The purity of the starting material **3** was checked by ^{11}B-NMR spectroscopy, and small impurities of unreacted KBH_4 as well as presumably the intermediate dihydrobis(indazolyl)borato anion, were detected.

Mass Spectrometry

The mass-spectrometric characterization shows the molecular ion for all the complexes. The Jahn−Teller-distorted Cu complex **7** gives, however, a significantly lower molecular ion intensity, and apparently also an immediate loss of one hydrogen. The most likely fragmentation for the bis[hydrotris(indazolyl)borato]metal(II) complexes involves the loss of indazolyl or indazole rings ($C_7H_5N_2$/H) and the loss of one hydrotris(indazolyl)borato ligand. The occurrence of doubly charged ions of high abundance is remarkable. The typical fragments together with their proposed fragmentation path are given in Scheme 1. For iron and cobalt, the doubly charged ion that was obtained after the loss of two indazolyl rings, $[M - 2\,(C_7H_5N_2)]^{2+}$, even represented the base peak. Figure 1 shows the mass spectrum of the iron complex **4** together with its assignment, as an example.

Scheme 1. Typical fragments in the mass spectra of the $[M\{HB(C_7H_5N_2)_3\}_2]$ complexes and proposed fragmentation path (*M in italics* = molecular complex)

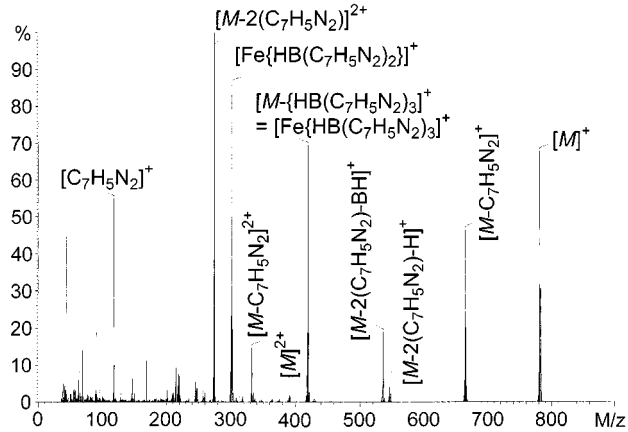

Figure 1. Mass spectrum of **4** with assignment; peak assignment was based on the calculation of the most abundant isotope combination, containing ^{56}Fe and ^{11}B; note the doubly charged ions

Optical Spectra

The positions of electronic absorption maxima and the extinction coefficients for the complexes **4**−**7** are given in Table 1 together with the assignments. The optical spectra of the complexes feature weak d-d transitions and strong metal-to-ligand charge-transfer (CT) bands. The latter start

at 340 nm. Hence, the highest energetic spin-allowed transition for the nickel complex **6**, $^3A_{2g} \rightarrow {}^3T_{1g}$ (P), could not be observed. The spectra are related to those of the analogous bis[hydrotris(pyrazolyl)borato]- and bis[hydrotris(triazolyl)-borato]metal compounds.[18–21] Data for comparison is included in Table 1. It is evident that corresponding bands for the indazolyl complexes are shifted to lower wave length by about 25 to 70 nm for most transitions. This shift to higher energy can be correlated to a stronger ligand field of the tris(indazolyl)borato anion versus the tris(pyrazolyl)borato analog. The ligand-field strength can be quantified by the *f* value relative to H_2O (*f* = 1.00). The value *f* is calculated from $\Delta_O = f \times g$(central ion).[23] The Ni^{II} transition $^3A_{2g} \rightarrow {}^3T_{2g}$ corresponds to Δ_O = 12890 cm^{-1}. Together with $g(Ni^{2+})$ = 8900 one obtains *f* = 1.45 for hydrotris(indazolyl)borate, which is slightly larger than *f* = 1.35 for hydrotris(pyrazolyl)borate.[20] Both ligands are stronger than 2,2′-bipyridine (*f* = 1.33) or ammonia (*f* = 1.25). We note that the copper complex **7** does not follow the aforementioned hypsochromic shift.

Electrochemistry of 4 and 5

The cyclic-voltammetric investigations on the (indazolylborato)iron and -cobalt complex **4** and **5**, respectively, can be compared to the data available for the iron and cobalt analog with the hydrotris(pyrazolyl)borato and the hydrotris(triazolyl)borato ligand.[8] The results are collected in Table 2. The cyclic voltammograms for **4** and **5** are shown in Figure 2. Based on the difference of the peak potentials, ΔE_p, the iron complex **4** exhibits a reversible and fast electron transfer. The electron processes for the cobalt complex **5** are only quasi-reversible and slow. This agrees with the behavior found for the respective tris(pyrazolyl)borato derivatives. It is suggested that the slow electron transfer for cobalt is due to different spin states for Co^{II} (high spin) and Co^{III} (low spin). In comparison with the (pyrazolyl)- and (triazolyl)borato complexes, the potentials of **4** lie at intermediate values. Hence, the [(indazolyl)borato]iron complex is more difficult to oxidize than the pyrazolyl analog, but easier to oxidize than the triazolyl compound. Whereas the cobalt complex **5** is easier to oxidize than its pyrazolyl congener. This may seem contradictory at first, but the phenomena can be explained with the slightly stronger ligand field of **Tp^{4Bo}** versus **Tp** according to Scheme 2. An increase in the σ-donor and π-acceptor strength increases the ligand-field splitting. In octahedral symmetry (assumed for simplicity), the t_{2g} levels are lowered, the antibonding e_g levels raised in energy. The d^6-Fe^{II} complex **4** is low spin with the electron configuration $t_{2g}{}^6$. Thus, it becomes more difficult

Scheme 2. The effect of an increase in ligand-field strength for Co^{II} (high spin) in O_h symmetry; from the raised e_g levels the complex becomes easier to oxidize when going from the **Tp** to the **Tp^{4Bo}** complex

to oxidize. The d^7-Co^{II} complex **5** is high spin with the electron configuration $t_{2g}^5e_g^2$. With the e_g levels raised in energy, it becomes easier to oxidize.

Mössbauer Spectroscopy of 4

Hexa-coordinated complexes of iron(II) with nitrogen donor ligands are good candidates for a temperature-induced spin crossover between the diamagnetic $^1A_{1g}$ low-spin state and the paramagnetic $^5T_{2g}$ high-spin state.[24] Also, the iron complexes of tris(pyrazolyl)borato ligands exhibit such a spin equilibrium [8,9,18,25–28] and the transition temperature was found to vary strongly with substitution on the pyrazolyl rings or the boron atom.[19,20,29] The interplay of the steric effects of substituents with the different sizes of the low- and high-spin Fe^{II} ions was demonstrated to be the decisive factor in controlling the relative stability of the spin states.[26,28] As such, we have investigated the possible spin crossover behavior of **4** by variable-temperature ^{57}Fe-Mössbauer spectroscopy. Figure 3 shows the Mössbauer spectra of **4** at three temperatures from 287 K

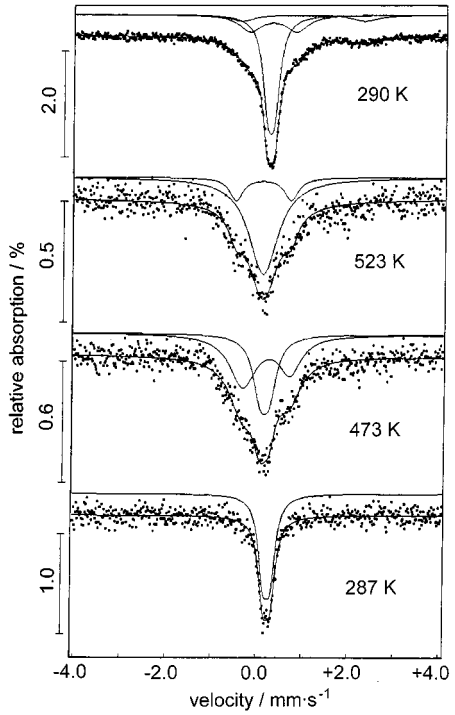

Figure 3. ^{57}Fe-Mössbauer spectra of **4** as a function of temperature; the isomer shift is scaled to the shift of α-Fe as the origin of the ordinate; the uppermost spectrum at 290 K was measured after heating the sample to 523 K and may contain some decomposition product

to 523 K. The corresponding Mössbauer parameters are collected in Table 3.

The initial room-temperature spectrum shows a doublet with a very small quadrupole splitting (0.16 mm s^{-1}). This, and the small positive isomer shift of 0.34 mm s^{-1}, is expected for a low-spin ($^1A_{1g}$) iron(II) complex with only a small distortion (D_{3d}) from octahedral ligand symmetry. The high-temperature spectra show a distinctly different line profile. Phenomenologically, they can be described as a broad singlet with a fine structure (shoulders). The spectra were fitted with a narrow doublet, or singlet and a wider doublet, both with a very similar isomer shift. The actual origin of the wide doublet is unclear. The small isomer shift

of 0.2 to 0.24 mm s^{-1} as well as the medium quadrupole splitting of 1.1 to 1.2 mm s^{-1} argue against iron(II) in the high-spin $^5T_{2g}$ state. Usually, for high-spin iron(II) in the quintet state an isomer shift of 0.7 to 1.2 mm s^{-1} and a large quadrupole splitting of 2.3 to 3.0 mm s^{-1} is expected.[8,24,29] Hence, we would not ascribe the fine structure to a quadrupolar relaxation phenomenon, i.e. to the onset of a spin transition. Possibly, the wide doublet may stem from partial decomposition: A second room-temperature spectrum, which was collected after heating the sample, still shows a broadened envelope around the main signal. In addition, a flat peak at positive isomer shift had emerged, which could be fitted to a doublet with an isomer shift of 0.95 mm s^{-1} and a large quadrupole splitting of 2.07 mm s^{-1}. The visual appearance of the sample was unchanged after the Mössbauer experiments.

For the bis(ligand) complex of iron with tris(pyrazolyl)borate (**1**) a transition temperature (50% low- and high-spin state) of about 133 °C was given.[26] It is suggested that the increased ligand-field strength of **2a** versus **1** may be the basis for the considerable increase in transition temperature beyond the decomposition point of the sample.

X-ray Structures of [M(Tp^{4Bo})$_2$] Complexes (M = Fe, Co, Ni, Cu, Zn) with Solvent of Crystallization

The bis[hydrotris(indazol-1-yl)borato]metal complexes could be crystallized from THF, dioxane or chloroform. The following complexes were investigated by single-crystal X-ray structure determination: **4** • 3.5 $CHCl_3$, **5** • 3.5 $CHCl_3$, **6** • 3 THF, **6** • 1.67 dioxane, **7** • 1.33 $CHCl_3$, **7** • 2.5 THF, and **8** • 1.67 dioxane. The number of solvent molecules was derived from the structure refinement. The interest in different solvents of crystallization stems from a solvent-dependent crystal packing, which became apparent in the course of these studies.

The (common) molecular structure of the M(Tp^{4Bo})$_2$ complexes for M = Fe, Co, Ni, and Zn (**4**, **5**, **6**, and **8**, respectively) is shown in Figure 4. The metal complexes exhibit the usual D_{3d}-symmetrical geometry for two tripodal ligands. In each space group found here, the metal atom occupies a center of inversion as a special position. Hence, both ligands in a complex molecule are symmetry-related. The copper compound **7** is depicted in Figure 5. The metal atoms are pseudo-octahedrally coordinated by the tris(chelate) ligand **2a**, and complex **7** exhibits the expected Jahn–Teller distortion for the d^9 ion with four short and two long Cu–N distances. The metal–nitrogen bond lengths and angles are summarized in Table 4. They are unremarkable with respect to those of other bis[tris(pyrazolyl)borato]-[30–33] and bis[tris(triazolyl)borato]metal complexes[7,18,34,35] and M–N bond lengths in general.[36] A comparison of the average M–N bond lengths from Table 4 shows the expected decrease for high-spin ions from Co to Ni, and again an increase towards Zn.[37] The rather short metal–ligand bond length for the iron compound **4** is indicative of a low-spin complex, in agreement with the Mössbauer data (see above).

One might have thought that the crystal packing of the complex molecules could be dictated by so-called face-to-face π-stacking interactions between six-membered rings of the indazolyl moieties. Such a parallel or a parallel-displaced π-stacking with a ring separation between 3.3 to 3.8 Å is an important non-covalent organization possibility in supramolecular chemistry.[38–40] Yet, the crystal packing between the molecular complexes appears to be controlled more by C–H•••π interactions from the indazolyl moieties, which is exemplified in Figure 6 and 7. Such a C–H•••π interaction between aromatic rings is referred to as a point-to-face or T-shaped arrangement.[41] Only in the structure of the nickel derivative **6** • 3 THF was a slipped face-to-face

aromatic−aromatic interaction more prominent (see Figure 9). The preference for a C−H•••π interaction can be understood when keeping in mind the fact that a parallel face-to-face geometry for aromatic rings is not necessarily attractive. For non-polarized π-systems π−π repulsion prevents a parallel π-stacking and σ−π attraction favors either a T-shaped or a displaced geometry.[42] According to the so-called Hunter−Sanders rules, a face-to-face interaction requires π-deficient and σ-positive atoms in polarized π-systems.[40,43] At the same time, a charge-charge interaction

[a] This has to be compared to an expected solvent volume for small molecules of 100−300 Å^3. − [b] A full listing of the intermolecular C−H•••π contacts [C−H•••C < 3.1 Å, C−H•••centroid < 3.4 Å (distances and angles)] and of the ring-centroid−ring-centroid contacts (< 6.0 Å) has been deposited as supporting information. − [c] The sum of the contact radii of carbon (1.70 Å) and hydrogen (1.20 Å) is 2.90 Å as given by: A.Bondi, *J. Phys. Chem.* **1964**, *68*, 441. (or covalent radius + 0.8 Å. when not given). − [d] R5 denotes the 5-membered nitrogen-containing pyrazol-type ring, R6 denotes the 6-membered anellated aryl ring of the indazolyl group.

dominates for highly charged π-systems. We suggest that delocalization of the negative ligand charge into the indazolyl rings may be the basis of a charge repulsion and C−H$^{\delta+}$−$^{\delta-}$π attraction.

The T-shaped C−H•••π interaction is found for example in the crystal structure of benzene.[44] Molecular dynamics calculations for benzene gave an optimum distance of 4.99 Å between the two ring centers in the T-shaped orientation. The theoretical interaction energy is about 10 kJ/5mol. Even at a benzene−benzene center of mass separation of 6 Å the T-shaped point-face dimer is bound by about 1.6 kJ/mol.[41,42] Table 5 summarizes the shortest intermolecular C−H•••π contacts with distances and angles. Ring-centroid−ring-centroid contacts shorter than 4.99 Å can be observed. From Figure 6 and 7 and the comparison of the interplanar angles, it is evident that the aromatic rings do not lie perpendicular to one another. Most angles are between 40 and 80° (cf. supporting information), i.e. we have tilted structures intermediate between the parallel displaced and the point-face geometry.[41] The intermolecular C−H•••π contacts start around 2.7 Å for C−H•••C and C−H•••ring centroid distances (Table 5). As such, these shortest C−H•••π contacts in the structures of **4** to **8** lie at the short end of the accepted distance range for this type of contact.[45] A full listing of the intermolecular C−H•••π contacts [C−H•••C < 3.1 Å, C−H•••centroid < 3.4 Å (distances and angles)] and of the ring-centroid−ring-centroid contacts (< 6.0 Å) can be found in the supporting information.

The solvent-incorporating structures of **4** to **8** indicate that even the very weak intermolecular C−H•••π interactions can be used to construct porous framework structures.[46] This mode of assembly gives rise to large non-covalent framework structures with voids and channels from about 19 to 39% of the unit cell volume (see Table 5). Figure 8 to 11 provide example views of these open spaces in six compounds. There, most of the potential solvent areas are built as channels. Only in the structure of **7** • 1.33 $CHCl_3$ (not shown) are cavities solely formed. The open space is filled by solvent molecules and probably based on very weak C−H•••O or C−H•••Cl hydrogen bonding. Because of the weak host−guest interactions the

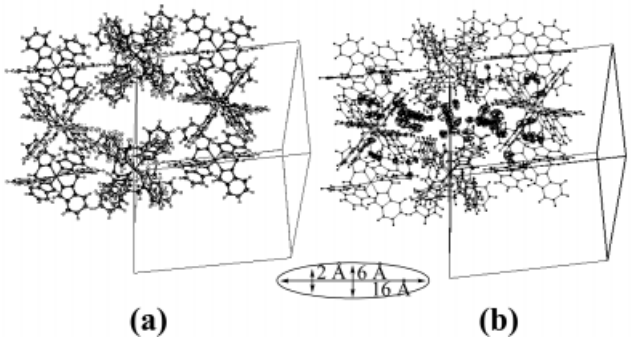

Figure 8. (a) Solvent-omitted crystal structure of **4** • 3.5 $CHCl_3$ (isostructural with **5** • 3.5 $CHCl_3$) to illustrate the channel formation along the *ab* diagonal (110 plane) and (b) the same view with a wire-frame model of the metal complexes together with the solvent molecules

solvent molecules are prone to disorder. The disorder model for the dioxane molecules in Figure 11b, which lie within the channels, is sketched in **9**. These disordered dioxane molecules give the impression of a close-packed cluster. A three-fold inversion axis ($\bar{3}$), perpendicular to the plane of projection in Figure 11 passes through them. It is suggested that the inversion axis is parallel to but does not coincide with the molecular C_2 axis bisecting the C−C bonds. The three-fold rotation wraps the molecule around with the oxygen atoms pointing outward.

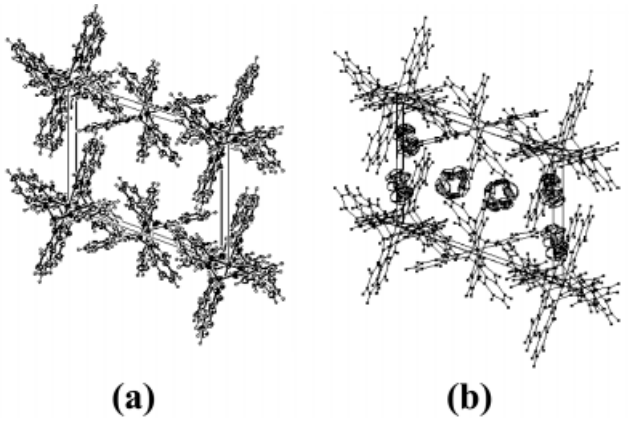

Figure 9. (a) Solvent-deleted crystal structure of **6** • 3 THF showing the channel formation along *a* and (b) the same view with a wire-frame model of the metal complexes together with the THF molecules

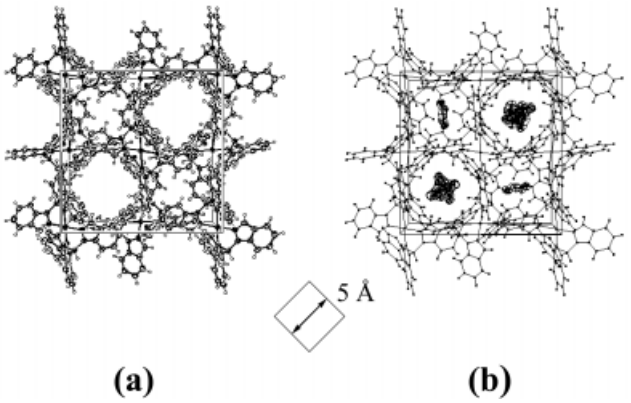

Figure 10. (a) Solvent-omitted crystal structure of **7** • 2.5 THF with the channel formation along the *c* axis and (b) the same view with a wire-frame model of the metal complexes together with the, in part, disordered solvent molecules

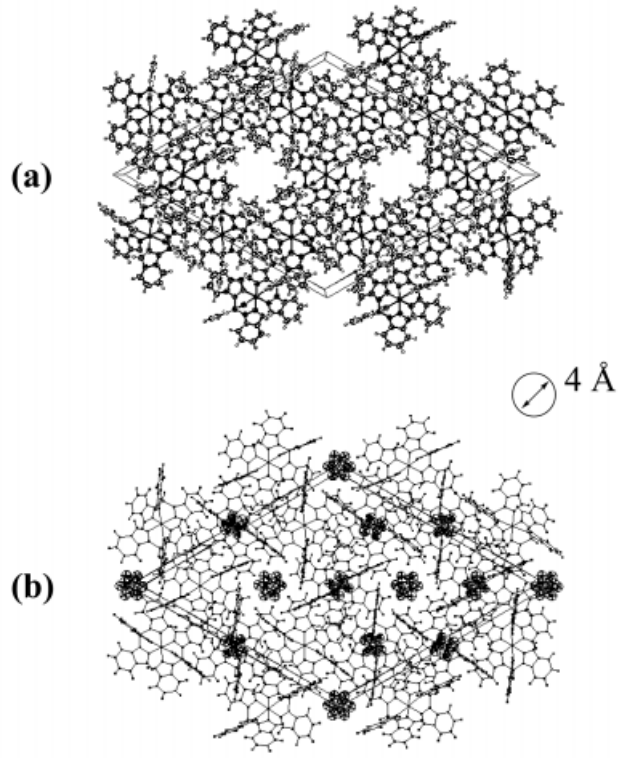
The calculated solvent volumes (Table 5) fall well into the expected solvent volume range of 100−300 Å^3 for small molecules. This gives some indication that the number of solvent molecules has been correctly determined within the structure refinement. The crystal packing and the space



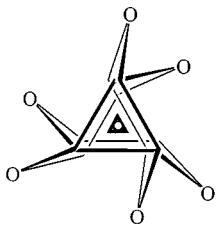


Figure 11. (a) Solvent-deleted crystal structure of **8** • 1.67 dioxane (isostructural with **6** • 1.67 dioxane) to illustrate the channel formation along *c* and (b) the same view with a wire-frame model of the metal complexes together with the disordered solvent molecules

group then depend on the type of solvent. It is well known that solvents of crystallization can have a substantial effect on the molecular and/or crystal structure of a compound.[47−49] We are currently investigating if the dioxane molecules can, at least in part, be reversibly removed from and reinserted into the framework. If so, one may envision the construction of supramolecular sensors for such small molecules in combination with a quartz crystal micro-balance.[50]

9

Conclusion

A UV/Vis-spectrometric comparison of the metal complexes shows that the tris(indazolyl)borate ligand **2a** is a somewhat stronger ligand than the long-known hydrotris(pyrazolyl)borate parent system **1**. From cyclic voltammetric studies on the iron and cobalt complexes of **2a** and **1** it is evident that the former has the effect of decreasing the energy of the t_{2g} orbitals and increasing the energy of the e_g orbitals. Unlike other homologue failed to exhibit a

temperature-induced low- to high-spin crossover before the decomposition point.

The molecular bis[hydrotris(indazolyl)borato]metal complexes can pack only loosely in the crystal leaving voids and channels which amount to as much as 38% of the unit cell volume. The voids are filled by solvent molecules. The low density packing of the molecular complexes may be due to a reluctance of the indazolyl moieties to enter into face-to-face π-stacking interactions. Instead, the crystal packing is controlled more by tilted point-face C−H•••π interactions. Most indazolyl ring planes form intermolecular angles between 40 and 80°. On the other hand, the solvent-incorporating structures of the bis[hydrotris(indazolyl)borato]metal complexes **4**−**8** indicate that even the very weak intermolecular C−H•••π interactions can be used to construct porous framework structures.

Experimental Section

The solvent, methanol, was dried with CaO by heating under reflux for 4 h under inert gas, followed by distillation. − UV/Vis spectra were obtained with a Jasco V-570, MHT-344 spectrometer in the range 1800−300 nm, and with a Polytec XDAP diode-array spectrometer with a quartz immersion probe in the range 1000−280 nm. NMR spectra were recorded with a Bruker ARX200 (200.1 MHz for ^{1}H, 50.3 MHz for ^{13}C), and calibrated against the solvent signal ([D_6]DMSO: ^{1}H NMR: δ = 2.53, ^{13}C NMR: δ = 39.5; $CDCl_3$: ^{1}H NMR: δ = 7.26, ^{13}C NMR: δ = 77.0; [D_8]THF: ^{1}H NMR: δ = 1.73, ^{13}C NMR: δ = 25.2; CD_3OD: ^{1}H NMR: δ = 3.31). The ^{11}B- and ^{10}B-NMR spectra were measured with a Bruker ARX200 (64.21 MHz for ^{11}B, 21.50 MHz for ^{10}B) relative to neat $BF_3 \bullet Et_2O$ as an external standard. A 1:2 v/v solvent mixture of [D_6]DMSO and normal DMSO was used with a sample concentration of about 130 mg/mL. Mass spectra were obtained with a Varian MAT 311A/AMD in solid-probe EI mode, at an ionization energy of 70 eV. The MS peaks listed refer to the most abundant isotope combination with ^{56}Fe, ^{59}Co, ^{58}Ni, ^{63}Cu, ^{54}Zn, and ^{11}B. Elemental analyses were carried out with a Perkin−Elmer 2400 Series II CHNS/O Analyzer. IR spectra were measured with a Nicolet Magna 750 as KBr disks.

Synthesis

Potassium Hydrotris(indazol-1-yl)borate, K[HB($C_7H_5N_2$)$_3$] (3): The potassium salt of **2a** was prepared following a general procedure by Trofimenko for tris(pyrazolyl)borate ligands:[51] KBH_4 (1.6 g, 30.0 mmol) and indazole (11.3 g, 95.9 mmol) were heated to 220 °C in a Schlenk flask that was connected to a volumetric gas measurement system. A strong gas evolution starts upon melting, and ceases towards the end of the reaction. After 4 h, 2.1 L of H_2 was evolved, which corresponds to 86.1 mmol or 96% when assuming the ideal gas law. Excess indazole was separated by sublimation (160 °C bath temperature, 1.5 mbar), to leave the product as a yellow powder (yield 10.57 g, 88%). NMR spectroscopy still showed indazole impurities that could not be removed, even after prolonged sublimation. The product was used as such for the following reactions with metal salts. M.p. 256−258 °C (ref.[12] 256−258 °C) − ^{1}H NMR (CD_3OD): 6.70−7.70 (m, 12 H, 4-, 5-, 6-, 7-H), 8.01 (s, 3 H, 3-H), the BH signal could not be observed; possibly due to its broad resonance because of quadrupolar coupling and relaxation effects from the boron atom.[52] − ^{13}C NMR (CD_3OD): δ = 113.8 (C-7), 120.3 (C-5), 121.0 (C-4), 125.7 (C-6), 125.8 (C-3a), 134.3 (C-3), 145.7 (C-7a) (the assignment of the quaternary C atoms C-3a and C-7a agrees with their lower signal intensity; the signals of the nitrogen-neighboring atoms C-3 and C-7a can be discerned by their low-field shift[7]). − ^{11}B NMR ([D_6]DMSO): δ = −3.5 (br), −9.3 (sh, assigned to the disubstituted borate), −35.6 (s, sharp signal, unchanged KBH_4). − ^{10}B NMR ([D_6]DMSO): δ = −5 (very broad with shoulder to high-field end), −35.6 (s, sharp signal, KBH_4). − MS (284 °C); *m/z* (%): 402 (4) [*M*]$^+$, 375 (4) [*M* − HCN]$^+$, 285 (20) [*M* − $C_7H_5N_2$]$^+$, 245 (12) [B($C_7H_5N_2$)$_2$]$^+$, 118 (100) [$C_7H_6N_2$]$^+$, 91 (28) [$C_7H_6N_2$ − HCN]$^+$. − IR (KBr): $\tilde{\nu}$ = 3090 cm^{-1} w, 3056 w, 3038 w (νCH), 2440 w, 2416 w, 2382 w (νBH), 1615 m (νCN), 1574 m, 1496 m, 1459 m, 1436 sh, 1400 m, 1375 sh, 1364 w, 1337 m, 1263 m, 1209 w, 1155 s, 1110 s, 1024 sh, 1010 s, 994 m, 942 m, 908 s, 855 w, 835 m, 794 w, 787 w, 779 w, 759 s, 740 s, 663 m, 656 w, 646 w, 634 w, 622w, 609 w, 600 m, 569 w, 552 w, 458 w, 429 m.

[Bis{hydrotris(indazol-1-yl)borato]metal(II) Complexes, [M{HB($C_7H_5N_2$)$_3$}$_2$]. − General Procedure: A solution of **3** (400 mg, 1.0 mmol) in CH_3OH (10 mL) was added to a solution/slurry of the metal salt (0.5 mmol) in CH_3OH (5 mL) under stirring. The precipitate formed was filtered and dried in air. The product was separated from KCl by dissolution in THF, dioxane, or chloroform, followed by filtration. Crystallization was achieved either by cooling, overlayering with petroleum ether (30/50) or slow solvent evaporation. After crystallization, the crystals contained solvent of crystallization which in the case of $CHCl_3$ or THF was rapidly lost when removed from the mother liquor.

[Fe{HB($C_7H_5N_2$)$_3$}$_2$] (4): Starting material $(NH_4)_2Fe(SO_4)_2$. Pink to red needle-shaped crystals were initially obtained from chloroform under cooling to −15 °C. After 2 d at this temperature, the needles dissolved again and red rhombic crystals formed within another day. Yield 440 mg, 95%. − M.p. 446 °C (DSC). − ^{1}H NMR ($CDCl_3$): δ = 1.59 (s, br, 1 H, BH), 6.98 (t, 3 H, *J* = 7.2 Hz, 5-H), 7.35 (overlapping d and t, 6 H, *J* = 8.4 Hz, 6-H, 7-H), 7.42 (s, 3 H, 3-H), 8.15 (d, 3 H, *J* = 8.4 Hz, 4-H); ([D_8]THF): δ = 2.55 (s, br, 1 H, BH), 6.93 (t, 3 H, *J* = 7.5 Hz, 5-H), 7.34 (overlapping d and t, 6 H, *J* = 7.8, 8.3 Hz, 6-H, 7-H), 7.48 (s, 3 H, 3-H), 8.16 (d, 3 H, *J* = 8.4 Hz, 4-H). − ^{13}C NMR ([D_8]THF): δ = 111.2 (C-7), 119.8 (C-6), 120.5 (C-5), 126.0 (C-4), 126.3 (C-3a), 143.6 (C-3), 146.6 (C-7a). − MS (469 °C); *m/z* (%): 782 (68) [*M*]$^+$, 665 (46) [*M* − $C_7H_5N_2$]$^+$, 547 (7) [*M* − 2 ($C_7H_5N_2$) − H]$^+$, 536 (19) [*M* − 2 ($C_7H_5N_2$) − BH]$^+$, 419 (69) [*M* − {HB($C_7H_5N_2$)$_3$} = Fe{HB($C_7H_5N_2$)$_3$}]$^+$, 391 (5) [*M*]$^{2+}$, 332.5 (14) [*M* − $C_7H_5N_2$]$^{2+}$, 301 (86) [Fe{HB($C_7H_5N_2$)$_2$}]$^+$, 274 (100) [*M* − 2 ($C_7H_5N_2$)]$^{2+}$, 118 (55) [$C_7H_6N_2$]$^+$. − IR (KBr): $\tilde{\nu}$ = 3110 cm^{-1} w, 3064 w, 3039 w, 2905 w (νCH), 2490 sh, 2475 m (νBH), 1623 s, 1505 m, 1461 s, 1416 vs (νCN), 1378 sh, 1362 m, 1350 s, 1330 w, 1265 m, 1216 s, 1140 vs, 1135 sh, 1123 w, 1110 s, 1016 vs, 998 m, 920 m, 912 w, 848 m, 822 s, 757 vs, 740 vs, 726 s, 680 m, 597 m, 572 w, 560 w, 499 m, 440 m. − $C_{42}H_{32}B_2FeN_{12} \bullet (THF)_2$ (926.5): calcd. [Co{HB($C_7H_5N_2$)$_3$}$_2$] (5): Starting material $CoCl_2 \bullet 6\,H_2O$. An initial crystallization from dioxane/petroleum ether yielded red-brown needles and a yellow solid. The brown impurity could be removed after treatment of a $CHCl_3$ solution with Al_2O_3. This changed the relative solubility of the two phases. After evaporation of $CHCl_3$ in vacuum, the remaining solid was treated again with $CHCl_3$ (5 mL) which led to the dissolution of the brown impurity leaving a citrus-yellow solid behind. The yellow solid was crystallized from hot/cold $CHCl_3$ to give initially yellow needle-shaped crystals and after longer standing yellow rhombic crystals. Yield 220 mg, 56%. − M.p. > 300 °C. − ^{1}H NMR ($CDCl_3$): δ = +111.7 (1 H, BH),

+50.2 (3 H, 7-H), +20.1 (3 H, 6-H), +10.6 (3 H, 5-H), −9.9 (3 H, 4-H), −97.8 (3 H, 3-H); ([D$_6$]DMSO): δ = + 117 (1 H, BH), + 52.2 (3 H, 7-H), + 20.8 (3 H, 6-H), + 10.8 (3 H, 5-H), − 10.3 (3 H, 4-H), −101 (3 H, 3-H); ([D$_8$]THF): δ = + 117 (1 H, BH), + 52.1 (3 H, 7-H), + 20.7 (3 H, 6-H), + 10.7 (3 H, 5-H), −10.5 (3 H, 4-H), −102 (3 H, 3-H) (corresponds to ref.[12]). − MS (438 °C); *m*/*z* (%): 785 (83) $[M]^+$, 668 (76) $[M - C_7H_5N_2]^+$, 550 (16) $[M - 2(C_7H_5N_2) - H]^+$, 422 (69) $[M - \{HB(C_7H_5N_2)_3\} = Co\{HB(C_7H_5N_2)_3\}]^+$, 392.5 (3) $[M]^{2+}$, 334 (10) $[M - C_7H_5N_2]^{2+}$, 304 (67) $[Co\{HB(C_7H_5N_2)_2\}]^+$, 275.6 (100) $[M - 2(C_7H_5N_2)]^{2+}$, 118 (33) $[C_7H_6N_2]^+$. − IR (KBr): $\tilde{\nu}$ = 3103 cm^{-1} w, 3063 w (νCH), 2498 m, 2478 m (νBH), 1623 s, 1507 s (νCN), 1462 s, 1431 m, 1412 s, 1381 m, 1367 s, 1351 s, 1321 w, 1266 s, 1217 s, 1158 s, 1148 s, 1113 s, 999 s, 947 w, 916 s, 857 m, 835 s, 826 s, 760 vs, 748 s, 728 s, 666 s, 645 w, 599 s, 434 m. − $C_{42}H_{32}B_2CoN_{12}$ (785.35): calcd. Electrochemical Measurements: All electrochemical experiments were carried out in specially constructed cells containing an internal drying column with highly activated alumina. The working electrode was a Pt disk sealed in soft glass (1.00 mm diameter). A Pt wire, wrapped around the glass of the working electrode, was used as the counter electrode. The reference electrode was an Ag wire on which AgCl had been deposited electrolytically. Potentials were calibrated with ferrocene (+0.352 V vs. Ag/AgCl). The measurements were performed with a Jaissle Potentiostat IMP 88 and a PAR 175 programmer.

Mössbauer Spectroscopy: ^{57}Fe-Mössbauer spectra were measured in constant acceleration modus with a triangular velocity profile [accelerator, control unit and multichannel analyzer (1024 data channels) from WISSEL]. The ^{57}Co source in an Rh matrix (AMERSHAM) had an activity of about 115 MBq. The Mössbauer transition at 14.41 keV was used for the γ-radiation. The transmission of the γ-radiation was detected by means of an NaI (Tl) scintillation counter as the detector coupled with a secondary electron multiplier (HARSHAW/ELSCINT); amplifier and energy discriminator from INTERTECHNIQUE. The experimental spectra were iteratively approximated in a least-squares fit with Lorentz functions in the thin absorber approximation (program package NORMOS).[53] Singlets were fitted with a single Lorentz curve, doublets with a symmetric or asymmetric superposition of two Lorentz functions. The spectral parameters ($\delta^{\alpha-Fe}$, Γ/2, and possibly ΔE_Q) could each be fixed or correlated in groups in the case of a multi-line fit. Fits were aimed for with largely open parameters. The $\delta^{\alpha-Fe}$ scale of the isomer shift is related to the shift of α-iron as origin of the ordinate ($\delta^{\alpha-Fe}$ = 0.11 ± 0.01 mm/s + $\delta^{Fe/Rh}$). The iron contamination in the beam, especially in the beryllium windows of the detector was taken into account with two fixed

[a] Two independent molecules in the unit cell. − [b] Largest difference peak and hole. − [c] $R1 = (\Sigma||F_o| - |F_c||)/\Sigma|F_o|$; $wR2 = \{\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]\}^{1/2}$ − [d] Goodness-of-fit, Gof = $\{\Sigma [w(F_o^2 - F_c^2)^2]/(n - p)\}^{1/2}$; $w = 1/[\sigma^2(F_o^2) + (a•P)^2 + b•P]$ where $P = [\max(F_o^2 \text{ or } 0) + 2•F_c^2]/3$.

base lines. The sample was heated under vacuum to collect the high-temperature spectra.

X-ray Structure Determinations: Data were collected with Mo-K_α radiation (λ = 0.71073 Å) and the use of a graphite monochromator. Structure solution was performed by direct methods; refinement was done by full-matrix least squares on F^2 using the SHELXTL program package (Version 5.1, Bruker AXS). All non-hydrogen positions were found and refined. The atoms were refined with anisotropic temperature factors except for the disordered dioxane solvent molecules in **6** • 1.67 dioxane and **8** • 1.67 dioxane and part of the THF solvent in **7** • 3 THF. The hydrogen atoms on the indazolyl rings and on the boron atom were placed at calculated positions, using appropriate riding models and an isotropic temperature factor of B_{eq} = 0.08 [for **8** • 1.67 dioxane B_{eq}(H) = 1.2 B_{eq}(C)]. For **6** • 1.67 dioxane and **8** • 1.67 dioxane the hydrogen position on the boron atom was found and refined. For the THF and dioxane solvent molecules no hydrogen atom positions were calculated or only on less disordered moieties. Crystal data are listed in Table 6 and 7. Graphics were computed with ORTEP3 for Windows.[54] Special computations for the crystal structure discussions were carried out with PLATON for Windows.[55] Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Center as supplementary publication No. CCDC-136881 (**4** • 3.5 $CHCl_3$), -136882 (**5** • 3.5 $CHCl_3$), -136883 (**6** • 3 THF), -136884 (**6** • 1.67 dioxane), -136885 (**7** • 1.33 $CHCl_3$), -136886 (**7** • 3 THF), -136887 (**8** • 1.67 dioxane). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: int. code + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk]. A full listing of the intermolecular C−H•••π contacts [C−H•••C < 3.1 Å, C−H•••centroid < 3.4 Å (distances and angles)] and of the ring-centroid−ring-centroid contacts (< 6.0 Å) can be found in the supporting information.

Interplay between Metal Aminoalkoxides and β-Diketonates: Volatile Mixed-Metal Pr−Cu and Y−Cu Species without Fluorinated Ligands − Molecular Structures of $[PrCu(\eta^2\text{-thd})_3(\mu,\eta^2\text{-}OC_2H_4NMe_2)_2]$ and of $[Y_2(\eta^2\text{-thd})_4\{\mu,\eta^2\text{-}OCH(CH_2NMe_2)_2\}_2]$

Keywords: Chemical vapor deposition / Copper / Lanthanides / β-Diketonates / Heterometallic species / Barium

The reactions between copper or lanthanide (Y, Pr) 2,2,6,6-tetramethylheptane-3,5-dionates and copper or barium aminoalkoxides were investigated in hexane. Aminoalkoxide ligands of different constraints and/or flexibility namely 2,4,6-tris(dimethylaminomethyl)phenoxide (Otamp), 2-dimethylaminoethoxide $OC_2H_4NMe_2$, 2-dimethylamino-2-propoxide $OCH(Me)CH_2NMe_2$, and 1,3-bis(dimethylamino)-2-propanol $OCH(CH_2NMe_2)_2$ were selected. Mixed-metal BaCu, PrCu, $PrCu_2$, and YCu species, as well as β-diketonatoalkoxides of barium and yttrium were isolated and characterised by analytical data, FT-IR, ^1H NMR, and ESR spectroscopy. Their thermal behaviour was investigated by TGA. The tridentate aminoalkoxide $OCH(CH_2NMe_2)_2$ was found to destabilise mixed-metal species with tetramethylheptanedionate as ancillary ligands. $[BaCu(\eta^2\text{-thd})_2(\mu,\eta^3\text{-Otamp})(\mu,\eta^{2-}\text{Otamp})(H_2O)]$, $[PrCu(\eta^2\text{-thd})_3(\mu,\eta^2\text{-}OC_2H_4NMe_2)_2]$, and $[Y_2(\eta^2\text{-thd})_4\{\mu,\eta^2\text{-}OCH(CH_2NMe_2)_2\}_2]$ were also characterised by single crystal X-ray diffraction. The latter two were volatile, whereas the volatility of the former was reduced by intramolecular hydrogen bonding. The assembling aminoalkoxide ligands ensure high coordination numbers for the heavy metals, namely seven for barium and yttrium, eight for praseodymium. The formation of the mixed-metal species improves stability toward ambient atmosphere, especially for the systems involving copper aminoalkoxides. The $[Ba(thd)\{OCH(CH_2NMe_2)_2\}_2\{OHCH(CH_2NMe_2)_2\}_2]$ species distils at 130 °C/10^{-3} Torr.

Introduction

The exploitation of the properties of anisotropic ceramics such as high T_c superconductors requires the elaboration of textured or epitaxial layers.[1] Although epitaxial layers might be obtained by sol-gel processing, this goal is more easily achieved by MOCVD techniques.[2] However, this requires appropriate precursors, namely volatile molecules which can be decomposed into the oxide within a comparable temperature range, and that are reasonably stable thermally in the container for reuse.[3] β-Diketonates are the most commonly used precursors, especially the tetramethylheptanedionate β-diketonates.[4] Besides the problems related to the use of solids as precursors, volatility and stability properties remain unsatisfactory in the case of barium, despite a large body of synthetic efforts.[5] Various liquid-source MOCVD delivery techniques that assist the transport of the precursor to the substrate and allow for maintaining the precursors at room temperature have been considered as ways to overcome the drawbacks.[6] Solubility of the precursors becomes a crucial issue for high growth rates since a solvent is an undesired ballast in a CVD process. The use of heterometallic species is an approach which reduces the number of precursors, and might improve solubility.[7] If these species are volatile, a reduction of the temperature of pyrolysis can sometimes be achieved. A large number of Ba−Cu,[8,9] Y(Ln)−Cu,[10] and a few Y−Ba[11] species of different stoichiometries have been reported. Only a few of them are volatile, they are supported by fluorinated ligands, mainly alkoxides, as assembling ligands. High Lewis acidity resulting in facile hydration or solvation and thus change in the physical properties, as well as fluoride residues in the deposits are the most common drawbacks. Aminoalkoxide ligands are often more favourable for increasing volatility than alkoxyalkoxides.[12] Schiff bases have been used recently as an alternate assembling ligand, and species such as $[M(salen)Ln(hfac)_3]$ [M = Ni, Cu; Ln = Y, Gd; H_2salen = *N*,*N*′-ethylenebis(salicylideneimine)] have been reported.[13]

We report here our investigations of the interactions between metal aminoalkoxides and tetramethylheptanedionate derivatives related to the formulation of high T_c superconductors. These were aimed at the building of mixed-metal species as well as obtaining insight into the compositions of solutions using precursors of different types.[6] The OR-type ligands, namely 2,4,6-tris(dimethylaminomethyl)-phenoxide (Otamp), 2-dimethylaminoethoxide $OR^n = OC_2H_4NMe_2$, 2-dimethylamino-2-propoxide $OR^N = OCH(Me)CH_2NMe_2$, and 1,3-bis(dimethylamino)-2-propoxide $OR'^N = OCH(CH_2NMe_2)_2$, were selected in order to cover different constraints and/or flexibility. Mixed-metal species namely $[BaCu(thd)_2(Otamp)_2(H_2O)]$, $[MCu(thd)_3(OR)_2]$

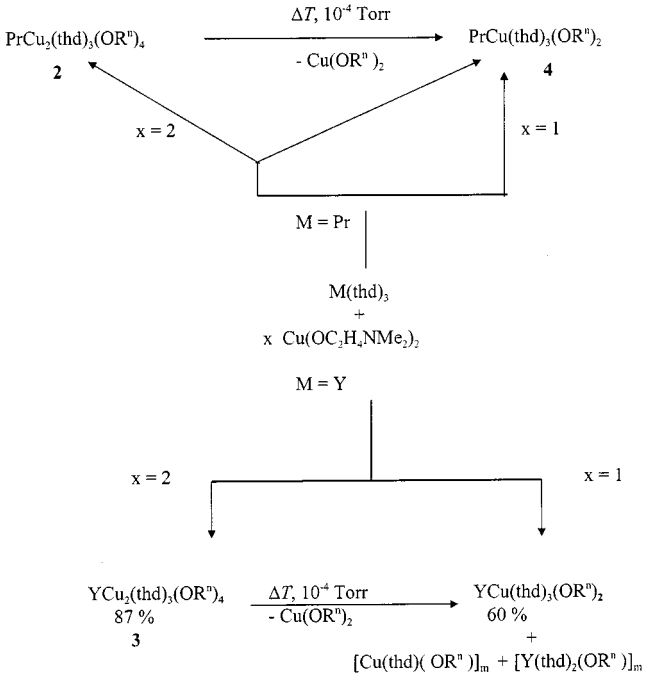
(M = Y, Pr, R = R^n, R'^N) and $[MCu_2(thd)_3(OR^n)_4]$ could be stabilised. By contrast, the trifunctional aminoalkoxide ligand $OCH(CH_2NMe_2)_2$ favoured the formation of volatile homometallic Y and Ba β-diketonatoalkoxides. The various species were characterised by elemental analyses, FT-IR, NMR, ESR, and TGA, and in the case of $[BaCu(\eta^2\text{-}thd)_2(\mu\text{-}Otamp)_2(H_2O)]$, $[PrCu(\eta^2\text{-}thd)_3(\mu,\eta^2\text{-}OR^n)_2]$, and $[Y(\mu,\eta^2\text{-}OR'^N)(\eta^2\text{-}thd)_2]_2$, by single crystal X-ray diffraction.



Results and Discussion

Synthesis and Characterization

Direct liquid injection MOCVD techniques are attractive for overcoming the drawbacks of the limited stability and/or volatility of solid oxide precursors such as barium derivatives.[2,6] Whereas β-diketonates are generally attractive precursors due to their commercial accessibility and easy handling, the limited solubility of the copper derivatives − as compared to the Ba and Y analogues − determines the concentration.[2c] Besides high solubility, the compounds used as sources of the metal oxide should be inert toward evolution into insoluble species during storage of the solution. This requirement is especially important for multimetallic oxides, since a unique container is generally used for convenience, and a constant stoichiometry between the different elements in solution is crucial for the composition of the multimetallic material. Previous studies have revealed the limitation encountered by mixing β-diketonates and β-oxo esters due to rapid ligand scrambling.[6−14] Copper alkoxides based on aminoalkoxide ligands are highly soluble and volatile, but quite hydrolysable.[15] The mixing of metal alkoxides and β-diketonates, namely 2,2,6,6-tetramethylheptane-3,5-dionates was expected to be more favourable despite the fact that higher susceptibility to moisture could result. The Cu−M systems (M = Y, Pr, or Ba) were investigated. Indeed, whereas yttrium is involved in the formula of superconducting YBCO materials, the praseodymium analogue is an insulator, and is thus of interest for building up heterostructures.[1]

Aryloxide-type ligands allow a great deal of control of steric hindrance, and thus solubility, volatility, and robustness toward atmosphere via the substituents in 2- and 6- positions.[12] An aryloxide with potentially chelating dimethylaminomethyl arms (Otamp) could also act as an efficient "pincer" ligand. A Ba−Cu species, $[BaCu(thd)_2(Otamp)_2(H_2O)]$ (**1**) was obtained in high yield by reaction of either Cu(thd)2 and $Ba_4O(Otamp)_6$ or $Cu(O\text{-}tamp)_2$ and $[Ba(thd)_2]_4$.

The reactions between the 2,2,6,6,-tetramethylheptane-3,5-dionates $M(thd)_3$ (M = Y or Pr) and copper 2-dimethylamino-2-propoxide $Cu(OR^N)_2$ in hexane afforded mixed-metal species $[MCu(thd)_3(OR^N)_2]$ in nearly quantitative yields by self-assembly. The same compounds were obtained using $M(thd)_2(OR^N)$, but in lower yields (ca. 60%). More complex reactions were observed with copper 2-dimethylaminoethoxide $Cu(OC_2H_4NMe_2)$. Indeed, mixed-metal β-diketonatoalkoxides of two stoichiometries, MCu and MCu_2, could be stabilised. Whereas the reaction between $Y(thd)_3$ and $Cu(OR^n)_2$ (1:2 stoichiometry) afforded only $[YCu_2(thd)_3(OR^n)_4]$ (**3**) (87% yield), for praseodymium the complexes $[PrCu_2(thd)_3(OR^n)_4]$ (**2**) and $[PrCu(thd)_3(OR^n)_2]$ (**4**) crystallised under similar conditions (35 and 45% yields, respectively). On the other hand, the yield of $[YCu(thd)_3(OR^n)_2]$, obtained by reaction of $Y(thd)_3$ and $Cu(OR^n)_2$ (1:1 stoichiometry), is reduced to ca. 60% by the formation of the homometallic species $[Cu(thd)(OR^n)]_m$ and $[Y(thd)_2(OR^n)]_m$ as by-products (established by comparison with authentic samples). The $[MCu_2(thd)_3(OR^n)_4]$ (M = Y, Pr) species are both volatile, but their sublimation (140 °C, 10^{-4} Torr) proceeds with decomposition to $[MCu(thd)_3(OR^n)_2]$ and copper aminoalkoxide. The lower stability of the MCu_2 species with respect to the MCu ones is also reflected in their sensitivity to hydrolysis and partial dissociation in solvents such as toluene. The absence of isolation of MCu_2 species in the case of the bis(2-dimethylamino-2-propoxide) ligand is probably related to its greater bulkiness. The lower stability of $[YCu(thd)_3(OR^n)_2]$ with respect to the praseodymium analogue might be due to the lower tendency of yttrium to attain octa-coordination as observed for the solid-state structure of **4** (see below) The various synthetic pathways for the aminoethoxide derivatives are summarised in Scheme 1.

Scheme 1. Synthetic routes to M−Cu (M = Y, Pr) β-diketonato-aminoethoxides ($OR'^n = OC_2H_4NMe_2$) (all reactions in hexane at room temperature)

Reactions with derivatives of the trifunctional aminoalkoxide $OR'^N = OCH(CH_2NMe_2)_2$ were also investigated. By contrast with reactions between a copper aminoalkoxide generated in situ and acetates or trifluoroacetates of alkaline-earth metals,[16] the reaction between $Y(thd)_3$ and $Ba(OR'^N)_2$, obtained in situ by alcoholysis of barium bis-

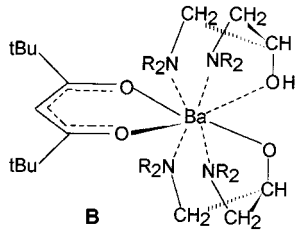
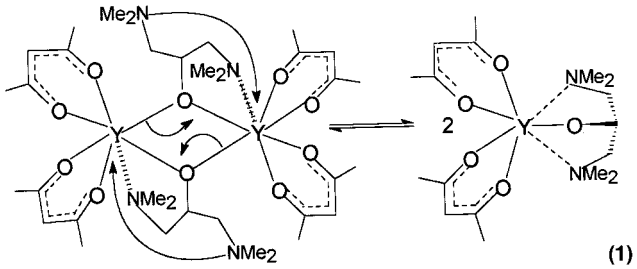
[a] Masked by the C=C and C=O absorption bands.

(trimethylsilylamide), gave no evidence of stable mixed-metal species, and $[Y(thd)_2(OR'^N)]_2$ (**8**) was isolated in nearly quantitative yields. The barium by-product, assumed to be a barium β-diketonatoalkoxide, could not be crystallised under such conditions. An adduct $[Ba(thd)(OR'^N)(R'^NOH)]$ (**7**) was however isolated by ligand exchange reactions applied to the insoluble homometallic alkoxide $Ba(OR^N)_2$. Similar observations, namely redistribution reactions, were made for the $Cu(thd)_2$–$Ba(OR'^N)_2$ system. Adduct **7** was quite air-sensitive, and attempts to make the species more robust toward ambient atmosphere by ligand exchange reactions, between the coordinated alcohol and diglyme for instance were not successful.



The various species were characterised by elemental analysis, FT-IR, ^{1}H-NMR, or ESR spectroscopy (Table 1). Their FT-IR spectra display strong absorption bands between 1600–1480 cm^{-1} characteristic of νC=O and νC=C vibrations of the β-diketonate ligands, other absorption bands correspond to νC–N and C–O vibrations between 1230 and 1000 cm^{-1}, and to νM–OR vibrations below 500 cm^{-1}. Compound **7** also displays absorption bands at 3178 and 3442 cm^{-1}, confirming the presence of an alcohol molecule in the metal coordination sphere. The similarity of the FT-IR spectra of the $PrCu_2$ and PrCu species suggests limited structural differences between their solid-state structures. Their FT-IR data indicate the absence of bridging thd ligands. The solid-state structure of **2** could not be solved due to disorder problems, but the cell parameters are definitely different from those of **4**. A plausible structure corresponds to **A**, in which the metal atoms are assembled by bridging alkoxide ligands where each metal centre bears a terminal η^2-thd ligand. Such a framework allows the metal atoms to reach common coordination numbers, namely eight for praseodymium and five for both copper centres. The transformation of **2** to **4** implies redistribution of one thd and OR^n ligand.

The paramagnetic praseodymium–copper and yttrium–copper species **2**, **4**, **5**, and **6** were characterised by ESR spectroscopy. The isotropic spectra at room temperature display a four line pattern centred around $<g> = 2.10$, characteristic of the coupling of the unpaired electron with copper [coupling constants A ranging from 78.6 to 92.4 G (^{63}Cu: $N = 69\%$, $I = 3/2$; ^{65}Cu: $N = 31\%$, $I = 3/2$).



The solubility of the diamagnetic species, namely the homometallic (β-diketonato)yttrium and -barium alkoxides **7** and **8** allowed us to gain structural information by ^{1}H NMR. The poor stability of **7** under the X-ray beam at room temperature, and a destructive phase transition at lower temperature, precluded structural information in the solid state. Its molecular complexity was established by the Signer method. The value obtained in benzene accounts for a monomer. Its volatility (distillation at 130 °C/10^{-3} Torr) is in agreement with a low molecular weight, and thus a monomeric character. Its ^{1}H-NMR spectra in $CDCl_3$ are a function of the dilution, and suggest the presence of several molecular species as indicated by three resonances for the CH group of the thd ligand. The CH resonance of the aminoalkoxide at $\delta = 3.91$ is broad, suggesting fast-exchange on the NMR time scale between the aminoalkoxide and the coordinated amino alcohol molecule – each of them having the potential for different coordination modes. The signals of the CH_2NMe_2 moieties appear as a complex pattern around $\delta = 2.25$. The signal due to the OH group was found as a very broad resonance at $\delta = 5.0$. In view of the complexity of the spectra (the carbon atom in α-position

becomes asymmetric for a bidentate coordination mode) the behaviour in solution was not further investigated. Compound **7** distils as the adduct. The coordinated alcohol could not be exchanged by diglyme, dissociation of the adduct in solution is thus not very likely. Octa-coordination can be achieved for **7** when all NMe_2 donor sites are involved in interactions with the metal centre, resulting in, for instance, structure **B**. Other isomers are, however, possible, since 1,3-bis(dimethylamino)-2-propoxide can display bidentate and tridentate coordination modes and barium can quite easily adopt coordination numbers from six to eight.[4,5]

B

The ^{1}H-NMR spectra of **8** are also very complicated, and are a function of the dilution. The presence of a species in which the 1,3-bis(dimethylamino)propoxide ligand is bidentate is illustrated by the unequivalence of the protons of the CH_2 groups in α-position to the asymmetric carbon atom. The signal at $\delta = 4.21$ was attributed to an aminoalkoxide ligand displaying a symmetrical, tridentate coordination behaviour. The overall behaviour of **8** in solution can be rationalised on the basis of an equilibrium between a dimeric species **8a** (see below), having the structure found in the solid state, and a monomeric one [$Y(\eta^2\text{-thd})_2(\eta^3\text{-}OR'^N)$] (**8b**) according to Equation (1). The signals due to the thd ligands were observed at $\delta = 5.59$ and 1.05, and at $\delta = 5.67$ and 1.09 for **8a** and **8b**, respectively.

8a **8b** **(1)**

Compound **8** sublimes, although the sublimate displays small modifications in the FT-IR spectrum (with respect to **8**). Analytical and NMR data of the sublimate were identical to those of the species before sublimation. The behaviour observed in solution suggests that sublimation of **8** proceeds with partial dissociation into monomer **8b**, which might be responsible of the additional bands observed in the FT-IR at 1001, 917, 653, and 540 cm^{-1}. Yttrium is hepta-coordinated in both species **8a** and **8b**, but the Y−N coordination bonds are probably less labile in **8a** than **8b**, and this might explain the higher hydrolytic susceptibility of the compound in solution.

Molecular Structures of $[BaCu(thd)_2(Otamp)_2(H_2O)]$ and of $[PrCu(thd)_2(\mu,\eta^2\text{-}OR^n)_2]$

The structure of **1** corresponds to $[BaCu(\eta^2\text{-thd})_2(\mu,\eta^3\text{-Otamp})(\mu,\eta^2\text{-Otamp})(H_2O)]$ as depicted in Figure 1. Despite the limited number of reflections, the connectivity between the atoms could be established unambiguously. The most salient feature is the presence of a water molecule in the coordination sphere of barium. Barium and copper are clamped together by two aryloxide ligands. These display different coordination behaviours, one is bidentate (μ,η^2-), the other is tridentate (μ,η^3-). The Ba···Cu distance of 3.680(3) Å is comparable to the value reported for other Ba−Cu β-diketonatoalkoxides.[6] Barium surrounded by two NMe_2 groups (one of each Otamp ligand) and five oxygen atoms due to a chelating tetramethylheptanedionate. It is thus hepta-coordinated, with a distorted pentagonal-bipyramidal stereochemistry, the nitrogen atoms being in apical positions. Copper is five-coordinated with a tetragonal-pyramidal surrounding, and also bears a chelating tetramethylheptanedionate ligand. The Cu−O bond lengths vary from 1.89(1) to 2.11(2) Å. The longest one corresponds to Cu−O(5). The disymmetrical linkage of the thd ligand is most probably due to the elongation of the Cu−O(5) bond − with respect to the Cu−O(6) one − by Jahn−Teller effect, as commonly observed for copper.[9,17] The Ba−O distances are spread over the range 2.57(2) to 2.67(1) Å. The Ba−O(tamp) bond lengths are comparable to the values reported in the literature for aryloxides.[18] They are slightly shorter when the ligand is tridentate [Ba−O(1) 2.62(1) to compare to Ba−O(2) 2.67(1) Å and Cu−O(1) = 1.92(1) vs 1.99(1) Å for Cu−O(2)]. The Ba−N coordination bonds [2.97(2) Å av.] are longer than the Ba−O ones, but in agreement with the data reported in the literature for other barium derivatives such as $Ba_4O(Otamp)_6$ [19] or $[Ba_2Cu(thd)_4(OR^N)_2(i\text{PrOH})_2]$.[9] The Cu−N distance of 2.14(2) Å is comparable to the values observed for other Cu^{II} aminoalkoxides.[15] The short contacts between O(7)(H_2O) and two dangling nitrogen atoms of the aryloxide ligand [O(7)···N(4) 2.72 Å and O(7)···N(1) 2.79 Å, respectively] indicate the presence of intra- and intermolecular hydrogen bonding.[20] These observations are supported by a broad absorption band at 3162 cm^{-1} in the infrared spectra, and account for the poor volatility. The presence of water is most probably due to the hygroscopic phenol, as previously observed for $Pr(Otamp)_3(H_2O)_2$.[21] It also indicates that **1** is relatively stable toward hydrolysis. A number of Ba−Cu species of various stoichiometries have been reported.[8,9] Those having a 1:1 stoichiometry are usually tetranuclear species such as $[Ba_2Cu_2(\beta\text{-diket})_4(OC_2H_4OMe)_4(OHC_2H_4OMe)_2]$ (β-diket = acac, thd), in which copper is planar whereas barium is 7-coordinate.[8] The presence of one Otamp ligand acting as a tetradentate ligand and water as additional ligand allows barium to reach hepta-coordination in a monomeric unit.

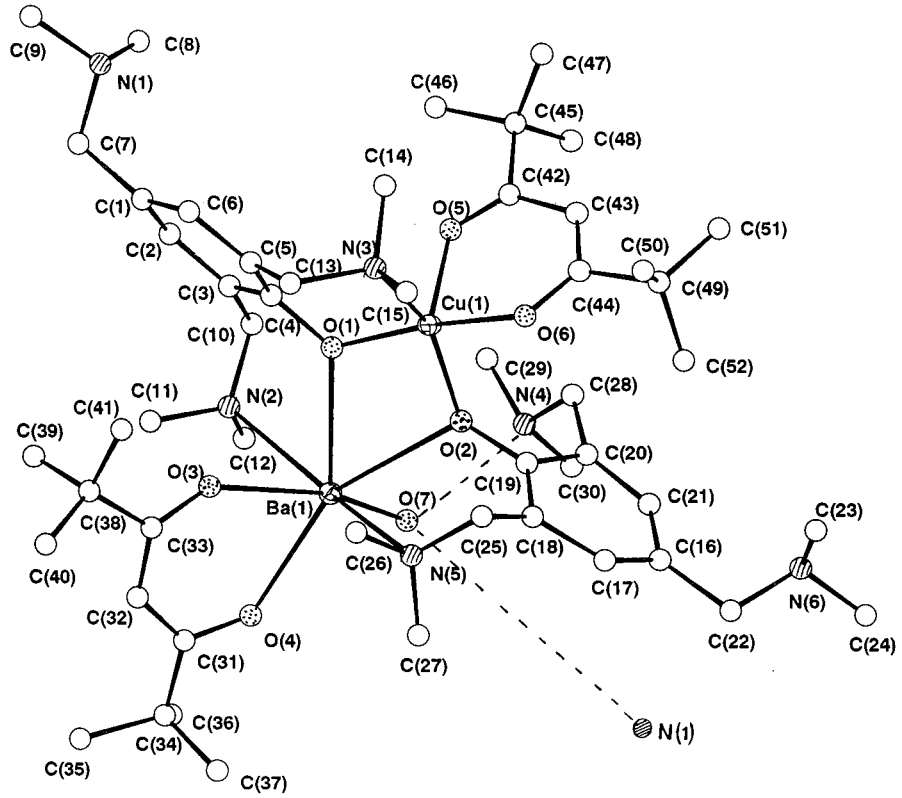


Figure 1. Molecular structure of $[BaCu(\eta^2thd)_2(Otamp)_2(H_2O)]$ showing the atom numbering scheme (dotted lines indicate H bonding)

Compound **4** is obtained by the self-assembly between $Cu(OR^n)_2$ and $Pr(thd)_3$. Its molecular structure $[PrCu(\eta^2\text{-}thd)_3(\mu,\eta^2\text{-}OR^n)_2]$ is depicted in Figure 2. Selected bond lengths and angles are collected in Table 2. From a structural point of view it can be considered as the assembly between $Pr(thd)_2(OR^n)$ and $Cu(thd)(OR^n)$ moieties. These

units are connected by the O centre of the aminoalkoxide ligand, the pendant amino functionalities being both linked to the praseodymium atom. Praseodymium is thus eight-coordinated with a bipyramidal hexagonal geometry, in which the nitrogen atoms occupy the axial positions. Copper has a square-planar distorted surrounding. The Pr···Cu distance has a value of 3.345(1) Å, comparable to those observed for $[PrCuL(hfac)_2(O_2CCF_3)(R'^NOH)_2]$[22] [L = 2-methyl-2,4,6-tris(trifluoromethyl)-1,3-dioxane-4,6-diolato] and $[PrCu(OH)(hfac)_3(bdmmp)(bdmmpH)]$[16] [bdmmp = 2,6-bis(dimethylaminomethyl)-4-methylphenoxide]. The Pr−O bond lengths are spread over the range 2.367(1) to 2.460(7) Å, they vary according to the generalisation: Pr−μOR < Pr−O(thd), in agreement with the literature.[22−24] The Pr−N coordination bonds are considerably longer [2.695(9) Å] as reported previously.[16,21,22,25] The Cu−O bond lengths are similar for the tetramethylheptanedionate as well as the bridging alkoxide ligands [1.896(7)−1.9101(7) Å].[17] The bite angles of the thd and aminoalkoxide ligands are also similar with values of 67.3(2)° and 65.5(2)°, respectively.

Molecular Structure of $[Y_2(\eta^2\text{-thd})_4(\mu,\eta^2\text{-OR}'^N)_2]$

The structure of **8** is that of a centrosymmetric dimer $[Y_2(\eta^2\text{-thd})_4(\mu,\eta^2\text{-OR}'^N)_2]$ (Figure 3, Table 3). The yttrium atoms are hepta-coordinated, and are connected by two bridging-chelating aminoalkoxide ligands with one NMe_2 of each alkoxide ligand remaining pendant (Y···N distance of 5.22 Å). The Y···Y non-bond length has a value of 3.739(2) Å, comparable to that observed for other dinuclear yttrium species such as $[Y_2(O_2CCF_3)_6(OR'^N_2)]^{2-}$ [25], or polynuclear clusters.[12] The OR'^N ligand is generally tridentate − both NMe_2 sites interacting with the metallic centres. The only example of a μ,η^2-coordination mode is that of $Cu_2Cl_4(R'^NOH)_2$.[26] Although octa-coordination has been achieved for yttrium in β-diketonatoalkoxides such as $[Y_3(acac)_4(OC_2H_4OMe)_5]$,[27] the steric hindrance of the tetramethylheptanedionate ligands probably precludes coordination of the second N-donor site for **8**. The Y−O bond lengths are spread over the range 2.236(5) to 2.307(5) Å. These values are in agreement with the literature.[28] The Y−O−Y bridge is unsymmetrical, the intra-chelate Y−O(5′) distance being about 0.069 Å longer than Y−O(5). The Y(1)−N(1) coordination bond of 2.544(7) Å is in the range of the values observed.[25,29]The structure of **8** is related to that of $[Y(\mu,\eta^2\text{-OAc})(acac)_2(H_2O)]_2$ [30] and of $[Pr(hfac)_2(\mu,\eta^3\text{-OR}'^N)(H_2O)(THF)]_2$.[22] However, the larger ionic radius of praseodymium (1.013 Å as compared to 0.880 Å for Y) allows the metal to attain nona-coordination via a tridentate assembling coordination mode of the aminoalkoxide ligand and two additional neutral ligands.

Physical Properties: Solubility and Volatility Data

A general observation for these mixed-metal species is, as anticipated, an increase in solubility as well as a better stability toward ambient atmosphere. For instance, whereas soluble copper alkoxides are highly moisture-sensitive and the praseodymium tetramethylheptanedionate hygroscopic, **4** is air-stable. Stability to ambient atmosphere was also achieved for **1**, **5**, and **6**.

The Ba−Cu species **1** is soluble in polar, as well as non-polar media. It is stable in solvents such as diglyme (UV evidence). It is non-volatile. The TGA analysis shows a first weight loss in the 95−125 °C temperature range, due to the elimination of the water ligand. An aminophenoxide ligand is eliminated at 170−280 °C. Two identical weight losses are observed between 280−550 °C. They correspond to the elimination of the two tetramethylheptanedionate ligands. The last Otamp ligand is only partially decomposed between 550 and 970 °C. Thus, despite a quite low onset of decomposition for an aryloxide, the amount of a residue (ca. 38%) is quite higher than that expected for $BaCuO_2$ (20.9%).

The heterometallic species MCu_2 and MCu were soluble in aliphatic or aromatic hydrocarbons, or ethers such as THF or diethyl ether, but only slightly in diglyme. The M−Cu species **4**, **5**, and **6** sublime at 155 °C/10^{-4}, 130 °C/10^{-4}, and 150 °C/10^{-4} Torr, respectively. They are the first volatile Ln−Cu or Y−Cu species not supported by fluorinated ligands. It is noticeable that none of the Pr−Cu and Pr species with related aminoalkoxide ligands such as $[PrCu(OH)(hfac)_3(bdmmp)(bdmmpH)]$ and $[Pr(hfac)_2(OR'^N)(H_2O)(THF)_2]$ were volatile, despite the presence of the fluorinated diketonate in the coordination sphere.[25,26] The thermal behaviour of the novel M−Cu species was analysed by TGA under nitrogen (1 atm). The amount of

[a] Atoms labelled with ′ are connected by an inversion centre.

residues obtained for the Y−Cu species **3** and **6** are lower than the values expected for $Y_2Cu_4O_7$ (24.3%) and $Y_2Cu_2O_5$ (21.5%), respectively. Partial sublimation has thus occurred during the TGA experiments. A similar thermal behaviour was observed for the praseodymium−copper species **2**, **4**, and **5**. The properties of the bimetallic Pr−Cu and Y−Cu species are compatible with their use in conventional as well as liquid delivery MOCVD techniques.

The homometallic species based on the OR'^{N} ligand display quite limited solubility, even in polar solvents (THF, diglyme). Both **8** and **7** are volatile. The yttrium species sublimes at 215−220 °C/10^{-3} Torr. This temperature is quite high, but in agreement with the dimeric character and thus a relatively high molecular weight.[6] The TGA profile accounts for sublimation up to 350 °C. By contrast with the barium derivative, it is air-stable in the solid state (FT-IR evidence). $[Ba(OR'^{N})(thd)(HOR'^{N})]$ distils as the adduct at 130 °C/10^{-3} Torr, it is thus one of the most volatile barium species reported to date.[4] The TGA analysis indicates a first weight loss from 120 to 245 °C, corresponding to the elimination of the coordinated alcohol. The second weight loss between 245 and 375 °C is due to the elimination of the aminoalkoxide ligand, the thd ligand is decomposed partially, leading to a $BaCO_3$ residue. Although no carbonate was observed under reduced pressure, the high moisture sensitivity of the compound is a hurdle. $[Ba(tdfnd)_2(H_2O)]_m$ and $[Ba(tdfnd)_2(diglyme)]$ [tdfndH = $C_3F_7C(O)CH_2C(O)C_3F_7$ = tetradecafluorononane-4,6-dione], which are liquid at the temperature of use and could be repeatedly transported in the vapour without decomposition, remain the most attractive Ba species for Ba oxide, along with BaF_2.[31]

Experimental Section

All reactions were performed under an inert atmosphere using Schlenk tube techniques. Solvents were dried and purified by distillation. $M(thd)_3$ (M = Y, Pr),[32] $Ba_4O(Otamp)_6$,[19] $Ba[N(SiMe_3)_2]_2$ [33] and Cu aminoalkoxides[15]were obtained according to literature methods. $Ba(OR'N)_2$ was prepared by alcoholysis of the silylamide. $Pr(thd)_2(OR^n)$ was obtained by alcoholysis of Pr silyl-

amide followed by reaction with thdH. ^{1}H- and ^{13}C-NMR, and FT-IR spectra were run with Bruker AC-200 and IR-FTS 45 spectrometers, respectively. IR spectra were obtained as Nujol mulls. ESR spectra were done with a Bruker spectrometer. Analyses were obtained from the Centre de Microanalyses du CNRS. TGA analyses were done under nitrogen with a Setaram system using a temperature ramp of 5 °C/min. FT-IR data are collected in Table 1.

$BaCu(thd)_2(Otamp)_2(H_2O)$ (1): A solution of $[Ba(thd)_2]_4$ (2.80 g, 1.39 mmol) in 20 mL of hexane was added to $Cu(Otamp)_2$ (5.50 mmol) in 20 mL of hexane. The solution turned rapidly from blue to green and was concentrated to dryness after 17 h. The crude solid was recrystallized in diethyl ether at −25 °C (4.90 g, 80%). Compound **1** was very soluble in polar and nonpolar solvents. − $C_{52}H_{92}BaCuN_6O_7$: calcd. C 56.05, H 8.32, Ba 12.33, Cu 5.70; C 56.32, H 8.42, Ba 12.35, Cu 5.70. − ESR (solid, 20 °C): $<g>$ = 2.14; $<A>$ = 106 G. − TGA (N_2, 1 atm): 95−125 °C (− H_2O), 170−280 °C (− tampOH), 280−400 °C (− thdH), 400−500 °C (− thd), 550−970 − OH, residue 38%. A similar procedure applied to $Cu(thd)_2$ (0.37 g, 0.85 mmol) and $Ba_4O(Otamp)_6$ (0.46 g, 0.2 mmol) gave **1** (0.57 g, 60%).

$MCu_2(thd)_3(OR^n)_4$ [M = Pr (2), Y(3)]: $Pr(thd)_2(OR^n)$ (1.11 g, 1.96 mmol) in 20 mL of hexane was added to $Cu(OR^n)_2$ (0.93 g, 3.88 mmol) in 10 mL of hexane. $Cu(OR^n)_2$ dissolved. Compound **2** was isolated as needles by crystallisation (1.36 g, 63%). − $C_{49}H_{97}Cu_2N_4O_{10}Pr$: calcd. C 50.28, H 8.28, Cu 10.86, N 4.78, Pr 12.04; found C 49.80, H 8.12, Cu 10.92, N 4.84, Pr 12.35. − ESR (hexane, 20 °C): $<g>$ = 2.12; $<A>$ = 79.3 G. − Crystal data (−100 °C): a = 9.806(3), b = 19.792(6), c = 31.535(7) Å, α = β = γ = 90°. − Same procedure applied to $Y(thd)_3$ (1.06 mmol, 25 mL of hexane) and $Cu(OR^n)_2$ (2.12 mmol, 10 mL of hexane) gave **3** (1.02 g, 87%). − $C_{49}H_{97}Cu_2N_4O_{10}Y$ (***mol. mass?***): calcd. C 52.63, H 8.74, Cu 11.36, N 5.01, Y 7.95; found C 52.66, H 8.7, Cu 10.50, N 4.74, Y 7.50. − ESR (hexane, 20 °C): $<g>$ = 2.10; $<A>$ = 92.4 G. − TGA (N_2, 1 atm, °C): 155−230 (− 3 × R^NOH), 230−315 (− R^NOH − 2 × thd), 315−470 (− thd), residue 19.5%.

$PrCu(thd)_3(OR)_2$ [R = R^n (4), R^N (5)] and $YCu(thd)_3(OR^N)_2$ (6): Same procedure as for **2** applied to 0.10 g of $Cu(OR^n)_2$ (0.41 mmol) in 5 mL of hexane and $[Pr(thd)_3]_2$ (0.29 g, 0.21 mmol) in 12 mL of hexane gave **4** as needles (0.37 g, 94%). − $C_{41}H_{77}CuN_2O_8Pr$: calcd. C 52.91, H 8.27, Cu 6.80, N 3.00, Pr 15.10; found C 53.88, H 8.31, Cu 6.9, N 3.13, Pr 14.600. − ESR (hexane, 20 °C): $<g>$ = 2.10; $<A>$ = 78.6 G. − TGA (N_2, 1 atm, °C): 190−235 (− 2 × R^NOH), 235−365 (− 2.5 × thd), 365−550 (− 0.5 × thd), residue 21.8%. − $[Pr(thd)_3]_2$ (0.30 g, 0.21 mmol) in 20 mL of hexane added to $Cu(OR^N)_2$ (0.12 g, 0.43 mmol) in 10 mL of hexane gave **5** (0.38 g, 92%). This could also be obtained from $Pr(thd)_2(OR^N)$ and $Cu(OR^N)_2$ (1:1 stoichiometry), but in lower yield (61%). − $C_{43}H_{81}CuN_2O_8Pr$: calcd. C 53.87, H 8.45, Cu 6.62, N 2.92, Pr 14.69; found C 53.52, H 8.42, Cu 6.95, N 2.72, Pr 15.30. − ESR (hexane, 20 °C): $<g>$ = 2.18; $<A>$ = 86.2 G. − TGA (N_2, 1 atm): 125−220 °C (− 2 × R^NOH), 220−360 (− 2 × thd), 360−600 (− thd), residue 23%. − $Y(thd)_3$ (0.69 g, 1.08 mmol) in 20 mL of hexane added to $Cu(OR^N)_2$ (0.29 g, 1.08 mmol) in 10 mL of hexane gave **6** (0.87 g, 90%). Compound **6** was also obtained by reacting $Y(thd)_2(OR^N)$ and $Cu(OR^N)_2$ (1:1) in hexane (50%). − $C_{43}H_{81}CuN_2O_8Y$: calcd. C 56.97, H 9.01, Cu 7.01, N 3.09, Y 9.81; found C

56.76, H 9.06, Cu 7.18, N 3.07, Y 9.97. − ESR (hexane, 20 °C): $<g> = 2.08$; $<A> = 92.4$ G. − Compounds **4**, **5**, and **6** are soluble in hexane, toluene, diethyl ether, and THF, and slightly soluble in diglyme.

Ba(thd)(OR′^{N})(HOR′^{N}) (7): A solution of thdH (0.43 g, 2.34 mmol) in 5 mL of THF was added to a suspension of $Ba(OR'^N)_2$ (1.07 g, 2.34 mmol) in 35 mL of THF. Rapid dissolution was observed. The solid obtained by concentrating to dryness was recrystallised in hexane to yield compound **7** (1.36 g, 95%). Dist. 120−130 °C/10^{-3} Torr. − Soluble in usual solvents (hexane, toluene, diethyl ether, THF). − $C_{25}H_{54}BaN_4O_4$: calcd. C 49.05, H 8.82, N 9.15; found C 49.03, H 8.85, N 9.10. − ^{1}H NMR ($CDCl_3$, 20 °C): δ = 5.52, 5.47, 5.44 [s, 1 H, CH(thd)], 5.0 (br, 1 H, OH), 3.91 [s, br, 2 H, CH(OR′^{N})], 2.25 (m, 32 H, CH_2NMe_2), 1.08, 1.06 and 1.02 (s, 18 H, *t*Bu). − ^{13}C{^{1}H} NMR (C_7D_8, 28 mg/mL, 20 °C): δ = 197.3 (C=O), 88.5 [CH(thd)], 67.1 [CH(OR′^{N})], 66.2 (CH_2), 45.9 (NMe_2), 41.3 [C(*t*Bu)], 29.5 [Me(*t*Bu)]. − TGA (N_2, 1 atm): 120−245 °C (− R′^{N}OH), 245−375 (− R′^{N}OH), 375−970 (decomposition of thd), residue 34%. − Crystal data (20 °C): a = 10.652(2), b = 16.006(2), c = 19.486(3) Å, α = β = 97.03(1)°, γ = 90°.

[Y(thd)$_2$(OR′^{N})]$_2$ (8): $Y(thd)_3$ (1.24 g 1.94 mmol) in 35 mL of hexane was added to a suspension of $Ba(OR'^N)_2$ (1.94 mmol, 0.83 g) in 25 mL of hexane. $Ba(OR'^N)_2$ dissolved after 15 min. Compound **8** was isolated by crystallisation (1.11 g, 96%). It sublimes at 215−220 °C/10^{-3} Torr and is only slightly soluble even in polar solvents (acetonitrile, acetone, THF). − Compound **8** could also be obtained from Ba(thd)(OR′^{N})(HOR′^{N}) (0.15 mmol) and $Y(thd)_3$ (0.15 mmol) in 15 mL of hexane (80 mg, 90%). − $C_{58}H_{110}N_4O_{10}Y_2$: calcd. C 57.99, H 9.23, N 4.66; found C 57.22, H 9.01, N 4.50. − ^{1}H NMR ($CDCl_3$, 20 °C): δ = 5.67, 5.59 [s, 4 H, CH(thd)], 4.48 (m, J = 10.9 Hz), 4.21 (quint, J = 5.6 Hz), 3.67 [sept, J = 4.1 Hz, 2 H, CH (OR′^{N}, R′^{N}OH)], 3.67 [s, br, OH (R′^{N}OH)], 2.9, 1.9 (32 H, CH_2NMe_2), 1.09, 1.05 (s, 72 H, *t*Bu). − TGA (1 atm): sublimation between 225−400 °C.

X-ray Structure Determination for 1, 4, and 8: Suitable crystals were obtained from the reaction medium for **1** and **8**, and by recrystallisation in Et_2O for **4**, and were mounted onto an Enraf−Nonius CAD-4 automatic diffractometer. The unit cell parameters and basic information about data collection and structure refinement are given in Table 4. Accurate lattice parameters and orientation matrix were obtained from least-squares refinements of the setting angles of 25 well-centred reflections. The intensities of two standard reflections monitored every hour showed no decay. Corrections for Lorentz and polarization effects were applied. Computations were performed using the PC version of CRYSTALS.[34] Scattering factors and corrections for anomalous dispersion were taken from ref.[35] Structures were solved using direct methods (SHELXS)[36] and standard Fourier techniques. All non-hydrogen atoms were refined anisotropically for **4** and **8**, and only Ba and Cu were anisotropically refined for **1**, in view of the limited number of data. In addition, only a partial structure report will be given. Hydrogen atoms were calculated and included as fixed contributors in the last refinement. Models converged for the R and R_w values in Table 4. Tables of atomic coordinates, of thermal parameters, of non-essential bond lengths and angles for the structures reported have been deposited at Cambridge Crystallographic Data Centre. CCDC reference numbers for **1**, **4**, and **8**: 137676, 137675, and 101724. Copies of the data are available free of charge on application to CCDC 12 Union Road Cambridge CB2 IEZ, UK [Fax: (internat.) + 44-1223/336-033].

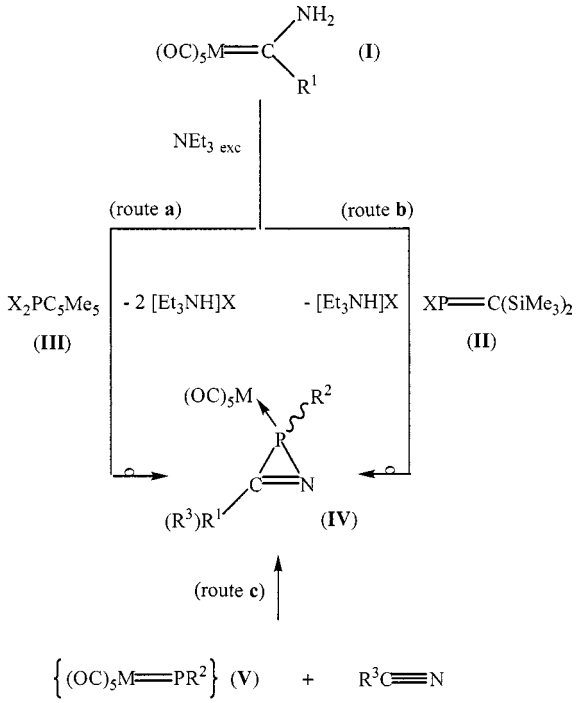
Chemistry of 2*H*-Azaphosphirene Complexes, 20[‡]

Study on the Ring Formation of 2*H*-Azaphosphirene Complexes Using Sterically Demanding *C*-2,4,6-Trialkylphenyl-Substituted Aminocarbene Tungsten Complexes − Detection of a Key Intermediate

Rainer Streubel,*[a] Siegfried Priemer,[a] Frank Ruthe,[a] and Peter G. Jones[a]



Dedicated to Professor Gerd Becker on the occasion of his 60th birthday

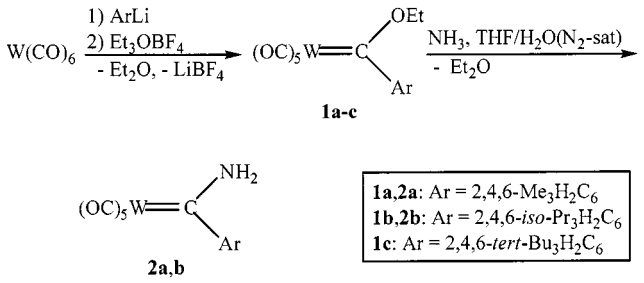
Keywords: Phosphorus heterocycles / 2*H*-Azaphosphirene complexes / Carbene complexes / Tungsten / Cyclizations

The synthesis of *C*-2,4,6-trialkylphenyl-substituted ethoxy- and aminocarbene tungsten complexes **1a–c** (R = Me, *i*Pr and *t*Bu) and **2a,b** (R = Me, *i*Pr) and the reaction of **2a,b** with [bis(trimethylsilyl)methylene]chlorophosphane (**3**) in the presence of triethylamine is reported. The reaction course, which finally leads to the 2*H*-azaphosphirene complexes **7a,b**, depends strictly on the steric demands of the aryl group bonded to the carbene atom; only in the case of complex **2a** was a dinuclear tungsten carbene complex formed, which was isolated and characterized by single crystal X-ray diffraction. Relative to phenyl-substituted derivatives, the 2*H*-azaphosphirene complexes **7a,b** showed enhanced reactivity towards triethylammonium chloride, furnishing the [bis(trimethylsilyl)methyl]chlorophosphane complex **8**. Condensation of **8** with complex **2a** afforded the novel dinuclear tungsten complex **9a** containing an acyclic C,N,P structural unit with a κ-C and a κ-P coordination mode; an H-bonded adduct of complex **9a** and mesitylnitrile, complex **10**, was investigated by single crystal X-ray diffraction.

Introduction

Two routes are currently known to provide access to 2*H*-azaphosphirene complexes (**IV**) (Scheme 1). The first utilises a rearrangement cascade starting from aminocarbene complexes (**I**) and either [bis(trimethylsilyl)methylene]halophosphanes (**II**) (X = Cl,[2] Br[3]) (route **a**) or alkyldihalophosphanes (**III**) (X = Cl, R = C_5Me_5[4]) (route **b**) in the presence of triethylamine. The second, a [2+1] cycloaddition reaction[5] of an electrophilic terminal phosphanediyl complex (**V**) with dialkylamino nitriles (R = R_2N) (route **c**) was detected quite recently and is especially useful for 3-donor-atom-substituted 2*H*-azaphosphirene complexes that cannot be obtained from routes **a** or **b**. Because of the increasing synthetic usefulness of 2*H*-azaphosphirene complexes as starting material for unsaturated three-,[6] four-[7] and five[5,8]-membered monocyclic and polycyclic[9] P-heterocycle complexes, we were interested in obtaining further insight into the ring forming process of 2*H*-azaphosphirene complexes based on route **a**.

Scheme 1. Routes to 2*H*-azaphosphirene metal complexes **IV** (M = Cr, Mo, W; R, R′ = alkyl, aryl)



Results and Discussion

Our former investigations of the rearrangement cascade leading to 2*H*-azaphosphirene complexes (route **a**) had already shown that, in the case of a chromium complex, a transiently formed 2-aza-1-phospha-4-chroma-1,3-butadiene derivative could be trapped by addition of the NH function of [(aminobenzylidene)pentacarbonylchromium(0)] to

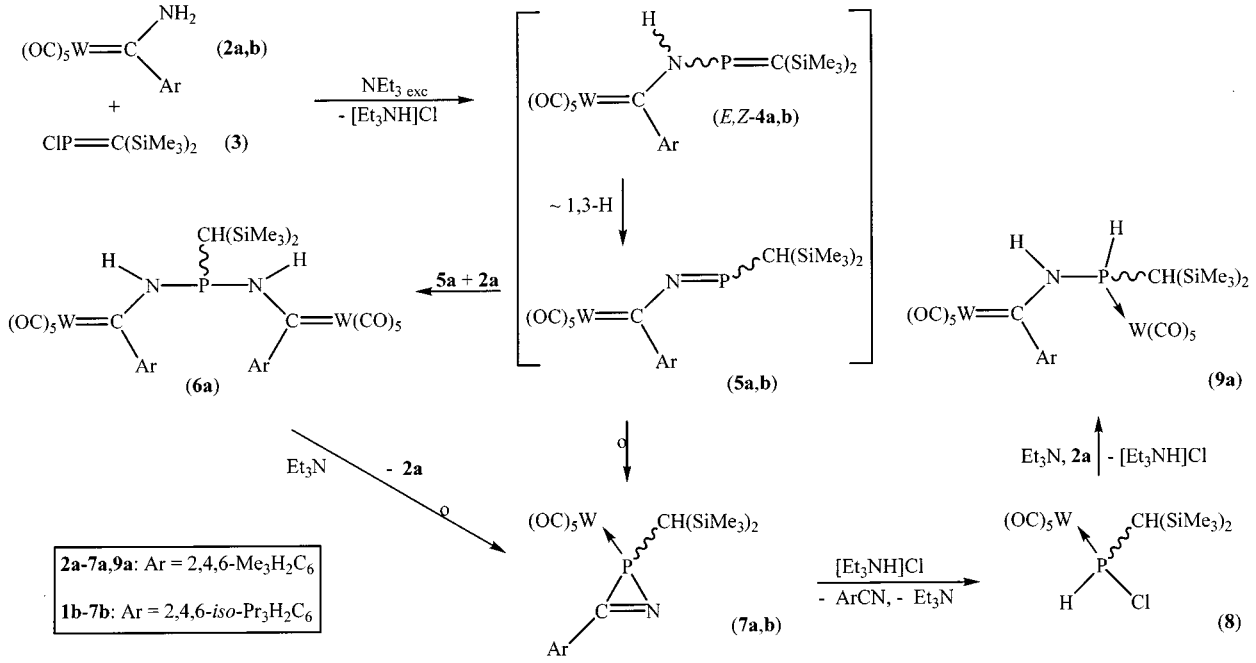
Scheme 2. Synthesis of carbene complexes **1a−c** and **2a,b** with sterically demanding aryl groups

the P−N double bond of the reactive intermediate, giving a dinuclear *N,N′*-PR-bridged carbene chromium complex.[2c] We suggested that this depends mainly on the lifetime of such metallaheterobutadiene intermediates, which should be enhanced by sterically demanding and thus kinetically protecting groups at either the metal or the carbene centre, especially if the rearrangement is truly intramolecular and the ligand does not dissociate prior to the formation of the three-membered ring. Therefore, we decided to investigate the rearrangement route **a** by employing sterically demanding *C*-2,4,6-trialkylphenyl-substituted aminocarbene complexes.



Whereas the ethoxy(aryl)carbene complexes **1a−c** were accessible by reacting aryllithium derivatives, prepared in situ, and hexacarbonyltungsten under standard conditions[10] (Scheme 2), the amino(aryl)carbene complexes **2a**,**b** were obtained only with difficulty by ammonolysis of **1a**,**b** in a 12:1 mixture of THF and a concentrated NH_3/water solution. Even after six weeks under these rather severe conditions (relative to standard procedures[10]) complex **2c** was not formed. The observation that bulky substituted alkoxy(alkyl/aryl)carbene complexes have low reaction rates and/or are remarkably inert in ether towards ammonia had already been reported; this reactivity was explained by their fourth-order reaction rate law.[10]

We therefore reacted, under standard conditions,[2] the *C*-2,4,6-trialkylphenyl-substituted aminocarbene complexes **2a**,**b** and [bis(trimethylsilyl)methylene]chlorophosphane[11] (**3**) in ether in the presence of an excess of triethylamine; the assumed reaction course is shown in Scheme 3. In the case of complex **2a** we obtained a mixture of various phosphorus-containing products, whereby the complexes **6a**, **7a**, **8** and **9a** were final products and the ^{31}P resonances of two transient species at δ = 305 and 330 were assigned to the *E*/*Z*-isomers of complex **4a** (ratio 1:1). Lowering the concentration of this reaction led to the preferred formation of complexes **8** and **9a** (ratio 1:2). It is also noteworthy that complex **6a** was only slowly transformed by base to the 2*H*-azaphosphirene complex **7a**. Whereas complexes **6a**, **8** and **9a** could be isolated in pure form by low temperature column chromatography, complex **7a** decomposed during the chromatographic separation. Nevertheless, a **7a**-enriched solution was obtained by twofold extraction of the reaction mixture with *n*-pentane at low temperature and, therefore, complex **7a** could be unambiguously characterized by ^{13}C and ^{31}P NMR spectroscopy of this solution. The nature of complexes **6a** and **9a** was also confirmed by X-ray analyses, but, to our surprise, complex **9a** crystallised only as the mesitylnitrile adduct **10**.

In the case of complex **2b**, the reaction with **3** in ether was significantly different; ^{31}P NMR spectroscopy revealed completeness of the reaction after ≈20 h, but the only phosphorus-containing product was complex **8**. Repeating the reaction in dichloromethane gave a different picture. Apart from intermediates at δ = 300 and 329 (*E*/*Z* complexes of **4b**), **7b** and **8**, another intermediate compound was formed in relatively large amounts and could be observed throughout the whole reaction, which was complete after ≈2.5 h (Figure 1). This intermediate decreased in favour of the 2*H*-azaphosphirene complex **7b** and the complex **8**, which is formed by a subsequent fast reaction of **7b** with $[Et_3NH]Cl$;[2] the marked tendency of complex **7b** to undergo this reaction is remarkable. Complex **7b** was characterized by its typical ^{31}P NMR parameters [δ = −121.7 (s, $|^1J(W,P)|$ = 303.3 Hz], but could not be isolated either by low temperature column chromatography or by an extraction procedure (see above).

The ^{31}P resonance of this new intermediate at δ = 183.3 is *not* in agreement with either a compound having a free or tungsten-coordinated $P{=}C(SiMe_3)_2$ structural unit,[12] or with analogues of complexes **6a** or **9a**. Assuming that the rearrangement cascade proceeds intramolecularly[13] two conceivable structures for this intermediate remain: complex **5b**, with the 2-aza-1-phospha-4-tungsta-1,3-butadiene moiety (or its zwitterion analogue **5b′**), and the zwitterionic complex **11** with the phosphorus atom incorporated in a three-membered ring with a partially formed P−N double bond.[14] Although the assignment of the NMR spectroscopic data to complex **5b** (**5b′**) seems more plausible, complex **11** cannot be completely excluded (Figure 2). Subsequent intramolecular rearrangements such as a nucleophilic attack of the phosphorus at the "carbene" centre in **5b**/**5b′** (thus forming complex **11**) or a shift of the pentacarbonyltungsten group in **11** from carbon to phosphorus (thus forming complex **7b**) are possible; such rearrangements, however, should be significantly hindered by bulky substituents at the "carbene" centre.

Elemental analyses and IR, MS and NMR spectroscopic data confirm unambiguously the proposed structures of the complexes **1a−c**, **2a,b**, **6a**, **7a**, **8** and **9a**. In particular, for **1a−c**, **2a,b**, **6a** and **9a** the carbene atom resonances, which are observed at low field, are of interest. In the case of the ethoxy-substituted carbene complexes, enhancement of the steric demand of the aryl substituent leads to a deshielding of the carbene atom (**1a**: δ = 334.8; **1b**: δ = 337.2; **1c**: δ = 341.2). This is just the opposite of the expected electronic influence of these aryl groups on the carbene atom. For complexes **2a**, **6a** and **9a** a deshielding of the carbene atoms was also observed [**2a**: δ = 276.2; **6a**: δ = 283.1 and 301.0 ($|^2J(P,C)|$ = 4.2 Hz); **9a**: δ = 288.3 ($|^2J(P,C)|$ = 14.3 Hz)]. Taking into account that the aryl substitution does not effect the aminocarbene resonance (**2b**: δ = 276.1), the formal substitution of an N−H function in **2a** by a PR_2 or a $PR_2W(CO)_5$ moiety influences the chemical shift of the car-

Scheme 3. Formation of 2*H*-azaphosphirene complexes **7a**,**b** and subsequent reactions

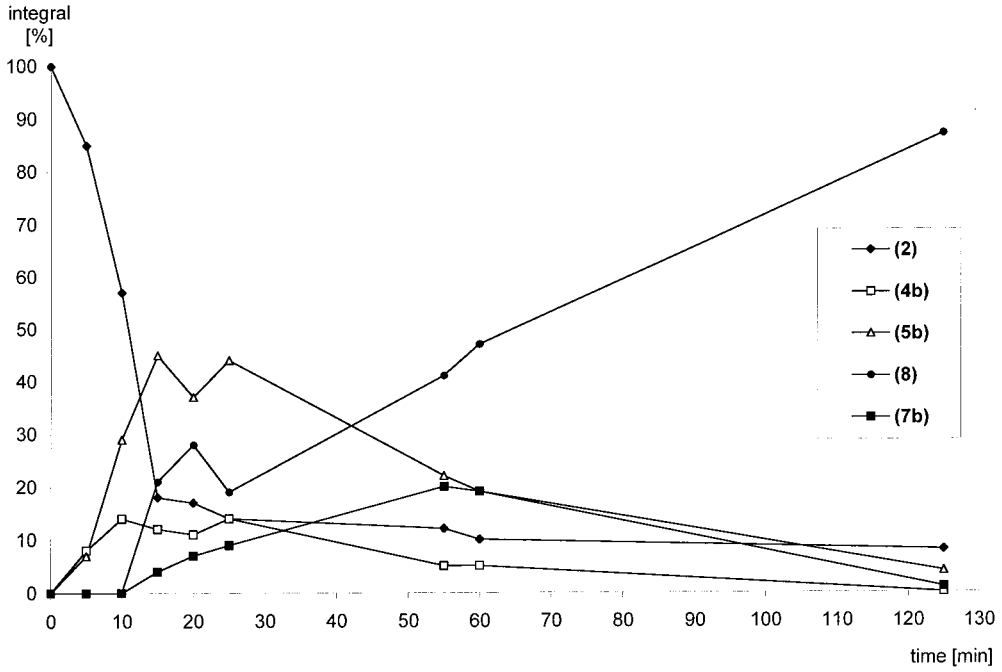


Figure 1. ^{31}P NMR monitoring of the reaction of complex **2b** with **3**

bene atoms mainly electronically. The observation of two magnetically nonequivalent carbene atoms in complex **6a** points to a remarkable intramolecular steric crowding and is so far unique.[2] This special steric situation also explains the relative stability of complex **6a** towards base-induced elimination to form complex **7a**. The P−H functions of complexes **8** and **9a** are well established by their phosphorus−proton coupling constants of $|^1J(P,H)|$ = 349.4 and 378.9 Hz, respectively. It is also remarkable that the two isotopomers of complex **8** could be distinguished by ^{31}P NMR spectroscopy (CH_2Cl_2; at 121.5 instead of 81.0 MHz) [**8**(^{35}Cl): δ = 53.23 ($|^1J(W,P)|$ = 268.38 Hz); **8**(^{37}Cl): δ = 53.3 ($|^1J(W,P)|$ = 268.80 Hz]. EI-MS experiments showed that all complexes analyzed predominantly lost carbon monoxide subsequent to the ionisation process.

The molecular structure of complex **6a**, as determined by X-ray crystallography (Figure 3), consists of two ($Me_3Si)_2HCP$-bridged amino(aryl)carbene complex moieties, which have an *E,E*-configuration of the pentacarbonyltungsten and the $(Me_3Si)_2HCP$ fragment with respect to the

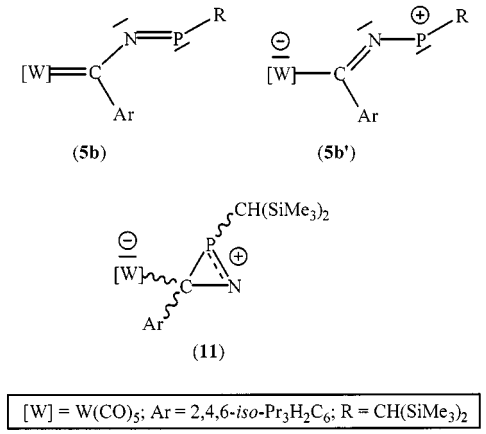

Figure 2. Plausible structures of the new intermediate in the 2*H*-azaphosphirene complex ring forming process

C−N bond, and which differ somewhat in the metal−carbon and nitrogen−phosphorus bond lengths of their nearly planar W−C−P−N skeletons [torsion angles: W(1)−C(28)−N(1)−P = −171°; W(2)−C(18)−N(2)−P = −175°]. The interplanar angle between the W−C−N and the mesityl ring plane [W(1)−C(28)−N(1)/Mes = 89.4° and W(2)−C(18)−N(2)/Mes = 81.9°] excludes any π-electron interactions between the carbene centres and the aryl rings.

The structure of complex **9a** in the mesitylnitrile adduct **10** (Figure 4) is similar with respect to the W−C−N−P subunit [W(2)−C(18)−N(1)−P = 175°] and also to the interplanar angle between the W−C−N and the mesityl ring plane [W(2)−C(18)−N(2)/Mes = 87.9°]. The freely defined hydrogen atoms at nitrogen and phosphorus adopt approximately an *E*-configuration with respect to the N−P bond. Of special interest are the dimensions of the hydrogen bond N(1)−H···N(2) unit: N−H···N = 176(7)°, N(1)···N(2) = 3.049(7) Å, N(1)−H(1) = 0.74(6) Å and N(2)···H(1) = 2.31(7) Å; a similar situation is often found for hydrogen bonds between nitriles and amides.

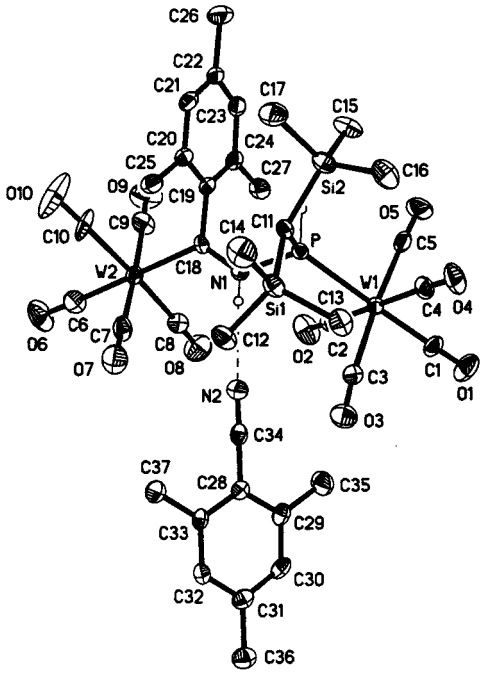

Figure 4. Molecular structure of complex **10** (ellipsoids represent 50% probability level; hydrogen atoms except P−H and N−H are omitted for clarity); selected bond lengths [Å] and angles [°]: W(1)−C(1) 2.015(7), P−W(1) 2.504(2), N(1)−P 1.769(5), P−C(11) 1.820(6), C(18)−N(1) 1.330(7), C(18)−W(2) 2.224(6), W(2)−C(6) 2.017(7); N(1)−C(18)−W(2) 126.7(4), C(18)−N(1)−P 130.1(4)

Experimental Section

General: All operations were carried out under an inert atmosphere of deoxygenated dry nitrogen. Solvents were dried according to standard procedures. − NMR spectra were recorded on a Bruker

AC-200 spectrometer (200 MHz for ^1H; 50.3 MHz for ^{13}C; 81 MHz for ^{31}P) using [D_3]chloroform and [D_6]benzene as solvents, the latter as internal standard, or a Bruker AMX-300 (30.4 MHz for ^{15}N) using dichloromethane as solvent and nitromethane as external standard; shifts are given relative to tetramethylsilane (^1H, ^{13}C), nitromethane (^{15}N) or 85% H_3PO_4 (^{31}P); only coupling constant magnitudes are given. − MS: Finnigan Mat 8430 (70 eV). − Elemental analyses: Carlo Erba analytical gas chromatograph. − IR: Biorad FT-IR-165; only ν(NH) and/or ν(CO) bands are given.

Preparation of {[Ethoxy(2,4,6-trimethylphenyl)carbene]pentacarbonyltungsten(0)} (1a): *n*-Butyllithium (6.25 mL, 1.6 M in *n*-hexane) was added at ambient temperature to a solution of 1-bromo-2,4,6-trimethylbenzene (2.0 g, 10 mmol) in 20 mL diethyl ether. After stirring for 70 min the reaction mixture was added to a suspension of hexacarbonyltungsten (3.5 g, 10 mmol) in 150 mL diethyl ether. The reaction mixture was stirred for 1 hour before the solvent was removed under reduced pressure (0.1 mbar). The residue was dissolved in 80 mL of water and triethyloxonium tetrafluoroborate (2.4 g, 13 mmol) was added in small portions. The mixture was extracted twice with 200 mL of *n*-pentane and the red *n*-pentane phases were filtered through a short column (SiO_2, *n*-pentane). The combined red *n*-pentane phases were concentrated under reduced pressure (0.1 mbar) and the red oily residue was purified by column chromatography (SiO_2, *n*-hexane). Removing the solvent afforded a red oil. The red oil was dissolved in 5 mL of *n*-pentane, the product precipitated at −100 °C and then dried in vacuo to give **1a** (1.95 g, 39%) as an orange powder. M.p. 80 °C (decomp.). − ^1H NMR ($CDCl_3$): δ = 1.65 [t, ^3J(H,H) = 7.10 Hz, 3 H, CH_2-CH_3], 2.17 (s, 6 H, *o*-Ar−CH_3), 2.31 (s, 3 H, *p*-Ar−CH_3), 5.14 [q, ^3J(H,H) = 7.10 Hz, 2 H, O−CH_2], 6.84 (s, 2 H, Ar−*H*3/3′). − $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 14.1 (s, CH_2-CH_3), 19.3 (s, *o*-Ar−*C*H_3), 20.9 (s, *p*-Ar−*C*H_3), 80.7 (s, O*C*H_2), 126.4 (s, Ar−*C*2/2′), 128.8 (s, Ar−*C*3/3′), 137.5 (s, Ar−*C*4), 153.0 (s, Ar−*C*1), 198.0 (s, *cis*-*C*O), 203.7 (s, *trans*-*C*O), 334.8 (s, W=*C*R_2). − IR (KBr) $\tilde{\nu}$ = 2069 (m), 1984 (m), 1951 (s), 1921 (s), 1913 (s) cm^{-1} (CO). − MS (70 eV; ^{184}W): *m*/*z* (%) = 500 (34) [M^+], 472 (40) [M^+ − CO], 444 (31) [M^+ − 2CO], 416 (46) [M^+ − 3CO], 387 (57) [M^+ − 3CO − C_2H_5], 372 (9) [M^+ − 3CO − C_2H_5 − CH_3], 358 (100) [M^+ − 4CO − $2CH_3$]. − $C_{17}H_{16}O_6W$ (500.2): calcd. C 40.82, H 3.22; found C 41.30, H 3.24.

Preparation of {[Amino(2,4,6-trimethylphenyl)carbene]pentacarbonyltungsten(0)} (2a): Ammonia was slowly bubbled through a solution of 3 mmol of the complex **1a** in 60 mL of THF at 0 °C until it was saturated with ammonia. The reaction mixture was stirred for 20 hours at ambient temperature until a yellow colour persisted and thin liquid chromatography (SiO_2) indicated that all starting material had reacted. All volatile compounds were removed under reduced pressure (0.1 mbar) and the yellow residue, was purified by column chromatography (SiO_2, 20 °C; *n*-hexane/diethyl ether 10:1) to give **2a** (1.33 g, 94%) as a yellow powder. M.p. 163 °C (decomp.). − ^1H NMR ($CDCl_3$): δ = 2.23 (s, 6 H, *o*-Ar−*C*H_3), 2.30 (s, 3 H, *p*-Ar−*C*H_3), 6.86 (s, 2 H, Ar−*H*3/3′), 8.64 (s, br, 1 H, N*H*), 8.97 (s, br, 1 H, N*H*). − $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 19.6 (s, *o*-Ar−*C*H_3), 20.8 (s, *p*-Ar−*C*H_3), 127.6 (s, Ar−*C*2/2′), 128.8 (s, Ar−*C*3/3′), 137.0 (s, Ar−*C*4), 149.1 (s, Ar−*C*1), 198.1 [s, ^1J(W,C) = 127.4 Hz, *cis*-*C*O], 203.2 (s, *trans*-*C*O), 276.2 (s, W=*C*R_2). − IR (KBr) $\tilde{\nu}$ = 3404 (m), 3275 (m), 3217 (m) (NH); 2065 (s), 1975 (s), 1913 (s), 1883 (s), 1861 (s) cm^{-1} (CO). − MS (70 eV); ^{184}W): *m*/*z* (%) = 471 (42) [M^+], 443 (26) [M^+ − CO], 415 (18) [M^+ − 2CO], 387 (86) [M^+ − 3CO], 359 (76) [M^+ − 4CO], 329 (100) [(M^+ − 4CO − $2CH_3$], 301 (31) [M^+ − 5CO − $2CH_3$]. − $C_{15}H_{13}NO_5W$ (471.1): calcd. C 38.24, H 2.78, N 2.97; found C 38.46, H 2.83, N 2.91.

General Procedure for the Preparation of (2,4,6-Triisopropylphenyl)- and (2,4,6-Tri-*tert*-butylphenyl)-Substituted {[Ethoxy(aryl)carbene]-pentacarbonyltungsten(0)} Complexes 1b and 1c: *n*-Butyllithium (1.6 molar in *n*-hexane, 6.25 mL) was added at −80 °C to a solution of the 1-bromo-2,4,6-trialkylbenzenes (R = *i*Pr, *t*Bu; 10 mmol) in 20 mL THF. After stirring for 90 min at −80 °C hexacarbonyltungsten (3.5 g, 10 mmol) was added in small portions to the reaction mixture, which was stirred for 18 hours and warmed up to ambient temperature before the solvent was removed under reduced pressure (0.1 mbar). The residue was dissolved in 40 mL of dichloromethane and triethyloxonium tetrafluoroborate (2.4 g, 13 mmol) was added in small portions. The solvent was removed under reduced pressure (0.1 mbar) and the residue was purified by low temperature column chromatography (SiO_2, −20 °C, *n*-hexane).

{Ethoxy[(2,4,6-triisopropylphenyl)carbene]pentacarbonyltungsten(0)} (1b): Compound **1b** (0.7 g, 12%) was obtained as a yellow orange powder. M.p. 76 °C (decomp.). − ^1H NMR ($CDCl_3$): δ = 1.04 (s, br, 6 H, *o*-Ar−CH(CH_3)$_2$), 1.21 [d, ^3J(H,H) = 6.8 Hz, 6 H, *o*-Ar−CH(CH_3)$_2$], 1.30 [d, ^3J(H,H) = 6.6 Hz, 6 H, *p*-Ar−CH(CH_3)$_2$], 1.62 (s, br, 3 H, CH_2-CH_3), 2.83 [m_c, br, 3 H, *p*-Ar−C*H*(CH_3)$_2$, *o*-Ar−C*H*(CH_3)$_2$], 5.01 (s, br, 2 H, O−CH_2), 6.94 (s, 2 H, Ar−*H*3/3′). − $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 13.7 (s, CH_2CH_3), 21.1 [s, *o*-Ar−CH(*C*H_3)$_2$], 23.0 [s, *p*-Ar−CH(*C*H_3)$_2$], 25.2 [s, *o*-Ar−CH(*C*H_3)$_2$], 29.5 [s, *o*-Ar−*C*H(CH_3)$_2$], 33.1 [s, *p*-Ar−*C*H(CH_3)$_2$], 79.4 (s, O*C*H_2), 119.6 (s, br, Ar−*C*3/3′), 138.1 (s, br, Ar−*C*2/2′), 147.7 (s, Ar−*C*4), 149.9 (s, Ar−*C*1), 195.8 (s, *cis*-*C*O), 202.6 (s, *trans*-*C*O), 337.2 (s, W=*C*R_2). − IR (KBr) $\tilde{\nu}$ = 2069 (m), 1989 (m), 1950 (s), 1932 (s), 1905 (s), cm^{-1} (CO). − MS (70 eV; ^{184}W): *m*/*z* (%) = 584 (25) [M^+], 556 (26) [M^+ − CO], 528 (100) [M^+ − 2CO], 500 (64) [M^+ − 3CO], 472 (54) [M^+ − 4CO], 444 (74) [M^+ − 5CO], 231 (74) [($C_6H_2(C_3H_7)_3CO)^+$], 203 (5) [$(C_6H_2(C_3H_7)_3^+$], 43 (20) [$C_3H_7^+$]. − HR-MS ($C_{23}H_{28}O_6W$): calcd. 584.1397; found 584.1395 (±2 ppm).

{Ethoxy[(2,4,6-tri-*tert*-butylphenyl)carbene]pentacarbonyltungsten(0)} (1c): Compound **1c** (3.5 g, 56%) was obtained as a yellow orange powder. M.p. 82 °C (decomp.). − ^1H NMR ($CDCl_3$): δ = 1.29 [s, 9 H, *p*-Ar−C(CH_3)$_3$], 1.31 [s, 18 H, *o*-Ar−C(CH_3)$_3$], 1.77 [t, 3J(H,H) = 7.2 Hz, 3 H, CH_2CH_3], 5.03 [q, ^3J(H,H) = 7.2 Hz, 2 H, OCH_2], 7.29 (s, 2 H, Ar−H3/3′). − $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 14.2 (s, CH_2CH_3), 31.3 [s, *p*-Ar−C(CH_3)$_3$], 34.5 [s, *o*-Ar−C(CH_3)$_3$], 34.7 [s, *p*-Ar−C(CH_3)$_3$], 38.5 [s, *o*-Ar−C(CH_3)$_3$], 80.9 (s, O*C*H_2), 122.6 (s, Ar−*C*3/3′), 137.8 (s, Ar−*C*2/2′), 149.0 (s, Ar−*C*4), 151.6 (s, Ar−*C*1), 198.3 [s, ^1J(C,W) = 129.0 Hz, *cis*-*C*O], 204.3 (s, *trans*-*C*O), 341.2 (s, W=*C*R_2). − IR (KBr) $\tilde{\nu}$ = 2069 (m), 1981 (m), 1953 (s), 1928 (s), 1910 (s) cm^{-1} (CO). − MS (70 eV; ^{184}W): *m*/*z* (%) = 626 (11) [M^+], 598 (20) [M^+ − CO], 570 (12) [M^+ − 2CO], 542 (86) [M^+ − 3CO], 513 (100) [M^+ − 3CO − C_2H_5], 485 (59) [M^+ − 4CO − C_2H_5], 273 (43) [$C_6H_2(C_4H_9)_3CO^+$], 57 (35) [$C_4H_9^+$]. − $C_{26}H_{34}O_6W$ (626.4): calcd. C 49.85, H 5.47; found C 50.07, H 5.59.

Preparation of {Amino[(2,4,6-triisopropylphenyl)carbene]pentacarbonyltungsten(0)} (2b): A concentrated solution of ammonia in water (4 mL, 50 mmol) was added at ambient temperature to a solution of **1b** (0.7 g, 1.2 mmol) in 60 mL of THF. The reaction mixture was stirred for 21 days at ambient temperature until a yellow colour persisted and thin liquid chromatography (SiO_2) indicated that all starting material was consumed. All volatile compounds were removed under reduced pressure (0.1 mbar) and the yellow residue was purified by low temperature column chromatography (SiO_2, −15 °C; *n*-hexane/diethyl ether 10:1) to give **2b** (0.6 g, 90%) as a yellow powder. M.p. 116 °C (decomp.). − ^1H NMR ($CDCl_3$):

δ = 1.17 [d, ^3J(H,H) = 6.8 Hz, 6 H, *o*-Ar−CH(CH_3)$_2$], 1.25 [d, ^3J(H,H) = 7.0 Hz, 6 H, *p*-Ar−CH(CH_3)$_2$], 1.33 [d, ^3J(H,H) = 6.8 Hz, 6 H, *o*-Ar−CH(CH_3)$_2$], 2.88 [sept, ^3J(H,H) = 7.0 Hz, 1 H, *p*-Ar−C*H*(CH$_3$)$_2$], 2.92 [sept, ^3J(H,H) = 6.8 Hz, 2 H, *o*-Ar−C*H*(CH$_3$)$_2$], 7.0 (s, 2 H, Ar-*H*3/3′), 8.64 (s, br, 1 H, N*H*), 8.97 (s, br, 1 H, N*H*). − ^{13}C{^{1}H} NMR (CDCl$_3$): δ = 23.3 [s, CH(*C*H$_3$)$_2$], 24.0 [s, CH(*C*H$_3$)$_2$], 26.4 [s, CH(*C*H$_3$)$_2$], 30.4 [s, *o*-Ar−*C*H(CH$_3$)$_2$], 34.1 [s, *p*-Ar−*C*H(CH$_3$)$_2$], 121.4 (s, Ar−*C*3/3′), 139.5 (s, Ar−*C*2/2′), 146.5 (s, Ar−*C*1), 148.6 (s, Ar−*C*4), 198.2 [s, ^1J(C,W) = 127.4 Hz, *cis*-*C*O], 202.8 (s, *trans*-*C*O), 276.1 (s, W=*C*R$_2$). − IR (KBr) ṽ = 3413 (m), 3319 (m), (NH); 2063 (s), 1971 (s), 1938 (vs), 1920 (vs), 1903 (vs) cm^{-1} (CO). − MS (70 eV; ^{184}W): *m*/*z* (%) = 555 (20) [M$^+$], 527 (8) [M$^+$ − CO], 499 (19) [M$^+$ − 2CO], 497 (19) [M$^+$ − 2CO − 2CH$_3$], 471 (85) [M$^+$ − 3CO], 469 (100) [M$^+$ − 2CO − 2CH$_3$], 203 (16) [C$_6$H$_2$(C$_3$H$_7$)$_3^+$], 43 (13) [C$_3$H$_7^+$]. − HR-MS (C$_{21}$H$_{25}$NO$_5$W): calcd. 555.1246; found 555.1240 (±2 ppm).

Preparation of *N*,*N*′-Bis{amino[(2,4,6-trimethylphenyl)carbene]pentacarbonyltungsten(0)}bis(trimethylsilyl)methylphosphane (6a), {[2-Bis(trimethylsilyl)methyl-3-(2,4,6-trimethylphenyl)-2*H*-azaphosphirene-κP}pentacarbonyltungsten(0)] (7a) and {Pentacarbonyl-[bis(trimethylsilyl)methylchlorophosphane]tungsten(0)} (8): NEt$_3$ (3.3 mL) was added at ambient temperature to a solution of complex **2a** (0.47 g, 1 mmol) and [bis(trimethylsilyl)methylene]chlorophosphane **3** (0.22 g, 1 mmol) in 10 mL of diethyl ether. The reaction mixture was stirred for 20 hours at ambient temperature until **3** was consumed (^{31}P NMR). To the yellow-orange reaction mixture was added 100 mL of pentane and the mixture then filtered. The solvent was removed under reduced pressure (0.1 mbar) and the residue was separated into two fractions by low temperature column chromatography (SiO$_2$, −20 °C; *n*-hexane/diethyl ether 15:1). Removing the solvent from the first yellow fraction under reduced pressure (0.1 mbar) gave complex **8**; similarly, the second yellow fraction gave a mixture of **6a** and **7a** as a yellow powder. The yellow powder was washed twice with 10 mL of *n*-pentane. The remaining yellow-orange residue was identified as **6a**. The solvent of the combined organic pentane phases was removed under reduced pressure (0.1 mbar) to give a yellow-orange powder, which was **7a**−enriched.

***N*,*N*′-Bis{amino[(2,4,6-trimethylphenyl)carbene]pentacarbonyltungsten(0)}bis(trimethylsilyl)methylphosphane (6a):** Compound **6a** (50 mg, 8.8%) was obtained as a yellow-orange powder. Preparation of *N*-{Amino[(2,4,6-trimethylphenyl)carbene]pentacarbonyltungsten(0)}-[bis(trimethylsilyl)methylphosphane]pentacarbonyltungsten(0) (9a): [Bis(trimethylsilyl)methylene]chlorophosphane **3** (0.49 g, 2.2 mmol) and 11 mL of NEt$_3$ were added at 0 °C to a solution of complex **2a** (1.10 g, 2.2 mmol) in 33 mL of diethyl ether. The reaction mixture was stirred for 70 hours at ambient temperature until **3** was consumed (^{31}P NMR) and a 1:2 mixture of **8**:**9a** was detected. The solvent was evaporated slowly to dryness under reduced pressure (0.1 mbar). The residue was extracted twice with 50 mL of *n*-pentane and filtered. The remaining residue was washed twice with 5 mL of *n*-pentane, the organic phases combined and the solvent removed under reduced pressure. The residue was separated in two fractions by low temperature column chromatography. Removing the solvent of the first yellow fraction (SiO$_2$, −20 °C; *n*-pentane) under reduced pressure (0.1 mbar) gave complex **8**. Removing the solvent of the second yellow fraction (SiO$_2$, −20 °C; *n*-pentane/diethyl ether 7:1) under reduced pressure (0.1 mbar) gave **9a**. Orange crystals of the mesitylnitrile adduct **10** were obtained by crystallisation of **9a** in the presence of mesitylnitrile in *n*-pentane.

9a: 0.44 g (40%) as an orange powder. M.p. 112 °C (decomp.). − ^{1}H NMR (C$_6$D$_6$): δ = −0.3 [d, 9 H, ^4J(P,H) = 1.1 Hz, Si(CH_3)$_3$], 0.21 [s, 9 H, Si(CH_3)$_3$], 1.33 [dd, ^3J(H^C,H^P) = 19.0 Hz, ^2J(P,H) = 3.1 Hz, 1 H, PC*H*], 1.97 (s, 3 H, Ar−CH_3), 2.10 (s, 3 H, Ar−CH_3), 2.18 (s, 3 H, Ar−CH_3), 6.45 (s, 1 H, Ar−*H*), 6.52 (s, 1 H, Ar−*H*), 6.87 [ddd, ^1J(P,H) = 378.9 Hz, ^3J(H^P,H^C) = 19.0 Hz, ^3J(H^P,H^N) = 8.0 Hz, 1 H, P*H*], 9.6 [dd, br, ^3J(H^N,P) = 27.5 Hz, ^3J(H^N,H^P) = 8.0 Hz, 1 H, N*H*]. − ^{13}C{^{1}H} NMR (C$_6$D$_6$): δ = 0.4 [d, ^3J(P,C) = 5.1 Hz, Si(*C*H$_3$)$_3$], 2.0 [d, ^3J(P,C) = 3.3 Hz, Si(*C*H$_3$)$_3$], 18.8 [d, ^1J(P,C) = 17.1 Hz, P*C*H], 19.6 (s, Ar−*C*H$_3$), 20.5 (s, Ar−*C*H$_3$),

Dimethoxyhydroxycarbenium Hexafluorometallate – Synthesis, Spectroscopic Characterization and the Crystal Structure of $(MeO)_2COH^+SbF_6^-$

Rolf Minkwitz*[a] and Frank Neikes[a]

Keywords: Carbocations / IR spectroscopy / Raman spectroscopy / NMR spectroscopy / Protonations

Dimethyl carbonate reacts in the superacidic system HF/MF_5 (M = As, Sb) with formation of $(MeO)_2COX^+MF_6^-$ (M = As, Sb; X = H, D). $(MeO)_2COH^+SbF_6^-$ crystallizes in the orthorhombic space group $Pna2_1$ (No. 33) with a = 9.668(2) Å, b = 8.340(2) Å, c = 11.135(4) Å and four formula units per cell. The unit cell contains $(MeO)_2COH^+$ cations of approximate C_s symmetry with an almost central trigonal planar CO_3 skeleton and C–O bond lengths in a range between 1.26(1) Å and 1.30(2) Å. The salt contains long O–H and Sb–F bond and an F···H contact of 1.62(9) Å. With regard to the formation of the salts, the reaction of dimethyl carbonate with the superacidic systems XF/MF_5 (X = H, D; M = As, Sb) is discussed and the Raman, IR, ^1H and ^{13}C NMR spectra of $(MeO)_2COX^+MF_6^-$ (M = As, Sb; X = H, D) are reported.

Introduction

The formulation of protonated compounds as reactive cationic intermediates is important for the explanation of reaction mechanisms. The evidence for such intermediates is of great importance in modern chemistry and can be used to confirm or deny known mechanisms. It has been shown that protonated compounds, for example, are not only short lived intermediates, but are even available in stabilized forms. A kinetic stabilization is possible due to protonation with superacids like HF/MF_5 or HSO_3F/MF_5 (M = As, Sb). This field of chemistry has been mainly developed by Olah, who was able to prove the existence of many protonated organic compounds in superacidic systems by NMR spectroscopy.[1–3]

In superacidic systems like FSO_3H/SbF_5 or HF/MF_5 (M = As, Sb) an extended spectrum of organic and inorganic species, for example element hydrides of group 15 and 16, can be protonated and stabilized.[4–14] Almost all known carbocations are mainly identified in solution by NMR spectroscopy. However, the crystal structures of protonated acetic acid, protonated carbonic acid and protonated formic acid have been investigated.[15–18] Attempts to isolate the H_2COH^+ cation failed because of the formation of the $(CH_2)O(CH_2)OH^+$ cation.[19] Substances with a CO_3 skeleton, such as the carbonate anion, the protonated carbonic acid or the monoperoxocarbonic acid anion are known and have been spectroscopically and structurally investigated.[17,20] In the row of the simplest mono-, di- and trioxocarbenium ions, we tried to isolate the dimethoxyhydroxycarbenium hexafluorometallates at low temperature in order to study their chemical behavior in acidic systems.

Results and Discussion

Formation of $(MeO)_2COH^+$ Salts

Protonation of dimethyl carbonate by the superacidic systems HF or DF/MF_5 (M = As, Sb) gives dimethoxyhydroxycarbenium hexafluorometallates [Equation (1)].

$$(MeO)_2CO + XF + MF_5 \rightarrow (MeO)_2COX^+MF_6^- \quad (X = H, D; M = As, Sb) \quad (1)$$

The resulting colorless, moisture-sensitive salts, which are soluble in SO_2, decompose in the case of the arsenate above –38 °C, and in the case of the antimonate above –35 °C. Under inert conditions at –70 °C the salts can be stored for several weeks without decomposition. The remaining $(MeO)_2COH^+SbF_6^-$ contained crystals suitable for X-ray diffraction studies.

X-ray Crystal Structure of $(MeO)_2COH^+SbF_6^-$

Dimethoxyhydroxycarbenium hexafluoroantimonate crystallizes in the orthorhombic space group $Pna2_1$ (No. 33) with four units per cell (see Table 1).[21] Table 2 lists important bond lengths and angles and Figure 1 shows the crystal structure with atom labels. The arrangement of the $(MeO)_2COH^+SbF_6^-$ in the unit cell is shown in Figure 2. For data collection and reduction, a semiempirical correction determined from single ψ-scan data, and programs in the SHELXL package and PARST, were used.[22–25] The antimony layers were found by the Patterson method. All other atoms, including protons, were determined by difference Fourier synthesis. A final refinement with anisotropic (except H atoms) thermal parameters gave a value of R = 0.0198.

The CO bond lengths [1.26(1) Å, 1.274(8) Å and 1.30(2) Å] show no significant differences and can be compared to the lengths of the CO bonds in the dihydroxymethylcarbenium

F(3)···H(1)	1.68(8)		

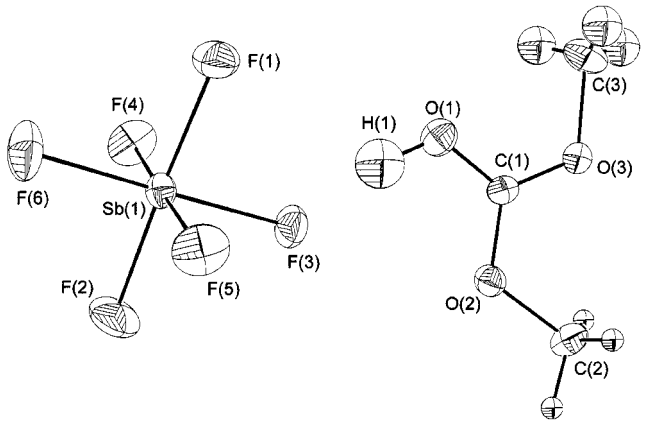

Figure 1. Projection of the asymmetric unit; thermal ellipsoids are drawn at the 50% probability level

cation and the $C(OH)_3^+$ cation as well as the almost trigonal planar CO_3 skeleton with OCO angles of 122(1)°, 117.8(6)° and 119.4(8)°.[17,18] The CO_3 skeleton geometry and the CO bond lengths, which are in a range between a single [1.508(8) Å for C(2)–O(2) and 1.48(1) Å for C(3)–O(3)] and a double CO bond [1.222(2) Å in formic acid], imply that the positive charge is delocalized. The two Me–O–C–O torsion angles [73.2(6)° and 3.1(9)°] show that the methyl groups are not located in the CO_3 plane. The O(1)···F(3) distance of 2.570(1) Å indicates a strong O(1)–H(1)···F(3) hydrogen bond,[26] which causes the Sb(1)–F(3) bond [1.919(3) Å] to be 2.7% longer than the other Sb(1)–F bonds. The maximum deviation from ideal octahedron angles in the SbF_6^- anion is 2.4°. As observed in the Raman and IR spectra the ideal octahedron structure is distorted. In the AB plane only alternating hydrogen-bonded ion pairs are formed; these planes are piled up the C axes with no contacts between adjacent planes.

Raman and IR Spectra of $(MeO)_2COX^+MF_6^-$ (X = H, D; M = As, Sb)

The infrared and Raman spectra of $(MeO)_2COD^+SbF_6^-$ are shown in Figure 3. The observed frequencies of $(MeO)_2COX^+MF_6^-$ (X = H, D; M = As, Sb) are summarized in Table 3. The assignments for the $(MeO)_2COX^+$ cation were made by a comparison with the precursor $(MeO)_2CO$ and several alkyl derivatives.[27–32] The assignments of the anions were made according to known literature data.[17,18,33]

On the condition that $(MeO)_2COX^+MF_6^-$ (X = H, D; M = As, Sb) has a C_S point symmetry, 21 (A') and 12 (A'') fundamental Raman and IR active vibrational modes are expected. Referring to the complex spectra observed, many vibrational modes are split, which could be a sign for a change to a lower symmetry in the crystal. The vibrational spectra of liquid and solid dimethyl carbonate show that, as the temperature is lowered, the observed splitting in the low-temperature spectra increases. This behavior is typical of crystal splitting in crystals of organic compounds, probably due to lattice concentration effects. The spectra become complex so that it gets difficult to assign the vibrational modes. Therefore vibrational modes are only assigned in their typical range. Without the X-ray studies and NMR spectra, the complex Raman and IR spectra could give no evidence for the existence of protonated dimethyl carbonate.

There is no denying that differences in the spectra between $(MeO)_2COH^+AsF_6^-$ and $(MeO)_2COH^+SbF_6^-$ are noticed. One possible reason for this is the crystallization in different space groups, so that varying crystalline field-splitting can be observed. Another reason might be that the influence of the anion to the vicinity of the cations differs. The measured spectra of protonated dimethyl carbonate show no further overtones, fermi resonances or combination tones in the region 1700–2900 cm^{-1}.

The antisymmetric and symmetric stretching modes of the methyl groups are observed in the region of 2960–3100 cm^{-1}. The Raman spectra of the hexafluoroantimonate anion show four different antisymmetric stretching modes at

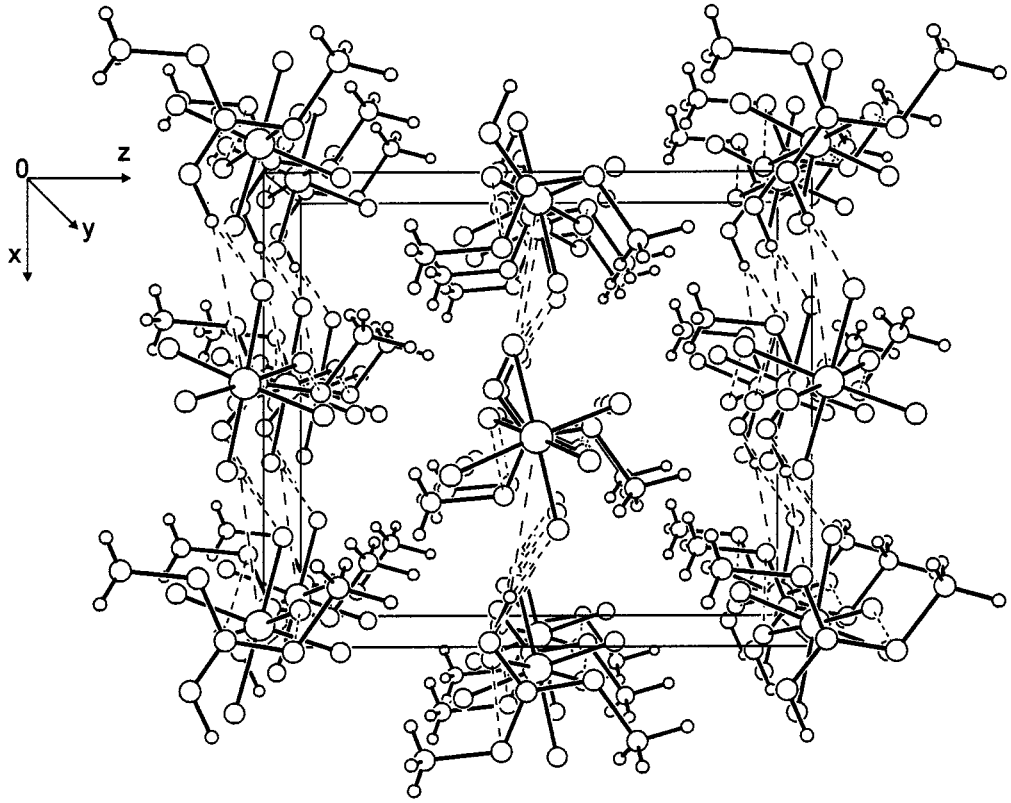

Figure 2. Projection of the $(MeO)_2COH^+SbF_6^-$ salt with contacts

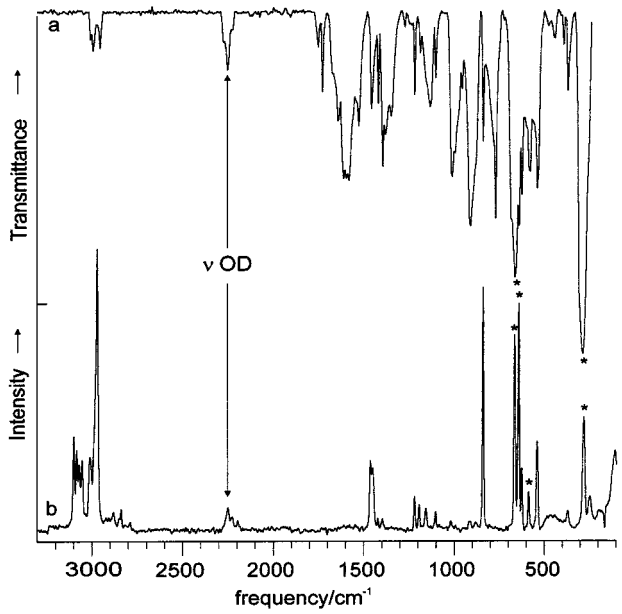

Figure 3. Infrared spectrum (trace A) and Raman spectrum (trace B) of $(MeO)_2COD^+SbF_6^-$; vibrations of the SbF_6^- anion are marked by an asterisk

3099, 3084, 3071 and 3056 cm^{-1}, but the spectra of the hexafluoroarsenate show only two modes (3090 and 3067 cm^{-1}). The same phenomenon is noticed in the area of the methyl deformation modes (1554–1349 cm^{-1}), where as many as six different frequencies are measured. Between 1220 cm^{-1} and 1153 cm^{-1} as well as between 1098 cm^{-1} and 993 cm^{-1} the rocking modes ρCH_3 are observed. A sharp Raman line and IR band is detected at 845 cm^{-1} and assigned to the CO_3 out-of-plane mode, whose position is comparable to the measured frequency in a range of 890–774 cm^{-1} for simple, complex, acidic and organic carbonate compounds.[22] The νOH absorption is observed at 3160 cm^{-1} with the H/D shifted signal at 2275 cm^{-1} (νOD) for the AsF_6^- compound and 2156 cm^{-1} for the SbF_6^- compound, which is within the expected shift range of about 900 cm^{-1}.[34]

Because of cation–anion interactions, the MF_6^- ions (M = As, Sb) do not show ideal O_h symmetry. This lowered symmetry can be seen in the spectra, where splitting of the anion vibrational modes are observed.[33]

^1H and ^{13}C NMR Spectra of $(MeO)_2COH^+MF_6^-$ (M = As, Sb)

The ^1H NMR spectra of freshly prepared $(MeO)_2COH^+MF_6^-$ (M = As, Sb) dissolved in SO_2 with TMS as external standard at –50 °C shows a singlet at δ = 4.59 (AsF_6^-) and δ = 4.63 (SbF_6^-) for the methyl groups and a singlet at δ = 11.74 (AsF_6^-) and δ = 11.8 (SbF_6^-) for the hydroxyl group. This result is comparable to the results of Olah, who observed at –80 °C a singlet at δ = 11.27 for the hydroxyl group and a singlet at δ = 4.52 for the methyl group.[35,36] The singlet for the proton of the hydroxyl group of the $C(OH)_3^+$ cation is detected at δ = 11.55; Ramsey observed a singlet at δ = 4.9 in an H_2SO_4 solution for the methyl group (Table 4).[17,37] The singlet at δ = 163 in the ^{13}C NMR (^1H coupled) is assigned to the carbon atom of the CO_3 skeleton. In the region of δ = 63 a quadruplet

with a coupling constant of 141 Hz is observed and assigned to the methyl groups.

Experimental Section

Caution! *Avoid contact with these compounds as the hydrolysis of AsF_6^- and SbF_6^- salts forms HF, which burns the skin and causes irreparable damage. Safety precautions should be taken when using and handling these materials.*

All synthetic work and sample handling was performed by employing standard Schlenk techniques and a vacuum line (stainless steel or glass). SbF_5 (Merck) was purified by fractional distillation. The synthesis of $(MeO)_2CO$ and the drying of HF and SO_2 were carried out by known literature methods (R. Minkoite, A. Kornath, D. Savodny, *Angew. Chem. Int. Ed. Engl.* **1992**, *31*, 643–644). Reactions in HF/DF were carried out in a KEL-F reactor with a KEL-F valve.[38] Infrared spectra were recorded with a Bruker IFS 113V spectrophotometer. The spectra of dry powders were obtained on a CsI plate in a cooled IR cell.[39] The Raman spectra were recorded

[a] Ref.[27] – [b] Ref.[37] at –80 °C. – [c] Own measurements at –60 °C with TMS as external standard. – [d] In parts per million from CS_2. – [e] Ref.[17] – [f] CD_3NO_2 as standard.

with a T64000 (ISA) using a CCD detector (EEV CCD15–11) and an Ar^+ laser tube (514.5 nm) from Spectra Physics. The spectra were recorded in a glass cell cooled with liquid nitrogen. The NMR spectra were recorded with a Bruker DPX 300 spectrometer with TMS as external standard. Single crystals were placed in Lindemann capillaries in a cooled stream of dry nitrogen, and an X-ray diffraction study was carried out at –100 °C using an Enraf Nonius Mach3 automated diffractometer.

Preparation of $(MeO)_2COX^+MF_6^-$ (M = As, Sb; X = H, D): In a 50 mL KEL-F reactor, SbF_5 (1.09 g, 5 mmol) or AsF_5 (0.85 g, 5 mmol) was dissolved in HF (3 g). The solution was frozen at –196 °C and $(MeO)_2CO$ (0.45 g, 5 mmol) was added under an inert atmosphere (N_2). The mixture was warmed to –70 °C and kept for 30 minutes. The excess HF was slowly removed under dynamic vacuum at –78 °C. The reactions with DF were made analogously to the above described synthesis.

Protonation of the Copper(I) Form of the Blue Copper Proteins Plastocyanin and Amicyanin – A Molecular Dynamics Study

Christian Buning[a] and Peter Comba*[a]

Keywords: Blue copper proteins / Molecular dynamics / Cluster analysis / Protonated histidine / Protonation mechanism

The conformational space of the copper(I) forms of the cupredoxines amicyanin (ami) (*Paracoccus versutus*) and plastocyanin (pla) (*Populus nigra*) with a protonated histidine donor close to the C-terminus ("C-terminal histidine" ami: His96; pla: His87) was investigated with force field calculations that involve the experimentally determined structures of the protonated or unprotonated copper(I/II) forms: a setup of 36 conformers with a constrained torsional angle that involves the $C_{imidazole}$–$C_{methylene}$ (C^{γ}–C^{β}) bond (chi2; 10° increments); strain energy minimization of all constrained conformers; a 10 ps molecular dynamics search around each conformer; constrained, followed by unconstrained optimization of each of the resulting low energy structures; cluster analysis of the resulting conformations. For both cupredoxines there are two major conformers which differ in their solvent accessibility. The plastocyanin and amicyanin structures are in excellent agreement with the experimentally observed crystallographic data; the two analyses lead to the proposal for a general mechanism for the protonation of reduced blue copper proteins. This is also in agreement with the results of a conformational analysis of a complex of the protonated copper(I) form of amicyanin with phosphate.

Introduction

Blue copper proteins (cupredoxines) are relatively small metalloproteins (approximately 10–14 kDa, 100–150 amino acid residues) with a single copper center in a trigonal pyramidal coordination geometry (two histidines, a cysteine, and an axial methionine; type 1 copper center). Cupredoxines are one-electron transfer centers which are part of redox chains in plants and bacteria.[1] Among the most prominent properties are the typical intense blue color in the oxidized form [ε (≈600 nm) ≈ 5000 $L \cdot mol^{-1}cm^{-1}$; proteins with rhombic sites have increasing intensity of a second transition at ≈460 nm], attributed to charge transfer from the cysteinate donor, a small A_z hyperfine coupling in the EPR spectrum ($A_z \approx 50 \cdot 10^{-4}$ cm^{-1}), relatively high reduction potentials [≈200 to ≈680 mV vs. 150 mV for the aqueous copper(II/I) couple] and fast electron self-exchange rates [10^3 to 10^6 $M^{-1}s^{-1}$ vs. $5 \cdot 10^{-7}$ $M^{-1}s^{-1}$ for the aqueous copper(II/I) couple].[2–5] A plot of the structure of amicyanin from *Paracoccus versutus* is shown in Figure 1.

An interesting feature is that for some of the blue copper proteins the reduction potential is strongly pH-dependent, and this has been attributed to the protonation of the coordinating histidine residue close to the C-terminus ("C-terminal histidine"; His96 in amicyanin shown in Figure 1). This histidine is supposed to be the gate for electron transfer, and protonation/deprotonation (i.e. bond breakage/bond formation may then be a switch to turn off and on the electron transfer reactivity.[6]). There is experimental

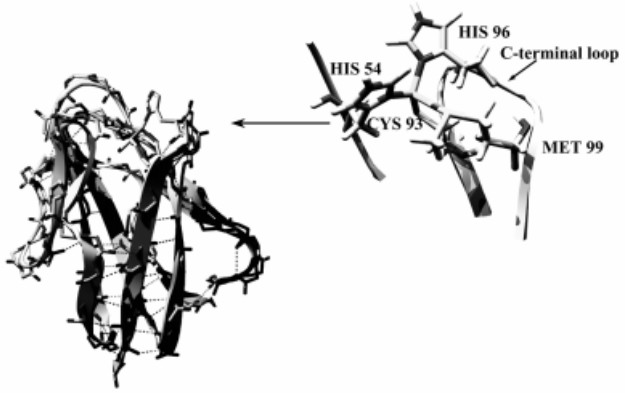

Figure 1. Representation of the tertiary structure and of the copper chromophore of amicyanin (*Paracoccus versutus*)[23]

electrochemical evidence for this protonation in plastocyanin, pseudoazurin, and amicyanin.[6–9] Structural support for the protonation has been obtained from X-ray studies of plastocyanin, pseudoazurin, and amicyanin.[10–12] [see Figure 2 for plastocyanin (His87)].

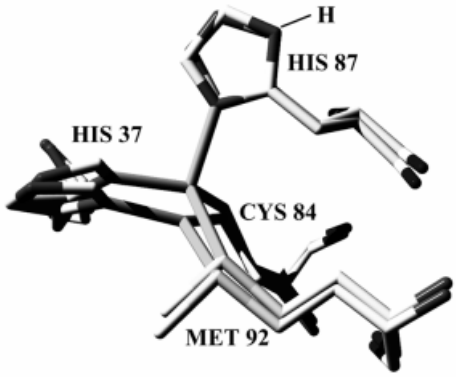

Figure 2. Overlay of the protonated and the unprotonated Cu^{I}-structures of plastocyanin[11]

There are two known structures for the protonated copper(I) form of plastocyanin.[11] The major difference is the conformation of the corresponding histidine side chain. One of the structures has the protonated N^{δ} directed towards the copper center whereas in the other structure the residue is rotated around chi2 by 180° (see Table 1 for nomenclature of the torsional angles), so that the protonated N^{δ} becomes solvent accessible and forms a hydrogen bond with a water molecule. During the protonation the geometry around the copper center changes from trigonal pyramidal to trigonal planar (see Figure 2). The distance to S^{δ} from the methionine decreases from 2.9 Å to 2.5 Å in the trigonal planar form, the bond distances to S^{γ} from the cysteine and to N^{δ} from the histidine do not change significantly. The trigonal planar geometry as well as the presence of two soft donors disfavors the copper(II) oxidation state, and this leads to the observed increase of the reduction potential.

Table 1. Definition of the torsion angles

Torsion	Atom type			
ϕ	C	C^{α}	N	C
Ψ	N	C	C^{α}	N
Ω	C^{α}	N	C	C^{α}
$\chi 1$	N	C^{α}	C^{β}	C^{γ}
$\chi 2$	C^{α}	C^{β}	C^{γ}	$N^{\delta 1}$
Tor	C^{α}	C^{β}	C^{γ}	$C^{\delta 2}$

For amicyanin there are detailed kinetic studies, suggesting that two protonated forms (His96) with different structures are involved[6] (Scheme 1). The rearrangement (k_2) is slow compared to the protonation (k_1). The observed pK_a value depends on the phosphate ion concentration, suggesting that some phosphate coordination is involved. Structural information on the protonated forms is available from an EXAFS study of amicyanin at variable pH.[13] This indicates the loss of one histidine donor at low pH and a reorganization of the copper site towards a trigonal planar geometry. There are also recent X-ray studies of the protonated form of amicyanin.[10] These indicate that, for amicyanin, there are two conformers for the protonated side chain of the C-terminal histidine.

$$A \underset{k_{-1}}{\overset{[H^+]\ k_1}{\rightleftharpoons}} B \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} C$$

Scheme 1. Three site exchange equilibrium describing the protonation of Cu^{I}-amicyanin

A pH-dependent electrochemical study of azurin (*Pseudomonas aeruginosa*) indicates that, in this cupredoxine, the coordinating histidine residues may not be protonated.[14–16] Factors that might prevent protonation are: (i) the length of the C-terminal loop: based on the observation that only those wildtype cupredoxines protonate which have two spacing amino acids between the Cys and the His[7] it was suggested that the length of the C-terminal loop is the determining factor for the protonation; (ii) the presence of the sterically demanding side chain Phe114 (azurin) in close proximity to the C-terminal His might prevent the rotation around chi2;[2,17] (iii) the absence of a proline residue next to the C-terminal His (Pro95 in amicyanin):[2,7,18] for all wildtype cupredoxines that protonate there is a Pro residue in the i-1 position with respect to the C-terminal histidine; this proline is known to interact with the protonated His of plastocyanin.[11] Recent loop-mutation studies yielded an amicyanin mutant with an azurin C-terminal loop (AmiAzu), where the coordinating C-terminal histidine may be protonated in the copper(I) form.[19] This mutant is the first cupredoxine which undergoes a protonation of the C-terminal histidine and which has more than two noncoordinating amino acids between the Cys and His donors in the C-terminal loop and no proline residue in the i-1 position which might interact with the protonated histidine side chain.

We have used molecular dynamics calculations to analyze the structural details of the protonated copper(I) forms of two blue copper proteins, plastocyanin and amicyanin, which are known to have protonated coordinating histidine groups (His96, pK_a = 6.8; His87, pK_a = 4.7, respectively). The results of the two MD calculations were also used to propose a detailed, general mechanism for the protonation of reduced cupredoxines. For amicyanin, an MD calculation of an amicyanin/phosphate complex was used to model the phosphate-dependence of the proton transfer reaction.

Computational Details

Force Field and Structural Models

DISCOVER 2.9.5.[20] with the force field AMBER[21] was used for all MM and MD calculations. The chromophore [copper(I) center and the three donor atoms of the coordinated amino acid residues (S, S, N)], the protein backbone outside a shell with a radius of 10 Å around C^{γ} of the C-terminal histidine (see Table 2), on the basis of entire amino acid residues, and the water molecules outside a shell with a radius of 7 Å were held at fixed positions. A distance-

dependent dielectric constant ($\varepsilon = 1 \times r$) and a cutoff of 12 Å for the nonbonded interactions were used. The point charges were those of the AMBER force field,[21] except for the copper(I) chromophore, where the charge distribution was computed with GAUSSIAN94.[22] [Merz-Kollmann scheme; B3LYP, Dζpdf/6-31G* basis set; model compound: $Cu^{I}(SCH_3)\{S(CH_3)_2\}(Im)$ with experimental coordinates of copper(I) plastocyanin, PDB-code 6pcy[11]]. The parameters for the chromophore are [copper(I) was treated as a cation, i.e. no bonds to the donor atoms; point charge, R, ε]: Cu^{I}, 0.118, 2.4, 0.05; S_{cys}, –0.546, 4.0, 0.2; N_{His}, –0.163, 3.5, 0.16. The point charges of the entire model compound are given as supplementary material.

Conformations of the Protonated Copper(I) Form of Plastocyanin and Amicyanin

The starting structures for the conformational searches were based on experimentally determined crystallographic data; plastocyanin: *Populus nigra*, copper(I) pH = 3.8; PDB-code 6pcy;[11] amicyanin: *Paracoccus versutus*, copper(II) form;[23] the trigonal copper(I) chromophore of amicyanin was set up from this structure, based on published EXAFS data:[13] $d_{Cu-S(Cys)}$ = 2.18 Å, $d_{Cu-S(Met)}$ = 2.41 Å, $d_{Cu-N(His)}$ = 1.89 Å; assigned pH = 5.5. The copper chromophores were constrained to the experimentally observed geometries in all MD calculations. The experimentally observed water molecules were deleted from the structural data files and a solvation shell with a radius of 17 Å around C^{γ} of the C-terminal histidine (see Table 2) was constructed with a simple point charge model (SPC).

A set of 36 structures for each of the two protonated copper(I) proteins was created by a variation (10° increments) of the C^{α}–C^{β}–C^{γ}–C^{δ} torsional angle (tor) of the C-terminal histidine (see Table 1). The resulting structures were optimized (constrained angle tor, 1000 cycles, steepest descent). A 10 ps MD simulation was then performed for each of these structures (constrained angle tor, T = 600 K, 10 structures each were collected). During the MD simulation the temperature was regulated with a temperature relaxation time τ of 0.1 ps. In all calculations a time step of 1 fs was used.[24] The resulting 360 structures for each of the two copper proteins were then optimized with a constrained angle tor (10000 cycles conjugate gradient), followed by a full optimization without constraints (10000 cycles conjugate gradient).

A cluster analysis was performed for the fully energy minimized structures. The protein backbone torsions of the C-terminal loop and the side chain torsions of the protonated histidine were taken as criteria for the clustering; plastocyanin: chi1/chi2 His87, phi/psi Ala90, phi/psi Gly89, chi1/chi2 Pro86, and phi/psi Gly91; amicyanin: chi1/chi2 His96, phi/psi His96, chi1/chi2 Pro95, chi1/chi2 Pro97, and phi/psi Met99 (see Table 1 for the definition of the torsional angles and Table 2 for the amino acid sequences of the C-terminal loops of plastocyanin and amicyanin). A clustering according to these torsions allowed the definition of 12 families for amicyanin and 21 families for plastocyanin (only the highest populated clusters were examined in detail; the assignment to a cluster was based on a graphical analysis of the corresponding phi/psi plots and chi1/chi2 plots, respectively).

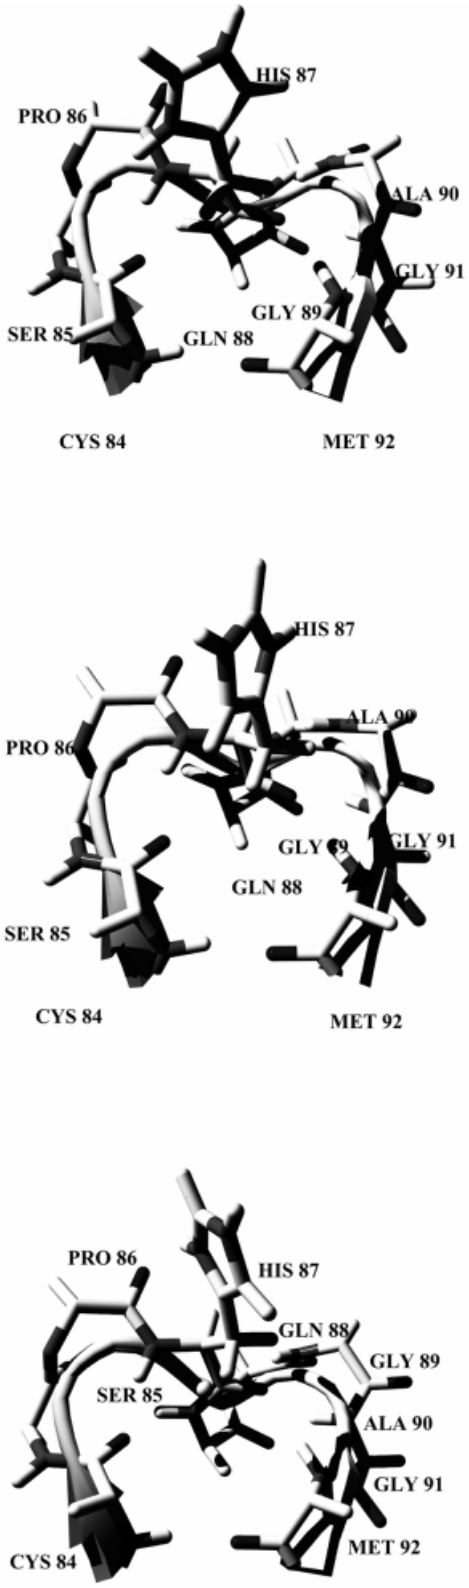

Figure 3. Representatives of the determined plastocyanin cluster: plasto1 (*top*), plasto2 (*middle*), plasto3 (*bottom*). The protein backbone of the C-terminal loop is shown plus the side chain of His 87

The Amicyanin Phosphate Complex

The structure of the protonated copper(I) amicyanin, as defined above, was used as the starting structure. Hydrogenphosphate was put in a position favorable for hydrogen bonding to N^{δ} of His96 and N–H of Arg100. The hydrogen bonds were constrained to a value of 2.5 Å. This model was energy-minimized using 10000 steps of conjugate gradient. An MD simulation at 900 K, taking 80 ps dynamics and 15 ps equilibration time was performed (τ = 0.1 ps, time step of 1 fs, see above). 80 conformations were collected and energy-minimized, using 10000 steps of conjugate gradient.

Results and Discussion

Plastocyanin

Three clusters of plastocyanin (plasto1, plasto2, plasto3) and two of amicyanin (ami1, ami2) were identified, each of which had a high population and characteristic features with respect to the histidine side chain and the C-terminal loop conformation (details of the cluster analyses are available as Supplementary Material); representative structures of the C-terminal loops are shown in Figure 3 and Figure 4, respectively. Table 3 gives detailed information on the conformation of the C-terminal loop and the protonated histidine side chain for the computed clusters and relevant experimental structures. From a comparison of the chi1/chi2 values of the three plastocyanin clusters with experimental data from X-ray studies[11] it emerges that plasto1 is very similar to the copper(I) structure at pH = 7 (deprotonated) and plasto2 is equivalent to the structure at pH = 3.8 (protonated). For plasto3 with a chi2 value of –11° there is no corresponding experimental data, and it appears that plasto3 is an intermediate between the two experimentally observed conformations. It is interesting to note here that the results of the crystallographic study of the low pH copper(I) form of plastocyanin suggest that this could be a mixture of two different conformations.[11] Thus, plasto3 might be a

Amicyanin

The good agreement between the computed and observed copper(I) structures of plastocyanin (see above) indicates that, based on the same MD scheme, a reasonable and accurate structural model for the protonated copper(I) form of amicyanin should be available. The cluster ami1 with a chi1/chi2 combination of –74°/142° has, in terms of the conformation of the histidine side chain, a structure that is similar to the copper(II) crystal structure.[23] In the other cluster, ami2, the protonated N^{δ} is directed towards the solvent; this conformation is similar to that of plasto2. Thus, for amicyanin there are conformations of the histidine side chain that are very similar to those of plastocyanin (see Table 3). Very recently, some experimental data on the protonated form of amicyanin became available.[10] These are in full agreement with our computed structural data.

It is instructive to extend the structural comparisons for amicyanin and plastocyanin [copper(I), unprotonated and protonated forms, experimental and computed data] to the first turn of the loop (see Table 3). A type 1 geometry is conserved in all structures. Overlay plots of all relevant structures are presented in Figure 5. The most significant structural differences for amicyanin are those of the conformations of the second turn and, for plastocyanin, those of the conformations of the third turn.

The Amicyanin/Phosphate Complex

The fact that the pK_a of amicyanin depends strongly on the phosphate anion concentration[6] suggests that an amicyanin/phosphate complex mediates the proton transfer. Published experimental data[6] indicate that the protonation rate, based on a mechanism that does not involve phosphate-protein interactions (k_1 in Scheme 1), is about two orders of magnitude faster than the diffusion-controlled limit and that, in the presence of phosphate, the proton is transferred from phosphate to the histidine nitrogen without any involvement of water molecules. A possible interpretation of these observations is that a phosphate anion binds to the positively charged Arg100 side chain. The fixed phosphate anion could then act as an anchor for protons, leading to a high local concentration. Furthermore, the Arg100-coordinated phosphate might have an ideal geometry for the stabilization of the protonated form C in Scheme 1, where the protonated N^{δ} of His96 is directed towards the solvent. There are experimental data that support a histidine/phosphate complex formation. X-ray data are available for structures which contain the motif of a phosphate or sulfate anion forming a salt bridge between a protonated histidine and a second basic amino acid.[25,26] For amicyanin, these structural and mechanistic hypotheses were examined by MD. The most favorable optimized structure of a corresponding amicyanin/phosphate complex is shown in Figure 6.

The structural model visualizes the feasibility of the discussed protonation mechanism and the stabilization of the protonated form. The hydrogen bonds between the phosphate anion and the protein are around 1.6 (± 0.1) Å (OH distances), which is at the shorter limit of the expected range. The main structural differences in the C-terminal loop of this structure, in comparison with the experimentally observed structure[23] are conformational changes at

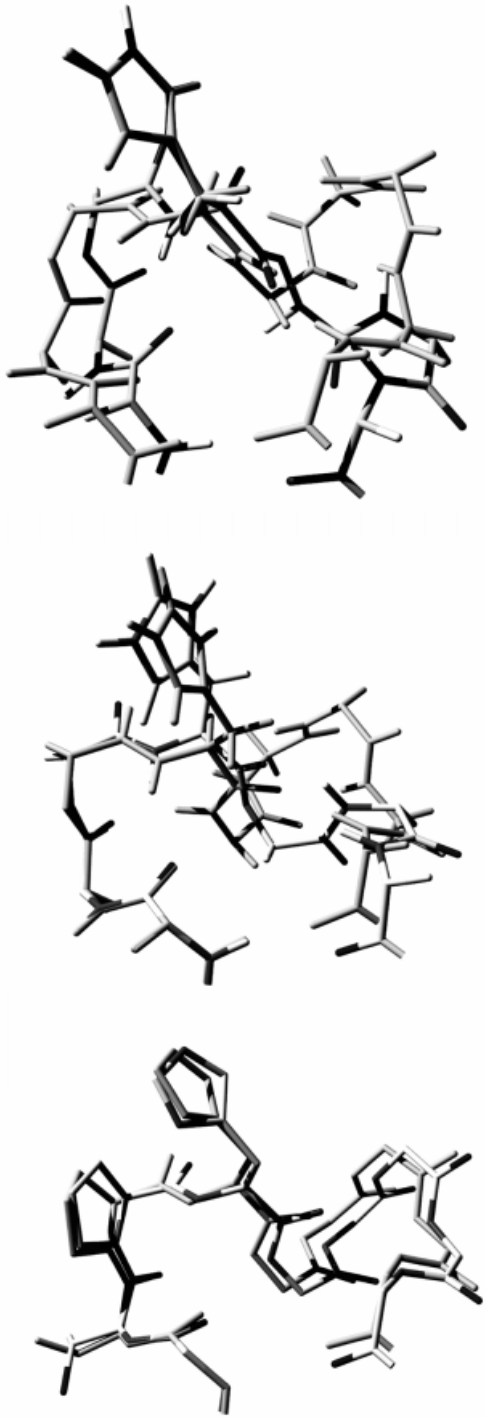

Figure 5. *Top:* Overlay of the clusters from amicyanin and plastocyanin with the protonated N^{δ} directing towards the Cu center; *middle:* Overlay of the clusters from amicyanin and plastocyanin with the N^{δ} directing into the solvent; *bottom:* Overlay of the protonated Cu^{I} structures from plastocyanin and pseudoazurin showing the protein backbone of the C-terminal loop and the side chain of the protonate histidine and the proline from the first turn

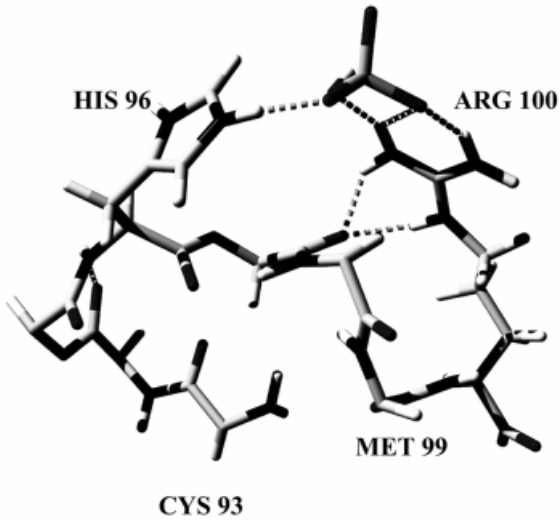

Figure 6. Calculated structure of the possible His 96-phosphate-Arg 100 complex for amicyanin from *Paracoccus versutus* (hydrogen bonds are indicated by dotted lines)

Pro95, His96, and Pro97. The conformation of His96, enforced by the coordinated phosphate anion, leads to chi1/chi2 values of –176°/52° (t/g^+). This is different from the X-ray structure of the unprotonated form[23] but one of the theoretically favored conformations (see above and Supplementary Material; g^+/g^+; g^+/g^-; t/g^+; g^-/g^+; k^-/k^-). Especially notable, however, are the phi/psi combinations for the two proline and the histidine residues (His96: 69°/100°, Pro95: –66°/82°, Pro97: –78°/57). The computed torsional angle combinations are in the ranges that are usually observed for left-handed helices (His96) or β-sheets (Pro95, Pro97), i.e., this is a reasonable conformation for the protonated C-terminal loop of the copper(I) form of amicyanin.

Conclusion

The general MD scheme used here is validated by the observation that, for plastocyanin, the experimentally observed structures are accurately reproduced. Therefore, the computed structures of the protonated copper(I) forms of amicyanin are a reliable model. The corresponding amicyanin/phosphate complex indicates how phosphate may mediate the proton transfer. All published experimental data and the computational results presented here indicate that the following steps are involved in the protonation of the C-terminal histidine in reduced blue copper proteins (see Figure 7):

(i) Decomplexation of the C-terminal histidine (structure **B**); (ii) isomerization to structure **C** with a solvent accessible histidine; (iii) protonation of the C-terminal histidine (structure **D**); (iv) isomerization to structure **E** (stabilization of the protonated structure). The rotational barrier involved in the first isomerization (**B→C**) and the solvent accessibility of structure **C** determine whether a protonation takes

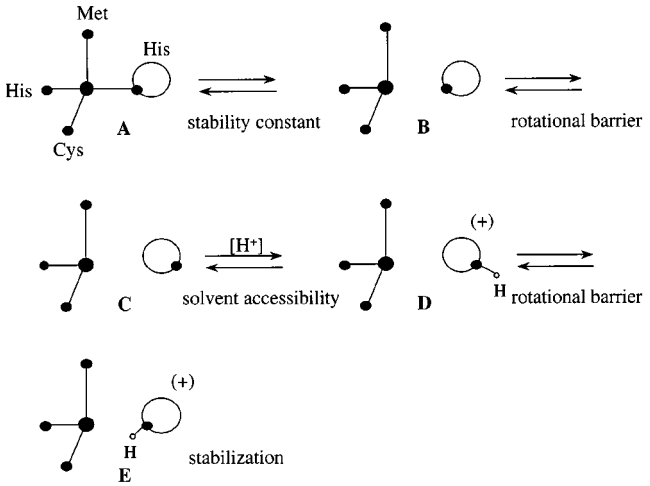

Figure 7. Schematic representation of the basic steps during the protonation of the histidine in a blue copper protein

place or not. The second rotational barrier (**D→E**) and the stabilization of structure **E** have a strong influence on the pK_a value.

Metal Iodides in Polyiodide Networks − The Structural Chemistry of Complex Thallium Iodides with Excess Iodine

Per H. Svensson,[a] Günther Raud,[b] and Lars Kloo*[c]

Keywords: Polyiodides / Iodine / Thallium / NMR spectroscopy

The TlI/$(R_3S)I_x$ systems (R = Me/Et, x = 3,5,7) have been investigated by means of Raman, far-IR, ^{205}Tl NMR spectroscopy and X-ray diffraction. The reaction between $(Me_3S)I_7$ and TlI results in the polyiodide compound $(Me_3S)_3I_{26}$. Raman spectra also reveal the presence of a solid thallium- and iodine-containing product. However, all attempts to structurally characterise this product were unsuccessful. The compound $(Et_3S)TlI_4$ is obtained from the reaction between $(Et_3S)I_7$ and TlI. ^{205}Tl NMR spectra show that Tl^{III} is present in the reaction mixtures of TlI/$(R_3S)I_x$ and that the peak assigned to TlI_4^- in the TlI/$(Et_3S)I_7$ system splits upon heating. This effect is reversible and indicates an equilibrium between two Tl^{III} species.

Introduction

Iodine (I_2) and the ions I^- and I_3^- can be regarded as the "building blocks" of polyiodides and by combination of these it is possible to rationalise almost all known polyiodide fragments (viz. I_5^-, I_7^-, I_8^{2-} and I_9^-). The smaller polyiodides can easily be made with many different cations. However, the larger polyiodides usually have to be stabilised with quite bulky and/or polarisable cations. Many of the larger polyiodides consist of long chains, layers or intercalated structures, which in many cases are electronically conducting and even superconducting.[1−4]

A still greater variety of iodine-rich compounds with interesting structural properties can be achieved by the incorporation of metal centres into the polyiodide structures. The inclusion of different metal compounds gives endless possibilities for structural variation. Wells' salt ($K_3Pb_2I_8{\cdot}4H_2O$) is an early example of such a substance, though not structurally characterised until 1984 by Tebbe.[5,6] Recently, several late transition metals have been incorporated into polyiodide networks.[7−11] The exchange of linear I−M−I units for I−I−I units has also been shown for M = Au.[10]

According to the literature, less, if any, effort has been devoted to heavy main-group metals in this context. These metal ions, being borderline cases between hard and soft acceptors by the hard-soft acid-base formalism, are capable of forming iodide complexes in different or sometimes mixed oxidation states.

Thallium, with its most common oxidation states +I and +III, forms several well-known, non-polyiodide compounds and complexes, such as TlI and TlI_4^-. A TlI_6^{3-} ion has not been verified, though its bromide congener $TlBr_6^{3-}$ was identified.[12] The compound TlI_3 actually consists of Tl^+ and I_3^- units.[13,14] Another less conventional property of thallium is that it is softer in the oxidation state +III than in +I. These facts indicate that the possibility of Tl^{III} oxidising I^- must be taken into account, even though the converse, iodine oxidition of Tl^I to Tl^{III}, can be induced by the right choice of ligands and reaction conditions.[14,15] Polyiodides incorporating only thallium are rather rare (TlI_3 and Tl_3I_4)[3], but they readily form $(Tl_6I_6M_x)[I_4^{2-}]$ compounds if mixed with other metals (M = Pb^{2+}, Bi^{3+}, Au^+, Ag^+).[16]

In this work, we have investigated the possibility of incorporating thallium into polyiodide networks via the reaction between Tl or TlI and the polyiodide melts of trialkylsulfonium iodide. The results have been analysed by means of X-ray diffraction, Raman, IR and ^{205}Tl NMR spectroscopy.

Results and Discussion

Spectroscopic Studies

The Raman spectrum of the reaction mixture between TlI and $(Me_3S)I_7$ (molar ratio 1:3) displays a broad peak at 176 cm^{-1}, almost identical to that of pure $(Me_3S)I_7$ (Figure 1, top). The very strong peak from the heptaiodide makes it difficult to extract any information about the reaction mixture by means of Raman and far-IR spectroscopy. However, the absence of TlI (103 cm^{-1} and 86 cm^{-1}) indicates that a reaction has taken place. The far-IR spectrum shows very similar spectral features to that of unchanged $(Me_3S)I_7$. There are some weak extra bands, but they are difficult to assign. The Raman spectrum of the solid thal-

lium-containing product separated from the reaction melt shows the same spectral features as the reaction mixture. However, if the solid product is left to decompose under ambient conditions its Raman spectrum changes (Figure 1, bottom). Two new peaks are observed at 105 and 128 cm^{-1}. The latter peak corresponds favourably to the asymmetric stretch of TlI_4^-, while the former is in the region where both TlI and triiodide ions normally give rise to spectral features.[12,17−22] This implies that the solid product has decomposed to TlI_4^- and possibly TlI or I_3^-.

The vibrational spectra of the reaction mixture from TlI and $(Et_3S)I_7$ (molar ratio 1:3) show spectral features that differ from the analogous mixture with $(Me_3S)I_7$ (Figure 2, top). The Raman spectrum displays a distinct peak at 130 cm^{-1} which is not seen in $(Me_3S)I_7$. This peak corresponds favourably with the asymmetric stretch of TlI_4^-.[12,17−22] The symmetric stretch of TlI_4^-, which should appear around 150 cm^{-1}, is probably masked by the strong polyiodide bands. The far-IR spectrum also displays differences with respect to the pure polyiodide system. These can also be assigned to TlI_4^- ions. The Raman spectra of the crystals obtained from the synthesis show that the spectral features of the polyiodides have decreased in intensity and as a consequence it is possible to identify a peak at 156 cm^{-1} corresponding to the symmetric stretch of TlI_4^- (Figure 2, bottom). A weak band at 196 cm^{-1} is also observed; it may be the overtone of the ν_1 of TlI_4^- or I_3^-, or the ν_1 of iodine. The spectral features of the crystals after some days under ambient conditions are invariant, thus indicating that the compound is stable under these conditions.

Structural Investigation

The only product that could be isolated and fully characterised from the reaction between TlI and $(Me_3S)I_7$ was found to be a polyiodide compound with no incorporation of thallium, $(Me_3S)_3I_{26}$ (**1**). However, there must be at least two different products under the chosen set of conditions: a polyiodide of the $(Me_3S)I/I_2$ system, and a thallium compound (whose spectral properties were discussed above). The structure of the thallium-containing compound could not be characterised because of its thermal instability (loss of I_2).

The structure of **1** can be described in terms of a pyramidal I_7^- ion, V/L-shaped I_5^- ions, intercalated iodine and Me_3S^+ cations (Figure 3 and Figure 4). The intramolecular I−I distances for the penta- and heptaiodides are in the range 2.75−3.29 Å (Table 1). The two independent I_5^- ions are at the limit where they may be regarded either as two I_2 molecules coordinating to an iodide ion (V-shaped) or as a

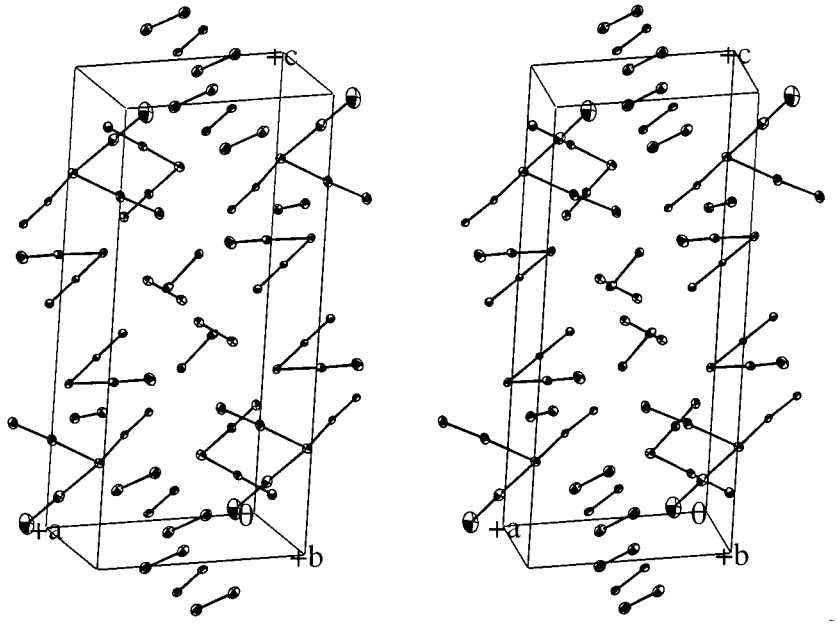

Figure 3. Stereoscopic view of the crystal structure of **1**; the cations are omitted for clarity

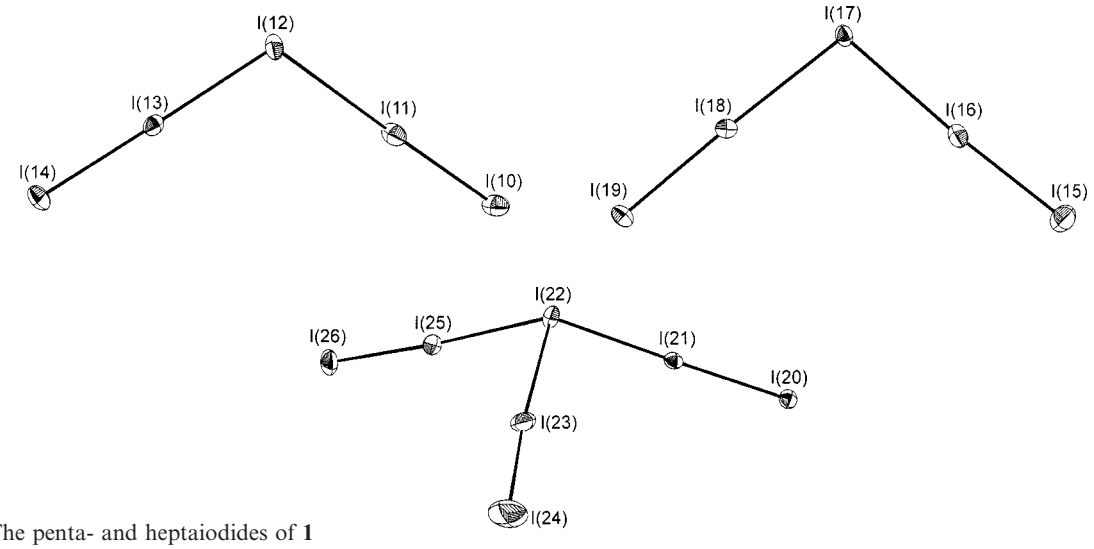

Figure 4. The penta- and heptaiodides of **1**

triiodide coordinated to an I_2 molecule (L-shaped). If the latter description is chosen, the very asymmetric triiodides I(12)−I(13)−I(14) [I(12)−I(13) 3.007(4) and I(13)−I(14) 2.843(4) Å] and I(17)−I(18)−I(19) [I(17)−I(18) 3.089(4) and I(18)−I(19) 2.805 Å] are linked to the iodine molecules I(10)−I(11) [2.751(4) Å] and I(15)−I(16) [2.790(4) Å], respectively. The triiodides are slightly bent [I(12)−I(13)−I(14) 179.3(1)° and I(17)−I(18)−I(19) 178.1(1)°].

The I_7^- anion can be described in terms of two I_2 molecules I(23)−I(24) [distance 2.748(5) Å] and I(25)−I(26) [distance 2.748(4) Å] coordinating to an asymmetric triiodide I(20)−I(21)−I(22) [distances 2.811(4) Å and 3.069(4) Å and angle 176.10(10)°]. The top angles of the "pyramid" are 94.8(1)° and 91.7(1)° [I(21)−I(22)−I(23) and I(23)−I(22)−I(25), respectively]. Consequently, with this description the formula of **1** can be written as $(Me_3S)_3[I_7(I_5)_2]\cdot 9/2I_2$. A comparison with structurally characterised pentaiodides and heptaiodides shows that the geometrical parameters of **1** are of normal magnitude.[23,24]

The intramolecular I−I distances of the intercalated I_2 units [I(1)−I(2), I(3)−I(4), I(5)−I(6), I(7)−I(8) and I(9)−I(9*)] vary from 2.73 to 2.77 Å. Pure iodine has intramolecular distances significantly shorter [2.715(6) Å in the solid state and 2.667(2) Å in the gas phase],[25,26] thus indicating a substantial charge-transfer interaction. The intermolecular I−I distances of the intercalated I_2 molecules are 3.36 Å and greater.

With the limits between intra- and intermolecular distance applied above it is easy to describe and visualise the structure of **1**. However, the situation becomes much more complicated if the limit for intramolecular distances is increased. Intermolecular I−I distances in the range 3.5−3.7 Å have been regarded as secondary bonds (van der Waals diameter of iodine 4.30 Å) and if the limit is set to 3.7 Å

in **1**, the structure instead adopts a complicated network structure.[27,28] This structure is difficult to visualise but it is possible to give a general understanding of its constitution by dividing the network into two layers. The first layer is parallel to the *ab* plane and is constructed of the pentaiodide I(10)−I(11)−I(12)−I(13)−I(14) and two of the "intercalated" iodine molecules I(5)−I(6) and I(7)−I(8) (Figures 5 and 6). The pentaiodide and the I(5)−I(6) iodine form edge-sharing, rectangular I_{16} units, while the iodine I(7)−I(8) and the "leg" of the pentaiodide I(10)−I(11) are not incorporated into the rectangular framework. The second layer is built up from I_{51} units, which are connected to each other through all edges (Figure 7). This layer intersects an equivalent layer in a chain-like manner.

The two layers are only connected to each other by I(17) which is linked to the free leg of the L-shaped pentaiodide I(10) [I(10)ΛI(17)]. Figure 8 shows how this connection ties the whole network together.

The highly crosslinked network of **1** is quite surprising considering the small cation used. There are few other polyiodides known in the literature that form extended, three-dimensional networks. All these have very bulky cations. There are some polyiodides that constitute network structures with metal centres incorporated, with the same type of cation as in **1**. These networks do not have any structural similarity with **1**, but they share the property of being highly connected and unstable under ambient conditions.[8−9]

The solid product from the reaction between TlI and $(Et_3S)I_7$ (molar ratio of 1:3) was identified as $(Et_3S)[TlI_4]$ (**2**) (Figure 9). The structure of **2** consists of tetrahedral TlI_4^- anions with Tl−I distances of 2.757(1)Å and I−Tl−I angles of 109.47(7)°, which agrees with mean values found in literature. X-ray diffraction studies on similar compounds have shown the anion to be sensitive to distortion,

especially by smaller cations (such as $Cs[TlI_4]$)[18] or for reasons of asymmetric coordination.[15] A directly related compound is $(Bu_4N)[TlI_4]$,[17] which shows a slight distortion of the anion, even though the ammonium cation is bulkier than Et_3S^+.

Thallium deviates from the other members of group 13, being averse to the oxidation state +III.[29] This fact, which has often been regarded as an inert-pair effect, makes Tl^{III} compounds strongly oxidising in all kinds of solvents.[29] However, the favoured Tl^{I} has to compete with the strong Lewis acidity of Tl^{III}, exemplified by the stability of the TlI_4^- complex anion. The absence of any other known Tl^{III} complexes with iodide is a consequence of thallium's reluctance to form Tl−Tl or halogen-bridged compounds, in contrast to the other elements in group 13.[29] The equilibrium between redox behaviour and complex formation, going from a weakly complex-forming Tl^{I} to a strongly complex-forming Tl^{III}, is affected by solvent properties, iodine and iodide concentration and not the least by lattice energies of the solid compounds that may be formed.[29]

In this work two iodides [TlI and $(Me_3S)I$ or $(Et_3S)I$] are present which complicates the situation even further. Not only because the iodide will interfere by "pushing the system away" from the desired Tl^{I} compounds in many solvents, but also because there is a new contribution to the lattice energy to be expected for every possible precipitate.

All these factors, summed up for the $TlI/(R_3S)I/I_2^-$ system, demand a finely tuned choice of cation size and symmetry, and stoichiometric composition of the reaction mixture. This enables a balance between the two extreme results of all parameters [Equation (1)].

$$Tl^{I}\text{/polyiodide} \leftarrow \text{choice of reaction conditions} \rightarrow Tl^{III}\text{ complex} \quad (1)$$

Reported syntheses with thallium most often lead to products to the right-hand side of Equation (1), due to the extreme stability of this complex anion.[29] Another system offering a choice between the left- and right-hand side of Equation (1) is reported by Tebbe et al.[15] Here, a crown ether is used to stabilise and increase the bulkiness of the, otherwise rare, TlI_2^+ cation. This large cation forms compounds with TlI_4^- as well as polyiodide anions. The variable in these syntheses is the iodine concentration in the solvent used.

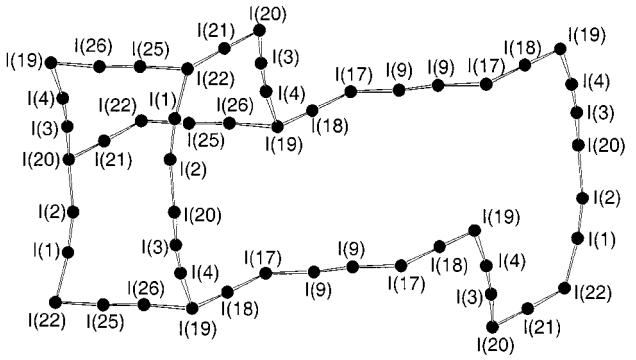

Figure 7. One of the I_{51} units that assemble the second layer

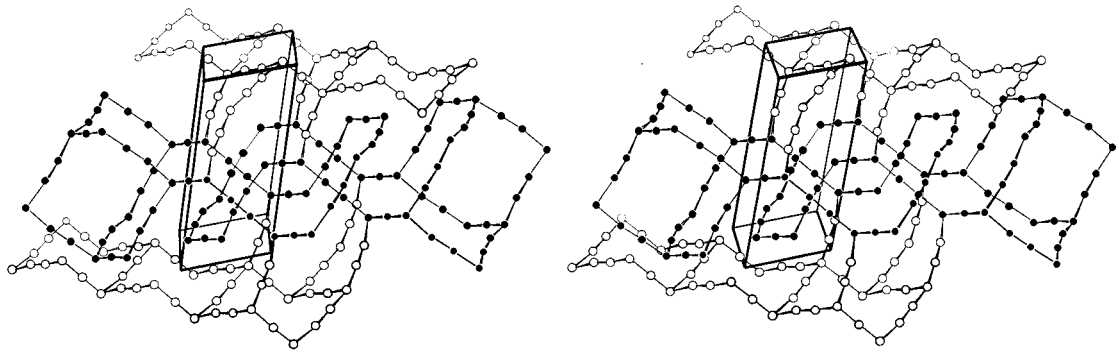

Figure 8. Stereoscopic view illustrating how the two layers are connected

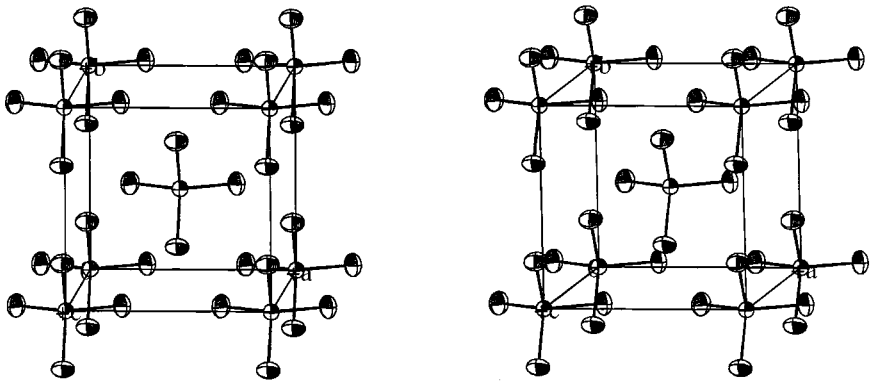

Figure 9. Stereoscopic view of the crystal structure of **2**; the cations are omitted for clarity

Under our choice of conditions, the shift in cation size going from R = Me to R = Et proved successful in the formation of both a polyiodide compound (compound **1**) and a Tl^{III} iodide complex (compound **2**). The stability of the crystalline products obey the established trends of both the Tl/I_2 and polyiodide systems: i.e. large cations (i) stabilise polyiodides[1−4] and (ii) push TlI/I towards TlI_4^-.[17,30] Following the decomposition process with Raman spectroscopy, a minor change in the I_2/I^- ratio, caused by the removal of I_2, causes compound **1** to collapse. This shifts the equilibrium towards the production of TlI_4^- [Equation (2) and (3)]. Compound **2**, on the contrary, is stable and resembles the congeners with other cations.

The oxidation of TI^{I} to Tl^{III} results in the reduction of iodine to two iodide ions. Consequently, an increase in the iodide activity is obtained [Equation (2)]. However, the complex formation of TlI_4^- requires four iodide ions [Equation (3)]. Thus, the I_2/I^- ratio is increased overall. This may explain why larger polyiodides such as $(Me_3S)_3I_{26}$ are formed by reaction with TlI.

$$Tl^{I} + I_2 \rightarrow Tl^{III} + 2\,I^- \quad (2)$$

$$Tl^{III} + 4\,I^- \rightarrow TlI_4^- \quad (3)$$

The structural and spectroscopic data obtained do not reveal which thallium species is present in the $TlI/(Me_3S)I_7$ reaction mixture.

^{205}Tl NMR Investigations

Different mixtures of TlI and $(Et_3S)I_7$ in the composition range 1:5 to 1:40 and temperature range 20 to 90 °C were investigated. Group-13 elements normally display a large chemical shift separation between the formal oxidation states +I and +III; at least as long as the ligands are relatively hard, viz. Cl^- or Br^-.

However, very soft ligands, such as I^-, have a tendency to decrease the chemical shift separation between formally Tl^{I} and Tl^{III} making unambiguous assignments of peaks in the NMR spectra more difficult. For Tl^{III} a decrease is seen for the chemical shift according to the series $Cl^- > Br^- > I^-$.[31] This series is reversed for Tl^{I} and the increase in chemical shift is coupled with growing covalency of the Tl^+-X^- bond.[31]

A mixture rich in $(Et_3S)I_7$ (1:6), preheated to 90 °C and cooled to room temperature, produces a single NMR peak at $\delta = -1414$. With the vibrational spectroscopy results in mind, this peak is assigned to TlI_4^-. Dilution with respect to $(Et_3S)I_7$ continuously shifts the frequency down to $\delta \approx -1350$ (at 1:40). The corresponding $TlI-(Me_3S)I_7$ mixtures are not liquid at room temperature and unchanged TlI can be observed visually. A 1:20 mixture displays a TlI_4^- peak at $\delta = -1368$ and a broad band (about 6 kHz) at $\delta = -1180$ assigned to TlI_3.[32]

The same features are shown by $TlI-(Et_3S)I_7$ mixtures which had not been previously treated at 90 °C. The two peaks appear at $\delta = -1400$ and -1188. A gradual increase in temperature up to 90 °C produces three spectral effects (Figure 10).

(1) The intensity of the broad band decreases and disappears after some time at 90 °C. Cooling shows that this change is reversible and suggests a simple temperature-dependent complex equilibrium.

(2) Both the broad band and the TlI_4^- peak move to more negative chemical shifts (about −1.5 ppm/°C).

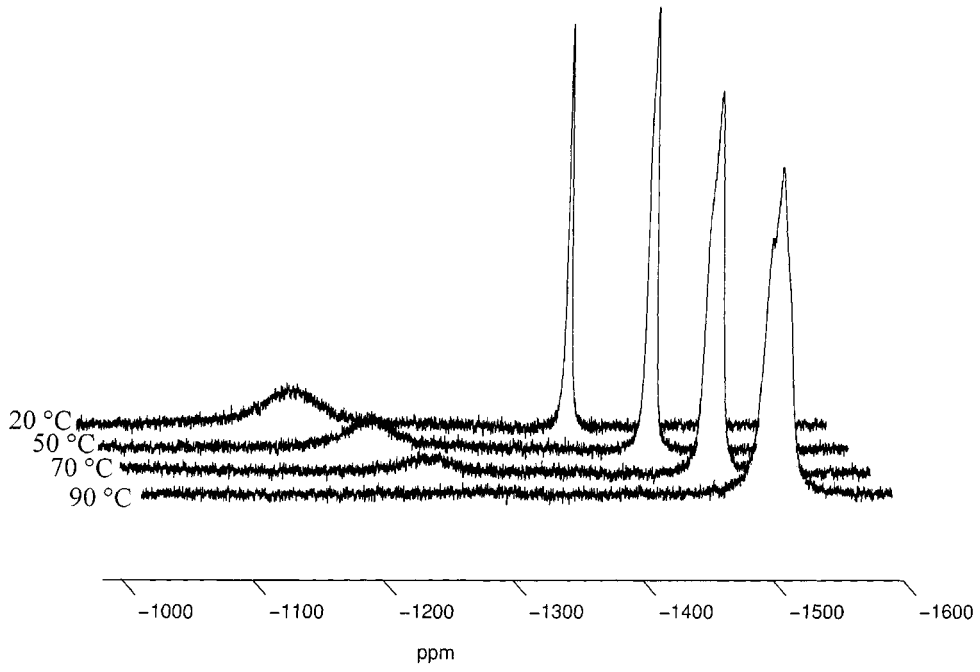

Figure 10. The ^{205}Tl NMR spectra of $TlI-(Et_3S)I_7$ with increasing temperature

(3) The peak assigned to TlI_4^- splits at higher temperatures; the new component appearing at an about 12 ppm more positive shift. This effect is reversed upon cooling, indicating a temperature-dependent equilibrium between two very similar $Tl^{III}-I^-$ species. The small difference in chemical shift and the vibrational spectroscopic data invariantly infer a Tl^{III} species of tetrahedral TlI_4^- character. The equilibrium in Equation (4) thus seems to be a logical assumption. However, recent spectroscopic and theoretical work show that the corresponding $Ga_2I_7^-$ and $In_2I_7^-$ ions only seem to be stable in solid state because of a strong tendency towards reduction of M^{III} to M^{I}.[33] Keeping in mind the easier reduction of Tl^{III} to Tl^{I}, $Tl_2I_7^-$ is a less likely species in solution. An equilibrium of the type of Equation (5) can possibly be suggested.[34]

$$2\,TlI_4^- \rightleftarrows Tl_2I_7^- + I^- \quad (4)$$

$$TlI_4^- + I_2(s) \rightleftarrows (TlI_4)^- \cdot I_2 \text{ or } TlI_3(I_3^-) \quad (5)$$

A gradual increase in temperature up to 90 °C of a $TlI-(Me_3S)I_7$ melt not preheated to 90 °C shows the features (1) and (2) (about −1 ppm/°C); however, the peak assigned to TlI_4^- surprisingly does not split at higher temperatures.

Conclusion

This work has shown that thallium does not have the same ability to be incorporated into polyiodide networks as the late transition metals (e.g. Au, Hg and Cd). A Tl/[(Me/Et)$_3$S]I_x polyiodide compound is probably formed but it is very unstable under ambient conditions and could not be detected or isolated with the methods applied. However, the polyiodide $(Me_3S)_3I_{26}$ could be isolated; which is surprising considering the small cation used. Consequently, the TlI/$(R_3S)I_x$ system indicates that it is possible to synthesise large polyiodides, even though a small cation is used, by supplying a strong Lewis acid which is not necessarily incorporated in the produced polyiodide compounds.

The Tl/[(Me/Et)$_3$S]I_x system is very complicated and the small change from Me_3S^+ to Et_3S^+ cations generate clear differences in the chemistry. In order to obtain a further understanding of which Tl species are present in the Tl/$(R_3S)I_x$ system other polyiodides with larger cations need to be investigated.

Experimental Section

Vibrational Spectroscopy: The far-infrared (far-IR) spectra were recorded with a Bio-Rad FTS 6000 FT-IR spectrometer using a resolution of 8 cm^{-1}. A globular light source was used, and a 6.25-mm Mylar beamsplitter in combination with a PE-DTGS detector produce an effective spectrum range of 50−550 cm^{-1}. The window material of the sample cells was of spectroscopic-quality polyethylene (Merck). The backscattering of the compounds was recorded using the 1064-nm radiation from an Nd:YAG laser in a Bio-Rad FT-Raman spectrometer. The radiation was recorded using a nitrogen-cooled, Ge-diode detector and 4-cm^{-1} resolution.

^{205}Tl NMR Spectroscopy: The ^{205}Tl NMR spectra of the $TlI-(R_3S)I_7$ (R = Me or Et) reaction media (1:5 to 1:40 ratios and 20−90°C) were recorded with a Varian Unity 300-MHz spectrometer operating at 172.925 MHz. A solution of 0.3 M $TlNO_3$ in water was used as standard and assigned a shift of $\delta = -7$.[35]

Synthesis of 1 and 2: The syntheses of compounds **1** and **2** were performed by direct reaction of TlI and the $(R_3S)I_7$ (R = Me or Et) melts at 90 °C. Both reactions were performed with a molar ratio of 1:3. A metal iodide/trialkylsulfonium heptaiodide ratio was chosen so that all metal iodide was dissolved in the reaction step with enough liquid polyiodide remaining to solvate the crystals produced. The latter condition is a necessary requirement for growing single crystals and for the survival of the otherwise air- and moisture-sensitive product **1**. The solid products were also examined after a few days of exposure to light and air, separated from the stabilising polyiodide melt, in order to determine the products after decomposition. A similar experiment was performed avoiding the contact with air and humidity, by sealing a tube containing the crystals and slightly heating the sample (T = 323 K) for 72 h.

Analogous syntheses starting from pure thallium metal were also performed. The products obtained were identical to those of using the TlI-based routes.

The crystalline products from the syntheses described above were recrystallised from methanol, ethanol, acetonitrile, acetone and *N*,*N*-dimethylthioformamide. In all cases, the resulting crystals observed after slow evaporation of the solvent apparently contain less iodine, i.e. they become lighter in colour than their precursors. This behaviour has previously been observed for similar compounds, most likely arising because of the effective and undesired solvation of I_2 by the solvents used. In order to minimise the loss of iodine we also recrystallised the solid compounds **1** and **2** from iodine-saturated ethanol. The latter resulted in darker crystals with a more porous habit as compared to the crystals obtained from other solvents.

X-ray Crystallographic Study: Single crystals of **1** and **2** were obtained from the reaction mixture at room temperature. The crystal data for the structures are presented in Table 2. The data for **1** were collected at 150 K, because of the tendency to lose iodine, while the data for **2** were collected at room temperature. All data were corrected for Lorentz-polarisation effects and an empirical absorption correction was applied using the Difabs (compound **1**) and ψ-scan (compound **2**) methods.[36,37] The structures were solved by the direct methods of SIR92 (**1**) and SHELXTL-PLUS (**2**) program packages.[38,39] The structure of **1** was refined on F, while the structure of **2** was refined on F^2.[40,39] The carbon and sulfur atoms of **1** were refined isotropically due to the high thermal displacement. One of the cations in **1** has the sulfur [S(1)] atom disordered in two positions. The cation of **2** is highly disordered and only the positions of the sulfur atoms were located (refined isotropically). Hydrogen atoms were placed in calculated positions for **1** (except for the disordered cation), and completely omitted in **2** because of the cation disorder. − Crystallographic data (excluding structure factors) for the structures in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-134329 [for $(Me_3S)_3I_{26}$] and CCDC-34330 [for $(Et_3S)TlI_4$]. Copies of the data can be obtained, free of charge, on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336033; E-mail: deposit@ccdc.cam.ac.uk].

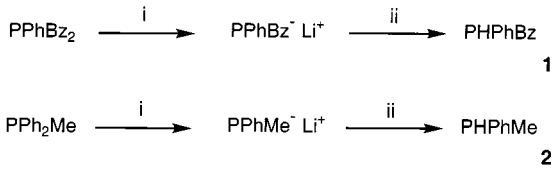
Resolution of Secondary Phosphanes Chiral at Phosphorus by Means of Palladium Metallacycles

Joan Albert,[a] J. Magali Cadena,[a] Jaume Granell,*[a] Guillermo Muller,[a] David Panyella,[a] and Carolina Sañudo[a]

Keywords: Phosphanes / Palladium / Metallacycles / Chiral resolution / Configuration determination

The synthesis of new epimeric compounds [PdCl(C–N){(±)-PHPhR}] (C–N = (*R*)-$C_{10}H_6CHMeNH_2$ and (*R*)-$C_6H_4CHMeNH_2$, R = Me and $PhCH_2$) containing chiral secondary phosphanes is reported. Some of these diastereomers can be separated by column chromatography; subsequent reaction of these complexes with 1,2-bis(diphenylphosphanyl)-ethane (dppe) affords the free phosphanes PHBzPh and PHMePh. The configurational stability of the secondary phosphanes resolved has also been studied.

Introduction



Due to the reactivity of their P−H bonds, secondary phosphanes are versatile synthons for the preparation of chiral mono- and bidentate ligands[1] but only one secondary phosphane chiral at phosphorus has been resolved to date. Six consecutive recrystallizations from acetonitrile in the presence of sodium acetylacetonate afforded the [R_P-(1*R*,2*S*,5*R*)] diastereomer of menthylmesitylphosphane in 94% optical purity.[2] The low configurational stability of P-chiral secondary phosphanes has been explained by acid-catalyzed racemization, in which the protonation of secondary phosphanes affords achiral phosphonium ions with two enantiotopic protons that can be removed at identical rates. Wild et al. have shown by ^{31}P NMR experiments that the H/D exchange between PHMePh and PDEtPh is negligible in highly purified acetonitrile in the presence of sodium acetylacetonate as a proton scavenger, showing that the resolution of secondary phosphanes may be feasible under mildly basic conditions.[3] When the phosphane is attached to metal ions, a borane or chalcogens by means of the lone pair the racemization does not occur and some diastereomers containing coordinated secondary phosphanes have been separated.[3,4] However, with the exception of the remarkable results described by Wild et al. with menthylmesitylphosphane,[2] recovery of the free optically pure ligand has not been accomplished.

Here we report the synthesis and separation of some diastereomers of compounds [PdCl($C_{10}H_6CHMeNH_2$)-(PHPhR)] (R = Me and $PhCH_2$) and the isolation of the free secondary phosphanes by the action of 1,2-bis(diphenylphosphanyl)ethane (dppe) on these cyclopalladated derivatives. The configurational stability of the secondary phosphanes resolved and the isotopic exchange between these ligands and D_2O has also been studied.

Results and Discussion

(±)-Benzylphenylphosphane was synthesized by reaction of dibenzylphenylphosphane and lithium metal in tetrahydrofuran under a dry nitrogen atmosphere. After 16 h of stirring at room temperature complete cleavage of one of the CH_2−P bonds of the starting phosphane was accomplished, with formation of the benzylphenylphosphide anion. The ^{31}P NMR spectrum, under nitrogen, clearly illustrated the formation of this anion ($\delta = -37.1$) and was used to monitor the progress of the reaction. Subsequent addition of H_2O gave the secondary phosphane (±)-**1** in THF solution (Scheme 1). When methyldiphenylphosphane and lithium metal reacted in the same conditions complete cleavage of one of the Ph−P bonds of the starting phosphane was accomplished, with formation of the methylphenylphosphide anion ($\delta_P = -77.3$). Subsequent addition of H_2O gave (±)-methylphenylphosphane **(2)** in THF solution. It should be noted that these secondary phosphanes are air sensitive and careful workup under nitrogen is needed to obtain them in the free form. The separation of some diastereomers containing PHMePh or PHBzPh coordinated to iron[4b] or platinum[3][4c] has been reported but, to the best of our knowledge, these phosphanes have not been obtained in free form, optically pure.

The versatility of *ortho*-palladated derivatives of optically active N-donor ligands as resolving agents for Lewis bases has been convincingly demonstrated.[5] The optically pure cyclopalladated dinuclear compounds **3** and **4** were obtained from the optically active amines as reported.[6] Reaction of these dimers with the secondary phosphanes (±)-

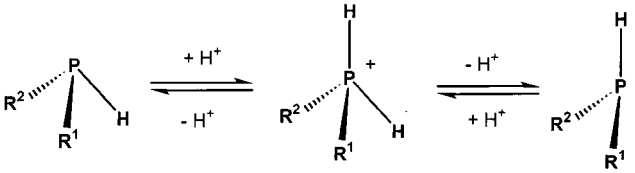
PHPhR afforded the mononuclear compounds [PdCl(C−N)(PHPhR)] (**5**, **6** and **7**), as a 1:1 mixture of the diastereomers (R_C,R_P) and (R_C,S_P) (Scheme 2). All the new organometallic compounds obtained were characterized by elemental analysis and IR, ^{1}H and ^{31}P NMR spectroscopy. In some cases, 2D NMR experiments (COSY and NOESY) were carried out to complete the characterization. The high-field shift of the aromatic protons of the palladated ring in the mononuclear derivatives, due to the aromatic rings of phosphanes, indicates the *cis* disposition of the phosphorus relative to the metallated carbon atom and the chemical shift in the ^{31}P NMR spectra confirms this arrangement.[7]



Scheme 2. L, 20 °C, $CHCl_3$ for **5** and **6** and THF for **7**

All attempts to separate the diastereomers of compounds **5**, **6** and **7** by recrystallization and all attempts to separate the diastereomers of **7** by column chromatography were unsuccessful. In contrast, the elution of compounds **5** and **6**, which contain the metallated (*R*)-(+)-1-(1-naphthyl)ethylamine, in a SiO_2 column (see Experimental Section) allowed the separation of the first diastereomer eluted **5′** and **6′**, in 45 and 63% yield, respectively (22.5 and 31.5% with respect to the total Pd), with a *de* higher than 95% in both cases [the superscripts (′) and (′′) indicate the first and the second diastereomer eluted in the column]. These results are consistent with previous reports since naphthyl adducts generally provide greater enantiomeric discrimination than their phenyl counterparts. It has been proposed that this is due to the fact that the methyl substituent of the chiral carbon atom adopts an axial disposition to avoid the unfavorable interaction with H^2 in the naphthyl adducts (see Scheme 2), and, in consequence, the five-membered metallacycle has a locked asymmetric envelope conformation. In contrast the methyl group is either axial or equatorial and this metallacycle adopts different conformations in 1-phenylethylamine derivatives.[8] The NOESY spectra of compounds **5** and **6** show that H^1 has strong negative off-diagonal peaks with H^2 and H^b and, in contrast, the methyl protons of the chiral carbon atom present only strong NOE interactions with H^a and H^1. These data confirm the axial disposition of this methyl group and the equatorial disposition of H^1 in both complexes.[9]

When a stoichiometric amount of 1,2-bis(diphenylphosphanyl)ethane was added to an ether solution of the optically pure cyclopalladated derivatives **5′** and **6′** the quantitative precipitation of the ionic compound [Pd(C−N)(dppe)]Cl took place and solutions of the enantiopure free phosphanes PHBzPh and PHMePh (^{31}P NMR : $\delta = -41.0$ or -71.7, respectively) in diethyl ether were obtained. No racemization of benzylphenylphosphane was observed when this ligand was stored in solution for 20 minutes, as verified by ^{31}P NMR spectroscopy, which showed the quantitative regeneration of the starting material **5′** from the dinuclear cyclopalladated derivative **3** and the corresponding free ligand. Three hours later significant racemization of the free phosphane was observed. In contrast, when this experiment was carried out with methylphenylphosphane, the formation of a ca. 1:1 mixture of diastereomers of **6** was observed in less than five minutes. The high configurational stability of PHBzPh is remarkable; it should be noted that an acetonitrile solution of menthylmesitylphosphane, the only secondary phosphane resolved until now, led to immediate epimerization at phosphorus in the absence of sodium acetylacetonate.[2]

Secondary phosphanes are difficult to obtain in an optically active form due to acid-catalyzed racemization, which involves the formation of an achiral phosphonium salt (see Scheme 3). In order to evaluate the tendency to protonation of the secondary phosphanes **1** and **2**, we analyzed the H/D exchange between the free phosphanes and D_2O in an NMR tube. A few drops of D_2O were added to THF solutions of the free secondary phosphanes **1** and **2** and ^{31}P NMR spectra were recorded (Figure 1). These spectra show that after 15 minutes a significant amount of PDMePh was formed, and after six hours PDMePh was the major compound. In contrast only a small amount of PDBzPh was formed after six hours. These findings suggest that the high configurational stability of PHBzPh is related to its stability against acid-catalyzed racemization, although the contribution to the racemization of other mechanisms cannot be ruled out.

Scheme 3. Acid-catalyzed racemization

The free secondary phosphanes described here are readily oxidizable and should be stored under nitrogen, although when coordinated to palladium (compounds **5** and **6**) they can be handled in air and are stable for several months. In consequence, these naphthyl cyclopalladated derivatives can also be used to store the phosphanes and to obtain them in free form when needed by reaction with dppe.

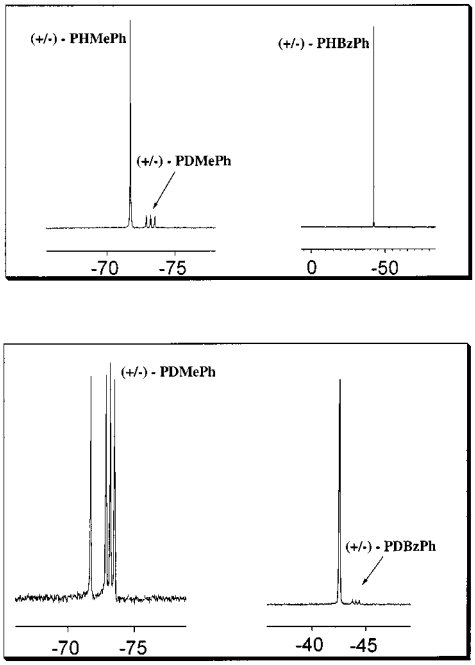


Figure 1. $^{31}P\{^{1}H\}$ NMR spectrum in THF solution of the free secondary phosphanes **1** and **2**: (a) five minutes after the addition of D_2O; (b) after six hours

Experimental Section

^{1}H NMR at 200 MHz or 500 MHz, and $^{31}P\{^{1}H\}$ at 101.26 MHz spectra were recorded on Varian Gemini 200, Varian VXR 500 and Bruker DRX 250 spectrometers, respectively. Chemical shifts (in ppm) were measured relative to $SiMe_4$ for ^{1}H and to 85% H_3PO_4 for ^{31}P. The solvents used were $CDCl_3$ for ^{1}H NMR and THF or $CHCl_3$ for ^{31}P NMR. Microanalyses were performed at the Institut de Química Bio-Orgànica de Barcelona and the Serveis Científico-Tècnics de la Universitat de Barcelona. The optical rotations of the complexes were determined at 20 °C using a Perkin−Elmer 241-MC polarimeter. Infrared spectra were recorded as KBr disks on a Nicolet 520 FT-IR spectrometer.

Materials and Synthesis: All the reactions involving free phosphanes were carried out using Schlenk techniques under a nitrogen atmosphere. All solvents were dried and degassed by standard methods. Tetrahydrofuran and diethyl ether were distilled over sodium/benzophenone, under nitrogen, before use. All chemicals were of commercial grade and used as received. Cyclopalladated compounds **3** and **4**, and $PPhBz_2$ were prepared according to procedures described elsewhere.[6,10]

Synthesis of [PdCl{(*R*)−$C_{10}H_6CHMeNH_2$}{(±)-PHBzPh}] (5): Small pieces of lithium (86.0 mg, 12.4 mmol) were added to a solution of dibenzylphenylphosphane (1.5 g, 5.2 mmol) in THF (40 mL) and the reaction mixture was stirred for 16 hours at 20 °C. The unreacted lithium was removed by decantation, and then 0.5 mL of water was added and the mixture stirred for a further 10 min. The resulting solution was dried over anhydrous Na_2SO_4 and filtered off to obtain a THF solution of (±)-PHBzPh [^{31}P NMR (101.26 MHz, $CDCl_3$): δ = −41.0 (d, J_{H-P} = 205 Hz)]. This solution was slowly added to a suspension formed by 0.24 mmol of the corresponding cyclopalladated dimer **3** in $CHCl_3$ (30 mL) until complete dissolution of the precipitate. The resulting solution was concentrated in vacuo and the solid obtained was eluted by SiO_2 column chromatography with $CHCl_3$/acetone (100:4) as eluent. Compound **5** [ca. 1:1 mixture of the diastereomers (R_C,R_P) and (R_C,S_P)] was isolated as a yellow solid. The yield of the process was 65% (160 mg) relative to the cyclopalladated compound **3**. − $C_{25}H_{25}ClNPPd$ (512.31): calcd. C 58.61, H 4.91, N 2.73; found C 58.7, H 4.8, N 2.5. − ^{31}P NMR (101.26 MHz, $CDCl_3$): δ = 26.9 (d, J_{H-P} = 362 Hz), 25.2 (d, J_{H-P} = 367 Hz).

Separation of Diastereomers 5: The 1:1 mixture of the diastereomers (R_C,R_P)- and (R_C,S_P)-**5** (100 mg) was carefully eluted at room temperature on an SiO_2 column (30 × 400 mm, 50 g SiO_2) with $CHCl_3$/acetone (100:2) as eluent. Fractions of 15 mL were collected, concentrated in vacuo and checked by ^{1}H NMR spectroscopy. The fractions were selected using the aromatic or the methylic proton signals. The first diastereomer eluted, **5′**, was obtained in 45% yield (22.5 mg), with a *de* higher than 95%, and the second diastereomer, **5′′**, was obtained in 38% yield (19 mg), with 52% diastereomeric purity.

5′: ^{1}H NMR (500 MHz, $CDCl_3$): δ = 7.88 (m, 2 H, H_{ar}), 7.67 (d, J_{HH} = 7.5 Hz, 1 H, H_{ar}), 7.59 (d, J_{HH} = 8.0 Hz, 1 H, H_{ar}), 7.47 (m, 1 H, H_{ar}), 7.40−7.30 (m, 5 H, H_{ar}), 7.19−7.12 (m, 5 H, H_{ar}), 6.97 (t, J_{HH} = 9.0 Hz, 1 H, H^7), 5.23 (sextuplet, J_{HH} = 5.5 Hz, 1 H, H^1), 5.02 (dt, J_{HH} = 6 Hz, J_{PH} = 367 Hz, 1 H, *H*P), 4.04 (br s, 1 H, H_a), 3.92 (m, 1 H, CH_2P), 3.63 (m, 1 H, CH_2P), 3.46 (br s, 1 H, H_b), 1.84 (d, $^{3}J_{HH}$ = 6.5 Hz, 3 H, *Me*). − ^{31}P NMR ($CDCl_3$): δ = 25.2 (d, J_{H-P} = 367 Hz). − $[\alpha]_D^{20}$ = +62.4 (*c* = 204 mg/100 mL, in $CHCl_3$).

5′′: ^{1}H NMR (500 MHz, $CDCl_3$): δ = 7.72−7.60 (m, 4 H, H_{ar}), 7.40−7.13 (m, 10 H, H_{ar}), 6.85 (m, 2 H, H^6, H^7), 4.91 (dt, J_{HH} = 5.6 Hz, J_{PH} = 362 Hz, 1 H, *H*P), 5.25 (q, J_{HH} = 5.8 Hz, 1 H, H^1), 4.71 (br s, 1 H, H_a), 3.57 (m, 3 H, CH_2P, H_b), 1.82 (d, $^{3}J_{HH}$ = 6.2 Hz, 3 H, *Me*). − ^{31}P NMR ($CDCl_3$): δ = 26.9 (d, J_{H-P} = 362 Hz).

[PdCl{(*R*)-$C_6H_4CHMeNH_2$}{(±)-PHBzPh}] (7): To a suspension of **4** in THF (30 mL) as starting material, the synthesis of **7** was analogous to the preparation of **5**. Compound **7** [ca. 1:1 mixture of the diastereomers (R_C,R_P) and (R_C,S_P)] was isolated as a yellow solid. The yield of the process was 30% (70 mg).

7: $C_{21}H_{23}ClNPPd$ (462.25): calcd. C 54.57, H 5.02, N 3.03; found C 54.4, H 5.2, N 3.2. − ^{1}H NMR (200 MHz, $CDCl_3$): δ = 7.90−7.70 (m, 4 H, H_{ar}), 7.50−7.30 (m, 6 H, H_{ar}), 7.20−7.10 (m, 10 H, H_{ar}), 6.95−6.85, (m, 8 H, H_{ar}), 5.05 (d, J_{HP} = 360 Hz, 2 H, *HP*), 4.10−3.50 (m, 6 H, *NH*, CH_2), 3.30 (br m, 2 H, *NH*), 1.67 (d, J_{HH} = 6.5 Hz, 3 H, *Me*), 1.60 (d, J_{HH} = 6.5 Hz, 3 H, *Me*). − ^{31}P NMR (101.26 MHz, $CDCl_3$): δ = 29.4 (d, J_{HP} = 360 Hz), 27.7 (d, J_{HP} = 362 Hz).

Synthesis of [PdCl{(*R*)-$C_{10}H_6CHMeNH_2$}{(±)-PHMePh}], 6: Small pieces of lithium (37.0 mg, 5.37 mmol) were added to a solution of methyldiphenylphosphane (0.5 mL, 2.68 mmol) in THF (20 mL) and the reaction mixture was stirred for 16 hours at 20 °C. The unreacted lithium was removed by decantation, and then 0.5 mL of water was added and the mixture stirred for a further 10 min. The resulting solution was dried over anhydrous Na_2SO_4 and filtered to obtain a THF solution of (±)-PHMePh [^{31}P NMR (101.26 MHz, $CDCl_3$): δ = −71.7 (d, J_{H-P} = 203 Hz)]. This solution was slowly added to a suspension formed of **3** (150.0 mg, 0.24 mmol) in 30 mL of $CHCl_3$ until dissolution of the precipitate. The resulting solution was concentrated in vacuo and the solid obtained was eluted by SiO_2 column chromatography with $CHCl_3$/methanol (100:3) as eluent. Compound **6** [ca. 1:1 mixture of the diastereomers (R_C,R_P) and (R_C,S_P)] was isolated as a yellow solid

in 75% yield (160 mg). – $C_{19}H_{21}ClNPPd$ (436.21): calcd. C 52.31, H 4.85, N 3.21; found C 51.3, H 4.8, N 3.1. – ^{31}P NMR ($CDCl_3$): δ = −0.8 (d, J_{H-P} = 360 Hz); −1.2 (d, J_{H-P} = 364 Hz).

Separation of Diastereomers 6.: The 1:1 mixture of the diastereomers (R_C,R_P)- and (R_C,S_P)-**6** (100 mg) was carefully eluted at room temperature on a SiO_2 column (30 × 400 mm, 30 g SiO_2) with $CHCl_3$/acetone (100:6) as eluent. Fractions of 15 mL were collected, concentrated in vacuo and checked by ^1H NMR spectroscopy. The fractions were selected using the aromatic or the methylic proton signals. The first diastereomer eluted, **6′**, was obtained in 63% yield (31.5 mg), with a *de* higher than 95%, and the second diastereomer, **6′′**, was obtained in 15% yield (7.5 mg), with 86% diastereomeric purity.

6′: ^1H NMR ($CDCl_3$): δ = 8.00 (m, 2 H, H_{ar}), 7.70 (d, J_{HH} = 6.0 Hz, 1 H, H_{ar}), 7.63 (d, J_{HH} = 8.0 Hz, 1 H, H_{ar}), 7.49−7.32 (m, 7 H, H_{ar}), 7.07 (t, J_{HH} = 8.5 Hz, 1 H, H^7), 5.28 (dq, J_{HH} = 6.0 Hz, J_{HP} = 364 Hz, 1 H, *HP*), 5.26 (sextuplet, J_{HH} = 5.5 Hz, 1 H, H^1), 4.10 (br s, 1 H, H_a), 3.46 (br s, 1 H, H_b), 1.99 (dd, J_{HH} = 6.0 Hz, J_{PH} = 11.5 Hz, 3 H, *Me*P), 1.88 (d, $^3J_{HH}$ = 6.5 Hz, 3 H, *Me*). – ^{31}P NMR ($CDCl_3$): δ = −1.2 (d, J_{H-P} = 364 Hz).

6′′: ^1H NMR ($CDCl_3$): δ = 7.75−7.60 (m, 4 H, H_{ar}), 7.43−7.20 (m, 7 H, H_{ar}), 5.07 (dq, J_{HH} = 6.0 Hz, J_{HP} = 360 Hz, 1 H, *HP*), 5.28 (sextuplet, J_{HH} = 6.2 Hz, 1 H, H^1), 4.93 (br s, 1 H, H_a), 3.45 (br s, 1 H, H_b), 1.84 (d, $^3J_{HH}$ = 6.5 Hz, 3 H, *Me*), 1.50 (dd, J_{HH} = 6.1 Hz, J_{HP} = 11.4 Hz, 3 H, *MeP*). – ^{31}P NMR ($CDCl_3$): δ = −0.8 (d, J_{H-P} = 360 Hz).

Acknowledgments

We thank the DGICYT (projects: PB 96−104 and PB97−407-C5−4) and the Comissionat per a Universitats i Recerca (project: 1997SGR 00174) for financial support. J. M. C. thanks the Agencia Española de Cooperación Internacional for a fellowship.

Chiral Diphosphites as Ligands for the Rhodium- and Iridium-Catalysed Asymmetric Hydrogenation: Precatalyst Complexes, Intermediates and Kinetics of the Reaction

Oscar Pàmies,[a] Gemma Net,[a] Aurora Ruiz,*[a] and Carmen Claver[a]

Keywords: Asymmetric hydrogenation / Chiral diphosphites / Iridium / Rhodium

Rh^I and Ir^I complexes $[M(cod)PP]BF_4$ were synthesised from diphosphite ligands PP with a backbone derived from xylofuranose. They were used in the rhodium- and iridium-catalysed asymmetric hydrogenation of itaconic acid, α-acetamidocinnamic acid and methyl α-acetamidoacrylate. The kinetics of the reaction was investigated. The solution structures of the intermediates were studied by ^{31}P- and ^{1}H-HPNMR spectroscopy and a catalytic cycle is proposed.

Introduction

Most of the phosphorus ligands that have been developed for catalytic applications, particularly in asymmetric catalysis, are derivatives of aryl- or alkylphosphanes.[1] Recently, a group of less electron-rich phosphorous compounds, chelating diphosphite ligands, has received considerable attention. New reports on the use of these ligands in regio- and stereoselective hydroformylation[2] and asymmetric hydrocyanation,[3] have appeared, in which their potential utility have been demonstrated.

Very little attention has been paid to phosphites as ligands in hydrogenation, probably because of their high π-acidity, which makes the metal centre less suitable for bringing about the H_2-oxidative addition reactions. However, some catalysts based only on organyl phosphites have been applied to hydrogenation.[4] To our knowledge, only Selke et al.,[4g] Reetz et al.[4i] and Brunner et al.[4j] have reported the use of chiral diphosphites in asymmetric hydrogenation. In spite of the supposed disadvantage mentioned above and the ability to undergo hydrolysis or Arbuzov-type side reactions (starkly reduced in the case of bulky phosphites or coordinated phosphites[3b,5]), phosphites are a very attractive group of compounds for catalysis. They have many advantages, the most important of which are that they are easy to prepare from readily available starting materials and that they are less sensitive to air than phosphanes are.[3,6]

The large number of chiral diols available from asymmetric catalysis and from the chiral pool, the excellent results obtained in asymmetric hydrogenation with diphosphinites derived from D-glucose (intermediate basicity between diphosphanes and diphosphites)[7] and, more recently, with diphosphites[4i] encourage further study of the application of diphosphites in this reaction.

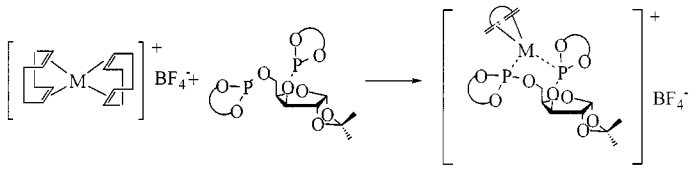
Here we report the synthesis of rhodium and iridium complexes with diphosphites derived from D-(+)-xylose and their use in the asymmetric hydrogenation of acrylic acid derivatives. We also investigated the kinetics of the catalysis and the catalytic cycle. These ligands were developed by van Leeuwen and co-workers and were applied to the asymmetric hydroformylation of styrene with enantioselectivities up to 62%.[2o] These bulky diphosphites are not only derived from a readily available carbohydrate, they are also fairly robust towards hydrolysis.

Results and Discussion



1. Synthesis of Olefinic Complexes

The reaction of the corresponding chiral diphosphites **1−3** with $[M(cod)_2]^+BF_4^-$ (M = Rh, Ir) in dichloromethane solution proceeded rapidly, with the displacement of one molecule of 1,5-cyclooctadiene ligand, even in a large excess of diphosphite ligand, to afford the cationic mononuclear complexes $[M(PP)(cod)]^+$ **4−9** (Scheme 1). These complexes were characterised by elemental analysis, ^{1}H-, ^{13}C-, and ^{31}P-NMR spectroscopy and FAB mass spectrometry.

The presence of two sets of signals in the ^{31}P-NMR spectra of all these complexes revealed the existence of two isomers in very different proportions. The relative abundance of these isomers did not change with temperature in the NMR, thereby indicating that there is no interconversion between them. The presence of isomers may be attributed to different atropisomers of the bis(phenol) moiety in the bis(phosphite) ligands, but the rapid ring inversion of the seven-membered dioxaphosphepin rings detected on the ^{31}P-NMR time scale in the free ligands and its $[HRh(PP)(CO)_2]$[2o] complexes suggest another origin for these isomers. A second, more plausible possibility is that there are different conformers for the eight-membered metal chelate ring.

Molecular mechanics calculations for complexes **4−9** were carried out. Two different conformers, **a** (boat−chair) and **b** (twist−boat−chair), which differ in the orientation

of the oxygen atom attached to C-5 in the sugar moiety, could be minimised for each complex. Figure 1 shows the minimised structures of the two conformers for complex **4**. The relative strain energies of these conformers for all complexes **4−9** are listed in Table 1. The results show that the most stable conformer is **a** for all the complexes. Their non-interconversion in VT-^{31}P NMR and the large difference in strain energy between the two conformers indicates that their transition state is extremely inaccessible.

The chemical shifts of the two different phosphorus atoms in **4−9** are in the range expected for tricoordinate P^{III} esters coordinated to Rh or Ir.[9] The rhodium−phosphorus coupling constants are very similar to those found for other $[Rh(diolefin)(PP)]^+$ complexes where PP is also a diphosphite.[4g] Coupling constants between 27 and 50 Hz can be observed between the two non-equivalent phosphorus atoms. The absence of P−P coupling in the free ligand[2o] suggests that these constants should be considered as ^2J(P−P), which means that the through-metal coupling predominates over through-backbone coupling.[9]

The characterisation by ^{13}C and ^{1}H NMR could not always be carried out because of the low intensity of some signals, partial overlapping of the spectra of mixtures of the two isomers or because the signals were too broad (especially important for product **7**). For **6**, a lowering of the temperature allowed the assignment of the ^{1}H-NMR peaks for both isomers.

2. Hydrogenation of Acrylic Acid Derivatives

The complexes $[M(cod)(PP)]^+$ (M = Rh, Ir; PP = **1**, **2**, **3**) **4−9** catalyse the asymmetric hydrogenation of itaconic acid **10** under mild conditions (5 bar, 40 °C) (Scheme 2, Table 2). In all cases, the (*R*) absolute configuration formed predominantly.

10 R^1 = H; $R^2 = CH_2COOH$; R^3 = COOH
11 R^1 = Ph; $R^2 = NHCOCH_3$; R^3 = COOH
12 R^1 = H; $R^2 = NHCOCH_3$; $R^3 = COOCH_3$

Scheme 2. Hydrogenation of acrylic acid derivatives with **4−9**

Table 1. Strain energies [kcal mol^{-1}] for conformers **a** and **b** of complexes **4−9**; experimental relative abundance (^{31}P-NMR data) in parentheses

Conformer[a]	4	5	6	7	8	9
a	484.4 (95)	380.7 (80)	237.8 (75)	404.8 (75)	297.0 (90)	153.1 (75)
b	530.1 (5)	401.0 (20)	268.9 (25)	456.6 (25)	318.9 (10)	184.5 (25)

[a] Recent investigations by our group have shown that relative strain energies between two conformers calculated by MM are very similar to those calculated with methods based on density functional theory (DFT) (see ref.[8]).

[a] Toluene/methanol (2:1). − [b] CH_2Cl_2/methanol (2:1). − [c] Not determined.

In contrast to the results reported by Reetz and Neugebauer,[4i] the precursors with the most hindered ligands (**2** and **3**) brought about the best conversions. The most hindered ligands, however, are also ligands with electron-donating groups, which probably enhance the rate of conversion because they favour the oxidative addition reactions in the catalytic cycle. The increase in activity with electron-donating groups in the phenyl groups is lower in the case of the iridium complexes.

The $[Rh(cod)(PP)]^+$ complexes **4−6** gave better conversions in toluene/methanol than in CH_2Cl_2/methanol (e.g., Entries 3 and 4) while the $[Ir(cod)(PP)]^+$ complexes **7−9** were more efficient in CH_2Cl_2/methanol. Within the accuracy of this experiment, there was no change in the enantioselectivities over time. This agrees with the presence of a unique catalytic species during the hydrogenation (though there is no proof for it).

The iridium complexes **7−9** were more active than their rhodium analogues, but the asymmetric inductions were lower (between 11 and 35% for the iridium compounds, between 20 and 50% for the rhodium compounds). The asymmetric inductions with precursors containing ligand **1** (Entries 1 and 5) are much lower than those with ligands **2** and **3** (Entries 2, 3, 6, and 7), as would be expected by its smaller bulkiness. The lower asymmetric induction of precursors containing ligand **1**, compared to **2** and **3**, was also observed in the hydroformylation of styrene.[2o] The change of the substituent at the *para* position of the bis(phenol) moiety showed very little effect on rate and asymmetric induction (Entries 2, 3, 6, and 7).

The high activity of the iridium complexes allowed a decrease of pressure and temperature of the reaction. Lowering the reaction temperature from 40 to 25 °C at 5 bar resulted in lower conversions but the asymmetric inductions did not change (Entries 5 vs. 8, 6 vs. 9, 7 vs. 10). Lowering the hydrogen pressure from 5 to 1 bar at 40 °C increased the asymmetric inductions (Entries 11 vs. 6, 12 vs. 7). In contrast to the observations at 5 bar, the asymmetric inductions at 1 bar are temperature-dependent. For both complexes with ligands **2** and **3**, the enantioselectivity of the reaction is decreased by a lowering of the temperature from 40 °C to 25 °C at 1 bar (Entries 11 vs. 13, 12 vs. 14). This is probably because there are different mixtures of hydride species at 1 bar and 5 bar.

Diphosphites **2** and **3** were also tested for the hydrogenation of other acrylic acid derivatives, α-acetamidocinnamic acid (**11**) and methyl α-acetamidoacrylate (**12**) (Scheme 2). The results obtained are given in Table 3.

Table 3. Hydrogenation of α-acetoamidocinnamic acid (**11**) and methyl α-acetamidoacrylate (**12**) with $[M(cod)(PP)]BF_4$ **5**, **6**, **8**, **9**; M = Rh, Ir {conditions: *T* = 40 °C, *t* = 20 h [cat]/[substrate] = 1:100; substrate (2 mmol); solvent (12 mL)}

Entry	Precursor	Substrate	*P* [bar]	Conv. (%)	*ee* (%)

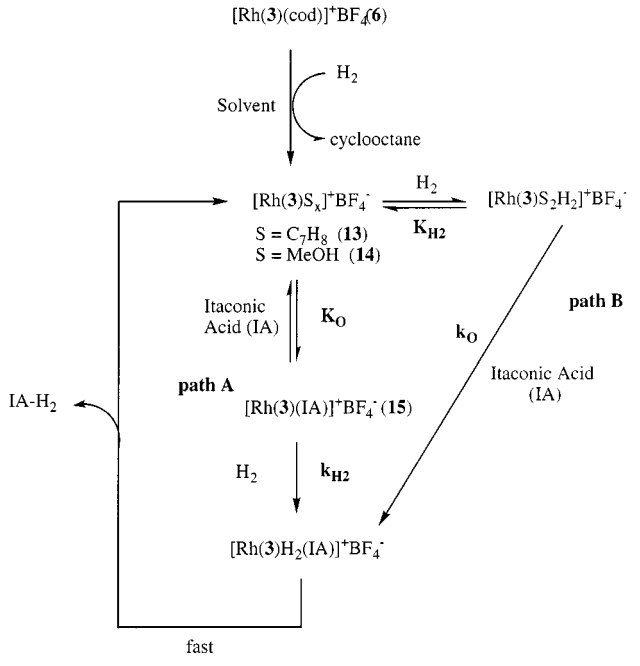
[a] Toluene/methanol (2:1). − [b] CH_2Cl_2/methanol (2:1). − [c] CH_2Cl_2.

At 5 bar, the hydrogenation of **11** and **12** with the rhodium complexes **5** and **6** proceeded at a similar rate to the hydrogenation of itaconic acid (**10**), but enantiomeric excesses were lower (Entries 1, 2, 5, and 8). Lowering the pressure in the hydrogenation of **12** resulted in lower enantioselectivity (Entry 5 vs. 6). The effect was the same when the solvent was changed from toluene/methanol to CH_2Cl_2 (Entry 7 vs. 5). At 5 bar, the iridium complexes **8** and **9** were less active and enantioselective than their rhodium counterparts in the hydrogenation of **11** and **12** (Entry 1 vs. 3, 2 vs. 4; 5 vs. 9, 8 vs. 10). At 5 bar, the iridium complexes were more active and enantioselective in the hydrogenation of **11** than in that of **12** (Entries 3, 4 vs. 9, 10). The iridium compounds were unable to hydrogenate **11** at 1 bar, while they could hydrogenate **12** (Entries 11, 12) with better enantioselectivity than at 5 bar (Entries 11, 12 vs. 9, 10). However, the asymmetric induction was lower than for substrate **10** (Table 3, Entries 11, 12 vs. Table 2 Entries 11, 12).



3. Catalytic Cycle Elucidation

Enantioselective hydrogenation catalysed by cationic (diolefin)(diphosphane)rhodium complexes has been thoroughly studied mechanistically. The widely accepted catalytic cycle, a result of the work of the groups of Brown, Halpern, Landis and Bosnich[10] involves the so-called alkene path, the first step of which is the hydrogenation of the diolefin coordinated to the rhodium centre, followed by the coordination of the alkene to the free site generated on the metal centre, the oxidative addition of molecular hydrogen, insertion and reductive elimination. Complexes with diphosphites do not necessarily have to follow the same se-

quence of steps, because their electronic properties are different from those of phosphanes. To identify the intermediates of the Rh-catalytic cycle of the hydrogenation of itaconic acid with phosphites and therefore to determine the sequence in the catalytic cycle, ^{1}H- and ^{31}P-HPNMR studies were carried out with the complexes of the most hindered ligand, **3**.

3.1. Characterisation Experiments of Rhodium-Cycle Intermediates

When complex [Rh(**3**)(cod)]$^+$BF$_4^-$ was dissolved in [D$_8$]toluene and kept for four hours at room temperature under 5 bar of H_2 pressure, an ABX pattern was obtained in ^{31}P HPNMR, which did not change after the system was cooled to −40 °C and then warmed up to 60 °C. The new compound was identified as [Rh(**3**)(C$_7$D$_8$)$_x$]$^+$ (Scheme 3). The stable yellow compound [Rh(**3**)(C$_7$H$_8$)$_x$]$^+$ (**13**) was isolated in a larger-scale preparative experiment in toluene. Elemental analysis and ^{1}H NMR in CCl_4 suggested that two toluene molecules was present in the compound. In general, arenes show a high tendency to form [M(η^6-arene)L$_2$]$^+$ species when L is a phosphane.[11] The (benzene)(dppe) compound was isolated as [Rh(dppe)(η^6-C$_6$H$_6$)]$^+$BF$_4^-$ · C$_6$H$_6$.[12] Compound **13** could then be formulated as [Rh(**3**)(η^6-C$_7$H$_8$)]BF$_4^-$ · C$_7$H$_8$. However, only one kind of methyl signal for toluene was detected in the ^{1}H-NMR spectrum of this complex. It appeared at δ = 2.71, in contrast to 2.37 for free toluene. There is probably a rapid exchange between them on the NMR time scale.

Scheme 3. Intermediates of the Rh catalytic cycle of the hydrogenation of itaconic acid

The two different phosphorous atoms in [Rh(**3**)(η^6-C$_7$H$_8$)]$^+$ show large P−Rh coupling constants (344.5 and 333.6 Hz), more than 100 Hz larger than in [Rh(**3**)(cod)]$^+$BF$_4^-$. These large constants may be explained by the smaller *trans* influence of the toluene rather than an olefin as ligand.

When [Rh(**3**)(η^6-C$_7$H$_8$)]$^+$BF$_4^-$ · C$_7$H$_8$ was treated with 5 bar of H_2, no formation of hydride species was detected by HPNMR as has been reported for different arene [M(η^6-arene)L$_2$]$^+$ complexes.[13]

Moreover, when the complex [Rh(**3**)(cod)]$^+$BF$_4^-$ was dissolved in [D$_8$]toluene/[D$_4$]methanol (2:1) and pressurised to 5 bar of H_2 at room temperature for four hours, the ABX pattern in the ^{31}P-HPNMR spectrum was similar. The compound could be assigned to [Rh(**3**)(CD$_3$OD)$_x$]$^+$ (Scheme 3). Cooling it to −40 °C did not change the spectrum. [Rh(**3**)(CH$_3$OH)$_2$]$^+$BF$_4^-$ (**14**) was isolated in a larger scale experiment in methanol as a stable yellow solid. The P−Rh coupling constants are also very large and similar to those obtained with the toluene complex (341.9 and 332.1 Hz). As has been reported for methanol [Rh(diphosphane)(CH$_3$OH)$_2$]$^+$ complexes,[14] the formation of hydride species was not detected by HPNMR when complex [Rh(**3**)(CH$_3$OH)$_2$]$^+$ was treated with 5 bar of H_2.

To study the coordination of itaconic acid in the cationic complex, the complex [Rh(**3**)(cod)]$^+$BF$_4^-$ was dissolved in [D$_8$]toluene and was pressurised to 5 bar at room temperature for four hours. After [Rh(**3**)(η^6-C$_7$D$_8$)]$^+$BF$_4^-$ · C$_7$D$_8$ was formed, the system was depressurised and an excess of itaconic acid in [D$_4$]methanol (2:1 with respect to [D$_8$]toluene) was added. After 17 minutes, two products, [Rh(**3**)(IA)]$^+$ (**15**) (IA denotes itaconic acid) and [Rh(**3**)(CD$_3$OD)$_2$]$^+$ were observed by ^{31}P-NMR spectroscopy. After 50 minutes, only [Rh(**3**)(IA)]$^+$ was observed in solution. Itaconic acid makes competitive or cooperative binding by α- and β-carboxylates possible. This usually results in three distinct types of complexes (for a 1:1 stoichiometry), which may coexist, where coordination takes place through the olefin and the α-carboxylate, the β-carboxylate, or both (Figure 2).[15] Despite the moderate enantiomeric excesses obtained in the asymmetric hydrogenation of itaconic acid with [Rh(**3**)(cod)]$^+$BF$_4^-$, complex [Rh(**3**)(IA)]$^+$ exists as a single isomer. Unfortunately, all attempts to isolate this compound were unsuccessful. The P−Rh coupling constants are very large (329.5 and 334.5 Hz). The P−P coupling constant is much larger than those for **13** and **14**, which could suggest that the complex has another geometry. This means that the itaconic acid is probably terdentate-coordinated through the olefin and both α- and β-carboxylates. Five-coordination is a usual geometry for itaconic acid diphosphane Rh$^{\mathrm{I}}$ complexes.[15] An IR spectrum of the solution revealed a broad carboxylic band at higher energy than in the free acid (1667 cm^{-1} vs. 1635 cm^{-1}), which supports the hypothesis about the coordination of both carboxylates. The 2D-NOESY spectrum showed cross-peaks between the olefinic protons of the itaconic acid and the *tert*-butyl groups of the ligand. This supports the hypothesis that the structure is five-coordinated.

No hydride species were observed in the ^{1}H-HPNMR spectra when a solution of complex **15** was pressurised at 5 bar of H_2.

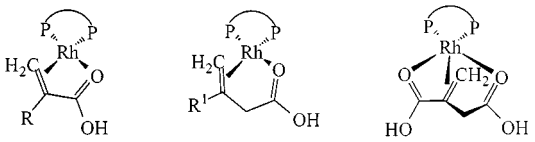


Figure 2. Possible types of coordination for itaconic acid

We can assume from the HPNMR results that the first step is the formation of $[Rh(\mathbf{3})S_2]^+$ by hydrogenation of the olefin coordinated to the rhodium centre. From this species, there are two ways in which itaconic acid can be hydrogenated (Scheme 3). The first (path A) involves the oxidative addition of the H_2 after the coordination of the alkene, while in the second (path B) the oxidative addition of H_2 takes place first.

3.2. Kinetic Study

To find out more about the mechanism of the Rh-catalyzed hydrogenation of itaconic acid at 5 bar of H_2 and 40 °C, we studied the dependence of the rate on the reaction parameters (itaconic acid concentration, H_2 pressure and Rh concentration). The formation of the hydrogenated product over time at [Rh] = 1.66 mM is depicted in Figure 3. The rate of hydrogenation increases after an initial induction period (which is independent on the H_2 pressure used), due to the hydrogenation of the coordinated cyclooctadiene. The formation of methylsuccinic acid is zero-order in substrate concentration, first-order in rhodium concentration (Table 4) and almost first-order in hydrogen pressure (Figure 4) between 5 and 11 bar. Above 11 bar, the pressure dependence of the rate is no longer linear and declines, which suggests a change in the mechanism.

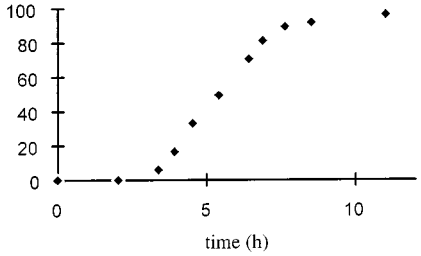

Figure 3. Variation of the conversion of itaconic acid vs. time

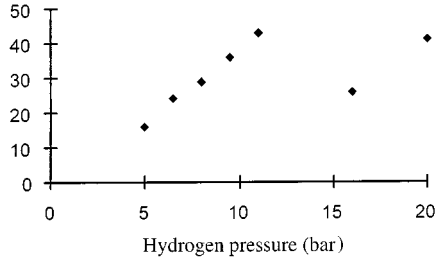
Table 4. Influence of the total rhodium concentration on the reaction rate at 5 bar and 40 °C

$[Rh]_T$ 10^{-3} M	k [h^{-1}]
0.83	8.1
1.66	18.9
3.33	35.6

Consequently, and due to the complexity of such a system (Scheme 3), the individual steps of the catalytic cycle had to be studied separately. K_O[IA] (Scheme 4) can be estimated from the HPNMR populations. In this way, and from the solubility of H_2 at 40 °C in toluene/methanol (2:1) ($s = 2.2 \cdot 10^{-2}$ M), which was calculated by HPNMR with CH_3CN as a standard, we can estimate K_{H2} (Scheme 4). A



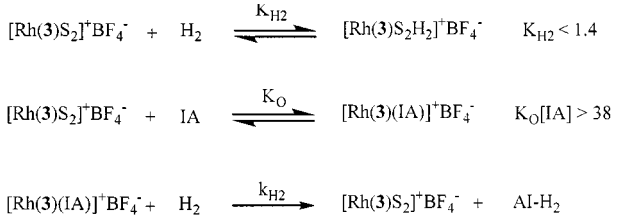


Figure 4. Dependency of the conversion of itaconic acid on H_2 pressure at 40 °C and [Rh] = 1.66 mM

sample of $[Rh(\mathbf{3})(IA)]^+BF_4^-$, generated in situ by mixing isolated $[Rh(\mathbf{3})(CH_3OH)_2]^+BF_4^-$ and 1 equiv. of itaconic acid, was charged in the HPNMR tube at 5 bar, to calculate k_{H2} by HPNMR (Scheme 4). However, the results are not conclusive because of the drop in pressure during the hydrogenation experiment.

Scheme 4. Individual steps of the catalytic cycle

From these results and the fact that the resting state observed by HPNMR at 5 bar is always complex **15**, we cannot conclude that the rate-determining step is not the addition of H_2 to the complex $[Rh(\mathbf{3})S_2]^+$, since it should have a negative order in the itaconic acid concentration. In spite of this, path B cannot be discarded because the same pattern in the rate law derived from mechanism A can be obtained from path B if the rate-determining step is the addition of IA to the complex $[Rh(\mathbf{3})S_2]^+$.

According to the improved conversion when a more basic diphosphite was used, the hydrogenation of itaconic acid with precursor **6** is in agreement with path A, where the rate-determining step is the oxidative addition after partial decoordination of IA to complex $[Rh(\mathbf{3})(IA)]^+$.

Conclusions

Complexes [M(diphosphite)(cod)]BF_4, M= Rh, Ir, with diphosphites derived from xylose, are active in the hydrogenation of some acrylic acid derivatives and achieve moderate enantioselectivities. The most basic hindered diphosphites provided better conversions and selectivities. Under the same conditions, the rhodium-catalysed hydrogenation achieved better enantioselectivities than the iridium-catalysed reaction. Kinetic studies of the Rh-catalysed hydrogenation of itaconic acid between 5 and 11 bar were consistent with a reaction rate which is zero-order in itaconic acid concentration, first-order in rhodium concentration and first-order in H_2 pressure. Despite the electronic differences between phosphanes and phosphites, the Rh-catalysed hy-

drogenation of itaconic acid with diphosphites seems to follow the same mechanism as the one proposed for diphosphanes in the hydrogenation of α-acetamidocinnamic acid.

Experimental Section

General Comments: All syntheses were performed by standard Schlenk techniques under nitrogen or argon. The complexes $[Rh(cod)_2]^+BF_4^-$,[16] $[Ir(cod)_2]^+BF_4^-$,[16] and the diphosphite ligands **1**, **2**, and **3**[2o] were prepared by previously described methods. Solvents were purified by standard procedures. All other reagents were used as commercially available. Elemental analyses were performed with a Perkin−Elmer 240 B instrument. ^{1}H-, ^{13}C{^{1}H}-, and ^{31}P{^{1}H}-NMR spectra were recorded with a Varian Gemini 300 MHz spectrometer. Chemical shifts are relative to $SiMe_4$ (^{1}H and ^{13}C) as internal standard or H_3PO_4 (^{31}P) as external standard. All assignments of NMR spectra were determined by means of COSY and HETCOR spectra. Standard pulse sequences were employed for the ^{1}H-^{2}D-NOESY.[17] EI mass spectra were obtained with an HP 5989 A spectrometer. VG-Autospect equipment was used for FAB mass-spectral analyses. The matrix was *m*-nitrobenzyl alcohol. Optical rotations were measured at 25 °C with a Perkin−Elmer 241 MC polarimeter. Hydrogenation reactions at high pressure were carried out in a home-made 100-mL stainless steel autoclave. The reaction under 1 atm of H_2 was performed in a previously described hydrogen−vacuum line.[18] The molecular mechanics calculations were carried out with the program CERIUS2 developed by Molecular Simulations (MSI)[19]and the force field UFF developed by Rappe et al.[20] Electrostatic interactions were taken into account from atomic charges generated by the Qeq method.[21]

Preparation of Rhodium Complexes. − General Procedure: The diphosphite ligand (0.1 mmol) was added to a solution of $[Rh(cod)_2]BF_4$ (40.5 mg, 0.1 mmol) in dichloromethane (2 mL). After 10 min, the desired products were obtained by precipitation with hexane.

[Rh(3)($CH_3OH)_2$]$^+$BF$_4^-$ (14): A 10-mL Schlenk flask was filled with a solution of **13** (0.05 mmol) in methanol (10 mL). After a reaction time of 30 min at room temperature, the product was obtained as a yellow-orange solid by concentration to dryness (62 mg, quant.). − $C_{66}H_{100}BF_4O_{11}P_2Rh$: calcd. C 60.00, H 7.63; found C 60.11, H 7.87. − ^1H NMR (300 MHz, CD_3OD): δ = 1.05 (s, 3 H, CH_3), 1.32 (s, 3 H, CH_3), 1.36 (s, 18 H, CH_3 *t*Bu), 1.38 (s, 18 H, CH_3 *t*Bu), 1.62 (s, 18 H, CH_3 *t*Bu),1.90 (s, 18 H, CH_3 *t*Bu), 2.32 (s, OH), 3.17 [d, 1 H, H-2, ^3J(H2,H1) = 3.3 Hz], 3.48 (s, CH_3−O), 4.09 (m, 2 H, H-5, H-5′), 4.56 (m, 1 H, H-4), 4.74 (m, 1 H, H-3), 5.52 [d, 1 H, H-1, ^3J(H1,H2) = 3.3 Hz]. − ^{31}P NMR (121.4 MHz, CD_3OD): δ = 132.32 [dd, 1 P, ^2J(P,P) = 50.3 Hz, ^1J(P,Rh) = 341.9 Hz], 133.07 [dd, 1 P, ^2J(P,P) = 50.3 Hz, ^1J(P,Rh) = 332.1 Hz].

[Rh(3){CH_2=C(CH_2COOH)(COOH)}]$^+$BF$_4^-$ (15): Itaconic acid (6.1 mg, 0.05 mmol) was added to a solution of **14** (62 mg, 0.05 mmol) in [D_4]methanol (1 mL). After 1 h, the NMR tube was filled and the mixture analysed. − ^1H NMR (300 MHz, CD_3OD): δ = 1.04 (s, 3 H, CH_3), 1.32 (s, 3 H, CH_3), 1.35 (s, 18 H, CH_3 *t*Bu), 1.37 (s, 18 H, CH_3 *t*Bu), 1.61 (s, 18 H, CH_3 *t*Bu),1.88 (s, 18 H, CH_3 *t*Bu), 3.18 [d, 1 H, H-2, ^3J(H2,H1) = 3.6 Hz], 3.30 (s, 2 H, CH_2), 4.08 (m, 2 H, H-5, H-5′), 4.43 (m, 1 H, H-4), 4.75 (m, 1 H, H-3), 5.52 [d, 1 H, H-1, ^3J(H1,H2) = 3.6 Hz], 5.72 (m, 1 H, CH=), 6.27 (m, 1 H, CH=). − ^{13}C NMR (75.4 MHz, CD_3OD): δ = 27.1 (CH_3), 27.5 (CH_3), 32.3 (CH_3 *t*Bu), 32.4 (CH_3 *t*Bu), 32.9 (CH_3 *t*Bu), 33.2 (CH_3 *t*Bu), 33.6 (CH_3 *t*Bu), 33.8 (CH_3 *t*Bu), 38.8(CH_2), 65.2(d, C-5, *J*(C,P) = 5.8 Hz), 78.2 (dd, C-4, *J* = 10.0 Hz, *J* = 6.3 Hz), 81.4 (d, C-3, *J*(C,P) = 9.5 Hz), 84.7 (C-2), 107.9 (C-1), 114.4 (CMe_2), 129.1 (d, CH_2=, *J* = 30.6 Hz). − ^{31}P NMR (121.4 MHz, CD_3OD): δ = 138.59 [dd, 1 P, ^2J(P,P) = 79.1 Hz, ^1J(P,Rh) = 329.5 Hz], 139.86 [dd, 1 P, ^2J(P,P) = 79.1 Hz, ^1J(P,Rh) = 334.5 Hz].

Hydrogenation Experiments: The reactions were performed in a home-made autoclave. The autoclave was purged three times with H_2. In a typical run, catalytic precursor (0.02 mmol) and substrate (2 mmol) were dissolved in the appropriate mixture of solvents (12 mL) and introduced in the purged autoclave. After pressurising to the desired pressure with hydrogen and heating the autoclave to the reaction temperature, the reaction mixture was stirred. During the reaction, a number of samples were taken and analysed by NMR. After the desired reaction time, the autoclave was cooled to room temperature and depressurised. The solvent was evaporated.

Workup of the Hydrogenation Product: The following procedures were used to isolate the hydrogenation product. For methylsuccinic acid and *N*-acetylphenylalanine, the residue was dissolved in 0.5 M NaOH and separated from the insoluble catalyst by filtration. The filtrate was acidified with diluted HCl, extracted with ether, and washed with a little water. The ethereal phase was dried with sodium sulfate and concentrated to dryness. The extent of conversion was measured by ^1H-NMR spectroscopy. The enantiomeric excesses were determined by polarimetry.[22] For *N*-acetylalanine methyl ester, gas chromatography analyses were performed in a Hewlett−Packard 5890A instrument (fused silica capillary column 25 m × 0.25 mm permabond L-Chirasil-Val).

Acknowledgments

We thank the Spanish Ministerio de Educación y Cultura and the Generalitat de Catalunya (CIRIT) for financial support (PB97-0407-CO5-01) and the Generalitat de Catalunya (CIRIT) for awarding a research grant (to O. P.). We are also very much indebted to Prof. P. W. N. M van Leeuwen and Prof. B. R. James for their useful discussions and suggestions on this work.

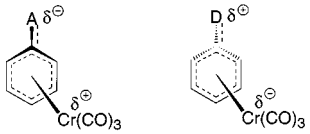
"Distorted" (η^6-Arene)tricarbonylchromium Complexes: Correlation of Structural Parameters with the Electronegativity χ_G and Hammett Constants σ_p of Arene Substituents

Jean-Pierre Djukic,*[a] Françoise Rose-Munch,[b] Eric Rose,*[b] and Jacqueline Vaissermann[c]



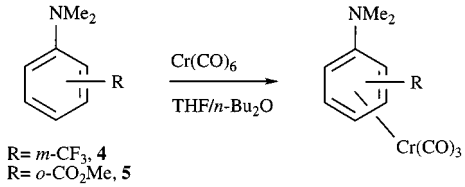
Keywords: Substituent effect / Carbonyl complexes / Chromium / Arene complexes / Structure-activity relationships

The molecular structures of 34 (η^6-arene)tricarbonylchromium complexes have been retrieved from the Cambridge Structural Data Base and investigated by focusing essentially on the distortions of the arene ligand caused by the electronic properties of the substituents connected to it. Two additional *meta*-disubstituted and one *ortho*-disubstituted arene complexes have been synthesized and their structure established by X-ray diffraction analysis. Two types of geometrical parameters have been chosen. The first one is the deviation Δ_i of the value of the endocyclic angle α_i at carbon *ipso* with respect to the ideal value α_0. The second one encompasses the chromium to *ipso*-carbon and the chromium to ring distances, d_{ipso} and d_0 respectively. It is shown that as long as no resonance effects interfere, Δ_i correlates with the group electronegativity for a wide variety of substituents whose central atom belongs to the first, second or even the third row of the periodic table. Similarly, we find that for mono-substituted arene complexes, d_{ipso} as well as d_0 correlate with the Hammett constants σ_p and σ_p^+. It is further evident that for a large variety of mono- and di-substituted (η^6-arene)tricarbonylchromium complexes, d_{ipso} correlates linearly with the σ_p^+ constant, thus indicating that d_{ipso} is a specific geometric constraint imposed by the electronic properties(e.g. inductive and mesomeric) of a given substituent connected to the arene ligand.

Introduction

The outstanding potential that (η^6-arene)tricarbonylchromium complexes bring to metal-mediated syntheses stems essentially from the stereochemical and electron-withdrawing properties of the $Cr(CO)_3$ moiety.[1] This has naturally led many groups of researchers to consider the $Cr(CO)_3$ moiety as a particularly electrophilic group which could activate a coordinated aromatic ligand toward many types of reactions that would otherwise not be feasible. It is well established that the conformational behavior of the $Cr(CO)_3$ moiety is controlled by two main parameters: first, the electronic intrinsic properties of the substituents of the arene ring and, second the steric interactions of the substituents with the metal centered rotor.[2] In the absence of any perturbing bulky group, it may be expected that electron-donating groups will favor a *syn*-eclipsed conformation of $Cr(CO)_3$ while electron-withdrawing groups will induce an *anti*-eclipsed conformation. In the solid state, the $Cr(CO)_3$ unit frequently adopts the theoretically predicted conformation although some exceptions suggest that crystal packing may impose unexpected geometries.

In a series of reports,[3] Hunter and co-workers underlined the peculiar strong distortion of complexed aromatic rings caused by π-donor substituents such as $-NR_2$. The authors investigated the possible relationship between the π-donating or π-accepting capability of a given group and the amplitude of the distortions operating over the aromatic ligand, and proposed in some cases that a π-accepting substituent **A** would induce a bending of the aromatic *ipso* carbon toward the $Cr(CO)_3$ moiety while the opposite would be observed with a π-donating substituent **D**[3a] (Scheme 1).



Scheme 1

This empirical model was proposed without fully considering the fact that the distortions induced by π-accepting substituents(eg. out of mean-plane folding of the arene ring toward Cr) were quite rare and small. Relevant distortions of the mean-plane in the vicinity of C_{ipso} may generally be observed only with derivatives of aniline. Therefore we decided to reinvestigate the matter by systematically analyzing the molecular structures of mono-substituted and *para*-, *meta*- and *ortho*-disubstituted (η^6-arene)$Cr(CO)_3$ complexes for their main structural properties. This was done by focusing on a set of selected structural parameters that are likely to vary depending exclusively on the electronic effects of the substituent. We show, herein, in an unprecedented manner, that these structural parameters can be correlated in a ma-

jority of cases to the Hammett constants σ_p, σ_p^+, to a lesser extent to σ_p^- and to the group electronegativity χ_G of a given substituent −G, hence allowing further empirical predictions of the structure-reactivity features of any (η^6-arene)$Cr(CO)_3$ complex.

Results and Discussion

For this study, we have investigated a total of 33 X-ray structures and 1 neutron diffraction structure deposited with the Cambridge Structural Data Base (CSDB). Among these, 17 are structures of mono-substituted arene complexes, 13 are of *para*-disubstituted arene complexes and 3 are of hetero-*ortho*-disubstituted arene complexes. We have synthesized three additional complexes, two *meta*-, and one *ortho*- hetero-disubstituted arene complexes, **3**, **4**, and **5**, respectively.

Preparation of Complexes 3−5

Preparation of complex **3** was performed by sequential lithiation and silylation of **1**, (η^6-NMe_2−C_6H_5)$Cr(CO)_3$ (Scheme 2). The use of *n*BuLi as a lithiation agent afforded, after silylation, a mixture of complexes **2** and **3**[4] in a ratio of 46:54, respectively (48% overall yield). In order to optimize the yield of complex **3** we used another method of lithiation first proposed by Kündig and co-workers for (η^6-naphthalene)tricarbonylchromium.[5] 1-Lithio-2,2,6,6-tetramethylpiperidine (Li-TMP) reacted with **1** and Me_3SiCl. Complexes **2** and **3** were obtained in a ratio of 21:79 (72% overall yield). In addition, we noticed that a slight excess of 2,2,6,6-tetramethylpiperidine (H-TMP) in the basic reaction medium could cause the formation of a 50:50 mixture of complexes **2** and **3** after silylation (63% overall yield).

Scheme 2

Complex **4** was prepared by the usual method of thermolysis of $Cr(CO)_6$ in a THF/(nBu)$_2$O mixture in the presence of 1-dimethylamino-3-trifluoromethylbenzene [Equation (1)].[6] Complex **5** was obtained in a similar manner to complex **4,** by thermolysis of $Cr(CO)_6$ in presence of methyl 2-(dimethylamino)benzoate (Equation 1).

The bright orange complex was purified by the usual techniques and crystallized from a toluene/hexane solution. Single crystals of compounds **3−5** were analyzed by X-ray diffraction. It is worthy to note that the crystal system of compound **3** was found to fit the noncentrosymmetric space group $P2_12_12_1$, thus indicating that complex **3** afforded, upon crystallization, a conglomerate[7] of spontaneously resolved enantiomers (Figure 1). Acquisition and refinement data for **3−5** are provided in Table 7 in the Experimental Section of this paper. Selected interatomic distances and valence angles for compounds **3−5** are given in Table 1. Figures 1−3 display ORTEP diagrams and the atom numbering scheme for these three complexes. The three molecular structures display a significant shift of the *ipso* carbon bearing the $-NMe_2$ substituent, out of the mean-aromatic plane away from the Cr center. Compound **5** possesses a pronounced helicity due to both the distortion induced by the $-NMe_2$ group and the *ortho* relationship between the two arene substituents from which steric repulsions arise (Figure 3). The latter helicity is characterized by an absolute value of the torsion angle N−C1−C2−C9 of 15.2°.

Selection of the Structural Parameters Investigated

Although all the structures that were analyzed presented distortions of various parameters such as interatomic distances, valence angles, torsion angles, along with some unexpected conformations of the tripod, we decided to focus essentially on the variation of two elementary parameters that were expected to be sensitive to relatively independent effects. Thus, we somewhat aimed at a rationalization of the causes of arene ligand distortions through a decomposition of the overall phenomenon into a sum of independent contributions. Hence, the following parameters were selected:

1. the deviations Δ_i of the endocyclic angles α_i from the ideal α_0 value of 120.0°,

$\Delta_i = \alpha_i - \alpha_0$, and especially the one centered at C_{ipso}, e.g Δ_{ipso} (Scheme 3).

2. the chromium to C_{ipso} interatomic distance, d_{ipso}, and the distance from the Cr atom to the mean-aromatic plane, d_0 (Scheme 4).

To justify the study of the endocyclic angle, it must be recalled that with uncoordinated aromatics it is well established that the electronegativity χ_G of a given substituent -G affects the values of both the six endocyclic angles and the corresponding intracyclic $C_{Ar}-C_{Ar}$ bond lengths.[8] Several studies have shown that a linear correlation between Δ_{ipso} and χ_G, the electronegativity of the group or element,

may be obtained provided that the central atom of the substituent -G connected to the arene ring belongs to the second or third row of the periodic table and/or does not show propensity to conjugate a doublet of electrons with the π-system of the considered aromatic.[9] A rationalization of the distortion of α_{ipso} by the VSEPR theory has been proposed: *a σ-electron-withdrawing substituent polarizes the localized C_{ipso}-G bonding molecular orbital, so that the bonding electron pair occupies less space in the valence shell of carbon and interacts less strongly with the two neighboring C_{ipso}–C_{ortho} σ-bonding pairs*; this causes an increase in the actual value of the internal angle α_{ipso} with respect to the value α_0, greater than that expected for a substituent having the same electronegativity as the ring; the reverse is expected with a σ-donating substituent. It has been further

Scheme 4

stressed that *if the substituent is conjugated with the ring, there is a build-up of π-electron density alongside the σ-bond and an increase of electron density within the σ-bonding molecular orbital,* in the region of the C_{ipso}−G bond, causing a decrease in the value of α_{ipso} below that of α_0. Similar trends can be expected for aromatic ligands coordinated to a $Cr(CO)_3$ moiety as it is often the π orbitals of the aromatic fragment that are involved in the interaction with molecular orbitals of $Cr(CO)_3$. The main results of the first part of our investigations are presented in the following paragraph. A preliminary and similar approach has recently been applied to a few examples of metallated (η^6-arene)$Cr(CO)_3$ σ-π complexes by Lotz and co-workers.[10]

Our interest in the study of the variation of metal-to-ring distances arose from the numerous comparative studies of the IR spectroscopic properties of substituted arene complexes. They concluded, in a convergent manner, that both the resonance and inductive electronic effects of the substituent can be readily transmitted to the CO ligands *via* the chromium center.[11] This has been shown by a net correlation between Hammett σ constants and the force constant k_{CO} of the studied carbonyl ligand C−O bond. This important fact suggested that the arene carbon σ-framework participates in the metal-ring bonding, although the metal-3d and $4p_\pi$/arene-$2p_\pi$ interaction dominates.[12] Early semi-empirical molecular orbital calculations carried out by Carroll and McGlynn[13] pointed out the importance of the ring σ-framework in the arene−Cr bonding. Recently, Phillips and co-workers studied the charge distribution in a series of poly-methyl-substituted (η^6-benzene)$Cr(CO)_3$ derivatives. They noted that with increasing methyl substitution, the major electron reorganization occurs in the arene−Cr segment of the molecule.[14] This reorganization, caused by an increase of the degree of substitution of the arene ring by methyl groups, was shown to induce an increase in the arene−Cr bond charge and order. Furthermore, it showed a progressive displacement of the bond charge from the arene ligand toward the chromium atom.

While retrieving the X-ray diffraction structural information of a large series of complexes we noticed that severe foldings of the arene ring away from the $Cr(CO)_3$ group were mostly occurring in aniline derivatives bearing $-NR_2$ groups. In a few examples, other π-electron donating or accepting substituents seemed to induce a significant folding of the ring. However, the main trend observed for complexes bearing π/σ-donor and π/σ-acceptor substituents was an increase and a decrease, respectively, in the chromium-to-*ipso*-carbon distance relative to the reference compound (η^6-benzene)$Cr(CO)_3$. This general trend somewhat rectifies and refines the empirical rule formulated by Hunter and co-workers and suggests that a folding of the arene ring is generally not necessary for the minimization of intramolecular electronic repulsions, especially in complexes bearing π-donor/acceptor substituents.

Influence of the Electronegativity of a Substituent over the Value of Endocyclic Angles: the Case of Mono-Substituted and *para*-Disubstituted (η^6-Arene)$Cr(CO)_3$ Complexes

A first approach involved the study of the angular distortion of mono-substituted (η^6-arene)$Cr(CO)_3$ complexes. Retrieval of atomic coordinates of compounds **6a**−**o**[15] from the CSDB allowed the measure of the endocyclic angles; the corresponding estimated standard deviation for the considered data were extracted from available published reports and averaged. In the cases of **6a**, **6f** and **6h**, exact values of σ(α) were not available to us. Among all the selected examples grouped in Table 2, only one complex, namely **6g**, presented a fairly high σ(α) value of 4 (entry 7, Table 2). However, this complex was considered, and the corresponding values of the endocyclic angle variations are provided.

Table 2 gives the values of Δ_i, deviations of the endocyclic angles from the ideal averaged value of 120.0 which was determined by the neutron-diffraction crystal structure of (η^6-benzene)$Cr(CO)_3$.[15b]

It can be noticed that almost all endocyclic angles deviate significantly from the ideal value. This is in contrast with observations made for uncoordinated aromatics. Indeed, it is generally observed that arene substituents cause significant distortions at the *ipso*, *ortho* and *meta* positions while *para* positions are mostly unaffected.[9] Two points can be observed: first, two related *ortho* and *meta* positions display fairly different values of $\Delta_{2,6}$ and $\Delta_{3,5}$, and second, the value of Δ_4 is often different from zero (Table 2). The presence of the $Cr(CO)_3$ tripod on the one side of the arene induces a loss of symmetry and induces distortions of the arene ring that can be characterized by the sum of the endocyclic angular deviations $\Sigma\Delta_i$. The lower values of $\Sigma\Delta_i$ are obtained for the two aniline derivatives, **6c** (−0.7) and **6i** (−0.7), the acetophenone complex **6a**, and **6g**. A negative value of $\Sigma\Delta_i$ indicates an overall decrease in the value of endocyclic angles, a possible slight change of hybridization of the orbitals of aromatic carbons and thus an actual nonplanar nature of the aromatic ligand. For the compounds considered in this table, values of $\Sigma\Delta_i$ inferior in absolute value to σ(α) correspond to an almost planar arene ligand. Deviations of atomic position from the calculated least-square mean-aromatic planes confirm the significant distortions for **6c**, **6i**, **6a**, **6g** and corroborate the information suggested by values of $\Sigma\Delta_i$. A plot of the *ipso* endocyclic distortion *versus* the electronegativity of the group as defined and calculated by Inamoto,[16] confirms that mono-substituted arene complexes follow a trend similar to that of uncoordinated arenes. Figure 4 presents a scattered distribution of data points around a mean diagonal line.

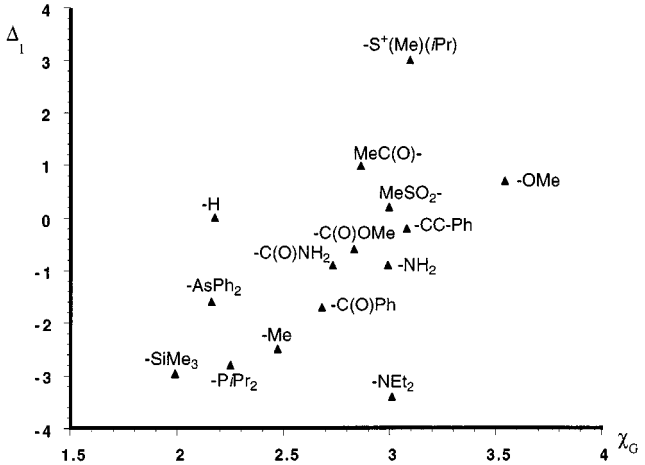

Figure 4. Graph of Δ_{ipso} (deg) *versus* χ_G for mono-substituted arene complexes

Few points are positioned out of the main statistical cloud. These data points correspond to arene complexes substituted by $-NEt_2$ (**6c**), $-S^+$(Me(iPr) (**6g**), −C(O)Me (**6a**). Strikingly, the data point corresponding to the benzene complex is found outside the statistical ascending cloud that groups together data from compounds **6f**, **6m**, **6d**, **6h**, **6n**, **6o**, **6i**, **6l**, **6k** and **6j**. This could be in part due to an underestimation of the value of χ_G for −H in aromatic compounds. It is known that the electronegativity of a given group may take significantly different values depending on

the nature of the organic or inorganic radical connected to it.[17] Therefore the plot displayed in Figure 4 must be considered as an informative qualitative picture.

We have applied a similar treatment to selected examples of hetero- and homo- *para*-disubstituted complexes bearing various types of substituents. For compounds **7a**−**h**[18] the endocyclic angular distortion at aromatic carbon 1 bearing the considered substituent located *para* to the acetal group $-CH(OR)_2$, was corrected for the distortions caused by the latter group. The correction terms applied to Δ_1 of compounds **7a**−**h** in Table 3, were extracted from the value of the *para* endocyclic angular deviations Δ_4 in the molecular structures of mono-substituted complexes **6p**−**q**. This consequently allowed the determination of approximated values of Δ_{ipso} for the following substituents: $-NMe_2$, Cl, $SiMe_3$, CF_3. A similar treatment was applied to values extracted from the molecular structure of compound **7j**[19] in order to obtain a corrected value of Δ_{ipso} for $-OCF_3$; this was carried out by applying a correction term which corresponded to the value of Δ_4 of the aniline complex **6i**. For the *para*-homo-disubstituted complexes **7i**,[20] **7k**−**m**, no corrections were applied to the values of Δ_1 and Δ_4.

A plot of these corrected and uncorrected values of Δ_{ipso} *versus* χ_G is displayed in Figure 5. A combination of the data of Table 2 and 3 allowed us to establish a new graph (Figure 6) in which it can clearly be seen that the value of the *ipso* carbon endocyclic angular deviation correlates with the Inamoto group and Pauling element[21] electronegativity χ_G, unless resonance interactions perturbe such a phenomenon as in complexes bearing $-NR_2$ (R = Me, Et), and the isolobal $-S^+RR'$ group. Electronegativities of substituents play a significant part in the overall distortion of the aromatic ring of (η^6-arene)$Cr(CO)_3$ complexes.

Correlation of Metal-to-Ring Distances with Hammett Constants in Monosubstituted (η^6-arene)$Cr(CO)_3$ Complexes: Nonlinear and Linear Correlations of the C_{ipso}−Cr and the Metal-to-Ring Mean-Plane Distances with σ_p

Metal to aromatic carbon distances have been often reported to be influenced by the "electron richness" of the

[a] Approximate value taken from $-S^+Me_2$.

aromatic ring and many authors pointed out indirectly that this parameter was a sensitive probe for assessing the magnitude of electron density transfer within (η^6-arene)$Cr(CO)_3$ complexes.[19] We decided to verify whether variations of d_{ipso} and d_0 could be linked to quantified effects such as inductive or resonance effects of substituents connected to the ring. Table 4 lists the values of d_{ipso} and d_0 obtained from structural information. All standard deviations $\sigma(d_{ipso})$ were obtained from the corresponding published reports except for **6h** (entry 8, Table 4); in the case of compound **6a** (entry 1, Table 4), a geometric σ(d) value was calculated from the standard deviations of the atomic coordinates extracted from the published report. It must be noted that d_0 was determined by considering the mean-plane, including all six arene carbons, even in strongly distorted rings: in doing so we established a reliable way of "idealizing" the distortion of the arene as even in strongly distorted molecules, the p-orbital at C_{ipso} is supposedly still engaged in aromaticity[22] and in a bonding interaction with the Cr atom. In many previous reports Cr-to-ring distances were calculated without taking into account the *ipso* carbon bearing the "perturbing" substituent, thus leading to a systematic underestimation of the value of d_0.

A plot of d_{ipso} versus the Hammett constant σ_p for various substituents[23] is given in Figure 7. The constant σ_p is defined for reactions taking place at a reactive site located *para* to a substituent, a position greatly favored by both inductive and resonance effects. For a given substituent of an aromatic compound, the σ_p constant is approximately the sum of the contributions of the inductive/field parameter, *F*, and the resonance parameter, *R*.[24] As can be noticed from Figure 7, there is a clear nonlinear correlation between the two parameters d_{ipso} and σ_p. A much better result is obtained by plotting d_{ipso} versus σ_p^+. The Hammett constant σ_p^+ has been devised for substituents conjugated with a reaction center which could effectively delocalize a positive charge.[25] As a result, values of σ_p^+ for π-electron donor substituents are considerably enhanced relative to the corresponding σ_p. The former σ_p^+ Hammett constant seems more appropriate in our study as the

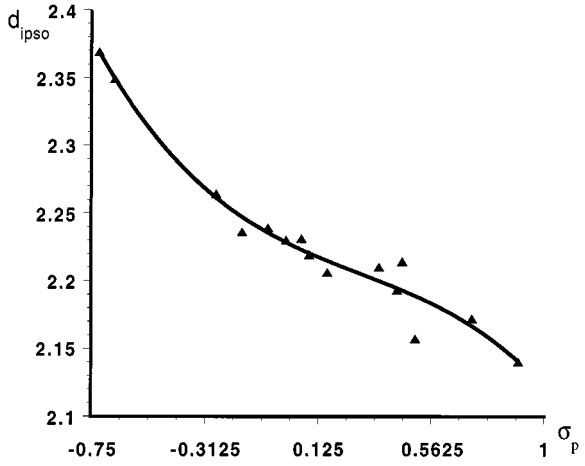

Figure 7. Plot of d_{ipso} (Å) *versus* σ_p for mono-substituted arene complexes

$Cr(CO)_3$ moiety decreases π-electron density on the aromatic ring and acts in a similar manner to an π-electron-withdrawing arene substituent inducing the creation of a positive charge in the Cr-arene segment; Kinomura and coworkers[26] have evaluated the partial charges in (η^6-benzene)$Cr(CO)_3$ to be −0.12e at benzene, +0.54e at the chromium atom, +0.15e at carbonyl carbons and −0.29e at carbonyl oxygen. Figure 8 displays a linear correlation between d_{ipso} and σ_p^+ which can be formulated by the following least-squares Equation:

$d_{ipso} = 2.23\ (\pm 0.01) - 0.07(\pm 0.01) \times \sigma_p^+$ ($n = 6$, $R = 0.955$, $\chi^2 = 0.002$).

The value of the intercept corresponds exactly to the value of d_{ipso} for the reference compound (η^6-benzene)$Cr(CO)_3$, **6b**. Figure 9 displays a plot of d_{ipso} versus σ_p^- which affords, according to expectations, a nonlinear relationship between the two parameters .

A plot of d_0 versus σ_p gives a distribution of points that strongly suggests a linear relationship between the two

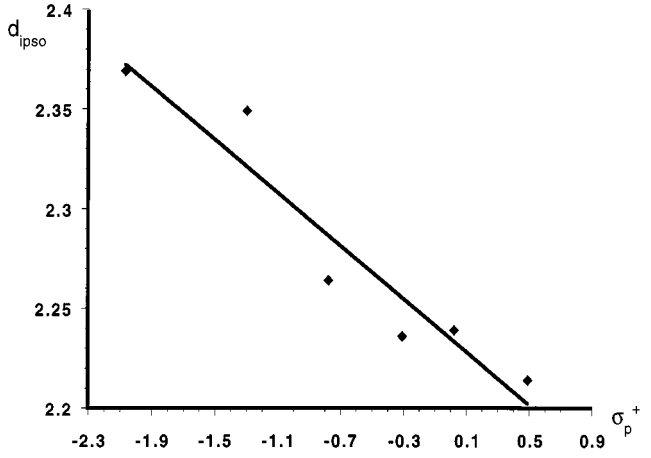

Figure 8. Plot of d_{ipso} (Å) *versus* σ_p^+ for mono-substituted arene complexes

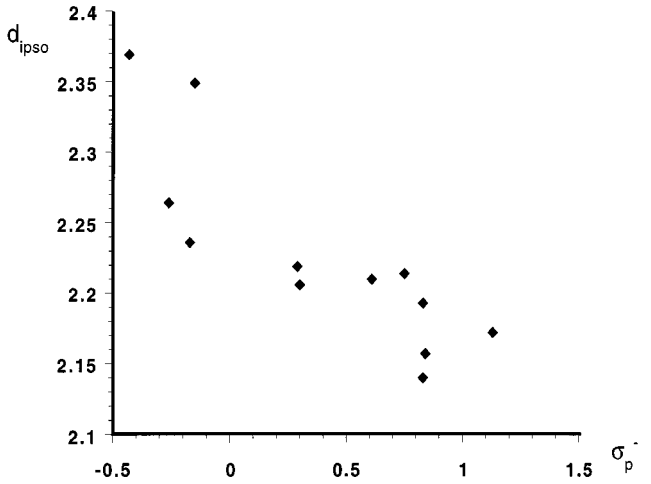

Figure 9. Plot of d_{ipso} (Å) *versus* σ_p^- for mono-substituted arene complexes

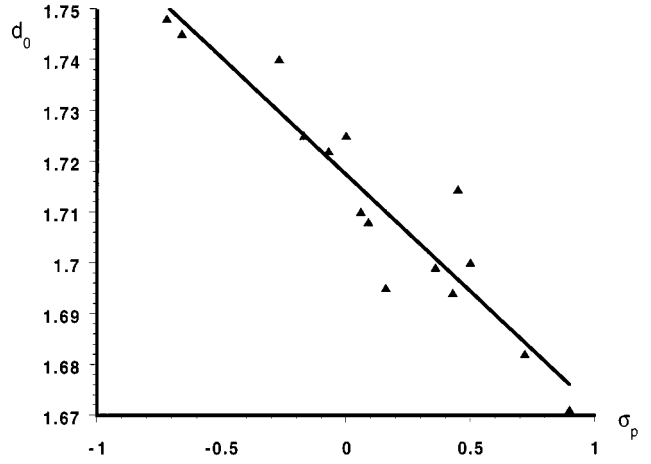

Figure 10. Plot of d_0 (Å) *versus* σ_p for mono-substituted arene complexes

parameters (Figure 10). A curve fitting carried out by the least-squares method affords the following linear relationship between d_0 and σ_p for the mono-substituted arene complexes in question:

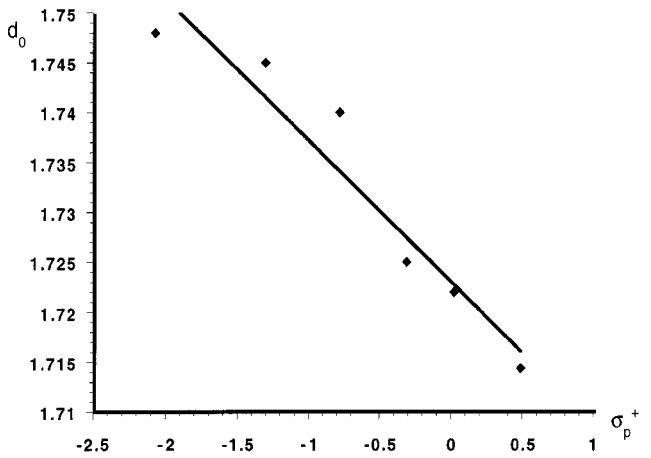

Figure 11. Plot of d_0 (Å) *versus* σ_p^+ for mono-substituted arene complexes

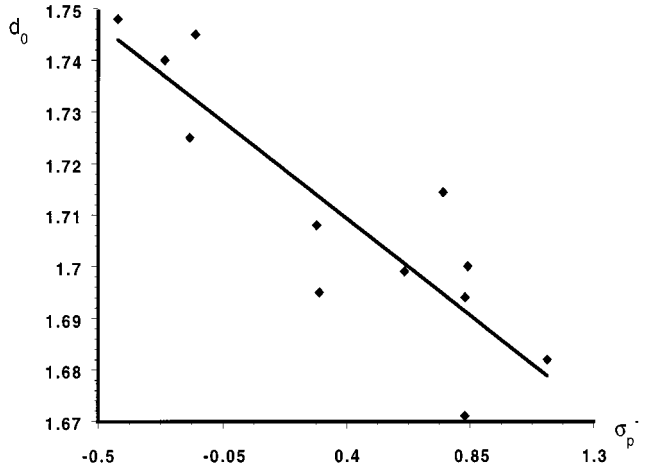

Figure 12. Plot of d_0 (Å) *versus* σ_p^- for mono-substituted arene complexes

$d_0 = 1.717(\pm 0.002) - 0.045(\pm 0.004) \times \sigma_p$, ($n = 15$, $\chi^2 = 0.0008$, $R = 0.939$).

Here the intercept is significantly lower than the value of 1.725 Å measured for the reference compound **6b**. Interestingly, plots of d_0 versus σ_p^+ (Figure 11) and σ_p^- (Figure 12) give more convincing values for the intercept, although the value of the correlation coefficient R for the expression involving σ_p^- is not optimal. The least-squares fitting carried out from the latter plots affords the following Equations:

$d_0 = 1.723(\pm 0.002) - 0.014(\pm 0.002) \times \sigma_p^+$ ($n = 6$, $\chi^2 = 7 \times 10^{-5}$, $R = 0.959$)

and

$d_0 = 1.726(\pm 0.004) - 0.041(\pm 0.007) \times \sigma_p^-$ ($n = 12$, $\chi^2 = 0.001$, $R = 0.880$).

Application of this relationship to the determination of σ_p of the two acetal groups $-CH(OMe)_2$ ($d_0 = 1.717$ Å in **6p**) and $-CH(OEt)_2$ ($d_0 = 1.709$ Å in **6q**) affords values of 0.00 and 0.17 respectively which compare satisfactorily with those established for $-CH(OMe)_2$ (σ_p value calculated

[a] Calculated value.

from ^{19}F NMR = 0.03) and other analogous groups such as $-CH_2OMe$ (0.01), and $-C(OMe)_3$ (−0.04). Accordingly, σ_p^+ and σ_p^- values for the two aforementioned acetal groups are estimated from the corresponding values of d_0 in **6p**−**q** as being equal to 0.43 and 0.22 for $-CH(OMe)_2$ and 1.0 and 0.41 for $-CH(OEt)_2$, respectively.

Disubstituted Arene Complexes

Values of d_{ipso} for a variety of *para*, *meta* and *ortho* disubstituted arene complexes are grouped in Table 5: *para*-disubstituted arene complexes are compounds **7a**−**m** and **7n**,[27] *meta*-disubstituted arene complexes are compounds **3**−**4**, *ortho*-disubstituted arene complexes are compounds **8a**−**b**[28] and **8c**[29] and **5**. A plot of d_{ipso} *versus* σ_p is given in Figure 13 and shows a nonlinear distribution of the data points. The largest scattering of the data points in Figure 13 is observed for the $-NMe_2$ groups in the disymmetric *para*-homodisubstituted complex **7l**, for −C(O)Me in **8a** and **8b** and for −C(O)OMe in **5**. In the three latter cases which correspond to *ortho*-disubstituted arene complexes the deviation, may be attributed to the predominant electronic effects imposed by −OH, −OMe and NMe_2 groups over the shifting of the $Cr(CO)_3$ moiety; such predominant electronic effects may induce exaggerated values of d_{ipso} for the vicinal *ortho*-position depending on the privileged direction of the shift of the chromium atom in the tripod.

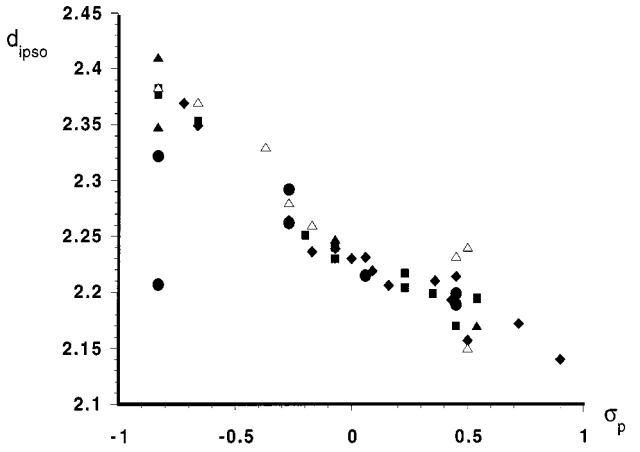

Figure 13. Plot of d_{ipso} (Å) *versus* σ_p for mono- and di-substituted arene complexes: (▲) compounds **3** and **4**; (■)compounds **7a**−**h** and **7n**; (◆) compounds **6a**−**o**; (●) compounds **7i** and **7k**−**m**; (△) compounds **8a**−**b**, **8c** and **5**

Combined values of d_{ipso} for mono- and di-substituted arene complexes (except those from **8a**−**c**, **5** and **7l**) are ploted versus σ_p in Figure 13. The shape of the plot assesses the dependency of d_{ipso} on both the inductive and resonance effects of a given aromatic substituent. It shows a relative independence towards the position and the nature of a second substituent of the arene ring (as long as it is not located at the *ortho* position).

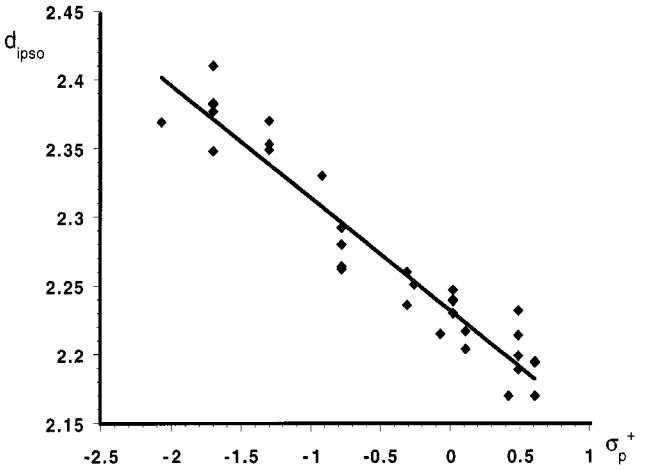

Figure 14. Plot of d_{ipso} (Å) *versus* σ_p^+ for mono- and di-substituted arene complexes having a defined value of the considered Hammett constant.

A plot of d_{ipso} *versus* σ_p^+ (Figure 14) that includes the data provided by the structures of *meta*-disubstituted arene complexes and excludes those of **8a**−**c**, **5** and **7l**, indicates now a clear linear relationship between the two parameters which is illustrated by the following linear Equation:

$d_{ipso} = 2.232(\pm 0.004) - 0.082(\pm 0.005) \times \sigma_p^+$ ($n = 33$, $\chi^2 = 0.013$, $R = 0.959$).

Table 6. List of values of d_0 (Å) for *para*-disubstituted arene complexes

entry	compound	substituents	d_0 (Å)
1	**7a**	1-NMe_2, 4-$CH(OMe)_2$	1.751
2	**7b**	1-NMe_2, 4-$CH(OEt)_2$	1.750
3	**7c**	1-Cl, 4-$CH(OMe)_2$	1.709
4	**7d**	1-Cl, 4-$CH(OEt)_2$	1.703
5	**7e**	1-$SiMe_3$, 4-$CH(OMe)_2$	1.716
6	**7f**	1-$SiMe_3$, 4-$CH(OEt)_2$	1.714
7	**7g**	1-CF_3, 4-$CH(OMe)_2$	1.702
8	**7h**	1-CF_3, 4-$CH(OEt)_2$	1.702
9	**7i**	1-F, 4-F	1.718
10	**7j**	1-OCF_3, 4-NH_2	1.743
11	**7k**	1-OCH_3,4-OCH_3	1.759
12	**7l**	1-NMe_2, 4-NMe_2	1.756
13	**7m**	1-CO_2Me, 4-CO_2Me	1.698

Here again, the value of the intercept fits the value of d_{ipso} for (η^6-benzene)$Cr(CO)_3$, **6b**.[15b] Values of σ_p^+ for the acetal groups $-CH(OMe)_2$ and $-CH(OEt)_2$ have been recalculated from the corresponding averaged values of d_{ipso} (e.g $<d_{ipso}>$) extracted from the structures of **6p−q** and **7a−h** and by applying the latter Equation. The following values were obtained and differ from those obtained from the aforementioned Equations based on the parameters d_0 of mono-substituted arene complexes: for $-CH(OMe)_2$ ($<d_{ipso}>$ = 2.223 Å), σ_p^+ = 0.11; for $-CH(OEt)_2$ ($<d_{ipso}>$ = 2.217 Å), σ_p^+ = 0.18. As for such substituents no peculiar resonance effect may be expected. The two values of σ_p^+ determined here are in our opinion more acceptable than those obtained from the previous correlation, as they are fairly close to the values reported for structurally similar groups such as $-CH_2OCH_3$ ($\sigma_p^+ = -0.05$) and $-CH_2OH$ ($\sigma_p^+ = -0.04$).[23]

Again, we find that d_{ipso} does not correlate with the σ_p^- substituent constants (graph not shown).

Values of d_0 for *para*-disubstituted complexes have been calculated in several examples and are presented in Table 6. They display a nonlinear dependence of d_0 *versus* the sum of the σ_p values for each substituent connected to the arene ligand (plot not shown here). We were not successful in establishing a simple relationship that would link d_0 either to the respective substituent electronic effects or to the molecular dipolar moment of the molecule which is presumably oriented from the arene ring to the chromium atom along the d_0 axis.[30] However, it may be noted that the value of d_0 for a given *meta*- or *para*- disubstituted arene complex is certainly significantly influenced by the values of the d_{ipso} parameter of a given substituent.

On the Prediction of the Distortions in (η^6-Arene)tricarbonylchromium Complexes

Hence, the d_{ipso} and d_0 parameters appear to be two intrinsic constraints imposed by the electronic properties of a given substituent over the geometric position of the $Cr(CO)_3$. Therefore, the main structural features of arene complexes can be predicted for mono- as well as *meta* and *para* di-substituted arene complexes regardless of the conformation of the $Cr(CO)_3$ tripod. Provided that σ_p^+ constants are established for the most common groups, it should now be possible to predict the approximate position of the Cr atom relative to the relevant C_{ipso} positions. A combination of effects related to the electronegativity, the resonance and the inductive properties of a given substituent governs the overall geometry of the arene ligand. It appears that a strong resonance effect such as that produced by amino groups emphasizes, in a rather predictable way on the basis of Hammett's σ_p^+ constants, the electronic repulsion between the Cr-centered moiety and the *ipso* position. A strong substituent resonance effect concomitantly causes a decrease of the *ipso* endocyclic angle at C_{ipso} and an increase of the related d_{ipso} value thus conceding a significant folding of the arene ligand.

Conclusion

In this article we have established that the distortions of the arene ligand in (η^6-arene)$Cr(CO)_3$ complexes are influenced by the electronegativity, the inductive and the resonance effects of arene substituents. We have shown that endocyclic angular deviations at a carbon substituted by a given substituent was generally directed by the electronegativity of the latter in the absence of perturbing resonance effects. It was shown that mesomeric effects could partially obliterate electronegativity based effects. We have also demonstrated that the chromium-to-*ipso*-carbon distance is a specific constraint imposed to the molecular spacial arrangement by the electronic properties of an arene substituent. It was established that d_{ipso} correlates linearly with σ_p^+ Hammett constants, providing us with the confirmation of a relevant participation of electrons of the σ-framework in the metal-arene ring bonding interaction and with an understanding of the role of resonance effects in the overall structural distortions. Further investigations on the possible deduction of the value of Hammett constants for uncommon organic and organometallic substituents from the structural parameters of (η^6-arene)tricarbonyl chromium complexes are currently in progress.

Experimental Section

General Remarks: All reactions were carried out under a dry nitrogen atmosphere. The complexes were, in general, stable in the solid state, in air for long periods of time. Consequently, all experiments involving arenetricarbonylchromium complexes were protected from exposure to light and oxygen. Tetrahydrofuran (THF) and di-*n*-butyl ether (DBE) were dried over sodium benzoketyl under dry nitrogen and distilled just before use. Products were separated by flash chromatography on a silica gel column (15 or 60 μm) under a dry positive nitrogen pressure. Diethyl ether (Et_2O) and petroleum ether were used as solvents for elution. − ^1H and ^{13}C NMR spectra were acquired on a Bruker AC 200 (resonance frequencies: 200 MHz for ^1H and 50 MHz for ^{13}C) spectrometer and chemical shifts were reported in parts per million downfield of Me_4Si. ^1H NMR spectra were referenced against the residual ^1H impurity of the deuterated solvent and ^{13}C NMR spectra were referenced

against the ^{13}C resonance of the solvent. − Infrared spectra (reported in cm^{-1}) were performed on Perkin−Elmer 1420 and Bruker FT spectrometers. − Elemental analyses (reported in % mass) were performed by "Le Service de Microanalyses de l'Université P. et M. Curie". The crystallographic information files (CIF) provided by the CSDB were analyzed with ORTEP-3[31] version 1.03 and ORTEX-6b[32] software. The CSDB acronyms for some of the structures of monosubstituted arene complexes studied in this paper are the following: **6a**, ACTPCR; **6b**, BZCRCO12; **6c**, ANLCRA10; **6d**, ASPHCR; **6e**, CCRTOL; **6f**, CMSICR; **6g**, CRSLFN; **6h**, DEDHAV; **6i**, KOZROG; **6j**, KOZRUM; **6k**, LEPNEZ; **6l**, RAYJAC; **6m**, RIHPED; **6n**, POLTUF.

Preparation of (η^6-*N*,*N*-Dimethyl-3-trimethylsilylaniline)tricarbonylchromium, Complex 3:[4] A solution of *n*BuLi (1.6 M, 3.0 mL, 4.8 mmol) in hexane was added dropwise to a solution of 2,2,6,6-tetramethylpiperidine (678 mg, 0.81 mL, 4.8 mmol) in THF (10 mL) at −78 °C. The resulting medium was stirred for 10 min and a solution of **1** (1.0 g, 4 mmol) in THF (10 mL) was added. The resulting mixture was stirred for an additional 30 min at −78 °C and Me_3SiCl was added (1.3 g, 1.53 mL, 12.0 mmol) dropwise. The reaction medium was slowly warmed to room temperature and extracted with Et_2O. The organic phase was washed with water and brine, dried over $MgSO_4$, filtered through Celite and the solvents removed by vacuum distillation. The yellow residue was purified by flash chromatography over silica gel. The starting substrate was first eluted (petroleum ether 100%), followed by complex **2** (Et_2O/petroleum ether = 10:90) and complex **3** (Et_2O/petroleum ether = 20:80). Recrystallization in pentane afforded complexes **2** (200 mg, 0.61 mmol, 15% yield) and **3** (739 mg, 2.25 mmol, 57% yield).

Preparation of (η^6-*N*,*N*-Dimethyl-3-trifluoromethylaniline)tricarbonylchromium, Complex 4: *N*,*N*-Dimethyl-3-trifluoromethylaniline (9.45 g, 50.0 mmol), $Cr(CO)_6$ (11 g, 50.0 mmol), THF (15 mL), nBu_2O (150 mL), 6 days. Yield of **4**: 61% (10.0 g). − M.p. 116 °C. − MS (IE); *m*/*z*: 325 (M^+). − $C_{12}H_{10}F_3NCrO_3$ (325.2): calcd. C 44.32, H 3.10, N 4.31; found C 44.26, H 3.10, N 4.19. − IR (nujol): $\tilde{\nu}$ = 1950, 1865 (C=O) cm^{-1}. − ^1H NMR (C_6D_6): δ = 4.64 (t, ^3J = 7 Hz, 1 H, H-5), 4.43 (d, ^3J = 7 Hz, 1 H, H-4), 4.41 (d, ^4J = 1.5 Hz, 1 H, H-2), 3.75 (dd, ^3J = 7 Hz ^4J = 1.5 Hz, 1 H, H-6), 1.87 (s, 6 H, NMe_2). − ^{13}C NMR ($CDCl_3$): δ = 39.7 ($(CH_3)_2$−N), 68.8−73.8−79.4−94.4 (C-2, C-4, C-5, C-6), 101.5 (q, ^2J = 30 Hz, C-3), 130.0 (q, ^1J = 120 Hz, CF_3), 133.7 (C-1), 232.9 (CO).

(η^6-*N*,*N*-Dimethyl-2-methoxycarbonylaniline)tricarbonylchromium, Complex 5: $C_{13}H_{13}O_5NCr$ (315.2): calcd: C 49.62, H 4.13, N 4.44; found C 49.82, H 4.23, N 4.48. − IR (CCl_4): $\tilde{\nu}$ = 1997, 1938 (C=O), 1735 [C(O)OMe] cm^{-1}. − ^1H NMR ($CDCl_3$): δ = 2.83 (s, 6 H, NMe_2) 3.87 (s, 3 H, OCH_3) 4.84 (t, *J* = 6 Hz, 1 H, H-4) 4.97 (d, *J* = 6 Hz, 1 H, H-6), 5.67 (t, *J* = 6 Hz, 1 H, H-5), 6.04 (d, *J* = 6 Hz, 1 H, H-3). − ^{13}C NMR ($CDCl_3$): δ = 42.7 ($N(CH_3)_2$), 52.9 (OCH_3), 76.5, 82.6, 96.6, 98.4 (C_{3-6}), 82.4 (C_2), 136.7 (C_1), 165.5 (*C*(O)OMe), 238.8 (Cr−CO).

Structural Determination of Complexes 3, 4, 5. Intensity data were collected at room temperature on an Enraf−Nonius CAD4 diffractometer using Mo-K_α radiation. Accurate cell dimensions and orientation matrices were obtained from least-square refinements of the setting angles of 25 well-defined reflections. No decay in the intensities of two standard reflections was observed during the course of the data collections. Complete crystal data, collection parameters and other significant details are listed in Table 7.

The usual corrections for Lorentz and polarization effects were applied. Computations were performed by using CRYSTALS.[33] Scattering factors and corrections for anomalous dispersion were taken from the International Table for X-ray Crystallography.[34] The structures were resolved by direct methods (SHELXS 86[35]) and refined by least squares with anisotropic thermal parameters for all nonhydrogen atoms. For compound **4**, hydrogen atoms were located on a Fourier difference map and introduced as fixed contributors in the last refinements with an overall refinable isotropic thermal parameter. The structure was refined to $R = 0.031$ with the use of 1813 reflections for 22 least-squares parameters. For compound **3**, hydrogen atoms were introduced as fixed contributors in theoretical posi-

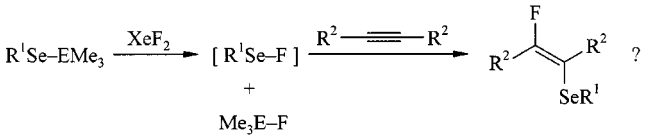
Reactions of $RSe–EMe_3$ (E = Si, Ge, Sn, Pb) with XeF_2 – RSe–F Equivalents in the Fluoroselenenylation of Acetylenes[1]

Helmut Poleschner,*[a] Matthias Heydenreich,[b] and Uwe Schilde[c]

Dedicated to Professor Egon Fanghänel on the occasion of his 65th birthday

Keywords: Xenon / Fluorine / Selenides / Acetylenes / Silicon / Germanium / Tin / Lead



Selenides of the type $R^1Se–EMe_3$ (E = Si, Ge, Sn, Pb) react with xenon difluoride by cleavage of the Se–E bond to yield the $R^1Se–F$ intermediate and the fluorides $Me_3E–F$, whereas the Se–C bond in PhSe–*t*Bu (E = C) is stable against XeF_2. The presence of $R^1Se–F$ intermediates is confirmed by addition to acetylenes (4-octyne, 3-hexyne). Thus, the fluoroselenenylation of acetylenes gives fluoro(organylseleno)olefins in preparative yields. In the cases of E = Si, Ge, Sn, and Pb, aryl and *n*-alkyl groups are suitable as the substituent R^1. The X-ray crystal structural analysis of (*E*)-3-(*p*-carboxyphenylseleno)-4-fluorohex-3-ene – the first example of an uncharged fluoroselenoolefin synthesized from *p*-$EtO_2C–C_6H_4–Se–SnMe_3$, XeF_2, and 3-hexyne followed by an ester hydrolysis – shows that the addition of the selenenylfluoride intermediate to the acetylene proceeds via a *trans*-addition, as is known for the $R_2Se_2–XeF_2$ reagents.

Introduction

Selenium reagents are good tools for the introduction of fluorine into organic substrates. Known methods for the addition of PhSe–F equivalents to olefins and acetylenes are PhSeBr–AgF–ultra sound,[2,3] PhSeCl–AgF–MeCN,[4] *N*-phenylselenophthalimide (NPSP)–Py·9HF,[5,6] and $NPSPEt_3N·3HF$.[7] The PhSe–F intermediate was obtained exceptionally elegantly by reaction of Ph_2Se_2 with XeF_2 in a molar ratio of 1:1[8] and used in the fluoroselenenylation of olefins[8–10] and bis-selenenylation of phosphaacetylenes.[11] $PhSeF_3$ (Ph_2Se_2+3 XeF_2) reacts either by addition of $PhSeF_2/F$[9,12,13] or as the F_2 equivalent, depending on the olefin concerned,[13,14] and $PhSeF_5$ (Ph_2Se_2 + 5XeF_2) (and $PhTeF_5$) react with olefins as the F_2 equivalent.[15]

In earlier papers we reported a highly efficient synthesis of vicinal fluoro(organylseleno)olefins by fluoroselenenylation of acetylenes with $R_2Se_2–XeF_2$ reagents.[16,17] This method was shown to be useful in a very broad range concerning the acetylenes (symmetrical and unsymmetrical dialkylacetylenes, arylalkylacetylenes, terminal acetylenes, and cycloalkynes) and the applied diselenides (diaryl-, primary and secondary dialkyldiselenides, functionalized diselenides). The fluoroselenoolefins were characterized by X-ray crystal structural analysis in the form of a fluorovinyldimethylselenonium picrate as (*E*)-isomers,[17,18] and investigated in detail by ^{13}C, ^{19}F, and ^{77}Se NMR spectroscopy.[19]

Preliminary experiments showed that silyl selenides of the type $PhSe–SiR_3$ ($PhSe–SiMe_3$ and PhSe–Si*t*BuMe_2) react with XeF_2 by cleavage of the Se–Si bond to yield the PhSe–F intermediate which is added to acetylenes.[16] The high affinity of the fluorine for the silicon is the driving force responsible for the Se–Si bond breaking. However, nothing is known about the reactivity of the selenides $RSe–EMe_3$ of the higher group 14 elements, i.e., the corresponding germanium, tin, and lead selenides, with XeF_2. Therefore, the question was which of the trimethylelementorganyl selenides $R^1Se–EMe_3$ (E = C, Si, Ge, Sn, Pb) would react with XeF_2 to give the $R^1Se–F$ intermediate and $Me_3E–F$ by cleavage of the Se–E bond. Thus, the aim of the present paper is to report on our investigations of the reactions of the selenides $R^1Se–EMe_3$ (E = C, Si, Ge, Sn, Pb) with XeF_2. Aryl and *n*-alkyl groups were used as the substituents R^1. In order to prove their formation, the $R^1Se–F$ moieties were trapped with simple reactive dialkylacetylenes (3-hexyne, 4-octyne) as model compounds to give fluoro(organylseleno)olefins (Scheme 1).

Results and Discussion

The compounds investigated are shown below:

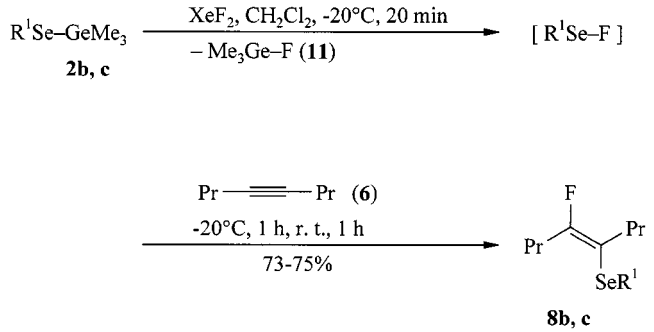
1-5 **6, 7** **8, 9** **10-13** **14**

	1, 10	2, 11	3, 12	4, 13	5
E	Si	Ge	Sn	Pb	C

	6, 8	7, 9
R^2	*n*Pr	Et

	a	b	c	d	e
R^1	Me	Et	Ph	*p*-C_6H_4-CO_2Et	*p*-C_6H_4-CO_2H

Si Selenides



Ethylselenotrimethylsilane (**1b**) and phenylselenotrimethylsilane (**1c**) react in CH_2Cl_2 at –20 °C with one equivalent of XeF_2 to give the trimethylfluorosilane (**10**) and the $R^1Se–F$ intermediate by cleavage of the Se–Si bond. 4-Octyne (**6**) was added to the selenenyl fluoride intermediates to give the fluoroselenoolefins **8b,c** in good yields (72–82%) (Scheme 2). $Me_3Si–F$ (**10**) was identified after reaction of **1b** with XeF_2 and **6** in $CDCl_3$ by ^{19}F NMR spectroscopy. Thus, the reaction of the $R^1Se–SiMe_3$ **1** with XeF_2 takes place analogous to the synthesis of the trialkylsilyl halides $R_3Si–X$ (X = Cl, Br, I) from $PhSe–SiR_3$ and the halogens.[20]

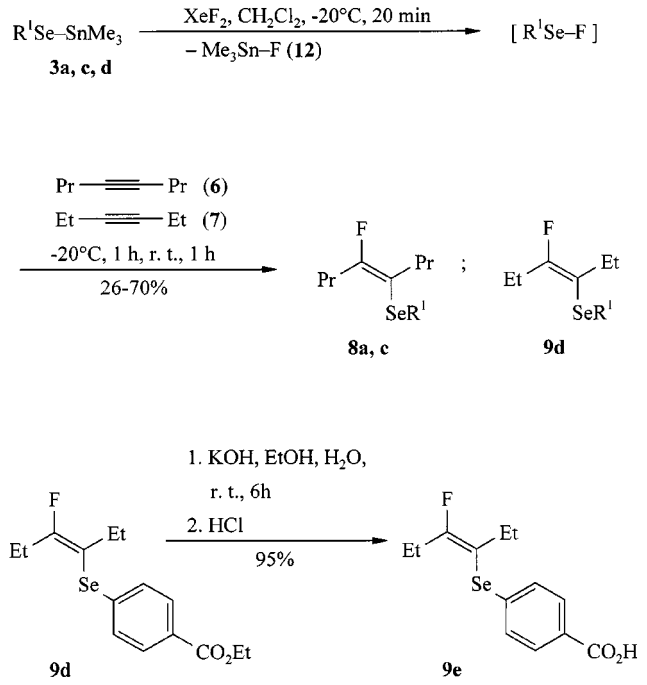
Scheme 2. Reactions of the Si selenides

Ge Selenides

Ethylselenotrimethylgermane (**2b**) and phenylselenotrimethylgermane (**2c**) react in CH_2Cl_2 at –20 °C with XeF_2 in a molar ratio of 1:1; the intermediates are trapped with **6**.

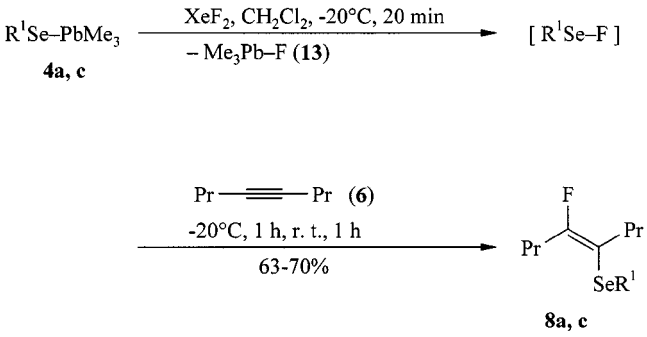
Scheme 3. Reactions of the Ge selenides

The resulting fluoroselenoolefins **8b** and **8c** (73–75% yield) showed the cleavage of the Se–Ge bond caused by the fluorinating agent. After the reaction of **8c** with XeF_2 and **6** in $CDCl_3$, $Me_3Ge–F$ (**11**) was observed by ^{19}F NMR spectroscopy (Scheme 3).



Sn Selenides

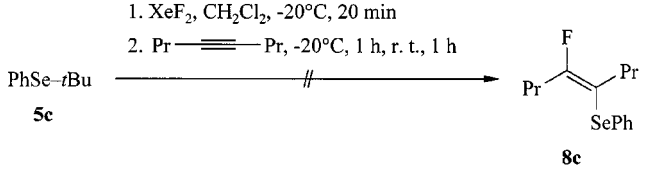
Methylselenotrimethylstannane (**3b**) and phenylselenotrimethylstannane (**3c**) react in CH_2Cl_2 at –20 °C with one equivalent XeF_2 to give trimethyltin fluoride (**12**), which precipitates immediately. The corresponding fluoroselenoolefins **8a** and **8c** (66–70% yield) were obtained after addition of **6** to this suspension (Scheme 4). The reaction of *p*-(ethoxycarbonyl)-phenylselenotrimethylstannane (**3d**) with XeF_2 and 3-hexyne (**7**) led to the formation of trimethyltin fluoride (**12**) and the adduct **9d**. Its yield was with 26%, as in the case of the corresponding *p*-CO_2Et-substituted diphenyldiselenide,[17] much smaller than with non-functionalized PhSe precursors.[16,17] $Me_3Sn–F$, which was isolated in almost quantitative yields, was confirmed by mass spectrometry and by ^{119}Sn Mößbauer spectroscopy. The resulting spectra were in good agreement with the literature.[21] The elementary composition of the ions $[M^+]$, $[M^+ – Me]$ and $[M^+ – F]$ was confirmed by high-resolution mass spectrometry. The cleavage of the Se–Sn bond by fluorination of the tin selenides **3** with XeF_2 corresponds to the reaction of $R'Se–SnR_3$ with iodine to give $R_3Sn–I$ and R'_2Se_2.[22]



The carboxylic acid **9e** was synthesized by saponification of the carboxylic acid ester **9d**. Suitable crystals for the X-ray structural analysis could be obtained from *n*-hexane (Scheme 4).

Pb Selenides

Analogous to the tin compounds **3**, precipitation of trimethyllead fluoride (**13**) occurred during the reaction of methylselenotrimethylplumbane (**4a**) or phenylselenotrimethylplumbane (**4c**) with one equivalent XeF_2 at –20 °C in CH_2Cl_2. Subsequent reaction of the selenenyl fluoride intermediates with **6** resulted in the fluoroselenoolefins **8a** and **8c** (63–70%) (Scheme 5). $Me_3Pb–F$ (71–83%) was characterized by mass spectrometry after isolation. The elementary composition of the ions $[M^+ – Me]$ and $[M^+ – F]$ was confirmed by high-resolution mass spectrometry.



Scheme 4. Reactions of the Sn selenides

Scheme 5. Reactions of the Pb selenides

C Selenides

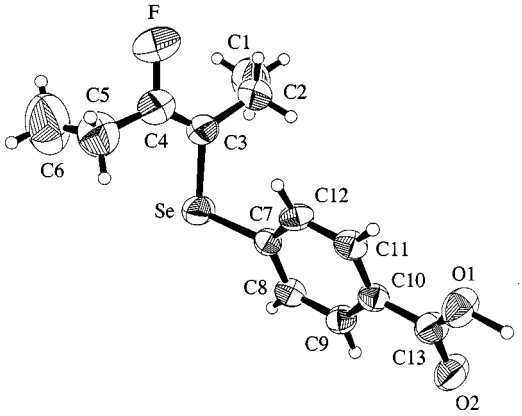
The reaction of *tert*-butylphenylselenide (**5c**) with XeF_2, under the conditions described above, differs from that of compounds **1-4.** The PhSe–F intermediate was not obtained and the adduct **8c** could not be obtained after treatment with **6** (Scheme 6). Cleavage of the Se–C bond by XeF_2 was not observed. This is also reported for the compound PhSe–CN.[16] However, a possible fluorination of the selenide **5c** to *t*BuPhSeF_2, in analogy to Me_2SeF_2,[23] was not investigated.

Scheme 6. Experiment with a C selenide

The mass spectra of the synthesized fluoroselenoolefins **8a–c** and **9d,e** showed the correct molecular peak with the expected isotope pattern for one Se atom. The high resolution of these peaks proved the elemental composition of these compounds. The ^{13}C NMR spectra of **8a–c** and **9d,e** agreed well with the spectra of the products obtained from the R'_2Se_2–XeF_2 reagents.[16,17] A detailed assignment and discussion of the spectra of these compounds is given in ref.[19]

X-ray Crystal Structure Analysis of 9e

Although the structure of the selenonium ion Pr(F)C=CPr(Se^+Me_2) has previously been reported,[17,18] this is the first structure of a noncharged vicinal fluoroselenoolefin. Details of the structure solution and refinement are given in the experimental section (Table 4). As can be seen from Figure 1, this compound possesses an (*E*)-configuration [torsional angles: Se–C3–C4–F –170.1(4)°; C2–C3–C4–F 3.0(9)°]. This is the most important structural information regarding the reaction course: *trans*-addition of the R^1Se–F intermediate (R^1Se–$SnMe_3$ + XeF_2) to an acetylene.



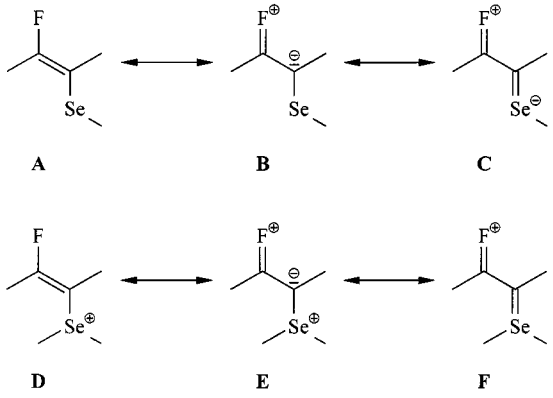


Figure 1. ORTEP plot (thermal ellipsoids 40%) of the molecular structure of the carboxylic acid **9e**; selected bond lengths [Å] and angles [°]: C1–C2 1.472(10), C2–C3 1.507(8), C3–C4 1.285(8), C4–C5 1.498(10), C5–C6 1.353(11), F–C4 1.385(7), Se–C3 1.914(5), Se–C7 1.906(4), C7–C12 1.384(6), C7–C8 1.391(6), C8–C9 1.374(7), C9–C10 1.380(6), C10–C11 1.389(6), C11–C12 1.384(6), C10–C13 1.466(6), C13–O2 1.247(6), C13–O1 1.280(5), O1–H1 1.18(5); C3–C4–F 115.6(6), C3–C4–C5 132.9(6), C4–C3–Se 117.4(5), C4–C3–C2 123.9(5), C7–Se–C3 100.3(2), Se–C3–C4–F –170.1(4), C2–C3–C4–F 3.0(9), C7–Se–C3–C2 64.4(4), C12–C7–Se–C3 23.5(4), C1–C2–C3–C4 –98.1(8), C3–C4–C5–C6 –107.8(12).

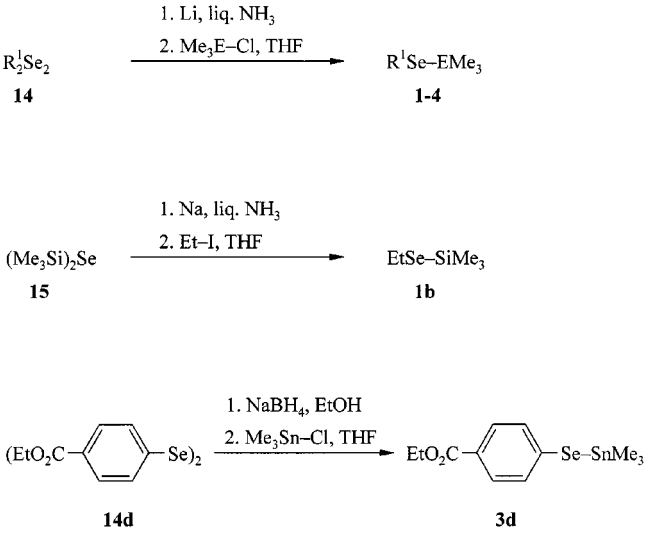
Compared with the above-mentioned selenonium ion [C–F 1.368(3) Å, C–Se 1.927(2) Å, C=C 1.328(3) Å] **9e** has a longer C–F and a shorter C–Se bond (Se–C3). The considerably shortened C=C distance in **9e** is especially noticeable. This corresponds well with the longer C–F bond and, thus, with a stronger participation of the mesomeric structure **A** against **B** and **C** in the electronic structure of the fluoroselenoolefins than of the mesomeric structure **D** against **E** and **F** in the selenonium ion. The C3–C4–C5 bond angle in **9e** is made considerably larger by the fluoro-substitution as it was found also in other fluoroolefins and the selenonium ion [133.8(2)°].[18] Both of the ethyl substituents on the C=C moiety are situated behind the π-bond plane with torsional angles of –98.1(8)° (C1–C2–C3–C4) and –107.8(12)° (C3–C4–C5–C6), respectively. The Ar–Se substituent is situated in front of the C=C plane with a torsional angle of 64.4(4)° (C7–Se–C3–C2); the Ar group is

twisted towards the C=C double bond with a torsional angle of 23.5(4)° (C12–C7–Se–C3). Obviously, in this conformation, the steric interaction between the H atoms on C2 and in the *o*-position of the aryl group is small. Two molecules are linked by two hydrogen bonds between O1 and O2 via H1 forming pairs [O1···O2 2.640(4) Å, H1···O2 1.489(11) Å, O1–H1···O2 164.55(4)°; symmetry operator 1 – *x*, 1 – *y*, –*z*].

Conclusions



XeF_2 is able to cleave the Se–Si, Se–Ge, Se–Sn or Se–Pb bond of the selenides $R^1Se–EMe_3$ with E = Si, Ge, Sn or Pb, respectively, to give $R^1Se–F$ intermediates and $Me_3E–F$ fluorides. By contrast, the Se–C bond in PhSe–*t*Bu is not broken by XeF_2. The formation of $R^1Se–F$ intermediates is confirmed by their addition to acetylenes. The yields of the obtained fluoro(organylseleno)olefins are in the same range as in the case of $XeF_2–R^1_2Se_2$ reagents.[16,17] In this reaction the substituents R^1 can be *n*-alkyl or aryl. The reaction proceeds as a *trans*-addition of the $R^1Se–F$ intermediates to acetylenes, as is the case for $R^1_2Se_2–XeF_2$ reagents.[17,18] Comparable yields of fluoro(organylseleno)olefins from $R^1Se–EMe_3–XeF_2$ and $R^1_2Se_2–XeF_2$, and the corresponding stereochemistry of additions for the two reactions, indicate that the same reaction course is taking place in both cases.

Of further interest is whether there are other groups besides the Me_3Si and *t*BuMe_2Si moieties, for example, OH-protecting groups[24–27] such as Me_2PhSi, *i*Pr_3Si and *t*BuPh_2Si, that permit cleavage of $R^1Se–SiR_3$ by XeF_2. A further question is a possible bond cleavage by XeF_2 of other selenides of elements with a strong affinity to fluorine, e.g. compounds with Se–B, Se–Al, and Se–P bonds.

Syntheses of the Selenides $R^1Se–EMe_3$ 1–4

Different methods are known to synthesize selenides of the type $R^1Se–EMe_3$ (E = Si: PhLi/Se/Me_3SiCl,[28] Ph_2Se_2/Na(THF)/Me_3SiCl,[29,20c] Ph_2Se_2/Na(THF)/R_3SiCl(18-crown-6),[24] PhSeH/BuLi/Me_3SiCl,[20c] PhSeH/Me_3SiH/Rh-cat.[20c] and PhMgBr(Et_2O)/Se/Me_3SiCl resp. ($Me_3Si)_2Se$/Na(liq. NH_3)/RX;[30] E = Ge: $PhSeSiMe_3$/Me_3GeF[28] and Ph_2Se_2/Na(THF)/Me_3GeCl;[31] E = Sn: PhSeH/Me_3SnCl/NaOH(H_2O),[32] RSeH/Me_3SnCl/Et_3N,[33,22] Li[Al($SeMe)_4$]/Me_3SnCl,[34] Me_6Sn_2/BuLi/Se/RX (R = alkyl);[35] E = Pb. Only two patents are known: RMgBr(Et_2O)/Se/Me_3PbCl (R = Me, Ph).[36]

In this work, we report a uniform synthesis of the compounds **1–4** using the same selenium starting materials. The diselenides $R^1_2Se_2$ (**14**) were found to be most suitable, because of the possibility of their quantitative reduction to their corresponding lithium selenolates R^1SeLi in liquid ammonia with lithium. This way is superior to the reduction in the heterogeneous system Na/THF. Further reaction with the chlorides $Me_3E–Cl$ to the compounds **1–4** was carried out in THF after complete removal of the ammonia. The reaction course using the bis(trimethylsilyl)selenide (**15**) was chosen for the synthesis of ethylselenotrimethylsilane **1b** only. The reduction of the functionalized diselenide **14d** was carried out with $NaBH_4$ and subsequent stannylation in EtOH (Scheme 7).

Scheme 7. Syntheses of the selenides **1**−**4**

For $R^1Se–EMe_3$ derivatives, NMR spectroscopic data are known for only a few Ge[31a,37] and Sn compounds.[33,38] For this reason, ^{13}C and ^{77}Se NMR data of the compounds **1b**,**c**, **2b**,**c**, **3a**,**c**,**d**, **4a**,**c** and **15** are given in Table 1.

Experimental Section

The diselenides **14a**,**b**,[39] **14d**,[17] the selenides **5c**[40] and **15**[30,41] and XeF_2[42] were prepared by literature methods. **14c**, the acetylenes **6** and **7** and the chlorides $Me_3E–Cl$ (E = Si, Ge, Sn, Pb) are commercially available. – Mass spectra were recorded with Finnigan–MAT 95 and Finnigan–MAT 711 at 70 eV and 80 eV, respectively. The measurements of high-resolution spectra were carried out by the peak-match method using PFK as a reference substance. – NMR spectra were measured with a Bruker ARX 300 spectrometer in $CDCl_3$ in 5 mm sample tubes at room temperature: ^{13}C at 75.47 MHz (^{13}C reference $CDCl_3$: δ = 77), ^{19}F at 282.40 MHz (^{19}F reference $CFCl_3$: δ = 0), and ^{77}Se at 57.25 MHz (^{77}Se reference Me_2Se: δ = 0).

Reactions of $R^1Se–EMe_3$ (1–4) with XeF_2/Acetylene. – General Procedure: XeF_2 (4.1 mmol, 694 mg) was added in small portions un-

Table 1. ^{13}C and ^{77}Se NMR chemical shifts (δ) and related coupling constants (Hz) of compounds **1–4** and **15**

der argon to a solution of 4 mmol selenide **1–4** in 20 mL of dry CH_2Cl_2 at –20 °C and stirred for 30 min. The acetylene **6** or **7** (4 mmol) was then added and stirred for 1 h at –20 °C and for 1 h at room temperature. In the cases of **3** and **4** the precipitate $Me_3Sn–F$ (**10**) and $Me_3Pb–F$ (**11**), respectively, was separated and washed with *n*-pentane (2 × 10 mL) and the solvent was then removed under vacuum. The crude product was purified by column chromatography (10 cm silica gel, diameter 2 cm, *n*-hexane). For yields see Table 2.

Table 2. Reactions of the selenides **1–4** with XeF_2 and acetylenes **6**, **7** to the products **8**, **9**, **12** and **13**

Starting material	Products	Yields
1b, XeF_2, **6**	**8b**	0.68 g (72%)

$Me_3Pb–F$ (13): MS: *m*/*z* = 257 [M^+ – Me], 253 [M^+ – F]. – HR-MS ($C_2H_6F^{208}Pb$) [M^+ – Me]: calcd. 275.02199; found 275.02688. ($C_3H_9{}^{208}Pb$) [M^+–F]: calcd. 253.04707; found 253.04321.

(*E*)-3-(*p*-Carboxyphenylseleno)-4-fluorohex-3-ene (9e): The saponification of the ester **9d** was carried out with KOH/EtOH/H_2O, as described in ref.[17] Yield of **9e** (from 2 mmol) 0.57 g (95%), m.p. 115–117 °C (*n*-hexane). – HR-MS ($C_{13}H_{15}FO_2{}^{80}Se$): calcd. 302.02212; found 302.02003. – ^{13}C NMR ($CDCl_3$): δ = 11.4 (C-6), 13.5 (C-1), 24.6 ($^3J_{F–C}$ = 6.8 Hz, C-2), 25.1 ($^2J_{F–C}$ = 28.8 Hz, C-5), 109.3 ($^2J_{F–C}$ = 21.8 Hz, C-3), 126.8 (*p*-C), 128.6 (*o*-C), 130.7 (*m*-C), 140.4 ($^4J_{F–C}$ = 2.1 Hz, *i*-C, C–Se), 165.7 ($^1J_{F–C}$ = 269.7 Hz, C-4), 172.1 (CO_2H).

Syntheses of $R^1Se–EMe_3$ (1–4). – General Procedure: Approximately 100 mL liquid ammonia was added to 15 mmol diselenide **14**. To this stirred solution, 30 mmol (210 mg) lithium was added, until the solution was slightly blue. After evaporation of the solvent under argon the remaining NH_3 was completely removed under vacuum. To the colorless solid 50 mL dry THF was added. To this

mixture was added a solution of 30 mmol Me_3Si–Cl (3.26 g), Me_3Ge–Cl (4.60 g) or Me_3Sn–Cl (5.98 g) in 10 mL THF, or solid Me_3Pb–Cl (8.63 g), over 20 min under Ar at room temperature, and subsequently stirred for 3 h. For the Si, Ge, and Sn derivatives the THF was removed at normal pressure and the product was distilled directly from the reaction flask. It was then redistilled for further purification. For the Pb derivatives, after adding 500 mL ice water, the organic layer was separated. The aqueous phase was treated with ether (3 × 100 mL), the ether-containing phases were washed with ice water (1 × 100 mL) and dried (Na_2SO_4). After removal of the solvent the product was purified by column chromatography (5 cm silica gel, *n*-hexane). For yields see Table 3.

Table 3. Syntheses of the selenides **1–4**

$R^1Se–EMe_3$	Yield	
PhSe–$SiMe_3$ (**1c**)	4.13 g (60%)	b.p. 66–68 °C/1.3 mbar
EtSe–$GeMe_3$ (**2b**)	5.42 g (80%)	b.p. 52–55 °C/23 mbar
PhSe–$GeMe_3$ (**2c**)	6.82 g (83%)	b.p. 65 °C/0.07 mbar
MeSe–$SnMe_3$ (**3a**)	6.11 g (79%)	b.p. 65–67 °C/23 mbar
PhSe–$SnMe_3$ (**3c**)	8.16 g (85%)	b.p. 72 °C/0.09 mbar
MeSe–$PbMe_3$ (**4a**)	8.31 g (80%)	after chromatography
PhSe–$PbMe_3$ (**4c**)	10.54 g (86%)	after chromatography

[a] $R1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$. – [b] $R2 = [\Sigma w(F_o^2 - F_c^2)^2/\Sigma w(F_o^2)^2]^{1/2}$. – [c] $w = 1/[\sigma^2(F_o^2) + (aP)^2 + bP]$; $P = (F_o^2 + 2F_c^2)/3$

Ethylselenotrimethylsilane (1b): Analogously to ref.[30] bis(trimethylsilyl)selenide (**15**; 50 mmol, 11.3 g) was added to a solution of Na (50 mmol, 1.15 g) in ca. 100 mL of liquid NH_3 and stirred until it decolorized. After evaporation of the ammonia under Ar, the resulting $(Me_3Si)_2NH$ was removed under vacuum at 50 °C. 50 mL of pure THF was added to the remaining Me_3Si–SeNa. To this mixture ethyl iodide (50 mmol, 7.80 g) was added over 30 min under argon and stirring. It was then stirred for a further 4 h. After filtration and washing of the NaI precipitate with 30 mL of pentane the filtrate was fractionated using a short Vigreux column. Yield of **1b** 5.93 g (65%), b.p. 32–34 °C/20 mbar.

***p*-(Ethoxycarbonyl)phenylselenotrimethylstannane (3d):** Bis[*p*-(ethoxycarbonyl)phenyl]diselenide (**14d**; 5 mmol, 2.28 g) was suspended in 40 mL EtOH under stirring at room temperature and Ar and reduced by addition of small portions of $NaBH_4$ (10 mmol, 380 mg). After stirring (30 min), a solution Me_3Sn–Cl (10 mmol, 2.00 g) in 5 mL of THF was added to this suspension and further stirred for 30 min. This mixture was taken up with 250 mL of H_2O and extracted with $CHCl_3$ (3 × 50 mL). The extract was washed with water and dried (Na_2SO_4). The product was purified by column chromatography (silica gel, *n*-hexane/ether 10:1).Yield of **3d** 2.77 g (71%).

X-ray Crystal Structure Analysis of Compound 9e: A single crystal of compound **9e** was examined with a four-circle diffractometer at room temperature in air. Intensity data were corrected for Lorentz and polarization effects. An absorption correction had to be applied with the ψ-scan technique. The structure was solved by direct methods and refined by full-matrix least-squares techniques against F^2 (see Table 4).[45] The thermal motion of all non-hydrogen atoms was treated anisotropically. The hydrogen atom at O1 was located from the difference Fourier map. All the other hydrogen atoms were calculated in idealized positions and allowed to ride on their corresponding carbon atoms. Their isotropic thermal parameters were set to 1.2 times that of the adjacent C atom.

Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-138770. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

H. Poleschner was encouraged by the Wissenschaftler-Integrations-Programm (WIP, 1994–1996) at the Universität Potsdam, Institut für Organische Chemie und Strukturanalytik. We thank Ms. C. Hense-Lamatsch for her committed laboratory assistance. We would like to acknowledge Dr. A. Lehmann, Bundesanstalt für Materialforschung und -prüfung (BAM), Berlin-Adlershof, and Dr. G. Holzmann, Institut für Chemie, Organische Chemie, Freie Universität Berlin, for recording the mass spectra. Also we are grateful to Dr. H. Mehner, Bundesanstalt für Materialforschung und -prüfung (BAM), Berlin-Adlershof, for recording the Mößbauer spectrum. We are indebted to Dr. D. Lentz, Institut für Chemie, Anorganische und Analytische Chemie, Freien Universität Berlin, for the synthesis of xenon difluoride.

Rhodium(III)-Assisted Nucleophilic Addition of Ammonia to Metal-Bound Benzyl Cyanide: Crystal Structures of *mer*-$[RhCl_3(PhCH_2CN)_3]\cdot 1/2\ C_6H_5CH_3$ and *mer*-$[RhCl_3\{PhCH_2C(NH_2)=NH\}_3]$

Vadim Yu. Kukushkin,*[a] Igor V. Ilichev,[a] Gabriele Wagner,[b] Mikhail D. Revenco,[c] Viktor H. Kravtsov,[d] and Kinga Suwinska[e]

Keywords: Nitrile complexes / Rhodium / Nucleophilic additions / Amidines / Hydrogen bonding / Clathrates

Heating of $[RhCl_3(MeCN)_3]$ in benzyl cyanide at 100 °C gives the substitution product *mer*-$[RhCl_3(PhCH_2CN)_3]$ (90% yield), whose recrystallization from an acetone/toluene mixture leads to formation of the toluene solvate *mer*-$[RhCl_3(PhCH_2CN)_3]\cdot 1/2\ C_6H_5Me$. The crystal structure of the latter, determined by X-ray single-crystal diffractometry, shows an unusual self-assembly due to intermolecular CH···Cl hydrogen bonding with concomitant clathration of toluene. Diffusion of ammonia into a solution of *mer*-$[RhCl_3(PhCH_2CN)_3]$ in neat benzyl cyanide brings about a facile rhodium(III)-assisted addition of NH_3 to the coordinated nitrile species to produce the amidine complex *mer*-$[RhCl_3\{PhCH_2C(NH_2)=NH\}_3]$ (83% yield). Both starting material and the product were characterized by elemental analyses, FAB-MS, IR and ^1H and $^{13}C\{^1H\}$ NMR spectroscopy. The crystal structure of *mer*-$[RhCl_3\{PhCH_2C(NH_2)=NH\}_3]$ provides the first example of a rhodium(III) complex with a monodentate amidine ligand.

Introduction

The application of organonitrile transition metal complexes as synthons for preparation of a great variety of new compounds by the addition of nucleophiles − such as water/hydroxide, amines with sp^3 or sp^2 nitrogen atoms or mercaptans − to the carbon atom of the nitrile group has recently been reviewed comprehensively by Michelin and colleagues.[1] Our own research in this field has so far been focused on the hydrolysis of nitriles coordinated to a Rh−Rh unit to give a novel type of metallacycle,[2] addition of ethylenediamine to $[PtCl_2(PhCN)_2]$ to afford $[Pt(NH=C(Ph)NHCH_2CH_2NH_2)_2]^{2+}$, a complex that contains two unusual seven-membered organic metallacycles bound to the same platinum(II) center,[3] and the addition of nucleophiles with concerted cyclization of cyanoguanidine that yielded a novel type of azametallacycle, *cis*-$[(PPh_3)_2Pt\{NHC(Nuc)=NC(NH_2)=NH\}][BPh_4]$[4] and facile hydrolysis of organonitriles in platinum(IV) complexes to yield $[Pt^{IV}]-NH_3$ species.[5] Furthermore, we have recently observed a reaction between platinum(IV),[6−9] rhenium(IV)[10] and rhodium(III)[11] nitrile complexes and ketoximes, aldoximes, *vic*-dioximes, or dialkylhydroxylamines which led to isolation of iminoacylated compounds containing $[M]-\{NH=C(R)ON=CR'R''\}$,[6,9−11] $[M]-\{NH=C(R)ON=C(R')-C(R')=NOH\}$[7] or $[M]-\{NH=C(R)ONR'_2\}_2]$[8] moieties.

As part of our continuing interest in ligand reactivity in general,[12−15] and in reactions of coordinated nitriles[2−11] in particular we have now studied the ammination of the rhodium(III) complex *mer*-$[RhCl_3(PhCH_2CN)_3]$ by NH_3 giving the amidine complex *mer*-$[RhCl_3\{PhCH_2C(NH_2)=NH\}_3]$; these results, along with crystal structures of both starting material and the addition product, are reported herein.

Results and Discussion

There is much current interest in the chemistry of amidine/amidato transition metal complexes as evidenced, in particular, by the large number of papers published and also by detailed reviews written on the subject.[16,17] In the vast majority of cases complexes containing $RC(NH_2)=NH$ species are prepared by direct addition of the *amidine* to a complex. Metal-assisted reactions of *coordinated organonitriles* and ammonia lead to a very attractive route for preparation of complexes containing $RC(NH_2)=NH$ ligands. Despite the isolation of the first amidine metal compound formulated as $[Pt\cdot 2MeCN\cdot 4NH_3]Cl_2$,[18] the proposal of its amidine structure[19] and the first crystallographic determination of the amidine complex, $[Pt(NH_3)_2$-

$(MeC(NH_2)=NH)_2]^{2+}$,[20] this exciting chemistry was not developed much further, although additions of *substituted* amines to RCN ligands are fairly well-documented.[1] Besides the above-mentioned work[18] on the addition of NH_3 to the acetonitrile complex $[PtCl_2(MeCN)_2]$, attention should be drawn to ammination by liquid ammonia of $[Co(NH_3)_5(NCR)]^{3+}$ complexes[21] and addition of NH_3 to acetonitrile in a cationic tungsten compound.[22]

Although the kinetics and mechanisms of the reaction of metal-bound organonitriles and *primary* amines have been investigated in a limited number of cases,[1] it is generally believed[23–26] that the reaction takes place by nucleophilic attack of the amine N atom to the nitrile carbon, which is electrophilically activated by its ligation to a metal center; metal ions in high oxidation states should provide a stronger electrophilic activation towards nucleophiles thus facilitating the addition. For this study we chose a benzyl cyanide complex of rhodium(III) for the following reasons: first, it has been proved that the rhodium(III) ion provides a high degree of activation of an organonitrile. Indeed, a ca. 10^6-fold increase in the rate of base-catalyzed hydration of RCN has been reported when these species are coordinated to a Rh^{III} center.[27] Second, the electron-acceptor benzyl group of the nitrile, in contrast to the electron-donor methyl in $[RhCl_3(MeCN)_3]$, should provide an additional activation of the C atom.

The starting material for this work, *mer*-$[RhCl_3(PhCH_2CN)_3]$, was prepared in high (90%) yield by a route described earlier for phenyl- and benzyl cyanide complexes of platinum(II),[28] i.e. by heating of the easily obtained acetonitrile complex $[RhCl_3(MeCN)_3]$[29] in neat benzyl cyanide at 100 °C in an open beaker. It has been suggested that both the large excess of $PhCH_2CN$ and removal of MeCN from the reaction mixture at high temperature drive the reaction. Recrystallization of *mer*-$[RhCl_3(PhCH_2CN)_3]$ from an acetone/toluene mixture gave a toluene solvate *mer*-$[RhCl_3(PhCH_2CN)_3]\cdot 1/2\ C_6H_5CH_3$ that was characterized by X-ray single-crystal diffractometry.

The coordination polyhedron of the complex is a slightly distorted octahedron (Figure 1) with both the $PhCH_2CN$ and chloride ligands in *mer* positions. The *mer*-configuration of the rhodium(III) compound persists also in $CDCl_3$ solution as evidenced by observation of the two nonequivalent $PhCH_2CN$ species in a 1:2 ratio in ^1H and $^{13}C\{^1H\}$ NMR spectra (see Experimental Section).

The two mutually *trans* Rh–Cl bonds [Rh–Cl(1) and Rh–Cl(3)] are equal and slightly longer than the third one [Rh–Cl(2)] (Table 1) thus reflecting a higher ground-state *trans*-influence of the Cl^- ligand than the benzyl cyanide one. A higher *trans*-influence of the other nitrile, i.e. acetonitrile, was also detected in *mer*-$[RhCl_3(MeCN)_3]\cdot MeCN$,[29] while the *trans*-influence of RCN and Cl^- ligands are almost the same for (organonitrile)Pt^{II} complexes.[30–33] The geometry and bond lengths in $PhCH_2CN$ ligands (Table 1) are normal and agree well with the previously reported data on organonitrile Rh^{III} complexes.[33–41]

The packing diagram (Figure 2) shows that molecules of *mer*-$[RhCl_3(PhCH_2CN)_3]$ are assembled by intermolecular hydrogen bonding C(2)–H···Cl(2) between the methylene group from one molecule and the chloride from the adjacent molecule thus forming polymeric chains. The observed C(2)H···Cl(2) distances are in the range 2.84–2.85 Å indicating rather weak interactions [the combined contact radius

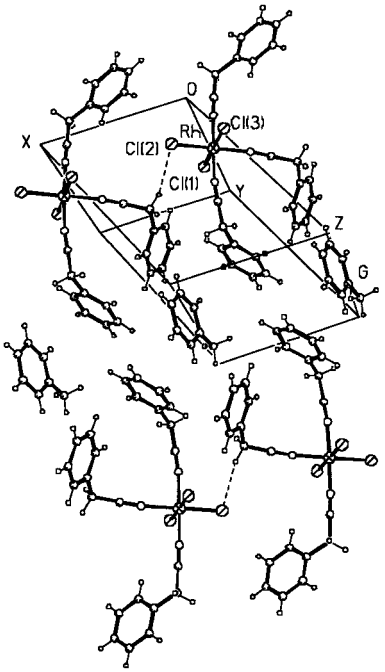

Figure 2. Packing diagram for *mer*-$[RhCl_3(PhCH_2CN)_3]\cdot 1/2\ C_6H_5CH_3$ indicating hydrogen bonding pattern

is H(1.20) + Cl(1.75) = 2.95 Å[42]].[29] Furthermore, the unit cell of *mer*-$[RhCl_3(PhCH_2CN)_3]\cdot 1/2\ C_6H_5Me$ contains half a molecule of clathrated and disordered toluene. The latter has no contacts less than the sum of the van der Waals radii with the *mer*-$[RhCl_3(PhCH_2CN)_3]$ molecule. It is worthwhile to mention that clathration of the solvent was observed in the case of the analogous complex *mer*-$[RhCl_3(MeCN)_3]\cdot MeCN$[29] that is also assembled into infinite chains by CH···Cl hydrogen bonding. These two observations together point to the need for a study on the self-assembly/clathration in similar systems. In fact, self-assembly of metal complexes by hydrogen bonding is the rapidly developing area of paramount importance for crystal engineering and material science[43−45] and it is likely − from that viewpoint − that the observation of H-bonding in the (organonitrile)Rh^{III} compounds with concomitant clathration of solvents deserves further investigations.

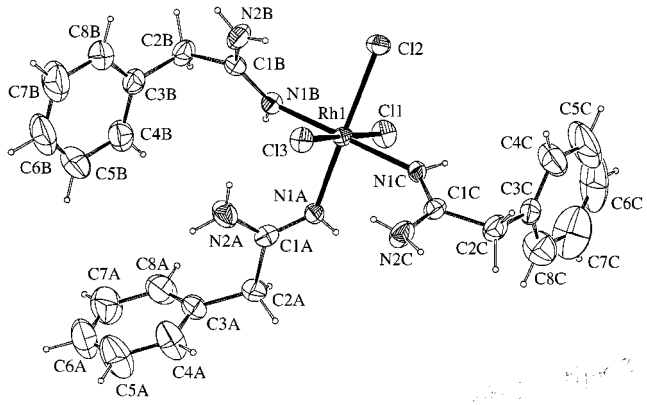

Figure 3. ORTEP drawing of *mer*-$[RhCl_3\{PhCH_2C(NH_2)=NH\}_3]$ with atomic numbering scheme

Diffusion of ammonia into a solution of *mer*-$[RhCl_3(PhCH_2CN)_3]$ in neat benzyl cyanide at 20−25 °C for one day led to the addition of NH_3 across the C≡N bond giving the rhodium(III) complex containing neutral amidine ligands *mer*-$[RhCl_3\{PhCH_2C(=NH)(NH_2)\}_3]$ which was isolated in good yield. The structure of the product of ammination has been determined by X-ray crystallography (Figure 3).

The coordination at rhodium is octahedral with small deviations from ideal geometry. The amidine species are coordinated through their imino nitrogens, adopting the *mer*-configuration which remains in $CDCl_3$ solution (see Experimental Section). The $PhCH_2C(NH_2)=NH$ ligands are in a *Z*-configuration in the solid state. Moreover, no evidence for existence of an *E*-conformation in solution can be derived from the NMR spectroscopic data. The HN=C [1.239(5)−1.285(5) Å] and H_2N−C [1.305(5)−1.330(5) Å] bonds (Table 2) lie in the normal range.[46] Hydrogen atoms from all three amidine species are involved in both *intra*-)

and *inter*molecular hydrogen bonding with chlorides thus precluding any conclusions about the "pure" ground-state *trans*-influence of $HN{=}C(NH_2)CH_2Ph$ ligands. The crystal structure of *mer*-$[RhCl_3\{PhCH_2C(NH_2){=}NH\}_3]$ is so far the only one for a rhodium(III) complex with monodentate amidines.

In conclusion, it is important to point out that *free* benzyl cyanide does not react with ammonia in $CDCl_3$ at room temperature (proved by ^1H NMR spectroscopy) or on a preparative scale (verified by a synthetic experiment) and these facts imply that the ammonia addition to *mer*-$[RhCl_3(PhCH_2CN)_3]$ is metal-assisted. To the best of our knowledge the ammination of coordinated RCN species in rhodium(III) complexes has not yet been investigated and this is the first example of its kind.

Experimental Section

Materials and Instrumentation: Solvents were obtained from commercial sources and used as received. $[RhCl_3(MeCN)_3]$ was prepared following a published method.[29] C, H and N elemental analyses were carried out by the Microanalytical Service of St. Petersburg State Technological Institute. Melting points were determined on a Kofler table. For TLC, Merck UV 254 SiO_2-plates were used. Positive-ion FAB mass spectra were obtained on a Trio 2000 instrument by bombarding 3-nitrobenzyl alcohol matrices of the samples with 8 keV (ca. 1.28×10^{15} J) Xe atoms. Mass calibration for data system acquisition was achieved using CsI. Infrared spectra (4000−400 cm^{-1}) were recorded on a BIO-RAD FTS 3000MX instrument as KBr pellets. ^1H and $^{13}C\{^1H\}$ NMR spectra were measured on a Varian UNITY 300 spectrometer at ambient temperature.

***mer*-$[RhCl_3(PhCH_2CN)_3]$:** $[RhCl_3(MeCN)_3]$ (0.1 g, 0.3 mmol) was dissolved in benzyl cyanide (1.0 mL, 8.7 mmol) and heated at 100 °C for 4 h in an open beaker. After this time the mixture was cooled to 20−25 °C and diethyl ether (20 mL) added dropwise with continuous stirring. The precipitate released was collected on a filter, washed with three portions of Et_2O (each 3 mL)and dried in air at room temperature. Yield: 0.15 g (90%); m.p. 122 °C. − TLC on SiO_2, R_f = 0.69 (eluent $CHCl_3/Me_2CO$ = 3:1, v/v). − $C_{24}H_{21}Cl_3N_3Rh$ (560.7): calcd. C 51.4, H 3.7, Cl 19, N 7.5, Rh 18.4; found C 52.3, H 3.7, Cl 18.6, N 7.5, Rh 18.5. − FAB^+-MS: *m/z* = 561 $[M]^+$, 524 $[M - Cl]^+$, 489 $[M - 2Cl]^+$, 372 $[M - 2Cl - PhCH_2CN]^+$. − IR (selected bands): $\tilde{\nu}$ = 2938 w and 2894 w ν(CH), 2316 m ν(C≡N), 1497 s and 1455 s ν(C=C), 742 s, 730 s and 695 s δ(CH) cm^{-1}. − ^1H NMR ($CDCl_3$): δ = 4.17 (s, 2 H) and 4.26 (s, 4 H, CH_2), 7.32−7.40 (m, 15 H, Ph). − $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 25.2 (CH_2, 1C), 25.4 (CH_2, 2C), 128.1, 128.6, 129.4 (CH, 2C each) and 128.0, 128.7, 129.5 (CH, 1C each), 127.5 (C_{ipso}, 3C, Ph), 121.9 (1C) and 122.8 (2C) (C≡N). For the toluene solvate $[RhCl_3(PhCH_2CN)_3]\cdot 1/2\ C_6H_5Me$, $C_{27.5}H_{25}Cl_3N_3Rh$ (606.8): calcd. C 54.4, H 4.2, N 6.9; found C 54.9, H 4.4, N 6.6.

***mer*-$[RhCl_3\{PhCH_2C(=NH)(NH_2)\}_3]$:** A solution of *mer*-$[RhCl_3(PhCH_2CN)_3]$ (0.1 g) in benzyl cyanide (1.0 mL) in an open beaker was placed in a dessicator with 25% aqueous ammonia at the bottom and kept for 1 d at room temperature. After this time diethyl ether (20 mL) was added dropwise with continuous stirring. The precipitate formed was collected on a filter, washed with three portions of Et_2O (each 3 mL) and dried in air at room temperature. Yield: 0.09 g (83%); m.p. 170 °C. − TLC on SiO_2, R_f = 0.36 (eluent $CHCl_3/Me_2CO$ = 3:1, v/v). − $C_{24}H_{30}Cl_3N_6Rh$ (611.8): calcd. C, 47.1, H 4.9, N 13.7, Cl 17.4, Rh 16.8; found C 47.2, H 4.9, N 13.7, Cl 17.3, Rh 16.9. − FAB^+-MS: *m/z* = 612 [M], 575 $[M - Cl]^+$. − IR (selected bands): $\tilde{\nu}$ = 3490 w, 3427 m-w, 3400 m-w, 3329 m-w, 3269 m-w ν(NH), 2921 m-w ν(CH), 1650 vs, br. ν(C=N), 749 s and 702 s δ(CH) cm^{-1}. − ^1H NMR ($CDCl_3$): δ = 3.59 (s, 2 H)

X-ray Crystallography: All crystallographic measurements were carried out with a Nonius Kappa CCD diffractometer equipped with a graphite monochromated Mo-K_α radiation source using θ rotations with 2° frames and a detector-to-crystal distance of 35 mm. The unit cell determination and integration was carried out by the program DENZO-SMN.[47] Data sets were corrected for Lorentz and polarization effects. Structures were solved using heavy-atom methods SHELXL-97.[48] All non-hydrogen atoms were refined anisotropically, whilst hydrogen atoms were fixed in the idealized position and allowed to ride. All crystallographic data and information about refinement of the two structures are given in Table 3 and bond lengths and angles in Table 1 and Table 2.

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publications no. CCDC-137154 $C_{27.5}H_{25}N_3Cl_3Rh$ and CCDC-137155 $C_{24}H_{30}N_6Cl_3Rh$. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Titanium Complexes Containing a Disulfide-Bridged Bis(phenolato) Ligand: Synthesis and Structural Characterization of Three Different Bonding Modes

Jun Okuda,*[a] Stefan Fokken,[a] Thomas Kleinhenn,[a] and Thomas P. Spaniol[a]

Keywords: Titanium / O ligands / Bulky phenols / Lewis acids / S ligands

A series of titanium(IV) complexes containing the 2,2′-dithiobis(6-*tert*-butyl-4-methylphenolato) ligand (dtbmp) were synthesized and characterized. Treatment of titanium tetra(isopropoxide) with 2,2′-dithiobis(6-*tert*-butyl-4-methylphenol) (dtbmpH_2) gave, regardless of the molar ratio of the starting materials, a C_2-symmetric dinuclear complex [Ti_2(O*i*Pr)$_2$(μ_2-O*i*Pr)$_2$(dtbmp)]. According to the results of a single crystal X-ray analysis, the two Ti(O*i*Pr)$_2$ fragments in this complex are bridged by a dtbmp ligand and two isopropoxide ligands. The disulfide link of the dtbmp ligand is bonded to each of the titanium centers [Ti–S 2.795(1) and 2.768(1) Å], thus completing an octahedral coordination sphere around titanium. Reaction of [Ti_2(O*i*Pr)$_4$(μ_2-O*i*Pr)$_2$(dtbmp)] with Me_3SiX (X = Br, I) gave the mononuclear complex Ti(dtbmp)X_2. Crystallographic study revealed a distorted octahedral coordination with the disulfide link of the dtbmp dihapto-bonded through a relatively short Ti–S distance of 2.637(1) Å (X = Br) or 2.645(2) Å (X = I). Finally, the reaction of titanium tetra(*n*-butoxide) with dtbmpH_2 gave a C_i-symmetric dimer [Ti_2(O*n*Bu)$_2$(μ_2-O*n*Bu)$_2$(dtbmp)$_2$] that exhibits a monohapto coordination of the disulfide bridge in the dtbmp ligand with Ti–S bond lengths of 2.692(1) Å and 2.694(1) Å in the crystal.

Introduction

As precursors for homogeneous α-olefin polymerization catalysts, titanium complexes with bulky bisphenolato ligands such as the 2,2′-methylenebis(6-*tert*-butyl-4-methylphenolato) ligand (mbmp)[1] are attracting some interest as alternatives for both the *ansa*-metallocenes[2] and the chelating diamido complexes.[3] Following the remarkable finding by Kakugo et al.[1c] that in such catalyst precursors the replacement of a methylene bridge[4] by a sulfide group imparts a significant increase in the polymerization activity when activated with methylaluminoxane, crystallographic[5] and computational studies[6] have indicated that the sulfide donor plays an active role. In the putative alkyl cation, the weakly coordinating sulfide is thought to decrease the activation barrier for the olefin insertion into the alkyl−titanium bond. More recently, we noted that nine-membered chelate complexes of titanium are formed with remarkable ease with the ethylene-bridged bisphenolato ligand 2,2′-ethylenebis(6-*tert*-butyl-4-methylphenolato) ligand (ebmp).[5b,7] They copolymerize ethylene with styrene with significant incorporation of the bulky monomer styrene.[8] Since no examples for titanium complexes of 2,2′-dithiobis(6-*tert*-butyl-4-methylphenol) were known in the literature,[9] we decided to study its coordination at tetravalent titanium centers. In this contribution, we describe the synthesis and structural characterization of titanium complexes incorporating the disulfide analogue of the ebmp ligand, 2,2′-dithiobis(6-*tert*-butyl-4-methylphenolato) (dtbmp).

Results and Discussion

When titanium tetrachloride was reacted with one equivalent of 2,2′-dithiobis(6-*tert*-butyl-4-methylphenol) (dtbmpH_2)[9] in hexane for 4 h, the dichloro complex Ti(dtbmp)Cl_2 (**1**) could be isolated in 78% yield as a dark red powder. Analytical, mass and ^{1}H and ^{13}C NMR spectroscopic data are consistent with a mononuclear structure with two terminal chloro ligands in which the dtbmp ligand acts as a chelating ligand. Upon complexation, all ^{1}H and ^{13}C NMR signals are shifted to lower field. In contrast to the sparingly soluble dichloro titanium complexes with the chelating bridged bisphenoxy ligands of the type [Ti{Z(OC_6H_2-4-Me-6-*t*Bu)$_2$}Cl_2] (Z = S,[5] SO,[10] and SO_2),[5b] but similar to the methylene- and ethylene-linked derivatives [Ti(mbmp)Cl_2][4a] and [Ti(ebmp)Cl_2],[7] hexane-soluble **1** appears to be mononuclear in solution.

The homologous dark red dibromo and black diiodo complexes **2** and **3** were prepared by reaction of the novel tri(isopropoxy) derivative [Ti_2(O*i*Pr)$_4$(μ_2-O*i*Pr)$_2$(dtbmp)] (**4**), described below, with an excess of Me_3SiX (X = Br, I) in ca. 40% yield. Since the analytical, mass, and ^{1}H and ^{13}C NMR spectroscopic data of **2** and **3** are similar to those of **1**, a structure analogous to that of **1** can be implied for both. Single crystals obtained by slow crystallization from pentane solutions could be analyzed by X-ray diffraction. The two complexes are isomorphous. The crystallographic data are summarized in Table 1 and an ORTEP diagram of the diiodo complex **3** is depicted in Figure 1. The molecule resides on a crystallographically imposed C_2 axis. The coordination sphere around the tetravalent titanium center can be described as strongly distorted octahedral. Whereas the two halo ligands and the two sulfur atoms of the disulfide bridge form a sort of equatorial plane [dihedral angle be-

ORTEP diagram of the molecular structure of Ti(dtbmp)I_2 (**3**); thermal ellipsoids are drawn at 50% probability level; hydrogen atoms are omitted for the sake of clarity; selected bond lengths (Å) and angles (°): Ti−I 2.6225(6), Ti−O 1.847(2), Ti−S 2.637(1), S−S′ 2.137(2); I−Ti−I 111.00(3), O−Ti−O 158.2(1), C1−O−Ti 135.9(2), C2−S−S′ 99.8(1), S−Ti−S′ 47.82(4)

tween the TiI_2 and TiS_2 planes 12.68(2)°], the phenoxy oxygen atoms can be considered as adopting the apical sites [O−Ti−O 158.2(1)°]. While the titanium−iodine bond lengths are within the expected range of 2.65 Å,[11] the titanium−sulfur bond of 2.637(1) Å is shorter than that observed in most other tbmp titanium complexes.[5] In agreement with a stronger titanium−disulfide interaction, the sulfur−sulfur distance of 2.137(2) Å is significantly longer than that in $dtbmpH_2$ (2.086 Å).[9b] The angles at the phenoxy oxygen atoms are 135.9(2)° and are considerably smaller than the corresponding values in Ti(ebmp)Br_2[5b,7]

and mononuclear nonchelating phenolato titanium complexes.[12]

Attempts to alkylate the dihalo complexes invariably resulted in the formation of dark intractable material. We suspect that the disulfide bridge is irreversibly cleaved by the reducing alkylating reagents. As anticipated, polymerization tests upon activation with MAO and ethylene were irreproducible and showed no significant activity.

When titanium tetra(isopropoxide) was reacted with one equivalent of dtbmpH_2 in toluene for three days, orange crystals of what was initially thought to be [Ti(dtbmp)(O-*i*Pr)$_2$] could be isolated. Analogous reactions of titanium tetra(isopropoxide) with methylene-, ethylene-, thio-, sulfinyl- and sulfone-bridged bisphenol all gave the di(isopropoxy) complexes [Ti{Z(OC$_6$H$_2$-4-Me-6-*t*Bu)$_2$}](O*i*Pr)$_2$ in quantitative yield.[5] However, the elemental analysis and mass spectrum of **4** indicated a dinuclear structure with only one half dtbmp ligand per titanium with a formula corresponding to [Ti$_2$(O*i*Pr)$_6$(dtbmp)]. The ^{1}H NMR spectrum has the rather striking feature of all methyl groups of the six isopropoxy groups being diastereotopic. Accordingly, the ^{13}C NMR spectrum gives rise to three inequivalent isopropyl groups. The molecule therefore does not contain any mirror plane, although the two halves of the dtbmp ligand are equivalent. This appearance is temperature independent in the range of −80 to +110 °C.

Single crystals of **4** obtained by slow cooling of a saturated solution in 2-propanol were studied by X-ray crystallography. The ORTEP diagram of the molecule is shown in Figure 2 and the crystallographic data are listed in Table 1. The results of the diffraction study reveal a dinuclear structure in which two Ti(O*i*Pr)$_2$ fragments are linked by two O*i*Pr groups and one bridging dtbmp ligand. The bulky dtbmp ligand spans the Ti$_2$(O*i*Pr)$_2$ plane so as to be located in a highly skewed way, rendering the molecule chiral. The coordination geometry around the titanium centers can be regarded as distorted octahedral. The titanium−sulfur distances with 2.7954(9) and 2.768(1) Å are clearly longer than the distance in **3**, whereas the sulfur−sulfur distance is 2.100(1) Å. The coordination mode of the disulfide fragment in **4** is comparable to that found in [(TiCl$_3$)$_2$(μ-Cl)$_2$(μ-MeSSMe)], for which titanium−sulfur distances of 2.712(3) and 2.742(3) Å and a sulfur−sulfur distance of 2.052(3) Å were reported.[13]

When equimolar mixtures of titanium tetramethoxide and tetra(*n*-butoxide) are reacted with dtbmpH_2 in toluene, orange precipitates of the dialkoxo complexes of the formula [Ti(dtbmp)(OR)$_2$] [R = Me (**5**), *n*Bu (**6**)] are formed. Based on the low solubility of **5** and **6**, a dimeric structure similar to that of [Ti{Z(OC$_6$H$_2$-4-Me-6-*t*Bu)$_2$}(O*i*Pr)$_2$]$_2$ (Z = S,[7] SO,[10] and SO$_2$[5b]) is inferred. The ^{1}H and ^{13}C NMR spectroscopic data are consistent with a C_{2h} symmetry, since two separate sets of signals for the *n*-butoxy groups are recorded. Most notably, the α-protons of the bridging group are diastereotopic and appear as two higher-order multiplets, whereas those of the terminal *n*-butoxy group give rise to a binomial triplet at 4.87 ppm with $^3J_{HH}$ = 4 Hz. The single crystal structure analysis of **6** confirmed a related dimeric structure (Table 1, Figure 3). The centrosymmetric molecule consists of two Ti{S$_2$(OC$_6$H$_2$-4-Me-6-*t*Bu)$_2$}(O*n*Bu) fragments bridged by two O*n*Bu groups in the familiar manner. The most striking feature relates to the coordination of the disulfide bridge. Only one sulfur atom is coordinated to the titanium center with a bond length of 2.692(1) and 2.694(1) Å. These distances are somewhat shorter than those in [Ti{S(OC$_6$H$_2$-4-Me-6-*t*Bu)$_2$}(O*n*Bu)$_2$]$_2$ [2.738(1) Å[5b]] and in other titanium(IV) complexes containing the tbmp ligand,[5] and may reflect a stronger titanium−sulfur bond. The other sulfur atoms of the disulfide links have a distance to the titanium of 3.828(2) and 3.832(2) Å and can be considered to be nonbonding. In agreement with this unsymmetrical bonding situation, the titanium−oxygen bonds Ti1−O4 and Ti2−O7 within the phenoxy moieties with the nonbonding

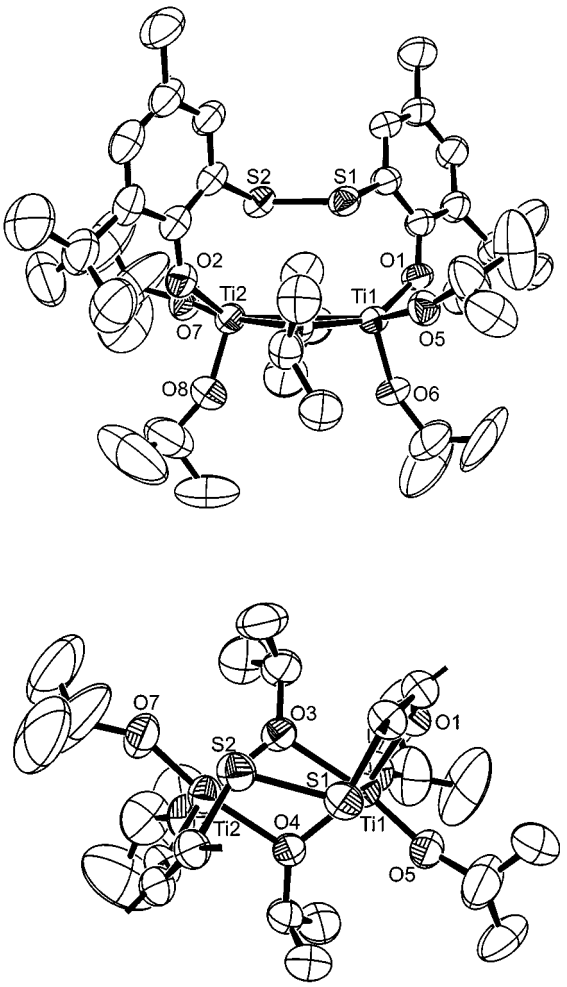

Figure 2. ORTEP diagram of the molecular structure of Ti$_2$(O*i*Pr)$_4$(μ-O*i*Pr)$_2$(dtbmp) (**4**): (a) side view; (b) top view; ring carbon atoms except those at the *ipso* and *ortho* positions have been omitted; thermal ellipsoids are drawn at 50% probability level; hydrogen atoms are omitted for the sake of clarity; selected bond lengths (Å) and angles (°): Ti1−O1 1.920(2), Ti1−O5 1.784(2), Ti1−O6 1.773(2), Ti1−O3 2.100(2), Ti1−O4 1.971(2), Ti1−S1 2.7954(9), Ti2−O2 1.923(2), Ti2−O7 1.786(2), Ti2−O3 1.972(2), Ti2−O4 2.087(2), Ti2−O8 1.779(2), Ti2−S2 2.768(1), S1−S2 2.100(1); O6−Ti1−S1 170.95(8), O3−Ti1−O5 164.97(9), O1−Ti1−O4 147.39(8), O3−Ti1−O4 72.26(7), S2−S1−Ti1 100.45(4)

sulfur atoms are significantly shorter than Ti1−O3 and Ti2−O6 and the angles at the oxygen atoms O4 and O7 are larger than those at O3 and O6. The sulfur−sulfur bond length is 2.059(2) Å and significantly shorter not only than that in **3** and **6**, but also that in dtbmpH_2. This observation can be explained by a partial sulfur−sulfur double bond character of the disulfide bridge, when only one sulfur atom is coordinated. Finally, the apparent mirror plane in the solution structure can be accounted for by a fast 1,2-shift of the titanium center from one sulfur atom to the other.

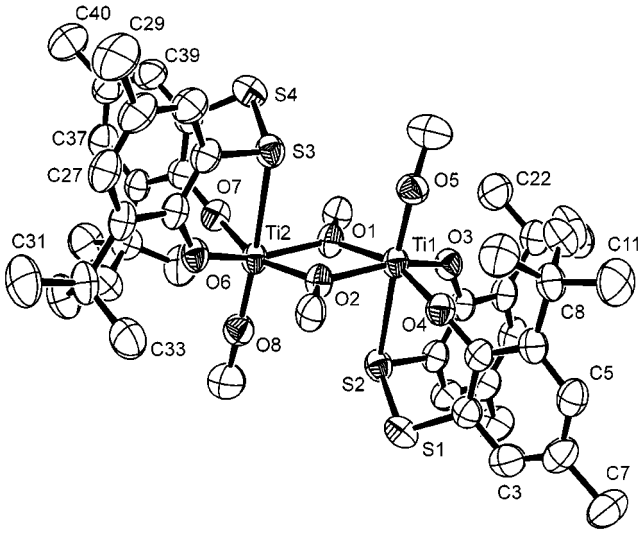

Figure 3. ORTEP diagram of the molecular structure of Ti_2(O*n*Bu)$_2$(μ-O*n*Bu)$_2$(dtbmp)$_2$ (**6**); thermal ellipsoids are drawn at 50% probability level; carbon atoms of the *n*-butoxy groups except those in the α-positions and hydrogen atoms are omitted for the sake of clarity; selected bond lengths (Å) and angles (°): Ti1−O1 2.038(3), Ti1−O2 1.997(2), Ti1−O3 1.903(2), Ti1−O4 1.855(3), Ti1−O5 1.767(3), Ti1−S2 2.692(1), Ti1−S1 3.828(2), S1−S2 2.059(2), S3−S4 2.063(2), Ti2−S3 2.694(1), Ti2−S4 3.832(2); C2−S1−S2 109.2(2), C2−S1−Ti1 76.3(1), S2−S1−Ti1 42.36(4), O1−Ti1−O2 72.91(9), O3−Ti1−O4 96.8(1) O5−Ti1−S2 171.03(9), Ti2−O1−Ti1 107.0(1), Ti1−O2−Ti2 107.5(1), C13−O3−Ti1 133.3(2), C1−O4−Ti1 153.2(3), C53−O5−Ti1 153.1(4).

In summary, we have synthesized and structurally characterized a series of tetravalent titanium complexes containing a disulfide-linked bis(phenolato) ligand dtbmp. Compared with the ethylene-bridged ligand ebmp, the coordination of the disulfide function at the tetravalent titanium center results in various coordination modes: η^2-S_2 in **2** and **3**, μ-η^1-S_2 in **4**, and η^1-S_2 in **6**. In the literature, most of the disulfide coordination chemistry is confined to that of softer late transition or coinage metals.[13] The facile reduction may, however, limit the application of titanium complexes containing the disulfide-linked bis(phenolato) ligand in polymerization catalysis.

Experimental Section

General: All experiments were performed under argon with standard Schlenk techniques. Solvents were purified, dried and distilled under argon. − ^{1}H and ^{13}C NMR: Bruker DRX 400, AC 200 or AM 400; all spectra in $CDCl_3$ at 25 °C. − Mass Spectra: Finnigan 8230. − Elemental analyses: Microanalytical laboratory of this department.

2,2′-Dithiobis(6-*tert*-butyl-4-methylphenol) (dtbmpH_2): To a solution of 2-*tert*-butyl-4-methylphenol (126 g, 767 mmol) in 120 mL of toluene was added over a period of 2 h a solution of disulfur dichloride (34.2 mL, 57.7 g, 433 mmol) in 100 mL of toluene at room temperature. The reaction mixture was stirred at 80 °C for an additional 90 min. The solvent was evaporated and the viscous, orange-brown crude product was dissolved in hot ethanol. After cooling and recrystallization from methanol in order to remove 2,2′-trithiobis(6-*tert*-butyl-4-methylphenol), yellow crystals of 2,2′-dithiobis(6-*tert*-butyl-4-methylphenol) were obtained. Yield 53.6 g (36%), m.p. 107 °C. − ^{1}H NMR: δ = 1.36 [s, 18 H, C(CH_3)$_3$], 2.18 (s, 6 H, 4-CH_3), 6.53 (s, 2 H, OH), 6.99 (d, $^4J_{HH}$ = 2 Hz, 2 H, 3-H), 7.11 (d, $^4J_{HH}$ = 2 Hz, 2 H, 5-H). − ^{13}C{^{1}H} NMR: δ = 20.5 (4-*C*H_3), 29.5 [C(*C*H_3)$_3$], 35.0 [*C*(CH$_3$)$_3$], 120.6 (C-2), 129.1 (C-4), 131.4 (C-5), 134.0 (C-3), 136.3 (C-6), 153.2 (C-1). − EI MS: *m*/*z* (%) = 390 (57) [M$^+$], 358 (82) [$C_{21}H_{26}OS_2^+$], 195 (52) [M^{2+}], 164 (100) [$C_{11}H_{16}O^+$], 149 (41) [$C_{10}H_{13}O^+$], 91 (17) [$C_7H_7^+$]. − $C_{22}H_{30}O_2S_2$ (390.6): calcd. C 67.65, H 7.74; found C 67.53, H 7.55.

Dichloro{2,2′-dithiobis(6-*tert*-butyl-4-methylphenolato)}titanium (1): To a solution of titanium tetrachloride (0.38 mL, 3.48 mmol) in 30 mL of hexane was added slowly a solution of 2,2′-dithiobis(6-*tert*-butyl-4-methylphenol) (1.36 g, 3.48 mmol) in 35 mL of hexane at room temperature. A dark red powder started to precipitate and the reaction mixture was stirred for an additional 4 h. After evaporation of the solvent, the residue was washed with 10 mL of hexane to afford 1.38 g of dark red microcrystals (78%). − ^{1}H NMR: δ = 1.49 [s, 18 H, C(CH_3)$_3$], 2.33 (s, 6 H, 4-CH_3), 7.25 (d, $^4J_{HH}$ = 1.4 Hz, 2 H, 3-H), 7.45 (d, $^4J_{HH}$ = 1.4 Hz, 2 H, 5-H). − ^{13}C{^{1}H} NMR: δ = 20.9 (4-*C*H_3), 29.5 [C(*C*H_3)$_3$], 35.4 [*C*(CH$_3$)$_3$], 122.6 (C-2), 127.8 (C-4), 132.0 (C-5), 132.2 (C-3), 137.5 (C-6), 168.0 (C-1). − EI MS: *m*/*z* (%) = 506 (27) [M$^+$], 471 (32) [M$^+$ − Cl], 194 (52) [$C_{11}H_{14}OS^+$], 91 (100) [$C_7H_7^+$]. − $C_{22}H_{28}Cl_2O_2S_2Ti$ (507.4): calcd. C 52.08, H 5.56; found C 50.98, H 5.41.

Dibromo{2,2′-dithiobis(6-*tert*-butyl-4-methylphenolato)}titanium (2): To a solution of **4** (100 mg, 119 μmol) in 15 mL pentane was added bromotrimethylsilane (97.4 μL, 715 μmol) at room temperature. After 2 d dark red crystals precipitated from the solution. Filtration and washing with 2 mL of pentane afforded the product, yield 31 mg (44%). − ^{1}H NMR: δ = 1.52 [s, 18 H, C(CH_3)$_3$], 2.33 (s, 6 H, 4-CH_3), 7.26 (d, $^4J_{HH}$ = 1.4 Hz, 2 H, 3-H), 7.45 (d, $^4J_{HH}$ = 1.4 Hz, 2 H, 5-H). − ^{13}C{^{1}H} NMR: δ = 20.9 (4-*C*H_3), 29.6 [C(*C*H_3)$_3$], 35.4 [*C*(CH$_3$)$_3$], 120.6 (C-2), 129.0 (C-4), 131.4 (C-5), 133.9 (C-3), 137.4 (C-6), 168.1 (C-1). − EI MS: *m*/*z* (%) = 596 (100) [M$^+$], 517 (78) [M$^+$ − Br], 460 (52) [M$^+$ − Br − C_4H_9], 196 (12) [$C_{11}H_{16}OS^+$]. − $C_{22}H_{28}Br_2O_2S_2Ti$ (596.3): calcd. C 44.32, H 4.77; found C 44.27, H 4.73.

Diiodo{2,2′-dithiobis(6-*tert*-butyl-4-methylphenolato)}titanium (3): To a solution of **4** (180 mg, 324 μmol) in 20 mL pentane was added iodotrimethylsilane (0.26 mL, 1.92 mmol) at room temperature. After 2 d black crystals precipitated from the solution. Filtration and washing with 5 mL of pentane afforded the product, yield 86 mg (38%). − ^{1}H NMR: δ = 1.61 [s, 18 H, C(CH_3)$_3$], 2.32 (s, 6 H, 4-CH_3), 7.30 (d, $^4J_{HH}$ = 2 Hz, 2 H, 3-H), 7.45 (d, $^4J_{HH}$ = 2 Hz, 2 H, 5-H). − ^{13}C{^{1}H} NMR: δ = 20.8 (4-*C*H_3), 29.7 [C(*C*H_3)$_3$], 35.3 [*C*(CH$_3$)$_3$], 122.8 (C-2), 129.0 (C-4), 131.2 (C-5), 131.9 (C-3), 133.7 (C-6), 168.2 (C-1). − EI MS: *m*/*z* (%) = 564 (13) [M$^+$ − I], 436 (100) [M$^+$ − 2I,], 331 (14) [M$^+$ − 2 I − 2 C_4H_9], 127 (96) [I$^+$] − $C_{22}H_{28}I_2O_2S_2Ti$ (690.3): calcd. C 38.28, H 4.09; found C 38.08, H 4.14.

Tetra(isopropoxy)di(μ-isopropoxy){μ-2,2′-dithiobis(6-*tert*-butyl-4-methylphenolato)}dititanium (4): To a suspension of 2,2′-dithiobis(6-*tert*-butyl-4-methylphenol) (1.88 g, 4.81 mmol) in 50 mL of dry 2-propanol was added titanium tetra(isopropoxide) (2.84 mL, 9.62 mmol) and the reaction mixture stirred for 2 d at room temperature. During this time the color of the solution changed from yellow to orange. The solution was concentrated to a volume of ca. 30 mL and cooled to −78 °C for 16 h to give orange crystals, yield 2.58 g (64%). − ^{1}H NMR: δ = 0.97 [d, $^3J_{HH}$ = 6.2 Hz, 6 H, CH(CH_3)$_2$], 1.00 [d, $^3J_{HH}$ = 6.2 Hz, 6 H, CH(CH_3)$_2$], 1.07 [d, $^3J_{HH}$ = 6.2 Hz, 6 H, CH(CH_3)$_2$], 1.22 [d, $^3J_{HH}$ = 6.2 Hz, 6 H, CH(CH_3)$_2$], 1.34 [d, $^3J_{HH}$ = 6.2 Hz, 6 H, CH(CH_3)$_2$], 1.40 [s, 18 H, C(CH$_3$)$_3$], 1.48 [d, $^3J_{HH}$ = 6.2 Hz, 6 H, CH(CH_3)$_2$], 2.26 (s, 6 H, 4-CH$_3$), 4.58 [sept, $^3J_{HH}$ = 6.2 Hz, 2 H, CH(CH$_3$)$_2$], 4.97 [sept, $^3J_{HH}$ = 6.2 Hz, 2 H, CH(CH$_3$)$_2$], 5.06 [sept, $^3J_{HH}$ = 6.2 Hz, 2 H, CH(CH$_3$)$_2$], 7.04 (d, $^4J_{HH}$ = 2 Hz, 2 H, 3-H), 7.38 (d, $^4J_{HH}$ = 2 Hz, 2 H, 5-H). − ^{13}C{^{1}H} NMR: δ = 20.8 (4-CH$_3$), 24.1 [CH(CH$_3$)$_2$], 24.8 [CH(CH$_3$)$_2$], 25.7 [CH(CH$_3$)$_2$], 26.1 [CH(CH$_3$)$_2$], 26.3 [CH(CH$_3$)$_2$], 26.3 [CH(CH$_3$)$_2$], 29.7 [C(CH$_3$)$_3$], 35.2 [C(CH$_3$)$_3$], 74.4 [CH(CH$_3$)$_2$], 78.5 [CH(CH$_3$)$_2$], 79.8 [CH(CH$_3$)$_2$], 118.7 (C-2), 127.0 (C-4), 131.1 (C-5), 133.8 (C-3), 137.0 (C-6), 167.2 (C-1). − EI MS: *m*/*z* (%) = 554 (2) [M$^+$ − Ti(OC$_3$H$_7$)$_4$], 436 (6) [C$_{22}$H$_{28}$O$_2$S$_2$Ti$^+$], 269 (100) [(M$^+$ − Ti(OC$_3$H$_7$)$_4$ − CH$_4$)$^{2+}$], 225 (13) [C$_{11}$H$_{13}$OS$_2^+$]. − C$_{40}$H$_{70}$O$_8$S$_2$Ti$_2$ (838.9): calcd. C 57.27, H 8.41; found C 57.08, H 9.20.

Tetramethoxybis{2,2′-dithiobis(6-*tert*-butyl-4-methylphenolato)}-dititanium (5): A mixture of 2,2′-dithio(6-*tert*-butyl-4-methylphenol) (1.68 g, 4.30 mmol) and titanium tetramethoxide (741 mg, 4.30 mmol) in 25 mL of toluene was stirred for 3 d at room temperature. After the solvent was evaporated, residual titanium tetramethoxide was removed by filtration of chloroform extracts of the reaction mixture. Evaporation of the solvent afforded a yellow powder, yield 894 mg (42%). − ^{1}H NMR: δ = 1.38 [s, 18 H, C(CH$_3$)$_3$], 2.18 (s, 6 H, 4-CH$_3$), 3.98 [br s, 3 H, OCH$_3$], 4.55 [3 H, OCH$_3$(term.)], 6.89 (d, $^4J_{HH}$ = 2 Hz, 2 H, 3-H), 7.05 (d, $^4J_{HH}$ = 2 Hz, 2 H, 5-H). − ^{13}C{^{1}H} NMR: δ = 20.7 (4-CH$_3$), 29.8 [C(CH$_3$)$_3$], 35.1 [C(CH$_3$)$_3$], 63.6, 67.1 [OCH$_3$], 119.1 (C-2), 128.2 (C-4), 128.7 (C-5), 129.0 (C-3), 129.5 (C-6), 162.8 (C-1). − EI MS: *m*/*z* (%) = 390 (65) [M/2$^+$ − 2OCH$_3$ − Ti], 195 (52) [(M/2 − 2OCH$_3$ − Ti)$^{2+}$], 164 (100) [C$_{11}$H$_{16}$O$^+$], 91 (85) [C$_7$H$_7^+$]. − C$_{48}$H$_{68}$O$_8$S$_4$Ti$_2$ (997.1): calcd. Crystal Structure Determinations of 2, 3, 4, and 6: Relevant crystallographic data are summarized in Table 1. X-ray data were collected with an Enraf−Nonius CAD4 diffractometer at 296(2) K by using Mo-K_α radiation and ω scans. Data reductions were carried out using the program system MOLEN.[15a] The structures of **2, 4,** and **6** were solved by direct methods (SHELXS-86);[15b] the structure of **3** was solved by isotypic replacement using the coordinates of **2**. All structures were refined by full-matrix least squares against F^2 (SHELXL-93).[15c] Non-hydrogen atoms were located in difference Fourier maps and refined anisotropically. All hydrogen atoms in **2** and **3** were located in difference Fourier maps and refined isotropically, whereas in **4** the hydrogen atoms of several methyl groups are included in calculated positions. In **6**, all hydrogen atoms were included into calculated positions. Four of the isopropyl groups in **4** were refined with disordered split positions. The structure of **6** also shows strong disorder of the *n*-butyl groups. Crystallographic data (excluding structure factors) for the structures included in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-140742 for **2**, -140743 for **3**, -170744 for **4**, and -140745 for **6**. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Keywords: Cations / Alkali metals / Cyclooligomerizations / Si ligands / Cluster compounds

The Cu_4 derivatives of $[EtSiO_2]Na$ have been synthesised and their cyclic voltammetry, spectroscopic behaviour and X-ray structure determination described. The changes in the alkali cation, Na^+ in place of K^+, might have a "tuning" effect in the organisation on the siloxanolate clusters resulting in a macrocyclic ($[EtSiO_2]_{12}$) ligand instead of two cyclic ($[EtSiO_2]_6$) ligands.

Introduction

Efforts at modelling[1] silica-supported transition metal catalysts[2] resulted in the discovery of reactions leading to cyclosiloxanolate clusters of higher valent transition metals.[3] This new class of metal clusters showed redox,[4] catalytic[5] and magnetic[6] features, which are interesting in their own right.

One of the most remarkable features of this chemistry is the high chemoselectivity of the organisation of these complexes.[3c,7] However, almost nothing is known about the factors which influence the architecture of the cyclosiloxanolate clusters. In this paper we report an observation which might be the first step in this direction.

Results and Discussion

It has been observed by one of our groups that the reaction of potassium ethylsiloxanolate with copper(II) chloride gives the sandwich-type complex **1** [Equation (1)].[8]

$$12\ \text{"}EtSiO_2K\text{"} + 4\ CuCl_2 \rightarrow K_2\{[\text{cyclo-}(EtSiO_2)_6]_2Cu_4K_2\}\cdot 4n\text{BuOH}\ (\mathbf{1}) + 8\ KCl \quad (1)$$

Since copper(II) in earlier studies showed a tendency to also give tetrahedrally arranged Cu_4 derivatives with *only one* macrocyclic ($[RSiO_2]_{12}$) ligand, we tested whether changes in the experimental conditions would also result in tetrahedral moieties from ethylsiloxanolate anions. We therefore decided to try to change the alkali cation, which might be a "tuning" factor in the organisation of the siloxanolate clusters. In fact we observed that using sodium ethylsiloxanolate, we obtained the new complex **2** according to Equation (2)

$$12\ \text{"}EtSiO_2Na\text{"} + 4\ CuCl_2 \rightarrow Na_4[\text{cyclo-}(EtSiO_2)_{12}Cu_4]\cdot L_x\ \mathbf{(2)} + 8\ NaCl \quad (2)$$

where L_x = (**a**) 2 *n*BuOH·4NaCl; (**b**) 4 *n*BuOH. The yields observed from Equation (2) were comparable with the yields obtained with other cyclosiloxanolate clusters,[3c,7] which shows that the chemoselectivity observed in Equation (1) could *de facto* be changed by changing the alkali cation.

The new complex **2** has been characterised by elemental analysis and physical methods. Conductivity measurements showed the presence of a nondissociated cluster and relatively easy dissociation of the externally coordinated sodium ions, with λ_{eq} similar to that of other tetrahedral Cu_4 complexes.[9] Cyclic voltammetry showed a nearly reversible redox process at very negative potentials, more than 1.5 V more negative than the peak potential reported for the non-complexed Cu^{II}/Cu^0 couple.[10] This indicates a considerable stability of the complex core of **2** in solution towards dissociation, as well as survival of the reduction/oxidation process involved in the CV cycles. This behaviour seems to be

a general feature of the transition metal cyclosiloxanolate complexes.[4,9]

The medium (4000−400 cm^{-1}) and far (500−50 cm^{-1}) infrared spectra confirmed the presence of the structural elements proposed for the structure of complex **2** (C−H, Si−C, Si−O, Cu−O, Na−O interactions) indicating fairly weak Na−O interactions.

The single crystal X-ray structure determination gives a final proof for the structure of complex **2b** which, lying about the *a* Wickoff position, has a crystallographically imposed S_4 (−4) symmetry (Figure 1). The complex consists of a dodecahapto 36-membered macrocyclic ligand of formula $[(EtSiO_2)_{12}]^{12-}$ (Figure 2) binding four Cu^{2+} cations spatially arranged in a flattened tetrahedral unit. Four Na^+ cations are also loosely connected to the surface of the macrocycle leading to an overall neutral 44-membered cage. The twelve silicon and the four sodium atoms carry one exo ligand each (twelve ethyl radicals and four *n*-butyl alcohols, respectively) and the resulting "flattened spherical" moiety has a substantial lipophilic surface.

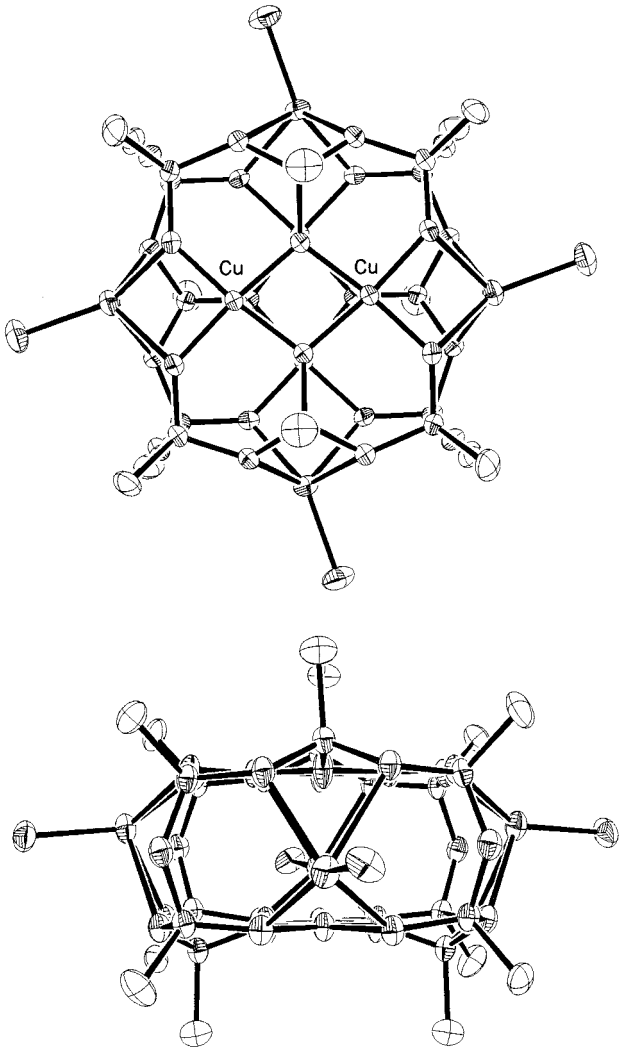

Figure 1. Two ORTEP drawings of $[(EtSiO_2)_{12}Cu_4Na_4]\cdot 4n$BuOH **(2b)**; the four disordered *n*-butyl alcohol ligands and the terminal methyl groups of the ethyl radicals are omitted for clarity; top: view down the S_4 axis; bottom: normal to the first view

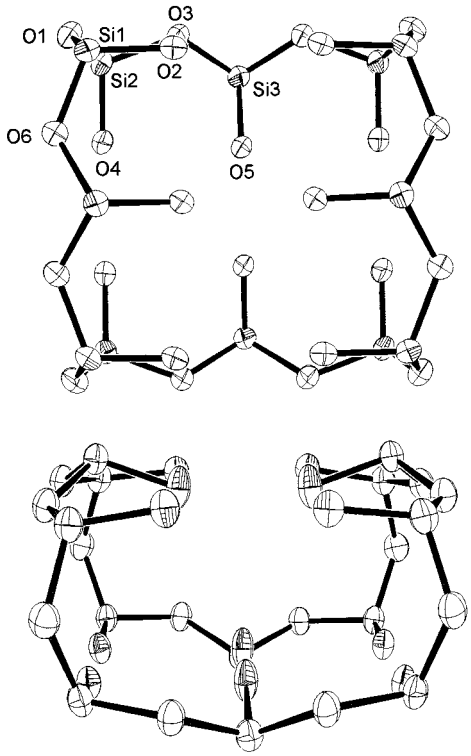

Figure 2. ORTEP drawing of the 36-membered macrocyclic cyclododeca(ethyl-siloxandodecanolate) ligand; top: view down the S_4 axis (the silicon atoms have shaded octants); bottom: almost normal to the first view (the silanolate oxygen atoms have shaded octants)

The Cu···Cu distances (≈ 3 Å) are too large to allow considerable metal−metal interactions. The coordination environment of the Cu^{2+} ions (four silanolate oxygens) is distorted square planar (as far as is allowed by the flexibility of the large ring). The Na^+ ions are coordinated to both silanolate (2) and siloxane (2) oxygens as well as to an "external" solvate butyl alcohol oxygen, thus reaching an approximately tetragonal pyramidal coordination environment.

Selected bond lengths and angles for the macrocyclic ligand are reported in Table 1; their average values ($Si-O_{silanol}$ 1.608 Å; $Si-O_{siloxane}$ 1.643 Å; Si−C 1.861 Å; $O_{siloxane}-Si-O_{siloxane}$ 106.7°; $O_{siloxane}-Si-O_{silanol}$ 109.46°; $O_{siloxane}-Si-C$ 109.2°; $O_{silanol}-Si-C$ 112.5°; Si−O−Si 128.9°) are close to those observed previously.[7,8]

The regiochemistry of the cyclododecasiloxandodecaolate ligand shows a peculiar distribution of the organic and silanol substituents with respect to each other (Figure 2). The stereospecificity of the cyclooligomerisation leading to the macrocyclic ligand is a clear indication that the metal "core" is organised first in the formation of the cyclosiloxanolate clusters, perhaps using also solvent (butyl alcohol) ligands, and this is followed by the building up of the siloxane chain from *suitably oriented* monomeric units. In the initial phase of the organisation we can thus identify the weak, but geometrically different,[11] orienting role ("template" effect) of the alkali cations. The stereochemistry of the Si_{12}-macrocycle in the present study is especially informative, especially when contrasted with the all-*cis* stereo-

chemistry of the Si_6[6,7,9] and Si_8[3c,12] ligands obtained in earlier studies.

Experimental Section

Starting materials were of commercial origin with the exception of the sodium ethylsilanolate, which was prepared in situ as described for the corresponding Ph derivative.[3c] − Conductivity measurements were obtained with a Conductimeter Crison mod 525 (all constant 1.02) instrument. − Cyclic voltammetric (CV) measurements were performed by Potentiostat-Galvanostat PAR 273A instrument under Ar atmosphere. − Infrared spectra were obtained by Bruker FT-IR IFS 113V spectrophotometer, using KBr pellets for the 4000−400 cm^{-1} range, and PE pellets for the 500−50 cm^{-1} range.

Preparation of the "$EtSiO_2Na$" Reagent: In a 100-mL two-necked round-bottom reaction vessel, equipped with a reflux condenser (closed with a $CaCl_2$ desiccator tube) and an Ar inlet poly(ethylsiloxane) "resin"[3c] (2.56 g, 0.03 mol) was suspended in 50 mL of dry *n*BuOH. To this suspension, under a dry, deoxygenated Ar atmosphere was added sodium hydroxide (0.60 g, 0.015 mol) in one portion while the suspension was (magnetically) stirred. Then, the reaction mixture was heated and refluxed (≈ 30 min) until it turned clear, indicating that the "resin" was completely dissolved. After the solution had cooled to room temp. metallic sodium (0.345 g, 0.015 mol), cut into small pieces, was added. After the Na had completely dissolved, the reaction mixture was again heated to reflux for an additional 30 min. This solution was used for the subsequent reaction.

Preparation of $Na_4[(EtSiO_2)_{12}Cu_4]$: The "$EtSiO_2Na$" reagent, prepared as described above, was used for the following preparation in the same reaction vessel, substituting the Ar inlet tube for a dropping funnel. A solution of anhydrous $CuCl_2$ (1.35 g, 0.01 mol), in 15 mL of dry *n*BuOH was poured into the dropping funnel and this (green) solution was then added dropwise to the solution of the "$EtSiO_2Na$" reagent during 30 min. After the first drops, the (blue) reaction mixture became turbid as a consequence of the

formation of a fine white precipitate (NaCl). After the addition was complete the dropping funnel was removed and the reaction mixture was heated to reflux under a dry Ar atmosphere for an additional 5 h. After this period the NaCl precipitate was centrifuged off while the solution was still warm, then the reaction mixture was left to cool to room temp. and the solvent was evaporated at reduced pressure and room temp. The residue was extracted with 20 mL of *n*BuOH. This extract was chilled to −30 °C. Blue crystals were obtained. Recrystallisation from *n*BuOH was repeated 2−3 times. The yield of the crude product was 2.633 g (62.4%), and that of the re-crystallised product 0.672 g (15.7%).

Crude Product: $C_{32}H_{80}Cl_4Cu_4Na_8O_{26}Si_{12}$ {[$(EtSiO_2)_{12}Cu_4Na_4$]·2*n*BuOH·4NaCl}: calcd. C 21.38, H 4.49, Cu 14.13, Na 10.22; found C 21.3, H 4.6, Cu 12.7, Na 15.5.

Recrystallised Product: $C_{40}H_{100}Cu_4Na_4O_{28}Si_{12}$ {[$(EtSiO_2)_{12}Cu_4Na_4$]·4*n*BuOH}: calcd. C 28.06, H 5.89, Cu 14.84, Na 5.37; found C 27.9, H 5.6, Cu 14.3, Na 6.2.

The deviations of the measured elemental composition from the calculated formulae are attributed to minor amounts of co-crystallised NaCl and to instability of the crystal solvates. The re-crystallised product was characterised by conductivity, cyclic voltammetry, infrared spectroscopy and X-ray single crystal diffraction.

Conductivity: Solvent: *n*BuOH, concentration 1×10^{-4} M, λ_{eq} = 10.4 Ω^{-1} cm^2 mol^{-1}.

Cyclic Voltammetry: Solvent: *n*BuOH, supporting electrolyte: 0.05 M nBu_4NClO_4 (TBAP), redox system: HMDE//Ag/AgCl//Pt, scan speed: 100 mV/s, E_{pc} = −1.78V, E_{pa} = −1.68 V, $E^0 = (E_{pc} + E_{pa})/2$ = 1.73 V.

Table 2. Crystal data and structure refinement for [$(EtSiO_2)_{12}Cu_4Na_4$]·4*n*BuOH

Empirical formula	$C_{20}H_5Cu_2Na_2O_{14}Si_6$
Formula weight	856.20
Temperature	173(2) K
Wavelength	0.71069 Å
Crystal system, space group	Tetragonal, $I4_1/a$ (No 88)
Unit cell dimensions	a = 22.814(5) Å
	b = 22.814(5) Å
	c = 14.767(3) Å
Volume	7686(3) Å^3
Z, Calculated density	8, 1.480 Mg/m^3
Absorption coefficient	1.371 mm^{-1}
F(000)	3568
Crystal size	0.1 × 0.1 × 0.1 mm
Theta range for data collection	1.64−27.03°
Limiting indices	$-22 \le h \le 29$
	$-28 \le k \le 27$
	$-17 \le l \le 18$
Reflections collected/unique	20814/3894 [R(int) = 0.0339]
Completeness to φ = 27.03	92.5%
Absorption correction	SADABS
Max. and min. transmission	1.000 and 0.904
Refinement method	Full-matrix least-squares on F^2
Data/restraints/parameters	3894/6/227
Goodness-of-fit on F^2	1.097
Final R indices [$I > 2\sigma(I)$]	$R1$ = 0.0413, $wR2$ = 0.1227
R indices (all data)	$R1$ = 0.0585, $wR2$ = 0.1309
Largest diff. peak and hole	0.623 and −0.380 e·Å^{-3}

Medium-Infrared Spectroscopy: (4000−400 cm^{-1}) (KBr pellet): $\tilde{\nu}$ = 3664 w (νO−H, assoc.); 2960 m, 2939 w, 2912 w, 2876 w, 2848 w (νC−H); 1644 m (νC−O); 1592 m, 1462 m, 1416 m, 1247 m (νC−C); 1126 s (νSi−C); 1033 s, 991 s, 954 m (νSi−O), 771 m (δC−H); 695 m (δC−C + νCu−O); 488 m, 470 w, 462 w (νSi−O skeletal + νCu−O?).

Far-Infrared Spectroscopy: (500−50 cm^{-1}) (polyethylene pellet): $\tilde{\nu}$ = 440 w (δSi−O skeletal); 364 w (νCu−O); 274 vw (δCu−O + Si−O−Si skeletal); 181 vw, 154 vw, 102 w (νNa−O).

X-ray Structure Determination of [*n*BuOH Na]$_4$[cyclo($EtSiO_2)_{12}$-Cu_4]·[2b]: A suitable crystal of **2b** was chosen and mounted, in air, on a glass fiber onto a goniometer head. Data were collected at 170 K on a Siemens SMART CCD area-detector diffractometer equipped with a Siemens LT3 cooling device. Crystal data are reported in Table 2.

Graphite-monochromated Mo-K_α (λ = 0.71073 Å) radiation was used with the generator working at 45 kV and 40 mA. Cell parameters and orientation matrix were obtained from least-squares refinement on reflections measured in three different sets of 15 frames each, in the range $0 < \varphi < 23°$. The data collection was performed by measuring 1400 frames (20 s per frame; ω scan method, Δω = 0.3°; sample-detector distance fixed at 5 cm) which, upon data reduction, afforded almost all reflections belonging to the sphere with $2\varphi < 54°$. The first 100 frames were recollected at the end to monitor crystal decay, which was not observed; an absorption correction was applied (SADABS).[13]

A total of 20814 reflections were collected (3894 unique, R_{int} = 0.0339; R_σ = 0.0283[14]). The structure was solved by direct methods (SIR97[15]) and refined with full-matrix-block least-squares (SHELX97[16]); anisotropic temperature factors were assigned to all non-hydrogen atoms except for the disordered C8A/C8B. Due to the disorder of some of the aliphatic residues hydrogen atoms were omitted from the structural model. A summary of crystal data and refinement details are reported in Table 2.

Crystallographic data (excluding structure factors) for the structure included in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-142093. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Steric Hindrance in Substitution Reactions on Arsenic Acid by Pentaam(m)ine Complexes of Co^{III} and Cr^{III}

Gabriel González,[a] Manuel Martinez,*[a] and Elisa Rodríguez[a]

Keywords: Reaction mechanisms / Kinetics / Arsenates / Acid catalysis

The kinetics of the substitution reaction of water by $H_2AsO_4^-$ in $[M(N)_5(H_2O)]^{3+}$ (M = Co^{III}, Cr^{III}) complexes have been studied at 25 °C for a series of $(N)_5$ groups, from monodentate $(NH_3)_5$ and $(CH_3NH_2)_5$ to macrocyclic 12-methyl-1,4,7,10-tetraazacyclotridecane-12-amine (L_{13}), 6-methyl-1,4,8,11-tetraazacyclotetradecane-6-amine (L_{14}), and 10-methyl-1,4,8,12-tetraazacyclopentadecane-10-amine (L_{15}) in their *cis* (L_{13} and L_{14}, Co^{III} and Cr; L_{15}, Co^{III}) and *trans* (L_{15}, Co^{III} and Cr^{III}) water-amino geometrical arrangements around the metal ion. Equilibration rate constants were found to be too large to be interpreted as occurring through the M–OH_2 bond scission that takes place in standard substitution processes on these t_{2g}^3 and t_{2g}^6 pentaamine complexes, and were also found to be highly dependent on the acidity of the medium. The results are interpreted in view of previously studied, similar reactions, where protonation played a very important role. This role was expected for reactions occurring via As–O bond scission; that is, the data fits well with that expected for oxygen exchange reactions of the labile tetrahedral $\{AsO_4\}$ moiety. The values found are a clear indication of the differences in steric requirements of the metal-bound water attacking the tetrahedral As^V centre [i.e. for M = Co^{III}, $k^+_{\text{non acid catalysed}}$ = 93, 1.9, 0.76, and 0.44 $M^{-1}s^{-1}$ for the $(NH_3)_5$, $(CH_3NH_2)_5$, *cis*-L_{13}, and *trans*-L_{15}, respectively], as well as of electronic influences of the amines of the cobalt complex on the As^V centre when attacked by the bulk water [i.e. for M = Co^{III}, $10^3k^-_{\text{non acid catalysed}}$ = 280, 5.7, 4.4, and 4.5 s^{-1} for the $(NH_3)_5$, $(CH_3NH_2)_5$, *cis*-L_{13}, and *trans*-L_{15} respectively].

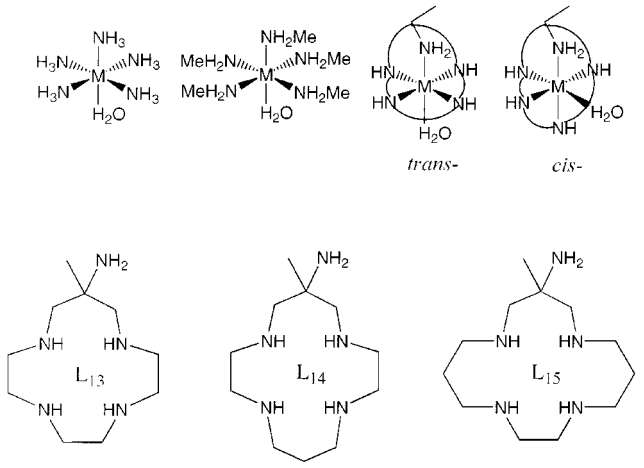
Introduction

The kinetics and mechanisms for the substitution reactions on inert Co^{III} and Cr^{III} am(m)ine complexes have been thoroughly studied both from an anation[1] and a hydrolysis[2] approach; all the mechanistic implications have already been described, and only small differences due to fine tuning are still being carried out in view of the importance of their application to other systems.[3] On the other hand, substitution reactions on labile tetrahedral oxoanions are not as well known. Few oxygen exchange studies have been carried out,[4] and very little is known about the formal metal complex substitution reactions as shown in Equation (1).[5]

$$[M(L)_5(H_2O^*)]^{n+} + EO_x^{m-} \rightleftharpoons [M(L)_5(^*OEO_{(x-1)})]^{(n-m)+} + H_2O \quad (1)$$

We have already been involved in the study of this type of reaction with H_3AsO_4 in highly acidic media.[6] These reactions are traditionally avoided[7] because of the important $[H^+]$ acceleration of the reaction rate as well as the small equilibrium displacement in kinetically measurable conditions. In our previous study, a clear $[H^+]$-catalysed path was found, its quantification was achieved, in part, thanks to the ability of Cr^{III} to form fairly stable outer-sphere complexes.[8] More recently, a study on the oxygen exchange on H_3AsO_4 with bulk water in acidic media has also been carried out;[9] an $[H^+]$-catalysed path involving a pentacoordinated As^V species has been tentatively proposed as being responsible for the important acceleration of the interchange. This is in good agreement with our previous findings. The previously undetected reaction of $[Cr(NH_3)_5(H_2O)]^{3+}$ with the $H_3AsO_4/H_2AsO_4^-$ system,[6] has been revised in view of the new instrumentation available that allows us to measure the evolution, with time, of the full spectrum at 0.8 ms intervals, even at relative high concentrations. The results obtained are discussed in view of the complete information obtained in this study.

In this paper we present the kinetic and mechanistic study of the substitution reactions shown in Equation (2).



$$[M(N)_5(H_2O)]^{3+} + H_2AsO_4^-/H_3AsO_4 \rightleftharpoons [M(N)_5(H_2AsO_4)]^{2+} + H_2O/H_3O^+ \quad (2)$$

M = Co^{III} and Cr^{III}, and $(N)_5$ = $(NH_3)_5$, $(CH_3NH_2)_5$, 12-methyl-1,4,7,10-tetraazacyclotridecane-12-amine (L_{13}), 6-methyl-1,4,8,11-tetraazacyclotetradecane-6-amine (L_{14}), and 10-methyl-1,4,8,12-tetraazacyclopentadecane-10-amine (L_{15}) (Scheme 1) in highly acidic media, where all the arsenic oxoanions are present in the form of H_3AsO_4 and $H_2AsO_4^-$. For all the Co^{III} systems, no build-up of outer-sphere encounter complexes was detected, while for some of the Cr^{III} pentaamine complexes limiting kinetics were observed. As a whole, important differences have been found both for the anation and aquation reactions that could be related to the steric demands on the M^{III} centre and the electronic differences of the $(N)_5$ skeleton, as expected for an associatively activated substitution on the tetrahedral As^V centre.

Scheme 1

Results and Discussion

All the values of k_{obs} as a function of the different M metals, $(N)_5$ groups, acidity, and total arsenic acid concentration, $[As]_T$ are collected in the Tables of the Supporting Information. Figure 1 shows some of the plots of k_{obs} versus $[As]_T$, as a function of the acidity, found in this study. No curvature is observed for any of the Co^{III} systems, indicating that there is no build-up of any outer-sphere complex in solution. As in other chromium(III) systems,[6,8] significant curvature of the above-mentioned plots for the $(N)_5$ monodentate systems is obtained, indicating that the amount of outer-sphere complex present in solution is measurable. Finally, for the macrocyclic Cr^{III} anation reactions, again, no build-up of outer-sphere complex is observed. Furthermore, with the exception of Cr^{III}/L_{15} system, an equilibrium of the substitution reaction is observed at this $[H^+]$, with a fairly unfavourable constant for the formation of the arsenato complexes. No second-order dependence on the value of $[As]_T$ has been found for the systems studied, indicating that the involvement of dimeric arsenic species is not present under the conditions used in this study.[4]

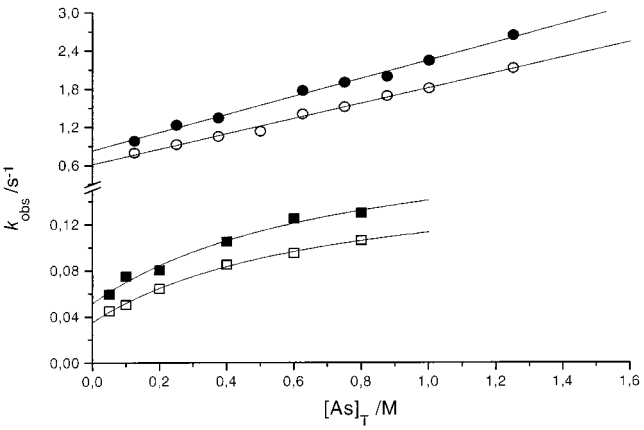

Figure 1. Selected plots of the values of k_{obs} versus $[As]_T$ at different acidities for the anation reaction of some of the complexes (T = 25 °C; $[H^+]$, $HClO_4$; I = 1.0 M, $LiClO_4$); ○: $[Co(NH_3)_5(H_2O)]^{3+}$, $[H^+]$ = 0.125 M; ●: $[Co(NH_3)_5(H_2O)]^{3+}$, $[H^+]$ = 0.175 M; □: $[Cr(MeNH_2)_5(H_2O)]^{3+}$, $[H^+]$ = 0.40 M; ■: $[Cr(MeNH_2)_5(H_2O)]^{3+}$, $[H^+]$ = 0.57 M

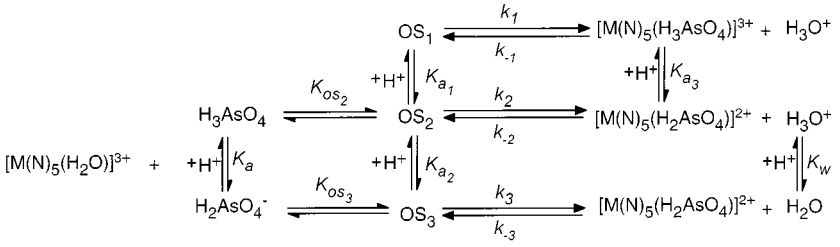
It is important to note that, with the exception of the Cr^{III} macrocyclic systems, even at acidities where all the arsenic and arsenato complexes in the reaction medium are present as H_3AsO_4 and $[M(N)_5(H_2AsO_4]^{2+}$, respectively, an acceleration in the equilibration reaction rate occurs on increasing the values of $[H^+]$. Taking this into account, as well as similar previously published studies,[6] a reaction scheme and a rate law such as those depicted in Scheme 2 and Equation (3) are proposed.



$$K_{obs} = \frac{A[As]_T}{[H^+] + K_a + B[As]_T} + C$$

$$A = k_1\left(\frac{K_{OS2}}{K_{a1}}\right)[H^+]^2\, k_2K_{OS2}[H^+] + k_3K_aK_{OS3} \qquad (3)$$

$$B = K_aK_{OS3} + K_{OS2}[H^+] + \left(\frac{K_{OS2}}{K_{a1}}\right)[H^+]^2$$

$$C = \left(\frac{k_{-1}}{K_{a3}}\right)[H^+]^2 + k_{-2}[H^+] + k_{-3}$$

Figure 2 and Figure 3 show selected plots of A and C versus $[H^+]$ for some of the systems studied. The values found for the different terms in Equation (3) at 25 °C are collected in Table 1 and Table 2. Given the fact that most of the terms turn out to be composite of rate and equilibrium constants, no attempts to measure activation parameters have been carried out. Unlike the study with $[Cr(H_2O)_6]^{3+}$ under the same conditions (Table 1), where only acid-catalysed, **1**, and protic, **2**, paths were detected,[6] in this study, important differences exist depending on the metal centre and the nature of the $(N)_5$ group of ligands. Only in the case of the Co^{III} complexes was the non-protic path **3** detected, both for anation and hydrolysis reactions, while for all the Cr^{III} and Co^{III} systems rather important contributions to the observed equilibration rate constants are that of the acid-catalysed, **1**, and protic, **2**, paths. In all, the complete set of kinetic rate constants and active reaction paths (Scheme 2) is rather complex, and highly dependent on the nature of the metal centre, the mono- or polydentate nature of the $(N)_5$ skeleton, the size of the macrocycle, and the stereoisomery of the macrocyclic ligand. Nevertheless, in all cases, given the reaction rate constants obtained in this study as well as the available substitution data on analogous $[Co(N)_5Y]^{2/3+}$ and $[Cr(N)_5Y]^{2/3+}$ systems, it is clear that the substitution processes are taking place on the As^V centre as already described for other arsenate substitution reactions.[6][7b,9] Being a tetrahedral p-block element, this process is bound to be associatively activated in character with a transition state involving a direct attack of the M-bound oxygen to the As^V centre. Scheme 3 represents such a postulated transition state, where oxygen atoms labelled with ***i*** and ***ii*** indicate possible protonation sites for reaction paths **1** and **2**, respectively. In any of both cases, the As^V centre attains a lower electron density, allowing for the entrance of the oxygen from the water bound to the cobalt complex for the anation process, or for the entrance of a bulk water molecule for the aquation (reverse) reaction. In this respect,

Scheme 2

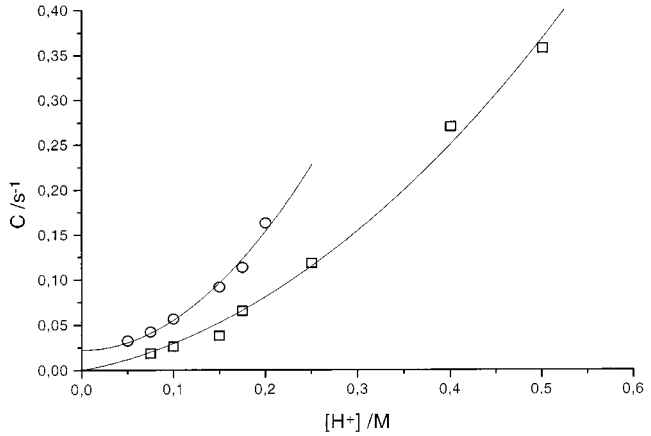

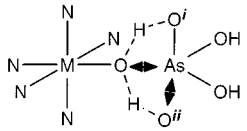

Figure 3. Plot of the values of *C* [Equation (3)] versus $[H^+]$ for the anation reactions of some of the complexes studied (T = 25 °C; $[H^+]$, $HClO_4$; I = 1.0 M $LiClO_4$); ○: *cis*-$[CoL_{15}(H_2O)]^{3+}$; □: $[Cr(NH_3)_5(H_2O)]^{3+}$

apart from obvious steric and electronic reasons affecting the magnitude of the reaction rate, the fact that some of the reaction pathways are selectively detected for some of the systems has to be looked into very carefully. Finally, the magnitude of the intrinsic errors involved due to the complex dependence of the equilibration rate constants on the acidity [Equation (2)], makes even small differences in the values very unreliable; factors of less than ca. two have to be taken with great caution specially when referring to paths **1** and **3**.

Scheme 3

Data in Table 1 indicates a clear-cut difference between chromium monodentate and macrocyclic systems. That is, while the observation of active forward path **2** and reverse path **3** in any of the substitutions studied at this $[H^+]$ is perfectly attributable to the major species existing in solution, namely H_3AsO_4 (90–98% of the total added arsenate at this $[H^+]$)[6] and *cis*-$[CrL_{13}(H_2AsO_4)]^{2+}$ (predominant at this pH, given the increase in acidity of coordinated ligands).[10] The observation of forward and reverse paths **1** and reverse path **2** seems to be a specific characteristic of monodentate pentaam(m)ine aqua complexes for these Cr^{III} derivatives {as for the already studied $[Cr(H_2O)_6]^{3+}$}.[6] In all, for the macrocyclic complexes, the active reaction paths are directly related to those involving the predominant species in solution at this pH range. Comparison of the monodentate pentaam(m)ine aqua systems clearly indicates, for the forward reaction, that the steric bulk of the entering chromium complex plays a very important role; a rate decrease of nearly one order of magnitude is observed on go-

Table 1. Values for the different rate terms in Equation (3) for the anation reactions of complexes $[Cr(N)_5(H_2O)]^{3+}$ as a function of the $(N)_5$ group (T = 25 °C; $[H^+]$ = 0.05–0.2 M $HClO_4$; I = 1.0 M $LiClO_4$); $[Cr(H_2O)_6]^{3+}$ data from ref.[6] are included for comparative purposes

ing from ammine to methylamine. The electronic effect created for the more basic CH_3NH_2 ligands seems to be counterbalanced by the steric demands created on the substitution process; in this respect, the value found for K_{OS2}/K_{a1} agrees quite well with the latter assumption. A comparison of these monodentate $(N)_5$ systems with the hexaaquachromium(III) substitution studied, indicates that steric reasons have to be held responsible for the small differences in reactivity; the weaker Lewis acid character of the aqua ligand would point to the inverse of the observed effect.[11] When we move to the *cis*-L_{13} and *trans*-L_{15} $Cr^{III}/(N)_5$ systems, the most striking feature is the immediate disappearance of the acid catalysed path **1**, both for forward and reverse reactions. The values determined for k_2K_{OS2} for these two macrocyclic systems agree with the slight better steric availability of the chromium(III)-bound oxygen atom for the *trans*-L_{15} macrocyclic complex (see Scheme 1); electronic differences being at a minimum between the two macrocyclic complexes. On the one hand, it seems that the existence of a macrocyclic (including hydrogen bonding) wrapping of the Cr^{III} metal does not allow for protonation of the $[CrL_n(H_2AsO_4)]^{2+}$ final complex (Scheme 2). On the other hand, for OS_1 and OS_2, it is clear that we are not dealing with simple ion-pairing,[12] the existence of such aggregates with octahedral d^3 complexes showing larger stability constants than their d^6 analogues is a generally accepted fact.[8] Steric reasons that produce shorter $Cr–OH_2$ bond lengths for the macrocyclic systems, in spite of their shorter Cr–N bond lengths,[13] can be held responsible of a rather close approach of the arsenic acid species to the chromium-bound water oxygen. The presence of nitrogen-bound hydrogen atoms in the macrocycle are bound to produce hydrogen bonding with the available oxo groups in the H_3AsO_4 within the outer-sphere complex, deactivating protonation reaction K_{a1}. Finally, for the remarkable stability of the *trans*-$[CrL_{15}(H_2AsO_4)]^{2+}$ complex, the special capping geometry of the macrocycle (Scheme 1), with the possibility of hydrogen atoms directed to the oxo groups of the arsenate ligand, probably add up to an important increase in the stability of the complex when compared with *cis* arrangements.

With reference to cobalt data in Table 2, although monodentate and macrocyclic pentaam(m)ine complexes are still differentiable, striking differences are observed with the general trends obtained for the analogous Cr^{III} complexes, shown in Table 1. Paths **1** and **3** are operative for all the $[Co(N)_5H_2O]^{3+}/H_2AsO_4^-$ substitution processes, while path **2** is only detected for forward reactions with the macrocyclic complexes. The reactivity cannot be associated, in this case, to the dominant species in solution at this acidity (see above).

Monodentate systems have the most homogeneous reactivity pattern, as with their Cr^{III} analogues. For the equilibrium reactions, both for the acid-catalysed and the non-protic paths, the steric effect of the increased size of the Co^{III} complex is clear, the difference between $(N)_5 = (NH_3)_5$ and $(MeNH_2)_5$ rate constants being even larger than with the Cr^{III} complexes. The usual differences in M–L bond lengths for cobalt and chromium pentaamine complexes can be held responsible for the enhanced hindrance of the Co^{III} systems.[13] The preference for path **3** versus path **2** for the cobalt complexes has to be considered much more carefully. For the reverse reaction, the attack of a protonated water molecule on an As^V centre would be much less favoured for the electronically richer t_{2g}^6 Co^{III} complexes; in fact, acidity of coordinated water is higher for the $[Cr(NH_5)_5H_2O]^{3+}$ than for the $[Co(NH_5)_5H_2O]^{3+}$ complexes.[10][11a] Consequently, while attack of H_3O^+ on the tetrahedral As^V is only possible once protonation has taken place (path **1**), its attack on the non-protonated arsenato complex (path **2**) is suppressed. For the forward reactivity, the rationalisation is not so straightforward; a plausible explanation involves the (possibly complex) hydrogen bonded nature of the postulated transition state depicted in Scheme 3. Given the less positive character of the hydrogen atoms from the cobalt-bound water, the proton-receiving oxygen atoms bound to the arsenic centre must be very sensitive to the existing degree of protonation. That is, while the presence of two protons attached to oxygen atoms ***i*** and ***ii*** in Scheme 3 accelerates the reaction by enhancement of the good leaving character of one of them, the attachment of only one of such proton is not enough. Furthermore, in the latter situation,

Table 2. Values for the different rate terms in Equation (2) for the anation reactions of complexes $[Co(N)_5(H_2O)]^{3+}$ as a function of the $(N)_5$ group {T = 25 °C; $[H^+]$ = 0.05–0.2 M ($HClO_4$); I = 1.0 M $LiClO_4$}

$(N)_5$	Path **1**		Path **2**		Path **3**	
	$k_1(K_{OS2}/K_{a1})$ /s^{-1}	k_{-1}/K_{a3} /M s^{-1}	k_2K_{OS2} /$M^{-1}s^{-1}$	k_{-2} /s^{-1}	k_3K_{OS3} /$M^{-1}s^{-1}$	k_{-3} /s^{-1}
$(NH_3)_5$	8.0±0.6	(2.1±1.4)×10	---	---	(9.3±3.0)×10	(2.8±0.3)×10^{-1}

cis-L_{14}	---	(1.3±0.1)×10^{-1}	(1.4±0.1)×10^{-1}	---	---	(6.4±2.5)×10^{-3}
cis-L_{15}	---	3.3±0.2	1.1±0.1	---	---	(2.2±0.5)×10^{-2}
trans-L_{15}	---	(4.2±0.5)×10^{-1}	(6.9±0.4)×10^{-2}	---	(4.4±0.2)×10^{-1}	(4.5±1.1)×10^{-3}

the depicted hydrogen bonding between metal-bound water and arsenate is not enough for good attack of the cobalt-bound oxygen atom on the As^V centre, only the loss of the last proton restores the reaction rate by a best hydrogen bonding interaction in the transition state.

With respect to the macrocyclic systems the situation is dramatically different. While reverse paths are the same as those found for the monodentate systems, forward path **1** is never observed, and the forward reactivity of path **3** is now shared with that from path **2**. The reasoning mentioned for the reactivity for the aquation reactions through path **1** and **3** remains valid; nevertheless, the value of the rate constants determined for the *cis*-$[CoL_{15}H_2AsO_4]^{2+}$ complex is surprisingly high. We can speculate about the fact that the increased size of the macrocycle, with shorter Co–N bond lengths than in the Cr^{III} analogues,[14] can produce a ''back-folded'' geometry of the macrocycle when a rather large $\{AsO_4\}$ tetrahedral centre is attached. Furthermore, this has to be more possible for Co^{III}, given the richer electron density of the complex that does not favour hydrogen bonding between amine protons and arsenic-bound oxygen atoms. This is contrarily to what has been said for the chromium derivatives. As for the forward reaction paths, the change in reactivity from path **1** to path **2** has to be related to the preferential nature of the interaction in the outer-sphere complex OS_2 that does not allow for reactive protonation. Thus, protonation of the OS_2 complex is prevented, even when hydrogen bonding should be less important than for the Cr^{III} analogues.[10] The value found for k_2K_{OS2} for the largest *cis*-L_{15} metal complex is definitively larger, again suggesting the possibility of a certain degree of ''back-folded'' effect in the preferential outer-sphere interaction,[12] producing a much more efficient attack on the As^V centre. With respect to the forward path **3**, the rate constant values for the *cis*-L_{13} and *trans*-L_{15} are rather important. At the moment we are not able to understand this fact, nevertheless the two systems for which k_3K_{OS3} have a definite value are those which are bound to be the less sterically demanding by themselves, and their forward rate constants are larger than those for the protic path, **2**.

Conclusions

The study carried out on the formal substitution reactions on pentaam(m)ine Cr^{III} and Co^{III} shows the ''oppressive'' array of terms typical for substitution processes taking place on tetrahedral As^V species, where the importance of protonation is evident. For the monodentate metal complexes studied, an acid catalysed path is always present, which enhances the reaction rate by the formation of a good protonated leaving group. The operation of a path with fully protonated species is only found for the chromium complexes, where fewer electrons present in the systems allows even the entrance of weak Lewis bases, as fully protonated species are, without the assistance of a good leaving group. With reference to the macrocyclic systems studied, although the same reasoning can be used for some of the reactivity, an increased influence of the steric effects are evident. In this case, not only size, but hydrogen bonding and differences in Cr^{III} and Co^{III} bond lengths, seem to be responsible for the trends observed. In all, the reactivity has proven to be extremely complex, with many factors to be accounted for. Substitution processes on p-block elements have been traditionally avoided; therefore, further studies in this field have to be carried out in order to have a good overview of the processes taking place in their reactions.

Experimental Section

Materials: $[Co(NH_3)_5(H_2O)](ClO_4)_3$, $[Cr(NH_3)_5(H_2O)](ClO_4)_3$, $[Co(CH_3NH_2)_5(H_2O)](ClO_4)_3$, $[Cr(CH_3NH_2)_5(H_2O)](ClO_4)_3$, *cis*-$[CoL_{13}(H_2O)](ClO_4)_3$, *cis*-$[CoL_{14}(H_2O)](ClO_4)_3$, *cis*-$[CoL_{15}(H_2O)](ClO_4)_3$, *trans*-$[CoL_{15}(H_2O)](ClO_4)_3$, $[Co(NH_3)_5(H_2AsO_4)](H_2AsO_4)_2$, and $[Cr(NH_3)_5(H_2AsO_4)](ClO_4)_2$ were prepared as described in the literature.[7b,12,15] $LiClO_4$ was prepared from Li_2CO_3 and recrystallized three times before use. Arsenic acid was prepared by nitric acid oxidation of As_2O_3;[16] commercially available Aldrich As_2O_5 was too impure to be used (a solution of commercial Aldrich As_2O_5 was found to produce a brown precipitate that was very difficult to eliminate, making all kinetic runs impossible).

cis-$[CrL_{13}(H_2O)](CF_3SO_3)_3$ and *trans*-$[CrL_{15}(H_2O)](ClO_4)_3$ were prepared in a similar manner to their cobalt analogues from the corresponding $[CrL_nCl](ClO_4)_2$ precursors.[15] In these cases, the base hydrolyses were carried out at pH = 9–10, and once acidified with perchloric or triflic acid, the stoichiometric amount of $AgClO_4$ was added to remove all existing chlorides in the reaction medium. On standing, the complexes are collected as orange-red solids. Occasionally, the isolated complexes were contaminated with $NaClO_4$, their recrystallisation from diluted $HClO_4$ produced analytically pure samples. The aqua complexes were characterised by their elemental analyses and UV/Vis spectra in 0.1 M $HClO_4$. – Analyses (calcd./found): *cis*-$[CrL_{13}(H_2O)](CF_3SO_3)_3 \cdot 3.5\ H_2O$: C 19.6/19.2, N 8.8/9.0; *trans*-$[CrL_{15}(H_2O)](ClO_4)_3 \cdot 2\ H_2O$: C 22.3/22.4, N 10.8/10.5. – UV/Vis (λ/nm, $\varepsilon/M^{-1}cm^{-1}$): *cis*-$[CrL_{13}(H_2O)](CF_3SO_3)_3 \cdot 3.5\ H_2O$: 486 (137), 362 (79) and *trans*-$[CrL_{15}(H_2O)](ClO_4)_3 \cdot 2\ H_2O$: 486 (61), 450 (sh), 356 (81).

cis-$[CoL_{13}(H_2AsO_4)](ClO_4)_2$, *trans*-$[CoL_{15}(H_2AsO_4)](ClO_4)_2 \cdot H_2O$, and *trans*-$[CrL_{15}(H_2AsO_4)](H_2AsO_4)_2$ were prepared as their pentaammine analogues.[17] The aqua complexes were dissolved in 3–4 M H_3AsO_4, the cherry red solution formed immediately was concentrated to a syrupy consistency. Addition of ethanol produced a red solid on standing at –30 °C. The complexes were characterised by their elemental analyses and UV/Vis spectra in solid (to avoid the fast aquation reaction) or in 2 M H_3AsO_4. – Analyses (calcd./found): *cis*-$[CoL_{13}(H_2AsO_4)](ClO_4)_2$: C 19.6/19.0, N 11.4/11.7; *cis*-$[CoL_{15}(H_2AsO_4)](ClO_4)_2 \cdot H_2O$: C 21.8/21.8, N 10.6/10.8; *trans*-$[CrL_{15}(H_2AsO_4)](H_2AsO_4)_2$: C 20.1/19.9, N 9.8/9.5. – UV/Vis in solid (λ/nm): *trans*-$[CoL_{15}(H_2AsO_4)](ClO_4)_2 \cdot H_2O$: 507; *trans*-$[CrL_{15}(H_2AsO_4)](H_2AsO_4)_2$: 509, 368. – UV/Vis in 2 M H_3AsO_4 (λ/nm, $\varepsilon/M^{-1}cm^{-1}$): *cis*-$[CoL_{13}(H_2AsO_4)](ClO_4)_2$: 500 (sh), 454 (145), 346 (132); *cis*-$[CoL_{15}(H_2AsO_4)](ClO_4)_2 \cdot H_2O$: 528 (100), 354 (139); *trans*-$[CrL_{15}(H_2AsO_4)](H_2AsO_4)_2$: 514 (73), 372 (100).

All UV/Vis spectra were recorded with an HP8452A instrument. The spectra of the final $[M(N)_5(H_2AsO_4)]^{2+}$ complexes were determined, as done[17] for the similar $[Cr(NH_3)_5(H_2AsO_4)]^{2+}$ by solution of the corresponding aqua complexes in 2 M H_3AsO_4 (the

known spectra of the characterised arsenato derivatives were used as a reference of the validity of the method).

Kinetics: The general kinetic technique has already been described.[6] All kinetic measurements were performed under pseudo-first-order conditions, with the total concentration of arsenic acid in excess over the cobalt complex. Typical M^{III} complex concentrations were within the $1–5\cdot10^{-3}$ M range. Solutions for the kinetic runs were made up from the corresponding stock solutions of $HClO_4$, metal complex, H_3AsO_4, and $LiClO_4$. Runs were carried out in a Durrum D-110 stopped-flow instrument at the desired wavelength, determined from the differences between initial and final products. Alternatively, the instrument was connected to a J&M Tidas instrument and the complete spectra were recorded and analysed; this technique allowed us to revise the anation reaction of the $[Cr(NH_3)_5(H_2O)]^{3+}$ complex, obtaining reasonable results. All the k_{obs} values were derived from the obtained absorbance versus time exponential traces using a nonlinear least-squares fitting method. All post run data fitting were done by unweighted least-squares fit to the desired equations.

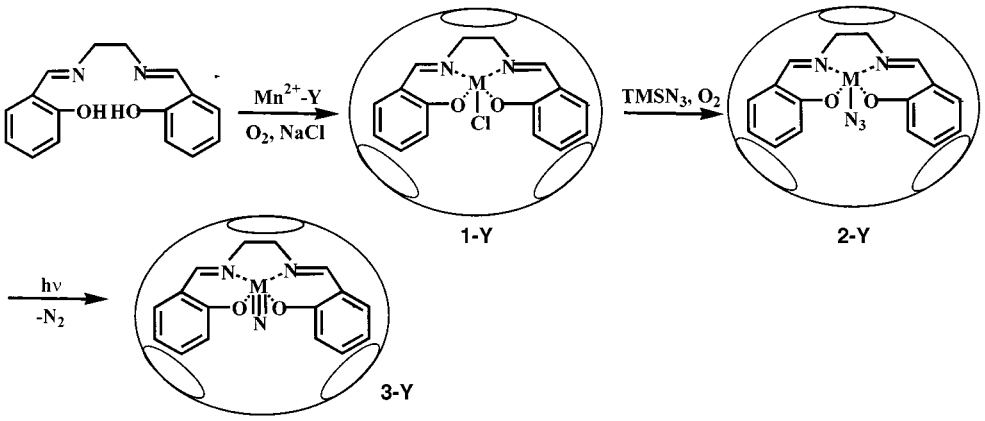
Combined Electrochemical and EPR Studies of Manganese Schiff Base Complexes Encapsulated within the Cavities of Zeolite Y

Antonio Doménech,[a] Pilar Formentin,[b] Hermenegildo García,*[b] and María J. Sabater*[b]

Keywords: Manganese / Electrochemistry / Zeolites

Encapsulation of manganese(III) and manganese(V) Schiff base complexes within the cavities of zeolite Y has been accomplished by means of established synthetic procedures. The samples have been characterized by a combination of various analytical and spectroscopic techniques that probe either the bulk encapsulated complexes or the species present in the outermost layers of the zeolite grains. Importantly, whereas EPR measurements indicated that aerial oxidation had transformed only about 15–20% of the initially present Mn^{II} cations to Mn^{III}, electrochemical techniques revealed a predominance of Mn^{III} at the external surface. This striking result is due to the fact that electrochemical techniques specifically probe the fraction of electroactive species present in the outermost layers of the zeolite particles. In view of the fact that these complexes are the most accessible and active in heterogeneous catalytic reactions in the liquid phase, the voltammetric measurements provide important information concerning the specific evolution of the reversible Mn^{III}/Mn^{II} redox couple near the surface of the zeolite particles. Furthermore, the unequivocal electrochemical detection of intra-zeolite Mn^{V} species (not observable by EPR spectroscopy) highlights the importance of combining surface characterization tools (electrochemistry) with conventional spectroscopic techniques (IR, UV/Vis, and EPR) of the bulk particle in order to assess the differing nature and distribution of the entrapped transition metal complexes.



Introduction

Immobilization of transition metal complexes within the supercages of X- and Y-type zeolites has been a topic of intense research in recent years, the aim being to produce materials that combine the activity of a molecular catalyst with the sieving capability and ease of separation from the reaction mixture of a microporous solid support.[1–3] One of the most extensively studied systems has been zeolite Y encapsulated (salen)manganese(III) complexes, which have served as efficient epoxidation catalysts in both the homogeneous and heterogeneous phases.[4–7] The incorporation of such catalysts within microporous solids by so-called "ship-in-a-bottle" syntheses basically requires the manipulation of Mn^{II} salts, complex formation, and ulterior oxidation to Mn^{III} by molecular oxygen. In order to gain a detailed knowledge of these hybrid materials and to characterize the intra-zeolite complexes, a set of complementary techniques is required. Routine IR spectroscopy can give information on the intra-zeolite assembly process by probing mainly the organic ligand moiety. However, it cannot reliably distinguish between different metal oxidation states and does not give information about any residual populations of uncomplexed manganese ions that may be present. This is not the case with EPR spectroscopy and electrochemistry, since these techniques can be suitably applied to provide information on the oxidation state and redox chemistry of specific metal ions. This gives them a distinct advantage over other analytical tools. In the case under consideration here, Mn^{II} is EPR-active whereas Mn^{III} is EPR-inactive. Thus, for a given total amount of manganese, the oxidation of Mn^{II} to Mn^{III}, either complexed or uncomplexed, can be conveniently followed by monitoring the decrease in the area of the Mn^{II} EPR signal. This provides information relating to the bulk material.

On the other hand, electrochemical techniques specifically probe the fraction of electroactive species residing in the outermost layers of the zeolite grains. This is due to the fact that, on the time scale of the electrochemical measurement, the diffusion of the accompanying electrolyte that is necessary to maintain the electroneutrality of the solid only occurs to a shallow depth in the zeolite particles.[8–10] Nevertheless, the electrochemical response provides information not only on the oxidation state of the manganese ions, but also on the coordination of the metal center, since the redox potential of the complex has a distinctive value. In practice, the specific information concerning the complexes located in the external layers is very useful since, being most accessible to reagents, these complexes are the most active in heterogeneous catalysis. On the other hand, the population of complexes located at or near the external surface is also more likely to differ from that of the bulk encapsulated complexes in terms of the distribution of metal ion oxidation states. Thus, while spectroscopy gives information on the global population of complexes (i.e. those predominantly located in the internal pores), it might well be that a given catalytic activity is due almost exclusively to the distinct fraction at the outermost sites. Thus,

Scheme 1. Preparation of salen-derived manganese(III) and manganese(V) Schiff base complexes in the supercages of zeolite Y

with the aim of obtaining a quantitative estimation of the amount and distribution of Mn^{II}, Mn^{III}, and Mn^{V} species through the zeolite, we have prepared various salen-derived Mn^{III} and Mn^{V} complexes in the cavities of zeolite Y. Whereas EPR measurements and electrochemical techniques were indicative of significant differences in the Mn^{II}/Mn^{III} ratio between the bulk and the external layers, Mn^{V} species were detected only by cyclic voltammetry. This study highlights the importance of combining spectroscopic techniques with surface-specific analytical tools in differentiating between different populations of entrapped complexes.

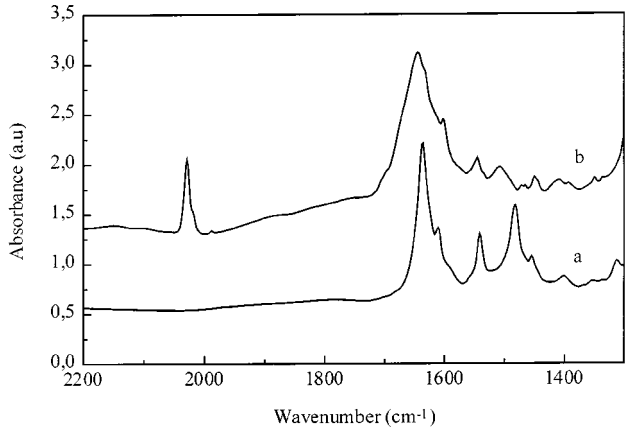

Figure 1. IR spectra of heterogeneous complexes (a) **1-Y** and (b) **2-Y**; the spectra were recorded at room temperature after heating at 100 °C and degassing at 10^{-5} mbar for 1 h

Results and Discussion

Encapsulation of the (salen)Mn complex [salen = 1,2-bis(salicylidenimino)ethylene] within the cavities of zeolite Y, to give **1-Y**, was achieved by treatment of Mn^{2+}-pre-exchanged zeolite Y (0.48% Mn^{2+}; 1 Mn^{2+} every 5 supercages) with the pre-synthesized ligand 1,2-bis(salicylideniminoethylene), followed by treatment with molecular oxygen. As we reported previously, ulterior treatment of **1-Y** with trimethylsilyl azide ($TMSN_3$) allowed access to **2-Y** (Scheme 1).[11] After removal of the excess salen ligand by Soxhlet extraction with dichloromethane, the resulting complexes **1-Y** and **2-Y** were characterized by direct comparison of their DR and IR spectra with those of the corresponding unsupported complexes (**1** and **2**), which were synthesized independently according to previously described methods.[13] The most salient spectroscopic features supporting the formation of **1-Y** were a characteristic imine stretching vibration at 1615 cm^{-1} and a band typical of metallosalen complexes at 1535 cm^{-1}. In the case of **2-Y**, an additional sharp IR absorbance due to the azide ligand at 2037 cm^{-1} confirmed the formation of this heterogenized complex (Figure 1).[11] The corresponding encapsulated nitride complex **3-Y** was obtained by photochemical denitrogenation of the (azido)metal complex **2-Y** as we have reported previously.[11] The transformation of **2-Y** into **3-Y** could be conveniently monitored by IR and Raman spectroscopies, by following the disappearance of the intense azide stretching vibration in the IR spectrum and the concomitant increase in the Raman absorption band characteristic of an Mn≡N triple bond.

The electrochemistry of the related pure complex (salen)$Mn^{III}Cl$ **1** in solution (CH_3CN, DMSO) has been thoroughly studied and essentially involves a reversible one-electron process at a formal potential close to −0.20 V vs. SCE.[8] On the other hand, the cyclic voltammogram for the parent (azido)manganese(III) complex **2**, immobilized on a polymer-film electrode and immersed in neutral aqueous or CH_3CN solution, shows a one-electron reversible couple (C_1/A_1) close to −0.25 V vs. SCE (Figure 2). In both cases, the absence of additional peaks in the +0.8 to −1.0 V potential range indicates that there is no significant dissociation of the complex.

As expected on the basis of previous literature reports, the electrochemical responses obtained for the respective zeolite-modified electrodes **1-Y** and **2-Y** have common features with the patterns and potential values observed for the species in solution and in polymer-film-modified

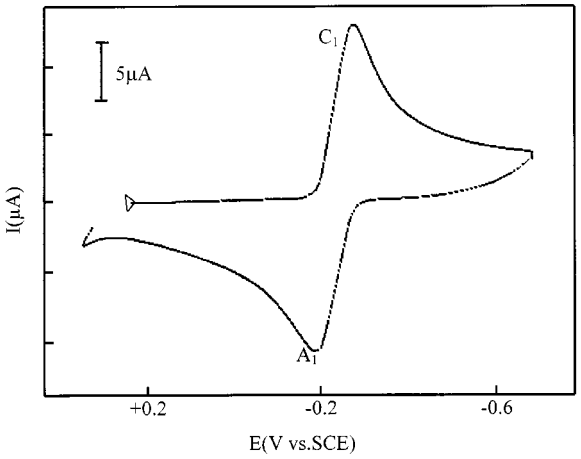

Figure 2. Cyclic voltammogram of a polymer-film-modified electrode of the (salen)MnN_3 complex immersed in H_2O (0.15 M $NaClO_4$); v = 20 mV/s

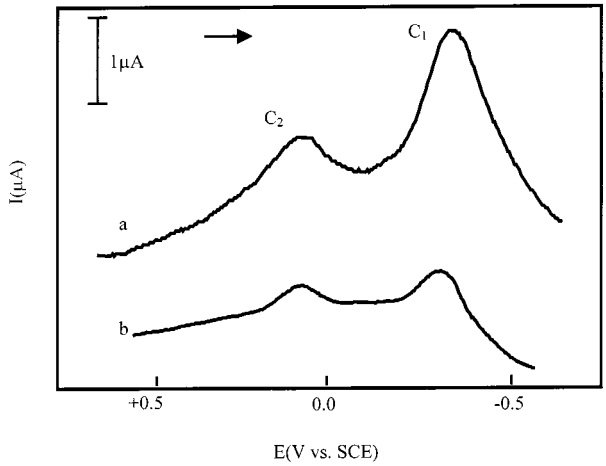

Figure 4. Differential pulse voltammograms of a zeolite-modified electrode containing **2-Y** immersed in H_2O (0.15 M $NaClO_4$); (a) first and (b) second scan; v = 10 mV/s, ΔU = 80 mV

electrodes.[14−16] In fact, both heterogeneous complexes **1-Y** and **2-Y** showed the C_1/A_1 redox couple around −0.25 V vs. SCE together with an additional cathodic peak (C_2) in the +0.3 to −0.2 potential range (Figures 3 and 4). Although comparison of the peak profiles of C_1/A_1 and C_2 suggests that they are similar, no conclusions can be drawn concerning the relative number of electrons transferred in the two processes since the populations of the relevant species are likely to be very different. The (azido)manganese(III) complex **2-Y** showed an additional two-electron oxidation process (A_3) at +0.30 V vs. SCE (Figure 3).

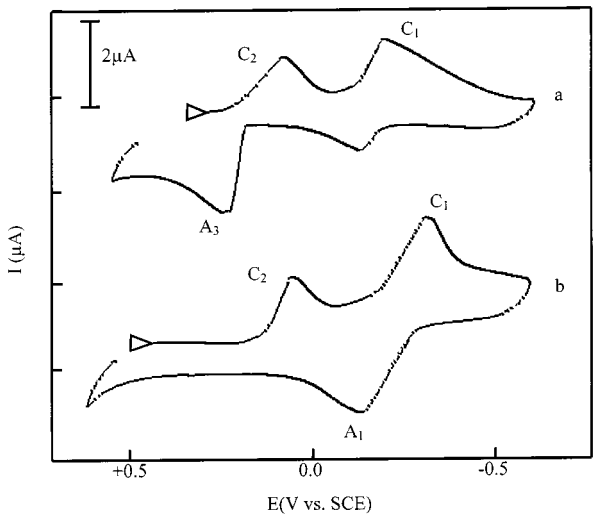

Figure 3. Cyclic voltammograms of zeolite-modified electrodes containing (a) **2-Y** and (b) **1-Y** in aqueous media (0.15 M $NaClO_4$); v = 20 mV/s

Assignment of these redox processes can be partly achieved on the basis of the electrochemical responses observed for the respective non-supported complexes. Thus, the C_1/A_1 couple clearly corresponds to redox transformations affecting those Mn(salen)X (X = Cl^-, N_3^-) complexes located in the boundary sites of the zeolite surface as indicated in eq. 1, where s represents species in the solution phase, b represents adsorbed boundary species, and M^+ is the charge-balancing cation of the salt acting as the supporting electrolyte.[14−16]

$$(salen)Mn^{III}X\,(b) + M^+(s) + e^- \rightarrow (salen)Mn^{II}X\,(b) + M^+(b) \qquad (1)$$

On the other hand, the C_2 process is also observed as a single peak in the electrochemical response of the original Mn-Y sample prior to addition of the ligand. Thus, this peak cannot correspond to any manganese Schiff base complex, but rather to other manganese species present in the outermost layers. These adventitious Mn species are most probably small oxide clusters deposited at the zeolite surface, which would not participate in the complexation.

Finally, the third redox peak A_3 can most probably be attributed to free azide ligands N_3^-. Strong support for this assignment is provided by the observations that: (i) the A_3 peak is not observed on scanning the electrochemical response of the parent complex **1-Y**, and (ii) an aqueous solution of NaN_3 shows an oxidation peak at the same potential. While azide N_3^- displacement from complex **2** by other ligands or solvent cannot be ruled out, the appearance of this specific N_3^- peak can more probably be attributed to residual traces of azido compounds employed in the synthesis of **2**.

Quantification of the Mn^{II}/Mn^{III} ratio present in electrochemically probed sites of the zeolite particle was accomplished by comparing the experimental data with theoretical voltammetric curves. These theoretical simulations were obtained by dividing the intensities of the first and second scans of the anodic peak (I'_{ap}/I''_{ap}) and assuming single reversible redox processes and equal diffusion coefficients for the species involved in the oxidation and reduction processes.[17] Although these measurements are subject to relatively large errors (25%), our estimates of the initial amount of Mn^{III} present in the non-exchanged samples was 45% for **1-Y** and 55% for **2-Y**. Furthermore, when samples of **1-Y** and **2-Y** were submitted to supplementary ion-exchange with NaCl, which supposedly replaces uncomplexed Mn^{2+} by Na^+, the proportion of Mn^{III} increased to 85% and 90% in the samples of **1-Y** and **2-Y**, respectively (the amounts of

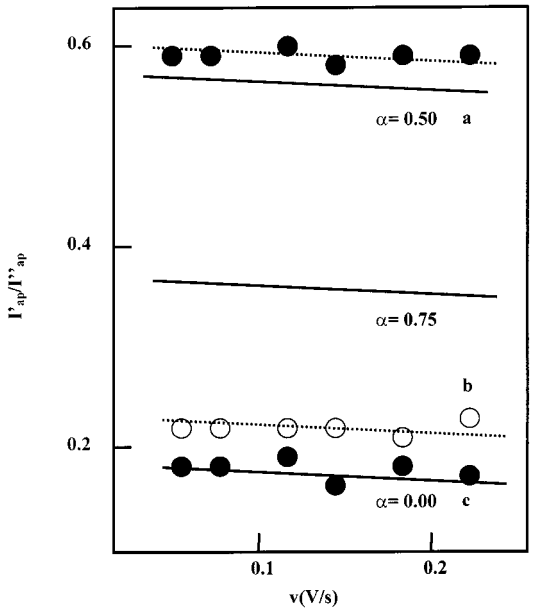

Figure 5. Comparison between theoretical and experimental plots of anodic peak intensity ratios of the first and second scans (I'_{ap}/I''_{ap}) vs. potential scan rate in CVs of different modified electrodes: (a) **2-Y** before treatment with 1 M NaCl; (b) **2-Y** after ion exchange with 1 M NaCl, and (c) pure complex **2**; the dotted lines correspond to experimental data for the supported complexes; α denotes the Mn^{II}/Mn^{III} molar fraction

Mn^{III} calculated to be present in the pure complex **2** and the supported complex **2-Y** before and after ion-exchange are represented in Figure 5).

In striking contrast, EPR measurements comparing the relative intensities of the signals before and after oxidative treatment indicated that a high proportion of the initial Mn^{II} cations of the bulk particle remained unaltered. We estimate that only about 15−20% (error 10%) of the initially present Mn^{II} cations were oxidized to Mn^{III} in both the encapsulated complexes **1-Y** and **2-Y**, reflecting the difficulty in achieving complete oxidation within the zeolite cavities.[18−20] Although absolute quantitative EPR measurements are subject to relatively large experimental errors compared to more accurate chemical analysis, we found the aforementioned ratio of oxidation states to be readily reproducible between samples examined under exactly the same conditions by EPR. Hence, this apparent contradictory result [predominant Mn^{II} by EPR but no detectable (salen)Mn^{II} complexes by cyclic voltammetry] can only be reconciled by considering that only a fraction of the total loading is really probed by cyclic voltammetry (the maximum total charge uptake was found to be 10^{-4} coulomb/mg zeolite, i.e. 10^{-9} mol e^-/mg zeolite, which roughly corresponds to 1.1% of the total complex calculated by chemical analysis). In fact, although the actual mechanisms of intrazeolite electrochemical processes remain controversial, a consensus has been reached that the electrochemical response is exclusively due to those species located in the outermost supercavities.[14−16] To obtain experimental support for the prevalence of Mn^{III} over Mn^{II} at the most exposed layers of the zeolite grains, we also measured the XPS of **1-Y**. As expected, and in accordance with the electrochemical measurements, the electronic transition at 641.7 eV, characteristic of the 2p orbital of Mn^{III} ($Mn2p_{(3/2)}$) predominated, whereas that corresponding to Mn^{II} (the characteristic satellite peak of its 2p orbital appears around 647 eV) was virtually absent.

Finally, the differential pulse voltammetric curve (DPV_s curve) of the irradiated zeolite **3-Y** featured an additional cathodic peak C_4 at +0.65 V, which, on the basis of its redox potential, could be assigned to reduction of the nitridomanganese(V) species generated photochemically from the corresponding Mn^{III} azide precursor complex (Figure 6). Since the current associated with this peak was comparable to that associated with the prior redox processes in the **2-Y** precursor, it seems reasonable to conclude that upon irradiation a significant amount of the (salen)$Mn^{III}N_3$ was transformed into the high-valent Mn^V complex, at least in the outermost layers of the particles. This interpretation is also in agreement with previous IR and Raman studies, which showed a disappearance of the N_3 stretching vibration at 2039 cm^{-1} and a concurrent appearance of the nitrido N≡M band upon irradiation.[11] We recorded an EPR spectrum of the sample under consideration here. However, in the present case, EPR spectroscopy was unable to detect the formation of any Mn^V species since the intense signal due to the residual Mn^{II} ions in the bulk zeolite completely masked any weaker signals due to the high-valent manganese complex that may have been present.

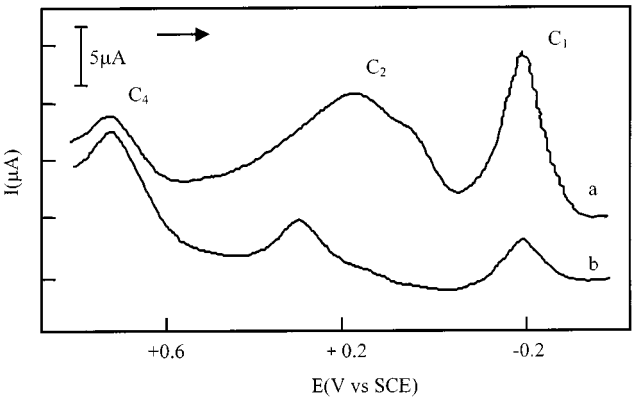

Figure 6. Differential pulse voltammograms (DPVs) for a zeolite-modified electrode containing the **3-Y** complex immersed in H_2O (0.15 M $NaClO_4$); (a) first and (b) second scan; v = 10 mV/s, ΔU = 80 mV

Conclusion

According to the data derived from the electrochemical measurements, the manganese Schiff base complexes **1-Y**, **2-Y**, and **3-Y** residing in the outermost layers of the zeolite Y particles have the oxidation state that would be expected on the basis of literature reports concerning the preparation of unsupported complexes **1**−**3**. Moreover, cyclic voltammetry and differential pulse voltammetry have confirmed the presence of coexisting Mn^{III} and Mn^V species in the supported (nitrido)manganese(V) samples **3-Y**. However, the electrochemical data relates only to a minor fraction of the bulk

(salen)Mn complexes, the total current uptake being much smaller than the amount of encapsulated complex.

In contrast, parallel EPR measurements indicated that in the bulk zeolite particles only about 20% of the Mn^{II} initially present in complexes **1-Y** and **2-Y** had been oxidized to Mn^{III}. This apparent discrepancy between electrochemical and EPR measurements indicates that the oxidation of Mn^{II} to Mn^{III} is only complete in the outermost layers, thus establishing a non-uniform distribution of manganese oxidation states through the zeolite grain.

Our work highlights the fact that, in the case of transition metal complexes encapsulated within zeolites, the catalytic behaviour could be due to a minor fraction of the total population residing in the outermost layers and having an oxidation state distinct from that of the bulk of the complex located deeper inside the zeolite particles.

Experimental Section

Preparation of Complexes 1-Y, 2-Y, and 3-Y: A mixture of 1 g of calcined and dehydrated Mn^{2+}-pre-exchanged zeolite Y (0.48% Mn^{2+}; measured by atomic absorption spectroscopy) and 0.150 g (0.56 mmol) of the previously synthesized ligand 1,2-bis(salicylideniminoethylene) was refluxed in 10 mL of dichloromethane for 12 h under nitrogen. The resulting yellow slurry was then refluxed for a further 12 h while air was bubbled through it. After filtration, the inorganic solid was subjected to Soxhlet extraction with dichloromethane for 8 h to remove excess complex and reactants. The solid was then treated with 10 mL of 1 M aq. NaCl solution for 4 h to afford the supported complex **1-Y**.

The preparation of **2-Y** was carried out by stirring 1 g of the supported complex **1-Y** with 0.02 g (0.173 mmol) of trimethylsilyl azide in 10 mL of dichloromethane for 12 h at room temperature under air bubbling. The heterogeneous complex **2-Y** thus obtained was collected by filtration and subjected to Soxhlet extraction with dichloromethane for 8 h to remove excess complex and reactants.

Sample **3-Y** was prepared through photochemical decomposition of the heterogeneous azide complex **2-Y**. The conversion could be followed by monitoring the disappearance of the characteristic IR azide stretching band and the concomitant increase of a Raman absorption at 1050 cm^{-1} assigned in the literature to the manganese(V) nitride triple bond that is progressively formed during the course of the irradiation.[11] The photolysis was carried out at room temperature in the solid state using self-supporting compressed pellets. These were irradiated through Pyrex (λ 300 nm) with light from a medium-pressure 125-W mercury lamp equipped with an outer jacket refrigerating system.

IR Spectra: FT-IR spectra of the complexes in the zeolites were recorded at room temperature using a greaseless CaF_2 cell in a Nicolet 710 FT spectrophotometer. Self-supporting wafers (ca. 10 mg) were prepared by compressing the zeolite powder at 1 $toncm^{-2}$. The samples were degassed at 100 °C and 10^{-2} Pa for 1 h prior to recording of the spectra.

EPR Spectra: Room-temperature EPR spectra were recorded with a Bruker ER200D spectrometer, working at the X-band (9.65 GHz) and using DPPH (g = 2.0036) as a reference standard. The total number of Mn^{II} ions was calculated by double integration of the signal and comparison of its area with that of the signal of the original Mn^{2+}-Y zeolite.

Electrochemical Measurements: Electrochemical measurements were performed in a conventional three-electrode cell at room temperature under argon. Cyclic voltammograms were obtained using a Newtronics 200P wave generator and an HQ 1000 potentiostat. Differential pulse voltammograms were recorded with a Metrohm E506 Polarecord.

Polymer-film electrodes were prepared as reported previously.[12a] A few μL of a dispersion of the zeolite (10 mg) in acetone (5 mL) was deposited onto the surface of a freshly polished glassy carbon electrode and the coating was allowed to dry in air at room temperature. Then, one drop of a solution of Palaroid B72 (Rohm Haas) in acetone was added and the modified electrode was dried in air. Palaroid provides a uniform thin film that exhibits good adherence and mechanical resistance.[12b]

Voltammograms of the pure complexes were recorded from 1−2 mM solutions in CH_3CN or DMSO using a freshly polished glassy carbon electrode (GCE). A platinum gauze pseudo-reference electrode was used for experiments in organic solvents, whereas a saturated calomel electrode (SCE) was used as a reference in aqueous solutions. All potentials mentioned in the text are referred to aqueous SCE. A platinum wire was used as an inert auxiliary electrode.

For experiments in organic solvents, Et_4NClO_4 (0.1 M) and Bu_4NPF_6 (0.1 M) were used as supporting electrolytes. For experiments in aqueous media, 0.15 M $NaClO_4$ was used.

XPS Measurements: XPS measurements were made at room temperature using a concentric hemispherical analyzer operated in the constant pass energy mode (50 eV). An Mg-K_α X-ray source (hν = 1253.6 eV) was used. A vacuum of ca. 5×10^{-9} Torr in the analysis chamber was maintained throughout the XPS recording. Charging effects were calibrated by analysis of the C (1s) line at 284.6 eV.

[17] The theoretical response as a function of the relative Mn^{III}/Mn^{II} population was generated using the SIMULA (10) program. Comparison with theoretical curves is feasible since it has been observed that these plots depend on the scan rate, the Mn^{III}/Mn^{II} ratio, as well as the initial and switching potentials.
[18] Mn^{III} is EPR inactive, hence it has been quantified by assuming that the increase in this species corresponds to the decrease in Mn^{II}, as estimated from the area of the EPR signal before and after oxidative treatment.

The Redox Behaviour of the Family $(C_{60})[Mo(CO)_2(phen)(dbm)]_n$ ($n = 1-3$) – A Comparison with the Analog $(\eta^2\text{-}C_{70})[Mo(CO)_2(phen)(dbm)]$ (phen = 1,10-Phenanthroline; dbm = Dibutyl Maleate)

Keywords: Fullerenes / Electrochemistry / EPR spectroscopy / Molybdenum / Carbonyl complexes

The electrochemical behaviour of the series $(C_{60})[Mo(CO)_2(phen)(dbm)]_n$ (n = 1–3) has been studied in dichloromethane solution. Each member of the family displays three reversible, fullerene-centred, one-electron reductions at potential values which linearly shift towards more negative potential values by 0.15 V for each appended molybdenum fragment. Such reduction processes are in turn followed by a metal-centred reduction, which causes decomplexation of the C_{60} ligand. EPR spectra recorded on the electrogenerated monoanions $[(C_{60})\{Mo(CO)_2(phen)(dbm)\}_n]^-$ (n = 1, 2) exhibit features indicative of some interaction between the electron entering the fullerene ligand and the metallic centre(s). Comparison with the redox behaviour of the C_{70}-analog $(C_{70})[Mo(CO)_2(phen)(dbm)]$ reveals significant differences; namely that the C_{70}-analog exhibits two reversible one-electron reductions followed by a single two-electron reduction, all of these reductions being centred on the fullerene ligand. A further cathodic step centred on the metallic fragment is present, which, also in this case, causes framework destruction releasing the C_{70} ligand.

Introduction

Metallofullerenes should display a rich redox propensity because the well-known ability of fullerenes to undergo reversibly multiple one-electron transfers[1] is coupled to that of the appended metal fragments. However, only few of them have been studied from the electrochemical viewpoint[2–7] and essentially no data are available for C_{70} complexes.[2] A number of fullerenes containing exohedral multimetallic frames have been structurally characterised. They include binuclear C_{60}-Ir_2,[8,9] -Ru_2,[10] -Si_2,[11] -Fe_2,[2] -Re_2,[3] C_{70}-Ir_2,[12] trinuclear C_{60}-Ru_3,[13] -Os_3,[4] C_{70}-Ru_3,[14] tetranuclear C_{60}-Ir_4,[15] C_{70}-Pt_4,[16] pentanuclear C_{60}-Ru_5,[17] and hexanuclear C_{60}-Pt_6,[18] C_{60}-Ru_6,[17] C_{60}-Ru_5Pt,[17] and C_{70}-Ru_6[14] assemblies. Some of these multimetallic complexes are constituted with a number of identical metal fragments appended to one fullerene ligand, such as $C_{60}[Pt(PR_3)_2]_n$ ($1 \le n \le 4$)[6] and $C_{60}[S_2Fe_2(CO)_6]_n$ ($1 \le n \le 3$).[2] These derivatives have also been studied from the electrochemical viewpoint. Based on these results, we decided to perform a spectroelectrochemical study on the series $(\eta^2\text{-}C_{60})[Mo(CO)_2(phen)(dbm)]_n$ ($1 \le n \le 3$; phen = 1,10-phenanthroline; dbm = dibutyl maleate), Scheme 1.

In addition, we compared the electrochemical behaviour of $(\eta^2\text{-}C_{60})[Mo(CO)_2(phen)(dbm)]$ with that of its C_{70} analog $(\eta^2\text{-}C_{70})[Mo(CO)_2(phen)(dbm)]$. We have already reported on the mononuclear complexes $(\eta^2\text{-}C_{60})[M(CO)_2(phen)(dbm)]$ (M = Mo, W).[7]

Scheme 1

Results and Discussion

Electrochemistry and Coupled EPR Spectroscopy of $(C_{60})[Mo(CO)_2(phen)(dbm)]_n$

Figure 1 compares the cyclic voltammetric response of the three complexes $(C_{60})[Mo(CO)_2(phen)(dbm)]_n$ (n = 1–3) with that of C_{60}.

A preliminary glance shows that, as with other multimetallic fullerenes,[3,5,6] the di- and (particularly) the tri-molybdenum derivatives contain some amounts of the corresponding mono- and di-metallic precursors. These unwanted precursors do not appear to arise from the electron transfer processes, and further studies will be needed to clarify whether they originate from difficult separation or from dissociation equilibria setting up in solution. An analysis of the responses obtained by varying the scan rate, shows that in the case of $(C_{60})[Mo(CO)_2(phen)(dbm)]$, the first three

reversible one-electron reductions are shifted towards more negative potentials values (by about 0.15 V) with respect to those of free C_{60}, Figure 1b. A fourth reduction, not shown in Figure 1b, is also present at more negative potential values ($E_p \approx -1.9$ V). This reduction involves an ECE mechanism, in which the reduction of the Mo-fragment triggers decomplexation of $[C_{60}]^{3-}$ followed by the concomitant reduction of this trianion to the corresponding tetraanion.[7b] As Figure 1c illustrates, the insertion of the second $Mo(CO)_2(phen)(dbm)$ fragment does not substantially modify the overall reduction sequence, but results in a further cathodic shift of all the redox changes. Based on the relative peak heights of the reduction steps of the monoadduct by-product (monostarred peak-systems in Figure 1c), it seems that the second reduction of the bis-adduct triggers partial decomplexation of one Mo-fragment. Unfortunately, the interpretation of the cyclic voltammetric response of the tris-adduct illustrated in Figure 1d is less straightforward, because of the presence of excessively large amounts of mono- and bis-adducts, the reduction processes of which are labelled by single and double asterisks, respectively. By way of speculation, the reoxidation peak at about −1.0 V seems to be directly associated with the first one-electron reduction of the tris-adduct, the cathodic peak of which is partially overlapped by the second reduction of the monoadduct. Some support to such an assignment could come from the comparison between the differential pulse voltammograms of the bis- and tris- adducts shown in Figure 2, in which the first reduction of the tris-adduct seems to lie at $E_p = -1.04$ V, in between the two reductions of the bis-adduct by-product.

This being allowed, we could tentatively assign the second reversible reduction of the tris-adduct to the peak-system located at about −1.4 V. Because of the complex pattern, any attempt to assign the subsequent steps is ruled out. All the pertinent redox potentials are summarised in Table 1.

Table 1. Formal electrode potentials (V, vs. SCE) for the one-electron reductions exhibited by the metallafullerenes $(C_{60})[MoL]_n$ and $(C_{70})[MoL]$ [L = $(CO)_2(phen)(dbm)$] in dichloromethane, $T = -10$ °C

Complex	$E^{\circ\prime}_{1st}$	$E^{\circ\prime}_{2nd}$	$E^{\circ\prime}_{3rd}$	$E^{\circ\prime}_{4th}$
C_{60}	−0.63	−1.00	−1.45	−1.88

C_{70}	−0.61	−0.98	−1.41	−1.75
$(C_{70})[MoL]$	−0.71	−1.09	−1.51[b]	−1.82[c]

[a] Peak potential for metal-centred ECE mechanisms; measured at 0.2 Vs^{-1}. – [b] Averaged potential value for an overlapping two-electron process; see text. – [c] Peak potential for an irreversible process; measured at 0.2 Vs^{-1}.

Further support to the above assignments comes from the trend of the formal electrode potentials of the reduction processes with respect to the number of metal fragments, illustrated in Figure 3.

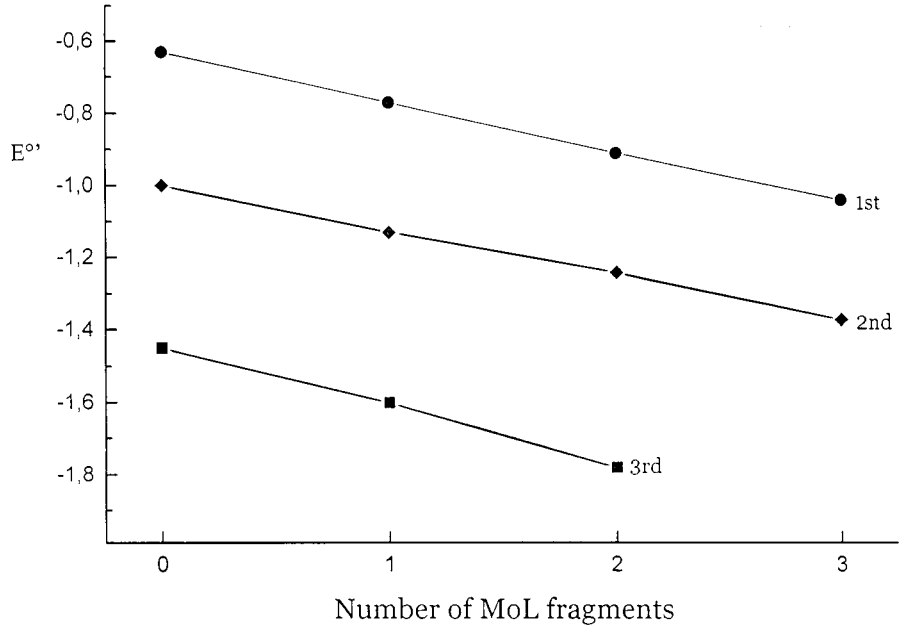

Figure 3. Plot of the formal electrode potentials of the first (1st), second (2nd), and third (3rd) fullerene centred reductions of $C_{60}[Mo(CO)_2(phen)(dbm)]_n$ vs. the number of molybdenum fragments

As it happens, for the series $C_{60}[Pt(PR_3)_2]_n$,[6] the formal electrode potentials of the first reduction increase linearly with the number of metal fragments (correlation coefficient = 1.0); the same trend substantially holds for the subsequent fullerene-centred reductions. This result points out that the electronic effects played by each metal subunit are fully additive. It should however be taken into account that the shifts of the redox potentials must arise either from the inductive effects exerted by the metal fragment(s), which can favour or disfavour the reduction processes, or from the progressive interruption of the double-bond conjugation operated by the metal coordination, which makes the reductions more difficult. This is confirmed by the examination of the redox potentials of the first one-electron reduction of the series $C_{60}[Mo(CO)_2(phen)(dbm)]_n$, $C_{60}[Pt(PEt_3)_2]_n$, and $C_{60}[S_2Fe_2(CO)_6]_n$ with respect to that of free C_{60} reported in Table 2: in spite of the fact that all complexes are η^2-6:6 coordinated, either negative or positive redox shifts occur.

Table 2. Potential shifts (in V) for the first one-electron reduction of the complexes $(C_{60})[MoL]_n$ [L = $(CO)_2(phen)(dbm)$], $C_{60}[Pt(PEt_3)_2]_n$, and $C_{60}[S_2Fe_2(CO)_6]_n$ with respect to the $[C_{60}]^{0/-}$ couple

[a] Present work.

The X-band EPR spectrum of the monoanions $[(\eta^2\text{-}C_{60})M(CO)_2(phen)(dbm)]^-$ (M = Mo, W) electrogenerated in dichloromethane solutions have been previously discussed.[7b] As a matter of fact, the freshly electrogenerated monoanion $[(\eta^2\text{-}C_{60})Mo(CO)_2(phen)(dbm)]^-$ exhibits a well separated, broad, and unresolved axial structure having $g_{\parallel} > g\perp \neq g_{electron} = 2.0023$, Figure 4a.

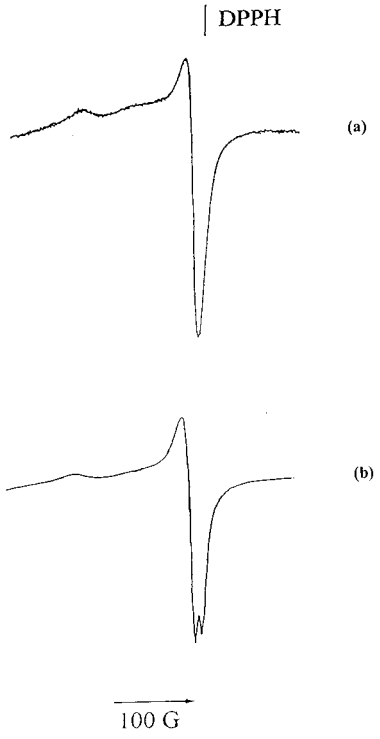

Figure 4. X-band EPR spectra of $[(\eta^2\text{-}C_{60})\{Mo(CO)_2(phen)(dbm)\}]^-$ in CH_2Cl_2 recorded at 100 K: (a) just after its electrogeneration at 250 K; (b) after exposure to air for a few seconds

Even if the low abundance of the Mo-95/97 nuclei does not allow their satellite hyperfine resolution to be detected ($I_{Mo\text{-}95}$ = 5/2; natural abundance = 15.7%; $I_{Mo\text{-}97}$ = 5/2; natural abundance = 19.5%), the width of the signal coupled to its g_i values could be interpreted as being due to a paramagnetic species possessing a partial metallic character, i.e., the fullerene based SOMO of the monoanion could have a significant contribution from the 4d-Mo AO's. In spite of the stability of the monoanion under inert atmosphere, handling the sample even for short times in air causes the appearance of a new absorption that is quite coincident with that of free $[C_{60}]^-$, Figure 4b.

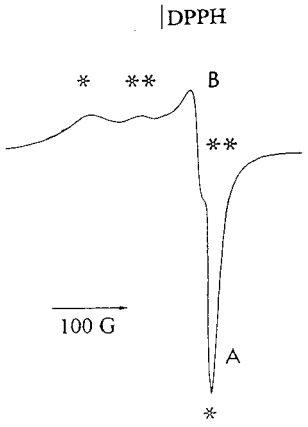

Figure 5. X-band EPR spectrum of a CH_2Cl_2 solution of the freshly electrogenerated monoanion $[(C_{60})\{Mo(CO)_2(phen)(dbm)\}_2]^-$ recorded at 100 K

Figure 5 shows the low-temperature EPR spectrum of the freshly electrogenerated monoanion $[C_{60}\{Mo(CO)_2(phen)(dbm)\}_2]^-$, and exhibits two partially overlapping signals [hereafter indicated as A (*) and B (**), respectively], both of them being resolved in axial structures with $g_{\|i} > g_{\perp i} \neq g_{electron} = 2.0023$.

Table 3. X-band EPR parameters of the electrogenerated monoanions $[(C_{60})\{MoL\}_n]^-$, [L = $(CO)_2$(phen)(dbm)] recorded at 100 K in CH_2Cl_2 solution. ($g_i = \pm 0.002$)

Monoanion	$g_{\|}$ [a]	$g_{\perp}$ [a]	$<g>$ [a][b]	g_{iso}
$[(C_{60})\{MoL\}]^-$	2.089	2.014	2.039	–
$[(C_{60})\{MoL\}_2]^-$ (A)*	2.058	1.960	1.993	–
$[(C_{60})\{MoL\}_2]^-$ (B)**	2.016	1.973	1.987	–
$[C_{60}]^-$	–	–	1.998	1.995[c]

[a] T = 100 K. – [b] $<g> = (g_{\|} + 2g_{\perp})/3$. – [c] T = 295 K; * = outer signals, ** inner signals.

The relevant best fit parameters are collected in Table 3 and can be suitably computed, taking into account an S = 1/2 Electron Spin Hamiltonian for the two axial signals. The line-shape analysis reveals that the species A and B are present in a 2:1 molar ratio. It does not seem too ventured to assume that the two paramagnetic species are geometrical isomers, with the major component likely possessing the commonest geometry in which the two Mo fragments lie at the opposite sides of C_{60}.[8,11] Also, no EPR evidence for the Mo-95/97 satellite hyperfine resolution has been gained in this case, but the spectral pattern might be interpreted in the sense that the overall SOMO likely has a contribution from either the fullerene 2p-C AO's or the two 4d-Mo AO's.

As in the case of the monoadduct, raising the temperature at the glassy-fluid transition induces disappearance of the anisotropic features, while the typical sharp signal of free $[C_{60}]^-$ anion appears as a minor species. A fast refreezing of the solution does not, however, restore the original signal, as is the case for $[(C_{60})Mo(CO)_2(phen)(dbm)]^-$,[7b] thus pointing out that $[(C_{60})\{Mo(CO)_2(phen)(dbm)\}_2]^-$ is more reactive with traces of air than $[(C_{60})Mo(CO)_2(phen)(dbm)]^-$.

Because of the multiple species present in a solution of $(C_{60})[Mo(CO)_2(phen)(dbm)]_3$, we did not attempt the EPR characterization of its monoanion.

Electrochemistry of $(\eta^2\text{-}C_{70})[Mo(CO)_2(phen)(dbm)]$

Figure 6 and Figure 7 show the cyclic voltammetric behaviour of $(C_{70})[Mo(CO)_2(phen)(dbm)]$, in comparison with that of free C_{70}, at different potential windows.

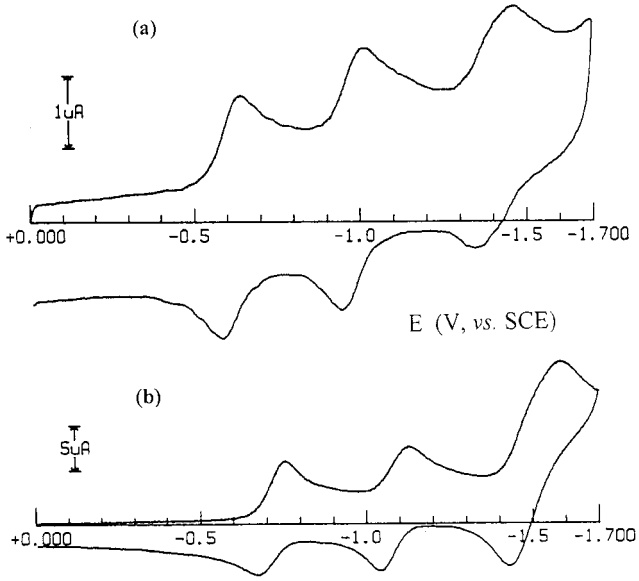

Figure 6. Cyclic voltammetric responses recorded at a platinum electrode in CH_2Cl_2 solutions containing $[NBu_4][PF_6]$ (0.2 mol dm^{-3}) and: (a) C_{70} (saturated solution); (b) $C_{70}[Mo(CO)_2(phen)(dbm)]$ ($4\cdot10^{-4}$ mol dm^{-3}); scan rate 0.2 Vs^{-1}, T = −10 °C

It is easily seen from the first three cathodic waves, Figure 6, that the presence of the Mo fragment also induces a cathodic shift of the first two C_{70}-centred one-electron reductions with respect to free C_{70}. Nevertheless, at variance with the C_{60} analog, the third cathodic process appears as an essentially overlapping two-electron step. Based on the reversibility of such processes and on the fact that the one-electron reductions of either the molybdenum fragment in $(C_{60})[Mo(CO)_2(phen)(dbm)]$ or that of the precursor $Mo(CO)_2(phen)(dbm)_2$ occur at more negative potential values (−1.9 V and −1.7 V, respectively),[7b] we are keen to assume that this closely-spaced two-electron step is due to the substantial concomitance of the third and fourth one-electron reductions of the C_{70} moiety. Finally, as far as the fourth reduction process is concerned, Figure 7, the appear-

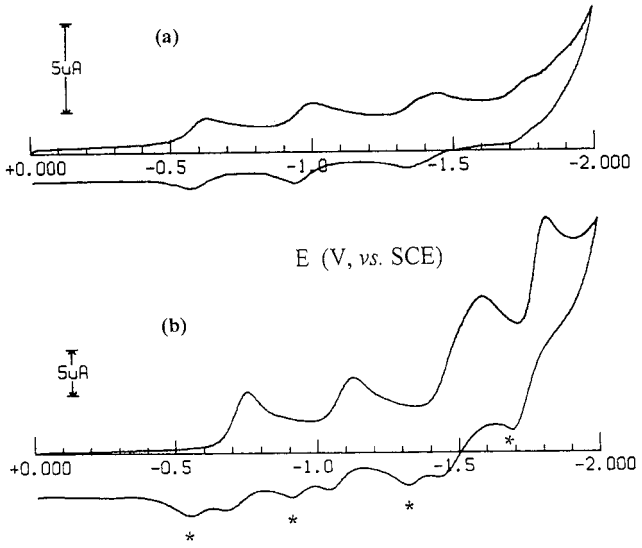

Figure 7. Cyclic voltammetric responses recorded under the same experimental conditions as for Figure 5, along a more extended potential window

ance in the back-scan of the sequential re-oxidations of the free fulleride anions (starred peaks) points out that it induces C_{70} decomplexation as a consequence of the simple EC step:

$$[M^0(\eta^2\text{-}C_{70})]^{4-} \xrightarrow{+e^-} [M^{-1}(\eta^2\text{-}C_{70})]^{5-} \xrightarrow{k} [M]^- + [C_{70}]^{4-}$$

$M = Mo(CO)_2(phen)(dbm)$

In summary, the reduction pathway of $(C_{70})[Mo(CO)_2(phen)(dbm)]$ is rather different from that of its C_{60} analogue in two respects: (i) the electronic perturbation played by the metal fragment forces the third and fourth one-electron additions to C_{70} to become concomitant; (ii) the fourth reduction involves a simple metal-centred process, whereas in the C_{60} derivative it involves the following metal-centred ECE mechanism:

$$[M^0(\eta^2\text{-}C_{60})]^{3-} \xrightarrow{+e^-} [M^{-1}(\eta^2\text{-}C_{60})]^{4-} \xrightarrow{k} [M]^- + [C_{60}]^{3-}$$

$$[C_{60}]^{3-} \xrightarrow{+e^-} [C_{60}]^{4-}$$

$M = Mo(CO)_2(phen)(dbm)$

The relevant electrochemical data are compiled in Table 1.

Finally, it is interesting to note that under the same experimental conditions, the cathodic shift induced by appending the $Mo(CO)_2(phen)(dbm)$ unit to C_{70} is lower than for C_{60}, (0.10 V vs. 0.15 V), thus suggesting that the extent to which the double bond conjugation is broken by the coordination to C_{70} should be lower than with C_{60}. Unfortunately, such a conclusion cannot be generalised because in the case of $(C_{70})[(S_2)Fe_2(CO)_6]$ and $(C_{60})[(S_2)Fe_2(CO)_6]$ the shifts with respect to the corresponding free fullerenes are −0.01 V and +0.02 V, respectively,[2] indicating that the extent of double bond saturation is higher in the C_{70} complex. Underlined that in the last case the interaction of the metal centre with the fullerene ligand is mediated by the disulfur bridge, more data on complexes bearing the same metal fragment directly bound to both C_{60} and C_{70} are needed to clarify such an electronic aspect.

Experimental Section

Material and apparatus for electrochemistry and coupled ESR measurements have been previously described.[7b] All the potential values are referred to the saturated calomel electrode (SCE). Under the present experimental conditions, the one-electron oxidation of ferrocene occurs at $E^{\circ\prime} = +0.34$ V in the temperature range from −10 °C to +10 °C, and at $E^{\circ\prime} = +0.35$ V at +20 °C. The external magnetic field H_0 for ESR spectroscopy was calibrated by using a DPPH powder sample ($g_{DPPH} = 2.0036$). Computer simulation of the ESR spectra was carried out by using the SIM14 A program.[19]

Synthesis: All the reactions were carried out under a nitrogen atmosphere with the use of standard Schlenk techniques. The preparation of $(\eta^2\text{-}C_{60})[Mo(CO)_2(o\text{-phen})(dbm)]$ has been previously reported.[7a]

$(C_{60})[Mo(CO)_2(o\text{-phen})(dbm)]_n$ (n = 2, 3): $Mo(CO)_2(o\text{-phen})(dbm)_2$ (178 mg, 0.225 mmol) was added to a solution of C_{60} (54 mg, 0.075 mmol) in benzene (25 cm^3). The mixture was heated under reflux for 2 h, and then concentrated. The resulting dark green solution was separated by column chromatography (silica gel) using benzene/THF (7:1, then 5:1, and finally 4:1) as eluent. The two main chromatography bands were collected separately, and the solvents were removed. Both the residues were washed with petroleum ether (ca. 30−60 °C) and pentane, and then dried in vacuo to give dark green powders. One is $(C_{60})[Mo(CO)_2(o\text{-phen})(dbm)]_2$ (60 mg, 44%). − Found: C 73.70, H 2.84, N 3.53; calcd.: C 73.04, H 3.07, N 3.04. − IR: $\tilde{\nu}_{max}$ = 1963 (s), 1898 (s) [νC≡O], 1689 (s) [νC=O], 1423 (m), 1159 (s), 573 (w), 525 (m) [νC_{60}]; 428(w) [ν(Mo-(η^2-C=C))], 367cm^{-1} (w) [ν(Mo−N)]. − UV/Vis (CH_2Cl_2): λ_{max} = 258 nm. − The other is $(C_{60})[Mo(CO)_2(o\text{-phen})(dbm)]_3$ (30 mg, 17%). − Found: C 71.34, H 3.05, N 3.24; calcd.: C 69.00, H 3.53, N 3.50. − IR: $\tilde{\nu}_{max}$ [cm^{-1}] = 1959 (s), 1894 (s) [νC≡O]; 1690 (s) [νC=O]; 1422 (m), 1157 (s), 570 (w), 522 (m) [νC_{60}]; 430 (w) [ν(Mo-{η^2-C=C})]; 371(w) [ν(Mo−N)]. − UV/Vis (CH_2Cl_2): λ_{max} [nm]: 258.

$(\eta^2\text{-}C_{70})[Mo(CO)_2(o\text{-phen})(dbm)]$: $Mo(CO)_2(o\text{-phen})(dbm)_2$ (39 mg, 0.05 mmol) was added to a solution of C_{70} (42 mg, 0.05 mmol) in benzene (25 cm^3). The mixture was heated under reflux for 1 h, and then concentrated. The resulting red-brown solution was separated by column chromatography (silica gel) using benzene/acetone (12:1) as eluent. The main chromatography band was collected. The solvents were removed and the residue dried in vacuo to give a red brown powder, (23 mg, 32%). Crystals were obtained by slow diffusion of pentane into a dichloromethane solution. − Found: C 81.90, H 2.55, N 1.85; calcd. for $C_{70}[Mo(CO)_2(o\text{-phen})(dbm)]$: C 82.29,; H 2.01, N 2.00}. IR: $\tilde{\nu}_{max}$ [cm^{-1}] = 1957 (s), 1890 (s) [νC≡O]; 1684(s) [ν(C=O)]; 1427 (s), 1410 (s), 1159 (s), 1131 (m), 797 (w), 674 (w), 640 (w), 573 (w), 535 (w), 456 (w) [νC_{70}]; 434 (w) [ν(Mo-{η^2-C=C})]; 367 (w) [ν(Mo−N)]. − UV/Vis (CH_2Cl_2): λmax [nm]: 238. − ^1H NMR: δ_H (Solvent $CDCl_3$ + CS_2, standard $SiMe_4$): 0.9 (t, 6 H, $CH_2CH_2CH_2CH_3$), 1.3 (m, 4 H, $CH_2CH_2CH_2CH_3$), 1.5 (m, 4 H, $CH_2CH_2CH_2CH_3$), 4.1 (t t, 4 H, O=C−O$CH_2CH_2CH_2CH_3$, s, 2 H, =C*H*), 7.8 (m,m, 2 H, $H^{3,8}$ of

phen), 7.9 (d, 2 H, $H^{5,6}$ of phen), 8.4 (m, 2 H, $H^{4,7}$ of phen), 9.0 (d,d, 2 H, $H^{2,9}$ of phen). – ^{13}C NMR: δ_C (Solvent $CDCl_3$ + CS_2): 14 (s, $CH_2CH_2CH_2CH_3$), 20 (s, $CH_2CH_2CH_2CH_3$), 31 (s, $CH_2CH_2CH_2CH_3$), 64 (s, $O{=}C{-}OCH_2CH_2CH_2CH_3$), 77 (dd, *C*=*C* of C_{70} and dbm), 124–163 (s, 41 signals comprising 6 phen and 35 C_{70} signals, 1 signal omitted), 172 (s, *C*=O)

Synthesis and Solid-State Characterization of Isopropoxy Carboxylate Clusters of Ti^{IV}

A. Pandey,[a] V. D. Gupta,[a] and H. Nöth*[b]

Keywords: Titanium / Oxygen ligands / Alkoxy carboxylates / Structure elucidation

Reaction of $Ti(OiPr)_4$ with chloroacetic acids (1:1 and 1:2 stoichiometric ratio) in toluene gives the corresponding mono- and bis-substituted products in quantitative yield. The products $Ti(OiPr)_3(OOCR)$ (R = CH_2Cl **1a,** $CHCl_2$ **1b**, CCl_3 **1c**) are proposed to have a dimeric structure on the basis of ^1H,^{13}C NMR and IR spectroscopy. On standing in toluene, solutions of **1c** form the trinuclear species $Ti_3(\mu_3\text{-}O)(\mu_3\text{-}OiPr)_2(OiPr)_5(\mu\text{-}O_2CCCl_3)_3$ (**2**) with the three titanium atoms forming an isosceles triangle and the μ_3-O moiety at the center. On standing in toluene, solutions of **1b** form a hexanuclear product $Ti_6(\mu_3\text{-}O)_6(OiPr)_6(\mu\text{-}O_2CCHCl_2)_6$ (**3**), the structure of which consists of two stacked six-membered [Ti-μ_3-O]$_3$ rings connected by Ti–O bonds. Under comparable conditions, the *bis-substituted* product $Ti(OiPr)_2(O_2CCCl_3)_2$ (**4c**) forms the dinuclear species $Ti_2(\mu\text{-}O)(OiPr)_2(HOiPr)_2(\mu\text{-}O_2CCCl_3)_2(O_2C\text{–}CCl_3)_2$ (**5**) in which the two symmetric octahedral titanium centers are bonded to a common oxygen atom.

Introduction

Metal alkoxides [1–4] are the preferred precursors in the sol-gel process of preparing ceramic materials. However, their high hydrolytic instability needs to be overcome by the incorporation of hydroxylated nucleophilic ligands[5] such as carboxylic acids[6–15] and β-diketones[16,17] to produce new molecular precursors. Titanium oxoalkoxy carboxylates have received considerable attention in recent years. These precursors generally consist of four to six titanium atoms with one of six[6–14] types of metal-oxygen core skeletons. Recently,[18] a nonanuclear product was isolated. These highly condensed oxo species are usually generated by a secondary process i.e. esterification. For alkoxides, ether elimination[19–21] and naturally controlled hydrolysis[22] are other routes to oxo products.

Acetic acid[6–9,13,14] has been used most often for preparing the above oxoalkoxy carboxylates, perhaps because addition of acetic acid to sol-gel processes with titanium alkoxides prevents precipitation and increases the gelation time.[23] We wanted to examine the structural changes caused by gradually increasing both the acidity and steric bulk of the carboxylic acid. Therefore, we examined the reactions of chloroacetic acids with titanium isopropoxide. Initially, to produce smaller amounts of condensed/uncondensed species, these reactions were performed in excess solvent (toluene) at room temperature. Surprisingly, these toluene solutions of the simple substitution products formed oxo species on standing, which were characterized by X-ray crystallography. The extent of condensation seems to be dependent on the time the solution is left standing.

We report here the first simple di- and trinuclear oxoalkoxytitanium carboxylates. A hexanuclear species having a Ti_6O_6 core was also obtained.

Results and Discussion

Structurally characterized carboxylic acid-modified titanium alkoxides have generally been reported to contain four to six titanium atoms with one of six[6–14] metal-oxygen core skeletons. Most of these products have been obtained from either neat[9] reaction mixtures or very small solvent volumes.[12–14] Some of the products are obtained from excess solvent, but only at high temperatures[10] or under reflux[15] conditions. In excess solvent, at room temperature, the reaction of $Ti(OEt)_4$ with $(CO)_9Co_3(\mu_3\text{-}CCO_2H)$ was recently reported[11] to give the single product $Ti_6O_4(OEt)_{12}\{\mu\text{-}(CO)_9Co_3(\mu_3\text{-}CCO_2)\}_4$.

Since both the absence of solvent and high temperatures of reflux facilitate condensation *by* esterification, we have examined the reactions of $Ti(OiPr)_4$ with chloroacetic acids in solvent at room temperature (25 °C). Initially $Ti(OiPr)_4$ was dissolved in toluene and then a toluene solution of the acid was added to it dropwise while stirring.

The products of the reactions of $Ti(OiPr)_4$ with mono-, di-, and trichloroacetic acids in 1:1 stoichiometric ratio in toluene are $Ti(OiPr)_3(O_2CR)$ (R = CH_2Cl **1a**, $CHCl_2$ **1b**, CCl_3 **1c**), which were obtained in quantitative yields (Equation 1). The liberated 2-propanol was determined by chromic acid oxidation.[24]

$$Ti(OiPr)_4 + RCOOH \rightarrow Ti(OiPr)_3(OOCR) + HOiPr \quad (1)$$

The ambient-temperature ^1H NMR spectrum of **1a** shows two doublets and two septets (intensity ratio 1:2) for the *gem*-dimethyl protons corresponding to the bridging

and terminal isopropoxy groups respectively. The ^{13}C NMR spectrum also shows the presence of two types of isopropoxy group and one type of carboxylate group. In the IR spectrum of **1a** the difference between the antisymmetric (1580 cm^{-1}) and symmetric (1460 cm^{-1}) stretching bands of the carboxylate group ($\Delta\tilde{\nu}$ = 120 cm^{-1}) suggests[25] a bridging bidentate bonding mode. The bridging and terminal isopropoxy groups are accounted for by the bands at 1020 cm^{-1} and 1090 cm^{-1} respectively. The IR and ^{13}C NMR spectra of the products **1b** and **1c** are similar to those of **1a** but their ambient temperature ^1H NMR spectra show one doublet for the methyl protons, which is probably due to fast exchange of the O*i*Pr groups at the probe temperature. Attempts to grow single crystals of compounds **1** were not successful. Therefore, on the basis of the available spectral evidence, and in accordance with a report of Doeuff and Sanchez,[26] compounds **1** may have dimeric structures.

An attempt to crystallize **1c** by leaving the reaction mixture for two days in toluene (at –15 °C) led to a white crystalline product which was shown to be $Ti_3(\mu_3\text{-}O)(\mu\text{-}O\text{-}i\text{Pr})_2(O\text{-}i\text{Pr})_5(\mu_3\text{-}O_2C\text{–}CCl_3)_3$ (**2**) by X-ray crystallographic analysis (Equation 2).

$$3\ Ti(O\text{-}i\text{Pr})_3(OOCCCl_3) \rightarrow Ti_3O(O\text{-}i\text{Pr})_7(OOCCCCl_3)_3 + O\text{-}i\text{Pr}_2 \quad (2)$$

We were able to obtain crystalline material of **1b** from the reaction mixture of $Ti(O\text{-}i\text{Pr})_4$ with $CHCl_2COOH$ in toluene. When the mother liquor was left for a few days, a small crop of crystals was obtained, which were characterized as $Ti_6(\mu_3\text{-}O)_6(O\text{-}i\text{Pr})_6(\mu\text{-}O_2CCHCl_2)_6$ (**3**) by X-ray crystallographic analysis. The formation of this highly condensed product may also be accounted for by ether elimination (Equation 3).

$$6\ Ti(O\text{-}i\text{Pr})_3(OOCCHCl_2) \rightarrow Ti_6(O)_6(O\text{-}i\text{Pr})_6(OOCCHCl_2)_6 + 6\ O\text{-}i\text{Pr}_2 \quad (3)$$

The bis-substituted products $Ti(O\text{-}i\text{Pr})_2(O_2CR)_2$ (R = CH_2Cl **4a**, $CHCl_2$ **4b**, CCl_3 **4c**) are obtained quantitatively from the reaction of $Ti(O\text{-}i\text{Pr})_4$ with chloroacetic acids (1:2 stoichiometric ratio) according to Equation 4.

$$Ti(O\text{-}i\text{Pr})_4 + 2\ RCOOH \rightarrow Ti(O\text{-}i\text{Pr})_2(OOCR)_2 + 2\ HO\text{-}i\text{Pr} \quad (4)$$

The IR spectrum of **4c** shows four absorptions due to the carboxylate group. The two $\tilde{\nu}_{CO2}$ bands at 1766 cm^{-1} (antisymmetric) and 1377 cm^{-1} (symmetric) ($\Delta\tilde{\nu}$ = 389 cm^{-1}) were assigned as a unidentate carboxylate group while those at 1658 cm^{-1} (antisymmetric) and 1462 cm^{-1} (symmetric) ($\Delta\tilde{\nu}$ = 120 cm^{-1}) were assigned as a bridging bidentate carboxylate group. The peaks at 1015 cm^{-1} and 1089 cm^{-1} were assigned as bridging and terminal isopropoxy groups, respectively.[25] However, the ambient temperature ^1H and ^{13}C NMR spectra of **4c** were not structurally informative. The IR and the ambient temperature ^1H and ^{13}C NMR spectra of **4a** and **4b** are similar to those of **4c**. We were unable to structurally characterize **4** since we could not obtain single crystals of these compounds. As before, we tried to crystallize **4c** by leaving the reaction mixture to stand for two days, and obtained the white crystalline dinuclear species $Ti_2(\mu\text{-}O)(O\text{-}i\text{Pr})_2(HO\text{-}i\text{Pr})_2(\mu\text{-}O_2C\text{–}Cl_3)_2(O_2C\text{–}Cl_3)_2$ (**5**) (Equation 5).

$$2\ Ti(O\text{-}i\text{Pr})_4 + 4\ CCl_3COOH \rightarrow Ti_2(O)(O\text{-}i\text{Pr})_2(HO\text{-}i\text{Pr})_2(OOCCCl_3)_4 + O\text{-}i\text{Pr}_2 + 2\ HO\text{-}i\text{Pr} \quad (5)$$

The IR spectra of the volatiles from reactions (2), (3) and (5) showed strong absorptions around 1165 cm^{-1}, characteristic of isopropyl ether. No absorptions were observed in the carbonyl region. Therefore, ester formation does not appear to take place under the mild conditions of these reactions. A similar observation has been reported[10] in the reaction of $Ti(O\text{-}i\text{Pr})_4$ with $(CO)_9Co_3(\mu_3\text{-}C\text{–}CO_2H)$.

X-ray Crystallographic Structures

The X-ray structure (Figure 1, Table 1) of **2** shows the three titanium atoms sitting at the corners of an isosceles triangle with the triply bridged oxo group at the center.

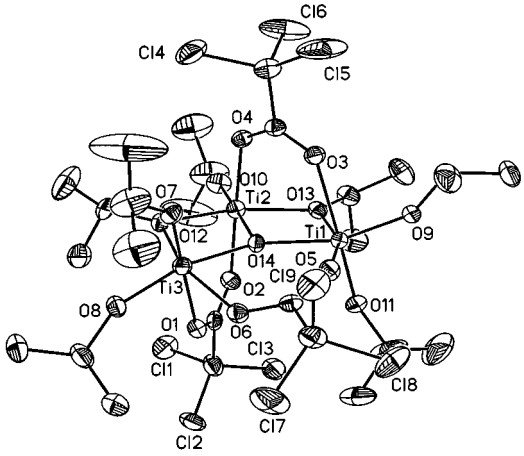

Figure 1. Molecular structure of compound **2** in ORTEP description; hydrogen atoms omitted for the sake of clarity; thermal ellipsoids represent a 25 % probability

All three trichloroacetate groups are bidentate and symmetrically bridge the three titanium centers with a propeller arrangement. All three titanium atoms are six coordinate with two of the atoms (Ti1, Ti3) in a similar coordination environment. The third titanium atom (Ti2) has one terminal O*i*Pr group, making the structure asymmetric. The bridging O*i*Pr groups are also asymmetrical with one O*i*Pr group bridging Ti1 and Ti2, and the other Ti2 and Ti3; there is no bridge between Ti1 and Ti3. This Ti_3O skeletal arrangement is the first[12] of its type reported for titanium oxo alkoxy carboxylates. It is interesting to note that if the fourth coordination site (the one generating the cubic framework) of the μ_4-O group in the structure of $Ti_4(\mu\text{-}O)(\mu_4\text{-}O)(O_2CH)_2(\mu\text{-}O\text{-}i\text{Pr})_4(O\text{-}i\text{Pr})_6$[12] was removed, a Ti_3O_3 core similar to **2** would be obtained.

The geometry around the μ_3-O group is remarkable as the sum of the angles is 360°, making it perfectly planar. The constraints of the two four-membered rings (Ti2, O13,

Ti1, O14 and Ti2, O14, Ti3, O12) cause the angle Ti3–O14–Ti1 (148.5°) to open up, while the other two angles (105.8°) are equal. The $Ti(2)O_6$ octahedron shares two of its edges with the other two octahedra, while the tricoordinate oxygen atom O14 is the only common point between $Ti(1)O_6$ and $Ti(3)O_6$. The three octahedra are distorted with angles ranging from 76.2° to 105.9°.

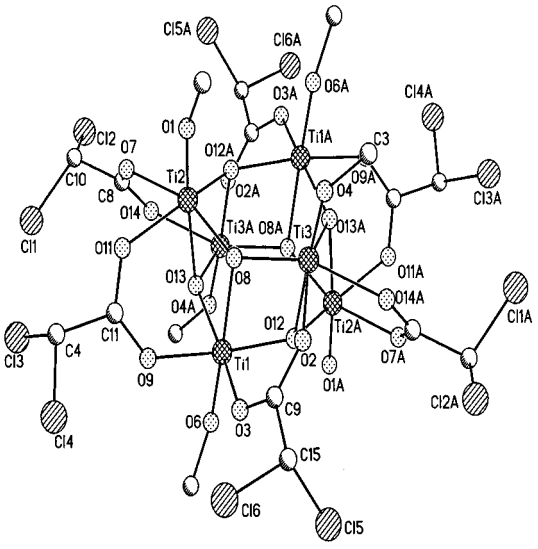

Figure 2. Stick-and-ball model of the molecular structure of the hexatitanium hexaoxo complex **3**; hydrogen atoms and the methyl carbon atoms are omitted for clarity

The X-ray crystal and molecular structure (Figure 2) of **3** shows two stacked six-membered rings consisting of alternating titanium and oxygen atoms. The rings are connected through Ti–O bonds. There is one terminal isopropoxy group attached to each titanium atom. Six dichloroacetate groups bridge the six titanium centers in a bidentate fashion, one from the upper and one from the lower ring. The angles at the alternating titanium and oxygen atoms of the hexagonal rings average 102.6° and 133.7°, respectively, showing considerable distortion in the hexagons. These angles are within the range recently reported.[12] The angles at the atoms binding the upper ring to the lower average 100.4°. While this work was in progress two oxo alkoxy carboxylates with a Ti_6O_6 core i.e. $Ti_6O_6(OiPr)_6(O_2CR)_6$ and $Ti_6O_6(OEt)_6(O_2CR)_6$ (R = H,[12] C_6H_4-*o*-OPh[15]) were reported, with their formation being attributed to ester elimination reactions. It has been ar-

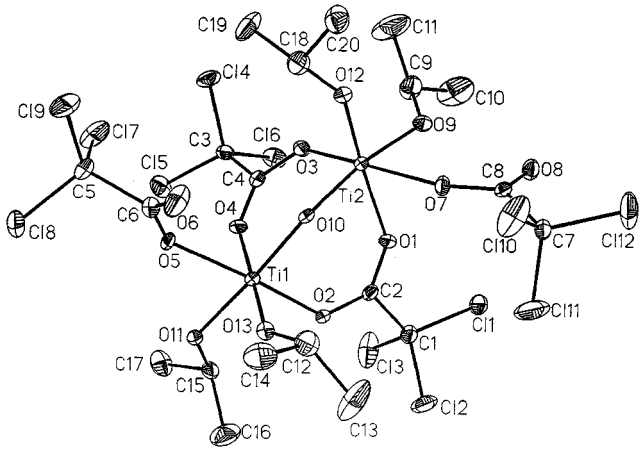

Figure 3. Molecular structure of the dititanoxane complex **5** in ORTEP description; hydrogen atoms omitted; thermal ellipsoids represent a 25 % probability

gued[12] that the sterically less demanding nature of R and increased acidity may be the reasons for the formation of highly condensed species. However, almost isostructural systems are obtained from either dichloroacetic acid (present work) or 2-phenoxybenzoic acid,[14] which does not substantiate this observation. In fact a number of oxo alkoxy carboxylates with Ti_6O_4 core, $Ti_6O_4(O_2CMe)_4(OR)_{12}$ (R = CH_2Me,[11] $CHMe_2$[14]), $Ti_6O_4(O_2CMe)_8(OR)_8$ [R = $CHMe_2$,[7] $(CH_2)_3CH_3$[9]] and $Ti_6O_4(O_2C_6H_4)_4\{\mu$-$(CO)_9Co_3(\mu_3$-$O_2CC)\}_4(OiPr)_4$[11] have been found to retain their basic structural skeleton irrespective of the steric bulk of the alkoxide and/or the carboxylic acid.

The structure of **5** (Figure 3) consists of two symmetrical, octahedral titanium centers Ti1 and Ti2 with a common μ-oxo group O10, thereby forming a novel Ti_2O core.

Each titanium atom is bound to three terminal oxygens, one each from 2-propanol, an isopropoxy and a monodentate trichloroacetate group. The two octahedrons are joined by two bridging bidentate trichloroacetate groups which are slightly distorted. The angles for the octahedrons range from 78.5° to 100.5°. Compound **5** is the first oxo alkoxy carboxylate with an alcohol attached by a dative bond. This may be due to its low nuclearity relative to other complexes. At both titanium atoms the HO*i*Pr groups are *trans* to the oxo group. The terminal groups give rise to intermolecular interactions (Cl···Cl and O–H···O contacts). Both octahedrons show a hydrogen-bonding interaction between the carbonyl oxygen of the terminal trichloroacetate group and the hydrogen of 2-propanol. Also observed are chlorine–oxygen and chlorine–titanium interactions.

$Ti(OiPr)_4$ + $2CCl_3COOH$ (0.911, 3.20) (1.049, 6.41)	**4c**	$Ti(OiPr)_2(OOCCCl_3)_2$ (1.575, 99.9)	White solid	9.90 (9.75)	24.01 (24.03)	0.37 (0.39)

Selected bond lengths and angles for **2**, **3** and **5** are given in Table 1, Table 2 and Table 3. The Ti–O*i*$Pr_{terminal}$ distances [**2** (av. 1.772 Å), **3** (av. 1.745 Å), **5** (av. 1.742 Å)] for the three complexes are in accordance with reported[14,17] values. The Ti–HO*i*Pr (Ti1–O13, Ti2–O9) distances (av. 2.110 Å) are, as expected, longer than the isopropoxy distances. The Ti–μ-O*i*Pr lengths (av. 1.997 Å), which are present only in **2**, are shorter than the terminal Ti–O*i*Pr lengths.[12] For **2** the Ti–μ_3-O distances (av. 1.920 Å) and for **5** the Ti–μ-O distances (av. 1.811 Å) are consistent with literature[13] values.

However, for **3** the Ti–μ_3-O distances (av. 1.885 Å) are somewhat shorter than values recently reported.[12]

For **2** the distances Ti1···Ti2 and Ti2···Ti3 (av. 3.066 Å) correspond to two octahedra sharing an edge[15] while for **3** the distances from upper to lower hexagonal rings (av. 2.176 Å) are consistent with those recently reported.[10] The center of the molecule **3** is empty, resulting in a hole.

The Ti–μ-OAc distances [**2** (av. 2.115 Å), **3** (av. 2.070 Å) and **5** (av. 2.113 Å)] are also in accordance with literature values while for **5** the Ti–OAc lengths (av. 1.968 Å) are shorter than the bridging carboxylate distances.

Conclusions

The reaction of $Ti(OiPr)_4$ with chloroacetic acids in excess toluene at room temperature prevents esterification, thereby giving simple substitution products. However the propensity of the metal atoms to achieve higher coordination numbers through oxo ligands is so strong that it can even be achieved through ether elimination reactions. In this way the formation of products **2** and **5** can be accounted for. The generation of **3** from **1b** on standing in toluene suggests that the extent of the ethereal loss is directly proportional to length of time in solution. In the process significant structural changes are observed. However, due to our limited findings, no conclusions regarding effects of increasing acidity and steric bulk of carboxylic acids on the structures could be drawn.

Experimental Section

All reactions were performed under a dry argon atmosphere, using standard Schlenk and glovebox techniques. Toluene and $CDCl_3$ were dried by standard procedures. Titanium isopropoxide was obtained from $TiCl_4$ (Aldrich) by the ammonia method[27] and purified by vacuum distillation. Mono-, di- and trichloroacetic acids were distilled before use. Infrared spectra were recorded on a JASCO FT-IR-5300 as Nujol mulls between NaCl plates. ^1H and ^{13}C NMR spectra were recorded in $CDCl_3$ with a JEOL-FX 90Q spectrometer with $SiMe_4$ as internal reference. Ti was determined as TiO_2 and isopropoxy analysis by the method of Bradley[24] et al.

Synthesis

General Method for the Complexes 1a–c, and 4a–c (Table 4): A solution of the acid in toluene (ca. 20 mL) was added dropwise with stirring to a solution of $Ti(OiPr)_4$ in toluene (ca. 25 mL) over 1/2 h at room temperature (ca. 25 °C). The reaction mixture (colorless) was stirred for six hours to give a light red solution. The volatiles were removed in vacuo to give a solid residue.

1a: ^1H NMR: δ = 1.26 (d), 1.35 (d, *gem*-Me_2 of O*i*Pr), 4.80 (sept), 5.30 (sept, CH of O*i*Pr), 4.00 (s, CH_2 of the acid, 18:3:2). – ^{13}C NMR: δ = 192.91 (CO of acid), 63.43, 64.45 (CH of O*i*Pr), 41.49 (CH_2Cl of acid), 23.62, 24.32 (*gem*-Me_2 of O*i*Pr). – IR: $\tilde{\nu}$ = 1580 (ν_{as} CO_2), 1460 (ν_s CO_2), 1120 (terminal O*i*Pr), 1010 (bridging O*i*Pr).

1b: ^1H NMR: δ = 1.40 (d, *gem*-Me_2 of O*i*Pr), 4.16, 5.00 (sept, CH of O*i*Pr), 6.08 (s, CH_2 of acid, 18:3:1). – ^{13}C NMR: δ = 191.97 (CO of acid), 67.43, 68.21 (CH of O*i*Pr), 55.49 ($CHCl_2$ of acid), 23.32, 24.35 (*gem*-Me_2 of O*i*Pr). – IR: $\tilde{\nu}$ = 1589 (ν_{as} CO_2), 1460 (ν_s CO_2), 1119 (terminal O*i*Pr), 1011 (bridging O*i*Pr).

1c: ^1H NMR: δ = 1.31 (d, *gem*-Me_2 of O*i*Pr), 4.10, 5.10 (sept, CH of O*i*Pr). – ^{13}C NMR: δ = 180.97 (CO of acid), 63.43, 65.10 (CH of O*i*Pr), 86.58, (CCl_3 of acid), 23.51, 24.21 (*gem*-Me_2 of O*i*Pr). – IR: $\tilde{\nu}$ = 1658 (ν_{as} CO_2), 1460 (ν_s CO_2), 1112 (terminal O*i*Pr), 1009 (bridging O*i*Pr).

4a: ^1H NMR: δ = 1.15 (d, *gem*-Me_2 of O*i*Pr), 4.80 (sept, CH of O*i*Pr), 4.00 (CH_2 of acid) (6:1:2). – ^{13}C NMR: δ = 189.97 (CO of acid), 63.46 (CH of O*i*Pr), 43.58 (CH_2Cl of acid), 23.59 (*gem*-Me_2 of O*i*Pr). – IR: $\tilde{\nu}$ = 1769, 1654 (ν_{as} CO_2), 1378, 1460 (ν_s CO_2), 1112 (terminal O*i*Pr), 1009 (bridging O*i*Pr).

4b: ^{1}H NMR: δ = 1.40 (d, *gem*-Me_2 of O*i*Pr), 5.02 (sept, CH of O*i*Pr), 6.00 (s, CH_2 of acid) (6:1:1). – ^{13}C NMR: δ = 190.57 (CO of acid), 67.79 (CH of O*i*Pr), 57.48 ($CHCl_2$ of acid), 24.35 (*gem*-Me_2 of O*i*Pr). – IR: $\tilde{\nu}$ = 1777, 1589 (ν_{as} CO_2), 1380, 1460 (ν_s CO_2), 1110 (terminal O*i*Pr), 1010 (bridging O*i*Pr).

4c: ^{1}H NMR: δ = 1.39 (d, *gem*-Me_2 of O*i*Pr), 4.85 (sept, CH of O*i*Pr). – ^{13}C NMR: δ = 192.97, (CO of acid), 70.26 (CH of O*i*Pr), 87.81 (CCl_3 of acid), 23.29 (*gem*-Me_2 of O*i*Pr).

Ti(μ$_3$-O)(μ-O*i*Pr)$_2$(O*i*Pr)$_5$(μ-O$_2$C–CCl$_3$)$_3$ (2): A solution of Cl_3C–C(O)OH (1.295 g, 7.92 mmol) in toluene (ca. 20 mL) was added dropwise with stirring to a solution of Ti(O*i*Pr)$_4$ (2.245 g, 7.91 mmol) in toluene (ca. 25 mL) over 30 min at room temperature (30 °C). The reaction mixture (colorless) was stirred for 6 h to give a dark yellow solution. It was concentrated to half of its volume and kept at –15 °C. After 2 d, a white crystalline product (1.932 g of **2**, 65%) was obtained. – $C_{27}H_{49}Cl_9O_{14}Ti_3$ (1060.4): calcd. Ti 13.55, O*i*Pr 39.01; found Ti 13.91, O*i*Pr 38.91. – ^{1}H NMR (25 °C): δ = 1.31 (d, CH_3 of O*i*Pr), 4.11, 5.01 (sept, CH of O*i*Pr). – ^{13}C{^{1}H} NMR: δ = 180.99 (CO of acid), 90.85 (CCl_3 of acid), 63.92 (CH of O*i*Pr), 23.51, 24.21 (CH_3 of O*i*Pr). – FT-IR (Nujol): $\tilde{\nu}$ = 1658 (ν_{as} CO_2), 1460 (ν_s CO_2), 1112 (terminal O*i*Pr), 1009 (bridging O*i*Pr) cm^{-1}. – Single crystals were grown in toluene at –15° C.

Ti(O*i*Pr)$_3$(O$_2$C–CHCl$_2$ (1b) and Ti$_6$(μ$_3$-O)$_6$(O*i*Pr)$_6$(μ-O$_2$C–CHCl$_2$)$_6$ (3): White crystalline **1b** (1.110 g, 65%) was obtained by concentrating the reaction mixture of Ti(O*i*Pr)$_4$ (1.158 g, 4.07 mmol) and dichloroacetic acid (0.526 g, 4.07 mmol) in toluene by the general method. – $C_{11}H_{22}Cl_2O_5Ti_2$ (353.1): calcd. Ti 13.56, O*i*Pr 50.20; found Ti 13.89, O*i*Pr 50.01. – ^{1}H NMR (25 °C): δ = 1.42 (m, CH_3 of O*i*Pr), 4.16, 5.01 (sept, CH of O*i*Pr), 6.08 (s, CH_2 of acid). – ^{13}C{^{1}H} NMR: δ = 192.91 (CO of acid), 63.43 (CH of O*i*Pr), 55.51 ($CHCl_2$ of acid), 23.91, 24.38 (CH_3 of O*i*Pr). – FT-IR (Nujol): $\tilde{\nu}$ = 1589 (ν_{as} CO_2), 1458 (ν_s CO_2), 1120 (terminal O*i*Pr), 1006 (bridging O*i*Pr) cm^{-1}. – The mother liquor upon standing for 5 days at –15 °C gave a small batch of crystals which was shown to be **3** by X-ray crystallography.

Ti$_2$(μ-O)(HO*i*Pr)$_2$(O*i*Pr)$_2$(O$_2$C–CCl$_3$)$_2$(μ-O$_2$C–CCl$_3$)$_2$ (5): A reaction mixture comprising Ti(O*i*Pr)$_4$ (1.362 g, 4.80 mmol) and trichloroacetic acid (1.57 g, 9.60 mmol) in toluene was stirred for six hours. It was then concentrated to half of its volume and kept at –15 °C. After 2 d, a white crystalline product was obtained. – Yield: 1.651 g of **5** (72 %). – $C_{20}H_{30}Cl_{12}O_{13}Ti_2$ (999.6): calcd. Ti 9.56, O*i*Pr 23.64; found Ti 9.57, O*i*Pr 23.91. – ^{1}H NMR (25 °C): δ = 1.39 (d, CH_3 of O*i*Pr), 4.85 (sept, CH of O*i*Pr). – ^{13}C{^{1}H} NMR: δ = 192.31, 181.37 (CO of acid), 87.91 (CCl_3 of acid), 70.26 (CH of O*i*Pr), 23.29 (CH_3 of O*i*Pr). – FT-IR (Nujol): $\tilde{\nu}$ = 1787 (ν_{as} CO_2), 1378(ν_s CO_2), 1649 (ν_{as} CO_2), 1460 (ν_s CO_2) 1090 (terminal O*i*Pr), 1012 (bridging O*i*Pr) cm^{-1}. – Single crystals were obtained from toluene.

Crystallography

The structure determinations were performed using a Siemens P4 diffractometer equipped with a CCD area detector. Mo-K_α radiation (λ = 0.71013 Å) was used and the samples cooled to 193 K (**2**, **3**) and 183 K (**4**) respectively. Data reduction was achieved with the program SAINT and absorptions by SADABS (**2**, **3**) and semi-empirical methods (**4**). Computer calculations were carried out using the SHELXS-97 (Sheldrick, 1997) program package and the structures were solved by direct methods. Refinements were performed by SHELXL-97 (Sheldrick, 1997) using anisotropic thermal parameters for the non hydrogen atoms. Hydrogen atoms were placed in calculated positions and refined with a riding model. The crystallographic data for **2**, **3** and **5** are given in Table 5. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-138443 (**2**), -138445 (**5**), -138444 (**3**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: int. code + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

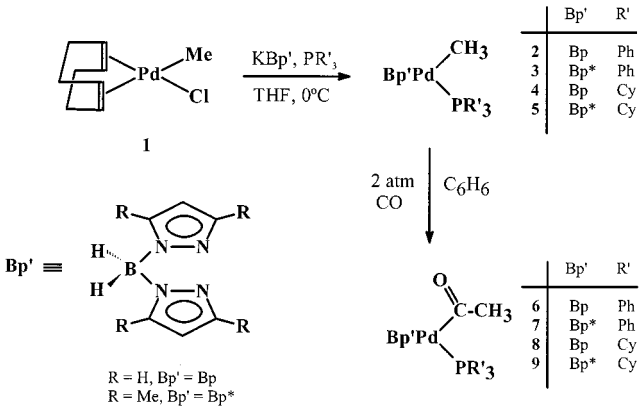
Novel (Methyl)- and (Acetyl)palladium Complexes Containing Bis(pyrazolyl)borate Ligands – Dynamic Equilibrium between η^2 and η^1 Forms for the Complex Bp*(Me)(PCy_3)Pd [Bp* = dihydridobis(3,5-dimethylpyrazolyl)borate]



M. Mar Díaz-Requejo,[a] M. Carmen Nicasio,[a] Tomás R. Belderrain,[a] Pedro J. Pérez,*[a] M. Carmen Puerta,[b] and Pedro Valerga[b]

Keywords: Polymerisation / (Methyl)palladium complexes / Poly(pyrazolyl)borates

A series of (methyl)palladium complexes of general formula Bp′Pd(CH_3)(L) [Bp′ = Bp = dihydridobis(pyrazolyl)borate; Bp′ = Bp* = dihydridobis(3,5-dimethylpyrazolyl)borate, L = phosphane] has been synthesised. The interaction of these alkyl complexes with carbon monoxide produces the acetyl derivatives Bp′Pd(C(O)Me)(L), one of the members of this series, BpPd[C(O)Me](PPh_3), being structurally characterised by X-ray diffraction studies.

Introduction

After Brookhart's discovery of (diimine)nickel and -palladium complexes as highly efficient catalysts for olefin polymerisation,[1] the synthesis of new alkyl complexes of group-10 metals has emerged. The number of such complexes reported in the recent literature is considerable, but the catalytic capabilities towards polymerisation seem to be restricted to cationic compounds containing few, selected nitrogen-based ligands such as the above-mentioned diimine ligand.[1–3] Recently, Grubbs and co-workers have reported several neutral (aryl)(salicylaldimininato)nickel(II) complexes which act as good olefin polymerisation catalysts.[4] On the other hand, although there exist an important number of palladium complexes containing poly(pyrazolyl)borate ligands,[5] few examples of simple (alkyl)palladium(II) species have been reported.[6] The synthesis of (methyl)palladium complexes containing tris- and tetrakis-(pyrazolyl)borate has been described,[5] but, to our knowledge, there is no report on the synthesis of the analogous bis(pyrazolyl)borate derivatives. With the aim of preparing new Pd complexes bearing nitrogen donor ligands as possible olefin polymerisation catalysts, in this contribution we describe the synthesis, characterisation and chemical behaviour of several complexes of general formula Bp′Pd(Me)(PR'_3) as well as their corresponding acyl derivatives (Scheme 1).

Scheme 1

Results and Discussion

Synthesis of the Alkyl Complexes

When 1 equivalent of the KBp′ (Bp′ = Bp or Bp*) salt is added to cold (0 °C) THF solutions of Pd(Me)Cl(cod) (**1**) and PR'_3 (R′= Ph, Cy), a ligand exchange reaction takes place as shown in Scheme 1. After work up, white microcrystalline compounds **2–5** (see Table 1) are isolated in good yields. Some of these complexes are not very stable in solution at room temperature, so temperature control becomes crucial during their synthesis reactions as well as during the work up of their crystallisation solutions.

The NMR data of **2–4** are in accordance with a square-planar environment around the palladium atom, assuming that both pyrazolyl rings are bound to the metal centre. The resonances in the ^{1}H- and ^{13}C{^{1}H}-NMR spectra are well

defined (see Table 2 and Table 3). For instance, the proton signals of the Pd–CH_3 groups in the ^{13}C{^{1}H}-NMR spectra range from δ = –9.9 to δ = –2.4, each resonance splitting into a sharp doublet. The values of J_{CP} coupling constants are small (J_{CP} = 6–8 Hz), in agreement with a mutually *cis* distribution of the alkyl and phosphane ligands. The pyrazolyl rings are inequivalent since two sets of signals are observed in the ^{1}H- and ^{13}C{^{13}H}-NMR spectra. In contrast,

the ^{1}H-NMR spectrum of **5** at room temperature consists of one broad resonance for the C*H* protons (δ = 5.66) and two broad singlets for the methyl protons of the two pyrazolyl rings (δ = 2.1 and 2.3, respectively). At low temperature, –30 °C, the low-field resonance splits into two peaks centred at δ = 5.67 and 5.65, corresponding to two inequivalent C*H* protons (see Figure 1 for the VT experiment).

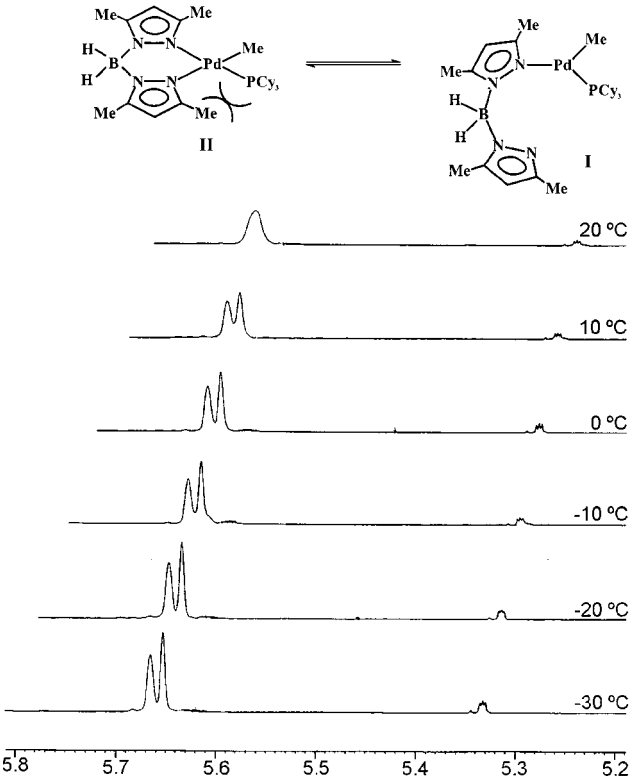

Figure 1. Variable-temperature ^{1}H-NMR spectra (CD_2Cl_2, 400 MHz) of **5** and proposed mechanism for the observed fluxionality

A phosphane exchange process cannot be responsible of the observed fluxionality, based of the following: (i) when PCy_3 is added to a solution of complex **5** in CD_2Cl_2 at room temperature, no change is observed for the resonances observed in the ^{1}H-NMR spectrum of **5**; (ii) the J_{HP} coupling constant for the methyl group remains unchanged through studied the temperature range, clearly confirming the strength of the Pd–P bond.

A possible alternative explanation for the fluxional process would invoke dissociation and re-association of one pyrazolyl ring to the Pd centre. This would be the result of steric repulsions between the methyl groups and the bulky PCy_3. Subsequently, an equilibrium between the η^2-Bp* species and an η^1-Bp* species might occur (Figure 1). Furthermore, the absence of any band in the 2100–1900 cm^{-1} range in the IR spectrum of **5** (see Table 1) indicates that no agostic interactions exist between the palladium centre and any of the B–H bonds,[7,8] making the species **I** the more reasonable proposition. An example of a process similar to the one represented in Figure 1 has been recently reported for the Rh^I complex [Rh(CO)($PMePh_2$)$_2$-($Tp^{Me2,4-Cl}$)] containing a bulky η^2-Tp ligand.[9] Etienne et al. concluded that steric effects were undoubtedly responsible of the observed structure. In addition, Ni^{II} complexes containing bulky poly(pyrazolyl)borate ligands coordinated in an η^1- fashion [e. g., Tp*t*BuNi(C_6H_5)(PMe_3)$_2$] have been described.[10,11] In the case of **5**, the existence of a 14-electron species, similar to that of structure **I**, has been proposed an intermediate in insertion-type reactions.[12] More information can be extracted from the NMR study shown in Figure 1. The calculated value of $\Delta G^{\neq}$ [13] of ca. 59.1 kJ mol^{-1} compares well with those values reported by Espinet and co-workers,[14] 45–60 kJ mol^{-1}, for exchange of pyridine groups in palladium complexes containing $P(CH_2CH_2Py)_nPh_{3-n}$ ligands.

Reaction of 2–5 with Olefin and/or CO

Our main interest in the study of these complexes was their possible application as catalysts in olefin polymerisation and/or CO/olefin copolymerisation processes. Previously, there had been examples described of the use of cationic (methyl)palladium(II) complexes for the polymerisation of ethylene and α-olefins.[1] Unfortunately, in our case, attempts to polymerise ethylene with the neutral complexes **2–5** yielded no polyethylene, even under ethylene pressure (2 atm) and the presence of phosphane scavengers like $B(C_6F_5)_3$.[15]

On the other hand, since Sen's report of palladium(II) catalysts for the CO–olefin copolymerisation reaction,[16,17] and later, Drent and co-workers' report of the perfectly alternating copolymerisation of such substrates,[18,19] the synthesis and study of new (alkyl)palladium compounds containing P–P or N–N ligands have been developed.[20,21,22] We have also tested our Bp′Pd(Me)(L) complexes as catalysts in such processes, but again, no polymer formation was observed and only the CO insertion products, Bp′Pd(COMe)(PR'_3) (**6–9**) were obtained (Scheme 1), even under CO and olefin pressure or heating conditions. These acyl derivatives **6–9** can be prepared by exposure of a solution of the corresponding alkyl complex under CO pressure (2 atm).

Spectroscopic data of the complexes **6–9** have unambiguously revealed the presence of the acyl function. Thus, the intense absorbances observed at ca. 1680 cm^{-1} in their IR spectra are attributed to ν(COR) (Table 1). In addition, in the $^{13}C\{^1H\}$-NMR spectra, the quaternary carbon atoms of the acyl moiety resonate as doublets within the range δ = 231.1–234.6 (see Table 4). Both pyrazolyl rings are inequivalent as inferred from the well-defined resonances observed in the $^{13}C\{^1H\}$-NMR spectra (see Table 5). In contrast to the observations for the other acyl derivatives, and in agreement with its alkyl precursor, complex **9**, Bp* Pd(COMe)(PCy_3) appears to also be fluxional.

A single-crystal X-ray diffraction study has been carried out on the compound BpPd(COMe)(PPh_3) (**6**). An ORTEP[22] perspective view of the molecule is depicted in Figure 2. Selected bond lengths and angles are shown in Table 6. Compound **6** has a similar geometry around the

metal centre as other palladium poly(pyrazolyl)borate complexes.[5] The molecule of **6** presents a distorted square-planar geometry in the solid state, with the values of the angles P(1)–Pd(1)–N(22) [169.4(2)°] and N(12)–Pd(1)–C(1) [171.0(3)°] slightly deviated from the ideal of 180°. The Pd–N(12) and Pd–N(22) distances [2.189(7) and 2.107(7) Å, respectively] are also in the range of those reported, for instance, in the related compound Bp*Pd(CH_2SiMe_3)(PMe_3)

[2.123(5) and 2.098(4) Å].[6] Finally, the palladium–carbon bond length found in compound **6** [1.973(8) Å] is within the range reported for the related (acyl)palladium bidentate nitrogen donor complexes [for example, 1.952(5) Å for (bpy)($MeOCC_7H_{10}COC_7H_{10}CO$)PdI[21]].

Experimental Section

All preparations were carried out using standard Schlenk techniques under nitrogen using freshly distilled and degassed solvents. Potassium bis(pyrazolyl)borates[23] and the complex (COD)-(CH_3)PdCl[24] were prepared according to literature procedures. PCy_3 and PPh_3 were purchased and used without further purification. – Infrared spectra were recorded with a Perkin–Elmer spectrophotometer, model 884. – ^{1}H- and ^{13}C-NMR spectra were recorded with a Bruker DRX400 spectrometer, chemical shifts being referred to TMS. – ^{31}P-NMR spectra were obtained with the same spectrometer using 85% aqueous H_3PO_4 as the standard. – Microanalyses were carried out by the Microanalytical Service of the Instituto de Investigaciones Químicas (Sevilla, Spain).

Synthesis of the Alkyl Derivatives Bp′(CH_3)(PR'_3)Pd [Bp′= Bp, R′ = Ph (2), Cy (3); Bp′= Bp*, R′ = Ph (4), Cy (5)]: (COD)-(CH_3)PdCl (0.5 mmol, 128 mg) was dissolved in THF (40 mL) and the corresponding phosphane ligand (0.5 mmol) was added. To the resulting solution, cooled at 0 °C, 1 equiv. of KBp′ was added and the mixture was stirred for 2 h. The solvent was removed under vacuum and the residue was extracted with THF/petroleum ether (1:1). Complexes Bp′(CH_3)(PR_3)Pd were isolated as microcrystalline white solids upon cooling of these solutions to –20 °C (75–90% yield).

Synthesis of the Acyl Derivatives (CH_3CO)Bp′(PR_3)Pd [Bp′= Bp, R′ = Ph (6), Cy (7); Bp′= Bp*, R′ = Ph (8), Cy (9)]: A typical preparation is the following: Synthesis of (MeCO)Bp*(PPh_3)Pd (**8**): Complex **4** (0.25 g, 0.43 mmol) was dissolved in dried THF (15 mL) and the resulting pale yellow solution was transferred to a pressure vessel which was charged with CO (2 atm). The reaction mixture was stirred for ca. 1 h affording a dark yellow solution. The solvent was pumped off and the crude residue investigated by NMR (C_6D_6), revealing that compound **8** was formed in almost quantitative yield. Crystallisation from petroleum ether/Et_2O (1:2) mixtures led to the isolation of complex **8** as pale yellow crystals of analytical purity (yield 75%).

Compounds **6**, **7**, **9** were obtained in a similar procedure in 65–70% yield after crystallisation. (MeCO)Bp(PPh_3)Pd (**6**) was crystallised from Et_2O/CH_2Cl_2 (1:1) mixtures; (MeCO)Bp(PCy_3)Pd (**7**) was crystallised from Et_2O solutions and (MeCO)Bp*(PCy_3)Pd (**7**) was purified by crystallisation from petroleum ether solutions.

Crystallography: A colourless crystal of $C_{26}H_{26}BN_4OPPd$ having approximate dimensions of 0.35 × 0.24 × 0.10 mm was mounted on a glass capillary and transferred to a Rigaku AFC6S diffractometer. Graphite-monochromated Mo-K_α radiation was used.

Cell constants were obtained from a least-squares refinement using the setting angles of 25 carefully centred reflections. The system was determined to be orthorhombic, space group $P2_12_12_1$ (number 19, acentric). The data were collected using the ω/2θ scan method. The intensities of three standard reflections were measured after every 100 reflections to apply the decay correction. Lorentz-polarization and absorption correction (ψ-scan method) were also applied. A summary of experimental details is shown in Table 7.

Table 7. Summary of crystal data collection and structure analysis for complex **6**

Empirical formula	$C_{26}H_{26}BN_4OPPd$
Molecular mass	558.70
Crystal size [mm]	0.35 × 0.24 × 0.10
Colour, shape	colourless, plate
Cell measurements (25 refl.)	12.6 < 2θ < 15.5°
Crystal system	orthorhombic
Space group	$P2_12_12_1$ (number 19)
Cell parameters	a = 13.849(6) Å
	b = 14.687(6) Å
	c = 12.202(5) Å
Volume	V = 2481(1) Å^3
Z	4
$\rho_{calcd.}$	1.495 g cm^{-3}
λ(Mo-K_α)	0.71069 A
μ(Mo-K_α)	8.26 cm^{-1}
F(000)	1136
Absorption correction	ψ-scan method
Transmision factors	0.715–1.000
Standards number, interval	3 refl., 100 refl.
Decay (%)	–1.00
Temperature	290(1) K
Scan method	ω/2θ
Scan Speed (ω)	4° min^{-1}
2θ interval	5° < 2θ < 50.1°
Measured reflections	2349
Unique reflections	2349
Observed reflections ($I > 3\sigma_I$)	1965
Number of parameters	172
Reflection/parameter ratio	11.42
Refinements	Full-matrix least squares on F
$R = (\|F_o\| - \|F_c\|)/\|F_o\|$	0.0434
R_w ($w = \sigma_F^2$) = $[(w(\|F_o\| - \|F_c\|)^2/wF_o^2)]^{1/2}$	0.0503
g.o.f.	1.727
Residuals peaks [e/Å^3]	+1.31, –0.53

The structure was solved by the Patterson method. The refinement was carried out on F by full-matrix least-squares methods. Pd, O and N atoms were anisotropically refined. The carbon atoms were isotropically refined, most of the hydrogen atoms (20) were included in difference Fourier and the remainder in idealised positions and were not refined. A set of 1965 observed reflections [$I > 3\ \sigma(I)$] and 172 variable parameters were used in the last cycles of refinements. The enantiomorph with slightly lower R, R_w and goodness of fit was selected. Final values of R = 0.0434 and R_w = 0.0503 were obtained. All calculations were carried out using the TEXSAN software package on a VAX 3520 computer at the "Servicio Central de Ciencia y Tecnología de la Universidad de Cádiz". Crystallographic data have been deposited with the Cambridge Crystallographic Data Center: CCDC-135559. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Photoinduced Ligand Isomerization in Dimethyl Sulfoxide Complexes of Ruthenium(II)

Matthew K. Smith,[a] John A. Gibson,[b] Charles G. Young,[b][+] John A. Broomhead,[b][++] Peter C. Junk,[a] and F. Richard Keene*[a]

Keywords: Dimethyl sulfoxide / Isomerizations / Photochemistry / Ruthenium

Upon exposure to sunlight or UV irradiation, a DMSO solution of $[Ru(bpy)_2(DMSO)_2]^{2+}$ **(1)** (bpy = 2,2′-bipyridine; DMSO = dimethyl sulfoxide) turns rapidly from yellow to red, but subsequently slowly reverts to yellow in the dark. The photochemical sequence is explained in terms of a photopromoted linkage isomerization of the DMSO ligands from *S*- to *O*-bound, with a relaxation back to the thermodynamically stable yellow *S*-bound form in the dark by an intermolecular mechanism. The "dark" reaction has been studied by UV/Vis spectrophotometry, NMR and IR spectroscopy. The *S*-bound ligation of DMSO in the yellow cation was established by X-ray crystallographic studies of *cis*-$[Ru(bpy)_2(DMSO)_2](CF_3SO_3)_2$.

Introduction

Polypyridyl complexes of ruthenium(II) and their photochemistry have been widely studied, particularly with regard to potential application to storage of light energy and light-activated switches.[1,2] In the latter context, the development of systems which undergo reversible photoactivated chemical or structural changes are of particular interest.[3]

The complex $[Ru(bpy)_2(DMSO)_2](PF_6)_2$ {bpy = 2,2'-bipyridine, DMSO = dimethyl sulfoxide} undergoes an interesting reaction of this type. A yellow solution of the complex in DMSO rapidly turns red upon exposure to sunlight; in the dark, the solution subsequently slowly reverts to the yellow form. This process appears completely reversible as it can be performed many times on the same solution with no apparent degradation of the complex. The phenomenon appears to arise from linkage isomerization: photoactivated linkage isomerizations are known but uncommon in ruthenium chemistry,[4−6] and the present study was undertaken to elucidate aspects of the process.

Results and Discussion

Synthesis and Characterization

Reactions of blue $[Ru(bpy)_2(CO_3)]$ or $[Ru(Me_2bpy)(CO_3)]$ with non-coordinating acids HX {$X^- = PF_6^-$, $CF_3SO_3^-$} in DMSO resulted in the formation of the yellow bis(dimethyl sulfoxide) complexes, $[Ru(bpy)_2(DMSO)_2]^{2+}$ and $[Ru(Me_2bpy)_2(DMSO)_2]^{2+}$, which were precipitated as the X^- salts by addition of ethanol/hexane. Microanalytical and spectroscopic data for the dimethyl sulfoxide complexes were consistent with the proposed formulations, and IR, NMR and X-ray diffraction data (vide infra) indicate the dimethyl sulfoxide ligands are *S*-bound. In DMSO solution, the complexes undergo a reversible colour change to red upon irradiation with intense sunlight (ca. 5 min) or UV radiation [0.5 h; 100 W medium-pressure Hg lamp (354 nm)].

X-ray Crystallographic Studies

The structure of $[Ru(bpy)_2(DMSO)_2](CF_3SO_3)_2$ was determined by X-ray crystallography. The Ru centre shows a distorted octahedral environment; the DMSO ligands are *S*-bound and exhibit a *cis* relationship.

Two different conformations were observed in the asymmetric unit (Figure 1); in one form the O-atom of each of the DMSO ligands was orientated towards the opposite DMSO molecule (Figure 1a), and in the other form the oxygen atoms were orientated towards the aromatic ligands (Figure 1b). The origin of this anomaly may be steric. Selected bond lengths and angles are given in Table 1. The Ru−S bond lengths [2.292−2.293 Å] are slightly longer than those observed in other DMSO-containing ruthenium species, such as $[Ru(NH_3)_5(DMSO)]^{2+}$ [2.188 Å],[7] and *cis*-

S(4)−O(4)	1.479(4)		

$[RuCl_2(DMSO)_4]$ [2.276−2.277 Å; *trans* to Cl^-].[8] This observation possibly results from competition for π-backbonding electron density exerted by the *trans* bipyridine ligands: precedence for this may be seen in the structures of complexes *cis*(Cl)-$[RuCl_2(PzH)(DMSO)_3]$ [2.281−2.286 Å, *trans* to Cl^-; 2.310Å *trans* to pyrazole (which is π-backbonding)],[9] and *trans*-$[RuCl_2(DMSO)_4]$ [2.352 Å; *trans* to DMSO ligands (which are π-backbonding)].[10] Steric interactions between the *cis*-disposed DMSO ligands may also contribute to the bond lengthening. The S−Ru−S bond angle was slightly less than 90° [89.45° and 88.93° in the two conformers].

It is noted that on the basis of steric interactions alone, O-ligation would be preferred. Accordingly, electronic and bonding factors seem to be critical in the determination of the binding mode.

Electronic Spectroscopy and Kinetic Studies

The UV/Visible absorption spectra for the yellow solution in DMSO of the freshly synthesized complex $[Ru(bpy)_2(DMSO)_2](PF_6)_2$ and the irradiated (red) solution are

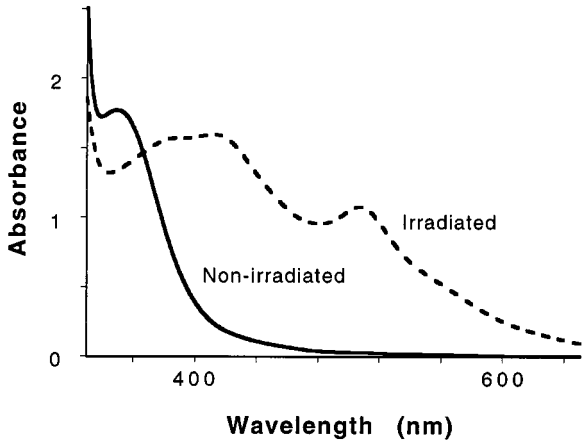

Figure 2. Absorbance spectra of $[Ru(bpy)_2(DMSO)_2](PF_6)_2$ (DMSO solution) before and after irradiation

shown in Figure 2 [λ_{max} = 348 nm, ε = 5760 $M^{-1}cm^{-1}$; λ_{max} = 507 nm, ε = 3500 $M^{-1}cm^{-1}$ and λ_{max} = 412 nm, ε = 5530 $M^{-1}cm^{-1}$, respectively]. The bathochromic shift on irradiation is consistent with a change from the "soft" *S*-bound (high field) to the "hard" *O*-bound (low field) ligands.

In DMSO solution, the red solution formed on irradiation reverted slowly in the dark to the original yellow spe-

cies. The initial light-induced reaction only occurred in DMSO, or non-coordinating solvents which contained DMSO. In other solvents the reaction proceeded not at all or to a minor extent (e.g. nitromethane, acetonitrile, dichloromethane, methanol, 1-methyl-2-pyrrolidinone), or there was an irreversible change due to the formation of a solvated species (e.g. water, *N*,*N*-dimethylformamide).[11]

The sequence observed for the "dark reaction" in DMSO solution is shown in the two segments of scan cycles (Figure 3), which illustrate a rapid initial reaction and a slower subsequent process. For the first reaction, continuous scans of the spectrum in the wavelength range 320−700 nm showed isosbestic points at λ = 440 nm and 390 nm (Figure 3a). The rate of the reaction was measured by following the time-dependence of the decay of the absorbance at 507 nm of the red complex ($t_{1/2}$ = 2.91 min. at 25 °C). The subsequent slower decay ($t_{1/2}$ = 111 min. at 25 °C) showed a different isosbestic point at 370 nm, which remained for the duration of the reaction (Figure 3b). Accordingly, the reaction proceeds via a two-step process from the red (irradiated) solution to the original yellow compound via an intermediate species.

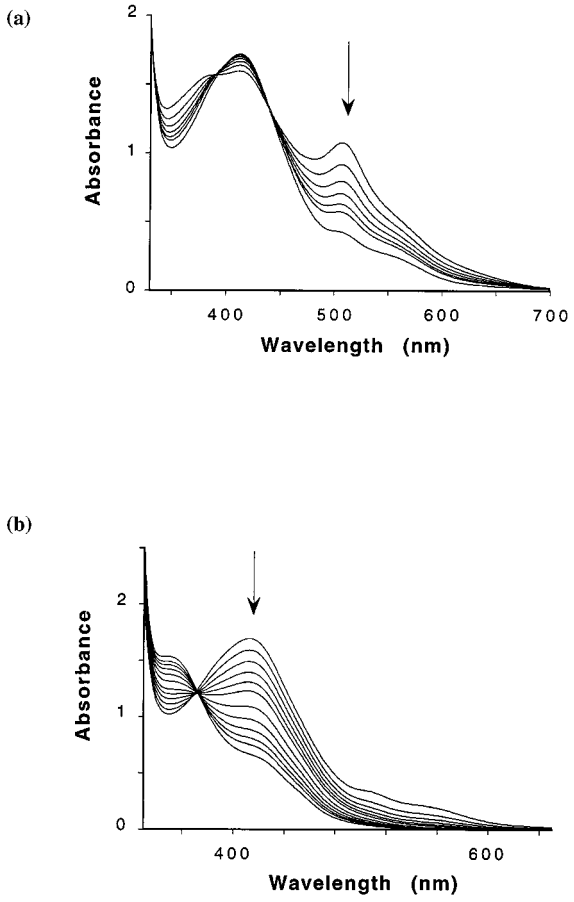

Figure 3. Absorbance spectra of $[Ru(bpy)_2(DMSO)_2](PF_6)_2$ (DMSO solution) after irradiation: (a) first 10 minute period (scan every 1 min), and (b) subsequent 285 minute period (15 min cycles)

The kinetics of the "dark" reactions which occurred after irradiation were followed using UV/Visible absorption spectral techniques over a range of temperatures. The two reactions observed were found to be pseudo-first order [plots of $\ln(A - A_{inf})$ vs. t were linear for > 3 $t_{1/2}$ in the two time domains]. The reaction rates were found to be unaffected by sample concentration, as expected.

Rate constants for the two reactions in DMSO solution at various temperatures are given in Table 2. The activation parameters for these two reactions were calculated: for the initial fast Red→Intermediate [**R**→**I**] reaction, $\Delta H^{\ddagger}$ = 58 (± 5) kJ mol^{-1} and $\Delta S^{\ddagger}$ = 83 (± 6) J mol^{-1}K^{-1}; for the slower Intermediate→Yellow [**I**→**Y**] reaction, $\Delta H^{\ddagger}$ = 92 (± 4) kJ mol^{-1} and $\Delta S^{\ddagger}$ = 162 (± 14) J mol^{-1}K^{-1}.

Table 2. Reaction rates for "dark" reactions [**I**→**Y**] for $[Ru(bpy)_2(DMSO)_2]^{2+}$ [complex concentration ca. 3−6 × 10^{-4} M]

Temp (K)	Solvent	k (s^{-1})[a] Slow Reaction	k (s^{-1})[a] Fast Reaction
25 °C (298 K)	DMSO	1.1 × 10^{-4}	4.0 × 10^{-3}
30 °C (303 K)	DMSO	2.1 × 10^{-4}	6.4 × 10^{-3}
35 °C (308 K)	DMSO	3.9 × 10^{-4}	8.7 × 10^{-3}
40 °C (313 K)	DMSO	6.9 × 10^{-4}	1.4 × 10^{-2}
45 °C (318 K)	DMSO	1.2 × 10^{-3}	1.8 × 10^{-2}
25 °C (298 K)	DMSO (50%) Nitromethane (50%)	9.1 × 10^{-5}	4.1 × 10^{-3}
25 °C (298 K)	DMSO (75%) Nitromethane (25%)	1.0 × 10^{-4}	4.2 × 10^{-3}

[a] Average of triplicate runs: estimated error ±5%.

From the structural studies reported above, the yellow form contains two *S*-bound DMSO ligands and it is highly probable that the red species formed immediately after irradiation contains two *O*-bound DMSO ligands. This may be rationalized in terms of the nature of the metal centre before and on irradiation: before irradiation, the Ru^{II} metal centre has a preference for ligands which possess the ability to backbond via ligand π-electron donation (i.e. "soft" ligands). After irradiation, however, the metal will have Ru^{III}-like character in the MLCT excited state and consequently will prefer ligands with strong σ-donating properties (i.e. "hard" ligands). Since DMSO has both "soft" (sulfur) and "hard" (oxygen) donor atoms, it is believed the DMSO switches its mode of bonding to the *O*-bound form to suit the nature of the metal. There is some precedence for this assertion: in Ru^{II} complexes involving strongly backbonding carbonyl (CO)[12] and nitrosyl (NO^+)[13] ligands, and in complexes involving Ru^{III} centres,[14,15] there is a significantly greater occurrence of *O*-bound DMSO than in the body of Ru^{II} species. In one case, Taube and coworkers have studied the kinetics of S→O isomerization on oxidation of $[Ru(NH_3)_5(DMSO)]^{2+}$.[16] More recently, an electrochemical study by Rack and Gray[17] of the system *mer*-$[RuCl_3(DMSO)(tmen)]$ {tmen = *N*,*N*,*N*',*N*'-tetramethylethylenediamine} demonstrated *S*-DMSO⇄*O*-DMSO isomerizations associated with Ru^{II}⇄Ru^{III} changes. It is probable therefore that the intermediate species observed in the "dark" reaction contains one *S*-bound and one *O*-bound DMSO ligand. This proposal is consistent with the IR analysis (see later), and is consistent with the UV/Visible spectral changes observed (Figure 3).

In principle, there are two possible mechanistic paths for the linkage isomerization reactions of *O*- to *S*-bound

DMSO; *viz.* an intermolecular substitution process in which the original DMSO ligands are replaced by solvent molecules, or an intramolecular switching mechanism involving a seven-coordinate species. There have been several investigations of linkage isomerization reactions involving the calculation of volumes of activation ($\Delta V^{\ddagger}$) which have also investigated the activation parameters $\Delta S^{\ddagger}$ and $\Delta H^{\ddagger}$.[18,19] In these mechanistic studies, for those reactions which were assigned as intramolecular in nature from the $\Delta V^{\ddagger}$ data, the corresponding $\Delta S^{\ddagger}$ values were found to be near-zero or negative, whereas a positive value indicated an intermolecular mechanism. This distinction is rationalized in terms of the increase in the number of individual molecules in going from the reactants to the transition state because of the dissociation of the ligands involved in an intermolecular process, thereby increasing the entropy of the system and resulting in a positive $\Delta S^{\ddagger}$ value. In the present system, the $\Delta S^{\ddagger}$ values for the **R→I** and **I→Y** reactions are positive, indicating that the reactions are intermolecular; i.e. the original DMSO ligands are replaced by DMSO solvent molecules during the isomerization process.

Photo-induced intramolecular linkage isomerization reactions involving tumbling mechanisms have been observed in thiocyanate-isothiocyanate, nitro-nitrito and cyanide-isocyanide conversions.[20] The reported cases of linkage isomerization involving DMSO ligands have been intermolecular[10,21,22] including Ru-DMSO systems, and it is possible that some steric or electronic factor prevents the intramolecular mechanistic path.

The rate constants of the **R→I** and **I→Y** reactions in nitromethane solutions containing 50% DMSO and 75% DMSO were comparable to those of pure DMSO solutions at 25 °C (see Table 2).

Infrared Analysis

The IR spectra of complexes containing DMSO ligands provide a means of differentiating between the *S*- and *O*-bound attachment. In ruthenium complexes, an *S*-bound DMSO exhibited a distinctive $\nu_{S=O}$ peak between 1080 and 1150 cm^{-1}, depending on the electronic nature of the other ligands in the coordination sphere. An *O*-bound form had a signal of slightly lower energy between 900 and 1000 cm^{-1}. In addition, a ν_{Ru-S} vibration occurred between 410−430 cm^{-1}, while the Ru−O signal occurred at slightly higher energy (460 to 490 cm^{-1}).[12]

The IR spectrum of yellow $[Ru(bpy)_2(DMSO)_2](PF_6)_2$ using KBr discs showed two distinct peaks which confirmed the *S*-DMSO ligation: $\nu_{S=O}$ = 1096 cm^{-1}, and ν_{Ru-S} = 425 cm^{-1}. Solid-state investigations of the red form were not possible, since a solid sample could not be isolated. Accordingly, solution IR studies were undertaken to enable assignment of the red form. A solution of the yellow complex in DMSO exhibited a peak at 1098 cm^{-1} ($\nu_{S=O}$), confirming the *S*-bound configuration remained after dissolution. Due to absorption by the DMSO solvent, the ν_{Ru-S} peak at ca. 425 cm^{-1} was obscured.

Upon irradiation of the solution and immediate measurement of its spectrum, the peak at 1098 cm^{-1} disappeared and a new absorption at 997 cm^{-1} was observed, consistent with *O*-bound DMSO. A second scan recorded ten minutes later showed this latter peak had decreased significantly, while the peak at 1098 cm^{-1} had increased slightly. A final scan five hours later showed the peak at 1098 cm^{-1} had reverted to its original intensity. This evidence indicates that, upon irradiation, the yellow solution containing the *S*-bound form converted into the *O*-bound red form. As the red species returned to the yellow form, the $\nu_{S=O}$ absorption corresponding to *O*-DMSO decreased in intensity, suggesting the DMSO ligands were reverting to the *S*-bound configuration. This decrease in intensity of this peak occurred rapidly in the first ten minutes, but slowed markedly as time progressed: this is consistent with the observations from UV/Visible spectroscopy, where the "dark" reaction of the irradiated red complex to the yellow form occurred in two stages, interpreted as a rapid conversion of the *O*-bound form rapidly to an *S*-bound/*O*-bound intermediate, which in turn slowly reverted to the fully *S*-bound form.

^{1}H NMR Spectroscopic Studies

^{1}H NMR spectral studies were also used to probe the nature of bonding changes in the DMSO ligands upon irradiation. For *S*-bound DMSO, the methyl proton resonance(s) shift downfield by up to 1 ppm from free DMSO, whereas for *O*-bound DMSO there is little shift.[21]

The aliphatic region of the spectrum of yellow $[Ru(bpy)_2(DMSO)_2](PF_6)_2$ in [D_6]dimethyl sulfoxide is shown in Figure 4a. Two peaks were observed at δ = 2.81 and 2.69, assigned as the CH_3 resonances from the *S*-bound DMSO ligands.

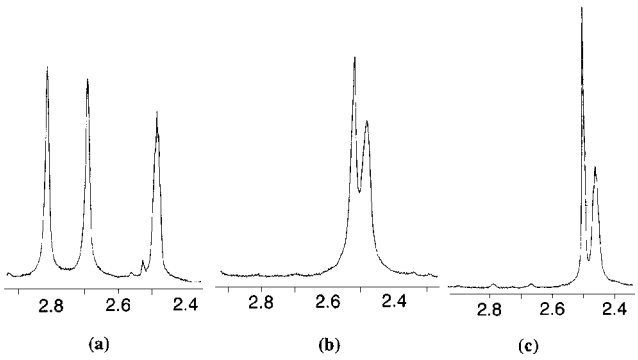

Figure 4. The 300 MHz ^{1}H NMR spectrum ([D_6]dimethyl sulfoxide solution) of the complex $[Ru(bpy)_2(DMSO)_2](PF_6)_2$: (a) before irradiation; (b) the same solution immediately after irradiation, and (c) the same solution after 5 h in the dark; ratio of integration of peaks at δ = 2.52 and 2.49 is identical in (b) and (c)

On irradiation by direct sunlight, the solution turned red and the ^{1}H NMR spectrum recorded immediately revealed the two CH_3 resonances observed in the original yellow solution had disappeared. A new resonance had developed at δ = 2.52, on the lowfield side of the solvent resonance centred at δ = 2.49 (Figure 4b), and consistent with either *O*-bound or free DMSO. When the irradiated solution was placed in the dark for five hours and the ^{1}H NMR spectrum re-measured, it was unchanged from that observed immediately after irradiation, even though the solution had

reverted completely back to the yellow form (Figure 4c). Repeating this irradiation procedure did not alter the spectrum. The loss of the peaks assigned to the *S*-bound form was established to be a consequence of the irradiation and not due to simple solvent exchange, as a freshly-prepared non-irradiated solution of the yellow complex in DMSO retained these two *S*-bound peaks for several days.

The data provide a number of insights into the photochemical sequence. The disappearance of the two resonances at $\delta = 2.81$ and 2.69 on irradiation and development of the new peak at $\delta = 2.52$ are consistent with the photoisomerization of *S*-bound form to the *O*-bound form, although the new peak is consistent with either *O*-bound or free DMSO. Following the subsequent reversion to the yellow form in the "dark" reaction, no change was observed within the aliphatic region of the spectrum: since the conversion of the *O*-bound to the *S*-bound form is known to be intermolecular (see above), the implication is that the photo-induced S→O linkage isomerization is also intermolecular. On the basis that the solvent [D_6]dimethyl sulfoxide would then be attached to the metal, no change would be expected in NMR spectra if the sequence was repeated, as was observed. This conclusion is in contrast to an earlier assessment on the system $[Ru(NH_3)_5(DMSO)]^{2+}$, where oxidation-induced S→O isomerization was thought to occur via a seven-coordinate intermediate i.e. via an intramolecular process.[16] The conclusion is also consistent with the observation that the photoreaction does not occur in the absence of DMSO and is not reversible in coordinating solvents which do not contain DMSO.

Other Systems

An attempt was made to obtain a further insight into the reaction by variation of the ligands not directly involved in the isomerization; for example, by replacement of the bpy ligands with 4,4'-dimethyl-2,2'-bipyridine (Me_2bpy), in which the substituent methyl groups are electron donating. The same general chemistry was observed, but the rate at which the photo-promoted red form reverted back to the yellow form was seen to increase relative to that of the non-methylated complex; this increase was marginal for the faster reaction (4.4×10^{-3} *cf.* 4.04×10^{-3} s^{-1}; 25 °C) but nearly double for the slower process (2.0×10^{-4} *cf.* 1.1×10^{-4} s^{-1}; 25 °C). It is not known at this stage whether the reasons for the difference are steric or electronic.

We have also observed similar photo-promoted linkage isomerizations for other ligands {such as SCN^- in the complex $[Ru(tpy)(bpy)(SCN)]^+$; tpy = 2,2':6',2''-terpyridine}[23,24] and we will report on these studies in due course.

Conclusions

The photo-induced linkage isomerization of *cis*-$[Ru(bpy)_2(DMSO)_2](PF_6)_2$ was investigated in DMSO solution. The complex contained two *S*-bound DMSO ligands (established in the solid state by X-ray crystallography) and underwent a colour change from yellow to red when irradiated with sunlight or UV light. On the basis of NMR, electronic and IR spectral studies, this was attributed to linkage isomerization from *S*- to *O*-bound DMSO. The complex subsequently slowly reverted to the yellow form in the dark in a two-step process. Kinetic studies, in association with NMR and IR spectral observations, show that these two "dark" reactions are intermolecular and involve an intermediate which is the $[Ru(bpy)_2(S\text{-DMSO})(O\text{-DMSO})]^{2+}$ species.

Experimental Section

Materials: 2,2'-Bipyridine (bpy; Aldrich), 4,4'-dimethyl-2,2'-bipyridine (Me_2bpy; Aldrich) hexafluorophosphoric acid (Aldrich), and dimethyl sulfoxide (DMSO; Aldrich, HPLC grade) were used as received. Nitromethane (BDH) was distilled over anhydrous calcium chloride before use. Trifluoromethanesulfonic acid (3 M) was distilled under vacuum and used in the short term.

Measurements: ^{1}H NMR spectra were recorded on a Varian Unity Inova-300 spectrometer in [D_6]dimethyl sulfoxide solutions at room temperature. Electronic absorption spectra were obtained using a Varian Cary 5E UV/Vis-NIR spectrophotometer in DMSO solution using 1 cm quartz cells. A Varian temperature control system was used to thermostat the kinetic studies. Infrared measurements were carried out on a Perkin−Elmer 1600 series FTIR spectrophotometer using solid KBr pressed plates, or a Presslok solution cell (32 mm diameter), comprising KBr plates and a 0.1 mm Teflon spacer. Elemental microanalyses were performed within the School of Biomedical and Molecular Sciences at James Cook University.

Syntheses: $[Ru(bpy)_2CO_3]\cdot 2H_2O$ and $[Ru(Me_2bpy)_2CO_3]$ were prepared using the literature method.[25]

$[Ru(bpy)_2(DMSO)_2](PF_6)_2$: $[Ru(bpy)_2(CO_3)]\cdot 2H_2O$ (0.05 g, 0.098 mmol) was dissolved in DMSO (0.4 mL) and HPF_6 (6 drops) added to the dark blue solution, which turned yellow. The mixture was stirred for 2 mins. to ensure the reaction went to completion. Ethanol (40 mL) and hexane (20 mL) were then sequentially added to the solution, producing a yellow precipitate. After stirring for twenty mins., the suspension was refrigerated overnight. The bright yellow crystals were collected by vacuum filtration. Yield: 0.066 g, 78%. $C_{26}H_{28}F_{12}N_4O_2P_2RuS_2$ (883.67): calcd. C 33.5, H 3.3, N 6.5, S 7.5; found C 33.7, H 3.1, N 6.3, S 6.9.

$[Ru(bpy)_2(DMSO)_2](CF_3SO_3)_2$: This complex was synthesized as described above except trifluoromethanesulfonic acid was substituted for hexafluorophosphoric acid. Yield: 0.067 g, 79%. $C_{28}H_{28}F_6N_4O_8RuS_4$ (891.86): calcd. C 36.1, H 3.23, N 6.5, S 14.7; found C 36.0, H 3.57, N 6.4, S 14.9.

$[Ru(Me_2bpy)_2(DMSO)_2](PF_6)_2\cdot[(C_2H_5)_2O]$: This compound was synthesized as for the bpy analogue, except $[Ru(Me_2bpy)_2CO_3]$ was used as the precursor. The complex was recrystallized from acetone/diethyl ether. Yield: 0.0606 g, 71%. $C_{32}H_{46}F_{12}N_4O_3P_2RuS_2$ (989.88): calcd. C 38.8, H 4.68, N 5.7; found C 39.0, H 4.71, N 6.1.

X-Ray Cystallographic Structure Determination of $[Ru(bpy)_2(DMSO)_2](CF_3SO_3)_2$: Crystals of $[Ru(bpy)_2(DMSO)_2](CF_3SO_3)_2$ were grown by slow evaporation of an ethanol/hexane solution of the complex. A unique room temperature diffractometer data set (Enraf−Nonius CAD-4 diffractometer; $T \approx 295$ K; monochromatic Mo-K_α radiation, $\lambda = 0.7107_3$Å; $2\theta/\theta$ scan mode) was measured, yielding 12314 independent reflections, 8800 with $I > 3\sigma(I)$

being considered "observed" and used in the large-block least-squares refinements. Anisotropic thermal parameters were refined for all non-hydrogen atoms. Hydrogen atoms were placed in calculated positions and were not refined. Conventional residuals R, R_w on $|F|$ are quoted, statistical weights derivative of $\sigma^2(I) = \sigma^2(I_{diff}) + 0.0004\sigma^4(I_{diff})$ being used. Neutral atom complex scattering factors were employed, and computation was by the XTAL 3.4 program system, implemented by Hall et al.[26] For crystal and refinement details see Table 3.

Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Centre as supplementary publication no. CCDC-134337. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Kinetic Studies: Temperature-dependent kinetic studies were carried out using UV/Vis spectroscopy. Individual spectra of the yellow and red forms were obtained by measurement of a fresh solution of $[Ru(bpy)_2(DMSO)_2](PF_6)_2$ in DMSO (0.0066 g in 25 ml; $c = 3.07 \times 10^{-4}$ M) before and after irradiation for 10 min by sunlight. For the kinetic studies, the above solution of $[Ru(bpy)_2(DMSO)_2](PF_6)_2$ in DMSO was irradiated and the absorption spectra between 700 nm and 350 nm recorded in scan mode at 1 min intervals for 12 min, followed immediately by a cycle period of 15 min intervals for up to 6 h, depending on the temperature. The A_{inf} for both the **R→I** [Red→Intermediate] and **I→Y** [Intermediate→Yellow] reactions were estimated using a correlation program within Microsoft Excel software, and refined iteratively. The reactions were performed in triplicate, and agreement between the three replicates was high (within 5%).

The same procedure was repeated for $[Ru(Me_2bpy)_2(DMSO)_2](PF_6)_2$ at 25 °C.

IR Analysis: Solid state IR analyses were measured using pressed KBr discs (3 mg complex and 60 mg anhydrous KBr). Solution IR spectra (in DMSO) were obtained using a 32 mm Presslok solution cell with a 0.1 mm teflon spacer and KBr windows in absorbance mode, and the DMSO background subtracted. The spectra were recorded before and immediately after irradiation (10 mins. in sunlight). In the latter case, a second spectrum of the solution was recorded 10 mins. later, and a third after an interval of 5 h.

^{1}H NMR Spectoscopic Analysis: The ^{1}H NMR spectra of $[Ru(bpy)_2(DMSO)_2](PF_6)_2$ in $[D_6]$dimethyl sulfoxide solution were recorded on a fresh solution, then immediately after irradiation in sunlight (10 minutes with shaking in the NMR tube), and 5 h after irradiation.

Self-Assembly of Square Molecular Boxes Containing Dirhodium(II,II) Units

Sandra Lo Schiavo,*[a] Gabriella Pocsfalvi,[b] Scolastica Serroni,[a] Paola Cardiano,[a] and Pasquale Piraino*[a]

Keywords: Macrocycles / Dirhodium compounds / Porphyrins / Mass spectrometry

Dirhodium(II,II) based square molecular boxes were easily obtained by reaction of $[Rh_2(form)_2(CF_3COO)_2(H_2O)_2]$ (form = *N*,*N*′-di-*p*-tolylformamidinate) with both linear (terephthalate and oxalate) and angular [5,10-diphenyl-15,20-bis(4-carboxyphenyl)porphyrin] dicarboxylate dianions; liquid secondary ionization mass spectrometry (LSI MS) was used to establish the nuclearity of the new macrocycles. Their electrochemical properties were also investigated.

Introduction

Self-assembly of so-called "molecular squares" by means of appropriate transition metal complexes represents an attractive field of current research owing to their implication in nanotechnology. The molecular squares so far reported are mainly based on *cis*-coordinated square-planar transition metal complexes and rigid or semirigid bidentate ligands as connectors or, alternatively, on *trans* square-planar metal complexes as connectors and bidentate angular units.[1] In any case this synthetic strategy, which requires transition metal complexes with two *cis*- or *trans*-coordinated labile ligands, has been limited to the use of mononuclear transition metal complexes as building blocks.[1] Only recently have molecular squares incorporating dinuclear species as corner units have been reported.[2]

Our experience in the chemistry of dirhodium(II,II) complexes with "lantern" structures led us to plan the synthesis of molecular boxes involving dirhodium(II,II) species. These complexes, in addition to the well-known redox and axial reactivity, may exhibit equatorial reactivity too. In fact, the complex $[Rh_2(form)_2(CF_3COO)_2(H_2O)_2]$ (**1**) (form = *N*,*N*′-di-*p*-tolylformamidinate), characterized by two formamidinate and two trifluoroacetate groups symmetrically bridged in a cisoid arrangement around the Rh_2^{4+} core, exhibits a remarkable lability of the trifluoroacetate groups.[3] This leads to mild conditions for the substitution of neutral bidentate ligands at the equatorial positions without rupture of the cisoid $Rh_2(form)_2$ fragment.[4] Furthermore, complex **1** has been successfully used to synthesize a series of new mixed dirhodium(II,II) derivatives by metathetical reactions with a variety of carboxylates.[5]

These results show that **1** may be able to act as an appropriate precursor of angular building blocks, through the *cis*-$Rh_2(form)_2$ fragment, which is able to produce neutral square molecular boxes in combination with the appropriate dicarboxylate dianions as ligand connectors. The nuclearity of the boxes will depend on the dicarboxylates used: linear dicarboxylates will generate boxes with four $Rh_2(form)_2$ units at the corners, while angular ones will generate boxes with two alternating $Rh_2(form)_2$ units at the corners.

This paper deals with the synthesis and LSI MS (Liquid Secondary Ionization Mass Spectrometry) characterization of the square molecular boxes $[Rh_2(form)_2(tp)]_4$ (tp = terephthalate) (**2**), $[Rh_2(form)_2(ox)]_4$ (ox = oxalate) (**3**) and $[Rh_2(form)_2(porphy\{COO\}_2)]_2$ (**4**) [porphy$(COO)_2$] = 15,20-di-(4-carboxyphenyl)-5,10-diphenylporphyrin] incorporating the $Rh_2(form)_2$ fragment as angular units. These macrocycles represent the first examples of square molecular boxes incorporating dirhodium units as building blocks; while the manuscript was in preparation Cotton et al. anticipated the synthesis of **3**.[2]

More interestingly, looking at the redox properties of porphyrins [porphy$(COO)_2$, E = +1.1 V vs. SCE in 1,2-dichloroethane] and $[Rh_2(form)_2(CF_3COO)_2(H_2O)_2]$ [$E°(Rh_2^{4+}/Rh_2^{5+})$ = +0.59 V vs. SCE in CH_2Cl_2], **2**, **3** and **4** represent examples of multiredox molecular squares. The paper also reports a study of their redox behaviour as well as the luminescence properties of **4**.

Results and Discussion

Synthesis and Characterization

$[Rh_2(form)_2(dicarboxylate)]_4$: Treatment of $[Rh_2(form)_2(CF_3COO)_2(H_2O)_2]$ with an excess of terephthalate (tp) or oxalate (ox) disodium salts results in the formation of $[Rh_2(form)_2(tp)]_4$ (**2**) or $[Rh_2(form)_2(ox)]_4$ (**3**) in good yields. Both the compounds are green stable solids, which we were unable to obtain in a suitable crystalline form. Their solution behaviour and their spectroscopic features closely resemble those of the parent dinuclear species, **1**.[3] IR and proton NMR spectroscopic data unambiguously show that the formamidinate and carboxylate groups are coordinated

in the usual way, namely symmetrically bridged across the Rh_2^{4+} core. The proposed structures for **2** and **3** (Figure 1) were determined by elemental analysis and LSI MS spectrometry. Mass spectrometry using different "soft" ionisation techniques, namely LSI, ESI (electrospray ionisation) and MALDI (matrix assisted laser desorption) is currently used, in the absence of X-ray data, as a powerful tool for establishing the structure of compounds of this type.[1,6]

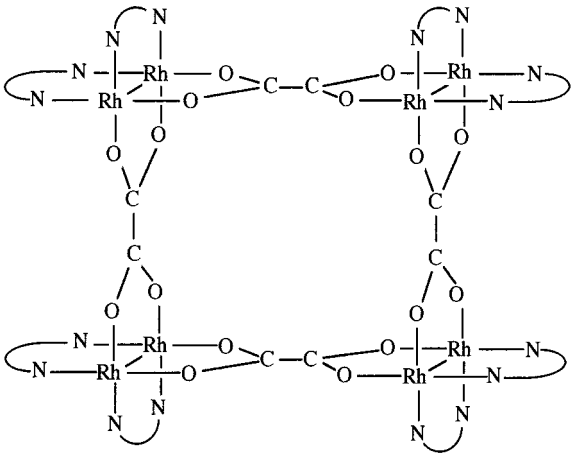

Figure 1. Proposed structure for $[Rh_2(form)_2(ox)]_4$ (**3**)

The positive ion LSI mass spectrum of **2** yields an abundant protonated molecular ion (MH^+) peak at *m/z* = 3265.5 (the *m/z* values reported here are the measured isotopically resolved, ^{12}C-containing, monoisotopic mass-to-charge ratios) corresponding to the expected $[Rh_2(form)_2(tp)]_4H^+$ composition. The loss of one or two hydrogen atoms from MH^+ can be observed with relative abundances of 50 and 15 percent to the monoisotopic molecular ion peak, respectively. This was to be found characteristic of all the three compounds investigated here. The loss of hydrogen is a frequently observed fragmentation process for molecules under conditions of liquid secondary ionization. This determines a difference in the appearance of the isotope peak cluster with respect to that theoretically expected.[7] The spectrum also shows less abundant peaks, with $[Rh_2(form)_2(tp)]_3H^+$ and $[Rh_2(form)_2(tp)]_2H^+$ compositions, at *m/z* = 2449.5 and 1633.3, respectively, which could be indicative of a systematic fragmentation of the molecule upon ionization, or, in the light of recent reports, of the presence of by-products in the sample.[2]

The LSI MS spectrum of **3** results in a base peak at *m/z* = 2961.3 (MH^+), with an isotopic distribution consistent with the expected protonated molecular ion with hydrogen loss. In this case a probe-accurate mass measurement on the MH^+ peak cluster was performed. The exact mass of the monoisotopic molecular ion peak was measured to be 2961.1581 (theoretically calculated mass is 2961.1587 for $C_{128}H_{121}N_{16}O_{16}Rh_8$ with an error of 0.2 ppm) again giving evidence for hydrogen loss. A doubly charged molecular ion (MH_2^{2+}) is also found at *m/z* = 1482.7. Analogously to the spectrum of **2**, peaks with lower abundance, corresponding to $[Rh_2(form)_2(ox)]_2H^+$ and $[Rh_2(form)_2(ox)]_3H^+$, are observed at *m/z* = 1481.2 and 2221.0, respectively.

$[Rh_2(form)_2(dicarboxylate)]_2$: We also turned our attention to self-assembly of the $Rh_2(form)_2$ fragments with functionalized porphyrins which, in the past, have been successfully used both as linear and angular connectors.[8,9] In particular we planned the synthesis of molecular boxes of lower nuclearity by combining two angular building units such as $[Rh_2(form)_2]$ and 15,20-di-(4-carboxyphenyl)-5,10-diphenylporphyrin.

$[Rh_2(form)_2(CF_3COO)_2(H_2O)_2]$ reacts with the disodium salt of 15,20-di-(4-carboxyphenyl)-5,10-diphenylporphyrin affording the complex $[Rh_2(form)_2(porphy\{COO\}_2)]_2$ (**4**) (Figure 2).

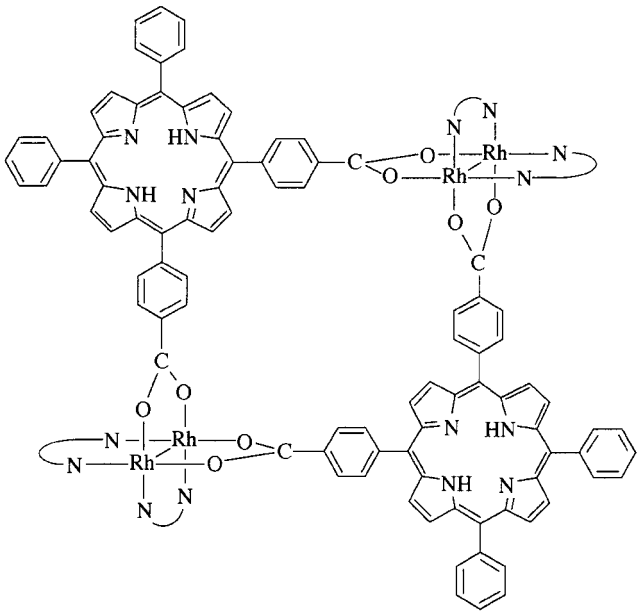

Figure 2. Proposed structure for $[Rh_2(form)_2(porphy\{COO\}_2)]_2$ (**4**)

Compound **4** is a dark red-brown microcrystalline solid very soluble in benzene and chlorinated solvents and sparingly soluble in coordinating solvents. ^1H NMR and IR spectroscopic data were consistent with the proposed structure. Even in this case LSI MS mass spectrometry was employed to assess the nuclearity of **4** (Figure 3). The mass spectrum yields the molecular ion peak (MH^+) at *m/z* = 2705.7, with a good isotopic resolution, as shown in Figure 3. No other significant peak is noted in the spectrum. The slight difference in the measured isotopic distribution with respect to the theoretical pattern of MH^+ rises from the loss of one or two hydrogen atoms from MH^+, as already observed in the mass spectra of **2** and **3**.[7]

Electrochemistry

The electrochemical data for this new family of molecular squares are collected in Table 1, together with those of the parent complex **1**, $[Rh_2(form)_4]$ and the uncoordinated porphy$(COO)_2$ ligand. The cyclic voltammograms of all the compounds are shown in Figure 4.

As shown in Figure 4a, the macrocycle **3** undergoes three reversible oxidations. A cursory look at the data reported

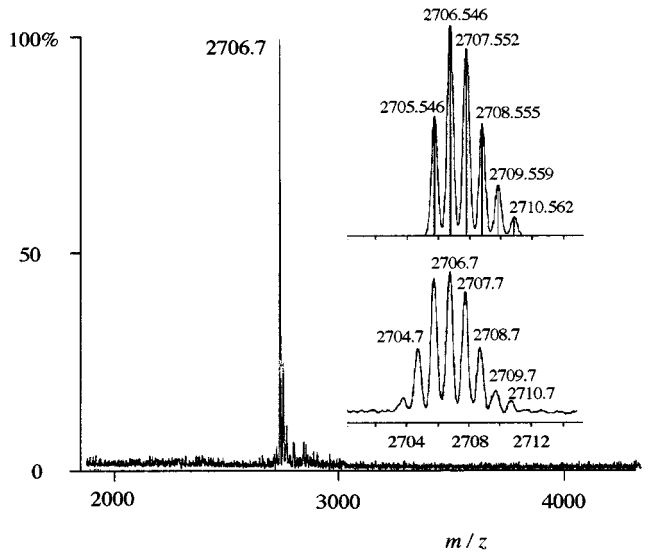

Figure 3. LSI mass spectrum of **4**, including the calculated (top) and experimental (bottom) isotopic distribution of MH^+

Table 1. Redox data; experiments were performed in argon-purged 1,2-dichloroethane solutions; all the processes are reversible except where otherwise noted; the number of exchanged electrons are reported in brackets

Compound	Oxidation (V vs. SCE)[a]		Reduction (V vs. SCE[a])
3	+0.42,[2] +0.57[2]	+1.41[4]	
2	+ 0.43[4]	+1.30[4]	
4	+0.38,[2] +1.11[b]	+1.37[b]	−1.12[2]
1[c]	+0.59[1]	+1.40[1]	
$[Rh_2(form)_4]$[c]	+0.12	+0.95	
$Porphy(COO)_2$[d]	+1.10[b]		−1.18[b]

[a] $E_{1/2}$ values are reported for reversible processes and E_{peak} values are reported for irreversible processes. – [b] Irreversible process. – [c] Data obtained in dichloromethane solution. The two one-electron reversible oxidations of **1** and $[Rh_2(form)_4]$ are due to Rh_2^{4+}/Rh_2^{5+} and Rh_2^{5+}/Rh_2^{6+} processes, respectively.[10] – [d] The oxidation and reduction processes of the uncoordinated porphyrin are centered in the π and π* molecular orbitals of the porphyrin framework, respectively.

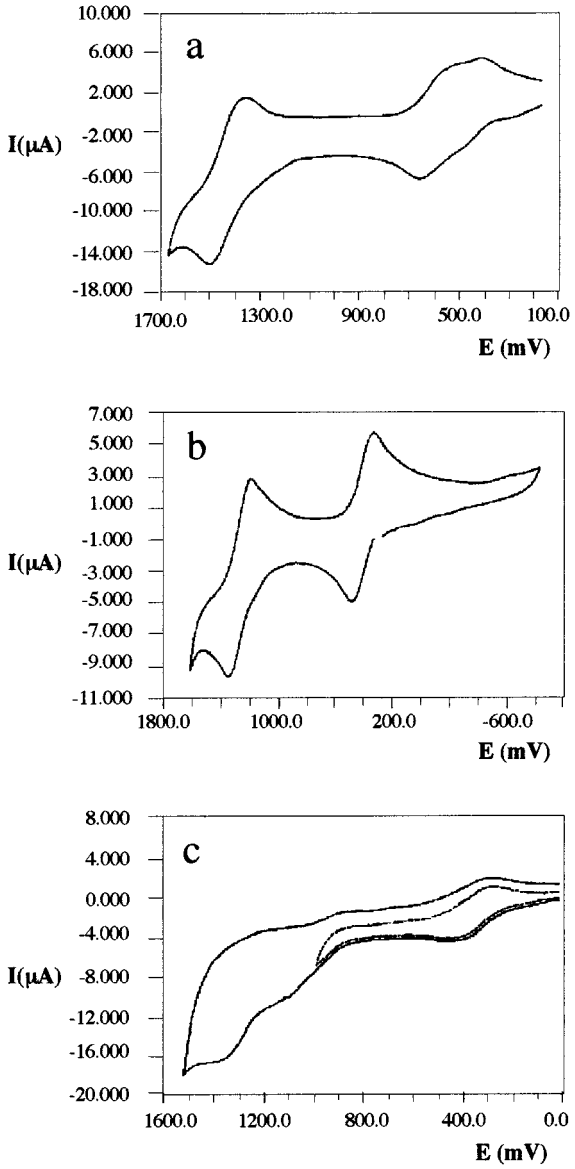

Figure 4. Cyclic voltammograms of **3** (a), **2** (b), and **4** (c); for **4** the CV obtained by scanning the potential up to +1 vs. SCE is also shown to underline the increase of the reversibility of the first process in the absence of the second and third oxidations

in Table 1 allows us to assign the first two anodic processes to the Rh_2^{4+}/Rh_2^{5+} oxidation and the third one to Rh_2^{5+}/Rh_2^{6+}. It is interesting to note that the two bielectronic Rh_2^{4+}/Rh_2^{5+} oxidation processes occur at very close potential values. These anodic processes are shifted to lower potentials with respect to that of **1** and significantly higher with respect to that of $[Rh_2(form)_4]$ as a consequence of the different electron richness of the complexes.[10] Most likely, the first dirhodium units to be oxidized are at opposite corners of the box, with no electronic interaction between them: therefore, the process at +0.42 V is best described as a two simultaneous one-electron process involving noninteracting units.[11] The CV response of **4** (Figure 4c), which does not show splitting of the Rh_2^{4+}/Rh_2^{5+} oxidation processes, supports this suggestion. The following oxidation (+0.57 V) may be assigned to two simultaneous one-electron processes involving the unoxidized Rh_2^{4+} units, whose value is displaced to more positive potential because of the interactions with the nearby Rh_2^{5+} corners. The third oxidation (+1.41 V) can be assigned to four simultaneous one-electron processes involving all the Rh_2^{5+} units and leading to Rh_2^{6+} species. This oxidation pattern suggests that the electronic interaction among Rh_2^{4+} units in the molecular square is larger than that among the Rh_2^{5+} ones.

The CV pattern of **2** (see Figure 4b) resembles that of the parent complex **1** and $[Rh_2(form)_4]$ and is significantly different from **3**. The CV and DPV experiments indicate two quantitatively identical processes, arising from two successive series of four simultaneous one-electron oxidations leading to Rh_2^{5+} and Rh_2^{6+} species, respectively. The decreased interaction between the Rh_2^{4+} units in **2** with respect to **3**, evidenced by the absence of the splitting of the Rh_2^{4+}/Rh_2^{5+} processes, reflects the larger distance between the dirhodium units.

On the basis of the assignment of the CV response given by **2** and **3** and porhy$(COO)_2$, the redox behaviour of **4** appears straightforward (Figure 4c). The first oxidation is reasonably assigned to two simultaneous Rh_2^{4+}/Rh_2^{5+} processes, the second one to the oxidation of both porphyrins, and the third one to the simultaneous Rh_2^{5+}/Rh_2^{6+} oxidation processes of the Rh_2 cores. Although a precise estimation of the exchanged electrons cannot be obtained for the second and third oxidations because of their irreversible nature, an analysis of the intensity of the cathodic peaks suggests that these processes also involve two electrons each. The irreversibility of the Rh_2^{5+}/Rh_2^{6+} process in **4** is probably a consequence of the irreversible porphyrin-based oxidation which precedes such a process. The reduction process of **4** is easily assigned as a porphyrin-based process, on the basis of the reduction behaviour of the uncoordinated porphyrin (Table 1).

Luminescence

Complexes **1**, **2**, and **3** are not emissive in fluid solution at room temperature. On the contrary, however, compound **4** exhibits a room-temperature emission with maxima at $\lambda = 648$ nm and $\lambda = 712$ nm, assigned to the porphyrin units.[12] Interestingly, such an emission is strongly reduced ($\Phi = 7 \times 10^{-5}$; $\tau < 500$ ps, which is the limit of our apparatus) with respect to the free porphyrin emission ($\Phi = 0.017$; $\tau = 10$ ns), although it is spectrally identical. The luminescence decrease can most likely be attributed to reductive electron-transfer quenching of the porphyrin excited state by the dirhodium units. This process is indeed exoergonic, by about 0.4 eV, on the basis of redox and photophysical data.[13] The rate constant of the process, calculated by taking into account the luminescence quantum yields of **4** and the free porphyrin, and the luminescence lifetime of the free porphyrin, is of the order of 10^{11} s^{-1}, in agreement with literature data concerning electron transfer at relatively short distances.[14]

Conclusions

As a final comment we would like to underline that dirhodium(II,II) compounds appear to be suitable substrates for the construction of molecular squares and, by exploiting their well-known axial reactivity, to connect these to form square channels.

Furthermore, besides providing angular building blocks, they may also be used as *exo*-bidentate building blocks linking angular species through their two axial coordination sites. This synthetic strategy opens the way to the construction of a large variety of dirhodium(II,II) based molecular boxes simply varying the angular connectors.

Experimental Section

Materials: The starting complex $[Rh_2(form)_2(CF_3COO)_2(H_2O)_2]$ was prepared according to a published procedure.[3] The 15,20-di-(4-carboxyphenyl)-5,10-diphenylporphyrin was purchased from Mid-Century Company, Illinois. All other chemicals are commercially available and were used as supplied. None of the compounds reported here are air sensitive, but all reactions were carried out under an atmosphere of dry nitrogen. Elemental analyses were performed by REDOX snc Laboratorio di Microanalisi, Cologno Monzese (Milano), Italy.

Apparatus: Infrared spectra were recorded as KBr pellets with a Perkin−Elmer FT 1720X spectrometer. Electronic absorption spectra were recorded on a Perkin−Elmer Lambda 5 UV/Visible spectrophotometer. The NMR measurements were performed with a Bruker AMX 300 spectrometer using standard pulse sequences. Liquid secondary ion mass spectrometry (LSI MS) experiments were carried out on a VG-ZAB-T (Micromass, Wythenshawe, Manchester, U.K.) four-sector mass spectrometer equipped with a 40 kV caesium ion gun. Ionization was achieved by bombardment of 30 keV of caesium ions. Samples were dissolved in chloroform. Mass spectra were obtained employing 1μL of *m*NBA matrix followed by careful addition of 1 μL sample solution on the probe. The spectra were recorded in the positive ion mode at 8 kV accelerating potential. The resolution was set to 2500 (static resolution measured at 5% valley definition), mass range was $m/z = 1500-4200$ with a scan rate 8 s $decade^{-1}$. Ions were detected by a photomultiplier detector and acquisitions were performed in continuum mode using the OPUS V3.1X software. Calibration of the mass scale was carried out on the cluster peaks of CsI. The average error was measured to be less than 0.2 Da for the entire mass range. Probe-accurate mass measurement was performed using a slow linear voltage scanning at 8000 resolution and applying polyethylene glycol as internal calibrant.

Electrochemical measurements were carried out in argon-purged 1,2-dichloroethane at room temperature with a PAR 273 multipurpose equipment interfaced to a PC. The working electrode was a glassy carbon (8 mm^2, Amel) electrode. The counter electrode was a Pt wire, and the quasi-reference electrode was an Ag wire (ferrocene was used as internal standard). The concentration of the complexes was about 5×10^{-4} M. Tetrabutylammonium hexafluorophosphate was used as supporting electrolyte and its concentration was 0.05 M. Cyclic voltammograms were obtained at scan rates of 20, 50, 200, and 500 mV/s. For reversible processes, half-wave potentials (vs. SCE) were calculated as the average of the cathodic and anodic peaks. The criteria for reversibility were the separation between cathodic and anodic peaks, the close to unity ratio of the intensities of the cathodic and anodic currents, and the constancy of the peak potential on changing scan rate. For irreversible processes, the values reported in Table 1 are the peaks estimated by differential pulse voltammetry (DPV). The number of exchanged electrons was measured with differential pulse voltammetry (DPV) experiments performed with a scan rate of 20 mV/s, a pulse height of 75 mV, and a duration of 40 ms. Experimental error on the redox potentials is ± 10 mV.

The luminescence experiments were performed in air-equilibrated dichloromethane solution at 298 K. Luminescence spectra have been obtained with a Jobin Yvon-Spex Fluoromax 2 fluorimeter. The spectra were corrected for detector response. Luminescence lifetimes were measured with an Edinburgh FL 900 time-correlated single-photon-counting spectrometer, with nitrogen discharge as the excitation pulse and using a Marquadt algorithm for pulse deconvolution. Luminescence quantum yields have been calculated by the optically diluted method,[15] using $Ru(bpy)_3^{2+}$ as quantum yield standard ($\Phi = 0.028$) in air-equilibrated aqueous solution.[16]

Experimental uncertainties on luminescence spectra, lifetimes and quantum yields are ± 2 nm, 10%, and 20%, respectively.

Syntheses

$[Rh_2(form)_2(tp)]_4$ (2): To an aqueous solution (40 mL) of disodium terephthalate (0.300 g, 1.43 mmol) was added a chloroform/acetone solution (1:3, 20 mL) of **1** (0.200 mg, 0.218 mol) and the resulting mixture left to stir for ca. 24 h. After this time the organic volatiles were removed on a rotary evaporator and the green solid was collected by filtration, washed several times with warm water and methanol and dried. The crude green solid was then dissolved in $CHCl_3$ (30 mL) and filtered through Celite. Addition of *n*-hexane (20 mL) to the filtrate afforded **2** (0.156 g, 0.048 mmol) as a green precipitate in 88% yield. − $C_{38}H_{34}N_4O_4Rh_2$: calcd. C 55.9, H 4.20, N 6.86; found C 55.64, H 4.30, N 6.88. − IR (KBr): $\nu_{asym}(CO_2)$ = 1620 (s), ν(N−C−N) = 1591 cm^{-1} (s). − UV/Vis ($CHCl_3$): λ_{max} = 520, 630. − LSI MS: *m/z* (%) = 3265.5 (100) [MH^+], 2449.5 (10) [$\{Rh_2(form)_2(tp)\}_3H^+$], 1633.3 (10) [$\{Rh_2(form)_2(tp)\}_2H^+$].

$[Rh_2(form)_2(ox)]_4$ (3): Complex **3** was prepared by following the same procedure as used for **2**. Yield 80%. − $C_{32}H_{30}N_4O_4Rh_2$: calcd. C 51.91, H 4.08, N 7.57; found C 51.95, H 4.44, N 7.26. − IR (KBr): $\nu_{asym}(CO_2)$ = 1626 (s), ν(N−C−N)= 1598 cm^{-1} (s). − UV/Vis ($CHCl_3$): λ_{max} = 625. − ^1H NMR ($CDCl_3$): δ = 2.23 (s, 12 H, CH_3), 6.80 (dd, *J* = 19.4 and 7.9 Hz, 16 H, H_{tol}), 7.41 (t, br, 2 H, N−CH−N). − LSI MS: *m/z* (%) = 2961.2 (100) [MH^+], 1482.7 [MH_2^{2+}], 2221.0 (5) [$\{Rh_2(form)_2(ox)\}_3H^+$], 1481.2 (5) [$\{Rh_2(form)_2(ox)\}_2H^+$].

$[Rh_2(form)_2(porphy\{COO\}_2)]_2$ (4): To a methanol (20 mL) mixture of 15,20-di-(4-carboxyphenyl)-5,10-diphenylporphyrin (0.120 g, 0.171 mmol) was added an aqueous solution (10 mL) of NaOH (0.015 g, 0.375 mmol). The resulting solution was stirred for ca. 30 min and then filtered. A chloroform solution (10 mL) of **1** (0.110 g, 0.121 mmol) was added dropwise to the filtrate and the resulting mixture left to stir for 24 h. During this time **4** was formed as a dark red-brown solid, which was collected by filtration and crystallized from benzene/*n*-heptane. Yield 55%. − $C_{76}H_{58}N_8O_4Rh_2$: calcd. C 67.96, H 4.32, N 8.28; found C 66.21, H 4.58, N 8.48. − IR (KBr): $\nu_{asym}(CO_2)$ = 1620 (m), ν(N−C−N) = 1594 cm^{-1} (s). − UV/Vis ($CHCl_3$): λ_{max} = 419, 515, 549, 589, 644 nm. − ^1H NMR ($CDCl_3$): δ = −2.85 (s, 2 H), 2.23 (s, 12 H), 7.11 (m, 16 H), 7.79 (m, 10 H), 8.23 (m, 8 H), 8.55 (t, br, 2 H), 8.88 (s, 8 H). − LSI MS: *m/z* (%) = 2705.9 (100) [MH^+].

Pentacarbonylhydridochromates $M^+[HCr(CO)_5]^-$: Reactivity in Organic Synthesis and Homogeneous Catalysis

Jean-Jacques Brunet[a]

Keywords: Carbonyl complexes / Hydrido complexes / Homogeneous catalysis / Hydrogenations / Reductions / Chromium

As compared to the main group hydrides (boron, aluminum, ...) and their derivatives, which are very useful *stoichiometric* reagents for selective reductions in organic synthesis, hydrides of transition metals provide the chemist with potential *catalysts* or catalyst precursors. This interesting property is enhanced by the possibility of modifying the coordination sphere, which allows access to a wide variety of hydride complexes with tunable chemical reactivities. Among these, a great variety of carbonylhydridometallates is becoming available and studies of their reactivities continuously appear in the literature. This article reviews the current state of the art as regards the synthesis and reactivity of one of the more promising and versatile carbonylhydridometallates, $[HCr(CO)_5]^-$, the simplest anionic hydride derived from hexacarbonylchromium. Its reactivity in stoichiometric reactions is considered first, and then its generation and involvement as a reactive intermediate in catalytic reactions are reviewed.

1. Introduction

The first preparation of tetracarbonylnickel by Mond in 1890[1] and of pentacarbonyliron by Berthelot[2] and Mond[3] in 1891 are among the first historic landmarks in organotransition metal chemistry.[4] Soon after, extensive work led to the development of the Fischer−Tropsch process[5] and the cobalt-catalyzed oxo process,[6] while many homogeneously catalyzed processes were devised by Reppe's group.[7] Simultaneously, increasing interest in the field of carbonylmetal compounds resulted in the preparation of carbonyl complexes of a large number of transition metals.[8] Subsequently, some derivatives of these carbonylmetal compounds were generated and characterized, including the anionic complexes or "carbonylmetallates". The latter include dianionic carbonylmetallates $[M_x(CO)_z]^{2-}$ {e.g. $[Fe(CO)_4]^{2-}$, the sodium salt of which is commercially available as the Collman reagent[9]} and carbonylhydridometallates $[HM_x(CO)_y]^-$.

From a general point of view, several potential properties of carbonylhydridometallates $[HM_x(CO)_y]^-$ are noteworthy. Firstly, they exhibit reducing properties (as either H^-- or electron-transfer agents). Secondly, they can add to unsaturated carbon−carbon double bonds, generating organometallic derivatives prone to carbon monoxide insertions, thereby allowing access to carbonylated compounds.[10] Last but not least, a great variety of derivatives is a priori available owing to the number of carbonylmetal compounds available. This interest is further increased by the possibility of formally substituting one (or two) carbon monoxide ligand(s), e.g. with phosphanes, or even with chiral phosphanes, giving rise to a wide variety of reagents with tunable reactivities.

Ten years ago, the author published an exhaustive review on the properties and applications in organic synthesis and catalysis of the versatile tetracarbonylhydridoferrates, $M^+[HFe(CO)_4]^-$, which are easily prepared from $Fe(CO)_5$.[11] A further review concerned the coordination chemistry associated with ligand substitution processes in

Jean-Jacques Brunet was born in Clermont-Ferrand, France, in 1945. He attended the Faculté des Sciences and the Ecole Nationale Supérieure de Chimie de Clermont-Ferrand, where he received his Chemical Engineering degree in 1968. He obtained his PhD (These d'Etat) in 1972 at the University of Nancy under the supervision of Pr. P. Caubère. In 1985, he joined the Laboratoire de Chimie de Coordination of the CNRS (Toulouse) where he is one of the ten group leaders. His current research interests lie in organometallic chemistry and homogeneous catalysis directed towards organic synthesis, with some emphasis on both carbonylation reactions and on the functionalization of alkenes by hydroamination.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

$M^+[HFe(CO)_4]^-$.[12] The present review is devoted to the properties and applications in organic synthesis and homogeneous catalysis of the hitherto less well studied pentacarbonylhydridochromates $M^+[HCr(CO)_5]^-$, which are prepared from $Cr(CO)_6$. Some properties of these complexes have already been reported by Darensbourg et al. in 1987 in a more general review dealing with anionic transition metal hydrides.[13]

Hexacarbonylchromium, $Cr(CO)_6$, was first prepared by Job and Cassal in 1927.[14] It is a stable, nonvolatile colorless solid, and is less toxic and easier to handle than the liquid $Fe(CO)_5$.[15] Its synthesis has been improved throughout the years and it is now a commercial product.[8,16] It melts at 130 °C (dec.) and can be purified by sublimation in a static vacuum at 60−70 °C.[17] As in the carbonyliron series, several anionic carbonylchromium complexes are known, including monoanionic carbonylhydridometallates and dianionic carbonylmetallates (Scheme 1).[8]

$[HCr(CO)_5]^-$ $[Cr(CO)_5]^{2-}$

$[HCr_2(CO)_{10}]^-$ $[Cr_2(CO)_{10}]^{2-}$

$[Cr_3(CO)_{14}]^{2-}$

Scheme 1. Main carbonylchromates

The preparation procedures and structural and spectroscopic properties of $[HCr(CO)_5]^-$ salts are summarized below, and then their reactivity in stoichiometric reactions and their involvement in catalytic reactions is considered. The author is obliged to recall that the chemistry of pentacarbonylhydridochromates is largely based on the pioneering work of the groups of M. Y. and D. J. Darensbourg.

2. Preparation Procedures

2.1. Discovery

The first report of an $[HCr(CO)_5]^-$ salt was made by Behrens and Weber in 1957.[18] By protonation of $Na_2Cr(CO)_5$ with an aqueous solution of tris(*o*-phenanthroline)iron(II) sulfate, a crystalline complex could be isolated, which was formulated as $[Fe(o\text{-phen})_3][HCr(CO)_5]_2$ (elemental analysis) [Equation (1) and (2)].

$$Cr(CO)_6 + 2Na \xrightarrow{\text{liq. } NH_3} Na_2[Cr(CO)_5] + CO \quad (1)$$

$$Na_2[Cr(CO)_5] + H_2O \xrightarrow{Fe(phen)_3SO_4} [Fe(C_{12}H_8N_2)_3][HCr(CO)_5]_2 \quad (2)$$

The reaction of $[HCr(CO)_5]^-$ with water was also reported;[18,19] molecular hydrogen was liberated with formation of the hydride-bridged binuclear species $(\mu\text{-}H)[Cr_2(CO)_{10}]^-$, the structure of which was determined later.[20]

It was not until 1981 that salts of $[HCr(CO)_5]^-$ were spectroscopically characterized (IR and ^{1}H-NMR data, vide infra). Darensbourg and Deaton isolated the Et_4N^+ (26% yield) and Ph_4As^+ salts according to the above sequence [Equation (3) and (4)], followed by metathesis with Et_4NBr or Ph_4AsBr.[21]

$$Cr(CO)_6 + Na \xrightarrow{\text{liq. } NH_3} Na_2Cr(CO)_5 \xrightarrow[THF]{\text{recrist.}} [Na(THF)_x]_2Cr(CO)_5 \quad (3)$$

$$[Na(THF)_x]_2Cr(CO)_5 + MeOH \xrightarrow{CH_3CN} [Na][HCr(CO)_5] + MeONa \quad (4)$$

2.2. Preparation Procedures

Three methods have proven successful.

Firstly, a general method based on hydride/labile ligand exchange in Group 6B carbonylmetal derivatives [Equation (5)] has been reported to be feasible for M = Cr (unreported yield).[22]

$$M(CO)_5(pip) + [PPN]^+[BH_4]^- \xrightarrow{THF} [PPN]^+[HM(CO)_5]^- + pip\text{->}BH_3 \quad (5)$$

Secondly, protonation of the mononuclear dianion $[Cr(CO)_5]^{2-}$ has also been developed as a synthetic method [Equation (6) and (7)].[23]

$$Cr(CO)_5(pip) + 2\,Na[C_{10}H_8] \xrightarrow[-78°C]{THF} Na_2[Cr(CO)_5] + pip + 2\,C_{10}H_8 \quad (6)$$

$$Na_2[Cr(CO)_5] + [PPN]^+[I]^- + CH_3OH \xrightarrow[-78°C]{THF} [PPN]^+[HCr(CO)_5]^- + NaI + NaOCH_3 \quad (7)$$

70%

Thirdly, the synthesis of $[HCr(CO)_5]^-$ can be achieved by reaction of hexacarbonylchromium with hydroxide ions. Several preparations have been reported, which differ in the nature of the associated cation.

The reaction of $Cr(CO)_6$ with 2 equiv. of KOH, solubilized by cryptand 222 in THF or CH_3CN, at room temperature has been reported to quantitatively afford the $[HCr(CO)_5]^-$ derivative within minutes, as shown in a simplified manner in Equation (8).[24]

$$Cr(CO)_6 + [K(\text{crypt } 222)]^+[OH]^- \xrightarrow[\text{or } CH_3CN]{THF} [K(\text{crypt } 222)]^+[HCr(CO)_5]^- + CO_2 \quad (8)$$

Phase-transfer of hydroxide ions by a quaternary ammonium salt in a liquid−solid reaction also leads to a rapid synthesis of the $[HCr(CO)_5]^-$ derivative (75% yield), Equation (9).[25] Some amounts (≤ 20%) of the binuclear dianion $[Cr_2(CO)_{10}]^{2-}$ are also formed, which are easily separated by virtue of differences in solubility.

$$Cr(CO)_6 + [Et_4N]^+[HSO_4]^- + 15\ KOH \xrightarrow[60°C,\ 30\ min]{CH_3CN/H_2O} [Et_4N]^+[HCr(CO)_5]^- \quad (9)$$

The potassium salt $[K]^+[HCr(CO)_5]^-$ can be prepared by treatment of $Cr(CO)_6$ with KOH (7 equiv.) in a THF/MeOH/H_2O solvent mixture. Yields are in the range

60−70%, but the selectivity $[HCr(CO)_5]^-/[HCr_2(CO)_{10}]^-$ is seemingly difficult to control. Both the water content and the temperature are important factors.[26]

More recently, a rapid and useful preparation of $[K]^+[HCr(CO)_5]^-$ has been reported, which is carried out in a CH_2Cl_2/EtOH solvent mixture at room temperature [Equation (10)].[27] The advantages of this procedure are its high reproducibility (70−78% yield from each of 30 runs) and the fact that only 2 equiv. of KOH are needed, in accordance with the stoichiometry.

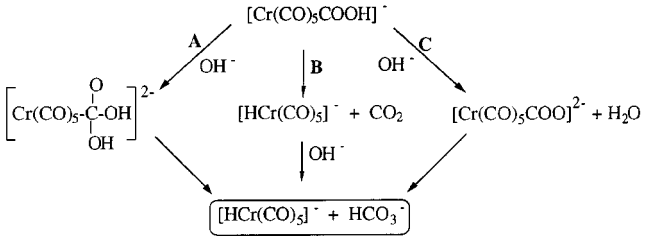
$$Cr(CO)_6 + 2\ KOH \xrightarrow[\text{RT, 10 min}\ \text{evaporation}]{CH_2Cl_2\text{-}EtOH} [K]^+[HCr(CO)_5]^- + KHCO_3 \quad (10)$$

70-78%

Some amounts of the bridged binuclear hydride $[K]^+[HCr_2(CO)_{10}]^-$ are also formed, which are easily eliminated (together with $KHCO_3$) by filtration of a THF solution. The purity of the thus formed potassium pentacarbonylhydridochromate can easily be verified by ^{1}H-NMR analysis since the chemical shifts of the monomeric and dimeric carbonylmetal hydrides are very different (vide infra, Table 2).

It must be noted that the chemistry of carbonylhydridochromates is characterized by the fact that the dimeric carbonylhydridochromate, $(\mu\text{-H})[Cr_2(CO)_{10}]^-$, acts as a thermodynamic sink. The monomeric hydride, $[HCr(CO)_5]^-$, reacts readily with traces of H^+ to yield the binuclear hydride according to Equation (11)−(13).

$$[HCr(CO)_5]^- + H^+ \longrightarrow H_2Cr(CO)_5 \quad (11)$$



$$H_2Cr(CO)_5 \longrightarrow H_2 + Cr(CO)_5 \quad (12)$$

$$Cr(CO)_5 + [HCr(CO)_5]^- \longrightarrow (\mu H)[Cr_2(CO)_{10}]^- \quad (13)$$

As in the case of $Mo(CO)_6$ and $W(CO)_6$, the mechanism of the reaction of OH^- with $Cr(CO)_6$ is thought to involve a transient metallocarboxylic acid species [Equation (14)].[28]

$$Cr(CO)_6 + OH^- \longrightarrow [Cr(CO)_5COOH]^- \quad (14)$$

Considering the stoichiometry (2 equiv. OH^-) necessary to obtain complete conversion of the hexacarbonylmetal compound, different reaction pathways have been proposed (Scheme 2).[29]

Scheme 2. Mechanisms for the formation of $[HCr(CO)_5]^-$

In aprotic media, pathway A is considered to be the most likely, whereas pathway C should become important in aqueous alcoholic systems.[29] A different mechanism has been proposed for the in situ generation of $[HCr(CO)_5]^-$ under thermal WGSR (water gas shift reaction) conditions, i.e. under CO pressure in basic $MeOH/H_2O$ solutions at elevated temperature, as well as under photocatalyzed WGSR conditions (vide infra).

3. Main Structural and Spectroscopic Properties

3.1. Structure in the Solid State

The first solid-state characterization of a $[HCr(CO)_5]^-$ salt was performed on $[Ph_4P]^+[HCr(CO)_5]^-$.[30] The complex was found to exhibit a pseudooctahedral geometry (Figure 1), with a small *trans* effect of the hydride ligand being evident, the $Cr-C_{trans}$ distance being slightly shorter than the $Cr-C_{cis}$ distance [1.852(4) Å vs. 1.865(4) Å]. The hydride ion is located 1.66(5) Å from the chromium atom. The equatorial carbon monoxide ligands are at 90° angles to one another, but the $(CO)_{eq}-(CO)_{ax}$ bond angle is 95.4°, indicating a substantial bending of the equatorial CO ligands towards the hydride ligand. Nevertheless, this bending is less pronounced than that observed for the equatorial CO ligands in the distorted trigonal bipyramid of $[HFe(CO)_4]^-$, for which the $(CO)_{eq}-(CO)_{ax}$ bond angle is 99.1°.[31]

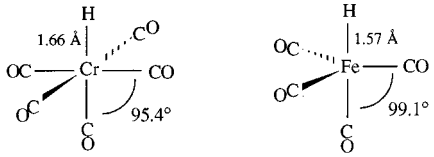


Figure 1. Comparison of solid-state geometries of $[HCr(CO)_5]^-$ and $[HFe(CO)_4]^-$

γ-Irradiated single crystals of $[PPN]^+[HCr(CO)_5]^-$ exhibit persistent anisotropic EPR spectra attributable to the free radical ($S = {}^1/_2$) anion $[Cr(CO)_5]^-$. Measurements of the *g* value and hyperfine interaction anisotropies in crystallographically aligned single crystals at 77 K are consistent with a square-pyramidal geometry for the radical.[32]

3.2. Spectroscopic Properties

3.2.1. Infrared Spectroscopy

It is well known that infrared spectroscopy is particularly useful for analyzing solutions of carbonylmetal compounds and their derivatives. The case of carbonylhydridometallates has been thoroughly studied by Darensbourg et al., whereby evidence for ion-pairing effects was found.[13]

As in the case of similar carbonylhydridometallates, e.g. $[HFe(CO)_4]^-$, no ν(M−H) band is observed. The IR spectrum of $Na^+[HCr(CO)_5]^-$ consists of one strong band (E vibration mode) at 1884 cm^{-1} (four equatorial CO ligands), one medium band ($A_1{}^1$) at 1854 cm^{-1} (CO *trans* to the hydride) with a shoulder at 1894 cm^{-1}, a weak band at 1814

cm^{-1}, and finally a very weak band at 2016 cm^{-1}.[33] Addition of HMPA to a THF solution leads to the disappearance of the band at 1814 cm^{-1} and of the shoulder at 1894 cm^{-1} (with a concomitant increase in the intensity of the 1884 cm^{-1} band), eventually giving the same spectrum as that of $PPN^+[HCr(CO)_5]^-$ (see Table 1).

Table 1. Infrared data for $[M]^+[HCr(CO)_5]^-$

M^+	Solvent	$\tilde{\nu}$(CO) [cm^{-1}] A_1^2 (vw)	E (s)	A_1^1 (m)	Ref.
Li^+	THF	2016	1885	1857	[33]
Na^+	THF	2016	1884 (1894 sh)	1854 (1814 w)	[33]
Na^+/HMPA	THF	2016	1884	1856	[33]
PPN^+	THF	2016	1884	1856	[22]
Et_4N^+	THF	2023	1892	1860	[21]
Ph_4As^+	THF	2020	1889	1860	[21]
[K-crypt]$^+$	CD_3CN	2023	1888	1857	[29]

These observations can be taken as evidence that reversible contact ion pair formation is responsible for the spectral changes. Furthermore, a change in the intensity of the A_1^1 band (CO *trans* to the hydride) has been interpreted in terms of site-specific interaction of the sodium cation with the *axial* CO oxygen atom. It must be noted that in the case of $Na^+[HFe(CO)_4]^-$ evidence has been found for a similar site-selective interaction with an *equatorial* CO oxygen atom (Figure 2).[13]

3.2.2. NMR Spectroscopy

The ^1H- (and ^2H-) NMR chemical shifts of $[HCr(CO)_5]^-$ salts invariably appear at $\delta \approx -7$ and differ considerably from those of the bridged binuclear hydride $[HCr_2(CO)_{10}]^-$ salts ($\delta \approx -20$) (Table 2). This difference is much larger than that between the corresponding mononuclear and binuclear carbonylhydridoferrates [e.g. $NaHFe(CO)_4$: $\delta_H = -8.74$; $NaHFe_2(CO)_8$: $\delta_H = -8.47$].[11]

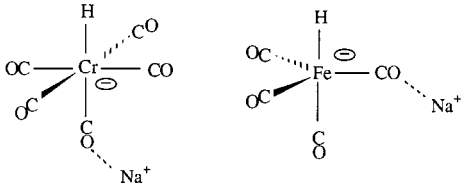

Figure 2. Comparison of Na^+ interactions in solution

Table 2. ^1H-NMR data for $[M]^+[HCr(CO)_5]^-$ and $[M]^+[HCr_2(CO)_{10}]^-$

Compound	Solvent	δ	Ref.
$[Li]^+[HCr(CO)_5]^-$	$[D_8]THF$	−6.80	[33]
$[Na]^+[HCr(CO)_5]^-$	$[D_8]THF$	−6.75	[33]
$[K]^+[HCr(CO)_5]^-$	$[D_8]THF$	−6.7	[26][27]
$[PPN]^+[HCr(CO)_5]^-$	$[D_8]THF$	−6.73	[13][33]
$[PPN]^+[HCr(CO)_5]^-$	CD_3CN	−6.92	[22]
$[Et_4N]^+[HCr(CO)_5]^-$	CD_3CN	−7.0	[21][25]
$[Ph_4As]^+[HCr(CO)_5]^-$	CD_3CN	−7.0	[21]
$[K(crypt)]^+[HCr(CO)_5]^-$	CD_3CN	−7.0	[29]
$[Na]^+[HCr_2(CO)_{10}]^-$	$[D_8]THF$	−19.17	[13][34]
$[K]^+[HCr_2(CO)_{10}]^-$	$(CD_3)CO$	−19.10	[35]
$[K]^+[HCr_2(CO)_{10}]^-$	$[D_8]THF$	−19.53	[27]
$[Et_4N]^+[HCr_2(CO)_{10}]^-$	$[D_8]THF$	−19.47	[13][34]
$[PPN]^+[HCr_2(CO)_{10}]^-$	$[D_8]THF$	−19.50	[36]

A theoretical study aimed at rationalizing the ^1H-NMR chemical shifts of these and other low-valent transition metal hydrides has recently been reported.[37] Calculations based on density functional theory and gauge-including atomic orbitals (DFT-GIAO) were in good agreement with experimental data. The negative "hydridic" shift observed for transition metal hydrides $H-ML_n$ was attributed to a paramagnetic current present in the adjacent ML_n fragment.

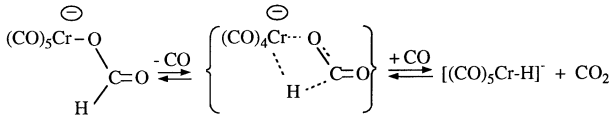
The ^{13}C-NMR spectrum of $[PPN]^+[HCr(CO)_5]^-$ under ambient conditions is indicative of a $CO_{cis}-CO_{trans}$ intramolecular exchange process.[22] Thus, at room temperature in CD_3CN, the five CO ligands are apparently equivalent, giving rise to just one signal (at $\delta = 228.7$), whereas at temperatures below 0 °C, two signals are observed, corresponding to four equatorial CO ligands ($\delta = 227.9$) and one axial CO ligand ($\delta = 235.1$). The same phenomenon has been observed for the $[K(crypt)]^+[HCr(CO)_5]^-$ derivative.[29]

4. Reactivity in Stoichiometric Reactions

4.1. Reactions with CO_2, CS_2, and COS

The reaction of $[HCr(CO)_5]^-$ with carbon dioxide has been studied in the context of the water gas shift reaction [Equation (15)].[38]

$$CO + H_2O \rightleftharpoons CO_2 + H_2 \quad (15)$$



$[K(crypt\ 222)]^+[HCr(CO)_5]^-$ readily reacts with carbon dioxide or carbon disulfide in THF or CH_3CN to yield the corresponding pentacarbonylchromium formate or thioformate [Equation (16)].[24]

$$[HCr(CO)_5]^- + CX_2 \rightleftharpoons [HC(X)XCr(CO)_5]^- \quad (16)$$

The formato derivative (X = O) was shown to be identical to that prepared by the more conventional route [Equation (17)].[39]

$$[PPN]^+[Cr(CO)_5Cl]^- + TlOOCH \xrightarrow{CH_2Cl_2} [PPN^+[HC(O)OCr(CO)_5]^- + TlCl \quad (17)$$

As compared to the tungsten analogue, the pentacarbonylchromium formate exhibits two main characteristics. Firstly, it is readily decarboxylated (25−50 °C) with regeneration of $[HCr(CO)_5]^-$, and secondly, it undergoes rapid CO ligand exchange with free ^{13}CO in solution (80% incorporation within 10 min at room temp.). These observations suggest that CO lability is a requisite step for the rupture of the C−H bond of the formate ligand, leading to decarboxylation and regeneration of $[HCr(CO)_5]^-$ (Scheme 3).[24,29,40]

Scheme 3. Mechanism for the decarboxylation of $[HC(O)OCr(CO)_5]^-$

The reaction with COS proceeds instantaneously in CH_3CN, giving the addition product in which the thioformate ligand is bound to the $[Cr(CO)_6]$ moiety through its sulfur atom [Equation (18)]. This mode of binding has been established by X-ray diffraction analysis of the $[PPN][HC(O)SCr(CO)_5]$ derivative.[29,40]

$$[HCr(CO)_5]^- + COS \xrightarrow{CH_3CN} [HC(O)SCr(CO)_5]^- \quad (18)$$

Alternatively, the pentacarbonylchromium thioformate may be obtained quantitatively by reaction of the formate derivative with COS, Equation (19).[40]

$$[HC(O)OCr(CO)_5]^- + COS \xrightarrow[12h]{CH_3CN} [HC(O)SCr(CO)_5]^- + CO_2 \quad (19)$$

In contrast to its formate analogue, the thioformate complex shows no tendency for COS expulsion (owing to the greater strength of the Cr−S bond) and does not undergo ligand exchange with CO_2 or CS_2. Reaction according to Equation (19) is thus irreversible.

Ab initio calculations seem to indicate that the insertion of CO_2 into the H−Cr bond of $[HCr(CO)_5]^-$ involves an acid−base adduct (η^1-C coordination of CO_2 to the hydride), which is more stable than the reactants. The reaction pathway probably then involves a low-energy cost rearrangement into the η^2-O,H formate structure coupled with simultaneous CO dissociation.[41]

An extension of this facile insertion of CO_2 into $[HM(CO)_5]^-$ led to the catalytic synthesis of alkyl formates (vide infra, Part 5).

4.2. Reaction with Acyl Chlorides

Group 6B transition metal hydrides $[HM(CO)_4L]^-$ (M = Cr, W; L = CO or PR_3) exhibit the interesting property of reducing acyl chlorides to aldehydes without further reduction to the corresponding alcohols [Equation (20)].[42] Such selective reductions have previously been observed using $[HFe(CO)_4]^-$ [43] and $[CpV(CO)_3H]^-$.[44]

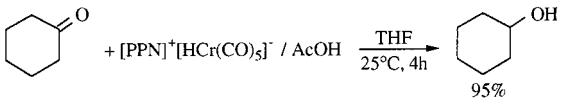
$$[PPN]^+[HCr(CO)_5]^- + RCOCl \xrightarrow[25°C]{THF} \underset{90\text{-}95\%}{RCHO} + [PPN]^+[ClCr(CO)_5]^- \quad (20)$$

These reactions are almost quantitative for both aliphatic and aromatic acyl chlorides under mild conditions. Competitive experiments involving the reduction of $PhCH_2COCl$ indicated the reactivity order: $[HW(CO)_5]^- > [HCr(CO)_5]^- > [HFe(CO)_4]^-$, which parallels their hydride-transfer abilities, as established for the reduction of non-hindered alkyl halides (vide infra).[45] Furthermore, it is noteworthy that the reductions with $[HCr(CO)_5]^-$ can be performed in the presence of other reducible functional groups such as aryl bromides, alkyl bromides, or nitroaromatics. For example, 4-bromobutyraldehyde may be obtained in 95% yield from the corresponding acyl chloride. Reduction of the bromo group requires a second equivalent of $[HCr(CO)_5]^-$.

The reagent is also useful for the delivery of deuterium to the aldehydic carbon to give RCDO-type products. Indeed, taking advantage of the facile H/D exchange with CH_3OD of the $[PPN]^+$ salt, Equation (21), the reduction of benzoyl chloride with the reagent prepared in situ from $[PPN]^+[HCr(CO)_5]^-$ and CH_3OD (2-fold molar excess) in THF affords PhCDO [Equation (22)].[46]

$$[PPN]^+[HCr(CO)_5]^- + CH_3OD \rightleftharpoons[THF] [PPN^+[CDCr(CO)_5]^- + CH_3OH \quad (21)$$

$$PhCOCl + [PPN]^+[HCr(CO)_5]^- \xrightarrow[THF]{CH_3OD} PhCDO \quad (22)$$



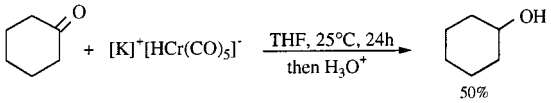
4.3. Reaction with Aldehydes and Ketones

In the course of their study on the selective reduction of acyl halides, Darensbourg et al. also discovered that $[HCr(CO)_5]^-$ is an effective reducing agent for aldehydes *under acidic conditions*.[42] Further studies allowed a determination of the scope and limitations of the stoichiometric reduction of aldehydes and ketones.[47]

$[PPN]^+[HCr(CO)_5]^-$ reacts rapidly with paraformaldehyde in THF (as shown by IR analysis) to yield methanol (98%, 0.5 h) after hydrolysis with a Brønsted acid (AcOH or H_2O). With propionaldehyde or benzaldehyde, only a sluggish reaction is observed. In contrast, rapid reductions to 1-propanol (98%, 1 h) and benzyl alcohol (90%, 1 h) are observed when the reactions are conducted in the presence of acetic acid [Equation (23)].[47]

$$RCHO + [PPN]^+[HCr(CO)_5]^- \xrightarrow[THF]{AcOH} RCH_2OH + [PPN]^+[AcOCr(CO)_4]^- \quad (23)$$
$$R = C_2H_5, C_6H_6$$

Ketones show no reaction with $[PPN]^+[HCr(CO)_5]^-$. However, in the presence of acetic acid, a range of ketones do react at room temperature in THF, cyclohexanone being more easily reduced [95%, 4 h, Equation (24)] as compared to acetophenone (45%, 72 h) and norbornanone (50%, 8 h, *endo* alcohol).



(24)

Where long reaction times are required, a drawback arises from decomposition of the reagent through H_2 elimination [Equation (25)].

$$[HCr(CO)_5]^- + AcOH \longrightarrow H_2 + [AcOCr(CO)_5]^- \quad (25)$$

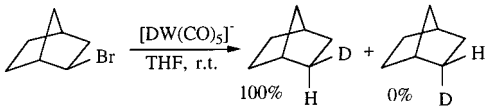
With regard to the reaction mechanism, it has been shown that the reductions are not affected by the presence of an excess of the CO ligand (saturated THF solution). It was thus proposed that the ketone carbonyl group must be activated (H^+ assistance) towards nucleophilic attack by $[HCr(CO)_5]^-$. Similar K^+ assistance has been demonstrated for the reduction of ketones by hydrido(phosphane)ruthenate complexes.[48]

These conclusions are relevant to the recent observation that, in contrast to the $[PPN]^+$ salt, the potassium salt $[K]^+[HCr(CO)_5]^-$ does react with cyclohexanone *in the absence* of acid.[49] The stoichiometric reaction of $[K]^+[HCr(CO)_5]^-$ with cyclohexanone at room temperature in THF leads, after hydrolysis, to cyclohexanol (50% yield, 24 h) [Equation (26)].

(26)

However, the yield could not be increased by using longer reaction times (120 h). Spectroscopic analysis of the reaction medium prior to hydrolysis indicated that free cyclohexanol was already present. These observations were rationalized in terms of the consumption of $[HCr(CO)_5]^-$ by in situ reaction with an intermediate alkoxochromate, $[RR'CHOCr(CO)_5]^-$,[50] yielding cyclohexanol and $[Cr_2(CO)_{10}]^{2-}$. As previously proposed by Marko et al. (vide infra),[51] $[HCr(CO)_5]^-$ is thus believed to act both as a hydride and a proton donor. These hypotheses have been used to design a system for the catalytic reduction of ketones in the presence of a hydrogen-transfer agent $[KHCr(CO)_5/HCO_2H/Et_3N]$ (vide infra, Part 5).[49]

4.4. Reaction with Organic Halides



Darensbourg et al. reported a thorough study of the reactivities of anionic transition metal (Groups 6B and 8) hydrides.[52] They compared the reactivities of $[HM(CO)_4L]^-$ compounds (M = Cr, W; L = CO, PR_3) with those of $[HM(CO)_3L]^-$ analogues (M = Fe, Ru; L = CO, PR_3) in the reduction of primary, secondary, and tertiary alkyl halides. For the reaction with *n*BuBr, the following reactivity order was established [P = $P(OMe)_3$]:

$[HW(CO)_4P]^- > [HCr(CO)_4P]^- > [HW(CO)_5]^- > [CpV(CO)_3H]^- > [HCr(CO)_5]^- > [HRu(CO)_4]^- >$ *trans*-$[HFe(CO)_3P]^- >> [HFe(CO)_4]^-$ (no reaction)

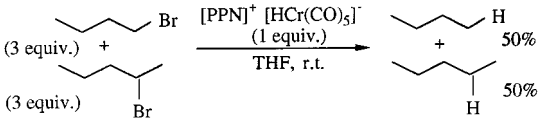
This order compares well with the well-known nucleophilicity scale devised by Dessy, Pohl, and King for the series of simple transition metal carbonyl anions:[53]

$[CpFe(CO)_2]^- > [CpRu(CO)_2]^- > [CpNi(CO)]^- > [Re(CO)_5]^- > [CpW(CO)_3]^- > [Mn(CO)_5]^- > [CpMo(CO)_3]^- > [CpCr(CO)_3]^- > [Co(CO)_4]^-$

The Group 6B hydrides are efficient hydride-transfer agents towards a wide variety of C−X bonds, including tertiary centers and aromatic C−X bonds.[52] Interestingly, from a synthetic point of view, they tolerate the presence of functionalities such as nitro groups, ketones, and aldehydes. The convenient in situ method for H/D exchange allows deuterium labelling of the resulting alkane without isolation of the transition metal deuteride [Equation (27)].

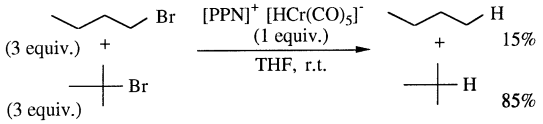
(27)

The propensity for H^- transfer (vs. the SET process) could also be correlated with the propensity for $Na^+\cdots HM^-$ interaction (vs. the tendency for $Na^+\cdots OC-M^-$ interaction), whereby a useful general scale was established:



Increasing propensity for H^- transfer:

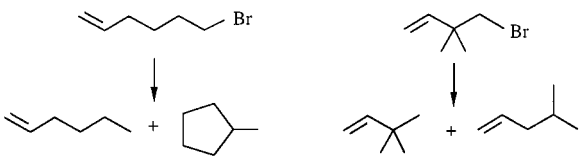
$[HFe(CO)_4]^- \rightarrow [HV(CO)_3]^- \rightarrow [HCr(CO)_5]^- \rightarrow [HW(CO)_5]^- \rightarrow [HCr(CO)_4P(OMe)_3]^- \rightarrow [HW(CO)_4P(OMe)_3]^-$.



Increasing propensity for SET processes:

$[HW(CO)_4P(OMe)_3]^- \rightarrow [HCr(CO)_4P(OMe)_3]^- \rightarrow [HW(CO)_5]^- \rightarrow [HCr(CO)_5]^- \rightarrow [HV(CO)_3]^- \rightarrow [HFe(CO)_4]^-$.

As can be seen, $[HCr(CO)_5]^-$ is placed in the middle of the scale. As a matter of fact, it reacts almost equally well with primary, secondary, and tertiary alkyl bromides. However, in competition experiments it exhibits a preference for tertiary alkyl bromides [Equation (28) and (29)]. No coupling (R−R) or elimination products could be detected.[52]



(28)

(29)

A still more interesting quantitative assessment of the competing pathways (ionic H^- transfer, S_N2, vs. radical chain mechanism, S_H2) was achieved by studying the reaction of $[HM(CO)_5]^-$ complexes with two mechanistic probes, namely 6-bromo-1-hexene and 4-bromo-3,3-dimethyl-1-butene (Scheme 4).[54]

Scheme 4. Possible reduction products from mechanistic probes

Computation of the results indicated the relative contributions of the S_N2 and S_H2 mechanisms given in Table 3.

Table 3. Relative contributions of S_N2 and S_H2 mechanisms to the reactivity of hydridometallates

Hydridometallate	S_H2 vs. S_N2 participation
$[PPN]^+[HCr(CO)_5]^-$	10% S_H2, 90% S_N2
$[PPN]^+[HW(CO)_5]^-$	0.3% S_H2, 99.7% S_N2
$[PPN]^+[HW(CO)_4P(OMe)_3]^-$	0.03% S_H2, 99.97% S_N2

Interestingly, this work also pointed out that the unrearranged reduction products arise from *both* hydride displacement of Br^- (S_N2 path) and direct trapping of the unrearranged radical $R^\cdot$ (S_H2 path).

4.5. Reactivity Towards C=C Double Bonds

No reaction was observed on stirring a THF solution of $[Et_4N]^+[HCr(CO)_5]^-$ at 50 °C under 1 atm of ethylene for 3−4 h.[21]

The reaction of $[PPN]^+[HCr(CO)_5]^-$ with a large excess of acrylonitrile results in quantitative formation of the stable insertion complex, together with large amounts of polymeric materials [Equation (30)]. The regioselectivity of the reaction was ascertained by IR, ^1H- and ^{13}C-NMR spectroscopy.[55]

$$[PPN]^+[HCr(CO)_5]^- + CH_2{=}CH\text{-}CN \xrightarrow[(20\ equiv.)]{THF} CH_3CH(CN)[PPN]^+Cr(CO)_5^- \quad (30)$$

The course of this reaction is unaffected if it is performed under CO (1 atm). Furthermore, the observed second-order kinetics and activation parameters are consistent with an associative hydride-transfer process. For the above reaction, the reactivity order of comparable hydrides $\{[HCr(CO)_5]^- < [HW(CO)_5]^- < [HW(CO)_4P(OMe)_3]^-\}$ is the same as that found for the hydride/halide displacement reactions with organic halides (vide supra).[54]

The reaction of $KHCr(CO)_5$ with *stoichiometric* amounts of α,β-unsaturated ketones and esters has recently been studied.[56] The reaction with mesityl oxide was found to proceed rapidly (within 30 min) at room temperature to selectively afford the corresponding saturated ketone without significant formation of high molecular weight products [Equation (31)]. In this reaction, $KHCr(CO)_5$ proved to be much more reactive than $KHFe(CO)_4$ or $KHCr_2(CO)_{10}$.[49]

$$Me_2C{=}CH\text{-}C(=O)Me + KHCr(CO)_5 \xrightarrow[then\ H_3O^+]{THF,\ r.t.,2h} Me_2CH\text{-}CH_2\text{-}C(=O)Me \quad (31)$$

Methyl acrylate was also found to be rapidly reduced, yielding methyl propionate within 10 min (90% yield). However, in several cases the α,β-unsaturated ketones and esters were only partially reduced to the saturated ketones and high molecular weight products were generated. Interestingly, in the case of methyl acrylate, dimethyl fumarate, and dimethyl maleate, analysis of the reaction mixture prior to hydrolysis revealed the presence of the insertion product (^1H and ^{13}C NMR) [Equation (32)].[56]

$$[K]^+[HCr(CO)_5]^- + CH_2{=}CH\text{-}C(O)OMe \xrightarrow{THF} CH_3CH(C(O)OMe)[K]^+Cr(CO)_5^- \quad (32)$$

4.6. Reactivity Towards C=N Bonds of Imines

Further to their study on the catalytic hydrogenation of imines in MeOH (vide infra, Part 5), Marko et al. reported the stoichiometric reactivity of $[Et_4N]^+[HCr(CO)_5]^-$ towards benzylideneaniline in aprotic solvents.[57]

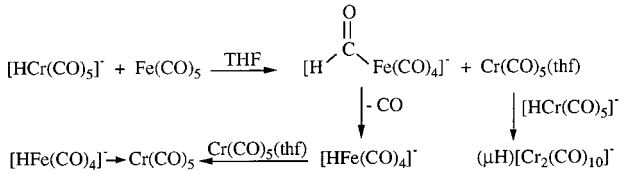
In MeCN solution, $[Et_4N]^+[HCr(CO)_5]^-$ was found to react with *N*-benzylideneaniline at 75 °C under argon to yield the corresponding amine. Since the conversion did not exceed 50% and IR analysis indicated that the mononuclear hydride had been completely transformed into $[Cr_2(CO)_{10}]^{2-}$, the overall reaction was formulated as shown in Equation (33).[57] Under the same conditions, the binuclear hydride $[Et_4N]^+[HCr_2(CO)_{10}]^-$ proved to be practically inert.

$$PhCH{=}NPh + 2\ [HCr(CO)_5]^- \xrightarrow[75°C]{MeCN} PhCH_2NHPh + [Cr_2(CO)_{10}]^{2-} \quad (33)$$

Although the intermediate addition complex could not be observed experimentally, it was formulated as $[PhCH_2N(Ph)Cr(CO)_5]^-$. In the second step, $[HCr(CO)_5]^-$ may act as a proton donor, affording benzylaniline and the dianionic complex $[Cr_2(CO)_{10}]^{2-}$ in situ.

4.7. Miscellaneous

4.7.1. Reaction with Diselenides



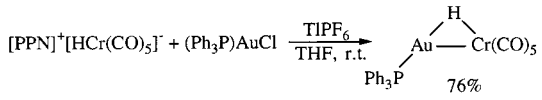
$[PPN]^+[HCr(CO)_5]^-$ reacts with dimethyl (or diphenyl) diselenide by nucleophilic cleavage of the Se−Se bond to yield the corresponding anionic chromium selenate complex [Equation (34)].[58]

$$[PPN]^+[HCr(CO)_5]^- + MeSeSeMe \xrightarrow[r.t.]{THF} \underset{96\%}{[PPN]^+[MeSeCr(CO)_5]^-} + MeSeH \quad (34)$$

4.7.2. Reaction with Electrophilic Metal Carbonyls

As part of their studies on the hydride-transfer abilities of anionic transition metal hydrides, Darensbourg et al. reported the reaction of $[HCr(CO)_5]^-$ with $Fe(CO)_5$.[59]

Whereas no reaction occurs upon mixing $[HFe(CO)_4]^-$ with $Cr(CO)_6$ (THF, room temp.), the reaction of $[HCr(CO)_5]^-$ with $Fe(CO)_5$ yields products resulting from hydride transfer. The formation of the observed products was rationalized on the basis of an ionic mechanism (Scheme 5).

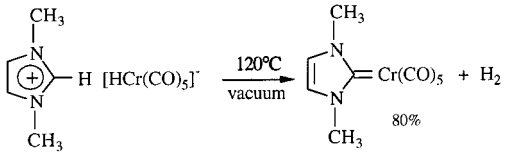


Scheme 5. Reaction of $[HCr(CO)_5]^-$ with $Fe(CO)_5$

The intermediate iron formyl complex, $[(CO)_4FeCHO]^-$, was identified on the basis of its IR and NMR characteristics.[60,61]

4.7.3. Reaction with Au^I and Ag^I Complexes

The reaction of $[HCr(CO)_5]^-$ with the gold(I) complex $(Ph_3P)AuCl$ leads to the formation of a hydrido-bridged heterobimetallic complex [Equation (35)], which has been subjected to single-crystal X-ray diffraction analysis. The three-center two-electron bond is characterized by the following distances: Au−H = 1.72(11) Å, Cr−H = 1.64(12) Å, Au−Cr = 2.770(2) Å.[62]



(35)

Similarly, reaction with $(Me_3P)AgI$ yields $(Me_3P)(\mu\text{-}H)AgCr(CO)_5$ in 65% yield.

4.7.4. Reaction with Imidazolium Cations

In 1968, Öfele et al. exploited the acidic nature of imidazolium salts to synthesize the first (diaminocarbene)chromium complex [Equation (36)].[63]

(36)

5. Reactivity in Catalytic Reactions

The pentacarbonylhydridochromate $[HCr(CO)_5]^-$ is involved as a key intermediate in several catalytic reactions, where it plays the role of a species active towards electrophiles. These are summarized below.

5.1. Water Gas Shift Reaction

The water gas shift reaction (WGSR) [Equation (37)] finds extensive use in industry for hydrogen enrichment of synthesis gas (CO + H_2). Current processes involve the reaction of steam with synthesis gas over iron oxide/chromium oxide or zinc oxide/copper oxide catalyst beds at high temperatures (> 300 °C).[64,65]

(37)

Interestingly, it has been shown that the WGSR can be carried out at lower temperatures (< 200 °C) with water present in liquid form [Equation (38)] by using homogeneous catalysts.[66] The interest in carrying out the WGSR with liquid water rather than steam stems mainly from the considerable energy saving that this would represent.[67]

(38)

The WGSR using $Fe(CO)_5$ as a catalyst precursor has been thoroughly studied.[68] Although it soon became apparent that this catalyst was unlikely to have any practical use, due to low turnover, studies of the elementary steps of the catalytic cycle provided very useful information on the reactivity of $[HFe(CO)_4]^-$.[69]

The hexacarbonyls of the Group 6B transition metals (Cr, Mo, W) have also been studied as catalyst precursors for the WGSR.[70] Indeed, it was soon recognized that, in contrast to $Fe(CO)_5$, these catalysts exhibit considerable tolerance to sulfur poisoning, an important attribute in the context of synthesis gas treatment.[71] The catalytic behavior of $Cr(CO)_6$ is representative of that of all three Group 6B hexacarbonylmetal compounds. Turnover numbers as high as 8530 mol H_2/mol $Cr(CO)_6$ per day can be achieved at 200 °C (initial CO pressure 20 bar).[67] These reactions exhibit considerably different kinetics as compared to the situation found in the case of $Fe(CO)_5$ (associative mechanism). Thus, the rate of hydrogen formation is found to be proportional to the amount of $Cr(CO)_6$ and inversely proportional to the CO pressure, and increases with base concentration. The overall kinetics led the authors to propose a dissociative mechanism based on formate decomposition [Equation (39)−(45)].[67]

(39)

(40)

(41)

(42)

(43)

(44)

(45)

Most of these elementary steps have been studied independently.[72−76]

However, Darensbourg et al. presented compelling evidence that the *initial* mechanistic step in the *thermal* WGSR by Group 6B carbonylmetal compounds is in fact transition metal activation of CO towards attack by hydroxide ions [Equation (46)].[29][74]

$$Cr(CO)_6 + OH^- \rightleftharpoons [(CO)_5CrCOOH]^- \xrightarrow{OH^-} [(CO)_5CrH]^- + [HCO_3]^- \quad (46)$$

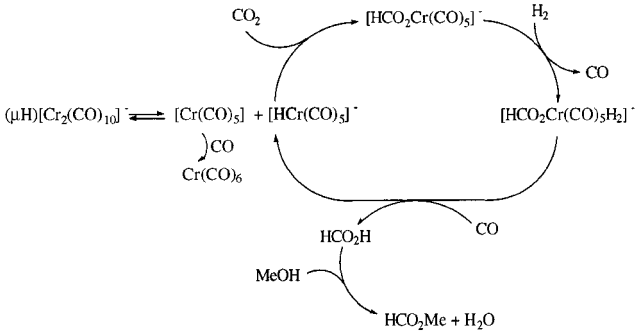
Once the active $[HCr(CO)_5]^-$ is formed, the formato complex $[HCO_2Cr(CO)_5]^-$ could then be generated according to Equation (43), (44), and (41).

The dissociative step [Equation (40)] is certainly involved in the photocatalyzed WGSR.[72][75] It has been shown that UV irradiation ($\lambda < 360$ nm) accelerates the conversion of $Cr(CO)_6$ into the formate complex $[HCO_2Cr(CO)_5]^-$, which is thermally activated, as evidenced by in situ IR and UV spectroscopy. The reaction is inhibited by increased CO pressure. An activation energy of 30 kJ/mol has been determined, as compared to 145 kJ/mol for the purely *thermal* WGSR.[75]

Confirmation of the dissociative mechanism [Equation (40) and (41)] is provided by the observation that $Cr(CO)_6$ is an efficient catalyst precursor for the photocatalytic decomposition of the formate ion into H_2 and CO_2 (or HCO_3^-) [Equation (47)].[76]

$$HCO_2^- + H_2O \xrightarrow[h\nu]{[Cr(CO)_6]} H_2 + HCO_3^- \quad (47)$$

5.2. Catalytic Synthesis of Alkyl Formates from Carbon Dioxide



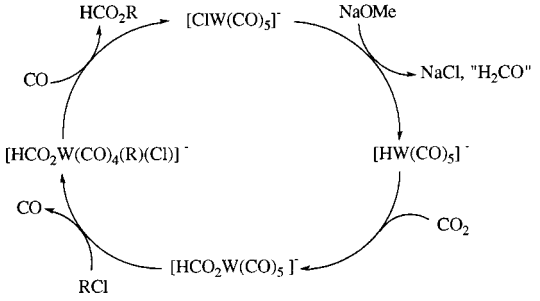
The observation that $[HCO_2M(CO)_5]^-$ complexes (M = Cr, W) undergo facile CO ligand dissociation (vide supra) led Darensbourg et al. to consider these complexes for dihydrogen binding.[77] Indeed, η^2-H_2 bonding has been evidenced (neutron diffraction studies) in some neutral Group 6B transition metal complexes such as $H_2W[P(OMe)_3]_5$.[78] Thus, $[HM(CO)_5]^-$ salts, which readily undergo insertion of CO_2 with generation of the corresponding $[HCO_2M(CO)_5]^-$ complexes, appeared to be good candidates for hydrocondensation reactions of carbon dioxide to yield alkyl formates.

Both $[PPN]^+[HCr(CO)_5]^-$ {generated in situ from $(\mu\text{-}H)[Cr_2(CO)_{10}]^-$} and the formato complex $[PPN]^+[HCO_2Cr(CO)_5]^-$ proved to be effective catalysts for the hydrogenation of CO_2 in methanol to provide methyl formate [Equation (48)]. Typical reaction conditions were a temperarure of 125 °C and loading pressures of CO_2 and H_2 of 250 psi each.

$$CO_2 + H_2 + MeOH \xrightarrow{[cat]} HCO_2Me + H_2O \quad (48)$$

Turnover numbers of 14−15 were achieved in reaction times of 24 h. These activities are higher than those reported for the same reaction using $[PPN]^+[HFe(CO)_4]^-$ or $[PPN]^+[HFe_3(CO)_{11}]^-$ as catalysts.[79]

At the end of catalytic runs, only $[HCO_2M(CO)_5]^-$ and $M(CO)_6$ could be detected by IR spectroscopy. The neutral hexacarbonylmetal compounds $M(CO)_6$ are catalytically inactive under the reaction conditions. One final point is that the catalytic activity was greatly diminished when the reactions were performed in the presence of added CO (100 psi loading pressure). On the basis of these observations, a catalytic cycle was proposed (Scheme 6). The possible formation of methyl formate through carbonylation of methanol (CO originating from the reverse of the WGSR) has been ruled out on the basis of labelling experiments. Methyl formate is formed by a rapid reaction of HCO_2H with methanol.



Scheme 6. Catalytic cycle for the formation of methyl formate

The catalytic synthesis of higher alkyl formates can also be performed by the reaction of alkyl halides, CO_2, and H_2 in the presence of anionic Group 6B carbonyl catalyst precursors {$[M(CO)_5Cl]^-$ or $(\mu\text{-}H)[M_2(CO)_{10}]^-$; M = Cr, W} and sodium alkoxides [Equation (49)].[80]

$$RX + CO_2 + H_2 \xrightarrow[NaY]{[cat]} HCO_2R + NaX + HY \quad (49)$$

In these reactions, terminal hydrides $[HM(CO)_5]^-$ are also involved as key intermediates in the generation of formato complexes $[HCO_2M(CO)_5]^-$. In Scheme 7, the proposed catalytic cycle is represented in the case of the tungsten complex.

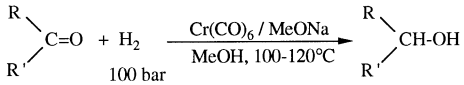
Scheme 7. Catalytic cycle for the formation of alkyl formates

The intriguing steps of this catalytic cycle are the regeneration of the hydrides from the anionic carbonyl halides [activation of dihydrogen, Equation (50)], the kinetics of which have been studied, and the reaction of the formato

complexes with RX. The latter reaction has been proposed to proceed according to Equation (51)−(53).

$$[ClW(CO)_5]^- + H_2 + NaHCO_3 \longrightarrow [HW(CO)_5]^- + NaCl + H_2CO_3 \quad (50)$$

$$[HCO_2W(CO)_5]^- \rightleftharpoons [HCO_2W(CO)_4]^- + CO \quad (51)$$



$$[HCO_2W(CO)_4]^- + n\text{BuCl} \longrightarrow HCO_2W(CO)_4(n\text{Bu})(Cl)]^- \quad (52)$$

$$HCO_2W(CO)_4(n\text{Bu})(Cl)]^- \xrightarrow{CO} [Cl(W(CO)_5]^- + HCO_2n\text{Bu} \quad (53)$$

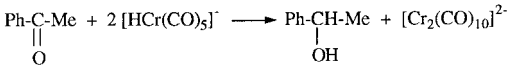
It must be noted that such an oxidative addition of alkyl halides to $[W(CO)_5X]^-$ species [Equation (52)] is without precedent. Nevertheless, this mechanism [Equation (51)−(53)] is consistent with the experimental results.

5.3. Catalytic Hydrogenations of Aldehydes and Ketones

The first report on the use of carbonylchromium derivatives as catalysts for the hydrogenation of ketones was that of Marko et al. in 1985.[51] The hydrogenation of ketones was found to be catalyzed by $Cr(CO)_6$ in the presence of NaOMe in methanol under 100 bar H_2 at 100−120 °C [Equation (54)].

(54)

Both aliphatic and aromatic ketones could be hydrogenated in > 98% yield within 3 h (Table 4). Aromatic aldehydes were also hydrogenated, whereas aliphatic ones proved to be prone to secondary reactions.



In these reactions, $Cr(CO)_6$ is a more active catalyst precursor than $W(CO)_6$, but less active than $Mo(CO)_6$, which can be used at lower temperatures.

The mechanism of this catalytic reaction has been studied.[51] The stoichiometric reaction of $[Et_4N]^+$-$[HCr(CO)_5]^-$ with acetophenone (no solvent) was monitored by GC and IR analysis. The results were interpreted in terms of Equation (55), where both H atoms involved in the reduction originate from $[HCr(CO)_5]^-$, a proposal that has been criticized,[81] but also seems to be valid for the reduction of cyclohexanone with $[K]^+[HCr(CO)_5]^-$.[49]

Table 4. Hydrogenation of carbonyl compounds in the presence of $Cr(CO)_6$/NaOMe catalyst under H_2 pressure

Carbonyl compound	Conv. to alcohol (%)[a]
acetophenone	99.8
cyclohexanone	100
acetone	100
isobutyl methyl ketone	98.8
benzaldehyde	99.6
methyl benzoate	0
4-*tert*-butylcyclohexanone	99.4[b]

[a] Ketone/$Cr(CO)_6$/NaOMe = 10:0.5:1 mmol in 4 mL MeOH, 100 bar H_2 at 20 °C, 120 °C, 3 h. − [b] *cis*/*trans* = 0.34:1.

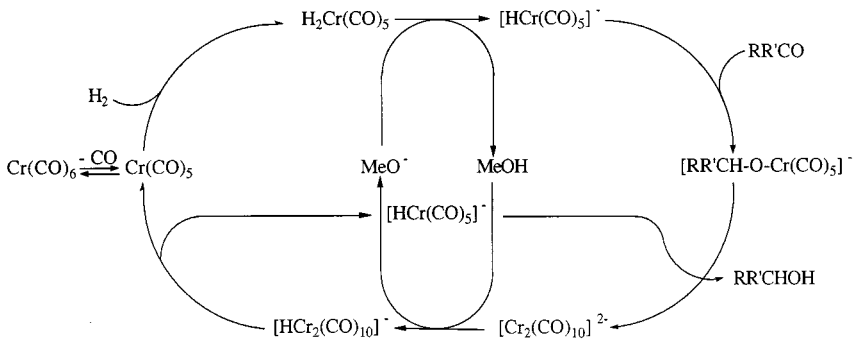
(55)

On the basis of these results, it has been proposed that the intermediate is an alkoxocarbonylchromate.[51] Evidence supporting this hypothesis is provided by the stereochemical outcome of the hydrogenation of 4-*tert*-butylcyclohexanone (Table 4). With the catalytic system $Cr(CO)_6$/MeONa, the hydrogenation of 4-*tert*-butylcyclohexanone leads preferentially to the *trans* alcohol (75%). This observation led the authors to suggest that the primary intermediate formed from $[HCr(CO)_5]^-$ and the ketone is an alkoxocarbonylchromate $[RR'CHOCr(CO)_5]^-$. In such a complex, the bulky "$OCr(CO)_5$" group would tend to occupy the less crowded equatorial position of the 4-*tert*-butylcyclohexane ring. Reaction with a second equivalent of $[HCr(CO)_5]^-$ would then liberate the *trans* 4-*tert*-butylcyclohexanol.

In contrast, the analogous $Fe(CO)_5/Et_3N$ system furnishes only 38% *trans* 4-*tert*-butylcyclohexanol. The difference in behavior between $[HCr(CO)_5]^-$ and $[HFe(CO)_4]^-$ in the reactions with ketones stems from the fact that the former is hexacoordinate whereas the latter is only pentacoordinate. The reaction with $[HCr(CO)_5]^-$ may be regarded as a hydride transfer to the carbon atom of the ketone carbonyl group, leading to an alkoxocarbonylchromate $[RR'CHOCr(CO)_5]^-$. In contrast, the reaction with $[HFe(CO)_4]^-$ involves nucleophilic attack of the iron center, leading to an alkyliron hydride $[HFe(CO)_4(RR'CO)]^-$ with an Fe−C bond. These differences in the natures of the catalytic intermediates account for the different stereochemical outcomes in the hydrogenation of 4-*tert*-butylcyclohexanone with the chromium- and iron-based systems.

It has been proposed that in catalytic reactions, $[HCr(CO)_5]^-$ is generated through H_2 activation by the unsaturated species "$[Cr(CO)_5]$" [Equation (56)−(58)].

$$Cr(CO)_6 \rightleftharpoons Cr(CO)_5 + CO \quad (56)$$



$$Cr(CO)_5 + H_2 \rightleftharpoons H_2Cr(CO)_5 \quad (57)$$

$$H_2Cr(CO)_5 + MeO^- \rightleftharpoons [HCr(CO)_5]^- + MeOH \quad (58)$$

The overall catalytic cycle is shown in Scheme 8.

The same monomeric anionic hydride is considered to be the active species when $[PPN]^+[Cr(CO)_5OAc]^-$ is used as a catalyst precursor.[81] Indeed, the acetatopentacarbonylchromate has been shown to be efficient for the hydrogenation of benzaldehyde and cyclohexanone under hydrogen pressure (47 bar, 125 °C) in THF (turnovers of 16−18 in 24 h).

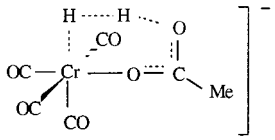
With this system, generation of the active monomeric hydrido species has been proposed to occur according to Equation (59) and (60).

Scheme 8. Catalytic cycle for the hydrogenation of ketones with $Cr(CO)_6$/MeONa

$$[(CO)_5CrOAc]^- \rightleftharpoons [(CO)_4CrOAc]^- + CO \quad (59)$$

$$[(CO)_4CrOAc]^- \xrightarrow{H_2,\ CO} [HCr(CO)_5]^- + AcOH \quad (60)$$

Mechanistic models of H_2 activation by $[(CO)_4CrOAc]^-$ start with addition to generate an η^2-H_2 complex. Subsequent oxidative addition and reductive elimination would then generate $[HCr(CO)_5]^-$ and AcOH [Equation (60)]. As an alternative, the authors proposed an intramolecular ligand-assisted heterolytic cleavage, as represented in Figure 3.



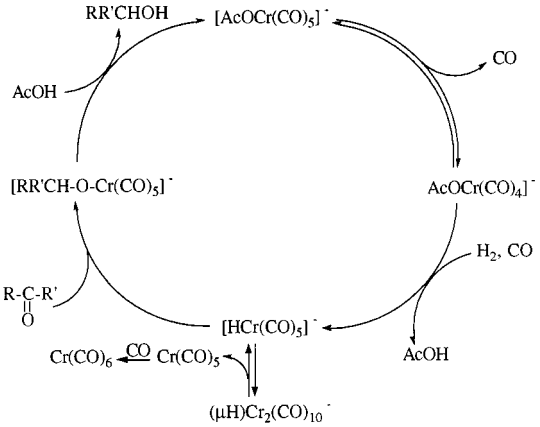


Figure 3. Intramolecular ligand-assisted heterolytic cleavage of H_2

The overall catalytic cycle is represented in Scheme 9. As a matter of fact, the hydrido binuclear complex $(\mu\text{-H})[Cr_2(CO)_{10}]^-$ ("6 o'clock position") is also an active catalyst precursor, albeit a less active one than the acetatocarbonylchromate.

Scheme 9. Catalytic cycle for the hydrogenation of ketones with $[PPN]^+[Cr(CO)_5OAc]^-$

Based on the photocatalytic decomposition of formate ion using $Cr(CO)_6$ (vide supra), in situ generation of $[HCr(CO)_5]^-$ has been used for the catalytic hydrogenation of aldehydes [Equation (61)].[82]

$$RCHO + HCO_2^- + H_2O \xrightarrow[h\nu]{Cr(CO)_6\ /\ MeOH} RCH_2OH + HCO_3^- \quad (61)$$

Typical conditions, for instance in the case of heptanal: aldehyde/HCO_2Na/$Cr(CO)_6$ = 7.2:13:0.12 mmol in 40 mL of 95% aqueous MeOH at 60 °C (60 turnovers in 100 h).

As already stated, the photocatalytic decomposition of formate ion with $Cr(CO)_6$ generates $[HCr(CO)_5]^-$.[76] In the absence of an added substrate, this decomposition reaction produces dihydrogen [Equation (62) and (63)].

$$[HCr(CO)_5]^- + H_2O \longrightarrow H_2Cr(CO)_5 + OH^- \quad (62)$$

$$H_2Cr(CO)_5 \rightleftharpoons Cr(CO)_5 + H_2 \quad (63)$$

In the presence of an aldehyde, the reactive $[HCr(CO)_5]^-$ is diverted (partially or completely) from the above WGSR cycle into an aldehyde hydrogenation cycle. On the basis of kinetic and mechanistic studies, Equation (64)−(67) have been proposed.

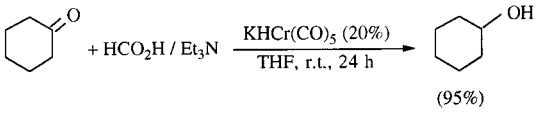
$$[HCr(CO)_5]^- + RCHO \rightleftharpoons [HCr(CO)_4(RCHO)]^- + CO \quad (64)$$

$$[HCr(CO)_4(RCHO)]^- \longrightarrow [Cr(CO)_4(OCH_2R)]^- \quad (65)$$

$$[Cr(CO)_4(OCH_2R)]^- + H_2O \longrightarrow [HCr(CO)_4(OCH_2R)] + OH^- \quad (66)$$

$$[HCr(CO)_4(OCH_2R)] + CO \longrightarrow RCH_2OH + Cr(CO)_5 \quad (67)$$

Replacement of one CO ligand of $[HCr(CO)_5]^-$ by the aldehyde [Equation (64)] has been proposed to account for the fact that the aldehyde hydrogenation process is inhibited by carbon monoxide.



More recently, on the basis of the aforementioned stoichiometric reactivity of $KHCr(CO)_5$ with cyclohexanone (vide supra) and the hypothesis of an alkoxocarbonylchromate intermediate, a catalytic system has been designed for the transfer hydrogenation of ketones under very mild conditions.[49] In the presence of stoichiometric amounts of HCO_2H/Et_3N as a hydrogen-transfer agent, cyclohexanone was almost quantitatively (95%) reduced to cyclohexanol within 24 h using 20% $KHCr(CO)_5$ at room temp. in THF

Table 5. Transfer hydrogenation of ketones using 20% $KHCr(CO)_5$ in the presence of HCO_2H/Et_3N

Ketone	Conv. (%)[a]	Product (yield %)[b]
2-hexanone	38	2-hexanol (38)
acetophenone	25	1-phenylethanol (25)
3-methyl-2-butanone	45	3-methyl-2-butanol (45)
cyclohexanone	95	cyclohexanol (95)
4-*tert*-butylcyclohexanone	80	4-*tert*-butylcyclohexanols (80)[c]

[a] Ketone/$KHCr(CO)_5$/HCO_2H/Et_3N = 1:0.2:1:1, 24 h at room temp. in THF. – [b] GC analysis with internal standards. – [c] *cis*/*trans* = 33:67.

[Equation (68)]. Using even lower amounts of $KHCr(CO)_5$ also proved possible [e.g. 10% $KHCr(CO)_5$: 83% yield after 24 h; 5% $KHCr(CO)_5$: 70% yield after 24 h], but complete conversion of cyclohexanone was only achieved after several days.

(68)

When the catalytic reaction was performed at 0 °C, the rate was found to be lower. However, if after 24 h at 0 °C the mixture was allowed to warm to room temperature, the expected catalytic activity was restored. From reactions conducted at 60 °C, the yield of cyclohexanol remained below 50% (24 h) and did not increase further, suggesting competitive destruction of the catalytically active species.

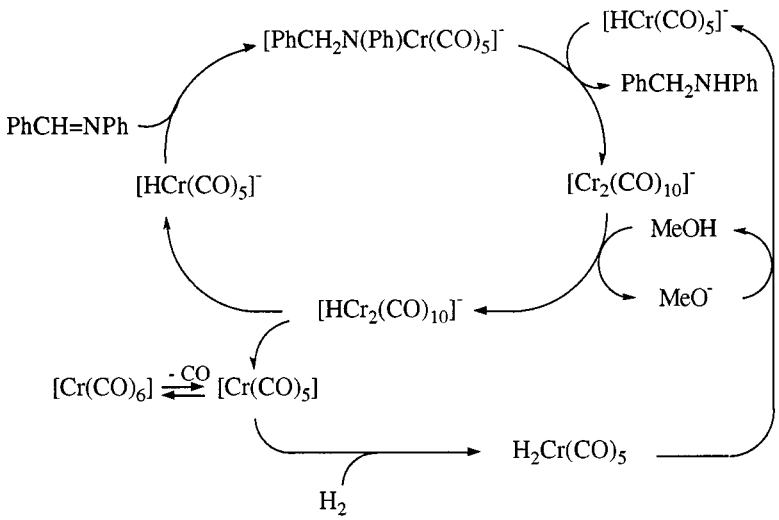
The above system was tested for the catalytic reduction of some representative ketones for 24 h at room temperature (Table 5).

As expected in the light of literature data on the reduction of ketones with hydridometallates,[47,51,83] cyclohexanones are more rapidly reduced than methyl ketones. In the case of 4-*tert*-butylcyclohexanone, the preponderant formation of the *trans* alcohol is consistent with the hypothesis of an alkoxocarbonylchromate intermediate (vide supra).

5.4. Catalytic Hydrogenation of Imines

In combination with NaOMe in methanol, all Group 6B carbonylmetal compounds catalyze the hydrogenation of *N*-benzylideneaniline into *N*-benzylaniline under ca. 100 bar hydrogen pressure at 60–160 °C.[57] Although $Mo(CO)_6$ is the most active of the three hexacarbonylmetal compounds at low temperatures, the best conversions are achieved using $Cr(CO)_6$. Typical conditions are a temperature of 120 °C, 100 bar initial H_2 loading, and a catalyst/substrate ratio of 1:50 (Table 6).

The reaction rate increases with increased H_2 pressure, while the process is inhibited by carbon monoxide. Accordingly, the active species has been suggested to be generated through the equilibrium described by Equation (69).



(69)

On the basis of a study of the stoichiometric reaction of $[Et_4N]^+[HCr(CO)_5]^-$ with imines (vide supra, Part 4), a catalytic cycle similar to that proposed for the hydrogenation of ketones has been suggested (Scheme 10).

6. Conclusion

The purpose of this review has been to point out the versatile properties of pentacarbonylhydridochromates

Scheme 10. Catalytic cycle for the hydrogenation of imines with $Cr(CO)_6$/MeONa

$M^+[HCr(CO)_5]^-$. These complexes are easy to prepare from $Cr(CO)_6$, and may find interesting applications as selective reducing agents in organic synthesis. As stoichiometric reagents, they have been shown to react either by H^- (or D^-) transfer or by a SET process, depending on the substrate. In comparison with similar carbonylhydridometallates, $[HCr(CO)_5]^-$ is a better H^--transfer agent than $[HFe(CO)_4]^-$ and a better electron-transfer agent than $[HW(CO)_6]^-$. As homogeneous catalysts, $M^+[HCr(CO)_5]^-$ species can be generated under various conditions and react mainly as H^--transfer agents towards electrophiles. The mechanisms of these reactions have been delineated and regeneration of the active species is generally well understood. It is to be expected that the knowledge of the different reaction pathways established for $M^+[HCr(CO)_5]^-$ species will allow extension of their application to other catalytic reactions. For instance, it is somewhat surprising that no attempted carbonylation reaction has hitherto been reported. Efforts in this area are currently underway in this laboratory.

Metal-Mediated Oxidation of Tertiary Alcohols and Related Fragmentations

Karine Wietzerbin,[a] Jean Bernadou,*[a] and Bernard Meunier*[a]

Keywords: Tertiary alcohols / Oxidation / Fragmentation reactions / Metal salts / Acid catalysis / Basic catalysis / Reaction mechanisms

In contrast to the abundant literature available on the oxidation of primary and secondary alcohols, examples of oxidation of tertiary alcohols are rather rare and a general review on this topic does not exist. Therefore, this microreview will briefly describe the different existing methods, mainly metal-mediated, which consist of one or two-electron oxidations and usually lead to rearrangement, cyclization or fragmentation products. Some related data is also given for fragmentation reactions observed in basic or acid medium, or catalyzed by metal complexes without a real oxidation step.

Introduction

Primary and secondary alcohols can be easily oxidized, as exemplified by the abundant literature available on this subject.[1–6] In contrast, examples of tertiary alcohol oxidations are rather rare, and often related to a structural specificity of the substrate. In this review, we describe the different existing methods to oxidize tertiary alcohols. These reactions consist of one- or two-electron oxidation processes leading to rearrangement, cyclization or fragmentation products.

The first Part deals with 2-electron oxidations of tertiary alcohols and concerns transpositions, cyclizations and fragmentations by chromium(VI) oxides or vanadium(IV) complexes. The latter type of reaction leads to the formation of a ketone and a carbocation. The second Part is dedicated to one-electron oxidations observed with cerium(IV) and cobalt(III) derivatives. They result in fragmentation reactions yielding a ketone and a carbon radical. The third Part describes tertiary alcohols fragmentations in basic or acid

Karine Wietzerbin was born in France in 1971, and studied chemistry at the "Ecole Nationale Supérieure de Chimie" in Montpellier. In 1995 she joined the group of Bernard Meunier at the "Laboratoire de Chimie de Coordination du CNRS" in Toulouse, where she studied the mechanism of the oxidation of tertiary alcohols catalyzed by metalloporphyrins. She received a PhD for this research work in 1998. She is currently working at Eurofins Scientific (Nantes, France), where she works on food analysis using isotopic techniques.

Jean Bernadou was born in Villefranche-de-Rouergue (France) in 1947, and studied Chemistry, Pharmacy (Doctorate in Pharmaceutical Sciences in 1975) and Medicine (Doctorate in 1985) at the University Paul Sabatier of Toulouse, where he was appointed Professor of Medicinal Chemistry in 1987. His collaboration with the group of Bernard Meunier started in 1980 with his research interests in the mechanism of the action of antitumor drugs. He is currently working on biological applications of metalloporphyrins, in particular, oxidative DNA cleavage, biomimetic oxidation of drugs and characterization of reactive metal-oxo intermediates.

Bernard Meunier was born in 1947 and educated at the Universities of Poitiers (B.Sc.), Montpellier (with R. J. P. Corriu) and Orsay (with H. Felkin, ICSN-CNRS). After a period of post-doctoral study at the University of Oxford, he joined the "Laboratoire de Chimie de Coordination du CNRS" in Toulouse in 1979. His current research interests include catalytic oxidations, oxidative DNA cleavage, oxidation of pollutants, and the mechanism of action of artemisinin derivatives. He is the author of more than 230 publications and patents.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

media or catalyzed by ruthenium(II) complexes, i.e. without the need of an external oxidant. These reactions cannot be considered as genuine oxidations but they help in understanding the reactivity of tertiary alcohols under diverse conditions. The three sections are summarized in Figure 1.

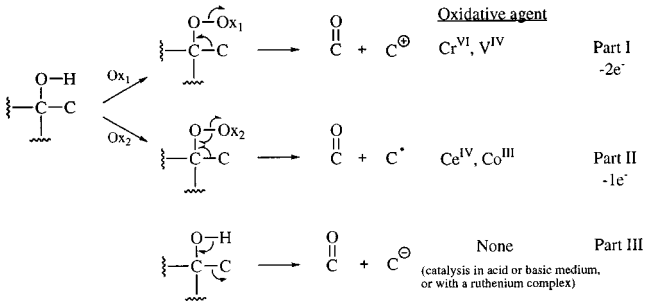

Figure 1. Modes of tertiary alcohol oxidations and fragmentations in non-oxidative media

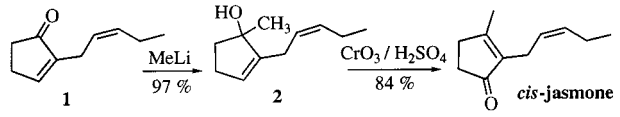

Finally, Part 4 is focused on oxidations with heme compounds. The complexity of these reactions does not allow us to classify them in one of the first three sections.

I. Two-Electron Oxidations

I.1. Oxidations Leading to Rearrangements

I.1.a. Allylic Alcohols

The ability to efficiently transpose a functional group from one carbon atom to another offers a wide degree of latitude in synthetic design of many naturally occurring compounds. For example, in 1972, the 1,3-alkylative carbonyl transposition of an α,β-unsaturated ketone *via* the oxidation of an intermediate tertiary allylic alcohol allowed Grieco[7] to prepare *cis*-jasmone (found in the essential oil of several varieties of *Jasminium*) with a reduced number of steps. The last steps of this synthesis are described in Scheme 1: The tertiary alcohol **2**, obtained by addition of methyllithium to dienone **1**, is oxidized to its transposed equivalent *cis*-jasmone using chromium trioxide in sulfuric acid (Jones reagent).[8]

Scheme 1. Last steps of formation of *cis*-jasmone

During the same period, other procedures were developed to convert tertiary allylic alcohols to α,β-unsaturated ketones. However, most of them are multi-step and indirect processes which include an initial rearrangement to a secondary alcohol, followed by oxidation to the ketone.[9,10] Moreover, the reagents used lead to a poor selectivity and low yields.

In 1976 and 1977, Babler and Coghlan,[11] and Dauben and Michno,[12] respectively, discovered a new method for 1,3-alkylative carbonyl transposition using pyridinium chlorochromate [$(ClCrO_3)^-PyH^+$] (PCC) as oxidant, which is less acidic than the Jones reagent and had been already used by Corey and Suggs[13] for oxidation of primary and secondary alcohols. The PCC oxidation of tertiary allylic alcohols (either cyclic or noncyclic), generated by 1,2-addition of organometallic reagents to α,β-unsaturated ketones, affords transposed 3-alkyl α,β-unsaturated ketones (Scheme 2). Several examples of such transpositions are reported in Table 1.[12]

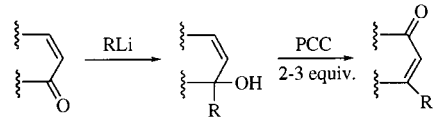

Table 1. Examples of 1,3-alkylative carbonyl transpositions by PCC (case of a starting α,β-unsaturated ketone)

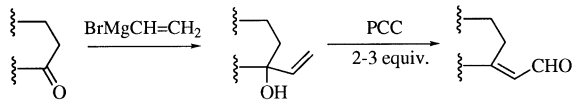
Enone substrate	RLi	Allylic alcohol	Transposed enone	Yield (%)
	MeLi			94
	PhLi			90
	MeLi	 **3**	 **4**	88
	*n*BuLi	 **5**		50[a]
	PhLi	 **6**		51[b]

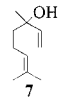


[a] 4:3 mixture of *E* and *Z* isomers, respectively. – [b] 4:1 mixture of *E* and *Z* isomers, respectively; in addition, 35% of acetophenone was also isolated.

With this method, oxidation of 1-methylcyclooct-2-en-1-ol (**3**) gives 3-methylcyclooct-2-en-1-one (**4**) in 88% yield, while the use of Jones reagent with the same compound gives a mixture of α,β- and β,γ-enones (4:3, respectively) in 48% yield. However, when the acyclic allylic alcohols **5** and **6** are oxidized, the yield is lowered due to the formation of side products generated by fragmentation reactions. For example, oxidation of 2-phenylbut-3-en-2-ol (**6**) affords acetophenone in 35% yield in addition to the transposed aldehyde.

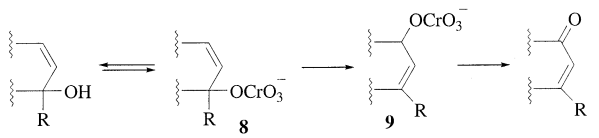
When the initial ketone is not α,β-unsaturated, the unsaturation is conveniently introduced by reaction with an α,β-

Scheme 2. 1,3-Alkylative carbonyl transposition with PCC (case of a starting α,β-unsaturated ketone)



Scheme 3. 1,3-Carbonyl transposition with PCC (case of a starting saturated ketone)

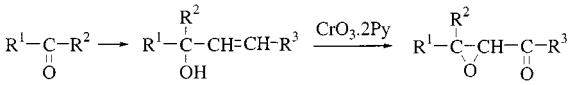
unsaturated organometallic compound, e.g. vinylmagnesium bromide. Treatment of the corresponding allylic alcohol with PCC leads to an α,β-unsaturated aldehyde (Scheme 3). Such a process involves a two-carbon homologation of the starting ketone, and is equivalent to a directed aldol condensation between the latter compound and acetaldehyde. Furthermore, this is the first method described in the literature of a direct rearrangement of a tertiary allylic alcohol to an α,β-unsaturated aldehyde.



The results obtained by Dauben[12] and Babler[11] using this procedure are reported in Table 2. It is interesting to note that the 6,7-unsaturation of linalol **7** remains untouched during the oxidation process.

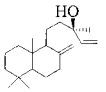
Table 2. Examples of 1,3-carbonyl transpositions with PCC (case of a starting saturated ketone)

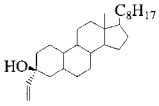
Starting ketone	Allylic alcohol	Aldehyde formed	Selectivity (%)	Reference
			89	12
			83	12
			73	12
			90[a]	12
			85	11
			80-86[a]	11 + 12
			87	11



[a] 2:1 Mixture of *E* and *Z* isomers, respectively.

The mechanism proposed by Dauben and Michno[12] involves the oxidation of the substrate through its chromate ester **9**, which results from the rearrangement of the initial chromate ester **8** (Scheme 4).[12] This is consistent with the fact that formation of chromate esters from primary, secondary or tertiary alcohols is a very fast process.[14]





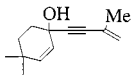
Scheme 4. Proposed mechanism for oxidation of tertiary allylic alcohols by PCC

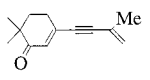
Other chromium(VI)-oxo reagents were tested for the oxidative rearrangement of tertiary allylic alcohols and compared to PCC. Surprisingly, the use of Collins reagent ($CrO_3 \cdot 2Py$)[16] resulted in oxidative rearrangement to α-epoxy aldehydes or ketones (Scheme 5).[15]

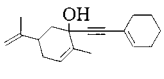
Scheme 5. Tertiary allylic alcohol oxidation with Collins reagent

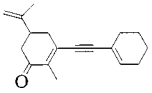
Table 3. Examples of oxidation of tertiary allylic alcohols with Collins reagent or PCC

Substrate	Oxidant	Epoxy-aldehyde[a] (% yield)	α,β-unsaturated aldehyde[b] (% yield)
			
	Collins	69	21
	PCC	–	98
			
	Collins	81	15
	PCC	–	98
			
	Collins	50	10
	PCC	–	80
			
	Collins	50	traces
	PCC	–	79
			
	Collins	70	traces
	PCC	–	72



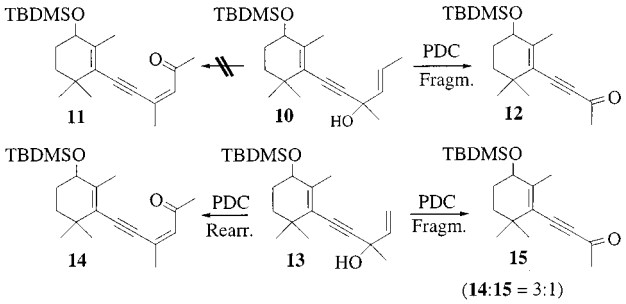






[a] 1:1 mixture of both epimers. – [b] 1:1 mixture of *E* and *Z* isomers.

The results of Table 3[15] show that for the same substrate, oxidation with Collins reagent yields mainly the α-epoxy aldehyde together with a small amount of the transposed α,β-unsaturated aldehyde, while the latter is the only product obtained with PCC as oxidant.

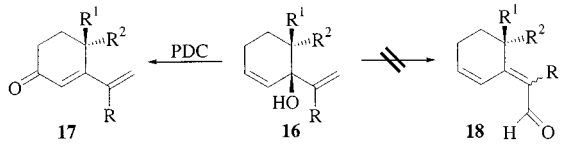


This interesting oxidative rearrangement with Collins reagent appears to be an excellent method for converting a ketone to the bis(homologous) epoxy aldehyde via a tertiary allylic alcohol.

Another chromium(VI)-amine oxidant, pyridinium dichromate [$(Cr_2O_7)^{2-}(PyH)_2^+$] (PDC),[17] was successfully used to oxidize various allylic acetylenic alcohols.[18] Prepared by addition of a lithium acetylide to an enone, the

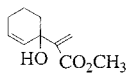
Table 4. Examples of oxidation of enynols with PDC

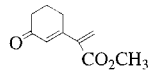
Enynol substrate	Oxidation product	Yield (%)
		88
		78
		62
		90

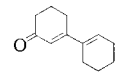


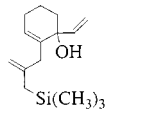
resulting enynols gave upon oxidation with PDC the transposed ketone with good to excellent yields (Table 4).[18] This PDC-induced oxidative rearrangement proceeded with complete regiospecificity since it occurred only at the olefinic site. The reaction seems to be more selective with *Z*-substituted enynols. Indeed, exposure of compound **10**, containing an *E*-double bond, to the action of PDC did not give the expected transposed product **11** (Scheme 6). Instead, ketone **12** was quantitatively produced. This product is probably the result of a vinyl hydrogen abstraction from **11**, followed by a carbon−carbon bond scission. PDC treatment of the demethylated alcohol **13** afforded a 3:1 mixture of the transposed product **14** and the fragmentation product **15**. These observations suggest that in situations where both *E*- and *Z*-vinyl hydrogen atoms are available, the rearrangement and fragmentation processes are competitive. This assumption is also consistent with the poor yields obtained by Dauben and Michno[12] for the PCC-induced oxidative rearrangement of allylic alcohols **5** and **6** (see Table 1), where the *E*-double bond could favor fragmentation reactions.

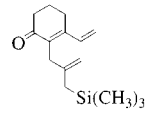
Scheme 6. Oxidation of compounds **10** and **13** with PDC

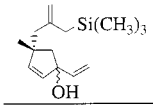


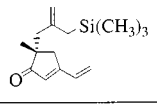






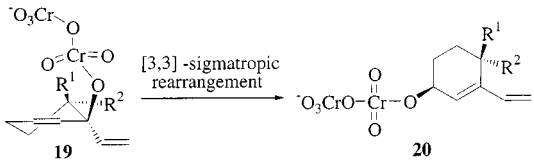






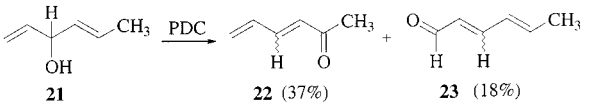
I.1.b. Bis(allylic) Alcohols

Pyridinium dichromate (PDC) was also used by Majetich et al. to oxidize dienols to dienones.[19] Their experiments established that the PDC-induced oxidative rearrangement of bis(allylic) tertiary alcohols such as **16** is regiospecific since the conjugated enone **17** is exclusively formed (Scheme 7). Several examples of these oxidations are reported in Table 5.[19]



Scheme 7. Oxidation of bis-allylic alcohols with pyridinium dichromate

Table 5. Examples of oxidations of bis(allylic) tertiary alcohols with PDC

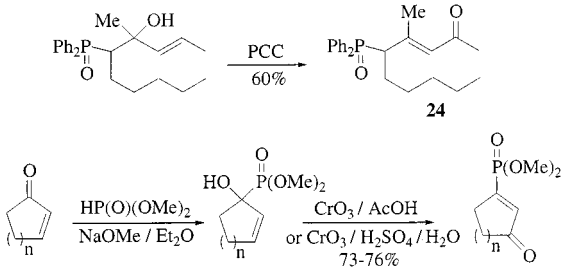


Substrate	Dienone formed	Yield (%)
		57
		62
		58
		57
		70

The regiospecificity of the [3,3]-sigmatropic rearrangement may be explained by examining the conformer **19** of the initially formed chromate ester (Scheme 8), where the Cr=O bond is above the rigid C=C double bond of the cyclohexene ring (while the exocyclic double bond is free to rotate). The rearrangement then affords the transposed chromate ester **20**, whose subsequent oxidation produces the corresponding enone.

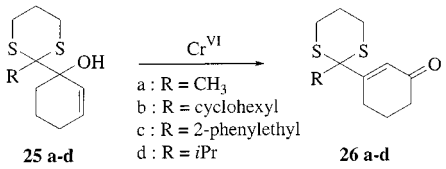
Scheme 8. Rearrangement of the chromate ester **19** derived from **16**

This hypothesis has been supported by the oxidation of dienol **21**, in which both vinyl groups are free to rotate (Scheme 9). Treatment of **21** with PDC gave a 2:1 mixture of dienone **22** and dienal **23**, showing that the regiospecificity was lost.



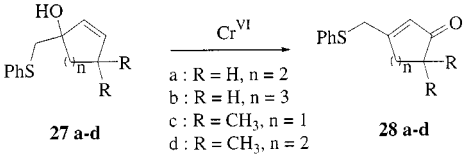
Scheme 9. Oxidation of hexan-1,4-dien-3-ol **21** with pyridinium dichromate

I.1.c. Allylic Alcohols Containing Heteroatoms



In order to extend the synthetic possibilities offered by these rearrangements, several authors attempted to use more complex substrates that would lead to attractive synthetic intermediates. They particularly focused on tertiary allylic alcohols containing heteroatoms.

Brown et al[20] and Öhler and Zbiral[21] showed that phosphorus-containing tertiary allylic alcohols could be efficiently oxidized with PCC or chromic acid (Scheme 10).[20,21]



Scheme 10. Oxidations of phosphorus-containing tertiary allylic alcohols (n = 1 or 2)

Since the oxidation of sulfides to sulfoxides and sulfones with oxochromium(VI)-amine reagents is slower than the oxidation of alcohols to carbonyl compounds under the same conditions, Luzzio and Moore[22] examined the oxidative rearrangement of tertiary allylic alcohols bearing a dithianyl protecting group (general structure **25**, Scheme 11) or a (phenylthio)methyl substituent (general structure **27**, Scheme 12). This work was the continuation of early studies realized by Corey and Crouse,[23] who reported in 1968 the oxidative transposition of compounds such as **25**.

Scheme 11. Oxidation of tertiary allylic alcohols bearing a dithianyl substituent

Scheme 12. Oxidation of tertiary allylic alcohols bearing a (phenylthio)methyl substituent

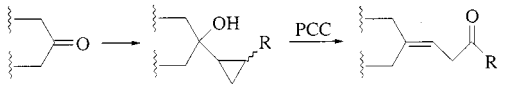
In order to achieve optimal conversion, compounds **25d** and **27a** have been oxidized with different oxochromium(VI) reagents: Jones reagent, PCC, PDC, Collins reagent and 2,2′-bipyridinium chlorochromate (BPCC). The results reported in Table 6[22] established that the efficiency of conversion follows the order PCC > PDC > Collins > BPCC. The Jones reagent, which is less selective and more acidic than the oxochromium(VI)-amine complexes, led only to decomposition products.

Table 6. Oxidation of **25d** and **27a** with a series of oxochromium(VI)-amine reagents

Oxidant		Conversion (%)	
		25d	**27a**
$(ClCrO_3)^-PyH^+$	PCC	53	74
$(Cr_2O_7)^{2-}(PyH)^+$	PDC	31	62
 $ClCrO_3^-$	BPCC	<1	13
$CrO_3.2Py$	Collins	37	37

Yields could be improved by adding silica gel to the reaction medium in order to absorb the reduced chromium tars. Table 7[22] indicates the results obtained for oxidation of compounds **25a−d** to **26a−d** and of **27a−d** to **28a−d** with PCC in the presence of silica gel.

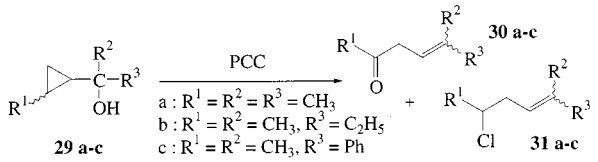
Table 7. Oxidation of **25a−d** and **27a−d** with PCC



Substrate	Product	Yield(%)
25a	**26a**	28
25b	**26b**	56
25c	**26c**	62
25d	**26d**	74
27a	**28a**	75
27b	**28b**	82
27c	**28c**	83
27d	**28d**	92

In the case of the dithiane series (compounds **25a−d**), it appears that the yield increases with increasing steric hindrance of the R substituent. A possible explanation could be that as R becomes more bulky, the binding of the dithiane moiety to the unchanged reagent or reduced chromium species is disfavored, and the yields are thus increased. The ability of the dithiane moiety to bind the reduced chromium species may also explain why better yields are obtained with the (phenylthio)methyl series.

I.1.d. α-Cyclopropyl Alcohols

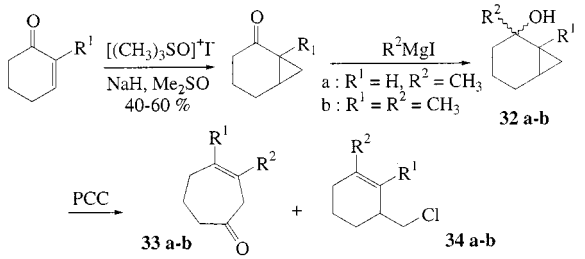


Like allylic tertiary alcohols, 2-alkylcyclopropyl carbinols are able to undergo PCC-oxidative rearrangement to give the corresponding β,γ-unsaturated ketones. The overall process is a synthetically useful method of effecting 1,4-carbonyl transposition (Scheme 13).[24] Moreover, when the tertiary alcohols used as substrates are prepared by addition of cyclopropyl organometallic reagents to ketones (as in Scheme 13), the oxidative rearrangement is also an excellent

method for converting ketones to the tris(homologous) β,γ-enones.

Scheme 13. 1,4-carbonyl transposition with PCC

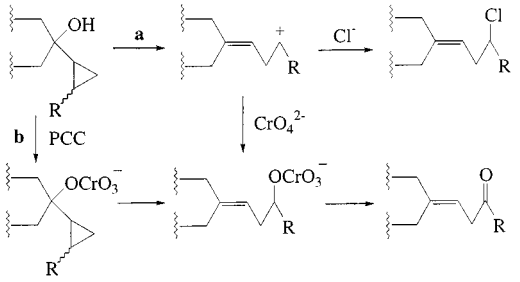
The PCC-induced oxidation of tertiary 2-alkylcyclopropyl carbinols of general structure **29** (Scheme 14) yields the expected β,γ-enones **30** but also the chloro olefins **31** (48% and 15% for **30a** and **31a**, respectively). This result indicates that both the desired oxidation and the nucleophilic attack by the chloride ion take place at the homoallylic carbon atom.



Scheme 14. Oxidation of alcohols **29a−c** with PCC

However, when the chloride ligand of the chromium complex is replaced by a tetrafluoroborate, only the desired β,γ-enone is obtained (50% for **30a**). Additionally, the use of a small amount of water together with PCC not only improved the yield of **30**, but also considerably reduced the formation of **31**. The yields obtained under these conditions are reported in Table 8.[24]

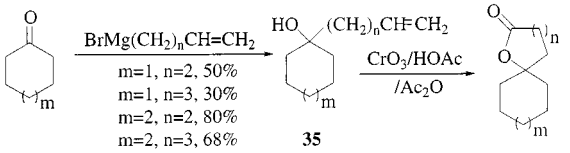
Table 8. Results of the oxidation of **29a−c** and **32a−b** with PCC in the presence of water



Substrate	β,γ-Enone	Yield (%)	Other products (yield, %)
29a	**30a**	60	**31a** (5)
29b	**30b**	62	**31b** (3)
29c	**30c**	57	**31c** (3)
32a	**33a**	28	**34a** (10)
32b	**33b**	30	**34b** (6)

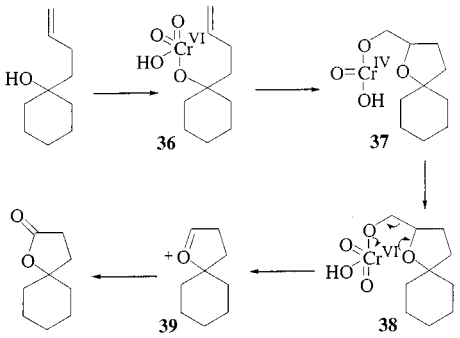
The availability of tertiary cyclopropyl carbinols via cyclopropanation of cyclic α,β-enones followed by organometallic addition enables 1,4-carbonyl transpositions on starting ketones that already contain a cyclopropyl moiety to be performed, as depicted in Scheme 15. However, in such a process, yields are lower than above, probably because of the steric hindrance developed in these systems (Table 8, substrates **32a** and **b**).

Scheme 15. 1,4-Carbonyl transposition on α-cyclopropyl ketones



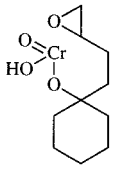
Two mechanisms have been proposed by the authors for the oxidative rearrangement of α-cyclopropyl alcohols (Scheme 16).[24] Path **a** involves a prior solvolysis of the tertiary alcohol to give a homoallylic carbocation, which then collapses in the presence of a nucleophilic species such as chloride to give a chloro olefin, or the chromate ion to give a chromate ester and then the β,γ-enone. Path **b** requires chromate ester formation prior to the rearrangement. However, path **a** appears to be more favorable for the present oxidative rearrangement since it explains the formation of chlorinated compounds.

Scheme 16. Mechanism proposed for the oxidation of 2-alkylcyclopropyl carbinols with PCC



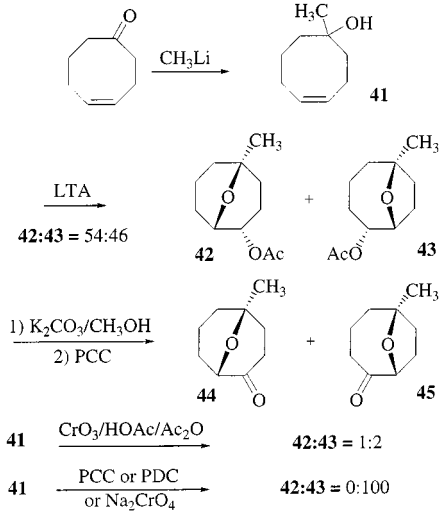
I.2. Oxidations Leading to Cyclizations

Some γ- and δ-unsaturated tertiary alcohols are able to undergo oxidative cyclizations. Treatment of tertiary alcohols of general structure **35** with the Fieser reagent CrO_3/AcOH/acetic anhydride easily gives lactones with the loss of one carbon atom (Scheme 17).[25]



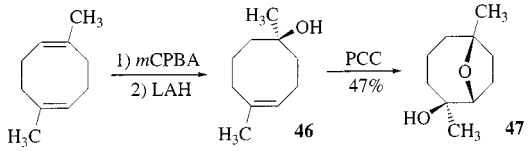
Scheme 17. Oxidative cyclization of γ- and δ-unsaturated tertiary alcohols with the Fieser reagent

The role played by the hydroxy group during the process appeared to be essential (when replaced by a methoxy or an acetoxy group, no reaction was observed). Additionally, oxidation of simple alkenes such as 1-dodecene gives only a mixture of the starting product with epoxides and acids. In an attempt to explain the cyclization process, Schlecht and Kim[25] proposed the mechanism depicted in Scheme 18. It involves the formation of the chromate ester **36**, followed by intramolecular oxidation of the double bond, which leads to the chromium(IV) ester **37**. The latter is then reoxidized to **38** by excess reagent. The oxidative fragmentation of **38** produces **39**, and then the lactone with another equivalent of oxidant.

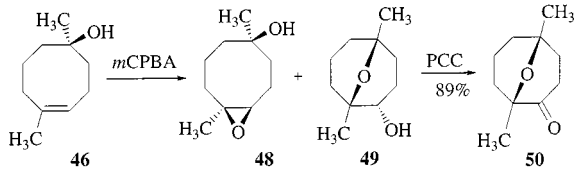


Scheme 18. Mechanism proposed for the oxidative cyclization of γ- and δ-unsaturated tertiary alcohols with the Fieser reagent

However, an alternative pathway for the transformation of **36** to **37** could proceed through the epoxy intermediate **40**, the opening of which would lead to **37**.



When cycloalkenols are used as the substrate, the oxidative cyclization becomes a transannular oxidative cyclization and gives β-functionalized bicyclic ethers.[26] This method is particularly convenient for preparing the oxygen-bridged bicyclic skeleton which appears in a number of biologically active natural products. Schlecht and Kim[27] observed that the oxidation of 1-methylcyclooct-4-en-1-ol (prepared from cyclooct-4-en-1-one) with lead tetraacetate (LTA) provides both acetates **42** and **43** in a ratio of 54:46, which are then converted into oxo ethers **44** and **45** by hydrolysis and oxidation (Scheme 19).



Scheme 19. Transannular cyclization of tertiary cycloalkenol

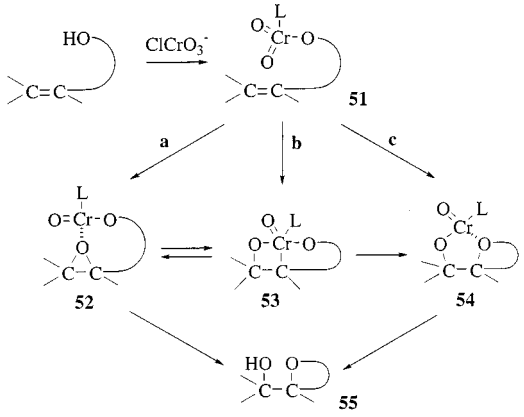
The nature of the oxidant has a great influence on the regioselectivity of the reaction since the use of the Fieser reagent instead of LTA leads to the same oxo ethers in a 1:2 ratio, while treatment with PCC, sodium chromate or PDC produces only oxo ether **45**. The cyclization process is also catalyzed by acids: the reaction rate is inhibited by addition of sodium acetate but increased in the presence of acetic acid. Additionally, no reaction occurs with the Collins reagent. These observations suggest that two different mechanisms operate depending on the nature of the oxidant. One possible mechanism involves an intermediate epoxide which undergoes internal opening by attack of the hydroxy group on one of the two carbon atoms to form two cyclic β-hydroxy ethers, subsequently oxidized to **44** and **45**. However, this mechanism does not explain the observed regioselectivity with chromium(VI) reagents. Treatment of **41** with *m*CPBA yields both the *cis*-epoxy alcohol, and a 3:2 mixture ratio of two β-hydroxy ethers corresponding to the hydrolysis products of **42** and **43** (and probably derived from the *trans*-epoxy alcohol). With either PCC or the Fieser reagent, these β-hydroxy ethers are converted into **44** and **45**, while the *cis*-epoxide gives only a complicated mixture of products under the same conditions. Consequently, the involvement of an epoxide in the course of oxidation with PCC, PDC or Na_2CrO_4 can be ruled out since it does not explain the observed regioselectivity. It seems more reasonable to postulate the formation of a chromate ester of the hydroxy group, which would be acid-catalyzed, followed by an intramolecular attack on the double bond by the tethered chromate ester moiety. In the oxidation with LTA, which occurs without selectivity, epoxide opening is likely to be involved in the mechanism. In the case of the Fieser reagent, which is a stronger oxidant than PCC, PDC and Na_2CrO_4, a contribution of both mechanisms is a reasonable assumption.

In order to obtain further information about the reaction mechanism, Schlecht and Kim studied the transannular oxidative cyclization of cyclooctenol **46**, where the methyl substituent on position 5 does not permit the further oxidation to the carbonyl, thus allowing the authors to follow the stereochemistry of the reaction.[28] The oxidation of **46** with PCC provides the β-hydroxy cyclic ether **47** exclusively (Scheme 20). The cyclization process is then not only regiospecific but also stereospecific.

Scheme 20. PCC-induced oxidative cyclization of cyclooctenol **46**

Scheme 21. Oxidation of **46** with *m*CPBA followed by PCC

As in the previous case, the action of *m*CPBA on compound **46** gives the *cis* hydroxy epoxide **48** and the cyclic

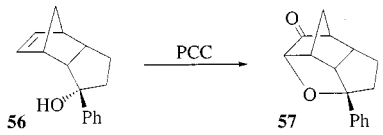


endo-β-hydroxy ether **49**, whose oxidation with PCC yields **50** (Scheme 21).

These observations are in accordance with the involvement of a chromate ester rather than an epoxide in the reaction pathway. On the basis of the *syn* configuration of the resulting product, Schlecht[28] proposed three possible mechanistic pathways after the initial step of chromate ester formation (Scheme 22):

− Pathway **a**: formation of an epoxide by an intramolecular attack of the tethered oxidant (**51** → **52** → **55** or **51** → **52** → **53** → **54** → **55**);

− Pathway **b**: formation of a metalloxetane (**51** → **53** → **54** → **55** or **51** → **53** → **52** → **55**);



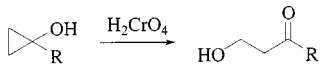
− Pathway **c**: [3+2] cycloaddition and fragmentation (**51** → **54** → **55**).

Scheme 22. Mechanism proposed for the transannular oxidative cyclization of tertiary cycloalkenols; L = Cl, O

However, the failure to convert the epoxide **52** into cyclization products upon treatment with PCC appears to rule out pathway **a** as the mechanism for the transannular oxidative cyclization.

Working with more complex substrates, where the tertiary hydroxy group was positioned in a conformationally fixed orientation with respect to the alkene group, Waddell et al.[29] obtained results which parallel those reported by Schlecht, since PCC treatment of compound **56** leads to the β-oxo ether **57** in 70% yield (Scheme 23). The process is a transannular cyclization similar to the one described by Schlecht, which probably follows the same mechanism.

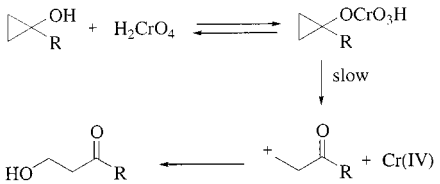
Scheme 23. Oxidative cyclization of **56** with PCC



However, the strained double bond of **56** might be more reactive toward PCC than the same group in **46**. Therefore, considering a possible intermolecular attack of the double bond by the oxidant, the dicyclopentadiene was submitted to the action of PCC under the same conditions. The products proved to be only α-chloro ketones obtained in 25% yield. Consequently, the intermolecular mechanism is unlikely, and the pathway demonstrated by Schlecht may also explain the transformation of **56** to **57**.

I.3. Oxidations Leading to Fragmentations

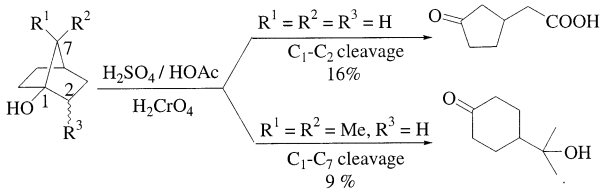
I.3.a. Fragmentations with Chromium Oxides



One of the first oxidative tertiary alcohol fragmentations described in the literature was reported by Barbier and Locquin in 1913.[30] They observed at that time the formation of carboxylic acids R−COOH and acetone while heating in sulfuric acid alcohols of general structure $R-CH_2-C(CH_3)_2OH$ in the presence of chromic acid. However, the reaction mechanism has been shown to involve prior dehydration of the alcohol, so that the products were in fact the result of oxidation of the intermediate olefin. This was demonstrated by Sager in 1955 by conducting kinetic studies during the oxidation of 3-ethylpentan-3-ol with chromic acid.[31]

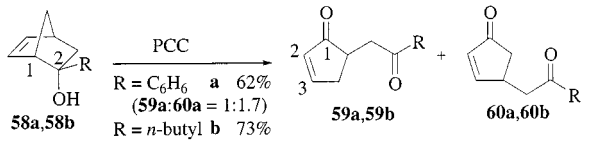
The first example of a direct oxidation of a tertiary alcohol with chromic acid was reported by Rocek and Radkowsky in 1968.[32] They studied the oxidation of 1-methylcyclobutyl alcohol, a compound which is very reluctant to undergo dehydration[33] and whose large ring strain should favor fragmentation reactions. Although they did not identify the oxidation products, they performed kinetic measurements which revealed a first order dependence on the chromic acid concentration, thus excluding any prior dehydration. Further investigations then showed that chromic acid-induced oxidation of tertiary cyclopropanols provided β-hydroxylated ketones through ring opening (Scheme 24).[34]

Scheme 24. Oxidation of tertiary cyclopropanols with chromic acid



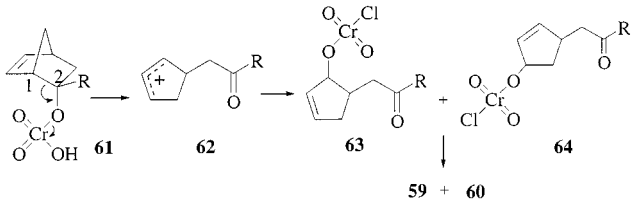
For example, 1-phenylcyclopropanol is oxidized with 43% conversion and 73% selectivity to 3-hydroxy-1-phenylpropan-1-one. Tertiary cyclopropanols are even more reactive than the corresponding secondary cyclopropanols, and the reactivity is greatly increased by alkyl substitution on the ring. This is consistent with the mechanism depicted in Scheme 25,[34] where the rate-limiting step is the formation of a carbocation by oxidative decomposition of a chromate ester of the alcohol. The reaction is then accelerated by substituents stabilizing the incipient carbocation.

Scheme 25. Reaction pathway for oxidation of tertiary cyclopropanols with chromic acid



Although their conversion is low, Cawley and Spaziano showed that norbornanol derivatives are able to undergo

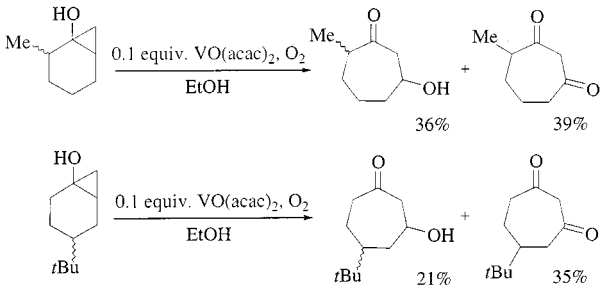
oxidation in a same way.[35] The C−C bond cleavage occurs on C^1-C^2 or C^1-C^7 bonds, depending on the nature of the substituents. Two kinds of product are thus obtained (Scheme 26).



Scheme 26. Oxidation of norbornanol derivatives with chromic acid

In the same series, norbornenols of structure **58** are easily oxidized with PCC to two isomeric cyclopentenones **59** and **60** resulting from C^1-C^2 bond cleavage, the latter being the main product (Scheme 27).[29]

Scheme 27. Oxidation of **58** with PCC

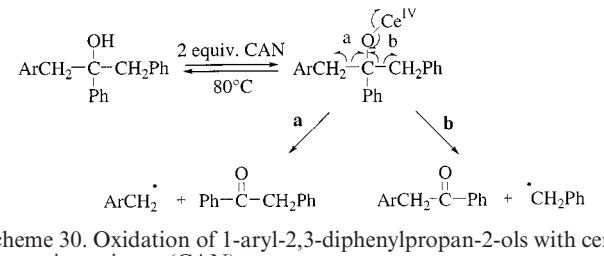


It is interesting to note that an oxidative cyclization (see section I.2) would have been reasonable given the *endo* position of the hydroxy group, but the expected highly strained 5-oxo-2,6-oxetane is not formed. The oxetane is neither a reaction intermediate, since if it were, the $O-C^2$ bond would break to give products not observed in the present case. Interestingly, PCC-induced oxidation of the *exo* isomer of **58a** leads to the same fragmentation products **59a** and **60a**. Consequently, an intramolecular oxidation of the double bond can be ruled out. The mechanism assumed for the transformation is illustrated in Scheme 28,[29] and parallels that proposed by Rocek et al.[34] in Scheme 25. It requires the formation of a chromate ester **61**, which suffers fragmentation to give the allylic carbocation **62**. Capture of **62** by a chromate species gives two new chromate esters **63** and **64**, and subsequent elimination leads to the 4- and 5-substituted cyclopentenones. It is noteworthy that this mechanism also explains the observed product ratio since **62** is not symmetric and the capture of the chromate moiety at the least hindered positive center gives **64** and the 4-substituted isomer **60** as the major product.

Scheme 28. Mechanism proposed for oxidation of **58** with PCC

I.3.b. Fragmentations with Vanadium Oxides

Bicyclic cyclopropanols undergo oxidation in the presence of catalytic amounts of vanadyl acetylacetonate $VO(acac)_2$ under oxygen to afford ring-enlarged β-hydroxy ketones and β-diketones.[36] Two examples of such reactions are represented in Scheme 29. β-Diketones are not obtained by the reaction of β-hydroxy ketones with $VO(acac)_2$, suggesting that β-diketones originate directly from the cyclopropanol systems.

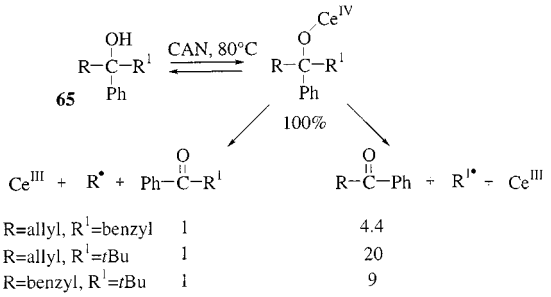


Scheme 29. Oxidation of bicyclic cyclopropanols catalyzed by vanadyl acetylacetonate

Molecular oxygen acts as the co-oxidant and reoxidizes the low valent vanadium compound formed. Nevertheless, it is possible to perform the reaction under a nitrogen atmosphere using stoichiometric amounts of $VO(acac)_2$. Although the absence of inhibition with a radical trap suggests that a radical pathway is not involved, the precise reaction mechanism is still unknown.

II. One-Electron Oxidations

II.1. Oxidative Cleavages with Ceric Ammonium Nitrate (CAN)

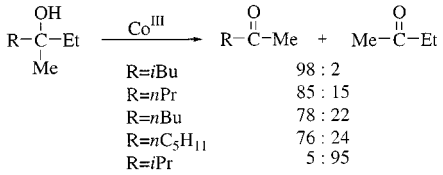


Oxidations of tertiary alcohols using ceric ammonium nitrate (CAN) as oxidant produce fragmentation products. The experiments carried out by Trahanovsky et al. on 1-aryl-2,3-diphenylpropan-2-ols showed that, in the presence of CAN, two competitive cleavages occur, producing two different ketones. The use of radical scavengers revealed the presence of aryl and benzyl radicals.[37] Therefore, the reaction likely proceeds through an intermediate $R-O-Ce^{IV}$ complex, whose homolytic cleavage affords the oxidation products (Scheme 30).

Scheme 30. Oxidation of 1-aryl-2,3-diphenylpropan-2-ols with ceric ammonium nitrate (CAN)

In order to determine whether the fragmentation regioselectivity depends on the stability of the released radicals, Trahanovsky and Macaulay investigated the oxidation of tertiary alcohols of general structure **65**, where R and R′

are allyl, *tert*-butyl or benzyl groups.[38] The relative ratios of the resulting ketones are given in Scheme 31.

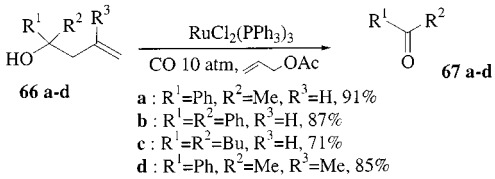


Scheme 31. Relative ratio of the ketones obtained from oxidation of **65** with CAN

It appeared that even though *tert*-butyl radical is less stable than allyl and benzyl radicals,[39] its formation was preferred. Thus, the stability of the released radicals is not the only factor controlling the selectivity of the reaction. The authors suggested that steric (release of the steric strain) or conformational factors (preventing vinyl or phenyl groups from stabilizing the incipient radicals) might play an important role during the reaction.

II.2. Cleavages with Cobalt Salts

Similarly to Ce^{IV}, Co^{III} is able to oxidize tertiary alcohols to form a ketone and a radical. Hoare and William examined the oxidation of a series of substituted tertiary alcohols in the presence of cobalt(III) perchlorate.[40,41] The results obtained and the relative ratio of the resulting ketones are indicated in Scheme 32.



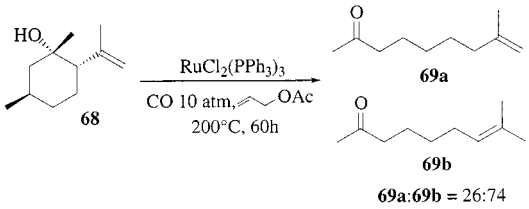
Scheme 32. Relative ratio of ketones resulting from the oxidation of alkylethylmethylcarbinols with Co^{III}

Evidence is given that the ease of elimination of the alkyl radicals increases according to the order: $Me^{\bullet} < RCH_2CH_2^{\bullet} < Et^{\bullet} < iPr^{\bullet}$. Therefore, it seems that for these simple tertiary alcohols, the fragmentation regioselectivity depends on the stability of the released radicals.

III. Fragmentations in Non-Oxidative Media

III.1. Fragmentations with Ruthenium Complexes

The selective cleavage of tertiary homoallylic alcohols has been recently investigated by Kondo et al.[42] They showed that treatment of such alcohols with allyl acetate in the presence of a ruthenium complex $[RuCl_2(PPh_3)_3]$ caused a β-allyl elimination to generate the corresponding ketone

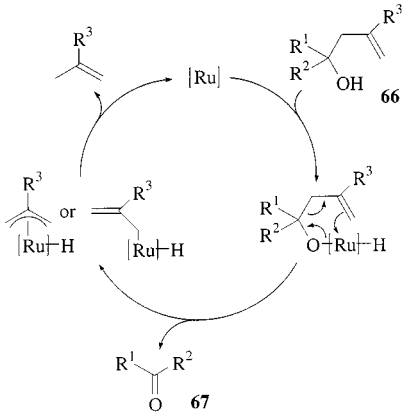


Scheme 33. Catalytic fragmentation of tertiary homoallylic alcohols with $RuCl_2(PPh_3)_3$

(Scheme 33). Thus, 2-phenylpent-4-en-2-ol (**66a**) is converted into acetophenone in 91% yield. In a same way, other derivatives bearing alkyl or aryl groups (**66b−d**) undergo a deallylation to afford various ketones **67b−d**.

Several ruthenium complexes such as $Ru_3(CO)_{12}$ or *cis*-$RuCl_2(CO)_2(PPh_3)_2$ were examined with regard to their ability to catalyze the deallylation of **66a** to **67a**. All of them show catalytic activity, and among them $RuCl_2(PPh_3)_3$ is the most efficient. In contrast, among the other transition metals examined (Pt, Pd, Ni, Rh), only the rhodium complex $[RhCl(PPh_3)_3]$ shows moderate catalytic activity (45% conversion for the deallylation of **66a** to **67a**).

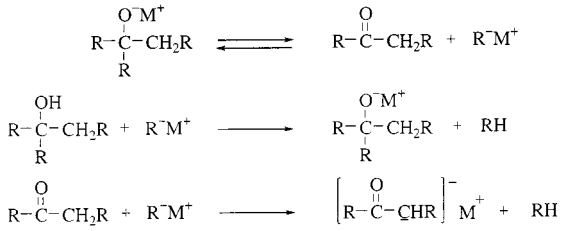
A synthetic application of this procedure is illustrated in the following ring opening reaction of cyclic homoallylic alcohols (Scheme 34). Treatment of **68** with $RuCl_2(PPh_3)_3$ affords the unsaturated ketones **69a−b** in 76% yield. This catalytic system thus represents an efficient and convenient method to perform catalytic ring-opening reactions on general 2-vinylcycloalkanols.



Scheme 34. Ring-opening reaction catalyzed by $RuCl_2(PPh_3)_3$

The following observations provide insight into the mechanism: (i) The treatment of a **66a** derivative bearing an acetoxy instead of the hydroxy group does not lead to **67a**. This result indicates that the first step of the reaction is the oxidative addition of a hydroxy group of **66a** to ruthenium; (ii) treatment of the saturated analogue of **66a**, i.e. 2-phenylpentan-2-ol, does not afford **67a** through propyl elimination. This suggests that the driving force of the reaction is the formation of an allylruthenium species; (iii) treatment of the secondary allylic alcohol 1-phenylbut-3-en-1-ol, which bears both a hydrogen atom and an allyl group at the β-position, yields the α,β-unsaturated ketone (1-phenylbut-2-en-1-one) from hydrogen β-elimination and not benzaldehyde from allyl elimination.

Considering all of these observations, Kondo et al. propose the mechanism depicted in Scheme 35.[42] The initial step might consist of oxidative addition of the hydroxy group of **66** to an active ruthenium center. Subsequent β-allyl elimination from the alkoxyruthenium intermediate



gives ketone **67** together with a (allyl)(hydrido)ruthenium species, which undergo a reductive elimination to give $R_3(CH_3)C{=}CH_2$.

Scheme 35. Proposed mechanism for the fragmentation of tertiary homoallylic alcohols with $RuCl_2(PPh_3)_3$

III.2. Alkoxide Fragmentations

Tertiary alcohols are easily cleaved in their alkoxide forms, obtained for example in the presence of metallic potassium, lithium hydride or sodium amide. At high temperatures, their oxidative fragmentation produces a ketone with elimination of a carbanion. The latter then captures a hydrogen atom from either the excess alcohol or the resulting ketone when it is an enol. The whole process is described in Scheme 36.

Scheme 36. Fragmentation of tertiary alcohols under the alkoxide form (M = metal)

In 1959, Zook et al. applied this procedure on various tertiary alcohols. The results are summarized in Table 9.[43] The experiments show that the ease of cleavage increases with the branching in the substituent R. For example, triisopropyl carbinol required a temperature of 300 °C to be cleaved to diisopropyl ketone, while 200 °C is sufficient to cleave *tert*-butyl diisopropyl carbinol, and triethyl carbinol cannot be cleaved at 335 °C (experiments 5, 6 and 8). Therefore, it seems that steric strain favors the fragmentation reaction.

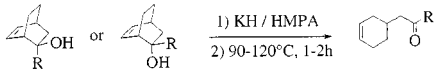
Experiments 1, 2 and 3 (Table 9) carried out on diisopropylalkyl carbinols demonstrate that the ease of cleavage of primary alkyl substituents increases with increasing bulkiness of the group, the order being *n*-propyl < isobutyl < neopentyl. Additionally, primary alkyl substituents are more readily eliminated than the isopropyl group, since no trace of alkyl isopropyl ketone was detected. Phenyl and *tert*-butyl are likewise eliminated preferentially to isopropyl (experiments 4 and 5).

The nature of the metallic cation also plays an important role. The results of the experiments performed on *tert*-butyl diisopropyl carbinol showed that the temperature required for the cleavage depends on the cation used (Table 10).[43] The order of ease of cleavage is Li < Na < K, which corresponds to the order of decreasing electronegativities. This is explained by the fact that as the electronegativity of the metal decreases, the negative charge developed on the anion becomes greater and the alkoxide is then more reactive.

Table 10. Influence of the cation on the fragmentation of $(i\text{Pr})_2t\text{Bu}$-COH

Cation	Temp.(°C)	Products (%)		
		$i\text{Pr}_2t\text{BuCOH}$	$i\text{Pr}_2\text{CO}$	$i\text{PrCO}t\text{Bu}$
K	160−182	0	60	35
Na	199−215	7	52	32
Li	213−320	24	35	25

Other authors used milder conditions compared to those used by Zook et al.[44−46] For example, using potassium dimesylate $[(CH_3SOCH_2)^-K^+]$ in DMSO is a convenient way to readily cleave tertiary alcohols at room temperature. Thus, in addition to the metallic cation, the solvent chosen also has an influence on the reaction.



Snowden et al. have studied alkoxide cleavages, particularly with bis- and tris(homoallylic) alkoxides.[47,48] It is noteworthy that allylic homoallylic alkoxides undergo oxy-Cope rearrangement rather than fragmentation under the same conditions.[48] The authors also examined more com-

plex bicyclic substrates. Thus, 2-substituted bicyclo[2.2.2]-oct-5-en-2-ols can be cleaved by heating the alkoxides at 120 °C.[49] The results obtained with such alcohols are summarized in Table 11.[49]

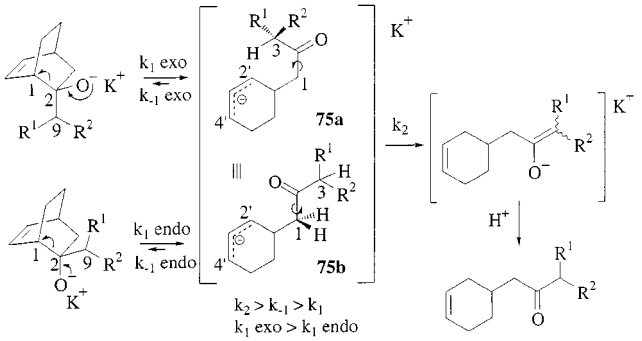

Table 11. Examples of bicyclo[2.2.2]oct-5-en-2-ols fragmentations

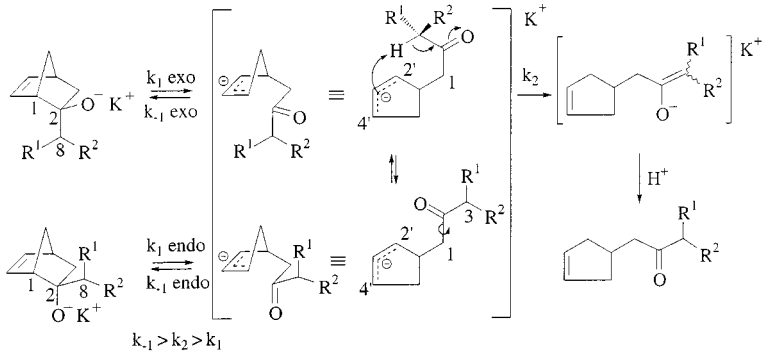
10		 **74**	54	
11		**74**	<5	 + PhOH (70) 3:1

Experiments 1 to 5, in which substituents are saturated alkyl groups, demonstrate that epimeric alcohols give the same product, i.e. 1-(cyclohex-3′-enyl)alkan-2-one resulting from C^1-C^2 bond cleavage (in each case only 10% of the 2′-enyl isomer is formed). However, the *exo*-alkoxide reacts noticeably faster than its *endo* epimer. On the other hand, no epimerization of the substrate is observed during the reaction. These results are consistent with a reaction mechanism in which the rate determining step is the heterolytic cleavage of the allylic C^1-C^2 bond to form a transient allylic anion which is then irreversibly quenched by intramolecular capture of a proton on C^3 adjacent to the carbonyl group. The resulting enolate subsequently affords the ketone by external protonation (Scheme 37).[49]

The high regioselectivity with respect to the position of the cyclohexenyl double bond may be rationalized by the strong preference for intramolecular proton transfer from the C^3-position to the $C^{2'}$-position of the allylic anion (rather than the $C^{4'}$-position) via a six-membered transition state (see conformation **75a**, Scheme 36). Additionally, an intermolecular protonation would not be expected to be regioselective. The observed rate difference between the *exo*- and *endo*-epimeric alkoxides is possibly the result of stabilization of the C^1-C^2 bond in the *endo*-alkoxide by electron donation from the O-anion to the cyclic double bond.

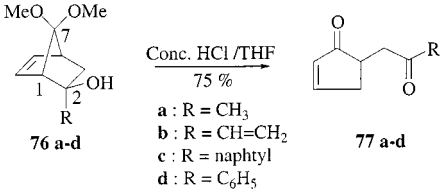
Scheme 37. Mechanism proposed for the cleavage of bicyclo[2.2.2]-oct-5-en-2-ols in the presence of potassium hydride



Experiments 6−11 (Table 11) were performed on substrates bearing an unsaturated C^2-substituent. In contrast with 2-alkyl-substituted alkoxides, the reaction products from these epimeric alkoxides are dependent on the substrate stereochemistry: The *exo*-alkoxides afford (4:1)-mixtures of β,γ- and α,β-unsaturated ketones via C^1-C^2 bond cleavage while the *endo*-alkoxides yield mostly the ketone resulting from C^2-C^9 bond cleavage. This marked difference between the epimeric alkoxides may be due to a strengthening of the C^1-C^2 bond in the *endo*-alkoxide caused by selective electron donation from the O-anion to the structurally rigid, cyclic double bond. In the *exo*-alkoxide, the C^2-C^9 bond may be stabilized by a similar electron donation from the O-anion to the double bond of the C^2-substituent.

Alkoxides derived from C^2-substituted norbornenols react similarly to the above compounds, producing 1-(cyclopent-3′-enyl)alkan-2-ones resulting from C^1-C^2 bond cleavage.[50] Nevertheless, an important epimerization of the substrate is observed during the reaction, suggesting that the rate determining step is the intramolecular protonation step which follows reversible C^1-C^2 bond cleavage to give the allylic anion (Scheme 38).[50]

When the substituents are unsaturated, the selectivity with regard to the cyclopentenyl double bond is decreased, indicating that an intermolecular protonation by reaction with the substrate also occurs. This is consistent with the reversibility of the first step which ensures an appreciable concentration of alkoxide during the reaction.

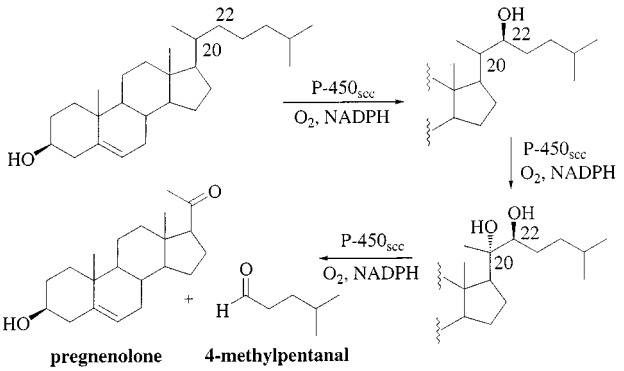


III.3. Fragmentations in Acidic Media

Norbornenols are able to undergo fragmentation, not only under basic conditions as described above, but also in acidic media. Thus, Palani et al. showed that several 7,7-dimethoxynorbornenols derivatives afford the corresponding substituted cyclopentenones through C^1-C^2 bond

Scheme 38. Mechanism proposed for the cleavage of norbornenols in the presence of potassium hydride

cleavage upon treatment with hydrochloric acid in THF (Scheme 39).[51]

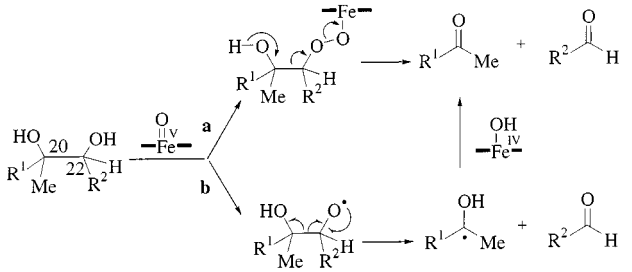


Scheme 39. Fragmentation of 7,7-dimethoxynorbornenols in acidic media

The behavior of compounds **76b** and **76c** is in remarkable contrast to that observed in basic media, since in the presence of sodium hydride the oxy Cope rearrangement products are obtained.[52] The use of hydrochloric acid is then an interesting option when the fragmentation process competes with the oxy Cope rearrangement under basic conditions.

IV. Oxidations Catalyzed by Heme-Containing Systems

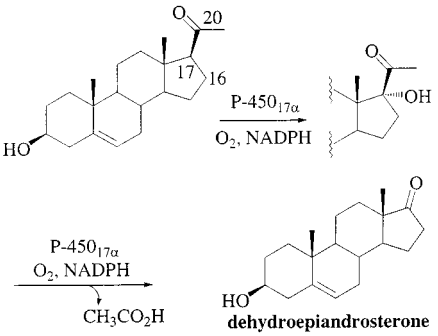
IV.1. Catalysis with Cytochrome P-450



Cytochromes P-450 belong to the monooxygenase family and are able to catalyze several oxidation reactions in the presence of molecular oxygen and NADPH. Among them, alkane hydroxylations and alkene epoxidations have been widely studied.[53,54] Some of these heme-enzymes play an important role in steroids biosynthesis by catalyzing two or three successive oxidation steps, where the last one can be

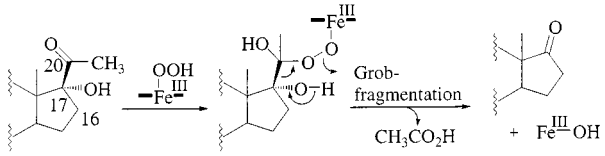
Scheme 40. Cholesterol side chain cleavage catalyzed by P-450 scc/O_2/NADPH

C−C bond cleavage. These cleavages sometimes occur at carbon atoms bearing a tertiary alcohol functionality. For example, P-450$_{scc}$ (cholesterol **s**ide **c**hain **c**leavage P-450) catalyses the side chain degradation of cholesterol via two hydroxylations at C^{20} and C^{22}, followed by an oxidative cleavage of the $C^{20}-C^{22}$ bond. The whole process leads to the formation of pregnenolone and 4-methylpentanal (Scheme 40).[54−56]



Although the first two steps are classical, the last one, where the enzyme acts as a lyase, is more original and interesting from a mechanistic point of view. The proposed mechanism is represented in Scheme 41. The active species of the catalyst is a high valent oxo-iron complex Fe=O. In the first hypothesis, the reaction pathway proceeds through the addition of the hydroxy group at C^{22} to the activated oxygen atom to form an iron-peroxo species. Deprotonation of the adjacent hydroxy group then induces the C−C bond cleavage (Scheme 41, path **a**). However, this hypothesis requires the formation of a peroxo complex with a poorly stable O−O bond, which is a thermodynamically unfavorable process. A second hypothesis involves the formation of an alkoxyl radical resulting from the abstraction of a proton and an electron at one of the hydroxy groups by the oxo-iron species. The subsequent β-fragmentation affords the oxidation products (Scheme 41, path **b**).[55,56]

Scheme 41. Mechanism of the side chain cleavage of cholesterol by P-450$_{scc}$

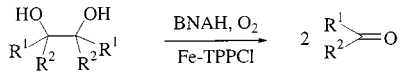


Another type of cytochrome P-450, 17α-hydroxylase-17,20-lyase or P-450$_{17\alpha}$, catalyses the pregnenolone deacetylation to form mainly dehydroepiandrosterone via an intermediate tertiary alcohol (Scheme 42).

This peculiar reaction has been widely studied by Akhtar et al.[57−59] Labeling experiments performed with $^{18}O_2$ and deuterium led to the proposal of a reaction mechanism for

Scheme 42. Deacetylation of pregnenolone by P-450$_{17\alpha}$

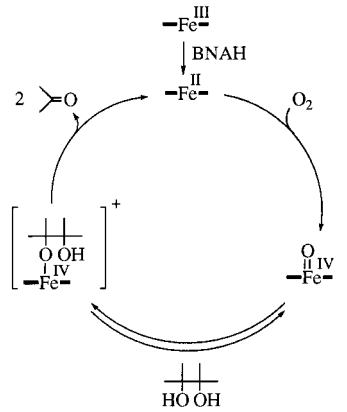
the last step, which is depicted in Scheme 43. Its originality lies in the nature of the active species of the catalyst, which is a Fe^{III}-hydroperoxo species. After its addition to the carbonyl group, the $C^{17}-C^{20}$ bond breaks according to a Grob-type fragmentation, releasing acetic acid. The results of the labeling experiments are in accordance with this mechanism: when hydroxypregnenolone bears a trideuteriated methyl at position 21 and reaction is performed under $^{18}O_2$, the acetic acid produced contains three deuteriums and one ^{18}O atom, whereas no labelled oxygen is incorporated into dehydroepiandrosterone.



Scheme 43. Mechanism of the oxidation of hydroxypregnenolone with P-450$_{17\alpha}$

IV.2. Catalysis by Synthetic Metalloporphyrins

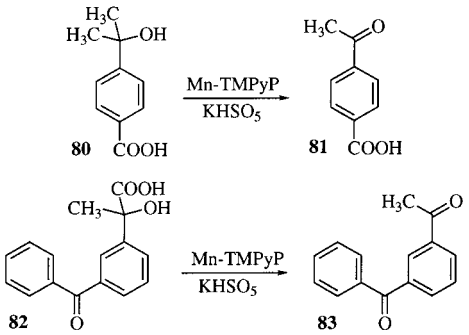
Synthetic metalloporphyrins are excellent biomimetic oxidation catalysts mimicking cytochrome P-450. They have been widely studied for hydroxylation and epoxidation reactions,[60] but only very few examples of tertiary alcohol oxidation have been reported in the literature up to now.



One of them concerns the oxidation of ditertiary 1,2-diols catalyzed by an iron porphyrin in the presence of molecular oxygen and 1-benzyl-3-carbamoyl-1,4-dihydropyridine (BNAH, which acts as the reducer).[61] The reaction simulates the final step of the side chain cleavage of cholesterol catalyzed by P-450$_{scc}$ (vide supra). The products formed are two ketones resulting from the cleavage of dihydroxylated C−C bond (Scheme 44).

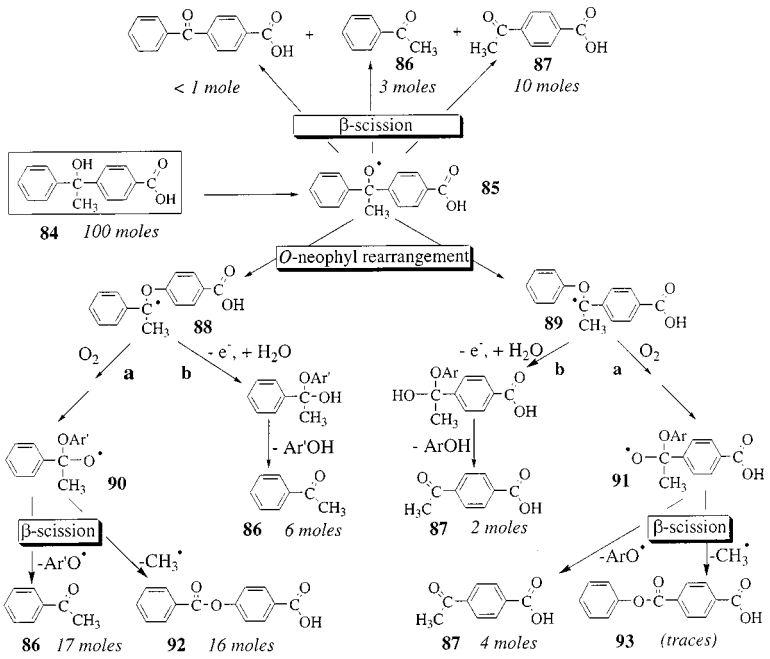
R^1	R^2	Conv (%)	Yield (%)
	CH_3	100	95
	CH_3	100	86
		80	48
		95	91

Scheme 44. Examples of fragmentations of ditertiary 1,2-diols with the system (TPP)FeCl/BNAH/O_2



Kinetic studies enabled the authors to propose a reaction mechanism (Scheme 45) in which the active species $Fe^{IV}=O$ reacts reversibly with the diol to form a Fe^{IV}-alkoxo complex before the fragmentation. This mechanism represents an alternative to the one proposed with P-450$_{scc}$ in Scheme 41.

Scheme 45. Mechanism of the oxidation of ditertiary 1,2-diols with the system Fe−TPPCl/BNAH/O_2



The fragmentation of ditertiary 1,2-diols can also be performed photocatalytically in the presence of a water soluble iron porphyrin and dioxygen.[62]

Recently, a catalytic system able to oxidize tertiary alcohols has been developed in our laboratory.[63] It consists of a water soluble manganese porphyrin (Mn−TMPyP) together with an oxygen atom donor, potassium monopersulfate ($KHSO_5$). The latter avoids the use of a reductant to form the active species of the catalyst. The tertiary alcohols used as substrates are the compounds **80** and **82**, whose oxidation leads respectively to the ketones **81** and **83** corresponding to the loss of a methyl or a carboxyl group (Scheme 46).

Scheme 46. Tertiary alcohols oxidation by the system Mn−TMPyP/$KHSO_5$

Labeling experiments performed with $H_2{}^{18}O$ revealed that no oxygen atom coming from water is incorporated in compound **83** (this study cannot be performed with compound **81** owing to the rapid exchange of the carbonyl oxygen atom with water). This observation suggests that **83** is formed through β-fragmentation of the alkoxyl radical of **82** resulting from the abstraction of a proton and an electron by the active species of the catalyst.

Scheme 47. Mechanism and diverse reaction pathways in oxidation of the tertiary alcohol **84** with the system Mn−TMPyP/$KHSO_5$; the number of mol is the amount of each product formed if the initial amount of **84** is 100 mol

Such a β-fragmentation of an alkoxyl radical may in fact compete with a *O*-neophyl rearrangement as has been shown in the catalytic oxidation of the tertiary alcohol **84** by the Mn−TMPyP/$KHSO_5$ system (Scheme 47).[64] Labeling experiments using $^{18}O_2$ or $H_2{}^{18}O$ under different reaction conditions demonstrate that the carbonyl oxygen atoms of acetophenone **86** and acetylbenzoic acid **87** originate either from substrate, water or dioxygen. The direct β-scission of the alkoxyl radical **85** leads to unlabelled compounds **86** and **87**. In a competitive reaction pathway, the *O*-neophyl rearrangement of **85** affords the carbon-based radicals **88** and **89** which then react with dioxygen (path **a**) or Mn^{IV}−OH/water (path **b**) to give in several steps labelled compounds **86** and **87** (the label comes either from water or dioxygen) and the unexpected esters **92** and **93** (from β-scission of the intermediate alkoxyl radicals **90** and **91**).

Conclusion

Metal-mediated oxidations of tertiary alcohols are mainly based on the use of stoichiometric or an excess of environmentally unfriendly metal oxides or metal oxy compounds (chromium oxide, ...). Consequently, this domain of tertiary alcohol oxidation is open to new catalytic methods using " green oxidants " (dioxygen, hydrogen peroxide, ...). In addition, the fragmentation reactions observed during the tertiary alcohol oxidations should be controlled by the metal center in order to ensure the product selectivity and avoid the formation of several products resulting from free-radical chemistry. Metal-controlled radical chemistry will be the future for metal-catalyzed oxidation of tertiary alcohols.

Alkali Metal Templated Assembly of an Iron Trigonal Prism

Jeremy C. Goodwin,[a] Daniel J. Price,[b] Annie K. Powell,*[c] and Sarah L. Heath*[a]

Keywords: Iron / Cluster compounds / Magnetic properties / Self-assembly / Alkali metals

A novel hexanuclear iron(III) complex $[Fe_6(C_7H_{11}NO_5)_6(\mu_2\text{-}O)_3Na][NO_3]\cdot 18H_2O$ has been synthesised from *N*-(2-hydroxypropyl)iminodiacetic acid and has been shown by X-ray crystallography to possess a prismatic structure containing a sodium ion in the core.

Introduction

Metal-directed spontaneous self-assembly has been shown to be a versatile tool in the construction of some spectacular three dimensional polymetallic architectures.[1–6] In recent years there have been several examples of the use of alkali metals to template the assembly of two dimensional metallomacrocycles[7–10] and, more recently, a three dimensional cobalt/rhenium box.[11] In the case of the metallomacrocycles, the size of the macrocycle is controlled by the radii of the templating cation. For example, with sodium Fe_6,[8,9] Cu_6[7] and Mn_6[10] wheels have been synthesised, whereas caesium promotes the synthesis of an Fe_8 wheel.[9] The metallobox formed with cobalt and rhenium is also cation selective, preferentially binding caesium over potassium. The organisation of transition metal based motifs around templating cations offers prospects for the production of tailored molecular materials and the creation of size selective host species. We have been investigating the reactions of transition metals with molecules based on the ligand heidi [H_3heidi = $N(CH_2COOH)_2(CH_2CH_2OH)$] which we have reported previously in the synthesis of polyiron(III) oxyhydroxide clusters.[12] Here we report the alkali metal templated synthesis of a new, three dimensional architecture formed with the related ligand pida [H_3pida = *N*-(2-hydroxypropyl)iminodiacetic acid], which produces an arrangement where the iron atoms form a twisted trigonal prism.

Results and Discussion

The reaction of equimolar amounts of H_3pida [*N*-(2-hydroxypropyl)iminodiacetic acid] with hydrated iron(III) nitrate and sodium hydroxide in a threefold molar excess results in the formation of **1**. An X-ray analysis of **1** reveals the formation of a beautiful three dimensional Fe_6 cage structure assembled around a central sodium cation, $[Fe_6(C_7H_{11}NO_5)_6(\mu_2\text{-}O)_3Na][NO_3]\cdot 18H_2O$, the cation of which is shown in Figure 1. The cage is formed through the interaction of three μ_2-oxide-bridged iron dimer units $\{LFe\}_2O$, linked by carboxylate bridges and templated about the central Na^+ through further carboxylate interactions. Each iron centre is in a distorted octahedral geometry consisting of a nitrogen, two carboxylate oxygens and a protonated alcohol oxygen from the ligand, a bridging μ_2-oxide and a bridging carboxylate from a symmetry related ligand. The iron-oxy core of **1** is shown in Figure 2a. The central sodium ion lies on a three fold rotation axis and is surrounded by a slightly distorted trigonal prism of oxygen atoms (Figure 2b) formed from the coordinating carboxylate oxygens of the ligand (O2, O2A, O2B, O7, O7A, O7B) with sodium to oxygen bond lengths of 2.444(3) and

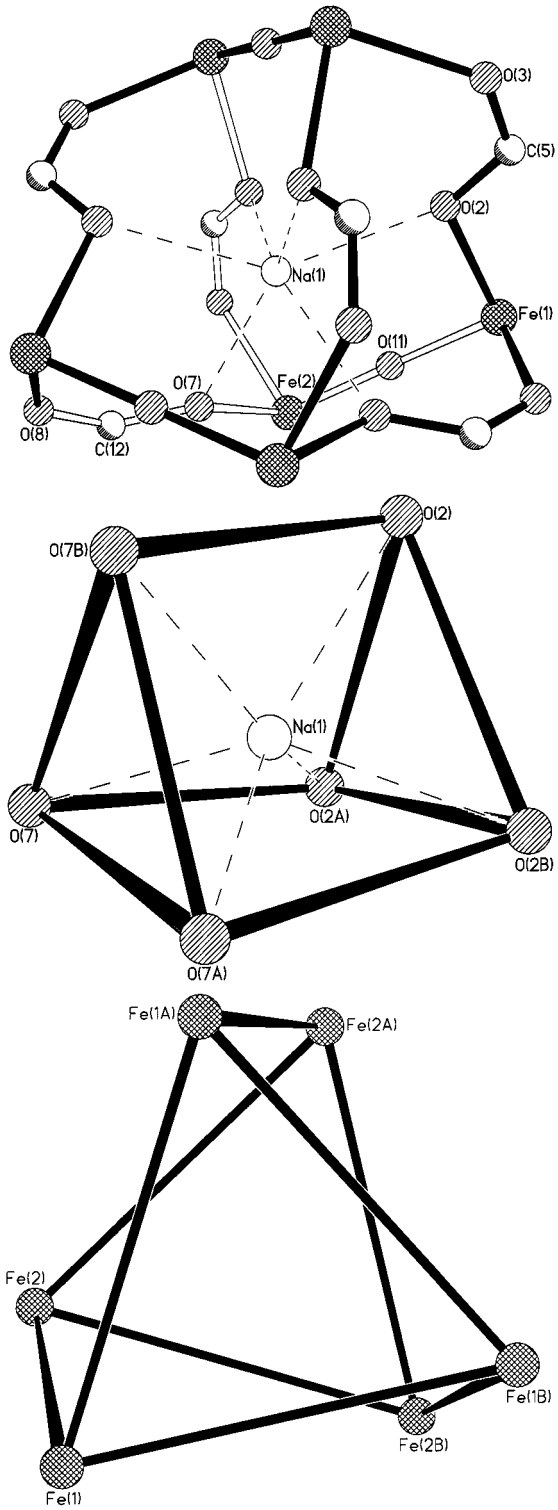

Figure 2. a) The central core of **1**; b) the coordination environment of the Na^+ cation; c) the distorted trigonal prismatic arrangement of the iron atoms

2.446(3) Å. The bridging μ_2-oxide oxygen (O11) is further away from the sodium at a distance of 2.986(3) Å. The volume of the oxygen prism, as calculated using the area of the smaller triangular face defined by O2, O2A, O2B, O7, is 14.11 $Å^3$.

The iron atoms are arranged in a much more distorted trigonal prism with the trigonal faces rotated at an angle of 27.3° to each other, as illustrated in Figure 2c. The iron atoms that form the trigonal faces of the prism are bridged by the carboxylate oxygens and are separated by distances of 5.362 Å (Fe2, Fe2A, Fe2B) and 5.365 Å (Fe1, Fe1A, Fe1B). The intra-trigonal interactions are afforded by an almost linear μ_2-oxide bridge [Fe1−O11−Fe2 = 179.1(2)°] and, consequently, the iron atoms have a much shorter separation, Fe1−Fe2 = 3.548 Å.

Reactions of equimolar equivalents of iron(III) nitrate and the barium salt of *N*-(2-hydroxypropyl)iminodiacetic acid with two equivalents of sodium hydroxide, results in the formation of the alkoxo bridged dimer $[Fe_2(C_7H_{10}NO_5)_2(H_2O)_2]$ **(2)**. The product is isostructural with the iron/heidi alkoxo bridged dimer synthesised by us previously.[12]

Preliminary magnetic studies have been performed on a powdered sample of **1** between 2 and 300 K in an applied field of 50 G. The susceptibility versus temperature is shown in Figure 3. It is clear from the product $\chi T(T)$ and the effective moment $\mu_{eff}(T)$ that **1** shows a very strong anti-ferromagnetic character, although the system does not follow a Curie-Weiss law. The room temperature net moment per iron ion is 1.83 μ_B which is much smaller than the expected value of 5.92 μ_B for isolated spin 5/2 ions implying a strong exchange coupling even at this temperature.

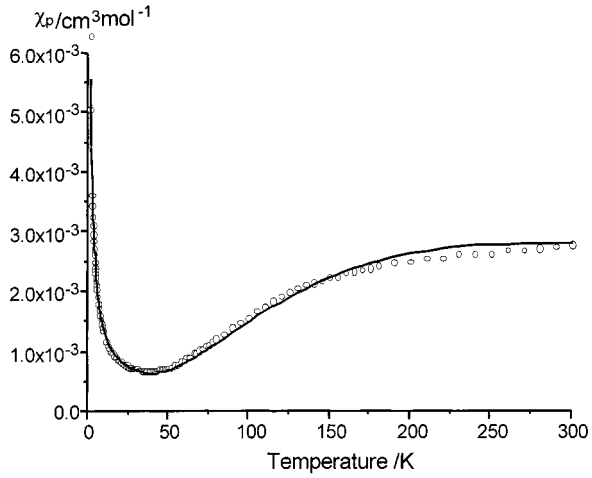

Figure 3. The molar susceptibility of **1** per unit dimer as a function of temperature (circles = experimental values, solid line = calculated for $J = -92 cm^{-1}$)

Although structurally **1** forms an Fe_6 cluster with two coupling pathways: J mediated by the μ_2-oxide bridge and J' through the carboxylate links, we expect $|J| >> |J'|$. Thus neglecting J' allows us to use a simple Heisenberg dimer model:[13]

$$\hat{H} = -2J\mathbf{S}_A \bullet \mathbf{S}_B$$

$$\chi_{dimer} = \frac{2Ng^2\mu_B^2}{k_BT}\frac{\left(e^{2x} + 5e^{6x} + 14e^{12x} + 30e^{20x} + 55e^{30x}\right)}{\left(1 + 3e^{2x} + 5e^{6x} + 7e^{12x} + 9e^{20x} + 11e^{30x}\right)}$$

where $x = J / k_BT$

The equation is often convoluted with a paramagnetic contribution from monomeric impurities (P) and a temperature independent component (C):[14]

$$\chi = (1 - P)\chi_{dimer} + 2P\chi_{monomer} + C$$

The iron(III) ion has a $^6A_{1g}$ ground term and should show Heisenberg behaviour with the temperature-independent contribution zero and the g value exactly 2.0. Fixing these and allowing the two other parameters to vary freely we obtain a good fit with $J = -82(1)$ cm^{-1} and $P = 0.4\%$.

A better fit could be obtained by allowing a nonzero temperature-independent component. This gave $J = -92(1)$ cm^{-1}, $P = 0.3\%$ and $C = 0.00032$ cm^3·mol^{-1}. In part, the problem to determine J precisely stems from the fact the J is so large, and even at room temperature the spins remain quite strongly coupled. It is interesting to note that the value of J is very sensitive to the value of C even though it is only a fraction of the estimated diamagnetic correction. Although temperature-independent behaviour may be caused by Van Vleck paramagnetism, in this case we believe that the constant (C) corresponds to a further diamagnetic correction since Pascal's constants are only approximate and no allowance had been made for the contribution of the sample capsule. We therefore conclude that the value of J for **1** is $-92(1)$ cm^{-1}. This large value of J is similar to those found in other materials where a near linear Fe−O−Fe exchange pathway is present.[15]

Conclusion

The small cavity size generated by the oxygen prism in **1** (14.11 Å^3) means that the cluster should only form in the presence of metal cations with an ionic radius similar to that of Na^+. Preliminary studies show that this may well be the case, with infrared evidence indicating that it is possible to synthesise the cluster with Ca^{2+} and Eu^{3+} templating the assembly but not with K^+, Mg^{2+} and Li^+. Hexamer formation was confirmed by the occurrence of the Fe−O−Fe asymmetric stretch at 845 cm^{-1} and the general similarity of the fingerprint region of the spectrum (1600−400 cm^{-1}). Presumably, the extra positive charge introduced by these cations will be compensated for by the presence of an additional one or two nitrate anions. The encapsulation of an ion such as Eu^{3+} or Tb^{3+} offers the possibility of creating luminescent species with long lifetimes. We are currently undertaking further characterisation of these reactions and their products.

Experimental Section

General Remarks: The magnetic behaviour of a powdered sample of **1** was measured on a Quantum Design MPMS SQUID magnetometer between 2 and 300 K in an applied field of 50 G. The molar susceptibility was corrected for diamagnetism using a value of $\chi_{dia} = -890 \times 10^{-6}$ cm^3·mol^{-1} determined from Pascal's constants. Single crystal X-ray data were collected on a Bruker SMART-CCD equipped with an Oxford Cryostream low temperature device.

***N*-(2-hydroxypropyl)iminodiacetetic Acid (pida):** DL-1-Amino-2-propanol (7.5 g, 0.1 mol), ethylbromoacetate (33.4 g, 0.2 mol) and potassium hydrogen carbonate (20.0 g, 0.2 mol) were refluxed in EtOH (50 cm^3) for 24 hours. The solid KBr formed was filtered off and the solvent removed in vacuo. The resultant pale yellow oil was refluxed in H_2O (80 cm^3) and 37% HCl (2 cm^3) for 24 hours. The solution was then reduced down to 30 cm^3 and placed in the fridge. In four days white crystals of $C_7H_{13}NO_5$ (6.12 g, 32%) formed. − $C_7H_{13}NO_5$ (191.18): calcd. C 43.98, H 6.85, N 7.33; found C 43.73, H 7.15, N 7.33. − ^{1}H NMR (250 MHz, D_2O): δ = 1.20 (d, 3 H, CH_3), 3.30 (m, 2 H, CH_2), 4.05 (s, 4 H, CH_2), 4.15 (m, 1 H, CH).

Pida Hexamer, $[Fe_6(C_7H_{11}NO_5)_6(\mu_2\text{-}O)_3Na][NO_3]\cdot 18H_2O$ (1): A solution of *N*-(2-hydroxypropyl)iminodiacetic acid (2.5 mmol) and sodium hydroxide (7.5 mmol) in water (10 cm^3) was added slowly with stirring to a solution of hydrated iron(III) nitrate (2.5 mmol) in water (10 cm^3). The pH of the resultant red solution was 2.47. Red hexagonal crystals of **(1)** formed in 59% yield after three weeks. − $C_{42}H_{104}Fe_6N_7NaO_{54}$ (1927.40): calcd. C 26.15, H 5.43, Fe 17.37, N 5.08; found C 25.94, H 4.97, Fe 17.45, N 5.24.

Pida Dimer, $[(FeC_7H_{10}NO_5)_2]\cdot 6H_2O$ (2): A solution of the barium salt of *N*-(2-hydroxypropyl)iminodiacetic acid (2.5 mmol) and sodium hydroxide (5 mmol) in water (10 cm^3) was added slowly with stirring to a solution of hydrated iron(III) nitrate (2.5 mmol) in water (10 cm^3). The pH of the resultant green solution was 2.54. Green crystals of **2** formed in 32% yield after three months. − $C_{14}H_{32}Fe_2N_2O_{16}$ (596.12): calcd. C 28.21, H 5.41, Fe 18.74, N 4.70; found C 28.14, H 5.21, Fe 18.61, N 4.94.

X-ray Crystallographic Study

Crystal Data for 1: $[Fe_6(C_7H_{11}NO_5)_6(\mu_2\text{-}O)_3Na][NO_3]\cdot 18H_2O$, red hexagonal block of dimension 0.45 × 0.33 × 0.31, M = 1927.4, trigonal, space group $P6(3)$, Z = 2, $a = b$ = 14.1386(7) Å, c = 22.3076(16) Å, U = 3861.9(4) Å^3, D_c = 1.658 g cm^{-3}, T = 150(2) K, $F(000)$ = 2004, Mo-K_α radiation (λ = 0.71073), μ = 1.217 mm^{-1}, 28695 reflections measured in the range 2.47° ≤ θ ≤ 28.29°, unique 6173 (R_{int} = 0.0514) which were used in all calculations. The structure was solved by direct methods and refined using full-matrix least-squares on F^2 to $R1$ = 0.0543, S = 0.991, for 5145 reflections with $F > 4\sigma(F)$ and 368 refined parameters, $wR2$ (all data) = 0.1411.

Crystal Data for 2: $Fe_2C_{14}H_{32}N_2O_{16}$, green needles of dimension 0.35 × 0.06 × 0.05, M = 596.12, monoclinic, space group $C2/c$, Z = 4, a = 14.0792(15) Å, b = 11.6006(12) Å, c = 14.5675(12) Å, β = 97.415(2), U = 2359.4(4) Å^3, D_c =1.678 g cm^{-3}, T = 150(2) K, $F(000)$ = 1240, Mo-K_α radiation (λ = 0.71073 Å), μ = 1.309 mm^{-1}, 6203 reflections measured in the range 2.28° ≤ θ ≤ 25.00°, 2079 unique (R_{int} = 0.091) which were used in all calculations. The structure was solved by direct methods and refined using full-matrix least-squares on F^2 to $R1$ = 0.0541, $wR2$ = 0.1396, S = 1.070, for 1698 reflections with $F > 4\sigma(F)$ and 188 refined parameters, $wR2$ (all data) = 0.1562.

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-137361 (**2**), CCDC-137362 (**1**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

The Chemistry of New Nitrosyltungsten Complexes with Pyridyl-Functionalized Phosphane Ligands

Jürgen Baur,[a] Heiko Jacobsen,[a] Peter Burger,[a] Georg Artus,[a] Heinz Berke,*[a] and Lutz Dahlenburg[b]

Keywords: Tungsten / Hydride complexes / P ligands / N ligands / Chelates / Ligand dynamics

The coordination chemistry of pyridylphosphanes, such as 2-(6-*tert*-butylpyridyl)diphenylphosphane (Ph_2P-*tert*-Bupy) (**6**) and 2-(6-*tert*-butylpyridyl)dimethylphosphane (Me_2P-*tert*-Bupy) (**7**) towards a number of nitrosyltungsten complexes is reported. Displacement of the loosely coordinated MeCN from $[W(CH_3CN)_3(CO)_2(NO)][BF_4]$ led to the following cationic compounds incorporating mono- and bidentate coordinated phosphane ligands: *cis*,*cis*-$[W(CO)_2(NO)(Ph_2PR)(\eta^2\text{-}Ph_2PR)][BF_4]$, [R = 2-pyridyl (**9a**), 2-picolyl (**11**)], *cis*,*cis*-$[W(CO)(NO)(\eta^2\text{-}Ph_2Ppy)_2][BF_4]$ (**20**), *trans*,*trans*-$[W(CO)(NO)(\eta^2\text{-}Ph_2Ppy)_2][BPh_4]$ (**21**), *fac*-$[W(CO)_2(NO)(Me_2P\text{-py})_3][BF_4]$ (**16**), *fac*-$[W(CO)_2(NO)(Me_2P\text{-}tert\text{-Bupy})_3][BF_4]$ (**18**), *cis*,*cis*-$[W(CO)_2(NO)(Me_2Ppy)(\eta^2\text{-}Me_2Ppy)][BF_4]$ (**22**), and *cis*,*cis*-$[W(CO)_2(CH_3CN)(NO)(Me_2P\text{-}tert\text{-Bupy})_2][BF_4]$ (**23a**). The cationic complex *cis*,*mer*-$[W(CO)_3(NO)(Ph_2P\text{-}tert\text{-Bupy})_2][PF_6]$ (**14**) has been prepared by nitrosylation of *cis*/*trans*-$W(CO)_4(Ph_2P\text{-}tert\text{-Bupy})_2$ (**13**). Reactions of **9a**, **11**, **14**, **16**, and **18** with hydride transfer reagents afforded *trans*,*trans*-$HW(CO)_2(NO)(Ph_2Ppy)_2$ (**10**), *trans*,*trans*-$HW(CO)_2(NO)(Ph_2Ppic)_2$ (**12**), *trans*,*trans*-$HW(CO)_2(NO)(Ph_2\text{-}t\text{Bupy})_2$ (**15**), *cis*/*trans*-$HW(CO)_2(NO)(Me_2Ppy)_2$ (**17**), and *cis*/*trans*-$HW(CO)_2(NO)(Me_2P\text{-}tert\text{-Bupy})_2$ (**19**), respectively. Reactivity experiments with acetic acid, hydroiodic acid, carbon dioxide, and acetylenedicarboxylic acid were performed, and were found to afford *trans*-$W(CO)(NO)(Ph_2Ppy)_2(\eta^2\text{-}CH_3CO_2)$ (**24**), *trans*,*trans*-$IW(CO)_2(NO)(Ph_2Ppy)_2$ (**25**), *trans*-$W(HCO_2)(CO)_2(NO)(Ph_2Ppy)_2$ (**26**), and *trans*-$W\{\eta^2\text{-}(Z)\text{-}C(CO_2Me)=CH[C(O)OMe]\}(CO)(NO)(Ph_2Ppic)_2$ (**27**), respectively. The influence of the pyridyl substituent in **10** was probed by a comparative H/D exchange experiment in which **10** and the analogous complex $HW(CO)_2(NO)(PPh_3)_2$ were treated with MeOD. The deuterated complex *trans*,*trans*-$WD(CO)_2(NO)(Ph_2Ppy)_2$ (**28**) could be isolated. The structures of **9a**, **11**, **14**, and **20** have been determined by single-crystal X-ray diffraction analysis.

Introduction

Previously, we have demonstrated that nitrosyltungsten hydride complexes are efficient reducing agents for aldehydes and ketones, the best results being achieved in the presence of a weak acid.[1−3] Furthermore, it has been shown that O−H and N−H bonds can act as weak acid components towards weakly basic M−H bonds.[4−8] Thus, intramolecular H···H interactions may be established, which could also play an important role in the heterolytic splitting of dihydrogen.[9] The pyridylphosphane ligand offers the possibility of either abstracting a proton from an external source or of activating a dihydrogen ligand coordinated to an unsaturated metal centre.[10] Therefore, this base-promoted splitting of dihydrogen through formation of a (ligand−H^+)−(metal−H^-) intermediate is of great significance with regard to catalytic ionic hydrogenations, as recently described by Noyori.[11,12] In order to design such a bifunctional system, we set out to prepare a series of cationic nitrosyltungsten and nitrosyltungsten hydride species having basic pyridyl substituents present in their coordination spheres. Similar investigations with P,N-, P,O-, and P,S-hybrid ligands have been described previously.[13−15]

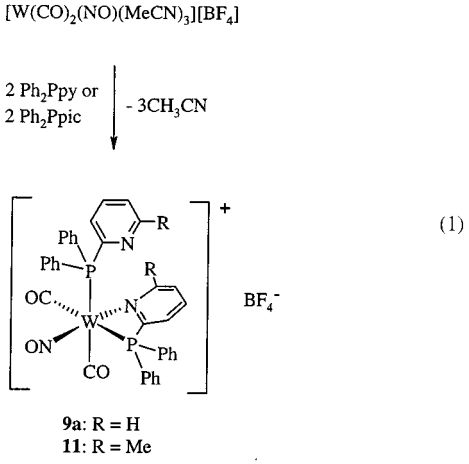
Results and Discussion

Preparation of Pyridyl-Substituted Phosphane Ligands



Diphenylpyridylphosphane (Ph_2Ppy)[16] and dimethylpyridylphosphane (Me_2Ppy)[17] were prepared according to literature procedures. On the other hand, new methods were developed for the synthesis of phosphanes bearing bulkier pyridyl substituents. Thus, the picolyl-substituted derivative 2-(6-methylpyridyl)diphenylphosphane (Ph_2Ppic) was synthesized by a route different from that reported in the literature[18] by adding 6-chloro-2-picoline to a solution of $LiPPh_2$, prepared from *n*-butyllithium and diphenylphosphane. For the preparation of the *tert*-butyl-substituted phosphanes, 2-(6-*tert*-butylpyridyl)diphenylphosphane (Ph_2P-*tert*-Bupy) and 2-(6-*tert*-butylpyridyl)dimethylphosphane (Me_2P-*tert*-Bupy), the starting material 2-*tert*-butyl-6-chloropyridine was synthesized according to a method described by Mariella for analogous compounds.[19]

Preparation of the Cationic Complexes

With the exception of the bulkiest phosphane, Ph_2P-*tert*-Bupy, the best yields of the cationic metal complexes were

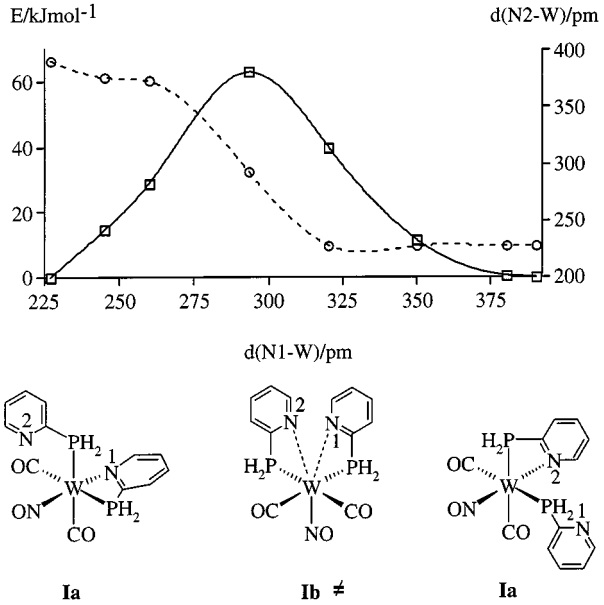
 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 2000 1434−1948/00/0707−1411 $ 17.50+.50/0

obtained by using $[W(CH_3CN)_3(CO)_2(NO)][BF_4]$[20] as the starting material. Thus, the addition of two equivalents of Ph_2Ppy or Ph_2Ppic to $[W(CH_3CN)_3(CO)_2(NO)][BF_4]$ in dichloromethane resulted in substitution of the three acetonitrile ligands by two phosphanes, one of which coordinated in a monodentate fashion and the other in a bidentate mode, thereby affording complexes **9a** and **11**, respectively [Equation (1)]. Spectroscopic studies showed that no further phosphane coordination occurred, even in the presence of an excess of the ligand.

(1)

The variable-temperature (VT) NMR spectra of compound **9a** reveal dynamic behaviour. At room temperature, two broad resonances are observed in the ^{31}P-NMR spectrum at $\delta = 24.8$ and $\delta = -18.3$, which sharpen into two doublets below -15 °C. The energy of activation for the exchange process was estimated to be 57(2) kJ/mol by lineshape analysis. When the pyridyl groups in **9a** are replaced by picolyl groups as in complex **11**, no dynamic behaviour is observed, even at 70 °C. In order to obtain more information regarding the mechanism of the pyridyl exchange process, DFT calculations were performed on the model compound $[W(CO)_2(NO)(H_2Ppy)(\eta^2\text{-}H_2Ppy)]^+$. The energy profile of the exchange reaction, together with a systematic sketch of the reaction coordinate, is presented in Figure 1. The distance d_{N1-W} was allowed to vary from 225 pm to 395 pm; it can be seen that the energy rises smoothly from 0 kJ/mol (the reference value for the ground state) to 62 kJ/mol (the transition state) and then decreases again (see Figure 1, solid line).

More interesting still are the changes in d_{N2-W} as a function of the value of d_{N1-W} (Figure 1, dashed line). We analysed this by following the actual linear transit mode, i.e. by bringing the uncoordinated atom N1 in towards the distance for binding to the metal centre. As the N1 atom approaches (d_{N1-W} in the range from 395 pm to 325 pm), the four-membered metallacycle remains essentially intact and d_{N2-W} does not change significantly. At the transition state, two equally long d_{N-W} distances are present. If N1 is now brought closer to the metal centre, d_{N2-W} immediately takes on values around 380 pm, the distance corresponding to the uncoordinated ring. From this, it might be concluded that bond cleavage and bond formation do not occur in a



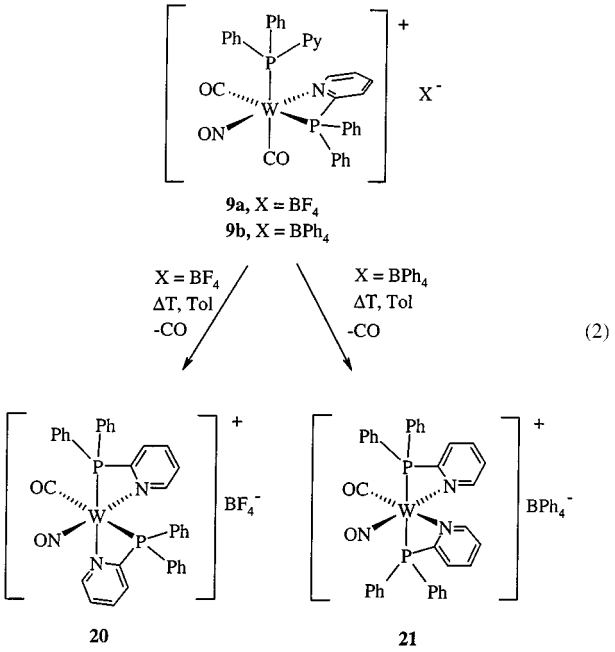


Figure 1. Energy profile for the pyridyl exchange reaction; the solid line refers to the left ordinate axis, the dashed line to the right ordinate axis

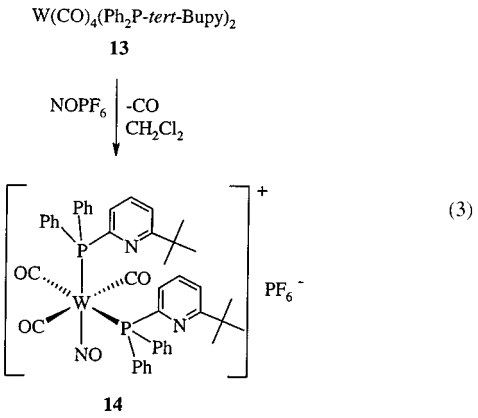
concerted fashion and one may envisage the exchange process as follows. The N2 atom of the free pyridyl unit first approaches the metal centre, which requires about two-thirds of the energy of activation. Bond cleavage then occurs, and in the transition state the two N atoms are only weakly coordinated to the tungsten centre. The formerly bound pyridyl unit rotates away to relieve steric hindrance, allowing formation of the bond between N2 and W. The calculated activation energy of 62 kJ/mol is in good agreement with the experimentally determined value of 57(2) kJ/mol. This result can thus be taken as strong evidence in favour of the suggested reaction mechanism.

Furthermore, it is noteworthy that the two pyridyl groups in complex **11** do not exchange. Taking the geometry of the transition state for **9**, replacing the H atoms in the positions α to N by methyl groups, and assuming a C−C bond length of 153 pm, it can be calculated that the two CH_3 carbon centres are separated by just 213 pm. This is within the range of the effective van der Waals radius of a methyl group (200 pm). It seems likely that the transition-state geometry of the intramolecular rearrangement of **11** does not allow the two pyridyl rings to pass each other. Thus, the exchange process is hindered for steric reasons.

When a solution of **9a** in chloroform was set aside for several hours at room temperature, the formation of small amounts of decarbonylated complex isomers with both phosphane ligands coordinated in a bidentate fashion was observed. On warming the solution to 70 °C, however, decomposition was observed by NMR spectroscopy. In order to confirm the structures of the isomers, a specific synthesis was developed [Equation (2)]. The monocarbonyl complex **20** with the phosphorus donors coordinated in a *cis* arrangement was prepared by heating a suspension of **9b** in toluene to 100 °C with slow removal of the solvent under slightly reduced pressure. A similar procedure was em-

ployed to synthesize the *trans* isomer **21**. In order to increase the solubility of the cationic species, it was necessary to replace the BF_4 anion of **9a** by BPh_4, thereby affording the analogous complex **9b**. Dissolution of **9b** with a few drops of acetonitrile in toluene, heating to 95 °C, removal of the solvent under reduced pressure, and repeating of this procedure afforded a red powder. Recrystallization from dichloromethane at −30 °C gave **21** as dark-red crystals. The ^{31}P-NMR spectrum of the product featured an AB system ($^2J_{AB}$ = 121 Hz) along with the respective tungsten satellites and characteristic J_{PW} values of 277 Hz and 299 Hz for the two P atoms located in *trans* positions.

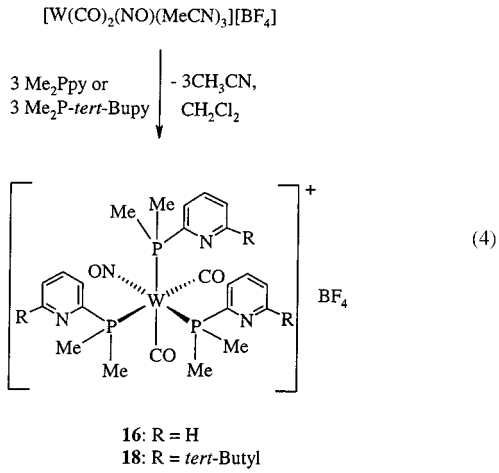


9a, X = BF_4
9b, X = BPh_4

(2)

20 **21**

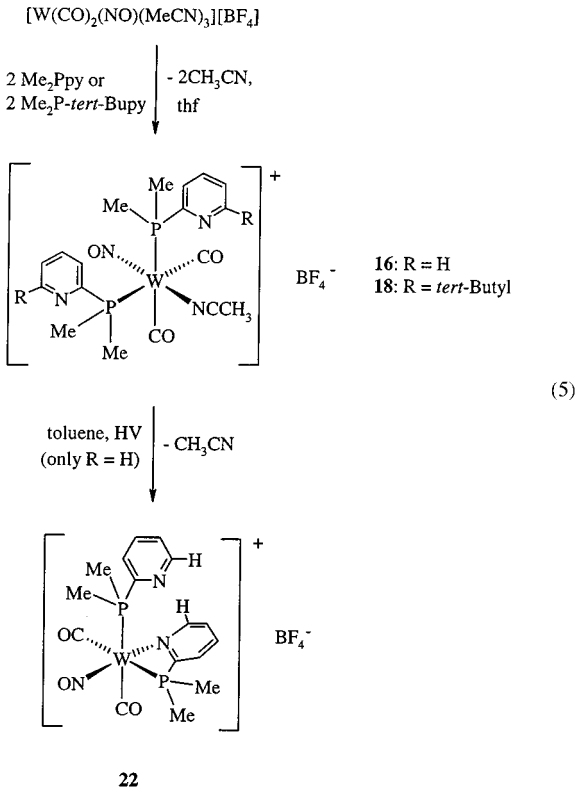
A suitable reaction for preparing the cationic complex **14** bearing the bulky Ph_2P-*tert*-Bupy ligands that avoided coordination of the pyridine substituents, was found to be nitrosylation of the neutral tetracarbonyl compound **12**, Equation (3).



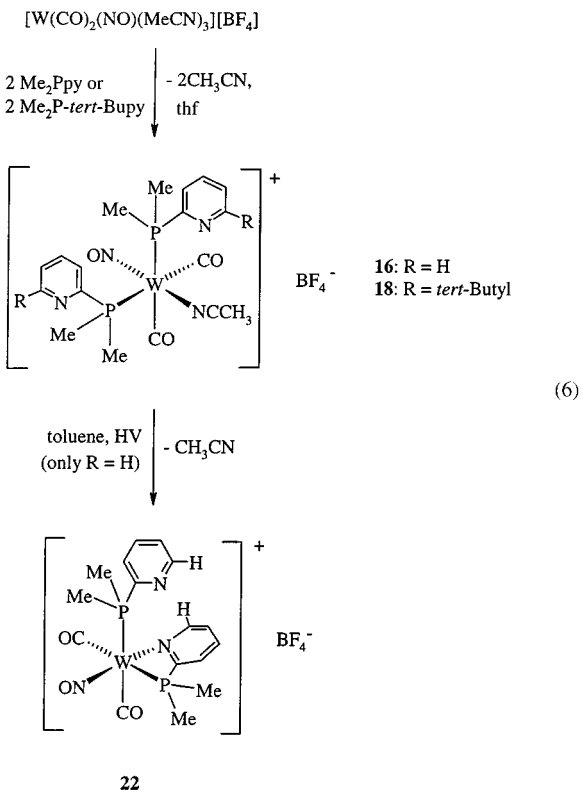
(3)

14

A 20% excess of $NOPF_6$ was found to be essential to achieve complete transformation of **13**. The crude product consisted of **14** (70%) and unidentified impurities (ca. 25%), as well as uncoordinated phosphane (5%). The collected solid was washed several times with diethyl ether and then taken up in a mixture of diethyl ether/dichloromethane. Slow evaporation of the solvents afforded bright-yellow crystals of the desired product.

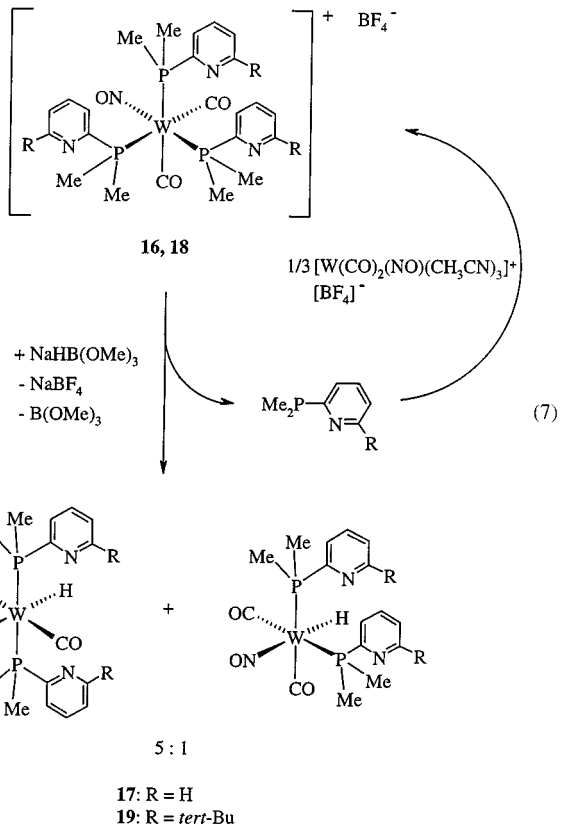


In contrast, the reaction of the more basic phosphanes Me_2Ppy or Me_2P-*tert*-Bupy with $[W(CH_3CN)_3(CO)_2(NO)][BF_4]$ in dichloromethane resulted in the substitution of three acetonitrile ligands by *P*-coordinated phosphanes [Equation (4)]. The formation of the trisubstituted complexes **16** and **18** could be observed by ^{31}P-NMR spectroscopy even after the addition of just one equivalent of the phosphane ligand to the acetonitrile complex.



(4)

16: R = H
18: R = *tert*-Butyl



Complexes **16** and **18** were found to be very stable in air in the solid state, and only slightly moisture-sensitive in solution. When the former reaction was carried out in THF using exactly two equivalents of the phosphane, the ^{31}P-NMR spectra of the reaction mixtures showed one singlet with a J_{PW} of 254 Hz for the Me_2Ppy derivative and 257 Hz for the Me_2P-*tert*-Bupy derivative, indicating a *cis* arrangement of the two phosphanes coordinated to the tungsten centre. A further resonance of lower intensity was observed in each case, which disappeared upon addition of acetonitrile to the THF solution [Equation (5)]. Removal of the solvents in vacuo (10^{-1} mbar) afforded complex **22** with one Me_2Ppy ligand coordinated to the metal centre in a monodentate fashion and the second coordinated in a bidentate fashion, akin to the situation in complexes **9a** and **11**. With Me_2P-*tert*-Bupy ligands, however, the sterically demanding *tert*-butyl substituent prevents coordination of the pyridine ring and so complex **23a**, with one acetonitrile ligand remaining coordinated to the metal centre, is formed. In contrast to the complexes bearing less bulky phosphanes, the remaining acetonitrile ligand could not be removed from the metal coordination sphere, even at elevated temperatures. Exchange of the BF_4 anion by the more inert tetrakis[3,5-bis(trifluoromethyl)phenyl]borate (TFPB) **23b** and subsequent heating in vacuo (10^{-4} mbar) led only to slow decomposition of the complex.

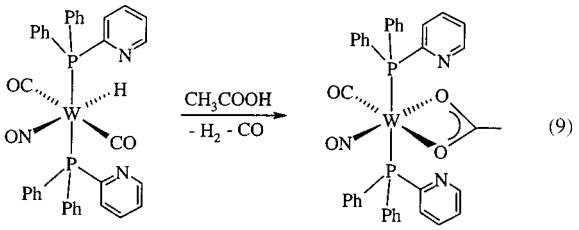
(7)

Preparation of the Tungsten Hydrides

Depending on the nature of the cationic nitrosyltungsten complexes, three different hydride reagents were used to obtain the corresponding tungsten hydride compounds. For the cationic complexes **9a** and **11**, which have pyridine substituents coordinated at their metal centres, sodium bis(2-methoxyethyloxy)aluminium hydride (RedAl) was found to give the best yields, whereas for complex **14** sodium tetrahydroborate proved to be most efficient in displacing the carbonyl ligand. The resulting tungsten hydride complexes **10**, **12**, and **15** bearing diphenyl-substituted phosphanes were readily precipitated by rapid addition of ethanol to the reaction mixtures. The *tert*-butyl-substituted derivative **15** was found to be slightly more soluble than **10** and **12** and therefore had to be precipitated at low temperature to prevent further reaction of the hydride with the alcohol [Equation (6)].

Sodium hydrotrimethoxyborate was chosen for the reactions with the trisubstituted phosphane cations **16** and **18**, which afforded the tungsten hydride complexes **17** and **19**. The phosphane ligands abstracted during these reactions could not easily be removed from the products due to similar solubility properties. However, in both cases $[W(CH_3CN)_3(CO)_2(NO)][BF_4]$ proved to be an efficient phosphane scavanger affording the cationic starting complex, from which the product could simply be separated by extraction with pentane [Equation (7)].

Reactivity Studies

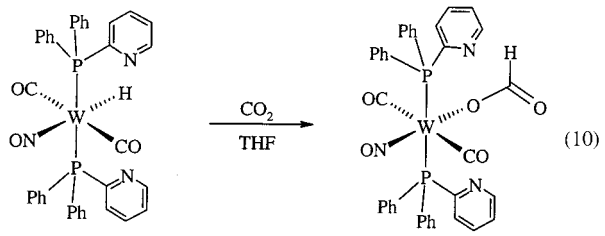


In order to assess the influence of the pyridyl substituents, complexes **10** and **12** were compared with the analog-

ous compound *trans*-$HW(CO)_2(NO)(PPh_3)_2$ prepared by Hillhouse.[21] The NMR chemical shifts and coupling constants of the carbonyl and hydride resonances, as well as the IR stretching vibrations for NO and CO, were found to be essentially identical for the three hydride complexes. Therefore, one can also expect a similar hydridic behaviour, as discussed previously by Berke et al.[22,23] for related compounds.

The reaction of **10** with HI (0.75 M in $CHCl_3$) led to the immediate evolution of hydrogen affording *trans*-$IW(CO)_2(NO)(PPh_2py)_2$ (**25**) [Equation (8)], as described for the PPh_3 derivative.

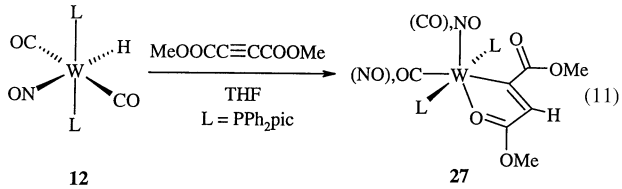
trans,trans-$HW(CO)_2(NO)(Ph_2Ppy)_2$ + HI
10
$\downarrow$ - H_2 (8)
trans,trans-$IW(CO)_2(NO)(Ph_2Ppy)_2$
25



Hydrogen was also evolved when **10** was treated with glacial acetic acid in a mixture of dichloromethane and 2-propanol. Subsequent loss of one carbonyl ligand resulted in the formation of a four-membered metallacycle with the formula *trans*-$W(CO)(NO)(Ph_2Ppy)_2(\eta^2\text{-}CH_3CO_2)$ (**24**) [Equation (9)].

10 **24** (9)

The same decarbonylation reaction was also observed by Hillhouse and afforded the analogous complex bearing PPh_3 ligands.

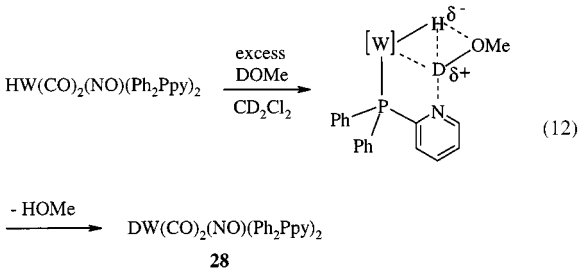


The insertion of carbon dioxide into the metal hydride bond yielding the formato complex **26** was achieved by slowly bubbling a stream of CO_2 gas through a solution of **10** in THF [Equation (10)].

10 **26** (10)

The ^{1}H-NMR resonance of the formate proton in **26** appears at $\delta = 7.06$ ($\delta = 7.08$ for the PPh_3 derivative). The oxo carbonyl resonance is seen at $\delta = 166.4$ in the ^{13}C-NMR spectrum. Identical shifts have been observed for other phosphane complexes incorporating monodentate formate ligands prepared in our laboratory, such as the analogous $P(OiPr)_3$ derivative.[24] The carbonyl intensity patterns [2050 (w), 1962 (s) cm^{-1}] in the infrared spectra are characteristic of a *trans*-dicarbonyl geometry by analogy with the PPh_3 derivative.

A further insertion experiment was performed by treating **12** with dimethyl acetylenedicarboxylate in THF. The resulting IR spectrum featured one carbonyl band at 1935 cm^{-1} indicating the loss of a single carbonyl ligand. The ^{1}H- and ^{13}C-NMR data of the resulting complex **27** were compared with those of the PMe_3 derivative.[22] However, it could not be unambiguously established which of the two isomers with regard to the positions of the NO and CO ligands had been formed [Equation (11)].



12 **27** (11)

The above reactions displayed approximately the same characteristics irrespective of whether a PPh_2py or a PPh_3 ligand was coordinated to the tungsten centre. According to the spectroscopic data and the reactivities of the tungsten hydride complexes, the pyridyl substituents seemingly have no influence on the electronic character of the hydride ligand.

Nevertheless, an H/D exchange experiment was performed in order to assess whether the basic pyridine N atom had any effect on the reactivities of the hydride complexes. The interaction of a protic alcohol function with the pyridyl substituents located in the ligand sphere could facilitate proton transfer to the hydride. In order to compare the H/D exchange rates of $HW(CO)_2(NO)(PPh_3)_2$ and $HW(CO)_2(NO)(PPh_2py)_2$ (**10**) with [D_4]methanol, a 1:1 mixture of the two complexes in CD_2Cl_2 was prepared and then a 150-fold excess of [D_4]methanol was added at 0 °C. Higher temperatures (+5 °C) led to rapid decomposition of the complexes with evolution of HD. By monitoring the reaction by ^{1}H-NMR spectroscopy for 25 min at 0 °C, it was observed that the hydride resonance of **9** at $\delta = -0.07$ completely disappeared while in the ^{31}P{^{1}H}-NMR spectra a triplet due to deuterated **9** with a PD coupling constant of $J = 3$ Hz appeared. In contrast, the analogous resonances due to $HW(CO)_2(NO)(PPh_3)_2$ did not change. After 22 hours, **10** had been completely consumed while only 30% of the PPh_3 complex had been transformed to the deuteride with partial decomposition through ligand abstraction [Equation (12)]. After a reaction time of one hour under the same conditions and further addition of [D_1]methanol to the mixture, the deuteride complex **28** readily precipitated and could be fully characterized.

Although no spectroscopic evidence was found to support the concerted mechanism proposed in Equation (12), it could be concluded from these experiments that the interaction of the protic alcohol with the pyridyl substituent is responsible for the accelerated H/D exchange.

We also carried out exploratory catalytic experiments with the hydride complexes **10** and **19** in order to investigate their activities in the ionic hydrogenation of imines. This type of catalysis has been reported for a variety of Ru, Ir, Rh, and Ti complexes. With compound **10**, we obtained the most promising results when a 5:1 mixture of isopropylisopropylideneamine and its corresponding BPh_4 salt were dissolved in a 2:1 mixture of THF/CH_2Cl_2. The amount of tungsten hydride catalyst used was 10 mol-% with respect to the imine. Stirring the reaction mixture at 70 °C for 14 hours under 60 atm of hydrogen resulted in the conversion of 35% of the imine and iminium salt to the corresponding amine and ammonium salt, respectively. The ^{31}P-NMR spectra showed one resonance corresponding to the free phosphane ligand. We conclude that about 3−4 turnovers were reached before decomposition of the catalyst occurred. Addition of the BPh_4 salt was found to be essential to initiate the reaction; no hydrogenation was observed if only the pure imine was present in solution.

When the same experiment was performed using **19** as the catalyst, an additional product could be observed in the ^1H-NMR spectrum. Reference spectra and GC-MS analysis confirmed the formation of both mono- and diisopropylamine. Further investigations using hydrogen pressures up to 100 atm and temperatures up to 90 °C led to changes in the isopropylamine/diisopropylamine ratio from 1:2 (60 °C/60 atm) up to 3:1 (90 °C/100 atm). The mechanisms of these reactions have not yet been clarified and are currently under investigation in our laboratory.

X-ray Crystal Structure Determinations

The following complexes were characterized by X-ray analysis: *cis,cis*-$[W(CO)_2(NO)(Ph_2Ppy)(\eta^2\text{-}Ph_2Ppy)][BF_4]$ (**9a**), *cis,cis*-$[W(CO)_2(NO)(Ph_2Ppic)(\eta^2\text{-}Ph_2Ppic)][BF_4]$ (**11**), *cis,mer*-$[W(CO)_3(NO)(Ph_2P\text{-}tert\text{-}Bupy)_2][PF_6]$ (**14**), and *cis,cis*-$[W(CO)(NO)(\eta^2\text{-}Ph_2Ppy)_2][BF_4]$ (**20**). In the Figures the anions of all the structures have been omitted for the sake of clarity.

Compounds **9a** (Figure 2) and **11** (Figure 3) show strongly distorted octahedra due to the formation of the four-membered metallacycle with P−W−N bond angles of approximately 64.5° in each case. The W−N(pyridyl) bond length in **11** is only slightly lengthened to 2.259(5) Å compared to 2.240 Å in **9a**. However, the steric influence of the methyl substituent in **11** is clearly apparent from the opening of the corresponding equatorial bond angles, N(1)−W(1)−C(36) in **9a** and N(2)−W(1)−C(1) in **11**, from 94.12° to 101.4(2)°.

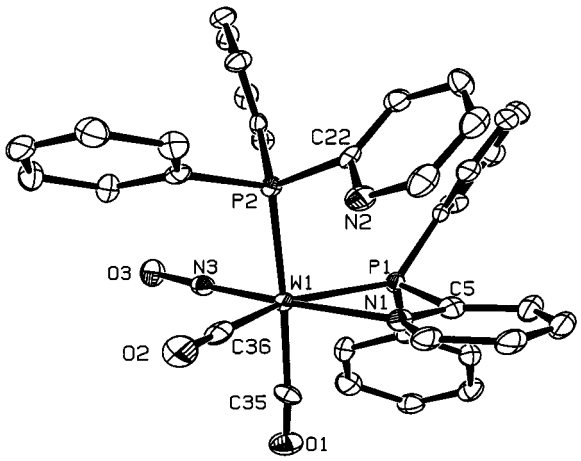


Figure 2. View of the structure of the cation of **9a**; selected bond lengths (Å) and angles (°): W(1)−N(1) 2.240, W(1)−P(1) 2.537, W(1)−P(2) 2.536, W(1)−C(36) 2.046, W(1)−N(3) 1.809, W(1)−C(35) 2.051; N(3)−W1−C(36) 95.11, N(3)−W1−C(35) 92.08, N(3)−W1−N(1) 170.70, N(3)−W1−P(2) 87.89, N(3)−W1−P(1) 106.24, C(36)−W1−C(35) 89.41, C(36)−W1−N(1) 94.12, C(36)−W1−P(2) 86.15, C(35)−W1−N(1) 86.95, C(35)−W1−P(1) 86.70, N(1)−W1−P(2) 93.80, N(1)−W1−P(1) 64.48, P(2)−W1−P(1) 97.59

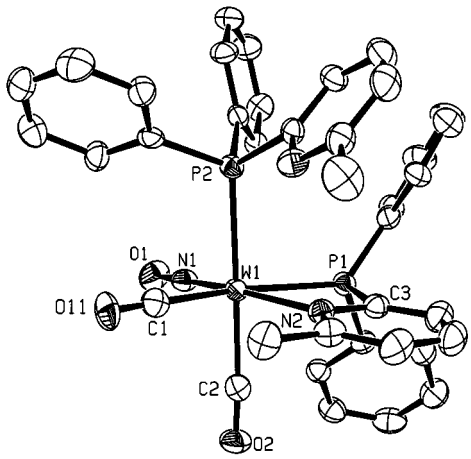

Figure 3. View of the structure of the cation of **11**; selected bond lengths (Å) and angles (°): W(1)−N(2) 2.259(5), W(1)−P(1) 2.539(2), W(1)−P(2) 2.564(1), W(1)−C(1) 2.046(7), W(1)−N(1) 1.810(5), W(1)−C(2) 2.047(6); P(1)−W(1)−P(2) 94.08(5), P(1)−W(1)−N(1) 104.1(2), P(2)−W(1)−N(1) 91.5(2), P(1)−W(1)−N(2) 64.5(1), P(2)−W(1)−N(2) 94.8(1), N(1)−W(1)−N(2) 167.3(2), P(2)−W(1)−C(1) 87.9(2), N(1)−W(1)−C(1) 89.8(2), N(2)−W(1)−C(1) 101.4(2), P(1)−W(1)−C(2) 88.2(2), N(1)−W(1)−C(2) 90.9(2), N(2)−W(1)−C(2) 83.4(2), C(1)−W(1)−C(2) 89.2(3), W(1)−P(1)−C(3) 83.6(2)

The W−N(pyridyl) bond lengths in the monocarbonyl complex **20** (Figure 4) are 2.258(3) Å for N(2) and 2.210(3) Å for N(1). The longer W−N(2) bond length can be attributed to the strong *trans* influence of the nitrosyl ligand. This effect is also manifested in the bond angles in the less strained metallacycle, 65.50(9)° for N(2)−W(1)−C(2) [cf. 64.12(9)° for N(1)−W(1)−C(1)].

In compound **14** (Figure 5), the *trans* influence of the nitrosyl ligand is also reflected in the longer phosphorus−tungsten bond length, which is 2.640(2) Å for W(1)−P(30), as compared to 2.591(2) Å for W(1)−P(10) with a carbonyl ligand coordinated in a *trans* orientation.

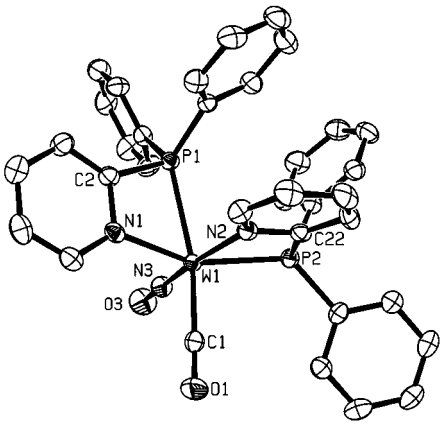

Figure 4. View of the structure of the cation of **20**; selected bond lengths (Å) and angles (°): W(1)−P(10) 2.591(2), W(1)−P(30) 2.640(2), W(1)−N(4) 1.896(7), W(1)−C(1) 1.977(8), W(1)−C(2) 2.080(9), W(1)−C(3) 2.06(1); P(1)−W(1)−P(2) 98.41(3), P(1)−W(1)−N(1) 64.12(9), P(2)−W(1)−N(1) 152.51(9), P(1)−W(1)−N(2) 84.40(8), P(2)−W(1)−N(2) 65.50(9), N(1)−W(1)−N(2) 90.7(1), P(1)−W(1)−N(3) 96.7(1), P(2)−W(1)−N(3) 105.3(1), N(1)−W(1)−N(3) 98.0(1), P(2)−W(1)−C(1) 95.0(1), N(1)−W(1)−C(1) 99.1(1), N(2)−W(1)−C(1) 90.9(1), N(3)−W(1)−C(1) 90.7(2), W(1)−P(1)−C(2) 82.5(1), W(1)−P(2)−C(22) 84.6(1), W(1)−N(1)−C(2) 108.9(3), W(1)−N(2)−C(22) 104.4(2)

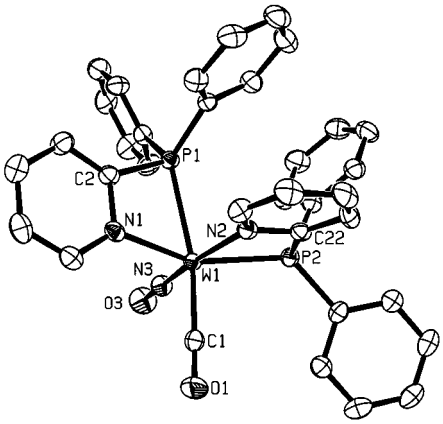

Figure 5. View of the structure of the cation of **14**; selected bond lengths (Å) and angles (°): W(1)−P(10) 2.591(2), W(1)−P(30) 2.640(2), W(1)−N(4) 1.896(7), W(1)−C(1) 1.977(8), W(1)−C(2) 2.080(9), W(1)−C(3) 2.06(1); P(10)−W(1)−P(30) 104.39(6), P(10)−W(1)−N(4) 82.0(2), P(30)−W(1)−C(1) 86.7(2), N(4)−W(1)−C(1) 87.3(3), P(10)−W(1)−C(2) 91.2(2), P(30)−W(1)−C(2) 82.5(2), N(4)−W(1)−C(2) 91.7(3), C(1)−W(1)−C(2) 93.0(3), P(10)−W(1)−C(3) 87.0(2), P(30)−W(1)−C(3) 91.5(2), N(4)−W(1)−C(3) 94.7(3), C(1)−W(1)−C(3) 90.0(4), W(1)−P(10)−C(4) 113.3(3), W(1)−P(10)−C(13) 108.3(2), W(1)−P(10)−C(19) 121.5(3), W(1)−P(30)−C(34) 108.3(2), W(1)−P(30)−C(43) 114.7(3), W(1)−P(30)−C(49) 118.3(2)

Experimental Section

General Techniques: All preparations were carried out under dry nitrogen using conventional Schlenk or glove-box techniques and dry, air-free solvents. − IR spectra were recorded with a Bio-Rad FTS-45 instrument. − ^{1}H-, ^{13}C-, and ^{31}P-NMR spectra were recorded with a Varian Gemini 200 (200 MHz for ^{1}H, 50.3 MHz for ^{13}C), a Varian Gemini 300 (300 MHz for ^{1}H, 121.5 MHz for ^{31}P, 75.4 MHz for ^{13}C), or a Bruker Avance 500 (125.8 MHz for ^{13}C). All ^{31}P-NMR spectra were proton-decoupled. The spectra were simulated using the program gNMR 4.1 (Cherwell Scientific) in the automatic iteration mode. Sodium bis(2-methoxyethyloxy)aluminium hydride (RedAl, 3.5 M in toluene) was purchased from Aldrich Chemical Co.

Sodium 3,3-Dimethyl-2-oxobutoxide (1): Sodium ribbon (15.2 g, 0.66 mol) was added to 350 mL of dry diethyl ether. A mixture of ethyl formate (48.9 g, 0.66 mol) and pinacoline (66.1 g, 0.66 mol) was then added dropwise to the reaction mixture over a period of 2 h at −30 °C. When the addition was complete, the solution was allowed to warm to room temperature and stirring was continued for a further 1 h. After evaporation of the solvent, the residual brown slurry was washed with small amounts of diethyl ether and hexane. The crude product was used in the next step without further purification. Yield: 92.4 g (0.55 mol, 83%).

6-*tert*-Butyl-3-cyano-2-pyridone (2): Sodium salt **1** (92.4 g, 0.55 mol) and cyanoacetamide (46.25 g, 0.55 mol) were dissolved in water (200 mL). Meanwhile, a solution consisting of glacial acetic acid (8 mL) and water (20 mL) was adjusted to pH = 8 by the addition of piperidine. The two solutions were then mixed and the mixture was refluxed for 2 h, cooled, and acidified with glacial acetic acid. After filtration, the brown residue was washed with water (200 mL), taken up in ethanol (200 mL), and the resulting solution was treated with activated charcoal (5 g). Evaporation of the solvent in vacuo gave the product as a white powder. Yield: 22 g (0.125 mol, 23%); m.p. 194 °C. − ^{1}H NMR (200 MHz, $CDCl_3$): δ = 12.59 (br., 1 H), 7.81 (d, $^3J_{HH}$ = 7.7 Hz, 1 H), 6.26 (d, $^3J_{HH}$ = 7.7 Hz, 1 H), 1.41 [s, 9 H, $C(CH_3)_3$]. − ^{13}C NMR (200 MHz, $CDCl_3$): δ = 164.3 (s), 162.6 (s), 148.4 (s, CH), 115.6 (s), 102.2 (s, CH), 35.9 (s, *C*Me$_3$), 28.7 [s, C(*C*H$_3$)$_3$]. − MS (EI); *m*/*z* (%): 176 [M$^+$] (22), 161 [M$^+$ − CH$_3$] (100), 134 [M$^+$ − CH$_3$ − CN − H] (12). − $C_{10}H_{12}N_2O$ (176.22): calcd. C 68.16, H 6.86, N 15.90; found C 67.89, H 6.47, N 15.82.

6-*tert*-Butyl-2-oxo-3-pyridinecarboxylic Acid (3): A solution of **2** (20.0 g, 0.11 mol) in concentrated hydrochloric acid (200 mL) was refluxed for 5 h, poured onto 200 g of ice, and washed several times with cold water. Evaporation of the water in vacuo gave the product as a white solid. Yield: 18.76 g (96 mmol, 84%); m.p. 240 °C. − ^{1}H NMR (200 MHz, $CDCl_3$): δ = 13.80 (br., 1 H), 12.40 (br., 1 H), 8.54 (d, $^3J_{HH}$ = 8 Hz, 1 H), 6.61 (d, $^3J_{HH}$ = 8 Hz, 1 H), 1.46 [s, 9 H, $C(CH_3)_3$]. − ^{13}C NMR (200 MHz, $CDCl_3$): δ = 166.1 (s), 165.4 (s), 164.0 (s), 148.1 (s, CH), 115.6 (s), 106.0 (s, CH), 36.4 (s, *C*Me$_3$), 29.3 [s, C(*C*H$_3$)$_3$]. − MS (EI); *m*/*z* (%) = 194 [M$^+$] (100), 179 [M$^+$ − CH$_3$] (76), 177 [M$^+$ − OH], 162 [M$^+$ − CH$_3$ − OH] (100). − $C_{10}H_{13}NO_3$: calcd. C 61.53, H 6.71, N 7.17; found C 61.96, H 6.30, N 7.33.

6-*tert*-Butyl-2-pyridol (4): In a 500-mL flask fitted with a cold finger, **3** (18.0 g, 92.3 mol) was heated to 315 °C for 20 min by means of a molten-metal bath. When the evolution of carbon dioxide had ceased, the residual black material was sublimed at 150 °C and a pressure of 0.1 mbar. The product was obtained in the form of white crystals. Yield: 9.4 g (62 mmol, 67%); m.p. 141 °C. − ^{1}H NMR (300 MHz, $CDCl_3$): δ = 11.76 (br., 1 H), 7.34 (m, 1 H), 6.40 (m, 1 H), 6.09 (m, 1 H), 1.34 [s, 9 H, $C(CH_3)_3$]. − ^{13}C NMR (300 MHz, $CDCl_3$): δ = 165.0 (s), 157.1 (s), 141.7 (s, CH), 117.3 (s, CH), 101.9 (s, CH), 36.4 (s, *C*Me$_3$), 29.3 [s, C(*C*H$_3$)$_3$]. − MS (EI); *m*/*z* (%): 151 [M$^+$] (100), 136 [M$^+$ − CH$_3$] (100). − $C_9H_{13}NO$ (151.21): calcd. C 71.49, H 8.67, N 9.26; found C 71.26, H 8.48, N 9.33.

2-*tert*-Butyl-6-chloropyridine (5): To a solution of **4** (9.0 g, 59.6 mmol) in refluxing phosphorus oxychloride (10 mL), phosphorus pentachloride (13.8 g) was added in small portions over a period of 30 min. The bath temperature was then increased to 160

°C and maintained at this temperature for 1 h. After cooling the mixture to room temperature and removing the solvent under reduced pressure, the residue was poured onto ice. The resulting black mixture was made strongly basic with sodium hydroxide and steam distilled to afford a pale oil. The crude product was taken up in diethyl ether and dried with Na_2SO_4. Removal of the solvent and distillation of the oil (b.p. 47 °C, 1 mbar) afforded a colourless liquid. Yield: 5.4 g (32.3 mmol, 48%). – ^{1}H NMR (300 MHz, $CDCl_3$): δ = 7.55 (m, 1 H, py), 7.22 (m, 1 H, py), 7.10 (m, 1 H, py), 1.35 [s, 9 H, $C(CH_3)_3$]. – ^{13}C NMR (300 MHz, $CDCl_3$): δ = 170.6 (s, α-C, py), 150.2 (s, α-C, py), 138.7 (s, py), 121.1 (s, py), 117.4 (s, py), 37.5 (s, *C*Me$_3$), 29.9 [s, C(*C*H$_3$)$_3$]. – MS (EI); *m*/*z* (%): 169 [M^+] (88), 154 [$M^+ - CH_3$] (100). – $C_9H_{12}NCl$ (169.66): calcd. C 63.72, H 7.13, N 8.26; found C 63.94, H 7.08, N 8.18.

2-(6-*tert*-Butylpyridyl)diphenylphosphane (6): To a solution of diphenylphosphane (2.75 g, 14.8 mmol) in THF (50 mL) at room temperature, 1.6 M *n*BuLi in THF (9.25 mL, 14.8 mmol) was added dropwise over a period of 30 min. The resulting red solution was stirred for a further 30 min and then a solution of **5** (2.5 g, 14.7 mmol) in THF (10 mL) was slowly added. The reaction mixture was stirred for a further 14 h, then quenched with ethanol (15 mL), and the solvents were evaporated under reduced pressure. The resulting pale-yellow solid was redissolved in hexane (200 mL) and this solution was treated with activated charcoal (5 g). After filtration and evaporation of the solvent, white crystals were obtained. Yield: 3.0 g (9.46 mmol, 64%). – ^{1}H NMR (300 MHz, $CDCl_3$): δ = 7.51–7.35 (m, 10 H, Ph; 1 H, py), 7.21 (m, 1 H, py), 6.97 (m, 1 H, py), 1.34 (s, 9 H, *t*Bu). – ^{31}P NMR (300 MHz, $CDCl_3$): δ = –3.4 (s). – ^{13}C NMR (200 MHz, $CDCl_3$): δ = 169.3 (d, $^1J_{CP}$ = 10 Hz, *ipso*-py), 161.6 (d, $^3J_{CP}$ = 5 Hz, *ipso*-py), 137.1 (d, $^1J_{CP}$ = 9 Hz, *ipso*-Ph), 135.6 (d, J_{CP} = 4 Hz, py), 134.2 (d, J_{CP} = 20 Hz, Ph), 128.6 (s, Ph), 128.2 (d, J_{CP} = 7 Hz, Ph), 125.0 (d, *J* = 20 Hz, py), 117.3 (s, py). – MS (FAB); *m*/*z* (%): 319 [M^+] (95), 185 [M^+ – *tert*-Bupy] (10). – $C_{21}H_{22}NP$ (319.39): calcd. C 78.97, H 6.94, N 4.39; found C 78.74, H 6.73, N 4.21.

2-(6-*tert*-Butylpyridyl)dimethylphosphane (7): To a solution of tetramethyldiphosphane (4.4 g, 36 mmol) in THF (300 mL) was added potassium metal (2.82 g, 72.1 mmol). The mixture was stirred for 1 day at 35 °C and then the unchanged potassium metal was removed. To the yellow solution of potassium dimethylphosphide was added **5** (12.1 g, 71.3 mmol). The resulting dark-red solution was stirred for 2 h, the solvent was evaporated in vacuo, and the residue was extracted with diethyl ether (3 × 50 mL). The combined dark-red extracts were distilled under reduced pressure (b.p. 62–72 °C, 0.1 mbar) to give a colourless oil (9.4 g), which proved to be an azeotropic mixture of **7** and unchanged 2-*tert*-butyl-6-chloropyridine. The ratio of the mixture was estimated from the ^{1}H-NMR spectrum to be 3:2. – ^{1}H NMR (300 MHz, $CDCl_3$): δ = 7.45 (m, py, 2 H), 7.15 (m, py, 1 H), 1.36 [d, 6 H, $^2J_{PH}$ = 2.2 Hz, $(CH_3)_2$P], 1.35 (s, 9 H, *t*Bu). – ^{31}P NMR (300 MHz, $CDCl_3$): δ = –40.6 (s).

2-(6-Methylpyridyl)diphenylphosphane (8): To a solution of diphenylphosphane (3.68 g, 19.8 mmol) in THF (70 mL) at room temperature, 1.6 M *n*-butyllithium (12.4 mL, 20.2 mmol) was added over a period of 30 min. After stirring for a further 30 min at room temperature, the red reaction mixture was cooled to 0 °C and a solution of 6-chloro-2-picoline (2.53 g, 19.8 mmol) in THF (20 mL) was added dropwise. Further stirring for 3 h at room temperature and subsequent addition of ethanol (20 mL) gave a pale-yellow solution. The solvent was evaporated under reduced pressure and the residue was extracted with hexane (400 mL). After filtration through Celite and crystallization at –30 °C, the product was obtained as large white needles. Yield: 460 mg (0.294 mmol, 77%). – ^{1}H NMR (300 MHz, $CDCl_3$): δ = 7.44 (m, 1 H, py), 7.37 (m, 10 H, Ph), 7.05 (m, 1 H, py), 6.83 (m, 1 H, py), 2.58 (s, 3 H, CH_3). – ^{31}P NMR (300 MHz, $CDCl_3$): δ = –4.4 (s). – ^{13}C NMR (300 MHz, $CDCl_3$): δ = 162.9 (d, $^3J_{CP}$ = 7 Hz, *ipso*-py), 158.9 (d, $^1J_{CP}$ = 15 Hz, *ipso*-py), 136.5 (d, $^1J_{CP}$ = 15 Hz, *ipso*-Ph), 135.8 (d, J_{CP} = 2 Hz, py), 134.0 (d, J_{CP} = 20 Hz, Ph), 128.8 (s, Ph), 128.4 (d, J_{CP} = 7 Hz, Ph), 124.8 (d, *J* = 11 Hz, py), 121.9 (s, py), 24.6 (s, CH_3). – MS (EI); *m*/*z* (%): 277 [M^+] (100), 200 [M^+ – Ph] (30), 185 [M^+ – Ph – CH_3] (12). – $C_{18}H_{16}NP$ (277.31): calcd. X-ray Structural Determinations: Data collection for all structures was performed in a cold N_2 stream (see Table 1) with a Nicolet−Siemens P4 diffractometer in the range 2.0° ≤ φ ≤ 25.0°. The structures of complexes **9**, **11**, and **20** were solved by Patterson synthesis (SHELXS-86)[25] and refined using SHELXTL-PLUS[26] for **11** and **20** or SHELXL-93[27] for **9**. The structure of complex **14** was solved by direct methods (SIR-92,[28] SHELXTL-PLUS). Pertinent crystallographic parameters for the four structures are listed in Table 1.

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cam-

Computational Details: The calculations utilized the Amsterdam Density Functional package ADF release 2.0.1 and release 2.3. The ADF basis set III was chosen for the main group elements, whereas W was described with a modified basis set IV with 6p functions. The self-consistent DFT calculations were based on the local exchange correlation potential of Vosko, Wilk, and Nussair,[29] with the addition of gradient corrections due to Becke[30] and Perdew[31] (NL-SCF). Relativistic effects were included using a quasi-relativistic approach.[32] The accuracy parameter for the numerical integration was set to 4.0. All molecules were fully optimized at the quantum mechanical level. Default convergence criteria[33] were employed, except for the gradients in the geometry optimizations, which were set to 0.006 hartree/Å or hartree/radian, respectively. In the transition state search, the W−N(pyridyl) distances were assumed to be equal.

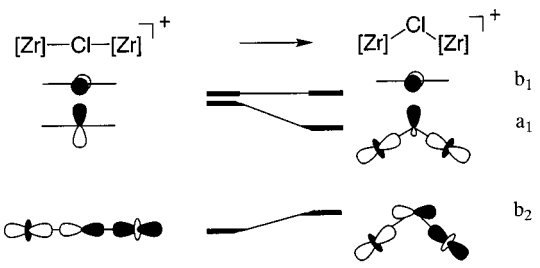
Keywords: Bridging ligands / Cations / Density functional calculations / Zirconium

Treatment of the tris(cyclopentadienyl) cation (**1**$^+$) with zirconocene dichloride **2** gave, in almost quantitative yield, the 1:1 adduct **7**$^+$, which was isolated with $[(CH_3)B(C_6F_5)_3]^-$ as the counterion. Reaction of **1**$^+$ with the organometallic ligand Cp_3ZrCl afforded the 1:1 adduct **8**$^+$, again isolated with $[(CH_3)B(C_6F_5)_3]^-$. The X-ray analysis revealed that **7**$^+$ displays a strongly bent Zr–Cl–Zr coordination mode, in contrast to **8**$^+$, which has a tendency to linear coordination. A theoretical analysis suggests that a subtle balance between steric and electronic factors determines the geometries in such organometallic adducts.

Introduction

We have recently investigated the coordination chemistry of the tris(cyclopentadienyl) zirconium cation $[Cp_3Zr]^+$ (**1**$^+$) and determined the crystal structures of several $[Cp_3Zr-L]^+$ adducts.[1] The transition metal cation **1**$^+$ displays Lewis acid behavior and forms adducts with a variety of donor ligands, such as nitriles, isonitriles, or carbon monoxide. Further, it is known that catalytically important $[Cp_2ZrR]^+$ cations show a marked tendency to bind to their neutral $[Cp_2ZrR_2]$ precursors and related $[Cp_2ZrX_2]$ systems, yielding less active resting stages or dormant derivatives of their active metallocene catalyst systems.[2] It was tempting to find out whether the $[Cp_3Zr]^+$ cation (**1**$^+$) would react in a similar fashion as $[Cp_2ZrR]^+$ species and bind the neutral metallocene derivatives $[Cp_2ZrCl_2]$ (**2**) or $[Cp_3ZrCl]$ (**3**) despite its higher coordinative saturation.



During the course of this investigation the question of the coordination geometry around the bridging Cl^- became of special interest. We were able to determine the structures of two similar {[Zr]−Cl−[Zr]}$^+$ cations, which in the solid state show very different bridging geometries. Only a few systems with unsupported $(Cp)_nZr-Cl-M$ bridges have been described in the literature. Two adducts between Cp_2ZrCl_2 and the Lewis acids AlR_3 [R = Cl, $C(CH_3)_3$] have been structurally characterized.[3] In these systems the bridging chloride and the two metal centers form Zr−Cl−M bond angles τ of 126° and 149°, respectively.

Independent of our experimental work, we initiated a theoretical study on {[Zr]−Cl−[Zr]}$^+$ cations, based on density functional theory,[4] in which we examined various coordination geometries not only around the μ-Cl bridge, but also around the Zr center. We begin the discussion with our computational work before giving an account of our experimental results and comparing theory and experiment.

Results and Discussion

Theoretical Studies

Molecular Orbital Considerations: From a molecular orbital point of view, the question of the coordination geometry of $[R_3Zr-(\mu\text{-}Cl)-ZrR_3]^+$ complexes is related to the problem of the geometries of AH_2 molecules.[5] We can analyze the bonding angle τ by considering the interaction of two cationic metal fragments $[Zr]^+$ with a Cl^- ion. The LUMO of the metal fragment is in any case a Zr-based d_{z^2}-orbital and is independent of the coordination around the transition metal center, which might be planar or trigonal pyramidal. When interacting with the p-orbitals of the chloride ion, these orbitals have the same nodal characteristics as the 1s orbital of H, and we might consider $HClH^+$ as an isolobal analog of {[Zr]−Cl−[Zr]}$^+$. The three highest occupied orbitals of such a C_{2v} symmetric moiety are shown in Scheme 1, and the bent geometry would be stabilized due to the energetic lowering of the orbital a_1.

Scheme 1. Orbital interaction diagram for bent and linear {[Zr]−Cl−[Zr]}$^+$, classified according to C_{2v} symmetry

Thus, if the geometry of $\{[Zr]-Cl-[Zr]\}^+$ systems is determined by orbital interactions of the bridging fragments, we would predict a bent geometry for such molecules. The analysis is complicated, however, by the fact that the orbitals introduced above are normally not amongst the frontier orbitals of such systems. The highest occupied orbitals are usually based on ligands of the transition metal fragments. Bending also leads to an increase in steric repulsion, which then counteracts the electronic stabilization.[6]

In order to explore possible coordination geometries of $\{[Zr]-Cl-[Zr]\}^+$ systems, we choose $[ZrCl_3]^+$ (**4**$^+$) and $ZrCl_4$ (**5**) as models for the adduct-forming reaction $R_3ZrCl + [ZrR_3]^+ \rightarrow \{[Zr]-Cl-[Zr]\}^+$. From these fragments, a variety of $[Zr_2Cl_7]^+$ (**6**$^+$) complexes containing a single bridging μ-Cl^- can be constructed. Our preliminary excursion led to the conclusion that a variety of coordination modes might be realized by $\{[Zr]-Cl-[Zr]\}^+$ systems, which coexists as local minimum structures.[7a] The predictions arising from the qualitative molecular orbital arguments are met,[7b] the energetic differences between linear and bent coordination, however, are fairly small. Keeping these results in mind, we now proceed with the analysis of complexes involving the $[Cp_3Zr]^+$ cation (**1**$^+$).

Interaction of 1$^+$ with Organometallic Zirconium Chlorides: We begin with a brief introduction of the Zr fragments considered (Figure 1).

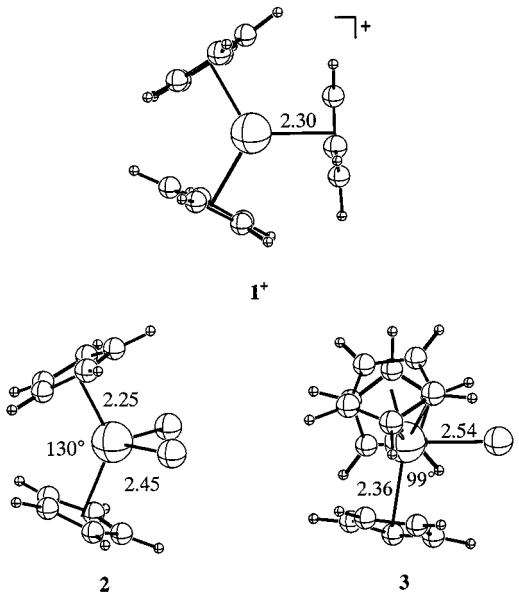

Figure 1. Optimized structures for the Zr-based building blocks **1**$^+$, **2**, and **3**

The cation **1**$^+$ has already been extensively studied.[1] An important feature is the planar coordination around the transition metal center. Whereas the structure of $[Cp_2ZrCl_2]$ (**2**) is well-known,[8] the geometry of complex $[Cp_3ZrCl]$ (**3**) has not yet been described. The system with ansa-cyclopentadienyl rings $[(CpCMe_2Cp)CpZrCl]$ that was reported by Green and co-workers[9] is similar to compound **3**. The calculated Zr−Cl bond in **3** is elongated by 0.09 Å compared to **2**, and it agrees very well with the experimental value of d(Zr−Cl) = 2.536 Å for Green′s complex. The coordination of the Cp rings deviates only slightly from a planar arrangement, resulting in $\sigma_P = 352°$, with $\sigma_P = \Sigma <$ [Cp(centroid)−Zr−Cp(centroid)].

Two coordination geometries have been calculated for the complex $[Cp_3Zr-(\mu\text{-}Cl)-ZrCp_2Cl]^+$ (**7**$^+$) (Figure 2).

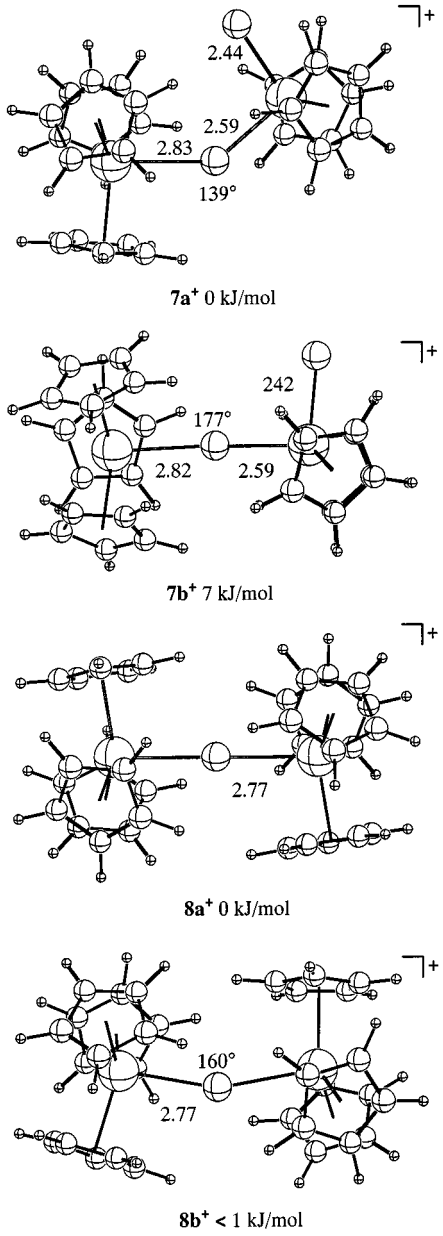

Figure 2. Optimized linear and bent geometries for the cations $[Cp_3Zr-(\mu\text{-}Cl)-ZrCp_2Cl]^+$ (**7**$^+$), and $[Cp_3Zr-(\mu\text{-}Cl)-ZrCp_3]^+$ (**8**$^+$)

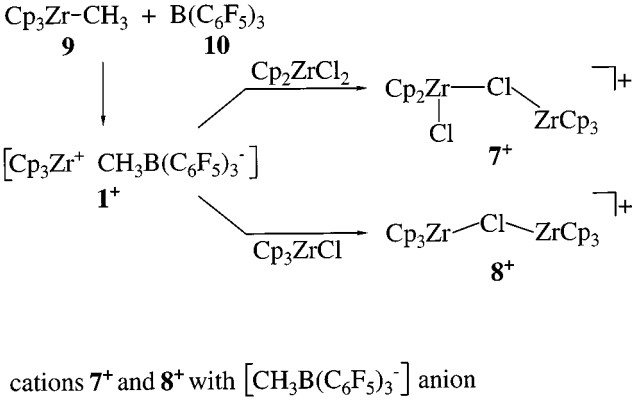
The geometric features of **7a**$^+$ and **7b**$^+$ are similar but again the bent complex **7a**$^+$, with $\tau = 139°$, is energetically more stable. The bending angle τ is larger than those found for the complexes **8** but the stabilization energy for bent coordination is of the same order of magnitude and is again rather small. Two different Zr−(μ-Cl) bond lengths are ob-



tained, again with a longer bonding contact for the metal center coordinated in a planar fashion. The σ_P values in both cases are 354°, indicating that the coordination around the $\{Cp_3Zr\}$ fragment is essentially planar.

The increase in steric bulk in $[Cp_3Zr-(\mu\text{-}Cl)-ZrCp_3]^+$ (**8**$^+$) further lowers the energy difference between a bent and a linear coordination. The two calculated geometries **8a**$^+$ and **8b**$^+$ (Figure 2) are virtually identical in energy, with a marginal preference for the linear coordination.

The potential energy hypersurface around the Zr−Cl−Zr bending mode is very shallow, and one can expect that effects due to the nature of the counterion and crystal packing will influence the molecular arrangement of **8** in the solid state. All calculations indicate that τ can take on values that vary over a larger range and are influenced by the steric bulk of the interacting fragments. The crystal structure of the $Cp_2ZrCl_2-AlR_3$ adducts further support this observation. The Zr−(μ-Cl) separation is about 0.07 Å larger than the average obtained for both Zr−Cl distances calculated for **7**$^+$. Again, the σ_P values for all $ZrCp_3$ systems amount to 353°, and are close to the ideal value of 360° for a perfectly planar coordinated Zr.

Experimental Studies

The tris(cyclopentadienyl)zirconium cation (**1**$^+$) was generated in situ by treatment of $[Cp_3ZrCH_3]$ (**9**) with the strong organometallic Lewis acid tris(pentafluorophenyl)-borane (**10**) and trapped by added zirconocene dichloride (**2**). The 1:1 adduct **7** was formed almost quantitatively (Scheme 2).

Scheme 2. Preparation of adducts **7** and **8** from the cation $[Cp_3Zr^+]$ (**1**$^+$)

Compound **7** is characterized by the occurrence of a pair of ^{1}H-/^{13}C-NMR Cp-resonances (2:3 intensity) at δ = 6.67, 6.24/118.2, 117.0 in addition to the signals of the separated $[CH_3B(C_6F_5)_3]^-$ anion. Single crystals of **7** suitable for X-ray crystal analysis were obtained from a saturated solution in dichloromethane at −30 °C. In the crystal the $[Cp_3Zr-(\mu\text{-}Cl)-ZrCp_2Cl]^+$ cation (**7**$^+$) is well separated from the $[CH_3B(C_6F_5)_3]^-$ anion (shortest B−Zr distance: 7.142 Å). The cation **7**$^+$ (Figure 3) features a Cp_3Zr subunit that is close to trigonal planar.

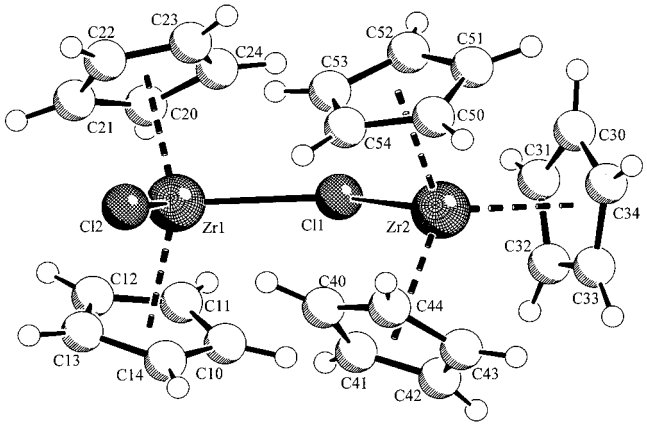


Figure 3. A view of the molecular geometry of the cation $[Cp_3Zr-(\mu\text{-}Cl)-ZrCp_2Cl]^+$ (**7**$^+$), as obtained from X−ray crystal structure analysis. Selected bond lengths [Å] and angles [°]: Zr1−Cl1 2.544(1), Zr1−Cl2 2.405(1), Zr1−C(Cp1) 2.490, Zr1−Cp1 2.187, Zr1−C(Cp2) 2.480, Zr1−Cp2 2.190, Zr2−Cl1 2.722(1), Zr2−C(Cp3) 2.596, Zr2−Cp3 2.311, Zr2−C(Cp4) 2.576, Zr2−Cp4 2.290, Zr2−C(Cp5) 2.570, Zr2−Cp5 2.281; Cl1−Zr1−Cl2 95.80(4), Cl1−Zr1−Cp1 107.4, Cl1−Zr1−Cp2 104.0, Cl2−Zr1−Cp1 107.6, Cl2−Zr1−Cp2 106.6, Cp1−Zr1−Cp2 130.2, Zr1−Cl1−Zr2 137.15(5), Cl1−Zr2−Cp3 95.2, Cl1−Zr2−Cp4 99.8, Cl1−Zr2−Cp5 100.0, Cp3−Zr2−Cp4 117.7, Cp3−Zr2−Cp5 117.7, Cp4−Zr2−Cp5 118.3. Zr−C(Cp) is the average Zr−C distance between Zr and the C atoms of the Cp ring, Zr−Cp is the distance between the calculated centroid of the Cp ring zirconium

The sum of the corresponding Cp(centroid)−Zr−Cp(centroid) angles σ_P amounts to 353.7° (Cp3−Zr2−Cp4: 117.7°, Cp4−Zr2−Cp5: 118.3°, Cp3−Zr2−Cp5: 117.7°). The zirconium atom (Zr2) is located 0.333 Å above the plane of the Cp3 to Cp5 centroids. The $[Cp_2ZrCl_2]$ donor is coordinated to the $[Cp_3Zr^+]$ cation through one of its chloride ligands (Cl1). The Zr2−Cl1 vector is oriented normal to the Cp3 to Cp5 plane. The Zr2−Cl1 bond is rather long at 2.722(1) Å, which is markedly longer than the adjacent terminal Zr1−Cl2 linkage [2.405 (1) Å] of the bent metallocene unit. The remaining bonding features at the coordinated Cp_2ZrCl_2 unit are not exceptional [angle Cl2−Zr−Cl1: 95.80(4)°]. The adduct is strongly bent at the bridging μ-chloride ligand [angle Zr1−Cl1−Zr2: 137.15(5)°], and the substituents Cl2 and Zr(2)Cp_3 are found in a *syn*-periplanar orientation at the Zr1−Cl1 bond [dihedral angles Zr2−Cl1−Zr1−Cl2 7.50(8)°].

We also synthesized the $[Cp_3Zr-Cl]$ adduct of the $[Cp_3Zr]^+$ cation. In this case the salt $[Cp_3Zr^+ CH_3B(C_6F_5)_3^-]$ (**1**) was prepared and the organometallic ligand Cp_3Zr-Cl was added to it in CH_2Cl_2 at −60 °C (Scheme 2). Workup at ambient temperature furnished the adduct complex $\{[Cp_3Zr-(\mu\text{-}Cl)-ZrCp_3]^+[CH_3B(C_6F_5)_3]^-\}$ (**8**). Complex **8** features a single ^{1}H-/^{13}C-NMR resonance at δ = 6.25 (30 H)/116.6 along with the anion methyl resonance at δ = 0.51 (3 H, broad)/10.5. Single crystals of **8** were again obtained from a saturated solution in dichloromethane at −30 °C.

The $[Cp_3Zr-(\mu\text{-}Cl)-ZrCp_3]^+$ cation (**8**$^+$) contains two Cp_3Zr units that each feature an almost trigonal pyramidal

arrangement of the three η^5 Cp ligands and the single bridging chloride around zirconium (Figure 4).

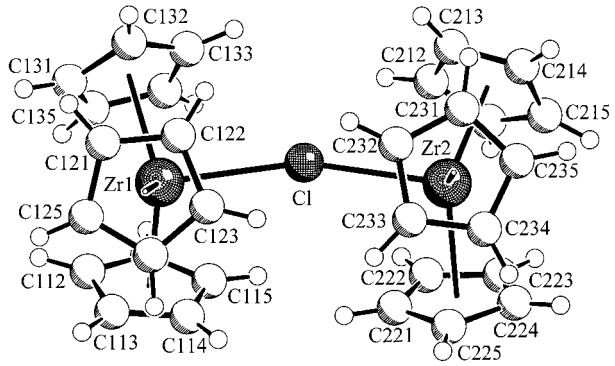

Figure 4. Molecular structure of $\mathbf{8}^+$ in the crystal. Selected bond lengths [Å] and angles [°]: Zr1−Cl 2.6918(6), Zr1−C(Cp11) 2.586, Zr−Cp11 2.296, Zr1−C(Cp12) 2.576, Zr1−Cp12 2.286, Zr1−C(Cp13) 2.586, Zr1−Cp13 2.297, Zr2−Cl 2.6893(6), Zr2−C(Cp21) 2.589, Zr2−Cp21 2.298, Zr2−C(Cp22) 2.582, Zr2−Cp22 2.291, Zr2−C(Cp23) 2.577, Zr2−Cp23 2.286; Cl−Zr1−Cp11 99.7, Cl−Zr1−Cp12 100.2, Cl−Zr1−Cp13 96.4, Cp11−Zr1−Cp12 117.5, Cp11−Zr1−Cp13 117.7, Cp12−Zr1−Cp13 117.9 Zr1−Cl−Zr2 160.88(2), Cl−Zr2−Cp21 97.9, Cl−Zr2−Cp22 99.1, Cl−Zr2−Cp23 99.8, Cp21−Zr2−Cp22 117.9, Cp21−Zr2−Cp23 117.4, Cp22−Zr2−Cp23 117.6. Nomenclature as described for Figure 3

The angle σ_P, as defined above, is 353.1° at Zr1 and 352.9° at Zr2. Again, the Zr−Cl vector is arranged almost normal to the respective Cp planes [Cp(centroid)−Zr−Cl angles at Zr1: 99.7°/100.2°/96.4°; at Zr2: 97.9°/99.1°/99.8°]. The Zr1−Cl bond length in **8** is 2.692(1) Å, which is almost identical to Zr2−Cl [2.689(1) Å], but both are slightly shorter that the $Cp_3Zr-(\mu\text{-}Cl)$ bond in **7** (see above). The Zr1−Cl−Zr2 angle in **8** is 160.88(2)°. This represents the most pronounced difference between the structures of the adducts **7** and **8**. The marked tendency of $[Cp_3Zr-(\mu\text{-}Cl)-ZrCp_3]^+$ ($\mathbf{8}^+$) towards a linear Zr−Cl−Zr structure, in contrast to the strongly bent $[Cp_3Zr-(\mu\text{-}Cl)-ZrCp_2Cl]^+$ ($\mathbf{7}^+$) framework, is in accord with the theoretical analysis and probably reflects the subtle balance of steric and electronic factors that eventually determines the structural features of such organometallic adducts of the C_{3v}-symmetrical Cp_3Zr^+ cation systems.

Comparison between Calculated Geometries and Experimental Structures

Both the X-ray crystal structure analyses, as well as the density functional calculations, result in the same molecular shape for $\mathbf{7}^+$ and $\mathbf{8}^+$. Measured and optimized bond angles are in good agreement for both cations. It is striking, however, that the calculated Zr−Cl distances are significantly overestimated by up to 0.09 Å in the calculation, as shown for $\mathbf{7}^+$ in Figure 5.

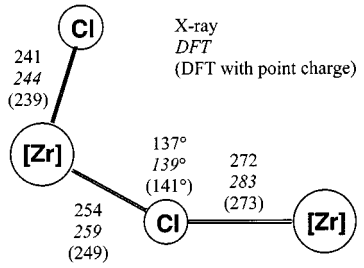

Figure 5. A comparison of the molecular framework of $\mathbf{7}^+$ obtained from crystal structure analysis and theoretical calculations

We performed additional calculations for this complex, including a negative point charge, which was located in space in close proximity to the position where the boron atom of the counterion would be found in the crystal. The Zr−Cl bonds shorten under the influence of the point charge, and are now in closer agreement to the value obtained from the X-ray structural analysis (Figure 5). The molecular environment has a significant influence on the molecular geometry of the cations for $\mathbf{7}^+$ and $\mathbf{8}^+$, especially concerning geometric parameters that are associated with the shallow potentials on the energy hypersurface.

Conclusion

In this work we have demonstrated that the tris(cyclopentadienyl)zirconium cation ($\mathbf{1}^+$) displays a similar coordination chemistry to the well studied $[Cp_2ZrR]^+$ species and is able to bind the neutral metallocene derivatives $[Cp_2ZrCl_2]$ (**2**) or $[Cp_3ZrCl]$ (**3**) as ligands. The X-ray crystal structure analyses revealed that the Zr−Cl−Zr bridging angle τ can take on values representing both a strongly bent and an almost linear coordination geometry. Our theoretical analysis suggests that a subtle balance between steric and electronic factors determines the geometries in such organometallic adducts.

Experimental Section

General Remarks: All reactions were carried out under argon using Schlenk-type glassware or in a glove-box. All solvents, including deuterated solvents used for NMR spectroscopy, were dried and distilled under argon prior to use. Tris(pentafluorophenyl)borane (**10**),[10] $[Cp_3ZrCH_3]$ (**9**),[1] $[Cp_3ZrCl]$ (**3**),[11] and $[Cp_2ZrCl_2]$ (**2**)[12] were prepared as described in the literature. − M.p. DSC 2010 (TA Instruments). − IR spectra: Nicolet-5-DXC-FT IR spectrometer; $\tilde{\nu}$ in cm^{-1}. − NMR spectra: Bruker AC-200P (^1H 200 MHz, ^{13}C 50 MHz) and Bruker AM 360 (^1H 360 MHz, ^{13}C 75 MHz) spectrometer; δ in ppm. − Elemental analyses: Foss Heraeus CHNO Rapid.

$[Cp_3Zr-(\mu\text{-}Cl)-ZrCp_2Cl]^+[CH_3B(C_6F_5)_3]^-$ (7): To a mixture of tris(η^5-cyclopentadienyl)methylzirconium (**9**) (80.0 mg, 0.27 mmol), tris(pentafluorophenyl)borane (**10**) (136 mg, 0.27 mmol) and zirconocene dichloride (**5**) (78.0 mg, 0.27 mmol) was added 15 mL of dichloromethane by means of vacuum distillation. The resulting yellow solution was allowed to warm up to room temperature with

stirring. After stirring for an additional 10 min at room temperature the solvent was removed in vacuo to yield 285 mg (97%) of the orange-yellow salt **7**. Single crystals of **7** were obtained from a saturated dichloromethane solution at −30 °C, m.p. 171 °C (DSC, decomp.). − $C_{44}H_{28}BCl_2F_{15}Zr_2$ (1106): calcd. C 47.49, H 2.55; found C 46.68, H 2.72. − IR (KBr): $\tilde{\nu}$ = 3124 cm^{-1}, 2949, 1642, 1511, 1458, 1381, 1366, 1266, 1088, 1017, 978, 966, 952, 818, 740. − ^{1}H NMR (200.13 MHz, [D$_2$]dichloromethane, 300 K): δ = 6.67 (s, 10 H, Cp-*H*), 6.24 (s, 15 H, Cp-*H*), 0.51 (br s, 3 H, B−C*H*$_3$). − ^{13}C NMR (75.47 MHz, [D$_2$]dichloromethane, 300 K): δ = 148.8 (d, $^1J_{CF}$ = 238 Hz), 137.9 (d, $^1J_{CF}$ = 243 Hz), 136.9 (d, $^1J_{CF}$ = 251 Hz) and 129.8 [br, *o*-, *p*-, *m*- and *ipso*-B(C_6F_5)$_3$], 118.8 and 117.0 (each Cp), 10.5 (s, B−CH_3).

[Cp$_3$Zr−(μ-Cl)−ZrCp$_3$]$^+$[CH$_3$B(C$_6$F$_5$)$_3$]$^-$ (8): A Schlenk flask was charged with tris (η^5-cyclopentadienyl)methylzirconium (**9**) (80.0 mg, 0.27 mmol) and tris(pentafluorophenyl)borane (**10**) (136 mg, 0.27 mmol). Dichloromethane (15 mL) was added and the resulting solution was cooled to −60 °C. At that temperature a cold solution of tris(η^5-cyclopentadienyl)chlorozirconium (**6**) (86.0 mg, 0.27 mmol) in dichloromethane (10 mL) was added. The reaction mixture was stirred for 10 min at −60 °C and then allowed to warm up to room temperature. The solvent was removed from the resulting pale yellow solution to yield 287 mg (95%) of **8**. Single crystals were obtained from a saturated dichloromethane solution at −30 °C, m.p. 159 °C (DSC, decomp.). − $C_{49}H_{33}BClF_{15}Zr_2$ (1135): calcd. C 51.83, H 2.93; found C 49.94, H 2.61. − IR (KBr): $\tilde{\nu}$ = 3125 cm^{-1}, 2959, 1642, 1510, 1458, 1366, 1267, 1087, 1010, 980, 963, 952, 845, 813, 737. − ^{1}H NMR (200.13 MHz, [D$_2$]dichloromethane, 300 K): δ = 6.25 (s, 30 H, Cp-*H*), 0.51 (br s, 3 H, B−C*H*$_3$). − ^{13}C NMR (75.47 MHz, [D$_2$]dichloromethane, 300 K): δ = 148.8 (d, $^1J_{CF}$ = 238 Hz), 137.9 (d, $^1J_{CF}$ = 243 Hz), 136.8 (d, $^1J_{CF}$ = 240 Hz) and 129.8 [br, *o*-, *p*-, *m*-, and *ipso*-B(C_6F_5)$_3$], 116.6 (Cp), 10.5 (s, B−CH_3).

Computational Details: Gradient-corrected density functional calculations were carried out with corrections for exchange and correlation according to Becke[13] and Perdew,[14] respectively (BP86). Geometries were optimized using the program system TURBOMOLE[15] within the framework of the RI-*J* approximation.[16] A triple ζ valence basis plus polarization (TZVP) was employed for all elements.[17]

X-ray Crystallographic Study: Data sets were collected with a Nonius Kappa CCD diffractometer, using a rotating anode generator FR591. Lanthanide(III) Dodecanoates: Structure, Thermal Behaviour, and Ion-Size Effects on the Mesomorphism

Koen Binnemans,*[a] Liesbet Jongen,[a] Christiane Görller-Walrand,[a] Willem D'Olieslager,[a] Dirk Hinz,[b] and Gerd Meyer[b]

Keywords: Rare-earth compounds / Lanthanides / Metallomesogens / Liquid crystals / Metal soaps

Rare-earth salts of dodecanoic acid (lauric acid) have been prepared and characterized. The compounds have the stoichiometry $Ln(C_{11}H_{23}COO)_3$, where Ln = Y, La, Ce–Lu (except Pm). The thermal behaviour of these rare-earth dodecanoates has been investigated by hot-stage polarized optical microscopy, differential scanning calorimetry (DSC), thermogravimetry (TG), and high-temperature X-ray diffraction analysis. The compounds have a lamellar bilayer structure in the solid state, with the alkyl chains in an *all-trans* conformation normal to the ionic sublayer. The size of the trivalent lanthanide ion has proved to be a critical factor with regard to the existence of mesophases of this type of metallomesogens bearing carboxylate ligands. Thus, it was found that a mesophase can only be formed with the light lanthanide ions having large ionic radii. The mesophase stability range decreases rapidly on traversing the lanthanide series. Whereas a smectic A phase has been observed for the La^{III}, Ce^{III}, Pr^{III}, and Nd^{III} dodecanoates, no mesomorphism is apparent for the other lanthanide complexes.

Introduction

Although rare-earth containing metal soaps have long been studied,[1–15] their mesomorphism was discovered only recently. Thus, Marques et al.[16] found liquid-crystallinity in Ce^{III} soaps and, based on the textures observed by hot-stage polarized optical microscopy, the authors suggested that Ce^{III} tetradecanoate and its higher homologues formed disordered smectic mesophases, whereas more complex mesophase behaviour was observed for Ce^{III} soaps with shorter chain lengths. By high-temperature X-ray diffraction analysis, Binnemans et al.[17] identified the mesophase formed by La^{III} tetradecanoate and its higher homologues as a smectic A (SmA) phase. These compounds were found to adopt a lamellar bilayer structure. The layer spacing in the crystalline lamellar phase at moderate temperature was close to the calculated thickness of a bilayer with the *all-trans* alkyl tails *normal* to the ionic sublayer.

Since Binnemans et al.[18] observed a very pronounced effect of the contraction of the lanthanide ion radius on the transition temperatures of lanthanide-containing metallomesogens with Schiff-base ligands, we were interested in ascertaining whether a similar effect could be found for the lanthanide(III) dodecanoates. For the Schiff-base complexes, the mesophase stability range decreases on traversing the lanthanide series (broad mesophase range for the La^{III} compound → a very narrow mesophase range for the Lu^{III} compound). We have found that in the case of the lanthanide(III) dodecanoates, the ionic radius of the trivalent lanthanide ion has a critical effect on the transition temperatures in that a mesophase can only be formed with the lighter lanthanide elements. Since there have been several reports on the industrial applications of lanthanide(III) soaps as catalysts,[19,20] polymer stabilizers,[21] and photosensitizers,[22,23] as well as on their medicinal applications,[12] a good understanding of the structural properties of compounds of this type is clearly desirable.

In this paper, we report on the structures and thermal behaviour of these lanthanide(III) dodecanoates. The structures of the compounds have been studied by IR and X-ray powder diffraction analysis. Their thermal behaviour has been investigated by hot-stage polarized optical microscopy, differential scanning calorimetry (DSC), thermogravimetry (TG), and high-temperature X-ray diffraction analysis.

Results and Discussion

The dodecanoates of all the trivalent rare-earth ions other than Sc^{III} and the radioactive Pm^{III} have been synthesized. The compounds were prepared by a metathesis reaction between the sodium salt of dodecanoic acid and the appropriate rare-earth salt (hydrated nitrate or chloride) in aqueous ethanol solution (ethanol/water, 1:1). The crude soaps were recrystallized from 1-pentanol/ethanol (5:1). The yield after recrystallization ranged from 68 to 87%.

The carbon and hydrogen contents of the rare-earth soaps were determined by C/H elemental microanalysis (combustion analysis), whereas the rare-earth contents were determined by complexometric titrations with EDTA using xylenol orange as an indicator. The fatty acid contents were measured titrimetrically using a standardized NaOH solution. For all the rare-earth dodecanoates, the ratio of the

[a] The calculated values are given in brackets. For the calculations, the stoichiometries $Ln(C_{11}H_{23}COO)_3 \cdot 1/2\ H_2O$ or $Ln(C_{11}H_{23}COO)_3 \cdot H_2O$ were used, depending on the water content. The theoretically expected $C_{11}H_{23}COOH$/Ln ratio is 3.00 in all cases.

dodecanoic acid content to the rare-earth content was found to vary between 2.84 and 3.05, which is close to the theoretically expected value of 3.00 for the stoichiometry $Ln(C_{11}H_{23}COO)_3$. C, H, and Ln analyses were supportive of these findings, but also indicated that, under the reaction conditions used, the compounds could not be obtained in completely anhydrous form. Water molecules were present in all the rare-earth dodecanoates; the compounds were found to be hemihydrates, $Ln(C_{11}H_{23}COO)_3 \cdot 1/2\ H_2O$, or monohydrates, $Ln(C_{11}H_{23}COO)_3 \cdot H_2O$. The analysis results of the soaps are presented in Table 1. However, on heating, the water molecules were lost before or at the melting point and hence anhydrous lanthanide(III) dodecanoates could be obtained by cooling the melts. The water loss and the subsequent thermal decomposition of the compounds were studied by thermogravimetry in combination with DTA (heating to 1000 °C in a static air atmosphere). The TG curves show that, in general, less than 1 mol water is lost per mol of rare-earth soap. The greatest water loss is observed for Ce^{III} dodecanoate, i.e. 1.04 mol. All the rare-earth dodecanoates, with the exception of Ce^{III} dodecanoate, decompose between 360 and 380 °C. The final decomposition product is the rare-earth oxide. In the case of the Ce^{III} dodecanoate, thermal decomposition was found to commence at 200 °C. The lower thermal stability of the cerium soap may be attributed to oxidation of Ce^{III} to Ce^{IV}, which was evident from the orange colour of the ash after decomposition (CeO_2).

The lanthanide(III) dodecanoates are powders that are waxy to the touch and take on the characteristic colour of the corresponding trivalent lanthanide ion.[24] Not unexpectedly, these metal soaps have very low solubilities in water. The compounds are hydrophobic and have low wetting abilities. At room temperature, no organic solvent could dissolve appreciable quantities of these metal soaps. Their solubilities in methanol, ethanol, 1-propanol, 2-propanol, 1-butanol, 1-pentanol, 1-hexanol, 1-octanol, hexane, chloroform, dichloromethane, toluene, benzene, ethylene glycol, DMSO, DMF, and pyridine were tested. At elevated temperatures, the lanthanide(III) dodecanoates proved to be fairly soluble in the higher alcohols (1-pentanol, 1-hexanol, 1-octanol) and in the aromatic solvents (toluene, benzene). 1-Pentanol was preferred as the crystallization solvent as the product separated from solutions in this solvent as a powder rather than as a gel (as is often the case when toluene or benzene is employed). Moreover, 1-pentanol is easier to remove from the purified product than 1-hexanol or 1-octanol. The crystallinity of the product was improved when some ethanol was added to the 1-pentanol (i.e. using 1-pentanol/ethanol, 5:1).

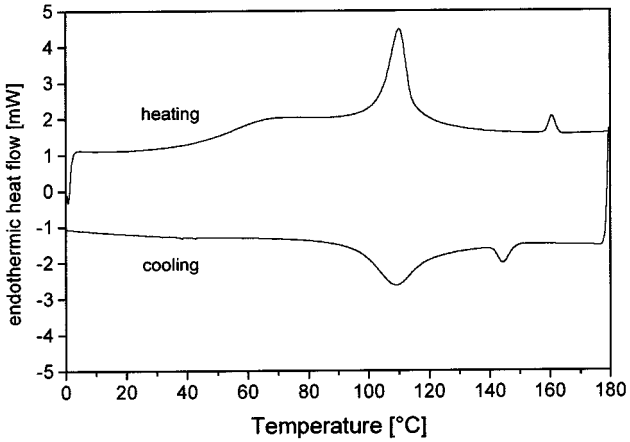

Figure 1. DSC thermogram of La^{III} dodecanoate (first heating−cooling cycle); endothermic peaks are shown pointing upwards

The melting points of the rare-earth dodecanoates $Ln(C_{11}H_{23}COO)_3$ were determined by hot-stage polarized optical microscopy, by the capillary melting technique, and by differential scanning calorimetry (DSC). Whereas in the DSC thermograms of the $Ln(C_{11}H_{23}COO)_3$ compounds with Ln = Sm−Lu, Y just a single peak is observed (corresponding to the melting point), the DSC thermograms of the dodecanoates of La^{III}, Ce^{III}, Pr^{III}, and Nd^{III} show an additional weaker peak above the melting point, indicating that these compounds form a mesophase on heating. In Figure 1, the first heating and cooling cycle in the DSC thermogram of $La(C_{11}H_{23}COO)_3$ is shown. It can be seen

that the melting peak is rather broad and shows a much higher enthalpy change than the clearing peak. Before the melting peak, a broad, weak endothermic transition is observed, which is due to the loss of water (as can be proved by thermogravimetry). In the cooling run, a slight supercooling is observed for the clearing transition. At high cooling rates (> 10 °C min^{-1}), no crystallization is observed and the samples are supercooled to a glassy state. The formation of a mesophase was also evident from the melting point determinations by hot-stage polarized optical microscopy and the capillary melting technique. Whereas the compounds showing only one peak in their DSC thermograms melted directly in a heated capillary tube to give a clear liquid (of rather low viscosity), the La^{III}, Ce^{III}, Pr^{III}, and Nd^{III} dodecanoates first melted to a highly viscous, turbid liquid and then, upon further heating, the viscosity decreased markedly and the melt became clear. Such a turbid melt is typical of a liquid-crystalline phase (i.e. a mesophase). Under the microscope, the compounds exhibited first a soft, waxy appearance and then melted to a birefringent liquid. However, it proved very difficult to obtain a good defect texture, even by cooling the isotropic liquid, as the compounds showed a very strong tendency to align homeotropically. By pressing with a needle on the cover glass it was possible to observe birefringence, but the molecules quickly re-orientated to the homeotropic alignment. The texture was suggestive of a smectic mesophase, most probably a smectic A phase (considering the presence of regions with a homeotropic alignment). It was not easy to visually observe the melting points of the mesomorphic lanthanide(III) dodecanoates owing to the high viscosities of the mesophases. The melting temperatures are thus quoted as the temperature at which the compound showed some fluidity. These temperatures are corroborated by the DSC thermograms and correspond to the maxima of the endothermic melting peaks. The clearing points were detected by hot-stage polarized optical microscopy. The transition temperatures and the corresponding enthalpy and entropy changes are listed in Table 2. For the enthalpy and entropy changes of the melting peak, the values of both the first and the second heating runs are listed. Large differences are observed between the first and the second heating runs; this is due to the fact that the evaporation enthalpy of water in the hydrated lanthanide soaps contributes to the transition enthalpy of the first heating run, whereas in the second heating run the enthalpy values are likely to be smaller owing to the fact that the samples are not completely crystalline (i.e. that they are partially amorphous). However, the enthalpy values of the clearing peak are consistent for the various compounds.

Room-temperature X-ray powder diffractograms were recorded for all of the synthesized compounds. Up to 4 peaks are observed in the low-angle region of the X-ray powder diffractograms of the solid lanthanide(III) dodecanoates, with the peak at the lowest angle showing by far the greatest intensity. The *d*-spacing values are in the ratio $1:{}^1/_2:{}^1/_3:\ \ldots\ :{}^1/_n$. These peaks correspond to the successive (00*l*) reflections and indicate the presence of a lamellar structure. Because the *d*-spacing is about twice the calculated length of the dodecanoate molecule, a bilayer structure can be postulated. The maximum average *d*-spacing of the bilayer structure was calculated for an *all-trans* conformation of the dodecanoate chain perpendicular to the metal ion base plane using Equation (1):[16]

$$d_{max} = 2d_{C-H} + 2(n-1)d_{C-C}\sin 55° + 2d_{C-O} + 2r_{Ln^{3+}} \quad (1)$$

where $n = 12$ (total number of carbon atoms), $d_{C-H} = 1.09$ Å, $d_{C-C} = 1.54$ Å, and $d_{C-O} = 1.36$ Å. For the ionic radii $r_{Ln}{}^{3+}$ of the trivalent lanthanide ions, we took the values reported by Shannon for rare-earth complexes with a coordination number of six.[25] The calculated and experimental d_{max} values, which correspond to two consecutive Ln^{III}

Lu^{III}	34.37	33.98

basal planes, are given in Table 3. Good agreement is found between the experimental and calculated values, any differences invariably amounting to less than 1% of the calculated value. As the ionic radii of the trivalent lanthanide ions decrease smoothly on traversing the lanthanide series ($r_{La}{}^{3+}$ = 1.045 Å, $r_{Lu}{}^{3+}$ = 0.861 Å for CN = 6), a corresponding decrease in the layer spacing might be expected, but this is not found experimentally. The small difference in ionic radius between La^{3+} and Lu^{3+} is outweighed by the experimental error in the determination of the *d*-values from the rather broad diffraction peaks. That the *d*-spacing does not follow the expected decrease on traversing the lanthanide series can be attributed to small variations in the conformations of the alkyl chains in the different compounds. For the calculation of the *d*-spacing, we assume an *all-trans* conformation for the alkyl chains, but random deviations can occur due to the flexibility of the alkyl chains.

The size of the lanthanide ion does have a very significant effect on the thermal behaviour of the lanthanide(III) dodecanoates. As the ionic radius of the lanthanide cation decreases, the distance between the carboxylate groups mutually opposite with respect to the plane containing the lanthanide ions also decreases. The thermal vibrations increase in amplitude at increasing temperatures and thereby induce unfavourable electrostatic interactions (repulsions) between the carboxylate groups, not only of the two opposing layers, but also between adjacent carboxylate groups within the same layer. When the repulsive forces between the negative charges are stronger than the attractive forces between the negative (carboxylate groups) and positive charges (lanthanide ions), the bilayer structure of the solid metal soap is no longer stable and breaks down. In this case, a rearrangement of the carboxylate groups and lanthanide ions to obtain a more stable solid-state structure (i.e. a crystal−crystal transition) might be expected. However, melting of the compounds is observed. The alkyl chains have sufficient thermal energy such that when the layer structure breaks down, their *all-trans* conformation is lost and they adopt a less extended conformation (which is more or less random). On melting, the metal soaps are transformed into ionic liquids with rather low viscosities. In such an ionic liquid, the total negative charge (due to the carboxylate groups) is, of course, equal to the total positive charge (due to the lanthanide ions), but the oppositely charged species can move independently of one another.

The melting points of the lanthanide(III) dodecanoates decrease over the lanthanide series; the smaller the lanthanide ion, the more unstable the layer structure becomes, and hence less thermal energy is required to break down the solid-state structure. The influence of the ion size on the melting point is also evident from the melting points of Y^{III} dodecanoate (m.p. 85 °C) and Ho^{III} dodecanoate (m.p. 85 °C), these similar values reflecting the similar ionic radii of Y^{3+} and Ho^{3+}.

A mesophase is formed when, at the melting point of the alkyl chains, the electrostatic interactions between the lanthanide ions and the carboxylate groups are still sufficiently favourable to maintain a layer structure. This is the case for the La^{III}, Ce^{III}, Pr^{III}, and Nd^{III} dodecanoates. The thermal behaviour of these compounds has been investigated by high-temperature X-ray diffraction analysis. Although the general features of the X-ray diffractograms remained the same in comparison to those of the solid compounds (except for the disappearance of the peaks of an order higher than 2), decreases in the *d*-spacings were observed at the melting points (vide infra). The X-ray diffractogram of each mesophase was consistent with a disordered smectic mesophase, indicating that the layered structure present in the solid phase is retained in the mesophase, whereas the in-plane ordering is largely lost. The loss of the in-plane ordering is reflected by the disappearance of the peak at large angles (at $2\theta \simeq 21°$, equivalent to $d \simeq 4.2$ Å) and the appearance of a much broader one, which is typical for disordered alkyl chains. Thus, the bilayer structure seen in the solid phase still represents an energetically favourable packing of the carboxylates in the mesophase. Additionally, the ratio of the peak positions in the low-angle region is $1:{}^1/_2$, indicating a one-dimensional stacking of the layers. The mesophase can be identified as a smectic A mesophase in that the layer spacing decreases slightly with increasing temperature. For a smectic C phase, an increase in layer spacing would be expected with increasing temperature.[26] The presence of an SmA phase is further supported by the homeotropically aligned regions in the optical texture observed by hot-stage polarized optical microscopy. After the clearing point, only one weak broad band is observed in the X-ray diffractograms. This is typical for the X-ray diffractogram of a liquid, indicating that the melts are isotropic. The mesophases have very high viscosities as, unlike in neutral organic molecules, the layers in the metal soaps are held together by electrostatic forces. It is difficult to shear the layers. In this sense, the mesophases can be considered as partially solid compounds, the alkyl chains exhibiting a molten behaviour, while to some extent the ionic part the structure remains intact. Consequently, sharp melting points are not observed for the lanthanide(III) dodecanoates forming a mesophase, but rather melting processes that occur over certain temperature ranges. Not all the alkyl chains melt at the same temperature. This became evident

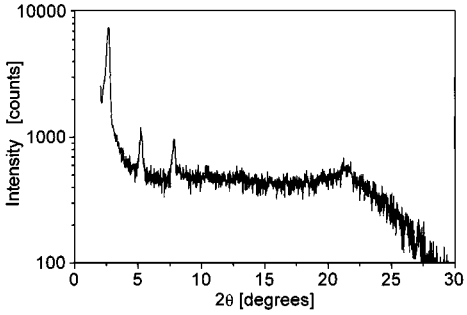

Figure 2. X-ray powder diffractogram of La^{III} dodecanoate at 50 °C

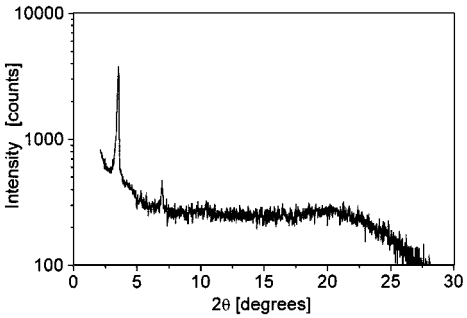

Figure 3. X-ray diffractogram of La^{III} dodecanoate in the mesophase at 135 °C

when X-ray diffractograms of the compounds forming a mesophase were recorded close to their melting points. Such X-ray diffractograms show more peaks than those of the solid phase or the mesophase and it turned out that they were in fact a superposition of these respective diffractograms. In Figure 2, the X-ray diffractogram of solid La^{III} dodecanoate at 50 °C is shown; Figure 3 shows the corresponding diffractogram of the mesophase (135 °C).

The La^{III}, Ce^{III}, Pr^{III}, and Nd^{III} dodecanoates all form mesophases, which can be identified by high-temperature X-ray diffraction analyses as smectic A phases, although some structural differences between the mesophases can be observed. For La^{III} dodecanoate, the structure of the mesophase is much closer to that of the corresponding solid compound than in the case of the Ce^{III}, Pr^{III}, and Nd^{III} compounds. This is evident from the smaller change in layer spacing upon melting of the La^{III} compound as compared with the decreases in layer spacing at the melting points of the other compounds. The change in layer spacing gradually increases from 1.28 Å for La^{III} dodecanoate, through 6.73 Å for Ce^{III} dodecanoate and 8.26 Å for Pr^{III} dodecanoate, to 8.67 Å for Nd^{III} dodecanoate (Figure 4). The decrease in *d*-value upon melting may either be due to more vigorous thermal movements of the alkyl chains giving rise to larger tilts (the average tilt remains at zero, however, and the alkyl chains are perpendicular to the layer planes) or to a curling of the chains. For Nd^{III} dodecanoate in the solid phase, the *d*-layer spacing shows a very small temperature dependence and remains virtually constant between room temperature and the melting point (Figure 5). For solid La^{III} dodecanoate, however, another phenomenon is observed: close to the melting point, a distinct decrease in the

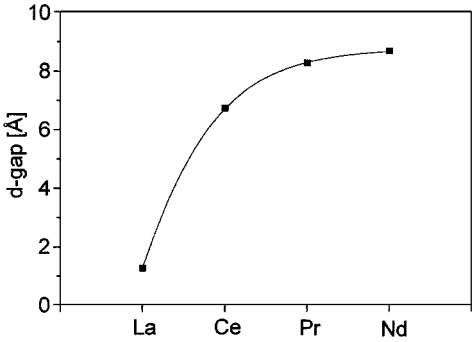

Figure 4. Variation of the change in the *d*-spacing at the melting point for the mesomorphic lanthanide(III) dodecanoates

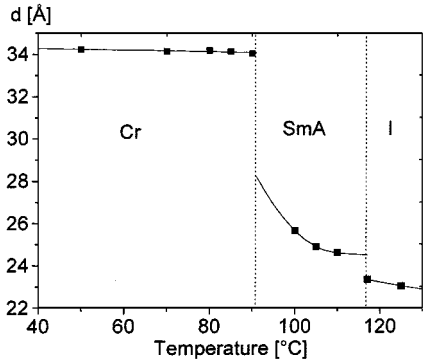

Figure 5. Evolution of the *d*-spacing of Nd^{III} dodecanoate as a function of temperature

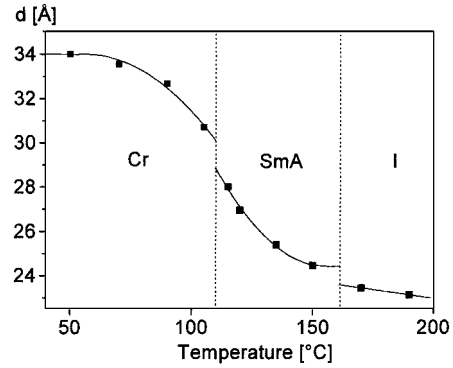

Figure 6. Evolution of the *d*-spacing of La^{III} dodecanoate as a function of temperature

layer spacing is seen (Figure 6). For Ce^{III} and Pr^{III} dodecanoate, intermediate behaviour is observed. This indicates differences in the pre-melting behaviour of the metal complexes.[27]

The layer structure is gradually lost in the compounds that form a mesophase, whereas it is lost much more abruptly in the compounds that melt without forming a mesophase. It must be emphasized that in the compounds forming a mesophase, the layer structure breaks down at the clearing point, whereas in the case of the non-mesogenic compounds total break-down of the layer structure occurs

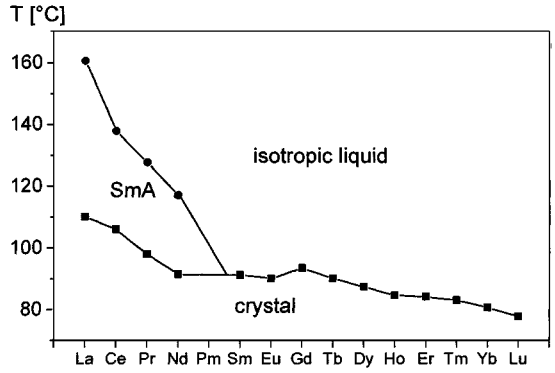

Figure 7. Phase diagram for the lanthanide(III) dodecanoates

only at the melting point. The phase diagram for the lanthanide(III) dodecanoates is shown in Figure 7.

The bilayer structure described herein is not restricted to lanthanide soaps. In fact, this mesophase structure was first described by Skoulios and Luzatti for alkali metal soaps in the "neat soap" lamellar mesophase.[28] The liquid-crystallinity of ionic metal soaps has been reviewed by Mirnaya et al.,[29] by Polishchuk and Timofeeva,[30] and by Giroud-Godquin.[31]

Although X-ray powder diffraction experiments revealed a bilayer structure for the solid lanthanide(III) dodecanoates, this technique did not give any information concerning the coordination of the lanthanide(III) ions. All that is known is that the metal ions form a layer that is sandwiched between two layers of carboxylate groups. From the stoichiometry $Ln(C_{11}H_{23}COO)_3$, it could be deduced that three carboxylate groups are present for each lanthanide ion, and that the lanthanide ions cannot be confined to one single carboxylate group (as in the case of the carboxylates of monovalent cations). We investigated the coordination around the lanthanide ion by IR spectroscopy.

The IR spectra of the various rare-earth dodecanoates proved to be all very similar. Moreover, the absorption maxima due to vibrations of the aliphatic chain of dodecanoic acid are not modified upon formation of the metal soaps. However, the IR absorptions due to the carboxyl group do change drastically. The IR spectrum of dodecanoic acid indicates the presence of a localized C=O bond and an OH bond within the COOH unit. The carbonyl (C=O) stretching vibration is observed as a very strong transition at 1700 cm^{-1}, whereas the OH stretching vibration at ca. 2660 cm^{-1} is broad due to intermolecular hydrogen bonding between two molecules of dodecanoic acid (dimeric structure). In the rare-earth dodecanoates, these transitions disappear and are replaced by the symmetric and asymmetric stretching vibrations of the carboxylate group (COO^-): ν_{symm} is seen at 1410 cm^{-1} and ν_{asymm} at 1540 cm^{-1}, giving a splitting of $\Delta\tilde{\nu} = \nu_{asymm} - \nu_{symm} =$ 130 cm^{-1}. This splitting is comparable to that seen for sodium soaps ($\Delta\tilde{\nu} = 138$ cm^{-1}), in which the metal−carboxylate bonding is essentially ionic.[16] Since in the rare-earth compounds the positions of the bands are shifted to smaller wavenumbers in comparison to the sodium soaps, there is a strong evidence to suggest that the carboxylate groups coordinate in a bidentate fashion. However, there is insufficient evidence to discriminate between a chelating bidentate or a bridging bidentate coordination mode, and even a mixture of both coordination types within the same compound cannot be ruled out. Marques et al.[16] have discussed in detail all the other transitions observed in the IR spectra of Ce^{III} carboxylates, and our results are in agreement with theirs. Recently, Corkery and Martin investigated Eu^{III} dodecanoate and Eu^{III}-doped La^{III} dodecanoate by high-resolution luminescence spectroscopy.[32] These authors found that at least two symmetrically distinct Eu^{III} sites are present in samples obtained by slow cooling of melts.

Conclusion

The lanthanide(III) dodecanoates are waxy compounds with a stoichiometry corresponding to $Ln(C_{11}H_{23}COO)_3 \cdot x\,H_2O$ ($0 \leq x \leq 1$). Water is often present in non-stoichiometric amounts, with compositions being close to the hemihydrate ($x = 0.5$) or the monohydrate ($x = 1$). TG-DTA has revealed that on heating the water molecules are lost before or at the melting point, and that cooling of the melts results in the anhydrous compounds (albeit often in a glass-like state). The X-ray powder diffraction patterns are consistent with a bilayer structure, in which an infinite layer of lanthanide ions is separated by a double layer of dodecanoate groups. The dodecanoate groups are arranged tail-to-tail. The experimentally determined layer spacing d_{max} is close to the calculated length of the dodecanoate group with the $C_{11}H_{23}$ chain in an *all-trans* conformation. The melting points of the lanthanide(III) dodecanoates decrease smoothly on traversing the lanthanide series, ranging from 110 °C for La^{III} dodecanoate to 78 °C for Lu^{III} dodecanoate. This can be attributed to an ion-size effect; the behaviour of Y^{III} dodecanoate is very similar to that of Ho^{III} dodecanoate, in accordance with the similarity of the radii of these cations. The dodecanoate salts of La^{III}, Ce^{III}, Pr^{III}, and Nd^{III} form mesophases, and the mesophase stability range decreases rapidly on traversing the lanthanide series. On the basis of hot-stage polarized optical microscopy observations and high-temperature X-ray diffraction measurements, the mesophase could be identified as a smectic A phase (SmA). The smectic phase has a very high viscosity owing to the strong electrostatic interactions between the anionic and cationic layers. Just above the melting point, the structure of the mesophase formed by La^{III} dodecanoate is close to that of the solid compound, but on proceeding towards Nd^{III} dodecanoate, the respective mesophases exhibit more liquid-like behaviour. This is reflected by the changes in *d*-spacing at the melting points. For Sm^{III} dodecanoate and the other dodecanoates, no mesomorphism is observed, not even monotropic mesomorphism. The difference in thermal behaviour between the dodecanoates of the light and heavy lanthanides can be quantitatively explained in terms of a model that takes into account the size of the lanthanide ion and the electrostatic

repulsions between the carboxylate groups. Although the present study confirms the results of earlier work on the thermal and structural properties Ce^{III} and La^{III} carboxylates,[16,17] the observation of an SmA mesophase only for the larger lanthanides $La^{III}-Nd^{III}$ is somewhat surprising and was not expected. A decrease in the mesophase stability ranges over the lanthanide series has been found for Schiff-base complexes,[18] but the lanthanide(III) dodecanoates show that small differences in ionic radius between the lanthanide ions are critical with regard to the formation or absence of a mesophase.

Experimental Section

General Remarks: Elemental analyses (CHN) were performed on a CE Instruments EA-1110 elemental analyzer. − Differential scanning calorimetry (DSC) measurements were made on a Mettler-Toledo DSC821e module. Solid samples weighing 2−5 mg were placed in aluminium pans (40 μL) with pierced lids and heated or cooled at a scan rate of 10 °C min^{-1} under a nitrogen flow. Indium metal was used as a standard to calibrate the instrument (T_m = 156.6 ± 0.3 °C, ΔH_m = 28.45 ± 0.6 J g^{-1}). − The optical textures of the mesophases were observed with an Olympus BX60 polarized optical microscope equipped with a LINKAM TMS600 hot-stage and a LINKAM TMS93 programmable temperature-controller. − High-temperature X-ray diffraction was measured on a STOE transmission powder diffractometer system STADI P with a high-temperature attachment version 0.65.1 (temperature range from room temp. to 1000 °C). Monochromatic Cu-$K_{\alpha 1}$ radiation (λ = 1.54 Å) was obtained with the aid of a curved germanium primary monochromator. Diffracted X-rays were measured by a linear position-sensitive detector (PSD). The sample was placed in a quartz capillary (outer diameter 0.3 mm, wall thickness 0.01 mm) and spun during the measurement. In general, data were collected in the range $1 \leq 2\theta \leq 30°$. − Melting points were measured on an Apotec melting-point apparatus using samples in capillaries. − Thermogravimetric curves were obtained using a Polymer Laboratories STA 1000H TG-DTA apparatus. The sample (ca. 15 mg) was heated in a static air atmosphere from 30 to 1000 °C at a rate of 10 °C min^{-1}. − FT-IR spectra were recorded on a Bruker IFS-66 spectrometer with samples in KBr pellets or as Nujol mulls. − All chemicals were used as received, without further purification. Dodecanoic acid (lauric acid) was obtained from Acros. Hydrated rare-earth nitrates were purchased from Aldrich.

Synthesis of La^{III} Dodecanoate: Dodecanoic acid (2.75 g, 13.8 mmol) was dissolved in 1:1 ethanol/water (100 mL) and converted to sodium dodecanoate by adding an equivalent amount of a standardized 0.5 M NaOH solution by means of a burette. Lanthanum nitrate hexahydrate (2.00 g, 4.6 mmol) was also dissolved in 1:1 ethanol/water (100 mL). The solution of sodium dodecanoate was then added dropwise with stirring to the solution of lanthanum nitrate at ambient temperature, which led to the immediate deposition of a white precipitate. After the addition was complete, the mixture was stirred for 1 h at ambient temperature. The precipitate was then collected by filtration through a Büchner funnel, and washed with water (3 × 100 mL), ethanol (3 × 50 mL), and acetone (3 × 50 mL) in order to remove residual traces of the lanthanum salt or of dodecanoic acid. The crude lanthanum(III) dodecanoate was dried for 24 h in vacuo at 50 °C and then recrystallized from 1-pentanol/ethanol (5:1). Crystallization was completed by placing the solution in a refrigerator. The purified soap was collected by filtration, washed with ethanol (25 mL) to remove most of the 1-pentanol, and then dried in vacuo (10^{-3} mbar) at 50 °C for at least 24 h. Lanthanum(III) dodecanoate was obtained as a white powder. Yield: 2.25 g (87%). − Elemental analysis: calcd. for $C_{36}H_{69}O_6La \cdot {}^1/_2\,H_2O$: C 58.0, H 9.5, La 18.6; found C 57.8, H 9.3, La 18.6; ratio $C_{11}H_{23}COOH$/Ln: theoretical for $La(C_{11}H_{23}COO)_3$: 3.0; found 2.93. − IR (KBr): $\tilde{\nu}$ = 1540 (s, COO^-, asymm. C−O stretch), 1410 cm^{-1} (m, COO^-, symm. C−O stretch).

All the other lanthanide(III) dodecanoates were prepared by the same method.

Analysis Procedures: − 1. Determination of Rare-Earth Content: The compound (200 mg) was dissolved in hot 0.1 M H_2SO_4 solution (15 mL). After cooling, the solution was extracted with diethyl ether to remove dodecanoic acid. An aliquot (5 mL) of the aqueous solution was transferred to a beaker by means of a volumetric pipette and its pH was adjusted to 6 by adding hexamethylenetetraamine buffer. Xylenol orange was added as an indicator and the solution was titrated with standardized 0.01 M EDTA solution until the indicator changed color from purple to yellow. Titrations were performed at 60 °C, at which temperature the color change was more easily observed. − **2. Determination of the Dodecanoic Acid Content:** The combined diethyl ether extracts containing dodecanoic acid (obtained by extracting the H_2SO_4 solution after decomposition of the soap; see above) were washed with saturated brine and then the solvent was removed under reduced pressure. The residual dodecanoic acid was redissolved in ethanol and this solution was titrated with 0.025 M NaOH solution using phenolphthalein as indicator.

New Studies on the Reactivity of Hydride-Containing Niobocene Complexes Towards Insertion and Protonation Processes

Antonio Antiñolo,*[a] Fernando Carrillo-Hermosilla,[a] Juan Fernández-Baeza,[a] Santiago García-Yuste,[a] Antonio Otero,*[a] Javier Sánchez-Prada,[a] and Elena Villaseñor[a]

Keywords: Niobium / Metallocenes / Hydrides / Dihydrogen / Protonations / Insertions

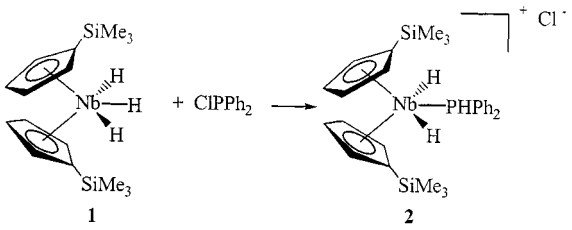
The trihydride complex [Nb(η^5-$C_5H_4SiMe_3)_2(H)_3$] **(1)** reacts with diphenylphosphane to afford the monohydride [Nb(η^5-$C_5H_4SiMe_3)_2(H)(PHPh_2)$] **(3)**. The synthesis of complex **3** has also been achieved from the initial formation of the phosphonium salt [Nb(η^5-$C_5H_4SiMe_3)_2(H)_2(PHPh_2)$]Cl **(2)** by reaction of the trihydride complex [Nb(η^5-$C_5H_4SiMe_3)_2(H)_3$] **(1)** with chlorodiphenylphosphane, followed by deprotonation of this salt in aqueous NaOH. Protonation of complex **3** at low temperature with a slight excess of CF_3COOH or CF_3COOD leads to the η^2-dihydrogen complex [Nb(η^5-$C_5H_4SiMe_3)_2(\eta^2$-$H_2)(PHPh_2)$]CF_3CO_2 **(4)** or its monodeuterated isotopomer [Nb(η^5-$C_5H_4SiMe_3)_2(\eta^2$-HD)$(PHPh_2)$]CF_3CO_2 **(5)**. When the temperature is increased to room temperature, complexes **4** and **5** transform into the *transoid* dihydrides [Nb(η^5-$C_5H_4SiMe_3)_2(H)_2(PHPh_2)$]$CF_3CO_2$ **(6)** and [Nb(η^5-$C_5H_4SiMe_3)_2(H)_2$-$(PDPh_2)$]CF_3CO_2 **(7)**, respectively. Complex **3** undergoes an insertion of CS_2 into the niobium–hydrogen bond to give the η^1-dithioformato complex [Nb(η^5-$C_5H_4SiMe_3)_2(PHPh_2)(\eta^1$-*S*-S(S)CH)] **(8)**. This complex could be detected by NMR spectroscopy but could not be isolated due to rapid conversion into the η^2-dithioformato complex [Nb(η^5-$C_5H_4SiMe_3)_2(\eta^2$-*S*,*S*-SSCH)] **(9)** by loss of the phosphane molecule. Complex **3** also reacts with CO_2 to give the η^2-formato complex [Nb(η^5-$C_5H_4SiMe_3)_2(\eta^2$-*O*,*O*-OOCH)] **(10)**; in this case the η^1-formato complex could not be detected. The reagent $ClPPh_2$ very smoothly inserts into the Nb–H bond of the complexes [Nb(η^5-$C_5H_4SiMe_3)_2(H)(L)$] [L = $PHPh_2$, CN(xylyl), CO; xylyl = 2,6-dimethylphenyl], yielding the new ionic complexes [Nb(η^5-$C_5H_4SiMe_3)_2(PHPh_2)(L)$]Cl [L = $PHPh_2$ **(11)**, CN(xylyl) **(12)**, CO **(13)**]. All the complexes described have been characterized by analytical and spectroscopic methods.

Introduction

Hydride complexes of transition metals represent one of the most important classes of compounds due to their chemical reactivity and importance in catalysis.[1] Furthermore, the chemistry of phosphorus-substituted early transition metal complexes has also recently received a great deal of attention.[2] Several groups[3,4] have found that the trihydrides [Cp_2MH_3] (M = Nb, Ta) react with chlorophosphanes PR_2Cl to afford the phosphonium salts [Cp_2MH_2-(PR_2H)]Cl. Depending on the metal (Nb or Ta) and on the nature of the phosphane substituent, deprotonation of these salts leads to hydride(phosphane) [$Cp_2MH(PR_2H)$] or hydride(phosphide) [$Cp_2MH_2(PPh_2)$] metalloligands. As part of a study of the electronic and steric influence of trimethylsilyl-substituted cyclopentadienyl ligands on the properties of niobocene complexes, we have studied the reaction of the trihydride niobocene complex [Nb(η^5-$C_5H_4SiMe_3)_2H_3$][5] with $ClPPh_2$ and the subsequent deprotonation of the phosphonium salt obtained. We have previously prepared[6] the hydride(phosphane) niobocene complexes [Nb(η^5-C_5H_4Si-$Me_3)_2(H)(PR_3)$] by heating the trihydride complex [Nb(η^5-$C_5H_4SiMe_3)_2H_3$] (**1**) in the presence of the corresponding phosphane PR_3. We have now used this method to synthesize the monohydride phosphane complex [Nb(η^5-C_5H_4Si-$Me_3)_2(H)(PHPh_2)$] (**3**) by thermal reaction of [Nb(η^5-$C_5H_4SiMe_3)_2H_3$] (**1**) with $PHPh_2$. In addition, and in keeping with our interest in dihydrogen complexes,[6,7] we report here the results for the low temperature protonation of the new monohydride complex [Nb(η^5-$C_5H_4SiMe_3)_2(H)$-$(PHPh_2)$] (**3**) and, for the first time, the deprotonation reaction of the cationic species obtained in this kind of reaction when the temperature is increased to room temperature.

Finally, the insertion of unsaturated molecules into the metal−hydride bond is considered as a fundamental chemical step in several catalytic cycles and frequently leads to reactive intermediates.[8] In connection with our recent studies of metal-promoted activation of unsaturated molecules such as heterocumulenes,[9] carbon disulfide,[10] carbon dioxide,[11] and activated alkynes,[12] we also decided to explore the reactivity of the new hydride phosphanyl complex **3** with carbon disulfide and carbon dioxide. These reactions have permitted the isolation of dithioformato- and formato-derivatives as well as the insertion of $ClPPh_2$ into the Nb−H bond of the monohydride derivatives [Nb(η^5-$C_5H_4SiMe_3)_2(H)(L)$] [L = $PHPh_2$, CN(2,6-$Me_2C_6H_3$), CO], and this has allowed us to prepare new cationic Nb^{III} species.

Results and Discussion



Reaction of [Nb(η^5-$C_5H_4SiMe_3)_2(H)_3$] With $ClPPh_2$

The reaction of [Nb(η^5-$C_5H_4SiMe_3)_2(H)_3$] (**1**) with $ClPPh_2$ proceeds smoothly to give quantitatively the ionic

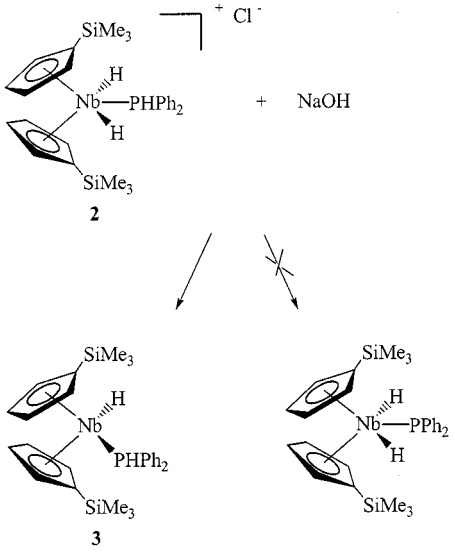
complex $[Nb(\eta^5\text{-}C_5H_4SiMe_3)_2(H)_2(PHPh_2]Cl$ (**2**) as depicted in Equation (1).

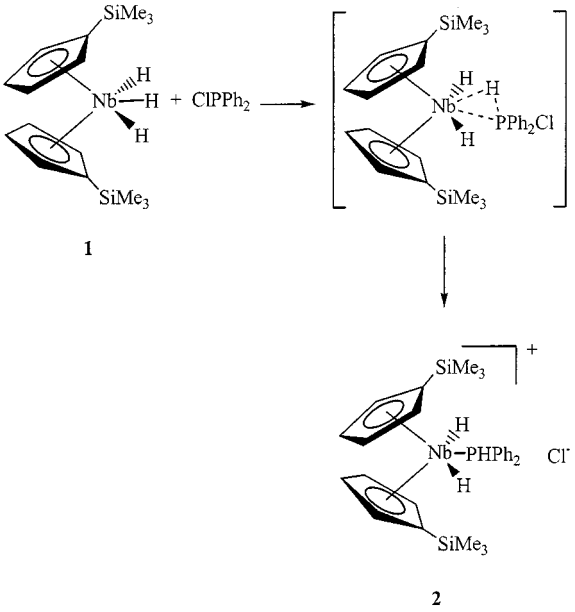


1 2 (1)

Complex **2** immediately precipitates as grey voluminous flakes after mixing Et_2O solutions of $[Nb(\eta^5\text{-}C_5H_4SiMe_3)_2(H)_3]$ (**1**) and $ClPPh_2$ at room temperature. Even at low temperature (253 K) the rate of the reaction is very fast. The low solubility of complex **2** in hydrocarbons, ethers and aromatic solvents means that the product can be isolated very easily in an analytically pure form. However, it is sufficiently soluble in acetone to allow its NMR spectrum to be recorded. The ionic nature of complex **2** was confirmed by measurement of the molar conductivity (Λ_M = 135 $\Omega^{-1}mol^{-1}$), which is in agreement with a 1:1 electrolyte.[13] Complex **2** was formed in high yield and was characterized by ^1H and ^{31}P NMR and IR spectroscopy. In the ^1H NMR spectrum ([D$_6$]acetone) only the symmetric isomer $[Nb(\eta^5\text{-}C_5H_4SiMe_3)_2(H)_2(PHPh_2)]Cl$ was observed. The cyclopentadienyl rings are equivalent and give rise to two broad resonances (see Experimental Section) for an A_2B_2 spin system in the ^1H NMR spectrum, which indicates a symmetrical disposition at the niobium centre with a rapid rotation of the phosphane moiety around the Nb−P bond. The ^1H NMR spectrum also shows a resonance due to the hydride ligands at $\delta = -2.16$ and this value is similar to those reported for the equivalent hydride ligands in $[Nb(\eta^5\text{-}C_5H_4SiMe_3)_2(H)_2(L)]PF_6$[6a] [L = P(OR)$_3$, PMe$_2$Ph] and $[M(\eta^5\text{-}C_5H_5)_2(H)_2(PR_3)]^+$.[14] The hydride ligands are equivalent and show a single resonance that appears as a doublet due to coupling with the phosphorus atom ($^2J_{HP}$ = 78.2 Hz). The signal for the hydrogen atom of the P−H group appears as a doublet at $\delta = 6.67$ ($^1J_{HP}$ = 283 Hz). The $^3J_{HH}$ value could not be observed due to the broadness of the signals. The ^{31}P NMR spectrum shows a broad doublet at $\delta = 20$ that corresponds to a second-order spin system due to the couplings $^1J_{HP}$ and $^2J_{HP}$. The IR spectrum shows a ν(P−H) band at ca. 2293 cm^{-1}, which confirms the existence of the coordinated phosphane molecule, and also a ν(Nb−H) band of medium intensity at ca. 1703 cm^{-1} (see Experimental Section).

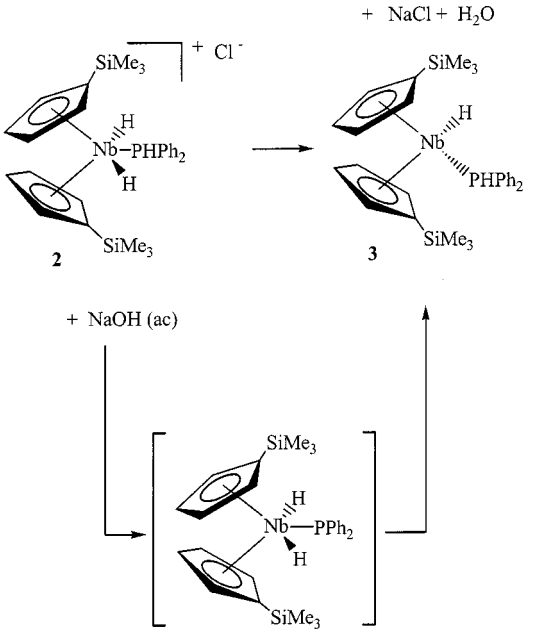
A characteristic feature of complex **2** is the existence of two acidic centres: the P−H and the Nb−H bonds. The reaction between complex **2** and an aqueous solution of NaOH in toluene affords only the hydride(phosphane) complex **3** in good yield (75%); the corresponding phosphido complex could not be observed (Scheme 1).

The tantalum phosphido complex $Cp_2TaH_2(PPh_2)$ has been isolated by Nikonov et al. while the homologous niobium compound $Cp_2NbH_2(PPh_2)$ was not observed.[3] The



Scheme 1. Formation of **3** by reaction of **2** with NaOH

reaction was carried out in a two-phase system (water/toluene), which enabled easy extraction and isolation of the product as a red oily material. The characterization of complex **3** was performed by NMR and IR spectroscopy. The ^1H NMR spectrum shows a high-field resonance at $\delta = -7.37$ for the hydride ligand, which appears as a doublet ($^2J_{HP}$ = 29.30 Hz), whereas the P−H resonance appears as a doublet at $\delta = 6.90$ ($^1J_{HP}$ = 332 Hz). Three multiplets can also be observed that integrate for 4, 2 and 2 protons, respectively, and correspond to an AA′BB′ spin system. These signals are due to the cyclopentadienyl rings and are in accordance with an asymmetrical environment for the niobium centre (see Experimental Section). Finally, the IR spectrum shows two bands at ca. 1643 and 2281 cm^{-1}, which correspond to ν(Nb−H) and ν(P−H), respectively, and confirm the existence of the coordinated phosphane molecule.

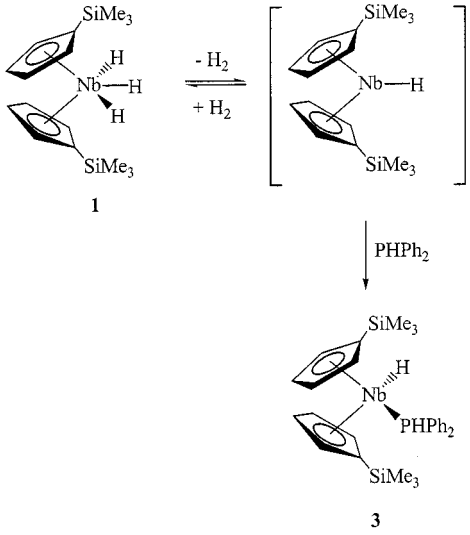


The reaction of $[Nb(\eta^5\text{-}C_5H_4SiMe_3)_2(H)_3]$ (**1**) with $ClPPh_2$ can be rationalized in terms of an insertion of the chlorophosphane into the Nb−H bond, followed by elimination of the chloride ion and rearrangement of the molecule as shown in Scheme 2. The nature of the insertion process can be considered as an interaction of the empty d-orbitals on the phosphorous with the Nb−H σ-bond, a situation that means a pentavalent phosphorus structure should be initially formed.

Deprotonation of **2** should initially occur at the more labile hydrogen atom, which is, according to the spectroscopic data, the P−H proton. This implies that deprotonation of **2** should initially produce a dihydride(phosphide) complex. However, such a complex could not be detected and probably transforms rapidly into complex **3** through a hydride shift into the vacant d-orbital at phosphorus (see Scheme 3).

Further experiments, which are described later in this paper, allowed us to confirm unequivocally that deprotonation occurs at the P−H bond. This is not unexpected

Scheme 2. Proposed reaction pathway for the formation of **2**



Scheme 3. Proposed reaction pathway for the deprotonation of **2**

as the P−H bond is kinetically more labile than the Nb−H bond.

Reaction of $[Nb(\eta^5\text{-}C_5H_4SiMe_3)_2(H)_3]$ With $PHPh_2$

We also prepared complex **3** in an alternative manner by reaction of $[Nb(\eta^5\text{-}C_5H_4SiMe_3)_2(H)_3]$ with $PHPh_2$. In fact, $[Nb(\eta^5\text{-}C_5H_4SiMe_3)_2(H)_3]$ (**1**) reacts slowly (3 hours) with $PHPh_2$ in THF at ca. 70 °C to afford the complex $[Nb(\eta^5\text{-}C_5H_4SiMe_3)_2(H)(PHPh_2)]$ (**3**). The initial step should be the formation of the coordinatively unsaturated 16-electron species $[Nb(\eta^5\text{-}C_5H_4SiMe_3)_2(H)]$ by thermolytic loss of H_2, followed by coordination of the phosphane ligand [Equation (2)].

(2)

The reaction is similar to that previously reported[6a,7,10] for the preparation of several families of niobocene complexes $[Nb(\eta^5\text{-}C_5H_4SiMe_3)_2(H)(L)]$ (L = π-acid ligand). Complex **3** was isolated as a spectroscopically pure, air-sensitive red oily material and the spectroscopic data are in agreement with those recorded for the complex isolated by the first method described in this paper. This one-step synthesis gives a better yield (90%) and represents a cleaner way of preparing complex **3**.

Protonation Reaction of $[Nb(\eta^5\text{-}C_5H_4SiMe_3)_2(H)(PHPh_2)]$ (3)

Complex **3** was easily protonated with CF_3COOH at low temperature to give the corresponding *cisoid* dihydrogen-containing complex **4** according to Equation (3).

$$[Cp'_2Nb(H)(PHPh_2)]\ \mathbf{(3)} + CF_3COOH \longrightarrow [Cp'_2Nb(\eta^2\text{-}H_2)(PHPh_2)]^+CF_3COO^-\ \mathbf{(4)} \quad (3)$$

When CF_3COOD is used, the monodeuterated complex **5** is obtained [Equation (4)]:

$$[Cp'_2Nb(H)(PHPh_2)]\ \mathbf{(3)} + CF_3COOD \longrightarrow [Cp'_2Nb(\eta^2\text{-}HD)(PHPh_2)]^+CF_3COO^-\ \mathbf{(5)} \quad (4)$$

These processes were carried out by adding a slight excess of CF_3COOH/D to a solution of complex **2** in $[D_6]$acetone in an NMR tube at 183 K.

The ^1H NMR spectrum of **4** at low temperature shows a dihydrogen resonance at ca. $\delta = -4.57$ that appears as a doublet due to the H-P coupling ($J_{HP} = 19.7$ Hz). The signal broadens at very low temperature but does not show decoalescence. The high-field $^1H\{^{31}P\}$ NMR spectrum of **5** at 183 K shows two triplets (1:1:1) at ca. $\delta = -4.7$ due to the existence of two different rotamers; *endo* **5a** and *exo* **5b**

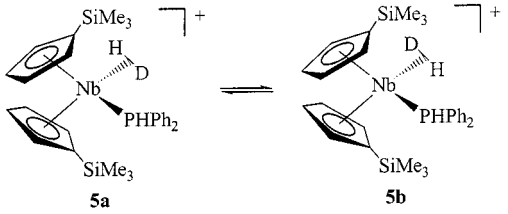


Figure 1. Rotation process of the HD coordinated molecule

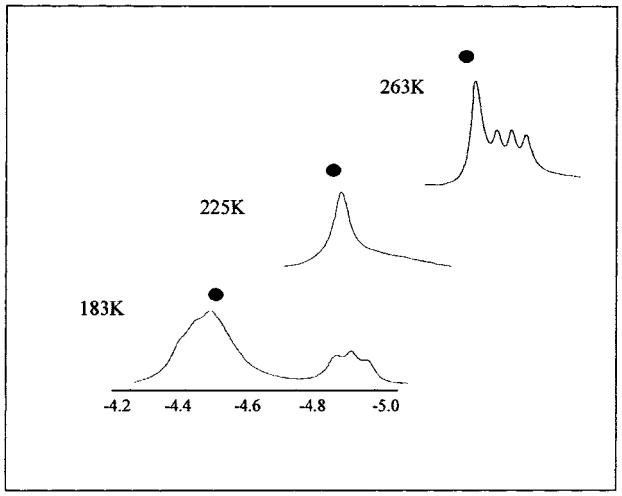
(Figure 1). Both isomers show a similar J_{HD} coupling of ca. 18.20 Hz.

These rotamers exist due to the fact that the rotation of the coordinated HD molecule is frozen on the NMR time scale at this temperature.[6a,7]

When the temperature is raised, the rotamers *endo* H **5a** and *exo* H **5b** interconvert by rotation of the HD molecule. Coalescence is reached at 225 K, and at this temperature it is not possible to distinguish between the two isomers. At 263 K a single resonance (1:1:1 triplet) is observed at ca. $\delta = -4.70$ for the HD fragment (Figure 2).



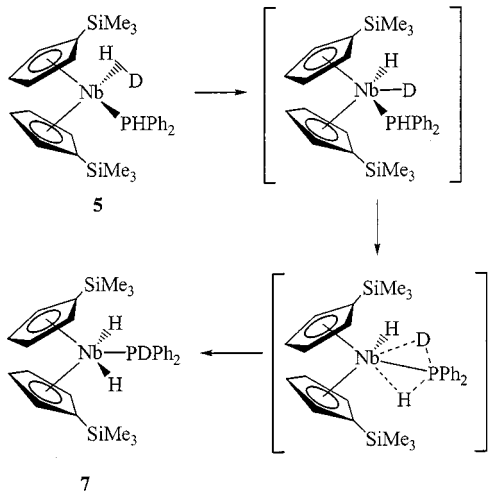


Figure 2. High-field $^1H\{^{31}P\}$ NMR spectrum (300 MHz) of **5** at variable temperature; the point denotes the presence of residual complex **4**

This phenomenon allowed the estimation of the free energy of activation of the internal rotation at the coalescence temperature ($\Delta G^{\neq} \approx 10.43$ kcal/mol K). Similar values have been observed previously for the related complexes $[Nb(\eta^5\text{-}C_5H_4SiMe_3)_2(\eta^2\text{-}HD)(PMe_2Ph)]^+$ ($\Delta G^{\ddagger} \approx 11$ kcal/mol K)[6a] and $[Nb(\eta^5\text{-}C_5H_4SiMe_3)_2(\eta^2\text{-}HD)(CNR)]^+$ ($\Delta G^{\ddagger} \approx 8-9$ kcal/mol K).[7] As a consequence of this high barrier, rotation of the HD molecule can be blocked on the NMR time scale. The value of the J_{HD} coupling constant (18.2 Hz) verifies the presence of an H−D bond and is strong evidence for the presence of a dihydrogen complex.[7] Moreover, the observation of low longitudinal-relaxation times, T_1, is very useful in providing evidence for the existence of a dihydrogen ligand. The T_1 values of the dihydrogen nuclei of **4**, $T_1(H_2)$, and the hydride ligand of complex **3**, $T_1(H)$, were determined using the method described by Crabtree et al.[15] The T_1 minima were found to be 15.8 ms at 215 K for **4** and 95 ms at 186 K for complex **3**. According to Crabtree's proposal, the H−H distance r_{H-H} in the coordinated H_2 ligand can be determined from the T_1 measurements. The observed relaxation, R_{obs}, for **4** is the sum of that due to the H−H dipole−dipole interaction (R_{H-H}) and that due to all other effects (R_O), which can be estimated using the observed relaxation for **3** [R_{obs} (3)], as a reasonable indication of the niobium and solvent contributions. From this equation we calculated $R_{H-H} = 52.68$ (μs^{-1}). Using the Morris approximation,[16] we found that $r_{H-H} = 1.16$ Å assuming rapid rotation of dihydrogen and $r_{H-H} = 0.92$ Å assuming a slow rotation. These values are in agreement with the J_{H-D} value measured for complex **5** and indicate significant stretching of the coordinated H−H bond. Similar results were found for the related compounds $[Nb(\eta^5\text{-}C_5H_4SiMe_3)_2(\eta^2\text{-}HD)(L)]^+$ [L = $P(OEt)_3$, PMe_2Ph].[6a]

After low-temperature protonation the temperature was raised to room temperature and **4** and **5** transformed into the *transoid* isomers $[Nb(\eta^5\text{-}C_5H_4SiMe_3)_2(H)_2(PHPh_2)]\text{-}CF_3CO_2$ (**6**) and $[Nb(\eta^5\text{-}C_5H_4SiMe_3)_2(H)_2(PDPh_2)]\text{-}CF_3CO_2$ (**7**), respectively, through an irreversible process. Complex **6** shows similar spectroscopic data to complex **2**, with the counterion being the only difference between the two. Complex **7** also shows very similar spectroscopic data and these are in agreement with a symmetrical disposition of the niobium centre, showing an A_2B_2 spin system in the ^1H NMR spectrum for the cyclopentadienyl ligands. Thus, the $^1H\{^{31}P\}$ NMR spectrum shows a singlet resonance at $\delta = -1.76$ due to the hydride ligands; no resonance due to a possible PH moiety is observed. Moreover, the ^{31}P NMR spectrum shows a 1:1:1 triplet resonance due to coupling with the deuterium atom ($^1J_{PD} = 34$ Hz). This signal allowed us to confirm the existence of the P−D bond for complex **7**.

The formation of complexes **6** and **7** could be considered to be the result of an oxidative addition of a coordinated dihydrogen molecule to give a *cisoid* dihydride derivative that transforms rapidly into the *transoid* isomer. According to the results obtained, the *cisoid*−*transoid* isomerization may involve the phosphorus atom, as shown in Scheme 4.

Scheme 4. Proposed reaction pathway for the formation of **7**

Isomerization of **5** may proceed by attack of the Nb−D bond at an empty d-orbital of the phosphorus atom. At the same time the P−H bond interacts with the niobium centre, thus making possible the rearrangement of the molecule to give the *transoid* derivative **7**.

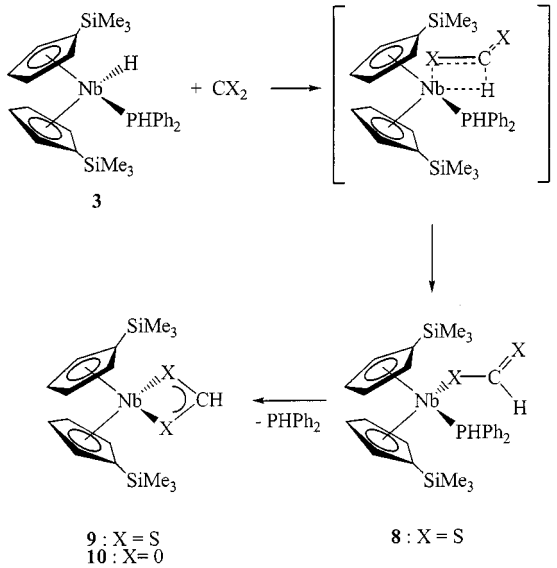
When the reaction between **3** and CF_3COOH/D in acetone is performed on a Schlenk-tube scale, the only isolated products are the *transoid* dihydrides **6** and **7**. The low solubility of these complexes in hydrocarbons, ethers and aromatic solvents enabled very easy isolation of the products as colourless, analytically pure solids.

The similarity between complexes **6** and **7** and the phosphonium salt **2**, which was obtained by the reaction between trihydride **1** and $ClPPh_2$, led us to study their behaviour towards deprotonation reactions. Both complexes react with aqueous sodium hydroxide in toluene to give the previously characterized hydridophosphane **3**. This observation confirms that deprotonation of complexes **2**, **6** and **7** occurs at the P−H(P−D) bond, as discussed above.

Reaction of [Nb(η^5-$C_5H_4SiMe_3$)$_2$(H)(PHPh$_2$)] (3) with CX$_2$ (X = S, O)

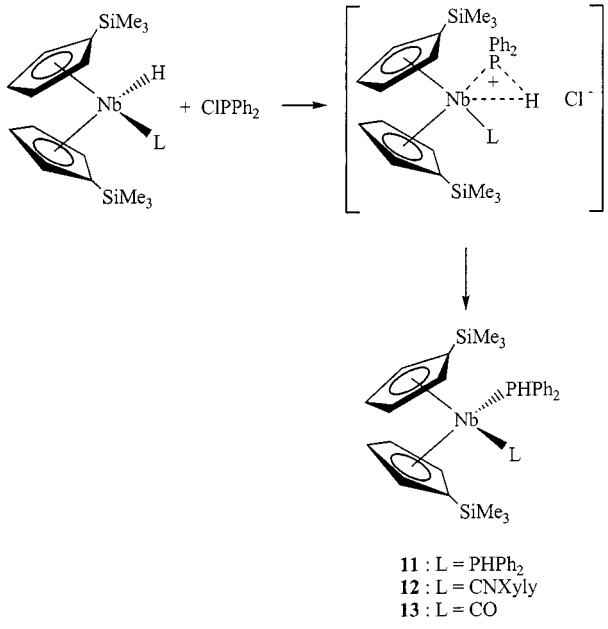
Insertion of CS_2 into the Nb−H bond of [Nb(η^5-$C_5H_4SiMe_3$)$_2$(H)(PHPh$_2$)] results in the formation of an η^1-dithioformato intermediate [Nb(η^5-$C_5H_4SiMe_3$)$_2$(PHPh$_2$)(η^1-*S*-S(S)CH)] (**8**), which could not be isolated but could be detected by ^{1}H NMR spectroscopy. This complex rapidly evolves by an elimination of phosphane (due to a substitution reaction of phosphane by the noncoordinated sulfur atom) to give an η^2-dithioformato complex [Nb(η^5-$C_5H_4SiMe_3$)$_2$(η^2-*S*,*S*-SSCH)] (**9**) (Scheme 5). This complex was isolated as an air-sensitive orange solid and was previously isolated and characterized by some of us.[10]

This behaviour has previously been found in the reactions of some complexes of the type [Nb(η^5-$C_5H_4SiMe_3$)$_2$(H)(L)] with CS_2.[10]



The most significant ^{1}H NMR spectroscopic data for **8** is the resonance at δ = 12.33, which corresponds to the C−H group and appears as a doublet ($^4J_{PH}$ = 2 Hz). This coupling constant confirms the presence of the coordinated phosphane. In addition, the ^{1}H NMR spectrum shows four multiplets for the cyclopentadienyl rings in accordance with an asymmetrical environment for the niobium centre.

The reaction of [Nb(η^5-$C_5H_4SiMe_3$)$_2$(H)(PHPh$_2$)] (**3**) with CO_2 in THF under 2.5 atm. of CO_2 results in the formation of the η^2-formato complex [Nb(η^5-$C_5H_4SiMe_3$)$_2$(η^2-*O*,*O*-OOCH)] (**10**) (Scheme 5) as a brown, air-sensitive oily product after appropriate workup. Complex **10** was previously prepared by some of us using different methods.[11] We have been unable to detect the η^1-formato complex due to the difficulties involved in carrying out test reactions on an NMR-tube scale. The spectroscopic data of **10** agree with those previously described.[11]



Reactivity of [Nb(η^5-$C_5H_4SiMe_3$)$_2$(H)(L)] (L = PHPh$_2$, CN(xylyl), CO) Towards ClPPh$_2$

$ClPPh_2$ very smoothly inserts into the Nb−H bond of [Nb(η^5-$C_5H_4SiMe_3$)$_2$(H)(L)] [L = $PHPh_2$, CN(xylyl), CO] to give the ionic phosphanyl complexes [Nb(η^5-$C_5H_4SiMe_3$)$_2$(PHPh$_2$)(L)]Cl [L = $PHPh_2$ (**11**), CN(xylyl) (**12**), CO (**13**)] (Scheme 6). These reactions can be rationalized in terms of an electrophilic attack of the phosphorus atom (which contains empty d orbitals) at the Nb−H bond, forming a three-centre transition state that evolves with elimination of chloride.

Complexes **11**−**13** were formed in high yield (≈ 85%) as red solids after precipitation from Et_2O. The ^{1}H NMR spectrum of **11** reveals the equivalence of the cyclopentadienyl rings, with two pseudotriplets observed at δ = 5.36 and δ = 5.50. In contrast, an asymmetrical environment for the niobium centre is observed for complexes **12**

Scheme 5. Proposed reaction pathway for the formation of **9** and **10**

Scheme 6. Insertion process of $ClPPh_2$ into an Nb−H bond

and **13**. In addition, the ^{1}H NMR spectra of **11**−**13** show a doublet resonance for the P−H moiety ($^1J_{PH} \approx 370$ Hz). The IR spectra of **11**−**13** reveal the absence of an ν(Nb−H) band and the existence of ν(P−H) at ca. 2280 cm^{-1}.

In conclusion, several aspects of the reactivity of hydride-containing niobocene species have been considered in the work described here. In particular, the reactions of $ClPPh_2$ towards hydride-niobocene complexes [Nb(η^5-$C_5H_4SiMe_3)_2(H)_3$] (**1**) and [Nb(η^5-$C_5H_4SiMe_3)_2(H)(L)$] occur through insertion of chlorophosphane into an Nb−H bond. Furthermore, the protonation reaction of **3** at low temperature gives an η^2-dihydrogen complex, which evolves at high temperature to the corresponding *transoid* dihydride species. Further work in this field is in progress.

Experimental Section

General Remarks: All operations were performed under an inert atmosphere using standard vacuum line (Schlenk) techniques. Solvents were purified by distillation from the appropriate drying agents before use. NMR spectra were obtained on a Varian Unity FT-300 and Varian Gemini FT-200 instruments. IR spectra were recorded on a Perkin−Elmer PE 883 IR spectrophotometer. Elemental analyses were performed on a Perkin−Elmer 2400 microanalyzer. [Nb(η^5-$C_5H_4SiMe_3)_2(H)_3$] was prepared as described previously.[5]

Preparation of [Nb(η^5-$C_5H_4SiMe_3)_2(H)_2(PHPh_2)$]Cl (2): [Nb(η^5-$C_5H_4SiMe_3)_2(H)_3$] (**1**) (0.30 g, 0.80 mmol) was dissolved in 40 mL of Et_2O to form a tan solution. To this solution was added $ClPPh_2$ (180 μL, 1 mmol). A colourless precipitate formed immediately. When sedimentation was complete, the colourless solution was filtered and the residue washed twice with 10 mL of Et_2O and dried in vacuo. Complex **2** was isolated as a grey solid (yield: 90%). − IR (KBr): $\nu_{(Nb-H)} = 1703$ cm^{-1}; $\nu_{(P-H)} = 2293$ cm^{-1}. − ^{1}H NMR (300 MHz, $CDCl_3$): δ = 0.08 (s, 18 H, Si*Me*$_3$), 4.76 (m, 4 H, C_5H_4), 5.86 (m, 4 H, C_5H_4), 6.67 (d, $^1J_{PH}$ = 283 Hz, 1 H, P−*H*), −2.16 (d, $^2J_{PH}$ = 78.20 Hz, 2 H, Nb−*H*), 7.33−7.45 (m, *Ph*). − ^{13}C NMR (300 MHz, $CDCl_3$): δ = −0.2 (Si*Me*$_3$), 98.0 (*C*$_5$H$_4$, *C*$_1$), 99.9 (*C*$_5$H$_4$), 97.2 (*C*$_5$H$_4$), 131.9 (s, *Ph*, *C*$_1$), 130.9 (*Ph*), 128.9 (*Ph*). − ^{31}P NMR (300 MHz, $CDCl_3$): δ = 20.00 (d, $^1J_{PH}$ = 283 Hz, *P*−H). − $C_{28}H_{39}ClNbPSi_2$ (590.45): calcd. C 56.86, H 6.60; found C 56.20, H 6.45.

Preparation of [Nb(η^5-$C_5H_4SiMe_3)_2(H)(PHPh_2)$] (3): (a) [Nb(η^5-$C_5H_4SiMe_3)_2(H)_3$] (**1**) (0.30 g, 0.80 mmol) was dissolved in 40 mL of THF to form a tan solution. To this solution was added $PHPh_2$ (0.14 mL, 0.80 mmol) by syringe. The mixture was stirred at 343 K for 4 h. The resulting red solution was evaporated to dryness. Complex **3** was isolated as a red oily material after maintaining it under vacuum for a lengthy period (yield: 95%). − (b) [Nb(η^5-$C_5H_4SiMe_3)_2(H)_2(PHPh_2)$]Cl (**2**) (0.30 g, 0.51 mmol) in 30 mL of toluene was treated with an excess (4 mL) of 0.5 M aqueous NaOH. The mixture was vigorously stirred. Within 1 h the precipitate had dissolved and the organic phase turned dark red. The toluene solution was filtered and evaporated to dryness. Complex **3** was obtained as a red oily material (yield: 75%). − IR (CsI): $\nu_{(Nb-H)} = 1643$ cm^{-1}; $\nu_{(P-H)} = 2281$ cm^{-1}. − ^{1}H NMR (300 MHz, C_6D_6): δ = 0.26 (s, 18 H, Si*Me*$_3$), 3.63 (pst, 2 H, C_5H_4), 4.03 (pst, 2 H, C_5H_4), 4.72 (m, 4 H, C_5H_4), 6.90 (d, $^1J_{PH}$ = 322 Hz, 1 H, P−*H*), −7.37 (d, $^2J_{PH}$ = 29.30 Hz, 2 H, Nb−*H*), 7.36−7.71 (m, *Ph*), 8.12 [s, 2 H, *H*$_{para}$ (*Ph*)]. − ^{13}C NMR (300 MHz, C_6D_6): δ = 0.9 (Si*Me*$_3$), 90.6 (*C*$_5$H$_4$, *C*$_1$), 91.2 (*C*$_5$H$_4$), 89.1 (*C*$_5$H$_4$), 88.7 (*C*$_5$H$_4$), 83.4 (*C*$_5$H$_4$), 134.3 (s, *Ph*, *C*$_1$), 133.3 (*Ph*), 129.0 (*Ph*), 128.3 (*Ph*). − ^{31}P NMR (300 MHz, C_6D_6): δ = −38.20 (d, $^1J_{PH}$ = 322 Hz, *P*−H).

Protonation of [Nb(η^5-$C_5H_4SiMe_3)_2(H)(PHPh_2)$] (3): Either CF_3COOH or CF_3COOD was added to a [D_6]acetone solution of [Nb(η^5-$C_5H_4SiMe_3)_2(H)(PHPh_2)$] (**3**) in a 5 mm NMR tube at 183 K, to give either the dihydrogen complex [Nb(η^5-$C_5H_4SiMe_3)_2(\eta^2$-$H_2)(PHPh_2)$]CF_3CO_2 (**4**) or its isotopomer [Nb(η^5-$C_5H_4SiMe_3)_2(\eta^2$-HD)$(PHPh_2)$]CF_3CO_2 (**5**).

Preparation of [Nb(η^5-$C_5H_4SiMe_3)_2(H)_2(PHPh_2)$]$CF_3CO_2$ (6) and [Nb(η^5-$C_5H_4SiMe_3)_2(H)_2(PDPh_2)$]$CF_3CO_2$ (7): To a solution of [Nb(η^5-$C_5H_4SiMe_3)_2(H)(PHPh_2)$] (**3**) (0.30 g, 0.55 mmol) in 30 mL of THF at 183 K was added CF_3COOH or CF_3COOD (42 μL, 0.55 mmol) by syringe. The solution was allowed to reach room temperature and stirred for 2 h. The resulting solution was evaporated to dryness. Complexes **6** and **7** were obtained as colourless solids after precipitation with Et_2O (yield: 80%).

Preparation of [Nb(η^5-$C_5H_4SiMe_3)_2(\eta^2$-*S*,*S*-SSCH)] (9): To a solution of [Nb(η^5-$C_5H_4SiMe_3)_2(H)(PHPh_2)$] (**3**) (0.30 g, 0.55 mmol) in THF (40 mL) was added CS_2 (93.1 μL, 0.55 mmol) and the reaction mixture was stirred for 1 h. The resulting solution was evaporated to dryness to give a red oily material. Complex **9** was isolated as an orange solid after precipitation from hexane (yield: 95%). − ^{1}H NMR (300 MHz, $CDCl_3$): δ = 0.22 (s, 18 H, Si*Me*$_3$), 5.05 (4 H, C_5H_4), 5.44 (4 H, C_5H_4), 4.17 (s, 1 H, SSC*H*). − ^{13}C{^{1}H} NMR (300 MHz, $CDCl_3$): δ = 0.5 (Si*Me*$_3$), 98.6 (*C*$_5$H$_4$, *C*$_1$), 103.6 (*C*$_5$H$_4$), 106.9 (*C*$_5$H$_4$), 120.0 (S*C*HS). − $C_{17}H_{27}NbS_2Si_2$ (444.12): calcd. C 45.95, H 6.08; found C, 45.81, H 5.96.

Preparation of [Nb(η^5-$C_5H_4SiMe_3)_2(\eta^2$-*O*,*O*-OOCH)] (10): A THF solution of [Nb(η^5-$C_5H_4SiMe_3)_2(H)(PHPh_2)$] (**3**) (0.30 g, 0.55 mmol) was saturated with CO_2 (2.5 atm.) in a Fischer−Porter bottle for 8 h at room temperature. The solution became increasingly dark and a brown solution was finally obtained and then evaporated to dryness. Complex **10** was obtained as an oily brown material (yield: 90%). − IR (Nujol): ν_{asym} (CO_2^-) = 1638 cm^{-1}; ν_{sym} (CO_2^-) = 1545 cm^{-1}. − ^{1}H NMR (300 MHz, C_6D_6): δ = −0.04 (s, 18 H, Si*Me*$_3$), 4.14 (m, 4 H, C_5H_4), 5.68 (m, 4 H, C_5H_4), 7.47 (s, 1 H, O_2CH). ^{13}C{^{1}H} NMR (300 MHz, C_6D_6): δ = 0.1 (Si*Me*$_3$), 107.8 (*C*$_5$H$_4$, *C*$_1$), 105.0 (*C*$_5$H$_4$), 108.1 (*C*$_5$H$_4$), 184.3 (O_2CH).

Preparation of [Nb(η^5-$C_5H_4SiMe_3)_2(PHPh_2)(L)$]Cl [L = $PHPh_2$ (11), CN(xylyl) (12), CO (13)]: To a solution of [Nb(η^5-$C_5H_4SiMe_3)_2(H)(L)$] [L = $PHPh_2$, CN(xylyl), CO] (0.55 mmol) in 40 mL of Et_2O was added $ClPPh_2$ (125 μL, 0.70 mmol) by syringe. A red-orange precipitate formed immediately. When sedimentation was complete the solution was filtered and the residue washed twice with 20 mL of Et_2O and dried in vacuo. Complexes **11**, **12** and **13** were obtained as orange or red solids. − **11:** IR (KBr): $\nu_{(P-H)}$ = 2297 cm^{-1}. − ^{1}H NMR (300 MHz, [D_6]acetone): δ = 0.05 (s, 18 H, Si*Me*$_3$), 5.36 (m, 4 H, C_5H_4), 5.50 (m, 4 H, C_5H_4), 7.87 (d, $^1J_{HP}$ = 362 Hz, 1 H, P−*H*), 7.35−7.60 (m, *Ph*), 8.12 [s, 2 H, *H*$_{para}$ (*Ph*)]. − ^{13}C NMR (300 MHz, [D_6]acetone): δ = 0.1 (Si*Me*$_3$), 102.9 (*C*$_5$H$_4$, *C*$_1$), 92.5 (*C*$_5$H$_4$), 103.7 (*C*$_5$H$_4$), 135.7 (*Ph*, *C*$_1$), 133.0 (*Ph*), 129.0 (*Ph*), 128.3 (*Ph*). − ^{31}P NMR (300 MHz, [D_6]acetone): δ = 32.00 (d, $^1J_{HP}$ = 362 Hz, *P*−H). − $C_{40}H_{48}ClNbP_2Si_2$ (774.45): calcd. C 61.98, H 6.20; found C 62.10, H 6.18.

12: IR (KBr): $\nu_{(P-H)} = 2280$ cm^{-1}; $\nu_{(CNAr)} = 2058$ cm^{-1}. − ^{1}H NMR (300 MHz, [D_6]acetone): δ = 0.17 (s, 18 H, Si*Me*$_3$), 5.36 (m, 2 H, C_5H_4), 5.55 (m, 2 H, C_5H_4), 5.65 (m, 2 H, C_5H_4), 6.11 (m, 2 H, C_5H_4), 8.70 (d, $^1J_{HP}$ = 387 Hz, 1 H, P−*H*), 7.35−7.90 (m, *Ph*),

2.31 [CN(2,6-$Me_2C_6H_3$)]. – ^{13}C NMR (300 MHz, [D_6]acetone): δ = 0.1 (SiMe_3), 100.2 (C_5H_4, C_1), 92.3 (C_5H_4), 100.0 (C_5H_4), 100.8 (C_5H_4), 102.4 (C_5H_4), 132.5 (*Ph*, C_1), 133.0 (*Ph*), 129.0 (*Ph*), 127.6 (*Ph*), 19.4 [CN(2,6-$Me_2C_6H_3$)], 248.0 [*C*N(2,6-$Me_2C_6H_3$)]. – ^{31}P NMR (300 MHz, [D_6]acetone): δ = 38.50 (d, $^1J_{HP}$ = 387 Hz, *P*–H). – $C_{37}H_{46}NNbPSi_2$ (684.00): C 66.86, H 6.93; found C 66.01, H 6.95.

13: IR (KBr): $\nu_{(P-H)}$ = 2276 cm^{-1}; $\nu_{(CO)}$ = 1940 cm^{-1}. – ^{1}H NMR (300 MHz, [D_6]acetone): δ = 0.24 (s, 18 H, SiMe_3), 5.10 (m, 2 H, C_5H_4), 5.82 (m, 2 H, C_5H_4), 5.93 (m, 2 H, C_5H_4), 6.03 (m, 2 H, C_5H_4), 7.90 (d, $^1J_{HP}$ = 381 Hz, 1 H, P–*H*), 7.35–7.60 (m, Ph), 8.12 [s, 2 H, H_{para} (*Ph*)]. – ^{13}C NMR (300 MHz, [D_6]acetone): δ = –0.5 (SiMe_3), 102.9 (C_5H_4, C_1), 97.0 (C_5H_4), 98.1 (C_5H_4), 100.6 (C_5H_4), 101.8 (C_5H_4), 131.5 (*Ph*, C_1), 131.0 (*Ph*), 129.5 (*Ph*), 128.0 (*Ph*), 250 (*C*O). – ^{31}P NMR (300 MHz, [D_6]acetone): δ = 38.00 (d, $^1J_{HP}$ = 381 Hz, *P*–H). – $C_{29}H_{37}NbOPSi_2$ (581.16): C 62.03, H 6.60; found C 61.82, H 6.68.

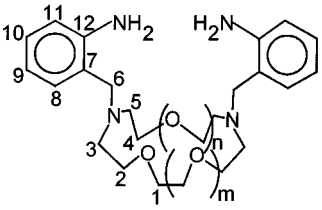
Cadmium(II) and Lead(II) Complexes with Novel Macrocyclic Receptors Derived from 1,10-Diaza-15-crown-5

David Esteban,[a] Daniel Bañobre,[a] Andrés de Blas,*[a] Teresa Rodríguez-Blas,*[a] Rufina Bastida,[b] Alejandro Macías,[b] Adolfo Rodríguez,[b] David E. Fenton,[c] Harry Adams,[c] and Jose Mahía[d]

Keywords: Cadmium / Crown compounds / Cryptands / Lead / Macrocyclic ligands

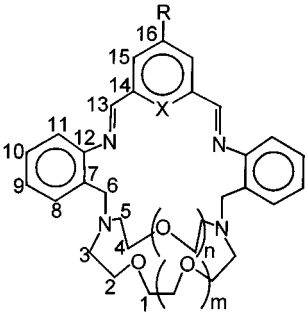
Two novel macrocycles, *N*,*N*′-bis(2-aminobenzyl)-1,10-diaza-15-crown-5 (L^1) and a non-symmetric cryptand incorporating a pyridinyl Schiff-base spacer (L^3), both derived from 1,10-diaza-15-crown-5, have been shown to act as receptors for lead(II) and cadmium(II) guests. The X-ray crystal structures reveal an *anti* conformation for the free ligand L^1, but a *syn* arrangement in the lead(II) complex, $[PbL^1](ClO_4)_2$. The corresponding cryptates of L^3 can be prepared by simple transmetallation reactions starting from the barium cryptate, showing the preference of L^3 for the heavy metal ions. The lead(II) ion, unlike cadmium(II), has been shown to be capable of acting as a template agent in the synthesis of L^3. The X-ray crystal structures of the metal cryptates allow an insight into the influence of the nature of the metal ion guest on the conformation of the macrobicyclic receptor L^3; the most significant changes are a different folding of the crown and variations in the distance between the two pivotal nitrogen atoms and the imine nitrogen atoms. The cryptand can thus expand or contract its cavity in order to accommodate the different metal ions.

Introduction



The coordination chemistry of macrocyclic ligands is currently a fascinating area of intense study for inorganic chemists. One aspect of the interest that macrocyclic ligands have promoted stems from the fact that depending on features such as the nature, number, and arrangement of the ligand donors, ligand conjugation, substitution, and flexibility, the nature of the ligand backbone, macrocyclic hole size, and the number and sizes of the chelate rings, it is possible to tailor-make different types of macrocyclic molecules for specific uses. Thus, such systems can be used as models for biological systems, to study magnetic exchange phenomena, as synthetic ionophores, to study guest−host interactions, or as therapeutic reagents for the treatment of metal intoxication. In particular, macrocycles have been widely studied as complexing agents that may be used for the selective extraction of heavy and precious metals,[1−3] an area of great interest in environmental chemistry. Furthermore, the development of new technologies in this field depends on the design of new receptors capable of binding metal ions selectively or specifically.

The direct synthesis of a free macrocycle from its organic precursors often results in a low yield of the desired cyclic product, with side reactions such as polymerization predominating. Consequently, synthetic strategies such as the use of high dilution conditions, the incorporation of a rigid group in the open-chain precursors, and the use of template agents have been developed. In a previous paper,[4] we described a synthetic route for preparing a novel family of Schiff-base cryptands derived from bibracchial lariat ethers incorporating pendant aniline moieties and various dialdehyde functions (Scheme 1; L^3, L^4, L^5, L^6). Structurally, these systems belong to the group defined as lateral macrobicycles.[5] We found that they can not be prepared by direct reaction between the organic precursors, but that barium(II) ion can act as a template, thereby allowing access to the required macrobicycles in high yields.



Here, we describe lead(II) and cadmium(II) complexes with the receptors L^1 and L^3 (Scheme 1), macrocycles belonging to two different structural classes, namely bibracchial lariat ethers and cryptands, respectively. The lariat ethers constitute a sub-class of macrocyclic polyethers and are characterized by the presence of one (monobracchial) or more (polybracchial) side-arms attached to pivotal atoms of the parent macrocyclic ring. The incorporation of additional donor atoms in the side arms can be used to enhance the coordination potential of these polybracchial ligands. These compounds may be regarded as having structural characteristics intermediate between those of flexible mac-

rocyclic polyethers and relatively rigid macrobicyclic cages or cryptands.

Two issues are addressed in the present paper. Firstly, we have studied different synthetic routes and strategies for preparing lead(II) and cadmium(II) complexes with the macrobicycle L^3. Secondly, we have carried out structural studies to assess the different complexation capabilities of the two classes of macrocycles towards the heavy metal ions lead(II) and cadmium(II) as well as the influence of the nature of the metal ion guest on the conformation of the macrobicycle receptor L^3.

Results

Synthesis and Characterization of the Bibracchial Lariat Ether L^1 and its Cadmium(II) and Lead(II) Complexes

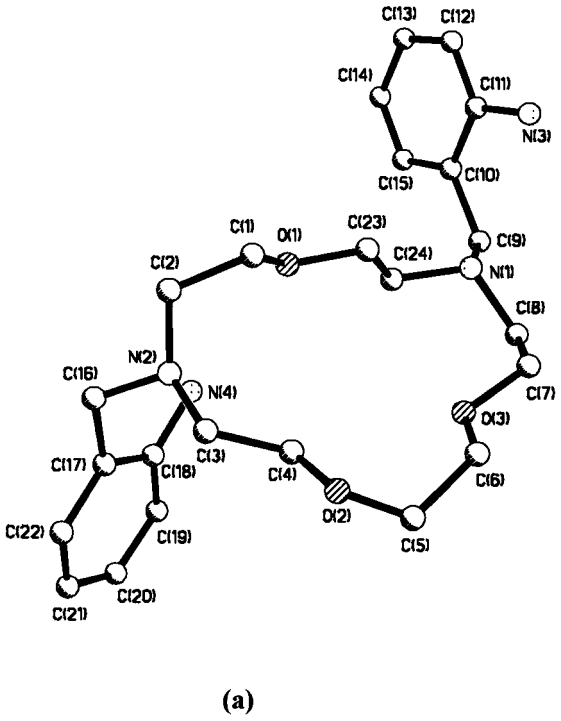
Our synthetic route to the novel bibracchial lariat ether L^1 involves two key steps, specifically *N*-binding of 2-nitrobenzyl chloride to the diaza-crown and subsequent reduction of the NO_2 groups of the resulting *N*,*N*′-bis(2-nitrobenzyl)-diaza-crown to $-NH_2$ groups with hydrazine hydrate in the presence of Pd/C as a catalyst. The synthesis can be carried out in a one-pot procedure by reducing the intermediate *N*,*N*′-bis(2-nitrobenzyl)-diaza-crown prepared in situ. In this way, better yields are obtained. Single crystals of L^1 suitable for X-ray diffraction analysis were grown by slow evaporation of the solvents from an absolute ethanol/diethyl ether (1:1) solution. As expected, the IR spectrum (KBr discs) features two bands due to a $\nu_{as}(NH_2)$ mode at 3430 and 3390 cm^{-1}, and two further bands corresponding to a $\nu_s(NH_2)$ mode at 3293 and 3275 cm^{-1}.

Reactions of the perchlorate salts $M(ClO_4)_2 \cdot n\,H_2O$ (M = Pb, Cd) with the bibracchial lariat ether L^1 yielded the complexes $[PbL^1](ClO_4)_2$ (**1**) and $[CdL^1](ClO_4)_2$ (**2**). Both were isolated as white solids. Colourless crystals of **1** suitable for single-crystal X-ray diffraction analysis were grown by allowing diethyl ether to diffuse into an acetonitrile solution of the complex. In the IR spectra (KBr discs), the amine groups give rise to $\nu_{as}(NH_2)$ and $\nu_s(NH_2)$ stretching bands at 3334 and 3277 cm^{-1} for **1** and at 3320 and 3281 cm^{-1} for **2**. Bands corresponding to the $\nu_{as}(ClO)$ stretching and $\delta_{as}(O-Cl-O)$ bending modes of the perchlorate groups appear without splitting at ca. 1100 and 625 cm^{-1}, respectively, as befits an uncoordinated anion.

The molar conductivities of the complexes at 20 °C in a ca. 10^{-3} M acetonitrile solution were measured as Λ_M = 285 $cm^2 \cdot \Omega^{-1} \cdot mol^{-1}$ for **1** and 289 $cm^2 \cdot \Omega^{-1} \cdot mol^{-1}$ for **2**. These data reveal that both complexes behave as 2:1 electrolytes in this solvent, and hence are completely dissociated.[6]

The ^1H- (Table 1) and ^{13}C-NMR spectra of the complexes were recorded in CD_3CN solution. The ^1H-NMR spectra of the complexes are clearly more complicated than that of the free lariat ether L^1. This is particularly apparent in the region $\delta = 0-4$, where signals due to the protons of the ethylenic and methylenic chains are observed. On coordination, the ligand becomes more rigid, restricting any exchange, and so the protons become non-equivalent and give rise to more signals. While the signals due to the aromatic protons are shifted downfield by ca. 0.5 ppm in the complexes, the signal due to the amine protons is shifted upfield by 0.79 ppm in **1** and by 0.04 ppm in **2** as compared to its position in the spectrum of the free ligand, thus confirming the coordination of the amine groups to the metal.

The UV/vis spectrum of the free ligand L^1, recorded in acetonitrile solution, features three absorption bands at λ_{max} = 213, 237, and 284 nm, corresponding to E_1, E_2, and B charge-transfer bands of the aromatic rings, respectively. The spectra of the complexes also feature the three expected bands, at λ_{max} = 209, 228, and 272 nm for **1**, and 213, 226, and 274 nm for **2**, shifted to lower wavelengths due to the coordination of the amine groups.



X-ray Crystal Structures of L^1 and **1**

The crystal structure of the free receptor L^1 is shown in Figure 1; selected bond lengths and angles are given in Table 2. The arms of the lariat ether are arranged on opposite sides of the crown moiety resulting in an *anti* conformation. The crystal packing is determined by intermolecular hydrogen-bonds, which involve one proton of the amine group and an oxygen atom of the neighbouring molecule. Weak intramolecular hydrogen-bonds exist between the amine groups and the pivotal nitrogen atoms, with N(pivotal)···HN(amine) bond lengths of 2.362 and 2.339 Å, N(amine)···N(pivotal) bond lengths of 2.959 and 2.894 Å, and N(amine)−H−N(pivotal) angles of 123.8° and 119.8°.

Figure 2 illustrates the crystal structure of the complex cation $[PbL^1]^{2+}$ of **1**, while Table 2 provides a listing of selected bond lengths and angles. Only six of the seven available donor atoms of L^1 are coordinated to the lead(II) ion with one of the aniline pendant arms uncoordinated. The metal ion lies 1.71 Å above the plane defined by the three ether oxygen atoms and is asymmetrically disposed with respect to the crown ether moiety being closer to O(3) [Pb–O(3) 2.568(5) Å] than to the other oxygen atoms [Pb–O(2) 2.702(6) Å, Pb–O(1) 2.732(6) Å]. All of these distances fall within the ranges reported for the $Pb-O_{ether}$ bonds in lead(II)–crown ether complexes.[7] The lead(II) atom lies closer to the pivotal nitrogen atom bearing the coordinating pendant arm [Pb–N(2) 2.688(7) Å] than to the pivotal nitrogen atom bearing the non-coordinating pendant arm [Pb–N(1) 2.757(6) Å]. The lead atom and the donor atoms O(3), N(1), and N(2) are essentially coplanar, with a deviation from planarity of just 0.0118 Å. This may be viewed as an equatorial plane with oxygen atoms O(2) and O(1) located 2.2017 Å and 2.4650 Å above it and the

nitrogen atom N(4) lying 2.568 Å beneath it. The coordination polyhedron at the metal may be described as a dodecahedron with two unoccupied sites (Figure 3). The presence of these unoccupied sites leads to an empty zone in the coordination sphere at the metal, as indicated in Figure 3.

From a recent extensive survey of lone-pair functionality in lead(II) complexes, it has emerged that two distinct structural groups, with geometries that are holo-directed and hemi-directed, are possible. In the former group, the metal−ligand bonds can be directed to any point on the surface of an encompassing globe, whereas in the latter group there is a distinct void, or empty zone, in the global array of ligands.[8] The presence of such a void in the angular distribution of the coordination sphere about lead(II) is

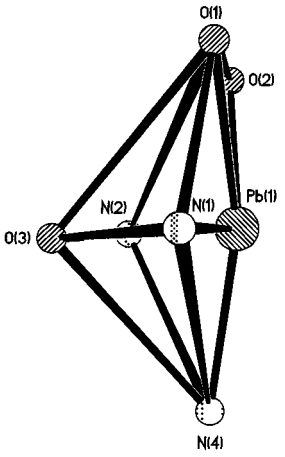

Figure 3. Coordination polyhedron of the cationic complex $[PbL^1]^{2+}$

usually taken as an indication of the presence of a stereochemically active lone pair of electrons on the lead atom.[9,10] It has also been suggested that there will be a concomitant shortening of the Pb−X bond on the side of the lead(II) away from the site of the stereochemically active lone pair.[9,11] In these hemi-directed compounds, the differences between Pb^{II}−X and Pb^{II}−*lp*-X (the latter being the distance between Pb^{II} and a ligand in the direction of the lone pair, opposite to the Pb^{II}−X direction) have been

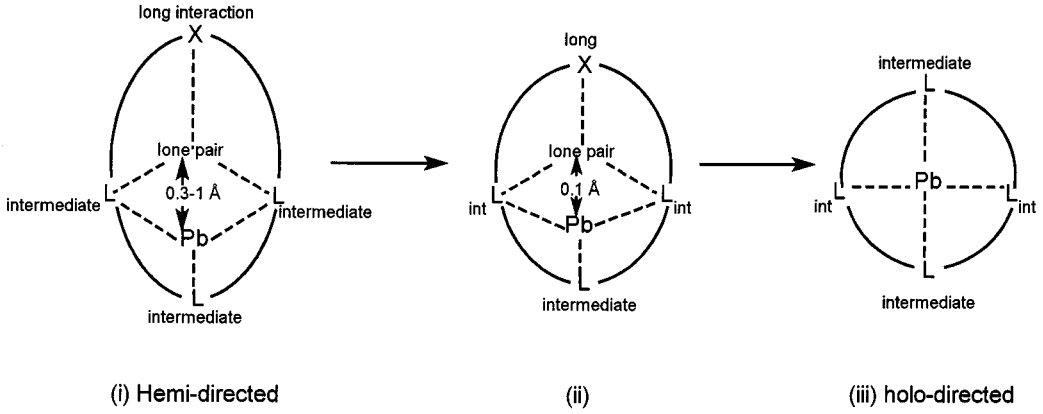

Figure 4. Hemi- and holo-direction

found to range from 0.3−1.2 Å. When the difference between these distances is small (ca. 0.1 Å), the coordination is regarded as holo-directed and the role of the lone pair becomes less clear, i.e. as to whether it exerts an effect on the stereochemistry (Figure 4). Generally speaking, hemi-directed ligand distribution is found for lead(II) compounds having coordination numbers 2−5, although lead(II) compounds having coordination numbers 6−8 have also been found to exhibit hemi-direction, particularly when harder oxygen and/or nitrogen donor atoms are available, as in the present set of ligands.[8]

Two important features of the structure of complex **1** are the empty zone in the coordination sphere about the lead(II) ion and the shortened distance between the metal and O(3) [Pb−O(3) 2.568(5) Å] relative to the other $Pb-O_{ether}$ distances. It is possible that these features may be directly attributed to a hemi-directed structure and the presence of a stereochemically active lone pair of electrons. However, this presumes that the perchlorate oxygen atoms O(3A) and O(4A) and the pendant amino nitrogen atom N(3) are distant from the lead [Pb−O(3A) 2.877, Pb−O(4A) 3.236, Pb−N(3) 2.892 Å] and thus not involved in coordination. If, however, the Pb−O(3A) and Pb−N(3) distances are considered as being long, ca. 0.3 Å in excess of the Pb−O(3) distance opposite, then the structure is close to the limit of being hemi-directed and the role of the lone pair is less clear.

Both aniline pendant arms are orientated on the same side of the macrocycle plane, resulting in a *syn* conformation, in contrast to the *anti* conformation found for free L^1. Planes containing the aromatic rings form an angle of 112.1°. Inspection of the crystal packing of **1** reveals that one of the two perchlorate anions is well-removed from the complex cation and has no interactions with neighbouring molecules. The second perchlorate anion, however, is involved in both a weak hydrogen-bonding interaction with a hydrogen atom on the non-coordinated pendant amino nitrogen atom N(3) [O(1A)···HN(3) 2.278 Å, O(1A)···N(3) 3.122 Å, O(1A)···HN(3)···N(3) 167.3°] and a weak interaction with the lead(II) atom [O(3A)···Pb 2.877 Å] (Figure 2b). This anion acts as a bridge between the metal and non-coordinated pendant amine group, thereby reinforcing the *syn* conformation present in complex **1**.

Synthesis and Characterization of Complexes of the Schiff-Base Lateral Macrobicycle L^3

Reaction of equimolar amounts of 2,6-diformylpyridine and *N*,*N*′-bis(2-aminobenzyl)-1,10-diaza-15-crown-5 (L^1) in the presence of lead(II) perchlorate in absolute ethanol under the conditions described in the Experimental Section gave the analytically pure product $[PbL^3](ClO_4)_2 \cdot EtOH$ (**3**) in 70% yield. The IR and FAB-mass spectra confirmed that condensation and [1+1] cyclization had occurred. Thus, the IR spectrum (KBr discs) of **3** features bands attributable to $\nu(C{=}N)_{imine}$ and $\nu(C{=}N)_{py}$ stretching modes at 1631 and 1583 cm^{-1}, respectively, but no bands due to carbonyl or amine vibration modes. The FAB-mass spectrum, obtained using 3-nitrobenzyl alcohol as the matrix, displays peaks at *m*/*z* (%) = 834 (37), 735 (20), and 528 (64) due to $[\mathbf{3} - (ClO_4)]^+$, $[\mathbf{3} - 2(ClO_4)]^+$, and $[L^3 + 1]^+$, respectively. Compound **3** can also be prepared by a transmetallation reaction using $[BaL^3](ClO_4)_2$ and lead(II) perchlorate; reaction in a 1:1 molar ratio in absolute ethanol solution gave **3** in 57% yield. The absence of peaks corresponding to species containing the BaL^3 fragment in the FAB-mass spectrum coupled with the presence of peaks due to $[\mathbf{3} - (ClO_4)]^+$, $[\mathbf{3} - 2(ClO_4)]^+$, and $[L^3 + 1]^+$ confirms that the transmetallation reaction has occurred and that the macrobicycle L^3 remains intact in the lead(II) complex.

^1H- and ^{13}C-NMR spectra recorded in acetonitrile solution also confirmed the integrity of the macrobicycle L^3 in this solvent; no resonances attributable to amino or aldehydic functions were seen. As expected, the signals due to the ethylenic protons of the crown moiety appear at high field as complicated multiplets as a result of the coordination of the metal by the oxygen atoms of the crown. The signals due to aromatic and pyridine protons, appearing at low field, are well-resolved and could be fully assigned. Considering the X-ray crystal structure (vide infra), two discrete signals due to the azomethine protons would be expected in the ^1H-NMR spectrum if structural integrity were to be maintained in solution. In fact, the spectrum recorded at 298 K features only one signal at δ = 9.09 (2 H) due to both of these protons. The spectrum recorded at 235 K shows a broadening of this signal, indicating a fluxional behaviour of **3** in acetonitrile solution. A striking feature of

the ^{1}H-NMR spectrum of this compound at 298 K is the rare observation of satellites attributable to proton coupling to the naturally abundant $I = 1/2$ nuclei of the metal, reflecting kinetic inertness in the complex as well as a degree of covalency in the interaction with a nearby donor atom. In the present case, the signal at $\delta = 9.09$ due to the imine protons appears as a singlet flanked by the satellites due to proton coupling to ^{207}Pb; the $^3J(^{207}\text{Pb-H}_{\text{imine}})$ coupling constant has a value of just 2.93 Hz, which corresponds with the weak $\text{Pb}-\text{N}_{\text{imine}}$ interaction observed in the crystal structure. Coupling to $I = 1/2$ metal nuclei is an emerging feature of the ^{1}H-NMR spectra of complexes containing the pyridine-2,6-diimine unit;[10,12,13] the case presented here would appear to be the third report of ^{207}Pb-^{1}H coupling in compounds of this type.

Attempted reactions between 2,6-diformylpyridine and L^1 in the presence of cadmium perchlorate under various experimental conditions yielded neither the expected cadmium complex of the Schiff-base macrobicycle L^3 nor uncoordinated L^3. In all cases, the IR spectra of the products exhibited bands attributable to $\nu(\text{C}=\text{N})_{\text{imine}}$ along with bands due to carbonyl and/or amine groups, thus indicating the presence of acyclic compounds. In contrast, a transmetallation reaction between $[\text{BaL}^3](\text{ClO}_4)_2$ and cadmium perchlorate in a 1:1 molar ratio gave rise to a yellow analytically pure product $[\text{CdL}^3](\text{ClO}_4)_2$ (**4**) in 55% yield. The FAB-mass spectrum, which features peaks due to $[\mathbf{4} - (\text{ClO}_4)]^+$, $[\mathbf{4} - 2\,(\text{ClO}_4)]^+$, and $[\text{L}^3 + 1]^+$ at *m/z* (%) = 740 (23), 641 (12), and 528 (100), respectively, and no peaks corresponding to species containing the BaL^3 fragment, provided initial evidence that the transmetallation reaction had indeed occurred and that the macrobicycle L^3 had remained intact in **4**. The IR spectrum features bands due to the C=N stretching modes of the imine and pyridine at 1641 and 1589 cm^{-1}, respectively, and bands due to the asymmetric stretching and bending modes of the perchlorate groups at 1095 and 623 cm^{-1}, respectively.

Conductivity measurements on 10^{-3} M solutions of the two cryptates in acetonitrile at 20 °C led to values of Λ_M = 291 $\text{cm}^2\Omega^{-1}\text{mol}^{-1}$ for **3** and 266 $\text{cm}^2\Omega^{-1}\text{mol}^{-1}$ for **4**, showing that both behave as 2:1 electrolytes in this solvent.[6] In the light of the X-ray crystal structure of **3** (vide infra), it is clear that its solution and solid-state structures must be different, the coordinated perchlorate anion being replaced by acetonitrile in solution.

X-ray Crystal Structure of 3

The crystal structure of the cryptate complex **3** contains the cation $[\text{PbL}^3(\text{ClO}_4)]^+$, a well-separated perchlorate anion, and a molecule of acetonitrile. Figure 5 shows a view of the structure of the cationic complex, while selected bond lengths and angles are given in Table 3. The metal ion is asymmetrically positioned in relation to the ligand cavity and only six of the eight available heteroatoms of L^3 are coordinated to it. One pivotal nitrogen atom and one imine nitrogen atom remain only weakly coordinated with long interactions [Pb−N(1) 2.857 Å, Pb−N(3) 2.837 Å]. This may possibly be linked to the influence of the lone pair as

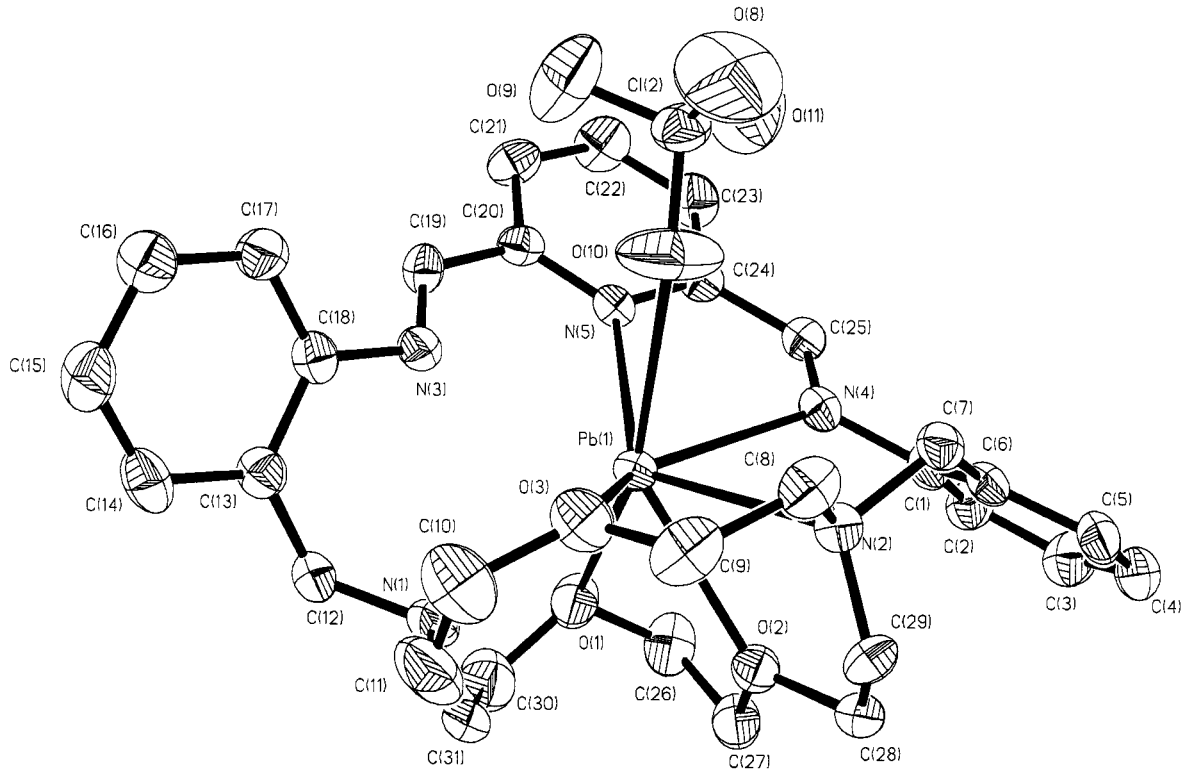

Figure 5. X-ray crystal structure of the cation of **3** with atom labelling; hydrogen atoms are omitted for simplicity; the ORTEP plot is drawn at a 30% probability level

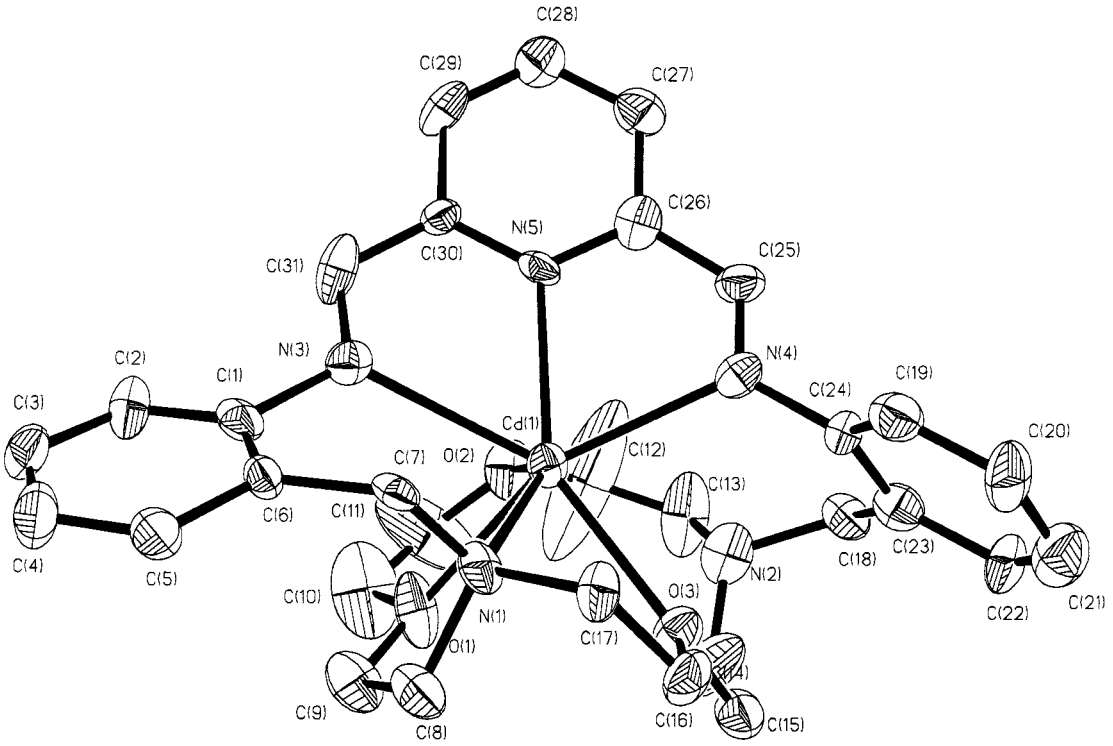

Figure 6. X-ray crystal structure of the cation of **4** with atom labelling; hydrogen atoms are omitted for simplicity; the ORTEP plot is drawn at a 30% probability level

discussed earlier. Two of the metal−oxygen bond lengths are practically equal [Pb−O(1) 2.718(6) Å, Pb−O(2) 2.719(6) Å] and slightly longer than the third [Pb−O(3) 2.670(6) Å]. These three distances fall within the range found for lead(II) crown-ether complexes;[7] the first is shorter than the corresponding distance found in compound **2**, whereas the other two are slightly longer. The distance of 2.740(6) Å for Pb−N(4) is also within the usual range found for lead(II) imine complexes,[12,14] while the Pb−N(5) distance is slightly longer than typically observed $Pb-N_{pyridine}$ distances.[15] The coordination sphere of the lead is completed by one oxygen atom of a monodentate perchlorate group and the coordination polyhedron may be described as a dodecahedron with an unoccupied site. The lateral aromatic rings of the cryptand L^3 are in different planes, which intersect at 87.2°. The pyridine ring and the two imine groups are coplanar and their plane forms dihedral angles of 52.9° with the plane containing the benzene ring bound to N(1) and 49.7° with the plane containing the other aromatic ring.

X-ray Crystal Structure of 4

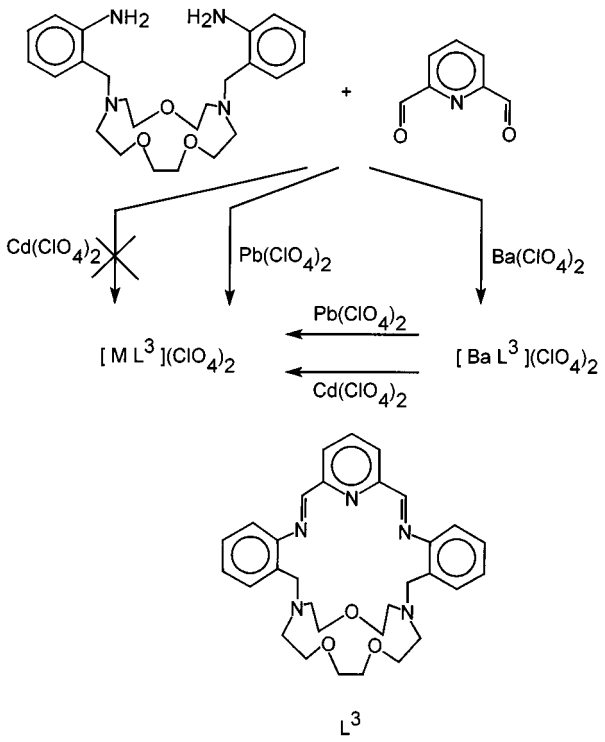

Figure 6 shows the structure of the dication $[CdL^3]^{2+}$ in crystals of $[CdL^3](ClO_4)_2$ (**4**). Selected bond distances and angles are given in Table 3. The cadmium(II) ion resides in a distorted monocapped octahedral N_4O_3 environment, bound by seven of the eight donor atoms of the macrobicyclic receptor; the pivotal nitrogen N(2) is rather distant from the metal ion [Cd−N(2) 3.134 Å] and remains uncoordinated. The bond lengths between the imine nitrogen atoms and the cadmium ion differ by 0.147 Å and fall within the range reported for similar bonds in X-ray crystal structures containing similar fragments.[14,16] The cadmium is positioned slightly closer to O(1) (2.374 Å) than to the other two oxygen atoms (2.493, 2.459 Å). As in the lead(II) cryptate **3**, the pyridine ring and the two imine groups are coplanar although in **4** this plane forms dihedral angles of 145.7° with the plane containing the benzene ring bound to N(1) and 96.9° with plane of the other aromatic ring; the lateral aromatic rings of L^3 are in different planes which intersect at 61°.

Discussion

Two points of interest emerge from the above data. The first relates to the synthetic strategies followed in preparing the lead(II) and cadmium(II) cryptates with the Schiff-base lateral macrobicycle L^3 (compounds **3** and **4**), while the second concerns the different complexation capabilities of the two types of macrocycles (lariat ether L^1 and macrobicycle L^3) towards the heavy metal ions lead(II) and cadmium(II), as well as the influence of the nature of the metal ion guest on the conformation adopted by the macrobicycle receptor L^3.

In a previous paper,[4] we reported that it proved impossible to prepare the Schiff-base lateral macrobicycle L^3 by a direct reaction between the organic precursors due to the *anti* arrangement adopted by the diamine L^1, not only in the solid state but also in solution, and that a barium cation

was required to template the reaction between L^1 and 2,6-diformylpyridine to build L^3. Herein, we have shown that the corresponding lead(II) and cadmium(II) cryptates of L^3 can be prepared by transmetallation reactions starting from the barium cryptate (Scheme 2). This indicates a coordinative preference of L^3 for these soft metal ions.

Scheme 2

The efficiencies of these soft metal ions as template agents in the synthesis of L^3 have been studied. Whereas the lead(II) ion was found to be capable of acting as an effective template in this synthesis, this was not the case with the cadmium ion. The effectiveness of lead in the templating process stems from its ability to orientate the pendant arms of the diamine L^1 in a *syn* conformation. This is evident in the X-ray crystal structure of the lead(II) complex of L^1 (**1**) and the situation is likely to be maintained in solution. An important feature of the structure of **1** is the *syn* conformation of the bibracchial macrocyclic ligand L^1, even when one pendant arm is not directly coordinated to the metal. A *syn* arrangement of L^1 has also been observed in the crystal structure of the barium complex $[BaL^1](ClO_4)_2$,[4] while an *anti* arrangement has been found in the crystal structure of the octahedral copper(II) complex $[CuL^1](ClO_4)_2$.[17] It seems likely that the disposition of the pendant arms in complexes of L^1 is related to the size of the cation present. The copper(II) cation (r_{CN4} = 0.57; r_{CN6} = 0.73 Å),[18] with a penchant for square-planar geometry, resides in the macrocyclic cavity bound by two ether oxygen and two pivotal amino nitrogen atoms. The donor atoms of the pendant arms coordinate apically so as to form an octahedral coordination sphere. The larger barium cation (r_{CN9} = 1.47 Å)[18] may be regarded as spherically symmetrical and the geometries found in its complexes are not constrained by *d*-orbital orthogonality or crystal-field stabilization energies. Consequently, in $[BaL^1](ClO_4)_2$ the barium is found in a position that allows optimal interaction with the seven ligand donor atoms and a bidentate perchlorate anion. This necessitates a *syn* orientation of the pendant arms and the overall structure resembles that of molecular clefts reported for barium complexes of bibracchial tetraimine Schiff-base macrocycles,[19–21] and for potassium and barium complexes of the related lariat ethers derived from the larger [18-aneN_2O_4] macrocyclic polyether with alcohol-bearing 2-hydroxy-1,1-dimethylethyl and [(2-hydroxyethyl)oxy]ethyl pendant arms.[22,23] The lead(II) cation is intermediate in size (r_{CN6} = 1.19 Å)[18] and its geometry is free of *d*-orbital control, as a result of which it resides above the macrocyclic cavity towards the pendant arms, one of which coordinates weakly [Pb–N(3) 2.892 Å]. It can also be suggested that the ineffectiveness of the cadmium ion as a template agent in the synthesis of the macrobicycle L^3 stems from the unsuitable conformation adopted by the diamine L^1 in the presence of this metal ion. Considering the small size of the cadmium ion (r_{CN6} = 0.95 Å) and in the light of spectroscopic characterization of the cadmium complex of the diamine L^1 (**2**), it can be stated that the metal ion lies inside the cavity of the crown in a coordination environment rather similar to that found for the copper complex;[17] L^1 must therefore adopt an *anti* arrangement.

Viewing the crystal structures of cryptates **3** and **4**, as well as that of the corresponding barium cryptate,[4] from a side perspective through the axis of the pivotal nitrogen atoms (Figure 7) allows an appraisal of the influence of the metal ion on the conformation of the macrobicycle receptor L^3. The most significant changes concern the folding of the crown, the distance between the two pivotal nitrogen atoms, and the distance between the imine nitrogen atoms. In the case of the barium cryptate (Figure 7a), the crown moiety folds in such a way that both pivotal nitrogen atoms and the two oxygen atoms of one chain form a plane (deviation from planarity 0.0425 Å). However, in neither the lead cryptate **3** nor the cadmium cryptate **4** is it possible to find a plane formed by four of the six donor atoms of the crown moiety of L^3. While the distance between the two pivotal nitrogen atoms [N(1)–N(2)] is clearly longer in the case of **4** (4.870 Å) than in the case of **3** (4.688 Å), the distance between the imine nitrogen atoms [N(3)–N(4)] is shorter in the case of **4** (4.442 Å) than in the case of **3** (4.855 Å). In both cryptates, these distances are considerably shorter than the corresponding distances in the barium cryptate, which amount to 5.389 Å and 5.002 Å, respectively. These data illustrate how the macrobicycle L^3 can either expand or contract in order to accommodate the metal ion in its cavity, in spite of the presence of a relatively rigid unsaturated chelating chain in its backbone. Some minor differences are evident from the values of the angles N(pivotal)–C–C(aryl); whereas angles N(1)–C(7)–C(6) and N(2)–C(18)–C(23) in complex **4** are practically equal, having values of 115.8(10)° and 115.3(11)°, respectively, the

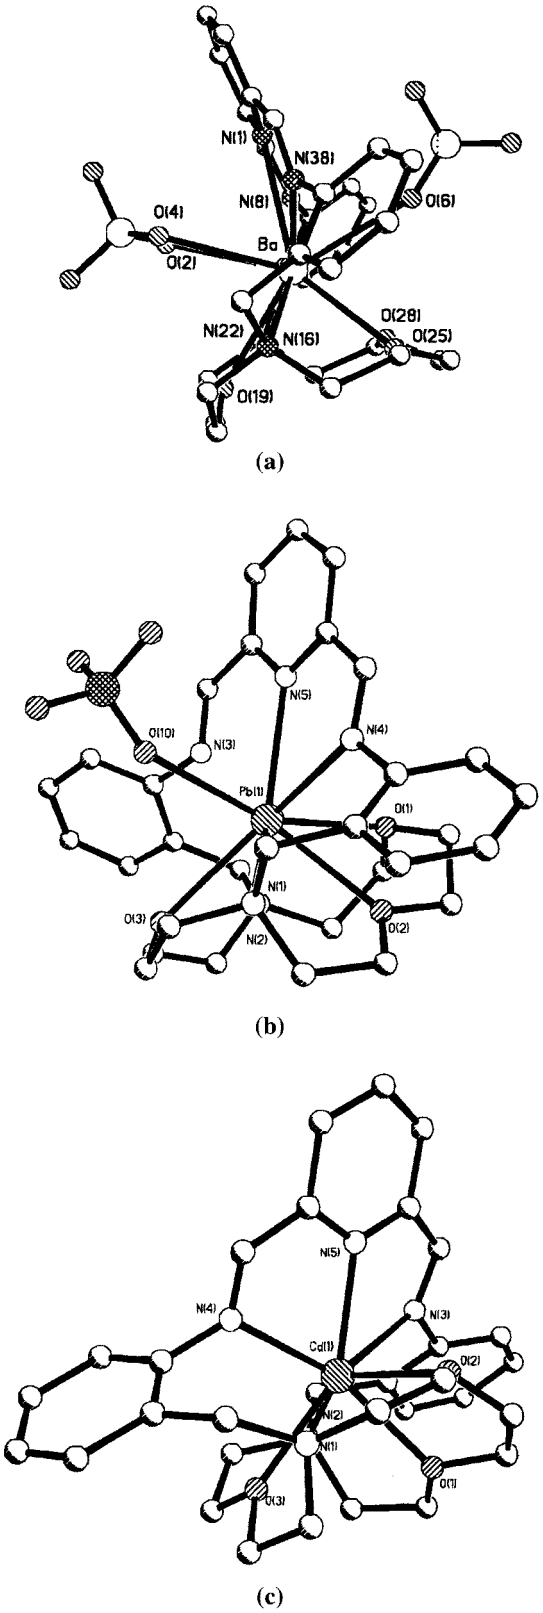

Figure 7. Side view of (a) $[BaL^3]^{2+}$(see ref.[4]), (b) $[PbL^3(ClO_4)]^+$, and (c) $[CdL^3]^{2+}$

corresponding angles in **3** have values of 114.7(7)° and 117.0(8)°.

The effect of the pyridine moiety on the arrangement of the diamine fragment in the case of lead(II) cryptate **3** can be also appreciated by comparing the X-ray crystal structure of this complex with that of the lead(II) complex with the bibracchial lariat ether L^1 (**1**). The folding of the crown moiety is clearly different in the two compounds. In **1**, the three oxygen atoms and the pivotal nitrogen N(2) form a plane (deviation from planarity 0.077 Å), with the lead(II) ion residing 1.652 Å above it, in contrast to the situation in **3**. Moreover, the distance between the two pivotal nitrogen atoms [N(1)−N(2)] is clearly longer in **1** (4.881 Å) than in **3** (4.688 Å).

Concluding Remarks

The Schiff-base lateral macrobicycle L^3 has been shown to act as a receptor for both lead(II) and cadmium(II) guests. The respective cryptates can be prepared by simple transmetallation reactions starting from the analogous barium cryptate, which highlights the preference of L^3 for the heavy metal ions. The lead(II) ion has been found to be capable of acting as a template agent in the synthesis of L^3, whereas this is not the case for the cadmium(II) ion.

The nature of the guest metal ion has been found to have a significant influence on the conformation adopted by the receptor L^3. Macrobicycle L^3 can either expand or contract to accommodate the metal ion in its cavity, in spite of the fact that its backbone incorporates a relatively rigid unsaturated chelating chain.

Experimental Section

Measurements: Elemental analyses and FAB-MS spectra were provided by the Servicios Xerais de Apoio á Investigación of the Universidade da Coruña; elemental analyses were carried out on a Carlo Erba 1180 elemental analyzer, and FAB-MS spectra were recorded on a Fisons Quatro mass spectrometer with a Cs^+ ion gun using 3-nitrobenzyl alcohol as a matrix. − ^{1}H- and ^{13}C-NMR spectra were recorded on a Bruker AC 200 F or a Bruker WM-500 spectrometer. − IR spectra were recorded from samples between KBr discs on a Perkin−Elmer 1330 spectrophotometer. − UV/vis spectra were recorded on a Uvikon 942 Plus spectrophotometer. − Melting points were measured on a Gallenkamp apparatus. − Conductivity measurements were carried out at 20 °C with a Crison Micro CM 2201 conductivimeter using 10^{-3} M solutions of the complexes in acetonitrile.

Materials: 2,6-Diformylpyridine was synthesized according to literature methods.[24,25] The barium cryptate $[BaL^3](ClO_4)_2$ was prepared as described previously.[4] All other chemicals were purchased from commercial sources and used without further purification. Solvents were of reagent grade and were purified by the usual methods.

Caution! Although we have experienced no difficulties with the perchlorate salts, these should be regarded as potentially explosive and handled with care.

Preparation of *N*,*N*′-Bis(2-aminobenzyl)-1,10-diaza-15-crown-5 (L^1): A solution of 2-nitrobenzyl chloride (1.6 g, 9.2 mmol) in acetonitrile (20 mL) was added to a stirred solution of 1,10-diaza-15-

crown-5 (1.0 g, 4.6 mmol) and Na_2CO_3 (2.4 g, 23 mmol) in acetonitrile (30 mL). The reaction mixture was stirred under reflux for 24 h. It was then filtered, the filtrate was concentrated, and the yellow oily residue was extracted with CH_2Cl_2/water. The organic phase was dried with anhydrous $MgSO_4$ and concentrated in vacuo. The resulting yellow oil was dissolved in absolute ethanol (60 mL) and Pd/C was added. Hydrazine hydrate (1.5 mL) was slowly added and the reaction mixture was heated and stirred for 24 h. It was then filtered and the solvent was removed from the filtrate in a rotary evaporator. Addition of cold diethyl ether to the oily residue led to the deposition of a white precipitate. Recrystallization from absolute ethanol/diethyl ether (1:1) gave crystals suitable for X-ray diffraction analysis. Yield: 1.2 g (61%); m.p. 92−94 °C. − $C_{24}H_{36}N_4O_3$: calcd. C 67.2, H 8.5, N 13.1; found C 66.7, H 8.5, N 13.1. − ^{13}C NMR (500 Mz, CD_3CN): δ = 54.1, 54.2 (C-3, C-1), 59.1 (C-6), 69.2, 68.3 (C-5, C-2), 70.0 (C-4), 114.9 (C-11), 116.4 (C-9), 122.9 (C-7), 128.0 (C-10), 130.1 (C-8), 148.1 (C-12). − FAB-MS: *m/z* = 429 [L^1 + 1]. − IR (KBr discs): ṽ = 3430, 3390, 3293, 3275 (NH_2), 1618, 1495, 1463, 1448 (C=C) cm^{-1}.

Preparation of the Complexes

[PbL^1](ClO$_4$)$_2$ (1): A solution of $Pb(ClO_4)_2 \cdot H_2O$ (0.11 g, 0.26 mmol) in absolute ethanol (5 mL) was added to a stirred solution of the ligand L^1 (0.12 g, 0.26 mmol) in absolute ethanol (10 mL). The reaction mixture was stirred under reflux for 6 h. During the course of the reaction, the solution became turbid and a white precipitate was deposited. This was collected by filtration, washed with absolute ethanol, and dried in air. Slow diffusion of diethyl ether into a solution of **1** in acetonitrile gave crystals suitable for X-ray crystallography. Yield: 0.15 g (73%); m.p. 268 °C (decomp.). − $C_{24}H_{36}Cl_2N_4O_{11}Pb$: calcd. C 34.5, H 4.3, N 6.7; found C 34.6, H 4.3, N 6.7. − ^{13}C NMR (200 Mz, CD_3CN): δ = 53.1, 53.2 (C-3, C-1), 56.5 (C-6), 70.0, 69.5, 68.4 (C-5, C-4, C-2), 121.4 (C-11), 123.7 (C-9), 125.1 (C-7), 131.5 (C-10), 134.6 (C-8), 142.5 (C-12). − FAB-MS: *m/z* = 735 [**1** − ClO_4], 635 [**1** − 2 ClO_4]. − IR (KBr discs): ṽ = 3334, 3277 (NH_2), 1613, 1586, 1495, 1457 (C=C), 1110, 617 (ClO_4) cm^{-1}.

[CdL^1](ClO$_4$)$_2$ (2): This white complex was prepared as described for **1** by using $Cd(ClO_4)_2$ (0.10 g, 0.26 mmol). Yield: 0.13 g (65%); m.p. 308 °C (decomp.). − $C_{24}H_{36}CdCl_2N_4O_{11}$: calcd. C 38.9, H 4.9, N 7.6; found C 39.1, H 4.6, N 7.5. − FAB-MS: *m/z* = 641 [**2** − ClO_4], 541 [**2** − 2 ClO_4]. − IR (KBr discs): ṽ = 3320, 3281 (NH_2), 1617, 1590, 1499, 1464 (C=C), 1110, 623 (ClO_4) cm^{-1}.

[PbL^3](ClO$_4$)$_2$·EtOH (3) − Method A: A solution of $Pb(ClO_4)_2 \cdot H_2O$ (0.048 g, 0.100 mmol) in absolute ethanol (5 mL) was added to a stirred solution of [BaL^3]$(ClO_4)_2$ (0.045 g, 0.050 mmol) in absolute ethanol (35 mL) and the resulting mixture was stirred under reflux for one day. During the course of the reaction, the solution became deep-yellow. It was filtered while still hot, and then the filtrate was allowed to cool to room temperature. A yellow microcrystalline precipitate formed, which was collected by filtration. Yield: 0.039 g (57%); m.p. 333 °C (decomp.). − $C_{31}H_{37}Cl_2N_5O_{11}Pb \cdot EtOH$: calcd. C 40.45, H 4.4, N 7.1; found C 40.5, H 4.5, N 7.0.

Method B: A solution of $Pb(ClO_4)_2 \cdot H_2O$ (0.122 g, 0.25 mmol) in absolute ethanol (50 mL) was added to a stirred solution of *N*,*N*′-bis(2-aminobenzyl)-1,10-diaza-15-crown-5 (0.114 g, 0.250 mmol) in absolute ethanol (120 mL). The mixture was vigorously stirred and heated while a solution of 2,6-diformylpyridine (0.036 g, 0.250 mmol) in absolute ethanol (60 mL) was added dropwise during the course of a day. After the addition was complete, the resulting pale-yellow solution was stirred under reflux for a further day. The solution was filtered while hot; upon cooling the filtrate to room temperature, a pale-yellow microcrystalline precipitate formed, which was collected by filtration. Yield: 0.170 g (70%). − $C_{31}H_{37}Cl_2N_5O_{11}Pb \cdot EtOH$: calcd. C 40.45, H 4.4, N 7.1; found C 40.7, H 4.4, N 6.9. − ^{13}C NMR (200 Mz, CD_3CN): δ = 57.8, 58.2, 58.8, 69.1, 69.6, 121.2, 129.4, 131.3, 131.8, 132.6, 133.5, 142.6, 150.1, 154.2, 164.6. − FAB-MS: *m/z* = 834 [**3** − ClO_4], 735 [**3** − 2 ClO_4]. − IR (KBr discs): ṽ = 1631 $(C=N)_{imine}$, 1583 $(C=N)_{py}$, 1490, 1456 (C=C), 1093, 623 (ClO_4) cm^{-1}. Slow diffusion of diethyl ether into a solution of **3** in acetonitrile gave crystals suitable for X-ray crystallography.

[CdL^3](ClO$_4$)$_2$ (4): A solution of $Cd(ClO_4)_2$ (0.038 g, 0.100 mmol) in absolute ethanol (5 mL) was added to a stirred solution of [BaL^3-$(ClO_4)_2$] (0.045 g, 0.050 mmol) in absolute ethanol (35 mL) and the resulting mixture was stirred under reflux for one day. During the course of the reaction, the solution became turbid and a yellow precipitate was deposited. This was collected by filtration, washed

X-ray Crystallographic Study − Crystal Structure Determinations of L^1 and Complex 3: Macrocycle $\mathbf{L^1}$ was crystallized from absolute ethanol/diethyl ether (1:1) in the form of colourless blocks (dimensions of the selected crystal: 0.85 × 0.43 × 0.25 mm^3). Complex **3** was crystallized in the form of yellow blocks by slow diffusion of diethyl ether into an acetonitrile solution (dimensions of the selected crystal: 0.76 × 0.45 × 0.32 mm^3). X-ray data were collected at room temperature in the range $3.5 < 2\varphi < 50°$ on a Siemens P4 diffractometer by the ω-scan method. 4972 reflections were measured for L^1, 8062 for **3**, all of which were corrected for Lorentz and polarization effects and for absorption by the analysis of 10 azimuthal scans (minimum and maximum transmission coefficients 0.4373 and 0.9788 for L^1, 0.273 and 0.709 for **3**); 3218 and 4656 independent reflections, respectively, exceeded the significance level $F/\sigma(F) > 4.0$. The structure was solved by direct methods and refined by full-matrix least-squares methods on F^2. Hydrogen atoms were included in calculated positions and refined in riding mode. For L^1, convergence was reached at a final R = 0.0660, wR_2 = 0.1930; 281 parameters for all 4201 unique data, allowing for the thermal anisotropy of all non-hydrogen atoms. Minimum and maximum final electron density: −0.396 and 0.859 $eÅ^{-3}$. For **3**, convergence was reached at a final R = 0.0474, wR_2 = 0.0971; 468 parameters for all 6631 unique data, allowing for the thermal anisotropy of all non-hydrogen atoms. No residual density was found outside −0.613 and 0.648 $eÅ^{-3}$. In all cases, complex scattering factors were taken from the program package SHELXL-93[26] as implemented on a Viglen 486dx computer. Crystal data and details of the data collection and refinement are presented in Table 4.

Crystal Structure Determinations of Complexes 1 and 4: Both were crystallized in the form of yellow blocks by slow diffusion of diethyl ether into acetonitrile solutions (dimensions of the selected crystals: 0.55 × 0.25 × 0.15 mm^3 for **1** and 0.35 × 0.15 × 0.10 mm^3 for **4**). X-ray data for **1** and **4** were collected on a Siemens SMART CCD area detector single-crystal diffractometer operating at room temperature. Preliminary unit cell constants were determined from a set of 45 narrow-frame (0.3° in ω) scans. A total of 1255 frames of intensity data were collected with a frame width of 0.3° each in ω and a counting time of 10 s/frame at a crystal-to-detector distance of 4.0 cm. The collected frames were integrated using an orientation matrix determined from the narrow-frame scans and refined using Siemens SAINT software on all the observed reflections. A semiempirical absorption correction using an ellipsoidal model (maximum and minimum transmission coefficients 0.455 and 0.299) was applied for **1**, whereas an absorption correction using the SADABS program (maximum and minimum transmission coefficients 1.000 and 0.467) was applied for **4**. The integration process yielded 8176 reflections, of which 5118 were independent for **1**, and 8855 reflections, of which 5693 were independent for **4**. The structures were solved by Patterson and Fourier methods using Siemens SHELXTL-PC software[27] and refined by full-matrix least-squares methods on F^2. Hydrogen atoms were included in calculated positions and refined in riding mode. For **1**, convergence was reached at R = 0.0440, wR_2 = 0.1026; 379 parameters for all 5056 unique data, allowing for the thermal anisotropy of all non-hydrogen atoms. A final difference Fourier map showed no residual density outside −1.624 and 1.574 $eÅ^{-3}$. For **4**, convergence was reached at R = 0.0883, wR_2 = 0.1972; 460 parameters for all 5693 unique data, allowing for the thermal anisotropy of all non-hydrogen atoms; minimum and maximum final electron density: −0.829 and 1.431 $eÅ^{-3}$. Crystal data and details of the data collection and refinement are summarized in Table 4.

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-136178, CCDC-136179, CCDC-136180, and CCDC-136181. Copies of the data can be obtained free of charge on application to the CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) +44 (0)1223/336033; E-mail: deposit@ccdc.cam.ac.uk].

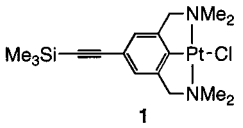
Mixed Metal Acetylides: The Pt^{II} Aryl Acetylide "$[PtC_6H_2(CH_2NMe_2)_2$-2,6-(C≡C)-4]" as a Connective Fragment

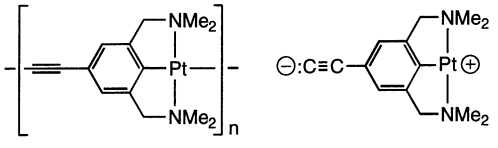


Stephan Back,[a] Robert A. Gossage,[b] Heinrich Lang,*[a] and Gerard van Koten*[b]

Keywords: Alkynes / Cyclic voltammetry / Metal-metal interactions / Conjugation / Platinum

Using $Me_3SiC{\equiv}C\{Pt\}Cl$ (**1**; $Me_3SiC{\equiv}C\{Pt\}$ = $[Pt(C_6H_2\{CH_2NMe_2\}_2$-2,6-$\{C{\equiv}CSiMe_3\}$-4]$^+$) a series of platinum monoacetylides of the type $XC{\equiv}C\{Pt\}C{\equiv}CR$ [X = $SiMe_3$: **2**, R = Ph; **3**, R = $(\eta^5$-$C_5H_4)Fe(\eta^5$-$C_5H_5)$ (abbreviated as Fc); **4**, R = C_6H_4CN-4; **5**, R = $C_6H_4(C{\equiv}CSnMe_3)$-4; X = H: **7**, R = Ph; **8**, R = Fc; **9**, R = C_6H_4CN-4] have been prepared. Studies directed towards the coordinative properties of the C_2 unit of **1** have been carried out and heterotrimetallic [μ-$(Me_3SiC{\equiv}C\{Pt\}Cl][Co_2(CO)_6]$ (**10**) could be synthesised. The successful attachment of **1** to a Ph_3PAu unit leads to linear $Ph_3PAuC{\equiv}C\{Pt\}Cl$ (**11**). Treatment of **11** with $FcC{\equiv}CSnMe_3$ produces the heterotrimetallic rigid-rod shaped complex $Ph_3PAuC{\equiv}C\{Pt\}C{\equiv}CFc$ (**13**). Cyclic voltammetric studies carried out on these Ph_3PAu-capped molecules show that the attachment of an organometallic entity on either side of the $C{\equiv}C\{Pt\}$ fragment leads to a facilitation of the Pt^{II}/Pt^{IV} oxidation.

Introduction



The growing interest in the application of organometallic compounds as building blocks for new materials has led to a large number of publications on their synthesis,[1] and the evaluation of theoretical aspects.[2] In particular, the assembly, chemistry, and the physical properties of a number of homo- and heterometallic acetylenic compounds have been investigated containing metals such as Re,[3] Pt,[4] Pd,[5] Ru,[6] Os,[7] Fe,[8] Rh,[9] or Ti,[10] and Au.[11] Also, a variety of tungsten carbonyl containing complexes have been studied, e.g. by McCleverty et al.[12] and other groups.[13] Many of these mixed-metal σ-acetylide compounds contain a Fc group [Fc = $(\eta^5$-$C_5H_4)Fe(\eta^5$-$C_5H_5)$] as electron "reservoir". The main features of these molecules include: (i) high and readily modified electron density at the metal centres, which should lead to (ii) facile hyperpolarisability due to interaction(s) along the π-conjugated backbone, which connects the different metals.[14] In this context, the application of ethynyl functionalised molecules such as $Me_3SiC{\equiv}C\{Pt\}Cl$ (**1**, $Me_3SiC{\equiv}C\{Pt\}$ = $[Pt(C_6H_2\{CH_2NMe_2\}_2$-2,6-$\{C{\equiv}CSiMe_3\}$-4]$^+$) seems attractive, since in this platinum containing molecule a metal centre is directly attached to a conjugated π-system, and is further stabilised by the N-donor units of the ligand framework.[15] The Pt-monochloride **1** (Scheme 1) was therefore chosen as a precursor of such heterometallic compounds.

1

Scheme 1. Precursor complex **1**

A useful property of **1** is that it possesses two chemically unique reactive sites. These can be used for building-up bi- or trimetallic systems in sequential steps. Therefore, the C≡C unit of **1** can be attached to a transition metal (TM) complex fragment in two different binding modes: (i) either *via* σ-bonding or (ii) through η^2-coordination. Both approaches are presented herein. Furthermore, the Cl ligand of **1** can be substituted by, for example, σ-acetylides. This leads to the formation of linear heterometallic monoacetylides. This structural motif can be found in long-chain molecules, such as the hypothetical molecule **A** (Scheme 2), which offers a high degree of directionality along the acetylene-arene-metal vector.

A **B**

Scheme 2. Model of a long-chain molecule showing high directionality (**A**) and its repeating unit (**B**)

Molecule **A** can be considered as being built-up from repeating units of the di-ionic substructure **B**. Thus, the attachment of the C_2 unit present in **1** to a TM complex fragment, and the substitution of Cl by a σ-acetylide group leads to the transformation of **1** into the structural type **B** molecule. Such molecules can be envisioned as model compounds of **A**. With the synthesis of these complexes, the

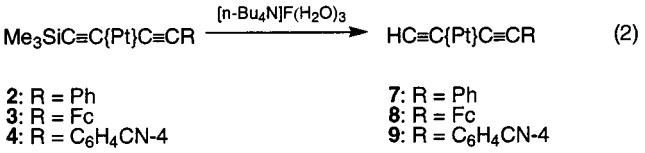
behaviour of the subunit **B** can be studied and evaluated towards its application in materials science.

Since Au is known to form very stable linear σ-acetylide complexes,[11] we choose to investigate the Ph_3PAu moiety as the terminating fragment on the 4-ethynyl unit. The formation of Pt monoacetylides containing the anionic potentially tridentate NCN "pincer" ligand (NCN = $[C_6H_3(CH_2NMe_2)_2$-2,6$]^-$) has been previously reported.[16]

Results and Discussion

Preparation of Platinum Acetylides



Reaction of the platinum monochloride $Me_3SiC{\equiv}C\{Pt\}Cl$ (**1**; $Me_3SiC{\equiv}C\{Pt\}$ = $[Pt(C_6H_2\{CH_2NMe_2\}_2$-2,6-$\{C{\equiv}CSiMe_3\}-4]^+$)[15] with an equimolar amount of $LiC{\equiv}CR$ {R = Ph, Fc [Fc = $(\eta^5$-$C_5H_4)Fe(\eta^5$-$C_5H_5)$], C_6H_4CN-4, $C_6H_4(C{\equiv}CSnMe_3)$-4} leads to the formation of the platinum acetylides **2**–**4** as air-stable, off-white solids (Equation 1). The rigid-rod like molecule **5** has been obtained by a procedure that uses a Me_3Sn-substituted acetylene.[17] Heterobimetallic **3** was synthesised alternatively by both routes. We tested this different approach because Cu^I catalysed reactions for the formation of Pt monoacetylides of this type have failed.[16]

(1)

The deprotection of the acetylenic unit of compounds **1**–**4** yields the mono-substituted acetylenes **7**–**9** (Equation 2).[15] The compound $HC{\equiv}C\{Pt\}Cl$ (**6**) has been described elsewhere.[15]

Analytic and spectroscopic data of compounds **1**–**9** are listed in Table 1. For comparison, the data of the previously reported Pt monochlorides **1** and **6** are included.[15]

(2)

Compounds **1**–**9** display the $\nu_{C\equiv C}$ frequencies of the acetylene units attached to the NCN system at the expected wavenumbers between 2090 and 2150 cm^{-1} in their IR spectra.[15,18] For the Pt σ-bound acetylenic units, the C≡C stretching band appears between 2070 and 2090 cm^{-1}, respectively (Table 1). These values lie in the range reported for this type of vibration.[4,16] In the ^1H NMR spectra of compounds **2**–**5** and **7**–**9**, a common general feature can be observed with respect to the chemical shift of the signals of the CH_2NMe_2 units. A comparison with the chloride-substituted Pt compounds **1** and **6** reveals that upon substitution of Cl by an acetylide, the singlet of the NMe_2 unit experiences a slight but diagnostic low-field shift, as does the resonance signal of the benzylic protons (Table 1). Both singlets appear with a set of satellites, due to the presence of spin active ^{195}Pt (I = 1/2, 33% abundance) with coupling constants ($^3J_{PtH}$) between 40 and 46 Hz (Table 1). Of particular interest in the $^{13}C\{^1H\}$ NMR spectra is the signal of the Pt-substituted carbon atom of the NCN system. Compared to its position in compound **1** (δ = 147.4) and **6** (δ = 147.6) this signal appears strongly shifted to lower field in the spectra of **2**–**5** and **7**–**9** (Table 1). The C_{ortho} resonance signal is also shifted to lower field (by around 3 ppm), when compared to **1** or **6**, respectively. This mirrors results obtained with the Pt monochloride $[PtCl(C_6H_3\{CH_2NMe_2\}_2$-2,6$)]$.[16] The carbon atoms of the

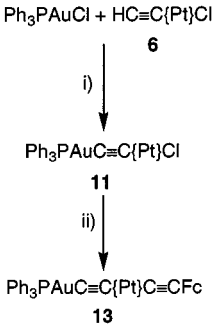
[a] Recorded in KBr [cm^{-1}]. – [b] All spectra were recorded in $CDCl_3$, with the solvent signal [rel. to $SiMe_4$ (0.00 ppm)] as internal standard.

Pt-bound acetylenic unit exhibit signals at chemical shifts that are comparable to those of other known Pt-acetylides.[4] Due to the low intensity of the C_{ipso} atom signals of the NCN unit [C(1)] and the platinum bonded acetylide ligands, ^{195}Pt-C satellites could not be detected.

The FAB mass spectra show the peak of the respective molecular ion M^+ at the expected *m/z* values as well as a typical fragmentation pattern such as *m/z* 481 $[C_{17}H_{28}N_2PtSi]^+$ or *m/z* 409 for $[C_{14}H_{19}N_2Pt]^+$.

Reactions of [4-Me$_3$SiC≡CC$_6$H$_2$(CH$_2$NMe$_2$)$_2$-2,6]PtCl (1) with Cobalt Carbonyl and Copper(I) Salts

The replacement of two CO ligands of $[Co_2(CO)_8]$ by the C_2 unit of acetylene derivatives leads to the formation of dicobaltatetrahedranes.[19] Hence, organometallic acetylides can readily yield mixed metal compounds. In order to study whether the same reactivity could be achieved with a {Pt}-substituted acetylene (i.e., with retention of the Pt−C and Pt−Cl bonds), **1** was reacted with equimolar amounts of $[Co_2(CO)_8]$ in toluene at 0 °C. This leads to the formation of the green trimetallic complex **10** in 50% isolated yield (Equation 3).



Compound **10** features a dicobaltatetrahedrane unit with the Pt-containing entity directly connected to this polyhedron. The values and pattern of the ν_{CO} frequencies resemble typical values found for $Co_2(CO)_6$ fragments.[19] The resonance signals in the ^{1}H NMR spectrum are generally slightly shifted to higher field, compared to **1**.[15] The $^{13}C\{^1H\}$ NMR spectrum displays virtually the same signal pattern as for **1**. However, the chemical shifts of the μ-C_2 unit with δ = 79.3 (C≡*C*Si) and δ = 107.6 (*C*≡CSi) experience a high-field shift of approximately 13 ppm for ≡*C*Si and a slight shift to lower field by ca. 1 ppm for *C*≡CSi. The signals assigned to the carbonyl ligands are found as a broad singlet at δ = 196.7. The FAB mass spectrum exhibits a peak for the molecular ion $[M]^+$ at *m/z* = 796. Also, the sequential loss of all six CO ligands can be observed.

The reaction of copper(I) halides with acetylene derivatives is well-known and generally yields dimeric η^2-acetylene copper(I) halides.[20] In order to investigate if the C≡C unit present in **1** can be used for the design of other bimetallic compounds, **1** has been reacted with $[CuCl]_n$ or $[Cu(NCMe)_4][BF_4]$. However, even after prolonged stirring (48 h) at low (−20 °C, CH_2Cl_2) or elevated temperatures (40−50 °C, C_6H_6), **1** did not react with $[CuCl]_n$. All spectroscopic evidence (IR, ^{1}H NMR, $^{13}C\{^1H\}$ NMR) indicated the presence of starting materials only. This mirrors results obtained earlier in a Cu^I−(Me$_3$SiC≡CPh) system.[21] This result contrasts with reports on the formation of complexes of the type $[Cu_2X_2(R'C{\equiv}CR')_2]$ [e.g. R′ = SiMe$_3$,[20] $Re(CO)_5$[22]]. In contrast to this lack of reactivity, the reaction of **1** with $[Cu(NCMe)_4][BF_4]$ led to a mixture of products that could not be separated. Moreover, the IR spectrum of the crude reaction mixture gave no indication for the occurrence of Cu^I-alkyne coordination.

Preparation of Linear Mixed Metal Compounds

Due to their stability and easy accessibility, Au^I acetylides have attracted a great deal of interest. Also, the preferred geometry and the electron-rich character of the Au^I centre makes this class of compounds attractive candidates for materials science.[11] In principle, the preparation of Au^I acetylides can be achieved by two routes: i) first a silyl-protected Pt acetylide is prepared, followed by deprotection of the C≡C functionality, and subsequent reaction of the monosubstituted acetylene with Ph_3PAuCl, or ii) treatment of HC≡C{Pt}Cl (**4**) with Ph_3PAuCl and then substitution of Cl by acetylide anions. The first route seemed to us being of little advantage because the platinum monoacetylides of this type have been reported to be sensitive to halide sources, i.e., giving rise to cleavage of the Pt-acetylide bond.[16] Therefore, the Au σ-acetylide complex **11** was synthesised first, according to well-established literature procedures (Scheme 3).[23] For comparative purposes, the gold-ferrocenyl acetylide complex $Ph_3PAuC{\equiv}CFc$ (**12**) was also prepared.

Scheme 3. Preparation of linear mixed metal (Au, Fe) complexes. i. $[CuCl]_n$, $HNEt_2$, 25 °C; ii. FcC≡CSnMe$_3$, THF, 50 °C.

Subsequently, complex **11** was reacted with FcC≡CSnMe$_3$ to form linear trimetallic **13** in virtually quantitative yield (Scheme 3). This reaction variation has been previously used in the synthesis of compound **5** (vide supra).

Experimental data with respect to the spectroscopic characterisation of complexes **11**−**13** are listed in Table 2.

The IR spectra of compounds **11**−**13** exhibit the C≡C stretching modes for the Au-bonded acetylide at typical values (Table 2).[23] The corresponding band for the Pt-bonded acetylide appears at much lower frequency than ob-

C≡CFc	**12**	2109	–	42.9	102.5[c]
C≡C{Pt}C≡CFc	**13**	2098	1971	43.1	–[d]

[a] Recorded in KBr ($\tilde{\nu}$ [cm^{-1}]). – [b] All spectra were recorded in $CDCl_3$ with the solvent signal [rel. to $SiMe_4$ (0.00 ppm)] as internal standard. – [c] Only one signal could be detected. – [d] Due to the low solubility of **13** in any organic solvent, a $^{13}C\{^1H\}$ NMR spectrum could not be recorded.

served in compounds **2**−**5** (around 2070 cm^{-1}, Table 1). This points to a bond weakening of the Pt-centred C≡C unit, which is obviously caused by the remote presence of the Ph_3PAu fragment. The ^1H NMR spectra exhibit no change in the chemical shifts of the C≡C{Pt} fragment compared to **1** (Table 1). In the ^1H NMR spectrum of **13**, however, the resonance signals of the {Pt} unit only appear as very broad singlets. In the $^{13}C\{^1H\}$ NMR spectra of compounds **11** and **12**, the acetylenic carbon resonance signals are found at chemical shifts that are typical for gold acetylides.[11,23] Due to the low solubility of **13** in all common organic solvents, a $^{13}C\{^1H\}$ NMR spectrum could not be obtained. Compared with Ph_3PAuCl (δ = 33.8), the signal for the phosphorus atom datively bonded to Au has shifted by about 10 ppm to lower field when Cl is substituted by an acetylide anion (**11**−**13**, Table 2). This shift is characteristic for Au^I acetylides carrying organic groups and indicates that the presence of a remote Pt atom does not influence the behaviour of the $AuPPh_3$ unit in a spectroscopically noticeable manner. The FAB mass spectrum reveals the peak for the molecular ion $[M]^+$ at the expected *m*/*z* values, together with an expected fragmentation pattern. Most characteristic fragments are found at *m*/*z* = 459 $[C_{18}H_{15}AuP]^+$, *m*/*z* = 409 $[C_{14}H_{18}N_2Pt]^+$ and *m*/*z* = 210 $[C_{12}H_9Fe]^+$.

At −30 °C, crystals of the bimetallic complex **11** could be grown from a CH_2Cl_2/pentane solution. Unfortunately, these crystals were not of sufficient quality to obtain a full X-ray structural analysis (*R* = 0.1544). Nevertheless, the representation given in Figure 1 serves to corroborate the predicted linear arrangement of the metal centres in the heterobimetallic complex **11**.

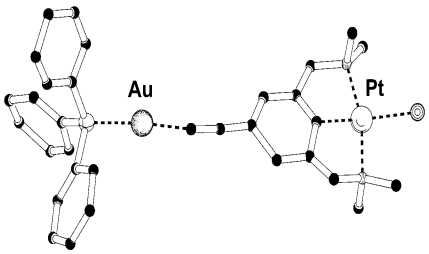

Figure 1. Structural representation of the heterobimetallic complex **11**

Electrochemical Behaviour

The mononuclear complex $Me_3SiC{\equiv}C\{Pt\}Cl$ (**1**), the heterobinuclear molecules **3**, **11**, and **12**, as well as the heterotrinuclear compound **13** have been investigated by cyclic voltammetry. The results of the electrochemical measurements are listed in Table 3. For comparative purposes, the electrochemical data of Ph_3PAuCl have been measured and these are also presented.

It appears that the reductive irreversible one-electron process for the system Au^I/Au^0 is generally shifted to a more negative potential upon substitution of the Cl ligand by acetylide (Table 3). However, the strength of the shift depends on the nature of the organometallic fragment. While for the NCN−Pt substituted acetylide a shift by approximately 0.2 V is found, the same effect for C≡CFc is larger (ca. 0.4 V). This indicates that the reduction of Au^I to Au^0 is more hampered by the presence of a Fc fragment than by the NCN−Pt unit. However, in the cyclic voltammetric experiment with the heterotrimetallic complex **13**, the Au-centred reductive process could not be detected due to the low solubility of **13** and the proximity of the edge of the electrochemical window in this system. This may also be explained by a shift of the Au^I/Au^0 reduction potential beyond this electrochemical edge. The cyclic voltammogram of **1** exhibits a concerted irreversible two-electron oxidative process that can be assigned to the system Pt^{II}/Pt^{IV}. This process is typical for Pt monochlorides of this type.[16] Upon substitution of the Cl by acetylide, as demonstrated in $Me_3SiC{\equiv}C\{Pt\}C{\equiv}CFc$ (**3**), a similar effect can be observed as in the Au^I-centred reductive process: a shift to a more negative value of the Pt^{II}/Pt^{IV} oxidation potential by ca. 0.4 V. A similar observation has been reported earlier for $PtCl[C_6H_3(CH_2NMe_2)_2$-2,6].[16] In this case, a shift of the Pt^{II}/Pt^{IV} oxidation to a more negative potential by ca. 0.2 V was reported when Cl was replaced by, e.g. $C{\equiv}CSiMe_3$. Surprisingly, the Pt-containing unit of the complexes described in the present study shows no reduction process at all. The attachment of the C≡C{Pt}Cl fragment to Ph_3PAu also leads to a shift of the Pt^{II}/Pt^{IV} oxidation to a more negative potential. As in the case of the Pt−Fc complex **3**, this indicates a facilitation of the oxidative process (Table 3). In the heterotrimetallic complex **13**, this process is shifted to a more negative value than in the bimetallic compound **11** (Table 3) but less than in complex

Table 3. Cyclic voltammetric data of compounds **11**−**13**, Ph_3PAuCl and **1** are presented for comparison; the cyclic voltammograms have been recorded in THF solutions in the presence of $[n-Bu_4N][PF_6]$ (c = 0.1 mol dm^{-3}) at 25 °C under N_2; scan-rate 100 mV s^{-1}; potentials are referenced to FcH/FcH^+ couple ($E_{1/2}$ = 0.00 V)

Compound		Oxidation $E_{1/2}$(Fc) [V]	ΔE [mV]	E_{ox}(Pt) [V]	Reduction E_{red}(Au) [V]	E_{red}(Pt) [V]

$Ph_3PAuC{\equiv}C\{Pt\}C{\equiv}CFc$	**13**	−0.02	90	0.41	−[a]	−

[a] Due to low solubility of **13** and the proximity of the reductive process Au^I/Au^0 to the edge of the electrochemical window, a reductive process could not be observed.

3. Looking at the reversible one-electron redox process of the Fc entity, the attachment of C≡CFc to Ph_3PAu or $Me_3SiC{\equiv}C\{Pt\}$ also results in a shift to a more negative potential, with about equal magnitude. Still, the assembly of these three fragments to form complex **13** does not result in changes to the redox potential of the Fc unit with respect to the reference potential FcH/FcH^+.

It can be concluded that the stepwise increase of size and composition of the organometallic systems in the described complexes **3**−**12** induces a facilitation of the oxidative processes in each of the metal-containing subunits. This indicates that the linking of further organometallic fragments to the 4-ethynyl-substituted Pt−NCN system induces a change in the electronic system of the Pt^{II} centre. The fact that this is also induced by the remote Ph_3PAu unit suggests that the extended π-system of the $-C{\equiv}CC_6H_2(CH_2NMe_2)_2$-2,6-$Pt^+$ fragment, which also includes the coplanar coordination plane of the Pt^{II} centre, is able to conduct electronic information.

Conclusions

A series of Pt monoacetylides containing the 4-ethynyl-substituted NCN−Pt unit has been synthesised and characterised. Their use as the basis for the preparation of multimetallic systems has been shown by the assembly of $Ph_3PAuC{\equiv}C\{Pt\}C{\equiv}CFc$, **13**. Apart from the use of Li-acetylides, Me_3Sn-substituted acetylenes have been applied to the high-yield synthesis of Pt monoacetylides. The C≡C unit of $Me_3SiC{\equiv}C\{Pt\}Cl$ (**1**) can act as an η^2-coordinating ligand, as was shown by the formation of a characteristically green-coloured dicobaltatetrahedrane complex by reaction of **1** with $Co_2(CO)_8$. Electrochemical studies of these heterometallic systems revealed that the reversible oxidation of the Fc units in complexes $Me_3SiC{\equiv}C\{Pt\}C{\equiv}CFc$ (**3**) and $PPh_3AuC{\equiv}C\{Pt\}C{\equiv}CFc$ (**13**), and the irreversible Pt^{II}/Pt^{IV} oxidation are both facilitated. On the basis of these results we conclude, that the 4-ethynyl NCN unit supports electronic communication between two metal atoms through the conjugated π-system. Further work will be directed towards the construction of longer chains of repeating C≡C{Pt} units with high directionality approximating an organometallic polymer as suggested in type **A** complexes (vide supra) in a stepwise approach.

Experimental Section

General: All reactions were carried out under an atmosphere of dry nitrogen using standard Schlenk techniques. Tetrahydrofuran (THF) and diethyl ether (Et_2O) were purified by distillation from sodium/benzophenone ketyl; pentane was purified by distillation from CaH_2. − IR: Mattison Galaxy Series FTIR 5000. − NMR: Bruker AC 300 (^1H, ^{31}P, and ^{13}C); chemical shifts are reported in δ units (parts per million) downfield from tetramethylsilane with the solvent as the internal reference signal. − FAB-MS: JEOL JMS SX/SX 102A four sector mass spectrometer (10 kV accelerating voltage) at the Department of Mass Spectrometry, Bijvoet Center, Utrecht University. − MP: Büchi melting point apparatus. − Elemental analyses: H. Kolbe, Mikroanalytisches Laboratorium, Mülheim/Ruhr, Germany. − CV: Princeton Applied Research EG& G 263A analyser in a solution of $[n-Bu_4N][PF_6]$ (c = 0.1 mol dm^{-3}) in THF at 25 °C; all potentials were referenced to the ferrocene/ferrocenium couple as internal reference ($E_{1/2}$ = 0.00 V).

Remarks: The starting materials $Me_3SiC{\equiv}C\{Pt\}Cl$ (**1**),[15] $HC{\equiv}C\{Pt\}Cl$ (**6**),[15] $HC{\equiv}CC_6H_4CN$-4,[24] 1,4-$(Me_3SnC{\equiv}C)_2C_6H_4$,[25] $HC{\equiv}CFc$,[26] Ph_3PAuCl,[23] and $Me_3SnC{\equiv}CFc$[25] were prepared following published procedures. Other reagents were purchased from commercial suppliers.

Synthesis of $Me_3SiC{\equiv}C\{Pt\}C{\equiv}CPh$ (2): To a Et_2O solution (150 mL, −78 °C) of $LiC{\equiv}CPh$ (190 mg, 1.80 mmol) was added **1** (880 mg, 1.70 mmol). The mixture was allowed to warm up (25 °C) and stirred (16 h, 25 °C). All volatile material was then evaporated in vacuo and the residue was extracted with Et_2O (3 × 50 mL) and CH_2Cl_2 (3 × 40 mL). Separation from the solid residue was effected by centrifugation. The combined CH_2Cl_2 fractions were then concentrated to ca. 5 mL and addition of pentane (50 mL) yielded **2** (580 mg, 60% yield based on **1**) as off-white solid; m.p. > 200 °C. − IR (KBr): $\tilde{\nu}$ = 2148 [$\nu_{C{\equiv}C}$], 2077 [$\nu_{C{\equiv}C}$] cm^{-1}. − ^1H NMR ($CDCl_3$): δ = 0.21 (s, 9 H, SiMe_3), 3.18 s, $^3J_{HPt}$ = 42 Hz, NMe_2), 4.05 (s, $^3J_{HPt}$ = 44 Hz, 4 H, CH_2), 7.01 (s, 2 H, C_6H_2), 7.1−7.5 (m, 5 H, C_6H_5). − $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 0.1 (SiMe_3), 55.9 (NMe_2), 79.5 (CH_2), 91.8 (Si$C{\equiv}C$), 107.2 (Si$C{\equiv}C$), 108.2 (Pt$C{\equiv}C$), 117.4 (iC/C_6H_2), 122.4 (CH/C_6H_2), 124.8 (CH/C_6H_5), 127.8 (CH/C_6H_5), 128.5 (iC/C_6H_5), 131.6 (CH/C_6H_5), 135.8 (Pt$C{\equiv}C$), 145.9 (iC/C_6H_2), 169.0 (iC/C_6H_2). − FAB-MS; m/z (rel. int.): 583 (30) [M^+], 482 (100) [$M^+ - C_8H_5$]. − $C_{25}H_{32}N_2PtSi$ (583.73): calcd. C 51.44, H 5.53, N 4.80; found C 51.32, H 5.55, N 4.73.

Synthesis of $Me_3SiC{\equiv}C\{Pt\}C{\equiv}CFc$ (3): Experimental conditions and workup were identical to those for the preparation of **2**. Experimental details: $LiC{\equiv}CFc$ (170 mg, 0.80 mmol), **1** (400 mg, 0.77 mmol), Et_2O (100 mL). Yield: 330 mg, 60% based on **1**. − Mp:

> 200 °C. − IR (KBr): $\tilde{\nu}$ = 2144 [$\nu_{C\equiv C}$], 2089 [$\nu_{C\equiv C}$] cm^{-1}. − ^1H NMR ($CDCl_3$): δ = 0.22 (s, 9 H, Si*Me*$_3$), 3.19 (s, $^3J_{HPt}$ = 42 Hz, 12 H, N*Me*$_2$), 4.04 (br s, 2 H, C_5H_4), 4.04 (s, $^3J_{HPt}$ = 40 Hz, 4 H, CH_2), 4.15 (s, 5 H, C_5H_5), 4.36 (br s, 2 H, C_5H_4), 7.01 (s, 2 H, C_6H_2). − $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 0.1 (Si*Me*$_3$), 55.9 (N*Me*$_2$), 66.9 (*CH*/C_5H_4), 69.4 (C_5H_5), 70.0 (*iC*/C_5H_4), 70.9 (*CH*/C_5H_4), 79.5 (CH_2), 90.9 (Si*C*≡C), 103.7 (PtC≡*C*), 107.2 (SiC≡*C*), 117.3 (*iC*/C_6H_2), 122.4 (*CH*/C_6H_2), 130.6 (Pt*C*≡C), 145.9 (*iC*/C_6H_2), 166.2 (*iC*/C_6H_2). − FAB-MS; *m*/*z* (rel. int.): 692 (20) [M^+], 481 (100) [$M^+ - C_{12}H_9Fe$]. − $C_{29}H_{36}FeN_2PtSi$ (691.95): calcd. C 50.36, H 5.25, N 3.71; found C 50.48, H 5.23, N 3.97.

Synthesis of Me$_3$SiC≡C{Pt}C≡CC$_6$H$_4$CN-4 (4): Experimental conditions and workup were identical to those for the preparation of **2**. Experimental details: LiC≡CC$_6$H$_4$CN-4 (100 mg, 0.80 mmol), **1** (390 mg, 0.76 mmol), Et_2O (100 mL). Yield: 200 mg, 40% based on **1**. − Mp: > 200 °C. − IR (KBr): $\tilde{\nu}$ = 2220 [ν_{CN}], 2144 [$\nu_{C\equiv C}$], 2089 [$\nu_{C\equiv C}$] cm^{-1}. − ^1H NMR ($CDCl_3$): δ = 0.22 (s, 9 H, Si*Me*$_3$), 3.19 (s, $^3J_{HPt}$ = 41 Hz, 12 H, N*Me*$_2$), 4.08 (s, $^3J_{HPt}$ = 42 Hz, 4 H, CH_2), 7.03 (s, 2 H, C_6H_2), 7.3−7.5 (m, 4 H, C_6H_4). − $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 0.1 (Si*Me*$_3$), 55.9 (N*Me*$_2$), 79.5 (CH_2), 92.1 (Si*C*≡C), 106.9 (SiC≡*C*), 107.4 (PtC≡*C*), 107.7 (*C*N), 117.9 (*iC*/C_6H_2), 119.7 (*iC*/C_6H_4), 122.5 (*CH*/C_6H_2), 131.5 (*iC*/C_6H_4), 131.6 (*CH*/C_6H_4), 131.9 (*CH*/C_6H_4), 133.6 (Pt*C*≡C), 145.9 (*iC*/C_6H_2), 168.3 (*iC*/C_6H_2). − FAB-MS: *m*/*z* (rel. int.): 608 (10) [M^+], 481 (100) [$C_{17}H_{27}N_2PtSi]^+$. − $C_{26}H_{31}N_3PtSi$ (608.74): calcd. C 51.30, H 5.13, N 6.90. A satisfactory elemental analysis could not be obtained.

Synthesis of Me$_3$SiC≡C{Pt}C≡CC$_6$H$_4$(C≡CSnMe$_3$)-4 (5): Compound **1** (50 mg, 0.10 mmol) and 1,4-(Me$_3$SnC≡C)$_2$C$_6$H$_4$ (90 mg, 0.20 mmol) were dissolved in THF (40 mL). The solution was stirred (10 h, 25 °C) and then concentrated to ca. 5 mL. Addition of pentane (50 mL) formed a precipitate that was separated from the supernatant solution. The residue was then dried (5 h, *vacuo*). **Note: Me$_3$SnCl is volatile and very toxic. An extra cooling trap has to be installed right after the reaction vessel.** Complex **5** (60 mg, 80% based on **1**) was obtained as off-white solid. − Mp: > 200 °C. − IR (KBr): $\tilde{\nu}$ = 2148 [$\nu_{C\equiv C}$], 2132 [$\nu_{C\equiv C}$], 2089 [$\nu_{C\equiv C}$] cm^{-1}. − ^1H NMR ($CDCl_3$): δ = 0.22 (s, 9 H, Si*Me*$_3$), 0.34 (s, $^3J_{HSn}$ = 59.8 Hz, 9 H, $SnMe_3$), 3.19 (s, $^3J_{HPt}$ = 37 Hz, 12 H, N*Me*$_2$), 4.07 (s, $^3J_{HPt}$ = 40 Hz, 4 H, CH_2), 7.02 (s, 2 H, C_6H_2), 7.29 (s, 4 H, C_6H_4). − $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = −7.7 ($SnMe_3$), 0.1 (Si*Me*$_3$), 55.9 (N*Me*$_2$), 79.5 (CH_2), 91.8 (Si*C*≡C), 93.2 (Sn*C*≡C), 107.3 (SiC≡*C*), 108.2 (PtC≡*C*), 109.7 (SnC≡*C*), 117.5 (*iC*/C_6H_2), 122.4 (*CH*/C_6H_2), 131.1 (*iC*/C_6H_4), 131.4 (*CH*/C_6H_4), 131.5 (*CH*/C_6H_4), 131.7 (*iC*/C_6H_4), 139.3 (Pt*C*≡C), 145.9 (*iC*/C_6H_2), 168.8 (*iC*/C_6H_2). − FAB-MS; *m*/*z* (rel. int.): 770 (10) [M^+], 607 (20) [$M - SnMe_3]^+$, 481 (100) [$C_{17}H_{27}N_2PtSi]^+$, 73 [$C_3H_9Si]^+$. − $C_{30}H_{40}N_2PtSiSn$ (770.53): calcd. C 46.76, H 5.23, N 3.64; found C 47.01, H 5.01, N 3.32.

Synthesis of HC≡C{Pt}C≡CPh (7): To a solution of **2** (400 mg, 0.76 mmol) in CH_2Cl_2 (100 mL), was added [*n*Bu$_4$N]F·3H$_2$O (240 mg, 0.76 mmol). After stirring (2 h, 25 °C), all volatile material was evaporated and the residue was extracted with acetone (2 × 10 mL). Separation by centrifugation and drying (*vacuo*) yielded **5** (190 mg, 50%) as a brown solid. − Mp: > 200 °C. − IR (KBr): $\tilde{\nu}$ = 3302 [$\nu_{\equiv CH}$], 2126 [$\nu_{C\equiv C}$], 2083 [$\nu_{C\equiv C}$] cm^{-1}. − ^1H NMR ($CDCl_3$): δ = 3.01 (s, 1 H, ≡C*H*), 3.21 (s, $^3J_{HPt}$ = 43.4 Hz, N*Me*$_2$), 4.08 (s, $^3J_{HPt}$ = 44 Hz, 4 H, CH_2), 7.04 (s, 2 H, C_6H_2), 7.2−7.5 (m, 5 H, C_6H_5). − $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 55.9 (N*Me*$_2$), 75.0 (≡*C*H), 79.6 (*C*H$_2$), 85.6 (*C*≡CH), 108.2 (PtC≡*C*)[a] , 116.4 (*iC*/C_6H_2), 122.5 (*CH*/C_6H_2), 124.6 (*CH*/C_6H_5), 127.8 (*CH*/C_6H_5), 128.5 (*iC*/C_6H_5), 131.6 (*CH*/C_6H_5), 131.1 (Pt*C*≡C), 146.0 (*iC*/C_6H_2), 169.1 (*iC*/C_6H_2). − FAB-MS; *m*/*z* (rel. int.): 512 (20) [M^+], 409 (100) [$M^+ - C_8H_5$]. − $C_{22}H_{24}N_2Pt$ (511.54): calcd. Synthesis of HC≡C{Pt}C≡CC$_6$H$_4$CN-4 (9): Experimental conditions and workup were identical to those for compound **7**. Experimental details: **4** (260 mg, 0.51 mmol), [*n*Bu$_4$N]F·3H$_2$O (160 mg, 0.51 mmol), CH_2Cl_2 (30 mL). Yield: 100 mg, 40% based on **4**. − Mp: > 200 °C. − IR (KBr): $\tilde{\nu}$ = 3302 [$\nu_{\equiv CH}$], 2220 [ν_{CN}], 2102 [$\nu_{C\equiv C}$], 2083 [$\nu_{C\equiv C}$] cm^{-1}. − ^1H NMR ($CDCl_3$): δ = 3.01 (s, 1 H, ≡C*H*), 3.20 (s, $^3J_{HPt}$ = 39 Hz, 12 H, N*Me*$_2$), 4.11 (s, $^3J_{HPt}$ = 40 Hz, 4 H, CH_2), 7.05 (s, 2 H, C_6H_2), 7.3−7.5 (m, 4 H, C_6H_4). − $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 55.9 (N*Me*$_2$), 75.3 (≡*C*H), 79.5 (s, $^3J_{CPt}$ = 38 Hz, *C*H$_2$), 85.4 (*C*≡CH), 107.4 (*C*N), 107.7 (PtC≡*C*), 116.8 (*iC*/C_6H_2), 119.7 (*iC*/C_6H_4), 122.6 (*CH*/C_6H_2), 131.7 (*CH*/C_6H_4), 132.2 (*CH*/C_6H_4), 133.6 (Pt*C*≡C), 146.0 (s, $^3J_{CPt}$ = 35.9 Hz, *iC*/C_6H_2), 168.4 (*iC*/C_6H_2). − FAB-MS; *m*/*z* (rel. int.): 536 (10) [M^+], 409 (60) [$C_{14}H_{19}N_2Pt]^+$. − $C_{23}H_{23}N_3Pt$ (536.55): calcd. C 51.49, H 4.32, N 7.83; found C 51.32, H 4.40, N 7.69.

Synthesis of [μ-(Me$_3$SiC≡C{Pt}Cl)][Co$_2$(CO)$_6$] (10): To a toluene solution (100 mL) of **1** (200 mg, 0.39 mmol), was added $Co_2(CO)_8$ (140 mg, 0.43 mmol) in one portion. After stirring (3 h, 25 °C), the solvent was reduced to ca. 10 mL and pentane (100 mL) was added. The supernatant solution was carefully decanted and the green precipitate redissolved in toluene (5 mL). Crystallisation at − 20 °C yielded **10** (140 mg, 50% based on **1**) as a green solid. − Mp: 140 °C (dec). − IR (KBr): $\tilde{\nu}$ = 2087, 2035, 2015, 1990 [ν_{CO}] cm^{-1}. − ^1H NMR ($CDCl_3$): δ = 0.40 (s, 9 H, Si*Me*$_3$), 3.11 (s, $^3J_{HPt}$ = 32 Hz, 12 H, N*Me*$_2$), 4.06 (s, $^3J_{HPt}$ = 42 Hz, 4 H, CH_2), 6.96 (s, 2 H, C_6H_2). − $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 0.9 (Si*Me*$_3$), 54.5 (N*Me*$_2$), 79.3 (C≡*C*Si), 107.6 (*C*≡CSi), 121.0 (*CH*/C_6H_2), 132.7 (*iC*/C_6H_2), 143.2 (*iC*/C_6H_2), 147.0 (*iC*/C_6H_2), 201−204 (CO). − FAB-MS; *m*/*z* (rel. int.): 796 (20) [M^+], 768 (25) [M^+ − CO], 740 (30) [M^+ − 2 CO], 712 (20) [M^+ − 3 CO], 684 (10) [M^+ − 4 CO], 656 (20) [M^+ − 5 CO], 628 (20) [M^+ − 6 CO], 481 (100) [$C_{16}H_{27}N_2PtSi]^+$. − $C_{22}H_{27}ClCo_2N_2O_6PtSi$ (791.96): calcd. C 33.37, H 3.44, N 3.54; Si 3.55; found C 33.45, H 3.36, N 3.46; Si 3.59.

Reaction of 1 with [CuCl]$_n$. − Method A: $[CuCl]_n$ (20 mg, 0.20 mmol) and **1** (50 mg, 0.10 mmol) are stirred in C_6H_6 (30 mL, 48 h, 50 °C). − **Method B:** $[CuCl]_n$ (10 mg, 0.10 mmol) and **1** (30 mg, 0.6 mmol) are stirred in CH_2Cl_2 (30 mL, 24 h, − 20 °C).

In both cases, after removal of the solvent (in vacuo), the spectroscopic investigation (IR, ^1H NMR, $^{13}C\{^1H\}$ NMR) of the crude residue revealed the presence solely of **1**.

Reaction of 1 with [Cu(NCMe)$_4$][BF$_4$]: Compound **1** (100 mg, 0.19 mmol) and $[Cu(NCMe)_4][BF_4]$ (30 mg, 0.10 mmol) are dis-

solved in CH_2Cl_2 (30 mL]. During the course of the reaction, the solution gradually turns brown. After stirring (24 h, 25 °C),the solvent is removed (in vacuo). Spectroscopic investigation (IR, ^1H NMR, ^{13}C $\{^1H\}$ NMR) of the residue showed that a complicated mixture of compounds had been formed.

Synthesis of $Ph_3PAuC{\equiv}C\{Pt\}Cl$ (11): Compound **6** (127 mg, 0.30 mmol), Ph_3PAuCl (140 mg, 0.30 mmol) and $[CuCl]_n$ (8 mg, 0.08 mmol) were dissolved in degassed $HNEt_2$ (30 mL). After stirring (12 h, 25 °C) and evaporation (in vacuo), the residue was extracted with water (3 × 10 mL) and then with C_6H_6 (3 × 20 mL). The combined C_6H_6 extracts were evaporated and redissolved in CH_2Cl_2. The CH_2Cl_2 solution was dried over $MgSO_4$, filtered and evaporated (in vacuo). Complex **11** (170 mg, 60% based on **6**) was obtained as an off-white solid. − Mp: > 200 °C. − IR (KBr): $\tilde{\nu}$ = 2102 [$\nu_{C\equiv C}$] cm^{-1}. − ^1H NMR ($CDCl_3$): δ = 3.05 (s, $^3J_{HPt}$ = 37.8 Hz, 12 H, N*Me*$_2$), 4.09 (s, $^3J_{HPt}$ = 44 Hz, 4 H, C*H*$_2$), 6.92 (s, 2 H, C_6H_2), 7.3−7.6 (m, 15 H, C_6H_5). − $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 54.4 (N*Me*$_2$) 77.6 (*C*H$_2$), 105.4 (C≡C), 105.7 (C≡C), 119.4 (*iC*/C_6H_2), 123.2 (s, $^3J_{PtC}$ = 33 Hz, *CH*/C_6H_2), 129.1 (d, $^3J_{PH}$ = 11 Hz, *CH*/C_6H_5), 129.8 (d, $^1J_{PH}$ = 63 Hz, *iC*/C_6H_5), 131.5 (*CH*/C_6H_5), 134.3 (d, $^2J_{PH}$ = 14 Hz, *CH*/C_6H_5) 142.9 (s, $^2J_{PtC}$ = 76 Hz, *iC*/C_6H_2), 144.8 (*iC*/C_6H_2). − ^{31}P $\{^1H\}$ NMR ($CDCl_3$): δ =43.1 (PPh_3). − FAB-MS; *m*/*z* (rel. int.): 904 (10) $[M]^+$, 868 (60) $[M - Cl]^+$, 459 (100) $[C_{18}H_{15}AuP]^+$, 401 (20) $[C_{14}H_{18}N_2Pt]^+$. − $C_{34}H_{33}AuClFeN_2PPt$ (928.17): calcd. C 42.51, H 3.68, N 3.10; found C 42.45, H 3.74, N 3.12.

Synthesis of $Ph_3PAuC{\equiv}CFc$ (12): Ph_3PAuCl (100 mg, 0.21 mmol), $FcC{\equiv}CH$ (50 mg, 0.24 mmol) and K_2CO_3 (100 mg) were dissolved in MeOH (40 mL). After stirring (12 h, 25 °C), the reaction mixture was evaporated (in vacuo). The orange residue was extracted with Et_2O (2 × 20 mL) and CH_2Cl_2 (2 × 10 mL). The combined CH_2Cl_2 extracts were concentrated to ca. 5 mL and pentane (30 mL) was added. The supernatant solution was decanted. After drying (in vacuo), **12** (120 mg, 90% based on Ph_3PAuCl) was obtained as an orange solid. − Mp: 141 °C. − IR (KBr): $\tilde{\nu}$ = 2109 [$\nu_{C\equiv C}$] cm^{-1}. − ^1H NMR ($CDCl_3$): δ = 4.11 (t, $^3J_{HH}$ = 3.6 Hz, 2 H, C_5H_4), 4.22 (s, 5 H, C_5H_5), 4.44 (t, $^3J_{HH}$ = 1.4 Hz, C_5H_4), 7.4−7.6 (m, 15 H, C_6H_5). − $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 67.8 (*CH*/C_5H_4), 68.7 (*iC*/C_5H_4), 70.0 (C_5H_5), 102.5 (C≡C), 129.1 (d, $^3J_{PH}$ = 11 Hz, *CH*/C_6H_5), 129.9 (d, $^1J_{PH}$ = 63 Hz, *iC*/C_6H_5), 131.5 (*CH*/C_6H_5), 134.3 (d, $^2J_{PH}$ = 14 Hz, *CH*/C_6H_5). − ^{31}P $\{^1H\}$ NMR ($CDCl_3$): δ = 42.9 (PPh_3). − FAB-MS; *m*/*z* (rel. int.): 668 (90) $[M]^+$, 459 (100) $[C_{18}H_{15}AuP]^+$, 210 (10) $[C_{12}H_9Fe]^+$. − $C_{30}H_{24}AuFeP$ (668.35): calcd. C 53.91, H 3.62; found C 53.82, H 3.51.

Synthesis of $Ph_3PAuC{\equiv}C\{Pt\}C{\equiv}CFc$ (13): Compound **11** (120 mg, 0.13 mmol) and $FcC{\equiv}CSnMe_3$ (75 mg, 0.20 mmol) were dissolved in THF (20 mL). After stirring (6 h, 50 °C), the solution was concentrated to ca. 5 mL and Et_2O (40 mL) was added. The supernatant solution was decanted from the precipitate that had formed. Subsequently, this was extracted with Et_2O (2 × 10 mL) and then dried (in vacuo). Complex **13** (100 mg, 80% based on **11**) was obtained as an amber solid. − Mp: > 200 °C. − IR (KBr): $\tilde{\nu}$ = 2098 [$\nu_{C\equiv C}$], 1971 [$\nu_{C=C}$] cm^{-1}. − ^1H NMR ($CDCl_3$): δ = 3.19 (s, 12 H, N*Me*$_2$), 4.04 (br s, 2 H, C_5H_4), 4.04 (s, 4 H, C*H*$_2$), 4.15 (s, 5 H, C_5H_5), 4.36 (br s, 2 H, C_5H_4), 7.01 (s, 2 H, C_6H_2), 7.4−7.6 (m, 15 H, C_6H_5). − ^{31}P $\{^1H\}$ NMR ($CDCl_3$): δ = 43.1. − FAB-MS; *m*/*z* (rel. int.): 1078 (20) $[M^+]$, 867 (50) $[M - Fc]^+$, 668 (10) $[C_{30}H_{24}AuFeP]^+$, 459 (100) $[C_{18}H_{15}AuP]^+$, 409 $[C_{14}H_{18}N_2Pt]^+$, 210 (10) $[C_{12}H_9Fe]^+$. − $C_{44}H_{43}AuFeN_2PPt$ (1078.76): calcd. C 48.99, H 4.02, N 2.60; found C 49.12, H 4.08, N 2.68.

Acknowledgments

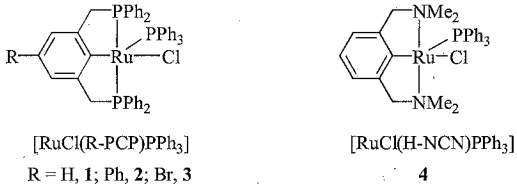
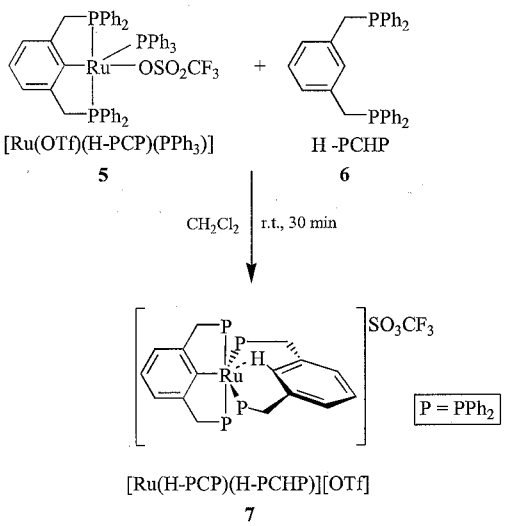
Structural Investigation in Solution of a Series of Five-Coordinate Bisphosphanylaryl Ruthenium(II) Complexes



Paulo Dani,[a] Gerard P. M. van Klink,[a] and Gerard van Koten*[a]

Keywords: Ruthenium / NMR spectroscopy / NOESY / P ligands / Monoanionic terdentate *P,C,P′*-bisphosphanylaryl ligand

The structure of the ruthenium(II) complexes [RuCl{$C_6H_2(CH_2PPh_2)_2$-2,6-R-4}(PPh_3)] [R = H (**1**), Ph (**2**) or Br (**3**)] was investigated in solution using two-dimensional NMR techniques (^{1}H-^{1}H-, ^{13}C-^{1}H- and ^{31}P-^{1}H-correlation NMR spectroscopy and ^{1}H NOESY). The ^{1}H and ^{13}C NMR spectra of the complexes **1**–**3** were similar and could be completely assigned. The results of the NOESY study indicated that these complexes have a distorted square-pyramidal geometry in solution as was established for the parent complex R = H in the solid state by an X-ray crystal structure determination. The strategies used for the interpretation of the ^{1}H, ^{13}C and ^{31}P NMR spectra of these compounds and the resulting assignments form the basis for future in situ studies involving these complexes in catalytic processes.



Introduction

During the last two decades a new class of organometallic species has emerged containing the metal in a terdentate monoanionic framework. In these compounds, the ligand binds to the metal through two heteroatoms (e.g. N, P, S) and an anionic carbon atom usually from an aryl fragment. Examples of this type of complexes, containing a bis-orthochelating amine[1] or phosphane,[2,3] aryl monoanion (commonly known as a "pincer" ligand) bound to a ruthenium(II) center, are presented in Scheme 1.

Scheme 1. Schematic representation of Ru−PCP and −NCN complexes

Examining the reaction behavior of these compounds revealed that [Ru(OSO_2CF_3)(H−PCP)(PPh_3)] (**5**) reacted with the parent arene $C_6H_4(CH_2PPh_2)_2$-1,3 (H−PCHP, **6**) to give **7** (see Scheme 2). In **7**, which was structurally characterized by X-ray diffraction, a neutral H−PCHP ligand is η^3-*P,H,P′* ligated to the bis-orthochelated bisphosphanylaryl ruthenium cation. Complexes like **7**, containing an aromatic C−H group coordinated to a metal center (i.e., an agostic contact),[4] are rare and are thought to be intermediates in processes leading to the formation of a metal−carbon bond (cyclometalation).[5−7]

Scheme 2. Formation of ruthenium complex **7**, containing an aryl C−H···Ru interaction

Attempts to study the structure of **7** in solution by NMR spectroscopy were hampered by a complex resonance pattern and fluxional behavior. Interpretation of the ^{1}H, ^{13}C and ^{31}P NMR patterns of **7** was further frustrated by the lack of a detailed assignment of the ^{1}H and ^{13}C NMR spectra in complexes where the PCP-type ligand had phenyl groups attached to the phosphorus atoms,[8] mainly those with geometries other than square-planar.[2,3,5,9,10] In particular, a detailed understanding of the binding mode of the H−PCHP ligand in **7** requires an accurate assignment of the aromatic region of the ^{1}H and ^{13}C NMR spectra of related complexes such as **1**−**3**. Furthermore, these PCP metal complexes have an increasing importance as novel catalysts[8b,8c,11−13] as well as materials with interesting new physico-chemical properties.[14] A detailed knowledge of the

NMR spectroscopic features of these compounds, i.e., coupling network, chemical shift and relative spatial positioning of the various nuclei, mainly the ones closer to the metal center, can play an important role in further investigations of reactivity, bonding, structure-energy relationships and in the understanding of the intimate steps of catalytic processes involving these pincer ruthenium complexes. Therefore, we set out to study in detail the NMR spectra of the [RuCl(R−PCP)PPh_3] compounds **1−3**.

Due to the presence of several aromatic rings, an obvious and nontrivial problem in compounds **1−3** is to distinguish the resonances belonging exclusively to one particular type of aromatic group. The structures of these complexes in solution were studied by ^1H, ^{13}C and ^{31}P NMR spectroscopy with the application of two-dimensional techniques (^1H-^1H-COSY, ^{13}C-^1H-COSY and ^{31}P-^1H-COSY) to allow full assignment of the ^1H and ^{13}C resonances, in particular those in the aromatic regions. Furthermore, a study of the three-dimensional structure in solution was performed by applying standard NOE techniques (^1H-NOESY). More importantly, these assignments were performed without any sort of chemical modification of the complexes studied, like, for instance, replacement of hydrogen atoms by deuterium or fluorine or NMR "silent" nuclei.

Results

The structure of [RuCl(H−PCP)(PPh_3)] (**1**) in the solid state has been determined by X-ray diffraction.[15] The local geometry around the Ru^{II} center in **1** has been described as distorted square-pyramidal (see Figure 1). The PPh_3 ligand occupies the apical position, while the other two phosphorus centers, together with the chlorine and C_{ipso} atom, form the base of the square-pyramidal arrangement. As a result, the complex has a mirror-type arrangement of the two fused five-membered chelate rings. The phosphorus center in each of the puckered chelate rings has one phenyl group equatorially and one axially (i.e., opposite to the apical PPh_3 ligand) orientated.

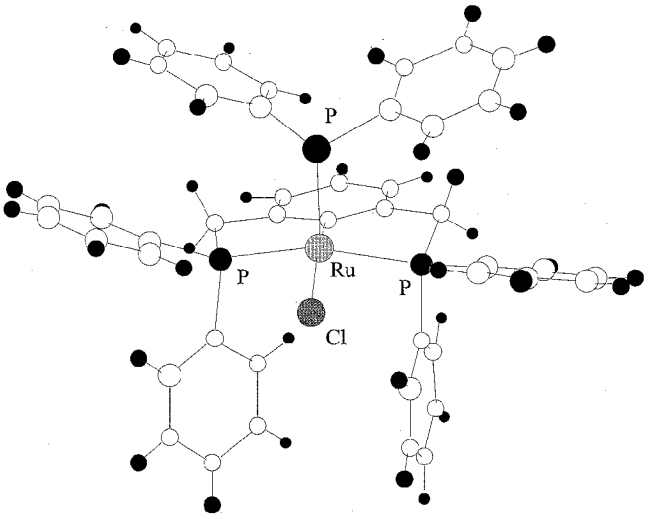

Figure 1. The molecular geometry of [RuCl(H−PCP)(PPh_3)] (**1**) in the solid state;[15] one phenyl ring from the PPh_3 ligand is omitted for clarity; the mirror-type arrangement (apparent mirror-plane) through the C_{ipso}−Ru−Cl is clearly visible

As a common feature, the ^1H NMR spectra of **1−3** contain a set of doublets of virtual triplets for the diastereotopic benzylic protons (for instance, see the abscissa in Figure 2[16]). Moreover, the $^{31}P\{^1H\}$ NMR spectra of these compounds consist of a doublet and a lower field triplet ($^2J_{pp} \approx 30$ Hz) for the R−PCP and PPh_3 phosphorus nuclei, respectively. In the $^{13}C\{^1H\}$ NMR spectra a small $^2J_{C_{ipso}-PPh_3}$ coupling constant of about 15−20 Hz is observed. These observations establish the *trans*-positioning of the R−PCP phosphorus atoms and the *cis*-arrangement of the R−PCP and PPh_3 phosphorus atoms, and suggest that the square-pyramidal structure of **1** found in the solid state exists in solution as well.

As the complexes **1−3** gave very similar results in the NMR analysis, compound **1** will be used as a representative compound for the following discussion.

^{31}P-^1H Correlation Spectroscopy (^{31}P-^1H-COSY)

The ^{31}P-^1H-COSY NMR spectra of a solution of **1** in CD_2Cl_2 allowed us to readily locate all P−Ph *ortho* protons, see Figure 2.[16] Only three cross-peaks (therefore, only three types of *ortho* protons) were observed in the aromatic region of the ^1H NMR spectrum, one for the PPh_3 ligand and the other two for the H−PCP ligand. This indicates that the four phenyl rings from the H−PCP ligand are divided into two sets of diastereotopic phenyl groups (hereafter labeled as Ph-a and Ph-b) which later could be assigned to the equatorial and axial phenyl groups, respectively (see ^1H NOESY experiments), whereas the phenyl rings of the PPh_3 ligand are equivalent. These findings imply that there is no restricted rotation about any P−Ph bond or about the Ru−PPh_3 bond. Also, no Ru−P bond dissociation-association process is operative on the NMR time scale at room temperature. Consequently, under these conditions there is a *pseudo*-molecular symmetry plane containing the C_{ipso}−Ru−P(PPh_3) atoms.

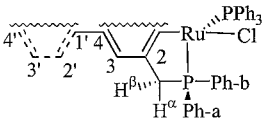
^1H-^1H Correlation Spectroscopy

In the ^1H-^1H-COSY spectrum of the ruthenium complexes **1−3** the location of protons H-3,5 (see Figure 3)[16] could easily be determined due to a cross-peak between these protons and one set of benzylic protons. The related $^4J_{HH}$ indirect coupling between these protons in the one-dimensional 300 MHz ^1H spectrum could not be observed. Interestingly, this behavior is quite general and is not restricted to cyclometalated R−PCP-type ligands. A similar phenomenon was also observed in a ^1H-^1H-COSY analysis involving related nitrogen-based ligands and can be explained by analogy with allylic systems:[17a,18a] the smaller the torsional angle between the benzyl C−H bond and the axis of the arene π-orbitals, the larger is the four-bond coupling. Therefore, the presence of this cross-peak brings interesting structural consequences because it suggests that these benzylic protons are occupying a *pseudo*-axial posi-

tion in the two fused five-membered chelate rings in relation to the ruthenium coordination plane. This idea was later confirmed by a ^{1}H NOESY experiment (see below), and it has become quite important in the structural analysis of [RuCl(H−PCP)PPh$_3$] in which the H−PCP ligand has one of the benzylic protons of each methylene carbon atom replaced by a methyl or ethyl group (i.e., the ligand has two chiral centers in the molecule).[24]

The multiplet at lowest field in the ^{1}H NMR spectrum (between δ = 7.80−7.90 for **1**), showing cross-peaks with the R−PCP phosphorus atoms in Figure 2,[16] integrates to four protons and it was observed by ^{13}C-^{1}H-COSY analysis (Figure 4)[16] to have a cross-peak with only one type of aromatic carbon atom. Therefore, it can be safely assigned as the resonance due to the four *ortho* Ph-a protons. This multiplet shows a cross-peak in the ^{1}H-^{1}H-COSY (Figure 3)[16] with protons located in a second multiplet at δ = 7.30−7.50. The nonexistence of any other cross-peak involving these two regions of the ^{1}H-^{1}H-COSY spectrum allows us to conclude that the *meta* and *para* protons of the Ph-a are overlapping and located in the multiplet at δ = 7.30−7.50.

^{13}C-^{1}H Correlation Spectroscopy



Entering the information gathered so far into normal- and long-range ^{13}C-^{1}H-correlation NMR spectra {and using the assignments of the ^{13}C{^{1}H} NMR spectrum of [RuCl(H-NCN)(PPh$_3$)] (**4**)},[1] it was possible to locate all C−H resonances as well as most of the quaternary carbons (C$_{quat}$) in the ^{1}H and ^{13}C NMR spectra of **1**−**3**. In particular, all proton and carbon resonances of the parent complexes **1** and **2** could be assigned (see Figure 4[16] for **1**). Only in the case of compound **3** could the C$_{quat}$ of the Ph-a rings not be located. Table 1 summarizes all ^{1}H and ^{13}C NMR spectroscopic data and assignments for complexes **1**−**3**.

The presence of an apparent molecular symmetry plane involving C$_{ipso}$−Ru−P(PPh$_3$)−Cl is even clearer in these ^{13}C-^{1}H-COSY NMR spectra. For instance, Figure 4[16] shows that the *ortho*-protons and -carbons of the PPh$_3$ ligand are chemically equivalent (i.e., they have identical chemical shifts) and the same conclusion can be drawn for the *meta* and *para* nuclei. Furthermore, each phenyl group of the −PPh$_2$ fragment has an individual set of resonances related to either Ph-a or Ph-b. However, the *ortho* (or *meta* or *para*) Ph-a protons and carbons appear as single resonances. The same conclusion is valid for the Ph-b group. The *ortho* and *meta* carbon nuclei as well as the C$_{quat}$ of the Ph-a and Ph-b rings give distinct *pseudo*-triplets which is the expected pattern for carbons connected to a *trans* phosphorus atom.[17b,19]

NOE Analysis

More precise information about the three-dimensional structure of species **1**−**3** in solution can be obtained from

Table 1. ^{1}H (300 MHz) and ^{13}C NMR (75 MHz) data of compounds **1**, **2** and **3** in CD_2Cl_2 (relative to internal tetramethylsilane)

		^{1}H (δ, mult., $^2J_{HH}$, $^{vt}J_{HP}$ Hz)			^{13}C (δ, mult., J_{CP} Hz)		
		1[a]	**2**	**3**[b]	**1**	**2**	**3**

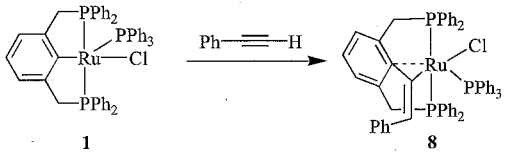
[a] s = singlet, d = doublet, m = multiplet, b = broad and vt = virtual triplet. Non reported multiplicities are related to resonances only detected indirectly by two-dimensional techniques. − [b] See Figure at head of Table. − [c] Splittings due to the virtual triplet not resolved. − [d] One C$_{quat}$ is at δ = 134.03 and overlaps with PPh$_3$ *ortho* carbons. The other is at δ = 135.50 (vt, $^{vt}J_{CP}$ = 17 Hz). It was not possible to determine to which phenyl ring they were related to.

phase-sensitive ^{1}H NOESY measurements. The intensity of cross-peaks originating from dipolar interactions is very sensitive to the distance between the participating nuclei and they are often too weak to be detected when this distance is larger than 3 Å.[18b] A series of ^{1}H NOESY spectra was recorded. The interactions between benzylic and aromatic protons proved to be an excellent structural probe. Figure 5[16] shows this region for compound **1**. Only the benzylic protons at $\delta = 2.36$ (H^{α}) show a cross-peak with the *ortho* PPh_3 protons. This indicates that the PPh_3 ligand is in the apical position, as is observed in the solid state (Figure 1). The high-field chemical shift of H^{α} is then probably caused by a magnetic anisotropic effect originating from the PPh_3 ligand.

NOE correlation signals involving the aromatic protons H-3,5 and both benzylic protons H^{α} and H^{β} are also observed. However, the different intensities of these cross-peaks reveal that H^{β} is closer to protons H-3,5 than H^{α}. This is a clear reflection of the puckering occurring in the two fused five-membered chelate rings. The benzylic protons are not bisecting the xylylene plane. In order to be closer to H-3,5, H^{β} must be in a nearly periplanar conformation with the xylylene plane. H^{α}, on the other hand, is directed toward an *anti*-planar conformation with the same plane (Scheme 3). As a consequence, the H−PCP phosphorus atoms that are occupying the flip of an envelope conformation assumed by each one of the two fused rings, are pointing away from the PPh_3 ligand.



Scheme 3. Spatial interactions involving the benzylic protons in **1**

Protons H^{α} and H^{β} interact almost equally with the *ortho* protons of the Ph-a ring placing the $P-C_{quat}$ bond of Ph-a in an approximately coplanar situation with the plane formed by the $P-CH_2-C$-2 (or -6) bonds. On the other hand, the (weak) interaction between the *ortho* Ph-b protons and the H^{β} protons is consistent with a *pseudo*-axial position of the former.

The same features observed in the NOESY spectrum of **1** were also present in the spectra of complexes **2** and **3**, showing that the presence of different substituents in the *para* position relative to the metal center (H, Ph or Br for **1**, **2** or **3**, respectively) does not affect the geometry around the metal. An analysis of the NOESY spectra also showed that the structures in solution of these complexes are very similar to that found in the solid state for complex **1**.

Discussion

In the case of the unsaturated ruthenium complex $[RuCl_2(PPh_3)_3]$ it has been found in the solid state that one of the *ortho* phenyl protons is directed toward the empty coordination site, blocking this position.[20] The NMR analysis performed with complexes **1**−**3** (and the solid structure of **1** as well) did not reveal any equivalent feature. On the contrary, all Ph-a and Ph-b rings in these complexes are freely rotating and do not exhibit any preferred configuration other than being equatorial or axial, respectively. This suggests that the vacant site *trans* to the PPh_3 ligand is relatively available for the coordination of nucleophilic species. Indeed, a facile reaction between **1** and 4-phenylpyridine (4-PhPy) producing the 18-electron complex [RuCl(H−PCP)(PPh_3)L] (L = 4-PhPy) has been reported.[15] Furthermore, species in which L is either a coordinated phenyl acetylene molecule or a vinylidene substituent [L = PhC(H)=C=] are thought to be involved in the formation of ruthenium complex **8** in the reaction of **1** with phenyl acetylene (Scheme 4).[10]

Scheme 4. Reaction of **1** with phenylacetylene yielding vinylidine-substituted ruthenium complex **8**

Dissociation of PPh_3 is a common phenomenon in ruthenium complexes such as $[RuCl_2(PPh_3)_n]$ ($n = 3$ or 4).[21] However, despite the fact that the PPh_3 ligand in **1**−**3** is easily replaced by two-electron donor ligands (e.g. CO,[15] PMe_3,[15] R−PCHP[23,25]), solutions of the pure complexes did not reveal the presence of any free PPh_3. Furthermore, if intra- or intermolecular processes were operative leading to PPh_3 exchange, they would cause an interchange between the Ph-a and Ph-b protons, as well as between the benzylic protons H^{α} and H^{β}. Nevertheless, cross-peaks indicating fluxional processes were not present in any of the ^{1}H NOESY spectra recorded. Therefore, the replacement of PPh_3 in complexes **1**−**3** by the two-electron donor ligands mentioned above is most likely the result of dissociation of the PPh_3 from saturated species of these complexes.

The chemical shift of the C_{ipso} in complexes of the R−NCN ligand is sensitive toward the type of R substituent.[22] Taking the H−NCN complex as reference (i.e., R = H), downfield shifts greater than 1 ppm in the $\delta_{C_{ipso}}$ of com-

plexes containing electron-withdrawing R groups and the converse effect (i.e., upfield shifts) when electron-donating groups were present. Similar behavior was recently observed in palladium complexes of the pyridine PCP-type ligand [$C_5H_2N(CH_2PPh_2)_2$-3,5] upon coordination of Lewis acidic species to the pyridine nitrogen atom.[9c] In the case of the complexes reported here, the electronic effect of the bromo and phenyl *para* substituents on the C_{ipso} chemical shift is negligible (see Table 1) and probably reflects the buffer effect exerted by π-acidic phosphorus groups on the overall electron density of the complexes.

Conclusion

The results of the present study are currently being applied for the assignment and the understanding of more complex structures containing free and anionic PCP-type ligands, such as compound **7**,[23] ruthenium complexes containing chiral H−PCP type ligands[24] as well as other PCP-metal complexes which have recently been published. The results of these studies will be published shortly.

Experimental Section

Complexes **1, 2**[2] and **3**[25] were prepared according to literature procedures. All manipulations were performed under a dry nitrogen atmosphere using standard Schlenk techniques. Typically, ca. 30 mg of complex was dissolved in 0.7 mL of CD_2Cl_2 and then transferred to a 5 mm NMR tube provided with a glass stopper. Chemical shifts are in ppm relative to $(CH_3)_4Si$ (^1H and ^{13}C NMR spectra) or H_3PO_4 85% (^{31}P NMR spectra). CD_2Cl_2 was degassed prior to use (four times) using the freeze-pump-thaw methodology and then stored under nitrogen over molecular sieves 4 Å. ^1H, $^{13}C\{^1H\}$ and $^{31}P\{^1H\}$ NMR spectra were recorded at 298 K on a Varian Unity Inova 300 MHz spectrometer using standard pulse sequences. Except in the case of the NOESY measurements, all other two-dimensional experiments were performed in a nonphase-sensitive mode. The second pulse in the ^1H-^1H-COSY experiment was set to 45°. Normal-range ^{13}C-^1H-COSY NMR spectra were recorded considering $^1J_{HC} = 140$ Hz and for the long-range experiment the appropriate delays were adjusted for $^nJ_{HC} = 8$ Hz. T_1 times for complexes **1−3** were in the range 0.4−1.5 s. NOESY spectra were recorded with mixing times of 0.5, 1.0 and 1.5 s with a relaxation delay of 2.0 s.

Oxidative Stannylation with $K_6Sn_2Se_6/SnCl_2$: Synthesis and Crystal Structures of $SnCl_3$-Substituted *pseudo*-Tetrahedral Cobalt(III) Complexes

Stefanie Dehnen*[a] and Christian Zimmermann[a]

Keywords: Zintl anions / Cobalt / Oxidation / Tin / Insertions

The ternary Zintl phase $K_6Sn_2Se_6$ was recently shown to mildly oxidize Cp*-ligated Co^{II} complexes, although Sn in the formal +III oxidation state usually tends to be a reducing species. Depending on the reaction conditions, different ratios of Co^{II} and Co^{III} were observed within the product molecules. Cyclovoltammetric investigations indicated that reversible electron transfer occurred between some of the isolated molecules synthesized that way. In order to study the redox behavior of the oxidizing Sn^{III} species in the reaction system, large excesses of Sn^{II} were added to the solvent THF. A suppression of the $Co^{II} \rightarrow Co^{III}$ transition was expected if the oxidation was reversible. Herein we report the synthesis and crystal structures of $[Co_2(\mu\text{-}Cl)_3(thf)_6][CoClCp^*(SnCl_3)_2]$ (**1**) and $[Li(thf)_4][CoCp^*(SnCl_3)_3]$ (**2**) formed from reactions of $[CoClCp^*]_2$ with $K_6Sn_2Se_6$ in the presence of $SnCl_2$ in THF. The results show that oxidation could not be inhibited, indicative of irreversible redox mechanisms. Additionally, one observes the formal insertion of $SnCl_2$ units in Co–Cl bonds. For completion of the 18-electron configuration, the Cp^*Co^{III} 14-electron fragment forms sterically strained anionic structures that may in the future be relevanct as precursors for the formation of Cp*Co-coated heteroatomic aggregates. Furthermore, the cation in **1** is one of the few examples of threefold μ_2-bridged binuclear Co^{II} complexes.

Introduction

In the course of our current studies on the chemical reactivity of binary Zintl anions, we recently synthesized and structurally characterized compounds $[Co_3Cp^*_3(\mu_3\text{-}Se)_2]$, $[Co_3Cp^*_3(\mu_3\text{-}Se)_2][CoCl_2(\mu\text{-}Cl)_2Li(thf)_2]$, and $[Co_4Cp^*_4(\mu_3\text{-}Se)_4]$ which were obtained from reactions of ternary Zintl salt $K_6Sn_2Se_6$[1] with $[CoClCp^*]_2$ under different reaction conditions.[2] Due to unusual oxidation by Sn in the formal +III oxidation state, both Co^{II} and Co^{III} were observed in the mixed valence products as well as Se^{2-} ligands from $K_6Sn_2Se_6$. In order to explore whether the occurring redox processes (which have been shown to be reversible for the isolated products) – can be suppressed by addition of Sn^{II}, we treated $K_6Sn_2Se_6$ with $[CoClCp^*]_2$ in the presence of large excesses of $SnCl_2$ (see Experimental Section). The use of different ratios of Co^{II}/Sn^{II} and slightly varied reaction conditions yielded compounds $[Co_2(\mu\text{-}Cl)_3(thf)_6][CoClCp^*(SnCl_3)_2]$ (**1**) or $[Li(thf)_4][CoCp^*(SnCl_3)_3]$ (**2**) in good yields [Equation (1) or Equation (2)]. Compounds **1** and **2** were structurally characterized by single-crystal X-ray analysis.[3]

$$K_6Sn_2Se_6 + 4\ SnCl_2 + 6\ CoCl_2 + 2\ LiCp^* \xrightarrow{\text{THF}} 2\ [Co_2(\mu\text{-}Cl)_3(THF)_6][CoClCp^*(SnCl_3)_2] + 3\ K_2Se + 2\ SnSe + Li_2Se \quad (1)$$

(**1**)

$$K_6Sn_2Se_6 + 7\ SnCl_2 + 2\ CoCl_2 + 2\ LiCp^* \xrightarrow{\text{THF}} 2\ [Li(THF)_4][CoCp^*(SnCl_3)_3] + 3\ K_2Se + 3\ SnSe \quad (2)$$

(**2**)

However, instead of suppressing the oxidative effect of $K_6Sn_2Se_6$ by excess Sn^{II}, Co^{II} was again partly oxidized to Co^{III}, while $SnCl_2$ was formally inserted in Co–Cl bonds in both cases. However, the formation of the counterion $[Co_2(\mu\text{-}Cl)_3(thf)_6]^+$ is evidence of a stepwise mechanism, rather than of a direct insertion. This was possibly initialized by the partial ionization of $CoCl_2$ in THF giving $CoCl^+$ and Cl^-, followed by the aggregation of THF-solvated $CoCl^+$ with $CoCl_2$ to yield $[Co_2(\mu\text{-}Cl)_3(thf)_6]^+$, while Cl^- reacted with $SnCl_2$ to form the $SnCl_3^-$ anion. The latter finally coordinated to the Cp*-ligated Co^{III} center resulting from the oxidation reaction. Although we were not yet in the position to identify all reaction by-products with certainty, one further hint existed for the reduction of the Sn centers to Sn^{II} rather than for an oxidation to Sn^{IV}: Small $SnSe^+$ peaks were always found in the mass spectra of the primary reaction precipitates, whereas no further Sn products – such as $SnCl_4$, $SnSe_2$ or $SnCl_2$ – were observed either in the mass spectrum or in the NMR measurement of the reaction solution. Moreover, unwanted oxidation of Co^{II} by traces of oxygen in the reaction mixture can be excluded as the products are not formed by means of pure selenide donors such as K_2Se or $Se(SiMe_3)_2$ instead of $K_6Sn_2Se_6$. The observations ultimately suggest the irreversibility of the oxidation by Sn^{III} in the investigated system which correlates with the precipitation of insoluble SnSe during the reaction.

A $[Co_2(\mu\text{-}Cl)_3(thf)_6]^+$ complex similar to the cation in **1** was already reported by Sobola and co-workers[4] but has, in contrast to the analog iron and nickel species,[4,5] not yet been structurally determined. The molecular structure of the complex cation in **1** is shown in Figure 1.

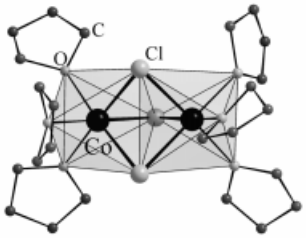

Figure 1. Molecular structure of the cation in **1** in the crystal; the drawn polyhedra illustrate the octahedral environment around the Co centers; H atoms are omitted for clarity; selected distances [pm] and angles [°]: Co−Cl 242.6(6)−248.0(6), Co−O 207.6(2)−216.0(2), Co···Co 302.4(4); Cl−Co−Cl 85.4(2)−86.8(2), O−Co−O 87.2(6)−91.4(5), O−Co−Cl(*cis*) 90.1(4)−95.5(4), O−Co−Cl-(*trans*) 175.7(4)−179.2(4)

Three oxygen atoms and three μ_2-Cl ligands surround the two Co atoms to form two face-sharing octahedra. Featuring nearly perfect octahedral angles, a slight trigonal compression results from the Co−O distances being naturally shorter than the Co−Cl bonds. The cation in **1** represents one of the few examples of octahedrally coordinated Co^{II} ions and also of threefold μ_2-bridged binuclear Co^{II} complexes. Another example is a cation coordinated terminally by 1,4,7-trimethyl-1,4,7-triazacyclononan.[6] More frequently, either the terminal ligands are negatively charged as in $[Co_2(\mu\text{-}Cl)_3(C_5Me_4R)_2]^+$ (R = Me, Et)[7,8] and thus give reason for a Co^{III} compound, or the Co^{II} complex is only doubly μ_2-Cl bridged, leading to the preferred tetrahedral coordination pattern. For instance, the latter is found in $[Co_2Cl_4(\mu\text{-}Cl)_2]^{2-}$,[9,10] in the trinuclear dianion $[\{CoCl_2\}_2\{Co(thf)_2\}(\mu_2\text{-}Cl)_4]^{2-}$ [11] or in the tetranuclear complex $[\{CoCl(thf)\}_2\{Co(thf)_2\}_2(\mu\text{-}Cl)_6]$.[12]

The anions in **1** (Figure 2) or **2** (Figure 3) are strongly related and only differ in one ligand at the Co center. Formal substitution of one $SnCl_3$ group in **2** for a Cl ligand in **1** correlates with the larger excess of $SnCl_2$ in the reaction mixture yielding **2** relative to that in the reaction leading to **1**. Both structures exhibit 18 electrons at the Co atom.

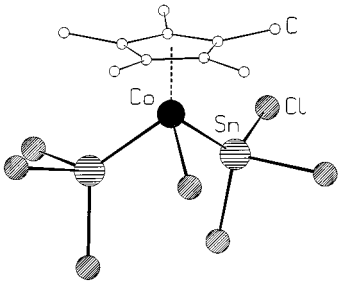

Figure 2. Molecular structure of the anion in **1** in the crystal; H atoms are omitted for clarity; selected distances [pm] and angles [°]: Co−Sn 247.4(3)−247.5(3), Sn−Cl 235.0(7)−240.3(7), Co−Cl 224.1(7), Co−C 207.1(2)−209.3(3); Sn−Co−Sn 96.2(1), Sn−Co−Cl 83.4(2)−87.2(2), Sn−Co−Cp*(*centroid*) 124.8(3)−127.1(2), Cl−Co−Cp*(*centroid*) 125.5(2), Cl−Sn−Cl 94.8(3)−97.6(3), Co−Sn−Cl 112.4(2)−125.9(2)

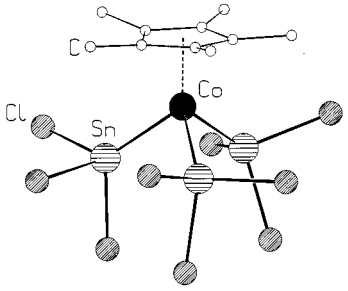

Figure 3. Molecular structure of the anion in **2** in the crystal; H atoms are omitted for clarity; selected distances [pm] and angles [°]:Co−Sn 247.1(1)−248.1(1), Sn−Cl 234.2(7)−241.1(5), Co−C 209.1(8)−215.1(7); Sn−Co−Sn 90.8(4)−93.6(4), Sn−Co−Cp*(*centroid*) 122.6(3)−125.8(3), Cl−Sn−Cl 91.3(1)−100.4(1), Co−Sn−Cl 114.1(1)−126.3(2)

In the complex anions, one Cp* ring and three further ligands *pseudo*-tetrahedrally coordinate the Co atom. Due to the steric demand of the Cp* groups, the angles around the Co center enclosed by the other ligands decrease by more than 13° with regard to the ideal tetrahedral angle of 109.47°. Steric problems that occur in the structures become clear when considering the Sn−Co−Cl angles in **1** which are narrowed even beyond orthogonal angles. In **2**, three bulky $SnCl_3$ groups inhibit this relaxation. The Sn atoms, two in **1** or three in **2**, are also placed in the center of distorted rather than ideal tetrahedra. Cl−Sn−Cl angles that are at least 9° smaller than 109.47° correspond to Cl−Sn−Co angles somewhat more obtuse than perfect tetrahedral angles. Showing similar Co−Sn bond lengths, the steric influence of the different substituents in the anions of **1** or **2** can mainly be seen from slightly elongated Co−C distances in **2** with regard to the corresponding distances in **1**.

Besides the fact that the syntheses of partly oxidized **1** and **2** suggest that the mild oxidant $K_6Sn_2Se_6$ acts irreversibly, the anions in the described products could also be relevant for another reason. Similar to other organometal-substituted tin halides, both complexes could serve to synthesize heteroatomic aggregates ligated by organometallic fragments. For example, compounds of the type $[ML_n(SnCl_3)]$ (L = Cp, CO, PR_3; R = organic group; M = Fe, Ni)[13,14] or $[(ML_n)_2(SnCl_3)_2]$ (L = Cp, CO; M = Fe, Co)[15,16] that are obtained in analogous insertion reactions (without redox processes) of either $[Cp(CO)_2Fe]Cl$, $[Co(CO)_4]Cl$ or $[NiCp(PPh_3)]Cl$ with $SnCl_2$, form organometallic saturated binary rings or cages when reacted with silylated chalcogens $E(SiMe_3)_2$ (E = S, Se, Te) or Na_2Se.[17] However, whereas the L_nM fragments of the quoted compounds contain 17 valence electrons and therefore provide only one metal−chlorine bond each for insertion of $SnCl_2$, the Cp^*Co^{III} fragments in **1** and **2** formally exhibit 14 valence electrons at the Co center. Thus, owing to the larger electronic requirements, one observes the coordination to three $SnCl_3$ units or to two $SnCl_3$ units and one Cl ligand. Whether these molecules can aggregate with silylated main-group elements, or whether the *ipso* position of two or even three $SnCl_3$ ligands at the metal center would result in a sterically overloaded product shall be further investigated.

Experimental Section

All reactions were carried out with exclusion of air and moisture, either under dry nitrogen or under argon (glove box). All solvents were dried and freshly distilled prior to use.

$[Co_2(\mu\text{-}Cl)_3(thf)_6][CoClCp^*(SnCl_3)_2]$ (1): $CoCl_2$ (26 mg, 0.20 mmol) and LiCp* (28 mg, 0.20 mmol) were stirred at room temperature for 20 min in THF (2 mL), resulting in a brown−black solution of $[CoClCp^*]_2$. After cooling down to −40 °C, $SnCl_2$ (133 mg, 0.70 mmol) in THF (1.5 mL) was added. During warming up to room temperature, the color changed to dark brown. Addition of $K_6Sn_2Se_6$ (28 mg, 0.03 mmol) at −78 °C terminated the synthesis. After 10 weeks at −40 °C, bundles of fine blue−black needle-like crystals of **1** appeared; yield: 0.071 g (0.053 mmol; 80%). − $C_{34}H_{63}Cl_{10}Co_3O_6Sn_2$ (1336.621): calcd. C 30.55, H 4.75; found C 30.52, H 4.68.

$[Li(thf)_4][CoCp^*(SnCl_3)_3]$ (2): $CoCl_2$ (78 mg, 0.60 mmol) and LiCp* (85 mg, 0.60 mmol) were stirred at room temperature for 20 min in THF (2 mL), resulting in a brown−black solution of $[CoClCp^*]_2$. A saturated solution (6 mL) of $SnCl_2$ (1.950 g, 10.28 mmol) in THF was added, causing a color change to dark blue. $K_6Sn_2Se_6$ (95 mg, 0.10 mmol) was introduced into the reaction mixture at −78 °C. After addition of 10 mL of toluene, the sample was stored at −40 °C. Within one week, large red−black cube-like crystals of **2** were found; yield: 454 mg (0.39 mmol; 65%). − $C_{26}H_{47}Cl_9CoLiO_4Sn_3$ (1164.739): calcd. C 26.81, H 4.07; found C 26.97, H 4.02.

Tri(supersilyl)dialanyl $(t\mathrm{Bu_3Si})_3\mathrm{Al_2}^{\bullet}$ and Tetra(supersilyl)cyclotrialanyl $(t\mathrm{Bu_3Si})_4\mathrm{Al_3}^{\bullet}$ − New Stable Radicals of a Group 13 Element from Thermolysis of $(t\mathrm{Bu_3Si})_4\mathrm{Al_2}$

Nils Wiberg,*[a] Thomas Blank,[a] Wolfgang Kaim,[b] Brigitte Schwederski,[b] and Gerald Linti[c]

Keywords: Ab initio calculations / Aluminum / ESR Spectroscopy / Radicals / Silicon

The thermolysis of tetra(supersilyl)dialane $R^{*}{}_2Al–AlR^{*}{}_2$ (R^{*} = $SitBu_3$ = Supersilyl) in heptane or cyclohexane at 50 °C leads under Al–Al dissociation reversibly to monoalanyl radicals $[R^{*}{}_2Al]^{\bullet}$, which could be trapped by hydrogen or iodine (formation of $R^{*}{}_2AlH$, $R^{*}{}_2AlI$). Simultaneously, SiAl dissociation and elimination of supersilyl radicals $t\mathrm{Bu_3Si}^{\bullet}$ leads irreversibly and slowly to radicals $[R^{*}{}_2Al–AlR^{*}]^{\bullet}$, the existence of which could be established by ESR spectroscopy. The structure was clarified by ab initio calculations (nearly planar $Si_2Al–AlSi$ and linear Al–Al–Si skeleton; short Al–Al distance). By thermolyzing $R^{*}{}_2Al–AlR^{*}{}_2$ at 100 °C, the radical $[R^{*}{}_4Al_3]^{\bullet}$ (ESR spectroscopically detected) and the *tetrahedro*-tetraalane $R^{*}{}_4Al_4$ (NMR spectroscopically seen) are formed via radicals $[R^{*}{}_3Al_2]^{\bullet}$; the supersilyl radicals $t\mathrm{Bu_3Si}^{\bullet}$, formed at the same time, are stabilized by dimerization to superdisilane $R^{*}–R^{*}$ and by taking up hydrogen, giving supersilane $R^{*}–H$. According to X-ray structure analysis, the Al atoms in $[R^{*}{}_4Al_3]^{\bullet}$ are located at the corners of a triangle; one Al atom is connected with two groups R^{*}, the remaining two Al atoms each bind one substituent R^{*} in different ways.

Introduction

Unlike aluminum triorganyls R_3Al with aluminum in the oxidation state III, which were synthesized for the first time in the middle of the 19th century,[1] aluminum organyls R_mAl_n with aluminum in the oxidation state < III were unknown for a long time because of their high tendency for disproportionation into R_3Al and Al.[2,3] Therefore, dehalogenations of diorganylaluminum chlorides R_2AlCl with substituents R of *lower to medium bulkiness* like CH_2R' (R' = H, Me, Et, CMe_3, $SiMe_3$) or 2,4,6-$Me_3C_6H_2$ lead to R_3Al and Al. The results were interpreted as disproportionations of intermediately formed tetraorganyldialanes R_4Al_2.[2] According to Equation (1), the latter disproportionations may proceed via aluminum cluster compounds R_mAl_n, which are formed from starting materials with a higher *m*/*n* ratio and transform into products with a lower *m*/*n* ratio.

$$3\ R_4Al_2 \xrightarrow{-(\text{over } R_mAl_n)} 4\ R_3Al + 2\ Al\ (\text{or } 6\ R_2 + 6\ Al) \quad (1)$$

The substituents R in R_2AlCl with *higher bulkiness* like $CH(SiMe_3)_2$ or 2,4,6-$iPr_3C_6H_2$ inhibit this disproportionation. As a result of this, the dehalogenation of R_2AlCl stopped under normal conditions at the tetraorganyldialanes R_4Al_2 with aluminum in the oxidation state II.[2] Exactly the same holds for the bulky substituent Supersilyl (R^{*} = $SitBu_3$), which also allows the isolation of a dialane(4), namely tetra(supersilyl)dialane $R^{*}{}_4Al_2$ (**1**), at room temperature.[4] At higher temperatures, compound **1**, amongst others, decomposes into the *tetrahedro*-tetraalane $R^{*}{}_4Al_4$ with aluminum in the oxidation state I (and the *m*/*n* ratio decreases from 2 to 1).[4]

In this paper, two established intermediates of the mentioned dialane(4) thermolysis will be introduced, namely the dialanyl radical $R^{*}{}_3Al_2^{\bullet}$ (**2**) and the cyclotrialanyl radical $R^{*}{}_4Al_3^{\bullet}$ (**3**). The starting material $R^{*}{}_4Al_2$ (**1**) required for the thermolysis is − as was recently reported − easily prepared in quantitative yields by reaction of supersilyl sodium NaR* with aluminum trihalides AlX_3 (X = Cl, Br) in heptane at room temperature according to Equation (2):

$$6\ NaR^{*} + 2\ AlX_3 \rightarrow R^{*}{}_4Al_2\ (\mathbf{1}) + R^{*}R^{*} + 6\ NaX \quad (2)$$

Isolable reaction intermediates in the formation of the red **1** are yellow di(supersilyl)aluminum halides $R^{*}{}_2AlX$ ($AlX_3 + 2\ NaR^{*} \rightarrow R^{*}{}_2AlX + 2\ NaX$).[5] Excess supersilylsodium converts $R^{*}{}_2AlX$ into the radicals $R^{*}{}_2Al^{\bullet}$ and $R^{*\bullet}$, which, for steric reasons, cannot combine to form R_3Al, but

instead dimerize to $R^*_2Al-AlR^*_2$ and R^*R^* according to Equation (3) (see also Scheme 1):

$$2\,R^*_3AlX + 2\,NaR^* \rightarrow 2\,R^*_2Al^\bullet + 2\,NaX + 2\,R^{*\bullet} \rightarrow \mathbf{1} + 2\,NaX + (R^*)_2 \quad (3)$$

Formation of Dialanyl Radicals $R^*_4Al_3^\bullet$ and Cyclotrialanyl Radicals $R^*_4Al_3^\bullet$

The first step of thermolysis of **1** may involve a homolytic dissociation of the Si−Al or the Al−Al bonds (cf. Scheme 1). Mild warming of **1** in heptane or cyclohexane to 50 °C leads by fast and reversible Al−Al bond dissociation to the di(supersilyl)alanyl radical $R^*_2Al^\bullet$ in low equilibrium concentration. This is supported − as we mentioned previously[4] − by the reaction of **1** with hydrogen or iodine which leads to di(supersilyl)alane R_2AlH or di(supersilyl)aluminum iodide R^*_2AlI (cf. Scheme 1). In the absence of trapping reagents for $R^*_2Al^\bullet$ and by heating the solution to 80 °C, compound **1** slowly but irreversibly gives the tri(supersilyl)dialanyl radicals $R^*_3Al_2^\bullet$ (**2**) by Si−Al bond dissociation. The latter transforms slowly and irreversibly into the tetra(supersilyl)cyclotrialanyl radical $R^*_4Al_3^\bullet$ (**3**) and tetra(supersilyl)-*tetrahedro*-tetraalane $R^*_4Al_4$ (**4**) (Scheme 1). Thereby, compound **3** may be formed by reaction of **2** with $R^*_2Al^\bullet$, and compound **4** by reaction of **2** with itself. The simultaneously obtained supersilyl radicals $R^{*\bullet}$ dimerize to superdisilane R*−R* (cf. Scheme 1). After heating **1** in heptane or cyclohexane for 4 hours at 70 °C, the dialane(4) is completely decomposed and the black-green solution then contains **2, 3** and **4**, as well as $(R^*)_2$.

By heating the solution to 100 °C, or by heating compound **1** for 10 hours in heptane at 100 °C (reflux), the intermediately formed **2** transforms completely into **3** and red-violet **4** (cf. Scheme 1; $R^*_4Al_4$ has been prepared previously by a different method and is well characterized).[6] At the same time the superdisilane $(R^*)_2$ present in the mixture decomposes slowly into supersilyl radicals, which are then stabilized by abstracting H atoms from the chemical surroundings (formation of supersilane R*−H; cf. Scheme 1). Compound **3** crystallized after two months from a heptane solution as black-green, paramagnetic, moisture- and air-sensitive crystals. Heating **3** in heptane at higher temperatures transforms the radicals into other products, the identities of which are currently being investigated.

Scheme 1. Thermolysis of tetra(supersilyl)dialane **1**

It should be mentioned here that the heavier homologue of **2**, tri(supersilyl)digallanyl $R^*_3Ga_2^\bullet$ forms so easily that the initial stage, tetra(supersilyl)digallane $R^*_4Ga_2$, is not isolable.[7] Thermolysis of $R^*_3Ga_2^\bullet$ in heptane at 100 °C leads exclusively to tetra(supersilyl)-*tetrahedro*-tetragallane $R^*_4Ga_4$.[8] This fact supports our proposal in Scheme 1 that the tetrahedranes $R^*_4E_4$ (E = Al, Ga) are formed by reaction of $R^*_3E_2^\bullet$ with $R^*_3E_2^\bullet$, and the cyclic radicals $R^*_4E_3^\bullet$ by reaction of $R^*_3E_2^\bullet$ with $R^*_2E^\bullet$ (not present in the case of $R^*_3Ga_2^\bullet$); in fact, $R^*_4Ga_3^\bullet$ has been prepared by another route). However, other mechanisms are also imaginable. Interestingly, dilute solutions of **1** form the *tetrahedro*-tetrahedrane **4** under the action of light.

Unlike $R^*_4Al_2$ and $R^*_3Ga_2^\bullet$, tetra(supersilyl)diindane $R^*_4In_2$ thermolyzes in heptane at 100 °C within 18 hours to octa(supersilyl)dodecaindane $R^*_8In_{12}$.[9] The diindanyl $R^*_3In_2^\bullet$ and cyclotriindanyl $R^*_4In_3^\bullet$ radicals, which may be reaction intermediates, have not yet been observed by ESR spectroscopy [tetra(supersilyl)-*tetrahedro*-tetraindane $R^*_4In_4$ is not formed under these conditions].

Structure and ESR Spectrum of Dialanyl Radicals $R^*_3Al_2^\bullet$ (2)

As mentioned above, the thermolysis of **1** in heptane leads to compounds **2**, **3** and **4**. Until now, only compound **3** has been isolated as crystals from such solutions.

According to ab initio calculations at the RI-DFT level, the structure of the radical **2** is comparable to the structure of the black-blue radical $R^*_3Ga_2^\bullet$, which has previously been examined by an X-ray structure analysis.[7] Figure 1 shows the results of these calculations[10] together with selected bond lengths for $R^*_3Al_2^\bullet$ (ab initio calculation) and $R^*_3Ga_2^\bullet$ (X-ray structure analysis). Both radicals show almost a planar Si_2E-ESi skeleton (sum of angles at E1 = Al1/Ga1 359.7/359.3°); in addition, the E−E−Si skeleton is nearly linear (angles at E2 = Al2/Ga2 174.9/170.0; the E1−E2−Si3 plane is nearly orthogonal to the Si1−E1−Si2 plane). In both cases the E−E distance is comparatively short. This points to an E−E bonding order greater than one. The observed shortening of the E−E bond length in the order $R^*_3Al_2^\bullet \rightarrow R^*_3Ga_2^\bullet$ (2.537 → 2.423 Å; difference 0.114 Å) may be due to a reduction of the radius or of the charge separation in the order Al → Ga [analogously, the E−E single bond length decreases in the order $Disyl_4Al_2 \rightarrow Disyl_4Ga_2$: 2.660 → 2.541 Å; difference 0.119 Å;[2] Disyl = $CH(SiMe_3)_2$]. According to this, $R^*_3E_2^\bullet$ contains sp^2- and

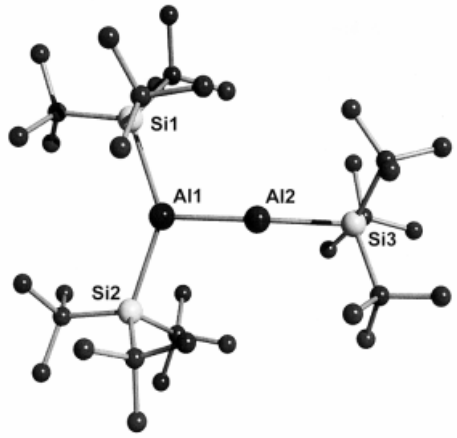

Figure 1. Structure of $R^*_3Al_2^\bullet$ (**2**) from RI-DFT calculations; selected calculated bond lengths [Å] and angles [°] (in brackets, for comparison, analogous bond lengths and angles for $R^*_3Ga_2^\bullet$; in the latter case, the mean values of two independent molecules in the cell): Al1−Al2 2.537 (2.423), Al1−Si1 2.583 (2.513), Al1−Si2 2.571 (2.499), Al2−Si3 2.562 (2.504); Al2−Al1−Si1 107.87 (109.32), Al2−Al1−Si2 109.58 (109.90), Si1−Al1−Si2 142.21 (140.44), Al1−Al2−Si3 174.90 (170.03)

sp-hybridized E atoms, which are connected via two-electron σ- and one-electron π-bonds.

The constitution of **2** is deduced from the ESR spectrum of solutions in pentane or cyclohexane. Well-resolved spectra of **2** are only obtained from alkane solutions of the dialane **1**, which always contain traces of the radical **2**, but no traces of the radical **3**.

Solutions of $R^*_2Al-A1R^*_2$ in alkanes exhibit a simple room-temperature ESR spectrum for the paramagnetic species $[R^*_2Al-A1R^*]^\bullet$. The hyperfine coupling of the unpaired electron with the two- and the three-coordinate aluminum atom (^{27}Al, nuclear spin $I = 5/2$, 100% nat. abundance) is rather similar and leads to groups of peaks with from one to six EPR lines (Figure 2a). The observed coupling constants are $a(Al1) = 2.18$ mT and $a(Al2) = 1.89$ mT; the isotropic g factor is 2.0011 (cf. Figure 1 for atom numbering and Figure 2b for simulation of the ESR spectrum). As described for a number of related radicals,[7,11,12] $[R^*_2Al-AlR^*]^\bullet$ shows a strong anisotropic broadening of the outer lines (Figure 2a). The reason for this known effect is the comparatively slow rotation of the heavy molecule in solution as a result of the large moment of inertia. Therefore, strong anisotropic contributions of the g factor and hyperfine tensors, which result from the π character of the radical electron, are not completely averaged out at room temperature. The strikingly small difference between the two ^{27}Al coupling constants does not allow a clear assignment. Obviously, the π character of the unpaired electron at the center of the two-coordinate Al atom leads to a comparatively low $a(^{27}Al)$ value, whereas the center of the three-coordinate approximately non-radical Al atom has a rather high coupling constant. The latter follows from spin polarization and from the bulkiness of the supersilyl group which may favor a large spin density. The stronger participation of s contributions is illustrated by the generally higher coupling constants for $[R^*_2Al-AlR]^\bullet$ compared to those of

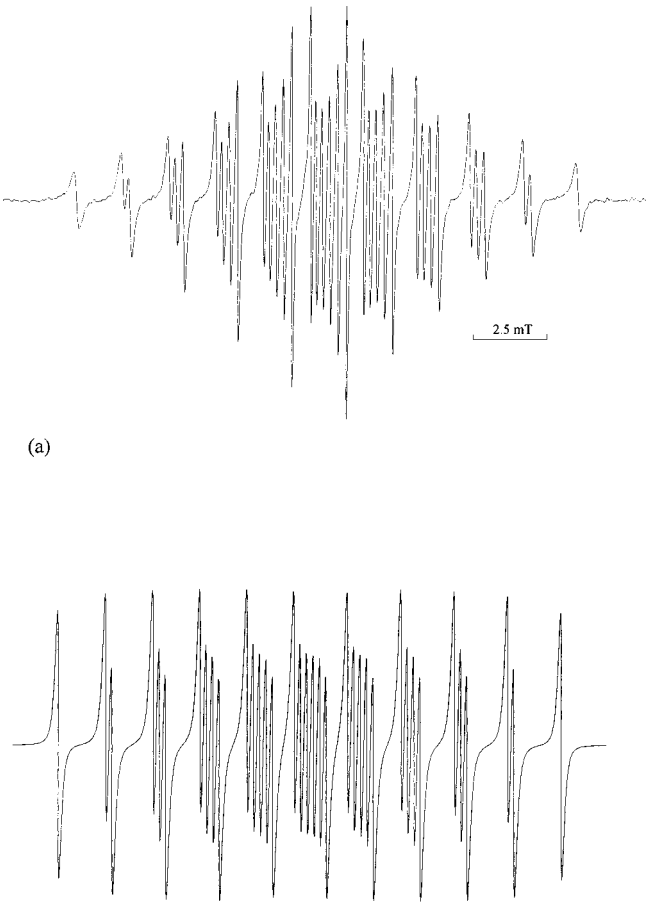

Figure 2. ESR spectrum of **2** in *n*-pentane: (a) with strong anisotropic broadening of lines, and (b) its simulation with hyperfine coupling constants $a(Al1) = 2.18$ mT and $a(Al2) = 1.89$ mT

$[R_2Al-AlR_2]^{\bullet-}$ [R′ = $CH(SiMe_3)_2$; $a(^{27}Al) = 1.11$ mT]. As the g factor differs only slightly from g (electron) = 2.0023, the radical $[R^*_2Al-AlR^*]^\bullet$ must be a π-radical. The deviation to lower g agrees with observations for the radical $[R^*_2Ga-GaR^*]^\bullet$, which shows clearer effects as a consequence of the higher spin-orbit coupling factor for gallium.[7]

Structure and ESR Spectrum of the Cyclotrialanyl Radical $R^*_4Al_3^\bullet$ (3)

The structure of the radicals $R^*_4Al_3^\bullet$ (**3**) in the black-green crystals (monoclinic; obtained from heptane) is shown in Figure 3, together with selected bond lengths and angles. According to this figure, the position of the atoms Al1 and Al3 is split. The Me groups of the *t*Bu groups at Si2 were refined in the split positions with occupancy factors of 0.5; Al1 and Al2 also have occupancy factors of 0.50. Evidently, the three Al atoms occupy the corners of a triangle with two longer sides (average Al−Al distance: 2.756 Å) and a slightly shorter base (Al−Al distance: 2.703 Å). The atom Al2 at the top of the triangle binds two supersilyl groups and each Al atom of the base is connected

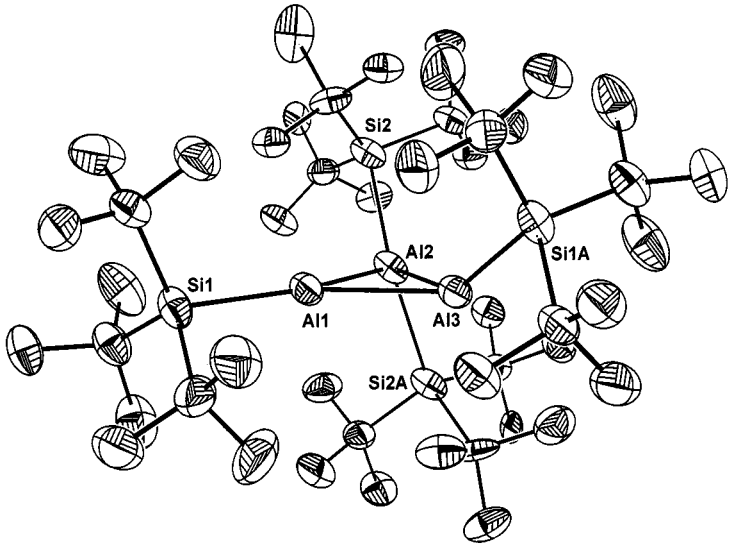

Figure 3. Structure of radicals $R^*_4Al_3^\bullet$ (**3**) in the crystal and atom numbering used (ORTEP-Plot; 25% thermal probability ellipsoids; H atoms omitted for clarity); selected distances [Å] and angles [°] in the structure of radical **3** with standard deviations (the positions of Al1 and Al2 are doubly split): Al1−Al2 2.737(2), Al1−Al3 2.703(3), Al2−Al3 2.776(2), Al1−Si1 2.519(1), Al2−Si2 2.556(1), Al3−Si3A 2.586(2); Al2−Al1−Al3 61.35(6), Al1−Al2−Al3 58.33(8), Al2−Al3−Al1 59.92(7), Si1−Al1−Al2 152.6(1), Si1−Al1−Al3 146.0(1) (angle sum at Al1 359.9), Si1A−Al3−Al2 44.5(1), Si1A−Al3−Al1 123.6(1) (angle sum at Al3 328.0), Si2−Al2−Al1 110.48(6), Si2−Al2−Al3 125.47(6), Si2A−Al2−Al1 107.66(6), Si2A−Al2−Al3 90.71(6), Si2−Al2−Si2A 137.28(8)

to only one supersilyl group. The structural data may be interpreted by assuming that the R*Al groups are more weakly bonded to R^*_2Al than to each other [cf. the Al−Al distance in $R^*_4Al_2$ (2.751 Å)].[4] If the R^*_2Al group provides one and each R*Al group two electrons for the Al_3 framework, there are 5 electrons available for the Al_3 cluster. Possibly, the radical electron acts as a π-electron for the connection of the two R*Al groups. Intuitively, one might argue that the observed geometry of **3** looks as if cyclisation of *catena*-$[R^*_2Al-R^*Al-AlR^*]^\bullet$ (a derivative of **2** with one R* exchanged by R^*_2Al) − in the course of which the connection of R*Al−AlR* becomes weather, the connection $R^*_2Al\cdots AlR^*$ becomes stronger − is stopped half way on the reaction coordinate (cf. ab initio calculations).

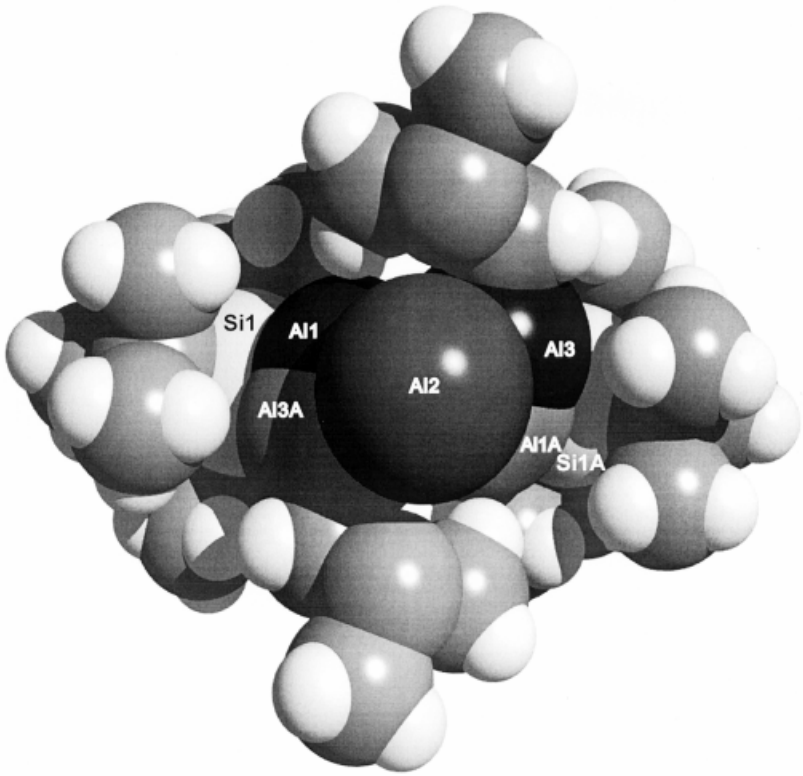

Figure 4. Space filling model of the radical **3** (Si2 and Si2A each with two *t*Bu groups are omitted for clarity)

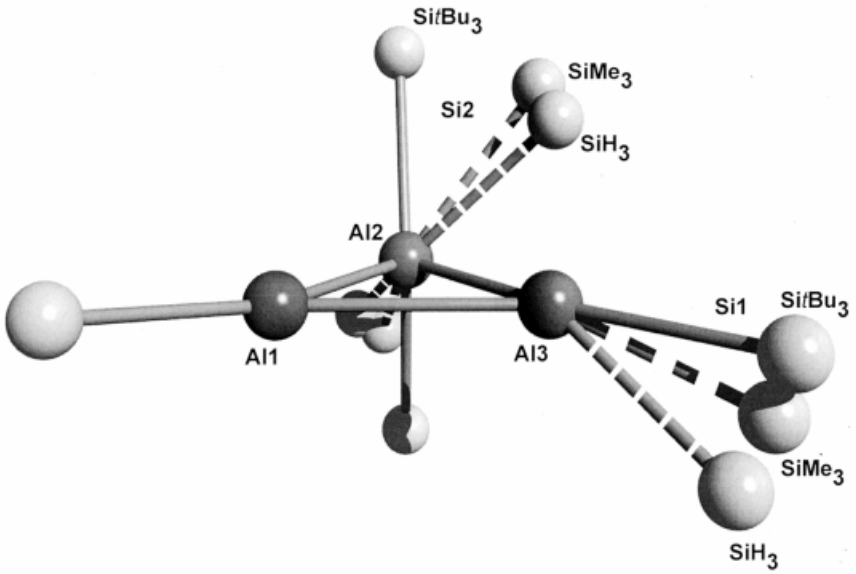

Figure 5. Structure of $R^*_4Al_3^\bullet$ with R = SiH_3, $SiMe_3$, $SitBu_3$ as derived from RI-DFT calculations;selected calculated bond lengths [Å] and angles [°] in each case for $(H_3Si)_4Al_3^\bullet$/$(Me_3Si)_4Al_3^\bullet$/$(tBu_3Si)_4Al_3^\bullet$: Al1−Al3 2.532/2.645/2.902, Al1−Al2 2.489/2.463/ 2.625, Al2−Al3 3.065/2.560/2.623, Si1−Al3 2.798/2.908/4.292; angle sum at Al1 356.80/ 349.50/360.00, angle sum at Al3 334.43/359.75/360.00

According to Figure 3, the four Si atoms of the supersilyl groups of **3** occupy the corners of a tetrahedron with five edges of roughly equal length (average Si−Si distance: 6.321 Å) and one shorter side which is connected to the atom Al2 in its center (Si−Si distance: 4.760 Å). The reason for the nearly regular tetrahedral packing of the supersilyl groups comes probably from considerable van der Waals attraction between the methyl groups of the substituents R*.[13]

The Al atoms of the Al_3 ring now fill up the interstices of the $(R^*)_4$ entity, whereby an arrangement of two planar three-coordinated atoms Al1 and Al3 and, at the same time, of a tetrahedral four-coordinated atom Al3 is obviously impossible. Consequently, in order to fill cavities in the $(R^*)_4$ entity (cf. Figure 4), one of the three-coordinated Al atoms is planar, the other one is pyramidal and the planar Si_2Al is not orthogonal to the plane of Al_3 (cf. Figure 3). Over and above that, the splitting positions of the two atoms Al1 and Al3 point to a fast structural fluctuation of the conformations of the mentioned atoms.

An ab initio calculation (RI-DFT) of the structure of radical **3** differs from the experimentally observed one in several points (cf. Figure 5); in particular, Al2 is tetrahedrally coordinated whereas Al1 and Al3 are each planar coordinated. In addition, the calculated Al1−Al3 distance is much longer than the other Al−Al bonds, contrary to the bonding situation in the experimentally observed structure of **3** (on the other hand, $R^*_4Ga_3^\bullet$ shows the predicted structure). Whether this predicted open chain structure is the global minimum was not checked, although it resulted during minimization of the energy, starting from the experimental structure. The structure of radicals $R_4Al_3^\bullet$ proved to be dependent on the bulkiness of the four substituents. Therefore, a decrease of bulkiness of the four substituents leads, according to ab initio calculations, to a bonding relation of an Al2 bonded silyl group to Al1 or Al3 (cf. Figure 5), that is a bridging position of a silyl group.

In the ESR spectrum of very dilute solutions of **1** in C_6D_{12} at 80 °C, the typical hyperfine structure of the signal for the radical **2** is observed (Figure 2a). After a few minutes this spectrum disappears. Solutions which are thermolyzed in C_6D_{12} at 80 °C for longer periods of time exhibit a low resolution ESR spectrum: many lines separated by about 1.1 mT are now seen. Obviously, two ESR signals from two different radicals overlap. After leaving this solution for a long time at room temperature, radical **2** reappears in the ESR spectrum. Finally, an ESR spectrum of a dilute solution of pure, isolated radical **3** is shown in Figure 6 (the fact that no NMR signal is detected from this solution confirms the radical character of **3**).

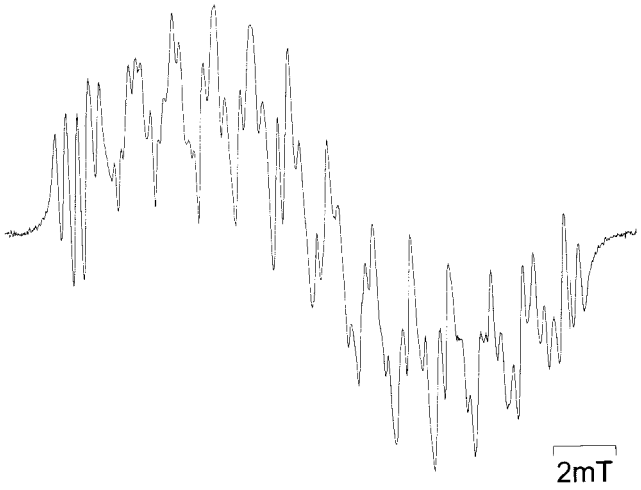

Figure 6. ESR spectrum of **3** in *n*-pentane

The resolution of the ESR spectrum of **3** at room temperature is lower and the number of lines is higher than for the ESR spectrum of **2**. Therefore, the hyperfine structure of the signal, centered at $g = 2.0053$, could not yet be analyzed completely. Besides a clearly determined small coupling

constant for one Al atom of nearly 0.3 mT, two larger and obviously different coupling constants for the second and third Al atoms of nearly 1.3 mT are determined. This assignment is in agreement with the total spectral width of 15.0 mT. According to the *g* factor and the hyperfine structure, the radical **3** is predominantly a π radical. The smaller ^{27}Al coupling constant may be associated with the four-coordinate Al center (cf. AlR_n-coordinated organic π radicals).[14,15] On the other hand, the non-equivalence of the two remaining Al centers with hyperfine coupling constants in conventional ranges is well in agreement with the results of the X-ray structure analysis of **3** (see above) and also with an equilibrium *cyclo*-**3** ⇄ *catena*-**3**, where by $R^*_4Al_3^•$ shows a cyclic structure in the solid state and a chain structure in solution.

Experimental Section

All experiments were carried out in flame-dried glass apparatus with standard Schlenk techniques under an atmosphere of dry argon or nitrogen. During all manipulations air and moisture were strictly excluded. The solvents (cyclohexane, heptane, pentane, benzene) were distilled from sodium/lead or sodium/benzophenone. For NMR spectra a JEOL GSX-270 ($^1H/^{13}C/^{29}Si$: 270.17/67.94/53.67 MHz) and a JEOL EX-400 ($^1H/^{13}C/^{29}Si$: 399.78/10.54/79.43 MHz) were available. The ^{29}Si NMR spectra were recorded with the INEPT pulse sequence using empirically optimized parameters for polarization transfer from the *t*Bu substituents. The ESR spectra were recorded with a Bruker System ESP 300.

Formation of Tri(supersilyl)dialanyl 2: In an evacuated and sealed NMR tube a solution of **1**[4] (0.020 g, 0.023 mmol) in C_6D_{12} (0.6 mL) was heated to 70 °C for 4 hours and then cooled to room temperature. After this procedure, the black-green solution was found to be free of starting material **1** (by NMR spectroscopy); however, it contained superdisilane $tBu_3Si-SitBu_3$ (identification by comparison with an authentic sample)[13] and also, according to an ESR spectrum, the radical **2** (not visible in the NMR spectrum). It did not prove possible to isolate crystals of **2** suitable for an X-ray structure analysis.

Formation of Tetra(supersilyl)cyclotrialanyl 3: A solution of **1**[4] (0.264 g, 0.308 mmol) in heptane (25 mL) was heated to 100 °C for 10 hours (reflux) and then cooled to room temperature. After this procedure, the black-green solution was found to be free of starting material **1** (by NMR spectroscopy); however, it contained supersilane tBu_3Si-H, superdisilane $tBu_3Si-SitBu_3$ and **4** [identification by comparison with an authentic samples;[6,13] δ(^1H; C_6D_{12}) = 1.148, 1.382. 1.263] and also, according to an ESR spectrum, the radical **3** (cf. Figure 6; not visible in the NMR spectrum). The area ratio of the ^1H NMR signals for tBu_3Si-H, $tBu_3Si-SitBu_3$ and $(tBu_3Si)_4Al_4$ (**4**) amounts to 6:5:4 (measured for $SitBu_3$). Consequently, besides one molecule of **4** with four silicon-bonded supersilyl groups, eleven supersilyl radicals are formed which stabilize by formation of tBu_3Si-H and $tBu_3Si-SitBu_3$. Since four tBu_3Si radicals arise during the formation of one molecule of **4** from two molecules of **1** ($2 \times \mathbf{1} \rightarrow \mathbf{4} + 4\ tBu_3Si$), $11 - 4 = 7\ tBu_3Si$ radicals must come from the formation of **3**. As two tBu_3Si radicals are produced per radical of **3** from 1.5 molecules of **1** ($1.5 \times \mathbf{1} \rightarrow \mathbf{3} + 2\ tBu_3Si$), 7 tBu_3Si radicals originate from the formation of 3.5 radicals of **3**. For the formation of 3.5 molecules of **3** and 1 molecule of **4**, therefore, $(3.5 \times 1.5) + (1 \times 2) = 7.25$ molecules of **1** are needed. Consequently, **3** and **4** are formed in yields of 70 and 30%. In another experiment dialane (0.339 g, 0.395 mmol) was heated in 25 mL cyclohexane at 80 °C for 15 hours. The solvent and all volatile components (C_6H_{12}, tBu_3Si-H) were then removed in vacuo and the remaining residue was dissolved in 10 mL heptane. After 2 months tetra(supersilyl)cyclotrialanyl **3** (0.22 g) crystallized from this solution at −25 °C as black-green cubes.

DFT Calculations: All RI-DFT calculations (AL2 and AL3) were carried out with the program package TURBOMOLE with the BP86-Functional and SV(P) basis sets.[10]

X-ray Structure Determination of 3: Stoe IPDS diffractometer, Mo-K_α radiation with λ = 0.71073 Å, graphite monochromator, image plate detector, crystal dimensions 0.15 × 0.20 × 0.28 mm, fixed on glass fiber, measurement temperature 200(2) K, $C_{48}H_{108}Al_3Si_4 \cdot 0.25C_6H_{14}$, M_r = 921.73, black-green rhombus, monoclinic space group *C*2/*c*, *a* =21.344(4), *b* = 12.794(3), *c* = 23.955(5) Å, *V* = 6514(2) Å^3, *Z* = 4, ρ_{ber} = 0.940 g·cm^{-3}, μ = 0.159 mm^{-1}, *F*(000) = 2064. − *Data collection*: 2θ =4.08 − 51.84° in $-26 \le h \le 26$, $-15 \le k \le 15$, $-29 \le l \le 29$; of 22750 reflections 6316 were independent (R_{int} = 0.068) and 4446 were observed [$F > 4\sigma(F)$], 377 parameters, R_1 = 0.0887, wR_2 = 0.2870, weighting factor $w^{-1} = \sigma^2F_0^2 + 0.194P^2$ with $P = F_0^2 + 2F_c/3$. − *Structure determination:* The structure was solved by direct methods (SHELX-97). All non-hydrogen atoms were refined anisotropically, and H atoms were included in the refinement at calculated positions with a riding model and fixed isotropic U_i values. In a distorted arrangement of four supersilyl groups the Al_3 ring is disordered embedded over the C_2 axis. In both positions of the atoms Al1 and Al2 click into free inlets of the $SitBu_3$ envelope.

Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no CCDC-120209. Copies of this data can be obtained free of charge on application to the Director, CCDC, 12 Union Road, Cambridge CB2 1EZ [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

We are grateful to the Deutsche Forschungsgemeinschaft and the Fonds der Chemische Industrie for their generous financial support. We thank Dr. A. Purath for mounting a crystal of the cyclotrialanyl.

Synthesis and Crystal Structures of Mono-Helical Complexes of Zinc(II) and Europium(III) with 1,2-Bis{[3-(2-pyridyl)pyrazol-1-yl]ethoxy}ethane

Michael H. W. Lam,*[a] Derek Y. K. Lee,[a] Sammi S. M. Chiu,[a] K. W. Man,[a] and W. T. Wong[b]

Keywords: Zinc / Europium / Helical structures / Ligand design / N ligands

A new multidentate ligand L, 1,2-bis{[3-(2-pyridyl)pyrazol-1-yl]ethoxy}ethane, has been synthesized by linking two 3-(pyridin-2-yl)pyrazoles with a 1,2-bis(ethoxy)ethyl spacer. Coordination of L with zinc(II) and europium(III) centres has led to mononuclear complexes of $[Zn(L)](ClO_4)_2$ (**1**) and $[Eu(L)Cl_2](ClO_4)$ (**2**). X-ray crystal structures of both complexes have shown that L adopted a helical coordination geometry around both metal centres. The spectroscopic properties of both complexes have also been determined. In **1**, photoluminescence was dominated by ligand centred $^1(\pi\text{-}\pi^*)$ fluorescence. In **2**, ligand-to-metal energy transfer leading to $^5D_0 \rightarrow {}^7F_n$ luminescence at the europium(III) centre was observed.

Introduction

Molecular architecture showing helical arrangement of multidentate ligands around one or more metal centres has long been one of the goals in the field of supramolecular chemistry.[1] Besides their structural elegance, molecular helices are emblems of synthetic chemists′ ability to make use of the various steric and electronic interactions within/among molecular units to engineer preferred molecular structures. While double-helical and triple-helical multinuclear (most often dinuclear) coordination complexes are the most common classes of supramolecular helix,[2,3] mononuclear molecular helices are believed to offer better control over the assembly of molecular units into desirable crystal lattices.[4] Among the various ligand systems that are capable of promoting self-assembly of mononuclear and multinuclear helical coordination complexes, oligopyridine[1b,2c−2e,2g] is the most famous and thoroughly studied one. Other ligands such as substituted bis(benzimidazolyl)pyridines,[3b,3g] substituted pyridine-2,6-dicarboxamide and pyridine-2,6-dicarboxylate,[3f,4c] as well as bis- and tris-catechol[5] are also known to induce helical coordination configurations. Recently, Ward et al.[6] has demonstrated the versatile coordination chemistry of the ligand 3-(pyridin-2-yl)pyrazole. The ease of substitution at the pyrazolyl-N^1 position provides convenient access to multidentate pyridyl-pyrazolyl ligands with the potential to induce high nuclearity supramolecular assemblies. In fact, a dicopper(I) double helicate with ligands containing two pyridyl-pyrazolyl units joined by an *o*-$CH_2C_6H_4CH_2$ spacer has been synthesized.[6h] We are particularly interested in linking two 3-(pyridin-2-yl)pyrazoles through the pyrazolyl-N^1 by a flexible carbon chain containing additional donor atoms. In this way, multidentate ligands capable of wrapping around metal centres with much greater flexibility can be formed. Compared with oligopyridine ligands, where helical configuration has to be achieved by the twisting of interannular C−C bonds between adjacent pyridine rings, the new ligand system is expected to be more energetically and sterically favourable for a helical coordination geometry. In this work we report a new, potentially hexadentate ligand formed by the linkage of two 3-(pyridin-2-yl)pyrazoles by a 1,2-ethoxyethane spacer − the 1,2-bis{[3-(2-pyridyl)pyrazol-1-yl]ethoxy}ethane (L) (Figure 1) − and its mononuclear helical complexes $[Zn(L)](ClO_4)_2$ (**1**) and $[Eu(L)Cl_2](ClO_4)$ (**2**).

Results and Discussion

Formation of the polyether-linked pyridyl-pyrazole ligand L is straightforward. Deprotonation of the pyrazolyl-

N^1 of 3-(pyridin-2-yl)pyrazole by NaH followed by alkylation by 1,2-bis(chloroethoxy)ethane affords L in good yield. The coordination chemistry of 3-(pyridin-2-yl)pyrazole has been thoroughly explored by Ward et al.,[6] who have also applied a similar approach to link two 3-(pyridin-2-yl)pyrazoles by *o*-$CH_2C_6H_4CH_2$ and propyl spacers.[6h,15] In the former case, the dinuclear double helicate with copper(I) was obtained while no helical coordination geometry was observed in Fe^{II}, Cu^{II}, Zn^{II}, Ag^{I} and Pb^{II} complexes containing the latter, relatively more-flexible ligand. In our case, reacting the polyether linked L with $ZnCl_2$ or $EuCl_3 \cdot 6H_2O$ in refluxing absolute ethanol gives the hygroscopic mononuclear complexes $[Zn(L)](ClO_4)_2$ (**1**) or $[Eu(L)Cl_2](ClO_4)$ (**2**), where the two ether oxygens also participate in metal coordination. In both complexes, L acts as a hexadentate ligand resulting in a helical coordination geometry around the metal centres. The hygroscopic nature of both complexes prevented accurate elemental analysis. Therefore, the characterization relied on FAB-MS and an X-ray crystal analysis.

Perspective views of the crystal structures of complexes **1** and **2**, with atom numbering, are shown in Figure 2 and Figure 3, respectively. Selected bond lengths and angles of the two complexes are tabulated in Table 1 and Table 2. In both complexes, each symmetric unit contains one complex molecule. In $[Zn(L)](ClO_4)_2 \cdot H_2O$ (**1**·H_2O), the 22-electron zinc(II) centre is coordinated to two pyridyl-*N*, two pyrazolyl-*N* and two ether-*O* donors. The bond lengths between Zn(1)−N(1)-pyridyl and Zn(1)−N(6)-pyridyl are 2.146(7) and 2.163(7) Å, respectively. The bond lengths between Zn(1)−N(2)-pyrazolyl and Zn(1)−N(5)-pyrazolyl are 2.081(7) and 2.071(7) Å, respectively. These bond lengths are typical for zinc(II) polypyridyl and pyridyl-pyrazolyl complexes.[15] The bond lengths between Zn(1)−O(1)-ether and Zn(1)−O(2)-ether are 2.203(5) and 2.211(5) Å, respectively.

The coordination geometry at Zn(1) is a distorted octahedron with L helically wrapped around the metal centre.

The dihedral angles between Py1/Py2 and Pz1/Pz2 are 80.64° and 79.64°, respectively.

Figure 4 shows the space filling representation of the $[Zn(L)]^{2+}$ core. The pyridine and pyrazole rings in L are nearly coplanar with interannular angles in Py1/Pz1 and Py2/Pz2 of 1.14° and 0.74°, respectively. The degree of interannular twisting is much smaller than that in found in

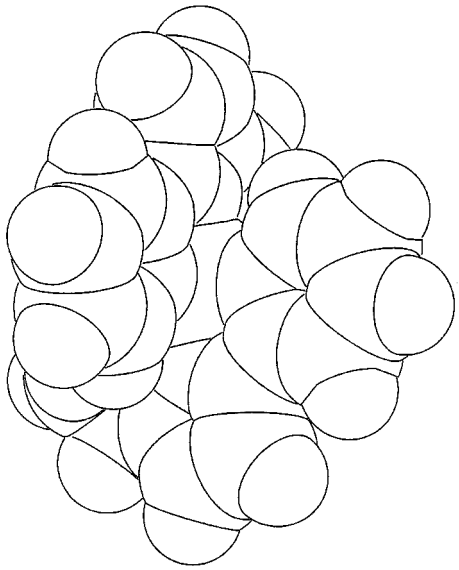

Figure 4. Space filling representation of $[Zn(L)]^{2+}$ cation with counter anions omitted

oligopyridyl helices, which normally range from 5 to 20°.[1b,16b] Presumably this is due to the presence of a flexible polyether chain in L that eases the requirement for twisting of the aromatic rings from a co-planar configuration to achieve the helical conformation.

In $[Eu(L)Cl_2](ClO_4)$ (**2**), the coordination number of the europium(III) centre is eight. The ligand L adopts a helical twist about the equatorial plane of the complex while the two coordinated chlorides occupy the apparent axial posi-

tions, although they are not exactly at 180° to each other. The bond lengths between Eu(1)−N(3)-pyridyl and Eu(1)−N(6)-pyridyl are 2.623(4) and 2.648(4) Å, respectively, and those between Eu(1)−N(1)-pyrazolyl and Eu(1)−N(5)-pyrazolyl are 2.497(4) and 2.496(4) Å, respectively. These bond lengths are typical for europium(III) pyridyl complexes.[16] The bond lengths between Eu(1)−O(1)-ether and Eu(1)−O(2)-ether are 2.530(3) and 2.507(3) Å, respectively, and those between Eu(1)−Cl(1) and Eu(1)−Cl(2) are 2.678(1) and 2.661(1) Å, respectively. The angle Cl(1)−Eu(1)−Cl(2) is 152.30(4)° and the two chlorides are evidently bent away from the two pyridine rings, probably because of steric interactions. The helical arrangement of the coordinated ligand L is more clearly demonstrated in complex **2** than in complex **1**. In **2**, the dihedral angles between Py1/Py2 and Pz1/Pz2 are 60.42° and 69.35°, respectively; the interannular angles in Py1/Pz1 and Py2/Pz2 are 7.83° and 8.58°, respectively. The degree of interannular twisting is significantly larger than that of complex **1** and is moderate compared to that found in oligopyridyl helices. Figure 5 shows the space filling representation of the $[Eu(L)Cl_2]^+$ core.

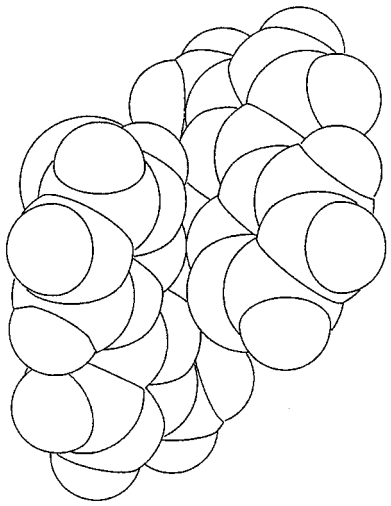

Figure 5. Space filling representation of $[Eu(L)Cl_2]^+$ cation with chlorides and counter anion omitted for clarity

[a] In acetonitrile. – [b] At 298 K.

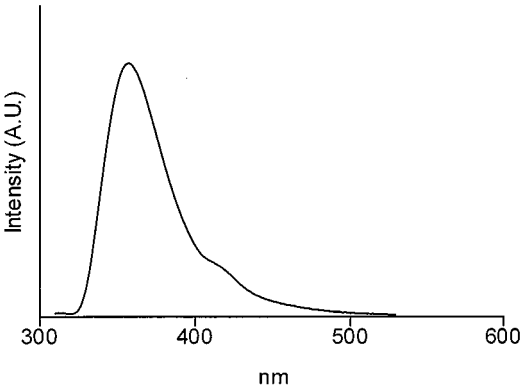

Figure 6. Room temperature emission spectra of $[Zn(L)](ClO_4)_2$ (**1**) in acetonitrile; excitation at 300 nm

Table 3 tabulates the solution spectroscopic and emission properties of complexes **1** and **2**. The UV/Visible absorption bands of both complexes are attributable to intraligand transitions. Complex **1** gives violet-blue photoluminescence in acetonitrile at room temperature (Figure 6) due to the $^1(\pi\text{-}\pi^*)$ fluorescence of the ligand. On the other hand, complex **2** produces an intense red emission in acetonitrile at room temperature. Figure 7 shows the room-temperature solution emission spectrum of **2** upon excitation at 300 nm. Emission peaks in the range 595−750 nm are characteristic of $^5D_0 \rightarrow {}^7F_n$ (n = 0 to 4) transitions at the Eu^{III} centre.[17] The observation of Eu^{III}-centred emission indicates the occurrence of energy transfer from the ligand to the metal centre **2**.

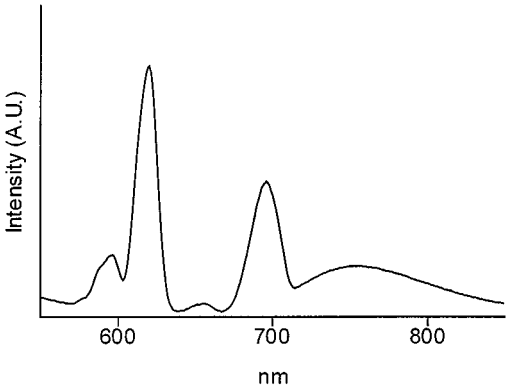

Figure 7. Room temperature emission spectra of $[Eu(L)Cl_2](ClO_4)$ (**2**) in acetonitrile; excitation at 300 nm

Conclusion

The strategy of linking two bidentate polypyridyl/pyrazolyl moieties by a flexible alkyl chain containing additional donor atoms has led to helical coordination architectures. With a 1,2-bis(ethoxy)ethyl linker, mononuclear helical complexes of $[Zn(L)]^{2+}$ and $[Eu(L)Cl_2]^+$ are obtained. Induction of a helical coordination geometry is probably assisted by the affinity of both metals for oxygen donors. An efficient ligand-to-metal energy transfer is observed in $[Eu(L)Cl_2]^+$ which leads to intense Eu^{III} centred lumines-

cence in the region 595−750 nm. This makes $[Eu(L)Cl_2]^+$ a potentially useful luminescent material in organic electroluminescent devices. Work on induction of higher nuclearity helices by L is in progress. The synthesis of analogous ligands with donor atoms other than oxygen in the linker is also being pursued.

Experimental Section

General Remarks: Europium(III) chloride hexahydrate, anhydrous zinc(II) chloride, sodium hydride (60% in mineral oil) and 1,2-bis(chloroethoxy)ethane were obtained from Aldrich. All solvents used were of analytical reagent grade (Riedel-de Haën and BDH). UV/vis spectra were measured by a Hewlett−Packard 8452A ultraviolet visible diode array spectrophotometer. Emission spectra were measured on an SFM 4800C spectrofluorometer and Perkin−Elmer LS-50B luminescence spectrometer. ^{1}H NMR spectra were measured on a Varian YH300 300 MHz NMR spectrometer. All manipulations were carried out under an N_2 atmosphere with standard Schlenk vacuum line techniques.

1,2-Bis{[3-(2-pyridyl)pyrazol-1-yl]ethoxy}ethane (L): 3-(Pyridin-2-yl)pyrazole[6a] (2.03 g, 14.0 mmol) was added to a suspension of NaH (60%, 0.56 g, 14.0 mmol) in 30 mL THF. The mixture was stirred at room temperature for 15 min. 1,2-Bis(chloroethoxy)-ethane (1.31 g, 7.0 mmol) was then added to the resultant reddish brown solution and the mixture was refluxed for 12 h. After cooling to room temperature, the mixture was filtered and the filtrate evaporated in vacuo to yield L as a light brown oil [1.9 g, 67% based on 1,2-bis(chloroethoxy)ethane]. The product was pure enough for further reaction. − ^{1}H NMR ($CDCl_3$, 300 MHz): δ = 8.61 (d, J = 4.2 Hz, 2 H, pyridyl-H^6), 7.87 (d, J = 8.1 Hz, 2 H, pyridyl-H^3), 7.69 (td, J = 8.5, 7.5 Hz, 2 H, pyridyl-H^4), 7.51 (d, J = 2.1 Hz, 2 H, pyrazolyl-H^4 or H^5), 7.18 (m, 2 H, pyridyl-H^5), 6.84 (d, J = 2.1 Hz, 2 H, pyrazolyl-H^4 or H^5), 4.33 (t, J = 5.5 Hz, 4 H, CH_2), 3.82 (t, J = 5.3 Hz, 4 H, CH_2), 3.49 (t, J = 6.3 Hz, 4 H, CH_2).

$[Zn(L)](ClO_4)_2$ (1): A mixture of anhydrous $ZnCl_2$ (0.14 g, 1.0 mmol) and L (0.40 g, 1.0 mmol) in 30 mL of absolute ethanol was refluxed for 24 h. $NaClO_4·H_2O$ (0.31 g, 2.2 mmol) was then added and the mixture was refluxed for a further 30 mins. The resultant mixture was evaporated in vacuo and the white residue was dissolved in DMF. The DMF solution was filtered into a Schlenk tube and a layer of diethyl ether was carefully laid on top of the DMF solution. The whole assembly was allowed to stand at −10 °C for two days to yield colourless crystalline $[Zn(L)](ClO_4)_2$ (**1**) (0.42 g, 62%). − MS (FAB$^+$, *m*-NBA): *m*/*z* = 569 [$M(ClO_4)^+$]. − ^{1}H NMR ([D$_6$]DMSO, 300 MHz): δ = 8.32 (d, J = 4.1 Hz, 2 H, pyridyl-H^6), 7.7 (m, 6 H, pyridyl-H^3 & H^4 and pyrazolyl-H^4 or H^5), 7.2 (m, 2 H, pyridyl-H^5), 6.6 (m, 2 H, pyrazolyl-H^4 or H^5), 4.1 (t, J = 5.4 Hz, 4 H, CH_2), 3.6 (t, J = 5.5 Hz, 4 H, CH_2), 1.98 (t, J = 6.0 Hz, 4 H, CH_2).

X-ray quality crystals of $[ZnN_6O_2C_{22}H_{24}](ClO_4)_2·H_2O$ were obtained by repeated recrystallization from DMF/Et_2O.

$[Eu(L)Cl_2](ClO_4)$ (2): The synthesis was similar to **1** except $EuCl_3·6H_2O$ (0.37 g, 1.0 mmol) was used. Layering of diethyl ether on top of a DMF solution of the reaction mixture and standing at −10 °C for three days gave colourless crystals of $[Eu(L)Cl_2](ClO_4)$ (**2**) (0.55 g, 76%). − MS (FAB$^+$, *m*-NBA): *m*/*z* = 627 [M^+]. The crystals obtained were already of a quality suitable for an X-ray crystal structure determination.

X-ray Crystallographic Study: Crystal structures of **1** and **2** were determined by X-ray diffraction using a Rigaku AFC 7R diffractometer with graphite monochromated Mo-K_α radiation and a 12-kW rotating anode generator. To avoid loss of solvent, the crystals were sealed in a layer of paraffin. Crystal data and details of measurements for complexes $[Zn(L)](ClO_4)_2·H_2O$ (**1**·H_2O) and $[Eu(L)Cl_2](ClO_4)$ (**2**) are summarized in Table 4. Absorption correlation was applied using Lorentz and polarization effects, and for absorption effects by an empirical method based on azimuthal scans of several reflections.

The structures were solved by heavy-atom Patterson Methods[7] (for **1**) and Direct Methods[8] (for **2**) and expanded using Fourier techniques.[9] Some non-hydrogen atoms were refined anisotropically, while the rest were refined isotropically by full-matrix least-squares calculations. Reliability factors were defined as $R = \Sigma(|F_o| - |F_c|)/\Sigma|F_o|$ and $R_w = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2}$. Neutral

A General Route for the Synthesis of Triazacyclononane Functionalised with Pendant Phosphane Arms − Crystal Structures of $[NiL^1Cl(HOEt)][ClO_4]$ and $[NiL^1(NCS)_2]$ with L^1 = *N*-(Diphenylphosphanylpropyl)-1,4,7-triazacyclononane

David Ellis,[a] Louis J. Farrugia,[a] Paul A. Lovatt,[a] and Robert D. Peacock*[a]

Keywords: Macrocyclic ligands / Phosphanes / Nickel / Zinc

We present a general route for the synthesis of triazacyclononane functionalised with one, two or three pendant phosphane arms, by the free radical addition of PPh_2H to the appropriate alkene precursor *N*-[3-(diphenylphosphanyl)-propyl]-1,4,7-triazacyclononane (L^1). L^1 forms structurally characterised complexes with Zn^{II} and Ni^{II}. $[Zn_2L^1{}_2Cl_3][ClO_4]$ has a dinuclear structure in which a bridging chloride ion allows both zinc centres to be formally six-coordinate, while $NiL^1Cl(HOEt)][ClO_4]$ achieves pseudo-octahedral geometry around the nickel centre by coordinating an ethanol molecule. The ethanol molecule and the chloride ion bound to $[NiL^1Cl(HOEt)][ClO_4]$ are both labile and can be replaced by $[NCS]^-$ to give $[NiL^1(NCS)_2]$.

Introduction

The small, facially coordinating, three-nitrogen macrocycle 1,4,7-triaza-cyclononane (9[ane]N_3) has been *N*-functionalised with a wide variety of pendant arms ending in hard donor groups (−COOH, −OH, $-NH_2$, pyridyl, polypyridyl etc).[1]−[3] There are a few recent examples of functionalisation by soft donor arms, for example 4-mercaptobenzoyl,[4] $-CH_2CH_2$ SH[5] and 2-mercaptobenzyl,[6] but so far 9[ane]N_3 has not been functionalised with pendant arms ending in a phosphane group.[7]

When this work was started there were only two published examples of nitrogen macrocycles with pendant phosphane arms: 1,4,8,11-tetrakis[(diphenylphosphanyl)methyl]-1,4,8,11-tetraazacyclotetradecane which is prepared by a "one-pot" synthesis[8] which cannot be generalised, and a series of N_2O_2, N_2S_2 and NO_3 macrocycles with 2-phosphanylethyl arms.[9] Although the synthetic method used to prepare the latter series of ligands should be applicable to all nitrogen macrocycles we have not found it to be suitable in practice for 9[ane]N_3, possibly because of the high basicity of the nitrogen atoms in this ligand. Since our original communication[10] two papers have appeared reporting the synthesis of 9[ane]N_3[11] and cyclam[12] with pendant [*o*-(diphenylphosphanyl)benzyl]alkyl arms.

In view of the ubiquitous use of phosphane ligands in organometallic and coordination chemistry, and in particular the predominance of phosphane ligands in homogeneous catalysis, we have embarked upon a program designed to prepare ligands based on nitrogen macrocycles (hard ligands) bearing pendant phosphane arms. Of particular interest is the combination of three nitrogen atoms and one phosphane group giving a ligand which contains both hard and soft ligands and which is capable of forming coordinatively unsaturated complexes.

We report a general method for the preparation of phosphane pendant-arm macrocycles in which 9[ane]N_3 is functionalised with one, two or three arms. This is accomplished by free radical addition of PPh_2H to the appropriate alkene precursor. The only restriction on the method is that the arms must contain a minimum of three carbon atoms. The method is also applicable to larger nitrogen macrocycles e.g. cyclam or cyclen. A preliminary communication[10] has been published in which the crystal structure of $[Zn_2L^1{}_2Cl_3][ClO_4]$ (**3**) is described.

Results and Discussion

Preparation of the Phosphane Ligands

The pendant-arm phosphane ligands were prepared by free-radical addition of diphenylphosphane across the alkene double bond of their corresponding alkene pendant-arm derivatives (Scheme 1). The only restriction to this

Scheme 1. Reagents and conditions: L^1 (n = 1): i: allyl bromide, THF; ii: $NaOH/H_2O$; iii: PPh_2H, hν; L^2 (n = 2): i: 4-bromobut-1-ene; ii: $NaOH/H_2O$; iii: PPh_2H, hν

method is that the pendant arm must contain a minimum of three carbon atoms. The free-radical additions were accomplished in essentially quantitative yields by photolysis under strictly anaerobic conditions using a mercury lamp. The reactants were irradiated as neat liquids; *the use of solvents increased the amount of phosphane oxides in the product and was found to severely hinder the reaction rate.* Excess diphenylphosphane was removed from the reaction mixture by washing with petroleum ether (boiling range 40−60 °C) or by distillation under reduced pressure.

Free radicals are electron-deficient species and their stability decreases in the order tertiary > secondary > primary. The addition is therefore strictly *anti*-Markovnikov, since the formation of a secondary radical is preferred over the formation of a primary radical. It was originally believed that the free amine functions in L^1 and L^2 would quench the radical addition but it was soon realised that this was not the case. It was anticipated that branched alkene ligands would undergo free-radical addition with diphenylphosphane to produce racemic phosphane pendant-arm macrocycles; however, the addition reaction was extremely slow and the alkene macrocycle degraded under the photolytic conditions before any significant amount of addition was achieved. No addition products were observed for, for example, *N*-(2-methylbut-2-en-1-yl)triazacyclononane even when radical initiators such as AIBN were added.

The synthetic method is exemplified by the preparation of L^1 and L^2 and has also been used to prepare *N,N′,N′′*-tris[3-(diphenylphosphanyl)propyl]-1,4,7-triazacyclononane from *N,N′,N′′*-triallyl-1,4,7-triazacyclononane and *N*-methyl-*N′,N′′*-bis[3-(diphenylphosphanyl)propyl]-1,4,7-triazacyclononane from *N,N′*-diallyl-*N′′*-methyl-1,4,7-triazacyclononane.

Metal Complexes

The only crystals of metal complexes which were suitable for crystallographic studies were obtained with L^1 using the perchlorate counteranion. Numerous attempts were made to form complexes of the other ligands with a variety of transition metal ions. In most cases spectroscopic evidence (UV/Vis, ^{31}P NMR) indicated that reaction had occurred.

Nickel Complexes

$[NiL^1Cl(EtOH)][ClO_4]$ (1)

Reaction of L^1 with $NiCl_2{\cdot}6H_2O$ in ethanol followed by the addition of excess $LiClO_4$ produced $[NiL^1Cl(EtOH)][ClO_4]{\cdot}H_2O$ (**1**) (Figure 1). The nickel atom is coordinated to the three amine functions and the phosphane pendant arm of L^1. An ethanol molecule and chloride ion complete the coordination sphere around the nickel centre to give a pseudo-octahedral geometry. The bonding trends in the complex are similar to those observed in the zinc dimer.[10] The longest Ni−N bond is to the nitrogen atom bearing the pendant arm and the shortest Ni−N bond is to the nitrogen atom *trans* to the phosphane group. The Ni−P bond is much longer than the average of Ni−PPh_3 bond lengths (2.321 Å) and well above the upper quartile (2.331 Å).[13]

$[NiL^1(NCS)_2]$ (2)

The addition of KSCN to $[NiL^1Cl(EtOH)]^+$ displaced the coordinated chloride ion and ethanol molecule to give a new nickel(II) complex containing two coordinated thiocyanate groups (Figure 2). The thiocyanate ion coordinates to the nickel(II) centre via the nitrogen function of the ligand. The Ni−N bonds of the macrocycle follow the same trends observed in $[NiL^1Cl(EtOH)]^+$, but the bond lengths are slightly longer in the thiocyanate complex. The Ni−P bond length in $[NiL^1(NCS)_2]$ is slightly shorter to that observed in $[NiL^1Cl(EtOH)]^+$, but is still very much longer than those observed for Ni−PPh_3. The closest reported structure related to $[NiL^1(NCS)_2]$ is the *trans*-phosphane complex $[Ni(NCS)_4\{P(CH_2CH_2CN)_3\}_2]^{2-}$ [14] in which the Ni−P bond length is 2.420Å and is only slightly longer than that in $[NiL(NCS)_2]$. The Ni−NCS bond lengths are also very similar at 2.072 and 2.068Å.

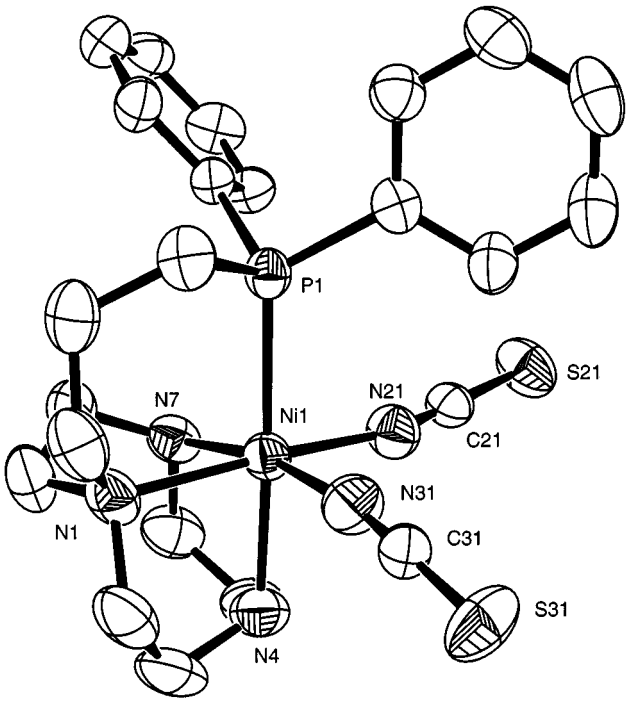

Figure 2. ORTEP for Windows[21] plot of **2** (thermal ellipsoids are drawn at 50% probability); selected bond lengths [A] and angles [°]: Ni(1)−N(31) 2.056(3), Ni(1)−N(21) 2.066(3), Ni(1)−N(4) 2.109(3), Ni(1)−N(7) 2.128(2), Ni(1)−N(1) 2.186(3), Ni(1)−P(1) 2.4165(9); N(31)−Ni(1)−N(21) 95.19(11), N(31)−Ni(1)−N(4) 89.76(11), N(21)−Ni(1)−N(4) 90.71(11), N(31)−Ni(1)−N(7) 169.03(11), N(21)−Ni(1)−N(7) 90.25(10), N(4)−Ni(1)−N(7) 80.64(10), N(31)−Ni(1)−N(1) 91.93(11), N(21)−Ni(1)−N(1) 70.32(11), N(4)−Ni(1)−N(1) 82.76(11), N(7)−Ni(1)−N(1)-81.67(10), N(31)−Ni(1)−P(1) 89.20(9), N(21)−Ni(1)−P(1) 92.61(8), N(4)−Ni(1)−P(1) 176.60(8), N(7)−Ni(1)−P(1) 100.09(7), N(1)−Ni(1)−P(1) 94.04(8), C(21)−N(21)−Ni(1) 167.2(3), C(31)−N(31)−Ni(1) 168.3(3)

Zinc Complex

[ZnL^{1}Cl(μ-Cl)ZnL^{1}Cl][ClO$_4$] (3)

Reaction of L^1 with anhydrous $ZnCl_2$ in ethanol followed by the addition of excess $LiClO_4$ precipitated [ZnL^{1}Cl(μ-Cl)ZnL^{1}Cl]ClO_4 which was recrystallised from acetonitrile. The crystal structure of the complex has been described previously.[10] It consists of a asymmetric cation in which both zinc atoms are coordinated by the three amine functions and the pendant phosphane arm of L^1. Both the zinc atoms achieve pseudo-octahedral geometry via a terminal and a bridging chloride ion.

Conclusion

We have described a general method for preparing N-macrocycles with pendant phosphane arms. The method is illustrated with the synthesis of mono-substituted L^1 and L^2 but can be used to prepare pendant-arm macrocycles in which all, or any number of, N atoms are "armed" by selective alkylation.

Experimental Section

Triazacyclononane was synthesised by the Richmond−Atkins method,[15] detosylation being effected by heating in concentrated H_2SO_4 at 115−120 °C for 36−48 h. 1,4,7-triazatricyclo-[5.2.1.0^{4,10}]decane[16] and *N*-allyltriazacyclononane[17] were prepared by published routes.

Caution: Perchlorates are potentially dangerous. Caution is advised and the handling of only small quantities is recommended.

***N*-[3-(Diphenylphosphanyl)propyl]-1,4,7-triazacyclononane (L^1):** A Schlenk tube was equipped with a magnetic stirring bar, attached to a Schlenk line and charged with *N*-allyl-1,4,7-triazacyclononane (1 g, 5.92 mmol), dissolved in dry degassed dichloromethane (5 mL). The Schlenk tube was evacuated and purged with nitrogen and diphenylphosphane (1.29 g, 1.2 mL, 6.93 mmol) was transferred to the Schlenk tube using a syringe under a strong flow of nitrogen. The contents of the flask were mixed and the dichloromethane was removed under reduced pressure. The flask was then irradiated with a 125-W Hanovia medium-pressure mercury lamp with stirring under nitrogen for 72 h. Excess diphenylphosphane was removed by washing with dry degassed petroleum ether (boiling range 40−60 °C) (2 × 5 mL). The remaining viscous oil was then left under vacuum overnight to remove any solvent and volatiles. The product was obtained in essentially quantitative yield as a very viscous yellow oil. − ^{1}H NMR (200 MHz, $CDCl_3$): δ = 1.51 (m, 2 H, −CH$_2$−C*H*$_2$−P), 1.98 (m, 2 H, −C*H*$_2$−CH$_2$−P), 2.45−2.78 (m, 14 H, N−C*H*$_2$−), 7.21−7.39 (m, 10 H, Ar−*H*). − ^{13}C NMR (51 MHz, $CDCl_3$): δ = 24.25 (d, J_{PC} = 16 Hz, N−CH$_2$CH$_2$*C*H$_2$−P), 25.69 (d, J_{PC} = 11.5 Hz, N−CH$_2$*C*H$_2$CH$_2$−P), 46.73, 46.82, 53.06 (N−*C*H$_2$−, ring), 58.73 (d, J_{PC} = 13 Hz, N−*C*H$_2$CH$_2$CH$_2$−P), 128.36, 132.68, 133.95, 138.94 (all d, aromatic). − ^{31}P NMR (81 MHz, $CDCl_3$): δ = −16.2.

***N*-[3-(Diphenylphosphanyl)butyl]-1,4,7-triazacyclononane (L^2):** The same procedure was used as described for *N*-[3-(diphenylphosphanyl)propyl]-1,4,7-triazacyclononane. Quantities used were 1.5 g (8.2 mmol) of *N*-(but-3-en-1-yl)-1,4,7-triazacyclononane, 1.68 g (1.56 mL, 9.1 mmol) of diphenylphosphane and an irradiation time of 96 h. Yield 3 g (quant.). − ^{1}H NMR (200 MHz, $CDCl_3$): δ = 1.52 (m, 4 H, N−CH$_2$CH$_2$C*H*$_2$C*H*$_2$−P), 2.05 (m, 2 H, N−CH$_2$C*H*$_2$CH$_2$CH$_2$−P), 2.47−2.70 (m, 14 H, N−C*H*$_2$−), 2.85 (b, 2 H, N−H), 7.25−7.55 (m, 10 H, Ar−*H*). − ^{13}C NMR (51 MHz, $CDCl_3$): δ = 23.63 (d, P−*C*H$_2$−, J_{PC} = 16.3 Hz), 27.83 (d, N−CH$_2$CH$_2$*C*H$_2$CH$_2$−P, J_{PC} = 11.6 Hz), 28.86 (d, N−CH$_2$*C*H$_2$CH$_2$CH$_2$−P, J_{PC} = 12.1 Hz), 43.83, 45.14, 50.67 (N−*C*H$_2$−, ring), 56.42 (N−*C*H$_2$−, arm), 128.47, 132.63, 133.85, 138.51 (all d, aromatic). − ^{31}P NMR (81 MHz, $CDCl_3$): δ = −16.43.

[NiL^{1}Cl(EtOH)][ClO$_4$]·H$_2$O (1): $NiCl_2·6H_2O$ (107 mg, 0.45 mmol) and $LiClO_4$ (240 mg, 2.25 mmol) were dissolved in degassed ethanol (20 mL) and a solution of L^1 (200 mg, 0.56 mmol) in degassed ethanol (2 mL) was added. An initial red precipitate formed which turned blue on stirring overnight. This was filtered off and recrystallised from acetonitrile/nitromethane to yield 50 mg (18%) of **1**. − $C_{23}H_{38}Cl_2N_3NiO_6P$ (613.14): calcd. C 45.1, H 6.25, N 6.85; found C 45.1, H 6.2; N 6.85.

[NiL^1(NCS)$_2$]·CH$_3$NO$_2$ (2): A solution of KNCS (20 mg, 0.21 mmol) in acetonitrile was added to a solution of **1** (27 mg, 0.045 mmol) also in acetonitrile. The resulting purple solution was left to crystallise. Crystals of **2** suitable for crystallography were obtained from nitromethane. − $C_{24}H_{33}N_6NiO_2PS_2$ (591.36): calcd. C 48.8, H 5.6, N 14.2; found C 48.7, H 5.85, N 14.9.

Crystallography: Details of the data collection and analysis of **1** and **2** are given in Table 1. Single crystals of suitable size were attached to a glass fibre using acrylic resin, and mounted on a goniometer head in a general position. Data were collected with an Enraf−Nonius TurboCAD4 diffractometer for **2** and with a Siemens P4 diffractometer for **2**, both using graphite-monochromated X-radiation (λ = 0.71073 Å). Precise unit-cell dimensions were determined by refinement of the setting angles of high-angle reflections which were flagged during data collection. Standard reflections were measured every 2 h during data collection, and a small decay of ca 7% (**1**) and 11% (**2**) was noted, and interpolated corrections were applied to the reflection data. Lorentz-polarization corrections were then applied to the reflection data. ψ-scans for **1** indicated that no absorption correction was necessary, while a semi-empirical correction was applied to **2**. The structures were solved by direct methods (SIR92).[18] All non-H atoms were allowed anisotropic thermal motion. Aliphatic CH hydrogen atoms were included at calculated positions, with C−H = 0.96 Å, while the two NH hydrogen atoms were found from difference Fourier maps and refined using a riding model. Refinement (SHELXL97)[19] was by full-matrix least squares on F^2. The weighting scheme $w = [σ^2(F_o)^2 + (AP)^2 + BP]^{-1}$ where $P = [F_o^2/3 + 2F_c^2/3]$ was used, with values of *A*, *B* = 0.0610, 0.2733 for **1** and 0.0591, 0.8873 for **2**. Counting statistics were used to estimate $σ(F_o)^2$. Neutral atom scattering factors, coefficients of anomalous dispersion and absorption coefficients were obtained from ref.[20].

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-132772 (**1**) and -132773 (**2**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

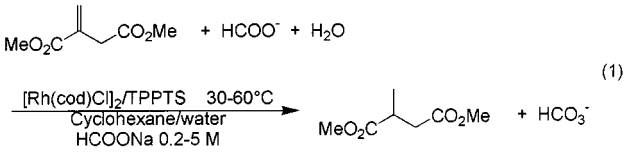
Kinetic and Mechanistic Study of the H-Transfer Reduction of Dimethyl Itaconate by a Rh/TPPTS Catalyst under Biphasic Conditions: Evidence for a Rhodametallacycle Intermediate

Nathalie Tanchoux[a] and Claude de Bellefon*[a]

Keywords: H-transfer / Kinetics / Reaction mechanisms / Biphasic catalysis / Rhodium / Metallacyclobutanes

The H-transfer reduction of dimethyl itaconate under biphasic catalysis using sodium formate/water as the hydrogen source with a Rh/TPPTS complex was studied. Labelling experiments reveal that the reduction proceeds through a 1,3-hydrogen addition. Kinetic studies allow us to propose a catalytic cycle going through a rhodametallacyclobutane intermediate with a rate-determining step involving sodium formate. A formal kinetic rate law was then derived from this mechanism which accounts for the results. This work evidences the switch between the mechanism of diacid reduction and that of the corresponding esters.



Introduction

The asymmetric hydrogenation of unsaturated substrates by either molecular hydrogen or H-transfer reduction is now one of the most important applications of homogeneous catalysis by chiral transition metal complexes.[1–4] Many studies report the use of optically pure phosphane complexes of Rh and Ru in organic[1,3] as well as in aqueous[2,5] or biphasic media.[6] The mechanisms of these reactions have been extensively studied, but very few details are known about the H-transfer reduction of α,β-unsaturated carboxylic esters using sodium formate/water in biphasic catalysis. As these reactions catalysed by chiral diphosphane complexes in aqueous medium are generally very complex, the racemic reduction of a prochiral substrate with a non-chiral monophosphane ligand was first studied. The kinetics of this reaction using dimethyl itaconate as a substrate and Rh/TPPTS as a catalytic complex were further investigated,[7] and labelling studies were undertaken in order to understand the mechanism and propose a catalytic cycle reflecting both the kinetic and mechanistic studies.

Results

Reaction

The reaction studied is the reduction of dimethyl itaconate (DMI) to dimethylmethylsuccinate (DMS) with sodium formate, catalysed by a water-soluble Rh complex in a biphasic medium (Equation 1). The catalytic system was generated by mixing the dimer $[Rh(cod)Cl]_2$ and the sodium salt of triphenylphosphanetrisulfonate (TPPTS) in an aqueous sodium formate solution.

(1)

Analysis of the organic layer by gas chromatography and mass balance calculations confirm the near quantitative (> 95%) conversion of the substrate, DMI, into the product, DMS. A side product (< 5%) was detected and identified as an isomer of DMI, 2-dimethylmesaconate (DMM), formed by the shift of the double bond from the external to the internal position. Such an isomerisation of terminal to internal olefins has been frequently reported as a side reaction in for example hydrogenations.[8–10]

Liquid–Liquid Partition Equilibrium

As the course of the reaction is more conveniently followed by analysis of the organic phase, it is primordial to correlate the measured concentrations in the organic phase to the concentrations in the aqueous phase, since the latter is where the catalytic reaction actually takes place. The concentration of species A in the aqueous and organic layers were described by the linear relationship of Equation 2.

$$P_A = \frac{C^A_{Org}}{C^A_{Aq}} \qquad (m^3_{Aq} \cdot m^{-3}_{Org}) \tag{2}$$

All the measurements of partition coefficients have already been described in a previous paper.[7] The coefficients calculated from the experimental results are given in Table 1.

Kinetic Studies in a Well-Mixed Batch Reactor

The absence of mass transfer limitations in a well mixed batch reactor at 1100 rpm was previously checked.[11] A previous study[7] allowed the extraction of an activation energy of 71 kJ·mol^{-1}, in good agreement with those reported for other hydrogen transfer reductions of olefins.[12] The study also led us to propose the semi-empirical rate model of Equation 3, taking into account all the results obtained during that preliminary study.

$$r_{Aq} = \frac{kC_{Aq}^{Rh}C_{Aq}^{DMI}}{(KC_{Aq}^{DMI}+1)} \qquad (kmol.m_{Aq}^{-3}.s^{-1}) \qquad (3)$$

This model being based on preliminary results, it is only partial and does not take into account important parameters such as the concentrations of sodium formate or phosphane. More tests varying these parameters were performed in order to propose a more complete kinetic model that included the new information obtained. The range of conditions for this study is given in Table 2.

Table 2. Range of conditions for kinetic study in the batch reactor (other conditions: cyclohexane as organic phase solvent; stirring speed: 1100 rpm)

Concentration of catalyst [kmol·m$^{-3}_{Aq}$]	0.00132 to 0.005
Temperature [K]	303–313–323–333
Initial concentration of DMI in the organic phase [kmol·m$^{-3}_{Org}$]	0.024 to 0.144
Initial concentration of DMI in the aqueous phase [kmol·m$^{-3}_{Aq}$]	0.0021 to 0.013
Aqueous phase volume [10^{-6} m^3]	20 to 100
Organic phase volume [10^{-6} m^3]	10 to 20
Volume ratio α [m$^3_{Org}$·m$^{-3}_{Aq}$]	0.2 to 1
Concentration of sodium formate in the aqueous phase [kmol·m$^{-3}_{Aq}$]	0.2 to 5
TPPTS/Rh ratio	3.1 to 11.3

Formate decomposition in molecular hydrogen and sodium hydrogen carbonate has been noted, with or without substrate. This hydrogen production appears to be independent of the catalytic cycle of the DMI reduction. Tests have been performed under hydrogen pressures of 0.1 and 0.2 MPa to check for this, and no acceleration effect was noticed on the reduction rate. Thus, the DMI is not reduced by the molecular hydrogen formed from formate decomposition.

As seen in Figure 1, the observed initial reaction rate shows a first order dependence with respect to the catalyst concentration for formate concentrations of 5 and 1 kmol·m^{-3}.

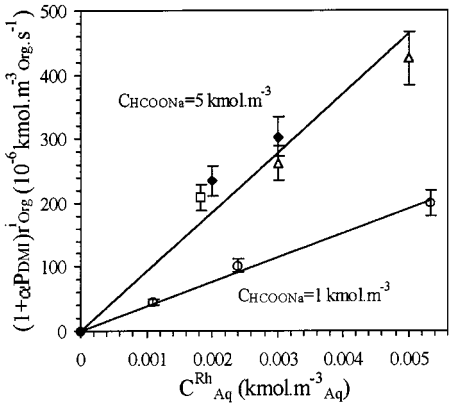

Figure 1. Influence of the catalyst concentration on the observed initial reaction rate r^i_{Org} [T = 313 K, C_{Org}^{DMI} = 0.155 kmol·m$^{-3}_{Org}$, TPPTS/Rh = 6; (◆ and ○): α = 1; (Δ): α = 0.5; (□): α = 0.45)

The influence of initial substrate concentration (Figure 2) on the observed initial rate shows an apparent zero order for the experiments carried out at a formate concentration of 1 kmol·m^{-3}, whereas it is complex for a concentration of 2.5 kmol·m^{-3} and close to an order of 1 for the most concentrated formate solution (5 kmol·m^{-3}).

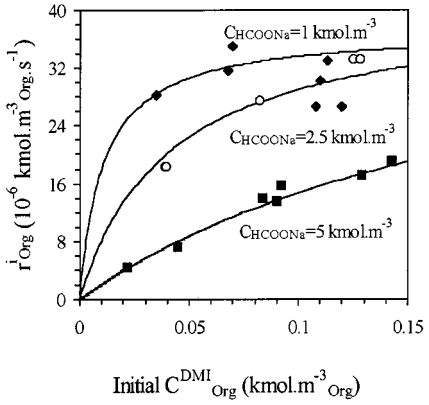

Figure 2. Influence of the initial substrate concentration on the observed initial reaction rate r^i_{Org} for different sodium formate concentrations (C_{Aq}^{Rh} = 0.002 kmol·m$^{-3}_{Aq}$, α = 1, TPPTS/Rh = 6, 313 K); the points represent the experimental data and the curves represent the semi-empirical model described by Equation 5

The effect of the phosphane on the initial rate exhibits a negative order with respect to the phosphane concentration, since the initial reaction rate decreases with increasing phosphane amounts in the aqueous phase (Figure 3).

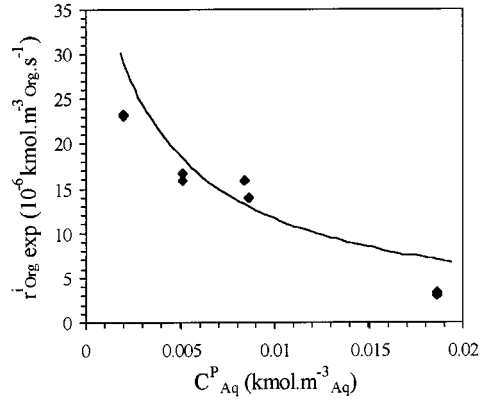

Figure 3. Influence of the phosphane concentration on the observed initial reaction rate r^{i}_{Org} (C^{DMI}_{Org} = 0.1 kmol·m$^{-3}_{Org}$, C^{Rh}_{Aq} = 0.002 kmol·m$^{-3}_{Aq}$, α = 1, C^{HCOONa}_{Aq} = 5 kmol·m$^{-3}_{Aq}$); the points represent the experimental data and the curves represent the semi-empirical model described by Equation 5

The influence of the sodium formate concentration was also studied, and it seems more complex. As shown in Figure 4, a linear increase of initial rate is observed until the formate concentration reaches 1 kmol·m$^{-3}_{Aq}$. Above this concentration, the rate decreases with increasing formate concentration. Such a complex behaviour has already been observed by Joó et al.[13] in the reduction of aldehydes by water-soluble phosphane complexes of ruthenium in biphasic medium. Joó evoked a salting-out effect due to the high formate concentration to explain this result. Formate concentration does indeed have a strong influence on the partition coefficients of the substrate and product (see Table 1).

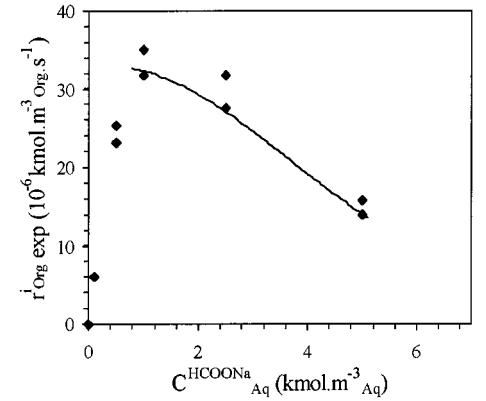

Figure 4. Influence of the sodium formate concentration on the observed initial reaction rate r^{i}_{Org} (C^{DMI}_{Org} = 0.1 kmol·m$^{-3}_{Org}$, C^{Rh}_{Aq} = 0.002 kmol·m$^{-3}_{Aq}$, α = 1, TPPTS/Rh = 6); the points represent the experimental data and the curves represent the semi-empirical model described by Equation 5

All these new results led us to propose a new semi-empirical model (Equation 4 and Equation 5), which represents all the experimental results rather well.

Knowing that $n_{DMI} = n^{DMI}_{Aq} + n^{DMI}_{Org}$, and from the mass balance in the batch reactor we can obtain

$$r_{Aq} = k\frac{C^{Rh}_{Aq}C^{DMI}_{Aq}}{\left(KC^{DMI}_{Aq} + C^{HCOO^-}_{Aq}C^{P}_{Aq}\right)} \quad (kmol.m^{-3}_{Aq}.s^{-1}) \quad (4)$$

$$-\frac{dC^{DMI}_{Org}}{dt} = r_{Org} = \frac{kC^{Rh}_{Aq}}{\left(1+\alpha P_{DMI}\right)}\frac{C^{DMI}_{Org}}{\left(\frac{K}{P_{DMI}}C^{DMI}_{Org} + C^{HCOO^-}_{Aq}C^{P}_{Aq}\right)} \quad (kmol.m^{-3}_{Org}.s^{-1}) \quad (5)$$

with α = volumetric ratio of the organic phase and the aqueous phase (m$^{3}_{Org}$·m$^{-3}_{Aq}$).

The kinetic parameters of the above model were estimated by means of a dynamic estimation and simulation software, able to perform numerical integrations using the entire concentration vs. time profiles and not only the initial rates of reaction.

As shown in Figure 2 to Figure 5 and Figure 6, the model fits rather well the experimental data except for low formate concentrations (< 1 kmol·m$^{-3}_{Aq}$). The results of the estimation are presented in Table 3.

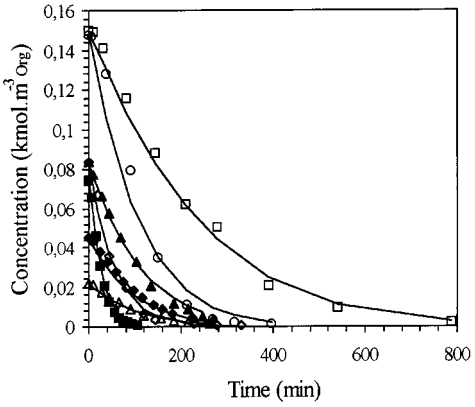

Figure 5. Concentration vs. time profiles. Comparison between experimental data (symbols) and semi-empirical model (lines). (Δ): Standard test: T = 313 K; C^{DMI}_{Org} = 0.1; C^{HCOONa}_{Aq} = 5, TPPTS/Rh = 6.3, α = 1, C^{Rh}_{Aq} = 0.002. Other tests: same with: (○) α = 0.2; (◆): α = 0.53, C^{Rh}_{Aq} = 0.005; (□): $C^{DMI}_{Org}(0)$ = 0.155, C^{HCOONa}_{Aq} = 1; (■): $C^{DMI}_{Org}(0)$ = 0.05, C^{HCOONa}_{Aq} = 2.5; (●): TPPTS/Rh = 3.1. Units: C^{DMI}_{Org} in kmol·m$^{-3}_{Org}$; C^{HCOONa}_{Aq} and C^{Rh}_{Aq} in kmol·m$^{-3}_{Aq}$; α in m$^{3}_{Org}$·m$^{-3}_{Aq}$.

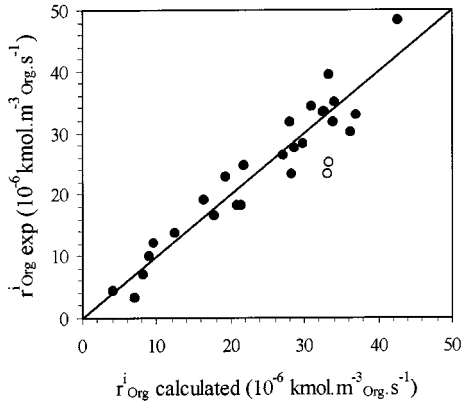

Figure 6. Calculated vs. experimental initial rates of reaction; conductions see Table 2 except for symbol (○) for which C^{HCOONa}_{Aq} = 0.5 kmol·m$^{-3}_{Aq}$

Labelling Studies

This study was completed by labelling experiments, in order to determine the chemistry occurring, and maybe obtain a better understanding of the mechanism of this reaction. Table 4 gives the regioselectivity of the deuterium distribution in the products obtained by the reduction of DMI, carried out with $D_2O/HCOO^-$ first, then with $H_2O/DCOO^-$. Deuterium was never incorporated in the methyl ester groups.

Table 4. Amount of deuterium incorporated by the dimethyl methylsuccinate

% labelled in position	H^1	H^2	H^3	$H^{3'}$
$D_2O/HCOO^-$	31±2	n.d.	58±3	47±2
$H_2O/DCOO^-$	13±3	n.d.	n.d.	n.d.

n.d.=not determined (<3%).

The extent of deuterium incorporation was determined by ^{1}H-NMR spectroscopy using the signal of the methoxy group as an internal standard (Figure 7).

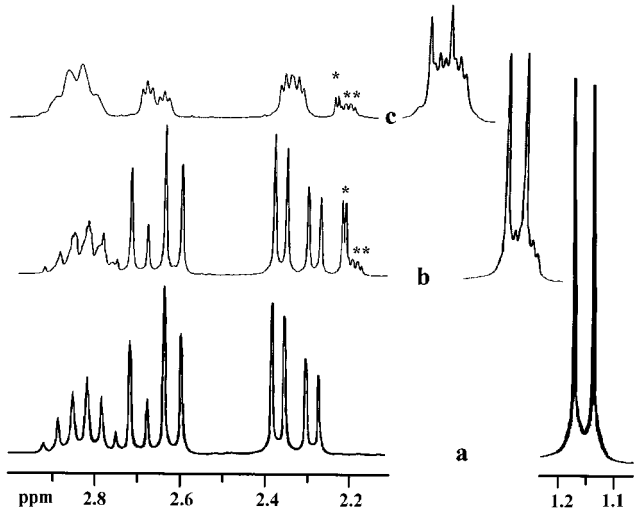

Figure 7. ^{1}H-NMR spectra of DMS (a) and of the products from reduction in $DCOONa/H_2O$ (b) and in $HCOONa/D_2O$ (c); signals of the vinylic proton in the by-product DMM: (*) **5**, (**) **6** (see Table 5)

In the case of reduction with $D_2O/HCOO^-$, the methine proton H^2 appears at δ = 2.84 as a broad multiplet (Figure 7c), showing no incorporation at this position. The two diastereotopic protons H^3 and $H^{3'}$ appear as two broad multiplets at δ = 2.33 and 2.65, corresponding to an AB system. Theses signals allowed us to determine a deuterium incorporation of 58 and 47% for each proton, respectively, i.e. a global quantitative deuterium incorporation at C^3. The methyl H^1 appears as a broad multiplet at δ = 1.14, showing a 31% deuterium incorporation at C^1. The $^{13}C\{^1H\}$-NMR spectra and DEPT sequence of the product confirmed there was no incorporation at the C^2 position. The triplet at δ = 37 corresponds to a quantitative monodeuteration –CHD in the C^3 position, confirmed by the DEPT sequence. The multiplet at δ = 16.7 shows an incorporation at the C^1 position. In the case of reduction with $H_2O/DCOO^-$, the ^{1}H-NMR spectra of DMS showed a broad multiplet at δ = 2.93 (Figure 7b) corresponding to the proton H^2, and showing no incorporation at this position. The two proton H^3 and $H^{3'}$ appeared as two doublets of doublets at δ = 2.4 and 2.72, corresponding to the coupling with the methine proton. These signals showed no deuterium incorporation at this position. The methyl appeared as a doublet and a small broad multiplet at δ = 1.21, showing 13% deuterium incorporation at C^1. The $^{13}C\{^1H\}$-NMR spectra and DEPT sequence confirmed these results. At δ = 35.7 and 37.4, two singlets showed no deuterium incorporation at C^2 and C^3, respectively. At δ = 16.7, C^1 appeared as a multiplet due to coupling with deuterium incorporated at this position.

Attempted Complex Characterization in situ

The ^{31}P-NMR spectrum of the catalytic complex in sodium formate shows broad signals centred at ca. δ = 31 and –5, probably due to a fluxional process including free TPPTS. Under catalytic conditions ([Rh] = 0.013 kmol·m^{-3}_{Aq}, TPPTS/Rh = 4), i.e. in the presence of sodium formate (3.3 kmol·m^{-3}) and DMI (0.02 kmol·m^{-3}), the NMR spectrum shows two types of compounds. The singlet at δ = 24.5 is assigned to a phosphonium according to previous reports.[14,15] It is formed by nucleophilic attack of the free TPPTS on the DMI, assisted by the Rhodium complex. Indeed, as proved in a separate experiment, the formation of the phosphonium is much slower when performed without Rhodium. Thus a yield of ca. 10%, based on TPPTS, is obtained without Rhodium, whereas a quantitative conversion of the free TPPTS is evidenced in the presence of the Rhodium complex. The change from fluxional to well defined ^{31}P spectra is thus attributed to the consumption of free TPPTS by DMI under catalytic conditions, which leads to the observation of the complex $[Rh(TPPTS)_3X]$ (X = Cl or OH)[16] based on the doublets and triplets at δ = 35.5 and 52.4 ($^1J_{Rh,P1}$ = 147 Hz, $^1J_{Rh,P2}$ = 182 Hz, and $^2J_{P1,P2}$ = 40 Hz), respectively. In water alone, under non-catalytic conditions, signals due to the complex $[Rh(TPPTS)_3(OH)]$, the phosphonium, and the TPPTS oxide are observed. A further signal at δ = 29.8 (d, $^1J_{Rh,P}$ = 145 Hz) is assigned to the cationic complex $[Rh(TPPTS)_2(cod)]^+$.[17]

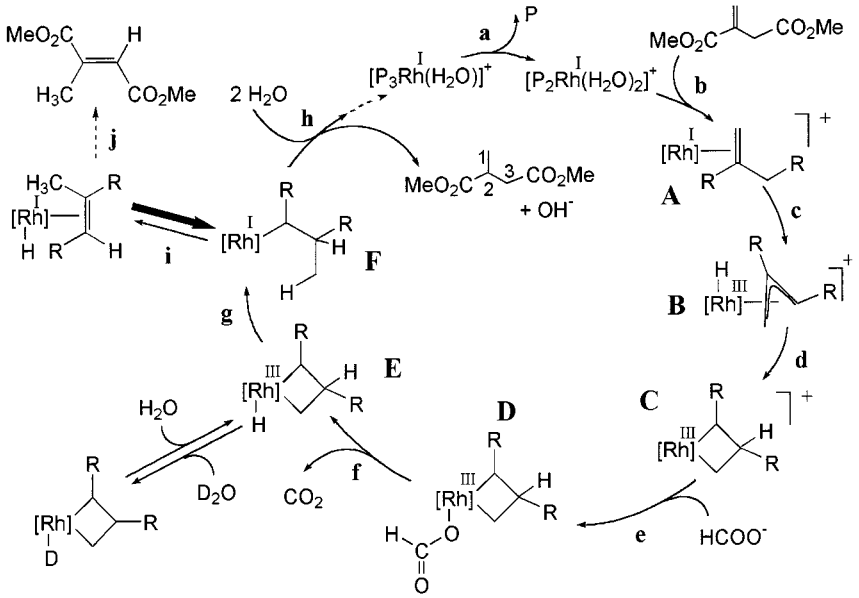
Discussion

Mechanism

The results of labelling studies differ considerably from those obtained for mechanistic studies of slightly different systems, i.e. formic acid as the hydrogen source, itaconic acid as the substrate, or monophasic systems.[1–4]

The most surprising result was the absence of deuterium incorporation in the C^2 position while reducing the DMI in either a $D_2O/HCOO^-$ medium or in $H_2O/DCOO^-$. Very low incorporation of deuterium in the C^2 position has been reported recently in the H-transfer reduction of dimethyl itaconate with a Rh/diphosphane catalyst in DMSO.[18] This result indicates that the hydrogen atom incorporated in the C^2 position *must* come from the substrate dimethyl itaconate itself.

The mechanism of reduction is not likely to be close to the one proposed by Sinou[2] for the hydrogenation of DMI, as it was demonstrated that water did not play any role as a reactant, which is not the case here. Indeed, after reduction with $D_2O/HCOO^-$, the product DMS presented a 31% deuterium incorporation in the C^1 position and a complete monodeuteration in the C^3 position. As it is known that the exchange of hydrogen by deuterium in the formyl position is very slow compared to hydrogen transfer,[1] the incorporation of deuterium by the product cannot be attributed to $DCOO^-$, which is unlikely to be present in the catalytic phase.



When the reduction is carried out with $H_2O/DCOO^-$, a primary kinetic isotope effect of $k_H/k_D = 2.8$ is measured. This value, in agreement with those obtained by Brunner,[1] clearly shows that the sodium formate is involved in the rate-determining step.

The only mechanism accounting for all these experimental results seems to involve going through a rhodametallocyclobutane (Scheme 1). Only this type of intermediate allows the C^2 position to remain untouched, without any incorporation of deuterium, and only partial incorporation in the methyl group when reduction is carried out with $H_2O/DCOO^-$.

The first step of the mechanism is a de-coordination of one phosphane ligand to give a Rh complex containing two phosphane equivalents. Step **b** is the coordination of the olefin to the Rh complex. Step **c** is an intramolecular oxidative addition of the olefin to the rhodium complex, which gives a π-allyl rhodium hydride. This type of intermediate is very well-known in the π-allyl mechanism of olefin isomerization with complexes of palladium[19] and rhodium.[20] The formation of the phosphonium salt may well occur by nucleophilic attack of free TPPTS at the coordinated π-allyl, which supports the view of complex B being part of the cycle.

The next step is an intramolecular rearrangement of a π-allyl rhodium hydride complex to a rhodametallacyclobutane. The formation of such a complex with addition of hydride reagents to a π-allyl rhodium complex has already been reported.[21,22] Steps **b** to **d** consist of the shift of a hydrogen atom from position 3 to position 2. The resulting sp^2 carbon (C^2) is reduced to an sp^3 carbon *intramolecularly* before any possible exchange with the reaction medium. This mechanism is the only one we could propose that explains the results of the labelling experiments.

The formate then coordinates to the metallacyclobutane intermediate. Step **f** of hydride transfer from formate to rhodium has already been postulated for the mechanism of itaconic acid reduction by hydrogen transfer,[1] although it was not possible to decide whether it occurs externally or through an intramolecular pathway. It has been shown that in this type of rhodium hydride or dihydride intermediate, scrambling always occurs.[1,23] That explains very well the partial incorporation of deuterium (13%) at the C^1 position when the reduction is carried out with $H_2O/DCOO^-$. The

Scheme 1

exchange Rh-D/H_2O must be quite slow, as the incorporation obtained in the C^1 position (31%) is close to the theoretical incorporation (33%) with $D_2O/HCOO^-$.

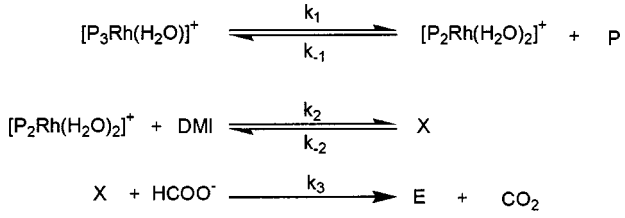
Step **g** is an intramolecular reductive elimination that opens the metallacyclobutane and rapidly gives a rhodium alkyl intermediate. This type of equilibrium between a metallacycle and a metal alkyl intermediate has already been seen in such reactions as C–H activation,[24–26] the metal alkyl intermediate being thermodynamically more stable than the metallacycle hydride.[26]

The final product is then recovered by hydrolysis, which explains the quantitative incorporation observed at the C^3 position when the reduction is carried out with $D_2O/HCOO^-$. This result is confirmed by the lack of incorporation at C^3 when $H_2O/DCOO^-$ is used. Hydrolysis of alkyl complexes of transition metals such as palladium (II)[27] and selective incorporation of H^+ in Rh-alkyl fragments[28] has already been reported.

The by-product, dimethylmesaconate, is formed by an isomerisation of the substrate DMS by migration of the double bond from an external to an internal position. The *cis* isomer, dimethylcitraconate, is not formed (^{13}C and ^1H NMR). A similar secondary isomerisation reaction is reported for the reduction of itaconic acid with formic acid/triethylamine.[8] Curiously, in this case, the cis isomer, i.e. citraconic acid, is formed. In the by-product, only the methyl group (position 1) incorporates deuterium (10–15% with $H_2O/DCOO^-$ and 20–25% with $D_2O/HCOO^-$), which is in accordance with the position of step **i** in the proposed mechanism.

Kinetics

Choice of the rate determining step:



(i) The sodium formate is involved in or before the rate determining step as a primary kinetic isotope effect is noted when the reduction is carried out with $H_2O/DCOO^-$.

(ii) Hydrolysis occurs after the last rate determining step as no isotope effect is measured when the reduction is carried out with $D_2O/HCOO^-$.

(iii) Addition of sodium hydrogenocarbonate has no influence on the course of the reaction.[7] The CO_2, a product of the reaction, is not involved before the last rate determining step.

(iv) The liberation of one equivalent of phosphane ligand occurs before the last rate determining step, as addition of phosphane inhibits the reaction.

The last rate determining step is then step **f**, as it occurs after the formate coordination and before the liberation of CO_2 and the final, hydrolysis step. In addition, only the steps involving terminal products have been considered. Thus, steps **b** to **d** involving intermediates A, B, and C have been lumped in one step in the kinetics (Scheme 2), otherwise the kinetic rate law would have been more complex and would have induced more constants and larger uncertainty in their estimation. The X letter used represents intermediates A, B, and C (Scheme 2). The same process has been used for the steps **e** and **f**. The kinetic Scheme allowed us to derive a formal kinetic rate law for the formation of DMS using the Bodenstein approach for catalytic intermediates (Equation 6).

Scheme 2

$$r = k_3 \frac{C_{Aq}^{HCOO^-} C_{Aq}^{DMI} C_{Aq}^{Rh}}{\frac{k_{-2}}{k_2} + \frac{k_{-1}k_{-2}}{k_1 k_2} C_{Aq}^{P} + C_{Aq}^{HCOO^-}\left(\frac{k_3}{k_2} + \frac{k_{-1}k_3}{k_1 k_2} C_{Aq}^{P}\right) + C_{Aq}^{DMI}\left(1 + \frac{k_3}{k_1} C_{Aq}^{HCOO^-}\right)} \quad (6)$$

This rate law is in accordance with experimental results, i.e. a negative order with respect to phosphane, first order with respect to the catalyst concentration, and complex order with respect to the substrate. It was not possible, however, to take into account the influence of the sodium formate concentration. The semi-empirical model (Equation 4 and Equation 5) presents a negative order with respect to the formate concentration, whereas the formal kinetic rate law presents a positive order of between 0 and 1.

Although this expression gives a complex order with respect to formate concentration, it was not possible to take its influence into account over the whole range of concentration used for the kinetic study.

The model is in good agreement with the experiments, but it was not possible to estimate one set of kinetic parameters for both series of experiments with sodium formate concentrations of 5 and 1 $kmol \cdot m^{-3}$. In addition, as the model possesses an intrinsic inaccuracy due to constants coupling, it was not possible to determine values of intrinsic kinetic constants with a sufficient accuracy, but only ratios of constants. More tests under a wider range of conditions where kinetic constants would not be coupled need to be performed.

Conclusion and Future Work

The kinetic and mechanistic study of H-transfer reduction of dimethyl itaconate by sodium formate/water under biphasic catalysis has been presented. A complex, semi-empirical kinetic model was first validated. It exhibits complex order with respect to the substrate concentration, and inhibition by the phosphane. Numerical integration using the entire concentration vs. time profiles provided values for the kinetic parameters of this model. Labelling studies and ^1H- and ^{13}C-NMR analysis were also performed. A catalytic cycle has been proposed based on these results. A rhodametallacyclobutane intermediate best accounts for the systematic non-deuteriation of the C^2 position of the product, the reduction being carried out either by $H_2O/DCOO^-$ or $D_2O/HCOO^-$. The mechanism is also supported by the good fit between the empirical model and the formal rate law, de-

rived from the mechanistic steps, despite a poor agreement concerning the influence of sodium formate.

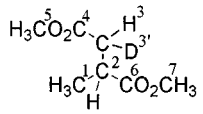
The main conclusion concerns the shift in the mechanism on going from diacids to their ester derivatives. Unsaturated acids reduction proceeds through a *cis*-1,2-hydrogen addition,[1,8] whereas this work shows that reduction of esters should undergo a 1,3-addition.[1] This switch in mechanism may well account for the lower optical yields observed in the enantioselective H-transfer reduction of esters compared to their corresponding acids.[8]

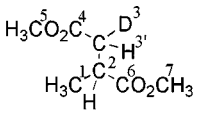
Experimental Section

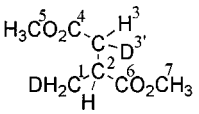
General: ^{31}P-NMR spectra (external reference H_3PO_4 85% D_2O) were recorded on a Bruker AM 300 (121.51 MHz) and a Bruker AM 200 (81.015 MHz). ^{1}H- and ^{13}C-NMR spectra (external reference $SiMe_4$) were recorded on a Bruker AM 200 (200.13 MHz and 50.32 MHz, for ^{1}H and ^{13}C, respectively). Deuterated water (99.9 atom% D, Aldrich) and [D_2]formic acid (99+ atom%, 95% in D_2O, ACROS) for the labelling study were degassed and used without further purification. – TPPTS 30% wt in water, sodium formate (97%, Aldrich), dimethyl itaconate (97%, Aldrich), decane (99%, Aldrich), mesaconic acid (99%, Aldrich), and the catalyst precursor [Rh(cod)Cl]$_2$ (98%, Strem) were used as received. All the experiments were performed under argon or nitrogen. – Partition isotherms determination: The experimental procedure for determining partition isotherms has already been described in a previous paper.[7] – Kinetic studies in a well mixed batch reactor: All the details have already been described in a previous paper.[7] The reduction of dimethyl itaconate (DMI) was performed under a range of conditions, given in Table 2. The initial rate of reaction is calculated from the slope of concentration vs. time profiles at low conversion (< 10%).

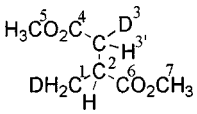
Labelling Study/Reduction of DMI in D_2O/HCOONa: A solution of TPPTS in water (30% wt, 2 cm^3, 1.22 mmol) was evaporated. D_2O (2 cm^3) was then added to the residue, and the procedure was repeated twice. A solution of sodium formate in D_2O (5, 8 cm^3, 40 mmol) was then added to an orange slurry of [Rh(cod)Cl]$_2$ (48.9 mg, 0.2 mmol) in the solution of TPPTS in D_2O previously prepared. The mixture was stirred at room temperature for about 12 h and stored at 4 °C. The catalytic run was performed as previously described.[7] After reduction, the organic layer was separated, dried with $CaCO_3$, and the solvent was evaporated. The oily product was analysed by NMR spectroscopy. – ^{13}C NMR: δ = 16.7 (m, $^1J_{CD}$ = 19.7 Hz, C^1), 35.5 (m, C^2), 37.0 (t, $^1J_{CD}$ = 20.0 Hz, C^3), 51.5 (s, C^7), 51.8 (s, C^5), 172.1 (s, C^6), 175.5 (s, C^4). – ^{1}H NMR data for the isotopomers identified in the organic layer: **1**: δ = 1.15 (d, $^3J_{12}$ = 7.1 Hz, 3 H, H^1), 2.65 (dt, $^3J_{32}$ = 8.0 Hz, $^2J_{HD}$ = 2.3 Hz, 1 H, H^3), 2.80 (m, 1 H, H^2), 3.61, 3.63 (s, 3 H, H^5, H^7). – **2**: δ = 1.15 (d, $^3J_{12}$ = 7.1 Hz, 3 H, H^1), 2.33 (m, $^3J_{3'2}$ = 6.0 Hz, $^2J_{HD}$ = 2.3 Hz, 1 H, H$^{3'}$), 2.80 (m, 1 H, H^2), 3.61, 3.63 (s, 3 H, H^5, H^7). – **3**: δ = 1.13 (dt, $^3J_{12}$ = 7.1 Hz, $^2J_{HD}$ = 1.8 Hz, 2 H, H^1), 2.65 (dt, $^3J_{32}$ = 8.0 Hz, $^2J_{HD}$ = 2.3 Hz, 1 H, H^3), 2.80 (m, 1 H, H^2), 3.61, 3.63 (s, 3 H, H^5, H^7). – **4**: δ = 1.13 (dt, $^3J_{12}$ = 7.1 Hz, $^2J_{HD}$ = 1.8 Hz, 2 H, H^1), 2.33 (m, $^3J_{3'2}$ = 6.0 Hz, $^2J_{HD}$ = 2.3 Hz, 1 H, H$^{3'}$), 2.80 (m, 1 H, H^2), 3.61, 3.63 (s, 3 H, H^5, H^7). – **5**: δ = 2.22 (d, $^4J_{13}$ = 1.5 Hz, 3 H, H^1), 3.74, 3.70 (s, 3 H, H^5, H^7), 6.71 (broad, 1 H, H^3). – **6**: δ = 2.22 (m, $^4J_{13}$ = 1.5 Hz, $^2J_{HD}$ = 1.46 Hz, 2 H, H^1), 3.74, 3.70 (s, 3 H, H^5, H^7), 6.71 (broad, 1 H, H^3).

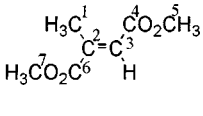
Labelling Study/Reduction of DMI in H_2O/DCOONa: A solution of [D_2]formic acid in D_2O (95% wt, 10 g, 0.19 mmol) was added to an aqueous solution of sodium hydroxide (10, 20 cm^3, 0.2 mmol). The mixture was then evaporated and water was added to the residue. This procedure was repeated twice to remove traces of D_2O and D^+. Water (40 cm^3) was finally added to the thus prepared [D]sodium formate. Preparation of the catalyst and realization of the kinetic tests were then performed as already described.[7] – After reduction the organic layer was separated, dried with $CaCO_3$, and the solvent was evaporated. The oily product was analyzed by NMR spectroscopy. – ^{13}C NMR: δ = 16.7 (m, $^1J_{CD}$ = 19.7 Hz, C^1), 35.7 (m, C^2), 37.4 (s, $^1J_{CD}$ = 20.0 Hz, C^3), 51.7 (s, C^7), 51.9 (s, C^5), 172.3 (s, C^6), 175.7 (s, C^4).

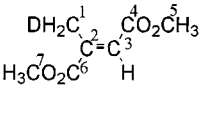


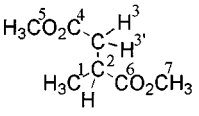


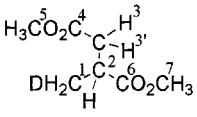












The ^{1}H-NMR data showed the presence of isotopomers **5**, **6**, **7**, and **8**. – **7**: δ = 1.16 (d, $^3J_{12}$ = 7.1 Hz, 3 H, H^1), 2.35 (dd, $^2J_{33'}$ = 16.3 Hz, $^3J_{23'}$ = 6.0 Hz, 1 H, H$^{3'}$), 2.67 (dd, $^3J_{23}$ = 8.0 Hz,1 H, H^3), 2.85 (m, 1 H, H^2), 3.61, 3.63 (s, 3 H, H^5, H^7). – **8**: δ = 1.16 (dt, $^3J_{12}$ = 7.1 Hz, $^2J_{HD}$ = 1.9 Hz, 2 H, H^1), 2.35 (dd, $^2J_{33'}$ = 16.3 Hz, $^3J_{23'}$ = 6.0 Hz, 1 H, H$^{3'}$), 2.67 (dd, $^3J_{23}$ = 8.0 Hz, 1 H, H^3), 2.85 (m, 1 H, H^2), 3.61, 3.63 (s, 3 H, H^5, H^7).

Synthesis of the By-Product DMM: A drop of sulfuric acid 98% was added to a solution of mesaconic acid (2 g, 15.3 mmol) in methanol (50 cm^3). The mixture was stirred at room temperature for 3 days. The solvent was then evaporated and the crude product obtained was characterised by ^{1}H-NMR (200 MHz, $CDCl_3$) spectroscopy. – ^{1}H NMR: δ = 2.30 (d, $^4J_{13}$ = 1.6 Hz, 3 H, H^1), 3.78, 3.82 (s, 3 H, H^5, H^7), 6.80 (q, 1 H, H^3).

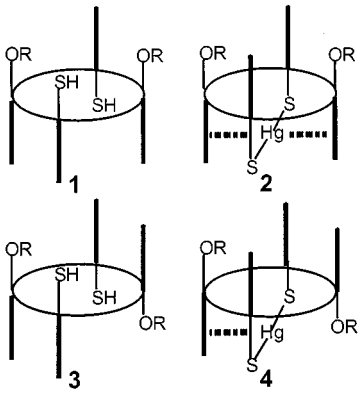
Mercaptocalixarenes as Mercury(II) Extractors: Synthesis, Structural Analysis and Extraction Properties of Lipophilic Dimercaptocalix[4]arenes

Photon Rao,[a] Olivier Enger,[a] Ernest Graf,[a] Mir Wais Hosseini,*[a] André De Cian,[b] and Jean Fischer[b]

Keywords: Calixarenes / Cyclophanes / Macrocycles / Mercury / S ligands



Lipophilic calix[4]arene derivatives that contain two O–C_{12} alkyl chains and two SH groups at the lower rim were synthesized and characterized in the 1,2- and partial-cone conformations. Both conformers were treated with Hg^{2+} and formed neutral mononuclear Hg^{2+} complexes, in which the cation was linearly coordinated to two sulfur atoms. The lipophilic dimercaptocalixarenes were shown to extract Hg^{2+} cations exclusively and efficiently from an aqueous phase into chloroform.

Introduction

The presence of toxic heavy metals in aqueous reservoirs is an important environmental issue.[1] In particular, the mercury(II) cation represents an environmental danger to a variety of living organisms, including mammals,[2] due to its toxicity. Because of the use of mercury derivatives in fungicides and insecticides, Hg^{2+} cations are present in our environment at a rather high level.[3] Since the extraction of heavy metal cations such as Hg^{2+} from aqueous solutions into organic phases may be a possible alternative for water purification, the design of selective extractors for heavy metals appeared to us to be an interesting challenge.

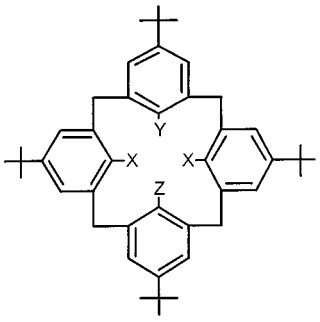
The affinity of mercury for sulfur-containing ligands has been well established.[4] Based on this observation, calixarene derivatives bearing pendent sulfur atoms,[5] and thiacrown ethers[6] have been used as extractors for Hg^{2+} cations. In this context, we and others have been working on sulfur-containing calixarene derivatives such as di-[7] and tetramercaptocalix[4]arenes,[8,9] in which two and four OH groups were replaced by two or four SH functions, respectively as well as mercaptoparacyclophane[10] and thiacalix[4]arenes.[11,12]

We have previously demonstrated that di-[7] and tetramercaptocalix[4]arenes[9] were able to form mono- and binuclear mercury complexes, respectively, in which the calix unit adopted the 1,3-alternate conformation. The cation was therefore strongly coordinated to two thiolate centres, and experienced other interactions with two aromatic rings, thus fulfilling its "2 + 4" coordination requirements. With this insight, the ligand **1**, composed of the *p-tert*-butylcalix[4]arene backbone bearing two SH and two OC_{12} groups, was designed. The two alkyl chains were introduced in order to increase the lipophilicity of the Hg^{2+} complex **2** (Scheme 1).

Scheme 1

In this contribution we report the synthesis of **1** and **3**, and their Hg^{2+} complexes **2** and **4**, respectively, as well as the extraction of mercury from water into chloroform by conformers **1** and **3**.

Results and Discussion



Synthesis

The synthetic strategy used to prepare **1** was based on dithiacarbamoylation of *p-tert*-butylcalix[4]arene **5**[13] at the 1- and 3-positions, followed by transformation of the remaining two OH groups into ether fragments by treatment with bromododecane. Thermal rearrangement of the $OCSNMe_2$ fragments into the $SCONMe_2$ groups was then accomplished by the Newman–Kwart method,[14] and finally, the reductive deprotection of the sulfur atoms using $LiAlH_4$ yielded the desired mercapto derivatives **1** and **3** (Scheme 2 and 3).

Thiacarbamoylation of *p-tert*-butylcalix[4]arene with $(Me)_2NCSCl$ in the presence of K_2CO_3 in refluxing acetone for 24 h yielded 5–10% of the trisubstituted derivative, as

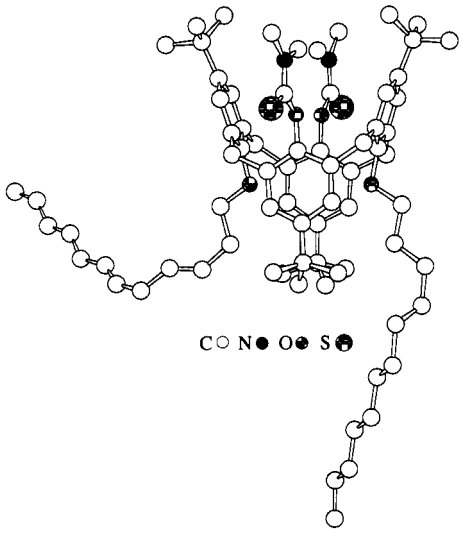
Scheme 2



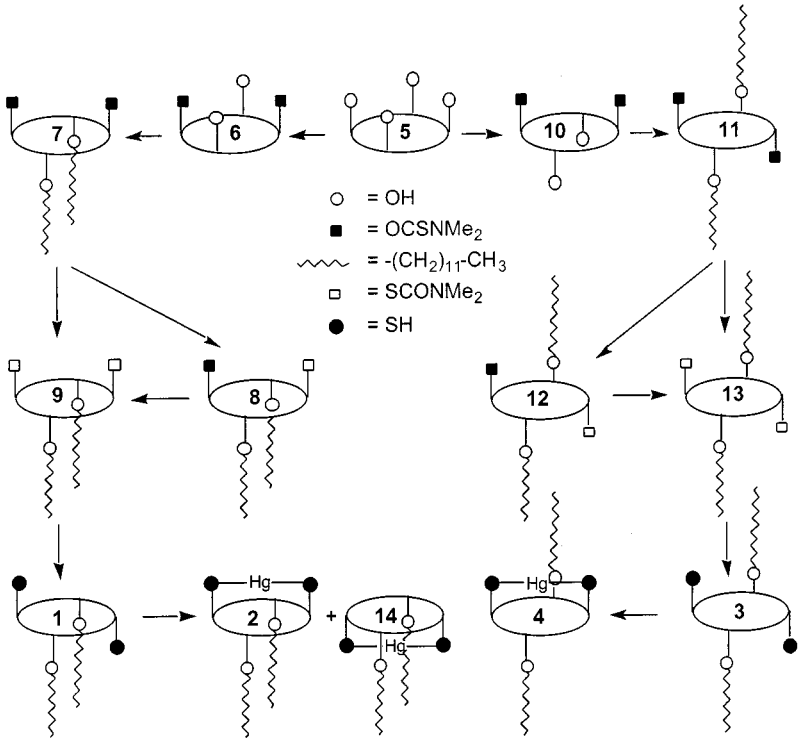


Figure 1. X-ray structure of the disubstituted compound **7** in the 1,3-alternate conformation; for the sake of clarity, H atoms are not represented; selected average bond lengths and angles: $d_{C=S}$ = 1.66 Å, d_{C-N} = 1.33 Å, d_{C-OPh} = 1.36 Å, d_{N-CH3} = 1.45 Å, OCS angle = 124.5°, NCS angle = 125.5°, NCO angle = 110.05°

well as the disubstituted conformers **6** (13%) and **10** (40%), non interconvertible at room temperature. While the treatment of **6** with bromododecane in the presence of NaH in refluxing THF afforded the tetrasubstituted compound **7** in the 1,3-alternate conformation in quantitative yield after 24 h, surprisingly, under the same conditions, the reaction of **10** afforded the compound **11** in the 1,2-alternate conformation. Both compounds **7** (Figure 1) and **11** (Figure 2) were characterized in the solid state by single-crystal X-ray diffraction methods.

The thermal rearrangement of **7** was performed in vacuum on the melt at 340 °C, and yielded the mono-rearranged compound **8** (50%), the bis-rearranged compound **9** (25%) and the unchanged starting material **7** (25%). Subsequently, compound **8** could be rearranged in 20% yield to **9** under similar conditions. Attempts to increase the yield

Scheme 3

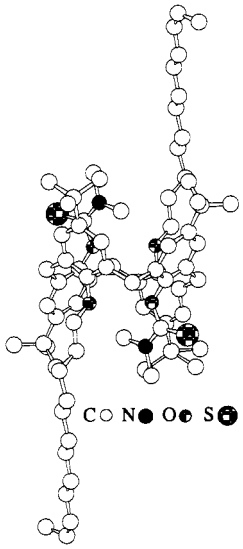

Figure 2. X-ray structure of compound **11** in the 1,2-alternate conformation; for the sake of clarity, H atoms are not represented; selected bond lengths and angles: $d_{C=S}$ = 1.66 Å, d_{C-N} = 1.32 Å, d_{C-OPh} = 1.36 Å, d_{N-CH_3} = 1.47 Å, OCS angle = 123.8°, NCS angle = 126.4°, NCO angle = 109.7°

by performing the reaction in refluxing ditolyl ether failed.[8] Reductive deprotection of **9** was performed using $LiAlH_4$ in refluxing THF, yielding the dimercapto compound **1** (80%) in the partial cone conformation. On the other hand, performing the same sequence of reactions on **11** afforded **12** (40%), the bis-rearranged derivative **13** (20%), and the starting compound **11** (40%). As before, **12** could be rearranged into **13** under the same conditions in 15% yield. Compound **13**, in the 1,2-alternate conformation, was transformed into the desired compound **3** in 74% yield by treatment with $LiAlH_4$ in refluxing THF. The final structural assignment of both **1** and **3** was based on 2D-ROESY NMR data.

Complexation

In order to isolate the mercury complexes **2** and **4**, compounds **1** and **3** were treated with mercuric acetate in refluxing THF for 30 min. For the Hg^{2+} complex **2** that formed with compound **1**, the calix unit was in the 1,3-alternate conformation, whereas in the case of the complex **4** formed with compound **3**, the calix unit was found to be in the partial cone conformation (Scheme 1). These two conformations for the calix backbone were established by 2D-ROESY as well as by ^{199}Hg-NMR experiments. Mercury resonances were observed at $\delta = -1375$ for **2** and at $\delta = -1294$ for **4**. These values are close to the one observed previously ($\delta = -1394$) for the bis(binuclear) mercury complex formed with tetramercaptocalix[4]arene,[9] in which the 1,3-alternate conformation was established by X-ray crystallography. The difference in the chemical shifts observed for **2** and **4** may be rationalized in terms of the Hg^{2+}−aromatic interactions. Indeed, based on previous observations, the rather negative chemical shift value observed may be attributed to the local environment of the metal centre in both **2** and **4** complexes, where the Hg^{2+} cation is completely and half-sandwiched between two aromatic rings, respectively. The observation of a ^{199}Hg-NMR signal at $\delta = -1054$ for the (*p-tert*-butyl−Ph−S)$_2$Hg complex supports the above explanation, because in that case, no Hg^{2+}−aromatic interactions would be present.

Extraction

In this contribution, we report only some preliminary investigations dealing with the extraction of heavy metal cations. The extraction ability of both compounds **1** and **3** was studied under the following conditions: A 5-mL $CHCl_3$ solution of **1** or **3** (mM concentration) was stirred for 30 min in the presence of a 5-mL 95% aqueous acetic acid solution containing $Hg(OAc)_2$ (mM concentration). Aliquots were taken from the aqueous phase, and the amount of mercury remaining was determined by colourimetric titration with dithizon (see Table 1).

Table 1. Extraction of M^{2+} by **1** and **3**

	(mM)[a]	M^{2+}	[M^{2+}] (mM)[b]	%[c]
1	2.8	Hg^{2+}	1.5	100
1	2.8	Hg^{2+}	3.0	87
1	2.8	Hg^{2+}	10.0	34
3	2.8	Hg^{2+}	10.0	34
1	2.8	Pb^{2+}	11.0	none[d]
1	2.8	Cd^{2+}	10.0	none[d]
3	3.0	Pb^{2+}	11.0	none[d]
3	3.0	Cd^{2+}	10.0	none[d]

[a] A solution of the ligand prepared in $CHCl_3$. − [b] A solution of $M(OAc)_2$ in 95% aqueous acetic acid. − [c] Determined (accuracy 0.05 mM) by titrating the aqueous layer after extraction with a solution of dithizon. − [d] Also confirmed by ^{1}H NMR which shows only the presence of the free ligand after the removal and evaporation of the $CHCl_3$ layer.

The nature of the complexes formed between ligands **1** or **3** and mercury cation under extraction conditions was investigated in the following manner: A biphasic mixture composed of a $CHCl_3$ solution containing either the ligand **1** or **3** in mM concentration, an aqueous phase containing 5% acetic acid, added in order to avoid the hydrolysis of the mercuric salt, and $Hg(OAc)_2$ in mM concentration, was stirred at room temperature. As expected, it was found that Hg^{2+} cations were extracted from the aqueous phase into the organic layer. After removal of the organic phase and evaporation of the $CHCl_3$, the nature of the extracted complexes was elucidated by ^{1}H NMR ($CDCl_3$, 25 °C), which showed that in both cases the extracted complexes were identical to the prepared and independently identified complexes **2** and **4**, respectively. However, in the case of ligand **1**, a small amount of another complex showing a rather high symmetry was detected by ^{1}H NMR. This compound was separated by preparative thin layer chromatography and was investigated by mass spectrometry in the FAB^+ mode, and showed a peak at 1216.8 (100%) identical to that observed for mercury complexes **2** and **4**. Furthermore, performing ^{1}H NMR ($CDCl_3$, 25 °C) on the isolated complex, demonstrated that it was the other possible complex **14** (Scheme 3), where the calix unit adopts the cone conformation. However, in marked contrast with complex **2**, where

the calix unit, by adopting the 1,3-alternate conformation, allows both the coordination of the metal cation to two thiolate centres as well as metal−π interactions through the formation of the sandwich complex, in the case of **14** only the coordination of the metal cation to two thiolate groups is possible. This fact may explain the formation of **14** in rather low yield.

When compound **1** (2.8 mM) was present in excess with respect to Hg^{2+} (1.5 mM), 100% of the cation was extracted into chloroform, indicating the high affinity of **1** for mercury cations (see Table 1). On the other hand, in the case of a slight (3.0 mM) or a large (10.0 mM) excess of Hg^{2+} cations, 87% and 34% extraction was observed, respectively. Interestingly, under the same conditions, no extraction of Cd^{2+} or Pb^{2+} cations was observed using **1** or **3**, demonstrating the remarkable selectivity of both compounds **1** and **3** for the Hg^{2+} cations with respect to cadmium and lead cations. The latter observation demonstrates the validity of the design of selective extracting agents for mercury cations.

Conclusions

In conclusion, the synthesis of two new mercaptocalix[4]-arene derivatives bearing long alkyl chains was achieved. Both compounds were shown to efficiently and selectively extract the Hg^{2+} cation from acidic aqueous solution into chloroform. Both compounds showed remarkable selectivity towards Hg^{2+} cation with respect to Cd^{2+} and Pb^{2+} cations. A systematic study of the extraction ability of the reported compounds is currently under investigation.

Experimental Section

General: ^{1}H-, ^{13}C- and ^{199}Hg-NMR spectra were recorded with Bruker WP 200SY and AM 400 instruments operating at 200.13, 50.32, and 71.66 MHz, respectively. ^{1}H-NMR peak positions are reported relative to $CHCl_3$ (δ = 7.26). ^{13}C-NMR peak positions are reported relative to $CDCl_3$ (δ = 77. 0). ^{199}Hg-NMR peak position are reported relative to $CH_3S-Hg-SCH_3$ as external reference. Mass spectra (FAB^+) were recorded in nitrobenzyl alcohol.

Procedure for the Preparation of Compounds 6 and 10: To a slurry of **5**[13] (16.00 g, 25 mmol) in acetone (600 mL), K_2CO_3 (13.8 g, 100 mmol) was added, and the mixture was heated under reflux for 30 min. Then, a solution of *N*,*N*-dimethylthiocarbamoyl chloride (12.5 g, 100 mmol) in acetone (20 mL) was added and refluxing was continued for a further 16 h. Volatile components were removed under vacuum, and the contents of the flask was diluted with water (50 mL) and acidified to pH = 2 by careful addition of dilute aqueous H_2SO_4. The solid thus obtained was extracted with CH_2Cl_2 (5×100 mL) and the removal of the solvent left a crude material which was purified by column chromatography (SiO_2, CH_2Cl_2), and yielded 13% (2.7 g) of **6** and 40% (8.1 g) of **10**.

Compound 6: M.p. > 350 °C. − ^{1}H NMR (200 MHz, $CDCl_3$): δ = 1.00 (s, 18 H), 1.32 (s, 18 H), 3.13 (s, 12 H), 3.49 (s, 12 H), 3.48 (d, *J* = 15 Hz, 4 H), 3.82 (d, *J* = 15 Hz, 4 H), 4.79 (s, 2 H), 6.88 (s, 4 H), 7.07 (s, 4 H). − ^{13}C NMR (50 MHz, $CDCl_3$): δ = 31.1, 31.8, 33.7, 34.0, 34.1, 38.4, 43.6, 125.5, 126.1, 128.0, 132.2, 142.5, 146.6, 148.9, 150.6, 186.8. − MS (FAB^+); *m*/*z* (%): 823.3 (100) [$M^{\cdot+}$], 734.2 (90) [M^+ − $OCSN(Me)_2$]. − $C_{50}H_{66}N_2O_4S_2{\cdot}H_2O$ (841.23): calcd. C 71.39, H 8.15; found C 71.53, H 7.95.

Compound 10: M.p. > 350 °C. − ^{1}H NMR (200 MHz, $CDCl_3$): δ = 1.28 (s, 18 H), 1.32 (s, 18 H), 1.71 (s, 12 H), 3.21 (s, 12 H), 3.63 (d, *J* = 15 Hz, 4 H), 4.00 (d, *J* = 15 Hz, 4 H), 4.81 (s, 2 H), 7.06 (s, 4 H), 7.26 (s, 4 H). − ^{13}C NMR (50 MHz, $CDCl_3$): δ = 31.4, 31.8, 34.0, 34.4, 36.7, 43.4, 125.0, 126.4, 133.1, 142.8, 147.3, 149.1, 149.8, 184.7. − MS (FAB^+); *m*/*z* (%): 823.3 (100) [M^+].

General Procedure for the Preparation of Compounds 7 and 11: To a slurry of either compound **6** or **10** (0.50 g, 0.6 mmol) in THF (50 mL) was added NaH (0.20 g, 8.3 mmol) followed by bromododecane (2.0 mL, 8.7 mmol), and the mixture heated under reflux for 8 h. Volatile components were removed under vacuum, and the reaction mixture quenched by dropwise addition of water (5 mL). After acidification with dilute aqueous H_2SO_4, the solid was extracted in CH_2Cl_2. Volatile components were again removed under vacuum, and the crude material was purified by column chromatography (SiO_2, CH_2Cl_2/hexane: 1:1) affording **7** or **11** in quantitative yields.

Compound 7: ^{1}H NMR (200 MHz, $CDCl_3$): δ = 0.89 (t, *J* = 6.6 Hz, 6 H), 1.15−1.35 (m, 36 H), 1.50−1.65 (m, 4 H), 2.16 (s, 6 H), 3.39 (s, 6 H), 3.51 (t, *J* = 8 Hz, 4 H), 3.60 (d, *J* = 2.2 Hz, 2 H), 3.71 (d, *J* = 15 Hz, 4 H), 6.87 (s, 4 H), 7.09 (s, 4 H). − ^{13}C NMR (50 MHz, $CDCl_3$): δ = 14.1, 22.6, 25.7, 26.1, 29.3, 29.5, 29.6, 29.7, 31.4, 31.6, 31.8, 33.9, 34.0, 38.2, 38.6, 43.4, 71.1, 126.0, 126.8, 132.5, 134.4, 143.3, 145.8, 148.6, 155.8, 185.9. − MS (FAB^+); *m*/*z* (%): 1159.7 (100) [M^+]. − $C_{74}H_{114}N_2O_4S_2$ (1159.86): calcd. C 76.63, H 9.91, N 2.42; found C 76.76, H 9.80, N 2.38.

Compound 11: ^{1}H NMR (200 MHz, $CDCl_3$): δ = 0.87 (t, *J* = 6.6 Hz, 6 H), 1.11−1.37 (m, 40 H), 1.32 (s, 18 H), 1.34 (s, 18 H), 1.42 (s, 6 H), 3.13 (s, 6 H), 3.32 −3.52 (m, 6 H), 3.82−3.95 (m, 6 H), 6.91 (d, *J* = 2.2 Hz, 2 H), 7.09 (d, *J* = 2.2 Hz, 2 H), 7.28 (d, *J* = 2.2 Hz, 2 H), 7.35 (d, *J* = 2.2 Hz, 2 H). − ^{13}C NMR (50 MHz, $CDCl_3$): δ = 14.1, 22.6, 25.5, 29.2, 29.5, 30.2, 31.5, 31.7, 31.8, 34.0, 34.2, 37.2, 39.3, 43.2, 74.2, 125.1, 125.3, 125.5, 125.8, 132.7, 133.3, 133.4, 134.8, 145.1, 147.0, 147.5, 154.0, 184.7. − MS (FAB^+); *m*/*z* (%): 1159.7 (100) [M^+]. − $C_{74}H_{114}N_2O_4S_2$ (1159.86): calcd. C 76.63, H 9.91, N 2.42; found C 76.57, H 9.76, N 2.36

Compounds 8 and 9: In a round-bottomed flask, compound **7** (0.21 g, 0.18 mmol) was heated under vacuum to 340 °C for 3 h. The reaction mixture was purified by column chromatography (SiO_2, CH_2Cl_2) affording 50% (0.10 g) of the mono-rearranged compound **8** and 25% (0.05 g) of the bis-rearranged compound **9**, along with 25% (0.06 g) of the starting material **7**.

Compound 8: ^{1}H NMR (200 MHz, $CDCl_3$): δ = 0.90 (t, *J* = 6.6 Hz, 6 H), 1.26 (s, 58 H), 1.32 (s, 18 H), 1.66 (s, 3 H), 2.70−3.00 (m, 6 H), 3.29 (s, 3 H), 3.35−3.50 (m, 4 H), 3.72 (d, *J* = 17 Hz, 2 H), 3.87 (d, *J* = 17 Hz, 2 H), 6.87 (d, *J* = 2.2 Hz, 2 H), 7.02 (s, 2 H), 7.02 (d, *J* = 2.2 Hz, 2 H), 7.19 (s, 2 H). − ^{13}C NMR (50 MHz, $CDCl_3$): δ = 14.1, 14.2, 22.8, 25.9, 29.0, 29.4, 29.7, 30.1, 31.4, 31.7, 31.8, 32.0, 34.0, 34.2, 34.3, 36.6, 38.7, 39.7, 42.5, 43.5, 70.6, 77.4, 122.7, 125.5, 126.4, 128.0, 128.6, 133.0, 134.2, 134.8, 144.2, 146.4, 146.9, 148.9, 150.3, 155.0, 167.4, 184.4. − MS (FAB^+); *m*/*z* (%): 1160.0 (100) [$M^{\cdot+}$].

Compound 9: ^{1}H NMR (200 MHz, $CDCl_3$): δ = 0.90 (t, *J* = 6 Hz, 6 H), 1.10−1.40 (m, 40 H), 1.26 (s, 18 H), 1.30 (s, 18 H), 2.60−2.80 (br. s, 6 H), 2.80−3.30 (br. s, 6 H), 3.35−3.45 (m, 4 H), 3.89 (s, 8

H), 7.00 (s, 4 H), 7.12 (s, 4 H). − ^{13}C NMR (50 MHz, $CDCl_3$): δ = 14.2, 21.0, 22.0, 25.9, 29.2, 29.4, 29.7, 30.0, 31.0, 31.4, 31.7, 34.0, 34.3, 36.7, 42.5, 71.1, 123.0, 126.1, 127.9, 134.5, 144.0, 146.3, 149.5, 150.0, 168.0. − MS (FAB^+); *m/z* (%): 1160.0 (100) [$M^{\cdot+}$].

Compounds 12 and 13: In a round-bottomed flask, compound **11** (0.1 g, 0.08 mmol) was heated under vacuum to 340 °C for 3 h. The reaction mixture was purified by column chromatography (SiO_2, CH_2Cl_2) affording 40% (0.04 g) of the mono-rearranged compound **12** and 20% (0.02 g) of the bis-rearranged compound **13**, along with 40% (0.04 g) of the starting material **11**.

Compound 12: ^{1}H NMR ($CDCl_3$, 200 MHz): δ = 0.8−1.5 (m, 88 H), 2.74 (s, 6 H), 3.1−4.1 (m, 10 H), 4.54 (d, *J* = 12 Hz, 2 H), 6.88−7.43 (m, 8 H).

Compound 13: ^{1}H NMR ($CDCl_3$, 200 MHz): δ = 0.8−0.9 (m, 6 H), 1.0−1.4 (m, 88 H) 2.6−4.0 (m, 10 H), 4.2−4.6 (m, 2 H), 6.84, − 7.38 (m, 8 H).

Compound 1: To a solution of **9** (0.08 g, 0.07 mmol) in dry THF (10 mL) was added $LiAlH_4$ (0.02 g, 0.5 mmol) and the solution was heated under reflux for 3 h. After cooling, the reaction mixture was quenched by dropwise addition of H_2O, and acidified to pH = 2 with aqueous 10% H_2SO_4. The crude product was extracted with CH_2Cl_2 (20 × 2 mL). After removal of the solvent, the crude material was purified by column chromatography (SiO_2; CH_2Cl_2/hexane, 75:25) affording the desired compound **1** in 80% yield (0.06 g). − ^{1}H NMR (500 MHz, $CDCl_3$): δ = 0.90 (t, *J* = 6 Hz, 6 H), 1.04 (s, 18 H), 1.20−1.45 (m, 40 H), 1.32 (s, 9 H), 1.35 (s, 9 H), 2.15 (s, 1 H), 3.37 (s, 1 H), 3.48 (d, *J* = 3.2 Hz, 2 H), 3.63 (dd, *J* = 7.2 Hz, 4 H), 3.85−4.00 (m, 6 H), 6.60 (d, *J* = 2.5 Hz, 2 H), 7.11 (s, 2 H), 7.15 (d, *J* = 2.5 Hz, 2 H), 7.43 (s, 2 H). − ^{13}C NMR (50 MHz, $CDCl_3$): δ = 14.2, 22.8, 26.6, 29.4, 29.7, 30.9, 31.3, 31.5, 32.0, 33.8, 34.0, 34.3, 34.9, 40.6, 75.5, 125.0, 125.6, 128.5, 130.3, 130.7, 130.8, 140.0, 140.5, 141.7, 143.6, 145.7, 146.7, 154.1. − MS (FAB^+); *m/z* (%): 1016.8 (100) [$M^{\cdot+}$], 829.6 (60). − HRMS ($C_{68}H_{104}O_2S_2$): calcd. 1016.7478; found 1016.7474.

Compound 3: To a solution of **13** (0.05 g, 0.043 mmol) in dry THF (10 mL) was added $LiAlH_4$ (0.02 g, 0.5 mmol) and the solution was heated under reflux for 3 h. After cooling, the reaction mixture was quenched by dropwise addition of H_2O, and acidified to pH = 2 with aqueous 10% H_2SO_4. The crude product was extracted with CH_2Cl_2 (20×2 mL). After removal of the solvent, the crude material was purified by column chromatography (SiO_2; CH_2Cl_2/hexane, 75:25) affording the desired compound **3** in 74% yield (0.04 g). − ^{1}H NMR (200 MHz, $CDCl_3$): δ = 0.89 (t, *J* = 6.6 Hz, 6 H), 1.10−1.40 (m, 40 H), 1.24 (s, 18 H), 1.33 (s, 18 H), 2.84 (s, 2 H), 3.40 (t, *J* = 6.6 Hz, 4 H), 3.70 (d, *J* = 14 Hz, 4 H), 4.24 (d, *J* = 14 Hz, 4 H), 7.08 (s, 4 H), 7.19 (s, 4 H). − ^{13}C NMR (50 MHz, $CDCl_3$): δ = 15.0, 24.0, 27.2, 30.0, 30.2, 30.3, 30.8, 32.7, 32.8, 33.0, 35.5, 74.8, 125.3, 127.4, 128.0, 134.6, 143.2, 145.0, 155.0, 157.5.

General Procedure for the Preparation of Complexes 2 and 4: To a THF solution (1.0 mL) of the dithiol **1** or **3** (0.010 g, 0.01 mmol), excess $Hg(OAc)_2$ (0.10 g, 0.3 mmol) was added and the mixture stirred for 30 min. After evaporation of the solvent, the residue was extracted with CH_2Cl_2 (5×4 mL). After removal of the solvent, the crude mixture was purified by column chromatography (SiO_2) using as eluent 10−20% CH_2Cl_2/hexane in the case of the complex **2** and 20−40% CH_2Cl_2/hexane in the case of the complex **4**. Whereas complex **2** was obtained in quantitative yield (0.012 g), complex **4** was isolated in 74% yield (0.009 g).

Complex 2: ^{1}H NMR (200 MHz, $CDCl_3$): δ = 0.90 (t, *J* = 6 Hz, 6 H), 1.28 (s, 18 H), 1.31 (s, 58 H), 3.56 (t, *J* = 8 Hz, 4 H), 4.05 (d, *J* = 15 Hz, 4 H), 4. 17 (d, *J* = 15 Hz, 4 H), 7.11 (s, 4 H), 7.32 (s, 4 H). − ^{13}C NMR (50 MHz, $CDCl_3$): δ = 14.0, 22.8, 26.1, 29.5, 29.6, 29.7, 29.8, 31.4, 31.7, 31.9, 34.2, 43.3, 72.0, 126.5, 132.0, 134.1, 145.0, 154.5. − ^{199}Hg NMR (72 MHz, $CDCl_3$): δ = −1375. − MS (FAB^+); *m/z* (%): 1216.8 (75) [M^+, $C_{68}H_{102}HgO_2S_2$], 1159.9 (25) [M^+ − isobutene], 1016.1 (25) [M − Hg]$^+$, 829.6 (55) [M^+ − Hg − $O(CH_2)_{11}CH_3$].

Complex 4: ^{1}H NMR (200 MHz, $CDCl_3$): δ = 0.88 (t, *J* = 6.6 Hz, 3 H), 0.89 (t, *J* = 6.6 Hz, 3 H), 1.20 (s, 18 H), 1.26 (s, 54 H), 1.95 (dd, *J* = 9.4 Hz, *J* = 7.2 Hz, 4 H), 3.13 (t, *J* = 8 Hz, 2 H), 3.54 (d, *J* = 12 Hz, 2 H), 3.95 (t, *J* = 7.0 Hz, 2 H), 4.07 (d, *J* = 16 Hz, 2 H), 4.33 (d, *J* = 16 Hz, 2 H), 5.29 (d, *J* = 12 Hz, 2 H), 6.92 (d, *J* = 2 Hz, 2 H), 7.23 (s, 2 H), 7.25 (d, *J* = 2 Hz, 2 H), 7.40 (s, 2 H). − ^{13}C NMR(50 MHz, $CDCl_3$): δ = 14.2, 22.7, 25.7, 26.4, 29.4, 29.7, 31.3, 31.6, 31.8, 32.0, 34.1, 34.3, 35.0, 44.6, 71.0, 124.8, 125.2, 125.6, 130.9, 134.2, 134.7, 144.7, 147.9. − ^{199}Hg NMR (72 MHz, $CDCl_3$): δ = −1294. − MS (FAB^+); *m/z* (%): 1216.8 (40) [M^+, $C_{68}H_{102}HgO_2S_2$], 829.6 (30) [M^+ − Hg − $O(CH_2)_{11}CH_3$].

Complex 14: ^{1}H NMR (200 MHz, $CDCl_3$): δ = 0.88 (t, *J* = 2.5 Hz, 6 H), 0.89 (s, 18 H), 1.20 −1.40 (m, 40 H), 1.32 (s, 18 H), 3.45 (d, *J* = 13 Hz, 4 H), 3.92 (t, *J* = 8 Hz, 4 H), 5.40 (d, *J* = 13 Hz, 4 H), 6.73 (s, 4 H), 7.18 (s, 4 H). − MS (FAB^+); *m/z* (%): 1216.8 (100) [M^+], 829.5 (87) [M^+ − Hg − $O(CH_2)_{11}CH_3$].

Crystal Structures: X-ray structure determinations of single crystals were performed with an Enraf−Nonius Kappa CCD. For all computations the Nonius OpenMoleN package[15] was used. Absorption corrections were partially integrated in the data reduction procedure. Both structures were solved using direct methods and refined against |*F*|. Hydrogen atoms were introduced as fixed contributors when a residual electron density was observed near their expected positions. Crystallographic data (excluding structure factors) for structures reported have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-138614 and -138615. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Crystallographic Data for 7: Colourless crystals, 173 K, $C_{74}H_{114}N_2O_4S_2$, *M* = 1159.87, triclinic, *a* = 14.2423(5), *b* = 15.5842(5), *c* = 19.1515(4) Å, α = 107.436(9), β = 91.359(9), γ = 118.149(9), *V* = 3506 (1) Å^3, space group *P*−1, *Z* = 2, $D_{calcd.}$ = 1.10 gcm^{-3}, Mo-K_α graphite kappa CCD, μ = 0.117 mm^{-1}, 6192 data with $I > 3\sigma(I)$, *R* = 0.078, *Rw* = 0.092.

Crystallographic Data for 11: Colourless crystals, 173 K, $C_{74}H_{114}N_2O_4S_2$, *M* = 1159.87, triclinic, *a* = 10.0750(4), *b* = 13.6749(6), *c* = 13.7344(6) Å, α = 107.099(9) Å, β = 90.294(9) Å, γ = 101.117(9) Å, *V* = 1749.8(4) Å^3, space group *P*−1, *Z* = 1, $D_{calcd.}$ = 1.10 gcm^{-3}, Mo-K_α graphite kappa CCD, μ = 0.117 mm^{-1}, 3575 data with $I > 3\sigma(I)$, *R* = 0.079, *Rw* = 0.102.

Extraction: In a 1.5-cm diameter tube, a $CHCl_3$ solution (5 mL, 2.8−3.0 mM) of the dithiol **1** or **3** was layered with a water/acetic acid (95:5) solution of $M(OAc)_2$ (5 mL, 1.5−11.0 mM, M = Hg, Cd, Pb), and the biphasic system was stirred vigorously at 26 °C for 45 min. Continued stirring beyond this period (up to 24 h) failed to show any additional extraction for any of the metals studied. An aliquot (25−100 μL, depending on the expected residual concentration of the metal ion) was taken from the top aqueous layer and added to a solution of dithizon[16] (300 mM) in $CHCl_3$, and the absorbance (*A*) measured at 480 nm. The metal concentration (*C*) was determined from the standard *A* versus *C* plot.

Determination of Standard (*A*/*C*) Plot for Metal Salts: Aliquots (10−60 μL) in 10-μL increments were withdrawn from a 95% aqueous acetic acid solution of the metal acetate [$M(OAc)_2$, 10 mM], and added to a solution of dithizon (300 mM, 10 mL) in $CHCl_3$ in a stoppered volumetric flask. After shaking the contents of the flask for 2 min, the absorption at 480 nm was measured and plotted against the concentration to yield a straight line. The unknown concentration of the metal salt was determined following the corresponding absorbance from the *A*/*C* plot with an accuracy of 0.05 mM.

Multicomponent Polyanions, 49

A Potentiometric and (^{31}P, ^{51}V) NMR Study of the Aqueous Molybdovanadophosphate System

Anna Selling,*[a] Ingegärd Andersson,[a] John H. Grate,[b] and Lage Pettersson[a]

Keywords: Polyoxometalates / Phosphorus / Vanadium / Potentiometry / Formation constants

The equilibrium speciation of the quaternary system H^+/MoO_4^{2-}/HVO_4^{2-}/HPO_4^{2-} in aqueous 0.600 M Na(Cl) at 25 °C and 90 °C was studied by pH potentiometry and ^{31}P (202.5 MHz) and ^{51}V (131.6 MHz) NMR spectrometry. The study focused on solutions containing the oxoanion components in the ratios (Mo + V)/P = 12:1 and Mo/V ≥ 3.8, in the pH range 0–5, wherein Keggin anions of the formula $[H_zMo_{12-x}V_xPO_{40}]^{(3+x-z)-}$ with x = 1–3 are the predominant species. Formation constants (log β) and pK_a values for Keggin anions with x = 1–3 were determined from ^{31}P and ^{51}V resonance chemical shift data, ^{31}P resonance intensity data, and pH potentiometric data with the multidata least squares calculation program LAKE. The $[Mo_{11}VPO_{40}]^{4-}$ anion does not protonate, $[Mo_{10}V_2PO_{40}]^{5-}$ anions can be monoprotonated, and $[Mo_9V_3PO_{40}]^{6-}$ anions can be triprotonated. The six most intense ^{31}P NMR resonances of $[H_zMo_9V_3PO_{40}]^{(6-z)-}$ could be followed over the pH range studied. It was also possible to assign some ^{31}P resonances to a specific isomer of $[Mo_9V_3PO_{40}]^{6-}$.

Introduction

Speciation and structures in aqueous heteropoly- and isopolyoxometalate systems have been studied at Umeå University by potentiometric [H^+] titrations and multinuclear NMR spectrometry. Data obtained by these methods were used in the least-squares calculation program LAKE,[1] which can consider different types of data simultaneously; it thus proved possible to determine speciation and formation constants in complicated systems. These methods were applied in this study for characterising Keggin molybdovanadophosphate anions, $[H_zMo_{12-x}V_xPO_{40}]^{(3+x-z)-}$, in the aqueous H^+/MoO_4^{2-}/HVO_4^{2-}/HPO_4^{2-} system.[2] Keggin molybdovanadophosphates are dioxygen-regenerable oxidants capable of mediating a variety of catalytic oxidation reactions,[3] such as Wacker-like aqueous palladium-catalysed oxidations of olefins to carbonyls.[4] Understanding the nature of the aqueous Keggin molybdovanadophosphates is essential to rational development of this chemical process and motivated the present study. We therefore studied acidic, aqueous molybdovanadophosphate solutions containing the oxoanion components in the ratio (Mo + V)/P = 12:1, in which the Keggin molybdovanadophosphates, $[H_zMo_{12-x}V_xPO_{40}]^{(3+x-z)-}$, are formed as the predominant species.

The α-Keggin structure, first reported by Keggin in 1933,[5] is the structure encountered most frequently by far. Rotation of each M_3O_{13} group in turn by π/3 gives the β-, γ-, δ-, and ε-structures.[6,7] These are increasingly disfavoured, in this order, by increasing internal electrostatic repulsions of the M atoms. Some β-structures and, recently, one γ-structure[8] have been reported for XM_{12}^{VI} species, but we are unaware of any δ- and ε-structures. β-Structures become more likely when the internal electrostatic repulsions are decreased, either by the substitution of M^{VI} by lower-valence M atoms or by the reduction of M^{VI} atoms.

In the parent α-Keggin $[Mo_{12}PO_{40}]^{3-}$ structure, which has T_d symmetry, all Mo sites are equivalent by symmetry, so that one isomorphous substitution of V for Mo results in a single α-$[Mo_{11}VPO_{40}]^{4-}$ structure. By isomorphous substitution of two, three, or four V for Mo, 5, 13, or 27 positional α-Keggin isomers and an increasing number of β-isomers can be formed.[7] Consequently, the present study was restricted to solutions containing Keggin molybdovanadophosphates with $x \leq 3$ to somewhat simplify this complicated system.

The binary H^+/HVO_4^{2-},[9–11] H^+/MoO_4^{2-},[12] and H^+/HPO_4^{2-} [13] and the ternary H^+/HVO_4^{2-}/HPO_4^{2-},[13] H^+/MoO_4^{2-}/HPO_4^{2-},[14,15] and H^+/MoO_4^{2-}/HVO_4^{2-} [16,17] subsystems in 0.6 M Na(Cl) at 25 °C have all been previously characterised and are used in the present study of the quaternary system. The present study was extended to a higher temperature, 90 °C, to assess the effect of temperature on speciation. Many applications of Keggin molybdovanadophosphates in oxidation reactions[4] are performed at such elevated temperatures.

Our ^{31}P- and ^{51}V-NMR characterisation of the isomeric Keggin decamolybdodivanadophosphate ions, $x = 2$, at 25 °C and 90 °C, and their individual pK_a values, has already been reported.[18] Many of the conclusions presented herein for the Keggin nonamolybdotrivanadophosphates, $x = 3$, rely substantially, by analogy, on the findings presented in that report. Some preliminary results from the present study were presented earlier at an international workshop.[19]

Notations and Designations

The polyanion formation constants are reported with H^+, MoO_4^{2-}, HVO_4^{2-}, and HPO_4^{2-} as the components, and equilibria are written according to Equation (1).

$$p\,H^+ + q\,MoO_4^{2-} + r\,HVO_4^{2-} + s\,HPO_4^{2-} \rightleftarrows [(H^+)_p(MoO_4^{2-})_q(HVO_4^{2-})_r(HPO_4^{2-})_s]^{p-2(q+r+s)} \quad (1)$$

The resulting polyanions will, for brevity, sometimes be denoted by their (p,q,r,s) integers and formation constants are reported as $\beta_{p,q,r,s}$. The potentiometric $[H^+]$-titration data establish only the composition, that is, (p,q,r,s), of the various polyanions. Their actual ionic formulae are related to their (p,q,r,s) values by loss of water, Equation (2).

$$[(H^+)_p(MoO_4^{2-})_q(HVO_4^{2-})_r(HPO_4^{2-})_s]^{p-2(q+r+s)} \rightleftarrows [H_{(p+r+s-2w)}Mo_qV_rP_sO_{(4q+4r+4s-w)}]^{p-2(q+r+s)} + w\,H_2O \quad (2)$$

Complementary structural information, such as NMR and X-ray data, is required to establish the formulae. Compositions given in brackets, as in $[HMo_9V_3PO_{40}]^{5-}$, designate the ionic formulae of discrete Keggin ions. To designate Keggin structures without regard to protonation state and charge, the abbreviated form Mo_9V_3P is sometimes used.

Compositions given in braces, as in $\{Na_5HMo_9V_3PO_{40}\}$, designate the macroscopic elemental compositions of certain solutions and solids of Keggin salts. This designation rigorously specifies the known mole ratios of Na, Mo, V, and P present. In the solids and in the majority of solutions, Mo, V and P are present in exactly the Keggin proportions, (Mo + V) = 12 P, and are predominantly incorporated into Keggin anions. The macroscopic composition in braces therefore corresponds, essentially, to the average Keggin anion formula and the countercations present to balance its average anionic charge. These average formulae in braces can have nonintegral ratios of the elements.

To designate the positional isomers of α and β Keggin species, the recommended IUPAC numbering schemes are used.[20] Like Pope[21] and most other authors, however, we indicate the vanadium positions in Keggin molybdovanadophosphates by the lowest possible numbers (1,*a*,*b* for α-$[Mo_9V_3PO_{40}]^{6-}$ isomers), not by the highest possible numbers (12,*c*,*d*) as in the recommended IUPAC schemes. In this paper, all references to dissymmetric positional isomers refer to both enantiomers together.

The acidity measurements are on the concentration scale, where pH = $-\log [H^+]$, *not* on the activity scale, where pH = $-\log \{H^+\}$. We will, for simplicity, use pH instead of $-\log [H^+]$. For brevity, the total concentrations of molybdenum, vanadium, and phosphorus are often denoted by Mo, V, and P.

Results and Discussion

Equilibrium Analysis

Since the present study focused on solutions containing the oxoanion components in the ratio (Mo + V)/P = 12:1, in the pH range 0−5, the predominant oxoanion species present were the Keggin anions, $[H_zMo_{12-x}V_xPO_{40}]^{(3+x-z)-}$. Figure 1 maps the solutions, in (Mo/V) vs. pH space, for which data were collected.

The equilibrium calculations were simplified by the use of data only from solutions with Mo/V ≥ 3.8, and in these solutions only $[H_zMo_{12-x}V_xPO_{40}]^{(3+x-z)-}$ species with $x =$

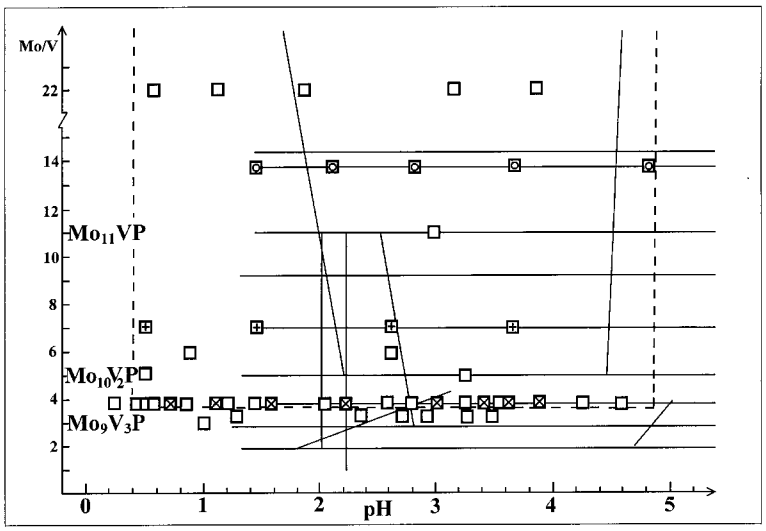

Figure 1. Mo/V ratios and pH values of Keggin molybdovanadophosphate solutions for which experimental data were collected by EMF titrations (continuous lines) from ^{31}P- and ^{51}V-NMR spectroscopy (□). Note the break in the Mo/V scale. The data used in the equilibrium calculations is from solutions within the dashed lines. NMR data from the points marked with ○, +, and X are included in the distribution diagrams of Figures 3, 4, and 5, respectively

Table 1. Polyhedral structures of the thirteen positional isomers of α-$[Mo_9V_3PO_{40}]^{6-}$ with their designation, symmetry point group, statistically predicted abundance in these α-isomers, and ^{31}P NMR resonance assignment (Figure 8). The VO_6 octahedra are shaded. Statistically predicted abundance 1 is for the α-isomers only. Statistically predicted abundance 2 is found for both the α- and β-isomers when approx. 17% of phosphorus is bound in β-isomers (see text)

Polyhedral Structure	Designation (enantiomer)	Symmetry	Statistical Abundance 1	Assignment ^{31}P	Statistical Abundance 2	Integral

1−3 are present. Solutions with Mo/V < 3.8 contain $[H_zMo_8V_4PO_{40}]^{(7-z)-}$ species and, at lower Mo/V, even higher V-content species. ^{31}P- and ^{51}V-NMR data from solutions with Mo/V < 3.8 were collected to help in assigning resonances and obtaining accurate relative abundances (by resonance integration) for the isomeric Mo_9V_3P species.

α-Keggin compositions with $x \geq 2$ can exist as positional isomers. Table 1 shows the polyhedral structures, symmetries, and statistically predicted relative abundances for the α-isomers of Mo_9V_3P. We were able to track the pH dependence of the ^{31}P resonances of the more abundant, but not all, Mo_9V_3P isomers at 25 °C. Figure 2 shows the ^{31}P chemical shifts of six Mo_9V_3P resonances plotted against pH over the range 0−6, along with the ^{31}P chemical shift vs. pH dependence for $[Mo_{11}VPO_{40}]^{4-}$ and the $Mo_{10}V_2P$ isomers determined previously.[18]

Equilibrium calculations were directed at identifying the Keggin compositions, $[H_zMo_{12-x}V_xPO_{40}]^{(3+x-z)-}$, present and for determining their formation constants, for x = 1−3. The equilibrium analysis of this system is complicated by two factors. First, the Keggin species exist in solution as equilibrium distributions over compositions of varying x, centred on the solution bulk composition. Consequently, it is not possible to EMF titrate species that have one x composition in the near absence of species of higher and lower x compositions. (The exception is $[Mo_{11}VPO_{40}]^{4-}$ (x = 1), which is present only as the single α-isomer, which remains unprotonated up to pH < 0, and does not significantly disproportionate at equilibrium into x = 0 and x = 2 species.[18]) Second, compositions with $x \geq 2$ exist as equilibrium mixtures of isomers, each with its own pK_a, which cannot be individually EMF titrated. Consequently, EMF titration data for solutions containing $Mo_{10}V_2P$ and Mo_9V_3P compositions manifest simultaneous titrations of numerous species.

The data from EMF titrations at different Mo/V ratios allow the calculations to distinguish the titration of the abundance-weighted average x = 2 species from the titration of the abundance-weighted average x = 3 species. Only the NMR chemical shifts vs. pH data (equivalent to spectrometric titrations) allow the titration curves, and thus the pK_a values and formation constants, of individual isomeric

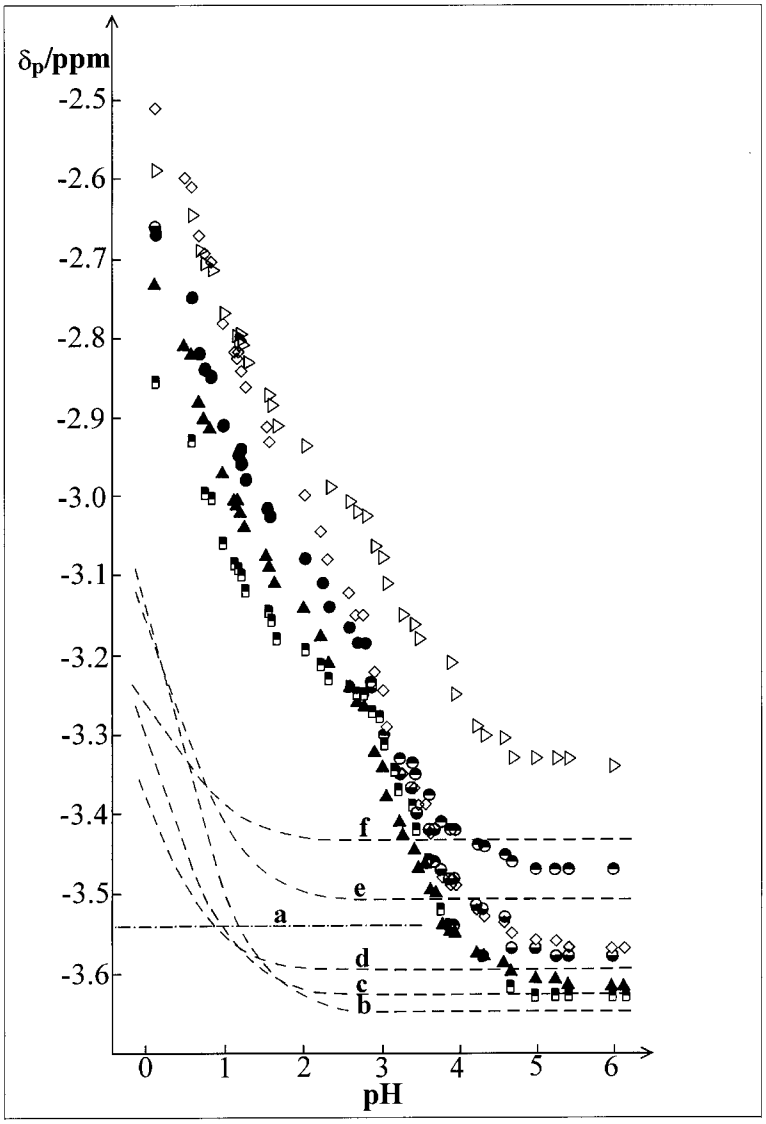

Figure 2. ^{31}P chemical shifts, at 25 °C, of the most intense Keggin Mo_9V_3P isomers, plotted as a function of pH. The dashed dotted line (a) shows the chemical shift of $[Mo_{11}VPO_{40}]^{4-}$ and the dashed curves (b−f) show the chemical shifts of the $Mo_{10}V_2P$ isomers: **b**: α-1,4; **c**: α-1,2 + α-1,5; **d**: α-1,6 + α-1,11; **e**, **f**: β-4,10 and β-4,11[18]

species to be distinguished. For the $Mo_{10}V_2P$ composition, it proved possible to resolve and track the ^{31}P- and ^{51}V-NMR resonances of the different isomers against pH sufficiently to assign the resonances to isomeric structures, to determine the pK_a values of the monoprotonated anions, and to evaluate their relative abundances.[18] Those data have been used to calculate the individual formation constants of $[H_zMo_{10}V_2PO_{40}]^{(5-z)-}$ species where $z = 0$, 1, as described below. As mentioned earlier, it was not possible to resolve and track the resonances of all the significant Mo_9V_3P isomers over pH, either by ^{31}P- or ^{51}V-NMR, and only "average" pK_a values and formation constants for these isomers could be determined.

To establish the formation constants for the $[H_zMo_{12-x}V_xPO_{40}]^{(3+x-z)-}$ compositions, the EMF potentiometric and NMR data were extensively evaluated with the LAKE multimethod least-square program, as described below. The "best" model obtained is reported in Table 2.

The determination of the formation constants began with the evaluation of the combined EMF and NMR integral data for solutions with the oxoanion component ratios (Mo+V)/P ≥ 11.8. At Mo/V ratios above or at 13.75, α-$[Mo_{11}VPO_{40}]^{4-}$ is strongly favoured over compositions with higher vanadium content, and is the only molybdovanadophosphate species present at pH < 2. Because this composition contains so much more P and Mo than in the $Mo_{11}VP$ Keggin composition, some molybdophosphate species are also present in these solutions. Since the formation constants of the species in the molybdophosphate system were previously determined in the same ionic medium,[15] the formation constant of α-$[Mo_{11}VPO_{40}]^{4-}$ could be determined accurately.

Table 2. The formation constants of $[Mo_{11}VPO_{40}]^{4-}$, $[H_zMo_{10}V_2PO_{40}]^{(5-z)-}$ (z = 0, 1), and $[H_zMo_9V_3PO_{40}]^{(6-z)-}$ (z = 0, 1, 2, 3), based on EMF data, NMR integral data for the molybdovanadophosphate species and the ^{31}P chemical shift data for the $Mo_{10}V_2P$ species and the most intense Mo_9V_3P resonance. The formation constants reported for the $Mo_{10}V_2P$ and Mo_9V_3P compositions are each the abundance-weighted average formation constants over all the isomeric species with that composition

NMR symbol	(p,q,r,s) notation	Formula	log β ± (3σ)	pK_a
Δ	22,11,1,1	$Mo_{11}VPO_{40}^{4-}$	141.5 (2)	
○	21,10,2,1	$Mo_{10}V_2PO_{40}^{5-}$	146.9 (3)	
	22,10,2,1	$HMo_{10}V_2PO_{40}^{4-}$	147.2 (3)	0.3
◇	20,9,3,1	$Mo_9V_3PO_{40}^{6-}$	147.1 (3)	
	21,9,3,1	$HMo_9V_3PO_{40}^{5-}$	150.2 (3)	3.1
	22,9,3,1	$H_2Mo_9V_3PO_{40}^{4-}$	151.7 (3)	1.5
	23,9,3,1	$H_3Mo_9V_3PO_{40}^{3-}$	152.2 (3)	0.5

By next expanding the evaluation to include data from solutions in which $Mo_{10}V_2P$ species are also present, but in which Mo_9V_3P species are still absent, the formation constants for the $Mo_{10}V_2P$ compositions were determined. In addition to the combined EMF and NMR integral data for such solutions, this evaluation also included the chemical shift vs. pH data for the ^{51}V resonance of the α-1,2-$[H_zMo_{10}V_2PO_{40}]^{(5-z)-}$ (z = 0, 1) isomer. This isomer was chosen as a surrogate for the average $Mo_{10}V_2P$ composition, as its pK_a (0.26) is midway between the most extreme pK_a values of the $Mo_{10}V_2P$ isomers (0.04 for α-1,6 + α-1,11 and 0.48 for α-1,4).[18] The formation constants so determined for $[Mo_{10}V_2PO_{40}]^{5-}$ and $[HMo_{10}V_2PO_{40}]^{4-}$ are essentially the abundance-weighted average formation constants for the manifold of $Mo_{10}V_2P$ isomers. (They are strictly this average except to the extent that the surrogate pK_a differs from the actual average pK_a.)

The solutions whose data were used to determine formation constants for the $Mo_{10}V_2P$ compositions included solutions with the oxoanion component ratios (Mo + V)/P ≥ 11.8, as above, but at pH > 2. Above pH = 2, $[Mo_{11}VPO_{40}]^{4-}$ is partly (pH = 2−4) or completely (pH > 4) disproportionated to molybdophosphate species and $Mo_{10}V_2P$ species at equilibrium. Figure 3 shows a phosphorus distribution diagram for solutions of this composition over the entire pH range of this study, 0−5. Experimental points from the ^{31}P-NMR integral data are included in Figure 3, showing that the fit of experimental data to the calculated formation constants is good.

Also among the solutions containing $Mo_{10}V_2P$ species, but not Mo_9V_3P species, that were used to determine the $Mo_{10}V_2P$ formation constants, were solutions with the oxoanion components in the Keggin ratio (Mo + V)/P = 12.0 and with the Mo/V ratio decreased to above or equal to 7 (average composition $Mo_{10.5}V_{1.5}P$). Figure 4 shows a calculated phosphorus distribution diagram as a function of pH and experimental ^{31}P NMR integral data points for solutions of this composition, with Mo/V = 7.

After the evaluation was expanded to include EMF, NMR integral, and shift data from solutions with the Mo/V ratio decreased to above or at 3.8 (average composition

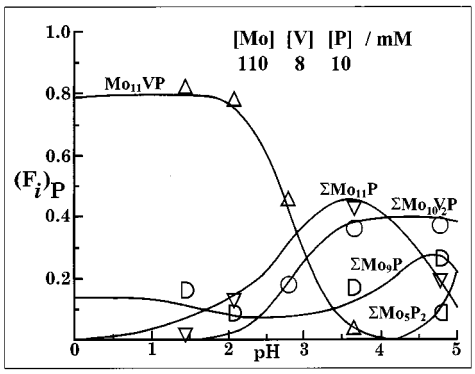

Figure 3. Distribution diagram of phosphorus-containing species as a function of pH in a solution with the oxoanion components in the ratio (Mo + V)/P = (11 + 0.8):1 = 11.8 and 10 mM P. $(F_i)_P$ is the fraction of the total phosphorus. At this ratio, some well-known molybdophosphate species, $Mo_{11}P$, Mo_9P, and Mo_5P_2, are present. The symbols represent experimental ^{31}P-NMR integral data

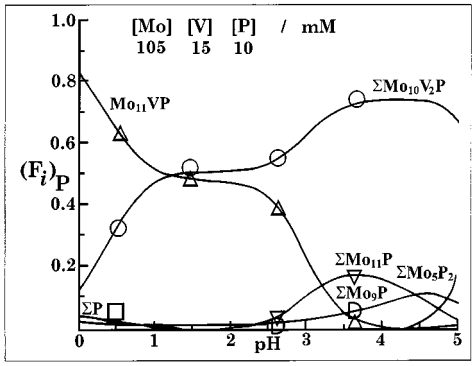

Figure 4. Distribution diagram of phosphorus-containing species as a function of pH in a solution with oxoanion components in the ratio (Mo + V)/P = (10.5 + 1.5):1 and 10 mM P. The symbols represent experimental ^{31}P-NMR integral data

$Mo_{9.5}V_{2.5}P$), the formation constants for the Mo_9V_3P compositions were determined. The final calculation is a simultaneous variation of all constants in which all kinds of data with Mo/V ≥ 3.8 are used, and the result is shown in Table 2. Only the ^{31}P chemical shift data vs. pH for the highest intensity Mo_9V_3P resonance (▲ in Figure 2) were included. A model with four $[H_zMo_9V_3PO_{40}]^{(6-z)-}$ compositions (z = 0,1,2,3) gave the best explanation of included data. (For the manifold of Mo_9V_3P isomers, the pH dependence of the chemical shift of the most intense ^{31}P resonance was taken as a surrogate for the abundance-weighted average pH dependence.)

The pK_a values for the highest intensity Mo_9V_3P ^{31}P-NMR resonance (▲ in Figure 2) were also determined in a LAKE calculation in which only the chemical shift vs. pH data were used. These pK_a values (pK_{a3} = 3.18, pK_{a2} = 1.66, pK_{a1} = 0.56) agree well with the three pK_a values determined by equilibrium in Table 2 (pK_{a3} = 3.1, pK_{a2} = 1.5, pK_{a1} = 0.5).

Figure 5 shows a distribution diagram of phosphorus, as a function of pH, at a Mo/V = 3.8 ratio, based on the results showed in Table 2. In this figure, each of the protonation states is plotted individually with dotted lines and the solid lines show the sums of "homonuclear" species.

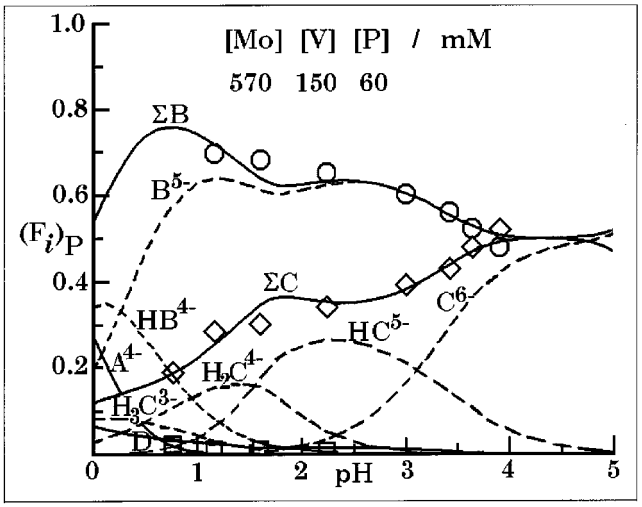

Figure 5. Distribution diagram of phosphorus-containing species as a function of pH in a solution with the oxoanion components in the ratio (Mo + V)/P = (9.5 + 2.5):1 and 60 mM P. Each of the protonation states is plotted individually with dotted lines and the solid lines show the sums of "homonuclear" species. $\mathbf{A^{4-}}$ = $[Mo_{11}VPO_{40}]^{4-}$; $\mathbf{B^{5-}}$ = $[Mo_{10}V_2PO_{40}]^{5-}$; $\mathbf{HB^{4-}}$ = $[HMo_{10}V_2PO_{40}]^{4-}$; $\mathbf{\Sigma B}$ = B^{5-} + HB^{4-}; $\mathbf{C^{6-}}$ = $[Mo_9V_3PO_{40}]^{6-}$; $\mathbf{HC^{5-}}$ = $[HMo_9V_3PO_{40}]^{5-}$; $\mathbf{H_2C^{4-}}$ = $[H_2Mo_9V_3PO_{40}]^{4-}$; $\mathbf{H_3C^{3-}}$ = $[H_3Mo_9V_3PO_{40}]^{3-}$; $\mathbf{\Sigma C}$ = C^{6-} + HC^{5-} + H_2C^{4-} + H_3C^{3-}; **D** = H_3PO_4. The symbols represent experimental ^{31}P-NMR integral data

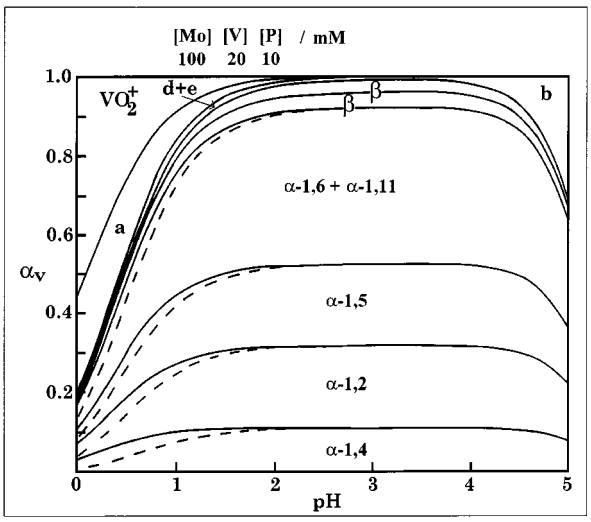

Figure 6. Diagram showing the cumulative distribution of vanadium-containing species, α_V, as a function of pH in solutions; the oxoanion components appear in the ratio (Mo + V)/P = (10 + 2):1, at P = 10 mM. The area between a solid curve and the dashed curve below it represent the protonated species, $[HMo_{10}V_2PO_{40}]^{4-}$. **a**: $[Mo_{11}VPO_{40}]^{4-}$; **b**: $[Mo_9V_3PO_{40}]^{6-}$; **d**: $[H_2Mo_9V_3PO_{40}]^{4-}$; **e**: $[H_3Mo_9V_3PO_{40}]^{3-}$

NMR integral data have an error of about 5−10%, which can explain the disparity between the model and the experimental data in the figure. In this solution $Mo_{10}V_2P$ species contain 40−50% of the total amount of vanadium and 60−70% of phosphorus over almost the entire pH range.

The relative abundances of the $[Mo_{10}V_2PO_{40}]^{5-}$ isomers, determined previously,[18] and the abundance-weighted average formation constant determined in this study (Table 2) were used for calculating the formation constants of the individual $[Mo_{10}V_2PO_{40}]^{5-}$ isomers; these are reported in Table 3. The pK_a values determined for the conjugate, monoprotonated $[HMo_{10}V_2PO_{40}]^{4-}$ isomers[18] were used for the determination of their formation constants (Table 3).

Table 3. Individual formation constants for the $[H_zMo_{10}V_2PO_{40}]^{(5-z)-}$ (z = 0, 1) isomers, calculated from the abundance-weighted average formation constants for the composition, their relative abundances among themselves (NMR integral data), and their pK_a values; the latter data is from ref.[18]

(*p,q,r,s*) notation	Formula	IUPAC notation	log β	pK_a

Figure 6 shows a calculated vanadium distribution diagram, distinguishing between the individual $Mo_{10}V_2P$ isomers, for solutions containing the oxoanion components in the (Mo + V)/P = (10 + 2):1 ratio. Comparison between different total concentrations shows that a decrease in concentration gives a decrease in the pH stability range of the $Mo_{10}V_2P$ compositions as well. This is especially pronounced at the acidic end of the pH range, where the $Mo_{10}V_2P$ composition dissociates VO_2^+ and reconstitutes as $[Mo_{11}VPO_{40}]^{4-}$. This equilibrium decomposition of $Mo_{10}V_2P$ and Mo_9V_3P compositions to $[Mo_{11}VPO_{40}]^{4-}$ with increasing acidity in the pH region where they become monoprotonated (pH ≈ 1 and less) can also be discerned in the distribution diagrams of Figure 5 and 6. Similarly, Figure 5 shows that the Mo_9V_3P compositions decompose to $[Mo_{10}V_2PO_{40}]^{5-}$ with increasing acidity in the pH region where they become protonated. The decomposition of Keggin molybdovanadophosphates, dissociating VO_2^+ and redistributing to lower vanadium-content Keggin species, is favoured by: (1) decreasing Keggin ion concentrations, favouring dissociative equilibria, (2) increasing acidity, and (3) increasing vanadium content in the Keggin composition. It is also favoured by (4) reduction of vanadium(V) to vanadium(IV), in which case VO^{2+} is dissociated.

Assignments of NMR Resonances to Mo_9V_3P Isomers

In the previous study,[18] it proved possible to completely assign the ^{31}P and ^{51}V resonances of α-$[Mo_{11}VPO_{40}]^{4-}$, of all five of the α-$Mo_{10}V_2P$ isomers, and of the couple of β-$Mo_{10}V_2P$ isomers existing in detectable concentrations in the equilibrium solutions. The assignments of the resonances to the α-isomers relied on a number of factors:

– The ability to resolve the ^{31}P and ^{51}V resonances and to track them over pH

– Interpretations based on comparisons of the relative intensities of the resonances to the statistically predicted relative abundances of the α-isomers[28]

– The expected relative magnitudes of the ^{51}V chemical shift changes of the different isomers in response to their protonation

– The expected relative pK_a values of the monoprotonated anions

– The expected broader ^{51}V resonance line width of the α-(1,2) isomer with corner-sharing V-octahedra[21]

– Correlations between the ^{31}P and ^{51}V resonances based on these factors

It did not prove possible to make a similar complete assignment of the detected ^{31}P and ^{51}V resonances of the individual Mo_9V_3P isomers. The ^{51}V resonances proved too broad and overlapping, at 131.5 MHz, to be resolved and to be tracked over the pH range. The ^{31}P resonances of only six of the most abundant Mo_9V_3P isomers could be resolved and tracked over pH, at 202.5 MHz (Figure 2). Nonetheless, partial assignments of the ^{31}P and ^{51}V resonances to structural motifs of the Mo_9V_3P isomers did prove possible. These interpretations depended substantially on analogy to the more definitive assignments of the ^{31}P and ^{51}V resonances of the $Mo_{10}V_2P$ isomers. This analysis focused on the spectra of solutions with the oxoanion components in the (Mo + V)/P = (9 + 3):1 ratio at pH ≥ 4.5. The ^{31}P spectrum of such a solution (120 mM P) at pH = 5.96 at 25 °C showed that about 87% of the phosphorus was present in the Mo_9V_3P species, with the balance distributed in essentially equal amounts between the $Mo_{10}V_2P$ species and the Mo_8V_4P species. (See Figure 8 and the discussion of the ^{31}P spectrum below.) At pH ≥ 4.5, all the $Mo_{10}V_2P$ and Mo_9V_3P isomers are fully deprotonated, so that protonation effects on their chemical shifts could be avoided when they were compared.

^{51}V NMR Spectra

The ^{51}V resonances of vanadium oxoanions have narrower line widths, and are therefore better resolved, at higher temperature. Our previous study[18] determined that the relative abundances of the $Mo_{10}V_2P$ isomers are approximately the same at 25 and 90 °C. This is also expected to be the case for the Mo_9V_3P isomers. Consequently, our analysis of the ^{51}V resonances of the $[Mo_9V_3PO_{40}]^{6-}$ species focused on spectra of solutions at 90 °C. However, even at this higher temperature, and with resolution enhancement algorithms, it was not possible to resolve the ^{51}V resonances of all the isomers.

The 13 α-isomers of the $[Mo_9V_3PO_{40}]^{6-}$ composition (Table 1) will, by symmetry, exhibit 30 potentially resolvable ^{51}V-NMR resonances. Table 4 shows the 30 inequivalent vanadium environments among the 13 α-isomers. Many of these inequivalent vanadium environments are obviously very similar, so it is expected that many of their resonances would have very close chemical shifts and are not resolved.

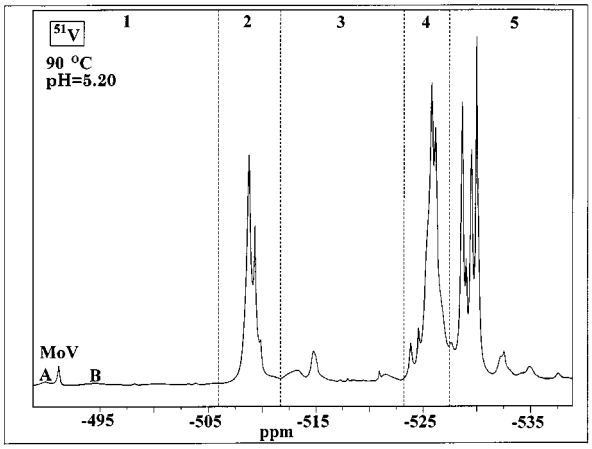

Figure 7. The ^{51}V spectrum of a solution containing the oxoanion components in the ratio (Mo + V)/P = (9 + 3):1 (120 mM P) at 90 °C, at which temperature the pH = 5.20. The chemical shift regions 1–5 are discussed in the text

Figure 7 shows the ^{51}V spectrum of a solution containing the oxoanion components in the ratio (Mo + V)/P = (9 + 3):1 (120 mM P) at pH = 5.20 at 90 °C. By analogy to the ^{51}V resonances of the α-$[Mo_{10}V_2PO_{40}]^{5-}$ isomers,[18] five regions of the spectrum, divided as shown in Figure 7, were assigned to five distinct types of vanadium environments within the $[Mo_9V_3PO_{40}]^{6-}$ isomers, as described below.

α-1,4-$[Mo_{10}V_2PO_{40}]^{5-}$, the sole $Mo_{10}V_2P$ α-isomer in which the two vanadium octahedra are edge-sharing, is distinguished by the most downfield ^{51}V resonance of the $[Mo_{10}V_2PO_{40}]^{5-}$ isomers, 16 ppm downfield from the nearest other $[Mo_{10}V_2PO_{40}]^{5-}$ resonance, at δ = −509.75 at 90 °C. By analogy, region 2, at δ = −506 to −512 in the Mo_9V_3P spectrum at 90 °C (Figure 7), is assigned to pairs of vanadium octahedra that are edge-sharing, but are separated from the third vanadium octahedron in the Keggin structure.

By analogy to the α-1,4-$[Mo_{10}V_2PO_{40}]^{5-}$ resonance's chemical shift being distinctly far downfield from the resonances of other $[Mo_{10}V_2PO_{40}]^{5-}$ isomers, the most downfield resonances of the Mo_9V_3P isomers, in region 1, are assigned to isomers in which all three vanadium octahedra are mutually edge-sharing in a V_3O_{13} unit. The narrow resonance labelled MoV in Figure 7 is known to be that of the molybdovanadate species $[Mo_4V_2O_{19}]^{4-}$.[16,17] In this region, there are two minor resonances, marked A and B, of Mo_9V_3P species. However there is only one α-Mo_9V_3P isomer (α-1,4,9) where all three vanadium octahedra are mutually edge-sharing. The furthest downfield resonance, A, is tentatively assigned to the vanadium atoms of α-1,4,9-$[Mo_9V_3PO_{40}]^{6-}$. The very broad resonance B might arise from a β-isomer in which all three vanadium octahedra are mutually edge-sharing. This could be the β-10,11,12 or the β-1,4,9 isomer, in which the mutually edge-sharing V_3O_{13} unit or a mutually edge-sharing Mo_3O_{13} unit, respectively, in the α-1,4,9 structure is rotated by π/3, or possibly both isomers.

Table 4. The 30 possible ^{51}V NMR resonances of the 13 α-$[Mo_9V_3PO_{40}]^{6-}$ isomers. The VO_6 octahedra are shaded and the octahedron(s) responsible for the resonance is/are in dark colour. The table reports the statistically predicted relative intensities of the resonances and the regions of the spectrum in which the specific resonance is thought to appear (see Figure 7)

Polyhedral Structure	Designation	Statistical Abundance	Region	Polyhedral Structure	Designation	Statistical Abundance	Region
	α-1,4,9	1.82 %	1		α-1,2,8	3.63 %	4
	α-1,2,3	1.82 %	4		α-1,2,8	3.63 %	4

	α-1,4,7	3.63 %	2		α-1,5,7	3.63 %	5
	α-1,4,7	3.63 %	5		α-1,5,7	3.63 %	5
	α-1,4,8	3.63 %	2		α-1,6,12	3.61 %	5
	α-1,4,8	3.63 %	2				
	α-1,4,8	3.63 %	5				

α-1,2-$[Mo_{10}V_2PO_{40}]^{5-}$, the sole $Mo_{10}V_2P$ α-isomer in which the two vanadium octahedra are corner-sharing, exhibits the next most downfield ^{51}V resonance of the $[Mo_{10}V_2PO_{40}]^{5-}$ isomers, at δ = −526.10 at 90 °C. By analogy, region 4 at δ = −523 to −527 in the Mo_9V_3P spectrum at 90 °C (Figure 7) is assigned to pairs of vanadium octahedra that are corner-sharing, but are separated from the third vanadium octahedron in the Keggin structure. The α-isomer with three mutually corner-sharing vanadium octahedra (α-1,2,3) could be expected to have its resonance in this region (but see below).

The resonances in region 3, between region 2 of edge-sharing vanadium octahedra pairs and region 4 of corner-sharing vanadium octahedra pairs, are consequently assigned to individual vanadium octahedrons that are positioned between the two others, edge-sharing with one and corner-sharing with the other. Since edge-sharing with another vanadium octahedron has such a strong downfield effect on the chemical shift, the two resonances that are both the most downfield and the most intense within region 3 are reasonably assigned to these "in-between" vanadium octahedrons in the α-1,2,4 and α-1,2,6 isomers. The more upfield and more minor resonances within region 3 may be the "in-between" vanadium octahedrons in the β-isomers. It is also possible that the resonance of the α-1,2,3 isomer (with *three* mutually corner-sharing vanadium octahedra) may be downfield of region 4, in region 3.

The α-1,2-$Mo_{10}V_2P$ isomer is also unique among the α-$Mo_{10}V_2P$ isomers in having a distinctively broad resonance line width.[18] This is expected for corner-sharing vanadium octahedra, as revealed by Leparulo-Loftus and Pope's study of isostructural tungstovanadates, including α-Keggin decatungstodivanadophosphate isomers, and is supported by the theoretical explanation provided in that report.[21] It also was a key factor, but not an isolated factor, in the complete assignment of the ^{51}V resonances of the $Mo_{10}V_2P$ isomers. By an extensive evaluation of line widths of the resonances in the major intensity regions 2, 4, and 5 by line shape

Table 5. The statistically predicted relative abundance of the α-$[Mo_{10}V_2PO_{40}]^{5-}$ isomers and their actual relative abundance by ^{51}V resonance intensities. The statistically predicted relative intensities of groups of ^{51}V resonances of the α-$[Mo_9V_3PO_{40}]^{6-}$ isomers, grouped by type of vanadium environment, and the actual relative intensities among the regions of the spectrum assigned to these groups, as shown in Figure 7. The last column gives, as a percentage, the disparity between the actual relative intensities and those statistically predicted

Isomers	Statistical abundance	Integral ^{51}V	Disparity %
$Mo_{10}V_2P$			
α-1,4 (pair of edge-sharing V)	18.2%	13.3%	73%
α-1,2 (pair of corner-sharing V)	18.2%	23.3%	128%
α-1,5 + α-1,6 + α-1,11 (separated V)	63.7%	63.3%	99%
Mo_9V_3P			
Region 1 (edge-sharing V_3O_{13} units)	1.8%	0.7%	39%
Region 2 (pairs of edge-sharing V)	25.4%	20.5%	81%
Region 3 (V edge-sharing to another V and corner-sharing to a third V)	7.3%	4.9%	67%
Region 4 (pairs of corner-sharing V)	27.2%	37.0%	136%
Region 5 (V separated from other V)	38.1%	37.0%	97%

analysis, the resonances in region 4 were determined to have broader line widths than the resonances in these other regions. This further supports the assignment of the resonances in region 4 to corner-sharing vanadium octahedra. The resonances in region 3, assigned to the "in-between" vanadium octahedrons that are corner-sharing with another vanadium octahedron, have visually broad line widths, as seen in Figure 7.

The three α-$Mo_{10}V_2P$ isomers, and the one detected β-$Mo_{10}V_2P$ isomer with separated vanadium octahedra have resonances with narrow line widths at $\delta = -528$ to -529 at 90 °C.[18] By analogy, region 5 in the Mo_9V_3P spectrum, upfield of $\delta = -527$ at 90 °C (Figure 7) and comprising narrow resonances closely grouped between $\delta = -528$ and -530, is assigned to the isolated vanadium octahedrons within the Mo_9V_3P isomers.

This assignment of the resonances by chemical shift region to five different types of vanadium environments found in the Mo_9V_3P isomers accords well with the expected relative abundances of these environments in the α-isomers. The statistically predicted relative abundances of the 30 inequivalent vanadium environments among the α-isomers are listed in Table 4. A direct comparison of the resonance intensities, integrated region-by-region, with these statistically predicted relative abundances of the different types of vanadium environments among the α-isomers is complicated by two factors. First, this analysis ignores the presence of β-isomers. Second, it assumes that the 13 α-isomers are all of equal stability, so their distribution is governed solely by the statistics of their structural degeneracies. The results of this comparison are presented below after these complicating factors are discussed.

As discussed in the introduction, β structures become more likely as molybdenum(VI) in the parent Keggin molybdophosphate ion, $[Mo_{12}PO_{40}]^{3-}$, is increasingly substituted by vanadium(V). In the previous work, no β-isomer of $[Mo_{11}VPO_{40}]^{4-}$ was detected, and about 10% of the total vanadium in the $Mo_{10}V_2P$ species was present in β-isomers.[18] Therefore, more than 10% of the total vanadium in the Mo_9V_3P species is expected to be present in β-isomers in this case. The ^{31}P spectrum (Figure 8) of the solution, at 25 °C, whose ^{51}V spectrum, at 90 °C, is shown in Figure 7, indicates that about 17% of the P in the Mo_9V_3P species is present in β-isomers. (See discussion below.)

The ^{51}V resonances of similar vanadium environments (edge- or corner-sharing with another vanadium octahedron, separated, etc.) are expected to have similar chemical shifts whether in an α- or a β-isomer, and to appear in the same region of the spectrum. This is the case for the ^{51}V resonances of the deprotonated $Mo_{10}V_2P$ isomers.[18] In the ^{51}V NMR spectrum at 90 °C, two β-$[Mo_{10}V_2P_{40}]^{5-}$ were detected. One, assigned to the β-4,11 isomer with separated vanadium octahedra, has the chemical shift $\delta = -528.8$ and is overlapped by the resonances of the α-isomers with separated vanadium octahedra. The other, assigned to the β-4,10 isomer with corner-sharing vanadium octahedra, the assignment being based in part on its relatively broad line width, characteristic of corner-sharing vanadium octahedra, has its chemical shift at $\delta = -526.7$, nearest to the α-1,2-$[Mo_{10}V_2P_{40}]^{5-}$ isomer with corner-sharing vanadium octahedra. The chemical shifts for these β-isomers are within the designated regions (Figure 7) for separated (region 5) and corner-sharing (region 4) vanadium octahedra.

Accordingly, the presence of β-isomers should not compromise the assignments of the spectral regions to the various types of vanadium environments. However, to the extent that certain structural relationships among the vanadium octahedra (edge- or corner-sharing with another vanadium, separated, etc.) are more conducive to stabilising β-structures than others, the distribution of the types of vanadium environments determined by resonance integration region-by-region will be skewed by their distribution among only the α-isomers.

The previous study revealed that the α-isomers of $[Mo_{10}V_2P_{40}]^{5-}$ are not of equal stability.[18] While their relative abundances in solution approximate their statistically predicted relative abundances, there are some significant deviations. Table 5 lists the α-$Mo_{10}V_2P$ isomers with their type of vanadium environment and compares the statistically predicted relative abundances of the types of vanadium environments with their relative abundances in the deprotonated α-isomers, (only) determined by their resonance intensities. The α-1,4 isomer, with edge-sharing vanadium octahedra, is substantially less abundant than predicted by

statistics. In contrast, the α-1,2 isomer, with corner-sharing vanadium octahedra, is substantially more abundant than predicted by statistics. The total abundance of the remaining α-isomers, with spread (separated) vanadium octahedra, closely agrees with their total statistically predicted abundance.

Table 5 also lists the types of vanadium environments of the Mo_9V_3P isomers, assigned by spectral region, and compares the statistically predicted relative abundances of these types of vanadium environments among the α-Mo_9V_3P isomers, with their relative abundances determined by region-by-region integration of the spectrum shown in Figure 7. This comparison shows that the relative abundances of the types of vanadium environments approximate their statistically predicted relative abundances, but with discrepancies directly analogous to those found for the $Mo_{10}V_2P$ isomers. The abundance of pairs of edge-sharing vanadium octahedra (region 2) is substantially less than statistically predicted. The abundance of pairs of corner-sharing vanadium octahedra (region 4) is substantially greater than statistically predicted. The abundance of isolated vanadium octahedrons separated from others (region 5) closely agrees with the statistics.

The abundance of isomers in which all three vanadium octahedra are mutually edge-sharing in a V_3O_{13} unit (region 1) is even more depressed relative to the statistically predicted abundance of the α-1,4,9 isomer than the abundance of pairs of edge-sharing vanadium octahedra (region 2) relative to their statistical prediction. This appears directionally consistent, but it must be noted that it is difficult to obtain accurate integrated intensities for such weak resonances as in region 1.

In view of this analogy to the relative abundances of the $Mo_{10}V_2P$ isomers, the assignment of the ^{51}V resonances of the Mo_9V_3P isomers by chemical shift region to the different types of vanadium environments appears well supported by the region-by-region integration of their resonance intensities.

^{31}P-NMR Spectra

The ^{31}P-NMR resonances of Mo_9V_3P species proved to be difficult to assign to specific isomers. Our examination of the ^{31}P-NMR resonances of the Keggin $[Mo_9V_3PO_{40}]^{6-}$ species focused on the spectra of solutions at 25 °C. Contrary to their ^{51}V-NMR resonances, the ^{31}P resonances of these Keggin oxoanions have narrower line widths and are better resolved at 25 °C than at higher temperatures.

Figure 8 shows the ^{31}P spectrum of the same solution, at 25 °C, whose ^{51}V spectrum at 90 °C is shown in Figure 7. (Its pH at 25 °C is 5.96.) The ^{31}P spectrum allows an assessment of the relative amounts of the $Mo_{(12-x)}V_xP$ compositions present. Resonances can be readily sorted by x of the $Mo_{(12-x)}V_xP$ compositions, when their relative intensities in solutions of various Mo/V ratios are observed.[18] Region A in Figure 8 contains resonances of Mo_8V_4P species, which comprise approx. 6.4% of the total phosphorus in solution. Some minor Mo_8V_4P resonances, further upfield among the resonances in region B of Figure 8, are unresolved. On the

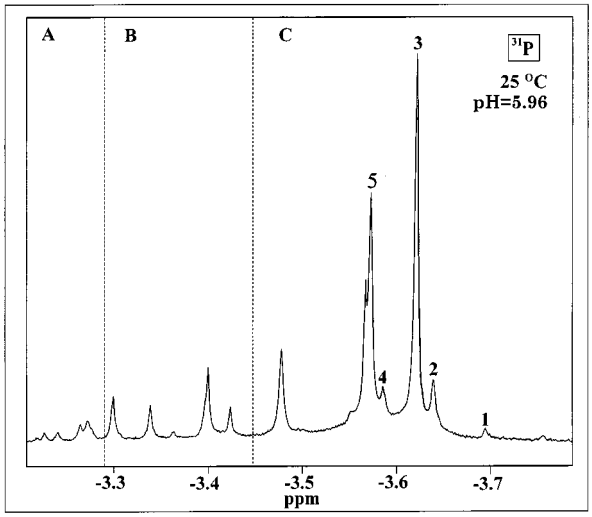

Figure 8. The ^{31}P spectrum of the same solution whose ^{51}V spectrum is shown in Figure 7, but at 25 °C, at which temperature the pH is 5.96. The chemical shift regions, A, B, and C are discussed in the text

basis of the overall composition of the solution, corresponding to the average composition Mo_9V_3P, it is concluded that an essentially equal amount of the total phosphorus in the solution is present as $Mo_{10}V_2P$ species, whose resonances are among the Mo_9V_3P resonances in region C of Figure 8.[18] Consequently, about 87% of the total phosphorus in this solution is present in Mo_9V_3P species.

A partial assignment of the ^{31}P resonances of Mo_9V_3P species proved possible by analogy to what was learned previously from the full assignment of the ^{31}P resonances of the $Mo_{10}V_2P$ isomers.[18] The resonances of the α- and β-$[Mo_{10}V_2PO_{40}]^{5-}$ isomers appear in separate chemical shift groups. This can be seen in Figure 2 from the chemical shift vs. pH curves of the $Mo_{10}V_2P$ species at pH > 3 where all the species are completely deprotonated. The resonances of the five α-isomers (all within the three resolved resonances labelled b, c, and d in Figure 2) appear closely grouped at distinctly higher field than the resonances detected for the two β-isomers (e and f in Figure 2), which also have a broader spread in chemical shifts. Figure 2 also shows that, at pH > 5 where the Mo_9V_3P species are completely deprotonated, four of the six most intense ^{31}P resonances are closely grouped in the same chemical shift region as the resonances of the five α-$[Mo_{10}V_2PO_{40}]^{5-}$ isomers. (Only the most intense phosphorus resonances are plotted in Figure 2, as only they could be tracked as a function of pH as the various resonances converged and diverged.) These four high-field, more intense Mo_9V_3P resonances, and the minor resonances in the same chemical shift region are confidently assigned to α-$[Mo_9V_3PO_{40}]^{6-}$ isomers.

The most downfield $[Mo_9V_3PO_{40}]^{6-}$ resonance plotted in Figure 2, which is downfield of even the most downfield detected β-$[Mo_{10}V_2PO_{40}]^{5-}$ resonance, appears on this basis to be a β-$[Mo_9V_3PO_{40}]^{6-}$ isomer. Similarly, the most downfield resonance in region C of Figure 8 has a chemical shift between the two detected β-$[Mo_{10}V_2PO_{40}]^{5-}$ resonances, but its intensity, greater than that of any resonance

in region B, is more consistent with an α-isomer. There is probably no distinct chemical shift border between the resonances of the 13 α-isomers and 43 β-isomers of Mo_9V_3P composition.

To get an approximation of the relative amounts of α- and β-Mo_9V_3P isomers, we considered the resonances in region C to be α-Mo_9V_3P isomers, subtracting the contribution from $Mo_{10}V_2P$ isomers, and the resonances in region B to be β-Mo_9V_3P isomers. The integrated resonance intensities over these regions indicate approximately 17% β- and 83% α-Mo_9V_3P isomers. Table 1 lists two columns of statistically predicted abundances of the α-Mo_9V_3P isomers. The first (1) gives the statistically predicted distribution of the α-isomers among the total α-isomers, as if only α-isomers were present (total 100%). The second (2) gives the statistically predicted distribution of the α-isomers among the total α-isomers, corrected for only 83% of the total phosphorus being present in α-isomers (total 83%). This second "predicted relative abundance" distribution was used for comparing individual ^{31}P resonance intensities, as a percentage of the total intensity of the ^{31}P resonances of Mo_9V_3P (regions B + C, corrected for the $Mo_{10}V_2P$ contribution), to the predicted percentage relative abundance of the isomers (see below).

A partial assignment of the ^{31}P resonances in region C of Figure 8 to specific α-$[Mo_9V_3PO_{40}]^{6-}$ isomers is based on their relative intensities and a trend revealed by the assignment of the ^{31}P resonances of the α-$[Mo_{10}V_2PO_{40}]^{5-}$ isomers.[18] The ^{31}P resonances of the unprotonated α-$[Mo_{10}V_2PO_{40}]^{5-}$ isomers reflect, in chemical shift order from upfield to downfield, decreasing polarity in the charge distribution surrounding the phosphorus. The more the vanadium atoms are separated in the Keggin structure, decreasing the charge polarity, the lower the field of the chemical shift. On this same basis, the α-$[Mo_9V_3PO_{40}]^{6-}$ isomers have been ordered in Table 1, from top-to-bottom, in the expected chemical shift order, from upfield to downfield.

The α-$[Mo_9V_3PO_{40}]^{6-}$ isomer with the most unbalanced charge distribution, expected to be most upfield, is the α-1,4,9 isomer (at the top of Table 1), with a predicted relative abundance of 1.5%. The most upfield significant resonance in Figure 8, labelled 1, contains 0.8% of the total phosphorus of regions B and C. The next resonance, labelled 2 in Figure 8, contains 5.4% of the total phosphorus in regions B and C. The α-1,2- and α-1,5-$[Mo_{10}V_2PO_{40}]^{5-}$ species also appear at this chemical shift,[18] unresolved, and contribute to about half of this integrated relative intensity. Thus, approx. 2.7% of the total phosphorus intensity may be assigned to the α-1,2,3 isomer. A comparison with the two most unbalancedly charged α-$[Mo_{10}V_2PO_{40}]^{5-}$ isomers shows that the integral of α-1,4,9 should be underestimated and α-1,2,3 overestimated. One would expect to find these two resonances well separated, since vanadium atoms are connected by sharing oxygen either in a corner or on an edge.

The next downfield, resolved resonance in Figure 8, labelled 3, which is the most intense resonance in the spectrum, has a total relative intensity of approx. 31% over regions B and C. This resonance overlaps the resonances of α-1,6- and α-1,11-$[Mo_{10}V_2PO_{40}]^{5-}$, which should contribute approx. 2.7% to this integrated relative intensity, leaving approx. 28% for Mo_9V_3P species. The three α-Mo_9V_3P isomers which appear next in the charge distribution order (Table 3), α-1,2,4, α-1,2,6 and α-1,4,8, have very similar charge distributions (unique in having all vanadium octahedra connected in series, but not all mutually connected as in the preceding two isomers in Table 1). Their predicted statistical abundance of 27.3% makes assignment of the resonance labelled 3 plausible. Examination of this resonance by curve fitting shows that it is composed of two resonances in a 2:1 ratio. According to charge distribution, the α-1,2,4 and α-1,2,6 isomers with a pair of edge-sharing vanadium octahedra and a third corner-sharing vanadium octahedron are more alike in charge than the α-1,4,8 isomer in which the third vanadium octahedron is separated from the other two.

The next downfield resonance (labelled 4 in Figure 8) is expected to be that of the α-1,4,6 isomer. Its relative intensity over regions B and C, 5.2%, agrees well with the predicted statistical abundance of 4.5%. The still next downfield resonance (labelled 5 in Figure 8), with a relative intensity of approx. 20% of the total phosphorus in regions B and C, agrees well with the sum of the predicted statistical abundances (18.2%) of the next two expected α-1,2,8 and α-1,4,7 isomers.

Beyond this, the remaining ^{31}P resonances could not be assigned to Mo_9V_3P species with any confidence. At increasingly downfield chemical shift, above $\delta = -3.5$, it becomes less and less certain whether the resonances arise from α-isomers or β-isomers or both. We can note that the α-1,6,12-$[Mo_9V_3PO_{40}]^{6-}$ isomer, with the most balanced internal charge distribution among the α-Mo_9V_3P species, is expected to have the most downfield chemical shift among the α-$[Mo_9V_3PO_{40}]^{6-}$ species. With a very low predicted statistical abundance (Table 1), however, its resonance could not be clearly assigned.

Experimental Section

Concentrated Molybdovanadophosphate Solutions and Solids: Molybdovanadophosphate sodium salt solutions were prepared by the method developed at Catalytica.[22] Free molybdovanadophosphoric acid solutions were prepared by the method developed by Onoda and Otake,[23] with modifications.[22] The solutions 0.30 M $\{Na_5Mo_{10}V_2PO_{40}\}$, 0.317 M $\{H_{4.9}Mo_{10.1}V_{1.9}PO_{40}\}$, 0.10 M $\{Na_4Mo_{11}VPO_{40}\}$, and 0.30 M $\{H_4Mo_{11}VPO_{40}\}$, and the solids $\{Na_5Mo_{10}V_2PO_{40}\} \cdot 13.6\ H_2O$, $\{H_5Mo_{10}V_2PO_{40}\} \cdot 10.1\ H_2O$, $\{Na_4Mo_{11}VPO_{40}\} \cdot 12.4\ H_2O$, and $\{H_4Mo_{11}VPO_{40}\} \cdot 21.5\ H_2O$ are those whose preparations were previously described.[18] A solution of 0.30 M $\{Na_5HMo_9V_3PO_{40}\}$, also used in the present studies, was prepared by neutralisation of 0.30 M $\{Na_3H_3Mo_9V_3PO_{40}\}$. These solutions were prepared as described below. Raw material sources were the same as for the previously reported preparations.[18]

Solution of 0.30 M $\{Na_3H_3Mo_9V_3PO_{40}\}$: In a 12 L Morton flask equipped with an electric heating mantle, efficient reflux condenser, and high torque overhead mechanical stirrer, granular V_2O_5 (4.50

mol, 818.46 g) was suspended in 3.5 L of distilled water, and the mixture was heated to about 60° C. Granular anhydrous Na_2CO_3 (4.50 mol, 476.95 g) was slowly added in portions to the rapidly stirred mixture, causing CO_2 liberation and dissolution of the V_2O_5 to give an essentially homogeneous solution. The solution was heated at reflux for 1 h. The solution was then dark blue-green due to dissolved V^{IV} which was originally present in the V_2O_5. Approximately 1 mL of 30% H_2O_2 was added dropwise, causing the dark blue-green colour to fade, leaving a slightly turbid, pale-tan sodium metavanadate solution. The solution was maintained at reflux for an additional 60 min to ensure the decomposition of excess peroxide and it was then cooled to room temp. The solution was filtered to remove the small amount (< 0.2 g) of brown solid, which contained almost all the iron and silica impurities originally present in the V_2O_5. The clear sodium metavanadate solution (orange coloured owing to small amounts of decavanadate species present at this very high vanadate concentration) was then returned to the Morton flask, diluted with 4.0 L of distilled water; then MoO_3 (27.00 mol, 3886.38 g) was added with rapid stirring. The mixture was heated to about 60 °C and H_3PO_4 (3.00 mol, 344.25 g, 85.4% w/w) was added. The mixture was heated at reflux and thereby converted into a clear, dark, burgundy-red solution. After 3 h at reflux, the homogenous solution was cooled to room temp and was volumetrically diluted with distilled water to a total volume of 10.00 L, giving 0.30 M $\{Na_3H_3PMo_9V_3O_{40}\}$.

Solution of 0.30 M $\{Na_5HMo_9V_3PO_{40}\}$: Granular Na_2CO_3 (0.15 mol, 15.90 g) was slowly added to $\{Na_3H_3PMo_9V_3O_{40}\}$ (0.15 mol, 0.500 L, 0.30 M) with rapid stirring. The resulting solution was boiled for 1.5 h, cooled to room temp, and volumetrically diluted with distilled water to 0.500 L, giving 0.30 M $\{Na_5HMo_9V_3PO_{40}\}$.

Solutions for Potentiometric and Quantitative NMR Studies: Stock solutions of the components (HCl, Na_2MoO_4, $NaVO_3$, and NaH_2PO_4) were prepared as previously described, from the same source materials.[13,18] The solutions for the potentiometric and NMR studies were prepared by mixing of the stock solutions of the components, from the concentrated molybdovanadophosphate solutions (listed above), and/or from the solid Keggin molybdovanadophosphoric acids and sodium salts (listed above) in the same manner as previously described.[18] Boiled distilled water was used to prepare all the solutions. After the components were mixed, the molybdovanadophosphate solutions required up to 24 h at 25 °C to reach equilibrium. For measurements at 90 °C, see ref.[18]

Ionic Medium: The pH potentiometry at 25 °C and the NMR studies at 25 °C and 90 °C were all conducted on solutions of the ionic 0.6 M Na(Cl), to maintain constant activity coefficients. Since anion equilibria are studied, the cation concentration in the ionic medium was kept constant, 0.600 M Na^+, and the Cl^- concentration was varied to provide the balance of counteranions not provided by the molybdate, vanadate, and phosphate oxoanion species. This is the same medium referred to in previous studies as 0.6 M Na(Cl).

pH Potentiometry: Titrations were conducted at 25.0 ± 0.1 °C with an automated potentiometric titrator. Free H^+ concentrations were determined by measurement of the EMF of the cell given below, with an Ingold type 201-NS glass electrode, an Ag/AgCl reference electrode prepared according to Brown,[24] and a Wilhelm bridge.[25] Cell: − Ag,AgCl | 0.6 M NaCl || equilibrium solution | glass electrode +

The free H^+ concentration was calculated from the measured EMF, E (in mV), by Equation (3), where the last term is the liquid junction potential in acid solutions for the 0.6 M Na(Cl) medium and the Wilhelm-type bridge used.

$$E = E_0 + 59.157\log[H^+] - 76[H^+] \quad (3)$$

The constant E_0 was determined before and after each titration with separate solutions of known $[H^+]$. A fluoropolymer-encased magnetic bar was used to stir the solution in the titration vessel. The solution was protected from atmospheric carbon dioxide by a stream of argon gas. The argon was sparged through 10% NaOH solution to remove any acid impurities, 10% H_2SO_4 solution to remove any alkaline impurities, and, finally, a 0.6 M NaCl medium before introduction to the titration vessel.

pH Potentiometric Data: A total of 42 titrations covering the ranges of pH from 1.3 to 5.2, Mo/V ratios from 2 to 22, and (Mo + V)/P ratios from 11.5 to 15.4 were performed, and 187 selected points were used in the calculations. The solid lines in Figure 1 show the EMF titrations over (Mo/V) vs. pH space, and show that the titrations were done at constant pH with varying Mo/V ratios, at a constant Mo/V ratio with varying pH, and at simultaneously varied pH and Mo/V ratio. The total concentration of phosphorus was varied between 8 and 20 mM. To confirm that solutions reached equilibrium, pH titrations were done in both directions, acidic towards neutral and neutral towards acidic. The titration data used in the calculations were restricted to Mo/V ratios greater than 3.8 (corresponding to $x \leq 2.5$ in the average Keggin composition $[Mo_{12-x}V_xPO_{40}]^{(3+x)-}$), to avoid solutions containing Mo_8V_4P anions. The data used in the calculations were also restricted to pH > 1.3, as data from titrations at lower pH values were not considered accurate enough.

NMR Measurements: The ^{31}P- and ^{51}V-NMR measurements were obtained on a Bruker AM500 spectrometer at 202.5 and 131.6 MHz, respectively. The probe temperature was thermostatted at 25.0 ± 0.5 °C or 90.0 ± 1.0 °C. The field frequency stabilisation was locked to deuterium by insertion of the 8 mm sample tubes into 10 mm tubes containing D_2O. The samples were spinning in all experiments.

The spin-lattice relaxation times (T_1) were evaluated with the Bruker software inversion recovery method and were determined for the different Keggin species to approx. 30 s for ^{31}P and just a few ms for ^{51}V. For determining the relative abundances of species from their resonance intensities, spectra were recorded quantitatively with the relaxation delay set to at least $5 \cdot T_1$, and the free induction decay (FID) was multiplied by an exponential line-broadening function (LB = 1), with the Bruker software, to improve the signal/noise ratio. A Gaussian-Lorentzian double apodization was applied to the FID, also with the Bruker software, to enhance resolution to obtain more accurate chemical shifts of overlapping resonances. Chemical shifts are reported relative to external $VOCl_3$ and external 85% H_3PO_4, with positive chemical shifts (δ) corresponding to higher frequency.

In acid solutions the α-$[Mo_{11}VPO_{40}]^{4-}$ ion was used as internal ^{31}P and ^{51}V chemical shift standard to determine the chemical shifts with high accuracy and precision. In the more neutral solutions, the chemical shifts of the fully deprotonated $[Mo_{10}V_2PO_{40}]^{5-}$ isomers had a constant "plateau" vs. pH and could be used as internal ^{31}P and ^{51}V chemical shift standards. The ^{31}P chemical shifts are dependent on the concentration of Keggin ions, and 10 mM Keggin ions was used as the reference state for chemical shifts.[18]

NMR solutions were collected from titrations and from separately prepared solutions ("point solutions") corresponding to points in a hypothetical pH titration. After equilibration, the pH values in these point solutions were measured with a combination electrode, ORION Research 81-03 ROSS or INGOLD U402-M6-S7/100. The

electrodes were calibrated with solutions of known $[H^+]$ in 0.6 M Na(Cl). Due to the long relaxation time of ^{31}P resonances in Keggin species, the phosphorus concentrations were sometimes as high as 120 mM, which improves the signal/noise ratio in the spectra and facilitates the determination of chemical shifts with fewer scans.

NMR Data for the Calculations: Integrals from 44 NMR spectra ($0.44 < pH < 4.78$), shown with as □ in Figure 1, and 67 shift values from different spectra ($0 < pH < 6.13$) were used in the calculations. The total concentration of phosphorus was varied between 8 and 60 mM for integral data and between 8 and 120 mM for chemical shift data. Mo_8V_4P species appear in acid solutions with a Mo/V ratio of 3 ($x = 3$ in the average Keggin ion composition). NMR data used in the calculations were, in the same way as titration data, restricted to Mo/V ratios above 3.8, to avoid solutions containing Mo_8V_4P anions, and to thereby simplify the calculations.

The ^{31}P resonances are much better resolved than the ^{51}V resonances at 25 °C. Consequently, we mainly used the integral data from ^{31}P spectra, and not from ^{51}V spectra, in the calculations. In the more neutral solutions, however, the ^{31}P resonances were severely overlapped, so that it was not possible to obtain reliable integral values. For this reason, the NMR data used in the calculations were restricted to those obtained at $pH \leq 4.8$.

Computer Programs: Resonance intensities were computed by integration with the Bruker software, or, for overlapping resonances, by line shape analysis with the programs NMR*i*,[26] UXNMR/P version 1.1, and WIN-NMR version 950901.0, with the chemical shifts determined by resolution enhancement (see above) as input. Using these programs, it is possible to obtain integral values with errors less than 10%. The mathematical analysis of combined $[H^+]$-EMF data, and ^{31}P-NMR shift and integral data, was accomplished with the least-squares program LAKE.[1] LAKE is capable of treating multimethod data simultaneously; this considerably refines the equilibrium analysis. Compositions, (*p,q,r,s*), and formation constants, $\beta_{p,q,r,s}$, are varied so that the error squares sum, $U = \Sigma(W_i \Delta A_i)^2$ is minimised. The complex, or set of complexes, with the lowest U value forms the model that best explains the experimental data. A_i can be either the total concentration of components, free species concentrations, NMR peak integrals, chemical shifts or a combination of these. W_i are weighting factors that are subjectively set to give different types of data appropriate contributions to the results. In the present study, we used weighting factors that give NMR peak integrals and shift values a predominant contribution to the sum of residuals. Calculation and plotting of distribution diagrams were performed with the program SOLGASWATER.[27]

[2] The ionic formulae of these Keggin anions are more commonly written as $[H_zPMo_{12-x}V_xO_{40}]^{(3+x-z)-}$). We usually denote the composition of a solution species by the stoichiometric integers of the components used in our potentiometric study of its equilibrium formation. We also find it convenient to use our standard order − H, Mo, V, P − when writing ionic formulae.

[28] The statistically predicted relative abundances correspond to the α isomers′ degeneracies, and are reported herein as percentages of the total of their degeneracies. The degeneracy of each isomer equals the number of ways x vanadium can be substituted for x molybdenum in the parent T_d α-$[Mo_{12}PO_{40}]^{3-}$ structure, to provide that α-$[Mo_{(12-x)}V_xPO_{40}]^{(3+x)-}$ isomer. For dissymmetric isomers, the degeneracies of their enantiomorphs are added together.

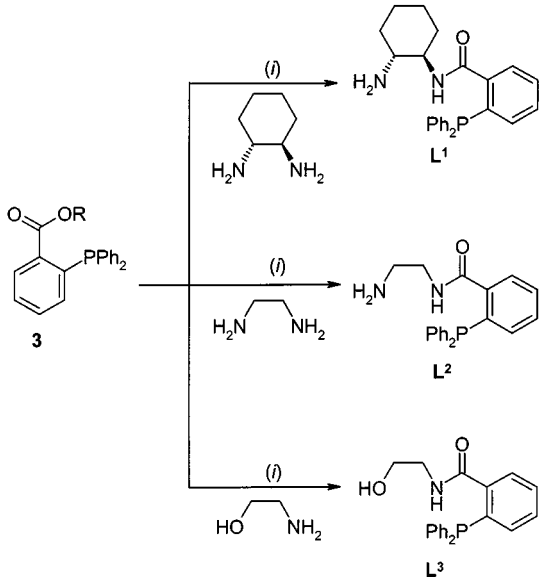
Neutral Trichlorooxorhenium(V) Complexes Containing New Heterofunctionalized Phosphane Ligands of the Type PN_2 and PNO

João D. G. Correia,[a] Ângela Domingos,[a] and Isabel Santos*[a]

Keywords: Rhenium / P ligands / Chelates / Radiopharmaceuticals

The new heterofunctionalized phosphane [(1*R*,2*R*)-*N*-(2-aminocyclohexyl)]-2-(diphenylphosphanyl)benzamide (**L¹**), *N*-(2-aminoethyl)-2-(diphenylphosphanyl)benzamide (**L²**) and 2-(diphenylphosphanyl)-*N*-(2-hydroxyethyl)benzamide (**L³**) were synthesized by reaction of *N*-[2-(diphenylphosphanyl)-benzoyloxy]succinimide (**3**) in dichloromethane with (1*R*,2*R*)-(–)-diaminocyclohexane, ethylenediamine and ethanolamine, respectively. Reactions of $[Re(O)Cl_4]^-$ with **L¹**, **L²** and **L³**, at a 1:1 metal/ligand molar ratio gave neutral trichlorooxorhenium(V) complexes of the type $[Re(O)Cl_3\{\kappa^2\text{-L}\}]$ [L = **L¹** (**4**), **L²** (**5**), **L³** (**6**)]. The characterization of the compounds involved IR, ^{1}H- and ^{31}P-NMR spectroscopy, and X-ray crystallographic analysis for **L¹**, **5** and **6**. The Re atom is six-coordinate in complexes **4**–**6**, with an oxo ligand, three chloride ligands and a neutral bidentate heterofunctionalized phosphane ligand.



Introduction

The continuous demand for more sensitive and specific probes for targeting diseased organs or physiological functions in Nuclear Medicine, both in the diagnostic or therapeutic field, has led to an increasing interest in the development of receptor-binding radiopharmaceuticals.[1] Due to its physico-chemical properties and widespread availability, ^{99m}Tc is still the most used radionuclide for diagnosis, and both ^{186}Re and ^{188}Re appear as interesting radionuclides for the development of radiopharmaceuticals with therapeutic potential.[2] For the metal centre in the oxidation state (V) and an $[M{=}O]^{3+}$ core, the use of a bifunctional tetradentate or a tridentate ligand, and a bifunctional unidentate coligand ([3+1] approach) are among the most popular strategies for the design and preparation of new, more specific radiopharmaceuticals.[3] Due to its σ-donor and π-acceptor properties, phosphanes are known to stabilize complexes of rhenium and technetium with the metal centre in different oxidation states.[4,5] A number of heterofunctionalized phosphane-containing ligands have previously been described and used to stabilize the core $[M{=}O]^{3+}$ (M = Re, Tc).[6–8] However, they are all either bidentate, with PN, PO or PS donor sets [6–8] or tetradentate.[9] We have synthesized new tridentate PNO- and PN_2-type ligands, with potential tridentate character, with the aim of designing new radiopharmaceuticals using the [3+1] approach. Surprisingly, we observed that, depending on the reaction conditions, these ligands are very versatile in terms of coordination mode and charge. Indeed, they can act as neutral, mono- or dianionic bi/tridentate chelates.[10] In this paper we report on the synthesis and characterization of the new heterofunctionalized phosphane ligands as well as on the preparation of Re^V adducts where the ligands coordinate to the metal centre in a bidentate and neutral fashion.

Results and Discussion

Synthesis and Characterization of the Ligands

The heterofunctionalized phosphane ligands **L¹**, **L²** and **L³** were synthesized as depicted in Scheme 1. The activation of 2-(diphenylphosphanyl)benzoic acid with *N*-hydroxysuccinimide was achieved in good yield (94%) by a slight modification of a reported method.[11] Reaction of *N*-[2-(diphenylphosphanyl)benzoyloxy]succinimide (**3**) in CH_2Cl_2 at room temperature with (1*R*,2*R*)-(−)-diaminocyclohexane, ethylenediamine and ethanolamine afforded, after appropriate workup, **L¹** (89%), **L²** (74%) and **L³** (87%), respectively.

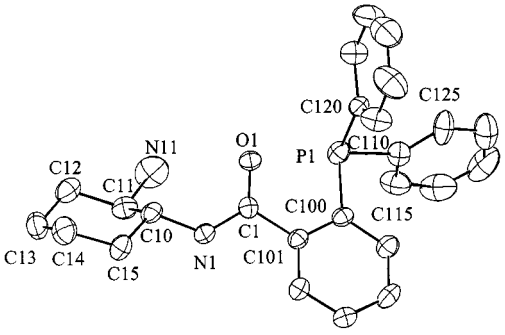
The IR spectra of $\mathbf{L^1}$ and $\mathbf{L^2}$ exhibit $\nu(NH_2)$ stretching bands at 3220 cm^{-1} and 3320 cm^{-1}, respectively, and for $\mathbf{L^3}$ the IR spectrum shows a strong band at 3310 cm^{-1} which is assigned to ν(OH). In all the spectra a strong band appears at 1630 cm^{-1} due to ν(C=O). In the ^{1}H-NMR spectra of $\mathbf{L^1}$ a doublet appears at δ = 5.71 due to the NH of the amide group. For $\mathbf{L^2}$ and $\mathbf{L^3}$ the signals of these groups appear as broad singlets at δ = 6.23 and 6.27, respectively.

Unlike $\mathbf{L^1}$, where a multiplet at δ = 1.89, assigned to the protons of the amine group, is observed, the ^{1}H-NMR spectrum of $\mathbf{L^2}$ does not present any signal for this group. For $\mathbf{L^3}$, no resonance signal is observed for the hydroxy group. The ^{31}P-NMR spectra of $\mathbf{L^1}$, $\mathbf{L^2}$, and $\mathbf{L^3}$ show only one peak at δ = −10.5, −9.3 and −9.9, respectively. $\mathbf{L^3}$ decomposed slightly in solution on standing, leading to the corresponding phosphane oxide, as indicated by the new ^{31}P-NMR signal which appears at δ = 36.6.[12]

Single colorless crystals of $\mathbf{L^1}$, suitable for X-ray diffraction analysis, were obtained from a mixture of dichloromethane/hexane. $\mathbf{L^1}$ crystallizes in the monoclinic acentric space group $P2_1$ with three crystallographically independent molecules in the asymmetric unit. The three independent molecules are labelled similarly, being distinguished by the first digit of the atom label.



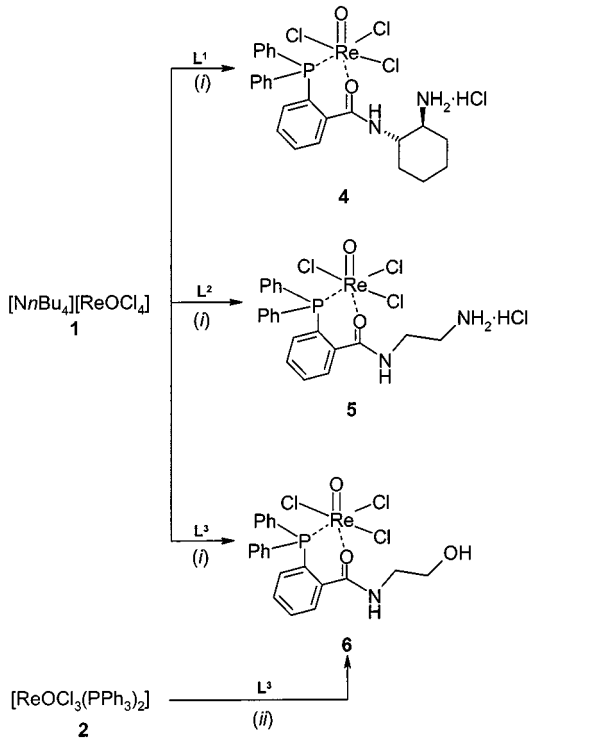


Figure 1. ORTEP drawing of ligand $\mathbf{L^1}$ with the atom numbering scheme; thermal ellipsoids are drawn at the 30% probability level; selected mean bond lengths [Å] and angles [°]: C(1)−O(1) 1.231(8), N(1)−C(1) 1.329(9), N(1)−C(10) 1.448(9), C(11)−N(11) 1.449(11), C(1)−C(101) 1.498(10), P(1)−C(100) 1.848(8), P(1)−C(110) 1.838(9), P(1)−C(120) 1.837(8), av. $(C-C)_{cyclohex}$ 1.51(1), av. $(C-C)_{Phenyl}$ 1.37(2); N(1)−C(1)−O(1) 123.3(7), O(1)−C(1)−C(101) 120.7(7), N(1)−C(1)−C(101) 116.1(7), C(10)−N(1)−C(1) 124.5(6)

Figure 1 shows an ORTEP view of one molecule with the atom numbering scheme as well as selected bond lengths and angles. Within two standard deviations the three molecules can be considered chemically equivalent, presenting similar molecular dimensions. The packing of the molecules forms a network of hydrogen bonds involving the amide N−H group and the carbonyl oxygen atoms. The shortest intermolecular distances are 2.887 Å for O(1) and N(2′) (x, y, $-1 + z$), 2.862 Å for O(2) and N(3′) ($1 - x$, $-0.5 + y$, $1 - z$) and 2.858 Å for O(3) and N(1′) ($2-x$, $y + 0.5$, $-z$) (the average N···O contact distance is 2.929 Å for the hydrogen bonds "C=O···H−N").[13] The cyclohexane ring shows the usual chain conformation.

Scheme 2. Synthesis of the complexes **4**−**6**; (*i*) MeOH, room temperature; (*ii*) dichloromethane, room temperature

Synthesis and Characterization of the Complexes

Reactions of $\mathbf{L^1}$, $\mathbf{L^2}$ and $\mathbf{L^3}$ with [nBu$_4$N][Re(O)Cl$_4$] (**1**) in methanol, at a 1:1 molar ratio, at room temperature, afforded the new unusual neutral trichlorooxorhenium(V) complexes **4**−**6** (Scheme 2). To the best of our knowledge, several compounds containing the "Re(O)Cl$_3$" moiety are known. However, this unit is stabilized either by diphosphanes or by neutral monodentate ligands.[14]−[16] When a heterofunctionalized phosphane ligand such as (2-hydroxyphenyl)diphenylphosphane (PO) is used, deprotonation occurs with formation of the monoanionic complex [Re(O)Cl$_3$(PO)]$^-$.[7c] Phosphane-containing peptides (PN$_2$O donor set) were studied, and deprotonation was also observed. In this case, the ligands coordinate in a dianionic and tetradentate fashion.[9b] Thus, the neutral behavior of our ligands and the observed coordination mode are not very common, probably as a result of the influence of the type of substituents attached to the amide nitrogen atom.

Complex **6** was also obtained by stoichiometric reaction of $\mathbf{L^3}$ with [Re(O)Cl$_3$(PPh$_3$)$_2$] (**2**) in CH$_2$Cl$_2$. After evaporation of the solvent, complexes **4** and **5** were obtained as light blue and pale green solids, respectively. Complex **6**, unlike **4** and **5**, precipitated from its reaction mixture and, upon appropriate workup, was obtained as a dark green solid in an almost quantitative yield. Complexes **4**−**6** are stable towards air and moisture and almost insoluble in most organic solvents and water. Complexes **5** and **6** are moderately soluble in acetonitrile, whereas **4** is insoluble in this solvent. Complex **4** is moderately soluble in tetrahydrofuran and dimethyl sulfoxide but tends to decompose in these solvents. The characterization of **4**−**6** has been done

by elemental analysis, IR, ^{1}H- and ^{31}P-NMR spectroscopy, and by X-ray crystallographic analysis in the case of **5** and **6**.

The IR spectra of complexes **4**–**6** exhibit Re=O stretching vibrations at 1000 cm^{-1}. These values are in the normal range as those found for monooxorhenium complexes (945–1067 cm^{-1}).[17] The C=O stretching vibration of the carbonyl group appears at 1570, 1590 and 1590 cm^{-1} for **4**, **5** and **6**, respectively. These values are lower in energy (by ca. 40–60 cm^{-1}) relative to the corresponding free ligands, confirming the coordination of the carbonyl group to the metal centre. In addition, all the complexes display IR absorptions typical of ν(Re–Cl) at 320 cm^{-1} and at 315 cm^{-1}; and absorptions of coordinated phosphane ligands, in particular two strong absorption bands at 750 cm^{-1} and at 697 cm^{-1}, associated with C–H and C–C out-of-plane bending vibrations in monosubstituted benzene rings.[18]

Due to the low solubility of all complexes their NMR spectra were run either in CD_3CN or in $(CD_3)_2SO$. The ^{31}P-NMR spectra of **5** and **6** in CD_3CN show only one resonance signal, which appears at δ = −15.4 and −16.5, respectively. These resonance signals are shifted slightly upfield in $(CD_3)_2SO$, and appear at δ = −18.1 for both complexes. When compared with those of the free ligands, the resonance signals found for **5** and **6** are shifted upfield (ca. 6 ppm). For complex **4**, it was only possible to run the ^{31}P-NMR spectrum in $(CD_3)_2SO$ and, in this solvent, the initial blue solution turned green within seconds. Two resonance signals are observed in the spectrum at δ = −17.2 and 32.9. The resonance signal at δ = −17.2 compares well with the value of δ = −18.1 found for complexes **5** and **6** in the same solvent, and led us to assign the signal to adduct **4**. An upfield shift (about 7.6 ppm) relative to the resonance signal of the free ligand [−9.6 ppm in $(CD_3)_2SO$], is observed for the resonance signal of **4**. This also compares well with the shift found for complexes **5** and **6**. The resonance at δ = 32.9 is assigned to the phosphane oxide of the ligand.[12] This result confirms that $(CH_3)_2SO$ is able to oxidise aromatic tertiary phosphanes coordinated to oxoRe complexes by oxygen transfer, as previously reported.[19] In order to confirm the presence of phosphane oxide signals in this region of the spectrum, **L^1** was oxidized with hydrogen peroxide in a parallel experiment. The ^{31}P-NMR spectrum of the resulting product in $(CD_3)_2SO$ reveals only one resonance signal at δ = 32.0.

The ^{1}H-NMR spectra of **5** and **6** present three sets of multiplets assigned to the protons of the aromatic rings. Two of the multiplets integrate for one proton each and the third for twelve protons. The chemical shifts are comparable in both complexes and the protons are slightly deshielded with respect to those of the free **L^2** and **L^3**. The remaining signals observed in the spectra are due to the amide and to the ethylene protons of the coordinated heterofunctionalized phosphane ligands. In both complexes the amide proton signal is significantly shifted downfield relative to those of the free ligands and this is certainly due to the more acidic character of this proton after the coordination of **L^2** and **L^3** to the rhenium atom through the carbonyl group.

As mentioned above, complex **4** decomposed in $(CD_3)_2SO$ yielding partially the oxidised form of the ligand. However, in the phenyl and amide region of the ^{1}H-NMR spectrum, we could easily identify some resonance signals that correspond to the remaining adduct **4**. In fact, we observe signals at δ = 11.16 (1 H, d, NH), 8.71 (1 H, t, aromatic), 8.11 (1 H, s, br., aromatic) and 7.19 (1 H, m, aromatic). The pattern, the chemical shifts and type of splitting compare very well with what is observed in the spectrum of complex **5**, in the same solvent. The region of the cyclohexyl protons is quite complicated and the assignment of the resonance signals of **4** is not possible.

Crystal Structures of Complexes 5 and 6

The X-ray crystallographic analysis on a poor-quality crystal of **5** did not provide an adequate data set for an accurate determination of the structure of this complex. It was not possible to refine the structure with acceptable *R* values (R_1 = 0.0925, wR_2 = 0.1946) and with sufficient accuracy. However, it was possible to unambiguously define the connectivities of the atoms around the Re atom (Figure 2), and to confirm that the molecular structure of complex **5** is analogous to that of **6**.

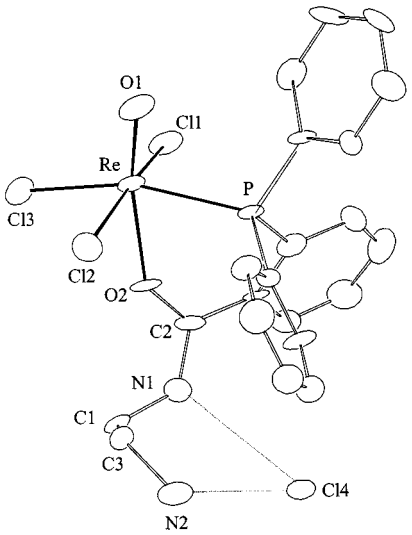

Figure 2. ORTEP drawing of complex **5** with the atom numbering scheme; thermal ellipsoids are drawn at the 30% probability level

Compound **5** crystallized from boiling acetonitrile as dark green crystals in the triclinic space group $P\bar{1}$ with cell parameters *a* = 9.840(2) Å, *b* = 12.000(3) Å, *c* = 13.604(3) Å, α = 66.12(2)°, β =86.01(2)°, γ = 68.30(1)°, *V* = 1358.7(5) Å^3, *Z* = 2, D_c = 1.788 gcm^{-3}. Besides a disordered acetonitrile molecule of solvent in the lattice, a residual peak of electron density of the order of 18 eÅ^{-3} was found which refined properly as a chloride ion. The chloride ion is hydrogen-bonded to the two nitrogen atoms of the molecule: to the amide N(1) atom [N(1)···Cl(4) 3.073 Å] and to the amine N(2) atom [N(2)···Cl(4) 3.273 Å]. The molecular structure of **6** as well as selected bond lengths and angles are shown in Figure 3.

The overall geometry around the six-coordinate rhenium atom is described as an highly distorted octahedron, as can

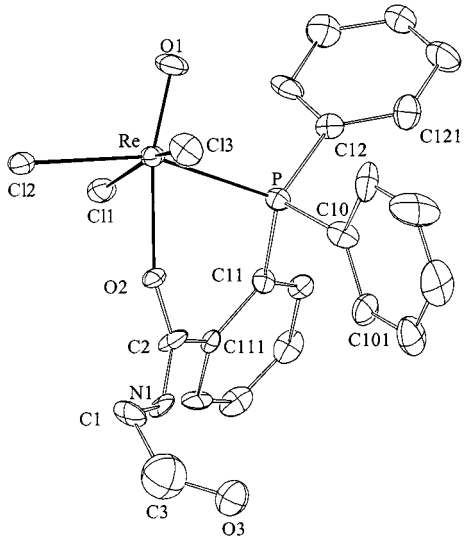

Figure 3. ORTEP drawing of complex **6** with the atom numbering scheme; thermal ellipsoids are drawn at the 30% probability level; selected mean bond lengths [Å] and angles [°]: Re−O(1) 1.659(10), Re−O(2) 2.133(10), Re−Cl(1) 2.367(5), Re−Cl(2) 2.377(4), Re−Cl(3) 2.355(4), Re−P 2.425(5), C(2)−O(2) 1.26(2), N(1)−C(2) 1.28(2), N(1)−C(1) 1.46(2), av. P−C 1.82(2); O(1)−Re−O(2) 167.2(5), O(1)−Re−Cl(1) 97.6(4), O(1)−Re−Cl(2) 107.5(4), O(1)−Re−Cl(3) 95.5(4), O(1)−Re−P 93.1(4), Cl(1)−Re−Cl(3) 166.1(2), Cl(2)−Re−Cl(3) 85.9(2), Cl(1)−Re−P 89.0(2), Cl(2)−Re−P 159.3(2), O(2)−Re−Cl(1) 85.3(4), Cl(3)−Re−P 94.9(2), Re−O(2)−C(2) 141.0(13), O(2)−C(2)−N(1) 121(2), O(2)−Re−P 74.5(3), C(2)−N(1)−C(1) 124.1(14), N(1)−C(2)−C(111) 118(2)

be seen by the bond angles around the Re atom. With the axial direction being defined along the Re=O bond, three equatorial positions are occupied by the chloride ions, whereas the fourth equatorial position is occupied by the phosphorous atom of the ligand. The equatorial plane deviates from planarity (atomic deviations from −0.091 to 0.087 Å), and the Re atom is displaced 0.34 Å towards the multiply bonded oxygen. The bidentate chelate forms a non-planar six-membered ring through the phosphorus and the carbonyl oxygen atoms bonded to the metal centre. The oxygen atom of the carbonyl group coordinates to the axial position *trans* to Re=O [O(1)−Re−O(2), 167.2(5)°].

As far as we are aware, this is the first structural characterization of an Re^V neutral adduct complex of the type $[Re(O)Cl_3(\kappa^2\text{-L})]$. For comparison, we have complexes with neutral monodentate ligands or with monoanionic bidentate ligands. The Re−O(1) bond length [1.659(10) Å] in **6** compares well with the values found in $[Re(O)Cl_3(Ph_3PO)(PPh_3)]$ [1.669(4)Å],[15] $[Re(O)Cl_3(PPh_3)(DMF)]$ [1.664(4) Å],[16] and in the anionic monooxorhenium(V) compound $[Re(O)Cl_3(PO)]^-$ [1.669(6) Å; PO = (2-hydroxyphenyl)diphenylphosphane].[7c] This distance in **6** is slightly shorter than the corresponding values 1.692(7) and 1.69(1) Å found in $[Re(O)(PN)_2(OEt)]$ and in the orthorhombic form of $[Re(O)(PN)_2Cl]$ [PN = (2-aminophenyl)diphenylphosphane], respectively.[6b]

The Re−P bond length [2.425(5) Å] compared well with the value found in the anionic monooxorhenium(V) compound $[Re(O)Cl_3(PO)]^-$ [2.422(2) Å] but is shorter than in $[Re(O)Cl_3(Ph_3PO)(PPh_3)]$ [2.506(2) Å], $[Re(O)(PN)_2(OEt)]$ [av. 2.494(3) Å] and in $[Re(O)(PN)_2Cl]$ [av. 2.450(5) Å].[7c,6b,15]

The Re−Cl bond length [av. Re−Cl, 2.366(5) Å] compares well with that found in $[Re(O)Cl_3(PO)]^-$ [av. 2.380(3) Å], but is shorter than in the Re^V complex containing two PN phosphane ligands $[Re(O)(PN)_2Cl]$ [2.422(6) Å].[6b,7c]

The shorter Re−P and Re−Cl bond lengths in complex **6**, relative to the corresponding bond lengths in the complexes mentioned above, are most likely due to steric factors, chelating mode of the ligands and nature of the atoms involved in the coordination with the rhenium centre. The *trans*-Re−O(2) (oxygen atom of the carbonyl group of the ligand) distance [2.133(10)Å] compares well with the value found in $[Re(O)Cl_3(PPh_3)(DMF)]$ [2.133(4)Å] for the bond between the oxygen atom of DMF and the metal centre.[16a] This bond length is considerably longer than that between the amide oxygen atom of MAG_1 (mercaptoacetyl glycine) and the rhenium atom in the complex $[Re(O)(MAG_1Et)_2]$ [2.051(5)Å].[16b] This difference is probably due to the different nature of the donor atoms of the ligands involved in the coordination sphere of the metal centre.

The severe problem of disorder in the terminal C(3)−O(3)H atoms prevents any discussion or comparison of bond lengths within the group, as can be seen by the large standard deviations. Nevertheless, we can say that there is no short intermolecular interaction involving the O(3) atom. An intermolecular interaction involving Cl(2)···N(1) atoms (distance of 3.272 Å) is observed in the packing of the molecules in the crystalline state.

Concluding Remarks

New tridentate heterofunctionalized phosphane ligands have been synthesised and fully characterized. No deprotonation of these ligands occurs under mild conditions when they react with $[nBu_4N][Re(O)Cl_4]$. The new complexes formed are the neutral trichlorooxorhenium(V) adducts $[Re(O)Cl_3\{\kappa^2\text{-L}\}]$, which are rare examples of oxo complexes stabilized by neutral heterofunctionalized phosphane ligands. The rhenium atom is six-coordinate in an octahedral configuration with the oxo function *trans* to the oxygen atom of the carbonyl group and with the phosphorous atom in the equatorial position.

Experimental Section

General Procedures: All chemicals were of reagent grade. Ethylenediamine and ethanolamine were purchased from Aldrich and distilled prior to use. (1*R*,2*R*)-(−)-diaminocyclohexane was purchased from Aldrich and was used as received. The reactions were performed in air unless otherwise indicated. 2-(Diphenylphosphanyl)-benzoic acid and the complexes $[nBu_4N][Re(O)Cl_4]$ (**1**) and $[Re(O)Cl_3(PPh_3)_2]$ (**2**) were prepared as reported in the literature.[20−22] ^1H- and ^{31}P-NMR spectra were recorded with a Varian Unity 300-MHz spectrometer; ^1H chemical shifts were referenced with the residual solvent resonance relative to tetramethylsilane and the ^{31}P chemical shifts were measured with an external H_3PO_4 solution

(85%) as a reference. Chemical shifts are given in ppm. The NMR samples were prepared in $CDCl_3$, CD_3CN or $(CD_3)_2SO$. Infrared spectra were recorded in the range 4000−200 cm^{-1} with a Perkin−Elmer 577 spectrometer using KBr pellets. Elemental analyses were performed with a Perkin−Elmer automatic analyser.

***N*-[2-(Diphenylphosphanyl)benzoyloxy]succinimide (3):** 2-(Diphenylphosphanyl)benzoic acid (1.00 g, 3.27 mmol) and *N*-hydroxysuccinimide (0.75 g, 6.54 mmol) were dissolved in dichloromethane (20 mL) at room temperature, and a solution of dicyclohexylcarbodiimide (1.35 g, 6.54 mmol) in dichloromethane was added dropwise. The reaction was complete after 3 h (TLC: ethyl acetate/hexane, 50:50). The formed urea was separated by filtration through a pad of Celite wetted with dichloromethane, and the filtrate concentrated to dryness. The resulting white residue was chromatographed on an appropriate column of silica gel with 20−35% ethyl acetate/hexane (gradient), to afford a white yellowish solid, which was further recrystallized from dichloromethane/hexane to give **3** in an analytical pure form. Yield 1.24 g (94%). − ^{1}H NMR ($CDCl_3$): δ = 2.81 (4 H, s, CH_2), 6.99 (1 H, m aromatic), 7.19−7.32 (9 H, m, aromatic), 7.45 (3 H, m, aromatic), 8.31 (1 H, m, aromatic). − ^{31}P NMR($CDCl_3$): δ = −4.4. − IR (KBr): $\tilde{\nu}$ = 1760 cm^{-1} (vs, C=O). − $C_{23}H_{18}NO_4P{\cdot}0.5CH_2Cl_2$ (445.8): calcd. C 63.31, H 4.30, N 3.14; found C 63.77, H 4.63, N 3.23.

[(1*R*,2*R*)-*N*-(2-Aminocyclohexyl)]-2-(diphenylphosphanyl)benzamide (L^1): *N*-[2-(Diphenylphosphanyl)benzoyloxy]succinimide (0.89 g, 2.20 mmol), dissolved in dichloromethane (10 mL), was added dropwise to a solution of (1*R*,2*R*)-(−)-diaminocyclohexane (0.50 g, 4.40 mmol) in the same solvent (25 mL). The reaction was complete after 3 h, as indicated by the TLC (ethyl acetate/hexane, 50:50). The mixture was washed with 25 mL of water and the organic phase was separated. The aqueous phase was extracted with dichloromethane (2 × 30 mL). The organic phases were collected, dried with $MgSO_4$, filtered and concentrated to dryness. The resulting viscous oil was recrystallized from dichloromethane/hexane, affording colourless crystals of $\mathbf{L^1}$. Yield 0.79 g (89%). − ^{1}H NMR ($CDCl_3$): δ = 0.85 (1 H, m, cyclohexyl), 1.17 (4 H, m, cyclohexyl), 1.65 (3 H, s, br., cyclohexyl), 1.89 (2 H, m, NH_2), 2.15 (1 H, m, C*H*NH_2), 3.60 (1 H, m, C*H*NH), 5.71 (1 H, d, NH), 6.92 (1 H, m, aromatic), 7.19−7.40 (12 H, m, aromatic), 7.62 (1 H, m, aromatic). − ^{31}P NMR($CDCl_3$): δ = −10.5. − ^{31}P NMR [$(CD_3)_2SO$]: δ = −9.6. − IR (KBr): $\tilde{\nu}$ = 3220 cm^{-1} (m, NH_2), 1630 cm^{-1} (vs, C=O). − $C_{25}H_{27}N_2OP$ (402.5): calcd. C 74.61, H 6.76, N, 6.96; found C 73.75, H 6.55, N 6.89.

***N*-(2-Aminoethyl)-2-(diphenylphosphanyl)benzamide (L^2):** *N*-[2-(Diphenylphosphanyl)benzoyloxy]succinimide (0.70 g, 1.74 mmol), dissolved in dichloromethane (10 mL), was added dropwise to a solution of ethylenediamine (0.25 mL, 3.70 mmol) in the same solvent. After 2 h (TLC: ethyl acetate/hexane, 50:50), the white precipitate was removed by filtration through a pad of Celite and the filtrate was concentrated to dryness. The resulting yellowish viscous oil was dissolved in the minimum amount of ethanol and water was added dropwise until no more white solid precipitated. The solid was recovered by filtration, washed twice with water and dried under vacuum, yielding $\mathbf{L^2}$ in an analytical pure form. Yield 0.45 g (74%). − ^{1}H NMR ($CDCl_3$): δ = 2.68 (2 H, t, CH_2), 3.30 (2 H, q, CH_2), 6.23 (1 H, s, br., NH), 6.92 (1 H, m, aromatic), 7.23−7.39 (12 H, m, aromatic), 7.59 (1 H, m, aromatic). − ^{31}P NMR ($CDCl_3$): δ = −9.3. − ^{31}P NMR (CD_3CN): δ = −8.6. − IR (KBr): $\tilde{\nu}$ = 3320 cm^{-1} (m, NH_2), 1630 cm^{-1} (vs, C=O). − $C_{21}H_{21}N_2OP{\cdot}H_2O$ (366.4): calcd. C 68.84, H 6.33, N 7.65; found C 69.61, H 6.08, N 8.17.

2-(Diphenylphosphanyl)-*N*-(2-hydroxyethyl)benzamide (L^3): *N*-[2-(Diphenylphosphanyl)benzoyloxy]succinimide (3.30 g, 8.20 mmol), dissolved in dichloromethane (20 mL), was added dropwise to a solution of ethanolamine (1.08 mL, 19.60 mmol) in the same solvent (45 mL). After 3 h (TLC: ethyl acetate/hexane, 50:50), the white solid, which precipitated, was eliminated by filtration through a pad of Celite and the filtrate was concentrated to dryness. The resulting yellowish viscous oil afforded a white solid after drying for several hours under vacuum. The compound was washed with water and recovered by filtration. After drying, $\mathbf{L^3}$ was obtained in an analytical pure form. Yield 2.50 g (87%). − ^{1}H NMR ($CDCl_3$): δ = 3.39 (2 H, q, CH_2), 3.59 (2 H, t, CH_2), 6.27 (1 H, s, br., NH), 6.94 (1 H, m, aromatic), 7.24−7.39 (12 H, m, aromatic), 7.59 (1 H, m, aromatic). − ^{31}P NMR ($CDCl_3$): δ = − 9.9. − ^{31}P NMR (CD_3CN): δ = − 8.4. − IR (KBr): $\tilde{\nu}$ = 3310 cm^{-1} (m, OH), 1630 cm^{-1} (vs, C=O). − $C_{21}H_{20}NO_2P$ (349.1): calcd. C 72.18, H 5.77, N 4.01; found C 71.74, H 6.56, N 4.25.

[{(1*R*,2*R*)-*N*-(2-Aminocyclohexyl)}-2-(diphenylphosphanyl)benzamide]trichlorooxorhenium(V), [Re(O)(κ^2-L^1)Cl_3]·HCl (4): $\mathbf{L^1}$ (0.068 g, 0.17 mmol), dissolved in MeOH (5 mL), was added dropwise to a solution of **1** (0.10 mg, 0.17 mmol) in MeOH (10 mL). The reaction turned brown immediately and within a few minutes turned green. After 3 h at room temperature, the solution was concentrated to dryness giving an highly viscous oil. After washing several times with dichloromethane, a light blue solid precipitated, which was vacuum-dried. Yield 0.066 g (52%). − ^{31}P NMR: [$(CD_3)_2SO$]: δ = −17.2, 32.9. − IR (KBr): $\tilde{\nu}$ = 1570 cm^{-1} (vs, C=O), 1000 cm^{-1} (vs, Re=O), 320 cm^{-1} (m, Re−Cl). − $C_{25}H_{28}Cl_4N_2O_2PRe$ (747.5): calcd. C 40.17, H 3.78, N 3.75; found C 40.18, H 3.68, N 3.81.

[*N*-(2-Aminoethyl)-2-(diphenylphosphanyl)benzamide]trichlorooxorhenium(V), [Re(O)(κ^2-L^2)Cl_3]·HCl (5): Compound **5** was prepared in a similar manner to **4**. $\mathbf{L^2}$ (0.20 g, 0.58 mmol) and **1** (0.34 g, 0.58 mmol) were allowed to react to form a light green solid, **5**. Yield 0.23 g (58%). Single crystals of poor quality for X-ray crystallographic analysis were obtained by recrystallization of **5** from boiling acetonitrile. − ^{1}H NMR (CD_3CN): δ = 2.98 (2 H, s, br., CH_2), 3.45 (2 H, s, br, CH_2), 7.16 (1 H, m, aromatic), 7.52−7.80 (12 H, m, aromatic), 8.68 (1 H, t, br., aromatic), 11.48 (1 H, s, br., NH). − ^{1}H NMR [$(CD_3)_2SO$]: δ = 2.82 (2 H, m, CH_2), 3.26 (2 H, m, CH_2), 7.09 (1 H, m, aromatic), 7.48−7.66 (8 H, m, aromatic), 7.84 (2 H, m, aromatic), 8.08 (2 H, s, br., aromatic), 8.54 (1 H, m, aromatic), 11.42 (1 H, s, br., NH). − ^{31}P NMR (CD_3CN): δ = −15.4. − ^{31}P NMR [$(CD_3)_2SO$]: δ = −18.1. − IR (KBr): $\tilde{\nu}$ = 1590 cm^{-1} (vs, C=O), 1000 cm^{-1} (vs, Re=O), 320 cm^{-1} (s, Re−Cl). − $C_{21}H_{22}Cl_4N_2O_2PRe$ (691.9): calcd. C 36.42, H 3.20, N 4.05; found C 36.02, H 2.60, N 3.74.

Trichloro[2-(diphenylphosphanyl)-*N*-(2-hydroxyethyl)benzamide]-oxorhenium(V), [Re(O)(κ^2-L^3)Cl_3] (6). − Method a: $\mathbf{L^3}$ (0.10 g, 0.29 mmol), dissolved in MeOH (5 mL), was added dropwise to a solution of **1** (0.17 g, 0.29 mmol) in MeOH (10 mL). The reaction turned dark green immediately, then violet-blue and finally bright green. A dark green solid precipitated which was then isolated by filtration, washed 3 times with MeOH and vacuum-dried. Complex **6** was obtained in an almost quantitative yield. − **Method b:** A suspension of complex **2** (0.092 g, 0.11 mmol) in dry dichloromethane (25 mL) was treated with $\mathbf{L^3}$ (0.040 g, 0.11 mmol) under an inert atmosphere. Within a few minutes a green reaction mixture was obtained. After 1 h, a dark green solid started to precipitate. The reaction was allowed to proceed for 18 h. The solid was then isolated by filtration and washed 3 times with dry dichloromethane. Single crystals, suitable for X-ray crystallographic analysis, were

X-ray Crystallographic Analysis: A colourless crystal of **L[1]** and a dark green crystal of **6** were fixed inside thin-walled glass capillaries. Data were collected at room temperature with an Enraf–Nonius CAD-4 diffractometer with graphite-monochromatized Mo-K_α radiation, using an ω-2θ scan mode. Unit cell dimensions were obtained by least-squares refinement of the setting angles of 25 reflections with 16.6° < 2θ < 24.0° for **L[1]**, and 16.2° <2θ< 29.7° for **6**. A summary of the crystallographic data is given in Table 1. Data were corrected[23] for Lorentz polarization effects, for linear decay (no decay was observed for **L[1]**, and a decay of 16.7% was observed for **6**) and for absorption by empirical corrections based on ψ scans. The structures were solved by Patterson methods[24] and subsequent difference Fourier techniques and refined by full-matrix least-squares procedures on F^2 using SHELXL93[25]. For **6**, an acetonitrile solvent molecule of crystallization was also located in the Fourier difference map. During the isotropic refinement of **6** the terminal C(3)–O(3) atoms showed rather large thermal parameters and were found to be disordered over two different positions with 0.52 and 0.48 occupancies. All the non-hydrogen atoms were refined with anisotropic thermal motion parameters, with isor restraints being applied to the disordered atoms. The contributions of the hydrogen atoms were included in calculated positions [except that of the disordered O(3)H atom]. The absolute configuration of both crystals studied were determined by refinement of the Flack parameters, and the refined models proved to be the correct enantiomorphs. A final Fourier difference synthesis was featureless for **L[1]**, and revealed residual electron densities of +1.11 and −1.27 e.Å^{-3} for **6** without any chemical meaning. Atomic scattering factors and anomalous dispersion terms were taken as in ref.[25] The ORTEP drawings were made with ORTEP II[26] and all calculations were performed with a Decα 3000 computer. A summary of the crystal data and of the refinement procedures is given in Table 1. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-137148 (**L[1]**) and -137149 (**6**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: int. code + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

$[Fe_3(hyetrz)_6(H_2O)_6](CF_3SO_3)_6$ [hyetrz = 4-(2′-hydroxyethyl)-1,2,4-triazole] represents the first structurally characterized iron(II) spin crossover compound for which the structure has been solved above and below room temperature in both spin states. The compound crystallizes in the trigonal system, space group $R\bar{3}$, a = 12.763(1) Å, β = 67.144(1)°, V = 1684.3(1) Å^3, Z = 6 at 120 K. At 330 K the space group is retained and a = 13.0183(3) Å, β = 67.376(3)°, V = 1805.8(1) Å^3. The molecular structure consists of trinuclear Fe^{II} entities linked together by an unprecedented three-dimensional network of hydrogen bonds. This compound shows a gradual spin crossover behavior centered around room temperature, which has been followed by temperature-dependent magnetic susceptibility measurements as well as by ^{57}Fe Mössbauer spectroscopy. The nature of the spin crossover behavior is discussed on the basis of the structural features.

Introduction

One of the appealing aspects of the phenomenon of spin crossover between high-spin (HS) and low-spin (LS) states resides in the occurrence of bistability, i.e. the possibility of observing two electronic states in a given range of external perturbation.[1−3] In this respect, Fe^{II} spin crossover compounds have been widely investigated.[4−7] For an assembly of spin crossover molecules governed by the thermodynamical regime, the perturbation may be caused by the temperature and then bistability leads to the occurrence of thermal hysteresis, which endows the system with a memory effect.[1] A challenging field of research concerns the design of new Fe^{II} polynuclear spin crossover materials exhibiting strong inter-site interactions. A strategy towards obtaining such compounds consists of linking the active sites by chemical bridges to give extended or polymeric structures.[8] Extensive research efforts have been directed towards Fe^{II} polymeric chain compounds containing 4-R-substituted derivatives of 1,2,4-triazole, because of the favorable characteristics of their spin crossover behavior.[8−17] Such behavior generally involves very abrupt transitions, as well as important thermal hysteresis effects accompanied by a pronounced thermochromic response, making them the compounds of choice for various applications in molecular electronics[3,8,9,18] or as temperature sensors.[8,14,17] So far, no crystal structure is available for these materials although several Cu^{II} structures have been solved.[19−21]

Oligomers are generally used as model systems for the polymers because they are better defined from a crystallographic point of view and the physical properties can be easily correlated to the structural data. This is also the case for the Fe^{II} linear trinuclear compounds containing 4-R-substituted 1,2,4-triazole as ligands. Several crystal structures of these model compounds have been solved[22−24] or have been studied by EXAFS spectroscopy.[25] It was with this goal in mind that we decided to investigate the structure and magnetic properties of the new trinuclear compound of formula $[Fe_3(hyetrz)_6(H_2O)_6](CF_3SO_3)_6$ with hyetrz = 4-(2′-hydroxyethyl)-1,2,4-triazole (see Scheme 1).

This ligand was selected in order to increase the dimensionality through hydrogen bonding interactions. The compound shows a spin crossover behavior centered around room temperature. Its crystal structure has been solved in its LS and HS states. In addition, the dynamic character of the spin crossover behavior has been evidenced by ^{57}Fe Mössbauer spectroscopy.

Results

Description of the Structure of $[Fe_3(hyetrz)_6(H_2O)_6](CF_3SO_3)_6$

An atomic displacement ellipsoid plot of the molecule is represented in Figure 1 and relevant information on bond lengths and bond angles is given in Table 1.

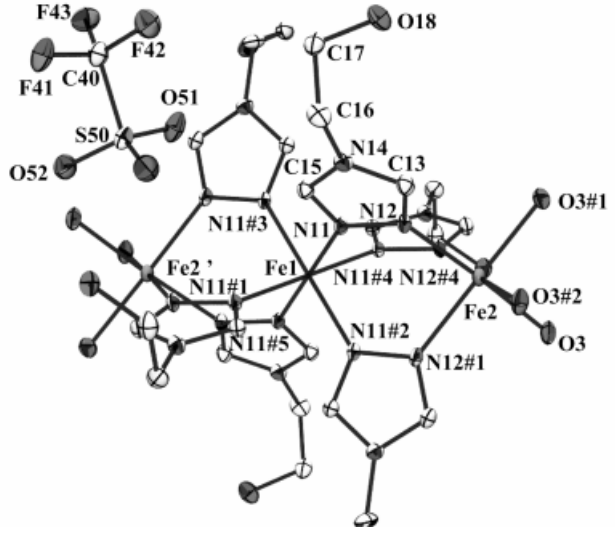

Figure 1. Atomic displacement ellipsoid view (50% probability) of the molecule of $[Fe_3(hyetrz)_6(H_2O)_6](CF_3SO_3)_6$ at 120 K. Hydrogen atoms have been omitted for clarity. Labeled atoms are generated by the following symmetry operations: #1 *z*, *x*, *y*; #2 *y*, *z*, *x*; #3 $-x$, $-y$, $-z$; #4 $-z$, $-x$, $-y$; #5 $-y$, $-z$, $-x$

Table 1. Selected bond lengths [Å] and angles [°] of $[Fe_3(hyetrz)_6(H_2O)_6](CF_3SO_3)_6$ at 120 K and 330 K. Estimated standard deviations are given in parentheses

[a] Labeled atoms are generated by the following symmetry operations: #1 *z*, *x*, *y*; #2 *y*, *z*, *x*; #4 $-z$, $-x$, $-y$.

The title compound crystallizes in the trigonal space group $R\bar{3}$. The asymmetric unit contains one trifluoromethanesulfonate anion, one hyetrz ligand, one water molecule, one iron(II) ion, which is labeled as Fe1 and located at the origin (occupancy factor of 1/6), and another iron(II) ion, Fe2, which lies at the special position $x = y = z$ (occupancy factor of 1/3). Thus, the crystalline unit contains one $[Fe_3(hyetrz)_6(H_2O)_6]^{6+}$ cation and six trifluoromethanesulfonate anions. The third iron(II) ion of the cation, labeled as Fe2′, is the homolog of the Fe2 ion by the center of inversion on which the Fe1 ion lies. Three of the hyetrz ligands, which are homologous to one other by the 3-fold symmetry, act as bidentate ligands linking Fe1 to Fe2 through the nitrogen atoms N11 and N12. The three other hyetrz ligands, which are homologous to the former by the center of inversion, link Fe1 to Fe2′. Finally, the water molecules, linked to Fe2 and Fe2′, complete the extremities of the trinuclear unit.

The Fe1 and Fe2 ions present octahedral surroundings. The environment of Fe1 is very regular as the six Fe1−N distances are all equal by symmetry. At 120 K, these bond lengths of 2.003(1) Å correspond to the expected values for an Fe^{II} ion in the LS state.[26] The adjacent N−Fe1−N bonds form an angle of 91.67(6)° when the nitrogen atoms are homologous by the 3-fold symmetry and an angle of 88.33(6)° when the nitrogen atoms are homologous by the center of symmetry. At 330 K, the Fe1−N distances are much longer [2.169(1) Å] and correspond to a HS state.[26] The N−Fe1−N angles are slightly different [89.2(2)° and 90.8(2)° respectively]. The environment of Fe2 is heterogeneous as this ion is bonded to three oxygen atoms and three nitrogen atoms, with only one atom of each species being crystallographically independent. The Fe2−N bond lengths are 2.161(2) Å at 120 K [2.176(5) Å at 330 K] and the Fe2−O bond lengths were found to be 2.124(2) Å at 120 K [2.113(6) Å at 330 K]. Thus, the Fe2 ions are in the HS state whatever the temperature and only the central iron(II) ion shows spin crossover behavior. The increase of the Fe1−N bond length from 120 K to 330 K is equal to 0.166 Å, which is larger than the relatively weak increase (0.143 Å) found for $[Fe_3(etrz)_6(H_2O)_6](CF_3SO_3)_6$.[22] At 330 K, peripheral iron(II) octahedra become more compressed and regular. One can see this effect in a more pronounced way from the side of the oxygen atoms. This is a consequence of the increasing volume of the central iron(II) ion on going from the LS to the HS state. The Fe−Fe intramolecular distance significantly increases with temperature (see Table 1).

The least square planes through the triazole ligands form angles of 60°. This characteristic has already been observed for instance in the linear trinuclear compounds with the related ligand 4-ethyl-1,2,4-triazole (etrz), $[M^{II}_3(etrz)_6(H_2O)_6](CF_3SO_3)_6$ [M = Fe (HS and LS),[22] Mn,[27] Zn[28]], where a $C3_2$ symmetry is present. The *N*1,*N*2−1,2,4-triazole bridging ligands are all identical by symmetry and link the Fe^{II} ions with Fe−N−N bond angles of 127.59(8)° and 122.66(8)° in the LS state and of 125.7(2)° and 122.8(2)° in the HS state. All 1,2,4-triazole rings are planar; the deviation from the least-squares plane through the ring atoms is smaller than 0.002(1) Å.

The crystal packing is built from the translation of the cation contained in the unit cell and thus, by symmetry, all

[a] At 330 K, the hydrogen atoms could not be localized. Labeled atoms are generated by the following symmetry operations: #3. −*x*, −, −*z*; #5: −*y*, −*z*, −*x*.

the cations are parallel to each other. They are aligned along the *a*, *b*, and *c* directions. This crystal packing is very different from the packing of [Fe_3(iptrz)$_6$(H_2O)$_6$](tosylate)$_6$ · 2 H_2O (iptrz = 4-isopropyl-1,2,4-triazole) where the adjacent entities are perpendicular to each other in one direction.[24]

The water molecules are all coordinated to an iron(II) ion, and no free water molecules have been found in the network. This characteristic has already been observed in the structures of the trinuclear compounds [Fe_3(etrz)$_6$(H_2O)$_6$](CF_3SO_3)$_6$ [22] and [Fe_3(iptrz)$_6$(H_2O)$_6$]I_6.[29] However, this lack of supplementary water molecules does not imply the absence of a hydrogen-bonding network. Figure 2 displays a view of the intermolecular interactions at 120 K and Table 2 gives the relative bond lengths and angles.

Hydrogen-bonding through the oxygen atoms of the sulfonate groups of the triflate anions (O3···O52 #3) links the coordinated water molecules. These anions are also linked by hydrogen-bonding to the hydroxy groups of the ethyl chain in the 4-position of the triazole ligands (O18···O51 #5). The trinuclear units are not isolated. Indeed, they are linked to each other by hydrogen-bonding interactions. These are situated between the water molecules and the hydroxy groups of the triazole ligands (O3···O18; −*y*, −*z*, −*x*). The related O···O distances do not vary with temperature (Table 2).

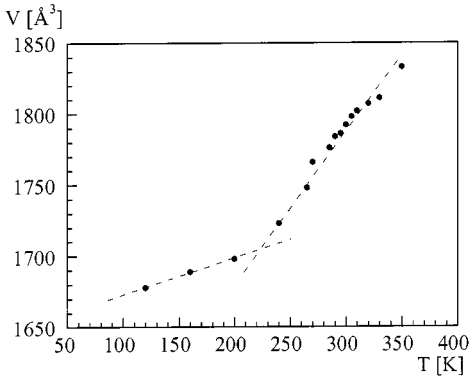

Figure 3. Temperature dependence of the cell volume of [Fe_3(hyetrz)$_6$(H_2O)$_6$](CF_3SO_3)$_6$

No intramolecular interaction between different hydroxy groups of the same trinuclear unit has been detected. This situation is in contrast to the structure of the Cu^{II} linear chain compound [Cu(hyetrz)$_3$](ClO_4)$_2$ · 3 H_2O, where hydrogen bonding between hydroxy groups arising from different *N*1,*N*2−1,2,4-triazole bridges were found.[20]

Temperature Dependence of the Cell Parameters

The symmetry of the cell is the same on both sides of the spin transition. The crystal system implies a strict isotropy of the thermal contraction. Figure 3 shows the temperature dependence of the cell volume from 120 K to 350 K. Within this range, the volume variation of 7.3% and the differential dV/VdT of 3.44 10^{-4} K^{-1} are comparable to the average value calculated for a series of mononuclear iron(II) spin crossover compounds (6.5% and ≈ 3.5 10^{-4} K^{-1}).[30] Two different domains can be defined in this curve: a first one from 350 K to 225 K where the volume contraction (5.6%, 5.6 10^{-4} K^{-1}) corresponds to the contributions of the spin transition and the thermal contraction, and a second one from 225 K to 120 K where the volume decrease is only due to the thermal contraction (1.7%, 1.6 10^{-4} K^{-1}). In the first domain, we can roughly estimate the volume variation due to the spin transition by subtracting the contribution due to the thermal variation with the hypothesis that the behavior is the same as in the second domain. Such a value, $\Delta V_{SC} \approx 90$ Å^3, is very similar to the volume contraction due to the spin crossover found in previously published mononuclear compounds, $\Delta V_{SC} \approx 80-90$ Å.[30,31]

Magnetic Properties

The magnetic behavior of [Fe_3(hyetrz)$_6$(H_2O)$_6$](CF_3SO_3)$_6$ is shown in Figure 4 in the form of a $\chi_M T$ vs. T plot, χ_M being the molar magnetic susceptibility and T being the temperature. At 77 K the $\chi_M T$ value is 7.40 cm^3 K mol^{-1}, which is about the value expected for two iron(II) ions in the HS state. The value of $\chi_M T$ remains constant upon heating up to 235 K, after which it increases progressively reaching a value of 10.92 cm^3 K mol^{-1} at 360 K, which corresponds to the expected value for three iron(II) ions in

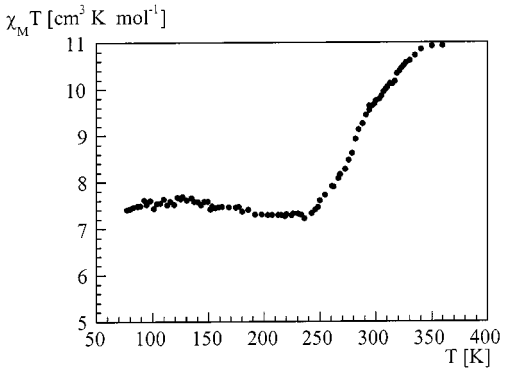

Figure 4. Evolution of $\chi_M T$ vs. T for $[Fe_3(hyetrz)_6(H_2O)_6](CF_3SO_3)_6$

the HS state. A similar magnetic behavior has been observed upon cooling for this gradual transition. The transition temperature $T_{1/2}$, for which 50% of the sites involved in the conversion are HS and 50% are LS, is equal to 290 K. The temperature range in which 80% of central iron(II) ions change spin state (ΔT_{80}) is 70 K. This value has to be compared with the 40 K found for $[Fe_3(etrz)_6(H_2O)_6](CF_3SO_3)_6$.[22]

The assumption of negligible magnetic exchange between second-neighbor iron(II) ions is justified in view of the study of the *N*1,*N*2−1,2,4-triazole triply-bridged $Fe^{II}-Fe^{II}-Fe^{II}$ [22] and $Co^{II}-Co^{III}-Co^{II}$ [32] trinuclear clusters, where the central metal ion is diamagnetic, and no magnetic interactions could be detected between the paramagnetic terminal metal ions.

Optical Measurements

Since this compound is highly thermochromic, the Fe^{II} spin transition has been studied optically using a specially designed device.[12,13] This technique provides an accurate determination of the transition temperature although it does not give any information regarding the percentage of Fe^{II} ions involved in the spin transition. A similar ST behavior as found by magnetic measurements has been observed, with $T_{1/2} = 292$ K.

Mössbauer Measurements

^{57}Fe Mössbauer spectra were recorded at several temperatures between 4.2 K and 293 K. Parameters derived from least-squares fitting are listed in Table 3.

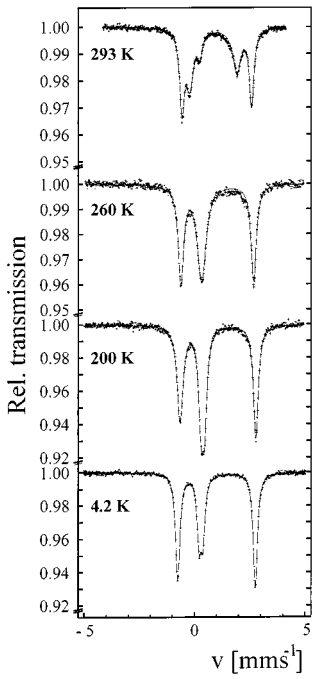

Figure 5. Selected ^{57}Fe Mössbauer spectra of $[Fe_3(hyetrz)_6(H_2O)_6](CF_3SO_3)_6$ recorded at different temperatures

As can be seen from Figure 5, the spectrum measured at 4.2 K shows the expected structure for a trinuclear iron(II) 1,2,4-triazole compound with two iron(II) ions in the HS state and one in the LS state with a relative intensity 1:2. The outer two lines refer to the quadrupole doublet arising from the two peripheral iron(II) ions in the HS state. The signal in the middle represents the poorly resolved quadrupole doublet of the central iron(II) ion in the LS state. The small splitting of the LS doublet indicates that the local environment of the central iron(II) ion is not symmetric, which is not seen in the crystal structure at 120 K. On heating the sample up to 200 K, the spectrum remains essentially the same, with the difference observed between the intensities of the LS and HS doublets being attributed to the known difference of the Debye−Waller factors for the two species. The Debye−Waller factor for the LS state is generally larger (by ca. 20%) than that for the HS state and shows a different temperature dependence for the two states. The consequence of this situation is that the area fractions of the Mössbauer resonance lines do not reflect exactly the actual concentrations of the two states; the LS

[a] The temperature of the ^{57}Co(Rh) source was 4.2 K.

state rather is overestimated due to the higher tightness of binding in the LS iron complex molecules as compared to the HS complex molecules. At 260 K, the HS doublet attributed to the external iron(II) ions remains the same but the HS doublet of the central iron(II) ion is not distinguishable while the spin crossover occurs at this temperature (cf. Figure 3 and Figure 4). An unusual broadening of the lines of the LS doublet is observed, which is most likely due to the dynamic nature of the spin crossover behavior. At room temperature the spectrum shows two additional lines attributed to the LS and HS species of the central iron(II) ion with an approximate intensity ratio of 1:1, indicating that the transition temperature $T_{1/2}$ is near to 290 K [the peak in the middle refers to the LS state of the central iron(II) ion, the two neighboring signals constitute the HS quadrupole doublet of the central iron(II) ion, and the outer two signals are the quadrupole doublet of the two peripheral iron(II) ions]. Because the relaxation phenomenon is still present at room temperature, the lines of the new HS species together with the remainder of the LS species are about twice as broad as the lines of the external Fe^{II} ions. In the present study, we have restricted ourselves to a qualitative approach to the relaxation phenomenon. For a quantitative analysis, the ^{57}Fe Mössbauer relaxation spectra in the spin crossover region should be fitted using the corresponding relaxation theory,[33] which is a very elaborate task and is beyond the scope of this study. At room temperature, one notices that the isomer shift and the quadrupole splitting of the central and the peripheral iron(II) ions in the HS state do not coincide (see Table 3). This is clear from the fact that the first coordination spheres are different, namely the presence of only nitrogen atoms for the central iron(II) ion and mixed nitrogen-oxygen surroundings for peripheral iron(II) ions. This, of course, gives rise to different electric field gradients and thus different electric quadrupole interactions for the two inequivalent iron sites.

The Mössbauer experiment at 4.2 K was also carried out in an external magnetic field of 5 T directed parallel to the γ-ray beam. The obtained spectrum (Figure 6) exhibits two groups of sextets with the following hyperfine parameters:

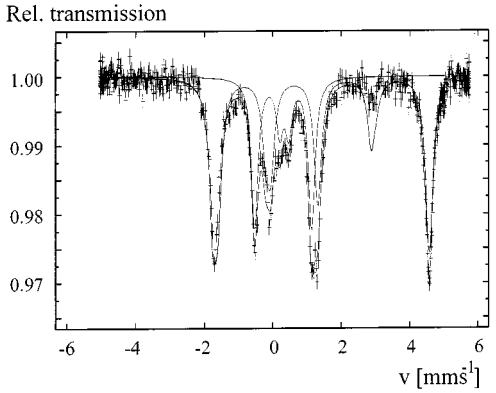

Figure 6. ^{57}Fe Mössbauer spectrum of [Fe_3(hyetrz)$_6$(H_2O)$_6$](CF_3SO_3)$_6$ recorded at 4.2 K in an external magnetic field of 5 T parallel to the direction of the γ rays

H_{LS} = 5.16 T, δ_{LS} = 0.307 mm s^{-1}, ΔEQ_{LS} = −0.03 ± 0.01 mm s^{-1}, φ_{LS} = 0°; H_{HS} = 13.1 T, δ_{HS} = 1.004 mm s^{-1}, ΔEQ_{HS} = −3.51 ± 0.01 mm s^{-1}, φ_{HS} = 87.3°. φ_{LS} and φ_{HS} characterize the polar angles between the principal axis V_{ZZ} of the electrical field gradient and the local magnetic field H at the iron nuclei of LS and HS states. Analyzing the values of the hyperfine parameters, one can conclude the following. Negative signs of the quadrupole splitting on both states indicate that the orbital singlet is the ground state. This means that the three octahedra are elongated along the trigonal axes of the trinuclear unit. This conclusion is in agreement with the structural data obtained at 120 K. In the LS state the iron nuclei only "see" the external magnetic field. Because of the spatial averaging for the powder sample the effective value of the polar angle φ_{LS} is zero. In the HS state, the external magnetic field induces slow spin-lattice relaxation and the effective field on the iron nuclei is a superposition of both external and internal fields. The internal magnetic field is nearly perpendicular to the direction of V_{ZZ} (φ_{HS} = 87.3°), which apparently coincides with the axial axis of the trinuclear unit. It is noteworthy that the deviation of the magnetic field axis from the nearly perpendicular V_{zz} axis almost coincides with the deviation of 3° found between the parts containing oxygen and nitrogen atoms of the peripheral irregular octahedra of the trinuclear unit.

Discussion and Conclusion

In this paper we have described the molecular structure as well as the magnetic properties of a new linear trinuclear iron(II) spin crossover compound. The spin transition regime is centered in the room temperature region. The crystal structure has been solved above and below the transition temperature. If we compare the hyetrz ligand with its homolog, the etrz ligand, the chain in the 4-position of the 1,2,4-triazole has been functionalized by the introduction of a hydroxy group. This substituent has been selected for its potential to be linked by hydrogen bonding interactions to other entities of the network. Therefore, we can expect an increase in the intermolecular interactions in comparison to the trinuclear compound formed with the etrz ligand, [Fe_3(etrz)$_6$(H_2O)$_6$](CF_3SO_3)$_6$.[22] This has been borne out experimentally, because a molecular assembly of linear trinuclear entities linked by an unprecedented three-dimensional network of hydrogen bonds has been discovered for the title compound. The hydroxy groups play the role of bridges between the trinuclear units by hydrogen bonding with the water molecules coordinated to metal ions. Besides, the triflate anions allow the strengthening of the interactions, by hydrogen bonding with the water molecules and the alcohol groups.

Regarding the magnetic properties, a weak cooperative spin crossover behavior was observed. This can be understood if one considers the isolated molecule where only the central metal ion undergoes the spin crossover. However, surprisingly, the ST curve of this material is less abrupt than

the one found for $[Fe_3(etrz)_6(H_2O)_6](CF_3SO_3)_6$, as given by the comparison of the ΔT_{80} values for these two compounds. This could indicate that the presence of intermolecular interactions by hydrogen bonding would not have a favorable effect on the cooperativity developed by such trinuclear systems. A loss of cooperativity in this way has already been observed for the linear trinuclear compounds $[Fe_3(iptrz)_6(H_2O)_6](CF_3SO_3)_6$ and $[Fe_3(iptrz)_6(H_2O)_6]$-(tosylate)$_6 \cdot 2\,H_2O$.[24] The tosylate derivative, which presents a less cooperative spin crossover behavior, shows a crystal structure in which the trinuclear units are linked to the anions and the noncoordinated water molecules by hydrogen bonding. This network, assumed to be more flexible than the one found for the triflate derivative (which does not include any lattice water molecules) was taken as being responsible for the less cooperative behavior of the observed transition. This hypothesis could also be valid for $[Fe_3(hyetrz)_6(H_2O)_6](CF_3SO_3)_6$. It is interesting to note that the transition temperature, which is 203 K for $[Fe_3(etrz)_6(H_2O)_6](CF_3SO_3)_6$, is now 290 K for the title compound. Thus, a pronounced shift of $T_{1/2}$ towards higher temperatures has been observed. This behavior can be directly attributed to the introduction of hydrogen bonds into the network, a property that apparently increases the ligand field strength at the central iron ion. This stabilization of the LS state by hydrogen bonding has already been reported for other ST compounds; for instance the case for the Fe^{II} linear chain compound [Fe(hyetrz)$_3$](3-nitrophenylsulfonate)$_2$.[14,17] The dehydrated material shows a spin crossover behavior at low temperature whereas the hydrated material is LS at room temperature. Thus, in this case, the inclusion of water molecules through hydrogen bonding stabilizes the LS state. Such an effect has also been observed in the mononuclear spin crossover complex [Fe(2-pic)$_3$]Cl$_2 \cdot$ Sol with 2-pic = 2-picolylamine, where the system with Sol = H_2O still exhibits thermal spin crossover although with a very large hysteresis, but the system with Sol = $2{\cdot}H_2O$ shows LS behavior up to room temperature.[34]

Pronounced relaxation effects have been evidenced by ^{57}Fe Mössbauer spectroscopy for $[Fe_3(hyetrz)_6(H_2O)_6](CF_3SO_3)_6$ by virtue of considerable resonance line broadening. Clear evidence of the dynamic nature of the spin crossover behavior was revealed from the very beginning of the spin transition (260 K). This is in contrast with $[Fe(2\text{-pic})_3](PF_6)_2$ ($T_{1/2}$ = 178.5 K) where relaxation effects were only found below 200 K, which is near to the completion of the spin transition.[33] In addition, intersystem crossing dynamics in the solid state for this mononuclear compound were found to be very similar to other Fe^{II} compounds in solution. In the case of trinuclear compounds, the analogy with liquids is much more reasonable because the spin crossover entities are more isolated from each other in comparison to mononuclear compounds. In this case we are dealing with a diluted system. For this reason one could consider trinuclear systems as good candidates for the study of the dynamics of the spin crossover interconversion in the solid state. To the best of our knowledge, the title compound is the first to exhibit such pronounced features of relaxation in the solid state.[33,35]–[39] This is probably related to its very high transition temperature,[37] or to the simultaneous onset of molecular motions and spin crossover behavior. In other words, these two latter processes may be interconnected. Having learned that Fe^{II} trinuclear compounds could exhibit relaxation effects, we cannot exclude that this could also be responsible for the broadening of the lines of the LS doublet at 242 K for $[Fe_3(iptrz)_6(H_2O)_6]$(tosylate)$_6$ with iptrz = 4-isopropyl-1,2,4-triazole.[24] This effect could also be present for other Fe^{II} spin crossover compounds like, for example, $[Fe\{HB(trz)_3\}_2]$ with HB(trz)$_3$ = hydrotris(1,2,4-triazolyl)borate.[40]

Mössbauer experiments performed in the presence of an external magnetic field could allow us to confirm the structural data. This technique could, in future, provide structural information for other Fe^{II} trinuclear compounds for which the crystal structure is not yet available.[23,24] We intend to revisit this aspect in a subsequent paper.

Experimental Section

Starting Materials: Commercially available solvents, monoformyl hydrazine, triethylorthoformate, 2-ethanolamine, and iron(II) triflate were used without further purification.

Synthesis of [Fe_3(hyetrz)$_6$(H_2O)$_6$](CF_3SO_3)$_6$: The ligand 4-(2′-hydroxyethyl)-1,2,4-triazole (hyetrz) was prepared as described previously.[20] A solution of hyetrz (1.06 mmol, 0.12 g) in water (10 mL) was added to a solution of $Fe(CF_3SO_3)_2 \cdot 6\,H_2O$ (0.54 mmol, 0.25 g) in water (20 mL). The volume of the solution was reduced to 15 mL. After two weeks, the mauve compound crystallized upon slow evaporation of the colorless solution at room temperature. The crystals were filtered off, washed with water and dried under ambient air. Yield: 17%. IR: $\tilde{\nu}_{am}(SO_3^-) = 1279\ cm^{-1}$.

Physical Measurements: Magnetic susceptibilities were measured in the temperature range 77−400 K with a fully automated Manics DSM-8 susceptometer equipped with an Oxford instruments DN170 continuous-flow cryostat and a Bruker BE15f electromagnet operating at ca. 0.8 Tesla. Data were corrected for magnetization of the sample holder and for diamagnetic contributions, which were estimated from the Pascal constants. − Optical measurements were carried out using the device described previously[12,13] with a heating rate of 1 K min^{-1} in the temperature range 77−400 K. Mössbauer spectra were recorded in transmission geometry with a Co/Rh source kept at liquid helium temperature and a conventional spectrometer operating in the constant-acceleration mode. The samples were sealed in a Plexiglass sample holder and mounted in a helium-bath cryostat. The cryostat was equipped with a superconductor solenoid operating with a field of 5T. The spectra were fitted to Lorentzian-shaped lines using a nonlinear iterative minimization routine (MOSFUN).

Crystallographic Data Collection and Structure Determination: Experimental and crystal data are reported in Table 4. The single crystals appear pink at 293 K and purple at 120 K. This color is due to the $^1A_{1g} \rightarrow {}^1T_{1g}$ d-d transition of LS Fe^{II} occurring at 520 nm. The color of the compound changes to colorless upon heating to ca. 330 K. This is due to the fact that the spin-allowed d-d transition of lowest energy of the compound in the HS state, $^5T_{2g} \rightarrow {}^5E_g$, occurs at the limit of the visible and IR regions. The structural properties have been investigated from 120 K to 330 K with a Bruker Smart diffractometer associated with an Oxford Cryo-System nitrogen open cryostat. A first sample was cooled to 120 K at a rate of 2 K min^{-1}. 3024 frames were collected using ω scans in 0.2° steps with a 10 s time exposure per frame. Complete data collection was also performed at 293 K and at 310 K but no coherent data could be obtained and the structure could not be solved. A second crystal was used to collect the data at 330 K where the spin crossover is almost complete. Unfortunately, the single crystals melt at this temperature after around four hours, which did not allow us to finish the data collection. The same strategy of data collection as at 120 K was used but only the first 770 frames could be used, which nevertheless gave enough unique observed reflections (1976 observed reflections for 165 refined parameters). Finally, a third crystal was used to determine the cell parameter evolution from 120 K to 330 K. The computing data reduction was performed using the SAINT package including absorption correction using the SADABS program.[41] Such a correction slightly improved the internal R factor (decrease of 1.5%). The crystal structures were solved and refined with SHELXTL.[42] The full-matrix least square refinement of the atomic parameters was based on F^2. All the non-hydrogen atoms were refined with anisotropic thermal parameters. The crystal structure at 330 K is clearly not very accurate, mainly due to the very large thermal motion. Hydrogen atoms were placed using difference Fourier maps at 120 K and their atomic positions were refined, while it was not possible to locate them at 330 K.

Crystallographic data have been deposited at the Cambridge Crystallographic Data Centre as supplementary publication no CCDC-134366 for the structure at 330 K and CCDC-134367 for the structure at 120 K. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB21EZ, UK [Fax: (+44) 1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Pseudotetrahedral Organocobalt(III) Compounds Containing Specific Coordination Sites for Brønsted Acids

Mario Roberto Meneghetti,[c] Mary Grellier,[a] Michel Pfeffer,*[a] André De Cian,[b] and Jean Fischer[b]

Keywords: Cobalt / Acids / Hydrogen bonds / Organometallic receptors / N ligands

Transmetallation of the lithiated derivative 2,6-bis[dimethyl(amino)methyl]phenyllithium with the cobalt(III) centre of the dimer bis[(η^5-cyclopentadienyl)cobalt(iodo)(μ-iodo)] has been found to afford the organocobalt compound [CoI{2-(Me_2NCH_2)-6-($Me_2NH^+CH_2$)C_6H_3}(η^5-C_5H_5)]I, **3**, in which the potentially terdentate (pincer) ligand is bound to Co through the formerly lithiated aryl carbon atom and one NMe_2 unit only, whilst the second NMe_2 group is protonated by HI. In the presence of aqueous KPF_6, **3** has been found to undergo both substitution of the iodide bound to Co by a water molecule and deprotonation of the Me_2NH group to afford [CoI{2,6-(Me_2NCH_2)$_2$$C_6H_3$}(η^5-$C_5H_5$)($H_2O$)]$PF_6$, **4a**. It was found that the water ligand in **4a** could be substituted by neutral ligands such as PMe_2Ph as well as by Brønsted acids such as HCl, HI, HF, or HOAc to afford the compounds [CoX{2-(Me_2NCH_2)-6-($Me_2NH^+CH_2$)C_6H_3}(η^5-C_5H_5)]PF_6, **5a**–**d**, where X = Cl, I, F, or OAc, respectively. Crystal structure analyses of some representative examples of these compounds, including **4a**, have shown unambiguously that an intramolecular hydrogen bond is present between X and the proton of the Me_2NH^+ unit. ^{1}H-NMR evidence that this interaction persists in solution has been found for compounds **4a**, **5a**, **5c**, and **5d**.

Introduction

We have recently shown that organometallic compounds of Co^{III} containing a metallacyclic unit may readily be synthesized by transmetallation reactions of lithiated tertiary amines.[1] Such reactions have afforded a wide variety of stable pseudotetrahedral organocobalt compounds in which the cobalt is a stereogenic centre. While investigating the scope of this procedure, we became interested in ascertaining whether other lithiated polydentate amino derivatives could be used to extend the synthetic potential to other organocobalt compounds with a view to varying the nature of the resulting compounds. Thus, we first attempted to synthesize derivatives using the well-known "pincer" ligand [2,6-(Me_2NCH_2)$_2$$C_6H_3$]$^-$ = N^C^N, the chemistry of which with transition metals has been extensively studied by van Koten et al.[2]

This ligand usually bonds to a metal centre through an aryl−M σ bond, but it is also capable of donating a further two electron pairs to the metal through N coordination. The potentially terdentate "pincer" ligand has been shown to be extremely flexible in its coordination and bonding modes (see Figure 1). Its use has led to the isolation and characterization of bis(amino)aryl metal complexes of both main group and transition metals, which exhibit novel reactivities and structural features.[3] Consequently, although it was reasonable to assume that the lithiated derivative of the "pincer" ligand would interact with a Co^{III} centre, we could not predict a priori the type of structure that would be formed.

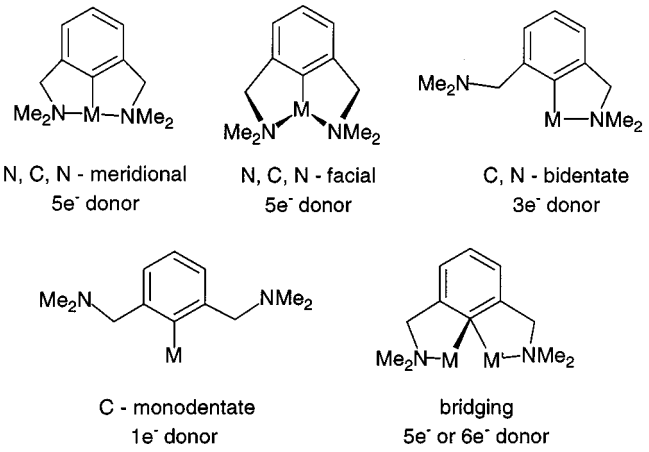

Figure 1. Encountered bonding modes of the pincer ligand

Prior to our work, we were aware of only one cobalt(II) complex, namely Co[2,6-(Me_2NCH_2)$_2$$C_6H_3$]X(L) (X = Cl, Br, I; L = py, PPh_3),[4] in which this "pincer" ligand is coordinated to Co through one aryl carbon and the two nitrogen atoms in a meridional geometry (see Figure 2). Its structure was deduced on the basis of ESR studies and it

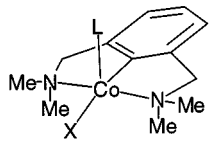

Figure 2. Proposed structure of $Co^{II}[C_6H_3(CH_2NMe_2)_2$-2,6]XL

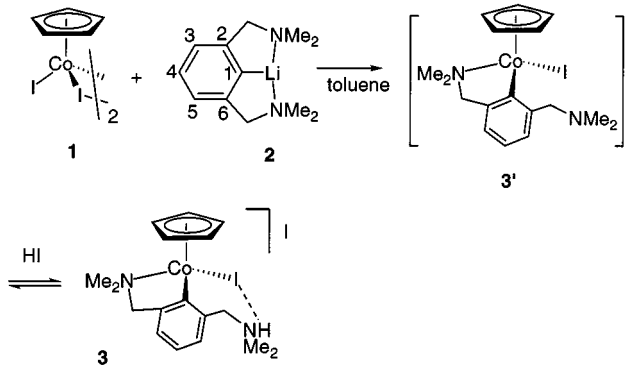


proved to be isostructural with the related Ni^{III} compound $Ni[C_6H_3(CH_2NMe_2)_2$-2,6]Br_2.[5]

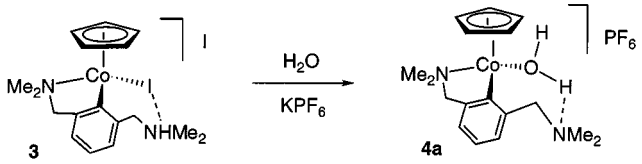
We describe herein the synthesis of a number of novel aryl Co^{III} complexes in which the "pincer" ligand is coordinated to the cobalt centre through the carbon and one nitrogen atom while significant intramolecular H-bonding interactions are in evidence between the third anionic ligand and the protonated non-coordinated NMe_2 unit.

Results

1. Synthesis of the Organometallic Complexes

We have recently shown that *ortho*-lithiated N-containing ligands (LiC^N) can be readily transmetallated with $[CpCoI_2]_2$, thereby generating a series of stable organocobalt complexes of the type CpCo(C^N)I. However, we found that when any lithiated aryl compound substituted at its 2-position by CH_2NMe_2 and at its 6-position by another substituent (Me, OMe, or F) was used, the expected product was not obtained.[1] Nevertheless, in marked contrast, reaction of the lithiated "pincer" ligand **2** with $[CpCoI_2]_2$ (**1**) in toluene at room temperature afforded the organocobalt compound **3** as a green powder in good yield (see Scheme 1).

Scheme 1



Complex **3** was found to be very soluble in acetone, THF, and chlorinated solvents, quite soluble in C_6H_6, sparingly soluble in Et_2O and MeOH, and insoluble in alkanes. Analytical samples of this complex were obtained by slow diffusion of *n*-hexane into a CH_2Cl_2 solution. It proved to be stable towards air, both in the solid-state and in solution (2 days in $CDCl_3$).

Compound **3** has been fully characterized by ^{1}H- and ^{13}C-NMR spectrometry, IR spectroscopy, and X-ray analysis (see below). The ^{1}H- and ^{13}C-NMR spectra in $CDCl_3$ feature resonances consistent with a diamagnetic Co^{III} complex associated with the relevant organic fragments. From the ^{1}H-NMR spectrum of **3**, it can be concluded that only one of the NMe_2 units is diastereotopic, giving rise to two signals at $\delta = 3.16$ and 2.31. A broad singlet at $\delta = 2.93$ can be assigned to the second NMe_2 unit. This latter chemical shift is at rather low field compared to the signals of non-coordinated NMe_2 groups in related molecules, which usually appear at around $\delta = 2.1-2.3$.[6,7]

Since both combustion analyses and ^{1}H-NMR spectra suggested that **3** was actually a 1:1 adduct of $[CoI\{C_6H_3(CH_2NMe_2)(CH_2NMe_2)$-2,6$\}(\eta^5$-$C_5H_5)]$, **3′**, and HI, we propose that some hydroiodic acid was produced during the synthesis of **3′**, which then protonated the non-coordinated NMe_2 group. Addition of an excess of HI to a $CDCl_3$ solution of **3** in an NMR tube led to splitting of the aforementioned broad signal resulting in two doublets at $\delta = 3.02$ and 2.82 with $^3J_{H-H} = 5.64$ Hz, as well as to the appearance of a well-defined broad singlet at $\delta = 10.0$. These signals can be assigned to the methyl groups and the acidic proton, respectively, of the protonated Me_2NH^+ group. Thus, it would seem that in solution **3** is in equilibrium with **3′** and HI according to Scheme 1; in the presence of excess of HI, this equilibrium is shifted completely towards **3**. The same phenomenon was evident from the ^{13}C-NMR spectra. On treatment of **3** with HI, a broad signal at $\delta = 42.03$ was transformed into two signals at $\delta = 44.17$ and 40.69, corresponding to the two diastereotopic methyl groups of the Me_2NH^+ unit.

2. Reaction of 3 with Water (Synthesis of 4a)

By washing a solution of **3** in CH_2Cl_2 several times with water and combining the aqueous extracts, a new complex, **4a**, was obtained (Scheme 2). This could be isolated as a red powder following the addition of KPF_6.

Scheme 2

IR spectroscopy confirmed the presence of a water molecule in the complex through the appearance of an intense, sharp absorption at 3575 cm^{-1}. Combustion analysis clearly revealed that one water molecule was present and, significantly, that hydroiodic acid was no longer incorporated. By NMR spectrometry, two distinct diastereotopic NMe_2 groups were observed in $CDCl_3$ solution. It is remarkable that the NMe_2 group coordinated to the cobalt centre displays chemical shifts separated by more than 2.0 ppm, whereas for the second NMe_2 group the chemical shift difference is just 0.65 ppm.

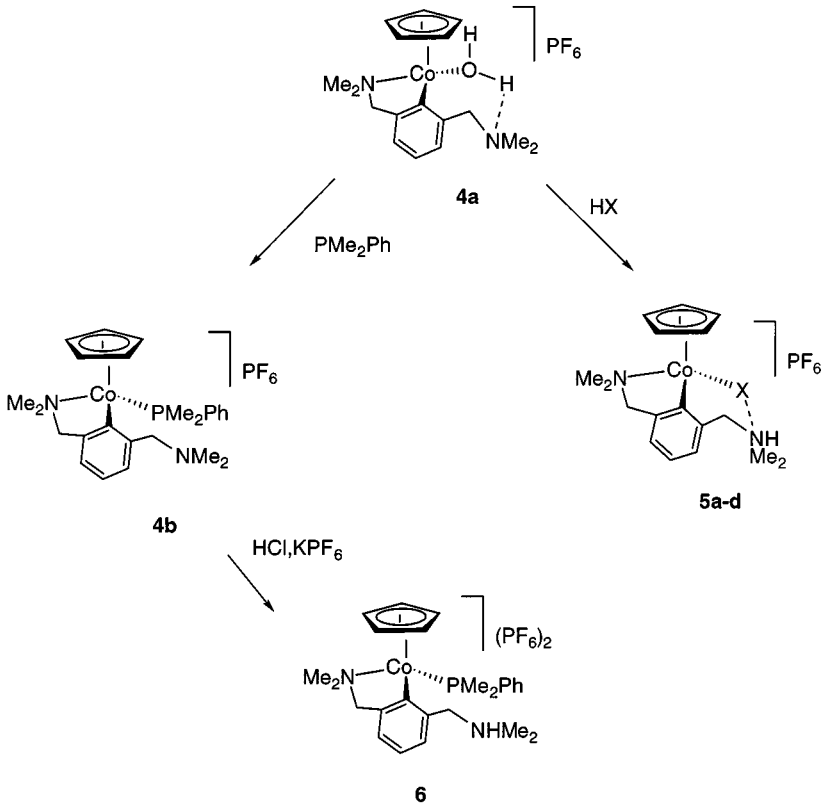
3. Reactions of 4a with Phosphanes and Brønsted Acids

3.1 Reaction with PMe_2Ph

It was found that the water ligand in **4a** could be substituted by a phosphane (PMe_2Ph) to quantitatively afford **4b** as a violet powder. The ^{1}H-NMR spectrum of **4b** features

the expected signals with two singlets due to a coordinated NMe_2 unit at $\delta = 2.89$ and 2.23 and a singlet at $\delta = 2.34$ due to the "free" amine. Additionally, two discrete AB spin systems for the CH_2 groups are observed. In the presence of traces of hydrochloric acid, the "free" NMe_2 unit of **4b** is protonated to give **6**, which could be isolated as a red powder. In its ^{1}H-NMR spectrum, **6** exhibits a signal at $\delta = 9.25$ attributable to the H^+ of the Me_2NH^+ group, and a broad unresolved peak due to the methyl groups of the Me_2NH^+ unit, which appears further downfield ($\delta = 3.37$) compared to the corresponding signal of the unprotonated amine. Moreover, in the IR spectrum a typical absorption band for an $N-H^+$ unit is observed at 2704 cm^{-1}.

3.2 Reactions with Brønsted Acids



3.2.1 Reaction with HCl (Synthesis of 5a)

In order to find out why the aquo complex **4a** was obtained, we tried to expand this series of compounds by employing related ligands. We found that neither primary or secondary amines nor alcohols led to adducts analogous to **4a**, i.e. no products of substitution of the water molecule by these OH- or NH-containing ligands were obtained. However, we have found that a series of Brønsted acids are capable of substituting the water ligand in **4a** to afford stable organocobalt compounds, and that such reactions occur without any hydrolysis of the Co−C bond of the complex (see Scheme 3). Thus, treatment of **4a** with HCl afforded **5a** as a red-violet powder. This substitution was best achieved using ammonium chloride as a source of HCl with **4a** in methanol.

The ^{1}H-NMR spectrum of **5a** is similar to that of **4a** in that the large chemical shift difference ($\Delta\delta \approx 2.0$ ppm) for the NMe_2 unit coordinated to the cobalt is again apparent and the protonated NMe_2 group is also diastereotopic ($\Delta\delta \approx 0.5$ ppm). Furthermore, the effect of "HCl coordination" versus "H_2O coordination" on the cobalt centre can easily be detected. In **5a**, both the CH_2 and NMe_2 protons of the non-coordinating CH_2NMe_2 unit are very much deshielded as compared to those of the corresponding unit in **4a** (see Experimental Section). The coordinated hydrochloric acid gives rise to a broad signal at $\delta = 9.48$. In the IR spectrum a typical absorption for the M_2N-H^+ group is seen at 2692 cm^{-1}.

3.2.2 Reaction with HI (Synthesis of 5b)

The reaction of **4a** with HI (derived from NH_4I) furnished **5b** as a green powder of a similar hue as **3**. The IR spectrum of **5b** confirmed the presence of an Me_2NH^+ group through the appearance of an absorption band at 2697 cm^{-1}. The ^{1}H-NMR spectrum of **5b** provides strong evidence that this compound has a different magnetic environment compared to **4a** and **5a**, with the $\Delta\delta$ of the diastereotopic Me groups of the NMe_2-Co unit being comparable to that in **3** (0.6 ppm). The acidic proton of the Me_2NH^+ group could be observed as a broad feature at $\delta = 9.33$, but the J_{H-H} between H^+ and NMe_2 in this group was not detectable. It seems likely that the structure of **5b** is similar to that observed in **3**, i.e. with the same ligands about the cobalt centre, and most likely the same electronic interac-

Scheme 3

tion between the iodo ligand and the Me_2NH^+ unit (see below).

3.2.3 Reaction with HF (Synthesis of 5c)

Compound **5c** could easily be obtained in good yield by treatment of **4a** with 40% aq. HF. The IR spectrum of **5c** features a large, prominent absorption band at 2260 cm^{-1} due to the stretching vibration of an $N-H^+$ bond. In order to unambiguously confirm that this band was indeed due to a stretching mode of an $N-H^+$ unit, a H/D exchange experiment using D_2O was carried out. Under these conditions, a new absorption at 1800 cm^{-1} was observed, while the absorption at 2260 cm^{-1} disappeared, thus confirming our assignment. This significant shift to lower frequency for the ν_{sN-H} band of a tertiary ammonium salt[8] may be explained in terms of a hydrogen-bonding interaction between NH^+ and F, which would increase the $N-H^+$ bond length and consequently decrease the associated stretching frequency. Moreover, the ν_{sN-H}/ν_{sN-D} ratio (1.25) gives an additional indication of the existence of a strong hydrogen bond between N−H and F in **5c**.[9]

The ^{1}H-NMR spectrum of **5c** displays the same trends as observed for the previous complexes. This feature suggests that the structures are closely related, i.e. the water ligand in **4a** is merely replaced by HCl and HF to form **5a** and **5c**, respectively. The large Δδ chemical shift difference (2.43 ppm) for the NMe_2-Co unit is strongly indicative of interactions akin to those found in **4a** and **5a**. Some interesting features of the ^{1}H-NMR spectrum of **5c** arise from the presence of the F atom: (i) the signal of the NH^+ proton is located at δ = 11 and shows a sizable J_{H-F} coupling constant (89 Hz);[10] (ii) the highfield resonating methyl group of the NMe_2 unit directly coordinated to the cobalt centre displays a $^4J_{H-F}$ coupling (6.90 Hz); (iii) the two methyl groups of the non-coordinated NMe_2 unit display a $^4J_{H-F}$ coupling (≈ 4.1 Hz), proving the existence of bonding interactions between N−H and F−Co.

3.2.4 Reaction with CH_3COOH (Synthesis of 5d)

Treatment of **4a** with an excess of CH_3COOH in methanol led to the formation of **5d** in very good yield. The IR spectrum of **5d** features a series of overtones consistent with the presence of an Me_2NH^+ group (2700−2400 cm^{-1}) and a typical C=O absorption band at 1634 cm^{-1}. The ^{1}H-NMR spectrum of **5d** also shows a large Δδ chemical shift difference (2.24 ppm) for the NMe_2 unit coordinated to Co, as observed for **4a**, **5a**, and **5c**.

4. X-ray Crystal Structure Analysis of 3, 4a, 5a, and 5d

In order to obtain more structural information on this series of novel complexes, X-ray diffraction studies on some representative compounds have been undertaken. In Table 1, selected geometrical parameters for the complexes **3**, **4a**, **5a**, and **5d** are presented. ORTEP representations of the cationic parts of these salts are depicted in Figures 3−6, while crystallographic data is collected in Table 2. Despite the rather different ^{1}H-NMR data observed for these compounds, their molecular geometries display several analo-

gies, at least as far as the "CpCo(pincer)" fragments of the molecules are concerned.

In all cases, the cobalt atoms are found in a distorted octahedral (pseudotetrahedral) environment. The metal coordination sphere comprises a η^5-C_5H_5 ligand and the "pincer" coordinated through the central aryl carbon atom and the nitrogen atom of one NMe_2 unit only. The final coordination site at Co is occupied by an iodide, a water molecule, a chloride, or an acetate group coordinated through an oxygen atom, respectively (throughout this section these ligands will be denoted as "X").

The bite angles of the five-membered chelated rings, N1−Co−C14, and the distances Co−centroid Cp, Co−C14, and Co−N1 are similar in all the complexes. The chelate ring (note that comparable distances and angles have recently been reported for related organocobalt species)[1,11] appears to display a somewhat unfavourable orientation of the N1−C6 bond with respect to the Co−X bonds, which are more or less eclipsed; the torsion angle C6−N1−Co−X is in the range 12.6° to 19.3°. This geometry leads to a puckering of the five-membered chelate ring, which may minimize the steric interactions of the CH_2NMe_2 unit, the N of which does not interact with the Co or the Cp ring (see Figures 3, 5, and 6). However, this NMe_2 unit is positioned in such a way that it resides at a suitable distance from the X groups.

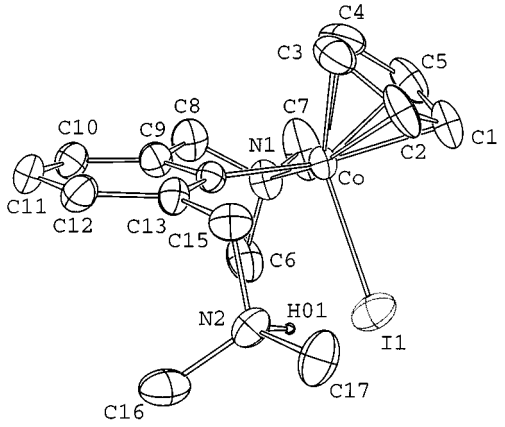

Figure 3. ORTEP view of the cation of **3** [CoI{C_6H_3(CH_2NMe_2)-($CH_2NMe_2H^+$)-2,6}(η^5-C_5H_5)]I

In complexes **3** (Figure 3), **5a**, and **5d**, these nitrogen atoms are protonated and the N−H bond of the $NHMe_2^+$ unit points towards the group X. On the other hand, in compound **4a** the lone pair on the NMe_2 group is oriented towards one O−H vector of the water coordinated to Co. These interactions lead to rather short N···X distances in all four cases. In **3**, however, the N2···I1 distance amounts to 3.43 Å, which is 0.2 Å shorter than the sum of the relevant van der Waals radii and corresponds to the upper range for hydrogen bonds between I and NH^+.[12]

In **4a**, the N2···O distance measures 2.59 Å, which is indicative of significant hydrogen-bonding between the water

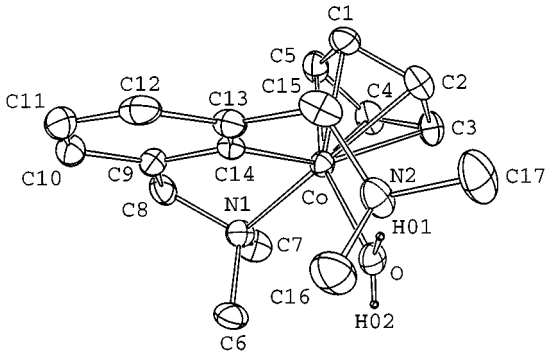

Figure 4. ORTEP view of the cationic part of **4a** [Co{C_6H_3-(CH_2NMe_2)(CH_2NMe_2)-2,6}(η^5-C_5H_5)(H_2O)]PF_6

coordinated to Co and the nitrogen lone pair (Figure 4). This N2···O distance falls at the short end of the range of distances reported for similar types of hydrogen bonds; the O···N distances in O−H···N systems are more typically in the range 2.68−2.79 Å.[13]

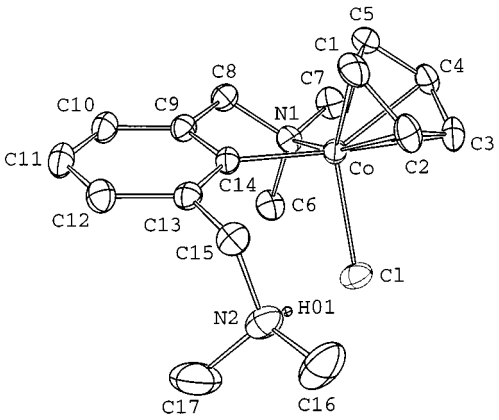

Figure 5. ORTEP view of the cationic part of **5a** [CoCl{C_6H_3-(CH_2NMe_2)($CH_2NMe_2H^+$)-2,6}(η^5-C_5H_5)]PF_6

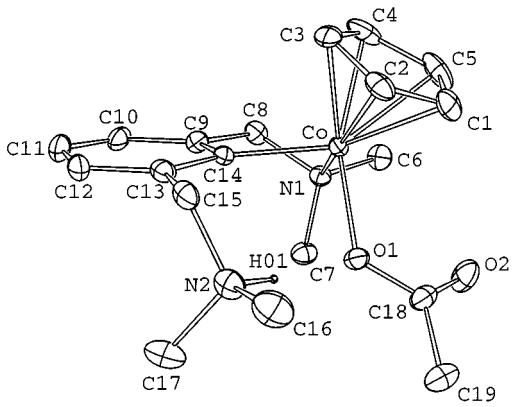
In the crystal structure of compound **5a** (Figure 5), the N···Cl distance [3.02(8) Å] is also shorter than is typically found for related intermolecular interactions.[12] It is noteworthy that in this case the proton attached to the nitrogen atom could be located [(N2−H = 1.08(7) Å; N−H···Cl = 158.1(4)°].

Related intramolecular N−H···Cl interactions have recently been described for ruthenium compounds built-up from simple tridentate ligands bearing two distal pyridine bases uncoordinated to the Ru; such compounds, in which the pyridine ligands are protonated, display intramolecular N···Cl distances analogous to that reported here.[14]

Finally, the O···N distance in **5d** (Figure 6) amounts to 2.72 Å, at the short end of the range for N−H···O systems (2.81−3.04 Å).[12] Here, too, the hydrogen atom was successfully located (N2−H = 0.92 Å). These structural data are indicative of a significant hydrogen bond in this molecule as well, as the N2−H···O angle is very close to 180° [173.0(3)°].[12] Note that in this latter complex the N···O distance is significantly longer than in **4a** (see above), which



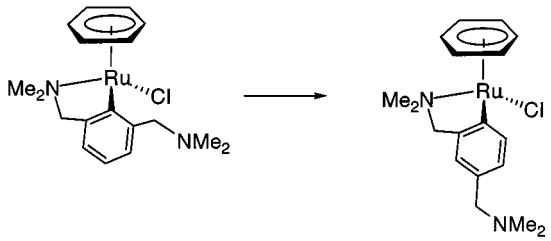


Figure 6. ORTEP view of the cationic part of **5d** [Co(CH_3COO)-{$C_6H_3(CH_2NMe_2)(CH_2NMe_2H^+)$-2,6}($\eta^5$-$C_5H_5$)]$PF_6$

Scheme 4

rules out the possibility of considering the aquo complex as an association between OH^- and an NH^+ unit.

It thus appears that the CH_2NMe_2 unit is remarkably flexible in adapting its orientation to the nature of the ligand attached to Co, although in all cases the nitrogen atom points towards the ligand X.

This latter behaviour is in marked contrast to that exhibited by some recently reported organoruthenium compounds incorporating the same pincer ligand. Indeed, Steenwinkel et al.[15] have shown that the pincer ligand in two such Ru^{II} compounds also interacts with Ru through the central carbon atom and just one nitrogen atom of an NMe_2 unit. However, in these compounds, in contrast to what we have seen in our cobalt complexes, the lone pair of the non-coordinated NMe_2 unit appears to be oriented away from the metal *and* from a chloride/phosphane ligand, respectively. In fact, these complexes proved to be unstable and isomerized to two compounds (see Scheme 4) in which the ruthenium atoms had migrated from the central carbon to carbons *ortho* and *para* to the two CH_2NMe_2 groups through a sequence of intramolecular C−H activation reactions. The driving force for this rearrangement most probably stems from the increased steric bulk of the non-coordinated CH_2NMe_2 moiety, which must interact with the arene ligand.

The stabilities of our complexes may thus be interpreted in terms of some extra stabilization of the organocobalt molecule owing to the presence of a hydrogen bond, a feature that is not possible in their ruthenium analogues. We have checked that treatment of the corresponding ruthenium complex by an acid such as HCl does not lead to any such intramolecular hydrogen bond; instead, we only observed extensive decomposition of the organoruthenium complex. We may thus view the cobalt complexes as dimetallacyclic species, in which five-membered and pseudo seven-membered chelated rings are present about the cobalt atom.

5. Behaviour of the Co-Pincer Compounds in Solution

A common feature of the structures of the four compounds is an intramolecular interaction between an NH^+ unit and X in **3**, **5a**, and **5d**, and between N and H−O in **4a**. In addition to these close contacts, puckering of the five-membered chelate rings of all complexes appears to result in an unfavourable orientation with respect to the Co−X vectors of the molecules. This latter phenomenon has also been observed in the related ruthenium compounds.[15] A reasonable explanation for this is that this ring puckering minimizes the steric interaction between the non-coordinated NMe_2 unit and the arene moiety of the Ru derivatives. A driving force behind adoption of the same conformation of the related organocobalt metallacycles in our compounds might also be a minimization of the steric interaction between the Cp ring and the NMe_2 group. However, it is evident from the chemical shifts of the NMe_2 unit of the five-membered chelate that we can unequivocally identify two different types of compounds.

The Δδ of the diastereotopic NMe_2 group coordinated to Co is very much dependent on the conformation of the five-membered chelate ring. We have seen previously in related metallacyclic compounds that when the conformation of this chelate ring is such that one N−Me bond and a Co−X bond are eclipsed (X = PR_3, for instance), then the Δδ of the two NMe_2 groups is usually greater than 1.6 ppm. Thus, in the ^{1}H-NMR spectrum of compound **3**, in which the hydrogen bond between $N-H^+$ and I is likely to be the weakest of the series studied, this Δδ is 0.85 ppm. A value of the same order of magnitude is observed for **4b**, **5b**, and **6**, for which no such hydrogen bond can be invoked. It is interesting to note that the Ru analogues of our compounds,[15] in which no hydrogen bonds are present, display analogous Δδ values (0.1−0.5 ppm). On the other hand, for the other compounds, Δδ is equal to or larger than 2.0 ppm, which can be taken as strong evidence that the conformation of the five-membered chelate is maintained in solution. Since this conformation is thermodynamically not the most stable, one may infer from these results that the strength of the intramolecular hydrogen bond[10] is sufficient to prevent a conformational change of the organocobalt chelate ring, which would lead to staggered N−Me and Co−X bonds in solution (see Figure 7).

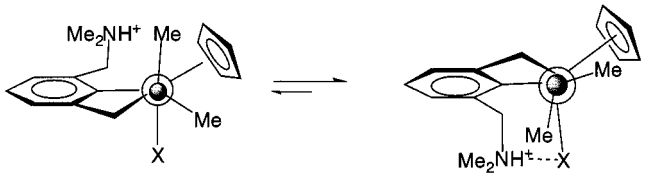

Figure 7. Newman projection along the N−Co vector of the complexes **5** showing the relationship between the intramolecular NHX interaction and the degree of ring puckering

Conclusion

We have synthesized an organometallic compound possessing a coordination site at which Brønsted acids can be accommodated. This behaviour is seemingly specific to Co^{III} since analogous ruthenium(II) compounds, despite their close structural analogies, are not capable of similar interactions with acids. It would also seem to be a specific feature of the metallated ligand since our previous closely related organocobalt complexes consisting of N^C chelates do not display such behaviour. Further work is currently in progress with the aim of defining the scope of this behaviour with different acid derivatives and extending the range of pseudo terdentate ligands that may exhibit analogous behaviour.

Experimental Section

General: All reactions were performed in Schlenk flasks under oxygen-free, dry nitrogen. Solvents were dried and distilled under nitrogen, toluene from sodium and CH_2Cl_2 from P_2O_5. − IR spectra were recorded from samples in KBr on a Bruker IFS-66 spectrometer. − Elemental analyses were performed by the Service Central d'Analyse de l'Université Louis Pasteur (Strasbourg). − ^{1}H-NMR spectra were recorded at 300.13 MHz, ^{13}C{^{1}H}-NMR spectra at 75.47 MHz, and ^{31}P{^{1}H}-NMR spectra at 121.51 MHz on a Bruker FT instrument (AC-300) and were externally referenced to TMS. Chemical shifts (δ) and coupling constants (*J*) are expressed in ppm and Hz, respectively.

The starting materials $[CpCoI_2]_2$ [16] and $Li[C_6H_3(CH_2NMe_2)_2]$ [17] were prepared according to published methods.

[CoI{2-(Me_2NCH_2)-6-($Me_2NH^+CH_2$)C_6H_3}(η^5-C_5H_5)]I (3): To a stirred suspension of $[CpCoI_2]_2$ (1.511 g, 2.00 mmol) in toluene (100 mL) at 0 °C was slowly added 2,6-bis[dimethyl(amino)methyl]-phenyllithium (**2**) (0.79 g, 4.00 mmol). The resulting green suspension was stirred for 16 h at room temperature and then the volatiles were completely removed in vacuo. The residue was taken up in CH_2Cl_2/MeOH (98:2) and the resulting solution was stirred for 30 min and then filtered. The filtrate was concentrated to a volume of 30 mL and hexane was slowly added. The green solid thus formed was washed with hexane and dried in vacuo to give **3** as green crystals. Yield: 0.88 g (50%). − IR (KBr): $\tilde{\nu}$ = 2733 cm^{-1} (ν_s Me_2N-H^+). − ^{1}H NMR ($CDCl_3$): δ = 10.01 (br. s, 1 H, NH^+), 7.97 (d, $^3J_{H-H}$ = 7.44, 1 H, Ar), 7.08 (t, $^3J_{H-H}$ = 7.14, 1 H, Ar), 6.90 (d, 1 H, Ar), 5.07 (s, 5 H, C_5H_5), 5.09 and 4.98 (AB spin system, $^2J_{H-H}$ = 13.17, 2 H, CH_2N), 3.94 and 3.39 (AB spin system, $^2J_{H-H}$ = 13.20, 2 H, CH_2N-Co), 3.16 and 2.31 (2 s, 6 H, $Co-NMe_2$), 2.93 (br. s, 6 H, NMe_2H^+). − ^{13}C{^{1}H} NMR ($CDCl_3$): δ = 153.9, 149.8, 142.1, 128.9, 125.2, 122.1 (C_6H_3), 85.1 (C_5H_5), 75.7 (CH_2N-Co), 64.1 (CH_2N), 58.9 and 58.5 ($Co-NMe_2$), 42.0 (br. s, NMe_2). − $C_{17}H_{25}CoI_2N_2$ (570.1): calcd. C 35.81, H 4.42, N 4.91; found C 33.67, H 4.23, N 4.38.

[2,6-(Me_2NCH_2)$_2$Co{C_6H_3(CH_2NMe_2)}(η^5-C_5H_5)(H_2O)]PF_6 (4a): A solution of **3′** (0.44 g, 1.00 mmol) in CH_2Cl_2 (20 mL) was washed several times with water (10 mL). The combined red aqueous solutions were then treated with excess KPF_6, which led to the immediate deposition of a red-brown solid. After stirring for 15 min, the solid was collected by filtration, washed with hexane, recrystallized from acetone/hexane, and dried in vacuo to give **4a** as brown-red crystals. Yield: 0.28 g (60%). − IR (KBr): $\tilde{\nu}$ = 3575 cm^{-1} (ν_s H−OH). − ^{1}H NMR ([D$_6$]acetone): δ = 7.25 (d, $^3J_{H-H}$ = 6.93, 1 H, Ar), 7.16 (t, $^3J_{H-H}$ = 7.32, 1 H, Ar), 7.09 (d, 1 H, Ar), 5.49 (s, 5 H, C_5H_5), 4.64 and 3.65 (AB spin system, $^2J_{H-H}$ = 12.24, 2 H, CH_2NMe_2), 4.40 and 3.69 (AB spin system $^2J_{H-H}$ = 13.90, 2 H, CH_2N-Co), 3.49 and 1.34 (2 s, 6 H, NMe_2-Co), 2.20 (br. s, 6 H, NMe_2).[18] − ^{13}C{^{1}H} NMR ([D$_6$]acetone): δ = 158.0, 152.1, 130.2, 125.3, and 122.7 (C_6H_3), 85.4 (C_5H_5), 76.7 (CH_2N-Co), 67.7 (CH_2N), 58.4 and 49.2 (NMe_2-Co), 43.0 (NMe_2). − $C_{17}H_{26}CoF_6N_2OP$ (478.3): calcd. C 42.69, H 5.48, N 5.86; found C 43.02, H 5.43, N 5.84.

[Co{2,6-(Me_2NCH_2)$_2$$C_6H_3$}($\eta^5$-$C_5H_5$)($PMe_2Ph$)]$PF_6$ (4b): To a solution of **4a** (0.48 g, 1.00 mmol) in CH_2Cl_2 (10 mL) was added PMe_2Ph (0.17 mL, 1.20 mmol). After 3 h, *n*-hexane (100 mL) was added, which led to the deposition of a dark-violet solid. The solid was collected by filtration and dried in vacuo to give **4b** as a red-violet powder. Yield: 0.46 g (77%). − ^{1}H NMR ([D$_6$]acetone): δ = 7.70−7.40 (m, 5 H, PPh), 7.29 (d, $^3J_{H-H}$ = 7.32, 1 H, Ar), 7.08 (t, 1 H, Ar), 6.81 (d, $^3J_{H-H}$ = 7.08, 1 H, Ar), 5.91 (s, 5 H, C_5H_5), 3.44 and 3.33 (AB spin system, $^2J_{H-H}$ = 12.18, 2 H, CH_2N), 3.44 and 3.33 (AB spin system, $^2J_{H-H}$ = 14.40, 2 H, CH_2N), 2.89 and 2.23 (2 s, 6 H, NMe_2-Co), 2.34 (s, 6 H, NMe_2), 2.21 and 1.97 (2 d, $^2J_{H-P}$ = 9.51 and $^2J_{H-P}$ = 10.26, 6 H, PMe_2). − ^{31}P{^{1}H} NMR ([D$_6$]acetone): δ = 12.8 (s, PMe_2Ph), −143.6 (sept., PF_6, $^1J_{P-F}$ = 707.0). − ^{13}C{^{1}H} NMR ([D$_6$]acetone): δ = 151.4 (d, $^2J_{C-P}$ = 35.77), 150.1, 149.4, 131.2, 124.6, 122.9 (C_6H_3), 135.5 (d, $^1J_{C-P}$ = 60.98), 131.3, 129.6 (d, $^2J_{C-P}$ = 8.41) (PPh), 88.2 (C_5H_5), 74.3 (CH_2N-Co), 67.5 (CH_2N), 60.0 and 55.2 (NMe_2-Co), 45.0 (NMe_2), 22.2 and 15.3 (2 d, $^1J_{C-P}$ = 31.69 and $^1J_{C-P}$ = 33.67) (PMe_2). − $C_{25}H_{35}CoF_6N_2P_2$: (598.4): calcd. C 50.18, H 5.89, N 4.68; found C 50.62, H 5.75, N 4.38.

[CoCl{2-(Me_2NCH_2)-6-($Me_2NH^+CH_2$)C_6H_3}(η^5-C_5H_5)]PF_6 (5a): To a solution of **4a** (0.48 g, 1.00 mmol) in MeOH (20 mL) was added excess NH_4Cl. After 7 h, the volatiles were removed. The residue was redissolved in CH_2Cl_2 and this solution was filtered. The brown filtrate was concentrated and the residue was recrystallized from acetone/hexane and dried in vacuo to give **5a** as dark, red-violet crystals. Yield: 0.40 g (81%). − IR (KBr): $\tilde{\nu}$ = 2692 cm^{-1} (ν_s Me_2N-H^+). − ^{1}H NMR ([D$_6$]acetone): δ = 9.48 (br. s, 1 H, NH^+), 7.41 (d, $^3J_{H-H}$ = 6.90, 1 H, Ar), 7.18 (t, $^3J_{H-H}$ = 7.14, 1 H, Ar), 7.12 (d, $^3J_{H-H}$ = 6.45, 1 H, Ar), 5.46 (s, 5 H, C_5H_5), 5.07 and 4.60 (AB spin system, $^2J_{H-H}$ = 12.63, 2 H, CH_2N), 4.60 and 3.72 (AB spin system, $^2J_{H-H}$ = 14.05, 2 H, CH_2N), 3.50 and 1.51 (2 s, 6 H, NMe_2-Co), 3.21 and 2.68 (2 br. s, 6 H, NMe_2). − ^{13}C{^{1}H} NMR ([D$_6$]acetone): δ = 157.4, 152.6, 143.0, 132.2, 125.2, 123.4 (C_6H_3), 86.6 (C_5H_5), 76.7 (CH_2N-Co), 66.3 (CH_2N), 58.6 and 52.4 (NMe_2-Co), 43.4 and 39.8 (2 br. s, NMe_2). − $C_{17}H_{25}ClCoF_6N_2P$ (496.7): calcd. X-ray Data and Structure Determinations for 3, 4a, 5a, and 5d: Single crystals suitable for X-ray diffraction analysis were obtained as described above. In the case of **3**, **4a**, and **5a**, data were collected on a Nonius KappaCCD diffractometer, while for **5d** a Nonius MACH3 machine was used. All four data collections were performed using Mo-K_α graphite-monochromated radiation (λ = 0.7107 Å), φ and ω scans for **3**, **4a**, and **5a**, and θ/2θ scans for **5d**. Absorption corrections were computed from the psi scans of 7 reflections for **5d**, while for **3**, **4a**, and **5a** these corrections were partially included in the data reduction procedure. The structures were solved using direct methods and refined against |*F*|. Hydrogen atoms were introduced in structure factor calculations as fixed contributors by their computed coordinates [*d*(C−H) = 0.95 Å, *B*(H) = 1.3*Beqv Å^2 of the attached carbon atom] except for the NH protons of **3**, **5a**, and **5d** and the water protons of **4a**, which were located in difference Fourier maps. The absolute structures of **3**, **4a**, and **5d** were determined by refinement of Flack's *x* parameter. For all computations, the Nonius OpenMoLeN package[19] was used. Crystal data and results for all four compounds are given in Table 2.

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-132438 (**3**), -132439 (**4a**), -132440 (**5a**), and -132441 (**5d**). Copies of the data can be obtained free of charge on application to the CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) +44 (0)1223/336033; E-mail: deposit@ccdc.cam.ac.uk].

Biomimetic Zinc Complexes With A New Tripodal Nitrogen-Donor Ligand: Tris[2-(1-methyl-4-tolylimidazolyl)phosphane] ($Pim^{Me,pTol}$)

Wolfgang Kläui,*[a] Claudia Piefer,[a] Gerd Rheinwald,[b] and Heinrich Lang[b]

Dedicated to Prof. Dr. H. Vahrenkamp on the occasion of his 60th birthday

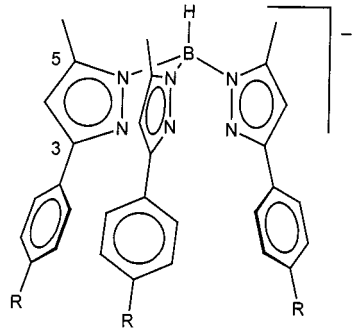
Keywords: Bioinorganic chemistry / Carbonic anhydrase / Zinc / N ligands / Tripodal ligands

The new potentially threefold-chelating ligand tris[2-(1-methyl-4-tolylimidazolyl)]phosphane ($Pim^{Me,pTol}$) has been prepared. The *p*-tolyl substituents on the imidazole rings form a shielded hydrophobic cavity. The first X-ray-structure analysis of this ligand system confirms the proposed structure. The reaction of $Pim^{Me,pTol}$ with ZnX_2 salts (X = Cl, Br, I, NO_3) yields monomeric Zn^{II} complexes. The X-ray crystal structures of $[Pim^{Me,pTol}ZnCl]_2(ZnCl_4)$ and $[Pim^{Me,pTol}ZnNO_3]NO_3$ prove that the Zn^{2+} centres are in a tetrahedral environment with threefold *N*-imidazole coordination. This arrangement mimics the active centre of carbonic anhydrase (CA).

Introduction

Zinc is an essential element in biological systems.[1] Its first biological function was found in the enzyme carbonic anhydrase (CA), a hydrolase which catalyses the hydration of carbon dioxide at physiological pH, according to (Equation 1).

$$CO_2 + 2\,H_2O \overset{CA}{\rightleftharpoons} HCO_3^- + H_3O^+ \quad (1)$$



In the absence of a catalyst, this apparently simple reaction is extremely slow. However, it is imperative to nearly all living organisms that this reaction is fast. CA accelerates the rate of hydration of CO_2 10^7-fold.[2] In order to understand the essential structure and reaction characteristics of bioinorganic systems, small molecular model complexes are a convenient approximation. One model system for CA is based on sterically demanding tris(pyrazolyl)hydroborate (Tp) ligands **A**. This type of ligand forms zinc(II) complexes with structural and functional properties similar to those of the active site of CA. An essential prerequisite for the successful application of such systems is the introduction of bulky groups R, such as *tert*-butyl[3], phenyl[4], *p*-cumyl[5] or *p*-tolyl,[6] in the 3-position of the pyrazolyl rings. The presence of these sterically demanding substituents inhibits the formation of bis-ligand complexes $[Zn(Tp)_2]$ and it forces coordination numbers smaller than six. Whereas *tert*-butyl substituents reduce the coordination number exclusively to four, aryl substituents enable Zn^{II} to extend its coordination sphere to five.[7] In addition, the aryl groups form a hydrophobic pocket around the zinc ion. The hydrophobic surrounding should help the coordinated water in complexes $[TpZnOH_2]$ to become acidic at physiological pH. While with this, the importance of steric factors in CA model systems has been established, it remains unclear whether the negative charge of the Tp ligands is required to stabilise biomimetic zinc complexes. One of the main problems in this context is the sensitivity of Tp ligands toward hydrolysis.

Tris(imidazolyl)phosphane ligands are neutral and hydrolytically stable analogues of the Tp ligands to which they are sterically and electronically very similar. Zinc complexes of tris[2-(4,5-diisopropyl)imidazolyl]phosphane[8] and tris[2-(4,5-di-*n*-propyl)imidazolyl]phosphane[9] have been synthesised. It turned out that these complexes are remarkably different in their efficiency in catalysing the CO_2/HCO_3^- equilibrium. Unfortunately the 1,3-tautomerism in the imidazole rings makes it difficult to assess the geometry of the catalytically active zinc complexes. Knowing that the histidyl-imidazol *N*-ligation to metal ions is ubiquitous in nature, further development of zinc coordination chemistry with other imidazole-derived ligands is obviously desirable.

Until now two tris(imidazolyl)phosphane ligands of type **B** have been prepared (Scheme 1).[10] They have 1,4- rather than 4,5-substituted imidazole rings. While in Tp ligands **A** the 5-methyl groups serve as a protecting unit for the hydrolytically sensitive B−N bonds, the 1-alkyl substituent in **B** is only necessary to suppress the 1,3-tautomerism in the imidazole. These tripodal ligands of type **B** have been described only with bulky alkyl substituents in the 1-position as well as in the 4-position. This can be attributed to the fact that the synthesis of substituted imidazole rings is relatively difficult. Thus, only very few zinc-containing enzyme model complexes incorporating substituted imidazole *N*-donor groups have been reported.

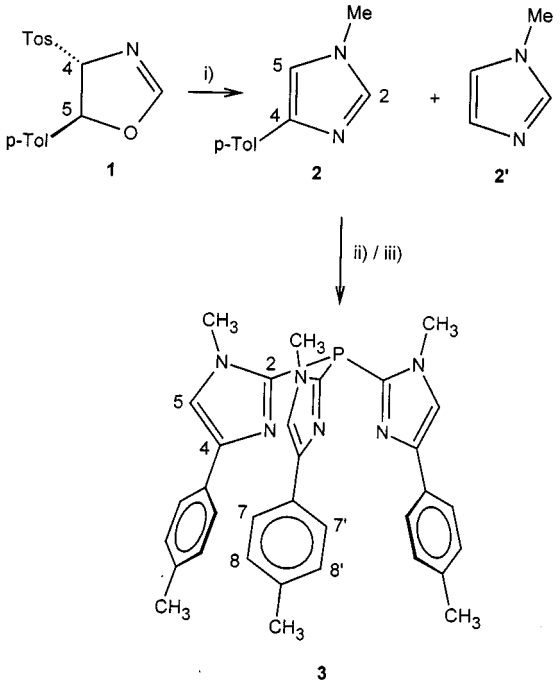


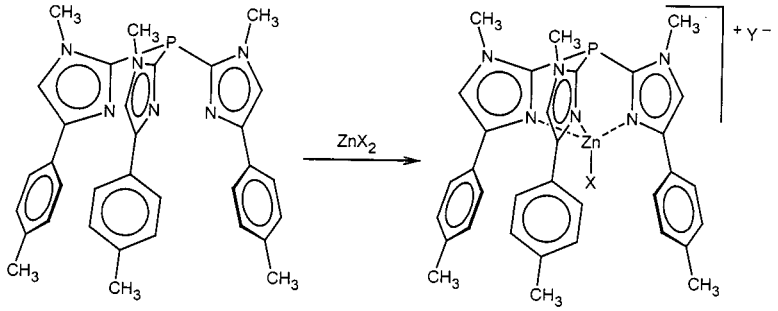
Scheme 1. Schematic structures of aryl-substituted tris(pyrazolyl)-borate ligands and of bulky 1,4-dialkyl-substituted tris(imidazolyl)-phosphane ligands

We describe here the synthesis of the new tripodal *p*-tolyl-substituted tris(imidazolyl)phosphane ligand $Pim^{Me,pTol}$ (**3**) and its reaction behaviour towards Zn^{II} salts in order to develop model systems which can mimic CA enzyme characteristics. This ligand is the first ligand of its type with aryl substituents in the 4-position of the imidazole rings. The aryl substituents were expected to play the same role as in the analogous Tp ligands, i.e. they should form a sterically demanding and hydrophobic cavity around the zinc ion. A bulky isopropyl substituent in the 1-position as in the known ligands $Pim^{iPr,iPr}$ and $Pim^{iPr,tBu}$ [10] seems unnecessary. We have chosen the small methyl group to keep the solubility in protic solvents as high as possible.

Results and Discussion

Synthesis and Spectroscopic Characterisation

The well-established way of preparing tris(imidazolyl)-phosphanes of type **B**[11] was not suitable for synthesising the desired ligand $Pim^{Me,pTol}$ (**3**). Because of the difficulty of introducing an aryl substituent into the imidazole ring regiospecifically, we applied an alternative route, via oxazolines **1**, to prepare the 1,4-disubstituted imidazoles **2**.[12] The mechanism of this reaction did not exclude, a priori, the formation of the second regioisomer **2′**. The isomer **2** as the only product could be confirmed by 2D NMR experiments.[13] Flash chromatography of the reaction mixture afforded crude 1-methyl-4-tolylimidazole in an acceptable yield. In the following step, the imidazole was lithiated in the 2-position and then treated with PCl_3 in THF at −78 °C (Scheme 2) yielding **3** as a colourless solid after crystallisation from dichloromethane/hexane.



Scheme 2. Synthesis and schematic structure of the aryl-substituted tris(imidazolyl)phosphane ligand $Pim^{Me,pTol}$ (**3**); i) $MeNH_2$ in benzene, autoclave, T = 120 °C, ii) *n*BuLi, THF, −78 °C; iii) PCl_3, THF

The ^1H NMR spectrum of **3** shows C_{3v} symmetry with an $[AB]_2$-system at δ = 7.43 for the *p*-tolyl protons. The doublet at δ = 7.18 ($^3J_{HH}$ = 8 Hz) of the $[AB]_2$-system is assigned to the *m*-protons of the *p*-tolyl group and the doublet at δ = 7.68 ($^3J_{HH}$ = 8 Hz) is assigned to the protons in the *o*-position on the basis of correlated $^1H,^{13}C$ HMBC NMR spectra. The singlet at δ = 7.38 can be assigned to the proton in the 5-position of the substituted imidazole ring and the singlet at δ = 3.76 can be assigned to the protons of the $N-CH_3$ group. In the $^{31}P\{^1H\}$ NMR spectrum of **3** the ^{31}P signal appears at δ = −57.9 as a singlet. The EI mass spectrum of **3** exhibits the peak for the molecular ion at the expected *m/z* value together with a characteristic fragmentation pattern.

The zinc(II) complexes $[Pim^{Me,pTol}ZnX]Y$ were prepared in high yield by stirring the tris(imidazolyl)phosphane **3** with ZnX_2 salts in THF (X = NO_3, Cl, Br) or in ethanol (X = I), under reflux (Scheme 3). The complexes **4a**−**4d** form colourless solids and can be crystallised from acetonitrile or nitromethane to yield analytically pure colourless crystals.

The ^1H NMR spectra of the zinc complexes **4a**−**4d** also show a signal pattern corresponding to C_{3v} symmetry. The signal of the proton in the 5-position of the imidazole ring

4	X	Y

b	Br	Br
c	I	I
d	NO_3	NO_3

Scheme 3. Synthesis and schematic structures of the zinc complexes [$Pim^{Me,pTol}ZnX$]Y (**4a−d)**

is shifted to lower field and split into a doublet (**4a:** δ = 7.53, $^4J_{PH}$ = 4 Hz; **4b:** δ = 7.49, $^4J_{PH}$ = 4 Hz; **4c:** δ = 7.46, $^4J_{PH}$ = 5 Hz; **4d:** δ = 7.56, $^4J_{PH}$ = 4 Hz) when compared to the signal in the free ligand **3**. Upon coordination to Zn^{II}, the ^{31}P signal for complexes **4a−4d** is shifted to higher field (**4a:** δ = −113.7; **4b:** δ = δ = −118.2; **4c:** δ = −119.4; **4d:** δ = −117.8). A similar shift has also been reported for the ^{31}P signal of ligands of type **B** in Cu^I complexes, e.g. [$Pim^{iPr,iPr}CuCH_3CN$][BF_4].[10b] The FAB mass spectra of the Zn^{II} complexes **4a−4d** exhibit the peak for the molecular ion at the expected *m/z* value together with a characteristic fragmentation pattern.

Solid State Structure of 3, 4a and 4d

Crystals of **3** suitable for an X-ray crystal structure determination were obtained by slow evaporation of an acetone solution. It crystallises in the monoclinic space group *Cc* with four independent molecules per unit cell. Crystals of the complexes **4a** and **4d** were grown by diffusion of hexane into a nitromethane solution. Both complexes crystallise in the triclinic space group $P\bar{1}$. The structure of **4a** contains two independent cationic molecules and three solvent molecules of nitromethane per unit cell. The two independent cationic molecules differ only within the ranges of standard deviations, except for one Zn−N distance and some torsion angles.[14] Crystals of **4d** contain one strongly disordered nitromethane molecule. The solid-state structure of the ligand **3** is shown in Figure 1, the structure of the cation [$Pim^{Me,pTol}ZnCl$]$^+$ of **4a** in Figure 2 and the structure of [$Pim^{Me,pTol}ZnNO_3$]$^+$ of **4d** is presented in Figure 3. Selected bond length, angles and torsion angles are given in Table 1. The structure of the free ligand **3** is the first solid-state structure reported for a tris(imidazolyl)phosphane ligand.

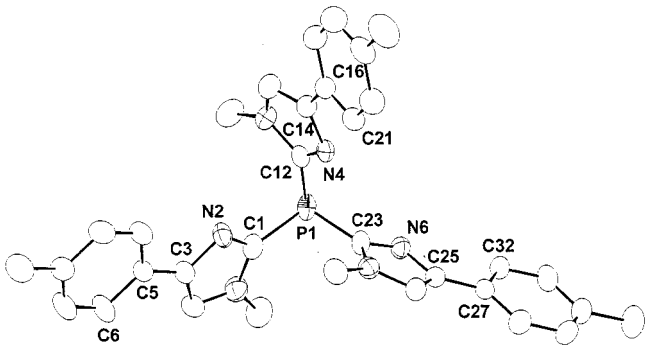

Figure 1. ZORTEP plot[25] (50% probability) of $Pim^{Me,pTol}$ (**3**)

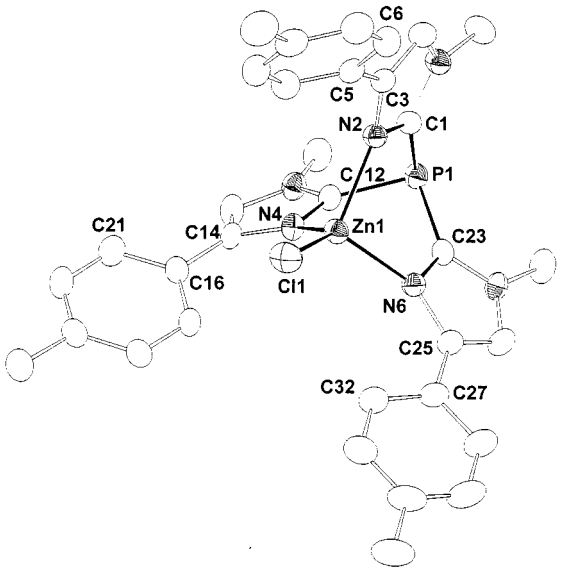

Figure 2. ZORTEP plot[25] (50% probability) of [$Pim^{Me,pTol}ZnCl$]$^+$ in **4a**

Figure 1 shows a trigonal pyramidal environment of P(1) with P−C σ-bond lengths and C−P−C bond angles comparable to those of aromatic phosphanes such as tri-*o*-tolylphosphane[15] or tri-*m*-tolylphosphane.[16] The P−C σ-bond lengths of **3** (1.813−1.841 Å) are similar to those found for tri-*o*-tolylphosphane[15] (1.830−1.837 Å) or tri-*m*-tolylphosphane[16] (1.829−1.838 Å). Only one C−P−C bond angle [96.8(2)°] is smaller than those found for tri-*o*-tolylphosphane[15] (101.6−103.4°) or tri-*m*-tolylphosphane[16] (100.6−102.2°). The small deviation of the N−C−C−C bond torsion angles of **3** (Table 1) from 0° or 180°, respectively, indicates that the *p*-tolyl rings are nearly coplanar with the imidazolyl-system in the free ligand.

Zn(1)−Cl(1)/−O(1)		2.1725(10)	1.9592(19)

The structures of the two cationic Zn^{II} complexes **4a** and **4d** reveal a slightly distorted tetrahedral coordination environment of Zn^{II} with threefold *N*-imidazolyl coordination. The Zn(1)−Cl(1) bond length in **4a** [2.1725(10)Å] does not differ significantly from that of the other known tris(imidazolyl)phosphanezinc chloride complex chloro{tris[2-(4,5-diisopropylimidazolyl)phosphane]}zinc chloride [2.170(2)-Å].[17] The Zn(1)−O(1) bond length [1.9592(19)Å] pertaining to the coordinating NO_3 in **4d** is similar to the Zn−O distances in the nitrato complex tris[2-(1-isopropyl-4-*tert*-butylimidazolyl)phosphane]zinc nitrate [1.986(4)-Å].[10a] The nitrate ligand in complex **4d** acts as a monodentate ligand[18] unlike the coordinating nitrate in tris[2-(1-isopropyl-4-*tert*-butylimidazolyl)phosphane]zinc nitrate which shows an anisobidentate coordination mode. This is surprising in view of the different steric bulk of the *p*-tolyl and *tert*-butyl groups. We expected that the less bulky *p*-tolyl groups would allow for bidentate coordination of the nitrate ligand. The N−Zn−N bond angles in both **4a** (90.3−99.9°) and **4d** (94.0−100.2°) are smaller than the tetrahedral angle. These angles do not differ significantly from previously reported values for tris(imidazolyl)phosphanes, e.g. chloro{tris[2-(4,5-diisopropylimidazolyl)phosphane]}-zinc chloride[17] or $[Pim^{iPr,tBu}ZnX]^+$ (X = OH, I, NO_3).[10a] The three Zn−N bond lengths in the structure **4a** are equal (mean: 2.064 Å) and are very similar to the Zn−N bond lengths in **4d** (2.025−2.092 Å) and $[Pim^{iPr,tBu}ZnX]^+$ (X = OH, I, NO_3).[10a] It is worth mentioning that the Zn−N bond lengths and N−Zn−N bond angles in the analogous hydrotris(pyrazolyl)borate complexes $[Tp^{Me,Ph}ZnNO_3]$[4a] and $[Tp^{Me,Ph}ZnCl]$,[19] do not differ significantly from those found for tris(imidazolyl)phosphanes. The P−C bond lengths of **4a** (mean: 1.818 Å) and **4d** (mean: 1.823 Å) are equivalent within the standard deviation and show no significant differences to those found for the free ligand **3**. The C−P−C bond angles of **4a** (97.4−98.7°) and **4d** (95.6−100.4°) are slightly smaller than the C−P−C bond angles of the free ligand **3** (96.8−103.5°). This suggests that the tridentate coordination of **3** to Zn^{II} induces no significant strain on the ligand independent of the coordinating anion. The natural bite of the ligand seems to be ideally tailored to the tris-chelating coordination of Zn^{II}. The already mentioned N−C−C−C torsion angles of **4a** and **4d** (Table 1) vary a bit more than those observed for **3**. This small deviation from coplanarity can be interpreted as being caused by weak interactions of the coordinating anion with the *p*-tolyl substituents.

Conclusion

We have synthesised the new *p*-tolyl-substituted tris(imidazolyl)phosphane ligand $Pim^{Me,pTol}$ (**3**) and prepared a variety of stable Zn^{II} complexes. $Pim^{Me,pTol}$ (**3**) is the first tris(imidazolyl)phosphane ligand with a hydrophobic cavity formed by three aryl substituents. The geometry of its zinc complexes (bond lengths, angles, bite of the ligand) is similar to the geometry of the tris(pyrazolyl)borate zinc complexes. A comparison of the X-ray structure analyses of the free ligand $Pim^{Me,pTol}$ (**3**) and the two complexes $[Pim^{Me,pTol}ZnCl]_2ZnCl_4$ (**4a**) and $[Pim^{Me,pTol}ZnNO_3]NO_3$ (**4d**) reveals that the tris(imidazolyl)phosphane ligand hardly changes its bond angles upon metal coordination. The natural bite angle of the ligand is obviously ideally suited for zinc ion complexation. The orientation of the *p*-tolyl groups in the Zn^{II} complex **4d** shows that the hydrophobic cavity can adjust to the nonspherical shape of the nitrate ligand. The cavity seems deep and wide enough to allow access of an additional small molecule. This aspect is probably important to the mimicry of carbonic anhydrase activity. We think that the $Pim^{Me,pTol}$ ligand **3** is more suitable for reaction in protic solvents than the $Tp^{R,R'}$ ligands with their B−N bonds that are inherently sensitive to hydrolysis.

Experimental Section

General Remarks: The compounds 5-tolyl-4-tosyloxazoline[12] and tris[2-(1-methyl-4-tolylimidazolyl)phosphane[10b] **3** were synthesised according to the literature procedures for analogous systems. Ethanol was purified and degassed by standard procedures. All other solvents and reagents were used without further purification. ^{1}H NMR spectra, ^{31}P NMR spectra and ^{13}C NMR spectra were recorded on a Bruker DRX 200 spectrometer, the 2D NMR spectra were recorded on a Bruker DRX 500 spectrometer. The chemical shifts (δ) are reported in ppm with the solvent signal as reference. The EI-mass spectra were recorded on a double focussing mass spectrometer, model 311 A Varian MAT, ionisation energy 70 eV. The FAB mass spectra were recorded on a mass spectrometer Finnigan, Model MAT 8200, with an NBA matrix.

5-Tolyl-4-tosyloxazoline (1): Prepared according to a literature procedure[12] with tosylmethyl isocyanide (25.0 g, 128 mmol), tolylaldehyde (15.4 g, 128 mmol) and finely powdered sodium cyanide (0.4 g, 8 mmol) in 100 mL of dry ethanol. Yield: 38 g (90%) as a colourless crystalline solid. − ^{1}H NMR ($CDCl_3$): δ = 2.39 (s, 3 H, tolyl C*H*$_3$), 2.49 (s, 3 H, tosyl C*H*$_3$), 5.07 (dd, $^3J_{HH}$ = 6 Hz, $^4J_{HH}$ = 2 Hz, 1 H, oxazoline C^5 *H*), 6.05 (d, $^3J_{HH}$ = 6 Hz, 1 H, oxazoline C^4 *H*), 7.24 (s, 5 H, tosyl C_6H_4, oxazoline C^2 *H*), 7.42 (d, $^3J_{HH}$ = 8 Hz, 2 H, $C_6H_2H_2CH_3$), 7.88 (d, $^3J_{HH}$ = 8 Hz, 2 H, $C_6H_2H_2CH_3$).

1-Methyl-4-tolylimidazole, Im^{Me,pTol} (2): A suspension of 5-tolyl-4-tosyloxazoline (102 g, 310 mmol) in 250 mL of benzene was stirred under nitrogen in a 500 mL autoclave fitted with an inlet tube and a PTFE insert. The hole device was cooled to −78 °C. Then, dry methylamine (39.9 g, 1.28 mol) was condensed into the autoclave which was subsequently heated with stirring to 120 °C. After 20 h a red orange mixture was obtained and flash chromatography (ethyl acetate/dichloromethane, 4:1) afforded crude 1-methyl-4-tolylimidazole (15 g, 87 mmol; 28% relative to **1**) which was recrystallized from diethyl ether as colourless flakes. − ^{1}H NMR ($CDCl_3$): δ = 2.39 (s, 3 H, $C_6H_4CH_3$), 3.74 (s, 3 H, NC*H*$_3$), 7.16 (d, $^4J_{HH}$ = 1 Hz, 1 H, imidazolyl C^5*H*), 7.22 (d, $^3J_{HH}$ = 8 Hz, 2 H, *m*-*H* of *p*-tolyl), 7.49 (s, 1 H, imidazolyl C^2*H*), 7.69 (d, $^3J_{HH}$ = 8 Hz, 2 H, *o*-*H* of *p*-tolyl). − ^{13}C{^{1}H} NMR ($CDCl_3$): δ = 21.6 (s, $C_6H_4CH_3$), 33.9 (d, *J* = 3 Hz, N*C*H$_3$), 115.9 (s, imidazole *C*^{2} H), 125.1 (s, 2C, *p*-tolyl *C*$^{7,7'}$H), 129.7 (s, 2C, *p*-tolyl *C*$^{8,8'}$H), 131.9 (s, *p*-tolyl *C*), 136.7 (s, *p*-tolyl *C*), 138.8 (d, *J* = 2 Hz, imidazole *C*^{5}H), 142.8 (s, imidazole *C*^{4}). − MS (EI): *m*/*z* (%) = 172 (100) [M$^+$], 157 (16) [M$^+$ − CH_3], 130 (21) [M$^+$ − CH_3 − NCH], 103 (16) [$C_8H_7^+$], 77 (12%) [$C_6H_5^+$].

Tris[2-(1-methyl-4-tolylimidazolyl)]phosphane, Pim^{Me,pTol} (3): The procedure for Pim^{iPr,iPr} [10b] was modified by using THF as solvent instead of diethyl ether and replacing the THF with dichloromethane before adding the ammonia solution. Preparation of **3** from 1-methyl-4-tolylimidazole (15 g, 87 mmol), *n*-butyllithium (62 mL, 99 mmol, 1.6 M in hexane), freshly distilled PCl_3 (4.2 g, 30 mmol) and 150 mL of THF. Yield: 7.4 g (14 mmol; 45% rel. to PCl_3) of tris[2-(1-methyl-4-tolylimidazolyl)]phosphane as a colourless solid after recrystallization from dichloromethane/hexane. − ^{1}H NMR ($CDCl_3$): δ = 2.38 (s, 9 H, $C_6H_4CH_3$), 3.76 (s, 9 H, NC*H*$_3$), 7.18 (d, $^3J_{HH}$ = 8 Hz, 6 H, $C_6H_2H_2CH_3$), 7.38 (s, 3 H, imidazole C^5 *H*), 7.68 (d, $^3J_{HH}$ = 8 Hz, 6 H, $C_6H_2H_2CH_3$). − ^{13}C{^{1}H} NMR ($CDCl_3$): δ = 21.7 (s, $C_6H_4CH_3$), 35.2 (m, N*C*H$_3$), 121.0 (s, imidazole *C*^{2}P), 125.2 (s, 2C, *p*-tolyl *C*$^{7,7'}$H), 129.6 (s, 2C, *p*-tolyl *C*$^{8,8'}$H), 131.7 (s, *p*-tolyl *C*), 136.8 (s, *p*-tolyl *C*), 141.1 (d, *J* = 11 Hz, imidazole *C*^{5}H), 143.5 (d, *J* = 9 Hz, imidazole *C*^{4}). − ^{31}P{^{1}H} NMR ($CDCl_3$): δ = −57.9. − MS (EI): *m*/*z* (%) = 544 (13) [M$^+$], 372 (16) [P($N_2C_{11}H_{11}$)$_2^+$ − H], 359 (76) [P($N_2C_{11}H_{11}$)$_2^+$ − CH_2], 202 (20) [$PN_2C_{11}H_{11}^+$], 173 (52) [Im$^{Me,pTol+}$ + H], 130 (30) [Im$^{Me,pTol+}$ − CH_3 − NCH].

Bis[chloro{tris[2-(1-methyl-4-tolylimidazolyl)]phosphane}zinc] Tetrachlorozincate, [Pim^{Me,pTol}ZnCl]$_2$ZnCl$_4$ (4a): A stirred solution of Pim^{Me,pTol} (546 mg, 1.00 mmol) in 40 mL of THF was treated with $ZnCl_2$ (126 mg, 0.925 mmol) in THF. The reaction mixture was heated under reflux for 30 min then stirred for an additional 12 h at 25 °C. The complex precipitated as a colourless powder, which was collected by filtration and washed with 30 mL of THF. Drying under vacuum afforded **4a** (0.37 g, 0.25 mmol; 82% rel. to $ZnCl_2$). − ^{1}H NMR (CD_3NO_2): δ = 2.37 (s, 9 H, *p*-tolC*H*$_3$), 4.12 (s, 9 H, NC*H*$_3$), 7.25 (d, $^3J_{HH}$ = 8 Hz, 6 H, $C_6H_2H_2CH_3$), 7.53 (d, $^4J_{PH}$ = 4 Hz, 3 H, imidazolyl C^5*H*), 7.61 (d, $^3J_{HH}$ = 8 Hz, 6 H, $C_6H_2H_2CH_3$). − ^{31}P NMR (CD_3NO_2): δ = −113.7. − MS (FAB): *m*/*z* (%) = 643 (83) [Pim^{Me,pTol}ZnCl]$^+$, 472 (14) [P($N_2C_{11}H_{11}$)$_2$ZnCl]$^+$, 438 (5) [P($N_2C_{11}H_{11}$)$_2$Zn]$^+$, 373 (6) [P($N_2C_{11}H_{11}$)$_2^+$], 202 (3) [$PN_2C_{11}H_{11}^+$] 77 (36) [$C_6H_5^+$].

Bromo{tris[2-(1-methyl-4-tolylimidazolyl)]phosphane}zinc Bromide, [Pim^{Me,pTol}ZnBr]Br (4b): This compound was prepared according to the procedure described for [Pim^{Me,pTol}ZnCl]$_2$ZnCl$_4$ (**4a**) with **3** (273 mg, 0.501 mmol) and $ZnBr_2$ (113 mg, 0.502 mmol). Yield: 0.31 g (80%) of **4b** as a colourless powder. − ^{1}H NMR (CD_3NO_2): δ = 2.38 (s, 9 H, *p*-tolC*H*$_3$), 4.22 (s, 9 H, NC*H*$_3$), 7.24 (d, $^3J_{HH}$ = 7 Hz, 6 H, $C_6H_2H_2CH_3$), 7.49 (d, $^4J_{PH}$ = 4 Hz, 3 H, imidazolyl C^5 *H*), 7.55 (d, $^3J_{HH}$ = 7 Hz, 6 H, $C_6H_2H_2CH_3$). − ^{31}P{^{1}H} NMR (CD_3NO_2): δ = −118.2. − MS (FAB): *m*/*z* (%) = 689 (25) [Pim^{Me,pTol}ZnBr]$^+$, 518 (5) [P($N_2C_{11}H_{11}$)$_2$ZnBr]$^+$, 438 (3) [P($N_2C_{11}H_{11}$)$_2$Zn]$^+$.

Iodo{tris[2-(1-methyl-4-tolylimidazolyl)]phosphane}zinc Iodide, [Pim^{Me,pTol}ZnI]I (4c): This compound was prepared according to the procedure described for [Pim^{Me,pTol}ZnCl]$_2$ZnCl$_4$ (**4a**) with **3** (273 mg, 0.501 mmol), ZnI_2 (159 mg, 0.498 mmol) and ethanol as solvent. Yield: 0.36 g (84%) of **4c** as a colourless powder. − ^{1}H NMR (CD_3NO_2): δ = 2.37 (s, 9 H, *p*-tolC*H*$_3$), 4.23 (s, 9 H, NC*H*$_3$), 7.24 (d, $^3J_{HH}$ = 7 Hz, 6 H, $C_6H_2H_2CH_3$), 7.46 (d, $^4J_{PH}$ = 5 Hz, 3 H, imidazolyl C^5*H*), 7.50 (d, $^3J_{HH}$ = 8 Hz, 6 H, $C_6H_2H_2CH_3$). − ^{31}P{^{1}H} NMR (CD_3NO_2): δ = −119.4. − MS (FAB): *m*/*z* (%) = 735 (100) [Pim^{Me,pTol}ZnI]$^+$, 564 (18) [P($N_2C_{11}H_{11}$)$_2$ZnI]$^+$, 438 (23) [P($N_2C_{11}H_{11}$)$_2$Zn]$^+$, 373 (26) [P($N_2C_{11}H_{11}$)$_2^+$].

Nitrato{tris[2-(1-methyl-4-tolylimidazolyl)]phosphane}zinc Nitrate, [Pim^{Me,pTol}ZnNO$_3$]NO$_3$ (4d): This compound was prepared according to the procedure described for [Pim^{Me,pTol}ZnCl]$_2$ZnCl$_4$ (**4a**) with $Zn(NO_3)_2{\cdot}6H_2O$ (298 mg, 1.00 mmol). Yield: 0.67 g (92%) of **4d** as colourless powder. − ^{1}H NMR (CD_3CN): δ = 2.40 (s, 9 H, *p*-tolC*H*$_3$), 4.10 (s, 9 H, NC*H*$_3$), 7.30 (d, $^3J_{HH}$ = 8 Hz, 6 H, $C_6H_2H_2CH_3$), 7.48 (d, $^3J_{HH}$ = 8 Hz, 6 H, $C_6H_2H_2CH_3$), 7.56 (d, $^4J_{PH}$ = 4 Hz, 3 H, imidazolyl C^5*H*). − ^{31}P{^{1}H} NMR (CD_3CN): δ = −117.8. − MS (FAB): *m*/*z* (%) = 670 (100) [Pim^{Me,pTol}ZnNO$_3$]$^+$, 438 (18) [P($N_2C_{11}H_{11}$)$_2$Zn]$^+$, 373 (16) [P($N_2C_{11}H_{11}$)$_2^+$], 202 (11) [$PN_2C_{11}H_{11}^+$], 77 (94) [$C_6H_5^+$], 51 (69) [$C_4H_3^+$].

X-ray Crystallographic Study: For all compounds Pim^{Me,pTol} (**3**), [Pim^{Me,pTol}ZnCl]$_2$ZnCl$_4$ (**4a**), and [Pim^{Me,pTol}ZnNO$_3$]NO$_3$ (**4d**) data collection was carried out using a Bruker Smart CCD system. All data were corrected for absorption using SADABS.[20] The structures were solved using direct methods [SHELX-97[21] (**3**) and (**4a**), SIR-97[22] (**4d**)] and refined using least-squares methods (SHELX-97). Before the final refinement of **4d** the electron density of a strongly disordered nitromethane molecule was treated with PLATON[23] using the built-in SQUEEZE routine.[24] Crystal data for **3**, **4a** and **4d** are summarised in Table 2. Requests concerning the

X-ray crystal structure section should be addressed to one of the authors (Dr. Gerd Rheinwald).

Crystals of **3** with X-ray quality were obtained by evaporation of an acetone solution. The selected crystal was a colourless rectangular rod with dimensions of $1.2 \times 0.3 \times 0.1$ mm^3 and data collection proceeded at 173 K.

X-ray quality colourless triangular plates of **4a** were grown by diffusion of hexane into a nitromethane solution at 293 K. A crystal of dimensions $0.45 \times 0.25 \times 0.2$ mm^3 was selected and data collection proceeded at 173 K.

Colourless triclinic crystals of **4d** suitable for an X-ray study were also grown by diffusion of hexane into a nitromethane solution at 293 K. A crystal of dimensions $0.4 \times 0.4 \times 0.08$ mm^3 was selected and data collection proceeded at 173 K.

All crystals were prepared and handled under perfluoropolyalkyl ether (ABCR GmbH & Co KG, viscosity 1600 cSt.).

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-137726 **(3)**, -137727 **(4a)** and -137728 **(4d)**. Copies of the data can be obtained free of change on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

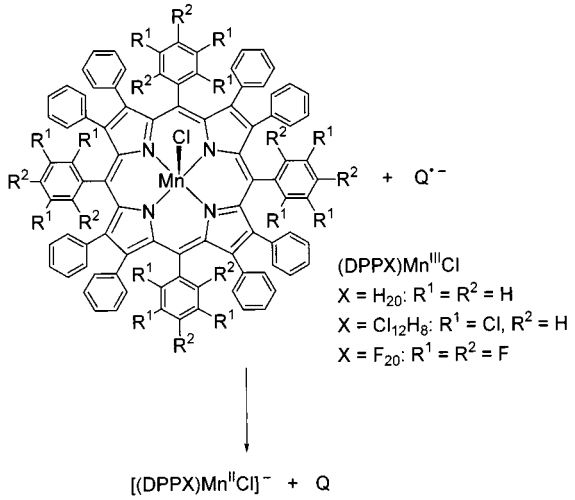
Base Control of Electron-Transfer Reactions of Manganese(III) Porphyrins

Ikuo Nakanishi,[a] Shunichi Fukuzumi,*[a] Jean-Michel Barbe,[b] Roger Guilard,*[b] and Karl M. Kadish*[c]

Keywords: Electron transfer / Kinetics / Manganese / Metalloporphyrins / Quinones

Homogeneous electron-transfer kinetics for the reduction of four different manganese(III) porphyrins using different reductants were examined in deaerated acetonitrile, and the resulting data were evaluated in light of the Marcus theory of electron transfer to determine electron-exchange rate constants between manganese(III) and manganese(II) porphyrins. The investigated compounds are represented as (P)MnCl, where P = the dianion of dodecaphenylporphyrin (DPPX; X = H_{20}, $Cl_{12}H_8$, or F_{20}) or tetraphenylporphyrin (TPP). The electron transfer from semiquinone radical anion derivatives to $(P)Mn^{III}Cl$ leads to formation of the corresponding Mn^{II} complex, $[(P)Mn^{II}Cl]^-$. The electron-exchange rate constants derived from the electron-transfer rate constants decrease with an increasing degree of nonplanarity of the porphyrin macrocycle and follow the order: (TPP)MnCl (3.1×10^3 $M^{-1}\cdot s^{-1}$) > ($DPPH_{20}$)MnCl (1.1×10^{-2} $M^{-1}\cdot s^{-1}$) > ($DPPCl_{12}H_8$)MnCl (3.5×10^{-4} $M^{-1}\cdot s^{-1}$) > ($DPPF_{20}$)MnCl (4.3×10^{-6} $M^{-1}\cdot s^{-1}$). The coordination of two molecules of pyridine (py) or DMSO to ($DPPH_{20}$)MnCl to form $[(DPPH_{20})Mn(py)_2]^+$ or $[(DPPH_{20})Mn(DMSO)_2]^+$ enhances the rate of electron-transfer reduction. This indicates that there is a significant decrease in the reorganization energy upon axial ligand coordination of pyridine or DMSO.



Introduction

Metalloporphyrins have been utilized as important electron carriers in a variety of biological and chemical redox systems, since electron-transfer reactions of metalloporphyrins can be finely tuned by the metal, the porphyrin macrocycle and the axial ligands.[1] The axial ligand has merited special attention among the factors which control the rates of electron-transfer reactions of metalloporphyrins, since the redox properties of metalloporphyrins can be finely tuned by the addition of an external base ligand. Although there seems to be no need to accelerate further the electron-transfer reactions of metalloporphyrins, which are normally fast, the rates of electron transfer of some metalloporphyrins are known to be relatively slow because of the large reorganization energy associated with the electron transfer.[1] In this context, we have recently reported that the rates of metal-centered electron-transfer oxidation of $(OETPP)Fe^{III}(R)$ (OETPP = the dianion of octaethyltetraphenylporphyrin and R = σ-bonded axial ligand such as Ph), which has a saddle-shaped nonplanar porphyrin macrocycle, are much slower than those of $(OEP)Fe^{III}(R)$ (OEP = the dianion of octaethylporphyrin), which has a planar porphyrin macrocycle, and this can be associated with the large reorganization energies upon electron-transfer oxidation of the metal center of the nonplanar porphyrins.[2] It has also been shown that the slow electron transfer of a nonplanar iron(III) porphyrin is significantly accelerated by axial coordination of pyridine due to the decreased reorganization energy upon electron-transfer oxidation.[2] Such nonplanar conformations of porphyrins have been suggested as being related to their functions in biological systems.[3−8]

We report herein the effects of conformational distortions of the porphyrin ring on the electron-transfer kinetics for reduction of (P)MnCl, where P represents either the dianion of tetraphenylporphyrin (TPP), which is planar, or the dianion of dodecaphenylporphyrins (DPPX, X = H_{20}, $Cl_{12}H_8$, F_{20}) which are known to adopt a nonplanar conformation.[3,9−11] Manganese is an essential metal in several biological systems which are involved in electron-transfer reactions,[12] and extensive efforts have therefore been devoted to elucidating electron-transfer processes in synthetic manganese porphyrins.[13−18] The detailed kinetics for the electron-transfer reduction of (P)MnCl by the semiquinone radical anion ($Q^{\bullet -}$) in Equation (1) enables us to compare the reorganization energies λ for reduction of manganese porphyrins with a planar macrocycle, as in (TPP)MnCl, and a nonplanar macrocycle, as in (DPPX)MnCl.[19] We also report the acceleration in the rate of electron-transfer reduction of ($DPPH_{20}$)MnCl upon axial coordination of pyridine or DMSO, and this data should provide valuable insights into those factors which control the electron-transfer reactivities of metalloporphyrins.

Results and Discussion

Slow Electron-Transfer Reduction of Nonplanar Manganese Porphyrins

The one-electron reduction potentials (E^0_{red}) of (P)MnCl determined by the cyclic voltammetry (CV) measurements[16] are shown in Table 1.

Table 1. Rate constants (k_{et}) and free energy changes (ΔG^0_{et}) for electron-transfer reduction of (P)MnCl with semiquinone radical anion ($Q^{\bullet -}$) in deaerated MeCN or deaerated DMSO at 298 K, their one-electron reduction potentials (E^0_{red}, V vs. SCE) and electron self-exchange rate constants (k_{ex}) of (P)MnCl/[(P)MnCl]$^-$

(P)MnCl	E^0_{red} [a] [V]	ΔG^0_{et} [eV]	k_{et} [b] [M^{-1} s^{-1}]	k_{ex} [c] [M^{-1} s^{-1}]
(TPP)MnCl	−0.22[d]	−0.28	5.4×10^7	3.1×10^3
$(DPPH_{20})$MnCl	−0.36	−0.14	1.3×10^4	1.1×10^{-2}
$(DPPH_{20})$MnCl	−0.36	−0.22[e]	4.1×10^4	6.6×10^{-3}
$[(DPPH_{20})Mn(py)_2]Cl$	−0.41	−0.09	1.9×10^6	1.5×10^3
$[(DPPH_{20})Mn(py)_2]Cl$	−0.41	−0.17[e]	5.8×10^6	8.4×10^2
$[(DPPH_{20})Mn(DMSO)_2]Cl$	−0.40	−0.10	2.3×10^6	1.6×10^3
$(DPPCl_{12}H_8)$MnCl	−0.15	−0.35	8.6×10^4	3.5×10^{-4}
$(DPPF_{20})$MnCl	0.04	−0.54	2.0×10^5	4.3×10^{-6}

[a] Determined in PhCN unless otherwise noted, 0.1 M TBAP, scan rate = 0.1 V s^{-1}. See ref.[16] The experimental error is within ±0.005 V. – [b] The experimental error is within ±5%. – [c] Determined using Equations 3–5. – [d] Determined in MeCN, 0.1 M TBAP, scan rate = 0.1 V s^{-1}. – [e] Electron-transfer reduction by methyl-*p*-benzosemiquinone radical anion ($MeQ^{\bullet -}$).

The CV measurements on (TPP)MnCl were performed in both MeCN and PhCN. The E^0_{red} value in MeCN (−0.22 V) is essentially the same as that in PhCN (−0.23 V). In spite of the electron-withdrawing effect of the additional phenyl groups in $DPPH_{20}$, the E^0_{red} value of $(DPPH_{20})$MnCl (−0.36 V) is more negative than that of (TPP)MnCl (−0.22 V). This may be ascribed to the stronger Mn^{III}–N binding of the nonplanar conformation of the $DPPH_{20}$ ligand than the planar TPP ligand. Since the E^0_{red} value of $(DPPF_{20})$MnCl remained unchanged after addition of excess Cl^- (0.1 M), there should be no dissociation of Cl^- after reduction of Mn^{III} to Mn^{II}.

Semiquinone radical anions are employed as one-electron reductants whose oxidation potentials[20] are low enough to reduce each Mn^{III} porphyrin to its Mn^{II} form [Equation (1)]. These reducing agents were prepared by comproportionation of the *p*-benzoquinone derivatives with the corresponding hydroquinone dianions, which were generated by reaction of the hydroquinones with tetra-*n*-butylammonium hydroxide.[21] The rates of electron transfer from the semiquinone radical anion to (TPP)MnCl or (DPPX)MnCl were measured by monitoring the increase in absorbance of the Mn^{II} Soret band {e.g. at 488 nm for $[(DPPH_{20})Mn^{II}Cl]^-$ in Figure 1a} using a stopped-flow technique.

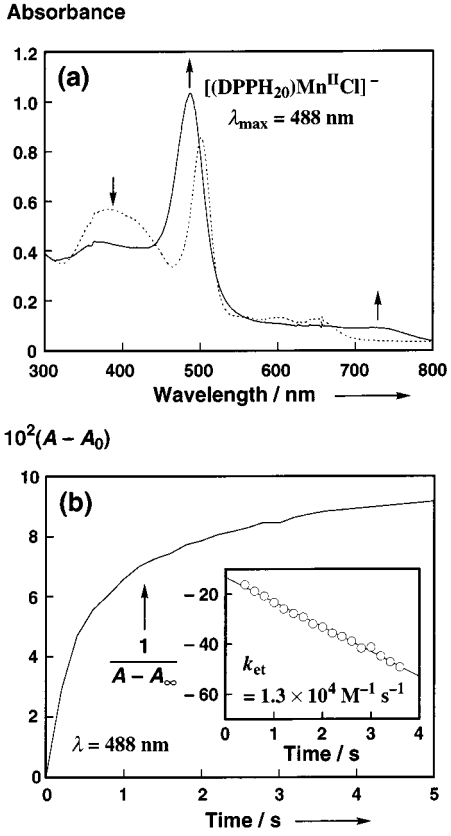

Figure 1. (a) Spectral changes upon addition of $Q^{\bullet -}$ (2.0×10^{-5} M) to a deaerated MeCN solution of $(DPPH_{20})$MnCl (2.0×10^{-5} M) at 298 K; (b) time course of the absorption change at 488 nm in the reaction of $(DPPH_{20})$MnCl (8.3×10^{-5} M) with $Q^{\bullet -}$ (8.3×10^{-5} M) in deaerated MeCN at 298 K; inset: the second-order plot

The electron-transfer rates obey second-order kinetics when the initial concentrations of (P)MnCl and the semiquinone radical anion are equal (Figure 1b). The observed second-order rate constants k_{et} of the electron-transfer reactions are listed in Table 1, which also lists the free-energy change of electron transfer from the semiquinone radical anion to (P)MnCl (ΔG^0_{et}). The ΔG^0_{et} values were calculated from the one-electron reduction potentials of (P)MnCl (E^0_{red}) and the one-electron oxidation potentials of the semiquinone radical anions (E^0_{ox}), which are equivalent to the one-electron reduction potentials of the corresponding quinones[20] by Equation (2), where F is the Faraday constant.

$$\Delta G^0_{et} = F(E^0_{ox} - E^0_{red}) \quad (2)$$

It was confirmed that the k_{et} value for electron transfer from the semiquinone radical anion ($Q^{\bullet-}$) to $(DPPF_{20})MnCl$ in the presence of 0.1 M tetrabutylammonium chloride (1.8×10^5 $M^{-1}\cdot s^{-1}$) is essentially the same as the k_{et} value in the absence of excess Cl^- (2.0×10^5 $M^{-1}\cdot s^{-1}$). This indicates that no dissociation of Cl^- is involved in the electron-transfer reduction of $(DPPF_{20})MnCl$.

The self-exchange rate constants (k_{ex}) of (P)MnCl/[(P)MnCl]$^-$ can be determined from k_{et} and the self-exchange rate constants (k_{ex}') of $Q^{\bullet-}$/Q by using the Marcus equations [Equation (3) and Equation (4)],[22] where K_{et} is the equilibrium constant for electron transfer, f is a correction factor (generally close to 1), and Z is the collision frequency, taken as 1×10^{11} $M^{-1}\cdot s^{-1}$. The self-exchange rate constants (k_{ex}') of $Q^{\bullet-}$/Q was previously determined as 8.1×10^7 $M^{-1}\cdot s^{-1}$ from the linewidth variation of the EPR spectrum of semiquinone radical anion ($Q^{\bullet-}$) in the presence of various concentrations of *p*-benzoquinone (Q) in PhCN at 298 K.[23] The K_{et} values are obtained from the ΔG^0_{et} values by using Equation (5). The k_{ex} values of (P)MnCl/[(P)MnCl]$^-$ thus obtained are listed in Table 1.

$$k_{ex} = k^2_{et}/(k_{ex}' K_{et} f) \quad (3)$$

$$\ln f = (\ln K_{et})^2/4[\ln(k_{ex}\, k_{ex}'/Z^2)] \quad (4)$$

$$K_{et} = \exp(-\Delta G^0_{et}/RT) \quad (5)$$

The k_{ex} values depend significantly on the type of porphyrin macrocycle and decrease in the order: (TPP)MnCl (3.1×10^3 $M^{-1}\cdot s^{-1}$) > $(DPPH_{20})MnCl$ (1.1×10^{-2} $M^{-1}\cdot s^{-1}$) > $(DPPCl_{12}H_8)MnCl$ (3.5×10^{-4} $M^{-1}\cdot s^{-1}$) > $(DPPF_{20})MnCl$ (4.3×10^{-6} $M^{-1}\cdot s^{-1}$). Hence, the electron-transfer rate at a given free energy change of electron transfer should also decrease in this order. This is clearly shown as the plots of lg k_{et} values vs. ΔG^0_{et} in Figure 2, which includes the data for other semiquinone radical anions used as reductants. The dependence of lg k_{et} on ΔG^0_{et} is given by Equation (6) which is derived from Equations 3−5.[22] The reorganization energy of electron transfer (λ) corresponds to the average of each component, λ_{11} for the electron self-exchange of Q/$Q^{\bullet-}$ and λ_{22} of (P)MnCl/[(P)MnCl]$^-$ [Equation (7)]. The fit of the curves to the Marcus theory of adiabatic outer-sphere electron transfer [Equation (6) and Equation (7)][22] indicates that the rate variations at a given ΔG^0_{et} value arise from the difference in the λ value given in Figure 2 and not from the nonadiabaticity.

$$\Delta G^{\ddagger} = (\lambda/4)(1 + \Delta G^0_{et}/\lambda)^2 \quad (6)$$

$$\lambda = (\lambda_{11} + \lambda_{22})/2 \quad (7)$$

The significantly small k_{ex} value of $(DPPF_{20})MnCl$ (4.3×10^{-6} $M^{-1}\cdot s^{-1}$) as compared with that of (TPP)MnCl (3.1×10^3 $M^{-1}\cdot s^{-1}$) may be related to differences in the conformation of the porphyrin macrocycles. The crystal structure of $(DPPF_{20})MnCl$ reveals a nonplanar conformation of the macrocycle because of peripheral congestion of the porphyrin.[16] The Mn^{III} center is located inside the curved

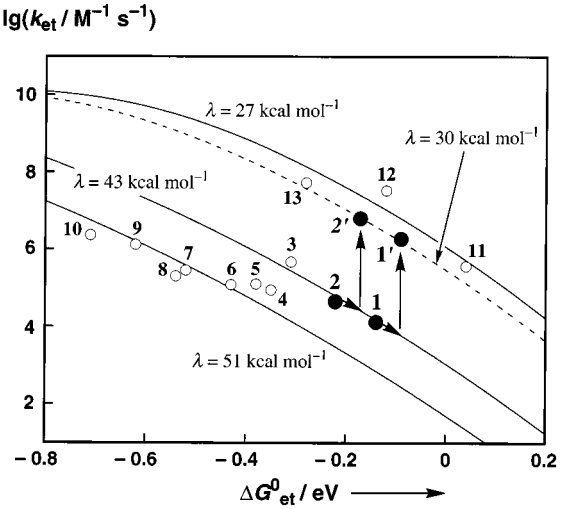

Figure 2. Dependence of lg k_{et} on ΔG^0_{et} for the electron-transfer reductions of the (P)MnCl derivatives by semiquinone radical anions in deaerated MeCN at 298 K; the numbers refer to the system: **1**: $(DPPH_{20})MnCl/Q^{\bullet-}$; **1′**: $[(DPPH_{20})Mn(py)_2]^+/Q^{\bullet-}$; **2**: $(DPPH_{20})MnCl/MeQ^{\bullet-}$; **2′**: $[(DPPH_{20})Mn(py)_2]^+/MeQ^{\bullet-}$; **3**: $(DPPH_{20})MnCl/2,6\text{-}Me_2Q^{\bullet-}$; **4**: $(DPPCl_{12}H_8)MnCl/Q^{\bullet-}$; **5**: $(DPPF_{20})MnCl/ClQ^{\bullet-}$; **6**: $(DPPCl_{12}H_8)MnCl/MeQ^{\bullet-}$; **7**: $(DPPCl_{12}H_8)MnCl/2,6\text{-}Me_2Q^{\bullet-}$; **8**: $(DPPF_{20})MnCl/Q^{\bullet-}$; **9**: $(DPPF_{20})MnCl/Q^{\bullet-}$; **10**: $(DPPF_{20})MnCl/Q^{\bullet-}$; **11**: (TPP)MnCl/2,5-$Cl_2Q^{\bullet-}$; **12**: (TPP)MnCl/$ClQ^{\bullet-}$; **13**: (TPP)MnCl/$Q^{\bullet-}$; 2,6-$Me_2Q$ = 2,6-dimethyl-*p*-benzoquinone, MeQ = methyl-*p*-benzoquinone, Q = *p*-benzoquinone, ClQ = chloro-*p*-benzoquinone, 2,5-Cl_2Q = 2,5-dichloro-*p*-benzoquinone; the solid and dashed lines are drawn based on the Marcus theory of electron transfer [Equation (6)and Equation (7)] using the λ values shown in the figure (see text)

surface of the nonplanar porphyrin macrocycle with a Mn^{III}−N distance of 1.99(1) Å.[16a] The strong binding of Mn^{III} to the nonplanar porphyrin causes a major bond-reorganization on the reduction of Mn^{III} to Mn^{II} and this is accompanied by a metal out-of-plane displacement since an electron is added to the $d_{x^2-y^2}$ orbital which directly interacts with the pyrrole nitrogen orbitals. Hence, the greater the nonplanarity of the porphyrin ligand, the stronger seems to be the binding of Mn^{III} to the ligand, the larger is the reorganization energy of the electron-transfer reduction and the smaller is the k_{ex} value, as was experimentally observed in the present study.

Effects of Axial Coordination on Electron Transfer

The slow electron-transfer reduction of nonplanar manganese porphyrins can be accelerated by axial coordination of a base since the addition of a nitrogenous base such as pyridine (py) to five-coordinate metalloporphyrins often results in substantial changes in the redox reactivities.[1,2,24,25] The addition of pyridine to an MeCN solution of $(DPPH_{20})MnCl$ results in a significant change in the UV/vis spectrum, as shown in Figure 3.

These changes can be analyzed by Equation (8), which is derived by assuming that *n* molecules of pyridine coordinate to $(DPPH_{20})MnCl$.

$$\lg[(A_0 - A)/(A - A_\infty)] = n\lg[py] + \lg K \quad (8)$$

In this Equation A_0 is the absorbance of $(DPPH_{20})MnCl$ in the absence of pyridine, A_∞ is the absorbance of the fully

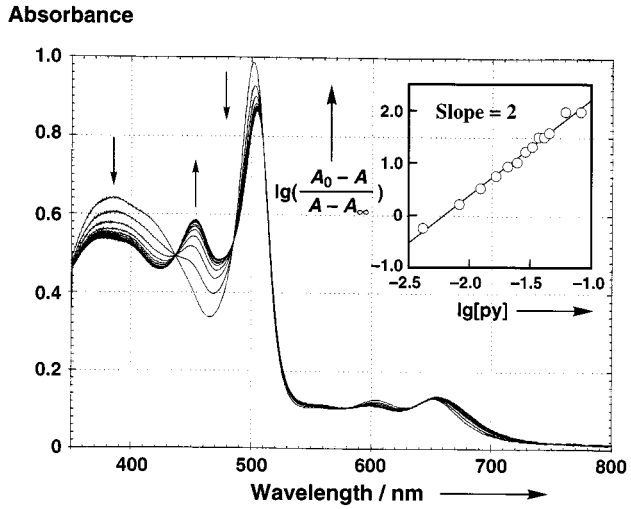

Figure 3. Spectral changes upon addition of py (4.1×10^{-3} M, each) to a deaerated MeCN solution of $(DPPH_{20})Mn^{III}Cl$ (1.8×10^{-5} M) at 298 K; inset: plot of $\lg[(A_0 - A)/(A - A_\infty)]$ vs. lg[py]; A_0, A, A_∞: absorbance at 452 nm

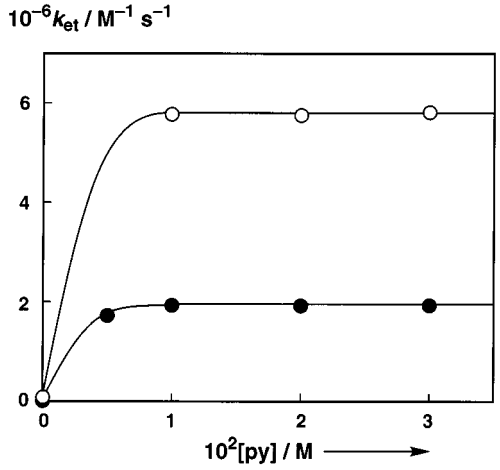
formed complex with pyridine, A is the absorbance of the equilibrium mixture, and K is the formation constant. The slope, n, in such plot gives the number of molecules of pyridine coordinated. The plot of $\lg[(A_0 - A)/(A - A_\infty)]$ vs. lg[py] (inset in Figure 3) indicates that two molecules of pyridine coordinate to $(DPPH_{20})MnCl$ to form the six coordinate complex $[(DPPH_{20})Mn(py)_2]^+$ (λ_{max} = 477 nm) and a lg$K$ value of 4.0 is calculated under the given experimental conditions [Equation (9)].

$$(DPPH_{20})Mn^{III}Cl + 2py \overset{K}{\rightleftharpoons} [(DPPH_{20})Mn^{III}(py)_2]Cl \quad (9)$$

The addition of pyridine to the $(DPPH_{20})MnCl$/reductant system results in a significant increase in the rate of electron transfer from the reductant to $(DPPH_{20})MnCl$. Most electron-transfer rates of (DPPX)MnCl in the presence of pyridine were so rapid so as to fall outside the stopped-flow range. Thus, the least reactive systems in Table 1, i.e. the $(DPPH_{20})MnCl/Q^{\bullet-}$ and $(DPPH_{20})MnCl/MeQ^{\bullet-}$ systems were chosen to determine the effect of pyridine on the electron-transfer rate. The electron-transfer rate constant k_{et} increases with an increase in the pyridine concentration to reach a constant value as shown in Figure 4.

The acceleration of the rate of electron transfer by the binding of pyridine may be ascribed to the much faster electron-transfer rate-constant for the six-coordinate complex ($k_{et(6)}$), $[(DPPH_{20})Mn(py)_2]^+$, than that for the five-coordinate complex ($k_{et(5)}$), $(DPPH_{20})MnCl$, as shown in Scheme 1. The $k_{et(6)}$ value for electron transfer from $Q^{\bullet-}$ to $[(DPPH_{20})Mn(py)_2]^+$ of 1.9×10^6 $M^{-1}\cdot s^{-1}$ was determined from the constant value in Figure 4 and is two orders of magnitude larger than the $k_{et(5)}$ value (1.3×10^4 $M^{-1}\cdot s^{-1}$) as shown in Table 1. Similarly, the $k_{et(6)}$ value for electron transfer from $MeQ^{\bullet-}$ to $[(DPPH_{20})Mn(py)_2]^+$ was determined from the data in Figure 4 to be 5.8×10^6 $M^{-1}\cdot s^{-1}$, which is also two orders of magnitude larger than the $k_{et(5)}$ value (4.1×10^4 $M^{-1}\cdot s^{-1}$).



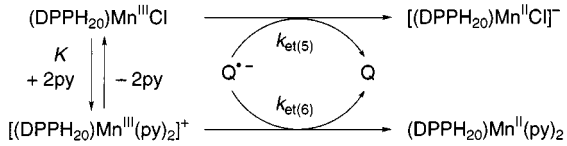


Figure 4. Plot of k_{et} vs. [py] for the electron transfer from $Q^{\bullet-}$ (filled circles; 9.1×10^{-6} M) or $MeQ^{\bullet-}$ (open circles; 9.1×10^{-6} M) to $(DPPH_{20})MnCl$ (9.1×10^{-6} M) in the presence of py in deaerated MeCN at 298 K

Scheme 1. Base-catalyzed electron transfer

The one-electron reduction potential might be expected to shift in a negative direction by the axial ligand coordination of pyridine when the electron-transfer reduction becomes energetically less favorable. However, the reduction of $[(DPPH_{20})Mn(py)_2]^+$ occurs at $E^0_{red} = -0.41$ V vs. SCE which is only slightly more negative than the E^0_{red} value (−0.36 V) of the five-coordinate complex $(DPPH_{20})MnCl$ (Table 1). Such a small negative shift of the reduction potential by coordination of pyridine cannot account for the large acceleration in the rate of electron transfer for the six-coordinate complex as compared to the five coordinate complex, as shown by the arrows along the curve with a constant λ value in Figure 2. Thus, the acceleration in the rate of electron transfer upon axial coordination of pyridine results from a significant decrease in the reorganization energy associated with the electron-transfer reduction of $[(DPPH_{20})Mn(py)_2]^+$. This is shown by the vertical arrows in Figure 2 where the dependence of k_{et} for the electron-transfer reduction of $[(DPPH_{20})Mn(py)_2]^+$, using a λ value of 30 kcal mol^{-1}, is given by the dashed line. The λ value becomes close to the value for the planar porphyrin (27 $kcal\cdot mol^{-1}$ for TPPMnCl). The acceleration effect of pyridine on the rates of electron transfer for the other (DPPX)MnCl complexes could not be determined quantitatively because of the fast electron-transfer rates for $[(DPPX)Mn(py)_2]^+$ which are beyond the detection limit of a stopped-flow technique, but such a rate-acceleration effect of pyridine indicates a significant decrease in the reorganization energy upon the axial ligand-coordination of the base. The k_{ex} values of $[(DPPH_{20})Mn(py)_2]^+$ (1.5×10^3 $M^{-1}\cdot s^{-1}$) determined from the k_{et} value using Equation (3)

and Equation (4) is five orders of magnitude larger than that of $(DPPH_{20})MnCl$ (Table 1).

We have also examined the rates of electron-transfer reduction of $(DPPH_{20})MnCl$ by $Q^{\bullet-}$ in deaerated DMSO. The UV/vis spectrum of the Mn^{III} complex in DMSO is similar to that in pyridine, suggesting that the six-coordinate complex $[(DPPH_{20})Mn(DMSO)_2]^+$ (λ_{max} = 480 nm) is formed in DMSO. The rate of electron-transfer from $Q^{\bullet-}$ to the Mn^{III} complex in DMSO was determined to be 2.3×10^6 $M^{-1}\cdot s^{-1}$, which is essentially the same as that of $[(DPPH_{20})Mn(py)_2]^+$ (1.9×10^6 $M^{-1}\cdot s^{-1}$). Addition of one mol of pyridine to a deaerated DMSO solution of Mn^{III} complex resulted in little acceleration of the electron-transfer reduction of the Mn^{III} complex by $Q^{\bullet-}$ (2.7×10^6 $M^{-1}\cdot s^{-1}$). These results indicate that the rates of electron-transfer reduction of the six-coordinate Mn^{III} porphyrins are much faster than those of the five-coordinate Mn^{III} porphyrins because of the smaller reorganization energies in the six-coordinate complex upon electron transfer than the five-coordinate complex, as observed in the case of the electron-transfer oxidation of (OETPP)Fe(R).[2]

Experimental Section

Materials: The synthesis and characterization of (P)MnCl (P = TPP or DPPX where X = H_{20}, $C_{12}H_8$ or F_{20}) have been reported in the literature.[16,19] *p*-Benzoquinone derivatives (2,6-Me_2Q: 2,6-dimethyl-*p*-benzoquinone; MeQ: methyl-*p*-benzoquinone; Q: *p*-benzoquinone; ClQ: chloro-*p*-benzoquinone; 2,5-Cl_2Q: 2,5-dichloro-*p*-benzoquinone) as well as the corresponding hydroquinones were purchased from Tokyo Chemical Industry Co., Ltd., and recrystallized from ethanol prior to use. Tetra-*n*-butylammonium hydroxide (TBAOH: 1.0 M in methanol) was purchased from Aldrich and used as received. Acetonitrile (MeCN) and benzonitrile (PhCN) were purchased from Wako Pure Chemical Ind. Ltd., and purified by successive distillation over CaH_2 and P_2O_5 according to standard procedures.[26] Tetra-*n*-butylammonium perchlorate (TBAP) was purchased from Sigma Chemical Co., recrystallized from ethanol, and dried under vacuum at 40 °C prior to use.

Spectral and Kinetic Measurements: Typically, a 3.0 μL aliquot of semiquinone radical anion ($Q^{\bullet-}$: 0.02 M) in MeCN was prepared by comproportionation between *p*-benzoquinone (Q: 0.01 M) and hydroquinone (QH_2: 0.01 M) in the presence of 0.02 M TBAOH[21] and then added to a quartz cuvette (10 mm i.d.) which contained $(DPPH_{20})MnCl$ (2.0×10^{-5} M) in deaerated MeCN (3.0 mL). This led to an electron transfer from $Q^{\bullet-}$ to $(DPPH_{20})MnCl$. The UV/visible spectral changes associated with this electron transfer were monitored with the use of a Hewlett Packard 8453 diode array spectrophotometer. The same procedure was used to follow reactions of other manganese porphyrins. The binding of pyridine or DMSO to $(DPPH_{20})MnCl$ in MeCN was monitored by measuring the UV/vis spectral changes as a function of the ligand concentration. All measurements were carried out in a dark cell compartment using deaerated conditions. It was confirmed that the monitoring light did not affect the thermal rates.

Kinetic measurements for electron transfer from $Q^{\bullet-}$ to (P)MnCl were carried out using a Union RA-103 stopped-flow spectrophotometer under deaerated conditions. Typically, deaerated MeCN solutions of (P)MnCl and $Q^{\bullet-}$ were transferred to the spectrophotometric cell by means of a glass syringe which had earlier been purged with a stream of argon. The rates of the electron transfer (k_{et}) were followed by monitoring an increase in the absorbance due to the reduced porphyrin product, $[(P)MnCl]^-$ (e.g. at 488 nm for $[(DPPH_{20})MnCl]^-$), under second-order conditions where the initial concentrations of (P)MnCl and $Q^{\bullet-}$ are the same. In each case, it was confirmed that the k_{et} values derived from at least five independent measurements which agreed within an experimental error of ±5%. Second-order rate constants were determined by a least-squares curve fit using a Macintosh personal computer. The second-order plots of $(A_\infty - A)^{-1}$ vs. time (A_∞ and A are the final absorbance and the absorbance at the reaction time, respectively) were linear for three or more half-lives with the correlation coefficient, $\rho > 0.999$.

Cyclic Voltammetry: The redox potentials of (P)MnCl in PhCN or MeCN containing 0.1 M TBAP as supporting electrolyte were determined at room temperature by cyclic voltammetry under deaerated conditions using a three electrode system and a BAS 100B electrochemical analyzer. The working and counter electrodes were platinum while $Ag/AgNO_3$ (0.01 M) was used as the reference electrode. All potentials are reported as V vs. SCE. The $E_{1/2}$ value of ferrocene used as a standard is approximately 0.37 V vs. SCE in PhCN or MeCN under our solution conditions.[27]

Substitution Behaviour of an Alkylcobaltamine Complex − Evidence for a Limiting Dissociative Mechanism

Carlos Dücker-Benfer,[a] Mohamed S. A. Hamza,[a][+] Conrad Eckhardt,[a] and Rudi van Eldik*[a]

Keywords: Cobalt / High-pressure chemistry / Kinetics / Isomerization / Amine complexes

The substitution behaviour of pentaamminemethylcobalt(III) with ethylenediamine (en) was studied in detail in aqueous ammonia solution. The displacement of four ammonia ligands by two ethylenediamine (en) chelates was followed by a subsequent slow *cis* to *trans* rearrangement of the bis(ethylenediamine)(amine)methyl complex. The dependence of the substitution reaction on [en], [NH_3], temperature and pressure was studied, and the observed kinetic traces could be fitted to the sum of two exponentials. The rate law for both reaction steps showed saturation kinetics with respect to [en] and [NH_3], and the activation parameters confirmed the operation of a limiting dissociative reaction mechanism under all conditions. For the first substitution reaction, $k_{sat.}(en)_{10\ °C}$ = 1.8 ± 0.4 s^{-1}, $k_{sat.}(NH_3)_{10\ °C}$ = 1.7 ± 0.3 s^{-1} and $\Delta V^{\#}_{15\ °C}$ = +14 ± 1 $cm^3 \cdot mol^{-1}$, for the second substitution reaction, $k_{sat.}(en)_{10\ °C}$ = 0.55 ± 0.12 s^{-1}, $k_{sat.}(NH_3)_{10\ °C}$ = 0.58 ± 0.10 s^{-1} and $\Delta V^{\#}_{15\ °C}$ = +24 ± 1 $cm^3 \cdot mol^{-1}$. The subsequent isomerization reaction was also studied in detail, and a complete set of activation parameters confirm the operation of a dissociative mechanism for the *cis* to *trans* rearrangement for which $k_{iso25\ °C}$ = (1.48 ± 0.07) × 10^{-3} s^{-1}; $\Delta H^{\#}$ = 115 ± 5 $kJ \cdot mol^{-1}$; $\Delta S^{\#}$ = + 86 ± 16 $J \cdot K^{-1} \cdot mol^{-1}$and $\Delta V^{\#}$ = +14.2 ± 0.6 $cm^3 \cdot mol^{-1}$.

Introduction

The lability and substitution mechanism of Co^{III} complexes can largely be controlled by the nature of spectator ligands. In terms of a classical example involving complex-formation reactions of $[Co(NH_3)_5H_2O]^{3+}$, displacement of the four in-plane coordinated ammonia ligands by a porphyrin macrocycle, results in a large increase in lability of the coordinated solvent molecule in the axial position *trans* to the remaining amine ligand.[1] Such a modification not only enhances the lability of coordinated water, but also causes a changeover in the ligand substitution mechanism from a dissociative interchange (I_d) to a limiting dissociative (D) mechanism. Similarly, the introduction of a strong σ-donor ligand, such as a methyl group, *trans* to the coordinated solvent molecule is also expected to cause a significant increase in lability, and maybe even a changeover in substitution mechanism. [2−7]

Such effects have been observed in the past for model Rh^{III} complexes of the type *trans*-$[Rh(dmg)_2(R)(L)]$ (dmg = dimethylglyoximate; R = Me, CH_2Cl, CH_2CF_3; L = H_2O), which exhibit different substitution rates and substitution mechanisms depending on the σ-donor properties of R.[3] The introduction of several metal−carbon bonds through a ligand such as Cp* (pentamethylcyclopentadienyl) on aquated Rh^{III} not only causes an increase in the water exchange rate constant for $[Rh(Cp^*)(H_2O)_3]^{2+}$ by 11 orders of magnitude relative to $[Rh(H_2O)_6]^{3+}$, but also a changeover from an I_a water exchange mechanism for the hexaqua ion to an I_d mechanism for the Cp* complex, as supported by the significantly different volumes of activation reported for the water exchange reactions.[2,8]

Cobalt complexes with a metal−carbon σ-bond can mimic the reactivity and mechanistic behaviour of B_{12} coenzymes. Compounds that have been studied include *trans*-$[Co(dmg)_2(R)(L)]$ (R = CH_3, *i*-C_3H_7, 5′-deoxyadenosyl; L = NH_3, pyridine (py), 2-NH_2py, 5,6-dimethylbenzimidazole, MeOH, Me_2S, etc.) and many Schiff base complexes.[4,5,7,9−26] The simplest model for the B_{12} coenzyme was recently synthesized by Kofod and consists of a Co^{III} metal centre surrounded by five ammonia ligands and one methyl group.[27] The X-ray structure shows a large increase in the length of the Co−N bond *trans* to the metal−carbon bond compared to those of the equatorial positions.[28] An interesting question is to what extent the introduction of a single metal−carbon σ-bond affects the substitution behaviour of this Co^{III} complex.

We have undertaken a detailed kinetic study of the reaction of $[Co(NH_3)_5(CH_3)]^{2+}$ with ethylenediamine (en), and could identify the rapid stepwise formation of *cis*-$[Co(en)_2(NH_3)(CH_3)]^{2+}$ and the subsequent slower isomerization to the stable *trans*-$[Co(en)_2(NH_3)(CH_3)]^{2+}$ complex. All rate and activation parameters could be resolved and strongly support the operation of a limiting dissociative (D) mechanism for all reaction steps.

Results and Discussion

Preliminary Observations

The pentaamminemethyl complex is stable in solution only in the presence of a large excess of NH_3 (>3 M). In less concentrated ammonia, the complex undergoes slow decomposition due to hydrolysis and Co−C bond breakage, accompanied by the formation of the hexaammine complex and Co^{III} hydroxides. It was also observed that the pentaamminemethyl complex is sensitive to light and easily undergoes a photo-induced cleavage of the Co−C bond.

Experiments with monodentate ligands such as thiourea and derivatives, various substituted amines and thiocyanate, did not show significant spectral changes under the selected conditions, indicating that only weak complex formation occurred with these nucleophiles in the presence of the high concentration of ammonia. This is most probably due to the strong *trans* labilizing effect of the cobalt−carbon bond and the competition with the excess ammonia in solution. The reaction with cyanide leading to the formation of $[Co(CN)_5(CH_3)]^{3-}$ was recently reported by Kofod,[28] but the reaction was not studied kinetically. We therefore employed bidentate ligands that would lead to thermodynamically more stable products as a result of the chelate effect. Preliminary experiments were successful with bipyridine, phenanthroline or ethylenediamine (en). Of these, only en was soluble enough in water to perform kinetic measurements under pseudo-first-order conditions.

Important to note is that the pH had to be higher than 9.3, the pK_a of NH_4^+. At lower pH, protonation of ammonia reduces its coordination ability and therefore the stability of the complex. A pH of ca. 11 proved to be most convenient, since ethylenediamine then acts simultaneously as a nucleophile and as a buffer.

Application of the rapid scan technique revealed an increase in absorbance between 250 and 620 nm (Figure 1), and absorbance−time plots at several wavelengths exhibited good fits for the sum of two exponentials. Following this fast reaction, a slow subsequent step could be observed which then led to the final UV/Vis spectrum of *trans*-$[Co(en)_2(NH_3)(CH_3)]^{2+}$ (see Figure 2). Important to note is that in the presence of a high NH_3 concentration in solution, the formation of the amine complex was observed in the UV/Vis spectra, but when the NH_3 concentration was systematically decreased, the shoulder around 300 nm, which was assigned to the *trans*-amine complex,[28] disappeared. The final spectrum of the slower reaction at low $[NH_3]$ was identical to that of the *trans*-$[Co(en)_2(H_2O)(CH_3)]^{2+}$.[28] Only at high $[NH_3]$ (ca. 3 M) can the equilibrium be shifted to form the *trans* amine complex. This finding clearly demonstrates the high degree of *trans*-labilization caused by the methyl group at this position. The observed spectral changes (Figure 2) can be explained in terms of the *cis* to *trans* isomerization of $[Co(en)_2(NH_3)(CH_3)]^{2+}$, which followed the fast ligand-substitution reactions.

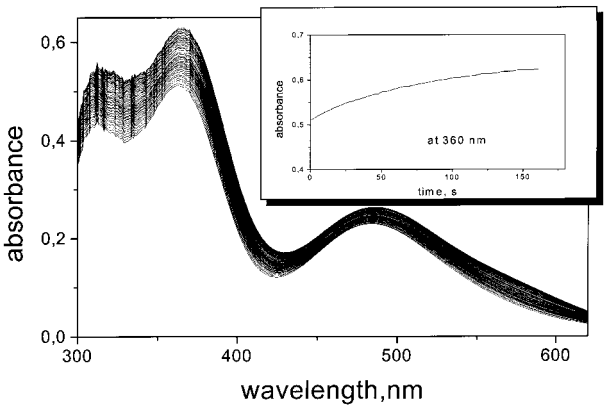

Figure 1. Repetitive-scan spectra for the reaction of $[Co(NH_3)_5(CH_3)]^{2+}$ with ethylenediamine; conditions: $[Co^{III}]$ = 2.5 mM, [en] = 0.2 M, $[NH_3]$ = 0.3 M, integration time for each spectrum 20 ms, total time 163.8 s, time between two spectra 2.64 and 4.64 s (two time bases), pH = 11 (not buffered); inset: the absorbance vs. time trace at 360 nm at room temperature

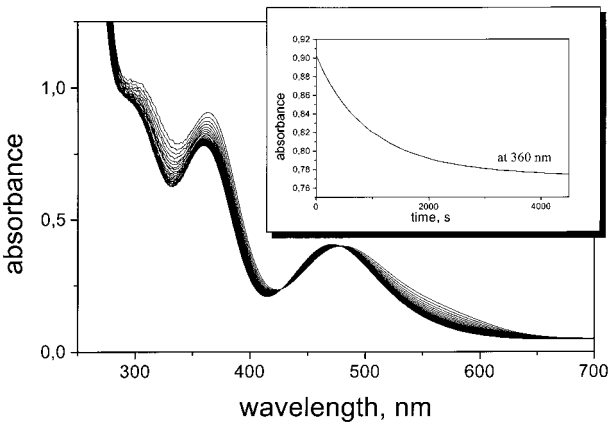

Figure 2. Repetitive-scan spectra recorded for the *cis* to *trans* isomerization of $[Co(en)_2(NH_3)(CH_3)]^{2+}$; conditions: [en] = 0.2 M, $[NH_3]$ = 0.3 M, 20.0 °C, time between two spectra 120 s, total time 38 min, pH ≈ 11(not buffered); inset: the absorbance vs. time trace at 360 nm

Ligand Substitution Mechanism

A study of the ethylenediamine concentration dependence of the fast reactions at a fixed 3 M ammonia concentration, revealed a decrease in k_{obs} for both reaction steps with increasing [en] as shown in Figure 3. Limiting rate constants of 1.8 ± 0.4 and 0.55 ± 0.12 s^{-1} at 10 °C were found for the first and second reaction steps, respectively, at high ethylenediamine concentrations. Under these conditions ([en] = 0.9 M) the effect of the ammonia concentration on the observed rate constants was studied (see Figure 4), and the values of $k_{obs(1)}$ again decreased with increasing $[NH_3]$ to reach a limiting value of 1.7 ± 0.3 s^{-1} (at 10 °C) at high ammonia concentration. The value of $k_{obs(2)}$ remains practically constant over the selected concentration range with a value of 0.58 ± 0.10 s^{-1} at high ammonia concentration. These limiting values are in excellent agreement with those reported for the dependence on [en] in Figure 3. At low

$[NH_3]$, the kinetic traces can only be fitted with a single exponential and no value for $k_{obs(2)}$ could be determined.

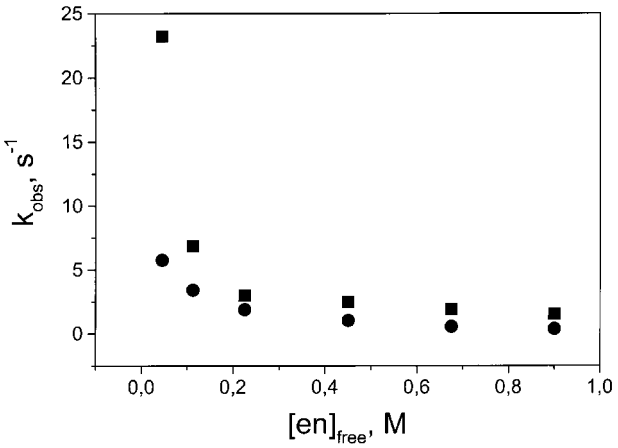

Figure 3. Plot of the observed rate constant (k_{obs}) vs. [en] at a constant $[NH_3]$ of 3 M at 10 °C, pH = 11, I = 0.5 M (NO_3^- medium); the filled squares are for the first ($k_{obs(1)}$) and the filled circles for the second ($k_{obs(2)}$) substitution reactions, respectively; $[en]_{free}$ is given as total [en] − $[enH^+]$

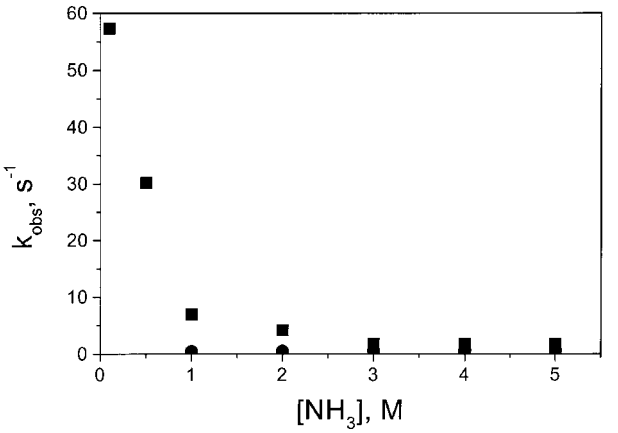

Figure 4. Plot of the observed rate constant (k_{obs}) vs. $[NH_3]$ at a constant [en] of 2 M at 10 °C, pH = 11, I = 0.5 M (NO_3^- medium); the filled squares are for the first ($k_{obs(1)}$) and the filled circles for the second ($k_{obs(2)}$) substitution reactions, respectively; $[NH_3]$ is given as total concentration

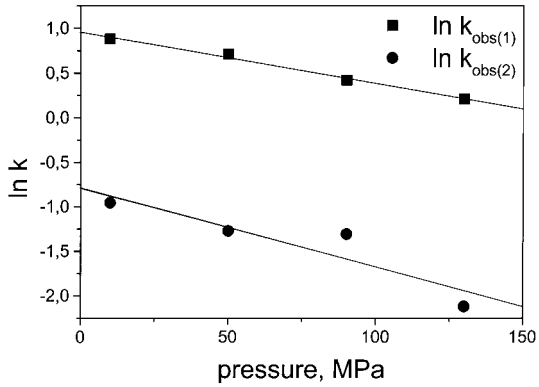
The temperature dependence of the reactions was measured under limiting concentration conditions, i.e. high concentrations of en and NH_3, over a rather limited temperature range due to the high ammonia concentration present in solution. The activation parameters could not be determined accurately and are therefore not reported. The pressure dependence of the reactions was measured under similar conditions and the results are summarized in Figure 5. Both $k_{obs(1)}$ and $k_{obs(2)}$ decrease significantly with increasing pressure. All rate and activation parameters are summarized in Table 1. The observed concentration dependences, as well as the reported activation volumes, strongly support the operation of a dissociative mechanism for both subsequent ligand-substitution processes. The unusual dependence of k_{obs} on $[NH_3]$ and [en] was also found by Malin et al. and Henderson et al. for substitution reactions of iron complexes, and a dissociative character was proposed for the mechanisms.1[29−31]



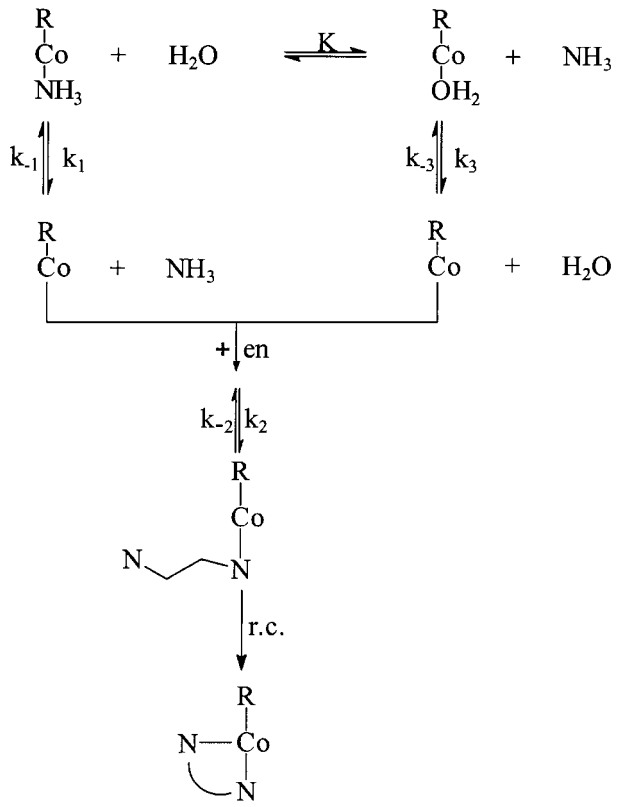


Figure 5. Pressure dependence of the observed rate constants for the two complex formation reactions $[Co(NH_3)_5(CH_3)]^{2+}$ with ethylenediamine, measured under limiting concentration conditions; conditions: [en] = 0.9 M, $[NH_3]$ = 3 M, temp. 15 °C, pH = 11, I = 0.5 M (NO_3^- medium)

Scheme 1

The first substitution reaction can be described by the mechanism outlined in Scheme 1.

As mentioned in the introduction, it is generally accepted that the metal−carbon bond in $[Co(NH_3)_5(CH_3)]^{2+}$ will induce a significant *trans*-labilization effect and cause a rapid spontaneous aquation reaction. The aquation equilibrium will be controlled by the concentration of ammonia in solution, for which the overall equilibrium constant can be ex-

Table 1. Rate and activation parameters for the reaction of $[Co(NH_3)_5(CH_3)]^{2+}$ with ethylenediamine (en) in ammonia solution

	k ($\times 10^3$) [s^{-1}]	$k_{sat}(NH_3)$[a] [s^{-1}]	$k_{sat}(en)$[a] [s^{-1}]	$\Delta H^{\#}$ [$kJ \cdot mol^{-1}$]	$\Delta S^{\#}$ [$J \cdot mol^{-1}K^{-1}$]	$\Delta V^{\#}_{15\,°C}$ [$cm^3 \cdot mol^{-1}$]
k_1	–	1.7 ± 0.3	1.8 ± 0.4	–	–	+14 ± 1
k'_1	–	0.58 ± 0.10	0.55 ± 0.12	–	–	+24 ± 1
k_{iso}[b]	1.48 ± 0.07	–	–	115 ± 5	+86 ± 16	+14.2 ± 0.6

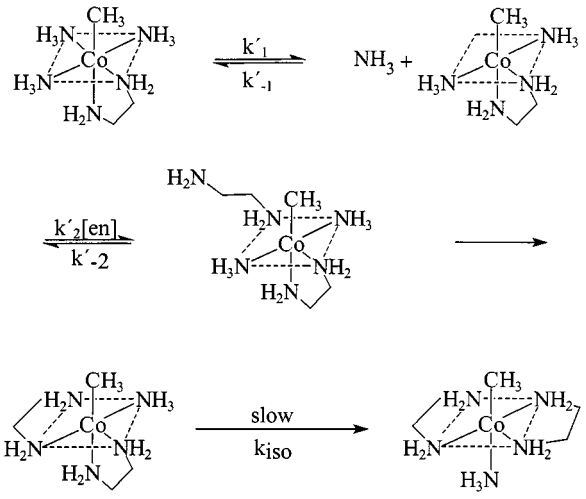
[a] k_{sat} was measured under limiting conditions, i.e. for $k_{sat}(NH_3)$, $[NH_3]$ = 5 M and [en] = 2 M; for k_{sat}(en), $[NH_3]$ = 3 M and [en] = 2 M at 10 °C; pH = 11, I = 0.5 M (NO_3^- medium). – [b] k_{iso} was measured at 25 °C in nonbuffered solution.

pressed by $K = [Co-H_2O][NH_3]/[Co-NH_3]$. It has been suggested that this equilibration involves the five-coordinate $[Co(NH_3)_4(CH_3)]^{2+}$ species, which can react with either water or ammonia in the absence of another nucleophile. In the presence of ethylenediamine, the five-coordinate intermediate can be scavenged by en to form the 1:1 *trans*-$[Co(NH_3)_4(en)(CH_3)]^{2+}$ product species. This species is stabilized by a ring-closure reaction of ethylenediamine, accompanied by the loss of an amine ligand. The operation of a limiting D mechanism was also supported by the presence of five-coordinate species that are stabilized by the Co–C bond among the Co^{III} complexes of bis(salicylaldehyde)ethylenediamine and bis(acetylacetonato)ethylenediamine prepared by Costa and co-workers [9,32,33] and among the Co^{III} porphyrin pentacoordinated complexes.[34] Application of steady-state conditions to the five-coordinate intermediate $[Co(NH_3)_4(CH_3)]^{2+}$, results in the following expression for k_{obs}, where $f_{Co-NH3} = [NH_3]/(K+[NH_3])$ and $f_{Co-H2O} = K/(K+[NH_3])$.

$$k_{obs} = \frac{k_1 k_2 f_{Co-NH_3}[en] + k_3 k_2 f_{Co-H_2O}[en] + k_{-1} k_{-2}[NH_3] + k_{-2} k_{-3}[H_2O]}{k_{-1}[NH_3] + k_{-3}[H_2O] + k_2[en]}$$

This rate law can account for the decrease in k_{obs} with increasing $[NH_3]$ and [en].[29–31] The [en] dependence in Figure 3 was studied at a fixed and high $[NH_3]$, under which conditions this equation simplifies to

$$k_{obs} = \frac{k_1 k_2 f_{Co-NH_3}[en] + k_3 k_2 f_{Co-H_2O}[en] + k_a}{k_b + k_2[en]}$$

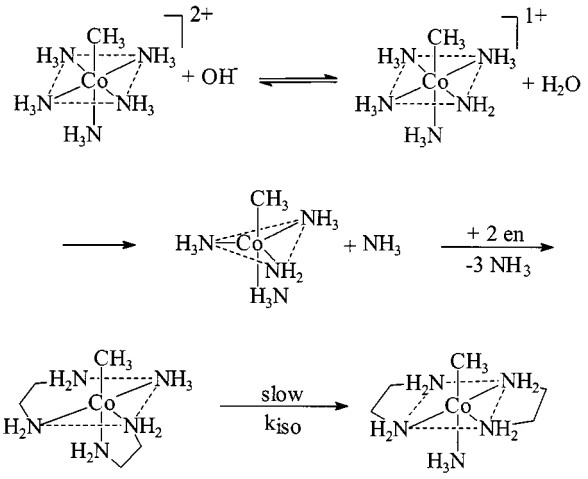


and reaches the limiting value

$$k_{obs} = k_1 f_{Co-NH_3} + k_3 f_{Co-H_2O} = \frac{k_1[NH_3] + k_3 K}{K + [NH_3]}$$

at high [en]. At high $[NH_3]$, this expression simplifies to $k_{obs} = k_1$. Furthermore, this expression can also account for the $[NH_3]$ dependence studied at high [en] (see Figure 4), from which the limiting rate constant found at high $[NH_3]$ must again be k_1. Thus under limiting conditions of high $[NH_3]$ and [en], the rate-determining step involves the dissociation of NH_3 from $[Co(NH_3)_5(CH_3)]^{2+}$. This accounts for the decrease in k_{obs} with increasing $[NH_3]$, since the aqua complex is expected to be much more labile than the corresponding amine complex. Extrapolation to $[NH_3] = 0$ results in $k_{obs} = k_3 \geq 60\ s^{-1}$, i.e. at least 50 times larger than k_1.

It follows that the suggested reaction mechanism and the given rate law can, in a qualitative way, account for the observed concentration dependences and the limiting rate constants reached at high NH_3 and en concentrations. A detailed fit of the data is limited by the complexity of the rate law. The activation parameters in Table 1 determined under limiting concentration conditions also support the dissociative nature of the substitution process.



The subsequent formation of the 1:2 complex *cis*-$[Co(en)_2(NH_3)(CH_3)]^{2+}$ is about three to five times slower than the formation of the 1:1 complex, and it was more difficult to extract accurate data from the kinetic traces. The overall observed trends are very similar to those of the first substitution process, and we therefore suggest a similar mechanism for the attack of the second en ligand. This reaction must involve the displacement of a *cis* ligand, i.e. one of the three remaining amine ligands, since the *trans* position is occupied by en. The *cis*-labilization effect of the methyl group is expected to be much smaller, and therefore also the release of NH_3 in this position should also be slower than in the first reaction. The weaker labilization may also account for the absence of a clear $[NH_3]$ dependence, i.e. a lower $[NH_3]$ is still sufficient to stabilize the amine complex such that the equilibration with the aqua complex (see Scheme 1) does not have to be included in this case. The reaction steps can be summarized as shown in Scheme 2, from which it follows that k'_1 will be the rate-determining step under limiting [en] conditions and repre-

Scheme 2

sents the dissociation of an equatorial amine ligand. The five-coordinate intermediate rapidly reacts with a second en ligand, followed by a ring-closure reaction to produce *cis*-$[Co(en)_2(NH_3)(CH_3)]^{2+}$. The reported activation volume for the second substitution process (Table 1) also supports the operation of a limiting dissociative mechanism. Subsequently, the slow *cis* to *trans* isomerization of the latter complex occurs (see further Discussion).

The volumes of activation found for the subsequent substitution reactions under limiting concentration conditions, viz. $+14 \pm 1$ and $+24 \pm 1$ $cm^3 \cdot mol^{-1}$, are significantly positive in line with a limiting D mechanism. The value for the first reaction is close to the value reported for the dissociation of NH_3 in various octahedral complexes.[35–37] Since the *trans* influence of the methyl group already labilizes the $Co-NH_3$ bond in the ground state, as seen from X-ray structure analysis,[28] the volume increase required to dissociate NH_3 in the transition state will be significantly smaller than the partial molar volume of ammonia, viz. 24.85 $cm^3 \cdot mol^{-1}$.[38,39] The significantly higher value found for the second reaction step is surprising. This value may suggest that not only ammonia is labilized in the *cis* position, but also the ethylenediamine chelate. Partial ring-opening could, along with the dissociation of ammonia, account for the larger volume of activation. Alternatively, the more positive volume of activation found for the second substitution reaction may be due to the operation of a conjugate-base mechanism under the selected conditions. Earlier studies have demonstrated that base hydrolysis reactions proceeding by means of a conjugate base mechanism are characterized by large positive volumes of activation as a result of conjugate base formation and the subsequent ligand dissociation step.[40–44] For this reason we have checked the base concentration dependence of the substitution reactions, and the results are reported in Figure 6. The first substitution process is significantly accelerated by base, whereas the second substitution reaction hardly shows any base concentration dependence. The suggested conjugate base mechanism which could account for the acceleration observed for the first substitution process is outlined in Scheme 3.

Scheme 3

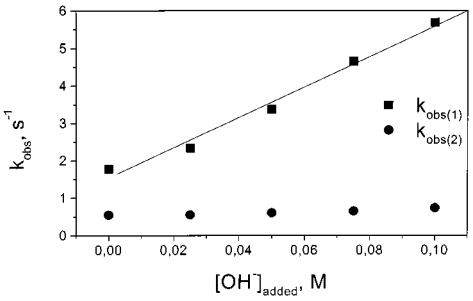


Figure 6. Plot of the observed rate constant (k_{obs}) vs. added $[OH^-]$ for the reaction of $[Co(NH_3)_5(CH_3)]^{2+}$ with ethylenediamine; conditions: [en] = 0.9 M, $[NH_3]$ = 3 M, temp. 10 °C, pH ≈ 11, I = 0.5 M (NO_3^- medium)

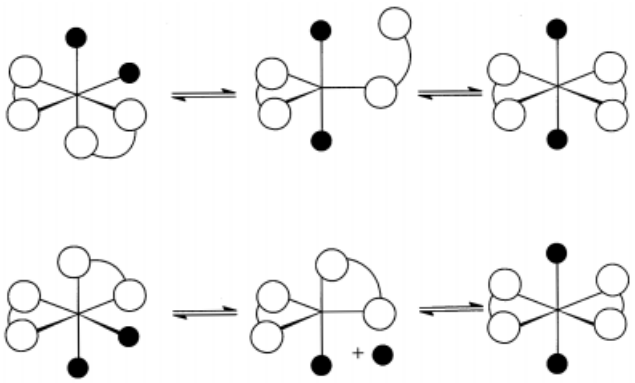

It follows from the data in Figure 6 that under the experimental conditions (pH ≈ 11, [en], $[NH_3]$) selected for the pressure dependence study, no significant contribution from base catalysis exists, and we can therefore rule out this possible explanation for the larger activation volume for the second substitution process.

cis–trans Isomerization Mechanism

The third and slower reaction step was assigned to the formation of the *trans* complex. The isomerization was followed as a subsequent reaction of the *cis*-complex rapidly produced on dissolving the pentaammine complex in a solution of en and NH_3. It was characterized by UV/Vis spectra with sharp isosbestic points at 427 and 492 nm, new bands formed at 358 and 466 nm, and a shoulder at 290 nm (see Figure 2). The positions of these bands shifted slightly to 363 and 470 nm when $[Co(NH_3)_5(CH_3)](NO_3)_2$ was dissolved in water without the addition of NH_3. This suggests that a water molecule occupies the trans position in the absence of NH_3.

The final spectrum is identical to the one published for the isolated and X-ray characterized *trans*-$[Co(en)_2(NH_3)(CH_3)](S_2O_6)$ complex.[28] The rate of the isomerization reaction was studied over a [en] range of 0.3 to 2.2 M, at a fixed $[NH_3]$ of 0.2 M. Absorbance–time traces were recorded and could be fitted with a single exponential. The rate of the *cis–trans* rearrangement was found to be independent of [en], with an average value of $(1.48 \pm 0.07) \times 10^{-3}$ s^{-1} for k_{iso} at 25 °C. The solutions were not buffered during these measurements. The activation parameters measured in the unbuffered solution, $\Delta H^{\#}$(iso) = 115 ± 5 $kJ \cdot mol^{-1}$, $\Delta S^{\#}$(iso) = 86 ± 16 $J \cdot mol^{-1} \cdot K^{-1}$ and $\Delta V^{\#}$(iso) = $+14.2 \pm 0.6$ $cm^3 \cdot mol^{-1}$, are all consistent with a limiting dissociative mechanism.

As known from a series of *cis-trans* isomerization reactions of cobalt complexes of the type $Co(en)_2XY$, the mechanism is in most cases a mixture of D or I type of reactions. In earlier papers isomerization mechanisms were discussed in terms of the possible reactions outlined in Scheme 4.[40,45]

Scheme 4

The main question that arises from Scheme 4 is how to distinguish between the two possible reaction paths that both involve ligand dissociation and will result in a positive volume of activation. It is not clear whether a square pyramidal or a trigonal bipyramidal intermediate is involved. On the one hand, we have the strong *trans* influence on the coordination site opposite to the carbon atom, as seen in the bond lengths of the solid state structure of $[Co(NH_3)_5(CH_3)](NO_3)_2$ [28] and in the fast Co^{III} substitution kinetics on the stopped-flow time scale. On the other hand, there are also the *cis* effects of both the methyl and the bidentate ligand which will weaken the $Co-NH_3$ bond and can therefore open another reaction path. It was necessary to keep the $[NH_3]$ at a low level in these reactions. At higher $[NH_3]$, the reaction was suppressed and the *cis* to *trans* rearrangement could no longer be observed. This is in line with the suggested rate-determining dissociation of NH_3. At high NH_3 concentration, the vacant coordination site will again be readily occupied by ammonia, and isomerization will be prevented. At low $[NH_3]$, competition between the free dangling end of en and NH_3 as entering ligands is at play. Once the second nitrogen donor of en is bound to the Co centre, the chelate effect prevails and stabilizes the *trans* product. The volume of activation data are also typical for the dissociation of NH_3 in the rate determining step.[35–37]

Under these circumstances we favour the reaction path involving the dissociation of NH_3 and the formation of the trigonal bipyramidal intermediate, since it readily provides the correct path for the isomerization reaction. The dissociation (ring-opening) of the en ligand may occur on a rapid time scale, but does not lead to isomerization of the complex due to an efficient ring-closure reaction.

This suggestion differs from what was suggested earlier for the isomerization of $[Co^{III}(en)_2(L)H_2O]$ complexes, where L is NH_3, Cl^-, Br^- or OH^-. The authors found that the reaction path is influenced by the strength of the Co–L bond relative to the strength of the Co–en bond.[45] However, in these studies the strong *trans* effect of the carbon donor, which will labilize any bond in that position, was not present.

To rule out the possible participation of a conjugate base mechanism during the *cis* to *trans* isomerization, the added base concentration was varied in a series of experiments. Only the loss of the isosbestic points and a general decrease in absorbance could be observed, suggesting that other processes interfere under such conditions.

Conclusions

The mechanism of ligand substitution in $[Co(NH_3)_5(CH_3)]^{2+}$ is strictly dissociative. The large volume increase found when going to the transition state can be accounted for in terms of only intrinsic volume effects. The high values of either $+14\ cm^3 \cdot mol^{-1}$ for the first or $+24\ cm^3 \cdot mol^{-1}$ for the second step strongly support the limiting dissociative character of the substitution process.

The $[Co(NH_3)_5(CH_3)]^{2+}$ cation is not favoured to be used as model for B_{12} chemistry due to the necessary presence of high ammonia concentrations and an unfavourable pH. The mechanistic understanding of the labilizing *trans* effect is important in terms of recent reports in the literature describing an interest in the activation of inert metal centres such as Co^{III}, Rh^{III}, and Ir^{III} complexes.[2,3,8,46–49] One major interest is the understanding of the electronic vs. steric tuning effects in simple substitution reactions, to enhance the understanding of catalytic cycles, and to synthesize specially designed complexes to be used as highly reactive and selective catalysts. In that respect, the final product of the substitution process reported here, *trans*-$[Co(en)_2(NH_3)(CH_3)]^{2+}$, may be a potential model for the vitamin B_{12} coenzyme and related systems.

Experimental Section

Methylhydrazine, cobalt(II) nitrate hexahydrate, ethylenediamine (en), sodium nitrate and ammonia solutions were all purchased from Aldrich or Merck and used as received, except for en which was distilled and stored under nitrogen before use. Pentaamminemethylcobalt(III) nitrate was prepared according to the method of Kofod,[27] but oxygen was bubbled through the reaction mixture for 4 h instead of exposure to air. The complex was stored under nitrogen in the dark. The purity of the complex was checked by elemental analysis and ^1H NMR and UV/Vis spectroscopy.[27,28] – All solutions for the kinetic measurements were freshly prepared with Millipore water in the dark before use. 10% of the total concentration of en was protonated with nitric acid to use en-enH$^+$ as buffer. – The NMR measurements were performed on a Bruker Avance DRX 400 WB NMR spectrometer. – UV/Vis spectra were recorded on either a Cary 1 or a Shimadzu UV-2101PC spectrophotometer. – Kinetic measurements for the fast substitution reactions were performed on an Applied Photophysics BioSX 18 MV instrument connected to a diode-array detector (TIDAS 200–620 nm, J&M, Aalen, Germany) to measure complete spectra on a ms time scale. The *cis* to *trans* rearrangement was followed as a subsequent slower step after mixing the complex and en solutions in a tandem cuvette or a pill box cell. In this case, no buffer was used. Kinetic measurements at elevated pressure were performed on a home-made high-pressure stopped-flow apparatus for the fast reactions or in a home-made high-pressure cell combined with a Shimadzu UV-2101PC spectrophotometer for the slower isomerization step.[50,51]

Deprotonation of *B*,*B*′-Di-*tert*-butyl-*B*,*B*′-difluorenyldiborane(4) and the Structure of the Di-*tert*-butyl-difluorenylidenediborate(2−) Anion

Ralf Littger,[a] Heinrich Nöth*[a] and Max Suter[a]

Dedicated to Prof. Dr. D. Walther on the occasion of his 60th birthday

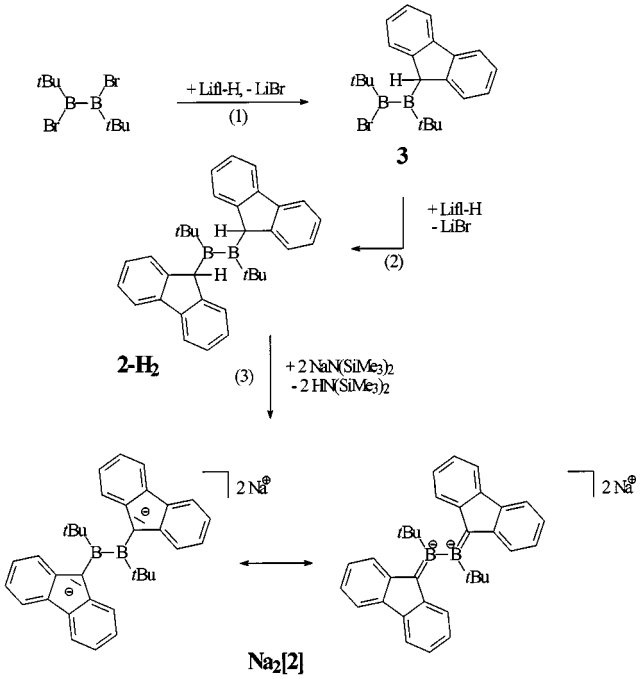
Keywords: Boranes / Borates / Deprotonation / Anions / Alkali metals

In contrast to the deprotonation of the diorganyl(fluorenyl)-boranes tBu$_2$B(fl-H) and Me$_2$B(fl-H), which cannot be achieved uniformly, the deprotonation of B$_2$(tBu)$_2$(fl-H)$_2$ in THF proceeds smoothly to give the anion B$_2$(tBu)$_2$(fl)$_2^{2-}$. The isolated salts have been identified as [Na(thf)$_n$]$_2$[B$_2$$tBu_2(fl)_2$] and [Na(thf)(OEt$_2$){Na(OEt$_2$)$_2$}][B$_2$$tBu_2(fl)_2$]. The X-ray structure of the latter compound reveals a longer B–B bond [1.744(9) Å] than that in the parent compound B$_2$(tBu$_2$)(fl-H)$_2$ [1.687(7) Å]. One sodium center is coordinated to the five-membered ring of one fluorenylidene substituent, while the other is coordinated to three C atoms of one of the six-membered rings. This results in a rather asymmetric structure. Each sodium center is also coordinated by two ether ligands.

Introduction

We have recently reported on the synthesis, molecular structures,[2] and synthetic potential[3] of the alkali and alkaline earth metal salts of bis(dimethylamino)difluorenyldiborane(4),[4] (Me$_2$N)$_2$B$_2$(fl-H)$_2$ (fl-H = fluorenyl = C$_{13}$H$_9$). A common feature of these compounds is a bent metallocene-type structure, in which the metal cations (Li, K, or Ca) are complexed by the two fluorenylidene ligands of the [(Me$_2$N)$_2$B$_2$(fl)$_2$]$^{2-}$ unit. The two fluorenylidene ligands are connected by a diborane(4)-*ansa*-bridge. The boron centers of (Me$_2$N)$_2$B$_2$(fl-H)$_2$ are shielded electronically by N−B π-bonding. Thus, in the dianion [(Me$_2$N)$_2$B$_2$(fl)$_2$]$^{2-}$, the lone pairs on the dimethylamino groups and the π-systems of the deprotonated fluorenyl substituents compete for the vacant p$_z$ orbitals at the boron centers. The π-interactions of the fluorenylidene substituents with the boron centers are, however, reduced by the complexation of the countercations, resulting in larger angles between the planes at the boron atoms and the planes of the fluorenylidene substituents than one might observe in the free dianions. Our interest has now been drawn to how substitution of the dimethylamino groups of [(Me$_2$N)$_2$B$_2$(fl)$_2$]$^{2-}$ by non-π-donor ligands affects the degree of π-interaction between the anionic fluorenyl groups and the boron centers and how this influences the ligand capacity of the [R$_2$B$_2$(fl)$_2$]$^{2-}$ unit (R = organyl group). To answer these questions, we have synthesized di-*tert*-butyl-difluorenyldiborane(4), (tBu)$_2$B$_2$(fl-H)$_2$, and have studied its deprotonation by sodium. For comparison purposes, we have also investigated the deprotonation of some related monoboranes, specifically fluorenyldimethylborane, Me$_2$B(fl-H), and di-*tert*-butyl-fluorenylborane, tBu$_2$B(fl-H).

Synthesis



In order to obtain a stable difluorenyl-diorganyldiborane(4), we decided to replace the dimethylamino groups of (Me$_2$N)$_2$B$_2$(fl-H)$_2$ (**1**-H$_2$) by *tert*-butyl groups. This group is known[5,6] to be sufficiently bulky to prevent redox disproportionation, which occurs in diborane(4) compounds that lack adequate electronic shielding. Indeed, di-*tert*-butyl-difluorenyldiborane(4) (**2**-H$_2$) could be readily prepared by the stepwise substitution of the bromine atoms of dibromo-di-*tert*-butyldiborane(4)[7] by the fl$^-$ anion. Unexpectedly, however, MeO substitution of (tBu)$_2$B$_2$(OMe)$_2$, which has been successfully employed for the preparation of the tetraalkyldiborane(4) derivatives (tBu)$_2$B$_2$(tBu)R (R = Me,[5] CH$_2$SiMe$_3$,[5] CH$_2$CMe$_3$[6]) and (tBu)$_2$B$_2$(CH$_2$CMe$_3$)$_2$,[6] did not work in the present case. No reaction occurred between (tBu)$_2$B$_2$(OMe)$_2$ and fluorenyllithium. On the other hand, (tBu)$_2$B$_2$(fl-H)Br (**3**), could be obtained almost quantitatively from the reaction of (tBu)$_2$B$_2$Br$_2$ with one equivalent of fluorenyllithium [Scheme 1, (1)]. The reaction of pure **3** with a further equivalent of fluorenyllithium also proceeded quantitatively [Scheme 1, (2)], as shown by the ^{11}B-NMR spectrum of the reaction mixture. The diborane(4) compounds **2**-H$_2$ and **3** were isolated as colorless solids. At room temperature, they were found to be stable in solution as well as in the solid state.

The syntheses of di-*tert*-butyl-fluorenylborane (**4**-H) and fluorenyl-dimethylborane (**5**-H) proved to be straightfor-

ward. These compounds could be obtained by treating fluorenyllithium with one equivalent of tBu$_2$BCl or Me$_2$BBr, respectively [Scheme 2, (4)], and were isolated as colorless, crystalline solids. Other diorganyl-fluorenylboranes, R$_2$B(fl-H) (R = Et, Ph), have been reported previously.[8]

boron atoms in this compound. The disodium salt of the dianion [**2**]$^{2-}$ was isolated as an orange solid as a THF solvate [Na(thf)$_x$]$_2$[**2**] and was characterized by multinuclear NMR spectroscopy. The dimetallation of **2**-H$_2$ was further confirmed by performing a single-crystal X-ray structure analysis on the related solvate [Na(thf)(OEt$_2$)][Na(OEt$_2$)$_2$][**2**].

The lithium monoborate, containing the anion [tBu$_2$B(fl)]$^-$ ([**4**]$^-$) is the main product of the reaction between tBu$_2$B(fl-H) (**4**-H) and one equivalent of LiNtBu(SiMe$_3$) in tetrahydrofuran solution [Scheme 2, (5)]. The ^{11}B-NMR spectrum of the reaction mixture not only shows a signal due to this anion (δ = 77.9), but further signals at δ(^{11}B) = 87.9 [tBu$_2$B(fl-H)] and 54.0 [possibly tBu$_2$B−NtBu(SiMe$_3$), 8%] and minor signals in the region δ(^{11}B) = +10.0 to 0.0 (tetracoordinated borates, 5%). The lithium salt [Li(thf)$_2$][**4**] was recovered as a 4:1 mixture with fluorenyllithium. All attempts to separate these compounds by crystallization were unsuccessful. The formation of fluorenyllithium leads us to believe that the fluorenyl ligand of **4**-H is substituted by the amide [NtBu(SiMe$_3$)]$^-$ in a competing reaction [Scheme 2, (6)]. This hypothesis is supported by the ^{11}B-NMR signal at δ(^{11}B) = 54.0, which is consistent with an amino-diorganylborane tBu$_2$B−NtBu(SiMe$_3$), a compound that could be formed through such a substitution reaction [cf. the ^{11}B resonance of Me$_2$B−NtBu(SiMe$_3$): δ(^{11}B) = 56.2].[9] The deborylation of alkylboranes upon treatment with strong bases is well known for Et$_2$B(Cp),[10,11] a compound akin to **4**-H.

Scheme 2

On treatment with two equivalents of NaN(SiMe$_3$)$_2$ in tetrahydrofuran solution, **2**-H$_2$ is doubly deprotonated [Scheme 1, (3)]. According to the ^{11}B-NMR spectrum of the reaction mixture, the dianion [(tBu)$_2$B$_2$(fl)$_2$]$^{2-}$ (**2**$^{2-}$) is the main product (90%). Unidentified boron species give rise to signals in the region δ (^{11}B) = +5 to −20 (altogether 10%). This indicates that the steric shielding of the boron centers of **2**-H$_2$ is insufficient to completely suppress the nucleophilic attack of Li(H)fl. On the other hand, the double deprotonation of the sterically less shielded **1**-H$_2$ is quantitative as a result of the additional electronic shielding of the

The lithium salt [Li(thf)$_2$][**4**] has been characterized by multinuclear NMR spectroscopy. Its data are especially interesting with regard to the interpretation of the NMR data of the title dianion [**2**]$^{2-}$. These will be discussed later.

The deprotonation of Me$_2$B(fl-H) (**5**-H) which contains a sterically and electronically poorly shielded boron center is difficult. As yet, we have been unable to extract any useful information from the NMR spectra of the reaction mixture generated when **5**-H is treated with alkali metal amides or sodium metal. From the reaction of Et$_2$B(fl-H) with Na[BHEt$_3$], a compound claimed[8] to be [Na(digly-

me)$_{1.5}$][Et_2B(fl)] has been isolated. However, its NMR data are not compatible with a tricoordinated boron atom (vide infra).

NMR Spectra

The NMR-spectroscopic data of compounds **3**, **2**-H_2, **4**-H, **5**-H, Na_2[**2**], and [Li(thf)$_2$][**4**] are reported in the Experimental Section. The ^{11}B-NMR resonance of **2**-H_2 at $\delta(^{11}B) = 102.5$ is indicative of a tetraalkyldiborane(4) compound.[5,6] However, only a single, albeit broad resonance at $\delta(^{11}B) = 92.9$ is observed for the two different boron atoms of **3**, this chemical shift being intermediate between those of the resonances of the corresponding symmetric species **2**-H_2 [$\delta(^{11}B) = 102.5$] and (tBu)$_2B_2Br_2$ [$\delta(^{11}B) = 88.0$].[7] The asymmetric structure of **3** is, however, reflected in its ^{1}H- and ^{13}C-NMR spectra, which show discrete signals due to the two different *tert*-butyl groups. The fluorenyl substituents of both **3** and **2**-H_2 give rise to double sets of signals. In the case of **3**, all the nuclei of the single fluorenyl group are chemically inequivalent, but the two fluorenyl substituents of **2**-H_2 should be equivalent. At the present time, the question as to whether the observed inequivalence is due to hindered rotation about the B−B bond and/or about the B−C_{fl} bonds remains unclear. Most probably, the barrier associated with rotation about the B−B bond is higher than that for rotation about the B−C bond and hence diastereomers arise. Indeed, diastereomers have been found for much less sterically demanding substituted diborane(4) derivatives, such as (Me_2N)$_2B_2i$Pr$_2$ and (Me_2N)$_2B_2$(benzyl)$_2$ (room temperature, 400 MHz).[12]

The NMR data of the monoboranes **4**-H and **5**-H are unexceptional: **4**-H shows two sets of signals due to the two *tert*-butyl groups in the ^{1}H- and ^{13}C-NMR spectra and a single set of signals due to the fluorenyl substituent. This corresponds to a preferred conformation in which the plane of the fluorenyl substituent is oriented perpendicular to the plane at the boron center, with hindered rotation about the B−C_{fl} bond. The two methyl groups of **5**-H are chemically equivalent and the observation of one set of signals due to the fluorenyl group indicates free rotation about the B−C_{fl} bond. This difference between **4**-H and **5**-H (one signal in the ^{1}H- and ^{13}C-NMR spectra due to the *B*-methyl groups for the latter) can therefore be attributed purely to steric factors.

The boron atoms in the disodium salt Na_2[**2**] [$\delta(^{11}B) = 74.0$] are better shielded by 28 ppm than in the protonated **2**-H_2 [$\delta(^{11}B) = 102.5$]. This can be rationalized in terms of a strong π interaction between the deprotonated fluorenyl substituents and the boron centers. Even larger shielding effects have been observed in other cases, e.g. $\Delta\delta = 43.2$ for the couple Mes_2B-CH_3 [$\delta(^{11}B$, THF) = 83.6]/[$Mes_2B-CH_2]^-$ [$\delta(^{11}B$, THF) = 40.4] (Mes = 2,4,6-trimethylphenyl)[13] and $\Delta\delta = 38.6$ for the couple Mes_3B/[$Mes_2B-(3,5\text{-}Me_2)C_6H_2CH_2]^-$.[14] We assume that the negative charges in Na_2[**2**] are not only stabilized by the boron centers, but by the π system of the fluorenyl substituents as well. Such additional stabilization is naturally not possible for a CH_2^- group, even less so for a $PhCH^-$ group. In this context, it seems unlikely that the anion of [Na(diglyme)$_{1.5}$][Et_2B(fl)][8] has the structure of a deprotonated trialkylborane with a trigonal-planar coordinated boron atom. For the system Et_2B(fl-H) [$\delta(^{11}B$, THF) = 50.9]/[$Et_2B(fl)]^-$ [$\delta(^{11}B$, THF) = −25.5], a shielding difference of $\Delta\delta^{11}B = 76.4$ has been reported. However, the ^{11}B resonance for [$Et_2B(fl)]^-$ would be consistent with a tetracoordinated borate anion (dimeric species?).[15]

Compared to the corresponding resonances in Na_2[(Me_2N)$_2B_2$(fl)$_2$], Na_2[**1**],[2] the ^{13}C nuclei of the fluorenyl substituents are seen to be deshielded in Na_2[(tBu)$_2B_2$(fl)$_2$], Na_2[**2**], on average by 2.4 ppm (see Table 1), thus indicating a stronger π interaction between the fluorenyl substituents and the boron centers in the latter compound.

Even more deshielded are the C atoms in fluorenylidene(tetramethylpiperidino)borane,[17] tmp−B=fl (tmp = 2,2,6,6-tetramethylpiperidyl), a compound related to Na_2[**2**] containing a true B=C_{fl} double bond. In this case, one observes a $\Delta\delta(^{13}C)$ value of 2.3 ppm (average for C2 to C13) compared to Na_2[**2**].

Despite the partial B=C_{fl} double-bond character in Na_2[**2**], the fluorenyl substituents give rise to single sets of signals in the ^{1}H- and ^{13}C-NMR spectra. This indicates that the rotation about the B−C_{fl} bond is still a fast process on the NMR time scale. On the other hand, the signals due to C-2,13, C-4,11, and 5-,10-H are significantly broader, showing the onset of coalescence.

The ^{11}B resonance of [Li(thf)$_2$][**4**] is shifted to higher field by just 8.4 ppm compared with that of protonated **4**-H. This is surprising as deprotonation of the fluorenyl substituents in the related **2**-H_2/[**2**]$^{2-}$ system leads to a downfield shift in the resonance of the ^{11}B nuclei by 28 ppm. In comparison with Na_2[**2**], the ^{13}C-NMR signals of the fluorenyl substituents in [Li(thf)$_2$][**4**] are upfield shifted by an average of 2.6 ppm (see Table 2). These observations are consistent with a lesser degree of B−C_{fl}-π interaction in the monoborane case, with more electron density residing in the fluorenyl system. This complies with a noncoplanar orientation of the plane of the fluorenyl substituent and the plane about the boron center in [**4**]$^-$ due to the presence of the two bulky *tert*-butyl substituents at the boron atom. The small difference in shielding can then readily be explained in terms of an essentially perpendicular arrangement of the fl-H and fl$^-$ group with respect to the tBu$_2$B moiety.

The ^{1}H- and ^{13}C-NMR data of [Li(thf)$_2$][**4**] are strongly solvent-dependent. In C_6D_6 solution, the ^{13}C nuclei of the central five-membered ring (C-1, C-2,13, C-7,8) of the fluorenyl substituent are better shielded by 4.5 ppm (average) than in THF solution (see Table 2). On the other hand, the protonated benzoid ^{13}C nuclei of the fluorenyl substituent are deshielded by 2.4 ppm (average) in C_6D_6 solution. The same is true for the ^{1}H nuclei, which are deshielded by 0.53 ppm (average) in C_6D_6 solution as compared to their resonances in THF solution. This behavior is not unusual for alkali metal fluorenides and can be explained in terms of a solvent dependency of the formation of contact ion

pairs (CIPs) and solvent-separated ion pairs (SSIPs).[18] In the poorly solvating solvent C_6D_6, CIPs are formed between [Li(thf)$_2$]$^+$ and [**4**]$^-$. The cation [Li(thf)$_2$]$^+$ is located above the five-membered ring of the fluorenyl substituent, polarizing the π electrons towards this central ring, thereby accounting for the enhanced shielding of the central ^{13}C nuclei and the deshielding of the nuclei of the peripheral carbon atoms. In the strongly solvating solvent THF, an equilibrium exists between CIPs and SSIPs, as a result of which the polarizing effect of the cation [Li(thf)$_2$]$^+$ towards the fluorenyl substituent is somewhat diminished.

Molecular Structures

In order to obtain further information on the degree of C_{fl}−B-π bonding in the dianion [**2**]$^{2-}$, an X-ray structure determination of [Na(thf)(Et$_2$O)][Na(Et$_2$O)$_2$][**2**] was performed. The protonated compounds **2**-H_2 (Figure 1) and **4**-H were also subjected to X-ray structure analyses for comparison purposes. To the best of our knowledge, the crystal structure of **2**-H_2 represents the first solid-state structure of a noncyclic tetraalkyldiborane(4). A structure useful for making comparisons is that of the cyclic diborane(4) derivative [−B(Me)−B(Me)−C(SiMe$_3$)$_2$−Si(Me)$_2$−C(SiMe$_3$)$_2$−], in which all the atoms connected to the diborane(4) unit are C(sp^3) atoms.[19] The most striking feature of **2**-H_2 is that the planes at B1 and B2 are arranged perpendicularly to one another (C1−B1−C27/C14−B2−C31 = 89.2°). Normally, the planes at the boron atoms in diborane(4) derivatives form angles in the range 60−80°. The orthogonal orientation of the planes at the boron atoms in **2**-H_2 can be attributed to the presence of the sterically demanding *tert*-butyl groups in this compound. Despite the bulky substitution of **2**-H_2, the B1−B2 distance is quite short at 1.688(8) Å and, indeed, is the shortest yet found for a neutral tetraorganyldiborane(4). Comparable diborane(4) derivatives are Mes_2B−BMesPh [1.706(12) Å],[20] Mes_2B−BMes(CH_2SiMe_3) [1.71(2) Å],[20] Mes_2B_2[$CH(SiMe_3)_2$]$_2$ [1.739(7) Å],[21] and the afore-mentioned diboracyclopentane [1.729(8), 1.709(9) Å].[19] The two fluorenyl substituents of **2**-H_2 show significantly different B−C_{fl} bond lengths [B1−C1 = 1.609(6) Å, B2−C14 = 1.641(6) Å] and two different orientations with respect to the diborane(4) unit, as indicated by the dihedral angles C31−B2−C14−H14a = 171.6° and C27−B1−C1−H1a = 9.4°. For the trialkylborane **4**-H (Figure 2), a B−C_{fl} distance of 1.612(8) Å is found. The most significant feature of the molecular structure of **4**-H is the perpendicular arrangement of the plane at the boron center and the plane of the fluorenyl substituent (C1−C14−C18/C1 to C13 = 89.0°), which has already been established on the basis of ^{1}H- and ^{13}C-NMR data.

We were unable to obtain single crystals of a THF solvate of Na_2[**2**] from THF or THF/hexane mixtures. However, crystals suitable for X-ray crystallography were formed when [Na(thf)$_x$]$_2$[**2**] (Figure 3) was crystallized from diethyl

ether at −20 °C. The structure determination confirmed the dimetallation of **2**-H$_2$ by sodium. The absence of protons at the fluorenyl carbon atoms bonded to the boron atoms is evident from the sum of the bond angles about these atoms (C1: 359.7°; C14: 360.0°). The dianion [**2**]$^{2-}$ and the two sodium cations form a monomeric contact ion triple. The sodium cations are complexed by one (Na2) or both (Na1) fluorenyl substituents of the dianion and by two additional ether molecules.

The angles between the planes at the boron atoms and the planes of the fluorenyl substituents are 12.7° and 13.8°, respectively. In the related dimetallated derivatives of **1**-H$_2$, the corresponding angles are 40.2 and 49.4°. The B−C$_{fl}$ distances in Na$_2$[**2**] are 10 pm shorter [1.529(8) and 1.533(9) Å] than those in the protonated **2**-H$_2$. These distances are also significantly shorter than those in (Me$_2$N)$_2$B$_2$Ph$_2$, a related compound with a B−C$_{sp2}$ bond (average B−C distance = 1.585 Å), but shorter than those in the analogous M$_2$[**1**] compounds (M$_2$ = Li$_2$, K$_2$, Ca) (average B−C$_{fl}$ distance of 1.547 Å). Together with the almost coplanar arrangement of the planes at the boron atoms and the fluorenyl planes, this gives an additional indication of significant B−C$_{fl}$-π bonding in Na$_2$[**2**].

The B−C$_{fl}$ distances in Na$_2$[**2**] are best compared with the B−C distance of 1.52(1) Å[22] in the anion [Mes$_2$B−(3,5-Me$_2$)C$_6$H$_2$CH$_2$]$^-$, as the boron atom has a similar acidity and the negative charge is also stabilized by an organic π system. In Na$_2$[**2**], steric repulsion between the fluorenyl substituents and the *tert*-butyl groups connected to the same boron atom is to be expected, and this indeed becomes apparent on comparing the pairs of angles B1−C1−C2/B1−C1−C13 = 122.5°/134.7° and B2−C14−C26/B2−C14−C15 = 122.5°/133.9° (see Figure 4). The two fluorenyl substituents are forced apart by the *tert*-butyl group connected to the same boron atom. This most probably accounts for the fact that the B−C$_{fl}$ distances in Na$_2$[**2**] are longer than they would be in a sterically less strained system. The two planes form an angle of 82.1°. Like the similar planes in the C$_2$BB starting material **2**-H$_2$, these are oriented almost perpendicularly to one another. The B−B distance in the dianion is 1.744(9) Å, which is 5.7 pm *longer* than the B−B distance in the parent protonated compound **2**-H$_2$ [1.687(7) Å]. An even more elongated B−B bond [1.859(8) Å] occurs in the less twisted (43°) diborane(4) unit of the related Li$_2$[Mes$_2$B$_2${C(SiMe$_3$)$_2$}$_2$].[23]

It is interesting to compare the rather unusual coordination modes of Na2 and especially of Na1 in Na$_2$[**2**] (Figure 4) with those observed in other fluorenyl sodium compounds.

Na2 is bonded in an asymmetric η^5 mode to the central five-membered ring of the fluorenyl substituent C1 to C13 (see Figure 4, top). It is not located centrally above the fluorenyl substituent, but is rather shifted towards C13 and C1, resulting in shorter contacts between Na2 and these carbon atoms [Na2−C13 = 2.599(6) Å, Na2−C1 = 2.671(6) Å]. A similar shift and similar Na−C distances have been reported for monomeric Nafl·PMDTA.[24] In both cases, the two shortest Na−C contacts are those to C1 and one of its neighbors. The coordination sphere about Na2 is completed by two ether molecules (one molecule of tetrahydrofuran

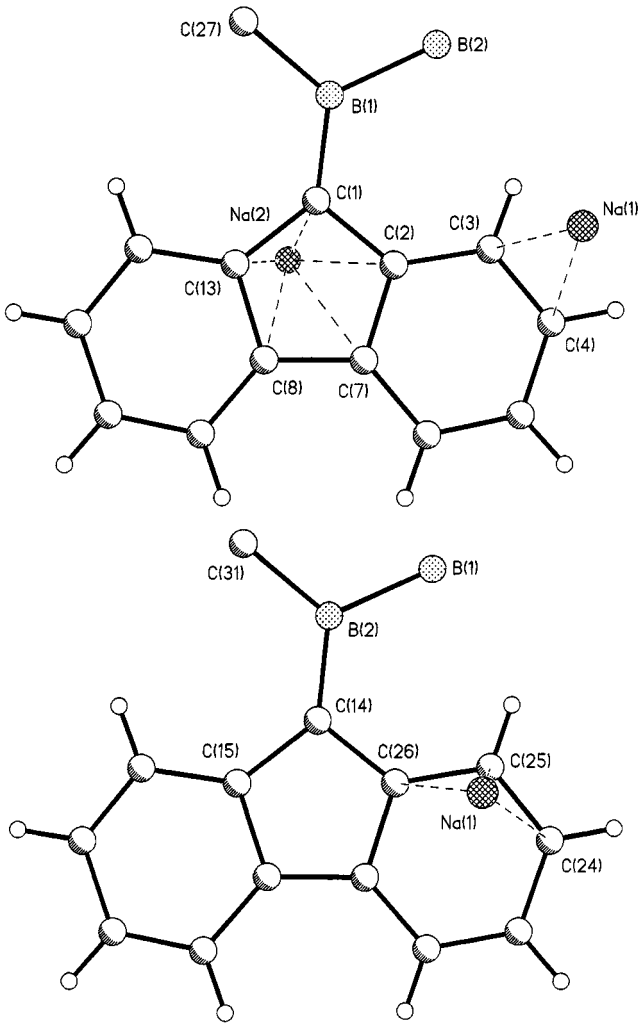

Figure 4. Plots showing the positions of the sodium cations Na1 and Na2 in $[Na(thf)(OEt_2)][Na(OEt_2)_2]$[**2**] with respect to the planes of the fluorenyl substituents C1 to C13 (top) and C14 to C26 (bottom); distances between the sodium cations and the fluorenyl planes [A]: Na2−(C1 to C13) 2.401, Na1−(C1 to C13) 2.642, Na1−(C14 to C26) 2.673

and one molecule of diethyl ether) and there is a weak interaction (Na2−H32a = 2.495 Å) between Na2 and a methyl group of the *tert*-butyl substituent bonded to B2. In contrast to monomeric $[Na(thf)(OEt_2)][Na(OEt_2)_2]$[**2**], solvates of fluorenylsodium in which the sodium cation is also coordinated to the fluorenyl anion and two donor atoms are either polymeric, such as $[Na(fl)\cdot TMEDA]_\infty$, or oligomeric, such as $[Na(fl)\cdot TMPDA]_4$. A monomeric solvate of fluorenylsodium is only formed with the tridentate PMDTA ligand.[24]

Na1 interacts with both fluorenyl substituents of the dianion $[\mathbf{2}]^{2-}$. The fluorenyl substituents do not coordinate Na1 through the carbon atoms of the central five-membered rings as has been observed for alkali metal compounds of the analogous dianion $[\mathbf{1}]^{2-}$. Such a di-η^5 coordination is impossible in the case of $[\mathbf{2}]^{2-}$ because of the almost perpendicular orientation of the planes at the boron atoms and the small angles between the planes at the boron atoms and the planes of the fluorenyl substituents. Na1 is coordinated by the benzoid carbon atoms of the fluorenyl substituents instead. It shows three contacts to the fluorenyl substituent C14 to C26 with Na−C distances of Na1−C25 = 2.720(6) Å, Na1−C26 = 2.822(6) Å, and Na1−C24 = 3.071(7) Å, and two contacts to the fluorenyl substituent C1 to C13 with Na−C distances of Na1−C3 = 2.818(6) Å and Na1−C4 = 2.987(7) Å (see Figure 4). If Na1 is projected perpendicularly onto the fluorenyl plane defined by the carbon atoms C1 to C13, it can be seen that this cation lies outside of the area of this fluorenyl substituent (see Figure 4, bottom). This coordination is strongly reminiscent of that of one of the sodium atoms in the cyclic tetramer $[Na(fl)\cdot TMPDA]_4$, in which the Na−C distances measure 3.025(5) and 3.032(5) Å.[24] Similar "out-of-ring coordination" has been observed in the dipotassium salt $[K(DME)]_2$[**1**].[2] The coordination sphere of Na1 is completed by two molecules of diethyl ether. The average Na−O distance is 2.315 Å, 7 pm longer than for Na2; the O−Na−O angle is 13° wider for Na1 (O1−Na1−O2 = 109.4°) compared to that at Na2 (O3−Na2−O4 = 96.4°).

Conclusion

The present study has again shown that the quantitative deprotonation of alkylboranes is not easily achieved. Even in the case of the compounds **2**-H_2 and **4**-H, in which the boron centers are sterically very shielded, the action of the weak nucleophilic bases $NaN(SiMe_3)_2$ and $LiNtBu(SiMe_3)$ leads to products in which significant numbers of boron atoms are tetracoordinated. As expected, the dianion $[\mathbf{2}]^{2-}$ displays a higher degree of C−B-π bonding than the related dimethylamino derivative $[\mathbf{1}]^{2-}$, as has been established on the basis of the following criteria: the B−C_{fl} bond lengths are shorter, the angles between the planes at the boron atoms and the planes of the corresponding fluorenyl substituents are smaller, and NMR studies show the ^1H and the ^{13}C nuclei of the fluorenyl substituents to be more deshielded. In $[\mathbf{2}]^{2-}$, the π system is not delocalized over the C_{fl}−B−B−C_{fl} unit as might be expected for an isoelectronic butadiene system. This is obvious as the planes at the boron atoms adopt an almost perpendicular arrangement. Therefore, $[\mathbf{2}]^{2-}$ is best described as a system in which two borylated carbanions are connected by a B−B single bond without B−C-π bond character. The question remains as to why butadiene-like structures are not realized for $[\mathbf{2}]^{2-}$ and the related anion $[Mes_2B_2\{C(SiMe_3)_2\}_2]^{2-}$, i.e. whether this is due to steric reasons or also due to the electronic situation.

Experimental Section

General: All manipulations were carried out under N_2 using Schlenk techniques. Solvents were dried by standard procedures. Commercial chemicals were purified prior to use as necessary; $(tBu)_2B_2Br_2$,[25] $(tBu)_2BCl$,[26] Me_2BBr,[27] Li(fl),[28] $NaN(SiMe_3)_2$, and $LiNtBu(SiMe_3)$[29] were prepared according to literature procedures. − NMR: Bruker AC-P 200 (^{11}B), Jeol EX 400 (^1H, ^{13}C);

standards: ext. $BF_3{\cdot}Et_2O$ (^{11}B), int. TMS or C_6D_6 (^1H, ^{13}C). – IR: Perkin–Elmer 325. – MS: Varian CH7 (70 eV). – X-ray structure determinations: Siemens P4 or Nicolet R3m diffractometer, Mo-K_α radiation, graphite monochromator.

1-Bromo-1,2-di-*tert*-butyl-2-(1-fluorenyl)diborane(4) (3): A suspension of fluorenyllithium (0.69 g, 4.01 mmol) in toluene (20 mL) was added dropwise to a solution of (tBu$_2$)B$_2$Br$_2$ (1.18 g, 3.99 mmol) in toluene (25 mL) at −78 °C. The mixture was allowed to warm to room temperature, stirred for 6 h, and then the insoluble material (0.32 g) was removed by centrifugation. The solution was concentrated to dryness, the residue was redissolved in hexane (12 mL), and this solution stored for 20 h at −20 °C. A colorless solid separated, which was filtered off, washed with cold hexane, and dried in vacuo. – Yield: 0.40 g of **3** (26%); m.p. 92–93 °C. – $C_{21}H_{27}B_2Br$ (381.0): calcd. C 66.21, H 7.14; found C 64.74, H 6.37. – MS (70 eV); *m*/*z* (%): 380 (100) [$M^{\bullet+}$], 233 (45) [$M^{\bullet+}$ − B(fl-H)Br], 165 (56) [fl-H]. – ^{11}B NMR (64.2 MHz, $CDCl_3$): δ = 92.9 ($h_{1/2}$ = 940 Hz). – ^1H NMR (400 MHz, $CDCl_3$): δ = 7.84, 7.78, 7.50, 7.45 [d, 1 H, ^3J(H,H) = 7.3 Hz; d, 1 H, ^3J(H,H) = 7.3 Hz; d, 1 H, ^3J(H,H) = 6.8 Hz; d, 1 H, ^3J(H,H) = 7.3 Hz, 3-,6-,9-,12-H], 7.32 (m, 4 H, 4-,5-,10-,11-H), 4.57 (s, 1 H, 1-H), 1.29, 0.37 [2 s, 2 × 9 H, 2 C(CH_3)$_3$]. – ^{13}C NMR (100.6 MHz, $CDCl_3$): δ = 147.1, 143.9 (C-2,13), 142.2, 140.5 (C-7,8), 126.7, 126.6, 126.5, 126.3, 126.1, 125.8 (C-3,4,5,10,11,12), 120.4, 119.9 (C-6,9), 49.3 (C-1), 30.1, 29.3 [*C*(CH$_3$)$_3$], 27.5, 26.2 [C(*C*H$_3$)$_3$].

1,2-Di-*tert*-butyl-1,2-bis(1-fluorenyl)diborane(4) (2-H$_2$): A suspension of fluorenyllithium (0.40 g, 2.32 mmol) in toluene (15 mL) was slowly added to a stirred solution of **3** (0.87 g, 2.28 mmol) in toluene (10 mL) at −78 °C. The mixture was allowed to warm to room temperature, stirred for 20 h, and then the insoluble material was separated by centrifugation. The solution was then concentrated to dryness in vacuo and the residue was redissolved in hexane (10 mL). Storing this solution for 3 d at −25 °C gave colorless, microcrystalline **2**-H$_2$, which was filtered off, washed with cold hexane (3 mL), and dried in vacuo for several hours. – Yield: 0.44 g of **2**-H$_2$ (41%); m.p. 138–139 °C. – $C_{34}H_{36}B_2$ (466.3): calcd. C 87.58, H 7.78; found C 85.47, H 7.57. – MS (70 eV); *m*/*z* (%): 466 (11) [$M^{\bullet+}$], 409 (5) [$M^{\bullet+}$ − C(CH$_3$)$_3$], 301 (91) [$M^{\bullet+}$ − $C_{13}H_9$], 233 (34) [$M^{\bullet+}$/2], 176 (77) [B(fl-H)], 165 (100) [fl-H]. – ^{11}B NMR (64.2 MHz, C_6D_6): δ = 102.5 ($h_{1/2}$ = 2250 Hz). – ^1H NMR (400 MHz, C_6D_6): δ = 7.76 [d, 2 H, ^3J(H,H) = 7.3 Hz, 6-H], 7.68 [d, 2 H, ^3J(H,H) = 7.3 Hz, 9-H], 7.57 [d, 2 H, ^3J(H,H) = 6.4 Hz, 3-H], 7.28 (pseudo-t, 2 H, 5-H), 7.19 (pseudo-t, 2 H, 10-H), 7.14 (pseudo-t, 2 H, 4-H), 7.04 (pseudo-t, 2 H, 11-H), 6.35 (m, very broad, 12-H), 4.66 (s, 2 H, 1-H), 0.75 [s, 18 H, C(CH_3)$_3$]. – ^{13}C NMR (100.6 MHz, C_6D_6): δ = 147.2, 145.6 (C-2,13), 142.9, 142.6 (C-7,8), 127.0 (C-4), 126.4 (C-5,10,11,12), 125.6 (C-3), 120.6 (C-6), 120.3 (C-9), 50.5 (C-1), 32.5 [*C*(CH$_3$)$_3$], 28.7 [C(*C*H$_3$)$_3$]. The ^1H and ^{13}C NMR resonances were assigned on the basis of ^1H-^1H-COSY and ^1H-^{13}C-HETCOR NMR experiments.

Di-*tert*-butyl-(1-fluorenyl)borane (4-H): A suspension of fluorenyllithium (2.14 g, 12.43 mmol) in toluene (30 mL) was slowly added to a stirred solution of tBu$_2$BCl (1.99 g, 12.40 mmol) in toluene (20 mL) at −78 °C. The mixture was allowed to warm to room temperature, in the course of which a brown-red color developed. After stirring for a further 20 h at room temperature, the insoluble material was separated by centrifugation and this solid was extracted with toluene (10 mL). The toluene solutions were combined and concentrated to dryness in vacuo. The residue (3.31 g) was redissolved in hexane (15 mL) and storage of this solution at −25 °C led to the deposition of large, colorless needles (0.50 g). Concentration of the mother liquor and further storage at −25 °C furnished a second crop of crystals (1.32 g). – Yield: 1.82 g of **4**-H (51%); m.p. 70–72 °C. – $C_{21}H_{27}B$ (290.3): calcd. C 86.90, H 9.38; found C 83.69, H 7.77. – ^{11}B NMR (64.2 MHz, C_6D_6): δ = 86.3 ($h_{1/2}$ = 670 Hz). – ^1H NMR (400 MHz, C_6D_6): δ = 7.75 [d, 2 H, ^3J(H,H) = 7.3 Hz, 6-,9-H], 7.28 [pseudo-t, ^3J(H,H) = 7.3 Hz, 2 H, 4-,11-H or 5-,10-H], 7.23 [d, 2 H, ^3J(H,H) = 6.8 Hz, 3-,12-H], 7.18 [pseudo-t, 2 H, ^3J(H,H) = 7.3 Hz, 4-,11-H or 5-,10-H], 4.41 (s, 1 H, 1-H), 1.24, 0.53 [2 s, 2 × 9 H, 2C(CH_3)$_3$]. – ^{13}C NMR (100.6 MHz, C_6D_6): δ = 147.9 (C-2,13), 143.2 (C-7,8), 126.8, 126.2 (C-4,5,10,11), 124.4 (C-3,12), 120.6 (C-6,9), 48.8 (C-1), 30.3, 29.9 [*C*(CH$_3$)$_3$], 28.6, 27.6 [C(*C*H$_3$)$_3$].

(1-Fluorenyl)dimethylborane (5-H): A suspension of fluorenyllithium (3.37 g, 19.6 mmol) in toluene (20 mL) was added dropwise to a stirred solution of Me_2BBr (2.37 g, 19.6 mmol) in toluene (20 mL) at −78 °C. The mixture was allowed to warm to ambient temperature, stirred for a further 3 d, and then the insoluble material (1.75 g) was separated by centrifugation. This solid was extracted with toluene (7 mL) and the toluene solutions were combined. Removal of all volatile compounds in vacuo left a red oil (3.45 g), heating of which at 110–130 °C/10^{-3} Torr resulted in the formation of very thin, colorless needles. – Yield: 2.79 g of **5**-H (69%); m.p. 49–50 °C. – $C_{15}H_{15}B$ (206.1): calcd. C 87.42, H 7.34; found C 86.67, H 7.87. – ^{11}B NMR (64.2 MHz, C_6D_6): δ = 83.8 ($h_{1/2}$ = 310 Hz). – ^1H NMR (400 MHz, C_6D_6): δ = 7.74 [d, 2 H, ^3J(H,H) = 7.3 Hz, 6-,9-H], 7.22 (m, 6 H, 3-,4-,5-,10-,11-,12-H), 4.29 (s, 1 H, 1-H), 0.53 (s, 6 H, CH_3). – ^{13}C NMR (100.6 MHz, C_6D_6): δ = 145.4 (C-2,13), 142.1 (C-7,8), 126.8, 126.3 (C-4,5,10,11), 124.8 (C-3,12), 120.5 (C-6,9), 53.8 (C-1), 13.0 (CH$_3$).

[Na(thf)$_x$]$_2$[(tBu)$_2$B$_2$(fl)$_2$] {[Na(thf)$_x$]$_2$[2]}: A solution of NaN(SiMe$_3$)$_2$ (0.31 g, 1.69 mmol) in tetrahydrofuran (7 mL) was added dropwise to a stirred solution of **2**-H$_2$ (0.41 g, 0.88 mmol) in tetrahydrofuran (10 mL) at room temperature. During the addition of the base, the color of the reaction mixture turned orange. Stirring was continued for 20 h and then the deep-red mixture was concentrated to dryness in vacuo. On treating the residue with hexane (10 mL), an orange powder formed, which was collected by filtration (0.28 g), washed with hexane (3 mL), and dried in vacuo. ^{11}B-, ^1H-, and ^{13}C-NMR spectroscopy showed the product to be a THF solvate of the disodium salt [Na(thf)$_x$]$_2$[**2**]. Crystals of the solvate [Na(thf)(OEt$_2$)][Na(OEt$_2$)$_2$][**2**] suitable for X-ray crystallography were obtained by recrystallizing the orange powdery [Na(thf)$_x$]$_2$[**2**] from diethyl ether at −20 °C. – ^{11}B NMR (64.2 MHz, THF/C_6D_6): δ = 72.0 ($h_{1/2}$ = 4100 Hz). – ^1H NMR (400 MHz, THF/C_6D_6): δ = 8.27 [d, 4 H, ^3J(H,H) = 8.3 Hz, 6-,9-H], 7.88 [d, 4 H, ^3J(H,H) = 7.3 Hz, 3-,12-H], 6.77 [(at +55 °C, t), 4 H, 4-,11-H], 6.60 (pseudo-t, 4 H, broad, 5-,10-H), 1.44 [s, 18 H, C(CH_3)$_3$]. – ^{13}C NMR (100.6 MHz, THF/C_6D_6): δ = 146.0 (broad, C-2,13), 130.2 (C-7,8), 122.5 (broad, C-4,11), 121.0 (C-6,9), 118.1 (C-3,12), 112.8 (C-5,10); (C-1) and [*C*(CH$_3$)$_3$] could not be detected; 34.7 [C(*C*H$_3$)$_3$].

Reaction of 4-H with LiN(tBu)(SiMe$_3$): A solution of LiNtBu(SiMe$_3$) (0.51 g, 3.37 mmol) in tetrahydrofuran (15 mL) was added dropwise to a solution of **4**-H (0.96 g, 3.31 mmol) in tetrahydrofuran (15 mL) at room temperature. The mixture was stirred for 1 d, in the course of which a deep-red color developed. After removing all volatile material in vacuo, a dark-red resinous residue (1.88 g) remained. Addition of hexane (20 mL) produced an orange powder (0.75 g), which was collected by filtration, washed with hexane (5 mL), and dried in vacuo. ^1H-, ^{13}C-, and ^{11}B-NMR spectroscopy showed this powder to consist of a 4:1 mixture of [Li(thf)$_2$][**4**] and fluorenyllithium. The powder proved to be very soluble in THF and benzene and moderately soluble in hexane. Separation of the

two components by fractional crystallization could not be achieved. − **NMR Data for [Li(thf)$_2$][4]:** ^{11}B NMR (64.2 MHz, THF/C_6D_6): δ = 77.9 ($h_{1/2}$ = 950 Hz). − ^{1}H NMR (400 MHz, THF/C_6D_6): δ = 7.76 [d, 2 H, ^3J(H,H) = 7.3 Hz, 6-,9-H], 7.19 [d, 2 H, ^3J(H,H) = 8.3 Hz, 3-,12-H], 6.71 [pseudo-t, 2 H, ^3J(H,H) = 7.1 Hz, 4-,11-H], 6.35 [pseudo-t, 2 H, ^3J(H,H) = 7.3 Hz, 5-,10-H], 1.15 [s, 18 H, C(CH_3)$_3$]. − ^{13}C NMR (100.6 MHz, THF/C_6D_6): δ = 142.1 (C-2,13), 126.4 (C-7,8), 120.4 (C-4,11), 119.2 (C-6,9), 118.3 (C-3,12), 108.7 (C-5,10), 105.2 (C-1), 31.0 [C(CH$_3$)$_3$], 30.3 [C(CH$_3$)$_3$]. − ^{1}H NMR (400 MHz, C_6D_6): δ = 8.27 [d, 2 H, ^3J(H,H) = 7.8 Hz, 6-,9-H], 7.61 [d, 2 H, ^3J(H,H) = 8.3 Hz, 3-,12-H], 7.25 [pseudo-t, 2 H, ^3J(H,H) = 7.6 Hz, 4-,11-H], 6.99 [pseudo-t, 2 H, ^3J(H,H) = 7.3 Hz, 5-,10-H], 2.66 (m, 8 H, THF), 1.35 [s, 18 H, C(CH_3)$_3$], 1.04 (m, 8 H, THF). − ^{13}C NMR (100.6 MHz, C_6D_6): δ = 137.4 (C-2,13), 122.0 (C-7,8), 121.6 (C-4,11), 121.5 (C-6,9), 120.3 (C-3,12), 112.6 (C-5,10), 100.7 (C-1), 67.6 (THF), 30.9 [C(CH$_3$)$_3$], 29.4 [C(CH$_3$)$_3$], 25.0 (THF). − **NMR Data for Fluorenyllithium:** ^{1}H NMR (400 MHz, THF/C_6D_6): δ = 7.85 (d, 2 H, 6-,9-H), 7.24 (d, 2 H, 3-,12-H), 6.75 (pseudo-t, 2 H, 4-,11-H), 6.37 (pseudo-t, 2 H, 5-,10-H), 5.87 (s, 1 H, 1-H). − ^{13}C NMR (100.6 MHz, THF/C_6D_6): δ = 138.0 (C-2,13), 123.4 (C-7,8), 119.4 (C-4,11), 118.9 (C-6,9), 116.5 (C-3,12), 108.4 (C-5,10), 81.4 (C-1).

X-ray Structure Determination: Single crystals were coated with perfluoroether oil and mounted on glass fibres. They were cooled to −80 °C on the goniometer head. Cell dimensions were determined by automatically centering reflections taken from rotation photographs. Data collections were performed in the ω/2θ mode with variable scan speeds and adjusted scan widths. After data reduction (Lorentz and polarization correction), direct methods were applied for structure solution. The model was initially refined after atom assignment with isotropic temperature parameters, and then the positions of the atoms were refined using an anisotropic description. Hydrogen atom positions were calculated and included in the final calculation with fixed isotropic thermal parameters as riding on the respective C-atoms. Selected crystallographic data and data related to the structure solution and refinement are summarized in Table 3. Programs used: SHELXTL and SHELXL-93. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-143688 to -143690. Copies of the data can be obtained free of charge on application to the CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

We thank the Fonds der Chemischen Industrie and Chemetall GmbH for support of this work. Thanks are also due to Mr. P. Mayer for recording many NMR spectra, and to the team in the microanalytical laboratory for performing the analyses.

Synthesis and Properties of Dinuclear Complexes with a Photochromic Bridge: An Intervalence Electron Transfer Switching "On" and "Off"

Sandrine Fraysse,[a] Christophe Coudret,*[a] and Jean-Pierre Launay*[a]

Keywords: Photochromism / Metallacycles / Molecular devices / Electron transfer

Two cyclometallated $Ru(bpy)_2(pp)$ units (bpy = 2,2′-bipyridine; pp = 2-phenylpyridine) were grafted via ethynyl spacers onto the photochromic cores of the norbornadiene or dithienylethene families, to give the bimetallic ruthenium(II) complexes **1** and **2a**, respectively. Two aspects of these compounds were studied: (i) photoisomerization (norbornadiene to quadricyclane for **1**, open form to closed form of the dithienylethene core for **2a**), and (ii) intervalence transitions in the mixed-valence ruthenium(II–III) state, with determination of the metal–metal electronic coupling (V_{ab}) by Hush's equation. Moderate metal–metal electronic coupling (0.068 eV) was found for **1**, but **1** cannot be isomerized into the quadricyclane form. On the other hand, **2a** can be reversibly photoisomerized to the closed form **2b**. An iodine(III) reagent, the triflate salt of bis(pyridyl)phenyliodonium, was used for the oxidation of **2a** and **2b**. During these oxidations, an intervalence band due to intramolecular electron transfer between ruthenium(II) and ruthenium(III) was detected for **2b**, but not for **2a**. This switching "on" or "off" of the intervalence transition is rationalized with extended Hückel calculations. Finally, the molecular orbital calculation explains the observed tendency of the closed form **2b** to reopen upon oxidation.

Introduction

Switching at the molecular scale is one of the great challenges of molecular electronics.[1a] It is important to devise molecules able to reproduce one of the most important functions of electronic devices, that is, the ability to change in a controlled manner between a "conducting" and a "nonconducting" state, which is a prerequisite for the realization of logical functions. Ideally, such molecules should be used in nanometric-scale devices involving a unique molecule, and experiments along these lines are in progress.[1b–1d] However, due to the difficulty of experiments dealing with unique molecules, one has to rely, for some time still, on more conventional studies involving a (noninteracting) ensemble of molecules in solution, probed by spectroscopic methods. An important issue is the ability to transfer electrons intramolecularly between clearly identified sites.

Intramolecular electronic coupling between two redox sites can be probed by the intervalence transition occurring in the near-infrared for the mixed-valence state.[2] Hush's equation[3] allows the intensity of this transition to be used to estimate the electronic coupling term V_{ab}, that is, the efficiency of the bridge at mediating electron transfer between the distant redox sites.

In the search for molecules able to show a switching effect, we have tried to introduce as bridging ligand a photochromic moiety exhibiting two states ("on" and "off") with respect to electronic coupling. Symmetrical photochromic cores were selected to preserve the formal "exchangeability" of the two metallic centers. The association of photochromism and intervalence electron transfer is schematically represented in Figure 1a.

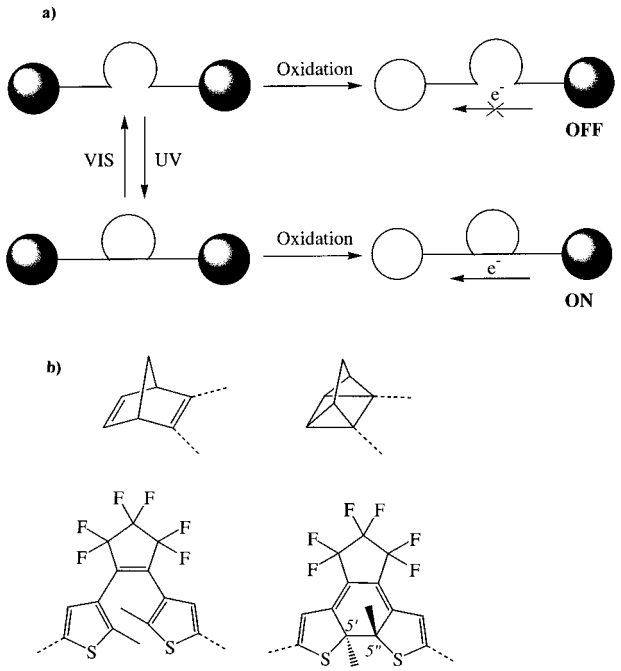

Figure 1. (a) Principle of the association of a switching moiety with intervalence electron transfer; (b) photochromic processes considered in the present paper; in the case of dithienylethene derivatives, the nomenclature **Na** and **Nb** will be used for the open and closed forms, respectively

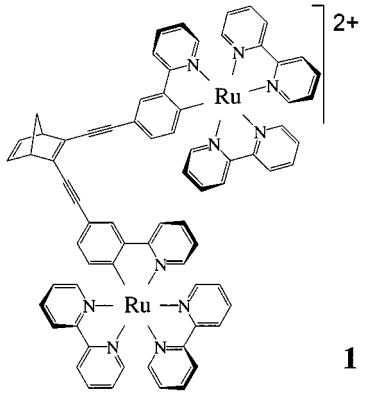

A previous attempt used the norbornadiene/quadricyclane isomerization in a bis(pentaammineruthenium) complex of dicyanonorbornadiene.[4] Extinction of the intervalence band occurred in the dicyanoquadricyclane complex, but the photoreaction was not reversible and the

ruthenium−nitrile bond was not stable enough for further studies.

In other respects, as photochromic moieties, systems of the dithienylethene family, discovered by Irie et al,[5] exhibit several attractive characteristics: good stability, reversibility, high quantum yield, separated absorption spectra for the two forms, resistance to fatigue after multiple cycling. Their interest (particularly when the central double bond is locked by a perfluorocyclopentene cycle), was recognized by Lehn et al.[6] who described several associations of such photochromic parts with redox groups and their peculiar electrochemical and nonlinear optical properties. Thus, complex functions were obtained, involving the association of photochromism and electrochromism, that is, the sensitivity to two different stimuli.[6]

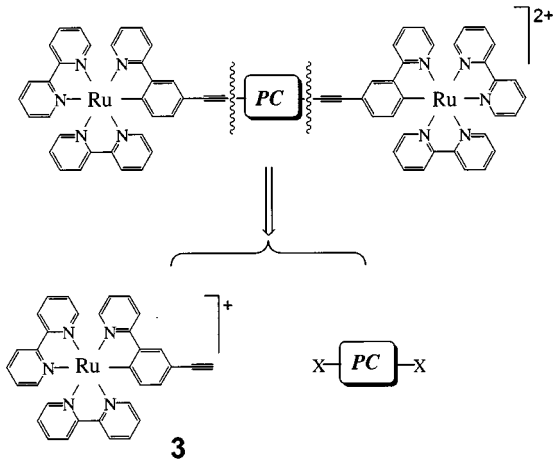
Scheme 1. Target molecules; **2** is represented as the open form **2a**

The redox sites we report on here are cyclometalated ruthenium complexes (Scheme 1). Cyclometalation has been shown to confer stability on the complexes, and, furthermore, strong electronic coupling, resulting in intense intervalence transitions, occurs.[2a,7,8] Strictly speaking, the coupling depends also on the nature of the spacer, but it turns out that most cyclometalated compounds associated with spacers such as phenylene units, or combinations of ethynyl units and aromatic groups are efficient for electron transfer. In the present paper, we report on our use of analogues of $[Ru(bpy)_3]^{2+}$, where one 2,2′-bipyridine is formally replaced by a deprotonated 2-phenylpyridine ligand.[9] We have recently shown how this easily functionalized cyclometalated complex could be used as an organometallic synthon.[9,10] Gram quantities are easily prepared and the corresponding chemistry has proved to be flexible and versatile. It is, in particular, possible to introduce ethynyl residues, which are efficient conjugated spacers, for example in tolane derivatives.[11] Such a "building block" approach involving a palladium-catalyzed cross-coupling reaction constitutes a very convergent synthesis of conjugated dinuclear complexes.

The present paper describes the properties of binuclear complexes with cyclometalated units as terminal groups, and with photochromic bridges such as norbornadiene or dithienylethene (Figure 1b). Their photochemistry in the homovalent $Ru^{II}-Ru^{II}$ state was studied. Note that the transformations expected are opposite: in the case of norbornadiene, photoisomerization drives the system from a conjugated state ("on") to a nonconjugated one ("off"), while the reverse is true when cyclization of the dithienylethene moiety occurs.



Results and Discussion

Syntheses

The general retrosynthetic route we adopted relies on extensive use of a palladium-catalyzed ethynylation reaction, which involves cross-coupling between a substituted acetylene and an electrophilic sp^2-hybridized carbon atom.[12] The disconnection we selected, outlined in Scheme 2, is mostly based on the fact that a ruthenium complex bearing a protected ethynyl group was readily available. While keeping the synthesis highly convergent, this also enabled us to circumvent some reactivity problems due to the use of the brominated ruthenium complex precursor.[10]

Organometallic Synthon

Two complexes, with an acetylene group protected by a trimethylsilyl (TMS) or by a 2-hydroxypropan-2-yl (POH) group, were available.[9] However, fluoride-induced desilylation of the TMS-protected compound was always accompanied by extensive decomposition of the cyclometalated part. On the other hand, the easily purified POH-protected alkyne **4** was found to be quantitatively deprotected with

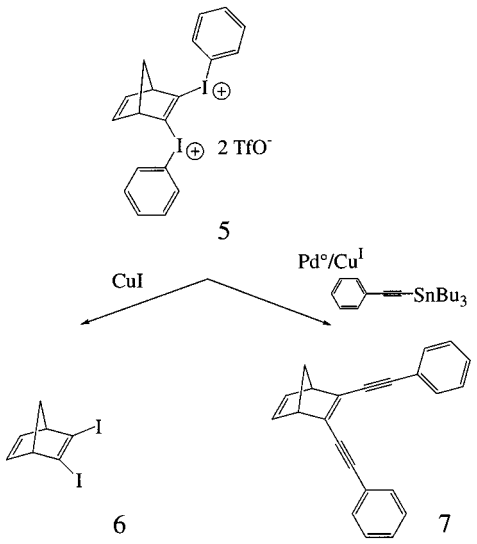
Scheme 2. General retrosynthetic route (PC = photochromic unit)

*t*BuOK in refluxing THF. No purification was found to be necessary, apart from removal of potassium salts and anion metathesis, thereby unnecessary exposure to air could be avoided (Scheme 3).

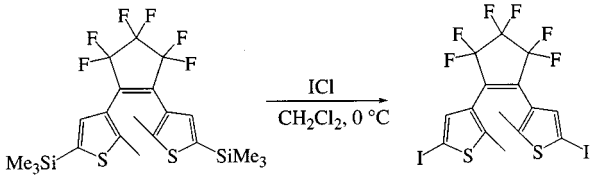


Photochromic Synthons

To use low reaction temperatures for the final cross coupling, we focused our attention on iodinated precursors of the photochromic core.

4 3

Scheme 3. Organometallic synthon



Scheme 4. Norbornadiene precursor **6** and model compound **7**

For the norbornadiene precursor, we thought of the bis(iodonium) derivative **5**, recently described by Stang and Zhdankin (Scheme 4).[13] This compound is easily prepared and can undergo either copper-mediated nucleophilic substitutions yielding dihalo- or dicyanonorbornadiene,[14] or palladium/copper ethynylation with an alkynylstannane, affording a family of new enediyne-containing molecules.[15]

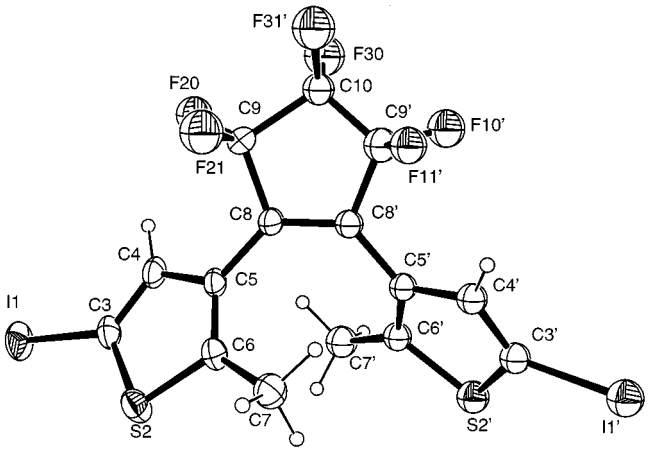
Only two reports were found in which the dithienylperfluorocyclopentene photochromic group is used as a synthon (i.e., a diboronic acid[6e]or a dibromide[16]): the usual strategy is to prepare the derivatives by the interaction of a suitably substituted 3-lithiothiophene and perfluororocyclopentene in the final step.[5,6a−6d]

A convenient precursor of the diiodinated synthon **9** is the bis(5-trimethylsilyl) derivative of 1,2-bis(2′-methylthien-3′-yl)perfluorocyclopentene (**8**), the synthesis of which was described by Irie.[16] In marked contrast to the difficulty of the analogous bromination reaction,[16] the electrophilic trimethylsilyl *ipso* substitution with ICl as iodinating agent smoothly afforded the previously unknown diiodo derivative **9** in virtually quantitative yield. (Scheme 5).

8 9

Scheme 5. Dithienylethene precursor

Crystallization from acetonitrile afforded crystals suitable for an X-ray study; an ORTEP diagram is given in Figure 2.



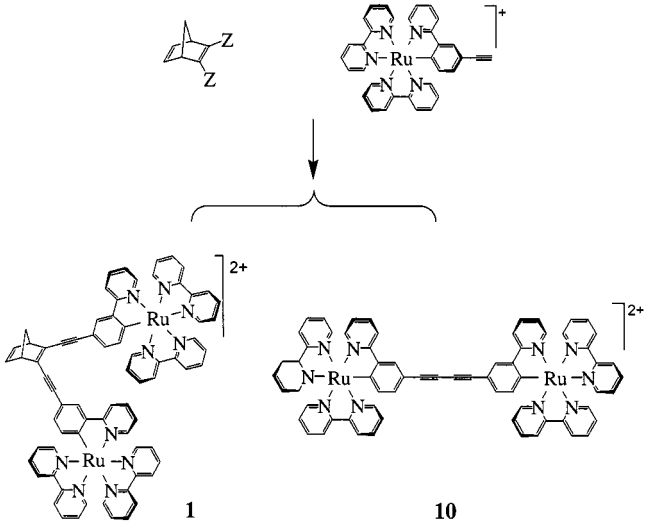


Figure 2. ORTEP plot of **9** with 30% probability displacement ellipsoids; the atoms with a superscript prime are related to those without superscript by a crystallographic twofold axis running though the middle of the C(8)−C(8′) bond; the nonplanar perfluorocyclopentene ring is partially disordered and only one conformer is shown here for clarity (bond lengths in Å, torsion angle in °): I1−C3 2.072(5), C3−C4 1.351(7), C4−C5 1.438(6), C5−C6 1.368(7), C3−S2 1.706(6), S2−C6 1.732(5), C5−C8 1.465(6), C8−C8′ 1.362(8); C6−C5−C8−C8′ 42(1)

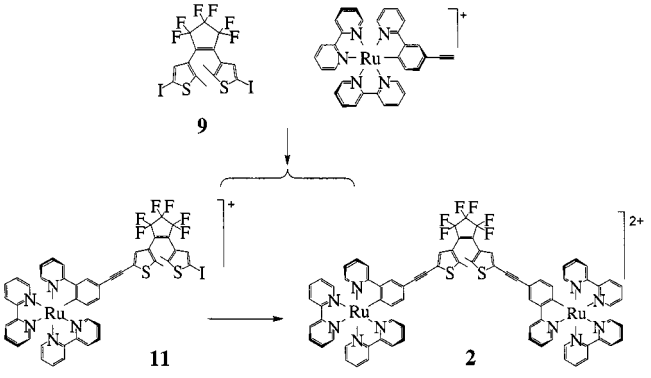
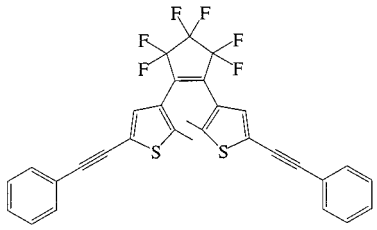
Compound **9** exhibits pseudo-C_2 symmetry. The general conformation is transoid, that is, the methyl groups of the thiophene rings are above and below the plane of the perfluorocyclopentene ring, as Irie et al. observed for the related 1,2-bis(2,5-dimethyl-3-thienyl)perfluorocyclopentene.[17] This conformation is adapted for the cyclization reaction which can occur with relatively small movements.[17] The angle between the thiophene rings and the perfluorocyclopentene ring is 42°. The perfluorocyclopentene ring is not strictly planar, and thus the molecule exists in two conformations with statistical disorder (only one is shown in Figure 2). The bond lengths are in agreement with an electronic structure made up of two thiophene rings linked essentially by a single bond to perfluorocyclopentene. There appears to be little or no conjugation between the three rings.

Final Coupling



In the case of norbornadiene derivatives, difficulties were experienced in the stannylation of the alkyne functionality,[18,19] so we attempted a direct coupling with the bis(iodinane) **5**. Dinuclear complexes were readily obtained.

Unfortunately, a careful mass-spectrometry analysis showed that the desired complex **1** was systematically contaminated with the butadiyne derivative **10**, resulting from an oxidative coupling reminiscent of the Glaser reaction, despite drastic precautions against atmospheric oxygen contamination. Suspecting the iodinane **5** to be the necessary oxidizer,[20] we thought of using the expectedly less reactive diiodonorbornadiene **6**. Adapting literature coupling conditions to this substrate,[21] we were able to prepare the desired complex **1** in 40% yield (Scheme 6).



Scheme 6. Norbornadiene dinuclear complexes

In the case of the dithienylethene derivative, ethynylation occurred at room temperature in DMF under Sonogashira's conditions with $Pd(PPh_3)_4$ as catalyst source,[10,22] yielding the dinuclear complex **2**, albeit in moderate yield (20%). The major by-product was the mononuclear complex **11** (30%) which could be, if needed, converted into the dinuclear complex **2** by the same reaction conditions (Scheme 7).

Scheme 7. Dithienylethene complexes

All the dinuclear complexes were purified by preparative thin layer chromatography on silica, with a mixture of toluene and acetonitrile as eluent. However, it was found that crude complexes had to be deposited in CH_2Cl_2 to get proper separation (vide infra). These complexes, isolated as hexafluorophosphates, were identified by conventional analytical techniques.[23]

12a

Scheme 8. Model compound **12a**

Finally, for comparison purposes, the model compound **12a** (Scheme 8), in which the conjugated part is similar to the one of **2a**, was synthesized from **9** and phenylacetylene.[24]

Electrochemistry and Intervalence Electron Transfer in the Native Forms 1 and 2a

The cyclic voltammograms of **1** and **2a** exhibit a single reversible oxidation wave at 0.50 and 0.53 V (MeCN) vs SCE, respectively, corresponding to the oxidation of both ruthenium(II) sites. However, as in similar complexes with large metal−metal separations, this does not preclude the generation of appreciable concentrations of the mixed valence $Ru^{II}-Ru^{III}$ form during partial oxidation.[2] Conproportionation constants (K_c) for the equilibria between the $Ru^{II}-Ru^{II}$, $Ru^{III}-Ru^{III}$ and $Ru^{II}-Ru^{III}$ (mixed valence forms) were obtained by differential pulse voltammetry. K_c was found to be 13 for **1** and to be 11 for **2a**, corresponding to ca. 65% of the mixed-valence form at half-oxidation. These K_c values compare well with the ones observed for complexes of similar length.[2c]

An estimation of the electronic coupling parameter V_{ab} from the intervalence band characteristics is possible through Hush's Equation [Equation (1)][3,25] where $\bar{\nu}$ is the band position, $\Delta\bar{\nu}_{1/2}$ is the full width at half-maximum, and ε_{max} is the maximum extinction coefficient, while R_{MM} is the metal−metal distance.

$$V_{ab} = \frac{2.05\ 10^{-2}\sqrt{\bar{\nu}\ \Delta\bar{\nu}_{1/2}\ \varepsilon_{max}}}{R_{MM}} \quad (1)$$

In the case of **1**, the progressive oxidation (either chemical or electrochemical) revealed an intervalence transition in the 1300−2000-nm range. After correction for the conproportionation equilibrium, and deconvolution of the mixed-valence spectrum to extract the profile of the intervalence transition, according to a method already published,[2a,2d] the intervalence band parameters were obtained (Table 1). The V_{ab} parameter is found to be 0.068 eV. It is interesting to compare this with the similar complex with dicyanonobornadiene as a bridge and pentaammineruthenium as end groups, for which the coupling (0.023 eV) was three times less.[4] This shows the advantage of cyclometalated units as redox groups.

In the case of **2a** (where ruthenium atoms are initially in oxidation states II−II), the progressive oxidation to the

Table 1. Intervalence band parameters for compounds **1** and **2b**

Compound	K_c	$\tilde{\nu}$ [cm^{-1}]	$\Delta\tilde{\nu}_{1/2}$ [cm^{-1}]	ε [mol^{-1} L cm^{-1}]	R_{MM} [Å]	V_{ab} [eV]
1	13±2	5500±200	5000±300	3460±200	11.1	0.068±0.005
2b	12±2	7400±500	5000±300	1400±100	23.4	0.025±0.003

III−III fully oxidized form could be achieved easily and was found to be reversible. During oxidation, a band near 850 nm kept appearing; it is assigned to a ligand-to-metal charge transfer transition. No intervalence band was observed, regardless of the oxidation method [electrochemical with concentration, $c = 4 \cdot 10^{-4}$ M, or chemical with bis(pyridyl)phenyliodonium triflate with concentration, $c = 6 \cdot 10^{-5}$ M, see below].

Photochemistry

Photoisomerizations were undertaken for complexes **1** and **2a**, with the aim of generating either a less conjugated form (norbornadiene to quadricyclane isomerization of **1**) or a more conjugated form (photocyclization of the dithienylethene derivative **2a**).

In the case of **1**, irradiations at 254 and 365 nm either in methanol or acetonitrile, monitored by ^{1}H-NMR spectroscopy, did not produce isomerization to quadricyclane. Experiments on the simpler compound 1,2-bis(phenylethynyl)-norbornadiene (**7**) did not result in photoisomerization either. Thus, it seems that for norbornadiene, the extension of conjugation due to the phenylethynyl parts is responsible for the lack of photochemical reactivity, probably by quenching the excited state of the norbornadiene part. Such negative effects of the conjugation length were described elsewhere.[26]

Irradiation of **2a** in MeCN or CH_3OH at different wavelengths (405, 313, 365, and 254 nm) was first followed by UV/Vis spectroscopy. A broad band appeared at 670 nm, which corresponds to the photocyclized isomer, according to similar examples.[6b][6e] The highest intensity at the photostationary state was obtained with 254-nm irradiation, and all following studies were performed at this wavelength. Since the other bands in the UV/Vis spectra did not disappear (see below), another technique was necessary to measure the degree of conversion into the closed form. We found that for concentrations of ca. $2 \cdot 10^{-4}$ mol L^{-1} it was possible to monitor the reaction (in CD_3OD) by both UV/Vis and ^{1}H-NMR spectroscopy, in the latter case the signals of the methyl protons closest to the newly created bond were used. During irradiation, the sharp singlet at $\delta = 1.98$, corresponding to methyl protons of the open form **2a**, decreased and was progressively replaced by a signal at $\delta = 2.21$, attributed to the methyl protons of the closed form. The relative integration of the two methyl signals showed that a photostationary state was reached after two hours of irradiation, the closed form **2b** concentration reaching 75% of the initial complex content. Since conversions up to 100% were reported for similar systems,[6] the incomplete isomerization in our case is probably related to the persistence of an absorption for the closed form at all wavelengths, due to the organometallic part. Thus, in contrast to other photochromic compounds of this family, it is not possible to find a wavelength for which only the open form **2a** would be excited.

Since the photochemical ring closure of **2a** was not complete, a purification step was necessary to obtain the spectroscopic behavior of the pure closed form **2b**. However, the conditions described above, involving thin-layer chromatography with a toluene/acetonitrile mixture as eluent failed; the two isomers migrated as a single and stretched spot. It was recently shown[27] that chromatographic elution of ionic compounds was made difficult because of some streaking of the bands. This was attributed to partial ion exchange between the ion pairs and the stationary phase. To force this equilibrium toward ion-pairing, and since dichloromethane gave the best results as deposition solvent, we chose to saturate the TLC plate with an excess of KPF_6. Despite their relatively small structural differences, separation of the two isomers **2a** and **2b** could be achieved: elution with a dichloromethane/ethyl acetate/pyridine mixture revealed a pink band (**2a**) followed by a blue band (**2b**) which migrated slightly more slowly (R_F = 0.40 and 0.34 for **2a** and **2b**, respectively). The ^{1}H-NMR spectrum of the blue product (Figure 3) agreed with structure **2b**, and showed, in particular, the displacement of the thiophene protons upon cyclization.

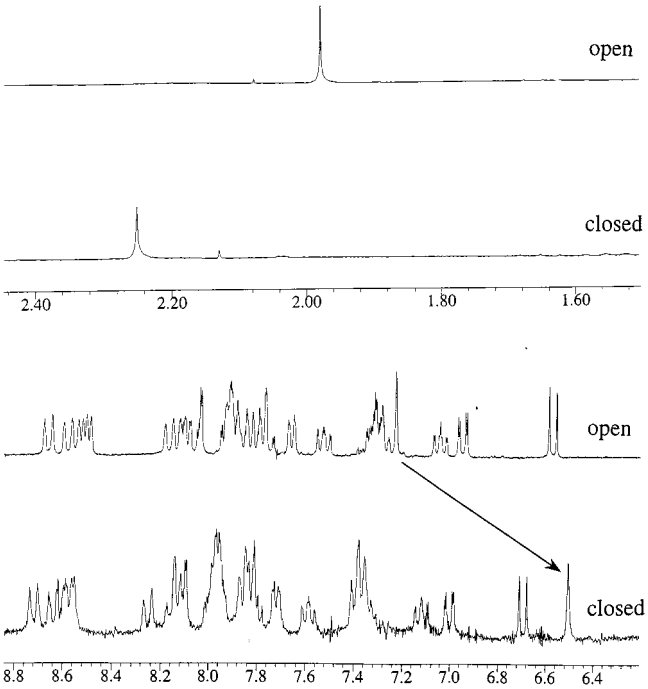


Figure 3. ^{1}H-NMR spectra of the open form **2a** and the closed form **2b** of the bis(ethynylcyclometalated) dithienylethene complex; the arrow shows the displacement of the thiophene protons

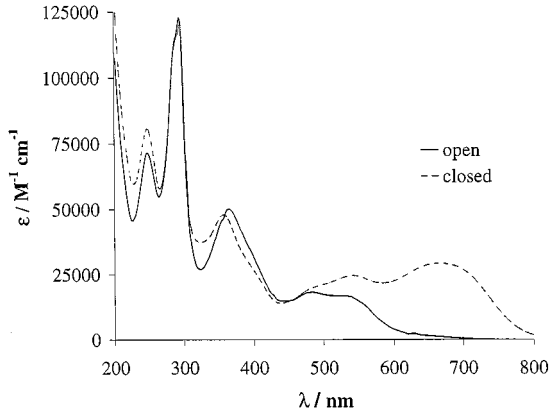

Figure 4. UV/Vis spectra of the open form **2a** and the closed form **2b** of the bis(ethynylcyclometalated) dithienylethene complex

The closed form did not revert thermally when kept for several hours in the dark. The back-reaction, that is, ring reopening, could be observed when irradiation was performed in the red part of the spectrum, with an incandescence lamp with a Kodak red filter excluding radiation below 600 nm.

The UV/Vis spectra of **2a** and **2b** are shown in Figure 4. Upon photocyclization, the UV/Vis spectrum is modified mainly in the red region, with the broad 670-nm peak rising. In the rest of the spectrum, only weak changes are observed, with a small decrease of some bands (see Figure 4). The extinction coefficient at 670 nm for the closed form is 29700 mol^{-1} L cm^{-1}. This high value can be related to the presence of donor substituents,[28] in our case the cyclometalated ruthenium(II) units, and also to the length of the conjugated system.

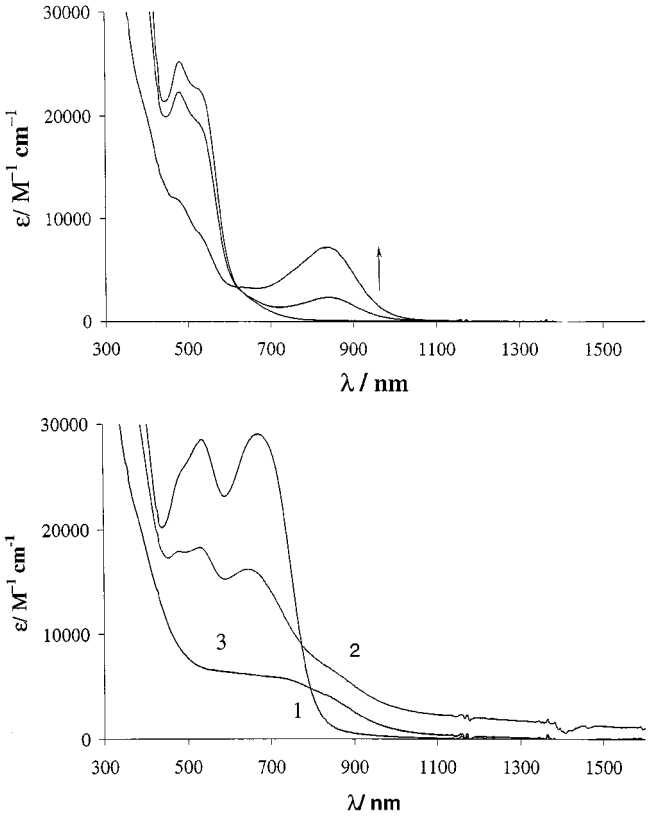

Figure 5. Spectra obtained during oxidation with bis(pyridyl)-phenyliodonium; top: *open* form **2a**; bottom: *closed* form **2b** exhibiting an intervalence absorption in the 1000−1500 nm range; total concentration: $5.7 \cdot 10^{-5}$ mol·L^{-1}; path length: 1 cm; 1: initial spectrum; 2: spectrum at half-oxidation; 3: spectrum of the fully oxidized solution

Electrochemistry and Intervalence Transition of 2b

The closed form **2b** gives rise to a single oxidation wave at 0.52 V (MeCN) vs SCE, corresponding to the oxidation of both ruthenium atoms. Differential pulse voltammetry yields $K_c = 12$.

The oxidation of **2b**, particularly by controlled-potential electrolysis, was not a simple process. During oxidation, the characteristic band of the closed form of the photochromic core, near 670 nm, decreased, suggesting a major alteration of the structure. Furthermore, after complete oxidation, a reduction by hydrazine did not restore the characteristic color and spectrum of **2b** in its reduced form, but instead a spectrum very close to the one of **2a**. Thus, during oxidation, a ring reopening occurred, and the final product was the oxidized form of **2a**.[29] (Incidentally, the same oxidation-induced ring reopening was also observed with the mononuclear **11b** complex.)

We found that the reopening during electrolysis was in fact a relatively slow reaction (half-reaction time ca. 5−10 min), consecutive to the oxidation step. Thus, it was conceivable to quench it with a faster oxidation procedure than controlled-potential electrolysis, the latter being limited by mass transport between the electrode and the bulk solution. After systematic search of chemical oxidation procedures, we chose an oxidation by the triflate salt of bis(pyridyl)phenyliodonium, formally containing iodine(III).[30] Interestingly, in our case, this reagent reacted instantaneously, did not generate acidic species (which would be harmful for the cyclometalated moieties), and the by-products are merely iodobenzene and pyridine. Finally, both the reagent and by-product (iodobenzene) are almost nonabsorbent in the visible and near-IR regions.

Upon chemical oxidation of pure **2b**, obtained from chromatography, we observed the decrease of the 670-nm band and the rising and subsequent decay of a weak absorption in the near-infrared, behavior characteristic of intervalence transitions (Figure 5, bottom). [The decrease of the 670-nm band comes from the fact that the ruthenium(II) donor groups, which increase the extinction coefficient of the closed form, [28] are no longer present.] In a control experiment, no near-IR absorption was obtained by oxidation of the monometallic complex **11a**, neither with the open form itself nor with the closed form **11b**; this suggests that the near-IR absorption in **2b** is indeed linked to the bimetallic nature of the complex.

To obtain the parameters for Hush's equation, after correction for the conproportionation equilibrium ($K_c = 12$), the spectrum was deconvoluted according to a procedure already described,[2d] to separate the intervalence band from the tail of the nearby more intense band located near 900 nm. Although no true maximum was observed for the

intervalence band, spectral simulation showed that a band exists. Additional evidence for an intervalence absorption was provided by the reproducibility of the results, and the typical increase followed by a decrease upon oxidation. The resulting parameters of the intervalence band are reported in Table 1. With the use of R_{MM} = 23.4 Å, from molecular modeling methods,[31] V_{ab} = 200 cm^{-1} (0.025 eV). By contrast, as said above, nothing was observed in the case of **2a** (Figure 5, top).

To understand the electronic mechanism of the coupling, an extended Hückel evaluation of V_{ab} in both **2a** and **2b** was performed. We showed elsewhere that this method is sufficient for obtaining realistic values of the electronic coupling and that it allows qualitative discussions.[2a] The geometries of **2a** and **2b** were first minimized by molecular mechanics.[31] Then molecular orbitals were computed by the extended Hückel method,[32] and V_{ab} was obtained from the "dimer splitting" procedure.[2a] For **2b**, a coupling of 0.021 eV was obtained versus 0.003 eV for **2a**. The former value is consistent with the observed coupling, while the latter explains the disappearance of the intervalence transition, since a 7-fold reduction in V_{ab} should result in a ca. 50-fold (i.e., 7^2) reduction in the extinction coefficient. In chemical terms, for **2a**, the useful part of the bridge (ignoring sulfur contributions) is made up of a nonconjugated octatriene, while in **2b**, it can be considered to be a conjugated octatetraene. Interestingly, values of V_{ab} in the 0.02-eV range have already been observed for conjugated systems with four double bonds and metal−metal distances near 20 Å.[2d] A more complete discussion of the spatial extension and properties of the orbitals involved in the electron transfer for such compounds is given elsewhere.[33]

The extended Hückel calculation also rationalizes the behavior of **2b** upon oxidation. While in **2a**, the ruthenium d orbitals are well separated from other molecular orbitals with mainly ligand character, so that the oxidation is truly metal-centered, in **2b**, a filled orbital of the ligand has moved up and appears at an energy very close to metal orbitals. Thus, although the oxidation bears primarily on the metal (as shown by the electrochemical behavior: **2a** is oxidized reversibly at 0.53 V, while the model compound **12a** is oxidized *irreversibly* at 1.04 V[24]), it is relatively easy to partially depopulate a *ligand* orbital by oxidation. Because this ligand orbital is bonding between carbon atoms C-5′ and C-5" (see Figure 1b), its depopulation should favor the reopening. In this respect, the oxidation process is somewhat analogous to the photochemical excitation.

Conclusion

The general synthetic strategy of using palladium-catalyzed ethynylation reactions between a substituted acetylene and an electrophilic sp^2-hybridized carbon atom proved to be versatile and could be adapted for the present purpose. Compounds with two redox groups linked by a photoisomerizable bridge were obtained, but their behavior differed markedly with respect to the bare photochromic parts. In particular, the extension of conjugation could suppress photoisomerization (**1**) or make it nonquantitative (**2a**), probably because the additional conjugated parts and the redox groups can act as energy sinks. Such an effect was also reported elsewhere.[26]

Despite these difficulties, we found two interesting features associated with the same molecule (**2a/2b**): full photoinduced electron transfer between two metal units, and reversible photochromism. The intervalence transition could be switched completely "on" or "off". The order of magnitude of the electronic coupling in both forms was correctly reproduced by an extended Hückel calculation. Compounds **2a** and **2b** allowed a fundamental study of switching (in the electrical sense) at the molecular level.

Experimental Section

Starting Materials: Reagents were of commercial grade. THF was dried with Na/benzophenone, CH_2Cl_2 with CaH_2, and MeCN with molecular sieves. Amines were used as received. Preparative TLC plates were purchased from Merck. Compound **4** was synthesized according to ref.[9] Octafluorocyclopentene was purchased from Interchim. Bis(iodonium)norbornadiene (**5**), diiodonorbornadiene (**6**), bis(phenylethynyl)norbornadiene (**7**) were synthesized according to literature procedures. For **8**, the procedure in ref.[16] was adapted: Octafluorocyclopentene was added to a ca. 0.2 M solution of 4-lithio-5-methyl-2-trimethylsilylthiophene in THF at −80 °C, and the mixture was allowed to warm up over 5 h. Compound **8** was obtained after chromatography (SiO_2, pentane) and recrystallization (MeCN), the yield was 50% on a gram scale. All the reactions and handling of the compounds sensitive to UV light were carried out in the dark.

Perfluoro-1,2-bis(2-iodo-5-methylthien-4-yl)cyclopentene (9): A solution of **8** (150 mg, 0.29 mmol) and iodine monochloride (190 mg, 1.17 mmol) in CH_2Cl_2 (10 mL) was stirred at −5 °C for 2 h. After solvent evaporation, the residue was purified by column chromatography (basic Al_2O_3, pentane) to give 165 mg of **9** as a waxy solid in 90% yield. M.p. 96 °C. − ^{1}H NMR: (250 MHz, $CDCl_3$, 20 °C, TMS): δ = 7.2 (s, 1 H), 1.9 (s, 3 H). − $^{13}C\{^1H\}$ NMR ($CDCl_3$, 250 MHz, 20 °C): δ = 147.7 (C-5′), 136.0,(C-3′), 135.2 (C-2′), 126.6 (C-4′), perfluorocyclopentene (multiplets) 111.7, 115.7, 119.9, 14.3 (CH_3). − ^{19}F NMR (CD_3OD, 200 MHz, 20 °C, external CF_3COOH as reference): δ = −31.7 to −31.9 (m, 2 F), −53.5 to −53.6 (m, 1 F). − MS (CI, NH_3); *m/z* (%): 620.0 (100). − $C_{15}H_8S_2F_6I_2{\cdot}CH_3CN$ (619.8): calcd. C 30.88, H 1.68, S 9.70; found C 30.86, H 1.50, S 9.53.

Ethynylcyclometalated Compound 3: A solution of **4** (150 mg, 0.19 mmol) and potassium *tert*-butoxide (25 mg, 0.22 mmol) in 5 mL of dry, oxygen-free THF was stirred at reflux temp. for 2 h. After the solvent was cooled and removed, the residue was taken up in dichloromethane and the filtered solution was concentrated, yielding **3** as an amorphous solid. The reaction was quantitative. − ^{1}H NMR (250 MHz, CD_3CN, 20 °C, TMS): δ = 3.27 (s, 1 H), 6.47 (d, *J* = 7.8 Hz, 1 H), 6.91 (dd, *J* = 7.7, 1.6 Hz, 1 H), 6.9 (td, *J* = 6.0, 1.4 Hz, 1 H), 7.21−7.26 (m, 3 H), 7.43 (td, *J* = 7.0, 1.2 Hz, 1 H), 7.60 (dd, *J* = 4.0, 1.0 Hz, 2H), 7.69−7.87 (m, 7 H), 7.96−8.08 (m, 3 H), 8.33 (dd, *J* = 8.0, 3.0 Hz, 2 H), 8.40 (d, *J* = 8.1 Hz, 1 H), 8.46 (d, *J* = 8.1 Hz, 1 H). − MS (FAB, NBA); *m/z* (%): 592 (100) $[M - PF_6]^+$. − $C_{33}H_{24}N_5PF_6Ru$ (736): calcd. C 53.81, H 3.28, N 9.51; found C 53.78, H 3.76, N 8.71.

Bis(ethynylcyclometallated) Norbornadiene Complex 1: Diiodonorbornadiene (30.9 mg 0.09 mmol), $Pd(PPh_3)_4$ (10 mg, 0.05 equiv.), CuI (10 mg, 0.3 equiv.) and finally 1 mL of diisopropylamine were added to 2 mL of a DMF solution containing 0.19 mmol of **3**. The solution was stirred at room temp under argon for 10 h. The solvent was then removed in vacuo and the crude product was purified by chromatography on a silica gel preparative plate (eluent: toluene/acetonitrile 60:40), with desorption by a concentrated solution of ammonium hexafluorophosphate in MeCN). Yield: 59 mg (40%). − ^{1}H NMR: (250 MHz, CD_3CN, 20 °C, TMS): δ = 2.17−2.19 (m, 1 H), 2.30−2.32 (m, 1 H), 3.70 (br. s, 2 H), 6.51 (d, *J* = 7.9 Hz, 2 H), 6.85−6.97 (m, 6 H), 7.10−7.25 (m, 6 H), 7.40−7.53 (m, 4 H), 7.58−7.86 (m, 14 H), 7.94 (sd, *J* = 1.5 Hz, 2 H), 7.97−8.03 (m, 6 H), 8.29−8.35 (m, 4 H), 8.38 (d, *J* = 8.2 Hz, 2 H), 8.46 (d, *J* = 8.2 Hz, 2 H). − MS (ES); *m/z*: 1417 $[M - PF_6]^+$, 859 $[M - 2PF_6 - (Ru(bpy)_2)]^+$, 790 $[M - 2PF_6 - (Ru(bpy)_2) - Cp]^+$, 636 $[M - 2PF_6]^{2+}$. − $C_{73}H_{52}N_{10}P_2F_{12}Ru_2{\cdot}3H_2O$ (1615): calcd. C 54.28, H 3.62, N 8.67; found C 54.21, H 3.88, N 8.09.

Mono- and Bis(ethynylcyclometalated) Dithienylethene Complexes in Their Open Forms 11a and 2a: The reaction was carried out with 55.8 mg (0.09 mmol) of **9** and was worked up in a manner identical to that described above for the synthesis of **1**. Yield 32 mg (20%) of **2a** and 33 mg (30%) of **11a**.

11a: ^{1}H NMR: (250 MHz, CD_3OD, 20 °C, TMS): δ = 1.96 (s, 3 H), 1.99 (s, 3 H), 6.56 (d, *J* = 7.7 Hz, 1 H), 6.95 (dd, *J* = 7.7, 1.7 Hz, 1 H), 7.04 (td, *J* = 6.7, 1.1 Hz, 1 H), 7.20 (s, 1 H), 7.28−7.35 (m, 4 H), 7.42 (d, *J* = 5.5 Hz, 1 H), 7.52 (td, *J* = 7.8, 1.6 Hz, 1 H), 7.65 (dd, *J* = 5.1, 1.0 Hz, 1 H), 7.72−7.97 (m, 6 H), 8.04 (sd, *J* = 1.9 Hz, 1 H), 8.08−8.13 (m, 2 H), 8.18 (d, *J* = 7.9 Hz, 1 H), 8.52 (dd, *J* = 8.4, 3.7 Hz, 2 H), 8.58 (d, *J* = 7.9 Hz, 1 H), 8.66 (d, *J* = 8.1 Hz, 1 H). − ^{19}F NMR (CD_3OD, 200 MHz, 20 °C, external CF_3COOH as reference): δ = −31.7 to −31.9 (m, 2 F), −53.5 to −53.6 (m, 1 F). − MS (ES); *m/z*: 1084.1 $[M - PF_6]^+$. − UV/Vis (MeCN): λ_{max} (ε, $M^{-1}{\cdot}cm^{-1}$) = 482 (12300), 364 (30800), 294 (81100), 248 (62000) nm. − $C_{48}H_{31}N_5PF_{12}S_2IRu{\cdot}2EtOH$ (1321.5): calcd. C 47.28, H 3.28, N 5.30; found C 47.94, H 2.97, N 5.31.

2a: ^{1}H NMR (250 MHz, CD_3OD, 20 °C, TMS): δ = 1.98 (s, 6 H), 6.57 (d, *J* = 7.9 Hz, 2 H), 6.96 (dd, *J* = 7.9, 1.6 Hz, 2 H), 7.04 (td, *J* = 6.4, 1.0 Hz, 2 H), 7.24 (s, 2 H), 7.26−7.37 (m, 6 H), 7.52 (td, *J* = 6.4, 1.2 Hz, 2 H) 7.65 (dd, *J* = 5.1, 1.0 Hz, 2 H), 7.72−7.96 (m, 14 H), 8.01 (sd, *J* = 1.6 Hz, 2 H), 8.08−8.19 (m, 6 H), 8.52 (dd, *J* = 8.2, 3.9 Hz, 4 H), 8.58 (d, *J* = 8.1 Hz, 2 H), 8.66 (d, *J* = 7.9 Hz, 2 H). − ^{19}F NMR (CD_3OD, 200 MHz, 20 °C, external CF_3COOH as reference): δ = −31.7 to −31.9 (m, 2 F), −53.5 to −53.6 (m, 1 F). − MS (ES); *m/z*: 1693 $[M - PF_6]^+$, 774 $[M - 2PF_6]^{2+}$. − UV/Vis in MeOH: λ_{max} (ε, $M^{-1}{\cdot}cm^{-1}$) = 480 (20600), 366 (50000), 295 (139000), 247 nm (84100). − $C_{81}H_{54}N_{10}P_2F_{18}S_2Ru_2{\cdot}6H_2O$ (1944): calcd. C 50.00, H 3.42, N 7.20; found C 49.86, H 3.14, N 6.93.

Bis(ethynylcyclometalated) Dithienylethene Complex in Its Closed Form 2b: Compound **2a** was converted into **2b** on a preparative scale as follows: An efficiently stirred solution of **2a** (16 mg) in 10 mL of acetonitrile or methanol was irradiated in a quartz vessel with two standard TLC-visualization UV lamps at 254 nm for 12 to 24 h. To the resulting mixture, 0.05 mL of hydrazine and 5 mg of NH_4PF_6 were added, and the solution was concentrated to dryness. The solid was dissolved in dichloromethane and subjected to preparative TLC chromatography on silica gel plates previously immersed in a saturated aqueous KPF_6 solution for 1 h and then dried in an oven overnight. Elution of the plate (eluent: dichloromethane/ethyl acetate/pyridine, 100:100:1) was carried out with careful protection from light. Washing of the silica with a mixture of dichloromethane/ethanol/triethylamine (91:8:1) readily provided desorption of the band corresponding to **2b** (6.5 mg).

2b: ^{1}H NMR (250 MHz, CD_3OD, 20 °C, TMS): δ = 2.21 (s, 6 H), 6.46 (s, 2 H), 6.65 (d, *J* = 7.4 Hz, 2 H), 6.80 (d, *J* = 7.5 Hz, 2 H), 7.04−7.10 (m, 2 H), 7.24−7.40 (m, 6 H), 7.48−7.59 (m, 2 H), 7.68 (d, *J* = 4.5 Hz, 2H), 7.74−8.00 (m, 14 H), 8.03−8.13 (m, 6 H), 8.21 (d, *J* = 7.9 Hz, 2 H), 8.46−8.61 (m, 6 H), 8.68 (d, *J* = 8.1 Hz, 2 H). − UV/Vis in MeOH: λ_{max} (ε, $M^{-1}{\cdot}cm^{-1}$) = 670 (29700), 545 (24800), 358 (48500), 295 (123000), 248 nm (82000). − $C_{81}H_{54}N_{10}P_2F_{18}S_2Ru_2{\cdot}10H_2O$ (2016): calcd. C 48.22, H 3.70, N 6.94; found C 48.31, H 3.47, N 6.49.

X-ray Crystal Structure of 9: Crystals were obtained by cooling of a saturated solution in acetonitrile, and were mounted on an Enraf Nonius Kappa CCD diffractometer. Mo-K_α (λ = 0.71073 Å) radiation was used and the temperature was 293 K. The space group was monoclinic *C*2/*c*; *a* = 20.7183(5) Å, *b* = 9.0480(5) Å, *c* = 11.9644(4) Å, β = 120.987(2)°, *V* = 1922.8(9) Å^3, *Z* = 4. Structure determination was performed with direct methods (SIR 92),[34] from 2470 reflections, of which 1810 with $I > 3\sigma(I)$ were used for refinement against F^2 (CRYSTALS).[35] Non-hydrogen atoms were treated anisotropically except for disordered atoms (C10 and F). H atoms (isotropic) were placed from difference Fourier maps and were not refined. Final values: *R* = 5.17%, *Rw* = 7.26%; residual electron density: −0.8, +1.2 e/Å^3. Drawings were made with ORTEP III.[36] Crystallographic data (excluding structure factors) for the structure reported in this paper were deposited at the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-136201. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ (UK) [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Photochemistry: For analytical investigations, photochemical irradiations of **2a** were performed in 2-mm or 1-cm quartz cells placed in front of either a standard TLC-visualization UV lamp (365 and 254 nm), or an optical system combining a medium-pressure Mercury lamp and interference filters (405, 365, and 313 nm). For the reopening reaction of **2b**, an incandescence lamp with a red filter was used. The solutions were stirred either with a small magnetic bar (1-cm cells), or by the cell being turned upside down every minute (2-mm cells incompletely filled under argon to imprison a bubble). Concentrations were in the 10^{-5} mol L^{-1} range (1-cm cells). For the combined UV/Vis/NMR experiment in CD_3OD at 254 nm, the concentration was $2{\cdot}10^{-4}$ mol L^{-1} (2-mm cells). After irradiation of the photostationary state, the solution (ca. 0.6 mL) was transferred to the NMR tube. Preparative photochemistry took place in a quartz vessel as described above.

Electrochemistry: Electrochemical techniques were performed with an AUTOLAB PC-controlled potentiostat. The reference electrode was a saturated calomel electrode (SCE) isolated from the solution by a double frit system. The solvent was acetonitrile and the supporting electrolyte was 0.1 M tetrabutylammonium hexafluorophosphate. For cyclic voltammetry, the working electrode was a Pt disk (diameter 1 mm), and the scan rate 0.1 $V{\cdot}s^{-1}$. Differential pulse voltammetry was performed with a Metrohm rotating platinum electrode (1000 rev/min) with pulses of 70 ms duration and 25 mV amplitude. For controlled potential electrolysis, the working electrode was a platinum grid, and the anodic and cathodic compartments were separated by a additional frit.

Iodine(III) Reagent: The reported preparation[30] starts from iodobenzene diacetate. However, the commercial reagent gave unsatis-

factory results. Thus, it was prepared from iodobenzene, acetic anhydride, and hydrogen peroxide according to ref.[37] Then iodobenzene diacetate was converted into the triflate salt of bis(pyridyl)-phenyliodonium by reaction with trimethylsilyl trifluoromethanesulfonate.[30] The obtained whitish solid was kept under argon at −20 °C.

For oxidation experiments, in a typical run, a $5.7\cdot10^{-5}$ mol L^{-1} solution of **2a** in anhydrous MeCN was prepared. A volume of 2.5 mL of this solution was started with, and the oxidation was performed in a 1-cm cell by addition of a solution of the iodine(III) reagent ($3.0\cdot10^{-2}$ mol·L^{-1} in MeCN) with a micropipette. Full oxidation was found to occur for 26 μL, at which the spectrum of the $Ru^{III}-Ru^{III}$ species was obtained. In a second experiment, half the above quantity (i.e., 13 μL) was added, and the absorption spectrum, corresponding to the mixed-valence species in conproportionation equilibrium, was immediately recorded. For the closed form **2b**, oxidation was performed as above on 1 mL of a $2.6\cdot10^{-4}$ M solution in a 5-mm cell.

Calculations: Compounds **2a** and **2b** were minimized[31] with the universal force field[38] modified with the following parameters: 350 kcal mol^{-1} $Å^{-2}$ and 2.05 Å for Ru−N bonds, 350 kcal mol^{-1} $Å^{-2}$ and 2.02 Å for Ru−C bonds. Since the energy was almost insensitive to a rotation around the acetylenic bonds, the thiophene rings and the phenyl groups were made coplanar to avoid rotational disorder. This gave molecules with only one element of symmetry, a C_2 axis. Molecular orbitals were computed by the extended Hückel method, with the CACAO program[32] with Ru(4d) orbital energies set at −11.0 eV. The V_{ab} parameters were extracted from the energy splitting between two orbitals with strong weights on metal atoms and opposite symmetries with respect to the C_2 axis of the molecules. Due to the low symmetry around the metal sites, it turned out that for each molecules *two* such couples of orbitals were found: one corresponding to an interaction propagating through the phenyl ring of the phenylpyridine ligand, and another corresponding to an interaction through the pyridine ring. Since the two couplings V_{phen} and V_{pyr} were of the same order of magnitude, they were combined by Equation (2).

$$V_{ab} = \sqrt{V_{phen}^2 + V_{pyr}^2} \quad (2)$$

Acknowledgments

We thank J. C. Cobas, J. Cruces and F. Sardina for providing a free copy of the NMR software MestRe-C 1.5.1 (http://qobrue.usc.es/jsgroup/MestRe-C/MestRe-C.html), Christine Viala for technical help, Robert Weiss for precious advice, Jean-Claude Micheau and Véronique Pimienta for photochemical experiments, Catherine Romero for UV/Vis measurements, André Gourdon for the resolution of the X-ray structure, and MENRT for a thesis grant to S. F.

[23] Due to the chirality of the organometallic group (Λ or Δ configuration), the complexes are obtained as mixtures of stereoisomers such as ΛΛ, ΔΔ and ΔΛ for **2a**. However, the chiral centers are generally sufficiently far apart for their steric interaction to be negligible, so that the chirality of the two metal centers can be considered to be independent. Moreover, in similar examples involving $Ru(bipy)_2$-like terminal units, no consequences of the chirality of the metal centers were reported, neither on the NMR spectra (J. Bolger, A. Gourdon, E. Ishow, J.-P. Launay, *Inorg. Chem*. **1996**, *35*, 2937), nor on the electrochemical and spectroscopic behavior (M. J. Powers, T. J. Meyer, *J. Am. Chem. Soc.* **1980**, *102*, 1289; A. C. Benniston, V. Goulle, A. Harriman, J.-M. Lehn, B. Marczinke, *J. Phys. Chem.* **1994**, *98*, 7798). See also the review: R. J. Crutchley, *Adv. Inorg. Chem.* **1994**, *41*, 273, and references therein. Thus, the stereochemical aspects are not considered in the rest of this paper.

[24] ^1H NMR (250 MHz, CD_3OD, 20 °C) of **12a**: δ = 2.02 (s, 3 H), 7.34 (s, 1 H), 7.40−7.46 (m, 3 H), 7.58−7.60 (m, 2 H). Electrochemistry: irreversible oxidation at 1.04 V vs SCE in MeCN. Colorless "open" compound **12a** undergoes photocyclization upon irradiation with UV light, to give the "closed" cobalt-blue isomer **12b**. For a $1.6\cdot10^{-5}$ M solution in MeCN, the photostationary state is reached within 25 s (cf. 30 s for **8**). UV/Vis in MeCN: λ_{max} (nm) (ε [M^{-1} cm^{-1}]): *open* form (**12a**): 306 (61250); *closed* form (**12b**): 604 (21900).

[25] In this expression, V_{ab}, $\bar{\nu}$, and $\Delta\bar{\nu}_{1/2}$ are in cm^{-1}, ε_{max} in mol^{-1} L cm^{-1}, and R_{MM} is in Å. The proportionality factor

0.0205 comes from (i) the definition of the oscillator strength f in terms of experimental quantities, (ii) the relation of f with the transition moment μ_{tr} (P. W. Atkins, *Physical Chemistry*, 4th ed., Oxford University Press, Oxford, **1990**, pp. 503−504), and (iii) the expression of μ_{tr} in the particular case of intervalence transitions, according to Hush.[3] The literal expression of this factor is $[3\,h\,C\,\varepsilon_0(\ln 10)/4\,\pi^2\,N_A\,e^2]^{1/2}\,(\pi/\ln 2)^{1/4}$ where h is Planck's constant, C is the velocity of light, ε_0 is the permittivity of a vacuum, N_A is Avogadro's number, and e is the elementary charge; a value of $6.513\cdot10^{-12}$ is obtained in SI units. Converted into the more common non-SI units, the result is $6.513\cdot10^{-12} \times (1000)^{1/2}\cdot10^8$, i.e., 0.0205.

Novel Mesityltellurium Cations from Selenenation and Tellurenation Reactions of Dimesityl Telluride in the Presence of the $Br_2/AgSbF_6$ Reagent

Jörg Jeske,[a] Wolf-Walther du Mont,*[a] Frank Ruthe,[a] Peter G. Jones,[a] Laura M. Mercuri,[b] and Paola Deplano[b]

Dedicated to Professor Brigitte Sarry on the occasion of her 80th birthday

Keywords: Tellurium / Cations / Hypervalency / Secondary interactions / Selenium / Xerox process

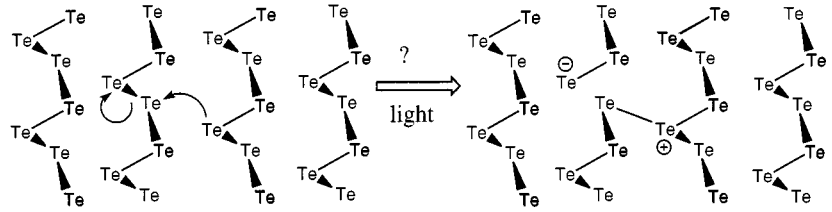
The reaction of dimesityl telluride (**2**) with bis(pentafluorophenyl) diselenide (**1**), Br_2 and $AgSbF_6$ provides small amounts of crystalline $[Mes_2TeSeC_6F_5][SbF_6]$ (**3**). The main products, however, are $[Mes_2TeTeMes][SbF_6]$ (**4**) and $MesSeC_6F_5$ (**5**). Reactions of **2** with Br_2 and $AgSbF_6$ provide – depending on the stoichiometric ratio – **4** and $[Mes_3Te][SbF_6]$ (**6**) or $[Mes_2TeBr][SbF_6]$ (**7**). **2**, Mes_2Te_2, Br_2 and $AgSbF_6$ provide **4** in a fair yield. Addition of **2** to **4** leads to the tritellurium salt $[Mes_5Te_3][SbF_6]$ (**8**). Cation–anion interactions due to the α-heteroatom electrophilicity of RSe-, RTe- and Br-substituted telluronium salts are followed by structure determinations of **3**, **4**, **6**, **7** and **8** and by Raman-spectroscopic observations of the Te–Te vibrations in compounds **4** and **8**.

Introduction

In the course of the Xerox process, undesired residual charges can persist after exposure of amorphous Se/Te alloys to light. These residual charges may be due to charge separation by formation of chalcogenonium cations (with 3 covalent bonds) and chalcogenolate anions (with only 1 covalent bond) in the solid sate, as depicted schematically in Scheme 1 for tellurium chains.[1]

Such polar defects in Se/Te alloys should be metastable with respect to thermal reactions (i.e. collapsing of the ion pairs) leading to "classical" chalcogen chains involving only di-coordinated selenium and tellurium. We propose an alternative, namely that persistent "-onium" and "-ate" functionalities might interact with each other in a nonclassical way (Scheme 2), leading to structural moieties related to Böttcher's hypervalent polytellurides.[2−4] As organic model compounds for such interactions and as novel "isomers" of the stable diaryl tellurides that might mimic unusual soft−soft interactions, telluronium tellurolates Ph_3Te^+ TeR^- were studied with respect to their existence, structure and mode of decomposition.[5] These compounds exist in the solid state as dimers of ion pairs exhibiting weak cation−anion tellurium−tellurium interactions. At room temperature, the orange-red solids decompose into the more stable diaryl tellurides, accompanied by small amounts of the related ditellurides and biphenyl [Equation (1)]. Telluronium selenolates are slightly more stable than the tellurolates, but they exhibit similar structures and decomposition pathways.

$$(Ph_3TeER)_2 \rightarrow Ph_2Te + PhTeER + R_2E_2 + Ph_2$$
$$ER = p\text{-}CH_3C_6H_4Te,\ p\text{-}CH_3C_6H_4Se^{[5]} \quad (1)$$



Intuitively, and from comparison with homonuclear cation−anion interactions by (n→σ*) overlap in iodophosphonium ions,[6] we expect that the cation−anion interactions and the colour of $[Ph_3TeER]_2$ (E = Se, Te) would be determined by n(E) → σ*(C−Te) interactions. These would also explain the VSEPR-consistent coordination geometries of the Te and Se atoms of the dimers of ion pairs.[5] The coordination geometries of pyramidal (3-Te-8) and hypervalent square-pyramidal (5-Te-12) tellurium atoms allow the application of extended (n→σ*) interactions (4 orthogonal 3-center-4-electron systems), involving p orbitals of the anions as donor functions and σ* (C−Te) energy levels as acceptors, as a qualitative bonding model. These cation−anion interactions, however, are much weaker than Te−Te contacts within "nonclassical" polytellurides[2−4,7] and polytellurium dications.[8]

Calculations on $[R_3TeER]_n$ (R = H, Me; n = 1, 2) on the basis of the experimental Te···Te and Te···Se distances,

Scheme 1. The valence-alternation model ($2C_2^0 \rightarrow C_3^+ + C_1^-$) for localised gap states in lone-pair semiconductors applied to tellurium (Kastner−Adler−Fritzsche model)[1]

Scheme 2. "Classic" (8-Te-3 and 8-Te-1) (left) and "hypervalent" (8-Te-3 and 10-Te-3) (right) version of the Kastner−Adler−Fritzsche model

however, do not indicate a positive contribution of Te−Te and Te−Se orbital overlap to the overall energy.[9] The poor acceptor properties of R_3Te^+ towards RTe^- and RSe^- reflect the relative strength (a kind of "*trans* effect") of Te−C bonds, which do not offer low-lying σ* levels to facilitate the attack of donating nucleophiles.[10] Atoms that are more weakly bonded to the telluronium centre, however, would encourage the attack of donating nucleophiles, as shown by the increased electrophilicity of hypothetical $TeI_3^+$and $MeTeI_2^+$ cations relative to R_3Te^+ cations in Me_3Te^+ $MeTeI_4^-$ [11] and $(Ph_3Te^+)_2$ TeI_6^{2-}.[12] For this reason, we decided to synthesise telluronium ions containing one "soft" chalcogen atom adjacent to the formally positively charged tellurium atom of the cation. As an electron-withdrawing substituent we chose the pentafluorophenylseleno group. As further substituents, mesityl groups were selected to enhance crystallisation. An initial experiment explored whether bis(pentafluorophenyl) diselenide (**1**) would add oxidatively to dimesityl telluride (**2**) yielding an, as yet unknown, compound of the type $R_2Te(SeR')_2$ (formally regarded as an adduct of a $[R_2TeSeR']^+$ cation with a RSe^- anion). ^{77}Se- and ^{125}Te-NMR spectra of the reaction mixture, however, did not provide evidence for the presence of the compound $Mes_2Te(SeC_6F_5)_2$.[13] To elucidate whether the failure of the desired oxidative addition of **1** to the diaryl telluride **2** was really due to thermal instability of $Mes_2Te(SeC_6F_5)_2$ (and not to kinetic factors), we then attempted to generate an $[R_2TeSeR']^+$ cation by an independent route.

Reactions

Triorganylperoxonium ions $[R_2OOR]^+$,[13] -disulfonium ions $[R_2SSR]^+$,[14,15] related organoselenium cations such as $[(MeSe)_2SeMe]^+$ [15] and $[Ph_2Se_6]^{2+}$ [16] and oxytelluronium cations $[R_2TeOTeR_2]^{2+}$,[17,18] are well-known species; corresponding selenotelluronium salts $[R_2TeSeR']^+$ X^-, however, have not yet been reported in the literature,[5,12] Such compounds will undergo reductive elimination when the counterion X^- is a good nucleophile towards the $R'Se^+$ group. Salts of the type $[RR'TeTeR']^+$ X^- have been proposed as reactive intermediates when dialkyl ditellurides were activated by alkyl halides for one-pot reactions with carbon nucleophiles.[19] Oxidation of molecules that contain two R_2Te functions in the presence of poorly nucleophilic counteranions has led to a number of cyclic dications with $[R_2Te-TeR_2]^{2+}$ moieties;[20] in the presence of two R_2Se donor functions, hypervalent species with dicationic $[RR'Se-TeR''_2-SeRR']^{2+}$ functions have been generated.[20]

For the generation of $(Mes_2TeSeC_6F_5)^+$ SbF_6^- (**3**) we chose the oxidation of bis(pentafluorophenyl) diselenide (**1**) in the presence of dimesityl telluride (**2**), and SbF_6^- as a poorly nucleophilic counteranion. On addition of few drops of the $Ag[SbF_6]$ solution in CH_2Cl_2 to the mixture of **1**, **2**, and Br_2, the solution became deep red; precipitation of AgBr occurred only after addition of the complete amount of $Ag[SbF_6]$. Crystallisation by diffusion of hexane first provided very dark crystals of a novel compound **4**, which did not contain selenium. Spectroscopic and analytical data and a crystal-structure determination confirmed that **4** is unexpectedly a dimesityl(mesityltelluro)telluronium salt $[Mes_2TeTeMes][SbF_6]$.[21] At a later stage of the crystallisation procedure, a small amount of the originally desired orange-brown selenotelluronium salt **3** and further crystals of black **4** were isolated. An NMR investigation of the remaining oil revealed the presence of mesityl pentafluorophenyl selenide (**5**) [$\delta^{77}Se = +370$, $^3J(^{77}Se, ^{19}F) = \pm 11$ Hz]. Unexpected products **4** and **5** indicated cleavage of the Te−C bonds (loss of a mesityl group of **2**) and formation of a new Se−C bond by attachment of a mesityl group to selenium providing **5** [Equation (2)]. To gain more insight into the loss of a mesityl group from **2**, we treated **2** with 1/2 Br_2 and $Ag[SbF_6]$ only. This reaction also provided crystals of compound **4**; however, these black crystals were ac-

companied by a small amount of greenish crystals of $[Mes_3Te][SbF_6]$ (**6**) [Equation (3)]. This "aryl scrambling" could be associated with a disproportionation by aryl transfer between two R_2Te^+ cations or within an $[R_2Te-TeR_2]^{2+}$ dication, with an aryl cation transfer from R_2Te^{2+} to R_2Te providing R_3Te^+ and RTe^+, the latter being trapped by coordination with R_2Te. A somewhat related formal tellurium analogue to the pinacol−pinacolone rearrangement had previously been discussed when the rearrangement of Wöhler's "α-base $R_2Te(OH)_2$" into the "β-base"[22] was recognised as an alkyl transfer between tellurium atoms.

$$(C_6F_5)_2Se_2 + Mes_2Te + Br_2 + 2\ AgSbF_6 \rightarrow (Mes_2TeSeC_6F_5)SbF_6$$

1 **2** **3**

$$+ (Mes_2TeTeMes)SbF_6 + MesSeC_6F_5 + 2\ AgBr \quad (2)$$

4 **5**

$$2\ \mathbf{2} + Br_2 + 2\ AgSbF_6 \rightarrow \mathbf{4} + (Mes_3Te)SbF_6 + 2\ AgBr \quad (3)$$

6

The observed partial decomposition of **2** upon oxidation with $Br_2/AgSbF_6$ into **4** and **6** would correspond to a dismutation $2\ R_2Te \rightarrow R_3Te^+ + RTe^-$,[6] if the cation of **4** were formally regarded as an adduct of the tellurolate anion $MesTe^-$ with the dication Mes_2Te^{2+}. Carrying out the bromination of **2** with *one* equivalent of Br_2 (Mes_2Te/Br_2, 1:1) and adding one equivalent of $AgSbF_6$ allowed the isolation of the bromotelluronium salt $[Mes_2TeBr][SbF_6]$ (**7**) as yellow crystals [Equation (4)]. In the absence of the diselenide **1**, mesityl group transfer between **7** or the intermediate dication $[Mes_2Te]^{2+}$ and **2**, provided Mes_3Te^+ (the cation of compound **6**), whereas coordination of the remaining $MesTe^+$ moiety with **2** then led to stable **4** [Equation (5)]. In the presence of diselenide **1**, mesityl group transfer to the arylseleno group provided **5**, the remaining $MesTe^+$ moiety was again coordinated by **2** furnishing stable **4**. The latter type of reaction can indeed be verified using Mes_2Te_2, Br_2, $AgSbF_6$ and **2**: this synthesis is an excellent large-scale preparation of compound **4** [Equation (5)].[21] The isolation of compound **4** was favoured by its extremely low solubility; no solution-NMR data of **4** could be obtained.

$$\mathbf{2} + Br_2 + AgSbF_6 \rightarrow (Mes_2TeBr)SbF_6 + AgBr \quad (4)$$

7

$$2\ \mathbf{2} + Mes_2Te_2 + Br_2 + AgSbF_6 \rightarrow 2\ \mathbf{4} + 2\ AgBr \quad (5)$$

However, on addition of one further equivalent of **2** to suspended **4**, the black precipitate dissolved and provided the soluble novel [bis(dimesityltelluronio)mesityl tellurolate(II)] hexafluoroantimonate, $Mes_5Te_3SbF_6$ (**8**). The cation of **4** was obviously still coordinatively unsaturated and by adding one more equivalent of **2** "saturated" **8** was obtained, which contains a hypervalent central tellurium atom [Equation (6)]. This addition of **2** to **4** forming **8** is closely related to the well-known addition of I^- to I_2 to give I_3^-, which contains a hypervalent central iodine atom. Related homonuclear trichalcogen moieties with linearly coordinated central hypervalent sulfur or selenium atoms have been known since the detection of trithiapentalenes,[23] the tris(selenocyanate) monoanion and related species.[24] A related tetracationic system with approximately linear Se−Se···Se arrangements is formed by the interaction of one molecule of 1,2-bis(3-methyl-2-selenoxo-4-imidazolinyl)ethane ("ebis") with two $[(ebis)_2]^{2+}$ dications.[25] An organotellurium anion with an approximately linear triiodide-like Te_3 moiety related to **8**[21] was detected only recently.[26]

$$\mathbf{2} + \mathbf{4} \rightarrow [(Mes_2Te)_2TeMes]SbF_6 \quad (6)$$

8

Spectroscopic and Structural Studies

Comparison of Selenotelluronium Salt 3 and Tellurotelluronium Salt 4

The description of the ditelluronium cation in **4** as a mesitylenetellurenyl cation $MesTe^+$, stabilised by the coordinating Lewis base **2**, is supported by the nature and extent of the various intermolecular interactions of the cations of **4** and of the closely related compound **3** with their SbF_6^- counteranions in the solid state. In solid **4** two cations and two anions form cyclic molecular dimers through secondary Te···F interactions,[21] in solid **3** similar sequences of Te···F and Se···F interactions lead to polymeric chains of cations and anions (Figure 1−4).

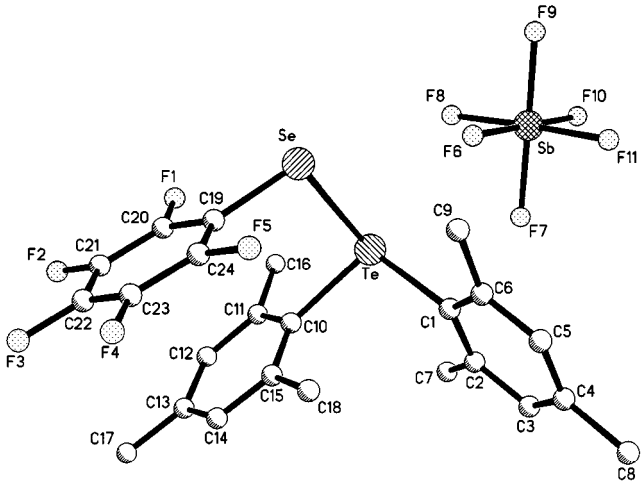

Figure 1. Molecular structure of **3** (cation−anion contacts neglected); selected distances [pm] and angles [°]: Te−C(10) 211.5(3), Te−C(1) 213.3(4), Se−C(19) 190.1(4), Te−Se 257.55(5), Sb−F(6) 189.1(2), Sb−F(7) 187.9(2), Sb−F(11) 185.8(2); C(10)−Te−C(1) 101.80(13), C(10)−Te−Se 96.10(9), C(19)−Se−Te 101.30(11)

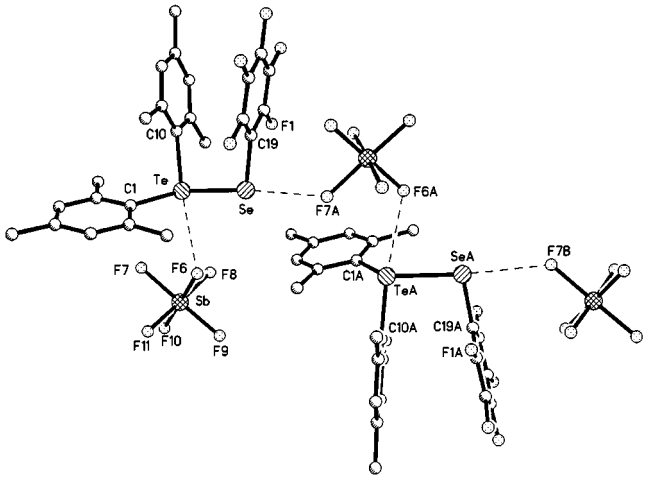

Figure 2. Cation−anion interactions in solid **3**; selected distances [pm] and angles [°]: Te−F(6) 296.2(2), Se−F(7)#1 301.1(2); C(10)−Te−F(6) 173.84(10), C(1)−Te−F(6) 81.28(10), Se−Te−F(6) 77.76(5), C(19)−Se−F(7)#1 84.25(12)

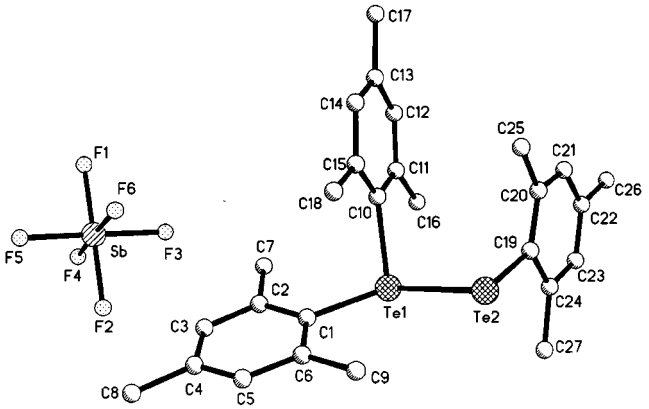

Figure 3. Molecular structure of **4** (cation−anion contacts neglected); selected distances [pm] and angles [°]: Te(1)−C(1) 214.1(4), Te(1)−C(10) 212.7(4), Te(2)−C(19) 213.1(5), Te(1)−Te(2) 276.45(5), Sb−F(1) 187.2(3), Sb−F(2) 186.7, Sb−F(5) 183.9(3); C(1)−Te(1)−Te(2) 112.76(12), C(10)−Te(1)−Te(2) 95.34(11), C(19)−Te(2)−Te(1) 86.18(12)

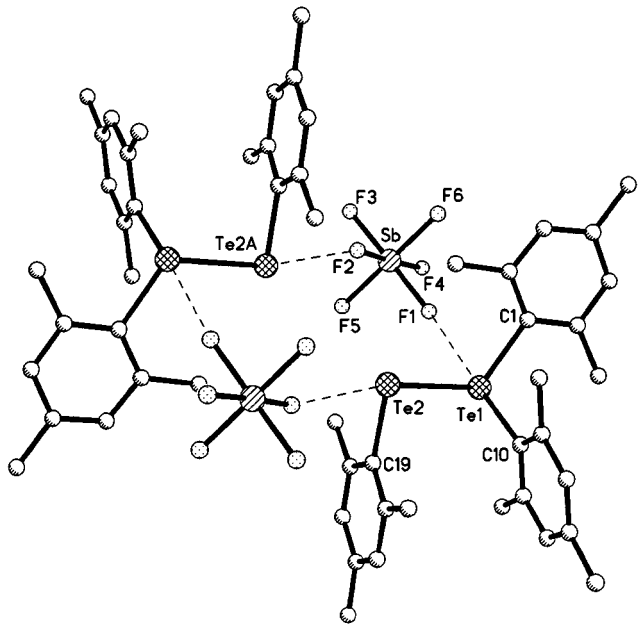
The coordination geometry of all chalcogen atoms in **3** and **4** can be described as pseudo-trigonal-bipyramidal, when secondary Te···F and Se···F contacts are taken into consideration. When Te1 is considered as the central atom (*one* lone pair of electrons, 10-Te-4[27]), the neighbouring F atom adopts an apical position (C10−Te−F6 in **3**: 173.8°, C10−Te1−F1 in **4**: 175.6°), and the neighbouring "two-coordinated" chalcogen atom is equatorial. Regarding the Se atom in **3**, the gradual transition from two-coordination towards a "T-type" surrounding (10-Se-3[27]) can be recognised from the nearly linear arrangement Te−Se···F (Te−Se−F7A 173.8°, Te−Se−C19 101.3°, C19−Se−F7A 84.2°). For the "two-coordinated" Te atom in **4** the geometric features of a typical "T-type" structure (Te1−Te2−F2 168.3°, Te1−Te2−C19 86.2°, C19−Te2−F2 83°) are fully expressed. The typical T-type geometry is associated with a short contact between the "two-coordinated" Te atom and a fluorine atom of the counterion. This Te···F contact of



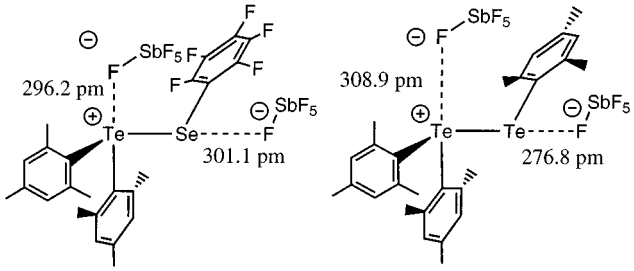


Figure 4. Intermolecular interactions within dimers of **4**; selected distances [pm] and angles [°]: Te(1)−F(1) 308.9(3), Te(2)−F(2A) 276.8(3); C(10)−Te(1)−F(1) 175.65(12), Te(2)−Te(1)−F(1) 88.94(6), Te(1)−Te(2)−F(2A) 168.27(9), C(19)−Te(2)−F(2A) 83.01(14)

the Te atom in the α-position to the telluronium centre of **4** (Te2···F2A 276.8 pm) is significantly shorter than the Te···F contact from the telluronium centre that bears the formal +1 charge (Te1−F1 308.9 pm) and is also shorter than the Se···F contact in **3** (**3**: Se···F7A 301.1 pm). The latter contact is longer (weaker) than the Te···F contact involving the telluronium centre, which is the predominant type of cation−anion interaction (Te···F6 296.2 pm) of the selenotelluronium salt; i.e. **3** is "the normal case" whereas **4** exhibits the unusual short Te···F contact involving the formally uncharged tellurium atom. This rather strong F→Te donor−acceptor interaction also coincides with a slight lengthening of the Te−Te bond in **4** (Mes_2Te_2: d = 270 pm;[28] **4**: d = 276.45 pm) and with a bathochromic shift of the Te−Te vibration mode in the Raman spectrum of **4** (143 cm^{-1}) compared with uncharged Me_2Te_2 [$\tilde{\nu}$(Te−Te) = 181 cm^{-1}] (Scheme 3).[29]

Scheme 3. Cation−anion interactions in **3** and **4**

Weakening of Te···Te bonds is to be expected when the F→Te donation leads to partial population of the σ* orbital of the Te−Te bond. The extent of the latter interaction al-

lows the prediction that the Te atom involved, in the α-position to the telluronium centre, will have acceptor properties as a Lewis acid. Following this, **4** can be understood as a type of arenetellurenyl cation (RTe^+) that is coordinated but not yet coordinatively saturated by one diaryl telluride nucleophile.[10,30] The bridging of the cations of **3** and **4** by the SbF_6^- anions through donor−acceptor interactions correlates well with the expansion of the bridging Sb−F bonds of the anions [**3**: *d*(Sb−F) between 185.8 ppm (terminal) and 189.1 pm (bridging); **4**: *d*(Sb−F) between 183.9 (terminal) and 187.2 pm (bridging)]. As a test of the electrophilicity of **4**, the reaction of **4** with another molecule of **2** as a nucleophile was carried out. This led to the detection of the hypervalent cation **8**.[21]

Structures of Trimesityltelluronium Salt 6 and Bromodimesityltelluronium Salt 7

The propeller-like conformation of the cation of **6** with angles C−Te−C close to tetrahedral (104−109°) is very similar to that of the known compound Mes_3TeI.[31] Te···F contacts are very long (363−367 pm), i.e. cations and anions are well separated (Figure 5, 6).

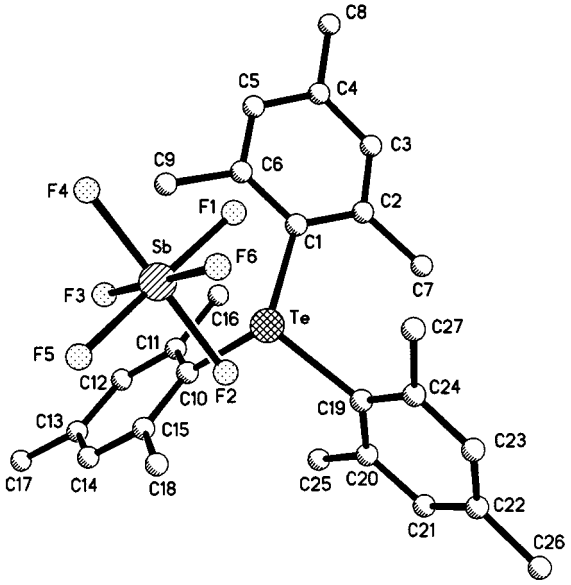

Figure 5. Molecular structure of **6**; selected distances [pm] and angles [°]: Te−C(1) 213.5(3), Te−C(10) 213.1(3), Te−C(19) 213.7(3), Te−F(1) 366.9(2), Te−F(2) 363.7(2), Te−F(3) 366.3(2) Sb−F(1) 187.3(2), Sb−F(4) 186.2(2); C(1)−Te−C(10) 104.42(11), C(1)−Te−C(19) 109.25(12), C(19)−TeC(19) 104.57(12)

The solid bromodimesityltelluronium salt **7** contains two independent ion pairs within the asymmetric unit. Since the fluorine atoms of both anions are disordered (they were refined on two different positions, see Figure 6), only a qualitative description of the cation−anion interactions can be given. The bromotelluronium salt **7** can be regarded as closely related to **3** and **4**: They contain telluronium cations with rather "soft" heteroatoms adjacent to the formally charged tellurium centre, offering two choices for cation−anion interactions. The shortest Te···F distances in **7** range from 262 to 324 pm, i.e., they are comparable to the Te···F distance of **3** and to that involving the formally charged telluronium centre of **4**. The coordination spheres of the Te atoms of **7** can be regarded as pseudo-trigonal-bipyramidal, with two carbon atoms and the lone pair in equatorial positions and an apical Te−F contact. The bromine atoms of the cations of **7** participate in the cation−anion interaction network by exhibiting contacts to (disordered) fluorine atoms of the SbF_6^- anions [Br(2)−F(3A) and Br(2)−F(3′A), depicted in Figure 6]. These Br···F distances, being shorter than the Se···F distances in **3**, indicate a certain Lewis acidity of the bromine atoms, a general property of heavy α-heteroatoms adjacent to onium centres.[5,12,21]

Compounds R_2TeBr_2 generally exist as molecular (10-Te-4) species with two apical Te−Br bonds, even when R is a very good electron-withdrawing substituent.[31] Being closer to an ideal 2c−2e bond, the Te−Br bond of **7** is significantly shorter than the apical Te−Br bonds of $(C_6F_5)_2TeBr_2$.[32]

Description of the Tritellurium Cation 8

Trialkyldisulfonium cations $[R_2SSR]^+$ do not tend to valence-shell expansion of sulfur by cation−anion interactions[14] or by addition of a second dialkyl sulfide nucleophile. The purple-black compound **4**, however, reacted in a straightforward manner with **2**, providing the novel brown-red "pentaaryltritelluranium" salt **8**. Due to its moderate solubility, a full set of solution-NMR data of **8** could be collected. The two Mes_2Te groups within the cation of **8** are NMR-equivalent; their ^{125}Te-NMR signal [$\delta(^{125}Te) = +854$] and the ^{125}Te-NMR signal of the central MesTe moiety of **8** [$\delta(^{125}Te) = +388$] are broadened to a somewhat different extent, and the Te−Te NMR coupling cannot be resolved. Dynamic exchange equilibria in solution were confirmed by addition of a small amount of **2** to a solution of **8**: from such a mixture, one averaged signal from free and coordinated **2** [$\delta(^{125}Te) = +842$] and a further signal from the unaffected central MesTe moiety [$\delta(^{125}Te) = +385$] were resolved. The related tritelluride anion $Ph_3Te_3^-$ [26] is also kinetically labile in solution. Crystalline **8**[21] contains $Mes_5Te_3^+$ cations, SbF_6^- anions and CH_2Cl_2. The cation contains an approximately linear Te_3 backbone. The two Te−Te distances are slightly different (Te1−Te2 304.9 pm, Te3−Te1 297.9 pm); they are both significantly longer in comparison with Te−Te single bonds such as those of **4** (Figure 7) or Mes_2Te_2. The average Te−Te distance of **8** (301.5 pm) is similar to that of $Ph_3Te_3^-$ (302.5 pm),[32] shorter than the typical Te−Te distances of linear Te−Te−Te moieties of "nonclassical" inorganic polytellurides, for instance the Te_5^{4-} ion within solid NaTe: *central*: *d*(TeTe) = 308 pm; *terminal*: *d*(TeTe) = 282 pm.[2,33] From the vibrational spectra of solid **8**, a strong Raman emission at 102 cm^{-1} can be assigned to the symmetric Te_3 stretching mode (Figure 8). The analogy of the position of this Raman emission to that of a slightly asymmetric triiodide anion is clear.[34,35] However, it is surprising, that the antisymmetric vibration is apparently not resolved in the IR spectrum.

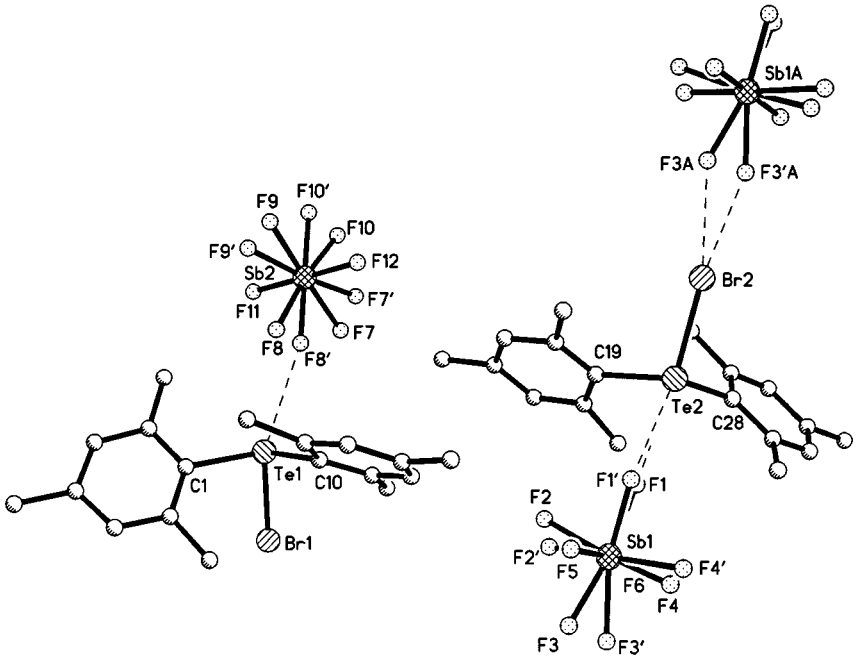

Figure 6. Structures of the two independent ion pairs and anion disorder of **7**; selected distances [pm] and angles [°], ion pair 1: Te(1)−C(1) 211.6(11), Te(1)−C(10) 212.9(10), Te(1)−Br(1) 250.9(2), Te(1)−F(8) 324(2), Te(1)−F(8′) 293(2); C(1)−Te(1)−C(10) 106.8(4), C(1(Te(1)−Br(1) 91.6(3), C(10)−Te(1)−Br(1) 101.8(3); ion pair 2: Te(2)−C(28) 213.9(12), Te(2)−C(19) 213.1(11), Te(2)−Br(2) 247.9(2), Te(2)−F(1) 262(2), Te(2)−F(1′) 266(2), Br(2)−F(3A) 269(2), Br(2)−F(3′A) 280(2); C(28)−Te(2)−C(19) 106.4(4), C(28)−Te(2)−Br(2) 93.4, C(19)−Te(2)−Br(2) 100.5(3)

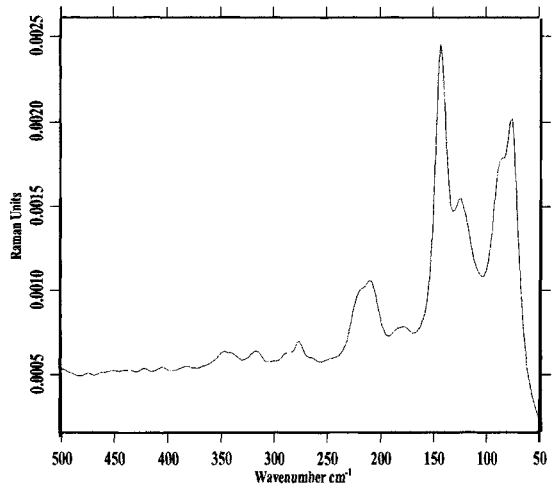

Figure 7. Raman emissions of solid **4**

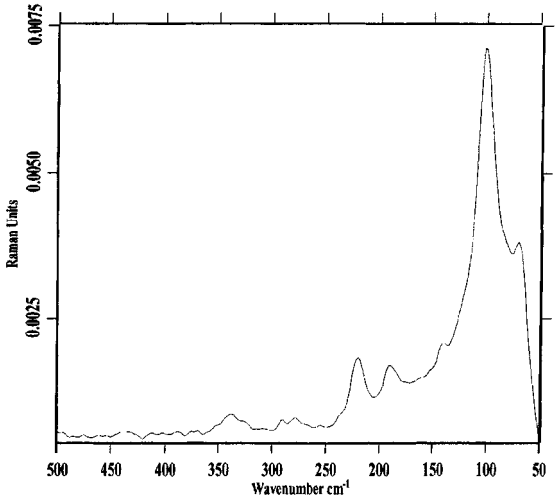

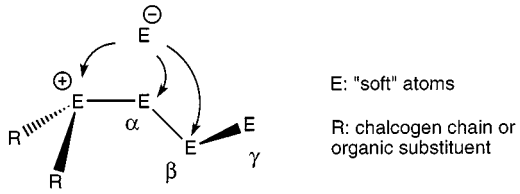

Figure 8. Raman emissions of solid **8**

A strong IR absorption at 289 cm^{-1} is observed in **8** and **4** (in the latter the band is less symmetric showing a shoulder at approximately 278 cm^{-1}). This band seems to confirm the presence of SbF_6 anions (it is present in all the samples containing this anion that we have investigated including $AgSbF_6$), while the vibrations expected in the Raman spectrum appear as weak peaks in **8** and **4**, the Raman spectra being dominated by the strong inter-tellurium vibrations. Surprisingly, to the best of our knowledge, a strong IR absorption at 289 cm^{-1} has not been reported previously in spite of numerous vibrational studies involving SbF_6 anions.[36] An (unassigned) strong IR absorption at 275 cm^{-1} has been reported for solid $[Cp_2ReCl_2](SbF_6)_3$.[37] For an SbF_6 anion in an octahedral structure, three Raman-active vibrations [$\nu_1(A_{1g})$ (668 cm^{-1}), ν_2 (E_g) (558 cm^{-1}) and ν_5 (F_{2g}) (294 cm^{-1})] and two infrared-active vibrations [$\nu_3(F_{1u})$ (669 cm^{-1}), ν_4 (F_{1u})(350 cm^{-1})] are expected.[38] The sixth vibration ν_6 (F_{2u}) calculated at 294 cm^{-1}, is predicted to be inactive in both the infrared and Raman spectra, but should become infrared-active in those structures that have lower symmetry than O_h.[39] We suggest that the band at 289 cm^{-1} is due to ν_4, and the presence of a shoulder at 278 cm^{-1} in **4** could be associated to ν_6, whose activity is related to the lowering of the symmetry as a result of the observed distortions in this anion (Figure 7).

The formation of nonclassical linear Te_3 moieties has been described theoretically as the hypothetical addition of Te^{2-} ions to Te_2^{2-} ions,[2,4] The above reaction of nucleophile **2** with electrophile **4** furnishing **8** is the first well-defined addition of two 8e⁻-tellurium species to form a linear 10e⁻-Te_3 species.[21,26] This model reaction provides an experimental approach to understanding how cationic defects in solid selenium−tellurium alloys (Scheme 1 and 2) may be stabilised by acceptor−donor interaction of adjacent two-coordinate tellurium atoms with tellurium atoms of neighbouring tellurium chains. However, it should be noted that soft heteroatoms (such as Se and Te) in β- and γ-positions from the onium centre can also exhibit certain Lewis-acidic properties (Scheme 4).

Scheme 4. Sites of nucleophilic attack in chalcogen cations

As in the stabilisation of onium-like cationic defects ("C-3") above, masking of the *negative* charges ("C-1") (Scheme 1) by local formation of hypervalent anionic Te_3 moieties (such as those in $LiTe_3$, $Ph_3Te_3^-$ or $NaTe_3$ [2,4,26,33,40]) will contribute to the stabilisation of anionic defects in tellurium.

Experimental Section

^{77}Se- and ^{125}Te-NMR spectra were run with a Bruker AM 200 spectrometer (38.2 MHz for ^{77}Se and 63.1 MHz for ^{125}Te) using CH_2Cl_2 as a solvent, if not otherwise specified. *J* values are given in Hz. − Raman spectra (resolution ± 4 cm^{-1}) were recorded with a Bruker RFS 100 FTR spectrometer (Nd:YAG laser excitation, 1064 nm). The solid samples, in the form of powders or crystals, were packed into glass capillary tubes and then fitted into the compartment designed for use with a 180° scattering geometry. The power level of the laser source was in the range of 70−150 mW. − Far-FTIR spectra (500−50 cm^{-1}) were recorded with a Bruker IFS 55 spectrometer (as polyethylene pellets). − Mass spectra were determined with Finnegan MAT 8430 and 4315 spectrometers [EI, 70 eV, CI, or FAB with *o*-nitrobenzylamine (NBA)]. − Melting points were determined with a Kofler hot-stage microscope and all values are uncorrected. − Elemental analyses were carried out by the Analytisches Laboratorium des Instituts für Anorganische und Analytische Chemie, Technische Universität Braunschweig. Solvents were dried by distillation under nitrogen from the appropriate drying agent, glassware was flame-dried and cooled under a stream of nitrogen.

3: A solution of $AgSbF_6$ (0.68 g, 2.0 mmol) in 10 mL of dichloromethane was added to a stirred mixture of Mes_2Te (1.1 g, 2.0 mmol), $(C_6F_5Se)_2$ (0.49 g, 1.0 mmol) and Br_2 (0.08 g, 0.50 mmol), dissolved in 30 mL dichloromethane. Upon addition of the first drops of the $AgSbF_6$ solution, the reaction mixture adopted an intense red colour. Precipitation of silver bromide occurred after all the $AgSbF_6$ had been added. After 30 min, the silver bromide was removed by filtration and a layer of 40 mL of hexane was carefully added to the red-brown solution. Within 18 h, the two phases had mixed by diffusion and black crystals (compound **4**) had separated from the mixture. The supernatant liquid was decanted and all volatiles were removed under vacuum until an oily residue remained. This residue was dissolved in a small amount of dichloromethane and a layer of hexane was again carefully added to the solution. Another crop of **4** (black crystals) was accompanied by a small amount of orange-brown crystals [m.p. 154 °C (dec.)] which were identified by X-ray crystallography as the desired compound **3**. Correct elemental analytical data were not obtained. Attempts to purify crude **3** by fractional crystallisation led to isolation of a further amount of **4**, which appeared to be a decomposition product of crude **3**. Evaporation of the solvents from the remaining slightly yellowish mother liquor furnished a viscous oil. ^{77}Se-NMR spectra and EI mass spectra allowed to the detection of mesityl (pentafluorophenyl) selenide (**5**) and bis(pentafluorophenyl) diselenide (**1**) in the the oily residue. − ^{77}Se NMR of the mixture: δ = 370 [$^3J(^{77}Se,^{19}F)$ = 11.0 Hz, $(C_6F_5)_2Se_2$ = **1**], 176 [$^3J(^{77}Se,^{19}F)$ = 14.3 Hz, C_6F_5−Se−Mes = **5**]. − EI-MS of the mixture; *m*/*z* (%): 494 (50) [$(C_6F_5)_2Se_2^+$], 366 (84) [C_6F_5−Se^+−Mes], 247 (100) [C_6F_5−Se^+], 119 (35) [Mes^+].

4: Bromine (0.12 g, 0.75 mmol) was added to a solution of Mes_2Te (0.55 g, 1.5 mmol) and Mes_2Te_2 (0.49 g, 0.75 mmol) in 30 mL of dichloromethane, at room temperature. Subsequently, silver hexafluoroantimonate (0.50 g, 1.5 mmol), dissolved in 5 mL of dichloromethane, was added to the mixture. The colour of the solution turned from brown to deep red and precipitation of silver bromide began. Stirring was continued in the dark for 1 h for the reaction to reach completion. After removal of the precipitate by filtration, hexane was added to the brown solution. **4** separated from the solution as a brown-violet powder (0.94 g; 74%) that melted at 189 °C (dec.). Black single crystals suitable for X-ray diffraction[21] were obtained with help of the diffusion method (dichloromethane solution/hexane). Crystalline **4** was only slightly soluble in dichloromethane (intensely greenish-brown solution) and in methanol (colourless solution). − $C_{27}H_{33}F_6SbTe_2$ (848.5): calcd. C 38.22, H 3.92; found C 38.37, H 4.03. − ^{1}H NMR (CD_2Cl_2): δ = 7.05 (2 H), 2.34 (6 H), 2.32 (3 H). − ^{125}Te NMR: no signal observed due to low solubility. − Raman: $\tilde{\nu}$ = ν(Te−Te) 143 cm^{-1}. − FAB-MS (NBA), positive mode; *m*/*z* (%): 741 (5) [$Mes_3Te_3^+$], 613 (40) [$Mes_3Te_2^+$], 494 (22) [$Mes_2Te_2^+$], 368 (100) [Mes_2Te^+], 248 (24) [$MesTe^+$−H], 119 (70) [Mes^+]; negative mode; *m*/*z* (%): 494 (7) [$Mes_2Te_2^-$], 472 (2.5) [$Sb_2F_{12}^-$], 235 (100) [SbF_6^-], 216 (2) [SbF_5^-], 197 (2) [SbF_4^-]. − FT-IR: $\tilde{\nu}$ = 341 (2.8), 321 (2.8), 289 (10), 278 sh, 218 (3.4) 62 (2.2) cm^{-1}. − FT-Raman: $\tilde{\nu}$ = 210 (4.0), 143 (10.0), 124 (5.0), 85 (shoulder), 76 (8.0) cm^{-1}.

7: A solution of 1 mmol of Mes_2TeBr_2 was prepared by oxidation of Mes_2Te (0.37 g, 1.0 mmol), dissolved in 10 mL of dichloromethane, with a solution of bromine (0.16 g, 1.00 mmol) in 5 mL of dichloromethane at 0 °C. Addition of silver hexafluoroantimonate (0.38 g, 1.0 mmol) led to a deep red solution and to the precipitation of AgBr, which was removed by filtration after continued stirring for 15 min. Upon addition of 35 mL of hexane to the red solution, a yellow precipitate separated from the yellowish supernatant solution. In order to remove the remaining amounts of silver bromide from the yellow crude product, the latter was again treated with 5 mL of dichloromethane and the undissolved solid (AgBr) was removed by filtration. Precipitation by addition of 10 mL of hexane provided 0.54 g (79%) of yellow **7** (m.p. 148 °C, dec.). − $C_{18}H_{22}BrF_6SbTe$ (681.6): calcd. C 31.72, H 3.25; found C 30.98, H

3.25. − ^{1}H NMR (CD_2Cl_2): δ = 7.16 (2 H), 2.52 (6 H), 2.39 (3 H). − ^{125}Te NMR (CH_2Cl_2/C_6D_6): δ = 1128. − FAB-MS (NBA), positive mode; *m/z* (%): 617 (8) [$Mes_3Te_2^+$], 520 (45) [NBA(Mes_2Te^+ − H], 447 (45) [Mes_2TeBr^+], 368 (85) [Mes_2Te^+], 248 (40) [$MesTe^+$ − H], 119 (100) [Mes^+].

8: A solution of **8**, prepared by slight warming of a mixture of $Mes_2TeTeMes\ SbF_6$ (**4**) (0.43 g, 0.50 mmol) and Mes_2Te (**2**) (0.25 g, 0.70 mmol) in 2 mL of dichloromethane, was kept at −18 °C in order to obtain crystals that were suitable for X-ray diffraction.[21] After separation of the clear brownish-red needles from the solution by filtration, the solvent-containing single crystals decomposed under vacuum into a brown powder of **8** (0.45 g, 74%) which melted at 169 °C (dec.). The given yield and analytical data concern the solvent-free final product. **8** was fairly soluble in dichloromethane; addition of hexane to such a solution led to a precipitate of **4**. − $C_{45}H_{55}F_6SbTe_3$ (1214): calcd. C 44.50, H 4.56; found C 44.64, H 4.48. − ^{1}H NMR (CD_2Cl_2): δ = 7.04 (2 H), 2.32 (6 H), 2.30 (3 H). − ^{125}Te NMR (CH_2Cl_2/C_6D_6): δ = 854, 388; after addition of a 20% excess of **1**: δ = 842, 385. − FAB-MS (NBA), positive mode; *m/z*: 741 (2) [$Mes_3Te_3^+$], 613 (40) [$Mes_3Te_2^+$], 494 (14) [$Mes_2Te_2^+$], 368 (100) [Mes_2Te^+], 248 (20) [$MesTe^+$−H], 119 (55) [Mes^+]; negative mode; *m/z*: 494 (7) [$Mes_2Te_2^-$], 472 (3) [$Sb_2F_{12}^-$], 235 (100) [SbF_6^-], 216 (2) [SbF_5^-], 197 (2) [SbF_4^-]. − FT-IR: $\tilde{\nu}$ = 326 (3.2), 289 (10.0), 204 (3.8), 100 (shoulder), 78 (4.6) cm^{-1}. − FT-Raman: $\tilde{\nu}$ = 220 (2.0), 189 (1.9), 141 (2.5), 102 (10.0), 78 (shoulder), 70 (5.2) cm^{-1}.

Crystal Structure Determination of 3: Empirical formula: $C_{24}H_{22}F_{11}SbSeTe$, M = 847.73; orthorhombic, space group *Pbca*, a = 1452.73(12) pm, b = 1583.6(2) pm, c = 2405.6(2) pm; V = 5.5341(9) nm^3; Z = 8; $d_{calcd.}$ = 2.035 Mg m^{-3}; μ = 3.433 mm^{-1}, T = 173 K. An orange prism (0.62 × 0.42 × 0.20 mm) was mounted in an inert oil. 6933 intensities were measured (2θ = 6−50°, ω-scans; $-17 < h < 6$, $-18 < k < 0$, $-28 < l < 0$) using Mo-K_α radiation (graphite monochromator) with a Siemens P4 diffractometer. After absorption correction (ψ-scans; min. and max. transmission: 0.516, 1.000), 4877 reflections were unique (R_{int} = 0.0190) and used for all calculations (program SHELXL-93[41]). The structure was solved by direct methods and refined anisotropically by full-matrix least squares on $|F|^2$. Rigid methyl groups were employed, all other protons were refined using a riding model. The final $wR(F^2)$ was 0.0576, with conventional $R(F)$ 0.0268 for 349 parameters and 267 restraints (highest peak 754, deepest hole −463 e/nm^3).

Crystal Structure Determination of 6: Empirical formula: $C_{27}H_{33}F_6SbTe$, M = 720.88; orthorhombic, space group *Pbca*, a = 1616.55(10) pm, b = 1738.52(12) pm, c = 1985.6(2) pm; V = 5.5804(7) nm^3; Z = 8; $d_{calcd.}$ = 1.716 Mg m^{-3}, μ = 2.067 mm^{-1}, T = 173 K. A green prism (0.62 × 0.60 × 0.55 mm) was mounted in an inert oil. 4908 intensities were measured (2θ = 6−50°, ω-scans; $-19 < h < 6$, $-20 < k < 0$, $-0 < l < 23$) using Mo-K_α radiation (graphite monochromator) with a Siemens P4 diffractometer. After absorption correction (ψ-scans; min. and max. transmission: 0.821, 0.948), 4908 reflections were unique (R_{int} = 0.0190) and 4906 were used for all calculations (program SHELXL-93).[41] The structure was solved by direct methods and refined anisotropically by full-matrix least squares on $|F|^2$. Rigid methyl groups were employed, all other protons were refined using a riding model. The final $wR(F^2)$ was 0.0509, with conventional $R(F)$ 0.0242 for 326 parameters and 249 restraints (highest peak 344, deepest hole −488 e/nm^3).

Crystal Structure Determination of 7: Empirical formula: $C_{36}H_{44}Br_2F_{12}Sb_2Te_2$, M = 1363.23; monoclinic, space group $P2_1/n$, a = 1144.2(2) pm, b = 1210.3(2) pm, c = 3171.8(5) pm; V = 4.3860(13) nm^3; Z = 4; $d_{calcd.}$ = 2.064 Mg m^{-3}, μ = 4.434 mm^{-1}, T = 143 K. A yellow cut needle (0.80 × 0.42 × 0.38 mm) was mounted in an inert oil. 8158 intensities were measured (2θ = 6−50°; ω-scans; $-13 < h < 6$, $0 < k < 14$, $-37 < l < 37$; data are composed of independent set plus some Friedel pairs) using Mo-K_α radiation (graphite monochromator) with a Stoe STADI-4 diffractometer. After absorption correction (ψ-scans; min. and max. transmission: 0.460, 0.764), 7722 reflections were unique (R_{int} = 0.0498) and 7703 were used for all calculations (program SHELXL-93).[41] The structure was solved by direct methods and refined anisotropically by full-matrix least squares on $|F|^2$. Rigid methyl groups were employed, all other protons were refined using a riding model. The final $wR(F^2)$ was 0.1982, with conventional $R(F)$ 0.0675 for 457 parameters and 24 restraints (highest peak 1849, deepest hole −1561 e/nm^3).

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-121862 (**3**), -100165 (**4**),[21] -121863 (**6**), -121964 (**7**), -100165 (**8**).[21] Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk).

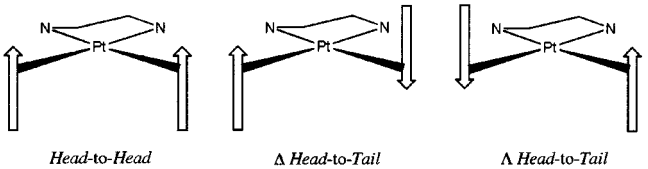
Synthesis and Structural Characterisation of a New Form of Bis(acyclovir)(ethylenediamine)platinum(II) − Correlation between the Puckering of the Carrier Ligand and the Canting of the Nucleobases

Renzo Cini,[a] Sabina Grabner,[b] Natasa Bukovec,[b] Leonardo Cerasino,[c] and Giovanni Natile*[c]

Keywords: Acyclovir / Platinum / Atropisomerism / Antitumor agents / Nucleobases



A new conformer of the $[Pt(en)(acv)_2]^{2+}$ cation (en = ethylenediamine; acv = acyclovir = 9-[(2-hydroxyethoxy)methyl]guanine) has been prepared by slow crystallisation of the $[Pt(en)(acv)_2]SO_4 \cdot 2.5H_2O$ salt. X-ray diffraction studies have shown that the guanine moieties have a *Head-to-Head* conformation (*HH*) with the two C(8)-H vectors pointing towards the same side with respect to the platinum coordination plane; the dihedral angles formed by the purine planes and the coordination plane are 58.3(2)° and 41.5(2)°, respectively. There is a correlation between the canting of the purine bases (right or left handed) and the puckering of the ethylenediamine chelate ring (δ or λ). Right-handed canting is associated with λ puckering of the chelate ring and left-handed canting with δ puckering of the chelate ring, so that in both cases one of the two purines forms an O(6)···H–N hydrogen bond with a "quasi equatorial" NH of the ethylenediamine. The "quasi equatorial" character of the NH appears to be a common feature for intramolecular H-bonds between guanine bases and *cis*-amines. The purine not involved in the H-bond has the six-membered ring portion leaning towards the *cis* purine rather than towards the *cis* amine and may give rise to a weak O(6)···Pt attractive interaction. Such an interaction is supported by density functional (DFT) molecular orbital calculations carried out on the model systems $[Pt(NH_3)_4(CH_2O)]^{2+}$ and *Head-to-Tail* *cis*-$[Pt(NH_3)_2\{N(=CH_2)–C(=CH_2)–C(=O)–NH_2\}_2]^{2+}$. The exocyclic chains linked to N(9) each have two different orientations, and all four are stretched away from the metal centre as well as from the purine N(1)H and N(2)H_2 protons. The acv and the en NH protons are instead involved in H-bonds with the sulfate anion.

Introduction

Combination drug chemotherapy has enjoyed much success in the treatment of cancer. This is attributed to the fact that development of resistant cell lines is delayed or prevented and that synergistic interactions between chemotherapeutic agents with different mechanisms of interactions can occur.[1] Observations of this kind have spawned the idea of binding two different cytotoxic moieties within the same molecule, i.e. the creation of multifunctional drugs,[2] and this has become a leading strategy in current studies.

The report that cisplatin was found to be an effective topical treatment in mice[3] prompted some investigators to explore the possibility that platinum(II) or palladium(II) complexes containing antiviral nucleosides might act in a synergistic fashion.[4−6] The prototype complex $[Pt(NH_3)_2(acv)_2](NO_3)_2$ appeared to be equally inhibitory as compared to acv when both were assayed against HSV-1 (KOS). Moreover the complex was not cytotoxic to normal cells at the highest concentration tested (400 mg/cm^3). The reason for such a dramatic decrease in toxicity of $[Pt(NH_3)_2(acv)_2](NO_3)_2$, when compared with the precursor $[Pt(NH_3)_2Cl_2]$, is not fully understood.

In a previous paper we reported the X-ray crystal structure of this multifunctional complex in which the two ammines had been replaced by a chelating ethylenediamine.[7] The two guanine bases adopted the usual *Head-to-Tail* conformation (*HT*) with the two purines tilted over the coordination plane and forming O(6)···H−N H-bonds with the *cis* amine groups. We have now succeeded in crystallising a second conformer of the same complex in which the two guanines are arranged in the very rare *Head-to-Head* (*HH*) conformation (see Scheme 1). To the best of our knowledge this is the only metal *cis*-bis(nucleobase) complex containing identical ligands that has been crystallised in its two possible rotamers to date.

The results of this investigation are reported here. The discussion will concentrate on the structural motifs induced by platinum coordination and their relevance to the primary lesion responsible for the cytotoxicity of platinum drugs to tumour cells, which involves the cross-linking of two adjacent guanine bases on one strand of the DNA double helix.[8−11]

Results

The preparation of the complex cation was given in the previous paper concerning a *Head-to-Tail* conformer.[7] Comparison of the FTIR spectra of the complex and of free acv indicates that binding of Pt(II) to N(7) shifts bathochromically the carbonyl frequency, ν[C(6)=O], which occurs at 1717 cm^{-1} for uncomplexed acv and at 1685 cm^{-1} for the complexed species. Platinum complexation also shifts the frequencies of ν[C(8)−N(7)] and δ[C(8)−H] from 1483 to 1498 cm^{-1}, respectively, as observed in related cases.[12] The typical absorptions for a free SO_4^{2-} ion are identified at 1071 and 630 cm^{-1}.[13]

Only one set of proton resonances [C(8)H: δ = 8.18; N(9)CH_2: δ = 5.43; OCH_2CH_2: δ = 3.55 and 3.49; N(*E*)CH_2: δ = 2.77] was observed suggesting free rotation of the two guanine bases around the Pt−N(7) bonds as proposed earlier for similar bifunctional platinum complexes.[14] The ^{195}Pt spectrum showed a signal at δ = −2664 which is in the expected chemical shift range for bifunctional *cis*-DDP complexes.

The complex cation and the proximal sulfate anion for the [Pt(en)(acv)$_2$]SO_4·2.5H_2O salt (**1**) are depicted in Figure 1, selected geometrical parameters are listed in Table 1 and Table 2.

Platinum Coordination Sphere

The platinum(II) centre has the usual square-planar geometry, the donors being the two nitrogen atoms from ethylenediamine and the N(7) atoms from the two guanine moieties, as recently found for a different salt of the same cation, [Pt(en)(acv)$_2$][PF_6]$_{1.5}$$Cl_{0.5}$·$H_2O$ (**2**),[7] in which, however, the two purine bases have the usual *HT* conformation. The metal centre does not show any appreciable deviation from the plane defined by the donors. The N(1*E*)−Pt−N(2*E*) bond angle is 83.4(3)° in perfect agreement with the values previously reported for the Pt(en) group present in other complexes (ref.[7] and references therein). A strict similarity between the present structure and that of **2** also exists for the N(7)−Pt−N(7) bond angle between the two acv ligands: 89.5(3)° and 90.7(6)° for **1** and **2**, respectively. However, it must be noted that the N(*E*)−Pt−N(7) angles be-

tween *cis* donors are significantly different in the present structure [91.8(3)° and 95.4(3)°, respectively] while they are equal in complex **2** with an *HT* conformation of the acv ligands. The bond lengths for Pt−N(*E*) [2.025(7) Å (average)] and for Pt−N(7) [2.030(7) Å (average)] are in good agreement with previous values for other platinum(II) complexes (ref.[7] and references therein).

The orientation of the two acv ligands with respect to the coordination plane is *HH*, with the C(8)−H vectors pointing towards the same side of the plane. The dihedral angles formed by the two purine systems with the coordination plane are significantly different: 58.3(2)° and 41.5(2)° for acv(1) and acv(2), respectively. It should be noted that the O(6) atom of acv(2) forms a strong intramolecular hydrogen bond with the *cis* amine [N(2*E*)···O(62) = 2.83(2) Å; N−H···O = 153(1)°]. In contrast, the O(61) atom from purine(1) is not involved in any intramolecular hydrogen bond. The different intramolecular contacts found for the two purine systems are reflected by the difference between the Pt−N(7)−C(5) and Pt−N(7)−C(8) bond angles, which is 7.2(6)° for acv(2) and 2.8(6)° for acv(1). Therefore, probably for geometrical reasons, the pseudo macrocycle formed by the O(62)···H−N(2*E*) H-bond linking acv(2) and N(2*E*) requires an opening rather than a narrowing of the Pt−N(7)−C(5) angle. There is also the possibility that the acv(1) ligand, not involved in an H-bond with the *cis*-amine, can feel a Pt···O(61) attractive interaction. This possibility is supported by DFT molecular orbital calculations (see following section) even though the Pt···O(61) contact distance of 3.474(6) Å is rather large [greater than the sum of the Van der Waals radii for Pt (1.8 Å) and O (1.5 Å)][15] and the values of the Pt−N(7)−C(5) and Pt−N(7)−C(8) angles [128.5(6)° and 125.7(6)°, respectively] are equal within two times the estimated standard deviations [it should be recalled, however, that in general the Pt−N(7)−C(5) angle is 4−10° greater than Pt−N(7)−C(8)].[7]

Acyclovir Ligand

The bond lengths and angles relevant to the two guanine systems are in good agreement with those previously reported for other acyclovir complexes (ref.[5,7] and references therein, and ref.[16]). The purine systems are planar, the largest deviations from the least-squares plane defined by the endocyclic atoms being that of N(32) [0.029(8) Å]. The linkages with exocyclic atoms, C(2)−N(2) and C(6)−O(6), have considerable double bond character as can be seen from the bond lengths of 1.338(11) and 1.218(10) Å (averages), respectively.

The aliphatic chains linked to N(9) are stretched away from the coordination sphere, as found for the *HT* conformer **2**. They do not interact intramolecularly with the N−H of the guanine and ethylenediamine systems. Both chains are affected by an extensive statistical disorder (see Experimental Section) which was refined to an acceptable degree of accuracy to permit a reliable analysis of the respective conformations.

The values of the glycosidic torsion angles C(4)−N(9)−C(1′)−O(1′) (χ) are 102(1)° and −101(2)° for acv(1), and −96(1)° and −56(2)° for acv(2). Therefore, all the orientations around N(9)−C(1′) can be described as *gauche*. Interestingly, the values for acv(1) are significantly different from those found for the free ligand [74.4(5)−90.5(6)°][17] and for all Pt−acv complexes so far reported [ref.[16] and references therein]. The N(9)−C(1′)−O(1′)−C(2′) torsion angles (φ) are 107(2)° and −82(3)° for acv(1), and 66(2)° and −64(3)° for acv(2); this *gauche* conformation was also found in the *HT* conformer **2**.[7] The C(1′)−O(1′)−C(2′)−C(3′) torsion angles (γ) are 68(3)° and −94(3)° for acv(1) and 174(1)° and −163(2)° for acv(2), therefore the conformations are *gauche* and *trans*, respectively. The conformations previously reported for this torsion angle were mostly *trans*. Finally, the O(1′)−C(2′)−C(3′)−O(3′) (ω) angles are 73(3)° and −43(4)° for acv(1) and −48(3)° and 69(3)° for acv(2), in agreement with the *gauche* conformation also found for free acv and the previously reported Pt−acv complexes.[5,7]

Ethylenediamine Ligand

The C−N [1.495(12) Å, average] and C−C [1.485(15)] bond lengths and the bond angles around the N and C atoms are in agreement with the typical sp^3 hybridisation of these atoms and with the values reported previously.[7] The five-membered chelate ring is puckered as shown by the deviations of C(1*E*) [−0.06(1) Å] and C(2*E*) [0.51(1) Å] from the least-squares plane of the donors. Both the λ and δ conformations for the Pt(en) chelate ring are present because of the inversion symmetry operation of the *C*2/*c* space group.

Crystal Packing

The sulfate anion has hydrogen bonds with the N(1) and N(2) atoms of acv(2) [N(12)···O(1*S*) = 2.84(3) Å, N−H···O = 161(1)°; N(12)···O(8*S*) = 2.67(2) Å, N−H···O = 165(1)°; N(22)···O(3*S*) = 2.98(2) Å, N−H···O = 160(1)°]. The sulfate anion at (x + 0.5, y + 0.5, z) interacts with the C(8)−H and the N(1*E*)−H groups [C(8)···O(2*S*) = 3.14(2) Å, C−H···O = 134(1)°; N(1*E*)···O(2*S*) = 2.96(2) Å, N−H···O = 170(1)°]. The water molecule O(1 W) (−x, y, −z + 0.5) interacts with N(11) [N···O = 2.85(1) Å, N−H···O = 174(1)°] whereas O(2 W) (−x + 0.5, y − 0.5, −z + 0.5) interacts with N(2*E*) [N···O = 3.03(1) Å, N−H···O = 143(1)°]. Other hydrogen bonds involve the exocyclic chain of the acv moieties and the water molecules, i.e. O(3′1) and O(2 W) (−x + 0.5, y + 0.5, −z + 0.5), O(3′2) and O(3 W) (−x − 0.5, −y + 0.5, −z + 1), and O(3′C) and O(8*S*) (x, y + 1, z) for which the O···O distances are 2.70(2), 2.77(2), and 2.67(1) Å, respectively.

Short contact distances are found between O(3′2), O(3′C) (−x, −y + 1, −z + 1) and C(82) [3.13(2) Å], between O(1′B) (x, y − 1, z) and C(2*E*) [3.39(2) Å], and between O(1′) and O(1′2) (−x, −y + 1, −z + 1) [3.13(1) Å], suggesting a significant repulsive interaction between these

atoms. The attractive and repulsive contacts, which involve several atoms of the exocyclic chains, explain the disorder of the chains themselves and justify the model refined in this work (see Experimental Section).

Finally, an important role for the crystal packing of the present structure is played by the stacking interactions between the purine systems (Figure 2). The shortest interatomic distance is between C(52) and N(32) ($-x$, $-y$, $-z$ + 1) [3.46(1) Å].

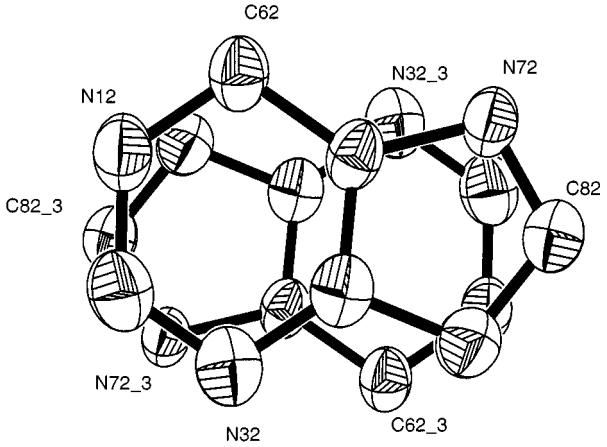

Figure 2. View of the two purine systems from acyclovir(2) which are involved in the strongest stacking interaction; the view is perpendicular to the planes

Molecular Orbital Analysis

The geometry optimized structure for $[Pt(NH_3)_4(CH_2O)]^{2+}$ is reported in Figure 3.

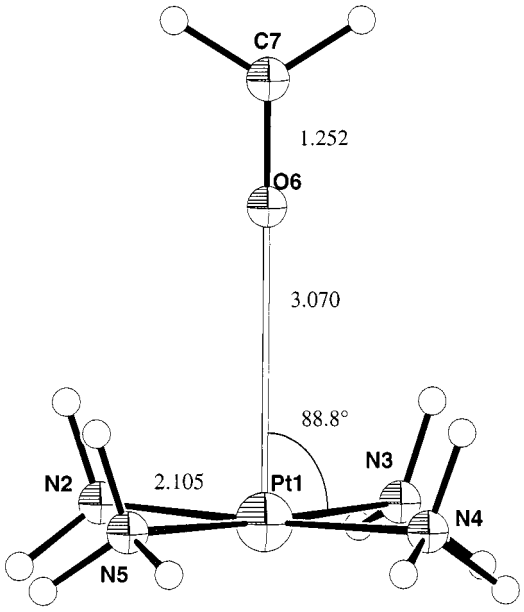

Figure 3. Geometry-optimized structure for $[Pt(NH_3)_4(CH_2O)]^{2+}$

The Pt···O equilibrium distance is 3.070 Å, significantly smaller than the sum of the Van der Waals radii of the two atoms (3.20−3.30 Å).[15] This suggests that an overall attractive interaction between $Pt(NH_3)_4{}^{2+}$ and the CH_2O molecule is operative. The analysis of the MO′s shows that the HOMO for $[Pt(NH_3)_4(CH_2O)]^{2+}$ is composed mostly of *z*-type atomic orbitals from Pt, O and C atoms [Pt: $5d_z^2$ (0.814), $6p_z$ (0.115), and $6d_z^2$ (0.199); O: $2p_z$ (−0.157) and 3s (0.190); C: $2p_z$ (0.120)]. Therefore a covalent interaction exists between the Pt atom and the carbonyl moiety which is assisted by electrostatic and/or hydrogen bonding contributions. In this system, the initial $[Pt(NH_3)_4]^{2+}$ species has an overall positive charge of 2; moreover the O−Pt−N and Pt−N−H (*syn* to O) bond angles (88.8° and 108.4°, respectively) are indicative of weak intramolecular N−H···O hydrogen bonds (N···O = 3.68 Å, N−H···O = 112.3°).

The computed C−O bond length is 1.241 Å in the free molecule and 1.252 Å in the complex molecule. This small lengthening effect might be related to the back donation from the filled Pt $5d_z^2$ orbital to the empty O 3s orbital. The energy of the complex formation for the formal reaction between $[Pt(NH_3)_4]^{2+}$ and CH_2O to form $[Pt(NH_3)_4(CH_2O)]^{2+}$ is −33.942 kcal·mol^{-1}.

The system $[PtCl_4]^{2-}$ and CH_2O was also analyzed. Starting from an initial interatomic Pt···O distance of 2.0 Å the geometry optimization leads to dissociation of the two components. Therefore the electrostatic repulsive interaction between $[PtCl_4]^{2-}$ and the electron rich O atom prevails on the covalent Pt−O linkage. For this latter system, the lack of hydrogen bond interactions is also in favour of dissociation.

The single point calculation on the *HT* isomer of *cis*-$[Pt(NH_3)_2\{N(=CH_2)-C(=CH_2)-C(=O)-NH_2\}_2]^{2+}$ (see Experimental Section) showed that one of the filled frontier orbital consists mostly of Pt $5d_z^2$ (ca. 0.130) and O $2p_z$ (ca. 0.160). The Pt−O distances {from X-ray diffraction on the *HT* *cis*-$[Pt(NH_3)_2(acv)_2]^{2+}$} are 3.320 and 3.409 Å.[18a] Therefore, a covalent interaction between the Pt centre and the O=C function might exist in both the *HT* isomer of *cis*-$[Pt(NH_3)_2(acv)_2]^{2+}$ (compound **3**, ref.[18a]) and *HH* $[Pt(en)(acv)_2]^{2+}$ (present work), although in the latter case the dihedral angle between the acyclovir and platinum-coordination planes is significantly smaller than 90°, and O(6) comes less close to the *z* axis. Intermolecular interactions and/or interligand interactions, related to the canting of the two nucleobases, may be responsible for the deviation of acv1 from orthogonality

Discussion

Nucleobase rotation has been intensively studied for purine complexes of general formula *cis*-$A_2Pt(II)$ (with A_2 = two monodentate or a bidentate amine).[11] The results obtained from these studies are meaningful with regard to the formation and stability of the bifunctional adduct formed in the reaction of the antitumor drug *cis*-$[PtCl_2(NH_3)_2]$ with DNA. Favourable or unfavourable interactions between nucleobases and between these and the carrier ligand are crucial as far as the formation and stability of a given bifunctional adduct are concerned.

In general, for nonbulky carrier ligands (these comprise all primary amines and most of the secondary amines), the rate of rotation of the guanine bases is fast on the NMR

time scale and therefore a single set of signals, which is the average of several possible conformers, is observed. This applies not only to the case of two untethered nucleotides, but also to guanines linked by a phosphodiester chain.[19] Under these circumstances a valuable help in the understanding of factors determining the stability of a given conformation can come from the structural characterisation of various conformers isolated in the solid state. Usually, however, only one of the stable conformers is obtained.

The use of acyclovir as a platinum-coordinating guanine base has been particularly fortunate since it has allowed the crystallisation of three different conformers of the *cis*-$[PtA_2(acv)_2]^{2+}$ species [$A_2 = (NH_3)_2$ or en], all of them possible models of the cisplatin−DNA bifunctional adducts. Two conformers have already been reported,[7,18a] both of which have the guanine base in the most common *HT* arrangement. Such an orientation of the two guanines is favoured by the electrostatic interaction between the two base dipoles. In one case (compound **3**)[18a] the two bases are nearly perpendicular to the coordination plane [dihedral angles of 81.0(4)° and 76.8(4)°]. This positioning of the bases optimises the dipole−dipole interaction but excludes the possibility of H-bond formation between the O(6) of the purine and the *cis* amine group. Interestingly, there was an indication of a possible attractive interaction between the O(6) atoms of the two guanines and the platinum centre. This possibility has been confirmed by the theoretical investigation reported in the present paper.

In the second *HT* conformer (compound **2**)[7] the two purines are tilted over the coordination plane [angles between the purine and the coordination plane of 50.5(3)° and 54.3(3)°]. The tilting of the bases decreases the stabilisation due to the interaction between the base dipoles but allows the formation of H-bonds between the O(6) of the purines and the *cis* amine groups. Interestingly, the two *HT* conformers characterised in the solid state correspond to the two energy minima deduced both from experimental results[20] and theoretical investigations for this type of adduct.[21]

By crystallisation of the same cation under slightly different experimental conditions a new conformer has been obtained (compound **1**). It has the two purines arranged in the rare *HH* conformation; a detailed description of the structure has been given in the previous section. While in the *HT* conformers the two nucleobases within each conformer had comparable inclinations with respect to the coordination plane (difference between dihedral angles $\leq 4°$), in the case of the *HH* conformer the inclination is very different for the two purines (difference between dihedral angles of 17°). The purine with the smaller dihedral angle has the O(6) forming an H-bond with the *cis* amine; such an H-bond is precluded for the second purine which, however, could have O(6) interacting with the platinum centre.

A DFT molecular-orbital analysis carried out on the model system $[Pt(NH_3)_4(CH_2O)]^{2+}$ (C_{2v} symmetry), gave indications of a covalent bonding interaction between the Pt and O atoms. The atomic orbitals mostly involved in this interaction are Pt $5d_z^2$ and $6d_z^2$, and O $2p_z$. The optimized geometry for the $[Pt(NH_3)_4(CH_2O)]^{2+}$ molecule converges to a Pt−O distance of 3.070 Å, a value much shorter than the sum of the Van der Waals radii. The bond formation energy for the formal reaction between $[Pt(NH_3)_4]^{2+}$ and CH_2O is −33.942 kcal·mol^{-1}. A similar DFT molecular-orbital analysis carried out on the *HT cis*-$[Pt(NH_3)_2\{N(=CH_2)-C(=CH_2)-C(=O)-NH_2\}_2]^{2+}$ also gave indications of a covalent bonding interaction between the Pt and O atoms, even though the Pt−O distances were set at 3.320 and 3.409 Å (geometrical parameters of compound **3**). Therefore, it can be concluded that even at long Pt−O distances such as those found in *HT* $[Pt(NH_3)_2(acv)_2]^{2+}$ [18a] and for one acyclovir in *HH* $[Pt(en)(acv)_2]^{2+}$ (present work) an attractive Pt−O interaction may also exist. Such an attractive interaction appears to be weaker in the latter case, where not only is acv1 far from being orthogonal to the coordination plane and the Pt···O distance is longer but also the Pt−N7−C5 angle has failed to become smaller than the Pt−N7−C8 angle (this was the case for the former complex). Moreover, it has to be noted that, for previously reported platinum complexes of guanine derivatives, Pt···O contact distances as short as 3.526(7) Å[18b] and 3.39(1) Å[18c] were found.

There is a correlation between the canting of the purine bases (right or left handed) and the puckering of the ethylenediamine chelate ring (δ or λ). Right-handed canting is associated with λ puckering of the chelate ring and left-handed canting with δ puckering of the chelate ring, so that in both cases one purine forms an H-bond with a "quasi equatorial" NH. Therefore, the H-bond between O(6) of the guanine and the NH of the *cis* carrier ligand appears to be preferentially formed with NH protons having a "quasi equatorial" character than with protons of the "quasi axial" type. This is true for both the *HH* conformation (only one guanine forming the H-bond, present work) and the *HT* conformation (both guanines forming H-bonds, ref.[7]).

It is also likely that in the case of chiral carrier ligands such as 1,2-diaminocyclohexane (DAC) and 2,3-diaminobutane (DAB) the effect of chirality is transmitted from the carrier ligands to the coordinated nucleobases via the stereochemistry of the hydrogen atoms on the coordinated amino nitrogens. Recent results on modifications of natural DNA and synthetic oligodeoxyribonucleotide duplexes by *cis*-$[PtCl_2(DAB)]$ complexes were consistent with the distortion induced in the platinated DNA being determined by hydrogen-bond formation between the carbonyl oxygen of the guanine residues and the "quasi equatorial" hydrogens of the *cis* diamine in the 1,2-d(GpG) intrastrand cross-link.[22]

Experimental Section

Starting Materials: Ethylenediamine, K_2PtCl_4, and Ag_2SO_4 were purchased from Fluka, and acyclovir (acv) was a gift of LEK, Pharmaceutical Works, Slovenia. [PtCl(dmso)(en)]Cl was prepared following the method by Romeo et al.[23]

Preparation of the Complex: $[Pt(en)(acv)_2](SO_4)\cdot 2.5H_2O$ was synthesized by mixing 0.50 mmol of Ag_2SO_4 and 0.50 mmol of [PtCl(dmso)(en)]Cl in 10 mL of water and stirring the solution for 24 h at 60 °C. After filtration 1.00 mmol of acv was added. This mixture was stirred at 50 °C for 24 h and then the solvents evaporated in the open air. Colourless crystals suitable for X-ray analysis were obtained from the solution in a few days. – $C_{18}H_{35}N_{12}O_{12.5}PtS$: calcd. C 25.5, H 4.2, N 19.9; found C 26.0, H 3.9, N 20.1.

Physical Measurements: Infrared spectra in the range 4000–370 cm^{-1} were recorded as nujol mulls on a Perkin–Elmer System 2000 FT spectrophotometer. NMR spectra were recorded on a Bruker Avance DPX 300 (^1H at 300.131 MHz, ^{195}Pt at 64.325 MHz) spectrometer. Sample concentration was 18 mg in 0.6 mL of D_2O (99.9% deuterium). Acetonitrile was used as internal reference [$\delta(^1H) = 2.00$; $\delta(^{13}C) = 1.3$; $\delta(^{15}N) = -135.8$ relative to nitromethane]. ^{195}Pt chemical shifts are referenced to H_2PtCl_6 which was recorded separately. The sample temperature was set at 302 K and controlled to approximately ±0.5 K. *ID spectra:* ^1H: 10 ppm sweep width, 32 k time domain, zero filling to 64 k; ^{195}Pt: 64.4 kHz sweep width, 1368 time domain, 100 k scans, line broadening of 50 Hz prior to FT.

X-ray Structure Analysis[24]

Data Collection: A colourless needle of **1** of dimensions 0.30 × 0.10 × 0.05 mm was selected under a polarising microscope, and then mounted on a glass fibre. The data were collected with a Siemens P4 automatic four-circle diffractometer. Graphite-monochromatized Mo-K_α radiation ($\lambda = 0.71073$ Å) was employed. Accurate cell constants (Table 3) were determined by full-matrix least-squares refinement of the values of 28 carefully centred randomly selected reflections in the range $10 \leq 2\theta \leq 33°$. The data were collected at 295 K and then corrected for Lorentz-polarization and absorption effects (ψ-scan technique based on at least three reflections). The collected reflections totalled 4751, 3365 of which were independent with $I > 2\sigma(I)$. The space group (*C*2/*c*, no. 15) is in agreement with the systematic extinctions. Three standard reflections were monitored periodically (97 reflections) during the data collection; no appreciable decay was observed.

Structure Solution and Refinement: The structure was solved with the Patterson and Fourier techniques. The difference-Fourier map computed after a twelve-cycles refinement at the isotropic level showed three new peaks in the proximity of three atoms of the exocyclic chains of both the acyclovir molecules. This was interpreted as a statistical disorder and the six new peaks were assigned as oxygen and carbon atoms, namely O(1′B), C(1′B) and C(2′B), and O(1′C), O(3′C) and C(2′C). On the basis of the peak height, the occupancies of the new atoms were fixed at 0.4 and 0.3, respectively, whereas those of the atoms O(1′1), C(1′1), and C(2′1) and O(1′2), O(3′2), and C(2′2) were fixed at 0.60 and 0.70, respectively. At the same stage of refinement four new peaks appeared close to the oxygen atoms [O(1*S*)–O(4*S*)] of the sulfate anion in agreement with a statistical disorder also for this part of the structure. The new peaks were assumed as possible positions for oxygen atoms [whose symbols were assigned as O(5*S*)–O(8*S*)]. The occupancies of the two sets of oxygen atoms were fixed at 0.5 each.

Three broad peaks from the Fourier-difference map were assigned to oxygen atoms of three water molecules whose occupancies are 1, 1, and 0.5, respectively, in agreement with the elemental analysis of the sample and with the analysis of the crystal packing and the hydrogen bonding scheme. The bond lengths for the atoms of the exocyclic chains of acyclovir were restrained as follows: C–O = 1.45 ± 0.02 Å; C–C = 1.52 ± 0.02 Å. The hydrogen atoms for the whole structure were included through the HFIX and AFIX options of SHELX97,[25] excluding the hydrogen atoms for the exocyclic chain of acyclovir and those of the water molecules, which were not included at all. The hydrogen atoms were allowed to ride on the atoms to which they are linked. At the final refinement stage the hydrogen atoms and all the atoms of the disordered chain from acyclovir(1) were treated as isotropic. All the other atoms were refined anisotropically. The thermal parameters for the H-atoms were restrained to be 1.2 times the U_{eq} values of the atoms to which they are bound. All the calculations were carried out with the SHELX 97,[25] PARST 97[26] and XPMA-ZORTEP[27] and ORTEP 3[28] computer programs implemented on Pentium machines.

Molecular Orbital Analysis and Computational Methods: All the calculations were performed with the GAUSSIAN94/DFT package[29] implemented on an Origin 2000 SG machine located at CINECA (Interuniversity Computing Center), Bologna, Italy. Geometry optimizations and energy calculations were obtained by using the B3LYP method[30] and the LANL2DZ basis set.[29] This consists of 6–31G-like functions for nontransition metal atoms, excluding the Cl atom for which the basis set 6–31G**[20] was used, and a valence double-zeta basis set for 3*s*, 3*p*, 3*d* and 4*s* electrons and orbitals along with an effective core potential (Hay and Wadt[31]) for the metal. All the geometrical parameters were fully optimized without symmetry constraints, unless otherwise specified. Other details are as those reported in ref.[32]. The systems investigated were CH_2O, $[Pt(NH_3)_4]^{2+}$, $[Pt(NH_3)_4(CH_2O)]^{2+}$, $[PtCl_4]^{2-}$ and $[PtCl_4]^{2-}\cdots CH_2O$. The starting structures for the metal-containing molecules have planar coordination geometries.

Finally, a single-point DFT calculation was carried out for the molecule *HT cis*-$[Pt(NH_3)_2\{N(=CH_2)-C(=CH_2)-C(=O)-NH_2\}_2]^{2+}$ as a model for *HT cis*-$[Pt(NH_3)_2$-(Guanine)$_2]^{2+}$. The coordinates for the nonhydrogen atoms were those from the *HT cis*-$[Pt(NH_3)_2(acv)_2]^{2+}$ complex reported in ref.[18a]. The hydrogen atoms were introduced in calculated positions by using the HyperChem 5.0 package;[33] whereas molecular drawings were obtained through XPMA-ZORTEP.[27] and ORTEP 32.[28] packages. All graphic calculations were performed on Pentium machines.

Acknowledgments

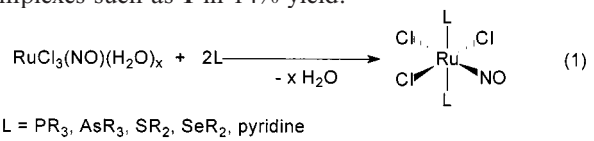
Linear and Bent Oxo-Bridged Dimers of Ruthenium Pyrazole Nitrosyls

D. Scott Bohle*[a] and Elizabeth S. Sagan[a]

Dedicated to Professor Heinrich Vahrenkamp on the occasion of his 60th birthday

Keywords: Pyrazole complexes / Nitrosyl complexes / Oxo-bridged complexes / Ruthenium / N ligands



The nitrosylation of $RuCl_3 \cdot (H_2O)_x$ in thionyl chloride affords anhydrous $[RuCl_3(NO)]$ which, when treated with a variety of ligands L, gives $[RuCl_3(L)_2(NO)]$. For L = 3,5-dimethylpyrazole (dmpH) it is possible to isolate and characterize the corresponding monomeric complex **1** as well as unusual oxo-bridged dimeric products with nitrosyl ligands *trans* to the oxo ligand with either a linear geometry, as in *trans*-$O[RuCl_2(NO)(dmpH)_2]$ **(2)** and $[Cl_4(NO)Ru]O[Ru(NO)(dmpH)_4]$ **(4)**, or with a bent geometry, as in *trans*-$O[RuCl(NO)(dmpH)(\mu\text{-dmp})]_2$ **(3)**. These compounds have been characterized by elemental analysis and vibrational and NMR spectroscopy, as well as by single crystal X-ray diffraction. Collectively the structural and spectroscopic data support a delocalized π-bonding model across the linear ON–Ru–O–Ru–NO framework.

Introduction

Although ruthenium is renowned for its propensity to form robust adducts of nitric oxide,[1] the majority of these compounds contain relatively soft ligands which favor low formal oxidation states. Thus, to the best of our knowledge there are no reported examples of ruthenium nitrosyl complexes with either terminal oxo or nitrido ligands. Even the number of such complexes where the oxygen or nitrogen atom bridges two centers is very small,[2,3] and there has been surprisingly little research into this area of chemistry. The recognition of the critical role nitric oxide has in biological signal transduction,[4,5] and the increasingly frequent observed interaction of iron proteins with nitric oxide,[6] spur considerable current interest in its coordination chemistry. Nitrosyl derivatives of the oxo-bridged diiron proteins, and related model iron or ruthenium compounds, is a surprisingly sparse area of chemistry and many issues of their stereochemistry, electronic structure, and spectroscopy need to be examined in detail. Herein we describe: (i) the facile synthesis of several examples of mononuclear and oxo-bridged dinuclear ruthenium pyrazole complexes; (ii) the X-ray diffraction structures of three of these derivatives which contain both linear and bent Ru−O−Ru bonds; and (iii) the characterization of these new derivatives. Taken together these results allow us to assess the degree of synergistic π-acceptance and π-donation across the ON−Ru−O−Ru−NO framework.

Results and Discussion

A common synthon in ruthenium(II) nitrosyl chemistry is "$RuCl_3(NO)$" which is readily obtained by passing NO through alcoholic solutions of $RuCl_3 \cdot (H_2O)_x$.[7] Although this solid can be isolated as a trihydrate, it is frequently used directly for reactions with excess ligands L (L = tertiary phosphanes and arsanes, thioethers, or selenyl ethers)[8−10] to give the diamagnetic complexes $[RuCl_3(NO)L_2]$ [Equation (1)]. In these cases the $[RuCl_3(NO)L_2]$ product can usually be isolated in high yield by simple filtration of the product from the ethanol solution; there are no reports of other hydrated or oxo-bridged products being isolated from this one-pot approach. With amines and nitrogen bases this strategy has considerably less general utility; for example, although pyridine, acetonitrile, 2,2′bipyridine, and 1,10-phenanthroline add to $[RuCl_3(NO)]$ to give six-coordinate products, the reaction with ammonia, 3,5-dimethylpyrazole or {[tris(3,5-dimethylpyrazolyl)borate]$^-$ = DMTPZ} under the conditions in Equation 1 leads to mixtures of products and low general yields of the desired product.[8,11] In the case of 3,5-dimethylpyrazole this is due to the formation of the oxo-bridged diruthenium products to be described below. In the case of DMTPZ, however, the low yields (ca. 9%) for $[(DMTPZ)RuCl_2(NO)]$ isolated from the reaction of commercial $[RuCl_3(NO)]$ and Tl(DMTPZ), are in part due to hydrolysis of the DMTPZ to give mono-pyrazole complexes such as **1** in 14% yield.[11]

(1)

L = PR_3, AsR_3, SR_2, SeR_2, pyridine

A simple solution to these problems is to dehydrate $RuCl_3 \cdot (H_2O)_x$ by performing the nitrosylation reaction in thionyl chloride. To this end we have modified a method devised by Demant et al. where $RuCl_3 \cdot (H_2O)_x$ is nitrosylated in thionyl chloride [Equation (2)] and the resulting product is filtered off and used directly.[12] When anhydrous $[RuCl_3(NO)]$ is prepared in this manner, and then treated

with excess 3,5-dimethylpyrazole in toluene at reflux [Equation (3)], the major product is *mer*-$[RuCl_3(NO)(dmpH)_2]$ **(1)**, which is isolated in 87% yield after chromatography on silica. This product is identical by IR and NMR spectroscopy to that isolated in low yield by Onishi.[11] A trace second product of this reaction is the known bright yellow $[RuCl_3(dmpH)_3]$.[13−15]

$$RuCl_3(H_2O)_x \xrightarrow[-\,x\,SO_2,\,-\,2x\,HCl]{NO,\ SOCl_2(solvent)} RuCl_3(NO) \qquad (2)$$

$$RuCl_3(NO) \xrightarrow[\Delta,\ T = 105\ ^\circ C,\ 22\ h]{2LH,\ toluene} \mathbf{1} \qquad (3)$$

LH = 3,5-dimethylpyrazole

The brick red mononuclear complex **1** has a relatively labile coordination sphere as it is readily converted into a range of other derivatives by hydrolysis or by treating it with an excess of a coordinating ligand, i.e. the reaction of **1** and triphenylphosphane in ethanol at reflux gives $[RuCl_3(NO)(PPh_3)_2]$ in high yield. When **1** is heated to reflux in wet benzene it rapidly hydrolyzes to give mainly the golden colored, oxo-bridged dimer **2** [Equation (4)] and a trace of the oxo and pyrazolato bridged dimer **3**. When **1** is treated with one equivalent of a silver salt there is the rapid formation of a silver chloride precipitate, but the only product isolated from this type of reaction is unchanged starting material, **1**, in ca. 60% yield. Chelating anions such as dibenzyldithiocarbamate also react rapidly with **1** at ambient temperatures to give a mixture of isomers with the formula $[RuCl(Bz_2NCS_2)_2(NO)]$.

$$\underset{\mathbf{1}}{RuCl_3(NO)(LH)_2} \xrightarrow[\Delta,\ T = 76\ ^\circ C]{H_2O,\ (benzene)} \underset{\mathbf{2}}{ON\text{-}Ru\text{-}O\text{-}Ru\text{-}NO} \quad + \mathbf{3}\ (trace) \qquad (4)$$

Under forcing conditions for the reaction of $RuCl_3(NO)\cdot(H_2O)_x$ with 3,5-dimethylpyrazole it is possible to isolate in good yield the mixed μ-oxo; di(μ-pyrazolato) bridged complex, **3** by the addition of excess sodium hydroxide and heating the solution at reflux in ethanol for 16 hours [Equation (5)]. This complex is also formed as a minor product of the synthesis of the linear oxo-bridged complex **2** from the hydrolysis of **1** in benzene. Finally the asymmetric linear complex $[Cl_4(ON)RuORu(NO)(dmpH)_4]$ **(4)** is a minor product of the reaction of thermolyzed $RuCl_3(NO)\cdot(H_2O)_x$ with 3,5-dimethylpyrazole, and can be separated from the major product of this reaction (compound **1**) by column chromatography. Although this product contains formal $16e^-$ and $20e^-$ centers, $\{(ON)RuCl_4\}^{-1}$ and $\{(ON)Ru(dmpH)_4\}^{+3}$, respectively, this distinction rests upon the presence of protons on the 3,5-dimethylpyrazole ligands. In light of the hydrogen bonding observed in the solid state, described below, these formal assignments should not be taken too seriously.

$$RuCl_3(NO)(H_2O)_2 \xrightarrow[EtOH\ \Delta,\ T = 76\ ^\circ C\ 16\ hours]{LH/NaOH} \mathbf{3} \qquad (5)$$

4

Single crystal X-ray crystallography has been used to characterize these derivatives: critical crystallographic parameters are collected in Table 1, views of the four molecules are shown in Figure 1−4, and selected geometrical parameters are collected in Table 2. With the exception of the disordered solvent in **2** the bond lengths and angles are determined precisely and allow for meaningful comparisons. In each case the Ru−NO fragments are linear with short metal−nitrogen bond lengths and a ruthenium geometry close to an ideal octahedron. Overall the ruthenium chloride bonds in these compounds have similar lengths, with the exception of Ru−Cl(1) in **1**, where the chloride *trans* to the nitrosyl is significantly shorter than the others. On average the ruthenium−nitrogen distances to the pyrazole ligands are similar for the terminal pyrazoles, which in turn are slightly longer than the bridging pyrazoles in **3**. This trend is also seen in $[\{(p\text{-cymene})Ru(\mu_2\text{-}OH)\}_2(\mu\text{-pyrazolato})]BF_4$ where the ruthenium−nitrogen bond lengths are 2.078(3) Å.[16]

As can be seen from the ORTEP representations of **2, 3**, and **4** in Figure 1−4 the planes defined by the pyrazole rings adopt an orientation which allow for relatively short N−H···Cl interactions in the solid state. In particular the linear, oxo-bridged dimers have short chlorine−hydrogen interactions: compound **2** has Cl(1)−HN(6) = 2.398(4) Å, Cl(2)−HN(8) = 2.392(4) Å, Cl(3)−HN(2) = 2.435(3) Å, and Cl(4)−HN(4) = 2.371(4) Å, while **4** has Cl(1)−HN(4) = 2.397(2) Å, Cl(2)−HN(6) = 2.330(2) Å, Cl(3)−HN(10) = 2.392(4) Å, and Cl(4)−HN(8) = 2.354(2) Å. On the other hand, in the mononuclear complex **1** and the bent oxo-bridged dimer **3**, the chloride−hydrogen separations are much longer; in **1** Cl(1)−HN(3) = 2.748(2) Å, and Cl(2)−HN(5) = 2.690(4) Å, while in **3** these separations are Cl(1)−HN(10) = 2.757(2) Å, and Cl(2)−HN(8) = 2.791(3) Å. Correlated with these structural observations are variations in the frequencies of the N−H stretching bands, ν(N−H) between 3598 cm^{-1} in **4** to 3140 cm^{-1} in **2**.

Characteristic vibrational and electronic spectroscopic data for these compounds are collected in Table 3. The nitrosyl stretching frequencies clearly fall into the region for linear nitrosyls, and all of the oxo-bridged dimers

2−**4** have lower ν(NO) frequencies than does the mononuclear complex **1**. In the case of complex **2** there is a single, strong and relatively broad ν(NO) band at 1809.1 cm^{-1} in the infrared spectrum and this is assigned as the asymmetric nitrosyl stretch across the ON−Ru−O−Ru−NO framework. In the Raman spectrum a single weak band at slightly higher energy (1821 cm^{-1}) is observed for **2**, and this is assigned as a symmetric nitrosyl stretch for the dinuclear framework. For complexes **3** and **4** both ν(NO) modes are IR active and in both cases are split by ca. 28 cm^{-1}, a value significantly higher than found for **2**. The similarity in splitting is somewhat surprising in light of the different ruthenium environments in the case of **4** and the C_2 symmetry present in **3**. The Ru−O−Ru framework also has a strong IR active $\nu(Ru{-}O{-}Ru)_{asym}$ at 791.7 cm^{-1} as well as a Raman active $\nu(Ru{-}O{-}Ru)_{sym}$ mode at 334 cm^{-1} for the linear dimer **2**. As shown in Figure 5, the low energy Raman spectra for **1**−**4** contain numerous common bands including a strong band 589−602 cm^{-1} and weaker bands at 441−448 cm^{-1}, 359−365 cm^{-1}, and 282−291 cm^{-1}. For the bent oxo-bridged dimer **3** there is a unique weak band at 495 cm^{-1} which may be due to either the $\nu(Ru{-}O{-}Ru)_{sym}$ band or to the bridging pyrazole. In **4** it is difficult to assign a unique band to the $\nu(Ru{-}O{-}Ru)_{sym}$ mode.

The electronic spectra for the oxo-bridged dimers are dominated by three bands, with the lowest energy band being relatively weak and broad and generally observed as a shoulder to the stronger UV bands. For the oxo-bridged dimer **3**, the two most prominent UV bands are at lower energies than for either of the linear oxo-bridged dimers **2** or **4**. For the mononuclear complex **1** the intense red color

is due to a comparatively strong low energy band at 538 nm. All of the new complexes described in this paper are clearly diamagnetic at room temperature and give sharp ^1H and ^{13}C NMR spectra with no indication of fluxional exchange broadening. In each case the solution spectra indicate that the structures determined by X-ray diffraction correspond to those in solution. The electrochemistry of species **1**−**4** is dominated by irreversible reductions at circa −0.9 V. In the cyclic voltammetry experiments no return wave is seen, even at relatively fast sweep rates (2000 mV s^{-1}) and the oxidative sweep indicates numerous new by-products from these processes.

There are surprisingly few well-characterized metallonitrosyl complexes with either bridging or terminal oxo ligands. This might be attributable to the widely perceived notion that the oxo ligand and strong π-accepting ligands such as a nitrosyl have differing preferences for a metal's oxidation state and environment. In terms of group 8 transition metals there are several early reports of oxo-bridged ruthenium nitrosyl dimers $Ru_2N_6O_{15}$ stemming from the addition of nitric oxide to RuO_4.[2,3] More recently, an oxo-bridged osmium porphyrin nitrosyl complex has been serendipitously isolated and structurally characterized from the reaction of [Os(OEP)(CO)] and ClNO.[17] Other examples of the ON−M−O−M−NO framework can be found for Ir, μ_2-$O[Ir(NO)(PPh_3)_2]_2$,[18,19] and its oxidative-addition products,[20,21] as well as more numerously for molybdenum.[22−25] In general the iridium examples are similar to those described here for ruthenium in the that the nitrosyl is *trans* to the oxo-ligand, while in the case of molybdenum the nitrosyls are *cis* to the oxo bridge. This trend may be due to the use of polyhapto chelate ligands in the molybdenum examples; in these cases the ancillary ligand is required to occupy the *trans* position. It remains an open question whether an oxo-bridged molybdenum nitrosyl dimer with a less constrained coordination sphere would

[a] All vibrational frequencies are given in cm^{-1} and measured in KBr for infrared bands (IR) or as a neat powder for the Raman active bands (RA).

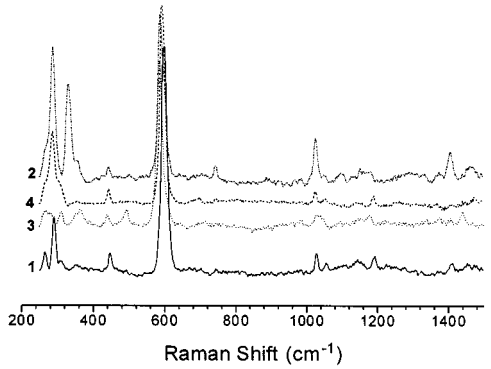

Figure 5. Raman spectra of compounds **1**–**4** measured as powders with 648 nm excitation radiation; **1** (bottom, solid line), **2** (top, dash double dotted line), **3** (second from bottom, dotted line ·····), and **4** (dashed line)

adopt a *cis* or *trans* oxo geometry. Thus there is little intrinsically incompatible with coordination of oxo and nitrosyl ligands within a single coordination sphere.

Attempts to prepare sulfur-bridged analogues to **2**–**4** have been unsuccessful. Thus when **1** is treated with hydrogen sulfide under the conditions which lead to hydrolytic dimerization to give **2**, there is rapid formation of an amorphous black powder that is completely insoluble in most solvents. This solid still contains a strong sharp nitrosyl stretching band at 1785 cm^{-1} in the IR and analyzes for RuS_4NO contaminated with some pyrazole species. Thus, excess hydrogen sulfide results not only in the loss of the *trans* chloride in **1**, but also the two remaining chlorides and the two 3,5-dimethylpyrazole ligands. In an attempt to control the stoichiometry of the sulfur substitution reaction more carefully, compound **1** was treated with $S(SiMe_3)_2$ in benzene at reflux. However under these conditions **1** was quantitatively recovered unchanged.

Complexes **2**–**4** have the potential of a "push-pull" in the bonding along the ON–Ru–O–Ru–NO framework. In this overly simplified model the nitrosyls act as π-accepting ligands while the oxo is a π-donor ligand. In higher oxidation states the bridging-oxo ligand is known to mediate strong ruthenium–ruthenium interactions as evidenced by reversible electrochemistry and by the strong coupling observed in the magnetic susceptibility of $[(bipy)_2ClRuORuCl(bipy)_2]^{n+}$ (n = 2 or 3).[26] In the qualitative molecular-orbital scheme proposed by Weaver et al.[26] two *p*-type lone pairs of the oxygen can π–bond with the six t_{2g} orbitals based on the two ruthenium to give pairs of π-bonding, nonbonding, and antibonding orbitals, as well as the two d_{xy} ruthenium orbitals. These π-orbital pairs are degenerate in the linear D_{4h}-symmetric complexes and are closely spaced for D_{2h}-symmetric species such as **2**. Regardless of the local symmetry, this molecular orbital scheme leads to no net stabilizing interaction for ruthenium(II) oxo-bridged dimers since the t_{2g} set is full. This correlates with the general absence of linear oxo-bridged complexes of d^6 metal centers. However, once a nitrosyl ligand is introduced into the *trans* position to the oxo-bridge there will be strong backbonding interactions between the filled π^* and π_{NB} orbitals and the accepting π^* orbitals of the nitrosyl ligands. In a qualitative sense these interactions should be stronger than in the parent complex because the energy match between the π^* and π_{NB} and the π^*_{NO} will be better since the former orbitals are of higher energy. In addition, the overlap between these orbitals will probably increase due to the spatial extension of these orbitals towards the nitrosyl. Thus in these qualitative terms the net π-interaction for the ON–Ru–O–Ru–NO fragment is expected to be highly stabilizing in a linear geometry, and stabilized to a similar extent in a bent Ru–O–Ru geometry.

The structural consequences of possible π-delocalization over the oxo-ruthenium-nitrosyl framework are expected to be manifested most strongly in the trends in the ruthenium–oxygen distances for the bridged oxo ligand. Thus the ruthenium–oxygen bonds in **2**–**4** might be expected to be shorter than those in related complexes which lack a strong π-accepting ligand *trans* to the bridging oxo group. There are few direct comparison complexes where oxo ligands bridge two ruthenium(II) d^6 centers. However there is little significant difference between the two Ru–O bond lengths in linear bridged **2** or **4** and the bent species **3**. There is a significant difference between the

ruthenium−oxygen bond lengths in the asymmetric linear bridged species **4** where the Ru(1)−O(3) for the $RuCl_4(NO)$ group, formally with a −1 charge, is 0.067(2) Å longer than Ru(2)−O(3) for the $Ru(LH)_4(NO)$ group which formally has a charge of +3. Note however that all of these bond lengths are about 0.05 and 0.1 Å longer than the ruthenium−oxygen bond lengths in linear Ru^{III} and Ru^{IV} oxo-bridged dimers found in the CCDB.[27] The Ru−O−Ru bending found in **3** is similar to that found in structurally characterized carboxylato, oxo-bridged ruthenium dimers where the mean ruthenium−oxygen−ruthenium bond angle is 122.3 °.[27]

For the nitrosyl stretching frequencies the formation of the oxo-bridge results in an 80 cm^{-1} decrease in the two ν(NO) bands, and this suggests increased Ru−NO back-bonding in all three of the oxo-bridged complexes. Correlated with this trend are the Ru−O bond lengths which range between 1.873(2) and 1.940(2) Å, values which are ca. 0.20 Å shorter than for the many nonchelating Ru^{II}−OR bond lengths in the CCDB. On the other hand these bond lengths are ca. 0.05−0.1 Å longer than for structurally characterized high-valent, oxo-bridged ruthenium dimers which typically contain electronegative ligands *trans* to the oxo-bridge. The ν(Ru−O−Ru) stretching frequencies for **2**−**4** are also lower than for high-valent species. For example, in $K_4Ru_2OCl_{10}$ $\nu(Ru-O-Ru)_{asym}$ = 888 cm^{-1} and $\nu(Ru-O-Ru)_{sym}$ = 259 cm^{-1}, and have a difference $\nu_{asym}-\nu_{sym}$ = 629 cm^{-1}.[28] For **2** the values are ν_{asym} = 791.7 cm^{-1} and ν_{sym} = 343 cm^{-1}, with a difference $\nu_{asym}-\nu_{sym}$ = 449 cm^{-1}. The ν_{asym} frequency is at the low end of the reported range for these modes, and this correlates with the small difference between the two Ru−O−Ru stretching modes.[29,30]

Although the most well understood receptor for nitric oxide is the heme protein soluble guanylate cyclase,[31,32] a diverse array of other physiological sinks for nitric oxide have been proposed.[33] In many cases the critical protein/nitric oxide interaction is the binding of nitric oxide to enzymatically active metals such as the diiron site in bacterioferritin,[34] the oxo-bridged diiron center in hemerythrin[35] or methane monooxygenase hydroxylase,[36] the [2Fe-2S] iron-sulfur cluster in mammalian ferrochelatase,[37] or the [4Fe-4S] cluster in HiPIP.[38] In these cases the new nitrosylated ferroproteins have markedly different redox, structural, and kinetic properties as compared to the parent protein, and a current major interest in metallobiochemistry is understanding how nitrosylation mediates these effects. For the oxo-bridged diiron proteins, nitrosylation of the iron(s) can potentially result in the introduction of the nitric oxide *cis* or *trans* to the oxo bridge. Although in most cases the specific coordination geometry of these nitrosylated diiron sites is not known, our work suggests that *trans* coordination geometries may be thermodynamically favored.

Conclusion

In all of the chemistry described in this paper the nitrosyl and oxo-ligands retain a rigorous *trans* geometry; there is no indication of either isomerization or the presence of isomers where these two ligands are *cis*. However, other isomers or related complexes may very well be accessible with a judicious choice of conditions or with other ligand sets. The *trans* arrangement of the oxo-bridge and nitrosyl allows for some π-delocalization as evidenced by the spectroscopic and structural results.

Experimental Section

General: The instrumentation, methods, apparatus, and experimental techniques have been described in detail in previous papers.[39] 3,5-Dimethylpyrazole and thionyl chloride were purchased from Aldrich and used as provided. Ruthenium(II)nitrosyl trichloride was either synthesized by a variation of the method of Demant et al.[12] or the solid was purchased from Strem Chemicals. In general the pyrazole complexes are stable towards aerial oxidation and hydrolysis and thus they can be stored, chromatographed, and handled in the open. Electrochemistry experiments were performed with a BAS-50 W potentiostat with a platinum disk electrode, a silver auxiliary electrode, and a silver/silver chloride reference electrode. All experiments were performed in dry oxygen-free dichloromethane at room temperature with 0.1 M $[N(n\text{Bu})_4][PF_6]$ backing electrolyte.

Anhydrous $RuCl_3(NO)$: Commercial hydrated ruthenium trichloride (321 mg) was suspended in 10 mL thionyl chloride in a Fisher−Porter bottle and the vessel flushed with nitrogen before pressurizing with nitric oxide to 2.76 bar (40 psi). This mixture was then heated at 65 °C for 12 hours during which time the original black suspension dissolved to give a deep red solution from which a fine red solid precipitated upon cooling to room temperature. After flushing the head space of the reactor with nitrogen, dry carbon tetrachloride (30 mL) was added and the solution filtered to give 350 mg (95%) of red product. − IR (Nujol): ν(NO) = 1894 cm^{-1}. − Cl_3NORu (237.43): calcd. Cl 44.79, N 5.90; found Cl 44.95, N 5.71.

***mer*-$[RuCl_3(NO)(dmpH)_2]$ (1):** $RuCl_3NO$ (0.07 g), prepared by treating $RuCl_3$ with nitric oxide in thionyl chloride, in dry toluene (20 mL) was treated with 3,5-dimethylpyrazole (1.4 g) at reflux for 22 h. During this period, and upon subsequent cooling, a deep-red precipitate formed, which was filtered and washed with copious quantities (50 mL) of ethanol, and subsequently with water, ethanol, and hexanes. The yield of this crude material, which is mostly **1** and a small quantity of bright yellow $[RuCl_3(dmpH)_3]$, was 122 mg. Final purification was achieved by column chromatography on silica gel (20 cm × 4 cm column, with chloroform as the eluent) to elute first the deep red-purple $[RuCl_3(NO)(dmpH)_2]$, which was recovered in a final yield of 87% (111 mg) by addition of ethanol and concentrating the solution on a rotary evaporator to remove the chloroform. Elution with acetone/chloroform (4:50) gave traces of a bright yellow compound, which was subsequently identified as $[RuCl_3(dmpH)_3]$.[14,15] $RuCl_3(NO)(dmpH)_2$: UV/Vis (CH_2Cl_2): λ_{max} (log ε[M^{-1} cm^{-1}]) = 538 (1.77) nm, 430 (1.89), 296 (3.36), 264 (3.34). − ^1H NMR (22 °C, $CDCl_3$): δ = 10.74 (s, 1 H, N−*H*), 5.99 (s, 1 H, C−*H*), 2.61 (s, 3 H, C*H*$_{3'}$), 2.37 (s, 3 H, C*H*$_{3'}$). − ^{13}C NMR (22 °C, $CDCl_3$) δ = 153.8, 143.1(s, *C*−CH_3), 108.0(s, *C*−H), 14.7, 11.4 (s, C−*C*H_3). − IR (KBr): ν(NH) = 3387.8 (m) cm^{-1}, 3329.9 (m); ν(NO) = 1883.4 (s); with additional bands at 1569 (m), 1276.8 (m), 1186.2 (w), 1157.3 (w), 1056.9 (m), 823.6 (w), 792.7 (m), 655.8 (m), 569 (w), 505.3 (m) cm^{-1}. − $C_{10}H_{16}Cl_3N_5ORu$

(429.73): calcd. C 27.95, H 3.75, N 16.30; found C 28.15, H 3.95, N 16.10. − M.p. 248 °C(dec). This complex is also a by-product of the addition of 3,5-dimethylpyrazole to the direct nitrosylation product of $RuCl_3{\cdot}(H_2O)_x$ in ethanol, followed by chromatographic separation. Crystals suitable for X-ray diffraction were grown by vapor-phase diffusion of 2-propanol into a chloroform solution of **1** at −20 °C.

***trans*-O[RuCl$_2$(NO)(dmpH)$_2$] (2):** $RuCl_3(NO)(dmpH)_2$ (**1**; 41 mg) in 20 mL (wet) benzene was heated at reflux for 16 hours in the open air. The resulting red-orange solution was cooled and the benzene removed on a rotary evaporator. The red crystalline solid was taken up in dichloromethane and chromatographed on a 30 × 2 cm silica column with dichloromethane. The first yellow-orange fraction was collected and recrystallized by the addition of an equal volume of ethanol and concentration to 20 mL. The resulting flaky orange-yellow solid was filtered and washed with ethanol and hexane and dried to give **2** (32 mg, 83%). Further elution of the column with dichloromethane gave 5 mg of the bent oxo-pyrazolato complex **3**. − UV/Vis (CH_2Cl_2): λ_{max} (log ε[M^{-1} cm^{-1}]) = 520 (shoulder) nm, 343 (4.35), 264 (3.95). − ^{1}H NMR (22 °C, $CDCl_3$): δ = 12.15 (s, 1 H, N-*H*), 5.67 (d, $^4J_{HH}$ = 1.14 Hz, 1 H, C−*H*), 2.59, 2.05 (s, 3 H, C$H_{3'}$). − ^{13}C NMR (22 °C, $CDCl_3$): δ = 151.2, 142.4 (s, *C*−CH_3), 106.3 (s, *C*−H), 14.0, 10.7(s, C−*C*H_3). − IR (KBr): ν(NH) = 3219 (s) and 3140 (w) cm^{-1}; ν(NO) = 1809.1 (s); $\nu(RuORu)_{as}$ = 791.7 (s); with additional bands at 1570.9 (m), 1473.4 (w), 1409.9 (m), 1377.1 (w), 1276.8 (m), 1191.9 (m), 1151.4 (w), 1056.9 (m), 746.4 (w), 690.5 (m), 582.5 (m), 446.5 (w) cm^{-1}. − $C_{20}H_{32}Cl_4N_{10}O_3Ru_2$ (804.56): calcd. C 29.86, H 4.01, N 17.41; found C 30.08, H 4.01, N 17.32. Crystals suitable for X-ray diffraction were grown by vapor-phase diffusion of ethanol into a dichloromethane solution of **2**.

***trans*-O[RuCl(NO)(dmpH)(μ-dmp)]$_2$ (3):** In a 100 mL Fisher−Porter pressure bottle $RuCl_3{\cdot}(H_2O)_x$ (0.118 g) was suspended in 30 mL absolute ethanol and sealed with a stainless steel pressure head. The solution and apparatus was purged for 30 minutes with a stream of nitrogen and then pressurized with 2.76 bar (40 psi) of nitric oxide at ambient temperature. After 5 hours the pressure was brought back to 2.76 bar (40 psi) and the mixture was allowed to stir for a total of 20 hours at room temperature during which time the color changed from a deep red-black to pink. Following the release of NO pressure the solution and apparatus was purged for an additional 40 minutes with a stream of nitrogen and the uniform ethanol solution of "$RuCl_3(NO)$" was transferred to a 100 mL round bottom flask to which was added 3,5-dimethylpyrazole (2.5 equiv., 0.137 g) and sodium hydroxide (1 equiv., 0.023 g) in 1 mL water. The resulting darkened solution was heated at reflux for 16 hours and then cooled to give a copious deep red precipitate of product. After filtration and successive washes with ethanol, water, and ethanol the burgundy-colored product was dried in a vacuum desiccator. Recrystallization from dichloromethane/ethanol gave **3** (0.124 g, 61%). − UV/Vis (CH_2Cl_2): λ_{max} (log ε[M^{-1} cm^{-1}]) = 520 (2.50) nm, 396 (3.35), 293 (4.24). − ^{1}H NMR (22 °C, $CDCl_3$): δ = 11.87 (s, 1 H, N−*H*), 5.88 and 5.73 (s, 1 H, C−*H*), 2.59, 2.58, 2.17, and 2.06 (s, 3 H, C$H_{3'}$). − ^{13}C NMR (22 °C, $CDCl_3$): δ = 152.9, 142.7 [s, *C*−CH_3(pyrazole)], 150.8 [s, *C*−CH_3(pyrazolate)], 108.5 and 107.2 (s, *C*−H), 14.6, 11.3 [s, C−*C*H_3(pyrazole)], 13.7, 13.8 [s, C−*C*H_3(pyrazolate)]. − IR (KBr): ν(NH) = 3208.4 (m); ν(NO) = 1829.4 (s) and 1802.4 (s); $\nu(RuORu)_{as}$ = 715.5 (s) cm^{-1}; with additional bands at 1565.1 (m), 1534.3 (w), 1473.4 (m), 1444.6 (m), 1419.5 (s), 1380 (m), 1353 (w), 1271 (m), 1187.1 (m), 1148.5 (m), 1016.3 (m), 788.8 (m), 775.3 (m), 649 (w), 580.5 (m), 496.6 (w), 440.7 (w) cm^{-1}. − $C_{20}H_{30}Cl_2N_{10}O_3Ru_2$ (731.64): calcd. C 32.84, H 4.13, N 19.15; found C 32.96, H 4.17, N 19.10. Crystals suitable for X-ray diffraction were grown by vapor-phase diffusion of ethanol into a dichloromethane solution of **3**.

[Cl$_4$(NO)Ru]O[Ru(NO)(dmpH)$_4$] (4): Hydrated ruthenium trichloride (1.1 g) was suspended in 50 mL ethanol in a 100 mL Fisher−Porter bottle, and was nitrosylated with 2.76 bar (40 psi) of nitric oxide pressure for 20 hours. During this period the initially black-red suspension became a uniform pale red color. After releasing the excess nitric oxide pressure and flushing the solution with nitrogen, the pale-red solution was transferred to a 100 mL round bottom flask and the solvent removed at room temperature. The resulting solid was heated to 86 °C under a water aspirator vacuum for 45 minutes and the red-black residue was then taken into an inert atmosphere box under nitrogen. This solid was suspended in 30 mL dry ethanol and allowed to react with 3,5-dimethylpyrazole (1.53 g) for 3 hours at reflux. This solution was cooled to room temperature to give a copious red precipitate and a black solution, which was then filtered and washed with ethanol and hexane to give 1.39 g of red solid. This crude product was a mixture of **1**, **2**, **3**, and **4**, which was separated by column chromatography on silica gel (20 × 5 cm column) with dichloromethane used to elute **1** (69%) and **2**(18%). Chloroform was used to elute **3** (trace) as a purple band, which was followed by a slow moving orange band **4**. The asymmetrical linear oxo-bridged product was separated by eluting with 5:1 chloroform/acetone and isolated by the addition of 20 mL ethanol followed by concentration and crystallization on the rotary evaporator. Filtration followed by successive washes with ethanol and hexane gave 25 mg (12%) of red-orange crystals UV/Vis (CH_2Cl_2): λ_{max} (log ε[M^{-1} cm^{-1}]) = 450 (shoulder) nm, 343 (4.72), 264 (4.33). − ^{1}H NMR (22 °C, $CDCl_3$): δ = 12.49 (s, 1 H, N−*H*), 5.91(s, 1 H,C−*H*), 2.39, 1.93 (s, 3 H, C$H_{3'}$). − ^{13}C NMR (22 °C, $CDCl_3$): δ = 150.6, 145.3 (s, *C*−CH_3), 107.1 (s, *C*−H), 12.8, 11.8 (s, C−*C*H_3). − IR (KBr): ν(NH) = 3598 (w), and 3148 (m) cm^{-1}; ν(NO) = 1818.2 (s) and 1790.2 (s); $\nu(RuORu)_{as}$ = 792.2 (s); with additional bands at 1569.9 (m), 1473 (w), 1409.3 (m), 1376 (w), 1284.4 (m), 1184.2 (m), 1060.2 (m), 711.6 (m), 655.2 (w), 579.5 (m) cm^{-1}. − $C_{20}H_{32}Cl_4N_{10}O_3Ru_2$ (804.56): calcd. C 29.86, H 4.01, N 17.41; found C 29.69, H 4.24, N 17.12. Crystals suitable for X-ray diffraction were grown by vapor-phase diffusion of ethanol into a dichloromethane solution of **4**.

X-ray Crystallographic Study

X-ray diffraction data were collected at room temperature for single crystals of compounds $[RuCl_3(NO)(dmpH)_2]$ **(1)**, $[O\{RuCl_2(NO)(dmpH)_2\}_2]$ **(2)**, $[O\{RuCl_2(NO)(dmpH)(\mu\text{-dmp})\}_2]$ **(3)**, and $[Cl_4(ON)RuORu(NO)(dmpH)_4]$ **(4)** on a Siemens P4 Diffractometer equipped with a molybdenum tube [$\lambda(K_{\alpha1})$ = 0.70926 Å; $\lambda(K_{\alpha2})$ = 0.71354 Å] and a graphite monochromator. In each case the diffraction data were measured using ω scans. The intensities of three standard reflections monitored every 100 reflections during the respective data collections indicated negligible crystal decomposition. The structures were solved by direct methods and refined by full-matrix least-squares techniques on F^2 using structure solution programs from the SHELXTL program.[40] Important crystallographic parameters are collected in Table 1.

Crystallographic data (excluding structure factors) for the structure(s) reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC 139381−139384, for **1**−**4** respectively. Copies of the data can be obtained free of charge on application to CCDC, 12

Peroxovanadium(V) Complexes of L-Lactic Acid as Studied by NMR Spectroscopy

Licínia L. G. Justino,[a] M. Luísa Ramos,[a] M. Madalena Caldeira,[a] and Victor M. S. Gil*[a]

Keywords: Vanadium / Peroxo complexes / L-Lactic acid / Multinuclear NMR spectroscopy

A multinuclear (^{1}H, ^{13}C, ^{17}O, ^{51}V) 1D and 2D NMR study of the complexation of L-lactic acid with vanadium(V) and hydrogen peroxide shows that four peroxo complexes are formed in aqueous solution in the pH range 1–7. Two isomeric 2:2:1 (metal:ligand:peroxo) complexes, together with a 2:2:2 species, are found over the entire pH range. At pH values below 2 an additional 1:1:1 complex is formed. The acid was found in all cases to act as a bidentate ligand through the carboxylic and the adjacent hydroxyl groups. To the best of our knowledge, this is the first report of dinuclear peroxovanadium complexes in which one of the metal centres is an oxovanadium centre (2:2:1 species).

Introduction

Over the past few years increasing attention has been paid to the chemistry of peroxovanadium(V) complexes. This interest is mainly due to the important role of these complexes in biological systems and their application in oxidation reactions. Peroxovanadium(V) complexes have been found to have antitumour[1] and insulin mimetic activities,[2,3] and have been studied as functional models for the vanadium haloperoxidase enzymes.[4,5] These enzymes catalyse the oxidation of halides by hydrogen peroxide and are thought to be involved in the biosynthesis of a large number of marine natural products, many of them with potent antifungal, antibacterial, antiviral (e.g. HIV) and antineoplastic properties.[6] In addition, a large variety of oxidation reactions can be efficiently performed by peroxovanadium(V) complexes. These complexes have been shown to hydroxylate benzene and other aromatics, epoxidise and hydroxylate alkenes and allylic alcohols and oxidise sulfides and primary and secondary alcohols.[7]

Previously, the vanadium(V) complexes that form with several α-hydroxycarboxylic acids were the object of a multinuclear NMR study carried out by this group.[8–10] In view of the interest in peroxovanadium(V) compounds and the need to know their structures in order to fully understand both their chemistry and biochemistry, we have now extended our previous work to the more complex systems involving hydrogen peroxide. This paper deals with the peroxo complexes that form when hydrogen peroxide is added to a mixture of a vanadate(V) salt and L-lactic acid in aqueous solution. Our intention was to investigate these species with respect to their number, stoichiometries, structures and stability by NMR spectroscopy. This technique has been intensively used in the study of vanadium(V)/hydrogen peroxide systems, both in the presence and absence of other ligands,[11–18] and has proved to be successful in the structural characterisation of the species present in solution.

A previous ^{51}V NMR study[17] revealed that a monoperoxovanadium complex of L-lactic acid is formed at pH 1. This species was characterised as being octahedral with a 1:1:1 stoichiometry (metal:ligand:peroxo). No additional studies of this system using NMR or other techniques were found in the literature.

Results and Discussion

Vanadium(V) undergoes very complex hydrolysis and polymerization reactions in aqueous solution, forming a large variety of products depending on the concentration, pH and ionic strength.[19,20] In the presence of hydrogen peroxide and a ligand such as an α-hydroxycarboxylic acid, new equilibria are established and, as a consequence, additional species can be formed, namely peroxovanadates, oxo complexes and peroxo complexes. The formation of peroxo complexes will result, therefore, from competition between several equilibria.

^{1}H, ^{13}C, ^{17}O and ^{51}V NMR spectra of V^{V}-L-lactic acid–H_2O_2 were obtained for D_2O solutions of the complexing species (concentrations ranging from 0.15 M to 2.0 M), with various molar ratios (H_2O_2:metal from 5:1 to 1:1 and metal:ligand from 3:1 to 1:3), and for different pH* values (1–9.5). Figure 1 shows a typical ^{1}H NMR spectrum of this system obtained for the pH* range 2–7. In this spectrum, signals due to several complexes, free ligand and degradation products (mainly acetaldehyde and acetic acid) are observed. The observation of distinct signals for both bound and free ligand is a consequence of slow ligand exchange on the NMR time scale.

Figure 1 also illustrates, through the presence of several L-lactic acid oxo complexes,[8,10] the various competing equilibria in which the ligand is involved.

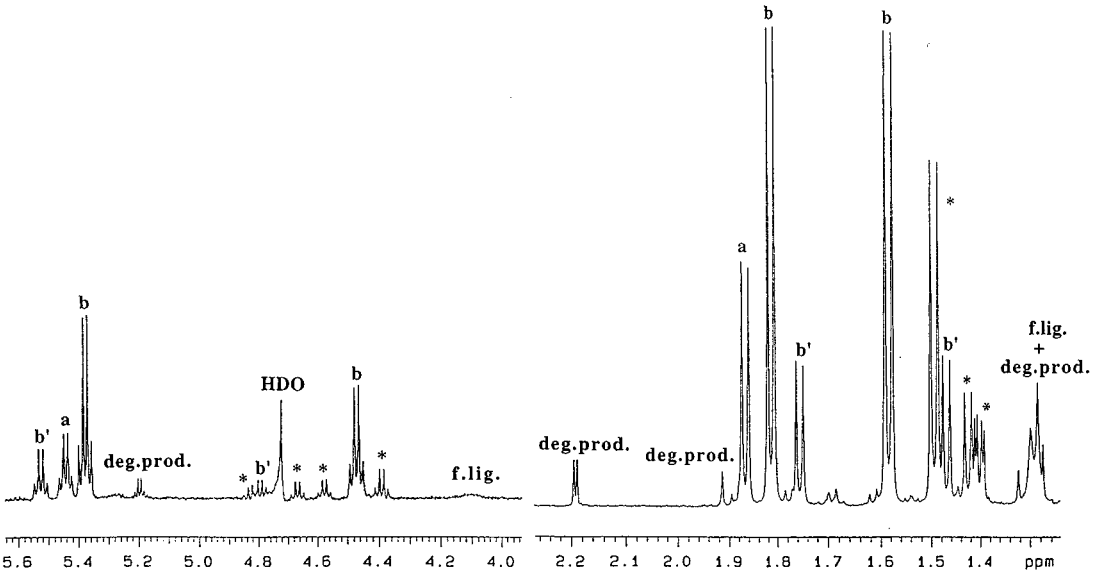

Figure 1. ^{1}H NMR spectrum (499.824 MHz) of a 0.05 M:0.05 M:0.05 M solution in D_2O of V^V−L-lactic acid−H_2O_2, pH* = 4.0, temp. 298 K, approximately 3 hours after preparing the solution, (*): oxo complexes.

Three peroxo complexes, **a**, **b** and **b′**, are formed in the pH* region between 2 and 7. Their concentrations relative to the other species present in solution are at a maximum in the pH* range 2−5. ^{51}V NMR results show that at higher pH* values the metal is essentially involved in the formation of peroxovanadates. At pH* values below 2, besides **a**, **b** and **b′**, an additional complex is formed: species **c**.

Dinuclear Complexes

The ^{1}H NMR spectra of complexes **b** and **b′** show the occurrence of two different sets (A_3X spectra) of ligand signals for each complex. Attributing two sets of signals to one complex is based on the observation that the two doublets due to the methyl protons have equal intensities, irrespective of concentration and pH* conditions. These observations suggest that both complexes **b** and **b′** have two ligand molecules in different magnetic environments. Complex **a**, on the other hand, shows only one set of signals for the ligand, suggesting either the existence of only one ligand molecule in the complex or that all the ligand molecules present are magnetically equivalent. Similarly, the ^{13}C NMR spectra show the occurrence of two sets of ligand signals for complexes **b** and **b′** and only one set for complex **a**.

Table 1 shows the ^{1}H and ^{13}C NMR parameters at pH* 4 for complexes **a**, **b** and **b′**. HETCOR and homonuclear decoupling experiments were performed in order to assign the proton and carbon shifts of complexes **b** and **b′**.

The ^{1}H and ^{13}C chemical shifts observed for the ligand on complexation indicate which groups are bound to the metal. The high frequency shifts observed for the carboxylic carbon nucleus and the adjacent carbinol carbon and proton nuclei in complexes **a**, **b** and **b′** are a clear indication that those groups are involved in complexation.

An analysis of Table 1 and Figure 1 shows that one of the ligand molecules in each one of the complexes **b** and **b′** undergoes significantly smaller ^{1}H shifts on complexation (0.15−0.68 ppm) than the other (0.44−1.41 ppm). In fact, while one set of signals for each complex is found near to those of the oxo complexes, the other is found at higher frequencies.

The metal to ligand molar ratio has no significant effect on the relative concentrations of the three peroxo complexes **a**, **b** and **b′**, which indicates that these complexes have similar metal:ligand stoichiometries. Simple calculations involving metal and ligand (CH_3 protons) signal intensities lead to the conclusion that the three peroxo complexes are n:n (metal:ligand) species.

The formation of peroxovanadium(V) complexes of L-lactic acid strongly depends on the hydrogen peroxide:metal molar ratio. Those species are present only if this ratio is equal to or smaller than 2. If greater than 2 equivalents peroxide to metal is used, peroxovanadates are the main species in solution. When equal molar amounts of hydrogen peroxide and vanadium(V) are used, the peroxo complexes are the major species present immediately after preparation of the solution. If the ratio is 2, the major species initially formed is the diperoxovanadate $[VO(OO)_2(H_2O)_n]^-$. Over time, as the peroxide concentration decreases due to disproportionation catalysed by vanadium(V),[13] the concentration of the peroxovanadates decreases and the concentration of L-lactic acid peroxo complexes increases. These results suggest that no more than one peroxide ion is involved for each metal centre. This conclusion is supported by ^{51}V NMR results. ^{51}V chemical shifts in vanadium complexes are known to be sensitive to the coordination number and to the nature of the ligands. For α-hydroxycarboxylic acids, such as L-lactic acid, ^{51}V signals at approximately $\delta = -595$ have been attributed to monoperoxo species which have a seven-coordinate VO^{3+} metal centre.[21] Figure 2 shows a ^{51}V NMR spectrum where three signals ascribed to complexes **a**, **b** and **b′** are observed at approximately $\delta = -595$, indicating that these complexes have monoperoxovanadium(V) centres. However, two additional signals attributed to

the complexes **b** and **b**′ are observed at approximately δ = −520 (Figure 2 and Table 2).

The assignment of the two signals at δ = −518.6 and −520.4 was made possible by a time-dependent ^{51}V NMR study, which shows that the disappearance of the signal due to complex **a** is followed by the appearance of two sets of signals, each with two peaks of equal intensity. By combining these data with the information provided by ^{1}H NMR spectra, the two ^{51}V signals of greater intensity can be attributed to complex **b** and the two weaker signals to complex **b**′. We note that in the meantime part of the hydrogen peroxide has

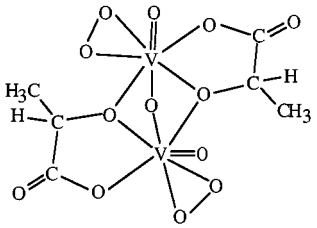
disproportionated and signals due to free metal can consequently be detected. ^{51}V chemical shifts at −520 ppm are not, however, expected for peroxo complexes, but for five-coordinate oxovanadium(V) complexes.[21]

These results, together with the previously mentioned observations concerning the ^{1}H NMR data, suggest that **b** and **b′** are probably isomers of stoichiometry 2:2:1 (metal:ligand:peroxo). Several hypotheses could be advanced for the structure of these complexes, depending on the groups involved in V−O−V bridges and on the possible arrangements of the oxo and peroxo groups. We choose to propose an equatorial position (relative to the axial V=O) for the peroxo group in a bipyramidal pentagonal geometry on the basis of the solid state structures found by X-ray diffraction for most peroxovanadium complexes.[7] In addition, OH bridging is expected to be preferred to CO_2H bridging, as found for numerous peroxovanadium complexes.[1,22,23] Accordingly, structure **1** (Scheme 1) can be proposed. The occurrence of two complexes can be explained by considering apical or equatorial positions for the V=O group in the oxovanadium centre.



1

Scheme 1

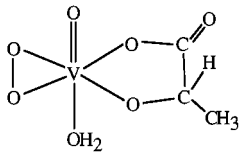
The two ligands and the two vanadium centres in **1** are clearly magnetically nonequivalent, one ligand spectrum showing a smaller shift on complexation and two ^{51}V signals arising, characteristic of oxovanadium(V) and peroxovanadium(V) centres. This kind of dinuclear peroxovanadium complex, in which one of the metal centres is an oxovanadium centre, has not been previously reported.

Regarding complex **a**, its ^{51}V chemical shift indicates a monoperoxo seven-coordinate metal centre,[21] similar to the peroxovanadium centres of complexes **b** and **b′**. Since a 1:1:1 species would require two water molecules bound to the metal, a 2:2:2 species, which does not have this requirement, is expected to be favoured. Based on these considerations, and on the fact that the ^{1}H and ^{13}C NMR results require that the two ligand molecules are magnetically equivalent, we propose structure **2** (Scheme 2) for complex **a**. A similar structure has been found by X-ray diffraction for the complex $K_2[\{VO(O_2)(L\text{-}tartH_2)\}_2(\mu\text{-}H_2O)]\cdot 5H_2O$.[23] Additional support for this proposal is provided by the kinetic behaviour observed for the three peroxo complexes. Over time, complex **a**, which has two peroxovanadium centres, will convert into complexes **b** and **b′** by losing one of the peroxo groups. This was confirmed by some experiments which showed that the addition of hydrogen peroxide to **b** and **b′** lead to the formation of **a**.

Some support for the proposed structures comes from the (natural abundance) ^{17}O NMR spectra. Although no signals due to V−O−V bridges and the peroxo groups could be detected, resonances due to terminal V=O atoms are consistent with the presence of two equivalent V=O groups in complex **a** and two nonequivalent V=O groups in complex **b** (complex **b′** is too weak to be detected by ^{17}O NMR). Thus, two signals at δ = 1179.0 and δ = 1188.8 are found for complexes **a** and **b**, respectively, in accordance with reported values for other peroxovanadium(V) complexes.[24] In addition, a signal at δ = 1054.5 is detected for complex **b**, which is in the region of V=O oxygen signals due to oxovanadium complexes with L-lactic acid (δ = 1094.9 and 1067.8).

2

Scheme 2



Mononuclear Complexes

The ^{51}V NMR spectra recorded for solutions at pH* 1 having a hydrogen peroxide:metal molar ratio equal to or smaller than 2 and metal:ligand molar ratios from 0.5 to 2 show, besides the signals of the complexes **a**, **b**, **b′** and $[VO(OO)_2(H_2O)_n]^-$ (δ = −690.3),[12] the signal of the monoperoxo cation $[VO(OO)(H_2O)_n]^+$ (δ = −536.3),[11,12] the peaks of the two major oxovanadium complexes of L-lactic acid (δ = −533.3 and −542.4)[8,10] and a signal at δ = −546.0. The latter is attributed to a new peroxovanadium(V) complex, species **c**. This species is especially favoured if the hydrogen peroxide:metal molar ratio is equal to 1. Over time, complex **c** disappears and the oxo complexes become the dominant species.

The ^{1}H NMR spectra of the same solutions show the peaks of complexes **a**, **b**, **b′**, those of one of the oxo complexes and a broad dominant signal at δ = 1.39 which coincides with the chemical shift of the CH_3 protons of the other oxo complex. However, the corresponding CH signal is not observed. Over time, as complex **c** disappears, the CH signal of the oxo complex becomes visible and the peak at δ = 1.39 becomes a well defined doublet. These results suggest that the ligand is involved in a rapid (on the NMR time scale) exchange process between species **c** and one of the oxo complexes, leading to extreme broadening of the CH signals (they are not observed) and to the coalescence of the CH_3 resonances into a broad signal. Because of rapid degradation of complex **c**, it was not possible to obtain any ^{13}C NMR spectra of this species.

Based on the ^{51}V chemical shift, which is typical of six-coordinated species,[21] we can propose **c** as being a six-coordinated complex having a 1:1:1 (metal:ligand:peroxo) stoichiometry. A 1:2:1 species would mean the metal is

seven coordinate. The ligand will probably be bound in the equatorial plane, as found by X-ray diffraction for the complex $VO(OO)(C_5H_4NCOO)(H_2O)_2$.[25] The remaining position in the coordination shell would be occupied by one water molecule. A possible structure for **c** is **3** (Scheme 3), which has been previously proposed by other authors.[17]

3

Scheme 3

Conclusion

In the presence of hydrogen peroxide and L-lactic acid, vanadium(V) forms several complexes in aqueous solution, L-lactic acid peroxovanadium complexes among them. The aim of the present study was to obtain information on the latter by using multinuclear NMR spectroscopy.

Four peroxo complexes were found to form under the conditions of this study. At low-intermediate pH (2−7), three dimeric complexes are formed, two of them (2:2:1 species) being the result of partial degradation (loss of one peroxide unit) of a bis(peroxide) complex (2:2:2 species). Dimeric 2:2:2 peroxovanadium complexes have been characterised by X-ray diffraction for other α-hydroxycarboxylic acids, such as citric,[1] DL-malic[22] and L-tartaric acids.[23] At very low pH (below 2) a 1:1:1 species is detected in addition to these complexes. This latter result is consistent with the tendency of vanadium ions to undergo depolymerization in very acidic media.

Experimental Section

Analytical grade ammonium vanadate(V) and commercially available L-lactic acid and hydrogen peroxide (35%) were used. Vanadate, lactic acid and hydrogen peroxide stock solutions were prepared. The hydrogen peroxide stock solution was prepared immediately prior to use. The concentrations of the vanadate and acid solutions were established by weight. Prior to use, the D_2O lactic acid solution was heated in boiling water for 2 hours to accomplish depolymerization. The samples were prepared by adding the appropriate amounts of the stock vanadate, lactic acid and hydrogen peroxide solutions. The pH was adjusted (cautiously, to reduce the possibility of drastic local disturbances of equilibria that may be slow to disappear) by addition of solutions of DCl and NaOD; the pH* values quoted are the direct pH-meter readings (room temperature) after standardization with aqueous (H_2O) buffers. The ^1H and ^{13}C NMR spectra were obtained on a Varian UNITY-500 NMR spectrometer (at 499.824 and 125.692 MHz, respectively). The residual water signal was reduced by using the Presat sequence. The ^{13}C spectra were recorded using proton-decoupling techniques with suppression of the nuclear Overhauser effect. The methyl signal of *tert*-butyl alcohol was used as internal reference for ^1H (δ = 1.2) and ^{13}C (δ = 31.2) relative to TMS. The ^{51}V and ^{17}O spectra were obtained on the same spectrometer (131.404 and 67.792 MHz, respectively) using $VOCl_3$ (δ = 0) and D_2O (δ = 0) as external references for ^{51}V and ^{17}O shifts, respectively. Typically, spectral widths of 30000 Hz, acquisition times of 1 s, pulse delays of 10 s and 5000 pulses were used when recording ^{13}C spectra. For ^{51}V and ^{17}O spectra, the corresponding parameters were 80000 and 100000 Hz, 0.04 and 0.02 s, 0.01 and 0 s, about 16000 and 4×10^6 pulses, respectively. The 2D NMR spectra, HETCOR,[26] were also recorded on the Varian UNITY-500 NMR spectrometer.

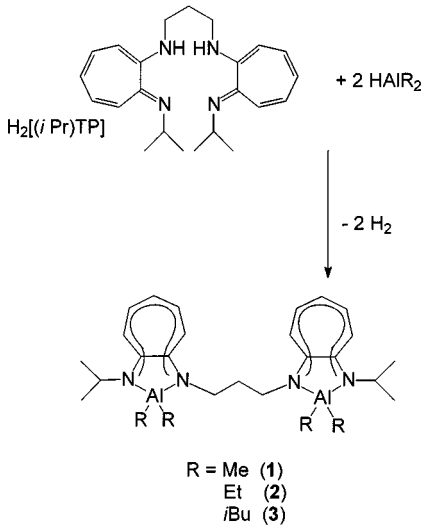
Dinuclear Aminotroponiminate Compounds Containing Two Dialkyl Aluminum Substituents

Stephan Schulz,*[a] Martin Nieger,[a] Heike Hupfer,[a] and Peter W. Roesky*[b]

Keywords: Aluminum / Aminotroponiminate / Coordination chemistry / N Ligands

Reaction of the *n*-propyl-bridged bis(aminotroponimine) H_2[(*i*Pr)TP] with various dialkylaluminum hydrides R_2AlH, in hexane, led to novel bimetallic compounds of composition [$(R_2Al)_2${(*i*Pr)TP}] (R = Me, Et, *i*Bu). Depending on the size of the substituents R bound to the Al centers the complexes crystallize either in a cisoid (R = Me) or a transoid (R = *i*Bu) conformation. The steric crowding at the aluminum centers is also observed in solution.

Introduction



Organoaluminum compounds have attracted much attention due to their varied applications including, for example, organic syntheses, industrial catalytic processes, and chemical vapor deposition (CVD) processes.[1] Aluminum alkyls are employed as activators of group 4 complexes in Ziegler−Natta catalysis or related systems, and are known to act themselves as ethylene oligomerization and polymerization catalysts.[2] Recently, several classes of dialkylaluminum-substituted compounds, which include bidentate, monoanionic, and nitrogen-based ligands, including amidinates,[3] guadinates,[4] and aminotroponiminates,[5,6] were reacted with activators such as $[HNMe_2Ph][B(C_6F_5)_4]$, $B(C_6F_5)_3$ or $[Ph_3C][B(C_6F_5)_4]$ to give aluminum cations. These cations, with weak counterion interactions, were used for the catalytic olefin polymerization.[3−5,7] Recent reports from our laboratory have described the preparation and characterization of monobridged aminotroponiminates as nitrogen-based ligands.[8] The tris(methylene)-bridged dianionic ligand 1,3-di[2-(isopropylamino)troponiminate]propane $[(i\text{Pr})\text{TP}]^{2-}$ was shown to coordinate in a chelating mode to various lanthanide ions.[8] Depending on the size of the lanthanide ion, products of composition [{(*i*Pr)TP}LnCl(THF)]$_2$ (Ln = La, Nd) or [{(*i*Pr)TP}LnCl]$_2$ (Ln = Er, Yb, Lu), in which the central atom has either a sevenfold (La, Nd) or a sixfold (Er, Yb, Lu) coordination sphere, were obtained.[8−10] Our interest in the coordination behavior of $[(i\text{Pr})\text{TP}]^{2-}$ with smaller metal ions than the lanthanides in the oxidation state +3 led us to group 13 metals. It has been demonstrated that in gallium and indium compounds of composition [{(*i*Pr)TP}MCl] (M = In, Ga), the structure reveals a chiral fivefold coordination sphere of the ligands around the center metal.[11] Analogous to the lanthanide complexes, the $[(i\text{Pr})\text{TP}]^{2-}$ ligand also coordinates in a chelating mode to indium and gallium.

Herein we report on the reaction of the neutral ligand H_2[(*i*Pr)TP] with various dialkylaluminum hydrides R_2AlH. We focused our attention mainly on the coordination behavior of $[(i\text{Pr})\text{TP}]^{2-}$ and its dependence on the size of the alkyl substituents.

Results

The bimetallic aluminum complexes [$(R_2Al)_2${(*i*Pr)TP}] [R = Me (**1**), Et (**2**), *i*Bu (**3**)] were synthesized by reactions of the neutral ligand H_2[(*i*Pr)TP][8] with the corresponding dialkyl aluminum hydrides R_2AlH in hexane (Scheme 1). Upon cooling **1**−**3** were obtained as yellow crystalline solids with fairly high sensitivity towards air and moisture.

The new complexes were characterized by standard analytical/spectroscopic techniques. Furthermore, the solid-state structures of **1** (Figure 1) and **3** (Figure 2) were investigated by single crystal X-ray diffraction. X-ray quality

crystals were grown either from hot hexane (**1**) or from pentane at −30 °C (**3**). In contrast to all other known structures in which the $[(i\text{Pr})\text{TP}]^{2-}$ ligand coordinates in a chelating fashion, **1** and **3** only show a metal-bridging coordination mode. Since the cisoid arrangement of both metal atoms in **1** suggests that a chelating coordination of the ligand might be possible, Me_2AlH was reacted with an excess of $H_2[(i\text{Pr})\text{TP}]$ at elevated temperature to force the ligand to coordinate in a chelating fashion. However, even under these reaction conditions only **1** was obtained. In contrast to **1** the two metal centers of **3** are located in a transoid conformation in the solid state which is mainly caused by the increased steric demand of the *i*Bu substituents of the aluminum atoms. Thus, **1** features a noncrystallographic C_2 symmetry through C3 (parallel to the planes of the seven-membered rings) whereas **3** has a noncrystallographic C_2 symmetry through C1. The heterocyclic five-membered ring systems (N, Al, N, C, C) are essentially planar with an average deviation from the least-square plane of 2 pm (**1**) and 1 pm (**3**). The four-coordinate aluminum centers in both **1** and **3** adopt a distorted tetrahedral geometry. The N−Al−N angles are 84.0(1)°, 84.0(1)° (**1**) and 83.2(1)°, 83.2(1)° (**3**). The larger steric demand of the *i*Bu substituents in **3** compared to Me in **1** leads to a slight decrease of the N−Al−N angle, while the C−Al−C angles are increased [114.5(1)°, 116.6(1)° (**1**) and 118.1(1)°, 118.1(1)° (**3**)]. The Al−N distances [190.3(2) pm to 191.4(2) pm (**1**); 191.6(2) pm, 191.7(2) pm (**3**)] are typical for four-coordinate Al, e.g. $[(i\text{Pr})_2\text{ATI}]AlMe_2$ [191.5(1) pm] and $[(i\text{Pr})_2\text{ATI}]AlH_2$ (ATI = aminotroponiminate) [188.2(4) pm, 188.6(4) pm] have similar bond lengths.[5] The $C_{ring}-N$ distances [av. 134.3(3) pm (**1**); 133.9(2) pm and 134.0(2) pm (**3**)] are similar to the values observed for $[(i\text{Pr})_2\text{ATI}]H$ [131.4(3) pm and 134.2(3) pm] and $[(i\text{Pr})_2\text{ATI}]AlMe_2$ (av. 133.8 pm).[5]

For compound **1** one sharp $Al-CH_3$ signal is observed in the ^1H and ^{13}C NMR spectra ($\delta = -0.25$ and $\delta = -6.1$, respectively). Due to the nonequivalence of the Al−αH in **2** and **3**, a splitting of the Al−αH resonance is seen in the ^1H NMR spectra [Al−C*H*$_2$: $\delta = 0.35$ and 0.36 (**2**); $\delta = 0.36$ and 0.38 (**3**)] but not in the ^{13}C NMR spectra [e.g. Al−*C*H$_2$: $\delta = 2.9$ (**2**); $\delta = 25.4$ (**3**)]. The ^1H and ^{13}C NMR spectra also point to a symmetrical coordination of the $[(i\text{Pr})\text{TP}]^{2-}$ anion in solution. The signals of the isopropyl C*H* of **1**−**3** are well-resolved into a septet and show only a slight high-field shift [$\delta = 3.50$ (**1**), 3.51 (**2**) and 3.54 (**3**)] compared to that of the free ligand $H_2[(i\text{Pr})\text{TP}]$ ($\delta = 3.55$).[8] This is in sharp contrast to comparable lanthanide alkyl compounds of composition $[\{(i\text{Pr})\text{TP}\}\text{Ln}-\text{R}]$ [Ln = La, Lu; R = $CH(SiMe_3)_2$, CH_2SiMe_3)] in which the isopropyl C*H* signal is strongly downfield shifted {$\delta = 3.67$ $[\{(i\text{Pr})\text{TP}\}_2LaCH(SiMe_3)_2]$;[8] $\delta = 3.93$ $[\{(i\text{Pr})\text{TP}\}_2LuCH_2SiMe_3]$[10]}. Besides the NMR investigations all new compounds were also characterized by elemental analyses and IR and EI mass spectroscopy. Compounds **1**−**3** show molecular ion peaks as well as characteristic fragmentation patterns.

Conclusions

In conclusion, it can be emphasized that the reactions of $H_2[(i\text{Pr})\text{TP}]$ with various aluminum alkyl compounds R_2AlH lead to bimetallic complexes of composition $[(R_2Al)_2\{(i\text{Pr})\text{TP}\}]$ (R = Me, Et, *i*Bu). In contrast to other complexes of group 3, 13 and the lanthanide metals the TP ligand does not bind in a chelating fashion; instead, a metal-bridging coordination is observed. Obviously, due to the smaller ion radius of the aluminum(III) center, bis(aminotroponiminate) complexes cannot be formed. Depending on the steric size of the alkyl groups bound to Al either a cisoid or a transoid conformation of $[(R_2Al)_2\{(i\text{Pr})\text{TP}\}]$ is observed in the solid state. In summary, our results extend

the series of the few known bimetallic complexes of group 13 elements such as salen complexes.[12−15]

Experimental Section

General: All manipulations were performed in a glovebox under an N_2 atmosphere or with standard Schlenk techniques. Solvents were dried over sodium/potassium and degassed prior to use. *i*Bu_2AlH was purchased from Aldrich and used as received. Me_2AlH,[16] Et_2AlH[17] and H_2[(*i*Pr)TP][8] were prepared by literature methods. − A Bruker AMX 300 spectrometer was used for NMR spectroscopy. ^1H and $^{13}C\{^1H\}$ NMR spectra were referenced to internal C_6D_5H (^1H: δ = 7.154; ^{13}C: δ = 128.0). − Infrared spectra were recorded in Nujol between KBr plates with a Nicolet Magna 550 and are reported in wave numbers. − Mass spectra were recorded at 70 eV on Varian MAT 711 spectrometer in the electron ionisation mode. − Melting points were observed in sealed capillaries and were not corrected. − Elemental analyses were performed at the Mikroanalytisches Labor der Universität Bonn.

[$(Me_2Al)_2$[(*i*Pr)TP]] (1): Me_2AlH (0.12 g, 2.00 mmol) was dissolved in hexane (20 mL). At ambient temperature a solution of H_2[(*i*Pr)TP] (0.36 g, 1.00 mmol) in hexane (30 mL) was added, immediately followed by gas evolution and precipitation of a yellow solid. After the gas evolution had stopped, the suspension was heated under reflux for 10 min, until the solid had dissolved. Cooling to −10 °C gave **1** as yellow crystals (0.45 g, 95%). Single crystals were formed from a solution of hot hexane. (60 °C to 25 °C within 8 h). M.p. 128 °C. − ^1H NMR (300 MHz, C_6D_5H, 25 °C): δ = −0.25 (s, 12 H, Al−CH_3), 1.17 [d, $^3J_{H-H}$ = 6.4 Hz, 12 H, CH(CH_3)$_2$], 2.12 (m, 2 H, CH_2−CH_2−CH_2), 3.18 (m, 4 H, CH_2−CH_2−CH_2), 3.50 [dsept, $^3J_{H-H}$ = 6.4 Hz, $^5J_{H-H}$ = 0.7 Hz 2 H, C*H*(CH_3)$_2$], 6.21 (t, $^3J_{H-H}$ = 9.3 Hz, 2 H, H_{ring}), 6.31 (d, J_{H-H} = 11.4 Hz, 2 H, H_{ring}), 6.36 (d, J_{H-H} = 11.1 Hz, 2 H, H_{ring}), 6.71−6.84 (m, 4 H, H_{ring}). − $^{13}C\{^1H\}$ NMR (80 MHz, C_6D_5H, 25 °C): δ = −6.1 (Al−CH_3), 22.9 [CH(CH_3)$_2$], 27.6 (CH_2−CH_2−CH_2), 44.8 (CH_2−CH_2−CH_2), 47.6 [CH(CH_3)$_2$], 113.5 (C_{ring}), 114.0 (C_{ring}), 119.7 (C_{ring}), 136.8 (C_{ring}), 136.9 (C_{ring}), 161.4 (N−C_{ring}), 162.1 (N−C_{ring}). MS (EI, 20 eV): *m*/*z* (%) = 476 (2) [M^+], 461 (64) [$M^+ - CH_3$], 389 (100) [$M^+ - Al - 4CH_3$], 208 (7) [$M^+/2 - 2CH_3$]. − IR (nujol): ṽ = 2362, 2337, 1511, 1259, 1095, 1018, 798, 721 cm^{-1}. − $C_{27}H_{42}Al_2N_4$(476.6): calcd. C 68.04, H 8.88, N 11.76; found C 67.93, H 8.82, N 11.71.

[$(Et_2Al)_2$[(*i*Pr)TP]] (2): Et_2AlH (0.17 g, 2.00 mmol) was dissolved in hexane (20 mL) and added at ambient temperature to a solution of H_2[(*i*Pr)TP] (0.36 g, 1.00 mmol) in hexane (30 mL). After the gas evolution had stopped the solution was heated under reflux for 15 min. Cooling to −30 °C gave **2** as a yellow solid (0.45 g, 85%). M.p. 111 °C. − ^1H NMR (300 MHz, C_6D_5H, 25 °C): δ = 0.35 (q, $^3J_{H-H}$ = 8.2 Hz, 4 H, CH_2Al), 0.36 (q, $^3J_{H-H}$ = 8.1 Hz, 4 H, CH_2Al), 1.18 [d, $^3J_{H-H}$ = 6.4 Hz, 12 H, CH(C*H*$_3$)$_2$], 1.33 (t, $^3J_{H-H}$ = 8.1 Hz, 12 H, C*H*$_3$$CH_2$Al), 2.13 (m, 2 H, CH_2−CH_2−CH_2), 3.27 (m, 4 H, CH_2−CH_2−CH_2), 3.51 [dsept, $^3J_{H-H}$ = 6.4 Hz, $^5J_{H-H}$ = 0.8 Hz, 2 H, C*H*(CH_3)$_2$], 6.21 (t, $^3J_{H-H}$ = 9.3 Hz, 2 H, H_{ring}), 6.33 (d, J_{H-H} = 11.4 Hz, 2 H, H_{ring}), 6.43 (d, J_{H-H} = 11.0 Hz, 2 H, H_{ring}), 6.71−6.87 (m, 4 H, H_{ring}). − $^{13}C\{^1H\}$ NMR (80 MHz, C_6D_5H, 25 °C): δ = 2.9 (CH_2Al), 10.2 (*C*$H_3$$CH_2$Al), 22.7 [CH(*C*$H_3$)$_2$], 27.0 ($CH_2$−*C*$H_2$−$CH_2$), 44.8 (*C*$H_2$−$CH_2$−*C*$H_2$), 47.5 [*C*H($CH_3$)$_2$], 113.4 ($C_{ring}$), 114.1 ($C_{ring}$), 119.8 ($C_{ring}$), 136.8 ($C_{ring}$), 136.9 ($C_{ring}$), 161.8 (N−$C_{ring}$), 162.5 (N−$C_{ring}$). − MS (EI, 20 eV): *m*/*z* (%) = 532 (4) [M^+], 503 (100) [M^+ − Et], 389 (70) [M^+ − Al − 4Et]. − IR (nujol): ṽ = 1595, 1511, 1423, 1274, 1234, 1160, 1043, 989, 962, 881, 731, 630, 576 cm^{-1}. − $C_{31}H_{50}Al_2N_4$ (532.7): C 69.89, H 9.46, N 10.52; found C 69.63, H 9.39, N 10.50.

[$(iBu_2Al)_2${(*i*Pr)TP}] (3): In a procedure similar that for **2**, compound **3** was obtained as a yellow solid (0.45 g, 70%) at −30 °C. Single crystals were formed from a pentane solution at −30 °C. M.p. 113 °C (dec). − ^1H NMR (300 MHz, C_6D_5H, 25 °C): δ = 0.36 (d, $^3J_{H-H}$ = 6.8 Hz, 4 H, CH_2Al), 0.38 (d, $^3J_{H-H}$ = 6.9 Hz, 4 H, CH_2Al), 1.12 [d, $^3J_{H-H}$ = 6.3 Hz, 12 H, (C*H*$_3$)$_2$CHCH_2Al], 1.14 [d, $^3J_{H-H}$ = 6.3 Hz, 12 H, (C*H*$_3$)$_2$CHCH_2Al], 1.23 [d, $^3J_{H-H}$ = 6.5 Hz, 12 H, NCH(*C*H_3)$_2$], 2.01 [sept, 2 H, $^3J_{H-H}$ = 6.5 Hz, 4 H, (CH_3)$_2$C*H*CH_2Al], 2.16 (m, 2 H, CH_2−CH_2−CH_2), 3.30 (m, 4 H, CH_2−CH_2−CH_2), 3.54 [dsept, $^3J_{H-H}$ = 6.4 Hz, $^5J_{H-H}$ = 0.6 Hz, 2 H, NC*H*(CH_3)$_2$], 6.23 (t, $^3J_{H-H}$ = 9.3 Hz, 2 H, H_{ring}), 6.34 (d, J_{H-H} = 11.5 Hz, 2 H, H_{ring}), 6.45 (d, J_{H-H} = 11.1 Hz, 2 H, H_{ring}), 6.76 (m, 2 H, H_{ring}), 6.93 (m, 2 H, H_{ring}). − $^{13}C\{^1H\}$ NMR (80 MHz, C_6D_5H, 25 °C): δ = 22.7 [CH(*C*H_3)$_2$], 25.4 (CH_2Al), 26.6 (CH_2−*C*H_2−CH_2), 27.5 [(CH_3)$_2$*C*HCH_2Al], 28.8 [(*C*H_3)$_2$CHCH_2Al], 29.0 [(*C*H_3)$_2$CHCH_2Al], 45.0 (*C*H_2−CH_2−*C*H_2), 47.6 [*C*H(CH_3)$_2$], 113.8 (C_{ring}), 114.6 (C_{ring}),

X-ray Structure Solution and Refinement: Crystallographic data are summarized in Table 1. Figure 1 shows the ORTEP diagram of the solid state structure of **1** and Figure 2 that of **3**. Data were collected on a Nonius Kappa-CCD diffractometer. Structures of **1** and **3** were solved by direct methods (SHELXS-97)[18] and refined by full-matrix least-squares on F^2. All non-hydrogen atoms were refined anisotropically and hydrogen atoms by a riding model (SHELXL-97).[19]

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-138108 (**1**) and CCDC-138109 (**3**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB21EZ, UK [Fax: (internat.) + (44)-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

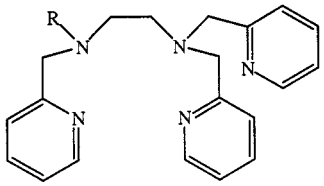
Fe^{III}-Hydroperoxo and Peroxo Complexes with Aminopyridyl Ligands and the Resonance Raman Spectroscopic Identification of the Fe−O and O−O Stretching Modes

A. Jalila Simaan,[a] Susanne Döpner,[b] Frédéric Banse,[a] Sophie Bourcier,[c] Guy Bouchoux,[c] Alain Boussac,[d] Peter Hildebrandt,*[b] and Jean-Jacques Girerd*[a]

Keywords: Iron / Peroxides / Nonheme iron models / Raman spectroscopy



Nonheme Fe^{III}-hydroperoxo and Fe^{III}-peroxo complexes with aminopyridyl-type ligands have been prepared and characterized by UV/Vis, EPR, mass and Resonance Raman (RR) spectroscopy. The $Fe^{III}(OOH)$ species are low-spin and exhibit a deep purple color due to the ligand-to-metal charge transfer (LMCT) band centered at ca. 550 nm. The RR spectra of the $Fe^{III}(OOH)$ complexes display two bands at ca. 620 and 800 cm^{-1} that are assigned to the respective Fe–O and O–O stretching modes on the basis of the characteristic H/D and $^{16}O/^{18}O$ frequency shifts. Upon deprotonation, $Fe^{III}(O_2)$ species are obtained which possess a high-spin configuration of nearly axial symmetry and a LMCT transition in the near infrared (ca. 750 nm). The frequencies of the Fe–O and O–O stretching modes at ca. 465 and 820 cm^{-1}, as well as their respective $^{16}O/^{18}O$ shifts of –16 and –45 cm^{-1}, indicate an η^2 coordination geometry for the $Fe^{III}(O_2)$ complex.

Introduction

The currently proposed mechanism for catalytic oxygenation by cytochrome P450 involves an Fe^{III}-peroxo intermediate that leads, upon protonation, to a ferryl species which is able to insert an oxygen atom into a C−H bond.[1] Whereas the Fe^{III}-peroxo species has been observed during the enzymatic reaction cycle, identification of the ferryl species has not yet been possible due to its high reactivity.[2] For nonheme systems such as bleomycin,[3] a ferryl species may also be implied, although in this case experimental proof has not yet been presented either. Specifically, the intermediate state denoted as "activated bleomycin" has been recently shown to be $(BLM)Fe^{III}(OOH)$.[4] In order to understand the reactivity of such nonheme hydroperoxoiron species, several chemical models have been prepared and studied.[5−14]

A well-known example of a nonheme Fe^{III}-peroxo complex is $[(EDTA)Fe^{III}(O_2)]^{3-}$.[15,16] Spectroscopic studies demonstrated a side-on coordination of the peroxo group in this complex. We recently reported the formation of a new type of nonheme Fe^{III}-peroxo complex using the ligand [*N*-methyl-*N*,*N*′,*N*′-tris(2-pyridylmethyl)ethane-1,2-diamine] (trispicMeen).[17] This Fe^{III}-peroxo species was obtained by deprotonation of the Fe^{III}-hydroperoxo complex.[8,11] Analogous species were obtained by Jensen et al.[14] RR spectroscopic studies by Ho et al.[18] indicated an η^2-coordination of the peroxo group in $[(N4py)Fe^{III}(O_2)]^+$.

The present study is dedicated to the RR spectroscopic characterization of the hydroperoxo and peroxo species of Fe^{III} complexes formed with trispicMeen as well as of the corresponding Fe^{III} complexes involving the ligands [*N*,*N*′,*N*′-tris(2-pyridylmethyl)ethane-1,2-diamine] (trispicen) and [*N*,*N*,*N*′,*N*′-tetrakis(2-pyridylmethyl)ethane-1,2-diamine] (TPEN) (Scheme 1).

R = Me trispicMeen
R = CH_2Py TPEN

Scheme 1. Ligands used in this study

Results and Discussion

The starting materials for preparing the hydroperoxo and peroxo species are Fe^{II} complexes. For the complex with the trispicMeen ligand, [(trispicMeen)FeCl]Cl was used as starting material.[17] The structure of the related species

[(trispicMeen)FeCl]BPh_4 has been recently determined.[11] For the complexes with the ligand trispicen, [(trispicen)-FeCl]PF_6 served as starting material. In the case of the TPEN ligand, the parent complex was prepared in THF and isolated as a yellow powder, the analysis of which corresponds to [(TPEN)Fe]$Cl_2 \cdot 0.5H_2O$. The yellow color and the magnetic susceptibility, measured as a function of temperature,[19] demonstrate a ferrous high-spin state which may be indicative of the coordination of chloride to Fe^{II}, i.e. [(TPEN)FeCl]$Cl \cdot 0.5H_2O$. In MeOH, an orange color was obtained and the UV/Vis spectrum was identical to that of [(TPEN)Fe]$(ClO_4)_2$ in the same solvent, suggesting dissociation of the chloride ligand in solution to give the $[(TPEN)Fe]^{2+}$ complex. The structure of [(TPEN)-Fe]$(ClO_4)_2$ has been previously published.[20]

UV/Visible Absorption Spectroscopy

The species containing the $Fe^{III}OOH$ unit absorb around 550 nm (Table 1) as already reported for [(trispicMeen)-$Fe(OOH)]^{2+}$.[8] Upon deprotonation, [(trispicMeen)Fe-$(O_2)]^+$ is formed which gives an absorption band at much lower energy (740 nm, Table 1).[14,17] The same observations were made for the corresponding transformation of $[(TPEN)Fe(OOH)]^{2+}$ to $[(TPEN)Fe(O_2)]^+$ (Figure 1). These bands are attributed to LMCT transitions from the HO_2^- or O_2^{2-} groups to Fe^{III}.

Table 1. Characteristics of the LMCT band in MeOH for the different complexes

Complex	λ_{max} (ε/м$^{-1}$.cm^{-1})	ref.
Hydroperoxo		
$[(trispicMeen)Fe(OOH)]^{2+}$	537 nm (1000)	[8][11]
$[(trispicen)Fe(OOH)]^{2+}$	531 nm (950)	this work
$[(TPEN)Fe(OOH)]^{2+}$	541 nm (900)	this work
Peroxo		
$[(trispicMeen)Fe(O_2)]^+$	740 nm (500)	[17]
$[(TPEN)Fe(O_2)]^+$	755 nm (450)	this work

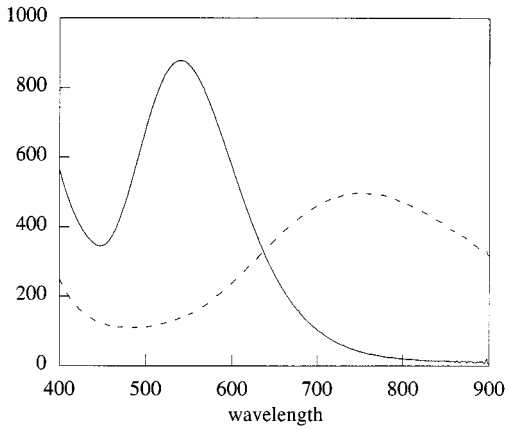

Figure 1. UV/Vis spectra of $[(TPEN)Fe^{III}(OOH)]^{2+}$ (1 мм in MeOH, 100 equiv. of H_2O_2) before ( ) and after addition of three equiv. of NEt_3 (− − −) measured at ambient temperature; the bands at 541 nm and 755 nm are attributed to the LMCT transitions of $[(TPEN)Fe^{III}(OOH)]^{2+}$ and $[(TPEN)Fe^{III}(O_2)]^+$, respectively

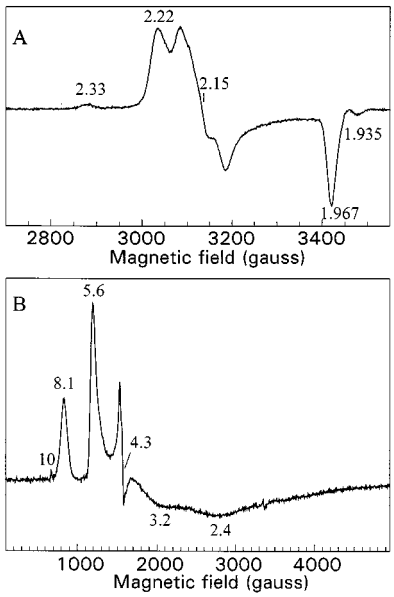
The formation of the purple complex [(trispicen)-$Fe(OOH)]^{2+}$ in MeOH was monitored by UV/Vis spectroscopy. Upon addition of base, the purple color disappeared although we failed to trap the putative $[(trispicen)Fe(O_2)]^+$ species.

EPR Spectroscopy

The $Fe^{III}OOH$ species display EPR spectra that are typical for ferric low-spin (LS) states. At 100 K, the g values of $[(trispicen)Fe(OOH)]^{2+}$ and $[(trispicMeen)Fe(OOH)]^{2+}$ were observed at 2.19, 2.14, 1.96 and at 2.19, 2.12, 1.95, respectively.[8,11] For $[(TPEN)Fe(OOH)]^{2+}$, we have found resonances at 2.22, 2.15, 1.967 (Figure 2).



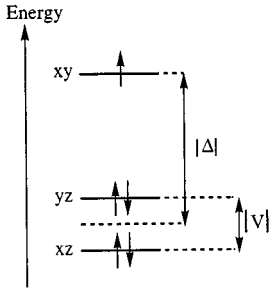


Figure 2. A: EPR spectrum of $[(TPEN)Fe^{III}(OOH)]^{2+}$ in MeOH measured at 15 K; B: EPR spectrum of $[(TPEN)Fe^{III}(OOH)]^{2+}$ in MeOH at 4 K in the presence of three equivalents of NEt_3; the signal at $g = 4.3$ corresponds to a degradation product

It is possible to describe the g values for a LS Fe^{III} by using the model of Griffith[21] as presented by Taylor,[22] which takes into account the spin-orbit coupling and distortion from octahedral geometry. These effects lift the six-fold degeneracy of the $^2T_{2g}$ ground state and three well-separated Kramers doublets are obtained. This corresponds to a lifting of the orbital degeneracy, as indicated in Scheme 2, where the rhombic and axial distortion energies are denoted by V and Δ, respectively.

Scheme 2. Splitting of the T_{2g} orbitals due to distorsions

Table 2. EPR g_{max}, g_{inter}, g_{min} values for $Fe^{III}OOH$ $s = 1/2$ units; parameters of the Griffith−Taylor model of the g tensor: *a, b, c* are the coefficients of the wavefunctions; $\Sigma = a^2 + b^2 + c^2$; V is the rhombic distorsion energy; Δ is the axial distorsion energy; both are in units of λ, the spin-orbit coupling constant

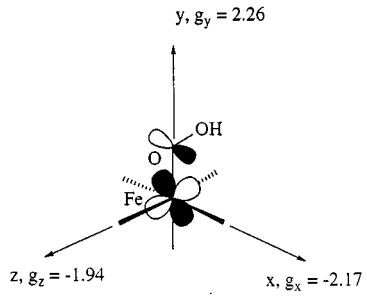
complex	$-g_{min}$, g_z	g_{max}, g_y	$-g_{inter}$, g_x	*a*	*b*	*c*	Σ	V/λ	Δ/λ
(BLM)Fe(OOH)	−1.94	2.26	−2.17	0.072	0.052	0.993	0.993	3.04	−8.74
$[(trispicMeen)Fe(OOH)]^{2+}$	−1.95	2.19	−2.12	0.055	0.039	0.992	0.988	4.05	−11.31
$[(trispicen)Fe(OOH)]^{2+}$	−1.96	2.19	−2.14	0.053	0.041	0.994	0.993	2.86	−11.19
$[(TPEN)Fe(OOH)]^{2+}$	−1.967	2.22	−2.15	0.056	0.040	0.999	1.002	3.98	−11.29

At 100 K, only the lowest doublet is populated. The two wave functions of the ground Kramers doublet are written as:

$$|+> = a\,|\xi\alpha> - i\,b\,|\eta\alpha> - c\,|\zeta\beta> \quad (1)$$

$$|-> = -a\,|\xi\beta> - i\,b\,|\eta\beta> - c\,|\zeta\alpha> \quad (2)$$

where $|\xi\alpha>$, $|\eta\alpha>$, $|\zeta\beta>$ refer to the states with the unpaired electron in the d_{yz}, d_{xz}, and d_{xy} orbital, respectively. The associated g values are given by:[22]



$$g_z = 2[(a + b)^2 - c^2] \quad (3)$$

$$g_y = 2[(a + c)^2 - b^2] \quad (4)$$

$$g_x = 2[a^2 - (b + c)^2] \quad (5)$$

These equations were used to evaluate the constants a, b, and c assuming that $g_x\,g_y\,g_z$ is positive. This assumption, originally suggested by Veselov et al.,[23] appears to be justified in view of the chemical meaning of the results. The a, b and c values were calculated from the experimental g values. As described by Taylor[22] we selected the axes such that $|V| < (2/3)\,|\Delta|$. The results are presented in Table 2.

For $(BLM)Fe^{III}OOH$, values of $g_z = -1.94$, $g_y = 2.26$, and $g_x = -2.17$ were found corresponding to $a = 0.072$, $b = 0.052$, and $c = 0.993$ with $V/\lambda = 3.04$ and $\Delta/\lambda = -8.74$. These values imply that the hole (and hence the unpaired electron) is in an orbital which has predominantly d_{xy} character, and that this orbital is strongly destabilized. The d_{xz} and d_{yz} orbitals would be lower in energy, with the d_{xz} being the lowest. Based on an ENDOR study of activated bleomycin, Veselov et al.[23] suggested, by comparison with LS hemes, that the axis of g_{max} (y from the calculation above) is perpendicular to the conjugated pyrimidine plane and parallel to the Fe-peroxo axis. This conclusion is not in contradiction with the above discussion and leads to the following proposal for the orientation of the g tensor (Scheme 3).

Scheme 3. Nature of the singly occupied T_{2g} orbital and orientation of the g tensor

The values for $[(trispicMeen)Fe(OOH)]^{2+}$ are similar to those of $(BLM)Fe^{III}OOH$ with $g_z = -1.95$, $g_y = 2.19$, $g_x = -2.12$, $a = 0.055$, $b = 0.039$, $c = 0.992$, $V/\lambda = 4.05$, $\Delta/\lambda = -11.31$. Thus, in analogy to bleomycin, it is concluded that in this model complex the unpaired electron is also in a d_{xy} type orbital. Note that the axial perturbation is stronger in the model complexes than in the activated bleomycin. This different behavior may be due to the stronger π-acceptor capability of the ligand in the model complexes so that the interaction between the d_{xy} type orbital and the π* orbital of OOH becomes stronger.

The $Fe^{III}-O_2$ species are high spin ($S = 5/2$) with resonances at $g = 7.5$ and 5.9 as determined for $[(trispicMeen)Fe(O_2)]^+$.[17] The $g = 7.5$ signal can be interpreted as arising from the upper Kramers doublet with $E/D = 0.08$ for $D < 0$, whereas the $g = 5.9$ signal may arise from the intermediate Kramers doublet.[17] The complex $[(TPEN)Fe(O_2)]^+$ displays resonances at $g = 10$, 8.1, 5.6, 3.2, 2.4 (Figure 2). These signals are due to the different Kramers doublets with $E/D = 0.10$ for $D < 0$. The $g = 10$ signal is tentatively assigned to the ground doublet whereas the signals at $g = 5.6$ and $g = 2.4$ may originate from the intermediate doublet. The $g = 8.1$ and $g = 3.2$ may then be attributed to the upper doublet. These findings suggest that $[(trispicMeen)Fe(O_2)]^+$ and $[(TPEN)Fe(O_2)]^+$ have similar structures.

Mass Spectrometry

$[(TrispicMeen)Fe(OOH)]^{2+}$ and $[(trispicMeen)Fe(O_2)]^+$ have been detected by Electrospray Ioniation Mass Spectrometry.[11,17] After addition of three equivalents of Et_3N to a purple 10^{-3} M solution of $[(TPEN)Fe(OOH)]^{2+}$ in methanol, the ESI-MS spectrum (Figure 3) exhibits a major peak at $m/z = 512.3$ which can be attributed to $[(TPEN)Fe^{III}(O_2)]^+$. Among the other peaks detected, those at $m/z = 425.3$ and 542.3 are assigned to $(TPENH^+)$ and $([(TPEN)Fe^{III}(OMe)_2]^+)$, respectively. The peak at $m/z = 512.3$ disappears after 10 min, which parallels the disappearance of the blue color of the solution.

Resonance Raman Spectroscopy

Excitation in resonance with the LMCT transitions should provide a preferential enhancement of the vibrational modes originating from the iron-(hydro)peroxo entities, which is indeed confirmed by the present experiments. The RR spectra of the hydroperoxo complexes were recorded with excitation at 568 nm. The spectral regions be-

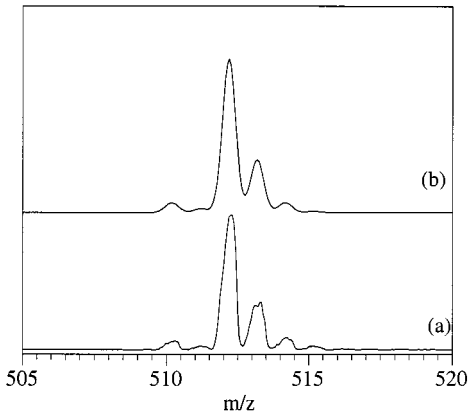


Figure 3. EI-MS features of $[(TPEN)Fe^{III}(O_2)]^+$ at m/z = 512.3: a) experimental spectrum; b) calculated spectrum

tween 570 and 640 cm^{-1} and 710 and 880 cm^{-1}, which are expected to include the iron−oxygen and oxygen−oxygen stretching modes, respectively, are shown in Figure 4 for the $[(trispicMeen)Fe(OOH)]^{2+}$ complex. The former region displays two bands at 617 cm^{-1} and 632 cm^{-1} that are possible candidates for the Fe−O stretching. The 617 and 632 cm^{-1} bands are not detected in the spectrum of the parent state, i.e. prior to the addition of H_2O_2, implying that both bands originate from the $[(trispicMeen)Fe(OOH)]^{2+}$ complex or derivatives thereof. The dominant band at 617 cm^{-1} shifts to lower wavenumbers 613 and 600 cm^{-1} upon H/D exchange and ^{18}O-labeling, respectively (Table 3). These shifts are consistent with the calculated values obtained from a simple two-body oscillator model for the Fe−OOH moiety of the presumed hydroperoxo complex.

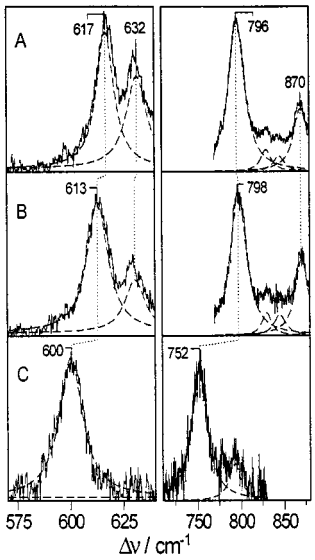

Figure 4. RR spectra of $[(trispicMeen)Fe(OOH)]^{2+}$ obtained with 568 nm excitation. (A) natural abundance, complex prepared with H_2O_2; (B) deuterated, complex prepared with D_2O_2; (C) ^{18}O-labeled, complex prepared with $H_2{}^{18}O_2$; the regions of the iron−oxygen and oxygen−oxygen stretching modes are displayed in the left and right panels, respectively; the dotted lines represent the fitted Lorentzian bandshapes.

Therefore, the band at 617 cm^{-1} is assigned to the Fe−O stretching mode of the $[(trispicMeen)Fe(OOH)]^{2+}$ complex. The second band in this region at 632 cm^{-1} remains essentially unchanged upon deuteration. The intensity of this band relative to the 617 cm^{-1} band reveals some variations in the different samples and, moreover, increases with time along with the decomposition of $[(trispicMeen)Fe(OOH)]^{2+}$. Samples which have been measured four hours after complex preparation show a broad band centered at ca. 630 cm^{-1} whereas no band can be detected at 617 cm^{-1}. We therefore attribute the band at 632 cm^{-1} to a degradation product of $[(trispicMeen)Fe(OOH)]^{2+}$. Note that this band is hardly detectable in the ^{18}O-labeled complex, which may be due to a relatively small contribution of this degradation product in the sample. The Fe−O frequency at 617 cm^{-1} is in agreement with the value found by Que and co-workers for $[(N4py)Fe(OOH)]^{2+}$ and $[(TPA)Fe(OOH)]^{2+}$.[12,13]

The O−O stretching mode is expected between ca. 770 and 850 cm^{-1}.[12,13] This part of the spectrum also includes a band at 870 cm^{-1} originating from the O−O stretching mode of H_2O_2 (Figure 4). In the deuterated solvent, this band reveals a small shift of 1 cm^{-1} as previously noted.[15] The strongest band in this region, at 796 cm^{-1}, is unambiguously assigned to the O−O stretching mode of $[(trispicMeen)Fe(OOH)]^{2+}$ since it shifts to lower wavenumber (752 cm^{-1}) in the ^{18}O-labeled sample (Table 3), which confirms the predictions for a hydroperoxo complex. Upon H/D exchange this mode reveals a similar shift to that for H_2O_2.[15]

The complex $[(TPEN)Fe(OOH)]^{2+}$ shows essentially the same RR spectra as $[(trispicMeen)Fe(OOH)]^{2+}$ (Figure 5) with nearly identical frequencies for the Fe−O and O−O stretching modes (Table 3). These similarities with $[(trispicMeen)Fe(OOH)]^{2+}$ indicate that the additional pyridyl arm of the TPEN ligand is not involved in the coordination to iron. In contrast, in the RR spectrum of $[(trispicen)Fe(OOH)]^{2+}$ both the Fe−O and the O−O modes are observed at higher frequencies than in $[(trispicMeen)Fe(OOH)]^{2+}$ and $[(TPEN)Fe(OOH)]^{2+}$ (Table 3). Furthermore, the isotopic shifts are also larger. These differences could be related to a different geometry of the FeOOH unit in $[(trispicen)Fe(OOH)]^{2+}$ as a consequence of the reduced steric hindrance upon replacement of the tertiary amino group by a secondary amino group (i.e. R = H vs. R = CH_2py in Scheme 4).

For the investigation of the blue peroxo complexes, excitation at 647 nm, albeit not in rigorous resonance with the LMCT transition, provides a preferential enhancement of the modes associated with the iron peroxo group. In the O−O stretching region, the RR spectrum of $[(trispicMeen)Fe(O_2)]^+$ displays a new band at ca. 819 cm^{-1} which shifts down to 776 cm^{-1} in the ^{18}O-labeled complex but remains unchanged upon H/D exchange so that it is unambiguously assigned to the O−O stretching mode (Figure 6). A careful inspection reveals an asymmetric shape of the 819 cm^{-1} band both in nondeuterated and deuterated solvents but not of the 776 cm^{-1} band of the ^{18}O-labeled species. A band-fitting analysis of the 819 cm^{-1} peak affords a strong band at 819 and a weaker one at 827 cm^{-1}

Table 3. Frequencies of the iron−oxygen and oxygen−oxygen modes of the various iron hydroperoxo and iron peroxo complexes; the accuracies of the frequencies (given in cm^{-1}) are ca. 0.3 cm^{-1} for the hydroperoxo species and ca. 1.0 cm^{-1} for the individual band components of the composite peaks in the peroxo complexes; the abbreviations H/D and $^{16}O/^{18}O$ denote the H/D and $^{16}O/^{18}O$ isotopic shifts

Scheme 4. Proposed structure for the FeOOH complex indicating the possible steric hindrance between the alkyl substituent and the hydroperoxo group

(Table 3). These band components are also found in the $[(TPEN)Fe(O_2)]^{+}$ complex, albeit with slightly different frequencies and relative intensities (Figure 7).

A comparable heterogeneity is observed for the iron−oxygen stretching of $[(trispicMeen)Fe(O_2)]^{+}$ and $[(TPEN)Fe(O_2)]^{+}$ which is attributable to the composite bands centered at 470 cm^{-1} (Figure 6). These bands are not affected by H/D exchange but shift to lower wavenumber by ca. 16 cm^{-1} in the ^{18}O-labeled complex. The relatively

Figure 6. Figure 7. RR spectra of $[(trispicMeen)Fe(O_2)]^{+}$ and $[(TPEN)Fe(O_2)]^{+}$ obtained with excitation at 647 nm; the regions of the iron−oxygen and oxygen−oxygen stretching modes are displayed in the left and right panels, respectively; the dotted lines represent the fitted Lorentzian bandshapes; the sharp peak labelled P originates from a plasma line of the laser

low frequencies of the Fe−O stretches are related to the spin configuration in the peroxo complexes. Whereas the LS configuration in the hydroperoxo complexes allows for the formation of a relatively strong Fe−O bond corresponding to a high Fe−O stretching frequency, the HS configuration of the peroxo complexes leads to a weakening of the Fe−O bond which is reflected by the substantially lower Fe−O stretching frequency.[13]

Both the Fe−O and O−O stretching frequencies and their $^{18}O/^{16}O$ shifts indicate a side-on structure of the iron-peroxo moiety, in agreement with previous findings for Fe^{III} peroxo complexes ligated by EDTA and N4py.[15,16,18] The coexistence of two closely spaced O−O stretching modes, as well as the asymmetric profile of the Fe−O stretching peak, may indicate two conformers which subtly differ in structural details.

Conclusion

All Fe^{III} compounds studied in this work form LS hydroperoxo complexes. Whereas the trispicMeen and TPEN derivatives reveal very similar spectroscopic properties, $[(trispicen)Fe(OOH)]^{2+}$ exhibits somewhat higher Fe−O and O−O stretching frequencies, indicating slightly different molecular structures. This compound evidently also displays a different reactivity since no peroxo complex could be detected at room temperature. It may be that the lifetime of this species is too short due to the sensitivity to oxidation of the secondary amine NH group of the trispicen ligand. In the peroxo complexes of the other compounds, the Fe^{III} adopts an HS configuration. However, the anisotropy of this $S = 5/2$ state depends on the auxiliary ligand. Whereas complexes with N4py and EDTA ligands lead to a rhombic state, a more axial state is found for the Fe^{III}-peroxo complexes formed with trispicMeen and TPEN ligands. Regardless of these differences, the present RR spectroscopic data indicate an η^2-coordination of the peroxo groups in the trispicMeen and TPEN complexes as well, implying that side-on coordination represents a structural motif that is largely independent of the type of auxiliary ligand.

Experimental Section

General: All manipulations were carried out using standard Schlenk techniques. Starting materials were purchased from Acros. Solvents were purchased from Merck and used without further purification. $^{18}O_2H_2$ was provided as a 2% aqueous solution from Leman. − UV/Vis: Varian Cary 5E equipped with a temperature controller. − MS: Quattro II (Micromass, Manchester, UK) triple quadrupole electrospray mass spectrometer. Typical optimized values for the source parameters were: capillary: 2.5 kV, counter electrode: 0.4 kV, cone voltage: 15 to 30 V, source temperature: 80 °C, RF lens: 0.7 V, skimmer lens offset: 5 V. − EPR spectra were recorded on a Bruker ESP 300 E spectrometer. For low-temperature studies, an Oxford Instruments continuous-flow helium cryostat and a temperature control system were used. Magnetic susceptibility measurements in the 10−300 K temperature range were carried out with a MPMS5 SQUID susceptometer (Quantum Design Inc.). The calibration was made at 298 K using a palladium reference sample furnished by Quantum Design Inc.

RR Measurements: RR experiments were carried out at ambient temperature using an U1000 spectrograph (ISA) equipped with 1200 lines/mm gratings and a liquid-nitrogen cooled CCD camera. The spectral bandwidth was 2.8 cm^{-1} and the increment per data point was ca. 0.2 cm^{-1}. The wavenumber stability of the monochromator was 0.1 cm^{-1}. The 568- and 647-nm lines of a Kr^+ laser, with a power 25 and 50 mW, respectively, at the sample were used for excitation. Further details of the experimental set-up are given elsewhere.[24] The samples with concentrations corresponding to an optical density of 1.4 at the excitation wavelength were prepared directly prior to the experiments. RR measurements were carried out by using a rotating cuvette to avoid photodecomposition. Under these conditions the samples were stable for ca. 30 min (Fe−O−O−H) and 10 min (Fe−O−O). The integrity of samples during the RR experiments was checked by comparing the consecutively measured RR spectra obtained with an integration time of 1 s. For improvement of the signal-to-noise ratio, the individual spectra were finally combined. The sum spectra obtained in this way represent measurements of a total accumulation time of between 10 and 40 s. After removal of the structureless background by polynomial subtraction, the spectra were analyzed by a band-fitting procedure using Lorentzian lineshapes.[25]

Synthesis of the Ligands: The trispicen, trispicMeen, and TPEN ligands were prepared according to previously described procedures.[8,11,20]

Syntheses of the Complexes: The complexes $[(TPEN)Fe](PF_6)_2$, $[(TPEN)Fe](ClO_4)_2$, $[(trispicMeen)FeCl]PF_6$ and [(trispicMeen)-FeCl]Cl were prepared as previously described.[8,17,20]

Synthesis of the Complex $[(TPEN)Fe]Cl_2 \cdot 0.5H_2O$: A solution of $FeCl_2 \cdot 4H_2O$ (0.49 mmol) in dry THF under argon was added to a solution of TPEN (0.51 mmol) in dry THF. The immediate yellow precipitate was collected by filtration (yield = 80%). − ESI MS: m/z = 240.2 $[\{(TPEN)Fe\}^{2+}]$, 515.1 $[\{(TPEN)FeCl\}^{+}]$ − UV/Vis (MeOH, 300 K): λ_{max} = 417 nm (ε = 10500 $M^{-1}.cm^{-1}$) − $C_{26}H_{28}Cl_2FeN_6 \cdot 0.5H_2O$ (560.31): calcd. C 55.73, H 5.22, N 15.0; found C 55.76, H 5.16, N 14.39.

Synthesis of the Complex $[(trispicen)FeCl]PF_6$: A solution of $FeCl_2 \cdot 4H_2O$ (0.30 mmol) in ethanol was added to a solution of trispicen (0.31 mmol) in ethanol. A yellow powder was obtained after addition of NH_4PF_6 (0.31 mmol) and collected by filtration (yield = 56%). − UV/Vis (MeOH, 300 K): λ_{max} = 395 nm (ε = 1900 $M^{-1}.cm^{-1}$).

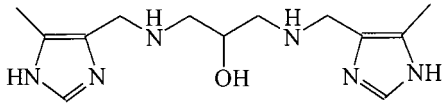
Structure, Equilibrium and Ribonuclease Activity of Copper(II) and Zinc(II) Complexes Formed with a Dinucleating Bis-Imidazole Ligand

Tamás Gajda,*[a,b] Roland Krämer,[b] and Attila Jancsó[a]

Keywords: Enzyme models / Hydrolyses / Phosphodiesters / Copper / Zinc



The syntheses, crystal structures, solution equilibria and ribonuclease activity are reported for copper(II) and zinc(II) complexes of a new potentially dinucleating, bis-imidazole ligand *N*,*N*′-bis(5-methylimidazol-4-ylmethyl)-1,3-diaminopropan-2-ol (**bimido**). The zinc(II) ion in [Zn(bimido)Cl]NO_3 is coordinated in a slightly distorted square pyramidal environment, with the four N atoms of bimido in the basal positions and the Cl^- ion in the axial one. The two copper(II) ions in $[Cu_2(bimido_{-1H})(DPP)(ClO_4)(CH_3OH)]ClO_4 \cdot 1/2\ H_2O$ (DPP = diphenyl phosphate) are bridged by the deprotonated alkoxo group of bimido and by the phosphate group of DPP in a 1,3-bridging mode. Depending on the [M]/[L] ratio, the ML and M_2L_{-2H} species are present in solution in the neutral pH range, having analogous structures as described above for the crystalline complexes. The zinc(II)-bimido (2/1) system, in a 65% EtOH-H_2O mixed solvent, shows an important increase of hydrolytic activity, parallel with the formation of the Zn_2L_{-2H} species, with a sigmoidal pH-rate profile modelling both steps of RNA hydrolysis. The k_{cat} value for the transesterification of 2-hydroxypropyl-*p*-nitrophenyl phosphate by Zn_2L_{-2H}, determined from saturation kinetic measurements (T = 298 K), corresponds to a maximum rate acceleration (k_{cat}/k_{uncat}) of ca. 10^4. The observed pseudo-first order rate constant for the hydrolysis of uridine 2′,3′-cyclic monophosphate, under nearly physiological conditions (T = 310 K, pH = 8, $[Zn_2L_{-2H}]$ = 3.6 mM, $k_{obs} = 2 \cdot 10^{-5}\ s^{-1}$) reflects a higher hydrolytic activity of Zn_2L_{-2H} towards this biologically relevant substrate (k_{obs}/k_{uncat} indicates ca. 10^4 fold rate acceleration). The proposed mechanisms include bifunctional Lewis-acid and general base catalysis.

Introduction

The fundamental role of the imidazole moiety in the active centre of a large number of metalloproteins is well established. During the past two decades a wide variety of imidazole-containing ligands have been investigated to mimic structural features of these enzymes, but less attention was devoted to functional mimicking. The presence of an imidazole moiety in the catalytic centres of enzymes is often related to hydrolytic reactions. Phosphoesterases are responsible for the hydrolysis of phosphate esters and are involved in a number of biological processes. Nucleases are an important class of these enzymes and are used in the repair and hydrolysis of DNA and RNA, as well as in viral defence (restriction enzymes).

Low molecular weight functional model complexes of phosphoesterases have attracted great interest due to their possible application in biotechnology, molecular biology and chemotherapy. A number of metalloenzymes that hydrolyse phosphate esters are activated by two or more cooperating metal ions.[1] The possible cooperative effect of the bimetallic core on the hydrolysis of phosphoesters has inspired a number of model studies dealing with dinuclear complexes.[2−14] Mechanistic features of some low molecular weight model complexes show notable similarities to the mechanism proposed for certain dinuclear phosphoesterases,[2] in particular the μ-1,3 bridging of the phosphoester substrate combined with nucleophilic attack of metal-bound hydroxide. Although important rate acceleration of phosphate ester hydrolysis has been demonstrated in many cases, only a few reflect on the catalytic centres of the native phosphoesterases, from both a structural and functional point of view.

As an extension of our study on coordination chemistry of the imidazole ring,[14−17] we report here the syntheses, crystal structures, solution equilibria and ribonuclease activity of copper(II) and zinc(II) complexes formed with a new multidentate, bis-imidazole ligand *N*,*N*′-bis(5-methylimidazol-4-ylmethyl)-1,3-diaminopropan-2-ol (bimido, Scheme 1).

Scheme 1. Schematic structure of bimido

Our aim was to design a dinucleating imidazole ligand which provides a relatively open coordination environment for the bound metal ions and an alkoxo-bridge which holds them relatively close to each other, allowing the metal-metal cooperation in the binding and the hydrolysis of phosphoesters. In the presence of an excess of metal ([Zn]/[L] = 2/1), the zinc(II)-bimido system was indeed found to be an

efficient accelerator, modelling both steps of RNA hydrolysis: transesterification of 2-hydroxypropyl-*p*-nitrophenyl phosphate (hpnp) and hydrolysis of uridine 2′,3′-cyclic monophosphate (2′,3′-cUMP).

Results and Discussion

Description of the Crystal Structures

a. [Zn(bimido)Cl]NO_3 (1)

The molecular structure of **1** is shown in Figure 1, selected bond lengths and angles are given in Table 1. The zinc(II) ion in complex **1** is coordinated in a slightly distorted square pyramidal environment, with the four N atoms of bimido in the basal positions and the Cl^- ion in the axial one. The zinc(II) ion is displaced by 0.527(1) Å from the least-square plane defined by N(2), N(3), N(4) and N(5). The O(1) oxygen of the alcohol is not coordinated to the metal ion. Several hydrogen bonds between the hydrogens on O(1), N(1), N(3) and the nitrate oxygens stabilise the crystal structure. In addition, two complex molecules are linked by a moderately strong hydrogen bonding interaction between the hydrogen on N(6) and O(1) (-x, y-1/2, -z+1/2) with an N(6)−O(1) bond length of 2.802 Å.

The penta-coordinated zinc(II) ion is less common in biological systems, but may be relevant to the catalytic reaction intermediates.[18] Although several square pyramidal zinc(II) complexes are known for linear or cyclic tetraaza ligands,[19] only a few examples can be found for imidazole derivatives.[20]

The average Zn−N_{im} distance (2.05 Å) is considerably shorter than the corresponding distance of the secondary amines (2.15 Å). The former value (Zn−N_{im}) is also somewhat shorter than the corresponding distance in the only available square pyramidal zinc(II) complex with basal imidazole coordination (2.08 Å).[20]

The largest distortion in complex **1** from the ideal square pyramidal structure is in the N2−Zn−N5 angle, which is 101.2° (Δ = 15.2°). This is due to the presence of the two fused 5-membered chelate rings in complex **1**, having N−Zn−N angles less than 80°.

b. [Cu_2(bimido$_{-1H}$)(DPP)(ClO_4)(CH_3OH)]ClO_4·1/2H_2O (2)

The complex crystallises with two identical dinuclear cations, four perchlorates and a lattice water per unit cell. The molecular structure of **2** is shown in Figure 2, while selected bond lengths and angles are provided in Table 2. The dinuclear complex consists of two distinct copper(II) centres, one is five (4+1) coordinated, the other is six (4+2) coordinated and they are doubly bridged by the alkoxide oxygen of bimido and by the phosphate oxygens of DPP in a 1,3-bridging mode. The five coordinated Cu(2) has a slightly distorted square-pyramidal geometry. The basal plane of Cu(2) is determined by the N(1), N(2), O(1) atoms of bimido in addition to the O(2) oxygen of DPP, while a non-

[a] Symmetry transformation: $x + 1$, y, z.

deprotonated methanol oxygen is coordinated in the apical position (Cu−O = 2.359 Å). The six coordinated Cu(1) has the same donors in the tetragonal plane (N(3), N(4), O(1) and O(3)), but both axial positions are occupied by loosely bound perchlorate oxygens with a Cu−O distance of ≈ 2.54 Å. As a result, the $Cl(1)O_4^-$ perchlorate ion bridges two neighbouring dinuclear complexes, forming an infinite chain within the crystal. This structural motif has been found in only a few dicopper complexes.[21b] In fact, the oxygen atoms of the methanol and perchlorate ion interact weakly with the metallic orbitals, as a result of the Jahn−Teller effect. The lattice water occupies a special position ($x = 0.5$, $y = 0.5$, $z = 0.5$). The interatomic distances between the water oxygen (O(15)) and the other non-hydrogen atoms are all ≥ 3.88 Å.

The bond lengths in the tetragonal planes of the copper ions ($Cu-N_{im}$ = 1.927 and 1.920, $Cu-N_{am}$ = 1.997 and 2.002, $Cu-O_{alc}$ = 1.901 and 1.880, $Cu-O_P$ = 1.915 and 1.917 Å) are similar for the two metal centres. The Cu−N distances are, however, considerably shorter (Δ = 0.05−0.15 Å) relative to the structurally similar tri- or tetrasubstituted (benz)imidazole derivatives of 1,3-diamino-2-propanol.[21] This is probably due to the less distorted tetragonal plane in **2**. On the other hand, the Cu−O distances are typical as compared with the related dinuclear complexes.

The Cu(1)−Cu(2) distance and the Cu(1)−O(1)−Cu(2) angle in **2** are 3.493 Å and 134.9°, respectively. These relatively large values are due to the constraint caused by the fused 5-membered chelate rings of the ligand backbone and are in the range obtained for similar complexes of substituted 1,3-diamino-2-propanol ligands.[21,22] The metal-metal separation and the μ-1,3 bridging fashion of the phosphodiester DPP in **2** is related with many dinuclear metallo-phosphoesterases.[1][2a] The double Lewis activation of phosphodiester achieved in this way is certainly a key feature concerning the observed hydrolytic activity of **2** (see later).

The least square calculation revealed only minor distortion of the basal plane of Cu(2), but the donor atoms are considerably deviated (average deviation 0.133 Å) from the best plane of Cu(1). As a consequence of the different geometry, only Cu(2) is deplaced considerably (0.1 Å towards O(4)) from its basal plane. The angle between the two least-square planes of the copper(II) centres is 9.4(1)° and between the best plane of the Cu_2O_3P unit and the basal plane of Cu(2) is 7.8(1)°. These facts result in an essentially planar structure of the complex cation.

Finally, several hydrogen bonds, e.g. between N(6)−H and O(11); N(3) −H and O9 ($x + 1$, y, z); O(4) −H and O8 ($x + 1$, y, z), stabilise the crystal structure.

Complex Formation in Aqueous Solution

The determined protonation and complex formation constants are listed in Table 3 together with some derived data. The two imidazole rings of bimido have pK values that are ca. one log unit higher than that of the structurally similar *N*,*N*′-bis(imidazol-4-ylmethyl)-1,2-ethanediamine[23] (bimeda, pK = 3.21 and 4.26), probably due to the electron-donating methyl groups on the imidazole rings.

Table 3. Logarithmic formation constants for copper(II) and zinc(II) complexes of bimido (T = 298 K, I = 0.1 M ($NaClO_4$) in water and I = 0.05 M (sodium benzenesulfonate) in a 65% (w/w) ethanol−water mixture); $\beta_{pqr} = [M_pL_qH_r]/[M]^p[L]^q[H]^r$, with estimated errors in parentheses (last digit)

In the presence of zinc(II) the same species are formed in both [Zn]/[L] = 1/1 and 1/2 systems. Complex formation starts at pH 4, with the formation of the 3N-coordinated MLH species (Figure 3A). The succeeding ZnL complex is the unique species in the neutral pH region. Its formation at slightly acidic pH suggests 4N coordination in this complex, which is, in fact, proven by X-ray analysis. At higher pH further base consumption is observed (pK = 9.53) which can be assigned to the deprotonation of a metal-bound water molecule (the formation of a metal-coordinated alkoxide anion is less likely due to steric reasons).

In the presence of the copper(II) ion ([Cu]/[L] = 1/1 or 1/2) only the CuL and CuL_{-1H} complexes are detected in the whole pH range. The formation of the CuL species is complete at pH 4. This fact, together with the spectroscopic parameters determined for this complex ($g_\perp$ = 2.057, $g_{//}$ = 2.221, $A_{//}$ = 0.0190 T, g_o = 2.112, A_o = 0.0079 T, λ_{max}^{d-d} = 570 nm), strongly suggest a 4N coordination in the equatorial plane of copper(II) in CuL. The presence of imidazole rings in bimido results in a rather high stability. The basicity corrected stability constants of the ML complex ($\log K_{ML,corr} = \log \beta_{110} - \log \beta_{014} = -7.1$ and −16.44 for Cu^{II} and Zn^{II}, respectively) are ca. 2−4 orders of magnitude higher than those of the 1,4,8,11-tetraazaundecane.[24] Similarly, the existence of the fused chelates causes significant stabilisation relative to the complexes of the strongly related 4-aminomethylimidazole (e.g. $\log K_{CuL2,corr}$ = −11.0,[25] $\Delta \log K_{corr}$ = 3.9). The deprotonation, leading to the CuL_{-1H} species, occurs at pK = 11.16. The observed slight change in the EPR parameters during this process (g_o = 2.109, A_o = 0.00806 T) indicates only minor variations in the coordination sphere of copper(II), i.e. deprotonation of the non-coordinating imidazole-N1 nitrogen. The observed high pK value agrees well with those obtained for analogous systems.[17]

Our intention was to achieve dinuclear complexes of bimido, but the solubility of the complexes formed at 2/1

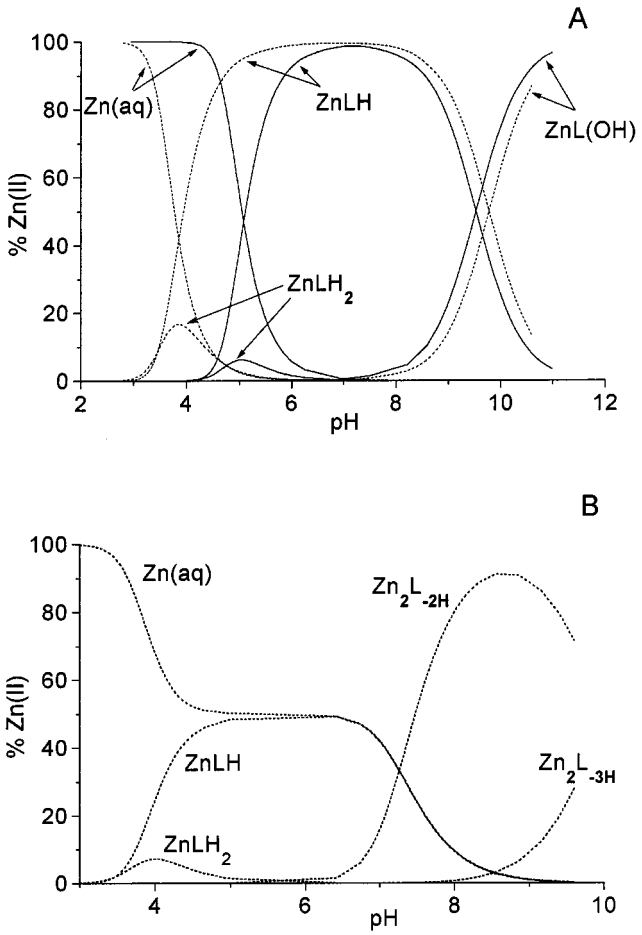

Figure 3. Species distribution curves in the zinc(II)-bimido system at metal-to-ligand ratio 1/1 (A) and 2/1 (B) in water (solid line) and in a 65% (w/w) EtOH-H_2O mixture (dotted line); [Zn] = 3 mM (A) and 1 mM (B)

metal-to-ligand ratio was found to be very sensitive to the solvent used and the background electrolyte. A relatively sharp and well-resolved ^{1}H NMR spectrum can be obtained by dissolving the crystalline complex **2** in [D_6]DMSO (see supporting information, Figure S1). The signals related to the ligand are spread over a 150 ppm range. The occurrence of the spectrum strongly supports the presence of the dinuclear unit in solution too, allowing magnetic interaction between the metal centres.[26] In the aqueous solution of copper(II)-bimido ([Cu]/[L] = 2/1) system, without background electrolyte, two strongly overlapping deprotonations are observed pH-metrically between pH 6 and 8, accompanied by the decrease in EPR signal intensity and by a red shift of the *d-d* transition (see supporting information, Figure S2). This indicates the rearrangement of the donor groups in the equatorial plane of copper(II) and the formation of magnetically coupled metal centres. Although no further information is available, the Cu_2L_{-2H} complex formed between pH 6−7, probably has an analogous structure to the crystallographically determined dinuclear complex **2** (the formation of protonation isomers, as in the case of zinc (see later), cannot be ruled out). However, in the presence of any common background electrolyte precipitation is observed preventing further study.

Complex Formation in a 65% (w/w) Ethanol-Water Mixed Solvent

In the case of the zinc(II)-bimido ([Zn]/[L] = 2/1−1/2) system, solubility problems are overcome by using a 65% (w/w) ethanol-water solvent mixture. This solution is clear in the whole pH range and thus it is suitable for equilibrium and kinetic measurements (see also the experimental section). The pK values of bimido are lower than those obtained in aqueous solution (Table 3), according to the somewhat lower permittivity of the solvent. Since the association is more favoured in this medium than in water, the stability of the ZnLH and ZnL complexes, reflected by the basicity corrected stability constants (Table 3), is considerably higher.

At a 2/1 metal-to-ligand ratio, two deprotonations (one per zinc(II) ion) are observed between pH 6.5−8, in a strongly overlapping manner, forming the M_2L_{-2H} species (Figure 3B). A similar observation is mentioned above for copper(II), but in the present case the deprotonation processes take place at higher pH values of ca. 0.7 units. With increasing pH, a further deprotonation is observed (pK = 10.0).

The ^{1}H NMR spectrum of the ZnL species is changed significantly relative to that of the free ligand (Figure 4).

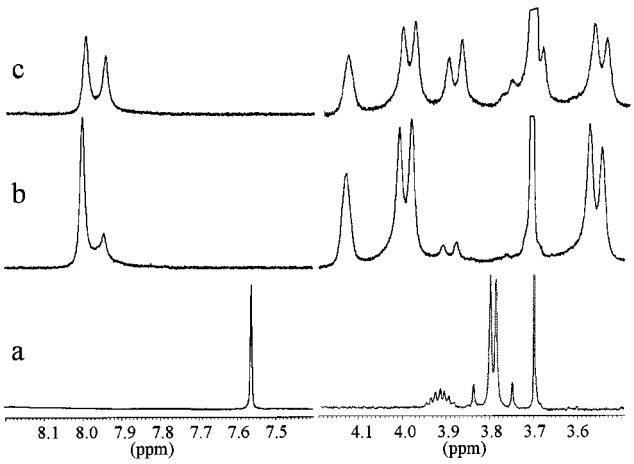

Figure 4. Selected regions of the ^{1}H NMR spectra measured in the zinc(II)-bimido system in 65% CD_3OD - D_2O at pH = 8.6 with the variaton of the metal to ligand ratio. [bimido] = 0.005 M (a) and 0.002 M (b, c). [Zn] = 0.0 M (a), 0.0022 M (b) and 0.004 M (c)

The hydrogens of CH_2, linked to the imidazole rings, become strongly inequivalent and all signals shift upon the coordination. The increasing metal-to-ligand ratio at pH 8.5 induces further characteristic changes on the spectra. A new set of peaks appears, indicating the formation of a complex, Zn_2L_{-2H} according to the pH-metric results, which is in a slow exchange on the NMR timescale. Kinetically inert complexes may originate from the formation of either imidazolate- or alkoxo-bridged metal centres. The chemical shift of the imidazole C2−H protons is, however, weakly influenced by the deprotonation. Metal-promoted

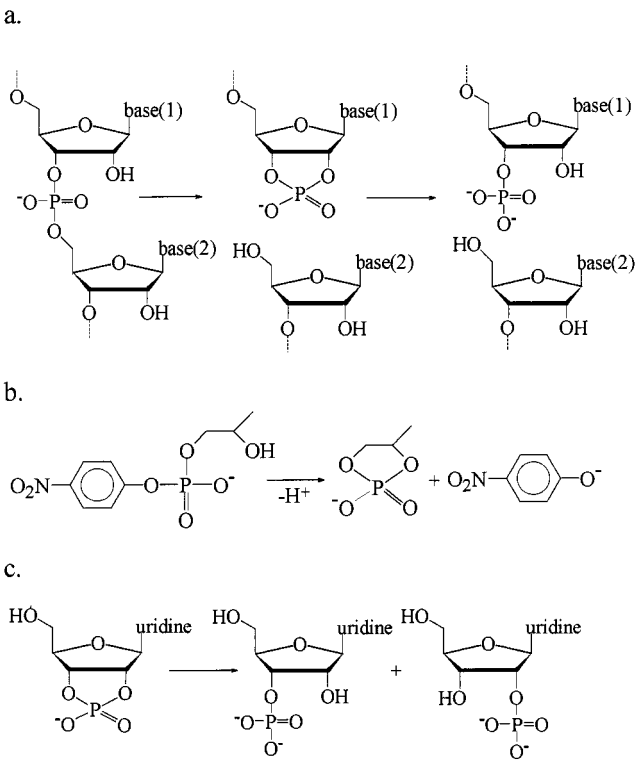
[a] Three bond couplings between C*H*−OH and the two inequivalent CH_2−CH hydrogens: ^3J = 4.7 and 7.4 Hz. − [b] Two bond couplings between the inequivalent CH_2-im hydrogens: ^2J = 13.4, 14.0, 15.0 and 13.8 Hz, respectively. − [c] Two bond couplings between the inequivalent CH_2−CH hydrogens: ^2J = 12.2, 11.7, 11.2 and 12.0 Hz, respectively. − [d] Chemical shift could not be determined due to the overlapping with the broad solvent signal.

proton loss of the neutral imidazole ring i.e. formation of an imidazolate-bridge, induces an important (more than 1 ppm) shift[14,16] which is not comparable with the presently observed 0.06 ppm. On the other hand, notable changes appear on the signals of the 2-hydroxypropyl unit, especially concerning the central CH group (Table 4). These facts suggest, that the new set of peaks is related to an alkoxo-bridged dinuclear complex. This complex probably has an analogous structure with the crystallographically determined dinuclear complex **2**. Such a structural motif has recently been found in a dinuclear zinc(II) complex of a four substituted 1,3-diamino-2-propanol derivative.[27] Complex **2** and Zn_2L_{-2H} are different, however, in their protonation states. The second deprotonation in Zn_2L_{-2H} can be assigned to the proton loss of a metal-bound water molecule.

However, as can be seen from Figure 4. only ca. 45% of the ligand is transformed into the above-mentioned complex at a two-fold metal excess and at pH 8.6, while 55% of the ligand remains as a fast exchanging species. A simple explanation of this behaviour would be the presence of 27.5% free metal ion beside the Zn_2L_{-2H} and ZnL complexes. In the absence of the ligand, however, a well defined $Zn(OH)_2$ precipitate can be observed above pH 7.0 even at a 0.3 mM metal concentration, which prevents any accurate pH-metric or kinetic study. Since the solution of zinc(II)-bimido complexes ([Zn]/[L] = 2/1) is clear even at a 7 mM metal concentration, the only plausible explanation for the above observation is the presence of protonation isomers, i.e. two complexes with the same Zn_2L_{-2H} composition. One of them is the above-mentioned alkoxo-bridged complex $Zn_2(L_{-1H})(OH)$ which is in a slow exchange. In the other isomer the metal ions are chelated by two nitrogens and both deprotonations are related to the metal-bound water molecules ($Zn_2L(OH)_2$) . The ^{1}H NMR signals of this species is only slightly shifted relative to those of the ZnL complex, since the ligand in both cases coordinates to the metal ion(s) by its four nitrogen donors.

Protonation isomers are generally in a fast mutual exchange but in the present case, the protonation of the alkoxide anion induces rearrangement of the coordination sites, which slows the entire process. The $Zn_2L(OH)_2$ complex remains in a fast mutual exchange with ZnL and L.

The further deprotonation around pH 10 results in the formation of Zn_2L_{-3H} species, which is probably better described as $Zn_2(L_{-1H})(OH)_2$.



Kinetic Study

The hydrolytic cleavage of RNA is a two-step process: the first step is a transesterification forming a cyclic phosphoester, while the second step is the ring opening.

The hydrolytic activity of the above systems is tested by modelling both steps of RNA hydrolysis i.e. transesterification of hpnp and hydrolysis of 2′,3′-cUMP (Scheme 2).

Hydrolytic Activity of the Copper(II)-bimido Complexes

The pH-rate profiles of the transesterification of hpnp and hydrolysis of cUMP, having sigmoidal character, are

Scheme 2. The two-step process of RNA hydrolysis (a) and the used model substrates: b. 2-hydroxypropyl-*p*-nitrophenyl phosphate (hpnp) and c. uridine 2′,3′-cyclic monophosphate (2′,3-cUMP). Base(1) and base(2) indicate organic base constituents of RNA

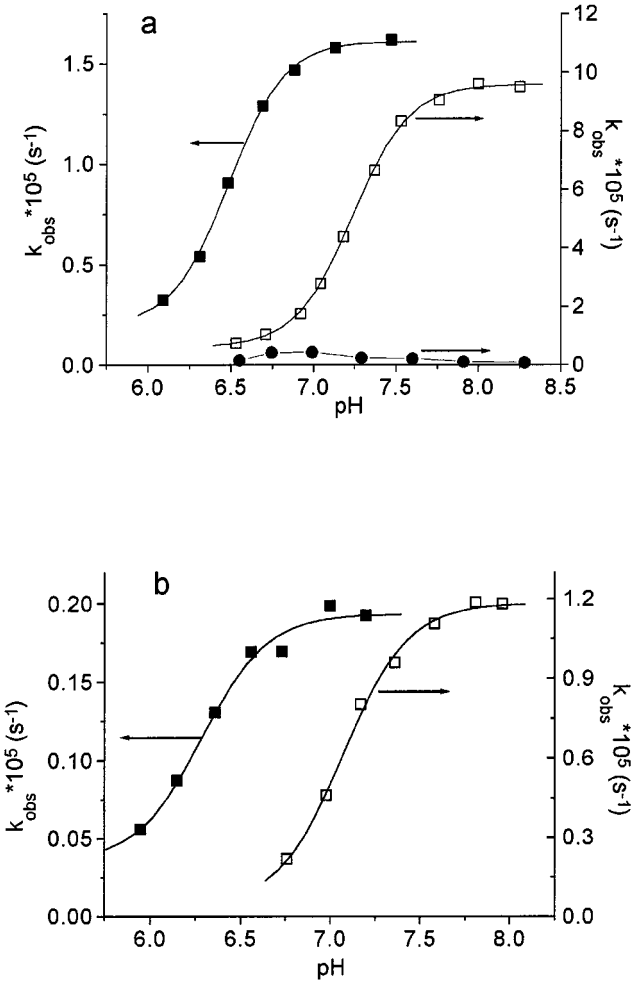


Figure 5a−b. The effect of pH on the observed kinetic data. − a) (■) transesterification of hpnp by the copper(II)-bimido complexes (T = 298 K, 0.51·[Cu] = [L] = 5·10^{-4} M, 0.01 M MES or HEPES, [hpnp] = 5.4·10^{-4} M); (□) transesterification of hpnp by the zinc(II)-bimido complexes (65% (w/w) EtOH-H_2O, T = 298 K, I = 0.05 M, 0.52·[Zn] = [L] = 5.6·10^{-4} M, [hpnp] = 5.4·10^{-4} M); (•) transesterification of hpnp by the zinc(II)-ion alone (65% (w/w) EtOH-H_2O, T = 298 K, I = 0.05 M, [Zn] = 3.0·10^{-4} M, [hpnp] = 9.8·10^{-4} M). − b) (■) hydrolysis of cUMP by the copper(II)-bimido complexes (T = 310 K, 0.51·[Cu] = [L] = 5.1·10^{-4} M, 0.01 M MES or HEPES, [cUMP] = 50 μM); (□) hydrolysis of cUMP by the zinc(II)-bimido complexes (65% (w/w) EtOH-H_2O, T = 310 K, I = 0.05 M, 0.52·[Zn] = [L] = 2.1·10^{-3} M, [cUMP] = 50 μM)

shown in Figure 5. In both cases, the observed rate increases between pH 6−7.5, which is parallel with the formation of the Cu_2L_{-2H} species (see also Figure S2), implying its active role in the reaction. However, due to the absence of background electrolyte, a detailed kinetic study was not performed.

Transesterification of hpnp by the Zinc(II)-Bimido Complexes

The pH-rate profile of the transesterification of hpnp shows a sigmoidal shape again (Figure 5,a). The increasing activity between pH 6.5−8 is parallel with the pH-metrically observed deprotonations at a 2/1 metal-to-ligand ratio (Figure 3.b). The pseudo-first order rate constant levels off between pH 8−8.8 and decreases at higher pH (not shown). The pK value determined from the kinetic data (pK = 7.24) agrees well with the pH-metric results. For comparative purposes, we also studied the hydrolytic activity of the zinc(II) solution in the absence of bimido (Figure 5,a). Due to the formation of a $Zn(OH)_2$ precipitate above pH 7, the observed rate constants are relatively uncertain. Nevertheless, the free zinc(II) induced rate enhancement is negligible relative to that of zinc(II)-bimido system. All these facts suggest that the hydrolytic activity is related to the Zn_2L_{-2H} species, although no distinction can be made concerning the two protonation isomers since their ratio is independent from pH and concentration. The uncatalysed reaction of hpnp at pH 8 is relatively slow ($k_{obs,uncat}$ = 1.3·10^{-7} s^{-1}, half lifetime 62 days) under the conditions used. However, in the presence of 0.54 mM Zn_2L_{-2H} complex at pH 8, the half lifetime decreases to 2 hours. Three turnovers are observed without significant loss of activity at pH 8 when a 3-fold excess of hpnp is present over the dinuclear complex (0.5 mM).

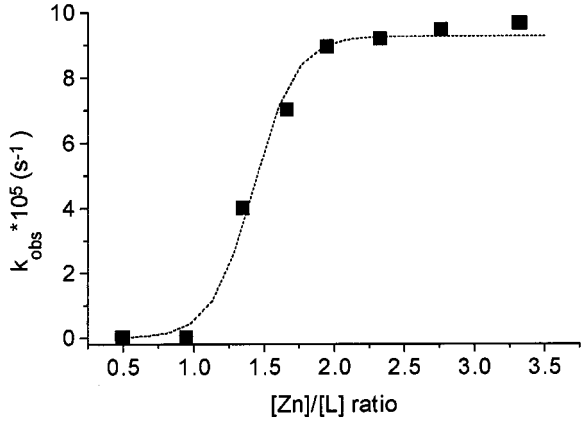

Figure 6. Dependence of the rate of transesterification on the [Zn]/[bimido] ratio at constant bimido concentration; pH = 7.98, [bimido] = 5.6·10^{-4} M

Figure 6 shows the observed pseudo-first order rate constants as a function of the [Zn]/[bimido] ratio at constant ligand concentration. The rate is negligible up to equimolar conditions, it sharply increases between a 1/1 and 2/1 ratio and finally levels off at a higher metal excess (where precipitation occurred). This observation provides further argument that the observed activity is a result of the Zn_2L_{-2H} species.

At a constant metal-to-ligand ratio and at pH 7.98, the rate of transesterification linearly depends on the concentration of the Zn_2L_{-2H} complex between 0.2 mM < [Zn] < 2 mM (Figure 7). The second order rate constant (k_2) determined from the slope of this plot is 0.186 M^{-1}s^{-1}. This value is 2.5 times higher than that of the hydroxide ion induced transesterification ($k_{2,OH}$ = 0.0745 M^{-1}s^{-1}), determined between pH 8.8−10.9 in water (in a 65% EtOH-H_2O mixture precipitation occurred using CAPS buffer).

The rate of transesterification is also measured as a function of the substrate concentration (Figure 8). At higher hpnp concentration, saturation kinetics is observed, implying that the transesterification proceeds through pre-equi-

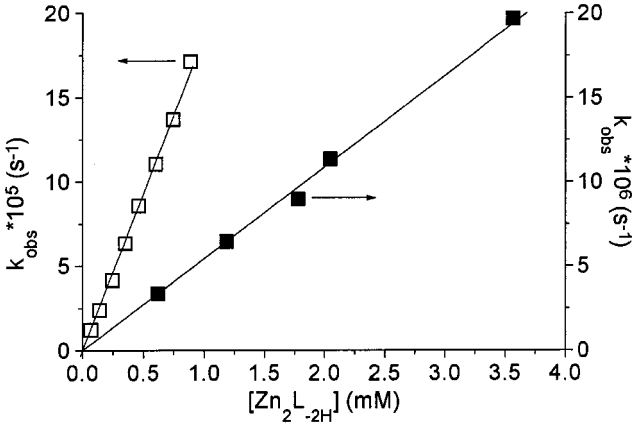

Figure 7. Dependence of the observed pseudo-first order rate constant on the concentration of $[Zn_2L_{-2H}]$ complex. – (□) transesterification of hpnp (65% (w/w) EtOH-H_2O, T = 298 K, I = 0.05 M, 0.52·[Zn] = [L], pH = 7.98, [hpnp] = $5\cdot10^{-4}$ M); (■) hydrolysis of cUMP (65% (w/w) EtOH-H_2O, T = 310 K, I = 0.05 M, 0.52·[Zn] = [L], [cUMP] = 50 μM)

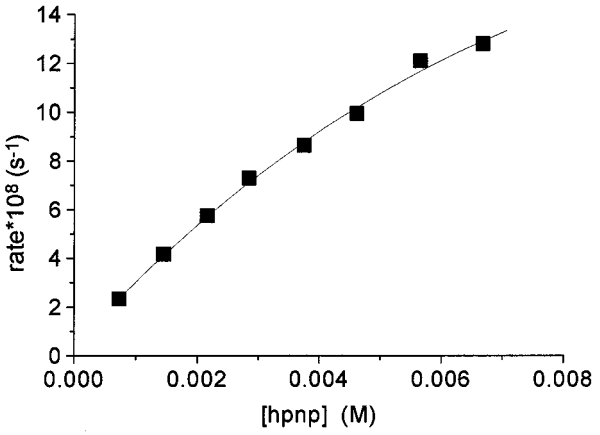

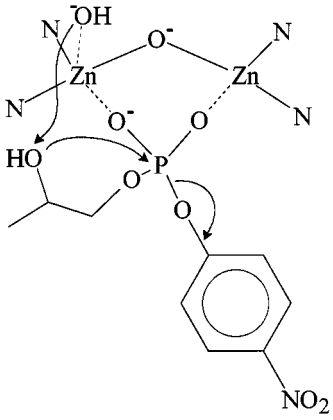

Figure 8. Saturation kinetic experiments for the transesterification of hpnp (65% (w/w) EtOH-H_2O, T = 298 K, I = 0.05 M, 0.52·[Zn] = [L] = $2.1\cdot10^{-4}$ M, pH = 7.98)

libration of an active (catalyst-substrate) complex. The Michaelis-Menten constant (K_M), determined by nonlinear parameter fitting, is 9.1 mM (K_{ass} = $1/K_M$ =110 M^{-1}) and the first order catalytic rate constant (k_{cat}) is $1.52\cdot10^{-3}$ s^{-1}. These values indicate the moderate binding affinity of hpnp to the dinuclear Zn_2L_{-2H} species, but high catalytic activity of this complex. As far as we are aware, the above k_{cat} value is the highest value reported to date for transesterification of hpnp by a zinc(II) complex.

The above experimental data, together with the crystal structure of complex **2**, provide some information on the possible mechanism of the transesterification. The pH-rate profile levels off between pH 8–8.8 (Figure 5.a) parallel with the concentration distribution of the Zn_2L_{-2H} species (Figure 3.b). This means that general base catalysis, activating the nucleophilic β-OH group, is provided mainly by the metal-bound hydroxide ion. However, the second order rate constant of the transesterification by the dinuclear zinc(II) complex is 2.5-fold higher than $k_{2,OH}$. This implies a bifunctional mechanism for the transesterification, since the nucleophilicity of the metal-bound hydroxide ion is considerably lower than that of the free OH^- ion. Thus, additional Lewis-acid activation, or in other words metal coordination of the phosphate group, should be considered. Based on the crystal structure of the dinuclear complex **2**, this probably occurs in a μ-1,3 bridging fashion (Scheme 3). In most cases, such double Lewis-activation is the key feature of highly active dinuclear complexes.[2,7,8,28]

Scheme 3. The proposed mechanism for hpnp transesterification by the alkoxo-bridged dinuclear complex

Since bridging alkoxide anions are not considered to be active as (general-)base catalysts,[2,4,6,8] the proposed mechanism should be valid for both protonation isomers. Due to the constant ratio of the protonation isomers, no experimental data are available for their individual activity. An overview of the literature data indicates, however, higher hydrolytic activity of rigidly pre-organised bimetallic cores,[2,29] allowing direct metal-metal cooperation, as compared with the more flexible dinuclear complexes. This would suggest the predominance of the $Zn_2(L_{-1H})(OH)$ isomer in the hydrolytic processes.

Hydrolysis of 2′,3′-cUMP

The use of *p*-nitrophenyl phosphates to mimic natural phosphoesterases is not fully justified, since in contrast to biological phosphoesters, the 4-nitrophenolate leaving group does not require electrophilic stabilisation. To mimic the second step of RNA hydrolysis we use the biologically more relevant 2′,3′-cUMP, which provides a direct analogy to the natural process (Scheme 2).

The pH-rate profile of 2′,3′-cUMP hydrolysis by the dinuclear zinc complex (Figure 5.b) shows similar sigmoidal behaviour as the hpnp transesterification. A pK value of 7.06 can be determined from the kinetic data which is somewhat smaller than the previously determined pK = 7.24. This difference is due to the four-fold increase in the metal concentration and the higher temperature (310 K) used in present case. 2′,3′-cUMP is highly resistant to hydrolysis. The second order rate constant[30] for the hydroxide-catalysed hydrolysis at 37 °C is ca. $6.5\cdot10^{-3}$ $M^{-1}s^{-1}$. Based on this value, the approximate parameters for the autohydrolysis at pH 8 are $k_{obs,uncat}$ = $1–2\cdot10^{-9}$ s^{-1} and the half-life time is ca. 11–22 years. In the presence of a 3.6 mM dinuclear zinc(II) complex the half-life time of 2′,3′-cUMP is 10

hours at pH 8. Thus, a 3.6 mM zinc complex provides ca. $1-2\cdot10^4$-fold rate acceleration, which is the highest value reported to date for the 2′,3′-cUMP hydrolysis promoted by a dinuclear zinc(II) complex. On the other hand, Komiyama′s dinuclear zinc(II) complex[4] hydrolyses ApA with a comparable rate and thus, although no numerical data is given, it probably provides a faster hydrolyses for cyclic monophosphates. We also tested the activity of the dinuclear zinc(II)-bimido complex towards the hydrolysis of UpU. In the presence of a 4 mM dinuclear species and at 310 K, ca. 5% conversion is achieved after 3 days. This suggests an accelerated reaction but the rate is too small for accurate measurement.

The rate of hydrolysis shows first order dependence on the concentration of the Zn_2L_{-2H} species (Figure 7) between 1.2 mM < [Zn] < 7.2 mM. The second order rate constant determined from the slope is 0.0054 M^{-1} s^{-1}. This value is close to that of the hydroxide ion (ca. 0.0065 M^{-1} s^{-1}).

The mechanism of the hydrolysis by the dinuclear complex is probably similar (as depicted in Scheme 3) to the hpnp transesterification. In the present case, however, the metal-bound hydroxide ion may act either as a general base (deprotonating the attacking water molecule) or as a direct nucleophile.

Experimental Section

Materials: Zinc(II) perchlorate (Fluka) solutions were standardised complexometrically. pH metric titrations were performed by Titrisol NaOH standard solution (Merck). HEPES, HEPPS, CHES, CAPS (Aldrich) and MES and 2′,3′-cUMP (Sigma) were used without further purification. The barium salt of 2-hydroxypropyl-*p*-nitrophenyl phosphate (hpnp) was prepared according to the literature procedure[31].

Synthesis of *N,N′*-Bis(5-methylimidazol-4-ylmethyl)-1,3-diaminopropan-2-ol·4 HCl (Bimido): 5-Methylimidazole-4-carboxaldehyde (1.67 g, 15 mmol) and 1,3-diamino-2-propanol (0.7 g, 7.5 mmol) were dissolved in 60 mL of dry methanol. To this solution 1.2 g of sodium borohydride were added in small portions while stirring. After 3 h at room temperature, the reaction was completed by refluxing for 1 h. The methanol solution was then acidified by concentrated hydrochloric acid. The precipitate was filtered , the solution was reduced to 2−3 mL and 30 mL of methanol was added. The precipitate was filtered off again. The solution was evaporated to dryness by codistillation with absolute ethanol. The crude product was recrystallised twice from methanol. Yield: 2 g, 63%. The structure and purity was confirmed by NMR spectroscopy and potentiometry. ^{1}H NMR (D_2O): δ = 8.63 (s, 2 H, C2−H(im)), 4.43 (s, 4 H, CH_2−im), 4.34 (m, ^3J = 4.0 and 11.3 Hz, 1 H, C*H*−OH), 3.30 and 3.16 (m, ^2J = 15.8 Hz, ^3J = 4.0 and 11.3 Hz, 2 H + 2 H, CH_2−CH) and 2.36 (s, 6 H, CH_3-im). No other signal was detected.

pH-metric Measurements: The complex formation equilibria were investigated by potentiometric titrations using an automatic titration set including a Dosimat 665 (Metrohm) autoburette, an Orion-710A precision digital pH-meter and an ORION ROSS 8103BN type combined glass electrode. The experimental procedure referring to the aqueous solution (0.1 M $NaClO_4$, and T = 298±0.1) was described in detail earlier.[15–17]

In 65% (w/w) ethanol-water mixture the zinc(II)-bimido ([Zn]/[L] = 2/1−1/2) solution was clear between pH 2−10 when only buffer was present, but gave slight precipitation using any common inorganic background salt. To avoid this precipitation sodium benzenesulfonate (0.05 M) was used as a background salt and a clear solution, in the used concentration ([Zn] = $0.4-7.0\cdot10^{-3}$ mol dm^{-3}) and pH range, was obtained. The pH-meter was calibrated by standard aqueous buffer solutions (pH = 4.01 and 7.0, Mettler−Toledo) and the actual pH in the mixed solvent was then determined by subtracting 0.24 units from the pH-meter reading according to the method of Bates.[32] The ionisation constant of water determined under the used conditions (pK_w = 14.92±0.02) is in good agreement with that of extrapolated value from the literature data.[33]

The protonation and the complex formation constants were calculated as the average of 4 and 8 independent titrations (50−80 data points per titration), respectively. The metal-to-ligand ratios were varied from 2:1 to 1:2 with metal-ion concentrations between $5\cdot10^{-4}$ and $4\cdot10^{-3}$ mol dm^{-3}. The species formed in the systems were characterised by the following general equilibrium process

$$pM + qL + rH \rightleftarrows M_pL_qH_r$$

(charges are omitted for simplicity; M denotes the metal ion and L the non-protonated ligand molecule) and the concentration stability constants of these species were calculated by the computer program PSEQUAD.[34]

X-ray Crystallography: The crystals suitable for X-ray analysis were obtained by the following ways:

[Zn(bimido)Cl]NO_3 (1): Bimido·4 HCl (66 mg, 0.15 mmol) dissolved in 5 mL of dry methanol was neutralised with 4 equivalents of NaOH (in MeOH). $Zn(NO_3)_2\cdot6H_2O$ (44.6 mg, 0.15 mmol) was then added. The solution was heated to 50 °C and gently concentrated to 2−3 mL. After slowly cooling the solution to room temperature, colourless crystals were obtained in 2−3 days. Anal. calculated for $C_{13}H_{22}ClN_7O_4Zn$: C 35.38, H 4.99, N 22.22; found C 35.08, H 4.91, N 22.42.

[Cu_2(bimido$_{-1H}$)(DPP)(ClO_4)(CH_3OH)]ClO_4·1/2 H_2O (2): In a similar way, bimido·4 HCl (66 mg, 0.15mmol) in 5 mL dry methanol was mixed with 6 equivalents of NaOH (in MeOH), diphenylphosphonic acid (32.7 mg, 0.15 mmol) and $Cu(ClO_4)_2\cdot6H_2O$ (111.2 mg, 0.3 mmol). After a similar treatment as in **1**, deep blue crystals were obtained. Anal. calculated for $C_{26}H_{36}Cl_2Cu_2N_6O_{14.5}P$: C 34.94, H 4.03, N 9.41; found C 35.06, H 4.08, N 9.34.

X-ray data were collected on a STOE IPDS diffractometer using Mo-K_α-radiation (λ = 0.71073 Å) at 213 K with sample-to-plate distance of 70 mm and a scan range from 100 to 301° (**1**) and from 5 to 205° (**2**), with an exposure time of 4 min per 1.5° increment for **1** and 1.3° for **2**. The structures were solved using the direct method[35] and refined[36] by full-matrix least square by minimising the function $\Sigma w(|F_0|-|F_c|)^2$, where F_0 and F_c are the observed and calculated structure factors. Anisotropic thermal parameters were used for all non-hydrogen atoms except for the lattice water oxygen in **2**. Hydrogen atoms were included in the refinement using the riding model. The isotropic thermal parameters for the methyl and hydroxyl protons were refined with 1.5 times, for all other hydrogen atoms with 1.2 times, U_{eq} of the attached atom. H atoms of the lattice water in **2** were not found. The residual electron density on the final difference Fourier map was relatively low for **1**

(0.33/−0.32 e/Å^3), while in case of **2** the two highest peaks were found to be 1.56 and 0.85 e/Å^3, associated with Cl(1). The thermal parameters of the complex cation in **2** were well behaved, but those of the perchlorate ions and lattice water were relatively large. Attempts to improve the model for the disordered Cl(1) perchlorate ion resulted in a lower final agreement index and residual electron density, but a higher thermal parameter for one of the disordered perchlorate oxygen and thus were unsatisfactory. Further data collection parameters and information related to the structure refinement are collected in Table 5.

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Center as supplementary publication no. CCDC-127400 (**1**) and CCDC-135915 (**2**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (Fax:+44−1223/336−033; E-mail: deposit@ccdc.cam.ac.uk).

NMR Spectroscopic Measurements: The ^{1}H NMR spectroscopic measurements were performed on a Bruker AM-360 spectrometer, operating at room temperature. The chemical shifts have been given as relative shifts from DSS (the sodium salt of 4,4-dimethyl-4-silapentane-1-sulfonate) using dioxane as the internal reference (3.7 ppm from DSS).

Kinetic Measurements. − Transesterification of hpnp: The reaction was followed in 65% (w/w) ethanol-water ($I \approx 0.05$ M with 0.02 M buffer (HEPES, HEPPS or CHES) and 0.03 M sodium benzenesulfonate). The increase in the absorbance maximum at 400 nm of the *p*-nitrophenolate anion (ε = 18900) was monitored. The pK of *p*-nitrophenol and the buffers were determined independently for our conditions (pK = 8.04±0.01 (hpnp), 7.13±0.01 (HEPES), 7.56±0.01 (HEPPS), 8.80±0.01 (CHES)). The initial concentration of hpnp varied from 0.4 mM to 7 mM. The initial slope method (≤ 4% conversion) was used to determine the pseudo first order rate constants. The reported data are the average of triplicate measurements (reproducibility ≤ 10%).

Hydrolysis of 2′,3′-cUMP: Kinetic data were measured by hydrolysing the 2′,3′-cUMP in a 65% (w/w) ethanol-water mixture (buffer concentration 0.05 M) in the presence of zinc(II)-bimido complexes at 310 K and by analysing the unchanged substrate and products (uridine-2′-phosphate, uridine-3′-phosphate and a small amount of uridine) by HPLC . The pH of the reaction solutions were measured at 298 K, before initiation of the hydrolysis. The initial substrate concentration was $5\cdot10^{-4}$ mol dm^{-3}. Ten aliquots of the reaction solutions were periodically taken up in each run. The progress of the reaction was stopped by mixing 0.1 mL aliquot with equal amount of eluent used for HPLC (0.025 moldm^{-3} acetate buffer, pH = 4.3, containing 0.1 mol dm^{-3} ammonium chloride). The sample was then injected into the HPLC column. The chromatographic separations were carried out on a Merck HPLC system. The column was a Lichrospher 100 RP-18 (150 × 4 mm i.d.), 5 mm particle size (Merck). The UV detection was carried out at 260 nm. The hydrolysis was followed for c.a. three half-lives, by observing the disappearance of uridine-2′,3′-cyclic monophosphate. In all cases pseudo first-order kinetics were observed. The rate constants (k_{obs}) were obtained from the plots of the ratio of the peaks area: [substrate]/([substrate]+[product]) (A_t) *vs* time fitted by the standard exponential model ($A_t = A_0\exp(-k_{obs}\cdot t)$), using a nonlinear least-squares treatment. The reported data are the average of duplicate measurements (reproducibility ≤ 10%).

Synthesis and Coordination of the New Chiral Tridentate O,N,O Ligand 2,6-Bis[(1*S*,2*S*,5*R*)-(−)-menthyl]pyridine to Molybdenum(VI) and Vanadium(V) Oxo Complexes: Crystal Structures of [(2,6-Bis{(−)-menthyl}pyridine)MoO_2] and [(2,6-Bis{(−)-menthyl}pyridine)$VO]_2$(μ-O)

Keywords: Molybdenum / Vanadium / Chiral ligands / Oxo complexes / Homogeneous catalysis

The novel tridentate chiral ligand 2,6-bis{(–)-menthyl}-pyridine (**1**), was readily prepared from the reaction of 2,6-dilithiopyridine with (–)-menthone. Reaction of **1** with $VO(OiPr)_3$ and $[MoO_2(acac)_2]$ resulted in the formation of the new metal-oxo complexes $[VO(ONO)]_2$(μ-O) (**2**) and $[MoO_2(ONO)]$ (**3**) [ONO = (**1** – 2 H)]. Both metal-oxo compounds **2** and **3** have demonstrated the ability to catalyze the asymmetric oxidation of prochiral olefins with *t*BuOOH as the oxidant. The compounds **1**–**3** have been fully characterized by ^1H, ^{13}C and ^{51}V (where appropriate) NMR spectroscopy, mass spectrometry, microanalysis and IR spectroscopy. Furthermore, the molecular structures of **2** and **3** have been determined by single-crystal X-ray diffraction.

Introduction

Vanadium(V) and molybdenum(VI) compounds[1,2] are of great importance in catalytic reactions involving oxidation processes. Nature makes use of both of these metal centers in oxidation reactions, for example in vanadium bromoperoxidases[3] and molybdenum oxotransferase enzymes.[4] Our interest in this area lies mainly in the development of new asymmetric oxidation catalysts[5,6] using novel tridentate chiral ligands possessing nitrogen and oxygen donor atoms. It has previously been demonstrated that asymmetric tridentate bis-alkoxy nitrogen donor ligands can be used in epoxidation reactions,[7,8] as well as oxo transfer reactions to sulfides,[9] with peroxides as the co-oxidant. However, in the former case, selectivity appears to be lower than in other known systems, while in the latter, the nature of the catalytically active species remains uncertain. Dioxomolybdenum(VI) complexes containing achiral pyridine alkoxy ligands have also been shown to have great potential in the oxidation of terminal olefins with molecular oxygen.[10,11] Herein we describe the synthesis of the novel tridentate chiral ligand 2,6-bis{(−)-menthyl}pyridine (**1**) and its coordination to vanadium and molybdenum to give the new asymmetric oxo complexes $[VO(ONO)]_2$(μ-O) **(2)** and $[MoO_2(ONO)]$ **(3)** {ONO = 2,6-bis{(−)-menthyl}-pyridine}. The molecular structures of **2** and **3** are presented and their potential as asymmetric epoxidation catalysts discussed.

Results and Discussion

The new chiral ligand 2,6-bis{(−)-menthyl}pyridine (**1**), characterized by ^1H and ^{13}C NMR spectroscopy, mass spectrometry and microanalysis, is readily prepared by the reaction of 2,6-dilithiopyridine with (−)-menthone. Reaction of the chiral pyridine-diol ligand **1** with $VO(OiPr)_3$ or $MO_2(acac)_2$ resulted in displacement of the weakly coordinated O*i*Pr or acac ligands to give the corresponding vanadium(V) and molybdenum(VI) oxo complexes $[VO(ONO)]_2$(μ-O) **(2)** and $[MoO_2(ONO)]$ **(3)** {ONO = 2,6-bis{(−)-menthyl}pyridine} in high yield (Scheme 1).

It was evident from the ^1H and ^{13}C NMR spectroscopic data that coordination of the C_2 symmetric ligand **1** to vanadium, to give complex **2**, resulted in two nonequivalent menthol moieties. Crystallographic analysis of a suitable crystal showed the complex to be dimeric in the solid state. The molecular structure of $\mathbf{2}\cdot C_6H_{12}$ is shown in Figure 1 and the selected bond lengths and bond angles are given in Table 1. Two five-coordinate vanadium atoms are bridged by an oxygen atom to form the binuclear asymmetric unit of the cell. The binuclear unit of **2** appears to be somewhat unique when compared to other V^V-V^V dimeric oxo complexes[12−14] as the two independent V atoms, V(1) and V(2), contain different coordination geometries. V(1) appears to possess a slightly distorted square pyramidal arrangement of ligands with the oxo ligand in the apical position and the metal center displaced 0.40 Å above the equatorial plane. However, V(2) is best approximated by a trigonal bipyramidal arrangement with the oxo and bridging oxo ligand in the equatorial plane (Figure 1). However, one could argue that V(1) is simply a more distorted trigonal bipyramidal arrangement of ligands than V(2). The V=O distances [V(1)−O(2) = 1.575(5) Å, V(2)−O(5) = 1.600(5) Å]

are characteristic of a double bond; however, the difference between the two values is intriguing and may be a consequence of the different coordination geometries of the two metal centers. The bridging oxo bond is unsymmetrical with V(1)−O(1) = 1.810(4) Å and V(2)−O(1) = 1.770(4) Å and the V(1)−O1−V(2) angle is 128.3(3)°, a rare example of a complex having a V−O−V angle near to 120°.[12] The two terminal oxygen atoms are *trans*-directed lying on opposite sides of the VOV plane (Figure 1). The remaining ligand-to-metal bonds are unexceptional.

The ^{1}H and ^{13}C NMR spectra of **3** showed, as expected, one set of resonances for the two menthol groups on the chiral pyridine-diol ligand suggesting the formation of a C_2-symmetric five-coordinate molybdenum dioxo complex. This was confirmed by solution IR spectroscopy which showed two sharp bands of equal intensity at 938 and 918 cm^{-1} for the symmetric and asymmetric stretch of the molybdenum-dioxo unit. However, interestingly, the IR spectrum in the solid state suggests that the molybdenum complex is oligomeric as no sharp or clear Mo=O stretches are observed. This was confirmed by a crystallographic analysis of a suitable crystal of **3**·C_6H_{14}, which revealed two independent five-coordinate mononuclear complexes that are weakly associated by two Mo=O···Mo interactions to give an essentially "binuclear" structure. The molecular structure of **3**·C_6H_{14} is shown in Figure 2, and selected bond lengths and bond angles are given in Table 1. A sim-

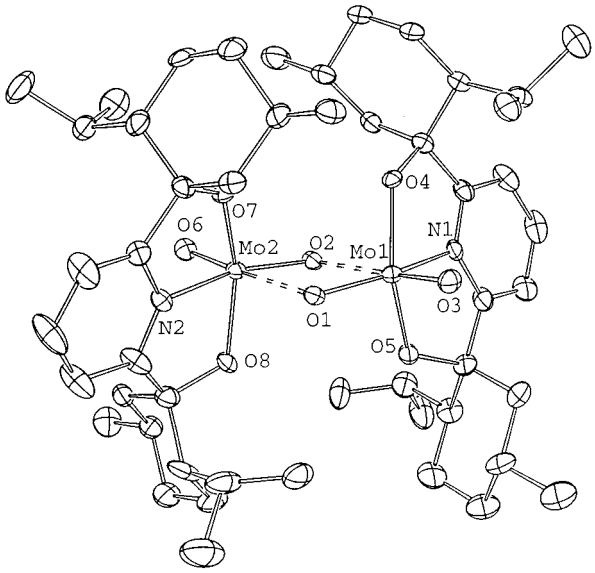

Figure 2. Molecular structure of [(2,6-Bis{(−)-menthyl}pyridine)-MoO_2]·C_6H_{14} (**3**).

ilar interaction can be seen in the structure of $[MoO_2(C_5H_3N\text{-}2,6\text{-}(CH_2O)_2)]_n$[15] where the Mo=O···Mo interaction in this case leads to a "linear" polymeric structure, with the sixth site in the distorted octahedral coordination sphere occupied by an oxo atom of an adjacent molecule. The "dimer" formation of **3** in the solid state provides a new structural type for dioxomolybdenum(VI) complexes. Typically, five-coordinate dioxomolybdenum(VI) complexes have been found to be monomeric[7,16] or polymeric.[15] Complex **3** has a distorted octahedral stereochemistry containing *cis*-oxo groups with the Mo=O unit of the second molecule *trans* to the oxo group. The terminal Mo=O distances [1.694(9) Å, 1.692(8) Å] are similar to other known Mo=O distances.[17] The Mo=O moiety that is found to interact with the second metal center is slightly longer [1.763(7) Å, 1.754(7) Å] than the other Mo=O bond lengths;[17] however, the distances are still short enough to suggest that the Mo=O bond retains much of its double bond character. The Mo···O interactions [2.438(9) Å, 2.426(8) Å] are too large to be considered a formal bond, but are in line with the Mo···O=Mo distance found in the polymeric complex $[MoO_2(C_5H_3N\text{-}2,6\text{-}(CH_2O)_2)]_n$ (2.518(3) Å). However, the Mo···O=Mo angles in **3** [105.88(3)°, 105.72(3)°] are considerably smaller than in the polymeric structure [151.7(2)°].[15] The remaining chiral pyridine-diol ligand bonds to the molybdenum center are unexceptional.

Conclusion

We have demonstrated the facile two-step synthesis of a new, inexpensive, chiral pyridine-diol ligand **1** and its coordination to both V^V and Mo^{VI} metal centers to form the metal oxo complexes **2** and **3**. Preliminary studies show that both complexes **2** and **3** (1 mol-%) are active in the catalytic asymmetric epoxidation of 1-hexene in conjunction with *t*BuOOH: 50% conversion into the epoxide has been observed for both metal complexes with an enantiomeric excess of up to 25%. Further work is underway to optimize the selectivity of this reaction and to test the versatility of complexes **2** and **3**. The coordination properties of the asymmetric ligand **1** to other metal centers will also be investigated further.

Experimental Section

General Remarks: Unless otherwise specified, all reagents were purchased from commercial suppliers and used without purification. All experiments were carried out using dried solvents and under a nitrogen or argon atmosphere, using a Schlenk line or a Vacuum Atmospheres glovebox equipped with a Dri-Train HE-493 inert atmosphere purifier. − ^1H (300 MHz) and $^{13}C\{^1H\}$ (75 MHz) NMR spectra were recorded on a Bruker AC300 NMR spectrometer and referenced to Me_4Si; ^{51}V (105 MHz) NMR spectra were recorded on a Bruker AM400 NMR spectrometer and referenced to $VOCl_3$. − FTIR spectra were recorded using a Perkin−Elmer Model FTIR-1600 spectrometer on KBr discs. − Mass spectrometry and elemental analyses were carried out by the corresponding facilities at the Chemistry Research Center at the Université Louis Pasteur, Strasbourg.

Synthesis of 2,6-Bis{(−)-menthyl}pyridine (1): To a solution of *n*BuLi (69.0 mmol, 43.50 mL, 1.6 M in hexane) in 100 mL of THF was added dropwise a solution of 2,6-dibromopyridine (7.50 g, 31.5 mmol) in 50 mL of THF at −100 °C. After 1 hour at −100 °C and 3 hours at −78 °C, a solution of (−)-menthone (11.55 g, 75.0 mmol) in 25 mL of THF was added slowly. The mixture was then left to warm to room temperature overnight. Distilled water (500 mL) was then added and the organic phase extracted with 2 × 150 mL of diethyl ether. The collected organic phases were washed with a solution of $NaHCO_3$, dried over $MgSO_4$ and the solvents removed under vacuum to afford a yellow oil. This yellow oil was purified by the preparation of the pyridinium salt by reaction with the resolving agent D-(1*S*)-(+)-camphor-10-sulfonic acid. Thus, a solution of D-(1*S*)-(+)-camphor-10-sulfonic acid (7.31 g, 31.5 mmol) in 100 mL of acetonitrile was added to the yellow oil. After reduction of the volume to 40 mL, 250 mL of diethyl ether was added. The flask was then cooled to −25 °C and colorless crystals formed overnight. The crystals were collected, washed with cold diethyl ether and dried under vacuum (8.80 g). Finally, the crystals were dissolved in CH_2Cl_2 and washed with an aqueous solution of $NaHCO_3$. The solution was then dried over $CaSO_4$ and the solvent removed to afford **1** as a colorless oil (4.0 g, 30%), which was shown to be optically pure by chiral HPLC (Chiralcel OD column). − ^1H NMR (300 MHz, $CDCl_3$): δ = 0.66 [d, ^3J = 6.9 Hz, 6 H, CH_3 (menthone)], 0.81 [d, ^3J = 6.8 Hz, 6 H, CH_3 (ment.)], 0.90 [d, ^3J = 6.4 Hz, 6 H, CH_3 (ment.)], 0.95−1.30 [m, 4 H, CH_2 (ment.)], 1.40−2.00 [m, 16 H, CH, CH_2 (ment.)], 4.2 (very broad, OH), 7.33 [d, ^3J = 7.8 Hz, 2 H, CH (arom.)], 7.70 [t, ^3J = 7.8 Hz, 1 H, CH (arom.)]. − $^{13}C\{^1H\}$ NMR (75 MHz, $CDCl_3$): δ = 18.5 [2 CH_3 (ment.)], 21.6 [2 CH_2 (ment.)], 22.2 [2 CH (ment.)], 23.4 [2 CH (ment.)], 27.2 [2 CH_3 (ment.)], 28.4 [2 CH_3 (ment.)], 35.1 [2 CH_2 (ment.)], 50.0 [2 CH_2 (ment.)], 49.6 [2 CH (ment.)], 78.0 (2 C−OH), 117.1 [2 C (arom.)], 137.4 [C (arom.)], 163.7 [2 C (arom.)]. − IR (KBr): $\tilde{\nu}$ = 3462 (s br), 2952 (s), 2868 (s), 1580 (w), 1577 (m), 1456 (s), 1386 (m), 1366 (m), 1294 (w), 1264 (w), 1165 (m), 1160 (m), 1094 (w), 1058 (m), 1023 (w), 978 (w), 948 (m), 910 (w), 891 (w), 852 (w), 807 (m), 756 (m), 714 (w), 671 (w), 641 (w), 516 (w) cm^{-1}. − MS (EI +): *m*/*z* = 387.3 [M^+]. − $C_{25}H_{41}NO_2$ (387.61): calcd. C 77.47, H 10.66, N 3.61; found C 77.36, H 10.45, N 3.62.

Synthesis of [(2,6-Bis{(−)-menthyl}pyridine)VO]$_2$(μ-O) (2): Ligand **1** (0.120 g, 0.31 mmol) was dissolved in CH_2Cl_2 (5 mL), treated with [VO(O*i*Pr)$_3$] (0.073 g, 0.30 mmol) and stirred for 2 hours at room temperature. The solvent was then removed under vacuum and the resulting solid redissolved in ether (3 mL). Distilled water (5 μL) was then added and the solution left to crystallize overnight at 4 °C. The resulting yellow crystals were collected and dried under vacuum (120 mg, 86%). − ^{1}H NMR (300 MHz, $CDCl_3$): δ = 0.73 [d, ^3J = 6.9 Hz, 6 H, CH_3 (menthone)], 0.81 [d, ^3J = 6.9 Hz, 6 H, CH_3 (ment.)], 0.87 [d, ^3J = 6.7 Hz, 6 H, CH_3 (ment.)], 0.90 [d, ^3J = 6.6 Hz, 6 H, −CH_3 (ment.)], 1.09 [d, ^3J = 6.8 Hz, 12 H, CH_3 (ment.)], 1.20−2.20 [m, 30 H, CH_2, CH (ment.)], 2.65 [m, 2 H, CH (ment.)], 7.14 [d, ^3J = 7.6 Hz, 2 H, CH (arom.)], 7.16 [d, ^3J = 7.7 Hz, 2 H, CH (arom.)], 7.88 (dd, ^3J = 7.7 Hz 2 H, CH (arom.)]. − ^{13}C {^{1}H} NMR (75 MHz, $CDCl_3$): δ = 19.0 [CH_3 (ment.)], 19.4 [CH_3 (ment.)], 21.4 [CH_2 (ment.)], 22.0 [CH_2 (ment.)], 22.4 [CH (ment.)], 22.7 [CH (ment.)], 23.9 [CH (ment.)], 24.2 (CH (ment.)], 28.3 [CH_3 (ment.)], 35.5 [CH_2 (ment.)], 50.7 [CH_2 (ment.)], 51.7 [CH (ment.)], 99.2 [C (ment.)], 99.7 [C (ment.)], 117.0 [CH (arom.)], 117.3 [CH (arom.)], 141.6 [CH (arom.)], 175.7 [C (arom.)]. − ^{51}V NMR (105 MHz, $CDCl_3$): δ = −533 ($\nu_{1/2}$ = 163 Hz). − IR (KBr): $\tilde{\nu}$ = 3069 (w), 2949 (s br), 2865 (s br), 1600 (m), 1579 (m), 1466 (s), 1384 (w), 1365 (w) 1296 (m), 1205 (w), 1144 (w), 1057 (w), 976 (s), 949 (s), 900 (w), 864 (w), 808 (m), 761 (s), 714 (s), 596 (m), 530 (m), 516 (m) cm^{-1}. − MS (CI (−)]: *m*/*z* (%) = 469.3 (100) 1/2 [M + H]$^-$. − $C_{50}H_{78}N_2O_7V_2$ (921.05): calcd. C 65.20, H 8.54; found C 66.11, H 8.48.

Synthesis of [(2,6-Bis{(−)-menthyl}pyridine)MoO$_2$] (3): [MoO_2(acac)$_2$] (0.820 g, 2.51 mmol) was dissolved in MeOH (40 mL) and treated with ligand **1** (1.00 g, 2.58 mmol). The solution was then refluxed for 30 mins and, upon cooling, a white precipitate was formed. The reaction mixture was filtered and the white solid dried in vacuo (0.900 g, 70%). − ^{1}H NMR (300 MHz, $CDCl_3$): δ = 0.78 [d, ^3J = 6.8 Hz, 6 H, CH_3 (menthone)], 0.93 [d, ^3J = 6.3 Hz, 6 H, CH_3 (ment.)], 0.95 [d, ^3J = 6.7 Hz, 6 H, CH_3 (ment.)], 1.01−2.01 [m, 18 H, CH_2, CH (ment.)], 7.34 [d, ^3J = 7.7 Hz, 2 H, CH (arom.)], 8.14 (dd, ^3J = 7.7 Hz, 1 H, CH (arom.)]. − ^{13}C {^{1}H} NMR (75 MHz, $CDCl_3$): δ = 18.9 [CH_3 (ment.)], 21.8 [CH_2 (ment.)], 22.1 [CH (ment.)], 23.9 [CH (ment.)], 28.4 [CH_3 (ment.)], 34.9 [CH_2 (ment.)], 50.1 [CH_2 (ment.)], 51.1 [CH (ment.)], 98.9 [C (ment.)], 118.4 [CH (arom.)], 143.7 [CH (arom.)], 173.3 [C (arom.)]. − IR (KBr): $\tilde{\nu}$ = 3071 (w), 2950 (s br), 1605 (m), 1578 (m), 1469 (s), 1384 (m), 1363 (m), 1297 (s), 1205 (m), 1173 (m), 1145 (m), 1106 (w), 1093 (w), 1062 (s), 1030 (m) 1010 (m), 978 (s), 936 (s br), 860 (s), 835 (m), 802 (m), 759 (m), 708 (s), 674 (w), 626 (w), 588 (m), 552 (m), 515 (s), 478 (m), 373 (w) cm^{-1}. − IR (CH_2Cl_2): $\tilde{\nu}$ = 938 ($\nu_{(Mo=O)}$, symmetric), 918 ($\nu_{(Mo=O)}$, asymmetric) cm^{-1}. − MS (EI +): *m*/*z* = 515.2 [M$^+$]. − $C_{25}H_{39}MoNO_4$ (513.52): calcd. C, 58.47, H 7.65, N 2.73; found C 58.53, H 7.77, N 2.89.

X-ray Crystallographic Study: The oxo complexes **2**·C_6H_{12} and **3**·C_6H_{14} were crystallized by slow diffusion of cyclohexane and hexane, respectively, layered onto a solution of the complex in dichloromethane. The intensity data were obtained at 173 K with graphite monochromated Mo-K_α radiation (λ = 0.71073 Å) on a Nonius Kappa CCD diffractometer. The structures were solved using direct methods and refined against $|F|$. Hydrogen atoms were introduced as fixed contributors. For all computations the Enraf−Nonius MolEN package was used.[18] Additional data collection and refinement parameters are presented in Table 2.[19] The absolute configuration of each compound was determined and confirmed: Flack parameters were 0.08(3) for **2**·C_6H_{12} and 0.03(7) for **3**·C_6H_{14}.

Table 2. Crystal data and summary of intensity data collection and structure refinement of **2**·C_6H_{12} and **3**·C_6H_{14}

Emperical formula	**2**·C_6H_{12} $C_{50}H_{78}N_2O_7V_2\cdot C_6H_{12}$	**3**·C_6H_{14} $C_{50}H_{78}N_2O_8Mo_2\cdot C_6H_{14}$
