close packing of organic molecules using the well-established principles of Kitaigorodskii.[21] A drawing of the molecule at 220 K is shown in Figure 1.

There are two main observations: The two "anionic" ligands within the molecule are opposite to each other in a cross-like manner, and are linked by two lithium "cations", which are bisphenoidally coordinated by two nitrogen and two oxygen atoms ("elongated" tetrahedron). The zigzag chain C−O−Si−N−Si−O−C is a little bit twisted, but the deviation from the plane is not intriguing, as the largest dihedral angle of two adjacent angles (O−Si−N−Si and Si−N−Si−O) is around 20°. As a consequence of these

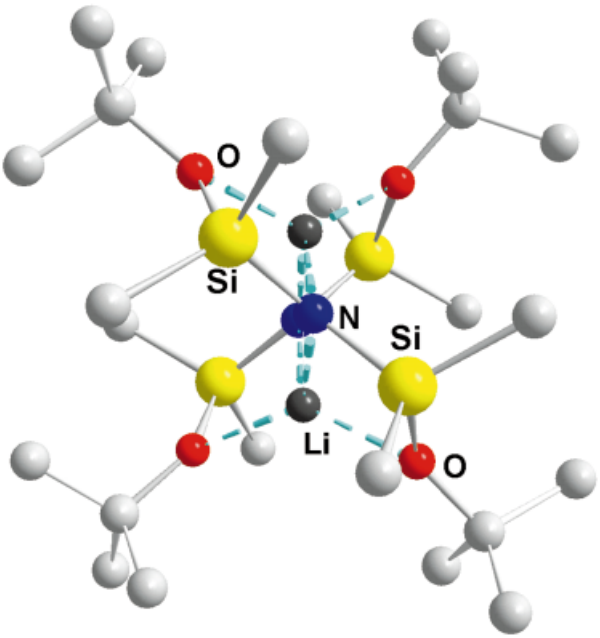

Figure 1. Spectroscopic view of $Li_2[t\text{Bu}-O-SiMe_2-N-SiMe_2-O t\text{Bu}]_2$, **$Li_2Z_2$**, in the monoclinic low-temperature phase (220 K), as obtained from X-ray diffraction analysis; view almost parallel to the NN axis of the molecule; for some distances and angles refer to Table 2

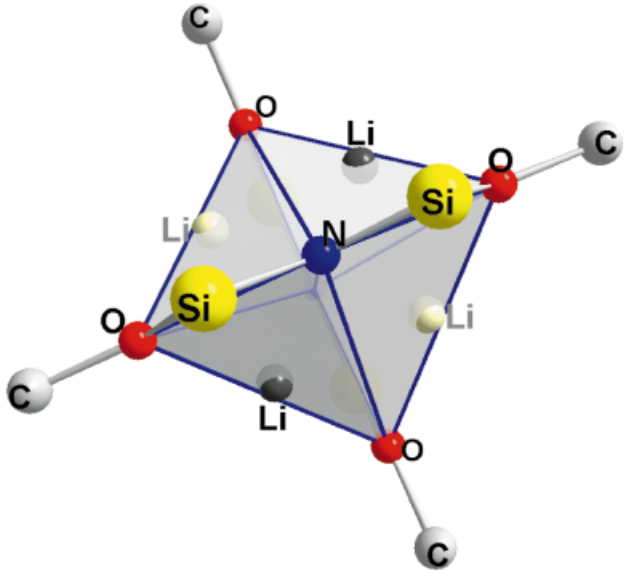

Figure 2. Inner part of the atomic skeleton of $Li_2[t\text{Bu}-O-SiMe_2-N-SiMe_2-O-t\text{Bu}]_2$ in the tetragonal phase (295 K), as obtained from X-ray diffraction analysis; the coordination polyhedra are drawn; each of the four N_2O_2 holes is occupied with Li/2 (see text)

mutual orientations of the ligands, two other bisphenoidal O_2N_2 coordination spheres are formed, that are unoccupied. In exact correspondence to the X-ray structure analysis of the monoclinic phase of **Li_2Z_2**, the ^{13}C-MAS NMR spectrum of the crystalline powder is quite complex, showing a multiplet of signals in the H_3C-Si region, that after deconvolution can be shown to be a superposition of eight equal signals due to eight different carbon atoms bonded to the four non-equivalent silicon atoms. Due to quadrupolar coupling of the coordinated nitrogen atoms, the ^{29}Si-MAS NMR resonances are broadened and structured, but it can again be shown that more than two resonances from silicon atoms are present in the spectrum (X-ray crystallography shows that four different silicon atoms are present in the unit cell).

When **Li_2Z_2** is allowed to warm up to room temperature (295 K), a new phase is found that is tetragonal (space group $P4_2/nmc$ with $Z = 2$). Whereas **Li_2Z_2**, in the monoclinic phase lacks symmetry [point symmetry $C_1(1)$], in the tetragonal phase the point symmetry is $D_{2d}(\bar{4}2m)$. The phase transition is reversible with a small hysteresis and an endothermic heat ($\Delta H = +0.45$ kJ/mol). The refinement of the X-ray structure of **Li_2Z_2** in $P4_2/nmc$ has only been possible with relatively high anisotropic displacement factors for Si, O, and N, and split atoms for most of the carbon atoms, the primary carbon atoms of the *tert*-butyl group being disordered around the O−C axis. The most striking feature is nevertheless the splitting of the two lithium atoms that occupy, with half of their electron count, the four coordination holes formed by the four oxygen and two nitrogen atoms (see Figure 2).

Again all the findings in the X-ray diffraction experiments are paralleled in the solid-state NMR spectra. The multiplet of the silyl carbon atoms of the monoclinic phase of **Li_2Z_2** after transition to the tetragonal phase degenerates to a single resonance line (^{13}C-MAS NMR). All carbon atoms of the dimethylsilyl groups become equivalent, consistent with the $D_{2d}(\bar{4}2m)$ point symmetry of the molecule. The silicon multiplet (^{29}Si-MAS NMR) also becomes a singlet after phase transition (not considering the quadrupolar splitting by N). These two experiments unambiguously show that the higher point symmetries found in the X-ray structure analysis are due to *dynamic* and not *static* disorder.

From the X-ray structure analysis of **Li_2Z_2** (considering temperature factors and split atom positions) we found that the lithium atoms (or in an ionic model: cations) clearly move to a larger extent than all other atoms of the molecule. The lithium movement can be followed directly by use of ^{6}Li- and ^{7}Li-NMR experiments applying the broad-line mode and the MAS mode. How can we describe this movement in the tetragonal phase? The most simple explanation would be that the lithium atoms (ions) are jumping from the occupied bisphenoidal O_2N_2 holes into the unoccupied ones. An approximate calculation (molecular mechanics in vacuo) of the barrier for this process using the parameters from the X-ray structure determinations of the monoclinic and tetragonal phase show that this jumping should be quite unfavourable, with activation energies around 60 kJ/mol (the lithium atoms are assumed to be positively charged).[20] Things become quite different, when the simultaneous movement of the ligands is included in the calculations: Now the barriers are drastically lowered and the activation energy is estimated to approximately 10 kJ/mol at 20°C.[20]

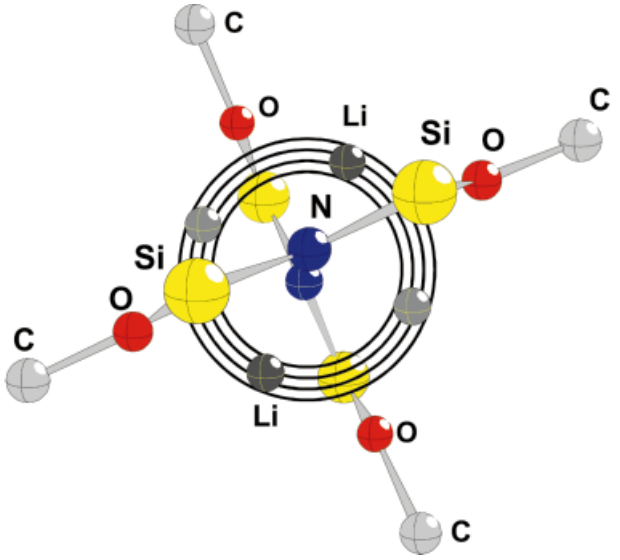

Figure 3. Sketch of the intramolecular lithium movements in the tetragonal phase of $Li_2[t\text{Bu}-O-SiMe_2-N-SiMe_2-O t\text{Bu}]_2$; the four split atom positions of lithium are shown; it should be noted that the lithium movements are accompanied by atom vibrations of the ligands (see also Figure 2)

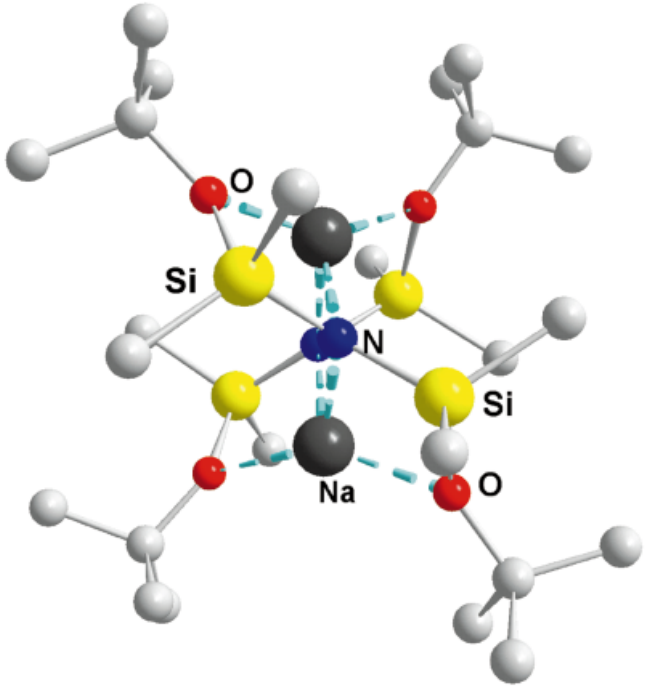

Figure 4. One of the two molecules [crystal point symmetry $C_2(2)$] present in the monoclinic phase of $Na_2[t\text{Bu}-O-SiMe_2-N-SiMe_2-O t\text{Bu}]_2$ (**Na_2Z_2**); for some distances and angles refer to Table 2; the view of the molecule is taken almost parallel to the NN axis of the molecule

In a crystalline solid, the amplitudes of movements of the atoms are nevertheless limited. On the other hand, the molecular shape and packing of **Li_2Z_2** is quite special; as can be deduced from two phenomena: The methyl groups of the *tert*-butyl moieties are turning around their O−C axes (as can be derived from X-ray structure analysis and ^{13}C-MAS NMR). The other phenomenon is found at temperatures > 400 K, where a second phase transition occurs and **Li_2Z_2** crystallises in a cubic face-centred lattice. This high-temperature phase is typical of a "plastic crystal phase", with molecules "tumbling" around their centres of gravity. Such "plastic crystal phases" are known for molecules that are either very globular in shape or possess weak intermolecular van der Waals interactions.[21]

Considering these two pieces of information, and the geometrical constraint of the O_2N_2 holes within the molecule, the movements of the lithium atoms can be described as follows: the lithium atoms, which to a first approximation can be assumed to be charged +1, are turning around the NN axis of the molecule, jumping from one O_2N_2 hole to the neighbouring hole. As the distances between two neighbouring N_2O_2 holes are small (the centres are 1.45 Å apart from one another in the tetragonal phase), the lithium atoms have to jump (or to turn) *simultaneously* to reduce the Li−Li repulsive forces. In Figure 3 the model of this rotation is sketched. Two models for the lowering of the activation energy can be discussed: One is using the tunnelling approach, assuming the lithium cations to be quite small. The other is considering, in addition to the jumping of the Li ions, a simultaneous high vibrational freedom of the ligands, which in the free molecule would lower the activation energy considerably (vide supra). Anyhow, the high displacements of vibration of the ligands have to be coupled to the lithium movements.

The two phase transitions in the solid **Li_2Z_2** are of first order, as can be deduced from the sharp changes of the cell parameters or of the spectroscopic properties (NMR) at the transition points. An elegant way to follow the phase transitions is Raman spectroscopy on single crystals: these methods show clearly that the two transitions occur instantaneously without softening of any vibrational mode.[22] Again this agrees with first-order phase transitions. Nevertheless, the hysteresis of the phase transition between the monoclinic and tetragonal phase is quite small, and the "lithium rotations" can be switched on and off, just by changing the temperature. Interestingly, this can even be made with a single crystal, which does not fall to pieces, as the volume of the cells is approximately unchanged (taking the double tetragonal cell). $P4_2/nmc$ and $P2_1/n$ are symmetry-related, but not in a direct super group/sub group relationship.[15]

We were very curious to know how an exchange of the lithium atom by sodium would influence the phase transitions, especially the movements in the molecules within the crystal lattice. Sodium has a larger radius compared to lithium [$r(Li^+) \approx 0.76$ Å; $r(Na^+) \approx 1.02$ Å], and its mass is approximately three times that of lithium.[23] Under these circumstances, a tunnelling of sodium cations seemed to be very improbable. The molecule $Na_2[t\text{BuO}-SiMe_2-N-SiMe_2-O t\text{Bu}]_2$, [**$Na_2Z_2$**], crystallises at temperatures below 250 K in an unknown lattice, and between 250 K and 350 K in the monoclinic space group $P2/n$ with $Z = 4$, very differently from **Li_2Z_2**. In the room-temperature phase there are two independent molecules in the unit cell, both situated on two-fold axes of the space group. In Figure 4 the

[a] N_2O_2 hole occupied by M. − [b] Unoccupied N_2O_2 hole.

molecular structure of one $\mathbf{Na_2Z_2}$ species is drawn; the two molecules differ from each other by the degree of disorder of the *tert*-butyl groups around the O−C axis. The molecules approach the D_2(222) point symmetry very closely, as may also be deduced from inspection of Figure 4.

Two major differences may be seen by comparing the monoclinic phases of $\mathbf{Na_2Z_2}$ with $\mathbf{Li_2Z_2}$. One discrepancy between the two compounds is easily recognised by closer inspection: The zigzag O−Si−N−Si−O chain in $\mathbf{Na_2Z_2}$ deviates more from an equiplanar arrangement (the mean O−SiSi−O dihedral angle is 73°) than in $\mathbf{Li_2Z_2}$ (45°). Consequently, looking down the NN axis of the molecule, the four silicon atoms with the nitrogen atoms are less perpendicularly oriented ($\mathbf{Na_2Z_2}$: Si−NN−Si = 116°) than in $\mathbf{Li_2Z_2}$ (Si−NN−Si = 100°). The second difference can be seen in the Na−O and Na−N distances in $\mathbf{Na_2Z_2}$. They are longer than the corresponding Li−O and Li−N distances in $\mathbf{Li_2Z_2}$ (monoclinic phases), and the sodium atoms (ions) are located far away of the centres of N_2O_2 holes (see also Δ values in Table 2). The lithium atoms are better accommodated in the O_2N_2 holes than the sodium atoms, which can for example be deduced from the O−Li−O angle (136°) and the corresponding angle in $\mathbf{Na_2Z_2}$ O−Na−O (155°). The large value of the latter shows that it tends towards linearity. The solid-state NMR spectra of $\mathbf{Na_2Z_2}$ agree with the structures found from X-ray diffraction. In the Si−C region of the ^{13}C-MAS NMR spectrum, at least four different peaks can be seen, that seem to come from the superposition of eight different resonances (four for each molecule, both of which have C_2 crystal symmetry). The four resonances are in accordance with the almost perfect D_2 symmetry of the molecules.

When crystals of $\mathbf{Na_2Z_2}$ are allowed to warm above 350 K, a phase transition can be observed by DTA with an endothermic $\Delta H \approx 5$ kJ/mol at 113°C. This phase transition can also be followed by temperature-dependent ^{13}C-MAS NMR (Figure 5). The crystal symmetry becomes orthorhombic, with a doubling of the volume of the monoclinic cell. An analysis of systematic absences in the X-ray powder diffraction experiment leads to a face-centred lattice (*Fd*2*d* or *Fddd*) with $Z = 8$, which has two consequences: All molecules in the unit cell are equal, and the point symmetry should be at least C_2, and is more likely D_2. In Figure 5 the two ^{13}C-MAS NMR spectra of the monoclinic and orthorhombic phase in the Me−Si region are shown for comparison.

As can be seen in the high temperature phase there are still *two* ^{13}C-NMR resonances for the CH_3−Si groups. This

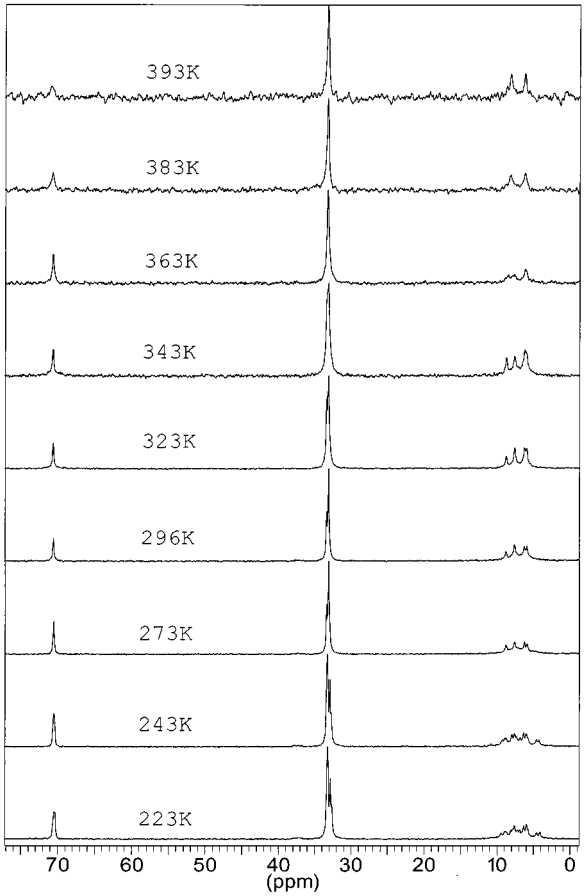

Figure 5. ^{13}C-MAS NMR spectra of $Na_2[t\text{Bu}-\text{O}-\text{SiMe}_2-\text{N}-\text{SiMe}_2-\text{O}t\text{Bu}]_2$ ($\mathbf{Na_2Z_2}$) between 190 and 380 K

agrees with either D_2 or C_2 point symmetry of the unique molecule present in the asymmetric unit. It also shows nicely, that *no sodium jumping* is occurring in this phase: If sodium jumping occurred then there should be a singlet for the 8 methyl groups attached to the silicon atoms. What might be the reason for the phase transition of $\mathbf{Na_2Z_2}$ at 400 K? The ^{13}C-NMR spectra indicate that most of the *tert*-butyl groups rotate in the high-temperature phase. At the same time, because of the new freedom of motion, the molecules can adopt higher point symmetries. This phase transition is another example of a temperature-dependent gain of motional freedom which we have already found for $Me_2Si(Nt\text{Bu})_2Sn(Nt\text{Bu})_2SiMe_2$ many years ago![24] The overall higher energy at 400 K cannot be used for sodium motions presumably because the trajectories for the heavy sodium atoms in $\mathbf{Na_2Z_2}$ are much longer than those of li-

thium atoms in **Li_2Z_2** and the sodium atom is larger and heavier than lithium (see before).

The high-temperature orthorhombic phase of **Na_2Z_2** can already be deduced from the monoclinic room-temperature phase as the cell dimensions may easily transformed to orthorhombic axes [a = 20.86(1), b = 10.303(8), c = 21.17(1) Å, β = 119.50(5)°]. The unusual presence of two different molecules of point symmetry C_2 in the $P2/n$ space group, on the other hand may be rationalised by a further low-temperature phase, the room-temperature structure being only a transient phase. Indeed, by cooling the polycrystalline sample, a further low-temperature phase was identified from ^{13}C-MAS NMR experiment (transition point: at 260 K). In this spectrum below 260 K, the C−Si region is split into many signals (at least 13−14 can be distinguished) which shows that in this low-temperature phase there are still two molecules in the asymmetric unit, but the point symmetry of these molecules is now reduced to C_1 (theoretically 16 signals should appear in the spectrum, Figure 5).

So far it seems that with the rise in temperature the **Na_2Z_2** compound is steadily gaining point symmetry showing two phase transitions: 260 K: 2 independent molecules with C_1 symmetries; > 260 → 400 K: 2 independent molecules with C_2 symmetries; > 400 K: 1 independent molecule with C_2 (or D_2) symmetry. The gain in point symmetry is paralleled by a gain in mobility of the ligand (for example rotations of *tert*-butyl groups around the O−C axes), but so far we have not found a clear hint from the temperature-dependent ^{13}C-MAS NMR spectra that the sodium atoms are moving like the Li in the **Li_2Z_2** compound.

The compounds $Li_2[Ph-O-SiMe_2NSiMe_2-O-Ph]_2$ [**Li_2Z_2'**] and $Li_2[Me_3Si-O-SiMe_2NSiMe_2-O-SiMe_3]_2$ [**Li_2Z_2"**] differ from **Li_2Z_2** in that the *tert*-butyl group of **Li_2Z_2** is replaced by phenyl and trimethylsilyl groups, respectively. **Li_2Z_2'** forms a normal van der Waals lattice at ambient temperature ($P-1$ with Z = 2), and there are no other low- or high-temperature phases within ±120°C.[16] The molecules (isostructural with **Li_2Z_2**) are dimeric with a central Li_2N_2 square, the Li−N distances being in the usual range of 2.061−2.097 Å.[25] The four Li−O distances are shorter than the Li−N distances, and have a mean value of 1.978(7) Å. In contrast with the phenyl derivative, the trimethylsilyl derivative **Li_2Z_2"** has long LiO distances [mean: 2.08(5) Å] and smaller Li−N distances [mean: 2.02(4) Å], but is similar to **Li_2Z_2** and **Li_2Z_2'** in its molecular structure. **Li_2Z_2"** crystalliszes in a monoclinic crystal system ($P2_1/c$ with Z = 4), and has a peculiar property when heated over 290 K. Its ^{13}C-MAS NMR spectrum becomes more simple, the multiple signals of the dimethylsilyl group of the room-temperature spectrum merging to two broad signals (δ = 5.0 and 7.1), and the four signals of the trimethylsilyl group changing into a singlet at δ = 2.7. This is a clear indication that ligand motions have to be considered, perhaps even accompanied by lithium hopping. At 355 K the spectrum becomes even simpler, with singlets for the dimethylsilyl and the trimethylsilyl groups. Unfortunately, until now, it has not been possible to obtain crystallographic proof for these assumptions.

We have also modified the O−Si−N−Si−O back bone by replacing O by other non-metallic elements such as nitrogen and carbon.[16] The following molecules have been prepared: $Li_2[Ph-SiMe_2NSiMe_2-Ph]_2$, $Li_2[(C_4H_3O)-SiMe_2-N-SiMe_2-(OC_4H_3)]_2$, $Li_2[Me_2N-SiMe_2-N-SiMe_2-NMe_2]_2$, $Li_2[Et_2N-SiMe_2-N-SiMe_2-NEt_2]_2$, $Li_2[i\text{Pr}(H)N-SiMe_2-N-SiMe_2-N(H)i\text{Pr}]_2$, and $Li_2[(C_4H_3S)-SiMe_2-N-SiMe_2-(SC_4H_3)]_2$. All these compounds show very similar structures to **Li_2Z_2**, **Li_2Z_2'**, or **Li_2Z_2"**, but none of these compounds has been found to give several solid crystalline phases. In summary, the lithium hopping or rotational movement found thus far has been restricted to the O−Si−N−Si−O back bone.

Siloxamides with the Skeleton N−Si−O−Si−N

The Lithium and Sodium Derivatives of $[Me_3E-N-SiMe_2-O-SiMe_2-N-EMe_3]^{2-}$, E = C, Si

As shown in the last chapter, the motion of the lithium atoms within the compound **Li_2Z_2** in the crystalline solid had a direct link to the empty holes within the molecules. Occupying these holes by further metal atoms should prevent the jumping of the metal atoms, and therefore the metal rotation should stop.

With this idea in mind we have exchanged the places of the oxygen and nitrogen atoms in the skeleton O−Si−N−Si−O. To maintain the number of electrons, the skeleton N−Si−O−Si−N has to adopt a further negative charge, raising the total charge to −2. Two of these ligands should therefore accommodate 4 positively charged metal atoms and consequently, assuming a similar general structure, should completely fill up the O_2N_2 coordination polyhedra.[17]

We have obtained crystalline solids of the compounds $Li_4[t\text{Bu}-N-SiMe_2-O-SiMe_2-Nt\text{Bu}]_2$; **$Li_4X_2$**, $Li_4[Me_3Si-N-SiMe_2-O-SiMe_2-N-SiMe_3]_2$; **$Li_4L_2$**, $Na_4[t\text{Bu}-N-SiMe_2-O-SiMe_2-Nt\text{Bu}]_2$; **$Na_4X_2$**, and $Na_4[Me_3Si-N-SiMe_2-O-SiMe_2-N-SiMe_3]_2$; **$Na_4L_2$**.[17] Between 190 and 380 K the compound **Li_4X_2** forms three crystalline phases, **Na_4X_2** two crystalline phases, and both **Li_4L_2** and **Na_4L_2** one unique crystalline phase. Except the low-temperature phase of **Li_4X_2** (powder diffraction) all phases have been analysed by single-crystal X-ray diffraction (see Table 3). Solid-state NMR spectra have been obtained for all compounds using ^{6}Li, ^{7}Li, ^{13}C, ^{29}Si in the temperature-dependent mode.

In Figure 6 and Figure 7 the results of the X-ray diffraction analyses on **Li_4L_2** and **Na_4L_2** at room temperature are depicted.[17] As may be deduced by comparison of **Li_4L_2** with **Li_2Z_2** (Figure 1 and 2) the overall structures are quite similar, with the metallic cations connecting the negatively charged ligands. As anticipated the four O_2N_2 coordination holes which originate like in **Li_2Z_2** from the mutual orientation of the ligands are filled. Surprisingly, the lithium atoms are not found at distinct places but occupy two sites in the polyhedra with 50% probability and which are 0.66 Å apart from one another. The crystal symmetry of the molecules in **Li_4L_2** is S_4, which means that all four coordination sites as well as the lithium atoms are symmetry-related.

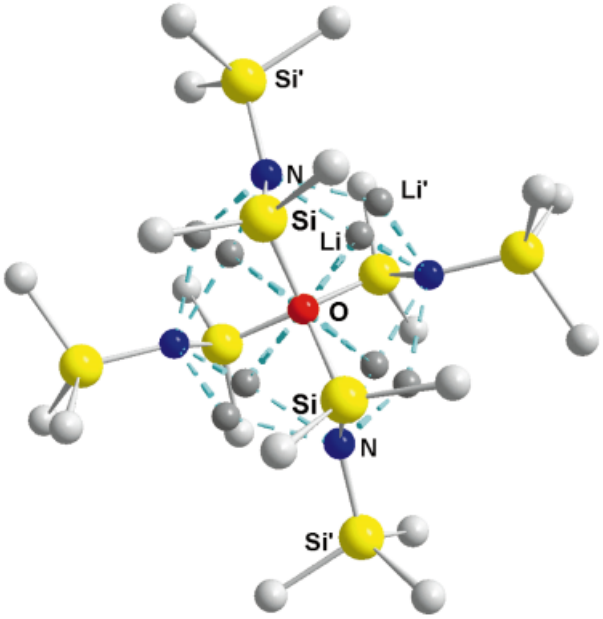

Figure 6. The molecular structure of $[Me_3Si-N-SiMe_2-O-SiMe_2-N-SiMe_3]_2Li_4$ (**Li_4L_2**) in the crystal at 290 K; the occupancy of the eight lithium positions is 50% (split atoms)

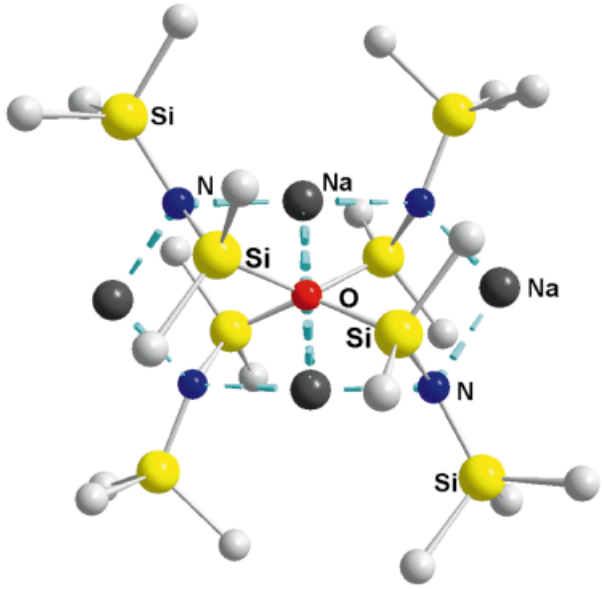

Figure 7. The molecular structure of $[Me_3Si-N-SiMe_2-O-SiMe_2-N-SiMe_3]_2Na_4$ (**Na_4L_2**) in the crystal at 290 K

What is the reason for equal distribution of four lithium atoms over eight sites in **Li_4L_2**? A closer look on the LiLi distances reveals that the inner sites, having the closest Li−O and Li−N distances [2.28(1) and 1.95(2) Å, respectively], are 2.37 Å apart. This distance should lead to a strong Li^+Li^+ repulsion, as may be deduced by a simple molecular mechanics calculation in the gas phase, or by comparison with other Li compounds (for the model calculation the lithium atoms have been assumed to have a charge of +1.0, and the N and O atoms −0.75 and −0.50, respectively).[20] Considering a combination of two inner and two outer sites of the lithium positions, the LiLi distances are increased to 2.91 Å and the Li^+Li^+ repulsions are consequently decreased. The outer sites of the lithium atoms show longer Li−N (2.037 Å) and Li−O distances (2.77 Å). Apparently there is a balance between the repulsion of the lithium atoms and the attraction from the O_2N_2 polyhedra. It seems likely that the splitting of the lithium positions is due to dynamical disorder with the two lithium sites representing the "return points" of lithium oscillations. This assumption can be verified as shown in the later sections.

The sodium derivative **Na_4L_2** is, to a crude approximation, similar to **Li_4L_2** and **Na_2Z_2**, as far as the general structure of the molecule is concerned. Closer inspection of Figure 7 nevertheless reveals that there are important differences. In contrast to the $S_4(\bar{4})$ symmetry of **Li_4L_2** the molecule **Na_4L_2** has no crystal symmetry but approaches $D_2(222)$ very closely. As a direct consequence of this different point symmetry, the four sodium atoms fall into two categories with two sodium atoms being coordinated by four basic atoms (two nitrogen and two oxygen atoms), and the other sodium atoms being coordinated only by two nitrogen atoms (not considering hydrogen interactions of CH_3 groups of the dimethylsilyl and trimethylsilyl entities). The dicoordinated sodium atoms have smaller Na−N distances when compared to the tetracoordinate (see Table 3) as expected. The N−SiSi−N dihedral angle in **Na_4L_2** is considerably larger than the corresponding angle in **Li_4L_2** (Table 3), and parallels our findings in the systems **Na_2Z_2** and **Li_2Z_2**. Another similarity to the former chapter is that in **Na_4L_2** there is no sodium movement, while in **Li_4L_2** lithium oscillations have to be considered.

Replacing the silicon atoms of the trimethylsilyl groups by the more electronegative carbon atoms should reduce the electron density at the nitrogen atoms. It should also reduce the ligating property of the nitrogen atoms to electropositive elements like Li or Na, and consequently should give more motional freedom to these atoms.

In Figure 8 the molecular structures of **Li_4X_2** and **Na_4X_2** are given either below 230 K or at ambient temperature as results of single-crystal X-ray diffraction analyses. It becomes evident, by comparison with Figure 6 and 7, that at lower temperatures, the structures of **Li_4X_2** and **Na_4X_2** compare almost perfectly with the structures of **Li_4L_2** and **Na_4L_2** (see also Table 3). The contrary is true for the structures determined at ambient temperature: Here the structural features are different, the crystal point symmetry of **Li_4X_2** being $D_{2d}(\bar{4}2m)$, and of **Na_4X_2** being $S_4(\bar{4})$. In the two cases the *tert*-butyl groups of the ligands are disordered around the C−O axes as result of rotational dynamics (which can be verified by solid-state ^{13}C NMR).

The LiLi separation of the two split positions is becoming longer by 0.13 Å in the room temperature phase [**Li_4X_2** (230 K): LiLi = 0.81 Å; **Li_4X_2** (290 K): LiLi = 0.94 Å] compared with that at 230 K. This is in accord with the model of Li oscillations becoming more important with raising temperature. A careful look at the electron-density map of the crystal-structure determination of **Li_4X_2** (290 K) reveals that other atoms of the compound besides lithium are

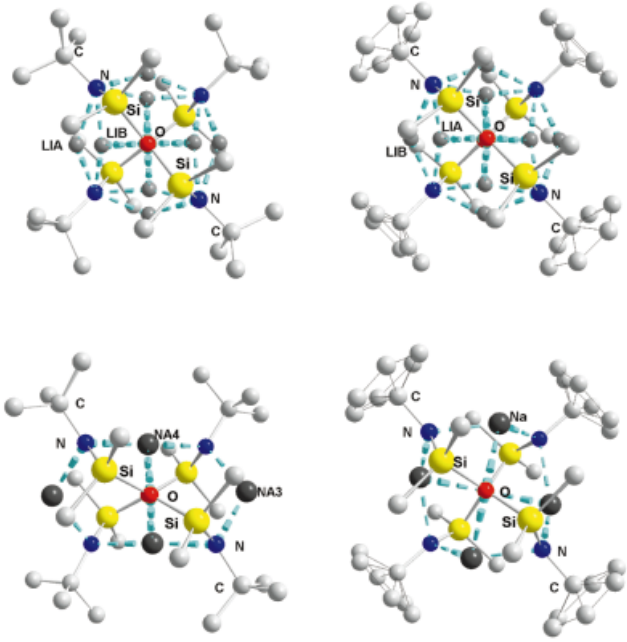

Figure 8. Comparison of the structures of [*t*Bu−N−$SiMe_2$−O−$SiMe_2$−N−*t*Bu]$_2M_4$, M = Li, Na (**Li_4X_2**, **Na_4X_2**) at different temperatures; on the left the low-temperature phases (200 K) are plotted, while on the right the same molecules are shown at ambient temperature

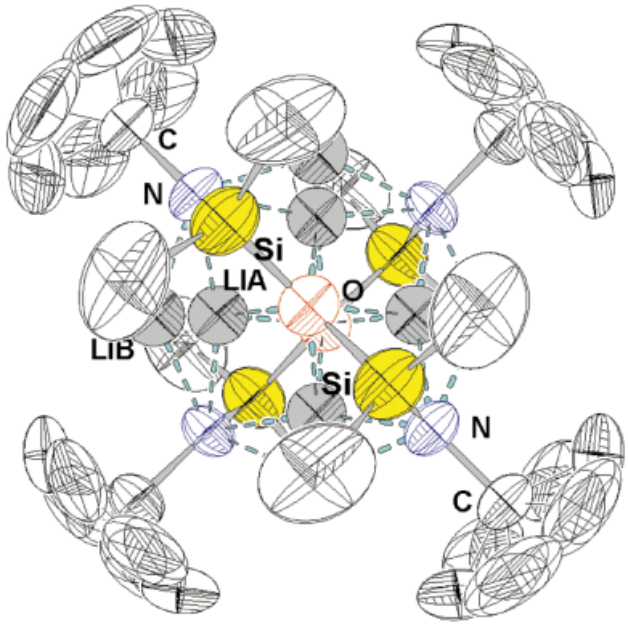

Figure 9. Molecular structure of Li_4[*t*Bu−N−$SiMe_2$−O−$SiMe_2$−N*t*Bu]$_2$ (**Li_4X_2**) at 290 K showing ellipsoids of thermal motion (50%)

"smeared out" (as may be seen from Figure 9 showing the anisotropic ellipsoids).

From Figure 9 it can also be concluded that apart from the rotations of the *tert*-butyl groups, the most important movement is that of the dimethylsilyl group that is perpen-

dicular to the mirror planes of the D_{2d} point symmetry. The phase transition of $\mathbf{Li_4X_2}$ (230 K) to $\mathbf{Li_4X_2}$ (290 K) has a direct group/subgroup relation ($P4_2/n \xrightarrow{t2} P4_2/nmc$): This is a serious hint for the presence of a second-order transition, which can be followed by spectroscopic techniques like NMR and Raman spectroscopy (see later).

The temperature-dependent structure change of $\mathbf{Li_4X_2}$ may be described as follows: At 230 K the molecules are highly librating in the crystal lattice, the movements becoming more important at higher temperatures. The most important amplitudes of movement are the lithium oscillations, followed by rotations of the *tert*-butyl groups and dimethylsilyl displacements perpendicular to the ON_2 plane of the ligand $[t\text{Bu}-\text{N}-\text{SiMe}_2-\text{O}-\text{SiMe}_2-\text{N}-t\text{Bu}]^{2-}$. A measurable quantity for the dimethylsilyl motion is the N−SiSi−N dihedral angle, which at 230 K has an equilibrium value of 13.7°. With raising temperature the dihedral value approaches 0°, corresponding with the equilibrium value of the high-temperature phase. The high molecular point symmetry D_{2d} is finally reached above 260 K (see NMR experiments) with free rotation of the *tert*-butyl groups. In the phase transition the N−SiSi−N angle can be defined, inter alia, as an ordering parameter.

The point symmetry of $\mathbf{Li_4X_2}$ (230 K) is $S_4(\bar{4})$, and from a packing point of view is not ideal for organic molecules.[21] It is not astonishing that at lower temperatures another crystalline phase for $\mathbf{Li_4X_2}$ is found which is stable below 170 K [$\mathbf{Li_4X_2}$ (160 K)]. We were not able to obtain single crystals from this phase, but have deduced from X-ray powder diffraction that the crystal system is lower than tetragonal, and could be orthorhombic or monoclinic.

The $\mathbf{Na_4X_2}$ compound shows two crystalline phases, the molecular structures of the compounds being quite different as may be concluded from Figure 8. At ambient temperature $\mathbf{Na_4X_2}$ crystallizes in the tetragonal lattice in space group $P4_2/n$ with $Z = 2$ as $\mathbf{Li_4X_2}$ at 230 K, and below 240 K $\mathbf{Na_4X_2}$ becomes orthorhombic (space group $Pna2_1$). While in the low-temperature phase the molecule has crystal point symmetry C_1 but deviates only a little from $D_2(222)$, in the high-temperature phase of $\mathbf{Na_4X_2}$ the crystal point symmetry is $S_4(\bar{4})$ (Table 3). In the low-temperature phase of $\mathbf{Na_4X_2}$ there are two types of sodium atoms, as in $\mathbf{Na_4L_2}$, and the structures of these two phases are very similar, omitting the *tert*-butyl/trimethylsilyl exchange. With respect to O and N in $\mathbf{Na_4X_2}$ (220 K) there are λ^2- and λ^4-Na atoms, while in $\mathbf{Na_4X_2}$ (290 K) all Na atoms are three-coordinate (see also Table 3). The phase transition in the Na_4X_2 system is of first order (vide NMR): The change in the molecular structure thus happens instantaneously.

The structural change in $\mathbf{Na_4X_2}$ associated with the phase transition from low to high temperature has three characteristics: (1) The sodium atoms become equivalent and change from $2 \times \lambda^2$-Na and $2 \times \lambda^4$-Na to $4 \times \lambda^3$-Na. The vibrations of the sodium atoms become stronger, but there is no evidence for a sodium oscillation as in the case of $\mathbf{Li_4X_2}$. (2) The different point symmetry of the molecule at higher temperature is accompanied by a substantial gain in volume [increase in volume/molecule = 34.6 Å^3 (3.6%); in the $\mathbf{Li_4X_2}$ system (230/290 K) the volume increase is 20.0 Å^3 (2.2%)]. This increase is used for rotational freedom of the *tert*-butyl groups. (3) The mutual orientation of the $[t\text{Bu}-\text{N}-\text{SiMe}_2-\text{O}-\text{SiMe}_2-\text{N}-t\text{Bu}]^{2-}$ ligands is changed, and the dihedral angles N−SiSi−N increase from 36.6° for $\mathbf{Na_4X_2}$ (220 K) to 44.9° for $\mathbf{Na_4X_2}$ (290 K). Whereas at 220 K the two ligands are symmetry-related by C_2 and have the same twisting direction (along the N−Si−O−Si−N skeleton), at 290 K the ligands have opposite twists. This is best seen by closer inspection of Figure 8.

In conclusion, the two phase transitions studied with $\mathbf{Li_4X_2}$ and $\mathbf{Na_4X_2}$ with X-ray diffraction techniques are similar with respect to obtaining motional freedom for the *tert*-butyl groups with increase in the temperature, but the effect on the metal atoms is different. While in the case of lithium the oscillations along two of the twofold axes of the D_{2d} symmetry become more important with increase in temperature, in the case of sodium there is one important displacement of these atoms at the transition point, without any further metal movements. The silicon derivatives $\mathbf{Li_4L_2}$ and $\mathbf{Na_4L_2}$ at ambient temperatures have molecular structures that can only be realised in $\mathbf{Li_4X_2}$ and $\mathbf{Na_4X_2}$ at lower temperatures. This is a direct consequence of the different charge distributions at nitrogen due to carbon/silicon exchange. The nitrogen atoms in $\mathbf{Li_4L_2}$ and $\mathbf{Na_4L_2}$ are more negatively charged than the same atoms in the $\mathbf{Li_4X_2}$ and $\mathbf{Na_4X_2}$ derivatives and therefore hinder the motional freedom of the metal atoms by a higher electrostatic component.

The models discussed so far have been checked by solid-state NMR. In Figure 10 and Figure 11 the ^{13}C-NMR spectra of $\mathbf{Li_4X_2}$ and $\mathbf{Na_4X_2}$ in the temperature range between 150 and 350 K are shown. In exact correspondence to the X-ray diffraction results the phase transitions in both systems are easily recognised, and temperatures of transition are paralleled. In the $\mathbf{Li_4X_2}$ system, starting with 150 K, the first transition occurs at 165 K. Below 165 K the ^{13}C-MAS NMR spectrum is highly structured especially in the dimethylsilyl region. Here at least six different signals can be recognised, which collapse at 165 K to two signals of equal intensity. From the number of signals it can be deduced that the point symmetry of the $\mathbf{Li_4X_2}$ below 165 K is less than C_2 and is most probably C_1 (8 signals are expected for this point symmetry). The broad peak of the primary carbon atoms in the *tert*-butyl groups hints at an ordered structure, ruling out any rotational movement. The spectral change at 165 K is sudden, in accord with a first order transition.

Above 168 K the spectrum of $\mathbf{Li_4X_2}$ is constantly changing with two major observations: (1) The intensity of the *tert*-butyl signal (methyl groups) with respect to the dimethylsilyl group is gradually increasing: This effect can be attributed to an initial rotation of the *tert*-butyl groups around the C−N axis becoming more and more important. (2) The space separation of the two methyl groups is almost constant between 165 K and 205 K. Between 205 K and 245 K the separation is constantly diminishing, the intensity of the signal growing and finally collapsing to a singlet at

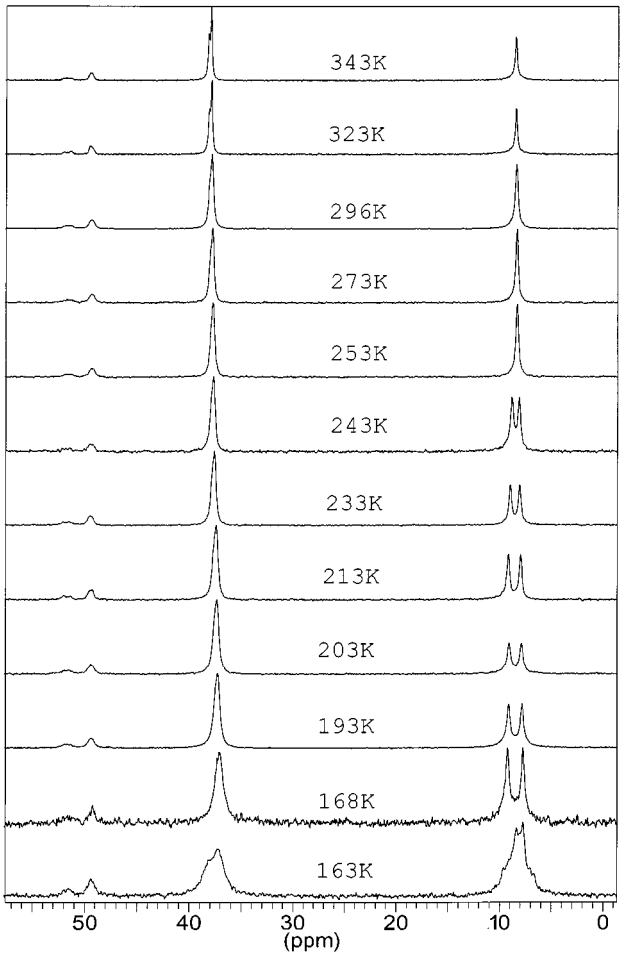

Figure 10. ^{13}C-MAS NMR spectrum of $\mathbf{Li_4X_2}$ between 150 and 350 K

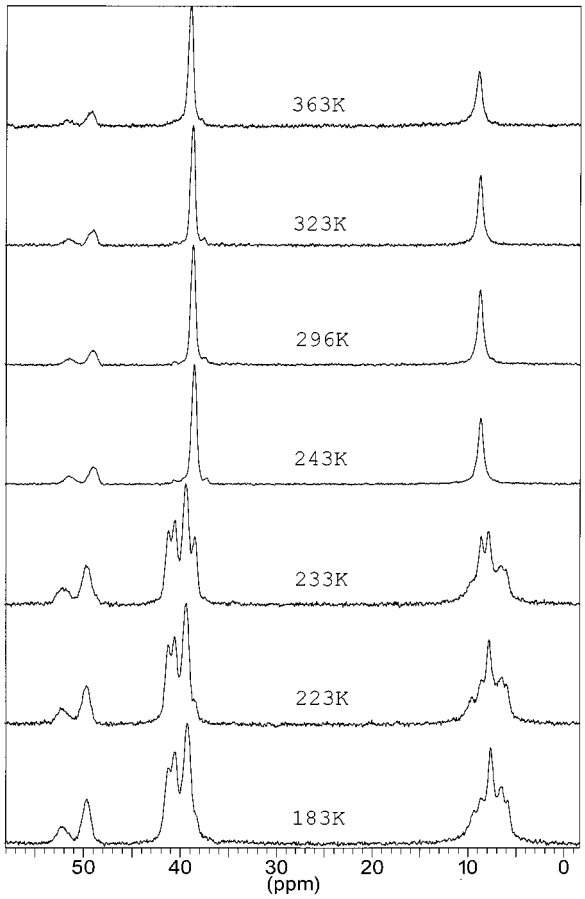

Figure 11. ^{13}C-MAS NMR spectrum of $\mathbf{Na_4X_2}$ between 150 and 350 K

245 K. The experiment seems to reflect the starting libration of the dimethylsilyl groups in the crystal, which become more and more intense with the N−SiSi−N dihedral angle approaching 0° (see before). It also confirms our assumption that the phase transition between $\mathbf{Li_4X_2}$ (230 K) and $\mathbf{Li_4X_2}$ (290 K) is of second order with a continuous change of parameters. It is interesting to note that the crystallographic S_4 symmetry is nicely reflected in the spectrum with one independent *tert*-butyl group and two independent methyl groups in the Me_2Si region.

Above 245 K the spectrum of $\mathbf{Li_4X_2}$ is in accordance with the crystallographic $D_{2d}(\bar{4}2m)$ symmetry, and two signals for all methyl groups within the molecule are measured. The tertiary carbon atom of the *tert*-butyl group is not affected during the phase transitions, as can be seen from Figure 10. This is due to the central position of the carbon atom which is shielded and suffers to a smaller extent from structural changes than a carbon atom situated on the outer sphere of the molecule. The two asymmetric resonances of the primary carbon atom are due to the quadrupole splitting of the nitrogen to which it is attached.

We have been lucky, to follow the phase transitions in $\mathbf{Li_4X_2}$ also by single-crystal Raman spectroscopy.[22] In Figure 12 a section of the spectrum (2600−3000 cm^{-1}) is shown, which has been obtained from a crystal oriented orthogonal to the [001] direction of the tetragonal phase.

The highest frequency of the C−H stretching modes is especially sensitive to the phase transition: At 150 K the signal at 2950 cm^{-1} is definitely different from the corresponding one at 160 K, which with increasing temperature is gradually changing. Very recently we have obtained a DSC curve of the phase transition around 245 K, which is shown in Figure 13.[26]

The λ curvature of the plot is reminiscent of the ideal second-order phase transition, the original model description being developed by P. Ehrenfest and L. D. Landau.[27] In conclusion, the Raman spectroscopy as well as the DSC experiment fully parallel our NMR and X-ray experiments and substantiate our earlier assumptions.

The solid-state ^{13}C-NMR experiments with $\mathbf{Na_4X_2}$ are not as straightforward as with $\mathbf{Li_4X_2}$ (Figure 11).

In accordance with the low crystal symmetry of the $\mathbf{Na_4X_2}$ molecule, in between 180 K and 220 K the Me_2Si group (at least 5 signals) and the *tert*-butyl groups (at least 3 signals) show up as multiplets. At 233 K the multiplets become more complex by addition of a further line to each of them. As can be deduced from the spectrum at 243 K, the additional peaks are from the high-temperature tetragonal phase. There is a coexistence of the two phases (orthorhombic and tetragonal) in accord with the first-order

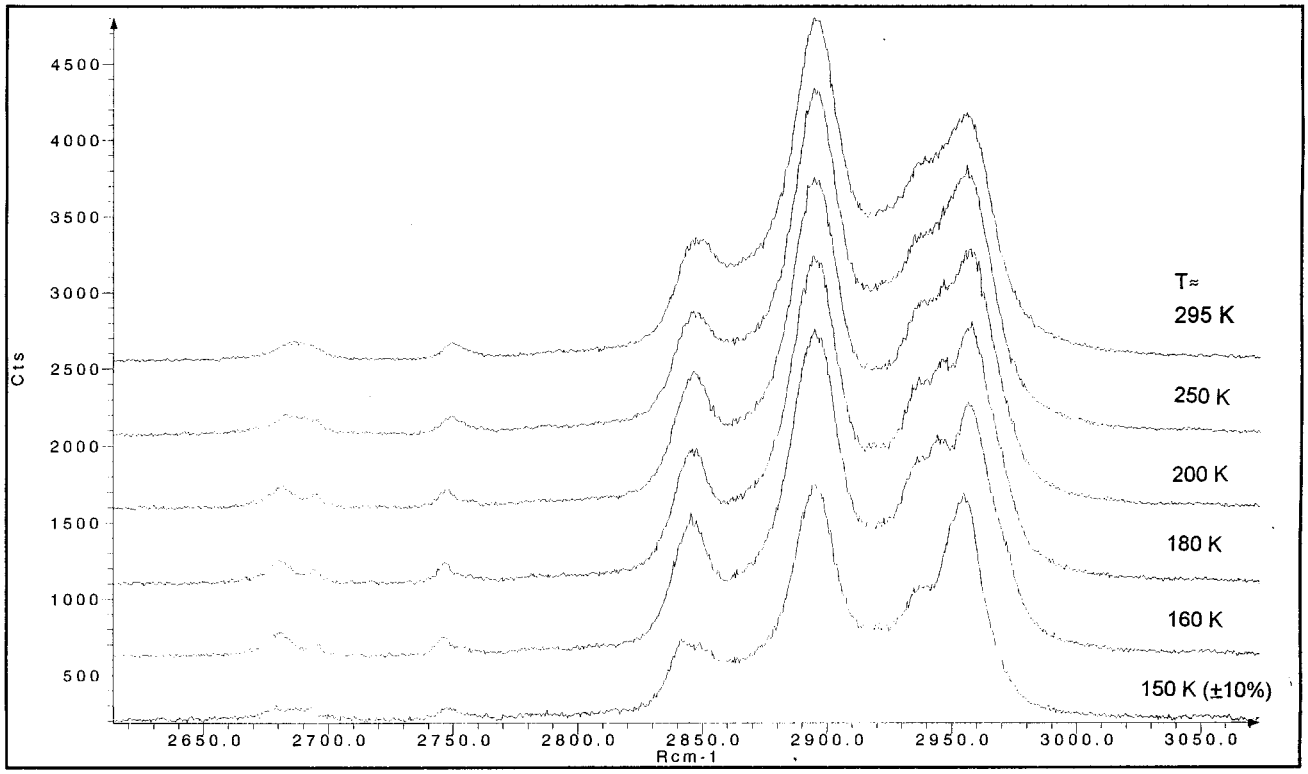

Figure 12. Section of Raman spectrum of $\mathbf{Li_4X_2}$ (2600−3100 cm^{-1}) at different temperatures (single crystal)

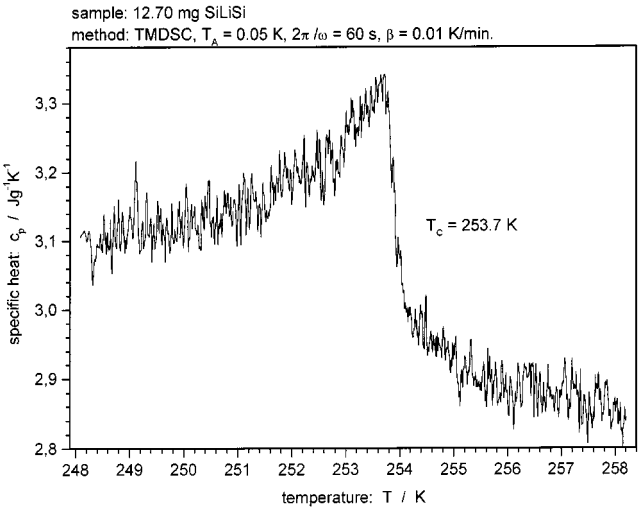

Figure 13. The "λ-transition" at 245 K found by micro-DSC for $\mathbf{Li_4X_2}$

phase transition. Above 233 K the spectrum of $\mathbf{Na_4X_2}$ is very simple, with two resonances for the *tert*-butyl and dimethylsilyl group and the quadrupolarly coupled tertiary carbon atom.

There is clearly a misfit between the X-ray results and the ^{13}C-NMR spectrum for the high-temperature phase of $\mathbf{Na_4X_2}$. As in the corresponding $\mathbf{Li_4X_2}$ (230 K) spectrum, the dimethylsilyl group should show up as two signals of equal intensity [in accordance with the $S_4(\bar{4})$ point symmetry]. What could be the reason for the observed singlet? There are several possibilities. As the signal of the high-temperature phase of $\mathbf{Na_4X_2}$ is very broad (the signal half-width broadness is double that of the corresponding $\mathbf{Li_4X_2}$ phase), the experiment could suffer from lack of resolution. Unfortunately, changing the experimental parameters (using a 500-MHz NMR equipment instead of a 200-MHz one) does not reveal any new insight, as the signal remains comparatively broad but is not structured. Another possible explanation could be that the X-ray structure solution of the tetragonal phase is wrong, due to undiscovered twinning. We are still in the process of proving or disproving these assumptions.

Besides ^{13}C-NMR techniques, ^{6}Li-, ^{7}Li-, and ^{29}Si NMR have also been used to follow the phase transitions (in $\mathbf{Li_4X_2}$ and $\mathbf{Na_4X_2}$). The most interesting is of course the Li NMR, as we could obtain direct information on the lithium mobility. To cut a long story short, two main observations have been made: (1) From the broad-line powder spectra the asymmetry parameter of the lithium position in $\mathbf{Li_4X_2}$ can be obtained. It changes from 0.11 at 150 K to 0.05 at 230 K and remains constant until 360 K, which is an accord with obtaining more axial symmetry (C_2). (2) Within the temperature range of 230 to 260 K the spinning side bands of the MAS spectra show a notable line broadening and consequently a reduced MAS sensitivity.[28] This dynamically induced line broadening seems to be a direct trace of the lithium movement. Above 270 K the spinning side bands sharpen again due to the increasing frequency of the molecular motion (see Figure 14).

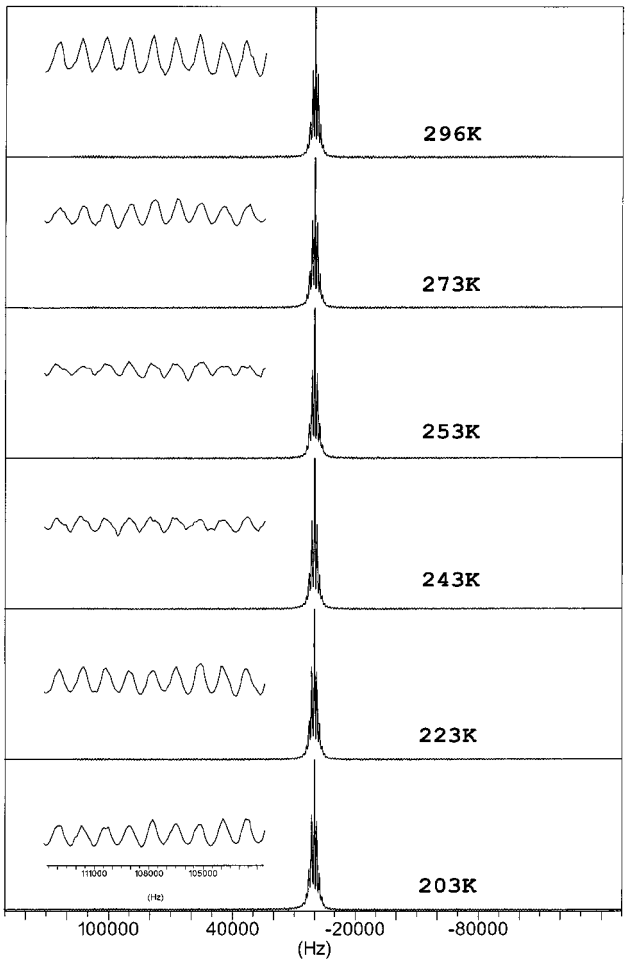

Figure 14. ^{7}Li-MAS spectra of $\mathbf{Li_4X_2}$; the expanded region of the spinning side bands shows the homogeneous line broadening with reduced efficiency of the MAS experiment at the phase transition

The N−Si−O−Si−N Skeleton with Different Substituents

Whereas in the last chapter the mobility of the lithium and sodium atoms has been shown to be influenced by a C/Si exchange at the nitrogen atoms of the N−Si−O−Si−N skeleton, in this chapter we present our results from more dramatically changing the substituents on the whole skeleton. Although we have followed these experiments by spectroscopic means, we only present the X-ray results.

The ligand $[t\text{Bu}-\text{SiMe}_2-\text{N}-\text{SiMe}_2-\text{O}-\text{SiMe}_2-\text{N}-\text{SiMe}_2-t\text{Bu}]^{2-}$ can be derived from $[\text{Me}_3\text{Si}-\text{N}-\text{SiMe}_2-\text{O}-\text{SiMe}_2-\text{N}-\text{SiMe}_3]^{2-}$ by exchange of a methyl group by the sterically demanding *tert*-butyl group at the outer silicon atoms. The compound $[t\text{Bu}-\text{SiMe}_2-\text{N}-\text{SiMe}_2-\text{O}-\text{SiMe}_2-\text{N}-\text{SiMe}_2-t\text{Bu}]_2\text{Li}_4$, $\mathbf{Li_4L'_2}$, has been analysed by X-ray diffraction, the result being shown in Figure 15.[17] Interestingly, even at room temperature, the lithium atoms are at rest and the structure obtained is quite different from $\mathbf{Li_4L_2}$. The molecule $\mathbf{Li_4L'_2}$ adopts almost $D_2(222)$ symmetry in the crystal (exact crystal symmetry C_1) with two pairs of different lithium atoms (λ^2-Li and λ^4-Li). The λ^2-Li atoms have further contacts with the methyl groups of the *tert*-butyl and the dimethylsilyl groups (LiC 3.0 Å), which explains nicely the stability of the structure.

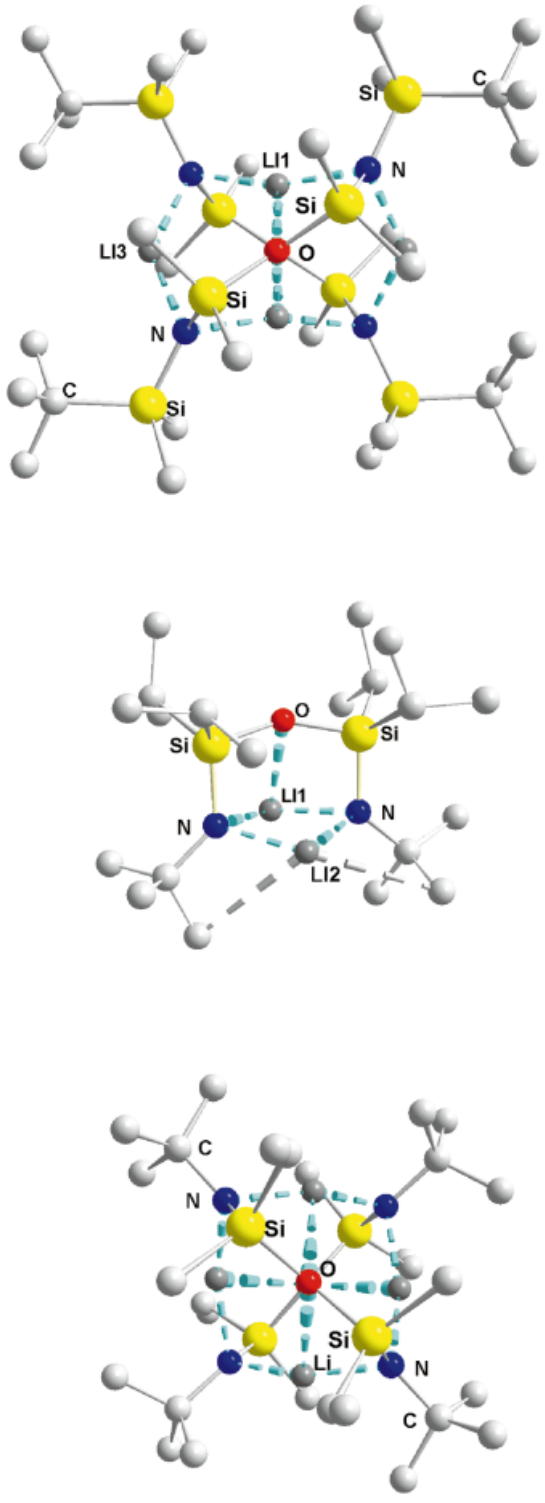

Figure 15. Molecular structures at 290 K of $\text{Li}_4[t\text{Bu}-\text{SiMe}_2-\text{N}-\text{SiMe}_2-\text{O}-\text{SiMe}_2-\text{N}-\text{SiMe}_2-t\text{Bu}]_2$ ($\mathbf{Li_4L_2}$), $\text{Li}_2[t\text{Bu}-\text{N}-\text{Si}(i\text{Pr})_2-\text{O}-\text{Si}(i\text{Pr})_2-\text{N}t\text{Bu}]$ ($\mathbf{Li_2X''}$), and $\text{Li}_4[t\text{Bu}-\text{N}-\text{Si}(\text{Me})(\text{CH}=\text{CH}_2)-\text{O}-\text{Si}(\text{Me})(\text{CH}=\text{CH}_2)-\text{N}-t\text{Bu}]_2$ ($\mathbf{Li_4X_2}$)

It seems likely that steric as well as electronic effects are responsible for the difference in the structure of $\mathbf{Li_4L_2'}$ compared with that of $\mathbf{Li_4L_2}$.

The steric influence can also be observed when the methyl groups at the silicon atoms of $[t\text{Bu}-\text{N}-$

$SiMe_2-O-SiMe_2-N-tBu]^{2-}$ are replaced by bulkier groups like isopropyl moieties. The corresponding lithium derivative of this ligand $[tBu-N-Si(iPr)_2-O-Si(iPr)_2-N-tBu]Li_2$, **$Li_2X$"**, is no longer dimeric, but monomeric. The isopropyl groups on the silicon atoms seem to prevent dimerisation, and **Li_2X"** can be obtained in its monomeric form even in the crystal (Figure 15). The two lithium atoms are very different in their coordination, the λ^3-Li possessing a small Li−O contact (2.34A) and longer Li−N bonds [1.99(1) Å], while the λ^2-Li has shorter Li−N bonds [1.978(2)Å]. Besides these bonds the λ^2-Li has two narrow distances to carbon (2.99 Å).

When the organic substituents on the silicon atoms in $[tBu-N-SiR_2-O-SiR_2-N-tBu]^{2-}$ are different, the silicon atoms become chiral, and the whole ligand can either belong to the *R*,*R* (*S*,*S*) or *R*,*S* (*S*,*R*) enantiomer (*R* and *S* designing the chirality of the two silicon centres). In the first case, assuming a planar ligand, the point symmetry of the anionic ligand is $C_2(2)$ while in the second case it is $C_s(m)$. We have prepared several examples of these ligands (see Table 1), and to our great surprise have found, that the ligands with the *R*,*R* (*S*,*S*) chirality exclusively crystallize as lithium salts, while in the mother liquor both enantiomers are present (^{1}H-NMR evidence). In Figure 15 the structure of $[tBu-N-Si\{(Me)(CH=CH_2)\}-O-Si\{(Me)(CH=CH_2)\}-NtBu]_2Li_4$, **$Li_4X_2$′**, is shown. The molecule crystallizes in the tetragonal space group $P\bar{4}2_1c$ with two molecules per unit cell, and has the crystal point symmetry S_4. As a consequence, each lithium atom is in the same atom environment, and is coordinated by two nitrogen, two oxygen, and two carbon atoms. Each molecule contains one ligand with (*R*,*R*) chirality at Si and a second one with (*S*,*S*) chirality. The lithium oscillation (not shown in the Figure) is less important than in the corresponding compound **Li_4X_2**, and the atoms can be refined without splitting positions (but with large anisotropic temperature factors). The N−SiSi−N dihedral angle is 12.4°, but as the substituents on silicon are different, there is no energetically equivalent position in the other twist form (dihedral angle −12.4°) and the system seems to avoid the passage to the other conformer. This explains the fact that **Li_4X_2** and **Li_4X_2′** are quite different at the same temperature (290 K), **Li_4X_2** showing large lithium oscillations while **Li_4X_2′** only has small amplitudes.

We can conclude from these substitution experiments that the structures of the molecules and the motion of the metal atoms can be easily manipulated. The results fit in nicely in our atomistic dynamic models.

The N−Si−O−Si−N Skeleton with Different Metallic Elements

So far we have compared the lithium and sodium derivatives of the same ligands. The compound $Li_2K_2[tBuN-SiMe_2-O-SiMe_2-NtBu]_2$, **$Li_2K_2X_2$**, belongs to the family **Li_4X_2** and **Na_4X_4** with the peculiarity of hosting two types of metallic atoms. Looking back to the structures we have known so far, it seemed unlikely that **$Li_2K_2X_2$** should adopt the S_4 symmetry of the tetragonal phase of **Na_4X_2** or the

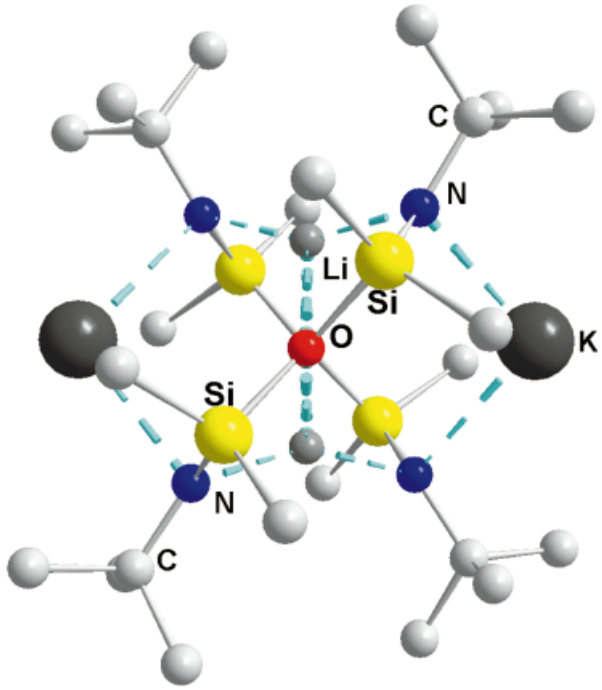

Figure 16. Molecular structure of $Li_2K_2[tBu-N-SiMe_2-O-SiMe_2-N-tBu]_2$ (**$Li_2K_2X_2$**) at 290 K in the solid; the smaller lithium atoms occupy the N_2O_2 holes while the bigger potassium atoms are situated on the outside

D_{2d} symmetry of the high-temperature phase of **Li_4X_2**. As a matter of fact, **$Li_2K_2X_2$** forms a structure very similar to the low-temperature phase of **Na_4X_2**, as can be seen from Figure 16.[17] Between 200 and 380 K we have found no hint for any phase transition as the ^{13}C-MAS NMR spectra remain unchanged.

While the smaller lithium atoms in **$Li_2K_2X_2$** occupy quasi-tetrahedral O_2N_2 holes, the two potassium atoms are too large to be accommodated in these coordination polyhedra and are only bonded by two nitrogen atoms. Furthermore, the potassium atoms have close contacts to carbon atoms of the *tert*-butyl ligands. The crystal symmetry of the whole molecule is C_2 (the two-fold axis passes through the lithium atoms), but the bond lengths and angles as well as the dispositions of the atoms reveal it to be close to D_2. As already discussed, **$Li_2K_2X_2$** is structurally similar to the orthorhombic phase of **Na_4X_2**. Contrary to this compound, no phase transition is observed as the two different elements are well accommodated in their respective coordination spheres. Comparing **$Li_2K_2X_2$** to **Li_4X_2** no lithium motion is observed in the former as there is no need to equilibrate between different lithium positions.

Other interesting cases to discuss are the monovalent transition metal derivatives $Cu_4[tBuN-SiMe_2-O-SiMe_2-NtBu]_2$, **$Cu_4X_2$**, and $Ag_4[tBuN-SiMe_2-O-SiMe_2-NtBu]_2$, **$Ag_4X_2$**. The two compounds have the same composition as **Li_4X_2** or **Na_4X_2** and are somewhat similar in their structures, but also show important differences to the alkali derivatives. In Figure 17, the structure of one of the two compounds, which are isotypic, is depicted as a result of an X-ray structure analysis.

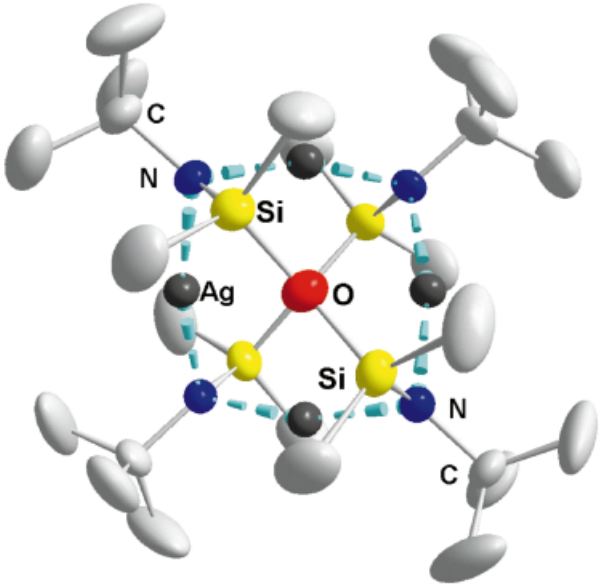

Figure 17. Molecular structure of $Ag_4[t\text{Bu}-N-SiMe_2-O-SiMe_2-N-t\text{Bu}]_2$ (**Ag_4X_2**) with ellipsoids of vibration (50%) at 290 K

The crystal point symmetry of the compounds is $C_2(2)$ but the deviation from $D_{2d}(\bar{4}2m)$ is almost negligible (the N−SiSi−N dihedral angles are 11.2° in **Cu_4X_2** and 11.7° in **Ag_4X_2**). Although belonging to the same molecular point symmetry, compared to the ambient-temperature phase of **Li_4X_2**, **Cu_4X_2**, or **Ag_4X_2** are distinctly different in their structures. The N−M−N bonds are almost linear (**Cu_4X_2**: N−Cu−N = 164.9°; **Ag_4X_2**: N−Ag−N = 165.2°) and there are no bonding interactions of the metal centres with the oxygen atoms. Furthermore, the anisotropic displacement factors of the metal atoms in the compounds are small and there is no evidence for metal oscillations as in compound **Li_4X_2**. The different behaviour of the copper and silver atoms compared to lithium is due to a well-known reason: The metal atoms are in a preferred s(d)p-bond configuration and there are numerous examples of this bonding type in the literature.[29]

Conclusions

We have been able to show that metal movements, especially of lithium (cations), are possible within a molecular skeleton in a crystalline solid. The motions of these metal atoms (ions) are linked to phase transitions and rotations or oscillations of atoms or groups within the molecular skeleton. The phase transitions are reflecting the change of overall symmetry of the molecular movements. The large vibrations within the ligands are necessary to minimize the activation energy of the metal motion.

In the systems **M_2Z_2** it can be clearly shown that only the lithium atoms (or in an ionic model: ions) are capable to jump from filled holes into empty ones. This jumping leads to a rotational motion that may proceed backwards or forwards (Figure 18). The rotational motion of the lithium atoms appears to be simultaneous, which means that the two metallic atoms within the molecule are jumping at the same time, because of electrostatic reasons. Although the sodium derivative also shows phase transitions to allow more motional freedom to the organic ligands, there is no evidence for a comparable sodium hopping or rotation. This leads to the conclusion that the lithium motion is perhaps better described as "lithium tunnelling". The trimethylsilyl derivative **Li_2Z_2**" has a structure very similar to **Li_2Z_2** in the monoclinic phase. Whereas the monoclinic phase of **Li_2Z_2** is stable up to 293 K, the monoclinic phase of **Li_2Z_2**" is stable up to 340 K. The higher charge transfer of the trimethylsilyl group to the oxygen atom compared to *tert*-butyl seems to be responsible for this effect.

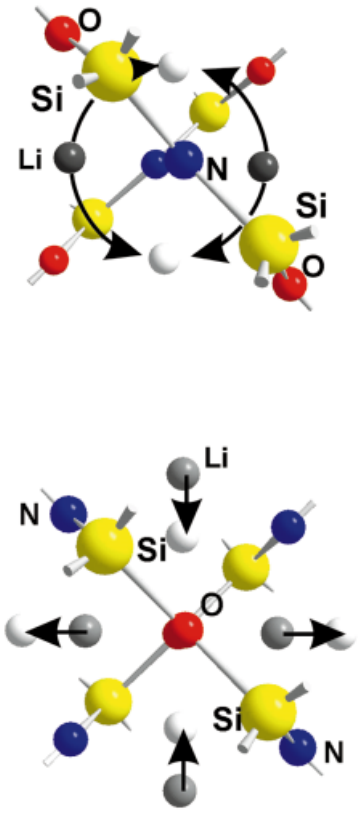

Figure 18. Comparison of the lithium movements within **Li_2Z_2** and **Li_4X_2** at ambient temperature. While in the case of **Li_2Z_2** there is a forward and backward rotation, in **Li_4X_2** there is a forward and backward oscillation; lithium positions are discriminated by white and grey colours; only one type of these coloured position is occupied at a time for electrostatic reasons

The complete fill-up of the N_2O_2 holes in siloxamides by metallic atoms has been realised by the use of the skeleton N−Si−O−Si−N in the place of O−Si−N−Si−O. Although the rotational lithium hopping is stopped by this transformation, the system is still highly fluctional in the crystal, with lithium oscillations occurring along two of the three twofold axes of the $D_{2d}(\bar{4}2m)$ point symmetry (Figure 18). As in the case of **Li_2Z_2**, temperature-dependent

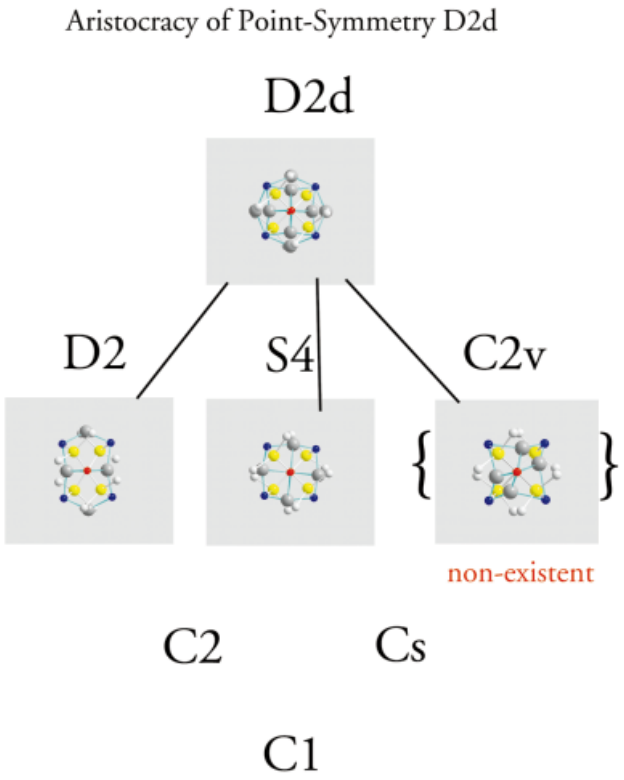

Figure 19. Symmetry tree of D_{2d}, S_4, and D_2; the sketch for C_{2v} is drawn for completeness but is not relevant

solid-state phase transitions have been found for $\mathbf{Li_4X_2}$. It is interesting to note that all structures determined within the $\mathbf{Li_4X_2}$ system or any other ligand derived from $[R-N-SiR'R''-O-SiR'R''-N-R]^{2-}$ can be classified within the $D_{2d}(\bar{4}2m)$ symmetry tree, as exemplified in Figure 19. From all point symmetries collected in Figure 19 only C_{2v} and C_s have not been realised in a crystalline compound, which is comprehensible because of the special arrangement of the two anionic ligands and the ionic repulsions of the four formal cations. As a matter of fact, all low-temperature structures can be classified to belong exactly or approximately to either D_2 or S_4 subgroup.

The second-order phase transition within $\mathbf{Li_4X_2}$ from space group $P4_2/n$ to $P4_2/nmc$ shows nicely that the amplitudes of the metal oscillations are temperature-dependent, and furthermore that ligand librations are involved in the whole process.

The replacement of lithium by sodium to form $\mathbf{Na_4X_2}$ parallels our findings within the O−Si−N−Si−O skeleton. Contrary to the lithium derivative $\mathbf{Li_4X_2}$ there are no important sodium oscillations. The phase transition from the orthorhombic to the tetragonal phase is again driven by entropy: In the high-temperature tetragonal phase all *tert*-butyl groups rotate around the N−C bonds, while in the low-temperature phase they are at rest. Only at the transition point do the sodium atoms show important displacements, but neither before nor after this transition point do the sodium atoms seem to be involved in important movements. The molecular point symmetry of $\mathbf{Na_4X_2}$ passes from approximately D_2 to S_4 at the transition, which means that in the transition state the D_{2d} symmetry has to be run through (Figure 19).

The *tert*-butyl/trimethylsilyl exchange on the nitrogen atoms in the lithium and sodium compounds enhances the ionic charge on nitrogen, and leads to a parallel effect with respect to the stability of structures. The structures found at room temperature with trimethylsilyl substituents and a N−Si−O−Si−N backbone can be only "copied" using *tert*-butyl in place of trimethylsilyl, if the temperature is maintained below ca. 250 K. Again, this corresponds with our findings in the O−Si−N−Si−O series.

The bulkiness of the ligands can influence the structure to such a point that no dimer can be formed any more (see $[t\mathrm{BuN-Si}(i\mathrm{Pr})_2-\mathrm{O-Si}(i\mathrm{Pr})_2-\mathrm{N}t\mathrm{Bu}]\mathrm{Li}_2$). The lithium/potassium derivative $\mathbf{Li_2K_2X_2}$ adopts the D_2 symmetry allowing different ligations to lithium and potassium atoms. The copper and silver derivatives $\mathbf{Cu_4X_2}$ and $\mathbf{Ag_4X_2}$ show almost linear N−M−N arrangements and no tendency to metal oscillations in accord with metal−nitrogen bonding different from that of lithium or sodium.

Metal motions in crystalline solids in distinct regions (metal movements in molecular boxes) merit increasing interest because they are anisotropic (in the cases discussed in this article the rotations or oscillations are perpendicular to the tetragonal [001] axis) and can be influenced. The simple switching on and off of these dynamics could lead to applications in solid-state physics. Instead of heat energy, a magnetic or electric field could also be used in principle.

Acknowledgments

I would like to thank S. Wieczorek, Dr. K. Fries, and Dr. J. Böhnlein-Maus for their synthetic work, Dr. V. Huch for the X-ray experiments, as well as Dr. M. Zimmer for solid-state NMR experiments. Prof. J. Krüger, Experimentalphysik, Saarbrücken, is acknowledged for the DSC curve of $\mathbf{Li_4X_2}$. With deep regret I have learnt of the sudden death of Prof. H. G. Unruh, Experimentalphysik, Saarbrücken, who conducted the single-crystal Raman experiments: I still remember well our fruitful discussions on phase transitions. This work has been financed partly by the Deutsche Forschungsgemeinschaft as well as the Fonds der Chemischen Industrie, which are acknowledged. I thank Dr. V. Subramanian for reading the manuscript.

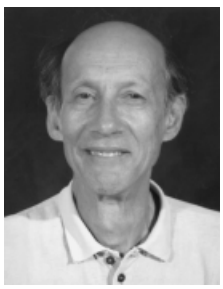
Increased-Valence Structures for Qualitative Valence-Bond Representations of Electronic Structure for Electron-Rich Molecules

Richard D. Harcourt[a]

Keywords: Valence bonds / Increased-valence structures / Three-electron bonds / Singlet diradical structures / Bohr orbits



Whereas familiar Lewis-type valence-bond structures for singlet-spin systems involve electron-pair bonds and lone-pairs of electrons, increased-valence structures involve one-electron bonds and fractional electron-pair bonds. An increased-valence structure may be easily derived from a familiar Lewis structure via one-electron delocalizations of lone-pair electrons into two-centre bonding molecular orbitals. The increased-valence structure is equivalent to resonance between several Lewis structures, including the familiar Lewis structure from which it was derived, and therefore it is more stable than the latter structure. Some of the properties of increased-valence structures, and their associated Pauling three-electron bonds as diatomic components of these structures, are discussed, with specific reference to N_2O and the $Fe^{II}O_2$ linkages of oxyhaemoglobin. Applications to numerous other systems that involve 4-electron 3-centre, 6-electron 4-centre, and 6-electron 5-centre bonding units are presented. Brief consideration is also given to a speculative Bohr approach to electronic structure.

Introduction

Over the last two decades, there has been a resurgence of interest in valence-bond (VB) descriptions of the electronic structures of molecules.[1–5] My research has been concerned primarily with the qualitative development of the subject, particularly through the formulation of the *increased-valence* theory[4,5] for the large class of electron-rich molecules. For these molecules, the theory enables their familiar, traditional Lewis-type VB structures, with lone-pairs of electrons and electron-pair bonds, to be stabilized by means of one-electron delocalizations into bonding molecular orbitals (MOs). The resulting increased-valence structures are then able to provide new insights into the origins of bond properties, and how molecules react. Using an $Fe^{II}O_2$ linkage for oxyhaemoglobin, and N_2O, as examples, I shall redescribe some essential features of this theory, and give consideration to a number of the many applications that we have made to inorganic systems. Recent reviews that discuss a variety of examples include those of ref.[5,6] The reader who is more interested in the applications may omit those sections of this review that involve detailed formulations of VB wavefunctions. I shall also briefly redescribe aspects of a speculative approach to qualitative descriptions of electronic structure via Bohr circular orbit theory.[7] The essential purpose of both types of approach to electronic structure is to help provide "primitive patterns of understanding",[8] using mostly qualitative VB methods.

The simplest definition of an electron-rich bonding unit is that it involves N overlapping (hybrid or non-hybrid) atomic orbitals (AOs) centred on N atomic centres, with n electrons occupying these AOs, when $N < n < 2N$. Familiar examples involve 3-electron 2-centre, 4-electron 3-centre, and 6-electron 4-centre bonding, and we shall give primary attention to them here. Pauling designated the 3-electron 2-centre bonding unit as a "three-electron bond",[9] and this designation has continued to be used very widely. Although modifications to the term,[10] such as "three-electron two-orbital bond" and "three-electron hemi-bond" or "three-

Richard Harcourt was born in Melbourne, Australia. In 1963, he received a Ph.D. degree in Chemistry from Monash University, under the supervision of Professor R. D. Brown. At the end of 1993, he took early retirement from his appointment as a Senior Lecturer in Physical Chemistry at the University of Melbourne, where he has continued to work as a Research Associate. His research has involved primarily valence-bond studies of the electronic structures of molecules, with particular emphasis given to the development and application of the increased-valence theory which he formulated three decades ago. Related research has involved energy transfer studies. A reformulation of Bohr orbit descriptions of electronic structure has also provided a fruitful (speculative) area of research.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

electron half-bond'' provide more accurate descriptions of its bonding properties, we shall use Pauling's designation here. Some of the properties of three-electron bonds will be discussed in the next Section. As will be discussed below, increased-valence structures for 4-electron 3-centre and 6-electron 4-centre bonding units involve three-electron bonds as diatomic components.

The Three-Electron Bond, or Three-Electron Half-Bond

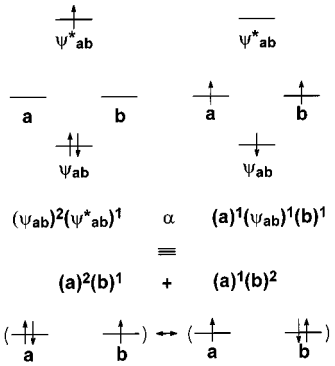
In MO theory, the diatomic three-electron bond involves two bonding electrons and one antibonding electron. Thus if a and b are the overlapping AOs centred on the atomic nuclei A and B, the MO configuration is $(\psi_{ab})^2(\psi^*_{ab})^1$, in which $\psi_{ab} = a + kb$ and $\psi^*_{ab} = k^*a - b$ are orthogonal bonding and antibonding MOs. The k is a variationally controlled polarity parameter with $k^* = (k + <a|b>)/(1 + k<a|b>)$, and the maximum bond-order of 0.5 occurs when $k = 1$, thereby indicating that the designations "three-electron hemi-/half-bond[10]" provide a clearer description of the bonding properties.

$$(\psi_{ab})^2(\psi^*_{ab})^1 \propto (a)^1(\psi_{ab})^1(b)^1 \equiv (a)^2(b)^1 + k(a)^1(b)^2 \qquad (1)$$

It is easy to demonstrate[4,5,11] that the identities of Equation (1) obtain, or in terms of Slater determinants [cf. Equation (2)], in which α and β are the $m_s = +1/2$ and $m_s = -1/2$ electron-spin wavefunctions, and the antibonding ψ^*_{ab} electron is assumed to have an $m_s = +1/2$ spin quantum number. (The identity $|\psi_{ab}{}^{\alpha}\psi_{ab}{}^{\beta}\psi^*_{ab}{}^{\alpha}| \propto |a^{\alpha}\psi_{ab}{}^{\beta}b^{\alpha}|$ was deduced by Linnett.[12]) The $(a)^1(\psi_{ab})^1(b)^1$ configuration involves parallel spins for the a and b electrons, and therefore these two electrons are non-bonding (more accurately, net antibonding[13]); the responsibility for bonding belongs solely with the ψ_{ab} electron, whose spin is opposed to the spin for each of the a and b electrons. In Figure 1, the orbital diagrams that pertain to the identities of Equations (1) or (2) are displayed for $k = k^* = 1$ in the MOs. These identities form the basis for much of the discussion of the properties of increased-valence structures.

$$|\psi_{ab}{}^{\alpha}\psi_{ab}{}^{\beta}\psi^*_{ab}{}^{\alpha}| \propto |a^{\alpha}\psi_{ab}{}^{\beta}b^{\alpha}| \equiv |a^{\alpha}a^{\beta}b^{\alpha}| + k|a^{\alpha}b^{\beta}b^{\alpha}| \qquad (2)$$

Various VB symbolisms have been used to represent the three-electron bond,[4,5,11]. These include VB structures **1**−**6** and **7** ↔ **8**.



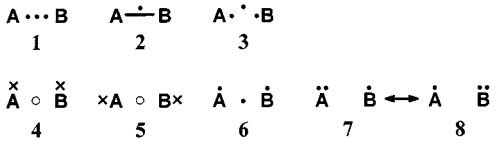


Figure 1. Orbital diagrams for the identities of Equation(1); ↑ ≡ $m_s = +1/2$, ↓ ≡ $m_s = -1/2$

(Atomic formal charges have been omitted from all generalized VB structures that use any of the symbols Y, A, B, C, and D to designate atomic centres.)

The symbolism of structure **1** was introduced by Pauling[9] in 1931, but since then, symbolisms such as **2** and **3** have sometimes been used.[3f,14] However because the equivalent MO theory indicates that the three-electron bond has a maximum bond order of 0.5, structure **2** is unsatisfactory and structures **1** and **3** do not make clear that two of the electrons are non-bonding (more-accurately, net antibonding) in character. Structures **4** and **5** (with spins, **x** for $m_s = +1/2$ and **o** for $m_s = -1/2$) and **6** (without spins) were introduced by Linnett,[12] and with only one bonding electron, they are more-clearly associated with the $|a^{\alpha}\psi_{ab}{}^{\beta}b^{\alpha}|$ configuration than are structures **1**−**3**. Therefore the Linnett symbolism is the preferred[4,5,11] VB symbolism for the three-electron bond. The second identity of Equation (1) shows that each of the three-electron bond VB structures **1**−**6** is equivalent to resonance between the canonical Lewis structures **7** and **8**.

When the odd-electron has $m_s = +1/2$ spin for example, each of the Lewis structures **7** and **8** may be used to generate the three-electron bond VB structure by delocalizing the $m_s = -1/2$ spin lone-pair electron into the ψ_{ab} bonding MO, as is indicated in **9** → **10** and **11** → **12**.

One-electron delocalizations of this type lead to stabilization of the Lewis structures **7** and **8**, and they will be used extensively throughout the paper to generate increased-valence structures from familiar Lewis-type VB structures for triatomic and polyatomic systems. When the extent of delocalization, via the value of the MO polarity parameter k, is determined variationally, a one-electron delocalization from an AO into a bonding MO, *always* generates a stabilization of the increased-valence structure relative to the Lewis structure from which it was derived.

Theory for the three-electron bond may be elaborated further by increasing the number of AOs which are used to accommodate the electrons.[11b] With three AOs (a′,a′′, and b) to accommodate the electrons of the Lewis structure **7**, and three additional AOs (a, b′, and b′′) to accommodate the electrons of the Lewis structure **8**, it has been deduced that a wavefunction of the form $\Psi = \Psi_1(VB) + \Psi_2(VB) = \Psi_1(MO) + \Psi_2(MO)$ may be constructed from each set of three AOs, for which the Ψ_1 and Ψ_2 are three-electron bond wavefunctions. The equivalence has been illustrated[11b] via the results of some ab initio calculations for the $^2\Sigma_u^-$ ground-states of H_2^- and He_2^+. The simplest example involves four AOs, (i.e. for $a' = a'' = a$, $b = b_0$, and $a = a_0$, $b' = b'' = b$) to give the $(a)^2(b_0)^1$ and $(a_0)^1(b)^2$ configurations for structures **7** and **8**, respectively. With H_2^- as the

example, use of these AOs is sufficient to ensure that the dissociation products are $H^- + H$ or $H + H^-$, rather than the $H^{-0.5} + H^{-0.5}$ for a three-electron bond with two equivalent AOs. For H_2^-, the use of canonical double-zeta molecular orbitals constructed from 1s′ and 1s′′ atomic orbitals on each atomic centre must lead to ionization of this anion[11b] to form $H_2 + e^-$ when the exponents of the diffuse (1s′′) orbital components of these molecular orbitals are energy-optimized.

The relevance of three-electron bonds for VB descriptions of the electronic structures of high-spin transition metal complexes, F^+-type colour centres, *n*-type semiconductors and high T_c superconductors is described in ref.[5c], and references 26, 28, and 30 therein.

Linnett-type VB structures with electron-spins either indicated, or not indicated, as in structures **4** for example, and structure **6**, will be used in this Review to provide VB representations of the Pauling three-electron bond.

The Oxygen Molecule

The $^3\Sigma_g^-$ ground-state for the oxygen molecule O_2, has an electron-pair σ-bond and two three-electron π bonds, $(\pi_x)^2(\pi^*_x)^1$ and $(\pi_y)^2(\pi^*_y)^1$ with parallel spins for the antibonding π^*_x and π^*_y electrons. The Pauling and Linnett VB structures[9,12] for this molecule are **13**,[9] **14**[12] without spins, and **15**[12] with spins when it is assumed that the antibonding π^*_x and π^*_y electrons have $m_s = +1/2$ spin quantum numbers.

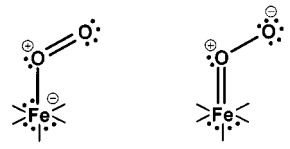
13 **14** **15**

Each of these structures is equivalent to resonance between the canonical Lewis structures **16**−**19**.

16 **17** **18** **19**

The results of ab initio VB calculations for O_2 from several laboratories[15,16] indicate that the uncharged VB structures **16** and **19** have larger weights than have the polar VB structures **17** and **18**. This result, which is not unexpected, reflects the operation of the electroneutrality principle.[9b]

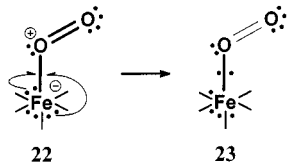
Bonding of O_2 to Haemoglobin



Theories of the bonding of O_2 to haemoglobin or myoglobin will be used here to introduce the concept of an increased-valence structure.

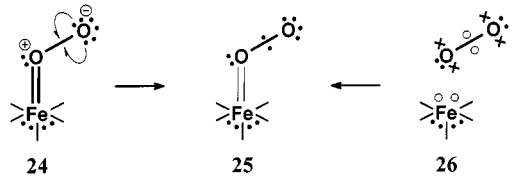
Haemoglobin (Hb) involves four iron atoms, each of which is formally high-spin ($S = 2$ spin) Fe^{II}, with four unpaired, parallel-spin electrons. When oxyhaemoglobin (HbO_2) is formed, four paramagnetic ($S = 1$ spin) O_2 molecules bind to the iron atoms, to give four $S = 0$ spin iron-O_2 linkages. Ever since this effect was first observed by Pauling and Coryell[17] in 1936, there has been debate with regard to how the electronic structure of each $S = 0$ spin iron-O_2 linkage should be (approximately) formulated.[18,19] The three primary models[17,20,21] that are usually considered are the following:

(a) Low-spin $Fe^{II}((t_{2g})^6, S = 0) + O_2^*((\pi^*_x)^2(\pi^*_y)^0, S = 0)$ (Pauling and Coryell);[17]



(b) Intermediate-spin $Fe^{II}((t_{2g})^5(e_g)^1, S = 1) + O_2((\pi^*_x)^1(\pi^*_y)^1, S = 1)$ (McClure, 1960),[20] with antiparallel spin-coupling of the unpaired antibonding π^*_x and π^*_y electrons of ground-state O_2 with those for the Fe^{II};

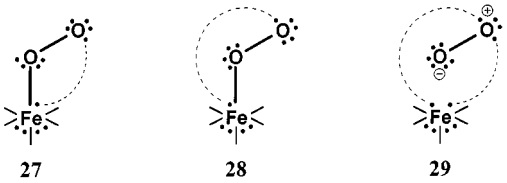
(c) Low-spin $Fe^{III}(S = 1/2) + O_2^-(S = 1/2)$ (Weiss, 1964),[21] with anti-parallel spin coupling for the unpaired electrons of Fe^{III} and O_2^-.



20 **21**

Attention will be given to models (a) and (b). The Pauling-Coryell model (a) involves[17] resonance between the familiar standard (or *Kekulé*-type) Lewis structures **20** and **21**, for which an $S = 0$ spin excited valence-state of O_2 :O::O: is coordinated with the low-spin Fe^{II} in structure **20**. From VB structures **20** and **21**, we can generate[18] VB structures **23** and **25** via the one-electron delocalizations indicated in **22** and **24** (cf. **9** → **10** and **11** → **12**).

22 **23**



24 **25** **26**

VB structure **25** can also be constructed[18] by spin-pairing the two unpaired electrons of ground-state O_2 with the two unpaired electrons of intermediate-spin Fe^{II}, as in **26** → **25**.

The latter procedure involves e_g-π^*_x and t_{2g}-π^*_y spin-pairings for the appropriate pairs of overlapping orbitals, and it provides the VB representation for the McClure model of (b). We shall focus attention on VB structure **25**, but of course it will participate in resonance with the higher-energy structure **23**, (which involves the O_2 excited state). For reasons that will be discussed later when the general theory of 4-electron 3-centre bonding is outlined, VB structures **23**, **25**, and **31** below for N_2O, are examples of *increased-valence* structures.[4,5]

Because the three-electron bond structure for the O_2 ground-state is equivalent to resonance between four canonical Lewis structures, via the identity **14** ≡ **16**↔**17**↔**18**↔**19**, it follows[18] that the $Fe^{II}O_2$ VB structure **25** for model (b) is equivalent to resonance between the canonical Lewis structures **24** and **27**−**29** when it is assumed that the four electrons of the Fe^{II}=O_2 bond of structure **24**

occupy AOs, i.e. a Heitler-London type formulation of the wavefunction [a(1)b(2) + b(1)a(2) with a and b overlapping AOs] is used for each $Fe^{II}-O$ electron-pair bond. Because structures **27**−**29** do not involve Fe=O double bonds, the Fe=O bond-number or bond-order for increased-valence structure **25** is less than two. Thin bond lines are used to represent the fractional electron-pair bonds which are present in this structure, and in all increased-valence structures.[4−6] The extent to which structures **24** and **27**−**29** contribute to the equivalent Lewis structure VB resonance scheme determines the strength of the Fe=O bond.

27 **28** **29**

Each of the VB structures **27**−**29** is an example of a "*long-bond*" or "*formal-bond*", or *Dewar*-type canonical Lewis structure. A "long" or formal bond has negligible strength, and therefore the function of the pecked bond-line (----) which is sometimes used to represent this type of bond[22] is to indicate that the associated pair of electrons are spin-paired. Some workers do not show the presence of formal bonds, and the VB structure is then designated as a *singlet diradical* or *spin-paired diradical* structure. The formal bonding is not indicated in the increased-valence structure. The more-familiar Lewis structures of types **20** and **21**, are designated as *standard* or *Kekulé*-type canonical Lewis structures.

Increased-valence structures for electron-rich systems are equivalent to resonance between Kekulé- and Dewar-type Lewis structures. Therefore when the polarity parameters that are associated with the one-electron bonds of the increased-valence structures are chosen variationally, use of increased-valence structures *must provide a more stable VB representation of electronic structure* than does use of only the more familiar Kekulé-type Lewis structures alone.

Structure **27** is equivalent to the singlet-biradical structure which Goddard and Olafson have used[23] to represent the electronic structures of the $Fe^{II}O_2$ linkages of oxyhaemoglobin, via the McClure model (b). Because increased-valence structure **25** is equivalent to resonance between structures **24** and **27**−**29**, structure **25** must provide a lower-energy representation of the electronic structure than does either **24** or **27** alone.

The observed reduction[24] in the value of the O−O stretching frequency in HbO_2, namely from 1556 cm^{-1} (free O_2) to 1107 cm^{-1} (HbO_2), is sometimes cited as evidence for the Weiss model (c), but the results of MO calculations[25] indicate that little Fe → O_2 charge-transfer occurs.

O−O Bond Making and Breaking

Either an $Mn^{V}=O$ or an $Mn^{IV}=O$ species has been implicated in the formation of an O−O bond in the photosynthetic process.[26] We give consideration to the $Mn^{IV}=O$ here. An $S = 1/2$ spin VB structure for this species is usually represented as **I** of Figure 2.

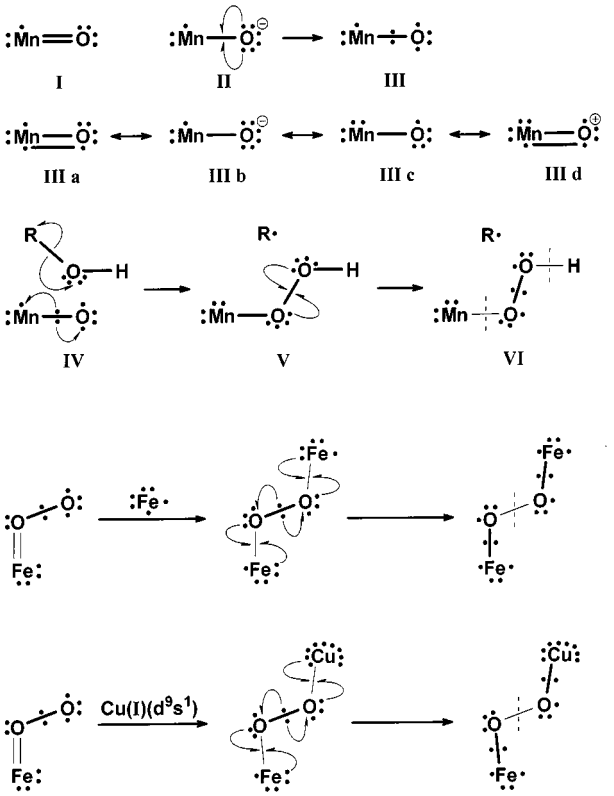


Figure 2. O−O bond-making via $Mn^{IV}O$ + ROH for photosyntheses, and O−O bond-breaking for $Fe^{II}O_2Fe^{II} \rightarrow 2\ Fe^{II}O$ and $Cu^{I}O_2Fe^{II} \rightarrow Cu^{I}O + Fe^{II}O$ decompositions; the $Fe^{II}O_2$ structure corresponds to the increased-valence structure **25**; formal charges are not indicated on the transition metal ions

However it may also be formulated as **II**, from which we may generate VB structure **III** with a three-electron bond. VB structure **III** has an Mn = O double bond whose electronic structure ($(\sigma)^2(\pi_x)^1(\pi_y)^1$) is similar to that of VB structure **15** for the O_2 ground-state. VB structure **III** is equivalent to resonance between the canonical Lewis structures **IIIa**−**IIId**, (with **IIIa** and **IIIb** corresponding to structures **I** and **II**), and therefore **III** is more stable than is either structure **I** or structure **II** alone. With a nitrogen atom replacing the Mn in these VB structures, a similar type of VB representation is relevant for the ground-state of NO.

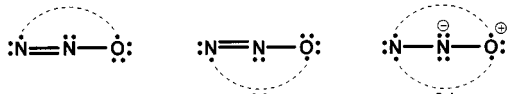
Unlike structure **I**, the three-electron bond structure **III** locates unpaired electron spin-density on the oxygen atom. Therefore the $Mn^{IV}=O$ is able to react with ROH to generate $Mn^{III}OOH$ ($S = 1/2$) according to **IV** → **V**. The $Mn^{III}OOH$ has been postulated[26b] to be the precursor for O_2 formation. Further electronic reorganization, as indicated in **V** → **VI**, weakens the Mn-O and O-H bonds to generate O_2 + Mn^{II} + H. The **IV** → **V** → **VI** mechanism for the formation of the postulated $Mn^{III}OOH$ species provides an alternative to those provided in references 26b,c.

In Figure 2, increased-valence structures[4,6a] are also displayed for $Fe^{II}-O_2-Fe^{II}$ and $Cu^{I}-O_2-Fe^{II}$, in which the O_2 ground-state is bonded to Fe^{II}($S = 1$, $(t_{2g})^5(e_g)^1$) and Cu^{I}($S = 1$,$(t_{2g})^6(e_g)^3(4s)^1$). The electronic reorganization for

the $Fe^{II}-O_2-Fe^{II} \rightarrow 2\ Fe^{II}O$ and $Cu^{I}-O_2-Fe^{II} \rightarrow Cu^{I}O + Fe^{II}O$ decomposition processes, which have been associated with the oxidation of Fe^{II} porphyrin complexes[4,6a] and cytochrome c oxidase catalysis[4,6a] of $4\ H^+ + 4e + O_2 \rightarrow 2\ H_2O$, are indicated. Each of these decomposition processes involves the breaking of O−O three-electron bonds as well as the O−O σ-bond.

Increased-Valence Structures and N_2O

Ab initio VB calculations on the $Fe^{II}O_2$ linkage have yet to be performed in order to determine which of the canonical Lewis structures are of primary importance. However the results of both semi-empirical[27] and ab-initio[28,29] calculations have been reported for N_2O, whose Kekulé-type Lewis structure **30** is similar to **24** for $Fe^{II}O_2$. By delocalizing an oxygen $p\pi_x$ and an oxygen $p\pi_y$ electron into bonding π_x(ON) and π_y(ON) MOs respectively, we obtain increased-valence structure **31**, which is similar in type to VB structure **25** for the $Fe^{II}O_2$ linkage.



30 **31**

Using the three-electron bond identity,

, it is easy to deduce that increased-valence structure **31** is equivalent to resonance between the Kekulé-type Lewis structure **30**, and the Dewar-type Lewis structures **32**−**34**, when the wavefunctions for the N−N π_x and π_y bonds are formulated using the Heitler−London type procedure (cf. discussion above for the $Fe=O_2$ bond of VB structure **25**).

32 **33** **34**

The results obtained from a variety of ab initio VB calculations for N_2O are reported in ref.[29] These results, which are in agreement with those obtained from our earlier semi-empirical VB studies,[27] show that the Dewar structures **32** and **33** in particular have an importance which is comparable with those for the familiar Kekulé-type structures **30**, **35**, and **36**.

30 **35** **36**

Resonance between the latter three structures is usually used to provide the primary qualitative VB representation of the electronic structure of N_2O, and of course increased-valence structures can also be generated[5,27,29] from the Lewis structures **35** and **36**, as well as from structure **30**.

The conclusion that N_2O has appreciable singlet diradical character has been exploited to develop VB mechanisms for a variety of reactions which involve this molecule. These reactions include: (a) thermal decomposition[29,30a] to generate either $N_2 + O^*$ or $2\ N_2 + O_2^*$, (b) $N_2O + X \rightarrow N_2 + OX$, for which X is a univalent radical,[29,30a,30b] (c) 1,3-dipolar cycloaddition reactions,[29,30a] (d) a unimolecular

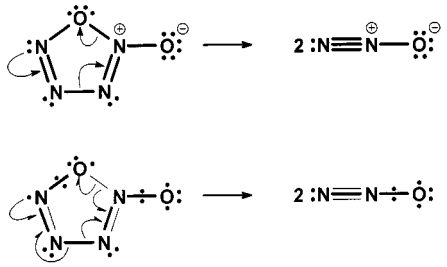


Figure 3. Standard Lewis VB and increased-valence representations for cyclic $N_4O_2 \rightarrow 2\ N_2O$ decomposition; the increased-valence representation involves lower energies for reactant and products

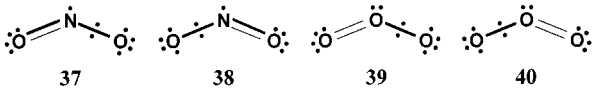
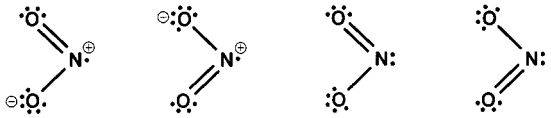
$C_{\infty v} \rightarrow C_{2v} \rightarrow D_{\infty h}$ isomerization process[31] and (e) NO + NCO → N_2O + CO.[5b] For each case, the primary "active space" involves four singly-occupied orbitals, and for them, the Rumer diagrams[30a,30b] allow for the existence of two $S = 0$ spin-pairing schemes − one for a reactant-like species and one for a product-like species. Therefore a crossing of potential energy curves is involved when proceeding from reactants to products[4,30a,30b,32]. The VB representation for the diradical mechanism for decomposition reactions of type (a) is contrasted[30b] with the usual type of polar mechanism that would be used to indicate how electronic reorganization might proceed, via the shifting of pairs of electrons. In Figure 3, these two types of VB representations[30b] are illustrated here for the decomposition of cyclic $N_4O_2 \rightarrow 2\ N_2O$, which has been calculated[33] to arise as an intermediate in the thermal decomposition of N_3-NO_2.



Some ab initio STO-6G VB calculations for N_2 have been performed,[34] in order to illustrate the effect of AO hybridization on the length of the N−N bond of N_2 relative to those of HN_3 and N_2O. For N_2, the electron-pair N−N σ-bond arises from the overlap of hybrid AOs of the form $h \approx 2p\sigma + 0.18(2s)$, whereas for N_2O, this bond involves the overlap of $2p\sigma + 0.18(2s)$ and $2p\sigma + 2s$ hybrid AOs. The results of calculations for N_2 with these two pairs of AOs give a bond shortening of 0.03 Å for the latter pair relative to the former pair. With this estimate, the N−N bond length of 1.13 Å for N_2O is ≈ 0.06 Å longer than is that for an N_2 with $2p\sigma + 0.18(2s)$ and $2p\sigma + 2s$ hybrid AOs. The fractionality of the N−N triple bond in increased-valence structure **31** is in agreement with the appreciable lengthening of the N−N bond of N_2O relative to that of an N_2 with the same AO hybridization.

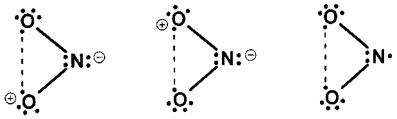
Inspection of increased-valence structure **31** for N_2O reveals that more than eight electrons appear to be involved in bonding to the central nitrogen atom, i.e. an *apparent violation of the Lewis-Langmuir octet rule* occurs for this atom. In each of references 34 and 35, it is demonstrated that this effect is a consequence of the inclusion of the Dewar-type Lewis structures **32**−**34** as well as the Kekulé structure **30** in the canonical structure resonance scheme.



Increased-Valence Structures for NO_2, O_3, and SO_2

Increased-valence structures **37**−**40** for NO_2 and O_3 have now been derived − either from Lewis VB structures via one-electron delocalizations, or from three-electron bond

VB structures for the reactants O + NO and O + O_2 − and displayed on numerous occasions.[4,5,35,36] These increased-valence structures will be used in subsequent discussions.



37 **38** **39** **40**

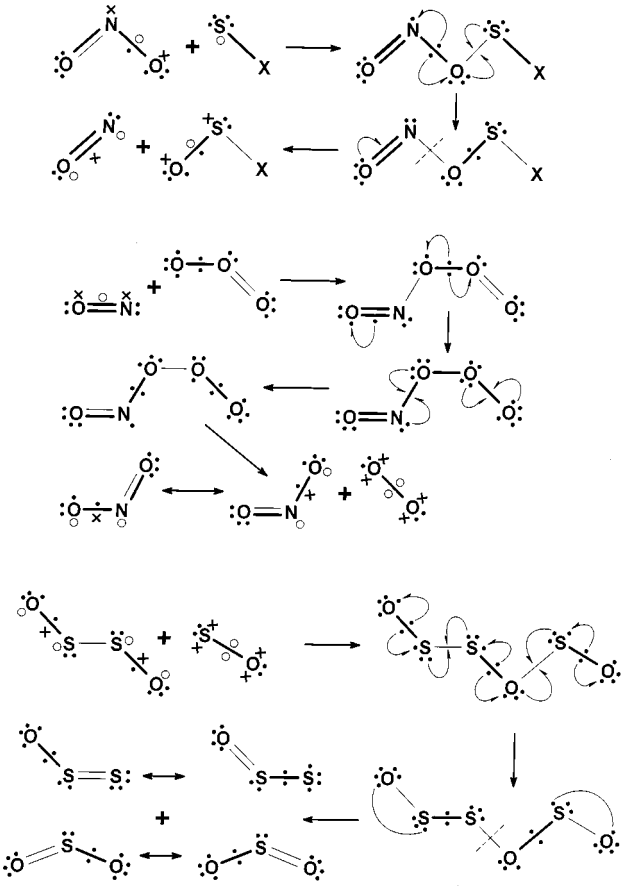
41 **42** **43** **44**

With $\sigma_v\Psi_{37} = \Psi_{38}$ and $\sigma_v\Psi_{38} = \Psi_{37}$, the $\Psi(^2A_1) = \Psi_{37} + \Psi_{38}$ resonance between increased-valence structures **37** and **38** for the ground-state of NO_2 is equivalent[35] to resonance between the canonical Lewis structures **41**−**47**.

45 **46** **47**

When the O−N−O bond-angle of NO_2 is near to the experimental value of 134°, a significant contribution from the Dewar-type Lewis structure **47** has been calculated to occur.[36] This structure is considered[35] to be primarily responsible for the retention of C_{2v} point-group symmetry for the experimentally-observed ground-state. For small bond-angles, the ground-state is calculated[37] to have $^2B_2$ symmetry in the C_{2v} point-group, and structure **47** then does not contribute[35] to the equivalent Lewis structure resonance scheme for $\Psi(^2B_2) = \Psi_{37} - \Psi_{38}$. Consequently for this state, one N−O bond can be stretched relative to the other, and $NO_2 \rightarrow NO + O$ dissociation then becomes possible.[35,36] Similar considerations may be used[35] to account for the $O_3 \rightarrow O_2 + O$ and $CO_2 \rightarrow CO + O$ thermal dissociations.

In Figure 4, increased-valence structures for NO_2 and O_3 are used to indicate how electronic reorganization can proceed for other reactions with these molecules as reactants.[4,5] The mechanisms displayed exploit the singlet diradical character which is present in the increased-valence structures. SO_2 and S_2O are homoelectronic with O_3, and with similar types of increased-valence structures, VB representations[38] for some reactions that involve these sulfur-containing molecules are displayed in Figure 4.



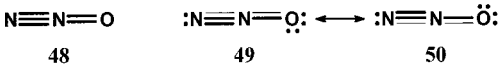


Figure 4. Increased-valence representations for $NO_2 + SX \rightarrow NO + OSX$ (X = halogen), $NO + O_3 \rightarrow NO_2 + O_2$, and $3\,SO \rightarrow SO_2 + S_2O$ via an $S = 1$ spin intermediate S_2O_2 (each of O_2, SO and S_2 has a $^3\Sigma_g^-$ ground-state; therefore an $S = 0 \leftarrow S = 1$ electronic excitation of one of the SO monomers must occur to obtain the $S = 1$ spin intermediate for S_2O_2; the reaction $2\,SO + S_2 \rightarrow 2\,S_2O$ may be similarly represented)

Spin-Coupled Valence-Bond Calculations

Other workers have used their *spin-coupled* VB techniques[3a,3b,39] to study the electronic structures of NO_2, N_2O, and other 1,3-dipolar (or zwitterionic-diradical hybrid)[32a] molecules, such as O_3, CH_2N_2, and HCNO. The calculations allocate a separate orbital for each active-space electron, and consider the different spin-pairing schemes that are available for these electrons. No orthogonality constraints are required for each pair of active-space orbitals in the spin-coupled calculations. These orbitals are designated as "distorted AOs" and may involve two or more atomic centres. Therefore they do not correspond to the one-centre AOs which are associated with the active-space electrons of the canonical Lewis structures.

The results of spin-coupled VB calculations have been interpreted to imply that 1,3-dipolar molecular species possess very little singlet diradical character.[3a,3b,39] For some of these molecules, such as N_2O, a similar conclusion was obtained from *biorthogonal* VB calculations.[40] In contrast, classical VB studies[27−29,36,41] indicate that singlet-diradical canonical Lewis structures can contribute appreciably to the ground-state resonance schemes. The difference in interpretation is associated[5a,28,35] with the use of the 2-centre or multicentre "distorted" AOs to accommodate at least some of the active-space electrons in the spin-coupled VB calculations. The use of these AOs conceals[5a,28,35] the presence of appreciable singlet-diradical character, which manifests itself in VB representations for reactions that involve 1,3-dipolar molecules[29−32] (for example, $NO + O_3 \rightarrow NO_2 + O_2$ in Figure 4).

48 **49** **50**

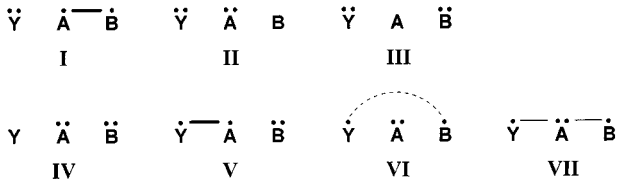

Figure 5. Canonical Lewis VB structures for $S = 0$ spin 4-electron 3-centre bonding unit, with three overlapping AOs; $\Psi_{\mathbf{I}} = |y^{\alpha}y^{\beta}a^{\alpha}b^{\beta}| + |y^{\alpha}y^{\beta}b^{\alpha}a^{\beta}|$, $\Psi_{\mathbf{II}} = |y^{\alpha}y^{\beta}a^{\alpha}a^{\beta}|$, $\Psi_{\mathbf{III}} = |y^{\alpha}y^{\beta}b^{\alpha}b^{\beta}|$, $\Psi_{\mathbf{IV}} = |a^{\alpha}a^{\beta}b^{\alpha}b^{\beta}|$, $\Psi_{\mathbf{V}} = |y^{\alpha}a^{\beta}b^{\alpha}b^{\beta}| + |a^{\alpha}y^{\beta}b^{\alpha}b^{\beta}|$, $\Psi_{\mathbf{VI}} = |y^{\alpha}a^{\beta}a^{\alpha}b^{\beta}| + |a^{\alpha}y^{\beta}b^{\alpha}a^{\beta}|$; with either a (non-orthogonal) double-zeta basis set, or an (orthogonal) expanded valence-shell AO basis set (a,d) for the two electrons on atom A in structure **VI**, canonical Lewis structure **VII** will also contribute to the VB resonance scheme; using the (a,d) basis, y-a and d-b spin-pairings give $\Psi_{\mathbf{VII}} = |y^{\alpha}a^{\beta}d^{\alpha}b^{\beta}| + |y^{\alpha}a^{\beta}b^{\alpha}d^{\beta}| + |a^{\alpha}y^{\beta}b^{\alpha}d^{\beta}| + |a^{\alpha}y^{\beta}d^{\alpha}b^{\beta}|$; a second $S = 0$ spin wavefunction, with a-d and y-b spin-pairings, may also be constructed

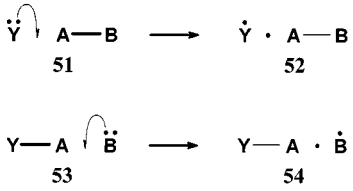
A 19th century-type of VB representation for N_2O is **48**, and a 20th century equivalent, **49** ↔ **50**, involve an apparent quinquevalence for the central nitrogen atom. VB structures of type **48** have been used frequently in discussions of the results of spin-coupled VB calculations. With a minimal basis set, it has been calculated that increased-valence structure **31** is more stable than the **49** ↔ **50** resonance.[42]



Increased-Valence Structures and 4-Electron 3-Centre Bonding

I shall now redescribe and develop further some of the general VB theory for 4-electron 3-centre bonding units, i.e. for four electrons distributed amongst three overlapping AOs located on three atomic centres.[4,5,30a,34,35,43]

For each of $Fe^{II}O_2$ and N_2O, there are two 4-electron 3-centre bonding units. For the purpose of the following discussion, it is easier to focus attention on those for N_2O. These bonding units arise from the presence of four π_x electrons and four π_y electrons, which are distributed between three overlapping $2p_x$ and three overlapping $2p_y$ AOs, respectively. For each $S = 0$ spin 4-electron 3-centre bonding unit, there are six[42,43] canonical Lewis VB structures, namely **I**−**VI** of Figure 5, in which Y, A, and B are the atomic centres, and y, a, and b are the associated (normalized) overlapping AOs. Each of the structures **I**, **V**, and **VI** has two singly occupied AOs, and their $S = 0$ spin wavefunctions are indicated in the caption for Figure 5.

Structures **I** and **V** are Kekulé-type structures, structure **VI** is a Dewar-type structure, and structures **II**−**IV** are of the polar type.

For any 4-electron 3-centre bonding unit, increased-valence structures[4,5,30a,34,35,43] may be constructed from Kekulé-type Lewis structures by delocalizing a non-bonding Y or B electron into a bonding Y−A or A−B MO, as is indicated in **51** → **52** and **53** → **54**.

The delocalized electron occupies the bonding localized MO (LMO) $\psi_{ay} = a + ly$ in structure **52** and the bonding LMO $\psi_{ab} = a + kb$ in structure **54**. When $\Psi_{\mathbf{I}}$ and $\Psi_{\mathbf{V}}$ are assumed to be the wavefunctions (cf. Figure 5) for structures **51** and **53** it follows that **52** ≡ **I** ↔ **VI** and **54** ≡ **V** ↔ **VI**, i.e. in each case, the increased-valence structure is equivalent to resonance between the Kekulé and Dewar canonical Lewis structures. Because of the absence of either an A−B or a Y−A electron-pair bond in the Dewar structure **VI**, the A−B bond in **52** and the Y−A bond of **54** are fractional electron-pair bonds.

The increased-valence structure **54** involves the $(y)^1(a)^1(\psi_{ab})^1(b)^1$ configuration. We have already demonstrated that the A-B three-electron bond configuration $(a)^1(\psi_{ab})^1(b)^1$ is proportional to the MO configuration $(\psi_{ab})^2(\psi^*_{ab})^1$, [cf. Equations (1) and (2), and Figure 1]. Therefore $(y)^1(a)^1(\psi_{ab})^1(b)^1$ is proportional to $(y)^1(\psi_{ab})^2(\psi^*_{ab})^1$, i.e. increased-valence structure **54** involves the spin-pairing of the y electron with the antibonding ψ^*_{ab} electron of the A-B three-electron bond. [In terms of Slater determinants, the $S = 0$ spin wavefunction is give by Equation (3).]

$$\Psi_{\mathbf{54}} = |y\beta a\alpha\psi_{ab}\beta b\alpha| + |y\alpha a\beta\psi_{ab}\alpha b\beta| \propto |y\beta\psi_{ab}\alpha\psi_{ab}\beta\psi^*_{ab}\alpha| + |y\alpha\psi_{ab}\beta\psi_{ab}\alpha\psi^*_{ab}\beta| \quad (3)$$

Consideration has been[34] given to the evaluation of atomic valencies for increased-valence structure **54**, with AO overlap integrals both excluded and included in the definition of valence. It has been demonstrated that the A-atom valence is able to exceed unity in this structure, whereas in each of the Kekulé-type Lewis structures, **I** and **V**, the A-atom valence is unity. Therefore with regard to its A-atom valence, VB structure **54** (and also **52**) may exhibit "increased-valence" relative to the Kekulé-type Lewis structures.

The results of experimental and theoretical studies of HXY-type rare-gas molecules (X = Kr or Xe; Y = Cl, Br, I, CN, ...) have been reviewed recently.[45] The H, X, and Y then correspond to the Y, A, and B of Figure 5. With X = Xe and Y = Cl, the origin of bonding is considered to be described[45,46] best as primarily an ion pair  , which is equivalent to structure **V** of Figure 5. However at non-dissociative interatomic distances, it will interact with , which corresponds to structure **VI** of Figure 5. Resonance between these canonical Lewis structures generates increased-valence structure **54** as  .

Increased-Valence Structures and Expansion of Valence-Shell

To stabilize further a 4-electron 3-centre bonding unit, additional AOs may be included on the atomic centres. We focus attention on the A-atom of increased-valence structure **54** by including a second orthogonal AO, which we designate as d. We now define a new A−B bonding MO as $\psi_{a'b} = a + kb + k'd = \psi_{ab} + k'd$. The resulting

$(y)^1(a)^1(\psi_{a'b})^1(b)^1$ configuration, (whose $S = 0$ spin wavefunction involves four Slater determinants, cf. $\Psi_{\mathbf{VII}}$ of Figure 5), may then be expressed according to Equation (4).

$$(y)^1(a)^1(\psi_{a'b})^1(b)^1 = (y)^1(a)^1(\psi_{ab})^1(b)^1 + k'(y)^1(a)^1(d)^1(b)^1 \quad (4)$$

$$\rightarrow \Psi_{\mathbf{54}}(k'=0) + k''\Psi_{\mathbf{VII}} \quad (5)$$

For $\Psi_{\mathbf{54}}(k' = 0)$, spin-pairing occurs between the y and ψ^*_{ab} electrons, whereas $\Psi_{\mathbf{VII}}$ involves y-a and d-b spin-pairings. Introduction of the d AO enables allowance for expansion of the A-atom valence-shell to occur via use of an increased-valence structure. To provide an example, we consider the axial F−Cl−F σ-bonding for ClF_3 of Figure 6.

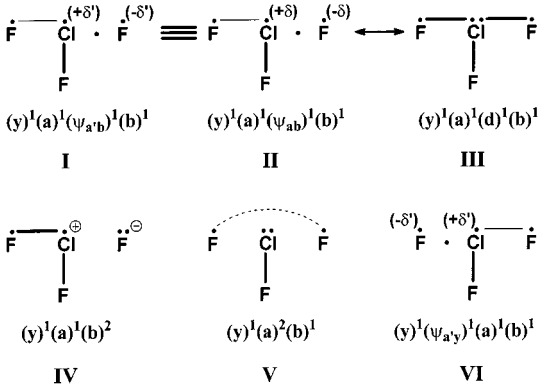


Figure 6. Increased-valence structures **I** and **VI** for ClF_3 with expanded valence-shell on the Cl atom; for the axial three-centre bonding, y, a, b and d are 2pσ(F), 3pσ(Cl), 2pσ(F) and $3d_{z^2}$(Cl) AOs; $\psi_{a'b} = a + kb + k'd = \psi_{ab} + k'd$, $\psi_{a'y} = a + ky + k'd = \psi_{ay} + k'd$, with y-a and $\psi_{a'b}$-b spin-pairings for structure **I** and b-a and $\psi_{a'y}$-y spin-pairings for structure **VI** (cf. $\Psi_{\mathbf{VII}}$ for structure **VII** in Figure 5)

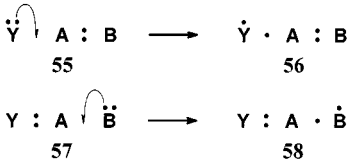
If y = F($2p_z$), a = Cl($3p_z$), b = F($2p_z$), and d = Cl($3d_{z^2}$), then increased-valence structure **I** for ClF_3 is equivalent to resonance between the increased-valence structure **II** ($k' = 0$) and the expanded valence-shell structure **III**. In turn, increased-valence **II** ($k' = 0$) is equivalent to resonance between the canonical Lewis structures **IV** and **V** of Figure 6. A similar type of identity may be developed for the mirror-image increased-valence structure **VI** of Figure 6.

In ref.[35], analagous theory has also been developed for a double-zeta basis set (with a′ and a′′ AOs replacing the a and d AOs) on the A-atom. In subsequent discussions we shall not consider explicitly either double-zeta basis sets or expansion of the valence shell, but recognize that when appropriate, these types of basis sets may be introduced into the wavefunction for an increased-valence structure.



Numerous MO studies of the phenomenon of valence-shell expansion have been reported.[47] The difficulty for atoms of first-row elements to form many stable hypercoordinate compounds has been associated[34,43] with large values for the ionization energies of A-atoms in Lewis structures of type **VI** in Figure 5, when A is a first-row atom.

Localized MO Increased-Valence Structures

The identities **52** ≡ **I** ↔ **VI** and **54** ≡ **V** ↔ **VI** utilize the a and b AOs to accommodate the electrons of the fractional A-B electron-pair bond in increased-valence structure **52**, and the y and a AOs of the fractional Y−A electron-pair bond in increased-valence structure **54**. For a more general formulation of these bonds, these AOs are replaced by the Coulson−Fischer-type[48] LMOs of Equations (6) and (7) for the fractional A−B and Y−A bonds, respectively. The LMO VB structures that correspond to the canonical Kekulé structures **I** and **V** and the increased-valence structures **52** and **54**, are symbolized[5,30a,43] as **55** and **57**, and **56** and **58**, respectively, for which **55** ≡ **I**↔**II**↔**III**, **57** ≡ **V**↔**IV**↔**III**, and structures **I**−**V** here are those of Figure 5.

$$\psi''_{ab} = a + k''b,\ \psi'_{ba} = b + k'a \quad (6)$$

$$\psi''_{ay} = a + l''y,\ \psi'_{ya} = y + l'a \quad (7)$$

In the LMO Kekulé-type structures **55** and **57**, the one-electron delocalization that is needed to generate the LMO increased-valence structures **56** or **58** is indicated. As is the case for the (Heitler−London-type) increased-valence structures **52** and **54**, the delocalized electron occupies the Y−A bonding LMO $\psi_{ay} = a + ly$ in increased-valence structure **56**, and the A−B bonding LMO $\psi_{ab} = a + kb$ in increased-valence structure **58**. The A-atom valence in the LMO increased-valence structures **56** and **58** can exceed unity,[30a,43] and a demonstration of this result is provided again in the Appendix.

LMO Increased-Valence Structures and Donor-Acceptor Complexes

The simplest types of $S = 0$ spin wavefunctions for the LMO increased-valence structures **56** and **58** are those of Equations (8) and (11) respectively.[30a,43]

$$\Psi_{\mathbf{56}} = |\psi'_{ba}\alpha\psi''_{ab}\beta\psi_{ay}\alpha y\beta| + |\psi''_{ab}\alpha\psi'_{ba}\beta y\alpha\psi_{ay}\beta| \quad (8)$$

$$\Psi_{\mathbf{56}} = l\{(1 + k'k'')\Psi_{\mathbf{I}} + 2k'\Psi_{\mathbf{II}} + 2k''\Psi_{\mathbf{III}}\} + k''\Psi_{\mathbf{V}} + \Psi_{\mathbf{VI}} \quad (9)$$

$$\Psi_{\mathbf{56}} = l\Psi_{\mathbf{55}} + \Psi_{\mathbf{54}}'' \quad (10)$$

$$\Psi_{\mathbf{58}} = |\psi'_{ya}\alpha\psi''_{ay}\beta\psi_{ab}\alpha b\beta| + |\psi''_{ay}\alpha\psi'_{ya}\beta b\alpha\psi_{ab}\beta| \quad (11)$$

$$\Psi_{\mathbf{58}} = k\{(1 + l'l'')\Psi_{\mathbf{V}} + 2l'\Psi_{\mathbf{IV}} + 2l''\Psi_{\mathbf{III}}\} + l''\Psi_{\mathbf{I}} + \Psi_{\mathbf{VI}} \quad (12)$$

$$\Psi_{\mathbf{58}} = k\Psi_{\mathbf{57}} + \Psi_{\mathbf{52}}'' \quad (13)$$

When the AO expressions for ψ_{ay}, ψ_{ab} and the LMOs of Equations (6) and (7) are substituted into Equations (8) and (11), we obtain the linear combinations of Equations (9) and (12) respectively. These linear combinations show that the Dewar structure **VI** of Figure 5 is included in the equivalent canonical structure resonance schemes for the LMO increased-valence structures **56** and **58**. Equations (9)

and (12) are also equivalent to Equations (10) and (13) respectively, in which the the $\Psi_{54''}$ and $\Psi_{52''}$ correspond to Ψ_{54} and Ψ_{52} when k'' and l'' replace k and l in the latter configurations.

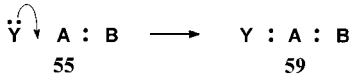
The lower-energy linear combination of Ψ_{56} and Ψ_{58}, via Equation (14), has seven variational parameters (k, l, k', k'', l', l'', and μ) whereas the lowest-energy linear combination of the $\Psi_{\mathbf{I}}-\Psi_{\mathbf{VI}}$ of Figure 5 involves five independent variational parameters. One type of correspondence between the two linear combinations is obtained when l' and l'' are set equal to k' and k'' respectively.

$$\Psi(\text{Increased-valence, LMO}) = \Psi_{56} + \mu\Psi_{58} \tag{14}$$

Each of Equations (10) and (13) represents a Mulliken-type wavefunction[30a,43] for either an intra- or an intermolecular complex when the complex involves an n-type donor (D), and a sacrificial acceptor (A). The simplest Mulliken-type representation for such a complex involves resonance between a "no bond" (D,A) and a dative (D^+-A^-) VB structure.[22] Thus when $\ddot{\mathbf{Y}}$ and **A : B** are identified as an electron-donor and an electron-acceptor, the VB structures **55** and **54** correspond to the (D,A) and (D^+-A^-) structures respectively, and according to Equation (10), increased-valence structure **56** is equivalent to resonance between these two structures. Similarly, increased-valence structure **58** is equivalent to resonance between (D,A) and (D^+-A^-) types of VB structures, with D = $\ddot{\mathbf{B}}$, A = **Y : A**, (D,A) = **57** and (D^+-A^-) = **52**. In each of the increased-valence structures, a one-electron bond links the donor to the acceptor.

One-Electron and Concerted Two-Electron Delocalizations into Bonding and Antibonding Molecular Orbitals

When $k'' = 1/k' = k$ in Equation (6), an approximate LMO wavefunction for VB structure **55** is given by Equation (15).



$$\psi_{\mathbf{55}} = |y^{\alpha}y^{\beta}\psi_{ab}{}^{\alpha}\psi_{ab}{}^{\beta}| \tag{15}$$

Some (concerted) delocalization of the y electrons into the antibonding MO $\psi^*_{ab} = k^*a - b$ generates the *approximate* MO wavefunction[49,50] of Equation (16), which provides the usual approximate MO formulation for the anomeric effect[51] and negative hyperconjugation.[52]

$$\Psi_1(\text{MO}) = |(y + \lambda\psi^*_{ab})^{\alpha}(y + \lambda\psi^*_{ab})^{\beta}\psi_{ab}{}^{\alpha}\psi_{ab}{}^{\beta}| \tag{16}$$

$$\Psi_1(\text{MO}) \equiv |y^{\alpha}y^{\beta}\psi_{ab}{}^{\alpha}\psi_{ab}{}^{\beta}| + \lambda(|y^{\alpha}\psi^*_{ab}{}^{\beta}\psi_{ab}{}^{\alpha}\psi_{ab}{}^{\beta}| + |\psi^*_{ab}{}^{\alpha}y^{\beta}\psi_{ab}{}^{\alpha}\psi_{ab}{}^{\beta}|) + \lambda^2|\psi^*_{ab}{}^{\alpha}\psi^*_{ab}{}^{\beta}\psi_{ab}{}^{\alpha}\psi_{ab}{}^{\beta}| \tag{17}$$

When the y electrons of structure **55** are delocalized into the Y−A bonding MO $\psi_{ya} = y + la$, according to **55** → **59**, the resulting wavefunction is given by Equation (18).

$$\psi_{\mathbf{59}} = |\psi_{ya}{}^{\alpha}\psi_{ya}{}^{\beta}\psi_{ab}{}^{\alpha}\psi_{ab}{}^{\beta}| \tag{18}$$

$$\psi_{\mathbf{59}} \equiv |y^{\alpha}y^{\beta}\psi_{ab}{}^{\alpha}\psi_{ab}{}^{\beta}| + l\{|y^{\alpha}a^{\beta}\psi_{ab}{}^{\alpha}\psi_{ab}{}^{\beta}| + |a^{\alpha}y^{\beta}\psi_{ab}{}^{\alpha}\psi_{ab}{}^{\beta}|\} + l2|a^{\alpha}a^{\beta}\psi_{ab}{}^{\alpha}\psi_{ab}{}^{\beta}| \tag{19}$$

Introduction of the identities $|\psi^*_{ab}{}^{\alpha}\psi_{ab}{}^{\alpha}| = (kk^* + 1)|a^{\alpha}b^{\alpha}|$ and $|\psi^*_{ab}{}^{\beta}\psi_{ab}{}^{\beta}| = (kk^* + 1)|a^{\beta}b^{\beta}|$ into Equation (17), and the identities $|a^{\alpha}\psi_{ab}{}^{\alpha}| = k|a^{\alpha}b^{\alpha}|$ and $|a^{\beta}\psi_{ab}{}^{\beta}| = k|a^{\beta}b^{\beta}|$ into Equation (19), we obtain[49] Equations (20) and (21), in which $\Psi_{\mathbf{IV}}$ is the wavefunction for VB structure **IV** of Figure 5. The $\Psi_1(\text{MO})$ and $\psi_{\mathbf{59}}$ are equivalent[49] when $\lambda = kl/(kk^* + 1)$. Therefore some concerted delocalization of the two lone-pair electrons of donor $\ddot{\mathbf{Y}}$ of VB structure **55** into the vacant *antibonding* MO of acceptor **A : B** is equivalent to the concerted delocalization of these electrons into the Y−A *bonding* MO, to give VB structure **59**.

$$\Psi_1(\text{MO}) \equiv \Psi_{\mathbf{55}} + \lambda(kk^* + 1)\Psi_{\mathbf{54}} + (kk^* + 1)^2\lambda^2\Psi_{\mathbf{IV}} \tag{20}$$

$$\psi_{\mathbf{59}} \equiv \Psi_{\mathbf{55}} + kl\Psi_{\mathbf{54}} + k^2l^2\Psi_{\mathbf{IV}} \tag{21}$$

VB Representations for Gas-Phase Nucleophilic Substitution Reactions

If Ÿ is a nucleophile and A:B is a substrate, then at each stage along the reaction coordinate, resonance between the LMO increased-valence structures **56** and **58** can be used to provide a "variationally-best" VB representation [cf. Equation (14)] for a gas-phase nucleophilic substitution reaction. In several publications,[5,30a,43,53] the generalized VB representation for this type of reaction has been presented. Here we consider a specific example, namely that of **I** → [**II** ↔ **III**] → **IV** of Figure 7 for the (Grotthuss) proton-transfer reaction $H_2O + H_3O^+ \rightarrow H_3O^+ + H_2O$. The LMO increased-valence structures **II** and **III** of Figure 7 are VB structures for reactant-like and product-like complexes respectively, and are formed via the one-electron delocaliz-

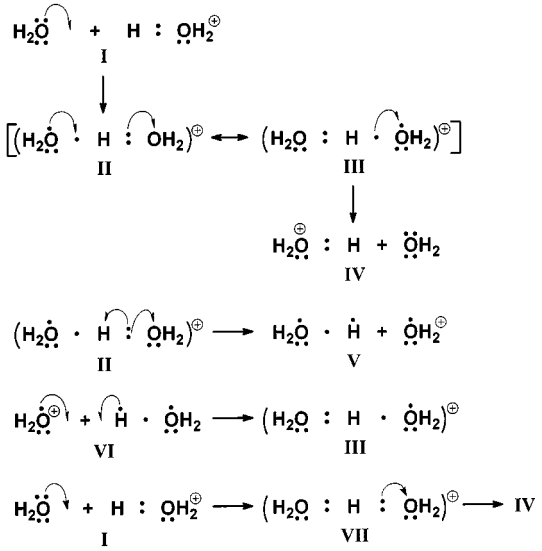


Figure 7. Valence-bond representations for the gas-phase proton-transfer reaction $H_2O + H_3O^+ \rightarrow H_3O^+ + H_2O$

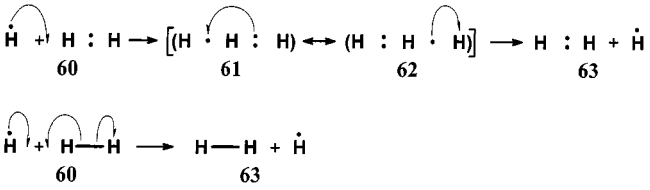
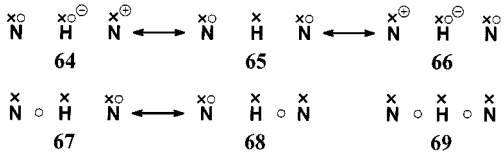
ations that are indicated in this Scheme. At the conclusion of the reaction, the reactant-like complex **II** would dissociate according to **II** → **V** of Figure 7, whereas near the commencement of the reaction, the formation of the product-like complex **III** proceeds according to **VI** → **III** of Figure 7.



In ref.[5b,30a,53], the generalized forms of VB structures **I**−**VI** of Figure 7 have been used to construct state correlation diagrams for the conversion of reactants into products. These diagrams use a VB symbolism which differs from the symbolism used by Shaik and co-workers[3f] for this purpose. Shaik and co-workers[3f] use VB structures of type **2** to represent the three-electron bond structures − for example $HO_2 \therefore H$ and $H \therefore OH_2$ for the H_3O structures **V** and **VI**.

A qualitative MO description for nucleophilic substitution reactions is often formulated approximately according to the Ψ_1(MO) of Equation (16), i.e. electrons delocalize from the nucleophile orbital (y) into the antibonding MO (ψ^*_{ab}) of the substrate. As has been deduced above, this delocalization is equivalent to the concerted delocalization of the y electrons into the bonding MO (ψ_{ya}), according to **55** → **59**, or **I** → **VII** of Figure 7 here. According to Equation (20), the Ψ_1(MO) configuration of Equation (16) alone cannot generate the $H_3O^+ + H_2O$ products; the inclusion of the Ψ_{IV} (of Figure 5) of this Equation, to give an $H_2O^{2+}H_3O^-$ structure, prevents this from occurring. To obtain the correct dissociation products, it is then necessary to form[49] the linear combination $\Psi = C_1\Psi_1(MO) + C_2\Psi_2(MO)$, with Ψ_2(MO) given by Equation (22), in which $\psi_{ay} = a + \kappa y$ and $\psi^*_{ay} = \kappa^* a - y$. The LMO equivalent for this type of linear combination is examined in ref.[43], where it is demonstrated that the formation of the primary contributor to the VB representation of a reactant-like complex must proceed according to an initial *one-electron* delocalization, as in **I** → **II** of Figure 7, rather than by the *concerted electron-pair* delocalization which is associated with the Ψ_1(MO) of Equation (16).

$$\Psi_2(MO) = |(b + \lambda'\psi^*_{ay})^\alpha (b + \lambda'\psi^*_{ay})^\beta \psi_{ay}{}^\alpha \psi_{ay}{}^\beta| \qquad (22)$$



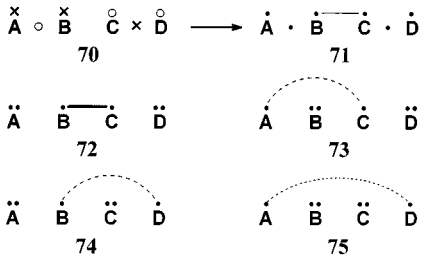
Three-Electron Three-Centre Bonding and VB Representations for Gas-Phase Radical Transfer Reactions

Although 3-electron 3-centre bonding units are not electron-rich, it is possible to construct increased-valence structures for them. The LMO VB structures **61** and **62** for H_3 in the formulation[54] **60** → [**61** ↔ **62**] → **63** for the radical transfer reaction H + H_2 → H_2 + H, provide examples. These structures represent reactant-like and product-like intermolecular species, respectively. The formulation **60** → [**61**↔**62**] → **63** indicates succinctly the nature of the electronic reorganization which may be involved in the conversion of reactants into products for a radical transfer reaction. This formulation is equivalent to the variationally best resonance between the eight (S = 1/2 spin) canonical Lewis structures that may be constructed from three overlapping AOs.[54] The electronic reorganization is also equivalent to the more familiar formulation of **60** → **63**.

Five-Electron Three-Centre Bonding

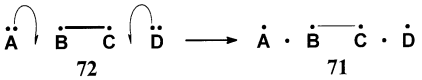
Each of NO_2, SO_2^-, and ClO_2 has a 5-electron 3-centre bonding unit;[5c,36,55] five electrons are distributed amongst three overlapping σ AOs (NO_2) or π-electron AOs (SO_2^- and ClO_2, when it is assumed that sulfur and chlorine 3d AOs do not participate in π-bonding as hybridization functions). For this type of bonding unit, three equivalent VB representations may be constructed,[5c,36,55] which we illustrate here for the NHN linkage[56] that arises when two nitrogen atoms are linked by a hydrogen atom in medium-ring bicyclic compounds.

(a) Resonance between the canonical Lewis structures **64**, **65**, and **66**.



(b) Resonance between the three-electron bond structures **67** and **68**.

(c) The VB structure **69**, with two (non-independent) three-electron bonds.



The wavefunction for each of these sets of VB structures is also equivalent[4,5c,36,55] to the 3-centre MO configuration $(\psi_1)^2(\psi_2)^2(\psi_3)^1$ for the five electrons.

Six-Electron Four-Centre Bonding: Theory

Six-electron 4-centre bonding units involve six electrons distributed amongst four overlapping AOs[4,5,57] located around four atomic centres. An increased-valence structure for an extended 6-electron 4-centre bonding unit is obtained[4,5,57a,57b] by spin-pairing in a Heitler−London manner the odd electrons of two three-electron bonds structures AB and CD, as is indicated in **70** → **71**.

Increased-valence structure **71** is equivalent to resonance between the canonical Kekulé structure **72** and the canonical Dewar structures **73**−**75**, and may also be derived[4,5,57] from the Kekulé structure **72** by delocalizing a non-bonding a and a non-bonding d electron into the A-B bonding MO and the C-D bonding MO, respectively.

72 **71**

For symmetrical 6-electron 4-centre bonding units it has been deduced[4,5c,57a] that Ψ_{71} is equivalent to the covalent component of the MO configuration $|\psi_1^{\alpha}\psi_1^{\beta}\psi_2^{\alpha}\psi_2^{\beta}\psi_3^{\alpha}\psi_3^{\beta}|$ with $\psi_1 = a + d + \lambda(b + c)$, $\psi_2 = a - d + k(b - c)$, $\psi_3 = \lambda^*(a + d) - (b + c)$, when the MO configuration is expressed as $\Psi_{covalent} + \Psi_{ionic}$. Configuration interaction increases the importance of $\Psi_{covalent}$ relative to Ψ_{ionic}. Theory for non-symmetrical 6-electron 4-centre bonding units is described in ref.[57d]

For a cyclic 6-electron 4-centre bonding unit, increased-valence structures **76** and **77** may be constructed.[4,5][57c] Resonance between these structures corresponds to the covalent component of a three-configuration MO-CI wavefunction.[5c,57c] It is also equivalent to resonance between four canonical Kekulé-type Lewis structures and two canonical Dewar-type Lewis structures.

76 **77**

Six-Electron Four-Centre Bonding: Some Applications

Over the last decade, we have studied the following systems, each of which involves one or more 6-electron 4-centre bonding units.

(a) $OClOClO_2$, to demonstrate that the existence of long intermolecular O−Cl bonds between the two ClO_2 moieties[58] is associated[55] with the presence of a Cl−O three-electron bond in each of these moieties.

(b) N_2O_4, N_2O_3, and N_2O_2 to account for variations in their N−N bond lengths (1.78 Å, 1.86 Å and 2.24 Å)[5b,59a,59b,60c] relative to the 1.45 Å for N_2H_4. The bond lengthenings are shown to be due primarily to (i) delocalization of oxygen lone-pair electrons into the AOs of the N−N σ-bond (N_2O_4), (ii) delocalization of NO_2-oxygen lone-pair electrons into the AOs of the N−N σ-bond and the orientations of the NO-nitrogen AOs, to give a (fractional) bent N−N σ-bond (N_2O_3), and (iii) orientations of the NO-nitrogen AOs to give a (fractional) bent N−N σ-bond, together with the consequent strong non-bonded repulsions between the nitrogen lone-pair electrons (N_2O_2).

(c) The D_{2h} and D_{2d} isomers of N_2O_4, in order to demonstrate[59c,60a] that *cis* O−O overlap in the planar conformer is primarily responsible for the barrier to rotation around the N−N bond of this species. The *cis* O−O overlap manifests itself in a stabilizing manner by appreciable delocalization of oxygen lone-pair electrons into the AOs of the N−N σ-bond, and covalent-ionic resonance (i.e. $O_2N-NO_2 \leftrightarrow O_2N^+NO_2^- \leftrightarrow O_2N^-NO_2^+$) is calculated to be needed to enhance this stabilizing effect.

(d) $S_2Cl_4^{2+}$,[57b] the linear cation $ICNI^+$,[57d] the N−N dimer of HNO,[60b] the D_{2h} dimer of O_2,[60d] and S_2N_2.[60e]

In Figure 8, increased-valence structures **I-III** are displayed for S_2O_2, $S_2O_4^{2-}$, and $S_2I_4^{2+}$, together with experimental estimates[4,38] for their bond lengths and those for S_2, SO, I_2^+, and "normal" S−S and S−I single bonds.The increased-valence structures are derived from either or both of the **70** → **71** or the **72** → **71** types processes for 6-electron 4-centre bonding units. Inspection of structures **I**−**III** reveals that the bond-orders implied by them are in qualitative accord with the experimental S−S, S−O, S−I, and I−I bond lengths for S_2O_2, $S_2O_4^{2-}$, and $S_2I_4^{2+}$. For example, the S−S bond order is less than two in **I**, less than unity in **II**, and equal to two in **III**, and the S-S lengths for S_2O_2, $S_2O_4^{2-}$, and $S_2I_4^{2+}$ are respectively longer than a double bond, longer than a single bond and somewhat shorter than a double bond.

In Figure 9, increased-valence structures for cyclic S_2N_2 are derived[60e] from the familiar zwitterionic Lewis structures via **72** → **71** type delocalizations. VB representations[38,61] for $S_2N_2 \rightarrow (SN)_x$ polymerization and electron conduction in the $(SN)_x$ polymer, are also displayed in Figure 9.

The Antiferromagnetism of the Copper Acetate Dimer

A 6-electron 4-centre bonding unit[5a,5c,62] is present in each $Cu^{II}(CH_3COO^-)Cu^{II}$ component of antiferromagnetic[63] $Cu_2(CH_3COO)_4 \cdot 2\,H_2O$, for which $J = (E_{singlet} - E_{triplet})/2 = -143\ cm^{-1}$.[63] It arises from the overlap of singly occupied $3d_{x^2-y^2}$ AOs on the Cu^{II} ions with a lone-pair AO on each oxygen atom of the CH_3COO^- ligand

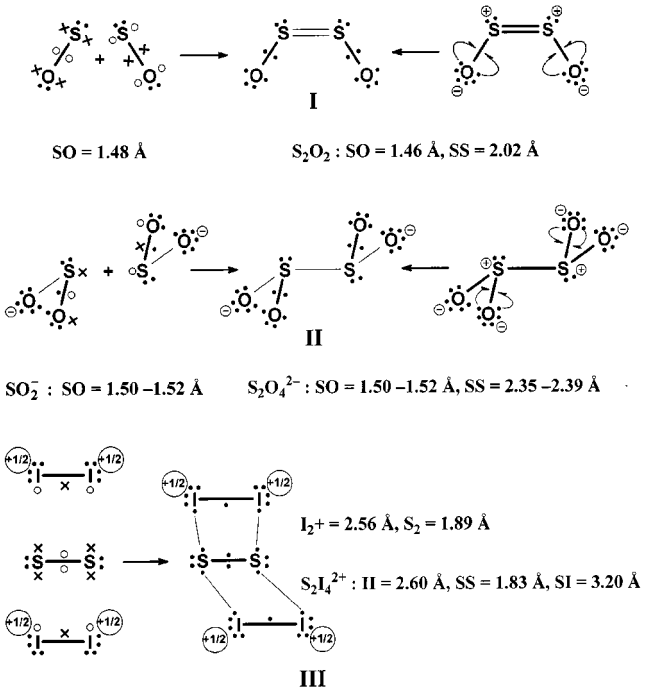


Figure 8. VB structures and bond-lengths for SO, S_2, SO_2^-, I_2^+, S_2O_2, $S_2O_4^{2-}$, and $S_2I_4^{2+}$ with 6-electron 4-centre bonding units; the increased-valence structure for SO_2^- is obtained by replacing the halogen X by O^- in the increased-valence structure displayed for XSO in Figure 4; estimates of the lengths of "normal" S−O, S−S, S−I, and I−I single bonds are 1.70, 2.06, 2.37, and 2.67 Å, respectively[4]

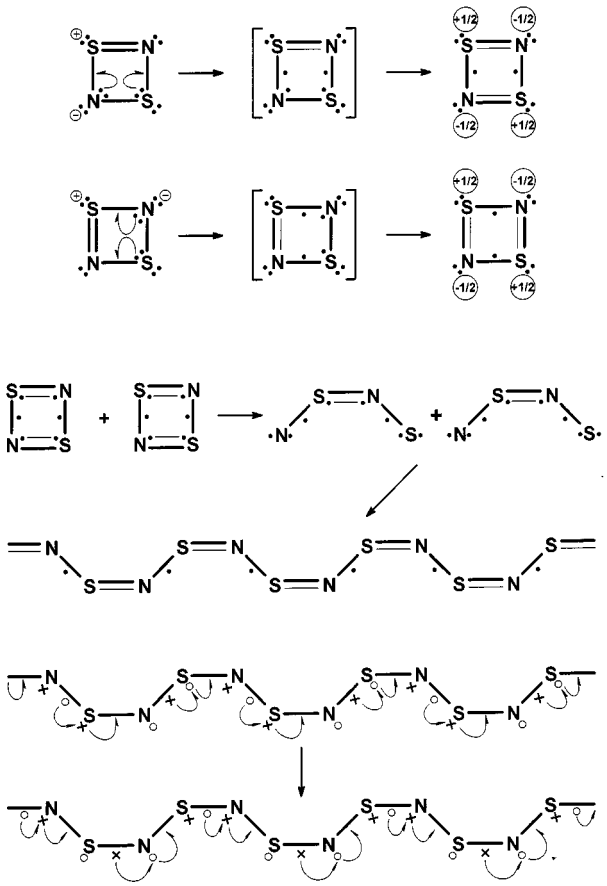

Figure 9. Derivation of increased-valence structures for S_2N_2, and VB representations for $S_2N_2 \rightarrow (SN)_x$ polymerization and electron conduction in $(SN)_x$

(Figure 10). The A and D atoms of VB structure **72** are the oxygen atoms, and B and C are the copper atoms. The oxygen lone-pair AOs overlap to a small extent, as do the $3d_{x^2-y^2}$ AOs. The origin of the antiferromagnetism has been associated primarily with superexchange, i.e. some delocalization of the oxygen lone-pair electrons into the singly-occupied $3d_{x^2-y^2}$ AOs, together with covalent-ionic resonance $[(CuO)(CuO) \leftrightarrow (CuO)^-(CuO)^+ \leftrightarrow (CuO)^+(CuO)^-]$.[5a,5c,62]

The primary type of covalent-ionic resonance involves[5a,5c,62] the $S = 0$ and $S = 1$ spin VB structures of Figure 10. These structures arise by the delocalization of one oxygen lone-pair electron into a singly-occupied copper AO. The $S = 0$ spin covalent and ionic structures correspond to the generalized Lewis structures of types **73** and **74** above, and **78** and **79**, respectively. (For the corresponding $S = 1$ structures, the two electrons that singly occupy AOs have parallel spins.) Because the AO overlap between the singly occupied non-adjacent AOs is small, the covalent VB structures are essentially degenerate, i.e. ${}^3E_{cov} \approx {}^1E_{cov} = E_{cov}$. It may be deduced[64] that the resulting expression for the magnetic exchange parameter that arises from these types of covalent-ionic resonance is approximately given by $J = (\beta_{bc} + \beta_{ad})^2 J_{CuO}/({}^1E_{ion} - E_{cov})^2$, in which β_{bc} and β_{ad} are O−O and Cu−Cu overlap-dependent resonance integrals, and J_{CuO} is the (negative) exchange integral for the

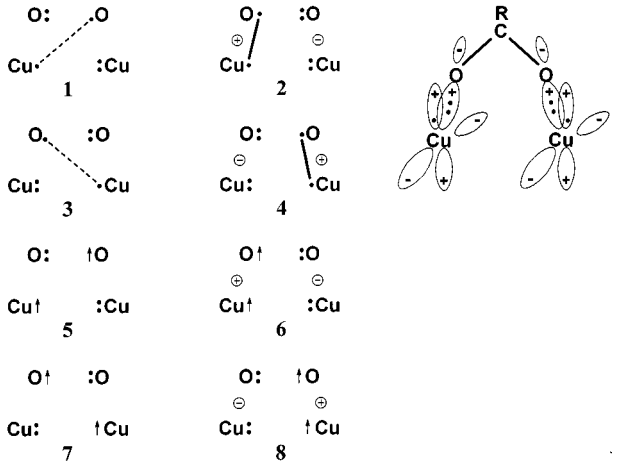

Figure 10. AOs for a 6-electron 4-centre bonding unit of $Cu^{II}(CH_3COO^-)Cu^{II}$,[5c] and the associated primary Lewis-type VB structures for a VB rationalization of the origin of the antiferromagnetism of Cu^{II} carboxylate dimers[5c]

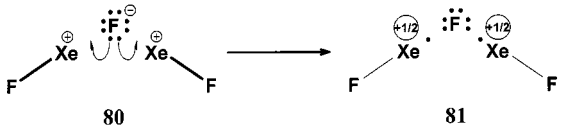
Cu−O electron-pair bond of each $S = 0$ spin ionic structure.

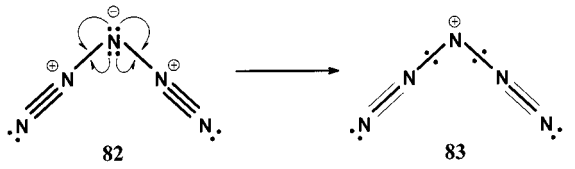
78 **79**

Of course, covalent structures of types **72** and **75**, together with their ionic partners, also participate in resonance with the VB structures of types **73**, **74**, **78**, and **79**, and their contributions to the magnetic exchange parameter will modify the above expression for it. With $\psi_{ab} = a + kb$ and $\psi_{dc} = d + kc$, the *simplest* expression for J is then given by[64] Equation (23).



$$J = -2\{(\beta_{bc})^2/(\gamma_{bb} - \gamma_{bc}) - k^2 J_{CuO}(\beta_{bc} + \beta_{ad})^2/(\gamma_{ab} - \gamma_{ac})^2 + k^4(\beta_{ad})^2/(\gamma_{aa} - \gamma_{ad})\}/(k^2 + 1)^2 \quad (23)$$

In Equation (23), k is the "superexchange" parameter, which measures the extent of delocalization of electrons from the oxygen AOs (a and d) into the copper AOs (b and c) The $\gamma_{\upsilon\upsilon}$ are (two-electron) Coulomb integrals which involve a pair of AOs.



Six-Electron Five-Centre Bonding: $Xe_2F_3^+$ and N_5^+

The anion H_5^-, with five overlapping 1s AOs, provides a prototype example of a molecular system with a 6-electron 5-centre bonding unit.[65] For the $\mathbf{X}_a-\mathbf{Y}_b\ \mathbf{X}_c^-\ \mathbf{Y}_d-\mathbf{X}_e$ type Lewis structures of the non-linear ions $H_2F_3^-$, I_5^-, and $Xe_2F_3^+$, the AO on each **Y** atom which helps to form the terminal $\mathbf{Y}_b-\mathbf{X}_a$ or $\mathbf{Y}_d-\mathbf{X}_e$ bond also overlaps with the valence-shell doubly-occupied p_x and p_y AOs of the central halide anion, to generate two (non-orthogonal) 6-electron 5-centre bonding units. For either bonding unit, an increased-valence structure may be generated, as indicated in **80** → **81** for $Xe_2F_3^+$ when the p_x electrons of the F^- are delocalized. (For linear systems, only the p_x electrons form a 6-electron 5-centre bonding unit.) In increased-valence structure **81**, the terminal and central Xe−F bonds are respectively fractional electron-pair bonds, and one-electron

bonds. The lengths[66] of these bonds, 1.90 and 2.14 Å, are in agreement with these bond properties.

80 **81**

82 **83**

The recently prepared cation[67] N_5^+ involves two orthogonal 6-electron 5-centre bonding units, and the associated Lewis and increased-valence structures are[67b] **82** and **83**.

VB structure **83** indicates immediately that the terminal and central N−N bonds should be longer than N≡N bonds with the same AO hybridization (≈ 1.07 Å, cf. discussion for N_2O above), and substantially shorter than those for N−N bonds (≈ 1.45 Å). The calculated lengths (1.11 Å and 1.30 Å)[67] are in agreement with these deductions.

Valence Bond Alternatives to Triple Bonds

In this section and in the following two, increased-valence considerations are not needed for the primary discussion of the VB phenomena.

The results of ab initio VB calculations[68] for N_2 show that resonance between VB structures :N÷N: and :N÷N: with electron-pair σ bonds and one-electron π bonds, generates a lower energy than does the triple-bond structure :N≡N: with Coulson−Fischer-type[48] LMOs to accommodate the four electrons that form the two π bonds. When the wavefunctions for these two sets of structures are expressed as linear combinations of the wavefunctions for nine canonical Lewis structures, it is found that the triple-bond structure overestimates the importance of the polar canonical structures :N(-2)—N(+2): and :N(+2)—N(-2):, and this effect provides the explanation for the origin of the higher energy for the triple-bond structure.

In 1916, Lewis[69] was unable to accommodate the triple bond in his cubical atom model of electronic structure. In contrast cubical atom models, and Bohr orbit diagrams[7] for :N÷N: and :N÷N: may be constructed.

One-Electron and Two-Electron Transfer Processes

For the O_2 ground-state, two-electron transfer processes are required to convert structure **16** into structure **19**, and structure **17** into structure **18**, whereas one-electron transfers are needed to convert either structure **16** or **19** into each of structures **17** and **18**. Examples of phenomena whose origins may be rationalized in terms of either one-electron or two-electron transfer processes include:[70] (a) the mode of protonation[16] of symmetric anions such as HCO_2^- and NO_2^-, which occurs preferentially at one oxygen atom, i.e. asymmetric rather than symmetric geometries are obtained for HCOOH and HONO; (b) the asymmetry of xanthate and dithiocarbamate ligands in various complexes;[71] (c) energy transfer between donor and acceptor chromophores.[72]

Bohr Orbit Descriptions of Electronic Structure

Of course, the orbital theory forms the primary basis for modern descriptions of the electronic structure of matter. However as has been discussed on several occasions,[7,73] the Bohr orbit theory is also able to be used for this purpose. A Bohr orbit approach to electronic structure is based on a $2n \times n$ factorization of the atomic shell-structure formula $2n^2$, for which $n = 1, 2, 3, \ldots$ is the principal quantum number. This factorization is derived[7,73] by the application of a Heisenberg uncertainty relationship to the movement of electrons around Bohr orbits with principal quantum number n. It is deduced that there are n circular orbits (designated as $n_1, n_2, \ldots, n_n$) each of which can accommodate a maximum of $2n$ electrons. Two alternative derivations of the $2n^2$ formula are presented in ref.[7] The Bohr orbit theory falls outside the normal paradigm which is used to describe electronic structure, but it does provide qualitative models of electronic structure that accommodate the Lewis cubical atom model,[69] and arrangements of electrons in molecules which are appropriate for VB structures that arise in normal orbital theory. Aspects of previously published accounts of this subject have been reviewed in ref.[7], with new types of orbit diagrams provided for some of the systems considered previously.

In Figure 11, orbit diagrams are provided[7] for B_2H_6, and a variety of AF_N systems, when it is asssumed that there are N A−F electron-pair bonds in the associated VB structures. These orbit diagrams are based on the deduction that orbits with $n = 1, 2, 3, 4$, and 5 may accommodate a maximum of 2, 4, 6, 8, and 10 electrons, respectively, and these are the occupation numbers for the equatorial n_1 orbit for the H, B, P, S, Cl, Se, Br, and I atoms in Figure 11. Examples of new types of Bohr orbit calculations of the energies for H_2^+, H_2, and the helium isoelectronic sequence are provided in ref.[7,74]

Conclusions

As indicated in the Introduction, the primary purpose of this work is to help to provide "primitive patterns of understanding" of the electronic structures of molecules. In very different ways, the work provides examples of how orbital VB theory and the Bohr orbit theory are able to do this. It is to be hoped that the approaches which have been used to provide qualitative VB descriptions of electronic structure are not difficult to comprehend − the increased-valence theory provides a natural extension of familiar Lewis theory by one-electron delocalizations − and there-

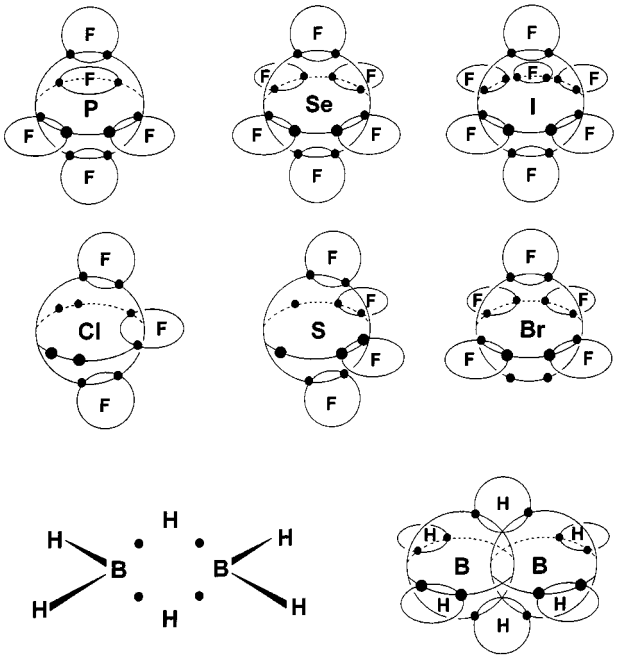


Figure 11. Bohr orbit diagrams for AF_N systems for (expanded valence-shell) Lewis VB structures with N A−F electron-pair bonds; six valence-shell electrons for each fluorine ligand are not indicated; a VB structure for B_2H_6 and the associated orbit diagram are also displayed

fore they may be useful to help bench chemists in their understanding of various aspects of chemical bonding.

Appendix: Valencies for LMO Increased-Valence Structures

For each of the LMO Kekulé structures **55** and **57**, the maximum valence for the A atom (V_a) is unity. In ref.[30a,43], expressions are deduced for the A-atom valencies for the LMO increased-valence structures **56** and **58**. The simplest definition of MO valence was used, namely that provided initally by Wiberg[75] for doubly occupied MOs, in which AO overlap integrals are omitted from the normalization constants. The derivation of the expression for V_a for increased-valence structure **56** is redescribed here.

If two electrons occupy the bonding MO $\psi_{ab} = (a + kb)/(k^2 + 1)^{05}$, the Wiberg valence[75] for the a-orbital is given by Equation (A1), in which P_{ab} is the Coulson bond order (with AO overlap integrals omitted). The maximum value for the valence is unity, which occurs when $k = 1$. However if ψ_{ab} is singly occupied, the bond-order is $k/(k^2 + 1)$, and the valence is then given by Equation (A2),[30a,43] with a maximum value of 0.5 when $k = 1$. When $k' = 1/k'' = k$ in Equation (9) for the LMO increased-valence structure **56**, we obtain Equation (A3) for the $(y)^1(\psi_{ay})^1(\psi_{ba})^2$ configuration, with $\psi_{ay} = a + ly$ and $\psi_{ba} = b + ka$. The A-atom valence is then given by Equation (A4) Pariser's procedure[76] is used to determine the P_{ay} and P_{ab} bond orders of Equations (A5) and (A6) from Equation (A3). An illustration of the use of this procedure is provided in ref.[77]

$$V_{ab} = (P_{ab})^2 = 4k^2/(k^2 + 1)^2 \quad \text{(A1)}$$

$$V_{ab} = 2(P_{ab})^2 = 2k^2/(k^2 + 1)^2 \quad \text{(A2)}$$

$$k\Psi_{31} = 2l(k\Psi_{I} + k^2\Psi_{II} + \Psi_{III}) + \Psi_{V} + k\Psi_{VI} \quad \text{(A3)}$$

$$V_a = V_{ay} + V_{ab} = 2(P_{ay})^2 + (P_{ab})^2 \quad \text{(A4)}$$

$$P_{ay} = 2l/\{2l^2(k^2 + 1) + 1\} \quad \text{(A5)}$$

$$P_{ab} = k\{4l^2(k^2 + 1) + 1\}/[\{2l^2(k^2 + 1) + 1\}(k^2 + 1)] \quad \text{(A6)}$$

When $k = l = 1$, $V_a = 1.13$. The maximum value for V_a is 1.212, which occurs when $k = 0.69$ and $l = 0.76$. In both cases, the A-atom valence exceeds the maximum value of unity that occurs in the Kekulé structures. Thus with regard to the valence of the A-atom, the designation "increased-valence" is appropriate for VB structure **56** (and also for VB structure **58**).

Acknowledgments

I thank (a) Professor T. M. Klapötke and Dr. A. Schulz at the Ludwig-Maximilians University, Munich, for their great enthusiasm and encouragement with regard to the use of VB methods, and (b) Mrs. Carmen Nowak, also at the Ludwig-Maximilians University, for her great help with the preparation and drawing of the VB structures and Figures.

As a consequence of the presence of four Slater determinants in the $S = 0$ spin wavefunction for Equation (4), the ψ_{ab} for the $\psi_{54}(k'=0)$ of Equation (5) is equal to $\psi_{ab} = a + 2kb$. It should also be stressed that the singlet diradical structure of type **VI** in Figure 5 contributes to the simplest canonical MO formulation of the wavefunction for a 4-electron 3-centre bonding unit (cf. C. A. Coulson, *J. Chem. Soc.* **1964**, 1442 for example). For a variety of MO and VB theorems that pertain to symmetrical 4-electron 3-centre bonding units, see R D. Harcourt, A. G. Harcourt, *J. Chem. Soc., Faraday Trans. 2* **1974**, *70*, 743.

Chem. Phys.* **1998**,*109*, 1310 and references 8,9 therein. With $D = (d)^2$, $A = (a)^2$, $D^* = (d)^1(d^*)^1$, and $A^* = (a)^1(a^*)^1$, in which d, d*, a, and a* are chromophore donor and acceptor orbitals, the initial and final wavefunctions for equivalent chromophores are expressed as $\Psi_i = \Psi_1(D^*,A) + \lambda\Psi_2(D^+A^-) + \mu\Psi_3(D^-A^+)$ and $\Psi_f = \Psi_4(D,A^*) + \mu\Psi_2(D^+A^-) + \lambda\Psi_3(D^-A^+)$. Two-electron transfers convert Ψ_1 into Ψ_4 and Ψ_2 into Ψ_3, whereas one-electron transfers convert each of Ψ_1 and Ψ_4 into either Ψ_2 or Ψ_3. Second-order perturbation theory is used to evaluate the electronic excitation matrix element. Analysis of this matrix element reveals that the Coulomb integral and the Dexter exchange integral arise from two-electron transfers, whereas the overlap interactions are associated primarily with one-electron transfers, rather than the Dexter exchange integral.

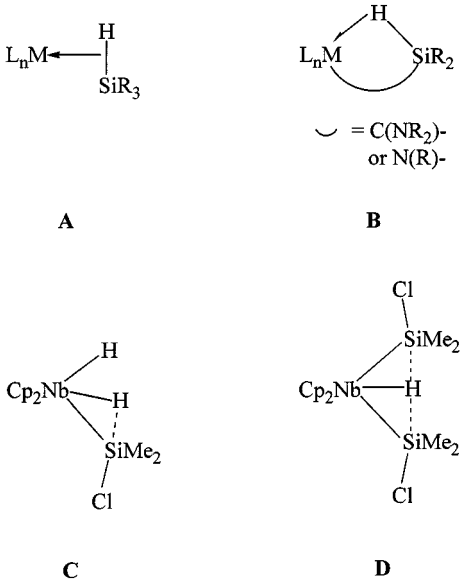
Contrasting Nonclassical Silicon−Hydrogen Interactions in Niobium and Tantalum Half-Sandwich Complexes: Si−H···M Agostic versus M−H···Si−Cl Interligand Hypervalent Interactions

Georgii I. Nikonov,*[a] Philip Mountford,*[b] Jennifer C. Green,[b] Paul A. Cooke,[c] Michael A. Leech,[d] Alexander J. Blake,[c] Judith A. K. Howard,[d] and Dmitry A. Lemenovskii[a]



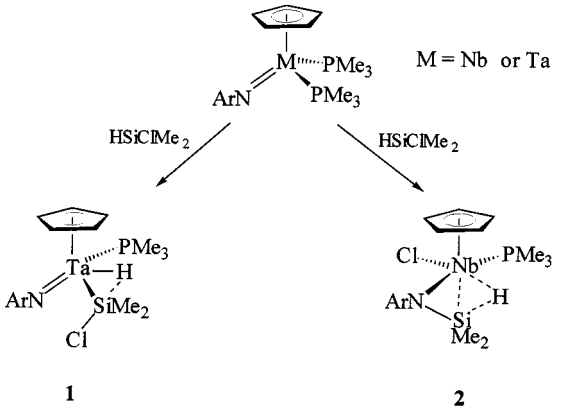
Keywords: Interligand interactions / Niobium / Tantalum / Silicon / Hydrides

Reaction of [CpM(NAr)(PMe_3)$_2$] (M = Nb, Ta; Ar = 2,6-C_6H_3*i*Pr$_2$) with $HSiClMe_2$ gives two remarkably different nonclassical Si···H···M products depending only on the identity of M; [CpTa(NAr)(H)($SiMe_2Cl$)(PMe_3)] possesses an unusual electron-rich M–H···Si interligand hypervalent interaction while [CpNb{η^3-N(Ar)$SiMe_2$–H}Cl(PMe_3)] is the first example of a β-agostic silylamine Si–H···M interaction showing a "stretched" Si–H bond.

Introduction

The study of complexes possessing interligand interactions is important for developing a better understanding of transition metal-mediated transformations. For example, nonclassical σ-complexes of the type $L_nM(\eta^2\text{-H}-X)$ (e.g. X = H, SiR_3, BR_2) serve as models for intermediates in oxidative addition/reductive elimination reactions,[1] while β-agostic $L_nM\cdots H-C$ systems lie on the reaction coordinate for the migratory insertion of alkenes into metal−hydride bonds.[2] Of particular relevance to this contribution are silicon-hydrogen bond complexes of the types **A** (η^2-silane species) and **B** (β-agostic M···H···Si) which are now well-established in the literature. Such metal−hydrogen−silicon interactions can best be described as three-centre, two-electron M···H···Si bonds formally arising from donation of Si−H σ-bond electron density to the metal (often with additional metal-to-Si−H σ* orbital back-donation); the interligand (i.e. Si···H) interactions in **A** and **B** may thus be classified as *electron deficient.*

We have recently reported a new type of M···H···Si interligand interaction found in certain niobocene silyl hydride complexes (**C** and **D**) which we classified as an *electron-rich*, interligand hypervalent interaction (IHI).[3] The IHI formally arises from donation of Nb−H bond electron density to the silicon−halogen antibonding orbital. this results in a three-centre, four-electron H···Si−Cl interaction, and in the case of **D** gives a five-centre, six-electron Cl−Si···H···Si−Cl bond. In both **C** and **D** silicon is five coordinate and hypervalent, with H and Cl occupying the apical sites of an approximate trigonal bipyramid. Experimental and theoretical studies by us[3] and others[4] have shown that the presence of a Si−Cl bond *trans* to hydride is crucial to developing shortened H···Si contacts and gives a concomitant lengthening of the Si−Cl bond. Analogous hypervalent interactions between a hydride ligand and a β-positioned silicon (β-IHI) have recently been found by Tilley and co-workers.[5]



Given the current interest and importance of understanding the underlying factors controlling interligand interactions we were interested in finding new examples of complexes with unusual M···H···Si interactions. It is well-estab-

lished that Cp^- and NR^{2-} (R is typically alkyl or aryl) are isolobal fragments,[6] and so complexes of the type $[Cp_2MX_3]$ and $[CpM(NR)(L)(X)_2]$ (M = group 5 metal; X, L = 1- and 2-electron donors) are also isolobal. Suitable group 5 precursor complexes $[CpM(NAr)(PMe_3)_2]$ (M = Nb or Ta; Ar = 2,6-$C_6H_3iPr_2$) were prepared from the corresponding $[CpM(NAr)Cl_2]$ complexes.[7]

The reactions of $[CpM(NAr)(PMe_3)_2]$ (M = Nb, Ta; Ar = 2,6-$C_6H_3iPr_2$) with $HSiClMe_2$ (see Scheme 1) give two dramatically different types of complex depending only on the identity of M. These are $[CpTa(NAr)(H)(SiMe_2Cl)(PMe_3)]$ (**1**, 60% isolated yield) and $[CpNb\{\eta^3\text{-}N(Ar)SiMe_2{-}H\}Cl(PMe_3)]$ (**2**, 84% isolated yield), each of which possesses a different type of nonclassical M···H···Si interaction.

1 **2**

Scheme 1. Reaction of $[CpM(NAr)(PMe_3)_2]$ (M = Nb or Ta; Ar = 2,6-$C_6H_3iPr_2$) with $HSiClMe_2$

The compound $[CpTa(NAr)(H)(SiMe_2Cl)(PMe_3)]$ (**1**) shows well-defined sets of signals for the Cp, NAr, $SiMe_2$ and PMe_3 ligands in its NMR spectra. The Ta−H resonance appears as a doublet [^2J(H−P) = 64.1 Hz] at δ = 5.13; the unusual low-field shift may be attributed to the anisotropy of the multiple bond to the imido ligand. Compound **1** is a rare example of a stable transition metal hydride complex supported by an imido group.[8] The solution NMR data are consistent with the solid state structure (Figure 1) which shows that the Ta-bound Si, hydride and P atoms all lie in the "bisecting plane" between the Cp and NAr ligands, consistent with the isolobal analogy between $[Cp_2MX_3]$ and $[CpM(NAr)(X)_2L]$. The silicon-bound chlorine atom is approximately *trans* to H(1) and also lies in this plane [maximum deviation from the calculated {Ta(1)−P(1)−H(1)−Si(1)−Cl(1)} least-squares plane = 0.13 Å].

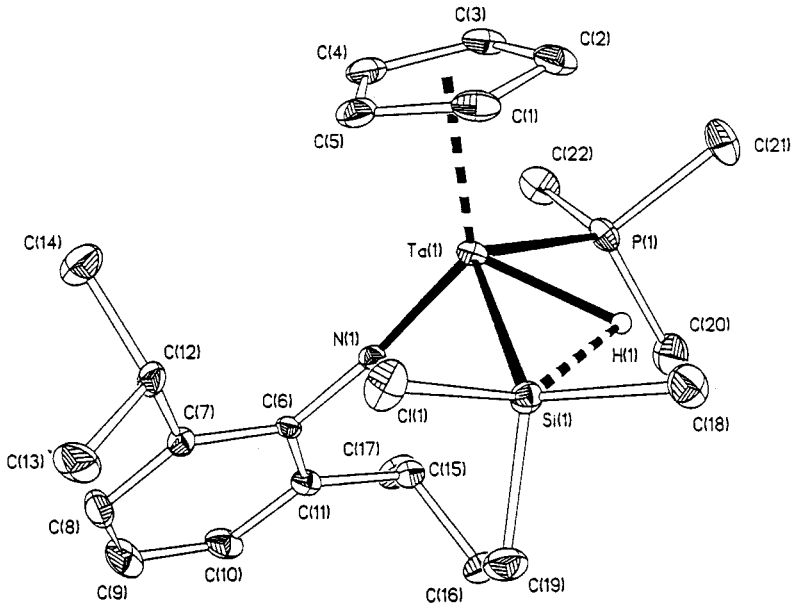
The geometry at Ta in **1** closely resembles that of Nb in the nonclassical complexes $[Cp_2Nb(X)(H)(SiMe_2Cl)]$ (X = H **C** or $SiMe_2Cl$ **D**),[3] assuming that the arylimido group occupies the coordination site of one of the Cp rings. An analogous approximately *trans* position of apical Si−Cl and metal-bound H with the $\{MMe_2\}$ unit formally comprising an equatorial plane was previously observed in **C** and **D**. Recent experimental and theoretical studies have shown that comparatively short M−Si and long Si−Cl bonds are associated with interligand hypervalent interactions between the Si and H ligands.[3] The Si−Cl bond length of 2.177(2) Å in **1** is one of the longest reported for $[L_nM(SiR_2Cl)]$ (R = alkyl, aryl) complexes.[9] Furthermore, it is comparable to that found in the nonclassical complex **C** [Si−Cl = 2.170(2) Å], but significantly longer than that of **D** [Si−Cl = 2.163(1) Å]. The Ta−Si bond of 2.574(1) Å in **1** is the shortest reported to date [avg. 2.638, range 2.611−2.671 Å for six Ta^V nondisordered observations],[10] and is comparable to the Nb−Si bonds in **C** and **D** [Nb−Si = 2.579(2) and 2.597(1) Å, respectively]; these in turn are shorter than in other silyl derivatives of niobocene.[11]

Although the hydride ligand in **1** was crystallographically located and isotropically refined, the characteristically large estimated standard deviations (ca. 0.1 Å) associated with Ta−H and Si−H contacts do not allow for detailed discussion of the Si−H interaction. However, density functional theory (DFT) has conclusively been shown to provide valuable insight into transition metal complexes, including those with metal−hydrogen−ligand interactions.[12] A DFT partial geometry optimisation[13] of **1** allowing only the hydride position to change (starting with non-hydride atom coordinates taken from the X-ray study, and the hydride initially positioned *symmetrically* between Si and P) resulted in a structure with an Si−H contact of 2.158 Å, a P···H distance of 2.469 Å and a Ta−H distance of 1.888 Å. By way of comparison, Si···H contacts of 1.993−2.154 Å were previously calculated for the nonclassical model complexes $[Cp_2Nb(H)(SiH_2Cl)_2]$ and $[Cp_2Nb(H)_2(SiH_2Cl)]$.[3c,4]

Unambiguous experimental verification of the existence of the predicted *direct* Si−H bonding in compound **1** is the observed ^1J(Si−H) coupling constant of 33 ± 0.5 Hz. This ^1J(Si−H) is significantly larger then the postulated "nonbonding" value of 20 Hz,[1b] but is somewhat lower than the values (40−60 Hz) usually observed in silane σ-complexes. The observation of a "diminished" Si−H coupling constant in **1** is in complete agreement with our previous report that Si−H bonding through the IHI mechanism mainly involves silicon 3p orbitals.[3c]

In contrast to the formation of the tantalum derivative **1**, reaction of the niobium complex $[CpNb(NAr)(PMe_3)_2]$ with $HSiClMe_2$ gives exclusively $[CpNb\{\eta^3\text{-}N(Ar)SiMe_2{-}H\}Cl(PMe_3)]$ (**2**, see Scheme 1). The ^{1}H NMR spectrum of **2** shows, in addition to characteristic Cp, Ar, PMe_3 and $SiMe_2$ resonances, a high-field Nb−H resonance at δ = −5.67 indicative of substantial hydridic character.

The IR spectrum of **2** displays a band at 1620 cm^{-1} attributable to vibrations associated with the hydrogen bridging the silicon and niobium atoms. This band is closer to the typical region for ν(Nb−H) in niobocene hydrides (1750−1650 cm^{-1})[11,14] rather than to the typical ν(Si−H) region. For comparison, uncoordinated Si−H bonds exhibit ν(Si−H) bands at about 2100 cm^{-1}, whereas in d^0 Si−H···M β-agostic systems of type **B** this band is shifted to about 1800 cm^{-1}.[15] Therefore, the IR data also establish substantial hydridic character of the niobium-interacting hydrogen. However, the observed ^1J(Si−H) coupling con-



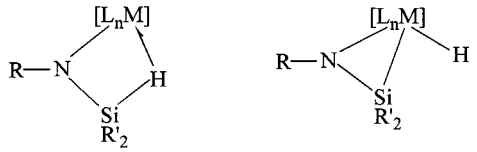


Figure 1. Molecular structure of [CpTa(NAr)(H)($SiMe_2Cl$)(PMe_3)] (**1**); displacement ellipsoids are drawn at the 25% probability level, except for H(1) which is shown as a sphere of arbitrary radius; H atoms except H(1) are excluded for clarity; selected bond lengths (Å) and angles (°) with estimated standard deviations in parentheses: Ta(1)−N(1) 1.821(4), Ta(1)−P(1) 2.550(1), Ta(1)−Si(1) 2.574(1), Cl(1)−Si(1) 2.177(2), Ta(1)−H(1) 1.6(1), Si(1)−H(1) 2.3(1), P(1)−H(1) 2.3(1); P(1)−Ta(1)−Si(1) 120.63(5), Cl(1)−Si(1)−Ta(1) 112.05(7)

stant of 96.6 Hz in **2** unambiguously reveals also direct bonding between this hydride and silicon (and comprehensively rules out the description of **2** as a classical η^2-silanimine hydride complex, **F**). It is noteworthy that this ^1J(Si−H) value is significantly diminished with respect to the values observed for d^0 Si−H···M β-agostic systems [^1J(Si−H) = 113−142 Hz] such as **E**.

β -agostic silylamine silanimine-hydride

E **F**

The X-ray structure of **2** (Figure 2) comprises of a Nb atom ligated by Cp, Cl and PMe_3 ligands, and the coordination sphere is completed by an η^3-N(Ar)$SiMe_2$−H ligand. The Nb···H···Si bridging hydrogen atom, H(1), was located from a Fourier difference map and refined isotropically. As for **1**, a DFT partial geometry optimisation[13] was carried out on **2** to assess the predicted position of H(1). All atomic positions were taken from the X-ray structure and the Nb···H···Si bridging hydrogen position was optimised while other atoms were kept fixed. The observed and calculated Nb−H distances are 1.91(5) and 1.931 Å; the corresponding Si−H distances are 1.52(5) and 1.771 Å, respectively. As for **1**, the experimental and theoretical values agree within the uncertainties and approximations associated with the two methods and are supported by the ^{1}H NMR spectroscopic data and ^1J(Si−H) values.

It is interesting to compare the Nb−H and Si−H distances for **2** with those of normal terminal Nb−H bonds (range ca. 1.60 −1.81 Å, depending on the experimental method[11b,14,16]), and with previously reported free or β-agostic Si−H bonds (range ca. 1.42−1.50 Å[15,17]). It is also instructive to consider the Nb(1)−N(1)−Si(1) angle of 89.1(2)° in **2**. This is comparable with M−N−Si angles found previously for silanimine compounds [86.1(1)° and 89.1(2)° for two examples[18]]; these are significantly smaller than the corresponding values for β-agostic (M···H−Si) silylamine (**E**) complexes [range 95.1(1) − 103.4(1)° for four examples[15]].

Therefore the elongated Nb−H and Si−H bonds, contracted Nb−Si−N angles, diminished ^1J(Si−H), along with other NMR and IR spectroscopic data suggest that the bonding in **2** is intermediate between a β-agostic d^2 silylamine (**E**) and a d^0 silanimine-hydride (**F**) structure. The electronic structure from the DFT calculations for **2** is in line with this interpretation and reveals a metal-based HOMO (corresponding formally to a d^2 complex) that is well set up for back-bonding into the Si−H σ* antibonding orbital. Compound **2** may be a useful model of the transition state for the as-yet-unknown migratory insertion of a silanimine into a metal−hydride bond.

In conclusion, the reaction of CpM(NAr)(PMe_3)$_2$ (M = Nb, Ta) with $HSiClMe_2$ gives remarkably different nonclassical Si···H···M products depending only on the identity of M. Compound **1** provides further evidence for the existence of electron-rich M−H···Si interligand hypervalent interactions, while compound **2** is the first example of a β-agostic

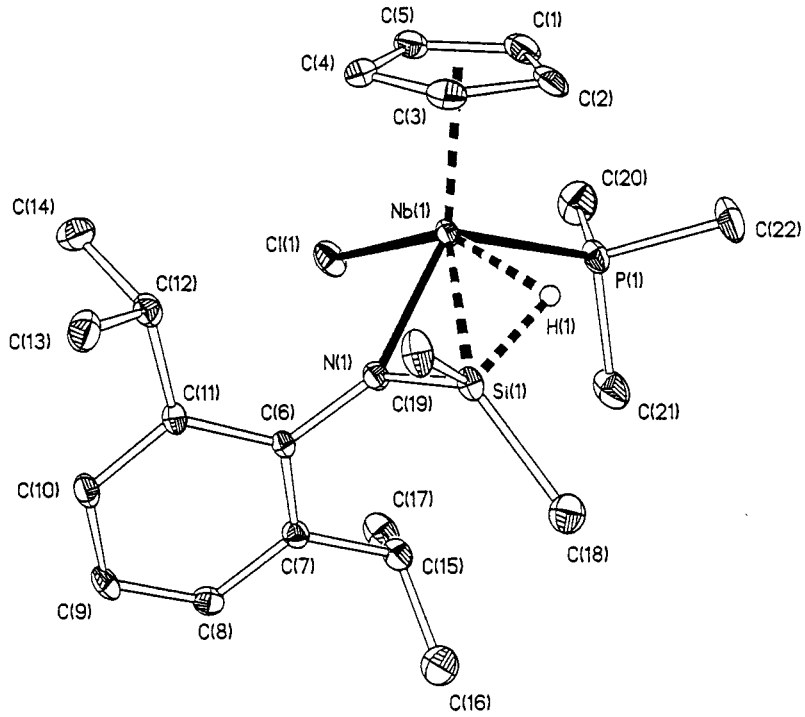

Figure 2. Molecular structure of [CpNb{η^3-N(Ar)SiMe$_2$−H}Cl(PMe$_3$)] (**2**); displacement ellipsoids are drawn at the 30% probability level, except for H(1) which is shown as a sphere of arbitrary radius; H atoms except H(1) are excluded for clarity; selected bond lengths (Å) and angles (°) with estimated standard deviations in parentheses: Nb(1)−N(1) 2.051(4), Nb(1)−P(1) 2.552(1), Nb(1)−Si(1) 2.646(1), Nb(1)−Cl(1) 2.497(1), Nb(1)−H(1) 1.91(5), Si(1)−H(1) 1.52(5), Si(1)−N(1) 1.704(4); Nb(1)−N(1)−Si(1) 89.09(16), Si(1)−Nb(1)−P(1) 109.37(5), Si(1)−Nb(1)−Cl(1) 123.42(5)

Si−H···M interaction showing such a "stretched" Si−H bond for a silylamine complex.

Experimental Section

Preparation of [CpTa(NAr)(H)(SiMe$_2$Cl)(PMe$_3$)] (1): To a solution of [CpTa(NAr)(PMe$_3$)$_2$] (1.03 g, 1.10 mmol) in pentane (30 mL) was added HClSiMe$_2$ (0.5 mL). After 14 h a light pink precipitate formed which was filtered off and dried in vacuo. Yield: 0.65 g (61%). − IR (Nujol): 1736 cm^{-1} ν(Ta−H). − ^{1}H NMR ([D$_6$]benzene): δ = 0.90 [d, J(H−P) = 8.5 Hz, 9 H, PMe$_3$], 0.95 (s, 3 H, SiMe$_2$), 1.23 (s, 3 H, SiMe$_2$), 1.23 [d, J(H−H) = 6.9 Hz, 6 H, CHMe_2], 1.27 [d, J(H−H) = 6.9 Hz, 6 H, CHMe_2], 4.04 [sept, J(H−H) = 6.9 Hz, 2 H, CHMe$_2$], 4.52 [d, J(H−P) = 1.5 Hz, 5 H, Cp], 5.13 [d, J(H−P) = 64.2 Hz, 1 H, Ta−H]. − ^{29}Si{^{1}H-selective} NMR ([D$_6$]benzene): δ = 91.7 [^1J(H−Si) = 33.3 Hz]. − ^{31}P{^{1}H} NMR ([D$_6$]benzene): δ = −4.3. − $C_{22}H_{38}ClNPSiTa$ (592.0): calcd. C 44.63, H 6.47, N 2.37; found C 44.72, H 6.46, N 2.30.

Preparation of [CpNb{η^3-N(Ar)SiMe$_2$−H}Cl(PMe$_3$)] (2): To a suspension of [CpNb(NAr)(PMe$_3$)$_2$] (1.46 g, 3.09 mmol) in pentane (15 mL) was added HSiClMe$_2$ (1.3 mL, excess). The mixture was kept 5 days to afford large dark-green crystals. These were filtered off, washed with cold pentane and dried in vacuo. Yield: 1.28 g (84%). The solution was reduced in volume to 5 mL and a second crop of **2** (0.20 g) crystallized after 3 days. − IR (Nujol): 1620 cm^{-1} ν(Nb−H). − ^{1}H NMR ([D$_6$]benzene): δ = −5.67 (s, 1 H, Nb−H), 0.22 (d, J = 0.9 Hz, 3 H, SiMe_2), 0.31 [d, J(H−P) = 2.0 Hz, 3 H, SiMe_2], 0.96 [d, J(H−P) = 7.8 Hz, 9 H, PMe$_3$], 1.14 (d, J = 6.8 Hz, 3 H, CHMe_2), 1.32 (overlapping 2 × d, J = 6.8 Hz, 6 H, 2 × CHMe_2), 1.50 (d, J = 6.7 Hz, 3 H, CHMe_2), 2.37 (sept, J = 6.8 Hz, 1 H, CHMe$_2$), 3.33 (sept, J = 6.7 Hz, 1 H, CHMe$_2$), 4.67 [d, J(H−P) 1.7 Hz, 5 H, Cp]. − ^{29}Si{^{1}H-selective} NMR ([D$_6$]benzene): δ = −52.1 [^1J(H−Si) = 96.6 Hz]. − ^{31}P{^{1}H} NMR ([D$_6$]benzene): δ = 11.5. − $C_{22}H_{38}ClNNbPSi$ (504.0): calcd. C 51.90, H 7.60, N 2.78; found C 51.9, H 7.71, N 2.60.

X-ray Crystallographic Study of 1 and 2: Crystals of **1** were grown from pentane, crystals of **2** from ether. For both structures the data were corrected for Lorentz and polarisation effects. Non-hydrogen atoms were refined anisotropically. All hydrogen atoms except hydride (which was located from Fourier difference synthesis and positionally refined isotropically), were placed in calculated positions and refined in a riding model.

Crystal data for 1: $C_{22}H_{38}ClNPSiTa$, 0.15 × 0.20 × 0.27 mm, monoclinic, space group $P2_1/c$, a = 15.893(1), b = 9.092(1), c = 19.136(2) Å, β = 112.568(3)°, V = 2553.47 Å^3, ρ = 1.54 g·cm^{-3}, μ(Mo-K_α) = 4.53 cm^{-1}, T = 150 K. Of 23837 data collected (0.96 ≤ θ ≤ 27.53°), 5838 [R(int) = 0.050] were independent and 4115 [$I > 3\sigma(I)$] reflections were used in the refinement of 249 parameters. An absorption correction based on multi-scans was applied (T_{min}, T_{max} = 0.368, 0.615). $R(F)$ = 0.030, $R(wF)$ = 0.035. Min./max. peaks in final difference map: 1.03/−0.63 e·Å^{-3}.

Crystal Data for 2: $C_{22}H_{38}ClNNbPSi$, 0.19 × 0.17 × 0.14 mm, monoclinic, space group $C2/c$, a = 31.391(6), b = 10.150(2), c = 16.945(3) Å, β = 111.30(3)°, V = 5030(2) Å^3, ρ = 1.331 g·cm^{-3}, μ(Mo-K_α) = 7.04 cm^{-1}, T = 150(2) K. Of 4813 data collected (1.0 ≤ θ < 25.5°), 4437 [R(int) = 0.0343] were independent [3557 reflections had $I > 2\sigma(I)$] and were used in the refinement of 313 parameters. An absorption correction (ψ-scans) was applied (T_{min}, T_{max} = 0.721, 0.913). $R(F)$ = 0.050, $R(wF^2)$ = 0.103. Min./max. peaks in final difference map: 1.427/−0.868 e·Å^{-3}.

Crystallographic data (excluding structure factors) for the two structures reported in this paper have been deposited with Cam-

bridge Crystallographic Data Centre as supplementary publication no. CCDC-33301 (**1**) and CCDC-33302 (**2**). Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk.

DFT Studies: Calculations were performed using the density functional methods of the Amsterdam Density Functional (ADF) code Version 2.3.0.[13a] The basis set used triple-ζ accuracy sets of Slater orbitals with a single polarisation function added to main group atoms. The cores of the atoms were frozen. Vosko, Wilk and Nusair's local exchange correlation potential[13b] was employed with nonlocal exchange corrections by Becke[13c] and nonlocal correlation corrections by Perdew.[13d]

Whereas calculation on the whole "real" complex is unfeasible for us because of the time that it would take, attempted full DFT geometry optimisation of an oversimplified model of **2**, having hydrogen substituents on Si, P and N atoms, converged to a structure with quite different distances between Si and N. This shows (as we found in the chemistry) that substituents are important. Note that in the calculations, all of the distances and angles were chemically realistic, but obviously were more appropriate to a compound further along the reaction coordinate. It is well-known that in certain cases involving "weak" interactions the influence of steric/electronic substituent effects can be crucial.

Acknowledgments

We thank the Royal Society (London) for financial support through a joint research grant and Dr. N. H. Rees for recording the ^{29}Si NMR spectra. Part of this work has been carried out using the computational resources of a DEC 8400 multiprocessor cluster (Columbus/Magellan), provided by the U.K. Computational Chemistry Facility at Rutherford Appleton Laboratory.

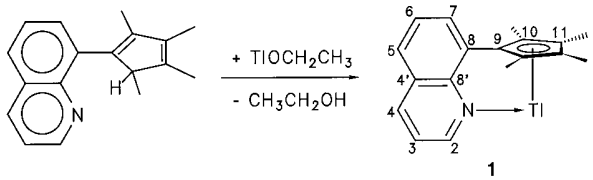
Quinolylcyclopentadienylthallium: A Donor-Stabilized Thallium(I) Compound

Markus Enders,*[a] Jochen Fink,[a] and Hans Pritzkow[a]

Keywords: Thallium / Sandwich complexes / N ligands / Hemilabile ligands



The synthesis and properties of 1-(8-quinolyl)-2,3,4,5-tetramethylcyclopentadienyl-thallium(I) (**1**) are described. The functionalised cyclopentadienyl ligand coordinates to the thallium through the five-membered ring and the nitrogen atom. Whereas the NMR investigation indicates a monomeric structure in solution, the crystal structure analysis shows the tendency to form an infinite zigzag polymeric chain in the solid state.

Introduction

Besides Cp thallium(I) compounds, most organothallium derivatives are Tl^{III} species.[1,2] Recently the synthesis of the first monomeric arylthallium(I) compound[2] has been reported. $CpTl^{I}$ compounds are mild reagents for the synthesis of cyclopentadienyl derivatives of main group elements, transition metals and lanthanoid metals.[3] Several solid-state structures of substituted CpTl compounds have been reported. For example C_5H_5Tl,[4] C_5Me_5Tl[5] and $(Me_3Si)C_5H_4Tl$[6] form infinite zigzag chain polymers. In contrast $(Me_3Si)_2C_5H_3Tl$[6] forms hexameric units. Our previous investigations on the complex chemistry of nitrogen-donor functionalised cyclopentadienyl ligands showed that rigid, bifunctional ligands prefer a chelating coordination with formation of half-sandwich compounds.[7] However for ligands in which a nitrogen-donor is connected with an alkyl chain to the cyclopentadienyl ring[8] many conformations are possible. Here we use a cyclopentadienyl system with a quinoline moiety directly attached. In this hemilabile chelate ligand, the two different functionalities are linked by a rigid C_2 spacer, which is itself embedded in the planar heterocycle. Only rotation about one bond is possible. In addition the nitrogen lone pair points towards the space below the plane of the Cp ring. As donor-stabilised thallium(I) compounds are very rare,[9,10] we tried to achieve an interaction between the thallium atom and the nitrogen donor with the help of the rigid 1-(8-quinolyl)-2,3,4,5-tetramethylcyclopentadienylligand (Cp^Q). Moreover the resulting Cp^Q-Tl should serve as a source of the Cp^Q ligand.

Results and Discussion

The reaction of 1-(8-quinolyl)-2,3,4,5-tetramethylcyclopentadiene with thallium(I) ethoxide in ethanol yields [1-(8-quinolyl)-2,3,4,5-tetramethylcyclopentadienyl]thallium(I) (**1**) (Cp^Q-Tl) as an orange precipitate in nearly quantitative yield (Scheme 1).

Scheme 1. Formation and numbering of **1**

Compound **1** is soluble in aromatic or polar aprotic solvents. Orange crystals are formed from toluene/pentane. They are air-stable for a few minutes and decompose at 142 °C. Compound **1** is less air- and light-sensitive than C_5Me_5Tl[5] or dimethylaminoethyl-Cp-thallium compounds, and the decomposition temperature is higher.[9] These properties indicate that the thallium atom is protected by an interaction with the quinolyl nitrogen. This assumption is supported by the ^1H and ^{13}C NMR spectra.

The ^1H NMR spectrum shows doublets due to coupling with thallium. Natural thallium consists of two isotopes ^{203}Tl (S = 1/2, 29.53%) and ^{205}Tl (S = 1/2, 70.47%). As the gyromagnetic ratios of the two isotopes differ only slightly ($\gamma(^{205}Tl)/\gamma(^{203}Tl) = 1.01$), the coupling constants $J(X,Tl^{205})$ and $J(X,Tl^{203})$ are nearly identical. The four methyl groups at the cyclopentadienyl ring form two doublets at $\delta = 2.27$ and $\delta = 2.38$ with a coupling constant $^3J(Tl,H) = 15.5$ Hz and 13.3 Hz, respectively. The $^3J(Tl,H)$ coupling constant for C_5Me_5Tl has been reported to be 18 Hz.[11] Only two methyl resonances are observed, because the molecule adopts C_S symmetry on the NMR time scale. Further structural information can be obtained by the analysis of the proton−thallium coupling constants in the quinoline substituent. The exact assignment of the proton resonances has been confirmed by double resonance techniques and by a H,H-COSY NMR spectrum. If the nitrogen atom is not coordinated to the thallium centre it must lie on the opposite side of the Cp ring. For this arrangement we would expect to observe a through-space $^1H,Tl$ coupling of the hydrogen atom H^7 [13] and no coupling to the protons H^2, H^3 and H^4. However, the opposite is true. All protons in the heterocyclic part of the quinoline couple with the thallium atom and no Tl,H coupling is observed in the homo-

cyclic part. The coupling constant for the H^2 atom is 17.1 Hz, and for H^3 and H^4 it is 8.2 Hz. The Tl,H coupling behaviour clearly indicates that the nitrogen atom is bound to the thallium atom in solution. In addition, the absence of coupling to a second thallium atom shows that the complex is monomeric in solution.

These interpretations are supported by the ^{13}C NMR spectra. Except for three carbon atoms from the homocyclic part of the quinoline, all resonances are split into doublets because of coupling to a single thallium atom. The largest coupling constants are observed for the quaternary carbon atoms of the Cp ring with values of 124 Hz and 127 Hz. The four methyl groups show two doublets [J(Tl,H) = 69 Hz and 59 Hz].

The EI-MS spectrum of **1** gives the molecular ion at m/z = 453 with an intensity of 27% and a characteristic isotope distribution. The base peak at m/z = 248 originates from the free ligand. The C,H analysis confirms that no solvent molecules are coordinated to **1** in the solid state.

The constitution of **1** in solution, a monomeric molecule with C_s symmetry and nitrogen coordination to the metal atom, is deduced from the NMR spectra. In addition, we investigated the solid-state structure of **1** by X-ray diffraction (Figure 1).

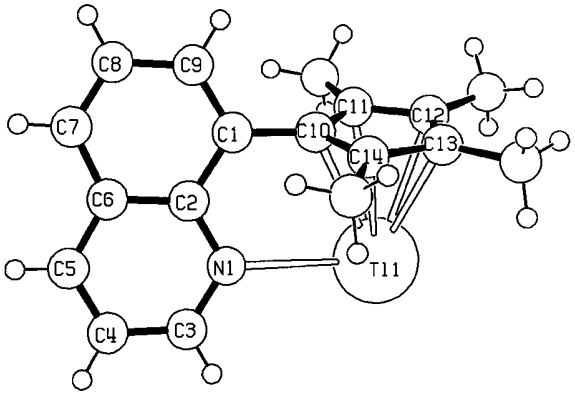

Figure 1. Solid state structure of **1**; selected bond lengths (Å) and angles (°):Tl1−N1 2.977(11), Tl1−C10 2.884(11), Tl1−C11 2.872(11), Tl1−C12 2.869(10), Tl1−C13 2.917(10), Tl1−C14 2.932(11), Tl1−C10′ 3.187(11), Tl1−C11′ 3.081(11), Tl1−C12′ 3.070(10), Tl1−C13′ 3.145(11), Tl1−C14′ 3.229(11), quinoline−Cp 110.2(8); C3−N1−Tl1 120.1(9), C2−N1−Tl1 120.2(8), C2−N1−C3 117.8(12)

In **1** the thallium atom is coordinated to the substituted Cp ring and the nitrogen atom. The distance between the metal and the centre of the Cp ring is 2.63 Å. A longer contact of 2.90 Å is observed to a neighbouring Cp ligand. Although this distance is quite long, **1** can be described as a zigzag chain polymer (Figure 2), an arrangement which is known for several CpTl compounds.[4−6,12] The Tl−Tl−Tl angle is 137.1°, a value similar to that in C_5H_5Tl (137°)[4] but smaller than in C_5Me_5Tl (145°).[5] However, in most reported structures of substituted CpTl complexes, the metal atom lies nearly equidistant between two Cp rings {e.g. C_5H_5Tl: d(Tl−Cp) = 2.75 Å,[4] C_5Me_5Tl: d(Tl−Cp) = 2.71 Å[5]}. In **1** the coordination of the nitrogen donor to the metal centre prevents a second Cp ring from binding strongly to the thallium atom. The Tl−N distance (2.97 Å) is quite long compared to reported Tl^I−N distances (2.52−2.95 Å).[14−18] Nevertheless there is a bonding interaction with formation of a chelating structure. This interpretation is supported by the sum of bonding angles around the nitrogen atom (C2−N−Tl, Tl−N−C3, C3−N−C2) which is 358.1°. Therefore the nitrogen atom lies in the plane of C2, C3 and Tl, so that the lone-pair of the nitrogen points directly at the thallium centre.

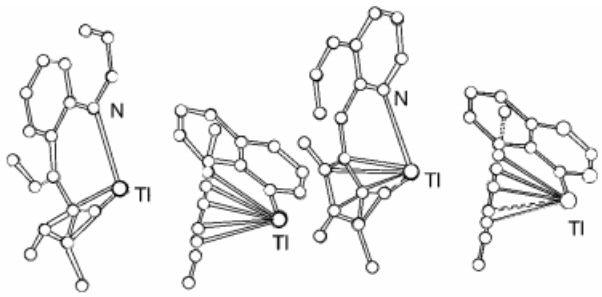

Figure 2. Solid state structure of **1** showing the arrangement as an infinite zigzag chain polymer; selected distances (Å) and angles (°): Tl−Cp 2.63 and 2.90, Tl−Tl 5.52(3); Tl−Tl−Tl 137.1(8)

Experimental Section

All reactions were carried out under nitrogen or argon atmosphere. 1-(8-quinolyl)-2,3,4,5,-tetramethylcyclopentadiene was prepared according to the reported procedure.[7]

1-(8-Quinolyl)-2,3,4,5-tetramethylcyclopentadienyl-thallium(I) (1): 1-(8-Quinolyl)-2,3,4,5-tetramethylcyclopentadiene (4.0 g, 16.0 mmol) was dissolved in 150 mL ethanol. At room temp. thallium ethoxide (4.0 g, 16.0 mmol) was added slowly to the pale yellow solution. Immediately the colour changed to deep orange. After 12 h magnetic stirring with the exclusion of light a bright orange precipitate was formed, which was then separated by filtration and washed with small portions of ethanol. After drying in vacuum, 7.0 g (96.8%) of **1** was obtained.

^1H NMR (C_6D_6): δ = 2.26 [d, ^3J(Tl,H) = 15.5 Hz, 6 H, 2 CH_3]; 2.38 [d, ^3J(Tl,H) = 13.3 Hz, 6 H, 2 CH_3], 6.78 [ddd, ^3J(H3,H4) = 4.0 Hz, ^3J(H3,H2) = 4.0 Hz, ^4J(Tl,H3) = 8.2 Hz, 1 H, H3], 7.31 [d, ^3J(H5,H6) = ^3J(H7,H6) = 4.0 Hz, 2 H, H5 and H7], 7.61 [ddd, ^3J(H4,H3) = 3.5 Hz, ^4J(H4,H2) = 1.9 Hz, ^5J(Tl,H4) = 8.2 Hz, 1 H, H4], 7.72 [t, ^3J(H6,H5) = ^3J(H6,H7) = 4 Hz, 1 H, H6], 8.21 [ddd, ^3J(H2,H3) = 4.2 Hz, ^4J(H2,H4) = 1.8 Hz, ^3J(Tl,H2) = 17.1 Hz, 1 H, H2]. − ^{13}C NMR: (C_6D_6) δ = 11.2 [d, J(Tl,C) = 59.2 Hz, CH_3], 11.7 [d, J(Tl,C) = 69.4 Hz, CH_3], 114.6 [d, J(Tl,C) = 145.2 Hz, C9], 115.1 [d, J(Tl,C) = 126.7 Hz, C10, C11], 117.3 [d, J(Tl,C) = 8.3 Hz, C8′], 120.4 [d, J(Tl,C) = 15.7 Hz, C3], 124.8 and 126.9 (s, C5, C7), 129.7 (s, C4′), 133.2 [d, J(Tl,C) = 29.6 Hz, C6], 136.9 [d, J(Tl,C) = 9.3 Hz, C4], 139.0 [d, J(Tl,C) = 26.8 Hz, C8], 147.2 [d, J(Tl,C) = 27.8 Hz, C2]. C 47.67, H 4.00, N 3.09; found C 47.53, H 4.21, N 2.98.

Crystal Structure Determination of 1: Crystal data: $C_{18}H_{18}NTl$, M = 452.7, monoclinic, $P2_1/a$, a = 10.282(7), b = 15.162(11), c = 10.862(8) Å, β = 109.86(5)°, V = 1593(2) Å^3, Z = 4, d = 1.89 g cm^{-3}, μ = 10.1 mm^{-1}. Intensity data were collected at −70 °C with a Siemens-Stoe AED2 diffractometer [Mo-K_α radiation (λ = 0.71073 Å), ω-scans] up to θ = 25° (2805 unique reflections, 1866

observed with [$I > 2\sigma(I)$]. An empirical absorption correction (ψ-scans) was applied. The structure was solved by direct methods (SHELXS86[19]) and refined by full-matrix least-squares techniques (SHELXL93[19]) based on F^2 using all measured reflections and with anisotropic temperature factors for all non-hydrogen atoms. Hydrogen atoms were inserted in calculated positions. $R1 = 0.050$, $wR2 = 0.106$, 187 parameters, rest electron density 0.96, -1.24 e·Å^{-3}.

Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no CCDC-142406. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

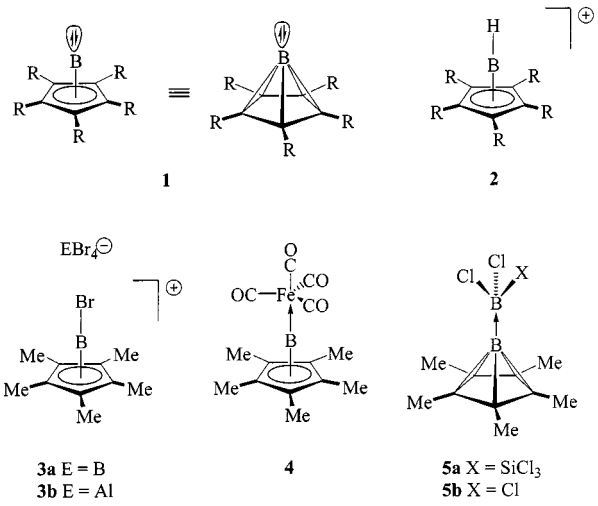
Borane-stabilized Boranediyls (Borylenes): Neutral *nido*-1-Borane-2,3,4,5,6-pentamethyl-2,3,4,5,6-pentacarbahexaboranes(6)

Peter Greiwe,[a] Alexandra Bethäuser,[a] Hans Pritzkow,[a] Thorsten Kühler,[b] Peter Jutzi,[b] and Walter Siebert*[a]



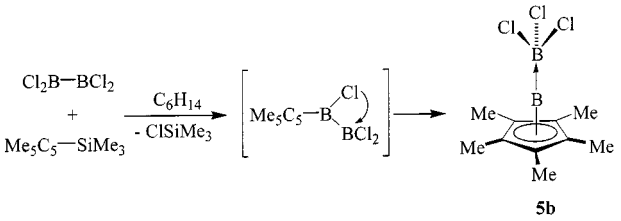
Dedicated to Professor Dr. Paul von Ragué Schleyer on the occasion of his 70th birthday

Keywords: Boranes / Borylene / Carboranes / Lewis acids

The reaction of $(C_5Me_5)_2Si$ or $(C_5Me_5)SiMe_3$ with B_2Cl_4 leads to the adducts $(C_5Me_5)B{\rightarrow}BCl_2SiCl_3$ (**5a**) or $(C_5Me_5)B{\rightarrow}BCl_3$ (**5b**), in which the Lewis acids stabilize the boranediyl fragments. Spectroscopic data and X-ray structure analyses confirm the adducts.

Introduction

In contrast to the heavier analogs of $[(\eta^5\text{-}C_5Me_5)E:]_n$, E = Al,[1] Ga,[2] In,[3] Tl[4] derivatives of (η^5-cyclopentadienyl)boranediyl **1** with a lone electron pair at boron are unknown. Protonation of hypothetical **1** could lead to the cation $[(\eta^5\text{-}C_5R_5)BH]^+$ (**2**) and formal addition of the bromonium ion Br^+ to the cation $[(\eta^5\text{-}C_5Me_5)B{-}Br]^+$, first obtained by Jutzi et al.[5] in the reaction of $Me_5C_5{-}GeMe_3$ with an excess of BBr_3 leading to **3a**. Schnöckel et al.[6] observed the formation of **3b** from the reaction of $[(C_5Me_5)Al]_4$ with BBr_3 and confirmed the proposed structure of the cation[5] as well as the calculated orientation of the substituents in **2** (R = H) towards the apical boron atom[7] by a crystal structure analysis. Very recently, Cowley et al.[8] prepared the tetracarbonyliron-pentamethylcyclopentadienylboranediyl complex **4** and reported a theoretical study on free and $Fe(CO)_4$-complexed borylenes.[9a] The related alanediyl compound $(C_5Me_5)Al{-}B(C_6F_5)_3$ has been synthesized.[9b] Compounds of the types **1**–**4** and the neutral polyhedron derivatives **5a,b** presented here are best described as *nido* clusters[10] with six skeletal atoms held together by $2n + 4 = 16$ skeletal electrons. We here present a new approach to stabilize the hypothetical boranediyl **1** (R = Me) as a Lewis base with the Lewis acids $Cl_3Si{-}BCl_2$ and BCl_3.



Results and Discussion

When $(\eta^5\text{-}C_5Me_5)_2Si$[11] is treated with B_2Cl_4 at −110 °C in pentane a red-brown suspension forms, which on warming to room temperature results in a yellow solution and a colorless solid, which turns violet on longer standing or on contact with air. The mass spectraof the crude product indicate the presence of two compounds (see Experimental Section), recrystallization from hot toluene yields **5a**.[12] Its EI and CI mass spectra do not show the M^+ peak; however, the $[M_2 - Cl]^+$ ion is seen in low intensity at *m/z* = 689. Besides the base peak in the CI spectrum at *m/z* = 327 $[M^+ - Cl]$ the only other fragment is found at *m/z* = 227 $[B_2SiCl_5]^+$ which is the base peak in the EI MS.

The ^1H NMR spectrum exhibits one signal at δ = 2.25 for the methyl groups indicative of a pentahapto structure, which is confirmed by two ^{13}C resonances at δ = 113.1 (C_5) and δ = 4.2 (CH_3). In the ^{11}B NMR spectrum two signals at δ = −6.2 (sp^3 boron) and δ = −51.7 (apical boron) are in agreement with a $C_5B{\rightarrow}B$ pyramidal arrangement. At room temperature, because of the partially relaxed scalar ^{11}B-^{11}B coupling, only the two inner lines of the 1:1:1:1 pattern are observed. At elevated temperatures (55 °C), due to the slower quadrupolar relaxation of the ^{11}B nuclei, the two outer lines appear as shoulders. The more precise value for

Scheme 1. Formation of **5b**

the coupling constant $^1J(^{11}B,^{11}B)$ is measured for the resonance of the apical ^{11}B nucleus (125 ± 3 Hz).

These data support the formation of the borane-stabilized boranediyl adduct **5a**, which is confirmed by a crystal structure analysis.

A much simpler transfer of a C_5Me_5 group to a diborane(4) molecule occurs with $Me_5C_5-SiMe_3$ (Scheme 1). The reaction of equimolar amounts of $Me_5C_5-SiMe_3$ and B_2Cl_4 in hexane at low temperature leads to a colorless solid which is thermally stable up to 280 °C. Its NMR and mass spectra confirm the formation of **5b**: one signal at δ_H = 2.21 indicates pentahapto bonding of the C_5Me_5 group and two high-field signals prove the presence of one sp^3 hybridized (δ_B = 2.8) and one *apex* boron atom (δ_B = −53.0). The two different ^{11}B nuclei couple as described for **5a** [$^1J(^{11}B,^{11}B)$ = 121 ± 5 Hz]. The CI mass spectrum exhibits the base peak $[M - Cl]^+$ (*m/z* = 227) and the $[M_2 - Cl]^+$ peak (*m/z* = 491). The EI spectrum shows the base peak $[M - Cl]^+$ and the molecular-ion peak M^+ (*m/z* = 262) with the isotopic pattern expected for $C_{10}H_{15}B_2Cl_3$. Compound **5b** is only slightly sensitive to moisture but is decomposed in CH_2Cl_2 by gaseous HCl.

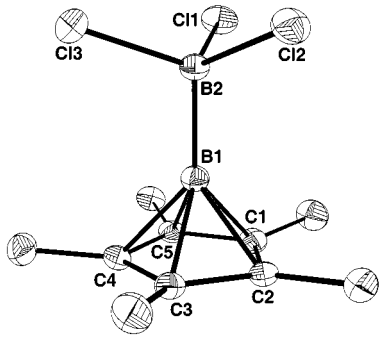

Figure 1. Molecular structure of **5b** in the crystal; selected bond lengths [Å] and angles [°] (values for **5a** given in brackets): B1−$C_{5\ plane}$ 1.260(3) [1.289(6)], B1−C_{ring} 1.747−1.756(3), av. 1.752 [1.752−1.773(8), av. 1.762], B1−B2 1.681(3) [1.686(7)]; X_{C5}−B1−B2 179.4 [176.7], B1−B2−Cl 110.0−110.5(1) [B1−B2−Si1 116.1(3); B1−B2−Cl1 110.1(4); B1−B2−Cl2 108.1(3)]; the methyl groups are bent out of the C_5 plane towards B1 by 5.6−7.2 (av. 6.4) in **5b** and by 3.3−5.2 (av. 4.5) in **5a**; hydrogens are omitted for clarity.

The ORTEP plot in Figure 1 shows the molecular structure of **5b**;[13] selected bond lengths and angles of **5a** and **5b** are listed in the legend. Both structures are very similar, the structure determination of **5b** being more accurate. Any small differences are caused by the presence of the $SiCl_3$ group. The average C−B bond length (1.75 Å) is identical to that in $[(\eta^5\text{-}Me_5C_5B-SiCl_2(\eta^1\text{-}C_5Me_5)]^+[Cl_3B(\eta^1\text{-}C_5Me_5)]^-$ [14] and lies between the values for **3b** (1.68 Å) and **4** (1.81 Å). The larger B−C distance in **4**[8] indicates a weaker bonding between boron and the C_5Me_5 ring, which is probably due to a less positive charge at the boranediyl moiety **1** (R = Me). In **5a,b** the $(C_5Me_5)B$ unit is attached to $XBCl_2$ with a B−B distance of 1.69 Å for **5a** and 1.68 Å for **5b**, which is in the range for a normal 2c-2e bond. The bulky $SiCl_3$ group causes a slight deviation of 3.3 ° from the expected linear B−B−X_{C5} arrangement (X_{C5} being the center of the C_5 ring) found for **5b**. The methyl groups of the C_5Me_5 ring are bent out of the C_5 plane towards the *apical* boron atom with an average angle of 4.6 (**5a**) and 6.4° (**5b**). Such a behavior was predicted theoretically[7] and has been verified experimentally in **3b** (3.9°) and in $[(\eta^5\text{-}Me_5C_5B-SiCl_2(\eta^1\text{-}C_5Me_5)]^+[Cl_3B(\eta^1\text{-}C_5Me_5)]^-$ (4.2°).[13]

The formation of **5a** may be rationalized by the assumption that the postulated oxidative addition product $(C_5Me_5)_2Si(Cl)-B(Cl)-BCl_2$ undergoes intra- and intermolecular substituent exchanges and a rearrangement occurs as proposed for **5b**.

Experimental Section

***nido*-1-(Trichlorosilyl)dichloroborane-2,3,4,5,6-pentamethyl-2,3,4,5,6-pentacarbahexaborane(6) 5a:** To a solution of decamethylsilicocene (1.19 g, 3.97 mmol) in 40 mL of pentane was condensed B_2Cl_4 (650 mg, 3.97 mmol) at −110 °C. A red-brown suspension immediately formed which, on warming to room temperature, became a yellow solution with a colorless precipitate (1.55 g). Its mass spectra indicated the presence of $(C_5Me_5)B-BCl_2-SiCl_2C_5Me_5$ (*m/z* = 462) and $(C_5Me_5)B-BCl_2-Si(C_5Me_5)_2Cl$ (*m/z* = 562) (or isomers). However, these products could not be isolated. The solid turned violet on contact with air or by storing under argon at room temperature for several weeks.[12] The crude product (80 mg) was recrystallized from hot toluene to give **5a** (25 mg).

^1H NMR ($CDCl_3$, 200 MHz): δ = 2.25 (s, 15 H). − ^{11}B NMR ($CDCl_3$, 64 MHz): δ = −51.7 (1 B, BC_5Me_5), −6.2 (1 B, sp^3B). − ^{13}C NMR ($CDCl_3$, 50 MHz): δ = 9.2 (CH_3), 113.1 (C_5). − CI-MS: *m/z* (%) = 689 (1.3) $[M_2^+ - Cl]$, 327 (100) $[M^+ - Cl]$, 227 (20) $[B_2SiCl_5^+]$. − EI-MS: *m/z* (%) = 327 (3) $[M^+ - Cl]$, 227 (100) $[B_2SiCl_5^+]$

***nido*-1-Trichloroborane-2,3,4,5,6-pentamethyl-2,3,4,5,6-pentacarbahexaborane(6) 5b:** A solution of B_2Cl_4 (600 mg, 3.57 mmol) in 60 mL of hexane was cooled to −100 °C and $Me_5C_5-SiMe_3$ (744 mg, 3.57 mmol) dissolved in 5 mL of hexane was added dropwise to give a red solution. The reaction mixture was allowed to warm to room temperature overnight yielding a yellow solution and a colorless precipitate (**5b**, 496 mg, 53%).

^1H NMR ($CDCl_3$, 200 MHz): δ = 2.21 (s, 15 H). − ^{11}B NMR ($CDCl_3$, 64 MHz): δ = −53.0 (1 B, BC_5Me_5), 2.8 (1 B, sp^3B). − ^{13}C NMR ($CDCl_3$, 50 MHz): δ = 8.9 (CH_3), 112.6 (C_5). − CI-MS: *m/z* (%) = 491 (63.0) $[M_2^+ - Cl]$, 227 (100) $[M^+ - Cl]$. − EI-MS: *m/z* (%) = 262 (0.7) $[M^+]$, 227 (100) $[M^+ - Cl]$

Crystal Structure Determinations: Data collection: Bruker AXS area detector (Mo-K_α λ = 0.71073 Å, −100 °C); structures solved by direct methods, full-matrix least-squares refinement on F^2.[14]

5a: Orthorhombic, $Pna2_1$, $C_{10}H_{15}B_2Cl_5Si{\cdot}C_7H_8$, *a* = 26.863(2), *b* = 9.0991(1), *c* = 9.0991(1) Å, *V* = 2224.1(5) Å^3, *Z* = 4; 3126 unique reflections, non-hydrogen atoms anisotropic, hydrogen atoms in

calculated positions (riding), 236 parameters $R_1 = 0.041$ (observed reflections), $wR_2 = 0.090$ (all reflections). The crystals were twinned showing tetragonal symmetry.

5b: Orthorhombic, $Pna2_1$, $C_{10}H_{15}B_2Cl_3$, $a = 11.9805(8)$, $b = 14.2209(10)$, $c = 7.5215(5)$ Å, $V = 1281.5(2)$ Å^3, $Z = 4$; 2713 unique reflections, non-hydrogen atoms anisotropic, hydrogen atoms isotropic, 209 parameters $R_1 = 0.030$ (observed reflections), $wR_2 = 0.070$ (all reflections).

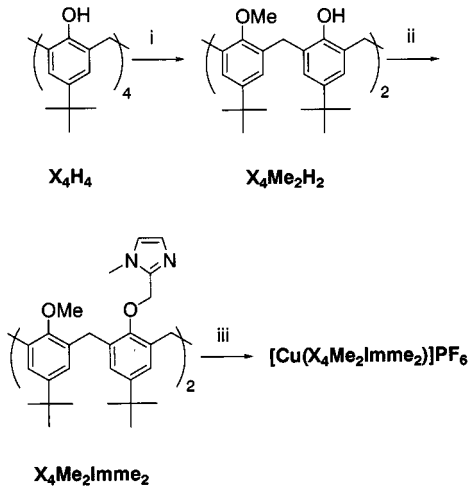
Synthesis and Characterization of a Novel Calix[4]arene-Based Two-Coordinate Copper(I) Complex That Is Unusually Resistant to Dioxygen

Loïc Le Clainche,[a] Michel Giorgi,[b] and Olivia Reinaud*[a]

Keywords: Calixarenes / Copper / N Ligands / Bioinorganic chemistry / Coordination chemistry



The ligand $X_4Me_2Imme_2$ was synthesized from *p-tert*-butylcalix[4]arene. Upon reaction with one equivalent of $Cu(NCMe)_4PF_6$, it led to the new two-coordinate copper(I) complex $[Cu(X_4Me_2Imme_2)]PF_6$ that was characterized by X-ray diffraction analysis. This complex revealed itself to be totally inert towards dioxygen in the solid state as well as in coordinating or protic solvents.

Introduction

Copper is a very important metal ion in biological systems, playing a very diverse role in living organisms.[1] It is involved in biochemical oxido-reduction processes, in electron transfers, as well as in the reversible binding of small gaseous molecules such as O_2 (Hemocyanin) or the plant hormone ethylene. Because the active form in these systems involves copper(I), the coordination chemistry of low-coordinate Cu^+ compounds is essential to the understanding of the metal reactivity. Due to the lack of useful spectroscopic probes for the Cu^I centers in native proteins, it is important to study its coordination chemistry with small artificial ligands.

Our main interest resides in the study of the chemical behavior of a metal ion in a biomimetic environment. For that purpose, we are trying to design supramolecular systems that allow the control of the metal nuclearity and reactivity. We recently showed that a calix[6]arene judiciously functionalized with three pyridine groups was particularly suited for stabilizing a cuprous ion in a tetrahedral mononuclear environment with a labile site included in a hydrophobic cavity. This was therefore a good model for type 2 centers in proteins.[2] We now describe the use of a calix[4]arene as a platform for the stabilization of a two-coordinate Cu^I complex with two biomimetic imidazolyl pendant arms. This complex appeared to be extremely resistant to O_2 oxidation and was stable in air for weeks, even in a potentially coordinating or protic solvent.

The new bidentate ligand $X_4Me_2Imme_2$ was prepared in two steps, as depicted in Scheme 1. *t*Bu-calix[4]arene (X_4H_4) was first converted into its 1,3-dimethyl ether ($X_4Me_2H_2$)[3] and then treated with 2-chloromethyl-1-methyl-1*H*-imidazole in the presence of NaH to produce $X_4Me_2Imme_2$ in 90% yield. Its ^1H NMR spectrum exhibited broad ill-defined resonances at room temperature. This indicated that the calixarene was mobile and not fixed in a cone conformation.

Scheme 1. Synthesis of the calixarene-based ditopic ligand $X_4Me_2Imme_2$ and complexation of copper(I); reagents and conditions: (i) K_2CO_3, MeOTs, MeCN, reflux 24 hours, 89%; (ii) NaH, 2-chloromethyl-1-methyl-1*H*-imidazole, THF/DMF, reflux 4 hours, 90%; (iii) $[Cu(MeCN)_4]PF_6$, $CHCl_3$, 90%

The reaction of $X_4Me_2Imme_2$ with one equivalent of $Cu(NCMe)_4PF_6$ in chloroform gave rise to a new cuprous complex, which spontaneously precipitated out of the solution (Scheme 1). Its elemental analysis was in good agreement with a compound of formula $[Cu(X_4Me_2Imme_2)]PF_6$. The corresponding ^1H NMR spectrum was well resolved and suggestive of a complex possessing a twofold symmetry. Suitable crystals for X-ray diffraction analysis were grown from a cold solution in $CHCl_3$/MeCN. The crystal structure of $[Cu(X_4Me_2Imme_2)]PF_6$ (Figure 1) showed a mononuclear complex where Cu^+ is coordinated to both imidazole

arms of the calix[4]arene-based ligand, which is in a cone conformation.

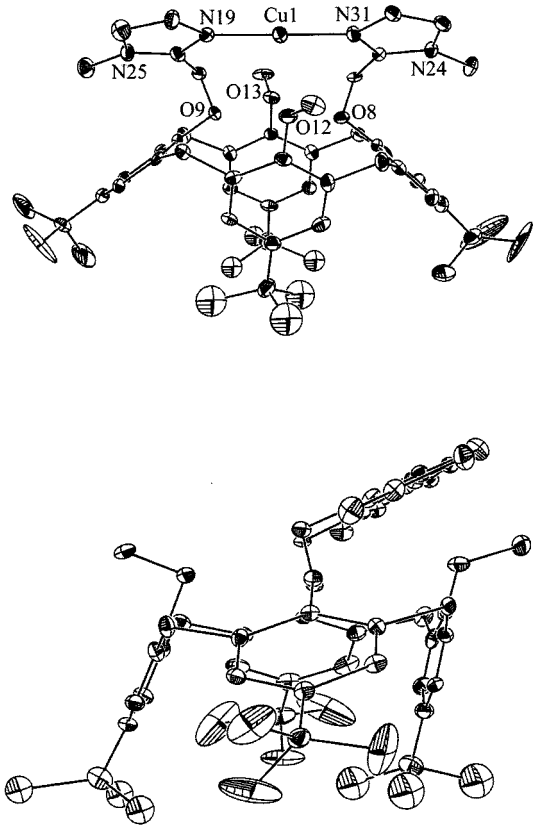

Figure 1. X-ray structure of $[Cu(X_4Me_2Imme_2)]PF_6$ (two different side views are displayed); selected atom distances (Å) and bond angles (°): Cu(1)−N(19) 1.87(1), Cu(1)−N(31) 1.867(9), N(19)−Cu(1)−N(31) 178.5(4); the counter ion and the solvent of crystallization have been omitted for clarity; for the same reason, only one occupancy site for each of the disordered *tert*-butyl groups is displayed

The Cu−N distances (1.87 Å) are similar to those previously reported for two-coordinate imidazole complexes.[4,5] The geometry at the metal center is almost linear (N−Cu−N = 178.5°) and the dihedral angle between the two imidazole rings is 3°, showing that they are almost coplanar. The plane of the imidazoles is bent on one side relative to the O13 oxygen, which is in close contact with the copper ion [Cu(1)···O(13) = 2.73 Å compared to Cu(1)···O(8) = 3.58 Å, Cu(1)···O(9) = 3.75 Å, Cu(1)···O(12) = 4.81 Å]. This may reflect a stabilizing electronic interaction between Cu^+ and one basic oxygen of the calixarene. In solution, however, the symmetrical ^1H NMR profile indicated that, if it exists at all, this interaction is averaged over both opposite phenoxyl groups and the coordination plane is probably flipping from one side to the other. $[Cu(X_4Me_2Imme_2)]PF_6$ exhibited an unusual stability towards dioxygen. In the solid state, it is indefinitely stable. In polar solvents such as DMSO or acetonitrile, or protic solvents like methanol, no oxidation of copper(I) has ever been observed, even if the solution is allowed to stand in an open flask for weeks.

This new copper(I) complex displays a geometry that is similar to previously reported two-coordinate copper(I) complexes with nitrogen donors.[4,5] Although the resulting linear geometry is known to disfavor O_2 and CO interaction,[4,5] our complex appeared to be unusually[4−6] resistant to oxidation with O_2 and did not coordinate CO. In contrast, the two-coordinate Cu^I complexes obtained with various unidentate imidazole ligands were reported to undergo rapid autoxidation in air, especially in a protic solvent. Curiously[6], we also found that the presence of two imidazole rings rather than two pyridine rings provided an enhanced stability of the copper(I) complex toward oxidation. Indeed, the copper(I) complex $[Cu(X_4Me_2Pic_2)]PF_6$ derived from the corresponding pyridine-based calix[4]arene ligand[7] was extremely sensitive to O_2 and underwent autoxidation in air within seconds.

The following points can rationalize these observations:
i) the exceptional inertness of the $[Cu(X_4Me_2Imme_2)]^+$ complex compared to the complexes derived from unidentate imidazole ligands is attributable to the highly favorable preorganization provided by the calix[4]arene platform rather than to steric hindrance;
ii) the enhanced stability of $[Cu(X_4Me_2Imme_2)]^+$ compared to the analogous pyridine-based complex is due to electronic factors and may be explained by an increased orbital overlap between the imidazole-nitrogen atom and copper(I) that stabilizes the two coordinate form for the imidazole-ligated species compared to the pyridine, as previously discussed by Sorrel.[4]

In conclusion, we have described a novel copper(I) complex that, although coordinatively unsaturated, revealed itself to be resistant to oxidation in a protic aerated environment. This emphasizes the importance of preorganization of the metal binding site as one of the key features that allows the control of the Cu^I reactivity. This may be reminiscent of biological systems, which either utilize copper(I) to bind or activate a small molecule[1] or stabilize it as in copper chaperones,[8] which transport and/or deliver Cu^I to other proteins in the cells.[9]

Experimental Section

$X_4Me_2Imme_2$: Under an argon atmosphere, a solution of $X_4Me_2H_2$ (500 mg, 0.74 mmol) in dry THF (10 mL) was introduced into a flask containing NaH (60% in oil washed twice with pentane; 0.9 g, 22 mmol) and the resulting mixture was stirred for 30 minutes. 2-Chloromethyl-1-methyl-1*H*-imidazole hydrochloride (0.74 g, 4.5 mmol) was added over a period of 5 minutes. After 4 hours at reflux, the solvents were removed under reduced pressure to a third volume and poured into water (110 mL). The crude precipitate was collected by filtration, washed with water (3 × 25 mL) and then chromatographed to give a white product which was dried under vacuum on KOH (580 mg, 90%). − M.p. 280 °C (dec.). − IR (KBr): $\tilde{\nu}$ = 1481, 1457, 1361, 1286, 1119, 1018, 978, 840 (PF_6) cm^{-1}. − ESI: *m/z* = 865.6 [M^+ + 1]. − $C_{56}H_{72}N_4O_4$ (864.6): calcd. C 77.78, H 8.33, N 6.48; found C 77.31, H 8.51, N 6.25.

$[Cu(X_4Me_2Imme_2)]PF_6$: To a solution of $X_4Me_2Imme_2$ (200 mg, 0.25 mmol) in $CHCl_3$ (1.4 mL) under an inert atmosphere was added dropwise $[Cu(NCMe)_4]PF_6$ (92 mg, 0.25 mmol). The mixture was stirred under argon. After 3 hours, the crude precipitate was

filtered, washed with heptane and dried under vacuum (KOH) to give a white solid (196 mg, 91%). M.p. 340 °C (dec.). − $C_{56}H_{72}N_4O_4CuPF_6{\cdot}2H_2O$ (1108): calcd. C 60.65, H 6.86, N 5.05; found C 60.90, H 6.62, N 4.95 − IR (KBr): $\tilde{\nu}$ = 1481, 1457, 1361, 1286, 1119, 1018, 978, 840 (PF_6) cm^{-1}. − ^1H NMR ([D$_6$]DMSO, 400 MHz, T = 298 K): δ = 0.72 (s, 18 H, *t*Bu), 1.29 (s, 18 H, *t*Bu), 2.98 (s, 6 H, OMe), 3.03 (s, 4 H, CH_{2eq}), 3.59 (s, 10 H, NMe and CH_{2ax}), 5.46 (s, 4 H, O−CH_2), 6.31 (s, 4 H, ArH), 7.19 (s, 4 H, ArH), 7.39 (s, 2 H, ImH), 7.48 (s, 2 H, ImH). The assignment of the signal corresponding to CH_{2ax} was achieved upon warming the sample to 50 °C: ^1H NMR ([D$_6$]DMSO, 400 MHz, T = 323 K): δ = 0.75 (s, 18 H, *t*Bu), 1.29 (s, 18 H, *t*Bu), 3.01 (s, 6 H, OMe), 3.03 (s, 4 H, CH_{2eq}), 3.59 (s, 6 H, NMe), 3.66 (s, 4 H, CH_{2ax}), 5.45 (s, 4 H, O−CH_2), 6.35 (s, 4 H, ArH), 7.18 (s, 4 H, ArH), 7.39 (s, 2 H, ImH), 7.50 (s, 2 H, ImH) − ^{13}C NMR ([D$_6$]DMSO, 100 MHz, T = 298 K): δ = 30.2 (Ar-α*C*H2), 30.8 (C*C*H$_3$), 31.5 (C*C*H$_3$), 33.3 (*C*CH$_3$ and N*C*H$_3$), 34.0 (*C*CH$_3$), 62.3 (O*C*H$_3$), 65.5 (Imme-α*C*H$_2$), 123.5 (C_{Imme}H), 124.6 (C_{Ar}H), 125.8 (C_{Ar}H), 127.4 (C_{Imme}H), 131.1 (C_{Ar}−CH_2), 135.6 (C_{Ar}−CH_2), 143.7 (C_{Ar}), 146.2 (C_{Ar}), 147.2 (C_{Imme}), 153.0 (C_{Ar}), 153.3 (C_{Ar}).

X-ray Crystallographic Study

[Cu ($X_4Me_2Imme_2$)]PF_6: [($C_{56}H_{72}N_4O_4$)Cu]PF_6: M = 1072, monoclinic, colorless crystals (0.3 × 0.2 × 0.2 mm) a = 17.552(1) Å, b = 16.955(1) Å, c = 21.860(1) Å, α = 90°, β = 100.44(1)°, γ = 90°, V = 6434.1(1) Å^3, space group $P2_1/c$, Z = 4, $\rho_{calcd.}$ = 1.54 g·cm^{-3}, μ(Mo-K_α) = 15.5 cm^{-1}, 9420 reflections collected at 298 K (Nonius KappaCCD diffractometer) in the 1−25° θ range, 9074 unique, 715 parameters refined on F using 5545 reflections [maXus][10] to final indices: $R1$ [$F > 3\sigma(F)$] = 0.087, $wR1$ ($w = 1/[\sigma^2(F) + 0.03F^2]$) = 0.099.

The complex and its counter ion co-crystallize with two molecules of chloroform in the asymmetric unit. During the refinement process, a disorder of position was observed for two *t*Bu groups. In each of them, the three terminal carbon atoms were split over two distinct sites with occupancy factors for the major and minor site, respectively, of 0.5−0.5 for one *t*Bu and 0.8−0.2 for the second *t*Bu. No hydrogen atoms were therefore introduced or refined on these disordered substituents.

Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Data Center as supplementary publication no. CCDC-138488. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1 EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

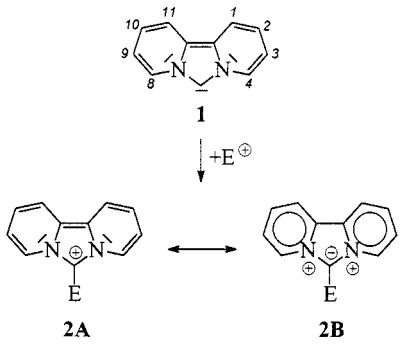
Novel Urea Derivatives as Two-Step Redox Systems



Robert Weiss,*[a] Sylvia Reichel[a]

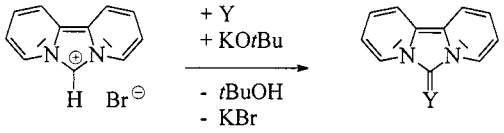
Keywords: Carbenes / Cations / Radicals / Two-step redox systems / Semiempirical calculations

The structurally novel urea derivatives **4**–**6** have been synthesized by treating the nucleophilic dipyridoimidazol-2-ylidene **1** with elemental chalcogens Y (Y = S, Se, Te). The oxygen analogue **8** has been obtained indirectly by alkylation of the seleno urea **5**, followed by alkaline hydrolysis. All of these urea derivatives share two novel structural features: (i) their nitrogen centers represent the termini of the RED form of a two-step viologen-type redox system, and (ii) they can also be viewed as formally resulting from a cheletropic addition of CY to 2,2′-bipyridine. It has been demonstrated electrochemically that for Y = O, S, Se these ureas can be reversibly oxidized to the corresponding radical cations (SEM forms) at remarkably constant and negative potentials. This also applies to the heaviest congener of the series with Y = Te, except that in this case the oxidation process exhibits only quasi-reversibility. Electrochemical generation of the corresponding OX forms is observed quasi-reversibly at increasingly positive potentials with increasing mass of the chalcogen Y. However, the bis-oxidation of the telluro species **6** cannot be observed. These experimental results are discussed on the basis of semiempirical calculations for the RED, SEM, and OX forms under consideration. Semiempirical calculations also suggest that fragmentation of the novel urea derivatives into CY and 2,2′-bipyridine should be mildly endothermic for Y = O, but increasingly strongly endothermic with increasing mass of Y. This result is qualitatively in line with expectation considering the increasing reluctance of the heavier chalcogens to take part in multiple bonding to carbon. This phenomenon is also reflected in the mass spectrometric fragmentation patterns of the urea derivatives **4**–**6** and **8**.

Introduction

Recently, we reported on the generation of a novel type of nucleophilic carbene **1**, which alternatively can be considered as a 1:1 complex of singlet carbon and 2,2′-bipyridine.[1] In solution at −30 °C this species is stable for several hours and can be trapped by a multitude of electrophiles, both organic and inorganic, to give stable derivatives **2** (Scheme 1).

Scheme 1



As can be inferred from inspection of the resonance structures **2A** and **2B**, the cationic substituent, which is introduced into a substrate through covalent bonding to **1**, is auto-adaptable to the electronic requirements of E. Thus, if the latter in **2** is a donor then resonance form **2A** is the major contributor, was **2B** more adequately describes the bonding situation when E is an acceptor. This unprecedented electronic flexibility intrinsic to **2** stems from the ability of the integrated two-step 2,2′-bipyridine redox system to act as an auto-umpolung device.[1]

In the present paper we report on the synthesis, structure, electrochemistry, and some reactions of adducts of **1** with S, Se, and Te as electrophiles, which represent novel redox-active urea derivatives. The synthesis of the corresponding oxygen analogue via an indirect route is also reported.

Results and Discussion

Synthesis and Characterization of Chalcogeno Ureas 4−6, 8[2]

Cyclic seleno and telluro ureas have previously been synthesized by treating Arduengo carbenes with Se and Te, respectively.[3] Similarly, dipyrido[1,2-*c*:2′,1′-*e*]imidazolylidene **1** can be transformed into the homologous chalcogeno ureas by treatment with elemental Te, Se, or even S. These orange-red to red compounds can be prepared most conveniently in yields > 80% in a one-pot reaction, where the carbene **1** is generated in situ from the imidazolium salt **3/Br⁻** with KO*t*Bu in the presence of the chalcogens. Compounds **4**−**6** are readily soluble in THF and are thus easily

separated from salt-like components of the reaction mixture (Scheme 2).

Attempts to synthesize the parent compound of this series, i.e. the 6*H*-dipyrido[1,2-*c*:2′,1′-*e*]imidazolone **8**, by treating the carbene **1** with O_2 met with failure. However, **8** can be obtained indirectly by methylation of selenone **5** with CH_3I, followed by treatment of the resulting salt **7/I**$^-$ with NaOH in ethanol (Scheme 3).

Scheme 3

Two discrete sets of signals attributable to the 2,2′-bipyridine unit are observed in the ^{1}H NMR spectra of all of these urea derivatives. The set at lower field (**a** in Figure 1) can be plausibly attributed to the protons at C-1/C-11 and C-4/C-8, while that at higher field (**b** in Figure 1) can be attributed to the protons at C-2/C-10 and C-3/C-9. This is exemplified in Figure 1 in the case of the thio urea **4**.

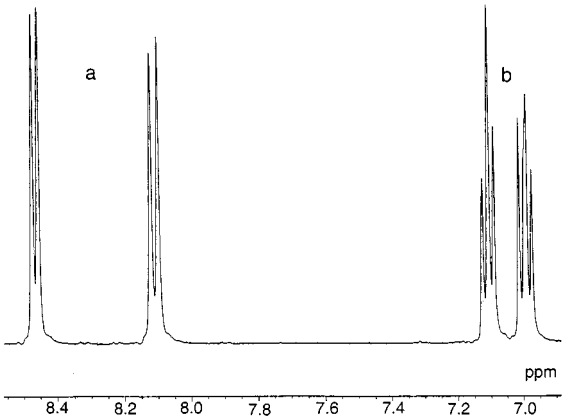

Figure 1. ^{1}H NMR spectrum of thio urea **4** (in $[D_6]$DMSO)

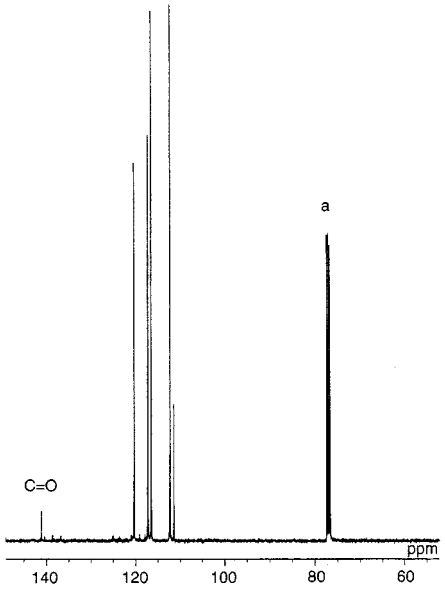
The ^{13}C NMR spectra of chalcogeno ureas **4**–**6**, **8** feature a set of five closely spaced signals due to the carbons of the bipyridine moiety, and one isolated signal due to the carbon atom adjacent to the chalcogen. The chemical shift of the latter varies with the nature of the chalcogen in a manner that does not lend itself to simple interpretation (see below). The complete set of data is collected in Table 1; Figure 2 shows the ^{13}C NMR spectrum of urea **8**.

Table 1. ^{13}C NMR shifts of the chalcogeno ureas **4**–**6** and **8**

	C=Y	C atoms of the 2,2′-bipyridine group
8 (Y = O)[a]	141.1	111.46, 112.29, 116.51, 117.24, 120.31
4 (Y = S)[b]	141.8	116.59, 118.26, 118.48, 118.92, 122.17
5 (Y = Se)[b]	133.4	117.53, 118.35, 119.69, 120.76, 123.45
6 (Y = Te)[b]	104.2	118.51, 118.64, 120.75, 123.47, 126.19

[a] in $CDCl_3$. – [b] in $[D_6]$DMSO.



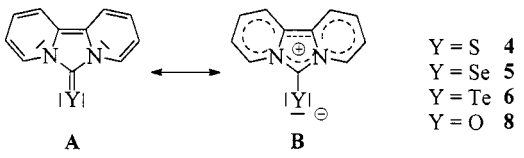


Figure 2. ^{13}C NMR spectrum of urea **8** (in $CDCl_3$ = **a**)

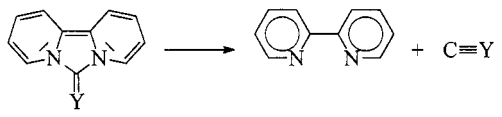
The heavy-atom effect of chalcogens Y in C=Y double bonds leads to increasingly low-field shifts of the signals of the corresponding C atoms with increasing atomic weight of Y, was the reverse is true for C–Y single bonds.[4] The data in Table 1 conform to the latter pattern, from which it can be concluded that the chalcogenones presented can best be characterized as having essentially single carbon–chalcogen bonds. This is particularly true for the heavier chalcogens Se and Te. Thus, resonance structure **B** (Scheme 4) will increasingly dominate the electron distribution in this set of chalcogenones on going from Y = O to Y = Te. This is in line with the increasingly low-field shifts observed for the ^{13}C NMR signals of the carbons of the bipyridine moiety within the same series of compounds (cf. Table 1).



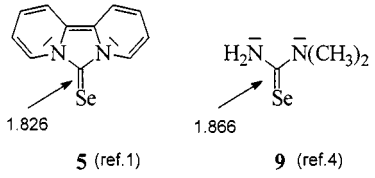
Scheme 4

The radical cations of chalcogenones **4**–**6**, **8** figure prominently in the mass spectra of these compounds. Their further decomposition depends dramatically on the specific

chalcogen present. Thus, while the radical cations of selenone **5** and tellurone **6** undergo loss of the chalcogen to yield the radical cation of carbene **1**, the corresponding radical cation of thione **4** would appear to be stable under the same mass spectrometric conditions. In contrast, the radical cation of 6*H*-dipyrido[1,2-*c*:2′,1′-*e*]imidazolone **8** decomposes into CO and the radical cation of 2,2′-bipyridine, a reaction that can be formally viewed as a C-transfer from carbene **1** to an oxygen atom.

Thermodynamic aspects of the thermal fragmentation of chalcogeno ureas **4**−**6** and **8** into 2,2′-bipyridine and the corresponding carbon monochalcogenides CY according to Scheme 5 have been assessed on the basis of semiempirical calculations (PM3).

Y	ΔH_R [kcal·mol^{-1}]
O	+10.19
S	+67.74
Se	+119.33
Te	+145.45



Scheme 5

For Y = O, this reaction is only moderately endothermic and would appear to be feasible either thermally or photochemically. Considering the more interesting fragmentations of **4**−**6**, for obvious reasons the endothermicity increases rapidly with increasing atomic weight of Y, such that these compounds do not appear to be useful precursors for the corresponding high-energy CY species (cf. Scheme 5). In any case, the reaction enthalpies given in Scheme 5 − although they are qualitatively reasonable − will have to be recalculated at higher levels of theory.

Two pieces of evidence indicate that the C−Y bonds in the novel chalcogenones presented in this paper are stronger than the corresponding bonds in known open-chain analogues:

(a) Imidazolone **8** exhibits a ν(CO) frequency of 1681 cm^{-1}, was the corresponding absorption in open-chain ureas is found at around 1660 cm^{-1}.

(b) The C−Se bond in selone **5**[1] is distinctly shorter than that in the open-chain seleno urea **9**[5] (Scheme 6).

Scheme 6

Theoretical calculations in conjunction with an NBO analysis[6] suggest that these effects are not due to an increase in π bond order relative to the open-chain urea analogues, but rather to an unusually high s content in the C(sp^x) orbital pointing towards the chalcogen Y. Bent's rules,[7] in agreement with the PM3 calculations, predict that the s content in this hybrid orbital should increase as the electronegativity of Y decreases. The results of calculations (PM3/NBO), as shown in Figure 3, point to an almost linear relationship between these two parameters.

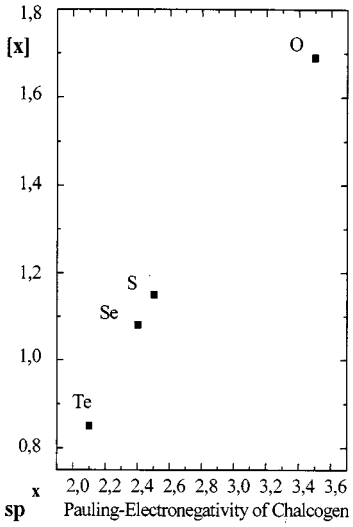


Figure 3. Hybridization C(sp^x) in the CY bond as a function of the electronegativity of the chalcogen

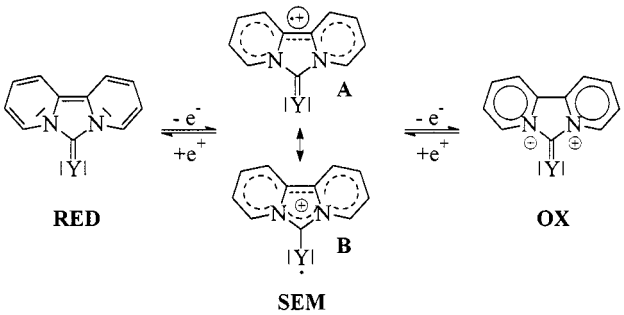

In this context, we refer to a recent communication[1] in which we presented NMR evidence showing that the carbon of the imidazolium C−H bond in **3** is virtually sp hybridized. This anomaly may be attributed to considerable angle strain in the five-membered ring, coupled with the pronounced electronegativity of the N centers. The same σ effect − albeit modulated by the nature of Y as indicated in Figure 3 − seems to be operative in the C−Y bonds of the chalcogenones considered in this paper.

Electrochemical Investigations

Chalcogenones **4**−**6** and **8** can be regarded as the RED[9] forms of a two-step redox system (cf. Scheme 7).

All members of the series of new chalcogenones presented show a first oxidation wave at around 0.3 V. The associated redox process is reversible for the three lighter chalcogens (see, for example, Figure 4) and quasi-reversible in the case of tellurium.

The measured $E_{1/2}$ values for the RED/SEM transition are seen to be remarkably insensitive to the nature of the chalcogen attached to the organic moiety. This is a consequence of resonance between the main contributors A and B in the SEM form (Scheme 7). The contribution of form A decreases as Y gets heavier as the bond energies of the corresponding CY double bonds rapidly increase. However, this is counterbalanced by a concomitant increase in the contribution of resonance structure B. In the latter, the high-energy structural element of a chalcogen radical center

According to cyclic voltammetric measurements, most of these redox processes can be realized electrochemically (Table 2).

[a] Supporting electrolyte: 0.1 N NEt_4BF_4/CH_3CN; reference electrode: Ag/AgCl; working and auxiliary electrode: platinum; standard: Ferrocene;[8] scan rate: 100 mVs^{-1}; rev = reversible; qrev = quasireversible

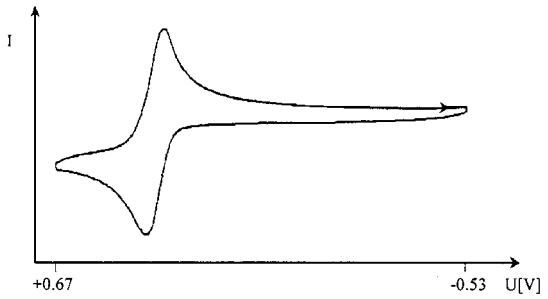

Figure 4. Cyclic voltammogram of thio urea **4**: first oxidation wave

is energetically compensated by the 14π aromatic dipyridoimidazolo substructure. As a consequence, the spin density on Y increases as Y gets heavier. This trend is corroborated by the results of calculations. An example is shown in Figure 5 and Figure 6, w the spin densities of SEM-**8** and SEM-**4** are compared.

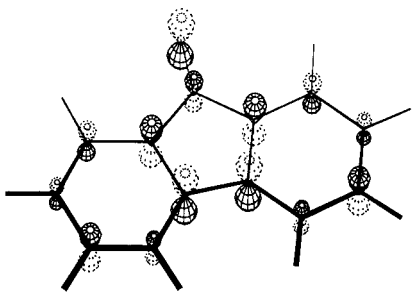

Figure 5. SOMO of the monooxidation product of **8** (Y = O, PM3)

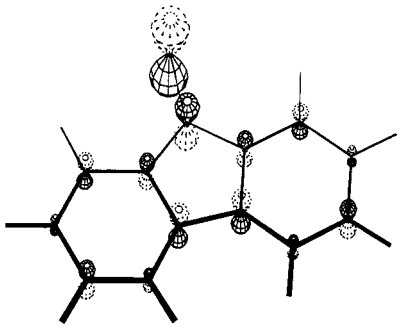

Figure 6. SOMO of the monooxidation product of **4** (Y = S, PM3)

Increasing concentration of spin density at the chalcogen center will increasingly favour dimerization of the corresponding SEM form to give a dichalcogenide. The observed loss of reversibility in the electrochemical oxidation of tellone **6** (Table 2) may be an indication of such a chemical process.

The second oxidation wave in the CV spectra corresponds in each case to the formation of the OX form. For this step, the $E_{1/2}$ values increase dramatically with increasing atomic weight of Y as a true CY double bond has to be formed – a distinct energetic disadvantage for the heavier chalcogens (see above).

Ongoing work in this area is focused on the chemical oxidation of chalcogenones **4**–**8**.

Experimental Section

General: All operations were performed under nitrogen atmosphere using standard Schlenk techniques. Solvents were dried by standard methods and distilled under N_2. – IR (KBr): Bruker IFS 25; abbreviations: w (weak), m (medium), s (strong), vs (very strong). – NMR: Jeol EX 400 and Jeol GX 400 (each 400 MHz and 100 MHz for ^1H and ^{13}C, respectively). For ^1H NMR: $CDCl_3$ as solvent, TMS as internal standard; [D_6]DMSO as solvent $\delta_H = 2.49$; for ^{13}C NMR: $CDCl_3$ as solvent $\delta_C = 77.0$; [D_6]DMSO as solvent $\delta_C = 39.5$. – EI-MS: Varian MAT 311A (70 eV). – Elemental analysis: Heraeus CHN-Rapid and Carlo Erba Elemental Analyser, Model 1106. Some of the compounds were found to absorb water during processing. – CV: PAR Model 170 Electrochemistry System.

6*H*-Dipyrido[1,2-*c*:2′,1′-*e*]imidazole-6-thione (4): To a suspension of dipyrido[1,2-*c*:2′,1′-*e*]imidazolium bromide **3/Br**$^-$ (0.41 g, 1.65 mmol) in THF (50 mL) was added sulfur (0.05 g, 1.65 mmol) followed, at −78 °C, by KO*t*Bu (0.19 g, 1.65 mmol). After 2 h, the mixture was filtered through Celite and the solid was washed with THF (20 mL). The combined filtrate and washings were concentrated to a volume of a few mL and petroleum ether (30 mL) was added. The resulting red suspension was filtered, and the collected solid was washed with petroleum ether (10 mL) and dried in vacuo for 2 h to give 0.28 g of **4** (85%); red solid; m.p. ≈ 200 °C. – IR (KBr): $\tilde{\nu}$ = 3078 (w), 1637 (s), 1615 (s), 1524 (s), 1413 (s), 1381 (vs), 1349 (w), 1336 (s), 1327 (s), 1302 (s), 1250 (s), 1212 (s), 1154 (s), 1131 (s), 1116 (s), 1001 (vs), 989 (s), 897 (w), 810 (w), 727 (vs), 689 (s), 671 cm^{-1} (w). – ^1H NMR ([D_6]DMSO): δ = 7.04 (m, 2 H), 7.14 (m, 2 H), 8.14 (m, 2 H), 8.47 (m, 2 H). – MS: *m*/*z* =

200 [M^+]. − $C_{11}H_8N_2S \cdot 0.25\ H_2O$ (with 0.25 H_2O: 204.7) (200.3): calcd. C 64.52, H 4.18, N 13.68; found C 64.72, H 3.89, N 13.90.

6*H*-Dipyrido[1,2-*c*:2′,1′-*e*]imidazole-6-selone (5): To a suspension of dipyrido[1,2-*c*:2′,1′-*e*]imidazolium bromide **3/Br**$^-$ (0.23 g, 0.93 mmol) in THF (50 mL) was added selenium (0.08 g, 1.03 mmol) followed, at −15 °C, by KO*t*Bu (0.13 g, 1.13 mmol). After 2 h, the mixture was filtered through Celite and the solid was washed with THF (10 mL). The combined filtrate and washings were concentrated to a volume of a few mL and pentane (30 mL) was added. The resulting red suspension was filtered, and the collected solid was washed with pentane (10 mL) and dried in vacuo for 2 h to give 0.20 g of **5** (87%); orange-red solid; m.p. ≈ 225 °C. − IR (KBr): $\tilde{\nu}$ = 3074 (w), 1644 (s), 1617 (w), 1558 (w), 1541 (w), 1524 (s), 1508 (w), 1415 (s), 1368 (vs), 1341 (w), 1325 (s), 1306 (w), 1252 (s), 1213 (s), 1154 (w), 1114 (w), 993 (s), 964 (w), 891 (w), 727 (vs), 689 cm^{-1} (w). − ^{1}H NMR ([D$_6$]DMSO): δ = 7.20 (m, 4 H), 8.28 (m, 2 H), 8.65 (m, 2 H). − MS: *m*/*z* = 248 [M^+], 168 [$C_{11}H_8N_2^+$ = carbene]. − $C_{11}H_8N_2Se$ (247.2): calcd. Regio- and Stereoselective Functionalization of *cyclo*-C_8 Compounds by Iterative Nucleophilic and Electrophilic Addition to Coordinated Cyclooctatetraene

Gerhard Lange,[a] Oliver Reimelt,[a] Lars Jessen,[a] and Jürgen Heck*[a]

Dedicated to Prof. Dr. Wolfgang Walter on the occasion of his 80th birthday

Keywords: Electrophilic additions / Hydrido complexes / Nucleophilic additions / Ruthenium / Cyclooctatetraene

The addition of various nucleophiles (Nu^1) to the cationic complex $[CpRu(\eta^6\text{-cot})]^+$ (**1**$^+$) has been performed and yielded the neutral complexes $CpRu(\eta^5\text{-}C_8H_8Nu^1)$ (**2**) [cot = cyclooctatetraene; Nu^1 = Me (**2a**), $CH(CO_2Me)_2$ (**2b**), CH=CH_2 (**2c**), C_6H_5 (**2d**), H (**2e**), D (**2f**), NMe_2 (**2g**), OMe, (**2h**), C≡C*t*Bu (**2i**)]. The nucleophiles Nu^1 add exclusively to the cot ring, and stereoselectively in the *exo* position with respect to the metal center. As evidenced by NMR spectroscopy the *cyclo*-C_8 ligand in **2c**, **2e**–**2i** is bound in a 1,2-η:5,6,7-η fashion in solution. The molecular structure analysis of **2c** [space group $P\bar{1}$, a = 757.9(1), b = 759.1(1), c = 1053.1(3) pm, α = 81.93(2), β = 80.22(1), γ = 88.73(1)°, V = 591.2(2) Å^3, Z = 2, R_{merge} = 0.0265] verifies the 1,2-η:5,6,7-η coordination mode of the *cyclo*-C_8 ligand in the solid state and shows the Nu^1 substituent to be in an *exo* position. For **2a** and **2b** a 1,2,3,4,5-η haptomer is also found, and this interconverts to the 1,2-η:5,6,7-η derivative in solution; in contrast, the *cyclo*-C_8 ligand of the phenyl derivative **2d** remains in the 1,2,3,4,5-η fashion. The protonation of the neutral complexes **2a**–**2d** by the addition of HBF_4 generates the new cationic products $[CpRu(\eta^6\text{-}C_8H_9Nu^1)]^+$ (**3**$^+$) [Nu^1 = Me (**3a**$^+$), $CH(CO_2Me)_2$ (**3b**$^+$), CH=CH_2 (**3c**$^+$), C_6H_5 (**3d**$^+$)]. When Nu^1 = $CH(CO_2Me)_2$ (**3b**$^+$) two different haptomers were isolated that exhibit 1,2-η:4,5,6,7-η and 1,2,3,4,5,6-η bonding modes, respectively. In solution the 1,2-η:4,5,6,7-η haptomer completely rearranges to the 1,2,3,4,5,6-η derivative. The crystal structure analysis of **3d**BF_4 [space group *Pbc*2(1), a = 1678.8(7), b = 1031.4(2), c = 981.8(2) pm, V = 1700.0(9) Å^3, Z = 4, R_{merge} = 0.032] confirms the 1,2-η:4,5,6,7-η bonding mode of the *cyclo*-C_8 ligand, which has also been indicated in solution. The second nucleophilic addition to the coordinated *cyclo*-C_8 ligand yields new neutral complexes that exist as two different haptomers depending on the steric demand of the two nucleophiles. The haptomer $CpRu(1,2,3,4,5\text{-}\eta\text{-}C_8H_9\text{-}6\text{-}Nu^1\text{-}8\text{-}Nu^2)$ (**4a**) is formed with Nu^1 = Nu^2 = $CH(CO_2Me)_2$ whereas with Nu^1 = Me, Nu^2 = $CH(CO_2Me)_2$ (**4b**) and Nu^1 = Nu^2 = Me (**4c**) the haptomer $CpRu(1,2\text{-}\eta\text{:}5,6,7\text{-}\eta\text{-}C_8H_9\text{-}4\text{-}Nu^1\text{-}8\text{-}Nu^2)$ is obtained. The protonation of **4a**–**4c** produces the cationic hydride species $[CpRu(H)(1,2,3,4,5\text{-}\eta\text{-}C_8H_9Nu^1Nu^2)]^+$ (**5**$^+$) [Nu^1 = Nu^2 = $CH(CO_2Me)_2$ (**5a**$^+$), Nu^1 = CH_3, Nu^2 = $CH(CO_2Me)_2$ (**5b**$^+$), Nu^1 = Nu^2 = Me (**5c**$^+$)] as indicated by the high-field shifted singlet for one proton below δ = −10 in the ^{1}H-NMR spectra. An X-ray structure analysis of a single crystal obtained from the protonation reaction of **4b** [space group $P2_1/c$, a = 1285.5(12), b = 1015.8(8), c = 1586.3(14) pm, β = 108.61(7)°, V = 1963(3) Å^3, Z = 4, R_{merge} = 0.0942] reveals a special disorder, the interpretation of which results in the structure determination of two independent complexes in a ratio of 59:41 differing by two hydrogen atoms in the formula. Both complexes are cations; one exhibits a disubstituted 1,2,3,4,5-η-bonded cyclooctadienyl ligand and an agostic interaction of the Ru center with a hydrogen atom at C5 of the *cyclo*-C_8 ligand (**5b**BF_4), whereas the second complex contains a cyclooctatriene ligand in a 1,2,3,4,5,6-η bonding mode without a metal hydride function (**6**BF_4). The coexistence of two different molecules in one single crystal that differ by two hydrogen atoms in addition to the agostic hydrogen atom in **5b**$^+$, points to an elimination of an H_2 molecule from **5b**$^+$ in the solid state to generate **6**$^+$. This suggestion is corroborated by the formation of a cationic complex **7**$^+$ as the main product in solution, which contains a *cyclo*-C_8 ligand without the malonate nucleophile [Nu^2 = $CH(CO_2Me)_2$], whereas a freshly prepared NMR sample only reveals **5b**$^+$ and **6**$^+$. In all of these products the Me nucleophile (Nu^1 = Me) is linked to a metal-coordinated carbon atom indicating an additional intramolecular hydrogen migration after the initial protonation.

Introduction

Nucleophilic addition to unsaturated organic ligands is very pertinent to synthetic organometallic chemistry.[1] Since this type of reaction displays pronounced stereo- and regioselectivity it is used in the synthesis of natural products.[2] More recent investigations demonstrate that this synthetic concept can be transferred to coordinated carbocycles like cyclooctatetraene,[3] which generates an access to multiple stereo- and regioselectively functionalized *cyclo*-C_8 ligands, and which may be of some importance in the synthesis of precursor compounds for *cyclo*-C_8 terpenoids.[4] In this paper we present results obtained from an iteratively applied reaction sequence of nucleophilic addition-protonation using different nucleophiles.

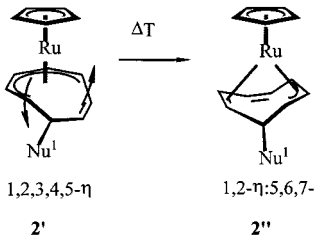
Results and Discussion

Primary Nucleophilic Addition



The initial nucleophilic addition to $[CpRu(\eta^6\text{-cot})]^+$ ($\mathbf{1}^+$) (Cp = cyclopentadienyl, cot = cyclooctatetraene) (Scheme 1) occurs exclusively at the cot ligand as predicted from the Davies−Green−Mingos rules.[5] In order to test the electrophilicity of the coordinated cot in $\mathbf{1}^+$, the charged heteronucleophiles OMe^- and NMe_2^- were also used; the nucleophilicity of neutral amines and phosphanes appeared to be too low to add to the cot ligand in $\mathbf{1}^+$.

Nu^1	Me	$CH(CO_2Me)_2$	$CH{=}CH_2$	C_6H_5	H	D	NMe_2	OMe	$C{\equiv}CtBu$
2	**a**	**b**	**c**	**d**	**e**	**f**	**g**	**h**	**i**

Scheme 1. Nucleophilic addition to $\mathbf{1}^+$

The assignment of the NMR signals can easily be performed by applying ^1H-^1H and ^1H-^{13}C correlation spectroscopy when the single proton signal of the nucleophile-bearing sp^3-carbon atom C8 is localized. When Nu^1 = Me or $CH(CO_2Me)_2$, two different isomers can be identified: in the isomer **2′** (e.g. **2a′** and **2b′**) the proton of the Nu^1-substituted carbon atom C8 couples with the vicinal protons of a coordinated and noncoordinated carbon−carbon double bond; in the second isomer **2′′** (e.g. **2a′′** and **2b′′**) the proton on C8 couples to protons of metal-bound carbon atoms only (Table 3). Since the number of metal-bound carbon atoms of the *cyclo*-C_8 ligands in both isomers are the same, and they only differ in the position of the coordinated carbon atoms in the *cyclo*-C_8 ring, we introduced the notation "hapticity isomers" or "haptomers".[6] Whereas haptomer **2a′** slowly rearranges in solution to **2a′′** at ambient temperature, the different haptomers of **2b** are sufficiently stable to be isolated separately.[6,7] ^1H-NMR experiments at T = 60 °C demonstrate a slow interconversion of **2b′** to **2b′′**. Apparently, the 1,2,3,4,5-η-haptomer **2′** is initially formed as the kinetically controlled product during the nucleophilic addition, and this gradually rearranges to the thermally more stable 1,2-η:5,6,7-η-haptomer **2′′** (Scheme 2).

Scheme 2. Proposed flip-flop mechanism for the 1,2,3,4,5-η/1,2-η:5,6,7-η haptomerism

For Nu^1 = $CH{=}CH_2$ (**2c**), H (**2e**), D (**2f**), NMe_2 (**2g**), OMe (**2h**), and $C{\equiv}CtBu$ (**2i**) the only isomer observed is the 1,2-η:5,6,7-η haptomer, a situation in contrast to **2d** (Nu^1 = C_6H_5), which has a 1,2,3,4,5-η structure as determined by NMR spectroscopy (see Table 3). No indications for a structural rearrangement in **2d** have been found. The reason for the interconversion of the haptomers **2a′** to **2a′′** and **2b′** to **2b′′** may be deduced from the steric demand of the nucleophile Nu^1. When sterically more crowded nucleophiles are used, such as a phenyl group or a substituted malonate $CR(CO_2Me)_2$ ($R \neq H$),[8] the 1,2,3,4,5-η haptomer is exclusively identified.

The influence of the steric demand of the nucleophile can also be rationalized by the crystal structure analysis of the vinyl derivative **2c**, which proves the 1,2-η:5,6,7-η coordination mode for **2c** in the solid state (Figure 1). The vinyl group is located in an *exo* position with respect to the metal center and opposite to the noncoordinating double bond. The carbon−carbon and ruthenium−carbon bonds are quite normal and are very similar to Ru−C bond lengths of pentadienyl−Ru moieties in open and semi-open ruthenocenes.[9] One exception is the Ru−C7 bond, which is elongated by more than 5 pm with respect to the other bond lengths between the Ru center and the metal-bound carbon atoms of the *cyclo*-C_8 ligand. Such a deviation of a Ru−C bond length in the vicinity to an sp^3-carbon atom from the mean value of other Ru−C bond lengths is found more often in (cyclooctatrienyl)ruthenium complexes.[10]

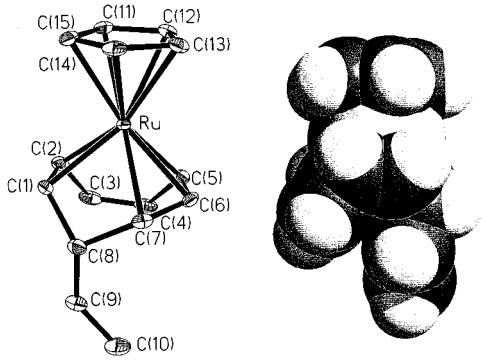


Figure 1. Molecular structure of **2c** (left: ORTEP plot, 30% thermal ellipsoids, the hydrogen atoms are omitted for clarity; right: space-filling model to illustrate the steric demand of the vinyl nucleophile and the noncoordinated double bond); selected bond lengths [pm]: Ru−C1 217.81(19), Ru−C2 219.0(2), Ru−C5 218.08(19), Ru−C6 215.74 (19), Ru−C7 224.3(2), C1−C2 142.3(3), C1−C8 154.2(3), C2−C3 149.1(4), C3−C4 132.2(4), C4−C5 149.5(3), C5−C6 143.2(3), C6−C7 138.9(3), C7−C8 153.1(3)

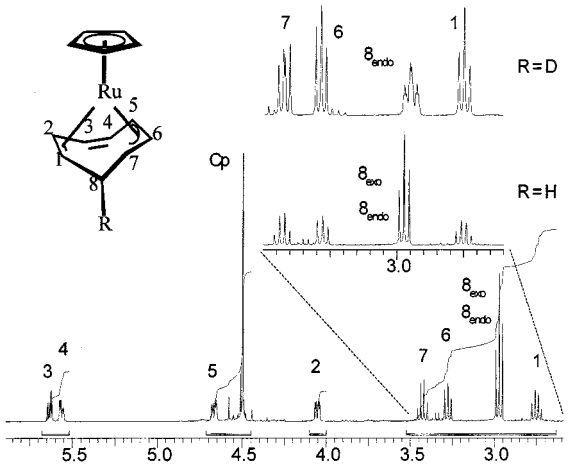
The most interesting structural features of **2c** concerning the formation of the different haptomers are the non-bond lengths between C8 and C9, and the carbon atom C3 of the non-coordinated double bond opposite to C8 and C9, which are 307.6(3) and 308.4(3) pm, respectively. The close proximity of these atoms to each other can be appreciated from the space-filling model shown in Figure 1. Larger nucleophiles would not allow the C3−C4 double bond to bend towards the nucleophile, and hence would favor the situation wherein C3 and C4 were kept in a metal-coordination mode.

To gain a deeper insight into the interconversion mechanism, hydride and deuteride addition from the borates $[BEt_3H]^-$ and $[BEt_3D]^-$ were performed and revealed the 1,2-η:5,6,7-η haptomers of **2e** (Nu = H) and **2f** (Nu = D). The NMR signals of the *endo* and *exo* protons of the sp^3-carbon atom (C8) in the *cyclo*-C_8 ligand of **2e** (Nu = H) are isochronic and show a triplet at δ = 2.87 due to the coupling with the two vicinal protons on C1 and C7, which are both quadruplets (Figure 2, A). The corresponding signal in the spectrum of **2f** (Nu = D, Figure 2, B) is now a doublet of doublets with similar coupling constants (J = 7.5 and 9.0 Hz). Each component is superimposed by a triplet caused by geminal coupling with the deuterium nucleus (J_{HD} = 1.7 Hz). Additionally, the integral of the signal at δ = 2.87 is only half that for **2e**. In agreement with this, the signals of the vicinal protons on C1 and C7 change their patterns to a triplet and a doublet of doublets, respectively, for **2f** (Table 3).



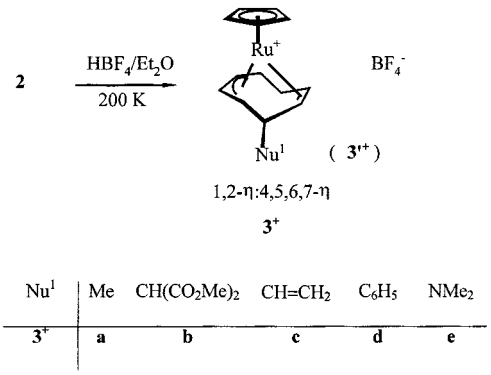


Figure 2. ^{1}H-NMR spectra of **2e** and **2f** illustrating the difference in the splitting pattern when the nucleophilic Nu^1 has changed from H^- to D^-

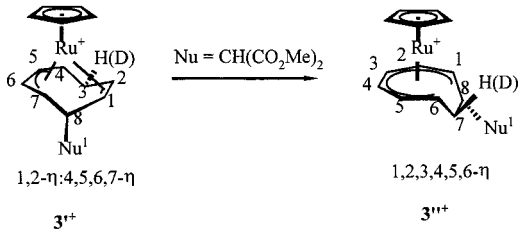
The ^{1}H-NMR spectra of **2e** and **2f** remain unchanged at temperatures up to 90 °C even after several days, which indicates that no hydrogen migration takes place. The thermal stability of the cyclooctatrienyl ligand in the Ru complexes **2f** is in sharp contrast to the corresponding iron complex, which demonstrates a complete scrambling of the deuterium atom under comparable conditions.[11] Therefore, assuming the *exo* addition of the hydride in strict analogy to the addition of any other nucleophile, the interconversion from the kinetically controlled 1,2,3,4,5-η product to the thermodynamically more stable 1,2-η:5,6,7-η haptomer is believed to be a flipping mechanism, as indicated in Scheme 2, rather than a hydrogen migration after the nucleophile has been added to the terminal carbon atom of the metal-coordinated part of the cot ligand.

First Protonation



A second nucleophilic addition to the *cyclo*-C_8 ligand again requires a cationic complex. Therefore, some of the complexes of **2** were protonated with HBF_4 to yield the new cationic products $\mathbf{3}^+$ (Scheme 3) except for the cases where Nu^1 = NMe_2 (**2g**) and Nu^1= OMe (**2h**). The protonation of **2g** leads to a gradual cleavage of the NMe_2 group whereas for **2h** the methoxy group is completely split off. As evidenced by 1D- and 2D-NMR experiments the protonation of **2** occurs in position 3 of the *cyclo*-C_8 ligand to afford the cationic complex in a 1,2-η:4,5,6,7-η bonding mode ($\mathbf{3'}^+$, Scheme 3).

Scheme 3. Protonation of the cyclooctatrienyl complexes **2**

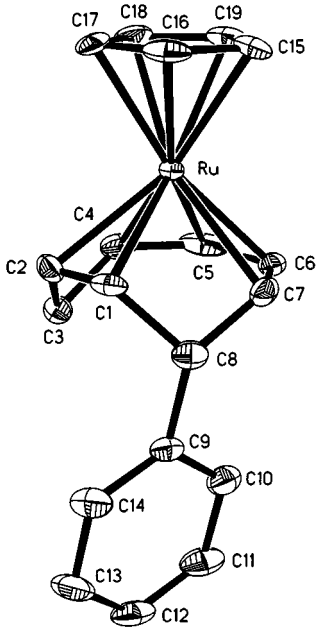
In order to ascertain the protonation site of the *cyclo*-C_8 ring (*exo* or *endo* with respect to the metal center) a protonation experiment was performed with **2b** [Nu^1 = $CH(CO_2Me)_2$] using a mixture of $DBF_4/HBF_4 \approx 4:1$. The comparison of the signal intensities in the ^{1}H-NMR spectra of the cationic product $\mathbf{3b}^+$ and its deuterated congener $\mathbf{3b}^+\mathbf{\text{-}D_1}$ clearly indicates position 3 as the site of the protonation (δ = 3.19) (Table 5). The resonance signal of the other proton of position 3 is found at δ = 1.99. Assuming that the anisotropy cone of diamagnetic sandwich compounds[12] also holds for the present Ru complexes, the signals of the protons in the *endo* position with respect to the metal center should be shifted downfield compared to the signal of the *exo* proton.[13] Conclusively, the protonation of **2** stereoselectively occurs in the *endo*-position with respect to the metal center, which is also in agreement with protonation experiments involving other sandwich compounds.[14] This stereoselectivity suggests a protonation of the metal center as a first step and a subsequent hydrogen migration to the *cyclo*-C_8 ligand.[14b]

The ^{1}H-NMR spectra of $\mathbf{3b}^+$ contain small signals due to a second isomer, which increase in intensity in the course of time. After 6 days at room temperature, the NMR signals of only one isomer are recorded and these correspond to the initial minor isomer, which was identified as the 1,2,3,4,5,6,-η haptomer. Apparently, the 1,2-η:4,5,6,7-η haptomer $\mathbf{3'}^+$ is converted into the 1,2,3,4,5,6,-η haptomer $\mathbf{3''}^+$ (Scheme 4). In addition to this haptotropic rearrangement it is evident from the ^{1}H-NMR spectra of $\mathbf{3b\text{-}D_1}^+$ that the *endo* proton on C3 of $\mathbf{3'}^+$ (δ = 3.19) has migrated to the *endo* position on C7 in $\mathbf{3''}^+$ (δ = 1.63) (Scheme 4). The position of this resonance still shows a distinct low-field shift compared to the signal of the other proton on C7 (δ =

Scheme 4. Proposed 1,5-hydrogen migration mechanism for the 1,2-η: 4,5,6,7-η/1,2,3,4,5,6-η haptomerism

−0.95, Table 5),[11,13] indicating the *endo* position of the deuterium atom.

It is interesting to note that the nature of the nucleophile does not consistently influence the hapticity of the eight-membered ligand. Whereas for $Nu^1 = CH(CO_2Me)_2$ the more stable isomer is the 1,2-η:5,6,7-η haptomer for the neutral complex **2b** and the 1,2,3,4,5,6-η haptomer for the cationic species **3b**$^+$, for $Nu^1 = C_6H_5$ the opposite is true: In **2d** the 1,2,3,4,5,-η bonding mode is favored, and upon protonation the coordination of the *cyclo*-C_8 ligand changes to the 1,2-η:4,5,6,7-η fashion in **3d**$^+$, a situation demonstrated by solution NMR studies and verified in the solid state structure (Figure 3).



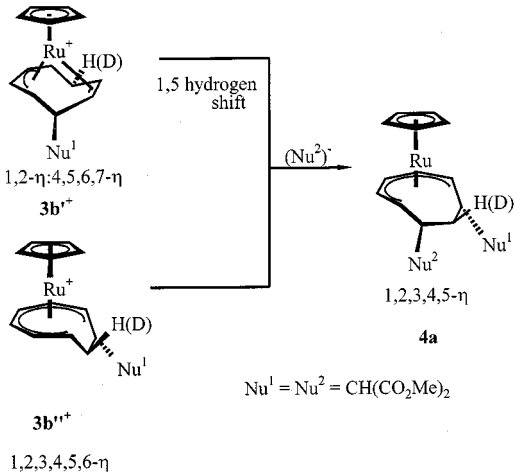


Figure 3. Molecular structure of **3d**BF_4 (ORTEP plot, 30% thermal ellipsoids, the hydrogen atoms and the counter ion are omitted for clarity); selected bond lengths [pm]: Ru−C1 228.1(4), Ru−C2 229.4(6), Ru−C4 226.5(6), Ru−C5 218.3(5), Ru−C6 220.7(5), C1−C2 135.8(8), C1−C8 150.7(7), C2−C3 150.7 (8), C3−C4 150.4(9), C4−C5 135.1(14), C5−C6 147.1(11), C6−C7 139.7 (10), C7−C8 153.7(8), C8−C9 154.9(6)

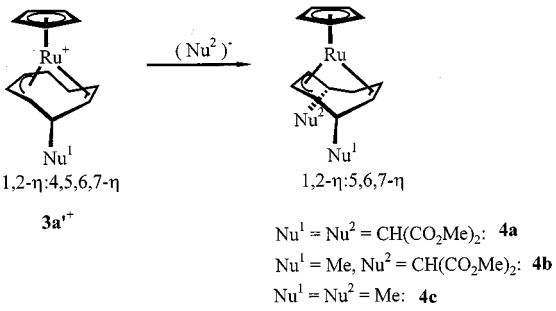
The crystal structure analysis of the phenyl derivative **3d**BF_4 reveals a η^6-coordination mode for the *cyclo*-C_8 ligand, wherein the noncoordinated carbon atoms of the eight-membered ring, C3 and C8, protrude from the plane of the metal-bound carbon atoms in an *exo* position with respect to the metal center. The non-bond lengths between C3 and C8, and C3 and C9 are 308.4(8) and 308.2(9) pm, respectively, which indicates a close proximity of the two sp^3-carbon atoms of the *cyclo*-C_8 ligand. A sterically more demanding nucleophile at C8 may push the C3 position to the metal center, thus inducing a metal−hydrogen interaction that could be a first step in the metal-assisted 1,5-hydrogen migration as found in **3b**$^+$ (see Scheme 4). The metal−carbon bond lengths in **3d**$^+$ are slightly elongated in comparison to the corresponding bond lengths of the neutral complex **2c** due to the positive charge in **3d**$^+$, which reduces the metal−ligand back donation. Accordingly, the C1−C2 bond length in **3d**$^+$ [135.5(8) pm] is distinctly shorter than the corresponding bond length in **2c** [142.3 (3) pm]. Also in agreement with the reduced metal−ligand back donation is the bond length alternation in the metal-bound butadiene part of the *cyclo*-C_8 ligand: C4−C5 135.1(14) pm, C5−C6 147.1(11) and C6−C7 139.7(10) pm.[15]

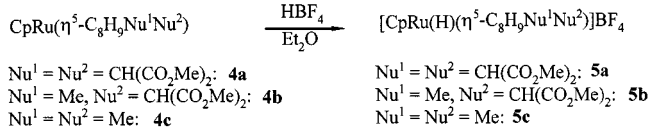


Second Nucleophilic Addition

The second nucleophilic addition can in principle give rise to two isomeric products depending on the type of haptomer used for this reaction. However, earlier attempts have already demonstrated that for $Nu^1 = CH(CO_2Me)_2$ the addition of the second nucleophile [$Nu^2 = CH(CO_2Me)_2$] only gives rise to the 6,8-bifunctionalized cyclooctadienyl complex **4a**[6] regardless of whether the starting haptomer is **3b**′$^+$ or **3b**′′$^+$. The nucleophilic addition to mixtures of partially deuterated **3b**′$^+$ and **3b**′′$^+$ yielded **4a** only with the deuterium atom exclusively in *endo* position at C7. Hence, **3b**′$^+$ has to rearrange to haptomer **3b**′′$^+$ by a 1,5-hydrogen migration before the second nucleophilic addition occurs (Scheme 5).[6]

Scheme 5. Nucleophilic addition to **3b**$^+$

This outcome contrasts the result of the second nucleophilic addition [Nu^2 = Me, $CH(CO_2Me)_2$] to complexes with Nu^1 = Me, which occurs exclusively in the 4-position of the cyclooctatriene ligand of **3a**$^+$ (Scheme 6).

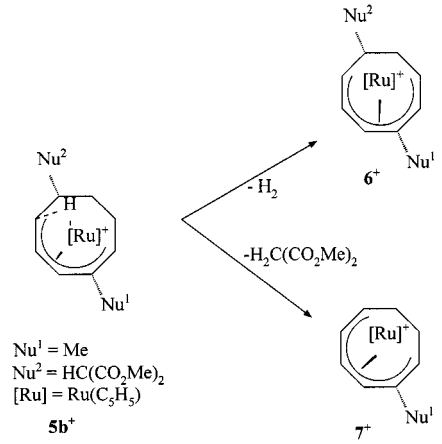


Scheme 6. Nucleophilic addition to **3a**$^+$

The ^{1}H- and ^{13}C-NMR spectra clearly demonstrate the low local symmetry (C_1) of the cyclooctadienyl ligand in **4b** [Nu^1 = Me, Nu^2 = $CH(CO_2Me)_2$] and **4c** (Nu^1 = Nu^2 = Me), in which the number of signals corresponds to the number of hydrogen and carbon atoms in the eight-membered ring in each case, whereas the NMR spectra of **4a** contain considerably fewer signals due to the C_s symmetry of the *cyclo*-C_8 ligand (Table 6). By means of ^{1}H-^{1}H and ^{1}H-^{13}C correlation spectra the different signals for **4b** and for **4c** can be assigned unequivocally and confirm the products **4b** and **4c** as 4,8-bifunctional cyclooctadienyl complexes.

Second Protonation

The bifunctionalized cyclooctadienyl complexes **4a**, **4b** and **4c** are easily protonated by the addition of HBF_4 to their ether solutions at low temperature. The products precipitate as light yellow solids and can be isolated by filtration (Scheme 7).



Scheme 7. Protonation of the cyclooctadienyl complexes **4a**−**4c**

In contrast to the first protonation, the second one gives rise to ruthenium complexes with a metal−hydride function as shown by the high-field shift of singlets from δ = −10.4 to −10.6 in the ^{1}H-NMR spectra.[16] No indication is found for the scrambling of proton positions that was observed in electronically related compounds like the protonated (cyclopentadienyl)(3-methylpentadienyl)ruthenium complex.[17,18] For **5a**$^+$ [Nu^1 = Nu^2 = $CH(CO_2Me)_2$] and **5c**$^+$ (Nu^1 = Nu^2 = Me) the ^{1}H-NMR spectra are similar to those of **4a** and **4c** apart from an overall distinct low-field shift of the signals for the metal-coordinated C−H units, which is due to the cationic nature of the complexes, and the hydrido signal at δ < −10 (Table 7). The coordination mode of the *cyclo*-C_8 ligand is therefore assumed to remain unchanged upon protonation of **4a** and **4c**. However, in solution the ^{1}H-NMR spectra provide evidence for a slow decomposition of the products, which form different Ru complexes that were not characterized further in the cases of **5a**$^+$ and **5c**$^+$.

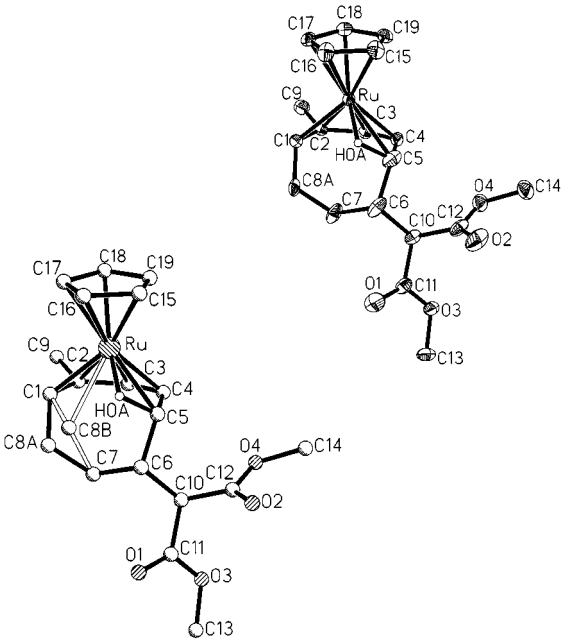
The ^{1}H-NMR spectrum of a freshly prepared sample of the protonated product of **4b** [Nu^1 = Me, Nu^2 = $CH(CO_2Me)_2$] indicates the existence of two different species and displays remarkable differences to the spectrum of the precursor complex. The signal due to the Me substituent in the neutral complex **4b** appears as a doublet at δ = 0.96 in accordance with the Me signals of **4c** (δ = 1.02 and 1.20). The corresponding Me signals of the protonated species of the starting complex **4b** are observed as singlets, which are low-field shifted to δ = 2.32 for the major component (**5b**$^+$) and even to δ = 2.62 for the minor one (**6**$^+$). In contrast, the position of the corresponding Me signals in **5c**$^+$ does not differ significantly from that in the starting complex **4c**. The lack of a ^{1}H-^{1}H coupling for the Me substituent in **5b**$^+$ and **6**$^+$, as well as the distinct low-field shift of the Me signals, point to a metal coordination of the Me-substituted carbon atom in **5b**$^+$ and **6**$^+$. Therefore, in **5b**$^+$ and **6**$^+$ a hydrogen migration had to occur on the *cyclo*-C_8 ligand upon protonation.

The most striking difference between the ^{1}H-NMR spectra of **5b**$^+$ and **6**$^+$ is the lack of the hydrido signal at δ ≈ −10 for the minor product **6**$^+$. A careful analysis of the ^{1}H,^{1}H-COSY spectrum also proves that **6**$^+$ contains two hydrogen atoms less than **5b**$^+$. On keeping the solution of the NMR sample under an inert gas, a further product **7**$^+$ can be identified as a cationic cyclooctatriene complex without the malonate substituent (Table 7). The former malonate nucleophile can be identified in the ^{1}H-NMR spectrum as a free methyl malonate (δ = 3.36 and 3.70). The signals due to complexes **6**$^+$ and **7**$^+$ both grow in the course of time, whereas the signals due to **5b**$^+$ vanish. Hence, the hydride complex **5b**$^+$ decomposes in solution under cleavage of dihydrogen or methyl malonate (Scheme 8). Most interestingly, the formation of **5b**$^+$ and **6**$^+$ has been observed in a single crystal analysis.

Scheme 8. Elimination of H_2 and $H_2C(CO_2Me)_2$ from the cationic complex **5b**$^+$ in solution

Suitable crystals for an X-ray structure analysis of the protonation product of **4b** [Nu^1 = Me, Nu^2 = $CH(CO_2Me)_2$] were obtained from a dichloromethane/diethyl ether solution. The determination of the molecular structure was successful on the assumption of a disorder of the two cationic complexes in a ratio of 59:41, which differ

in the *cyclo*-C_8 ligands. Attempts were made to separate the carbon atoms C1, C5, C7, and C8 of the *cyclo*-C_8 ligands in different split positions. However, this procedure was only successful for C8. The positions of C1, C5, and C7 do not vary sufficiently in the two species to be calculated in different split positions. The best fit could be obtained by taking into account two cationic species, one bearing a 1,2,3,4,5-η-cyclooctadienyl ligand (**5b**$^+$, 59%) and the other a 1,2,3,4,5,6-η-cyclooctatriene ligand (**6**$^+$, 41%) (Figure 4).



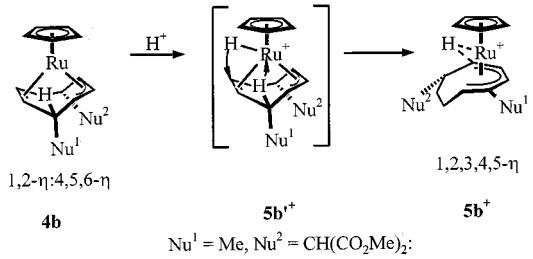


Figure 4. Molecular structures of **5b**BF_4 and **6**BF_4 as obtained from the X-ray crystal structure analysis of the protonation product of **4b**; top: **5b**BF_4 (ORTEP plot, 30% thermal ellipsoids, the anion and all H atoms except the H^- are omitted for clarity); bottom: superposition of **5b**BF_4 and **6**BF_4 (note the difference in the notation of C8A, C8B; C8A belongs to **5b**$^+$ and C8B to **6**$^+$); selected bond lengths [pm]: Ru−C1 217.7(7), Ru−C2 219.7(7), Ru−C3 220.8(7), Ru−C4 213.5(8), Ru−C5 227.3(8), Ru−C8A 246(2), Ru−H0A 173(13), C1−C2 140.8(10), C2−C3 144.0(10), C3−C4 143.8(10), C4−C5 147.6(13), C5−C6 151.0(12), C6−C7 151.8(11), C7−C8A 147.4(13), C7−C8B 152.0(10), C1−C8A 159.3(16), C1−C8B 143.6(9), C5−H0A 129(13)

The most prominent structural feature of **5b**$^+$ is the agostic hydrogen atom H0A between the Ru center and C5. The position of this hydrogen atom was found from the difference electron map. The Ru−H0A distance is 173(12) pm and the distance between C5 and H0A is calculated to be 129(13) pm. In accordance with the agostic hydrogen atom at C5, the Ru−C1−C4 bond lengths are distinctly shorter than the bond length between the Ru center and C5 [213.5(8)−220.8(7) pm vs. 227.3(8) pm]. The carbon−carbon bond length between C4 and C5, which is linked to the agostic hydrogen atom, seems to be elongated [147.6(13) pm] compared to the other carbon−carbon distances [140.8(10)−144.0(10) pm] of the metal-coordinated entity of the *cyclo*-C_8 ligand. Hence, the structural data of **5b**$^+$ much resemble those of the electronically related protonated (cyclopentadienyl)(3-methylpentadienyl)ruthenium.[18]

Another important result from the structure determination of **5b**$^+$ is the position of the first nucleophile (Nu^1 = Me) on the *cyclo*-C_8 ligand: the Me group is directly linked to the metal-bound carbon atom C2, as already indicated by the ^{1}H-NMR study. The carbon atoms C6, C7, and C8 are not metal-coordinated and are sp^3-hybridized with $Nu^2 = CH(CO_2Me)_2$ at C6.

Conclusively, the formation of **5b**$^+$ upon protonation of **4b** requires more than a simple protonation of the metal center, as evidenced for **5a**$^+$ and **5c**$^+$. Compound **4b** may first be protonated at the metal center to give the metal−hydride function (Scheme 9). Subsequently, the hydrogen atom could migrate to position 1 of the *cyclo*-C_8 ligand and, more or less simultaneously, the hydrogen atom at C3 migrates to the metal center leading to a 1,2,3,4,5-η coordination mode of the *cyclo*-C_8 ligand with the first nucleophile Me linked to a metal-coordinated carbon atom; the hydrogen atom at the metal center forms an agostic bond to C5. The formation of **6**$^+$ can be explained by the elimination of a hydrogen molecule from **5b**$^+$. It is worth mentioning that the dehydrogenated product **6**$^+$ is the only by-product when the crystalline material is freshly dissolved for an NMR sample, whereas the decomposition product **7**$^+$ is preferentially formed in solution (Scheme 8).

Scheme 9. Proposed mechanism for the formation **5b**$^+$

In a final step, the *cyclo*-C_8 ligand should be cleaved to yield stereo- and regioselectively functionalized cyclooctadiene compounds. This operation was successfully performed for **5a**$^+$ [$Nu^1 = Nu^2 = CH(CO_2Me)_2$][6] by the addition of a coordinating solvent (MeCN) to a suspension of **5a**$^+$ in diethyl ether, whereas for the methylated derivative **5b**$^+$ the cleavage of the corresponding cyclooctadiene failed. Alternatively, the cleavage of the *cyclo*-C_8 ligand was attempted by a protonation of the complexes **4b** and **4c** in the presence of a large excess of acetonitrile. As a result the cationic half-sandwich complex $[CpRu(MeCN)_3]^+$ could be recovered and this is the starting material for the synthesis of $[CpRucot]^+$ (**1**$^+$). However, the organic products of this reaction have not yet been characterized. The reaction conditions for a straight cleavage of the stereoselectively functionalized cyclooctadiene ligand are currently being investigated. Successful decomplexations of η^4-coordinated cyclooctatetraene and cyclooctadienes by photochemical and thermal methods have been reported previously.[19]

Conclusions

In this study we have shown that iterative nucleophilic and electrophilic additions to coordinated cyclooctatetraene

are useful tools for the synthesis of stereo- and regioselectively bifunctionalized *cyclo*-C_8 ligands. As demonstrated, the regioselectivity at the different stages of the nucleophilic additions and protonation reactions is controlled by the steric demand of the nucleophiles. Two different mechanisms for the rearrangements are proposed: (i) a flip-flop mechanism in which the product of the first nucleophilic addition changes from the kinetically controlled 1,2,3,4,5-η haptomer to the thermodynamically more stable 1,2-η:5,6,7-η haptomer (Scheme 2) in cases of small nucleophiles and (ii) a 1,5-hydrogen migration caused by the first protonation, which causes a rearrangement of the 1,2-η:4,5,6,7-η haptomer to the 1,2,3,4,5,6-η derivative [Nu^1 = $CH(CO_2Me)_2$] or vice versa when Nu^1 = Ph (see Scheme 5). A third rearrangement can be observed after the second protonation and leads to **5b**$^+$ [Nu^1 = Me, Nu^2 = $CH(CO_2Me)_2$], since the hydrogen atom of the carbon atom bearing Nu^1 is cleaved and a new sp^3-carbon atom is formed, as illustrated in Scheme 9 for **5b**$^+$. The cleavage of the desired *cyclo*-C_8 ligand was successful for the case where Nu^1 = Nu^2 = $CH(CO_2Me)_2$ but as yet has proved unsuccessful when Nu^1 = Nu^2 = Me and Nu^1 = Me, Nu^2 = $CH(CO_2Me)_2$. However, efforts to synthesize stereo- and regioselectively bifunctionalized cyclooctadienes through iterative nucleophilic and electrophilic additions will be continued due to the fact that it is a simple and hence attractive procedure to achieve more intricate organic reactions towards *cyclo*-C_8 terpenoids.

Experimental Section

All reactions were carried out under N_2 and all solvents were saturated with N_2. THF, Et_2O, hexane, and toluene were freshly distilled from the appropriate alkali metal or metal alloy. Dichloromethane was dried with CaH_2 and distilled under N_2. – NMR: Bruker AM 360 and Varian Gemini 200. – IR (Nujol mull, KBr cells): FT-IR 1720X (Perkin–Elmer). – EI-MS (70 eV): Finnigan MAT 311 A, Heraeus CHN-O-Rapid; Institut für Anorganische und Angewandte Chemie, Universität Hamburg. – [CpRu(η^6-cot)]PF_6 (**1**PF_6),[20] the sodium salts of the malonic ester[21] and lithium dimethylamide[22] were synthesized as described. Methyllithium as 5% solution in diethyl ether was purchased from Merck©, Li[BEt_3H] as a 1 M solution in THF from Aldrich and HBF_4 as a 54% solution in diethyl ether from Fluka.

X-ray Crystal Structure Analysis: Determination of the cell parameters and collection of the reflection intensities were performed with a Hilger & Watts [**2c**, **3d**BF_4] or Enraf–Nonius CAD4 [**5b**BF_4] four-circle diffractometer (see Table 1). SHELXS-86[23] was used for structure solving with direct methods and SHELXL-97[24] for structure refinement (refinement on F^2) (for crystallographic details see Table 1).

Crystal Structure Refinement of 2c: Hydrogen atoms on the Cp ring and on C8 were fixed in idealized positions. Positions of all other H atoms were refined free with equal C–H bond lengths in the sets of H1;H2;H5;H6;H7;H3;H4;H9 and H10a;H10b using the SADI operation. Thermal parameters of all protons were attached to the corresponding C atoms with a factor of 1.2.

Crystal Structure Refinement of 3d: Protons on the Cp and the phenyl ring, and on C3 and C8 were fixed in idealized positions. Positions of all other H atoms were refined free with equal C–H bond lengths using the SADI operation. Thermal parameters of all H atoms were attached to the corresponding C atoms with a factor of 1.2.

Crystal Structure Refinement of 5d: H atoms on the Cp ring and on C6, C8A, C9, C10, C13, and C14 were fixed in idealized positions. Positions of all other H atoms (except the agostic hydrogen atom) were refined free with C–H bond lengths fixed to 99 pm for H1, H3, H4, H5, H71, and H72, H71 and H72 were further fixed to equal distances to the vicinal C atoms C6 and C8A. Thermal parameters of all H atoms were attached to the corresponding C atoms with a factor of 1.5 for methyl and 1.2 for all others. The agostic hydrogen atom HOA was refined free in position and its thermal parameter set to 1.5 times the parameter of the Ru center. The site occupation factors for the disordered atoms were refined as a free variable.

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-137491 (**2c**), -137492 (**3d**BF_4), and -137493 (**5b**BF_4 and **6**BF_4). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

General Procedure for the Synthesis of Compounds 2a–2i: A solution of the nucleophile in THF (or diethyl ether for Nu^1 = Me) was added dropwise to a suspension of **1** in 50 mL of THF or diethyl ether. The solvent was removed under reduced pressure, the residue was extracted with hexane or diethyl ether, and the extract filtered through Celite. After removal of the solvent, the product was normally obtained as a pale yellow oil. For more preparative details see Table 2, for ^{1}H- and ^{13}C-NMR data see Table 3.

(η^5-Cyclopentadienyl)(1,2,3,4,5-η-8-*exo*-methylcyclooctatrien-6-yl)ruthenium(II) (2a′): $C_{14}H_{16}Ru$ (285.37): calcd. C 58.93, H 5.65; found C 58.94, H 5.38.

Synthesis and π-Tweezer Properties of *tripod*Cobalt-Bisalkynyl Compounds $[CH_3C(CH_2PPh_2)_3Co(C{\equiv}CR)_2]$ − Application to the Oxidative Coupling of Alkynyl Groups

Rolf Rupp,[a] Gottfried Huttner,*[a] Heinrich Lang,[b] Katja Heinze,[a] Michael Büchner,[a] and Eric Robert Hovestreydt[c]

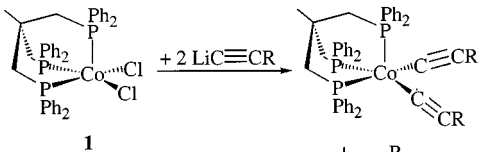
Dedicated to Prof. Peter Paetzold on the occasion of his 65th birthday

Keywords: Tripod ligands / Cobalt / π-Tweezers / Oxidative Coupling / Alkyne complexes

tripod$CoCl_2$ $[CH_3C(CH_2PPh_2)_3CoCl_2]$ (**1**) reacts with alkynyllithium reagents RC≡CLi to produce *tripod*$Co(C{\equiv}CR)_2$ (**2**). The neutral paramagnetic Co^{II} species **2** can be reduced to the anionic diamagnetic Co^{I} compounds $\mathbf{2}^-$, which can also be obtained by treating *tripod*CoCl (**3**) with two equivalents of LiC≡CR. Compounds **2** contain an $M(C{\equiv}CR)_2$ group with the alkynyl substituents in *cis*-positions to each other. The expectation that they might therefore act as π-tweezer ligands is born out by the characterisation of *tripod*$Co(C{\equiv}CR)_2$–NiCO (**4**). The *cis*-position of the alkynyl groups in **2** should also facilitate their oxidative coupling. This type of reaction is, in fact, observed when compounds **2** are treated with one-electron oxidants. Reaction of **2** with Cp_2Fe^+ leads to [*tripod*$Co(\eta^2$-R*C*≡*C*C≡CR)]$^+$ **(5)** in which one of the triple bonds of the diyne acts as a four-electron donor ligand while the other one remains uncoordinated. One-electron oxidation of **2** thus initiates a two-electron oxidative coupling of the alkynyl groups with concomitant one-electron reduction of Co^{II} (**2**) to Co^{I} (**5**). All compounds were characterised by the usual analytical and spectroscopic techniques including EPR spectroscopy. The structure of compounds **5** is exemplified by an X-ray analysis of [*tripod*$Co(\eta^2$-*t*Bu*C*≡*C*C≡C*t*Bu)](PF_6) (**5b**).

Introduction

The coordination chemistry of the [*tripod*cobalt] template $[CH_3C(CH_2PPh_2)_3Co]$ is characterised by the persistent pentacoordination in [*tripod*$CoL_2]^{n+}$ compounds, regardless of the oxidation state (Co^{III}: d^6, Co^{II}: d^7, Co^{I}: d^8).[1,2] While only pentacoordination is known for d^6- and d^7-electron configurations, lower oxidation states allow for pseudo-tetrahedral coordination.[2a,2b,3−8] With the geometric constraint imposed by the facial η^3-coordination of the *tripod* ligand, the co-ligands L in [*tripod*CoL_2] are necessarily *cis* to each other.



With this in mind, the synthesis of *cis*-bisalkynyl derivatives [*tripod*$Co(C{\equiv}CR)_2]^{n+}$ is a rewarding goal in view of the particular reactivity patterns documented for some specific *cis*-[$L_nM(C{\equiv}CR)_2$] *cis*-bisalkynyl compounds such as $[Cp_2M(C{\equiv}CR)_2]$ (M = Ti, Zr, Hf).[9] It is shown in this paper how the compounds [*tripod*$Co(C{\equiv}CR)_2]^{n+}$ (n = −1, 0) **2** are accessible, and how these bisalkynyl species may be used as π-tweezers in derivatives such as [*tripod*$Co(C{\equiv}CR)_2$−NiCO] (**4**). Compounds **2** may also serve as reagents for the oxidative coupling of the alkynyl ligands.

Results and Discussion

Cobalt(II) Derivatives

[*tripod*$CoCl_2$] **(1)**[2b] reacts with two equivalents of the alkynyllithium compound LiC≡CR (R = Ph, *t*Bu, TMS) to give the corresponding bisalkynyl derivatives **2a**−**c**.[2a,2b]

1

	R
2a	Phenyl
2b	tert. Butyl
2c	Trimethylsilyl

In order to produce **2** in high yields, the reaction has to be performed at −80 °C in THF. Even at this low temper-

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 2000 1434−1948/00/0909−1953 $ 17.50+.50/0

ature, the reactions are spontaneous and an immediate colour change from blue (**1** in THF[2b]) to brown (**2**) is observed. After changing the solvent from THF to toluene, with subsequent filtration, compounds **2** are obtained, by evaporation of the solvent, as microcrystalline black-brown powders. Derivatives of **1** that have only one alkynyl substituent and one remaining chloro substituent are not accessible by this procedure. If only one equivalent of LiC≡CR is used, a mixture of **1** and **2** results. This is in agreement with the observation that a 1:1 mixture of the clean compounds **1** and **2** does not result in alkynyl−chloro exchange.

While single crystals of **2** suitable for X-ray analysis could not be obtained, analytical data unequivocally established the structure as shown for **2**. Osmometric determination of the molecular mass of **2a** shows that compounds **2** are monomeric (see Experimental Section). Mass spectrometry shows the molecular ion in each case (Table 1). The C≡C bonds of **2** give rise to a characteristic ν(CC) absorption band in each case (Table 1). Compounds **2** are paramagnetic with an effective magnetic moment of 1.8 BM measured for **2a** at 25 °C (see Experimental Section).

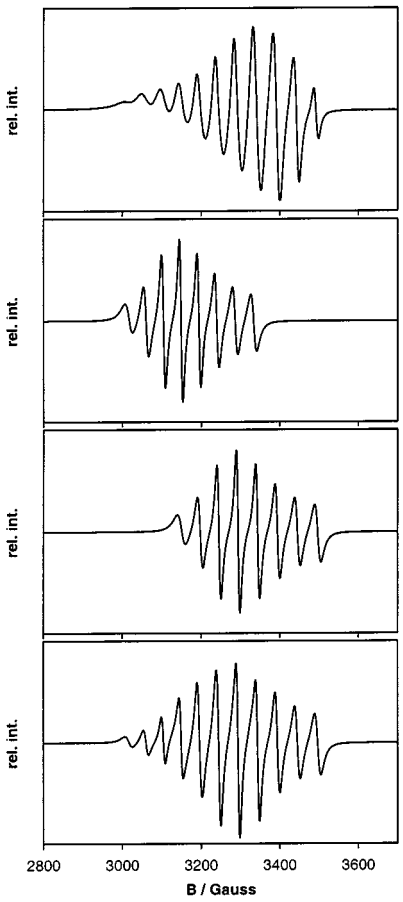
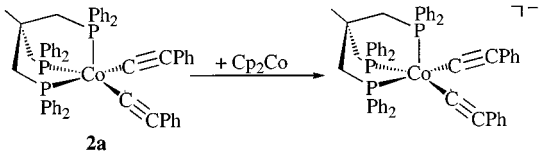
[a] The *g* factors and hyperfine splitting constants were obtained by simulation of the experimental spectra. – [b] All measurements were performed in CH_2Cl_2 solutions; the potentials are given relative to the SCE electrode. – [c] Calculated for **2a** · 2.5 toluene.

All compounds show an EPR pattern characteristic of pentacoordinated [*tripod*Co^{II}L$_2$] species (Table 1).[2c] Solution EPR spectra at 25 °C (Figure 1, top) revealed the presence of two species with individual *g* factors and hyperfine splitting constants (Figure 1, middle spectra) which, by analogy to literature data, were interpreted as being due to idealised square pyramidal and idealised trigonal bipyramidal coordination modes.[2c] Powder EPR spectra (25 °C and −173 °C) show only one broad resonance with no resolved coupling to the ^{57}Co ($I = {}^7/_2$) nucleus (Table 1).

Cobalt(I) Derivatives

Cyclovoltammetric studies of **2a** in CH_2Cl_2 indicated that compounds **2** should undergo one-electron reduction to produce the corresponding anionic Co^I species [*tripod*Co(C≡CR)$_2$]$^-$ (Table 1). Reversible reduction of **2a** is observed at −574 mV with reference to a SCE (Table 1). Treating **2a** with an equimolar amount of Cp_2Co in toluene led to a brown powder similar to **2a** in colour. FAB-negative mass spectra of this powder show a signal for **2a**$^-$ (*m/z* = 885), while FAB-positive mass spectra demonstrate the presence of $CpCo^+$ (*m/z* = 189).





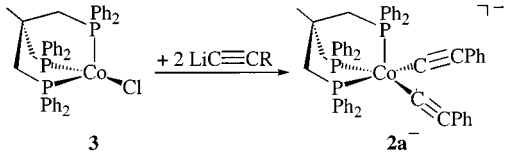


Figure 1. EPR spectrum of **2b** in THF at 298 K (top), simulations of the two individual components (middle) and composed simulated spectrum (bottom)

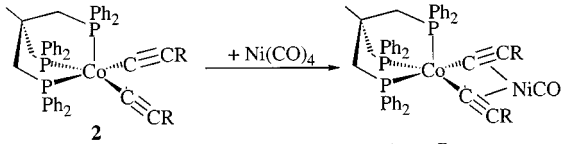
Due to difficulties in the purification of the [Cp_2Co][*tripod*Co(C≡CPh)$_2$] salt, a different preparative strategy to produce **2a**$^-$ was used. The cobalt(I) compound [*tripod*CoCl] (**3**)[2a,2b] was reacted with two equivalents of LiC≡CPh to produce the cobaltate(I) compound **2a**$^-$, which was isolated as its PPh_4^+ salt.



Elemental analysis and mass spectra are in agreement with the assigned structure (see Experimental Section). The ν(CC) vibration of **2a**$^-$ at 2049 cm^{-1} (see Experimental Section) is shifted to a lower wave number than that of **2a**

(2068 cm^{-1}) (Table 1), as would be expected if some charge is delocalised into the π-system of the ligand. Owing to the prolonged measuring time required, ^{13}C NMR spectra of the sensitive PPh_4^+**2a**$^-$ could not be obtained. A sharp ^{31}P NMR signal at δ = 32.1 and a well-resolved ^1H NMR spectrum clearly show that **2a**$^-$ is a diamagnetic Co^I compound. Anion **2a**$^-$ conforms to the 18-electron rule, and this may be one of the reasons for the observation that, regardless of the stoichiometry of LiC≡CPh and **3** (2:1 or 1:1), **2a**$^-$ is inevitably obtained and there is no indication of the formation of [*tripod*CoC≡CPh].

Reactions of the Bisalkynyl Compounds 2

The propensity of **2** to act as a π-tweezer compound is seen by the reaction of **2** with $Ni(CO)_4$ to give compounds **4**. A NiCO moiety is retained in the π-tweezer entity of **2**.

2

	R
4a	Phenyl
4b	tert. Butyl
4c	Trimethylsilyl

The structure of compounds **4** is in agreement with their analytical and spectroscopic data. Mass spectra of **4** show a prominent peak for [M^+ − CO] in each case (Table 2). The presence of the coordinated carbonyl group is evident from the corresponding ν(CO) IR bands for all compounds **4** (Table 2). This prominent band is observed at about 2000 cm^{-1}, which is in good agreement with the observation of the corresponding bands in π-tweezer compounds [$(RCp)_2M(C{\equiv}CR)_2{-}NiCO$] (M = Ti, Zr, Hf) at about the same wavenumbers.[9] This indicates that direct metal−nickel interactions are not really very important for the stability of this type of compound; if they were, the CO group would be sensitive to the presence of different types of L_nM entities to which the alkynyl groups are bound in [$L_nM(C{\equiv}CR)_2$].[9] In agreement with this interpretation is the observation that cyclovoltammetric reduction of **4b** (−605 mV vs. SCE, see Experimental Section) occurs at about the same potential as that of **2a** (−574 mV vs. SCE, Table 1). Compounds **4** are paramagnetic as are the parent compounds **2** from which they are derived. The EPR spectra of compounds **4** (Table 2) closely resemble those of **2** (Table 1) with only minor changes in *g* values and coupling constants. With **4c**, the hyperfine structure is not resolved and one broad resonance is observed at $g \approx 2.05$. The fact that two overlapping signals are observed for **4**, with the spectral pattern being similar to that observed for the parent compounds **2**, may be explained by the same type of reasoning as discussed for **2**. With **4**, it is of course necessary to assume that the bisalkynyl-Ni moiety changes place as a single unit such that the idealised trigonal bipyramidal and idealised square pyramidal coordination geometries may interchange.

[a] Calculated for **4c** · 2 CH_2Cl_2.

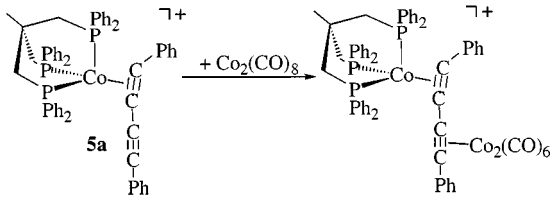
In the chemistry of π-tweezer ligands, Cu^I and Ag^I have been found to be specifically prone to engage in bonding with π-tweezers.[9c] When solutions of **2** are treated with salts of these cations, however, the reaction is complicated by the propensity of **2** towards oxidation. Cyclovoltammetry of **2a** shows that the compound is irreversibly oxidised (Table 1) and this is what presumably happens when compounds **2** are treated with potentially oxidising metal ions.

Preparative oxidation of **2** with Cp_2Fe^+ results in a transformation of **2** into **5**.

2

	R
5a	Phenyl
5b	tert. Butyl
5c	Trimethylsilyl

The alkynyl groups of **2** undergo oxidative coupling to result in 1,3-diyne ligands with one of the two triple bonds being coordinated to the cobalt centre. The process is brought about by a single-electron transfer-step such that, while the alkyne groups are oxidised in a formal two-electron oxidation, the cobalt centre is reduced from Co^{II} in **2** to Co^I in **5**. The coupling of σ-bonded alkynyl compounds is not without precedent: with rhodium as the central atom in [$Rh^{III}(C{\equiv}C{-}Ph)_2(SnPh_3)(PiPr_3)_2$], oxidative coupling by I_2 to give *trans*-[$Rh^I(\eta^2$-Ph*C*≡*C*C≡CPh)($PiPr_3$)$_2$I] is formally similar to the transformation of **2** into **5**, since reduction of the central metal (in this case reduction of Rh^{III} to Rh^I) necessarily accompanies the oxidative coupling of the alkynyl ligands.[10,11]



The salts **5**·PF_6 are obtained as analytically and spectroscopically pure green powders (Table 3) which show the peak for the molecular ion in their FAB mass spectra in each case. They are diamagnetic and show well-resolved NMR spectra. Their ^{31}P NMR resonances are observed in the range δ = 35 to 38 (Table 3). ^1H and ^{13}C NMR spectra reveal the signals of each constitutional group in the expected range (Table 3). The presence of one coordinated and one uncoordinated triple bond is evident from the corresponding ^{13}C NMR signals (Table 3). The presence of an

uncoordinated triple bond is also indicated by a weak ν(CC) IR band at 2100−2200 cm^{-1} (Table 3). Chemical proof for the existence of an uncoordinated reactive triple bond is found in the reaction of **5a** with $[Co_2(CO)_8]$.

[a] All NMR measurements were performed in CD_2Cl_2. – [b] *t*Bu for **5b**, $SiMe_3$ for **5c**. – [c] No ^{13}C NMR data could be obtained owing to decomposition of the compound during the measurement.

This reaction, as performed under standard conditions, gives $[tripodCo(\eta^2\text{-}PhC{\equiv}CC{\equiv}CPh{-}Co_2(CO)_6)]^+$ as the main product.[12] This is apparent from the FAB mass spectra of its PF_6 salt which show the molecular ion (*m/z* = 1171, see Experimental Section) together with the peaks corresponding to the consecutive loss of up to five CO groups. The last CO group is lost together with the Co_2 entity, which was part of the coordinated $Co_2(CO)_6$ unit, apparently in one step leading to the mass peak of $[tripodCo(\eta^2\text{-}PhC{\equiv}CC{\equiv}CPh)]^+$ **5a**. The IR data of the $Co_2(CO)_6$ adduct of **5a** are also in agreement with its formulation as **5a**·$Co_2(CO)_6$ (see Experimental Section).[12] The ^{31}P NMR resonance of this compound is found at δ = 36.9 (see Experimental Section). Under carbonylating conditions, the carbonyl derivative $[tripodCo(CO)_2]^+$ is formed as a minor side-product, as indicated by its ^{31}P NMR resonance at δ = 24.1 (see Experimental Section) and by the FAB-MS signal of the molecular ion (*m/z* = 739, see Experimental Section).[2f] This observation also shows that the diyne, once it has been formed as a ligand at the [*tripod*Co] template, can be set free from the metal by extensive carbonylation.[13] The presence of the PF_6 counterion is corroborated by a strong ν(PF) vibration and by the corresponding ^{31}P NMR signal in each case (Table 3).

The structure of **5** is confirmed by an X-ray analysis of the PF_6 salt of **5b** (Table 4 and 5). A general view of **5b** is given in Figure 2 (left), as well as a projection of the structure onto the plane of the three phosphorus atoms (right).

From this second view in Figure 2, it becomes clear that there are at least two sets of chemically different phosphorus nuclei in **5b**. The fact that only one ^{31}P NMR signal

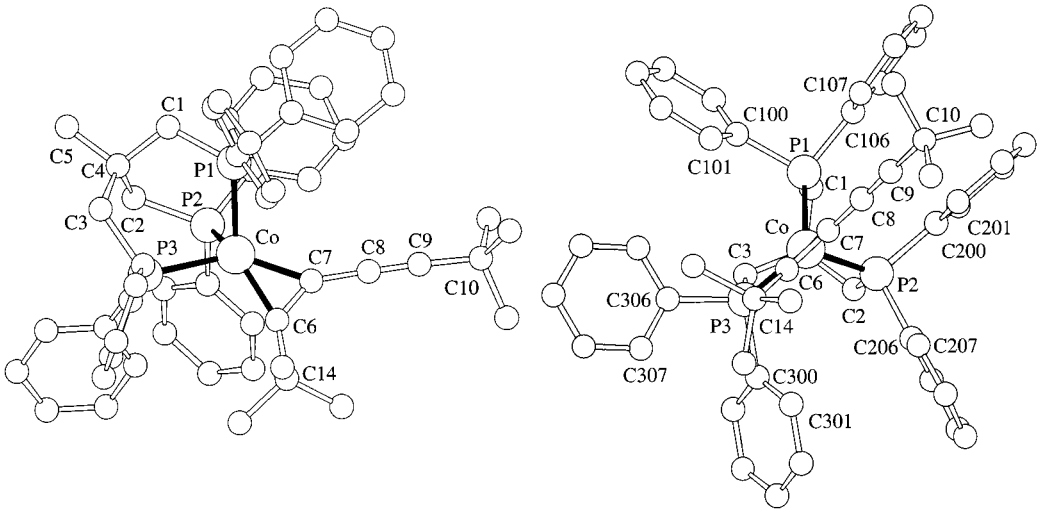

Figure 2. General view and projection of the structure of the cation of **5b**

is observed means that the coordinated alkyne group is free to adopt different rotational positions relative to the [*tripod*Co] scaffolding, with the vector radiating from the cobalt centre to the midpoint of the coordinated alkyne bond (C6−C7) interpreted as the axis of this rotation. With the coordinated alkyne bond seen as just one donor ligand, the coordination geometry around the cobalt may be described as idealised tetrahedral.

The *t*Bu substituent of the alkyne in **5b** makes the coordinated triple bond a rather bulky one. The rotational position of the alkyne ligand is such that the *t*Bu substituent (C14, Figure 2) of the coordinated alkyne ligand (C6−C7, Figure 2) is in an eclipsed position with respect to the Co−P3 bond. It follows that the *t*Bu−C≡C substituent (C8−C9−C10, Figure 2) at the other carbon centre of the coordinated alkyne (C7, Figure 2) is in a staggered position with respect to the Co−P1 and Co−P2 bonds (Figure 2). The steric strain imposed by the orientation of the alkyne ligand is mirrored by the geometric parameters of the $Co-P_3$ part of the compound. The distance Co−P3 (224 pm) is distinctly larger than the Co−P1 (220 pm) and Co−P2 (216 pm) distances. The P3−Co−P2 (92.5°) and P3−Co−P1 (96.3°) angles are definitely larger than the angle between the Co−P1 and Co−P2 bonds (84.6°). The rotational positions of the "phenyl-petals" also respond to this steric strain; the phenyl groups at P3 show distinctly larger rotation angles than those at P1 and P2 (Figure 2, Table 5).

The coordinated triple bond (C6−C7: 131.3 pm, Table 4 and 5) is approximately 11 pm longer than the uncoordinated one (C8−C9: 120.0 pm, Table 4 and 5). As expected, the coordination around the carbon atoms of the free triple bond is linear (C7−C8−C9: 176.6°; C8−C9−C10: 177.8°, Table 4 and 5), but the bond angles at the carbon atoms of the coordinated triple bond (C14−C6−C7: 134.5°; C6−C7−C8: 140.1°, Table 4 and 5) are distinctly different from 180°. The degree of this bending and the lengthening of the coordinated bond are indicative of a strong interaction between the alkyne and the metal.[15]

Based on the formalism of electron counting, the alkynes in **5** should act as four-electron donors since the compounds are diamagnetic and behave as 18-electron compounds,[14] while a 16-electron species [*tripod*CoL]$^+$ with L acting as a two-electron donor should be paramagnetic.[4−7] This follows from simple crystal-field-type arguments as well as from experience.[4−7,14] Assuming that the alkyne ligands in **5** act as four-electron donor moieties is in good agreement with the established rules correlating the ^{13}C NMR resonances of coordinated alkyne groups with the number of electrons which these groups donate to the metal.[15] The signals of the carbon atoms of the coordinated alkyne group in **5a** are observed at approximately δ = 160−180 and those of **5b** occur at δ = 164−200 (Table 3). The uncoordinated triple bonds give rise to signals between δ = 77 and δ = 101 in these compounds (Table 3). These latter shift values compare favourably with the ^{13}C NMR shifts reported for uncoordinated 1,3-diynes. In cobalt(I) compounds in which alkyne ligands can only act as two-electron donors (due to the electron count), ^{13}C NMR resonances of δ ≈ 100 are generally observed.[16] The C−C bond lengths in these compounds are found to be about 127 pm, which is definitely shorter than the C6−C7 distance (131 pm, Table 5) in **5b** where the alkyne acts as a four-electron donor.[16b]

The bonding of acetylenes at [*tripod*Co]$^+$ fragments has previously been reported, although no NMR spectroscopic data were given.[17]

Conclusion

*tripod*Co-bisalkyne compounds are easily prepared by the reaction of *tripod*Co-halides with LiC≡CR. Starting from [*tripod*$CoCl_2$] (**1**), neutral Co^{II} derivatives [*tripod*$Co(C{\equiv}CR)_2$] **(2)** are obtained. Anionic Co^{I} derivatives [*tripod*$Co(C{\equiv}CR)_2]^-$ **(2^-)** are found when [*tripod*CoCl] **(3)** is used as the starting material. The bisalkynyl compounds **2** are found to act as π-tweezer ligands with Ni(CO). It is

observed that they undergo one-electron oxidation which results in oxidative coupling of the alkynyl ligands to produce 1,3-diynes and concomitant reduction of Co^{II} to Co^{I} to produce $[tripodCo(\eta^2\text{-}RC{\equiv}CC{\equiv}CR)]^+$ **(5)**.

Experimental Section

General Remarks: Unless otherwise noted, all manipulations were carried out under argon by means of standard Schlenk techniques All solvents were dried by standard methods and distilled under argon.[18] The CD_2Cl_2 used for NMR spectroscopic measurements was degassed by three successive "freeze-pump-thaw" cycles and dried with 4 Å molecular sieves. − EPR: Bruker ESP 300 E, X-band, standard cavity ER 4102, temperature control unit Eurotherm B-VT 2000, external standard dipenylpicrylhydrazyl (DPPH); Simulation: XSophe Computer Simulation Software Suite, Version 1.0.4b, 1993−1999; XEPRView, Version 1.0, 1999; Bruker Analytik, Rheinstetten, Germany. − NMR: Bruker Avance DPX 200 at 200.12 MHz (^{1}H), 50.323 MHz (^{13}C{^{1}H}), 81.015 MHz (^{31}P{^{1}H}), T = 303 K; chemical shifts (δ) are given in ppm with respect to CD_2Cl_2 (^{1}H: δ = 5.32; ^{13}C: δ = 53.8) as internal standard. ^{31}P chemical shifts (δ) are given in ppm with respect to 85% H_3PO_4 (^{31}P: δ = 0) as external standard. − IR: Bruker IFS-66, KBr disks. − MS: Finnigan MAT 8230; Fast-atom bombardment (FAB) xenon, matrix: 4-nitrobenzyl alcohol. − HR-MS (FAB) JEOL JMS 700, matrix: 4-nitrobenzyl alcohol. − Magnetic measurements: Faraday balance with a Bruker electromagnet B-E 15 C8, Bruker Field Controller B-H 15, Sartorius vacuum-microbalance M25 D-S, Oxford Temperature Control Unit ITC-4; calibration with $K_3[Fe(CN)_6]$. − Molecular weight determinations: Knauer vapor-pressure osmometer No. 7311100000; calibration with dibenzil. − Elemental analyses: Microanalytical Laboratory of the Organisch-Chemisches Institut, Universität Heidelberg. − Melting points: Gallenkamp MFB-595 010, melting points are not corrected. − Cyclic voltammetry: Metrohm "Universal Meß- und Titriergefäß", Metrohm GC electrode RDE 628, platinum electrode, SCE electrode, Princeton Applied Research potentiostate Model 273, 10^{-3} M in 0.1 M nBu$_4$NPF$_6$/CH_2Cl_2.

General Procedure for the Synthesis of Compounds 2: Alkyne (2 mmol) was dissolved in Et_2O (5 mL) and deprotonated with nBuLi (0.8 mL, 2.5 M in n-hexane) at −80 °C. After 5 min, the reaction mixture was allowed to warm to room temperature. [$tripod$CoCl$_2$] (1 mmol, 753 mg) was dissolved in THF (25 mL) and cooled to −80 °C. The acetylide was added at −80 °C with a syringe, and a brown solution was immediately formed. After 10 min at −80 °C, the reaction mixture was allowed to warm to room temperature and the solvent was removed under reduced pressure. The resulting black-brown residue was dissolved in toluene and filtered to remove LiCl. After evaporation of the solvent, compounds **2** were obtained as microcrystalline black-brown powders. Attempts to obtain crystals suitable for X-ray crystallography were unsuccessful. Compounds **2** are highly soluble in organic solvents such as hexane, toluene, Et_2O, and methanol such that crystallisation by diffusion is unfeasible; slow evaporation of the solvent leaves them as microcrystalline powders only. Cooling the solutions down to −80 °C also did not result in single crystals.

μ_{eff} (**2a**, 25 °C) = 1.8 BM; osmometric determination of the molecular mass of compound **2a**: calcd./found: 885/887.

Preparation of PPh$_4$[$tripod$Co^{I}-(C≡CPh)$_2$], PPh$_4^+$2a$^-$: [$tripod$CoCl] **(3)** (1 mmol, 718 mg) was suspended in THF (20 mL). LiC≡CPh (2 mmol) in Et_2O (5 mL) was added at −80 °C. The reaction mixture was stirred for 10 min at this temperature and then allowed to warm to 25 °C resulting in a colour change from beige to red-brown. The solvent was evaporated and the residue dissolved in CH_2Cl_2. Ph_4PCl (1 mmol, 375 mg) was added and the reaction mixture stirred for 20 min. After removal of the solvent under reduced pressure, the residue was redissolved in toluene and filtered to remove LiCl. Evaporation of the solvent produced PPh_4^+**2a**$^-$ as a red-brown, air-sensitive powder. − ^{1}H NMR (CD_2Cl_2): δ = 1.28 (br. s, 3 H, CH_3), 2.46 (br. s, 6 H, CH_2), 7.07−7.48 (m, 60 H, H_{ar}). − ^{31}P NMR (CD_2Cl_2): δ = 26.8 (s, PPh$_4^+$), 32.1 (s, CH_2-P). − IR (KBr): ν(CC) = 2049 (w) cm^{-1}. − MS (FAB-negative): m/z = 885 [M$^-$]. − $C_{81}H_{69}CoP_4$ (1225.27): calcd. C 79.40, H 5.68; found C 78.21, H 5.82. − M.p. 145 °C (dec.).

General Procedure for the Synthesis of Compounds 4: Compound **2** (1 mmol) was dissolved in toluene and treated with a threefold excess of $Ni(CO)_4$. The reaction mixture was stirred for 2 h. No colour change took place, but a slow gas evolution was observed. The solvent was removed under reduced pressure and the residue recrystallised from CH_2Cl_2. After evaporation of the solvent, compounds **4** were obtained as black-brown microcrystalline powders.

CV (**4b**, CH_2Cl_2, vs. SCE): $E_{1/2}$ = 605 mV (rev.), ΔE = 90 mV.

General Procedure for the Synthesis of Compounds 5: Compound **2** (1 mmol) was dissolved in acetone (25 mL) and treated with $(Cp_2Fe)PF_6$ (1 mmol, 332 mg). The colour immediately changed from black-brown to green. The solvent was removed under reduced pressure and the resulting green residue was purified by chromatography on SiO_2 (ICN 32−63, 60 Å) with PE (boiling range 40−60 °C)/CH_2Cl_2 (5:1). After evaporation of the solvent, the PF_6 salts **5a**−**c** were obtained as fine black-green powders. Single crystals of compound **5b** suitable for X-ray diffraction were obtained after three months by diffusion of PE (boiling range 40−60 °C) into a solution of **5b** in THF.

Preparation of 5a·Co$_2$(CO)$_6$: Compound **5a** (0.1 mmol, 103 mg) was dissolved in acetone (10 mL). [$Co_2(CO)_8$] (0.15 mmol, 52 mg) was added and the reaction mixture was stirred for 1.5 h. A darkening of the solution was evident after a few minutes. The solvent was removed under reduced pressure and the residue was washed three times with Et_2O. After evaporation of the solvent, the $Co_2(CO)_6$ adduct of **5a** was obtained as a black microcrystalline powder.

^{31}P NMR (CD_2Cl_2): δ = 36.9 (s, CH_2-P). − IR (KBr): ν(CO) = 2100 (s), 2083 (s), 2054 (s), 2034 (s) cm^{-1}. − MS (FAB): m/z = 1171 [M$^+$], 1143 [M$^+$ − CO], 1115 [M$^+$ − 2CO], 1087 [M$^+$ − 3CO], 1059 [M$^+$ − 4CO], 1031 [M$^+$ − 5CO], 885 [M$^+$ − $Co_2(CO)_6$].

X-ray Crystallographic Study: The measurement was carried out on a Siemens AXS Smart CCD diffractometer using graphite-monochromated Mo-K_α radiation. All calculations were performed using the SHELXT PLUS software package. The structure was solved by direct methods with the SHELXS-97 program and refined with the SHELXL-97 program.[19] Graphical handling of the structural data during solution and refinement was performed with XPMA.[20] Atomic coordinates and anisotropic thermal parameters of the non-hydrogen atoms were refined by full-matrix least-squares calculations. Table 5 lists the data for the structure determination.

Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication

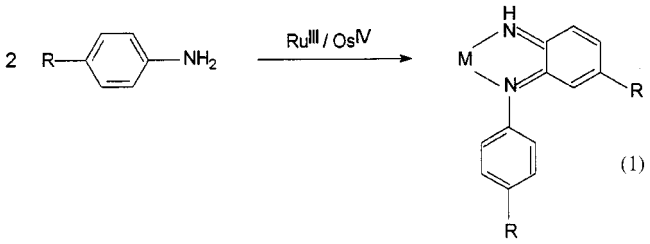
Ferric-Chloride-Promoted Oxidation of *p*-Anisidine to an *N*-Substituted Phenazine Derivative − Structural Elucidation, Protic Equilibria and Coordination Chemistry of the Phenazine



Amit K. Ghosh,[a] Kedar N. Mitra,[a] Golam Mostafa,[b] and Sreebrata Goswami*[a]

Keywords: C−N Bond formation / Oxidations / Polymerizations / Ruthenium / Osmium / Coordination chemistry / $FeCl_3$-promoted reactions

The reaction of hydrated ferric chloride and *p*-anisidine affords brown 6-*p*-anisyl-2-(*p*-anisylamino)-9-methoxy phenazine-3(4*H*)-*p*-anisylimine (LH) in moderate yield (35%). Plausible steps involved in this unusual fusion process are proposed. This phenazine spontaneously binds with H^+ to give a violet solution, p*K* for the reaction LH + $H^+ \rightleftarrows LH_2^+$ is 6.61 at 300 K. The protonated phenazine has been isolated as its chloride salt, $[LH_2Cl]$, the structure of which is described in authenticating the formation of LH directly from *p*-anisidine. The structural data reveal a planar dibenzo pyrazine moiety with an extensive delocalisation along the phenazine backbone. The protonation of LH occurs at the imine nitrogen. The spectral properties of both LH and $[LH_2]Cl$ are described. Both show well-resolved ^1H NMR spectra with four methyl resonances occurring in the range δ = 3.70 to 3.93. While $[LH_2]Cl$ shows two NH resonances at δ = 11.95 and 10.18, neutral LH displays only one such resonance at δ = 8.49. Aromatic proton resonances for these compounds appeared in the range δ = 5.79 to 8.04. The coordination abilities of the above phenazine were explored. It reacts spontaneously with $[M(aap)_2X_2]^{n+}$ (M = Ru^{II}, Os^{II}; aap = 2-(arylazo)pyridine; X = solvent, *n* = 2; X = Br^-, *n* = 0) to give cationic complexes of the general formula, $[M(aap)_2L]^+$ which were isolated as their perchlorate and bromide salts. These metal complexes were fully characterized. Their spectral properties indicate a bidentate anionic chelation of L^-, with deprotonation of the amine nitrogen. The complexes show multiple redox responses. The oxidised complexes are unstable and undergo chemical transformations. The reduction processes, on the other hand, are electrochemically reversible and presumably occur at the coordinated aap ligands.

Introduction

This work originated from our interest in metal-promoted oxidative dimerisation and polymerisation reactions of aromatic amines. In this respect, we have recently reported[1−3] the ruthenium(III)- and osmium(IV)-mediated *ortho* dimerisation of primary aromatic amines, $ArNH_2$, leading to *N*-aryl-1,2-diimino arenes [Equation (1)]. It may be relevant to add here that complexes of quinone-related 1,2-diimine ligands are of interest[4,5] in contemporary research and that *N*-substituted 1,2-diimino complexes of the above type were not possible to synthesise by conventional synthetic routes.

(1)

The above transformation is a combination of two major processes: oxidative *ortho* dimerisation of $ArNH_2$ and further oxidation of the resultant dimer would form the diimine ligand. Anodic oxidation of aromatic amines[6] associated with *para* coupling leading to *p*-benzidine or *p*-semidine are common. There are also examples of oxidation of $ArNH_2$ to diazo compounds, Ar−N=N−Ar. Oxidative dimerisation with C−N bond formation, as described in Equation (1), however, was not known in the literature. This transformation occurs only in the presence of O_2, which acts as an oxidising agent. It is proposed that the metal mediates this transformation by holding the amine residues in a suitable juxtaposition and also by taking part in the redox processes. The unusual observations in the above cases of ruthenium and osmium prompted us to seek parallel developments using iron as the mediator. Interestingly, a completely different set of reactions occur with hydrated $FeCl_3$. In this report we disclose our results of the $FeCl_3$-mediated polymerisation reaction of *p*-anisidine to an *N*-substituted phenazine derivative. A literature survey revealed that the formation of an intense violet colour on addition of $FeCl_3$ to a solution containing *p*-anisidine was noticed[7] long ago, but the nature of product of the reaction was not determined.

Successful isolation and characterisation of the above phenazine together with its coordination chemistry invol-

ving ruthenium and osmium constitute the major aspects of this report.

Results and Discussion

The Reaction

The reaction procedure consists of heating a mixture of hydrated $FeCl_3$ (100 mg) and a large excess of *p*-anisidine (2 g) at 120 °C in the air for one hour. The reaction occurs smoothly to produce an intense blue mixture. Usual work up (see Experimental Section) of the mixture followed by column chromatography (silica gel) afforded brown phenazine (LH) as the major product in 35% yield [(Equation (2)].

Beside the brown phenazine band, a mixture of blue and violet bands was also eluted with $CH_3CN/CHCl_3$ (1:4). We are as yet unable to obtain these in the pure state. This reaction only occurs neat and in the presence of O_2. It thus belongs to an example of the reaction class where catalytic activation[8] of dioxygen occurs by a transition metal ion.

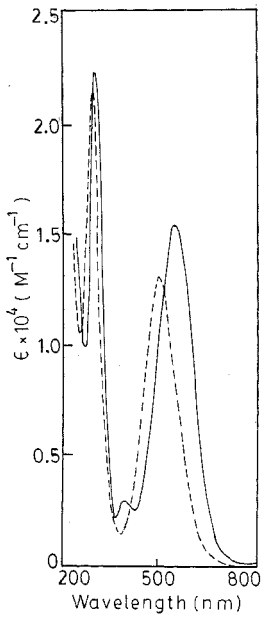

Figure 1. UV/Vis Spectra of LH (-------) and $[LH_2]Cl$ (− −) in acetonitrile

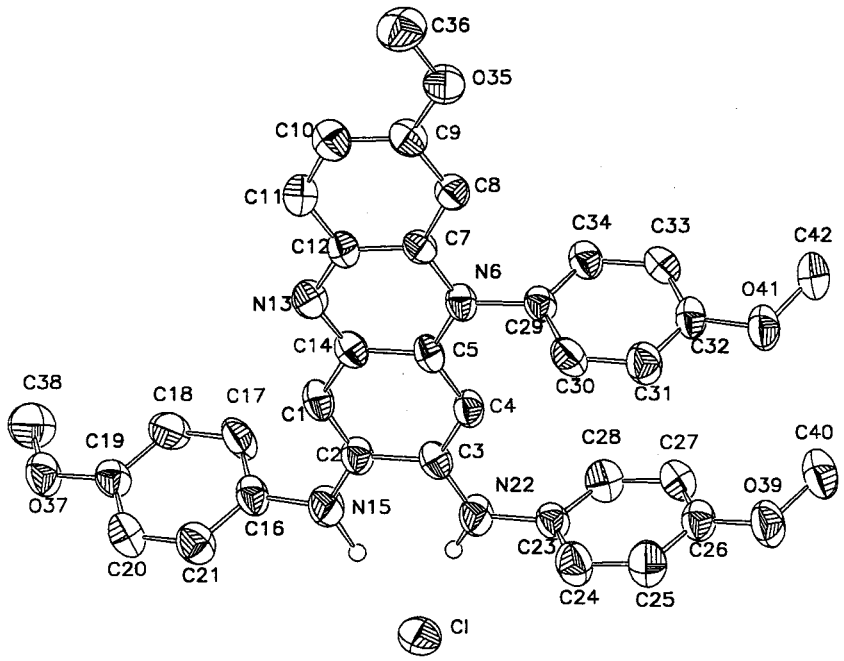
$$LH + H^+ \rightleftarrows LH_2^+ \cdots (3)$$

Characterisation of LH

The brown product isolated from the above reaction showed an intense FAB-MS peak at m/z = 558 confirming the formulation of the compound. The solution spectrum of LH in CH_3CN consists of a strong absorption at 505 nm



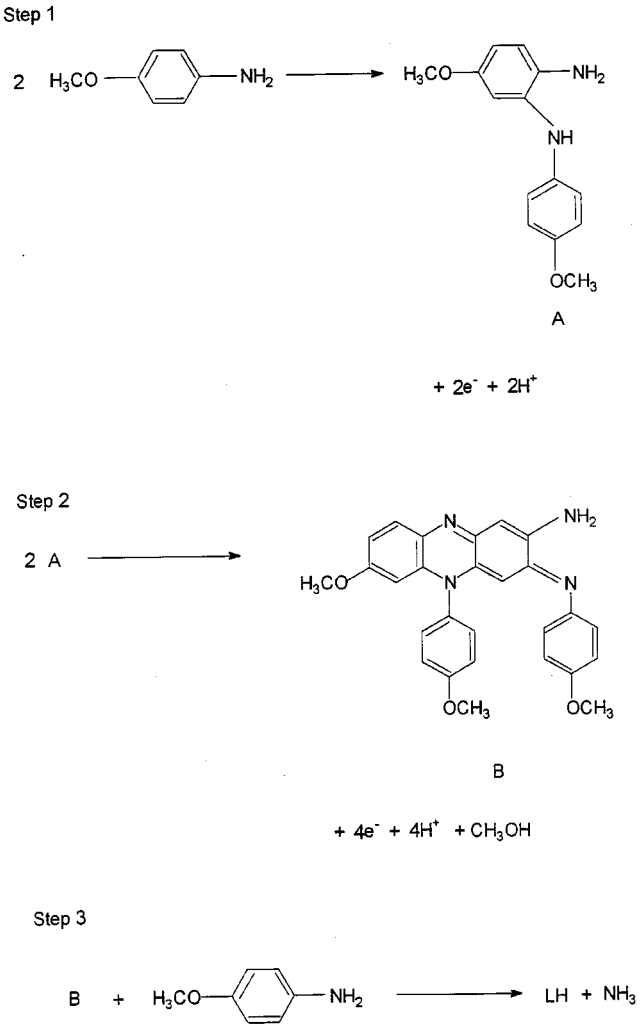


Figure 2. Molecular structure of $[LH_2]Cl$ showing the atom numbering scheme. Selected bond lengths [Å] : N(22)−C(3) 1.356(7), N(22)−C(23) 1.432(7), N(6)−C(5) 1.368(6), N(6)−C(7) 1.399(6), N(6)−C(29) 1.451(6), N(13)−C(14) 1.337(6), N(13)−C(12) 1.359(6), N(15)−C(2) 1.363(7), N(15)−C(16) 1.448(7), C(3)−C(4) 1.390(7), C(4)−C(5) 1.383(7), C(5)−C(14) 1.444(7), C(14)−C(1) 1.410(7), C(1)−C(2) 1.381(7), C(2)−C(3) 1.463(7)

Scheme 1. Plausible steps for the formation of phenazine

which may be attributed to extensive delocalisation (vide infra) along the phenazine backbone. Interestingly, the colour of the above solution became intense violet (λ_{max} 530 nm) on acidification. The spectra of these two are shown in Figure 1 and the spectral change as a function of $[H^+]$ is submitted as supplementary material (Figure S1). There is a sharp isosbestic point at 508 nm which indicates an acid-base equilibrium between LH and LH_2^+ [(Equation (3)]. The *pK* for this equilibrium reaction is 6.61±0.2 at 300 K. The chloride salt of the protonated phenazine, $[LH_2]Cl$ formed crystals suitable for X-ray structure determination. X-ray structure analysis[9] was used to authenticate the formation of $[LH_2]Cl$ and hence LH from a previously unknown reaction. A view of the molecule is shown in Figure 2, which indeed confirms the formation of a substituted phenazine with several C−N bond-formation processes.

The overall transformation is an 8 e^- + 8 H^+ transfer process and is accompanied by the elimination of one mol each of CH_3OH and NH_3. Oxidative dimerisation of *ortho* substituted aromatic amines, for example 1,2-diamino benzene or 2-amino phenol are documented in the literature.[8,10−11] These dehydrogenation processes proceed via radical intermediates[8,10b] which have been detected by EPR spectroscopy. It is proposed that the first and key step of *p*-anisidine → LH transformation is the dimerisation of the monoamine to produce *N*-aryl-1,2-diamino arene. This proposal is based on our results of the ruthenium- and osmium-promoted dimerisation reaction of *p*-anisidine. In those cases, however, the *N*-aryl diamine, once formed, undergoes dehydrogenation[2] to result in a coordinated 1,2-diimine [(Equation (1)]. In this case, once the *N*-aryl diamine is formed, it undergoes further dimerisation[11] and deamination processes to give LH. The plausible steps are shown in Scheme 1.

To the best of our knowledge, the formation of phenazine directly from a mono primary amine is not known. We wish to note here that identical reactions are also observed when neat *p*-anisidine is allowed to react with $CrCl_3$ or $RhCl_3$.

A close examination of the bond angles and distances of the salt $[LH_2]Cl$ reveals that the long chain, N15−C2−C1−C14−N13−C12−C11−C10−C9−C8−C7−N6−C5−C4−C3−N22 contains hybrid bonds. The ranges of bond lengths in this chain are C−C = 1.372 to 1.410Å and C−N = 1.337 to 1.399Å . Moreover, a least-square plane calculated through the 14 atoms of the dibenzo pyrazine fragment indicates that the skeleton is approximately planar; the largest deviation from the mean plane is 0.09Å. The planarity of the phenazine fragment, together with the bond length trends, indicates extensive delocalisation. This may be due to considerable contributions of the different resonance forms of the molecule. Furthermore, of the four substituents of the phenazine fragments, the two nitrogen atoms, *viz*. N15 and N22 deviate by 0.096 Å and 0.104 Å from the mean plane. The anisyl ring is almost perpendicular to the pyrazine ring. The torsion angle C5−N6−C29−C34 is 95.52°. This orientation minimises the steric interaction between *ortho* hydrogens *viz.* H30 and H34 and those on the phenazine, H4 and H8. Finally, it may be noted here that the crystal and molecular structure of $[LH_2]Cl$ is stabilised through[12] several hydrogen bonds.

Both LH and its conjugate acid $[LH_2]Cl$ show highly resolved ^1H NMR spectra (Figure 3). While there are two broad N−H resonances[13] at δ = 11.95 and 10.18 for $[LH_2]Cl$, the corresponding deprotonated compound LH showed only one broad resonance at δ = 8.49. The spectrum of the salt $[LH_2]Cl$ is better resolved and the resonances are shifted downfield from those for the corresponding neutral LH, as expected. The four methyl resonances appear in the range δ = 3.70 to 3.93, whereas the aromatic proton resonances are spread between δ = 5.79 and 8.04. Assignment of some of the resonances was not possible due to overlap of the resonances of unique protons. However, the H1 and H4 resonances in LH appear at δ = 6.18 and 5.79, respectively. The H1 signal appears as a doublet with *J* = 2.1 Hz. Irradiation of the signal at δ = 8.49 in LH results in the doublet at δ = 6.18 collapsing to a singlet, confirming that these two protons are magnetically coupled. These two resonances in the corresponding $[LH_2]Cl$ appear at δ = 6.38 and 6.24. Selected assignments

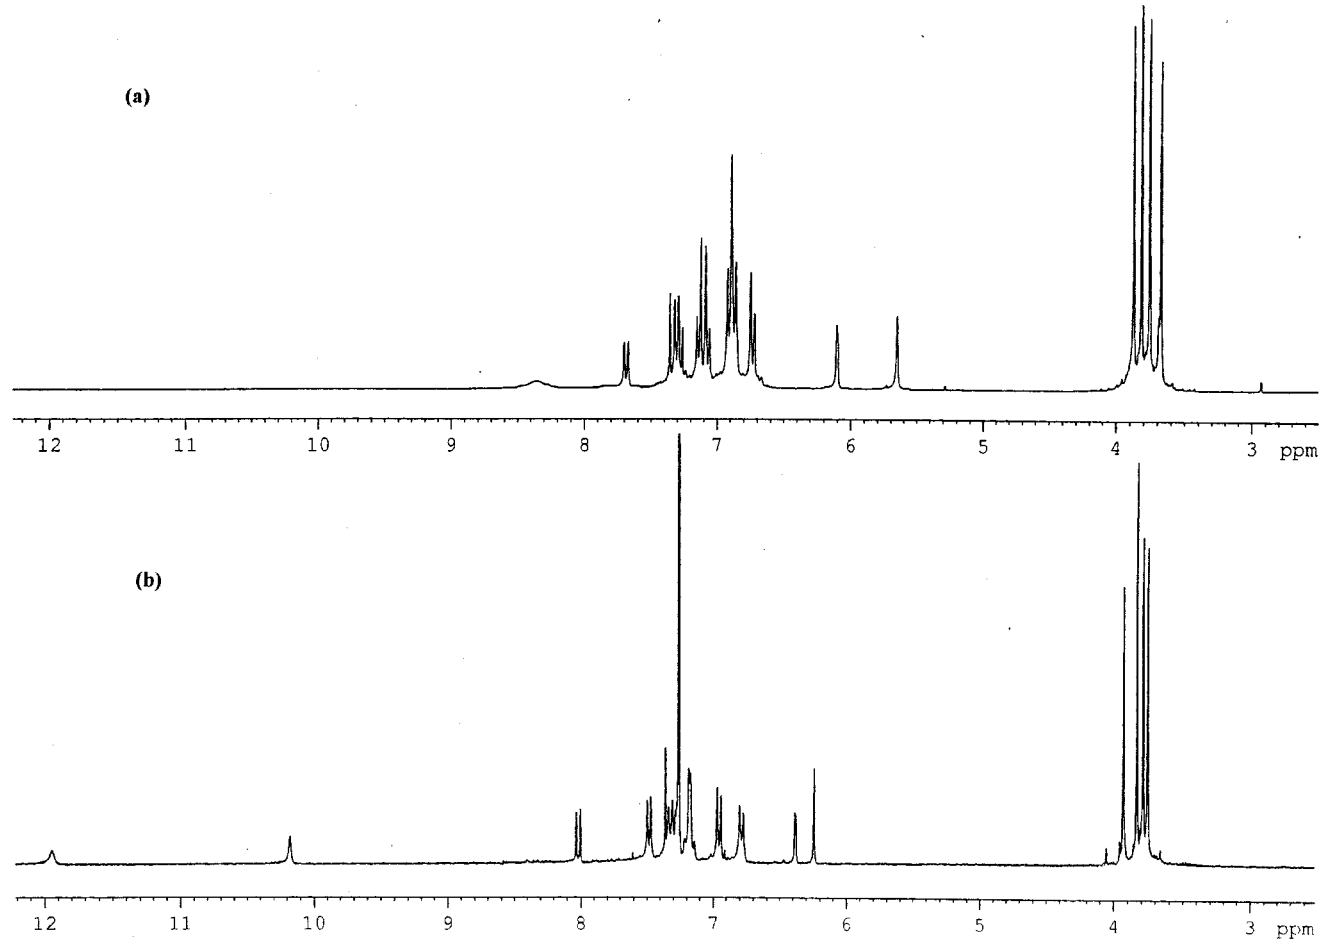

Figure 3. NMR spectra of (a) LH and (b) $[LH_2]Cl$ in $CDCl_3$

of the proton resonances are presented in the Experimental Section.

Binding of L to $M(aap)_2^{2+}$ moiety (M = Ru, Os)

The high affinity of the phenazine LH for H^+ led us to explore its coordination ability to transition metal ions. We chose $M(aap)_2^{2+}$ [M = Ru^{II} and Os^{II}, aap = 2-(arylazo)pyridine], as the possible binding sites. It may be relevant to note here that dipyrido phenazine complexes[14−16] of Ru^{II} and Os^{II} bind DNA and RNA by intercalation and represent an important class of molecular probes.

The compound LH reacts[17] smoothly with $[Ru(OH_2)_2(aap)_2]^{2+}$ in boiling methanol in the presence of a few drops of NEt_3 as base to yield a mixed *tris* chelate where L^- binds to Ru^{II} as a monoanionic bidentate ligand. Deprotonation of the amine nitrogen (N15), brought about by NEt_3, is essential for its chelation. The reaction of L^- with the dibromo analogue of osmium[18] under similar conditions proceeds at a much slower rate. The crude compounds were isolated as their perchlorate and bromide salts, respectively. Purification of the products was achieved by chromatography on silica gel column using different mixtures of $CHCl_3/CH_3CN$ as eluent. The mixed ligand complexes were obtained in high yields (75−80%). They are highly soluble in common organic solvents and their acetonitrile solutions behave as 1:1 electrolytes. The elemental analyses of these are consistent with the proposed composition $[M(aap)_2(L)]ClO_4$ (**1**).

Characterisation of $[M(aap)_2L]^+$

We employed several analytical methods to characterise the metal complexes, including ^1H NMR and UV/Vis spectroscopy, and cyclic voltammetry. The ^1H NMR spectrum of $[M(aap)_2(L)]^+$ contains several overlapping resonances in the aromatic region, owing to the presence of a large number of unique protons in these complexes. In this respect, the methyl resonances have been particularly useful for assessing the identity of the metal complexes. The $[M(pap)_2L]^+$ complexes display four −OMe signals in the range δ = 3.57−3.89 originating from the phenazine ligand; the corresponding *m*-tap complexes $[M(tap)_2L]^+$, on the other hand, display two extra methyl resonances at δ = 2.08 and 2.06, confirming the presence of two tap ligands in these compounds (Figure S2). Two methyl signals from the two tap ligands were expected due to the unsymmetric nature of the phenazine ligand. The disappearance of N−H

resonances in these complexes also indicates coordination of phenazine through N15 and N22. The number of ^{1}H NMR signals in these complexes is greater than those observed in LH and $[LH_2]^+$. The two pairs of doublets and one pair of triplets above $\delta = 7.5$ are assigned[19] to the pyridyl proton resonances, which further confirms the presence of two aap ligands in these compounds.

The phenazine ligand LH in the presence of 1 mM OH^- shows two intense transitions in the range 800−250 nm. One of these appears in the visible range at 490 nm while the other transition occurs at 280 nm. The solution colour of $[Ru(aap)_2L]^+$ is red-violet whereas that of the corresponding osmium analogue is blue-violet. The solution spectrum of the ruthenium complex consists of an intense transition at 545 nm. This transition is associated with at least two additional ill-defined shoulders occurring at longer wavelengths. The spectra of the corresponding osmium complexes showed multiple absorption peaks in the visible range. Each of them shows a transition at 790 nm and two more closely spaced transitions at 625 and 580 nm are also observed. The bivalent ruthenium and osmium complexes of aap, in general, display intense transitions in the visible range which are assigned to metal to ligand charge transfer (MLCT) transitions.[17−18] The number of absorption peaks in mixed ligand complexes varies depending on the presence of different acceptor orbitals. In the present complexes, the phenazine ligand itself has very intense visible range transition. Therefore, multiple transition possibilities,[20,21] originating from intra-ligand as well as MLCT transitions, exist in these complexes. The spectral data are collected in Table 1.

Redox Properties

We employed cyclic voltammetry to determine the redox properties of the above ruthenium and osmium complexes. Figure 4 shows the multiple reduction waves of $[Ru(m\text{-tap})_2L]^+$ and the voltammetric data for all the complexes are collected in Table 2. The ruthenium complexes display three responses on the positive side of the Ag/AgCl reference. Of these, the couple with the lowest potential (0.45 *V*) is quasireversible with $i_{pa} > i_{pc}$, followed by a reversible couple at 0.97 *V*. Besides these, an irreversible anodic response of uncertain origin at 1.57 V was also observed. The first anodic response may be assigned to the oxidation of ruthenium(II) → ruthenium(III) in **1**. The next reversible response represents the ruthenium(II) → ruthenium(III) oxidation of a diimine analogue of **1** formed by the chemical transformation of electrogenerated $\mathbf{1}^+$. Ruthenium- and osmium-mediated electrochemical oxidation of the coordinated amine function are documented[17,22,23] in the literature. Keeping the above electrochemical transformations in mind, we examined whether the electrogenerated $\mathbf{1}^+$ would chemically be transformed to the diimine analogue of **1**. In practice, however, $\mathbf{1}^+$, produced by exhaustive electrolysis

Table 2. Electrochemical data[a]

	$E_{1/2}$/V(ΔE_p/mV)[b] Oxidation			Reduction			
$[Ru(pap)_2L]ClO_4$	0.47(70)	0.94(90)	1.56[c]	−0.38(90)	−0.89(100)	−1.63(150)	−2.07[d]
$[Ru(tap)_2L]ClO_4$	0.43(80)	0.85(90)	1.59[c]	−0.45(90)	−0.97(100)	−1.63(150)	−2.00[d]
$[Os(pap)_2L]Br$	0.68[e]			−0.39(80)	−0.88(60)	−1.57(60)	−2.27[d]
$[Os(tap)_2L]Br$	0.76[c]	0.91[c]	1.63[c]	−0.42(100)	−0.92(100)	−1.65(160)	−1.95[d]

[a] Conditions: solvent, acetonitrile; supporting electrolyte, NEt_4ClO_4 (0.1 M); working electrode, platinum for oxidation processes and glassy carbon for reduction processes; reference electrode, Ag/AgCl; solute concentration, 10^{-3} M. − [b] $E_{1/2}$ is calculated as the average of anodic (E_{pa}) and cathodic (E_{pc}) peak potentials; $\Delta E_p = E_{pa} - E_{pc}$. − [c] Irreversible E_{pa}. − [d] Irreversible E_{pc}. − [e] Irreversible E_{pa} with very large current.

of **1** at 0.70 V, yielded a mixture of compounds from which no pure product could be isolated. The responses in the case of osmium are more closely spaced and irreversible in nature.

The cathodic responses, on the other hand, are well defined. All the complexes showed three reversible couples along with a cathodic response of equal current (Figure 4) in the range −0.38 to −2.27 V. The coordinated ligand, pap, is known[17a] to undergo successive two-step one-electron transfer processes. Hence, these four responses may be attributed to the reductions of two aap ligands.

Conclusions

The direct formation of *N*-aryl phenazine (LH) from a mono aromatic primary amine, *viz*. *p*-anisidine, occurs through several oxidative carbon-nitrogen bond formation and cyclisation processes which otherwise do not occur with the free amine. This reaction is mediated by the ferric ion through the activation of O_2. This reaction is important in connection with the studies of chemical as well as electrochemical oxidations of primary aromatic amines. The coordination abilities of the anionic phenazine ligand $[L]^-$ have been explored. Our study of carbon-nitrogen bond formation processes using transition metal complexes as mediators is continuing.

Experimental Section

Materials: $RuCl_3 \cdot nH_2O$ was obtained from Arora Matthey and was digested three times with concentrated HCl before use. Solvents and chemicals used for syntheses were of analytical grade and used as received. The supporting electrolyte (TEAP) and solvents for electrochemical works were obtained as before.[17] $[Ru(aap)_2(OH_2)_2](ClO_4)_2 \cdot H_2O$ and $[Os(aap)_2Br_2]$ were prepared by literature methods.[17b,18b]

Physical Measurements: A Shimadzu UV 2100 UV/Vis spectrophotometer was used to record electronic spectra. The IR spectra were recorded with a Perkin−Elmer 783 spectrophotometer. ^1H NMR spectra in $CDCl_3$ were recorded on a Bruker Avance DPX 300 spectrophotometer, with $SiMe_4$ as internal standard. A Perkin−Elmer 240C elemental analyser was used to collect microanalytical data (C, H, N). Electrochemical measurements were performed under a dry nitrogen atmosphere on a PAR model 273-A electrochemistry system as described earlier.[20] All potentials reported in this work are referenced to Ag/AgCl and are uncorrected for junction contribution. The pH measurements were made with a μ-pH System 361 Systronics pH meter, standardised with buffers 7.0 and 9.2. A 70% CH_3CN/H_2O buffer mixture was employed. Electrical conductivities were measured by using a Systronics Direct Reading Conductivity meter 304. FAB-MS was obtained from JEOL AX 500/DA 5050 model mass spectrometer having a 70 eV ion source and direct inlet temperature of 180 °C.

Syntheses of Ligands

6-*p*-Anisyl-2-(*p*-anisylamino)-3(4*H*)-*p*-anisylimine-9-methoxyphenazine, (LH): A large excess of *p*-anisidine (2 g, 16.20 mmol) was added to hydrated $FeCl_3$ (100 mg, 0.60 mmol) and the mixture heated at 120 °C for 1 h. A violet melt resulted which was then extracted with dichloromethane, filtered and purified on a silica gel column (diameter:1 cm, height: 50 cm) After elution of the unchanged *p*-anisidine with pure chloroform, an intense red-violet band was eluted with chloroform/acetonitrile (19:1). On evaporation of the solvent and subsequent crystallisation from dichloromethane/hexane solutions dark red-brown crystals were obtained. Yield: 35%. − IR (KBr): $\tilde{\nu}$ = 1600 cm^{-1} (C=N), 3300 (N−H). − ^1H NMR ($CDCl_3$): δ = 8.50 (s, N−H, H_{15}), 7.77 (d, H_{10}, J = 9 Hz), 6.18 (d, H_1, J = 2.1 Hz), 5.79 (s, H_4), 3.89, 3.83, 3.77, 3.70 (s, 3 H, OCH_3). − $C_{34}H_{30}N_4O_4$ (558.6): calcd. C 73.11, H 5.37, N 10.03; found C 73.57, H 5.6, N 10.08.

Protonated Phenazine $[LH_2]^+$: A mixture of LH (56 mg, 0.10 mmol), dissolved in dichloromethane (20 mL) and very dilute aqueous HCl (10 mL, 1:20) was shaken vigorously in a separating funnel. The violet organic layer was then washed with water, collected and dried over anhydrous Na_2SO_4. Dark crystals of $[LH_2]Cl$ were obtained by slow diffusion of toluene into a dichloromethane solution of the compound. Yield: 98%. − IR (KBr): $\tilde{\nu}$ = 1615 cm^{-1} (C=N), 3300 (N−H). − ^1H NMR ($CDCl_3$): δ = 11.95 (s, N−H, H_{22}), 10.18 (s, N−H, H_{15}), 8.02 (d, H_{10}, J = 9.0 Hz), 7.36 (s, H_8), 6.95 and 6.79 (d, 2 H, *ortho* C−H of the anisyl rings, J = 8.4, 8.7 Hz, respectively), 6.38 (d, H_1, J = 2.4 Hz), 6.24 (s, H_4), 3.93, 3.83, 3.79, 3.76 (s, 3 H, OCH_3). $-C_{34}H_{31}ClN_4O_4$ (595.1): calcd. C 68.62, H 5.21, N 9.41; found C 68.70, H 5.18, N 9.40.

Syntheses of Complexes

6-*p*-Anisyl-2-(*p*-anisylamino)-3[(4*H*)-*p*-anisyliminobis(2-arylazo)-pyridine]-9-methoxyphenazineruthenium(II) Perchlorate, $[Ru(pap)_2L]ClO_4$: $[Ru(pap)_2(OH_2)_2](ClO_4)_2 \cdot H_2O$ (0.10 g, 0.13 mmol) and LH (0.08 g, 0.14 mmol) were dissolved in methanol (20 mL) and a few drops of NEt_3 added to the mixture. This reaction mixture was then heated at reflux for three hours. The colour of the solution became blue violet. The resulting solution was evaporated to dryness in a water bath and the crude product was purified on a silica gel column. Bands of different colours were first eluted with $CHCl_3$. Unreacted phenazine was then eluted with $CH_3CN/CHCl_3$ (1:12). Finally, an intense blue violet fraction was eluted with $CH_3CN/CHCl_3$ (1:6). After evaporation of solvent and subsequent recrystallisation from dichloromethane/hexane mixture, dark crystals of $[Ru(pap)_2L]ClO_4$ were obtained. Yield: 75%. − IR (KBr): $\tilde{\nu}$ = 1590 cm^{-1}(C=N), 1290 (N=N), 1100, 630 (ClO_4). − ^1H NMR ($CDCl_3$): δ = 3.84, 3.76, 3.72, 3.57 (OCH_3). − $C_{56}H_{47}ClN_{10}O_8Ru$ (1124.6): calcd. C 59.81, H 4.18, N 12.46; found C 59.76, H 4.20, N 12.42.

The corresponding ruthenium compound of 2-(*m*-tolylazo)pyridine was prepared using the same procedure except that $[Ru(mtap)_2(OH_2)_2](ClO_4)_2 \cdot H_2O$ was used instead of $[Ru(pap)_2(OH_2)_2](ClO_4)_2 \cdot H_2O$. Yield: 75%. − IR (KBr): $\tilde{\nu}$ = 1600 cm^{-1}(C=N), 1290 (N=N), 1100, 630 (ClO_4). − ^1H NMR ($CDCl_3$): δ = 3.89, 3.84, 3.80, 3.64 (OCH_3), 2.08, 2.06 (CH_3). − $C_{58}H_{51}ClN_{10}O_8Ru$ (1152.6): calcd. C 60.44, H 4.43, N 12.16; found C 60.68, H 4.56, N 12.15

6-*p*-Anisyl-2-(*p*-anisylamino)-3[(4*H*)-*p*-anisyliminobis(2-phenylazo)-pyridine]-9-methoxyphenazineosmium(II) Bromide, $[Os(pap)_2L]Br$: This compound was synthesized by allowing $[Os(pap)_2Br_2]$ (0.10 g,0.14 mmol) to react with phenazine (0.08 g,0.14 mmol) in boiling 2-methoxyethanol under N_2 atmosphere for five hours, using Na_2CO_3 as base. The solution was then evaporated to dryness and the solid residue dissolved in chloroform and subjected to column chromatography on a silica gel bed. After elution of the unchanged phenazine with $CH_3CN/CHCl_3$ (1:12), an intense blue-

violet fraction was eluted with $CH_3CN/CHCl_3$ (1:6). Solvent evaporation followed by recrystallisation from dichloromethane/hexane mixture afforded dark crystalline $[Os(pap)_2L]ClO_4$. Yield: 75%. – IR (KBr): $\tilde{\nu}$ = 1590 cm^{-1} (C=N), 1280 (N=N). – ^1H NMR ($CDCl_3$): δ = 3.86, 3.83, 3.81, 3.66 (OCH_3). – $C_{56}H_{47}BrN_{10}O_4Os$ (1194.2): calcd. C 56.32, H 3.93, N 11.73; found C 56.40, H 3.96, N 11.73.

The osmium compound of 2-(*m*-tolylazo)pyridine was prepared by the same procedure except that $[Os(m\text{-}tap)_2Br_2]$ was used instead of $[Os(pap)_2Br_2]$; yield 80% . – IR (KBr): $\tilde{\nu}$ = 1590 cm^{-1} (C=N), 1285 (N=N). – ^1H NMR ($CDCl_3$): δ = 3.84, 3.82, 3.79, 3.63 (OCH_3), 2.03, 2.01 (CH_3). – $C_{58}H_{51}BrN_{10}O_4Os$ (1222.2): calcd. C 57.05, H 4.18, N 11.47; found C 57.50, H 4.16, N 11.94

Crystallographic Data: X-ray quality crystals (0.4 × 0.3 × 0.3 mm) of $[LH_2^+]Cl$ were obtained by slow diffusion of a dichloromethane solution of the compound into toluene. Cell parameters were obtained by least squares fits of 25 machine-centred reflections. Data were collected (1.67 ≤ 2θ ≤ 22.52°) on a Nicolet R3m/V diffractometer (295) with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). Two check-reflections measured after every 198 reflections showed no significant changes in intensity over 25 h. Data were corrected for Lorentz-polarisation effects. Of the 3948 reflections collected 3870 were unique (R_{int} = 0.0337) and 3867 reflections satisfying [$I > 2\sigma(I)$] were used for structure solution by direct methods and refined[9] by least-squares on F^2 using SHELXL93.The crystal data are collected in Table 3.

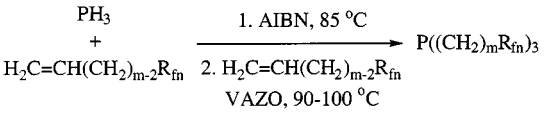
Syntheses and Carbonyliridium Complexes of Unsymmetrically Substituted Fluorous Trialkylphosphanes: Precision Tuning of Electronic Properties, Including Insulation of the Perfluoroalkyl Groups

Luke J. Alvey,[a] Ralf Meier,[a,b] Tibor Soós,[a,b] Paul Bernatis,[a] and John A. Gladysz*[a,b]



Keywords: Fluorine / Phosphanes / Donor−acceptor systems / Iridium / Carbonyl complexes

Reactions of iodides $I(CH_2)_mR_{f8}$ [m = 2–4; R_{f8} = $(CF_2)_7CF_3$] and $LiPH_2 \cdot DME$ (–45 °C, THF) give the primary phosphanes $PH_2(CH_2)_mR_{f8}$ (**7**–**9**; 48–76%). Radical-initiated reactions (100 °C) of **7** and $H_2C{=}CHCH_2R_{f8}$, **8** and $H_2C{=}CHR_{f8}$ or $H_2C{=}CHCH_2CH_2R_{f8}$, and **9** and $H_2C{=}CHCH_2R_{f8}$, give the title phosphanes $P[(CH_2)_mR_{f8}]_2[(CH_2)_{m'}R_{f8}]$ [m/m' = 2/3 (**10**), 3/2 (**11**), 3/4 (**12**), 4/3 (**13**); 70–76%]. The symmetrically substituted phosphane $P[(CH_2)_mR_{f8}]_3$ (m = 5, **6**) is similarly prepared from PH_3 and $H_2C{=}CHCH_2CH_2CH_2R_{f8}$, analogously to previously reported homologs [m = 2 (**2**), 3 (**4**), 4 (**5**)]. Reactions of **10**–**13** and **2**, **4**, **5**, and **6** with $[Ir(COD)Cl]_2$ and CO give *trans*-$Ir(CO)(Cl)(PR_2R')_2$ (70–83%). The IR ν_{CO} values show a monotonic decrease with increasing numbers of CH_2 groups. Phosphanes **13**, **5**, and **6** have the most CH_2 groups, and give ν_{CO} values 10, 7, and 4 cm^{-1} higher than the unfluorinated phosphane $P[(CH_2)_7CH_3]_3$. Hence, **6** provides nearly complete insulation of the iridium center from the electronegative perfluoroalkyl groups. Analogous rhodium derivatives of **4** and **5** are also described.

Introduction

The development of catalysts and reagents that have high affinities for "fluorous" phases has proceeded rapidly since Horváth described the concept and successful application of "fluorous biphase catalysis" in 1994.[1,2] This technique makes use of (1) the temperature-dependent miscibility of organic solvents with perfluorocarbons, perfluoroethers, or perfluoroamines,[3] and (2) "pony tails" of the formula $(CH_2)_m(CF_2)_{n-1}CF_3$ [abbreviated $(CH_2)_mR_{fn}$], which when added to catalysts and reagents in sufficient numbers, provide exceptional degrees of fluorous-phase immobilization. Reactions can be conducted in mixtures of organic and fluorous solvents under monophasic conditions at higher temperatures, and the products (which normally have much greater affinities for the organic solvent) separated from the fluorous catalyst or reagent under biphasic conditions at lower temperatures. The recovered catalyst can then be reused, or the transformed reagent can, in some manner, be recycled.

Most of the fluorous metal catalysts developed to date feature fluorous phosphanes.[1,4,5] This has in turn required syntheses of new phosphanes, as well as methodologies that are practical on larger scales. Earlier we reported convenient multigram syntheses of the symmetrically substituted fluorous trialkylphosphanes **1**−**5** listed in Scheme 1 by free-radical chain additions of PH_3 to the corresponding alkenes $H_2C{=}CH(CH_2)_{m-2}R_{fn}$.[6] The related phosphane **6** is new to this work and described further below. Note that **1**, **2**, and **3** define a series with progressively longer R_{fn} groups, and that **2**, **4**, **5**, and **6** define a series with progressively longer $(CH_2)_m$ segments between an R_{f8} group and the phosphorus atom.

Phosphane	$(CH_2)_mR_{fn}$	Partition coefficient $CF_3C_6F_{11}$/toluene (27 °C)
1	$(CH_2)_2R_{f6}$	98.8 : 1.2
2	$(CH_2)_2R_{f8}$	>99.7 : <0.3
3	$(CH_2)_2R_{f10}$	>99.7 : <0.3
4	$(CH_2)_3R_{f8}$	98.8 : 1.2
5	$(CH_2)_4R_{f8}$	98.9 : 1.1
6	$(CH_2)_5R_{f8}$	98.9 : 1.1

Scheme 1. Syntheses and partition coefficients of symmetrically substituted fluorous trialkylphosphanes **1**−**6**

The phosphanes **1**−**6** exhibit a number of interesting trends. For example, all fluorous-phase affinities − as measured by the partition coefficients in Scheme 1 − are high. However, they become higher as the R_{fn} group is lengthened in **1**−**3**. They also appear to decrease as the $(CH_2)_m$ segment is lengthened in **2**, **4**, **5**, and **6**. As would be intuitively expected, air oxidations become progressively faster in this

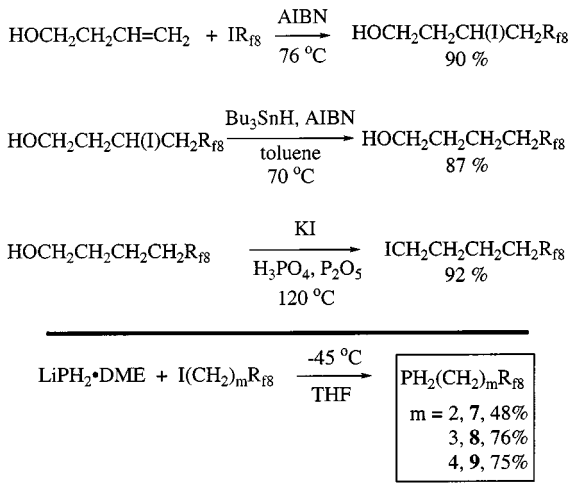
series. We sought to further fine tune these and other physical properties, and quantify the effect of the $(CH_2)_m$ segment length upon the phosphorus lone pair basicity.



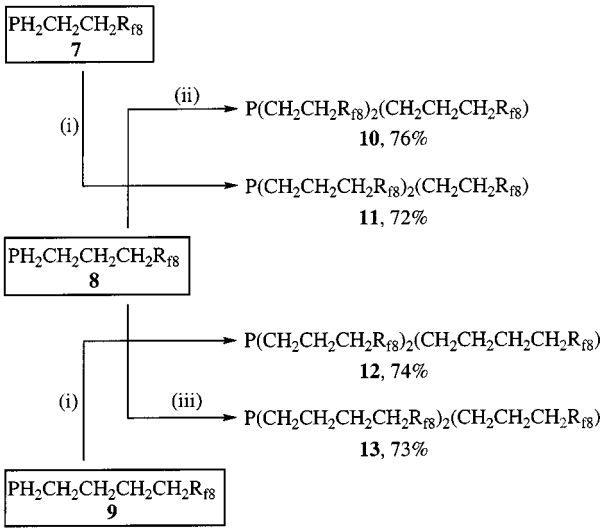
In this paper, we describe convenient syntheses of unsymmetrically substituted fluorous trialkylphosphanes of the formula $P[(CH_2)_mR_{f8}]_2[(CH_2)_{m'}R_{f8}]$. These feature mixtures of the types of pony tails in symmetrically substituted **2**, **4**, and **5**, and should thus have intermediate electronic characteristics. The unsymmetrical phosphanes are, together with **2**, **4**, **5**, and **6**, affixed to carbonylmetal fragments that provide IR assays of their donor/acceptor properties.[7] The most important results of this work are (1) a "toolkit" par excellence of nearly isosteric fluorous aliphatic phosphanes with precisely modulated electronic properties, and (2) the determination of the $(CH_2)_m$ segment lengths necessary to insulate the metal center from the electron-withdrawing R_{f8} groups.

Results

1. Phosphane Syntheses

We first sought convenient routes to the primary fluorous phosphanes $PH_2(CH_2)_mR_{f8}$ [m = 2 (**7**), 3 (**8**), 4 (**9**)]. These were anticipated to be versatile building blocks for many purposes, including free-radical additions to fluorous alkenes similar to those in Scheme 1. The strong nucleophile $LiPH_2 \cdot DME$ is easily prepared from PH_3 and *n*BuLi.[8] Hence, we set out to investigate alkylations, using the fluorous primary alkyl iodides $I(CH_2)_mR_{f8}$.

The iodide with two methylene groups, $I(CH_2)_2R_{f8}$, is commercially available. The next higher homolog, $I(CH_2)_3R_{f8}$, was prepared from the commercially available fluorous alcohol $HOCH_2CH_2CH_2R_{f8}$ and KI in an H_3PO_4/P_2O_5 slurry at 120 °C. A similar procedure has been communicated by another group.[9] The next higher homolog, $I(CH_2)_4R_{f8}$, has been reported only in patents.[10] It was synthesized on a 40-g scale in three steps as shown in Scheme 2 (top). First, the commercially available homoallylic alcohol $HOCH_2CH_2CH{=}CH_2$ and IR_{f8} were treated neat with a radical initiator to give $HOCH_2CH_2CH(I)CH_2R_{f8}$ in 90% yield after crystallization. Treatment with Bu_3SnH and a radical initiator gave the deiodinated alcohol $HOCH_2CH_2CH_2CH_2R_{f8}$ in 87% yield after crystallization. Related procedures for these two steps have been independently reported.[11] Subsequent reaction with KI in an H_3PO_4/P_2O_5 slurry at 120 °C gave analytically pure iodide in 92% yield after distillation.



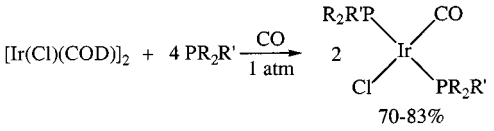
Scheme 2. Syntheses of building blocks for unsymmetrically substituted trialkylphosphanes

As depicted in Scheme 2 (bottom), $LiPH_2 \cdot DME$ and the fluorous iodides reacted in THF at −45 °C. Vacuum distillations gave the primary phosphanes **7** and **8** as clear liquids, and **9** as a low-melting white solid. The yield of **7** was slightly lower (49% vs. 75−76%), and some of the elimination product $H_2C{=}CHR_{f8}$ was detected in lower boiling fractions. A correct microanalysis was obtained for **9**, but not **7** and **8**. Accordingly, the ^1H NMR spectra of **7** and **8** (but not the ^{31}P NMR spectra) showed traces of impurities. The ^{31}P NMR spectra of **7**−**9** exhibited triplets diagnostic of two phosphorus-bound protons ($^1J_{PH}$ = 192−189 Hz; δ = −136.6 to −139.6, [D_8]THF), with much smaller longer-range couplings ($^2J_{PH}$ = 5−8 Hz) sometimes resolved. The ^1H NMR spectra showed PH_2 signals with the corresponding phosphorus coupling (dm, δ = 2.76−2.64, [D_8]THF).

The primary phosphanes **7**−**9** and slight excesses of the fluorous alkenes $H_2C{=}CH(CH_2)_{m-2}R_{f8}$ (m = 2−4;[6] 2.1−3.6 equiv.) reacted *neat* at 100 °C in the presence of a radical initiator (VAZO,[12] 5−6 mol-%). The combinations employed are illustrated in Scheme 3. The unsymmetrically substituted trialkylphosphanes $P[(CH_2)_mR_{f8}]_2[(CH_2)_{m'}R_{f8}]$ (**10**−**13**) were isolated as white powders in 76−72% yields (based upon **7**−**9**) after crystallization. They melted without decomposition between 49 and 69 °C, and were characterized by NMR spectroscopy and microanalysis, as described in the Experimental Section. The ^{31}P NMR signals of **10**−**13** (δ = −28.2, −31.3, −34.2, −33.6) were far downfield from those of **7**−**9**, as commonly seen for related tertiary and primary phosphanes. The $^1J_{CP}$, $^2J_{CP}$ and $^3J_{CP}$ values of **10**−**13** were of similar magnitude (17−15, 22−15 and 15−12 Hz), and always greater than those of **7**−**9** (e.g., $^1J_{CP}$ = 8−12 Hz). However, there were no obvious monotonic NMR-spectroscopic trends.

In the course of characterizing adducts of **12** and **13**, it became obvious that the inductive effect of the R_{f8} group was still being felt at the phosphorus atom. Hence, we sought the symmetrical phosphane with a five-methylene segment in every pony tail, $P[(CH_2)_5R_{f8}]_3$ (**6**). In order to apply the route in Scheme 1, the appropriate alkene was required. In previous work, we had shown that the iodides IR_{f8} and ICH_2R_{f8} were allylated by allyltri(*n*-butyl)stannane under free-radical chain conditions.[6] Thus, an analogous reaction was conducted with $I(CH_2)_2R_{f8}$, as shown in Equation (1). Workup gave the fluorous alkene $H_2C{=}CHCH_2CH_2CH_2R_{f8}$ in 52% yield after distillation (11-g scale). This compound has also been prepared by a related metal-catalyzed allylation.[13] Subsequent reaction with PH_3 (Scheme 1) gave **6** in 40% yield. Phosphane **6** was in general

Scheme 3. Syntheses of unsymmetrically substituted fluorous trialkylphosphanes **10**−**13** at 100 °C with VAZO (initiator) and i) $H_2C{=}CHCH_2R_{f8}$, ii) $H_2C{=}CHR_{f8}$, iii) $H_2C{=}CHCH_2CH_2R_{f8}$



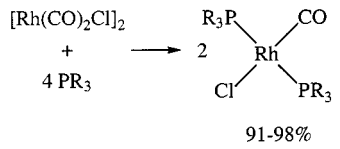
much less soluble than the lower homolog **5**. It dissolved in reasonable concentrations in the aromatic solvents toluene and $CF_3C_6H_5$, but was only sparingly soluble in perfluoro(methylcyclohexane), $CF_3C_6F_{11}$, the standard solvent for partition coefficients. Although **6** was always handled in a glove box, it would be expected to be more air-sensitive than **5**.[6]

$$\begin{matrix} Bu_3SnCH_2CH{=}CH_2 \\ + \\ ICH_2CH_2R_{f8} \end{matrix} \xrightarrow[\substack{CF_3C_6H_5 \\ \text{reflux}}]{\text{VAZO}} H_2C{=}CH(CH_2)_3R_{f8} \qquad (1)$$

2. Carbonylmetal Derivatives

We sought to probe the basicities of the preceding trialkylphosphanes. The IR ν_{CO} values of carbonylmetal complexes are sensitive measures of the donor/acceptor properties of the metal fragment and consequently the other ligands. As shown in Scheme 4, carbonyliridium compounds of the type *trans*-Ir(CO)(Cl)(PR_2R')$_2$ − analogs of Vaska's complex − are conveniently prepared by treating [Ir(COD)Cl]$_2$ with phosphanes and then carbon monoxide in appropriate stoichiometry.[14] We have previously synthesized such complexes of the R_{f6} phosphane **1** and tri-*n*-octylphosphane, $P[(CH_2)_7CH_3]_3$ (**14** and **23**, Scheme 4).[7] The latter phosphane contains the same number of carbon atoms as **1**, but no fluorine atoms. Hence, it is a good model for a fluorous trialkylphosphane where "complete insulation" of the phosphorus atom from the perfluoroalkyl groups has been achieved.

As summarized in Scheme 4, this procedure was repeated with the phosphanes **2** and **4**−**6** (Scheme 1), and **10**−**13** (Scheme 3). The corresponding iridium complexes **15**−**22** were isolated as analytically pure bright yellow powders in 70−83% yields. Adducts **15**−**21** were soluble in $CF_3C_6F_{11}$ and $CF_3C_6F_5$, but **22** was (like the free phosphane) only very slightly soluble in the former. All were sparingly soluble in THF, and insoluble in CH_2Cl_2. They were characterized by IR and ^{31}P NMR spectroscopy, as summarized in Scheme 4, as well as ^{1}H and/or ^{13}C NMR spectroscopy (Experimental Section). The IR measurements were made under identical conditions, at a resolution of ± 0.5 cm^{-1}. Analogous iridium complexes of some chiral, menthyl-substituted fluorous phosphanes are described elsewhere.[15]



Complex	R	R'	IR $\tilde{\nu}_{CO}$ (cm^{-1})[a]	^{31}P NMR (δ)[b]
14	$(CH_2)_2R_{f6}$		1973.6[c]	18.2
15	$(CH_2)_2R_{f8}$		1973.9	17.5[d]
16	$(CH_2)_2R_{f8}$	$(CH_2)_3R_{f8}$	1965.2	15.5
17	$(CH_2)_3R_{f8}$	$(CH_2)_2R_{f8}$	1962.3	14.8
18	$(CH_2)_3R_{f8}$		1956.7	14.1
19	$(CH_2)_3R_{f8}$	$(CH_2)_4R_{f8}$	1954.8	13.5

23	$(CH_2)_7CH_3$		1942.3	14.0[e]

Scheme 4. Syntheses and key data for iridium complexes: [a] In $CF_3C_6H_5$, 10 mg/mL, spectrometer resolution ±0.5 cm^{-1}; [b] in $CF_3C_6F_{11}$ (unlocked; see Experimental Section); [c] this value was determined in $CF_3C_6H_5$ as part of this work (see also ref.[7]); [d] measured with a different spectrometer than the other compounds; [e] in C_6D_6 (insoluble in $CF_3C_6F_{11}$)

Complexes **15**−**22** exhibited several monotonic trends. The ^{31}P NMR signals moved steadily upfield, except for **22** which was prepared and characterized in our new laboratories in Germany. There was also a progressive increase in air sensitivities in solution. Vaska-type complexes readily form η^2-O_2 adducts,[7] and the trend is consistent with increasing electron density on the iridium atom. As solids, several complexes oxidized more rapidly than the nonfluorinated species **23**, although the reverse order has been quantified in solution.[7] Finally, the IR ν_{CO} values steadily shifted to lower wavenumbers, nearly reaching that of nonfluorinated **23**. This important trend is also in agreement with increasing electron density on the iridium atom, but further analysis is deferred to the Discussion section.

A rhodium analog of the preceding complexes, *trans*-Rh(CO)(Cl)[P[$(CH_2)_2R_{f6}$]$_3$]$_2$ (**24**),[7,16] has been previously synthesized as shown in Scheme 5. Similar reactions of [Rh(CO)$_2$Cl]$_2$ with phosphanes **4** and **5** gave the higher homologs **25** and **26** as yellow prisms in 93−91% yields after recrystallization. The IR ν_{CO} values and ^{31}P NMR

chemical shifts of **24**−**26** showed trends parallel to the iridium complexes (Scheme 5). The crystal structure of **24** was determined earlier.[7,16] X-ray data were also collected with **25**, using a CCD detector. However, the crystals were soft, the quality of the data set was poor, and refinement was thwarted by too much disorder near the ends of the pony tails. Extensive attempts were made to obtain crystals of other complexes in this study suitable for X-ray diffraction. Unfortunately, all efforts were unsuccessful.

Discussion

The IR data for iridium complexes **14**−**23** in Scheme 4 and rhodium complexes **24**−**26** in Scheme 5 indicate a progressive increase in backbonding from the metal center to the carbonyl ligand. This in turn reflects the donor/acceptor properties of the phosphane ligands, and requires progressively increasing σ basicities, possibly augmented by very slightly diminishing π acidities. This conclusion is supported by collaborative photoelectron spectroscopy and calorimetric studies in progress,[17] as well as ongoing and earlier[1b] computational studies discussed below.

The IR data further show that the electronic properties of fluorous trialkylphosphanes can be precisely modulated by varying the lengths of the $(CH_2)_m$ segments. This can be done in concert, or by the new methodologies in Schemes 2 and 3, one pony tail at a time. Since the lengths of the $(CH_2)_m$ segments in a given phosphane do not differ by more than one (m/m' values), analyses can be cast in terms of the total number of methylene groups per phosphane − a quantity that varies from six (**1**, **2**) to fifteen (**6**). Complexes **14** and **15** also provide analytical reference points. Their nearly identical ν_{CO} values establish that the length of the perfluoroalkyl group can be neglected when it is six carbon atoms or longer.

Complexes **15**, **18**, **21**, and **22** feature symmetrically substituted phosphanes with six, nine, twelve, and fifteen methylene groups, respectively. The successive $\Delta\nu_{CO}$ increments (17.2, 7.5, 3.1 cm^{-1}) provide one basis for extrapolating to phosphanes with longer $(CH_2)_m$ segments. These represent 44−41% (7.5/17.2, 3.1/7.5) "transmission levels" per each increment of three methylene groups. As illustrated in Figure 1, this suggests ν_{CO} values of 1944.8, 1944.2, and 1943.9 cm^{-1} for the next three higher phosphanes $P[(CH_2)_mR_{f8}]_3$ (m = 6, 7, 8), and a limit of 1943.7 cm^{-1} for an infinite number of methylene groups. This is only slightly above the value for the nonfluorinated complex, **23** (1942.3 cm^{-1}). Thus, the phosphane **6** can be said to provide "nearly complete" insulation of the perfluoroalkyl groups from the iridium atom, the locus of the observed parameter. However, very slight improvements can be anticipated with additional methylene groups.

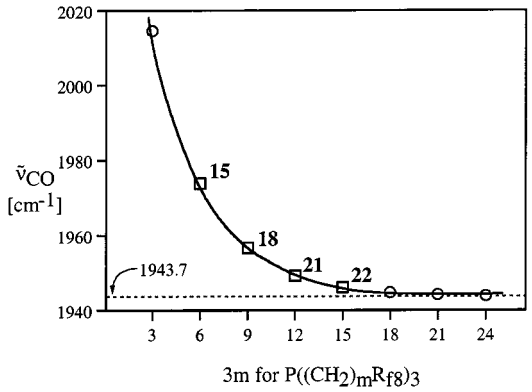

Figure 1. Relationship between IR ν_{CO} values of **15**, **18**, **21**, and **22**, and the total number of methylene groups in each phosphane ligand (□), and extrapolated values for homologous complexes (O)

Complexes **15**−**21** feature phosphanes in which the number of methylene groups increase from six to twelve. Here, the IR data illustrate the fine modulation of electronic properties. The largest $\Delta\nu_{CO}$ increments are 8.7 cm^{-1} (**15** vs. **16**) and 5.6 cm^{-1} (**17** vs. **18**). The others are in the range of 3.0−1.6 cm^{-1}. Although further arithmetic relationships can be noted, a particularly informative overview of all IR data is provided by Figure 2. In principle, any observable quantity that is a function of the number of repeat units x can be plotted versus $1/x$. Extrapolation to the y intercept ($1/x$ = 0) predicts a value for an infinite number of repeat units. The plot in Figure 2 is linear ($r^2 > 0.99$), and suggests a limit distinctly lower than that of the nonfluorinated complex **23**. However, we presently have greater confidence in the limiting value calculated from Figure 1.

There is the reciprocal question of the opposite limit − the ν_{CO} value of an analogous iridium complex of a tris(-perfluoroalkyl)phosphane, $P(R_{fn})_3$. We are not aware of any such compounds in the literature. However, tris(pentafluorophenyl)phosphane, $P(C_6F_5)_3$, gives a value of 1994 cm^{-1}.[18] Extrapolation of Figure 1, as described above, gives 2014.5 and 2109.7 cm^{-1} for the iridium complexes of $P(CH_2R_{f8})_3$ and $P(R_{f8})_3$. The former is in reasonable agreement with that expected from an extrapolation of Figure 2 [2019.2 cm^{-1}; $1/(2m + m')$ = 0.333], but such plots are not reliable for lower numbers of repeat units.

Returning to the most highly insulated complex **22**, note that the inductive effect of the perfluoroalkyl groups is transmitted through seven atoms − five methylene carbon atoms, a phosphorus, and an iridium atom. To be fair, three

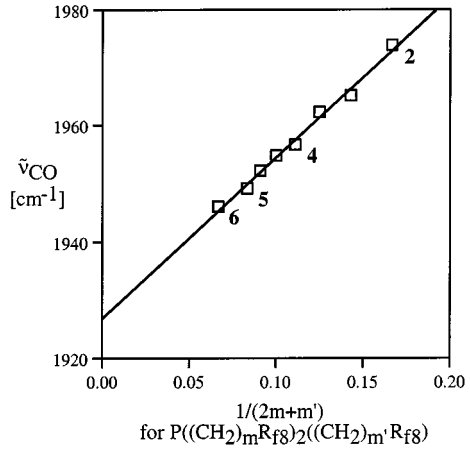

Figure 2. Relationship between IR ν_{CO} values of **15**−**22**, and the reciprocal of the total number of methylene groups in each phosphane ligand; selected ligands are designated by numbers for reference

pony tails converge at each phosphorus atom, and two phosphane ligands at the iridium atom. Normalization makes the data less dramatic. Nonetheless, to the best of our knowledge this represents the longest transmission of the inductive effect of a perfluoroalkyl group through a sequence of sp^3 atoms experimentally documented to date. Earlier, the pK_a values of amino acids $HO_2CCH(NH_2)(CH_2)_mCH_3$ and the ω-trifluoromethyl analogs $HO_2CCH(NH_2)(CH_2)_mCF_3$ were compared.[19] A measurable influence persisted through four sp^3 carbon atoms ($m = 3$).

We expect that the effect of the perfluoroalkyl groups in **1**−**6** and **10**−**13** will be more strongly felt when the locus of the observed parameter is the phosphorus atom (e.g., oxidation or ionization potential), and further studies are in progress.[17] We have characterized related fluorous trialkylamines $N[(CH_2)_mR_{f8}]_3$, and find a detectable influence upon basicities with five methylene groups.[20] At present, we have no evidence for "non-classical" transmission mechanisms (e.g., non-through-bond or non-field). However, in view of the tendency of fluorous groups to segregate − both intra- and intermolecularly − the possibility of a minor contribution remains an open question.

A computational study of the model fluorous trialkylphosphanes $P[(CH_2)_mCF_2CF_3]_3$ has been reported.[1b] The methylene chain lengths m were varied from zero to five. Both the phosphorus lone pair energies and the protonation energies reached asymptotic limits at five methylene groups (−9.2, −8.9 eV). However, they remained lower than those of the nonfluorinated reference compound $P[(CH_2)_3CH_3]_3$ (−8.7, −9.3 eV). Calorimetric data suggest that phosphane **1** is electronically similar to PMe_2Ph.[21] The latter gives an iridium complex with an IR ν_{CO} value of 1960 cm^{-1} (Nujol),[22] somewhat closer to those of phosphanes **4** and **11** (complexes **18**, **17**). However, in view of the different steric properties and measurement conditions, we regard this as a good agreement.

Phosphanes of the types **1**−**6** and **10**−**13** are very effective at immobilizing metal catalysts. For example, the tris(-phosphane)rhodium complexes $Rh(Cl)[P[(CH_2)_2R_{fn}]_3]$ give partition coefficients of 693:1 to 811:1 ($n = 6, 8$), and exhibit very low leaching levels when used for alkene hydroboration (e.g., 4.5−2.2 ppm rhodium/mol product).[4b] Related rhodium hydroformylation catalysts behave similarly.[1b] The bis(phosphane) iridium complexes **15**−**23** should have somewhat lower partition coefficients, but still at useful levels (**14**: ca. 333:1 or 99.7:0.3 by NMR spectroscopy).[7] Importantly, phosphanemetal catalysts are commonly optimized by extensive variation of the ligand. Thus, **1**−**6** and **10**−**13** provide an exceptional "tool kit" for the precise electronic tuning of tri-*n*-alkylphosphane based catalysts, irrespective of any recovery objective.

One of several obvious future directions for fluorous phosphane synthesis would involve extensions to secondary or tertiary alkyl-substituted systems. Bulky phosphorus substituents are a key design element in many catalysts of current interest,[23] and these would sterically complement the phosphanes described above. With regard to this objective and others, the primary phosphanes **7**−**9** constitute very attractive building blocks. Although the precursor $LiPH_2$ must be prepared from PH_3, one atmosphere is sufficient − in contrast to the autoclave conditions required for the symmetrical trialkylphosphanes **1**−**6** in Scheme 1.

In summary, this study has provided a series of nearly isosteric fluorous trialkylphosphanes with finely modulated electronic properties. The inductive effects of the perfluoroalkyl groups are almost completely insulated from the phosphorus atom in **6**, which features five methylene groups per pony tail. Future reports will describe additional characterization of the electronic properties of these ligands,[17] as well as related fluorous amines,[20] new types of fluorous phosphanes, and their applications in catalysis.

Experimental Section

General: All reactions and workups involving phosphanes were conducted under inert gases. Commercial chemicals were treated as follows: $CF_3C_6F_{11}$, $CF_3C_6H_5$, distilled from P_2O_5; THF, hexane, heptane, distilled from Na/benzophenone; CH_2Cl_2, distilled from CaH_2; C_6D_6, $CDCl_3$, [D$_8$]THF (Cambridge Isotope), IR_{f8}, $ICH_2CH_2R_{f8}$, $HOCH_2CH_2CH_2R_{f8}$, $H_2C{=}CHR_{f8}$ (Oakwood), $HOCH_2CH_2CH{=}CH_2$, $Bu_3SnCH_2CH{=}CH_2$, Bu_3SnH, AIBN, VAZO (Aldrich), $[Ir(COD)Cl]_2$, $[Rh(CO)_2Cl]_2$ (Strem), used as received; silica gel (Merck, grade 9385, 230−400 mesh), dried at 180 °C and $3{\cdot}10^{-3}$ Torr (24 h). − IR spectra were recorded with a Mattson Polaris spectrometer (0.5 cm^{-1} resolution). − NMR spectra were recorded with Varian or Jeol FT spectrometers at ambient probe temperature and referenced as follows: ^{1}H (300 MHz), external/residual C_6D_5H (δ = 7.16; external C_6D_6 lock for spectra in $CF_3C_6F_{11}$), residual [D$_7$]THF (δ = 3.58), residual [D$_5$]acetone (δ = 2.04), or residual $CHCl_3$ (δ = 7.27); ^{13}C (126 MHz), external C_6D_6 (δ = 128.39; lock for spectra in $CF_3C_6F_{11}$), internal [D$_8$]THF (δ = 67.57), or internal $CDCl_3$ (δ = 77.23); ^{31}P (121 MHz), external 85% H_3PO_4 (δ = 0.00); ^{19}F (282 MHz), external $CFCl_3$ (δ = 0.00). − Elemental analyses were conducted with a Carlo Erba EA1110 instrument (in-house, Erlangen), or by Atlantic Microlab (Norcross, Georgia).

$HOCH_2CH_2CH(I)CH_2R_{f8}$:[11a] A flask was charged with IR_{f8} (52.864 g, 96.826 mmol) and $HOCH_2CH_2CH{=}CH_2$ (8.456 g, 117.3 mmol). The solution was degassed (3 × freeze-pump-thaw) and AIBN (0.791 g, 4.82 mmol, 5 mol-%) was added. The mixture was heated at 76 °C. After 2 h, more AIBN (0.841 g, 5.12 mmol, 5 mol-%) was added. After 3 h, the solid mass was extracted with hot hexane (800 mL) and poured through filter paper. The filtrate was allowed to cool, and the resulting white crystals were collected on a frit. The filtrate was concentrated (100 mL), refluxed, and again cooled. A second crop of crystals was similarly collected. The filtrate was concentrated (20 mL), and a third crop similarly obtained. The crops were combined and dried by oil pump vacuum to give $HOCH_2CH_2CH(I)CH_2(CF_2)_7CF_3$ (53.578 g, 86.685 mmol, 90%), m.p. 82−83 °C (ref.[11a] 83 °C). − ^{1}H NMR ($CDCl_3$): δ = 4.56−4.47 (m, 1 H, C*H*I), 3.91−3.73 (m, 2 H), 3.07−2.75 (m, 2 H), 2.10−1.94 (m, 2 H), 1.46 (br s, 1 H, *H*O). − ^{19}F NMR ($CDCl_3$): δ = −81.3 (t, $^3J_{FF}$ = 9.2 Hz, 3 F, C*F*$_3$), −111.8 (dm, $^2J_{FF}$ = 272 Hz, 1 F), −114.6 (dm, $^2J_{FF}$ = 272 Hz, 1 F), −122.1 (m, 2 F), −123.2 (m, 4 F), −124.1 (m, 2 F), −126.6 (m, 2 F), −122.4 (m, 2 F). − MS (EI); *m*/*z* (%): 618 (3) [M^+], 491 (100) [M^+ − I], 473 (32) [M^+ − I, − H_2O], 441 (32), 395 (5), 219 (1) [$CF_3(CF_2)_3^+$], 169 (4) [$CF_3(CF_2)_2^+$], 119 (6) [$CF_3CF_2^+$], 69 (1) [CF_3^+]. − $C_{12}H_8F_{17}OI$ (618.06): calcd. C 23.32, H 1.30; found C 23.95, H 1.38.

$HOCH_2CH_2CH_2CH_2R_{f8}$:[11] A flask was charged with $HOCH_2CH_2$-$CH(I)CH_2R_{f8}$ (52.495 g, 84.933 mmol), Bu_3SnH (49.968 g, 171.68 mmol), AIBN (1.426 g, 8.684 mmol, 10 mol-%) and toluene (200 mL). The solution was stirred at 70 °C. After 4 h, the solvent was removed by rotary evaporation. The residue was dissolved in hexane (50 mL) and cooled to −20 °C. The resulting white crystals were collected on a frit. The filtrate was concentrated (10 mL) and cooled to −20 °C. A second crop of crystals was similarly collected. The crops were combined and dried by oil pump vacuum to give $HOCH_2CH_2CH_2CH_2R_{f8}$ (36.200 g, 73.551 mmol, 87%). − ^{1}H NMR ($CDCl_3$):[11] δ = 3.68 (t, $^3J_{HH}$ = 6.0 Hz, 2 H, HOC*H*$_2$), 2.19−2.01 (m, 2 H, C*H*$_2$CF$_2$), 1.75−1.61 (m, 4 H, C*H*$_2$C*H*$_2$CH$_2$CF$_2$), 1.36 (br s, 1 H, *H*O). − ^{19}F NMR ($CDCl_3$): δ = −81.3 (t, $^3J_{FF}$ = 9.2 Hz, 3 F, CF_3), −115.0 (m, 2 F), −122.2 (m, 2 F), −123.2 (m, 4 F), −124.0 (m, 2 F), −126.6 (m, 2 F), −122.4 (m, 2 F).

$ICH_2CH_2CH_2CH_2R_{f8}$:[10] A flask was charged with P_2O_5 (64.284 g, 452.88 mmol), H_3PO_4 (85%, 125 mL, 2.17 mol), KI (31.346 g, 188.83 mmol), and $HOCH_2CH_2CH_2CH_2R_{f8}$ (35.128 g, 71.372 mmol), and fitted with a condenser. The mixture was stirred at 120 °C for 4 h, allowed to cool, and diluted with water (100 mL). The solution was extracted with ether (3 × 100 mL). The combined ether extracts were washed with aqueous $Na_2S_2O_3$ (100 mL, 0.1 M) and dried ($MgSO_4$). The solvent was removed by rotary evaporation and the residue distilled (100−110 °C ca. $1{\cdot}10^{-3}$ Torr) to give $ICH_2CH_2CH_2CH_2R_{f8}$ as a white solid (39.575 g, 65.731 mmol, 92%), m.p. 50−51 °C. − ^{1}H NMR ($CDCl_3$): δ = 3.21 (t, $^3J_{HH}$ = 7 Hz, 2 H, IC*H*$_2$), 2.21−2.00 (m, 2 H), 1.99−1.87 (m, 2 H), 1.82−1.70 (m, 2 H). − ^{13}C{^{1}H} NMR ($CDCl_3$, partial): δ = 32.8 [s ($^1J_{CH}$ = 126 Hz),[25] one of *C*H$_2$*C*H$_2$CH$_2$CF$_2$], 30.1 [t, $^2J_{CF}$ = 22 Hz ($^1J_{CH}$ = 129 Hz),[25] *C*H$_2$CF$_2$], 21.6 [s ($^1J_{CH}$ = 129 Hz),[25] one of *C*H$_2$*C*H$_2$CH$_2$CF$_2$], 5.1 [s ($^1J_{CH}$ = 149 Hz),[25] I*C*H$_2$]. − ^{19}F NMR (δ, $CDCl_3$) −81.3 (t, $^3J_{FF}$ = 10 Hz, 3 F, C*F*$_3$), −114.8 (m, 2 F), −122.1 (m, 2 F), −122.3 (m, 4 F), −123.2 (m, 2 F), −123.9 (m, 2 F), −126.6 (m, 2 F). − MS (EI); *m*/*z* (%): 602 (10) [M^+], 475 (100) [M^+ − I], 455 (38) [M^+ − I, − HF]. − $C_{12}H_8F_{17}I$ (602.6): calcd. The Ligand 1,10-Phenanthroline-2,9-dicarbaldehyde Dioxime can Act Both as a Tridentate and as a Tetradentate Ligand − Synthesis, Characterization and Crystal Structures of its Transition Metal Complexes

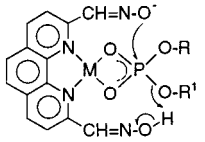
Ariane Angeloff,[a] Jean-Claude Daran,*[a] Jean Bernadou,*[a] and Bernard Meunier[a]



Keywords: Phenanthrolinedicarbaldehyde dioxime / N ligands / Cadmium / Cobalt / Zinc / Copper / Nickel

The polydentate ligand **L** has been prepared by treating 1,10-phenanthroline-2,9-dicarbaldehyde with hydroxylamine. This ligand and its complexes with Zn^{II}, Cu^{II}, Cd^{II}, Co^{II} and Ni^{II} were designed as potential agents for nucleic acid hydrolysis and have been characterized by elemental analysis, NMR spectroscopy, ES-MS and X-ray diffraction analysis. The ligand acts as a tridentate ligand in most cases, to form monomeric trigonal-bipyramidal, square-pyramidal or square-bipyramidal structures. In the case of metallation with cadmium nitrate it acts as a tetradentate ligand to give a pentagonal-bipyramidal structure. Dissociation of the oxime group to an oximate, which acts as an anionic bridging ligand, was observed in the case of metallation with zinc acetate thus giving rise to dimers and/or polymers.

Introduction

The metal-chelating properties of the 1,10-phenanthroline ligand and its derivatives have been utilized in a range of analytical reagents, as well as for the development of bioorganic probes.[1] In attempts to obtain hydrolytic chemical agents which are able to hydrolyze phosphodiester bonds in nucleic acids in the model of DNA or RNA nucleases,[2] we report here on the synthesis and the characterization of zinc, cadmium, copper, cobalt and nickel complexes of 1,10-phenanthroline-2,9-carbaldehyde dioxime. These complexes (metal cation) were designed to interact with the initial negatively charged phosphate, and to promote hydrolysis of the phosphodiester P−O bond through nucleophilic attack on the phosphorus atom by one oximate group, the other oxime group stabilizing the leaving oxygen atom (see hereafter for a possible schematic representation of the ternary system ligand/metal/phosphodiester: Scheme 1).[3−5] The oximate group has been chosen because it can effectively act as a nucleophile endowed with nucleolytic activity, as previously reported for free ligands such as pyridine-2-aldoxime[6] or simple inorganic complexes such as metallated complexes of 2-acetylpyridine oxime.[7] Although preliminary results on cleavage of nucleic acids models are rather deceiving, the interest for such structures lies also in the previously reported antitumor[8] and antimicrobial[9] activities of the phenanthrolinedicarbaldehyde derivative and/or of the corresponding dioxime ligand **L**. In the latter case, the activity might be related to the in vivo formation of metal chelates. In a related topic, the cytotoxic activity of tetradentate palladium complexes of phenanthroline-dimathanamines has been recently reported.[10]

The improved synthesis of the ligand 1,10-phenanthroline-2,9-dicarbaldehyde dioxime **L**, and the preparation and complete characterization of seven complexes of **L** are presented.

Synthesis and Characterization

The Ligand

The only reported method for the synthesis of 1,10-phenanthroline-2,9-dicarbaldehyde (Figure 1) involves the oxidation of the commercially available neocuproine by selenium dioxide in dioxane[11,12] or ethanol.[9] After completion of the reaction, the selenium separates as a yellow/red form which is difficult to filter, and some of it is retained in solution as a colloid. The elimination of selenium impurities is extremely difficult. This explains the fact that in the literature either the yield of the reaction is satisfactory (70%) but the product is analytically impure,[11] or the yields are not reported.[9,12] In addition, from an environmental viewpoint the replacement of SeO_2 by another oxidant is desir-

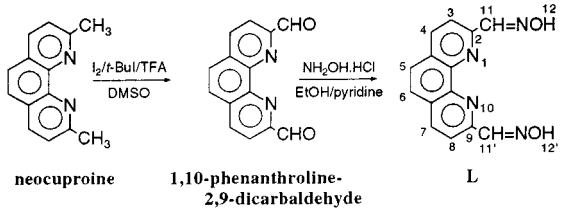

Figure 1. Synthesis of ligand **L**

able. Therefore, in order to prepare 1,10-phenanthroline-2,9-dicarbaldehyde, we used the procedure initially described for the oxidation of methyl to formyl groups in heteroaromatic derivatives with iodine in dimethyl sulfoxide,[13] a method which was improved later by using *tert*-butyl iodide.[14] This procedure, applied to neocuproine, gave pure 1,10-phenanthroline-2,9-dicrbaldehyde in 48% yield as a hemihydrate in crystalline form. This dialdehyde derivative was then converted into the dioxime **L** according to the method previously reported.[11] Compound **L** has been fully characterized, including a crystallographic study which allowed for the determination of the *E* configuration of the two oxime groups, and for the observation of the co-existence of two different conformations (*s-cis* and *s-trans*) around the $C_{Ar}-C(=N-)$ single bond between the oxime group and the phenanthroline unit in the crystal (see below). In solution, these two conformations are probably in fast equilibrium since the NMR spectrum for **L** in DMSO corresponds to a symmetrical molecule.

Metal Complexes (Figure 2)

The formation of nearly all complexes, besides one, was achieved at room temp. under approximately stoichiometric conditions (metal ion/ligand molar ratio was in the range 0.64 to 1.3), after 2−30 min of reaction in DMF ([Zn**L**Cl_2 and [Cu**L**Cl_2)], DMSO ([Zn**L**$(AcO)]_n$] or DMSO/H_2O ([Cd**L**Cl_2], [Co**L**Cl_2] and [Ni**L**(DMSO)Cl_2]). In all these cases, the reaction products were isolated as analytically pure species on spontaneous precipitation. Compound [Cd**L**(OH_2)(DMSO)$(NO_3)]^+$] was only prepared as crystals for X-ray diffraction analysis (see below). On the basis of elemental analyses, all complexes (whatever was the method of preparation), exhibited an unequivocal metal-to-ligand stoichiometry of 1:1. In some cases, one or two molecules of solvent were present (DMF, DMSO or water). Moreover, the CHN data showed that all complexes present existed as monomers, except [Zn**L**$(AcO)]_n$ which existed as dimer/polymer. The polymeric structure of this last compound was also confirmed by the NMR-spectroscopic data with

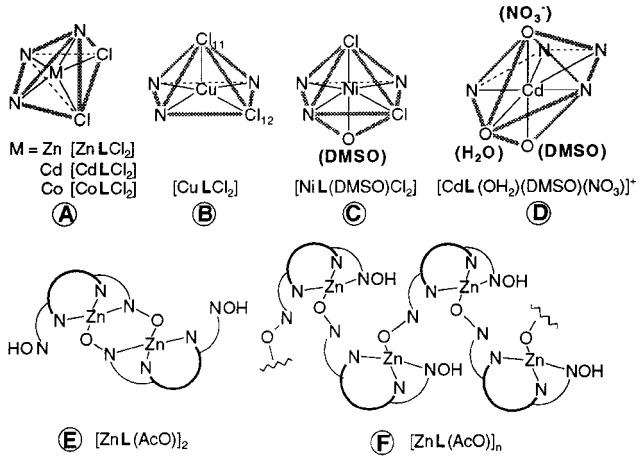

Figure 2. Proposed structures for complexes M−**L** (in structure **D**, one nitrate ion is outside the coordination sphere; in structure **E**/**F**, at least one acetate ion per metallated ligand is outside the coordination sphere)

the methyl resonance peak integrating for only one methyl group per metal unit and the other ligand in this case being an oximate bridging anion.

Data obtained by positive FAB-MS indicated that monocationic species corresponding to the complex having lost one proton $[\mathbf{L} + M - H^+]^+$ or retained one of the two anionic labile ligands $[\mathbf{L} + M + Cl^-]^+$, with an additional solvent molecule (water, DMSO), are usually observed. In addition, the redox-active copper complex gave some peaks corresponding to Cu^I monomeric $[\mathbf{L} + Cu^I]^+$ or dimeric species (dimer 2:1 $[2 \times \mathbf{L} + Cu^I]^+$). In ES-MS, only monocationic species were observed. They predominantly corresponded to the complex ligand/metal having lost one proton ($\mathbf{L} + M - H^+$) or retained one of the two anionic ligands ($\mathbf{L} + M + Cl^-$ or AcO^-). The presence of one or two solvent molecules could be observed, as well as in some cases, dehydration of the fragment (the aldoxime group giving possibly a nitrile function). In addition, we observed minor peaks, probably generated in the MS machine, corresponding to dimeric species of the type 2:1 (cases of $2 \times \mathbf{L} + Zn - H^+$, $2 \times \mathbf{L} + Cu^I$, $2 \times \mathbf{L} + Co^{III} - 2\,H^+$ and $2 \times \mathbf{L} + Ni^{II} - H^+$) or of the type 2:2 (cases of $2 \times \mathbf{L} + 2 \times Zn - 3\,H^+$, $2 \times \mathbf{L} + 2 \times Zn - 2\,H^+ + Cl^-$, $2 \times \mathbf{L} + 2 \times Zn - H^+ + 2\,Cl^-$, $2 \times \mathbf{L} + 2 \times Zn - 3\,H^+$, $2 \times \mathbf{L} + 2 \times Cu - 3\,H^+$ or $2 \times \mathbf{L} + 2 \times Cu - 2\,H^+ + Cl^-$, $2 \times \mathbf{L} + 2 \times Cd - H^+ + 2\,Cl^-$). The polymeric compound [Zn**L**$(AcO)]_n$ not only gave peaks for the monomeric species $\mathbf{L} + Zn - H^+$ (with addition or loss of one water molecule) but also for dimers of the type 2:2 ($2 \times \mathbf{L} + 2 \times Zn - 3\,H^+$ or $2 \times \mathbf{L} + 2 \times Zn - 2\,H^+ + AcO^-$) or trimers of the type 3:3 ($3 \times \mathbf{L} + 3 \times Zn - 5\,H^+$), these latter polymeric fragments being the most abundant.

On complexation of cadmium chloride with ligand **L** (giving [Cd**L**Cl_2]), we observed changes in the ^1H NMR spectrum with a broadening of the peaks corresponding to 4-H/7-H and 11-H/11′-H (pattern at $\delta = 8.92$), and to 12-H/12′-H (massif at $\delta = 12.73$). The other signals remained sharp and well resolved. Increasing the temperature up to 60° C allowed for the resolution of the broad signal at $\delta = 8.92$ into one doublet at $\delta = 8.90$ (4-H/7-H) and one singlet at $\delta = 8.89$ (11-H/11′-H) and for the significant reduction of the width of the 12-H/12′-H signal. A similar behaviour was observed for complex [Cd**L**(OH_2)(DMSO)$(NO_3)]^+$. Although the crystalline structures of [Cd**L**Cl_2] and [Cd**L**(OH_2)(DMSO)$(NO_3)]^+$ are different (see below), these NMR-spectroscopic data support a common symmetrical structure in solution, with the ligand acting as a tetradentate ligand. With regard to the two zinc derivatives [Zn**L**Cl_2] and [Zn**L**$(AcO)]_n$, the ^1H NMR spectra were too complex and did not give any structural information, except for [Zn**L**$(AcO)]_n$ where the aromatic/aliphatic proton ratio supports a structure with only one acetate group per molecule.

Description of the Crystal Structures of L, [ZnLCl_2], [CuLCl_2], [CdLCl_2], [CdL(OH_2)(DMSO)$(NO_3)]^+$, [CoLCl_2] and [NiL(DMSO)Cl_2]

The molecular structure of **L**, as determined by X-ray analysis, is shown with its atom labelling scheme in Fig-

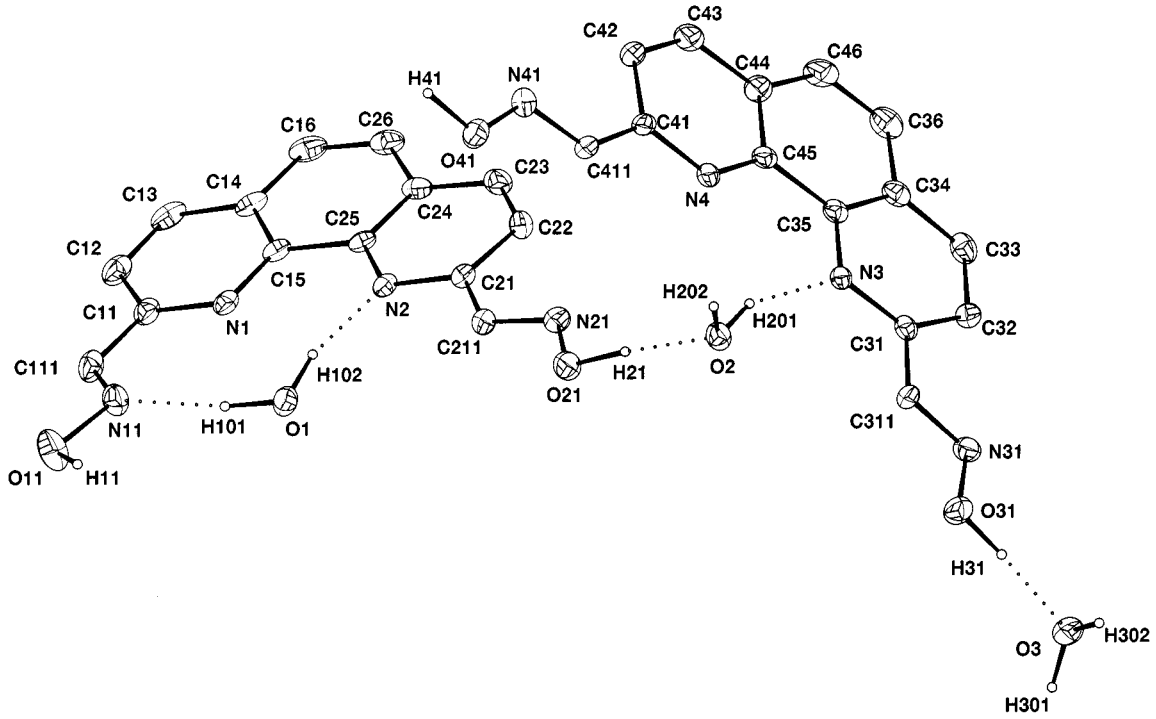

Figure 3. Molecular structure of **L** with atom labelling scheme illustrating the hydrogen bond between the two independent molecules (**La** and **Lb**) within the asymmetric unit; ellipsoids represent 30% probability; most of the hydrogen atoms have been omitted for clarity

ure 3. The asymmetric unit is composed of two independent molecules of the ligand and three water molecules. The two

molecules **La** and **Lb** (Table 1) are linked by hydrogen bonds through one of the water molecule (O2). Moreover, each of these water molecules is engaged in hydrogen bonding with symmetrically related molecules **La** and **Lb**, thus developing a three-dimensional hydrogen bond network (Table 2). The two molecules **La** and **Lb** have an essentially planar conformation with the largest deviation from the plane being 0.168(5)Å at O(11) for molecule **La** and −0.083(5) Å at O(41) for **Lb**. The largest deviation is observed for molecule **La** where there are hydrogen-bond interactions with the water molecule (O1) (Figure 3). The C−N and C−C distances in the phenanthroline fragment (Table 1) are within the range observed in related molecules.[15] In both molecules **La** and **Lb**, the oxime groups have an *E* configuration. However, if in molecule **Lb** the conformation of both oxime groups is *s-trans* with respect to the N atoms of the phenanthroline fragment, then in molecule **La** these two groups show two different conformations, *s-cis* and *s-trans*, around the C_{Ar}−C(=N) single bond. This difference in conformation is related to the occurrence of hydrogen bonds between the water molecule (O1) and the two N atoms, the N(11) of the oxime group and the N(2) of the phenanthroline fragment in molecule **La** (Table 2).

The crystallization of metal complexes, besides [Cd**L**Cl_2] (which was obtained by transmetallation of [Zn**L**Cl_2] in the presence of cadmium nitrate) and [Zn**L**(AcO)]$_n$ (unsuccessful crystallization attempts), was achieved at room temp. under approximately stoichiometric conditions (the metal/ligand ratio ranged from 1.3 to 1.9), after 2−7 days in DMSO or DMSO/H_2O. Since the three complexes [Zn**L**Cl_2], [Cd**L**Cl_2] and [Co**L**Cl_2] have closely related structures, only the molecular view of the cobalt complex [Co**L**Cl_2] with its atom labelling scheme is shown in Figure 4. The asymmetric unit also contains a DMSO solvent molecule which is hydrogen-bonded to the OH group of the

[a] Symmetry transformations used to generate equivalent atoms: $-x-1, -y+2, -z+2$. − [b] $x+1, y, z$. − [c] $-x, -y+1, -z+2$. − [d] $-x-1, -y+1, -z+2$.

With regard to the complex [Cu**L**Cl_2 (Table 4), the asymmetric unit is composed of two molecules **a** and **b** of the complex and four DMSO solvent molecules which are each hydrogen-bonded to the OH groups. Although the metal atom is surrounded by the same ligands as in the previous complexes, the geometry around the metal center is best described as being a distorted square-pyramidal structure (Figure 2B and 5, Table 4); the N(1)−Cu(1)−Cl(12) angle increases to the mean value 151.8° (the corresponding N(1)−M−Cl(1) angles range from 121.2 to 127.7° for [Zn**L**Cl_2], [Cd**L**Cl_2] and [Co**L**Cl_2]), whereas the N(1)−Cu−Cl11) angle decreases to the mean value 99.7° (the corresponding angles range from 113.7 to 118.7° for [Zn**L**Cl_2], [Cd**L**Cl_2] and [Co**L**Cl_2]. Thus, in [Cu**L**Cl_2], the nitrogen atoms N(1), N(2), N(11) and the chrorine atom

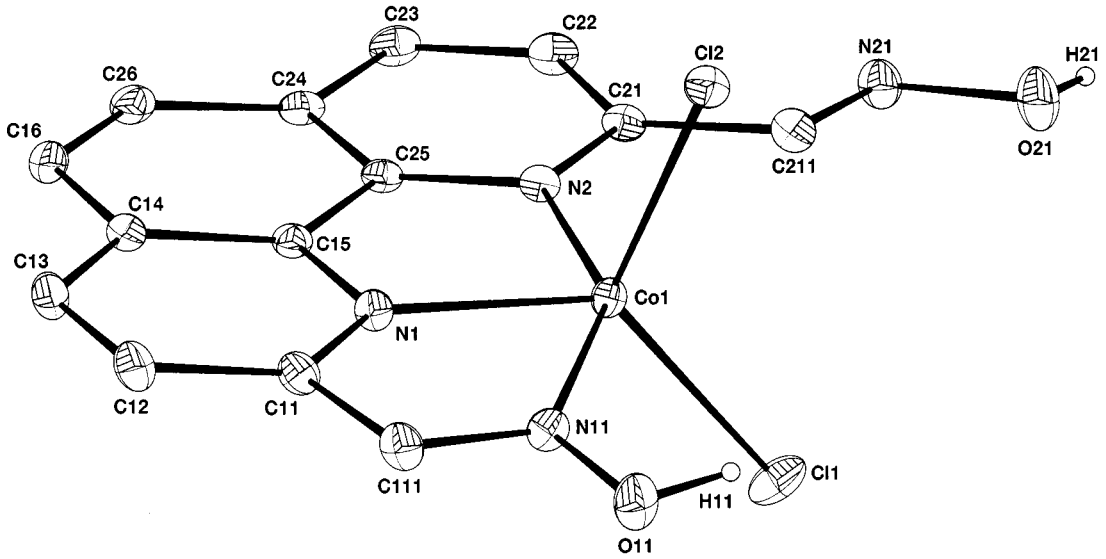

Figure 4. Molecular view of complex [Co**L**Cl_2 with atom labelling scheme; ellipsoids are drawn at 30% probability; hydrogen atoms have been omitted for clarity

coordinated oxime group. Such hydrogen bonding between the DMSO solvent and the complex occurs in all the related compounds. In these three complexes, the structure consists of a metal atom surrounded by one ligand **L** and two chlorine atoms in a distorted trigonal-bipyramidal geometry (Figure 2, **A** and Table 3). The axial positions are occupied by two nitrogen atoms N(2) and N(11) [N(2)−M−N(11) = 148.28(9)°, 138.03(15)° and 151.09(6)°, for the Zn, Cd and Co complexes, respectively]. The equatorial plane is made by the two chlorine atoms and the nitrogen atom N(1) of the phenanthroline fragment. The equatorial plane and the plane defined by the axial positions make a dihedral angle of 88.62(4)°. In the three complexes the metal center is coordinated to N(1), N(2) of the rigid 1,10-phenanthroline and to N(11) of the oxime group forming two fused five-membered rings with very acute N−M−N angles: N(1)−M−N(2) = 76.22(9)°, 69.58(15)° and 77.27(6)° and N(1)−M−N(11) = 72.07(9)°, 68.48(16)° and 73.94(6)°, for compounds [Zn**L**Cl_2], [Cd**L**Cl_2] and [Co**L**Cl_2], respectively.

Cl(12) form the basal plane, whereas Cl(11) occupies the apex position (Figure 2B). Applied to the five-coordinated structures [Cu**L**Cl_2), [Zn**L**Cl_2], [Cd**L**Cl_2] and [Co**L**Cl_2], the calculation of the geometric parameter $\tau = (\beta - \alpha)/60$ [α = N(1)−M−Cl (1 or 12), β = N(2)−M−N(11)] gives the values 0.03, 0.39, 0.28 and 0.42, respectively. Since τ is a parameter used as an index of the degree of trigonality,[16], these values support a tetragonal geometry for [Cu**L**Cl_2] (τ close to zero) and are in agreement with a structure intermediate between the perfectly tetragonal (τ = zero) and trigonal-bipyranidal (τ = 1) geometries for [Zn**L**Cl_2], [Cd**L**Cl_2] and [Co**L**Cl_2]. In [Cu**L**Cl_2], the Cu atom is 0.358 Å (mean value) above the best plane defined by the three N atoms and the Cl(12).. As in the previous three complexes, the metal center is coordinated to N(1) and N(2) of the rigid 1,10-phenanthroline and N(11) of one oxime group forming two fused five-membered rings with acute N−Cu−N angles: N(1)−Cu(1)−N(2) = 78.44(11)° for molecule **a** and 78.18(11)° for molecule **b**, N(1)−Cu(1)−

A molecular view of complex [Ni**L**(DMSO)Cl_2] is shown in Figure 6 with its atom labelling scheme. The structure consists of a metal atom surrounded by one ligand **L**, two chlorine atoms and one DMSO linked by the O atom, in a distorted octahedral geometry. As in the previous complexes, the metal center is coordinated to N(1) and N(2) of the rigid 1,10-phenanthroline ligand and N(11) of one oxime group forming two fused five-membered rings (Table 3) with acute N−Ni(1)−N angles: N(1)−Ni(1)−N(2) = 77.53(17)° and N(1)−Ni(1)−N(11) = 74.68(17)°. These three nitrogen atoms occupy the equatorial plane which also contains the Cl(1) atom, whereas the axial positions are occupied by the second chlorine atom Cl(2) and the oxygen atom O(1) of the DMSO. All C, N and O atoms of the ligand, as well as the Cl(1) and Ni(1) atoms make an almost perfect plane, with the largest deviation from the plane being −0.13 Å at C(22). The hydrogen atom H(11) also belongs to this plane and there is a bonding interaction between it and Cl(1) [O(11)−H(11) = 1.015 Å; O(11)···Cl(1) = 3.097 Å; H(11)···Cl(1) = 2.256 Å; O(11)−H(11)···Cl(1) = 139.4°]. The atom H(21), which is out of the plane by 0.42 Å, is engaged in a bonding interaction with the atom O(1) of the [$-x + 3/2$, $y + 1/2$, z] symmetry-related molecule [O(21)−H(21) = 0.840 Å; O(21)···O(1) = 2.679 Å; H(21)···O(1) = 1.891 Å; O(21)−H(21)···O(1) = 155.5°], resulting in the formation of a two-dimensional hydrogen-bond network parallel to the *ab* plane.

A molecular view of complex [Cd**L**(OH_2)-$(DMSO)(NO_3)]^+$ is shown in Figure 6 with its atom labelling scheme. The cadmium atom presents a distorted pentagonal-bipyramidal geometry (Figure 2, **D**, Table 5); the equatorial plane is occupied by the four N atoms of ligand **L** and the oxygen atom of a water molecule, and the axial positions are occupied by two oxygen atoms belonging to a DMSO molecule and a nitrate anion. In this complex, the cadmium is coordinated to the four nitrogen atoms of the ligand resulting in the formation of three fused five-membered rings with very acute N−Cd−N angles, N(2)−Cd(1)−N(1) = 70.34(9)°, N(1)−Cd(1)−N(11) = 63.82(8)° and N(2)−Cd(1)−N(21) = 64.98(9)°. Of the four Cd−N distances, the two bonds connecting the metal center to the N atoms of the oxime groups are much longer, 2.720(3) and 2.780(3) Å, than the bonds involving the N atoms of the phenanthroline fragment, 2.341(3) and 2.369(2) Å. This lengthening may be a result of steric constraints. As a consequence of the coordination of the two nitrogen atoms N(11) and N(21), the two oximes have the same *s-cis* conformation around the C_{Ar}−C(=N) single bond. The unit also contains a free nitrate ion and a DMSO solvent molecule. The oxygen atom of DMSO and one of the oxygen atoms of the NO_3^- anion are connected, through hydrogen bonding, to the OH groups and also to the water molecule.

Since all these metal complexes have initially been designed as artificial nucleases with the potential ability to hydrolyze phosphomonoester and phosphodiester bonds, we performed some preliminary cleavage experiments using *p*-nitrophenyl phosphate as a substrate. As it is shown in Table 6, the hydrolytic activities of the zinc, copper, cobalt

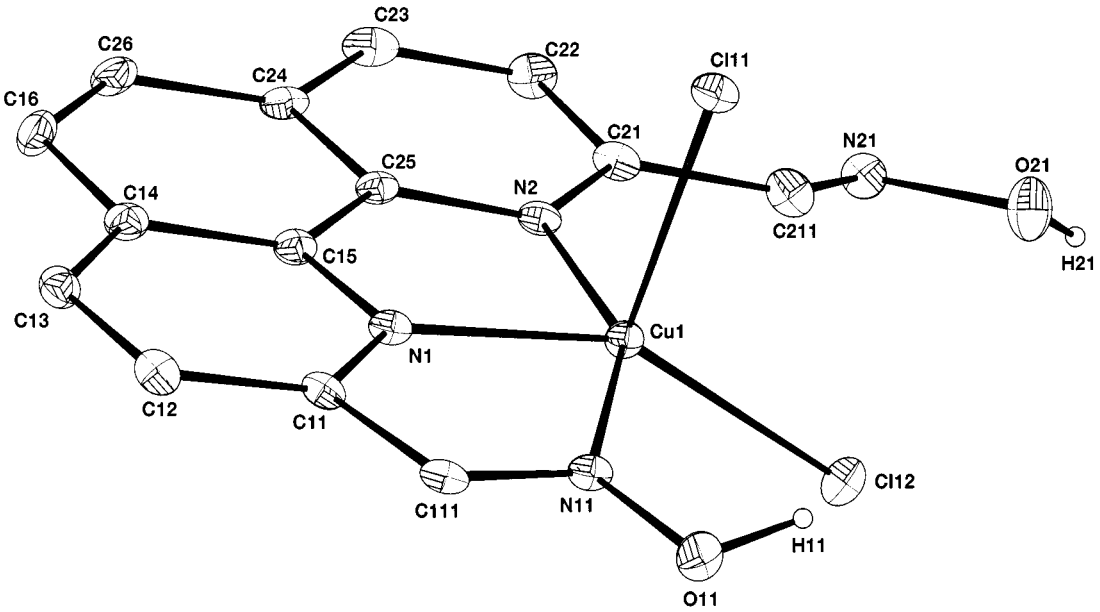

Figure 5. Molecular view of complex [Cu**L**Cl_2] with atom labelling scheme; ellipsoids are drawn at 30% probability; hydrogen atoms have been omitted for clarity

or nickel ions were not improved in the presence of ligand **L**. Moreover, the activity remained far below the activity of the lanthanide cerium salt alone, which is considered as one of the most reactive agents in the catalysis of DNA hydrolysis. It should be noted that in the case of cerium experiments, a slight but significant enhancement of its hydrolytic activity (+ 20 to + 80%) occurred in the presence of ligand **L**. This has also been observed during phosphodiester hy-

drolysis experiments using bis(*p*-nitrophenyl) phosphate as a substrate (data not shown).

Discussion

Previous studies[17] on complexes of the bidentate ligand 2,9-dimethyl-1,10-phenanthroline with Zn, Cu, Co and Ni have shown that these molecules possess a mirror plane which contains the metal and chlorine atoms and bisects the ligand molecule. The replacement of the two methyl groups by two oxime substituents introduces additional possibilities of chelation involving either the nitrogen or oxygen atoms of these groups. All the molecules presented here have provided unequivocal evidence for the structures of the 1:1 metal-ligand complexes. In all the complexes with chloro ligands, X-ray diffraction analyses showed a distorted trigonal-bipyramidal, a square-pyramidal or a square-bipyramidal structure involving the phenanthroline derivative as a tridentate ligand and coordination of the two chlorine atoms (Figure 2, **A**, **B** and **C**); the symmetry of the molecule was broken. However, as it was exemplified in two cases, the stereochemistry and the coordination number of the ligand may depend on the anion present.[18] Firstly, when ligand **L** was metallated with cadmium nitrate instead

Table 6. Hydrolysis of *p*-nitrophenyl phosphate (NPP) (expressed as mol-% conversion) by various metal ions and their complexes with and without ligand **L**

	Zn	Zn	Cu	Cu	Co	Ni	Ce	Ce
Run[a]	50 °C	80 °C	50 °C	80 °C	80 °C	80 °C	50 °C	80 °C
1 metal	−	20	−	25	18	−	85	100
2 metal + **L**	< 5	27	20	21	20	42	95	100

[a] Conditions: [NPP] = 500 μM; Zn^{2+}, Cu^{2+}, Co^{2+}, Ni^{2+} or Ce^{3+} cation 500 μM; metallated complex 500 μM (metal ion/**L**, 1:1); TRIS acetate buffer pH = 8 (50 mM) for 3 h at the indicated temperature.

of cadmium chloride, the crystal structure of $[Cd\mathbf{L}(OH_2)(DMSO)(NO_3)]^+$ appeared quite different from that of $[Cd\mathbf{L}Cl_2]$ (Figure 2, **D**). It showed a pentagonal-bipyramidal stereochemistry with the phenanthrolinedicarbaldehyde dioxime acting as a tetradentate ligand, whereas the three other ligands (H_2O, DMSO and one nitrato) contributed to the structure; the second nitrate ion was far away from the coordination sphere. In this molecule, the symmetry approaches C_{2v}, which is confirmed by the NMR-spectroscopic data. The second case is that of $([Zn\mathbf{L}(AcO)]_n$, obtained through metallation of **L** with zinc acetate. A polymer is probably formed, on the basis of elemental analysis, NMR and mass-spectrometric data. Figure 2 (**E** and **F**) shows two possible modes of connections for dimers or polymers. It is known that the oximate group can function as a bridge between two metal ions, through its deprotonated form, to afford bi- and trinuclear species[19] [in particular, see ref.[20] for an X-ray structure of a dimeric complex of 2,6-diacetylpyridine dioxime and Cu^{II} related to type **E** (Figure 2)]. It is probably the more acidic oximate group coordinated through the imine nitrogen atom on the metal center which is implicated in the coordination on the second metal ion through the deprotonated oxygen atom. This gives the proposed dimeric structure **E** that involves an almost planar six-membered ring (represented in Figure 2). Indeed, due to the linking effect involving the metal−ligand bond, the acid strength of the oxime group greatly increases, and depends on the nature of the metal ion.[21] As an example, the pK_a value of 2,6-diacetylpyridine dioxime is 10.2,[21] and that of the zinc complex is below 6[6b] and that of the copper(II) complex is 2.8.[22] So the oximate group can effectively compete with acetate as a ligand on the metal center (which is not the case when the anionic ligands are chloride ions), to give bridging coordination bonds resulting in the formation of dimeric or polymeric structures such as **E** and **F** in Figure 2. However, in the absence of an X-ray structure, we can neither exclude the "free" oxime ligand as a possible bridging group in the polymeric structure **F** (Figure 2), nor say if the acetate is within the coordination sphere (to give a five-coordinated structure as in $[Zn\mathbf{L}Cl_2]$ or outside (as a neutralizing charge).

All assignments of structures of complexes M−**L** were also confirmed by positive FAB-MS and ES-MS data. In addition, the ^1H NMR spectra of the diamagnetic zinc(II) and cadmium(II) complexes were recorded. The spectra of $[Zn\mathbf{L}Cl_2]$ (the broad peaks were not clearly resolved by an increase in temperature) and $[Zn\mathbf{L}(AcO)]_n$ (the complexity of NMR-spectroscopic patterns suggested a polymeric structure) did not afford further information on their structures in solution. The spectra of the cadmium complexes were more informative but rather atypical because of the coexistence of broad and sharp peaks for groups of protons of the same molecule. The exact nature of this unusual NMR spectrum (a similar case has been reported for cadmium complexes of 2,9-dihydrazino derivatives of 1,10-phenanthroline)[18] is debatable. A dynamic variation of coordination number of the cadmium(II) ions is a possible explanation. Equilibria between cadmium halide complexes are known,[23] and similar equilibria could be present here, ligand **L** acting either as a tridentate ligand (as in the crystal structure **A**, Figure 2) or a tetradentate ligand (as in crystal structure **D**, Figure 2), resulting in an asymmetrical or a symmetrical geometry of the complex, respectively. It was noteworthy that both complexes $[Cd\mathbf{L}Cl_2]$ and $[Cd\mathbf{L}(OH_2)(DMSO)(NO_3)]^+$ presented similar NMR profiles in solution (associating broad and sharp peaks), although the initial crystal structure was different. In both cases, the increase in temperature significantly reduced the width of the broad peaks to give signals corresponding to a symmetrical molecule (similar to that observed for the free ligand **L**). Therefore, in solution different species probably coexist.

We performed some preliminary experiments on the phosphomonoester bond cleavage with zinc, copper, cobalt and nickel acetate salts, both in the presence and absence of ligand **L**. No significant improvement of the catalytic activity of the metal cation in the presence of the ligand could be observed in these conditions. However, according to the present structural investigations on complexes M−**L**, the anions present in solution (introduced either as the counter ions of the metal cation or with the buffer) may play a crucial role in the structure of the various complexes in solution and, therefore, on their activity. Current investigations are focusing on defining the optimal conditions for use of these potential chemical nucleases as to expand the study to other metal complexes involving cerium or other lanthanides.

Conclusion

The attachment of an organic functional group to a metal-chelating ligand is an attractive way of developing the design of small metal complexes which are potentially able to hydrolyze the phosphodiester backbone of nucleic acids. In the present paper, we detailed the structure and the coordination geometry of an original series of metal complexes of a phenanthroline derivative bearing two aldoxime groups known for their highly nucleophilic properties. This series represents a range of complexes differing in the nature of the metal (Lewis acidity, size, etc.), the geometry of the crystal structure (trigonal-bipyramidal, square-pyramidal, square-bipyramidal and pentagonal-bipyramidal structures) or the conformational flexibility. These factors can affect the known in vivo biological interest of ligand **L** and its metal chelates and also their potential use as chemical nucleases in phosphodiester hydrolysis.[24]

Experimental Section

General: Commercially available reagents and all solvents were purchased from standard chemical suppliers and used without further purification. − ^1H NMR spectra were recorded with a Bruker AM 250 (250 MHz), [D_6]DMSO was used as a solvent δ_H = 2.62. − Elemental analyses were carried out by the "Service de Microana-

lyse du Laboratoire de Chimie de Coordination". − MS: Nermag R10−10, 70 eV (IE/DCI and FAB$^+$/*meta*-nitrobenzyl alcohol MNBA) or Perkin−Elmer SCIEX API 365 (electrospray) by the "Service de Spectrométrie de Masse de Chimie UPS−CNRS de Toulouse". For MS data, the indicated value for molecular or fragment peaks corresponded to the peak of higher intensity and are in agreement with calculated isotopic profiles. − UV/Vis: Hewlett−Packard 8452A diode array spectrophotometer, cuvettes of 1 cm pathlength. − IR: Perkin−Elmer 225 and 597. − Melting points were determined with a digital apparatus Electrothermal and are uncorrected.

1,10-Phenanthroline-2,9-dicarbaldehyde: Iodine was added (I_2, 7.02 g, 27.65 mmol, 2 equiv.) to a solution of neocuproine hemihydrate (2,9-dimethyl-1,10-phenanthroline, 3.0 g, 13.8 mmol, 1 equiv.) dissolved in DMSO (200 mL). The brown solution was stirred for 5 min at room temperature before 3.42 mL of 2-iodo-2-methylpropane (*t*BuI, 28.7 mmol, 2.07 equiv.) was added. Finally, trifluoroacetic acid (TFA, 3 mL, 38.94 mmol, 2.8 equiv.) was slowly added to the darkbrown solution by syringe and the mixture was stirred under reflux for 2 h (148 °C). After this, the solution was allowed to cool at room temperature. The excess of iodine was neutralized by slow addition of a solution of $Na_2S_2O_3$ (16 g/120 mL) and the dark precipitate formed was removed by filtration. 1,10-Phenanthroline-2,9-dicarbaldehyde was precipitated from the filtrate by addition of aqueous $NaHCO_3$ (10%) to pH = 4−5 and extracted with CH_2Cl_2. The organic phase was dried, concentrated and the residue was washed with ether to remove traces of DMSO. The crude product was recrystallized from acetone and dried under vacuum to give the pure compound (1.64 g, yield 48%). − M.p. 253 °C. − $C_{14}H_8N_2O_2 \cdot 1/2\ H_2O$ (245): calcd. C 68.57, H 3.70, N 11.42; found C 68.84, H 3.62, N 11.55. − ^{1}H NMR ([D$_6$]DMSO): δ = 10.48 (d, ^4J = 0.8 Hz, 2 H, CHO), 8.93 (dd, ^4J = 0.8 Hz, ^3J = 8.2 Hz, 2 H, 8-H and 3-H), 8.44 (d, ^3J = 8.2 Hz, 2 H, 4-H and 7-H), 8.42 (s, 2 H, 5-H and 6-H), 3.43 (s, 1 H, 0.5 H_2O). − MS (EI); *m*/*z* (%): 236 (30) [M$^+$], 208 (100) [M − CO]$^+$, 180 (3) [M − 2CO]$^+$. − MS (DCI/NH_3); *m*/*z* (%): 254 (100) [M + NH_4]$^+$, 237 (37) [MH]$^+$. − IR (KBr): $\tilde{\nu}$ = 1701 cm^{-1} (C=O) vs, 1617 (C=C) s. − UV/Vis (DMSO 0.2% in H_2O): λ_{max} (lg ε) = 236 nm (4.58), 278 (4.47), 314 (3.99), 332 (3.93), 348 (3.72).

1,10-Phenanthroline-2,9-dicarbaldehyde Dioxime (L): A suspension of 1,10-phenanthroline-2,9-dicarbaldehyde (400 mg, 1.69 mmol, 1 equiv.) in 10 mL of absolute ethanol was stirred at 60 °C for 10 min. $NH_2OH \cdot HCl$ was then progressively added (622 mg, 8.8 mmol, 5.2 equiv.). The addition of about 400 mg of hydroxylamine dissolved the dialdehyde within a few minutes to give a brown solution, after which a brown precipitate was obtained (after the complete addition of $NH_2OH \cdot HCl$). The reaction mixture, in 30 mL of absolute EtOH, was warmed to 80 °C and stirred for 20 min. The mixture was stirred at reflux (95 °C) for 2 h after the addition of pyridine (1.64 mL, 20.3 mmol, 12 equiv.). The reaction mixture was then allowed to cool at room temperature. After removal of the liquid phase, the precipitate was washed with 30 mL of water to eliminate the excess of $NH_2OH \cdot HCl$, recrystallized from water/DMSO (55:45, v/v) and dried under vacuum (352 mg, yield 78%). − $C_{14}H_{10}N_4O_2$ (266). − M.p. 267 °C. − $C_{14}H_{10}N_4O_2 \cdot 1/2\ H_2O$ 0.85 DMSO (341.3): calcd. C 55.20, H 4.71, N 16.40; found C 55.63, H 4.71, N 15.98. − ^{1}H NMR ([D$_6$]DMSO): δ = 12.07 (s, 2 H, NO*H*), 8.63 (d, ^3J = 8.2 Hz, 2 H, 3-H and 8-H), 8.53 (s, 2 H, C*H*(=NOH)), 8.29 (d, ^3J = 8.2 Hz, 2 H, 4-H and 7-H), 8.15 (s, 2 H, 5-H and 6-H). − MS (EI); *m*/*z* (%): 266 (30) [M$^+$], 248 (20) [M − H_2O]$^+$, 230 (18) [M − 2H_2O]$^+$. − IR (KBr): $\tilde{\nu}$ = 1615 cm^{-1} (C=N oxime) s. − UV/Vis (DMSO 0.2% in H_2O): λ_{max} (lgε) = 262 nm (4.33), 298 (4.35), 324 (4.00), 356 (3.40).

X-ray Diffraction Studies: Addition of a small amount of water in a concentrated solution of 1,10-phenanthroline-2,9-dicarbaldehyde dioxime in DMSO left at room temperature (25 °C), gave suitable yellow crystals for X-ray diffraction studies. Figure 3: ORTEP drawings of the ligand 1,10-phenanthroline-2,9-dicarbaldehyde dioxime hydrate. Selected bond lengths and angles are given in Table 1 and 2.

Dichloro(1,10-phenanthroline-2,9-dicarbaldehyde Dioxime)zinc [ZnLCl$_2$]: A solution of $ZnCl_2$ (12.8 mg, 94 μmol, final concentration 188 mM) in 100 μL of DMF was added to a brown solution of **L** (25 mg, 73 μmol, final concentration: 146 mM) in 400 μL of DMF. The expected complex, which precipitated immediately, was isolated by centrifugation and dried under vacuum to afford a brown powder (25 mg, 59.2 μmol, yield 81%). − $C_{14}H_{10}Cl_2N_4O_2Zn$ (402.5). − M.p > 360 °C. − $C_{14}H_{10}Cl_2N_4O_2Zn \cdot 1/3DMF$ (422.2): calcd. X-ray Diffraction Studies: Crystals of compound [Cd**L**Cl_2] were obtained independently by adding 100 μL of an aqueous solution of $Cd(NO_3)_2$·$4H_2O$ (2.0 mg, 6.5 μmol, final concentration: 1.62 mM) to a solution of Zn**L**Cl_2 (2.0 mg, 4.9 μmol, final concentration: 1.2 mM) in 4 mL of a mixture of DMSO/H_2O (1:3), to induce the transmetallation. The solution was allowed to crystallize for 3 months (by slow solvent evaporation) at room temperature to afford yellow crystals suitable for X-ray analysis. Selected bond lengths and angles are given in Table 3.

Aqua(dimethylsulfoxide)(nitrato)(1,10-phenanthroline-2,9-dicarbaldehyde Dioxime)cadmium Nitrate [CdL(OH_2)(DMSO)(NO_3)]$^+$. − Analytical and X-ray Diffraction Studies: A solution of $Cd(NO_3)_2$·$4H_2O$ (29 mg, 94 μmol) in 100 μL of H_2O was added to a brown solution of **L** (25 mg, 73 μmol, final concentration: 146 mM) in 400 μL of DMSO. The expected complex did not precipitate immediately and, by vapor diffusion of CH_2Cl_2, the solution afforded suitable pale yellow crystals after 2 d. Figure 7: ORTEP drawing of the dinitrato(1,10-phenanthroline-2,9-dicarbaldehyde dioxime)cadmium complex. Selected bond lengths and angles are given in Table 5. − M.p. > 360 °C. − $C_{14}H_{10}CdN_6O_8$·DMSO·H_2O (598.8) − ^{1}H NMR ([D_6]DMSO): δ = 11.81 (br. s, ca. 1.5 H, NO*H*), 8.99 (pattern massif, 2 H, 4-H and 7-H), 8.67 (pattern massif, 2 H, 11-H and 11′-H), 8.37 (d, 2 H, ^3J = 8.0 Hz, 3-H and 8-H), 8.35 (s, 2 H, 5-H and 6-H), 2.60 (s, 6 H, DMSO) [recorded at 60° C, the broad signal at δ = 8.99 gave: δ = 8.96 (d, 2H, ^3J = 8.0 Hz, 4-H and 7-H), the broad signal at δ = 8.67 became a sharp singlet]. − MS (positive FAB, solution in DMSO/H_2O); *m/z* (%): 379 (61) [**L** + Cd − H^+]$^+$, 442 (100) [**L** + Cd + NO_3^-]$^+$, 457 (13) [**L** + Cd − H^+ + DMSO]$^+$, 520 (30) [**L** + Cd + NO_3^- + DMSO]$^+$, 598 (8) [**L** + Cd + NO_3^- + 2DMSO]$^+$, 818 (5) [2 × **L** + 2 × Cd + NO_3^- − 2H^+]$^+$. − MS (ES, solution in DMSO/H_2O); *m/z* (%): 379 [**L** + Cd − H^+]$^+$. − UV/Vis (DMSO 0.2% in H_2O): λ_{max} = 264 nm, 322, 348 (sh).

Dichloro(1,10-phenanthroline-2,9-dicarbaldehyde DioxDme)cobalt Mono(dimethyl sulfoxide) [CoLCl_2]: 100 μL of an aqueous solution of $CoCl_2$·$6H_2O$ (22.4 mg, 94 μmol, final concentration 188 mM) was added to a brown solution of **L** (25 mg, 73 μmol, final concentration: 146 mM) in 400 μL of DMSO. The expected complex, which precipitated after 30 min, was isolated by centrifugation and dried under vacuum to afford a brown powder (24.7 mg, 49.4 μmol, yield 68%). − M.p. > 360 °C. − $C_{14}H_{10}CoCl_2N_4O_2$·DMSO·0.2$CoCl_2$ (500.2): calcd. C 38.42, H 3.22, N 11.20; found C 38.31, H 2.74, N 11.27. − MS (ES, solution in DMSO/H_2O); *m/z* (%): 265.9 [**L**]$^+$, 305.9 [**L** + Co^{II} − H^+ − H_2O], 322.8 [**L** + Co^{III} − 2H^+], 323.8 [**L** + Co^{II} − H^+]$^+$, 589.0 (dimer 2:1 [2 × **L** + Co^{III} − 2H^+]$^+$). − UV/Vis (DMSO 0.2% in H_2O): λ_{max} (lgε) = 230 nm (4.51), 268 (4.67), 296 (4.44), 348 (4.16).

X-ray Diffraction Studies: Crystals of [Co**L**Cl_2] were obtained independently by addition of 40 μL of an aqueous solution of $CoCl_2$·$6H_2O$ (6 mg, 25 μmol, final concentration: 126 mM) to 160 μL of a brown DMSO solution of **L** (6.7 mg, 19.6 μmol, final concentration: 98 mM). Under these conditions, the complex did not precipitate immediately and, by vapour diffusion of CH_2Cl_2, the solution afforded suitable green/red dichroic crystals after 7 d. Figure 4: ORTEP drawing of the dichloro(1,10-phenanthroline-2,9-dicarbaldehyde dioxime)cobalt complex. Selected bond lengths and angles are collected in Table 3.

(Dichloro)(dimethylsulfoxide)(1,10-phenanthroline-2,9-dicarbaldehyde Dioxime)nickel Dihydrate Mono(dimethylsulfoxide) (NiL(DMSO)Cl_2): 100 μL of an aqueous solution of $NiCl_2$·$6H_2O$ (22.3 mg, 94 μmol, final concentration 188 mM) was added to a brown solution of **L** (25 mg, 73 μmol, final concentration: 146 mM) in 400 μL of DMSO. After concentrating the mixture to 350 μL, the expected complex precipitated and was isolated by centrifugation and dried under vacuum to afford a brown powder (37.2 mg, 63.3 μmol, yield 87%). − M.p. > 360 °C. − $C_{14}H_{10}Cl_2N_4NiO_2$·2DMSO·$2H_2O$ (588.1): calcd. C 36.76, H 4.46, N 9.53; found C 36.97, H 4.26, N 9.18. − MS (positive FAB, solution in DMSO/H_2O); *m/z* (%): 323 (100) [**L** + Ni − H^+]$^+$, 359 (8) [**L** + Ni + Cl^-]$^+$. − MS (ES, solution in DMSO/H_2O); *m/z* (%): 266.9 [**L** + H^+], 304.9 [**L** + Ni − H^+ − H_2O]$^+$, 322.9 [**L** + Ni − H^+]$^+$, 589.0 [2 × **L** + Ni − H^+]$^+$. − UV/Vis (DMSO 0.2% in H_2O): λ_{max} (lgε) = 260 nm (4.84), 316 (4.65), 364 (4.11).

X-ray Diffraction Studies: Crystals of [Ni**L**(DMSO)Cl_2] were obtained independently by addition of 40 μL of a DMSO solution of $NiCl_2{\cdot}6H_2O$ (237.71) (6 mg, 25 μmol, final concentration: 126 mM) to 160 μL of a brown DMSO solution of **L** (6.7 mg, 19.6 μmol, final concentration: 98 mM). Under these conditions, the complex did not precipitate immediately and, by vapour diffusion of CH_2Cl_2, the solution afforded suitable green crystals after 5 d. Figure 6: ORTEP drawing of the dichloro(1,10-phenanthroline-2,9-dicarbaldehyde dioxime)nickel complex. Selected bond lengths and angles are collected in Table 3.

Crystal Structure Determination of the Ligand L and the Complexes [Zn$L$$Cl_2$], [Cu$L$$Cl_2$], [Cd$L$$Cl_2$], [Cd$L$$(OH_2)$(DMSO)$(NO_3)$]$^+$, [Co$L$$Cl_2$], and [Ni$L$(DMSO)$Cl_2$]: Data were collected with a Stoe IPDS (Imaging Plate Diffraction System) diffractometer equipped with an Oxford cryosystems Cooler Device. The final unit cell parameters were obtained by the least-squares refinement of 5000 reflections. Only statistical fluctuations were observed in the intensity monitors over the course of the data collections. All the structures were solved by direct methods (SIR92[25]) and refined by least-squares procedures on F^2. All H atoms attached to carbon atoms or to OH groups were introduced in calculations in idealised positions [d(CH) = 0.96 Å] and treated as riding models with isotropic thermal parameters, 20% higher than those of the carbon atoms to which they are attached. H atoms attached to water molecules were refined with an equivalent isotropic thermal parameter, the geometry of water molecules were restrained to have chemically reasonable dimensions. Some of the DMSO solvent molecules in [Zn$L$$Cl_2$], [Cd$L$$Cl_2$] and [Cd$L$$(OH_2)$(DMSO)$(NO_3)$]$^+$, and the free NO_3 in [Cd$L$$(OH_2)$(DMSO)$(NO_3)$]$^+$ are disordered. These disordered molecules were treated using the available tools in SHELXL-97. Least-squares refinements were carried out by minimising the function $\Sigma w(F_o^2 - F_c^2)^2$, where F_o and F_c are the observed and calculated structure factors. The weighting scheme used in the last refinement cycles was $w = 1/[\sigma^2(F_o^2) + (aP)^2 + bP]$ where $P = (F_o^2 + 2F_c^2)/3$. Models reached convergence with $R = \Sigma(||F_o| - |F_c||)/\Sigma(|F_o|)$ and $wR2 = \{\Sigma w(F_o^2 - F_c^2)^2/\Sigma w(F_o^2)^2\}^{1/2}$, having the values listed in Table 1. Crystal data and data collection parameters are summarized in Table 7. The calculations were carried out with the SHELXL-97 program[26] running on a PC. Molecular view was realised with the help of CAMERON[27] Fractional atomic coordinates, anisotropic thermal parameters for nonhydrogen atoms and atomic coordinates for H atoms have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-134158−134163 and -139259. The ligand **L** and the complexes [Zn$L$$Cl_2$], [Cu$L$$Cl_2$], [Cd$L$$Cl_2$], [Co$L$$Cl_2$], [Ni$L$(DMSO)$Cl_2$], and [Cd$L$$(OH_2)$(DMSO)$(NO_3)$]$^+$ are referenced under the following denominations, respectively: **2**, **3**·Cl_2, **4**·Cl_2, **5**·Cl_2, **6**·Cl_2, **7**·Cl_2 and **5**·$(NO_3)_3$. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk

Hydrolysis of *p*-Nitrophenyl Phosphate (NPP) with Various Metal Ions and Their Complexes with L: NPP was incubated with various metal ions in the absence (run 1) or the presence (run 2) of ligand **L** in 50 mM TRIS acetate buffer (pH = 8) at 50 or 80 °C, for 3.0 h. NPP and the metal salts were introduced as aqueous solutions and ligand **L** as a DMSO solution. The final volume (1 mL) contained 5% DMSO. Metal salts were introduced as acetates except for cerium (sulfate). The reactions were followed by reversed-phase HPLC (C18 Nucleosil, 10 μm, 250×4.6 mm; elution with methanol/5 mM ammonium acetate (45:55), adjusted to pH = 5 with acetic acid; detection at 320 nm).

Acknowledgments

We thank Anne Robert for her contribution to the recording and the interpretation of NMR spectra, Catherine Claparols for carrying out the mass analyses and Bruno Donnadieu for recording several X-ray data.

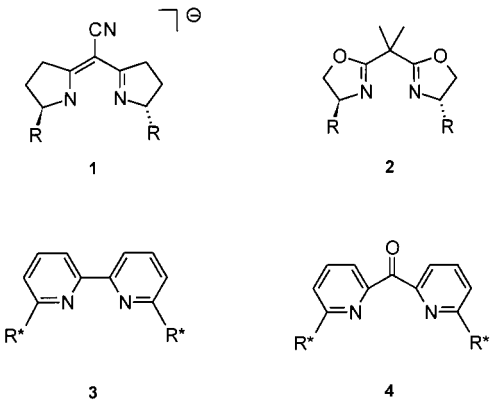
Novel Chiral Di-2-pyridyl Ketone Ligands: Crystal Structure of a Copper Complex and its Activity in the Copper-Catalyzed Enantioselective Cyclopropanation of Styrene



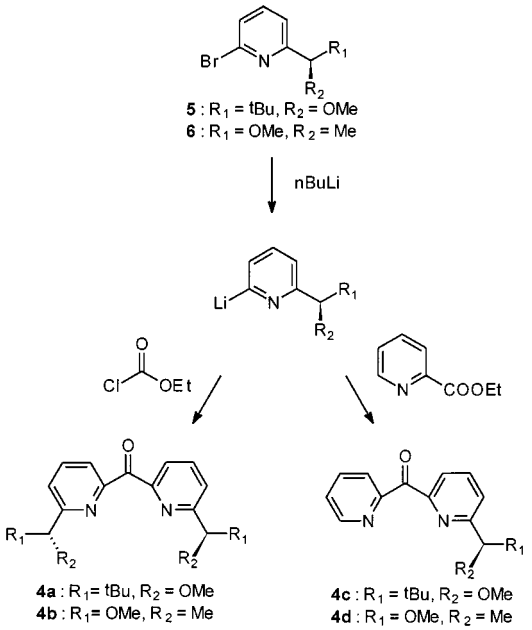
Hoi-Lun Kwong,*[a] Leung-Shi Cheng,[a] Wing-Sze Lee,[a] Wing-Leung Wong,[a] and Wing-Tak Wong[b]

Keywords: Chiral auxiliaries / Asymmetric catalysis / Pyridyl / Nitrogen heterocycles / Cyclopropanation / Copper

New C_2-symmetric chiral di-2-pyridyl ketones were prepared from readily available chiral bromopyridines. Their complexes with copper were synthesized and characterized by X-ray crystallography. The copper complexes were prepared in situ with the triflate anion and were found to be active in the catalysis of cyclopropanation with diazo esters and alkenes. Reaction yields were excellent and enantioselectivities of up to 61% were observed.

Introduction

The synthesis of chiral ligands has been of crucial importance in the development of transition metal-catalyzed enantioselective reactions.[1] Chiral *N*,*N*-bidentate ligands such as semicorrine **1** and bis-oxazoline **2** have been found to be highly effective chiral controllers in asymmetric reactions.[2−4] We are particularly interested in chiral 2,2′-bipyridines **3**, which are structurally similar to these ligands and have also been employed in asymmetric catalysis.[5−11] Our strategy has been to synthesize new chiral ligands based on chiral pyridine.[12] Although di-2-pyridyl ketone and its hydrated form are structurally similar to 2,2′-bipyridine and are known to form complexes with various metal ions,[13] to the best of our knowledge there have been no reports of the synthesis of chiral di-2-pyridyl ketone ligands or their use in asymmetric catalysis. Herein, we report the synthesis of the new chiral di-2-pyridyl ketone ligands **4** based on readily available chiral bromopyridines, and the preparation and crystal structure of a copper(II) complex. We also report the study of the catalytic activities of the copper complexes in asymmetric cyclopropanation.[14]



Results and Discussion

The synthesis of the chiral di-2-pyridyl ketone ligands **4a**−**d** is summarized in Scheme 1. The enantiomerically pure starting materials, the 2-bromopyridines **5** and **6**, could easily be prepared from commercially available 2,6-dibromopyridine.[6a][6b] Compounds **4a**−**b** were obtained by the reaction of lithiated **5** and **6** with ethyl chloroformate, while **4c**−**d** were prepared by using ethyl picolinate. The yields of **4a** and **4b** were both 65%, while those of **4c** and **4d** were 31 and 25%, respectively. The IR spectra of **4a**−**d** (KBr) show ν(C=O) in the range 1681−1687 cm^{-1}.

In order to investigate the coordination chemistry of these di-pyridyl ligands, the copper complex **7** was synthesized. It was obtained as a blue solid in good yield by mixing copper(II) perchlorate and **4a** in methanol and stirring overnight (Scheme 2). Crystals suitable for X-ray crystallography were obtained by recrystallization from acetonitrile/ether. The IR spectrum (KBr) shows ν(C=O) at 1687 cm^{-1}, which is identical to that of the free ligand. The X-ray crystal structure, shown in Figure 1, shows a 1:1 complex between Cu^{II} and the ligand. Table 1 summarizes the structural parameters of **7**. Ligand **4a** acts as a tetradentate ligand and the coordination geometry can be described as square pyramidal with the metal ion surrounded by two pyridine nitrogen atoms, two neutral oxygen atoms of the ether groups and one oxygen atom from one of the perchlorate anions. The perchlorate anion interacts with the copper(II) ion and occupies the apical position. Because of this interaction, the C_2 symmetry of the ligand is slightly distorted. The planar pyridine rings are twisted differently

Scheme 1. Synthesis of chiral di-2-pyridyl ketone ligands

around the planar ketone subunit C7−C(O)−C9 by torsional angles of 6.17° and 21.68°, and the planes of the two rings are twisted by 24.47° relative to each other. The copper−nitrogen bond lengths are 1.960 and 1.944 Å, which are slightly shorter than those of other achiral pyridyl ketone complexes.[13b][13f] They are also shorter than a related chiral dichloro(bipyridine)copper(II) complex reported previously,[11b] where the Cu−N bond lengths are both 2.017 Å. The bite angle of 96.3° made by the chiral dipyridyl ketone and copper is much larger than that observed for the chiral bipyridine complex (83°).[11b] The copper−oxygen bond lengths are 1.987 and 2.006 Å.

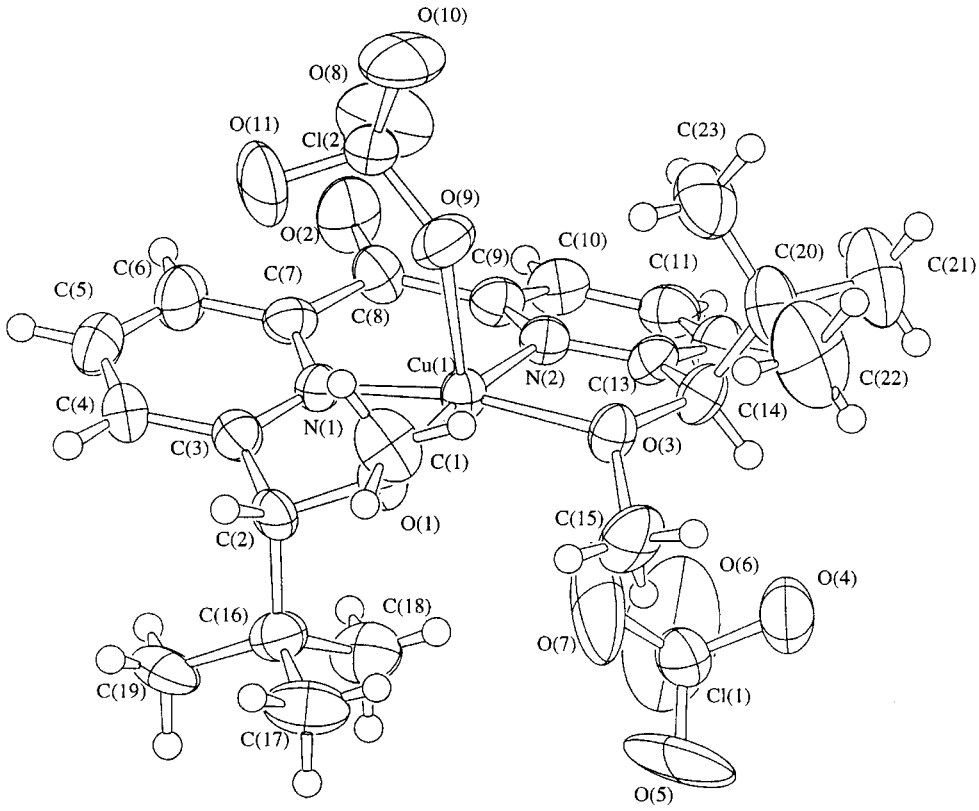

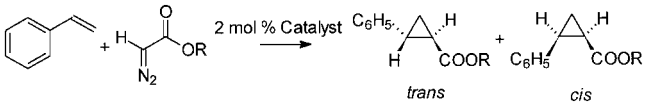

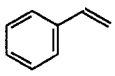

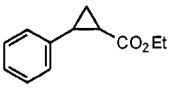

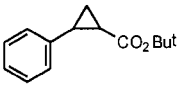

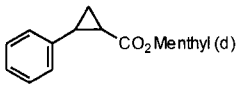

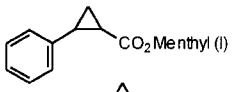

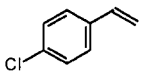

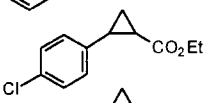

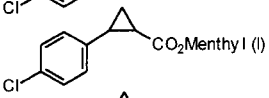

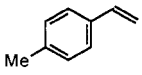

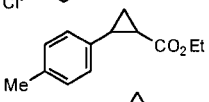

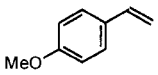

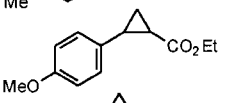

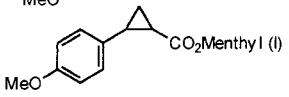

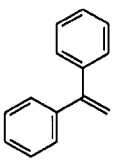

Figure 1. Molecular structure of complex **7**

The use of copper complexes prepared from CuOTf and bipyridines as catalysts in the cyclopropanation of alkenes have been reported by Katsuki et al. and our group.[9] To investigate if these dipyridyl ketone ligands had similar reactivity, we studied the cyclopropanation with complex **7** (Scheme 3). The perchlorate complex **7** was found to be an active catalyst in cyclopropanation with ethyl diazoacetate (EDA). A high *trans*/*cis* ratio (79:21) was obtained, but the complex showed very poor enantioselectivity (3% for both *trans* and *cis* isomers). On the other hand, the triflate complexes, which were prepared by reacting **4a**−**d** with copper(II) triflate, served as more selective catalysts. The results for asymmetric cyclopropanation of styrenes with different ligands are shown in Table 2. The reactions were carried out in the presence of 2 mol-% copper catalyst, 2.2 mol-% chiral ligand, 0.5 M alkyl diazoacetate and excess styrene (2.0 M). In all cases, the yields of the isolated cyclopropanes were excellent, but the enantioselectivities obtained were moderate. With EDA, the C_2-symmetric ligand **4a**, which contains the bulky *tert*-butyl group, gave the highest *ee* for both *trans* (50% *ee*) and *cis* (44% *ee*) isomers, whereas the C_2-symmetric ligand **4b** and the C_1-symmetric ligands **4c** and **4d** showed poor enantioselectivity. Compound **4a** was found to be the best ligand, although other styrene substrates were also tested. In all cases, the chemical yields of the cyclopropane ester were good. For substituted styrenes, the *trans*/*cis* ratios were about 60:40 (Table 2, entries 1, 8, 10 and 11) and the enantioselectivities were between 50 and 59% *ee* for the *trans* isomers and between 38 and 45% *ee* for the *cis* isomers. There is no strong dependence on en-

Scheme 3. Cyclopropanation of styrene

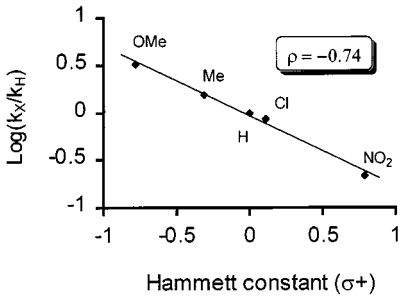
[a] Not determined.

antioselectivity and *trans*/*cis* selectivity with both electron-donating and withdrawing groups. A 49% *ee* was observed for 1,1-diphenylethene (entry 13).

The effect of the diazo ester structure on *trans*/*cis* diastereoselectivity and enantioselectivity was evaluated with *tert*-butyl-, L-menthyl- and D-menthyl diazoacetate. As can be seen from entries 1, 5, 6 and 7 in Table 2, the *trans*/*cis* ratios for styrene increase when the R group changes from an ethyl to a bulkier group. L-Menthyl shows the greatest improvement. This is consistent with the trend previously observed with other copper catalysts. However, the enantioselectivities for *trans* and *cis* isomers only show an improvement for the L-menthyl group (entry 7). Even higher *trans*/*cis* ratios are observed with chlorostyrene and methoxystyrene (entries 9 and 12). The enantioselectivities for chlorostyrene (entry 9), methoxystyrene (entry 12) and 1,1-diphenylethene (entry 14) all show an improvement with the use of L-menthyl diazoacetate. When the ligands **4a** and **4d** were used with copper (II) triflate, the absolute configurations of the cyclopropane ester products formed from styrene were determined to be (1*R*,2*R*) and (1*R*,2*S*) for the *trans* and *cis* isomers, respectively, while **4b** and **4c** induce the formation of the (1*S*,2*S*) and (1*S*,2*R*) enantiomers. It is interesting to note that although **4a** and **4c** were both synthesized from **5**, the C_2 ligand **4a** gives 1*R* products whereas the C_1 ligand **4c** leads to 1*S* products. A similar observation was also observed with **4b** and **4d**.

In order to know more about the active intermediate in the reaction, the relative rates of cyclopropanation for substituted styrenes using ligand **4a** with EDA were determined through competition experiments. The Hammett plot of $\log(k_x/k_H)$ versus $\sigma(+)$ is shown in Figure 2, and a good $\sigma(+)\rho$ correlation was obtained with $\rho = -0.74$. Although the ρ value is similar to that reported by Kodadek and Woo et al. (-0.85) and Pérez et al. (-0.68) for the cyclopropanation of substituted styrenes using an EDA/iron(II) phophyrin system[15] and EDA/copper(I) tris(pyrazolyl)borate,[16] respectively, correlations to σ instead of $\sigma(+)$ were found in the two latter systems. Nonetheless, the negative value for ρ supports the formation of an electrophilic metal−carbene complex intermediate and only a moderate positive-charge build-up at the benzylic carbon in the transition state. Although the mechanism is still elusive, it is believed that the metal carbene formed by the reaction between the Cu^I complex and the diazo compound is the active species. Based on the absolute configuration of the products obtained from the reaction with ligand **4a**, the sense of asymmetric induction observed here can be explained by the model shown in Scheme 4. This model is in agreement with that previously cited by Pfaltz for other *N*,*N*-bidentate ligands.[4a] In this model, ligand **4a** acts as a bidentate ligand and the metal carbenoid attacks the olefinic double bond according to pathway *a* and *b*. In case *a*, a repulsive steric interaction builds up between the ester group and the adjacent bulky *tert*-butyl group of the ligand. Therefore, pathway *b* is expected to be favored over pathway *a*. In case *b*, this will lead to the *cis*-(1*R*)- or *trans*-(1*R*)-cyclopropane esters, consistent with the experimental results.



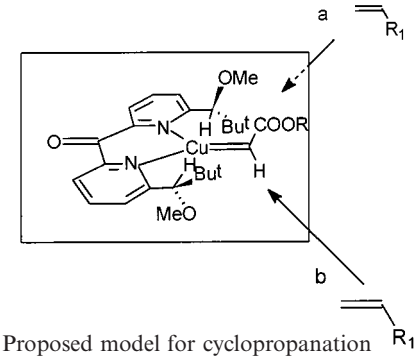


Figure 2. Hammett plot for the cyclopropanation of styrene with EDA using $Cu(OTf)_2$ and ligand **4a** as the catalyst

Scheme 4. Proposed model for cyclopropanation

Conclusion

In summary, we have successfully synthesized a novel chiral di-2-pyridyl ketone from the organometallic addition of a chiral pyridine derivative. The copper complexes of these ligands are active catalysts for cyclopropanation and *ee*s of up to 61% were observed. Comparison of the reactivity and enantioselectivity of ligand **4a** with other copper-catalyzed cyclopropanation reactions indicates that the active intermediates in these reactions are similar. We are continuing our efforts to study the use of these ligands in other catalytic asymmetric reactions.

Experimental Section

General Remarks: Toluene was distilled under N_2 from sodium. Dichloromethane and acetonitrile were distilled over calcium hydride. Diethyl ether and THF were distilled under N_2 over sodium/benzophenone. Chemicals were of reagent-grade quality and were obtained commercially. Infrared spectra were recorded in the range 500−4000 cm^{-1} as Nujol nulls or KBr plates on a Perkin−Elmer Model FTIR−1600 spectrometer. ^1H and ^{13}C NMR spectra were recorded on a Varian 300 MHz Mercury instrument. Positive ion FAB mass spectra were recorded as 3-nitrobenzyl alcohol matrices on a Finnagin MAT 95 spectrometer. Electron-ionization mass spectra were recorded on a Hewlett Packard 5890II GC instrument coupled with a 5970 mass-selective detector. Elemental analyses were performed on a Vario EL elemental analyser. Optical rotations were measured on a JASCO DIP−370 digital polarimeter.

Melting points were measured on an Electrothermal digital melting point apparatus.

General Procedure for the Synthesis of Ligands 4a and 4b: *n*-Butyllithium in hexane (2.5 M, 1.0 mL, 2.5 mmol) was added slowly to a solution of chiral bromopyridine (2.4 mmol) in THF (5.0 mL) at −78 °C. The resulting mixture was stirred at this temperature for 2 h. Ethyl chloroformate (1.2 mmol) in THF (5.0 mL) was cooled to −78 °C and added slowly to the yellowish brown solution. The solution was allowed to stir for 1 h. Methanol (5.0 mL) was then added and the mixture was warmed to room temperature. Water (5.0 mL) and HCl (10%, 5.0 mL) were then added. The layers were separated and the aqueous phase was extracted with CH_2Cl_2 (3 × 15 mL). The combined organic layers were washed with brine (50 mL) and dried with Na_2SO_4. The solvent was removed under reduced pressure and the crude product purified by column chromatography.

Ligand 4a: Following the above procedure with **5** and the usual workup, followed by chromatography with petroleum ether/EtOAc (7:1), gave **4a** (0.300 g, 65%). − $[\alpha]_D^{25}$ = +167.8 (*c* = 0.5, CH_2Cl_2). − IR (KBr): $\tilde{\nu}$ = 1687 cm^{-1}. − ^1H NMR ($CDCl_3$): δ = 0.92 (s, 18 H), 3.26 (s, 6 H), 4.06 (s, 2 H), 7.58 (d, *J* = 7.5 Hz, 2 H), 7.85 (t, *J* = 7.8 Hz, 2 H), 8.01 (d, *J* = 7.5 Hz, 2 H). − ^{13}C NMR ($CDCl_3$): δ = 26.1, 35.6, 57.8, 92.2, 123.9, 124.2, 135.8, 152.7, 160.2, 192.5. − Positive ion FAB mass spectra: *m*/*z* = 385 [M^+ + H]. − $C_{23}H_{32}N_2O_3$ (384.52): calcd. C 71.84, H 8.39, N 7.29; found C 72.49, H 8.29, N 6.78.

Ligand 4b: Following the above procedure with **6** and the usual workup, followed by chromatography with petroleum ether/EtOAc (5:1), gave **4b** (0.234 g, 65%). − $[\alpha]_D^{25}$ = −78.5 (*c* = 0.2, CH_2Cl_2). − IR (KBr): $\tilde{\nu}$ = 1681 cm^{-1}. − ^1H NMR ($CDCl_3$): δ = 1.48 (d, *J* = 6.0 Hz, 6 H), 3.34 (s, 6 H), 4.50 (q, *J* = 6.3 Hz, 2 H), 7.64−7.70 (m, 2 H), 7.89−8.10 (m, 4 H). − ^{13}C NMR ($CDCl_3$): δ = 22.1, 56.8, 80.4, 122.3, 123.9, 137.1, 153.2, 162.6, 192.5. − Positive ion FAB mass spectra: *m*/*z* = 301 [M^+ + H].

General Procedure for the Synthesis of Ligands 4c and 4d: *n*-Butyllithium in hexane (2.5 M, 1.0 mL, 2.5 mmol) was added slowly to a solution of chiral bromopyridine (1.2 mmol) in THF (5.0 mL) at −78 °C. The resulting mixture was stirred at this temperature for 2 h. Ethyl picolinate (1.2 mmol) in THF (5.0 mL) was cooled to −78 °C and added slowly to the yellowish brown solution and this mixture was then allowed to stir for 1 h. Methanol (5.0 mL) was then added and the mixture warmed to room temperature. Water (5.0 mL) and 10% HCl (5.0 mL) were then added. The layers were separated and the aqueous phase was extracted with CH_2Cl_2 (3 × 15 mL). The combined organic layers were washed with brine (50 mL) and dried with Na_2SO_4. The solvent was removed under reduced pressure and the crude product purified by column chromatography.

Ligand 4c: Following the above procedure with **5** and the usual workup, followed by chromatography with petroleum ether/EtOAc (5:1), gave **4c** (0.106 g, 31%). − $[\alpha]_D^{25}$ = +34.4 (*c* = 0.5, CH_2Cl_2). − IR (KBr): $\tilde{\nu}$ = 1686 cm^{-1}. − ^1H NMR ($CDCl_3$): δ = 0.94 (s, 9 H), 3.23 (s, 3 H), 4.02 (s, 1 H), 7.46−7.52 (m, 1 H), 7.60 (d, *J* = 8.1 Hz, 1 H), 7.84−7.92 (m, 2 H), 7.99 (d, *J* = 7.2 Hz, 1 H), 8.11 (d, *J* = 8.1 Hz, 1 H), 8.72 (d, *J* = 4.5 Hz, 1 H). − ^{13}C NMR ($CDCl_3$): δ = 26.1, 35.7, 57.7, 92.1, 123.4, 124.3, 125.2, 126.0, 136.1, 148.8, 152.7, 153.9, 160.1, 192.6. − Positive ion FAB mass spectra: *m*/*z* = 285 [M^+ + H].

Ligand 4d: Following the above procedure with **6** and the usual workup followed by chromatography with petroleum ether/EtOAc (1:1) gave **4d** (0.073 g, 25%). $[\alpha]_D^{25}$ = −78.4 (*c* = 1.0, CH_2Cl_2). − IR (KBr): $\tilde{\nu}$ = 1685 cm^{-1}. − ^1H NMR ($CDCl_3$): δ = 1.48 (d, *J* = 6.3 Hz, 3 H), 3.35 (s, 3 H), 4.52 (q, *J* = 6.0, 1 H), 7.44−7.56 (m, 1 H), 7.66 (d, *J* = 6.9 Hz, 1 H), 7.84−8.02 (m, 3 H), 8.13 (d, *J* = 7.2 Hz, 1 H), 8.68−8.82 (m, 1 H). − ^{13}C NMR ($CDCl_3$): δ = 22.1, 56.8, 80.3, 122.3, 123.9, 125.3, 126.2, 136.4, 137.1, 148.8, 153.0, 153.8, 162.9, 192.4. − Positive ion FAB mass spectra: *m*/*z* = 243 [M^+ + H].

Synthesis of Copper Complex 7: Complex **7** was synthesized by adding ligand **4a** (0.24 mmol) in methanol (5 mL) to a stirred solution of copper(II) perchlorate (0.1 mmol) in methanol (5.0 mL). The mixture was stirred overnight. The volume of the mixture was reduced to about 1 mL and ether was then added. The blue solid formed was collected (57 mg, 88% yield). − IR (KBr): $\tilde{\nu}$ = 1687 cm^{-1}. − $C_{23}H_{32}Cl_2CuN_2O_{11}$ (646.96): calcd. C 42.70, H 4.99, N 4.33; found C 43.08, H 4.78, N 3.93.

X-ray Crystallographic Study: Suitable crystals of complex **7** were grown by dissolving it in acetonitrile and allowing diethyl ether to diffuse into the solution. Diffraction data were obtained on a Rigaku AFC7R diffractometer at ambient temperature. Intensity data were corrected for Lorentz and polarization effects. Absorption corrections based on the χ-scan technique were also applied. The structure was solved by direct methods (SIR 92) and refined on *F* by least-squares analysis. The absolute structure of the molecule was determined by analysis of both configurations, including the anomalous scattering effect. Hydrogen atoms were placed in their ideal positions (C−H, 0.95 Å) and included in the structure factor calculations, but were not refined. All calculations were performed on a Silicon Graphics workstation using the TeXsan package. Crystal data and details of the measurements are collected in Table 3.

Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-140108. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44−1223/336−033; E-mail: deposit@ccdc.cam.ac.uk].

Procedure for Copper-Catalyzed Cyclopropanations: To a two-necked round bottom flask were added $Cu(OTf)_2$ (7.2 mg, 0.02 mmol), CH_2Cl_2 (2.0 mL) and the ligand (0.022 mmol) under

nitrogen. The solution was stirred at room temperature for 2 hours. The alkene (4.0 mmol) and diazoacetate (0.2 mmol) were then added and the mixture was warmed at an oil bath temperature of 40 °C for 0.5 h. A solution of diazoacetate (1.0 mmol) in CH_2Cl_2 (0.5 mL) was then added to the reaction mixture over a period of 4 hours using a syringe pump. After the addition of diazoacetate, the mixture was allowed to stir for 16 hours at room temperature. The mixture was then workedup by removing the solvent and purifying the crude product by column chromatography (hexane/EtOAc). All the cyclopropanes obtained are known compounds and were characterized by ^1H NMR, ^{13}C NMR and IR spectroscopy, and GC−MS. The enantiomeric excesses of the cyclopropanes were determined by capillary GC with Chiraldex β−PH column (30m × 0.25 mm) (entry 5) and HPLC with Daicel Chiralcel OJ column (entries 1−4, 8, 10, 13). For the substrates in entries 6, 7, 9, 11, 12 and 14, the *ee* values were determined by a previously reported procedure.[4a,17] Diastereoselectivities (*cis*/*trans* ratio) were measured by GC with an Ultra 2-crosslinked 5% PhMesilcone (25m × 0.2 mm × 0.33μm) column. Assignments of absolute configuration were by comparison with the elution order of authentic samples prepared by a literature procedure.[17]

General Procedure for Competition Reactions: To a two-necked round bottom flask were added $Cu(OTf)_2$ (3.6 mg, 0.01 mmol), CH_2Cl_2 (1.0 mL) and the ligand (0.011 mmol) under nitrogen. The solution was stirred at room temperature for 2 hours. Styrene (2.0 mmol), substituted styrene (2.0 mmol) and ethyl diazoacetate (0.1 mmol) were added and the mixture was warmed at an oil bath temperature of 40 °C for 0.5 h. A solution of diazoacetate (0.5 mmol) in CH_2Cl_2 (0.5 mL) was then added to the reaction mixture over a period of 4 hours using a syringe pump. After the addition of diazoacetate, the mixture was allowed to stir for 16 hours at room temperature. The ratios of the resulting cyclopropane esters were determined by GC.

The Ferrocenyldiphenylpropargyl Cation − A Spectroscopic Comparison Among Stabilizing Substituents and Nucleophilic Additions

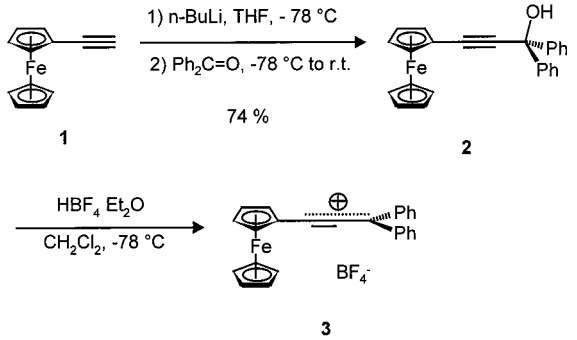
Markus Ansorge,[a] Kurt Polborn,[a] and Thomas J. J. Müller*[a]

Keywords: Ferrocene / Cations / Allenes / Pi interactions / NMR spectroscopy

The stable ferrocenyldiphenylpropargyl cation (**3**) is readily and quantitatively generated from the propargylic alcohol **2** with a slight excess of tetrafluoroboric acid in dichloromethane at −78 °C. The cationic species **3** was characterized by ^{1}H- and ^{13}C-NMR spectroscopy; nucleophilic trapping reactions gave rise to the formation of ferrocenyldiphenylallenes **9**.

Introduction

The discovery of transition metal stabilization of reactive intermediates[1] has not only initiated a remarkable theoretical interest but has also had a tremendous impact on the application of such species in synthetic chemistry, namely the synthesis of complex organic molecules.[2] Thus, carbenium ions can be stabilized by quite a number of organometallic substituents such as metallocene and half-sandwich complexes, particularly ferrocenyl, tricarbonylcyclobutadienyliron, cyclobutadienylcyclopentadienylcobalt, and benzenecarbonylchromium derivatives.[1,2] Electronically, this stabilization of cationic charges in the α-position of organometallic fragments can be rationalized by a strong d−p overlap from the transition metal centered occupied d orbitals to the vacant p_z orbital at the carbenium site, accompanied by a pronounced bending of the cationic side chain towards the metal center.[1a,1d,3] As a consequence, this strong electronic interaction manifests itself as a configurational and conformational fixation of the positively charged substituent and, ultimately, leads to highly stereoselective nucleophilic additions.



Although quite a number of substituted carbenium ions[4] have been known for some time, the investigation of the chemistry of transition metal stabilized cations with conjugated substituents, i.e. ambident electrophiles, is still in its infancy.[5] Recently, we showed that arenecarbonylchromium fragments efficiently stabilize α- and γ-propargyl cations and that α-propargyl cations can be trapped with nucleophiles to give arene complex substituted propargyl derivatives with excellent diastereoselectivity.[6] In particular, the peculiar ability to stabilize a cationic charge generated in the γ-position to the stabilizing substituent, as well as the ambident reactivity of propargyl cations giving rise either to allenes or alkynes,[7] prompted us to study the structure (UV/Vis and ^{13}C-NMR spectroscopy) and reactions of a related propargyl cation bearing the more powerful donor ferrocene as the stabilizing organometallic moiety in comparison to carbonylchromium-complexed arenes. Here, we wish to report our results on the spectroscopic characterization and nucleophilic trapping reactions of the stable ferrocenyldiphenylpropargyl cation[8] as well as on the spectroscopic comparison to the uncomplexed[9] and tricarbonylchromium-complexed[5b] phenyl analog.

Results and Discussion

Generation of the Ferrocenyldiphenylpropargyl Cation (3)

Generally, propargyl cations can be generated from the corresponding propargyl derivatives with suitable leaving groups upon treatment with Lewis or Brønsted acids, in particular, this can be achieved in a fairly facile way upon acid-mediated ionization of propargyl alcohols. According to the synthesis of highly stable perferrocenylated propargyl cations by Bildstein,[10] our strategy towards ferrocenyl-substituted γ-propargyl cations commences with the addition of ferrocenyl acetylide [by deprotonation of ethynylferrocene (**1**) with butyllithium] to benzophenone to give the propargyl alcohol **2** in good yield (Scheme 1). Treatment of the propargylic alcohol **2** with a 1.5-fold excess of tetrafluoroboric acid−diethyl ether in dichloromethane solution at −78 °C[5b] led to the formation of a deep-green solution of the persistent allenyl/propargyl cation **3** in quantitative yield (according to NMR and UV/Vis spectroscopy, vide infra) within 5 min.

Structure of the Propargyl Cation 3

As expected, and in agreement with cation generation studies of related propargyl cations,[5][9a] the ionization of the propargyl alcohol **2** to give the propargyl cation **3** results in a considerable downfield shift of almost all signals in the proton and carbon NMR spectra (Figure 1 and Figure 2, Table 1). Only the *ipso*-phenyl carbon resonance of **3** ($\delta = 141.52$, $\Delta_I = -3.35$) is shifted to high field, indicating an adjacent carbenium center. Thus, the positive charge is delocalized by resonance stabilization over the complete side chain including the substituted cyclopentadienyl ligand. Even the unsubstituted cyclopentadienyl ring of **3** (^{1}H: $\delta = 4.96$, $\Delta_I = +0.72$; ^{13}C: $\delta = 81.75$, $\Delta_I = +12.15$), and with it the ferrocenyl iron atom, experiences a significant downfield shift of the resonances, indicating their participation in the extensive charge stabilization. Most significantly, the downfield shifts of the carbon resonances of the quaternary signals of the propargyl/allenyl side chain reveal a dominant contribution of the allenylium canonical resonance structure **3B** to the stabilization of the cation generated at the γ-position as compared to the ferrocenyl moiety.

tribution of the allenylium resonance structure **4B** upon varying the α-substituent from phenyl (**5**) to the organometallic donors $(OC)_3(Ph)Cr$ (**6**) and ferrocenyl (**3**) (Table 2). More specifically, the α-, γ- and terminal *p*-phenyl resonances decrease in this order, indicating a charge delocalization shift towards the α-substituent fragment. Simultaneously, the β-resonances increase towards an "allenic" direction. As reference systems for localized cations, the benzylhydryl cation (**7**)[11] represents a model for a carbenium ion only delocalized at the C_γ position and its phenyl substituents, as depicted in structure **4A**, whereas 1,1-diphenylethene (**8**)[12] serves as a model for an allenylium structure (**4B**) assuming the γ-carbon atom does not bear a positive charge and the charge is completely stabilized at the C_α position.

A linear correlation between the C_γ resonance (carbenium or quaternary benzyl center) and the Δ_π values ($\Delta_\pi = \delta_{para} - \delta_{meta}$) of the propargyl cations **4** and the reference compounds **7** and **8** establishes the dominant influence of the α-substituent on the π-delocalization of the positive

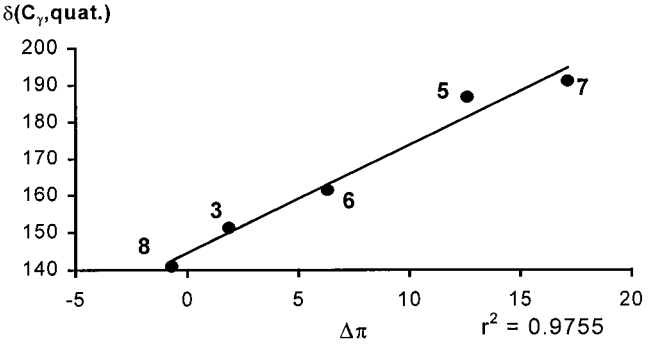

Figure 3. Correlation of the Δ_π values ($\Delta_\pi = \delta_{para} - \delta_{meta}$) and the C_γ resonance (carbenium or quaternary benzyl center) of the propargyl cations **3**, **5**, **6**, and the resonance compounds **7** and **8**

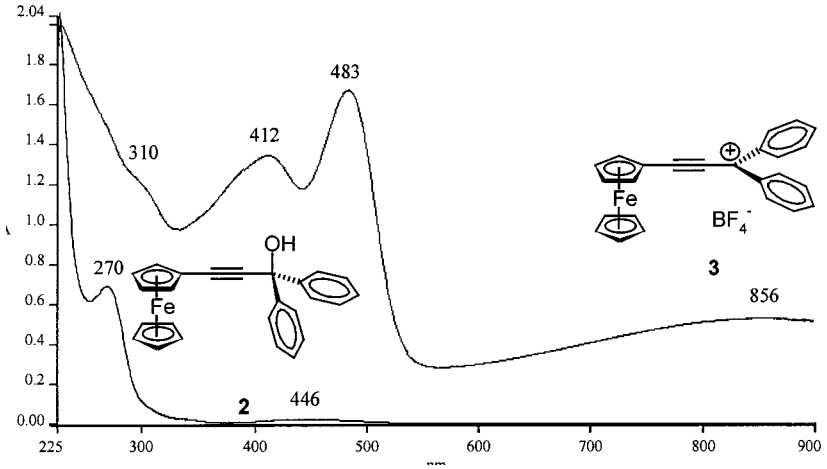
charge (Figure 3). According to a lever-rule model[5b,9a] the relative contributions of mesomeric forms to the stabilization of resonance-stabilized cations can be estimated by considering the C_γ-carbenium resonances or the *p*-phenyl carbon signal.[13] On applying the C_γ resonances the contribution of the α-substituent stabilization increases from 10 (**5**) to 59 (**6**) to 79% (**3**), whereas consideration of the *para* resonances gives rise to a 29 (**5**), 60 (**6**), and 78% (**3**) participation of the allenylium canonical structure **8B** in the electronic ground state.

Ionization with tetrafluoroboric acid−diethyl ether of a dichloromethane solution of **2** at −70 °C leads to a color change from yellow/orange to deep green. This change can be monitored by following the appearance of long-wavelength absorption bands with maxima at 310 (sh), 412, 483, and 856 nm (Figure 4) by UV/Vis spectroscopy. According to calculations on an MM2-optimized structure of **2** using the ZINDO/CI formalism with INDO/1 parameters[14] the absorptions at 856 nm (calcd. 688 nm; iron-centered $d_{x^2-y^2}$ orbital HOMO to the localized LUMO of the propargyl moiety), at 483 nm (calcd. 484 nm; d_{z^2} orbital HOMO-2 to the LUMO) and at 412 nm (calcd. 389 nm, d_{xz} orbital HOMO-3 to LUMO and calcd. 403 nm, d_{z^2} orbital HOMO-2 to LUMO) and at 310 nm (sh) [calcd. 326 nm, bound Cp ring (HOMO-8) to propargyl fragment (LUMO)



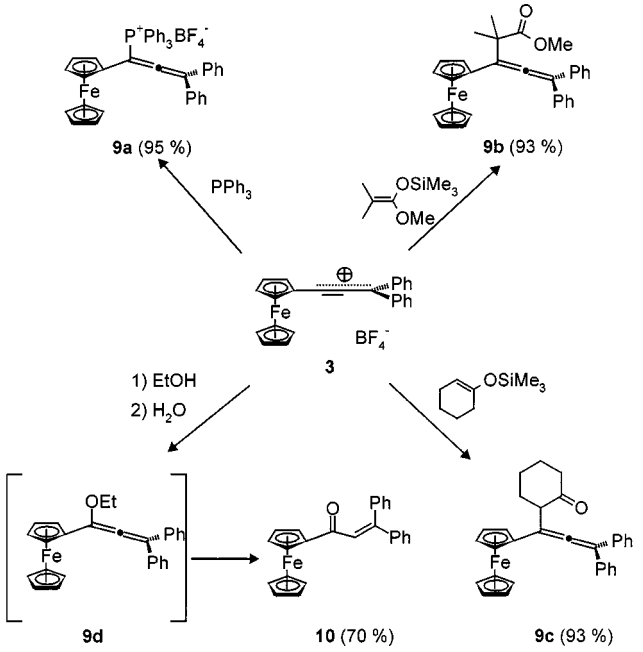


Figure 4. UV/Vis spectra of **2** (λ_{max} at 270 and 446 nm) and **3** (λ_{max} at 310sh, 412, 483, and 483 nm) at −70 °C (dichloromethane)

π-π* transition and calcd. 311 nm, from the phenyl rings to the propargyl fragment (HOMO-10 to LUMO)] are readily reproduced.

Nucleophilic Trapping Reactions of 3

The propargyl cation **3** can be trapped with different nucleophiles to furnish the allenes **9** in good to excellent yields (Scheme 2). Most interestingly, if ethanol is used as the nucleophile only the hydrolysis product, i.e. the enone **10**, can be isolated (70% yield). In significant contrast to the cations **5** and **6**, where the kinetically controlled ethanol attack gives rise to the formation of the corresponding propargyl ethers,[5b,15] the regioselectivity of the nucleophilic attack of ethanol on **3** is reversed to the α-position, which results in the generation of the allene intermediate **9d**. The increasing contribution of the allenylium canonical structure **4B** (vide supra) to the electronic ground state of **3** can be interpreted as an increase of the orbital coefficient at the α-position in the LUMO, the relevant orbital for kinetically controlled nucleophilic additions to the cations **4**.

Scheme 2

Due to the pronounced basicity the ferrocenyl-substituted allenes **9** tend to form ferrocenylallyl cations reversibly.[16] Only if the basicity is modulated by an electron-withdrawing group (**9a**), or if acid-sensitive nucleophiles, such as silyl enol ethers or silyl ketene acetals, successfully trap excess protons, by acting as proton sponges, can the formation of allyl cations be prevented.

The structural assignments of the allenes **9a**−**c** are fully supported by NMR, IR, elemental analysis and by an X-ray crystal structure analysis of **9b** (Figure 5, Table 3).[17] In the ^{1}H-NMR spectra the signals of the ferrocene protons appear between δ = 3.92 and 4.34. Most characteristically,

the ^{13}C-NMR signals of the central allene carbon atoms are found between δ = 204.6 and 216.7 depending on the electronic nature of the substituent at the α-position. According to the X-ray crystal structure analysis (Figure 5) of the allene **9b**, the allene moiety is linear [C(11)−C(12)−C(13): 175°] and the allenic double bond lengths [C(11)−C(12): 1.31 Å and C(12)−C(13): 1.32 Å] lie within the expected range. Interestingly, the cyclopentadienyl ring and the allene fragment are arranged in an almost coplanar manner, although the ferrocenyl substituent is considered to be sterically bulky.

Conclusion

Ferrocene stabilizes propargyl cations generated at the γ-position to a large extent by delocalizing the positive charge evenly over the iron center and the unsubstituted cyclopentadienyl ring, as shown by NMR spectroscopy of the cation **3**. Therefore, the increasing contribution of the allenylium canonical structures in three different organic/organometallic propargyl cations **4** can be detected by carbon NMR spectroscopy and compared. For the ferrocenyl-substituted system a regioselectivity shift for the nucleophilic attack of ethanol from the propargyl to the allenyl position is the most significant difference between the phenyl and $(OC)_3(Ph)Cr$ analogs. Thus, organometallic substituents not only stabilize ambident electrophiles such as propargyl cations but also could allow a fine tuning of the regioselectivity of nucleophilic additions.

Experimental Section

All reactions involving ferrocene complexes were carried out in flame-dried Schlenk flasks under nitrogen by using septum and syringe techniques. Solvents were dried and distilled according to standard procedures.[18] − Column chromatography: Silica gel 60 (0.063−0.2 mm/70−230 mesh, Firma Merck Darmstadt). − TLC: Silica gel plates (60 F_{254} Merck, Darmstadt). − Melting points (uncorrected values): Reichert−Jung Thermovar. − Ethynylferrocene was synthesized according to a procedure of Rosenblum.[19] All other reagents were purchased from Merck, Aldrich, or Fluka, and used without further purification. − ^{1}H- and ^{13}C-NMR spectra: Bruker WM 300, Bruker AC 300, Bruker ARX 300 or Varian VXR 400S; [D_6]DMSO and [D_2]dichloromethane. − IR: Perkin−Elmer FT-IR spectrometer 1000 or Perkin−Elmer FT-IR Paragon 1000 PC. The samples were pressed into KBr pellets and the spectra recorded on NaCl plates. − UV/Vis: Beckman DK-2a, Beckman UV 5240, or Perkin−Elmer model Lambda 16; J&M TIDAS (transputer integrated diode array spectrometer) with a Hellma low-temperature quartz probe (UV/Vis cation characterization). − MS: Finnigan MAT 311-A/100MS, Finnigan MAT 90, and MAT 95Q. − Elemental analyses were carried out in the Microanalytical Laboratories of the Institut für Organische Chemie, Ludwig-Maximilians-Universität München.

3-Ferrocenyl-1,1-diphenylprop-2-yne-1-ol (2): To a cooled solution (−78 °C) of 1.00 g (4.90 mmol) of ethynylferrocene (**1**) in 40 mL of THF was added dropwise 3.20 mL (5.10 mmol) of a 1.6 M solution of butyllithium in hexanes over a period of 1 min. The reaction mixture was stirred for a further 60 min. To this reaction mixture was added dropwise a solution of 0.89 g (4.90 mmol) of benzophenone in 5 mL of THF and, after the addition, the mixture was allowed to warm up to room temperature over a period of 60 min. After the addition of 20 mL of water and extraction of the aqueous phase with diethyl ether (3 × 50 mL), the combined organic phases were dried with magnesium sulfate. After evaporation of the solvents, the residue was purified by chromatography on silica gel with a gradient of diethyl ether/pentane (1:10 → 1:1) to afford 1.42 g (74%) of the propargylic alcohol **2** as an orange crystalline product, m.p. 90−92 °C. − ^{1}H NMR ([D_6]DMSO, 300 MHz): δ = 4.25 (s, 5 H), 4.29 (d, *J* = 1.7 Hz, 2 H), 4.53 (dd, *J* = 1.7 Hz, 2 H), 6.74 (s, 1 H), 7.22 (m, 2 H), 7.33 (m, 4 H), 7.60 (m, 4 H); (CD_2Cl_2, 400 MHz): δ = 3.29 (s, 1 H), 4.24 (s, 5 H), 4.25 (m, 2 H), 4.52 (m, 2 H), 7.28 (t, *J* = 7.3 Hz, 2 H), 7.36 (dd, *J* = 7.3 Hz, 4 H), 7.68 (d, *J* = 7.8 Hz, 4 H). − ^{13}C NMR ([D_6]DMSO, 75 MHz): δ = 64.5 ($C_{quat.}$), 69.0 (CH), 69.8 (CH), 71.3 (CH), 73.4 ($C_{quat.}$), 84.6 ($C_{quat.}$), 89.5 ($C_{quat.}$), 125.9 (CH), 127.2 (CH), 128.2 (CH), 146.8 ($C_{quat.}$). − ^{13}C NMR (CD_2Cl_2, 100 MHz): δ = 63.2 ($C_{quat.}$), 68.9 (CH), 69.6 (CH), 71.2 (CH), 74.1 ($C_{quat.}$), 85.6 ($C_{quat.}$), 86.8 ($C_{quat.}$), 125.1 (CH), 127.4 (CH), 128.1 (CH), 144.9 ($C_{quat.}$). − MS (70 eV, EI); *m*/*z* (%): 392 [M^+] (61), 327 [$M^+ - C_5H_5$] (13), 254 [M^+ − CpFeOH] (31), 210 [$M^+ - Ph_2CO$] (100), 182 [Ph_2CO^+] (52), 152 [$Ph_2CO^+ - CH_2O$] (18), 105 [$PhCO^+$] (70), 77 [Ph^+] (27), 56 [Fe^+] (8). − IR (KBr): $\tilde{\nu}$ = 2230 cm^{-1}, 1627, 1599, 1489, 1449, 1408, 1339, 1264, 1194, 1178, 1165, 1156, 1101, 1061, 1028, 998, 922, 903, 885, 843, 818, 772, 753, 715, 701, 641, 630, 594, 542, 519, 498, 488, 451, 415. − UV/Vis (DMSO): λ_{max} (ε) = 271 nm (8900), 445 (3200). − $C_{25}H_{20}FeO$ (392.28): calcd. Preparation of the Propargyl Cation 3 for the NMR-Spectroscopic Characterization: To a solution of 20 μL of tetrafluoroboric acid−diethyl ether in 0.3 mL of CD_2Cl_2, placed in a nitrogen-flushed NMR tube capped with a rubber septum, was added a solution of 25 mg of **2** in 0.4 mL of CD_2Cl_2 at −78 °C. The NMR tube with the dark green solution was then quickly transferred to the NMR spectrometer (precooled to −70 °C).

Generation of the Propargyl Cation 3 and Nucleophilic Trapping Reaction (General Procedure): To a cooled solution (−78 °C) of 52 μL (0.32 mmol) of tetrafluoroboric acid (54% in diethyl ether) in 10 mL of dichloromethane was added dropwise a solution of 100 mg (0.25 mmol) of **2** in 5 mL of dichloromethane. After stirring for 60 min, a solution of 1.0 mmol of the corresponding nucleophile in 5 mL of dichloromethane was added. The mixture was then allowed to warm up to room temperature. After the addition of 10 mL of water, the solution was extracted with diethyl ether (**9a**: dichloromethane) (3 × 50 mL) and the combined organic phases were dried with magnesium sulfate. Evaporation of the solvents under reduced pressure furnished the products **9** (or **10**), which were recrystallized from diethyl ether/pentane or dichloromethane/diethyl ether to give good to excellent yields.

1-Ferrocenyl-3,3-diphenyl-1-(triphenylphosphonium)propa-1,2-diene Tetrafluoroborate (9a): According to the GP with 131 mg (0.50 mmol) of triphenylphosphane to give 170 mg (95%) of **9a**. Red crystals, m.p. 216−218 °C (dichloromethane/diethyl ether). − ^{1}H NMR (CD_2Cl_2, 300 MHz): δ = 3.98 (s, 5 H), 4.15 (m, 2 H), 4.34 (m, 2 H), 7.04−7.88 (m, 25 H). − ^{13}C NMR (CD_2Cl_2, 75 MHz): δ = 70.2 (CH), 70.2 (CH), 70.4 (CH, $J_{P,C}$ = 3.3 Hz), 86.7 ($C_{quat.}$), 93.7 ($C_{quat.}$, $J_{P,C}$ = 86.2 Hz), 116.9 ($C_{quat.}$), 118.1 ($C_{quat.}$, $J_{P,C}$ = 88.2 Hz), 128.4 (CH), 129.7 (CH), 129.9 (CH), 130.6 (CH, $J_{P,C}$ = 12.6 Hz), 132.7 ($C_{quat.}$), 134.5 (CH, $J_{P,C}$ = 9.9 Hz), 136.0 (CH, $J_{P,C}$ = 2.6 Hz), 216.8 ($C_{quat.}$, $J_{P,C}$ = 5.9 Hz). − MS (FAB), *m*/*z*: 637 [$M^+ - BF_4^-$], 375 [$M^+ - BF_4^- - PPh_3$]. − IR

(KBr): $\tilde{\nu}$ = 3435 cm^{-1}, 3083, 3057, 1914, 1818, 1627, 1596, 1586, 1490, 1484, 1439, 1411, 1342, 1315, 1283, 1226, 1189, 1160, 1108, 1083, 1056, 998, 945, 923, 901, 825, 772, 754, 728, 717, 695, 626, 607, 574, 551, 533, 521, 497, 439. − UV/Vis (DMSO): λ_{max} (ε) = 275 nm (18490), 374 (1260), 470 (790). − $[C_{43}H_{34}FeP^+BF_4^-]$ (724.36): calcd. C 71.30, H 4.73; found C 71.37, H 4.47.

Methyl 3-Ferrocenyl-2,2-dimethyl-5,5-diphenylpenta-3,4-dienecarboxylate (9b): According to the GP with 0.20 mL (1.0 mmol) of 1-methoxy-2,2-dimethyl-1-trimethylsiloxyethene to give 108 mg (93%) of **9b**. Orange crystals, m.p. 132−133 °C. Crystals suitable for X-ray structure analysis were obtained by slow crystallization from a concentrated DMSO solution of **9b**. − ^{1}H NMR ([D$_6$]DMSO, 300 MHz): δ = 1.42 (s, 6 H), 3.63 (s, 3 H), 3.92 (s, 5 H), 4.22 (m, 4 H), 7.42−7.44 (m, 10 H). − ^{13}C NMR ([D$_6$]DMSO, 75 MHz): δ = 26.1 (CH_3), 45.5 ($C_{quat.}$), 52.4 (CH_3), 67.4 (CH), 68.2 (CH), 69.3 (CH), 80.5 ($C_{quat.}$), 112.4 ($C_{quat.}$), 112.5 ($C_{quat.}$), 127.7 (CH), 128.0 (CH), 128.9 (CH), 136.2 ($C_{quat.}$), 176.3 ($C_{quat.}$), 204.7 ($C_{quat.}$). − MS (70 eV, EI); *m/z* (%): 476 [M^+] (100). − IR (KBr): $\tilde{\nu}$ = 3430 cm^{-1}, 3116, 3100, 3087, 3061, 2992, 2947, 1723, 1636, 1599, 1491, 1464, 1442, 1432, 1412, 1379, 1359, 1256, 1191, 1145, 1106, 1074, 1052, 1031, 1013, 1002, 973, 916, 867, 847, 823, 772, 762, 732, 695, 636, 624, 609, 601, 586, 505, 478. − UV/Vis (DMSO): λ_{max} (ε) = 283 nm (15100), 458 (2800). − $C_{30}H_{28}FeO_2$ (476.39): calcd. C 75.63, H 5.92; found C 75.84, H 6.07.

2-(1-Ferrocenyl-3,3-diphenylpropa-1,2-dienyl)cyclohexan-1-one (9c): According to the GP with 0.19 mL (1.0 mmol) of 1-trimethylsiloxycyclohexene to give 110 mg (93%) of **9c**. Orange crystals, m.p. 107−109 °C. − ^{1}H NMR ([D$_6$]DMSO, 300 MHz): δ = 1.64−2.33 (m, 9 H), 4.08 (m, 5 H), 4.20−4.34 (m, 4 H), 7.26−7.46 (m, 10 H). − ^{13}C NMR ([D$_6$]DMSO, 75 MHz): δ = 24.2 (CH_2), 27.6 (CH_2), 33.3 (CH_2), 41.6 (CH_2), 52.4 (CH), 66.1 (CH), 66.9 (CH), 68.6 (CH), 68.6 (CH), 69.1 (CH), 82.5 ($C_{quat.}$), 106.8 ($C_{quat.}$), 112.8 ($C_{quat.}$), 127.5 (CH), 127.6 (CH), 128.0 (CH), 128.0 (CH), 128.7 (CH), 128.8 (CH), 136.1 ($C_{quat.}$), 136.6 ($C_{quat.}$), 205.0 ($C_{quat.}$), 209.5 ($C_{quat.}$). − MS (70 eV, EI); *m/z* (%): 472 [M^+] (100). − IR (KBr): $\tilde{\nu}$ = 3435 cm^{-1}, 3080, 3054, 3022, 2934, 2860, 1706, 1630, 1597, 1491, 1447, 1411, 1380, 1349, 1336, 1310, 1296, 1246, 1197, 1156, 1126, 1105, 1072, 1060, 1028, 1001, 962, 920, 900, 874, 818, 769, 740, 696, 625, 608, 551, 505, 478, 452. − UV/Vis (DMSO): λ_{max} (ε) = 281 nm (18320), 446 (4530). − $C_{31}H_{28}FeO$ (472.40): calcd. C 78.81, H 5.97; found C 78.80, H 5.85.

1-Ferrocenyl-3,3-diphenylprop-2-en-1-one (10): According to the GP with 100 mg (2.1) of ethanol to give 70 mg (70%) of **10**. Red crystals, m.p. 75−78 °C. − ^{1}H NMR ([D$_6$]DMSO, 300 MHz): δ = 4.24 (s, 5 H), 4.56 (m, 2 H), 4.81 (m, 2 H), 7.08 (s, 1 H), 7.12−7.46 (m, 10 H). − ^{13}C NMR ([D$_6$]DMSO, 75 MHz): δ = 69.6 (CH), 69.8 (CH), 72.5 (CH), 81.1 ($C_{quat.}$), 124.1 (CH), 127.7 (CH), 127.9 (CH), 128.3 (CH), 128.7 (CH), 129.2 (CH), 129.4 (CH), 139.5 ($C_{quat.}$), 141.3 ($C_{quat.}$), 151.0 ($C_{quat.}$), 193.4 ($C_{quat.}$). − MS (70 eV, EI), *m/z* (%): 392 [M^+] (100). − IR (KBr): $\tilde{\nu}$ = 3435 cm^{-1}, 3082, 2927, 1647, 1570, 1490, 1443, 1411, 1376, 1278, 1232, 1156, 1106, 1076, 1029, 1000, 892, 823, 788, 769, 725, 698, 582, 527, 500, 485. − UV/Vis (DMSO): λ_{max} (ε) = 300 nm (12940), 377 (2400), 490 (14450). − $C_{25}H_{20}FeO$ (392.28): calcd. C 76.54, H 5.13; found C 76.67, H 5.21.

Acknowledgments

The financial support of the Fonds der Chemischen Industrie, Deutsche Forschungsgemeinschaft and the Dr.-Otto-Röhm-Gedächtnisstiftung is gratefully acknowledged. We wish to express our appreciation to Prof. H. Mayr for his generous support and the possibility of using his J&M UV/Vis spectrometer. We cordially thank Dr. David S. Stephenson for recording the low-temperature NMR spectra.

A New Diphosphane Derived from Carbohydrates as an Effective Ligand for Asymmetric Hydrogenation

Oscar Pàmies,[a] Gemma Net,[a] Aurora Ruiz,*[a] and Carmen Claver[a]

Keywords: Asymmetric hydrogenation / Phosphanes / Chiral ligands / Carbohydrates / Rhodium

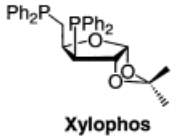
A novel chiral diphosphane derived from D-(+)-xylose, 3,5-dideoxy-1,2-*O*-isopropylidene-3,5-bis(diphenylphosphanyl)-α-D-xylofuranose (Xylophos), and its cationic cyclooctadiene rhodium(I) complex have been synthesised and characterised. Excellent results were obtained with Xylophos in the asymmetric Rh-catalysed hydrogenation of acrylic acid derivatives (*ee*'s up to 98%). Hydrogenation results are explained in terms of the structure of the precatalyst $[Rh(cod)(Xylophos)]^+BF_4^-$.

Introduction

The use of chiral metal complexes as homogeneous molecular catalysts is one of the most powerful strategies in asymmetric synthesis.[1] A careful molecular design of the chiral ligands is particularly important for efficient asymmetric catalysis. Although much progress has been made in this area, and despite the large amount of relevant literature,[2] there is no straightforward way of predicting, a priori, the type of ligand required to achieve high levels of enantioselectivity.[3] The design of new ligands is still often the result of empirical methodology.

Since the work of Kagan with Diop[4] and Knowles with Dipamp,[5] many optically active chelating diphosphanes have been successfully used in transition-metal-based asymmetric catalysis.[1,2,6] In a chiral diphosphane, chirality can occur within the tethering carbon chain between the two phosphanes or at the phosphorus atoms. In spite of the early success achieved with Dipamp,[5] bisphosphanes containing stereogenic phosphorus atoms have been outnumbered by ligands based on PPh_2 groups attached to C-chiral backbones.[2] One advantage of these C-chiral diphosphanes is that their design makes use of the great abundance of naturally occurring chiral compounds. Surprisingly, although carbohydrates are easily available and results with bisphosphinites derived from glucose are excellent,[3,7] the number of diphosphanes derived from these kinds of natural compounds is rather low.[8]

Following our previous work on ligands derived from furanoses,[9] we report here the synthesis of a new diphosphane derived from xylofuranose, Xylophos (Figure 1), the solution structure of the precatalyst $[Rh(cod)(Xylophos)]^+BF_4^-$ and its use in the asymmetric Rh-catalysed hydrogenation of alkenes. An important feature of this new ligand is its lack of C_2 symmetry. It is commonly held that C_2-symmetric diphosphane ligands are endowed with superior properties in catalysis, principally because of the fewer competing diastereomeric intermediates.[1,10] Nevertheless, ligands without C_2 symmetry can eventually match the intermediates better and lead to very good enantioselective discriminations.[3,6i–6l,7,11]



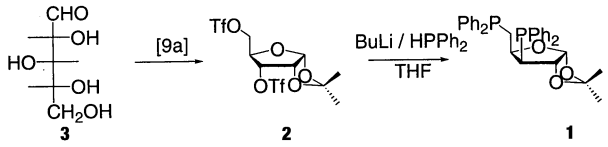


Figure 1. 3,5-Dideoxy-1,2-*O*-isopropylidene-3,5-bis(diphenylphosphanyl)-α-D-xylofuranose, Xylophos (**1**)

The related bisdiphenylphophinite,[12,13] 5-diphenylphosphane-3-diphenylphosphinite,[13] diphosphite,[9d,14] 5-diphenylphosphane[13] and 5-phosphane-3-methoxy[8a,15] molecules with the same protected xylofuranose backbone have already been described and applied to asymmetric catalysis with varying degrees of success.

Results and Discussion

Synthesis and Characterisation of Xylophos

The new diphosphane Xylophos (**1**) was obtained by adding a slight excess of lithium diphenylphosphide, in THF solvent at room temperature, to 1,2-*O*-isopropylidene-3,5-di-*O*-trifluoromethansulfonyl-D-ribofuranose (**2**), which had been prepared from commercially available D-(+)-xylose **3**[9a] (Scheme 1). It was isolated in high yield (75%) by flash chromatography under argon as a white crystalline solid, stable in the air in the solid state and slightly stable in solution.

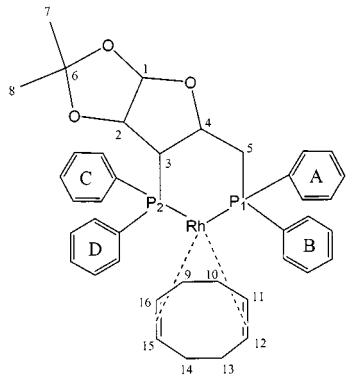
Xylophos (**1**) was characterised by elemental analysis, ^{1}H, ^{13}C and ^{31}P NMR spectroscopy and mass spectrometry. The signals of each of the phosphorus nuclei in the ^{31}P NMR spectrum are doublets, at $\delta = -27.4$ and -21.1, respectively, with $^{4}J(P,P) = 8.0$ Hz. Mass spectrometry shows the highest ion at $m/z = 526$, which corresponds to the molecular weight of Xylophos.

Synthesis and Characterisation of the Rh^{I} Complex

The reaction of Xylophos with $[Rh(cod)_2]^+BF_4^-$ in dichloromethane solution proceeded with the displacement of one cycloocta-1,5-diene ligand to afford the cationic complex $[Rh(cod)(Xylophos)]^+BF_4^-$ (**4**) (Scheme 2).

Scheme 2. Synthesis of the complex $[Rh(cod)(xylophos)]^+BF_4^-$ (**4**)



$[Rh(cod)(Xylophos)]^+BF_4^-$ was isolated as a yellow, moderately air-stable powder by adding diethyl ether. The elemental analysis of C and H matches the stoichiometry $[Rh(cod)(Xylophos)]_n^+(BF_4)_n^-$. The FAB mass spectrum shows the highest ion at $m/z = 737$, corresponding to the cationic mononuclear species. The IR spectrum shows a strong band between 1090 and 1050 cm^{-1} and a medium intensity band at 450 cm^{-1}, which are characteristic of the non-coordinated BF_4^- anion.[16]

Further details of the structure of the cation $[Rh(cod)(Xylophos)]^+$ were obtained by ^{1}H, ^{13}C and ^{31}P NMR spectroscopy. The spectral assignments (Table 1 and 2 and Experimental Section) were based on the information obtained by $^{1}H/^{1}H$ COSY, $^{13}C/^{1}H$ and $^{31}P/^{1}H$ correlation measurements in combination with the $^{1}H/^{1}H$ NOESY results. Special attention has been paid to conformational analysis of the six-membered chelate ring. This is directly related to the spatial orientation of the phenyl groups, which have been linked with the enantioselective efficiency of the catalysts.

Vicinal $^{1}H,^{1}H$ couplings in the sugar ring are in the typical range (0−7 Hz) of furanoside ring systems (Table 1)[17] and are similar to those found in other ligands derived from the same protected xylofuranose ring.[9] The coupling constant ^{3}J(1-H, 2-H) is larger than 3.5 Hz, which is consistent with the *cis* disposition of these protons in the 1,2-protected xylofuranose.[17]

In the ^{31}P NMR spectrum eight lines were obtained due to the ^{31}P, ^{31}P and ^{31}P, ^{103}Rh couplings (ABX system) (see Experimental Section). The signals of the phosphorus atoms P-1 and P-2 were assigned from the $^{31}P/^{1}H$ correlation spectrum, using the vicinal couplings between P-1/5-H and P-2/3-H, and the long range couplings between P-1/1-H and P-2/2-H (See supporting information).

Table 1. ^{1}H NMR assignments (500 MHz) of compound **4** in $CDCl_3$ solution (except aromatic protons)

Atom	δ (ppm)	Atom	δ (ppm)	Coupling constants (Hz)
1-H	5.27 (dd)	9-H	2.05 (m, 2 H)	^{3}J(1-H,2-H) = 4.0
2-H	4.71 (dd)	10-H	2.13 (m, 2 H)	^{x}J(1-H,P-1) = 1.8[a]
3-H	2.71 (dd)	11-H	4.12 (m)	^{3}J(2-H,P-2) = 6.0
4-H	4.22 (m)	12-H	4.83 (m)	^{3}J(3-H,4-H) = 6.5

				^{x}J(5′-H,Rh) = 3.0[a]

[a] Probably through space.

Table 2. Selected ^{1}H NMR spectroscopic data (500 MHz) of the aromatic part of compound **4** in $CDCl_3$ solution

Phenyl	δ (ppm) *o*	*m*	*p*	*J* (Hz) *J*(P, H-*o*)	*J*(H-*o*,H-*m*)	*J*(H-*o*,H-*p*)
A (P_1)	8.05	7.73	7.73	6.2	4.5	2.7
B (P_1)	7.73	7.51	7.51	5.8	4.5	1.2
C (P_2)	8.11	7.75	7.75	6.2	4.5	2.7
D (P_2)	7.35	7.56	7.56	6.1	4.3	2.4

The ^{1}H NMR signals of the four phenyl groups were assigned in pairs to the phosphorus atoms, P-1 and P-2, according to the $^{31}P/^{1}H$ correlation spectrum (See supporting information).

The signals at $\delta = 8.05$ (2 H) and 7.24 (2 H) were therefore assigned to the *ortho* protons of the phenyl groups (A and B) attached to the phosphorus atom P-1, whereas the *ortho* protons of the phenyl groups attached to P-2 (C and D) were found at $\delta = 8.11$ (2 H) and 7.36 (2 H). By means of a $^{1}H/^{1}H$ COSY experiment (See supporting information), it was also possible to assign the *meta*- and *para* protons of the corresponding phenyl groups (Table 2). It is interesting to note that, in the ^{1}H NMR spectra, the proton signals of the phenyl groups A and C appear as a symmetric group at room temperature. This could indicate that all of these protons, plus the two phosphorus atoms and the rhodium atom, are in the same spin system, giving a second order spectrum.

A 2D-NOESY experiment was performed to obtain a spatial orientation of phenyl groups A−D. In the 2D-

NOESY spectrum of **4**, strong cross-peaks of the furanose protons with the *ortho*-protons were found for only two of the four phenyl groups, which are attached to different phosphorus atoms (P-1 and P-2). The other two phenyl groups have strong cross peaks with the olefinic protons of the cod. This means that only two phenyl moieties are spatially close to the furanoside ring: the phenyl with the *ortho* protons at δ = 8.05 (A), which correlate well with sugar proton 1-H, and the phenyl at δ = 8.11 (C), which correlates with sugar proton 2-H. The *ortho* protons at δ = 7.24 (B) correlate with proton 12-H and the *ortho* protons at δ = 7.36 (D) correlate with proton 15-H and even with 3-H.

The ^{13}C NMR data are given in the Experimental Section. The absolute assignment of these signals was made possible by the $^{13}C/^{1}H$ correlation spectrum. For the furanoside ligand, the signals of the carbons C-2 and C-4 appear as doublets due to coupling with one of the phosphorus atoms, while the carbon atoms C-3 and C-5 appear as doublets of doublets due to coupling with both phosphorus atoms. In the aromatic part of the ^{13}C NMR spectra, the phenyl carbon atoms give well-separated signals, except for the quaternary carbon atoms, which could not be assigned absolutely. The olefinic carbons appear as a doublet due to the ^{13}C, ^{31}P coupling with the respective phosphorus atoms. The geminal couplings ^{2}J(P,C-*o*) of the phenyl moieties A and C are greater than those of moieties B and D, which indicates an axial spatial arrangement of the phenyls A and C.[18]

Examination of models of the different theoretically possible conformations of the six-membered chelate ring showed that only in the chair (Figure 2) and the twist-chair conformations are two axial phenyl groups close to the furanoside protons H-1 and H-2, whereas in the boat conformation (Figure 2) the axial phenyl groups (A and C) are located *trans* to the furanoside ring. The twist conformations δ and λ (Figure 2) can definitely be excluded because only one phenyl group is spatially close to the furanoside ring. Moreover, the λ twist conformation is inaccessible because of the strong steric hindrance between the axial phenyl group (attached to P-1) and the furanoside ring. For the different conformations, molecular mechanics calculations (CERIUS 2) showed that the λ-twist-chair conformation is the most stable (Figure 3). This conformation, which is compatible with the NMR spectroscopic data, follows from the distortion in the chair conformation due to the steric hindrance between both axial phenyl groups.

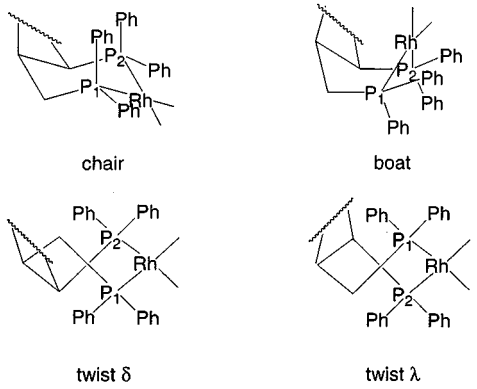

Figure 2. Schematic illustration of the usual possible conformations adopted by the six- membered chelate ring in **4**

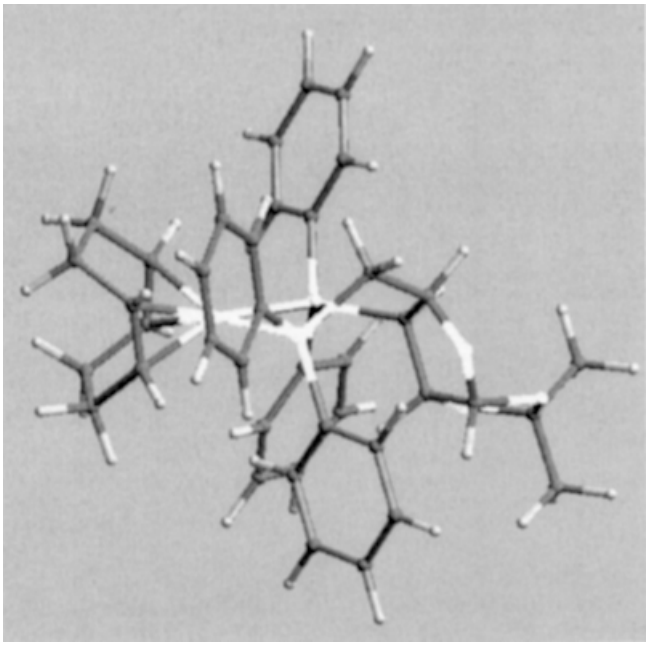

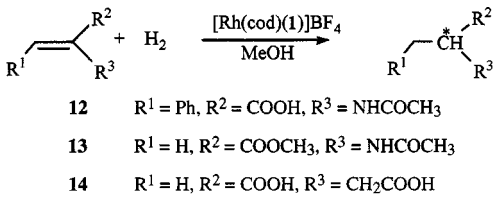

Figure 3. Minimised structure of $[Rh(cod)(xylophos)]^{+}BF_4^{-}$ (**4**) (CERIUS2)

The olefinic protons 11-H, 12-H, 15-H and 16-H of the cyclo-1,5-octadiene appear in the ^{1}H NMR spectrum as separate, broad signals, while the signals of the methylenic protons 9-H, 10-H, 13-H and 14-H are only partially resolved (Table 1). Only the signals of the two olefinic protons which are shifted downfield are well resolved, i.e. 12-H and 15-H. The relative assignment of the proton signals of the cod ring was made according to the $^{1}H/^{1}H$ COSY spectrum. The absolute assignment of these signals was possible from the NOESY spectrum. All carbon atoms of cyclo-1,5-octadiene are well resolved. The olefinic carbon atoms therefore appear as doublets of doublets due to the ^{13}C, ^{31}P and ^{13}C, ^{103}Rh couplings. The signals of only two methylenic carbons (C-13 and C-14) appear as doublets due to the ^{13}C, ^{31}P couplings, while the other two, which are significantly shifted downfield, appear as singlets.

Hydrogenation of Prochiral Olefins

The mononuclear cationic rhodium complex **4** with Xylophos was used in the asymmetric hydrogenation of prochiral olefins at 1 bar H_2 (Scheme 3). Conversion and enantioselectivities are shown in Table 3.

12 R^1 = Ph, R^2 = COOH, R^3 = $NHCOCH_3$

13 R^1 = H, R^2 = $COOCH_3$, R^3 = $NHCOCH_3$

14 R^1 = H, R^2 = COOH, R^3 = CH_2COOH

Scheme 3. Asymmetric hydrogenation of prochiral olefins

Table 3. Hydrogenation results using $[Rh(cod)(xylophos)]^+BF_4^-$ (**4**)[a]

Entry	Substrate	*t* (h)	% Conv.	% *ee*
1	**12**[b]	6	100	89 (*S*)
2	**13**[c]	6	100	91 (*S*)
3	**13**[c]	4	98	91 (*S*)
4	**13**[c]	1	50	92 (*S*)
5	**13**[c][d]	1	11	98 (*S*)
6	**14**[b]	6	100	62 (*R*)

[a] [Rh]/substrate = 1:100; substrate = 1 mmol; solvent = methanol (6 mL); T = 20 °C; P = 1 atm. − [b] Conversion measured by ^1H NMR and enantiomeric excesses determined by polarimetry. − [c] Conversions and enantiomeric excesses measured by GC. − [d] T = 0 °C.

Reaction of the prochiral olefin *Z*-α-acetamidocinnamic acid (**12**) afforded a quantitative yield of hydrogenation product with 89% *ee* at room temperature (entry 1). As with (*R*)-Prophos,[19] (*S*,*S*)-Diop[20] and (*R*,*R*)-Dipamp,[5b,21] the (*S*)-isomer of *N*-acetylphenylalanine was obtained. The sense of the asymmetric induction in this reaction has been widely studied and is correlated to the skewing of the ligand with respect to the P−Rh−P plane.[1e,3d,3e,11d] According to these studies, the formation of (*S*)-*N*-acetylphenylalanine indicates a λ-type array of the Rh-diphosphane chelate ring, which agrees with the structure determined by NMR spectroscopy (see NMR characterisation, above).

The related ester methyl 2-acetoamidoacrylate (**13**) gave similar results at room temperature (91% *ee*) (entries 2−4). Decreasing the temperature to 0 °C (entry 5) substantially improved the enantioselectivity (98% *ee*). These results are similar to those reported for such successful diphosphanes as Chiraphos, Dipamp, Diop, Binap, Bppfa, Duphos, Josiphos, Phanephos and Ferriphos.[22−25]

When itaconic acid (**14**) was used as the substrate, the enantioselectivity was significantly lower (62%) (entry 6). This agrees with the fact that diphosphanes which form five- or six-membered ring complexes are somewhat less tolerant in terms of substrate acceptability than the less-rigid seven-membered chelate rings e.g. 63% *ee* and 60% *ee* were obtained using the five-membered chelating ring Norphos[26] and the six-chelate ring Dioxop,[8a] respectively, while *ee*′s of up to 94% were obtained in the hydrogenation of **12**.[22]

Experimental Section

General Techniques: All syntheses were performed by standard Schlenk techniques under a nitrogen or argon atmosphere. The complex $[Rh(cod)_2]BF_4$ [16a] and 1,2-*O*-isopropylidene-3,5-di-*O*-trifluoromethan-sulfonyl-α-D-ribofuranose[9a] were prepared by previously described methods. Solvents were purified by standard procedures. All other reagents were used as purchased. Elemental analyses were performed on a Perkin−Elmer 240 B instrument. ^1H, $^{13}C\{^1H\}$ and $^{31}P\{^1H\}$ NMR spectra were recorded on a Variant Gemini 300 MHz or 500 MHz Spectrometer. Chemical shifts are relative to $SiMe_4$ (^1H and ^{13}C) as internal standard or H_3PO_4 (^{31}P) as external standard. All assignments of NMR spectra were determined by means of COSY, ^{31}P-^1H and ^{13}C-^1H correlation experiments. Standard pulse sequences were employed for the ^1H-2D-NOESY.[27] The phase-sensitive NOESY experiments used mixing times of 0.4 s. EI mass spectra were obtained on a HP 5989 A spectrometer. A VG-Autospec mass spectrometer was used for FAB mass spectral analyses. The matrix was *m*-nitrobenzyl alcohol. Gas chromatography analyses to obtain the enantiomeric excesses in the hydrogenation of methyl 2-acetoamidoacrylate were performed on a Hewlett−Packard 5890A instrument (fused silica capillary column 25 m × 0.25 mm Permabond L-Chirasil-Val) equipped with a Hewlett−Packard HP 3396 series II integrator. Optical rotations were measured at 25 °C on a Perkin−Elmer 241 MC polarimeter. Hydrogenation reactions were performed in a previously described hydrogen-vacuum line.[28] The molecular mechanics calculations were carried out with the program CERIUS[29] developed by Molecular Simulations (MSI) and the force field UFF developed by Rappe.[30] The electrostatic interactions were taken into account from the atomic changes generated by the Qeq method.[31]

Synthesis of 3,5-Dideoxy-1,2-*O*-isopropylidene-3,5-bis(diphenylphosphanyl)-α-D-xylofuranose (Xylophos, 1): *n*-Butyllithium (3.36 mL, 5.0 mmol) was slowly added to a solution of diphenylphosphane (0.7 g, 5.0 mmol) in THF (5 mL) at 0 °C. After 10 min at room temperature, a solution of 1,2-*O*-isopropylidene-3,5-di-*O*-trifluoromethanesulfonyl-α-D-ribofuranose (1.2 g, 2.64 mmol) in THF (3 mL) was added dropwise and the mixture was allowed to react for 1 hour after which the solvent was evaporated. The residue was purified by column chromatography (toluene) under argon to give the diphosphane as a white solid. Yield: 1.4 g (75%) (m.p. 171−172 °C). − ^1H NMR (300 MHz, $CDCl_3$, TMS): δ = 1.16 (s, 3 H, CH_3), 1.32 (s, 3 H, CH_3), 2.43 [ddd, ^2J(5′-H,5-H) = 13.2 Hz, ^3J(5′-H,4-H) = 6.6 Hz, ^2J(5′-H,P) = 1.9 Hz, 1 H, 5′-H′], 2.64 [ddd, ^2J(5-H,5′-H) = 13.2 Hz, ^3J(5-H,4-H) = 8.2 Hz, ^2J(5-H,P) = 2.2 Hz, 1 H, 5-H], 3.08 [d, ^3J(3-H,2-H) = 4.3 Hz, 1 H, 3-H], 4.41 (m, 1 H, 4-H), 4.49 [dd, ^3J(2-H,3-H)= 4.3 Hz, ^3J(2-H,1-H) = 4.0 Hz, 1 H, 2-H], 5.06 [d, ^3J(1-H,2-H) = 4.0 Hz, 1 H, H-1], 7.40−8.20 (m, 20 H, Ph). − ^{13}C NMR (75.432 MHz, $CDCl_3$, TMS): δ = 26.1 (CH_3), 26.3 (CH_3), 31.1 [dd, J(C-5,P) = 17.5 Hz, J(C-5,P) = 14.8 Hz, C-5], 46.2 [dd, J(C-3,P) = 20.9 Hz, J(C-3,P) = 5.5 Hz, C-3], 76.6 [dd, ^2J(C-4,P) = 16.9 Hz, ^2J(C-4,P) = 13.0 Hz, C-4], 83.9 [d, J(C-2,P) = 5.9 Hz, C-2], 104.2 (C-1), 110.7 (CMe_2), 128.4, 128.5, 128.6, 128.7, 128.8, 128.9, 129.0, 129.2, 132.6, 132.8, 133.0, 133.1, 133.2, 133.3, 133.9, 134.2 (CH=, Ph). − ^{31}P NMR (121.442 MHz, $CDCl_3$, H_3PO4): δ = −27.4 [d, ^4J(P,P) = 8 Hz, 1 P], −21.1 [d, ^4J(P,P) = 8 Hz, 1 P]. − MS (70 eV, EI): m/z = 526 [M^+]. − $C_{32}H_{32}O_3P_2$ (526.55): calcd. C 72.99, H 6.13; found C 72.61, H 6.25. − $[\alpha]_D^{20}$ = +16.1 (c = 1 in CH_2Cl_2)

Synthesis of $[Rh(cod)(Xylophos)]^+BF_4^-$ (4): Xylophos (**1**) (40.5 mg, 0.077 mmol) was added to a solution of $[Rh(cod)_2]^+BF_4^-$ (30 mg, 0.075 mmol) in dichloromethane (1 mL). After 10 minutes, the yellow product was obtained by precipitation with diethyl ether. Yield: 55 mg (88%). ^1H NMR (300 MHz, $CDCl_3$, TMS): see Table 1 and 2. − ^{13}C NMR (75.432 MHz, $CDCl_3$, TMS): δ = 26.2 (C-7 and C-8), 26.6 [dd, J(C-5,P) = 16.5 Hz, J(C-5,P) = 28.7 Hz, C-5], 27.6 (C-9), 27.7 (C-10), 32.6 [d, J(C-13,P) = 3.4 Hz, C-13], 32.9 [d, J(C-14,P) = 3.8 Hz, C-14], 43.4 [dd, J(C-3,P) = 12.9 Hz, J(C-3,P) = 25.8 Hz, C-3], 73.8 [d, J(C-4,P) = 7.6 Hz, C-4], 82.6 [d, J(C-2,P) = 4.78 Hz, C-2], 97.6 [dd, J = 8.1 Hz, J = 9.0 Hz, C-15], 100.15 [dd, J = 8.6 Hz, J = 10.0 Hz, C-16], 103.4 (C-1), 104.69 [dd, J = 9.8 Hz, J = 10.5 Hz, C-10], 105.8 [dd, J = 9.1 Hz, J = 10.8 Hz, C-9], 111.5 (C-6), 127.6 [dd, J(C,P) = 42.0 Hz, J = 1.9 Hz, C], 128.4 [d, J(C,P) = 43.8 Hz, C], 128.5 [d, J(C,P) = 40.5 Hz, C], 129.6 [d, J(C,P) = 10.3 Hz, C-*m* B], 129.8 [d, J(C,P) = 10.3 Hz, C-*m* D],

130.1 [d, J(C,P) = 12.2 Hz, C-*m* A], 130.2 [d, J(C,P) = 10.1 Hz, C-*o* B], 130.4 [d, J(C,P) = 13.7 Hz, C-*m* C], 130.6 [dd, J(C,P) = 43.9 Hz, J = 1.9 Hz, C], 130.9 [d, J(C,P) = 8.4 Hz, C-*o* D], 131.2 [d, J(C,P) = 2.3 Hz, C-*p* B], 131.4 [d, J(C,P) = 2.3 Hz, C-*p* D], 133.3 [d, J(C,P) = 2.3 Hz, C-*p* A], 133.6 [d, J(C,P) = 2.3 Hz, C-*p* C], 135.1 [d, J(C,P) = 12.2 Hz, C-*o* A], 135.5 [d, J(C,P) = 13.7 Hz, C-*o* C]. – ^{31}P NMR (121.442 MHz, $CDCl_3$, H_3PO_4): δ = 17 [dd, ^2J(P-1,P-2) = 43.7 Hz, ^1J(P-1,Rh) = 146.1 Hz, 1P, P-1], 17.4 [dd, ^2J(P-2,P-1) = 43.7 Hz, ^1J(P-2,Rh) = 145.4 Hz, 1P, P-2]. – MS (FAB): m/z = 737 [$M^{+\cdot}$]. – $C_{40}H_{44}BF_4O_3P_2Rh$ (824.44): calcd. C 58.27, H 5.38; found C 58.11, H 5.64.

Hydrogenation of Prochiral Olefins: In a typical run, a Schlenk flask was filled with a methanol solution (6 mL) of substrate (1 mmol) and catalyst precursor (8.24 mg, 0.01 mmol). It was then evacuated and purged three times with H_2. The reaction mixture was the shaken under H_2 (1 atm.) at 293 K. After the desired reaction time, the solvent was removed.

Work-Up of the Hydrogenation Products: The following procedures were used to isolate the hydrogenation products. For 2-methylsuccinic acid and *N*-acetylphenylalanine, the residue was dissolved in 0.5 M NaOH and separated from the insoluble catalyst by filtration. The filtrate was acidified with diluted HCl, extracted with ether and washed with water. The ether phase was dried over sodium sulfate and evaporated to dryness. The extent of the conversion was measured by ^{1}H NMR spectroscopy. The enantiomeric excesses were determined by polarimetry.[8a]

For *N*-acetylalanine methyl ester the residue was dissolved in CH_2Cl_2 and filtered through a plug of silica to remove the catalyst. Conversion and enantiomeric excesses were determined by gas chromatography.

Acknowledgments

We would like to thank the Spanish Ministerio de Educación y Cultura and the Generalitat de Catalunya (CIRIT) for their financial support (PB97−0407-CO5−01) and the Generalitat de Catalunya (CIRIT) for awarding a research grant (to O. P.). We thank Dr. P. Sandor (Varian, Darmstad) for recording the 500 MHz NMR experiments.

Gold(I) Complexes with Amine Ligands, 6[+]

Hydrogen Bonding Networks in Bis(amine)gold(I) Complexes with Disulfonylamide Anions

Birte Ahrens,[a,b] Steffi Friedrichs,[a,c] Regine Herbst-Irmer,[d] and Peter G. Jones*[a]

Keywords: Amines / Aurophilicity / Disulfonylamides / Gold / Hydrogen bonds

The use of disulfonylamines as counter-ions allows the synthesis of stable ionic gold(I) complexes with the amine ligands cyclohexylamine, benzylamine, 3-iodobenzylamine, morpholine, pyrrolidine, and piperidine. There is a considerable increase in stability for the morpholine complex compared to the previously synthesised chloro derivative; the benzylamine derivatives displayed better solubility and crystallinity than their chloro analogues. The use of silver disulfonylamine derivatives in the syntheses led in two cases to the incorporation of silver into the products, with concomitantly poor yields. Crystal structure determinations of eight complexes revealed, as expected, extensive systems of N–H···O hydrogen bonds. Amines with NH functions tend to form hydrogen-bonded chain motifs, those with NH_2 as donor group form layers of linked ring patterns. It thus seems that the packing can more easily be classified in terms of influence of the cation than of the anion. Some C–H···O hydrogen bonds were also observed, but play a less important role. Aurophilic contacts were not observed, although one mixed gold/silver complex displayed short Au···Ag contacts. Of the two compounds containing iodine, only one showed short I···I contacts.

Introduction

Our studies of gold(I) complexes with amine ligands have involved a detailed investigation of the role of secondary bonds in these compounds.[1] Two types of secondary contacts are most frequently observed: aurophilic interactions[2] and hydrogen bonds. Gold(I) complexes of aliphatic amines had previously been regarded as relatively unstable − a viewpoint easily rationalised in terms of incompatibility of the soft metal centre gold(I) and the hard nitrogen donor − in the absence of stabilising ligands, such as phosphanes. We believe that hydrogen bonds are particularly important in stabilising such complexes.

Until now we have generally used chloride as counter-ion or second ligand, because of the convenience of using chloro precursors such as chloro(tetrahydrothiophene)-gold(I). The use of more versatile hydrogen bond acceptors might be expected to increase the stability of gold(I)−amine complexes still further, at least in the solid state; we have therefore started to exchange the sterically and geometrically undemanding halogen anion for disulfonylamides, using as reagent the silver disulfonylamides in acetonitrile solution. For a similar recent example with the ligand (dppm)Se, see ref.[3]

Here we report the synthesis and structure of gold(I) compounds with cyclohexylamine (**1**, **6**, **8**), benzylamine (**2**), 3-iodobenzylamine (**3**), morpholine (**4**; this was not stable as a chloro complex), pyrrolidine (**5**), and piperidine (**9**) as the amine ligands and bis(methanesulfonyl)amide (**1**, **2**, **3**, **4**, **5**), bis(*p*-chlorobenzenesulfonyl)amide (**7**), bis(*p*-iodobenzenesulfonyl)amide (**8**), and *o*-benzenedisulfonylamide (= 1,1,3,3-tetraoxo-1,3,2-benzodithiazole; **6**) as the anions. The corresponding chloro derivatives of **2** and **3** were highly insoluble and at best microcrystalline, whereas that of **4** was unstable.[1]

Our previously studied chloride derivatives involved three chemically distinct types of complexes: LAuCl (e.g. L = 2-methylpyridine, piperidine),[4,5] $[L_2Au^+]Cl^-$ (e.g. L = piperidine, cyclohexylamine)[1] and $[L_2Au^+][AuCl_2^-]$ (e.g. L = pyridine,[6] 3-bromopyridine[7]). Some crystal structures showed more than one structural type in the same crystal. With L = pyrrolidine a by-product was obtained in which two molecules of LAuCl crystallised together with one ionic complex $[L_2Au^+]Cl^-$;[8] other workers have shown that with L = 2-aminopyridine, one molecule LAuCl crystallised together with one ionic complex $[L_2Au^+]$ $[AuCl_2]^-$.[9] However, none of the compounds we examined showed appreciable conductivity in acetone solution, hence an equilibrium favouring the molecular over the ionic form was proposed.[1] After exchanging the chloride for a disulfonyla-

mide, in the presence of additional amine ligand, only ionic structures are observed. These complexes do conduct in acetone solution, although not very strongly, e.g. Λ_c = 79 cm^2 Ω^{-1} mol^{-1} for [(cyNH$_2$)$_2^+$]NMs$_2^-$; cf. Λ_c = 140 cm^2 Ω^{-1} mol^{-1} in the case of 1:1 electrolytes such as PPN$^+$Cl$^-$. It is conceivable that some form of ionic association occurs in solution.

All crystallographically characterised complexes described here display hydrogen bonding. As would be expected, the resulting networks become more complex with increasing numbers of donor hydrogen atoms. Comparison of the resulting patterns shows a seemingly greater contribution to the packing from the cation than from the anion.

None of the complexes shows aurophilic interactions, although the unexpected complex **5** involves an Au···Ag contact (see below).

Within those complexes where iodine is present, either in the ligand or the anion, I···I ("soft-soft") interactions were expected. However, only in one case were I···I contacts observed [3.723(4) Å in **3**, cf. 4.3804(10) Å in **8**; sum of the van der Waals radii 3.96 Å].[10] This further supports the conclusion that the hydrogen bonds contribute most to the three-dimensional pattern in these complexes.

Results and Discussion

Complexes with Bis(methanesulfonyl)amide as Anion and Cyclohexylamine, Benzylamine, 3-Iodobenzylamine, Morpholine or Pyrrolidine as Ligand

[(CyNH$_2$)$_2$Au$^+$]NMs$_2^-$ [**1**, cyNH$_2$ = cyclohexylamine, NMs$_2$ = bis(methanesulfonyl)amide, Figure 1, Table 1] crystallised with two independent molecules in the asymmetric unit. [(Benzylamine)$_2$Au$^+$]NMs$_2^-$ (**2**, Figure 2, Table 2), [(3-iodobenzylamine)$_2$Au$^+$]NMs$_2^-$ (**3**, Figure 3, Table 3) and [(morpholine)$_2$Au$^+$]NMs$_2^-$ (**4**, Figure 4, Table 4) crystallised with one formula unit in the asymmetric unit. With pyrrolidine as the ligand, the "non-innocence" of the silver reagent was demonstrated by the formation of a different complex (**5**): instead of a single NMs$_2^-$ anion this complex contains the anion [Ag(NMs$_2$)$_2^-$], and involves a d^{10}–d^{10} interaction between Ag and the gold atom of the [(pyrrolidine)$_2$Au$^+$] cation (Figure 5, Table 5). Even under exact stoichiometric conditions for the expected reaction, only this complex was obtained. We assume that the d^{10}–d^{10} interaction, in addition to the hydrogen bonding, stabilises the complex. Its length [3.309(3) Å] lies in the typical range of purely aurophilic interactions,[11] but much shorter Au···Ag contacts have been observed in [Ag{[Au(μ-N^3,C^3-bzim)]$_3$}$_2$]$^+$BF$_4^-$ [2.731(2) to 2.922(2) Å, bzim = 1-benzylimidazolate][12] or in [Au$_4$Ag(CH$_2$SiMe$_3$)$_4$(μ-dppm)$_2$]SO$_3$CF$_3$ [2.7179(13) to 2.7822(13) Å, dppm = bis(diphenylphosphanyl)methane].[13]

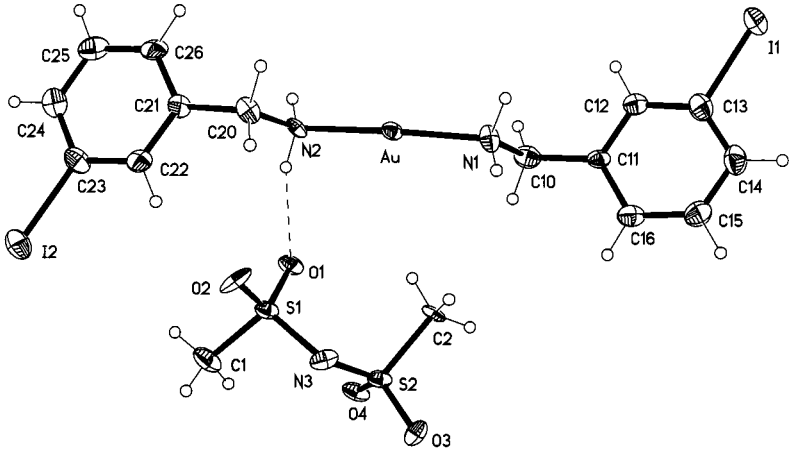

Figure 3. Bis(3-iodobenzylamine)gold(I) bis(methanesulfonyl)amide (**3**); asymmetric unit with numbering scheme; thermal ellipsoids are shown with 50% probability; hydrogen radii are arbitrary; dashed lines represent hydrogen bonds

[Au−N 2.052(5) to 2.055(7) Å].[1] The dimensions of **5** should however be interpreted with caution, because the cation is disordered over two positions (see Experimental Section; only the dimensions of the major component are discussed here) and because there is pseudosymmetry caused by the heavy atoms positioned approximately at 0.25,0.5,*z* in space group *Pna*2_1.[14]

The independent cations in **1** show different C−N···N−C torsion angles across the N−Au−N unit: The arrangement of the ligands at Au1 is antiperiplanar [C11−N1···N2−C21 169(1)°], and is eclipsed at Au2 [C31−N3···N4−C41 −18(1)°]. The former conformation is most common within this kind of cation, as in $[(cyNH_2)_2Au^+]Cl^-$ [C−N···N−C −174.2(9) and, because of inversion symmetry, 180°],[1] **2**

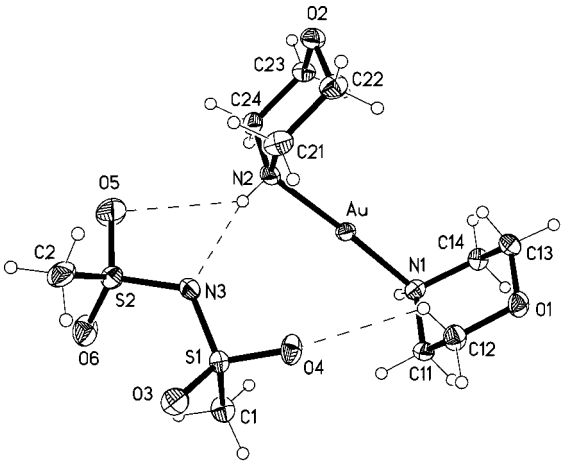

Figure 4. Bis(morpholine)gold(I) bis(methanesulfonyl)amide (**4**); asymmetric unit with numbering scheme; thermal ellipsoids are shown with 50% probability; hydrogen radii are arbitrary; dashed lines represent hydrogen bonds

Bis(pyrrolidine)gold(I) bis[bis(methanesulfonyl)amide]argentate(I) (**5**); major disorder component with numbering scheme; thermal ellipsoids are shown with 50% probability; hydrogen radii are arbitrary; dashed lines represent hydrogen bonds; in the minor disorder component, the pyrrolidine ring involving N2 inverts to form an intramolecular hydrogen bond from N2 to O3; see also the corresponding packing diagrams in Figure 10

[C10−N1···N2−C20 179.5(2)°], and **3** [C10−N1···N2−C20 178.3(13)°].

The S−N bond lengths [1.569(14) to 1.627(8) Å, Table 6] in the NMs_2 anions of complexes **1** to **5** are similar to those in other metal complexes with bis(methanesulfonyl)amide {e.g. $[Ag_4(NMs_2)_4(H_2O)]$,[15] S−N 1.603(6) to 1.632(6) Å; S−N−S 118.0(4) to 120.6(4)°}. The corresponding S−N−S angles [119.8(6) to 122.47(14)°, Table 6] support the assumption of sp^2 hybridisation of the amide nitrogen atom.

Table 5. Selected bond lengths and angles for **5** (only the major disorder component of the cation is given)

The silver atom of the anion $[Ag(NMs_2)_2]^-$ in **5** is linearly coordinated [N3−Ag−N4 171.1(3)°]. The Ag−N bond lengths of 2.123(7) (Ag−N3) and 2.122(7) Å (Ag−N4) are similar to those in $[Ag(NCCH_3)_4][Ag(NMs_2)_2]$ of 2.129(2) Å.[16] The NMs_2 ligands at Ag in **5** are rotated with respect to each other across the N−Ag−N unit [S2−N3···N4−S3 101.4(6), S2−N3···N4−S4 −78.3(6)°], which may be in order to accommodate the hydrogen bonds. The N−Au−N and N−Ag−N bond axes in **5** are perpendicular to each other [N1′−Au′···Ag−N3 86.3(8), N1′−Au′···Ag−N4 −92.8(8)°].

One oxygen atom of every sulfonyl group of NMs_2 anions lies in or near the S−N−S bond plane. The resulting "W" shape is characteristic of the bis(methanesulfonyl)amide anion.[17] The two other oxygen atoms and the methyl groups lie above or below this plane and show a staggered conformation [absolute O−S−N−S torsion angles: 30.5(11) to 43.2(2), 159.1(9) to 171.5(7)°; Table 6]. Different signs are associated with the two different chirally frozen conformers of bis(methanesulfonyl)amide.

Within all bis(amine)gold(I) complexes with disulfonylamide as the anion, more hydrogen bond acceptors (A) are present than classical hydrogen bond donor groups (D) such as NH. Every disulfonylamide anion has five acceptor groups: the four oxygen atoms and the amide nitrogen atom. The cations of the complexes **1**, **2**, and **3** have four amine hydrogen atoms, the cations of **4** and **5** each have two amine hydrogen atoms. Logically, therefore, not all of the hydrogen bond acceptors can be involved in classical hydrogen bonding, whereas every amine hydrogen atom in the complexes **1** to **5** *is* involved in hydrogen bonding. Associated H bond dimensions H···A, D···A and D−H···A are shown in Table 7.

In complexes **1**, **2**, and **3**, with four amine hydrogen atoms per formula unit, layers are formed, containing rings of hydrogen bonds. In complex **4** and **5** (major component), with two amine hydrogen atoms per formula moiety, the molecules are arranged in chains.

Graph theoretical analysis[18] of the hydrogen bond patterns led to the following conclusions: Each individual hydrogen bond forms a distinct pattern. Rings were formed by combining two (binary level, N_2) or four hydrogen bonds (quaternary level, N_4). In **1,** the combination of four different rings forms the layers parallel to (1 0 1), see Figure 6. The rings are described by the graph sets $R_4^4(12)$, $R_4^4(16)$, $R_4^4(20)$ [all N_2] and $R_4^4(18)$ [N_4]. In **2** and **3**, the layers are formed parallel to (1 1 0) from rings on binary level [N_2] (Figure 7 and Figure 8). In **2**, these rings are described by the graph sets $R_4^4(12)$ and $R_4^4(16)$ and in **3** by $R_4^4(8)$, $R_4^4(12)$, $R_4^4(16)$. The different ring pattern in the layers of the two complexes with benzylamine ligands, **2** and **3,** is presumably influenced by the iodine substitution of the benzylamine in **3**. Apart from the obvious steric effects, the iodine atom shows, as mentioned above, a short contact of 3.723(4) Å to an iodine atom of the next layer.

The chains in **4** (parallel to the *x* axis) and **5** (parallel to the *z* axis) are formed by combination of the two independent hydrogen bonds present in these complexes (Figure 9 and Figure 10a). The chain in **4** is described by the graph set $C_2^2(8)$, in **5** by $C_2^2(10)$. The minor disorder component of **5**, in which the ring at N2 is inverted, involves solely intra-

molecular hydrogen bonds; clearly the alternative direction of the N2−H2 vector presents a viable alternative hydrogen bonding system.

Complexes with Cyclohexylamine as Ligand and *o*-Benzenedisulfonylamide or Bis(*p*-halobenzenesulfonyl)amide as Anion

$[(CyNH_2)_2Au^+]-o$-benzodisulfonylamide (**6**, Figure 11) crystallised with half a formula unit in the asymmetric unit, together with dichloromethane (overall composition **6**/dichloromethane of 2:3). The gold and the amide nitrogen atom lie on a mirror plane; the gold atom is linearly coordinated [N1−Au−N1′ 177.1(4)°]. The Au−N bond length of 2.045(7) Å is similar to those in complex **1** [2.020(12) to 2.053(10) Å].

The *o*-benzenedisulfonylamide anion in **6** is conformationally more constrained than the other disulfonylamide anions, leading to a different arrangement of the acceptor groups. The S−N bond length of 1.554(5) Å is slightly shorter than in the NMs_2 anions in complexes **1** to **5** [1.569(14) to 1.638(9) Å] and also shorter than in the silver complexes of this anion {1.613(2) Å in $[Ag(H_2O)\{N(SO_2)_2C_6H_4\}]$,[19] 1.614(1) Å in $[Ag(NCCH_3)\{N(SO_2)_2C_6H_4\}]$}.[16] The S−N−S angle in **6** [119.7(7)°] is larger than in the silver complexes [111.6(2) and 116.7(1)°]. Hence, the shorter S−N bond length in **6** could be attributed to a greater sp^2 hybridisation of the amide nitrogen atom. This is in good agreement with the assumption of a greater degree of backbonding caused by the additional charge in the non-coordinating anion of **6**. The *o*-benzenedisulfonylamide anion is also present solely as a counter-ion in the structures of $[Ca(H_2O)_7][N(SO_2)_2C_6H_4]_2$[20] and $[Me_2Sn(H_2O)_4][N(SO_2)_2C_6H_4]_2$,[21] and here the situation is not so clear-cut; in both cases the S−N bond lengths [1.574(3) to 1.587(3) Å] are longer than in **6**, and the S−N−S bond angles [115.7(2), 114.9(2)°] are smaller than in **6**.

The five- and the six-membered ring of the anion are coplanar; the interplanar angle is 2.4(7)°. The oxygen atoms lie above or below the S−N−S′ plane. This conformation has an influence on the packing in the crystal, resulting in a cation showing the more unusual eclipsed conformation (C11−N1···N1′−C11′ 0°, by symmetry). Nevertheless, layers are also formed in **6** by combination of hydrogen-bonded rings (Figure 12, Table 8). The two crystallographically independent oxygen atoms of the anion are involved in hydrogen bonding (see Table 7). The amide nitrogen atom shows a long contact to the gold atom [Au···N2 3.382(10) Å; cf. sum of the van-der-Waals radii 3.21 Å][10] and is not involved in hydrogen bonding; a shorter Au···N contact of 3.009(7) Å was observed in the related complex bis(tetrahydrothiophene)gold(I) *o*-benzenedisulfonylamide.[22] Overall there are three independent hydrogen bonds present in **6**: N1−H1A···O2, N1−H1B···O2^{xii} and N1−H1B···O1^{xiii} (for symmetry operators see Table 7). H1B is the donor atom of a three-centre hydrogen bond, and O2 the acceptor atom of a bifurcated hydrogen bond.

The layers in **6** are in fact double layers, with the cations on the outside and the anions inside (Figure 12). The rings within the layers in **6** can be described with the graph sets $R_2^2(10)$ (combination of the two hydrogen bonds involving O2 with themselves), $R_4^2(8)$ and $R_2^4(8)$ (combination of two different hydrogen bonds).

Unfortunately, no crystals could be obtained from complex **7** with bis(*p*-chlorobenzenesulfonyl)amide as anion. $[(CyNH_2)_2Au^+]$−bis(*p*-iodobenzenesulfonyl)amide (**8**, Figure 13) crystallised with half a formula unit in the asymmetric unit. The gold atom lies on an inversion centre and the bis(sulfonyl)amide group of the anion is disordered over an inversion centre.

The gold atom in **8** is linearly coordinated by symmetry, with an N−Au bond length of 2.034(5) Å similar to those in $[(cyNH_2)Au^+]Cl^-$ [1] and complexes **1** to **3** [2.029(12) to 2.053(10) Å]. The ligands at Au are antiperiplanar (C−NN−C 180° by symmetry). The S−N bond lengths [1.569(9), 1.571(9) Å] are similar to those in the bis(methanesulfonyl)amide anions of complexes **1** to **5** [1.569(14) to 1.638(9) Å]. The S−N−S angle of 127.3(7)° in **8** is slightly larger [cf. 119.8(6) to 122.57(14)° in **1** to **5**], but this should be interpreted with caution because of the disorder of the anion.

Changing the anion from bis(methanesulfonyl)amide to bis(*p*-halobenzensulfonyl)amide should result in a greater influence of the anion on the crystal packing. With the latter anions, more secondary interactions, apart from hydrogen bonding, should be observable, e.g. halogen−halogen or even π···π interactions. However, none of these was observed in the crystal structure of **8**.

The disorder of the anion in **8** makes the bond lengths of the hydrogen bonds less precise, but the overall pattern, a layer parallel to (1 1 0), formed by combination of hydrogen-bonded rings, is similar to that in complexes **1** to **3** (Figure 14, Table 9). The rings in **8** can be described with the graph sets $R_4^4(12)$ and $R_4^4(20)$. Because of the disorder, assignment of a distinct level (N_2 or N_4) is not meaningful.

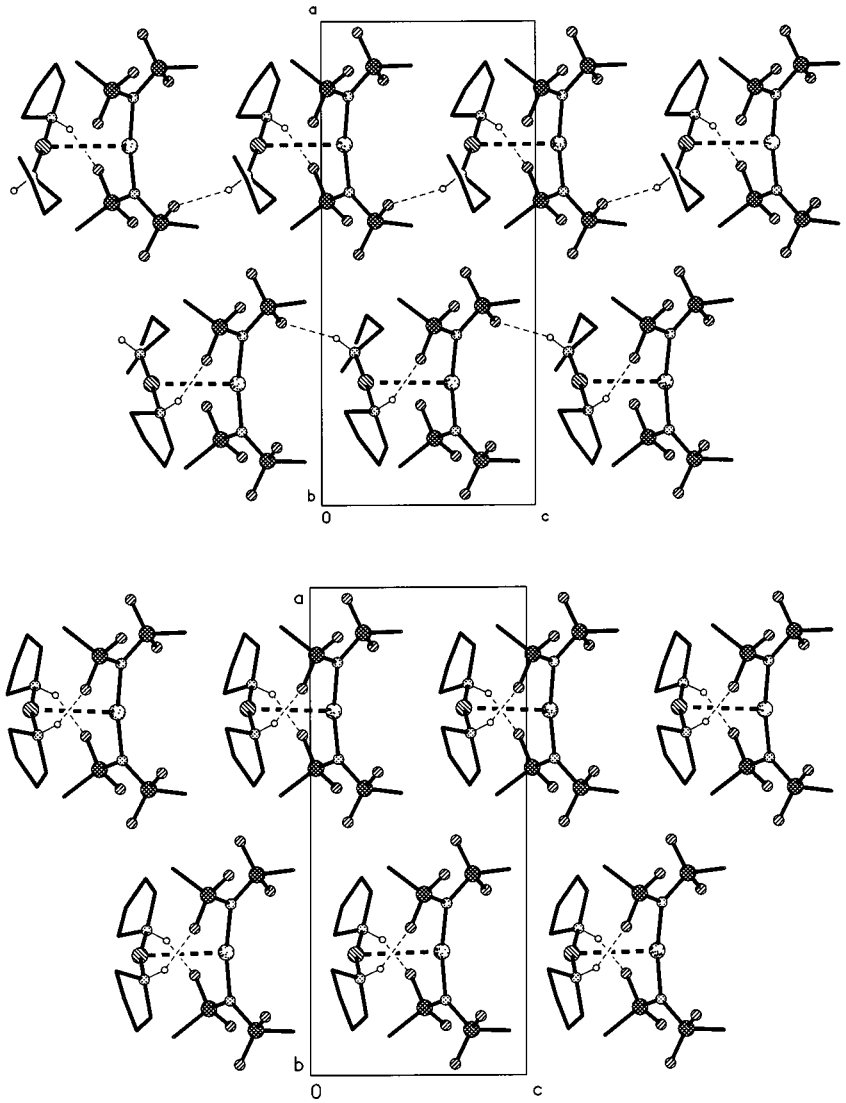

Figure 10. (a) Bis(pyrrolidine)gold(I) bis[bis(methanesulfonyl)amide]argentate(I) (**5**); projection of the chain structure involving the major disorder component; atom radii are arbitrary; dashed lines represent hydrogen bonds (Table 7); carbon-bonded hydrogen atoms are omitted for clarity; (b) an equivalent view of the minor disorder component showing the purely intramolecular hydrogen bonds

Non-Classical Hydrogen Bonding

Non-classical hydrogen bonds, i.e. hydrogen bonds with C−H as donor group, were previously the subject of controversial discussion, but are nowadays of accepted validity and the subject of great interest.[23] In complexes **1** to **4** the oxygen atoms not involved in classical hydrogen bonding showed hydrogen bonds of the type C−H···O, with uncorrected H···O in the range 2.35 to 2.73 Å (see Table 10). These hydrogen bonds can link neighbouring layers (complexes **1** to **3**) or chains (complex **4**); others connect molecules within the layer or chain. We do not discuss the disordered complexes, in which the alternative positions of the C−H functions render meaningful discussion impossible.

An Unexpected Complex with Piperidine as Ligand

Attempts to replace the chloride anion in $[(piperidine)_2Au^+]Cl^-$ [1] by NMs_2^-, as in the reactions described above, led not to the desired complex but to one with $AgCl_2^-$ as anion, again showing that silver can play an active (but undesired) role in such reactions. In the crystal structure of $[(piperidine)_2Au^+][AgCl_2^-]$ (**9**, Figure 15), the anion is not a discrete moiety, but forms polymeric chains, containing Ag_2Cl_2 squares [Ag−Cl 2.598(4) to 2.631(3) Å, Cl−Ag−Cl 96.96(9) to 113.78(12)°, see Table 11]. A search of the Cambridge structural database[24] revealed only two other complexes with this $[AgCl_2^-]_n$ chain, namely $[(CH_3)_4N^+][AgCl_2^-]$[25] and $[(CH_3C(O)CH_2C(O)CH_3)_3Si^+][AgCl_2^-]$.[26]

The cations in **9** lie above and below the Ag_2Cl_2 squares and form hydrogen bonds to the chlorine atoms (Figure 16). The conformation of the cation in **9** is slightly different from that of the $(piperidine)_2Au^+$ cation in the chloride complex.[1] The gold atom in **9** is, as usual, linearly coordinated [N1−Au−N2 179.3(4)°]. The N−Au bond lengths are slightly longer than in complexes **1** to **3** and in the chloride complex [N1−Au 2.104(10), N2−Au 2.098(11) Å, cf.

N−Au 2.029(12) to 2.055(6) Å], but are similar to those in [(pyridine)$_2$Au$^+$][AuCl$_2^-$] [N−Au 2.08(3), 2.10(4) Å]. The main difference of the conformation of the cation, compared to the chloride complex, is the arrangement of the ligands at Au. In **9** it is a more eclipsed arrangement, in the chloride complex the arrangement is better described as staggered [C11−N1···N2−C21 1.1(12), C11−N1···N2−C25 127.1(11)°, cf. C11−N1···N2−C21 −68.6(7), C11−N1···N2−C25 164.0(6)° in the chloride]. This change in the conformation is probably due to the restricted conformation of the anion in **9**; in both complexes $R_4^2(12)$ rings are formed, but in **9** the chloride anions are fixed by the $AgCl_2$ chain.

Conclusion

Considerable similarities were found between all structures containing either N−H or NH_2 as hydrogen donor groups. The complexes with N−H as donor groups and NMs_2 as the anion (**4**, **5**) displayed a secondary structure consisting of chains. The gold complexes with pyrrolidine as ligand and chloride as anion had also been found to involve mainly chains as secondary pattern.[1,8]

Those complexes with piperidine as ligand and chloride as the anion behaved somewhat differently, showing either dimeric $(L_2Au^+Cl^-)_2$[1] or tetrameric $(LAuCl)_4$[5] structures. In both structures ring systems of hydrogen bonds could be recognised. The ring pattern of the dimeric structure is again found in **9**, but now with polymeric $AgCl_2^-$ as anion.

In all complexes with NH_2 as donor group (**1**, **2**, **3**, **6**, and **8**) layers containing ring patterns were formed; evidently the "extra" H donor facilitates the formation of two-dimensional hydrogen bond systems. These ring patterns are topologically closely related to those in [(cyNH$_2$)$_2$Au$^+$]Cl$^-$ [1] and even to those in the metal-free cyclohexylamine hemihydrochloride.[27]

[a] Operators: xv: $-x, 2 - y, 1 - z$; xvi: $x, y + 1, z$; xvii: $x, y - 1, z$; xviii: $-x, -y, -z$. For operators up to xiv, see Table 7.

We thus conclude that the packing influence of the cation, as exercised through the NH functions of the ligands, is greater than that of the anion.

Experimental Section

General: NMR spectra were measured with a Bruker AC 200 spectrometer in $CDCl_3$ solution with TMS as the internal standard (if not otherwise stated). Frequencies: 200.1 MHz (^{1}H), 50.3 MHz (^{13}C). − Mass spectra were recorded with a Finnigan MAT 8430. − All complexes were prepared as follows: 0.5 mmol of $L_2Au^+Cl^-$

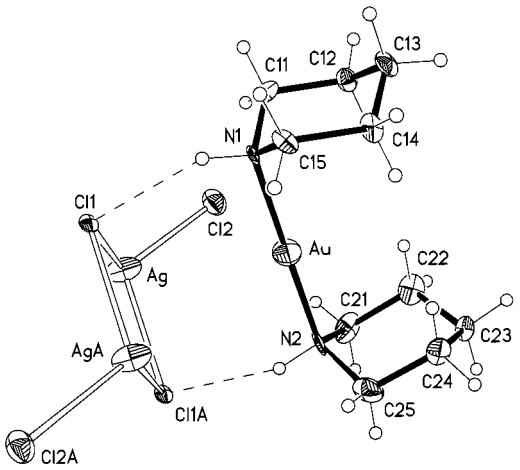

Figure 15. Bis(piperidine)gold(I) dichloroargentate(I), **9**, asymmetric unit with numbering scheme, extended by one $AgCl_2^-$ unit; thermal ellipsoids are shown with 50% probability; hydrogen radii are arbitrary; dashed lines represent hydrogen bonds

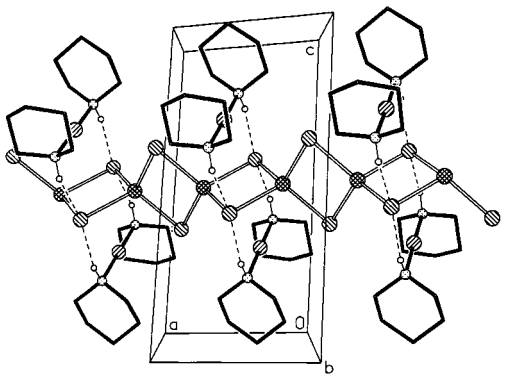

Figure 16. Bis(piperidine)gold(I) dichloroargentate (**9**); chain structure; atom radii are arbitrary; dashed lines represent hydrogen bonds (Table 7); carbon-bonded hydrogen atoms are omitted for clarity

(L = amine) was suspended in acetonitrile (10 mL). The silver salt of the disulfonylamide, kindly provided by Prof. A. Blaschette, TU Braunschweig, was added in 10% excess (0.55 mmol). The reaction mixture was stirred for 2 h at room temperature with exclusion of light. The precipitated AgCl was filtered off and washed with acetonitrile. The combined solutions were concentrated in vacuo and the white residue was recrystallised from CH_2Cl_2/petroleum ether (40:60) to obtain colourless crystals.

Bis(cyclohexylamine)gold(I) Bis(methanesulfonyl)amide (1): Yield 59%, dec. > 123 °C. − ^{1}H NMR ($CDCl_3$): δ = 1.29, m, 10 H, CH_2 (ax.); 1.66, m, 2 H, 4-CH_2 (eq.); 1.80, m, 4 H, 3-, 3′-CH_2 (eq.); 2.08, m, 4 H, 2-, 2′-CH_2 (eq.); 3.00, m, 2 H, CH; 3.08, s, 6 H, CH_3; 4.5, br., NH_2. − MS (FAB pos.): *m*/*z* = 395 (100% $[K]^+$); MS (FAB neg.): *m*/*z* = 172 (100% $[A]^-$). − Conductivity: Λ_c = 79 cm^2 Ω^{-1} mol^{-1}. − $C_{14}H_{32}AuN_3O_4S_2$ (567.52): calcd. C 29.63, H 5.68, N 7.40, S 11.30; found C 27.26, H 5.44, N 7.09, S 12.74.

Bis(benzylamine)gold(I) Bis(methanesulfonyl)amide (2): Yield 76%, dec. > 109°C. − ^{1}H NMR ($CDCl_3$): δ = 2.87, s, 6 H, CH_3; 3.96, br., 4 H, CH_2; 4.68, br., 4 H, NH_2; 7.32, m, 20 H, Ph. − $C_{16}H_{24}AuN_3O_4S_2$ (583.48): calcd. C 32.94, H 4.15, N 7.20, S 10.99; found C 33.03, H 4.21, N 7.29, S 11.03.

Bis(3-iodobenzylamine)gold(I) Bis(methanesulfonyl)amide (3): Dec. > 108°C. − ^{1}H NMR ($CDCl_3$): δ = 2.95, s, 6 H, CH_3; 4.11, s, 4 H, CH_2; 7.48, m, 8 H, Ph. − $C_{16}H_{22}AuI_2N_3O_4S_2$ (835.28): calcd. C 23.00, H 2.66, N 5.03, S 7.68; found C 22.94, H 2.61, N 4.82, S 7.61.

Bis(morpholine)gold(I) Bis(methanesulfonyl)amide (4): Yield 41%, dec. > 50°C. − ^{1}H NMR ($CDCl_3$): δ = 3.05, s, 6 H, CH_3; 3.27, m, 8 H, α-CH_2; 3.86, m, 12 H, β-CH_2. − $C_{10}H_{24}AuN_3O_6S_2$ (543.42): calcd. C 22.10, H 4.45, N 7.73, S 11.80; found C 21.39, H 4.33, N 7.43, S 10.86.

Bis(pyrrolidine)gold(I) Bis[bis(methanesulfonyl)amido-*N*]argentate(I) (5): Yield 81%, dec. > 104 °C. − ^{1}H NMR ($CDCl_3$): δ = 1.87, m, 8 H, β-CH_2; 2.99, m, 4 H, α-CH_2; 3.12, s, 12 H, CH_3; 3.54, m, 4 H, α-CH_2. − MS (FAB pos.): *m*/*z* = 72 (18% $[K\text{-}C_4H_8NAu]^+$); 339 (100% $[K]^+$); MS (FAB neg.): *m*/*z* (%) = 172 (100) $[A - C_2H_6AgO_4S_2]^-$; 450 (52) $[A - H]^-$; 452 (58) $[A + H]^-$. − $C_{12}H_{30}AgAuN_4O_8S_4$ (791.49): calcd. C 18.21, H 3.82, N 7.08 S, 16.21; found C 17.28, H 3.74, N 6.78, S 17.38.

Bis(cyclohexylamine)gold(I) *o*-Benzenedisulfonylamide (6): Yield 57%, dec. > 73°C. − ^{1}H NMR ($CDCl_3$): δ = 1.22, m, 10 H, CH_2 (ax.); 1.58, m, 2 H, 4-CH_2 (eq.); 1.73, m, 4 H, 3-, 3′-CH_2 (eq.); 2.02, m, 4 H, 2-, 2′-CH_2 (eq.); 3.08, m, 2 H, CH; 4.4, br., NH_2, 5.30, s, 2 H, CH_2Cl_2; 7.71, m, 2 H, β-Ph; 7.86, m, 2 H, α-Ph. − MS (FAB pos.): *m*/*z* (%) = 100 (100) $[K - C_6H_{12}NAu]^+$; 395 (71) $[K]^+$; MS (FAB neg.): *m*/*z* (%) = 218 (100) $[A]^-$. − $C_{18}H_{30}AuN_3O_4S_2$ (613.55) × 0.75 CH_2Cl_2: calcd. C 33.25, H 4.69, N 6.20, S 9.47; found C, 33.24 H, 4.65 N 6.25, S 10.90.

Bis(cyclohexylamine)gold(I) Bis(*p*-chlorobenzenesulfonyl)amide (7): Yield 57%, dec. > 88°C. ^{1}H NMR ([D$_6$]DMSO): δ = 1.17, m, 10 H, CH_2 (ax.); 1.58, m, 2 H, 4-CH_2 (eq.); 1.70, m, 4 H, 3-, 3′-CH_2 (eq.); 1.96, m, 4 H, 2-, 2′-CH_2 (eq.); 2.81, m, 2 H, CH; 5.4, br., NH_2; 7.42, m, 4 H, *m*-Ph; 7.63, m, 4 H, *o*-Ph. − MS (FAB pos.): *m*/*z* (%) = 100 (44) $[K - C_6H_{12}NAu]^+$; MS (FAB neg.): *m*/*z* (%) = 363 (100) $[A - H]^-$. − $C_{24}H_{34}AuCl_2N_3O_4S_2$ (760.56): calcd. C 37.90, H 4.51, N 5.52, Cl 9.32, S 8.43; found C 32.30, H 4.05, N 4.58, Cl 10.73, S 8.14.

Bis(cyclohexylamine)gold(I) Bis(*p*-iodobenzenesulfonyl)amide (8): Yield: very low (few crystals), dec. > 97°C. − $C_{24}H_{34}AuI_2N_3O_4S_2$ (943.49): calcd. C 30.55 H 3.63 N 4.45 S 6.80; found C 26.77 H 2.52 N 2.91 S 6.84.

Bis(piperidine)gold(I) Dichloroargentate(I) (9): Compound **9** was unexpectedly obtained following the general procedure using (piperidine)$_2$AuCl and $AgNMs_2$. − Yield: very low (few crystals), dec. > 87°C. − ^{1}H NMR ($CDCl_3$): δ = 1.76, br., 4 H, α-CH_2; 3.24, 6 H, β-, γ-CH_2. − $C_{10}H_{22}AgAuCl_2N_2$ (546.04): calcd. C 22.00, H 4.06, N 5.13; found C 22.58, H 4.24, N 5.11.

X-ray Structure Determinations: For crystal data, see Table 12 and Table 13. − *Data collection and reduction*: The crystals were mounted in inert oil on a glass fibre. Data were measured using Mo-K_α radiation (λ = 0.71073 Å) with a Siemens P4 diffractometer (**1**, **5**, **6**, **8**) or a Bruker Smart area detector (**2**, **3**, **4**, **9**), fitted with an LT-2 (P4) or LT-3 (Smart) low-temperature attachment. Semi-empirical absorption corrections were based on ψ-scans (XEMP) or on multiple scans (SADABS). *Structure solution and refinement*: Structures were solved by direct (**3**, **5**, **8**, **9**) or Patterson (**1**, **2**, **4**, **6**) methods and subjected to full-matrix least-squares refinement on F^2 (program SHELXL-97).[28] All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included using rigid methyl groups or a riding model, except that those bonded to a nitrogen atom were refined freely in **4** and with restrained bond lengths in **8**. For several structures (see Table 12 and 13), particularly the disordered **5** and **8**, an extensive system of restraints to displacement parameters was employed to improve refinement stability of light atoms in the presence of gold. The Flack *x* parameter for the non-centrosymmetric structure **5** refined to −0.001(7).[29] The complete cation of **5** is disordered over two positions with occupation factors 0.37 (unprimed atoms) and 0.63 (primed atoms). The gold and silver atom positions correspond closely to space group *Aba*2, in which a doubly disordered model can also be refined, but too many reflections are observed that should be systematically absent. By lowering the symmetry, it was hoped to find an ordered model, but this proved impossible even in *P*1. It is unlikely that X-ray methods alone can resolve the space group ambiguity. The central $N(SO_2)_2$ moiety of the anion of **8** is disordered over two positions with occupation factors 0.5. Clearly the dimensions of both disordered structures should be interpreted with caution. The high *R* values and high residual electron densities of structures **3** and **9** may be attributed to poor crystal quality, and unsatisfactory absorption correction with SADABS, associated with extreme crystal forms (thin plate, needle).

Crystallographic data (excluding structure factors) have been deposited with the Cambridge Crystallographic Data Centre

Reactions of Sodium-Potassium Alloys with Inert Gas Impurities − Potential Hazards after Oxidation

Jacqueline Desreumaux,*[a] Marielle Calais,[a] René Adriano,[a] Serge Trambaud,[a] Charles Kappenstein,[b] and Marcel Nguefack[b]

Keywords: FBR Chemistry / Oxidations / Sodium / Potassium / Alloys

A bibliographical study of the reactions of NaK alloys with their oxides did not explain the related accidents that have occurred in the past, particularly those involving the handling of bubblers installed to remove traces of oxygen and water vapor from blanket gases of LMFR (liquid metal fast reactors). Moreover, it revealed a controversy with respect to the explosive hazard of the NaK alloys + KO_2 reaction. A thermodynamic study of the reaction of a NaK alloy with oxygen as well as experimental work on mixtures containing NaK and different oxides (KO_2, Na_2O, Na_2O_2) led to the conclusion that violent reactions occurring at ambient temperature, were always linked to the presence of hydrated superoxides or hydroxides. On contact with NaK alloys, these hydrated compounds lead to the formation of hydrogen with a release of heat causing the decomposition of potassium superoxide KO_2 and the simultaneous release of oxygen. The oxidation of liquid NaK alloy, by bubbling a mixture of argon and air containing traces of water vapor ($H_2O < 5$ vpm), leads to the formation of mainly KO_2, besides the hydrated compounds $Na_2O_2{\cdot}2H_2O$, $NaOH{\cdot}H_2O$ and $KOH{\cdot}H_2O$. The gas follows preferential paths and the product obtained is highly heterogeneous in both composition and hardness (porous parts and dense parts). Hydrated superoxide and hydroxides treated under vacuum result in nearly quantitative dehydration after heating at 100 °C. For storage elements or safety valves, containing NaK that has been submitted to slow surface oxidation and hydration, the oxidized layer contains KO_2, $Na_2O_2{\cdot}nH_2O$ and hydrated hydroxides of sodium and potassium. In order to avoid any hazard due to the contact of the oxides with the residual NaK alloy during transport or under impact, it is necessary to freeze the alloy and to reheat it very slowly. Operations such as draining should also be performed slowly, after having calibrated the tanks (temperature and pressure). Therefore the use of NaK liquid alloy to purify gases is questionable; as preferential paths are established, it remains impossible to predict the period of efficiency of a bubbler. Moreover, the NaK alloy does not chemically transform all traces of water vapor; because some remains present in the form of hydrated products, leading to the formation of wastes with a potential hazard during storage or destruction. In our opinion, this method of purification should be abandoned.

Introduction

NaK alloys are liquids at room temperature and this peculiarity explains their common use in the nuclear industry:[1] coolants for fast neutron reactors, fluids in heat transfer systems, gas purifiers, moving barriers of pressure in safety valves, filling liquids of acoustic wave-guides in sonar systems. Nevertheless several accidents due to explosions have been described concerning the use or during storage of NaK alloys or even potassium alone. These accidents have been reviewed,[2] but no clear explanations were given concerning the possible chemical reactions leading to these explosions, although the influence of some of the oxidized products of the alloy seems to be a key factor.

A bibliographical study of the reactions of NaK alloys with their oxides remained scarce and did not allow for the explanation of all related accidents, particularly those linked to the handling of bubblers. Moreover, they revealed a controversy with respect to the NaK + KO_2 reaction, considered explosive by Sloan and Whitby[3] and harmless by Commander.[4] More recent laboratory tests[5,6] did not confirm the explosion hazard linked to the NaK + KO_2 reaction.

In order to have a better understanding of the reaction leading to the potential explosion due to the storage and destruction of NaK wastes, the present study was undertaken with the following objectives:

(i) to review the structural data of the different oxides of sodium and potassium;

(ii) to perform a thermodynamic analysis to obtain further knowledge on the formation of various sodium and potassium oxides and their identification and reactivity;

(iii) to carry out experimental work on different mixtures to confirm literature data concerning the melting and decomposition temperatures of various sodium and potassium oxides and to characterize these products using differential scanning calorimetry, mass spectrometry and X-ray diffraction;

(iv) to study the stability of a mixture of NaK liquid alloy with sodium oxide Na_2O, sodium peroxide Na_2O_2 or potassium superoxide KO_2, using differential calorimetry, mass spectrometry and tests in glove box; and finally

(v) to define as precisely as possible the conditions for a potential hazard.

The NaK alloy used for the tests was NaK-56 (56 wt-% K) which corresponds to the composition of the NaK alloy used for the cold traps of the Superphenix Reactor.

Finally, NaK oxidation tests have been performed through sweeping or bubbling of argon and dry air containing H_2O or CO_2 as impurities, in order to simulate realistic conditions of oxide formation and to characterize the products thus formed. The results will permit the proposal of new explanations concerning the accidents or incidents linked to the use of bubblers.

Results and Discussion

1. Structural Data

Structural data, density, molar volume and PDF references are gathered in Table 1 for the compounds: Na, K, KNa_2, K_2O, K_2O_2, KO_2, Na_2O, Na_2O_2, NaO_2, $Na_2O_2{\cdot}2H_2O$, $Na_2O_2{\cdot}8H_2O$. From this table the following conclusions can be obtained:

(i) The molar volume of the oxides is smaller than the molar volume of the metals or alloys, therefore the oxides cannot afford a protection against further oxidation.

(ii) Sodium peroxide presents hydrated phases.

(iii) The structure of Na_2O and K_2O are identical.

(iv) The other oxides display different structural data which means that there is no possibility of extended solid solutions.

2. Phase Diagram

The Na-K phase diagram is given in Figure 1.[7] Despite the identical structures of Na and K metals, the solubility in the solid state remains low (< 5% in atoms) which is in agreement with the rather high difference in metallic radii (1.86 Å for Na and 2.30 Å for K); the solubility curves are represented by dotted lines because the solubility limits are not precisely known. Only one stoichiometric compound Na_2K is present on this diagram, with a non-congruent melting point. Recent theoretical analyses of the liquid curves[8] and of the sodium-potassium eutectic,[9] agree with the experimental diagram. The vertical line corresponding to the NaK-56 alloy cuts the liquid curve and the eutectic segment at 5 and −12.5 °C, respectively. It can be noted that the real alloy composition is not constant and is dependent on the lot and storage conditions. It may vary from 56 to 52 weight% in K, corresponding to 43 to 39 atom%.

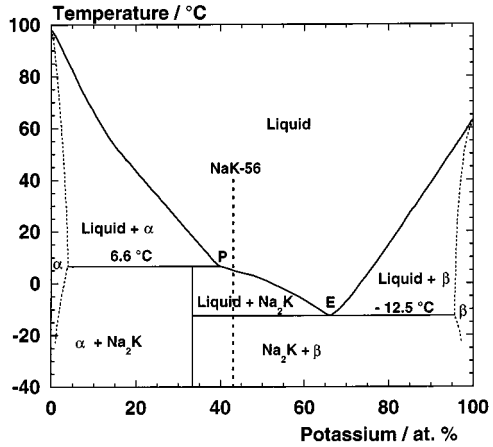

Figure 1. Sodium-potassium liquid solid phase diagram. The diagram was numerized from the figures given in ref.[7]

3. Thermodynamic Analysis

3.1. Formation of Liquid Alloy

The formation of the liquid NaK-56 alloy corresponds to the reaction:

$$0.57\ \mathrm{Na(s\ or\ l)} + 0.43\ \mathrm{K(s\ or\ l)} = \mathrm{Na_{0.57}K_{0.43}(l)} \quad (1)$$

[a] Calculated. − [b] Assumption.

The use of a liquid NaK alloy requires the knowledge of the values of the standard thermodynamic functions H, S and G for this alloy. The enthalpies of mixing versus the composition have been determined at 111 ± 2 °C from liquid sodium and potassium, by Yokokawa and Kleppa.[10] From these data, the authors concluded that the behavior is close to ideality for alloys with a sodium mol fraction x_{Na} higher than 0.5. The work of Cafasso et al.[11] on the determination of the excess Gibbs energies of mixing was performed at the same temperature in order to obtain the activities and activity coefficients of sodium and potassium for such alloys. Their results agree well with the previous conclusion on the range of ideality. From these data and the thermodynamic data of Na and K at 111 °C, it was possible to obtain the thermodynamic values for the formation of $Na_{0.57}K_{0.43}$(l), as well as the data for the reactants and product at the same temperature (reference temperature 25 °C):

$\Delta_r H° = 0.748$ kJ mol^{-1} $\Delta_r S° = 5.604$ J K^{-1} mol^{-1}
$\Delta_r G° = -1.404$ kJ mol^{-1}
for 0.57 Na(l) + 0.43 K(l):
$H°_{384} = 5.085$ kJ mol^{-1} $S°_{384} = 71.77$ J K^{-1} mol^{-1}
for $Na_{0.57}K_{0.43}$(l):
$H°_{384} = 5.833$ kJ mol^{-1} $S°_{384} = 77.37$ J K^{-1} mol^{-1}

The standard data at 25 °C were calculated from the melting enthalpies, melting entropies and constant pressure heat capacities for Na and K. The heat capacity of the liquid alloy was estimated from the heat capacities of liquid sodium (31.83 J K^{-1} mol^{-1} at 98 °C) and liquid potassium (32.14 J K^{-1} mol^{-1} at 63 °C) which change very slowly with temperature. The data for the formation of $Na_{0.57}K_{0.43}$(l) at 25 °C are:

$\Delta_r H° = 3.113$ kJ mol^{-1} $\Delta_r S° = 12.20$ J K^{-1} mol^{-1}
$\Delta_r G° = -0.514$ kJ mol^{-1}
for 0.57 Na(s) + 0.43 K(s):
$H°_{298} = 0$ kJ mol^{-1} $S°_{298} = 57.14$ J K^{-1} mol^{-1}
for $Na_{0.57}K_{0.43}$(l):
$H°_{298} = 3.113$ kJ mol^{-1} $S°_{298} = 69.34$ J K^{-1} mol^{-1}

The formation of the alloy is endothermic and the driving force is the entropy factor. These values are in agreement with different theoretical calculations using the pseudo-potential model applied to hard sphere mixtures.[12–15]

In comparison with the values calculated for the different oxidation reactions (vide infra), the data given above are lower by two to three orders of magnitude, therefore the corrections needed for the substitution of the pure metals by the liquid alloy can reasonably be neglected.

3.2. Sodium-Oxygen System

Figure 2 represents the Ellingham diagram (Gibbs energy versus temperature) for the formation of the oxygenated compounds of sodium according to the equations:

$$4\ Na(s\ ou\ l) + O_2(g) = 2\ Na_2O(s)\quad \Delta_r G°_{298} = -758\ kJ\ mol^{-1} \quad (2)$$

$$2\ Na_2O(s) + O_2(g) = 2\ Na_2O_2(s)\quad \Delta_r G°_{298} = -141\ kJ\ mol^{-1} \quad (3)$$

$$Na_2O_2(s) + O_2(g) = 2\ NaO_2(s)\quad \Delta_r G°_{298} = +12\ kJ\ mol^{-1} \quad (4)$$

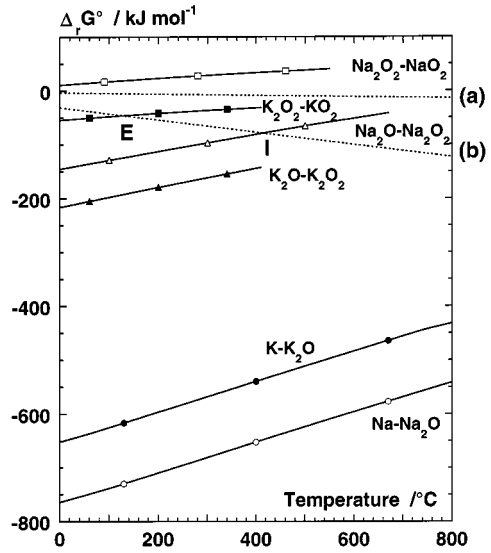

Figure 2. Ellingham diagram for the successive formation of oxygenated compounds of sodium (white points) and potassium (black points). The dotted lines represent the free enthalpy of dioxygen for a partial pressure of (a) 0.2 bar and (b) 10^{-6} bar. E and I are the crossing points between line (b) and the formation curves of KO_2 and Na_2O_2

This diagram shows that in the presence of excess sodium, the stable product is Na_2O, therefore, metallic sodium will reduce the higher oxides. The presence of an excess of oxygen leads to the formation of a stable peroxide, Na_2O_2, at atmospheric pressure. For the sodium superoxide NaO_2, the corresponding values are positive, implying that this compound is only stable under high oxygen pressure.

Figure 2 also represents the variations of the Gibbs energy of gaseous oxygen for the partial pressure of O_2 in air (0.2 bar, dotted line a), and also for a partial pressure of 10^{-6} bar (dotted line b) which corresponds to a dioxygen concentration of only 1 ppmv (part per million in volume). The latter is in line with the magnitude of the impurity level in the gases. The stability of the peroxide Na_2O_2, with regard to the decomposition at atmospheric pressure, can be deduced from the respective positions of the corresponding curve and line b; this peroxide is stable up to a temperature of about 420 °C which corresponds to the crossing point I. Sodium superoxide is not stable in the considered temperature range and decomposes according to the reverse of Equation (4). Therefore, in the presence of an excess of oxygen , there is a predominant formation of sodium peroxide Na_2O_2 on the oxide crust, while Na_2O is stable only in direct contact with sodium. From a kinetic point of view, Na_2O_2 represents the primary product of the reaction which maintains the O–O bond, while the formation of Na_2O requires the full breaking of this bond.

3.3. Reactions with Water Vapor

In the presence of water vapor, the oxide Na_2O can transform into sodium hydroxide NaOH and can then form the successive hydrates $NaOH{\cdot}nH_2O$ (n = 1, 2, ...). Sodium peroxide can also form hydrates $Na_2O_2{\cdot}nH_2O$ (n = 1, 2, 8) which should remain stable provided they are not in direct

contact with metallic sodium. Data are available for the octa-hydrate $Na_2O_2 \cdot 8H_2O(s)$ that allows for the checking of its stability according to the equation:

$$Na_2O_2(s) + 8\ H_2O(g) = Na_2O_2 \cdot 8H_2O(s) \qquad \Delta_r G^\circ_{298} = -193\ kJ\ mol^{-1} \quad (5)$$

The equilibrium at room temperature corresponds to a partial pressure $p(H_2O)$ of about 6×10^{-5} bar.[16] These data show that the hydrates can be formed in the presence of traces of water, in agreement with the highly hygroscopic nature of sodium peroxide.

3.4. Potassium-Oxygen System

The successive formation of oxygenated compounds of potassium are also displayed in Figure 2, according to the balanced equations:

$$4\ K(s\ or\ l) + O_2(g) = 2\ K_2O(s) \qquad \Delta_r G^\circ_{298} = -646\ kJ\ mol^{-1} \quad (6)$$

$$2\ K_2O(s) + O_2(g) = 2\ K_2O_2(s) \qquad \Delta_r G^\circ_{298} = -211\ kJ\ mol^{-1} \quad (7)$$

$$K_2O_2(s) + O_2(g) = 2\ KO_2(s) \qquad \Delta_r G^\circ_{298} = -53\ kJ\ mol^{-1} \quad (8)$$

All the species are stable at 20 °C with regard to decomposition. K_2O_2 is also stable with regard to disproportionation into KO_2 and K_2O. At ambient temperature, the superoxide KO_2 is in equilibrium with a very low partial pressure of oxygen $p(O_2)$ of about 10^{-9} bar at 20 °C. According to the diagram, KO_2 begins to decompose at 130 °C at a pressure of 10^{-6} bar (crossing point E on Figure 2). It will thus form and remain stable at ambient temperature, even if gaseous oxygen is present in trace amounts only.

As the superoxide is the first product to be formed (kinetic product), the stable product on the outer layer of the oxide crust will be $KO_2(s)$, which should constitute the predominant species in accordance with the results of Gardener.[6] Therefore, the conditions favorable to the formation of the superoxide are those in which oxygen is in the presence of a small proportion of metal, mainly on the walls and on the outer surface of the crusts that form above the NaK alloy. According to Gardener,[6] KO_2 begins to decompose at around 130 °C under 8×10^{-6} bar, a value of the same order of magnitude that can be deduced from the thermodynamic data (10^{-6} bar).

3.5. Sodium-Potassium Comparison: The Case of NaK Alloys

Figure 2 clearly shows differences in stability with respect to the decomposition of higher oxides into lower oxides: Na_2O is more stable than K_2O, whereas K_2O_2 and KO_2 are more stable than Na_2O_2 and NaO_2 ,respectively. At 25 °C and above 10^{-6} bar (dotted line b), KO_2 is stable and will be formed, whereas even with an oxygen pressure of 1 bar, NaO_2 cannot be formed from Na_2O_2 ($\Delta_r G > 0$).

The oxides Na_2O or K_2O can react with KO_2 according to the equations:

$$KO_2(s) + K_2O(s) = 1.5\ K_2O_2(s) \quad {}_{\Delta r}G^\circ_{298} = -80\ kJ\ mol^{-1} \quad (9)$$

$$2\ KO_2(s) + 2\ Na_2O(s) = K_2O_2(s) + 2\ Na_2O_2(s) \qquad \Delta_r G^\circ_{298} = -89\ kJ\ mol^{-1} \quad (10)$$

For both reactions, $\Delta_r G^\circ$ is negative in the temperature range 0−100 °C. On the other hand, KOH, NaOH and $NaOH \cdot H_2O$ cannot react with KO_2:

$$KO_2(s) + 2\ KOH(s) = 1.5\ K_2O_2(s) + H_2O(l) \qquad \Delta_r G^\circ_{298} = +119\ kJ\ mol^{-1} \quad (11)$$

$$2\ KO_2(s) + 4\ NaOH(s) = K_2O_2(s) + 2\ Na_2O_2(s) + 2\ H_2O(l) \qquad \Delta_r G^\circ_{298} = +198\ kJ\ mol^{-1} \quad (12)$$

For all these reactions, $\Delta_r G^\circ$ is positive in the same temperature range.

4. Model for Oxidation of Na-K Alloys

According to the above results, the most likely predominant phases in the presence of oxygen are: sodium peroxide Na_2O_2 and potassium superoxide KO_2. On direct contact with the alloy, a $Na_2O + K_2O$ mixture may occur since Na_2O and K_2O are the only thermodynamically stable oxides in the presence of an excess of NaK alloy.

All the oxygenated compounds display a higher density than the NaK alloy, and should therefore fall to the bottom of the containers, thus being protected against any further reactions. This behavior is not observed as the oxide layers remain on the surface of the alloy. This experimental result could be explained by the formation of a porous oxide layer that cannot be wetted by the metallic alloy. As the liquid alloy cannot penetrate this layer, the apparent density of the oxide layer (i.e. including the pore volume) has to be taken into account. This apparent density is therefore less than the bulk density of the alloy and leads to an apparent molar volume greater than that of the alloy.

Moreover, some oxygenated compounds are very hygroscopic and in the presence of traces of water vapor, the formation of hydrates such as $Na_2O_2 \cdot 8H_2O$, $Na_2O_2 \cdot 2H_2O$, $NaOH \cdot H_2O$ or $KOH \cdot H_2O$ is likely to occur.

Under these conditions, the layer of oxides can come off from the surface of the alloy, making any subsequent reduction of sodium peroxide or potassium superoxide by the alloy impossible. The layer or crust of oxides can be schematized as presented in Figure 3. In the areas that are in contact with the alloy, a thin layer of a $K_2O + Na_2O$ mixture can play the role of buffer between the alloy and the external part of the crust.

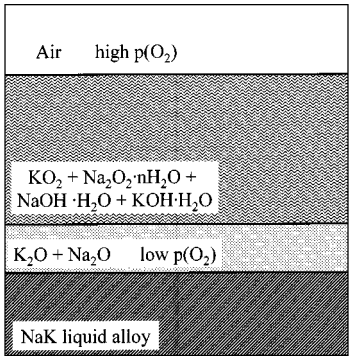

Figure 3. Model for the oxide layers on the surface of Na-K alloys

The accidents and explosions that occurred during handling or upon impact may be explained by the contact of the external part of the oxide crust with the liquid alloy. This contact is likely to cause an exothermic reduction of the potassium superoxide KO_2 by the NaK alloy if, the kinetics is not too slow. The heat released could then favor the decomposition or further reaction of KO_2 according to the strongly exothermic equations:

$$2\ KO_2(s) + 2\ K(l) = 2\ K_2O(s) + O_2(g) \qquad \Delta_rG°_{298} = -164\ kJ\ mol^{-1} \quad (13)$$

$$2\ KO_2(s) + 2\ Na(l) = K_2O(s) + Na_2O(s) + O_2(g) \qquad \Delta_rG°_{298} = -220\ kJ\ mol^{-1} \quad (14)$$

In the case of hydrated oxides, other possible reactions can lead to the release of hydrogen:

$$Na_2O_2{\cdot}8H_2O(s) + 8\ Na(l) = Na_2O_2(s) + 8\ NaOH(s) + 4\ H_2(g) \qquad \Delta_rG°_{298} \approx -1000\ kJ\ mol^{-1} \quad (15)$$

$$NaOH{\cdot}H_2O(s) + Na(l) = 2\ NaOH(s) + 1/2\ H_2(g) \qquad \Delta_rG°_{298} = -132\ kJ\ mol^{-1} \quad (16)$$

$$KOH{\cdot}H_2O(s) + K(l) = 2\ KOH(s) + 1/2\ H_2(g) \qquad \Delta_rG°_{298} \approx -130\ kJ\ mol^{-1} \quad (17)$$

The heat released by these reaction is likely to cause the endothermic decomposition of KO_2 and the simultaneous release of oxygen, which could lead to an explosion of the $H_2(g) + O_2(g)$ mixture.

On the basis of these assumptions, an experimental program was initiated, including the following tests:

(i) Reactions of pure KO_2, Na_2O_2 and Na_2O with the alloy NaK-56;

(ii) Reaction of hydrated peroxide or hydroxide with the alloy;

(iii) Reaction of a $Na_2O_2{\cdot}nH_2O + KO_2$ mixture placed in contact with the alloy;

(iv) Oxidation tests on NaK-56 and characterization of the products obtained.

5. Reactions of NaK-52 Alloy with Oxides, Peroxides, and Superoxides

5.1. Thermal Stability of Pure Compounds

The differential scanning calorimetry (DSC) measurements performed on pure NaK alloy show the eutectic point at −12.7 °C and that the liquid form exists at 8.3 °C in accordance with the phase diagram (Figure 1). The melting enthalpy of the alloy is 2.17 kJ mol^{-1} a value in good agreement with the calculated data for Na (2.21 kJ mol^{-1}) and K (2.11 kJ mol^{-1}).[22]

The stability of pure and hydrated oxides was studied using DSC and mass spectrometry. The reactants have been characterized by X-ray diffraction. The results are gathered in Table 2 and they give rise to the following observations:
Na_2O is stable up to 1000 °C (not given in Table 2);
For Na_2O_2, the endothermic phenomenon at 490 °C seems to be the melting of the peroxide. This value is slightly higher than that given in the literature i.e. 460 °C;[17]

KO_2 decomposes slowly under our operating conditions above 130 °C. From the literature, the melting point lies between 380 and 500 °C.

Hydrated Na_2O_2 releases water and oxygen above 50 °C with a maximum at 100 °C for H_2O and at 200 °C for oxygen.

The diffractograms show that pure sodium and potassium oxides are hygroscopic, as the hydrated compounds $NaOH{\cdot}H_2O$, $KOH{\cdot}H_2O$ and $Na_2O_2{\cdot}nH_2O$ were also observed. The hydration of Na_2O_2, performed in an exsiccator with water vapor under a water-pump vacuum, results in the formation of $Na_2O_2{\cdot}2H_2O$; when the hydration reaction is performed in air, there is the predominant formation of Na_2CO_3, $Na_2O_2{\cdot}2H_2O$ and $Na_2O_2{\cdot}8H_2O$.

For the superoxide KO_2, the mass spectrometry analysis revealed a release of oxygen at the beginning of heating (estimated between 50 and 100 °C), whereas the thermodynamic calculation predicted decomposition from 130 °C for an oxygen pressure of 10^{-6} bar. These values are not in

Table 2. Stability and characterization of pure and hydrated oxides.

Compounds	Na_2O_2	KO_2	Hydrated Na_2O_2
Supplier (purity)	Osi (95%)	Merck (96.5%)	Prepared
Phase identification	Na_2O_2 major	KO_2 major	$Na_2O_2{\cdot}2H_2O$
byX-ray diffraction	$Na_2O_2{\cdot}2H_2O$	$KOH{\cdot}H_2O$	Na_2O_2 and $NaOH{\cdot}H_2O$
Calorimetry:			
Reactant mass	0.538 g	0.520 g	
Temperature range	20−600 °C	20−600 °C	
Main thermal events under heating	Slight exotherm, 444 °C (−2.4 J g^{-1}) Endotherm, 490 °C (53 J g^{-1}) (melting)	Endotherm, 130 °C (50.3 J g^{-1}) Slight exotherm, 153 °C (−14 J g^{-1}) From 430 °C, reaction leading to loss of tightness at 500 °C	
Conclusion	Melting at 480−490 °C	Decomposition above 130 °C	
Mass spectrometry	1.49 g	0.996 g	3.72 g
Temperature range	20−500 °C	20−500 °C	20−300 °C
Gas release	Main but slight release of H_2O above 100 °C. Slight release of O_2; max. at 200 °C	Release of oxygen from 50−100 °C. Max. at 200 °C.	Release of water (predominant) and oxygen above 50 °C O_2 max. at 200 °C

disagreement as the vacuum needed for the MS measurements is much lower than this value. The maximum for oxygen release is situated at 200 °C and corresponds to a partial pressure of 10^{-6} bar (Figure 4).

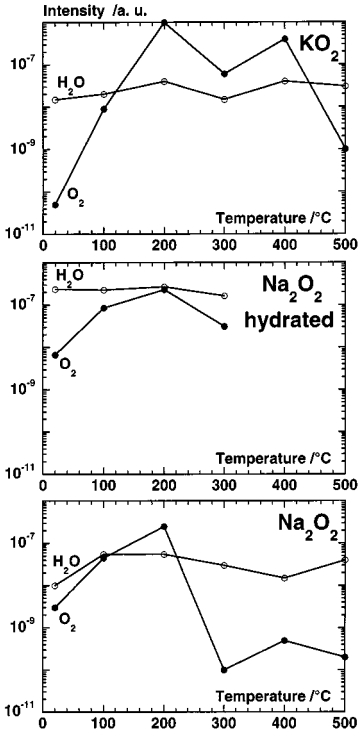

Figure 4. Mass spectra results for the release of water vapor and oxygen, versus temperature for the compounds KO_2, Na_2O_2 and hydrated Na_2O_2

Sodium peroxide displays a mass loss of 8.7 wt-% at the end of the test. This loss indicates the likely and partial formation of Na_2O, the whole decomposition corresponding to a loss of mass of 20.5%. In addition, Na_2O_2 contains impurities (H_2O, CO_2, etc.) evidenced by mass spectrometry in agreement with the very hygroscopic and basic character of Na_2O_2 (higher than that of KO_2). Its decomposition rate is lower than that of KO_2 by more than one order of magnitude.

The decomposition of hydrated sodium peroxide $Na_2O_2{\cdot}nH_2O$ shows a constant predominant loss of H_2O from the very beginning of heating (Figure 4), and a minor loss of oxygen with a maximum at 200 °C.

5.2. Reactions of NaK Alloy with Na_2O_2

Using the DSC 111 calorimeter, two tests were performed, with the aim to vary the temperature around 0 °C (cycles between − 20 and + 20 °C) in order to simulate natural thermal cycling, then followed by high temperature cycles. The results are given in Table 3.

1st test: 18 cycles −20 to 20 °C; 4 cycles 20 to 390 °C; 4 cycles −20 to 20 °C.

2nd test: 10 cycles −20 to 20 °C; 2 cycles 20 to 420 °C; 4 cycles −20 to 20 °C.

A significant part of the results of the second test are presented in Figure 5. Before the temperature rise, the thermograms of the thermal cycling around ambient temperature show the characteristic NaK melting and solidification peaks corresponding to the liquid and eutectic lines and we can see only minor changes between the first cycle and the tenth cycle. The heating leads to slightly endothermic reactions between 33 and 53 °C, followed by an exothermic reaction above 170 °C; after the first temperature rise, we observe the formation of metallic potassium which is revealed by the appearance of a peak at about 60 °C (Figure 5). For test 2 the weight of potassium is estimated to be about 10 mg.

From the thermodynamic data, an exothermic reaction is expected between the alloy and Na_2O_2 which would lead to the formation of the more stable oxide Na_2O:

$$2\ NaK(l) + Na_2O_2(s) \rightarrow 2\ Na_2O(s) + 2\ K(l)$$
$$\Delta r H^\circ_{298} = -327\ kJ\ mol^{-1} \quad (18)$$

This reaction consumes sodium and therefore leads to a change in the composition of the alloy, up to the formation of metallic potassium. The weight balance is given in Table 4 and takes into account the excess peroxide Na_2O_2 which can react with potassium in a second step giving, as final products, a mixture of Na_2O, K_2O and K. The calculated weight of remaining potassium (7.8 mg) is in agreement with the value deduced from DSC measurements (10 mg).

Table 3. Reaction of NaK-56 alloy with Na and K oxides. Results of differential scanning calorimetry

	NaK + Na_2O_2 Test 1	Test 2	NaK + KO_2 Test 1	Test 2	Test 3
Mass of NaK-56	0.037 g	0.024 g	0.024 g	0.0082 g	0.049 g
Mass of Na_2O_2 or KO_2	0.041 g	0.024 g	0.027 g	0.0057 g	0.050 g
Main thermal phenomena under heating	Endotherm at 45 °C Endotherm at 60 °C (melting of K) Exotherm at 166 °C Large exotherm at 240 °C	Endotherm 33 to 53 °C Large exotherm above 172 °C	Exotherm > 167 °C Large exotherm above 195 °C	Exotherm > 167 °C	Exotherm > 167 °C Large exotherm at 190 °C
NaK consumed	Yes	Yes	Yes, partially	Yes	
Potassium formation	Yes	Yes (0.010 g)	No	Yes (≈ 0.001 g)	Yes
Apparatus	DSC 111	DSC 111	DSC 111	DSC 111	HTC

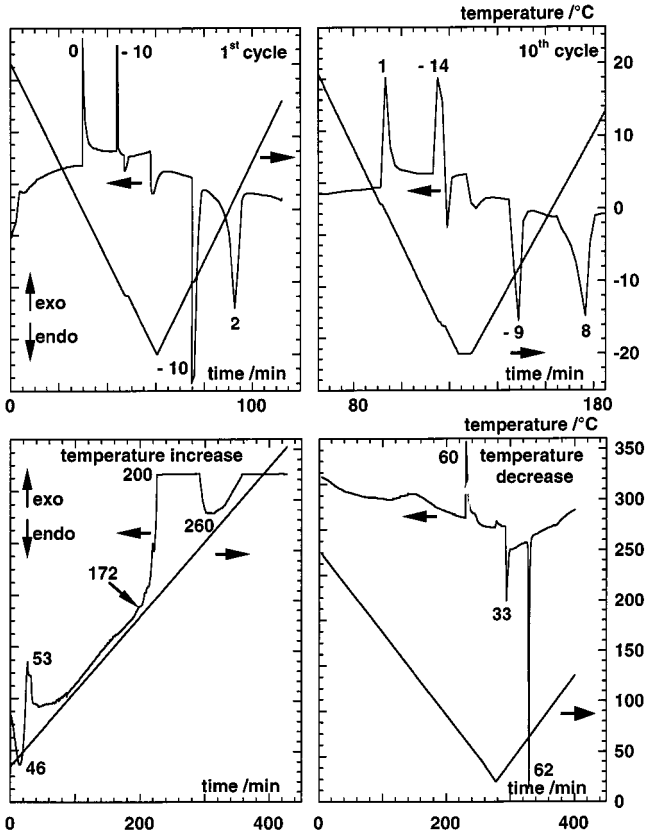

Figure 5. DSC curves for the reaction between NaK alloy and Na_2O_2:1st cycle between 20 and −20 °C; 10th cycle between 20 and −20 °C; increase from 20 to 420 °C and cooling from 420 to 20 °C. See test 2 in Table 3

Table 4. Example of mass and mol balance for the reaction NaK + Na_2O_2 (Test 2)

	NaK (24.3 mg)		Na_2O_2 (24.4 mg)			
	Na	K	Na	O	Na_2O	K_2O
Initial mass/48.7 mg	10.7	13.6	14.4	10.0	0	0
Initial amount/mmol	0.47	0.35	0.62	0.62	0	0
Intermediate amount/mmol	0	0.35	0.15	0.15	0.47	0
Final amount /mmol	0	0.2	0	0	0.545	0.075
Final mass/48.7 mg	0	7.8	0	0	33.8	7.1

Intermediate reaction: $Na_2O_2(s)$ (excess) + 2 Na(l) → 2 $Na_2O(s)$; Final reaction: $Na_2O_2(s)$ + 2 K(l) (excess) → $Na_2O(s)$ + $K_2O(s)$.

After the temperature rise, the low temperature cycles (−20 to +20 °C) do not show the previous NaK peaks, which is in agreement with the proposed reactions. Therefore, these results are consistent with the thermodynamic calculations which suggested the enrichment of the alloy in potassium due to the formation of the more stable Na_2O.

Another mixture of the NaK alloy (0.41 g) and Na_2O_2 (1.00 g) was analyzed by mass spectrometry, but no significant gas release was observed, in agreement with the explanations given in Table 4.

5.3. Reactions of the NaK Alloy with KO_2

Two tests were performed using the DSC 111 calorimeter and one test using the HTC calorimeter. The test conditions and results are gathered in Table 3. For test 1 and test 2 the same cycling as with Na_2O_2, i.e. between 20 and −20 °C, displays the characteristic peaks of the NaK alloy, even after heating at 150 °C. During heating (up to 300 °C), exothermic peaks appear above 167 °C (Figure 6 for test 3). For test 1, the expected reaction would lead, after completion, to the disappearance of the alloy and to the formation of a mixture of Na_2O, K_2O and K_2O_2; experimentally, the alloy is only partially consumed and no potassium can be evidenced, showing an incomplete reaction. Test 2, performed with more NaK alloy, displays the same exothermic peaks above 167 °C, but leads to a complete disappearance of the alloy and to the formation of potassium (about 1.0 mg). This is in agreement with a complete reaction leading to the formation of Na_2O, K_2O and K (calculated weight 1.1 mg).

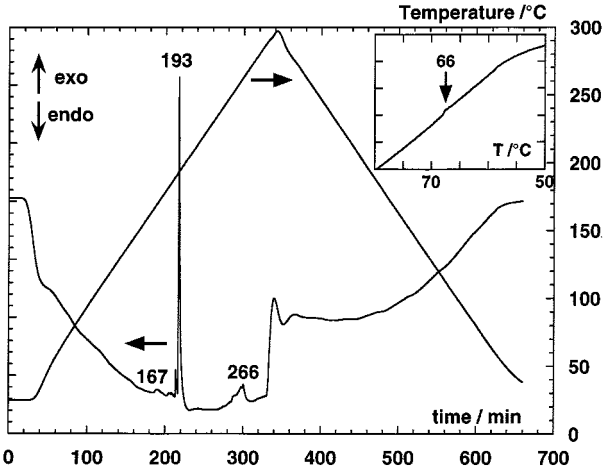

Figure 6. HTC curves for the reaction between NaK alloy and KO_2 (Table 3, test 3). The window represents an enlargement of the last part of the curve versus temperature

The exothermic reactions that appear at 167 °C (Figure 6) are reproducible since this temperature is strictly identical on both instruments, with different reactant masses and different proportions. Below this temperature, there is no violent reaction, even after an induction period. This is in agreement with Sloan.[1] Moreover, the low temperature thermal cycling has little effect on the reaction between the NaK alloy and KO_2 superoxide. For test 3, the reaction is incomplete and leads to a heterogeneous mixture of the products; the formation of potassium is seen by a very tiny exothermic peak at 66 °C (see window in Figure 6).

The influence of these exothermic events on the endothermic decomposition of potassium superoxide was examined by means of mass spectrometry. A mixture of NaK alloy (0.46 g) and KO_2 (0.49 g) was placed under inert atmosphere (glove box) into the sample container equipped with a tight connection. The temperature was increased in steps from ambient temperature up to 300 °C. The measurements performed in the 150−160 °C range showed a considerable increase in oxygen corresponding to the decomposition of KO_2. The same reaction performed in the presence of Na_2O from 20 to 200 °C displayed similar results,

showing that sodium oxide is very stable and plays no role in the reaction between the NaK alloy and KO_2.

5.4. Reaction of NaK + KO_2 + Na_2O_2

One test was performed using the DSC 111 calorimeter and one using the HTC calorimeter. The results are given in Table 5. Figure 7, obtained with the HTC apparatus (test 2), shows a rapid and significant exothermic reaction from 170 °C, greater than that observed during the NaK + KO_2 reaction. The formation of potassium is evidenced during the cooling (see window in Figure 7).

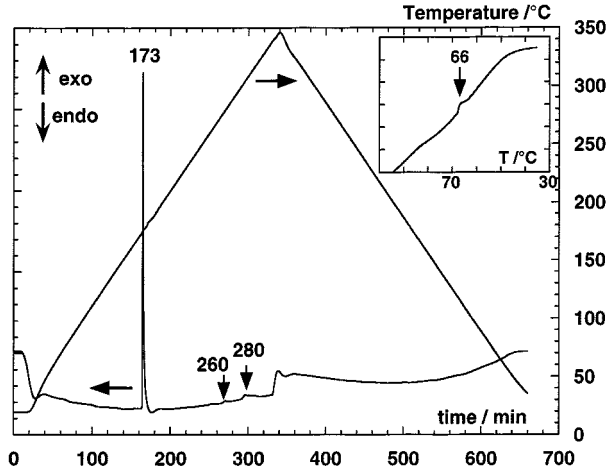

Figure 7. HTC curves for the reaction between NaK alloy and KO_2 + Na_2O_2 (Table 4, test 2). The window represents an enlargement of the last part of the curve versus temperature

5.5 Discussion About the Role of Potassium Superoxide

The tests carried out between the NaK alloy and sodium peroxide and/or potassium superoxide, revealed significant exothermic reactions above 170−180 °C. Therefore, KO_2 is effectively responsible for a significant heat release, but only above a temperature of about 170 °C, with subsequent consumption of the sodium of the NaK alloy. Na_2O_2 is also responsible for significant exothermic reactions above 200 °C, but only slight reactions with the alloy occur as soon as ambient temperature is reached. Therefore, the explosive behavior of such mixtures at ambient temperature imply another kind of reactions; KO_2 alone cannot be responsible for the triggering of this phenomenon.

The formation of metallic potassium during several tests was confirmed, displaying the selective consumption of the sodium of the NaK alloy, in accordance with the formation of the more stable Na_2O oxide. The completed reactions deduced from the thermodynamic data can be experimentally evidenced, but some tests leads to incomplete reactions and the products are more relevant to the kinetics of the processes (heterogeneous mixtures) than to the reaction thermodynamics.

6. Reactions of NaK-52 Alloy with Hydrated Oxides and Peroxides

These tests were performed in a glove box under argon in a 20 mL glass flask equipped with a thermocouple. The oxides were added separately or simultaneously to about two grams of NaK alloy. The mixture was then manually agitated so as to ensure good contact between the alloy and the oxides. The operating conditions and the results of all the tests are given in Table 6. Preliminary tests were carried out with KO_2 and non hydrated Na_2O_2 for comparison purposes. The reaction was slightly exothermic, but neither the addition of Na_2O_2, nor that of KO_2 caused a violent reaction, in agreement with the results of Gardener.[6] These results confirm, on larger scale (than that used in the calorimetric experiments), that there is no significant reaction at ambient temperature between NaK alloy and sodium peroxide or potassium superoxide, whether they are added successively or simultaneously (Table 6, tests 1 and 2). The results described by Commander,[4] i.e. ignition after an induction period of 18 minutes under inert gas, were therefore not confirmed.

6.1. Reaction of NaK with $Na_2O_2 \cdot nH_2O$

Test on NaK + Na_2O_2 Hydrated in Air

The sodium peroxide was hydrated in ambient air before the test and corresponds to a mixture of dihydrate $Na_2O_2 \cdot 2H_2O$ (minor) and octahydrate $Na_2O_2 \cdot 8H_2O$ (major), aside from sodium carbonate Na_2CO_3. Three tests were performed and the operating conditions and results are given in Table 6. The NaK + hydrated peroxide reaction, performed in a glove box, is violent (Photo 1) and occurs at ambient temperature when the two reagents come into contact (Tests 3a and 3b, Table 6). These tests are the

Table 5. Differential calorimetric analysis of the reactions of NaK-56 alloy with sodium peroxide and potassium superoxide

	NaK + KO_2 + Na_2O_2 Test 1	Test 2

Test N°	Initial conditions					Temperature evolution
1	NaK 2.035 g	+	Na_2O_2 0.604 g	+	KO_2 0.320 g	Slightly exothermic reaction 22 to 28 °C in 4 min
	Reactants added successively					
2	NaK 2.030 g	+	Na_2O_2 0.250 g	+	KO_2 0.321 g	Slight exothermic reaction 24 to 27 °C NaK brilliant under the film
	Reactants added simultaneously					
3a	NaK 2.04 g	+	Na_2O_2 hydrated in air 0.577 g			Violent reaction: 21 to 146 °C in 3 min, explosion, grey smoke. Glass flask broken
3b	NaK 2.05 g	+	Na_2O_2 hydrated in air 0.212 g			Violent reaction: smoke, sparks 23 to 78 °C in 3 min.
4	NaK 2.2 g	+	Na_2O_2 hydrated in air 0.632 g			Slightly exothermic reaction: 21 to 27 °C. Brilliant NaK alloy mixed with parts of oxide
	Na_2O_2 stored in glove box for one week					
5	NaK 2.74 g	+	hydrated Na_2O_2 0.326 g			Violent reaction: 25 to 306 °C in 2 min; flames, smoke
	Hydration in water vapor under vacuum					
6	NaK 2.45 g	+	KO_2 0.250 g	+	hydrated Na_2O_2 0.578 g	Violent reaction: 23 to 380 °C in 30 s; flames, smoke
	Hydration in water vapor under vacuum; oxides added simultaneously					
7	NaK 2.14 g	+	NaOH slightly hydrated 1.01 g + 0.519 + 0.52 g + 0.69 g			NaOH as received; slight reaction: 22 to 34 °C in 5 min 34 to 38 °C in 3 min 38 to 51 °C in 3 min
8	NaK 2.14 g	+	KOH slightly hydrated 0.63 g + 1.19 g			KOH as received Slight reaction: 25 to 31 °C in 1 min 31 to 33 °C in 3 min; dull grey mixture

first ones showing that the occurrence of an explosion is linked to the presence of water in the hydrated peroxide; moreover, the final temperature depends on the amount of hydrated peroxide (compare 3a and 3b). A possible explanation of these results is as follow: in a first step, a surface reaction between the water molecules and the liquid alloy alters the wetting ability of the oxide crust by the alloy; then the alloy penetrates rapidly into the porosity of the peroxide and the reaction becomes violent, resulting in the exothermic formation of hydrogen which first reacts with the peroxide, then with the oxygen released by the temperature increase. The explosion is therefore due to the simultaneous formation of hydrogen and oxygen from the following strongly exothermic reactions ($\Delta rH°$ in kJ mol^{-1}):

$$NaK(l) + Na_2O_2{\cdot}2H_2O(s) \rightarrow NaOH(s) + KOH(s) + Na_2O_2(s) + H_2(g) \quad -242 \quad (19)$$

$$Na_2O_2(s) + H_2(g) \rightarrow 2\ NaOH(s) \quad -339 \quad (20)$$

$$2\ Na_2O_2{\cdot}2H_2O(s) \rightarrow 4\ NaOH(s) + 2\ H_2O(g) + O_2(g) \quad -33 \quad (21)$$

$$2\ H_2(g) + O_2(g) \rightarrow 2\ H_2O(g) \quad -483 \quad (22)$$

The values for equations (19) and (21) are based on a value of about -1121 kJ mol^{-1} for the formation enthalpy of $Na_2O_2{\cdot}2H_2O$; this value was estimated from the corresponding value given for $Na_2O_2{\cdot}8H_2O$ (-2943 kJ mol^{-1}).[18]

Photo 1. Results of the reaction between NaK alloy and sodium peroxide hydrated in air (Table 6, test 3b)

The storage of hydrated Na_2O_2 for one week in glove box, apparently dried the compound with a loss of its reactivity (Test 4, Table 6). This test confirms that the water molecules of the hydrate are responsible for the highly exothermic reaction or explosion.

Test on NaK + Na_2O_2 Hydrated Under Water Pump Vacuum

The diffractogram (Figure 8) of the hydrated product protected by a layer of polyethylene film, displays the presence of the phases Na_2O_2, $Na_2O_2{\cdot}2H_2O$ and the hydrated hydroxide $NaOH{\cdot}H_2O$, showing that the peroxide was only partially hydrated. Although the hydrates formed are not the same as those observed in the previous tests ($Na_2O_2{\cdot}8H_2O$ in one case and $Na_2O_2{\cdot}2H_2O$ plus $NaOH{\cdot}H_2O$ in another case), the reaction is violent in both cases (Table 6, Test 5). These very violent exothermic reactions are due to the presence of hydration water in the solid mixtures. The release of hydrogen exhibits a limited risk as these operations were performed in a glove box, but in air, actual explosions could occur.

Test on NaK + KO_2 + Hydrated Na_2O_2

The previous hydrated peroxide was mixed with KO_2 inside the glove box and then inserted together into the NaK alloy (Table 6, Test 6). In comparison with Test 1, the very violent resulting reaction is clearly due to the hydrated peroxide.

Test on NaK + NaOH

Slightly hydrated sodium hydroxide pellets (97%) were ground in air, and analyzed using X-ray diffraction: NaOH is found to be the predominant species besides the hydrates $NaOH{\cdot}H_2O$ and $Na_2CO_3{\cdot}7H_2O$ (Table 6, Test 7). The alloy reacts only slightly in the presence of sodium hydroxide, with a release of hydrogen. Repeated additions of hydroxide does not produce significant reactions.

Test on NaK + KOH

Potassium hydroxide pellets (87%) were ground and analyzed. KOH is the predominant phase besides $KOH{\cdot}H_2O$ and K_2CO_3 (Table 6, Test 8). The reaction is less exothermic than that with the sodium hydroxide due to the the lower hygroscopic behavior of KOH.

In conclusion, the violence of the reaction between NaK alloys and hydrated sodium peroxide, sodium hydroxide or potassium hydroxide, depends on the degree of hydration of the reagents and therefore on their history. The reaction remains difficult to predict and therefore portrays a random character. The simultaneous presence of hydrated sodium peroxide and potassium superoxide leads to a faster and more exothermic reaction.

7. Oxidation of NaK Alloy by Oxygen in Presence of H_2O Impurities

7.1. Preparation of Oxidized NaK Alloy by Sweeping Argon and Air

Two tests were performed in glass crucibles and the operating conditions and results are given in Table 7. The first test was carried out in one day and shows that sweeping with argon and air containing H_2O impurities (<5 vpm) results in the formation of a yellow mixture containing hydrated peroxide and hydroxides, in addition to the predominant species KO_2 (Photo 2). The phases observed are in agreement with the thermodynamic data: the oxides Na_2O and K_2O can react with KO_2 and are therefore absent, whereas the hydrates $KOH{\cdot}H_2O$ and $NaOH{\cdot}H_2O$ do not react with KO_2 and can coexist.

The second test was performed over one week and the behavior of the NaK alloy differs from the one observed in the previous test. A few hours after the beginning of the oxidation, the ball of NaK shows numerous excrescences; after a few days, the swellings took on a cauliflower-like appearance (Photo 3) with two predominant phases: KO_2 and $Na_2O_2{\cdot}2H_2O$ (Table 7, test 2). In this case, the water impurities in the argon during the first step seem to play an important role.

In conclusion, sweeping with a gas containing water impurities leads to a concentration of the water molecules through the formation of hydrated hydroxides and peroxides and not to the reduction of water into hydrogen. The traces of water vapor are only partially eliminated and therefore the role assigned to the NaK alloy is not fulfilled

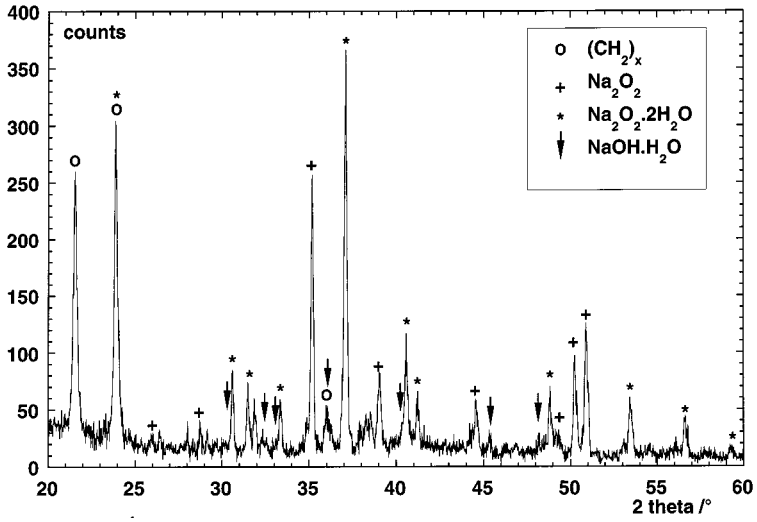

Figure 8. Raw diffractogram of sodium peroxide after hydration under water pump vacuum. The polyethylene peaks are due to the protecting layer. Dwell time 1 s; step 0.02 °

Table 7. Oxidation of the NaK alloy by argon and air sweeping

	Conditions	Aspect	Composition
Test 1 1.03 g	Sweeping 23 h with argon (3 L min^{-1}) and air (3 to 5 L min^{-1}), then storage in a closed flask	Intense yellow product	KO_2 predominant + $Na_2O_2{\cdot}2H_2O$ + $NaOH{\cdot}H_2O$ + $KOH{\cdot}H_2O$
Test 2 2.28 g	Sweeping 13 h with argon (6 L min^{-1}) then 8 h with argon and air (5 L min^{-1}) followed by 150 h with air (3 L min^{-1})	Cauliflower-like aspect, yellow at end of test	KO_2, major + $Na_2O_2{\cdot}2H_2O$, major + $NaOH{\cdot}H_2O$

Photo 2. Yellow product obtained during the oxidation of NaK alloy by argon and air sweeping (Table 7, test 1)

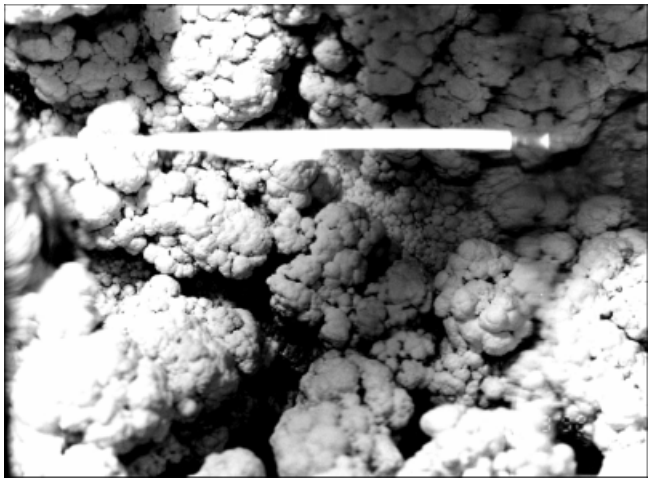

Photo 3. Product obtained during the oxidation of NaK alloy by argon and air sweeping (Table 7, test 2)

because it leads predominantly to an accumulation of the H_2O impurities. The products thus obtained confirm the reactions expected from a thermodynamic basis (NaK-56 is represented by the approximate formula NaK):

$$2\ NaK(l) + 3\ O_2(g) \rightarrow Na_2O_2(s) + 2\ KO_2(s) \quad (23)$$

$$NaK(l) + 2\ H_2O(g) \rightarrow NaOH(s) + KOH(s) + H_2(g) \quad (24)$$

$$Na_2O_2(s) + n\ H_2O(g) \rightarrow Na_2O_2{\cdot}nH_2O(s) \text{ with } n = 2 \text{ or } 8 \quad (25)$$

$$NaOH(s) + H_2O(g) \rightarrow NaOH{\cdot}H_2O(s) \quad (26)$$

$$KOH(s) + H_2O(g) \rightarrow KOH{\cdot}H_2O(s) \quad (27)$$

7.2. Preparation of Oxidized NaK Using Argon and Air Bubbling

The purpose of this test was to represent a real bubble chamber at a laboratory scale, with a continuous circulation of gas containing water impurities ($\leq$ 5 vpm) in the NaK liquid alloy. Air was added to the argon flow in order to accelerate the oxidation of the NaK alloy. The oxidation was performed in a glove box.

The test lasted three months (including 500 h of bubbling) during which a total of 30 m^3 of argon and 60 m^3 of azoxy (reconstituted dry air) were alternatively or simultaneously bubbled into the liquid alloy (9.95 g). The mass of water impurities passing through the alloy totals 0.36 g and it serves either to hydrolyze the NaK alloy into NaOH and KOH, or to hydrate Na_2O_2, NaOH and KOH.

During the argon bubbling, the previously very brilliant NaK alloy first becomes dull gray, then starts to whiten in selected areas due to the water and oxygen impurities. The bottom of the reactor is coated with very fine gray beads that are ejected. Bubbling with air results in the formation of yellowish areas, which then become clear yellow. This always occurs along the preferential paths. The start of the azoxy gas flow sometimes causes orange flames and grayish smoke which are then extinguished by argon sweeping. Throughout the test, the ejection of small gray beads is observed. At the end of the test, the mixture is very heterogeneous: orange crusts adhering closely to the walls, grayish parts and metallic NaK. After the test, four samples were taken from these various parts and the results of the X ray diffraction analyses are given in Table 8. Figure 9 represents the diffractogram of the sample BAG 2 and five species could be identified. After 30 min in air, we observe a swelling of the sample and the disappearance of the peaks corresponding to sodium hydroxide due the very hygroscopic behavior of these compounds.

These series of tests show that when the NaK alloy is exposed to the sweeping or bubbling of argon and dry air containing water impurities, the products KO_2, $KOH{\cdot}H_2O$, $NaOH{\cdot}H_2O$ and $Na_2O_2{\cdot}2H_2O$ are always formed The mixture is heterogeneous, certain areas are very hard, whereas others are flaky. Differences in color can be observed. It is also observed that the gas follows preferential paths due to the heterogeneous nature of the crust. Therefore certain areas are oxidized and hydrated whereas other parts of the alloy remain in the metallic state. The argon is likely to circulate without being really purified.

Table 8. Products obtained after oxidation of the NaK alloy by argon and air bubbling for three months

	Aspect	Identified products (XRD)
BAG 1	Yellow crust taken from the surface of the NaK during the test	KO_2 predominant + $KOH{\cdot}H_2O$ + $Na_2O_2{\cdot}2H_2O$
BAG 2	Grey ashes and yellow crusts taken during the test	KO_2 + $KOH{\cdot}H_2O$ + $Na_2O_2{\cdot}2H_2O$ + $NaOH{\cdot}H_2O$ + NaOH + amorphous phase
BAG 3	Grey area (end of test)	KO_2 + $Na_2O_2{\cdot}H_2O$ + $KOH{\cdot}H_2O$ + $NaOH{\cdot}H_2O$ + NaOH
BAG 4	Yellow area (end of the test)	KO_2 + $KOH{\cdot}H_2O$ + $Na_2O_2{\cdot}2H_2O$ + $NaOH{\cdot}H_2O$

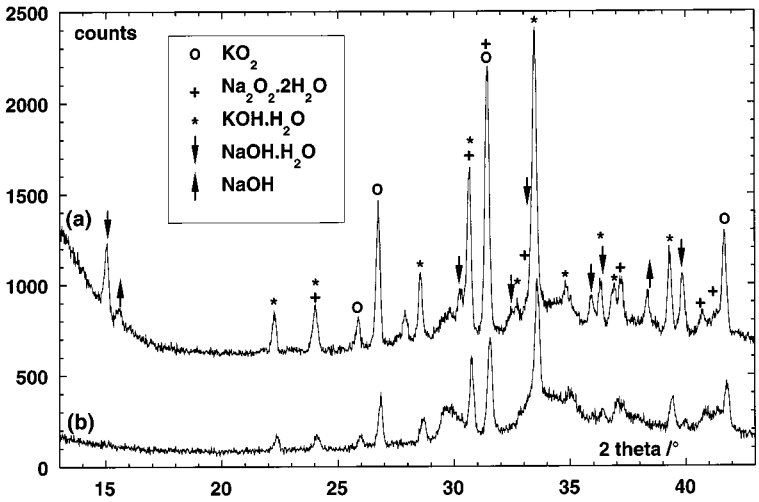

Figure 9. Raw diffractogram of NaK alloy after oxidation by argon and air bubbling during 3 months (Table 8, sample BAG 2).(a) Initial; (b) after 30 min in air. Dwell time 0.5 s; step 0.02 °

Photo 4. Product obtained during the oxidation of NaK alloy by argon and air bubbling for three months (Table 8)

These observations are very important as they explain the hazards of oxidized NaK alloy. Porous crusts containing superoxides, hydrated peroxides and hydroxides, can form on the surface or along the walls and can violently come into contact with the remaining alloy following impact. A slow surface reaction then occurs that can result in the modification of the wetting ability of the oxide crust. The NaK penetrates the pores, which then leads to a violent reaction.

8. Hydration and Dehydration of Sodium and Potassium Oxides and Hydroxides

The aim of these experiments was to examine the possibility to reduce or eliminate the hydration water of the oxidation crust through treatment in vacuum. Hydration was performed using water vapor under water pump vacuum for 12 h. The product was then placed under vacuum (10^{-2} to 10^{-3} bar) for 24 to 60 h at ambient temperature. Dehydration was completed by heating for 24 to 48 h at 110 °C under primary vacuum, followed by cooling. All the results are given in Table 9.

During the dehydration treatment, hydrated peroxide $Na_2O_2{\cdot}2H_2O$ disappears and is partially transformed into NaOH. The hydrated products $NaOH{\cdot}H_2O$ and $Na_2CO_3{\cdot}10H_2O$ are present only in minute amounts, and therefore less likely to react further. After being placed under vacuum, the sample of sodium peroxide becomes harder, but its apparent volume does not change. After

Table 9. Oxide and hydroxide hydration and dehydration tests. (tr = traces)

	Na_2O_2	KO_2	NaOH	KOH
Hydration				
Mass	8.274 g	1.301 g	23.076 g	6.091 g
Increase in mass	1.235 g	Change into liquid KOH	2.963 g	1.308 g
Hydrate obtained	$Na_2O_2{\cdot}2H_2O$ + Na_2O_2	No hydrate formation	$NaOH{\cdot}H_2O$ + NaOH	$KOH{\cdot}H_2O$ + KOH
Dehydration				
Mass	4.086 g		6.406 g	2.673 g

% initial water eliminated	83%		85%	86%
Products after dehydration	Na_2O_2 + NaOH + $NaOH{\cdot}H_2O$ (tr) + $Na_2CO_3{\cdot}10H_2O$		NaOH + $NaOH{\cdot}H_2O$ (tr)	KOH + $KOH{\cdot}H_2O$ (tr)

heating under vacuum, the sample expands considerably and migrats up to the upper level of the recipient.

Potassium superoxide KO_2 does not form hydrated products but is decomposed, giving KOH. For NaOH, the hydration leads to the formation of $NaOH{\cdot}H_2O$ and the vacuum treatment eliminates at least 85% of the water previously fixed. The product is practically dry. The same results are obtained for potassium hydroxide (Table 9).

The products rehydrate very rapidly, as soon as they are no longer under vacuum. Dehydration had to be completed by heating at 100 to 110 °C in order to reach irreversible dehydration levels of about 85%. It is observed during the tests that the hydrated products become partially dehydrated in the glove box (water content < 1 vpm). Therefore, it may be possible to dehydrate a product by circulating hot argon, provided the latter is completely dried. Before performing this type of dehydration on a larger scale in a bubbler containing liquid NaK, laboratory tests are essential to check whether the crust layers that detach and expand, could fall into the liquid NaK and cause exothermic reactions. Laboratory tests have to be developed in order to study the complex geometry, similar to that in real bubblers.

General Conclusion

To the best of our knowledge this is the first laboratory demonstration of an explosion due to gas contaminants (oxygen and water vapor). The previous results were obtained by addition of water or hydrocarbon to the alloy.[4]

The main results of the structural and thermodynamic analysis are as follows:

(i) All the oxygenated compounds of sodium and potassium are denser than the NaK alloy and should therefore fall to the bottom of recipients, which is not observed. The molar volumes of the different oxides are lower than the molar volumes of the metals or alloys.

(ii) The oxide layer that is formed must contain predominantly Na_2O_2 and KO_2. This crust is porous and cannot be wetted by the alloy.

(iii) There is a possible formation of hydrated compounds such as $Na_2O_2{\cdot}8H_2O$; $Na_2O_2{\cdot}2H_2O$; $NaOH{\cdot}H_2O$ and $KOH{\cdot}H_2O$.

(iv) If the oxide crust comes in contact with the NaK alloy, the hydration water can react, leading to a release of hydrogen. As the thermal decomposition of KO_2 results in a release of oxygen, a violent reaction could occur, resulting in an explosion.

The experimental study leads to the following conclusions:

(i) Sodium peroxide Na_2O_2 is stable up to 490 °C and potassium superoxide KO_2 decomposes above 130 °C, resulting in oxygen release.

(ii) The NaK + Na_2O_2 reaction shows great instability which results in the formation of several non-identified compounds. The exothermic reactions begin above 166 °C and increases considerably at 204 °C, but does not release any significant amount of gas.

(iii) The NaK + KO_2 reaction starts at 167 °C and is easily reproducible, with the formation of potassium metal and the release of oxygen due to the thermal decomposition of KO_2. Thermal cycling between −20 and +20 °C has little effect.

(iv) The NaK + KO_2 + Na_2O_2 reaction is highly exothermic above 170 °C; the presence of Na_2O_2 contributes significantly to an increase in released heat.

Tests performed in a glove box on greater quantities display the same results, in disagreement with the high exothermicity mentioned by several authors. On the other hand, the use of hydrated sodium peroxide leads to violent or even explosive reactions. The hydration of Na_2O_2 results in the formation of $Na_2O_2{\cdot}2H_2O$ and/or $Na_2O_2{\cdot}8H_2O$ and $NaOH{\cdot}H_2O$ and the quantity of water absorbed and the degree of hydration determine the random explosive character of the reaction.

The laboratory preparation of oxidized NaK alloy by the sweeping or bubbling of argon and air mixture, containing less than 5 vpm of H_2O, leads to the formation of potassium superoxide KO_2 and hydrated peroxide and oxides: $Na_2O_2{\cdot}2H_2O$, $KOH{\cdot}H_2O$ and $NaOH{\cdot}H_2O$. The water impurities are therefore not eliminated, but they are concentrated into the oxide product crust. In the presence of initial alloy, these products can produce exothermic or explosive reactions, depending on the degree of hydration of the peroxide and hydroxides.

The product mixture is very heterogeneous containing gray parts, orange crusts adhering closely to the walls together with metallic NaK alloy. The gas flow follows preferential paths, certain parts of the alloy are oxidized and hydrated, while other parts remain in the metallic state. These important observations explain the danger of oxidized NaK crusts formed at the surface or along the walls of the bubblers containing hydrated oxides; if they can rapidly come in contact with the remaining metallic alloy following impact, explosions can occur.

The bubblers in service on fast reactors are generally largely oversized. When argon follows preferential paths through the crust forming hydrates, and when saturation is reached, the argon is likely to circulate without being purified. It is therefore impossible to assess the duration of the efficiency of these bubblers. Therefore, in our opinion, this method of purification should be abandoned.

The dehydration tests performed on hydrated peroxide and hydroxide show that the products can be dried under primary vacuum at 100 °C. Drying of the products placed in glove boxes under purified argon ($\leq$ 1 vpm H_2O) is also observed. However, as these hydrated products expand when heated, the crusts could detach and come into contact with the remaining alloy. Therefore, to achieve dehydration on complex geometry, such as those of real bubblers, it is indispensable to perform laboratory tests in order to check whether exothermic reactions can occur, resulting in the accidental contact of these reagents.

Experimental Section

Structural Data: The structural data needed for this work (space group, cell parameters, density) were extracted from Powder Diffraction Files (PDF).[19] They are related to the sodium-potassium alloy phases and the different oxides of sodium and potassium. The main data are given in Table 1.

Thermodynamic Data: The purpose of this analysis was to establish the thermodynamic values concerning the various possible reactions: reaction enthalpy $\Delta_r H°$, entropy $\Delta_r S°$ and Gibbs energy $\Delta_r G°$. These values were calculated and tabulated according to the temperature in the 25−500 °C range and involve all the possible Na-K-O combinations available in the literature. The primary thermodynamic data concern the values tabulated for the following species:

K(s and l), KO_2(s), K_2O(s), K_2O_2(s); Na(s and l), NaO_2(s), Na_2O(s), Na_2O_2(s); O_2(g), H_2O(g), CO_2(g)

They were extracted from two recent data bases[20,21] or from the NIST files.[18] The HSC program was used for part of the calculations.[22] The effect of water vapor and carbon dioxide was taken into account. As standard thermodynamic data concerning NaK alloys were not found, all the diagrams, therefore, refer to sodium and potassium.

Chemicals: The commercially available potassium and sodium oxides are: sodium oxide Na_2O (Osi, France, 98%), sodium peroxide Na_2O_2 (Osi, France, 95%, aggregate size $\approx$ 1.5 mm) and potassium superoxide KO_2 (Merck, Germany, 96.5%, aggregate size $\approx$ 0.2 mm). They were ground before use. The NaK-56 liquid alloy was purchased from Callery Company, PA, USA. It corresponds to 56 wt-% K or 43 at-% K and will be denoted $Na_{0.57}K_{0.43}$. Data for $Na_{0.57}K_{0.43}$ alloy are: molar mass 29.8 g mol^{-1}; molar volume 33.5 cm^3 mol^{-1}; density 0.89 g cm^{-3}. The purity of the gases are: argon quality U, $O_2 < 5$ vpm, $H_2O < 5$ vpm; Azoxy N_2/O_2: 80%/20%, $H_2O < 5$ vpm. They were used without any further purification.

Apparatus and Measurements

***Differential Scanning Calorimetry*:** The tests involving pure oxides were performed between ambient temperature and 1300 °C by means of a Multi HTC SETARAM calorimeter with alumina as a reference. Inconel crucible (Ni-Cr-Fe alloy), volume 6.5 cm^3. The samples were studied under argon. Most of the calorimetric tests were performed using a DSC 111 SETARAM type calorimeter (temperature range −120 °C to 800 °C) in order to observe the melting point of NaK, (solid at −12.6 °C) and to calculate the amount of remaining NaK alloy. Volume of the stainless steel crucible: 0.170 cm^3. The samples were placed under argon. The results from the DSC 111 apparatus were numerized afterwards. For both apparatus, the calibration in temperature and enthalpy was performed with pure metals and the Joule effect. The heating rate was 1 K min^{-1}. The reported temperatures corresponded to the onset of the peaks.

***Mass Spectrometer*:** The laboratory mass spectrometer used was a quadripole-type residual gas analyzer, model Anagaz 200, marketed by the Quad/Service company. The samples were placed in a container equipped with a tight stainless steel connection, or in a crucible inserted into the container. They were first placed under primary vacuum, then swept with argon (N55 quality, $H_2O < 2$ vpm; $N_2 < 0.5$ vpm; $O_2 < 0.5$ vpm). The temperature of the sample was raised from ambient temperature up to 500 °C in a 100 °C step at a heating rate of 5 K min^{-1} between each 1 h plateau. The calibration was performed with the pure corresponding gases (H_2O, O_2).

***X-ray Diffraction*:** The diffractograms were obtained at room temperature with a Siemens D500 (Poitiers) or D5000 diffractometer (Cadarache) equipped with a copper anode [$\lambda(K_\alpha)$ = 1.54188 Å] and a back graphite monochromator, under the following conditions: dwell time 1 or 0.5 s; step 0.02 °; 2 theta range 5 to 80 °; divergence slit 1°. As most of the samples are air and particularly moisture sensitive, the samples were placed on the sample holder under argon and protected with polymer film for the D5000 diffractometer (Parafilm M, American National Can; XRD profile corresponding to polyethylene) or measured twice under air without protection for the D500 apparatus. The identified phases were the same but no quantitative analysis could be undertaken. The identification of the peaks was obtained by comparison with the PDF file (program Search of the Diffract-AT package, Socabim, France). Examples of raw diffractograms are given in Figure 8 and 9.

Reactivity Apparatus

***Measurement of the Reaction Temperature*:** In a glove-box filled with argon, about 2 g of liquid NaK alloy were introduced into a 20 mL glass flask equipped with a thermocouple. The oxide(s) were added separately or simultaneously and the mixture was manually stirred in order to ensure good contact between the alloy and the oxides.

***Preparation of Oxidized NaK by Sweeping*:** The apparatus (Figure 10) was made of a glass tube containing the boat (1 to 2 g of NaK alloy) and supplied by two inlets equipped with a flowmeter, one for argon and the other for the Azoxy mixture. The two gases were introduced independently or together. A coil was used to homogenize the mixture of argon and azoxy gases.

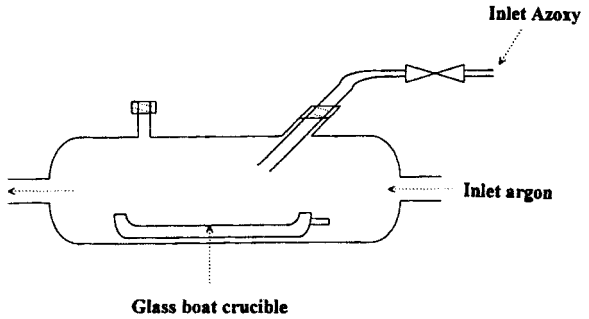

Figure 10. Device used for the preparation of oxidized NaK by sweeping

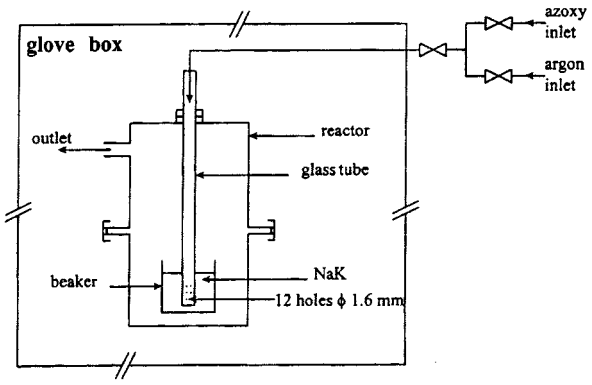

Figure 11. Device used for the preparation of oxidized NaK by bubbling

***Preparation of Oxidized NaK by Bubbling*:** Figure 11 shows the apparatus placed in a glove box. The NaK alloy (9.95 g) was placed in a beaker, which was itself enclosed in a reactor, with two gas inlet tubes (argon and Azoxy), permitting to bubble directly in the liquid alloy.

Keywords: Niobium / Tantalum / Metallacycles / η^2-Iminoacyl complexes / Insertions

Methylation of NbCp*Cl_2Me_2 using excess $ZnMe_2$ gives NbCp*$ClMe_3$ (**1**) which has been found to exhibit a Berry pseudorotation process on the NMR time scale (log A = 12.2 ± 0.3, E_a = 12.2 ± 0.4 kcal·mol^{-1}, $\Delta H^{\neq}$ = 11.6 ± 0.4 kcal·mol^{-1}, $\Delta S^{\neq}$ = −4.4 ± 1.3 e.u., $\Delta G^{\neq 298K}$ = 12.9 kcal·mol^{-1}). Alternatively, lithium dimethylamide reacts with NbCp*Cl_2Me_2 to form NbCp*$Me_2(NMe_2)_2$ (**2**) which decomposes in solution under the elimination of methane to give the (dimethylamido)methylazaniobacyclopropane derivative NbCp*Me(NMe_2)(η^2-CH_2NMe) (**3**). Reaction of NbCp*Cl_2Me_2 with 1 equiv. of 2,6-$Me_2C_6H_3NC$ results in a double methyl group migration to give the dichloroazaniobacyclopropane complex [NbCp*Cl_2\{η^2-CMe_2N(2,6-$Me_2C_6H_3$)\}] (**4**). Dialkyldichloro complexes TaCp*Cl_2R_2 [Cp* = η^5-C_5Me_5; R = CH_2SiMe_3 (**5**), CH_2CMe_2Ph (**6**), CH_2CMe_3 (**7**), $CH_2C_6H_5$ (**8**)] were obtained by treating TaCp*Cl_4 with the requisite amounts of the appropriate alkylating agents. Reactions of the dialkyldichloro complexes TaCp*Cl_2R_2 (**5**–**8**) with 1 equiv. of 2,6-$Me_2C_6H_3NC$ resulted in migration of only one of the two alkyl groups to give (alkyl)dichloro(η^2-iminoacyl) complexes [TaCp*Cl_2R\{η^2-C(R)=NAr\}] [Ar = 2,6-$Me_2C_6H_3$; R = CH_2SiMe_3 (**9**), CH_2CMe_2Ph (**10**), CH_2CMe_3 (**11**), $CH_2C_6H_5$ (**12**)]. The molecular structure of complex **10** has been determined by X-ray diffraction analysis. The η^2-iminoacyl complexes **9**–**12** decompose in [D_6]benzene or *n*-hexane solutions to give [TaCp*Cl_2\{N(2,6-$Me_2C_6H_3$)\}] and the corresponding *trans* or *cis* olefins R′–CH=CH–CH_2–R′ [R′ = $SiMe_3$ (**9o**), CMe_2Ph (**10o**), CMe_3 (**11o**), C_6H_5 (**12o**)]. A mechanism for this reaction is proposed. All the new compounds have been characterized by IR spectrophotometry, ^{1}H- and ^{13}C{^{1}H}-NMR spectroscopy, and elemental analysis.

Introduction

Migratory insertion of coordinated unsaturated molecules, such as carbon monoxide[1] or isocyanides,[2] into metal−alkyl bonds and the reactivity[3] of the resulting metal−acyl and metal−iminoacyl functions is one of the most important organometallic reactions, with many synthetic applications stemming from the C−C bond formation under mild reaction conditions. Several years ago, we reported the results of a systematic study[4] concerning the insertion of isocyanides into the tantalum−methyl bonds of various chloro(methyl)(pentamethylcyclopentadienyl) derivatives TaCp*$Cl_{4-x}Me_x$, which led to the synthesis of η^2-iminoacyl (x = 1), azatantalacyclopropane (x = 2), and (alkenylamido)imido (x = 3, 4) complexes.

In this context, the last years have witnessed a rapid development of early transition metal chemistry associated with imine ligands.[3,5] In these complexes, the imine linkage is typically found to bind strongly to the metal centre in an η^2-CN fashion and therefore they can be described as azametallacyclopropane derivatives. Although iminetantalum complexes have been postulated as intermediates in several organometallic transformations,[3a,3g,3i,6] only a few have been isolated and fully characterized.[4a,7] The formation of η^2-imino ligands at early transition metal centres can be achieved by the cyclometallation of dialkylamido ligands,[3g,3h] by alkyl or hydride reduction of η^2-iminoacyl ligands,[3b,3d,3e,3m,7e] by transfer of a hydrogen atom from an aminemetal complex,[7d] or in a few cases by addition of imines to low-valent metal derivatives.[3j,3k,5a,5j] Such an η^2 geometry has been identified in the crystal structures of some iminetantalum[4a] and -tungsten[3d,3e] complexes, and similar structures have been proposed for imine complexes of tantalum,[3a,8] zirconium,[3b] titanium,[9] and Group 8 metals.[10] Moreover, novel azazirconacyclopropane derivatives have been isolated[11] by orthometallation of 2,6-diethylpyridine with the cationic complex [$ZrCp_2Me(THF)$]$^+$. The analogous acetonetantalum or oxotantalacyclopropane complexes TaCp*X_2(η^2-$OCMe_2$), (X = Cl,[6] Me[1b]) are also thought to involve bonding through both the carbon and oxygen atoms.

In view of the high reactivities[3b,4,5a,5d,12] exhibited by these species, we decided to extend the study to bulky alkyltantalum derivatives. Thus, we report herein on the synthesis, insertion reactions, and intramolecular rearrange-

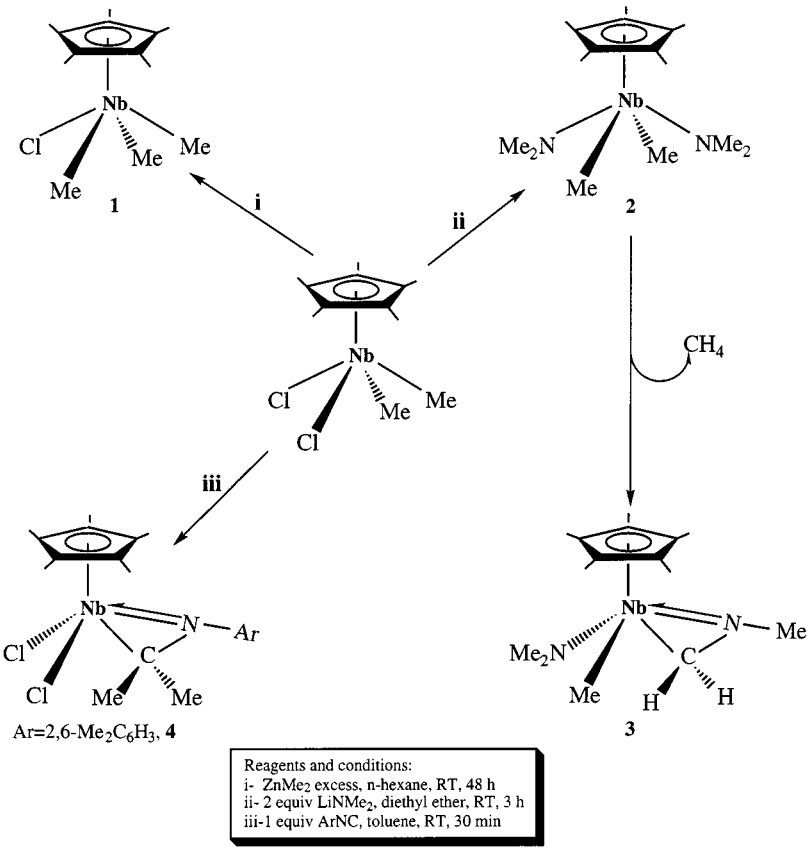
ment processes of the complexes obtained by treating dialkyldichloro(pentamethylcyclopentadienyl)niobium- and -tantalum(V) complexes with 2,6-$Me_2C_6H_3NC$.



Results and Discussion

Alkylation and Insertion Reactions of $NbCp^*Cl_2Me_2$

The (chloro)trimethyl complex $NbCp^*ClMe_3$, **1**, was obtained by treatment of the dichlorodimethyl derivative[13] with an excess of $ZnMe_2$ (see Scheme 1). The ^{1}H- and $^{13}C\{^1H\}$-NMR spectra of **1** in [D_6]benzene solution at room temperature show only one signal for the three methyl groups, whereas the ^{1}H-NMR spectrum in [D_8]toluene solution at 223 K shows two narrow resonances in a 1:2 ratio. This NMR behaviour corresponds to a Berry pseudorotation process,[3g,14] akin to that reported for other tantalum complexes,[15] and is consistent with a four-legged pianostool geometry in the ground state. The kinetic parameters (log A = 12.2 ± 0.3, E_a = 12.2 ± 0.4 kcal·mol^{-1}, $\Delta H^{\neq}$ = 11.6 ± 0.4 kcal·mol^{-1}, $\Delta S^{\neq}$ = −4.4 ± 1.3 e.u., $\Delta G^{\neq 298K}$ = 12.9 kcal·mol^{-1}), calculated on the basis of the ^{1}H-DNMR data,[16] are consistent with such an intramolecular process with only a small variation in the entropy and thus support our proposed interpretation.

$NbCp^*Cl_2Me_2$ also reacts with 2 equiv. of lithium dimethylamide at room temperature in diethyl ether to give the expected product $NbCp^*Me_2(NMe_2)_2$ (**2**), which rapidly decomposes in solution under elimination of methane to give the η^2-imine complex $NbCp^*Me(NMe_2)(\eta^2$-$CH_2NMe)$ (**3**). Several attempts to separate **2** and **3** as microcrystalline materials proved unsuccessful and their structures have been proposed solely on the basis of ^{1}H-NMR data (see Experimental Section). The ^{1}H-NMR spectrum of **3** features one singlet due to the Cp* ring, one signal due to the NMe_2 moiety, two signals due to the methyl resonances of Nb−Me and N−Me, respectively, and two doublets due to the methylene protons. This NMR behaviour is in accordance with the chiral character of the metal centre. In view of the observation of the resonances of the CH_2 unit at δ_{av} = 1.25 with a typical geminal proton-proton coupling constant value ($^2J_{H-H}$ = 4.88 Hz) for a cyclopropane ring,[17] **3** must be described as an azaniobacyclopropane complex (see Scheme 1).

On addition of 1 equiv. of 2,6-$Me_2C_6H_3NC$ to toluene solutions of $NbCp^*Cl_2Me_2$ under rigorously anhydrous conditions, brown-red solutions were obtained, from which [$NbCp^*Cl_2\{\eta^2$-$CMe_2N(2,6$-$Me_2C_6H_3)\}$] (**4**) was recovered as a brown solid on removal of the solvent (Scheme 1). The equivalence of the methyl groups in the NMR spectra is consistent with a C_s-symmetry complex possessing a plane of symmetry defined by the niobium, the nitrogen, and the carbon atoms that is perpendicular to the plane of the pentamethylcyclopentadienyl ring. Previously, we have reported[4a] the synthesis, the mechanism of formation, and the crystal structure of a similar azatantalacyclopropane com-

Scheme 1

plex. In the present case, we were unable to obtain adequate single crystals for X-ray diffraction analysis, but like the tantalum analogue the structure must be a distorted trigonal bipyramid with the chlorine and nitrogen atoms occupying the equatorial plane positions and the centroid of the Cp* ring and the azaniobacyclopropane C atom occupying the apical sites.

When the same reaction was repeated at room temperature using 2 equiv. of isocyanide, a different sequence of reactions occurred leading to the diamagnetic pseudooctahedral niobium(III) complex $NbCp^*Cl_2(CN\text{-}2,6\text{-}Me_2C_6H_3)_3$. We have isolated this complex previously[18] by reducing $NbCp^*Cl_4$ with 2 equiv. of Na/Hg in the presence of a stoichiometric amount of isocyanide. This behaviour is in contrast to that observed in the case of $TaCp^*Cl_2Me_2$,[4b] which, in the presence of 2 equiv. of an isocyanide, gives the corresponding dichloro imido complex $TaCp^*Cl_2(NAr)$ (Ar = 2,6-$Me_2C_6H_3$, 2,4,6-$Me_3C_6H_2$) under elimination of the arylimine ketene Ar−N=C=CMe_2. The same dichloro tris(isocyanide) complex is obtained when 1 equiv. of the appropriate isocyanide is added to a toluene solution of the azaniobacyclopropane complex **4** at room temperature.

Synthesis and Reactivity of Dialkyldichloro(pentamethylcyclopentadienyl)tantalum(V) Complexes

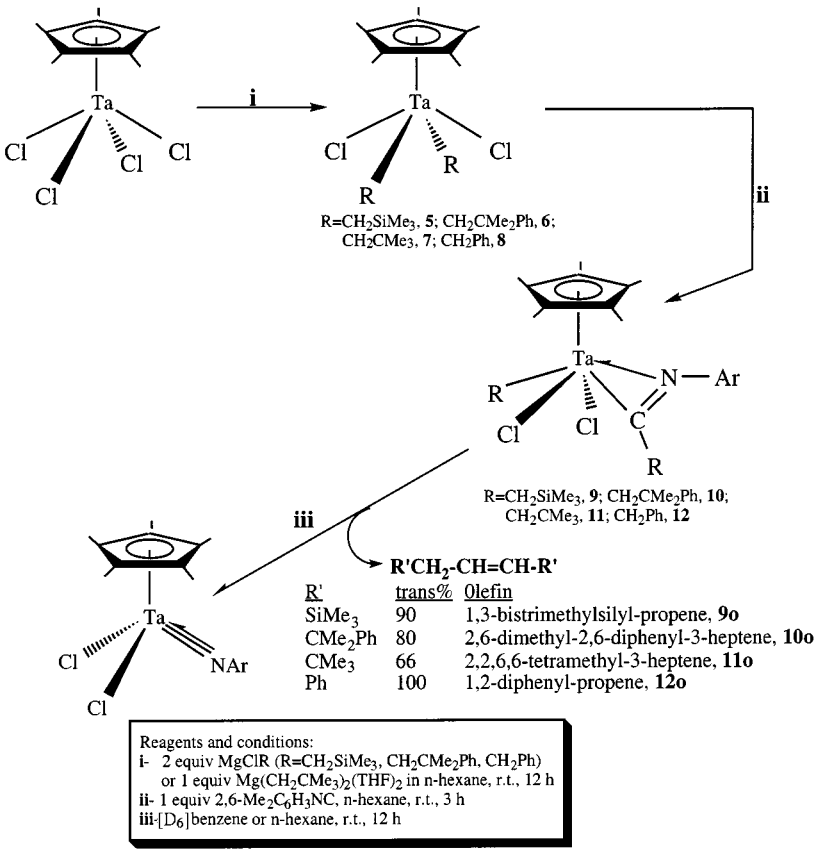
On treating *n*-hexane suspensions of the complex $TaCp^*Cl_4$ with stoichiometric amounts of the alkylating reagents MgClR (R = CH_2SiMe_3, CH_2CMe_2Ph, CH_2Ph) or $Mg(CH_2CMe_3)_2(THF)_2$ under rigorously anhydrous conditions at room temperature, suspensions were obtained from which the dialkyldichloro complexes $TaCp^*Cl_2R_2$ [R = CH_2SiMe_3 (**5**), CH_2CMe_2Ph (**6**), CH_2CMe_3 (**7**), CH_2Ph (**8**)] could be isolated in good yields (see Scheme 2). The dineopentyl and dibenzyl derivatives **7** and **8** have been described previously by Schrock et al.[19] Several attempts to prepare **5**−**8** using stoichiometric amounts of lithium reagents proved unsuccessful and in all cases only unidentified reduction products were obtained. Complexes **5**−**8** were found to be air- and moisture-sensitive, and soluble in both *n*-hexane and aromatic solvents.

When 1 equiv. of the isocyanide 2,6-$Me_2C_6H_3NC$ was added to *n*-hexane solutions of the dialkyldichlorotantalum complexes **5**−**8** under a rigorously dry inert gas or in a sealed NMR tube, reddish solutions were obtained. After work-up, the alkyldichloro(η^2-iminoacyl)tantalum complexes [$TaCp^*Cl_2R\{\eta^2\text{-}C(R)=NAr\}$] [Ar = 2,6-$Me_2C_6H_3$; R = CH_2SiMe_3 (**9**), CH_2CMe_2Ph (**10**), CH_2CMe_3 (**11**), CH_2Ph (**12**)] could be recovered (Scheme 2). This behaviour is in contrast to that observed for the dichlorodimethyl derivative,[4] which, in the presence of 1 equiv. of isocyanide, gives a dichloroazatantalacyclopropane complex as a result of a migration of the second methyl group to the electrophilic iminoacyl carbon atom of the dichloro(η^2-iminoacyl)(methyl) intermediate. In the present case, the remaining bulkier alkyl substituent does not migrate. On the other hand, the same η^2-iminoacyl complexes **9**−**12** are obtained upon reaction of 2 equiv. of the isocyanide with the starting dialkyldichloro compounds in [D_6]benzene at room temperature and no bis(η^2-iminoacyl) species are detected.

All of the complexes **9**−**12** were found to be soluble in most organic solvents, including saturated hydrocarbons. They are extremely air- and moisture-sensitive, and rigorously dried solvents and handling under dry inert gases were found to be imperative for successful preparations.

The molecular structure of compound **10** is shown in Figure 1 and selected bond lengths and angles are given in Table 1. Complex **10** crystallizes in the space group $P2_1/c$ with the two possible enantiomers of the molecule present in the unit cell.

As can be seen, complex **10** is a monomer with the tantalum atom in a pseudooctahedral environment, where the centroid of the pentamethylcyclopentadienyl ring and the carbon atom of the iminoacyl group occupy the axial positions. The tantalum atom is located 0.61(1) Å above the plane formed by the C21, Cl1, Cl2, and N1 atoms.[20] The C=N bond of the iminoacyl group is almost perpendicular [75.0(2)°] to the plane formed by the two chlorine atoms, N1, and C21 of the neopentyl group. The difference between this angle and that for ideal perpendicularity accounts for the fact that two enantiomers are present in the unit cell.



On the other hand, the *trans* effect of the iminoacyl group makes the distances between Ta1 and C11 [2.523(7) Å], C14 [2.528(7) Å], and C15 [2.591(7) Å] longer than the other two Ta−Cl distances [Ta1−C12 2.415(6) Å, Ta1−C13 2.437(6) Å].

Bond lengths in the η^2-iminoacyl group [N1−C41 1.262(7), N1−C42 1.482(7), and C41−C31 1.500(8) Å] are within the range found for other compounds[21] for which a C=N double bond and an η^2 coordination has been proposed. The plane formed by the aromatic ring C42−C47 is rotated by 70.6(2)° with respect to that formed by N1, C41, C42, and C31, partially preventing electronic delocalization over the iminoacyl and aromatic groups.

The IR, ^{1}H- and $^{13}C\{^1H\}$-NMR spectroscopic data (see Experimental Section) are consistent with the expected pseudooctahedral geometries of these η^2-iminoacyl complexes. The NMR spectra of **9**−**12** in [D_6]benzene solution at room temperature show the expected equivalence of the α-CH_2 protons of the inserted and non-inserted alkyl groups, in accordance with the *trans* disposition of the chlorine atoms and due to fast exchange between the two enantiomeric structures found in the solid state, the transition state of this process having C_s symmetry. Moreover, the 2,6-$Me_2C_6H_3$ ring of the η^2-iminoacyl ligand is characterized by C_{2v} local symmetry (Scheme 3).

The IR spectra of all the complexes show the characteristic absorptions for the pentamethylcyclopentadienyl ring ($\tilde{\nu}_{C-C}$ = 1027 cm^{-1})[22] and the trimethylsilyl substituent {$\tilde{\nu}$ = 1250 cm^{-1} [$\delta_{as}(CH_3)$]}.[23] Absorptions due to the C(R)=N, Ta−C, and Ta−Cl stretching vibrations are observed at $\tilde{\nu}$ = 1559,[23d,24] 525,[23d,25] and 278 cm^{-1},[23c,26] respectively.

In [D_6]benzene or *n*-hexane solution, **9**−**12** were found to spontaneously, albeit slowly, decompose at room temperature (see Scheme 4) to give a mixture of two components,

a dichloro(imido)tantalum compound [TaCp*Cl_2{N(2,6-$Me_2C_6H_3$)}][4a] together with *cis* and *trans* olefins R′−CH_2−CH=CH−R′ [R′ = $SiMe_3$ (**9o**), CMe_2Ph (**10o**), CMe_3 (**11o**), Ph (**12o**)],[27] which were fully characterized by NMR spectroscopy (see Experimental Section).

This transformation can be rationalized in terms of migration of the metal-bonded alkyl group to the iminoacyl carbon centre in the first step to give the intermediate dialkylazatantalacyclopropane complexes (see Scheme 4),

Scheme 3

Scheme 4

which cannot be detected during monitoring of the entire reaction by ^{1}H-NMR spectroscopy. However, the cyclopropane structure favours agostic interactions between the β-hydrogen atoms of the alkyl groups and the tantalum atom, leading to concerted four-centre transition states **A** and **B**.

Subsequent 2,1-migration of the hydrogen atom, probably through formation of a Ta hydride, and back-rearrangement gives the imido complex[4a] with elimination of the corresponding olefins **9o**−**12o**. The relative disposition of R′ and CH_2R' groups in **A** and **B** is dependent on the β-hydrogen atom that participates in an agostic interaction with the metal centre and thus determines the stereochemistry of the final olefins.

The data reported here are in contrast to our previous results concerning the insertion of isocyanides into Ta−C bonds of dimethyltantalum derivatives[4a] and show that these are more stable compared to the complexes **9**−**12**, probably due to steric factors.

Experimental Section

General: All reactions and manipulations were carried out under argon using standard Schlenk-tube and cannula techniques or in a conventional argon-filled MBraun glove-box.[28] Solvents were refluxed over appropriate drying agents and distilled and degassed prior to use: diethyl ether (sodium/benzophenone), *n*-hexane and [D_6]benzene (Na/K alloy). Literature methods were employed for the syntheses of the starting materials NbCp*Cl_2Me_2,[13] TaCp*Cl_2R_2 [19] [R = CH_2CMe_3 (**3**), CH_2Ph (**4**)], TaCp*Cl_4,[29] and $Mg(CH_2CMe_3)_2(THF)_2$.[30] 2 M $ZnMe_2$ in toluene (Aldrich), $LiNMe_2$ (Aldrich), 2,6-$Me_2C_6H_3NC$ (Aldrich), and MgClR (R = CH_2SiMe_3, 1 M in diethyl ether; CH_2CMe_2Ph, 0.5 M in diethyl ether; CH_2Ph 2 M in THF) (Aldrich) were purchased as reagent-grade materials and were used without further purification.

Infrared spectra were recorded with a Perkin−Elmer 583 spectrophotometer (4000−200 cm^{-1}) with samples as Nujol mulls between CsI plates or in polyethylene pellets. − ^{1}H- and $^{13}C\{^1H\}$-NMR spectra were recorded with Varian Unity 300 and Varian Unity 500 Plus spectrometers; chemical shifts were referenced to the ^{13}C (δ = 128) and residual ^{1}H (δ = 7.15) resonances of the [D_6]benzene solvent. − C, H, N analyses were carried out with a Perkin−Elmer 240C microanalyzer.

Synthesis of NbCp*$ClMe_3$ (1): A 2 M solution of $ZnMe_2$ in toluene (6.00 mmol, 3 mL) was added dropwise to NbCp*Cl_2Me_2 (1.00 g, 3.06 mmol) in *n*-hexane (100 mL) at room temperature to give an orange suspension. After stirring for 48 h, all volatiles were removed under reduced pressure and the residual red-orange solid was extracted with *n*-hexane (3 × 10 mL). The combined extracts were filtered and the filtrate was concentrated to a volume of 10 mL; on cooling overnight at −40 °C, **1** was deposited as a red-orange microcrystalline solid. Yield 0.37 g (40%). − IR (Nujol): $\tilde{\nu}$ = 1024 cm^{-1} s, 803 w, 723 w, 467 s, 326 s. − ^{1}H NMR (C_6D_6, 20 °C): δ = 1.54 (s, 15 H, C_5Me_5), 1.25 (s, 9 H, Nb−Me). − ^{1}H NMR (C_7D_8, −50 °C): δ = 1.44 (s, 15 H, C_5Me_5), 1.22 (s, 6 H, Nb−Me), 1.12 (s, 3 H, Nb−Me). − $^{13}C\{^1H\}$ NMR (C_6D_6, 20 °C): δ = 119.6 (C_5Me_5), 64.9 (br., Nb−Me), 11.6 (C_5Me_5). − $C_{13}H_{24}ClNb$ (308.694): calcd. C 50.58, H 7.84; found C 50.68, H 7.79.

Reaction of NbCp*Cl_2Me_2 with $LiNMe_2$: NbCp*Cl_2Me_2 (0.50 g, 1.53 mmol) and $LiNMe_2$ (0.16 g, 3.14 mmol) were stirred in diethyl ether (50 mL) at room temperature for 3 h. The resulting suspension was filtered and the solvent was removed from the filtrate to leave an oily residue. ^{1}H-NMR analysis showed this to consist of a mixture of [NbCp*$Me_2(NMe_2)_2$] (**2**) and [NbCp*$Me(NMe_2)(\eta^2$-$CH_2NMe)$] (**3**) in a 1:2 molar ratio. All attempts to separate the compounds by recrystallization were unsuccessful. − ^{1}H NMR (C_6D_6, 20 °C): **2**: δ = 3.00 (s, 12 H, Me_2N−Nb), 1.65 (s, 15 H, C_5Me_5), 0.38 (s, 6 H, Me−Nb); **3**: δ = 3.63 (s, 3 H, CH_2NMe), 2.72 (s, 6 H, Me_2N−Nb), 1.73 (s, 15 H, C_5Me_5), 1.51 (d, 1 H), 1.01 (d, $^2J_{H-H}$ = 4.88 Hz, 1 H, CH_2NMe), 0.53 (s, 3 H, Me−Nb).

Synthesis of [NbCp*$Cl_2\{\eta^2$-CMe_2−N(2,6-$Me_2C_6H_3$)}] (4): A solution of NbCp*Cl_2Me_2 (0.50 g, 1.53 mmol) in toluene (20 mL) was treated with (2,6-$Me_2C_6H_3$)NC (0.20 g, 1.53 mmol) under rigorously anhydrous conditions. The mixture was stirred for 30 min and then filtered. The filtrate was concentrated to dryness and the residue was washed with cold *n*-hexane (2 × 10 mL) to leave **4** as a brown microcrystalline solid. Yield 0.53 g (76%). − IR (Nujol): $\tilde{\nu}$ = 1259 cm^{-1} m, 1023 m, 768 m, 723 m, 371 m. − ^{1}H NMR (C_6D_6, 20 °C): δ = 6.94 (br., 3 H, $H_3C_6Me_2N$), 2.10 (s, 6 H, $Me_2C_6H_3N$), 2.00 (s, 6 H, Me_2C), 1.63 (s, 15 H, C_5Me_5). − $^{13}C\{^1H\}$ NMR

(C_6D_6, 20 °C): δ = 150.0, 132.2, 128.8, 124.0 (C_i, C_o, C_m, C_p, $C_6H_3Me_2N$), 122.8 (C_5Me_5), not observed (CMe_2), 28.7 (Me_2C), 20.4 ($Me_2C_6H_3N$), 11.1 (C_5Me_5). − $C_{21}H_{30}Cl_2NNb$ (460.29): calcd. C 54.80, H 6.57, N 3.04; found C 54.94, H 6.62, N 3.17.

Synthesis of TaCp*Cl$_2$R$_2$ [R = CH$_2$SiMe$_3$ (5), CH$_2$CMe$_2$Ph (6)]: A 1.0 M (**5**) or 0.5 M (**6**) solution of MgClR in diethyl ether (4.36 mmol; R = CH_2SiMe_3, 4.36 mL; CH_2CMe_2Ph, 8.73 mL) was added to a suspension of TaCp*Cl_4 (1.00 g, 2.18 mmol) in *n*-hexane (40 mL) at room temperature and the mixture was stirred for 12 h. The $MgCl_2$ formed was removed by filtration and the resulting filtrate was concentrated to a volume of ca. 10 mL. On cooling to −40 °C, orange (**5**) or red (**6**) microcrystalline solids were deposited.

Data for 5: Yield: 0.73 g (60%). − IR (Nujol): $\tilde{\nu}$ = 1327 cm^{-1} s, 1241 vs, 1024 m, 952 vs, 835 vs, 749 vs, 716 vs, 681 vs, 615 w, 567 m, 453 m, 365 m, 332 s, 269 vs. − ^{1}H NMR (C_6D_6, 20 °C): δ = 1.89 (s, 15 H, C_5Me_5), 0.79 (s, 4 H, H_2CSiMe_3), 0.42 (s, 18 H, Me_3SiCH_2). − ^{13}C{^{1}H} NMR (C_6D_6, 20 °C): δ = 124.78 (C_5Me_5), 94.57 (CH_2SiMe_3), 12.83 (C_5Me_5), 3.36 (Me_3SiCH_2). − $C_{18}H_{37}Cl_2Si_2Ta$ (561.52): calcd. C 38.50, H 6.64; found C 38.46, H 6.54.

Data for 6: Yield: 0.85 g (60%). − IR (Nujol): $\tilde{\nu}$ = 1597 cm^{-1} w, 1260 w, 1176 m, 1078 s, 1026 s, 804 w, 767 vs, 699 vs, 359 m, 301 vs. − ^{1}H NMR (C_6D_6, 20 °C): δ = 7.46 (d, $^3J_{H-H}$ = 7.5 Hz, 2 H), 7.25 (t, $^3J_{H-H}$ = 7.5 Hz, 2 H), 7.06 (t, $^3J_{H-H}$ = 7.5 Hz, 1 H, $H_5C_6CMe_2CH_2$), 1.83 (s, 6 H, CH_2CMe_2Ph), 1.73 (s, 15 H, C_5Me_5), 1.35 (s, 2 H, H_2CCMe_2Ph). − ^{13}C{^{1}H} NMR (C_6D_6, 20 °C): δ = 158.0, 125.75, 125.2, 116.05 (C_i, C_o, C_m, C_p, $C_6H_5Me_2CCH_2$), 124.34 (C_5Me_5), 44.05 (CH_2CMe_2Ph), 32.76 (CH_2CMe_2Ph), 31.4 (CH_2CMe_2Ph), 12.63 (C_5Me_5). − $C_{30}H_{41}Cl_2Ta$ (653.512): calcd. C 55.14, H 6.32; found C 54.96, H 6.18.

Synthesis of [TaCp*Cl$_2$R{η^2-C(R)=NAr}] [Ar = 2,6-Me$_2$C$_6$H$_3$; R = CH$_2$SiMe$_3$ (9), CH$_2$CMe$_2$Ph (10), CH$_2$CMe$_3$ (11), CH$_2$Ph (12)]

9−11: Under rigorously anhydrous conditions, *n*-hexane (20 mL) was added to a mixture of the complex TaCp*Cl_2R_2 (0.50 g; R = CH_2SiMe_3, 0.89 mmol; CH_2CMe_2Ph, 0.76 mmol; CH_2CMe_3, 0.94 mmol) and CN(2,6-$Me_2C_6H_3$) (R = CH_2SiMe_3, 0.116 g, 0.89 mmol; CH_2CMe_2Ph, 0.10 g, 0.76 mmol; CH_2CMe_3, 0.123 g, 0.94 mmol) in a Schlenk tube. The color quickly changed to dark red and after stirring for 3 h at room temperature, the resulting solution was filtered and the filtrate was concentrated to a volume of ca. 10 mL. Cooling at −40 °C overnight led to the deposition of microcrystalline solids identified as **9**, **10** (red), and **11** (red-orange).

Data for 9: Yield: 0.26 g (43%). − IR (Nujol): $\tilde{\nu}$ = 1553 cm^{-1} m, 1250 s, 1175 s, 1094 m, 1024 m, 980 s, 852 vs, 726 s, 672 m, 602 w, 573 w, 518 w, 449 w, 342 m, 268 s. − ^{1}H NMR (C_6D_6, 20 °C): δ = 6.90 (t, $^3J_{H-H}$ = 7.5 Hz, 1 H), 6.81 [d, $^3J_{H-H}$ = 7.5 Hz, 2 H, $H_3C_6Me_2N{=}C(CH_2SiMe_3)$], 3.44 [s, 2 H, $H_3C_6Me_2N{=}C(CH_2SiMe_3)$], 2.05 [s, 6 H, $H_3C_6Me_2N{=}C(CH_2SiMe_3)$], 1.93 (s, 15 H, C_5Me_5), 0.60 (s, 2 H, Ta−CH_2SiMe_3), 0.52 (s, 9 H, Ta−CH_2SiMe_3), 0.10 [s, 9 H, $H_3C_6Me_2N{=}C(CH_2SiMe_3)$]. − ^{13}C{^{1}H} NMR ($C_6D_6$, 20 °C): δ = 256.73 [$H_3C_6Me_2N{=}C(CH_2SiMe_3)$], 141.32, 132.92, 127.02, 125.41 [C_i, C_o, C_m, C_p, $H_3C_6Me_2N{=}C(CH_2SiMe_3)$], 129.45 ($C_5Me_5$), 51.76 [$H_3C_6Me_2N{=}C(CH_2SiMe_3)$], 31.32 (Ta−$CH_2SiMe_3$), 20.13 [$H_3C_6Me_2N{=}C(CH_2SiMe_3)$], 11.64 ($C_5Me_5$), 4.05 (Ta−$CH_2SiMe_3$), 0.66 [$H_3C_6Me_2N{=}C(CH_2SiMe_3)$]. − $C_{27}H_{46}Cl_2NSi_2Ta$ (692.698): calcd. C 46.82, H 6.69, N 2.02; found C 47.00, H 6.80, N 2.11.

Data for 10: Yield: 0.24 g (40%). − IR (Nujol): $\tilde{\nu}$ = 1536 cm^{-1} m, 1493 m, 1324 s, 1187 m, 1096 m, 1028 m, 982 m, 764 vs, 701 vs, 577 w, 548 w, 394 w, 350 s, 315 m, 285 m. − ^{1}H NMR (C_6D_6, 20 °C): δ = 7.70 (m, 2 H), 7.32 (m, 2 H), 7.11 (m, 2 H), 6.97 [m, 4 H, $H_3C_6Me_2N{=}C(CH_2CMe_2C_6H_5)$ and Ta−$CH_2CMe_2C_6H_5$], 6.80 (t, $^3J_{H-H}$ = 7.69 Hz, 1 H), 6.65 [d, $^3J_{H-H}$ = 7.69 Hz, 2 H, $H_3C_6Me_2N{=}C(CH_2CMe_2Ph)$], 4.19 [s, 2 H, $H_3C_6Me_2N{=}C(CH_2CMe_2Ph)$], 2.07 [s, 6 H, $H_3C_6Me_2N{=}C(CH_2CMe_2Ph)$], 1.82 (s, 15 H, C_5Me_5), 1.80 (s, 6 H, Ta−CH_2CMe_2Ph), 1.75 (s, 2 H, Ta−CH_2CMe_2Ph), 1.49 [s, 6 H, $H_3C_6Me_2N{=}C(CH_2CMe_2Ph)$]. − ^{13}C{^{1}H} NMR ($C_6D_6$, 20 °C): δ = 259.26 [$H_3C_6Me_2N{=}C(CH_2CMe_2Ph)$], 181.96−124.86 [several phenyl, $H_3C_6Me_2N{=}C(CH_2CMe_2C_6H_5)$ and Ta−$CH_2CMe_2C_6H_5$], 159.15−119.26 [several phenyl, $H_3C_6Me_2N{=}C(CH_2CMe_2C_6H_5)$], 125.57 ($C_5Me_5$), 88.56 [$H_3C_6Me_2N{=}C(CH_2CMe_2Ph)$], 51.10 (Ta−$CH_2CMe_2Ph$), 43.80 (Ta−$CH_2CMe_2Ph$), 40.18 [$H_3C_6Me_2N{=}C(CH_2CMe_2Ph)$], 32.81 (Ta−$CH_2CMe_2Ph$), 30.95 [$H_3C_6Me_2N{=}C(CH_2CMe_2Ph)$], 11.14 ($C_5Me_5$). − $C_{39}H_{50}Cl_2NTa$ (784.685): calcd. C 59.69, H, 6.42, N 1.78; found C 59.83, H 6.40, N 1.76.

Data for 11: Yield: 0.25 g (40%). − IR (Nujol): $\tilde{\nu}$ = 1556 cm^{-1} s, 1233 s, 1166 s, 1096 m, 1019 m, 830 m, 769 vs, 724 w, 649 m, 603 w, 510 w, 340 s, 279 vs, 231 m. − ^{1}H NMR (C_6D_6, 20 °C): δ = 6.83 (m, 1 H), 6.77 [m, 2 H, $H_3C_6Me_2N{=}C(CH_2CMe_3)$], 3.64 [s, 2 H, $H_3C_6Me_2N{=}C(CH_2CMe_3)$], 2.02 [s, 6 H, $H_3C_6Me_2N{=}C(CH_2CMe_3)$], 1.90 (s, 15 H, C_5Me_5), 1.59 [s, 9 H, $H_3C_6Me_2N{=}C(CH_2CMe_3)$], 1.54 (s, 2 H, Ta−$CH_2CMe_3$), 1.07 (s, 9 H, Ta−$CH_2CMe_3$). − ^{13}C{^{1}H} NMR ($C_6D_6$, 20 °C): δ = 260.94 [$H_3C_6Me_2N{=}C(CH_2CMe_3)$], 141.70, 132.63, 129.50, 127.00 [C_i, C_o, C_m, C_p, $H_3C_6Me_2N{=}C(CH_2CMe_3)$], 125.74 ($C_5Me_5$), 88.10 [$H_3C_6Me_2N{=}C(CH_2CMe_3)$], 50.36 (Ta−$CH_2CMe_3$), 37.41 [$H_3C_6Me_2N{=}C(CH_2CMe_3)$], 36.10 [$H_3C_6Me_2N{=}C(CH_2CMe_3)$], 34.22 (Ta−$CH_2CMe_3$), 31.70 (Ta−$CH_2CMe_3$), 20.19 [$H_3C_6Me_2N{=}C(CH_2CMe_3)$], 11.66 ($C_5Me_5$). − $C_{29}H_{46}Cl_2NTa$ (660.548): calcd. C 52.73, H 7.02, N 2.12; found C 52.93, H 7.04, N 2.28.

12: A solution of TaCp*$Cl_2(CH_2Ph)_2$ (0.50 g, 0.88 mmol) in *n*-hexane (15 mL) was treated with the isocyanide (2,6-$Me_2C_6H_3$)NC (0.115 g, 0.88 mmol) under rigorously anhydrous conditions. The color of the solution rapidly changed from brown-green to purple and after 2 h, a red microcrystalline precipitate had separated. This was collected by filtration, washed with a small volume of cold *n*-hexane, and dried in vacuo.

Data for 12: Yield: 0.31 g (50%). − IR (Nujol): $\tilde{\nu}$ = 1614 cm^{-1} m, 1590 m, 1290 m, 1262 s, 1162 s, 1100 s, 1064 s, 1024 s, 804 s, 724 vs, 690 s, 352 m, 280 m. − ^{1}H NMR (C_6D_6, 20 °C): δ = 7.84 (m, 3 H), 7.52 [m, 2 H, $H_3C_6Me_2N{=}C(CH_2C_6H_5)$], 6.96 (m, 2 H), 6.50 [m, 1 H, $H_3C_6Me_2N{=}C(CH_2Ph)$], 6.70 (m, 5 H, Ta−$CH_2C_6H_5$), 3.86 [s, 2 H, $H_3C_6Me_2N{=}C(CH_2Ph)$], 2.11 (s, 2 H, Ta−$CH_2C_6H_5$), 1.89 (s, 15 H, C_5Me_5), 1.61 [s, 6 H, $H_3C_6Me_2N{=}C(CH_2Ph)$]. − ^{13}C{^{1}H} NMR (C_6D_6, 20 °C): δ = 258 [$H_3C_6Me_2N{=}C(CH_2Ph)$], 152.58−122.31 [several phenyl, $H_3C_6Me_2N{=}C(CH_2C_6H_5)$ and Ta−$CH_2C_6H_5$], 124.94 (C_5Me_5), 70.53 [$H_3C_6Me_2N{=}C(CH_2Ph)$], 37.74 (Ta−$CH_2C_6H_5$), 20.45 [$H_3C_6Me_2N{=}C(CH_2Ph)$], 11.39 (C_5Me_5). − $C_{33}H_{38}Cl_2NTa$ (700.528): calcd. C 56.58, H 5.47, N 2.00; found C 56.48, H 5.63, N 2.28.

Decomposition Reaction of [TaCp*Cl$_2$R{η^2-C(R)=NAr}] [Ar = 2,6-Me$_2$C$_6$H$_3$; R = CH$_2$SiMe$_3$ (9), CH$_2$CMe$_2$Ph (10), CH$_2$CMe$_3$ (11), CH$_2$Ph (12)]: A solution of **9−12** (0.50 mmol) in [D_6]benzene was placed in a valved NMR tube under rigorously anhydrous conditions. The reaction was monitored by ^{1}H- and ^{13}C-NMR spectroscopy until no further change was observed (ca. 12 h). The final spectrum was indicative of complete transformation of the starting material to a mixture of the two components, i.e. a dichloro(imido)

complex $TaCp^*Cl_2(NAr)$ and an olefin **9o**−**12o** (*cis*/*trans* isomers).[27]

X-ray Structure Determination of 10: A red, block-shaped crystal of compound **10**, crystallized from *n*-hexane at −40°C, was mounted in a glass capillary in a random orientation on an Enraf−Nonius CAD-4 four-circle automatic diffractometer and examined with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). Crystallographic and experimental details for **10** are summarized in Table 2. Intensities were corrected for Lorentz and polarization effects in the usual manner. Intensity measurements were performed by ω-θ scans in the range $6° < 2\theta < 50°$.

Table 2. Crystal and X-ray structural analysis data for the compound $[TaCp^*Cl_2(CH_2CMe_2Ph)\{\eta^2\text{-}C(CH_2CMe_2Ph)=N(2,6\text{-}Me_2\text{-}C_6H_3)\}]$ (**10**)

Empirical formula	$C_{39}H_{50}Cl_2NTa$
Molecular mass	784.65
Temperature [K]	293(2)
Crystal system	monoclinic
Space group	$P2_1/c$
a, *b*, *c* [Å]	16.602(4), 11.411(5), 20.522(4)
β [°]	112.66(4)
Volume; *Z*	3587(2) Å^3; 4
Density (calculated)	1.453 g/cm^3
μ (Mo-K_α)	3.240 mm^{-1}
F(000)	1592
Crystal size	0.40 × 0.35 × 0.32 mm
Index ranges	$0 < h < 19$, $0 < k < 13$, $-24 < l < 22$
Reflections collected	6507
Independent reflections	6276 (R_{int} = 0.0454)
Observed reflections [$I > 2\sigma(I)$]	5251
Data/restraints/parameters	6276/0/399
Goodness-of-fit on F^2	0.903
Final R indices [$I > 2\sigma(I)$]	$R1$ = 0.040, $wR2$ = 0.101
R indices (all data)	$R1$ = 0.054, $wR2$ = 0.110
Largest diff. peak and hole	1.828 and −1.793 eÅ^{-3}

The structure was solved by direct methods (SHELXS-97)[31] using the WINGX package and refined by least-squares against F^2 (SHELXL-97). Of the 6507 measured reflections, 6276 were independent; $R1$ = 0.040 and $wR2$ = 0.101 [for 5251 reflections with $F > 4\sigma(F)$]. The values of $R1$ and $wR2$ are defined as $R1 = \Sigma||F_o| - |F_c||/[\Sigma|F_o|]$; $wR2 = \{[\Sigma w(F_o^2 - F_c^2)^2]/[\Sigma w(F_o^2)^2]\}^{1/2}$, where $w = 1/[\sigma^2(F_o^2) + (0.081)^2 + 9.023P]$, $P = (F_o^2 + 2F_c^2)/3$, and σ was obtained from the counting statistics. All non-hydrogen atoms were refined anisotropically, while the hydrogen atoms were introduced in calculated positions in the final cycle of the refinement and refined using a riding model with thermal parameters fixed at U = 0.08 Å^2.

Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-139661. Copies of the data can be obtained free of charge on application to the CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis and Single-Crystal X-ray Diffraction Studies of New Cyclometallated Phenylimidazole Palladium(II) Compounds

Mariela Lousame,[b] Alberto Fernández,[b] Margarita López-Torres,[b] Digna Vázquez-García,[b] José M. Vila,*[a] Antonio Suárez,[b] Juan M. Ortigueira,[a] and Jesús J. Fernández*[b]

Keywords: C−H activation / Nitrogen heterocycles / P ligands / Palladium

Cyclometallation of 1,4,5-trimethyl-2-phenylimidazole, **L**, with $Pd(OAc)_2$ gave exclusively the dinuclear *anti* isomer with bridging acetate ligands, **1**. Subsequent treatment of **1** with sodium chloride gave the corresponding dinuclear compound with bridging chloride ligands, **2**. Treatment of **2** with mono or diphosphanes led to partial or total bridge-splitting reactions, yielding mono or polynuclear compounds, **3**–**9**, depending on the palladium/phosphane ratio and the nature of the phosphane. The structure of **7** has been determined by X-ray diffraction analysis. Compounds **1** and **2** react with triphos to give the mononuclear compound, **10**, in which the phosphane acts as a terdentate ligand. The crystal structure of **10** confirms the pentacoordination of the palladium(II) centre, involving a long Pd–N interaction.

Introduction

Intramolecular activation of aromatic C−H bonds of coordinated ligands by transition metals, i.e. the cyclometallation reaction, has been widely investigated.[1−7] It has proved useful in numerous applications, such as the synthesis of new organometallic and organic compounds, many of which are obtained through insertions of unsaturated species into the metal−carbon bond,[8,9] the isolation of enantiomerically pure planar chiral compounds,[10] the design of complexes with interesting photochemical and electrochemical properties,[11] and their use as efficient catalytic materials[12−14] or liquid crystals.[15,16] The most abundant examples of cyclometallated compounds are those in which the metallated carbon atom is part of a phenyl ring.[4,5,17]

Cyclometallation reactions of heterocyclic derivatives have, in contrast, been less extensively studied, although such compounds can be expected to exhibit unique properties, not shown by their phenyl analogues, in applied fields of chemistry, biology, and pharmacy.[18] In recent years, the characterization of luminescent transition metal ions coordinated to heterocyclic organic ligands has attracted great interest; these systems exhibit new properties not seen for the pure organic molecules or transition metal compounds, which show only dd* transitions.[19] Other important aspects are the design of new liquid crystals,[20,21] as well as studies on cyclometallated palladium and platinum complexes that show remarkable and specific antitumor activity toward some forms of cancer[22,23] or other interesting biological properties.[24,25]

We have been interested in cyclometallation reactions of Schiff-base ligands derived from amines, diamines, and dialdehydes[26] and we have also reported five-membered metallacycles derived from substituted imidazoles with palladium(II)[27,28] and manganese(I).[29] In the present paper, we report the synthesis and characterization of a new series of mono- and polynuclear cyclometallated compounds of palladium(II) derived from a substituted imidazole ligand in conjunction with mono- and polyphosphanes

Results and Discussion

For the convenience of the reader, the compounds and reactions are shown in Schemes 1 and 2. The compounds described in this paper were characterized by elemental analysis (C, H, N), IR spectroscopy, and mass spectrometry (data in the Experimental Section), as well as by ^1H and $^{31}P\{^1H\}$ NMR spectroscopy (see Table 1).

The ligand was synthesized according to the method described by Lettau,[30] through reduction of the imidazole *N*-oxide derivative (see Scheme 1). Treatment of 1,4,5-trimethyl-2-phenylimidazole (**L**) with $Pd(OAc)_2$ in glacial acetic acid under argon at 50 °C gave the dimeric acetate-bridged *ortho*-palladated complex $[\{Pd[o\text{-}C_6H_4C{=}NC(Me){=}C(Me)NMe]\}(\mu\text{-}O_2CMe)]_2$, **1**. The FAB mass spectrum of **1** shows peaks at m/z = 701, 642, and 583 attributable to $[M^+]$, $[M^+ - OAc]$, and $[M^+ - 2OAc]$, respectively, taking into account the distribution of palladium isotopes.[31] The IR spectrum of **1** features two strong bands at 1580 cm^{-1} and 1420 cm^{-1}, attributable to the $\nu_{as}(COO)$ and $\nu_s(COO)$ stretching vibrations of the acetate ligand, respectively.[32] The methyl groups of the acetate ligands give rise to just one singlet in the ^1H NMR spectrum at δ = 2.13 (Table 1), indicating that they are equivalent. This is consistent with

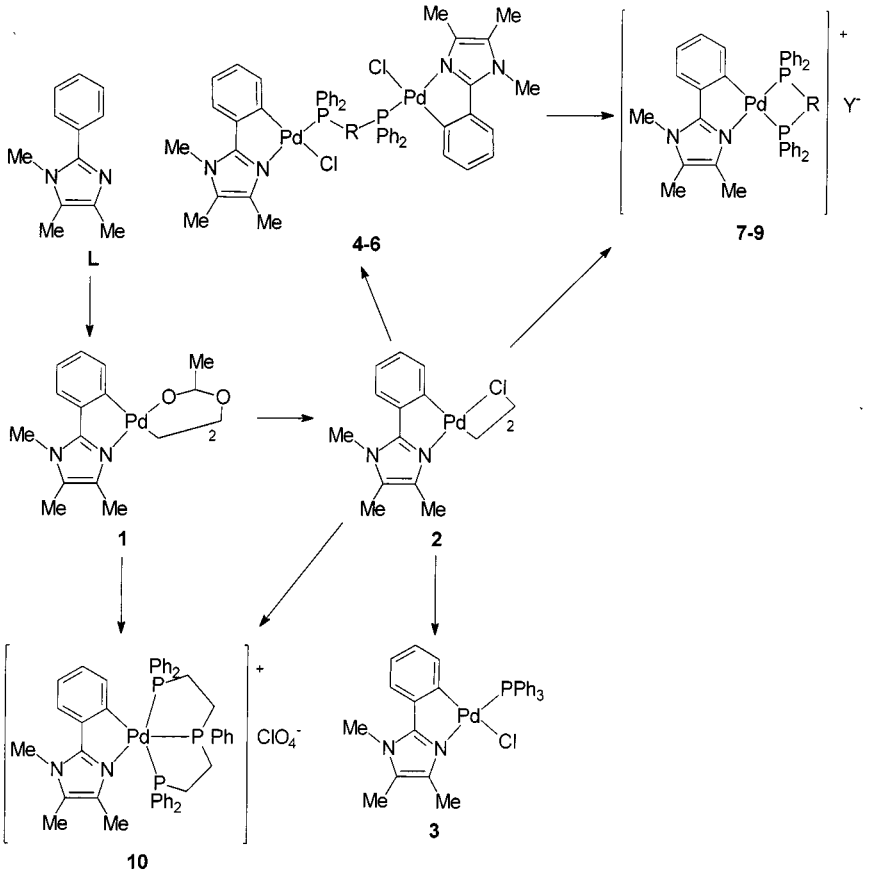
[a] ^{1}H NMR in $CDCl_3$, except for compound **2**, which was studied in [D_6]DMSO; measured at 200 MHz (ca. 20 °C), chemical shifts (δ) in ppm (±0.01) downfield from $SiMe_4$. – [b] ^{31}P{^{1}H} NMR in $CDCl_3$; measured at 81 MHz (ca. 20 °C), chemical shifts (δ) in ppm (±0.01) downfield from 85% H_3PO_4; *trans*-^4J(PH5) > *cis*-^4J(PH5); $\delta(P_{trans\text{-}N}) > \delta(P_{trans\text{-}C})$. – [c] s, singlet; d, doublet, dd, doublet of doublets, m, multiplet, b, broad. – [d] Coupling constants in Hz. – [e] Not assigned; obscured by the phosphane resonance.

Scheme 1

a *trans* geometry of the cyclometallated moieties in the *anti* isomer.[33–35] Some cyclopalladation reactions of substituted imidazoles lead to a mixture of the two possible geometrical isomers, *anti* and *syn*, but the reasons for this difference in behaviour are not clear.[28,36,37]

A doublet at δ = 6.96 can be assigned to the H2 proton, whilst the H3, H4, and H5 resonances appear as a multiplet centred at δ = 6.68. The shift towards lower frequency of these signals, as well as of those of the imidazole ring methyl groups, as compared with the signals of the free ligand, may be attributed to a shielding effect that arises as a result of the "open-book" configuration of the complex. The cyclometallated ligands are nearly face-to-face, similar to the situation observed in the related dimers.[38,39]

A metathesis reaction of **1** with aqueous sodium chloride afforded the chloride-bridged complex [{Pd[*o*-C_6H_4C=NC(Me)=C(Me)NMe]}(μ-Cl)]$_2$, **2**. The IR spectrum of the product shows two ν(Pd–Cl) bands at 321 and 289 cm^{-1}, consistent with an asymmetric Pd_2Cl_2 bridging unit.[40] Complex **2** was found to be poorly soluble in the common organic solvents, but its full characterization by ^{1}H NMR was possible in [D_6]DMSO. The phenyl proton signals were seen to be shifted to higher frequencies as compared with the corresponding signals for compound **1**. This can be rationalized in terms of the planar arrangement in **2**, as opposed to the "open-book" geometry of **1**, in agreement with previously reported structural data.[41,42] Whereas in the free ligand the resonance of the NMe group of the imidazole ring is close to the value found in 1-methylimidazole,[43] suggesting that the imidazole and phenyl rings are mutually tilted by ca. 45°, in compound **2** the N–Me resonance is seen to be shifted to higher frequency by 0.21 ppm. This shift may be caused by the deshielding effect of the metallated phenyl ring and shows that the two rings have an almost coplanar disposition.



In view of the importance of palladium-assisted synthesis of heterocycles, some reactions of compounds **1** and **2** with

unsaturated molecules were examined. Thus, **1** and **2** were treated with, e.g. phenylacetylenes, in order to ascertain the ability of the complexes to undergo insertion of organic molecules into the Pd−C bond. Unfortunately, our attempts did not meet with success and only intractable mixtures were obtained. Nevertheless, more recent results from our laboratory show that when these reactions are carried out with cyclomanganated phenylimidazole ligands, successful insertion of unsaturated organic molecules, e.g. 1-phenyl-1-propyne, into the Mn−C bond is observed with formation of a stable seven-membered ring containing the metal atom. We are currently engaged in developing this work further.

Chloride-bridge cleavage reactions were observed when [{Pd[*o*-C_6H_4C=NC(Me)=C(Me)NMe]}(μ-Cl)]$_2$ (**2**) was treated with triphenylphosphane in a 1:2 molar ratio, giving the mononuclear cyclometallated complex **3**. Likewise, treatment of **2** with the diphosphanes 1,1-bis(diphenylphosphanyl)ethene (vdpp), 1,3-bis(diphenylphosphanyl)propane (dppp), or 1,1′-bis(diphenylphosphanyl)ferrocene (dppf) in a 1:1 molar ratio was found to give the dinuclear cyclometallated complexes **4**, **5**, and **6**, respectively (see Scheme 2). The $^{31}P\{^1H\}$ NMR spectra feature a singlet in all cases, shifted to higher frequency compared with the free phosphane, consistent with phosphorus coordination to the metal centre.[44] The δP values suggest that the phosphane is *trans* to the nitrogen atom and, in the case of the dinuclear compounds with the diphosphane acting as a bridging ligand, indicate that the two phosphorus nuclei are equivalent. The ^1H NMR spectra show the H4 and H5 proton signals shifted to lower frequencies by 0.3−0.8 ppm, as a result of the shielding effect of the phosphane phenyl rings. These signals are overlapped for compounds **4**−**6**, but can be clearly distinguished in the case of compound **3**. The H5 resonance shows coupling to the phosphorus atom [^4J(PH5) = 6.5 Hz], confirming the *cis* geometry of the phosphane and the metallated phenyl group.

For complexes **3**−**6**, the IR spectra show a band at ca. 275 cm^{-1} attributable to the ν_{as}(Pd−Cl) *trans* to the C_{phenyl} atom,[45] confirming that only a single isomer is present in each case. The FAB mass spectra show, among others, peaks attributable to [M^+] (**3**, **5**), [$M^+ - CH_2$] (**4**), and [$M^+ - Cl$] (**6**) ions, thereby confirming the dinuclear nature of these complexes (see Experimental Section). We have recently reported that complexes similar to **4** are subject to an interconversion between two conformations in solution, leading either to electrolyte species or to molecular compounds.[46,47]

Treatment of the chloride-bridged complex (**2**) with vdpp, dppp, or dppf in a 1:2 molar ratio in the presence of silver trifluoromethanesulfonate, ammonium hexafluorophosphate, or sodium perchlorate in acetone at room temperature yielded the mononuclear cyclometallated compounds **7**, **8**, and **9**, respectively. The products no longer contain Pd−Cl bonds and the diphosphane is chelated to the metal

Scheme 2

centre through the two phosphorus atoms. These compounds could also be prepared by reaction of the corresponding dinuclear species with the diphosphane in a 1:1 molar ratio in the presence of the ionic salt. The FAB mass spectra show similar fragmentation patterns, featuring peaks attributable to [M^+] and [M^+ − diphosphane] ions (see data in the Experimental Section). The conductivity data for complexes **7−9** (125−150 $\Omega^{-1}cm^2mol^{-1}$ in 10^{-3} mol·dm^{-3} solutions in dry acetonitrile) show that they are 1:1 electrolytes.[48]

The $^{31}P\{^1H\}$ NMR spectra feature two doublets, suggesting that the two phosphorus atoms are non-equivalent. The assignment of the doublets was made on the assumption that a ligand of greater *trans* influence shifts the resonances of the phosphorus nuclei *trans* to it to lower frequency.[44] This was confirmed by means of selective decoupling experiments (see Table 1).

The H4 and H5 resonances are shifted to lower frequency in the ^1H NMR spectra (*cf.* compounds **3−6**), although the signal order is reversed in this case, with the H4 signal showing the largest shift. We suggest that this is due to the different spatial shielding of the phenyl rings on the phosphorus atom *trans* to nitrogen, i.e. whether the phosphane ligand is in a bridging or a chelating mode. The H5 resonance is seen to be coupled to both phosphorus nuclei [$^4J(P_{trans\text{-}C}H)$ ca. 11 Hz, $^4J(P_{trans\text{-}N}H)$ ca. 8 Hz]. The 4-Me signal is shifted downfield by ca. 0.5 ppm due to the shielding effect of the PPh_2 groups *trans* to carbon. This is most noticeable in compounds **8** and **9** due to the larger chelate ring size. These findings were confirmed by an X-ray crystal structure determination of compound **7** (see Experimental Section).

Reaction of **1** with bis(2-diphenylphosphanylethyl)phenylphosphane (triphos) and sodium perchlorate in a 1:2 molar ratio in acetone at room temperature yielded the mononuclear complex **10** (see Scheme 2). The compound could also be obtained by treatment of **2** with triphos under similar conditions. The IR spectrum revealed an absence of bands in the range 1600−1400 cm^{-1} characteristic of COO stretching vibrations of acetate groups. The microanalytical data were consistent with the empirical formula [(L−H)Pd(triphos)][ClO_4], while the FAB mass spectrum showed the appropriate peak attributable to the [M^+] ion.

The $^{31}P\{^1H\}$ NMR spectrum shows a triplet [δ = 82.56 ppm, 1 P, $^3J(PP)$ = 28.0 Hz] and a doublet (δ = 41.48, 2 P), shifted to higher frequencies with respect to the signals of the free phosphane, in agreement with phosphorus coordination to the metal centre. The ^1H NMR spectrum shows that the ligand proton signals appear at lower frequencies compared to the corresponding signals in compounds **7−9**, especially those attributable to H4, H5, N−Me, and 4-Me, which are shifted by ca. 0.4−0.6 ppm. This may be rationalized in terms of the remarkable shielding effect of the phenyl rings of the phosphane. The signal attributable to H5 only shows coupling to one phosphorus nucleus [$^4J(PH5)$ = 7.3 Hz]. The crystal structure of **10** has been determined by X-ray diffraction analysis (vide infra).

Crystal and Molecular Structures of 7 and 10

Suitable crystals were grown by slowly evaporating the solvent from chloroform solutions of complexes **7** and **10**. The labelling schemes for the complexes are shown in Figures 1 and 2. Both crystals consist of discrete molecules, separated by normal van der Waals distances. Crystallographic data and selected interatomic distances and angles are listed in Table 2 and 3.

In compound **7**, the palladium(II) centre is bonded to four atoms: one adjacent *ortho*-carbon and one nitrogen of the 1,4,5-trimethyl-2-phenylimidazole ligand, and two phosphorus atoms of a chelating 1,1-bis(diphenylphosphanyl)ethene in a slightly distorted square-planar coordination environment (see Figure 1). The sum of the angles about palladium is 360.03°, with the distortions more noticeable in the somewhat reduced "bite" angles enforced by the chelation. The requirements of the five- and four-membered chelate rings dictate C(1)−Pd(1)−N(1) and P(1)−Pd(1)−P(2) bond angles of 80.7(2)° and 72.75(5)°, respectively. The latter value is considerably smaller value than that of the corresponding angle in free vdpp, i.e. 118.4°.[49] The geometry about the palladium atom is almost planar; displacements from the least-squares plane formed by the metal centre and the atoms bonded to it [Pd(1), C(1), N(1), P(1), and P(2)] are as follows: Pd(1): 0.0157 Å, C(1): −0.0231 Å, N(1): 0.0127 Å, P(1): −0.0202 Å, and P(2): 0.0149 Å.

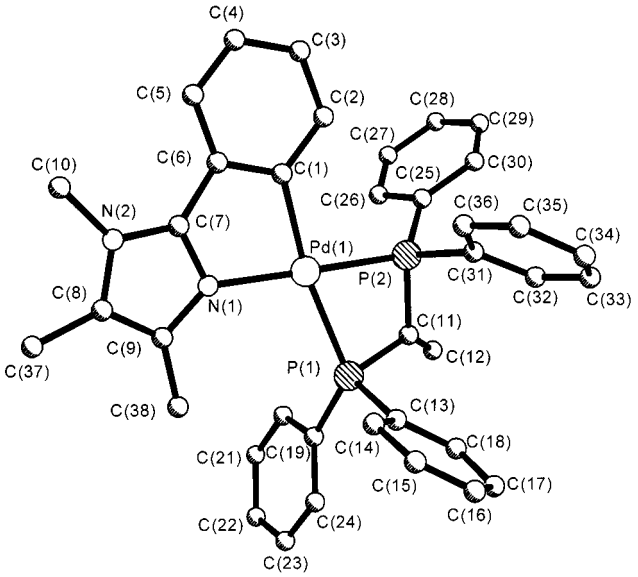

Figure 1. ORTEP projection of the $[\{Pd[o\text{-}C_6H_4C{=}NC(Me){=}C(Me)NMe]\}\{Ph_2PC(=CH_2)PPh_2\text{-}P,P'\}]^+$ cation, corresponding to complex **7**

The palladium−nitrogen bond length, 2.068(4) Å, is longer than the predicted single-bond value of 2.011 Å, based on the sum of the covalent radii for sp^2 nitrogen and palladium, i.e. 0.701 and 1.31 Å, respectively,[50] reflecting the *trans* influence of the phosphorus atom.[51] The palladium−carbon bond length, 2.033(5) Å, is slightly shorter than the expected value of 2.081 Å (based on the sum of covalent radii for sp^2 carbon and palladium, i.e. 0.771 and 1.31 Å, respectively), but is longer than in related complexes for which partial multiple-bond character of the Pd−C bond has been proposed.[27,52,53] This suggests some degree of multiple-bond character in the Pd−C(aryl) linkage, and also reflects the *trans* influence of the phosphorus atom responsible for the observed lengthening. The palladium−phosphorus bond lengths are shorter than the sum of the single bond radii for the relevant atoms, 2.41 Å, suggesting some partial double-bond character, as has also been observed in some related examples.[27,54] The differing *trans* influence is clearly illustrated by the palladium−phosphorus distances *trans* to carbon, Pd(1)−P(1), and *trans* to nitrogen, Pd(1)−P(2), i.e. Pd(1)−P(1) = 2.3843(13) Å vs. Pd(1)−P(2) = 2.2575(14) Å. In complex **7**, the C(11)−C(12) bond length is 1.308(9) Å, which is within the range expected for a carbon−carbon double bond and is shorter than the value of 1.34 Å found in free vdpp.

Apart from the phenyl phosphane rings and the methyl groups, the compound is approximately planar. The mean deviations from the least-squares planes determined for the metallated phenyl ring (C1, C2, C3, C4, C5, C6; plane 1), the imidazole ring (N1, C7, N2, C8, C9; plane 2), and the metallacycle (Pd1, C1, C6, C7, N1; plane 3) are 0.0025, 0.0022, and 0.0150 Å, respectively. The angles between the planes are as follows: plane 1/plane 2: 4.2°, plane 1/plane 3: 2.0°, and plane 2/plane 3: 3.1°. The chelate phosphane ring is not planar, showing a mean deviation from the ideal plane of 0.1619 Å. The vinylidene carbon atoms, C(11) and C(12), are displaced from the plane formed by the metal centre and the phosphorus atoms [Pd(1), P(1), P(2), plane 4] by 0.5323 and 1.3178 Å, respectively. The angles between plane 4 and the other planes are: plane 1/plane 4: 1.3°, plane 2/plane 4: 5.3°, and plane 3/plane 4: 2.5°.

In compound **10**, the palladium(II) centre is bonded to four atoms: the adjacent *ortho*-carbon and three phosphorus atoms of the bis(diphenylphosphanylethyl)phenylphosphane. An additional fifth linkage results from a weak interaction between the palladium and one nitrogen of the imidazole ligand, giving an overall distorted bipyramidal-trigonal coordination (see Figure 2). The equatorial plane is formed by the palladium, the nitrogen, and the terminal phosphorus atoms of the phosphane ligand. The metallated carbon and the central phosphorus complete the coordination sphere at the apical positions. The geometry about the palladium centre is almost planar; displacements from the least-squares plane formed by Pd(1), N(2), P(1), and P(3) are as follows: Pd(1): −0.186 Å, N(2): 0.0033 Å, P(1): 0.0071 Å, and P(3): 0.0081 Å. The main distortions in this plane are seen in the widened P(3)−Pd(1)−P(1) bond angle, 153.91(4)°, and the reduced P(1)−Pd(1)−N(2) bond angle, 88.06(9)°, although the sum of the angles at the palladium in the equatorial plane is 359.95°. On coordination, the donor atoms of the chelating imidazole occupy *cis* sites with a reduced bond angle [C(1)−Pd(1)−N(2)] of 76.88(15)°.

The palladium−nitrogen bond length, 2.488(4) Å, is longer than the predicted single bond value of 2.011 Å, and is slightly longer than the Pd−N bond length of 2.23(2) Å characteristic of an authentic trigonal-bipyramidal Pd^{II} complex.[55] Nevertheless, it is much shorter than the range of values, i.e. 2.71−2.80 Å and 2.576(4) Å,[55] hitherto reported for cyclopalladated compounds in which a weak Pd···N interaction has been assumed to be present.[56−59] More recently, we have found very short Pd−N bond lengths in palladium(II) cyclometallated compounds incorporating the triphos ligand.[60] We have reasoned that this is due to a change from the more common square-

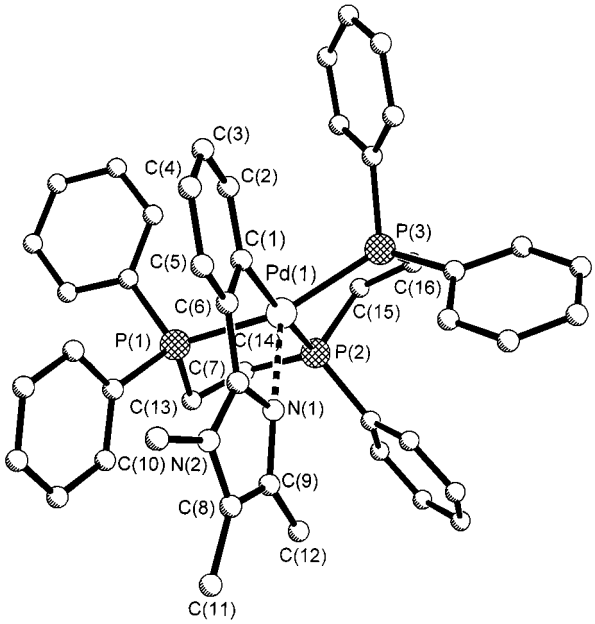

Figure 2. ORTEP projection of the $[\{Pd[o\text{-}C_6H_4C{=}NC(Me){=}C(Me)NMe]\}(Ph_2PCH_2CH_2)_2PPh\text{-}P,P'\text{-}P''\}]^+$ cation, corresponding to complex **10**

planar geometry of Pd^{II} towards a trigonal-bipyramidal arrangement, which brings the nitrogen atom sufficiently close to the palladium such that a true bonding interaction may be postulated. In the light of this result, we changed the organic metallated moiety in order to verify that it was indeed mainly the triphos ligand that was responsible for this new situation in the palladium coordination sphere. Thus, bidentate Schiff-bases, azobenzenes,[61] and phenylimidazoles were used. Compound **10** represents an example of the latter type of ligand, the results for which we describe in the present paper. Thus, the data presented here seem to confirm that with triphos as a terdentate chelating ligand, unusually short Pd−N distances may be obtained, allowing a new insight into the chemistry of cyclopalladated compounds.

The Pd(1)−C(1) bond length, 2.087(4) Å, is longer than is usually found in related complexes bearing a phosphane ligand in the *trans* position. The Pd−P bond lengths, Pd(1)−P(1): 2.3164(11), Pd(1)−P(2): 2.2889(12), and Pd(1)−P(3): 2.3036(12) Å, are suggestive of slight double-bond character of the palladium−phosphorus linkages.

The cyclometallated moiety is somewhat distorted from planarity, mainly due to the imidazole ring. The mean deviations from the least-squares planes determined for the metallated phenyl ring (C1, C2, C3, C4, C5, C6; plane 1), the imidazole ring (N1, C7, N2, C11, C12; plane 2), and the metallacycle (Pd1, C1, C6, C7, N2; plane 3) amount to 0.0099, 0.0035, and 0.0471 Å, respectively. The angles between planes are as follows: plane 1/plane 2: 17.6°, plane 1/plane 3: 4.7°, and plane 2/plane 3: 15.1°. The angles between the equatorial plane formed by Pd(1), P(1), P(3), and N(2) (plane 4) are as follows: plane 1/plane 4: 83.4°, plane 2/plane 4: 90.8°, and plane 3/plane 4: 87.9°. Thus, the compound is clearly pentacoordinated, even though the imidazole ring is slightly tilted with respect to the phenyl and cyclometallated rings, and the Pd−N distance is rather long. These distortions can be rationalized taking into account the low tendency of palladium(II) to generate pentacoordinated complexes.

Experimental Section

General Remarks: All solvents were dried according to standard methods.[62] The following compounds were used as received from commercial sources: palladium(II) acetate from Strem Chemicals, diacetylmonooxime from Carlo Erba, zinc, aqueous methylamine, PPh_3, and $Ph_2PCH_2CH_2CH_2PPh_2$ (dppp) from Acros, and silver trifluoromethanesulfonate, benzaldehyde, and $Ph_2PC_5H_4FeC_5H_4PPh_2$ (dppf) from Aldrich. $Ph_2PC(=CH_2)PPh_2$ (vdpp) was prepared according to procedures described elsewhere.[63] − Elemental analyses were carried out by the Servicios Generales de la Universidad de La Coruña using a Carlo Erba Model 1108 elemental analyzer. − IR spectra were recorded from samples in Nujol mulls or polythene discs on a Perkin−Elmer 1330 spectrophotometer. − NMR spectra were recorded from samples in $CDCl_3$ or [D$_6$]DMSO solutions on a Bruker AC 200F spectrometer and were referenced to internal $SiMe_4$ (^1H) or external 85% H_3PO_4 ($^{31}P\{^1H\}$). − Mass spectra were measured on a QUATRO mass spectrometer with a Cs ion-gun and NOBA or 3-NBA as the matrix.

Synthesis of 1,4,5-Trimethyl-2-phenylimidazole, $C_6H_5C{=}NC(Me){=}C(Me)NMe$ (L): Benzaldehyde (5.3 g, 0.049 mol), 40% aq. methylamine (3.87 g, 0.049 mol), and diacetylmonooxime (4.95 g, 0.049 mol) were added to glacial acetic acid (60 mL). After refluxing for 2 h, the solution was cooled, zinc (10 g, 0.152 mol) was added, and the resulting mixture was refluxed for a further 1 h and then kept overnight at room temperature. The zinc acetate formed was filtered off. Treatment of the filtrate with ammonium hydroxide resulted in the separation of a yellow oil, which was extracted with toluene (3 × 30 mL). The combined organic extracts were dried with anhydrous sodium sulfate, filtered, and then concentrated in vacuo to give a yellow solid, which was recrystallized from toluene. Yield: 55.9%. − $C_{12}H_{14}N_2$ (186.2): calcd. C 77.4, H 7.6, N 15.0; found C 77.0, H 7.4, N 15.2. − FAB-MS: *m*/*z* = 186 [M^+], 171 [M^+ − Me].

Synthesis of $[\{Pd[o\text{-}C_6H_4C{=}NC(Me){=}C(Me)NMe]\}(\mu\text{-}O_2CMe)]_2$ (1): 1,4,5-Trimethyl-2-phenylimidazole (0.432 g, 2.322 mmol) and palladium(II) acetate (0.500 g, 2.228 mmol) were added to glacial acetic acid (50 mL) to give a yellow solution. After heating at 50 °C for 10 min. under argon, the solution was cooled and filtered. The collected solid was washed with glacial acetic acid and cold ethanol, and dried in vacuo. Yield: 75.1%. − $C_{28}H_{32}N_4O_4Pd_2$ (701.4): calcd. C 48.0, H 4.6, N 8.0; found C 48.3, H 4.7, N 8.0. − IR: $\tilde{\nu}$ = 1580 [s, ν_{as}(COO)], 1420 [s, ν_s(COO)]. − FAB-MS: *m*/*z* = 701 [M^+], 642 [M^+ − OAc], 583 [M^+ − 2AcO], 476 [$(L-H)_2Pd^+$], 291 [$(L-H)Pd^+$].

Synthesis of $[\{Pd[o\text{-}C_6H_4C{=}NC(Me){=}C(Me)NMe]\}(\mu\text{-}Cl)]_2$ (2): An aqueous solution of NaCl (ca. 10^{-2} M) was added dropwise to a solution of **1** (0.252 g, 0.360 mmol) in acetone (ca. 20 mL). The resulting mixture was stirred for 4 days, after which a yellow solid had precipitated. This was filtered off, washed with water and cold acetone, and dried in vacuo. Yield: >95%. − $C_{24}H_{26}Cl_2N_4Pd_2$ (654.2): calcd. C 44.1, H 4.0, N 8.6; found C 44.2, H 3.9, N 8.5. − IR: $\tilde{\nu}$ = 321 [m, $\nu(Pd-Cl_{trans\text{-}N})$], 289 [m, $\nu(Pd-Cl_{trans\text{-}C})$].

Synthesis of [Pd{*o*-$C_6H_4C{=}NC(Me){=}C(Me)NMe$}($PPh_3$)(Cl)] (3): To a solution of **2** (32 mg, 0.049 mmol) in acetone (ca. 15 mL) was added PPh_3 (26 mg, 0.098 mmol). The resulting mixture was stirred for 3 h at room temperature, after which a precipitate had formed. This was filtered off, washed with cold acetone, and dried in vacuo. Yield: 74.5%. − $C_{30}H_{28}ClN_2PPd$ (589.4): calcd. C 61.1, H 4.8, N 4.7; found C 61.4, H 4.7, N 4.8. − IR: $\tilde{\nu}$ = 277 [m, ν(Pd−Cl)]. − FAB-MS: *m*/*z* = 589 [M^+], 553 [M^+ − Cl], 291 [(L−H)Pd^+].

Synthesis of [{Pd[*o*-$C_6H_4C{=}NC(Me){=}C(Me)NMe$]}$_2$[μ-$Ph_2PC(=CH_2)PPh_2$](μ-Cl)]Cl (4): To a solution of **2** (34 mg, 0.052 mmol) in acetone (ca. 15 mL) was added vdpp (20 mg, 0.052 mmol). The resulting mixture was stirred for 12 h at room temperature, after which a precipitate had formed. This was filtered off, washed with cold acetone, dried in vacuo, and recrystallized from dichloromethane/*n*-hexane. Yield: 90.9%. − $C_{50}H_{48}Cl_2N_4P_2Pd_2$ (1050.6): calcd. C 57.1, H 4.6, N 5.3; found C 57.1, H 4.6, N 5.2. − IR: $\tilde{\nu}$ = 282 [m, ν(Pd−Cl)]. − FAB-MS: *m*/*z* = 1001 [M^+ − Cl − CH_2].

Compounds **5** and **6** were similarly prepared and were isolated as solids.

[{Pd[*o*-$C_6H_4C{=}NC(Me){=}C(Me)NMe$](Cl)}$_2$(μ-$Ph_2PCH_2CH_2CH_2PPh_2$)] (5): Yield: 62.5%. − $C_{51}H_{52}Cl_2N_4P_2Pd_2$ (1066.6): calcd. C 57.4, H 4.9, N 5.2; found C 57.6, H 5.1, N 5.0. − IR: $\tilde{\nu}$ = 275 [m, ν(Pd−Cl)]. − FAB-MS: *m*/*z* = 1067 [M^+], 1031 [M^+ − Cl], 739 [(L−H)PdCl(PP)$^+$], 704 [(L−H)Pd(PP)$^+$], 291 [(L−H)Pd^+].

[{Pd[*o*-$C_6H_4C{=}NC(Me){=}C(Me)NMe$](Cl)}$_2$(μ-$Ph_2PC_5H_4FeC_5H_4PPh_2$)] (6): Yield: 78.1%. − $C_{58}H_{54}Cl_2FeN_4P_2Pd_2$ (1208.5): calcd. C 57.6, H 4.5, N 4.6; found C 57.6, H 4.3, N 4.7. − IR: $\tilde{\nu}$ = 285 [m, ν(Pd−Cl)]. − FAB-MS: *m*/*z* = 1173 [M^+ − Cl], 846 [(L−H)Pd(PP)$^+$], 291 [(L−H)Pd^+].

Synthesis of [{Pd[*o*-$C_6H_4C{=}NC(Me){=}C(Me)NMe$]}{$Ph_2PC(=CH_2)PPh_2$-*P,P′*}]($CF_3SO_3$) (7): To a solution of **2** (32 mg, 0.049 mmol) in acetone (ca. 15 mL) was added silver trifluoromethanesulfonate (25 mg, 0.098 mmol). The resulting mixture was stirred for 30 min. at room temperature, and then filtered through Celite to eliminate the silver chloride precipitate. To the filtrate was added vdpp (38 mg, 0.098 mmol) and the resulting solution was stirred for 2 days. The precipitate formed was filtered off, washed with cold acetone, dried in vacuo, and recrystallized from chloroform/*n*-hexane. Yield: 74.6%. − $C_{39}H_{35}F_3N_2O_3P_2PdS$ (837.1): calcd. C 55.9, H 4.2, N 3.3; found C 55.9, H 4.0, N 3.3.

Synthesis of [{Pd[*o*-$C_6H_4C{=}NC(Me){=}C(Me)NMe$]}($Ph_2PCH_2CH_2CH_2PPh_2$-*P,P′*)]($PF_6$) (8): To a solution of **2** (32 mg, 0.049 mmol) in acetone (ca. 15 mL) was added dppp (40 mg, 0.098 mmol). The mixture was stirred for 2 h at room temperature, and then an excess of ammonium hexafluorophosphate was added. The resulting mixture was stirred for 1 h, and then water was added dropwise until a precipitate formed. This was filtered off, washed with water, cold acetone, and ethanol, and dried in vacuo. Yield: 87.5%. − $C_{39}H_{41}F_6N_2P_3Pd$ (851.0): calcd. C 55.2, H 4.6, N 3.3; found C 55.5, H 4.4, N 3.2. − FAB-MS: *m*/*z* = 704 [M^+], 518 [Pd(PP)$^+$], 291 [(L−H)Pd^+].

Compound **9** was similarly prepared using dppf and sodium perchlorate as appropriate and was isolated as a solid.

[{Pd[*o*-$C_6H_4C{=}NC(Me){=}C(Me)NMe$]}($Ph_2PC_5H_4FeC_5H_4PPh_2$-*P,P′*)]($ClO_4$) (9): Yield: 94.8%. − $C_{46}H_{41}ClFeN_2O_4P_2Pd$ (945.5): calcd. C 58.4, H 4.4, N 3.0; found C 58.1, H 4.2, N 3.0. − FAB-MS: *m*/*z* = 846 [M^+], 660 [Pd(PP)$^+$], 291 [(L−H)Pd^+].

Synthesis of [{Pd[*o*-$C_6H_4C{=}NC(Me){=}C(Me)NMe$]}{($Ph_2PCH_2CH_2$)$_2$PPh-*P,P′-P″*}]($ClO_4$) (10): To a solution of **1** (27 mg, 0.038 mmol) in acetone (ca. 10 mL) was added triphos (41 mg, 0.077 mmol). The mixture was stirred for 2 h at room temperature, and then excess sodium perchlorate was added. The resulting mixture was stirred for a further 1 h and then water was added dropwise until a precipitate formed. This was filtered off, washed with water and ethanol, dried in vacuo, and recrystallized from chloroform/*n*-hexane. Yield: 84.0%. − $C_{46}H_{46}ClN_2O_4P_3Pd$ (925.6): calcd. C 60.0, H 5.0, N 3.0; found C 59.9, H 5.1, N 3.1. − FAB-MS: *m*/*z* = 826 [M^+], 640 [Pd(PP)$^+$], 291 [(L−H)Pd^+].

X-ray Crystallographic Study:[64] Three-dimensional X-ray data were collected for **7** and **10** at room temperature in the θ range 2.67 to 26.00° on a Siemens Smart CCD diffractometer by the ω-scan method. Reflections were measured from a hemisphere of data made up of frames each covering 0.3° in ω. Of the 12349 (**7**) and 13933 (**10**) reflections measured, all of which were corrected for Lorentz and polarization effects and for absorption by semiempirical methods based on symmetry-equivalent and repeated reflections [minimum and maximum transmission coefficients 0.57 (**7**), 0.74 (**10**), and 1.00 (**7**, **10**)]; 7081 (**7**) and 8028 (**10**) independent reflections exceeded the significance level $|F| > 4.0\,\sigma|F|$. The structure was solved by direct methods and refined by full-matrix least-squares on F^2. Hydrogen atoms were included in calculated positions and refined in riding mode. Refinement converged at a final R_1 = 0.0699 (**7**) 0.0597 (**10**) [wR_2 = 0.2000 (**7**), 0.1981 (**10**) for all data] with allowance for thermal anisotropy of all non-hydrogen atoms. Geometrical constrains were used in the trifluoromethanesulfonate (**7**) and perchlorate (**10**) ions. The structure solution and refinement were carried out using the program package SHELX-97.[65]

Electron-Poor Olefin Polymerization Catalysts Based on Semi-Fluorinated Bis(phosphane)s

Roland Wursche,[a] Tony Debaerdemaeker,[b] Martti Klinga,[c] and Bernhard Rieger*[a]

Keywords: Fluorine / Phosphanes / Palladium / Platinum / Polymerizations

Two semi-fluorinated bis(phosphane)s, *P,P′*-(1,2-ethanediyl)-bis[bis(2,4,5-trifluorophenyl)phosphane] (**3a**), *P,P′*-(1,2-ethanediyl)bis[bis(2,4-difluorophenyl)phosphane] (**3b**), and their corresponding Pd^{II}- and Pt^{II}-dichloro complexes (**4a**,**b** and **6a**,**b**) have been synthesized. Complexation of *P,P′*-(1,2-ethanediyl)bis{bis[3,5-di(trifluoromethyl)phenyl]phosphane} (**3c**) and *P,P′*-(1,2-ethanediyl)bis[bis(pentafluorophenyl)phosphane] (**3d**) afforded the related compounds **4c**,**d** and **6c**. The Pd^{II}-diiodo complexes **5c**,**d** have been obtained from **4c**,**d** by halide exchange with NaI. The solid-state structures of compounds **4b** and **5c**,**d** have been determined by single-crystal X-ray diffraction analysis. Activation of **4b**–**d** with MAO produced efficient catalysts for the polymerization of 2-norbornene, which have proved to be superior to the Pd^{II}-dichlorides derived from the more electron-rich, structurally related *P,P′*-(1,2-ethanediyl)bis(diphenylphosphane) (DPPE) or *P,P′*-(1,3-propanediyl)bis(diphenylphosphane) (DPPP).

Introduction

Bidentate phosphanes $R_2PCH_2CH_2PR_2$ (R = alkyl, aryl) play an important role in the synthesis of tailored organometallic complexes for catalytic purposes. Potential applications range from the field of asymmetric hydrogenation, as carried out with chiral rhodium(I) compounds, for example, to C−C bond-forming processes in the case of the Grignard cross-coupling reaction.[1−3] Apart from examples specific to isolated molecules, late transition metal complexes of bis(phosphane)s are also versatile catalysts for the construction of polymeric materials. With an appropriate choice of the ligand sphere, Ni^{II} compounds can be used to synthesize either high molecular weight poly(olefin)s or oligomeric products.[4,5]

Recently, bis(phosphane)s $(R^f)_2P(CH_2)_2P(R^f)_2$ (R^f may be, for instance, pentafluorophenyl- or perfluoroalkyl-) have attracted attention as a new class of chelating ligands.[6,7] The electron-withdrawing character of the fluorine substituents strongly alters the electronic behaviour of the phosphorus atoms, leading to ligands that show weak σ-donor characteristics, but a high level of π-acceptor capacity. Consequently, bis(phosphane)s of this type form electron-poor transition metal complexes, e.g. Cr, Mo, Fe, Pt, Ru, Rh, and Ir compounds.[8−15] For catalytic applications, it may be advantageous that, unlike most typical strong π-acceptor ligands such as CO, NO and PF_3, bis(phosphane)s can easily be modified in a steric or electronic way by changing their substitution pattern.

We report herein on the synthesis and structural characterization of new electron-poor Pd^{II} and Pt^{II} complexes based on ethylene-bridged ligands $(Ar^f)_2P(CH_2)_2P(Ar^f)_2$, which differ in the substitution patterns at their arene moieties. To explore the potential of this class of compounds as catalysts for the polymerization of olefinic substrates, polymerization experiments have been conducted with 2-norbornene as the monomer.

Results and Discussion

Ligands

Ethylene-bridged bis(phosphane)s are most conveniently prepared by reaction of *P,P′*-(1,2-ethanediyl)bis(dichlorophosphane) **(1)** with an organometallic reagent, usually a lithiated or Grignard compound.[16,17] This method not only circumvents the time-consuming and laborious synthesis of secondary phosphanes, it also proceeds smoothly to afford the desired bidentate phosphanes in a one-pot procedure.

For the syntheses of *P,P′*-(1,2-ethanediyl)bis[bis(2,4,5-trifluorophenyl)phosphane] **(3a)** and *P,P′*-(1,2-ethanediyl)-bis[bis(2,4-difluorophenyl)phosphane] **(3b)**, we employed fluorinated phenyllithiums as the metallated components, which were prepared from the corresponding bromo derivatives through halogen−metal exchange using *n*-butyllithium at −78 °C in diethyl ether (Figure 1). *P,P′*-(1,2-ethanediyl)bis{bis[3,5-di(trifluoromethyl)phenyl]phosphane} **(3c)** was prepared from the Grignard compound 3,5-bis(trifluoromethyl)benzenemagnesium bromide **(2c)**, generated according to a literature procedure from 1-bromo-3,5-bis(trifluoromethyl)benzene and magnesium tur-

nings.[18] A multi-step synthesis of **3c** has been reported previously, but is less favourable from an economic viewpoint.[19] Compounds **3a** and **3b** exhibit ^{31}P absorptions at $\delta = -30.2$ and -31.9, respectively. These signals are situated upfield from the resonance reported for the unsubstituted *P,P'*-(1,2-ethanediyl)bis(diphenylphosphane) ($\delta = -12.5$),[20] whereas in the case of **3d** a ^{31}P chemical shift of $\delta = -44.5$ is observed.[7] This reflects the partial fluorination of the phenyl substituents in compounds **3a**,**b** and further suggests that they may also form electron-poor complexes, although this effect should be less pronounced than in the case of **3d**.

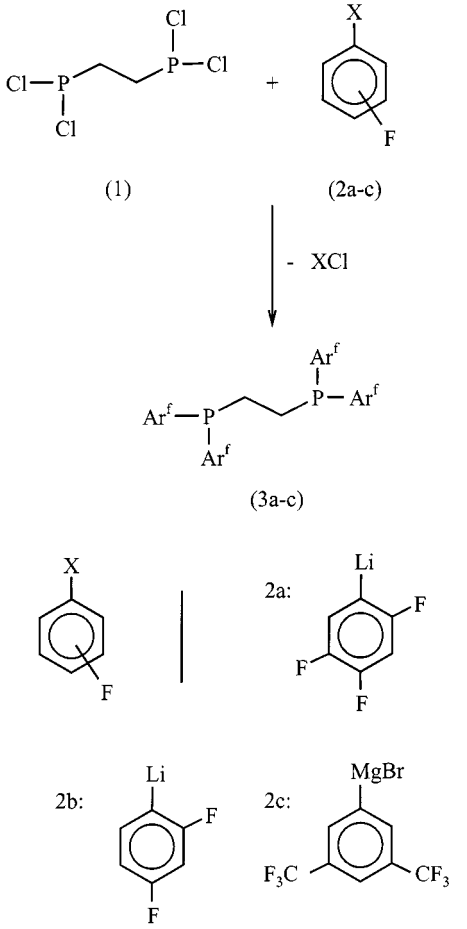

Figure 1. Synthesis of the semi-fluorinated bis(phosphane)s **3a**, **3b**, and **3c**

Complexes

For the synthesis of the Pd^{II}- and Pt^{II}-dichloro complexes of **3a**–**c** (denoted in Figure 2 as **4a**–**c** and **6a**–**c**, respectively) we used suitable organometallic precursors, which were reacted with the ligands at ambient temperature. Compound **4d** was prepared according to a modified literature procedure.[14] All the complexes were obtained as ivory-coloured, microcrystalline solids, except **4d**, which exhibited a distinct yellow aspect. Single crystals of **4b** were obtained from a tetrachloroethane solution.

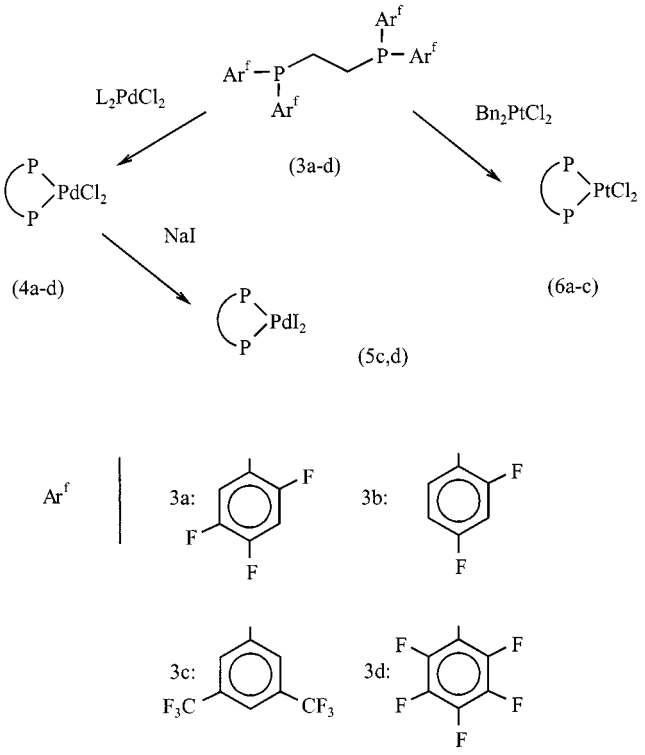

Figure 2. Preparation of the Pd^{II} and Pt^{II} complexes of the semi-fluorinated bis(phosphane)s **3a**, **3b**, **3c**, and **3d**; $\mathbf{L_2}$ = COD (1,5-cyclooctadiene) in the synthesis of **4b** and **4d**; Bn = benzonitrile

Replacement of the chloride substituents of **4d** by treatment with sodium iodide yielded **5d** as a dark-red complex. Slow evaporation of the solvent from an acetone solution produced crystals suitable for an X-ray structure analysis. Halide exchange was also performed on **4c**, leading to a red product that was identified as **5c** (Figure 3, Table 1). Single crystals of this compound suitable for structure investigation could be grown from an acetone solution; their analysis allowed a direct comparison with **5d**, any influence of the different halide ligands being excluded.

In the case of compound **5c** (space group: *C*2/*c*), 3.5 molecules of acetone were found to be included within the unit cell, which are omitted from the ORTEP plot for the sake of clarity. One of the crystallographically determined acetone molecules was found to have a site occupancy factor of 0.75, both showing a slight disordering. The anisotropic displacement factors were also rather large for the CF_3 groups, but dividing the fluorine atoms into two positions could not be satisfactorily accomplished. Similar effects have been observed in an X-ray structure analysis of [{BISBI-(3,5-CF_3)}(PPh_3)Ir(CO)H].[21] Here, three out of four CF_3 moieties were found to be disordered at 133 K. These observations may serve to illustrate the fluxional behaviour of trifluoromethyl substituents in the solid state. The average C–F bond lengths in **5c** (1.301 Å) are in agreement with the literature data (1.338 Å).[19]

Only a few crystal structures of complexes of **3d** have hitherto been reported, specifically those of [(**3d**)$_2$$Pt^0$],[12] *trans*-[$\eta^5$-($C_5H_5$)Mo(**3d**)(CO)Cl],[14] [(**3d**)Rh(PPh_3)Cl],[22]

C13−C14	1.531(13)		

Table 2). The P−C bond lengths are in the same range as observed previously, but in the present study the shortest distances have been seen in [(**3d**)PdI_2] **(5d)**.[12,14] The average C−F bond length calculated for **5d** (1.340 Å) matches the value determined for the Mo complex (1.344 Å).[16] The non-fluorinated complex diiodo-[*P*,*P*′-(1,2-ethanediyl)bis-(diphenylphosphane)]palladium(II) has Pd−I bond lengths of 2.6649(8)/2.6446(10) Å and Pd−P bond lengths of 2.2608(14)/2.2756 Å, which resemble the corresponding values found for **5c**,**d** (Table 1 and 2).[24] Moreover, the P−Pd−P bond angle of 85.59(5)° and the I−Pd−I bond angle of 92.73(3)° are similar to the results observed for the fluorinated species **5c**,**d**.

Complex **4b** (space group: *I*2/*a*) was found to crystallize with two molecules of tetrachloroethane (Figure 5, Table 3).

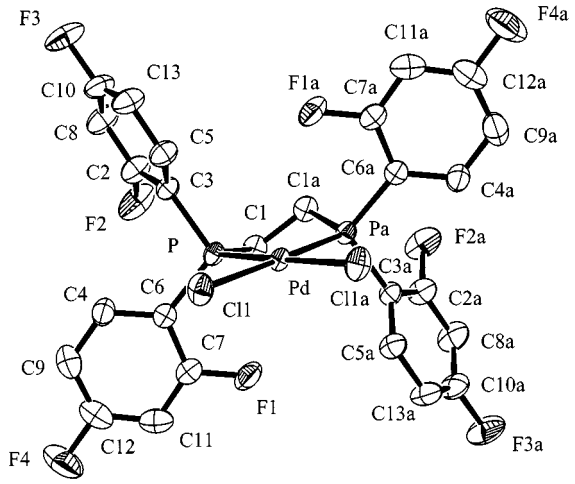

Figure 5. ORTEP plot of complex (**3b**)$PdCl_2$, **4b**, showing the atom labelling scheme; atoms labelled *a* were generated by symmetry operations; thermal ellipsoids are depicted at a 50% probability level

Table 3. Selected bond lengths [Å] and angles [°] in **4b**

Distances		Angles	
Pd−P	2.233(7)	P−Pd−Pa[a]	85.94(4)
Pd−Cl1	2.342(7)	Cl1−Pd−Cl1a[a]	92.11(4)

P−C1	1.835(3)	C6−P−C1	106.79(13)
P−C3	1.812(3)	C3−P−C1	106.97(13)

[a] Generated by symmetry operations: $-x + 3/2$, y, $-z + 1$.

Its P−C bonds are generally shorter than those in the structures of **5c**,**d**, whereas the C−P−C bond angles are seemingly widened. The C−F bond lengths to the *o*- and *p*-fluorines are on average 1.351 Å, slightly longer than in the pentafluorinated aromatics. Two crystal structures of the non-fluorinated parent compound, dichloro-{*P,P′*-(1,2-ethanediyl)bis[diphenylphosphane]}palladium(II) can be found in the literature.[25,26] These show significant deviations as regards, for example, the P−Pd−P bond angle [88.3(1)° vs. 85.82(7)°] and the Pd−P bond lengths [2.284(3) and 2.264(3) Å vs. 2.233(2) and 2.226(2) Å]. This has been attributed to a packing effect arising from the incorporation of one molecule of dichloromethane in the second case. The latter values are nevertheless in good agreement with the Pd−P bond length in **4b** [2.233(7) Å] and the associated P−Pd−P bond angle [85.94(4)°]. The Pd−Cl bond length in **4b** (2.342 Å) is also close to the values observed in the non-fluorinated complex [2.361(2) and 2.357(2) Å].

Polymerization

In contrast to early transition metal systems, complexes of the late transition metals are most often found to dimerize or oligomerize olefins as a result of a competition between chain propagation and β-hydride elimination.[27,28] This is illustrated by the fact that, until recently, just a few examples of late transition metal catalyzed formation of high molecular weight poly(ethylene) were known.[29−31] However, it has since been demonstrated that Pd^{II}- and Ni^{II}-based systems with bulky diimine ligands are not only capable of producing high molecular weight poly(ethylene), but even poly(α-olefin)s.[32,33] This finding was attributed to a blocking of β-hydride elimination by the sterically demanding ligand system. Since the ligands discussed in this work were not designed to meet this requirement, 2-norbornene was used as the monomer as, in this case, a chain termination process based on β-hydride elimination is thermodynamically unfavourable.[34,35] In the case of the semi-fluorinated complexes **4b−d**, addition of 2-norbornene to a solution of the MAO-activated[36] species led to the immediate precipitation of poly(norbornene). Due to the heat of reaction evolved in the polymerization process, this was accompanied by a warming of the reaction vessel. Under analogous experimental conditions, the structurally related complexes DPPE-$PdCl_2$, DPPP-$PdCl_2$,[37] and DPPP-$NiCl_2$[38] were found to give lower conversions, whereas the Pt^{II} complex **6c**[39] failed to produce any poly(norbornene) (Table 4).

Table 4. Polymerization results for semi-fluorinated complexes in comparison with the performances of structurally similar non-fluorinated compounds

	Catalyst	Reaction time (min.)	Monomer conversion (%)
1	DPPE-$PdCl_2$	15	51.4
2	DPPP-$PdCl_2$	15	49.7
3	4b	10	94.7
4	4c	15	100
5	4c	10	94.1
6	4d	15	85.7
7	6c	15	0
8	DPPP-$NiCl_2$	15	6.3

Polymer Characterization

The poly(norbornene)s synthesized in the course of this study were found to be completely insoluble in common organic solvents. In the case of the palladium-catalyzed norbornene polymerization, this lack of solubility has been proposed to originate from an *diisotactic* microstructure of the polymer, whereas Ni and Co complexes have been reported to produce *erythro-syndiotactic* material that shows satisfactory solubility up to molecular weights of one million and beyond.[35,40,41] In this regard, it is noteworthy that the polymer formed by DPPP-$NiCl_2$ was also found to be insoluble. As a consequence, polymer characterization could only be carried out by means of solid-state methods. The solid-state ^{13}C NMR spectrum features broad resonances in the range $\delta = 25-60$. Major absorptions are seen at $\delta = 52.5$, 48.6, 40.9, and 35.3 that are not fully baseline-resolved. This finding is due to the bicyclic nature of the monomer and can also be taken as evidence pointing to a complex polymer microstructure. As far as we can conclude from the spectral data, polymerization with the late transition metal catalysts examined here proceeds according to an insertion-type mechanism, since vinylic resonances resulting from a hypothetical ring-opening propagation step are not observed.[42−44] In the FT-IR (KBr) spectrum, strong bands are observed at 2946 cm^{-1} (CH_2 units) and 2867 cm^{-1} (CH units), resembling the typical C,H valence absorptions, whereas bands at 1478 cm^{-1} and 1454 cm^{-1} can be attributed to C,H bond deformation. A weak absorption at 707 cm^{-1} is assigned to CH_2 rocking. In accordance with the literature data, no glass transition below the onset of thermal decomposition could be detected for the prepared poly(norbornene)s by DSC methods.[34]

Conclusion

The treatment of novel electron-poor Pd^{II} complexes based on semi-fluorinated bis(phosphane)s with methylaluminoxane (MAO) affords active catalysts for the insertion polymerization of 2-norbornene, which display increased monomer conversions compared to catalysts derived from non-fluorinated, more electron-rich compounds. Comparisons of the crystallographic data of **4a** with those of the parent compound dichloro-[*P,P′*-(1,2-ethanediyl)bis(diphenylphosphane)]palladium(II), and those of **5c**,**d** with the data for diiodo-[*P,P′*-(1,2-ethanediyl)bis(diphenylphosphane)]palladium(II) revealed no significant structural differences. Therefore, despite the fact that there seems to be no clear relationship between the degree of fluorination and the monomer conversion, the improved polymerization results obtained with the fluorinated species may be ascribed to their altered electronic properties.

Owing to the comparatively low steric demand in the apical positions, the investigated catalysts are not suitable for the polymerization of α-olefins to high molecular weight poly(olefin)s since the competing displacement of β-H elimination products by incoming olefin molecules cannot be sufficiently suppressed.[27,28,32,33] Consequently, these complexes can be expected to act as oligomerization catalysts for α-olefins. In terms of activity towards the polymerization of 2-norbornene, ligand-free systems[35,40,41] based on simple metal salts, for instance Pd^{II}, Ni^{II}, or Co^{II} compounds, are presumably superior to the investigated catalysts, but lack the structural versatility of bis(phosphane) complexes, which potentially may be helpful in controlling olefin insertion processes. Thus, it should be interesting to combine a bulky ligand geometry, which meets the requirements outlined up above, with partial fluorination to obtain new late transition metal catalysts for the synthesis of poly(olefin)s.

Experimental Section

Materials: *P,P′*-(1,2-ethanediyl)bis[bis(pentafluorophenyl)phosphane] (99%), *P,P′*-(1,2-ethanediyl)bis(dichlorophosphane) (min. purity 97%; received in a sealed glass ampoule, which was opened immediately prior to use), and dichlorobis(benzonitrile)platinum(II) (Bn_2PtCl_2) (99%) were purchased from Strem Chemicals; 1-bromo-2,4-difluorobenzene (98%+), 1-bromo-2,4,5-trifluorobenzene (98%+), and 1-bromo-3,5-bis(trifluoromethyl)benzene (98%+) were from Lancaster. Mg turnings and 2-norbornene were obtained from Merck. Dichloro[*P,P′*-(1,3-propanediyl)bis(diphenylphosphane)]nickel(II), dichloro[*P,P′*-(1,2-ethanediyl)bis(diphenylphosphane)]palladium(II), dichloro[*P,P′*-(1,3-propanediyl)bis(diphenylphosphane)]palladium(II), and *n*-butyllithium (0.1 M in *n*-hexane) were purchased from Fluka. MAO was supplied by WITCO (10% *w*/*w* in toluene). Dichlorobis(benzonitrile)palladium(II) (Bn_2PdCl_2) and dichloro(1,5-cyclooctadiene)palladium(II) ($CODPdCl_2$) were prepared according to literature procedures.[45,46] Tetrahydrofuran was distilled from sodium benzophenone ketyl, toluene from potassium benzophenone ketyl. Dichloromethane was refluxed with calcium hydride and distilled. Ethanol was dried with sodium/diethyl phthalate. Dry acetone (max. 0.01% H_2O) was purchased from Merck. All operations relating to the preparation and complexation of the bis(phosphane) ligands were carried out under an argon atmosphere employing standard Schlenk techniques. The synthesized complexes were found to be stable towards air and moisture and do not require any special conditions for storage.

Methods: ^1H, ^{13}C, and ^{31}P NMR spectra were recorded on a Bruker AMX 500 spectrometer. Chemical shifts (δ) are given in ppm and were referenced to residual ^1H NMR signals and to the ^{13}C NMR signals of the deuterated solvents, respectively. ^{31}P chemical shifts were referenced to external 85% H_3PO_4. ^{19}F NMR spectra were recorded on a Bruker AC 200 spectrometer employing an external $CFCl_3$ standard for calibration. Solid-state ^{13}C NMR spectra (CP-MAS) were recorded on a Bruker DSX 400 spectrometer and referenced using glycine. − IR spectra were recorded on a Bruker IFS 113V spectrophotometer using samples in KBr pellets. − FAB mass spectra were measured on a Finnigan SSQ 7000 spectrometer using a matrix of 2-nitrophenyl octyl ether. − Elemental analyses were performed in the Microanalytical Section of the University of Ulm. − X-ray structure determinations of compounds **4b** and **5d** were carried out on a STOE IPDS diffractometer (Universität Ulm); **5c** was analyzed on a Rigaku AFC-7S diffractometer (University of Helsinki). All measurements were made using graphite-monochromated Mo-K_α radiation (wavelength 0.71073 Å; fine-focus sealed tube).

Synthesis of the Ligands L_2 (3a−c)

***P,P′*-(1,2-Ethanediyl)bis[bis(2,4,5-trifluorophenyl)phosphane] (3a):** In a 500-mL Schlenk flask equipped with a dropping funnel 1-bromo-2,4,5-trifluorobenzene (6.1 mL, 51.8 mmol) was dissolved in dry diethyl ether (50 mL) and the solution was cooled to −78 °C by employing a dry ice/2-propanol bath. Over a period of 30 min., a solution of *n*-butyllithium in *n*-hexane (32.4 mL, 1.6 M) was added by means of the dropping funnel. Following this addition, stirring was continued for 15 min. The funnel was then rinsed with dry diethyl ether (5 mL) and charged with a solution of *P,P′*-(1,2-ethanediyl)bis(dichlorophosphane) (2.0 g, 8.9 mmol) in diethyl ether (25 mL), which was added maintaining a temperature of −78 °C. The solution was then allowed to warm to room temperature. After hydrolysis with degassed water, the ethereal phase was separated and dried with anhydrous magnesium sulfate. The solvent was evaporated in vacuo to yield a yellowish product. Recrystallization from ethanol/acetone afforded **3a** as a white crystalline solid. Yield: 4.4 g (80.5%). − ^1H NMR ($CDCl_3$): δ = 7.03 (m, 4 H, Ar), 6.91 (m, 4 H, Ar), 2.17 (m, 4 H, CH_2). − ^{13}C NMR ($CDCl_3$): δ = 159.6 [d, $^1J(^{19}F,^{13}C)$ = 246.5 Hz], 151.4 [ddd, $^1J(^{19}F,^{13}C)$ = 242.7 Hz, $^2J(^{19}F,^{13}C)$ = 15.1 Hz, $^2J(^{19}F,^{13}C)$ = 12.6 Hz], 147.9 [dd, $^1J(^{19}F,^{13}C)$, = 249.0 Hz, $^2J(^{19}F,^{13}C)$ = 12.6 Hz], 121.1, 118.6, 106.3 [dd, $^2J(^{19}F,^{13}C)$ = 30.2 Hz, $^2J(^{19}F,^{13}C)$ = 8.8 Hz], 20.9. − ^{19}F NMR ($CDCl_3$): δ = −105.9 (m, *o*-F), −130.3 (m, *p*-F), −141.8 (m, *m*-F). − ^{31}P NMR ($CDCl_3$): δ = −30.2. − $C_{26}H_{12}F_{12}P_2$ (614.3): calcd. C 50.8, H 2.0; found C 50.6, H 2.1.

***P,P′*-(1,2-Ethanediyl)bis[bis(2,4-difluorophenyl)phosphane] (3b):** Compound **3b** was synthesized according to the procedure described for **3a** starting from 1-bromo-2,4-difluorobenzene (10 g, 51.8 mmol) and 1,2-bis(dichlorophosphanyl)ethane (2.0 g, 8.9 mmol). Yield: 3.6 g (74.5%). − ^1H NMR ($CDCl_3$): δ = 7.22 (m, 4 H, Ar), 6.84 (m, 4 H, Ar), 6.76 (m, 4 H, Ar), 2.19 (m, 4 H, CH_2). − ^{13}C NMR ($CDCl_3$): δ = 165.5 [dd, $^1J(^{19}F,^{13}C)$, = 56.6 Hz, $^2J(^{19}F,^{13}C)$ = 11.3 Hz], 163.4 [dd, $^1J(^{19}F,^{13}C)$ = 60.4 Hz, $^2J(^{19}F,^{13}C)$ = 12.6 Hz], 134.8 [dd, $^2J(^{19}F,^{13}C)$ = 15.1 Hz, $^2J(^{19}F,^{13}C)$ = 8.8 Hz], 118.6 (pseudo-triplet due to coupling with ^{19}F and ^{31}P; coupling constants are 20.1 Hz and 16.4 Hz but unequivocal assignment is not possible), 111.9 [d, $^2J(^{19}F,^{13}C)$ = 20.1 Hz], 104.3 [dd, $^2J(^{19}F,^{13}C)$ = 27.7 Hz, $^2J(^{19}F,^{13}C)$ = 25.2 Hz], 21.0. − ^{19}F NMR ($CDCl_3$): δ = −100.4 (m, *o*-F), −108.9 (m, *p*-F). − ^{31}P NMR ($CDCl_3$): δ = −31.9. − $C_{26}H_{16}F_8P_2$ (542.4): calcd. C 57.5, H 2.9; found C 57.3, H 2.8.

***P,P′*-(1,2-Ethanediyl)bis{bis[3,5-di(trifluoromethyl)phenyl]phosphane} (3c):** At 0 °C, a solution of bis(3,5-trifluoromethyl)phenylmagnesium bromide, prepared from magnesium turnings (1.75 g, 72.0 mmol) and 1-bromo-3,5-bis(trifluoromethyl)benzene (17.1 g, 58.4 mmol) in dry diethyl ether (130 mL) was added to a solution of *P,P′*-(1,2-ethanediyl)bis(dichlorophosphane) (2.0 g, 8.9 mmol) in dry diethyl ether (40 mL). Stirring was continued for 24 h at room temperature. The reaction mixture was then hydrolyzed with degassed water (100 mL) and the resulting precipitate was collected by filtration and extracted with warm acetone. Evaporation of the solvent left a slightly brownish solid, which was recrystallized from dichloromethane/acetone. Yield: 6.9 g (82.3%). − ^1H NMR ([D_6]acetone): δ = 8.10 (s, 8 H, Ar), 8.03 (s, 4 H, Ar), 2.73 (m, 4 H, CH_2). − ^{13}C NMR ([D_6]acetone): δ = 142.1, 134.2, 132.4 [q,

$^2J(^{19}F,^{13}C)$ = 34.0 Hz], 124.7 [q, $^1J(^{19}F,^{13}C)$ = 271.6 Hz, CF_3], 124.1, 23.5 [d, $^1J(^{31}P, ^{13}C)$ = 3.8 Hz]. − ^{19}F NMR ([D$_6$]acetone): δ = −62.6. − ^{31}P NMR ([D$_6$]acetone): δ = −3.4. − $C_{34}H_{16}F_{24}P_2$ (942.4): calcd. C 43.3, H 1.7; found C 43.3, H 2.1.

Preparation of the Complexes L_2PdCl_2 (4a−d)

Dichloro{*P,P′*-(1,2ethanediyl)bis[bis(2,4,5-trifluorophenyl)-phosphane]}palladium(II) (4a): Bn_2PdCl_2 (0.345 g, 0.9 mmol) was added to a solution of **3a** (0.61 g, 1.0 mmol) in dry CH_2Cl_2 (25 mL). After stirring for 16 h at room temperature, the yellowish white precipitate was collected by filtration, thoroughly washed with diethyl ether, and dried under high vacuum. Yield: 0.32 g (45.1%). − ^1H NMR ([D$_6$]DMSO): δ = 7.90 (m, 8 H, Ar), 2.85 (m, 4 H, CH_2). − ^{19}F NMR ([D$_6$]DMSO): δ = −99.1 (m, *o*-F), −124.1 (m, *p*-F), −140.3 (m, *m*-F). − ^{31}P NMR ([D$_6$]DMSO): δ = 64.4. − $C_{26}H_{12}Cl_2F_{12}P_2Pd$ (791.6): calcd. C 39.5, H 1.5; found C 39.1, H 1.5.

Dichloro{*P,P′*-(1,2-ethanediyl)bis[bis(2,4-difluorophenyl)-phosphane]}palladium(II) (4b): Compound **3b** (2.9 g, 53.5 mmol) was added to a solution of $CODPdCl_2$ (1.14 g, 40.0 mmol) in dry CH_2Cl_2 (75 mL). After stirring at room temperature for 16 h, the product was precipitated by pouring the reaction mixture into *n*-pentane (500 mL), collected by filtration, washed with *n*-pentane, and dried under high vacuum. Yield: 2.39 g (83.0%). − ^1H NMR ([D$_6$]DMSO): δ = 7.86 (m, 4 H, Ar), 7.58 (m, 4 H, Ar), 7.38 (m, 4 H, Ar), 2.74 (m, 4 H, CH_2). − ^{19}F NMR ([D$_6$]DMSO): δ = −94.4 (m, *o*-F), −100.7 (m, *p*-F). − ^{31}P NMR ([D$_6$]DMSO): δ = 64.3. − $C_{26}H_{16}Cl_2F_8P_2Pd$ (719.7): calcd. C 43.4, H 2.2; found C 43.6, H 2.7.

Dichloro[*P,P′*-(1,2-ethanediyl)bis{bis[3,5-di(trifluoromethyl)phenyl]-phosphane}]palladium(II) (4c): Compound **3c** (0.85 g, 0.9 mmol) was added to a solution of Bn_2PdCl_2 (0.345 g, 0.9 mmol) in dry acetone (20 mL). After stirring at room temperature for 16 h, the product was precipitated by pouring the reaction mixture into diethyl ether (50 mL). The yellowish-white solid was collected by filtration, washed with diethyl ether, and dried under high vacuum. Yield: 0.95 g (94.0%). − ^1H NMR ([D$_6$]acetone): δ = 8.76 (s, 4 H, Ar), 8.73 (s, 4 H, Ar), 8.34 (s, 4 H, Ar), 3.64 (m, 4 H, CH_2). − ^{19}F NMR ($CDCl_3$): δ = −62.5. − ^{31}P NMR ([D$_6$]acetone): δ = 67.7. − $C_{34}H_{16}Cl_2F_{24}P_2Pd$ (1119.7): calcd. C 36.5, H 1.4; found C 36.2, H 1.7.

Dichloro{*P,P′*-(1,2-ethanediyl)bis[bis(pentafluorophenyl)phosphane]}palladium(II) (4d): In a 250-mL Schlenk flask, $CODPdCl_2$ (0.358 g, 1.25 mmol) and **3d** (0.95 g, 1.25 mmol) were suspended in dry toluene (35 mL) and the mixture was heated to 110 °C for 5 h. After cooling to room temperature, the product was collected by filtration and washed with diethyl ether (2 × 25 mL). Drying under high vacuum yielded 1.1 g (94%) of a yellow powder. − ^1H NMR ([D$_6$]DMSO at 80 °C): δ = 3.21 (m, 4 H, CH_2). − ^{31}P NMR ([D$_6$]DMSO at 80 °C): δ = 37.8. − MS (FAB): *m/z* = 900.6 [M^+ − Cl], 863.8 [M^+ − 2Cl]. − $C_{26}H_4Cl_2F_{20}P_2Pd$ (935.6): calcd. C 33.4, H 0.4; found C 33.4, H 0.8.

Preparation of the Complexes L_2PdI_2 (5c,d)

[*P,P′*-(1,2-Ethanediyl)bis{bis[3,5-di(trifluoromethyl)phenyl]phosphane}]diiodopalladium(II) (5c): Compound **4c** (0.3 g, 0.27 mmol) was treated with NaI (0.12 g, 0.8 mmol) in dry acetone (30 mL). After evaporation of the solvent, the residue was extracted with CH_2Cl_2. The orange-red product was then precipitated from the concentrated CH_2Cl_2 solution by adding diethyl ether (50 mL). Yield: 0.23 g (65.9%). − ^1H NMR ([D$_6$]acetone): δ = 8.63 (d, 8 H, Ar), 8.35 (s, 4 H, Ar), 3.46 (m, 4 H, CH_2). − ^{19}F NMR ([D$_6$]acetone): δ = −62.5. − ^{31}P NMR ([D$_6$]acetone): δ = 69.3. − $C_{34}H_{16}F_{24}I_2P_2Pd$ (1302.6): calcd. C 31.4, H 1.2; found C 31.1, H 1.0.

{*P,P′*-(1,2-Ethanediyl)bis[bis(pentafluorophenyl)phosphane]}diiodo-palladium(II) (5d): With gentle heating, **4d** (0.3 g, 0.32 mmol) was dissolved in dry acetone (60 mL). NaI (0.144 g, 0.96 mmol) was added, the mixture was stirred for 30 min, and then the solvent was removed in vacuo. The red residue was redissolved in the minimum volume of acetone and purified by column chromatography (SiO_2, particle size 0.063−0.200 mm, Merck) using acetone as the eluent. Evaporation of the solvent from the appropriate fraction left a red microcrystalline product. Yield: 0.27 g (73.7%). − ^1H NMR ([D$_6$]acetone): δ = 3.21 (m, 4 H, CH_2). − ^{31}P NMR ([D$_6$]acetone): δ = 33.6. − $C_{26}H_4F_{20}I_2P_2Pd$ (1118.5): calcd. C 27.9, H 0.4; found C 27.4, H 0.8.

Preparation of the Complexes L_2PtCl_2 (6a−c)

Dichloro{*P,P′*-(1,2-ethanediyl)bis[bis(2,4,5-trifluorophenyl)-phosphane]}platinum(II) (6a): Prepared analogously to **6c** from Bn_2PtCl_2 (0.33 g, 0.7 mmol) and **3a** (0.47 g, 0.77 mmol). Yield: 0.32 g (52.0%). − ^1H NMR ([D$_6$]DMSO): δ = 7.91 (m, 4 H, Ar), 7.86 (m, 4 H, Ar), 2.76 (m, 4 H, CH_2). − ^{31}P NMR ([D$_6$]DMSO): δ = 43.0 [^1J (^{195}Pt, ^{31}P) = 3677.1 Hz]. − $C_{26}H_{12}Cl_2F_{12}P_2Pt$ (880.3): calcd. C 35.5, H 1.4; found C 35.7, H 1.2.

Dichloro{*P,P′*-(1,2-ethanediyl)bis[bis(2,4-difluorophenyl)-phosphane]}platinum(II) (6b): Prepared analogously to **6c** from Bn_2PtCl_2 (0.25 g, 0.53 mmol) and **3b** (0.30 g, 0.56 mmol). Yield: 0.35 g (81.7%). − ^1H NMR ([D$_6$]acetone): δ = 7.98 (m, 4 H, Ar), 7.26 (m, 8 H, Ar), 2.85 (m, 4 H, CH_2). − ^{19}F NMR ([D$_6$]acetone): δ = −95.4 (m, *o*-F), −102.4 (m, *p*-F). − ^{31}P NMR ([D$_6$]acetone):

R indices (all data)	*R*1 = 0.0900, *wR*2 = 0.1870
Largest diff. peak and hole [e/Å^{-3}]	1.181 and −1.702

[a] A relatively suitable crystal for diffraction was cut out of a soft crystalline bulk. This "crystal" diffracted only up to 24 degrees. Since the faces of the crystal were arbitrary they could not be used for conducting an absorption correction. The measured intensities were corrected for Lorentz and polarization effects. Data collection, cell refinement and data reduction were performed with STOE IPDS. The structure determination was done by direct methods using XMY (Debaerdemaeker, 1993),[47] for structure refinement SHELXL-97 (Sheldrick, 1997) was utilized. The positions of the hydrogen atoms were calculated (riding model) and refined isotropically. Molecular Graphics: ORTEP III.

δ = 42.5 [^1J (^{195}Pt, ^{31}P) = 3663.2 Hz]. − $C_{26}H_{16}Cl_2F_8P_2Pt$ (808.3): calcd. C 38.6, H 2.0; found C 38.9, H 2.3.

Dichloro[*P,P'*-(1,2-ethanediyl)bis{bis[3,5-di(trifluoromethyl)phenyl]-phosphane}]platinum(II) (6c): Compound **3c** (0.35 g, 0.37 mmol) was added to a solution of Bn_2PtCl_2 (0.159 g, 0.33 mmol) in dry CH_2Cl_2 (20 mL). The yellow colour of the starting material faded within a few minutes as a white precipitate formed. After stirring for 16 h at room temperature, the precipitate was collected by filtration, washed with diethyl ether and *n*-pentane, and dried under high vacuum. Yield: 0.31 g (78.5%). − ^{1}H NMR ([D$_6$]acetone): δ = 8.72 (d, 8 H, Ar), 8.34 (s, 4 H, Ar), 3.49 (m, 4 H, CH_2). − ^{31}P NMR ([D$_6$]acetone): δ = 50.9 [^1J(^{195}Pt, ^{31}P) = 3582.5 Hz]. − $C_{34}H_{16}Cl_2F_{24}P_2Pt$ (1208.4): calcd. C 33.8, H 1.3; found C 33.6, H 1.1.

General Procedure for the Polymerization of 2-Norbornene: A 250-mL Schlenk flask was evacuated and purged with argon three times. The vessel was then charged with the appropriate pre-catalyst (usually 3.74 × 10^{-5} mol) suspended in the requisite volume of dry toluene such that, together with the MAO solution, a final total volume of 100 mL was obtained. Addition of the MAO solution (10% *w*/*w* in toluene) led to an immediate conversion of the pre-catalyst, as was evident from the dissolution of the suspended material and the formation of a clear red-brown solution. Following the introduction of 2-norbornene (4.75 g, 50.5 mmol), the reaction was usually allowed to proceed for 10−15 min. and then the polymerization was quenched by pouring the mixture into a glass beaker containing MeOH (500 mL)/conc. hydrochloric acid (5 mL). The product was collected by filtration and dried under high vacuum at 80 °C for 24 h to yield a fine white powder. − ^{13}C NMR (CP-MAS): Resonances not baseline-resolved; peaks at δ = 57.4, 55.8, 52.5, 48.6, 40.9, 35.3, 30.1. − FT-IR (KBr): $\tilde{\nu}$ = 2946, 2867, 1478, 1454, 1300, 707 cm^{-1}.

Crystallographic Data: Crystallographic data for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publications nos. CCDC-136063 (**4b**, Table 5), -135995 (**5c**, Table 6), and -136062 (**5d**, Table 7). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

The authors would like to thank the Bundesministerium für Bildung und Forschung (BMBF) as well as BASF AG for generous financial support. The X-ray structure determination of **5c** was carried out by Martti Klinga (University of Helsinki, Finland), whose cooperation is gratefully acknowledged. Compounds **4b**, **5d** were kindly analyzed at the University of Ulm, Germany, by Dr. A. Debaerdemaeker.

[36] The dichloro complexes are presumably dimethylated by MAO and then one methyl group is abstracted to produce the active monomethyl species. Such an activation process has previously been proposed for an Ni^{II}-based system: D. Pappalardo, M. Mazzeo, C. Pellechia, *Makromol. Chem. Rapid. Commun.* **1997**, *18*, 1017.
[37] DPPP = *P,P′*-(1,3-propanediyl)bis(diphenylphosphane), DPPE = *P,P′*-(1,2-ethanediyl)bis(diphenylphosphane).
[38] Steric factors must be taken into account in understanding the polymerization behaviour of DPPP-$NiCl_2$. Due to the lower ionic radius of Ni^{II} and, as a consequence, enhanced steric interactions between the ligand, the growing polymer chain, and the coordinated monomer, this complex is less active in the polymerization of norbornene.
[39] In the case of Pt−alkyl complexes, the insertion process of a C=C bond is energetically less favourable than for Pd or Ni complexes due to the high stability of the Pt−C bond.

Stereochemical Equivalence of P^{III}-Bonded Hydrogen Atoms and $|Se^{IV}$ Lone Electron Pairs in $Sr(H_2PO_3)_2$ and $Sr(HSeO_3)_2$

Kai Boldt,[a] Bernward Engelen,*[a] Martin Panthöfer,[a] and Klaus Unterderweide[a]

Keywords: Hydrogen bonds / IR spectroscopy / Stereochemical equivalence / Strontium / Phosphates / Selenates

$Sr(H_2PO_3)_2$ and $Sr(HSeO_3)_2$ have been characterized by means of single crystal X-ray diffraction and FT-IR absorption spectroscopy. The IR spectra exhibit split AB band systems in the OH stretching mode region due to Fermi resonance interactions of the ν(OH) with the in-plane bending modes of the hydroxyl groups. The compounds crystallize in a new structure type and are isotypic, if the P-bonded hydrogen atoms of $Sr(H_2PO_3)_2$ and the lone electron pairs of $Sr(HSeO_3)_2$ are considered to be equivalent. The coordination of Sr is that of a distorted square antiprism. The SrO_8 polyhedra share three common edges and are additionally connected via O–X–O bonds of the isolobal XO_2OH^- ions (X = HP^{III}, $|Se^{IV}$) of tetrahedral and trigonal (ψ-tetrahedral) configuration, respectively. The resulting layers $^2_\infty[Sr(XO_2OH)_2]$ are connected via circular hydrogen bond systems of tetrameric $[XO_2OH^-]_4$ groups of a cyclooctane like chair topology. Both the P-bonded hydrogen atoms and the lone electron pairs of the $HP^{III}O_2OH^-$ and the $|Se^{IV}O_2OH^-$ ions, respectively, form channels along [001] and induce the same crystal structure. This is new for acid salts of the type $M^{II}(XO_2OH)_2{\cdot}nH_2O$ with X = HP^{III} and $|Se^{IV}$.

Introduction

Strontium hydrogen phosphate(III), $Sr(H_2PO_3)_2$, and strontium hydrogen selenate(IV), $Sr(HSeO_3)_2$, have been isolated by Ebert et al.[1−4] as part of their studies of the solubility diagrams of the quasiternary systems SrO-P_2O_3-H_2O and SrO-SeO_2-H_2O, respectively. The selenium compound has been characterized by means of thermal analysis as well as IR absorption spectroscopy and some X-ray data.[4−6] Since the corresponding phosphates(III) tend to form supersaturated solutions, they are difficult to obtain, especially in the form of single crystals. The knowledge about this class of compounds is thus poor.[1−3] Such acid salts are of special interest because of: i) the strong and medium-strong hydrogen bonds, and hence the formation and transformation of AB and ABC band systems in the OH stretching mode region of the existing hydroxyl groups,[6,7] ii) the possible stereochemical equivalence of the P-bonded hydrogen atom of the phosphate(III) and the lone electron pair of the selenate(IV), which one can find for some corresponding neutral salts, e.g., for $CuHPO_3{\cdot}2H_2O$[8]/$CuSeO_3{\cdot}2H_2O$[9] and $MgHPO_3{\cdot}6H_2O$[10]/$MgSeO_3{\cdot}6H_2O$[11−12], but not for acid compounds of the type $M^{II}(HXO_3)_2{\cdot}nH_2O$ (X = HP^{III} and $|Se^{IV}$), and iii) their possible nonlinear optical and dielectrical properties. In this context we report on the crystal structures and FT-IR absorption spectra of $Sr(H_2PO_3)_2$ and $Sr(HSeO_3)_2$.

Results and Discussion

Crystal Structures

$Sr(H_2PO_3)_2$ (*a*P26) and $Sr(HSeO_3)_2$ (*a*P22) both crystallize in a triclinic unit cell in the space group $P\bar{1}$ with Z = 2 (see Table 1). Except for the P-bonded hydrogen atoms of $Sr(H_2PO_3)_2$ they are isotypic. All atoms occupy general positions 2*i* with Sr^{2+} and two crystallographically different XO_2OH^- ions with X = HP^{III} and $|Se^{IV}$, P1, P2, Se1 and Se2, in the asymmetric unit.

In both structures, Sr is square antiprismatically surrounded by eight oxygen atoms of seven different XO_2OH^- ions (see Figure 1). The isolobal XO_2OH^- ions have tetrahedral (HPO_2OH^-) and trigonal pyramidal (ψ-tetrahedral, SeO_2OH^-) configuration and act as both bidentate and bridging ligands (Figure 1). Due to the mono- and bidentate coordination of Sr through XO_2OH^- (see Figure 1) the SrO_8 square antiprisms are strongly distorted. The Sr−O distances range from 251 to 276 pm and 254 to 285 pm for the acid phosphate(III) and selenate(IV) compound, respectively (see Table 2). Nevertheless, the respective mean values, 263(10) and 262(10) pm, are nearly equal. They are in the range of the Sr−O distances of other oxosalts of eight-coordinate Sr.[13−15]

Due to the different coordinations through Sr and H (see Figure 1) the non-hydrogen atoms of the two XO_2OH^- ions of the asymmetric unit are differently, but only slightly, distorted from the possible *m* symmetry (see Table 2). The mean X−O and X−OH distances (150 and 159 pm for X = HP^{III} and 166 and 178 pm for $|Se^{IV}$) and O−X−O angles (111 and 101° for X = HP^{III} and $|Se^{IV}$, respectively) are in good agreement with those found for other acid phosphates(III)[16] and selenates(IV).[7,17−19] Although O23 is not coordinated to Sr, the corresponding X−O distance is

[a] Further details of the crystal structure investigations, the atomic coordinates and the displacement parameters can be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (Germany) [Fax: (internat.) +49-7247/808-666; E-mail: crysdata@fiz.karlsruhe.de) on quoting the depository numbers CSD-410936 [$Sr(H_2PO_3)_2$] and CSD-410935 [$Sr(HSeO_3)_2$].

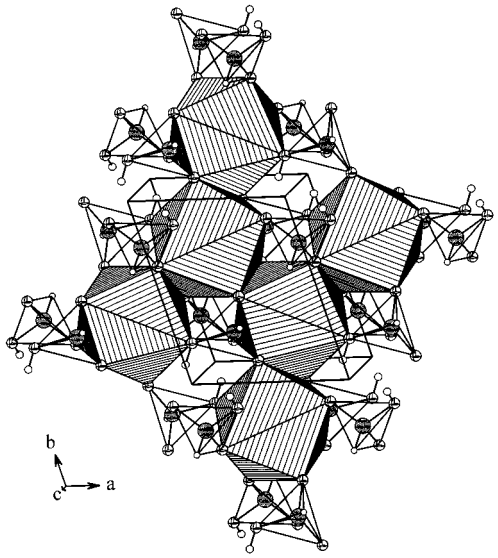

Figure 1. Crystal structure of $Sr(H_2PO_3)_2$ approximately (5°) along [001] representing the SrO_8 polyhedra and their linkage; except for hydrogen atoms H1 and H2, the crystal structure of $Sr(HSeO_3)_2$ is identical; the displacement ellipsoids are drawn at a level of 50% probability

only slightly shorter than that of the other hydroxyl group (O13, see Table 2). The dihedral angles H−P−O−H of the HPO_2OH^- ions (−70 and 64°) point to a *syn*-clinal conformation of the PH and OH groups. This means that the orientation of the HP and OH groups of $Sr(H_2PO_3)_2$ corresponds much better to that found in phosphorous acid, H_3PO_3, (76° for the mean value[20]) than to that found in other acid salts (e.g. 46° in LiH_2PO_3[21]).

The SrO_8 antiprisms share three edges and are additionally connected via O−X−O bonds with the result that layers $^2_\infty[Sr(XO_2OH)_2]$ are formed parallel to (001) (see Figure 1 and 2). The layers are interconnected via medium-strong hydrogen bonds, O23−H23···O22, with O−H···O distances of 277 and 280 pm for $Sr(H_2PO_3)_2$ and $Sr(HSeO_3)_2$, respectively, (see Figure 2 and Table 2). Thus the resulting structures are of type b1[22] with respect to the inter-layer forces. A second hydrogen bond, O13−H13···O22, appears in the layers with O−H···O distances of 272 and 274 pm, respectively. Thus O22 acts as a hydrogen-bond acceptor for both hydrogen bonds. As a result, a zero-dimensional hydrogen-bond system is formed, in which two XO_2OH^- ions (P2, Se2) form a cyclooctane-like ring system between the layers (see Figure 2 and Figure 3). The XO_2OH^- ions belonging to P1 and Se1, respectively, are connected biaxially to this ring system in the 1,5 position by the intra-layer hydrogen bond (see Figure 2 and 3). Because of the synergetic effect,[23] i.e., the coordination of O13 through Sr, the intra-layer H-bond (O13−H13···O22) is shorter than to the inter-layer H-bond (O23−H23···O22) although both hydrogen bonds have the same H-bond acceptor (O22, see Table 2 and Figure 2, 3).

The P-bonded H-atoms (H1 and H2) of $Sr(H_2PO_3)_2$ are not hydrogen-bonded. They are arranged around the centers of symmetry at the 1*e* (P1) and 1*c* (P2) positions of the space group $P\bar{1}$, respectively, to form channels along [100]

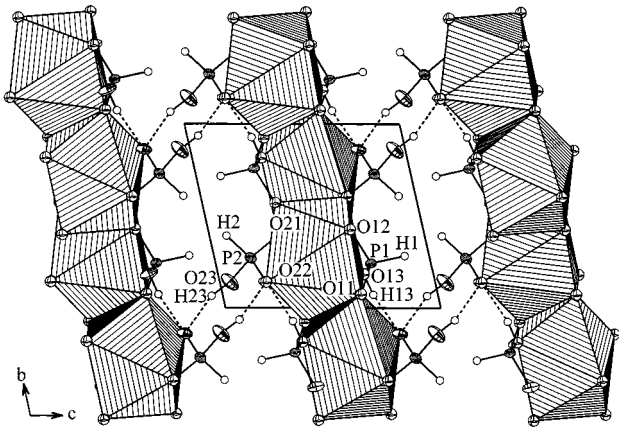

Figure 2. Crystal structure of $Sr(H_2PO_3)_2$ along [100] representing the $^2_\infty[Sr(HPO_2OH)_2]$ layers and the hydrogen bonds (dotted lines); see also Figure 1

(see Figure 2). In $Sr(HSeO_3)_2$, the free electron pairs of $|Se^{IV}$ are oriented in the same directions as the P−H bonds of $Sr(H_2PO_3)_2$. Because of the P···H and H···H repulsion of the nonbonded P and H atoms around the channels along [100], the mean values of the accompanying smallest P···P and Se···Se distances, are 12% larger in $Sr(H_2PO_3)_2$ (479pm) than in $Sr(HSeO_3)_2$ (427 pm). This gives an explanation for the finding that, despite the much longer Se−O distances, the cell volume is smaller in the selenate(IV) compound (see

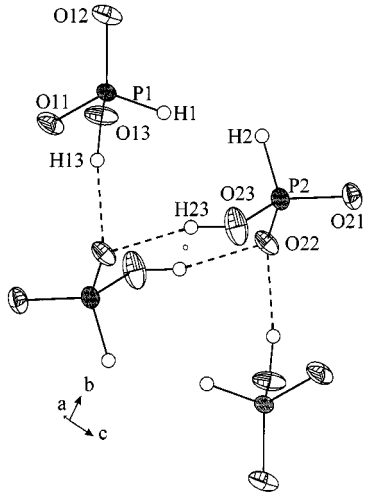

Figure 3. Zero-dimensional hydrogen bond system of $Sr(H_2PO_3)_2$; see also Figure 1

Table 1 and 2). Nevertheless, the interlayer hydrogen bond (O23−H23···O22) is shorter for $Sr(H_2PO_3)_2$, i.e., the oxygen atoms of HPO_2OH^- are stronger H-bond acceptors than those of SeO_2OH^- (see also[23,24]).

Vibrational Spectroscopy

The IR absorption spectra of $Sr(H_2PO_3)_2$ and $Sr(HSeO_3)_2$ at low (100 K) and room temperature are shown in Figure 4. The band assignment is given in Table 3. The IR spectra of acid salts are well-known for the splitting of the OH stretching modes, ν(OH), of hydroxyl groups into AB or ABC band systems (see ref.[6] and the literature cited therein). The broad bands around 3000 and 2350 cm^{-1} in the spectra of $Sr(HSeO_3)_2$ can be assigned to such an AB band system. Due to the two different hydroxyl groups of the asymmetric unit, both the A and B bands are split into at least two bands. The IR spectra of $Sr(H_2PO_3)_2$ also exhibit broad absorptions around 3000 cm^{-1} belonging to an A band, but the B band region is dominated by the PH stretching modes of the phosphate(III) groups.

In the region of the in-plane bending mode bands, δ(OH), of the hydroxyl groups for both compounds, band doublets appear between 1150 and 1250 cm^{-1}. Like the splitting of the PH stretching modes (see Figure 4 and Table 3), the appearance of these doublets confirms the presence of two crystallographically different hydroxyl groups and XO_2OH^- ions. The frequencies of the B bands of $Sr(HSeO_3)_2$ are slightly lower than the first overtones of the δ(OH) frequencies, pointing to a Fermi resonance interaction of the in-plane bending modes with the ν(OH) of the hydroxyl groups (see also ref.[6]).

Between 680 and 750 cm^{-1} a similar doublet is observed in the IR spectra of $Sr(H_2PO_3)_2$, which has to be assigned to the out-of-plane bending modes, γ(OH), of the hydroxyl groups. The band at 689 cm^{-1} in the LT spectrum of $Sr(HSeO_3)_2$ can also be assigned to one of the γ(OH) modes. The corresponding high frequency γ(OH) band is covered by the SeO stretching modes of the SeO_2OH^- ions.

Taking into account that both the δ(OH) and the γ(OH) are shifted to higher frequencies, if the respective hydrogen bond is strengthened and shortened, (see refs.[6,25]), the high frequency δ(OH) and γ(OH) bands can be assigned to the stronger intra-layer hydrogen bond O13−H13···O22, whereas the respective low frequency bands belong to the weaker inter-layer hydrogen bond O23−H23···O22. For both compounds, the respective pairs δ(OH)/d(O···O) and γ(OH)/d(O···O) fulfil the corresponding frequency vs. O−H···O distance correlations (see refs.[6,25] and the literature cited therein).

Experimental Section

Single crystals of $Sr(H_2PO_3)_2$ and $Sr(HSeO_3)_2$ were obtained from concentrated aqueous solutions of $Sr(H_2PO_3)_2$ and $Sr(HSeO_3)_2$ at 80 and 22 °C after 3 and 22 days, respectively (see also refs.[1,6]).

X-ray powder diffraction data for the lattice parameter refinement have been determined from X-ray powder diffractograms (Cu-$K\alpha_1$ radiation) using a Siemens D5000 X-ray powder diffractometer. For the profile fitting and the refinement of the lattice parameters the program package WinXPow[26] was used.

The X-ray intensities for the structure determination of $Sr(H_2PO_3)_2$ were collected on a STOE-IPDS image-plate diffractometer (Mo-$K\alpha$, graphite monochromator) in the oscillation mode. After data reduction a numerical absorption correction based on an experimental crystal description was applied.[27] The X-ray intensities for the structure determination of $Sr(HSeO_3)_2$ were collected on an Enraf−Nonius CAD4 diffractometer (Mo-$K\alpha$, graphite monochromator). After data reduction, an empirical absorption correction[28] was applied.

The structures were solved by direct methods and subsequent Fourier syntheses, and refined by full-matrix least-squares techniques with anisotropic displacement parameters for the non-hydrogen atoms using the programs SHELXS97[29] and SHELXL97.[30] All hydrogen atoms were located from difference Fourier maps. The coordinates of the hydrogen atoms bonded to phosphorous were refined with isotropic displacement parameters fixed at 1.2 times the equivalent isotropic displacement parameter of the bonded phosphorous atom. All hydrogen atoms bonded to oxygen were refined to an O−H distance of 92 pm (DFIX restraint) and isotropic displacement parameters were fixed at 1.5 times the equivalent isotropic displacement parameter of the bonded oxygen atom. Scattering factors for neutral atoms were used.[31] An empirical extinction correction had to be applied.[30] Graphics were obtained with DIAMOND 2.1.[32] Further details of data collection and refinement are given in Table 1.

FT-IR absorption spectra were recorded on a Bruker IFS 113v Fourier-Transform spectrometer equipped with a Graseby-Specac P/N 21.500 cryostat using the KBr-disc method.

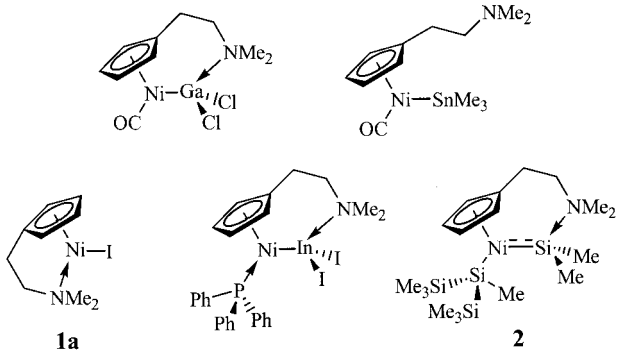
The Hemilabile [2-(Dimethylamino)ethyl]cyclopentadienyl Ligand and Nickel: Preparation and Structural Analysis of New Cationic and Neutral Complexes



Oliver Segnitz,[a] Manuela Winter,[a] Klaus Merz,[b] and Roland Fischer*[a]

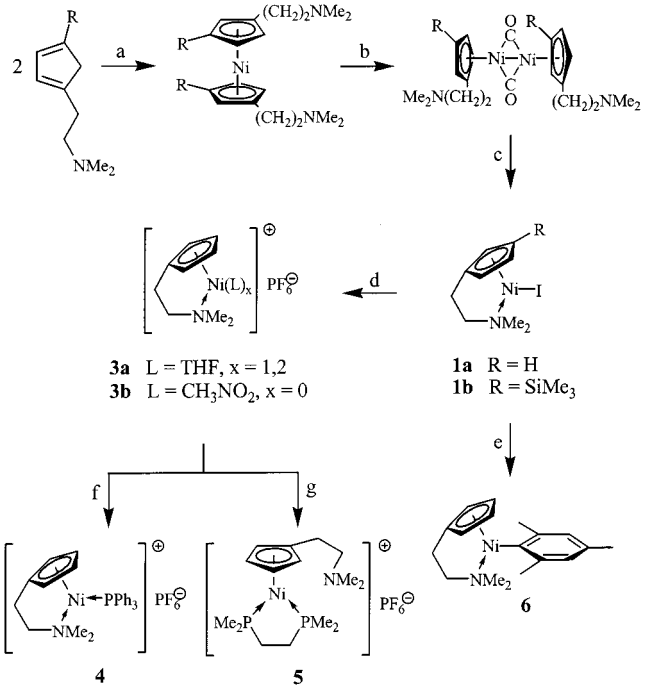
Keywords: Coordination chemistry / Nickel / Cyclopentadienes / Cations / Density functional calculations

Various new compounds containing the [2-(dimethylamino)-ethyl]cyclopentadienyl (Cp^N) moiety coordinated to a nickel centre have been synthesized. A new derivative Me_3SiCp^NNiI (**1b**) was obtained by a previously described pathway, while the reaction of its older analogue Cp^NNiI (**1a**) with $Tl[PF_6]$ and the subsequent interception of the intermediate cation in THF with two equivalents of PPh_3 or dmpe ($Me_2PCH_2CH_2PMe_2$) yielded the two ionic species $[Cp^NNi(PPh_3)]^+PF_6^-$ (**4**) and $[Cp^NNi(dmpe)]^+PF_6^-$ (**5**), respectively. The direct substitution of the halide functionality in **1a** with MesMgBr (Mes = 2,4,6-trimethylphenyl) in THF gave the pentane-soluble neutral complex Cp^NNiMes (**6**). Compounds **1b**, **4**, **5**, and **6** were characterized by ^1H, ^{13}C, and ^{31}P (if phosphorous is present) NMR spectroscopy, elementary analyis, mass spectrometry, and single crystal X-ray diffractometry. The model compounds $[Cp^NNi(PH_3)]^+$, Cp^NNiMe, Cp^NNiPh, and $[Cp^NNi(OH_2)]^+$ were further studied by DFT calculations at the B3LYP level of theory.

Introduction

Donor-functionalized cyclopentadienyl ligands in general, and their *N*-functionalized derivatives (carrying a side-chain containing an amino function) in particular, have been well renowned for their ability to either stabilize adjacent electron-deficient centres and unusual coordination states of the respective metal centre, or to promote hitherto unseen reactions when the donor is bound in a hemilabile way. The introduction of a donor-substituted alkyl side-chain has also provided additional room for other functionalities to further alter the steric demands, stability, solubility, catalytic activity and thus the electronic structure and chemical properties of the respective parent compound in general.[1] Our work on [2-(dimethylamino)ethyl]cyclopentadienyl complexes of group-10 metals (see Scheme 1) eventually led to the discovery of the rearrangement of a tris(trimethylsilyl)silyl group at the $[Cp^NNi]$ fragment to yield the first structurally characterized silanediyl(silyl)metal complex **2**.[2,3] The obvious importance of the $[Cp^NNi]^+$ fragment, and the fact that related indenyl derivatives like $[(1\text{-MeInd})Ni(PPh_3)]^+BF_4^-$ were reported to catalyze the dehydropolymerization of $PhSiH_3$ to linear chains[4] and the dimerization of ethylene at a very high rate,[5] as well as other similar systems containing cyclopentadienyl-substituted cationic nickel species as potential reactive intermediates [e.g. $(\pi\text{-}C_3H_5)Ni(PCy_3)Br/EtAlCl_2$[6]], led us to further investigate the chemistry of potential $[Cp^NNi]^+$ precursors and their behaviour towards various donors and nucleophiles.

Scheme 1



Results and Discussion

Synthesis

An overview of the work presented here is depicted in Scheme 2. The preparation and characterization of the complex Cp^NNiI (**1**) has already been reported earlier.[2] However, the synthesis outlined there suffered from rather low yields and was therefore slightly modified. The Cp^NH ligand was prepared according to a procedure described by Wang et al.[7] The deprotonation of Cp^NH was performed using Et_2NH instead of *n*BuLi in THF.[8] The use of the milder base allowed a much cleaner conversion of $NiBr_2$ to give the corresponding nickelocene derivative and therefore a high vacuum sublimation to obtain the pure product was no longer necessary.

Thus, the enhanced overall yield of **1a** made its use for more thorough investigations feasible. This new approach further enabled us to produce less readily available derivatives such as Me_3SiCp^NNiI (**1b**) {Me_3SiCp^N = [2-(dimethylamino)ethyl]-3-(trimethylsilyl)cyclopentadienyl}[9] with an additional substituent attached to the cylopentadienyl ring. We treated **1a** with several halide-abstracting reagents ($Na[BPh_4]$, silver and thallium salts), to introduce a more weakly bonded anion. This was done with the aim of preparing a "naked" cation $[Cp^NNi]^+$ and exploring its role in the synthesis of **2**. The use of $Tl[PF_6]$ proved to be the best choice in this case. It is not quite clear from the integral ratios derived from the ^1H NMR spectra of **3a** how many thf molecules are bound to the metal centre (see Figure 3). Compound **3b**, however, loses all its coordinated nitromethane molecules upon evaporation of the solvent and the red colour of its solution gives way to the green colour of the microcrystalline powder of compounds **3a** and **3b**. Both substances underwent decomposition at room temperature or upon redissolution. Additionally, compound **3b** could only be observed when the solvent was condensed into the reaction vessel and the mixture was allowed to slowly warm to room temperature. If the synthesis was performed at room temperature without any cooling or if a solution of **3b** was heated above 70 °C, the cation readily reacted with the nitromethane to produce a light-yellow substance. The nature of the new species has not yet been fully clarified and more investigations are currently underway. In order to obtain a derivative that can be better characterized and to prove the existence of the cationic species we introduced various phosphorus-containing ligands into the system to enhance the stability. The triphenylphosphane adduct **4** could be isolated as a dark red powder, while intercepting the cations **3a** and **3b** with 1,2-(dimethylphosphanyl)ethane (dmpe) produced the light-red coloured compound **5**. Both compounds were much more stable than **3a** and **3b** and were analyzed by ^1H, ^{13}C, and ^{31}P NMR spectroscopy, elementary analysis, and mass spectrometry. Suitable crystals for X-ray diffraction could be grown in both cases. It is also possible to substitute the iodine atom in **1a** by a more direct means. Various nucleophiles react in the expected way by replacing the halide on the nickel centre. There are, however, only a few known examples that do not suffer from decomposition even at relatively low temperatures. The compound $Cp^NNi(Mes)$ (Mes = 2,4,6-trimethylphenyl) was one derivative that was stable up to ambient temperatures and could be subjected to X-ray single crystal diffraction. Other analytical data for the intensely red substance was also found to be in excellent agreement with the proposed structure.

Analytical Data for Me_3SiCp^NNiI (1b)

As in the case of **1a**, the ^1H NMR spectrum indicates the presence of a coordinated (dimethylamino)ethyl moiety. The proton resonances for the ethylene bridge in the free ligand (both at δ = 2.47) shift upfield to δ = 0.15 for the H atom β to the amino group and to δ = 2.29 for the H atom in the α position. It is striking that the α-methylene group in **1a** undergoes a downfield shift upon coordination of the side-chain.[2] Another major difference is presented when comparing the δ values of the protons attached to the Cp ring; they differ by 1 ppm (δ ≈ 5.3 for **1a** and 4.3 for **1b**). The broad and not very well-resolved proton signals and the complete absence of any resonances even at low temperatures in the ^{13}C NMR measurement, hint at the presence of a paramagnetic species. It is still unclear whether this is caused by **1b** in its form given in Scheme 2, or whether it originates from an equilibrium in solution.

The trimethylsilyl derivative **1b** of **1a** was obtained by the same route[2] and crystals were grown from a pentane solution at 5 °C (Figure 1, Table 1). The monomeric species crystallizes in the space group *Pbca*.

At a first glance both molecules **1a** and **1b** seem to be closely related, but a more thorough look reveals the impact the additional trimethylsilyl group has on the overall symmetry of complex **1b**. Most of the crucial bond lengths for **1b** given in Table 1 are longer than those for **1a**, giving **1b** a "blown-up" appearance when compared with its parent compound. The now asymmetric substitution of the cyclopentadienyl ring and the size of the new substituent also effect a distortion that can be explained by various facts. The Ni−C(1···5) distances vary over an untypically long range from 2.03 to 2.22 Å, with the Ni−C3 bond of 2.223 Å being unusually long. The displacement of the nickel atom

N−Ni−Cp[a]	123.0	C6−C7−N	110.6(6)
Cp[a]−C1−C6	170.0		

[a] The abbreviation Cp denotes the center of the cyclopentadienyl ring.

away from the central Cp axis and the resulting disturbed coordination is also mirrored in the ring itself: a weak eneallyl distortion (the C2−C3 bond length of 1.433 Å, as opposed to the C4−C5 and C5−C1 bonds of length 1.431 Å and 1.430 Å, respectively), and a slightly higher RMS deviation of 0.028 Å from the plane than that in **4** and **5**. The Ni−I and Ni−N bonds are within the expected range, although the Ni−N bond with a length of 2.023 Å shorter.[10] Unlike in **1a** the deviations of e.g. C6−C7−N from the tetrahedral angle are not as remarkable, but this cannot be interpreted as a sign for a system under less stress. This will be discussed in more detail later on. The angles around the metal centre in **1b** compare well with those in **1a** and are within well-known limits.[11]

Analytical Data for $[Cp^NNi(PPh_3)]^+PF_6^-$ (4)

The ^{13}C NMR resonances of **4** (the first cation of its type) show nothing out of the ordinary even in comparison with those of non-charged Cp^NNiX complexes, but the ^1H NMR spectrum somewhat differs from those of other compounds with a coordinated side-chain.[2] Although the signals of the Cp protons appear in the same region as in **1b**, the signals of the H atoms in the amino moiety are both shifted downfield compared with those of free Cp^NH. Moreover, the resonances for the two methylene groups in **4** are very close to each other which is typical for a free, uncoordinated side-chain as was reported for $[Cp^{*N}Ni(CO)]_2$,[12] and $[Cp^NNi(CO)]_2$,[2] and confirmed with the preparation of **5**. In fact, this data and the fact that two equivalents of PPh_3 were used in the reaction and that species like $[Cp^NNi(PPh_3)_2]^+$ were detected in the FAB mass spectra of **4**, led us to the initial conclusion that the new compound was of the formula $[Cp^NNi(PPh_3)_2]^+PF_6^-$, with a dangling amino side-chain very similar to that in **5**. In the ^{31}P NMR spectra the phosphorus signal of the PPh_3 ligand shifts from $\delta = -6$ to $\delta \approx +30$ upon coordination. A related effect is observed for **5** where another downfield shift for the signals of the coordinated P donors occurs.

A crystal of the cationic product **4** grown from an acetone solution at −30 °C, revealed the true structure of $[Cp^NNi(PPh_3)]^+PF_6^-$ (Figure 2, Table 2). It was solved in the space group *P*2(1) and consists of monomeric cations with the formula indicated, with noninteracting hexafluorophosphate anions.

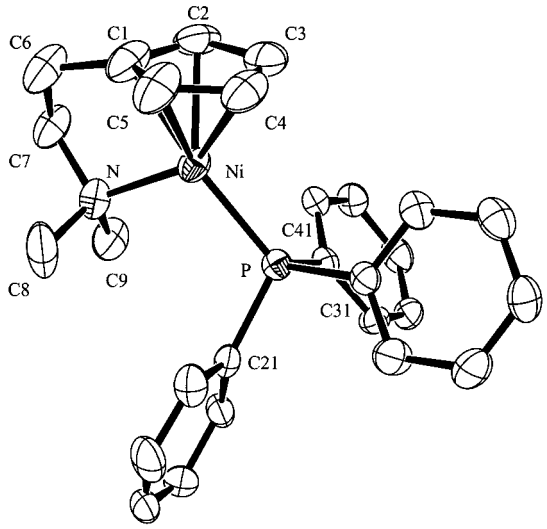

Figure 2. ORTEP drawing of the cation $[Cp^NNi(PPh_3)]^+$ in the solid state, using 50% probability ellipsoids; hydrogen atoms are omitted for clarity

C1−C6−C7	107.2(5)		

[a] The abbreviation Cp denotes the center of the cyclopentadienyl ring.

Although a twofold excess of PPh_3 was employed in the reaction only one molecule of the phosphane is found in the final product. This completes the distorted trigonal coordination sphere around the nickel centre that is otherwise

composed of the cyclopentadienyl ring and the amino function from its side-chain. The distortion is caused by the higher spatial demand of the 5-membered ring and the phenyl groups of the phosphane ligand, causing the N−Ni−P1 angle of 105.9° to be significantly smaller than 120°. Despite the link that exists between the ring and the N donor, the angle N−Ni−Cp (119.4°) corresponds quite well to the ideal value. Alternatively, the nickel(II) cation could also be described as a distorted trigonal bipyramid when the Cp group is viewed as a 6-electron ligand occupying three coordination sites. The ring itself is nearly planar with a deviation of 0.025 Å from the least-squares plane, although the bond lengths suggest some contribution from an ene-allyl form (two short adjacent bonds, C4−C5 and C5−C1, opposite an even shorter bond, C2−C3).[13] The Ni−C(1···5) bond lengths of 2.06−2.14 Å, and thus the Ni−Cp distance of 1.74 Å are within the range expected from similar unsubstituted derivatives.[13,14] The deviation of the C1−C6−C7 angle (107.5° in **1a** and 112.1° in **4**) and the C6−C7−N angle (116.2° in **1a** and 110.5° in **4**) from the ideal tetrahedral angle had already been attributed to the overall strain imposed on the molecule by the coordination of the donor-functionalized side-chain to the nickel atom.[2] The same angles in **5** with an uncoordinated side-chain, however, are equally large (C1−C6−C7 is 115.7° and C6−C7−N is 115.6°) which puts the former conclusion in question. In spite of the cationic nature of **4** the Ni−N and Ni−P1 bonds are not shorter when compared with related neutral complexes as one might instinctively expect. Other Ni−P bonds usually lie in the range from 2.14 to 2.20 Å (the Ni−P bond in **4** has a length of 2.20 Å which lies in the upper region of this range), regardless of the charge on the nickel centre. Steric and more subtle electronic reasons seem to prevail here. The same is true for the length of the Ni−N bond: 2.01 Å in **4** and 1.96 Å in **1a** (a closely related neutral species). It falls well within the usual range of dative amine−nickel bonds of 2.00−2.20 Å.[10] The bond lengths and angles in the phenyl ligands at the phosphorus atom are within normal limits. The idealized propeller-like arrangement of free PPh_3 is disturbed by steric interactions between one of the methyl groups of the N donor and the phenyl substituents.

DFT Calculations

Since it was not possible to structurally characterize a donor-free compound containing a $[Cp^NNi]^+$ cation we began to look for other means to describe this reactive species. Complex **4** was the first to be discovered of the complexes described herein, therefore it served as a starting point for our theoretical investigations. A modified model compound, $[Cp^NNi(PH_3)]^+$ (**4a**), was subjected to geometry optimizations using the Gaussian98 package.[15] A good agreement with the experimentally derived structure (while at the same time being computationally not too demanding for our systems) was obtained at the DFT level using Becke's three-parameter fit of the exchange-correlation potential (B3LYP)[16] in conjunction with the McLean-Chandler (12s, 9p) → (631111, 52111) basis set[17] for phosphorus, the Wachters-Hay all-electron basis set[18] for nickel (3d and 1f polarization functions were added for P and Ni) and the 6-31G(d) basis set[19] for C, H, and N atoms (Figure 3, Table 3).

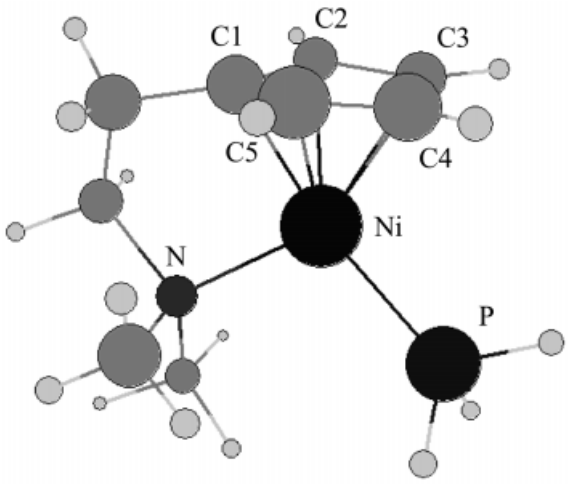

Figure 3. Structure obtained from a DFT calculation on $[Cp^NNi(PH_3)]^+$ (**4a**)

Table 3. Selected bond lengths [Å] and angles [°] for compound **4a**

Ni−P	2.209	N−C7	1.516

N−Ni−Cp[a]	122.7	C6−C7−N	111.2

[a] The abbreviation Cp denotes the center of the cyclopentadienyl ring.

The computed bond lengths and angles in **4a** compare very well with those in **4** which justifies the use of PH_3 instead of PPh_3 in the model complex. The experimentally derived Ni−N and Ni−P distances are in excellent agreement with those in **4a**. The Ni−C bond lengths in **4a** vary over a slightly wider range from 2.02 to 2.16 Å making the Cp ring more puckered. However, the distance between the metal centre and the centre of the 5-membered ring are identical in **4** and **4a**. In both complexes the C1 atom is tilted towards the nickel centre which is a result of the coordination of the side-chain. A similar ene-allyl distortion can be found in **4a** as well, with all C−C distances in the Cp ring being slightly larger than those in **4**. Both the HOMO and LUMO are dominated by two π-interactions between the metal centre and the Cp ligand which shows the closeness of **4** to other 18-electron $CpML_2$ fragments[13]: two molecular orbitals with distinct d character (d_{xz} for the HOMO and d_{yz} for the LUMO, respectively) at the nickel centre interact with the ring via two MOs that correspond to the energetically degenerate e_1 orbitals of a free Cp^- fragment of D_{5h} symmetry. The LUMO also shows some strong involvement with sp^3-like MOs located on the N and

P donor. According to an NBO analysis, the metal centre bears a charge of +0.97 while the nitrogen with the highest electronegativity in the system carries the lowest charge with −0.55. The phosphorus atom appears in a nearly neutral state (−0.12).

Encouraged by these initial results we extended our theoretical investigations to include the non-phosphorus systems Cp^NNiMes (**6**) and $[Cp^NNi(OH_2)]^+$. The latter one was introduced as a model complex for the intermediate $[Cp^NNi(thf)]^+$ and should bring us closer to the naked cation $[Cp^NNi]^+$, the focus of interest. The same method and basis sets that were employed for **4a** were used to calculate the optimized structures of Cp^NNiMe (**7**), Cp^NNiPh (**8**) and $[Cp^NNi(OH_2)]^+$ (**9**). Table 4 displays crucial bond lengths and angles for **4a**, **7**, **8**, and **9**.

The replacement of the mesityl moiety in **6** with a methyl group to give the simplified model compound **7** caused the Ni−C bond to increase from 1.908 Å in **6** to 1.936 Å in **7**. To remedy this, we returned to the computationally more demanding phenyl ligand (i.e. moving from an sp^3 to an sp^2 centre) to be closer to the actual complex Cp^NNiMes (**6**). This resulted in the desired contraction of the Ni−C bond that was now in very good agreement with the experimentally observed distance in **6**, while all other bonds and angles remained much the same. In both cases the three bond angles around the nickel centre are similar to those determined by X-ray diffraction. It has to be pointed out here that the computed Ni−C bond length in Cp^NNiMe (**7**) corresponds quite well to that in known complexes such as $CpNi(PPh_3)CF_3$[20] and $CpNi(PPh_3)(CH_2SO_2Ph)$[21] that also contain nickel-bonded sp^3 carbon centres, while those in $CpNi(PPh_3)C_6F_5$[22,23] and $CpNi(PPh_3)C_6H_5$[23] correspond to that in Cp^NNiPh (**8**). The substitution of the amine donor by an isolobal phosphorus ligand does not influence the Ni−C bond to a large extent, and the chosen theoretical method generally reproduces the experimental Ni−C bond lengths in those compounds.

With these facts in mind we subjected model compound **9** to geometry optimizations at the aforementioned level of theory. By replacing the PPh_3 ligand with a water molecule, most bond lengths in the complex core undergo a contraction while the hydrogen atoms of the water molecule are tilted away from the dimethylamino group. The Cp ligand is 1.738 Å from the nickel centre, with a very short Ni−C1 distance of 1.980 Å, while the amine donor lies 1.977 Å away from the metal atom. This trend is also mirrored in the charge distributions taken from an NBO analysis: The nickel atom carries a higher positive charge of +1.06 while the oxygen and nitrogen atoms bear negative charges of −0.97 and −0.55, respectively. Thus, both the Ni−N and Ni−O bond are much more polar than the corresponding bonds in complex **4a**, attributing to the comparatively short bonds in **9**. Not surprisingly, the frontier molecular orbitals of **9** are very similar to those of compound **4a** (Figure 4).

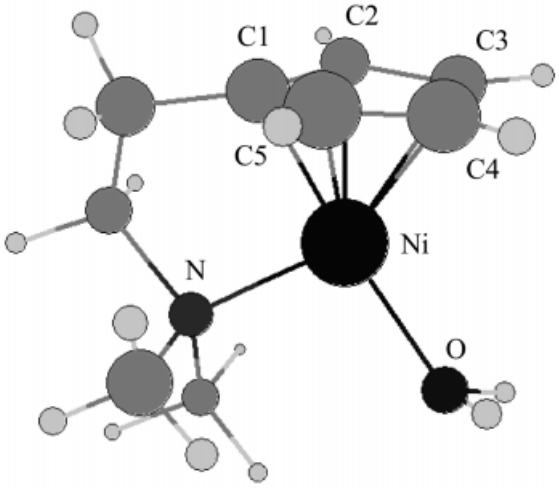

Figure 4. Structure obtained from a DFT calculation on $[Cp^NNi(OH_2)]^+$ (**9**)

One consequence of such a shortening of bond lengths could be the overall instability of this proposed intermediate. This would explain the experimental observations or cause the nitrogen donor to detach from the metal centre to possibly make room for the coordination of other thf molecules. Further research is currently in progress to elucidate this feature which would strongly influence the overall reactivity of the complex $[Cp^NNi]^+$ in terms of its possible catalytic behaviour.

Analytical Data for $[Cp^NNi(dmpe)]^+PF_6^-$ (5)

The spectroscopic behaviour of the aminoalkyl side-chain of **5** in the ^1H NMR spectra indicates the absence of a co-

[a] The abbreviation Cp denotes the center of the cyclopentadienyl ring.

ordinated side-chain to the nickel centre.[2,12] All proton signals of the ethylene bridge appear in the same region at δ ≈ 2.48 (almost identical to the values for free Cp^NH of δ ≈ 2.47) due to a coincidentally small difference in their chemical shifts. This results in a badly resolved muliplet. This feature has already been observed with several other related compounds [see discussion for $[Cp^NNi(PPh_3)]^+PF_6^-$ (**4**)]. The resonances for the Cp ring range from δ = 5.43 to 5.53 and are comparable with those of **1a** (δ = 5.26−5.31). A general downfield shift is observed for the δ values of the dmpe ligand signal. A comparison with the free donor shows that all proton signals move from δ = 1.41 and 1.00, respectively, to δ ≈ 1.78 in **5**. This shift is much smaller for the ^{13}C nuclei, but again more obvious for the signals of the two phosphorus atoms that move from δ = −47 to +57.

The second cationic species with a free donor-functionalized side-chain could be isolated by treating a thf solution of $[Cp^NNi(thf)_x]^+PF_6^-$ (x = 1,2) with one equivalent of dmpe and recrystallizing the product **5** from acetone at −30 °C (Figure 5, Table 5). Like compound **4** the solid-state structure shows monomeric cations $[Cp^NNi(dmpe)]^+$ with an Ni−P3 distance to the counter anion greater than 6 Å. It was solved in the space group *Pna*2(1).

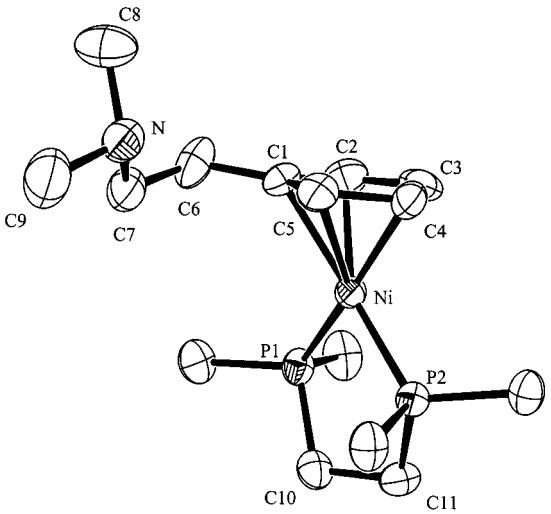

Figure 5. ORTEP drawing of the cation $[Cp^NNi(dmpe)]^+$ in the solid state, using 50% probability ellipsoids; hydrogen atoms are omitted for clarity

[a] The abbreviation Cp denotes the center of the cyclopentadienyl ring.

The use of the bidentate ligand dmpe as a donor had the expected result. Due to the stronger Ni−P bond and the chelate effect, the amine donor is now detached from the nickel atom and replaced by the second phosphorus atom of the ligand. The dmpe ligand and the cyclopentadienyl ring again form a distorted trigonal coordination sphere around the centre. The P1−Ni−P2 angle of 89.4° is a consequence of the ethylene bridge linking the two phosphorus centres resulting in the Cp−Ni−P1 and Cp−Ni−P2 angles larger than 120°. Ranging from 2.07 to 2.14 Å, the Ni−C(1···5) distances compare well with those in **4** and thus the Ni−Cp distances are 1.72 and 1.74 Å, respectively. The shape of the cyclopentadienyl rings with a deviation of 0.026 Å from the least-squares plane and a similar, yet more distinct, ene-allyl distortion in **5**, stress the analogy. However, the C1 carbon atom in **4** is part of the "allyl" group, while in **5** it belongs to the "ene" double bond. Other cations of the general formula $[CpNi(PR_3)_2]^+$ [R = Me, Et, Ph, or $(PR_3)_2$ = bis(diphenylphosphanyl)ethane] have been described previously.[13,14] While the Ni−C(1···5) bond lengths in **5** correspond to literature values (2.06−2.15 Å), the two Ni−P distances of 2.12 and 2.13 Å are shorter than those reported (2.14−2.20 Å). This could be because of the restrictions that the ethylene bridge forces upon the phosphorus ligands and the relatively small methyl groups that are less prone to steric encumbrance when compared with e.g. phenyl. As mentioned earlier, the magnitudes of the angles C1−C6−C7 (115.7°) and C6−C7−N (115.6°) in the free side-chain are similar to the corresponding ones in **4**, with a coordinated N donor and are thus also larger than 109.5°. Since the alkyl chain in **5** is not subject to any obvious strain the difference cannot be explained in this way.

Analytical Data for Cp^NNiMes (6) (Mes = 2,4,6-Trimethylphenyl)

With respect to the ^1H NMR spectrum complex **6** is the most well-behaved substance of those reported herein. All peaks are very clearly resolved and show no broadening. The protons of the Cp ring exhibit two resonances (δ = 4.69 and 6.22, respectively) expected from the simple substitution pattern. The δ values for the mesityl moiety in the

Cp[a]−C1−C6	167.1	Ni−C11−C16	122.1(5)

[a] The abbreviation Cp denotes the center of the cyclopentadienyl ring.

^{1}H and ^{13}C NMR spectra are all shifted to lower field in comparison with the free mesitylene, with the protons and carbon atoms closest to the metal centre experiencing the largest displacement.

Suitable crystals for X-ray crystallography of **6** were grown from a pentane solution. The deep-red solid contains the complex in monomeric form and was solved in the space group *Pbca* (Figure 6, Table 6).

Previously described complexes that bear a close relationship to **6** like $CpNi(PPh_3)C_6F_5$,[22,23] $CpNi(PPh_3)C_6H_5$,[23] or compounds that also contain an Ni−C bond such as $CpNi(PPh_3)CF_3$[24] and $CpNi(PPh_3)(CH_2SO_2Ph)$,[25] cover a range from 1.90 to 1.96 Å for the Ni−C distance. The corresponding bond length in **6** of 1.912 Å thus compares well with those of the above-mentioned aryl compounds (1.904 and 1.914 Å, respectively). All other bond lengths and angles resemble those found in compounds **1a** and **4**. The amine donor bond of 1.974 Å is a shorter example of its kind and is similar to that in **1a**. A range of 2.06 to 2.16 Å for the Ni−C(1···5) lengths and a look at the C−C distances within the 5-membered ring (1.39−1.44 Å) further emphasize the resemblance. However, the angle C6−C7−N of 122.9° in the donor-functionalized sidechain is somewhat larger than in any of the other complexes.

Conclusion

By employing the halide abstracting reagent $Tl[PF_6]$, it is possible to produce an unstable cation $[Cp^NNi]^+$ from the precursor Cp^NNiI (**1a**). The subsequent trapping with the two phosphorus ligands PPh_3 and dmpe leads to the isolabile complexes $[Cp^NNi(PPh_3)]^+PF_6^-$ (**4**) and $[Cp^NNi(dmpe)]^+PF_6^-$ (**5**) that can easily be characterized. The obvious cationic character of **1a** is further demonstrated by replacing the iodine functionality in a direct nucleophilic substitution with the Grignard reagent MesMgBr to give Cp^NNiMes (**6**). The preparation of the $[Cp^NNi]^+$ species and ongoing theoretical calculations making use of appropriate models will serve as a starting point for further exploration of other bond-activating reactions or catalytic applications besides the one that leads to complex **2**. Thus, reactions of $[Cp^NNi]^+$ created in situ, the study of other derivatives Cp^NNiX, and the behavior of **1a** towards other anions and neutral substrates will be the focus of our oncoming research.

Experimental Section

General Remarks: All reactions and manipulations were carried out under argon utilizing standard Schlenk and glovebox techniques. Solvents were dried with a sodium/paraffin suspension or sodium/potassium, distilled and stored over molecular sieves (Merck, 4 Å) under inert conditions. − NMR spectra were recorded with Bruker DPX 250 and Bruker DRX 400 spectrometers. ^{1}H and ^{13}C NMR chemical shifts are referred to the remaining proton signals of the deuterated solvents and referenced to TMS. ^{31}P NMR chemical shifts are referred to the external standard H_3PO_4. The NMR solvents were dried with sodium/potassium alloy as mentioned above and degassed prior to use. − The mass spectra were performed with a Varian MAT CH5 by FAB ionization unless otherwise indicated. − Elemental analysis was provided by the Microanalytical Laboratory of the Ruhr-Universität Bochum employing a C-,H-,N-Analysenautomat of the type CHN-O-Rapid with heat conductivity detection (Heraeus). The abbreviations used in this section are $Cp^N = \eta^5\text{-}C_5H_4(CH_2CH_2NMe_2)$, Me = CH_3, Ph = C_6H_5, dmpe = $Me_2PCH_2CH_2PMe_2$, and Mes = 2,4,6-trimethylphenyl (mesityl). [2-(Dimethylamino)ethyl]cyclopentadiene (Cp^NH)[7] and 1-[2-(dimethylamino)ethyl]-3-(trimethylsilyl)cyclopentadiene (Me_3SiCp^NH)[9] were prepared according to literature procedures. A modified procedure for the synthesis of $Cp^N{}_2Ni$ and $Me_3SiCp^N{}_2Ni$ was used to produce the two nickelocene derivatives,[8] all follow-up products through to **1a** and **1b** were synthesized as previously described.[2] It included the use of diethylamine as a milder base instead of *n*-butyllithium, and the extraction of the dark green oils with *n*-pentane without following sublimation. All other chemicals were commercially available and used without further purification.

Synthesis of Me_3SiCp^NNiI (1b): I_2 (0.64 g, 2.50 mmol) in THF (10 mL) was added slowly at −78 °C to a stirred solution of $Me_3SiCp^N{}_2Ni_2(CO)_2$ (1.50 g, 2.50 mmol) in 20 mL of THF. The resulting black suspension was warmed to room temperature and stirred for another hour. After evaporation of the solvent, the residue was extracted three times with 25 mL of *n*-pentane. The dark blue solution was concentrated to about 20 mL and the product crystallized at 5 °C. Complex **1b** was obtained as dark violet needles in 45% yield (0.89 g). − ^{1}H NMR (250.13 MHz, [D$_6$]acetone, 25 °C): δ = 0.03 [s, 9 H, Si(CH_3)$_3$], 0.15 (t, 2 H, $CH_2CH_2NMe_2$), 2.29 (t, 2 H, $CH_2CH_2NMe_2$), 2,47 [s, 6 H, N(CH_3)$_2$], 4.32−4.37 (m, br., 4 H, Cp*H*). − ^{13}C{^{1}H} NMR (62.90 MHz, [D$_6$]acetone, 25 °C): no signals detected. − MS(FAB); *m*/*z* (%): 393 (28) [M$^+$], 266 (50) [$Me_3SiCp^NNi^+$], 136 (24) [Cp^{N+}], 73 (50) [$SiMe_3^+$], 58 (100) [$CH_2NMe_2^+$]. − $C_{12}H_{22}INNiSi$ (394.0) ***((AUTHOR: Please check all molecular masses!))***: calcd. C 36.58, H 5.63, N 3.56; found C 34.78, H 5.24, N 3.25.

Synthesis of $[Cp^NNi(PPh_3)]^+PF_6^-$ (4) and $[Cp^NNi(dmpe)]^+PF_6^-$ (5): Compound **1a** (100 mg, 0.32 mmol) was dissolved in 10 mL of THF, cooled to −78 °C and $Tl[PF_6]$ (109 mg, 0.31 mmol) was added to the solution. The suspension was allowed to warm to −40 °C and stirred for 1 h until the violet colour of **1a** had disappeared and was replaced by the yellow color of the precipitated TlI.

Reaction with PPh_3: Addition of PPh_3 (170 mg, 0.65 mmol) immediately produced a deep red mixture. After stirring at room temper-

Reaction with dmpe: Addition of dmpe (48 mg, 0.32 mmol) gave the mixture a light pink colour. After warming to room temperature and stirring for 30 min, the solvent was evaporated. The residue was washed twice with 10 mL of toluene and extracted with acetone. Crystallization at −30 °C gave product **5** as red crystals in 60% yield (94 mg). − ^{1}H NMR (250.13 MHz, [D$_6$]acetone, 25 °C): δ = 1.78 (m, 4 H, C*H*$_2$PMe$_2$), 1.79 [d, 6 H, P(C*H*$_3$)$_2$], 2.47 (m, 4 H, C*H*$_2$C*H*$_2$NMe$_2$), 5.49 (m, 4 H, Cp*H*). − ^{13}C{^{1}H} NMR (62.90 MHz, [D$_6$]acetone, 25 °C): δ = 16.5 [P(*C*H$_3$)$_2$], 26.5 (*C*H$_2$CH$_2$NMe$_2$), 28.2 (*C*H$_2$PMe$_2$), 45.1 [N(*C*H$_3$)$_2$], 61.0 (CH$_2$*C*H$_2$NMe$_2$), 91.1 (*o*-*C*$_5$H$_4$), 91.8 (*m*-*C*$_5$H$_4$), no signal for *i*-*C*$_5$H$_4$ detected. − ^{31}P{^{1}H} NMR (101.25 MHz, [D$_6$]acetone, 25 °C): δ = −143.0 (*P*F$_6$), 57.0 (CH$_2$*P*Me$_2$). − MS(FAB); *m*/*z* (%): 344 (100) [Cp^{N}Ni(dmpe)$^+$], 329 (5) [Cp^{N}Ni(dmpe)$^+$ − CH$_3$], 208 (10) [Ni(dmpe)$^+$], 154 (32), 136 (27) [Cp^{N+}], 120 (6) [dmpe − 2 CH$_3$], 89 (7) [Me$_2$PCH$_2$CH$_2$]. − $C_{15}H_{30}F_6NNiP_3$ (490.0): calcd. C 36.77, H 6.17, N 2.86; found C 37.01, H 5.36, N 2.98.

Synthesis of Cp^{N}NiMes (6): At −78 °C, 0.95 mL of a 0.65 M solution of MesMgBr (0.62 mmol) in THF was added to **1a** (200 mg, 0.62 mmol), dissolved in 20 mL THF. The mixture was allowed to warm to room temperature. The colour turned from dark violet to dark red at about −40 °C and MgBrI started to precipitate. After stirring for 30 min at ambient temperature, the solvent was removed in vacuo and the residue was extracted with 20 mL of *n*-pentane. Concentration of the solution to a volume of about 5 mL and storing it at 5 °C yielded **6** as dark red prism-shaped single crystals in 75% yield (146 mg). − ^{1}H NMR (250.13 MHz, C$_6$D$_6$, 25 °C): δ = 1.37 (t, 2 H, C*H*$_2$CH$_2$NMe$_2$), 1.85 [s, 6 H, N(C*H*$_3$)$_2$], 2.02 (t, 2 H, CH$_2$C*H*$_2$NMe$_2$), 2.52 (s, 3 H, *p*-C*H*$_3$), 3.51 (s, 6 H, *o*-C*H*$_3$), 4.69 (s, 2 H, Cp*H*), 6.22 (s, 2 H, Cp*H*), 7.07 (s, 2 H, C$_6$*H*$_2$). − ^{13}C{^{1}H} NMR (62.90 MHz, C$_6$D$_6$, 25 °C): δ = 21.2 (*p*-*C*H$_3$), 25.7 (*C*H$_2$CH$_2$NMe), 29.3 (*o*-*C*H$_3$), 52.1 [N(*C*H$_3$)$_2$], 76.7 (CH$_2$*C*H$_2$NMe), 82.2 (*o*-*C*$_5$H$_4$), 99.1 (*m*-*C*$_5$H$_4$), 102.3 (*i*-*C*$_5$H$_4$), 125.4 (*i*-*C*$_6$H$_2$), 128.6 (*m*-*C*$_6$H$_2$), 138.3 (*p*-*C*$_6$H$_2$), 146.9 (*o*-*C*$_6$H$_2$). − MS(FAB); *m*/*z* (%): 313 (100) [M$^+$], 194 (21) [Cp^{N}Ni$^+$], 154 (83), 136 (61) [Cp^{N+}], 120 (10) [Mes$^+$]. − $C_{18}H_{25}NNi$ (314.1): calcd. C 68.83, H 8.02, N 4.46; found C 68.49, H 8.71, N 4.34.

Crystal Structure Determination: Additional crystallographic data on the structural determination of compounds **1b**, **4**, **5** and **6** are listed in Table 7. Intensity data for **4** and **5** were collected with a Siemens P4 diffractometer (Mo-K_α radiation, λ = 0.71073 Å, graphite monochromator, ω-scan). Empirical absorption corrections were applied. The structures were solved by direct methods[26]

and refined by least-squares methods based on F^2 with all observed reflections.[27] The thermal reliability index $wR2$ is defined as $[\Sigma w(F_o^2 - F_c^2)^2/\Sigma w(F_o^2)^2]^{1/2}$. All non-hydrogen atoms were refined anisotropically.

Crystals of **1b** and **6** were mounted on a goniometer using the perfluoro ether technique with cooling (T = 203 K). Data collections were performed with a Bruker-axs-SMART diffractometer (Mo-K_α radiation λ = 0.71073 Å, graphite monochromator, ω-scan). Empirical absorption corrections (ψ-scans) were applied. The structure solutions were done with direct methods[26] and the structure refinement (full-matrix least-squares against F^2) was undertaken with anisotropic structural parameters for all non-hydrogen atoms.[28]

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre: CCDC-138909 (**1b**), -138904 (**4**), -138903 (**5**), and -138905 (**6**). Copies of the data can be obtained free of charge by application to CCDC, 12 Union Road, Cambridge CB2, 1EZ, UK [Fax: (int. code) + 44-1223/336-001; E-mail: deposit@ccdc.cam.ac.uk].

Fe_4S_4 Clusters Functionalized with Molecular Receptor Ligands

Robertus J. M. Klein Gebbink,[a] Stephen I. Klink,[a] Martinus C. Feiters,*[a] and Roeland J. M. Nolte*[a]

Keywords: Iron−sulfur clusters / Electrochemistry / High-potential iron−sulfur proteins / Host−guest chemistry

Cubane-type Fe_4S_4 clusters have been functionalized with the concave dithiol ligands $\mathbf{L^{Xyl}}2H$ and $\mathbf{L^{Ac}}2H$, derived from a diphenylglucoluril-based receptor molecule. In the monomeric cluster compounds $[Fe_4S_4(\mathbf{L^{Xyl}})_2](PPh_4)_2$ (cluster **A**) and $[Fe_4S_4(\mathbf{L^{Ac}})_2](PPh_4)_2$ (cluster **B**), an Fe_4S_4 core is combined with receptor sites for alkali metal ions and aromatic guest molecules. Molecular modelling studies show that the Fe_4S_4 core in compound **B** is tightly encapsulated by its two dithiol ligands, whereas this is not the case for compound **A**. However, unlike the clusters in High-Potential Iron–sulfur Proteins (HiPIP′s), the Fe_4S_4 core in **B** is still accessible to solvent molecules, as has been established by solution electrochemical studies. Both cluster compounds bind alkali metal ions and undergo anodic shifts in their $2^-/3^-$ reduction potentials upon binding of these ions. Electrochemical titrations indicate the complexation of four alkali metal ions per cluster compound. Binding by cluster **B** takes place preferentially at the exterior of the receptor ligands, whereas in the case of cluster **A** the ions also bind to the interior of the receptor. The more open structure of **A** allows the binding of dimethylparaquat **5** [$K_{ass} = (5.6 \pm 0.6) \times 10^3\ m^{-1}$] to this cluster compound. On complexation, the first reduction potential of the guest molecule shifts in the cathodic direction, whereas the reduction potential of the cluster remains unaffected. This observation can be rationalized by assuming that the twofold positively charged guest molecule binds between the aromatic side-walls of the receptor ligands, whereas the one-electron reduced, singly charged positive species is not bound.

Introduction
