The properties of prosthetic groups in enzymes are often governed by the protein matrix. Well-known examples are the iron−porphyrin complexes in proteins and enzymes, which can have various properties and functions depending on, e.g., the axial ligation of the central metal ion.[1] Such effects have been studied in great detail in model systems.[2] Another well-studied example is the group of proteins that incorporate an Fe_4S_4 cluster in their active sites. The factors that determine the properties of the cluster are reasonably well understood, largely due to the pioneering model studies by the group of Holm.[3] Fe_4S_4-containing electron-transfer proteins can be divided into two classes, viz. ferredoxins and high-potential iron−sulfur proteins (HiPIP′s), which have low and high reduction potentials, respectively, compared to most physiological redox partners. Of the various oxidation states possible for Fe_4S_4 clusters, ferredoxins cycle between the $[Fe_4S_4(SR)_4]^{2-}$ and $[Fe_4S_4(SR)_4]^{3-}$ states, and HiPIP′s between the $[Fe_4S_4(SR)_4]^{1-}$ and $[Fe_4S_4(SR)_4]^{2-}$ states.[4a] Apart from this, the differences between these two classes are assumed to arise from (i) the number of hydrogen bonds between the peptide backbone and the cluster or its ligands,[4b] (ii) the hydrophobicity of the protein environment of the cluster,[4c] and (iii) the accessibility of the cluster to solvents. The first two aspects have been rather well mimicked with the help of model systems, but model studies on the latter aspect have been much more limited. Okuno and co-workers have described an Fe_4S_4 cluster ligated by a macrocyclic tetradentate thiol ligand.[5] In DMSO solution, the 1^- oxidized state of this cluster, which can be considered as a model of the oxidized form of a HiPIP, was found to be stabilized by the lipophilic macrocyclic ligand. Tabushi et al. have prepared a cluster sandwiched between two cyclodextrin rings.[6] Although this compound showed a remarkable stability in water, no effect of the cyclodextrin moiety on the redox potentials of the Fe_4S_4 cluster was observed. Gorman et al.[7] have shown that increasing the generation of ligands of Fe_4S_4 clusters encapsulated by dendrimers makes the cluster both kinetically and thermodynamically more difficult to reduce. Several half-encapsulated clusters have been reported in the literature, e.g. the 3:1 subsite-differentiated clusters prepared by Holm et al.,[4a−4c] Evans et al.,[8a] and Nolte et al.,[8b−8d] and a tetrathiol-derived cluster based on diphenylglycoluril.[8e][8f] For these clusters, only a slight influence of the ligands on the redox potentials of the Fe_4S_4 core was observed. Apparently, a snug and spherical ligand arrangement is needed to provide a synthetic Fe_4S_4 cluster with a solvophobic environment that stabilizes a higher oxidation state.

In this paper, we describe the synthesis of two bowl-shaped dithiol ligands $\mathbf{L^{Xyl}}2H$ and $\mathbf{L^{Ac}}2H$ (see Chart 1), together with the synthesis and characterization of their Fe_4S_4 cluster compounds **A** and **B**. These ligands were designed with the idea that binding to an Fe_4S_4 cluster would lead to a "closed shell" structure showing interesting redox properties. Figure 1 shows the energy-minimized structure

of cluster compound **B**. The space-filling representation (left) suggests that the cluster core (shown in light) is fully encapsulated within the two receptor ligands. Another reason for choosing $L^{Xyl}2H$ and $L^{Ac}2H$ is that these ligands contain receptor sites for binding metal ions and organic guest molecules.[9,10] This opens the possibility of investigating how the electrochemical properties of compounds **A** and **B** change under the influence of such ions and guests.

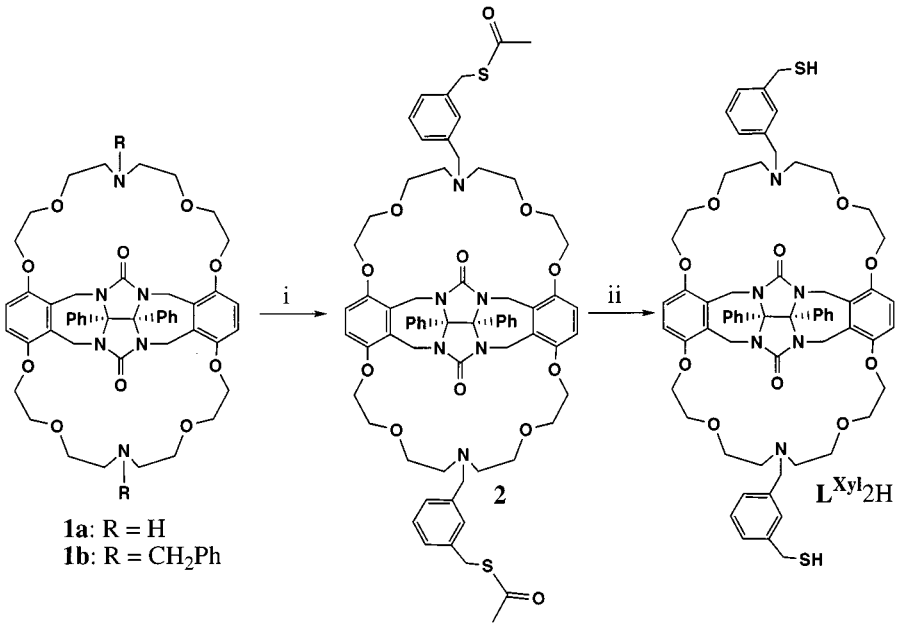
Results and Discussion

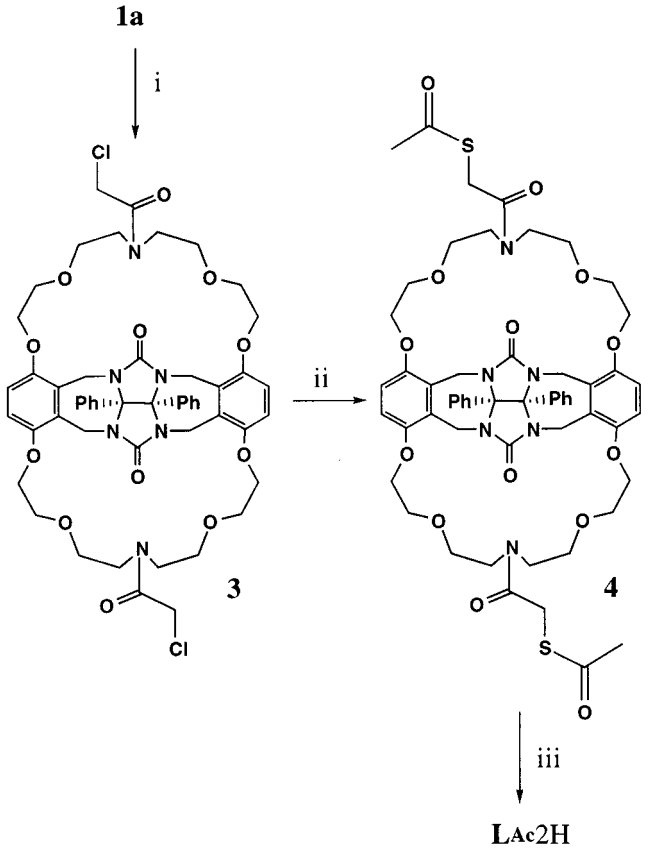
Ligand Synthesis

The ligands $L^{Xyl}2H$ and $L^{Ac}2H$ were synthesized by routes analogous to those that we have used previously for the synthesis of the corresponding crown ether thiols.[9] Starting from the diaza receptor molecule **1a**, alkylation with two equivalents of α-bromo-α′-thioacetyl-*m*-xylene yielded the protected dithiol **2** (see Scheme 1). Removal of the acetate protecting groups was effected by treatment with 3% HCl in methanol. As it was not desirable to subject dithiol $L^{Xyl}2H$ to any purification procedure due to its air sensitivity, the deprotection time was extended to 7 days. TLC analysis indicated that this period was required to ensure complete deprotection of **2**. The overall yield of $L^{Xyl}2H$ was 46%.



Scheme 2 depicts the synthetic route for the preparation of the dithiol ligand $L^{Ac}2H$. Amidation of receptor **1a** with 2 equivalents of α-chloroacetyl chloride gave compound **3** in reasonable yield (60%). Treatment of this compound with an excess of potassium thiocarboxylate resulted in the formation of the dithioacetate **4**, which was deprotected over a period of 5 days by treatment with 3% HCl in methanol. This procedure gave dithiol $L^{Ac}2H$ in 54% overall yield.

Conformational and Binding Properties of Amidated Receptors 3 and 4



Although chromatographic analysis indicated that the receptor compounds **3** and **4** were pure, ^{1}H NMR analysis was initially considered to be indicative of the additional presence of other receptor species. Due to conformational restrictions, the protons of the methylene groups connecting the aromatic side-walls to the diphenylglycoluril backbone in **3**, **4**, and $L^{Ac}2H$ behave as AX spin systems.[11] Figure 2 depicts the resonances of the two methylene protons (H_a) in **3** that point upwards in relation to the receptor backbone. The other half of the AX system is obscured by the signals of the crown ether rings. Three doublets for receptors **3** and $L^{Ac}2H$ and two for receptor **4** are observed at around $\delta = 5.7$, instead of just one doublet as anticipated beforehand. Additionally, a multiplet is found for the aromatic wall protons, which normally give a singlet. This splitting is also evident in the ^{13}C NMR spectra of these compounds, where multiple signals are seen for the carbon atoms to which the aforementioned protons are attached.

^{1}H NMR experiments in which the temperature dependence of the multiple signals was monitored showed that these features can be ascribed to the presence of slowly interconverting conformers of one and the same compound. Increasing the temperature results in coalescence of the multi-doublet signals into one doublet and of the multiplet into one singlet (not shown). The coalescence temperatures were determined as 340 K for receptor **3** and 325 K for receptor **4** (90 MHz).

Apparently, amidation of the nitrogen atoms in the aza-crown ether rings of the basket-shaped receptor molecules

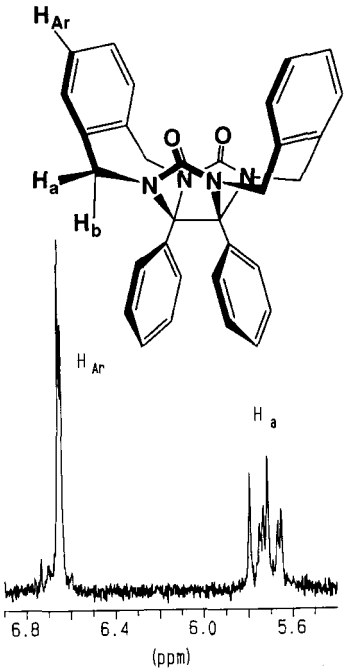

Figure 2. ^1H NMR spectrum of compound **3** in $CDCl_3$ (298 K)

introduces considerable rigidity into these systems. As a result, several conformations can be observed by NMR. Figure 3 shows the different orientations that the amide functions can adopt with respect to the rest of the receptor molecule; the corresponding conformers are proposed to be slowly interconverting on the NMR time scale. The amide functions can point either up or down with respect to the crown ether plane (Figure 3a) and in either position they can again occupy two orientations by rotation about the C(O)−N bond (Figure 3b). The latter two orientations are expected to interconvert more easily than the "up/down" conformers. In the "down" position, the amide groups can be expected to exert a significant influence on the methylene AX spin system, resulting in different signals due to the difference in local environment enforced by these groups. In the "up" position, the amide groups do not have such an influence on this spin system. This explanation accounts for

the observation of three AX doublets with approximate intensity ratios of 1:1:2 in the case of **3**. In a similar way, the amide groups in the "up" positions create a different environment for the aromatic wall protons, whereas in the "down" position no such modification of the environment is induced. This accounts for the observation of multiple resonances for the protons and carbon nuclei of the aromatic side walls. The ease of interconversion of the conformers and, therefore, the spectral characteristics, will depend on the functionalization of the amide group. For this reason, three doublets are observed for the methylene H_a protons of receptors **3** and $\mathbf{L^{Ac}}2H$, as opposed to just two doublets for receptor **4**.

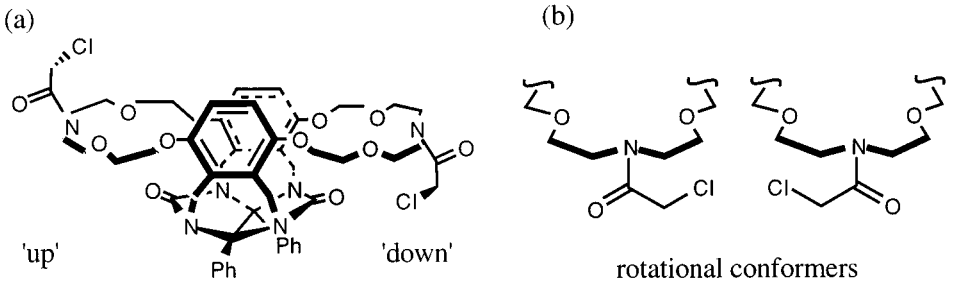

Figure 3. Different conformers of compound **3**

A liquid/liquid (chloroform/water) extraction experiment with potassium picrate revealed that potassium ions are weakly bound by receptor **3** (the association constant K_{ass} was not determined). NMR analysis showed that the presence of these ions did not influence the ratio of the conformers. Addition of resorcinol (1,3-dihydroxybenzene) to solutions of **3** in the presence or absence of K^+ ions resulted in one single AX pattern due to the H_a protons and a singlet due to the aromatic wall protons in the ^1H NMR spectrum. Apparently, the aromatic guest molecule is bound by just one of the conformers of **3**. On the basis of CPK models, we tentatively propose this to be the "up/up" conformer. The K_{ass} was determined as 640 ± 10 M^{-1}. This value is significantly lower than the association constants determined for resorcinol and the related receptors **1a** and **1b** (see Scheme 1, K_{ass} = 2000 and 2900 M^{-1}, respectively).[12] This low binding affinity is probably due to the extra energy that is needed to bring the receptor into the conformation for resorcinol binding.

Cluster Synthesis and Characterization

Procedures similar to those described previously[9] for the synthesis of crown ether-derived clusters were used to prepare the clusters $[Fe_4S_4(\mathbf{L^{Xyl}})_2](PPh_4)_2$ (cluster **A**) and $[Fe_4S_4(\mathbf{L^{Ac}})_2](PPh_4)_2$ (cluster **B**) from the two bidentate receptor ligands $\mathbf{L^{Xyl}}2H$ and $\mathbf{L^{Ac}}2H$, respectively. Initially, $[Fe_4S_4Cl_4](PPh_4)_2$ was used as the starting material for the synthesis of cluster **A**. A DMF solution of this compound was slowly added to a dilute DMF solution (< 1 mM) containing two equivalents of the ligand $\mathbf{L^{Xyl}}2H$ and four equivalents of $(NBu_4)OH$ as a base. The progress of the reaction was monitored by DPV analysis of aliquots withdrawn from the mixture. Besides the formation of the desired product, characterized by a reductive peak at −1.74 V, an unknown by-product was also observed ($E_{p,c}$ = −1.36 V). At the point where DPV analysis indicated no further change in the composition of the reaction mixture, the products were isolated by means of precipitation followed by filtration. The by-product was removed by washing with CH_2Cl_2. NMR analysis showed that the desired Fe_4S_4 product was isolated as the tetrabutylammonium salt, probably because this salt is less soluble than the tetraphenylphosphonium salt. After isolation and washing with CH_2Cl_2, the product obtained was indeed found to be poorly soluble; it did not dissolve in DMF and only very poorly in DMSO.

Attempts to prepare cluster **A** through in situ synthesis in an electrochemical cell failed. An unidentified precipitate was formed, which might have originated from the excess tetrabutylammonium salt present as the supporting electrolyte. These procedures either failed to yield the desired product or produced it in a form unsuitable for further analysis. $[Fe_4S_4(S\mathit{t}Bu_4)](PPh_4)_2$ was therefore used as the starting material in all subsequent experiments. The fact that no base is needed with this starting material was thought to be favourable for the syntheses of the clusters **A** and **B**. Ligand-exchange reactions were performed by applying a dynamic vacuum after rapid mixing of dilute DMF solutions of the *tert*-butyl thiolate cluster with two equivalents of the appropriate ligand. After six hours, DPV analysis was indicative of complete conversion into a single product in each case. Both cluster compounds were isolated as black, shiny solids. We were unable to grow crystals from the isolated materials; the use of counterions known to favour crystallization of related compounds, i.e. $(NBu_3Bzl)^+$,[13] was not successful in the present case.

The newly synthesized cluster compounds were first characterized by electrochemical means. Our earlier experience with crowned cluster compounds showed this to be an excellent method for examining the formation of the clusters as well as their redox chemistry.[9] Due to the sensitivity of the CV and DPV techniques, it was also anticipated that any formation of soluble oligomeric or polymeric materials would be detectable in this way.

Table 1 lists the electrochemical characteristics of the $2^-/3^-$ reduction of cluster compounds **A** and **B** in DMF solution. The half-wave potentials ($E_{1/2}$) for reduction of these compounds resemble the values determined for related crown ether-functionalized clusters, e.g. **D**.[9] On CV ana-

lysis, a chemically reversible reduction process was observed for cluster **A**, whereas this process was found to be electrochemically quasi-reversible due to a relatively slow electron-transfer rate. For cluster **B**, the opposite behaviour was found, viz. an electrochemically reversible but chemically quasi-reversible reduction (see Figure 4). These results are indicative of significantly better defined redox processes for clusters **A** and **B** than for the previously studied crowned cluster compounds. Apparently, the fact that the cluster cores in **A** and **B** are ligated by bidentate rather than monodentate ligands prevents the occurrence of irreversible redox chemistry involving thiolate ligands not coordinated to the cluster core. The peak separations suggested that no oligomeric or polymeric materials had been formed, as much larger separations would have been expected if this had been the case. For neither of the two cluster compounds was a reversible $2^-/1^-$ oxidation process observed.

Table 1. Electrochemical characteristics of the $2^-/3^-$ reduction of cluster compounds **A** and **B** in DMF

[a]	Electrode	**A** Pt	PGE	**B** Pt	PGE
CV	$E_{1/2}$ (V)	−1.78	−1.75	−1.60	−1.64
	ΔE_p (mV)	100	90	70	60
	i_b/i_f	1.0	−[b]	0.59	−[b]
DPV	E_p (V)	−1.74	−1.74	−1.62	−1.61
	$W_{1/2}$ (mV)	107	160	140	108

[a] Potentials are given against the Fc/Fc^+ couple in the same solvent. PGE = Pyrolytic graphite edge. − [b] Due to the large capacitative current these values could not be determined.

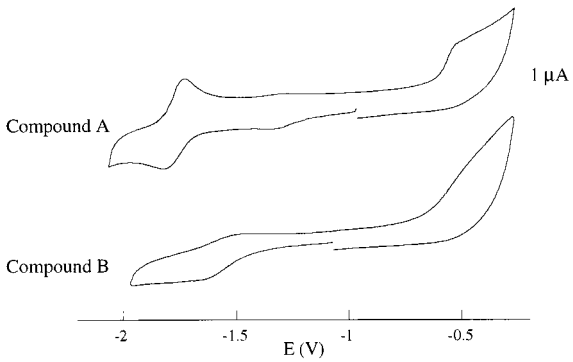

Figure 4. Cyclic voltammograms of compounds **A** and **B** in DMF (reductive scans, Pt working electrode)

Earlier studies by our group on semi-encapsulated cluster compounds showed that the use of graphite electrodes was advantageous in their electrochemical analysis.[7,8] In the present case, however, a graphite working electrode instead of a platinum one was not found to be beneficial. Instead, lower current responses were found, which complicated the analysis. No significant changes in peak potentials were observed. Moreover, compounds **A** and **B** could be electrochemically analyzed without the need for Ba^{2+} ions as promoting or modulating species. This clearly sets these compounds apart from their semi-encapsulated analogues[8b−8f] and suggests that the cluster cores in **A** and **B** are surrounded by the ligands in such a way that no effective dipole moment exists in these complexes. These results also confirmed that complexes **A** and **B** were isolated as monomeric materials.

It was hoped that by surrounding the Fe_4S_4 cluster with a large spherical ligand a solvophobic environment around the cluster core might be created and that the redox centre would be shielded from the electrode. However, the electrochemical properties of **A** and **B**, as outlined above, do not suggest that this shielding is effective for either of the two compounds. This is not unexpected for **A** because the xylylene spacers between the cluster and the receptor sites in this compound are relatively long, exposing the redox site to the solvent and to the electrode surface. On the other hand, modelling studies suggested that compound **B** should be able to adopt a compact and closed structure (see also Figure 1). As such a structure was seemingly not present in DMF, we decided to use DMSO as the solvent for the electrochemical measurements. The choice of DMSO was based on NMR studies (vide infra), which indicated that the Fe_4S_4 core of **B** is tightly embraced by its ligands in this solvent. For comparison purposes, the electrochemical properties of two structurally related cluster compounds were also studied in this solvent. These compounds bear dibutylamine (compound **C**) and monoaza-18-crown-6 acetyl thiolate ligands (compound **D**), respectively (see Chart 1).[9]

For the dibutylamine thiolate functionalized compound **C**, a reversible reduction process was observed under normal conditions (not shown). A small pre-wave was visible for the $2^-/3^-$ reduction process ($E_{1/2}$ = −1.52 V), which arises either because of coordination of solvent molecules to the cluster core or due to absorption of the reduced species onto the electrode. For the crown ether functionalized compound (cluster **D**), the current response was rather low and again a pre-wave associated with the reduction of the cluster was observed. The addition of $Ba(ClO_4)_2$ considerably improved the current response and also induced an anodic shift in the reduction potential ($E_{p,red}$ = −1.58 V). The origins of these effects have been discussed previously[9] and originate from metal ion binding by the crown ether ligands. For compound **B**, a poorly defined voltammogram was obtained, showing a very faint reductive feature at a similar potential as found for compound **D** in this solvent. Addition of $Ba(ClO_4)_2$ again led to an increased current response and an anodic shift in $E_{p,red}$. In this case, an irreversible reduction was observed at around −1.42 V, a potential similar to that measured for the pre-wave of compound **D**. For neither of the three cluster compounds was a clear, reversible oxidation process observed under any of the investigated conditions.

The results of the aforementioned experiments show that the increasing ligand size on going from cluster compound **C**, to **D**, and then **B** leads to increasingly hampered electron-transfer from the cluster compound to the electrode in DMSO. Furthermore, shielding of the cluster core by the large receptor ligand does not in this case lead to stabilization of higher oxidation states of the cluster. In previous studies, Okuno et al.[5] showed that their cluster compound, in which the cluster is coordinated by a sterically encum-

bered macrocyclic tetrathiolate ligand, undergoes a reversible $2^-/1^-$ transition in DMSO at a potential significantly more positive than that of several model compounds.[5] Data in DMF were not reported for this particular compound. Normally, higher oxidation states of iron–sulfur clusters would be expected to be stabilized in apolar solvents and destabilized in polar solvents such as DMF or DMSO.[14] Okuno and co-workers concluded that the compact structure of their compound in DMSO leads to stabilization of the 1^- oxidation state through the creation of a solvophobic environment. Although a similar behaviour might be expected in our system, the stabilization of a higher oxidation state is apparently not possible. This may be due to the rather polar nature of the crown ether fragments in our receptor ligands or due to the fact that the cluster core is still accessible to solvent molecules in spite of the tight ligand encapsulation.

The absorption spectra of compounds **A** and **B** were found to correlate very well with the spectra of the structurally related crown ether compounds (see Table 2).[9] This confirms that the Fe_4S_4 cubane core is retained in the new compounds. It also indicates that the local environment of the thiolate sulfur atoms[4c] in **A** and **B** is similar to that in the crown ether analogues. The ligand-to-metal charge-transfer (LMCT) absorption bands at ca. 400 nm in Fe_4S_4 clusters are known to undergo a blue shift in solvents of high ε.[15] Similar blue shifts have been observed for cluster compounds bearing sterically encumbered thiolate ligands, which were additionally shown to display reversible $2^-/1^-$ transitions in CV and were therefore presented as HiPIP

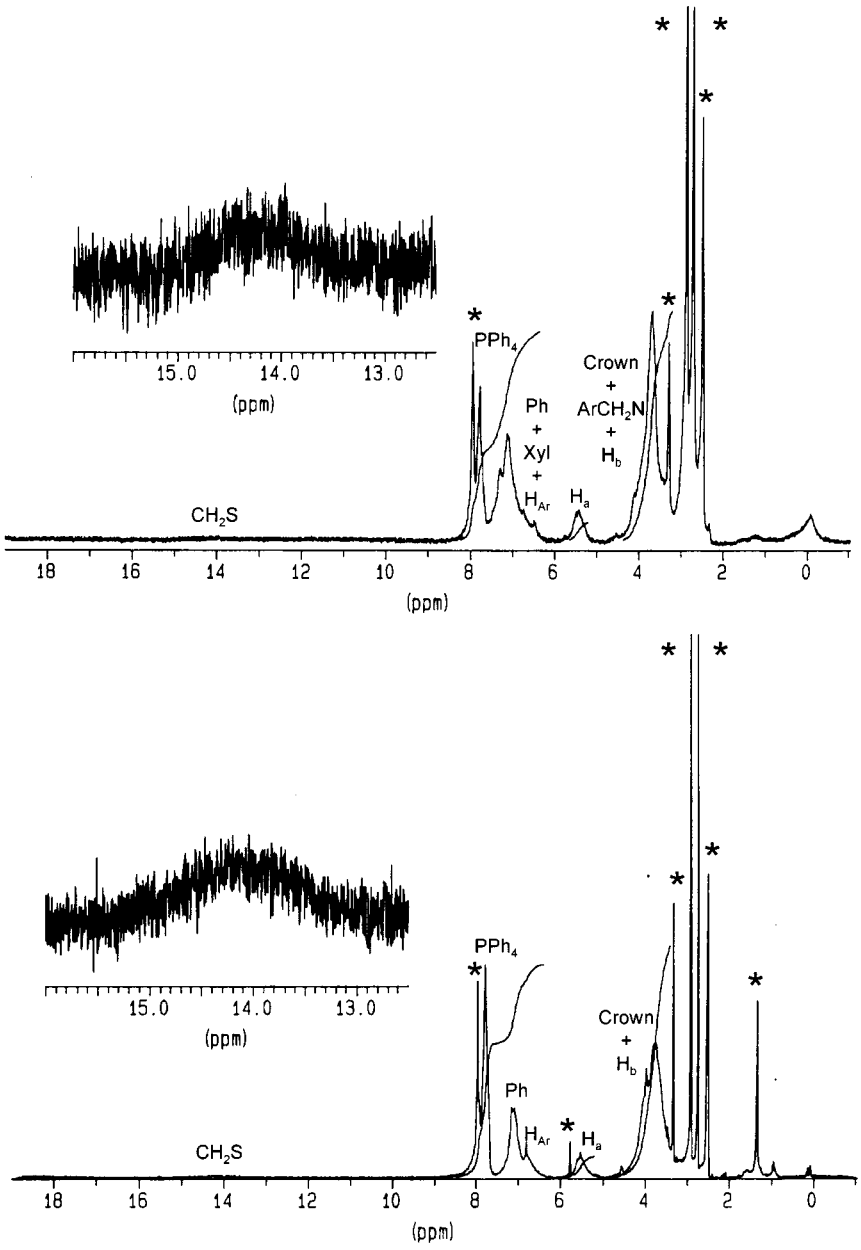

Figure 5. ^1H NMR spectra of cluster compounds **A** (top) and **B** (bottom) in $[D_6]$DMSO

models.[16] The fact that no such blue shifts are observed for compounds **A** and **B** is in line with their electrochemical behaviour (no reversible $2^-/1^-$ transitions).

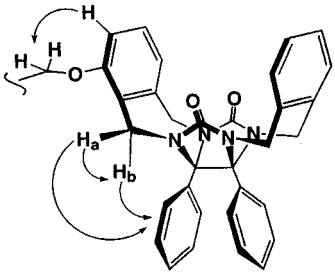

Table 2. UV/Vis data of cluster compounds in DMF

Compound	λ_{max}
A	290, 420, 620 (sh)
$[NBu_4]_2[Fe_4S_4(SBzl)_4]$	300 (sh), 420
B	295, 340 (sh), 415, 622 (sh)
C	301, 415, 620 (sh)
D	300, 410, 660 (sh)

The ^1H NMR spectra of compounds **A** and **B** exhibit the typical features of Fe_4S_4 thiolate clusters,[9] i.e. large chemical shifts and broadened peaks (see Figure 5). The resonances of the methylene protons adjacent to the thiolate sulfur atoms are observed as broad signals at around $\delta = 14$ (see Table 3 for details). The chemical shifts of these signals were found to increase linearly with temperature in the region 298−348 K (not shown). The other proton signals of **A** and **B** are also somewhat broadened, suggesting either that these protons lie in the proximity of a paramagnetic centre or that the complexes adopt different conformations that are in rapid exchange on the NMR time scale. A complete assignment of the peaks was performed in the case of compound **B** by means of a 2D-COSY experiment, the coupling constant of the $ArCH_2N$ protons of the diphenylglycoluril unit being determined by 2D-DQF-COSY experiments (see Experimental Section).

In cluster compound **D**, which, like compound **B**, also bears α-mercaptoacetyl ligands, the crown ether ligands have a somewhat restricted conformational freedom, as was concluded from the appearance of two discrete and relatively sharp signals due to the CH_2S protons.[9] Such an inequivalence in chemical shift is not observed for the CH_2S protons in **B**. Instead, the signals are broad, the width at half peak height being 1.4 ppm as compared to 0.4 ppm in the case of compound **D**. This broadening might be indicative of the superposition of several peaks, implying that two or more CH_2S groups in **B** have somewhat different orientations with respect to the cluster core, and hence that the ligation of the cluster core in **B** is not symmetrical. Moreover, some flexibility of the ligands with respect to the cluster core leading to slowly exchanging conformers might be possible. Similar considerations probably apply to compound **A**, the structure of which can be expected to be much more flexible than that of **B**.

Due to the broadening of the signals in the one-dimensional ^1H spectrum, it was not possible to establish whether the ligands of compound **B** existed in more than one conformation. The solution structure of compound **B** was therefore studied in more detail by means of a 2D-NOESY experiment. Part of the 2D-NOESY spectrum of compound **B** is shown in Figure 6. Several contact cross-peaks are apparent, first and foremost between the two $ArCH_2N$ protons of the diphenylglycoluril backbone themselves and between one of these protons (H_a) and the protons (PhH′s) of the phenyl rings at the bottom of the receptor ligand. In addition, an interaction is in evidence between the aromatic wall protons and the methylene protons in the crown ether part of the ligand. Most of these through-space interactions were expected on the basis of earlier NMR studies on diphenylglycoluril-based receptor molecules,[11] but the H_a−PhH interaction is new. 2D-NOESY experiments on compound **3** and cluster compound **A** showed no spatial proximity of these protons.

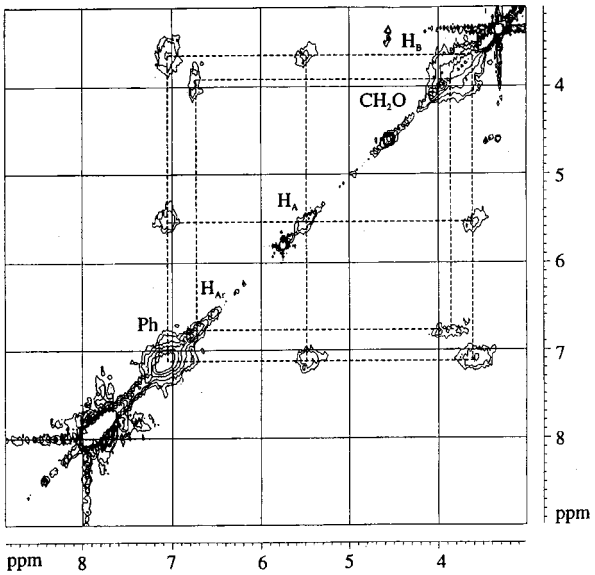

Figure 6. 2D-NOESY spectrum of cluster compound **B** in $[D_6]DMSO$

All the protons for which cross-peaks are observed (except the aforementioned H_a and PhH′s) can be assumed to lie in close proximity to one another on the basis of crystallographic analyses of two related receptor molecules[17] and of several other clip molecules.[18] Conformational isomers

Table 3. ^1H NMR temperature-dependence of isotropically shifted ligand signals in cluster compounds **A** and **B** in $[D_6]DMSO$

		Free ligand (δ/ppm)	Cluster (δ/ppm)	ΔH^{iso} (ppm)	$\Delta H^{iso}/T$ (Hz/K)
A	CH_2S	4.0	14.3	−10.3	−5.96
B	CH_2S	4.1	14.1	−10.0	−5.18

can be obtained by "flipping" the aromatic walls, as has been observed previously for receptor molecules bearing naphthalene walls.[19] Such a "flipping" process might explain the close proximity of H_a and the PhH′s, but it has never been observed for clip molecules with benzene walls. Examination of CPK models of compound **B** suggests that a different type of conformational rearrangement may occur in the backbone of ligand $\mathbf{L^{Ac}}$ upon coordination to an Fe_4S_4 cluster. In order to allow the two thiol groups of $\mathbf{L^{Ac}}$ to reach the cubane cluster, the receptor ligands have to adopt a bent conformation (see Figure 7). This leads to conformational stress in the two crown ether rings, which can be overcome by pushing the aromatic walls somewhat closer together; the latter process can be accomplished through rotation of the $ArCH_2N$ methylene groups. This, in turn, places these methylene groups in closer proximity to the phenyl rings at the rear side of the diphenylglycoluril framework. Overall, this would result in a more snug fit of the bidentate ligands around the cluster core.

pounds **A** and **B** in DPV upon the addition of various metal ions are listed in Table 4. These changes are all in the anodic direction, showing that reduction of the cluster cores is facilitated by the addition of metal ions. This also indicates a higher affinity of the reduced clusters for these metal ions as compared to the oxidized clusters. The addition of metal ions was found to have little if any influence on the chemical and electrochemical reversibility of the $2^-/3^-$ reductions of **A** and **B**, which was already satisfactory in the absence of any additive (vide supra).

The promoting effects of the various alkali metal ions, as evaluated from the increase in peak current (i_p) in DPV, are distinctly different for compounds **A** and **B** (not shown). For all the metal ions tested, a distinct promoting effect was seen in the case of **A**, but for **B** these effects were only observed with metal ions that also showed a significant modulating effect.[20] Except in the case of Li^+, addition of the first equivalents of a metal ion to compound **A** resulted in an increased current response in both DPV and CV, which

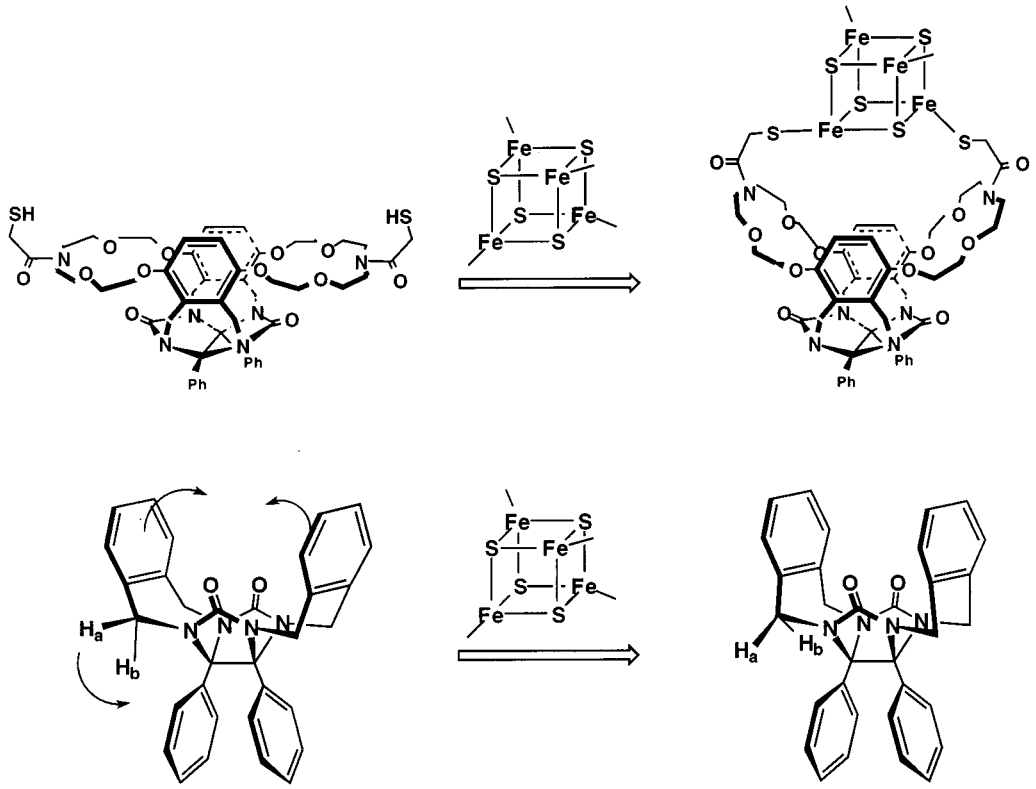

Figure 7. Proposed conformational rearrangement of the crown ether rings (top) and the aromatic walls (bottom) of the receptor ligands upon coordination to the cubane core in **B**

Electrochemical Response Towards Metal Ions

Compounds **A** and **B** each contain a redox-active site that lies in close proximity to two receptor sites for charged guests. It was therefore of interest to study the electrochemical behaviour of **A** and **B** towards alkali and alkaline earth metal ions. Figure 8 shows the titration curves of compound **A** with Na^+ and Ba^{2+} ions as followed by DPV and CV. The changes in the peak potentials (E_p′s) for compsuggests binding of the metal ions to this cluster compound (see Figure 8a and 8b, respectively, for Na^+). Figure 9 shows the titration curves, where E_p and i_p are plotted against the amount of metal ion added to compound **A**. For **B**, an increased current response was only observed with Ba^{2+} ions (titration curves not shown). We propose that the increased current responses seen in CV and DPV are not the result of electrode modifications (metal ion absorption), but are due to the fact that the overall negative

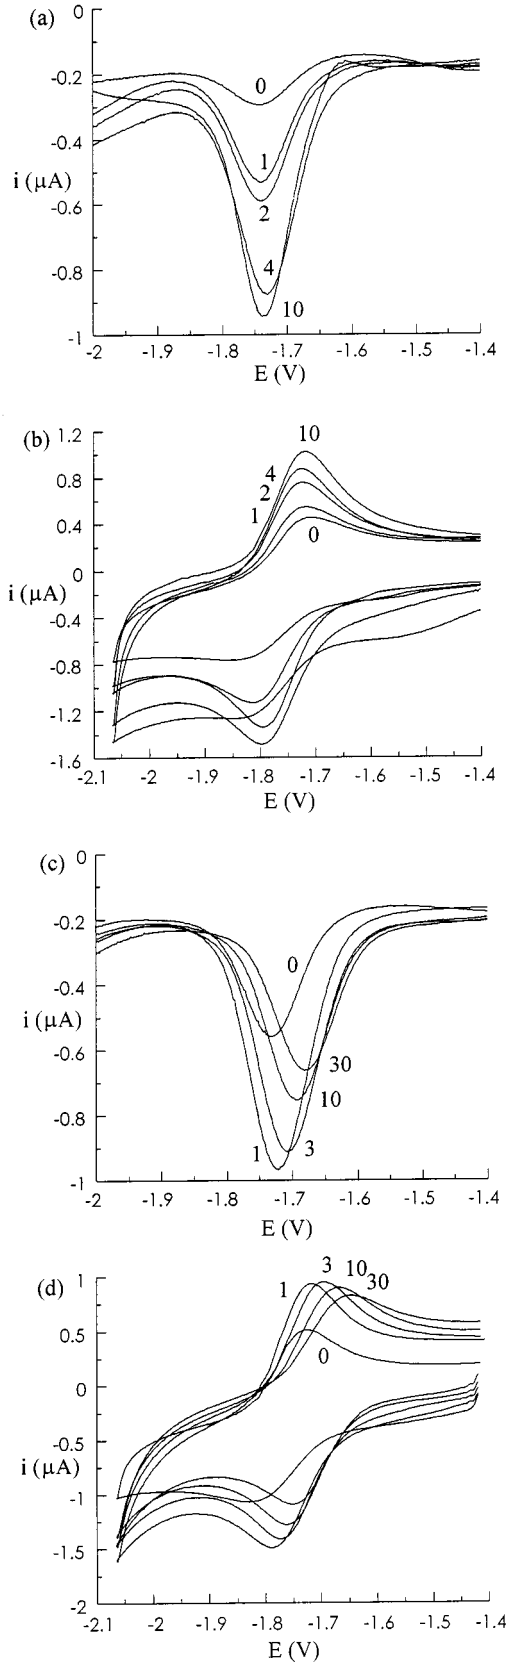

Figure 8. (a) DPV and (b) CV titrations of compound **A** with Na^+ ions; (c) DPV and (d) CV titrations of compound **A** with Ba^{2+} ions; numbers refer to the equivalents of metal ions per cluster

Table 4. Changes in DPV peak potentials (mV) of compounds **A** and **B** upon addition of 10 equivalents of various metal ions in DMF

	A[a]	**B**[a]
Li^+	(0)	(10)
Na^+	10 (30)	(0)
K^+	10 (20)	(20)
Mg^{2+}	0 (20)	(40)
Ba^{2+}	40 (50)	110 (140)

[a] The value for an excess of metal ions is given in brackets.

charge of the cluster is reduced or even becomes positive upon the binding of metal ions. The fact that no increase in current response is observed when Li^+, Na^+, or K^+ ions are added to compound **B** suggests that this receptor compound has a much lower affinity for these metal ions than compound **A**.

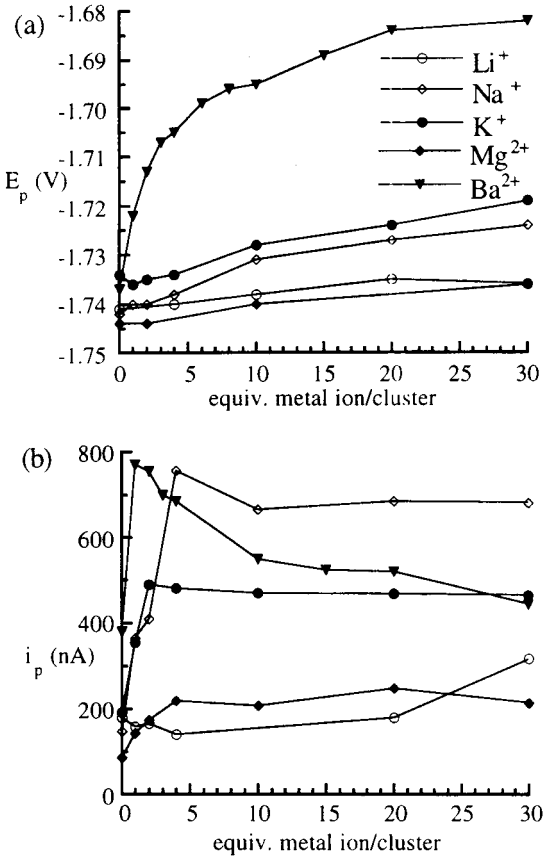

Figure 9. Titration of compound **A** with various alkali and alkaline earth metal ions as followed by DPV; (a) changes in E_p, (b) changes in i_p

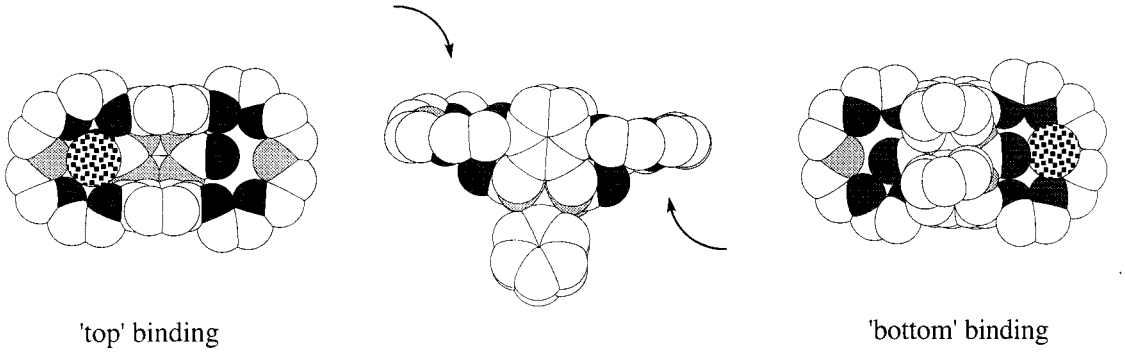
The changes in E_p for compound **A** are much smaller than those observed for the related crown ether cluster compound **E**.[9] Nevertheless, the trend in metal ion dependence is the same. In the case of the crown ether compound, the selective response was shown to stem from electrostatic forces, mediated in a "through-bond" manner by a putative "lariat-type" interaction. In the case of compound **A**, the response appears to be mainly determined by the affinities of the metal ions for the crown ether units of the ligands.

The metal ion binding properties in chloroform solution of the central framework of **A**, viz. the diphenylglycoluril-based basket compound **1a**, have been determined previously.[21] It was shown that Li^+, Na^+, and K^+ are bound to **1a** with K_{ass}'s of 0.38×10^6 M^{-1}, 0.83×10^6 M^{-1}, and 1.9×10^6 M^{-1}, respectively. The binding of these metal ions takes place in a 1:1 clamshell fashion.[21] The binding constants for Mg^{2+} and Ba^{2+} can be expected to be somewhat higher than those for Li^+ and K^+, respectively, taking into account the sizes and charge densities of these ions. Given the high binding affinities of the basket molecule **1a** for alkali metal ions, larger changes in E_p than those listed in Table 4 might have been expected for compound **A**. Apparently, the metal ions are not bound in close proximity to the redox centre in **A**. This is confirmed by the fact that in DPV and CV compound **A** displays continuous wave rather than multi-wave behaviour. The clamshell binding mode proposed for **1a** seems to be unlikely for **A** because the E_p titration curve with Ba^{2+} suggests that this cluster compound binds four metal ions rather than two. Each crown ether fragment in **A** seemingly takes up one metal ion. The metal ions can either "nestle" in the cavity of the receptor ligand ("top" binding) or bind at its exterior ("bottom" binding, see Figure 10). Examination of CPK models showed that the four oxygen atoms and nitrogen atom in each of the aza crown ether rings, together with one of the carbonyl groups from the ligand backbone, form a circular array of donor atoms with an internal diameter comparable to that of 18-crown-6. Analysis of the i_p titration curves suggests that compound **A** has a similar metal ion binding profile as 18-crown-6, *viz.* $Li^+ < Mg^{2+} < Na^+ < K^+ < Ba^{2+}$, which also explains the modulating effects observed for compound **A**.



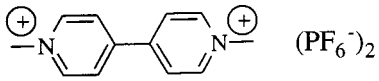


Figure 10. Proposed binding modes of metal ions by compound **A**

The modulation characteristics of compound **B** appear to be determined by similar, crown ether dependent binding factors. Due to the fact that the nitrogens in its crown ether rings are amidated, the binding characteristics of **B** are different from those of compound **A**. Furthermore, as there is less free space between the cluster core and the ligands in **B** than in **A**, the binding of metal ions can be expected to take place preferentially at the exterior (bottom side) of the cavities, as shown in Figure 10 (right). The absence of any increase in current response with Li^+, Na^+, and K^+ ions suggests that the affinity of compound **B** for these cations is low, probably due to the aforementioned amidation of the nitrogens of the crown ether rings. However, as a result of the smaller spacer groups, any bound metal ion will be closer to the cluster core in **B**. Electrostatic forces will therefore be more dominant in compound **B** than in **A**. This may explain the large electrochemical effect of Ba^{2+} ions compared to, e.g., Li^+ and Mg^{2+} ions in the case of the former compound.

Binding of Aromatic Guests by Cluster Compound A

The results presented in the previous sections suggest an open and relatively flexible structure for cluster compound **A**, with binding sites that are accessible to guests. In order to probe this accessibility, the binding of aromatic molecules by compound **A** was also investigated. Diphenylglycoluril receptors are known to bind various aromatic guest molecules in nonpolar solvents such as chloroform and dichloromethane.[12] For solubility reasons, the binding properties of compound **A** were evaluated in DMF. DPV titrations of **A** with 1,2-dinitrobenzene, 2,3-dicyanohydroquinone, and 2,3-dibromohydroquinone showed that the redox potential of the cluster was not affected by these additives. Separate UV/Vis titrations using compound **A** and receptor molecule **1a** revealed that in DMF neither of these host compounds binds the aforementioned guest molecules, in accordance with the outcome of the DPV experiments. Addition of *o*-phenylenediammonium dipicrate to the DMF solutions of **A** was found to result in degradation of the complex, probably due to protonation of the cluster core.

More recently, it has been shown that paraquats (1,1′-disubstituted 4,4′-bipyridinium salts) are very strongly bound by basket-shaped receptors based on diphenylglycoluril, even in polar solvents such as acetonitrile and methanol.[17b] Titration of model compound **1b** (Scheme 1) with dimethylparaquat **5** (Chart 2) in DMF resulted in the development of a band at 402 nm in the UV/Vis spectrum, indicating the formation of a charge-transfer (CT) complex between these two components.[22] The binding constant was determined to be $K_{ass} = 155 \pm 3$ M^{-1}. This value is considerably lower than the binding constant measured for this host–guest combination in 1:1 (*v*/*v*) chloroform/methanol, *viz.* $K_{ass} = 6000$ M^{-1}.[17b]

5

Chart 2

The binding of paraquat **5** by compound **A** was proven by electrochemical titration experiments. Figure 11a depicts the CV titration of **5** with **A**; it shows the two reversible reduction steps for **5** at −0.89 and −1.29 V, and the reduction of **A** at −1.78 V. Clearly, the first reduction of **5** is influenced by the host compound **A**, as was also indicated by DPV (see Figure 11b, where the change in $E_{p,red}$ is plotted against twice the host concentration). The second reduction potential of **5** and the reduction potential of **A** are not affected.

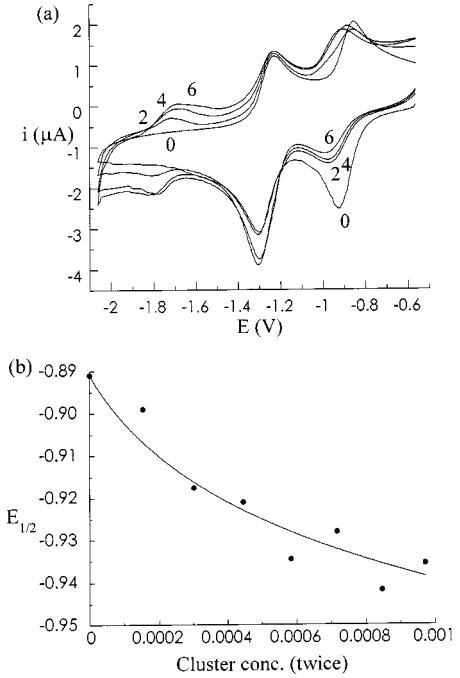

Figure 11. (a) CV titration of compound **5** with **A**, and (b) the change in E_p for the first reduction of **5** as function of twice the cluster concentration; for an explanation, see text; numbers in (a) refer to the number of molar equivalents of clusters relative to **5**

From these observations, it was concluded that only the twofold positively charged paraquat species is bound by **A**. The single positively charged and neutral species apparently have no affinity for this compound. This also explains why the reduction potential of **A** is unaffected by **5**; only a small increase in ΔE_p is observed. Binding stabilizes the dicationic form of **5** and makes it more difficult to reduce this compound, resulting in the observed anodic changes in $E_{1/2}$. We analyzed these changes, assuming the formation of a 2:1 paraquat−host complex, with the help of Equation (1), where $E_{1/2}$ is the observed half-wave potential, $E_{1/2}^{free}$ the half-wave potential of **5** without any additive, and [H] the concentration of the host compound.

$$E_{1/2} = E_{1/2}^{free} - 0.059 \log (1 + K_{ass}[H]) \quad (1)$$

Assuming that the two binding sites in **A** behave completely independently, the actual host concentration was taken as twice the concentration of cluster compound **A**. With the help of Equation (1), the curve in Figure 11b was obtained, from which a binding constant of $K_{ass} = (5.6 \pm 0.6) \times 10^3$ M^{-1} was calculated.

In separate experiments, we also added $[Fe_4S_4(SCH_2Ph)_4]^{2-}$ to paraquat **5**. This was shown to have no effect on the electrochemical behaviour of **5**. It is therefore concluded that the combination of a concave binding site and a negatively charged cluster fragment significantly enhances binding of paraquat **5** to basket-shaped receptors derived from diphenylglycoluril, viz. its binding constant increased from $K_{ass} = 155$ M^{-1} in **1b** to $K_{ass} = 5.6 \times 10^3$ M^{-1} in cluster compound **A**.

Conclusions

The electrochemical and spectral properties of the compounds **A** and **B** strongly suggest that these compounds, as isolated, are monomeric and contain an intact Fe_4S_4 cubane core. The formulation of **A** and **B** as $[Fe_4S_4(\mathbf{L^{Xyl}})_2](PPh_4)_2$ and $[Fe_4S_4(\mathbf{L^{Ac}})_2](PPh_4)_2$ therefore seems to be justified. NMR studies have shown compound **B** to have a relatively compact structure, in which the cluster is encapsulated by the concave receptor ligands. The extent of encapsulation is not such that it creates a solvophobic environment similar to that in Fe_4S_4 cluster containing proteins of the HiPIP class.

The structure of compound **A** was found to be less compact than that of compound **B**, implying that the binding sites of the receptor ligands in **A** are more accessible to guest molecules than those in **B**. The electrochemical responses of the two compounds towards alkali and alkaline earth metal ions indeed indicated that compound **A** has an "open" structure while compound **B** has a more or less "closed" structure. The cavity-forming ligands of **A** are also capable of binding a dicationic paraquat guest, but not its reduced forms. This binding interaction was found to influence the redox properties of the guest molecule.

Experimental Section

For a detailed description of the materials and methods used, the reader is referred to the related paper.[9]

Additional methods: 2D NMR spectra (COSY and NOESY) were recorded on a Bruker WM-200 instrument. In the NMR titration experiments, the changes in the chemical shifts of the host and guest molecules were monitored at varying host and at constant guest concentrations. − For electrochemical experiments, an Ag/AgCl reference electrode and 0.2 M tetrabutylammonium perchlorate supporting electrolyte solution were used, with DMSO as the solvent. − Calculations were performed on Silicon Graphics Challenge and Silicon Graphics Indigo II workstations using the QUANTA molecular modelling package with the CHARMm 3.3 force field. The Fe_4S_4 core was fixed and only the attached basket ligand structure was minimized.

2a,8,9,12,13,14,15,17,18,25,26,29,30,31,32,34,35,38b-Octadecahydro-2a,38b-diphenyl-13,30-1*H*,4*H*-6,37:20,23-dietheno-2,22:3,21-dimethano-5*H*,11*H*,28*H*,38*H*-7,10,16,19,24,27,33,36-octaoxa-2,3,4a,13,30,38a-hexaazacyclopenta[*cd*]cyclotetratriacont[*g*]azulene-1,4-dione (1a): This compound and derivative **1b** were synthesized according to a previously published procedure.[23]

2a,8,9,12,13,14,15,17,18,25,26,29,30,31,32,34,35,38b-Octadecahydro-2a,38b-diphenyl-13,30-bis(α-thioacetyl-*m*-xylyl)-1*H*,4*H*-6,37:20,23-dietheno-2,22:3,21-dimethano-5*H*,11*H*,28*H*,38*H*-7,10,16,19,24,27,33,36-octaoxa-2,3,4a,13,30,38a-hexaazacyclopenta[*cd*]cyclotetratriacont[*g*]azulene-1,4-dione (2): To a solution of **1a** (328 mg, 0.380 mmol) in DMF (15 mL) containing a small amount of K_2CO_3, a solution of α-bromo-α′-thioacetyl-*m*-xylene (195 mg, 0.75 mmol) in DMF (5 mL) was added dropwise. The resulting mixture was stirred overnight at 40 °C under an N_2 atmosphere. After removal of the solvent in vacuo, the residue was taken up in CH_2Cl_2 (40 mL) and the resulting solution was washed twice with brine and dried over $MgSO_4$. Purification by flash chromatography (silica, $CHCl_3$/MeOH/TEA, 96:3:1, *v*/*v*) yielded 425 mg (91%) of **2** as a white powder; m.p. 186 °C. − ^{1}H NMR (200 MHz, $CDCl_3$): δ = 2.31 [s, 6 H, C(O)CH_3], 2.88 (t, *J* = 5.7 Hz, 8 H, NC$H_2$$CH_2$O), 3.69−4.15 (m, 36 H, CH_2O, NC*H*HAr, NCH_2ArCH_2S), 5.67 (d, *J* = 16.1 Hz, 4 H, NCH*H*Ar), 6.73 (s, 4 H, ArH), 7.11 (s, 10 H, PhH), 7.31 (m, 8 H, ArH). − FT-IR (KBr, cm^{-1}): $\tilde{\nu}$ = 3057, 3029 (ArH), 2922, 2869 (CH_2), 1711 (C=O, urea), 1690 (C=O, thio ester), 1459, 1426 (CH_2), 1131, 1017 (COC), 770, 603 (Ar). − FAB-MS; *m*/*z*: 1233 [M + 1]$^+$. − No satisfactory elemental analysis could be obtained for this compound.

2a,8,9,12,13,14,15,17,18,25,26,29,30,31,32,34,35,38b-Octadecahydro-2a,38b-diphenyl-13,30-bis(α-thio-*m*-xylyl)-1*H*,4*H*-6,37:20,23-dietheno-2,22:3,21-dimethano-5*H*,11*H*,28*H*,38*H*-7,10,16,19,24,27,33,36-octaoxa-2,3,4a,13,30,38a-hexaazacyclopenta[*cd*]cyclotetratriacont[*g*]azulene-1,4-dione (L^{Xyl}2H): A solution of **2** (195 mg, 0.158 mmol) in methanol (10 mL) containing 3% HCl was stirred under N_2 atmosphere for 7 days at ambient temperature. Thereafter, TLC analysis showed one single, nitroprusside-positive spot. The reaction mixture was then partitioned between CH_2Cl_2 (20 mL) and water (10 mL). After neutralization with saturated aqueous $NaHCO_3$ solution, the organic layer was separated, washed with further water, and dried over $MgSO_4$. After removal of the solvent in vacuo, the desired product (90 mg, 50%) was obtained as a white powder. − ^{1}H NMR (200 MHz, $CDCl_3$): δ = 1.75 (t, *J* = 7.54 Hz, 2 H, SH), 2.89 (br. s, 4 H, NC$H_2$$CH_2$O), 3.62−4.08 (m, 36 H, CH_2O, NC*H*HAr, NCH_2ArCH_2, ArCH_2S), 5.60 (d, *J* = 16.1 Hz, 4 H, NCH*H*Ar), 6.63 (s, 4 H, ArH), 7.04 (s, 10 H, PhH), 7.19−7.32 (m, 8 H, ArH). − FAB-MS; *m*/*z*: 1149 [M + 1]$^+$. − No satisfactory elemental analysis could be obtained for this compound.

$(PPh_4)_2[Fe_4S_4(L^{Xyl})_2]$ (Cluster A): A suspension of $(PPh_4)_2[Fe_4S_4(StBu)_4]$ (55.2 mg, 0.040 mmol) in DMF (5−10 mL)

was added dropwise to a stirred solution of dithiol $\mathbf{L^{Xyl}}2H$ (93 mg, 0.081 mmol) in DMF (30 mL). The resulting mixture was stirred in vacuo for ca. 30 min. and then under N_2 atmosphere overnight. It was then filtered through a glass sinter disc and concentrated in vacuo. A large volume of Et_2O was carefully added to precipitate the product. After storage overnight at −20 °C, the product, a black solid, was isolated by decantation of the supernatant and drying in vacuo. The yield was not determined. − ^{1}H NMR (200 MHz, [D$_6$]DMSO): δ = 2.77 (br. m, 16 H, NCH_2CH$_2$O), 3.42−4.12 (m, 64 H, CH$_2$O, NC*H*HAr, NCH_2ArCH$_2$), 5.50 (br. m, 8 H, NCH*H*Ar), 6.50 (br. s, 8 H, ArH), 7.14 (br. s, 20 H, PhH), 7.80 (m, 40 H, PPh_4), 14.30 (br. s, 8 H, CH_2S). − UV/Vis (DMF): λ_{max} (ε/ M^{-1}·cm^{-1}) = 295 (33,600), 423 (11,100), 620 nm (sh, 1800). For further characterization, see text.

$(PPh_4)_2[Fe_4S_4(L^{Ac})_2]$ (Cluster B): To a suspension of dithiol $\mathbf{L^{Ac}}2H$ (100 mg, 0.097 mmol) in DMF (25 mL) was added dropwise a suspension of $(PPh_4)_2[Fe_4S_4(S\mathit{t}Bu)_4]$ (51 mg, 0.037 mmol) in DMF (10 mL). The resulting mixture was stirred under dynamic vacuum for 30 min. and then overnight under N_2 atmosphere. After filtration, the filtrate was concentrated in vacuo to a volume of a few mL. A large volume of Et_2O was then carefully added and the reaction flask was placed in a refrigerator at −20 °C overnight. This resulted in the precipitation of a black powder. After a second precipitation with Et_2O, the product was dried in vacuo. The yield was not determined. − ^{1}H NMR (200 MHz, [D$_6$]DMSO): δ = 3.42−3.96 (m, 60 H, CH$_2$O, CH$_2$N), 3.66 (8 H, NC*H*HAr), 5.51 (br. m, *J* = 13.3 Hz, 8 H, NCH*H*Ar), 6.80 (br. m, 8 H, ArH), 7.08 (m, 20 H, PhH), 7.78 (m, 40 H, PPh_4), 14.09 (br. s, 8 H, CH_2S). − UV/Vis (DMF): λ_{max} (ε/ M^{-1}·cm^{-1}) = 295 (40,200), 340 (sh, 17,400), 415 (13,400), 622 nm (sh, 3400). For further characterization, see text.

Crystal Structure and Magnetic Behavior of the Decamethylferrocenium and Decamethylchromocenium Salts of Bis(ethylenedithiolato)nickel, $[M(Cp^*)_2][Ni(edt)_2]$ − Magnetic Anisotropy and Metamagnetic Behavior of $[Fe(Cp^*)_2][Ni(edt)_2]$

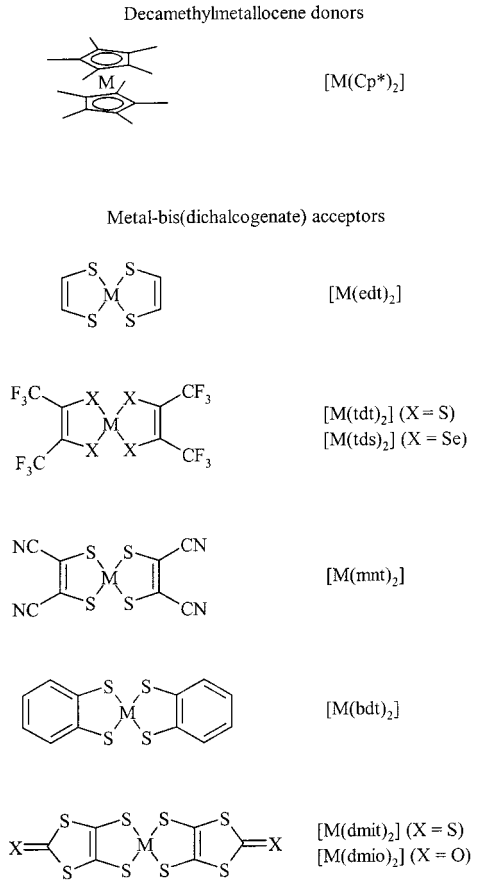
Keywords: Molecule-based magnets / Solid-state structures / Metamagnetism / Magnetic properties / Mössbauer spectroscopy

New electron-transfer salts, $[M(Cp^*)_2][Ni(edt)_2]$, with M = Fe and Cr, were prepared and shown to be isostructural by X-ray crystallographic studies. The molecular structure of $[Ni(edt)_2]^-$ is reported here for the first time. The solid-state structure consists of an array of parallel alternating donors, $[Fe(Cp^*)_2]^{\bullet+}$, and acceptors, $[Ni(edt)_2]^{\bullet-}$, ··DADADA·· stacks along [101]. At high temperatures ($T > 50$–100 K), the magnetic susceptibility obeys the Curie–Weiss expression, with the θ values of –5 and –6.7 K for the Ni and Cr compounds respectively, revealing dominant AFM interactions. At low temperatures metamagnetic behavior was observed in case of $[Fe(Cp^*)_2][Ni(edt)_2]$, with $T_N = 4.2$ K and $H_C = 14$ kG at 2 K, resulting from high magnetic anisotropy, due to the coexistence of strong FM DA intrachain interactions and strong AFM (DA and AA) interchain interactions. Single-crystal magnetization measurements with $[Fe(Cp^*)_2][Ni(edt)_2]$ showed that the transition from the AFM state to the FM high-field state was induced by the application of a magnetic field parallel to the stacking axis. In these compounds the AFM interchain (DA and AA) interactions play a dominant role, due to the large spin density on the periphery of the acceptor and the close AA and DA interchain contacts. Above 4.2 K the ^{57}Fe Mössbauer spectra of $[Fe(Cp^*][Ni(edt)_2]$ exhibit the classical low spin Fe^{III} ferrocenium singlet. Below this temperature a poorly resolved hyperfine pattern is observed (estimated hyperfine field ca. 350 kG at 3.5 K). The analysis of the spectra obtained in applied fields of 20 kG and 50 kG is consistent with a strongly anisotropic **g** tensor. A pronounced temperature dependence of the spectra in a field of 50 kG suggests the presence of spin-lattice relaxation effects.

Introduction



Since the observation of bulk ferromagnetism in $[Fe(Cp^*)_2](TCNE)$,[1,2] substantial efforts have been devoted to the study of molecule-based magnets, in particular to electron-transfer salts based on decamethylmetallocenium donors and planar acceptors.[3,4] Bulk ferromagnetism was observed in several other similar metallocenium-based electron-transfer salts,[4] and a study of the structure-magnetic property relationship revealed the need for a 1D $D^+A^-D^+A^-D^+A^-$ chain structure to achieve ferromagnetic coupling and bulk ferromagnetism.[4]

Following the extensive use of conjugated polynitriles like TCNE and TCNQ as acceptors, planar monoanionic $S = 1/2$ metal−bis(dichalcogenate) complexes, $[M(X_2C_2R_2)_2]^-$ (M = Ni, Pd and Pt; X = S, Se), have also been used in the preparation of molecule-based magnets. These acceptors seem particularly promising due to the presence of the peripheral heteroatoms, which are expected to favor the existence of extended magnetic interactions, thus giving rise to stronger magnetic interactions and higher magnetic ordering temperatures. However, up to now, in most cases the structural motifs obtained differ from the simple alternating form mentioned above, and were observed only in the decamethylmetallocenium $[M(tdt)_2]^-$,[5,6] and $[M(tds)_2]^-$ [7] salts. We believe this is due to the dimensions of the complexes, as in this case, in spite the bulky CF_3 group, the acceptors and the Me_5C_5 ligand of the donor have comparable dimensions and are quite suitable for the simple alternating chain motif. In the salts with other dithiolate complexes, the larger R groups lead to larger axial dimensions, as with $[M(mnt)_2]^-$,[5] $[M(bdt)_2]^-$,[8] $[M(dmit)_2]^-$,[9,10] and $[M(dmio)_2]^-$,[10,11] which show structural motifs where the acceptors, or face to face pairs of acceptors, alternate with side by side pairs of donors (Scheme 1).

As the structural aspect seems to be rather significant in determining the magnetic properties of these types of molecular materials, in order to obtain the desired 1D $D^+A^-D^+A^-D^+A^-$ chain structure motif, we decided to study the electron-transfer salts based on decamethylmetallocenium cations and the anionic complex $[Ni(edt)_2]^-$, for which some preliminary results were reported.[8] This is the smaller dithiolene complex and in this case the S and C

Scheme 1

atoms from the ligand are quite to interact with the atoms from neighboring molecules, and particularly strong intra- and interchain magnetic interactions are predicted for these salts.

The first model to achieve some consensus in the interpretation of the magnetic properties of this type of molecular materials was an extended version of McConnell's configuration interaction (CI) mechanism,[12] often designated as the McConnell II mechanism. However, the theoretical criticism and observation of FM in $[Cr(Cp^*)_2]^+$-based compounds,[13,14] in contradiction with the predictions of the McConnell II mechanism (AFM coupling) led to the appearance of alternative mechanisms, such as a more complex version of the McConnell II mechanism[15] and a model based on the molecular spin polarization effect,[3] designated as the McConnell I mechanism, which agreed quite well with the experimental observations. However, the recent report of a new series of compounds, $[M(Cp^*)_2][Ni(tds)_2]$ (M = Fe, Mn, Cr),[7] where the magnetic coupling is compatible with the predictions of the simple version of the McConnell II mechanism, and in contradiction with the McConnell I mechanism, which has been by far the most widely used tool for dealing with magnetic coupling and ordering in molecular magnetic materials, clearly indicates the need to reexamine the model. The study of the series of electron-transfer salts $[M(Cp^*)_2][Ni(edt)_2]$ (M = Fe, Mn, Cr) and, in particular, the nature of the magnetic coupling in the different compounds of the series is also expected to contribute to the debate regarding the mechanism of the intra- and intermolecular magnetic interactions in the decamethylmetallocenium-based salts.

Results and Discussion

Synthesis

The compounds $[M(Cp^*)_2][Ni(edt)_2]$, M = Fe (**1**) and Cr (**2**), were prepared by the same procedure: saturated equimolar solutions of $[Fe(Cp^*)_2]BF_4$ [12] or $[Cr(Cp^*)_2]PF_6$ [16] and $(Et_4N)[Ni(edt)_2]$[17] in acetonitrile were combined and the resulting compounds precipitated on standing. Dark brownish, needle-shaped crystals were collected by filtration. The preparation of $[Mn(Cp^*)_2][Ni(edt)_2]$ was also attempted by a similar method, but in this case a dark powder was obtained with an elemental analysis indicative of probable decomposition during the synthesis.

Crystal Structure

It was possible to determine the X-ray crystal structure of **1**, while in the case of compound **2**, it was only possible to determine the cell parameters due to the poor quality of the crystals, showing that **1** and **2** are isostructural. Crystal and experimental data are summarized in Table 1.

[a] Only the unit cell parameters were determined.

The monoclinic unit cell of **1** comprises unique cation and anion molecules. For $[Ni(edt)_2]^{\bullet-}$, whose structure is reported here for the first time, the atom labeling, selected

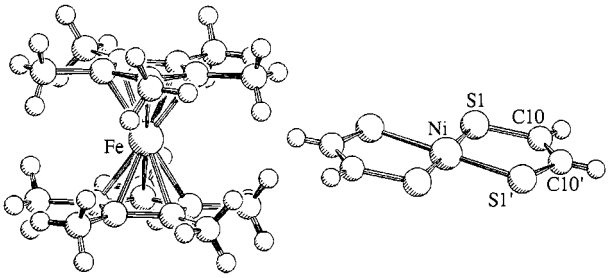

Figure 1. Perspective view of the molecular structure of **1** showing the numbering scheme for $[Ni(edt)_2]^-$; the primed and unprimed atoms are related by a mirror plane; selected bond lengths [Å] and angles [°]: Ni−S(1) 2.140(2), S(1)−C(10) 1.707(8), C(10)−C(10′) 1.32(2); S(1)−Ni−S(1′) 91.40(13), Ni−S(1)−C(10) 103.6(3), S(1)−C(10)−C(10′) 120.7(3)

bond lengths and angles are given in Figure 1. This radical anion shows a D_{2h} local symmetry, is planar and the Ni−S, S−C, and C−C distances, 2.140(2), 1.707(8), and 1.32(2) Å, 2are in good agreement with values found in other square-planar Ni^{III} dithiolate complexes.[18] The C−C distance in $[Ni(edt)_2]^-$ is relatively short when compared with the observed values in other complexes, such as $[Ni(tdt)_2]^-$, $[Ni(mnt)_2]^-$, and $[Ni(bdt)_2]^-$, 1.40(2), 1.352(8), and 1.404(2) Å, respectively.[18] This suggests the existence of a larger charge density on the C atoms for $[Ni(edt)_2]^-$. Preliminary data for the crystal structure of the neutral Ni^{IV} complex, $[Ni(edt)_2]^0$,[19] revealed shorter M−S and S−C distances, 2.100 and 1.687(5) Å, along with a larger C−C distance, 1.358(7) Å, which is consistent with the antibonding nature of the Ni−S and S−C interactions and the bonding nature of the C−C interaction.[20] The $[Fe(Cp^*)_2]^{\bullet+}$ radical cation has a C_5 local symmetry and the two C_5 rings show a staggered conformation, which is similar to those observed for a large number of salts with other acceptors.[5,12] The average Fe−C, C−C, and C−Me distances, 2.091(6), 1.416(8), and 1.502(9) Å, are in good agreement with the values observed for those salts.[5,12]

Similarly to the structures of the isostructural salts $[M(Cp^*)_2][M'(tdt)_2]$ (with M = Fe, M′ = Ni[5] and M = Mn, M′ = Ni, Pd, Pt[6]), in the case of **1** the crystal structure consists of a parallel arrangement of 1D chains of alternate radical donors (D), $[Fe(Cp^*)_2]^{\bullet+}$, and acceptors (A), $[Ni(edt)_2]^{\bullet-}$, DADADA, where the stacking axis corresponds to [101]. The intrachain Fe−Ni distance is 5.477 Å, as shown in Figure 2(a). Unlike the series $[M(Cp^*)_2]$-$[M'(tdt)_2]$, where no interionic short contacts were found, in the structure of **1** intrachain short contacts between the nickel and one of the carbon atoms from the cyclopentadienyl ring were observed, with a Ni−C distance of 3.678 Å, as illustrated in Figure 2 (a). The angle between the stacking axis and the C_5 ring from $[Fe(Cp^*)_2]^{\bullet+}$ is 79.69°. The angle between the NiS_4 plane of the radical anions and the stacking axis is 78.63°. The dihedral angle between the C_5 ring and the NiS_4 plane is 1.07° with a distance between the two planes of 2.984 Å. The existence of the short intrachain D-A contacts in this compound is expected to lead to a significantly stronger intrachain FM coupling than is observed in the case of the $[M(Cp^*)_2]$-$[M'(tdt)_2]$ series.

In the unit cell there are four distinct chains, shown in Figure 2 (b), displaying three unique interchain arrangements, I−II and II−IV, which are out-of-registry,[4] and I−III that has an in-registry[4] arrangement. The intrachain separations are 8.017, 8.678, and 13.698 Å, for the I−II, II−IV, and I−III pairs, respectively. Figure 3 shows these arrangements, along with the shortest distances between the metal centers from different chains and the closest interchain, interionic contacts (in italics). For the out-of-registry pair I−II, the shortest interchain MM distances are 8.119 (FeNi), 9.553 and 10.029 Å (FeFe or NiNi). In the case of the out-of-registry pair II−IV the shortest interchain MM separations are 8.720 (FeFe or NiNi), 9.835 and 10.740 Å (Fe Ni). For the in-registry pair I−III the

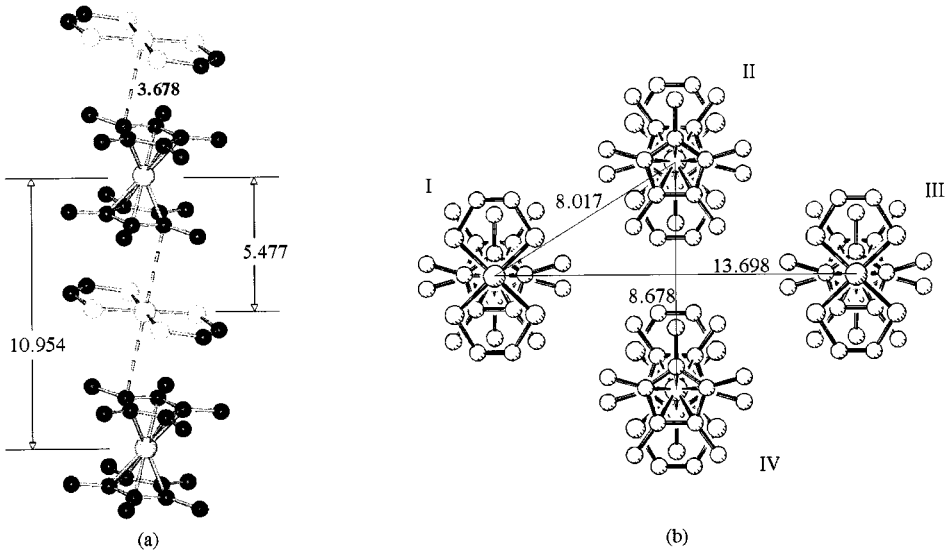

Figure 2. (a) 1D DADADA chain in **1**, the thick dotted lines represent the intraion Ni−C short contacts, 3.678 Å; (b) view normal to the chains (along [101]), showing the four unique chains, I, II, III, IV for **1** (hydrogen atoms were omitted for clarity)

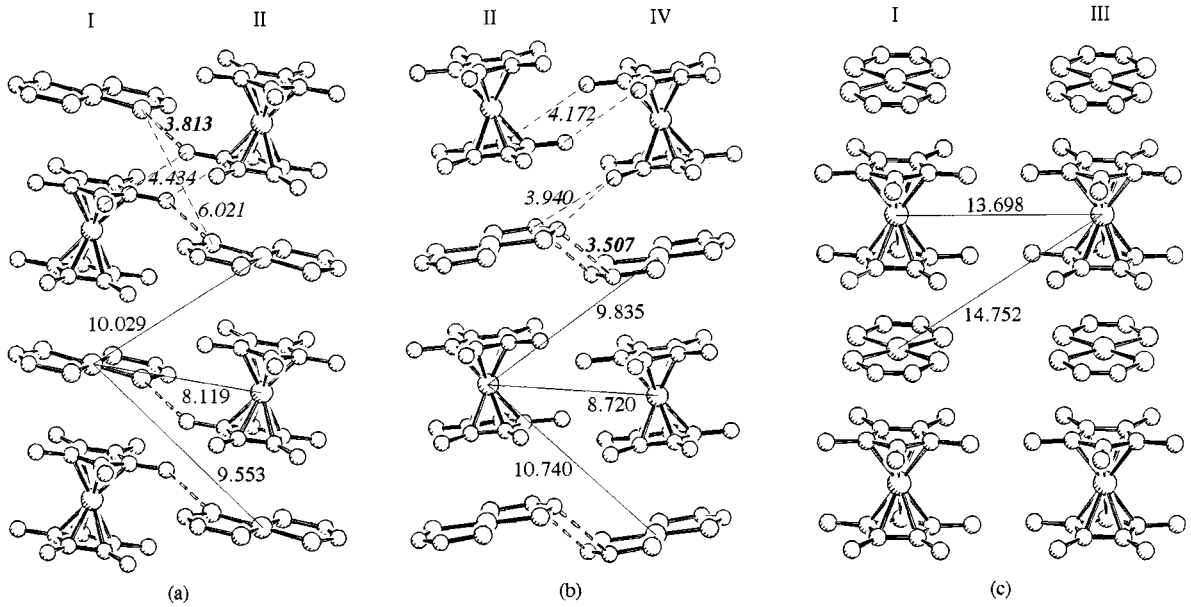

Figure 3. (a), (b) Out-of-registry arrangement of chains I−II and II−IV, respectively; (c) in-registry arrangement of chains I−III; the solid lines show the closest interchain M−M distances and the dashed lines the closest interchain interionic distances (hydrogen atoms were omitted for clarity)

shorter interchain FeFe (or NiNi) distance is 13.698 Å and the shorter FeNi distance is 14.752 Å.

Since the magnetic ordering is a bulk property, the interchain interactions are as important as the intrachain interactions and this information is essential in order to understand the spin-spin interactions that dominate the magnetic behavior. For compound **1**, although no interchain contacts shorter than the sum of the van der Waals radii were detected, relatively short DA and AA interionic interchain distances were observed in the cases of the arrangements I−II and II−IV, respectively. In the I−II pair the shortest distance (3.813 Å) corresponds to SC contacts, from a sulfur atom of the acceptor and a C from one of the methyl groups of the Me_5C_5 fragment, as shown in Figure 3 (a). In the II−IV pair, the shortest interionic interchain distance (3.507 Å) corresponds to CC contacts from the acceptors, as shown in Figure 3 (b).

As in the case of the intrachain interactions, the interchain coupling must also be considerably stronger in **1** than in the $[M(Cp^*)_2][M'(tdt)_2]$ compounds, as in these compounds the presence of the relatively bulky CF_3 groups isolate the S−C=C−S portion of the ligand, where most (50−70%) of the spin density must reside,[21] from the ions in the neighboring chains. In compound **1** the atoms of the S−C=C−S fragment are free to interact with the ions in the neighboring chains, and as shown in Figure 3, the S and C atoms are relatively close to atoms from different chains. The interchain spin interactions, due to the CC contacts from the acceptors, are expected to be of particular importance, since a considerable spin density must reside on those atoms. Additionally, in this case the interactions are predicted to be AFM in nature since the spin density on both atoms must have the same parity.

Magnetic Properties

Magnetization measurements with polycrystalline samples of **1** were obtained between 2 and 300 K using the Faraday method. The magnetic susceptibility, χ, follows the Curie−Weiss expression, $\chi_M = C/(T - \theta)$, between 100 and 300 K, with $\theta = -5 \pm 4$ K. From measurements made with three different samples considerable scatter was observed in the room-temperature effective moment, μ_{eff}, and values ranging from 3.15 to 3.95 μ_B were obtained. This can be attributed to orientation effects due to the applied field, together with the large anisotropy of the g value of $[Fe(Cp^*)_2]^{\bullet+}$, where $g_{\parallel} = 4.4$, $g_{\perp} = 1.3$ and $<g> = 2.8$.[12] In this case, assuming independent spins and a random orientation and a g value of 2.06 for the acceptor,[22] a value of 3.0 μ_B for μ_{eff} is predicted, but orientation effects could give rise to values as large as 4.2 μ_B. At low temperatures, the magnetic susceptibility was observed to show a considerable field dependence. The temperature dependence of the product, χ_T, for two measurements with the same sample of **1** is shown in Figure 4. The solid circles correspond to a ZFC measurement with an applied field of 10 kG, and fit (dotted line) Curie−Weiss behavior, with $\theta = -7.8$ K. The open circles refer to data obtained at 5 kG, where the alignment of the sample was induced through the application of a 50-kG magnetic field, the fit of the results with the Curie−Weiss expression (solid line) gave a θ value of −1.6 K. The different θ values observed for the random and field-oriented measurements suggest the existence of strong anisotropy in the magnetic coupling in the case of **1**.

In the case of compound **2**, the magnetic susceptibility data were obtained using a Faraday magnetometer, with a freshly prepared polycrystalline sample. The magnetic sus-

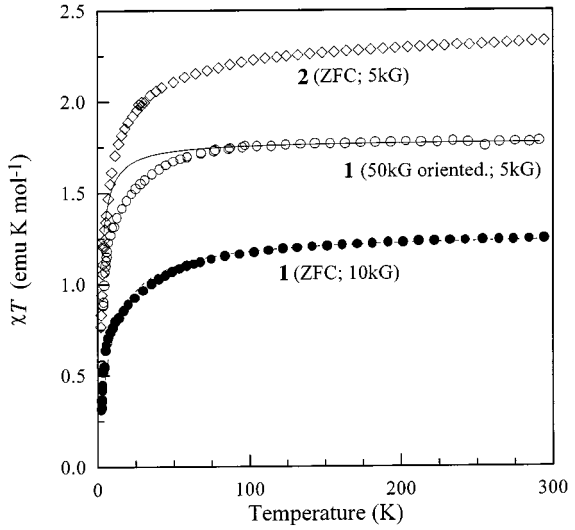

Figure 4. χ_T temperature dependence for compounds **1** (circles) and **2** (diamonds); in the case of **1**, the closed circles refer to a ZFC measurement at 10 kG and the open circles refer to a measurement at 5 kG, where the sample was previously subjected to a 50-kG applied field, at 2 K

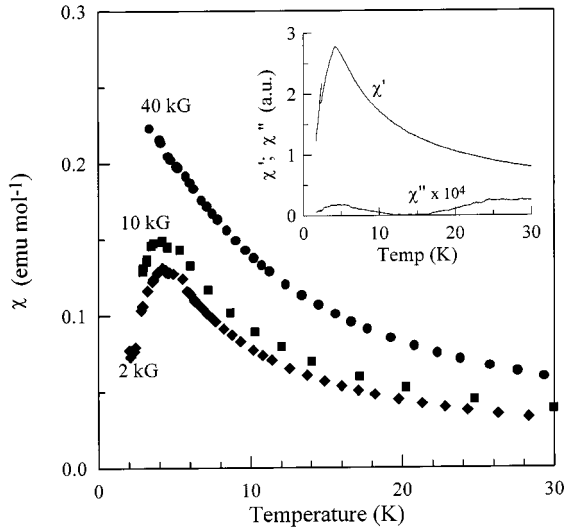

Figure 5. χ temperature dependence for **1**, with applied fields of 2 kG (diamonds), 10 kG (squares) and 40 kG (circles); the inset shows the χ' and χ'' temperature dependence

ceptibility, χ, relative to a ZFC measurement with an applied field of 5 kG, between 50 and 300 K follows the Curie−Weiss law, with $\theta = -6.7$ K. The χ_T temperature dependence for **2** is shown in Figure 4 (diamonds). The observed room-temperature effective moment ($\mu_{eff} = 4.31\ \mu_B$) is in good agreement with the expected value, 4.24 μ_B, calculated for two non-interacting spins, with $S = 1/2$ and $S = 3/2$, assuming that the g values of the donor and the acceptor are 2.0[16] and 2.06,[22] respectively. Previous measurements showed unexpectedly low values for the Curie constant, which can be attributed to partial decomposition of the sample. The observed values for the magnetization field dependence at 2 K in the case of this compound are considerably lower to those calculated from the Brillouin function, indicating a strong AFM coupling. Unexpectedly, this compound was observed to be EPR-silent, which may be due to the existence of a different phase of this compound, possibly neutral. This would also explain the lower values of the magnetic susceptibility observed in previous measurements.

In order to investigate the field-dependent behavior of **1** observed at low temperatures, a series of measurements of the field cooled magnetization temperature dependence at different values of the applied field were made, as shown in Figure 5. From these experiments it was possible to observe the existence of a field-induced transition. As the sample is cooled below 30 K, in a field of 2 kG (Figure 5 − diamonds) χ increases, reaches a maximum at 4.1 K and decreases significantly at lower temperatures, indicating that an AFM phase transition occurs. With an applied field of 10 kG (Figure 5 − circles), the behavior is similar, but there is small shift in the maximum to lower temperatures (3.9 K), at higher applied fields the maximum broadens and shifts to lower temperatures. At fields higher than 20 kG this maximum is no longer observed, suggesting that a field-induced transition occurs. Dynamic susceptibility measurements enabled the determination of the Néel temperature, $T_N = 4.2$ K, which corresponds to a peak observed on both the in-phase, χ' and the out-of-phase, χ'', components, as shown in the inset of Figure 5.

The field dependence of the magnetization at 2, 3, and 6 K for compound **1** is shown in Figure 6 for a polycrystal-

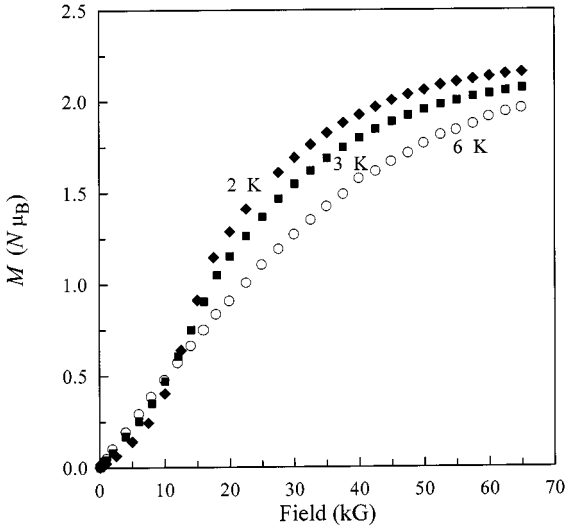

Figure 6. Magnetization field dependence for **1**, at 2, 3, and 6 K

line, pre-aligned sample. Below T_N, the curves exhibit sigmoidal behavior, typical of metamagnetism. At low fields, the magnetization increases slowly with the field and, at fields on the order of 5 kG, the increase is accentuated, showing an upward curvature. At fields in the order of 12−15 kG, the magnetization is nearly linearly dependent on the field and for higher fields a downward curvature is observed. This sigmoidal behavior is more pronounced at lower temperatures and, at fixed temperatures, it was observed to be more pronounced for previously aligned samples than nearly fixed, randomly oriented samples. For

this field-induced transition, at 2 K, the critical field, defined as the value of the field were dM/dH shows a maximum, is H_C = 14 kG. No hysteresis was observed in the isothermals, as expected for a metamagnetic transition. This behavior is very similar to that observed in other highly anisotropic compounds, such as the electron-transfer salts $[Mn(Cp^*)_2][M(tdt)_2]$ (M = Ni, Pd, Pt)[6] or compounds with extended covalent networks such as $M(pyr)_2Cl_2$ (M = Co, Fe, Ni).[23]

In order to study the magnetic anisotropy of compound **1**, single-crystal measurements were performed on a SQUID magnetometer. Due to the needle-shaped form of the crystals two configurations were used for these measurements, one (L) with the applied field parallel to the axis of the crystals, which correspondes to a^* and is relatively close to the stacking direction [101], making an angle of 5.65°. In a second configuration (T), the field was applied along a random direction in the plane perpendicular to a^*.

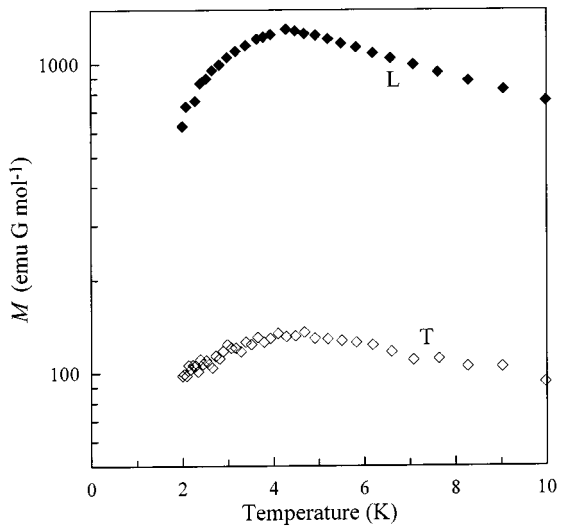

Figure 7. Single-crystal magnetization temperature dependence for **1** with an applied field of 5 kG, parallel (solid symbols) and perpendicular (open symbols) to the crystal axis

Figure 7 shows the magnetization temperature dependence for the two configurations, with an applied field of 5 kG. Crystals of 70 and 75 μg were used in L and T configurations, respectively, the results for configuration L are represented by the closed symbols and for T by the open symbols. The magnetization temperature dependence observed for both configurations is qualitatively similar, with a maximum at ca. 4.5 K, indicating the existence of AFM transitions in both configurations. The values relative to the L configuration are almost one order of magnitude higher than the ones from the T configuration, which is attributed essentially to the anisotropy in the g value of the donor.

In the case of the L configuration, at 2 K, the single-crystal magnetization field dependence is consistent with

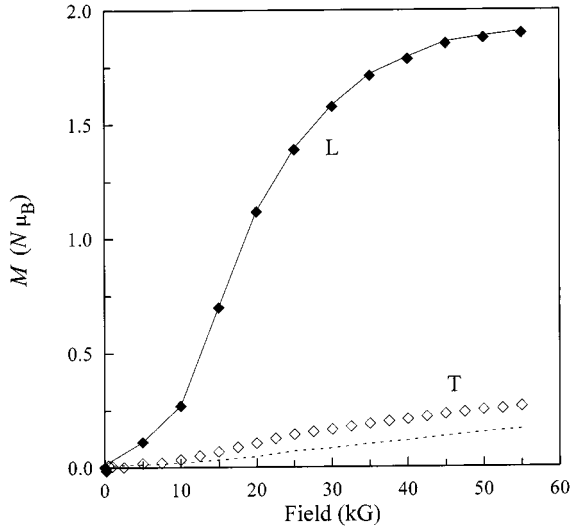

Figure 8. Single-crystal magnetization field dependence for **1**, at 2 K, with the applied field parallel (solid symbols) and perpendicular (open symbols) to the crystal axis; the estimated values of $M_{\parallel}$ and $M_{\perp}$ are represented by the solid and dashed lines, respectively

the existence of a field-induced phase transition, with a critical field of 14 kG, as indicated by the isothermal sigmoidal behavior, shown in Figure 8 (closed symbols). At 55 kG the magnetization reaches a value of 1.95 $N\mu_B$, and is not yet saturated, which is usual in metamagnetic materials if the temperature is not much lower than T_N.[6,23] The high-field state is consistent with an FM state, where the saturation magnetization, $M_S = g_D S_D + g_A S_A \approx 3\ N\mu_B$, with $S_D = S_A = 1/2$, $g_D = 3.95$ (a tilting of 10° of the axis of the donor relative to the field was considered) and $g_A = 2.06$. For a ferrimagnetic state the expected value for the saturation magnetization $M_S = g_D S_D - g_A S_A \approx 0.91\ N\mu_B$, is much smaller than the values obtained for the high-field state. For the T configuration, the magnetization is much lower than in L, and, as shown by the open symbols in Figure 8, the magnetization field dependence is almost linear, as expected for an AFM.

In order to estimate the field dependence of $M_{\parallel}$ and $M_{\perp}$, a mathematical treatment of the values measured along a^* ($M^{a*}{}_{\parallel}$), L configuration, and in the plane perpendicular to a^* ($M^{a*}{}_{\perp}$), T configuration, where made. For $M_{\parallel}$ a very good agreement with $M^{a*}{}_{\parallel}$ was obtained, with a negligible deviation (< 2%) in comparison to the experimental error, which is in the order of 5%. The field dependence of $M_{\parallel}$ is represented by the solid line in Figure 8. A linear field dependence was obtained for $M_{\perp}$ (dotted line in Figure 8). Unlike the values observed for the L configuration, in this case the values of $M^{a*}{}_{\perp}$ are clearly larger than the ones obtained for $M_{\perp}$ due to the contribution of $M_{\parallel}$.

The single-crystal magnetization measurements confirmed the high magnetic anisotropy of **1**. The transition from the AFM low-field state to a FM high-field state was observed to occur only with the applied field parallel to the stacking axis, which confirms the FM nature of the intrachain DA coupling and the AFM nature of the interchain interactions. The small dimensions of the crystals and air

sensitivity of **2** prevented determination of the single-crystal measurements on this compound.

The magnetic properties of **1** reveal features that are somewhat unusual among the class of highly anisotropic compounds displaying metamagnetism. The magnetic behavior of compound **1** seems to be dominated by AFM interactions, whereas in most compounds of this class the FM interactions are dominant. One other aspect is related to the magnitude of the critical field, which is particularly high in the case of compound **1**.

In order to achieve a better understanding of the magnetic behavior of compound **1,** its crystal structure and magnetic properties can be compared with those of the isostructural series $[M(Cp^*)_2][M'(tdt)_2]$.[6] The magnetic behavior of those compounds is dominated by strong intrachain FM interactions coexisting with weak interchain AFM interactions, which in the case of the Mn compounds leads to metamagnetism. In these highly anisotropic compounds $T_N \propto |E_{intra}E_{inter}|^{1/2}$,[14] where the intrachain DA interaction, $E_{intra} \propto S_D S_A J_{DA}$, and E_{inter} is the weaker effective interchain interaction. The absence of magnetic ordering in the case of $[Fe(Cp^*)_2][Ni(tdt)_2]$ is attributed to a lower value of E_{intra}, as the donor in this case has a smaller spin $S = 1/2$, while in the Mn compounds $S = 1$. As mentioned above, in the case of compound **1** stronger intrachain and interchain magnetic coupling are expected, which is consistent with the larger value of $T_N = 4.2$ K as compared with the observed values for the $[Mn(Cp^*)_2][M(tdt)_2]$ compounds, 2.4, 2.8, and 2.3 K for M = Ni, Pd, and Pt, respectively.[6] The interchain coupling in compound **1** is expected to be exceptionally strong, and the interchain AFM coupling must be comparable to the intrachain FM coupling, considering the apparent domination of AFM interactions observed from the magnetic susceptibility temperature dependence (Figure 4).

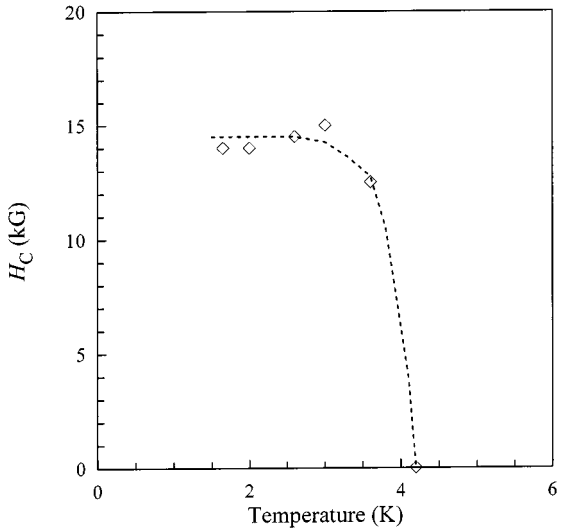

Figure 9. Critical field temperature dependence for **1**; the line represents a fit to the experimental results

A simple Ising model was used in the study of the metamagnetic transitions in the compounds $FeCl_2 \cdot 2\,H_2O$ and $CoCl_2 \cdot 2\,H_2O$,[24] with an intrachain and two interchain constants, and for those compounds the metamagnetic transition fields are proportional to the interchain exchange constants. In the case of compound **1**, the high value of the observed critical field of ca. 14 kG, one order of magnitude larger than in the case of the $[Mn(Cp^*)_2][M(tdt)_2]$ compounds, can be attributed to a considerably larger interchain coupling for **1**.

As compound **2** is isostructural with **1**, it is reasonable to expect that, as observed for **1**, the magnetic behavior must be dominated by the DA intrachain and by the AA and DA interchain interactions. The magnetic susceptibility temperature dependence and the magnetization field dependence indicate that in **2** the magnetic behavior is clearly dominated by strong AFM interactions. In this compound quite strong AFM interchain interaction are expected, as in **1**, and the DA intrachain interactions must be considerable weaker, as indicated by the magnetic behavior of the $[M(Cp^*)_2](TCNE)$, with M = Fe ($S = 1/2$), Mn ($S = 1$), and Cr ($S = 3/2$) salts.[15] These compounds show FM ordering, with $T_C = 4.8$, 8.8, and 3.1 K for the Fe, Mn, and Cr compounds, respectively, and as in a simple mean-field model T_C is proportional to J and $S(S+1)$.[15] The lower value of T_C in the $[Cr(Cp^*)_2]^+$ salt suggests that, in this case, J_{DA} is considerably weaker in relation to the other compounds, as this is the case with the higher S value. Therefore, in compound **2**, the strong AFM interchain interactions could dominate the magnetic behavior and thus it would not be possible to determine the (FM or AFM) nature of the DA intrachain interactions. Unlike the AFM DA intrachain coupling observed for $[Cr(Cp^*)_2][Ni(tds)_2]$,[7] in case of compound **2** the dominant interchain interactions enable discussion of the validity of the several spin-spin coupling mechanisms.

Mössbauer Spectroscopy

Mössbauer spectra of compound **1** from 78 to 4.4 K exhibit a single line (Figure 10). The ionic form of the compound, $[Fe(Cp^*)_2]^+[Ni(edt)_2]^-$, can be confirmed by the non-observation of quadrupole splitting along with the fact that the estimated values for the isomer shift, $\delta = 0.48$ mm/s (relative to metallic Fe at room temperature) are typical of low-spin, $S = 1/2$, Fe^{III} decamethyl ferrocenium.[25] This singlet is slightly larger at 4.4 K (half width, $\Gamma = 0.47$ mm/s) than at 78 K ($\Gamma = 0.38$ mm/s), but below 4.4 K the spectrum suddenly broadens and gives rise to a partially resolved hyperfine split spectrum in agreement with the magnetic ordering observed at 4.2 K in the magnetization measurements. At 3.5 K the broad sextuplet fitted to the observed spectrum (Figure 10) corresponds to a hyperfine field of ca. 350 kG.

The spectra obtained at 4.4 K with applied fields of 20 and 50 kG and at 20 K with a 50 kG applied field, shown in Figure 11, can be interpreted by the spin Hamiltonian for the $S = 1/2$ electronic ground state [Equation (1)]

$$\mathbf{H}_{NE} = \mu_B(\mathbf{H}_{ext} \cdot \mathbf{g} \cdot \mathbf{S}_{eff}) + \mathbf{I} \cdot \mathbf{A} \cdot \mathbf{S}_{eff} + \mathbf{I} \cdot \mathbf{P} \cdot \mathbf{I} - g_N \cdot \mu_N \cdot \mathbf{H}_{ext} \cdot \mathbf{I}, \quad (1)$$

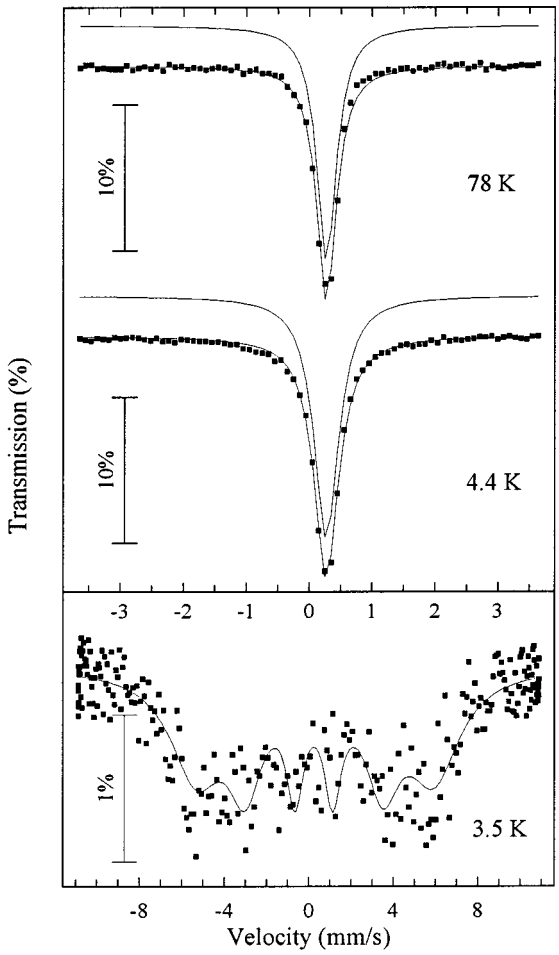

Figure 10. Mössbauer spectra of **1** obtained at 78, 4.4, and 3.5 K; the calculated functions are plotted on the experimental points; note the different velocity scale for the spectrum at 3.5 K

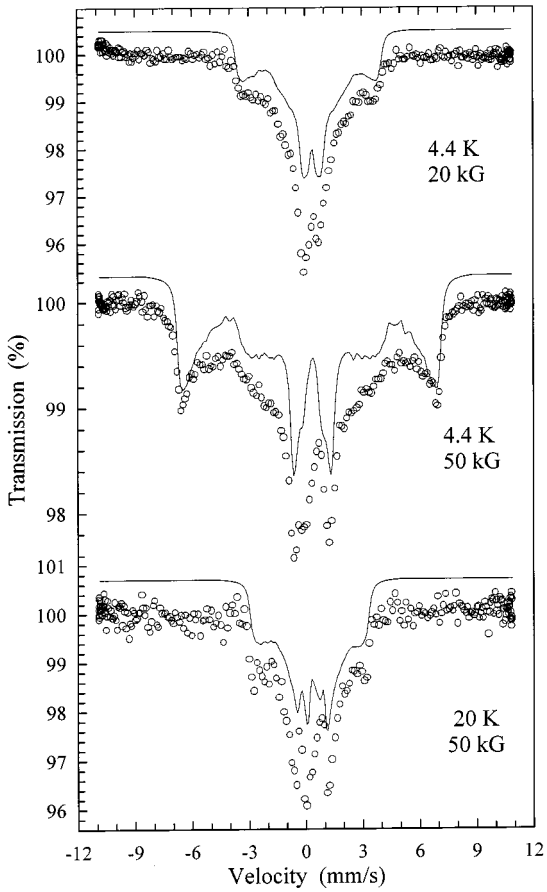

Figure 11. Mössbauer spectra of **1** with applied magnetic fields of 20 and 50 kG obtained at 4.4 K and of 50 kG at 20 K; the simulated spectra calculated using the spin Hamiltonian are also plotted slightly shifted

where **g**, **A** and **P** are tensors describing the electronic Zeeman interaction, the magnetic hyperfine interaction and the electricinteraction respectively. The principal axes of **g** and **A** are assumed to be the same but **P** is allowed to have different axes (ξ, ψ, ζ), which are obtained from those of **g** or **A** through a rotation with Euler angles α, β, γ. **I P I** may be rewritten as [Equation (2)]

$$\mathbf{I}\cdot\mathbf{P}\cdot\mathbf{I}=\frac{1}{4}eQV_{\zeta\zeta}\left\{\left[I_\zeta^2-\frac{1}{3}I(I+1)+\frac{\eta}{3}\left(I_\xi^2-I_\psi^2\right)\right]\right\}, \quad (2)$$

and we may define [Equation (3)]

$$\mathbf{H}_{\mathrm{int}}=-\frac{\mathbf{A}\cdot\langle\mathbf{S}_{\mathrm{eff}}\rangle}{g_{\mathrm{N}}\mu_{\mathrm{N}}}. \quad (3)$$

Theoretical simulations employing the above spin Hamiltonian were calculated by a modified version of the program by Münck et. al.[26] Assuming fast relaxation and using g_{xx} = 1.3, g_{yy} = 1.3, and g_{zz} = 4.4,[12] $\Delta E_{\mathrm{Q}} = eQV_{\zeta\zeta}$ = −0.17 mm/s, η = 0, $A_{xx}/(g_{\mathrm{N}}\mu_{\mathrm{N}})$ = −110 kG, $A_{yy}/(g_{\mathrm{N}}\mu_{\mathrm{N}})$ = −110 kG, and $A_{zz}/(g_{\mathrm{N}}\mu_{\mathrm{N}})$ = +820 kG, the calculated simulations are plotted on the experimental spectra (Figure 11). Non-zero values of α, β, and γ were considered but did not improve the fit of the simulation to the experimental spectra. The estimated ΔE_{Q}, as well as the **g** and **A** values, are similar to those reported for decamethylferrocenium hexafluorophosphate.[27]

Since electronic relaxation is fast, the ^{57}Fe nucleus is unable to follow the rapid fluctuations of the magnetic field $\mathbf{H}_{\mathrm{int}}$ due to the unpaired electrons and senses only the thermal average spin corresponding to the m_{S} = +1/2 and m_{S} = −1/2 levels. The magnetically split Mössbauer spectra reveal that the average $\mathbf{H}_{\mathrm{int}}$ is not zero. Furthermore a strong temperature and field dependence of the effective magnetic fields at the ^{57}Fe nuclei is shown by the smaller splitting between the outer peaks in the spectra at 20 K with $\mathbf{H}_{\mathrm{ext}}$ = 50 kG or at 4.4 K with $\mathbf{H}_{\mathrm{ext}}$ = 20 kG. These observations are consistent with an appreciable difference in the Boltzmann population of spin-up and spin-down molecules and reflect the decrease in the thermal population of the excited m_{S} sublevel with increasing temperature and decreasing applied external magnetic field.

The spectra obtained with an applied field of 50 kG (either at 4.4 or at 20 K) bear a close resemblance to those obtained under the same experimental conditions for other decamethylferrocenium compounds characterized by a fast relaxation rate.[27] Several factors (such as relaxation rates slower than the ideal fast relaxation limit, admixtures of

electronic excited states into the ground electronic state in high magnetic fields, etc.) already mentioned by Cohn et al.[27] can influence the appearance of the Mössbauer spectra of magnetically perturbed ferrocenium cations and may explain the lack of fit between the experimental data and the simulated spectra at the Doppler velocity range around 0 mm/s. In this case significant texture effects caused by the needle shape of the crystals used in the preparation of the Mössbauer absorber should also be considered. While calculating simulated spectra, 500 different applied field directions distributed uniformly over an octant of the unit sphere associated with the **g** and **A** axes were summed, assuming a randomly oriented sample. The needle shape of the crystals is expected to cause a significant increase in the relative number of particles with the needle axis approximately perpendicular to the external field. Since the angle of the g_{zz} axis relative to the stacking direction is of the order of 10°, the weight of the contribution to the spectra of the cations with g_{zz} perpendicular to the applied field is larger than in the case of a randomly oriented sample.

As observed for other decamethylferrocenium salts, $[Fe(Cp^*)_2]^+[Ni(edt)_2]^-$ also shows an appreciable **g** and **A** tensor anisotropy. Furthermore, the A_z value is positive, suggesting a large orbital contribution to the hyperfine field, which along the z axis is larger in absolute value than the negative isotropic contact term. This is explained by the appreciable orbital angular momentum in the electronic ground state of this complex.[27]

Conclusion

As predicted, the small dimensions of the acceptor, $[Ni(edt)_2]^-$, lead to a linear chain structural motif in the electron-transfer salts, $[M(Cp^*)_2][Ni(edt)_2]$, with M = Ni and Cr. The large spin density on the peripheral S−C= C−S fragment of the acceptor ligands and its accessibility were expected to lead to the existence of particularly strong inter- and intrachain magnetic interactions. In fact, for $[Fe(Cp^*)_2][Ni(edt)_2]$ there are strong FM intrachain interactions, due to DA intrachain short contacts coexisting with strong AFM interchain interactions, resulting from the AD and AA interchain contacts. In this compound magnetization measurements revealed the existence of a metamagnetic behavior (T_N = 4.2 K and H_C = 14 kG) in agreement with the high anisotropy of the magnetic coupling. Single-crystal measurements revealed that, below 4.2 K, the transition from the AFM low-field to the FM high-field state can be induced by the application of a magnetic field parallel to the stacking axis. The magnetic behavior of $[Cr(Cp^*)_2][Ni(edt)_2]$ is dominated by the strong interchain AFM interactions and in this case it was not possible to determine the exact (FM/AFM) nature of the intrachain DA interactions, which prevented a discussion of the validity of the spin-spin coupling models for these compounds.

Experimental Section

General Remarks: Decamethylferrocenium tetrafluoroborate and decamethylchromocenium hexafluorophosphate were obtained from decamethylferrocene (Aldrich) and decamethylchromocene (Strem), respectively, by literature procedures.[12,16] The $(Et_4N)[Ni(edt)_2]$ salt was prepared as described in the literature.[17] Acetonitrile was distilled from P_2O_5 under nitrogen, and deaereated either by successive alternate freezing and evacuation cycles or by bubbling argon through the solvent for ca. half an hour. All the syntheses were carried out under nitrogen or argon, in gloveboxes or using Schlenk techniques. − Elemental analyses were carried out with a Carlo Erba (EA 1110-CHNS-O).

$[Fe(Cp^*)_2][Ni(edt)_2]$ (1): Dark green needle-shaped crystals of this compound were obtained by mixing $[Fe(Cp^*)_2]BF_4$ (124 mg, 0.30 mmol) in acetonitrile (2 mL) with $(Et_4N)[Ni(edt)_2]$ (111 mg, 0.30 mmol) in acetronitrile (7 mL). After standing at room temperature overnight, the crystalline product was collected by vacuum filtration in 63% yield (107 mg, 0.19 mmol). − $C_{24}H_{34}FeNiS_4$ (565.3): calcd. C 50.99, H 6.06, S 22.68; found C 50.58, H 5.76, S 21.75. − Crystallization by slow solvent evaporation from concentrated acetonitrile or dichloromethane solutions of $[Fe(Cp^*)_2][Ni(edt)_2]$ afforded large needle-shaped crystals suitable for X-ray diffraction and single-crystal magnetic studies.

$[Cr(Cp^*)_2][Ni(edt)_2]$ (2): The compound was prepared by the addition of $[Cr(Cp^*)_2]PF_6$ (80 mg, 0.17 mmol) in acetonitrile (1.5 mL) to $(Et_4N)[Ni(edt)_2]$ (62.6 mg, 0.17 mmol) in acetonitrile (5 mL). After standing for 2 h, brown needle-shaped crystals were collected by vacuum filtration in 49% yield (47.1 mg, 0.84 mmol). − $C_{24}H_{34}CrNiS_4$ (561.5): calcd. C 51.34, H 6.10; found C 51.11, H 6.49. − Crystallization attempts, following the procedure described for **1**, gave small needle-shaped crystals. Partial decomposition during the crystallization was observed to occur.

Magnetic Characterization: Static magnetic susceptibility data of $[M(Cp^*)_2][Ni(edt)_2]$ (M = Fe and Cr) polycrystalline samples, using Teflon sample holders, were obtained between 1.8 and 300 K using an Oxford Instruments Faraday system having a 70-kG superconducting magnet. For $[Fe(Cp^*)_2][Ni(edt)_2]$ magnetization data, between 1.5 and 300 K, were also obtained using the extraction method with an Oxford Instruments Magnetometer (MagLab System 2000), with a 120-kG superconducting magnet. Dynamic susceptibility measurements, in a zero applied static magneticfield and an alternating field of 1 G at 1 kHz, were also obtained with the MagLab system. The single-crystal magnetization measurements were obtained with a Quantum Design SQUID (MPS) magnetometer, between 2 and 10 K, with a 55-kG superconducting magnet. Magnetization measurements, in case of $[Cr(Cp^*)_2][Ni(edt)_2]$, were also obtained with the SQUID magnetometer for polycrystalline samples, using a quartz sample holder. Susceptibility and magnetization data were corrected for contributions due to sample holder and core diamagnetism, estimated from tabulated Pascal constants. Electronic paramagnetic resonance spectra were obtained with an X-band spectrometer (Bruker ESP 300) equipped with a helium flow cryostat (Oxford ESR 300).

Mössbauer Spectroscopy: ^{57}Fe-Mössbauer spectra were collected at 78, 4.4, and 3.5 K using a conventional spectrometer with a 50-mCi ^{57}Co source in an Rh matrix and a sinusoidal velocity-vs.-time wave form. The spectrometer was calibrated with an α-Fe foil. Needle-shaped crystals of **1** were mixed with perspex powder and the resulting material was pressed into a perspex sample holder in order to obtain a disk-shaped Mössbauer absorber, containing ca. 5 mg of natural Fe/cm^2. Spectra with the sample in an applied external magnetic field, $\mathbf{H}_{ext}$ (20 and 50 kG), parallel to the γ-ray beam, were obtained at 4.4 and 20 K using a superconducting coil. The spectra obtained at zero applied field were fitted to Lorentzian

lines using a modified version of the non-linear least-squares computer method of Stone.[28]

X-ray Crystallographic Study: A single crystal of **1** with approximate dimensions of $1.4 \times 0.35 \times 0.25$ mm was used for X-ray data collection with an Enraf Nonius Cad4 diffractometer, with graphite-monochromated Mo-K_α radiation ($\lambda = 0.71069$ Å), at room temperature. The structure was solved by direct methods using SHELXS-86[29] and refined with SHELXL-93.[30] All non-hydrogen atoms were refined anisotropically and hydrogen atoms were placed at calculated positions with isotropic temperature factors $U(H) = 1.2U_{eq}(C)$. All crystal and molecular representations were prepared with SCHAKAL-97.[31] The unit cell of compound **2** was determined using a single crystal with approximate dimensions of $0.8 \times 0.15 \times 0.1$ mm with an Enraf Nonius Cad4 diffractometer (Mo-K_α radiation). However, in this case the poor quality of the crystal prevented the X-ray structure determination. A summary of the crystal data and refinement procedures is given in Table 1. Crystallographic data (excluding structure factors) for the structure(s) reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-137238. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Keywords: Macrocycles / Cryptands / Thermodynamics / Coordination chemistry

The protonation and metal ion (Cu^{2+}, Zn^{2+}, Cd^{2+}, Pb^{2+}) complexation abilities of three heteroditopic cryptands in solution are described and the relevant equilibrium constants are reported. The two distinct binding subunits of the ligands act cooperatively in the coordination of $M(H_2O)^{2+}$ (M = metal ion) species. The cryptand **L1** binds five protons in very acidic solution and crystallizes as $[(H_5\mathbf{L1})(ClO_4)_5]\cdot 4\,H_2O$ in the monoclinic space group $P2_1/n$ with a = 14.281(4), b = 14.313(7), c = 24.082(8) Å, β = 92.00(2)°, Z = 4, R = 0.079, and $wR2$ = 0.2010. The molecule shows an *endo-endo* conformation with a pseudo-threefold symmetry axis passing through the two bridgehead nitrogen atoms. All the cryptands (**L1**–**L3**) readily form inclusion complexes with Cu^{2+}, Ni^{2+}, Zn^{2+}, Cd^{2+}, and Pb^{2+} ions at the tren end of the cavity. The crystal structure of $[(Ni\mathbf{L2}Cl)Cl]\cdot 5.5\,H_2O\cdot CH_3OH$ is also reported [$C2/c$, a = 26.671(6), b = 16.784(4), c = 18.591(8) Å, β = 101.006(14)°, Z = 8, R = 0.091, and $wR2$ = 0.1424]. The Ni^{II} ion resides in a trigonal-bipyramidal coordination environment with the equatorial sites occupied by the three secondary nitrogen atoms of the cryptand and the axial sites occupied by a bridgehead nitrogen atom and a Cl^- ion.

Introduction

Macrocyclic ligands containing various binding functionalities are a topic of considerable current interest due to their ability to show highly selective recognition of different substrates, including both charged (cations, anions) and neutral molecules.[1−9] Among such ligands, macrobicyclic cryptands have attracted great interest since they are characterized by a three-dimensional arrangement of donor atoms and are capable of replacing the first solvation shell of the target species, thereby shielding the complexed species from the external environment.[8−19] However, when the number of cryptand donor atoms is insufficient to complete the coordination environment of the enclosed substrate, the inclusion of partially solvated species is observed. This is the case, for instance, with several transition metal complexes of the macrobicyclic cryptands **L1**−**L3** (Figure 1), where coordinated solvent molecules or anions are drawn into the cavity along with the metal ion.[20−23] Ligands such as **L1**−**L3** display interesting molecular structures composed of two different tripodal binding sites separated by three aromatic rings, which form a highly hydrophobic region. Such ligand structures have proved to be particularly effective in hosting metal ions since they stabilize metal−ligand bonds that are otherwise unstable.[24] The tripodal N_4 moiety represents a well-suited binding site for transition metal ions, although there are insufficient enough donor atoms to saturate the coordination spheres of many metal ions. As a result, the binding properties of the metal ions are directed towards the coordination of further species from the medium, which are constrained to occupy coordination sites located in, or in the proximity of, the hydrophobic region defined by the aromatic rings. Metal ions in such coordination environments, in conjunction with the remaining empty space in the ligand cavity, can be utilized in homogeneous catalytic reactions.[22] As a matter of fact, the secondary species linked to the metal ions display peculiar coordination features in that they are able to interact with both the donor atoms of the empty ligand moiety[21] and the π electron clouds of the benzene rings.[23] Moreover, derivatives of these cryptands have been shown to be well-suited for studying chelation-enhancement of fluorescence[25] and for the construction of ordered structures such as vesicles[26] and Langmuir−Blodgett films.[27] In spite of the large amount of information acquired about these ligands and their complexes, nothing is known regarding the thermodynamics of ligand protonation and metal ion complexation in solution. In order to fill in this gap, we performed the study described herein.

Results and Discussion

Ligand Protonation

The protonation constants of cryptands **L1**−**L3**, determined in 0.10 mol dm^{-3} Me_4NNO_3 at 298.1 K, are listed in Table 1. In the case of **L3**, it was not possible to determine the first protonation constant due to precipitation occurring in the pH region where the $HL3^{3+}$ species should be formed.

Table 1. Logarithms of ligand protonation constants determined in 0.10 mol dm^{-3} Me_4NNO_3 at 298.1 K

	L1 log K[a]	**L2**	**L3**
$L + H^+ = LH^+$	10.45(7)	9.74(6)	
$HL^+ + H^+ = LH_2^{2+}$	10.44(2)	8.68(6)	8.9(1)
$H_2L^{2+} + H^+ = LH_3^{3+}$	5.56(6)	7.47(8)	8.8(1)
$H_3L^{3+} + H^+ = LH_4^{4+}$	3.46(6)	5.6(1)	4.6(1)
$H_4L^{4+} + H^+ = LH_5^{5+}$		2.4(1)	2.9(1)

[a] Values in parentheses are standard deviations in the last significant figure.

The three molecules display rather different protonation properties. Firstly, it can be noted that while in very acidic solutions **L1** is able to form the fully protonated species, as demonstrated by the crystal structure of $[(H_5\mathbf{L1})(ClO_4)_5]\cdot 4\,H_2O$, in the pH range 2.5−10.5 used to determine the protonation constants it behaves, at most, as a tetraprotic base ($H_4\mathbf{L1}^{4+}$). In the same pH range, **L2** and **L3** are able to form the fully protonated species ($H_5\mathbf{L2}^{5+}$, $H_5\mathbf{L3}^{5+}$), indicating higher overall basicities. The first two protonation constants of **L1**, however, are considerably higher than the corresponding values for **L2** and **L3**, while the third and fourth values are significantly lower. Furthermore, the first two protonation constants of **L1** are surprisingly similar within experimental error. It is a common characteristic of cryptand polyamines to display peculiar protonation behavior. This can often be attributed to the presence of solvent molecules in the cavity, which contribute to the stabilities of the protonated species through hydrogen bonding.[23,28,30] As a matter of fact, as shown by recent crystal structures, $H_2\mathbf{L1}^{2+}$ and $H_2\mathbf{L2}^{2+}$ are able to bind one[30] and two[23] water molecules, respectively, forming significant hydrogen-bond networks within the cavity involving the ammonium groups. In $[(H_2\mathbf{L1})\subset H_2O]^{2+}$, the water molecule seems to be bound more strongly than in the $H_2\mathbf{L2}^{2+}$ cryptate due to the direct participation of both the binding moieties in the former. This is, in turn, a consequence of the different connectivity of the tripodal binding moieties to the benzene rings, the *ortho*-substituted cryptand allowing closer approach of the bridgehead nitrogen atoms than the *meta*-substituted one. Hence, it seems likely that efficient cooperativity of the two opposite binding subunits, as mediated by a cryptate water molecule, is responsible for the higher basicity of **L1** in the first two protonation steps. In **L3**, the benzene rings are *ortho*-substituted but, unlike **L1**, it is more flexible as the tren [tris(2-aminoethyl)amine] unit is replaced by trpn [tris(3-aminopropyl)amine] (Figure 1).

An alternative explanation of such behavior may be found in the abilities of similar cryptand molecules to promote the coordination of anionic species.[19] Inclusion of a negatively charged substrate would lead to stabilization of the positively charged receptor through charge neutralization and, depending on the nature of the anion, through the formation of intramolecular hydrogen bonds. Accordingly, the marked loss of basicity observed in the third and fourth protonation steps of **L1** might stem from disruption of the internal structure as a result of the guest species interacting with the final protonation sites. Indeed, the crystal structure of the compound $[(H_5\mathbf{L1})(ClO_4)_5]\cdot 4\,H_2O$ shows an empty $H_5\mathbf{L1}^{5+}$ cation (Figure 2) that displays evident stress stemming from the electrostatic repulsion between positive charges.

The crystal structure of $[(H_5\mathbf{L1})(ClO_4)_5]\cdot 4\,H_2O$ reveals the presence of discrete $H_5\mathbf{L1}^{5+}$ cations, perchlorate anions, and solvating water molecules. The $H_5\mathbf{L1}^{5+}$ cation interacts with three external perchlorate anions and a water molecule through strong hydrogen bonds (Figure 2, Table 2). The N···N and O···O interatomic distances (Table 2) are consistent with the presence of a pseudo-threefold symmetry axis passing through the two bridgehead nitrogen atoms of $H_5\mathbf{L1}^{5+}$. As a result of electrostatic repulsion, the cavity of $H_5\mathbf{L1}^{5+}$ is expanded, albeit only slightly, with respect to that of the free **L1** cryptand.[21] This expansion is mainly manifested in a lengthening of the distances between the secondary nitrogen atoms of the tetraamine moiety, the O···O distances within the opposite tripodal subunit being less affected by protonation (Table 2). The distance between the bridgehead nitrogen atoms in **L1** [6.249(5) Å][21] is maintained in $H_5\mathbf{L1}^{5+}$ [6.25(2) Å]. As a consequence of the aforementioned expansion, $H_5\mathbf{L1}^{5+}$ displays some molecular strain. This is evident from the bond angles in the ligand

[a] Values in parentheses are standard deviations in the last significant figure.

chains, which are, on average, significantly larger (mean value 112.4°) than the value expected for sp^3 carbon atoms. The protonated nitrogen atoms N(2), N(4), and N(5) interact with three external perchlorate anions (Figure 2), two of which are symmetry-related (Table 2). The other ClO_4^- anion (Cl3) bridges two ammonium groups (Figure 2). All the anions are strongly bound to the protonated cryptand, as evidenced by the short hydrogen-bond lengths (Table 2). While in the unprotonated **L1** and the diprotonated $[(H_2\mathbf{L1})\subset H_2O]^{2+}$ cryptate the bridgehead nitrogen atoms adopt an *endo-endo* conformation, in $H_5\mathbf{L1}^{5+}$ the acidic proton bound to the bridgehead N(3) points towards the exterior of the molecular cavity, interacting with an external water molecule [N(3)···O(100) distance 2.82(2) Å]. No such hydrogen bonding involving the other bridgehead nitrogen atom can be detected. Consequently, the bridgehead nitrogen atoms assume an *endo-exo* conformation (Figure 2). It thus seems reasonable that the formation of very stable cryptate species is responsible for the high stability of **L1** in the early stages of protonation, while conformational changes, disruption of the cryptate structure, and strong electrostatic repulsions between positive charges combine to produce a rapid loss of stability in the later protonation stages.

Further investigations are in progress aimed at ascertaining the nature of the cryptate species. As a matter of fact, in a recent communication the inclusion, both in solution and in the solid state, of two nitrate anions in the cavity of a similar cryptand has been reported.[19]

Complex Formation

The macrobicyclic ligands **L1**−**L3** are potential heteroditopic receptors for metal ions, being composed of two dissimilar tripodal binding subunits. While the tetraamine moiety has proved to be suitable for the coordination of transition metal ions,[20−23,31] the ethereal moiety can be expected to be effective in the binding of "harder" cations. In order to determine the coordination properties of these ligands in aqueous solution, we have studied the complexation of various metal ions such as Ni^{2+}, Cu^{2+}, Zn^{2+}, Cd^{2+}, and Pb^{2+}, as well as of alkali and alkaline earth cations. From the results of this study, it is clear that the three ligands do not show any tendency to form complexes with alkali or alkaline earth cations, while they are capable of forming stable complexes with the remaining metal ions. Nevertheless, the ethereal moieties of these ligands display a poor propensity to remain vacant; indeed, as shown by crystal structure determinations,[21,23] they are well suited for strong hydrogen-bonding interactions with water molecules inside the ligand cavity, in particular with water molecules linked to metal ions coordinated to the opposite tetraamine site, as is observed in the crystal structures of the Ni^{2+} complex[21] with **L1** and the Cu^{2+} complex[23] with **L2**. Similar features have been observed previously for other cryptand ligands.[28,32]

The cryptand **L2** readily forms a mononuclear complex with Ni^{2+}, which has been isolated as $[(Ni\mathbf{L2}Cl)Cl]\cdot 5.5\,H_2O\cdot CH_3OH$. The crystal structure of this complex reveals the presence of $[\mathbf{L2}\subset NiCl]^+$ cations (Figure 3), chloride anions, and methanol and water molecules of crystallization. The Ni^{2+} cation achieves pentacoordination through ligation by the N_4 ligand moiety and a chloride ion, Cl(1), in a trigonal-bipyramidal fashion (Table 2), where the secondary amino nitrogen atoms N(1) and N(2) occupy the axial positions (Figure 3). This coor-

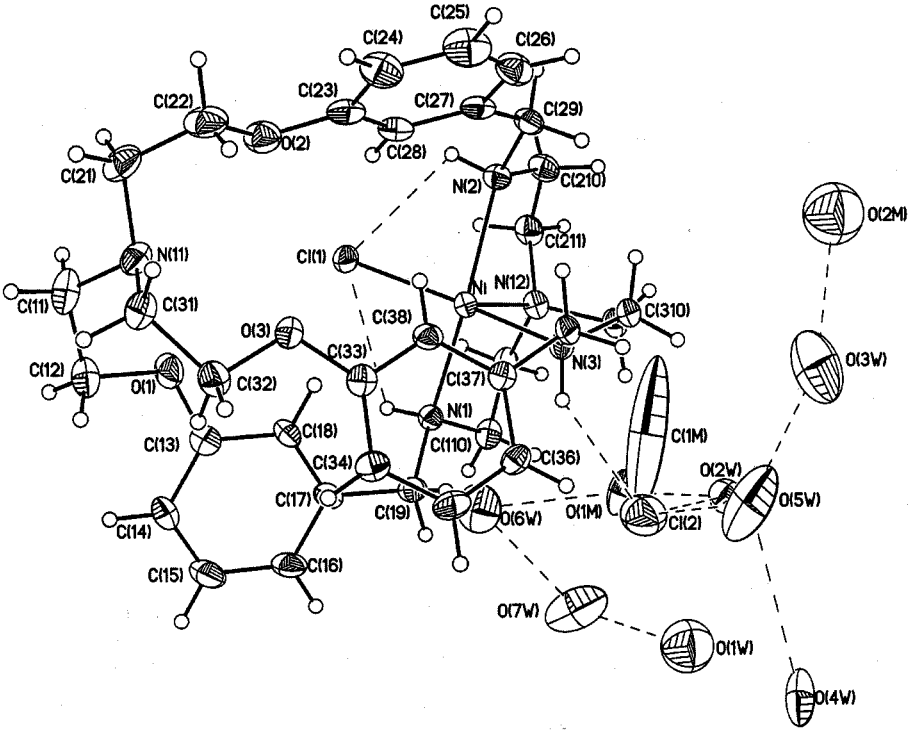

Figure 3. A perspective view of **2** showing the atom numbering scheme

dination geometry is quite similar to that in the pentagonal-bipyramidal cascade complex[20] of the Cu^{2+} ion with the same ligand. Cl(1) also shows hydrogen-bonding interactions with the amine nitrogen atoms N(1) and N(2) [Cl(1)···N(1) 3.121(5) Å; Cl(1)···N(2) 3.025(6) Å]. Seven water and two methanol molecules are also present in the crystal lattice. Both the methanol molecules and three of the water molecules show large thermal displacements and are assigned half-occupancy. All bond lengths and bond angles in the cryptand moiety have typical values within statistical error limits.

It is noteworthy that, although chloride anions and water molecules are similarly drawn into the cryptand cavity by coordinated metal ions, the water cryptate is stabilized by hydrogen bonding to the ethereal oxygen atoms, whereas the chloride ions form hydrogen bonds with the metal-coordinated amine groups.

Stability Constants

The stability constants for the Cu^{2+}, Zn^{2+}, Cd^{2+}, and Pb^{2+} complexes with **L1** and **L2**, as well as for the Cu^{2+} and Zn^{2+} complexes with **L3**, are reported in Table 3. As mentioned in the Experimental Section, it was not possible to study the complexation of Cd^{2+} and Pb^{2+} with **L3** due to solubility problems. Stability constants for the Ni^{2+} complexes of the three ligands could not be determined, again due to solubility problems.

L1 forms both $ML1^{2+}$ and hydroxylated $ML1(OH)^{+}$ species with all the metal ions except for Cu^{2+}, while **L2** and **L3** are also able to form the monoprotonated species. In the case of the Zn^{2+} and Cd^{2+} complexes with **L2**, however, formation of a hydroxylated species was not observed due to precipitation occurring in alkaline solution. Although the set of stability constants is incomplete, some interesting conclusions regarding the coordination properties of these ligands can be drawn. Firstly, it can be noted that some dimensional recognition is exhibited by these cryptands. As a matter of fact, considering the metal ions (Zn^{2+}, Cd^{2+},

$Pb^{2+} + L = PbL^{2+}$	13.09(2)	9.52(9)	
$Pb^{2+} + HL^{+} = PbLH^{3+}$	6.95(9)		
$PbL^{2+} + H^{+} = PbLH^{3+}$	7.16(9)		
$PbL^{2+} + OH^{-} = PbLOH^{+}$	3.25(5)	3.8(1)	

[a] Values in parentheses are standard deviations in the last significant figure.

Pb^{2+}) for which ligand-field stabilization is not possible, complex stability is seen to increase with increasing metal ion size. Such a trend in the coordination ability is evidently connected with the macrobicyclic nature of these ligands, since an opposite trend in stabilities is observed for the Zn^{2+} and Cd^{2+} complexes with the ligand tris(2-aminoethyl)amine, tren {log K = 14.5 for $Zn(tren)^{2+}$, log K = 11.7 for $Cd(tren)^{2+}$,[33a] log K = 10.21(1) for $[Pb(tren)]^{2+}$ [33b]}, which can be considered as an acyclic analogue of the tetraamine moieties of **L1** and **L2**. Due to their bicyclic structures, cryptands are more rigid than acyclic molecules. Consequently, they show a reduced tendency to modify their arrangements so as to satisfy the coordination requirements of metal ions. The present cryptands are apparently too large to give a good fitting with all the studied metal ions, which accounts for the observed stability increase with increasing cation dimensions.

The complexation ability has been found to be highly dependent on the ligand structure. While the lower tendency of **L3** to form complexes with the present metal ions was expected, due to the formation of six-membered chelate rings rather than the more stable five-membered ones formed by **L1** and **L2**, the difference in stability between the complexes of **L1** and **L2** is rather surprising. All complexes formed by **L1** are considerably more stable than those with **L2**, this difference in stability amounting to more than three orders of magnitude in the case of the Cd^{2+} and Pb^{2+} complexes. It is worth noting that, on the basis of X-ray crystallographic studies[20,22] on free **L1** and **L2** and their metal complexes, the cavity in **L2** has been shown to be much more rigid compared to that in **L1**. Consequently, the entering metal ion cannot adjust the coordination geometry to its liking in the former.

Conclusion

Cryptand ligands are characterized by rigid structures and consequently simple ligand modifications can lead to significant changes in their binding properties. This has clearly been shown to occur with **L1**−**L3**. In particular, the presence of *ortho*-substituted aromatic spacers in **L1** gives rise to an evident enhancement in basicity and metal ion coordination properties with respect to **L2**, which contains *meta*-substituted spacers. These cryptands show a particular tendency to form inclusion complexes in which multiple species are enclosed in the ligand cavity. In spite of this tendency and of the presence of two separate binding subunits in the ligands, **L1**−**L3** are not able to form binuclear metal complexes in aqueous solution. Nevertheless, in accordance with their structures, these ligands display heteroditopic properties in metal ion coordination since the two distinct binding subunits act cooperatively in the binding of $M(H_2O)^{2+}$ (M = metal ion) species. Furthermore, the abilities of these cryptands to promote inclusive coordination make these compounds promising candidates for the binding and recognition of anionic substrates, both in the presence and absence of coordinated metal ions.

Experimental Section

General Procedures and Materials: Cryptands **L1**−**L3** were synthesized as described previously[20,23,34] and were used in the form of free amines. − Crystals of $[(H_5\mathbf{L1})(ClO_4)_5] \cdot 4\,H_2O$ (**1**) suitable for single-crystal X-ray analysis were obtained by slow evaporation of the solvents at room temperature from a solution containing **L1** and an excess of $HClO_4$ in ethanol/H_2O (80:20, v/v). − $C_{33}H_{58}Cl_5N_5O_{27}$ (1134.1): calcd. C 34.95, H 5.16, N 6.18; found C 35.0, H 5.2, N 6.2. − ***Caution!*** *Care must be taken when treating organic compounds with perchloric acid as potentially explosive mixtures may be formed.* − $[(Ni\mathbf{L2}Cl)Cl] \cdot 5.5\,H_2O \cdot CH_3OH$ (**2**) was prepared by adding a solution of $NiCl_2 \cdot 6\,H_2O$ (0.24 g, 0.1 mmol) in MeOH (5 mL) to **L2** (0.056 g, 0.1 mmol) in MeOH (5 mL). A bluish-green solid separated immediately, which was collected by filtration, washed with MeOH, and dried in air. Recrystallization from MeCN afforded X-ray quality single crystals as green rectangular parallelepipeds. − $C_{34}H_{60}Cl_2N_5NiO_{9.5}$ (820.5): calcd. C 49.77, H 7.37, N 8.54; found C 49.7, H 7.4, N 8.5.

Crystal Structure Determination: A summary of X-ray data collection, structure solution, and refinement for both **1** and **2** is presented in Table 4. In each case, the cell parameters were determined by least-squares refinement of diffractometer setting angles for 25 carefully centered reflections. The intensities of two standard reflections were monitored every hour during data collection to check the stability of the diffractometer and of the crystal. Intensity data were corrected for Lorentz and polarization effects and, in the case of **1**, an absorption correction was applied once the structure had been solved by the DIFABS method.[35] In the case of **2**, an analytical absorption correction was applied. Both structures were solved by direct methods[36] and refined by full-matrix least-squares techniques on F^2 using SHELXL-97[37a] and SHELX-93[37b] for **1** and **2**, respectively, which use the analytical approximation for atomic scattering factors and anomalous dispersion corrections for all atoms taken from ref.[38] Anisotropic displacement parameters were used for all non-hydrogen atoms. In each case, hydrogen atoms were introduced in calculated positions. For **1**, an overall unrefined temperature factor was assigned for the hydrogen atoms, while for **2** overall refined thermal parameters were used for aliphatic, amino, and aromatic hydrogen atoms. Crystallographic data

CCDC-140417 and CCDC-140418 for **1** and **2**, respectively. Copies of the data can be obtained free of charge on application to the CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Potentiometric Measurements: All pH-metric measurements (pH = $-\log [H^+]$) used for the determination of protonation and complex formation constants were performed in 0.10 mol dm^{-3} Me_4NNO_3 solutions at 298.1 ± 0.1 K using equipment and methodologies described in a previous report.[39] The combined Ingold 405 S7/120 electrode was calibrated as a hydrogen concentration probe by titrating known amounts of HCl with CO_2-free Me_4NOH solutions and determining the equivalent point by Gran's method.[40] This allows determination of the standard potential E^o and the ionic product of water [pK_w = 13.83(1) at 298.1 ± 0.1 K in 0.1 mol dm^{-3} Me_4NNO_3]. At least three measurements were performed for each system. In all experiments, the ligand concentration [L] was $5 \cdot 10^{-4}$ mol dm^{-3}, while in the complexation experiments the metal ion concentration was about 0.8 [L]. Test measurements were performed in presence of higher metal ion concentrations in order to confirm that no polynuclear complexes were formed. The pH range investigated was 2.5−10.5 for all measurements, although in some cases the formation of precipitates curtailed the useful range for the determination of equilibrium constants. This was the case at pH > 8 in the titrations performed to determine the protonation constants of **L3** and the stability constants of the Zn^{2+} and Cd^{2+} complexes with **L2**. In the case of **L3**, only the complexes with Cu^{2+} and Zn^{2+} were sufficiently soluble for adequate study. Complexation reactions with these ligands were found to be rather slow. For this reason, equilibration times of 5−15 min were necessary after each addition of titrant. Conventional potentiometric titrations were performed to determine the stability constants in the system Pb^{2+}/tren ([tren] = $1 \cdot 10^{-3}$ mol dm^{-3}, [Pb^{2+}] = 0.8 [tren]) under the same experimental conditions (0.1 mol dm^{-3} Me_4NNO_3, 298.1 ± 0.1 K). The computer program HYPERQUAD[41] was used to calculate both protonation and complexation constants from the e.m.f. data.

Rhodium and Iridium Complexes Derived from *trans*-[MCl(CO)(PPh_3)$_2$] (M = Rh, Ir) and Pyridine-2-thiolate or 4,6-Dimethylpyrimidine-2-thiolate Ligands: *S*-Monodentate Coordination versus *S,N*-Chelation and *S,N*-Bridging; Reactivity of *trans*-[Ir('Spy')(CO)(PPh_3)$_2$] and *trans*-[Ir('SpymMe$_2$')(CO)(PPh_3)$_2$] towards Acid

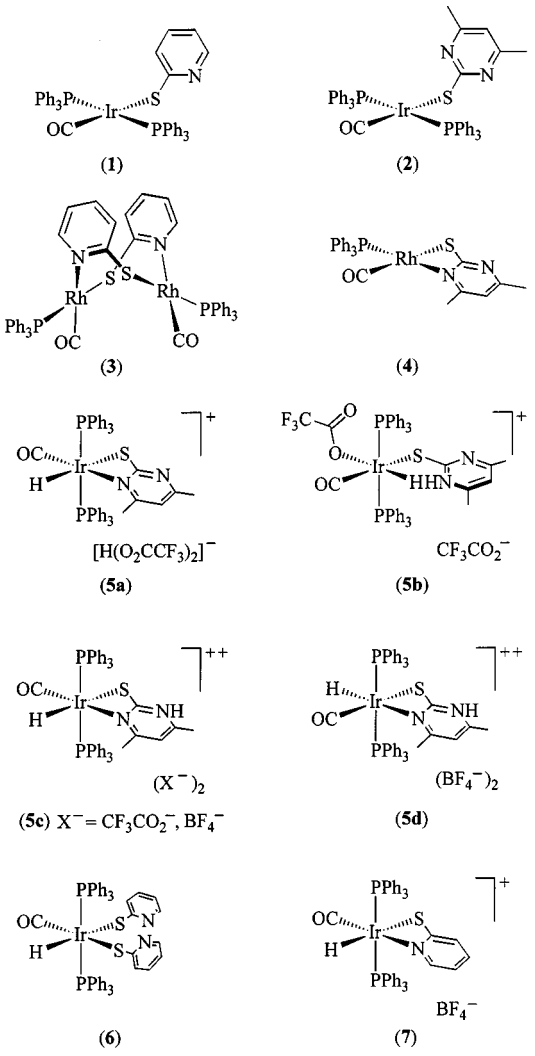
Lutz Dahlenburg*[a] and Michael Kühnlein[a]

Keywords: Iridium / Rhodium / S ligands / Chelates / Bridging ligands

Treatment of *trans*-[IrCl(CO)(PPh_3)$_2$] with the sodium salts of the *S,N*-hybrid ligands, pyridine-2-thiol ('pySH') and 4,6-dimethylpyrimidine-2-thiol ('Me$_2$pymSH'), produced *trans*-[Ir('Spy')(CO)(PPh_3)$_2$] (**1**) and *trans*-[Ir('SpymMe$_2$')(CO)(PPh_3)$_2$] (**2**), containing *S*-monodentate thiolato ligands. In contrast, the reactions between *trans*-[RhCl(CO)(PPh_3)$_2$] and the two bifunctional thiolate ligands yielded the PPh_3-loss products [{Rh(μ-'Spy'-κ*N*,κ*S*)(CO)(PPh_3)}$_2$] (**3**) and [Rh('SpymMe$_2$'-κ*N*,κ*S*)(CO)(PPh_3)] (**4**), whose structures in the solid state were determined by single-crystal X-ray diffraction. In binuclear complex **3**, the bridging pyridine-2-thiolate ligands are bound to the adjacent metal centers through their N and S atoms in a head-to-tail manner. The crystal structure of **4** consists of mononuclear molecules possessing four-membered Rh–S–C–N chelate rings with the sulfur atom *trans* to the CO ligand. In solution, both **3** and **4** display temperature-dependent dynamic behavior. Reaction of **2** with trifluoroacetic acid resulted in protonation of the iridium atom and ring closure to form the monopositive chelate complex [IrH('SpymMe$_2$'-κ*N*,κ*S*)(CO)(PPh_3)$_2$]$^+$, which was isolated and characterized by X-ray crystallography as the hydrogen bis(trifluoroacetate) salt [IrH('SpymMe$_2$'-κ*N*,κ*S*)(CO)(PPh_3)$_2$][H(O_2CCF_3)$_2$] (**5a**). Protonation of both the iridium and one pyrimidine nitrogen atom was observed in the analogous reaction of **2** with HBF_4, which afforded the 4,6-dimethylpyrimidinium-2-thiolato chelate complex [IrH(2-$SC_4HNN(H)Me_2$-4,6-κ*N*,κ*S*)(CO)(PPh_3)$_2$](BF_4)$_2$ as a mixture of two isomers, having the hydride ligand either *trans* to S (**5c**) or *trans* to N (**5d**). The complex [IrH('Spy')$_2$(CO)(PPh_3)$_2$] (**6**) resulted from oxidative addition of pyridine-2-thiol to **1** or reaction of *trans*-[IrCl(CO)(PPh_3)$_2$] with an excess of the 'pySH' ligand. Complex **6** reacted with HBF_4 in $CHCl_3$ with cleavage of one Ir–S bond and protonation at the metal center to produce the ionic chelate complex [IrH('Spy'-κ*N*,κ*S*)(CO)(PPh_3)$_2$]BF_4 (**7**) which was also fully characterized by X-ray analysis.

Introduction

Our recent interest has focused on the chelation of bidentate *P,N* and *P,O* ligands, in particular with respect to the reactivity of their transition metal complexes towards Brønsted acids.[1,2,3] In this context, two ring-opened iridium(III) compounds, [$IrHCl_2$(CO)(PPh_3)($PPh_2C_6H_4N$(-Me)H-2)][2] and [$IrHCl_2$(CO)(PPh_3)($PPh_2C_6H_4OH$-2)],[3] resulting from reaction of their parent iridium(I) chelate complexes *trans*-[Ir(CO)(PPh_3)($PPh_2C_6H_4$E-2)] (E = NMe, O) with hydrogen chloride, have been shown to exist as mixtures of Ir−$PPh_2C_6H_4$EH-2 rotamers which are stabilized by intramolecular −N(Me)H···Cl(Ir) and −OH···H(Ir)···Cl hydrogen bonding. Following these studies, we have turned our attention to iridium and rhodium complexes derived from the requisite Vaska-type precursors *trans*-[MCl(CO)(PPh_3)$_2$] and bifunctional ligands having soft *S* and hard *N* ends, such as pyridine-2-thiol, NC_5H_4SH-2 ('pySH'), and 4,6-dimethylpyrimidine-2-thiol, 4,6-$Me_2C_4HN_2$-SH-2 ('Me$_2$pymSH'), respectively.



Both the ligands and their conjugate bases are ubiquitous *S,N* donors that form a wide variety of complexes with p-, d-, and also f-block metals.[4−8] The published work concerning the chemistry of relevant coordination compounds of the platinum group metals rhodium and iridium in their lower oxidation states is dominated by di- and trinuclear complexes with *S,N*-bridging thiolates, derived from bimetallic olefin and carbonyl precursors, such as [M_2(μ-Cl)$_2$(diolefin)$_2$] (M = Rh,[9a−9c,10a] Ir[9d,10a]) or [Rh_2(μ-Cl)$_2$(CO)$_4$].[11]

The compounds reported in this paper (Scheme 1) were synthesized with the principal objectives of (i) investigating the coordination properties of the two *S,N* donors in Vaska-type environments and (ii) elucidating the reactivity of the resulting complexes towards Brønsted acids. Because of the basicity of the pyridine and pyrimidine heterocycles, and owing to the pronounced basic character of the metal ion in coordinatively unsaturated d^8 complexes, protonation of four-coordinate Rh^I and, specifically, Ir^I compounds [MX(CO)L$_2$] bearing *S*-monodentate 'Spy' or 'SpymMe$_2$' ligands by strong acids was expected to occur both at the

metal center and the nitrogen atom. The resulting products could exhibit intramolecular N−H···H−M hydrogen bonding, as it has been previously demonstrated that pyridine-2-thiol, if coordinated as a monodentate $HN^+C_5H_4S^-$ zwitterion, has a distinct propensity to behave as a weakly acidic N−H donor toward weakly basic Ir^{III}−H acceptor functions.[12] In this connection, the behavior towards protic acids of two related Rh^I and Ir^I complexes $[M(S_2NC_7H_4)(CO)(PPh_3)]$ with *S*-monodentate benzothiazole-2-thiolate ligands is worth mentioning: Protonation of the rhodium derivative with HBF_4 takes place at the noncoordinated nitrogen atom giving $[Rh(S_2N(H)C_7H_4)(CO)(PPh_3)_2]BF_4$,[9e,9f] in contrast to the iridium homologue where protonation occurs at the metal center with production of the hydridoiridium(III) complex $[IrH(S_2NC_7H_4)(CO)(PPh_3)_2]BF_4$.[9f]

Scheme 1

Results and Discussion

Syntheses and Solid-State Structures of Rh^I and Ir^I Thiolates

The *S*-monodentate pyridine-2- and 4,6-dimethylpyrimidine-2-thiolato derivatives *trans*-[Ir('Spy')(CO)$(PPh_3)_2$] (**1**) and *trans*-[Ir('SpymMe_2')(CO)$(PPh_3)_2$] (**2**) were formed smoothly by combining the sodium salts of the respective thiols and Vaska's complex, *trans*-[IrCl(CO)$(PPh_3)_2$], in a 1:1 stoichiometry in THF at room temperature. The $^{31}P\{^1H\}$ NMR spectra of the two compounds consist of singlets (δ = 23.1 for **1** and 19.4 for **2**), indicating the expected pairs of equivalent phosphane ligands (Scheme 1).

Under the conditions chosen for the preparation of **1**, the rhodium(I) complex *trans*-[RhCl(CO)$(PPh_3)_2$] and sodium pyridine-2-thiolate underwent Cl^-/'pyS^-' exchange accompanied by elimination of a phosphane ligand to give the binuclear PPh_3-loss product $[\{Rh(\mu\text{-'Spy'})(CO)(PPh_3)\}_2]$ (**3**). Prior to this work, a highly fluxional complex of identical composition was reported to result from solution equilibration of $[Rh_2(\mu\text{-'Spy'})_2(CO)_3(PPh_3)]$, affording $[\{Rh(\mu\text{-'Spy'})(CO)_2\}_2]$ together with $[\{Rh(\mu\text{-'Spy'})(CO)(PPh_3)\}_2]$.[9b] From the $^{31}P\{^1H\}$ NMR data observed at the slow exchange limit, an unspecified ground-state structure with equivalent PPh_3 ligands *trans* to the sulfur atoms was tentatively inferred for this dirhodium compound.[9b] Complex **3** is also fluxional in solution (see below) and adopts a solid-state structure consisting of bimetallic molecules in which both pyridine-2-thiolate ligands bridge two *cis* coordination sites of the metal centers through their S and N atoms, the pairs of Rh−N and Rh−S bonds being *trans* to the CO and PPh_3 ligands, respectively (Figure 1). The coordination planes of the two metal centers are inclined to each other at an angle of 34.9°. In addition, the donor atoms coordinated to Rh(1) and Rh(2) are staggered, the torsion angles being −46.4 and −51.3° for the N(1)−Rh(1)···Rh(2)−N(2) and C(1)−Rh(1)···Rh(2)−C(2) fragments, and 134.7 and 137.7° for S(1)−Rh(1)···Rh(2)−S(2) and P(1)−Rh(1)···Rh(2)−P(2), respectively. The molecular structure of **3** thus closely resembles those of the related tetracarbonyl and thiazoline-2-thiolato-bridged species $[\{Rh(\mu\text{-'Spy'-}\kappa N,\kappa S)(CO)_2\}_2]$[9b] and $[\{Rh(\mu\text{-}S_2NC_3H_4\text{-}\kappa N,\kappa S)(L)(L')\}_2]$ (L, L′ = COD;[10a] CO, PMe_3;[10b] CO, PPh_3[10b]), similarly containing twisted nonparallel metal coordination planes, linked in a head-to-tail fashion by the nitrogen and mercapto sulfur atoms of two *N*-heterocyclic thiolate bridges. The Rh(1)···Rh(2) separation, 3.1952(5) Å, is shorter than that of 3.2435(3) Å in $[\{Rh(\mu\text{-}S_2NC_3H_4\text{-}\kappa N,\kappa S)(CO)(PPh_3)\}_2]$[10b] and presumably reflects the observation that the tilt of the coordination planes in **3**, 34.9°, is somewhat closer to parallel than the 38.5° observed in the latter compound. All metal-to-ligand bond lengths (Figure 1) are as expected as compared to those of structurally analogous dirhodium derivatives.[9b,10a,10b]

Surprisingly, treatment of *trans*-[RhCl(CO)$(PPh_3)_2$] with 4,6-dimethylpyrimidine-2-thiolate did not afford any *S*,*N*-linked or *S*-bridged binuclear product, but resulted in formation of the unusual four-membered Rh−S−C−N metallaheterocycle [Rh('SpymMe_2'-$\kappa N,\kappa S$)(CO)(PPh_3)] (**4**). The X-ray structure analysis of this complex showed the presence of molecules with a slightly distorted planar coordination geometry (Figure 2), as evidenced (i) from the sum

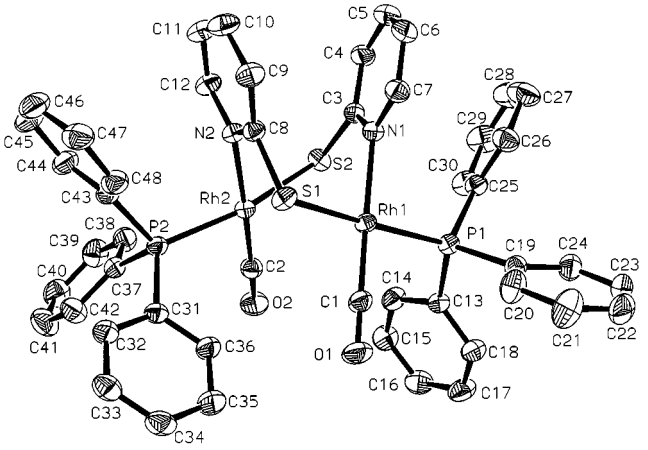

Figure 1. Molecular structure of [{Rh(μ-'Spy'-κ*N*,κ*S*)(CO)(PPh_3)}$_2$] (**3**); selected interatomic distances [Å] and angles [°]: Rh(1)···Rh(2) 3.1952(5), Rh(1)−S(1) 2.3929(8), Rh(1)−P(1) 2.2871(7), Rh(1)−N(1) 2.122(2), Rh(1)−C(1) 1.807(3), Rh(2)−S(2) 2.4053(7), Rh(2)−P(2) 2.2768(7), Rh(2)−N(2) 2.118(2), Rh(2)−C(2) 1.828(3), S(1)−C(8) 1.749(3), S(2)−C(3) 1.749(3), N(1)−C(3) 1.353(3), N(2)−C(8) 1.359(3); S(1)−Rh(1)−P(1) 169.98(3), N(1)−Rh(1)−C(1) 176.9(1), S(1)−Rh(1)−N(1) 88.35(6), S(1)−Rh(1)−C(1) 90.22(9), P(1)−Rh(1)−N(1) 92.53(6), P(1)−Rh(1)−C(1) 88.40(9), S(2)−Rh(2)−P(2) 165.96(3), N(2)−Rh(2)−C(2) 175.4(1), S(2)−Rh(2)−N(2) 87.93(6), S(2)−Rh(2)−C(2) 91.01(9), P(2)−Rh(2)−N(2) 91.36(6), P(2)−Rh(2)−C(2) 88.58(9), Rh(1)−S(1)−C(8) 105.62(9), Rh(2)−N(2)−C(8) 119.6(2), S(1)−C(8)−N(2) 117.6(2), Rh(2)−S(2)−C(3) 107.90(9), Rh(1)−N(1)−C(3) 120.0(2), S(2)−C(3)−N(1) 119.6(2)

of the of the four interligand *cis* angles, 354.08°, and (ii) from the angles between the normals to the planes defined by the P−Rh−C(1) and N(1)−Rh−S, or the C(1)−Rh−N(1) and P−Rh−S fragments, which are 3.94° and 4.06°, respectively. The four-membered chelate ring exhibits a bend along the N(1)···S vector of 4.31°, i.e., it adopts a very flat folded conformation. Considerable ring strain is evident from the small chelate bite angle of only 69.03(7)°. The metal-to-nitrogen bond in **4**, 2.128(2) Å, is somewhat longer than the two Rh−N distances observed for **3**, 2.118(2) and 2.122(2) Å, in spite of being *trans* to the PPh_3 ligand which has a weaker *trans* influence than the carbonyl ligand *trans* to the nitrogen atoms in **3**. By contrast, the length of the Rh−S bond opposite to the CO ligand with its strong *trans* influence in **4**, 2.371(1) Å, is slightly shorter than the Rh−S distances in **3**, 2.3929(8) and 2.4053(7) Å, where the mercapto groups are coordinated *trans* to the PPh_3 ligand. The small N(1)−Rh−S bite angle (see above) and the acute valence angle at the sulfur atom in **4**, 80.89(9)°, emphasize the strain within the small chelate ring, since an increase of the Rh−S bond length, accompanied by a shortening of the Rh−N linkage, would result in further unfavorable compression of the Rh−S−C angle.

Structures of Rhodium Complexes 3 and 4 in Solution

The structures adopted by two rhodium(I) thiolates in solution diverge considerably from those in the solid state, scrambling of the phosphane ligands and rearrangement processes arising from facile interconversion of the coordination modes of the two *S*,*N*-bonded thiolates being common phenomena.

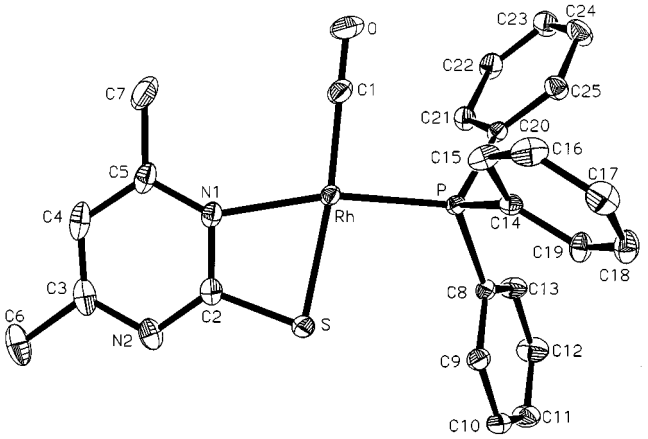

Figure 2. Molecular structure of [Rh('SpymMe$_2$'-κ*N*,κ*S*)(CO)(PPh_3)] (**4**); selected bond lengths [Å] and angles [°]: Rh−S 2.3715(14), Rh−P 2.2475(6), Rh−N(1) 2.128(2), Rh−C(1) 1.843(3), S−C(2) 1.743(3), N(1)−C(2) 1.362(3), N(2)−C(2) 1.326(3); S−Rh−C(1) 173.39(8), P−Rh−N(1) 165.88(6), S−Rh−P 97.15(3), S−Rh−N(1) 69.03(7), P−Rh−C(1) 89.27(9), N(1)−Rh−C(1) 104.6(1), Rh−S−C(2) 80.89(9), Rh−N(1)−C(2) 99.6(1), S−C(2)−N(1) 110.3(2)

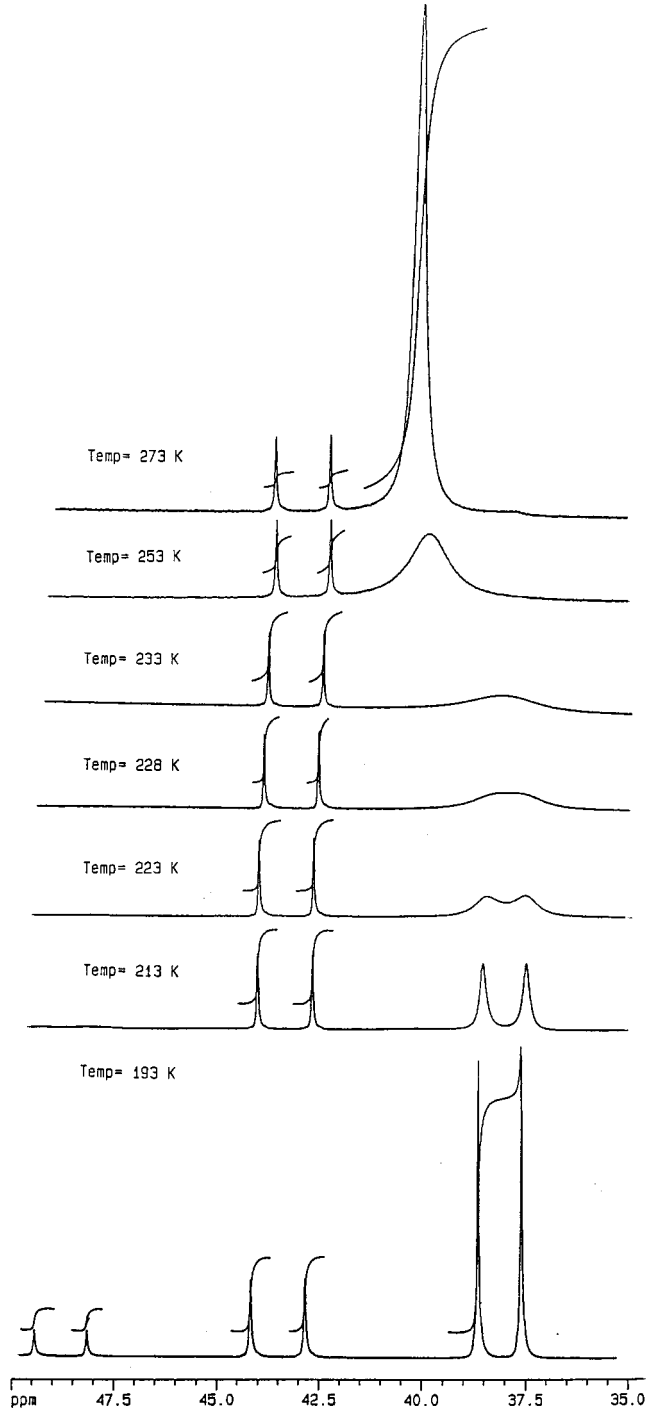
At 35 °C, the $^{31}P\{^1H\}$ NMR spectrum of chelate complex **4** consists of a time-averaged singlet (δ = 39.4 in CD_2Cl_2) rather than the expected ^{103}Rh-coupled doublet, thereby indicating rapid phosphane exchange at ambient temperature. On cooling to −80 °C, this signal broadens, shifts slightly upfield, and eventually becomes a sharp doublet centered at δ = 37.7 [^1J(Rh,P) = 126 Hz] which reversibly collapses into a single line as the temperature is raised (Figure 3). The corresponding proton spectra of **4**, recorded as a function of temperature in CD_2Cl_2, contain a sharp singlet (δ = 1.89) of relative intensity 6 at 25 °C, which broadens and finally collapses as the solution is cooled to −80 °C. At even lower temperatures (about −90 °C), two separate resonances of equal intensity begin to emerge at δ = 1.58 and 1.86. At the slow exchange limit, these data are in accordance with a ground-state structure showing two different environments for the methyl groups, as observed for the solid state. Obviously, at higher temperatures, the CH_3 residues undergo rapid site exchange, accompanied by reversible PPh_3 dissociation. Time-averaging of the methyl environments may occur by fast interconversion of species having either the pyrimidine nitrogen atom N-1 or its counterpart N-3 bound to the metal center; Scheme 2, Equation (1). Previously, such nitrogen scrambling between the coordinated and noncoordinated sites of pyrimidine chelates has been established for the monomeric (4-methylpyrimidine-2-thiolato)palladium complex [PdCl('SpymMe-4'-κ*N*,κ*S*)(PMe_3)], resulting from cleavage of the parent dimer [{PdCl(μ-'SpymMe-4'-κ*N*,κ*S*)(PMe_3)}$_2$] in solution.[6b] Alternatively, chelate complex **4**, with its Rh−P bond *trans* to the N atom could rapidly interconvert at room temperature with an isomer having the phosphorus and sulfur atoms in mutually *trans* positions; Scheme 2, Equation (2). On the basis of the available data, we cannot determine whether the dynamic behavior of **4** is caused by nitrogen scrambling or by interconversion of species with Rh−N or Rh−S bonds *trans* to Rh−P, nor can we rule out

the possibility that both mechanisms are operative. Note, however, that the exchange of PPh_3 ligands observed at higher temperatures, i.e., the intermediacy of the formally three-coordinate {Rh('SpymMe$_2$'-κ*N*,κ*S*)(CO)}, is more readily reconciled with the interconversion of species having either the sulfur or the nitrogen atom *trans* to the phosphorus atom than with ligand scrambling according to Equation (1), for which loss of chelation with intermediate formation of *S*-monodentate {Rh('SpymMe$_2$'-κ*S*)(CO)(PPh_3)} is the sole prerequisite.



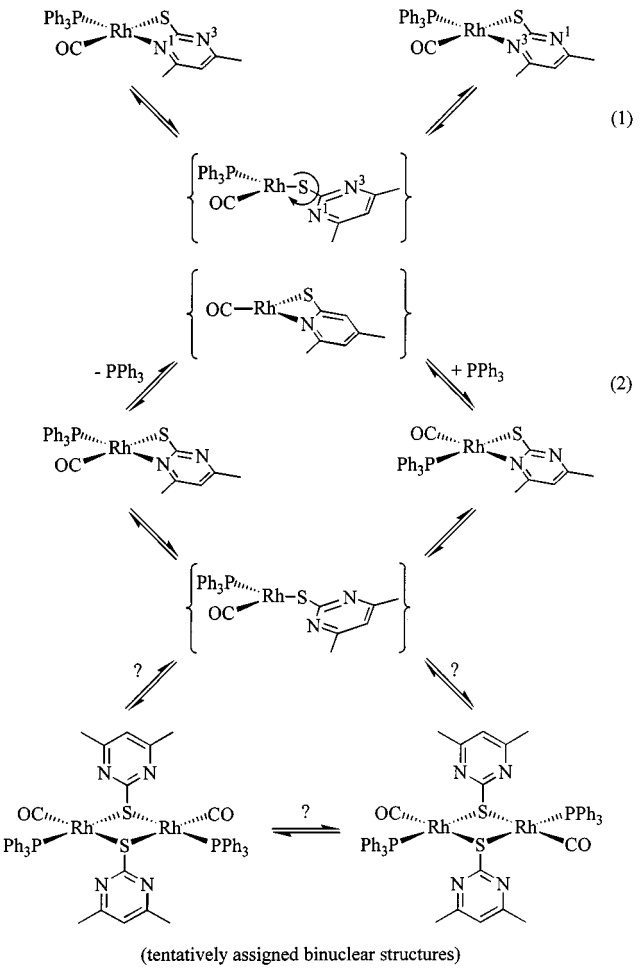


Figure 3. Temperature-dependent $^{31}P\{^1H\}$ NMR spectra of [Rh('SpymMe$_2$'-κ*N*,κ*S*)(CO)(PPh_3)] (**4**); CD_2Cl_2 solutions

Scheme 2. Structures believed to account for the dynamic behavior of [Rh('SpymMe$_2$'-κ*N*,κ*S*)(CO)(PPh_3)] (**4**) in solution

Complex **4** is not the only species present in solution at lower temperatures, since the temperature-dependent emergence of the ^{31}P doublet arising from **4** is accompanied by the appearance of additional Rh-coupled resonances which are *not* observed for freshly prepared samples at ambient temperature, but show up as sharp doublets centered at δ = 43.1 (J = 161 Hz) and 48.4 (J = 157 Hz) when the solution is first cooled to 0 °C and then to −80 °C (Figure 3). These shift values and coupling constants closely resemble those of the *cis*-(*P*,*P*) and *trans*-(*P*,*P*) forms of a number of thiolato-*S*-bridged dirhodium complexes [{Rh(μ-SAr)(CO)(PPh_3)}$_2$]: $\delta \approx 43$ (*cis*), 45 (*trans*); ^1J(Rh,P) ≈ 160 Hz.[13] For this reason, the low-field resonance at δ = 48.4 emerging below −60 °C is tentatively attributed to a thiolato-*S*-bridged binuclear isomer of **4** with the two phosphane ligands in *trans* positions, the signal located at δ = 43.1 correspondingly being assigned to the isomeric *cis* form. Both species can arise from **4** by loss of chelation (vide supra) followed by dimerization and, vice versa, may be cleaved to reform the monomer either with the Rh−N or the Rh−S bond *trans* to the PPh_3 ligand. Once formed, the resonance centered at δ = 43.1 persists as a sharp doublet on raising the temperature, which shows that the associ-

ated molecules are nonfluxional on the NMR time scale and interconvert with those of **4** only very slowly, if at all.

The $^{31}P\{^1H\}$ NMR spectrum of the dirhodium complex **3**, recorded in CD_2Cl_2 at −80 °C, displays two sharp doublets at δ = 37.0 [^1J(Rh,P) = 132 Hz] and 41.7 [^1J(Rh,P) = 162 Hz] with relative intensities 9 and 1, respectively. The latter signal obviously corresponds to the low-temperature resonance {δ = 42.1, ^1J(Rh,P) = 162 Hz; [D_6]acetone, −60 °C} previously assigned to the structurally uncharacterized PPh_3-disubstituted complex [{Rh(μ-'Spy')(CO)(PPh_3)}$_2$] which Oro and co-workers observed in acetone solution as a rearrangement product of [Rh_2(μ-'Spy')$_2$(CO)$_3$(PPh_3)].[9b] In line with the tentative spectral assignments made above, we attribute the less intense doublet exhibited by **3** in dichloromethane at δ = 41.7 to a thiolato-*S*-bridged *cis*-(*P*,*P*)-isomeric form of **3**, viz. [{Rh(μ-'Spy'-κ*S*)(CO)(PPh_3)}$_2$]. The more intense doublet at δ = 37.0 is then thought to arise from the *S*,*N*-bridged dirhodium complex **3** itself. It should be emphasized that in the structurally similar, albeit nonfluxional, thiazoline-2-thiolato-bridged complex [{Rh(μ-$S_2NC_3H_4$-κ*N*,κ*S*)(CO)(PPh_3)}$_2$], the ^{31}P nuclei resonate at δ = 39.8 although their coupling to the rhodium nucleus (164 Hz) is larger.[10b] On raising the temperature to −40 °C, the slow exchange limit signal attributed to **3** collapses reversibly into a time-averaged signal which remains broad and shifts upfield to δ ≈ 25 if the solution is warmed to ca. 35 °C, thereby indicating a chemical exchange process but providing no further information. Reversible broadening of the doublet assigned to the *S*-bridged dimer [{Rh(μ-'Spy'-κ*S*)(CO)(PPh_3)}$_2$] on warming and cooling the solution likewise points to some unknown dynamic behavior of the associated molecules, which in this respect are clearly different from the rigid species giving rise to the sharp doublet at δ = 41.3 in the temperature-dependent $^{31}P\{^1H\}$ spectra of **4** (Figure 3). Facile interconversion of binuclear structures bridged by pyridine-2-thiolato ligands in different bonding modes is well documented[9b,9c] but seems to be less feasible for structures involving the sterically more demanding 4,6-dimethylpyrimidine-2-thiolate system.

Protonation of Iridium Complexes 1 and 2

Treatment of **1** or **2** with hydrogen chloride in CH_2Cl_2 results in protolytic cleavage of the Ir−S bond and oxidative addition of HCl to give the long-known complex [$IrHCl_2$(CO)(PPh_3)$_2$].[14] While only uncharacterized mixtures of products were isolated from reactions between **1** and HBF_4 or CF_3CO_2H, clean protonation of the iridium atom was observed to occur if **2** was combined with excess trifluoroacetic acid in dichloromethane. The resulting product, formally a 1:2 adduct between **1** and CF_3CO_2H, was characterized by X-ray diffraction as the hydrogen bis(trifluoroacetate) salt of a monopositive hydridoiridium(III) complex, [IrH('SpymMe$_2$'-κ*N*,κ*S*)(CO)(PPh_3)$_2$][H(O_2CCF_3)$_2$], containing the pyrimidine-2-thiolate ligand in a chelating coordination mode (Scheme 1, **5a**; Figure 4), rather than the hoped-for trifluoroacetate-coordinated [IrH{OC(O)CF_3}(2-$SC_4HNN(H)Me_2$-4,6)(CO)(PPh_3)$_2$]-

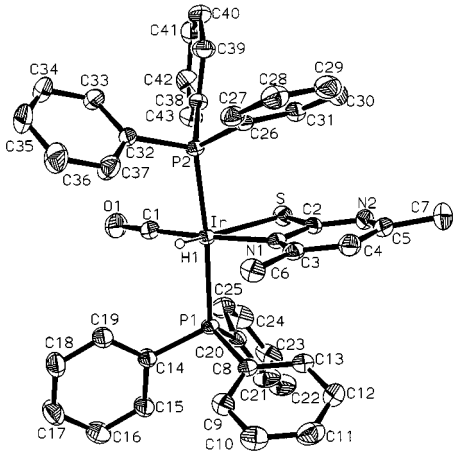

Figure 4. Molecular structure of [IrH('SpymMe$_2$'-κ*N*,κ*S*)(CO)(PPh_3)$_2$]$^+$ (cation of **5a**); selected bond lengths [Å] and angles [°]: Ir−S 2.481(2), Ir−P(1) 2.367(1), Ir−P(2) 2.367(1), Ir−N(1) 2.080(5), Ir−C(1) 1.858(8), Ir−H(1) 1.31(6), S−C(2) 1.727(7), N(1)−C(2) 1.360(8), N(2)−C(2) 1.320(8); P(1)−Ir−P(2) 173.02(6), N(1)−Ir−C(1) 174.5(3), S−Ir−P(1) 94.57(6), S−Ir−P(2) 92.31(6), S−Ir−N(1) 66.7(1), S−Ir−C(1) 108.0(2), P(1)−Ir−N(1) 91.5(1), P(1)−Ir−C(1) 90.5(2), P(2)−Ir−N(1) 90.1(1), P(2)−Ir−C(1) 88.5(2), S−Ir−H(1) 154(3), P(1)−Ir−H(1) 94(3), P(2)−Ir−H(1) 79(3), N(1)−Ir−H(1) 89(3), C(1)−Ir−H(1) 96(3), Ir−S−C(2) 79.5(2), Ir−N(1)−C(2) 104.3(4), S−C(2)−N(1) 109.5(5)

O_2CCF_3 (Scheme 1, **5b**), featuring intramolecular hydrogen bonding[12] between the Ir−H fragment and the N−H bond of a monodentate zwitterionic pyrimidinium-2-thiolate ligand. The sulfur atom of the four-membered Ir−S−C−N heterocycle is *trans* with respect to Ir−H, the metal-bound pyrimidine nitrogen atom being *trans* to the carbonyl group. The highly strained chelate ring [bite angle S−Ir−N(1), 66.7(1)°] exhibits a bend along the N(1)···S vector of 3.41°. As a consequence of the pronounced weakening of the *trans* influence of the hydride ligand, the Ir−S distance, 2.481(2) Å, is much longer than the metal−sulfur bond in chelate complex **4** [2.371(1) Å], resulting in the valence angle at the sulfur atom shrinking from 80.89(9)° in molecule **4** to 79.5(2)° in cation **5a**$^+$. The [H(O_2CCF_3)$_2$]$^-$ ion encountered in structure **5a** is precedented, typical examples are the alkali metal salts M[H(O_2CCF_3)$_2$)], where M = K, Rb, or Cs,[15] and the trifluoroacetic acid tetrahydrate which adopts the ionic structure [H_5O_2][H(O_2CCF_3)$_2$]·$6H_2O$.[16] The geometry, optimized for the "best"[17] hydrogen bond in the [H(O_2CCF_3)$_2$]$^-$ anion of **5a** (O−H, 0.82 Å; H···O, 1.71 Å; O···O, 2.53 Å, OHO, 170.7°), is quite normal and compares well with those of earlier determinations. The planes defined by the two carboxylate fragments are twisted about the O−H···O bond, such that the angle between them is 71.9°.

Although the hydrogen bis(trifluoroacetate) anion is known to be stabilized by short and strong hydrogen bonds,[16b] it is somewhat surprising that in the crystal structure analysis, the second molecule of CF_3CO_2H (pK_a = 0.18) consumed in the protonation of **2** binds to the $CF_3CO_2^-$ counterion rather than the basic pyrimidine nitrogen atom of the [IrH('SpymMe$_2$'-κ*N*,κ*S*)(CO)(PPh_3)$_2$]$^+$ cation formed in the first step.[18] It

is difficult to ascertain whether this bonding situation is restricted to the solid state or whether and to what extent the $[H(O_2CCF_3)_2]^-$ ion persists in solution. Proton NMR spectra of CD_2Cl_2 solutions of **5a** did contain a sharp singlet at $\delta = 15.0$, indicative of hydroxy protons involved in hydrogen-bonding, but otherwise remained inconclusive as the complex could not be isolated completely free from lattice water (see Experimental Section) which rapidly exchanges with the acid. Using HBF_4 to protonate compound **2** led to formation of the tetrafluoroborate [IrH('S-pymMe$_2$'-κ*N*,κ*S*)(CO)$(PPh_3)_2$]BF_4·HBF_4 as a formal analogue of the trifluoroacetate **5a**. In contrast with the latter, the cation of the BF_4^- salt exists as two isomers which differ in the bonding of the hydride ligand, which may be *trans* to the S atom, δ(IrH) = −14.46 (t), or *trans* to the N atom, δ(IrH) = −16.57 (t).[19] Based on the relative peak areas of these hydride signals and the associated methyl singlets at $\delta = 1.88$ and 2.45 (IrH *trans* to S) and $\delta = 2.17$ and 2.40 (IrH *trans* to N), the isomer ratio *trans*-(*H*,*S*)/*trans*-(*H*,*N*) can be estimated as 67:33, in good agreement with the ^{31}P spectra containing singlets at δ = 8.2 and 9.0 with relative intensities 60:40. Dichloromethane solutions of the tetrafluoroborate also displayed a concentration-dependent, broadened proton resonance in the range $8 < \delta < 13$, attributable to a nitrogen-bonded proton engaged in further hydrogen bonding, presumably to BF_4^-. Hence, the two isomeric tetrafluoroborates are tentatively assigned structures **5c** and **5d** with *N*-protonated 4,6-dimethylpyrimidinium-2-thiolato chelate ligands.

Pyridine-2-thiol oxidatively adds to *trans*-[Ir('Spy')(CO)$(PPh_3)_2$] (**1**), forming [IrH('Spy')$_2$(CO)$(PPh_3)_2$] (**6**). This complex is more directly prepared by reaction of *trans*-[IrCl(CO)$(PPh_3)_2$] with an excess of the 'pySH' ligand in the presence of triphenylphosphane to prevent PPh_3 dissociation. The *trans*-(*P*,*P*)-*cis*-(*S*,*S*) coordination geometry shown for **6** in Scheme 1 is suggested by spectral data. In particular, the $^{31}P\{^1H\}$ NMR spectrum displays a singlet ($\delta = 7.61$), and the proton NMR spectrum contains an IrH triplet which shows equal *cis* coupling (10.8 Hz) to the two equivalent ^{31}P nuclei and is shifted to much lower frequencies ($\delta = -13.54$) than appear to be diagnostic of the presence of *trans*-H−Ir−CO units ($\delta \approx -9$) in carbonylhydrido complexes of the general type [IrH(X)(Y)(CO)$(PR_3)_2$].[21−23] Iridium complex **6** reacts with HBF_4 in $CHCl_3$ solution by cleavage of one Ir−S bond and protonation at the metal center to form the ionic chelate complex [IrH('Spy'-κ*N*,κ*S*)(CO)$(PPh_3)_2$]BF_4 (**7**). The cation of this compound is isoelectronic with [OsH('Spy'-κ*N*,κ*S*)(CO)$(PPh_3)_2$] which was previously isolated as a mixture of two *trans*-(*P*,*P*) isomers having the hydrido ligand *trans* to the N atom or *trans* to the S atom.[5a][20a] The X-ray structure analysis of **7** showed that [IrH('Spy'-κ*N*,κ*S*)(CO)$(PPh_3)_2]^+$ exists in the *trans*-(*P*,*P*)-*trans*-(*H*,*S*) form (Figure 5). Bond lengths and angles within the near-planar four-membered ring (bend along N···S vector, 2.20°) are similar to those found for pyrimidine-2-thiolato derivative **5**: Ir−S 2.507(2) Å; Ir−N 2.069(5) Å; S−Ir−N 66.3(1)°; Ir−S−C(2) 78.7(2)°.

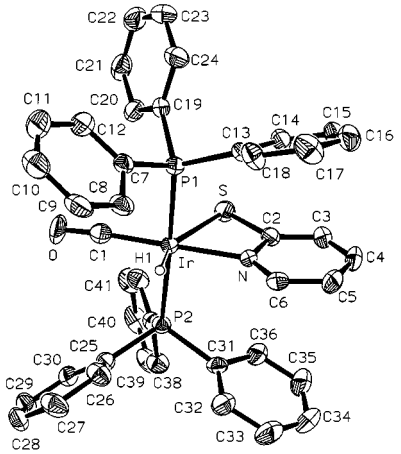

Figure 5. Molecular structure of [IrH('Spy'-κ*N*,κ*S*)(CO)$(PPh_3)_2]^+$ (cation of **7**); selected bond lengths [Å] and angles [°]: Ir−S 2.508(2), Ir−P(1) 2.371(1), Ir−P(2) 2.357(1) Ir−N 2.069(5), Ir−C(1) 1.853(8), Ir−H(1) 1.49(7), S−C(2) 1.725(6), N−C(2) 1.351(8); P(1)−Ir−P(2) 174.16(6), N−Ir−C(1) 177.9(3), S−Ir−P(1) 92.56(6), S−Ir−P(2) 93.14(6), S−Ir−N 66.3(1), S−Ir−C(1) 111.7(3), P(1)−Ir−N 90.3(1), P(1)−Ir−C(1) 90.4(2), P(2)−Ir−N 90.9(1), P(2)−Ir−C(1) 88.6(2), S−Ir−H(1) 154(2), P(1)−Ir−H(1) 84(2), P(2)−Ir−H(1) 91(2), N−Ir−H(1) 88(2), C(1)−Ir−H(1) 94(3), Ir−S−C(2) 78.7(2), Ir−N−C(2) 105.1(4), S−C(2)−N 110.0(5)

While treatment of the osmium(II) complex [OsH('Spy'-κ*N*,κ*S*)(CO)$(PPh_3)_2$] with HBF_4 resulted in the formation the highly acidic, yet stable, dihydrogen derivative [Os(H_2)('-Spy'-κ*N*,κ*S*)(CO)$(PPh_3)_2$]BF_4,[20] no similar transformation was observed on attempted protonation of **7**. Previously, a model for predicting the properties of dihydrogen complexes $[M(H_2)L_5]$ was described,[24] based on estimated electrochemical potentials $E_{1/2}(d^5/d^6)$ calculated by use of Lever's ligand additivity approach[25] for six-coordinate complexes. It was concluded that dihydrogen complexes $[M(H_2)L_5]$ that are stable with respect to loss of H_2 at ambient temperature will correspond to hypothetical dinitrogen complexes $[M(N_2)L_5]$ with potentials $E_{1/2}(d^5/d^6)$ of about 2 V versus NHE if the H_2 ligand is *trans* to a σ donor on a Group 7, 8, or 9 metal ion; on the other hand, dinitrogen complexes with potentials above 2 V will have corresponding $[M(H_2)L_5]$ species that lose dihydrogen irreversibly at 20−25 °C, possibly with the exception of $[Ir^{III}(H_2)L_5]^{n+}$ where stable metal−H_2 bonding appears feasible up to potentials $E_{1/2}([Ir^{IV}(H_2)L_5]^{n+}/[Ir^{III}(H_2)L_5]^{(n-1)+})$ of ca. 2.2 V.[24] By use of the sum of additive electrochemical ligand parameters, ΣE_L, as proposed by Lever (E_L = 0.99 V for CO, 0.68 V for N_2, and 0.39 V for PPh_3)[25a] and Morris ($E_L = -0.28$ V for chelating 'Spy$^-$'),[20b] and the linear correlation $E_{1/2} = 0.7\Sigma E_L + 1.3$, suggested by Morris for the Ir^{IV}/Ir^{III} redox couple,[24] the $E_{1/2}(d^5/d^6)$ value for a hypothetical dinitrogen-containing dication [Ir(N_2)('Spy'-κ*N*,κ*S*)(CO)$(PPh_3)_2]^{2+}$ is estimated at ca. 2.8 V, far beyond the limit where stable bonding of H_2 could be expected for a dipositive dihydrogen species [Ir(H_2)('Spy'-κ*N*,κ*S*)(CO)$(PPh_3)_2]^{2+}$!

Conclusion

This work has shown that the Vaska-type complexes *trans*-[MCl(CO)(PPh_3)$_2$] (M = Rh, Ir) react with bifunctional anionic pyridine- and 4,6-dimethylpyrimidine-2-thiolates to yield products whose nature is sensitive to the metal center and the steric requirements of the ligands. With iridium(I), both 'Spy$^-$' and 'SpymMe$_2^-$' act as *S*-monodentates to give the complexes, *trans*-[Ir('Spy')(CO)(PPh_3)$_2$] (**1**) and *trans*-[Ir('SpymMe$_2$')(CO)(PPh_3)$_2$] (**2**), which result from simple anion exchange. In similar reactions, *trans*-[RhCl(CO)(PPh_3)$_2$] undergoes loss of both the chloride ion and one PPh_3 ligand, affording derivatives in which the two anionic *S*,*N* donors act as bidentate bridging or chelate ligands. With 'Spy$^-$' as an entering ligand we see the formation of bimetallic [{Rh(μ-'Spy'-κ*N*,*S*)(CO)(PPh_3)}$_2$] (**3**) where the two pyridine-2-thiolate moieties act as *S*,*N* bridges in the head-to-tail arrangement frequently encountered[9b,10] for heterocyclic ligands with *N*−C−*S* donor sets. The sterically more demanding 4,6-dimethylpyrimidine-2-thiolate system, on the other hand, does not give any related doubly *S*,*N*-bridged binuclear product with nearly parallel heterocyclic rings but rather acts as a chelate ligand towards Rh^I, producing the unusual four-membered ring complex [Rh('SpymMe$_2$'-κ*N*,κ*S*)(CO)(PPh)$_3$] (**4**). Because of facile interconversion of the bonding modes of the *S*,*N*-coordinated ligands, the structures adopted by **3** and **4** in the solid state are not maintained in solution but show temperature-dependent dynamic behavior.

Reaction of iridium complexes bearing *S*-bonded 'Spy' and 'SpymMe$_2$' ligands with strong acids (CF_3CO_2H, HBF_4) results in protonation of only the metal center, except for the *trans*-(*H*,*S*) and *trans*-(*H*,*N*) isomers of [IrH(2-$SC_4HNN(H)Me_2$-4,6-κ*N*,κ*S*)(CO)(PPh_3)$_2$](BF_4)$_2$ where NMR spectroscopy suggests that protonation at the noncoordinated nitrogen atom of the pyrimidine heterocycle also occurs. There was no indication of reactions leading to products displaying "nonclassical" intramolecular IrH···HN hydrogen bonding. The failure to isolate such derivatives within the family of complexes studied here is accounted for by the ease of the 'Spy' and 'SpymMe$_2$' ligands to act as *S*,*N* donor chelates in spite of their small bite angles. This prevents the formation of hydridoiridium derivatives containing *S*-monodentate thiolate ligands with "dangling" pyridyl or pyrimidinyl substituents, which would allow a sufficiently close approach of the ring nitrogen atoms to the Ir−H bond.

Experimental Section

General Remarks: All manipulations were performed under nitrogen using standard Schlenk techniques. Solvents were distilled from the appropriate drying agents prior to use. − IR: Mattson Polaris. − NMR: Bruker DPX 300 (300.1 MHz for ^{1}H, 121.5 MHz for ^{31}P) at 20 ± 2 °C (if not stated otherwise) with TMS as internal or with H_3PO_4 as external standard (downfield positive). − The starting complexes *trans*-[RhCl(CO)(PPh_3)$_2$][26] and *trans*-[IrCl(CO)(PPh_3)$_2$][27] were prepared by literature methods; the ligands pyridine-2-thiol and 4,6-dimethylpyrimidine-2-thiol were used as obtained commercially.

***trans*-[Ir('Spy')(CO)(PPh_3)$_2$] (1):** A solution of pyridine-2-thiol (170.1 mg, 1.53 mmol) in THF (10 mL) was treated with sodium hydride (36.8 mg, 1.54 mmol) at room temperature for 1 h and then added to a suspension of *trans*-[IrCl(CO)(PPh_3)$_2$] (1.002 g, 1.28 mmol) in THF (25 mL). The dark red mixture was stirred for 1 h at ambient conditions and then concentrated to dryness. The residue was taken up in toluene (60 mL) and the solution was filtered through a layer of sea sand/Celite. Concentration of the filtrate to 5 mL and careful addition of pentane (60 mL) caused the precipitation of a yellow-orange powder which was recrystallized from dichloromethane to give the product complex as orange crystals; yield 880 mg (80%). − IR (KBr): $\tilde{\nu}$ = 1924 (CO) cm^{-1}. − ^{1}H NMR ($CDCl_3$): δ = 6.08 (d, *J* = 8.1 Hz, 1 H, C_5H_4N), 6.28 (d, *J* = 8.4 Hz, 1 H, C_5H_4N), 6.42 ("t", *J* = 13.2 Hz, 1 H, C_5H_4N), 6.62 ("t", *J* = 13.2 Hz, 1 H, C_5H_4N), 7.3−7.4 (m, 18 H, C_6H_5), ca. 7.6 (m, 12 H, C_6H_5). − ^{31}P{^{1}H} NMR ($CDCl_3$): δ = 21.3. − $C_{42}H_{34}IrNOP_2S$ (855.0): calcd. C 59.00, H 4.01, N 1.64, S 3.75; found C 59.15, H 4.00, N, 1.53, S 3.93.

***trans*-[Ir('SpymMe$_2$')(CO)(PPh_3)$_2$] (2):** 4,6-Dimethylpyrimidine-2-thiol (85.4 mg, 0.61 mmol) was deprotonated by treatment with an equimolar amount of sodium methoxide in methanol (5 mL). The resulting solution was added dropwise to a stirred suspension of *trans*-[IrCl(CO)(PPh_3)$_2$] (44.2 mg, 0.56 mmol) in THF. After stirring for 3 h at ambient conditions, the solvent was removed in vacuo to leave a semisolid residue which was re-dissolved in benzene (25 mL). Filtration through sea sand/Celite followed by concentration of the filtrate to ca. 3 mL gave a clear solution from which the product was isolated by slow addition of pentane (50 mL); yield 420 mg (85%) as orange microcrystals. − IR (KBr): $\tilde{\nu}$ = 1928 (CO) cm^{-1}. − ^{1}H NMR ($CDCl_3$): δ = 1.73 (s, 6 H, CH_3), 5.55 (s, 1 H, C_4H), ca. 7.3 (m, 18 H, C_6H_5), ca. 7.5 (m, 12 H, C_6H_5). − ^{31}P{^{1}H} NMR ($CDCl_3$): δ = 19.4. − $C_{43}H_{37}IrN_2OP_2S$ (884.2): calcd. C 58.36, H 4.22, N 3.17, S 3.62; found C 58.50, H 4.25, N 3.08, S 3.39.

[{Rh(μ-'Spy'-κ*N*,κ*S*)(CO)(PPh_3)}$_2$] (3): A procedure analogous to that for **1** was employed, using *trans*-[RhCl(CO)(PPh_3)$_2$] (549.7 mg, 0.80 mmol) and sodium pyridine-2-thiolate (117.2 mg, 0.88 mmol) in THF (30 mL) at room temperature for 3 h. Crystallization of the product from dichloromethane/pentane furnished the orange complex as the compound [{Rh(μ-'Spy'-κN,κS)(CO)(PPh_3)}$_2$·CH_2Cl_2 (**3**·CH_2Cl_2); yield 360 mg (82%). − IR (KBr): $\tilde{\nu}$ = 1937 (CO) cm^{-1}. − ^{1}H NMR (CD_2Cl_2, −40 °C): δ = 5.65 ("t", *J* = 12.4 Hz, 2 H, C_5H_4N), 6.19 (d, *J* = 8.2 Hz, 2 H, C_5H_4N), 6.37 ("t", *J* = 10.2 Hz, 2 H, C_5H_4N), 6.55 (d, *J* = 5.1 Hz, 2 H, C_5H_4N), 7.1−7.3 (m, 18 H, C_6H_5), ca. 7.5 (m, 12 H, C_6H_5). − ^{31}P{^{1}H} NMR (CD_2Cl_2, −80 °C): δ = 37.0 [d, ^1J(Rh,P) = 132 Hz]. − $C_{48}H_{38}N_2O_2P_2Rh_2S_2$·$CH_2Cl_2$ (1092): calcd. C 53.91, H 3.69, N 2.57; found C 54.26, H, 3.34, N, 2.25.

[Rh('SpymMe$_2$'-κ*N*,κ*S*)(CO)(PPh_3)] (4): The yellow-orange complex was prepared as for **2** by allowing *trans*-[RhCl(CO)(PPh_3)$_2$] (590.4 mg, 0.85 mmol) to react with a 10% excess of methanolic sodium 4,6-dimethylpyrimidine-2-thiolate in THF (20 mL); yield 410 mg (91%). − IR (KBr): $\tilde{\nu}$ = 1968 (CO) cm^{-1}. − ^{1}H NMR (CD_2Cl_2): δ = 1.89 (s, 6 H, CH_3), 5.72 (s, 1 H, C_4H), ca. 7.4 (m, 9 H, C_6H_5), ca. 7.7 (m, 6 H, C_6H_5). − ^{31}P{^{1}H} NMR (CD_2Cl_2, −80

°C): δ = 37.7 [d, ^1J(Rh,P) = 126 Hz]. − $C_{25}H_{22}N_2OPRhS$ (532.4): calcd. C 56.40, H 4.17, N 5.26, S 6.02; found C 56.84, H 4.22, N 5.28, S 5.92.

[IrH('SpymMe$_2$'-κ*N*,κ*S*)(CO)(PPh$_3$)$_2$][H(O$_2$CCF$_3$)$_2$] (5a): Complex **2** (144.6 mg, 0.16 mmol) was allowed to react with an excess of neat trifluoroacetic acid (40 μL, ca. 0.5 mmol) in dichloromethane (20 mL) at room temperature for 30 min. Slow concentration of the mixture caused the product to precipitate as bright yellow crystals containing 1 molecule of lattice water per formula unit (**5a**·H_2O); yield 160 mg (88%). − IR (KBr): ṽ = 1792 (C=O), 2053 (CO), 2170 (IrH) cm^{-1}. − ^{1}H NMR (CD_2Cl_2): δ = −13.01 [t, *cis*-^2J(P,H) = 10.5 Hz, 1 H, IrH], 1.47, 2.20 (both s, 3 H each, both CH_3), 6.28 (s, 1 H, C_4H), ca. 7.4 (m, 18 H, C_6H_5), ca. 7.7 (m, 12 H, C_6H_5), 15.0 (s, OH). − ^{31}P{^{1}H} NMR (CD_2Cl_2): δ = 8.2 (s). − $C_{47}H_{39}F_6IrN_2O_5P_2S$·$H_2O$ (1130): calcd. C 49.95, H 3.66, N 2.48; found C 49.54, H 3.24, N 2.16.

[IrH(2-SC$_4$HNN(H)Me$_2$-4,6-κ*N*,κ*S*)(CO)(PPh$_3$)$_2$](BF$_4$)$_2$ (Mixture of Isomers 5c and 5d): A solution of **2** (189.5 mg, 0.21 mmol) in dichloromethane (20 mL) was treated with HBF_4 (30 μL, 54% in Et_2O). The mixture was stirred for 2.5 h at ambient conditions and then concentrated to dryness. The residue was re-dissolved in CH_2Cl_2 (8 mL) and the resulting solution was filtered and diluted with pentane (40 mL) to furnish the product as a light yellow microcrystalline precipitate containing solvent of crystallization; yield 190 mg (79%). − **5c:** ^{1}H NMR (CD_2Cl_2): δ = −14.46 [t, *cis*-^2J(P,H) = 9.9 Hz, 1 H, IrH], 1.88, 2.45 (both s, 3 H each, both CH_3), 7.05 (s, 1 H, C_4H), ca. 7.6 (m, C_6H_5). − ^{31}P{^{1}H} NMR (CD_2Cl_2): δ = 8.2 (s). − **5d:** ^{1}H NMR (CD_2Cl_2): δ = −16.57 [t, *cis*-^2J(P,H) = 10.8 Hz, 1 H, IrH], 2.17, 2.40 (both s, 3 H each, both CH_3), 7.03 (s, 1 H, C_4H), ca. 7.6 (m, C_6H_5). − ^{31}P{^{1}H} NMR (CD_2Cl_2): δ = 9.0 (s). − Isomeric distribution (from ^{1}H NMR): **5**c, 67%; **5d**, 33%. − $C_{43}H_{39}B_2F_8IrN_2OP_2S$·$CH_2Cl_2$ (1145): calcd. C 46.17, H 3.61, N 2.45, S 2.79; found C 46.15, H 3.76, N 2.61, S 2.45.

[IrH('Spy')$_2$(CO)(PPh$_3$)$_2$] (6): A 1:2 mixture of *trans*-[IrCl(CO)(PPh$_3$)$_2$] (480.4 mg, 0.62 mmol) and pyridine-2-thiol (140.2 mg, 1.26 mmol) was combined with excess triphenylphosphane (880 mg, 3.35 mmol) in benzene (80 mL). Stirring at room temperature for 24 h caused the product complex to separate from solution as a light yellow precipitate; yield 350 mg (58%). − IR (KBr): ṽ = 2036 (CO), 2177 (IrH) cm^{-1}. − ^{1}H NMR ($CDCl_3$): δ = −13.54 (t, *cis*-^2J(P,H) = 10.8 Hz, 1 H, IrH), 5.87 (d, *J* = 7.2 Hz, 2 H, C_5H_4N), 6.48 ("t", *J* = 14.4 Hz, 1 H, C_5H_4N), 6.66 ("t", *J* = 14.3 Hz, 1 H, C_5H_4N), 6.94 ("t", *J* = 16.2 Hz, 2 H, C_5H_4N), 7.07 (d, *J* = 6.8 Hz, 2 H, C_5H_4N), 7.2−7.6 (m, 30 H, C_6H_5). − ^{31}P{^{1}H} NMR ($CDCl_3$): δ = 7.6 (s). − $C_{47}H_{39}IrN_2OP_2S_2$ (966.1): calcd. C 58.43, H 4.07, N 2.90; found C 58.60, H 4.20, N 2.68.

[IrH('Spy'-κ*N*,κ*S*)(CO)(PPh$_3$)$_2$]BF$_4$ (7): A solution of **6** (170.1 mg, 0.18 mmol) in chloroform (10 mL) was stirred with HBF_4 (0.3 mL, 54% in E_2O) at ambient conditions for 1 h. Dilution of the mixture with diethyl ether (70 mL) resulted in the precipitation of **7** (150 mg, 88%) as bright yellow crystals. − IR (KBr): ṽ = 2047 (CO), 2162 (IrH) cm^{-1}. − ^{1}H NMR ($CDCl_3$): δ = −13.52 (t, *cis*-^2J(P,H) = 11.0 Hz, 1 H, IrH), 5.94 (d, *J* = 8.3 Hz, 1 H, C_5H_4N), 6.34 ("t", *J* = 14.9 Hz, 1H, C_5H_4N), 6.93 ("t", *J* = 15.5 Hz, 1 H, C_5H_4N), 7.02 (d, *J* = 6.2 Hz, 1 H, C_5H_4N), 7.4−7.6 (m, 30 H, C_6H_5). − ^{31}P{^{1}H} NMR ($CDCl_3$): δ = 7.5 (s). − $C_{42}H_{35}BF_4IrNOP_2S$ (942.7): calcd. C 53.51, H 3.74, N 1.49, S, 3.40; found C 53.17, H 3.73, N 1.59, S 3.40.

X-ray Structure Determinations: Single crystals of **3**·CH_2Cl_2 (size 0.55 × 0.43 × 0.26 mm), **4** (size 0.45 × 0.40 × 0.24 mm), **5a** (size 0.38 × 0.30 × 0.13 mm), and **7** (approximate size 0.4 × 0.2 × 0.2 mm) were grown from dichloromethane/pentane (**3**·CH_2Cl_2, **4**), chloroform/diethyl ether (**7**), and by crystallizing the hydrate **5a**·H_2O from dichloromethane. Diffraction measurements were made at −70 ± 2 °C (**4**) and 20 ± 2 °C (**3**·CH_2Cl_2, **5a**, **7**) on an Enraf−Nonius CAD-4 diffractometer using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å): orientation matrices and unit cell parameters from the setting angles of 25 centered medium-angle reflections; collection of the diffraction intensities by ω scans (data corrected for absorption by ψ scans; **3**·CH_2Cl_2: T_{min} = 0.61, T_{max} = 0.78; **4**: T_{min} = 0.69, T_{max} = 0.81; **5a**: T_{min} = 0.40, T_{max} = 0.70; **7**: T_{min} = 0.33, T_{max} = 0.54;). The structures were solved by direct methods employing the SIR-92[28] program system and subsequently refined by full-matrix least-squares procedures on F^2 (SHELX-97[29]) with allowance for anisotropic thermal motion of all non-hydrogen atoms. The residual electron density remaining after refinement of the structural model resulting for **3**·CH_2Cl_2 suggested threefold rotational disorder of the solvate molecule about the Cl−C−Cl bisector, which was accounted for by assigning the particular chlorine positions split occupancies of 0.333 each. The CF_3 groups of the hydrogen-bridged trifluoroacetate ions in structure **5** were found to be disordered over two sites with refined occupancies of 0.25:0.75 and 0.33:0.67, respectively. H atoms were included in the molecular models assuming ideal geometry and using appropriate riding models (Ir*H* of **5a** and **7** located from final Δ*F* maps). Some diffuse residual electron density near the inversion center of the triclinic unit cell of **5a** was modeled by assuming the presence of 1 molecule of lattice water originating from the synthesis and remaining after crystallization. − **3·CH$_2$Cl$_2$:** $C_{49}H_{40}Cl_2N_2O_2P_2Rh_2S_2$ (1092); triclinic, $P\bar{1}$, *a* = 11.260(1), *b* = 13.436(1), *c* = 16.881(3) Å, α = 78.87(1), β = 74.57(1), γ = 76.848(7)°, *V* = 2373.3(5) Å^3, *Z* = 2, $d_{calcd.}$ = 1.528 g cm^{-3}, μ(Mo-K_α) = 1.004 mm^{-1}; 2.52° ≤ Θ ≤ 29.97°, 14439 reflections (0 ≤ *h* ≤ +15, −18 ≤ *k* ≤ +18, −22 ≤ *l* ≤ +23) collected, 13789 unique; *wR* = 0.096 for all data and 586 parameters, *R* = 0.039 for 10393 structure factors $F_o > 4\sigma(F_o)$. − **4:** $C_{25}H_{22}N_2OPRhS$ (532.4); triclinic, $P\bar{1}$, *a* = 9.254(7), *b* = 10.035(2), *c* = 13.0940(8) Å, α = 93.05(1), β = 93.71(2), γ = 101.33(2)°, *V* = 1187.1(9) Å^3, *Z* = 2, $d_{calcd.}$ = 1.489 g cm^{-3}, μ(Mo-K_α) = 0.894 mm^{-1}; 2.51° ≤ Θ ≤ 30.08°, 7187 reflections (−13 ≤ *h* ≤ +13, −14 ≤ *k* ≤ +14, 0 ≤ *l* ≤ +18) collected, 6908 unique; *wR* = 0.120 for all data and 283 parameters, *R* = 0.029 for 6215 structure factors $F_o > 4\sigma(F_o)$. − **5a·H$_2$O:** $C_{47}H_{41}F_6IrN_2O_6P_2S$ (1130); triclinic, $P\bar{1}$, *a* = 11.771(1), *b* = 14.100(1), *c* = 15.573(1) Å, α = 85.418(8), β = 83.124(9), γ = 69.235(9)°, *V* = 2397.4(3) Å^3, *Z* = 2, $d_{calcd.}$ = 1.565 g cm^{-3}, μ(Mo-K_α) = 2.967 mm^{-1}; 2.64° ≤ Θ ≤ 25.97°, 10526 reflections (−14 ≤ *h* ≤ +14, −17 ≤ *k* ≤ +17, −1 ≤ *l* ≤ +19) collected, 9397 unique; *wR* = 0.115 for all data and 612 parameters, *R* = 0.046 for 7494 structure factors $F_o > 4\sigma(F_o)$. − **7:** $C_{42}H_{35}BF_4IrNOP_2S$ (942.7); orthorhombic, *Pbca*, *a* = 18.766(3), *b* = 18.104(1), *c* = 23.404(2) Å, *V* = 7951(1) Å^3, *Z* = 8, $d_{calcd.}$ = 1.575 g cm^{-3}, μ(Mo-K_α) = 3.544 mm^{-1}; 2.60° ≤ Θ ≤ 23.97°, 7863 reflections (−1 ≤ *h* ≤ +21, −1 ≤ *k* ≤ +20, −26 ≤ *l* ≤ +2) collected, 6215 unique; *wR* = 0.074 for all data and 482 parameters, *R* = 0.033 for 3830 structure factors $F_o > 4\sigma(F_o)$. − Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited at the Cambridge Crystallographic Data Centre and allocated the deposition numbers CCDC-136220 (**7**), -136221 (**5a**·H_2O), -136222 (**4**), and -136223 (**3**·CH_2Cl_2). [17] H atom position generated by the HFIX 83 option of SHELX-97, see ref.[29]
[18] Structure **5a** was initially refined as the 1:2 complex salt [IrH(2-$SC_4HNN(H)Me_2$-4,6-κ*N*,κ*S*)(CO)(PPh_3)$_2$](O_2CCF_3)$_2$ (Scheme 1; **5c**; $X^- = CF_3CO_2^-$) containing a dipositive cation with a pyridinium-2-thiolato ligand protonated at N(2). A subsequent validation check with the PLATON-99 program package (see ref.[30]), however, revealed an unusual short nonbonded contact distance of 2.53 Å between two carboxylate oxygen atoms of the two trifluoroacetate counterions located at general positions x_1, y_1, z_1 and $-x_2 - 1$, $-y_2$, $-z_2 + 1$. Furthermore, checking of the derived structural model showed that the polar N(2)−H bond had no acceptor acting as a weak base towards the acidic pyrimidinium proton. To account for these problems, the 1:1 complex salt [IrH('$SpymMe_2$'-κ*N*,κ*S*)(CO)(PPh_3)$_2$][H(O_2CCF_3}$_2$] with an O−H···O-bridged hydrogen bis(trifluoroacetate) anion was taken as the basis for the final stages of refinement.
[19] These isomer assignments are in accordance with trends in the ^{1}H NMR data reported by others (ref.[20b,21−23]) according to which the hydride resonance of the isomeric form having the hydride ligands *trans* to the more electronegative atom, e.g. N, appears at lower frequencies than that in which the M−H bond is *trans* to a less electronegative donor atom such as sulfur.

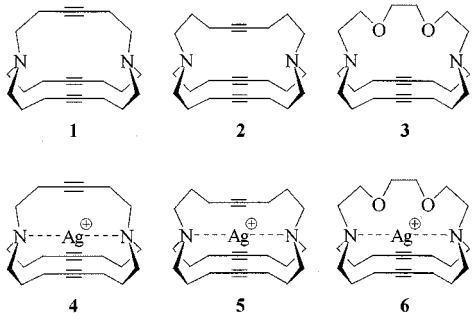
Ag^{I} Cryptates of *N,N′*-Bridged 1,10-Diazacyclooctadeca-5,14-diynes − A Comparison Between the Complexes and the Free Ligands

Rolf Gleiter,*[a] Thomas von Hirschheydt,[a] and Frank Rominger[a]

Dedicated to Professor Günter Helmchen on the occasion of his 60th birthday

Keywords: Silver / Alkyne Complexes / Cryptands / N Ligands

The bicyclic diaza alkynes **1**–**3** react quantitatively with silver triflate to give the corresponding cryptates **4**–**6**. The solid-state structures of the silver(I) complexes **4** and **6** were determined by means of X-ray diffraction studies. A comparison of the molecular structures of **4** and **6** with those of the uncomplexed ligands **1** and **3** reveals drastic changes in the conformations of the ligands. Evidence for an interaction of the silver ions with alkyne units in **4** and **6** was found from a high-field shift of the ^{13}C signal for the sp carbons in the ^{13}C NMR spectrum.



Introduction

Silver complexes of olefins are legion and have been reviewed on several occasions.[1] Less extensive are reports on silver complexes with benzene derivatives and alkynes even though several silver complexes with benzene derivatives[2] and alkynes[3] have been characterized by X-ray investigations. The formation of weak complexes between π-systems and silver ions has also been demonstrated by spectroscopic means[4] and solubility measurements,[5a] and has been used for analytical purposes.[5b]

We have recently synthesized a series of (1,*k*+2)diazabicyclo[*k,l,m*]alkanes[6] in which the bridges contain either alkyne or benzene units. The larger systems incorporate silver(I) and copper(I) ions[6c,6e] and thus provide further examples in which an alkyne or benzene unit is situated in close proximity to a metal ion. The examples shown so far reveal no evidence for an interaction of the metal ion with the π-system; instead, bonding to the amine center(s) is preferred. To contribute further to the question of silver−alkyne interactions we have investigated the silver complexes of the *N,N′*-bridged 1,10-diazacyclooctadeca-5,14-diynes **1**−**3**.[6d] These systems provide a rather flexible cage and thus might respond to a central silver ion with a considerable change of geometry, in such a way that a silver−alkyne interaction might result.

Results and Discussion

The reaction of the bicyclic compounds **1**−**3** with a small excess of silver(I) triflate in dichloromethane leads, in all three cases, to the corresponding cryptates **4**−**6** in quantitative yields (Scheme 1). The colorless crystals are sensitive to light in solution but proved to be stable in the solid state.

Scheme 1

X-ray Analysis

In the cases of **4** and **6**, we were able to grow single crystals by recrystallization from methanol. In Figure 1 and 2 we compare the molecular structures of **1** and **3** with those of **4** and **6**. Table 1 lists the most relevant bond distances in **1**, **3**, **4** and **6**.

A comparison between the congeners **1** and **4**, **3** and **6** reveals considerable conformational changes caused by the silver ion. This shows up in the torsional angle between the triple bonds of the 1,10-diazacyclooctadeca-5,14-diyne units and the N−N distances (Table 1). In compound **1** the bridgeheads adopt the *out/out* conformation with an N−N distance of 5.57 Å. In **4** this distance is reduced to 4.92 Å, while the torsional angle[7] between the triple bonds is enlarged from 23° in **1** to 82° in **4**. In compound **3** the *in/in* conformation is adopted with an N−N distance of 6.12 Å. In **6** the N−N distance is reduced to 4.57 Å. This reduction goes along with a considerable change of the torsional angle between the triple bonds from 20° in **3** to 81° in **6**.

In both silver complexes the metal ion is situated approximately in the center of the cage. The triflate anion no longer participates in the coordination sphere of the metal. Figure 1 and 2 also reveal that, in **4** and **6**, the N−Ag−N

bonds are not linear but slightly bent: 173° in **4** and 164° in **6**. The Ag−N distances vary between 2.45 Å and 2.48 Å for **4** and 2.32 Å and 2.28 Å for **6**. In both cases they are 0.1 to 0.3 Å longer than those Ag−N distances reported for several $Ag(NH_3)_2^+$ complexes.[8] The values obtained for the Ag−N distances in the cases of **4** and **6** are close to the Ag−N distances reported for the silver complex of 1,8-diazabicyclo[6.6.6]eicosa-4,11,17-triyne.[6c]

To judge the possibility of a metal−alkyne interaction we considered the distances between the triple bonds and the silver ions in **4** and **6** (Table 1). In compound **4** these distances vary between 2.55 Å and 2.67 Å. In compound **6** the variation of the Ag−C(sp) distances is larger and ranges from 2.77 Å to 4.00 Å. A comparison with the Ag−C(sp) distances of other silver alkyne complexes[3,6c] reveals values that are spread between 2.225 Å for a highly strained alkyne[3e] and from 2.85 Å to 3.05 Å in unstrained species.[3d] Based on this comparison we can describe the interaction between the silver ion and the triple bonds in **4** as a bonding one. The same arguments applied to **6** lead to the conclusion that only one triple bond (C5−C6) interacts with the metal. We ascribe this preference to a coordination of the silver ion in **6** with the oxygen atoms. The distances found in the case of **6** [Ag−O21 = 2.656(4) Å and Ag−O24 = 2.607(4) Å] are very similar to those reported for silver complexes of oligo(ethylenoxy)-bridged stilbenes.[9]

^{13}C NMR Investigations

In Figure 3 we have compared the ^{13}C NMR spectra of **1** and **4** (Figure 3a) as well as **3** and **6** (Figure 3b). The comparison between **1** and **4** shows a significant change in the area between δ = 75 and 80 where the sp-hybridized carbon signals are anticipated.

We find for **1** a small signal at δ = 81.8 for the two carbons of the hexyne bridge and at δ = 80.8 a signal of almost double intensity for the four sp carbon atoms of the two octyne bridges. After complexation with Ag^+, the latter signal remains almost unchanged, whereas the smaller signal is shifted upfield by 2.9 ppm.

In the case of the ^{13}C NMR spectrum of **6** at −60 °C we find two signals at δ = 81.1 and δ = 79.2. A comparison with the ^{13}C NMR spectrum of **3** (Figure 3b) suggests the

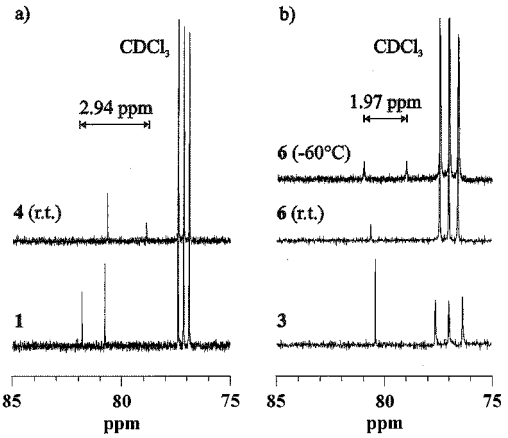

Figure 3. a) Section of the ^{13}C NMR spectrum ($CDCl_3$, 125.76 MHz) of **1** and **4** at room temperature; b) Section of the ^{13}C NMR spectrum ($CDCl_3$, 75.47 MHz) of **3** at room temperature and −60 °C

assignment of the low-field peak to the uncomplexed alkyne unit of **6** while the peak at δ = 79.2 should be assigned to the alkyne unit close to the silver ion.

The observed upfield shift due to complexation with the silver ion is unusual and has so far only been reported for the silver(I) complexes of highly strained thiacycloheptynes[3e] and some alkyne silver(I) hexafluoroacetylacetonato complexes.[3f] In the other silver complexes investigated so far[3] a low-field shift has been encountered. We ascribe the upfield shifts in **4** and **6** due to a close proximity of the metal ion and the triple bond, which is forced by the ligand. The observed upfield shift of the ^{13}C signal upon complexation with Ag^+ implies a better shielding of the sp carbon nuclei and, accordingly, a higher electron density at the coordinated triple bond than at the uncomplexed alkyne group. A possible explanation of this observation is due to the Dewar−Chatt−Duncanson model.[10] It suggests a back donation of electron density from the nitrogen lone pairs through the d orbitals of the silver ion into the antibonding π* orbital of the triple bond.

Conclusions

The incorporation of a silver ion into the cages of **1** and **3** results in drastic changes of the conformations of the ligands. The driving force for this change is a close interaction between the nitrogen centers and the metal. This has been achieved by torsion of both 4-octyne bridges around the N−N axis. As a side effect of these conformational changes we observe close contacts between the silver ion and the triple bonds in the solid state and in solution.

Experimental Section

General Remarks: All reactions were carried out under argon atmosphere with magnetic stirring in dry, degassed CH_2Cl_2. The ^1H and ^{13}C NMR spectra were recorded in $CDCl_3$ with Bruker WH 300 and Avance 500 instruments, respectively. Mass spectra were obtained with a JEOL JMS 700 spectrometer.

General Procedure for the Complexation: One equivalent of the cryptand (**1**−**3**) was added to 1.1 equivalents of silver(I) triflate in dry degassed CH_2Cl_2 under argon and stirred for one hour with the exclusion of light. The solvent was removed in vacuo and the

Ag^I⊂{1,10-Diazabicyclo[8.8.8]hexacosa-5,14-diyne}trifluoromethanesulfonate (5): FAB-MS: *m/z* (%) = 459.2 [**5** − CF_3SO_3]$^+$ ($^{12}C_{24}{}^1H_{36}{}^{107}Ag^{14}N_2$: 459.2).[11] − ^{1}H NMR ($CDCl_3$, 500 MHz): δ = 1.94 (br. s, 12 H), 2.44 (br. s, 12 H), 2.70 (br. s, 12 H). − $^{13}C\{^1H\}$ NMR ($CDCl_3$, 25.8 MHz) δ = 17.9, 27.4, 55.7 (CH_2), 81.5 (C≡C).

Ag^I⊂{4,7-Dioxa-1,10-diazabicyclo[8.8.8]hexacosa-14,22-diyne}-trifluoromethanesulfonate (6): FAB-MS: *m/z* (%) = 467.1 ($^{12}C_{22}{}^1H_{32}{}^{107}Ag^{14}N_2O_2$: 467.2).[11] − ^{1}H NMR ($CDCl_3$, 300 MHz): δ = 1.81−2.04 (m, 8 H), 2.28−2.42 (m, 8 H), 2.59−2.84 (m, 8 H), 3.69 (s, 4 H), 3.76−3.88 (m, 4 H). − $^{13}C\{^1H\}$ NMR ($CDCl_3$, 75.47 MHz, 25 °C) δ = 17.4, 28.1, 53.0, 55.2, 64.6, 67.4 (CH_2), 80.8 (C≡C); ($CDCl_3$, 75.47 MHz, −60 °C) δ = 15.9, 17.9, 26.8, 29.3, 51.6, 53.5, 55.1, 63.6, 66.6 (CH_2), 79.2, 81.1 (C≡C).

X-ray Crystallographic Study: The measurements on crystals of **4** and **6** were performed on a Bruker SMART CCD X-ray diffractometer using graphite-monochromated Mo-K_a radiation (λ = 0.71073 Å). The SMART software package[12] was used for data collection as well as frame integration. Structure solution was carried out using the SHELXTL V5.10 software package.[13] Intensities were corrected for Lorentz and polarization effects. All structures were solved by direct methods. Full-matrix least-squares refinement was carried out against F^2. The non-hydrogen atoms were refined anisotropically. The hydrogen atoms were taken into account at calculated positions. Further details are listed in Table 2. The crystal of **6** contained two independent molecules in the asymmetric unit (see Table 1 and 2).

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-138336 (**4**) and 138337 (**6**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

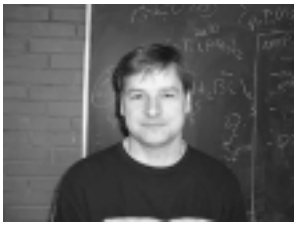
Highly Lewis Acidic Bifunctional Organoboranes

Warren E. Piers,*[a] Geoffrey J. Irvine,[a] and V. Clifford Williams[b]

Keywords: Boranes / Lewis acids / Anions / Metallocenes

Chelating Lewis acids have not been developed to the same degree as multidentate Lewis bases. Nonetheless, such compounds have attracted interest due to their potential for the enhanced activation of basic substrates and the selective binding of anions. Organodiboryl compounds form a class of bidentate Lewis acids which have a long, but relatively underdeveloped history. Many examples exist where donor groups on boron serve to stabilize the Lewis acid centers. More recently, advances in the chemistry of diboryls with highly Lewis acidic boron centers substituted with perfluoroaryl groups have been made. In particular, compounds of general formula $(F_5C_6)_2B$–linker–$B(C_6F_5)_2$ have been prepared and their chemistry examined. In this Microreview, we survey the classes of bifunctional boron Lewis acids known, including their synthesis, properties and anion binding chemistry. Particular emphasis is placed on the role these Lewis acids play in olefin polymerization catalyst generation from simple metallocene precursors.



Introduction

Despite the early recognition of the potential utility of multidentate Lewis acids, development in this area has lagged far behind the extensive chemistry associated with chelating Lewis bases.[1] The reasons for this stem partly from the synthetic difficulties associated with the preparation of molecules with multiple Lewis acid sites, which in turn is related to the high reactivity of these species. These factors can be partially ameliorated by the incorporation of groups capable of stabilizing the Lewis acid centers through either strong σ-donation or π-bonding. In fact, most of the examples of group 13 element based bidentate Lewis acids in the literature make use of this strategy, at least to some degree.[2] Since one of the primary reasons for investigating these molecules is to achieve a greater degree of substrate activation, reducing the Lewis acid strength of each center to some extent defeats the purpose of their preparation.

Warren Piers was born in Edmonton, Alberta in 1962 before moving to the Vancouver area where he grew up. He obtained his B. Sc. degree at the University of British Columbia in 1984 and continued there as a NSERC Postgraduate Scholar under the tutelage of Prof. Michael Fryzuk, graduating with a Ph. D. in 1988. He then spent two years at the California Institute of Technology as an NSERC and Killam Postdoctoral Fellow with Prof. John Bercaw, gaining expertise in early transition metal organometallic chemistry. In 1990, he joined the Chemistry and Biochemistry Department at the University of Guelph as an Assistant Professor. In 1995, he joined the Chemistry Department at the University of Calgary as an Associate Professor; he was recently promoted to Full Professor. Honors awarded include the Province of Ontario's John C. Polanyi Prize in Chemistry (1991) and an Alfred P. Sloan Foundation Research Fellowship (1996–2000).

Geoffrey J. Irvine, a native New Zealander, received his Ph. D. in 1996 from the University of Auckland under the supervision of Professor Warren Roper and Dr. James Wright. He then carried out Postdoctoral Research with Associate Professor Scott Bohle at the University of Wyoming, followed by a year of Postdoctoral work with Professor Warren Piers at the University of Calgary. His current interests are in the fields of homogeneous catalysis, materials chemistry and transition metal mediated organic transformations.

V. Clifford Williams studied chemistry at St Catherine's College Oxford, where he worked in the group of Prof. Malcolm L. H. Green. He received his D. Phil in 1998 having worked on high oxidation state imido and low coordination number amido complexes of uranium. Upon completion, he worked with Professor Warren Piers for a year on the synthesis of chelating boranes and noncoordinating anions. Currently, he is back at the Inorganic Chemistry Laboratory, Oxford with Malcolm Green as part of the team who are working on the synthesis and chemistry of single walled carbon nanotubes.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

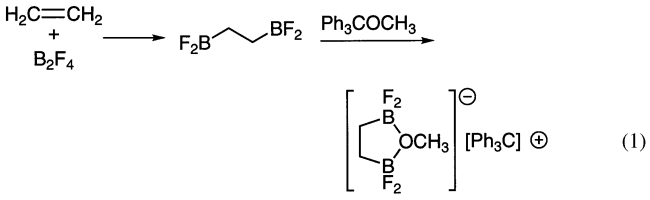
Nonetheless, impressive advances have been made in the synthesis and use of aluminum,[3] mercury,[4] tin[5] and titanium[6] based bifunctional Lewis acids, which show that two Lewis acid centers can act in concert to effect increased substrate activation or greater reaction selectivity.

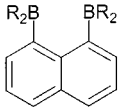


It has been recognized for many years that the pentafluorophenyl group is an excellent replacement for a halogen ligand in boron Lewis acids.[7] For example, the C_6F_5 group has similar σ-electron-withdrawing powers to those of Cl and F but the B−C_{aryl} bonds in $B(C_6F_5)_3$ are more kinetically inert in the presence of protic agents.[8] Therefore, although $B(C_6F_5)_3$ loses some Lewis acidity due to the front strain associated with the bulkier C_6F_5 substituents,[9] it is more easily handled and generally as effective as BX_3 Lewis acids in terms of strength,[9,10] without the problems inherent with reactive B−X bonds.

A natural extension of the rise to prominence of this monodentate Lewis acid[11] is a recent surge of activity in the preparation of multifunctional boranes (and other group 13 elements) in which the boron centers are of comparable Lewis acid strength to the highly Lewis acidic monofunctional boranes $RB(C_6F_5)_2$ (R = alkyl, alkenyl, aryl, C_6F_5). Although interest in these compounds arises primarily because of their role in the activation of neutral organometallic complexes for olefin polymerization processes, such diboryl targets are also of interest in the arenas of organic synthesis,[12] anion recognition[13] and the formation of new polymeric materials.[14] Furthermore, two strong, proximal Lewis acid centers have the potential to act as "superelectrophiles".[15]

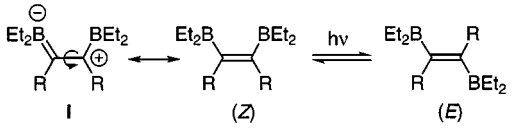
After setting the stage with a brief history of strongly Lewis acidic bifunctional boranes, we will discuss recent developments in this area, along with specific related examples. The bidentate Lewis acids will be grouped by the number of atoms in the bridge connecting them; diboranes with no atom in the bridge, i.e. diborane(4) compounds R_2B-BR_2, will not be considered here. Although it has been shown that such compounds can bind two Lewis bases,[16] their potential as chelating acids is negligible. These compounds do, however, have potential as reagents for the preparation of chelating organodiboryl Lewis acids, and this chemistry has to some extent been reviewed elsewhere.[2b]

History of Highly Lewis Acidic Organodiboryl Compounds



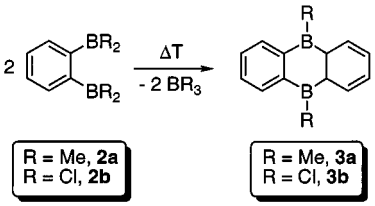
The first important study aimed at investigating the chelating properties of a bidentate Lewis acid was conducted by Shriver and Biallas in the late 1960's.[17] The reactions of a bidentate version of the quintessential boron-based Lewis acid (BF_3) with simple Lewis bases and anions were investigated. They found that $F_2BCH_2CH_2BF_2$, prepared by mixing ethylene and B_2F_4 at low temperature,[18] did not readily chelate neutral bases, but that anions such as OMe^- were bound by both borane centers. Given the high reactivity of the B−F bonds in this bidentate Lewis acid, incorporation of the anions required weakly basic reagents such as Ph_3COMe [Equation (1)] to avoid metathetical replacement of the boron fluorides. Amido bridging groups were also incorporated as their tropylium salts.

(1)



This compound was the first diboryl derivative with strongly Lewis acidic boron centers, but despite these early and very promising successes, research in bifunctional borane Lewis acid chemistry appears to have been sporadic for close to two decades subsequent to these publications. Although $F_2BCH_2CH_2BF_2$ is a relatively simple looking compound on paper, looks can be deceiving; undoubtedly the difficulties in preparing and handling this compound, in particular the synthesis of the precursor B_2F_4, have something to do with its disappearance from the literature since the seminal studies of Shriver and Biallas. Perhaps the disappointing performance of this acid in binding neutral Lewis bases, of most interest to organic chemists, also contributed to its demise.

A series of papers by Katz in the mid 1980's describing the use of a 1,8-bis(dimethylboryl)naphthalene (**1a**) as a "hydride sponge" was the next major study on the applications of a chelating diboryl.[19] Other anions, such as F^- and OH^- were also bound effectively by this compound. Katz showed quantitatively, through competitive binding studies involving monodentate analogs, that two boron centers are better than one for binding these anions. To bind chloride, however, the more Lewis acidic chloro derivative **1b** was required.[20] This compound was prepared via a transmetallation reaction between an organomercury precursor and BCl_3 in refluxing toluene in 86% yield. Although sensitive B−Cl functions tended to limit the usefulness of this species, the other side of the coin is that these bonds may be readily functionalized. To this end, Reilly and Oh have recently used the Katz compound to prepare chiral bidentate Lewis acids in situ via derivatization of the chloro boranes with chiral ligands such as (*R*)-BINOL, for use in Diels−Alder couplings.[21] However, it is unclear whether the two borane centers cooperate in activating the substrates in this system.

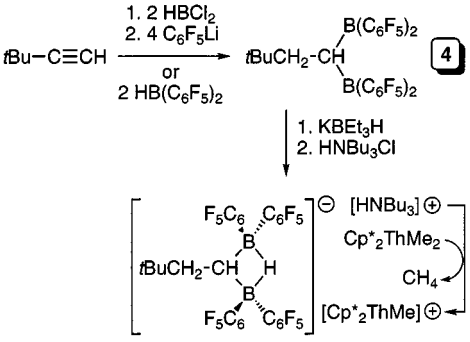


R = Me, **1a**
R = Cl, **1b**

Two final types of organodiboryls we wish to mention highlight some of the chemistry which might be expected to feature prominently in more strongly Lewis acidic organodiboryls. The groups of Köster and Wrackmeyer[22] and Siebert[23] have both published widely on 1,2-diboryls bridged by alkenyl fragments. A variety of methods for the synthesis of these compounds has been developed, including addition of X_2B-BX_2 or BI_3 across the C≡C bond of internal alkynes. Like the Katz compounds discussed above, the *cis*-alkenyl diboryls are capable of binding various first row halogen equivalents when the BR_2 fragments are *cis* disposed about the C=C double bond. In Köster's work, the R substituent was for the most part the relatively electron rich, but metathetically inert, ethyl group, and incorporation of the anions X^- can be accomplished by treatment of the diboryls with various potassium salts.[22a] The free *cis*-1,2-diboryls, however, were found to be susceptible to photoisomerization about the double bond, producing equilibrium mixtures of the (*Z*) and (*E*) isomers [Equation (2)].[22b] The barrier to double bond isomerization is decreased because the empty p orbital on the boryl centers can overlap with the C=C π-bond and lower the bond order of the double bond through resonance structures akin to **I**, allowing for more facile isomerization. This phenomenon might be expected to be more prevalent in diboryls with stronger Lewis acidic boron centers, such as the pentafluorphenyl-substituted family considered here. However, it should be noted that only the (*Z*) isomer is capable of chelating anions and the foundational work of Katz[19] has shown that these anions are thermodynamically favored over their monodentate analogs.

(2)

One way to avoid this problem is to incorporate backbones which cannot isomerize. Kaufmann et al. were the first to prepare the 1,2 phenylene bridged tetrachlorodiboryl species via metathesis from aryl silane[24] or stannane[25] precursors. This work brought to light the thermal instability of some of these compounds towards condensation reactions which eliminate BR_3. For example, heating 1,2-$C_6H_4(BR_2)_2$ (**2a**, R = Me; **2b**, R = Cl) leads to loss of BR_3 and production of the 9,10-diboraanthracene compounds **3** [Equation (3)]. As will be seen, these 9,10-diboraanthracene derivatives are interesting Lewis acids in their own right, but in terms of the synthetic targets **2**, their generation is an undesirable side reaction which must be overcome. Eisch and his group have extended the scope of boron−tin exchange reactions substantially in an effort to produce organodiboryls with a variety of backbones, including −C≡C−, RC=CR and 1,2-C_6H_4,[26] and note that this thermally induced condensation reaction is a feature of the chemistry of diboryls with backbones other than 1,2-C_6H_4.



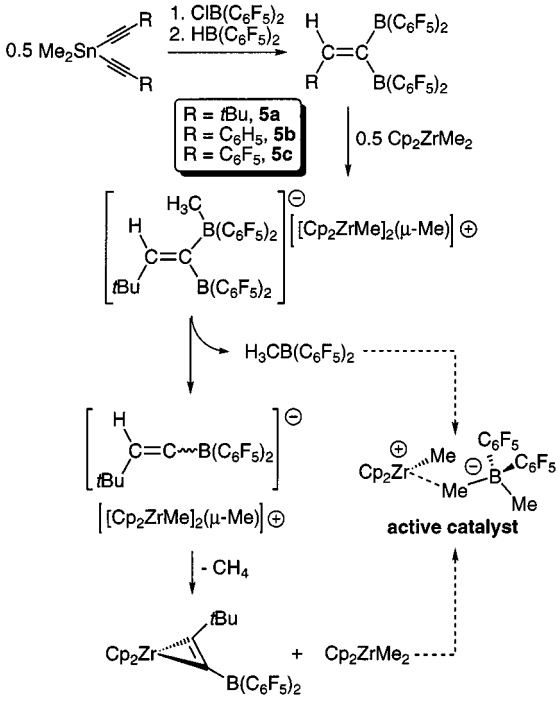
(3)

Development of the chemistry of chelating organoboranes, while not extensive, does have a rich history, as the above discussion briefly illustrates. Nevertheless, until very recently diboryl Lewis acids incorporating perfluoroaryl groups have not been explored. Given the considerable advantages of the C_6F_5 group, such compounds have great potential as anion receptors, olefin polymerization initiators and as synthons for the preparation of new weakly coordinating anions. The performance of a given diboryl in each of these areas will be influenced strongly by the nature of the bridge employed to link the two Lewis acid centers. In addition to its effects on the Lewis acid strength of the borane centers, the backbone will dictate the bite angle of the chelate and the separation of the two borane centers and hence the nature of the anions which will be most strongly bound. We now consider the recent progress in perfluoraryl-substituted diboryl Lewis acids, grouped by the number of atoms in the bridge connecting the two boron centers.

$B(Ar_F)_2$ Units Bridged by One Atom

The first report of a bidentate borane incorporating C_6F_5 groups came from the Marks group in 1994.[27] The borane $tBuCH_2CH[B(C_6F_5)_2]_2$ **(4)** was prepared by the metathetical route shown in Scheme 1.

Scheme 1



We have also shown that this borane, along with other examples, can be prepared via dihydroboration of terminal alkynes using the hydroboration reagent $HB(C_6F_5)_2$.[28] The motivation for this work was to employ these boranes as precursors to weakly coordinating anions in homogeneous olefin polymerization catalysts. To this end, Marks developed a route for converting the free 1,1-diboryl to the $[HNBu_3]^+$ salt of the μ-hydridodiborate which, in combination with the thoracene catalyst precursor $Cp_2*Th(CH_3)_2$ formed stable ion pairs capable of polymerizing ethylene, or

hydrogenating 1-hexene in the presence of dihydrogen. It was envisioned that diborate anions from this family of boranes would more effectively delocalize the negative charge, and thus reduce the coulombic interaction between cation and anion, leading to more active catalysts. This expectation was borne out in slightly increased activities for ethylene polymerization and 1-hexene hydrogenation compared to cationic permethylthoracene catalysts incorporating more conventional $[H_3CB(C_6F_5)_3]^-$ or $[B(C_6F_5)_4]^-$ counteranions.[27] The lack of H^- transfer back to the thorium center also suggested that the hydride is effectively chelated by the two borane centers, another potential advantage of bidentate Lewis acids for this particular application.

Although reactions of the free bifunctional borane tBuCH$_2$CH[B(C$_6$F$_5$)$_2$]$_2$ with dialkyl metallocenes were not reported in detail, the need to convert into an anionic hydridodiborate prior to use suggests that the free borane is not very effective as an activator by itself. In our brief exploration of the chemistry of these diboryl alkanes, we found evidence that facile retrohydroboration, yielding (*E*)-tBuCH=CHB(C$_6$F$_5$)$_2$ and HB(C$_6$F$_5$)$_2$, has a dominating influence on the reactivity of these species towards Lewis bases. As an example, when **4** was treated with one equivalent of acetone, the small amounts of HB(C$_6$F$_5$)$_2$ present in solutions of tBuCH$_2$CH[B(C$_6$F$_5$)$_2$]$_2$ reacted rapidly with the acetone to yield iPrOB(C$_6$F$_5$)$_2$, leaving (*E*)-tBuCH=CHB(C$_6$F$_5$)$_2$;[29] the reaction is pulled in this direction by the facile retrohydroboration equilibrium present in the system. Given the high reactivity of metallocenes toward HB(C$_6$F$_5$)$_2$,[30] this represents a potential problem for the use of this type of diboryl for direct activation of neutral organometallic alkyls which must be circumvented by prior formation of a diborate. Even if methide abstraction was favored, our study of a closely related system suggests that other problems can arise.

As an alternative to diborate formation, retrohydroboration can be precluded by incorporating unsaturation in the backbone; hence, we prepared the 1,1-diboryl alkenes[31] RCH=CH[B(C$_6$F$_5$)$_2$]$_2$ (R = tBu, **5a**; C$_6$H$_5$, **5b**; C$_6$F$_5$, **5c**) using tin−boron exchange/hydroboration procedures as shown in Scheme 2.[32]

In combination with Cp$_2$ZrMe$_2$, these 1,1-diboryls form reasonably active ethylene polymerization catalysts, although ion-pair stability was only moderate given the propensity of the methide anions formed to eject H$_3$CB(C$_6$F$_5$)$_2$[30a] (Scheme 2). Spectroscopic studies on the ion-pairs formed from **5a** and Cp$_2$ZrMe$_2$, in the absence of ethylene, show that the abstracted methide ligand is associated with the boron center *trans* to the tBu group, the most sterically accessible Lewis acid in this crowded system. Sterically undemanding Lewis bases also coordinate exclusively to this boron center in reactions with **5a**.[29] Loss of H$_3$CB(C$_6$F$_5$)$_2$ from this anion is presumably facilitated by the stability of the boryl-substituted vinyl anion,[33] which rapidly couples with the cationic zirconocene center. Separate experiments showed that the boryl alkyne zirconocene derivative is not capable of polymerizing ethylene under the reaction conditions and thus represents a catalytic dead-

Scheme 2

end. The methyl borane, however, is itself a strong Lewis acid capable of partial abstraction of methide from Cp$_2$ZrMe$_2$ and, indeed, careful analysis of the data from ethylene polymerization experiments led us to conclude that the active catalyst in these systems is in fact the ion pair derived from H$_3$CB(C$_6$F$_5$)$_2$ and Cp$_2$ZrMe$_2$! Clearly, Marks' strategy of preparing stable anions from groups which are readily chelated[27] (i.e. H^- and not CH_3^-) prior to incorporation into a catalyst system was appropriate for these systems.

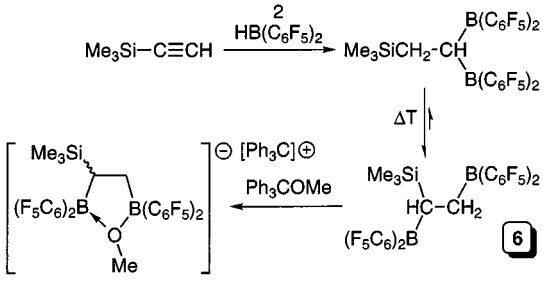
Two other one-atom bridged diboryl Lewis acids have been prepared and characterized. Green and co-workers incorporated an HN bridge,[34] while the μ-oxo species [(C$_6$F$_5$)$_2$B]$_2$(μ-O) (affectionately known as "BOB") has been prepared by both our lab and that of Collins[35] by controlled hydrolysis of either HB(C$_6$F$_5$)$_2$ or ClB(C$_6$F$_5$)$_2$. A priori, a reduction in the Lewis acid strength of the boron centers in both of these molecules may be expected due to π-donation from the bridging atom; geometrical parameters from the X-ray structures of (Me$_3$Si)$_2$NB(C$_6$F$_5$)$_2$[34] and "BOB" indicate that B−N and B−O π-bonding is significant. Interestingly, however, the B−O−B moiety in BOB is not linear; bending occurs so that one boron center is able to accept donation of a lone pair from one of the *ortho* fluorine groups of the other borane.[35] The binding of anions or Lewis bases to these compounds has not been explored as yet.

Selectivities for binding various anions X^- by bidentate Lewis acids will obviously be profoundly influenced by the bite angle provided by the backbone linker. In these one-atom bridged diboryls, the bite angle can be parameterized

Table 1. Selected geometrical parameters for 1,1-diboryl Lewis Acids

Compound	B···B (Å)	B−atom−B (°)
$[(C_6F_5)_2B]_2(O)$		154.05(12)
$[(C_6F_5)_2B]_2(NH)$	2.53[a]	134.0[a]
tBuCH$_2$CH[B$(C_6F_5)_2]_2$	2.63[a]	116.1[a]
$\{t$BuCH$_2$CH[B$(C_6F_5)_2]_2\}(\mu$-H)$^-$	1.94	75.0[b]
tBuCH=CH[B$(C_6F_5)_2]_2$	2.673(8)	118.7(4)
PhCH=CH[B$(C_6F_5)_2]_2$	2.731(2)	123.22(13)
(C_6F_5)CH=CH[B$(C_6F_5)_2]_2$	2.721(6)	121.7(4)

[a] Estimated values based on semi-empirical AM1 geometry optimization calculation. − [b] B−C−B.



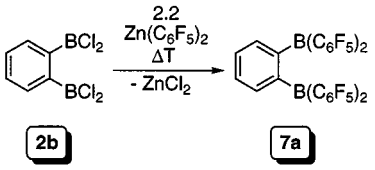
by the B−atom−B angle and the B···B distance; Table 1 collates these data for the compounds discussed in this section.

The values for the B−atom−B angles and interboron distances in $[(C_6F_5)_2B]_2$(NH) and tBuCH$_2$CH[B$(C_6F_5)_2]_2$ were obtained from a semi-empirical AM1 geometry optimization.[36] These calculated geometries around the central bridging atom are somewhat larger than the ideals of 120°and 109.5°, probably a consequence of the steric bulk of the bis-pentafluorophenylboryl substituents. Nonetheless, there is a high degree of flexibility in the saturated carbon backbone as demonstrated by the experimentally determined geometrical parameters found for the hydridodiborate anion. Although the chelation of halide anions by tBuCH$_2$CH[B$(C_6F_5)_2]_2$ is covered in the patent pertaining to Marks' work,[37] not much has been reported so far concerning the anion binding selectivities of this type of diboryl Lewis acid. The flexibility inherent in the system suggests it should bind larger anions than hydride.

In modifying the backbone to an alkenyl fragment, the bite angle of the chelate is necessarily affected since the bridging carbon is now sp^2 hybridized. Although the experimental values for B−C−B in the 1,1-diboryl alkenes **5a−c** are not much larger than the calculated value for the free, saturated analog, there should be markedly less flexibility than that associated with the unsaturated system. In particular, the variation possible in the B···B separation might be expected to be smaller for these diboryls. Indeed, treatment of **5a** with KEt$_3$BH indicated that hydride addition occurred, although pure material was not isolated and it was unclear if the hydride moiety was bound by both boron centers. Bromide, on the other hand, was not complexed at all when **5a** was treated with PPNBr, indicating perhaps that Br$^-$ (ionic radius = 1.82Å) is too large to fit into the chelate region of this type of diboryl. These preliminary results suggest that one-carbon bridged diboryls will not strongly bind larger anions and thus may be moderately hydride specific. However, more extensive investigations will be necessary to delineate the binding characteristics of this family of diboryls in more detail.

B(Ar$_F$)$_2$ Units Bridged by Two Atoms

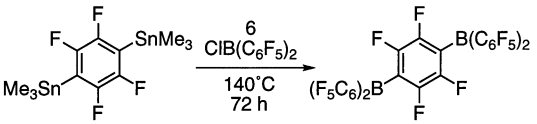
The pioneering work of Shriver,[17] Köster,[22] Siebert,[23] and Kaufmann[24,25] described above provides obvious choices for a two-carbon linker for highly Lewis acidic, chelating organodiboryls: saturated alkyl, *cis*-alkenyl, and 1,2-phenylene. As the foregoing discussion has highlighted, saturated alkyl backbones are generally problematic due to the facility of retrohydroboration reactions. We have found one exception, however, and that is the 1,2-diboryl alkane formed upon double hydroboration of Me$_3$SiC≡CH (Scheme 3).[28a]



Scheme 3

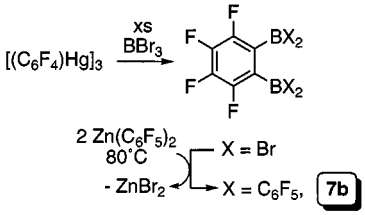
Initially, a mixture of the 1,1 and 1,2 substituted isomers is observed, but upon heating gently for a couple of hours, complete conversion into the thermodynamic 1,2 species **6** is observed. This isomer is favored due to a ground state β-silicon effect which is energetically appreciable in these highly electrophilic boranes.[38] Perhaps this effect also contributes to the observation that this particular saturated diboryl derivative is less prone to the retrohydroboration complication found for **4**.

Compound **6** is not a particularly effective olefin polymerization co-catalyst on its own: stoichiometric reactions with [Cp$_2$ZrMe$_2$] show that rapid C$_6$F$_5$ transfer back to the zirconium center from the putative [**6**·Me]$^-$ anion occurs in solution. We have found this to be a common decomposition pathway for anions of this general form, i.e. [RR′B$(C_6F_5)_2]^-$, perhaps a reflection of the greater nucleophilicity of this more electron-rich borate anion. Deployment of Marks' strategy, i.e., converting **6** into an anion with an activating countercation, yields more encouraging results. For example, **6** reacts smoothly with trityl methyl ether (Ph$_3$COMe) to give an OMe anion (Scheme 3) as an orange solid.[39] The precise details of its structure are unknown, but two signals at δ = 41.4 and 5.7 in the ^{11}B NMR spectrum and a complex (but clean) ^{19}F NMR spectrum containing signals for four chemically different C$_6$F$_5$ groups point to an unsymmetrical structure as depicted in the scheme. The metallocene activating properties of **6** and its derivatives are currently under investigation.



Of more interest as target diboryls are those with unsaturated *cis*-alkenyl- or 1,2-phenylene-type backbones, since these are more rigid and the effectiveness of electron-withdrawing backbones would be heightened due to the conjugation possible. Our efforts towards the 1,2 alkenyl objectives, in addition to inherent synthetic challenges, have to some extent been beset by the photoisomerization problem identified in Köster′s studies.[22b] We have, however, recently made significant progress towards the 1,2-phenylene-bridged systems, preparing both the unsubstituted and perfluorinated members of this family of compounds.[40]

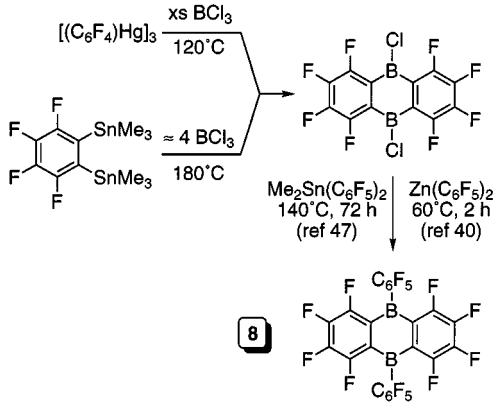
The proteo substituted 1,2-phenylene bridged derivative **7a** was straightforwardly prepared from Kaufmann's tetrachlorodiborane 1,2-$C_6H_4(BCl_2)_2$ (**2b**)[24,25,41] and $[Zn(C_6F_5)_2]$[42] as a C_6F_5 transfer agent[43] [Equation (4)]. The intraboron region of this molecule is quite sterically hindered and the Lewis acidity of the two boron centers is dampened by virtue of the nonfluorinated backbone substituent;[44] consequently the anion binding chemistry of this species is somewhat limited. Nevertheless, the B···B separation in this molecule is 3.263(3)Å and the anions SCN^-, Cl^-, Br^-, OMe^- were found to interact with both boron centers in a bridging binding mode. ^{19}F NMR spectroscopic studies on the interaction of **7a** with these anions revealed only weak coordination and, in some cases, an equilibrating mixture of reactants and products could be observed. In all cases examined, the weak binding of these anions precluded isolation of the products from solution. Neutral donor molecules such as THF did not appear to bind appreciably in solution, attesting to the steric demands of this Lewis acid.



(4)

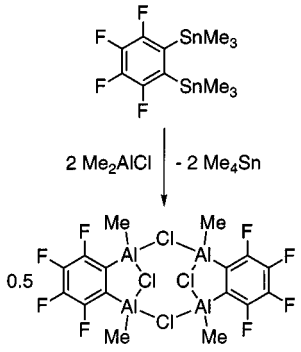
Of course, a system with a fully fluorinated phenylene backbone would be of more interest due to the increased Lewis acidity of the boron centers and the incorporation of more robust $B-C_{backbone}$ bonds. As is common, the more desirable target molecule is considerably more difficult to prepare! Our first attempts involved boron−tin exchanges between the trimethyltin-substituted perfluoroaryl precursor 1,2-$C_6F_4(SnMe_3)_2$[45] and $ClB(C_6F_5)_2$.[46] With two equivalents of the chloroborane, we found the major products to be 1,2-$C_6F_4(SnClMe_2)_2$ and $H_3CB(C_6F_5)_2$,[30a] the products of chloro−methyl exchange. We did not push this route any further, not wanting to sacrifice too much $ClB(C_6F_5)_2$, but Marks et al. have shown in a recently published patent[47] that the closely related 1,4-substituted diboryl Lewis acid can be prepared by this method [Equation (5)] using six equivalents of $ClB(C_6F_5)_2$.

(5)



Eventually, we settled on the mercury trimer $[(C_6F_4)Hg]_3$[48] as a "C_6F_4" synthon for the preparation of **7b**. Reaction of $[(C_6F_4)Hg]_3$ with BBr_3 gives 1,2-$C_6F_4(BBr_2)_2$ which must be converted relatively quickly to the fully perfluoroaryl-substituted system using $[Zn(C_6F_5)_2]$ due to its thermal instability [Equation (6)]. The first two C_6F_5 groups are incorporated at ambient temperatures, but the third and fourth require heating to install successfully. The solid state structure of **7b** reveals a B···B separation of 3.138(2)Å, large enough to incorporate at least first row element anions comfortably; indeed, this compound has a rich anion binding chemistry associated with it (vide infra).

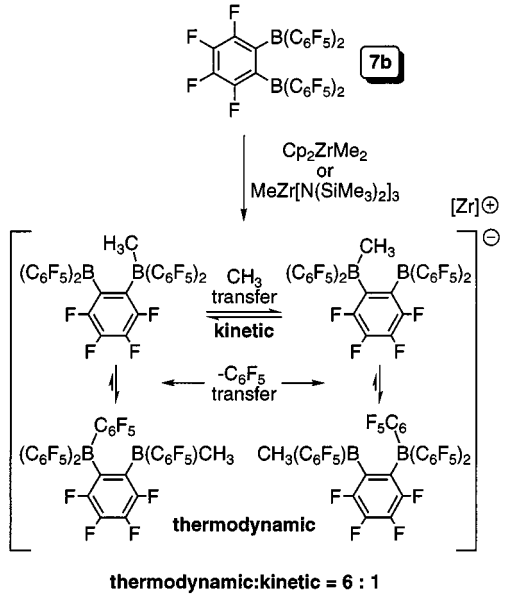
(6)



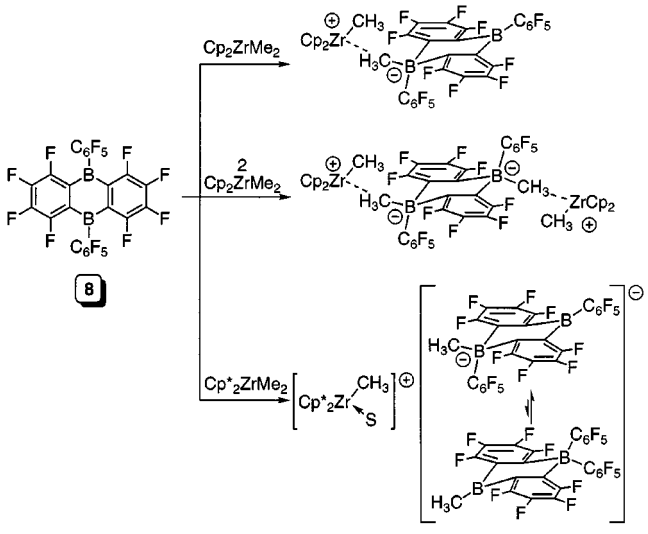
While **7b** is quite thermally stable, the tetrahalides are susceptible to the condensation reaction observed by Kaufmann and Eisch, producing 9,10-diboraanthracene derivatives. Both our group[40] and the Marks group[47] have made this observation independently (Scheme 4). In our laboratory, we noted that reaction of the mercury trimer with BCl_3 instead of BBr_3 leads directly to $[1,2\text{-}C_6F_4B(Cl)]_2$, which in turn could be converted into the pentafluorophenyl-substituted derivative **8** by treatment with $[Zn(C_6F_5)_2]$. Similarly, Marks' patent discloses a preparation of **8** which involves treatment of the organotin precursor 1,2-$C_6F_4(SnMe_3)_2$ with excess BCl_3 at high temperatures. In both procedures the high temperatures necessary to effect the transmetallations preclude isolation of 1,2-$C_6F_4(BCl_2)_2$, which condenses rapidly under these conditions. It is also possible that condensation occurs from the product of one transmetallation step, i.e. 1,2-$[C_6F_4(BCl_2)(SnMe_3)]$.[47b] To convert into **8**, Marks uses the organotin C_6F_5 transfer agent $[(C_6F_5)_2SnMe_2,]$,[49] which serves as well as the zinc reagent.

The entropically favorable condensation reaction is driven by the high temperatures used in the transmetallation reactions involving BCl_3 and the organomercury or -tin precursors. The greater facility of the transmetallation reaction between $[(C_6F_4)Hg]_3$ and BBr_3 (allowing for lower reaction temperatures) is part of the reason this reaction leads to the desired tetrabromide 1,2-$C_6F_4(BBr_2)_2$. Qualitatively, the condensation of 1,2-$C_6F_4(BCl_2)_2$ appears to occur under milder conditions. In

Scheme 4



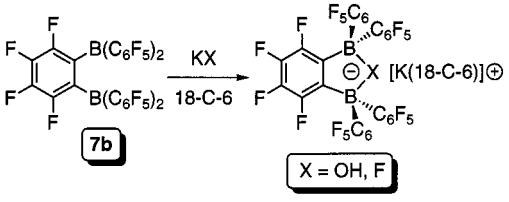
a closely related study recently reported by Gabbaï et al.,[50] the reaction of 1,2-$C_6F_4(SnMe_3)_2$ with Me_2AlCl at room temperature produces the dimer shown in Equation (7).[51] Possibly, this intriguing dimer provides a model for how the elimination of BCl_3 from 1,2-$C_6F_4(BCl_2)_2$ occurs. The Gabbaï group has also reported related derivatives of indium.[52]



(7)

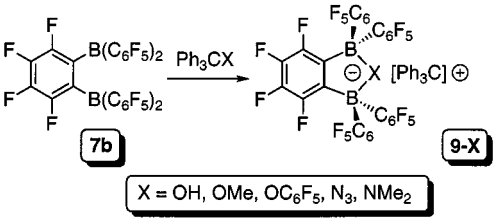
Both perfluorinated diboryl- **(7b)**[53] and diboraanthracene **(8)**[47,53] activate $[Cp_2ZrMe_2]$ to form active ethylene polymerization catalysts. In the case of the former activator, the anion formed upon methide abstraction from the metallocene is an equilibrating mixture of two species (Scheme 5). In other words, the poorly bridging methide anion is not chelated by the two Lewis acid sites. Nonetheless, detailed dynamic ^{19}F NMR spectroscopy experiments indicate that exchange of both CH_3 and C_6F_5 between the boron centers is occurring. In particular, the pattern of cross-peaks observed in the resonances for the backbone fluorine atoms can only be accounted for by invoking transfer of both groups, although, qualitatively, transfer of CH_3 is slower than transfer of the aryl group. In this system, the major anion is the one containing the tetraaryl borate moiety; this is apparent from the integrals observed for key resonances in the ^{19}F NMR spectrum of the mixture, and from an X-ray analysis of this major species using the tris-amido cation $\{Zr[N(SiMe_3)_2]_3\}^+$ to engender crystallinity. Thus, the other boron center consists of a neutral borane containing a $B-CH_3$ moiety. We postulate that this species is able to complex $[Cp_2ZrMe]^+$ in much the same way as $AlMe_3$,[54] accounting at least in part for the slightly lower activities observed for catalysts derived from **7b** and $[Cp_2ZrMe_2]$ in comparison to the parent $B(C_6F_5)_3$/$[Cp_2ZrMe_2]$ system.[53]

The bifunctional borane **7b** does not appear to abstract two methyl groups when treated with excess $[Cp_2ZrMe_2]$. In contrast, diboraanthracene **(8)** will react with one or two equivalents of $[Cp_2ZrMe_2]$ to form the ion pairs shown in Scheme 6. Marks has shown that the borane centers in **8** are strongly Lewis acidic,[47b][47c] relative to $B(C_6F_5)_3$, and they appear to act essentially independently to activate two equivalents of metallocene. It is likely that the ion pair formed from **8** and one equivalent of $[Cp_2ZrMe_2]$ is stabilized by close contact between the ions via the abstracted methide bridging group.[55] We have shown in unpublished work that when a more separated ion pair is formed by employing a bulkier metallocene such as $[Cp^*_2ZrMe_2]$, the anion formed from **8** and CH_3^- is susceptible to C_6F_5 migration as shown in the reaction scheme. As was observed for the related compound **7b**, the anion formed following methide abstraction from the metallocene is a mixture of two species. The major species in solution is the anticipated kinetic product containing the aryl−methyl−borate moiety and a neutral arylborane center. This species is readily identified in the ^{19}F NMR spectrum by comparison with the ion pair formed from $[Cp_2ZrMe_2]$. The minor species possesses a trigonal $B-CH_3$ center and a diarylborate functionality. This anion is C_{2v} symmetric, giving rise to a simplified ^{19}F NMR spectrum and comprises ca. 16% of the product mixture. The facility with which C_6F_5 migration occurs in this system is probably related to the magnitude of ion pair association. Our experiments show that **8** is comparable to $B(C_6F_5)_3$ as a co-catalyst for ethylene polymerization using $[Cp_2ZrMe_2]$,[53] and the Dow/North-



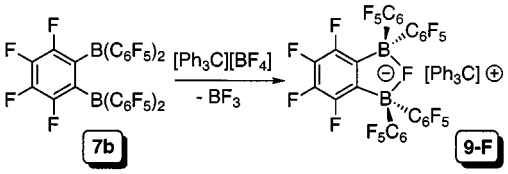
Scheme 5

Scheme 6

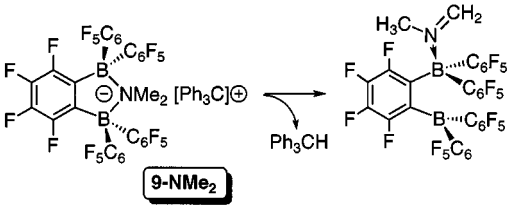


western Patent claims significantly higher performance (an order of magnitude) using **8** vs. $B(C_6F_5)_3$ in conjunction with a titanium based CGC catalyst.[47]

Since the methide anion of **7b** exhibits the behavior described above, we have sought to convert it into a weakly coordinating anion with countercations capable of activating neutral organometallic precursors. The B···B separation of 3.138(2)Å suggests that small first row anions may be incorporated. Indeed, solutions of **7b** in dichloromethane soak up one equivalent of KF or KOH rapidly; addition of 18-C-6 allows for isolation of these potassium salts [Equation (8)].[40] Spectroscopic data indicate that both F^- and OH^- are held between the two boron centers in a symmetrical fashion, although a crystal structure of the former does reveal that the fluoride is tilted out of the B−C−C−B plane.[56] A dynamic process in which this μ-F wags in and out of this plane could account for the observed temperature dependence of the chemical shift for this fluorine atom in the ^{19}F NMR spectrum.[40]

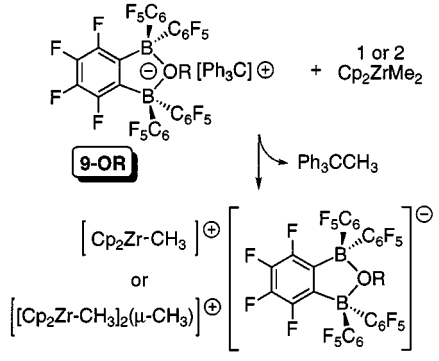


(8)



Anions with cations more amenable to olefin polymerization applications can be straightforwardly prepared by reacting **7b** with various trityl derivatives Ph_3C-X (X = OH, OMe,[57] OC_6F_5,[57] N_3, NMe_2); the fluoride derivative is generated upon treatment of **7b** with $[Ph_3C]^+[BF_4]^-$ [Equations (9) and (10)]. These reactions are generally rapid and quantitative by NMR spectroscopy and, with the exception of X = NMe_2, the resulting trityl salts, **9−X**, are stable in solution and the solid state. In **9−NMe$_2$**, the trityl cation abstracts H^- from a methyl group of the bridging amido to form an imine adduct of **7b** in which only one of the borane Lewis acids interacts with $H_2C{=}NMe$ [Equation (11)]. Interestingly, this type of behavior is not in evidence for **9−OMe**; even heating at moderate temperatures for several hours did not lead to formation of any Ph_3CH, although other decomposition processes did occur. Preparation of compounds **9−NR$_2$** without abstractable β-hydrogens using trityl amine reagents failed due to the greater steric bulk of these species. However, we are optimistic that NR_2 groups can be employed in conjunction with ammonium salts as cations allowing for study of this family of anions.

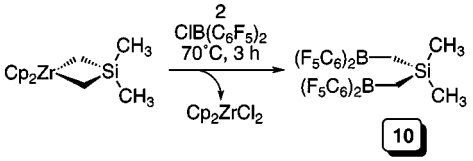
(9)



(10)

(11)

The bite angles (B−O−B) found for **9−OMe** [117.72(12)°] and **9−OC$_6$F$_5$** [115.4(5)°], which are close to ideal for sp^2 hybridized oxygen, suggest that the alkoxides are bound quite tightly by **7b**. Of the stable trityl salts **9**, the μ-alkoxides are highly effective as weakly coordinating anions in metallocenium chemistry, particularly **9−OC$_6$F$_5$**.[57] Thus, the monomeric and dimeric metallocenium cations derived from $[Cp_2ZrMe_2]$ and one or one half equivalents of **9−OR**, respectively, were found to be stable in bromobenzene solution for several hours (Scheme 7).[57] Little is known about the details of the ion−ion contact in these compounds as efforts to crystallize these species have thus far failed, and solution studies in more noncoordinating solvents such as toluene are plagued by the formation of liquid clathrates. Clearly, the OC_6F_5-derived anion is less coordinating towards $[Cp_2ZrMe]^+$ than the OMe species, as evidenced by the lower stability of the monomeric ion pair derived from **9−OC$_6$F$_5$** in the absence of monomer, and its greater polymerization activity in the presence of monomer.[57] It should be noted, however, that both anions are remarkably robust. Decomposition processes at room temperature appear to involve only the cation, since the ^{19}F NMR spectra of the anions remain unchanged over time. Upon heating, some C_6F_5 transfer to zirconium is observed, but no evidence of OR transfer is discernable. Furthermore, **7b** rapidly abstracts OCH_3^- from $[Cp_2Zr(OCH_3)_2]$; although the cation in the resulting species is not very stable, the ^{19}F and ^{11}B NMR spectra show clean formation of the μ-OCH_3 anion. Taken together, these observations suggest that these μ-OR anions of **7b** are ther-

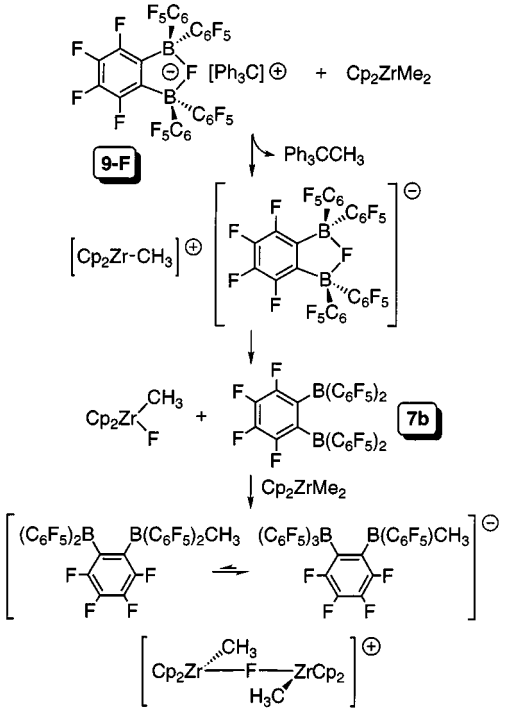


Scheme 7

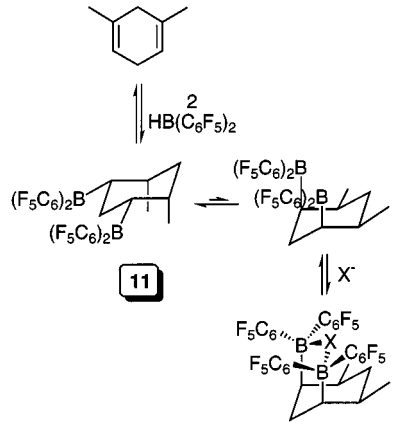
modynamically stable in the presence of metallocenium cations.

This contrasts with the anions **9−F** and **9−N_3**, which rapidly transfer the X^- anion to zirconium when the cationic center is formed upon removal of a methide by the trityl abstractor.[58] In these systems, clean reactions are observed when the trityl salts are treated with two equivalents of $[Cp_2ZrMe_2]$, and the chemistry which ensues is depicted in Scheme 8 for the case of **9−F**. The first equivalent of metallocene undergoes alkide abstraction but the ion pair formed forthwith is not observed. Rather, a new ion pair in which the anion is the methide anion of **7b** described above, is the only product seen. The cation is a μ-F dimer (^{19}F NMR resonance at δ = −90.4[59]) formed from $[Cp_2ZrMe]^+$ and the neutral methyl fluoride $[Cp_2Zr(Me)F]$ produced in the first step. Similar species appear to be formed in the reaction involving **9−N_3**, as evidenced by the signature ^{19}F NMR spectrum for **[7b·Me]**$^-$;[53] the cationic portion of this ion pair has not been rigorously characterized, although the ^1H NMR spectra are consistent with a dimeric μ-N_3 metallocenium ion.

$B(Ar_F)_2$ Units Bridged by Three or More Atoms



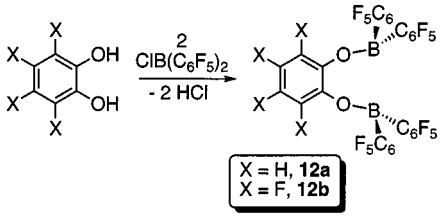
In theory, longer bridges should provide diboryl derivatives capable of binding larger anions. To this end, we prepared the three-atom bridged system **10**[60] shown in Equation (12). We felt the lack of β-hydrogens would make this an effective backbone and, furthermore, the compound is trivially synthesized using Petersen's zirconasilacyclobutane[61] and $ClB(C_6F_5)_2$. The 1,3-diboryl compound **10** is a relatively weak Lewis acid, binding acetophenone only at low temperature and failing to react with trityl methyl ether at room temperature. It is possible that the Lewis acidity of the borane centers is tempered somewhat by the β-silicon atom in the backbone (see above[38]), but other factors must be involved since **6** reacts smoothly with Ph_3COMe (see Scheme 3 above). The reactions of **10** with $[Cp_2ZrMe_2]$ are complex, characterized by the rapid production of $[Cp_2Zr(C_6F_5)Me]$. The ultimate fate of the anion is unknown and, given the compound's properties, we have not pursued its chemistry further.



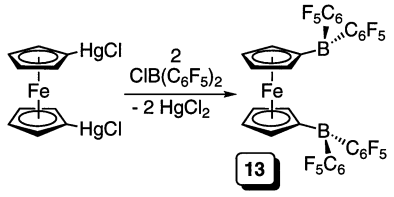
(12)

Green and co-workers have synthesised a 1,3 diborylcyclohexyl compound **11**, by hydroborating 1,3-dimethylcyclohexa-1,4-diene with two equivalents of $HB(C_6F_5)_2$ as shown in Scheme 9.[62] Addition of the borane is highly regiospecific, and the favored conformation places the two boryl groups in the equatorial sites. Binding studies with suitable anions suggest that the molecule can change conformation such that the two borane centers occupy axial sites, tethered via chelation. However, because of reversible anion binding, there are sufficient quantities of the unbound diboryl Lewis acid present. Due to the reversibility of the initial hydroboration, reactions involving reagents which react with $HB(C_6F_5)_2$ deplete the system of **11**.

Green and co-workers have also reported the preparation and reactivity of difunctional boronous esters with either tetrahydro or tetrafluorocatecholate bridges [Equation (13)].[62] Reaction of the catechols with $ClB(C_6F_5)_2$ produces **12a** and **12b** in good yield. Both compounds are weaker Lewis acids than most of the preceding C_6F_5-substituted diboryls discussed by virtue of the π donating oxygen on the boron centers. In the presence of neutral Lewis bases, both borons of **12b** act independently. Thus, with one equivalent of a Lewis base (such as acetone or THF) one boron center binds whilst the other remains three coordinate, but if the base is present in excess, both coordinate



Scheme 8



Scheme 9

weakly. In the presence of dimethyl zirconocene, compound **12b** rapidly transfers catecholate to zirconium, leaving two equivalents of $MeB(C_6F_5)_2$, suggesting that the thermodynamic stability of this type of ion pair relative to neutral products is poor.

(13)

A final example from our group utilizes a ferrocenyl backbone to connect two $B(C_6F_5)_2$ moieties. Although we have not explored the anion binding capabilities of this system to a great degree, others have found that 1,1′-substituted diboryl metallocenes bind hydroxide anion effectively.[63] The diborylferrocene compound **13** is straightforwardly prepared from a transmetallation reaction using the well-known 1,1′-bis(chloromercuri)ferrocene[64] [Equation (14)].[65] Direct borylation with $HB(C_6F_5)_2$ is possible but does not proceed selectively to the 1,1′ substituted system and requires harsh conditions. Competitive binding studies using ketones indicates that **13** is a poorer Lewis acid than a comparative species, namely $C_6H_5B(C_6F_5)_2$.

(14)

Conclusions and Future Prospects

Marks′ initial report in 1994[27] was the beginning of an intense period of research into diboryl compounds of general formula $(F_5C_6)_2B-linker-B(C_6F_5)_2$. Our work in this area has taught us some lessons regarding what the "linker" should be in order to be an effective bidentate Lewis acid. Specifically, the best performing compounds contain backbones which are both unsaturated (no β-hydrogens) and electron-withdrawing (preferably perfluorinated). The former feature prevents the facile retrohydroboration of $HB(C_6F_5)_2$, while the latter engenders more inert $B-C_{backbone}$ bonds (i.e., more stable backbones) and more Lewis acidic boron centers. This is an important point, since the greater steric bulk of these diboryls tends to dampen the Lewis acidity of the individual boron centers. Furthermore, a perfluorinated backbone prevents rapid back transfer of C_6F_5 groups to metallocenium cations in olefin polymerization applications by lowering the nucleophilicity of the borate formed upon methide abstraction.

With these features in mind, there is much opportunity for further development in this area. New backbones, different aryl groups on boron and more extensive and imaginative anion binding chemistry are areas we continue to explore. The development of chiral versions of these diboryls[66] is also of interest, both for stereospecific olefin polymerization and applications to organic synthesis.[67] While several of the compounds described are relatively poor activators themselves, their power lies in their use as synthons for the preparation of very weakly coordinating anions with other, stronger countercation activators (Ph_3C^+, HNR_3^+).[27,57] The effectiveness of these anions lies in the diboryl′s ability to sequester small anions through strong chelation and steric protection in the bidentate pocket of the bifunctional borane binding site.

Acknowledgments

WEP wishes to express his gratitude to all the talented co-workers cited for the work described herein, in particular Dr. Katrin Köhler, whose work laid the foundation for our efforts in this area. Also, the important contributions of collaborators Scott Collins (Waterloo) for polymerization studies, William Clegg (Newcastle) for X-ray crystallography and Todd Marder (Durham) are acknowledged. The authors also thank Prof. Malcolm Green (Oxford) for allowing inclusion of unpublished work from his group and Prof. Tobin Marks for sharing results prior to publication. Financial support for our work was provided by the Natural Sciences and Engineering Council of Canada's Strategic Projects program (STR192869) and the EPSRC (UK) . WEP thanks the Alfred P. Sloan Foundation for a Research Fellowship (1996−00).

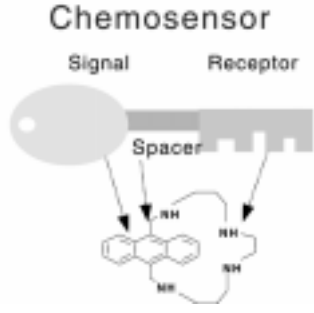
Fluorescent Chemosensors Containing Polyamine Receptors



Fernando Pina,*[a] M. Alexandra Bernardo,[a] and Enrique García-España[b]

Keywords: Sensors / Fluorescence / Polyamines / Receptors / Cation and anion coordination

Chemosensors have attracted interest in many different scientific fields, such as environmental chemistry, medicine, and the processing and storage of information. These molecular-scale devices have the advantage of working on the same spatial scale as the chemical structures that are responsible for macroscopic behaviour observed in the environment or those associated with health problems. Moreover, they allow the construction of molecular-scale devices for information storage. In this review, we describe a family of chemosensors based on a polyamine receptor and a fluorescent signalling unit. Polyamine receptors are water-soluble ambidentate receptors; they are able to coordinate either metal ions, when sufficient deprotonated amino groups are available, or anionic species, when there are sufficient protonated amino groups. On the other hand, the use of fluorescent signalling units confers the advantage of an immediate visual response/signal.

Introduction

A standard chemosensor can be defined as a molecule containing three basic units, each one performing a precise function: (i) a receptor unit, (ii) a signalling unit, and (iii) a spacer (Scheme 1).[1,2] The first of these, the receptor unit, plays the role of recognizing and reversibly binding a given target substrate. The signalling unit, in turn, must be capable of either producing a signal or significantly altering its signal intensity in response to the binding of the substrate,

Fernando Pina was born in Lisbon, Portugal. He has been Professor of Chemistry at the Faculdade de Ciências e Tecnologia, Universidade Nova de Lisboa, since 1985, and is coordinator of the Photochemistry Research Unit. His research interests are focused on the areas of supramolecular chemistry, chemosensors, and molecular-level devices.

M. Alexandra Bernardo was born in 1968 in Portugal. She graduated in Chemistry at the Faculdade de Ciências e Tecnologia, Universidade Nova de Lisboa, in 1992. She is currently completing her Ph.D. thesis on supramolecular photochemistry and fluorescent chemosensors.

Enrique García-España was born in Valencia, Spain, and has been Professor at the Inorganic Chemistry Department of the University of Valencia since 1985. His main research interests lie in the supramolecular chemistry of metal ions and anions.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

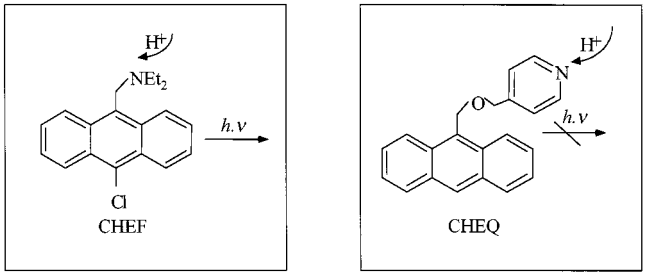
preferably without changing the other photochemical properties. With fluorescent chemosensors, chelation enhancement of the fluorescence (CHEF) or chelation enhancement of the quenching (CHEQ) are commonly encountered responses. Finally, the third unit, the spacer, links the binding and signalling units and controls their mutual separation and geometrical arrangement. These parameters play a crucial role in determining the performance of the device.

A particularly interesting goal is the development of chemosensors capable of functioning in aqueous solution, as highlighted by Czarnick.[2c] Many chemosensors that function efficiently in less polar solvents do not give adequate responses in water either due to low solubility limits or owing to weak complexation of the target species.[1,2] This is a severe drawback because water is the solvent in which most chemical processes occur. In order to achieve sufficiently strong complexation of anions or metal ions in water, a rational approach is the use of polyamine fragments as receptor units. Polyamine compounds are well known as ambidentate receptors capable of coordinating metal ions when sufficient deprotonated amino groups are available, or anionic species when there are sufficient protonated amino groups. Therefore, their binding capacities can be readily tuned by adjusting the pH value.[3] This is a further reason why these compounds have been synthesized and their properties explored.

In this paper, we have attempted to review the effects of the binding of protons, cations, and anions on families of fluorescent chemosensors containing receptor units based on open-chain or cyclic polyamine fragments (Scheme 2). Excellent reviews dealing with earlier work in the field of fluorescent sensors have been published by Czarnick[2c] and by de Silva et al.[1b]



Sensing Protons

CHEQ or CHEF effects on the fluorescence emission resulting from the binding of protons are rather common. Systems of this type have been used to construct ON/OFF switches, which is a very important goal in the growing field of semiochemistry.[4,5] The two effects can be illustrated by

Scheme 2. Chemical structures of the fluorescent chemosensors studied

the following examples based on the anthracene chromophore (Scheme 3).[6,7]

Scheme 3. Examples of systems that function as ON/OFF switches

In the first case, a quenching process involving photoinduced electron transfer (PET) from the free lone pair of the amine pendant arm to the excited fluorophore occurs. This process can be inhibited when the amine is protonated (pK_a = 7.7), resulting in the appearance of a fluorescence emission.[6,7] In the second case, the species containing the pyridinium fragment quenches fluorescence, while this is not the case with unprotonated pyridine. Therefore, protonation has the opposite effect and thus the intensity of the fluorescence emission decreases on increasing the mole fraction of the protonated form (pK_a = 5.0). In this case, the quenching effect has been ascribed to an electron-transfer process from the photo-excited fluorophore to the pyridinium fragment.[7]

Benzene Fluorophore

Polyazacyclophane Macrocyclic Receptors

The azacyclophanes 2,5,8,11-tetraaza[12]paracyclophane (L^1) and 2,6,9,13-tetraaza[14]paracyclophane (L^2) are cyclic chemosensors constructed by linking a polyamine chain and a 1,4-dimethylbenzene fragment (Scheme 2).

According to crystallographic, NMR, and molecular mechanics studies, in solution these compounds preferentially adopt conformations in which the polyamine chain is arched above the aromatic ring. Indeed, this feature could also be observed in a structure reported by Altava et al.[8] for the analogous compound 13,14,16,17-tetramethyl-2,6,10-triaza[11]paracyclophane, which contains a triamine chain as the receptor unit and a durene moiety as the fluorophore. On the other hand, the structure shows that the three acidic protons located on the aliphatic nitrogen atoms are in an *exo* disposition and that the macrocycle assumes an overall open conformation. This arrangement minimizes the electrostatic repulsion between the charged polyammonium groups. It is important to note that the benzylic nitrogen atoms are located ca. 1.45 Å above the plane defined by the aromatic ring. On the other hand, the distance between the benzylic nitrogen atoms is remarkably large, amounting to 6.85 Å.

In spite of the low fluorescence emission quantum yield of the benzene fluorophore, which precludes any practical application, the properties shown by chemosensors of this type are very much representative of the general behaviour exhibited by chemosensors based on a polyamine receptor. Owing to the presence of the spacer between the signalling and the receptor units, these compounds show absorption and fluorescence emission spectra that largely resemble those of the benzene chromophore. This behaviour is more or less general, also being observed when the benzene ring is substituted by other signalling units (vide infra).

The protonation sequence of this family of receptors has been studied in detail by ^{13}C and ^{1}H NMR.[9,10] According to these studies, the protons on the two central nitrogen atoms are the most easily removed. In Figure 1, the fluorescence emission titration curves of L^1 and L^2 are presented, showing the mole fraction distributions of the various protonated species as determined by potentiometry.

The deprotonation sequence of the chemosensors is also included for discussion purposes. By inspection of the figure it can clearly be seen that the fully protonated species gives rise to the highest emission intensity and that removal of the first proton leads to a large decrease in the fluorescence emission intensity. However, total extinction of the emission is only observed following loss of the second proton from the other central nitrogen atom.

The quenching effect of the fluorescence emission can easily be explained in terms of an exergonic intramolecular electron-transfer process from the lone pair of the amines to the excited fluorophore.[9] However, protonation of the amines increases their oxidation potential by ca. 2.1 eV,[11] changing the process from an exoergonic to an endergonic one. Therefore, the fully protonated forms of these chemosensors exhibit the highest fluorescence emission intensities. Another aspect to take into account is the relative position of the lone pairs with respect to the π system. The probability of electron transfer depends on the distance between the two partners, as well as on the overlap between the donor and the acceptor orbitals. Removal of the central protons leads to a decrease in the overall electrostatic repulsion and hence the nitrogen atoms labelled N2 and N3 can become closer to the π system favouring the quenching process (Figure 1).

Finally, the weak fluorescence emission observed for the triprotonated species $[H_3L^1]^{3+}$ can be ascribed to the fact that the two central nitrogen atoms are equivalent and hence share the proton; this would still provide a certain degree of protection for the lone pairs.

The fluorescence emission titration curve of L^2 is similar to that of L^1 (Figure 1), suggesting that it may be similarly interpreted. However, the triprotonated form of L^2 exhibits a less efficient quenching effect than in the case of L^1. The two compounds differ in the dimensions of their chains, i.e. 12 atoms in L^1 compared with 14 atoms in L^2. For this reason, the central nitrogen atoms in L^2 are further away from the π system than in L^1, and consequently the electron-transfer process is less efficient.

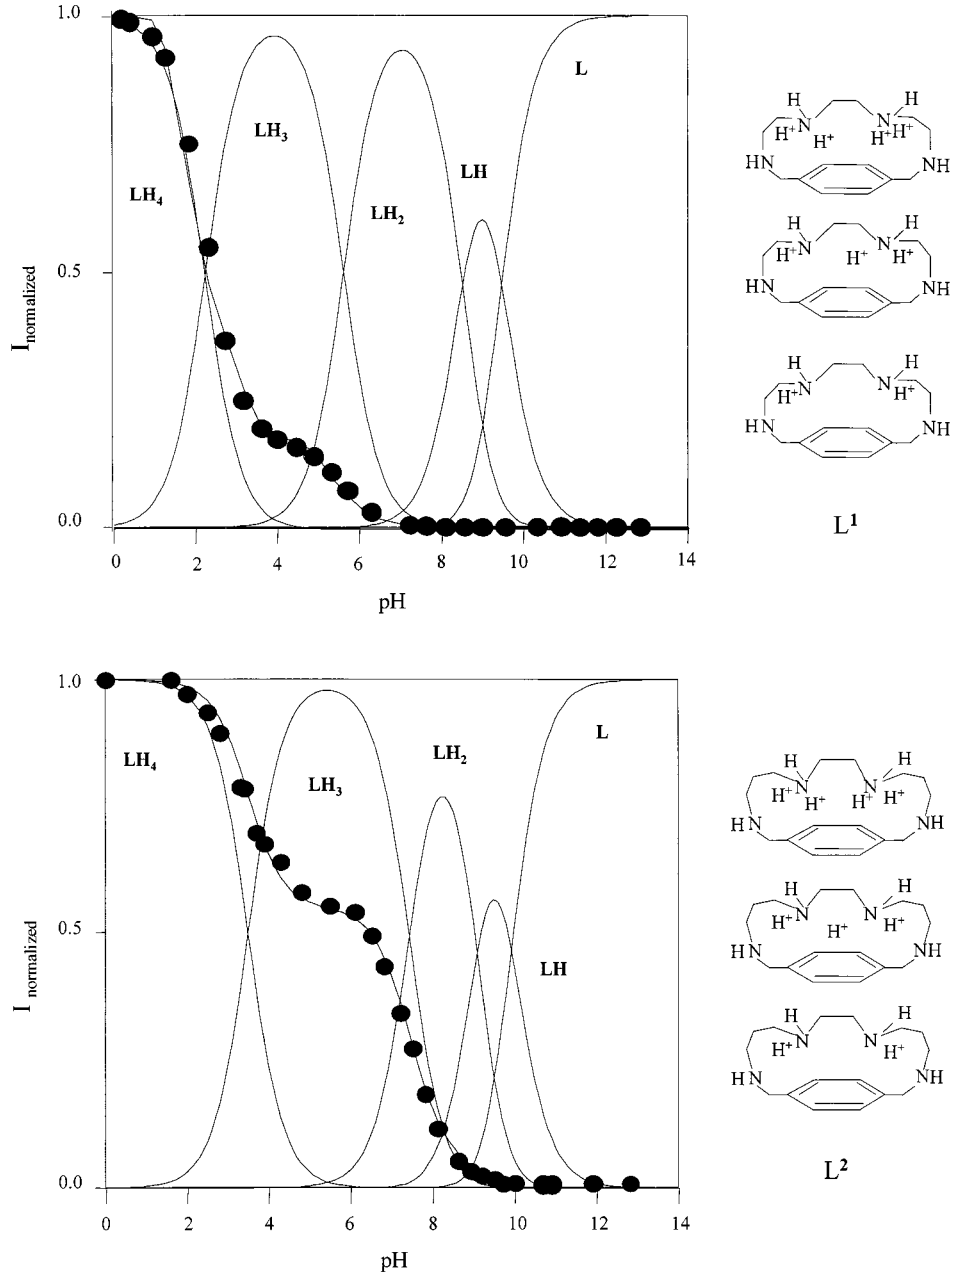


Figure 1. Fluorescence emission titration curves, along with the mole fraction distribution and deprotonation sequence of the chemosensors L^1 and L^2

N,N′-Dibenzylated Polyamine Receptors

In this class of compounds the signalling unit is made up of two terminal benzene rings, separated by a spacer from a polyamine open-chain receptor of variable length, L^3 to L^7 (Scheme 2).

The fluorescence emission titration curves (Figure 2) were obtained using the same methodology as mentioned above. The intensity of the fluorescence emission spectrum of the smallest member of this family, L^3, is practically unaffected by the loss of the first proton. This result suggests that, in contrast to the findings of Thomas and Davidson[12,13] regarding the naphthalene fluorophore, the benzylic nitrogen atoms in these compounds are not very efficient in inducing the quenching process. This becomes apparent when compound L^4 is used, for which a significant quenching effect is observed upon removal of the first proton from a nitrogen atom in the centre of the chain.

The fluorescence emission titration curve of L^5 raises another interesting question. In this case, a moderate quenching effect is seen following the first deprotonation. By comparing L^4 with L^5, it can be concluded that while in the former receptor electron transfer from the lone pair of the central deprotonated nitrogen atom to either benzene ring should be equally probable, in L^5 only one of the benzene rings is suitably orientated. The other ring is too distant from the free lone pair to permit an efficient electron trans-

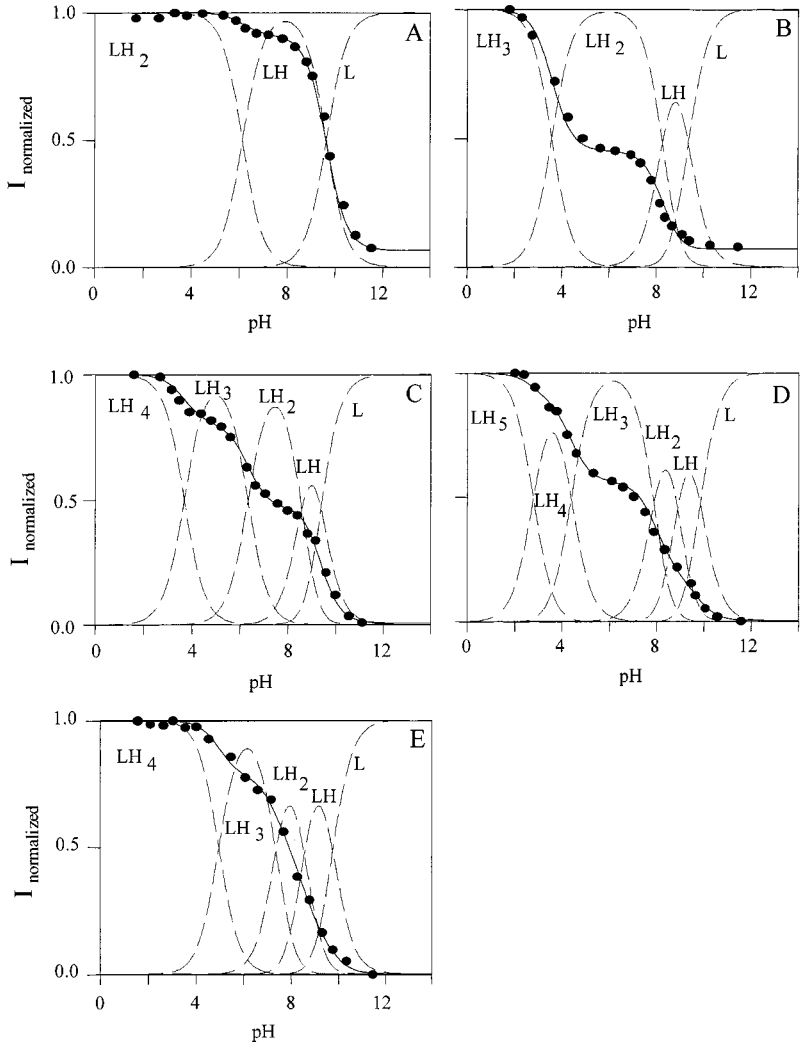

Figure 2. Fluorescence emission titration curves of A-L[3], B-L[4], C-L[5], D-L[6], and E-L[7], along with the respective mole fraction distribution curves

fer. On this basis, L[5] can be predicted to show ca. one-half of the efficiency of L[4], which is indeed borne out by experiment (see Figure 2). Removal of a second proton from L[5] (which is known to occur from the central atoms as well) should double the electron-transfer probability, as is also observed experimentally.

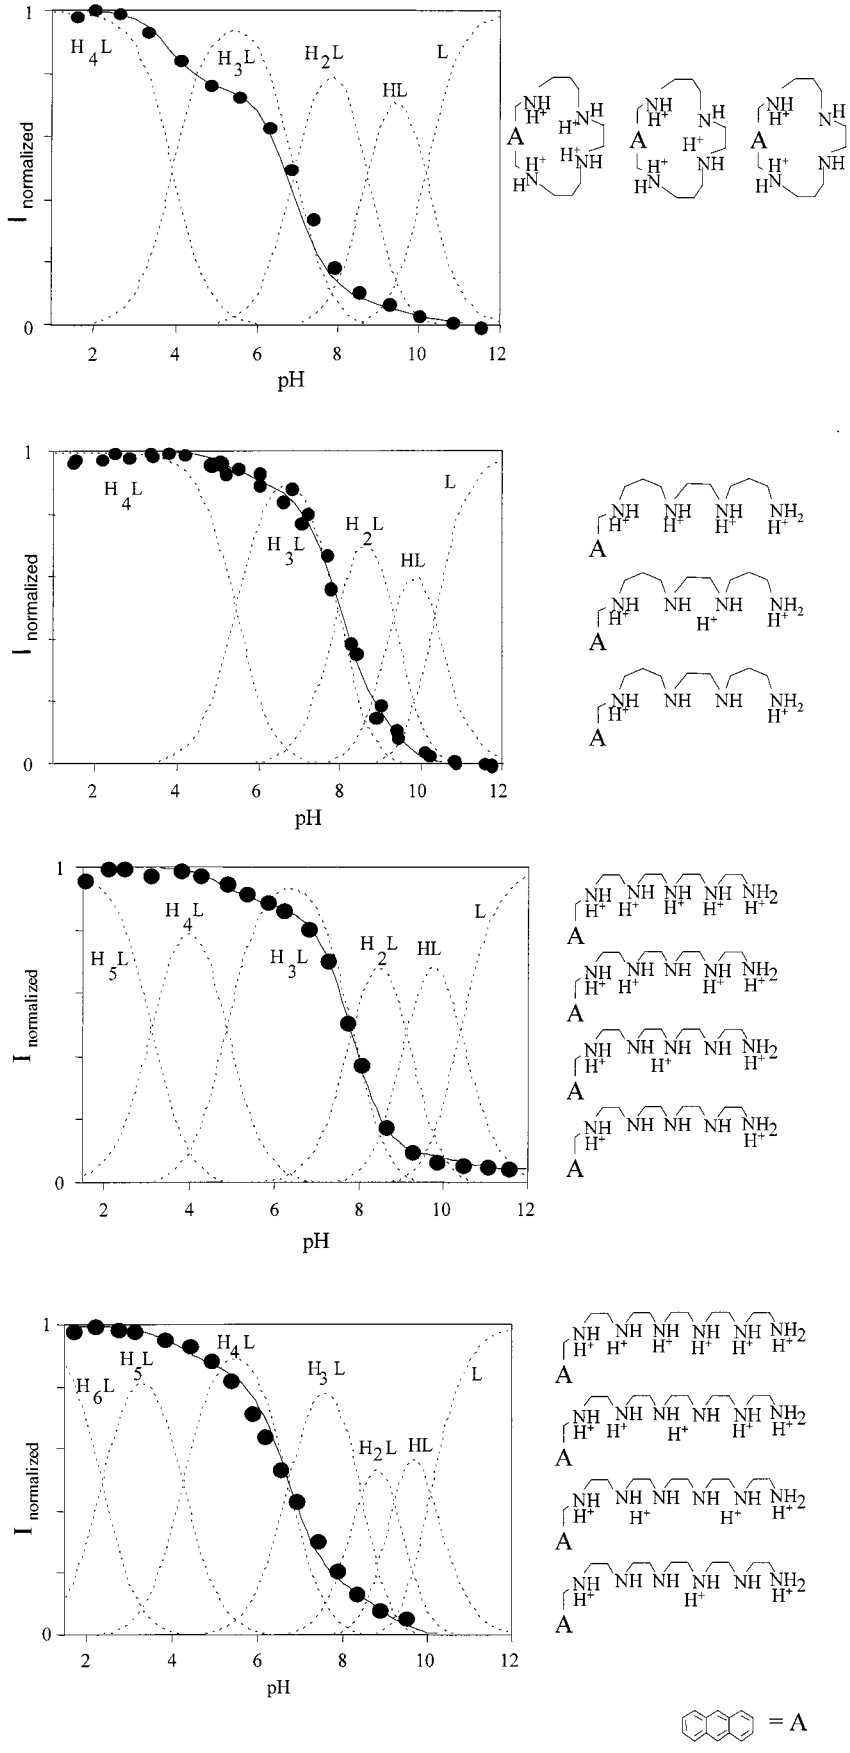
The largest member of this family, L[6], has a chain bearing five nitrogen atoms. The first two deprotonation steps occur at the nitrogen atoms labelled N2 and N4. At this stage, the situation can be compared with that resulting from the first deprotonation of L[3] or with that following the second deprotonation of L[5].

The fluorescence emission titration curves of compound L[7] were also determined. In this compound, nitrogen atoms N1 and N2 as well as N3 and N4 are separated from the benzene fragments by three carbon atoms, rather than two in the case of L[5]. This structural feature is reflected in the titration curve of L[7] in that the quenching observed upon removing two protons is less efficient than in the case of L[5].

Anthracene Fluorophore

A great improvement in the efficiency of polyamine-based chemosensors can be achieved by substituting benzene, which has a low fluorescence quantum yield, φ_f = 0.06, by a more intrinsically luminescent unit, such as naphthalene, φ_f = 0.21, or anthracene, φ_f = 0.3. In this section, we report a family of chemosensors incorporating anthracene fluorophore.[14,15] In Figure 3, the titration curves of the chemosensors L[8] and L[9] are presented. As for the benzene analogues, the fluorescence emission is almost totally quenched when the two central nitrogen atoms are deprotonated.

An identical pattern is apparent in the fluorescence emission titration curves of the linear analogues L[10] and L[11], also shown in Figure 3. The quenching effect is seen when nitrogen atoms N2 and N3 are completely deprotonated. In effect, according to CPK models, these two nitrogen atoms are the only ones that can overlap efficiently with the π system of the anthracene.



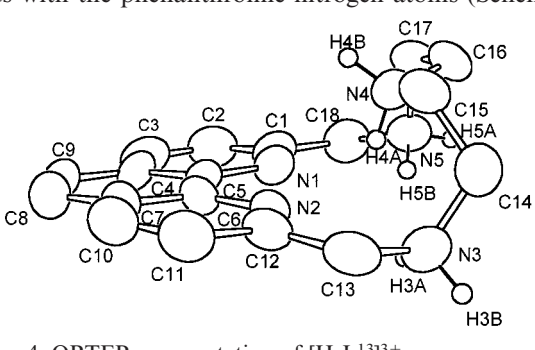


Figure 3. Fluorescence emission titration curves for L^8, L^9, L^{10}, and L^{11}, along with the respective mole fraction distribution curves and deprotonation sequence of the chemosensors

Phenanthroline Fluorophore

The first generation of chemosensors were based on aromatic heterocycles, e.g. those containing nitrogen or oxygen atoms, and their functions (binding and signalling) stemmed from the same part of the molecule. For this reason, they were called *intrinsic chemosensors*. Among these, phenanthroline derivatives have received much attention in recent years by virtue of their intense fluorescence and due to the presence of two aromatic nitrogen atoms that can act cooperatively in binding cations.[16] In the second generation of chemosensors, known as *conjugate chemosensors*, the binding and signalling moieties of the molecule are separated by a spacer and the two functions can be ascribed to different parts of the molecule, as shown in Scheme 2.[1]

In this context, a new series of polyamine macrocycles containing a phenanthroline unit as an integral part of the cyclic framework has recently been reported.[17,18] The simplest member of the series, 2,5,8-triaza[9]-10,23-phenanthrolinophane, L^{13}, contains a triamine chain linking the 2,9-phenanthroline positions. Therefore, this system can be considered as being both an intrinsic and a conjugate chemosensor: While the polyamine unit is used exclusively for the function of binding, the phenanthroline unit can be used not only for signalling but for binding as well.

In the crystal structure of the fully protonated form of L^{13}, containing three bromide anions as counterions, the macrocycle is seen to adopt a bent configuration. The phenanthroline unit and the benzylic nitrogen atoms N3 and N5 are almost coplanar, and this plane makes a dihedral angle of 104.10°, with the plane formed by the N3, N4, and N5 amino groups. The aliphatic amino groups (N4, N5, and N6) are in an *endo* conformation, enabling H-bond interactions inside the macrocyclic cavity. Specifically, the hydrogen atom linked to the central amine group points inside the macrocyclic cavity, giving rise to intramolecular H bonds with the phenanthroline nitrogen atoms. The nitrogen atoms N3 and N5 are also partially enclosed in the ligand cavity, and thus they can also form intramolecular H bonds with the phenanthroline nitrogen atoms (Scheme 4).

Scheme 4. ORTEP representation of $[H_3L^{13}]^{3+}$

As for the benzene and anthracene analogues, the absorption spectra of the whole molecules resemble that of the phenanthroline chromophore and protonation of the chain has only a small influence on their shape and intensity. However, the fluorescence emission spectra are completely quenched at basic pH values. When considering a fluorophore such as phenanthroline, containing lone pairs, the possibility of inversion between the strongly emissive π-π* state and the poorly emissive n-π* state has to be taken into account. In particular, protonation can stabilize the n-π* state relative to the π-π* state, leading to inversion of the states and thus to a decrease in the fluorescence emission intensity. This is the most probable explanation for the quenching effect observed for the fully protonated form. As discussed above, in this form, the nitrogen atoms of the phenanthroline unit are involved in H bonds with the protons of the chain. On removing the first proton, which is known to occur from the central nitrogen atom, the chemosensor becomes more emissive. At this point, two opposite effects come into operation. On the one hand, the intramolecular hydrogen bond becomes weaker and thus the fluorescence emission tends to increase. On the other hand, deprotonation of the central atom leaves the respective nitrogen lone-pair free to participate in the quenching process by electron transfer, which is thermodynamically favourable. However, a general feature of this class of compounds is that only when a benzylic nitrogen atom is deprotonated is the emission extinguished, and hence the diprotonated form is still emissive. This behaviour is exactly opposite to that seen with polyazacyclophane and *N,N′*-dibenzylated polyamine chemosensors (vide infra). This difference can be attributed to the fact that in the latter compounds the benzylic amino groups are in an *exo* conformation, whereas in the phenanthroline derivatives an *endo* conformation is adopted.

By increasing the length of the polyamine moiety, i.e. by replacing the diethylenetriamine chain by a triethylenetetraamine unit, L^{14}, or a tetraethylenepentaamine unit, L^{15}, larger macrocycles are obtained. The fluorescence emission titration curves show essentially the same features, i.e. a total quenching at basic pH and a partial quenching at very acidic pH values (Figure 4).

As a matter of fact, the marked decrease in the fluorescence emission intensity in very acidic media corresponds to the formation of the fully protonated forms of these compounds. This quenching effect increases in the order $L^{13} < L^{14} < L^{15}$, exactly mirroring the increasing involvement of the nitrogen atoms in stabilizing the protonated forms through hydrogen bonding. The observed decrease in the fluorescence emission can thus be rationalized in terms of possible inversion of the energy between the n-π* state and the π-π* state upon protonation (even partial) of the phenanthroline nitrogen atoms.

As observed for L^{13}, the larger macrocycles show a dramatic quenching effect at more basic pH values. In the case of L^{14}, the emission disappears with the loss of the second proton, while for L^{15} this is only seen on removing the third proton. In both cases, the resulting forms correspond to deprotonation at the benzylic nitrogen atoms. Once again, this behaviour seems to indicate a quenching process involving electron transfer from the lone pairs of the deprotonated amines to the excited phenanthroline. Because

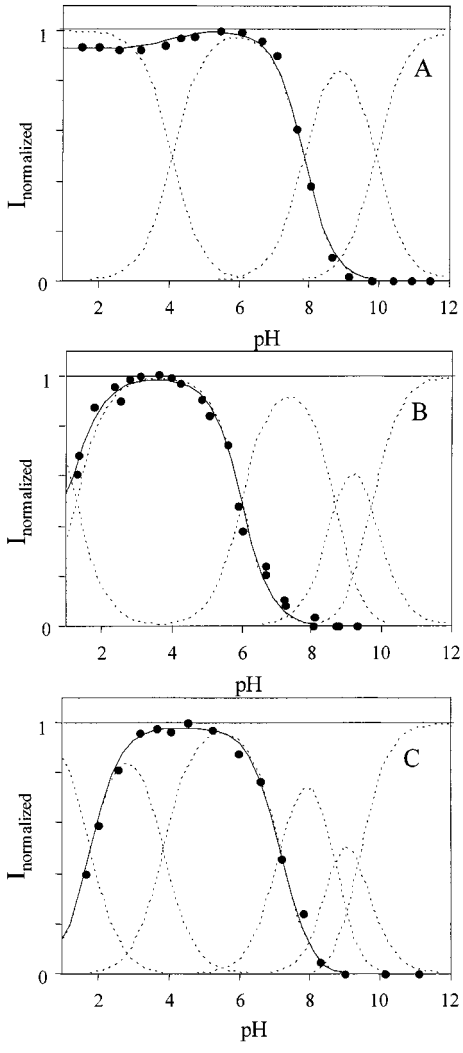

Figure 4. Fluorescence emission titration curves of A-L[13], B-L[14], and C-L[15], along with the respective mole fraction distribution curves

phenanthroline is only ca. 0.1 eV more difficult to reduce than anthracene, the process is also thermodynamically favourable.

Sensing Metal Cations

Photoelectron transfer from the amines to the excited fluorophore can also be suppressed by the binding of a cation at the receptor unit because, like the proton, the positively charged metal ion can increase the oxidation potential of the amine. However, coordination to metals such as copper(II) or nickel(II) can give rise to an enhancement of the quenching as the presence of such metal ions can offer alternative, non-radiative pathways, e.g. through the formation of non-radiative charge-transfer states. This situation can generally be detected through the appearance of new, intense absorption bands in the UV/Vis spectrum. The metal ion can also participate in the quenching by energy transfer or electron transfer, or quench through the heavy-atom effect. Some of these quenching processes are, however, precluded when the electronic configuration of the metal ion is d^{10}. This is the case with the zinc(II) and cadmium(II) cations, complexes of which can exhibit CHEF effects.

Sensing Zinc(II)

Complexes involving zinc(II) have attracted much attention, not only because of the large CHEF effect exhibited by this metal ion upon coordination, but also in view of the key roles played by such complexes in the active sites of zinc-containing enzymes such as carbonic anhydrase.[19−21]

The zinc(II) complexes of polyazacyclophanes and *N,N′*-dibenzylated polyamine receptors have been studied in detail. The absorption spectra of the chemosensors are not substantially altered in the presence of this metal ion, as reported by Czarnik in the case of a series of anthrylazamacrocycles.[2]

As for proton binding, plotting the fluorescence emission titration curves in conjunction with the mol fraction distributions of the various species present in solution, as determined by potentiometry, proved very helpful in understanding the emissive behaviour of these systems. This procedure led to good fitting and allowed us to dissect the relative contribution of each species present to the overall emission.

Zinc(II) Complexes with Polyazacyclophane Macrocyclic Receptors

In the case of polyazacyclophane macrocyclic receptors, the presence of a *p*-phenylene spacer prevents the simultaneous coordination of both benzylic nitrogen atoms to the same metal ion. This feature leads to unsaturated coordination sites, often of low symmetry, that are of interest with regard to the promotion of particular reactivities such as the stabilization of low-valent metal complexes or the activation of hydrolytic pathways.[22−25]

The structural characteristics of these compounds are reflected in the fluorescence emission properties of their various forms. In all the $[ML]^{2+}$ complexes, one of the benzylic nitrogen atoms is neither protonated nor coordinated and can thus take part in a PET quenching process, thereby accounting for the lack of an emission (Figure 5).

Curiously, in these cases, the two titration curves (in the presence and absence of the metal) are identical; only H_4L^{4+} and H_3L^{3+} are emissive and these species do not interact appreciably with zinc(II), hence their mol fraction distributions as a function of the pH value are not significantly affected.

At this point, the question arises as to why the benzylic nitrogen atoms should become efficient at quenching when involved in the metal complex, even though they are seemingly poor quenchers in the free chemosensor. A likely explanation for this behaviour is that these benzylic nitrogen atoms would be transformed from an *exo* conformation in the uncoordinated macrocycle to an essentially *endo* conformation in the coordinated complex.

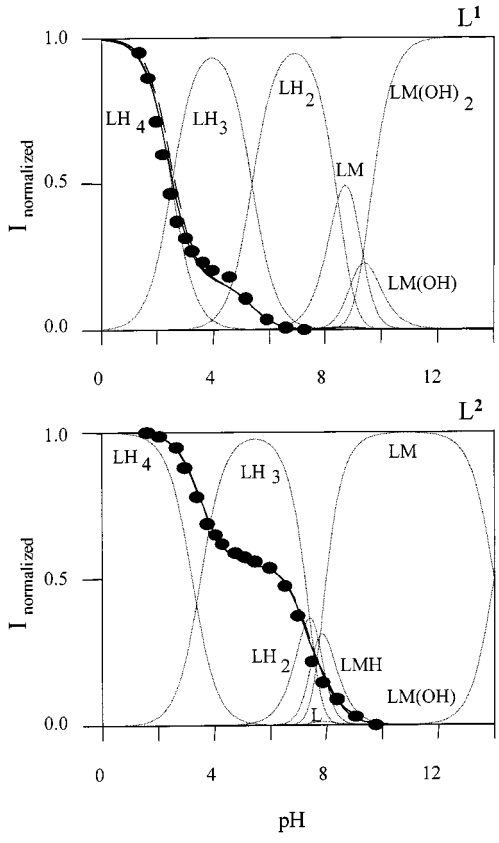

Figure 5. Steady-state fluorescence emission titration curves of (a) L^1, (b) L^2, in the absence of zinc(II) (traced line) and in the presence of an equimolar amount of zinc(II) (full line); mole fraction distributions in the presence of zinc(II) are also represented (full line)

Zinc(II) Complexes with *N*,*N*′-Dibenzylated Receptors

The fluorescence emission titration curves for the zinc(II) complexes with ligands L^3 to L^7 are presented in Figure 6.[26]

On comparing the fluorescence emission properties of these complexes with those of the polyazacyclophane analogues, it can be seen that for these ligands the $[ZnL]^{2+}$ complexes and the protonated analogues are emissive, except in the case of the largest member of this family.

In the case of the ligands L^4 and L^5, three complexes $[ZnL]^{2+}$, $[ZnL(OH)]^{+}$, and $[ZnL(OH)_2]$, could be detected by potentiometry, showing significant, weak, and no emission, respectively. In all the complexes, the nitrogen atoms can be expected to be fully involved in the coordination to the metal center, except in the case of the dihydroxy complexes, where the lack of an emission may be rationalized in terms of partial decomplexation. The zinc(II) complexes display emissions with quantum yields ca. half of that of the emissions detected for the fully protonated forms of the free ligands. This implies that coordination to the zinc(II) ion, like protonation, prevents the PET between the amines and the fluorophore, albeit less efficiently. When the water coordinated to the zinc(II) cation loses a proton, the protective effect of the metal ion decreases and is lost completely following removal of a second proton from another water ligand. In the case of L^6, potentiometric titrations

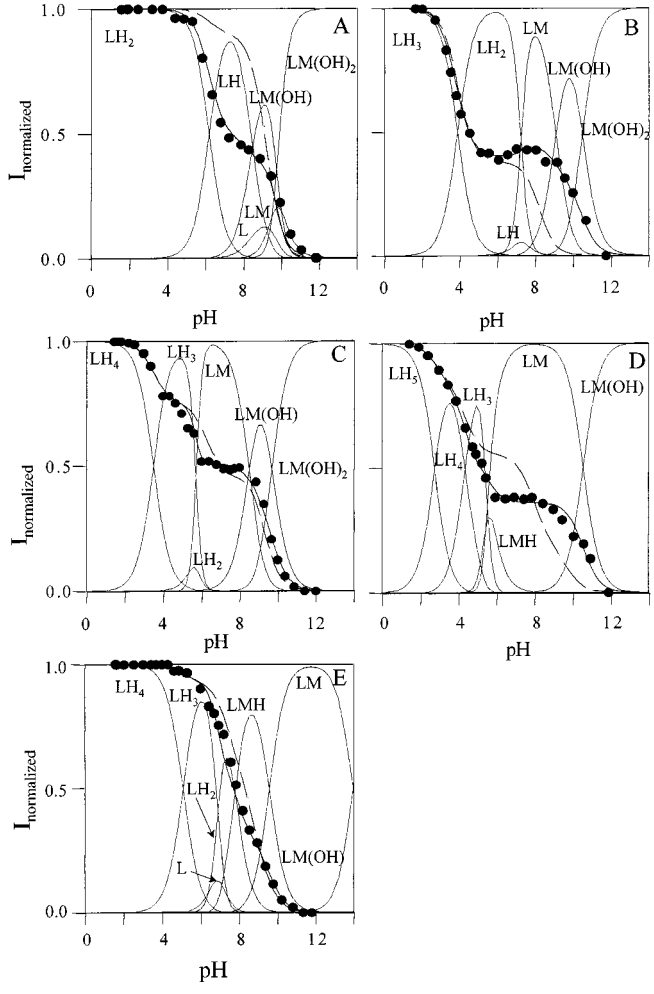

Figure 6. Steady-state fluorescence emission titration curves of A-L^3, B-L^4, C-L^5, D-L^6, and E-L^7 in the absence of zinc(II) (traced line) and in the presence of an equimolar amount of zinc(II) (full line); mole fraction distributions in the presence of zinc(II) are also represented (full line)

predict the existence of the species $[ZnHL]^{3+}$, $[ZnL]^{2+}$, and $[ZnL(OH)]^{+}$. The lack of fluorescence emission for the form $[ZnL]^{2+}$ can be explained by the fact that in this species only four of the five nitrogen atoms are involved in the binding, allowing the free nitrogen atom to carry out the quenching process.

Zinc(II) Complexes with Anthracene Fluorophores

The fluorescence emission titration curves for the zinc(II) complexes of the chemosensors L^9 to L^{11} are presented in Figure 7.[14]

This class of compounds shows some remarkable advantages in comparison with the chemosensors incorporating a benzene unit: (i) substantially higher fluorescence quantum yields, (ii) much greater differences in emission between the free and the complexed forms.

Inspection of Figure 7 shows that the metal complexes however $[ZnL]^{2+}$ as well as their protonated forms are strongly emissive, with the sole exception of the $[ZnL^{11}]^{2+}$ species. In contrast, the hydroxo complexes are not emissive. A puzzling matter that needs to be addressed is the contrast

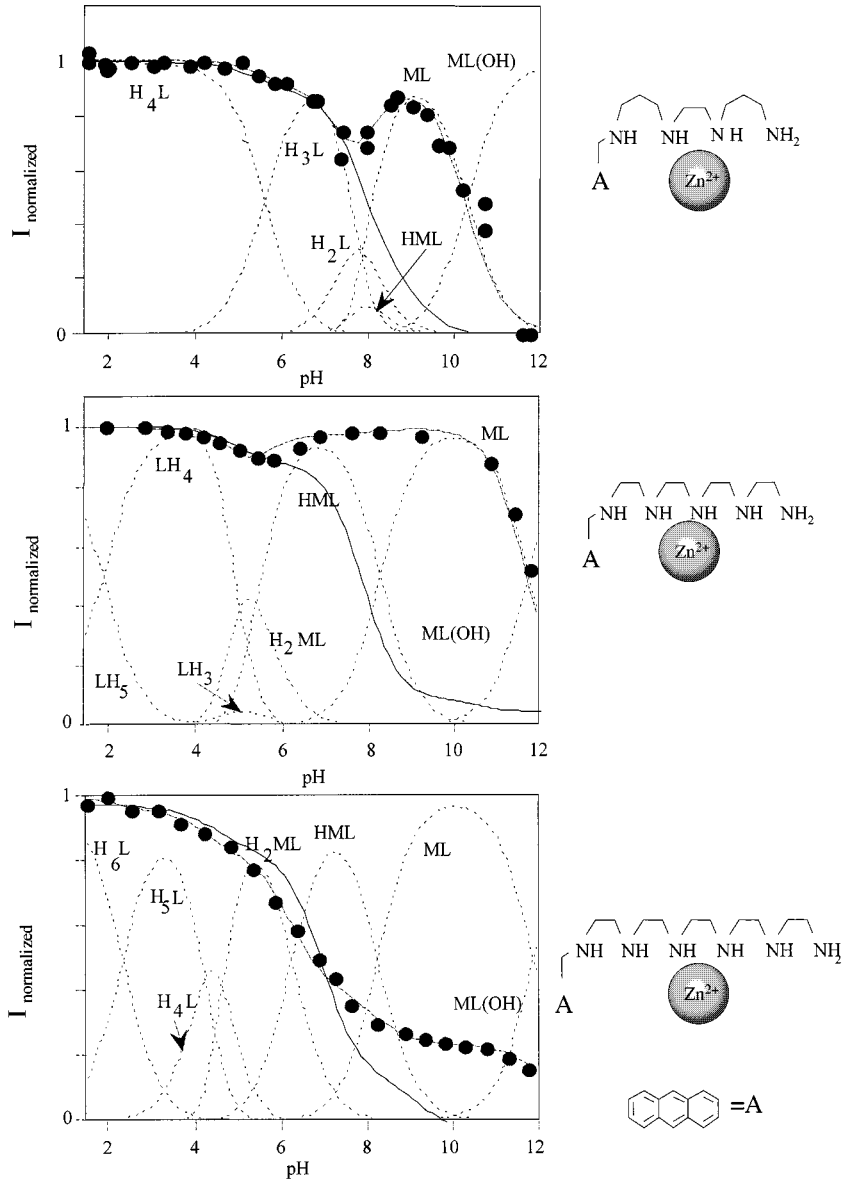

Figure 7. Steady-state fluorescence emission titration curves of L^9 to L^{11} in the absence of zinc(II) (full line) and in the presence of an equimolar amount of zinc(II) (traced dotted line); mole fraction distributions in the presence of zinc(II) are also represented (dotted line)

between the intense fluorescence emission of the species $[ZnL^{10}]^{2+}$ and the weak emission of the complex $[ZnL^{11}]^{2+}$.

Assuming that in these compounds the best coordination is achieved when four nitrogen atoms are simultaneously bound to the metal center, the $[ZnL^{11}]^{2+}$ species would possess a free or only weakly coordinated nitrogen atom, which could thus be responsible for quenching.

An interesting feature that emerges from Figure 7 is the crucial importance of the receptor length. The best performance was observed with the chemosensor of intermediate length.

In general, zinc(II) complexation by the conjugate chemosensors gives rise to two different effects: (i) the mol fraction distributions of the highly protonated and emissive forms of the free ligand are decreased and shifted to lower pH values, and these are replaced by less emissive metal complexes, thereby explaining the CHEQ effect; and (ii) it allows the existence of emissive metal complexes under conditions of moderately basic pH values where, in the absence of the metal ion, no emissive species of the free ligand are present, thereby leading to a CHEF effect. These two effects are thus the result of the existence of differentiated domains for each type of emissive species.

Zinc(II) Complexes with Phenanthroline Chromophores[17,18]

The crystal structure of the complex $[ZnL^{13}(H_2O)](ClO_4)_2$ indicates that the coordination geometry around the metal atom can be described as a distorted tetrahedron, the vertices of which are occupied by the phenanthroline nitrogen atoms N1 and N2, the central aliphatic nitrogen atom N4, and a water molecule. The zinc(II) cation forms two long bonds to the benzylic nitrogen atoms (N3−Zn 2.460 Å, N5−Zn 2.512 Å) so as to achieve a pseudo-prismatic geometry, the bases of the prism being defined by N2,

N3, N4 and N1, O1, N5, respectively (Figure 8A). According to this structure, both benzylic nitrogen atoms are weakly involved in metal coordination. A similar effect has been described for polyazamacrocyclic receptors containing a benzene unit as an integral part of the ring.[26] Furthermore, the phenanthroline unit displays electron-withdrawing properties, which reduce the basicity and the donor ability of the benzylic amino groups adjacent to the heteroaromatic moiety. These characteristics disfavour coordination of the metal center by the benzylic amino groups, leading to an unsaturated coordination environment for the zinc(II) ion. As a consequence, water molecules can be bound at the free binding sites of the metal center, as has indeed been shown by a crystal-structure analysis of the complex. Facile deprotonation of the coordinated water gives the hydroxo complex in aqueous solution at slightly alkaline pH values, as well as a dihydroxo species in strongly alkaline solutions. The aforementioned structural characteristics strongly affect the fluorescence emission features of this zinc(II) complex. Figure 8B shows the fluorescence emission titration curve of L^{13} in the presence of equimolar amounts of zinc(II) ions, from which an efficient quenching effect is apparent.

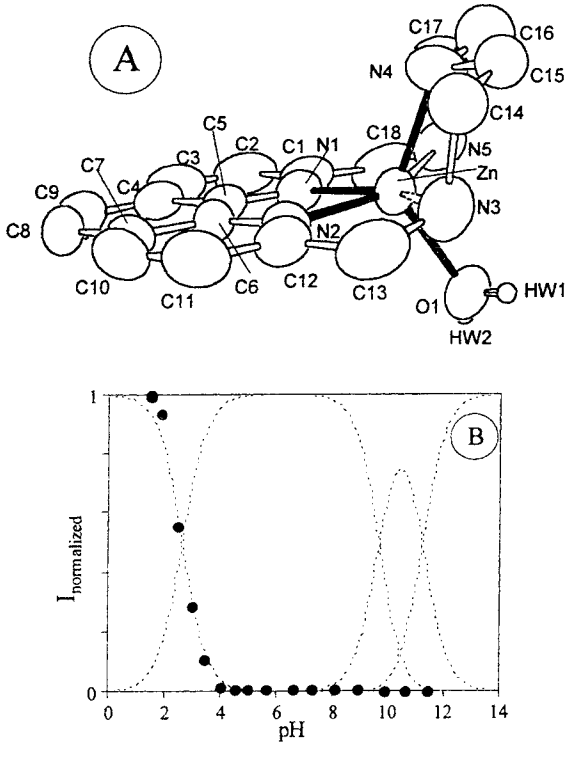

Figure 8. **A**: ORTEP representation of the $[ZnL^{13}(H_2O)]^{2+}$ cation; **B**: fluorescence emission titration curve of L^{13} in the presence of an equimolar amount of zinc(II)

This unexpected behaviour can be rationalized by considering the particular characteristics of the ligand L^{13} and of its zinc(II) complexes. According to the structure of the complex cation $[ZnL^{13}(H_2O)]^{2+}$, both benzylic amino groups are weakly involved in the metal coordination. These nitrogen atoms are close to the fluorophore and, as shown previously, they are able to efficiently quench the fluorescence. Moreover, no protonated forms of the zinc(II) complex could be detected by potentiometry. Therefore, in this complex the lone pairs on the benzylic nitrogen atoms are available for the electron-transfer process, accounting for the lack of fluorescence emission.

Sensing Cadmium(II)

Figure 9 shows the fluorescence emission titration curves obtained for the chemosensors L^9 to L^{11} in the presence of equimolar quantities of cadmium(II). The basic trend is similar to that observed for the complexes with zinc(II). However, due to the lower propensity of the cadmium(II) complexes to form hydroxo species when compared with zinc(II), the fluorescence emission extends to more basic pH values. For example, strong fluorescence emissions can still be detected at pH = 12.

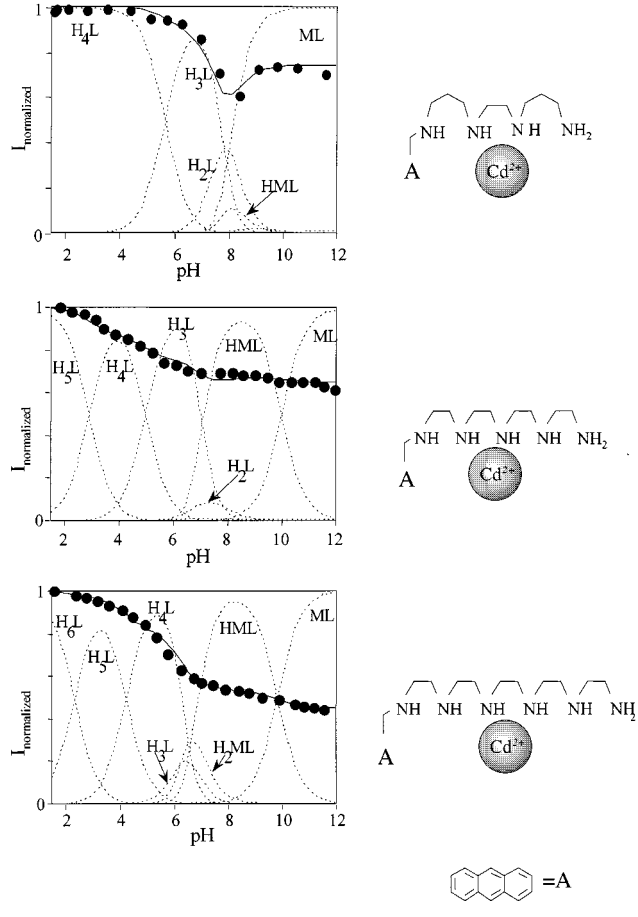

Figure 9. Fluorescence emission titration curves obtained for the chemosensors L^9 to L^{11} in the presence of equimolar quantities of cadmium(II)

Sensing Copper(II)

In contrast to the situation with zinc(II) ions, complexation of copper(II) ions by L^1 to L^7 leads to large increases in the molar absorption coefficients as well as to blue shifts in the UV/Vis absorption maxima. These new

and very intense bands are characteristic of charge-transfer processes and are indicative of significant interactions between the molecular orbitals of the ligand and those of the metal center (Figure 10A). As a consequence, the excited states are no longer centred on the ligand but display metal character. No fluorescence emission was observed for these complexes, the recorded fluorescence being purely due to protonated forms of the free ligands (Figure 10B). According to potentiometric studies, several species with all the nitrogen atoms involved in coordination to the metal ion and/or protonated are present in solution. In spite of this, no emission was observed. A possible explanation for the absence of fluorescence emission in the copper(II) complexes can be found in the charge-transfer characteristics of the excited state, which can offer a channel for the deactivation of the excited state involving the metal center.

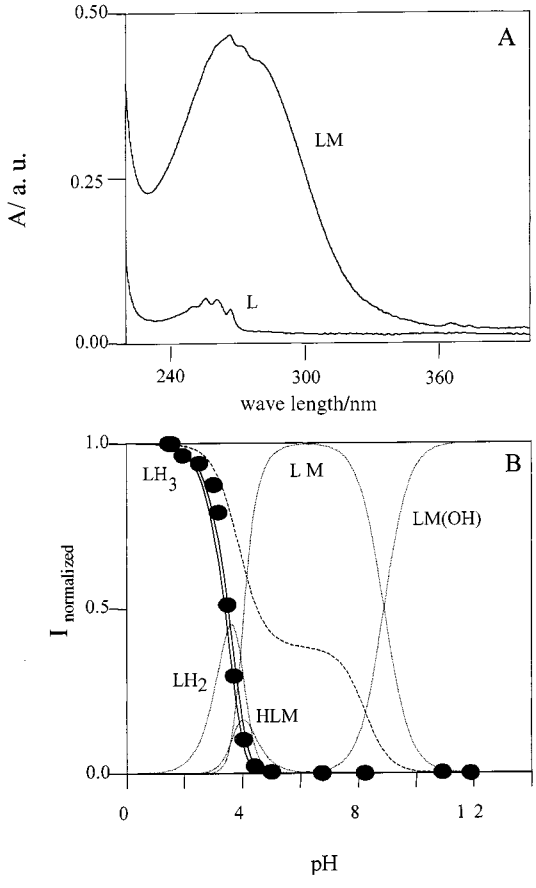

Figure 10. **A**: Absorption spectra of L^4 at pH = 6, in the absence and in the presence of an equimolar amount of copper(II); **B**: fluorescence emission titration curves obtained for L^4 in the presence of an equimolar amount of copper(II)

Sensing Anions

The chemosensors described throughout this work can also be used to bind anions. One of the obvious strategies for achieving this goal is to work at pH values at which the polyamine receptor is fully or partially protonated, thereby using electrostatic attraction as a driving force for anion binding. In another strategy, complexes of the polyamine ligands with strong Lewis acids such as divalent metal ions, in particular zinc(II), are used as receptors. Adducts of this type show strong affinities for anions as the metal center offers a coordination site at which the substrate can be bound. This latter strategy has been brilliantly developed by Kimura and co-workers. These authors have designed molecules based on the well-known [12]aneN_4 and [12]aneN_3 macrocyclic receptors. Coordination of substrates such as benzoic acid,[27] phthalic acid,[27] sulfonamides,[28] or carboxamides[29] is favoured by strong interactions between the zinc(II) ion and the respective anions. In this regard, macrocyclic receptors bearing pendant arms incorporating additional donor atoms are particularly interesting. This is exemplified by the receptor cyclen, which has pendant aromatic sulfonamide moieties that can bind to the metal center through their sulfonamide *N*-anions.[31] Pendant arms containing phenolate,[30] dimethylaminopropyl,[31] pyridine,[31] uracil,[32] and alcohol[33] moieties have also been described.

Sensing Nucleotides

Nucleotide sensing and quantification by means of luminescent probes represents an important target in supramolecular chemistry due to their many biological and biomedical implications. Lehn and co-workers have prepared two very interesting multi-site binding receptors based on the well-known macrocyclic structure of 1,13-dioxa-4,7,10,16,19,22-hexaazatetracosane (bisdien); to which one or two acridine luminescent groups, respectively, have been covalently bonded to the central nitrogen atoms of these polyamine fragments through aminopropyl side-arms. The second of these receptors seems to be particularly well suited for nucleotide recognition since, apart from displaying large variations in its emission properties upon coordination to nucleotides, it does not induce hydrolytic ATP cleavage.[34] Other types of receptors developed by Lehn and Zinic were based on bis(phenanthridinium) fragments; their emissions were subject to large quenching effects as a result of π-stacking interactions with the adenine moieties of nucleotides.[35] These interactions gave constants as high as ca. 5.8 logarithmic units and were independent of the polyphosphate chains of the nucleotides.

Recently, it was shown that, in spite of their apparent simplicity, the chemosensors L^9, L^{10}, and L^{11}, but not L^8, strongly interact with nucleotides exhibiting high degrees of selectivity for ATP. The presence of the anthracene unit allows the chemical inputs to be readily transformed into light signals.[36]

pH-Metric titrations of aqueous solutions of L^9 and ATP in a 1:1 molar ratio over the pH range 2.5−11 show the formation of ATP−L^9 adducts with degrees of protonation varying from 6 to 1.7. The distribution diagram is depicted in Figure 11. The conditional stability constants vary from 6.5 to 2 in the pH range explored. Fluorimetric titrations on the ATP−L^9 system show a bell-shaped curve; thus, light emission is strongly quenched at pH values lower than 4,

the emission reappears at pH ≈ 7, and then decreases once more, eventually disappearing at pH > 10. A similar result has been obtained by Czarnick et al.[37] in a study of the complexation of various anions, such as ATP, by two anthrylpolyamines.

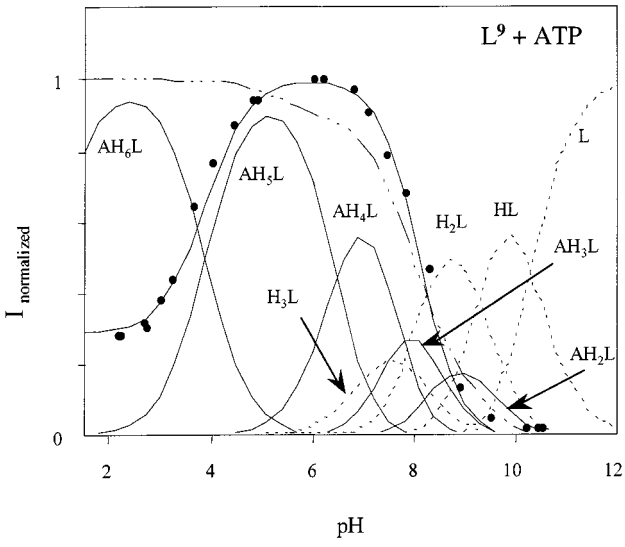

Figure 11. Fluorescence emission titration curves of L^9 in presence of equimolar amounts of ATP (•); fitting (——) was achieved as a linear combination of the mole fraction distribution of the various adducts as determined by potentiometry; the titration curve in the absence of ATP (—···—) is also included for comparison purposes

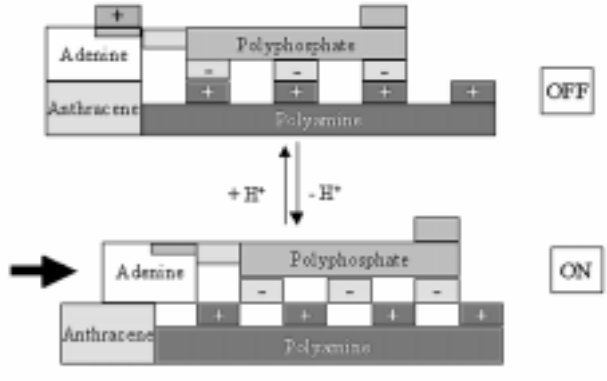


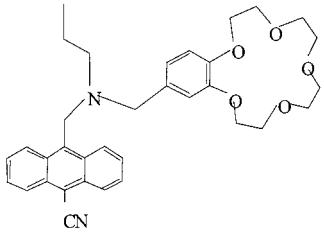
We suggest that this behaviour may be interpreted on the basis of the various species formed in solution, and considering the luminescent behaviour of the free receptor.

As mentioned above, from spectrofluorimetric titrations of the free receptor it could be inferred that H_4L^{4+} and H_3L^{3+} were the only emissive species, with a relative fluorescence emission quantum yield of $\Phi(H_4L^{4+})/\Phi(H_3L^{3+}) = 0.85$. In the presence of ATP, these species continue to emit, irrespective of whether they are complexed to ATP or free, except for the H_6LA^{6+} species formed by the association of the fully protonated receptor L^9 and the diprotonated form of ATP, which gives rise to a quenching effect. Comparing the fluorescence emission titration curves of the free and complexed receptor (Figure 11), the small increase in the fluorescence emission (CHEF) observed for the ATP−L^9 system at a neutral pH value can be attributed to the increase in apparent basicity of the receptor that occurs upon coordination to ATP. Perhaps the most striking feature of this system is the dramatic CHEQ effect (almost 60%) observed at pH < 4 (see Figure 11). A plausible interpretation of such quenching could be a π-stacking interaction between the anthracene unit of the receptor and the adenine fragment of the guest species, resulting by the charge state of both of them at these pH values. Evaluation of the stability constants at pH = 2.0 provides a value of 5.8 logarithmic units. Interestingly, the monoprotonated form of ATP does not give rise to such a quenching effect. It seems likely that the matching between the triphosphate chain of $HATP^{3-}$ and the polyammonium fragment of L^9 alters the relative disposition of the aromatic moieties in the two molecules, thereby preventing efficient π-stacking. On examining the behaviour of ADP, AMP, adenine, and tripolyphosphate, it was observed that only the first of these produced a CHEQ effect, however with a much lower constant (log K = 3.7 at pH = 2.2) than that found for ATP.

Therefore, it seems that the molecular topology of the receptor is a key factor in facilitating the π-stacking pattern. Indeed, experiments carried out with the anthracenophane 2,6,9,13-tetraaza[14](9,10)-anthracenophane (L^8) did not reveal any significant effect. On the other hand, analogous ligands containing the same fluorophore but with different polyamine chains (L^{10} and L^{11}) give rise to similar CHEQ effects with very similar association constants (L^{10}: log K = 5.6; L^{11}: log K = 5.4; both at pH = 2.2). It is noteworthy that the constants obtained are not affected by the chain length or the number of nitrogen atoms in the chain, but only by the molecular arrangement of the receptor. The values of these stability constants are, on the other hand, rather similar to those obtained by Lehn and Zinic for the interaction of ATP and other nucleotides with their bis-(phenanthridinium)-based receptors.[35]

A related receptor can be constructed by appending two methylanthracene fragments at both ends of a linear pentamethylenehexaamine chain, L^{12}. Interaction of L^{12} with ATP also leads to a very significant quenching of the emission at low pH values, from which an association constant of log K = 5.7 at pH = 2.2 can be calculated.

The similar values of the constants obtained for ATP binding with all the receptors at acidic pH values, together with the lack of notable effects for AMP and adenine, suggest that the requirements for observing significant CHEQ effects are: (i) a certain degree of anchorage of the polyphosphate chain of ATP by the polyammonium fragments of the receptor, and (ii) topological complementarity of the partners (see Scheme 5).



Scheme 5. Schematic representation of ATP "anchorage"

These results highlight the potential use of these simple receptors as efficient luminescent ATP chemosensors. Further work is currently in progress with the aim of obtaining related receptors with improved binding characteristics.[37]

Molecular Devices and Machines

Logic Gates at a Molecular-Level

Chemosensors can be regarded as devices that behave essentially as logic gates since in these systems chemical binding (the "input") results in a change in fluorescence intensity (the "output") of the receptor, which can be translated as a simple logic operation. Among other authors,[37,39,40] de Silva and co-workers were the first to contribute to this growing field of chemistry.[3] For example, an AND logic gate operating with two input channels was described.[41] In this system, the fluorescence signal depends on whether hydrogen ions, sodium ions, or both are bound to the receptor molecule (Scheme 6).

Scheme 6. Chemical structure of de Silva's ligand that operates as a logic device[41]

Recently, we described a NAND logic gate based on the system ATP−L^9 (Figure 11).[36] The initial state is that of the free chemosensor in the pH range 5−8. The inputs are obtained by: (i) addition of protons in order to reach a final pH of ca. 2, and (ii) addition of a slight excess of ATP at pH = 6. We consider there to be a final output of 1 when the intensity of the fluorescence emission exceeds 0.8 relative units, and of 0 when the intensity of the emission is below 0.4 relative units. In the absence of any input, the system exhibits fluorescence emission and thus the output signal is 1. The same output is obtained if only ATP or protons are added to the solution. When both inputs are present, a quenching effect occurs and the output becomes 0 (see Table 1).

Molecular Machines

Metal Scorpionate Complexes

One interesting system, based on the presence of a pendant arm, has been reported by Fabbrizzi and coworkers.[42] This system uses the Ni^{II} complex of a cyclam ring separated from an anthracene chromophore by a methylene spacer (Scheme 7).

Scheme 7. Chemical structure of Fabbrizzi's molecular machine[42]

The fully protonated form, corresponding to a structure where the protonated alkylamine side chain is forced away from the ring through electrostatic repulsion, exhibits the most intense emission. A fluorimetric titration in acetonitrile/water (4:1) showed that on removing the first proton (from the alkylamine side chain) the emission was reduced to 60% of the original. In this last species the metal center is hexacoordinated by the cyclam nitrogen donors at the equatorial positions and by the alkylamine group and water molecule at the axial positions. Complete quenching occurs upon removal of a second proton from the water molecule linked to the metal center. All these processes are reversible and thus the system can be considered as an elementary molecular machine driven by the pH value. The pendant arm is forced to oscillate between the metal center and a more distant point by modulation of an external parameter, i.e. the pH value.

Conclusions

The study of supramolecular species capable of existing in different states that may be interconverted by external stimuli is a topic of great interest and has led to predictable applications in the field of nanotechnology. Fluorescent chemosensors containing polyamine receptors are versatile systems capable of detecting cations or anions and, depending on their incorporated units, function as molecular devices or machines. The systems reported in this review are capable of detecting substrates at low concentrations and exhibit high sensitivity in water. However, their selectivities still need to be improved if they are to find application in real situations.

Synthesis and Crystal Structures of Monomeric Diamidonickel(II) Complexes

Hung Kay Lee,*[a] Yu Peng,[a] Steven C. F. Kui,[a] Ze-Ying Zhang,[a] Zhong-Yuan Zhou,[a] and Thomas C. W. Mak[a]

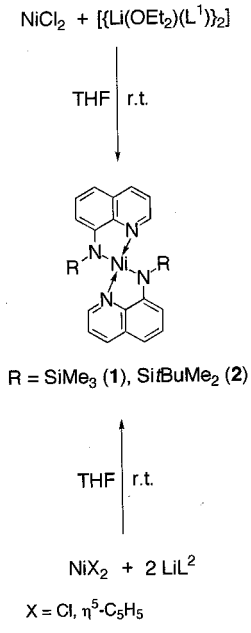
Keywords: Nickel / Amides / Chelates / Magnetic properties / N ligands

The thermally stable nickel(II) diamides [NiL_2] [L = $^-N(SiMe_3)(8\text{-}C_9H_6N)$ (**1**), $^-N(SitBuMe_2)(8\text{-}C_9H_6N)$ (**2**)] have been synthesized from the reaction of $NiCl_2$ with the appropriate lithium amide. X-ray crystallography revealed that the amido ligands bind in a chelating manner, forming a distorted tetrahedral environment around the nickel center. Complexes **1** and **2** have magnetic moments of 3.05 and 2.74 μ_B, respectively, which indicate a d^8 electronic configuration with two unpaired electrons.

Introduction

The study of late transition metal amides has elicited considerable interest due to their involvement in a number of important reactions, ranging from industrial processes[1] to biological phenomena.[2] Among these reactions, the formation of C−N bonds by insertion of unsaturated compounds into the highly reactive M−N bonds has attracted much attention in the past decade.[3] Although an enormous amount of effort has gone into the synthesis of late transition metal amides, structural data for these complexes are still scarce due to the lability of the M−N bonds. It is generally believed that M−N bonds are relatively weak due to an incompatibility that exists between the "hard" anionic amido ligand and the "soft" low-valent late transition metal center.[4−5] Alternatively, on the basis of orbital arguments, the "reluctance" of the electronically saturated late transition metal center to function as a π-acceptor for the amido nitrogen lone-pair electrons through M−N (*d*←*p*) π-interactions also imposes a destabilizing effect on these complexes.[6]

Examples of fully characterized nickel amide complexes containing $Ni-NR_2$ bonds are rare, in contrast to those of nickel complexes containing Ni−X bonds (X = alkyl, halide, hydrido). An early attempt to prepare nickel(II) diamides by reacting $NiCl_2(PPh_3)_2$ with $LiN(SiMe_3)_2$ was unsuccessful and only the three-coordinate nickel(I) complex $[Ni\{N(SiMe_3)_2\}(PPh_3)_2]$ was obtained.[7] By using a "hybrid" ligand consisting of both a hard amido ligand and soft phosphane donors, Fryzuk et al. have successfully synthesized the nickel(II) amide $[Ni(Cl)\{N(SiMe_2CH_2PPh_2)_2\}]$.[8] Recently, a series of monomeric nickel(II) amides $[Ni(Mes)(L)(PMe_3)_2]$ [Mes = mesityl; L = ^-NHPh, $^-N(Ph)C(O)CHPh_2$, $^-N(Ph)\{C(O)NHtBu\}$] that contain supporting phosphane ligands have been prepared and structurally characterized by Abboud, Boncella, and coworkers.[3d,9] Delocalization of the lone pair of electrons on the amido nitrogens to the π molecular orbitals of the ligands and/or π-interactions between the lone pair electrons with the nickel center in these complexes have been observed.



In recent years, a number of novel metal amides containing the bulky *N*-functionalized amido ligands [$^-N(Ph)(2\text{-}C_5H_4N)$],[10,11] [$^-N(SiMe_3)(2\text{-}C_5H_3N\text{-}6\text{-}Me)$],[12] [$^-N(SiMe_3)(2\text{-}C_5H_3N\text{-}4\text{-}Me)$],[13] and [$^-N(SiMe_3)(8\text{-}C_9H_6N)$],[12a,12b,12d,14] have been synthesized and structurally characterized. Interestingly, these amido ligands can bind to the metal centers in a number of bonding modes, for example as monodentate amido ligands, bidentate *N*,*N*-chelating ligands or bidentate *N*,*N*-bridging ligands. However, late transition metal amides derived from these ligands are still rare.[13a] Currently, we are interested in the structure and reactivities of metal amides. One of our synthetic strategies involves the use of bulky chelate ligands in order to stabilize those otherwise kinetically labile transition metal amido complexes. Several sterically more demanding *N*-functionalized amido ligands, namely [$^-N(SitBuMe_2)(2\text{-}C_5H_3N\text{-}6\text{-}Me)$], [$^-N(SitBuPh_2)(2\text{-}C_5H_3N\text{-}6\text{-}Me)$], and [$^-N(SitBuMe_2)(8\text{-}C_9H_6N)$] have been prepared in our laboratory and shown to be capable of stabilizing a number of novel main group and transition metal amides with unusual coordination geometries.[15] In this communication, we report the synthesis and crystal structures of two novel monomeric nickel(II) amido complexes, namely $[Ni\{N(SiMe_3)(8\text{-}C_9H_6N)\}_2]$ (**1**) and $[Ni\{N(SitBuMe_2)(8\text{-}C_9H_6N)\}_2]$ (**2**).

Addition of $[\{Li(OEt_2)(L^1)\}_2]$ [L^1 = $^-N(SiMe_3)(8\text{-}C_9H_6N)$][12a] to a slurry of anhydrous $NiCl_2$ in THF at ambient temperature gave the homoleptic nickel(II) amide **1** in satisfactory yield (Scheme 1). Complex **2** was prepared analogously by the reaction of $NiCl_2$ with two molar equivalents of the lithium reagent LiL^2 [L^2 = $^-N(SitBuMe_2)(8\text{-}C_9H_6N)$]. The latter was prepared by lithiation of HL^2 [15] with a solution of *n*BuLi in hexane. Compound **2** could also be obtained by the reaction of nickelocene with two molar equivalents of LiL^2 in THF at

room temperature. Both **1** and **2** were isolated as very air-sensitive, reddish brown crystals. They are thermally stable at room temperature and can be stored indefinitely under an inert atmosphere. They have been characterized by ^{1}H NMR spectroscopy, mass spectrometry and elemental analysis,[16] in addition to single-crystal X-ray diffraction studies. In the solid state, complex **1** consists of two independent molecules of nearly the same structure (Figure 1), which are also analogous to that of **2** (Figure 2). Both complexes are mononuclear and exhibit a distorted tetrahedral coordination geometry around the nickel center, with each pair of amido ligands binding in an *N*,*N*-chelating manner. The Ni−$N_{quinolyl}$ bond lengths in **1** [1.92−2.06(1) Å] and **2** [2.00−2.03(1) Å], are slightly shorter than the Ni−$N_{pyridyl}$ bond lengths of 2.093 Å (av.) in the trinickel(II) complex of dipyridylamide $[Ni_3(L^3)_4Cl_2]$ [L^3 = $^-$N(2-$C_5H_4N)_2$], in which the amido ligands bind in a *N*,*N*-bridging manner.[17]

Scheme 1

The nearly trigonal planar geometry around the amido nitrogen centers [sum of bond angles (av.): 359.7° and 360.0° in **1** and 359.3 in **2**] are consistent with sp^2-hybridized nitrogen atoms. The average Si−N bond lengths of 1.710 and 1.716 Å in **1** and 1.739 Å in **2**, are not significantly different from those typical for aminosilanes (ca. 1.73 Å).[4] This suggests the presence of a significant Si−N ($d\leftarrow p$) π-bonding interaction. Delocalization of the lone-pair electrons of the amido nitrogen onto the quinolyl ring is also evidenced by the relatively short N_{amido}−$C_{quinolyl}$ distances of 1.361 and 1.365 Å (av.) in **1**, which are similar to the N_{amido}−C_{phenyl} distance of 1.354(5) Å in *trans*-[Ni(Mes)(NHPh)(PMe_3)$_2$] (**3**).[3d,9a] The observed Ni−N_{amido} distances of 1.92−1.94(1) Å in **1** are relatively short and are similar to the observed Ni−N distances of 1.924(2) Å in [Ni(Cl){N($SiMe_2CH_2PPh_2$)$_2$}][8] (**4**) and 1.932(3) Å in

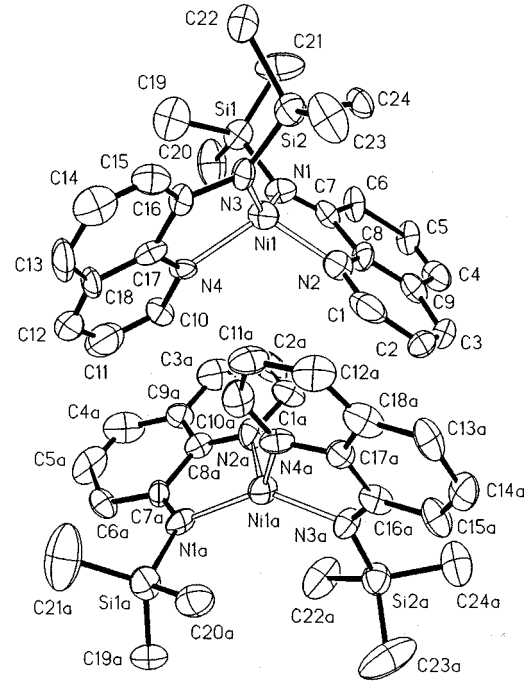

Figure 1. Perspective view of the two independent molecules (30% thermal ellipsoids) in the crystal structure of [Ni{N($SiMe_3$)(8-C_9H_6N)}$_2$] (**1**) with the atomic labeling scheme; selected bond lengths [Å] and bond angles [°]: Ni(1)−N(1) 1.94(1), 1.93(1), Ni(1)−N(2) 1.92(1), 2.00(1), Ni(1)−N(3) 1.92(1), 1.93(1), Ni(1)−N(4) 2.06(1), 2.00(1), Si(1)−N(1) 1.73(1), 1.67(1), Si(2)−N(3) 1.69(1), 1.76(1), N(1)−C(7) 1.26(2), 1.34(2), N(3)−C(16) 1.46(1), 1.39(1); N(1)−Ni(1)−N(2) 82.2(7), 84.5(6), N(3)−Ni(1)−N(4) 85.0(6), 82.4 (6), N(1)−Ni(1)−N(3) 138.2(2), 138.9(2), C(7)−N(1)−Si(1), 126(1), 127(1), C(7)−N(1)−Ni(1) 114(1), 113(1), Si(1)−N(1)−Ni(1) 119.6(8), 120.7(7), C(16)−N(3)−Si(2) 127(1), 128(1), C(16)−N(3)−Ni(1) 112(1), 114(1), Si(2)−N(3)−Ni(1) 121.6(7), 117.9(8)

3,[3d,9a] suggesting that weak π-bonding interactions between the amido nitrogens and the nickel center may be present in **1**. Apparently, ligand L^1 behaves as a weak π-acceptor in this case. The average Ni−N_{amido} distance in **2** [1.94(1) Å] is similar to those in **3** and **4**, but slightly shorter than that of 1.974(3) Å in *trans*-[Ni(Mes)-{N(Ph)C(O)$CHPh_2$}(PMe_3)$_2$] (**5**),[3d,9b] where an Ni−N π-interaction was suggested to be absent in the latter complex. Since the structures of ligands L^1 and L^2 are similar, we surmise that Ni−N π-bonding interaction may also be present in complex **2**.

The N_{amido}−Ni−$N_{pyridyl}$ bite angles in **1** and **2** are similar, falling within the range 79.6(7)° to 89.1(6)°. The interligand angles N_{amido}−Ni−N_{amido} of 158.1(4)° in **2** are much larger than the corresponding angles of 138.2(2)° and 138.9(2)° in **1**. This may be due to the presence of the sterically more demanding Si*t*BuMe_2 groups in **2**.

The ^{1}H NMR spectra of **1** and **2** show broad signals with significant isotropic shifts. The resonance signals have been assigned on the basis of their relative intensities and are summarized in Table 1. Both complexes show one set of resonance signals, indicating that each pair of amido ligands in each complex molecule are chemically equivalent. Complex **1** shows one signal due to the $SiMe_3$ groups, whereas two signals are observed for the $SiMe_2$ moiety of

Figure 2. complex **2**. It is noteworthy that the two Me substituents on the Si*t*BuMe$_2$ group of ligand L^2 are prochiral. The two prochiral Me substituents on the Si*t*BuMe$_2$ groups in complex **2** are nonequivalent due to the presence of the chiral nickel center. A similar case has been observed for the *cis*-dioxo-Mo^{VI} and -W^{VI} amido compounds, [MoO$_2$(L^2)$_2$] and [WO$_2$(L^2)$_2$].[18] Mass spectra of both complexes show the presence of the respective parent ion [M]$^+$. This suggests that both complexes are monomeric in the gas phase, as they are in the solid state. The respective magnetic moments of 3.05 and 2.74 μ_B for **1** and **2**, as measured by the Evans NMR method,[19] are close to the spin-only value of 2.83 μ_B for two unpaired electrons but slightly lower than the expected values for tetrahedral nickel(II) species.[20] One plausible reason for these values may be the presence of a tetrahedral-to-square-planar-type equilibrium for both complexes in solution.[21]

In conclusion, the two homoleptic mononuclear nickel(II) amide complexes [Ni(L^n)$_2$] [L^n = L^1 (**1**), L^2 (**2**)] have been successfully synthesized and structurally characterized. To the best of our knowledge, they are the first example of *homoleptic* mononuclear nickel(II) diamides containing *N*-functionalized amido ligands to be reported. We are currently investigating the reactivities of these two complexes towards carbon−nitrogen bond formation by their reactions with unsaturated electrophilic compounds such as PhNCO and PhCN.

Experimental Section

Synthesis of [Ni(L^1)$_2$] (1): To a stirred suspension of anhydrous NiCl$_2$ (0.09 g, 0.66 mmol) in THF (20 mL) at 0 °C was slowly added a solution of [{Li(OEt$_2$)(L^1)}$_2$] (0.39 g, 0.66 mmol) in THF (20 mL). The resulting solution was stirred at room temperature for 12 h, whereupon a reddish brown solution with a white precipitate was obtained. All volatiles were removed in vacuo and the residue was extracted with hexane. The extract was filtered and concentrated to ca. 10 mL. Upon cooling of the solution to −30 °C, complex **1** was obtained as reddish brown crystals. They were washed with cold pentane and dried under vacuum. Yield: 0.23 g (71%), m.p. 192−194 °C (dec.). − MS (70 eV, EI): *m*/*z* (%) = 489 (93) [M]$^+$, 474 (91) [M − CH$_3$]$^+$, 459 (23) [M − 2CH$_3$]$^+$. − ^{1}H NMR (300 MHz, C$_6$D$_6$): δ = −52.8 (br, 2 H, qui), −27.9 (br, 2 H, qui), −18.0 (br, 2 H, qui), 19.8 (br, 18 H, SiMe$_3$), 25.8 (br, 2 H, qui), 74.9 (br, 2 H, qui), 179.0 (br, 2 H, qui). − Magnetic moment μ_{eff} = 3.05 BM. − C$_{24}$H$_{30}$N$_4$NiSi$_2$ (489.40): calcd. C 58.90, H 6.18, N 11.44; found C 58.63, H 6.06, N 11.65.

Synthesis of [Ni(L^2)$_2$] (2): This complex was prepared in 66% yield by an analogous procedure as described for **1**, starting from NiCl$_2$ and LiL^2. M.p. 218−219 °C (dec.). − MS (70 eV, EI): *m*/*z* (%) =

573 (34) $[M]^+$, 558 (4) $[M - CH_3]^+$, 516 (100) $[M - t\text{Bu}]^+$. – ^{1}H NMR (300 MHz, C_6D_6): δ = −46.3 (br, 2 H, qui), −21.6 (br, 2 H, qui), −14.6 (br, 2 H, qui), 6.7 (br, 18 H, Si*t*Bu), 22.6 (br, 6 H, $SiMe_2$), 23.7 (br, 2H qui), 35.2 (br, 6 H, $SiMe_2$), 74.1 (br, 2 H, qui), 185.2 (br, 2 H, qui). – Magnetic moment μ_{eff} = 2.74 BM. – $C_{30}H_{42}N_4NiSi_2$ (573.56): calcd. C 62.82; H,7.38, N 9.76; found C 61.22, H 7.17, N 9.39.

X-ray Crystallography:[22] The crystallographic data for complexes **1** and **2** are shown in Table 2. All crystals were grown from toluene solutions. Single crystals suitable for X-ray diffraction studies were sealed in capillaries under dinitrogen. X-Ray data were collected on a Rigaku RAXIS-IIC diffractometer at 294 K using graphite-monochromatized Mo-K_α radiation (λ = 0.71073 Å) by taking oscillation photos. The structures were solved by direct-phase determination using the computer program SHELX-97 on a PC 486 computer and refined by full-matrix least-squares with anisotropic thermal parameters for the non-hydrogen atoms. Hydrogen atoms were introduced in their idealized positions and included in structure-factor calculations with assigned isotropic temperature factors.

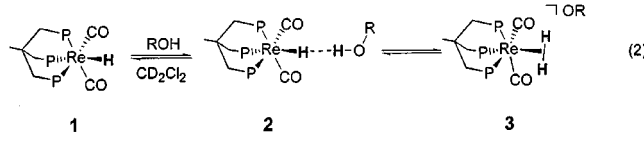
Keywords: Hydrides / Hydrogen bonding / Rhenium / IR spectroscopy / NMR spectroscopy

The enthalpy and entropy changes relative to the stepwise reaction of [(triphos)Re(CO)$_2$H] with perfluoro-*tert*-butyl alcohol in CH_2Cl_2 to give first the hydrogen-bonded adduct [(triphos)Re(CO)$_2$H···HOC(CF$_3$)$_3$] and then the stable non-classical dihydrogen complex [(triphos)Re(CO)$_2$(η^2-H$_2$)]$^+$ have been estimated by a combination of in situ IR and NMR experiments in the temperature range from 200 to 260 K [triphos = MeC(CH$_2$PPh$_2$)$_3$].

Introduction

The reactions of hydrido metal complexes with Brønsted acids yielding cationic nonclassical η^2-H$_2$ derivatives have been interpreted for a long time as proceeding straightforwardly by proton attack at terminal hydride ligands.[1] Experimental evidence for an alternative, stepwise, mechanistic picture has recently been provided, however. This involves the intermediacy of H-bonded species prior to H_2 ligand formation, as shown in Equation (1). In particular, the use of protic acids of different strength has allowed the interception and unambiguous characterisation of several H-bonded [MH]···HX species.[2,3]



$$\text{M-H} \rightleftharpoons \text{M-H}\cdots\text{HO-R} \rightleftharpoons \text{M-(H}_2\text{)} \qquad (1)$$

The enthalpy values associated with the formation of the H-bonded adducts have been determined for some systems in nonpolar or low-polarity solvents.[2a–2c,3b,3c] In contrast, the thermodynamic parameters relative to the M−H···H−OR → M−(η^2-H$_2$) step have only been reported for the reaction of the dihydride *trans*-[RuH$_2$(dppm)$_2$] (dppm = diphenylphosphanylmethane) with phenol in toluene.[3a] Unexpectedly large enthalpy (17 kcal mol^{-1}) and entropy (75.8 e.u.) values were obtained.[3a]

Results and Discussion

In this communication, we show that the energy associated with each stage of the proton transfer process in Equation (1), as well as the overall energy involved, can be calculated using a combined IR and NMR approach. To this purpose, the interaction of the Re^{III} hydride [(triphos)Re(CO)$_2$H] (**1**) [triphos = MeC(CH$_2$PPh$_2$)$_3$][4] with perfluoro-*tert*-butyl alcohol (PFTB) was studied in dichloromethane. We chose **1** for the simple reason that some data relative to the equilibrium shown in Equation (2) were already available.[3b,3c]

(2)

It may be useful to recall here that the η^2-H$_2$ complex [(triphos)Re(CO)$_2$(η^2-H$_2$)]$^+$ (**3**) is completely stable from 200 to 260 K in CH_2Cl_2.[3c,4] In this temperature range, the occurrence of a dynamic equilibrium involving the three species shown in Equation 2 was unambiguously demonstrated; moreover, the enthalpy values relative to the formation of several H-bonded adducts of the formula [(triphos)Re(CO)$_2$H···HOR] were calculated from IR spectroscopy using the Iogansen equation $-\Delta H = 18\Delta\nu/(720 + \Delta\nu)$.[2a,3b] For ROH = PFTB, a medium strength H-bonded adduct **2** was obtained with an enthalpy value of 6.0 kcal mol^{-1}.[3c]

The overall energy gain involved in the proton transfer reaction **1** → **3** has now been calculated from the temperature dependence of the protonation constant K_{1-3} for the equilibrium illustrated in Equation 2 [c(**1**) = 5 × 10^{-3} M, c(PFTB) = 5 × 10^{-2} M]. The values of K_{1-3} = [**3**]/[**2**+**1**] were determined from significant intensity changes of the ν_{sym}(CO) band at 2005 cm^{-1} of **3**. Figure 1 shows that this

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 2000 1434−1948/00/1010−2163 $ 17.50+.50/0

band is well separated from any other band in the region, while the ν(CO) bands of **2** (1930 and 1984 cm^{-1}) overlap with those of **1**, and the first band of **2** is partially masked by ν_{asym}(CO) of **3** at 1940 cm^{-1}. The values $-\Delta H°_{1-3}$ = 8.3 ± 0.4 kcal mol^{-1}, $-\Delta S°_{1-3}$ = 31.6 ± 1.8 e.u. were determined from a plot of $\ln K_{1-3}$ vs. $1/T$ (Table 1) in the temperature range from 200 to 260 K.

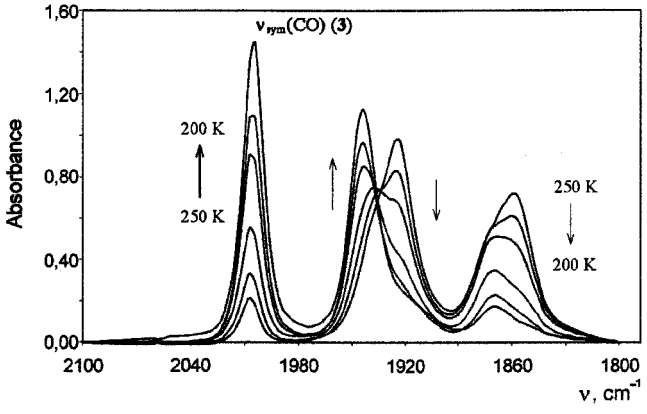

Figure 1. Variable-temperature IR spectra (ν_{CO} range) of complex **1** (0.005 M) in the presence of a 10-fold excess of PFTB in the temperature range between 250 and 200 K (interval 10 K)

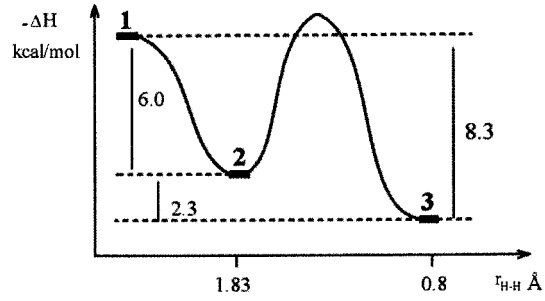
Table 1. Values of formation constants K_{1-3} and K_{2-3} obtained from IR and NMR spectroscopic data, respectively



T, K	K_{1-3}	*T*, K	K_{2-3}
200	176.6	200	5.2
210	43.4	230	2.8
220	24.8	240	1.7
230	9.5	260	1.4
240	4.5		
250	2.5		

A ^{1}H NMR analysis in CD_2Cl_2 for the system **1**/PFTB has allowed us to calculate the energy associated with the formation of **3** from **2**. The equilibrium constants K_{2-3} for this reaction were determined at several temperatures in the 200−260 K range from the integral intensities of the hydride signals of **3** (−4.8 ppm) and **2** (−6.28 ppm). For a large excess of alcohol (e.g. 10 equivalents of PFTB), there is no free **1** at 200 K and therefore the equilibrium constant K_{2-3} between **2** and **3** can easily be calculated. The molar fractions of the H-bonded species **2** at higher temperatures were calculated from the observed average chemical shifts using a standard procedure.[3c] From this study, the enthalpy ($-\Delta H°_{2-3}$ = 2.3 kcal mol^{-1}) and entropy ($-\Delta S°_{2-3}$ = 8.4 e.u.) associated with the transformation of **2** into **3** were thus estimated.

As reported above, the enthalpy relative to the formation of **2**, determined independently by IR spectroscopy,[3c] is 6.0 kcal mol^{-1}. Adding this value to the value of 2.3 kcal mol^{-1}, obtained for the **2** → **3** conversion by NMR spectroscopy, gives a total $-\Delta H°$ of 8.3 kcal mol^{-1} for the **1** + PFTB → **3** reaction, which is identical to the enthalpy calculated by IR methods for the same process.

In conclusion, we have shown here that the energy profile of a proton-transfer reaction involving an H-bonded intermediate can reliably be evaluated by a combination of independent IR and NMR experiments.

Scheme 1 illustrates the energy profile for the transformation of **1** into **3** *via* **2**. The potential energy curve shows two minima: the first is due to the formation of the H-bonded species with r = 1.83 Å[3c] while the lower energy one is due to the thermodynamically favoured η^2-H_2 complex **3**, for which an H−H distance of 0.81 Å was previously reported assuming fast rotation of the H_2 ligand.[4]

Scheme 1. Energy profile for the transformation of **1** into **3** via **2**.

The energetic level of the transition state for the **2** → **3** conversion is shown only qualitatively in Scheme 1, while that for the formation of **2** is not even shown as the formation of H-bonded adducts is a diffusion-controlled process.[5] Indeed, the transformation of **2** into **3** is too slow on the NMR timescale (10^1−10^{-6} s) and separated hydride signals for the two compounds were observed with no broadening of the resonances over the range of temperature investigated. Accordingly, the reaction has a lifetime longer than 10 s, which in turn provides an upper limit of 10^{-1} s^{-1} for the rate constant. The lower limit of the rate constant may be estimated roughly considering that our IR technique does not allow one to monitor the band intensity changes for processes faster than 10^{-2} s^{-1} (it takes one minute for mixing the reagents and loading the sample into the cryostat). Since no intensity change with time was observed, it could be assumed that the lifetime of the proton transfer is shorter than 1−2 min, which provides a lower limit of 10^{-2} s^{-1} for the rate constant.[6] It may be thus concluded that the transformation of **2** into **3** presumably proceeds with a rate constant between 10^{-2} and 10^{-1} s^{-1} with an activation barrier $\Delta G^{‡}$(200 K) from 12 to 13 kcal mol^{-1}. This estimate falls within the ranges reported in the literature (10^{-4}−10^{-1} dm^3 mol^{-1} s^{-1}; 1−40 kcal mol^{-1}).[7,8]

Experimental Section

All manipulations were carried out under a dry argon atmosphere using standard Schlenk techniques. Dichloromethane was distilled from CaH_2 prior to use. All IR and NMR measurements were carried out as previously described.[3c] Complex **1** was prepared as reported in the literature.[4]

P−H-Functionalized Phosphanyl Alcohols: $RHPCH_2CHMeOH$ and 2-PHR-1-OH-cyclo-C_6H_{10} (R = Ph, 2,4,6-$Me_3C_6H_2$, 2,4,6-iPr$_3C_6H_2$) and Molecular Structures of (C_R,C_R,P_R/C_S,C_S,P_S)-2-PH(2,4,6-iPr$_3C_6H_2$)-1-OH-cyclo-C_6H_{10} and its Dilithio Salt $[Li_2(THF)_{0.5}\{(C_R,C_R/C_S,C_S)$-2-P(2,4,6-$iPr_3C_6H_2$)-1-O-cyclo-$C_6H_{10}\}]_4$

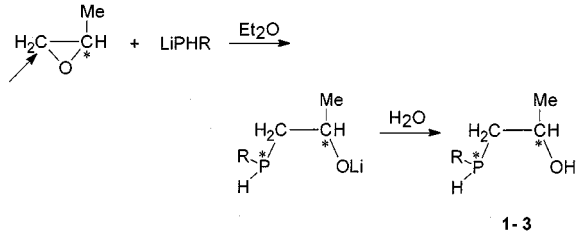
Keywords: P−H-Functionalized phosphanyl alcohols / Dilithium derivatives / Molecular structures

The P–H-functionalized phosphanyl alcohols $RHPCH_2CHMeOH$ [R = Ph (**1**), 2,4,6-$Me_3C_6H_2$ (Mes) (**2**), 2,4,6-iPr$_3C_6H_2$ (Tipp) (**3**)] and 2-PHR-1-OH-cyclo-C_6H_{10} [(R = Ph (**4**), Mes (**5**), Tipp (**6**)] have been prepared by ring-opening of propene oxide or cyclohexene oxide, respectively, with the appropriate LiPHR species, followed by hydrolytic workup and distillation (**1**–**4**) or recrystallization (**5**, **6**). **1**–**6**, which were obtained as diastereomeric mixtures, have been characterized spectroscopically (^{1}H, ^{13}C, ^{31}P NMR, IR, MS). Only in the case of **6** could separation of the diastereomers be achieved by fractional crystallization and the molecular structure of the racemic isomer (C_R,C_R,P_R/C_S,C_S,P_S) has been determined. In situ double deprotonation of **1**–**6** with BuLi gave the corresponding dianions **1a**–**6a**. The molecular structure of the dilithio salt $[Li_2(THF)_{0.5}\{(C_R,C_R/C_S,C_S)$-2-P(2,4,6-$iPr_3C_6H_2$)-1-O-cyclo-$C_6H_{10}\}]_4$ (**6a**) has been determined and shows that it is tetrameric in the solid state with a central Li_8 cluster.

Introduction

While tertiary phosphanyl alcohols are employed as ligands in catalytically active transition metal complexes,[1] the corresponding secondary P−H-functionalized phosphanyl alcohols have received only little attention. As early as 1965, Issleib et al. reported the ring-opening of oxiranes by alkali metal phosphanides, which, after hydrolytic workup, gave tertiary or secondary phosphanyl alcohols. The products were, however, only characterized by elemental analysis and IR spectroscopy.[2] In 1991, Heinicke et al. reported the formation of the primary phosphanyl alcohols $H_2PCH_2CHR'OH$ (R′ = H, Me, Ph) by ring-opening of ethene, propene, or styrene oxides with sodium phosphanide, $NaPH_2$.[3] In 1997, Thiel et al. used the stereoselective ring-opening of cyclohexene oxide by lithium diphenylphosphanide to prepare chiral phosphanyl alcohols.[4]



Primary[3,5] and secondary[6,7] phosphanyl alcohols have hitherto been used for the preparation of organic P heterocycles. Their ligation properties are, however, largely unstudied.

We now report the synthesis and spectroscopic characterization of the P−H-functionalized phosphanyl alcohols $RHPCH_2CHMeOH$ [R = Ph (**1**), 2,4,6-$Me_3C_6H_2$ (Mes) (**2**), 2,4,6-iPr$_3C_6H_2$ (Tipp) (**3**)] and 2-PHR-1-OH-cyclo-C_6H_{10} [(R = Ph (**4**), Mes (**5**), Tipp (**6**)], as well as the molecular structures of the diastereoisomerically pure phosphanyl alcohol (C_S,C_S,P_S/C_R,C_R,P_R)-2-PH(2,4,6-iPr$_3C_6H_2$)-1-OH-cyclo-C_6H_{10} (**6**) and its dilithio salt $[Li_2(THF)_{0.5}(C_S,C_S/C_R,C_R)$-2-P(2,4,6-$iPr_3C_6H_2$)-1-O-cyclo-$C_6H_{10}]_4$ (**6a**). Syntheses of **1**[2,7] and **4**[2] have been reported previously, but both compounds were only characterized by elemental analysis and IR spectroscopy.[2] Although a ^{1}H NMR spectrum has been reported for **1**, no diastereomers were observed.[7]

Results and Discussion

Synthesis of $RHPCH_2CHMeOH$ [R = Ph (1), 2,4,6-$Me_3C_6H_2$ (Mes) (2), 2,4,6-iPr$_3C_6H_2$ (Tipp) (3)] and 2-PHR-1-OH-cyclo-C_6H_{10} [(R = Ph (4), Mes (5), Tipp (6)] and their Dilithio Salts

The P−H-functionalized phosphanyl alcohols $RHPCH_2CHMeOH$ [R = Ph (**1**),[2,7] Mes (**2**), Tipp (**3**)] were obtained by ring-opening of propene oxide with LiPHR, followed by hydrolytic workup and distillation [Equation (1)].

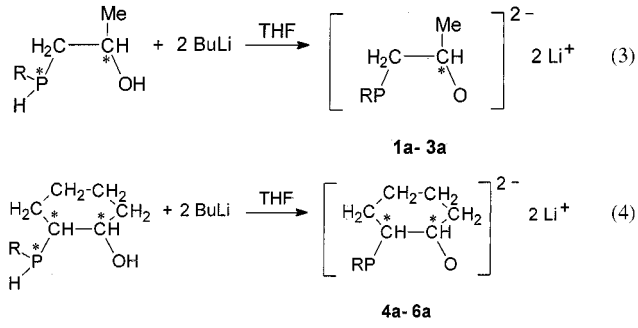
As in base-catalyzed ring-opening reactions, one C−O bond of the oxirane ring is selectively cleaved by the nucleophilic phosphanide anion, which attacks the sterically less hindered C atom.

As **1**−**3** have two chiral centres, two pairs of diastereomers are formed [*meso* (C_S,P_R/C_R,P_S) and *rac* (C_S,P_S/C_R,P_R)], which are obtained in a 1:1 ratio. Subsequent distillation furnished **1**−**3** as colourless, viscous oils. **3** was found to solidify at room temperature (m.p. 35 °C). The diastereomers could not be separated either by distillation or by fractional crystallization.

In their proton-coupled ^{31}P NMR spectra, **1**−**3** give rise to two doublets due to the two diastereomers. The spectrum of the Ph derivative **1** features a signal at low field compared to those of **2** and **3** [**1**: δ = −63.4 ($^1J_{P-H}$ = 210.6 Hz), −64.1 ($^1J_{P-H}$ = 210.6 Hz); **2**: δ = −97.7 (d, $^1J_{P-H}$ = 217.0 Hz), −98.9 (d, $^1J_{P-H}$ = 218.7 Hz); **3**: δ = −105.2 ($^1J_{P-H}$ = 215.5 Hz), −105.9 ($^1J_{P-H}$ = 217.1 Hz)].



Analogously to **1**−**3**, the phosphanyl alcohols 2-PHR-1-OH-cyclo-C_6H_{10} [(R = Ph (**4**),[2] Mes (**5**), Tipp (**6**)], which contain three chiral centres (C, C, P), could be prepared by selective ring opening of cyclohexene oxide with LiPHR, followed by hydrolytic workup [Equation (2)]. **4** was obtained as a colourless oil, whereas **5** and **6** were recovered as colourless solids. The diastereoselective ring-opening of the oxirane by the nucleophilic phosphanide anion yielded only two pairs of diastereomers (ratio 2:3 for **4** and **6**, 1:1 for **5**), which could not be separated by distillation. However, in the case of **6**, it was found that the diastereomers could be separated by fractional crystallization.

4-6 (2)

Compounds **4**−**6** give rise to two doublets in their proton-coupled ^{31}P NMR spectra due to the two pairs of diastereomers with C_S,C_S,P_R/C_R,C_R,P_S and C_S,C_S,P_S/C_R,C_R,P_R configurations. The signals of **5** (δ = −105.3 and −106.0) are shifted to high field relative to those of **4** (δ = −40.9 and −45.5) and **6** (δ = −77.6 and −89.9).

The bifunctionalized phosphanyl alcohols **1**−**6** could be doubly deprotonated with BuLi in THF to give the dianions Li_2[RPCH$_2$CHMeO] [R = Ph (**1a**), Mes (**2a**), Tipp (**3a**)] [Equation (3)] and Li_2[2-RP-1-O-cyclo-C_6H_{10}] [R = Ph (**4a**), Mes (**5a**), Tipp (**6a**)] [Equation (4)], which were characterized by ^{31}P NMR spectroscopy. The spectra of the dianions **2a**, **4a**, **5a**, and **6a** in THF feature two broad signals, indicating dynamic processes involving ligand exchange in solution. In the case of **6a**, this was further verified by a crystal structure determination.

Molecular Structures of (C_R,C_R,P_R/C_S,C_S,P_S)- 2-PH(2,4,6-*i*Pr$_3$C$_6$H$_2$)-1-OH-cyclo-C_6H_{10} (6) and Its Dilithio Salt [Li_2(THF)$_{0.5}${(C_R,C_R/C_S,C_S)-2-P(2,4,6-*i*Pr$_3$C$_6$H$_2$)-1-O-cyclo-C_6H_{10}}]$_4$ (6a)

Colourless crystals of **6** were obtained by repeated recrystallization from pentane. **6** crystallizes in the centrosymmetric monoclinic space group $P2_1/c$. Only the diastereomer with C_R,C_R,P_R/C_S,C_S,P_S configuration (OH and PHR in equatorial positions) was found to be present in the unit cell (Figure 1). A section of the three-dimensional structure shows that molecules of one enantiomer are stacked along the *b*-axis. Two such stacks are related by a 2_1 axis, and the molecules of these two stacks of the two enantiomers are connected through hydrogen (OH) bonds (Figure 2) resulting in a helical arrangement. The inversion centre generates the other enantiomer.

The excellent ligation properties of the 2-P(2,4,6-*i*Pr$_3$C$_6$H$_2$)-1-O-cyclo-C_6H_{10} dianion are exemplified by the solid-state structure of **6a**. This salt could be obtained from pentane in the form of small, pale-yellow, very air-sensitive crystals of rather poor quality (monoclinic centrosymmetric space group $P2_1/c$). In the solid state, the compound forms tetrameric molecules composed of eight lithium atoms and four phosphanidoalkoxides. Two independent molecules are present in the asymmetric unit. In both of these, the eight lithium atoms form a polyhedron in which two trigonal

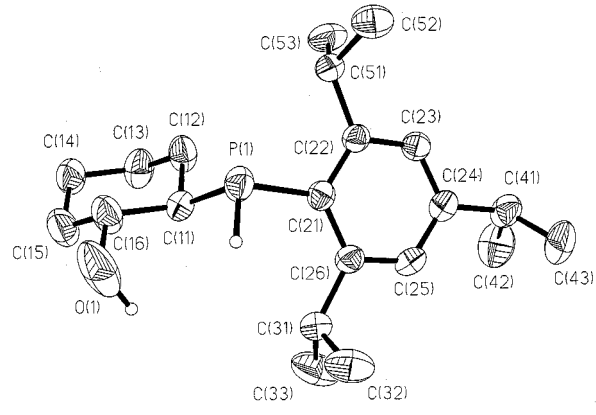

Figure 1. Molecular structure of **6**; only one enantiomer (C_R,C_R,P_R configuration) is shown; selected bond lengths [Å] and angles [°]: P(1)−C(21) 1.845(2), P(1)−C(11) 1.869(2), O(1)−C(16) 1.429(3), O(1)−HO(1) 1.19(4), P(1)−H(1) 1.27(2); C(21)−P(1)−C(11) 102.70(9), C(12)−C(11)−P(1) 110.9(2), C(16)−C(11)−P(1) 110.0(2), C(22)−C(21)−P(1) 118.3(1), C(26)−C(21)−P(1) 122.8(1), O(1)−C(16)−C(15) 111.0(2), O(1)−C(16)−C(11) 111.5(2)

prisms share one square face and are twisted by 90° (Figure 3). The Li−Li distances range from 2.47(2) to 2.83(2) Å. This polyhedron has four triangular faces and four square faces. The four phosphorus atoms of the phosphanidoalkoxide cover the triangular faces, while the four oxygen atoms of the ligand are located above the square faces in such a way that the oxygen and phosphorus atoms belonging to one phosphanidoalkoxide ligand are located on adjacent faces of the Li_8 polyhedron [P(1) and O(1), P(2) and O(2), P(3) and O(3), and P(4) and O(4) are located next to each other (Figure 4 and Figure 5); Li−O 1.962(16)−2.096(14) Å, Li−P 2.490(15)−2.699(16) Å for both molecules]. Thus, the four oxygen atoms and the four phosphorus atoms form distorted tetrahedra. In addition, four THF molecules are coordinated to four of the eight Li

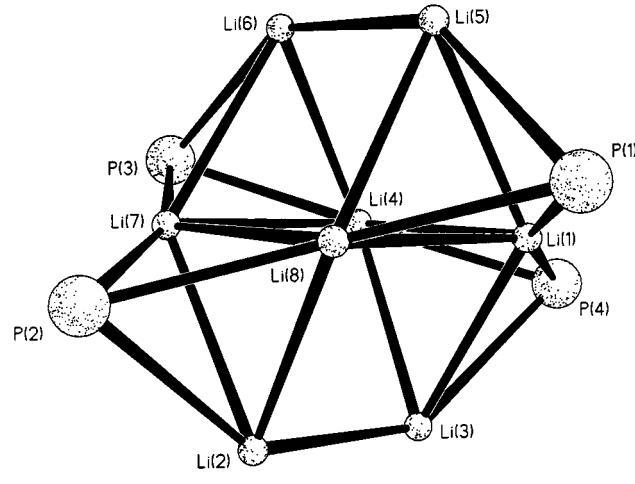

Figure 5. Central Li_8P_4 cluster in **6a** (only one of the two independent molecules is shown); P(1)−Li(8) 2.514(13), P(1)−Li(1) 2.563(15), P(1)−Li(5) 2.685(15), P(2)−Li(7) 2.523(15), P(2)−Li(8) 2.558(13), P(2)−Li(2) 2.699(16), P(3)−Li(4) 2.524(14), P(3)−Li(7) 2.589(15), P(3)−Li(6) 2.686(15), P(4)−Li(1) 2.490(15), P(4)−Li(4) 2.549(14), P(4)−Li(3) 2.680(14)

atoms, Li(2), Li(3), Li(5), and Li(6). A view of the whole molecule is given in Figure 6. The molecule has C_2 symmetry [the noncrystallographic C_2 axis bisects Li(2)−Li(3) and Li(5)−Li(6)], and the four phosphanidoalkoxide ligands have alternatingly *R*/*R*, *S*/*S*, *R*/*R*, and *S*/*S* configuration at the chiral C atoms. Thus, the formation of this cluster can be regarded as a self-assembly of chiral molecules.

Although Li_8 clusters are known,[9] the topology of the Li_8 core in **6a** is very unusual. While lithium clusters have been observed in electron-deficient alkyl or aryllithium compounds,[10] polyhedral arrangements of lithium phosphanides have been observed only recently. In 1995, Drieß et al. reported the formation of clusters of the di- and trimetallated compounds $R^1R^2Si(PR^3Li)_2$ (R^1 = *t*Bu, R^2 = Tipp,

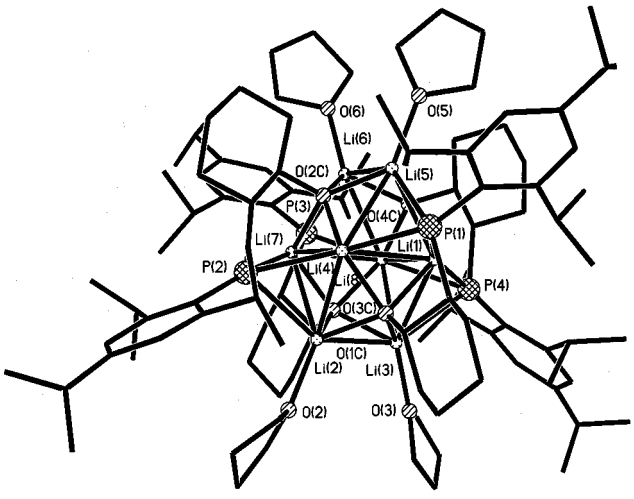

Figure 6. Molecular structure of $[Li_2(THF)_{0.5}\{(C_R,C_R/C_S,C_S)$-2-P(2,4,6-*i*Pr$_3C_6H_2$)-1-O-cyclo-C$_6H_{10}\}]_4$ (**6a**) (only one of the two independent molecules is shown)

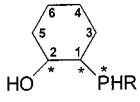
R^3 = $SiPh_3$) and $EtSi(PR^3Li)_3$ (R^3 = Si*i*Pr$_3$).[11] In the former, two dimeric molecules $[R^1R^2Si(PR^3Li)_2]_2$ are connected through an Li_2Cl_2 square. In the latter, a dimer of $EtSi(PR^3Li)_3$ is observed, in which the $Li_6P_6Si_2$ fragment forms a distorted rhombododecahedron. The Li−P distances range from 2.55(3) to 2.67(3) Å in the dimetallated compound and from 2.449(5) to 2.562(5) Å in the trimetallated compound and are thus comparable with those in **6a**.

We have already shown that the phosphanylalkoxides reported here can be employed as ligands in mono- and dinuclear complexes.[12] Further studies of the ligation properties of **1**−**6** and their dianions **1a**−**6a** in transition metal complexes are currently in progress.

Experimental Section

General Remarks: All experiments were carried out under purified dry argon. Solvents were dried and freshly distilled under argon. The NMR spectra were recorded with a Bruker AVANCE DRX 400 spectrometer. ^{1}H NMR: internal standard solvent, external standard TMS; ^{13}C NMR (100.6 MHz): internal standard solvent, external standard TMS; ^{31}P NMR (162 MHz): external standard 85% H_3PO_4; ^{7}Li NMR (155.5 MHz): external standard 1 M LiCl in D_2O. The ^{13}C NMR spectra were assigned with the aid of 2D $^{13}C\{^1H\}$ NMR spectra and $^{13}C\{^{31}P,^1H\}$ NMR spectra. − IR spectra were recorded on a Perkin−Elmer System 2000 FT-IR spectrometer in the range 350−4000 cm^{-1}. − Melting points were determined in sealed capillaries under argon and are uncorrected. − Propene oxide and cyclohexene oxide are commercially available. RPH_2 (R = Ph,[13] Mes,[14] Tipp[14]) were prepared according to literature procedures.

General Procedure for the Synthesis of the Phosphanyl Alcohols 1−6: The primary phosphane RPH_2 was dissolved in Et_2O (200 mL) and an equimolar amount of a BuLi solution in hexane was added at −50 °C. The mixture was allowed to warm to room temp. and stirred for a further 2 h. The pale-yellow solution was then cooled to −50 °C once more, whereupon an equimolar amount of propene oxide or cyclohexene oxide was slowly added. The resulting mixture was allowed to warm to room temp. once more, stirred for 2 h, and then hydrolyzed with 50 mL of a 4 M NH_4Cl solution. After stirring for 12 h, the ethereal phase was separated, the aqueous phase was washed with Et_2O (3 × 20 mL), and the combined ethereal phases were dried over Na_2SO_4. The solution was filtered and the solvent was removed in vacuo. The resulting oil was distilled under reduced pressure.



1-(Phenylphosphanyl)-2-propanol (1): Prepared from $PhPH_2$ (12.7 g, 115 mmol), 1.5 M BuLi solution in hexane (80 mL, 120 mmol), and propene oxide (6.8 mL, 140 mmol). Yield: 9.8 g (51%); colourless oil (b.p. 91 °C, 1 × 10^{-1} Torr). − ^{1}H NMR (C_6D_6): δ = 7.40 (m, 4 H, 2 isomers, Ph), 7.07 (m, 6 H, 2 isomers, Ph), 4.24 (d of t, $^1J_{P-H}$ = 210.5 Hz, $^3J_{H-H}$ = 1.7 Hz, 1 H, 1 isomer, PH), 4.18 (d of t, $^1J_{P-H}$ = 210.5 Hz, $^3J_{H-H}$ = 1.7 Hz, 1 H, 1 isomer, PH), 3.75 (sext., $^3J_{H-H}$ = 6.5 Hz, 1 H, 1 isomer, C*H*Me), 3.69 (sext., $^3J_{H-H}$ = 6.4 Hz, 1 H, 1 isomer, C*H*Me), 2.22 (br. s, 2 H, 2 isomers, OH), 2.1−1.73 (m, 4 H, 2 isomers, P−CH_2), 1.25−1.12 (m, 6 H, 2 isomers, CH_3). − $^{13}C\{^1H\}$ NMR (C_6D_6): δ = 136.7 (d, $^3J_{P-C}$ = 10.5 Hz, 4 C, 2 isomers, *m*-CH of Ph), 134.6 (d, $^2J_{P-C}$ = 15.9 Hz, 4 C, 2 isomers, *o*-CH of Ph), 130.9 (2 C, 2 isomers, *p*-CH of Ph), 67.4 (d, $^2J_{P-C}$ = 9.5 Hz, 1 C, 1 isomer, O−CH), 66.9 (d, $^2J_{P-C}$ = 10.1 Hz, 1 C, 1 isomer, O−CH), 35.0 (d, $^1J_{P-C}$ = 25.5 Hz, 1 C, 1 isomer, P−CH_2), 34.8 (d, $^1J_{P-C}$ = 27.5 Hz, 1 C, 1 isomer, P−CH_2), 25.3 (d, $^3J_{P-C}$ = 9.8 Hz, 1 C, 1 isomer, CH_3), 25.2 (d, $^3J_{P-C}$ = 10.6 Hz, 1 C, 1 isomer, CH_3); *ipso*-C of Ph not observed. − ^{31}P NMR (C_6D_6): δ = −63.4 (d, $^1J_{P-H}$ = 210.6 Hz), −64.1 (d, $^1J_{P-H}$ = 210.6 Hz). − $C_9H_{13}OP$ (168.17): calcd. C 64.3, H 7.8, P 18.4; found C 64.0, H 8.1, P 18.0.

1-Mesitylphosphanyl-2-propanol (2): Prepared from $MesPH_2$ (8.0 g, 53.0 mmol), 1.5 M BuLi solution in hexane (35 mL, 53.0 mmol), and propene oxide (3.7 mL, 53.0 mmol). Yield: 6.2 g (56%); colourless oil (b.p. 100−115 °C, 8 × 10^{-3} Torr). − ^{1}H NMR (C_6D_6): δ = 6.75 (s, 4 H, 2 isomers, *m*-CH of Mes), 4.39 (d of t, $^1J_{P-H}$ = 218.5 Hz, $^3J_{H-H}$ = 7.3 Hz, 1 H, 1 isomer, PH), 4.33 (d of t, $^1J_{P-H}$ = 218.0 Hz, $^3J_{H-H}$ = 7.5 Hz, 1 H, 1 isomer, PH), 3.76 (sext., $^3J_{H-H}$ = 6.2 Hz, 1 H, 1 isomer, C*H*Me), 3.69 (sext., $^3J_{H-H}$ = 6.3 Hz, 1 H, 1 isomer, C*H*Me), 2.51 (br. s, 2 H, 2 isomers, OH), 2.43 (s, 12 H, 2 isomers, *o*-CH_3), 2.10 (s, 6 H, 2 isomers, *p*-CH_3), 2.05−1.85 (m, 2 H, 1 isomer, P−CH_2), 1.65−1.50 (m, 2 H, 1 isomer, P−CH_2), 1.11 (d, $^3J_{H-H}$ = 6.2 Hz, 3 H, 1 isomer, CH_3), 1.09 (d, $^3J_{H-H}$ = 6.1 Hz, 3 H, 1 isomer, CH_3). − $^{13}C\{^1H\}$ NMR (C_6D_6): δ = 142.7 (d, $^2J_{P-C}$ = 12.0 Hz, 2 C, 1 isomer, *o*-C of Mes), 142.7 (d, $^2J_{P-C}$ = 12.0 Hz, 2 C, 1 isomer, *o*-C of Mes), 138.6 (d, $^4J_{P-C}$ = 11.0 Hz, 2 C, 2 isomers, *p*-C of Mes), 131.0 (d, $^1J_{P-C}$ = 14.2 Hz, 1 C, 1 isomer, *ipso*-C of Mes), 131.0 (d, $^1J_{P-C}$ = 14.2 Hz, 1 C, 1 isomer, *ipso*-C of Mes), 130.0 (4 C, 2 isomers, *m*-C of Mes), 68.2 (d, $^2J_{P-C}$ = 9.6 Hz, 1 C, 1 isomer, O−CH), 67.6 (d, $^2J_{P-C}$ = 10.7 Hz, 1 C, 1 isomer, O−CH), 32.9 (d, $^1J_{P-C}$ = 14.4 Hz, 1 C, 1 isomer, P−CH_2), 32.9 (d, $^1J_{P-C}$ = 14.9 Hz, 1 C, 1 isomer, P−CH_2), 25.3 (1 C, 1 isomer, CH_3), 25.2 (1 C, 1 isomer, CH_3), 23.9 (2 C, 1 isomer, *o*-CH_3 of Mes), 23.8 (2 C, 1 isomer, *o*-CH_3 of Mes), 21.7 (2 C, 2 isomers, *p*-CH_3 of Mes). − ^{31}P NMR (C_6D_6): δ = −97.7 (d, $^1J_{P-H}$ = 217.0 Hz), −98.9 (d, $^1J_{P-H}$ = 218.7 Hz). − EI MS: *m*/*z* (%) = 210 (78) [M^+], 150 (100) [$PHMes^+$], 119 (88) [Mes^+], and fragmentation products thereof. − IR (KBr): $\tilde{\nu}$ = 3356 cm^{-1} [br, s, ν(OH)], 2335 [s, ν(PH)]. − $C_{12}H_{19}OP$ (210.25): calcd. Dianions 1a−6a: 1−6 were treated with two equivalents of BuLi in THF at −50 °C. Subsequent warming to room temp. gave the dilithio salts Li_2[$RPCH_2CHMeO$] [R = Ph (**1a**), Mes (**2a**), Tipp (**3a**)] [Equation (3)] and Li_2[2-RP-1-O-cyclo-C_6H_{10}] [R = Ph (**4a**), Mes (**5a**), Tipp (**6a**)] [Equation (4)], of which only **6a** was isolated. The deprotonation could be monitored by ^{31}P NMR and ^7Li NMR spectroscopy (solvent THF/C_6D_6). − **1a**: ^{31}P NMR: δ = −76.9 (br. s). − ^7Li NMR: δ = 1.5 (s), 1.3 (s), 1.2 (s), 0.9 (s). − **2a**: ^{31}P NMR: δ = −82.0 (br. s), −87.2 (br. s). − ^7Li NMR: δ = 1.4 (s), 1.3 (s), 1.0 (s). − **3a**: ^{31}P NMR: δ = −42.9 (br. s). − ^7Li NMR: δ = 4.6 (br. s), 3.9 (br. s). − **4a**: ^{31}P NMR: δ = −18.3 (br. s), −45.9 (br. s). − ^7Li NMR: δ = 5.6 (br. s), 5.0 (br. s), 4.5 (br. s). − **5a**: ^{31}P NMR: δ = −81.5 (br. s), −96.0 (br. s). − ^7Li NMR: δ = 4.3 (br. s), 3.9 (br. s). − **6a**: ^{31}P NMR: δ = −81.4 (br. s), −95.6 (br. s). − ^7Li NMR: δ = 4.3 (br. s), 3.9 (br. s), 3.7 (br. s). Crystals of **6a** were obtained from pentane.

Data Collection and Structure Refinement of 6 and 6a:

6: Experimental data (a total of 13072 reflections) were collected at *T* = 220(2) K on a Siemens CCD (SMART) diffractometer in the range 1.5 < Θ < 26.2° using monochromated Mo-K_α radiation (λ = 0.71073 Å). Of these, a total of 3740 reflections were considered as unique (R_{int} = 0.0637). All observed reflections were used in the determination of the unit cell parameters. The studied specimen was a white single crystal of dimensions 0.4 × 0.2 × 0.1 mm. Crystal data for **6** are as follows: $C_{21}H_{35}OP$, M_r = 334.46, space group $P2_1/c$ (no. 14), *a* = 13.755(1), *b* = 5.955(1), *c* = 25.444(1) Å, β = 91.529(1)°, *V* = 2083.3(2) $Å^3$ at *T* = 220(2) K, *Z* = 4, $D_{calcd.}$ = 1.066 Mg m^{-3}, μ(Mo-K_α) = 0.136 mm^{-1}; absorption correction with SADABS.[15]

The positions of the P, O, and C atoms were located using direct methods (SHELXTL-PLUS).[16] Subsequent least-squares refinement and difference electron density map calculations revealed the positions of the H atoms. Final full-matrix least-squares refinement of 348 parameters with a unit weighting scheme (P, O, and C atoms anisotropic approximation; H atoms isotropic approximation) converged to *R*1 = 0.0497, *wR*2 = 0.1282 [for reflections with $I > 2\sigma(I)$], *R*1 = 0.0606, *wR*2 = 0.1363 (all data).

6a: Experimental data (a total of 160515 reflections) were collected at *T* = 210(2) K on a Siemens CCD (SMART) diffractometer in the range 1.0 < Θ < 25.6° using monochromated Mo-K_α (λ = 0.71073 Å) radiation. Of these, a total of 40798 reflections were considered unique (R_{int} = 0.1687). All observed reflections were used in the determination of the unit cell parameters. The studied specimen was a white single crystal of dimensions 0.4 × 0.3 × 0.1 mm. Crystal data for **6a** are as follows: $C_{100}H_{164}Li_8O_8P_4$, M_r = 1673.71, space group $P2_1/c$ (no. 14), monoclinic, *a* = 27.929(1), *b* = 36.492(1), *c* = 24.992(1) Å, β = 110.668(1)°, *V* = 23833(2) $Å^3$ at *T* = 210(2) K, *Z* = 8, $D_{calcd.}$ = 0.933 Mg m^{-3}, μ(Mo-K_α) = 0.106 mm^{-1}; absorption correction with SADABS.[15]

The positions of the Li, P, O, and C atoms were located using direct methods (SHELXTL-PLUS);[16] H atoms were placed in calculated positions. Final full-matrix least-squares refinement of 2161 parameters with a unit weighting scheme (Li, P, O, and C atoms anisotropic approximation; H atoms isotropic approximation) converged to *R*1 = 0.1559, *wR*2 = 0.3746 [for reflections with $I > 2\sigma(I)$], *R*1 = 0.3221, *wR*2 = 0.4570 (all data).

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre (**6:** CCDC-141876, **6a:** CCDC-141875). Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, U.K. [Fax: (internat.) +44 (0)1223 336033; E-mail: deposit@ccdc.cam.ac.uk].

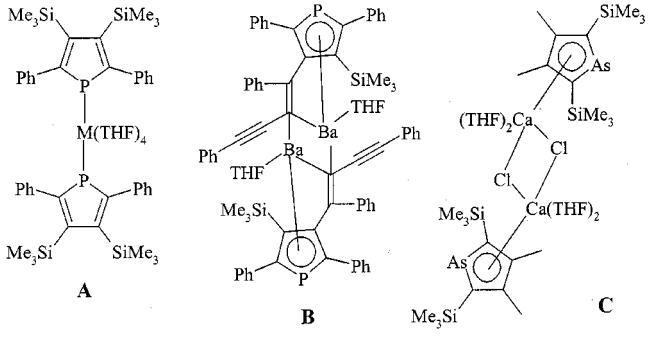
Synthesis of 2,2′,5,5′-Tetraphenyl-1,1′-diarsacalcocene and -strontocene

Matthias Westerhausen,*[a] Christin Birg,[a] and Holger Piotrowski[a]



Keywords: Arsenic / As ligands / Calcium / Strontium / Heterocycles / Reaction mechanisms

The metalation of $H_2As–Si\mathit{i}Pr_3$ with bis(tetrahydrofuran-*O*)calcium- and -strontium bis[bis(trimethylsilyl)amide] yields tetrakis(tetrahydrofuran-*O*)calcium- (**1a**) and -strontium bis(triisopropylsilylarsanide) (**2a**). These compounds are in equilibrium with their dimers **1b** (Ca) and **2b** (Sr) by elimination of THF. The addition of diphenylbutadiyne to a THF/toluene solution of **1** and **2** gives bis(tetrahydrofuran-*O*)calcium- (**3**) and -strontium bis(2,5-diphenylarsolide) (**4**). The proposed reaction mechanism explains the formation of the $(\mathit{i}Pr_3Si)_2As^-$ and 2,5-diphenyl-3,4-bis(phenylethynyl)arsolide anions based on an intermolecular $H/Si\mathit{i}Pr_3$ exchange reaction. The latter anion was characterized by X-ray crystallography with the binuclear cation $[(THF)_3Ca\{\mu\text{-}As(H)Si\mathit{i}Pr_3\}_3Ca(THF)_3]^+$ (**5**). The arsolide ligands of **3** and **4** are η^5-bonded to the metal centers, whereas **5** crystallizes as a solvent-separated ion pair.

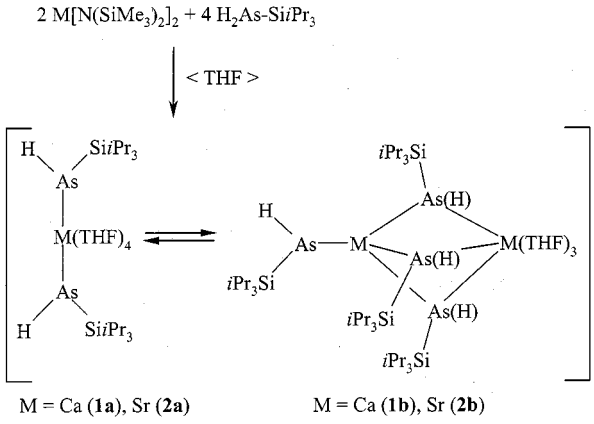
Introduction

The reaction of calcium and strontium bis[bis(trimethylsilyl)phosphanide] with diphenylbutadiyne yields the corresponding alkaline earth metal bis[2,5-diphenyl-3,4-bis(trimethylsilyl)-1-phosphacyclopentadienides] **A** (Scheme 1).[1] The reaction mechanism includes addition as well as 1,3-trimethylsilyl migration steps. The molecular structures of the calcium and strontium derivatives show metal−phosphorus σ-bonds. In contrast to this reaction, the homologous barium bis(phosphanide) $(THF)_4Ba[P(SiMe_3)_2]_2$ reacts differently with diphenylbutadiyne.[2] The main feature besides the central Ba_2C_2 cycle of the formed molecule **B** (Scheme 1) is a η^5-bonded phospholide moiety.

The reduction of 1-chloro-3,4-dimethyl-2,5-bis(trimethylsilyl)arsole yields the corresponding η^5-bonded arsolide **C**.[3] However, only heteroleptic compounds were prepared and no dismutation reactions of 1,1′-dipentelametallocenes have been observed thus far.

Scheme 1. Schematic representation of the phospholides **A** and **B**, and the arsolide **C**

In contrast to these recent examples of pentela-substituted alkaline earth metallocenes, the compounds calcocene[4] and decamethylcalcocene,[5] as well as their strontium analogues,[6,7] are well-known. This topic has been reviewed lately by Hanusa.[8]



We are interested in these 1,1′-dipentelametallocenes in order to investigate the coordination behavior of the anions, as well as the use of these compounds as transfer reagents for phospholide and arsolide ligands. In transition metal phospholides the anions are known to vary between η^1- and η^5- coordination depending on the transition metal fragment, and to obey the 18-electron rule.[9] Recently, a potassium phospholide with a chain structure and η^5-bonded bridging anions was published.[10] The most widely used phospholide transfer reagents are the lithium derivatives prepared by the reduction of 1-phenylphospholes with lithium metal.[9] Here we propose a reaction mechanism for the reaction of calcium- and strontium bis(triisopropylsilylarsanide) with diphenylbutadiyne. The drastically reduced tendency of the $Si\mathit{i}Pr_3$ substituent to show a 1,3-shift leads to a different mechanism than that suggested for the formation of **A** and **B**. This route offers the possibility of preparing trialkylsilyl-free 1,1′-diarsacalcocenes and -strontocenes.

Results and Discussion

The metalation of triisopropylsilylarsane[11] with calcium- and strontium bis[bis(trimethylsilyl)amide][12] yields the corresponding alkaline earth metal bis(arsanides) **1a** and **2a** according to Scheme 2. These monomeric derivatives are expected to be in equilibrium with their dimers **1b** and **2b**, as shown in Scheme 2. This fact leads to broadened resonances (**1a** and **1b**) or a doubling of the signals (**2a** and **2b**). Similar monomer−dimer equilibria are well-known in the chemistry of alkaline earth metal bis(phosphanides)[13] − strontium-[14] and barium bis(triisopropylsilylphosphanide)[15] show this equilibrium even in donor solvents such as THF.

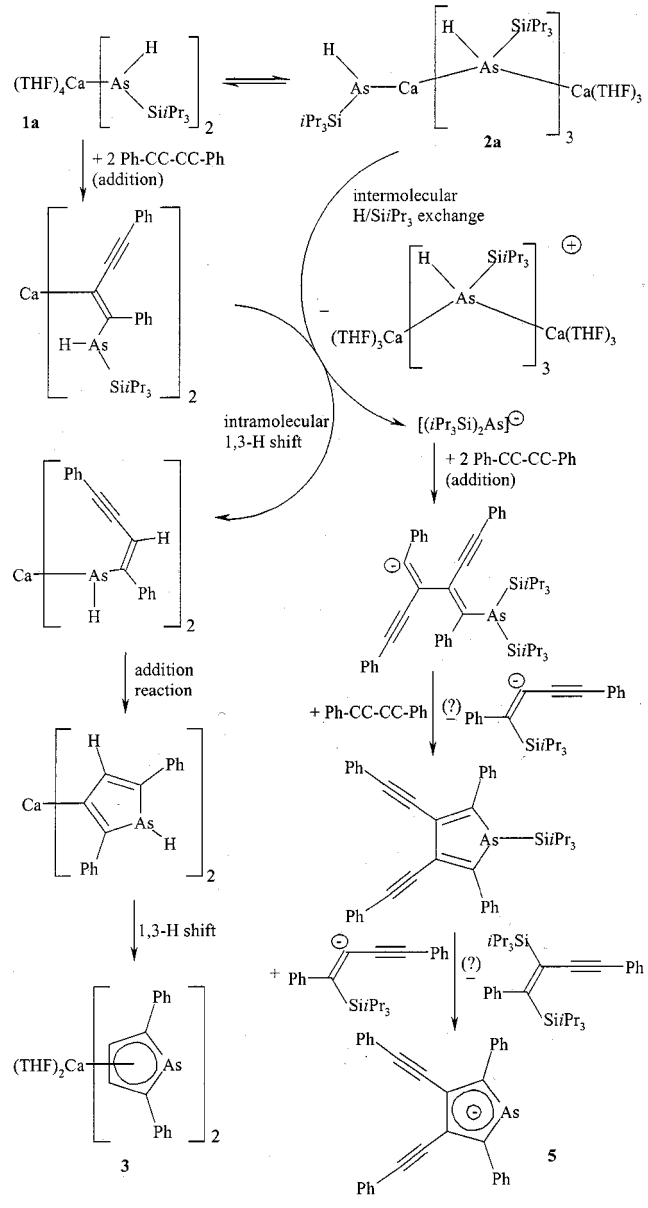

Scheme 2. Synthesis of tetrakis(tetrahydrofuran-*O*)calcium- and -strontium bis(triisopropylsilylarsanide) as well as their monomer-dimer equilibria

Dismutation reactions of alkaline earth metal bis(triisopropylsilylphosphanides) as well as -arsanides) have not been observed thus far. Even after prolonged heating of these compounds in THF or toluene neither bis(triisopropylsilyl)phosphanide and -arsanide anions, nor H_2P^- and H_2As^- ligands were detected.

The reaction of the above described triisopropylsilylarsanides of calcium (**1**) and strontium (**2**) with diphenylbutadiyne in a solvent mixture of toluene and THF gives the poorly soluble bis(tetrahydrofuran-*O*)calcium- (**3**) and -strontium bis(2,5-diphenylarsolide) (**4**). After precipitation of **3** the remaining solution was reduced to a few milliliters. Cooling to 5 °C gave crystalline **5** which was characterized by X-ray crystallography. Methanolysis of the reaction solution and mass spectrometric investigations allowed the identification of $HAs(SiiPr_3)_2$ and $C_{25}H_{31}Si$, a triisopropyl-substituted 1,4-diphenylbutenyne. The proposed mechanism based on these findings is represented in Scheme 3.

The first reaction step is the addition of **1a** and **2a** to a C≡C triple bond, followed by a 1,3-H migration. An intramolecular shift of a triisopropylsilyl substituent seems to be impossible in contrast to the mobility of the trimethylsilyl group.[16] However, an intermolecular H/Si*i*Pr$_3$ exchange reaction allows a second similar reaction sequence, namely the addition of the alkaline earth metal−arsenic bond to the remaining C≡C bond with a subsequent intramolecular 1,3-H migration. Thus, the 2,5-diphenylarsolide anion is formed (left column of Scheme 3).

This intermolecular H/Si*i*Pr$_3$ exchange yields a bis(triisopropylsilyl)arsanide ligand. The addition of this anion to a diphenylbutadiyne gives a carbanion which attacks another molecule of Ph−C≡C−C≡C−Ph. The elimination of a triisopropylsilanide leaves a 1-triisopropylsilyl-2,5-diphenyl-3,4-bis(phenylethynyl)-1-arsacyclopenta-2,4-diene. The silanide adds to another diphenylbutadiyne; the resulting carbanion abstracts the iPr_3Si^+ cation from the arsenic atom and leaves the 2,5-diphenyl-3,4-bis(phenylethynyl)arsolide anion. This would lead to the formation of 1,4-diphenyl-1,2-bis(triisopropylsilyl)but-1-ene-3-yne. The constitution of the anion was confirmed by crystallization as the solvent-separated ion pair **5** with the cation $\{(THF)_3Ca[\mu\text{-}As(H)SiiPr_3]_3Ca(THF)_3\}^+$, and X-ray structure determination, whereas the mass spectrometric investigation of the reaction solution gave fragments which could arise from the triisopropylsilyl-substituted but-1-ene-3-yne. Furthermore, methanolysis of the reaction mixture gave $HAs(SiiPr_3)_2$ which proves the intermolecular H/Si*i*Pr$_3$ exchange reaction. In the course of our investigations, elimination of the already well-known hexakis(triisopropyl)disilane, as well as $HSiiPr_3$, was not observed. However, despite not being able to isolate analytically pure **5**, the formation of this compound supports the reaction mechanism proposed in Scheme 3. Furthermore, Becker and co-workers[17] have investigated the reaction of lithium bis(trimethylsilyl)phosphanide with diphenylethyne in THF. Tetrakis(tetrahydrofuran-*O*)lithium tetraphenylphospholide has been isolated as a solvent-separated ion pair in approximately 60% yield.

Scheme 3. Proposed reaction mechanism for the synthesis of bis(tetrahydrofuran-*O*)calcium- and -strontium bis(2,5-diphenylarsolide)

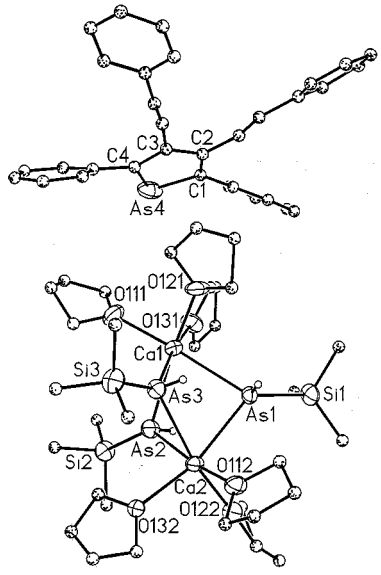

Figure 1. Molecular structure of the ion pair $[(THF)_3Ca[\mu\text{-}As(H)Si\mathit{i}Pr_3]_3Ca(THF)_3]^+$ $[2,5\text{-}Ph_2\text{-}3,4\text{-}(Ph{-}C{\equiv}C)_2AsC_4]^-$ (**5**); the carbon atoms are shown with arbitrary radii, the methyl groups and hydrogen atoms, with the exception of the As−H moieties, are omitted for clarity; all other atoms are drawn with 40% ellipsoids; neither of the THF molecules intercalated between the ions are shown for reasons of clarity; selected bond lengths (pm): Ca1−As1 304.5(2), Ca1−As2 307.9(3), Ca1−As3 307.1(2), Ca2−As1 305.3(2), Ca2−As2 306.7(2), Ca2−As3 305.7(3), As1−Si1 232.1(3), As2−Si2 231.3(3), As3−Si3 231.2(3), As4−C1 187.9(14), As4−C4 183.1(15), C1−C2 141(2), C2−C3 141(2), C3−C4 139(2)

However, in this reaction the fate of the trimethylsilyl groups remains unknown.[17]

Figure 1 shows the molecular structure of the solvent-separated ion pair **5**. The rather poor quality of the structure determination results from the disordering within the cation, which is not shown. Furthermore, two THF molecules with high thermal motion of the atoms are incorporated between the ions. The structural data are therefore not discussed in detail. The solvent-separated ion pair **5** consists of a binuclear cation with three bridging triisopropylsilylarsanide substituents; the central fragment is a trigonal Ca_2As_3 bipyramid. The Ca−As bond lengths vary in a very narrow range from 304.4(2) to 307.9(2) pm and are slightly longer than in $(THF)_4Ca[As(SiMe_3)_2]_2$.[18] The coordination spheres of the arsenic atoms As1, As2, and As3 are flattened with the Ca−As−Si and Ca1−As(n)−Ca2 angles ranging from 132.2(1)° to 139.6(1)° and from 84.99(6)° to 85.82(6)°, respectively, and neglecting the hydrogen atoms.

The arsolide cycle shows a delocalization of the anionic charge as expected for an isolated anion. The As−C bond lengths, taking into account the e.s.d. values, are of the same order of magnitude, and are comparable to those found in arsinine (arsabenzene)[19] and 2,3,6-triphenylarsinine.[20] The C−As−C angle in **5** has a value of 87.7(7)°.

NMR Spectroscopy

The NMR spectroscopic data of bis(tetrahydrofuran-*O*)calcium- (**3**) and -strontium bis(2,5-diphenylarsolide) (**4**) is summarized in Table 1. Their similarity and hence the lack of influence of the alkaline earth metal on the chemical shifts implies the mainly ionic character of the metal−arsolide interaction. The α-carbon atoms (C2,5) at the arsenic atom show a strong downfield shift. However, similar values are also found for tetrakis(tetrahydrofuran-*O*)calcium bis[2,5-diphenyl-3,4-bis(trimethylsilyl)phospholide] **A**[1] with η^1-bonded phospholide ligands. The chemical shifts of the ^{13}C atoms of the aromatic five-membered cycles are not dependent on either the binding mode, or on the pentele or alkaline earth metal atoms. This observation supports the interpretation of these compounds as mainly ionic.

[a] Solvent: [D_8]THF, 30 °C. − [b] Assignment to *meta* and *ortho* positions uncertain and probably reversed.

Molecular Structure of 3

Bis(tetrahydrofuran-*O*)calcium bis(2,5-diphenylarsolide) **3** crystallizes with two crystallographically independent molecules in the asymmetric unit. Figure 2 shows one of the essentially equal molecules and its numbering scheme. The arsolide ligands are η^5-bonded to the calcium centers. The distances between the calcium atoms and the centers of the arsolide cycles lie between 254.1 and 257.5 pm. The Ca−O bond lengths vary in the very narrow and characteristic[13] region of 235.7 and 238.9 pm.

The arsolide ligands show a delocalization of the anionic charge within the five-membered cycle, the C(1*n*)−As(*n*)−C(4*n*) angles are approximately 87 °. The mean As−C bond of 190.5 pm is longer than that in the isolated arsolide anion of **5**. On the other hand, the Ca−As distances are only slightly larger than in the polycyclic cation of **5**. However, these structural parameters are in agreement with those of a calcium-bonded 3,4-dimethyl-2,5-bis-(trimethylsilyl)arsolide ligand.[1]

An interaction between the arsolide anion and the phenyl substituents in the 2,5-positions can be excluded. The bond lengths C(1*n*)−C(11*n*) and C(4*n*)−C(14*n*) (n = 1, 2, 3, 4) with a mean value of 146.9 pm is characteristic of a C−C single bond between two sp^2 hybridized carbon atoms.[21]

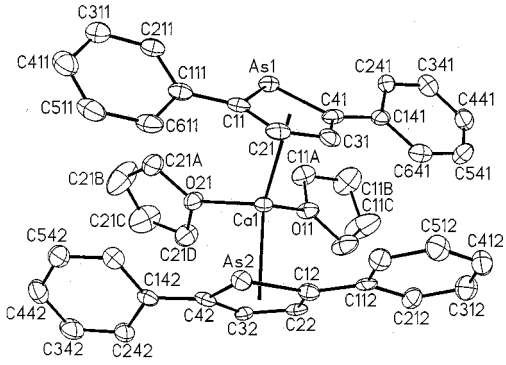

Figure 2. Molecular structure and numbering scheme of bis(tetrahydrofuran-*O*)calcium bis(2,5-diphenylarsolide) **(3)**; only one molecule is shown; hydrogen atoms are omitted for clarity, the ellipsoids represent a probability of 40%; selected bond lengths (pm): Ca1−As1 309.04(9), Ca1−C11 292.2(4), Ca1−C21 285.1(4), Ca1−C31 282.2(4), Ca1−C41 284.7(4), As1−C11 190.9(4), C11−C21 137.2(6), C21−C31 137.8(6), C31−C41 140.1(6), C41−As1 190.6(5), Ca1−As2 307.50(9), Ca1−C12 283.1(5), Ca1−C22 278.9(4), Ca1−C32 282.6(4), Ca1−C42 287.9(3), As2−C12 189.8(4), C12−C22 139.1(5), C22−C32 139.1(6), C32−C42 140.4(5), C42-As2 190.6(4), Ca1−O11 237.8(3), Ca1−O21 235.7(3); selected angles (°): C11-As1−C41 86.1(2), C12-As2−C42 87.1(2), O11−Ca1−O21 82.9(1)

The small angles between the normals of the phenyl planes on the one side and the arsolide plane on the other are rather small (25.2° and 20.4°); however, this orientation is a consequence of the intramolecular steric repulsion between the substituents and the packing of the molecules in the crystal.

Conclusion

The substitution pattern of the alkaline earth metal bis(arsanides) influence the mechanism of their reactions with diphenylbutadiyne. The migration of the sterically demanding triisopropylsilyl groups is avoided, instead an intermolecular H/Si*i*Pr$_3$ exchange reaction is observed. As a consequence of this reaction two different arsolide substituents have been characterized by X-ray crystallography: the 2,5-diphenylarsolide and the 2,5-diphenyl-3,4-diphenylethynylarsolide anion. The latter was not isolated as a diarsacalcocene, as the bulky binuclear cation $[(THF)_3Ca[\mu\text{-}As(H)Si\textit{i}Pr_3]_3Ca(THF)_3]^+$ was necessary for stabilization and crystallization.

The 1,1′-diarsacalcocene **3** and -strontocene **4** are available in high purity due to their poor solubility in toluene. However, these compounds have a limited use as synthons for arsolide transfer reactions because of a rather poor yield with regard to the alkaline earth metal or the arsenic atoms.

Experimental Section

General Remarks: All experiments and manipulations were carried out under argon purified by passage through a BTS catalyst and P_4O_{10}. Reactions were performed by using standard Schlenk techniques and using dried, thoroughly deoxygenated solvents. The starting materials $(THF)_2Ca[N(SiMe_3)_2]_2$,[12,22,23] $(THF)_2Sr[N(SiMe_3)_2]_2$,[12,22,23] and $H_2AsSi\textit{i}Pr_3$[11] were prepared according to literature procedures. NMR spectra were recorded on Jeol GSX270 and EX400 spectrometers. A Perkin−Elmer Paragon 1000 PC spectrophotometer was used to record the IR spectra; solid substances were examined as Nujol mulls between KBr plates (vs: very strong, s strong, m: medium, w: weak, vw: very weak, sh: shoulder). The frequencies in the region of the Nujol vibrations were not listed.

Tetrakis(tetrahydrofuran-*O*)calcium Bis(triisopropylsilylarsanide) (1): Triisopropylsilylarsane (1.17 g, 4.98 mmol) was added at room temp. to a solution of of bis(tetrahydrofuran-*O*)calcium bis[bis(trimethylsilyl)amide] (0.96 g, 1.90 mmol) in 20 mL of THF. The volume of the reaction mixture was reduced to approximately a quarter of the original volume. At 4 °C a precipitate of **1** was obtained as air- and moisture-sensitive colorless crystals, yield: 1.03 g (1.30 mmol), 68%. − Dec. above 140 °C without melting. − ^{1}H NMR ([D$_8$]toluene, 30 °C): δ = 1.03 (d, ^3J = 6.0 Hz, 18 H, CH$_3$), 0.97 (sept, ^3J = 6.0 Hz, 3 H, CH), 1.55 and 3.50 (THF). − ^{13}C{^{1}H} NMR ([D$_8$]toluene, 30 °C): δ = 15.1 (CH), 18.7 (CH$_3$), 25.4 and 67.4 (THF). − ^{29}Si{^{1}H} NMR ([D$_8$]toluene, 30 °C): δ = 31.1. − IR: $\tilde{\nu}$ = 2091 vs [ν(AsH)], 1293 w, 1260 w, 1249 w, 1232 sh, 1178 vw, 1159 vw, 1093 sh, 1071 s, 1036 s, 1016 s, 992 s, 967 w, 954 m, 918 s, 882 vs, 833 m, 803 w, 743 w, 672 s, 653 s, 609 s, 573 s, 560 s, 502 s, 464 s, 445 m, 420 m, 385 m, 363 sh cm^{-1}. − MS (70 eV); *m*/*z* (%): 59 (89) [SiC$_2$H$_7$], 61 (7), 73 (83) [SiC$_3$H$_9$], 75 (15) [As], 87 (54) [SiC$_4$H$_{11}$], 103 (11), 115 (100) [SiC$_6$H$_{15}$], 131 (16), 157 (24) [SiC$_9$H$_{21}$], 158 (21) [HSiC$_9$H$_{21}$], 207 (30), 300 (19) [Si$_2$C$_{17}$H$_{40}$], 390 (7) [CaAs$_2$Si$_2$C$_{10}$H$_{24}$]. − $C_{18}H_{44}As_2CaSi_2$ (506.6, THF-free): calcd. C 42.67, H 8.75; found C 43.16, H 8.84.

Tetrakis(tetrahydrofuran-*O*)strontium Bis(triisopropylsilylarsanide) (2): Triisopropylsilylarsane (1.17 g, 4.98 mmol) was added to a solution of bis(tetrahydrofuran-*O*)strontium bis[bis(trimethylsilyl)amide] (1.05 g, 1.90 mmol) in 10 mL of THF. All volatile materials were removed under vacuum and the remaining yellowish powder dried until a pressure of 0.01 Torr was reached. Yield: 1.43 g (1.70 mmol), 89%. − Dec. above 140 °C without melting. − ^{1}H NMR ([D$_8$]toluene, 30 °C):δ = 1.28 (d, ^3J = 6.4 Hz, 18 H, CH$_3$), 1.27 (sept, ^3J = 6.4 Hz, 3 H, CH), 1.48 and 3.56 (THF). − ^{13}C{^{1}H} NMR ([D$_8$]toluene, 30 °C): δ = 15.4 (CH), 20.3 (Me), 25.5 and 67.6 (THF). − ^{29}Si{^{1}H} NMR ([D$_8$]toluene, 30 °C): δ = 31.2. − IR: $\tilde{\nu}$ = 2052 s [ν(AsH)]; 1295 vw, 1249 sh, 1225 w, 1179 vw, 1071 s, 1036 vs, 1015 s, 968 w, 953 w, 917 s, 882 vs, 663 s, 646 vs, 593 s, 575 vs, 558 s, 503 s, 462 m, 424 vw, 386 w, 360 vw cm^{-1}. − $C_{18}H_{44}As_2Si_2Sr$ (554.2, THF-free): calcd. C 44.71, H 8.66; found C 42.18, H 8.30.

Bis(tetrahydrofuran-*O*)calcium Bis(2,5-diphenylarsolide) (3): 1 (1.12 g, 1.41 mmol) in 3 mL of THF, and diphenylbutadiyne (0.30 g, 1.41 mmol) were combined in 20 mL of unstirred toluene. After 7 days the NMR spectroscopic control measurements showed the complete consumption of diphenylbutadiyne. The brown reaction mixture was reduced to two thirds of the original volume. At 4 °C crystals of **3** precipitated. Washing of the solid with small portions of toluene left analytically pure **3** (0.31 g, 0.42 mmol, 30% with regard to calcium). The mother liquor and the toluene washing were combined. After reduction of the volume and cooling to 4 °C crystals of **3** and bis[tris(tetrahydrofuran-*O*)calcium] tris(μ-triisopropylsilylarsanide) 2,5-diphenyl-3,4-bis(phenylethynyl)arsolide (**5**) [m. p. 115 °C (dec.); ^{1}H NMR: δ = 1.16 (CH$_3$ and CH), 6.78−7.66 (phenyl), 1.77 and 3.64 (THF)], precipitated, however, analytically pure **5** was not obtained from this reaction. − Physical data of **3**: dec. above 250 °C without melting. − NMR data see Table 1. − IR: $\tilde{\nu}$ = 1315 vw, 1295 vw, 1267 s, 1249 w, 1202 vw, 1277 w, 1156 w, 1137 vw, 1105 vw, 1073 s, 1026 vs, 1019 vs, 999 w, 984 vw, 968

vw, 953 vw, 903 m, 875 s, 841 sh, 802 vs, 756 vs, 693 vs, 672 w, 666 w, 653 w, 620 vw, 590 vw, 554 w, 525 w, 514 vw, 452 w, 430 s, 299 vw, 291 vw cm^{-1}. – $C_{40}H_{40}As_2CaO_2$ (742.7): calcd. C 64.69, H 5.43; found C 63.09, H 5.78.

Bis(tetrahydrofuran-*O*)strontium Bis(2,5-diphenylarsolide) (4): Tetrakis(tetrahydrofuran-*O*)strontium bis(triisopropylsilylarsanide) (**2**) (1.60 g, 1.90 mmol) was dissolved in a mixture of 5 mL of THF and 15 mL of toluene. Diphenylbutadiyne (0.39 g, 1.9 mmol) was added to this yellowish solution which turned brown within a few hours. After two days stirring at room temp., the reaction mixture was concentrated to half its volume and **4** precipitated. Washing with toluene left an almost colorless powder of **4** (0.55 g, 0.7 mmol, 37% with regard to strontium). - Dec. above 250 °C without melting. – NMR data see Table 1. – IR: $\tilde{\nu}$ = 1316 vw, 1293 vw, 1265 s, 1185 vw, 1175 vw, 1157 w, 1099 m, 1073 s, 1029 s, 1023 s, 999 w, 982 vw, 970 vw, 902 m, 878 m, 847 w, 840 w, 800 s, 756 vs, 693 s, 666 vw, 620 vw, 589 vw, 554 w, 524 vw, 510 vw, 497 vw, 453 vw, 431 m, 422 vw, 405 vw, 396 vw cm^{-1}. – $C_{40}H_{40}As_2O_2Sr$ (790.2): calcd. C 60.80, H 5.10; found C 59.03, H 5.39.

Structure Determinations: Single crystals of **3** and **5** were covered with oil[24] and mounted on a STOE IPDS diffractometer with graphite monochromated Mo-K_α radiation (λ = 71.073 pm). Crystallographic parameters and details of data collection are summarized in Table 2. The structures were solved by direct methods and refined with the software packages SHELXL-93 and SHELXL-97.[26] Neutral scattering factors were taken from Cromer and Mann[27] and for the hydrogen atoms from Stewart et al.[28] For **3** neither absorption nor extinction corrections were applied.

[a] Definition of the R values: $R_1 = (\Sigma|\,|F_o| - |F_c|\,|)/\Sigma\,|F_o|$; $wR_2 = \{\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]\}^{1/2}$ with $w^{-1} = \sigma^2(F_o^2) + (aP)^2$. – [b] $s = \{\Sigma[w(F_o^2 - F_c^2)^2]/(N_o - N_p)\}^{1/2}$.

The non-hydrogen atoms of **3** were refined anisotropically. The H-atoms were considered with a riding model under restriction of ideal symmetry at the corresponding atom. The asymmetric unit contains two molecules.[29] The structure of **5** consists of a solvent-separated ion pair with two additional THF molecules in the cavities. Whereas the non-hydrogen atoms of the anion were refined anisotropically, all other C atoms were considered isotropically. The isopropylsilyl groups and part of the THF ligands show a two-site disorder. All hydrogen atoms were refined using a riding model with ideal geometry at the corresponding carbon and arsenic atoms.

Acknowledgments

This work was financially supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank Prof. Dr. P. Klüfers for his kind support. Furthermore, C. Birg wishes to express her gratitude to the State of Bavaria, Germany for a Ph. D. scholarship granted.

A Novel Triangular Trinuclear μ_3-CO_3 Ferromagnetic Cu^{II} Compound Prepared in situ from CO_2 Uptake in Air. X-ray Structure, Spectroscopy and Magnetism

Gerard A. van Albada,[a] Ilpo Mutikainen,[b] Olivier S. Roubeau,[a] Urho Turpeinen,[b] and Jan Reedijk*[a]

Keywords: X-ray structure / Copper / N ligands / Magnetic properties / Carbon dioxide fixation

The new trinuclear compound $[Cu_3(bpy)_6(\mu_3\text{-}CO_3)](BF_4)_4(H_2O)_2(C_2H_6O)$ (in which bpy = 2,2′-bipyridine) has been synthesized from $Cu(BF_4)_2$ and bpy in aqueous ethanol by rapid uptake of atmospheric CO_2. The structure of the compound has been determined by X-ray crystallography; it was found to crystallise in the triclinic space group $P\bar{1}$ with a = 13.405(7), b = 13.691(7), c = 21.446(8) Å, α = 82.87(4), β = 73.57(4), γ = 64.32(4)°, Z = 2. The three copper atoms are connected to each other through the oxygen atoms from the bridging carbonato group, giving a triangular array of copper atoms. Each copper has a distorted square-pyramidal environment with a basal plane formed by three nitrogen atoms of the two chelating bipyridine groups and the oxygen atom of the bridging carbonato group (Cu–N/O distances about 2.0 Å). The apical position is formed at each copper by the fourth nitrogen atom of the bipyridines with distances varying from 2.120(5) to 2.188(5) Å. A weak ferromagnetic interaction is observed between the copper(II) ions. All data were fitted using the Hamiltonian $H = -J_{12}(\mathbf{S_1}\cdot\mathbf{S_2}) - J_{13}(\mathbf{S_1}\cdot\mathbf{S_3}) - J_{23}(\mathbf{S_2}\cdot\mathbf{S_3})$. Observed parameters are J = 10.6 cm^{-1} and a very weak antiferromagnetic intercluster interaction with zj' = −1.2 cm^{-1}.

Introduction

Over the years many efforts have been made in the search for compounds that can act as a CO_2 catcher, i.e. insertion of CO_2 from the atmosphere into coordination compounds. Insertion reactions of CO_2, such as into metal−ligand bonds, are not uncommon and in recent years many review papers have been published on this subject.[1] Several dinuclear copper(II) compounds have been synthesized by means of fixation of CO_2 from air.[2] The carbonate anion itself is a versatile bridging ligand, which can bind in different modes to generate dinuclear, trinuclear, tetranuclear, and even one- or two-dimensional systems,[3] and the study of this subject is also important in relation to the zinc(II) compounds in carbonic anhydrases (CA).[4]

Absorption of CO_2 into a trinuclear copper(II) compound was suggested in 1968 on the basis of IR spectra,[10] but to the best of our knowledge only five crystal structures of this type of trinuclear copper(II) carbonato compound have been solved and published together with their magnetic properties.[4−9]

With the ligand 2,2-bipyridine (abbreviated as bpy), X-ray structures of dinuclear μ-hydroxo-bridged copper(II) coordination compounds with the general formula $[Cu(OH)(bpy)]_2(A)_x$ (x = 1,2 and A = ClO_4^-,[11] $CF_3SO_3^-$,[12] SO_4^{2-},[13] NO_3^-,[14a,14b] $C_4O_4^{2-}$ [14c] are known.

With perchlorate or nitrate as an anion, the X-ray structures of the mononuclear compounds with the general formula $Cu(bpy)_x(A)_2$ (x = 1−3) have been published.[14b,15] However, with tetrafluoroborate as an anion, only a mononuclear compound, $Cu(bpy)_2(BF_4)_2$, has been reported so far.[16] Following earlier research on dinuclear hydroxo and alkoxo-bridged copper(II) coordination compounds,[17] we attempted to synthesize the dinuclear hydroxo-bridged compound with the anion BF_4^- in the same way as for the other hydroxo-bridged compounds with bpy. However, in this case it was not the dinuclear hydroxo-bridged that was obtained, but surprisingly the trinuclear carbonato-bridged compound $[Cu_3(bpy)_6(\mu\text{-}CO_3)](BF_4)_4(H_2O)_2(C_2H_6O)$. It is remarkable that this compound has not been found earlier, considering the thorough research undertaken with the ligand bpy over many years. The title compound was subsequently easily synthesized in an artificial CO_2 atmosphere. With Zn^{II} and bpy as a ligand, the carbonato-bridged trinuclear compound $[Zn_3(bpy)_6(CO_3)(H_2O)](ClO_4)_4(bpy)\cdot 2H_2O$ is also known.[18] In this study we report the synthesis, spectroscopic and magnetic properties as well as the X-ray structure of the title compound.

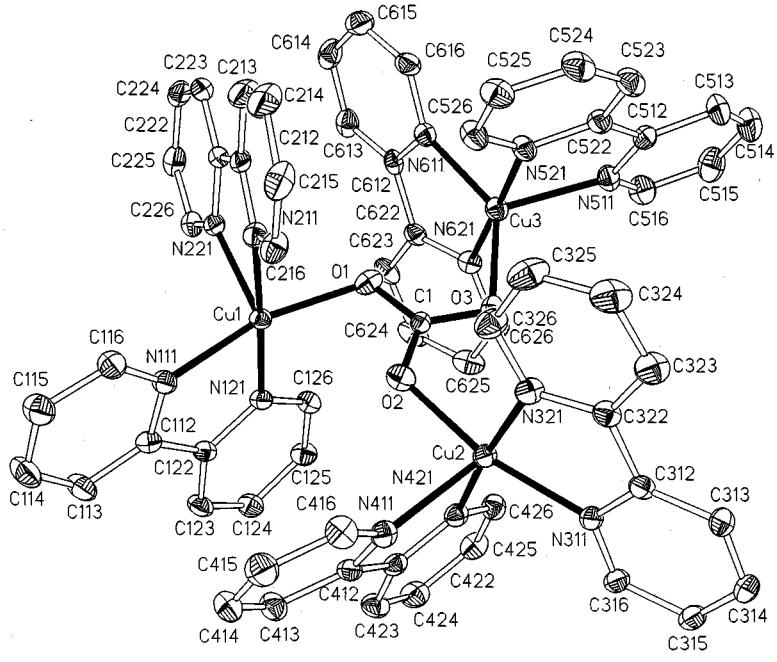

Figure 1. ORTEP plot showing the structure of $[Cu_3(bpy)_6(\mu\text{-}CO_3)](BF_4)_4(H_2O)_2(C_2H_6O)$ with atom-labeling scheme; hydrogen atoms, noncoordinating tetrafluoroborate anions, ethanol and water molecules are omitted for clarity

Results and Discussion

Description of the Crystal Structure of $[Cu_3(bpy)_6(\mu_3\text{-}CO_3)](BF_4)_4(H_2O)_2(C_2H_6O)$

The structure contains the unit $[Cu_3(bpy)_6(\mu_3\text{-}CO_3)]$, which is depicted in Figure 1, and the relevant bond length and bond angle information is given in Table 1. The unit cell also contains four noncoordinating tetrafluoroborate anions, one ethanol and two water molecules.

The three copper(II) atoms are connected to each other through the oxygen atoms from the bridging carbonato group, giving a triangular array of copper atoms. Each copper has a distorted square pyramidal environment with a basal plane formed by three nitrogen atoms of the two bichelating bipyridine groups and the oxygen atom of the bridging carbonato group (Cu−N/O distances about 2.0 Å). The apical position is formed at each copper by the fourth nitrogen atom of the bipyridines with distances that vary from 2.120(5) to 2.188(5) Å. The distortion from square pyramidal is different for each copper atom and this can be seen from the angles of each basal plane [Cu1 (basal plane O1−N211−N111−N121), angles 176.92(18) and 164.41(17)°; Cu2 (basal plane O2−N321−N311−N421), angles 172.8(2) and 166.76(17)°; Cu3 (basal plane O3−N521−N611−N621), angles 178.4(2) and 138.91(17)°]. This difference can be best expressed with the parameter τ (for 5 coordinated coordination compounds τ describes the relative amount of trigonality; τ = 0 for a square pyramid and τ = 1 for a trigonal bipyramid),[19] which has values of 0.21, 0.10 and 0.66 for Cu1, Cu2 and Cu3, respectively. The distances between the copper(II) atoms are also different and are large (Cu1−Cu2 4.64, Cu1−Cu3 4.72, Cu2−Cu3 5.00 Å).

The structures of compounds **1**−**4** in Table 2, in which the three coppers are almost equivalent, are quite different from that of compound **5**, in which all three copper atoms have a trigonal bipyrimidal geometry (τ values of 0.78, 0.81, and 0.83 for Cu1, Cu2, and Cu3, respectively).

The geometry in the related Zn compound, $[Zn_3(bpy)_6(\mu_3\text{-}CO_3)(H_2O)](ClO_4)_4(bpy)\cdot 2H_2O$,[18] is quite different; two of the Zn^{II} atoms have a distorted octahedral $N_4O(O_{water})$ geometry and the third Zn^{II} atom has a distorted trigonal-bipyramidal geometry with an N_4O environment.

Spectroscopy

The ligand field spectrum of the title compound shows a broad asymmetric band with a maximum at about $13.7\cdot 10^3$ cm^{-1} and a shoulder at about $10.1\cdot 10^3$ cm^{-1}; these absorptions are in agreement with a distorted square pyramidal $Cu(N)_x(O)_y$ geometry.[20]

In the infrared spectrum the most significant bands are those of the carbonato anion, which are reported in the literature at 1475, 1425, 837, 782, and 672 cm^{-1} for the compound $Cu_3(dpt)_3(\mu_3\text{-}CO_3)(ClO_4)_2\cdot 2H_2O$ (in which dpt = dipropylenetriamine)[10] and at 1476, 1423, 841, 694 cm^{-1} for the compound $[Zn_3(bpy)_6(\mu_3\text{-}CO_3)(H_2O)](ClO_4)_4(bpy)\cdot 2H_2O$.[18]

In the title compound the out-of-plane vibration at 839 cm^{-1} (medium intensity) is the best indication of the presence of CO_3 in the compound, as this spectral range is completely transparent in the monomeric compound $Cu(bpy)_3(BF_4)_2$.

EPR

The EPR spectrum of the title compound at room temperature shows a broad absorption centered around g =

2.13 with a very weak shoulder at about $g = 2.42$. For the five other known trinuclear carbonato-bridged compounds the g values also lie at around $g = 2.12$ (see Table 2).

In frozen solution (DMF/methanol mixture) at 77 K a resolved $d_{x^2-y^2}$ spectrum is obtained with a $g_\perp$ value of 2.06, a $g_{//}$ of 2.26, with an $A_{//}$ value of 15.9 mT. A poorly resolved nitrogen hyperfine splitting is observed with 5 lines, indicating 2 nitrogens around the copper atom. This observation indicates that the compound is dissociated in this solution.

Magnetic Properties

To better understand the magnetic interaction, mediated through the CO_3^{2-} bridge, the magnetic susceptibilities of powdered samples were measured from 4 to 250 K and the results are shown in Figure 2 in the form of χ_m vs. T and μ_{eff} vs. T plots. The effective magnetic moment, μ_{eff}, measured from 250 to about 100 K has an almost constant value of about 3.3−3.4 μ_B. This value compares well with that expected for three uncoupled spins $S = {}^1/_2$ ($\mu_{eff} = 3.0\ \mu_B$, spin only value) and is also observed in other trinuclear triangular compounds.[4,21] Below 100 K the magnetic moment increases gradually until a maximum is reached at 5 K. The increase can be ascribed to a ferromagnetic interaction between the Cu^{II} ions.[4,7] The magnetic data were fitted to the theoretical expression for the magnetic susceptibility for a trinuclear triangular system, which is based on the general Hamiltonian[22,23] for the description of the interaction: $H = -J_{12}\ (\mathbf{S}_1 \cdot \mathbf{S}_2) - J_{13}\ (\mathbf{S}_1 \cdot \mathbf{S}_3) - J_{23}\ (\mathbf{S}_2 \cdot \mathbf{S}_3)$

in which the exchange integrals, J_{ij}, are negative for antiferromagnetic and positive for ferromagnetic interactions.

Although the three Cu^{II} ions are not completely identical (not related by a C_3 axis), we have assumed the Cu^{II} triangle to be equilateral. Considering three different Cu^{II} ions would only yield more ambiguous J_{ij} parameters, since they are strongly related to each other,[23a] and in our case without a better quality of fit. The g tensors and the J_{ij} parameters were therefore considered to be identical for the three Cu^{II} ions, and only one J value was considered.

The expression for the molar susceptibility then becomes:[22,23] $\chi_m = [Ng^2\mu_B{}^2/(4\ k_B\ (T + \Theta))] \times F$, where $\Theta = -(zJ'/k_B) \times F$

In this formula $F = [1 + 5\ \exp(3J/2kT)]/[1 + \exp(3J/2kT)]$ and the parameters N, g, μ_B, k_B, and T have their usual meanings.[22,23] The exchange parameter is denoted as J and the parameter zJ' empirically takes into account the intercluster interactions of z nearest neighbors.

Using the g value given by the EPR spectra and free variation of J did not give satisfactory results; therefore both J and g were left free in the least-squares fitting procedure, first considering $zJ' = 0$. Once the best fit was reached, the intercluster interaction was also introduced into the fitting procedure.

So, with variation of the three parameters J, zj', and g, and by minimizing the function $R = (\chi_m T_{calc} - \chi_m T_{obs})^2/(\chi_m T_{obs})^2$, the best fit was obtained for $J = 10.6\ cm^{-1}$, $zj' = -1.2\ cm^{-1}$, $g = 2.22$, and $R = 2.4 \cdot 10^{-4}$.

This low J value and rather weak interaction is not surprising since the distances between the copper(II) atoms are quite large (Cu−Cu separation of about 4.78 Å). As can be seen from Table 2, the present parameters agree well with the first four carbonato-bridged trinuclear compounds (compounds 1−4 in Table 2) reported in the literature. In fact, only compound **5** shows a very weak antiferromagnetic interaction,[9] the reasons for which are currently not understood.

Conclusion

In this paper a compound is described that is readily formed by absorption of CO_2 from the atmosphere, yielding a trinuclear carbonato-bridged compound having a $[Cu_3(bpy)_6(\mu_3\text{-}CO_3)]$ chromophore. The Cu^{II} ions are weakly coupled in a ferromagnetic manner, as also observed

[a] Abbreviations: (v)w = (very)weak, br = broad, av = average value, O_w = O of water, RT = room temperature, av = average. − pip = 2-[2-(2-pyridyl)ethyliminomethyl]pyridine; L= macrocycle [15]aneN_3O_2; Medpt = bis(3-aminopropyl)methylamine; L2 = 1,4,7,10-tetraazabicyclo[5.5.3]pentadecane; TPA = tris(pyridylmethyl)amine; bpy = 2,2′-bipyridine. − [b] Each copper also has a distance of 2.69 Å to another carbonate oxygen. − [c] The magnetic susceptibility was also measured for the isostructural compound $[Cu_3(pip)_3(H_2O)_3(\mu_3\text{-}CO_3)](ClO_4)_4$, and is J = 8.94, zJ' = −0.075 cm^{-1} (ref.[5]). − [d] No intercluster interaction was considered in the fitting procedure. − [e] The magnetic susceptibility was also measured for the related compound $[Cu_3(dpt)_3(\mu_3\text{-}CO_3)](ClO_4)_4$ [dpt = bis(3-aminopropyl)amine] and is J = 15.8, zJ' = −0.015 cm^{-1} (ref.[7]). − [f] Not given.

in a few analogous compounds (see Table 2). In addition, a very weak antiferromagnetic coupling is observed between trinuclear moieties.

As yet only a few compounds of this type have been reported and characterized structurally and magnetically (Table 2). Further research aimed at the synthesis of more examples of this type of compound, using the synthetic methods described in this paper, is currently in progress.

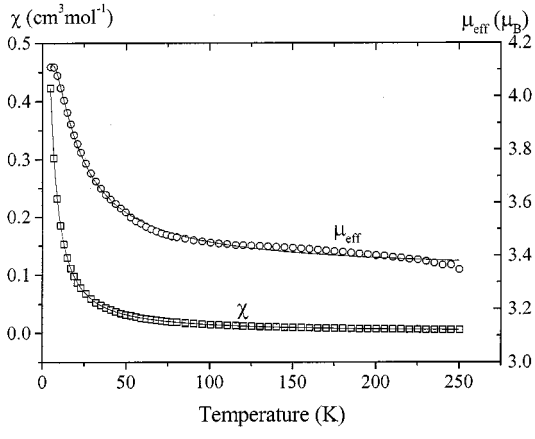

Figure 2. A plot of temperature dependence of χ_m vs. T (□) and μ_{eff} vs. T (○) is shown; the solid line represents the calculated curve for the parameters J = 10.6 cm^{-1}, zj' = −1.2 cm^{-1} and g = 2.22, see text

Experimental Section

General: All chemicals were used as received. The ligand 2,2′-bipyridine was obtained from Acros Organics, Belgium, and used without further purification.

C, H, N, and Cu determinations were performed by the Microanalytical Laboratory of University College, Dublin, Ireland. − Ligand field spectra were obtained on a Perkin−Elmer Lambda 900 spectrophotometer using the diffuse reflectance technique, with MgO as a reference. − X-band EPR spectra were obtained on a Jeol RE2x electron spin resonance spectrometer using DPPH (g = 2.0036) as a standard. − FTIR spectra were obtained on a Perkin−Elmer Paragon 1000 FTIR spectrophotometer equipped with a Golden Gate ATR device, using the reflectance technique (4000−300 cm^{-1}).

Magnetic susceptibility measurements (4−300 K) were carried out using a Quantum Design MPMS-5S SQUID magnetometer (measurements carried out at 1 T). Data were corrected for magnetization of the sample holder, for TIP of copper(II) and for diamagnetic contributions, which were estimated from the Pascal constants.

Synthesis of the Title Compound: 0.3 g (1.3 mmol) of copper(II) tetrafluoroborate and 0.4 g (2.6 mmol) of bpy were each dissolved in 10 mL of ethanol/water (1:1) and the solutions mixed carefully together. A few drops of 2 M sodium hydroxide solution was added in such a way that no precipitation was observed. The mixture was filtered and, after several weeks to a month standing in the open, air blue crystals separated. The crystals were filtered off and washed with ethanol.

When the same procedure was followed in an excicator under a CO_2 atmosphere (dry ice) the crystals were formed within a few days.

Attempts to synthesize the compounds by the addition of sodium or potassium carbonate yielded only the monomeric $Cu(bpy)_2(BF_4)_2$ compound.

Elemental analysis: $C_{63}H_{60}B_4Cu_3F_{16}N_{12}O_7$ (1635.1): calcd. C 46.3, H 3.7, N 10.3, Cu 11.7; found C 46.5, H 3.4, N 10.8, Cu 11.4.

X-ray Data Collection and Structure Determination: A blue prismatic crystal was selected and mounted on a glass fiber using the oil drop method.[24a] Data were collected on a Rigaku AFC-7S diffractometer (graphite-monochromated Mo-$K\alpha$ radiation, ω-2θ scans). The intensity data were corrected for Lorentz and polarization effects, for absorption (psi-scan absorption correction) and extinction. Two tetrafluoroborate groups and an ethanol solvent molecule were disordered. Two positions were assigned to F31, F32, and F33 atoms with a population parameter of 0.5. The other disordered tetrafluoroborate group was refined as two rigid groups with a population parameter of 0.5. The ethanol molecule was refined isotropically. All other non-hydrogen atoms were refined an-

isotropically. H atoms except those belonging to the water molecules were introduced in calculated positions and refined with fixed geometry with respect to their carrier atoms. The structure was solved by direct methods. The programs TEXSAN,[24b] SHELXS-97,[24c] SHELXL-97[24d] were used for data reduction, structure solution, and structure refinement, respectively. Refinement of F^2 was performed against all reflections. The weighted R-factor wR and goodness of fit S are based on F^2, while conventional R-factors are based on F, with F set to zero for negative F^2. Crystal data and numerical details of the structure determination are given in Table 3. Crystallographic data (excluding structure factors) for the structure in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-139540. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44(1223)336-033, E-mail: deposit@ccdc.cam.ac.uk].

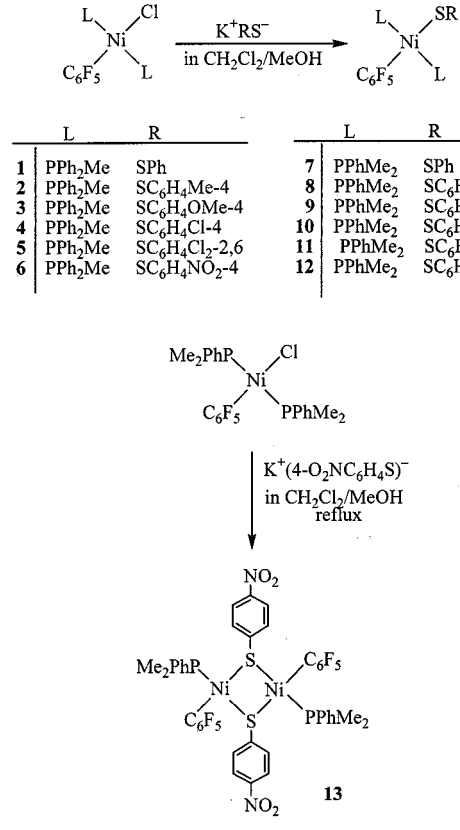
Organometallic Nickel(II) Complexes Containing Thiolate and Dithiocarbamate Ligands

Gregorio Sánchez,[a] Francisco Ruiz,[a] José L. Serrano,[b] M. Carmen Ramírez de Arellano,[c] and Gregorio López*[a]

Keywords: Phosphanes / Nickel / S ligands / Dithiocarbamate complexes / Bioinorganic chemistry

The mono(pentafluorophenyl)nickel(II) complexes $[Ni(C_6F_5)ClL_2]$ (L = $PPhMe_2$, PPh_2Me; L_2 = dppe) react with KSR (R = Ph, C_6H_4Me-*p*, C_6H_4OMe-*p*, C_6H_4Cl-*p*, $C_6H_3Cl_2$-2,6, $C_6H_4NO_2$-*p*) at room temperature in acetone/dichloromethane to give the mononuclear thiolate complexes $[Ni(C_6F_5)(SR)L_2]$. The binuclear μ-thiolate complex $[\{Ni(C_6F_5)(PPhMe_2)\}_2(\mu\text{-}SC_6H_4NO_2\text{-}p)_2]$ is obtained by reaction of $KSC_6H_4NO_2$-*p* with the same chloro complex in refluxing dichloromethane. A single-crystal X-ray diffraction study of $[Ni(C_6F_5)(SC_6H_4NO_2\text{-}p)(PPhMe_2)_2]$ and $[\{Ni_2(C_6F_5)_2(PPhMe_2)_2(\mu\text{-}SC_6H_4NO_2\text{-}p)_2]$ has established the mononuclear and binuclear nature of the complexes. The dithiocarbamatenickel complexes $[Ni(C_6F_5)(S_2CNR_2)L]$ (L = $PPhMe_2$, PPh_2Me, PEt_3; R = Et, *i*Pr; R_2 = C_5H_{10}, C_4H_8O) have been prepared by reaction of $[Ni(C_6F_5)ClL_2]$ (L = $PPhMe_2$, PPh_2Me, PEt_3) with the alkali metal salt of the corresponding dithioacid. A single-crystal X-ray diffraction study of $[Ni(C_6F_5)(S_2CNiPr_2)(PPhMe_2)]$ has established the mononuclear nature of the complex, and the geometry around each Ni atom as that of a tetrahedrally distorted square-planar geometry. Analytical (C, H, N), spectroscopic (IR, ^1H, and ^{19}F NMR), and mass spectrometry (FAB) data have been used for structural assignments.



Introduction

Monomeric late transition-metal thiolate complexes have been receiving increasing attention,[1−3] in part because of their relevance as models of biologically redox-active metalloproteins.[4] Nickel complexes with S-donor ligands are present in many hydrogenases.[5] Nickel(II) thiolates are generally square-planar species with a strong tendency to form dimers and oligomers.[6−9] Despite the great amount of work devoted to the study of metal−thiolate complexes,[1] fundamental knowledge of the structures of mononuclear species is relatively sparse.[10,11] Di- and trinuclear pentafluorophenylnickel complexes have been prepared by treating the di-μ-hydroxo-complex $[NBu_4]_2[\{Ni(C_6F_5)_2(\mu\text{-}OH)\}_2]$ with thiols.[12] Considering related complexes with S-donor ligands, mononuclear derivatives such as $[Ni(C_6F_5)_2(S_2CNR_2)]^-$,[13] $[Ni(S_2CNEt_2)(PPh_3)_2]^+$,[14] and $[Ni(S_2COEt)_2(PPh_3)]$[15] have also been studied.

Results and Discussion

Mononuclear Thiolate Complexes

The addition of a methanolic solution of the corresponding alkali metal arylthiolate to a solution of $[Ni(C_6F_5)ClL_2]$ (L = $PPhMe_2$, PPh_2Me) in dichloromethane results in the rapid formation of the mononuclear arylthiolate complexes $[Ni(C_6F_5)(SR)L_2]$ (**1**−**12**) shown in Scheme 1. The forma-

tion of these mononuclear complexes takes place at ambient temperature; on increasing the temperature, loss of a phosphane ligand may occur, and the binuclear μ-arylthiolate would be the reaction product. In fact, when the solution containing $[Ni(C_6F_5)Cl(PPhMe_2)_2]$ and $KSC_6H_4NO_2$-4 was boiled under reflux, the binuclear complex $[\{Ni(C_6F_5)(PPhMe_2)\}_2(\mu\text{-}SC_6H_4NO_2\text{-}4)_2]$ (**13** in Scheme 1) was obtained. The *trans* influence of the pentafluorophenyl ligand should favour the dissociation of one phosphane molecule, and the resulting vacant coordination site is occupied by a μ-arylthiolate group.

The ^{19}F NMR spectra of complexes **1**−**13** show the expected three-resonance signals for a pentafluorophenyl ring freely rotating around the carbon−nickel bond (2 F_o:1 F_p:2 F_m). The experimental NMR pattern consists of a doublet for the *o*-fluorine atoms, a triplet for the *p*-fluorine atom and multiplet for the *m*-fluorine atoms. The observation of a single signal in the ^{31}P NMR spectra indicates that complexes **1**−**12** all have the *trans* geometry shown in Scheme 1. The same *trans* geometry should also be assigned to complex **13** because only one set of ^1H resonances for the 4-$O_2NC_6H_4S$ group is found in the ^1H NMR spectrum (two doublets for 2,6-H and 3,5-H, respectively, although one doublet is overlapped with the multiplet of the phenyl group.

In acetone, $[Ni(C_6F_5)Cl(dppe)]$ reacts with $AgClO_4$ with elimination of AgCl; on removing the precipitated AgCl, the addition of an alkali metal thiolate (in methanol) to the resulting solution gives the corresponding mononuclear thiolates **14**−**19** shown in Scheme 2. The ^{19}F NMR spectra of these complexes are qualitatively similar to those of **1**−**12**, but the ^{31}P NMR spectroscopic data indicate the presence of two nonequivalent phosphorus atoms, one *trans* to S and one *trans* to C, and two ^{31}P resonances are found in the range δ = 50−56; the multiplet structure of the low-field signal is due to coupling to the *o*-fluorine atoms of the pentafluorophenyl group and this signal is consequently assigned to the phosphorus atom *trans* to C_6F_5.

19: R = $SC_6H_4NO_2$-4

Scheme 2

The neutral compounds **1**−**19** show the characteristic infrared absorptions of the pentafluorophenyl group[16] at ca. 1630m, 1495vs, 1050s, 950vs, and 780s cm^{-1}.

Crystal Structures of Complexes 12 and 13

The X-ray crystal structure determinations carried out for complexes $[Ni(C_6F_5)(SC_6H_4NO_2\text{-}4)(PPhMe_2)_2]$ **(12)** and $[\{Ni(C_6F_5)(PPhMe_2)\}_2(\mu\text{-}SC_6H_4NO_2\text{-}4)_2]$ **(13)** show the mono- and di-nuclearity of these complexes. A view of complex **12** is depicted in Figure 1, and relevant bond lengths and bond angles are shown in Table 1. The Ni atom and the four atoms coordinated to it deviate slightly from the plane defined by them. The Ni−C distance is similar to values found in other pentafluorophenylnickel compounds;[17,18] the strong *trans* influence of the C_6F_5 group is manifested by a lengthening of the Ni−S bond, giving a distance of 2.233 Å, which is significantly longer than those found in homoleptic nickel-thiolate complexes.[19]

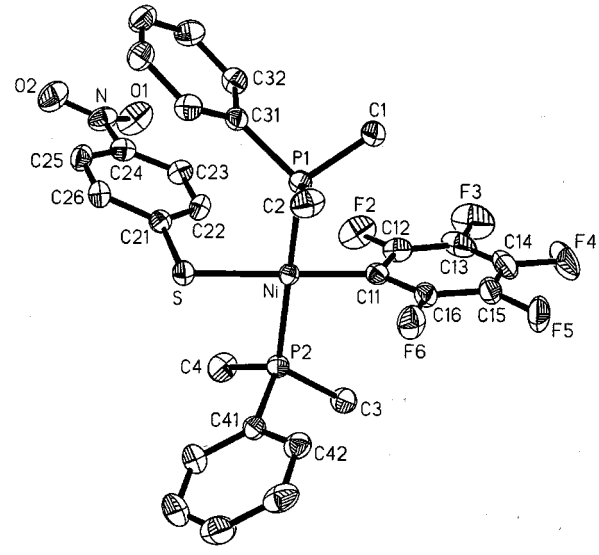

Figure 1. Molecular structure of compound **12**

The structure of complex **13** consists of centrosymmetric binuclear molecules with two Ni atoms bridged by arylthiolate groups (Figure 2). Bond lengths and bond angles are given in Table 1. The nickel atoms have approximately square-planar coordination, the deviation from the ideal geometry being revealed by the S−Ni−S angles. The Ni−S distances, 2.2140(11) and 2.2490(11), are quite similar to those found in the asymmetric binuclear complex $[(C_6F_5)_2Ni(\mu\text{-}SPh)_2Pd(dppe)]$ [2.214(2) and 2.2509(14)].[20] In the trinuclear complex $[Ni_3(C_6F_5)_4(\mu\text{-}SEt)_4]$ a weighted mean Ni−S distance of 2.203(5) was observed.[12]

Dithiocarbamate Complexes

The addition of a methanolic solution of the alkali metal dithiocarbamate (diethyldithiocarbamate, diisopropyldithiocarbamate, piperidinecarbodithioate, and morpholinecarbodithioate) to a solution of $[Ni(C_6F_5)ClL_2]$ (L = $PPhMe_2$, PPh_2Me, PEt_3) in dichloromethane results in the formation of the dithiocarbamate complexes $[Ni(C_6F_5)(S_2CNR_2)L]$ (**20**−**31**) with loss of one phosphane molecule (Scheme 3).

The ^{19}F NMR spectra of the dithiocarbamatenickel complexes exhibit the three signals (2 F_o:1 F_p:2 F_m) corresponding to a freely rotating C_6F_5 ring, and the ^{31}P NMR spectra show the single resonance expected for the phosphane ligand. The most relevant IR absorptions of coordinated dithiocarbamate are those originating from the thioureide group. In complexes **20**−**31**, the C−N and C−S stretching vibrations[21,22,23] are found at 1550−1450 cm^{-1} and 995−970 cm^{-1}, respectively, and the presence of only one

Scheme 3

band for ν(CS) is consistent with bidentate coordination of the dithiocarbamate.[24,25] Since the C=N and C−N stretching vibrations are usually found at 1690−1640 and 1350−1250 cm^{-1},[25] the thioureide band at 1550−1450 cm^{-1} indicates that the C−N bond in the coordinated $(S_2CNR_2)^-$ has considerable double bond character. However, the ^1H NMR spectra of complexes **20**−**31** indicate that rotation of the NR_2 group around the C−N bond is not hindered.

Crystal Structure of Complex 24

The structure of $[Ni(C_6F_5)(S_2CN\textit{i}Pr_2)(PPhMe_2)]$ (**24**) has been determined by X-ray crystallography. An ORTEP diagram is provided in Figure 3, and relevant bond lengths and angles are reported in Table 1. The overall coordination geometry about the nickel atom is essentially square planar. The S1−Ni−S2 angle is restricted by the chelate ring to 78.77(2)°. The P−Ni−S2 bond angle compensates to a great extent for the low angle by opening to 98.11(2)° with the C1−Ni−S1 angle at 91.40(5)°. The strong Ni−C_6F_5 bonding is evident in the nonequivalent Ni−S1 and Ni−S2 bond lengths and the *trans* influence exerted by the pentafluorophenyl ring is higher than that of the phosphane ligand lengthening the bond Ni−S2 giving a distance of 2.2144(5) Å, longer than the distance Ni−S1, 2.2029(5).

Conclusion

This work shows that mononuclear Ni-thiolate complexes $[Ni(C_6F_5)(SR)L_2]$ can be conveniently prepared by metathetical reactions carried out with the corresponding chloro complexes $[Ni(C_6F_5)ClL_2]$. The reaction temperature is a decisive factor in the formation of the mononuclear thiolate complex. At room temperature the mononuclear thiolato complex is the outcome of the metathetical reaction, but if the reaction is carried out in refluxing dichloromethane the binuclear thiolate complex is obtained with the concomitant release of one L molecule. The dithiocarba-

mate complexes are similarly obtained when $[Ni(C_6F_5)ClL_2]$ is treated with KS_2CNR_2.

Experimental Section

General Methods: C, H, and N analyses were carried out with a Carlo Erba instrument. − Infrared spectra were recorded with a Perkin−Elmer 16F-PC-FT spectrophotometer using Nujol mulls between polyethylene sheets. − ^1H, ^{31}P, and ^{19}F NMR spectra were recorded with a Bruker AC 200E or a Varian 300 spectrometer. − Conductance measurements were performed with a Crison 525 conductimeter (in acetone solution, $c \approx 5 \times 10^{-4}$ mol·dm^{-3}). − Decomposition temperatures were determined with a Reichert microscope. − All solvents were dried by conventional methods. − The compounds $[Ni(C_6F_5)Cl(PPhMe_2)_2]$,[18] $[Ni(C_6F_5)Cl(PPh_2Me)_2]$,[19] $[Ni(C_6F_5)Cl(dppe)]$,[26] and $[Ni(C_6F_5)Cl(PEt_2)_2]$[19] were prepared as described elsewhere.

$[Ni(C_6F_5)(SR)L_2]$; L = PPh_2Me and R = Ph (1), C_6H_4Me-*p* (2), C_6H_4OMe-*p* (3), C_6H_4Cl-*p* (4), $C_6H_4Cl_2$-2,6 (5), $C_6H_4NO_2$-*p* (6); L = $PPhMe_2$ and R = Ph (7), C_6H_4Me-*p* (8), C_6H_4OMe-*p* (9), C_6H_4Cl-*p* (10), $C_6H_4Cl_2$-2,6 (11), $C_6H_4NO_2$-*p* (12): A solution of $[Ni(C_6F_5)ClL_2]$ (0.164 mmol) in dichloromethane (10 mL) was added to a solution of KSR (0.164 mmol) in methanol (10 mL), and the solution was stirred at room temperature for 30 min. It was concentrated under reduced pressure to ca. 5 mL. The addition of water (ca. 1 mL) caused precipitation of a red solid, which was filtered off, washed with hexane and air-dried. The complexes were recrystallized from dichloromethane/hexane.

$[\{Ni(C_6F_5)(PPhMe_2)\}_2(\mu\text{-}SC_6H_4NO_2\text{-}p)_2]$ (13): A solution of $[Ni(C_6F_5)Cl(PPhMe_2)_2]$ (0.164 mmol) in dichloromethane (10 mL) was added to a solution of $KSC_6H_4NO_2$-*p* (0.164 mmol) in methanol (10 mL), and the solution was heated under reflux for 5 h.

The solvent was then partly evaporated under reduced pressure to half the original volume, and the addition of diethyl ether caused the precipitation of a red-brown solid, which was filtered off, washed with hexane and air-dried. The complex was recrystallized from dichloromethane/diethyl ether. − Yield: 83%. − $C_{40}H_{30}F_{10}N_2Ni_2O_4P_2S_2$ (1036): calcd. C 46.4, H 2.9, N 2.7, S 6.2; found C 46.1, H 3.1, N 2.6, S 6.5. − M.p. 165 °C (dec.). − ^{1}H NMR ([D$_6$]acetone): δ = 1.3 (t, 12 H, PPh*Me*$_2$), 7.3 (m, 14 H, PPh*Me*$_2$ + $SC_6H_4NO_2$-*p*), 7.8 (d, 4 H, $SC_6H_4NO_2$-*p*). − ^{19}F NMR ([D$_6$]acetone): δ = −116.2 (d, J_{om} = 30.2, 2 F$_o$), −160.2 (t, J_{mp} = 19.7, 1 F$_p$), −162.4 (m, 2 F$_m$). − ^{31}P{^{1}H} NMR ([D$_6$]acetone): δ = − 5.0.

[Ni(C_6F_5)(SR)(dppe)]; R = Ph (14), C_6H_4Me-*p* (15), C_6H_4OMe-*p* (16), C_6H_4Cl-*p* (17), $C_6H_4Cl_2$–2,6 (18), $C_6H_4NO_2$-*p* (19): $AgClO_4$ (0.157 mmol) was added to a solution of [Ni(C_6F_5)Cl(dppe)] (100 mg, 0.157 mmol) in acetone (20 mL). After stirring at room temperature for 1 h, the precipitated AgCl was filtered off and the resulting solution was added to a solution of KSR (0.157 mmol) in methanol (10 mL). The solution was then stirred at room temperature for 30 min. It was concentrated under reduced pressure to ca. 5 mL. The addition of water (ca. 1 mL) caused precipitation of a brown solid, which was filtered off, washed with hexane and air-dried. The complexes were recrystallized from dichloromethane/hexane.

14: Yield 77%. − M.p. 215 °C (dec.). − $C_{38}H_{29}F_5NiP_2S$ (733.3): C 62.2, H 4.0, S 4.4; found C 62.0, H 4.2, S 4.6. − ^{1}H NMR ([D$_6$]acetone): δ = 2.1 (m, 4 H, dppe), 6.6 (m, 3 H, SPh), 7.1 (d, 2 H, SPh), 7.4 (m, 16 H, dppe), 8.0 (m, 4 H, dppe). − ^{19}F NMR ([D$_6$]acetone): δ = −116.9 (m, 2 F$_o$), −164.1 (t, J_{mp} = 21.4, 1 F$_p$), −165.2 (m, 2 F$_m$). ^{31}P{^{1}H} NMR ([D$_6$]acetone): δ = 50.4 (m, P$_A$), 54.8 (d, ^2J = 40.4, P$_B$).

Determination of the X-ray Crystal Structures of 12, 13, and 24: Single crystals of complexes **12** (approximate dimensions 0.75 × 0.50 × 0.40 mm), **13** (0.50 × 0.30 × 0.20 mm), and **24** (0.60 × 0.50 × 0.30 mm) were mounted on a Siemens P4 diffractometer with LT2 temperature attachment. The crystallographic data are shown in Table 2. The scan method was ω with $2\Theta_{max}$ = 50° for the three cases, empirical Ψ-scan mode absorption was made. The structures were solved by direct methods and refined anisotropically on F^2.[26] The final R factors were 0.0367, 0.0451 and 0.0233 in **12**, **13**, and **24**, respectively {R_w = 0.0986, 0.1091, and 0.058, $w = 1/[\sigma^2 (F^2) + (aP)^2 + bP]$ where $P = (F_o^2 + 2F_c^2)/3$ and a and b are constants set by the program} over the observed reflections [$I > 2\sigma(I)$]. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publications no. CCDC-139088 to CCDC-139090. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44−1223/336-033, E-mail: deposit@chemcrys.cam.ac.uk].

Reactivity of The P_4 Molecule with Cobalt(I) and Rhodium(I) Polyphosphane Fragments

Massimo Di Vaira,[a] Markus P. Ehses,[a] Maurizio Peruzzini,[b] and Piero Stoppioni*[a]

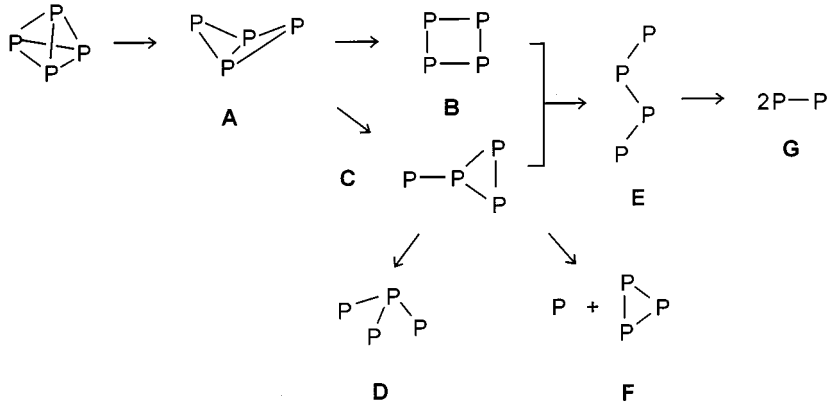
Keywords: Phosphorus / Cobalt / Rhodium / NMR spectroscopy / Phosphanes

The reaction of white phosphorus with the electronically and coordinatively unsaturated systems $[(PP_3)M]^+$ [PP_3 = tris(2-diphenylphosphanylethyl)phosphane; M = Co, Rh] and $[(NP_3)Rh]^+$ [NP_3 = tris(2-diphenylphosphanylethyl)amine] in tetrahydrofuran affords new tetraphosphorus complexes. The PP_3 metal fragments yield the trigonal bipyramidal $[(PP_3)M(\eta^1\text{-}P_4)]^+$ complex cations [M = Co^I **(1)**, Rh^I **(2)**] containing the intact P_4 molecule bonded end-on to the metal. In contrast, the $[(NP_3)Rh]^+$ system yields an octahedral rhodium(III) complex of formula $[(NP_3)Rh(\eta^2\text{-}P_4)]BPh_4$ **(3)** which contains a bicyclotetraphosphane ligand (P_4^{2-}) coordinated to the metal through the wing-tip P atoms. Compound **3** forms through the oxidative addition of the P_4 molecule to the metal fragment. These new tetraphosphorus derivatives, which are very reactive, have been characterized in solution at low temperature by ^{31}P NMR spectroscopy.

Introduction

White phosphorus, P_4, is highly reactive towards a variety of organometallic and transition metal fragments. Very often the reactions proceed through complicated multistep thermal or photochemical degradation and aggregation to form metal complexes containing P_n groups for which the original tetrahedral tetraphosphorus topology is no longer evident.[1] Although specific steps of the progressive disruption of the tetrahedral molecule have been documented only in some instances,[2] among the numerous compounds described there are many complexes containing P_n units which may be formally considered as resulting from the initial interaction of the metal fragment with the intact P_4 molecule, followed by stepwise disruption of P−P bonds. The P_n units which have been found to form through the metal-mediated degradation of P_4 are shown in Scheme 1 according to the number of bond(s) which have been cleaved. Coordination of the intact P_4 molecule has been achieved through the end-on[3] and side-on[4] coordination modes, the formally possible face coordination mode having only been postulated on spectroscopic grounds.[4a] The insertion of a metal fragment into a P−P bond to form a bicyclotetraphosphane (**A** in Scheme 1) is generally considered to be the first step in the degradation of the tetrahedral molecule.[5] A second bond of the original P_4 may be cleaved either next to the first one or opposite to it, yielding three-, **C**,[5a,6] or four-membered, **B**, cyclic P_4 ligands; planar and bent topologies of the latter are known.[5d,7] Starting from **C**, the cleavage of another bond may furnish tetraphosphorus ligands, with either tripodal, **D**,[8] or chain arrangements, **E**,[5f,9] or it may produce two separated units, **F**, i.e. one *cyclo*-P_3 ring and a single P atom.[10] Open P_3 structures are less common,[11] whereas numerous examples exist where P_4 is cleaved into two P_2 units, **G**.[12]

Up to now the course of the reaction of P_4 with a metal fragment has been difficult to predict. This is due in part to the small number of stable complexes containing the intact P_4 molecule. Furthermore, these complexes are either poorly soluble or too reactive to be isolated and characterized by standard techniques. Hence, systematic studies on the factors favouring specific activation modes and on the reactivity of such complexes are sparse.



We have investigated the reactivity of white phosphorus toward group 9 coordinatively and electronically unsaturated fragments stabilized by tripodal tetradentate ligands, which are known to be excellent precursors for the activation of H−H and C−H bonds.[13] The $[(PP_3)M]^+$ species [PP_3 = tris(2-diphenylphosphanylethyl)phosphane; M = Co, Rh] react with white phosphorus yielding adducts of formula $[(PP_3)M(\eta^1\text{-}P_4)]^+$ in which the intact P_4 molecule is η^1 bound to the metal. In contrast, the related $[(NP_3)Rh]^+$ [NP_3 = tris(2-diphenylphosphanylethyl)amine] fragment yields a compound of formula $[(NP_3)Rh(\eta^2\text{-}P_4)]BPh_4$, which contains a bicyclotetraphosphane ligand (P_4^{2-}) coordinated to the metal through the wing-tip P atoms. The complex forms through the oxidative addition of the P_4 molecule to the metal fragment. The compounds are extremely reactive and have been characterized in solution at low temperature.

Results and Discussion

The reaction at room temperature of $[(PP_3)CoH]$, dissolved in THF under argon, with CF_3SO_3Me, under nitrogen, yields the dinitrogen complex cation $[(PP_3)CoN_2]^+$ [14]

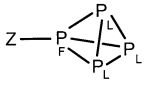
Scheme 1. Phosphorus units from formal stepwise cleavage of P−P bonds in the P_4 tetrahedron

and two species, denoted *a* and *b* in ref.[15], where their NMR spectroscopic data are reported. They exhibit an AC_3 $^{31}P\{^1H\}$ spin system suggestive of a trigonal geometry. Such species are likely to consist of the $[(PP_3)Co]^+$ cation and/or the complexes resulting from the interaction of the unsaturated 16e$^-$ fragment with the solvent or with the weakly coordinating $CF_3SO_3^-$ anion. These species react immediately with P_4 at temperatures as low as −70 °C to form a P_4 complex **(1)** (Scheme 2) which is stable up to −40 °C and decomposes unspecifically at higher temperature. Interestingly, the dinitrogen complex cation does not react with P_4 in the range of temperatures within which the P_4 adduct is stable.



Scheme 2. Reaction of $[(PP_3)M]^+$ species with white phosphorus

Monitoring the electrophilic attack on the rhodium complex $[(PP_3)RhH]$ at −20 °C with CF_3SO_3Me by ^{31}P NMR spectroscopy provides evidence for three species (*a′*, *b′* and *c′*; NMR in ref.[16]) each exhibiting an AC_3X spin system, characteristic of rhodium(I) complex cations with trigonal geometry; such species are likely to consist of the $[(PP_3)Rh]^+$ cation and of the complexes resulting from its interaction with the solvent or with the weakly coordinating $CF_3SO_3^-$ anion. Interestingly, such electrophilic attack, carried out at low temperature, does not yield the square pyramidal cations which have been observed by performing the reaction at room temperature.[13] The three $[(PP_3)Rh]^+$ synthons react at −50 °C with an equimolar amount of P_4 yielding the complex cation $[(PP_3)Rh(\eta^1\text{-}P_4)]^+$ **(2)**, Scheme 2, which is stable up to −20 °C and decomposes unspecifically at higher temperature. The high reactivity of the cations **1** and **2** prevented their isolation as pure solids, and accordingly they have been characterized in solution by $^{31}P\{^1H\}$ NMR spectroscopy.

The $^{31}P\{^1H\}$ NMR spectra of the complexes **1** and **2** do not change in the temperature ranges investigated (from −70 to −40 °C for **1** and from −50 to −20 °C for **2**), which allows us to exclude dynamic behaviour. They exhibit four resonances (see the Experimental Section) with intensity ratios 1:3:1:3, the most significant difference between the spectra of the cobalt and of the rhodium derivative being due to the coupling with ^{103}Rh in compound **2**. Thus the cobalt derivative exhibits an AC_3FL_3 spin system and the rhodium derivative gives an AC_3FL_3X spin system, which are both consistent with a trigonal bipyramidal geometry around the metal. The metal should therefore be bound to the four donors of the tripodal PP_3 ligand and to one phosphorus atom of the intact P_4 molecule. The shifts and the coupling constants of the polyphosphane P atoms are typical for cobalt(I)[14] and rhodium(I)[13] complexes with trigonal bipyramidal geometry. The phosphorus atom (P_F) of the P_4 molecule which is bound to the metal is deshielded with respect to those of the "distal" P_3 face; the latter are only slightly affected by the nature of the metal fragment and have chemical shifts close to that of free P_4. These data are in accordance with those found for the few other complexes containing an intact P_4 molecule end-on bound to a metal fragment (Table 1). The values of the direct coupling constants $^1J_{P_FP_L}$ for all compounds, ranging from 185 to 235 Hz, are relatively close to each other. The bridgehead phosphorus of the PP_3 ligand in the two compounds is highly deshielded with respect to the value found for PP_3 in cobalt(I)[17] and rhodium(I)[13] complexes with coligands such as CO, PPh_3, CH_3, Ph, Cl^- and H^- in the fifth position.

In an attempt to rationalize some aspects of the bonding in these compounds both extended-Hückel[18] (EH) and ab initio[19] Hartree−Fock (HF) calculations were undertaken on model systems where the presence of the polyphosphane ligand was simulated by four properly arranged PH_3 groups and the coligand was the η^1-coordinated P_4 cage or, for comparison, the CO or Cl^- moiety. The HF calculations were of the single-point energy type, except for a preliminary set in which the metal−phosphorus distances were optimized: the ratios between distances at the energy minimum (individual values being unreliable at the level of the

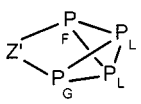
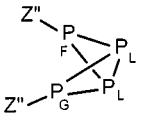
[a] Data of the present work.

model) showed that the P_4 cage is competitive with the PH_3 groups as a ligand. The basis set in the HF calculations was either the LANL2DZ,[20] or it ranged from the 6−31G(d)[21] to the 6−311+G(d,p)[22] if the Rh metal was replaced by Co in the model. The pattern of atomic charges yielded by the EH calculations run with standard parameters[18] agrees with the trend expected in view of the NMR results, with the phosphorus atom in the bridgehead position of the phosphane ligand bearing a higher positive charge than the peripheral P atoms and with positive/negative charges for the coordinating/distal P_4 atoms. The HF calculations yield a similar pattern if polarization functions are included in the basis set. Although with differences in detail, both types of calculations give the same picture for bonding of the cage molecule to the metal, through an analysis of the changes in the atomic-orbital occupancies as the P_4 molecule is allowed to approach the metal centre from a distance. A synergic mechanism is in action, with σ-donation from the apical P_4 atom to the metal and back-donation from metal π orbitals. The latter shift of electron density reaches the distal P atoms of the cage through its peripheral MO′s. As expected, there are substantial analogies with the picture obtained for the model with the CO coligand and notable differences with respect to the Cl^- model. The values of the isotropic shielding tensor for atoms of the P_4 model compound agree with the expected trend, but the calculations do not provide a clue to the significantly higher deshielding of the bridgehead polyphosphane P atom in a P_4 than in a (for example) CO derivative.

The *ortho*-metallated product[13] which forms by electrophilic attack of CF_3SO_3Me on $[(NP_3)RhH]$ reacts in a short time at −20 °C (see Scheme 3) with a stoichiometric amount of P_4 in THF yielding, after addition of $NaBPh_4$, a pale-red compound of formula $[(NP_3)Rh(\eta^2\text{-}P_4)]BPh_4$ **(3)**. The solid, which has been isolated at low temperature, may be stored under inert atmosphere at room temperature but it decomposes in solution above 10 °C. Compound **3** exhibits at 0 °C a $^{31}P\{^1H\}$ NMR spectrum (see the Experimental Section) which presents five resonances with intensity ratios 2:1:1:1:2; it has been successfully simulated as an A_2CFGL_2X spin system. The two low-field resonances at $\delta = 29.8$ and -12.5 are due to the phosphorus atoms of the NP_3 ligand and are consistent with an octahedral rhodium(III)[13] complex having two chemically and magnetically equivalent phosphorus atoms (P_A) *trans* to each other and the third one (P_C) in the *cis* position (Scheme 3). The three high-field resonances are due to the four phosphorus atoms of the P_4 unit. Those at comparatively low field are assigned to atoms, P_F ($\delta = -224.3$) and P_G ($\delta = -194.5$) occupying the coordination sites, hereafter "equatorial", lying opposite the P_C and the NP_3 nitrogen positions. Finally, the resonance ($\delta = -237.8$) occurring at higher field is attributed to the two phosphorus atoms of the bicyclotetraphosphane (P_L) which are not bound to the metal. The P_F and P_G signals, in view of their different multiplicities, have been assigned considering that the one with higher multiplicity should be due to the phosphorus atom (P_G) lying *trans* to the P_C phosphorus atom of NP_3. The equivalence of the P_L sites suggests that the bond joining them should be normal to the equatorial plane and parallel to the line connecting the P_A positions. The weak coupling (40 Hz; see Experimental Section) between the inequivalent wing-tip atoms (P_F and P_G) in compound **3**, points to an open P_4 frame, which accounts for the presence of "through-metal" geminal coupling of the coordinating P atoms.





Scheme 3. Reaction of $[(NP_3)Rh]^+$ species with white phosphorus

On lowering the temperature below −40 °C the P_L and P_A signals become more complex and the positions of the sites are no longer equivalent. On the other hand, the chemical shifts of all absorptions, and the shapes of the remaining three signals, are substantially unchanged. The reversibility of this diversification points to the presence of a dynamic behaviour. The low activation barrier and the small deviations in the NMR parameters for the P_A and P_L sets suggest limited changes in stereochemistry for the two pairs of phosphorus atoms on the NMR time-scale at low temperature.

The NMR spectroscopic data for coordinating bicyclotetraphosphane in complexes of this type reported up to now appear in Table 2; they refer to compounds which contain insertion products of one metal fragment into a P−P bond (*endo-endo*) or two metal fragments bound to the wing-tip P atoms of the butterfly skeleton (*exo-exo*). As might be expected, the chemical shift of the wing-tip atoms depends heavily on the electronic and steric properties of the metal fragment. These resonances are shifted to lower field with respect to the P_2 backbone phosphorus atoms, which exhibit absorptions between $\delta = -377$ and -214, in the high-field region typical for phosphorus atoms participating in small cycles.[23] Interestingly, the chemical shift difference ($\Delta\delta = \delta P_F - \delta P_L$) within the P_4 ligand is smaller for the heavier group-9 complexes.

[a] Data of the present work.

The remarkable difference in reactivity between $[(PP_3)Rh]^+$ and $[(NP_3)Rh]^+$ toward white phosphorus is in line with other results reported for the organometallic chemistry of the two systems.[13,14] The attainment of a pseudo-octahedral coordination geometry, as proposed for **3**, involves a considerable increase for one of the P−Rh−P angles formed by the peripheral P atoms of the ligand. It was pointed out on the basis of EH calculations on model systems for the tripod ligand and the four-coordinate metal[24] that such deformation should be easier for $[(NP_3)Rh]^+$ than for $[(PP_3)Rh]^+$ as a consequence of the early occurrence of a HOMO−LUMO avoided crossing in the former case. By similar (EH) calculational procedures we expect the $[(NP_3)Rh]^+$ system to be more prone to distortion than the $[(NP_3)Co]^+$ one because of a smaller HOMO−LUMO gap for the former, in the undistorted geometry over a range of reasonable metal−donor atom distances. These conclusions (easier angle opening in presence of the NP_3 ligand and of the Rh metal) are supported by trends in single-point energy values calculated by the HF method with LANL2DZ basis functions at various points of the deformation path and for various sets of metal−donor atom distances (one NH_3 group being used in addition to the PH_3 groups to mimic the NP_3 donors). However, the angle opening is definitely disfavoured in all cases if a fifth ligand, such as η^1-P_4, is allowed to approach the metal from the direction opposite the bridgehead atom position, since this has a dramatic effect on the HOMO−LUMO gap, reducing the extent of the intended crossing and the effects on the rehybridization at the metal, which are essential for a process of oxidative addition. On the other hand, it appears that suitable conditions for the oxidative addition may consist of a concerted P−Rh−P angle opening and side-on P_4 approach to the two prospective pseudo-octahedral sites. As shown in Figure 1, produced by the EH calculations, even in the early stages of such a path the metal atom develops a suitable hybrid HOMO to interact with the LUMO of the P_4 fragment. As a consequence of this, even at a distance of ca. 2.8 Å between the metal centre and each of the two P_4 atoms, set at 2.4 Å from each other, a 70% decrease in the value of the overlap population of the approaching P−P bond has already occurred, while the values for the incipient Rh−$P(P_4)$ bonds are already half as large as those for the bonds formed by rhodium with the phosphane P atoms.

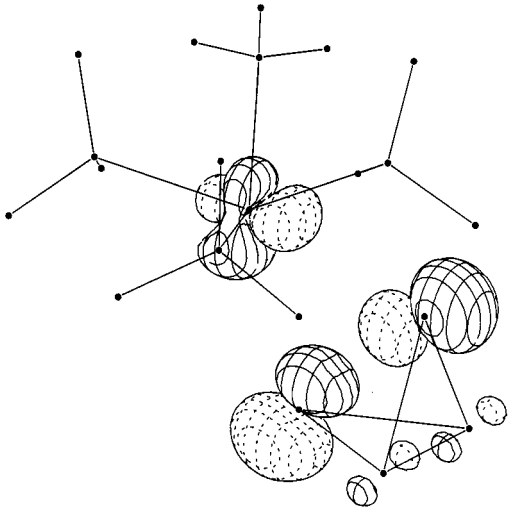

Figure 1. Drawing, from EH calculations, of significant parts of the HOMO for the model of $[(NP_3)Rh]^+$ interacting with partially cleaved P_4; according to a fragment orbital analysis, the main contributions are from the fragment cation HOMO and the P_4 LUMO; the bonding Rh···$P(P_4)$ and antibonding P···P interactions may be appreciated

Experimental Section

General: All reactions and manipulations were performed under an atmosphere of dry oxygen-free argon, unless otherwise stated. THF was freshly distilled from potassium; toluene and diethyl ether were freshly distilled from sodium. – $^{31}P\{^1H\}$ NMR spectra were measured in [D_8]THF on a Bruker AC 200 spectrometer at 81.02 MHz. Chemical shifts are relative to 85% H_3PO_4 as external standard at 0.00 ppm. – Analytical data for carbon, hydrogen, nitrogen and phosphorus were obtained from the Microanalytical Laboratory of the Department of Chemistry of the University of Florence. – The hydride complexes [(PP_3)CoH],[14] [(PP_3)RhH] and [(NP_3)RhH][13] were prepared according to the literature methods; CF_3SO_3Me (Aldrich) was used as purchased and stored at 0 °C.

Synthesis of [(PP_3)Co(P_4)]CF_3SO_3 (1): Neat CF_3SO_3Me (0.05 mmol) stored under nitrogen was added at room temperature to [(PP_3)CoH] (36 mg, 0.05 mmol) dissolved in [D_8]THF (0.8 mL). The resulting solution was stirred for 10 min and then cooled to −70 °C. P_4 (0.055 mmol) dissolved in THF (0.7 mL) was added and the resulting solution was immediately investigated at this temperature by NMR spectroscopy. – $^{31}P\{^1H\}$ ([D_8]THF, 233 K, 81.02 MHz): δ = 194.8 (dm, $^2J_{P_AP_C}$ = 35.0 Hz, $^2J_{P_AP_F}$ = 178.0 Hz, $^3J_{P_AP_L}$ = 5.0 Hz, 1 P, P_A), 73.6 (ddm, $^2J_{P_CP_F}$ = 71.0 Hz, $^3J_{P_CP_L}$ = 1.7 Hz, 3 P, P_C), −333.5 (m, $^1J_{P_FP_L}$ = 219.0 Hz, 1 P, P_F), −472.3 (dm, 3 P, P_L).

Synthesis of [(PP_3)Rh(P_4)]CF_3SO_3 (2): The rhodium derivative was prepared following the same procedure as described for **1** by adding P_4 (0.05 mmol) dissolved in THF (0.5 mL) to the clear solution obtained by adding CF_3SO_3Me (0.04 mmol) to [(PP_3)RhH] (31 mg, 0.04 mmol) in [D_8]THF (0.5 mL). – $^{31}P\{^1H\}$ ([D_8]THF, 223 K, 81.02 MHz): δ = 175.3 (ddm, $^1J_{P_ARh}$ = 111.9 Hz, $^2J_{P_AP_C}$ = 15.3 Hz, $^2J_{P_AP_F}$ = 399.3 Hz, $^3J_{P_AP_L}$ = 12.7 Hz, 1 P, P_A), 59.8 (ddd, $^1J_{P_FRh}$ = 134.8 Hz, $^2J_{P_CP_F}$ = 61.0 Hz, 3 P, P_C), −372.5 (m, $^1J_{P_FRh}$ = 111.0 Hz, $^1J_{P_FP_L}$ = 226.5 Hz, 1 P, P_F), −493.8 (dd, 3 P, P_L).

Synthesis of [(NP_3)Rh(P_4)]BPh_4 (3): CF_3SO_3Me (0.16 mmol) was added to a suspension of [(NP_3)RhH] (114 mg, 0.15 mmol) in THF (20 mL) at room temperature in a Schlenk tube and stirred for 30 min. The resulting clear yellow solution was cooled to −10 °C and P_4 (20 mg, 0.16 mmol) dissolved in THF (5 mL) was added. The solution turned dark red within 3 h. Solid $NaBPh_4$ (103 mg, 0.3 mmol) was then added. Concentration of the resulting solution at −30 °C yielded orange red microcrystals within 7 days, which were separated from the solvent, washed with toluene, diethyl ether and dried (120 mg, yield *ca* 67%). – $^{31}P\{^1H\}$ ([D_8]THF, 253 K, 81.02 MHz): δ = 29.8 (dd, $^1J_{P_ARh}$ = 110.6 Hz, $^2J_{P_AP_C}$ = 24.8 Hz, 2 P, P_A), −12.5 (ddt, $^1J_{P_CRh}$ = 86.0 Hz, $^2J_{P_CP_G}$ = 40.0 Hz, 1 P, P_C), −194.5 (tq, $^1J_{P_GRh}$ = 40 Hz, $^2J_{P_GP_L}$ = 166.0, $^2J_{P_GP_F}$ = 40 Hz, 1 P, P_G), −224.3 (tt, $^1J_{P_FRh}{}^1J_{PFRh}$ = 40 Hz, $^1J_{P_FP_L}$ = 160 Hz, 1 P, P_F), −237.8 (tm, 2 P, P_L). – $C_{66}H_{62}BNP_7Rh$ (1199.7): calcd. C 66.07, H 5.21, N 1.17, P 18.07; found C 66.02, H 5.26, N 1.09, P 17.85.

Synthesis, Structures, and Crystalline Packing Features of [Co(tren)(amino acidato-*N*,*O*)]$X_2 \cdot nH_2O$ (X = ClO_4^-, I^-)

Jiwen Cai,*[a] Xiaopeng Hu,[b] Xiaolong Feng,[a] Weiyan Shao,[a] Liangnian Ji,*[b] and Ivan Bernal*[c]

Keywords: Cobalt / Tripodal ligands / N ligands / Amino acids

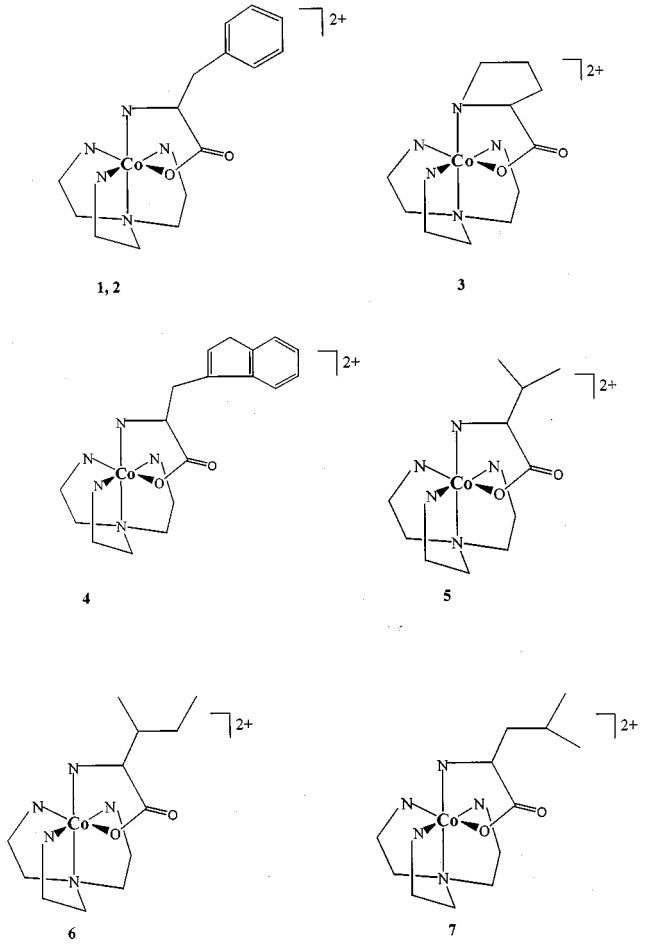
The crystal structures of several novel compounds, *trans*(*N*,*t*-*N*) isomers of [Co(tren)(DL-phenylalaninato)]$(ClO_4)_2$ (**1**), [Co(tren)(L-phenylalaninato)]$I_2 \cdot H_2O$ (**2**), [Co(tren)(L-prolinato)]$I_2 \cdot H_2O$ (**3**), [Co(tren)(L-tryptophanato)]$(ClO_4)_2 \cdot {}^1/_2H_2O$ (**4**), [Co(tren)(L-valinato)]$I_2 \cdot {}^1/_3H_2O$ (**5**), [Co(tren)(L-isoleucinato)]I_2 (**6**), and [Co(tren)(L-leucinato)]I_2 (**7**), have been determined. Their packing arrangements indicate that the complex cations in all of the compounds form helical strings running along their crystallographic axes, for both chiral and racemic amino acidato species. Intermolecular double and single hydrogen bonds are formed by the carbonyl oxygens and amino hydrogens of the tren ligand or of the amino acidato moiety, either directly or by the assistance of water molecules of hydration. In this fashion, [Co(tren)(amino acidato-*N*,*O*)]$^{2+}$ is strung together into helical arrays. In the racemic compounds, the complex cations of different strings have opposite chirality. Phenylalanine is racemized during the coordination process, under mild pH (7.5–8.0) and temperature (60 °C). This is quite unusual. Finally, 1D and 2D (COSY) ^{1}H NMR spectra were recorded, in which compound **4** shows interesting cross-peak correlations between the phenyl protons and amino protons.

Introduction

Recently, it was reported[1] that the monooxamide anion is hydrolyzed by dihalo-Co^{III} complexes containing various types of polyamine tetradentate ligands, such as $(en)_2$, 3,2,3-tet (1,5,8,12-tetraaminododecane), trien, or tren, to give their corresponding oxalato compounds. Thus, we decided to systematically investigate the mechanism of this hydrolytic process of amide and peptide cleavage catalyzed by *cis*-$[CoN_4Cl_2]^+$, in comparison with that of *cis*-$[CoN_4(H_2O)(OH)]^{2+}$ reported by Buckingham, et al.[2–9] Of particular interest are the chiral and stereochemical problems associated with this process.

Our first efforts were directed towards the synthesis and characterization of the structures of $[Co(N_4)(\text{amino acidato})]^{2+}$ (N_4 = trien and tren) complexes with different types of amino acids. This data could then be used to help identify the steric nature of the hydrolysis products, which is not available crystallographically. Here, we report the crystal structures, including packing features, of seven novel *trans*(*N*,*t*-*N*) isomers of [Co(tren)(DL-phenylalaninato)]$(ClO_4)_2$ (**1**), [Co(tren) (L-phenylalaninato)]$I_2 \cdot H_2O$ (**2**), [Co(tren)(L-prolinato)]$I_2 \cdot H_2O$ (**3**), [Co(tren)(L-tryptophanato)]$(ClO_4)_2 \cdot {}^1/_2H_2O$ (**4**), [Co(tren)(L-valinato)]$I_2 \cdot {}^1/_3H_2O$ (**5**), [Co(tren)(L-isoleucinato)]I_2 (**6**), [Co(tren)(L-leucinato)]I_2 (**7**), where *trans*(*N*,*t*-*N*) refers to one of the two possible geometric isomers in which the tertiary nitrogen atom of tren is in the position *trans* to the amide nitrogen of the amino acidato cation.[10]

The starting amino acids used for the preparation are all of the natural L form. The DL-phenylalaninato was obtained as a result of racemization during the synthesis in mild pH (7.5−8.0) and temperature (60 °C). Finally, of particular interest is the observation that chiral helical arrays are observed in all of the crystals examined, both in the optically active and the racemic forms of amino acidato complexes.



Results and Discussion

Racemization of Phenylalanine

The starting materials used in this study were all of the natural L form of the amino acids. Interestingly, we found that one of the amino acids, phenylalanine, racemized during the process of preparation under very mild conditions of pH (7.5−8.0) and temperature (60 °C); while no crystallographic evidence of racemization was observed for the other amino acids involved in this study. The mechanism of amino acid racemization reactions involves the removal of the α-hydrogen and the stabilization of the resulting planar carbanion. It has been reported that racemization of phenylalanine takes place in vitamin B_6-amino acid Schiff base copper complexes in mildly acidic solutions,[11] in which the activation of the αC−H group is due to the π-π intermolecular interaction which is claimed to be the reason

for the unusual racemization. Racemization of phenylalanine has also been observed in bis(2,2′-bipyridine) ruthenium(II) complexes in basic solution.[12] The asymmetric transformation of α-amino acids promoted by optically active Co^{III} complexes at pH 10−12 carbonate buffer has been examined by Yamaguchi.[13] However, the influence of substituents of the amino acid on the isomerization process was not elucidated, and further efforts are required to explain the unusual phenylalanine racemization observed in this study, for the following reasons: (1) It takes place under rather mild condition; (2) No crystallographic evidence of racemization is observed for other chelated amino acids, such as proline, tryptophan, valine, isoleucine, and leucine, under the same solution conditions.

Finally, we are aware that the fact that some of these complexes crystallize in enantiomorphic space groups does not necessarily mean that they are pure optically active compounds to begin with. It could be the result of conglomerate crystallization of the racemates.[14] Therefore, other experimental measurements, such as CD spectra, were required to exclude the possibility that other amino acids were racemized under the same conditions, and then proceeded to undergo conglomerate crystallization. Such a process has been documented in the case of Schiff base.[15]

Description of the Structures and Packing

Compounds **1** and **2**: With regard to the conformation of the coordination sphere, the most obvious difference between these two complexes is the orientation of the phenyl rings, as indicated in Figure 1 and Figure 2. The ^1H NMR spectra of these two compounds are identical implying that packing effects could be the driving force for this difference. In compound **1**, a single hydrogen bond between the carbonyl oxygen of one complex and the amino hydrogen of the amino acidato ligand from an adjacent complex leads to a head-to-tail linking of complexes of the same chirality to form cation strings running along the *c* axis. Looking down the *c* axis, one can see a column-like structure of the complexes, with the phenyl rings stacked on top of one another. The counter anions fill the gaps between the columns.

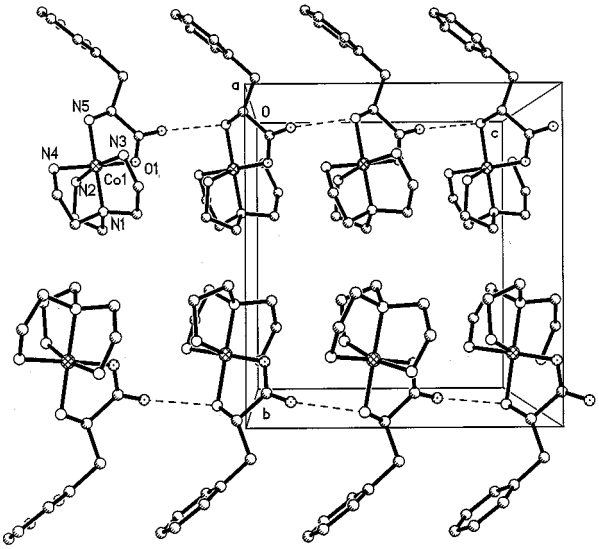

Figure 1. Spiral strings formed by the cations in the racemic compound **1**. The chirality of phenylanine shown is D. Cation strings run along *c* axis. When looking down along the *c* axis, phenyl rings and cations pack on top of each other, forming a column-like structure. Selected bond lengths: Co1−O1 1.903(3), Co1−N1 1.945(4), Co1−N2 1.955(4), Co1−N3 1.979(4), Co1−N4 1.954(4), Co1−N5 1.948(4) Å

The optically active form of compound **2** has a similar hydrogen-bonding motif, except that the chain runs along the *a* axis, and the phenyl rings are positioned around the chain axis.

Compounds **3**−**5**: Figure 3 shows that in compound **3** the cations are 'stitched' together in zigzag chains by an intermediary water molecule. In compound **4**, there are two independent molecules in the asymmetric unit. Figure 4 shows that the hydrogen-bonding motif is slightly different from that observed in compounds **1**−**3**. There are two cations in the repeating unit of the helical strings. Two intermolecular hydrogen-bonding interactions are observed in compound **5**, in which the cations interact in a head-to-tail fashion, see Figure 5. In this case, the carbonyl oxygen interacts with both the amino hydrogens of tren and with those of the amino acidato ligand.

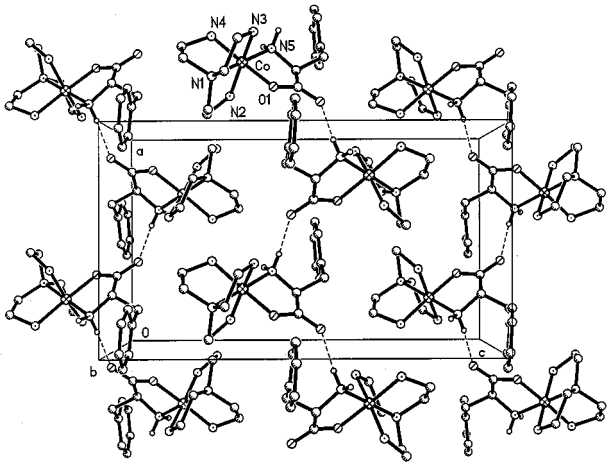

Figure 2. Spiral strings formed in compound **2**. Zigzag chains run along the *a* axis. When looking down along the *a* axis, phenyl rings wrap around the axis, instead of packing on top of each other as observed in compound **1**. Spiral strings run in space in ↑ ↓ fashion. Selected bond lengths: Co−O1 1.900(3), Co−N1 1.948(4), Co−N2 1.968(4), Co−N3 1.960(4), Co−N4 1.955(4), Co−N5 1.948(4) Å

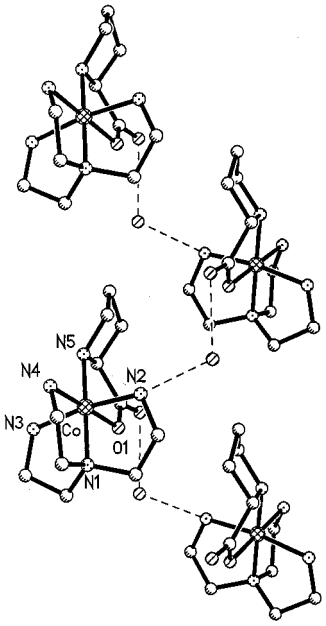

Figure 3. Spiral strings formed in compound **3**. The cations are "stitched" together by a water molecule, instead of direct cation-cation interaction. Selected bond lengths: Co−O1 1.900(3), Co−N1 1.960(5), Co−N2 1.965(5), Co−N3 1.974(5), Co−N4 1.956(5), Co−N5 1.959(5) Å

Compound **6**: Compound **6** contains helical strings running along the *b* axis with the typical head-to-tail hydrogen bonding observed in compound **5**, see Figure 6. In the reported racemic structure, a pair of head-to-head hydrogen bonds is formed between two complexes when the counter anions are iodides,[10b] whereas the perchlorate crystallizes in conglomerate solid solution, in the space group $P3_1$.[10c] A similar hydrogen-bonding motif is observed in the perchlorate complex as that in compound **6**, except that the

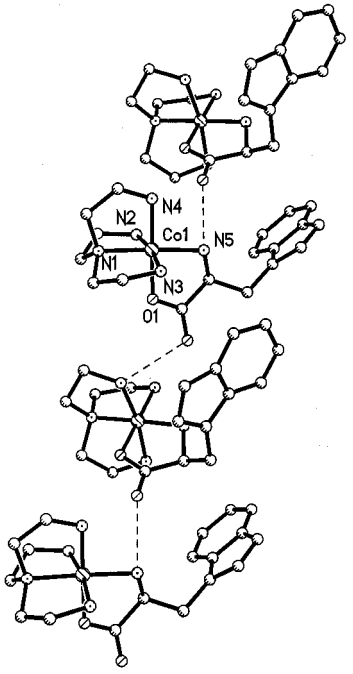

Figure 4. Spiral strings formed in compound **4**. There are two independent cations in the asymmetric unit and the conformation of the aromatic rings are slightly different. Selected bond lengths of Co1: Co1−O1 1.899(3), Co1−N1 1.949(5), Co1−N2 1.942(5), Co1−N3 1.957(5), Co1−N4 1.929(4), Co1−N5 1.952(4) Å

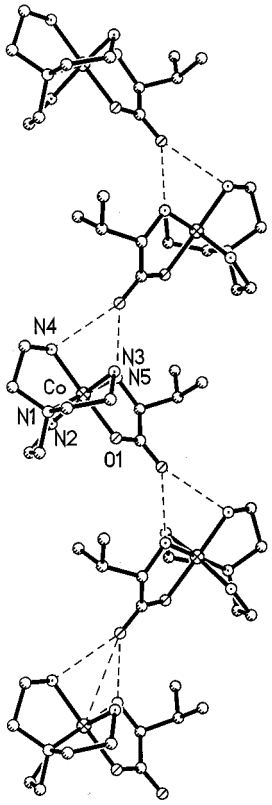

Figure 5. Spiral strings formed in compound **5**. Note that the hydrogen-bonding motif has been changed from single for the aromatic-substituted side chain to double for the aliphatic side chain. Selected bond lengths: Co−O1 1.921(3), Co−N1 1.949(4), Co−N2 1.953(4), Co−N3 1.968(4), Co−N4 1.940(4), Co−N5 1.948(4) Å

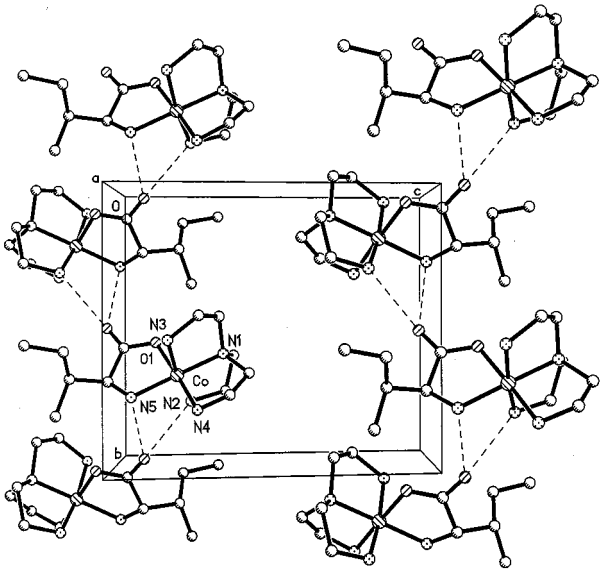

Figure 6. Spiral strings formed in compound **6**. Strings run in space in ↑ ↑ fashion. Selected bond lengths: Co−O1 1.906(4), Co−N1 1.943(5), Co−N2 1.974(5), Co−N3 1.984(6), Co−N4 1.935(5), Co−N5 1.940(5) Å

amino acidato groups in the different strings have different chirality.

Compound **7**: This compound crystallizes in the same unit cell, space group, and packing mode as the racemate reported previously.[10c] They make an interesting pair of optically active and racemic compounds that crystallize in the same space group with very similar packing properties. The racemic mixture is actually a conglomerate solid solution, in which the D and L form of the amino acidato group occupy alternative positions in the lattice. Interested readers are referred to the original copy for more detail.

Fundamental aspects of the packing modes adopted by the optically active and racemic species of [Co(tren)(amino acidato)]$^{2+}$ are the chiral helical strings observed in these systems:

(1) All helical strings are formed by intermolecular hydrogen bonds. In less bulky substituted amino acids such as valine, leucine, isoleucine, there are double hydrogen bonds; while with bulkier substituted amino acids such as phenylalanine, tryptophan, and proline, there are single hydrogen bonds. In both situations, the carbonyl oxygen atoms interact with the amino hydrogens of tren and/or with those of the amino acidato fragment.

(2) Hydrogen-bonding interactions can be very strong, as indicated by the favorable angles and distances. For instance, in compound **2**, the angle of N−H···O is 172° and N···O = 3.0 Å for the intermolecular hydrogen bond; while for **1**, the angle is 153° and the distance is 2.8 Å;

(3) Strings run in space either in a head-to-head ↑ ↑ fashion, as observed in compound **6**; or in a head-to-tail ↑ ↓ fashion, as observed in compound **2**;

(4) In the racemic form, helical strings have a similar packing mode as that observed in the optically active one, and intermolecular hydrogen-bonding interactions bring complexes of the same chirality together in those strings.

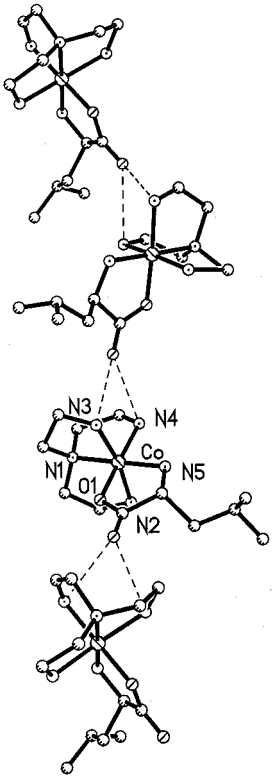

Figure 7. Spiral strings formed in compound **7**. The intermilecular hydroge-bonding interactions are the same as those observed in the racemic complex, except that the amino acidato ligands in different strings have different chirality in the racemic structure. Selected bond lengths: Co−O1 1.884(3), Co−N1 1.948(4), Co−N2 1.965(4), Co−N3 1.980(4), Co−N4 1.960(4), Co−N5 1.938(4) Å

However, the complexes of adjacent strings have opposite chirality. Since the hydrogen-bonding fashion observed in the racemic crystal is the same as that observed in the optically active form, we refer to it as the "chiral recognition motif" of these systems;

(5) Based upon our observations and understanding of conglomerate crystallization,[16] we can predict that [Co(tren)(amino acidato-*N*,*O*)]$^{2+}$ is a system that tends to favor conglomerate crystallization, if the "right stitching agents", (i.e. the counter anions and solvent), are chosen. This is consistent with the reported crystal structures of *trans*(*N*,*t*,*N*)-[Co(tren)(DL-leu)]I_2, *trans*(*N*,*t*,*N*)-[Co(tren)(DL-Ilu)]$(ClO_4)_2$, and *trans*(*N*,*t*,*N*)-[Co(tren) (DL-Val)]$(ClO_4)_2$.[10c]

1D and 2D ^{1}H NMR Spectra

In order to identify the individual protons, COSY spectra of compounds **1** to **4** were recorded. Individual peaks are resolved. Chemical shifts for the amino protons of tren range from δ = 3.92 to 5.09. It is difficult to assign chemical shifts for individual alkyl protons from the three different $N-CH_2-CH_2-NH_2$ arms. The spectra show that, for all four compounds, shifts from two arms are close, δ ≈ 2.9 and 3.3, while the others shift more upfield, δ ≈ 2.6 and 3.1. The upfield shifts are assigned to the arm that is *trans* to the carbonyl oxygen (referring to the coordinated position to Co^{III}). Interestingly, we observe that in the COSY

spectra of compound **4**, there are three cross peaks between three pairs of protons from the aromatic ring and the amino groups of tren; they are δ = 7.41 and 3.92, 7.13 and 4.18, 7.04 and 4.26, respectively. Based on the molecular structure shown in Figure 4, these protons are far away from each other and are not in parallel planes, therefore, there should not be any correlation. At present, we have no explanation for this long-range correlation.

Conclusion

It is interesting to note that chiral helical strings are formed among the cations $[Co(tren)(amino\ acidato)]^{2+}$, irrespective of the chirality and the nature of the substituted side chain of the amino acids. We hope that this observation will provide some information to further understand the chiral recognition processes that so readily occur in biological processes.

Experimental Section

All reagents were commercially available and used as received. − Elemental analyses were carried out with a Perkin−Elmer 240 elemental analyzer. − ^{1}H NMR spectra were recorded on a Varian UNITY/NOVA 500 NMR spectrometer using [D_6]DMSO as the solvent and TMS as the internal standard. A small amount of D_2O was added to the solution in order to assign the exchangeable protons after the spectra was recorded in [D_6]DMSO.

Safety Notes: Perchlorate salts of metal complexes with organic ligands are potentially explosive. Only a small amount of material should be prepared and handled with great care.

Syntheses: Compounds were prepared according to the synthetic procedure originally described by Collman.[4] The pH of an aqueous solution of *cis*-α-[Co(tren)Cl_2]Cl (1.0 g, 0.003mol), was adjusted to 7.5−8.0 using freshly prepared 10% NaOH solution, whereupon the color of the solution changed to pink. An equimolar amount of amino acid was added while the pH was kept at 7.5−8.0. After heating at 60 °C for several hours in a water bath, the resulting solution was cooled to room temperature and filtered. Calculated amounts of KI or $NaClO_4$ were added to the resulting solution, and crystals suitable for X-ray diffraction were obtained after several days.

Elemental Analyses and ^{1}H NMR Spectroscopic Data

[Co(tren)(DL-phenylalaninato)]$(ClO_4)_2$ (1): $C_{15}H_{28}Cl_2CoN_5O_{10}$ (568.25): calcd. C 31.70, N 12.33, H 4.97; found C 30.20, N 12.60, H 4.81. Yield: 0.54 g, 30%.

[Co(tren)(L-phenylalaninato)]$I_2 \cdot H_2O$ (2): $C_{15}H_{30}CoI_2N_5O_3$ (641.17): calcd. C 28.01, N 10.93, H 4.72; found C 27.92, N 10.82, H 4.80. Yield: 0.74 g, 36%.

Compounds **1** and **2** have identical ^{1}H NMR: δ = 7.41 (d, ^3J = 8.0 Hz, 2 H, CH), 7.32 (d, ^3J = 7.5 Hz, 2 H, CH), 7.31 (t, ^3J = 9.0 Hz, 1 H, CH), 5.70 (t, ^3J = 8.0 Hz, 1 H, NH), 5.01 (m, 1 H, NH), 4.99 (m, 1 H, CH_2), 4.54 (t, ^3J = 10.0 Hz, 1 H, NH), 4.42 (m, 1 H, CH_2), 4.18 (m, 1 H, CH_2), 4.04 (m, 1 H, NH_2), 3.93 (m, 1 H, NH_2), 3.54 (m, 1 H, CH), 3.26−3.42 (m, 5 H, CH_2), 3.11 (t, ^3J = 7.5 Hz, 2 H, CH_2), 2.98 (m, 4 H, CH_2), 2.88 (dd, ^2J = 15 Hz, ^3J = 11.5 Hz, 1 H, CH_2), 2.66 (t, ^3J = 7.5 Hz, 2 H, CH_2).

[Co(tren)(L-prolinato)]$I_2 \cdot H_2O$ (3): $C_{11}H_{28}CoI_2N_5O_3$ (591.11): calcd. C 22.35, N 11.85, H 4.77, found C 22.51, N 10.79, H 4.70. − ^{1}H NMR: δ = 6.75 (m, 1 H, NH), 5.09 (m, 1 H, NH_2), 5.04 (m, 1 H, NH_2), 4.74 (m, 1 H, NH_2), 4.55 (m, 2 H, NH_2), 4.09 (m, 1 H, CH_2), 3.87 (d, ^3J = 9.0 Hz, 1 H, CH), 3.41 (m, 2 H, CH_2), 3.21 (m, 4 H, CH_2), 3.01 (dd, ^2J = 10 Hz, ^3J = 5.0 Hz, 1 H, CH_2), 2.93 (m, 3 H, CH_2), 2.72 (m, 2 H, CH_2), 2.43 (m, 1 H, CH_2), 2.14 (m, 1 H, CH_2), 1.96 (m, 1 H, CH_2), 1.89 (m, 1 H, CH_2), 1.74 (m, 1 H, CH_2). − Yield: 0.65 g, 34%.

[Co(tren)(L-tryptophanato)]$(ClO_4)_2 \cdot {}^1/_2H_2O$ (4): $C_{17}H_{31}Cl_2CoN_6O_{10.50}$ (617.30): calcd. C 33.04, N 13.60, H 5.02; found C, 35.91, N 11.42, H 5.97. − Yield: 0.72 g, 39%. − ^{1}H NMR: δ = 10.99 (s, 1 H, NH), 7.52 (d, ^3J = 8.0 Hz, 1 H, CH), 7.41 (d, ^3J = 7.5 Hz, 1 H, CH), 7.31 (d, ^3J = 2.0 Hz, 1 H, CH), 7.13 (td, ^3J = 8.0 Hz, ^4J = 1.0 Hz, 1 H, CH), 7.04 (td, ^3J = 8.0 Hz, ^4J = 1.0 Hz, 1 H, CH), 5.8 (m, 1 H, NH_2), 5.04 (m, 2 H, NH_2), 4.56 (m, 2 H, NH_2), 4.28 (m, 1 H, NH_2), 4.18 (m, 1 H, NH_2), 3.92 (m, 1 H, NH_2), 3.61 (m, 1 H, CH), 3.39 (m, 1 H, CH_2), 3.31 (m, 4 H, CH_2), 3.11 (t, ^3J = 6.0 Hz, 2 H, CH_2), 2.98 (m, 4 H, CH_2), 2.91 (m, 1 H, CH_2), 2.63 (t, ^3J = 6.0 Hz, 2 H, CH_2).

[Co(tren)(L-valinato)]$I_2 \cdot {}^1/_3H_2O$ (5): $C_{11}H_{28.67}CoI_2N_5O_{2.33}$ (581.06): calcd. C 22.71, N 12.04; H 4.93; found C, 23.89, N 12.58, H 5.32. − Yield: 0.71 g, 39%. − ^{1}H NMR: δ = 5.96 (t, J = 9.5 Hz, 1 H, NH_2), 5.03 (m, 1 H, NH_2), 4.73 (t, ^3J = 10.0 Hz, 1 H, NH_2), 4.50−4.40 (m, 3 H, NH_2), 4.18 (t, ^3J = 9.5 Hz, 1 H, NH_2), 3.98 (t, ^3J = 9.0 Hz, 1 H, NH_2), 3.42−3.30 (m, 4 H, CH_2), 3.24 (m, 3 H, CH_2, CH), 3.16−2.99 (m, 4 H, CH_2), 2.75 (brt, ^3J = 5.5 Hz, 2 H, CH_2), 2.21 (m, 1 H, CH_2), 1.09 (d, ^3J = 6.5 Hz, 3 H, CH_3), 0.93 (d, ^3J = 7.0 Hz, 3 H, CH_3).

[Co(tren)(L-isoleucinato)]I_2 (6): $C_{12}H_{30}CoI_2N_5O_2$ (589.14): calcd. C 24.46, N 11.19, H 5.13; found C 25.01, N 11.30, H 4.92. − Yield: 0.78 g, 41%. − ^{1}H NMR: δ = 6.01 (t, ^3J = 9.0 Hz, 1 H, NH_2), 5.05 (m, 1 H, NH_2), 4.74 (t, ^3J = 10.5 Hz, 1 H, NH_2), 4.49 (m, 2 H, NH_2), 4.38 (m, 1 H, NH_2), 4.21 (m, 1 H, NH_2), 3.98 (m, 1 H, NH_2), 3.43−3.27 (m, 5 H, CH_2, CH), 3.20 (m, 2 H, CH_2), 3.03−2.92 (m, 4 H, CH_2), 2.73 (m, 2 H, CH_2), 1.89 (m, 1 H, CH), 1.49 (m, 1 H, CH_2), 1.17 (m, 1 H, CH_2), 1.06 (d, ^3J = 7.0 Hz, 3 H, CH_3), 0.90 (t, ^3J = 7.5 Hz, 3 H, CH_3).

[Co(tren)(L-leucinato)]I_2 (7): $C_{12}H_{30}CoI_2N_5O_2$ (589.13): calcd. C 24.46, N 11.19, H 5.13, found C 25.21, N 11.53, H 4.98. − Yield: 0.66 g, 35%. − ^{1}H NMR: δ = 5.95 (t, ^3J = 9.5 Hz, 1 H, NH_2), 5.00 (m, 2 H, NH_2), 4.77 (t, ^3J = 10.0 Hz, 1 H, NH_2), 4.50 (m, 1 H, NH_2), 4.35 (m, 1 H, NH_2), 4.04 (m, 2 H, NH_2), 3.34 (m, 5 H, CH_2, CH), 3.15 (m, 2 H, CH_2), 3.01−2.94 (m, 4 H, CH_2), 2.72 (m, 2 H, CH_2), 1.85 (m, 2 H, CH), 1.61 (m, 2 H, CH_2), 0.99 (d, ^3J = 7.0 Hz, 3 H, CH_3), 0.94 (d, ^3J = 6.5 Hz, 3 H, CH_3).

X-ray Crystallography

Experimental details of the X-ray analyses are provided in Table 1 and Table 2. All diffraction data were collected on a Bruker Smart 1000 CCD diffractometer with graphite monochromated Mo-K_α radiation (λ= 0.71073 Å) at room temperature using the program SMART[17] and processed by SAINT+.[18] Absorption correction was applied by SADABS.[19]

Space groups of these compounds were determined from systematic absences and further justified by the results of refinement. In compound **1**, it was noted that the $|E^*E - 1| = 0.831$ and that systematic absences indicate that it crystallizes in the polar (non-centro-

symmetric) space group $Pca2_1$, suggesting that phenylalanine racemizes during the synthetic procedure. In all cases, the structures were solved by direct methods and refined using full-matrix least-squares/difference Fourier techniques using SHELXTL.[20−22] All non-hydrogen atoms were refined with anisotropic displacement parameters. All hydrogen atoms of the ligands were then placed at idealized positions and refined as riding atoms with the relative isotropic parameters of the heavy atoms to which they are attached. Figure 1 through 7 show the cation conformations and packing feature of these complexes. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Center as supplementary publication number CCDC 141454 − CCDC 141460. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK. Fax: (internat.) + 44−1233/336-033; E-mail: deposit@ccdc.cam.ac.uk.

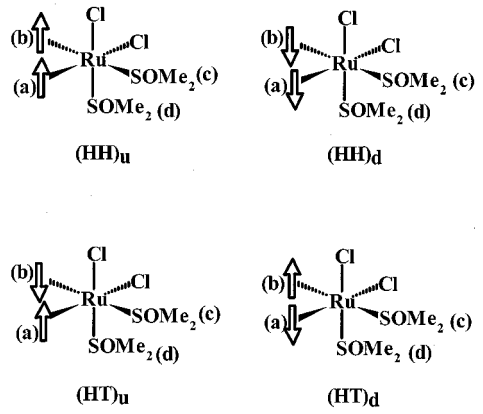
Keywords: Ruthenium / Dimethyl sulfoxide / N ligands / Molecular dynamics / Atropisomerism / Bioinorganic chemistry

In order to analyze the roles of steric and electrostatic factors in determining the orientation and dynamic behavior of benzimidazole-type ligands in Ru^{II}(dimethyl sulfoxide) complexes, compounds of the general formula $RuX_2(dmso\text{-}S)_{2-n}(CO)_n(L)_2$ [X = Cl, Br; L = 1,5,6-trimethylbenzimidazole (Me_3Bzm), benzimidazole (Bzm); n = 0–2] with *cis* and *trans* arrangements of the X ligands, have been prepared and structurally characterized both in solution and in the solid state, by NMR and X-ray techniques, respectively. New descriptors, based on the torsion angles about the Ru–N bonds, are introduced for a more efficient definition of the head-to-head (HH) and head-to-tail (HT) orientations of the heterocyclic nitrogen bases. Similar descriptors, based on the torsion angles about the Ru–S bonds, are used to define the orientation of the dimethyl sulfoxide ligands. The experimental molecular conformations are discussed on the basis of molecular mechanics (MM) calculations. The electrostatic interaction between the halide ligands and the positively charged N_2CH proton on the imidazole ring has been found to be the essential factor in determining the specific orientation of one Me_3Bzm base, both in the solid state and in solution. The different stabilities of the HH and HT base conformations observed in solution, in the solid state, and in the isolated molecules are rationalized in terms of solvation and packing effects. The larger solvent-accessible surface area in the HH conformation as compared with that in the HT form leads to more effective intermolecular interactions, which are responsible for stabilizing the former geometry in the condensed phase.

Introduction

The *cis*-M(L1)(L2) unit, where L1 and L2 are either the same or different planar aromatic N-donor ligands, is a common motif in biological systems, in particular in cross-links formed by DNA with metal anticancer drugs and in metalloenzymes.[1] These units are usually highly dynamic and difficult to evaluate in solution. Consequently, there have been relatively few cases where rotation of the L1 and L2 ligands about the M−N bond has proved to be sufficiently slow for structural and dynamic features to be assessed.[2−8] We have found that improved insight into the features of such units can be gained by studying complexes of the bioligand 1,5,6-trimethylbenzimidazole (Me_3Bzm) (Scheme 1) and comparing the results of studies on analogs with the non-biological pyridine ligands. Various types of information can be gained since bioligands are typically non-C_2-symmetric (i.e. lopsided), whereas the selected non-biological ligands are C_2-symmetric. When both ligands in the *cis*-M(L1)(L2) unit are lopsided, there are four possible major rotamers: two with head-to-head (HH) orientation and two with head-to-tail (HT) orientation (Scheme 2). When only one ligand is lopsided, there are two rotamers. When neither ligand is lopsided, there is only one possible rotamer. If the lopsided ligands L1 and L2 are identical, and the metal center and "spectator" (also called carrier) ligands form a highly symmetric carrier ligand−metal center moiety, only one HH rotamer is possible. One further feature is that some of the HT rotamers may be enantiomers.



Scheme 1. Schematic representation of the generic octahedral *c*,*c*,*c*-$RuCl_2(dmso\text{-}S)_2(L1)(L2)$[9] (left, with labeling scheme of ligand positions) and *t*,*c*,*c*-$RuCl_2(dmso\text{-}S)_2(L1)(L2)$[9] (right) isomers; in this work L1 = L2 = Me_3Bzm (bottom, showing numbering scheme and intraligand NOE connectivity path), while either one or both dmso-S ligands may be replaced by CO

We recently reported that restricted rotation about Ru−N bonds in octahedral complexes of the type *cis*,*cis*,*cis*-$RuCl_2(dmso\text{-}S)_2(L1)(L2)$[9] (L1 *trans* to Cl, L2 *trans* to dmso-S; Scheme 1) allows assessment of the relative ori-

Scheme 2. Schematic representation of the four possible major rotamers of *c*,*c*,*c*-$RuCl_2$(dmso-S)$_2$(Me_3Bzm)$_2$ (**1**); Me_3Bzm is indicated with an arrow, with the head corresponding to B2H

entation and dynamic motion of two *cis*-coordinated N-donor aromatic ligands. The use of C_2-symmetric ligands, such as pyridine (py) and 3,5-lutidine (3,5-lut), in combination with non-C_2-symmetric ligands such as Me_3Bzm and 1,2-dimethylimidazole (1,2-Me_2Im) provides more insight than the use of either type alone.[1−5,8] NMR investigations of the dynamic behavior of such compounds in solution showed that, at ambient temperature, they exist in a definite number of conformers that are in an essentially slow-exchange equilibrium, the position of which depends on the nature of the nitrogen bases.

The results obtained with Me_3Bzm were particularly significant as they indicated that its dynamic behavior was strongly influenced not only by steric factors, but also by electrostatic interactions.[1] In Me_3Bzm, which is a nucleopurine analog, the N_2CH proton on the imidazole ring (B2H) is relatively acidic and hence bears a partial positive charge (δ+), which is increased upon coordination to metal centers. We found that in ruthenium(II)[1−5] and rhenium(V)[8] Me_3Bzm complexes, the electrostatic attraction between the $N_2CH^{\delta+}$ proton(s) and the negative ligands (e.g. oxo, Cl) is important in determining the observed conformations. In particular, the solid-state structures of *c*,*c*,*c*-$RuCl_2$(dmso-S)$_2$(Me_3Bzm)$_2$, *c*,*c*,*c*-$RuCl_2$(dmso-S)$_2$(1,2-Me_2Im)(Me_3Bzm), and *c*,*c*,*c*-$RuCl_2$(dmso-S)$_2$(py)(Me_3Bzm) showed that the Me_3Bzm *trans* to dmso-S has the same orientation in the three complexes, with the mean plane of the ligand almost bisecting the Cl−Ru−Cl angle and B2H almost equidistant from the two Cl atoms. Moreover, for *c*,*c*,*c*-$RuCl_2$(dmso-S)$_2$(1,2-Me_2Im)(Me_3Bzm) and *c*,*c*,*c*-$RuCl_2$(dmso-S)$_2$(py)(Me_3Bzm) we found no evidence of the other possible geometrical isomer, i.e. that with Me_3Bzm *trans* to Cl. In solution, extensive NMR investigations provided strong evidence that, at ambient temperature, the Me_3Bzm *trans* to dmso-S remains relatively fixed, maintaining an orientation very similar to that found in the solid state; the dynamic behavior of the other N-donor ligand depends on its nature.[2−4] In *c*,*c*,*c*-$RuCl_2$(dmso-S)$_2$(Me_3Bzm)$_2$, the Me_3Bzm *trans* to Cl slowly (on the NMR time scale) flips between two orientations at ca. 180°, thus generating one HH and one HT rotamer of almost equal stability. Only the rare (at the time) HH atropisomer was found in the solid state.[2,3]

The imidazole ring is a common feature of many biological ligands. The electrostatic interaction between the $N_2CH^{\delta+}$ proton and the other ligands is likely to be of general relevance for all those biological systems in which metal sites are bound to imidazole rings (e.g. B_{12} systems, Pt drug adducts of DNA, metalloenzymes, and metalloproteins).[1]

In order to analyze in greater detail the roles of steric and electrostatic factors in determining the orientation and dynamic behavior of the Me_3Bzm ligand, we have prepared and studied some new Me_3Bzm (and Bzm) Ru^{II} compounds closely related to those mentioned above. As compared to the thoroughly investigated complex *c*,*c*,*c*-$RuCl_2$(dmso-S)$_2$(Me_3Bzm)$_2$ (**1**), we have changed the nature of the halogen (Br vs. Cl), the geometry of the complex (*trans*,*cis*,*cis* vs. *cis*,*cis*,*cis*),[9] and the number of dmso-S ligands (replaced by CO molecules). Thus, we have prepared and investigated on the basis of NMR and X-ray structural data in conjunction with molecular mechanics (MM) calculations, the two series of geometrical isomers of the formula *cis*,*cis*,*cis*- and *trans*,*cis*,*cis*-RuX_2(dmso-S)$_{2-n}$(CO)$_n$(L)$_2$ [X = Cl, Br; L = 1,5,6-trimethylbenzimidazole (Me_3Bzm), benzimidazole (Bzm); n = 0−2]. In particular, the compounds reported here are: *c*,*c*,*c*-$RuBr_2$(dmso-S)$_2$(Me_3Bzm)$_2$ (**2**), *t*,*c*,*c*-$RuCl_2$(dmso-S)$_2$(Me_3Bzm)$_2$ (**3**), *t*,*c*,*c*-$RuCl_2$(dmso-S)$_2$(Bzm)$_2$ (**4**), *c*,*c*,*c*-$RuCl_2$(dmso-S)(CO)(Me_3Bzm)$_2$ (**5**), *t*,*c*,*c*-$RuCl_2$(dmso-S)(CO)(Me_3Bzm)$_2$ (**6**), and *c*,*c*,*c*-$RuCl_2$(CO)$_2$(Me_3Bzm)$_2$ (**7**). Finally, with the aim of establishing whether the polarity of the medium of crystallization and/or packing interactions might affect the solid-state molecular conformation, we recrystallized **1** from hot benzene rather than from dmso/acetone mixtures,[3] which furnished crystals of *c*,*c*,*c*-$RuCl_2$(dmso-S)$_2$(Me_3Bzm)$_2$·2C_6H_6 (**8**). The crystal structure of **8** has been determined, as have those of **2**−**6**.

Results

Crystal and Molecular Structures

Coordination distances and sulfoxide bond lengths and angles for complexes **2**−**6** and **8** (Table 1 and 2) fall well within the ranges of values found in Ru^{II} compounds.[10] Merging the present data with those reported previously, mean values of 2.139(6) and 2.440(4) Å are obtained, respectively, for the Ru−N and Ru−Cl distances *trans* to sulfur, while those not *trans* to sulfur amount to 2.110(4) and 2.417(4) Å, respectively. The observed lengthenings of 0.029 Å (Ru−N) and 0.023 Å (Ru−Cl) confirm the *trans* influence of *S*-bonded dmso on the relevant Ru−N and Ru−Cl bonds.[10a] The Ru−C and Ru−S bond lengths in the carbonyl derivatives [1.832(6) and 2.284(1) Å, respectively, in **5**; 1.843(4) and 2.284(1) Å in **6**] are close to those reported for Ru^{II}(monocarbonyl)(dmso-S) complexes.[11] Interestingly, the Ru−S distances in **5** and **6** [2.284(1) Å] are significantly longer than those in **1**−**4** and **8** [av. 2.248(3) Å], as would be expected following the introduc-

tion of a strong π acceptor ligand into the coordination sphere.[11] Furthermore, the previously observed deformation of the Ru−N−C bond angles in benzimidazole complexes is also fully confirmed here. In fact, the average Ru−N(1)−C(5), Ru−N(1)−C(14), Ru−N(2)−C(15), and Ru−N(2)−C(24) bond angles measure 123.6(8)°, 130.8(6)°, 120.5(3)°, and 134.3(5)°, respectively, in agreement with previous data.[2,3,5]

A summary of the solid-state conformational parameters for the RuX_2(dmso-S)$_2$(L1)(L2) (X = Cl, Br; L1, L2 = Me_3Bzm, Bzm, or 1,2-Me_2Im) and $RuCl_2$(dmso-S)(CO)(Me_3Bzm)$_2$ complexes is given in Table 3 (see Discussion for conformation descriptors). These data show that, in spite of the presence of benzene molecules of crystallization, the molecular structure of the complex *c*,*c*,*c*-$RuCl_2$(dmso-S)$_2$(Me_3Bzm)$_2$ in **8** is comparable to that in **1**. Analogously, the molecular conformation of the bromo derivative *c*,*c*,*c*-$RuBr_2$(dmso-S)$_2$(Me_3Bzm)$_2$ (**2**) is very similar to that of **1**, and is practically unaffected by the presence of ethanol molecules in the lattice. The same labeling scheme has been used for the RuX_2(dmso-S)$_{2-n}$(CO)$_n$(Me_3Bzm)$_2$ moiety in all the complexes (X = Cl or Br, n = 0−2), as illustrated in Figures 1, 2 and 3, which show the molecular structures of **2**, **3**, **5**, and **6**.

Solution Studies

For the sake of clarity, the labeling schemes for the coordination positions of the ligands[9] and for the Me_3Bzm protons (Scheme 1) used in this work are the same as those used in our previous reports.[1−5] In particular, we label the base *trans* to Cl as "a", the base *trans* to S as "b", and the dmso ligands *trans* to "b" and Cl as "c" and "d", respectively.

cis,cis,cis Compounds

cis,cis,cis-$RuCl_2$(dmso-S)(CO)(Me_3Bzm)$_2$ (**5**)

This complex can be thought of as being formally derived from **1** through the replacement of dmso-S "d" by CO (Scheme 3). The ^{1}H NMR spectrum of **5** shows only one set of peaks for each non-equivalent Me_3Bzm ligand and one resonance for each diastereotopic dmso-S methyl group (Figure 4), as expected for an unsymmetrical *cis,cis,cis* complex. All resonances are sharp and no evidence for conformational equilibria due to hindered rotation of the nitrogen ligands is apparent at room temperature.

Table 3. Base and dmso solid-state conformational parameters, Ψ and Φ [°], with their diastereotopomer descriptors of some *c*,*c*,*c*- and *t*,*c*,*c*-$RuX_2(dmso\text{-}S)_{2-n}(CO)_n(L1)(L2)$ complexes, with X = Cl, Br; *n* = 0, 1; L1, L2 = Me_3Bzm, Bzm, 1,2-Me_2Im

Even though two isomers with a *cis*,*cis*,*cis* geometry are possible, depending on whether CO is *trans* to Cl or to Me_3Bzm, we isolated exclusively the compound in which CO is *trans* to Cl (as confirmed by the X-ray structure, see below) and found no evidence to suggest the existence of the other isomer. The resonances were assigned with the aid of a NOESY spectrum (Table 4); the intra-ligand NOE connectivity path ($B2H-B12H_3-B7H-B10H_3-B11H_3-B4H$; Scheme 1) allowed designation of the signals arising from each Me_3Bzm moiety, while the final assignment of the Me_3Bzm position as either "a" (i.e. *cis* to the dmso-S) or "b" (i.e. *trans* to dmso-S) was accomplished through the inter-ligand NOE contacts. In particular, from

Scheme 3

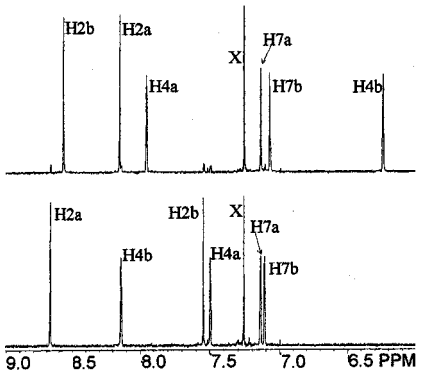

Figure 4. Downfield region of the ^{1}H NMR spectrum ($CDCl_3$, 400 MHz) of *c*,*c*,*c*-$RuCl_2$(dmso-S)(CO)(Me_3Bzm)$_2$ (**5**) (top) and *t*,*c*,*c*-$RuCl_2$(dmso-S)(CO)(Me_3Bzm)$_2$ (**6**) (bottom); resonances of Me_3Bzm "a" and "b" are labeled with a and b, respectively

a clear NOE cross-peak between the B4H resonance at δ = 7.96 and the dmso peak at δ = 3.11, it could be established that the two ligands are *cis* to one another. The overall chemical shift patterns of the Me_3Bzm "a" and "b" ligands in **5** closely resemble those found in the HH rotamer of *c*,*c*,*c*-$RuCl_2$(dmso-S)$_2$(Me_3Bzm)$_2$ (**1**-HH, Table 4); in particular, the (B4H)b and ($B10H_3$)b signals are upfield shifted, suggesting that these protons might reside within the shielding cone of Me_3Bzm "a". Similarly, the upfield shift of the (B2H)a signal and, to a lesser extent, that due to ($B12H_3$)a, can be attributed to their positions within the shielding cone of Me_3Bzm "b". According to such arguments, an HH conformation similar to that found in the crystal structure of **5** (see below and Table 3) is most likely maintained in solution.

of B4H, is maintained. It might be argued that such differences are caused by the presence of CO instead of dmso-S in the coordination sphere of the ruthenium center. However, the Me_3Bzm chemical shifts are very similar in the corresponding mono-Me_3Bzm derivatives, *c*,*c*,*c*-$RuCl_2$(dmso-S)$_2$(CO)(Me_3Bzm) and *cis*,*fac*-$RuCl_2$(dmso-S)$_3$(Me_3Bzm), which differ only in the presence of a CO molecule in place of a dmso-S ligand in position "a".[12] This finding suggests that the differences in Me_3Bzm chemical shifts found between **1**-HH and **5** are not due to the different ligand environments (CO vs. dmso-S), but rather to a slightly different average mutual tilt between the two HH ligands in solution.[1]

The ambient-temperature NMR spectrum of **5**, which shows only one set of resonances, is consistent with two hypotheses: either both the Me_3Bzm ligands are in rapid motion about the Ru−N bonds, averaging the HH conformation, or they both remain in relatively fixed positions. Variable-temperature NMR spectra of **5** in CD_2Cl_2 showed a partial broadening of the peaks only at $T < -90$ °C, which is still compatible with both hypotheses (the very low temperature broadening might also be due to restricted motion of the sulfoxides).

cis,*cis*,*cis*-$RuCl_2(CO)_2(Me_3Bzm)_2$ (**7**)

Further formal replacement of the remaining dmso-S ligand in **5** by CO led to compound **7**, in which both positions "c" and "d" are occupied by CO ligands (Scheme 3). Overall, the Me_3Bzm resonances of **7** give rise to a pattern similar to that seen for **5** and typical of the HH orientation

Table 4. Chemical shifts (δ values) of *c*,*c*,*c*-$RuCl_2$(dmso-S)(CO)(Me_3Bzm)$_2$ (**5**), *t*,*c*,*c*-$RuCl_2$(dmso-S)(CO)(Me_3Bzm)$_2$ (**6**), and *c*,*c*,*c*-$RuCl_2(CO)_2(Me_3Bzm)_2$ (**7**) in $CDCl_3$ compared to those of the corresponding ligands in the HH conformer of *c*,*c*,*c*-$RuCl_2$(dmso-S)$_2$(Me_3Bzm)$_2$ (**1**)

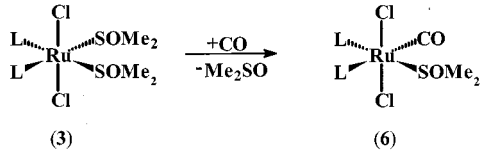
[a] Conformer HH.

Despite the general similarity between the Me_3Bzm chemical shift patterns of **5** and **1**-HH, there are, nevertheless, some notable differences, particularly in the signal shifts of Me_3Bzm "a". Thus, while in **1**-HH the B4H signal appears further downfield than that of B2H, in **5** the "normal" order, i.e. the B2H signal further downfield than that (Table 4); the presence of CO in place of the residual dmso-S apparently has no significant effect on the resonances of the *trans*-coordinated Me_3Bzm. In this case, a NOESY spectrum did not allow us to distinguish between positions "a" and "b" and thus we assumed the HH orientation of the two Me_3Bzm ligands to be very similar to that in **5**.

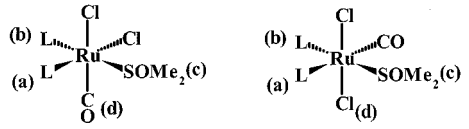
However, a "reciprocal" HH orientation cannot be excluded (see below for **6**). From the point of view of the dynamics of the Me_3Bzm ligands, the ^1H NMR spectrum of **7** (which remained essentially unchanged in the temperature range +20 to −90 °C) is consistent with both the hypotheses advanced for **5**.



trans,cis,cis Compounds

trans,cis,cis-$RuCl_2$(dmso-S)$_2$(Me_3Bzm)$_2$ (**3**)

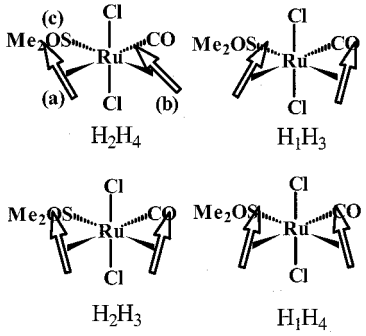
The room-temperature reaction of *trans*-$RuCl_2$(dmso-S)$_4$ with an excess of Me_3Bzm selectively yielded the bis-substituted adduct **3**, which is a geometrical isomer of *c,c,c*-$RuCl_2$(dmso-S)$_2$(Me_3Bzm)$_2$ (**1**) (Scheme 1). The NMR spectrum of **3** is very simple (one set of peaks due to the two equivalent Me_3Bzm ligands and one sharp resonance due to the four equivalent dmso-S methyl groups) and consistent with the C_{2v} symmetry of the complex (considering the ligands as point groups). This NMR spectral pattern indicates that at room temperature the two Me_3Bzm ligands are in rapid motion about the Ru−N bonds, most probably going from one HT conformation to the other, through the HH conformation. The variable-temperature behavior of the NMR spectrum of **3** (CD_2Cl_2) is rather complicated and scarcely informative; all resonances broaden as the temperature is lowered to below −20 °C, and at −60 °C two sets of peaks in an almost 1:2 ratio begin to appear. However, on decreasing the temperature further, some of the signals broaden once more. These findings suggest that on lowering the temperature the rate of more than one molecular motion in **3** is sequentially decreased.



trans,cis,cis-$RuCl_2$(dmso-S)(CO)(Me_3Bzm)$_2$ (**6**)

The formal replacement of a dmso-S ligand in **3** by a CO ligand (Scheme 4) led to *trans,cis,cis*-$RuCl_2$(dmso-S)(CO)(Me_3Bzm)$_2$ (**6**), which is a geometrical isomer of **5** (Scheme 5). Compound **6**, while maintaining the overall geometry of **3**, nevertheless, has lower symmetry and thus provided useful spectroscopic information.

(3) (6)



Scheme 4

Scheme 5 (5) (6)

The NMR spectrum of **6** (Figure 4), in agreement with the geometry of the complex (confirmed by X-ray structure analysis, see below), consists of a set of resonances due to each non-equivalent Me_3Bzm ligand and a singlet due to the two enantiotopic methyl groups of the dmso-S ligand (δ = 3.41). This means that the N,N,S,C plane is a plane of symmetry for the complex and, as in **3**, the two Me_3Bzm ligands have averaged "side" (S) orientations. The signals were assigned with the aid of an NOESY spectrum (Table 4); an NOE cross-peak between the dmso-S and the B4H signal at δ = 8.14 allowed us to establish which of the Me_3Bzm ligands was *cis* to dmso-S. In **6**, the two *cis*-Me_3Bzm ligands and the dmso-S ligand have the same *mer* arrangement as in the geometrical isomer **5**, so that the same labeling scheme can be used (Scheme 5). Indeed, the NMR spectra of **6** and **5** are quite similar and both are in agreement with an HH orientation of the two bases. However, in **6** the chemical shift patterns of Me_3Bzm "a" and "b" are inverted with respect to those in **5** (Figure 4).

It might be argued that the different Me_3Bzm chemical shift patterns in **5** and **6** are due to the strong *trans* effect of the CO ligand. However, on the basis of results obtained for similar compounds,[13] substitution of dmso-S by CO is expected to affect the resonance of the proton closest to the N−Ru, i.e. B2H of Me_3Bzm "a", only marginally (ca. 0.3 ppm). The large chemical shift variations for the protons of Me_3Bzm "a" quite distant from the coordination site (e.g. $B10H_3$) and, above all, for the protons of Me_3Bzm "b" can thus safely be ascribed to a different mutual tilt of the two HH bases in **6** as compared to the situation in **5**. Indeed, in **6**, due to the lower symmetry compared to **3**, the two HH bases may either be leaning toward the dmso-S in position "c" or toward the CO (conformers H_2H_4 and H_1H_3 in Scheme 6, respectively; see Discussion). The NMR spectrum suggests that in solution the HH orientation of the two bases in **6** is such that (B4H)a and ($B10H_3$)a reside within the shielding cone of Me_3Bzm "b"; models show that this is accomplished when the two HH bases are inclined toward the dmso-S (conformer H_2H_4). This orientation, which is the opposite to that found in **1** and **5**, is also evident in the solid-state structure (Figure 3, Table 3).

Scheme 6

Variable-temperature NMR experiments in CD_2Cl_2 showed that the resonances of the two bases in **6** begin to broaden only at temperatures below −80 °C, while at such temperatures the dmso-S resonance splits into two equally intense peaks (δ = 3.35 and 3.31). This behavior suggests that at room temperature the two HH bases are most probably in rapid motion between two equivalent HH orientations, one above and the other below the N,N,S,C plane, thus averaging out as an "S" orientation. These motions

might be accompanied by that of dmso-S [so that the electrostatic interaction between (B2H)a and the oxygen atom of dmso is maintained]. At very low temperature (−80 °C), these motions (or those of the dmso-S ligand) become slow on the NMR time scale, the N,N,S,C pseudo-symmetry plane is lost, and the two methyl groups of the dmso-S become diastereotopic.

Discussion

Conformational Definitions

In unsymmetrical octahedral complexes of the type *c*,*c*,*c*-$RuCl_2(X)(Y)(Me_3Bzm)_2$, where X, Y = dmso-S or CO, two HH and two HT diastereotopomers are possible. Thus, it is necessary to designate the possible HH and HT geometries. In fact, taking the chlorine atom *cis* to both N ligands as a reference, quite different environments are achieved if the head of the Me_3Bzm ligand (B2H) is directed toward this chlorine atom or points in the opposite direction. We will indicate these positions as "up" (u) and "down" (d), respectively, so that the two HH geometries will be labeled as $(HH)_u$ and $(HH)_d$ (Scheme 2). For a more precise description of the HT conformations, the orientation of one of the two bases must be selected; we shall assume that the "u" and "d" descriptors in $(HT)_u$ and $(HT)_d$ always refer to the head of ligand "a". Furthermore, for a complete stereochemical description of such complexes, we reiterate that they can exist as enantiomeric pairs, the chirality of which can be described as Δ and Λ, taking the N···N and Cl···Cl vectors as skew lines.[14] The schemes and Figures 1−3 depict Δ enantiomers.

In order to study hindered rotation about the Ru−N bonds, torsion angles must be introduced, such as $\Psi_a = N_b-Ru-N_a-C_{\alpha a}$ and $\Psi_b = N_a-Ru-N_b-C_{\alpha b}$, where the subscripts a and b refer to the two nitrogen bases and C_α is the carbon atom in position 2 (Scheme 1). These parameters provide a precise description of all the possible HH and HT conformations, and also allow a distinction to be made between the different "head" orientations (see below). In the case of the enantiomorph Δ, $-180° < \Psi_a < 0°$ and $0° < \Psi_b < 180°$ for $(HH)_u$, and $0° < \Psi_a < 180°$, $-180° < \Psi_b < 0°$ for $(HH)_d$. The angular relationships between $(HH)_u$ and $(HH)_d$ are interchanged for the enantiomorph Λ. For the isomers $(HT)_u$ and $(HT)_d$, the ranges for the torsion angles are $-180° < \Psi_{a,b} < 0°$ and $0° < \Psi_{a,b} < 180°$, respectively. The Ψ angles also provide a quantitative measure of the mutual tilt of the two bases, which vanishes only when $\Psi_a = \Psi_b = \pm 90°$. If $\Psi = 0°$ or 180°, the hypothetical side (S) orientation occurs.

However, the (u) and (d) descriptors alone cannot adequately describe all the possible HH and HT conformations. For example, in the case of *t*,*c*,*c*-$RuCl_2(X)(Y)(Me_3Bzm)_2$ complexes there are no enantiomorphs, and the distinction between the "up" and "down" conformers is meaningless. Obviously, when X = Y, positions "a" and "b" are interchangeable; however, when X = CO and Y = dmso-S, as in *t*,*c*,*c*-$RuCl_2$(dmso-S)(CO)$(Me_3Bzm)_2$ (**6**), the two Me_3Bzm ligands are no longer equivalent, and substantially different HH and HT geometries are possible (see Scheme 6 with four HH conformers in **6**). The same concept also applies to *cis*,*cis*,*cis* complexes in which, for each $(HH)_{u/d}$ and $(HT)_{u/d}$ conformation, the two lopsided bases can have a range of different reciprocal orientations.

On the basis of the Ψ values, it is possible to formulate a new descriptor, such as $H_{\Psi a}H_{\Psi b}$ (head Ψ_a−head Ψ_b), to represent the mutual orientation of two *cis* lopsided ligands. For a simpler representation, we can use the notation H_iH_j (head *i*−head *j*), where *i* and *j* refer to the quadrants of Ψ_a and Ψ_b, respectively (*i*, *j* = 1: $0° < \Psi < 90°$; *i*, *j* = 2: $90° < \Psi < 180°$; *i*, *j* = 3: $180° < \Psi < 270°$; *i*, *j* = 4: $270° < \Psi < 360°$). This provides a simple means of describing in detail each HH and HT conformation; for example, the four HH conformers depicted in Scheme 6 can be described as H_2H_4, H_1H_3, H_2H_3, and H_1H_4, respectively. The system is particularly convenient when the torsion angles are around ±45° (or supplementary values), as found for lopsided aromatic bases.

The inter-base dihedral angle (Φ) has often been used to describe the conformations of metal complexes containing *cis* nitrogen bases.[15−17] This parameter, however, is of limited scope since, as is clear from the data in Table 3, different orientations (HH and HT) may have almost identical Φ values.

In *cis*,*cis*,*cis* complexes, when X = Y = dmso-S, the same conformational descriptors defined above for Me_3Bzm can be used for the two *cis*-dmso ligands, considering the position of the sulfoxide oxygen atom (taken as the head of the ligand) with respect to the RuS_2 plane and of the chlorine atom *cis* to both dmso ligands. If the oxygen atom lies in the RuS_2 plane, it is in a "planar" (P) orientation. Rotation about the Ru−S bonds is described by the torsion angles $\Psi_c = O_c-S_c-Ru-S_d$ and $\Psi_d = O_d-S_d-Ru-S_c$. In the case of the Δ enantiomorph, $0° < \Psi_c < 180°$, $-180° < \Psi_d < 0°$ and $-180° < \Psi_c < 0°$, $0° < \Psi_d < 180°$, for $(HH)_u$ and $(HH)_d$, respectively. For the $(HT)_u$ and $(HT)_d$ isomers (descriptors u and d being referred to the head of ligand "c"), the ranges of both the torsion angles, Ψ (= Ψ_c, Ψ_d), are: $0° < \Psi < 180°$ for $(HT)_u$ and $-180° < \Psi < 0°$ for $(HT)_d$. However, when the torsion angles are close (±15°) to the limiting values of 0°, 90°, 180°, and 270°, as for Ψ_c and Ψ_d in *cis*-sulfoxides, the more general descriptor $H_{\Psi c}H_{\Psi d}$ would seem to be more appropriate, e.g. $H_0H_{\pi/2}$ and H_0H_π, when $\Psi_c = 0°$ and $\Psi_d = 90°$ and 180°, respectively (see Table 3).

Molecular Conformations

It is interesting (cf. Table 3) that all the Δ *c*,*c*,*c*-RuX_2(dmso-S)$_2(Me_3Bzm)_2$ derivatives display HH geometries (more precisely, H_4H_2) for the Me_3Bzm ligands in the solid state, irrespective of the nature of X (Cl or Br) or of their different packing and van der Waals interactions with polar (ethanol, **2**; methanol, **5**) or apolar (benzene, **8**) solvent molecules of crystallization. However, in solution they all undergo equilibration with HT isomers of comparable stability (Table 5). It is thus clear that intermolecular pack-

ing forces are responsible for the exclusive crystallization of one form. From Table 3, it is evident that the formal substitution of a Me_3Bzm ligand by 1,2-Me_2Im (which occurs only at position "a") causes a stabilization of the HT geometry in the solid state, which is partially maintained in solution (Table 5).[4] Interestingly, in the case of *c*,*c*,*c*-$RuCl_2(dmso\text{-}S)_2(1,2\text{-}Me_2Im)(3,5\text{-lut})$, two rotamers (R1, R2) with opposite orientations of the 1,2-Me_2Im ligand were found to be present in the same crystal (ratio 0.63:0.37) as well as in solution (ratio 0.7:0.3).[5] Overall, the results indicate that the nature and relative abundance of the rotamers in solution depends markedly on the nature of the nitrogen bases; in the solid state, the equilibrium position can easily be shifted from the solution position by crystal packing effects that stabilize only one of the conformers. Generally, as shown by MM calculations,[18] the solid-state geometry corresponds to the lowest strain energy structure.

As already mentioned, it has been postulated that the hindered rotation of Me_3Bzm "b" in *c*,*c*,*c*-$RuCl_2(dmso\text{-}S)_2(Me_3Bzm)_2$ (**1**) arises from the electrostatic attraction between its acidic B2H proton and the negatively charged Cl ligands.[1] This hypothesis is supported by the present MM calculations. In fact, in the two lowest-energy conformers of Δ **1**, $(HT)_d$ and $(HH)_u$, (Table 6), Ψ_b is always about 135.6°, well within the range of 131.5−138.1° found in the solid state (Table 3). In both cases, rotation of 180° about the Ru−N_b bond ($\Psi_b \approx -44°$) causes a significant increase in the molecular strain energy [4.4 kcal mol^{-1} $(HT)_d \rightarrow (HH)_d$; 4.0 kcal mol^{-1} $(HH)_u \rightarrow (HT)_u$]; about 3 kcal mol^{-1} of this increase can be attributed to a decrease in the attractive electrostatic term (Table 6).

The favorable features of this orientation for Me_3Bzm "b" are further shown by the results relating to *c*,*c*,*c*-$RuCl_2(dmso\text{-}S)_2(1,2\text{-}Me_2Im)(Me_3Bzm)$, for which only the $(HT)_d$ (namely H_2H_2) conformer is present in the solid state and also predominates in solution (Table 5). MM calculations are in agreement with this observation, the energy of the $(HT)_d$ conformer being 1.1 kcal mol^{-1} lower than that of the $(HH)_u$ form (Table 7).

Another important result of this work is the observation that in all the Δ *c*,*c*,*c*-$RuCl_2(dmso\text{-}S)_2(L1)(L2)$ compounds in Table 3, the dmso conformation is invariably $(HH)_d$, with average values for Ψ_c and Ψ_d of $-14 \pm 12°$ and $86 \pm 6°$, respectively. This conformation corresponds to structures in which the O atom of each dmso lies approximately in the coordination plane perpendicular to the Ru−S bond of the other dmso, with the methyl groups of each dmso straddling a Ru−Cl bond. Similar conformations are found in all the minimum-energy structures calculated for the $(Me_3Bzm)_2$ and $(1,2\text{-}Me_2Im)(Me_3Bzm)$ derivatives (Tables 6 and 7). When this conformation is changed, there is a marked increase in the strain energy (Table 7). Interestingly, NMR data suggest that this geometry of the *cis*,*cis*-$RuCl_2(dmso\text{-}S)_2$ fragment is also predominant in solution.[5] In **5**, the presence of a CO group in "d" induces a rotation of ca. 80° about the Ru−S bond for dmso-S "c" (dmso O atom in the coordination plane and methyl groups again straddling a Ru−Cl bond), showing that the interligand steric interactions play a crucial role in determining the dmso orientation. Furthermore, density functional calculations on Ru^{II}(dmso-S) model molecules have shown that, even in the case of significant π bonding, steric factors far outweigh electronic effects.[19]

For *t*,*c*,*c*-$RuCl_2(dmso\text{-}S)_2(Me_3Bzm)_2$ (**3**), in agreement with the solution NMR data, MM results show (Table 8) that molecules with HT and HH base conformations have almost the same energy (max. difference 0.32 kcal mol^{-1}). Each conformer can adopt two structures with very similar minimum energies, differing only in the dmso orientation. Similar results have been obtained for *t*,*c*,*c*-$RuCl_2(dmso\text{-}S)_2(Bzm)_2$ (**4**) (Table 9). In both cases, crystallization stabilizes the HH geometry (Table 3). In solution, in agreement with NMR results, quick flipping between the isoenergetic

Unlike in the *cis*,*cis*,*cis* compounds, the solid-state conformation of the dmso groups in the *trans*,*cis*,*cis* compounds (**3** and **4**) is HT, with Ψ values of about 31° and 161° (Table 3). These values are close to the minimum energy structure values of about 24° and 169° (Tables 8 and 9). In this conformation, the two oxygen atoms are significantly displaced from the Ru−S_2 plane (ca. ±0.45 Å). However, MM calculations indicate that the energy difference between these HT arrangements and the PP arrangement (both oxygen atoms in the Ru−S_2 plane) is very small (ca. 0.1 kcal mol^{-1}) (Tables 8 and 9). In fact, a strictly symmetry-determined PP geometry of pairs of *cis*-sulfoxide ligands has been observed in *trans*-RuX_2(dmso-S)$_4$ complexes (X = Cl, Br).[20]

As in the case of **5**, substitution of one dmso group in **6** by CO causes a significant rotation about the Ru−S bond of the remaining dmso (Ψ_c approximately from 32° to −109°, Table 3). Most interestingly, the HH base mutual orientation in **6** is opposite to that found in **3** (as well as **1** and **5**), as shown by the Ψ_a and Ψ_b values (Table 3 and Figure 3). In fact, the base orientation in **3** is H_4H_2, while in **6** it is H_2H_4, as also found in solution. Such an arrangement of the neutral ligands brings the positively charged B2H of base "a" close to the negatively charged oxygen atom of dmso (H···O 3.0 Å) and to one chloride ligand (H···Cl 2.9 Å).

Limitations and Prospects for the MM Force Field

As discussed above, the force field used in the present MM calculations can describe the lowest strain energy structures in good agreement with those found in the solid state. The force field has also been found to be adequate for studying the possible rotamer distributions in solution for Ru^{II}(dimethyl sulfoxide) complexes containing lopsided nitrogen ligands such as 3,5-lutidine and 1,2-dimethylimidazole.[18a] However, inspection of the data in Table 5 shows that, unlike for the other derivatives, for *c*,*c*,*c*-$RuCl_2$(dmso-S)$_2$(Me_3Bzm)$_2$ (**1**) the strain energy ratio is not in agreement with the solution NMR data, which show that the HH and HT diastereotopomers are present in an approximately equimolar ratio. In fact, according to the MM results (Table 6), the diastereotopomer $(HT)_d$ should be predominant with a strain energy 2.1 kcal mol^{-1} lower than that of $(HH)_u$ due to a more negative contribution of the van der Waals term. It seems likely that this "anomalous" solution behavior observed in the case of *cis*-Me_3Bzm ligands is related to the larger surface area of Me_3Bzm compared to smaller ligands such as 1,2-Me_2Im and the consequently stronger interactions with solvent molecules. In fact, in solution, the two isomers of **1** are present in an almost 1:1 ratio, but only one form is present in the solid state, showing the importance of the packing intermolecular interactions. The "failure" of the MM calculations to give the lowest energy topomer in solution for **1** should be mainly due to the neglection of the effects of solvent interactions. The solvent-accessible surface area (SA) for *c*,*c*,*c*-$RuCl_2$(dmso-S)$_2$(Me_3Bzm)$_2$ is 738.7 Å^2 for the HH diastereoisomer and 718.2 Å^2 for the HT form, while it amounts to 720.7 and 705.6 Å^2, respectively, for the HH and HT isomers of *c*,*c*,*c*-$RuCl_2$(dmso-S)(CO)(Me_3Bzm)$_2$ (**5**). The greater SA values for the HH geometries could allow for more effective interactions with the solvent molecules, thereby stabilizing these forms in solution.

In any case, it must be kept in mind that the force field constants used in this work have been optimized only on the basis of crystal structure data.[18a] No thermodynamically observable parameter has been introduced, hence the calculated energy differences must be considered with caution. Another limitation of the present MM method re-

lates to the evaluation of energy barriers for rotation about the Ru−N bonds. These barriers are probably overestimated owing to the inability of the force field to describe non-minimum-energy structures. For this, non-harmonic functions and correlation terms would need to be introduced. Thus, the energy barrier of about 17 kcal mol^{-1} calculated for rotation about the Ru−N bonds in **1** must be considered merely as an indication of hindered rotation. On the other hand, a similar energy barrier of about 16 kcal mol^{-1} has been calculated for the *trans* compound **3**, for which fast rotation about the Ru−N bonds has been found in solution, showing the limited meaning of these values.

Conclusions

We have investigated the factors that influence the relative orientation and dynamic motion of the *cis*-Ru$(Me_3Bzm)_2$ unit in Ru^{II}(dimethyl sulfoxide) compounds of the general formula $RuCl_2(dmso\text{-}S)_{2-n}(CO)_n(Me_3Bzm)_2$ ($n = 0-2$). Complexes with *cis* and *trans* arrangements of the Cl ligands have been prepared and structurally characterized both in solution and in the solid state by NMR and X-ray techniques, respectively. The results have been compared with those obtained previously with the thoroughly studied *c*,*c*,*c*-$RuCl_2(dmso\text{-}S)_2(Me_3Bzm)_2$ (**1**). The influences of the nature of the halide ligands (Br vs. Cl) and of the medium of crystallization on the solid-state conformation of **1** have been also investigated. The experimental molecular conformations have been discussed on the basis of molecular mechanics (MM) calculations.

While for **1** two almost equally populated ligand orientations (HH and HT) are found in solution, replacement of one or both dmso-S molecules by CO ligands leads to the complexes *c*,*c*,*c*-$RuCl_2(dmso\text{-}S)(CO)(Me_3Bzm)_2$ (**5**) and *c*,*c*,*c*-$RuCl_2(CO)_2(Me_3Bzm)_2$ (**7**), respectively, for which only one HH orientation is preferentially populated in solution. It remains unclear as to whether in such conformers rotation of the bases about the Ru−N bonds is slow or very fast on the NMR time scale; in other words, the torsional barriers have not been estimated. Only the HH orientation was found in the solid-state structure of **5**.

We have found that the two *cis*-Me_3Bzm bases also maintain a preferential HH orientation when the geometry of the Cl ligands is changed from *cis* to *trans*; the preference for such an orientation has been demonstrated in solution for *t*,*c*,*c*-$RuCl_2(dmso\text{-}S)(CO)(Me_3Bzm)_2$ (**6**) and in the solid state for both **6** and *t*,*c*,*c*-$RuCl_2(dmso\text{-}S)_2(Me_3Bzm)_2$ (**3**). In the corresponding benzimidazole (Bzm) compound, *t*,*c*,*c*-$RuCl_2(dmso\text{-}S)_2(Bzm)_2$ (**4**), the two bases are also HH disposed in the solid state. In solution at ambient temperature, NMR evidence indicates that the two *t*,*c*,*c* complexes **3** and **6** behave differently. Thus, while the two *cis*-Me_3Bzm ligands are in rapid motion about the Ru−N bonds in **3**, most probably going from one HT conformation to the other through the HH conformation, in **6** the two bases are seemingly in rapid motion between two equivalent HH orientations, one above and the other below the N,N,S,C plane, thus averaging out as an "S" orientation. Moreover, both in solution and in the solid state, the mutual tilt of the HH bases in **6** is the opposite to that found in **1** and **5**.

Electrostatic interaction between the halide ligands and the positively charged N_2CH proton on the imidazole ring has been found to be the essential factor in determining the specific orientation of one Me_3Bzm base, both in the solid state and in solution. Comparison of the solid-state and solution structures with those predicted by MM calculations has revealed that intermolecular interactions can play a significant role in determining the orientation of the second Me_3Bzm ligand.

Experimental Section

Reagents: Analytical-grade solvents were used without further purification. All reagents, including CD_2Cl_2 and $CDCl_3$, were purchased from Aldrich.

Starting Materials: *cis*-$RuCl_2(dmso)_4$,[20] *trans*-$RuCl_2(dmso\text{-}S)_4$,[20] *cis*,*fac*-$RuCl_2(dmso)_3(CO)$,[11] *trans*-$RuCl_2(dmso)_3(CO)$,[11] *c*,*c*,*c*-$RuCl_2(dmso)_2(CO)_2$,[11] *c*,*c*,*c*-$RuCl_2(dmso\text{-}S)_2(Me_3Bzm)_2$ (**1**),[3] *c*,*c*,*c*-$RuBr_2(dmso\text{-}S)_2(Me_3Bzm)_2$ (**2**),[3] and *t*,*c*,*c*-$RuCl_2(dmso\text{-}S)_2(Bzm)_2$ (**4**)[21] were prepared by known methods.

***trans*,*cis*,*cis*-$RuCl_2(dmso\text{-}S)_2(Me_3Bzm)_2$ (3):** The complex was synthesized using as starting material either *cis*-$RuCl_2(dmso)_4$ (path a) or, preferably, *trans*-$RuCl_2(dmso\text{-}S)_4$ (path b): (a) Me_3Bzm (0.36 g, 2.25 mmol) was added to a solution of *cis*-$RuCl_2(dmso)_4$ (0.5 g, 1 mmol) in chloroform (20 mL) and the reaction was allowed to proceed overnight at room temperature. The mixture was then concentrated in vacuo to a volume of ca. 5 mL, diethyl ether (5 mL) was added dropwise, and the resulting solution was stored at 4 °C. Deep-yellow microcrystals of the product formed within 24 h, which were collected by filtration, washed with diethyl ether, and dried in vacuo. Yield 0.3 g (40%). The product was found to crystallize with one molecule of chloroform and is therefore better formulated as *t*,*c*,*c*-$RuCl_2(dmso\text{-}S)_2(Me_3Bzm)_2 \cdot CHCl_3$. Further concentration of the mother liquor yielded a second crop of precipitate. However, ^1H NMR analysis showed this to be a mixture of **3** and the *c*,*c*,*c* isomer **1**. − (b) *trans*-$RuCl_2(dmso\text{-}S)_4$ was treated with Me_3Bzm under the same conditions as used for the *cis* isomer in procedure (a). In this case, the yield was higher (70%) and no evidence for formation of the corresponding *c*,*c*,*c* isomer **1** was found. − Recrystallization from CH_2Cl_2/dmso mixtures (50:1) and subsequent addition of diethyl ether yielded crystals suitable for X-ray analysis (yield 70%). − $C_{24}H_{36}Cl_2N_4O_2RuS_2$ (648.6): calcd. C 44.4, H 5.59, N 8.63, S 9.88; found C 44.4, H 5.54, N 8.58, S 9.98. − ^1H NMR ($CDCl_3$): δ = 2.19 (s, 6 H, $B11H_3$), 2.32 (s, 6 H, $B10H_3$), 3.33 (s, 12 H, dmso-S), 3.63 (s, 6 H, $B12H_3$), 7.06 (s, 2 H, B7H), 8.18 (s, 2 H, B4H), 8.34 (s, 2 H, B2H).

***cis*,*cis*,*cis*-$RuCl_2(dmso\text{-}S)(CO)(Me_3Bzm)_2$ (5):** *cis*,*fac*-$RuCl_2(dmso)_3(CO)$ (0.19 g, 0.44 mmol) was partially dissolved in toluene (12 mL). Me_3Bzm (0.21 g, 1.31 mmol) was added and the resulting mixture was heated to reflux. A clear, pale-yellow solution was obtained within 30 min and then a precipitate of the same color formed. After 1.5 h, the hot mixture was filtered, and the collected

solid was washed with cold toluene and diethyl ether and dried in vacuo at room temperature (yield 50%). ^{1}H NMR analysis showed the crude product to contain up to 20% *t*,*c*,*c*-$RuCl_2$(dmso-S)(CO)$(Me_3Bzm)_2$ (**6**). Pure **5** (according to NMR) was obtained by recrystallization of this crude product from acetone/dmso mixtures (0.25 g in 5 mL of acetone and 0.1 mL of dmso) and subsequent careful addition of diethyl ether at room temperature (yield 75%). − $C_{23}H_{30}Cl_2N_4O_2RuS$ (598.5): calcd. C 46.1, H 5.05, N 9.36; found C 46.2, H 5.06, N 9.46. − Crystals of **5** suitable for X-ray analysis were obtained by recrystallization from methanol.

***trans*,*cis*,*cis*-$RuCl_2$(dmso-S)(CO)$(Me_3Bzm)_2$ (6):** *trans*-$RuCl_2$-$(dmso)_3$(CO) (0.20 g, 0.46 mmol) was dissolved in methanol (16 mL) and Me_3Bzm (0.18 g, 1.15 mmol) was added. The reaction was allowed to proceed for 24 h at room temperature and then the mixture was concentrated to half of its original volume. A yellow, microcrystalline product precipitated within 24 h, which was collected by filtration, washed with cold methanol and diethyl ether, and dried in vacuo at room temperature (yield 80%). Crystals suitable for X-ray analysis were obtained upon slow diffusion of *n*-hexane into a chloroform solution of the complex. −

$C_{23}H_{30}Cl_2N_4O_2RuS$ (598.5): calcd. C 46.1, H 5.05, N 9.36; found C 45.9, H 5.16, N 9.30.

***cis*,*cis*,*cis*-$RuCl_2(CO)_2(Me_3Bzm)_2$ (7):** *c*,*c*,*c*-$RuCl_2(CO)_2(dmso)_2$ (0.11 g, 0.28 mmol) was partially dissolved in ethanol (20 mL). Me_3Bzm (0.10 g, 0.62 mmol) was added and the resulting mixture was heated to reflux for 1.5 h. A clear, colorless solution was obtained within 10 min. On cooling, a white precipitate formed, which was collected by filtration, washed with cold ethanol and diethyl ether, and dried in vacuo at room temperature (yield 52 mg, 40%). ^1H NMR analysis showed this precipitate to consist of *c*,*c*,*t*-$RuCl_2(CO)_2(Me_3Bzm)$(dmso-S). − $C_{14}H_{18}Cl_2N_2O_3RuS$ (466.3): calcd. C 36.0, H 3.89, N 6.01; found C 36.0, H 3.77, N 6.00. − ^1H NMR ($CDCl_3$): δ = 2.44 and 2.42 (s, 3 H each, $B10H_3$ and $B11H_3$), 3.53 (s, 6 H, dmso-S), 3.86 (s, 3 H, $B12H_3$), 7.23 (s, 1 H, B7H), 7.37 (s, 1 H, B4H), 8.45 (s, 1 H, B2H). − Concentration of the mother liquor to a volume of 3 mL and addition of diethyl ether induced the precipitation of a second crop of white solid, which was likewise collected by filtration, washed with cold ethanol and diethyl ether, and dried in vacuo at room temperature (yield 60 mg, 40%). ^1H NMR analysis showed this second precipitate to consist of *c*,*c*,*c*-$RuCl_2(CO)_2(Me_3Bzm)_2$ slightly contaminated by the first product. Pure **7** was obtained by slow diffusion of methanol into a chloroform solution of the complex. − $C_{22}H_{24}Cl_2N_4O_2Ru$ (548.4): calcd. C 48.2, H 4.41, N 10.21; found C 48.0, H 4.40, N 10.18.

X-ray Diffraction: X-ray data were collected at room temperature [273(2) K] with an Enraf−Nonius CAD4 diffractometer using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). The data were corrected for Lorentz and polarization effects by using a local program for data reduction. All the structures were solved by Patterson and Fourier methods,[22] and refined on F^2 by full-matrix least-squares methods.[23] Difference Fourier syntheses revealed the presence of a molecule of ethanol in **2** and of methanol in **5**, which were assigned occupancy factors of 0.5 on the basis of the Fourier peaks. Hydrogen atoms were placed in calculated positions (excluding those of the alcohol molecules in **2** and **5**) and were refined as riding, setting the U_{iso} to 1.2 × U_{eq} values of the parent carbon atoms. The crystal structure of the carbonyl derivative **5** is characterized by a disordered arrangement of the six-membered ring of the Me_3Bzm ligand [namely C(7)−C(10), C(20), C(21)] over two positions with statistical occupancy factors of 50%. Unit cell data and experimental conditions are summarized in Table 10. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre and allocated the deposition numbers CCDC-139103−139108. Copies of the data can be obtained free of charge on application to the CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Molecular Mechanics: Calculations were performed with a Pentium 130 PC with the HyperChem 4.5 molecular modeling package[24] using the force field and procedures previously described for other Ru^{II}(sulfoxide complexes).[18] In calculating the electrostatic contributions, a distance-dependent relative permittivity was used. For the carbonyl derivatives, C and O charges were calculated by the semi-empirical method ZINDO/1 (C 0.33, O −0.10).[24] Stretching and bending force field constants involving the Ru−CO group, not included in the previous force field,[18] were calculated by Badger's rule, using the parameters given by Herschbach and Laurie,[25] and by Halgren's equation,[26] respectively. The following *d* and θ values were assumed: Ru−C 1.85 Å, C−O 1.14 Å, Ru−C−O 180°, X−Ru−C 90° and 180° for *cis* and *trans* X donors, respectively. Solvent-accessible surface areas were calculated by means of a HyperChem routine using a radius of 1.4 Å for the probe molecule.

Rhodium(III) Aqua Ion Salts of Ambivalent Self Assembled Superanion Capsules

Alexander Drljaca,[a] Michaele J. Hardie,[a] Timothy J. Ness,[a] and Colin L. Raston*[a]

Keywords: Calixarenes / Capsules / Crown compounds / Rhodium / Supramolecular chemistry

The self assembled superanionic capsule [{Na^+⊂(18-crown-6)$(OH_2)_2$}⊂{(*p*-sulfonatocalix[4]arene^{4-})$_2$}]$^{7-}$ (X^{7-}) forms a 1:1 crystalline complex with dinuclear $[Rh_2(\mu\text{-}OH)_2(H_2O)_8]^{4+}$ when the cation is treated with sodium *p*-sulfonatocalix[4]arene and 18-crown-6 at pH 2. The overall composition of the crystalline solid is $[Rh_2(\mu\text{-}OH)_2(H_2O)_8][X + 3\ H^+]\cdot 11.5H_2O$. Treatment of a complex mixture of polynuclear rhodium(III) aqua ions in perchloric acid with excess sodium *p*-sulfonatocalix[4]arene and 18-crown-6 at pH 2, results in selective retrieval of the tri- and tetranuclear rhodium(III) species in a single 1:1 co-crystallised phase, isolated as the hydrate salt with overall composition $[Rh_3(\mu\text{-}OH)_4(H_2O)_{10}][Rh_4(\mu\text{-}OH)_6(H_2O)_{12}][2\ X + 3\ H^+][Na(H_2O)(ClO_4)]_2\cdot 27H_2O$. The tri- and tetranuclear Rh cations both have a cyclic structure with μ-hydroxide and terminal water ligands. Despite the differences in cation charge and size both complexes show the same arrangement of polynuclear cations and superanions although the trimer/tetramer complex shows additional coordination of a second Na centre by the calixarenes. At pH 0.35 the reaction leads to the selective retrieval of the tetranuclear cation in the complex $[Rh_4(\mu\text{-}OH)_6(H_2O)_{12}][X + \{X - 2\ H_2O\} + 8\ H^+]\cdot 33H_2O$, where a second type of dehydrated superanion is found, where the two sodium bound water molecules have been replaced by O-centres of calixarene sulfonate groups, illustrating the versatile nature of the superanion chemistry.

Introduction

Selective crystallisation of polynuclear metal aqua cations from solutions containing a range of complex polynuclear aqua species has recently been established for a self-assembled superanion capable of taking on different charge to accommodate the surrounding cations.[1,2] The superanion [{Na^+⊂(18-crown-6)$(OH_2)_2$}⊂{(*p*-sulfonatocalix[4]arene^{4-})$_2$}]$^{7-}$, abbreviated hereafter as X^{7-}, is composed of a central sodium ion bound by two *trans* water molecules and an 18-crown-6, and this complex is shrouded by two *p*-sulfonatocalix[4]arenes which hydrogen bond to the inner-sphere water molecules creating a Russian doll-like assembly (Figure 1). Cohesion in the solid state comes from interplay of different supramolecular interactions, notably hydrogen bonding, which includes those for water molecules of crystallisation, electrostatics, π-stacking, and van der Waals. Thus far $[Cr_4(OH)_6(H_2O)_{12}]^{6+}$ and $[Al_{13}O_4(OH)_{24}(H_2O)_{12}]^{7+}$ have been selectively retrieved from complex mixtures using this approach.[1,2] Electrostatic repulsion between the calixarenes in the superanions is overcome by the large cations being situated close to the sulfonate groups of adjacent calixarenes. Purified solutions of $[Cr_2(OH)_2(H_2O)_8]^{4+}$ and $[Cr_3(OH)_4(H_2O)_{10}]^{5+}$ can form crystalline complexes with protonated X^{7-}, however the cations are partially occupied with a high degree of dynamic disorder, and cohesion in the solid state is derived instead from extensive π stacking and hydrogen bonding interactions between the superanions.[1] The related though smaller anionic capsule [H_4(cyclam)⊂{(*p*-sulfonatocalix[4]arene)$_2$}]$^{4-}$ also forms a crystalline complex with $[Cr_2(OH)_2(H_2O)_8]^{4+}$ where the cation is once more ordered and forms close interactions with the sulfonate groups of the superanion.[3] The ionic capsules in this work relate to a recent surge of studies on the self assembly of molecular capsules constructed mainly using hydrogen bonding,[4,5] although hydrophobic interactions and metal coordination mechanisms are also known.[4] Examples of second sphere supramolecular complexation are rare, limited to a metal−cryptate−cavitand assembly[6] as well as second sphere cyclodextrin complexes.[7]

In further exploring this approach we have investigated superanion complexation of polynuclear rhodium(III) aqua cations. Solutions of pure dinuclear rhodium(III) cation $[Rh_2(\mu\text{-}OH)_2(H_2O)_8]^{4+}$ with crown ether and sulfonated calixarene at low pH give a crystalline complex of the superanion in a 1:1 ratio with the dinuclear rhodium(III) cation, with composition $[Rh_2(\mu\text{-}OH)_2(H_2O)_8][X + 3\ H^+]\cdot 11.5H_2O$, **1**. Remarkably, we find that with a mixture of Rh^{III} oligomers treated under the same conditions, the tri- and tetranuclear cations, $[Rh_3(\mu\text{-}OH)_4(H_2O)_{10}]^{5+}$ and $[Rh_4(\mu\text{-}OH)_6(H_2O)_{12}]^{6+}$, Figure 1, are retrieved from solution in a single 1:1 co-crystallised phase, as a hydrate salt of the self assembled ionic capsule and Na perchlorate with overall composition $[Rh_3(\mu\text{-}OH)_4(H_2O)_{10}][Rh_4(\mu\text{-}OH)_6(H_2O)_{12}][2\ X + 3\ H^+][Na(H_2O)(ClO_4)]_2\cdot 27H_2O$, **2**. The ability to co-crystallise two large polynuclear aqua cations in the same solid is without precedent. Moreover, of the two cations, only the trinuclear one has been studied with its existence in solution postulated on the basis of NMR experiments,[8] and there is considerable uncertainty on the nature of higher nuclearity species. Figure 1. Polynuclear rhodium(III) aqua ions identified as salts of the protonated superanion X^{7-}, and the dehydrated superanion $\{X - 2\,H_2O\}^{7-}$ formed on treating mixtures of the polynuclear species with excess sodium *p*-sulfonatocalix[4]arene and 18-crown-6 at low pH, isolated as hydrates of $[Rh_2(OH)_2(H_2O)_8][X + 3\,H^+]$, $[Rh_3(OH)_4(H_2O)_{10}][Rh_4(OH)_6(H_2O)_{12}][2\,X + 3\,H^+][Na(H_2O)ClO_4]_2$, and $[Rh_4(\mu\text{-}OH)_6(H_2O)_{12}][X + \{X - 2\,H_2O\} + 8\,H^+]$; X = $[\{Na^+(18\text{-crown-}6)(OH_2)_2\}\{(p\text{-sulfonatocalix[4]arene}^{4-})_2\}]^{7-}$

authenticating polynuclear rhodium(III) cations in the solid state is restricted to studies on the dinuclear cations,[9,10] with the related mixed Rh^{III}/Cr^{III} dimer also characterised.[11] Oligomeric chromium(III) solutions under the same conditions result in retrieval of the tetranuclear species rather than both the tri- and tetranuclear in the present system. Changes in pH can, however, lead to the selective retrieval of the tetranuclear Rh^{III} species in the complex $[Rh_4(\mu\text{-}OH)_6(H_2O)_{12}][X + \{X - 2\,H_2O\} + 8\,H^+]\cdot 33H_2O$, **3**. Here $[Rh_4(\mu\text{-}OH)_6(H_2O)_{12}]^{6+}$ crystallises with the superanion X^{7-} and a radically altered superanion $\{X - 2\,H_2O\}^{7-}$ which is devoid of the two *trans* water molecules with the two calixarenes coordinating directly to the central Na^+ via sulfonate groups, Figure 1, and demonstrates the hitherto unknown ability of the capsule to accommodate large cations by forming different structures, which adds to the previously established versatility inherent in being able to alter its degree of protonation.

Results and Discussion

Yellow crystals of complex **1** formed on the evaporation over several days of an aqueous solution containing $[Rh_2(\mu\text{-}OH)_2(H_2O)_8](ClO_4)_4$, and an excess of sodium *p*-sulfonatocalix[4]arene and 18-crown-6, acidified to pH 2 with aqueous perchloric acid. The solid-state structure was determined from X-ray diffraction data collected at 123(1) K. The complex $Rh_2(\mu\text{-}OH)_2(H_2O)_8][X + 3\,H^+]\cdot 11.5H_2O$, **1** crystallises in a triclinic cell [a = 13.5248(3), b = 16.7318(4), c = 25.1930(5) Å, α = 105.583(5), β = 97.061(4), γ = 108.522(5)°] and the structure was solved in $P\bar{1}$. The struc-

ture consists of three major structural components − the superanion capsule and the dinuclear cation in two orientations, as well as water molecules at hydrogen bond distances to these moieties. Three of the total of eight sulfonate groups of the superanion capsule are required to be protonated to achieve overall charge balance. These protons were not located crystallographically and could reside on any of the eight crystallographically distinct sulfonate groups. Surprisingly, the structure of **1** is not isostructural with, or extensively disordered, as in the chromium(III) analogue,[1] where the cations are disordered over several sites within the unit cell. These differences may relate to the larger size of the cation in the present case and/or different polarisation effects.

The $[Rh_2(\mu\text{-}OH)_2(H_2O)_8]^{4+}$ cation in **1** is unexceptional relative to that established for a less-versatile supramolecular approach.[9] The structure of the superanion X^{7-} is similar to those found in the analogous anions in the structures containing the di-, tri-, and tetranuclear chromium(III) cations,[1] and the Keggin ion aluminium(III) cluster, where there is also a calixarene in the crystal lattice that is not part of a capsule.[2] The crown ether within the superanion shows severe dynamic disorder, which is not unusual for crown ether structures.[12]

The extended structure of **1** features a complicated array of hydrogen bonds complemented by additional supramolecular interactions such as electrostatics. There are two types of cation behaviour with both positioned at the periphery of the hydrophilic sulfonate equator of the globular superanion. Numerous hydrogen bonds from the coordinated hydroxides and waters of the cations to the sulfonate groups of the superanion overcome electrostatic repulsion associated with the two sulfonated calixarene molecules, Figure 2. One cation, with the Rh−μ-$(OH)_2$−Rh plane roughly perpendicular to the approximate plane of the crown ether, is located very close to the hydrophilic periphery of two superanions in **1** with O···O hydrogen bond lengths 2.53 to 2.71 Å. The other type of cation sits at the outer edges of four superanions, bridging between them through hydrogen bonding interactions at O···O distances 2.63 to 2.70 Å. The array of hydrogen bonding interactions between the cations and superanions form an infinite two dimensional network, a section of which is shown in Figure 3. In the overall crystal lattice these 2D networks stack in layers through RSO···HOR′ hydrogen bonds (O···O distance 2.71 Å) between calixarenes of different networks. This is quite distinct from the inter-superanion stacking observed in the su-

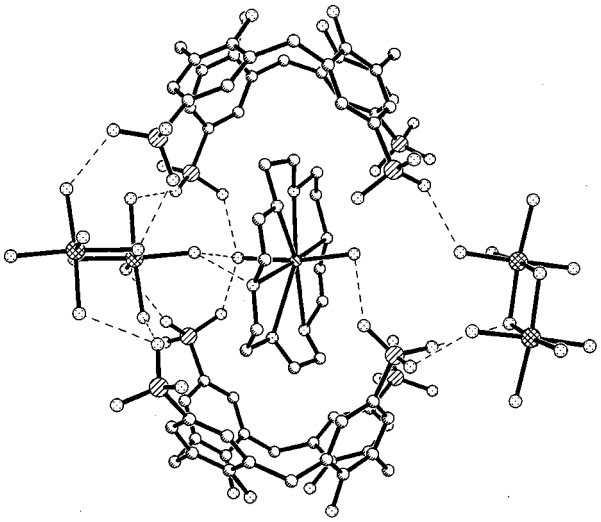

Figure 2. Close contacts between superanion and Rh dinuclear cations in $[Rh_2(\mu\text{-}OH)_2(H_2O)_8][X + 3\,H^+]\cdot 11.5H_2O$ (**1**); dashed lines indicate hydrogen bonds; only one disordered sulfonate group is shown for clarity

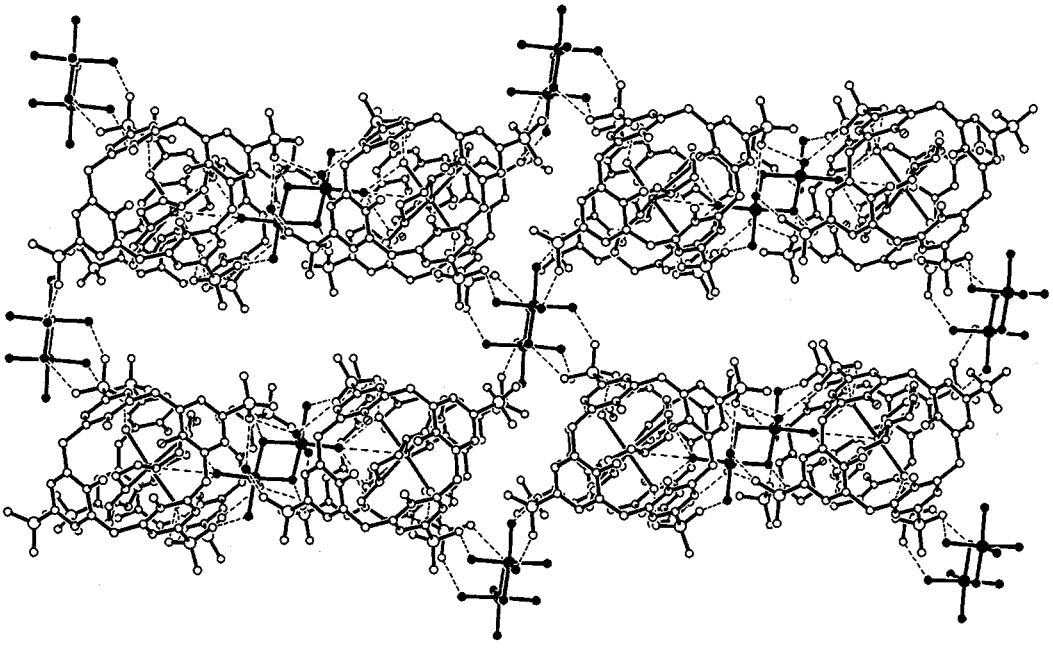

Figure 3. Section of the infinite two dimensional hydrogen bonded network of superanions and dinuclear cations (highlighted in black) of **1**

peranion complexes of $[Cr_2(OH)_2(H_2O)_8]^{4+}$ and $[Cr_3(OH)_4(H_2O)_{10}]^{5+}$ with X^{7-}, where RSO···HOR′ hydrogen bonding was more extensive and complemented by π stacking.

Pale yellow crystals of complex **2** were obtained in a similar manner to **1**, however with a mixture of polynuclear rhodium(III) aqua ions at pH 2 formed by treating aqueous rhodium(III) perchlorate (0.1 M) with sodium hydroxide (1 M) to give a pH 13, then acidifying the resulting solution after 2 hours with perchloric acid. Under such conditions, mononuclear, dinuclear, trinuclear, and higher oligomers are known to exist.[8,9] The solid-state structure was determined from X-ray diffraction data collected at 123(1) K. The complex $[Rh_3(\mu\text{-}OH)_4(H_2O)_{10}][Rh_4(\mu\text{-}OH)_6(H_2O)_{12}][2\,X + 3\,H^+][Na(H_2O)(ClO_4)]_2 \cdot 27H_2O$, **2** crystallises in a triclinic cell [a = 13.8992(2), b = 17.0191(5), c = 26.6441(7) Å, α = 75.268(3), β = 88.328(5), γ = 68.768(5)°] and the structure was solved in $P\bar{1}$. As for **1** the structure consists of three major structural components − the superanion capsule, trinuclear, and tetranuclear cations as well as sodium perchlorate with the sodium coordinated to the calixarenes, and numerous water molecules. Three of the sixteen sulfonate groups are required to be protonated for charge balance and could reside on any of the eight crystallographically independent sulfonates.

The trinuclear $[Rh_3(\mu\text{-}OH)_4(H_2O)_{10}]^{5+}$ of **2** is located close to a crystallographic inversion centre leading to a static disorder of the cation over two positions with some shared oxygen sites having both water and hydroxide character, Figure 4. Such a disorder makes the Rh−O distances

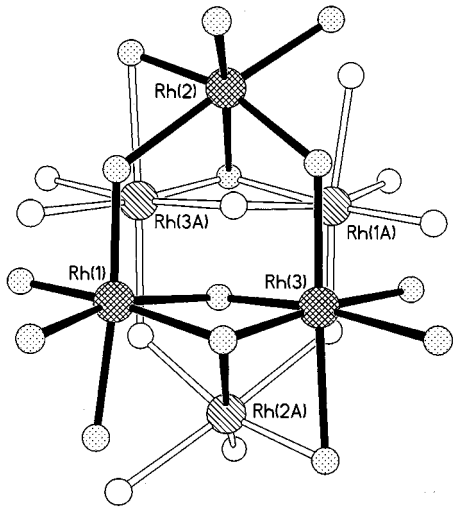

Figure 4. The disordered trinuclear cation $[Rh_3(\mu\text{-}OH)_4(H_2O)_{10}]^{5+}$ from the crystal structure of $[Rh_3(\mu\text{-}OH)_4(H_2O)_{10}][Rh_4(\mu\text{-}OH)_6(H_2O)_{12}][2\,X + 3\,H^+][Na(H_2O)ClO_4]_2 \cdot 27\,H_2O$ (**2**)

somewhat unreliable, however general structural features are unequivocal. The μ-OH bridged cyclic structure of the trinuclear cation is isostructural with that of the chromium(III) analogue,[1] but this is at odds with the assigned linear structure based on ^{103}Rh NMR studies. However, the NMR data showing two resonances in a 1:2 ratio is consistent with the triangular structure.[8] The structure of the tetranuclear $[Rh_4(\mu\text{-}OH)_6(H_2O)_{12}]^{6+}$ cation is likewise the same as that for the chromium(III) analogue,[1] and is cyclic with two Rh centres coordinated by two terminal water mo-

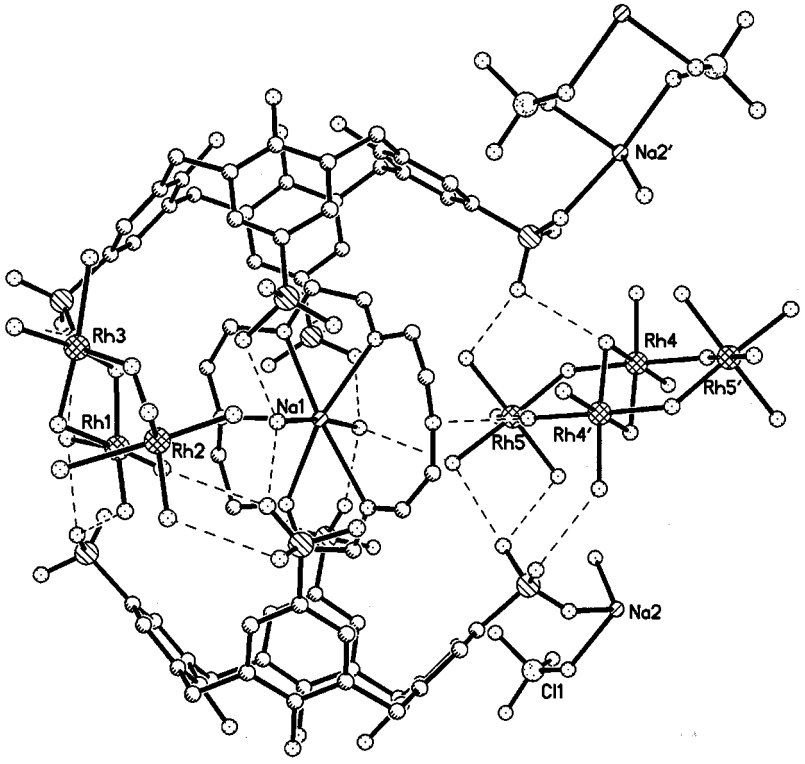

Figure 5. Interactions between the superanion and polynuclear cations in **2** and coordination of Na perchlorate moiety; for the sake of clarity only one position for the disordered sulfonate and trinuclear cation groups are shown

lecules and four bridging hydroxides, the other metal centres coordinated by four terminal water molecules and two bridging hydroxides. Rh−OH_2 distances ranges from 2.024(5) to 2.053(6) Å, and Rh−OH distances were from 1.991(5) to 2.007(5) Å.

The structure of the superanion X^{7-} is slightly different to that of **1** and analogous systems,[1,2] with the central Na^+ in **2** coordinating to only five of the six crown ether oxygen atoms at Na−O distances from 2.55(1) to 2.740(9) Å as well as two *trans* water molecules [Na−O distances 2.294(9) and 2.376(7) Å] in a distorted pentagonal bipyramidal geometry, Figure 5. The sixth oxygen is pulled out of the Na^+ coordination sphere by a weak hydrogen bond to a hydroxide of the Rh tetramer at an O···O separation 2.91 Å. The superanion is somewhat tilted when compared with analogous superanions, which appears to be caused by sulfonate groups coordinating to Na^+ centres, Figure 5.

Complexes **1** and **2** both have an overall polynuclear cation to superanion ratio of 1:1, and the packing of these components in their respective crystal lattices is similar, evident in their comparable unit cell parameters. The extended structure of **2**, however, combines two-dimensional hydrogen-bonded networks of polynuclear cations and superanions with metal-coordinated chains running parallel to the *a* axis formed by calixarenes coordinating to Na^+ metal centres. The hydrogen bonded networks are topologically identical to those found in **2**, with the disordered trinuclear $[Rh_3(\mu\text{-}OH)_4(H_2O)_{10}]^{5+}$ positioned close to the hydrophilic equator of two superanions forming hydrogen bonds at O···O separations 2.46 to 2.88 Å, and the tetranuclear $[Rh_4(\mu\text{-}OH)_6(H_2O)_{12}]^{6+}$ forming hydrogen bonding interactions (O···O separations 2.64 to 2.91 Å) at the outer edges of four superanions. The Na^+ centres within the coordinate chain are six-coordinate, bonding to a terminal water, two bridging perchlorates in a *cis* arrangement, two bridging calixarenes and a terminal calixarene, Figure 6. The bridging calixarenes coordinate to one Na^+ centre through a sulfonate group [Na−O 2.293(7) Å] and to a second Na^+ centre through a hydroxy group [Na−O 2.524(7) Å] of an arene ring adjacent to that of the coordinated sulfonate. Each Na^+ centre has a bridging calixarene coordinating through a sulfonate group and a calixarene bound through a hydroxy group, and these two calixarenes have their cavities oriented in opposite directions and belong to superanions of different 2D hydrogen bonded networks. The terminal calixarene coordinates through a dynamically disordered sulfonate group at distances 2.24(1) and 2.56(2) Å and is in the same orientation as the sulfonate-bound calixarene. Coordination of Na^+ by the sulfonate groups of sulfonated calixarenes has been previously reported;[13] however, this is the first structurally authenticated example of hydroxy coordination, which has been observed for other types of calixarenes.[14] The coordinated Na−perchlorate−calixarene chain is complemented by π-π stacking between arenes of calixarenes in opposite orientations with aromatic centroid−centroid separations ca. 3.9 Å.

Yellow crystals of $[Rh_4(\mu\text{-}OH)_6(H_2O)_{12}][X + \{X - 2\,H_2O\} + 8\,H^+]\cdot 33H_2O$ (**3**) were grown in a similar manner to **2** at pH 0.35, and the solid-state structure was determined from X-ray diffraction data collected at 123(1) K. The complex **3** crystallises in a triclinic cell [a = 17.2141(3), b = 18.1947(3), c = 20.7066(3) Å, α = 88.218(1), β = 77.304(1), γ = 62.429(1) °] and the structure was solved in $P\bar{1}$. The complex **3** has a 1:1:1 ratio of tetranuclear cation, superanion X^{7-}, and dehydrated superanion

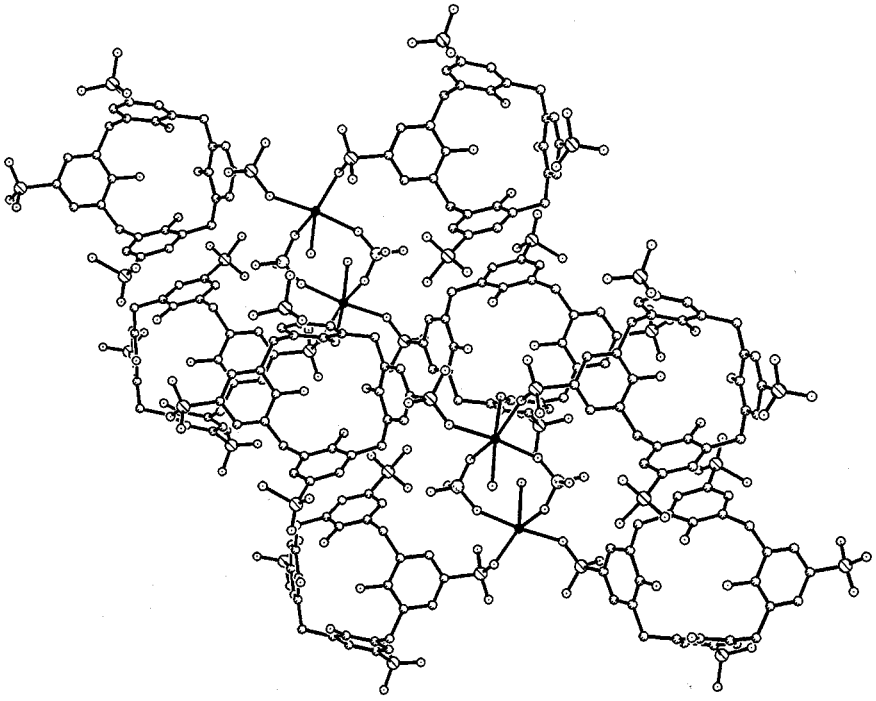

Figure 6. Chain structure of **2** formed by coordination of Na (highlighted in black) by two bridging perchlorates; two bridging calixarenes with sulfonate and hydroxy binding, with terminal water and calixarene ligands also shown

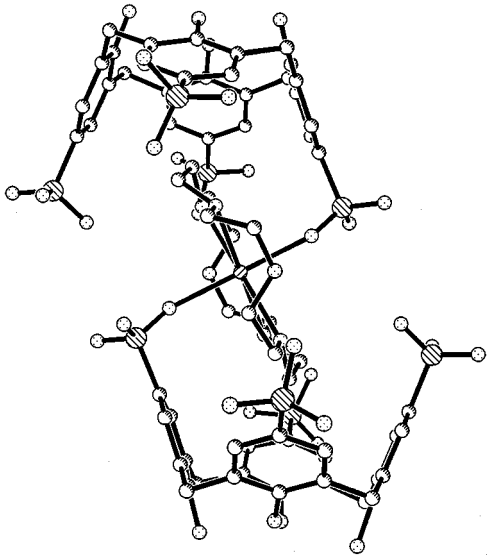

Figure 7. Dehydrated superanion $\{X - 2\,H_2O\}^{7-}$ from the crystal structure of $[Rh_4(\mu\text{-}OH)_6(H_2O)_{12}][X + \{X - 2\,H_2O\} + 8\,H^+]\cdot 33H_2O$ (**3**); displacement of the two calixarene bowls from their usual head-to-head arrangement is clearly visible

$\{X - 2\,H_2O\}^{7-}$ as well as 31 solvent water molecules, and requires a total of eight sulfonate groups to be protonated for charge balance. Not surprisingly given the size of the crystal structure determination, protons were not located crystallographically. The higher ratio of capsules to cations in this structure relative to that of **1** and **2** is consistent with complex formation from a more acidic solution.

The tetranuclear cation is identical to that of **2** and the superanion X^{7-} is similar to those previously reported.[1,2] The structure of the superanion $\{X - 2\,H_2O\}^{7-}$ is skewed considerably from the capsule structure of X^{7-}. The two axial water molecules coordinated to the Na^+ centre in X^{7-} are not present in the dehydrated superanion. Instead the axial coordination positions are occupied by oxygens of sulfonate groups from each of the two calixarene moieties that form the shell of the superanion. The Na−OS distance of 2.319(9) Å requires that one sulfonate group from each of the calixarene subunits is pulled in towards the Na perturbing the usual head-to-head arrangement of calixarenes, leaving the superanion open at each side, Figure 7. The central Na^+ is octahedral and coordinates to four of the six crown ether oxygens [Na−O distances 2.580(8)−2.539(8) Å], with the other two crown oxygens forming hydrogen bonds to solvent water at O···O separation 2.34 Å.

Hydrogen bonding is the dominant interaction present between the different components in complex **3**. Each tetranuclear cation forms hydrogen-bonding interactions to the sulfonate groups of four superanions; two X^{7-} capsules positioned opposite each other across the cation, and two $\{X - 2\,H_2O\}^{7-}$ superanions, at O···O separations of 2.61 to 2.79 Å. Each superanion, whether X^{7-} or $\{X - 2\,H_2O\}^{7-}$, hydrogens bonds to two tetranuclear cations, extending into a two dimensional rectangular grid array shown in Figure 8. Within the crystal lattice the two dimensional grids stack offset to one another and show hydroxy to sulfonate hydrogen bonding and π stacking between calixarenes of adjacent grids, Figure 9. Each superanion forms such interactions to other superanions of both the X^{7-} and $\{X - 2\,H_2O\}^{7-}$ persuasion, at π-π centroid separations 3.53 to 3.78 Å and O···O distances 2.81−3.01 Å. Interestingly, unlike in other examples of π stacking complemented by

Section of the infinite hydrogen bonded grid structure formed by tetranuclear cations $[Rh_4(\mu\text{-}OH)_6(H_2O)_{12}]^{6+}$ and superanions X^{7-} and $\{X - 2\,H_2O\}^{7-}$ in **3**; for the sake of clarity only one position for the disordered sulfonate in the X^{7-} superanion is shown

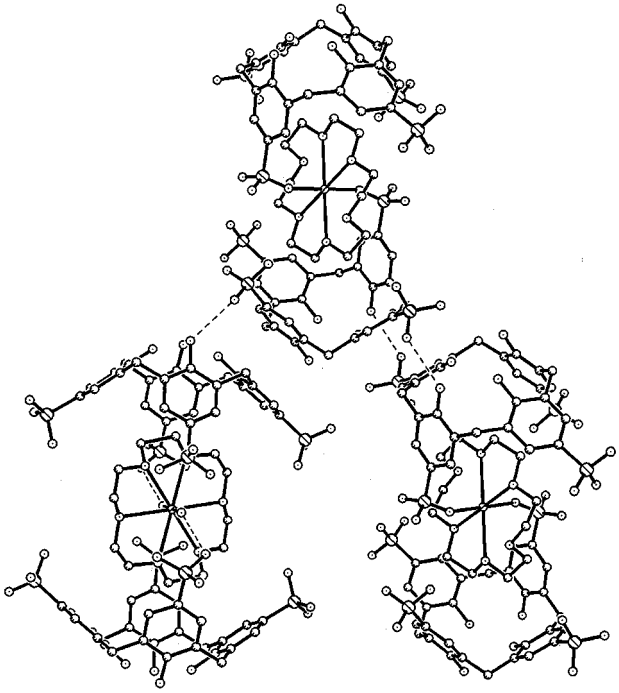

Figure 9. Hydrogen bonding and π-π stacking interactions between superanions of **3**; for the sake of clarity only one position for the disordered sulfonate in the X^{7-} superanion is shown

RSO···HOR′ hydrogen bonding where both interactions occur in the one pair of HO−aryl−SO_3 moieties, the sulfonate groups are oriented such that they accept a hydrogen bond from a hydroxy group adjacent to the aromatic ring involved in the π stack. Spaces within the lattice are occupied by disordered solvent water molecules.

Previously established types of superanions have demonstrated an ability to exist in various states of negative charge, and to either include or exclude Na^+ from the inner core of the capsule depending on reaction conditions. Now it is also seen that the nature of the coordination sphere of the capsule can be altered by a slight variation in reaction conditions. The ambivalent nature of the superanion assembly, either X^{7-} or $\{X - 2\,H_2O\}^{7-}$ in their various protonated forms, is noteworthy, and may be a consequence of crystal packing. The nature of the compounds present in solution is yet to be realised, and has proved a difficult task for all such systems to date.

Conclusions

The ability of the superanion to take on different charges via protonation of the terminal sulfonate is evident in the current structures, and the work further highlights its versatility in complexing two disparate polynuclear species both in charge, size, and shape, in the same lattice, which is without precedent in polynuclear aqua cation chemistry. The complexation of mixed Rh^{III} and Cr^{III} clusters is also likely to lead to some selectivity and for this system only the dinuclear species has been authenticated.[11] The ambivalent nature of the capsule X^{7-} versus $\{X - 2\,H_2O\}^{7-}$ is surprising and highlights the complexity in studying these systems introducing another structural assembly parameter. Overall, our approach to crystallising large cations is indeed more general than initially realised, and the concept of forming capsules by using large cations to overcome the electrostatic repulsion between the two calixarenes has implications in forming capsules with a large array of different organic and inorganic substrates in the core.

Experimental Section

Preparation of 1−3: A mixture of monomeric and oligomeric Rh^{III} cations was produced by treating aqueous rhodium(III) perchlorate (0.1 M) with sodium hydroxide (1 M) to pH 13, standing for 2 hours then acidifying with 60% perchloric acid to approximate pH 2. Solutions containing pure $[Rh_2(\mu\text{-}OH)_2(H_2O)_8](ClO_4)_4$ in aqueous acid were obtained by chromatographic techniques.[8] Crystals of $[Rh_2(\mu\text{-}OH)_2(H_2O)_8][X + 3\,H^+] \cdot 11.5\,H_2O$ (**1**) were obtained by adding an excess of sodium *p*-sulfonatocalix[4]arene and 18-crown-6 to such a solution, adjusting the pH to 2 with aqueous perchloric acid and standing the solution uncapped in ambient conditions for several days. Crystals of $[Rh_3(\mu\text{-}OH)_4(H_2O)_{10}][Rh_4(\mu\text{-}OH)_6(H_2O)_{12}][2\,X + 3\,H^+][Na(H_2O)(ClO_4)]_2 \cdot 27\,H_2O$ **2** were obtained in a similar fashion using the unpurified mixture of Rh^{III} cations in acid. Conditions for the formation and crystallisation of $[Rh_4(\mu\text{-}OH)_6(H_2O)_{12}][X + \{X - 2\,H_2O\} + 8\,H^+] \cdot 33\,H_2O$ **3** were identical to those of **2** except with the initial pH less than 1. Reliable elemental analytical data could not be obtained due to the large proportion of solvent water present in the crystalline complexes.

Crystal Structure Determination: All crystals were sensitive to loss of solvent and were mounted on a glass capillary under oil. Data for **1**−**3** were collected at 123(1) K on an Enraf−Nonius KappaCCD diffractometer with Mo-K_α radiation (λ = 0.71073 Å). Data were corrected for Lorentzian and polarisation effects but not absorption. The structures were solved by direct methods (SHELXS-97) and refined with either a full matrix or blocked-matrix least-squares refinement on F^2 (SHELXL-97). Unless otherwise indicated all non-hydrogen atoms were refined anisotropically. Results of the structure refinements are summarised in Table 1, while details of the treatment of disorder and hydrogens are given below.

$[Rh_2(\mu\text{-}OH)_2(H_2O)_8][X + 3\,H^+] \cdot 11.5H_2O$ (1): One sulfonate group and the crown ether showed dynamic disorder. The sulfonate group was modelled as having O sites disordered over two positions with occupancies 0.7 and 0.3. The behaviour of the crown ether moiety suggested a severe dynamic disorder, probably rotation about the $H_2O-Na-OH_2$ axis, that could not be adequately modelled. The eventual model used has all carbon positions refined with a common set of displacement parameters and all oxygen positions refined with a common set of displacement parameters, although it is recognised that some positions may have mixed C/O character. The higher than usual displacement parameters and some nonsensical bond lengths and angles are a consequence of this disorder. There were a number of disordered water molecules with low occupancy some of which were refined isotropically and C−H hydrogen atoms on the calixarenes were included at calculated positions with a riding refinement.

$[Rh_3(\mu\text{-}OH)_4(H_2O)_{10}][Rh_4(\mu\text{-}OH)_6(H_2O)_{12}][2\,X + 3\,H^+][Na(H_2O)(ClO_4)]_2\cdot 27H_2O$ (2): The trinuclear $[Rh_3(\mu\text{-}OH)_4(H_2O)_{10}]$ was located over an inversion centre resulting in a static disorder over two positions each at 0.5 occupancy with some shared oxygen sites at full occupancy. A disordered sulfonate was modelled with O sites over two positions at 0.5 occupancies. There were a number of disordered water molecules with low occupancy some of which were refined isotropically and C−H hydrogen atoms on the calixarenes and crown ether were included at calculated positions with a riding refinement.

$[Rh_4(\mu\text{-}OH)_6(H_2O)_{12}][X + \{X - 2\,H_2O\} + 8\,H^+]\cdot 33H_2O$ (3): The behaviour of the crown ether in the X^{7-} capsule suggested dynamic disorder, and was modelled in a similar manner to the disordered crown in **1**. Two of the sulfonate groups on the X^{7-} capsule also displayed dynamic disorder. The oxygen atoms of these sulfonates were refined isotropically, with the oxygen positions split over two sites at 0.7:0.3 occupancies for one of the disordered sulfonate groups, and S−O bond lengths, and O···O non-bond lengths restrained to maintain a chemically reasonable model. Disordered water molecules were also refined isotropically and C−H hydrogen atoms on the calixarenes and crown ethers were included at calculated positions with a riding refinement.

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-138364, (**1**), CCDC-138365, (**2**) and CCDC-138366, (**3**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [fax: (internat) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis, Structure, and Magnetic Properties of a Tris[3-(2-pyridyl)-1,2,4-triazole]iron(II) Spin-Crossover Complex

Arno F. Stassen,[a] Matthijs de Vos,[a] Petra J. van Koningsbruggen,[b] Franz Renz,[b] Jürgen Ensling,[b] Huub Kooijman,[c] Anthony L. Spek,[d][+] Jaap G. Haasnoot,*[a] Philipp Gütlich,[b] and Jan Reedijk[a]

Dedicated to Professor Heinrich Vahrenkamp on the occasion of his 60th birthday

Keywords: Spin crossover / Iron / Magnetic properties / Moessbauer spectroscopy / N ligands

The synthesis and characterization of tris[3-(pyridin-2-yl)-1,2,4-triazole]iron(II) bis(tetrafluoroborate), obtained from the reaction of 3-(pyridin-2-yl)-1,2,4-triazole (Hpt) and hexaaquairon(II) tetrafluoroborate, $[Fe(H_2O)_6](BF_4)_2$, is described, together with its crystal structures at two temperatures. X-ray crystallographic parameters are as follows: $[Fe(Hpt)_3](BF_4)_2 \cdot nH_2O$ ($n \approx 2$) at 250 K: orthorhombic space group *Pbam*, a = 15.8068(18) Å, b = 17.2800(14) Å, c = 21.215(2) Å, V = 5794.7(10) Å^3, and Z = 8. $[Fe(Hpt)_3](BF_4)_2 \cdot nH_2O$ ($n \approx 2$) at 95 K: orthorhombic space group *Pbam*, a = 15.7080(12) Å, b = 17.1023(16) Å, c = 21.006(2) Å, V = 5643.1(9) Å^3, and Z = 8. The Fe^{II} ions are (at both temperatures) octahedrally surrounded in a *mer*-configuration. The complex has been subjected to both ^{57}Fe Mössbauer spectroscopy and magnetic susceptibility measurements. The ^{57}Fe Mössbauer spectrum shows the presence of two different iron(II) sites. The high-spin fraction vs. T curve of the crossover, obtained by SQUID measurements, is gradual and without hysteresis, with $T_{1/2}$ = 135 K.

Introduction

Nowadays there is increasing interest in new bistable iron(II) spin-crossover compounds.[1,2] A variety of iron(II) compounds are known to show a transition from the high-spin state [HS, $S = 2$, $^5T_{2g}$ (O_h)] to the low-spin state [LS, $S = 0$, $^1A_{1g}$ (O_h)] on cooling.[2−4]

Iron(II) compounds incorporating substituted 1,2,4-triazole ligands have been found to undergo spin transition. In several cases, hysteresis effects and rather high transition temperatures have been found.[5−23] Generally speaking, when dealing with linear polynuclear Fe^{II} compounds of 1,2,4-triazole ligands, the spin-crossover behaviour is abrupt and may show hysteresis,[5,7,11−16,19,21,22,24,25] but this is not the case for shorter oligomers.[26−28] For mononuclear 1,2,4-triazole-containing iron(II) spin-crossover systems, the spin crossover has always been found to be gradual and without any hysteresis.[9,10,18,29,30]

^{57}Fe Mössbauer spectroscopy studies on $[Fe(Hpt)_3](Anion)_2(Solvent)_x$ [Hpt = 3-(pyridin-2-yl)-1,2,4-triazole (see Figure 1); Anion = Cl^-, ClO_4^-, PF_6^-, BF_4^-; Solvent = ethanol, water] and $[Fe(H3mpt)_3](Anion)_2(Solvent)_x$ [H3Mpt = 3-methyl-5-(pyridin-2-yl)-1,2,4-triazole; Anion = ClO_4^-, PF_6^-; Solvent = water] have been reported by Stupik et al.[9,10] and by Sugiyarto et al.[31] Clearly, these mononuclear compounds exhibit continuous Fe^{II} spin-crossover behaviour. The Fe^{II} ion resides in a six-nitrogen environment made up of three bidentate chelating 3-(pyridin-2-yl)-1,2,4-triazole ligands coordinating through N4 of the 1,2,4-triazole and the pyridine N. The asymmetric nature of the bidentate ligand may lead to the formation of FeL_3 units having *facial* or *meridional* geometry. Both Stupik and Sugiyarto observed[9,10,31] that the spin transition was affected by the presence of different solvent molecules. This contributes to the complicated spin-crossover behaviour evident from the ^{57}Fe Mössbauer spectra. They also observed two different iron(II) high-spin sites in the hydrated BF_4^- complex, but did not mention the ratio between the two sites. In addition, Sugiyarto et al.[31] reported comparable observations for the hydrated BF_4^- and ClO_4^- iron(II) tris[3-(pyridin-2-yl)-1,2,4-triazole] compounds.

However, these results have not yet been satisfactorily explained, and hence a further study on this interesting class of compounds was undertaken.

In this paper, the synthesis, crystal structures at 250 K and 95 K, and physical properties of the iron(II) Hpt coordination complex of the anion BF_4^- are described in detail.

Results and Discussion

Structure of the Complex

X-ray crystal structure analyses have been carried out at two temperatures, i.e. at 250 K, where the complex is almost completely high spin, and at 95 K, which is below the transition temperature and hence most of the iron(II) ions participating in the spin-crossover behaviour are in the low-spin state. The molecular structure showing the atomic numbering scheme is depicted in Figure 2, while relevant bond length and bond angle information is given in Table 1 and Table 2. At both temperatures, the space group is *Pbam* with $Z = 8$. The asymmetric unit contains one $Fe(Hpt)_3$ moiety. Structural analysis of the complex shows that at both temperatures the iron(II) is octahedrally surrounded by three Hpt ligands, which bind through N2 of the pyridine ring and N4 of the triazole ring in a *mer* configuration.

N(211)−Fe−N(311)	94.57(12)	95.42(14)

Because of rotational and positional disorder of the tetrafluoroborate and water molecules, it was not possible to determine any positional parameters for these molecules. This disorder suggests the absence of hydrogen bonding. This is surprising, because both N1 and N2 of the triazole ring can form hydrogen bonds, either in amino or imino form.[32]

Comparison of the bond angles of the N−Fe−N axes at the two temperatures shows that at low temperature the angles are closer to 180°, as would be expected for a $^1A_{1g}$ octahedral structure. The N−Fe−N angles involving the nitrogen atoms on different axes are also closer to those of a regular octahedron at 95 K than at 250 K. The ligand bite angles increase from 75.53−77.13° at 250 K to 80.17−80.86° at 95 K. The other nonlinear N−Fe−N angles decrease from 91.53−100.75° (average 95.1°) at 250 K to 90.77−96.25° (average 93.4°) at 95 K. Considering that at this temperature 35% of the complexes are still in the high-spin state, the actual angles in the low-spin complex will be even closer to 90°.

The Fe−N bond length contracts by approximately 0.15 Å on cooling to 95 K. These observations can be rationalized as follows. For iron(II) complexes surrounded by neutral ligands, Equation (1) holds, where μ is the dipole moment of the ligand and r the average metal−ligand distance.[1]

$$10Dq \approx \frac{\mu}{r^6} \quad (1)$$

From this equation, Equation (2) can be derived.

$$\frac{10Dq^{LS}}{10Dq^{HS}} = \left(\frac{r_{HS}}{r_{LS}}\right)^6 \approx 1.74 \quad (2)$$

The value for an iron(II) spin-crossover complex is normally ca. 1.74. The value obtained by applying Equation (2) in the case of $[Fe(Hpt)_3](BF_4)_2 \cdot n\,H_2O$ is lower than 1.74, specifically 1.57. The difference between the calculated and measured values arises from the fact that at both temper-

atures not all the iron(II) ions are in the same spin state. From magnetic and Mössbauer measurements, it has been concluded that at 95 K a residue of 36.1% high-spin and at 250 K a residue of 2.5% of low-spin iron(II) ions is present. The actual Fe−N bond length for a pure low-spin state will be closer to 2.00 Å, and using this value in Equation 2 would generate the expected dipole moment.

Because the contribution to the structure factors associated with the counter ions and solvent was taken into account using the SQUEEZE procedure as incorporated in PLATON,[33] no exact molecular formula could be determined from the crystal structure. However, considering the number of electrons associated with the counterions and solvent in conjunction with the elemental analysis, the molecular formula could be calculated. Assuming that only cations of the formula $[Fe(Hpt)_3]^{2+}$, anions BF_4^-, and water were present, the molecular formula $[Fe(Hpt)_3](BF_4)_2 \cdot nH_2O$, $n = 2$, was derived.

The stability of the complex was tested by heating it for several hours at 50 °C and by storing it in vacuo for one day. Under neither conditions were the elemental analysis or magnetic susceptibility affected. Thus, despite the fact that the water molecules are seemingly not involved in strong hydrogen bonding, they are not readily removed from the complex.

^{57}Fe Mössbauer Spectroscopic Measurements

^{57}Fe Mössbauer spectra were recorded at temperatures of 300 K, 205 K, 150 K, 80 K, 32 K, 10 K, and 4.2 K. A representative selection of the spectra is shown in Figure 3. Least-squares-fitted parameters are listed in Table 3. In all the spectra, three doublets have been assigned. Of these, one is characteristic of Fe^{II} in the low-spin state, while the other two are characteristic of Fe^{II} in the high-spin state.[34] We shall refer to the high-spin doublet with the larger quadrupole splitting as HSa, and to the other as HSb. Stupik[9,10] and Sugiyarto[31] also detected a second high-spin site, but it is not clear as to whether the site they detected was identical to HSb (these authors did not analyse the spectra in more detail). Schreiner[29] also detected a second high-spin site in $[Fe(Hpt)_3](BF_4)_2 \cdot H_2O/EtOH$, to the extent of 7% at 100 K (31% at 300 K), which was reported to behave similarly as that found in the present work. The area fraction of the HSb site is only 6% at 205 K and decreases to 3% at 4.2 K, which is close to the experimental limit. Its corresponding Fe^{II} low-spin state doublet probably coincides with the aforementioned major low-spin doublet. The molar ratios of the molecules in the spin states can be derived from the area fractions by taking equal Mössbauer−Lamb factors for the low-spin and high-spin states.[35,36]

At 300 K, a pure high-spin state doublet is present (unresolved HSa and HSb). At 205 K, a low-spin doublet of weak intensity is visible, associated with 8% of the ions. This low-spin doublet clearly increases in intensity on going from 205 to 80 K (from 8% to 67%), while the doublet associated with the HSa site gradually diminishes from 86% at 205 K to 30% at 80 K. At the latter temperature, the spin

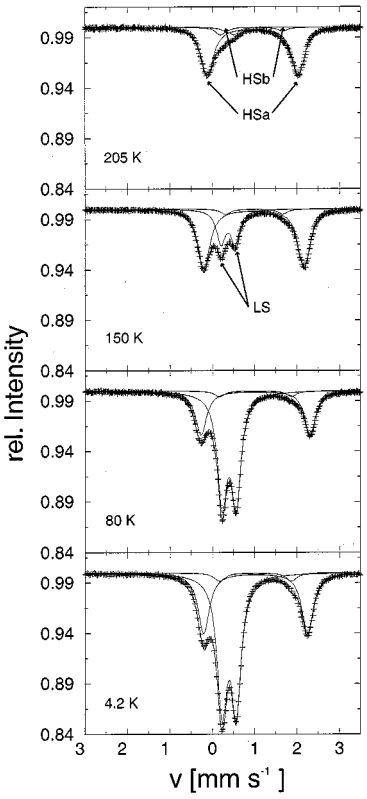

Figure 3. ^{57}Fe Mössbauer spectral measurements at 205, 150, 80, and 4.2 K

crossover is almost complete. Further cooling to 4.2 K results only in an additional 2% increase in the intensity of the low-spin doublet to 69%. The distribution of high-spin and low-spin species found at the measured temperatures is in agreement with the magnetic measurements.

When a spin-crossover compound is cooled very rapidly, i.e. quenched, it is possible that high-spin ions are unable to relax to the low-spin state, but remain thermally spin trapped in the metastable high-spin state.[37−39] This phenomenon is called thermal spin trapping. Mössbauer spectra measured after rapid cooling, i.e. by taking a sample at 300 K and placing it in a cryostat at 4.2 K, revealed that a fraction of the iron(II) ions, approximately 6%, is trapped in the high-spin state (see Table 3). It is mainly the HSb site that exhibits the spin state trapping.

The presence of a second high-spin site (HSb) indicates a different local surrounding from the majority (HSa), arising from the distribution of the solvent and anions.

Magnetic Susceptibility Measurements

Figure 4 shows the product of χT and T for $[Fe(Hpt)_3](BF_4)_2 \cdot 2\,H_2O$, where χT is the molar magnetic susceptibility, recorded in the temperature range 4−325 K as a function of temperature T. The curve provides evidence for $S = 2$ (HS) ⇄ $S = 0$ (LS) spin-crossover behaviour. At room temperature, all iron(II) ions are in the high-spin state ($\chi T = 3.52$ cm^{3}Kmol^{-1}). Below 75 K, the value of χT falls to 0.72 cm^{3}Kmol^{-1}. This indicates the presence of a signi-

[a] δ = isomer shift, ΔE_Q = quadrupole splitting, Γ = line width, A_{HS} = area fraction of the HS doublets. Statistical standard deviations are given in parentheses.

ficant residue of high-spin iron(II) ions, as is also evident from the low-temperature Mössbauer spectrum. The spin transition is very gradual, with $T_{1/2}$ = 135 K. The parameter $T_{1/2}$ is defined as the temperature in a thermally driven spin equilibrium at which, for the iron(II) ions involved in spin transition, the amounts of high-spin and low-spin molecules are equal. The entire measurement required 5 h 45 min, corresponding to a heating rate of approximately 1.1 $Kmin^{-1}$ in steps of 2.5 K.

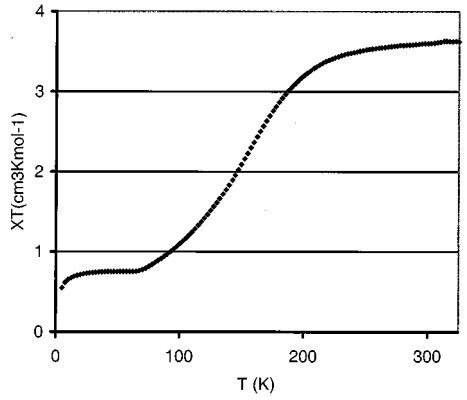

Figure 4. Plot of χT vs. T for $[Fe(Hpt)_3](BF_4)_2 \cdot 2\,H_2O$

The spin transition takes place without hysteresis. Furthermore, the spin-crossover behaviour is easily detected, since the compound is highly thermochromic. On cooling to 77 K, its colour changes from yellow to deep purple.

Figure 5 shows the γ_{HS} vs. T curve plotted over the temperature range 4−320 K. The high-spin molar fraction γ_{HS} was deduced from the ^{57}Fe Mössbauer data area fractions by taking equal Mössbauer−Lamb factors for low-spin state and high-spin state doublets.[35,36] It may be assumed from the Mössbauer measurements that below 80 K 30% of the high-spin sites are not involved in the spin-crossover process. This makes it possible to simulate the spin-crossover curve using Equation (3), which is derived from the regular solution model.[40]

$$\ln\left[\frac{1-\gamma_{HS}}{\gamma_{HS}}\right] = \frac{\Delta H + \Gamma(1-2\gamma_{HS})}{RT} - \frac{\Delta S}{R} \qquad (3)$$

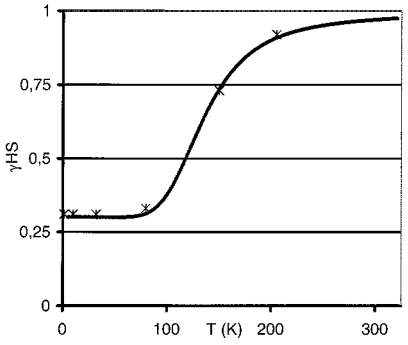

Figure 5. Fitted high-spin molar fraction, based on Mössbauer data, vs. T for $[Fe(Hpt)_3](BF_4)_2 \cdot 2\,H_2O$ (* = actual Mössbauer measurements)

In Equation (3), R is the molar gas constant, ΔH is the enthalpy change, and ΔS is the entropy change associated with the spin crossover. Least-squares fitting leads to ΔH = 6.4 kJ mol^{-1}, ΔS = 47 J K^{-1} mol^{-1}, and a mean-field interaction parameter Γ smaller than 0.1 kJ mol^{-1}. The spin crossover may be considered as being almost non-cooperative.[1,41]

Complexes of hexaaquairon(II) tetrafluoroborate with 3-(pyridin-2-yl)-1,2,4-triazole have been prepared in aqueous solutions at pH 7 to 14. The resulting complexes all exhibit identical spin-crossover behaviour and also give identical elemental analysis results. This excludes the presence of the deprotonated ligand (pt^-).

Ligand-Field Spectroscopy

The ligand-field spectrum of the present complex was measured in the diffuse reflection mode at room temperature and at liquid-nitrogen temperature. The $^5T_2 \rightarrow {}^5E$ transition is seen at 850 nm (11.765 cm^{-1}), while the $^1A_1 \rightarrow {}^1T_1$ transition appears at 530 nm (18.868 cm^{-1}). These values are in the regions normally observed for the corresponding d−d transitions in spin-crossover behaviour materials.[1]

Conclusion

In this paper, the spin-crossover complex tris(Hpt)Fe^{II} with tetrafluoroborate as anion has been reported. This complex is formed as the *meridional* isomer, just as the previously[9,10] studied $[Fe(Hpt)_3](ClO_4)_2 \cdot (Solvent)_x$. Bidentate coordination by the Hpt ligand takes place through N4 of the 1,2,4-triazole and the pyridine N. Details of the X-ray structure determination concerning the location of the tetrafluoroborate and water cannot be reported owing to high positional and rotational disorder of the counterion and solvent. The transition temperature $T_{1/2}$ has been determined as 135 K.

During the spin transition, the geometry of the complex does not change significantly. The average $Fe^{II}-N$ bond length decreases by approximately 0.15 Å. The average N−Fe−N bond angles become closer to those of an ideal octahedron on going from the high-spin to the low-spin state.

In the Mössbauer spectrum, two high-spin iron(II) sites with different populations are observed, with the HSa site clearly showing spin-crossover behaviour. Although a suitably intense doublet associated with the low-spin state is observed, it is not possible to determine whether only one low-spin site is present or whether the signals of two different sites are overlapping. The weak intensity HSb site is at the experimental limit of detection, hence no further conclusions can be made concerning the spin-crossover behaviour at this site. On rapid cooling, a small fraction of the high-spin ions can be thermally trapped in a metastable high-spin state.

It is difficult to compare these results with previously published observations on the $[Fe(Hpt)](BF_4)_2 \cdot 2H_2O$ complex.[9,10,31] These authors also noticed two types of high-spin site, but the data were not analysed further.

The disorder of the solvent molecules and counterions found in the crystal structure gives an indication that neither are involved in hydrogen bonding to the triazole rings of the Hpt ligands. Moreover, the distance between the nitrogens of the triazole ring and the electron density of the counterions and water molecules is too great for hydrogen bonding. The water molecules are nevertheless strongly bound to the complex and cannot be easily removed.

Approximately 30% of the Fe^{II} ions do not participate in the thermal spin transition. It is possible that the distribution of water molecules in the crystal lattice is responsible for this. In the almost identical system $[Fe(Hpt)_3](BF_4)_{1.2}(SO_4)_{0.4} \cdot 3H_2O$,[42] the spin transition does not have an associated high-spin residue at low temperature. It is known that in a few systems the solvent molecules are essential for the spin transition.[43,44] It seems likely that in the present system, due to a non-uniform distribution of water molecules in the lattice, some Fe^{II} ions remain in the high-spin state.

A small proportion (6%) of the iron(II) ions (HSb) experience a different coordination than that described in this article. There are several possibilities for the different coordination of HSb. One explanation is that the ligand is coordinated to the iron(II) through N2 of the triazole ring instead of N4. This would lead to a difference in the coordination sphere and hence in the Mössbauer spectrum; unfortunately, the difference that such a coordination would cause in the structural analysis is smaller than the experimental error. A further possibility is that the deprotonated ligand (pt^-) is present. In this case, 6% of the iron(II) ions would be surrounded by a deprotonated pt^- ligand and have only one tetrafluoroborate counterion in their coordination spheres. However, crystallization experiments at high pH (from 7 to 14) produced materials giving identical results in elemental analysis and susceptibility measurements. Therefore, this possibility can be excluded. A third possibility is that 6% of the crystals have the *facial* orientation. This different coordination could lead to a difference in both the ligand field and quadrupole splitting. In the *mer*-isomer, the three ligands are magnetically non-equivalent, whereas in the *fac*-isomer, the three ligands are magnetically equivalent as this isomer possesses a C_3-axis of symmetry.[45]

Both the first and third options are feasible. Triazole is known to be able to coordinate through N2 as well as through N4,[7,21,26] while both *fac*- and *mer*-isomers of (pydridin-2-yl)-1,2,4-triazole complexes are known.[31,45] Both the linkage and geometrical isomerism will cause a change in ligand field. Whether this variation is sufficiently large to be observed by Mössbauer spectroscopy remains uncertain.

Experimental Section

General Remarks: Ligand-field spectra of the solid were obtained on a Perkin−Elmer Lambda 900 spectrophotometer in the 2000−200 nm range using the diffuse reflectance technique, with MgO as a reference.

Magnetic susceptibilities were measured in the temperature range 5−325 K on a Quantum Design MPMS-5S SQUID operating at 0.1 Tesla. Data were corrected for magnetization of the sample holder and diamagnetic contributions, which were estimated using Pascal constants ($\chi_D = -2.85 \cdot 10^{-4}$ cm^3mol^{-1}).[46]

^{57}Fe Mössbauer spectra of the polycrystalline compound $[Fe(Hpt)_3](BF_4)_2 \cdot 2H_2O$ were recorded using a conventional spectrometer with the sample placed in a helium cryostat allowing variation of the temperature between 4 K and 300 K. As the source, ^{57}Co in rhodium at 293 K was used. The data were evaluated using the programs MOSFUN[35] and EFFI.[36] The high-spin molar fraction was estimated from the area fractions by taking equal Mössbauer−Lamb factors for low-spin and high-spin states.

Preparation of the Compounds: All chemicals were obtained commercially in adequately pure states. The ligand Hpt was synthesized from 2-cyanopyridine, hydrazine monohydrate, and formic acid according to the method described in literature.[32,47] Hpt: $C_7H_6N_4$ (146.2): calcd. C 57.53, H 4.14, N 38.33; found C 56.68, H 4.65, N 38.63.

$[Fe(Hpt)_3](BF_4)_2 \cdot 2H_2O$ was prepared under argon atmosphere by dissolving $[Fe(H_2O)_6](BF_4)_2$ (0.34 g, 1 mmol) and Hpt (0.44 g, 3 mmol) in hot, deoxygenated water (20 mL), to yield a clear brown solution. On standing in a closed flask at room temperature for

Crystal Structure Determination of $[Fe(Hpt)_3](BF_4)_2$: A single crystal of dimensions 0.10 × 0.15 × 0.30 mm was mounted on a Lindemann glass capillary and placed in the cold nitrogen stream of the diffractometer. Data were collected on an Enraf−Nonius KappaCCD diffractometer on a rotating anode (Mo-K_α radiation, graphite monochromator, λ = 0.71073 Å, Lp correction, no absorption correction). Two data sets were recorded from this crystal, one at T = 95 K and one at T = 250 K. Structure determination revealed that the only geometrical differences between these structures were those related to the spin transition. Since the data for the 250 K structure were rather poor due to crystal deterioration, an additional data set was collected on a second crystal of dimensions 0.20 × 0.35 × 0.35 mm. Geometric data pertaining to the two structures measured at 250 K proved to be equal within experimental error. The data for the 250 K structure reported here refer to the second data set. Pertinent data relating to the structure determinations are collected in Table 4. The structures were solved by direct methods using SHELXS-86.[48] Refinement on F^2 was performed with SHELXL-97.[49] The hydrogen atoms were included in the refinement in calculated positions riding on their carrier atoms. The non-hydrogen atoms were refined with anisotropic thermal parameters. The hydrogen atoms were refined with a fixed isotropic displacement parameter related to the value of the equivalent isotropic displacement parameter of their carrier atoms. The BF_4 counterions were found to be disordered and located in a region also containing disordered solvent molecules, probably water. The contribution to the structure factors associated with counterions and solvent was taken into account using the SQUEEZE procedure as incorporated in PLATON.[33] A total of 840 e were found in a volume of 1800 Å^3, equally distributed between two symmetry-related cavities. Neutral atom scattering factors and anomalous dispersion corrections were taken from the International Tables for Crystallography.[50] Geometrical calculations and the generation of illustrations were performed with PLATON.[33]

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-140484/140485. Copies of the data can be obtained free of charge on application to the CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) +44 (0)1223/336033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

Financial support by the European Union, allowing regular exchange of preliminary results with several European colleagues within the TOSS network under contract ERB-FMRX-CT980199, is gratefully acknowledged. Additional support by the ESF program Molecular Magnets is also kindly acknowledged. The work described in this paper has been supported by the Leiden University Study Group, WFMO, and has been performed under the aus-

pices of the Graduate Research School, HRSMC, a joint activity of Leiden University and the two Universities in Amsterdam. This work was also partly financially supported (A.L.S.) by the Council for the Chemical Sciences of the Netherlands Organization for Scientific Research (CW-NWO). Finally, financial support from the Materialwissenschaftliches Forschungszentrum der Universität Mainz and the Fonds der Chemischen Industrie is also gratefully acknowledged.

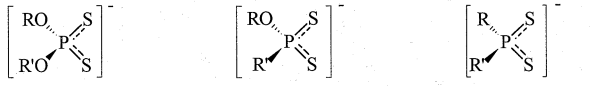
Ring-Opening of Lawesson's Reagent: New Syntheses of Phosphono- and Amidophosphono-Dithioato Complexes − Structural and CP-MAS ^{31}P-NMR Characterization of [*p*-$CH_3OPh(X)PS_2]_2M$ (X = MeO, *i*PrNH; M = Ni^{II}, Pd^{II}, and Pt^{II})



M. Carla Aragoni,[a] Massimiliano Arca,[a] Francesco Demartin,[b] Francesco A. Devillanova,[a] Claudia Graiff,[c] Francesco Isaia,[a] Vito Lippolis,[a] Antonio Tiripicchio,[c] and Gaetano Verani*[a]

Keywords: Nickel / Palladium / Platinum / S ligands / NMR spectroscopy / Phosphonodithioates / Lawesson's reagent

The opening of the P_2S_2 tetraatomic ring of Lawesson's reagent (**4**) has proved versatile in synthesizing phosphono- and amidophosphono-dithioato mononuclear complexes [*p*-$CH_3OPh(X)PS_2]_2M$ [X = CH_3O, *i*PrNH; M = Ni^{II}, Pd^{II}, Pt^{II}]. A one-step reaction of **4** with the appropriate metal salt in CH_3OH, or in the presence of a stoichiometric amount of *i*$PrNH_2$ in $CHCl_3$, is used in the direct synthesis of the Ni^{II} and Pd^{II} complexes, but does not work in the Pt^{II} complexes. Alternatively, these syntheses can be carried out: i) by preparation and isolation of *O*-methyl(4-methoxyphenyl)phosphonodithioate (**6**) salts or isopropylamido(4-methoxyphenyl)-phosphonodithioate (**7**) salts by treating **4** with CH_3O^- in CH_3OH or with *i*$PrNH_2$, respectively; ii) by reaction of **6** or **7** with MCl_2 or K_2MCl_4 [M = Ni^{II}, Pd^{II}, Pt^{II}] to give *trans*-bis[*O*-methyl(4-methoxyphenyl)phosphonodithioato]M and *trans*-bis[isopropylamido(4-methoxyphenyl)phosphono-dithioato]M complexes. Following these routes, *trans*-bis[*O*-methyl(4-methoxyphenyl)phosphonodithioato]M [M = Ni (**8a**), Pd (**8b**), and Pt (**8c**)] and *trans*-bis[isopropylamido(4-methoxyphenyl)phosphonodithioato]M [M = Ni (**9a**), Pd (**9b**), and Pt (**9c**)] complexes have been synthesized and fully characterized by FAB mass, FT-IR, FT-Raman, UV/Vis, and CP-MAS ^{31}P-NMR spectroscopy; the crystal structures of **7**, **8b**, **8c**, and **9a** are also reported.

Introduction

Organophosphodithio compounds, such as phospho-ro-,[1] phosphono-, and phosphanyl-dithioates[2] **1**, **2**, and **3** and corresponding metal complexes, play important roles in industrial and agricultural fields,[3] e.g. additives to lubricant oils,[4] extraction reagents for metal ions,[3,5] flotation agents for mineral ores,[3] insecticides,[3,6] rodenticides,[3,6] and pesticides.[3,6] Furthermore, phosphonate derivatives have assumed a great importance as a replacement of the phosphate moiety in biologically active molecules[7] in the past decades. Many papers have been published on the synthesis and coordination chemistry of **1** and **3**,[1,2,5,8] but, because of synthetic difficulties,[9] only a few have dealt with **2**.

In fact, phosphonodithioate syntheses from organophosphanyl chlorides[9a] or P_4S_{10},[10] involve several laborious reaction steps. A synthesis of phosphonodithioic acid derivatives developed by Martin et al. involves the use of the appropriate Grignard reagent and 2-chloro-1,3,2-dithiaphospholane,[11] but several reaction steps are also required. Under the appropriate conditions, compounds such as 1,3-dithia-2,4-diphosphetane 2,4-disulfide derivatives can give a ring opening, as shown for the well-known Lawesson's reagent (**4**).[12] Although a large amount of information describing the reactivity of **4** can be found in the literature, very little can be found about the reactions of these substrates with transition metal ions[13] or main group elements.[14] We report two novel and facile synthetic routes for preparing complexes with type **2** ligands, i.e. phosphono- and amidophosphono-dithioate, *p*-$CH_3OPh(X)PS_2^-$, X = CH_3O, *i*PrNH, with Ni^{II}, Pd^{II}, and Pt^{II}.

Results and Discussion

Reactivity

In an attempt to optimize the synthesis of a new class of nickel dithiolenes[15] using **4** as a sulfuring agent, we incidentally obtained Ni^{II} complexes of **2**, from which *trans*-bis[*O*-ethyl(4-methoxyphenyl)phosphonodithioate]Ni complex **5**, was structurally characterized;[21] this one-step reaction is shown in the pathway i) of Scheme 1. The ring opening of **4**, required in the formation of the complexes, requires a nucleophilic agent that is the same solvent, for example MeOH in i). Another way of inducing the ring opening of **4** to yield complexes is to use an amine in a stoichiometric amount relative to **4**, in an inert solvent in order to avoid competition reactions. Isopropylamine, $iPrNH_2$, has been chosen as a model compound and was used in $CHCl_3$ as shown in pathway ii). However, in both i) and ii) only phosphono- and amidophosphono-dithioate complexes of Ni^{II} (**8a**, **9a**) and Pd^{II} (**8b**, **9b**) were obtained, the former in higher yields than the latter. In contrast, in spite of several attempts, Pt^{II} complexes (**8c**, **9c**) were never obtained. To prepare Pt^{II} complexes, a different route was successfully attempted through the dithioato ligands **6** and **7**, see pathways iii), iv), and v). Here the two bases, sodium methoxide in MeOH and the amine working both as reagent and solvent, induce the ring opening of **4** to give phosphono- and amidophosphono-dithioate ligands **6** and **7**. As shown in pathway v), these ligands yielded phosphono- and amidophosphono-dithioato complexes **8a**−**8c** and **9a**−**9c**, respectively, almost quantitatively, when treated with $NiCl_2$ and K_2MCl_4 [M = Pd^{II}, Pt^{II}] in $MeCN/H_2O$. However, these experiments show that the difficulty in obtaining platinum complexes according to i) and ii) does not depend on their stabilities.

Ar = 4-methoxyphenyl. – [a] The reaction with K_2NiCl_4 has not been attempted.

Scheme 1

Crystal Structures

The crystal structures of **7**, **8b**, **8c**, and **9a** have been determined by single-crystal X-ray diffraction; ORTEP views of the structures together with atom-numbering schemes are shown for **7** (Figure 1), **8c** (Figure 2), and **9a** (Figure 3); some selected bond lengths and angles of **7**, **8b**, and **8c** are given in Table 1; those of compound **9c** in Table 2. The structures of the isostructural phosphonodithioates **8b** and **8c** consist of centrosymmetric square-planar complexes with the metal atom coordinated by the four S atoms of the two *S*,*S*-bidentate ligands. The two M−S bond lengths are comparable [Pd−S(1) and Pd−S(2) are 2.354(1) and

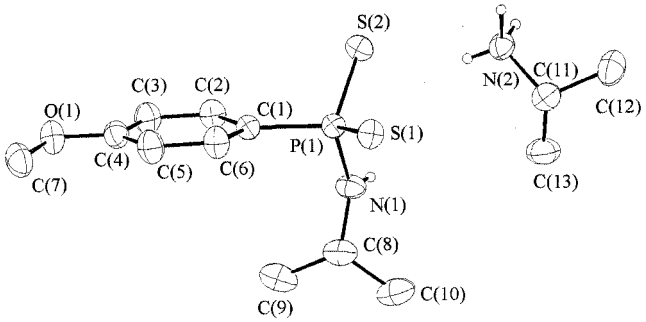

Figure 1. ORTEP drawing and atom-labeling scheme for the isopropylammonium salt of **7**; hydrogen atoms are partially omitted for clarity

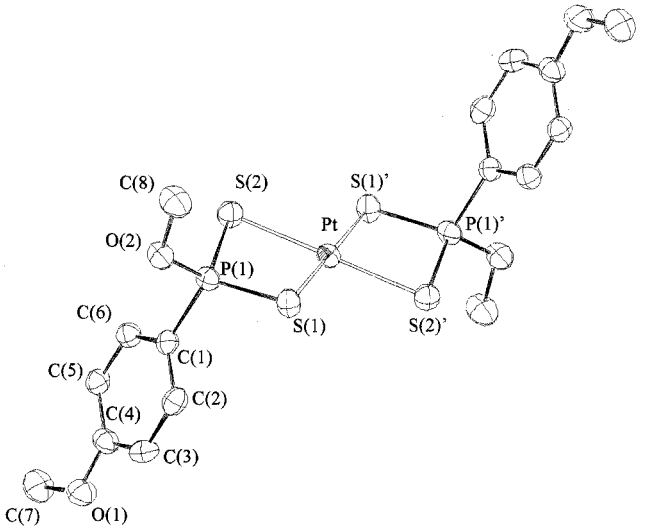

Figure 2. ORTEP drawing and atom-labeling scheme for compound **8c**; hydrogen atoms are omitted for clarity

2.353(1) Å, Pt−S(1) and Pt−S(2) are 2.336(2) and 2.349(2) Å] as previously found for the similar (phosphonodithioato)nickel(II) complex **5** [2.220(1) and 2.222(1) Å].[21] The P atoms are in a pseudo-tetrahedral environment involving the carbon atom of the 4-methoxyphenyl group, the oxygen atom of the methoxy group, and the two S atoms. The P−S bond lengths [2.010(1) and 2.009 (1) Å for **8b**, and 2.011(3) and 2.010 (1) Å for **8c**] are also equal, suggesting a symmetrically delocalized P−S π bond. The P−S bond lengths are comparable with those found in **5**, in the *trans*-bis(*O*-ethylphenyl)phosphonodithioate of Ni,[9d] Pd,[9e] and

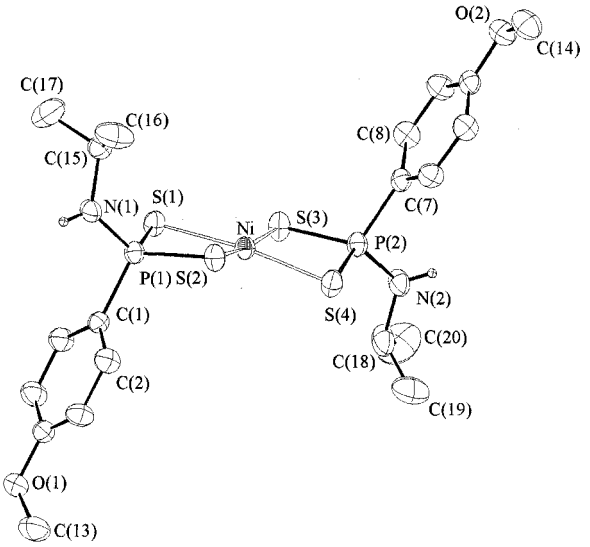

Figure 3. ORTEP drawing and atom-labeling scheme for compound **9a**; hydrogen atoms are partially omitted for clarity

Pt,[9e] and in analogous complexes with type **1** and **3** ligands,[8] and only differ from those found in *trans*-bis[(*O*-isopropyl)ethylphosphonodithioato]Ni[16] in which P−S single bonds, 2.031 Å, and P=S double bonds, 1.900 Å, are present.

The crystal structure of the *trans*-bis[isopropylamido(4-methoxyphenyl)phosphonodithioato]Ni complex **9a**, shows that the metal atom is coordinated by the four S atoms of two *S*,*S*-bidentate ligands. Also in this case, the four Ni−S bond lengths are comparable [2.225(2), 2.227(2), 2.228(2), and 2.216(2) Å], and the four P−S bond lengths [2.012(3), 2.016(3), 2.014(2), and 2.017(2) Å] are nearly identical, suggesting a delocalized P−S π bond, as for **8b** and **8c**. The structure of **9a** closely resembles that of **5**, where P−N bonds replace P−O bonds. The structure of **7**, which contains a unique example of an amidophosphonodithioate anion reported in the literature, displays structural features similar to those reported for type **1**[17] and **3**[18] salts, with similar P−S bond lengths [1.989(1) and 2.000(1) Å] according to a delocalization of the negative charge over the S−P−S fragment. A significant difference between the values of the two P−S bonds [1.945(2) and 1.969(2) Å] has only been found in the case of $K[S_2P(OCH_2Ph)_2]$.[17a] The P−N bond length [1.655(3) Å] in **7** is appreciably longer than those found in **9a** [1.619(4) and 1.622(4) Å].

CP-MAS ^{31}P NMR

Sodium *O*-methyl(4-methoxyphenyl)phosphonodithioate shows a signal at δ = 110.4, which is expectedly different from the value observed for the isopropylammonium isopropylamido(4-methoxyphenyl)phosphonodithioate (δ = 72.7). This value is comparable with the previously reported value for methylammonium methylamido(4-methoxyphenyl)phosphonodithioate (δ = 82.3), which was measured in methylamine solution.[19] Analogous differences are also observed for the corresponding Ni, Pd, and Pt complexes of the two classes of ligands; the ^{31}P-NMR chemical shift for **8a−c** (δ = 97.3, 110.2, 105.7, respectively) was always found downfield relative to those measured for **9a−c** (δ = 71.7, 84.1, 81.7, respectively). The observation that the variation of the S−P−S bond angle affects the ^{31}P chemical shifts[20] seems to be confirmed by these measurements. In fact, within the same series (e.g. **5**, **8b**, **8c**, and **7**, **9a**), a bigger value of the ^{31}P-NMR chemical shift corresponds to an increase in the bond angle.

Conclusions

The easy one-step reaction between Lawesson's reagent (**4**) and alcohols ROH or amines $R'NH_2$ leads to phosphono- and amido-phosphonodithioato ligands (**6** and **7** for R = Me and R′ = *i*Pr, respectively). From these ligands,

the corresponding Ni^{II}, Pd^{II}, and Pt^{II} complexes (**8a−c**, **9a−c**) have been synthesized and fully characterized by means of spectroscopic and diffractometric techniques. The mild reaction conditions and high yields allow the introduction of the desired groups in the phosphono- and amidophosphono-dithioato ligands. This opens interesting perspectives in obtaining novel materials starting from alcohols and amines having intrinsic peculiarities.

Experimental Section

General: All reagents and solvents were purchased from Aldrich or Merck and used without further purification. − Elemental analyses were performed with an EA1108 CHNS-O Fisons instrument. − Infrared spectra were recorded with a Bruker IFS55 spectrometer at room temperature using a flow of dried air. Far-IR (500−50 cm^{-1}) spectra (resolution 2 cm^{-1}) were recorded as polythene pellets with a Mylar beam-splitter and polythene windows. Middle IR spectra (resolution 2 cm^{-1}) were recorded as KBr pellets, with a KBr beam-splitter and KBr windows. − FT-Raman spectra were recorded with a resolution of 2 cm^{-1} using a Bruker RFS100 FT-Raman spectrometer, fitted with an In−Ga−As detector (room temperature) operating with an Nd-YAG laser (excitation wavelength 1064 nm) with a 180° scattering geometry. The excitation power was modulated between 100 and 250 mW. − CP-MAS solid-state ^{31}P-NMR spectra were recorded with a Varian Unity Inova 400-MHz instrument operating at 161.9 MHz with samples packed into a zirconium oxide rotor. The ^{31}P-NMR chemical shifts were calibrated indirectly through the 85% H_3PO_4 peak ($\delta = 0.0$).

(4-Methoxyphenyl)-*O*-methylphosphonodithioate (6), Sodium Salt: A mixture of MeONa (0.76 g, 15 mmol) and **4** (3.00 g, 7.42 mmol) in methanol was heated at reflux for 1 h, and the solvent was then removed under reduced pressure to give a white solid (3.41 g, 90%). − M.p. > 290 °C with decomposition. − $C_8H_{10}NaO_2PS_2$ (256.2): calcd. C 37.5, H 3.9, S 25.0; found C 36.7, H 4.2, S 24.2. − FAB mass spectrum (gly/MeOH/H_2O matrix); *m*/*z*: 233; calcd. for $C_8H_{10}O_2PS_2$ 233 with correct isotopic distribution. − FT-IR (3500−100 cm^{-1}): 3060vw, 3006vw, 2936w, 2833w, 2091w, 1601vs, 1570s, 1501vs, 1466m, 1441m, 1403m, 1383w, 1298s, 1261vs, 1179s, 1152w, 1131w, 1113s, 1106s, 1150w, 1025m, 996vs, 831s, 802m, 748vs, 671vs, 629m, 559s, 511m, 474m, 466w, 437w, 382m, 227w cm^{-1}. − FT-Raman (3500−50 cm^{-1}; relative intensities in parentheses related to the highest peak taken equal to 10.0): 3065 (4.0), 3014 (1.8), 2933 (1.9), 2833 (1.9), 1592 (5.4), 1450 (1.3), 1185 (1.8), 1107 (6.7), 1006 (1.3), 801 (4.9), 654 (2.2), 627 (2.7), 559 (6.9), 523 (1.9), 414 (2.8), 388 (5.4), 364 (2.3), 255 (2.7), 194 (2.7), 92 (10) cm^{-1}. − CP-MAS ^{31}P NMR: $\delta = 110.4$ (s), 111.1 (s), 113.8 (s).

Isopropylamido(4-methoxyphenyl)phosphonodithioate (7), Isopropylammonium Salt: A weighed amount of **4** (1.60 g, 3.96 mmol) was stirred in isopropylamine (50 mL). After a few minutes, the solvent was removed under reduced pressure to give the salt as a white solid (1.28 g, quantitative). Crystals suitable for X-ray analysis were grown from an isopropylamine solution. − M.p. 175 °C. − $C_{13}H_{25}N_2OPS_2$ (320.4): calcd. C 48.7, H 7.9, N 8.7, S 20.0; found C 49.4, H 8.2, N 9.0, S 20.3. − FAB mass spectrum (3-NOBA matrix); *m*/*z*: 321; calcd. for $C_{13}H_{25}N_2OPS_2$ 320 with correct isotopic distribution. − FT-IR (3500−100 cm^{-1}): 3328m, 3000mbr, 1597vs, 1571s, 1497vs, 1466s, 1392m, 1303s, 1294s, 1250vs, 1175s, 1161m, 1135m, 1101s, 1032s, 1004s, 831s, 815m, 798m, 647vs, 622vs, 562vs, 460w cm^{-1}. − FT-Raman (3500−50 cm^{-1}; relative intensities in parentheses related to the highest peak taken equal to 10.0): 3329 (0.9), 3062 (3.3), 2978 (4.2), 2941 (3.5), 2880 (1.7), 2839 (1.4), 1593 (3.8), 1465 (1.5), 1302 (1.4), 1183 (1.8), 1101 (5.4), 798 (4.0), 624 (1.7), 623 (1.9), 566 (5.9), 522 (2.2), 114 (5.9), 69 (10.0) cm^{-1}. − CP-MAS ^{31}P NMR: $\delta = 72.7$ (s).

[a] The cell parameters of **9c** have also been measured: triclinic, space group $P\bar{1}$, a = 11.173(2), b = 12.640(4), c = 11.266(3) Å, α = 91.06 (3), β = 104.67(2), γ = 115.72(1)°. The reflections have not been collected, since **9c** is isostructural with **9a**. − [b] $R1 = \Sigma|F_o - F_c|/|\Sigma(F_o)|$; $wR2 = [\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]]^{1/2}$.

494vw, 393vw, 382vw, 308m cm^{-1}. – FT-Raman (3500–50 cm^{-1}; relative intensities in parentheses related to the highest peak taken equal to 10.0): 3057 (3.2), 2959 (2.8), 2927 (1.9), 1594 (5.3), 1459 (1.2), 1247 (1.5), 1179 (2.7), 1121 (7.2), 800 (2.4), 659 (1.4), 631 (1.8), 542 (8.2), 463 (1.3), 399 (1.8), 383 (1.7), 349 (2.1), 316 (3.3), 234 (1.5), 169 (5.0), 103 (10.0) cm^{-1}. – CP-MAS ^{31}P NMR: δ = 81.7 (s).

X-ray Structure Determination of 7 (Isopropylammonium Salt), 8b, 8c, and 9a: Crystallographic and experimental details of the data collection and refinement of the structures of **7** (isopropylammonium salt), **8b**, **8c**, and **9a** are reported in Table 3, while the molecular structures are depicted in Figures 1–3. The intensity data of the salt of **7** and **9a** were collected with an Enraf–Nonius CAD-4 single-crystal diffractometer, using the graphite-monochromated Cu-K_α radiation and the $\theta/2\theta$ scan technique. The intensity data of **8c** were collected with a Siemens AED single-crystal diffractometer, using graphite-monochromated Mo-K_α radiation and the $\theta/2\theta$ scan technique. The intensity data of **8b** were collected with a CAD-4 single-crystal diffractometer, using graphite-monochromated Mo-K_α radiation and the ω scan technique. Data were corrected in the usual manner for Lorentz and polarization effects, as well as for absorption.[22,23] – The structures were solved by Patterson and Fourier methods, and refined by full-matrix least-squares procedures based on F_o^2, first with isotropic displacement parameters, and then with anisotropic displacement parameters in the last cycles of refinement for all non-hydrogen atoms. The hydrogen atoms were introduced into the geometrically calculated positions, and refined "riding" on the corresponding carbon atoms for **8b**, **8c**, and **9a**; in the case of **7** (isopropylammonium salt), the hydrogen atoms were clearly found in the ΔF map and refined isotropically. – All calculations were performed using the SHELXS[24] and SHELXL[25] systems of crystallographic computer programs. – Lists of atomic coordinates for the non-H atoms, coordinates for the hydrogen atoms, and anisotropic displacement parameters, crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Center as supplementary publications nos. CCDC-140139 (**7** isopropylammonium salt), -140140 (**8b**), -140141 (**8c**), and -140142 (**9a**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

We thank the University of Nottingham, School of Chemistry, Mass Spectroscopy Service for the FAB-mass determinations. We thank the Regione Autonoma della Sardegna and MURST (Ministero per l'Università e la Ricerca Scientifica e Tecnologica) for support.

Keywords: Density functional calculations / Phosphorus / Boron / Halides / NMR spectroscopy / Raman spectroscopy

The phosphorus halide–boron halide complexes X_3PBY_3 (X = Cl, Br, I; Y = Br, I) were prepared and characterized by Raman and IR spectroscopy. Density functional theory (B3LYP) was applied to calculate structural and vibrational data. Assignments of the vibrational normal modes for these Lewis acid–base adducts were made on the basis of their Raman and IR spectra in comparison with computational results. The compounds Cl_3PBBr_3, Br_3PBBr_3, I_3PBBr_3, and I_3PBI_3 were also studied by solid-state ^{31}P MAS NMR spectroscopy. Second-order ^{31}P–$^{79,81}Br$ dipolar coupling effects were observed in the ^{31}P MAS NMR spectrum of Br_3PBBr_3. The molecular structure of Br_3PBBr_3 was determined by X-ray diffraction.

Introduction

As early as 1893 Tarible synthesized the first phosphorus halide–boron halide complex Br_3PBBr_3 from the reaction of PBr_3 and BBr_3 in CS_2.[1] Subsequently, papers have appeared regarding the syntheses of the phosphorus halide–boron halide complexes Cl_3PBBr_3,[2,3] Cl_3PBI_3,[3,4] Br_3PBI_3,[3] I_3PBBr_3,[3,5] I_3PBI_3,[3,5–7] and the di-adduct of P_2I_4 with BBr_3 $P_2I_4{\cdot}2BBr_3$[7] although only elemental analyses, melting points, and the infrared spectra of the adducts I_3PBBr_3, I_3PBI_3, $P_2I_4{\cdot}2BBr_3$.[5,7] were published for the characterization of these species.

In 1978 Terao and co-workers reported nuclear quadrupole resonance (NQR) experiments (^{79}Br and ^{127}I) for the Lewis acid–base complexes X_3PBY_3 (X = Br, I; Y = Br, I).[8] In 1983 the same authors also published Br–P–Br and Br–B–Br bond angles for Br_3PBBr_3, which were derived from an ^{81}Br NQR study.[9] Nevertheless, X-ray structural data for these phosphorus halide–boron halide donor–acceptor complexes were not available in the literature except for the related phosphane–haloboranes Me_3PBY_3 (Y = Cl, Br, I),[10] $(SiMe_3)_3PBY_3$ (Y = Cl, Br)[11] and Ph_3PBBr_3.[12]

Previous work has shown that the donor behavior of phosphorus trihalides depends on the electronegativity of the halogen substituents.[13,14] For the phosphorus trihalides, the order of stability for the 1:1 donor–acceptor complexes with boron trihalides is $PCl_3 < PBr_3 < PI_3$.[3] PF_3 appears to have no donor properties if only σ bonding is considered.[15] The order of stability of the adducts formed from boron trihalides with phosphorus trihalides is $BF_3 < BCl_3 < BBr_3 < BI_3$.[16]

Prior to the study described here these complexes had only been poorly investigated and so we repeated the syntheses and characterized the complexes by Raman and IR spectroscopy. In comparison with the results of density functional theory calculations, the vibrational spectra of these species were studied and a systematic order for assigning the vibrational normal modes was found. The compounds Cl_3PBBr_3, Br_3PBBr_3, I_3PBBr_3, and I_3PBI_3 were studied by ^{31}P MAS NMR. The structure of Br_3PBBr_3 was determined by X-ray diffraction.

Results and Discussion

All the compounds reported here were prepared from the reaction of one equivalent of phosphorus trihalide with one equivalent of the boron trihalide.

We attempted to dissolve the iodine-containing adducts I_3PBBr_3 (**5**) and I_3PBI_3 (**6**) in solvents such as CS_2, CH_2Cl_2, CH_3CN, $CFCl_3$, and SO_2 but found the solubility of these complexes to be very limited. The saturated solution in CS_2 contains essentially only very small amounts of the phosphorus trihalide PI_3 and the corresponding boron trihalide BY_3 (Y = Br, I), as indicated by ^{31}P- and ^{11}B-NMR studies.

In contrast to **5** and **6**, the complexes Cl_3PBBr_3 (**1**), Cl_3PBI_3 (**2**), Br_3PBBr_3 (**3**), and Br_3PBI_3 (**4**) dissolve in CH_2Cl_2 and CS_2. ^{31}P- and ^{11}B-NMR studies showed, besides signals for PX_3 (X = Cl, Br, I) and BY_3 (Y = Cl, Br,

I), resonances for several of the mixed species PX_aY_b and BX_aY_b (a, b = 1, 2; $a \neq b$).

Sublimation of these adducts leads to decomposition into PX_3 (X = Cl, Br, I) and BY_3 (Y = Br, I) and we therefore concluded that all phosphorus halide−boron halide complexes **1**−**6** exist only in the solid state.

In the cases of Br_3PBBr_3 (**3**), I_3PBBr_3 (**5**), and I_3PBI_3 (**6**), sublimation could be used to purify these adducts. For Cl_3PBBr_3 (**1**), Cl_3PBI_3 (**2**), and Br_3PBI_3 (**4**) only decomposition products such as mixed species, halogen and uncharacterized products were observed.

Experimental data for the mixed halogen substituted species (X_3PBY_3, X ≠ Y) showed that halogen exchange only occurs in X_3PBY_3, where Y represents the heavier halogen [temperature for the halogen exchange; Cl_3PBBr_3 (**1**) 35−42 °C, Cl_3PBI_3 (**2**) 0 °C, and Br_3PBI_3 (**4**) room temp.].

Another aim of our investigation was the preparation of $P_2I_4{\cdot}2BBr_3$, a compound that was claimed as being isolated in 1901 by Tarible in the reaction of P_2I_4 with two equivalents of BBr_3.[17] Baudler and Fricke did not succeed in repeating Tarible's work,[18] whereas Cowley et al. claimed to have isolated the compound on the basis of IR data.[5]

The Raman spectrum of the yellow solid, obtained from the reaction of P_2I_4 and BBr_3 in CS_2 according to the literature,[5] displayed unequivocally the Raman lines of I_3PBBr_3 (**5**). The vibrational data are very similar to those obtained by Cowley and Cohen[5] and so it can be assumed that P_2I_4 disproportionates into PI_3 (which forms the observed adduct with BBr_3) and a polymeric iodide $(PI)_n$. The same disproportionation was suggested for the reaction of P_2I_4 with BI_3 resulting in the formation of I_3PBI_3.[5]

Vibrational Spectroscopy

Raman and IR Spectra of X_3PBY_3 (X = Cl, Br, I; Y = Br, I) (1−6)

Table 1 and Table 2 summarize the computed and experimentally observed vibrational frequencies of the compounds **1**−**6** synthesized in this study. Figure 1 shows the Raman spectra of the adducts X_3PBY_3 (**3**: X, Y = Br; **6**: X, Y = I) and Figure 2 the Raman spectra of Cl_3PBBr_3 (**1**), Cl_3PBI_3 (**2**), and I_3PBBr_3 (**5**). The vibrational spectra are in good agreement with our calculations (B3LYP) and allow structural assignments to be made. It should be noted that the computation was carried out for a single, isolated (gas-phase) molecule. There may well be significant differences between gas-phase and solid-state spectra.

The two broad peaks in the Raman spectra of **1**, **3**, and **5** in the range of ca. 700−590 cm^{-1} represent the asymmetric stretching vibration of the BBr_3 unit (ω_1) in the complex. The asymmetric B−I stretching mode (ω_1) can be observed in the Raman spectra of **2**, **4**, and **6** in the range of ca. 650−570 cm^{-1} (broad and weak peaks). In contrast to the Raman spectra, two very intense peaks can be assigned to this vibration in the IR spectrum of **6**. (The adducts **2** and **4** decompose rapidly at room temperature and, for this reason, IR data are not available. Compound **4** was contaminated with disproportionation products and therefore its spectrum is not included in Figure 2.) The asymmetric P−X stretching frequency, ω_3, can be found for X = Cl at 590 cm^{-1} (**1**) and for X = Br at 421 cm^{-1} (**3**). Similarly, the values for the asymmetric stretching mode [ν_4 (E), PX_3] for $OPCl_3$ and $OPBr_3$ are reported to be at 581 and 488 cm^{-1},

38 (0)			44 (0)		30 (0)		26 (0)			ω_{12} (torsion)

[a] In parentheses: IR intensity [km mol^{-1}].

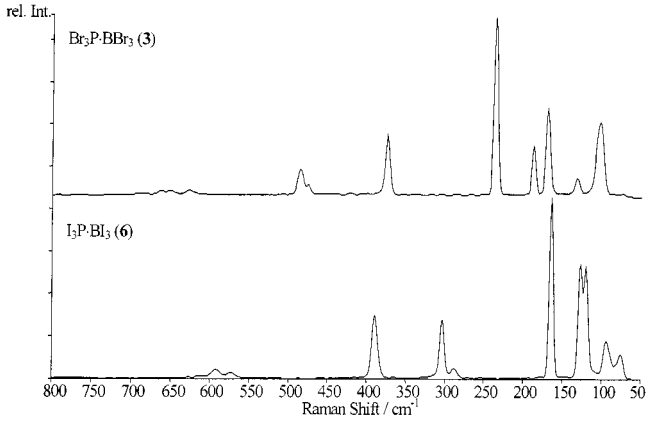

Figure 1. Raman spectra of Br_3PBBr_3 (**3**) and I_3PBI_3 (**6**)

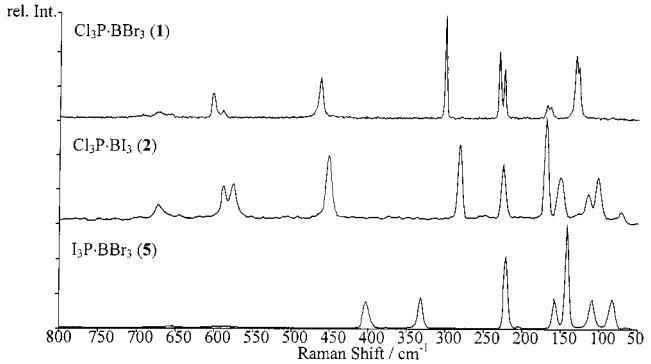

Figure 2. Raman spectra of Cl_3PBBr_3 (**1**), Cl_3PBBr_3 (**2**), and I_3PBBr_3 (**5**)

respectively.[19] The experimental values in the vibrational spectra (IR, Raman) of I_3PBI_3 (**6**) at 387 cm^{-1} and in the IR spectrum of I_3PBBr_3 (**5**) at 361 cm^{-1} can be assigned to the asymmetric stretching vibration of the PI_3 unit (ω_3). Similar vibrational frequencies were reported for the asymmetric stretching modes in the PI_4^+ salts $PI_4^+EI_4^-$ (E = Al, Ga, In)[20,21] at 380 cm^{-1} [ν_3 (T_2), PI_4^+] and in the $P_2I_5^+$ salts $P_2I_5^+EI_4^-$ (E = Al, Ga, In) at 382 cm^{-1}.[22]

Almost purely symmetric P–B stretching vibrations (ω_2) can be observed at 602 (**1**), 588 (**2**), 475 (**3**), 471 (**4**), 402 (**5**), and 422 cm^{-1} (**6**). With heavier halogen substituents the P–B stretching modes are shifted to lower frequencies. The experimental values for the corresponding modes of the related complexes H_3PBY_3 (Y = Cl, Br, I) are found in the range of 679 to 699 cm^{-1}.[23,24]

The assignments of ω_4 to ω_{12} are not as straightforward as those for ω_1 to ω_3. These motions can be described as mixtures of stretches and deformations.

The vibrational mode ω_4, which can be interpreted as a mixture of a P–B stretching mode and symmetric stretching vibrations of the phosphorus trihalide and the boron trihalide units, can be observed and has a similar trend to ω_2: 463 (**1**), 451 (**2**), 377 (**3**), 351 (**4**), 333 cm^{-1} (**5**), and 300 cm^{-1} (**6**).

The mode ω_{5a}, observed as intense peaks in the Raman spectra of **3** (235), **5** (220), and **6** (163), can be described as mixtures of P–B, symmetric PX_3 (X = Cl, Br, I) stretching and symmetric BY_3 (Y = Br, I) deformation modes. A sim-

ilar combination mode, assigned as ω_{5b}, can be observed at 301 (**1**), 281 (**2**), and 195 cm^{-1} (**4**).

The intense Raman frequencies (ω_{6a}), assigned as a combination mode of symmetric deformation modes of the phosphorus halide and boron halide units and a P−B stretching vibration ("umbrella" vibration, $PX_3 + BY_3$ out-of-phase), at 231(**1**), 168 (**2**), 186 (**3**), 147 (**4**), and 126 cm^{-1} (**6**) are reduced to lower wave numbers with heavier halogen substituents.

The bending modes of the PX_3 (X = Cl, Br, I) and BY_3 (Y = Br, I) units, ω_7, can be assigned to peaks with medium intensity in the Raman spectra at 224 (**1**, **2**), 169 (**3**), 127 (**4**), 157 (**5**), and 120 cm^{-1} (**6**).

The normal modes ω_8 to ω_{12} represent fairly complex mixtures of different deformation modes with the exception of the low-lying frequency ω_{10a}, which represents the stretching mode of the entire PX_3 unit towards the BY_3 unit.

Temperature-Dependent Raman Spectra

Br_3PBBr_3 (**3**) decomposes at 61 °C to give a colorless liquid that essentially contains PBr_3 and BBr_3. We recorded the Raman spectra of compound **3** in the temperature region between 20 and 80 °C in steps of 5 °C. Above 60 °C the Raman spectra showed five intense peaks at 383 [ν_1 (A_1), PBr_3], 279 [ν_1 (A_1'), BBr_3], 162 [ν_2 (A_1), PBr_3], 152 [ν_4 (E'), BBr_3], and 115 cm^{-1} [ν_4 (E), PBr_3], which can be assigned to the normal modes of PBr_3 and BBr_3 in the liquid phase.[25,26] The decomposition is reversible. The white Br_3PBBr_3 can be reformed by cooling the liquid to room temperature.

On recording the Raman spectrum of I_3PBBr_3 (**5**) in the temperature range between 20 and 170 °C, we observed that I_3PBBr_3 decomposes into liquid PI_3 {320 [ν_3 (E)], 298 [ν_1 (A_1)], 112 [ν_2 (A_1)], and 82 [ν_4 (E)] cm^{-1}}[27] and BBr_3. Slow cooling of the sample to room temperature led to a yellow solid, which was identified as I_3PBBr_3 with small amounts of I_2 as an impurity. This experiment indicates that halogen exchange does not occur as long as X is heavier than Y (X_3PBY_3).

The melting range of the complex Cl_3PBBr_3 (**1**) is 35−42 °C. The Raman spectrum of the colorless liquid, obtained by heating freshly synthesized Cl_3PBBr_3, shows that at 45 °C the complex decomposes into PCl_3 {514 [ν_3 (E)], 505 [ν_1 (A_1)], 259 [ν_2 (A_1)], and 190 [ν_4 (E)] cm^{-1}},[25] PBr_3 (see above), BCl_3 {472 [ν_1 (A')], 255 [ν_4 (E')] cm^{-1}}[26] and BBr_3 (see above) by halogen exchange. Heating of a sample for 2 d at 70 °C led to a colorless liquid that contained only PBr_3 and BCl_3. It appears that the complex undergoes total halogen exchange. An adduct of Br_3PBCl_3 was not formed after the halogen exchange had occurred, even at temperatures below −130 °C. This result is in agreement with the reports of Holmes,[4] who found that there is no reaction between PBr_3 with BCl_3. Moreover, our density functional calculations show that none of the phosphorus trihalides form 1:1 Lewis acid−base complexes with boron trichloride.

Solid-State ^{31}P-NMR Spectroscopy

The ^{31}P MAS NMR spectra of the compounds I_3PBI_3 (**6**), I_3PBBr_3 (**5**), Br_3PBBr_3 (**3**), and Cl_3PBBr_3 (**1**) are displayed in Figure 3 and the shift data derived from the spectra are summarized in Table 3. The two I_3PBY_3 (Y = Br, I) adducts **5** and **6** show typical spinning side band patterns due to chemical shift anisotropy as observed previously for $PI_4^+EF_6^-$ (E = As, Sb)[20] and $P_2I_5^+EI_4^-$ (E = Al, Ga, In).[22] The central lines of the anisotropy patterns were identified by variation of the spinning frequency and the magnitude of the shift anisotropy δ_{CSA} was estimated by simulation of the side band intensities using the PC program Bruker WINFIT. The spectrum of I_3PBBr_3 (**5**) shows a second weak pattern at δ_{iso} = 237, which originates from PI_3 impurities in the sample.[22]

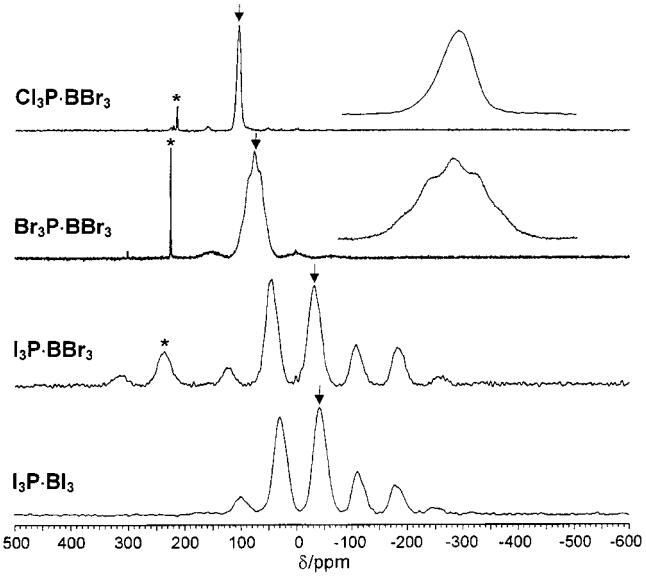

Figure 3. ^{31}P MAS NMR spectra (161.96 MHz) of X_3PBY_3 adducts; the isotropic resonance positions are indicated by arrows, asterisks denote PX_3 impurities (PI_3 in I_3PBBr_3, Br_3P in Br_3PBBr_3, and PCl_3 in Cl_3PBBr_3), all the other lines are spinning side bands; the inserts in the Br_3PBBr_3 and Cl_3PBBr_3 spectra are expanded plots of the resonances centered at δ = 76.9 and 105.3, respectively

Table 3. ^{31}P-NMR isotropic chemical shifts, δ_{iso}, shift anisotropies, δ_{CSA}, and coordination shifts, $\Delta\delta_{coord}$, of X_3PBY_3 compounds (in ppm)

	δ_{iso}	$\Delta\delta_{coord}$[a]	δ_{CSA}[b]
I_3PBI_3 (**6**)	−41.5	−278	−190
I_3PBBr_3 (**5**)	−31.0	−268	−210
Br_3PBBr_3 (**3**)	+76.9	−149	–
Cl_3PBBr_3 (**1**)	+105.3	−110	–

[a] $\Delta\delta_{coord} = \delta_{iso}(X_3P{\cdot}BY_3) - \delta_{iso}(PX_3)$. − [b] $\delta_{CSA} = \delta_{33} - \delta_{iso}$.

The spectra of Br_3PBBr_3 (**3**) and Cl_3PBBr_3 (**1**) exhibit only very weak spinning side bands, indicating small chemical shift anisotropies of the phosphorous atoms in these compounds. Besides the main signals of the adducts (indic-

ated by arrows in Figure 3), narrow lines appear at low field that are attributed to small amounts of PX_3 impurities with X = Br (δ = 226) in Br_3PBBr_3 (**3**) and X = Cl (δ = 214) in Cl_3PBBr_3 (**1**).

Surprisingly, the resonance of Br_3PBBr_3 (**3**) shows an apparent "multiplet" structure (see insert in Figure 3) that is independent of the spinning speed and may formally be simulated by seven overlapping component lines with an equidistant separation of about 1780 Hz. Both the line separation and the intensity distribution rule out a simple explanation in terms of scalar spin-spin coupling between the ^{31}P and the directly bonded $^{79,81}Br$ nuclei [both Br isotopes have a nuclear spin of 3/2, $^1J(^{31}P-^{79,81}Br)$ of 300−380 Hz is reported[28] for PBr_3]. Most probably, the observed "splittings" are caused by second-order effects resulting from dipolar couplings of the ^{31}P with the adjacent $^{79,81}Br$ nuclei, which are not averaged out by magic-angle spinning because of the large quadrupole interaction of the bromine nuclei. Similar effects arising from interactions of ^{31}P with neighboring spin-3/2 quadrupolar nuclei have been observed before for the spin pair $^{31}P-^{63,65}Cu$ in bis(trimethylphosphane) copper(I) nitrate[29] and, more relevant in the context of this study, for $^{31}P-^{35,37}Cl$ in the PCl_4^+ and PCl_6^- ions of solid phosphorus pentachloride.[29] In the latter case, "multiplet" resonances are observed in the ^{31}P MAS NMR spectra that are very similar to the one obtained for Br_3PBBr_3 (**3**). A detailed analysis of this type of second order effect[29] has shown that complex MAS NMR spectra of the spin-1/2 nucleus may arise if the Zeeman interaction of the spin-3/2 nucleus is comparable to, or smaller than, its quadrupole interaction. Under such circumstances the spin states of the quadrupolar nucleus are no longer quantized along the external magnetic field and new terms are introduced in the combined Zeeman-quadrupole Hamiltonian with a different angular dependence than the usual $(3\cos^2\theta - 1)$ term, which is averaged by MAS. The dipolar interaction between the spin-1/2 and the spin-3/2 nucleus may then be reintroduced and gives rise to complex spectral patterns. The quadrupole coupling constant $C_Q = e^2qQ/\mathrm{hbar}$ of the bromine nuclei in the PBr_3 group of Br_3PBBr_3 (**3**) is 426 MHz for ^{81}Br[9] and 518 MHz for ^{79}Br.[8] On comparing these values with the Larmor frequencies of $\nu_L(^{81}Br) = 108$ MHz and $\nu_L(^{79}Br) = 100$ MHz (at 9.4 T), it becomes clear that the quadrupole interaction far exceeds the Zeeman interaction and dipolar coupling may be effective in the ^{31}P MAS NMR spectrum of Br_3PBBr_3 (**3**). To estimate the magnitude of the effect on the spectrum, we calculated the line positions of the ^{31}P multiplets arising from the dipolar coupling with a single Br nucleus for both isotopes following the principles derived in ref.[29] To this end, the parameter $K = -3C_Q/[4S(2S-1)\gamma_S B_o]$ and the dipolar constant $D = (\mu_o/4\pi)\gamma_I\gamma_S\mathrm{hbar}r_{IS}^{-3}$ were calculated, where $C_Q = e^2qQ/\mathrm{hbar}$ is the quadrupole coupling constant; $S = 3/2$, the nuclear spins of $^{79,81}Br$; γ_I and γ_S the magnetogyric ratios of ^{31}P and $^{79,81}Br$, respectively; $B_o = 9.4$ T, the magnetic field used in this study; $r_{IS} = 2.152$ Å, the P−Br distance from Table 4. Values of $K = 1.291$ and 0.986 and $D = 1416$ and 1527 Hz are obtained for the ^{79}Br and ^{81}Br isotopes, respectively. Using these values, the expected spectra were taken from Figure 3 of ref.[29] and are schematically depicted in Figure 4. Theoretically the shape of each resonance is a powder pattern with characteristic divergences and shoulders, but in practice these will be smeared out resulting in broad lines that are approximated by Gaussian lines of equal peak height in Figure 4. It is apparent from this figure that the dipole interaction even with a *single* ^{79}Br or ^{81}Br nucleus already results in splitting of the ^{31}P MAS NMR spectrum into four resonances extending over a spectral range of about 6 kHz, in contrast to the single narrow line to be expected for the unperturbed ^{31}P MAS NMR spectrum. The theoretical spectra of Figure 4 are, of course, not very similar to that observed experimentally for Br_3PBBr_3 (**3**). However, in this molecule the ^{31}P nucleus is coupled to three ^{79}Br and three ^{81}Br nuclei (natural isotopic abundance about 50% each), and further complications by interactions with the ^{11}B nucleus cannot be ruled out. Theoretical calculations of MAS line shapes of spin-1/2 nuclei which interact with three or more spin-3/2 nuclei are difficult and, at present, not feasible. However, such calculations should result in very complex spectral patterns that are not simple superpositions of spectra characterized by interaction with a single quadrupolar nucleus. This conclusion is in full agreement with the experimental findings. It should be noted that, to the best of our knowledge, Br_3PBBr_3 (**3**) is the first example for the observation of second order $^{31}P-^{79,81}Br$ dipolar coupling effects in a ^{31}P MAS NMR spectrum.

Similar dipolar splittings are not observed in the ^{31}P MAS NMR spectra of the I_3PBY_3 (Y = Br, I) and the

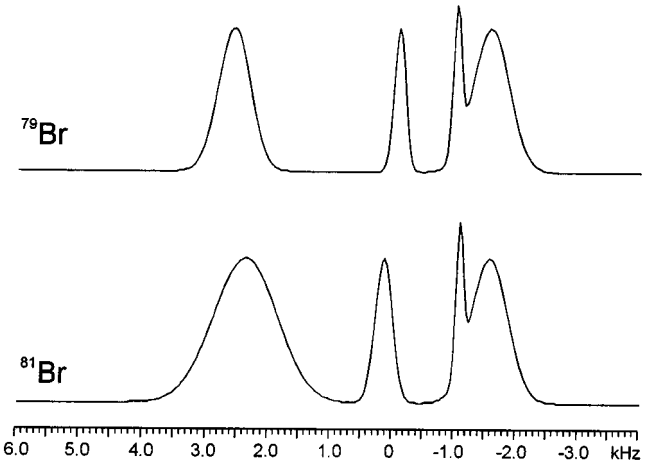

Figure 4. Schematic presentation of theoretical ^{31}P MAS NMR spectra resulting from second-order dipolar splittings with a single ^{81}Br and ^{79}Br nucleus (see text); the frequency scale is relative to the unperturbed ^{31}P resonance at 0 kHz

Cl_3PBBr_3 (**1**) compounds. ^{127}I has a nuclear spin of $S = 5/2$ and a very large C_Q [1931 MHz in I_3PBBr_3 (**5**)[8]] but no theoretical treatment of the dipolar interaction between spin-1/2 and spin-5/2 nuclei has been available so far. Since ^{35}Cl also has $S = 3/2$, the same calculations as considered above for Br_3PBBr_3 (**3**) were carried out for Cl_3PBBr_3 (**1**). The use of $C_Q = 60$ MHz[31] and $\nu_L = 39.2$ MHz for the ^{35}Cl nucleus and $r_{P-Cl} = 1.9$ Å results in the values $K = 0.383$ and $D = 668$ Hz. The theoretical spectrum derived from the data in Figure 3 of ref.[29] consists of two resonance lines that are 380 and 250 Hz wide and are separated by about 750 Hz. Considering the experimental line width of about 1400 Hz, these splittings cannot be resolved, which explains the observation of a single but slightly asymmetric resonance in the ^{31}P MAS NMR spectrum of Cl_3PBBr_3 (**1**) (Figure 3).

On complexing the phosphorus halide molecules with the boron halide the ^{31}P resonance is shifted significantly to higher field, the related "coordination shifts" $\Delta\delta_{coord} = \delta(X_3PBY_3) - \delta(PX_3)$ are summarized in Table 3. The upfield shift is largest for I_3PBI_3 (**6**) and decreases for the X_3PBBr_3 complexes in the order X = I > Br > Cl. However, the coordination shifts do not reflect the increasing charge transfer from the PX_3 donor to the BBr_3 acceptor groups (X = Cl > Br > I) and the concomitant increase of the ionicity of the P−X bonds in these compounds. The coordination shifts, on the other hand, have to be attributed to an increase of the heavy-atom effect at the four-coordinated phosphorus atom in the X_3PBY_3 complexes due to the increased s-character in the P−X bond.[20] Moreover, theoretical studies of NMR chemical shifts revealed that the chemical shift is largely determined by the topology of the electron density distribution at the atom rather than by its partial charge.[32]

Structure

Selected structural data for all X_3PBY_3 adducts (X = Cl, Br, I; Y = Br, I) and monomers are summarized in Table 4. The molecular structures of all species were fully optimized at the B3LYP level. Most of the P−B adducts were shown to possess stable minima at the B3LYP level (no imaginary frequencies), whereas a stable minimum could not be found for any of the X_3PBCl_3 adducts. All adducts possess C_{3v} symmetry with a staggered orientation of the BX_3 and PY_3 fragments. All structural parameters are in good agreement with those of other covalent P−B adducts.[10,11,12]

It should be noted, that the structures of such weakly bound systems may differ considerably between gas phase and the solid state.[33]

Br_3PBBr_3 (**3**, Figure 5) crystallizes in the orthorhombic space group *Pnma* with $Z = 4$. Single-crystal X-ray structure determination showed that the skeletal atoms of this molecule possess a slightly distorted C_{3v} symmetry with a staggered conformation. The P−B bond length was found to be 2.01(2) Å, which is significantly longer than in the corresponding phosphane−haloborane adducts R_3PBBr_3 (R = Me,[10] Ph,[12] $SiMe_3$[11]) and corresponds to a bond order of less than 1. This situation can be explained by the greater electron transfer within Me_3PBI_3 due to the positive inductive effect of the methyl groups, whereas in case of Br_3PBBr_3 and all the other X_3PBY_3 adducts the halogen Y decreases the donor strength of the P atom. In addition, the LP(Y) → σ*(BP) donor-acceptor interactions account for longer B−P distances and introduce a small amount of B−Y π bonding, which results in shorter B−Y distances.

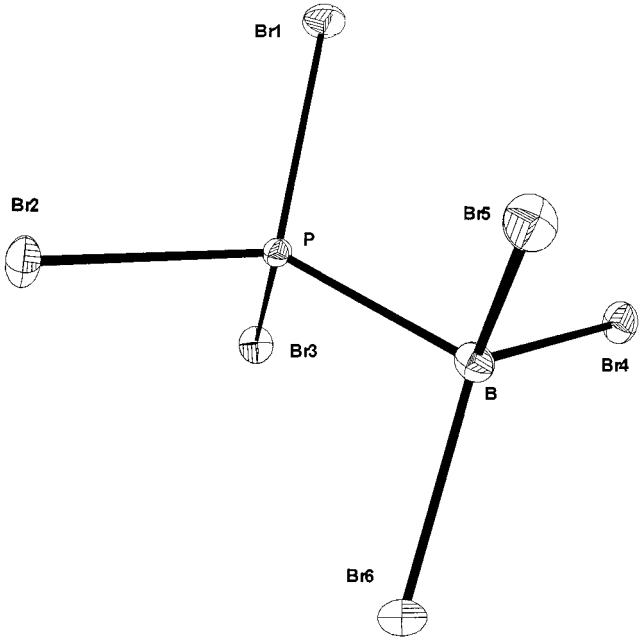

Figure 5. ORTEP plot of Br_3PBBr_3 (**3**)

Table 5 shows the comparison of bond lengths and bond angles of Br_3PBBr_3 (**3**) and the related phosphorus−boron adducts. The X-ray crystal data of **3** confirm that the Br−P−Br and Br−B−Br bond angles are significantly different from the experimental bond angles reported for Br_3PBBr_3 in a ^{81}Br NQR study.[9] The angles and B−Y and P−X distances in all adducts do not change much in the

different X_3PBY_3 species. However, there are more pronounced differences in the B−P distances.

Table 5. Selected bond lengths [Å] and angles [°] for Br_3PBBr_3 (**3**)

The calculated B−Y bond lengths in all adducts are much longer than in the isolated BY_3 moieties. Upon complexation, the lengthening of the B−Y bonds increases from BBr_3 to BI_3 adducts. This can be attributed to the greater π bonding character of the B−Y bonds in the isolated BY_3 molecules than in the adducts which increases from I to Cl.

Upon coordination, the lone pair electrons on the P atom are partially donated, resulting in a shrinking of the P−X bonds (compared to the PX_3 fragment) and opening of the X−P−X angles. This shortening is related to the dramatically increasing "s" character in the P−X bond of the complex [e.g. $h_P(PI_3) \approx sp^{17.20}$ vs. $h_P(I_3PBI_3) \approx sp^{2.71}$].

Additionally, the more electronegative Cl ligands in PCl_3 lead to better orbital overlap due to orbital contraction and, therefore, to a better electron transfer and a shorter B−P bond length. This feature is in agreement with Durig and Shen's finding for the H_3PBH_3 (1.943 Å) and F_3PBH_3 (1.836 Å) complexes.[34]

Conclusion

The structure and the vibrational normal modes of phosphorus halide−boron halide complexes Cl_3PBBr_3 (**1**), Cl_3PBI_3 (**2**), Br_3PBBr_3 (**3**), Br_3PBI_3 (**4**), I_3PBBr_3 (**5**), and I_3PBI_3 (**6**) have been calculated, discussed and compared with the experimental values. Vibrational assignments have been made on the basis of the Raman and IR spectra in comparison with computational results. Our calculations agree reasonably with the experimental data.

Temperature-dependent Raman experiments indicate that halogen exchange cannot be observed as long as X is heavier than Y in X_3PBY_3 (e.g. in I_3PBBr_3). In contrast, halogen exchange occurs when Y is heavier (e.g. within Cl_3PBBr_3).

The adducts Cl_3PBBr_3 (**1**), Br_3PBBr_3 (**3**), I_3PBBr_3 (**5**), and I_3PBI_3 (**6**) have been characterized by solid-state ^{31}P MAS NMR spectroscopy. The solid-state ^{31}P MAS NMR spectra reveal an increasing upfield shift for the X_3PBY_3 complexes in the order X = Br < I and Y = Cl < Br < I due to heavy-atom effects. The ^{31}P MAS NMR of Br_3PBBr_3 (**3**) represents the first example of second order $^{31}P-^{79,81}Br$ dipolar coupling effects.

All P−B bond lengths are rather long due to destabilizing donor−acceptor interactions. The increasing s character of the P−X bond in the complexes results in a opening of the X−P−X angles.

Adduct structures that represent true minima were found for all X_3PBY_3 species except for the cases where BCl_3 was the Lewis acid.

Experimental Section

General Remarks: All compounds reported here are moisture-sensitive, some extremely so, and decompose within a few seconds if exposed to the atmosphere. Consequently, strictly anaerobic and anhydrous conditions were employed for their synthesis. Any subsequent manipulations were carried out inside a dry-box under dry nitrogen. PBr_3, PCl_3, PI_3, BBr_3, and BI_3 (all Aldrich) were used as received. CS_2 was refluxed with P_4O_{10} and distilled before used. − ^{31}P-NMR spectra were measured at 161.96 MHz with a BRUKER MSL-400 NMR spectrometer under magic-angle-spinning (MAS) conditions. A standard double-bearing MAS probe for 4-mm rotors was used with spinning frequencies up to 12 kHz. Single-pulse acquisition with 1-μs pulse width (corresponding to 25° flip angle) and 5-s pulse repetition was applied. The samples were filled in 4-mm zirconia rotors under nitrogen in a glove box. The spectra were referenced to 85% aqueous phosphoric acid. Simulations of spectra were carried out with the PC program WINFIT from the BRUKER WINNMR software package. − Raman spectra of powdered solid samples contained in glass capillary tubes were obtained with with a Perkin−Elmer 2000 NIR spectrometer in the range 800−50 cm^{-1}. The low-temperature spectra were recorded using a Ventacon low-temperature cell and the high-temperature spectra were obtained using a Ventacon high-temperature cell. − IR spectra of Nujol mulls between CsI plates were taken in the range 800−200 cm^{-1} with a Nicolet 520 FT IR spectrometer. − For the determination of decomposition points, samples were heated in sealed glass capillaries in a Büchi B450 instrument.

Cl_3PBBr_3 (1): Cl_3PBBr_3 was prepared by addition of BBr_3 (1.56 g, 6.23 mmol) to PCl_3 (1.57 g, 11.40 mmol) with stirring at −40 °C. A colorless solid formed immediately. After warming the mixture to −30 °C, the remaining PCl_3 was removed under dynamic vacuum. − Yield: 1.50 g (44%) of a colorless solid, m.p. 35−42 °C (decomp.).

Cl_3PBI_3 (2): Cl_3PBI_3 was prepared by addition of PCl_3 (1.57 g, 11.40 mmol) to BI_3 (0.92 g, 2.35 mmol) with stirring at −40 °C. A colorless solid formed immediately. After warming the mixture to −30 °C, the remaining PCl_3 was removed under dynamic vacuum. − Yield: 1.30 g (95%) of a colorless solid, m.p. 0 °C (decomp.). − *Note:* Compound **2** undergoes halogen exchange above 0 °C, as indicated by a change in color from colorless to yellow. The impurity at 673 cm^{-1} in the Raman spectrum of **2** is due to this halogen exchange.

Br_3PBBr_3 (3): Br_3PBBr_3 was prepared by addition of PBr_3 (1.66 g, 6.13 mmol) in CS_2 to CS_2 solutions of BBr_3 (1.76 g, 7.03 mmol) with stirring at −40 °C. A colorless solid formed immediately. After

stirring for 15 min, the solid was filtered off. Traces of the solvent were removed under dynamic vacuum at room temperature. − Yield: 2.64 g (83%) of a colorless solid, m.p. 61 °C (decomp.).

Br_3PBI_3 (4): Br_3PBI_3 was prepared by addition of PBr_3 (0.42 g, 1.55 mmol) in CS_2 to CS_2 solutions of BI_3 (0.61 g, 1.55 mmol) with stirring at −40 °C. A yellow solid formed immediately. After stirring for 15 min, the solid was filtered off. Traces of the solvent were removed under dynamic vacuum at room temperature. − Yield: 0.92 g (90%) of a yellow solid, m.p. 150 °C (decomp., halogen exchange).

I_3PBBr_3 (5): I_3PBBr_3 was prepared by addition of PI_3 (1.63 g, 3.95 mmol) in CS_2 to CS_2 solutions of BBr_3 (0.99 g, 3.95 mmol) with stirring at −40 °C. A yellow precipitate formed immediately. After stirring for 15 min, the precipitate was isolated by filtering twice and washing with CS_2. Traces of CS_2 were removed under dynamic vacuum at room temperature. − Yield: 2.90 g (51%) of a yellow solid, m.p. 158−160 °C (decomp.).

I_3PBI_3 (6): I_3PBI_3 was prepared by addition of PI_3 (1.24 g, 3.01 mmol) in CS_2 to CS_2 solutions of BI_3 (1.17 g, 3.01 mmol) with stirring at room temperature. An orange precipitate formed immediately. After stirring for 15 min, the precipitate was isolated by filtration and washed with CS_2 until the filtrate was colorless. Traces of CS_2 were removed under dynamic vacuum at room temperature. − Yield: 1.88 g (78%) of an orange solid, m.p. > 250 °C (decomp.).

Computational Methods: The structure and vibrational data for the phosphorus halide−boron halide complexes **1**−**6** were calculated using the density functional theory with the program package Gaussian 94.[35] For P and B a standard 6-31G(d) basis set was used and for I, Br, and Cl a quasi-relativistic pseudopotential (I: ECP46MWB; Br: ECP28MWB; Cl: ECP10MWB)[36] and a (5s5p1d)/[3s3p1d]-DZ+P basis set.[37] The computations were carried out at the DFT level using the hybrid method B3LYP, which includes a mixture of Hartree−Fock exchange with DFT exchange-correlation. Becke's 3 parameter functional, where the non-local correlation is provided by the LYP expression (Lee, Yang, Parr correlation functional), was used as implemented in Gaussian 94. For a concise definition of the B3LYP functional see ref.[38]

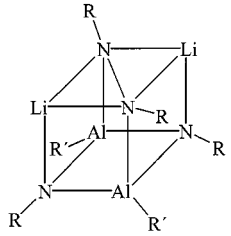
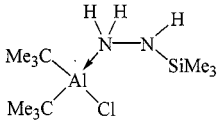
Aluminium Hydrazides: Dimeric Bis(*tert*-butyl)aluminium Hydrazides with Six-Membered Al_2N_4 and Five-Membered Al_2N_3 Heterocycles



Werner Uhl,*[a] Jens Molter,[a] and Rainer Koch[b]

Keywords: Aluminium / Hydrazides / Heterocycles / Rearrangements / Ab initio calculations



Treatment of the hydrazine adduct $(Me_3C)_2AlCl\cdot NH_2NHSiMe_3$ (**2**) with *n*-butyllithium afforded the colorless dialkylaluminium hydrazide $(Me_3C)_2AlN(SiMe_3)NH_2$ (**3**) by the release of butane and the precipitation of LiCl. Hydrazide **3** gave a dimer in solution and in the solid state. As shown by a crystal structure determination, a six-membered Al_2N_4 heterocycle with two intact endocyclic N–N bonds was formed by a head-to-tail dimerization. Upon sublimation of **3** in vacuum, a rearrangement was observed which gave an isomeric compound **4** after the migration of a hydrogen atom of a hydrazido ligand. The molecular core of **4** comprises a five-membered Al_2N_3 heterocycle, in which the Al atoms are bridged by one hydrazido ligand similar to **3**. The second ligand, however, has only one nitrogen atom in a bridging position with an exocyclic N–N bond. A similar compound (**5**) was obtained by the reaction of bis(*tert*-butyl)aluminium chloride with phenylhydrazine and *n*-butyllithium.

Introduction

Aluminium and gallium hydrazides found considerable interest in recent literature, because they are potentially useful as starting materials for the formation of the corresponding nitrides by chemical vapor deposition or by thermolysis of macroscopic samples. Several methods for the synthesis of those compounds were published, such as the treatment of hydrazines with trialkylelement compounds by the release of alkane,[1−3] the formation of hydrogen in a similar reaction by employing dialkylaluminium hydride[4] or $LiAlH_4$,[5] the reaction of lithium hydrazides with dialkylelement chlorides,[5,6] and the hydroalumination of azobenzene.[7] We tried to synthesize aluminium hydrazides by the reaction of dilithium bis(trimethylsilyl)hydrazide with dialkylaluminium chlorides. However, by partial cleavage of the N−N bonds, mixtures of products were formed from which cage compounds such as **1** were isolated in low yields (Scheme 1).[8] These cages contain a dimeric iminoalane, in which the Al_2N_2 heterocycle is bridged by a hydrazido ligand with an intact N−N bond. A heterocubane-type structure is formed by the addition of two lithium atoms. Boron hydrazides were obtained by the reaction of trimethylsilylhydrazine derivatives with boron halides[9] and the release of chlorotrimethylsilane. As was recently shown by our group, this method could not be applied to the synthesis of aluminium hydrazides.[10] Instead, bis(trimethylsilyl)hydrazine reacted with dialkylaluminium chlorides by dismutation to yield tris(trimethylsilyl)hydrazine and trimethylsilylhydrazine, which is thermally unstable[11] and was stabilized here by the formation of adducts **2** with the coordinatively unsaturated Al atoms (Scheme 1).[10] As is reported here, these adducts are excellent starting materials for the synthesis of aluminium hydrazides under mild conditions.

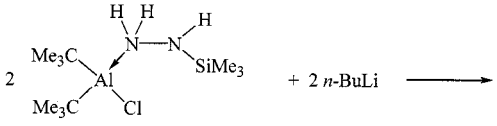
Results and Discussion

Reaction of the Adduct $(Me_3C)_2AlCl\cdot NH_2NHSiMe_3$ with *n*-Butyllithium



A suspension of the adduct $(Me_3C)_2AlCl\cdot NH_2NHSiMe_3$ (**2**) in *n*-hexane was treated with an equimolar quantity of *n*-butyllithium at −30 °C. A clear solution was formed upon heating the mixture to room temperature, and LiCl precipitated slowly by stirring the solution over a period of 12h. As shown by NMR spectroscopy, adduct **2** was completely consumed, and two products were formed in the ratio of 10 (**3**) to 1. This ratio remained unchanged despite many attempts at recrystallization from different solvents and at different temperatures. We assumed that compound **3** may exist in equilibrium with another species and may for instance dissociate in solution. Indeed, the concentration of the by-product increased with temperature, and at 80 °C we observed a ratio of about 3 (**3**) to 1. The similar reactions of adduct **2** with methyl- or *tert*-butyllithium gave the product **3** only in very poor yields, but in all cases the by-product was detected in almost the same ratio by NMR spectro-

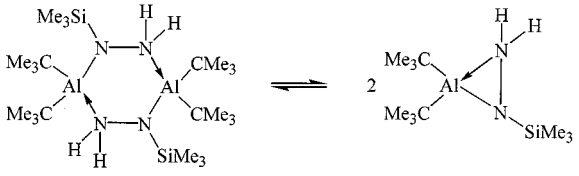
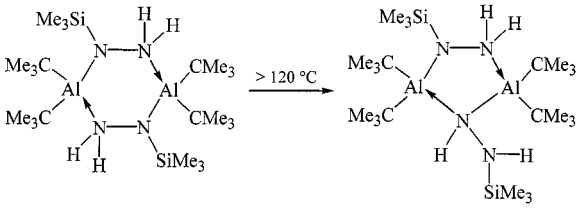
scopy. Some characteristics of this product are discussed below.

The mixture containing **3** as the main component was isolated in a yield of 69%. Compound **3** gave two singlets in the ^{1}H NMR spectrum, with an intensity ratio of 2:1 for the *tert*-butyl and trimethylsilyl hydrogen atoms. A single, broad resonance at $\delta = 4.32$ was assigned to the N−H protons. The integration gave one NH_2 group for each trimethylsilyl substituent, and thus one N−H proton had been removed from the adduct **2**. The composition of **3** as a dimeric dialkylaluminium hydrazide possessing a six-membered Al_2N_4 heterocycle was ascertained by a crystal structure determination (see below) and is depicted in Equation (1). As expected, the strong base *n*-butyllithium did not deprotonate the NH_2 moiety of adduct **2**, but the more acidic N−H proton of the $NH(SiMe_3)$ group, because an anion in this position is strongly stabilized by hyperconjugation[12] with the $SiMe_3$ substituent. The precipitation of lithium chloride led to the formation of an aluminium hydrazide, which gave a dimer owing to the presence of the NH_2 groups. The dimeric formula unit was also detected in benzene solution.



2

3



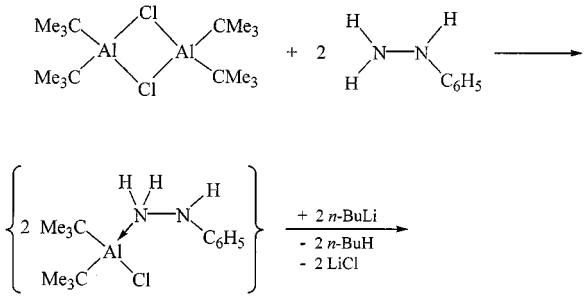
The by-product discussed above had two resonances for the $SiMe_3$ and CMe_3 hydrogen atoms in the intensity ratio of 1:2 ($\delta = 0.06$ and 1.29, respectively) similar to **3**, but two different resonances were now observed for two N−H protons at $\delta = 3.11$ and 2.68. In contrast to **3**, a strong dependence of the spectrum on temperature was observed. While the $SiMe_3$ singlet remained unchanged upon cooling of a solution in toluene to −80 °C, the resonance of the *tert*-butyl groups was split into two singlets ($\delta = 1.49$ and 1.24). The N−H protons gave a very broad resonance at +80 °C, which split into two resonances at about 50 °C. At 0 °C, two doublets were observed with chemical shifts of $\delta = 3.11$ and 2.68 and a coupling constant of $J = 4.6$Hz. We assume that this by-product results from partial dissociation of dimeric **3** into a monomeric species, which is favored in hot solutions [Equation (2)]. Its particular NMR data are in agreement with a three-membered AlN_2 heterocycle containing a dative $AlNH_2$ bond and a nonplanar environment of the negatively charged N atom, which is attached to the exocyclic trimethylsilyl group. A similar and still unpublished structure was recently observed by our group. The $SiMe_3$ substituent is thus neighbored by one hydrogen atom and one *tert*-butyl group, which causes the splitting of the corresponding resonances in the ^{1}H NMR spectrum. At higher temperature a rapid inversion of the configuration at that nitrogen atom occurs, which results in the equilibration of the hydrogen and the *tert*-butyl substituents in accordance with the observations in the temperature-dependent NMR spectra. The inversion barrier was estimated from these NMR data[13] to be about 65 kJ/mol. The low value of the molar mass of **3,** which was detected in benzene solution, may be caused by its partial dissociation. Other compounds are consistent with the NMR data. For instance, the dimeric aluminium hydrazide $[(Me_3C)_2Al-NH-NHSiMe_3]_2$ may be formed by a hydrogen shift in both hydrazido ligands. A similar shift was observed with compound **3** as discussed below, but in all cases the rearrangement was observed with only one hydrazido ligand of the dimer, even at an elevated temperature, and a prolonged reaction time in solution was required. That hydrogen shift is irreversible, and it seems quite implausible that the completely rearranged product may exist in a temperature-dependent equilibrium in our NMR experiment. Besides the resonances discussed so far, other signals with a very low intensity are observed in the NMR spectra. These are either characteristic of compound **4** (next section) or could not be assigned to a particular species (two resonances of equal intensity at $\delta = 3.78$).

3

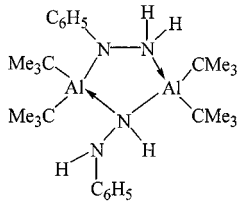
Rearrangement of 3

Owing to the unknown structure of the by-product in all isolated samples of **3**, we tried to purify this product by sublimation under vacuum. Sublimation occurred at a temperature of 120−140 °C at 10^{-3} Torr. However, NMR spectroscopy showed that a new product (**4**) was formed in a yield of 97% [Equation (3)]. Compound **4** was also obtained by heating solutions of **3** in benzene at 70 °C for 12 h. According to the NMR spectroscopic characterization and crystal structure determination, a hydrogen shift occurred with one of the hydrazido ligands so that each of its nitrogen atoms was attached to one hydrogen atom. The size of the central heterocycle changed. A five-membered ring was now observed with one bridging hydrazido ligand similar to compound **3** and one rearranged hydrazido group, only one nitrogen atom of which is in a bridging position. The latter hydrazido group has an intact N−N bond with an exocyclic $NH(SiMe_3)$ group.

3 4



Owing to this particular molecular symmetry, which is retained in solution, we obtained a more complicated ^{1}H NMR spectrum. The $SiMe_3$ substituents, one attached to an endocyclic and the other bonded to an exocyclic nitrogen atom, gave rise to two resonances. Four different *tert*-butyl groups resulted owing to the chiral environment of the bridging nitrogen atom. Similarly, all N−H protons are chemically different and give rise to two AX spin systems by vicinal or geminal H−H coupling. The downfield resonances were assigned to the NH_2 group, because of their larger coupling constants and smaller differences in their chemical shifts. To the best of our knowledge, a similar rearrangement of a hydrazido ligand in oligomeric aluminium or gallium compounds has never been observed before. However, the shift of hydrogen atoms and silyl groups was observed in disilylhydrazine derivatives, where this process seems to be catalyzed by bases and leads to an equilibration of the 1,1- and 1,2-substituted species.[14]



Reactions with Phenylhydrazine

Phenylhydrazine is insoluble in hexane, and all reactions were carried out in toluene as solvent. Treatment of bis(*tert*-butyl)aluminium chloride with phenylhydrazine yielded a colorless precipitate, which was soluble in warm toluene and which probably contained an adduct similar to compound **2** described above. It was not isolated here, but directly treated with *n*-butyllithium at room temperature. The ^{1}H NMR spectrum of the crude reaction product, which was obtained after filtration and evaporation of the solvent, showed that in contrast to the reaction of the trimethylsilyl derivative described above, a six-membered heterocycle was not formed. Instead, a rearranged compound analogous to **4** containing a five-membered heterocycle in its molecular center was obtained under mild conditions [**5**, Equation (4)]. After recrystallization from a mixture of toluene and *n*-hexane, colorless crystals of **5** were isolated. The NMR spectra of **5** were similar to those of compound **4** with four different *tert*-butyl resonances and two AX spin-systems of the N−H protons. Although we changed the reaction conditions such as temperature and solvents systematically, we never found any evidence for the formation of an intermediate analogous to **3** with a six-membered Al_2N_4 heterocycle.

Crystal Structures of Compounds 3, 4 and 5

Compound **3** crystallizes with two independent molecules in the unit cell, each of which is localized on a crystallographic center of symmetry. Both molecules are similar, and therefore only one of the molecular structures is depicted in Figure1. They possess centrosymmetric six-membered

5

Al_2N_4 heterocycles in their molecular centers, in which two hydrazido ligands bridge both aluminium atoms. Each Al atom has an Al−N bond to a N−$SiMe_3$ group and is further attached to one NH_2 group by a dative Al−N interaction. The heterocycles adopt a chair conformation. Similar structures with an endocyclic N−N bond are rare. One derivative was recently published by the group of Nöth with the compound $[Me_2AlN(SiMe_3)NH(CMe_3)]_2$.[5] Two six-membered Ga_2N_4 heterocycles were observed in the compound $[MeGa(\mu\text{-}NHNC_6H_5)_2GaMe]_2$, which adopts an overall hexagonal prismatic structure.[1] In most cases, however, only one nitrogen atom of the hydrazido group bridges two Al or Ga atoms with the N−N bond in an exocyclic position and the formation of E_2N_2 (E = Al, Ga) and Ga_3N_3 heterocycles.[1,3,4]

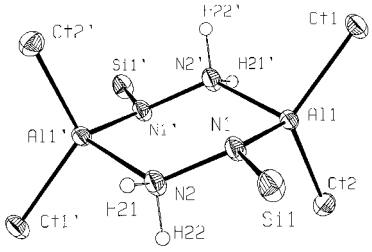


Figure 1. Molecular structure and numbering scheme of compound **3**; the thermal ellipsoids are drawn at the 40% probability level; methyl groups are omitted for clarity; hydrogen atoms with arbitrary radius; selected bond lengths [pm] and angles [°]: Al1−N1 186.7(1), Al1−N2 200.4(1), N1−N2 148.2(1), N1−Si1 174.4(1), Al2−N3 187.8(1), Al2−N4 199.8(1), N3−N4 148.3(2), N3−Si2 175.1(1); N2−Al1−N1 102.96(5), Al1−N1−N2 114.39(8), Al1−N1−Si1 131.14(6), N2−N1−Si1 109.23(8), N1−N2−Al1 126.69(8), N4−Al2−N3 102.84(5), Al2−N3−N4 111.80(8), Al2−N3−Si2 129.74(6), N4−N3−Si2 114.27(9), N3−N4−Al2 120.02(9)

The N−N bond lengths (148.2 pm on average) are similar to those usually observed in hydrazine derivatives,[15] in aluminium hydrazides[2−5,8,10] or in dilithium bis(trimethylsilyl)hydrazide.[16] The Al−N distances (187.2 and 200.1 pm) differ strongly. As expected, longer ones were observed

for the dative[17] bonds Al1−N2′ and Al2−N4′. The N atoms N2 and N4 of the NH_2 groups have a distorted tetrahedral coordination sphere, while the tricoordinated nitrogen atoms N1 and N3 attached to the Al and Si atoms deviate only slightly from planarity, with sums of the bond angles of 354.8° and 355.8°. As can be expected with a hyperconjugative interaction, the N−Si bond lengths are short (174.7 pm).

The compounds **4** (Figure 2), an isomer of **3**, and **5** (Figure 3) have five-membered Al_2N_3 heterocycles in their molecular centers. One hydrazido ligand bridges both Al atoms in a similar manner as in compound **3** with an intact NH_2 group, but only one nitrogen atom of the second ligand is in a bridging position, while the second nitrogen atom is part of an exocyclic $NH(SiMe_3)$ group. Thus, one hydrogen atom of the NH_2 group moved, and each N atom is attached to one H atom. To the best of our knowledge, a similar structure has not yet been observed. The heterocycles adopt a twisted conformation, as can be derived from the torsion angles in the ring[18] (clockwise starting with N1−N2: 34.9°, −25.3°, 7.5°, 6.8°, −25.0° of **4**; 45.4°, −34.1°, 8.4°, 9.3°, −32.1° of **5**).

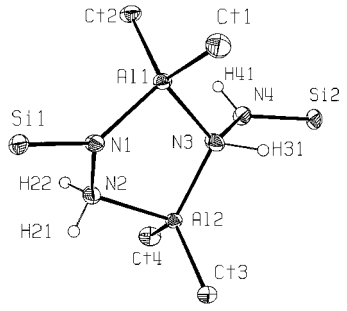

Figure 2. Molecular structure and numbering scheme of compound **4**; the thermal ellipsoids are drawn at the 40% probability level; methyl groups are omitted for clarity; hydrogen atoms with arbitrary radius; selected bond lengths [pm] and angles [°]: Al1−N1 188.5(2), Al1−N3 201.1(2), Al2−N2 200.3(2), Al2−N3 193.2(2), N1−N2 148.7(2), N3−N4 143.4(2), N1−Si1 174.4(2), N4−Si2 173.09(8); N1−Al1−N3 95.88(7), Al1−N3−Al2 112.64(7), N3−Al2−N2 93.34(7), Al2−N2−N1 115.2(1), N2−N1−Al1 114.0(1), Al1−N3−N4 116.2(1), Al2−N3−N4 115.2(1), Al1−N1−Si1 134.67(8), N2−N1−Si1 109.5(1)

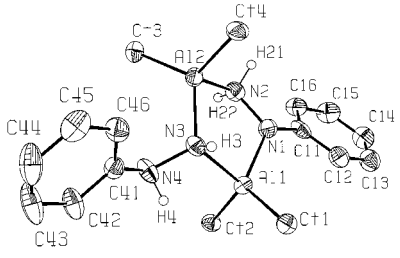

Figure 3. Molecular structure and numbering scheme of compound **5**; the thermal ellipsoids are drawn at the 40% probability level; methyl groups are omitted for clarity; hydrogen atoms with arbitrary radius; selected bond lengths [pm] and angles [°]: Al1−N1 193.9(3), Al1−N3 201.5(3), Al2−N2 205.9(2), Al2−N3 192.2(3), N1−N2 142.5(4), N3−N4 144.8(4), N1−C11 140.8(4), N4−C41 143.7(4); N1−Al1−N3 92.3(1), Al1−N3−Al2 113.3(1), N3−Al2−N2 93.3(1), Al2−N2−N1 109.7(2), N2−N1−Al1 115.7(2), Al1−N3−N4 108.5(2), Al2−N3−N4 114.5(2), Al1−N1−C11 124.5(2), N2−N1−C11 111.9(3)

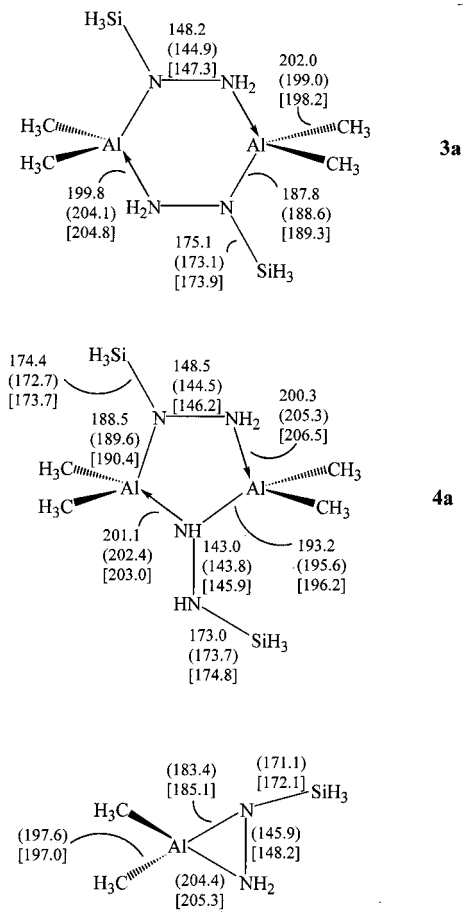
The exocyclic N−N bond of compound **4** is shorter (N3−N4 143.4 pm) than the endocyclic one (N1−N2 148.7 pm), which resembles that of the hydrazido bridges in **3**. The reverse situation was observed for the phenylhydrazine derivative **5**, which had the shortest N−N bond in the ring (N1−N2 142.5 pm; N3−N4 144.8 pm). This observation may reflect the different charge separation in the molecules with a more effective charge-transfer to the phenyl group than to the trimethylsilyl group. Indeed, the phenyl groups are almost ideally in plane with the N−N bonds to allow mesomeric stabilization (torsion angles N1−N2−C11−C12 167.2°, N1−N2−C11−C16 −15.0°; −162.8° and 20.7° for the second phenyl group). The C−N bond to the anionic nitrogen atom [140.8(4) pm] is slightly shorter than that to the exocyclic nitrogen atom [143.7(4) pm]. The N−Si bonds of **4** are similar (N1−Si1 174.4 pm and N4−Si2 173.1 pm) and comparable with those observed for **3**. Each Al atom of both compounds is coordinated by two N atoms with alternating short and long bond lengths. The distances to the bridging nitrogen atom N3 are very similar [201.3 (Al1) and 192.7 pm (Al2) on average for both compounds **4** and **5**], but the distances to the hydrazido bridges differ with larger separations to the phenyl hydrazido group (**4**: Al1−N1 188.5 pm; Al2−N2 200.3 pm; **5**: Al1−N1 193.9 pm; Al2−N2 205.9 pm).

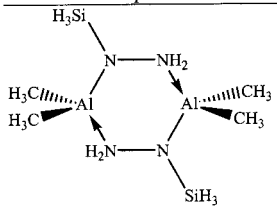
Quantum Mechanical Calculations

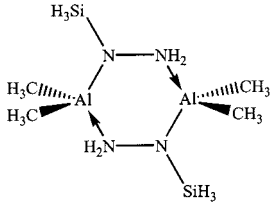
Two of the main issues of the preceding experimental findings are the rearrangement of compound **3** to give the five-membered ring **4** and the appearance of a by-product with an AlN_2 ring core. Previous studies on aluminium-containing molecules have shown that the application of the HF/6−31G* method/basis set combination gives good agreement with experimental structural data.[8,19,20] Larger basis sets led only to a slight improvement of the description of geometries and their use is not essential for our investigation.[19,20] We extended our current study to including density functional theory methods (in particular the hybrid functional approach Becke3LYP) and, where applicable, also to second-order perturbation theory (MP2) in order to assess the performance of the above methods for the calculation of relative energies. These studies were restricted to those compounds which had methyl instead of *tert*-butyl groups and *N*-silyl (SiH_3) instead of *N*-trimethylsilyl substituents (**3a**, **4a**).

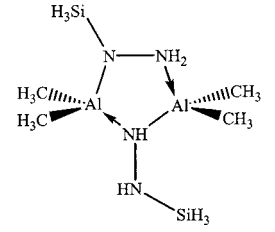
The rearrangement of compound **3** which may exist in both a chair or a twist-boat conformation leads to the five-membered ring **4**. When considering a second migration, a four-membered ring, **6**, is formed with two rearranged hydrazido groups and only one nitrogen atom of each ligand bridging both Al atoms. The results of the Hartree−Fock and B3LYP calculations are summarized in Figure 4 and Table 1. It can be seen clearly that once again the Hartree−Fock-predicted geometrical data of **3a** and **4a** agree well with the experimental structures. The same is true for the DFT-calculated geometry which is slightly better for contacts not involving Al. As for the relative energies of the four isomeric structures, both methods give the

same energetic ordering with almost identical differences separating the compounds: The five-membered ring **4a** is found to be the most stable isomer, followed by the chair conformation of **3a**. The least likely structures are the twist-boat conformation of **3a** and the Al_2N_2 heterocycle **6**. These data suggest that the rearrangement of **3** will indeed lead to **4**, which is thermodynamically favored over the former and over the completely rearranged compound **6**.









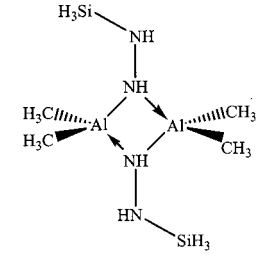


Figure 4. Selected bond lengths [pm] of compounds **3a**, **4a** and of the monomer of **3a** (experimental data without brackets, HF/6−31G* data in round brackets, B3LYP/6−31G* data in square brackets)

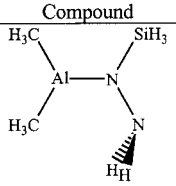
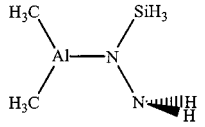
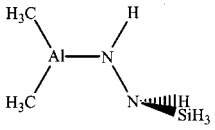
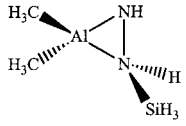
The existence of the second molecule which is in equilibrium with **3** [Equation (2)] and which is probably a monomer was also examined by means of quantum chemical methods. Five isomeric structures of this monomeric compound were calculated at the HF, the B3LYP and the MP2 level of theory (Table 2, structural parameters Figure 4). The most stable isomer is indeed the three-membered ring structure which has been previously assumed. It is favored over the next stable molecules by almost 20 kJ/mol. These results clearly show that if dissociation of **3** occurs, it will form the above-mentioned AlN_2 heterocycle. However, this process is calculated to be endothermic by almost 150 kJ/mol at 0 K. The entropy advantage reduces this difference to a surmountable barrier of 72 kJ/mol at 298 °C (laboratory conditions).

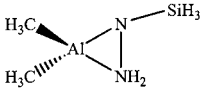
Table 1. Calculated relative energies [kJ/mol] with HF/6−31G* ZPVE corrections of compounds **3a**, **4a**, and **6**











Compound	HF/6-31G*	B3LYP/6-31G*
 **3a** chair conformation	0.0	0.0
 **3a** twistboat conformation	7.4	8.4
 **4a**	-2.4	-2.0
 **6**	7.8	9.0

It is interesting to note that the HF and the DFT approach are both suitable for the examination of the compounds reported here. Not only are the calculated geometries of comparable quality, but the relative HF and B3LYP energies of both series of monomeric and dimeric structures are also very close. This finding confirms previous observations with similar calculations.[19]

Experimental Section

General: All procedures were carried out under purified argon in dried solvents (toluene with Na/benzophenone; *n*-hexane with $LiAlH_4$). The adduct **2**, bis(trimethylsilyl)hydrazine and $(Me_3C)_2AlCl$ were synthesized as described in refs.[10,11,21]. Phenylhydrazine (Aldrich) was distilled prior to use, and the solution of *n*-butyllithium in *n*-hexane (Aldrich) was used without further purification.

Table 2. Calculated relative energies [kJ/mol] with HF/6−31G* ZPVE corrections of the monomeric isomers

Compound	HF/6-31G*	B3LYP/6-31G*	MP2/6-31G*
	0.0	0.0	0.0
	0.6	-0.6	0.6
	6.5	7.0	13.1
	17.6	18.5	10.2
	-17.4	-17.1	-20.0

Synthesis of (μ-2,2-Dihydro-1-trimethylsilylhydrazido-1κN¹:2κN²)-(μ-2,2-dihydro-1-trimethylsilylhydrazido-2κN¹:1κN²)bis[di(*tert*-butyl)aluminium] (3): A cooled (−30 °C) suspension of the adduct **2** (1.52g, 5.43mmol) in *n*-hexane (40mL) was treated with a solution of *n*-butyllithium in hexane (1.6 M, 3.4mL, 5.43mmol). The mixture was slowly warmed to room temperature, stirred for 12 h, filtered and concentrated. The residue was dissolved in a small volume of *n*-hexane. Colorless crystals of **4** (0.91g, 69%) were obtained on cooling the solution to −50 °C. − M.p. (argon, sealed capillary): 192 °C (dec.). − ^{1}H NMR (C_6D_6, 300MHz, 298K): δ = 0.15 (s, 18 H, $SiMe_3$), 1.11 (s, 36 H, CMe_3), 4.32 (s, 4 H, NH_2). − ^{13}C NMR (C_6D_6, 100.6MHz): δ = 0.25 ($SiMe_3$), 16.2 (AlC), 31.9 (C*Me*$_3$). − IR (CsBr, paraffin): ν = 3272 (w) cm^{-1}, 3243 (w), 3215 (w), 3201 (vw, νNH), 2925 (vs), 2855 (vs), 2726 (w), 2700 (w, paraffin, νCH_3), 1564 (m, δNH), 1462 (vs), 1378 (s, paraffin) 1285 (m), 1255 (s), 1231 (s, δCH_3), 1177 (w), 1000 (m), 972 (m), 955 (m), 901 (s, νC_3C), 868 (s), 836 (vs), 810 (s), 747 (s, ρCH_3) 677 (w, ν_{as}SiC) 626 (m, ν_sSiC), 579 (m), 547 (m), 511 (w), 493 (w, νAlC, νAlN), 403 (w), 357 (w, δSiC). − MS (EI); *m/z* (%): 431.3 (41) [$M^+ - C_4H_9$], 244.0 (58) [1/2 M^+]. − $C_{22}H_{58}Al_2N_4Si_2$ (488.86): calcd. Synthesis of (μ-2,2-Dihydro-1-phenylhydrazido-1κN¹:2κN²)(μ-1,2-dihydro-2-phenylhydrazido-1κN¹:2κN¹)bis[di(*tert*-butyl)aluminium] (5): A solution of of bis(*tert*-butyl)aluminium chloride (3.27g, 18.5mmol) in toluene (20mL) was added to a cooled (0 °C) solution of phenylhydrazine (2.00g, 18.5mmol) in toluene (40mL). The mixture was warmed to room temperature and stirred until the precipitate was completely dissolved. A mixture of a solution of *n*-butyllithium in *n*-hexane (1.6 M, 11.6mL, mmol) and toluene (20mL) was added. After stirring at room temperature for 5 h, LiCl was filtered off, and the solvent was removed under vacuum. The residue was treated with a mixture of toluene and *n*-hexane (50mL, 1:1) and filtered. The filtrate was concentrated and gave the colorless product **5** (2.77g, 60%) upon cooling to 0 °C. − M.p. (argon, sealed capillary): 146 °C. − ^{1}H NMR (C_6D_6, 300MHz): δ = 0.99, 1.16, 1.23 and 1.32 (each s, 9 H, CMe_3), 3.96 (d, $^3J_{HH}$ = 3.1Hz, 1 H, NH of the 1,2-bridging hydrazido ligand), 4.44 and 4.64 (each d, $^2J_{HH}$ = 10.7Hz, 1 H, NH of the 1,2-bridging hydrazido ligand), 5.48 (d, $^3J_{HH}$ = 3.1Hz, 1 H, NH of the 1,1-bridging hydrazido ligand), 6.64, 6.68, 6.70, 6.74, 6.80, 6.82 and 6.86 (all phenyl, not able to to assign further owing to the overlap of resonances), 7.28 and 7.13 (pseudo-t, line distance 7.7Hz). − ^{13}C NMR (C_6D_6, 75.5MHz): δ = 33.1, 33.5, 33.8 and 34.4 (C*Me*$_3$), 113.5, 114.5, 120.9, 123.4, 131.9, 132.0, 151.0 and 155.0 (all phenyl), AlC not detected. − IR (CsBr, paraffin): ν = 3394 cm^{-1} (w), 3349 (w), 3218 (w), 3183 (w), 3132 (vw, νNH), 2956 (vs), 2924 (vs), 2854 (vs), 2730 (w), 2701 (w, paraffin, νCH), 1600 (m, phenyl), 1578 (m, δNH), 1463 (vs), 1378 (s, paraffin), 1308 (m), 1259 (s, δCH_3), 1220 (m), 1180 (w), 1155 (w), 1091 (vw), 1082 (w), 1040 (w), 986 (m), 930 (w), 870 (m), 809 (m), 749 (s), 723 (w, νCN, νC_3C, ρCH_3), 686 (s), 675 (m), 601 (w, δphenyl), 564 (w), 539 (m), 523 (w), 464 (w), 435 (w, νAlC, νAlN), 412 (w), 371 (vw), 338 (w, δC_3C). − MS (EI); *m/z* (%): 439.3 (1) [$M^+ - C_4H_9$], 325.1 (100) [$M^+ - 3\ C_4H_9$], 248.0 (5) [1/2 M^+]. − $C_{28}H_{50}Al_2N_4$ (496.69): calcd. Al 10.9; found Al 10.6.

Crystal Structure Determinations: Single crystals of the compounds **3** and **4** were obtained by recrystallization from *n*-hexane. Compound **5** was recrystallized from a mixture of toluene and *n*-hexane. Crystal data and structure refinement parameters are given in Table3.[24] Compound **4** showed a disorder of the exocyclic N4−$SiMe_3$ group. Its atoms were refined in split positions with occupancy factors of 0.70 and 0.30. The atoms of the minor com-

ponent were refined isotropically with restrictions of bond lengths and angles. Two *tert*-butyl groups of compound **5** (CT4 and CT7) were rotationally disordered, the methyl groups were refined with restrictions of bond lengths and angles and occupancy factors of 0.64 and 0.36. Program: SHELXTL-Plus, SHELXL-93[23] solutions by direct methods; full-matrix refinement with all independent structure factors.

Quantum Chemical Calculations: The Hartree−Fock[25] method (including electron correlation at the MP2(fc) level of theory) and the Becke3LYP[26] approach in combination with the 6−31G* basis set were used to optimize the ground-state structure and to characterize the bonding situation. The located structures were confirmed as minima through calculation and analysis of the vibrational frequencies (HF/6−31G*). The energies given in Tables1 and 2 include the scaled zero-point vibrational energy corrections. All calculations were carried out with the GAUSSIAN 98 system of programs.[27]

Keywords: Mesoporosity / MCM materials / Oxo complexes / Molybdenum / Supported catalysts / Epoxidations

The dioxomolybdenum(VI) fragment MoO_2X_2 has been confined within the ordered mesopores of pure siliceous hexagonal MCM-41 and cubic MCM-48 molecular sieves either by direct grafting (solvent impregnation) with $MoO_2X_2(THF)_2$ or by using a spacer ligand [L = $NC(CH_2)_2Si(OEt)_3$]. The materials have been characterised by elemental analysis, powder X-ray diffraction, N_2 adsorption, IR spectroscopy, and magic-angle spinning NMR spectroscopy (^{13}C, ^{29}Si). All catalysts, homogeneous and heterogenised, are active in the epoxidation of cyclooctene with *tert*-butyl hydroperoxide.

Introduction

Homogeneous molybdenum(VI) (Halcon[1]) and heterogeneous titanium(IV)/SiO_2 (Shell[2]) catalysts are the basis of important industrial processes for the epoxidation of propylene, with alkyl hydroperoxides as the oxygen source. The high selectivities and (for a heterogeneous catalyst) high activities of the Ti^{IV}/SiO_2 catalyst prompted the design of novel shape-selective catalysts based on the concept of confinement of redox active metal centres in microporous and mesoporous oxides.[3] This strategy has been particularly successful in the case of titanium silicate materials.[4] Effective catalysts were obtained by incorporating titanium atoms into the framework sites of medium-pore silicalite I and II (TS-1 and TS-2, 5.5 Å pore size),[5] large-pore zeolite β (7 Å),[6] and mesoporous MCM-41 (typically 25−30 Å).[7] In a different approach, isolated tetrahedral Ti^{IV} species were grafted onto the surface of MCM-41 and MCM-48 by reaction of the pendant silanol (Si−OH) groups with titanocene dichloride precursors, followed by calcination.[8] Ti-MCM materials are important as catalysts as they are capable of oxidising relatively bulky reactants.

MCM-41 and MCM-48 are members of the M41S family of ordered mesoporous siliceous materials, formed by surfactant templating methods.[9] They both have very high surface areas (1000 $m^2\ g^{-1}$), high pore volumes (1 $cm^3\ g^{-1}$) and very narrow pore size distributions, tuneable in the range 16−100 Å. Despite the fact that MCM-48 and MCM-41 possess very different surfaces, it is evident that both materials behave similarly in grafting reactions with organometallics and coordination complexes, as observed for example in the case of derivatisation with the *ansa*-bridged ferrocene (1,1′-ferrocenediyl)dimethylsilane.[10] The structure of MCM-41 can be described as a hexagonal arrangement of cylindrical pores embedded in a matrix of amorphous silica. MCM-48 possesses a three-dimensional pore structure, with a silica interface that can be modelled by a minimal surface of the gyroid type.[11] MCM-48 therefore has some advantages over MCM-41 as a catalyst support material.

Early Mo^{VI}/SiO_2 catalysts were not as successful as Ti^{IV}/SiO_2 catalysts due to the rapid leaching of the metal ion. Recently, the synthesis of MoS-1 and MoS-2 has been described.[12] These would be expected to consist of the $Mo^{VI}O_2$ species attached to the framework defect sites. MoS-1 was reported to be an active catalyst for the chemoselective oxidation of thioethers to the corresponding sulfoxides, and MoS-2 was reported to be active in the oxidative dehydrogenation of ethanol to acetaldehyde. Isolated Mo^{VI} active sites have also been grafted onto the inner surfaces of MCM-41, via a molybdenocene dichloride precursor in a manner analogous to that mentioned above for titanium, to generate a catalyst which was tested for the oxidative dehydrogenation of methanol.[13] Another useful strategy for the confinement of metal centres in molecular sieves is the covalent attachment of coordination complexes via a spacer ligand (tethering). The tethering of chiral dioxomolybdenum(VI) complexes to the internal surface of a mesoporous USY-zeolite afforded a catalyst for the asymmetric epoxidation of allylic alcohols.[14]

We recently reported on the synthesis of *cis*-MoO_2^{2+} complexes of the type $MoO_2X_2L_n$ (X = Cl, Br) by reaction of solvent substituted $MoO_2X_2(Solv)_n$ complexes (Solv =

THF, CH_3CN, other nitrile molecules) with mono- and bidentate nitrogen and oxygen ligands.[15] The activity of the dissolved complexes as catalysts in olefin epoxidation with *tert*-butyl hydroperoxide (TBHP) was tested. In this article we report on the heterogenisation of the MoO_2X_2 fragment in MCM-41 and MCM-48 by either direct grafting with $MoO_2X_2(THF)_2$ or by using a spacer ligand [L = $NC(CH_2)_2Si(OEt)_3$]. The materials have been characterised by elemental analysis, powder X-ray diffraction (XRD), N_2 adsorption, IR spectroscopy, and magic-angle spinning (MAS) NMR spectroscopy (^{13}C, ^{29}Si). Preliminary experiments have been carried out to test the behaviour of the materials as catalysts for the epoxidation of cyclooctene with TBHP.

Results and Discussion

The supported materials MCM-41-MoO_2X_2 [X = Cl (**1**); X = Br (**2**)] and MCM-48-MoO_2X_2 [X = Cl (**3**); X = Br (**4**)] were prepared by diffusion of an excess of $MoO_2X_2(THF)_2$ (X = Cl, Br) into calcined and dehydrated MCM-41/MCM-48, in dry dichloromethane. The powders were washed repeatedly with dichloromethane to remove the unchanged oxides, and dried in vacuum at room temperature for several hours. Convenient and improved preparations of MCM-41-(spacer ligand)-MoO_2Cl_2 (**6**)/(**8**) were also developed by reacting MCM-41 with an excess of the nitrile with a triethoxysilyl group [$NC(CH_2)_2Si(OEt)_3$] in toluene, producing MCM-41-$Si(OEt)_nCH_2CH_2CN$ (**5**). This was followed by the addition of $MoO_2Cl_2(THF)_2$, or by the reaction of a solution of $MoO_2Cl_2NC(CH_2)_2Si(OEt)_3$ (**7**) with MCM-41. The products were isolated by filtration and washed thoroughly with ether to remove the unchanged oxide before drying in vacuum at room temperature. The molybdenum complex $MoO_2Cl_2NC(CH_2)_2Si(OEt)_3$ (**7**) was prepared by using a ligand exchange procedure,[15] in which the ligand was reacted with $MoO_2Cl_2(THF)_2$ in CH_2Cl_2 at room temperature. The resulting complex was isolated in excellent yield. The IR spectrum contained two bands assigned to Mo=O stretching modes (947, 916 cm^{-1}) as well as a band belonging to the nitrile ligand [ν(N≡C) = 2258 cm^{-1}]. This C≡N stretching mode is shifted to higher wavenumbers with respect to the free nitrile [ν(N≡C) = 2248 cm^{-1}] due to the coordination to the metal centre, and supports the presence of only one coordinating nitrile ligand.[15a] This unexpected result is not due to the steric bulk of the nitrile ligand but rather due to the fact that one of the ethoxide groups is directed towards the free coordinating position, *cis* to the position occupied by the nitrile group. A general summary of the reactions of these materials with the oxides is presented in Scheme 1.

The successful synthesis of the supported catalysts is confirmed by elemental analysis. The four initial materials **1**−**4** and **6** contained between 0.5 and 1.0 mass-% Mo, which is more than adequate for catalytic applications.[14] In compounds **1**−**4** the IR spectra do not clearly show bands for the two *cis*-Mo=O stretching modes, due to the small percentage of Mo. The products were pale blue powders and not visibly air-sensitive after exposure to air for several hours. Material **8** contained approximately 3.5 mass-% Mo. This is consistent with a coverage of molybdenum atoms of 4.6×10^{-25} mol/nm^2 (0.27 Mo atoms per nm^2). The IR spectra for the supported catalysts **6** and **8** provided evidence for the retention of the nitrile ligand [ν(N≡C) ≈ 2260 cm^{-1}].

The powder XRD patterns of the parent calcined (pristine) MCM-41 and MCM-48 can be indexed on a hexagonal unit cell (using the strongest reflection, d_{100}, a = 40.37 Å) and a cubic unit cell (using the strongest reflection, d_{211}, a = 82.38 Å), respectively,. The pattern for MCM-41 also displays a broad secondary feature at $2\theta \approx 4.6°$ where

Scheme 1

(110) and (200) reflections would be expected for a hexagonally ordered material such as MCM-41 (Figure 1). The absence of resolved peaks indicates that any structural order of the material did not extend over a long range. A very similar result was obtained by Schmidt et al. for a purely siliceous MCM-41 prepared as in this work using the surfactant $[(C_{14}H_{29})NMe_3]Br$.[16] The data for the Mo-modified MCM materials are consistent with the retention of the hexagonal and cubic mesoporous structures throughout the grafting process (Figure 1).

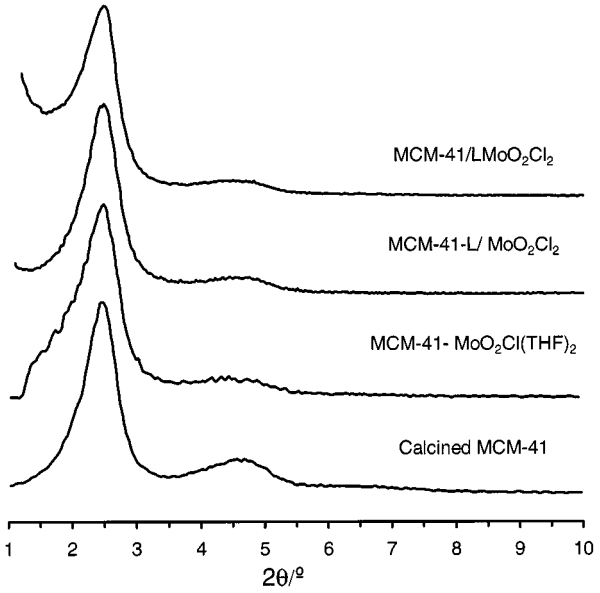

Figure 1. Powder XRD patterns of calcined (pristine) MCM-41 and functionalised samples

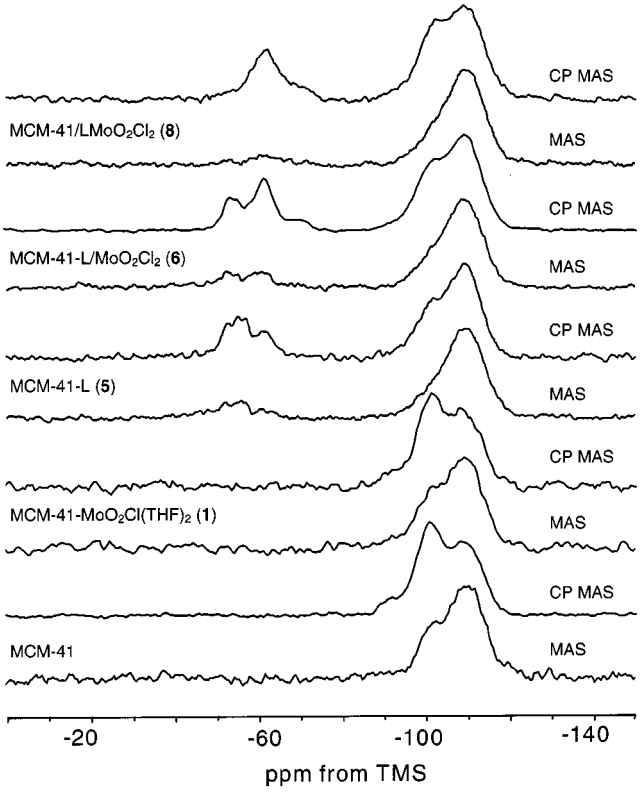

Figure 2. ^{29}Si MAS and CP MAS NMR spectra of calcined (pristine) MCM-41 and functionalised samples

The ^{29}Si CP MAS NMR spectra of MCM-41/MCM-48 functionalised with $MoO_2X_2(THF)_2$ (X = Cl, Br, **1**−**4**) exhibit two broad overlapping peaks at δ = −108 and −101 assigned to the Q^4 and Q^3 units of the silica framework, respectively, where $Q^n = Si(OSi)_n(OH)_{4-n}$, $n = 2-4$ (Figure 2, for material **1**). A small amount of Q^2 environments is also present (faint peak at δ = −91). The ^{29}Si CP MAS and MAS NMR spectra both show that the relative intensity of the Q^3 (and Q^2) peak changes only slightly upon functionalisation. This is consistent with the low metal loading (≤ 1% Mo) and perhaps also with a weak interaction (monopodal anchoring) of the molybdenum complexes with the surface.

For materials **5**, **6** and **8** the incorporation of the covalently linked organic group is confirmed by ^{29}Si CP MAS and MAS NMR spectroscopy, which shows distinct resonances for the organosilica species [$T^m = RSi(OSi)_m(OEt)_{3-m}$, $m = 1-3$] and for the silica network (Figure 2). For material MCM-41-Si(OEt)$_n$CH$_2$CH$_2$CN (**5**), grafting of the surface with the triethoxysilyl group [$NC(CH_2)_2Si(OEt)_3$] gives additional peaks between δ = −60.8 and −52.8, assigned to the T^1 and T^2 centres. The liquid-state ^{29}Si NMR spectrum for neat $NC(CH_2)_2Si(OEt)_3$ exhibits one resonance at δ = −49.8. As expected, the grafting process also shows a decrease in the relative intensity of the Q^3 resonance and a concomitant increase in the intensity of the Q^4 resonance. This is consistent with the IR spectrum which shows characteristic absorption bands for the covalently linked organic groups [ν(N≡C) = 2257 cm^{-1}].

After addition of the fragment MoO_2Cl_2 to material **5** to give material **6**, significant changes are observed in the region of the ^{29}Si CP MAS NMR spectrum corresponding to the organosilica centres. Three broad overlapping signals are observed at δ = −52.7, −60.7 and −70, assigned to the T^1, T^2 and T^3 environments, respectively. The relative intensities of the T^2 and T^3 resonances are noticeably enhanced in the spectrum of **6** relative to that of **5**, which suggests that the nitrile ligand underwent further condensation on the silica surface during the reaction. MCM-41/Si(OEt)$_n$CH$_2$CH$_2$CNMoO$_2$Cl$_2$ (**8**) presents a broad resonance at δ = −61.9 assigned mainly to the T^2 centres, $RSi(OSi)_2(OEt)$, and also a faint broad resonance at −70.1, assigned to the T^3 centres, $RSi(OSi)_3$. In comparison, the complex **7** exhibits only one well-defined resonance at δ = −62.5 in the ^{29}Si MAS NMR spectrum.

The ^{13}C CP MAS NMR spectrum of MCM-41-Si(OEt)$_n$CH$_2$CH$_2$CN (**5**) exhibits one faint peak at δ = 120 assigned to N*C*R, two peaks at δ = 58.6 and 10.4 assigned to the ethoxide group, and two well-defined peaks at δ = 16.6 and 7.7 assigned to NC−*C*H$_2$− and −*C*H$_2$−Si, respectively. The ^{13}C CP MAS NMR spectrum of MCM-41−Si(OEt)$_n$CH$_2$CH$_2$CN/MoO$_2$Cl$_2$ (**6**) is similar, except that the peaks corresponding to the ethoxide group (δ = 57.7 and 10.4) are not as intense as the peaks corresponding to the NC−CH$_2$−CH$_2$−Si fragment. Also, the resonance

at δ = 128 assigned to N≡*C* is shifted downfield slightly compared with **5** as a result of coordination to the MoO_2Cl_2 fragment. Material **8** presents a similar spectrum with δ = 128.6, 120.2 (*C*≡N), 59.0 (O−*C*H_2−), 15.9 (NC−*C*H_2−), 9.4 (−*C*H_3, −*C*H_2−Si) (Figure 3).

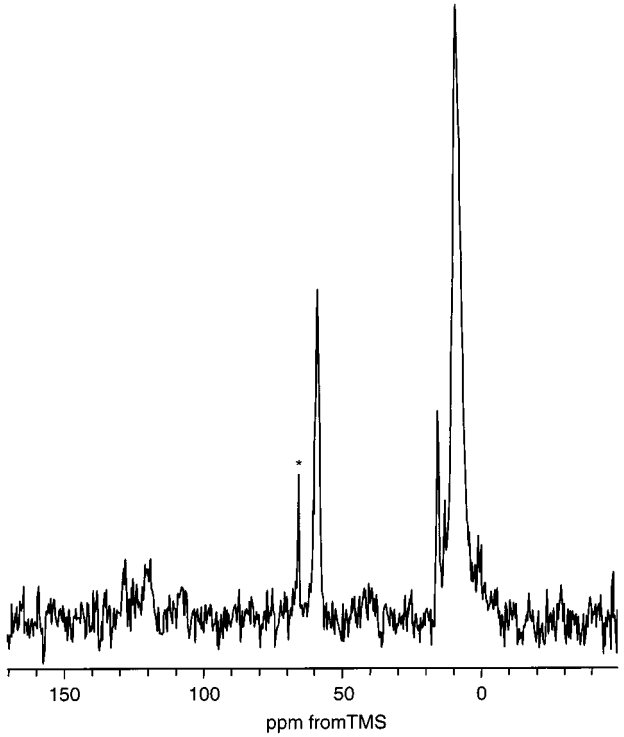

Figure 3. ^{13}C CP MAS NMR spectrum of MCM-41/LMoO_2Cl_2 (**8**), L = $NCCH_2CH_2Si(OEt)_n$; * denotes solvent

The N_2 adsorption-desorption isotherms of the solids recorded at 77 K are shown in Figure 4. The isotherms of the MCM-41 and MCM-48 materials are of Type IV according to the IUPAC, characteristic of mesoporous solids (intermediate pore size).[17] The physisorption process consists of monolayer-multilayer adsorption followed by capillary condensation of N_2 in the mesopores, below the expected condensation pressure of N_2. With the exception of MCM-41 and MCM-41/ LMoO_2Cl_2 (**8**), which show small hysteresis of adsorption and desorption (Figure 4), all samples have reversible N_2 adsorption isotherms.

The textural parameters determined from the isotherms are given in Table 1. The results for the parent MCM-41 and MCM-48 materials are in agreement with published values.[18,19] With direct grafting of $MoO_2X_2(THF)_2$ on MCM-41 (**1** and **2**), the N_2 adsorption isotherms of the modified and parent samples are very similar. The values of the BET specific surface areas (S_{BET}) and the specific total pore volumes (V_P) of the parent MCM-41 solid decrease between 4 and 7%. By changing the support to cubic mesoporous MCM-48, with the exception of the S_{BET} value for MCM-48-$MoO_2Br(THF)_2$ (**4**), no significant changes of the textural parameters are observed, and are negligible for MCM-48-$MoO_2Cl(THF)_2$ (**3**).

The N_2 adsorption isotherms of the functionalised MCM-41 materials **6** and **8** are different from that of the parent calcined MCM-41, demonstrating a lower uptake (Figure 4). On reaction of $MoO_2Cl_2(THF)_2$ with MCM-41-L (**5**) to give **6**, or on direct grafting of MoO_2Cl_2L (**7**) to give **8**, the values of S_{BET} decrease by 10.6 and 21.2%, respectively, and the values of V_P decrease by 45.1 and 39.0%, respectively (Table 1). These changes in adsorption properties can be attributed to successful grafting of the MoO_2Cl_2 fragment and/or to the tethering ligand $NCCH_2CH_2Si(OEt)_3$. The lower P/P_0 coordinates of the inflection points and the less sharp step of the isotherms in the region of capillary condensation of N_2 in the mesopores of the functionalised materials relative to that of the parent MCM-41 solid, may be assigned to changes in pore size distribution due to derivatisation of the internal silica surface of the mesoporous host. Brunel et al. observed similar changes in the features of the isotherms of MCM-41 upon grafting of functional molecules.[20]

The homogeneous and heterogenised Mo-complexes were tested for the epoxidation of cyclooctene with TBHP as the oxygen source at 55 °C. Typical catalytic runs are shown in Figure 5 and 6, and selectivities and total activities are given in Table 2 (calculated after 120 min reaction time). Reactions were also performed with pure calcined MCM-41/48 and, as expected, no significant epoxide formation was observed under these conditions. Pure calcined MCM-41 was previously found to be inactive in cyclohexene epoxidation with TBHP.[21]

For MCM-41-$MoO_2Cl(THF)_2$ (**1**), 31% conversion was observed after 2 h reaction with 100% selectivity to the epoxide (Figure 5, Table 2). Similar results were obtained for MCM-48-$MoO_2Cl(THF)_2$ (**3**). By contrast, the reaction with MCM-41-$MoO_2Br(THF)_2$ (**2**) was slow and the selectivity to cyclooctene oxide was very low (17% conversion of cyclooctene after 2 h with 56% selectivity to the oxide). This difference in activity between chlorodioxomolybdenum complexes and their bromo analogues has been noted recently by Kühn et al. for the homogeneous catalytic epoxidation of cyclooctene with complexes of the type $MoO_2X_2L_n$ (L = mono- and bidentate nitrogen and oxygen ligand).[15b] The time-dependent curves for MCM-41-$MoO_2X(THF)_2$ are of the same type as that reported recently for the catalytic activity of dissolved $MoO_2Br_2(CH_3CN)_2$ in cyclooctene epoxidation.[15a] This indicates that both reactions take place through the same mechanism, without any significant change in the reaction pathway. The appearance of these curves does not indicate the transformation of the original catalyst to another species during the reaction time and does not show an observable induction period. Similar results were obtained for the material prepared by reacting $MoO_2Cl_2(THF)_2$ with the ligand-grafted MCM-41-L. Indeed, the total activity, calculated after 2 h reaction and expressed as mols of cyclooctene produced per mol of molybdenum atoms per hour, is very similar for MCM-41-$MoO_2Cl(THF)_2$ (**1**) and MCM-41-L/MoO_2Cl_2 (**6**) (Table 2).

The kinetic profiles for the epoxidation of cyclooctene catalysed by homogeneous and heterogenised $MoO_2Cl_2NC(CH_2)_2Si(OEt)_3$ (**7**) are similar (Figure 6).

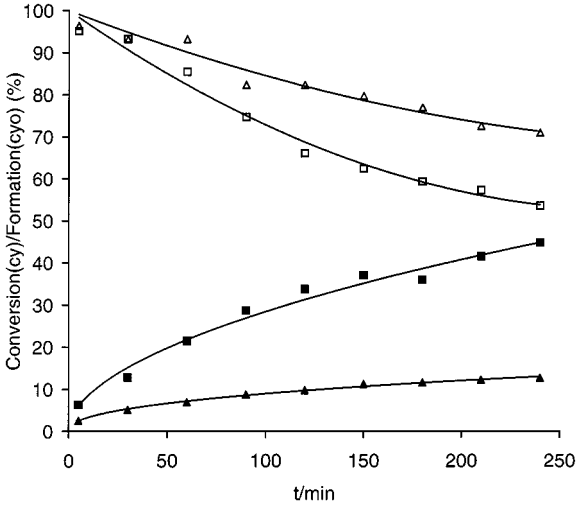

Figure 5. Kinetic profile for the epoxidation of cyclooctene with MCM-41-$MoO_2Cl(THF)_2$ (**1**) (solid square, open square) and MCM-41-$MoO_2Br(THF)_2$ (**2**) (solid triangle, open triangle) at 55 °C (solid symbols represent cyclooctene oxide formation and open symbols represent cyclooctene conversion); see text and Experimental Section for reaction details

After a very quick increase in the yield within the first 5 min the reaction velocities slow down. Thus, for the complex in solution, the yield of cyclooctene oxide formed was about 70% after 30 min, increasing by only a further 3% up to 4 h. A possible explanation for this sudden decrease in activity is the reaction of the active Mo complex in solution with *tert*-butyl alcohol. It has previously been reported that the epoxidation of 1-octene by a TiO_2-on-SiO_2 catalyst and TBHP in benzene at 80 °C exhibits marked autoretardation, attributed to the formation of *tert*-butyl alcohol during the epoxidation process.[22] For the MCM-41-supported complex, the yield of cyclooctene oxide formed was about 28% after 5 min, increasing to about 50% after 4 h. The total

Kinetic profile for the epoxidation of cyclooctene with MCM-41-L/MoO_2Cl_2 (**6**) (solid triangle, open triangle), MCM-41/LMoO_2Cl_2 (**8**) (solid square, open square) and MoO_2Cl_2L (**7**) (solid circle, open circle) at 55 °C (solid symbols represent cyclooctene oxide formation and open symbols represent cyclooctene conversion); see text and Experimental Section for reaction details

activity achieved after 2 h reaction was very similar to that for the complex in solution, when the conversion per Mo is considered (Table 2). An initial turnover frequency of 3.5 mmol cyclooctene oxide per g of catalyst per min could be achieved, or 9.5 mol cyclooctene oxide per mol molybdenum atoms per min. These values are of a similar magnitude to those reported for the catalytic oxidation of cyclohexene with surface-grafted Ti-MCM-41[8a] and Ti-ITQ-2[23] catalysts (ITQ-2 is a crystalline layered silica). In a duplicate reaction with MCM-41/LMoO_2Cl_2 (**8**), the reaction mixture was filtered at the reaction temperature after 60 min, and then the filtrate was continued to be tested for activity at the reaction temperature. It was found that cyclooctene continued to be converted at a low rate, similar to that observed for the unfiltered reaction. This indicates that leaching may have occurred during the reaction, and that after 60 min at least part of the observed activity was due to the molybdenum in solution. More detailed studies are required to ascertain if the initial catalytic activity (up to 1 h) was mainly heterogeneous in nature.

Experimental Section

General: All preparations and manipulations were performed using standard Schlenk techniques under oxygen-free and water-free nitrogen. Commercial grade solvents were dried and deoxygenated by refluxing at least 24 h over appropriate drying agents under nitrogen, and were freshly distilled prior to use. − Powder XRD data were collected with a Phillips X'pert diffractometer using Cu-K_α radiation filtered by Ni. − Microanalyses were performed at the TU Munich. − Infrared spectra were recorded with a BIORAD FTS 575 C spectrometer with 1000 scans, and KBr and PE windows for mid and far infrared, respectively. − ^{29}Si and ^{13}C NMR spectra were recorded at 79.49 and 100.62 MHz, respectively, with a (9.4 T) Bruker MSL 400P spectrometer. ^{29}Si magic-angle-spinning (MAS) NMR spectra were recorded with 40° pulses, spinning rates 5.0−5.5 kHz and 60 s recycle delays. ^{29}Si CP MAS NMR spectra were recorded with 5.5 ms ^1H 90° pulses, 8 ms contact time, a spinning rate of 4.5 kHz and 4 s recycle delays. Chemical shifts are quoted in parts per million with respect to TMS. ^{13}C CP MAS NMR spectra were recorded with a 4.5 μs ^1H 90° pulse, 2 ms contact time, a spinning rate of 8 kHz and 4 s recycle delays. Chemical shifts are quoted in parts per million with respect to TMS. − Nitrogen adsorption data were recorded gravimetrically using a CI electronic MK2-M5 microbalance. Equilibrium at each data point was monitored using CI electronics Labweigh software and the pressure was monitored with an Edwards Barocel pressure sensor. The parent calcined MCM-41 and MCM-48 solids were degassed at 723 K whereas the modified samples were degassed at a lower temperature of 413 K to further minimise the destruction of their functionalities. All samples were kept constant at the degassing temperature, overnight (> 14 h), to give a residual pressure of ca. 10^{-2} Pa, and then cooled to room temperature prior to the adsorption measurements. The BET specific surface areas (S_{BET}) were calculated using the BET equation for relative pressures, in the range P/P_0 = 0.05−0.3, taking the cross-sectional area of a nitrogen molecule as 16.2 $Å^2$. The specific total pore volumes (micropore plus mesopore, V_P) were estimated from the nitrogen uptake at $P/P_0 \approx 0.95$, using the density of N_2 in its normal liquid state ($\rho = 0.8081$ g cm^{-3}). − The hexagonal channel host MCM-41 was synthesised using $[(C_{14}H_{29})NMe_3]Br$ according to published procedures.[9] After calcination (540 °C/6 h), the material was characterised by powder XRD, N_2 adsorption and FTIR spectroscopy. − The cubic channel host MCM-48 was synthesised using $[(C_{16}H_{33})NMe_3]Cl$ according to published procedures.[24] After calcination (540 °C/6 h), the material was characterised by powder XRD, N_2 adsorption and FTIR spectroscopy. − The precursors MoO_2Br_2,[25] MoO_2Cl_2,[25] and $MoO_2X_2(THF)_2$ (X = Cl, Br)[26] were prepared as described previously. − ^{13}C MAS NMR spectroscopy of $MoO_2X_2(THF)_2$ (25 °C): δ = 74.3 (THF), 25.9 (THF).

Preparation of Materials of General Formula MCM-41/48-$MoO_2X(THF)_2$ (X = Cl, Br): Calcined MCM-41/48 (0.5 g) was activated at 180 °C in vacuum (10^{-2} Pa) for 3 h and treated with excess of $MoO_2X_2(THF)_2$ (X = Cl, Br) in CH_2Cl_2 (20 mL). The mixture was stirred at room temperature for 2 d. The solution was filtered and the pale blue solid washed three times with 15-mL portions of CH_2Cl_2, before drying in vacuum at room temperature for several hours.

MCM-41-$MoO_2Cl(THF)_2$ (1): Anal. found Mo 1.10. − ^{29}Si MAS NMR spectrum exhibits one broad resonance at δ = −109.4 and a shoulder at δ = −101.3. ^{29}Si CP MAS NMR spectrum exhibits two broad resonances at δ = −101.1 (Q^3) and δ = −108.2 (Q^4), and a faint peak at δ = −91.8 (Q^2).

MCM-41-$MoO_2Br(THF)_2$ (2): Anal. found Mo 0.7. – ^{29}Si MAS NMR spectrum exhibits one broad resonance at δ = −108.5 and a shoulder at δ = −100.8. ^{29}Si CP MAS NMR spectrum exhibits two broad resonances at δ = −100.6 (Q^3) and δ = −108.7 (Q^4), and a faint peak at δ = −91.2 (Q^2).

MCM-48-$MoO_2Cl(THF)_2$ (3): Anal. found Mo 0.7. – ^{29}Si MAS NMR spectrum exhibits one broad resonance at δ = −108.5 and a shoulder at δ = −101.7. ^{29}Si CP MAS NMR spectrum exhibits two broad resonances at δ = −101.7 (Q^3) and δ = −108.8 (Q^4), and a faint peak at δ = −91.2 (Q^2).

MCM-48-$MoO_2Br(THF)_2$ (4): Anal. found Mo 0.5. – ^{29}Si MAS NMR spectrum exhibits one broad resonance at δ = −108.8 and a shoulder at δ = −101.4. ^{29}Si CP MAS NMR spectrum exhibits two broad resonances at δ = −101.1 (Q^3) and δ = −108.8 (Q^4), and a faint peak at δ = −91.2 (Q^2).

Preparation of MCM-41-Si$(OEt)_n$$CH_2CH_2CN$ (5): Calcined MCM-41 (0.5 g) was activated at 180 °C under vacuum for 2 h and treated with excess of $NCCH_2CH_2Si(OEt)_3$ in toluene (30 mL). The mixture was stirred under reflux for 66 h. The solution was filtered and the white solid washed several times with 20-mL portions of ether, before drying under vacuum at 100 °C for several hours. – Anal. found C 7.90, H 1.86, N 2.14. – IR (KBr): $\tilde{\nu}$ = 3441 cm^{-1} (vs), 3038 (w), 2981 (m), 2932 (m), 2257 (m), 1706 (w), 1638 (s), 1397 (m), 1232 (vs), 1083 (vs), 955 (m), 795 (s), 700 (w), 592 (w), 455 (s). – ^{29}Si MAS NMR spectrum exhibits broad resonances at δ = −109.5, −60.8 and −52.8. – ^{29}Si CP MAS NMR spectrum exhibits two broad resonances at δ = −109.0 (Q^4) and δ = −101.6 (Q^3), a faint peak at δ = −92.3 (Q^2), and two broad overlapping signals at δ = −60.3 and −51.9. – ^{13}C CP MAS NMR spectrum (25 °C): δ = 120.2 (*C*≡N), 58.6 (O−*C*H_2−), 16.6 (NC−*C*H_2−), 10.2 (−*C*H_3), 7.7 (−*C*H_2−Si).

Preparation of MCM-41-Si$(OEt)_n$$CH_2CH_2CN$/$MoO_2Cl_2$ (6): A suspension of activated MCM-41-Si$(OEt)_n$$CH_2CH_2CN$ (0.46 g) was treated with excess of $MoO_2Cl_2(THF)_2$ in CH_2Cl_2 (30 mL). The mixture was stirred at room temperature for 8 h. The solution was filtered and the pale blue solid washed twice with 15-mL portions of CH_2Cl_2, and one portion of ether (20 mL), before drying under vacuum at room temperature for several hours. – Anal. found C 12.63, H 2.15, Mo 1.0, N 1.86. – IR (KBr): $\tilde{\nu}$ = 3432 cm^{-1} (vs), 2987 (m), 2259 (m), 1637 (s), 1429 (m), 1234 (vs), 1082 (vs), 946 (m), 887 (w), 796 (s), 566 (w), 455 (s), 299 (m). – ^{29}Si MAS NMR spectrum exhibits one broad resonance at δ = −108.3, and three broad overlapping signals at δ = −52.7, −60.7 and −70.0. – ^{29}Si CP MAS NMR spectrum exhibits two broad resonances at δ = −109.0 (Q^4) and δ = −102.0 (Q^3), a faint peak at δ = −90.8 (Q^2), and three broad overlapping signals at δ = −52.7, −60.7 and −70.0. – ^{13}C CP MAS NMR spectrum (25 °C): δ = 128 (*C*≡N), 57.7 (O−*C*H_2−), 16.8 (NC−*C*H_2−), 10.4 (−*C*H_3), 7.8 (−*C*H_2−Si).

Preparation of $MoO_2Cl_2NCCH_2CH_2Si(OEt)_3$ (7): A solution of $MoO_2Cl_2(THF)_2$ (0.83 g, 2.42 mmol) in CH_2Cl_2 (20 mL) was treated with $NCCH_2CH_2Si(OEt)_3$ (1.05 g, 4.84 mmol), and the mixture was vigorously stirred for 30 min. The resulting solution was filtered and concentrated to dryness to give a yellow-brown oil. The very air-sensitive product was washed with hexane and dried in vacuum. Yield: 0.97 g (96%). – $C_9H_{19}Cl_2MoNO_5Si$ (416.18): calcd. C 25.97, H 4.60, N 3.37; found C 26.18, H 4.83, N 3.61. – Selected IR (KBr): $\tilde{\nu}$ = 2258 cm^{-1} (s, N≡C), 947 (vs, Mo=O), 916 (vs, Mo=O). – ^{13}C NMR spectrum($CDCl_3$, 400 MHz, 20 °C): δ = 121.1 (*C*≡N), 59.3 (O−*C*H_2−), 18.7 (NC−*C*H_2−), 11.9 (−*C*H_3), 8.8 (−*C*H_2−Si). – ^{29}Si MAS NMR spectrum (25 °C): δ = −62.5.

Preparation of MCM-41/Si$(OEt)_n$$CH_2CH_2CNMoO_2Cl_2$ (8): Calcined MCM-41 (0.75 g) was activated at 180 °C under vacuum for 2 h and treated with excess of $MoO_2Cl_2NCCH_2CH_2Si(OEt)_3$ (**7**) (0.70 g) in toluene (30 mL). The mixture was stirred at room temperature for 2 h. The solution was filtered and the pale blue solid washed three times with 20-mL portions of ether, before drying under vacuum for several hours. – Anal. found C 9.04, H 1.81, Mo 3.5, N 1.27. – IR (KBr): $\tilde{\nu}$ = 3441 cm^{-1} (vs), 2982 (m), 2937 (m), 2912 (w), 2260 (m), 1706 (w), 1638 (s), 1495 (w), 1448 (w), 1429 (m), 1394 (m), 1373 (w), 1322 (w), 1232 (vs), 1083 (vs), 955 (m), 734 (w), 696 (w) 549 (m), 334 (w). – ^{29}Si MAS NMR spectrum exhibits one broad resonance at δ = −108.2. – ^{29}Si CP MAS NMR spectrum exhibits two broad resonances at δ = −108.9 (Q^4) and δ = −101.7 (Q^3), a faint peak at δ = −91.2 (Q^2), one broad resonance at δ = −61.9 and a faint broad resonance at −70.1. – ^{13}C MAS NMR spectrum (25 °C): δ = 128.6, 120.2 (*C*≡N), 65.8, 59.0 (O−*C*H_2−), 15.9 (NC−*C*H_2−), 9.4 (−*C*H_3, −*C*H_2−Si).

Catalytic Reactions with Modified Mesoporous Materials/Dioxomolybdenum(VI) Complexes as Catalysts: *cis*-Cyclooctene (800 mg, 7.3 mmol), di-*n*-butyl ether (800 mg,) internal standard), **1**–**8** (175 mg, as catalyst) and 2 mL of 5.5 M *tert*-butyl hydroperoxide in decane were added to a thermostated reaction vessel and stirred for 24 h at 50 °C. – The course of the reaction was monitored by quantitative GC analysis. Samples were taken every 30 min, diluted with dichloromethane, and chilled in an ice bath. For the destruction of hydroperoxide and removal of water, a catalytic amount of manganese dioxide and magnesium sulfate was added. After the gas evolution had ceased, the resulting slurry was filtered through a filter-equipped Pasteur pipette and the filtrate injected into the GC column. – The conversion of cyclooctene and the formation of cyclooctene oxide was calculated from a calibration curve (r^2 = 0.999) recorded prior to the reaction course.

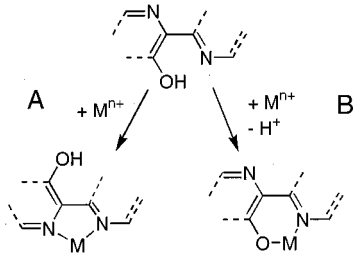
Transition Metal Ion Complexes of 2,2′-Bipyridyl-3,3′-diol and 2,2′-Bipyridyl-3-ol: Spectroscopic Properties and Solvent-Dependent Binding Modes



Knut Rurack*[a] and Reiner Radeglia[a]

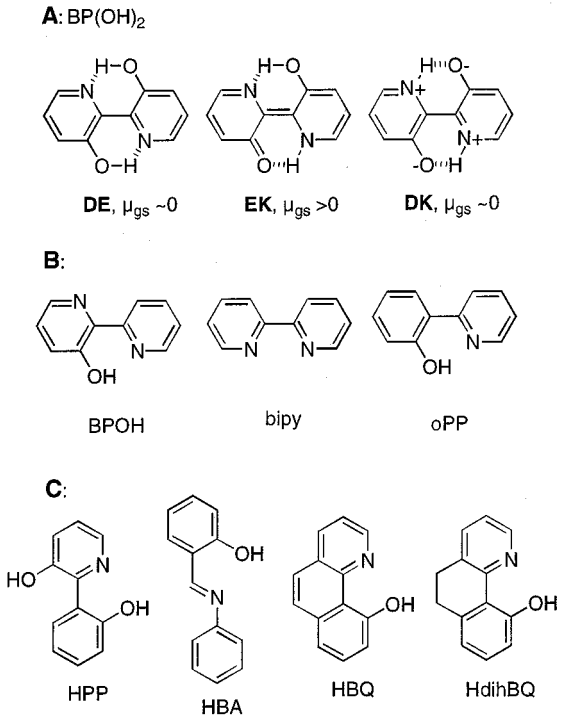
Keywords: Chelates / Hydroxy bipyridyls / Fluorescence / Cadmium / Zinc / N ligands

The complexation behaviour of 2,2′-bipyridyl-3,3′-diol and 2,2′-bipyridyl-3-ol, $BP(OH)_2$ and BPOH, with various heavy and transition metal ions has been investigated in aqueous, alcoholic, and acetonitrile solutions. Whereas the complexes with paramagnetic ions and Hg^{II} are non-fluorescent, Zn^{II} and Cd^{II} form highly fluorescent complexes, their coordination geometries depending on the solvent proticity and hydrogen-bond donating ability. Through a comparative study with the corresponding chelates of 2,2′-bipyridyl (bipy), *N*,*O*-coordination in a six-membered ring chelate has been found to be the dominant binding mode in both the Zn^{II} and Cd^{II} complexes in the protic solvents water and ethanol. Only for Zn^{II} and BPOH is exclusive *N*,*N*′-chelation found in acetonitrile. NMR measurements on $BP(OH)_2$, BPOH, and bipy in the presence of Zn^{II} and Cd^{II} in acetonitrile confirmed these findings.

Introduction

Controlling the binding modes of metal ion complexes is of particular interest in many fields of bioorganic and bioinorganic chemistry.[1] In many biochemical processes, metal ion complexes with specific or unusual coordination geometries are involved, e.g. in enzymes or metalloproteins.[2] Accordingly, metal ion complexes play an important role in medicinal chemistry and drug design.[3] Here, single conformers of chemically and stoichiometrically identical complexes often show drastically different biological activities.[4] Since many organic ligands possess various heteroatoms and functional groups, competing coordination reactions can interfere. For instance, many aminophilic transition metal ions strongly prefer a five-membered *N*,*N*′-chelate (route A, Scheme 1) over a six-membered *N*,*O*-chelate (route B).[5] However, when both binding sites are present in a single molecule as, e.g., in some hydroxy-substituted heterocyclic biaryls or Schiff-base derivatives,[6] the question arises as to how a certain ion coordinates in a particular environment (these features are not only restricted to open-chain ligands but are also found, e.g., in cavity-forming crown compounds).[7] Although important, the chemical nature and structure of the (bi- or multidentate organic) ligand, for instance the geometrical arrangement or flexibility of the molecule, or possible mechanisms of intramolecular stabilization, are not the only decisive factors governing the formation of a specific structure in a certain complex. In liquid media the (counter)ions present and/or the solvent molecules also play a role, depending on the number of free coordination sites at the central ion in the complex (as defined by the geometry of the coordination sphere and the number of chelating ligands present) as well as on the affinity between the metal ion and these other potential (usually monodentate) ligands. Moreover, interactions between the chelating ligand and the solvent can also have an effect on the structural features of a complex, i.e. the proticity or polarity of a particular (solvent) environment can favour certain intra- or intermolecular stabilization modes and can thus either promote or hamper specific central ion−ligand interactions. Especially for chelating ligands that are able to form stabilizing intramolecular hydrogen bonds, e.g. some derivatives of hydroxy-substituted bipyridyls, the proton affinity or protic character of the solvent should play a major role in directing complex formation along, for instance, route A or B (Scheme 1).

Scheme 1. Generalized scheme of possible chelation mechanisms operative in metal ion complexation by hydroxy-substituted *N*-containing heterocyclic biaryls (the structures do not indicate actual complex stoichiometries)



As an extension of our work on the metal ion binding and sensing abilities of 2,2′-bipyridyl-3,3′-diol [$BP(OH)_2$, Scheme 2, A] as well as the spectroscopic properties of its complexes in water,[8−11] we directed our studies towards the characterization of the actual binding modes in these coordination compounds as well as in the corresponding complexes of the reference compound 2,2′-bipyridyl-3-ol (BPOH, Scheme 2, B) in highly polar solvents. Considering the crucial role of the nature of the solvent and counterion, we aimed to elucidate the structures of the complexes dir-

ectly in solution by employing metal ion perchlorates (as weakly donating counterions with a low coordinating ability) and neat, highly polar, protic (water, ethanol) as well as aprotic (acetonitrile) solvents. Moreover, we included the chemically closely related ligand *o*-(2-pyridino)phenol (oPP) and the parent compound 2,2′-bipyridyl (bipy) in our studies (Scheme 2, B). Since in pure water at ambient pH, $BP(OH)_2$ and BPOH only bind to heavy and transition metal ions such as Zn^{II}, Cd^{II}, Cu^{II}, or Ni^{II} and since only the complexes of the first two ions are fluorescent,[8,10,11] the present work focuses on the investigation of the Zn^{II} and Cd^{II} complexes of the (bi)pyridyl ligands by means of absorption, steady-state as well as time-resolved fluorescence, and NMR spectroscopy.

Scheme 2. **A**: Chemical structure and enol-keto tautomerism of $BP(OH)_2$ (DE, EK, DK, and μ_{gs} denote the dienol, enol-keto, and "diketo" tautomers, and the ground state dipole moment, respectively); **B**: chemical structures of the investigated BPOH, bipy, and oPP; **C**: chemical structures of related HPP, HBA, HBQ, and HdihBQ

Results and Discussion

Uncomplexed Ligands

The photophysical properties of uncomplexed $BP(OH)_2$ and BPOH in water, ethanol, and acetonitrile are included in Table 1.

In accordance with results published by other research groups,[12−16] $BP(OH)_2$, with its two strong internal hydrogen bonds (Scheme 2, A), shows the characteristic features of ESIPT (*e*xcited *s*tate *i*ntramolecular *p*roton *t*ransfer) fluorescence in polar organic solvents. Thus, the absorption and emission bands are broad, structureless, and largely Stokes-shifted (absorption and fluorescence excitation spectra match) and are centred at the same energies as in apolar or medium polarity organic solvents (Table 1). Consequently, the photophysical mechanism involves excitation of the only stable ground-state dienol (DE) tautomer, an ultrafast double ESIPT process,[17] and emission from a zwitterionic "diketo" (^{1}DK*) tautomer. Besides unchanged spectral features, with increasing solvent polarity and proticity radiationless deactivation of the excited singlet state(s) is enhanced, resulting in larger rate constants for non-radiative decay on going from *n*-hexane [$k_{nr} = (1 - \varphi_f)/\tau_f = 2.2 \cdot 10^8$ s^{-1}] to acetonitrile ($9.0 \cdot 10^8$ s^{-1}). As possible mechanisms accounting for the non-radiative loss of energy of ^{1}DK*, solute−solvent interactions (especially in protic solvents), torsional motions of the two pyridyl rings or the occurrence of *t*wisted *i*ntramolecular *c*harge *t*ransfer (TICT), the proximity effect (due to close-lying nπ* states), and triplet population are discussed.[13,16,18,19]

In water, the intramolecular hydrogen bonds are partially broken up and stabilization of the planar conformation is reduced resulting in a spectroscopically very different ground-state behaviour and reduced fluorescence quantum yields.[8,10,11,15,20] For the doubly-distilled water employed here (pH = 6.4, see Experimental Section), the positions of the global and second absorption band maxima are included in Table 1. In contrast, the fluorescence spectrum consists of the characteristic strongly Stokes-shifted band suggesting that upon excitation all the various conformers or tautomers undergo rapid transformation to emissive ^{1}DK*. Accordingly, k_{nr} (= $21.3 \cdot 10^8$ s^{-1}) is also increased in water. In pure doubly-distilled water, time-resolved fluorescence measurements revealed bi-exponential decays with a relative amplitude of ≥ 0.98 for the main emitting species (Table 1), but since this behaviour is not critical with regard to the results and interpretations of the present complexation experiments, we will not go into further detail here (the same holds true for BPOH, see below.).

In the case of BPOH, the position of the absorption band in aprotic solvents is also independent of the solvent polarity. The emission band of very weak intensity is largely Stokes-shifted and, due to a non-zero dipole moment of the emitting monoketo tautomer, its spectral position is more strongly solvent polarity-dependent than that of ^{1}DK* of $BP(OH)_2$ {$\Delta\tilde{\nu}$(abs−em) [MeCN−3-MP] = 1000 cm^{-1} for BPOH cf. $\Delta\tilde{\nu}$(abs−em) [MeCN−Hex] = 300 cm^{-1} for $BP(OH)_2$; Table 1}.[13,16,21,22] The weaker fluorescence of BPOH as compared to $BP(OH)_2$ is mainly due to enhanced flexibility (with possible TICT-state formation), based on the lack of a second stabilizing hydrogen bond, and low-lying nπ* transitions.[13,16]

In protic solvents, solute−solvent interactions change the fluorescence behaviour of BPOH, i.e. the emission spectrum is blue-shifted and the fluorescence quantum yield increases (ethanol cf. acetonitrile in Table 1), but in alcohols the absorption spectrum remains unchanged. Only water induces stronger effects and a red-shifted shoulder appears in the absorption spectrum while emission occurs at 23000 cm^{-1}. Although the fluorescence quantum yield increases further on going from ethanol to water, it is still much lower than that of $BP(OH)_2$ and thus hampered fluorescence lifetime

[a] Hex = *n*-hexane, Et_2O = diethyl ether, MeCN = acetonitrile, EtOH = ethanol, MeOH = methanol, 3-MP = 3-methylpentane. – [b] Ref.[65]. – [c] Global maximum (see Figure 1, B), ratio of 28.8:24.8:23.2 = 2.4:1.4:1. – [d] With excitation at the absorption maximum. – [e] Relative amplitudes vary with excitation and emission wavelength and are always > 0.98 for the fast component. – [f] Ref.[22]. – [g] Ref.[24]. – [h] The room temperature fluorescence lifetime data published to date are controversial: whereas Tokumura et al. reported bi-exponential decay kinetics with lifetimes of 80 and 410 ps,[22] Kaczmarek et al. reported a value of 3.02 ns.[24] – [i] Ref.[16]. – [j] Not reported. – [k] Not determined due to limited time resolution of the instrumental set-up employed. – [l] Global maximum, ratio of 31.3:27.0 = 7.9:1.

measurements with the instrumental set-up employed (temporal resolution >100 ps).

The importance of the two internal hydrogen bonds in $BP(OH)_2$ is additionally stressed by the fact that similar observations as for BPOH were made for all the "flexible" related compounds, oPP (investigated here and in refs.[23,24]), HPP,[24] and HBA[25] (Scheme 2, C) in organic solvents, in which they are at best only weakly fluorescent (in aqueous solutions of $0.5 < pH < 13.5$, oPP is non-fluorescent[26,27]). On the other hand, all those compounds that are effectively "forced" to be planar are at least moderately fluorescent, e.g. HBQ[23,28,29] and HdihBQ[23] (Scheme 2, C), supporting the generally accepted reaction scheme outlined above. Most probably, besides close-lying nπ* states, rapid torsional motions break up the tight intramolecular hydrogen bond detected for some of these compounds in the ground state through the appearance of a characteristic signal at low field in the ^{1}H NMR spectra, i.e. at $\delta = 14.14$ for BPOH, at $\delta = 14.51$ for $BP(OH)_2$ (see below), and at $\delta = 14.3$ for oPP.[30]

The parent compound bipy is very weakly or non-fluorescent in pure water at room temperature. However, the origin of the weak fluorescence reported in some publications is still a matter of debate.[31]

Complexes

Before going into detail on the different binding modes of the fluorescent complexes of $BP(OH)_2$ and BPOH, the general implications concerning the effects of para- and diamagnetic cations, ion selectivities, complex stoichiometries, as well as the main absorption and emission features will be discussed, as exemplified by the complexes of $BP(OH)_2$ in water.

Complexes of $BP(OH)_2$ in Water

Steady-State Absorption and Fluorescence

In pure water, only complexation to the metal ions Zn^{II}, Cd^{II}, Hg^{II}, Cu^{II}, Ni^{II}, and Co^{II} leads to a change in both the absorption (Figure 1, A) and emission spectra (shown for the d^{10} metal ions in Figure 1, B); no effects are observed for Fe^{II}, Mn^{II}, or Pb^{II}, nor for Ca^{II}, Mg^{II}, or Na^{I}. Whereas the complexes $BP(OH)_2$ forms with paramagnetic transition metal ions, i.e. Cu^{II} or Ni^{II}, are non-fluorescent, in the case of the diamagnetic heavy metal ions of the d^{10} group, only Hg^{II} forms a non-fluorescent complex (Figure 1, B). The Zn^{II} and Cd^{II} complexes are highly fluorescent (Figure 1, B).[8,10,11] The spectroscopic data are collected in Table 2; the full overlap of the absorption bands of the complexes and the free ligand follows from Figure 1.

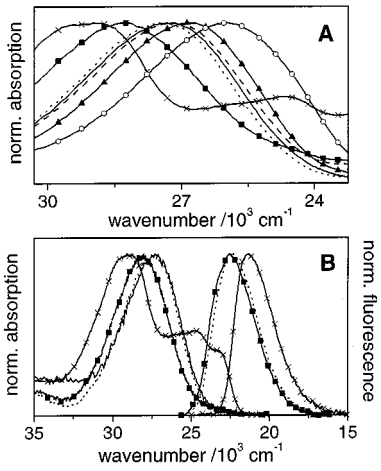

Figure 1. Normalized steady-state absorption spectra of [$M^{II}\subset$BP(OH)$_2$] in pure water: **A**: free $BP(OH)_2$ (×) and complexes with Cd^{II} (■), Zn^{II} (· · ·), Hg^{II} (−), Co^{II} (− − −), Ni^{II} (▲), and Cu^{II} (○); **B**: Spectra of the d^{10} metal ion complexes [excitation at 370 nm, $Hg^{II}\subset BP(OH)_2$ is non-fluorescent]; for both plots, $c_L = 3\cdot10^{-6}$ M and $c_M = 5\cdot10^{-5}$ (Cu^{II}), $1\cdot10^{-4}$ (Ni^{II}), $1\cdot10^{-3}$ (Co^{II}, Hg^{II}), $3\cdot10^{-3}$ (Zn^{II}), $7\cdot10^{-3}$ (Cd^{II}), i.e. full complexation is achieved

For all the complexes, the absorption bands of lowest energy remain ligand-centred electronic transitions of ππ* nature showing typical features of absorption bands of organic chromophores, i.e. broad, structureless bands with relatively high extinction coefficients ($\varepsilon > 10^3$ M$^{-1}\cdot$cm^{-1}). Metal-centred d-d transitions were not observed at the concentrations used and, in the case of the paramagnetic ions,

Table 2. Spectroscopic properties and apparent complex stability constants (see text) of the complexes of $BP(OH)_2$ in water at 298 K

M^{II}	$\tilde{\nu}$(abs) [10^3 cm^{-1}]	$\tilde{\nu}$(em) [10^3 cm^{-1}]	φ_f	τ_f [ns]	log K^{app}
Cu^{II}	26.0	–	–	–	5.9
Ni^{II}	26.9	–	–	–	5.0
Co^{II}	27.1	–	–	–	4.7
Zn^{II}	27.5	22.5	0.62	6.17	4.2
Cd^{II}	28.2	22.6	0.53	5.24	3.6
Hg^{II}	27.3	–	–	–	4.4

no metal-to-ligand (MLCT) or ligand-to-metal (LMCT) charge-transfer bands were found. However, due to its exceptional features (internal hydrogen bonds, enol-keto tautomerism), the characteristic shifts often observed upon complexation are obscured by the very broad absorption spectrum of $BP(OH)_2$ in neat aqueous solution. For example, with 8-hydroxyquinoline (8-HQ), the absorption bands of the metal ion complexes are well-separated and red-shifted by ca. 4500 cm^{-1}, most probably due to a more covalent nature of the transition metal−quinoline nitrogen bond.[32] Similar shifts as for 8-HQ are observed for the complexes of bipy (4460 cm^{-1} for the Zn^{II} complex, see below), but in the case of $BP(OH)_2$ the bands are strongly overlapped and only the maximum of the main band is slightly red-shifted (Figure 1).

Opposite tendencies can be derived from the emission measurements, i.e. different effects of para- and diamagnetic cations with strong similarities within each group, the only exception being Hg^{II}. All the paramagnetic ions and Hg^{II} quench the fluorescence without any spectral shifts, suggesting static quenching to be the main force. The emission spectra of the Zn^{II} and Cd^{II} complexes are very similar and largely overlap with the emission band of the free ligand [blue-shifted by ca. 20 nm (≈1000 cm^{-1}), Figure 1, B].[10,11] Fluorescence excitation spectra recorded at full complexation resemble the absorption spectra of both the Zn^{II} and Cd^{II} cation complexes.

Spectroscopic Titrations and Complex Stoichiometry

For all the cations studied, isosbestic points are observed in their UV/vis spectrophotometric titrations [as an example, see the titration of $BP(OH)_2$ with Cu^{II} in ref.[9]; for fluorometric titrations and the opposite effects of para- and diamagnetic cations, see Figure S2, Supplementary Material]. Analysis of the titration data according to the method of continuous variations[33] yielded a complex stoichiometry of 1:2, i.e. ML_2 (see ref.[9]; an example of an analysis according to this method is given in the Supporting Information). In all the UV/vis spectrophotometric and fluorometric titrations performed with $BP(OH)_2$ and various metal ions, no divergent spectral features were found, making a discrimination between the 1:1 and 1:2 complexes impossible in this way. However, fitting the titration curves was only found to yield acceptable results for a sum of a 1:1 and a 2:1 complexation model[34] in some cases (Zn^{II}, Cd^{II}), both complexes showing similar spectroscopic behaviour. For the other, more strongly coordinating ions, the complex stability constants are too high to be reliably determined by this method and the relatively poor solubility of $BP(OH)_2$ in terms of a c_{L0} titration (see Experimental Section) made such a reverse titration (titration of M with L) impossible. Thus, in order to compare the binding strengths of all the cations, the apparent complex stability constants log K^{app} were determined spectroscopically and are included in Table 2 (for a description of the procedure, see Experimental Section). As can be deduced from Table 2, the order of log K^{app} can be described by the Irving−Williams order[35] and the ion selectivity is comparable to that shown by other so-called "general" ligands with bidentate *N*,*O*-chelating sites such as 8-HQ, pyridine-2-carboxylic acid, or aryl-azomethine ligands.[6,36−39] Provided they are not significantly conformationally restricted, these ligands do not show any enhanced selectivity for particular ions.[6,36]

On analysis of the fluorescence excitation spectra recorded for solutions containing different amounts of free ligand and complex, the spectra could always be described by a linear combination of the fluorescence excitation spectra of the free ligand and the 1:1 complex. Thus, the 1:1 and 1:2 complexes show identical fluorometric behaviour and cannot be distinguished by steady-state fluorescence spectroscopy either.

Time-Resolved Fluorescence

The effect of complexation on the fluorescence decay kinetics of $BP(OH)_2$ reflects the observations made by means of the steady-state fluorescence experiments. Addition of quenching ions such as Cu^{II} and Hg^{II} to a solution of $BP(OH)_2$ in water leads only to a slight variation in fluorescence lifetime but to a strong decrease in the amplitude, when comparing the photons emitted over a certain time interval, i.e. static quenching occurs (this is observed at any combination of excitation and emission wavelengths).

In contrast, for Zn^{II} and Cd^{II}, in agreement with an increase in fluorescence quantum yield, a chelation-induced increase in fluorescence lifetime is observed, leading to the appearance of a new long-lived fluorescence decay component, its lifetime being cation specific (Table 2).[8,10,11] A time-resolved fluorometric titration reveals that with increasing metal ion concentration the relative amplitude of the short-lived decay component decreases and, correspondingly, the relative amplitude of the long-lived decay component increases. No ion concentration-dependent variations in the lifetime of the long-lived decay component are evident, thus supporting the observations made by steady-state spectroscopy, i.e. identical spectroscopic behaviour of the 1:1 and 1:2 complexes. This is also confirmed by fluorescence decay measurements at different emission wavelengths and global analysis of the data. Thus, ground-state heterogeneity[11] can be assumed and suggests that fluorescence deactivation is fast as compared to excited-state decomplexation, i.e. the complexes are stable in both the ground and excited states.

The faster decay of the fluorescence of the Cd^{II} complex can be rationalized in terms of the heavy atom effect.[40] Assuming that in the tightly bound complexes the main route of non-radiative deactivation is intersystem crossing ($k_{nr} \approx k_{isc}$), the heavy atom effect can be quantified by using a central field single-electron approximation for the relationship between k_{isc} and the spin−orbit coupling constant.[41] Accordingly, $\log k_{nr} + \log n^6$ (n = quantum number) gives a measure of the heavy atom effect and the values calculated for the Zn^{II} and Cd^{II} complex amount to 11.4 and 12.1, in good agreement with published values for the related 8-HQ complexes of these ions.[41]

Binding Modes of the Zn^{II} and Cd^{II} Complexes of the (Substituted) Bipyridyls (and oPP) in Water, Ethanol, and Acetonitrile

Although the spectroscopic behaviour of the complexes of $BP(OH)_2$ reveals certain tendencies, the real nature of the complexes in terms of Scheme 1 and the background given in the Introduction is still unclear. A theoretically possible route C (not shown in Scheme 1), the formation of a sterically unfavoured seven-membered ring due to coordination to both hydroxyl groups, can be ruled out on the basis of thermodynamic considerations.[42,43] The necessary deprotonation of two hydroxyl groups at pH ≈ 7, the order of complex stability constants (the highest K is observed for the aminophilic cation Cu^{II}), the general preferences of the "soft" metal ions (in terms of Pearson's concept of hard and soft acids and bases)[44] for "soft" donor heteroatoms, and the unfavoured geometry of the resulting chelate render this mechanism very unlikely. However, chelate formation according to routes A and B in Scheme 1 has to be considered, as has been shown by Cargill Thompson et al.[45]

Before going into detail on the various complexes, it is noteworthy that whereas $BP(OH)_2$, BPOH, and bipy show complexation-induced spectroscopic effects upon addition of Zn^{II} and Cd^{II} in all three solvents investigated, very weakly fluorescent oPP ($\varphi_f < 10^{-5}$) does not show any pronounced changes in its photophysical properties upon addition of cations. Even in organic solvents, only small effects are observed at a high excess of metal ion (e.g. >500-fold excess of Zn^{II}). Thus, the behaviour of oPP will be discussed separately below. The spectroscopic data for the Zn^{II} and Cd^{II} complexes of BPOH and bipy are reported in Table 3, along with the data for the corresponding $BP(OH)_2$ complexes.

Absorption and Fluorescence Spectroscopy in Water

In pure water, the Zn^{II} and Cd^{II} complexes of both BPOH and $BP(OH)_2$ show very similar absorption and emission behaviour (Figure 2, Table 3). The spectral band

[a] Intermediate complex observed in the titration experiments at $x_{M/L} \leq 0.5$. − [b] Data obtained at highest ion excess (ML complex). − [c] Center of the band displaying a double maximum. − [d] Intensity of the band at 26600 cm^{-1} ca. one-hundredth of the total fluorescence intensity. − [e] Data obtained at highest Zn^{II} excess possible: two different absorption and emission bands. − [f] From fluorescence excitation spectrum. − [g] Not determined because full complexation could not be reached. − [h] Observed at 25500 cm^{-1}; τ_1 = 0.61 ns and τ_2 = 5.30 ns when recorded at 21800 cm^{-1}. − [i] φ_f^{rel} (band at 21100 cm^{-1}) = 0.02. − [j] τ_2 = 5.44 ns (a_{rel} = 0.27) when observed at 21100 cm^{-1}.

positions for both absorption and emission differ by ≤ 1000 cm^{-1} and the fluorescence quantum yields and lifetimes are very similar as well. Consequently, this leads to similar rate constants for radiative and non-radiative deactivation.

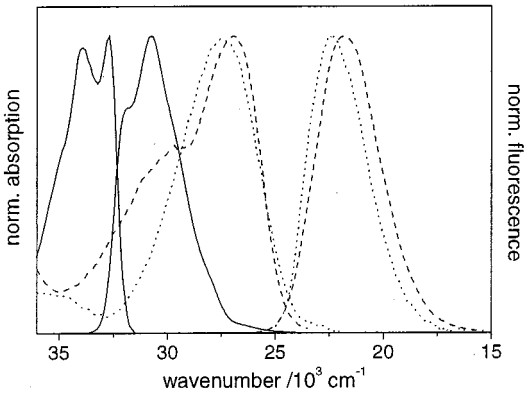

Figure 2. Steady-state spectra of the Zn^{II} complexes of $BP(OH)_2$ (· · · ·), BPOH (− − −), and bipy (−) in pure water [full complexation; excitation at absorption maximum; $c_L = 3 \cdot 10^{-6}$ M, $c_M = 7.5 \cdot 10^{-5}$ M in the case of bipy, $1 \cdot 10^{-3}$ in the case of BPOH, and for $BP(OH)_2$ see caption of Figure 1]

On the other hand, the behaviour of the corresponding complexes of bipy is clearly different. The Stokes shifts observed are only two-thirds the size of those observed for the hydroxy bipyridyls, the fluorescence quantum yields are considerably lower, and, in particular, the fluorescence decays more rapidly by a factor of ca. 4.5.

Accordingly, this effect should be predominantly reflected in different k_{nr} values. Indeed, the value found for Zn^{II}⊂bipy, for example, is almost an order of magnitude greater than those obtained for Zn^{II}⊂BPOH and Zn^{II}⊂B-$P(OH)_2$. This effect is even more pronounced in the case of Cd^{II}. Thus, the "activity" of nπ* state interaction is higher in the bipy complexes than in the other two complexes and the influence of the heavy atom (or ion) Cd^{II} is more pronounced in the case of these smaller chelates with a five-membered ring structure [note that because of the higher stability of the bipy complexes (see below), enhanced torsional motions about the central bipyridyl bond seem to play only a minor role]. Furthermore, besides the shift in absorption (electrostatic polarization induced by M^{II}), M^{II}-⊂bipy complexes show the characteristically structured absorption bands, with the vibrational structure being better resolved.[46] On the other hand, on comparing k_f and k_{nr} of M^{II}⊂$BP(OH)_2$ with those of free $BP(OH)_2$, it is obvious that the rate constant for fluorescence deactivation remains constant (within experimental error, Table 1), but that the contributions of competing non-radiative deactivation channels of the first excited singlet state are markedly reduced [it is interesting to note that tight binding of $BP(OH)_2$ in the complexes further reduces k_{nr} by a factor of 3.5 as compared to k_{nr} in apolar solvents such as *n*-hexane ($k_{nr} = 2.2 \cdot 10^8 s^{-1}$)].

Absorption and Fluorescence Spectroscopy in Ethanol

Ethanol, being less polar than water but still capable of hydrogen-bond formation, induces similar effects as water, but some noticeable differences in complex formation are observed, especially in the case of BPOH. For M^{II}⊂B-$P(OH)_2$ and M^{II}⊂bipy, a behaviour similar to that in water is observed. The only deviations are slightly blue-shifted spectra in the case of M^{II}⊂$BP(OH)_2$ and a marked drop in fluorescence quantum yield and lifetime for the Zn^{II} complex of bipy. The exceptional behaviour of this complex in ethanol is unclear and will not be discussed further. However, the data obtained for Zn^{II}⊂bipy are still different from those measured for the corresponding complexes of its hydroxy derivatives. Cd^{II}⊂bipy shows the expected features and, in acetonitrile (see below), the behaviour of Zn^{II}⊂bipy is again comparable to that in water.

For M^{II}/BPOH, complex formation is very remarkable. At low metal ion concentrations up to a metal-to-ligand ratio $x_{M/L} = 0.5$, the complex formed resembles that of $BP(OH)_2$. In Figure 3, A, the UV/vis spectrophotometric titration spectra for BPOH with Zn^{II} up to $x_{M/L} = 0.5$ are displayed, clearly showing the characteristic features (see Table 3 for the corresponding data). On addition of more Zn^{II} to the solution, the band at 25200 cm^{-1} diminishes and a new band appears at 30000 cm^{-1} (Figure 3, B). This band displays the typical characteristics of the Zn^{II}⊂bipy complex (blue-shifted and structured, cf. A and B, Figure 4). However, the emission spectra measured up to a 1000-fold excess of Zn^{II} (e.g. "− − −" in Figure 4, A) resemble that of Zn^{II}⊂$BP(OH)_2$ (Figure 4, B, " · · · · ") and the fluorescence decay has almost the same lifetime (Table 3).

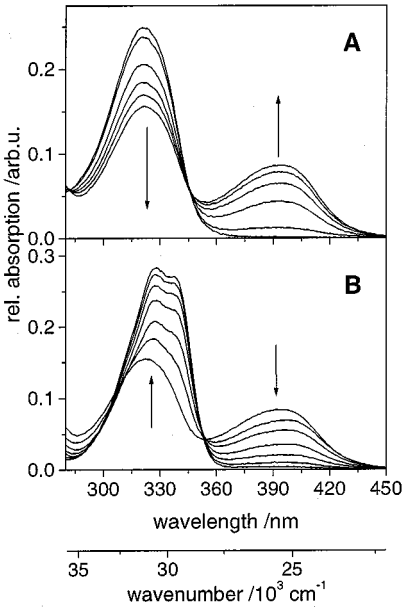

Figure 3. UV/vis spectrophotometric titration of BPOH with Zn^{II} in ethanol; **A**: steps for $x_{M/L} = 0.1-0.5$; **B**: steps for $x_{M/L} = 0.5-50$ (arrows indicate changes upon Zn^{II} addition); measurements were performed in 100 mm absorption cells with $c_L = 3.7 \cdot 10^{-6}$ M; the second *x* axis (wavenumber scale) is included for better comparison with data presented in the text and tables

Only on the high energy side (enlarged emission spectrum marked "—" in Figure 4, A) is a weak band centred at 26600 cm^{-1} visible. In view of the emission properties of Zn^{II}⊂bipy, i.e. low φ_f and fast decay kinetics, emission from

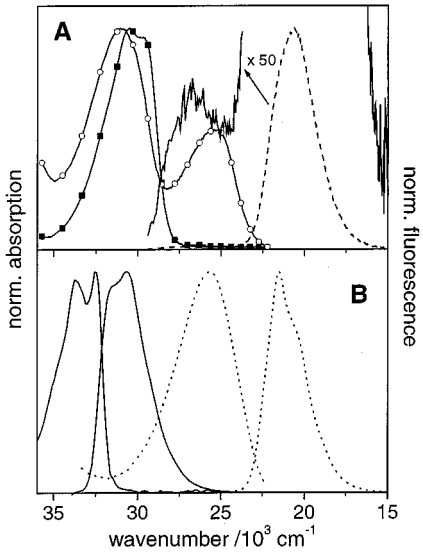

Figure 4. Steady-state spectra of the Zn^{II} complexes of the (substituted) bipyridyls in ethanol; **A**: absorption spectra of $Zn^{II}\subset(BPOH)_2$ (○), $Zn^{II}\subset BPOH$ (■), and emission spectrum of $Zn^{II}\subset BPOH$ (− − − −); the enlarged high-energy side (−) of the emission spectrum is also included ($c_L = 3\cdot10^{-6}$ M, $c_M = 1.5\cdot10^{-3}$ M); **B**: spectra of the Zn^{II} complexes of $BP(OH)_2$ (· · · · ·) and bipy (−) in ethanol (full complexation; excitation at absorption maximum; $c_L = 3\cdot10^{-6}$ M, $c_M = 7.5\cdot10^{-5}$ M)

an *N*,*N*′-chelated $Zn^{II}\subset BPOH$ complex might be expected to be weak in ethanol as well. However, the fluorescence excitation spectra recorded at 27000 cm^{-1} and 20800 cm^{-1} are similar and resemble the absorption spectrum of the 1:1 complex centred at 30000 cm^{-1}. Furthermore, closer inspection of Figure 4 provides a possible explanation for the fluorometric results. Assuming that in an equilibrium situation involving intermediately formed "$Zn^{II}\subset BP(OH)_2$-like" complexes still in the solution, light emitted from the "$Zn^{II}\subset$bipy-like" complex is absorbed by this species and is then re-emitted with its characteristic stronger fluorescence, the blue-shifted emission of the "$Zn^{II}\subset$bipy-like" complex should be quenched.

Absorption and Fluorescence Spectroscopy in Acetonitrile

In acetonitrile, a solvent of comparable polarity lacking H-bond donating ability, the tendencies observed in ethanol are even more pronounced. Only the Cd^{II} complex of $BP(OH)_2$ shows almost identical spectroscopic features in all three solvents employed. For $Zn^{II}/BP(OH)_2$, the metal ion concentration-dependent spectroscopic behaviour resembles that of Zn^{II}/BPOH in ethanol. At low concentrations, the features seen for $Zn^{II}\subset BP(OH)_2$ in aqueous solution are observed, but with a large excess of Zn^{II}, a blue-shifted band centred at 25500 cm^{-1} appears in the emission spectrum (Figure 5). The changes in absorption are negligible but in Figure 5 the differences between the fluorescence excitation spectra recorded in both emission bands can be seen. Observation at 19200 cm^{-1} yields a band corresponding to the absorption band of the 1:2 complex (cf. the close similarity of the spectra marked "−" and " ○" in Figure 5). Furthermore, emission wavelength-dependent

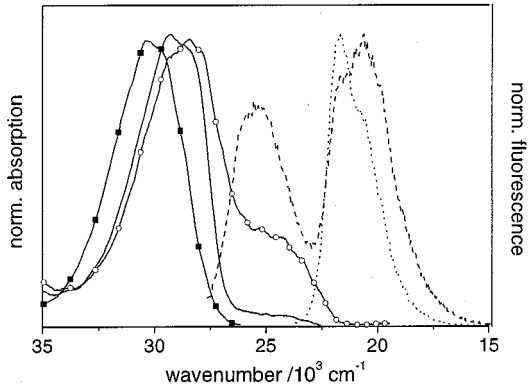

Figure 5. Steady-state spectra of $Zn^{II}/BP(OH)_2$ in acetonitrile; absorption (−) and emission (· · · ·, excitation at 24500 cm^{-1}) spectra of the ML_2 complex; emission spectrum at high Zn^{II} excess (both complexes present, − − −, excitation at 29500 cm^{-1}), and fluorescence excitation spectra at high Zn^{II} excess (observation at 25600 cm^{-1} = ■; observation at 19200 cm^{-1} = ○)

fluorescence decay data support the results (1.37 ns at 25500 cm^{-1} cf. ca. 6 ns at 21800 cm^{-1}, see Table 3).

For $Zn^{II}\subset BPOH$, only the absorption band at 30400 cm^{-1} and an emission band at 27500 cm^{-1} are seen, irrespective of the Zn^{II} concentration (Table 3). The similarity between the photophysical properties of $Zn^{II}\subset$bipy and $Zn^{II}\subset BPOH$, including typical characteristics (vibrational structure) of the $M^{II}\subset$bipy absorption bands, is remarkable (Table 3 and Figure S3, Supplementary Material). The higher-energy emission band, absent in ethanol, indicates the formation of a "$Zn^{II}\subset$bipy-like" chelate in acetonitrile. In accordance with the different behaviour of the Zn^{II} and Cd^{II} complexes of $BP(OH)_2$, for Cd^{II}/BPOH some "$Cd^{II}\subset BP(OH)_2$-like" chelate is still observed at low Cd^{II} concentrations.

The data presented thus far lead to the conclusion that the complexes investigated can be divided into two groups according to their spectroscopic behaviour in the different solvents [these "spectroscopic reference structures" are termed "$Zn^{II}\subset$bipy-like" and "$Cd^{II}\subset BP(OH)_2$-like"].

$Zn^{II}/BP(OH)_2$: "$Cd^{II}\subset BP(OH)_2$-like" in all the solvents except in acetonitrile at high excess of Zn^{II};

Zn^{II}/BPOH: "$Cd^{II}\subset BP(OH)_2$-like" in water and at low metal ion concentrations in ethanol, "$Zn^{II}\subset$bipy-like" in acetonitrile and at high metal ion concentrations in ethanol;

Cd^{II}/BPOH: "$Cd^{II}\subset BP(OH)_2$-like" in water and at low metal ion concentrations in ethanol and acetonitrile, "$Zn^{II}\subset$bipy-like" at high metal ion concentrations in ethanol and acetonitrile;

Cd^{II}/bipy: "$Zn^{II}\subset$bipy-like".

The fact that the bipy complexes display their characteristic behaviour in all the solvents and that the only other chelate structure that may conceivably be formed in the complexes of the hydroxy derivatives is that arising from *N*,*O*-chelation indicates that this structure is most probably the favourable one for the chelates of the *o*-hydroxy bipyridyls in protic solvents. Unfortunately, due to the different behaviour of oPP (see below), *N*,*O*-chelates could not be directly detected by means of optical spectroscopy and thus ^{1}H NMR experiments were additionally performed. [Note

that complexation of $BP(OH)_2$ to Cu^{II} in acetonitrile does not lead to the formation of an *N,N′*-chelate. The main absorption band remains centred at ca. 29000 cm^{-1}, but the shape of the spectrum very much resembles that of $BP(OH)_2$ in pure water, i.e. the Cu^{II} complex displays a second maximum at 23800 cm^{-1} ($\varepsilon \approx {}^1/_2\ \varepsilon_{max}$) and a shoulder at ca. 22600 cm^{-1} ($\varepsilon \approx {}^1/_3\ \varepsilon_{max}$). Thus, it seems possible that with the aid of complex formation, even the study of different enol(ate) and keto tautomers in solvents of different polarities and proticities is possible. As might have been expected, the Cu^{II} complex is non-fluorescent in acetonitrile (and also in ethanol).]

Stabilities of the Complexes

Analyzing titrations of $BP(OH)_2$, BPOH, and bipy with Zn^{II} in the three solvents studied, the apparent complex stability constants determined support the conclusions drawn on the basis of the photophysical properties.

In water, BPOH and $BP(OH)_2$ yield comparable log K^{app} values of 4.1 and 4.2 and the value for Zn^{II}/bipy amounts to 4.9. The particular behaviour of BPOH in ethanol is well-reflected by the shape of the titration curve monitored at 360 nm (Figure 6, middle section), while in acetonitrile the similarity of the Zn^{II}/bipy and Zn^{II}/BPOH complexes is evident. Furthermore, whenever *N,O*-chelation occurs, it is not only the work necessary for desolvation of the cation and ligand and the enthalpic and entropic contributions gained by complex formation that have to be considered, but the work necessary for deprotonation also becomes important. Since we determined the apparent (spectroscopic) complex stabilities here, further investigations are necessary to study the effect of the different solvents on the true log K_1 for the reaction $M + L \rightleftharpoons ML$ (see, e.g., ref.[47]).

oPP

As mentioned above, only very small cation-induced effects on the photophysical properties of oPP were found in the course of these investigations. This is consistent with results reported previously in the literature, where oPP was described as being non-fluorescent at room temperature[24] and the only complexation reaction in water to yield spectroscopic effects was found to be that involving Be^{II} ions.[27] Besides Kábrt and Holzbecher, Johnston and Freiser reported on the complexation of oPP with Cu^{II} in water/dioxane (50:50), but for all the *o*-(2-heterocycle)phenol derivatives (with heterocycle = pyridyl, imidazolinyl, benzimidazolyl, isoquinolinyl) investigated by these researchers, the stability constant obtained for oPP was the smallest.[26] In the crystalline state, the strong internal hydrogen bond (oPP shows the shortest N−O distance in X-ray structures of the *o*-hydroxy bipyridyls)[24] represents a counterforce to the conformation oPP has to adopt in all the complexes synthesized to date (e.g. a twist of ca. 25° between the aryl rings in a Co^{III} complex,[48] and of 34° in a $[Ru^{II}bipy_2oPP]$ complex[30]). Furthermore, for the Co^{III} complex of oPP, Ganis et al. observed a broad distribution of twist angles (22−29°) for the ligand in the crystalline state, suggesting that in the complex oPP has a low rotational energy barrier.[48] In accordance with our observations, this could point to the formation of a (loose) complex in solution, which is spectroscopically inaccessible.

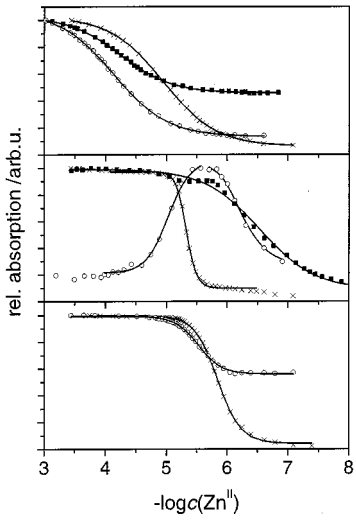

Figure 6. Titration curves $[A(\lambda)_{norm}$ vs. $-\log c_{Zn}]$ for $BP(OH)_2$, BPOH, and bipy with Zn^{II} in water (top), ethanol (middle), and acetonitrile (bottom); $BP(OH)_2$ = ■, monitored at 365 nm (H_2O) and 370 nm (EtOH); BPOH = ○, monitored at 371 nm (H_2O), 360 nm (EtOH), and 335 nm (MeCN); bipy = ×, monitored at 307 nm (H_2O), 307 nm (EtOH), and 305 nm (MeCN); solid lines represent fits according to the procedure described in the Experimental Section; because of the strong overlap of the bands of the two complexes involved in a titration of $BP(OH)_2$ with Zn^{II} in MeCN, the comparatively low complex stability of these complexes, and the limited solubility of $Zn(ClO_4)_2$ in MeCN, these data are omitted in the bottom graph for better clarity

NMR Spectroscopy in Acetonitrile

In order to verify the chelate structures anticipated for $M^{II}/BP(OH)_2$ in polar solvents, the ^1H NMR spectra of $BP(OH)_2$, BPOH, and bipy, as well as their Zn^{II} and Cd^{II} complexes were recorded in deuterated acetonitrile (CD_3CN). The data are collected in Table 4.

Table 4. ^1H NMR chemical shifts (ppm from TMS) of the heteroaromatic protons of $BP(OH)_2$, BPOH, and bipy (solvent = CD_3CN, counterion = perchlorate, $c_L = 1{\cdot}10^{-4}$ M, $c_{Zn} = 2{\cdot}10^{-3}$ M, c_{Cd} = 0.185 M)

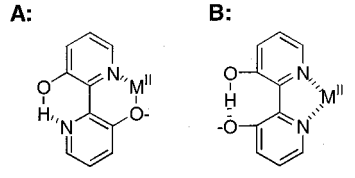
[a] Broad. – [b] Very broad.

An important feature with regard to the determination of the nature of the complexes is the presence and position of the signal due to the OH group involved in internal hydrogen-bond formation (Scheme 2). For the free ligands,

this signal was found at the expected low field position, i.e. at $\delta = 14.14$ for BPOH and at $\delta = 14.51$ for $BP(OH)_2$. In the case of BPOH, addition of Zn^{II} ions led to a drastic shift in the position of this signal such that it appeared at $\delta = 9.22$. In contrast to this observation, the signal remains at $\delta = 14.5$ in $Zn^{II}/BP(OH)_2$, although it is broadened. Thus, the "proton chelate" in BPOH is "cracked" upon Zn^{II} complexation, but remains at least partially intact in $Zn^{II}/BP(OH)_2$ (case A in Scheme 1; see ref.[45] and, concerning the effects of internal hydrogen bonding, cf. the ^{15}N and ^{17}O NMR studies by Sitkowski et al.[49]).

The same conclusion could be drawn from the changes in the chemical shifts of the signals of the heteroaromatic protons. It is well-known that upon complexation the conformation of bipy changes from its favoured *trans* form in inert solvents to the corresponding *cis* form in the complex (bidentate chelate).[50,51] Although complex formation with bipy is accompanied by only minor changes in chemical shifts,[51,52] the downfield shifts of the 4-H and 5-H signals are especially characteristic.



For BPOH, these shifts are of the same magnitude as for bipy (Table 4 and Figure S4, Supplementary Material). This result further supports the explanation that Zn^{II} is bound by BPOH in acetonitrile through *N*,*N*′-coordination with accompanying loss of the intramolecular hydrogen bond of the ligand. On the other hand, for $BP(OH)_2$, virtually no changes in the positions of the resonances of the aromatic protons are observed upon complexation. The signals are merely broadened due to the dynamics of exchange effects. This broadening is even more pronounced in the Cd^{II} complex, although the effects induced by both ions are similar (Table 4).

Unfortunately, due to the relatively high concentrations required for the NMR measurements and the rather poor solubility of Zn^{II} salts in acetonitrile, it was not possible to identify the proposed *N*,*N*′-chelate at high excess of Zn^{II} over $BP(OH)_2$ (see above). In the case of Cd^{II}, no such complex was observed in any experiment.

Five- vs. Six-Membered Chelates and the Influence of "Proton Chelates"

For some combinations of solvent, ion, and ligand [notably for protic solvents, Cd^{II}, and $BP(OH)_2$], the chelation behaviour found for the *o*-hydroxy bipyridyls is characterized by two unusual complexation features: (i) the formation of a six-membered ring in spite of the fact that the five-membered ring is usually more stable, and (ii) a preference for *N*,*O*-chelation over *N*,*N*′-chelation of "soft" or "borderline"[5,44] metal ions. These ions usually prefer coordination by π-donating (heterocyclic) nitrogen atoms to that by σ-donating oxygen atoms.[5]

In the case of $BP(OH)_2$, the chelate with a five-membered ring, which represents the only possible structure for $M^{II}\subset$bipy, is only favoured to some extent in solvents possessing no H-bond donating ability, e.g. acetonitrile. Only in such solvents does the possibility of forming the relatively unstable seven-membered "proton chelate" (case B in Scheme 3) with an intramolecular O−H−O bridge exist. Its formation or otherwise could not be clarified in this work. All attempts to grow crystals of this complex species were unsuccessful and the observation of a characteristic signal at $\delta \approx 18$ (O−H−O bridge)[45] in the ^1H NMR spectra was not possible due to the limited solubility of Zn^{II} salts in acetonitrile. Thus, the fact that the stability of hydrogen bond bridges ("proton chelate") is greatly enhanced for six-membered rings as compared to five- or seven-membered rings seems to be the main driving force here.[37,42,43] The strong seven-membered "proton chelate" reported by Cargill Thompson et al. for a mononuclear $Ru^{II}bipy_2-BP(OH)_2$ complex[45] seems to be the weaker structure in the present complexes. It is mainly the increase in mesomeric stabilization and resonance in the six-membered ring (higher degree of aromaticity) that renders the hydrogen bond stable in six-membered rings and accounts for this structural preference. The stabilizing mesomeric effect in the *N*,*O*-chelate can be rationalized as a "tautomeric electron-pair shift" leading to enhanced electron delocalization. Stabilization of six-membered metal ion chelates by six-membered "proton chelates" has been observed previously.[53] Furthermore, for six-membered chelates in azomethine derivatives, only minor differences between the "proton chelate" and the metal ion chelate have been observed, i.e. it is mainly the lone electron pair on the nitrogen atom that takes part in coordination and the aromatic ring π-electrons are little involved in the binding of the metal ion.[54] Here again, six-membered "proton chelates" are the most stable.[37,38] Moreover, all the observations of enhanced stability of six-membered chelates listed above have been made for systems in aqueous solutions. In the case of the *N*,*N*′-chelated $Ru^{II}bipy_2-BP(OH)_2$ complex described by Cargill Thompson et al., the limited possibilities in an $Ru^{II}bipy_2$-prearranged coordination sphere seem to favour deprotonation and *cis* chelation of $BP(OH)_2$ as the third ligand. Unfortunately, the low solubility of Zn^{II} in acetonitrile prevented the estimation of both the fluorescence quantum yield and lifetime of the 1:1 $Zn^{II}\subset BP(OH)_2$ complex, thus making a further verification of the conformation of the ligands impossible here. [Note that, as compared to the planarity of the type of chelate reported by Cargill Thompson et al., *N*,*N*′-chelation of $BP(OH)_2$ without deprotonation of a hydroxy group would lead to steric crowding of the OH groups and distortion of ligand planarity, resulting in blue-shifted spectra and a change in the rate constant, as has been observed for complexes of 3,3′-dimethyl-2,2′-bipyridyl.[55]]

Scheme 3. Chelation mechanisms for $M^{II}\subset BP(OH)_2$ formation, including possible stabilization modes by intramolecular hydrogen bonding (the structures do not indicate actual complex stoichiometries)

The results obtained for BPOH support the findings for $BP(OH)_2$. Even this ligand, for which *N*,*N*′-chelation should be more easily achievable owing to reduced steric hindrance (due to the lack of one *o*-hydroxyl group), favours *N*,*O*-chelation in aqueous solutions and for the primarily formed ML_2 complexes in ethanol. The formation of an additional "proton chelate" is not possible, but (a) solvent molecule(s) can saturate the second pyridyl nitrogen atom by hydrogen bonding [in the hydroxy bipyridyls where negative charge can be transferred from the oxygen to a nitrogen atom (Scheme 2), the pyridyl nitrogen atoms are more strongly π-basic]. In agreement with the solvent-dependent spectroscopic results, the only slightly smaller log-K^{app} value for $Zn^{II}\subset BPOH$ as compared to $Zn^{II}\subset BP(OH)_2$ in water suggests that in the latter the stabilization by the remaining intramolecular hydrogen bond is of a very delicate nature.

For the fluorescent complexes, a comparison of k_f and k_{nr} for $M^{II}/BP(OH)_2$ with those for the free ligand reveals that the stability of the planar ligand is increased in the complex, resulting in comparable rate constants for fluorescence deactivation (Table 1 cf. Table 3) but reduced rate constants for non-radiative deactivation. Thus, k_{nr} of the complexes is even smaller than that of the free ligand in apolar solvents such as *n*-hexane. The similarity of the photophysical properties of the "mono-enolate complex" $M^{II}\subset BPOH$ to those of $M^{II}\subset BP(OH)_2$ in water (and to some extent in ethanol) and the completely different behaviour of most M^{II}/oPP complexes suggests that the second pyridyl nitrogen atom (and not necessarily the whole PT site) may be important with regard to stabilization in both the ground and excited states in this medium. As for $BP(OH)_2$, upon charge-transfer in the excited state, the charge density on both nitrogen atoms was found to increase for BPOH and oPP.[12,13,24]

The stronger tendency of Cd^{II} to form six-membered *N*,*O*-chelates is in agreement with results obtained by other researchers on Cd^{II} and Zn^{II} complexes of mixed *N*,*O*-containing macrocyclic ligands.[56] Here, the tendency for exclusive *N*-coordination is generally higher for Zn^{II} than for Cd^{II}.[56]

Correspondingly, the observed drastic decrease in fluorescence intensity in the complexes with paramagnetic ions is due to the formation of a stable non-fluorescent complex, i.e. static quenching occurs.[57] Complexation of Hg^{II} results in the same static quenching effect, only in this case the heavy atom effect accounts for a higher intersystem crossing rate. For none of the quenching cations could complex-specific decay components with a fluorescence lifetime >100 ps be detected with the experimental set-up employed.

Conclusion

Investigations of the complexation behaviour of $BP(OH)_2$ and BPOH in aqueous, alcoholic, and acetonitrile solutions have revealed that the heavy and transition metal ion binding properties of $BP(OH)_2$ are rather non-selective and that chelation-induced fluorescence enhancement is only observed for the d^{10} metal ions Zn^{II} and Cd^{II}. Upon complexation to Hg^{II} or paramagnetic ions, static quenching occurs. Two different chelates of the Zn^{II} and Cd^{II} complexes of the *o*-hydroxy bipyridyls have been characterized by means of solvent-dependent optical spectroscopic and NMR studies. Here, the preference for *N*,*N*′-coordination over *N*,*O*-coordination increases with decreasing proticity of the solvent in the order water < ethanol < acetonitrile and is more pronounced for Zn^{II} than for Cd^{II} as well as for the complexes of BPOH compared to those of $BP(OH)_2$. The photophysical data of the *N*,*N*′-chelates of both hydroxy-substituted ligands are very similar to those of the *N*,*N*′-chelated reference complexes $M^{II}\subset$bipy. Thus, by controlling the proticity or hydrogen-bond donating ability of the environment in particular, it is possible to direct metal ion binding along a certain path to yield specifically coordinated complexes with multifunctional ligands.

Experimental Section

Materials: $BP(OH)_2$ (98%+, purchased from Aldrich and showing essentially the same features as a freshly prepared sample[58] kindly provided by Prof. H. Langhals, Ludwig-Maximilians-Universität München), bipy (99%+, Aldrich), as well as BPOH and oPP (both gifts from Dr. F. Vollmer, Technische Universität Berlin, synthesized according to ref.[24]) were checked by TLC (Kieselgel F_{254}, Merck) and used as received. Stock substrate solutions, typically $1\cdot10^{-3}$ M (in acetonitrile and ethanol) or $5\cdot10^{-5}$ M (in water), were kept under nitrogen and stored in the dark at 4 °C. Metal perchlorates purchased from Merck, Acros, or Aldrich were of the highest available purity and were dried (vacuum oven) to a definite water content employing various procedures adapted from ref.[59] For example, Hg^{II} perchlorate was dried at 75 °C for 12 h yielding $Hg^{II}(ClO_4)_2\cdot 3\,H_2O$, while $Zn^{II}(ClO_4)_2\cdot 2\,H_2O$ was obtained by drying the commercial product at 100 °C in vacuo for 12 h. Stock solutions, typically $1\cdot10^{-3}$ to 0.1 M (depending on the solubility of the metal salt in the relevant solvent), were stored under nitrogen in the dark at 4 °C (**Caution**: Perchlorate salts present a potential explosion hazard and should be handled with care and possibly only in small quantities!). Ethanol and acetonitrile (Aldrich) were of UV-spectroscopic grade. Doubly-distilled water (pH 6.39) was provided by the Laboratory for Trace Elemental Analysis, BAM, Berlin.

Steady-State Absorption and Fluorescence Spectroscopy: UV/vis spectra were recorded on a Carl Zeiss Specord M400/M500 absorption spectrometer, while steady-state emission spectra were measured with a Perkin−Elmer LS50B and a Spectronics Instruments 8100 spectrofluorometer. To determine the relative fluorescence quantum yields (φ_f), the optical densities (OD) of the solutions at the excitation wavelengths were adjusted to 0.1 ± 0.001 in 100 mm absorption cells. These solutions were then transferred to a 10 mm quartz cell and the fluorescence measurements were performed with a standard 90° geometry and with excitation and emission polarizers set at 0° and 54.7°. Quinine sulfate dihydrate (NIST standard reference material SRM 936) in 0.1 N H_2SO_4 (φ_f = 0.51 ± 0.03)[60] and $BP(OH)_2$ in cyclohexane (φ_f = 0.31 ± 0.02)[12b] were used as fluorescence standards. All fluorescence spectra presented here have been corrected for the spectral response of the detection system (calibrated quartz halogen lamp placed inside an integrating

sphere; Gigahertz-Optik) and for the spectral irradiance of the excitation channel (calibrated silicon diode mounted at a sphere port; Gigahertz-Optik). The fluorescence quantum yields were calculated from 4 independent measurements; the uncertainties in the measurements were estimated to be ±5% (for $\varphi_f > 0.2$), ±10% (for $0.2 > \varphi_f > 0.02$), ±20% (for $0.02 > \varphi_f > 5\cdot10^{-3}$), and ±30% (for $5\cdot10^{-3} > \varphi_f$), respectively.

Time-Resolved Fluorescence Spectroscopy: Fluorescence lifetimes (τ_f) were measured with synchrotron radiation from the Berlin Storage Ring for Synchrotron Radiation (BESSY).[61] The fluorescence was collected at right angles (monochromators with a spectral bandwidth of 8 nm) and the excitation wavelength of the synchrotron radiation was selected with a monochromator of 2 nm spectral bandwidth. The pulsed excitation source BESSY allowed for a temporal resolution of 100 ps (single-bunch mode; 4.8 MHz). The fluorescence decay curves were recorded with a time-correlated single-photon counting set-up and a time division of 55.5 ps channel^{-1}; typical count rates were of the order of $1\cdot10^3$ counts s^{-1}. For the fluorescence decay measurements, data were accumulated up to 5000 counts in the peak channel for a single decay. The temporal calibration of the experimental set-up for the time-resolved measurements was checked with Rose Bengal in methanol ($\tau_f = 0.50 \pm 0.02$ ns),[62] 1,4-bis(5-phenyloxazol-2-yl)benzene (POPOP) in ethanol ($\tau_f = 1.35 \pm 0.20$ ns),[63] and fluorescein 27 in 0.1 N NaOH ($\tau_f = 4.50 \pm 0.03$ ns).[63] For all the decay measurements, emission polarizers were set at 54.7°.

NMR Spectroscopy: One- and two-dimensional NMR spectra [COSY (90°) and $^{13}C/^{1}H$ HECTOR] were recorded on a Bruker DMX 400 spectrometer (5 mm tube, CD_3CN, deuterium lock). The ^1H NMR spectra of the free ligands were assigned on the basis of the typical coupling patterns for such compounds. In particular, the signals due to 6-H (α to the pyridyl nitrogen atom), showing a decreased vicinal coupling constant ^3J(5-H, 6-H),[64] were easily identified. Application of the method of incremental schemes,[64] well-established for pyridyl systems, revealed a good agreement between the measured and tabulated data and the coupling constants obtained correspond well with data reported for pyridyl systems in the literature.[64] In the case of BPOH, additional measurements were necessary to fully assign all the seven ^1H signals. A two dimensional ^1H-^1H correlation spectrum (COSY) allowed the separation of the three-spin system of the hydroxypyridyl moiety and the four-spin system of the pyridyl ring. The close similarity of the 4-H and 5-H signals (AB part of an ABX spectrum) and of the 3′-H and 6′-H signals could be resolved by means of hetero-correlated ^{13}C-^1H spectra (partly including ^1H-^1H homo-coupling).

Complex Stability Constants: The complex stability constants K reported herein were determined from absorption measurements (in 50 or 100 mm absorption cells) by adding aliquots of the appropriate metal ion solution to a solution of the ligand (c_{M0} titration). Besides large errors encountered in absorption (or fluorescence) measurements at (very) low ligand concentrations (very dilute solutions), the solubility of the ligands (especially in water and when a high excess toward the end of the titration is required) proved to be the limiting factor for performing c_{L0} titrations in order to determine K values of high order (1:2, 1:3 complexes) or successive K_n values. The latter was also hampered by the spectral similarities of the individual complexes. In the case of high complex stability constants [e.g. for complexes of $BP(OH)_2$ with paramagnetic ions] as well as mixed stoichiometries, fitting of the c_{M0} titration data to 1:1 and 1:2 complexes yielded no K_n values of acceptable accuracy. Thus, in order to obtain a measure for all the cations investigated, the apparent complex stability constant K^{app} was obtained by carrying out c_{M0} titrations with similar c_{L0} and fitting the sigmoidal curve of a $\Delta A(\lambda)$ vs. $-\log c_M$ plot. When no diverse spectral features occur in such a c_{M0} titration, K^{app} corresponds best to the process $M + ML_2 \rightarrow 2\,ML$.

Protonated *O,S*-Dimethyl Dithiocarbonate − Synthesis, Spectroscopic Characterization and the Crystal Structure of $(CH_3O)(CH_3S)CSH^+SbF_6^-$

Rolf Minkwitz*[a] and Frank Neikes[a]

Keywords: Carbocations / IR spectroscopy / Raman spectroscopy / NMR spectroscopy / Protonations

Dithiocarbonic acid *O,S*-dimethyl ester reacts with the super acidic system HF/MF_5 (M = As, Sb) to form $(MeO)(MeS)CSX^+MF_6^-$ (M = As, Sb; X = H, D). $(MeO)(MeS)CSH^+SbF_6^-$ crystallizes in the monoclinic space group $P2_1/n$ (No. 14) with a = 8.634(2) Å, b = 9.521(3)Å, c = 12.509(4) Å, β = 97.39 (2)° and 4 formula units per cell. The reaction of *O,S*-dimethyl dithiocarbonate with the super acidic systems XF/MF_5 (X = H, D; M = As, Sb) is discussed with regard to the formation of the salts, and Raman, IR, ^1H NMR, and ^{13}C NMR spectra of $(MeO)(MeS)CSX^+MF_6^-$ (M = As, Sb; X = H, D) are reported.

Introduction

In our investigations of mono-, di-, and trihydroxy carbenium ions and mercapto carbenium ions, we wanted to know how *O,S*-carbonic acids behave in super acidic media.[1−5] We had to fall back on derivatives of the acids, since the free monothio- and dithiocarbonic acids have not yet been isolated. Dialkylxanthogenic acids are well known in the literature, where the work of Gattow and co-workers in the area of the chalcogenocarbonic acids and sulfur chemistry should be mentioned.[6,7]

Nevertheless, until now, single-crystal X-ray investigations have only been conducted on metal xanthogenates, for example $Sn[S_2COMe]_2$ or $Cd[S_2COC_2H_5]_2$.[8,9] X-ray investigations of a positively charged OCS_2 skeleton are not known. Alkyl xanthogenates decompose in the presence of aqueous acids, since the alkyl xanthogenic acid intermediate is formed, which is not stable under normal conditions. To avoid decomposition in super acidic systems the use of dialkyl xanthogenates, which can be handled easily at ambient temperature, is recommended. As the crystal structures of the hydroxy dimethoxy carbenium cation and mercapto dimethylthio carbenium cation and Olah's NMR studies show, all methyl groups are located in *trans* positions.[4,5] The same configuration is expected for the cation formed by protonation of dimethyl xanthogenates. However, it remains to be determined whether a 1,3-methyl shift to form the $(MeS)_2COH^+$ cation (**I**), protonation to form an oxonium cation (**II**) or protonation to form a sulfonium cation (**III**) takes place (Figure 1). The X-ray structure and further investigations are of interest for this reason.

Results and Discussion

Formation of $(MeO)(MeS)CSH^+$ Salts

The best way to form the precursor (MeO)(MeS)CS for reaction in the super acidic system XF/MF_5 (M = As, Sb; X = H, D) is by the known reaction of NaOMe and CS_2 (Equation 1) followed by reaction with MeI[10] (Equation 2). Other reactions using alkali salts of dithiocarbonic acids such as $Na_2OC(S)S$ and methyl halides do not lead to uniform products (Equation 3).

$$NaOMe + CS_2 \rightarrow MeOC(S)SNa \quad (1)$$

$$NaS(S)COMe + MeI \rightarrow (MeO)(SMe)C{=}S \quad (2)$$

$$Na_2OC(S)S + 2MeI \rightarrow (MeO)(MeS)C{=}S + (MeS)_2C{=}O \quad (3)$$

Mercapto methoxy methylthio carbenium hexafluorometallate can be isolated from the protonation of (MeO)-(MeS)CS in the super acidic systems HF, $(DF)/MF_5$ (M = As, Sb) (Equation 4).

$$(MeO)(MeS)C{=}S + HF/MF_5 \rightarrow (MeO)(MeS)CSH^+MF_6^- \text{ (M= As, Sb)} \quad (4)$$

The resulting yellow salts, sensitive towards moisture and soluble in SO_2, decompose above −25 °C in the case of the arsenate and above −29 °C in the case of the antimonate into substances which were not further investigated. The salts can be stored without decomposition under inert conditions at −70 °C. Crystals of $(MeO)(MeS)CSH^+$-SbF_6^-suitable for X-ray diffraction studies could be isolated.

^1H and ^{13}C NMR Spectra of $(MeO)(MeS)CSH^+MF_6^-$ (M = As, Sb)

The ^1H NMR spectra at −60 °C of freshly prepared $(MeO)(MeS)CSH^+AsF_6^-$ and $(MeO)(MeS)CSH^+SbF_6^-$ in

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 2000 1434−1948/00/1010−2283 $ 17.50+.50/0

SO_2, with TMS as external standard, show singlets at δ = 4.98 and 4.90, respectively, for the protons of the methoxy groups and singlets at δ = 3.09 and 3.04, respectively, for the methylthio groups. The signals for the remaining mercapto groups are observed at δ = 6.99 and 7.2. In the ^{13}C NMR spectra, the signals at δ = 17.79 and 69.36 for the AsF_6^- species, and at δ = 17.68 and 68.79 for the SbF_6^- species, are assigned to the CH_3-S and CH_3-O groups and the singlets at δ = 221.9 and 221.4 are assigned to the carbon of the OCS_2 group. These results are comparable to the ^1H-NMR spectra of the $(HS)_3C^+$ and $(HO)(HS)_2C^+$ cations observed by G. A. Olah, as well as investigations of Barany et al. and our previous NMR investigations.[4,5,10,11]

Raman and IR Spectra of $(MeO)(MeS)CSX^+MF_6^-$ (M = As, Sb; X = H, D)

The infrared and Raman spectra of $(MeO)(MeS)CSD^+$ AsF_6^- are depicted in Figure 2. The observed frequencies of the $(MeO)(MeS)CSX^+$ salts of AsF_6^- and SbF_6^- (X = H, D) are summarized in Table 1. The assignments for the $(MeO)(MeS)CSX^+$ cation were made by comparison to the frequencies of $(MeS)_2CS$ and the $[MeOCS_2]^-$ anion.[4,5,12–14] On the assumption that the $(MeO)(MeS)CSX^+$ cation (X = H, D) has a C_1 point symmetry, 33 Raman- and IR-active fundamental vibrations are expected. The antisymmetric and symmetric stretching modes of the methyl groups are observed in the region 2933–3035 cm^{-1}.

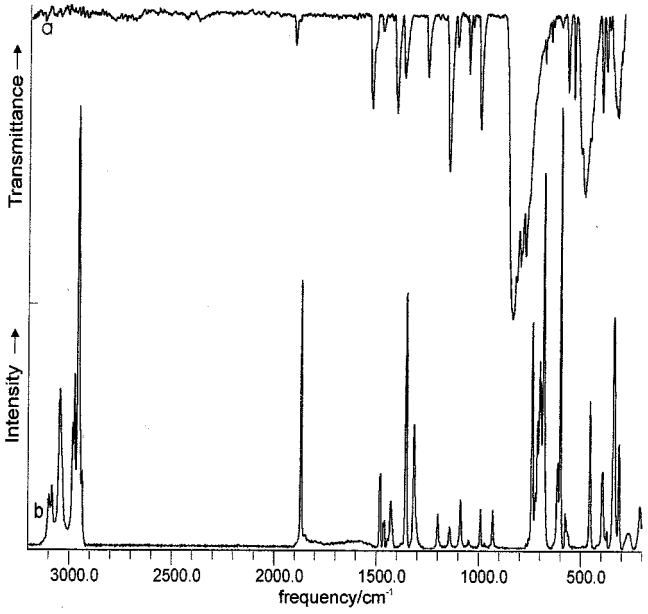

Figure 2. Infrared spectrum (trace A) and Raman spectrum (trace B) of $(MeO)(MeS)CSD^+AsF_6^-$

As with the precursor, different conformations arise in the solid, whereby the large number of valence modes can be explained.[15] The ν(SH) mode is observed at 2570 cm^{-1}, and the H/D shift to ca. 1860 cm^{-1} is almost in accordance with the expected shift.[16] The ν(SH) vibration mode in the AsF_6^- salt is shifted ca. 20 cm^{-1} to higher frequencies because the interaction between the anion and cation is weaker than in the SbF_6^- compound. This results in the loss of anion symmetry, which can be seen in the many anion vibration modes of the AsF_6^- salt. The deformation and rocking modes of the methyl groups are observed in their normal ranges of 1480–1300 cm^{-1} and 1000–880 cm^{-1}. A sharp Raman line and IR band is detected at 570 cm^{-1} and is assigned to the OCS_2 skeleton out of plane deformation mode.

The symmetric degradation is responsible for the additional As–F stretching modes. A complete assignment of the vibrational frequencies would require force field calculations.

Crystal Structure of $(CH_3O)(CH_3S)CSH^+SbF_6^-$

Mercapto methoxy methylthio carbenium hexafluoroantimonate crystallizes in the monoclinic space group $P2_1/n$ (No. 14) with four formula units per unit cell (Table 3).[17] The bond lengths and angles are listed in Table 2. Figure 3 shows the salt with atom labels, and the arrangement of $(MeO)(MeS)CSH^+SbF_6^-$ in the unit cell is depicted in Figure 4. For the data reduction, a semiempirical correction determined from ψ-scan data, and structure solution and refinement programs in the SHELXTL package and PARST were used.[18–21] The antimony and sulfur atoms were located by the Patterson method. All other atoms were determined by difference Fourier synthesis. A final refinement with anisotropic (except H atoms) thermal parameters gave a value of $R = 0.071$.

Both C(3)–S bond lengths of 1.702(7) Å and 1.692(7) Å and the C(3)–O(1) bond length of 1.293(9) Å lie in the range between typical single and double bonds.[22] If one takes the measured lengths as a basis, one comes to the conclusion that the positive charge is equally distributed over the central sp^2-hybridized C(3) carbon atom. The C(3)–O(1) bond length can be compared to the lengths of the CO bonds in the dihydroxy methyl carbenium cation and the $C(OH)_3^+$ cation. The C(3)–S(1) length, as well as the C(3)–S(2) bond length, is comparable with the corresponding lengths in the $(MeS)_2CSH^+$ cation.[1,2,4,5] The sum of angles around C(3) amounts to 360°, which indicates planar sp^2 hybridization. The torsion angles of the methyl groups, with a maximum deviation of 2.5°, indicate that they are not located in the OCS_2 plane.

The S(1)···F(4) distance of 2.903 Å indicates an S(1)–H(1)···F(4) hydrogen bond with an angle of 155°. A further donor–acceptor reciprocal effect exists between S(1) and F(2a) with a length of 2.903 Å, forming an eight-membered ring in a chair conformation (Figure 5). There are additional contacts but because of their longer interatomic distances, they are not considered. The ideal octahedron structure of the anion is not distorted, with almost ideal angles of 90° and lengths in the range of 1.863(5)–1.879(5) Å.

Table 1. Raman, IR frequencies, and possible assignment of $(CH_3O)(CH_3S)CSX^+MF_6^-$ (X = H, D; M = As, Sb)

$(CH_3O)(CH_3S)CSX^+AsF_6^-$				$(CH_3O)(CH_3S)CSX^+SbF_6^-$

Conclusion

The protonation of (MeO)(MeS)CS succeeds in super acidic systems, forming the expected carbenium ion. A clear statement about the structure of the cation can be made due to X-ray structure analysis. The Raman spectra of the salts show that in the solid state several conformations are present, which makes assignment of the spectra more difficult. The NMR spectra in SO_2 were assigned, and only one conformation was observed. If the solvent is carefully removed, crystals with a single conformation, in the all-*trans* position, are formed, as was shown by the X-ray diffraction study.

Experimental Section

All synthetic work and sample handling was conducted by standard Schlenk techniques and a standard vacuum line (stainless steel or glass). SbF_5 (Merck) was fractionally distilled. Drying of HF and SO_2 were carried out by literature methods. Reactions in HF/DF were carried out in a KEL-F reactor with a KEL-F valve. − Infrared spectra were recorded with a Bruker IFS 113V spectrophotometer. Spectra of dry powders were obtained on a CsI plate in a cooled IR cell. − The Raman spectra were recorded with a Yobin von T64000 (ISA) using a CCD detector (EEV CCD15-11) and an Ar^+ laser tube (514.5 nm) from Spectra Physics. The spectra were recorded in a glass cell cooled with liquid nitrogen. − The NMR spectra were recorded with a Bruker DPX 300 spectrometer with TMS as external standard. − Single crystals were placed in Lindemann capillaries in a cooled stream of dry nitrogen, and an X-ray diffraction study was carried out at −100 °C using an Enraf-Nonius Mach3 automated diffractometer.

Preparation of (MeO)(MeS)CS: *O*,*S*-Dimethyl dithiocarbonate was prepared by reaction of NaOMe (20 g, 0.37 mol) with excess dry CS_2 (35 g, 0.46 mol) in dry diethyl ether solvent. After filtration and drying under dynamic vacuum at room temperature the residue was treated with excess MeI (55 g, 0.38 mol) at 25 °C.[10] After 2 h, the excess MeI was removed under reduced pressure at −10 °C and the remaining yellow liquid distilled at 10 °C under dynamic vacuum in 89% yield based on NaOMe.

Preparation of (MeO)(MeS)CSX$^+$MF$_6^-$ (X = H, D; M = As, Sb): ***Caution! Avoid contact with these compounds and note that hydrolysis of AsF$_6^-$ salts and SbF$_6^-$ salts forms HF, which burns the skin and causes irreparable damage. Safety precautions should be taken when using and handling these materials!*** In a typical experiment, *O*,*S*-dimethyl dithiocarbonate (0.24 g, 2 mmol) and anhydrous XF (X= H, D) (4 g, 0.2 mol) were combined at −196° C and placed in a KEL-F reactor. Arsenic pentafluoride (0.34 g, 2 mmol) or antimony pentafluoride (0.44 g, 2 mmol) was added to this mixture at −196 °C and the contents of the reactor were warmed to −78 °C. After 10 min, slow removal of all volatile material under vacuum at −78 °C gave a slightly yellow solid residue that was identified as (MeO)(MeS)CSX$^+$MF$_6^-$ (X= H, D; M= As, Sb). The remaining (MeO)(MeS)CSH$^+$SbF$_6^-$ contained crystals suitable for X-ray diffraction studies. The salts can be stored under inert conditions at −70 °C without decomposition.

Structural Investigations of Tetra- and Octasubstituted (Phthalocyanine)ruthenium Complexes by EXAFS Spectroscopy

Achim Weber,[a] Teja S. Ertel,[a] Ulrich Reinöhl,[a] Helmut Bertagnolli,*[a] Meret Leuze,[b] Michael Hees,[b] and Michael Hanack*[b]

Keywords: EXAFS spectroscopy / Ruthenium / Phthalocyanines / Structure elucidation

To obtain more structural information of (phthalocyaninato)-ruthenium compounds, an EXAFS investigation was carried out on amorphous tBu$_4$PcRu (**1**), tBu$_4$PcRu(3-Clpy)$_2$ (**2**), PcRu(3-Fpy)$_2$ (**3**) and (C$_5$H$_{11}$O)$_8$PcRu(3-Clpy)$_2$ (**4**). Structural models for the four compounds are deduced from the atomic distances determined around the metal centre. A dimeric structure was found for **1**, while bisaxial arrangement of the ligands was shown for **2, 3** and **4**, and the structural parameters were also determined.

Introduction

In recent years (phthalocyanine)ruthenium complexes have been investigated with particular regard to their preparation, chemistry, and structure.[1−3] Some years ago, we reported the first synthesis of pure (phthalocyananinato)ruthenium(II) (PcRu) by thermal decomposition of PcRu(DMSO)$_2$·2DMSO.[4] Later, we developed a convenient method for obtaining PcRu from the corresponding bis-(isoquinoline) complex PcRu(iqnl)$_2$, which decomposes at 250 °C with formation of pure PcRu.[5]

Due to the insolubility of PcRu − like most other (phthalocyanine)metal complexes − in common organic solvents, bulky (e.g. *tert*-butyl) or long-chain (e.g. alkyl or alkyloxy) groups are introduced onto the periphery of the Pc macrocycles to improve their solubility. The *tert*-butyl group is particularly suitable for increasing the solubility of phthalocyanines in organic solvents. Tetrasubstituted phthalocyanines usually exhibit higher solubilities than the octasubstituted analogues. The two principal reasons are that the isomeric mixture of four tetrasubstituted phthalocyanines leads to a lower degree of order in the solid state compared to the symmetrically octasubstituted phthalocyanines, and the higher dipole moment of the tetrasubstituted Pcs caused by the unsymmetrical arrangement of the substituents on the periphery of the macrocycle.[2] [Tetrakis(*tert*-butyl)phthalocyaninato]ruthenium(II) tBu$_4$PcRu (**1**),[6a] bis(3-chloropyridine)[tetrakis(*tert*-butyl)-phthalocyaninato]ruthenium(II) tBu$_4$PcRu(3-Clpy)$_2$ (**2**)[6a] (all mixtures of structural isomers), and several (octaalkyloxyphthalocyaninato)ruthenium compounds[5,6b,6c] are examples of soluble (phthalocyanine)ruthenium complexes. The thermal decomposition of the peripherally substituted R$_m$PcRu(3-Clpy)$_2$ provided the basis for the preparation of novel bridged [R$_m$PcRu(L)]$_n$ oligomers with L = pyz (pyrazine), dib (1,4-diisocyanobenzene), tz (*s*-tetrazine), and others as a new class of intrinsic semiconductors.[2,6b]

The crucial problem in the exact structural determination of (phthalocyanine)ruthenium compounds (PcRu) is that most of the compounds can only be prepared as amorphous or microcrystalline samples. In a previous paper we reported EXAFS studies on dimeric PcRu.[7] Our results are consistent with a dimeric structure having a short Ru−Ru contact of 2.41 Å. This agrees with LAXS investigations on the same system.[3] The existence of a Ru−Ru double bond is also confirmed by measurement of the magnetic moment, which amounts to 2.54 μ_B at room temperature.[7]

Now the question arises as to whether the formation of dimers is restricted to PcRu or whether it is a common phenomenon of (phthalocyanine)ruthenium compounds. There are some indications for the latter assumption, for example the magnetic moment of tBu$_4$PcRu has a value which is similar to PcRu.[6a] Temperature-dependent measurements of the magnetic susceptibility show **1** to exhibit paramagnetic behaviour with strong coupling. The magnetic moment increases from 0.63 μ_B (T = 20 K) to 1.68 μ_B (T = 300 K), i.e. it approximates asymptotically the spin-only value of one unpaired electron (1.73 μ_B). Compound **1** therefore has only one spin per ruthenium(II) ion, although for a d^6 transition metal ion in a square-planar ligand field two unpaired electrons are expected. This implies that **1** exists as a dimeric structure with a ruthenium−ruthenium double bond. For homometallic (porphyrin)metal dimers a molecular orbital diagram was developed[8] which proposes that only d electrons participate in metal−metal bonding. In addition, the reasonable assumption that the dimers have D_{4h} (eclipsed) or D_{4d} (staggered) symmetry was made. The σ bonds to the porphyrin nitrogen atoms involve the metal $d_{x^2-y^2}$ levels, and the high-energy σ* orbitals may be ig-

nored for a metal-metal bonding.[8] The remaining d orbitals (d_{xz}, d_{yz}, d_{z^2}, and d_{xy}) are available for the metal−metal bonding along the *z* axis. Dimeric (porphyrin)- as well as (phthalocyanine)ruthenium(II) complexes possess 12 d-electrons and consequently the resulting electronic configuration, $\sigma^2\pi^4\delta^{nb4}\pi^{*2}$, produces a formal Ru−Ru double bond with two unpaired electrons (one per macrocycle). On the other hand one has to take into consideration that the four *tert*-butyl groups in **1** could cause steric hindrance if a dimeric structure is formed as in PcRu.

In order to answer these questions we performed EXAFS measurements on *t*Bu$_4$PcRu (**1**). In addition we carried out EXAFS measurements on *t*Bu$_4$PcRu(3-Clpy)$_2$ (**2**), PcRu(3-Fpy)$_2$ (**3**) and $(C_5H_{11}O)_8$PcRu(3-Clpy)$_2$ (**4**), for which crystal structures are not yet available, to obtain some structural data of these bissubstituted PcRu complexes. Furthermore, we intended to prove whether the different ligands are arranged in a strictly bisaxial disposition, and whether the different ligands (3-chloropyridine in **2** and **4**, 3-fluoropyridine in **3**) or the different phthalocyanine macrocycles [unsubstituted (**3**), 2,3-tetra- (**2**) and 1,4-octa-substituted (**4**) (see Figure 4)] have any structural effects on the local environment around the ruthenium centre.

Results and Discussion

[Tetrakis(*tert*-butyl)phthalocyaninato]ruthenium(II) (1)

As can be seen in the Fourier transform (see Figure 1b), there are several visible shells. In fitting the EXAFS function, we must describe it by at least six shells. Fitting the data by six shells seems to be many, but is not for two reasons. First, the coordination numbers were fixed to the known values of the phthalocyanine molecule. Second, the four shells of the phthalocyanine macrocycle marked with A in Table 1 (see Figure 2) can only be independently fitted such that the determined distances lead to meaningful interatomic distances in the macrocycle itself. Taking these considerations into account, the number of parameters decreases from 12 to 9 and are clearly less than the number of independent data points (22).[9] We successfully applied this data evaluation in previous work on (phthalocyaninato)ruthenium.[7]

Without any knowledge of the structure, one would expect that the ruthenium atom is located in the plane of the phthalocyanine ring. A planar arrangement of the atoms should give rise to a considerable contribution of multiple scattering to the EXAFS spectrum. Defining the multiple scattering unit as shown in Figure 3, we found in several calculations that for this geometrical arrangement the relevant maximum order of multiple scattering is three. But in all fits we could not describe the experimental spectrum satisfactorily. In particular, the characteristic features of the experimental $k^3\cdot\chi(k)$ function between 4.0 and 9.0 Å^{-1} could not be reproduced (see Figure 1c).

Since only single scattering contributes to the EXAFS function, we are forced to assume that either the ruthenium atom is not positioned in the plane of the ring, or the ring

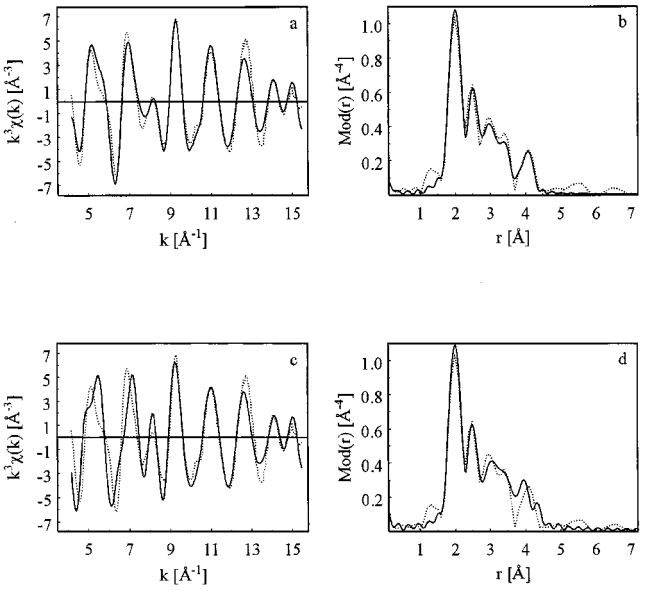

Figure 1. Experimental (dotted line) and calculated (solid line) $k^3\cdot\chi(k)$ function (a,c) (k range: 3.50−15.30 Å^{-1}) and their Fourier transforms (b,d) of *t*Bu$_4$PcRu (**1**) [see Table 1 for fitting parameters, considering single scattering only (a,b), including triple scattering paths (c,d)]

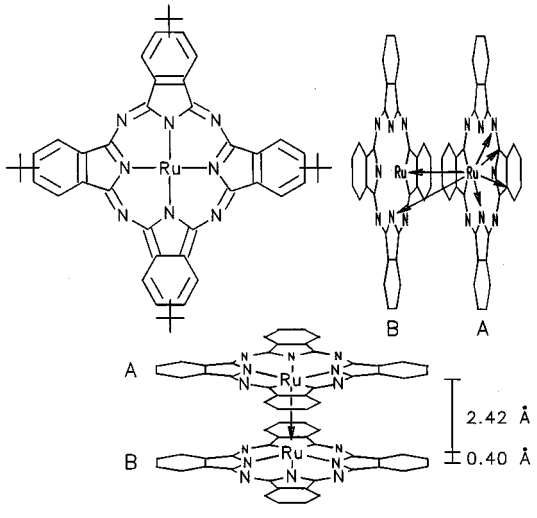

Figure 2. Structural model of *t*Bu$_4$PcRu (**1**) including the assignment of the determined distances to the corresponding atoms (see Table 1); for reasons of clarity, not all nitrogen atoms and *tert*-butyl groups are shown

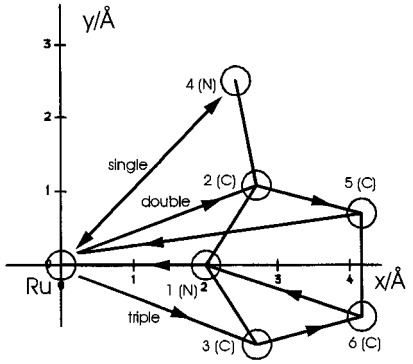

Figure 3. Defined multiple scattering unit for tBu$_4$PcRu (**1**) illustrating single, double and triple scattering paths

itself is not planar, or both. In order to check the dependence of the amount of multiple scattering from the out-of-plane displacement of the ruthenium atom in an idealized planar macrocycle we performed systematic calculations. We found the rather astonishing result that the amount of multiple scattering does not depend very strongly on the out-of-plane position of the ruthenium atom. Only if the displacement amounts to 1.75 Å does the contribution of the multiple scattering almost vanish. Since such a large displacement of the ruthenium atom is quite unlikely, we have to conclude that the nonplanarity of the macrocycle is the main cause of the absence of any multiple scattering and the possible displacement of the ruthenium atom − if existing − plays only a minor role. From the determined distances it is not possible to make any structural statements concerning the nonplanarity of the macrocycle.

Besides the four shells of the phthalocyanine macrocycle already discussed, a significant improvement in the fit index can be obtained if we assume a Ru−Ru distance of 2.42 Å in the simulation of the spectrum. Additionally, we found four nitrogen backscatterers at 3.38 Å. These distances can be assigned to the corresponding atoms in the macrocycle B (see Figure 2 and Table 1). In the context of the above discussion regarding the absence of any multiple scattering and the possible explanation for this, the presence of a Ru−Ru interaction at a distance of 2.42 Å is surely an indication that besides the nonplanarity of the macrocycle, an out-of-plane displacement of the ruthenium atom is also to a small degree responsible for the absence of any multiple scattering. Without the displacement, it is probably impossible to get the two ruthenium atoms this close. If we make the simplified assumption that the four nitrogen atoms of the phthalocyanine macrocycle forming the first coordination shell lie in a plane, the displacement of the ruthenium atom can be appraised in the following way. From crystallographic data[10,11] we know that the metal−nitrogen distance of planar systems, e.g. in phthalocyaninatomanganese tetracyanoethenide, is typically 1.97±0.3 Å. As an N−N diagonal distance of 3.94±0.6 Å follows from this value, we can calculate that the ruthenium atom is located 0.4±0.2 Å out of the plane of the macrocycle (see Figure 2). We note that this triangulation depends critically on both the measured Ru−N distance and the assumed N−center distance. It is given here only as a rough estimation of the amount of the possible displacement. Our data are also compatible with an in-plane geometry for **1**.

[Bis(3-chloropyridine)[tetrakis(*tert*-butyl)phthalocyaninato]-ruthenium(II) (2)

For a similar quality simulation of the EXAFS function of compound **2** (see Figure 4), at least six shells are necessary (see Table 2 and Figure 5a and 5b). These are the four shells of the phthalocyanine macrocycle and two nitrogen backscatterers at 2.53 Å, which can only be assigned to the ligand 3-chloropyridine, because no ring atoms are located within this distance. Furthermore, there are four carbon backscatterers at a distance of 3.43 Å, which also belong to 3-chloropyridine. As can be seen in Figure 5c and 5d, the four carbon backscatterers at 3.43 Å are necessary for a complete description of the experimental EXAFS function.

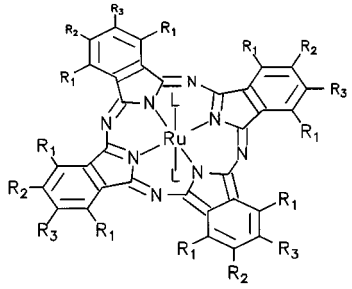

Figure 4. Schematic structural model of R$_n$PcRu(L)$_2$ (**2** for R$_2$ or R$_3$ = tBu, R$_1$ = H and L = 3-chloropyridine, **3** for R$_1$ = R$_2$ = R$_3$ = H and L = 3-fluoropyridine, **4** for R$_2$ = R$_3$ = H, R$_1$ = R$_4$ = C$_5$H$_{11}$O and L = 3-chloropyridine)

Ru−N	(A)	3.31±0.03	4.0	0.053±0.009		
Ru−C	(A)	4.00±0.04	8.0	0.075±0.010		
Ru−N	(L)	2.53±0.03	2.0	0.086±0.011		
Ru−C	(L)	3.43±0.03	4.0	0.048±0.009		

[a] Absorber−backscatterer distance r, coordination number N and Debye-Waller factor σ with their calculated standard deviation. The letters in parentheses refer to the model in Figure 4 and indicate the molecule where the backscattering atom is located.

With the distances to the ligand determined as Ru−N (2.53 Å) and Ru−C (3.43 Å), an N−C distance in 3-chloropyridine of 1.38 Å can be calculated (see Figure 6), in good agreement with the expected value of 1.34 Å for the intramolecular C−N distance in pyridine.[12] In one of our previous works[7] we found an Ru−Ru distance at 4.14 Å in PcRu(nBuNH$_2$)$_2$. No Ru−Ru distance in this range could be found in **2**. These results led us to the conclusion that the 3-chloropyridine molecule is vertically located below and above the phthalocyanine macrocycle and forms an octahedral arrangement around the ruthenium centre (see Figure 4 and Figure 6) together with the four nitrogen

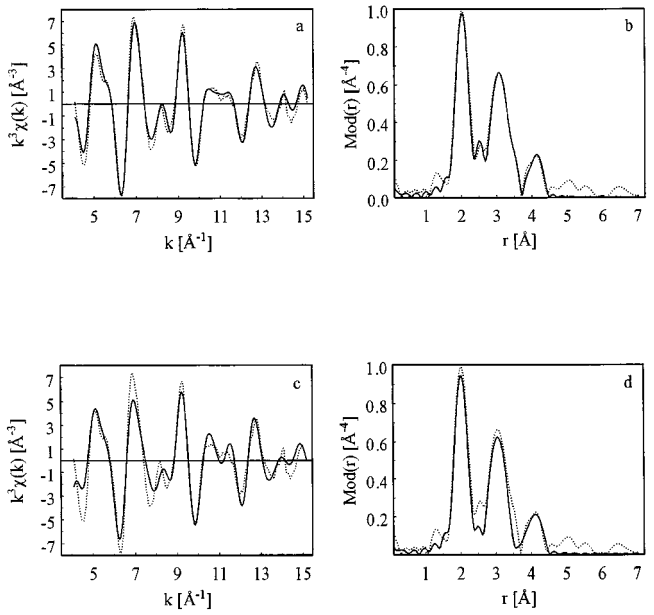

Figure 5. Experimental (dotted line) and calculated (solid line) $k^3 \cdot \chi(k)$ function (a,c) (k range: 3.45−15.15 Å^{-1}) and their Fourier transforms (b,d) of tBu$_4$PcRu(3-Clpy)$_2$ (**2**) [see Table 2 for fitting parameters, six shells model (a,b) and five shells model (c,d), respectively]

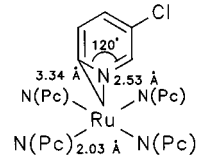

Figure 6. A detailed view from Figure 4; the ligand, the ruthenium centre and the first nitrogen backscatterers are shown

atoms of the phthalocyanine macrocycle. The axial coordination of the 3-chloropyridine ligand prevents the formation of a dimeric phthalocyanine unit coupled over an Ru−Ru double bond. The absence of any multiple scattering in **2** is surely only a result of the nonplanarity of the macrocycle and an out-of-plane displacement is very unlikely. This is because this displacement would lead to a distorted octahedral geometry, and the fact that in **2** no short Ru−Ru interaction is detectable as in compound **1** and PcRu.[7]

[Bis(3-fluoropyridine)phthalocyaninato]ruthenium(II) (3)

As in **2**, six shells are required to describe the EXAFS function (see Table 3 and Figure 7). Again, these are the four shells of the phthalocyanine macrocycle and, additionally, two nitrogen backscatterers at 2.57 Å, which only can be assigned to the ligand 3-fluoropyridine, because no ring atoms are located within this range. Furthermore, there are four carbon backscatterers at a distance of 3.41 Å, also from 3-fluoropyridine. In comparison to **2**, the distance of the ruthenium absorber and the nitrogen backscatterers of the ligand are not significantly different from each other.

Table 3. EXAFS-determined structural data of **3**

[Bis(3-chloropyridine)octakis(pentyloxy)phthalocyaninato]-ruthenium(II) (4)

As with compounds **2** and **3**, at least six shells are necessary to describe the EXAFS function (see Table 4 and Figure 8). As the structure and the determined structural para-

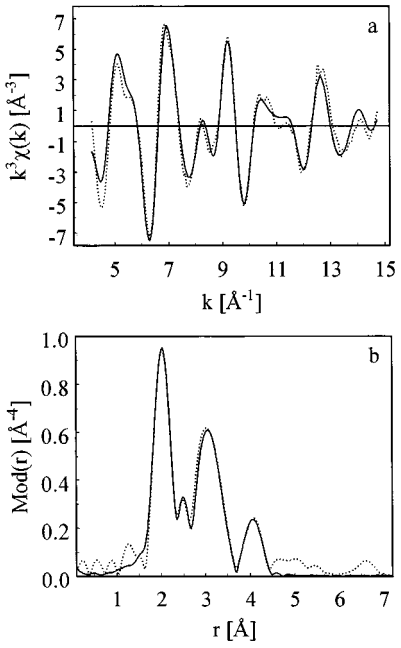

Figure 8. Experimental (dotted line) and calculated (solid line) $k^3 \cdot \chi(k)$ function (a) (k range: 3.50−14.80 Å^{-1}) and their Fourier transforms (b) of $(C_5H_{11}O)_8$PcRu(3-Clpy)$_2$ (**4**) (see Table 4 for fitting parameters)

meters of the PcRu complexes **2**, **3** and **4** are very similar, we refrain from further discussion of the structure of compound **4**.

Conclusion

It was possible to deduce structural models for tBu$_4$PcRu (**1**), tBu$_4$PcRu(3-Clpy)$_2$ (**2**), PcRu(3-Fpy)$_2$ (**3**) and $(C_5H_{11}O)_8$PcRu(3-Clpy)$_2$ (**4**) by EXAFS spectroscopy. The structure of tBu$_4$PcRu (**1**) is very similar to that of PcRu,[7] which forms a dimer. However, one has to take into consideration the four *tert*-butyl groups on both of the Pc rings, which could lead to severe steric hindrance in a dimeric structure of **1**. According to model considerations, the interaction between two *tert*-butyl groups, even in an eclipsed conformation, is not very high, e.g. if both rings adopt the C_{4h} structure, because the distance of the two coplanar Pc rings in **1** is 3.2 Å. This is also the case for the three additional structural isomers of tBu$_4$PcRu (**1**), namely the D_{2h}, C_{2v}, and the C_s isomers.[13] Less steric interaction of the *tert*-butyl groups will occur if the dimer (tBu$_4$PcRu)$_2$ is formed from two different structural isomers of tBu$_4$PcRu, e.g. if it is a mixture of the C_{4h} and the D_{2h} isomer. The Ru−Ru-distance in **1** and in the unsubstituted PcRu are quite similar.[7] This also points to a low steric interaction between the *tert*-butyl groups on both Pc rings in **1**. A dimeric structure for **1** is therefore quite feasible. Attempts to calculate the interactions between the *tert*-butyl groups by using the standard HyperChem program was not successful due to the large number of atoms in the dimer **1**.

Sixfold coordination of the ruthenium atom occurs in compounds in **2**, **3** and **4**. The ligands are axially located in an octahedral arrangement on both sides of the phthalocyanine macrocycle. The differences in the environment around the ruthenium centre between the PcRu with the 3-chloropyridine ligands and the 3-fluoropyridine ligands and the unsubstituted, tetra- and octa-substituted macrocycles are not very large, but it should be noted that the distances of the ruthenium atom to the nitrogen backscatterers of the pyridine ligands become smaller, and the distances of the ruthenium atom to the second nitrogen backscatterers of the phthalocyanine macrocycle increase in the sequence **3** > **4** > **2**. This could be interpreted as being due to non-planar Pc rings in these compounds.

Experimental Section

General Remarks: ^{1}H, ^{13}C NMR: Bruker AC 250 (^{1}H: 250.133 MHz, ^{13}C: 62.902 MHz). − UV/Vis: Shimadzu UV−365. − FT IR: Bruker IFS 48. − Elemental analyses: Carlo Erba Elemental Analyser 1104, 1106. − MS: Varian Mat 711.

[Tetrakis(*tert*-butyl)phthalocyaninato]ruthenium(II) (tBu$_4$PcRu, 1): [Tetrakis(*tert*-butyl)phthalocyaninato]ruthenium(II) was prepared by thermal decomposition of bis(3-chloropyridine)[tetrakis(*tert*-butyl)phthalocyaninato]ruthenium(II) (**2**).[6a] − $C_{48}H_{48}N_8Ru$ (838.03): calcd. C 68.71, H 5.77, N 13.36; found C 68.00, H 5.99, N 13.01.

Bis(3-chloropyridine)[tetrakis(*tert*-butyl)phthalocyaninato]-ruthenium(II) (tBu$_4$PcRu(3-Clpy)$_2$, 2): Bis(3-chloropyridine)[tetrakis(*tert*-butyl)phthalocyaninato]ruthenium(II) (**2**) was prepared from 4-*tert*-butylphthalonitrile, $RuCl_3 \cdot 3H_2O$ and 3-chloropyridine according to the method described.[6a] − $C_{58}H_{56}Cl_2N_{10}Ru$ (1065.13): calcd. C 65.39, H 5.30, Cl 6.57, N 13.16; found C 65.39, H 6.06, Cl 6.57, N 13.19.

Phthalocyaninatoruthenium PcRu (**5**) was prepared according to the method described earlier.[4,5]

Bis(3-fluoropyridine)phthalocyaninatoruthenium (PcRu(3-Fpy)$_2$, 3): A mixture of (phthalocyaninato)ruthenium (**5**) (100 mg, 0.16 mmol), 3-fluoropyridine (31.5 mg, 0.32 mmol) and chloroform (10 mL) was heated at reflux for 6 h. The solution was poured into methanol/water (3:1) and the precipitate was centrifuged and dried. Purification was carried out by column chromatography (silica gel, chloroform, R_f = 0.65). After drying (50 °C, 0.01 Torr), pure **3** was obtained; yield 79 mg (61%). − $C_{42}H_{24}F_2N_{10}Ru$ (808.12): calcd. C 62.37, H 2.99, N 17.33; found C 62.51, H 3.02, N 16.97. − ^{1}H NMR (250 MHz, $CDCl_3$): δ = 2.21 (m, 2 H, 3-Clpy), 2.36 (m, 2 H, 3-Clpy), 5.24 (m, 2 H, 3-Clpy), 5.83 (m, 2 H, 3-Clpy), 7.97 (m, 8 H, Pc), 9.22 (m, 8 H, Pc). − IR (KBr): $\tilde{\nu}$ = 3111 cm^{-1} (vw), 3057 (vw), 2924 (vw), 1607 (w), 1582 (m), 1489 (vs), 1433 (m), 1414 (m), 1325 (m), 1288 (m), 1242 (m), 1238 (m), 1169 (vs), 1124 (vs), 1065 (m), 845 (m), 804 (m), 773 (m), 690 (w). − UV/Vis ($CHCl_3$): λ_{max} = 627 nm (Q), 573 sh, 402 sh, 369 sh, 312 (B).

Bis(3-chloropyridine)[1,4,8,11,15,18,22,25-octakis(pentyloxy)phthalocyaninato]ruthenium(II) (4): A mixture of 3,6-dipentyloxyphthalonitrile (3.0 g, 10 mmol), $RuCl_3 \cdot 3H_2O$ (650 mg, 2.5 mmol), 3-chloropyridine (570 mg, 5 mmol) and DBU (1 mL) in 2-ethoxyethanol (30 mL) was heated at reflux for 7 d under nitrogen, while monitoring the reaction by TLC (SiO_2/$CHCl_3$, R_f = 0.8). The solution was poured into methanol/water (3:1) and the precipitate was centrifuged and dried. The dry precipitate was subsequently subjected to Soxhlet extraction with methanol for 10 h.

Purification was carried out by column chromatography (silica gel, chloroform). After drying (60 °C, 0.01 Torr, 6 h) pure **4** was obtained; yield 485 mg (12.7%), green powder. − $C_{82}H_{104}Cl_2N_{10}O_8Ru$ (1529.77): calcd. C 64.37, H 6.86, Cl 4.58, N 9.16; found C 64.04, H 6.88, Cl 4.60, N 9.13. − ^{1}H NMR (250 MHz, $CDCl_3$): δ = 1.02 (t, J = 6.8 Hz, 24 H, CH_3), 1.56 (m, 32 H, 2 CH_2), 2.30 (m, 16 H, CH_2), 2.50 (m, 2 H, 3-Clpy), 2.51 (m, 2 H, 3-Clpy), 4.84 (t, J = 6.4 Hz 16 H, CH_2), 5.22 (m, 2 H, 3-Clpy), 6.10 (m, 2 H, 3-Clpy), 7.29 (s, 8 H, Pc). − ^{13}C NMR (250 MHz, $CDCl_3$): δ = 13.9 (CH_3), 22.7 (CH_2), 28.3 (CH_2), 29.3 (CH_2), 71.5 (−O−CH_2), 115.7 (Pc), 122.5 (3-Clpy), 129.6 (Pc), 130.5 (3-Clpy), 133.0 (3-Clpy), 143.3 (Pc), 148.5 (3-Clpy), 148.9 (3-Clpy), 150.4 (Pc). − IR (KBr): $\tilde{\nu}$ = 3097 cm^{-1} (vw), 3033 (vw), 2954 (s), 2927 (s), 1597 (m), 1498 (vs), 1465 (m), 1308 (m), 1283 (s), 1261 (s), 1219 (vs), 1111 (s), 1062 (s), 972 (w). − UV/Vis ($CHCl_3$): λ_{max} = 699 nm (Q), 630, 405, 312 (B). − MS (FAB, NBA); *m/z*: 1529.9 [M^+], 1303.8 [$M^+ - 2 \times$ 3-Clpy].

The EXAFS measurements of tBu$_4$PcRu (**1**), tBu$_4$PcRu(3-Clpy)$_2$ (**2**), PcRu(3-Fpy)$_2$ (**3**) and ($C_5H_{11}O)_8$PcRu(3-Clpy)$_2$ (**4**) were performed at the ruthenium K edge at 22118.0 eV at the beamline A1 at the *Hamburger Synchrotronstrahlungslabor* (HASYLAB) at DESY, Hamburg, at 25 °C, with an Si<311> double crystal monochromator under ambient conditions (5.4 GeV, beam current 100 mA). The tilt of the second monochromator crystal was set to 30% harmonic rejection. Energy resolution was estimated to be about 10 eV at the ruthenium K edge. Data were collected in transmission mode with ion chambers, which were continuously flushed with argon. Energy calibration was monitored with a 20-μm thick ruthenium metal foil. All measurements were performed under an inert gas. The samples were embedded in a polyethylene matrix, of which the thickness was adjusted to an absorption jump of Δμ = 1.5. Data were analysed with a program package specially developed for the analysis of amorphous samples.[14] The program AUTOBK of the University of Washington[15] was used for background removal and the program EXCURV92[16] for the evaluation of the XAFS functions. First, background absorption was removed from the experimental absorption spectrum by subtraction of a Victoreen-type polynomial. Then the background-subtracted spectrum was convoluted with a series of increasingly broader Gauss functions and the common intersection point of the convoluted spectra was taken as energy E_0.[14] To determine the smooth part of the spectrum, corrected for pre-edge absorption, a piecewise polynomial was used. It was adjusted in such a way that the low-R components of the resulting Fourier transform were minimal. After division of the background-subtracted spectrum by its smooth part, the photon energy was converted into a photoelectron wave number scale. The resulting EXAFS function was weighted with k^3. Data analysis in k space was performed according to the curved wave multiple scattering formalism of the program EXCURV92.[16] The mean free path of the scattered electrons was calculated from the imaginary part of the potential (VPI was set to −4.00), the amplitude reduction factor AFAC was fixed at 0.8 and an overall energy shift ΔE_0 was assumed.

Acknowledgments

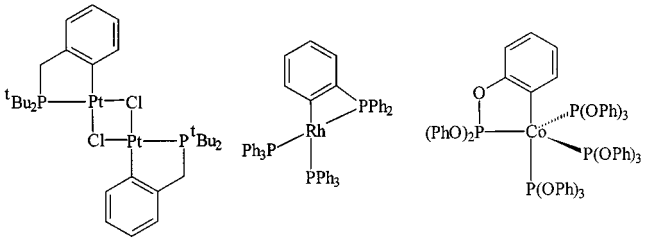
ortho-Metalation of Triarylphosphane at Cobalt and Template Synthesis of Chelating 2-(Diarylphosphanyl)aroyl Ligands



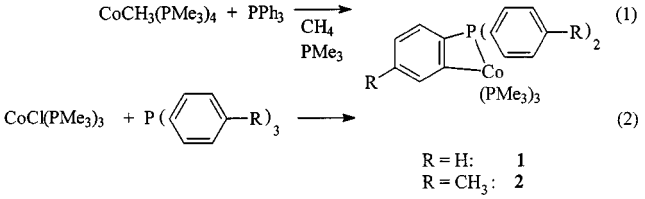
Hans-Friedrich Klein,*[a] Sven Schneider,[a] Mengzhen He,[a] Ulrich Floerke,[b] and Hans-Juergen Haupt[b]

Keywords: Metalations / Insertion reactions / Hydrogenations / Cobalt / Structure elucidation

Elimination of methane from thermally labile $CoMe(PPh_3)(PMe_3)_3$ generates *ortho*-metalated $Co(2\text{-}Ph_2PC_6H_4)(PMe_3)_3$ (**1**). Addition of dihydrogen causes ring-opening which is followed by a ligand dismutation reaction giving $CoH(PMe_3)_4$ and $CoH(PMe_3)_2(PPh_3)_2$. The system does not catalytically hydrogenate olefins. CO insertion into the Co–C bond of **1** results in ring expansion and constitutes a template synthesis of the anionic 2-phosphanylbenzoyl chelate ligand as shown in the molecular structure of $Co(2\text{-}Ph_2PC_6H_4CO)(CO)(PMe_3)_2$ (**3**). Oxidative addition of iodomethane transforms **1** into diamagnetic $CoMeI(2\text{-}Ph_2PC_6H_4)(PMe_3)_2$ (**7**), while benzoyl chloride oxidizes **1** to paramagnetic $CoCl(2\text{-}Ph_2PC_6H_4)(PMe_3)_2$ (**8**). The preservation of the four-membered metallacycle in three successive oxidation states is supported by single-crystal X-ray analyses of **1**, **7**, and **8**.

Introduction

C−H activation of hydrocarbons,[1] particularly that involving aromatic compounds, and cyclometalation[2] of arylphosphanes are important areas of research with respect to homogeneous catalysis. *ortho*-Metalations of triarylphosphanes, e.g. the metalation of benzylphosphanes (**A**) or phenyl phosphites (**C**), represent some early examples.



A B C

When coordinated to platinum metals, e.g. as in Keim's rhodium complex **B**,[3a] triphenylphosphane has in many cases been shown to form four-membered metallacycles.[3] With iron, cobalt, or nickel, only a few examples have been reported. While $Fe(C_2H_4)(Ph_2PCH_2CH_2PPh_2)_2$ is *ortho*-metalated only under irradiation,[4] $CoH(N_2)(PPh_3)_3$ has been shown by several groups to undergo H/D exchange in all *ortho* positions.[5] In solution, $CoCH_3(PPh_3)_3$ spontaneously eliminates methane. No *ortho*-metalated species have been isolated from these systems. Only in the presence of styrene was an *ortho*-metalated species generated, which has still to be fully characterized.[6] Although no *ortho*-metalation through C−H activation has been described for alkyl- or hydridonickel(II) or -nickel(0) complexes with phenylphosphanes, the reaction of (pentachlorophenyl)diphenylphosphane with nickel(0) affords a metallacyclic complex,[7] which undergoes ring-opening through substitution of its P-donor function with triphenylphosphane. Although H_2 smoothly hydrogenates the rhodium(I) complex **B** under ring-opening, retention of the four-membered metallacycle was observed in both oxidative addition reactions and ring-expansion reactions with CO[8] and diphenylacetylene.[9]

With trimethylphosphanes as supporting ligands, we have observed quite similar properties and reactivities in the cobalt(I) system and report here on the syntheses, reactions, and structural investigations of such complexes.

Results and Discussion

When combined with triphenylphosphane in tetrahydrofuran, $CoCH_3(PMe_3)_4$ eliminates methane to form the metallacyclic complex **1** according to Equation (1). Addition of triphenylphosphane to $CoCl(PMe_3)_3$, followed by methyllithium (Equation 2), affords **1** in essentially quantitative yield.

Using tris(4-methylphenyl)phosphane in place of triphenylphosphane in a synthesis according to Equation 2, the analogous complex **2** is obtained in 95% yield. Both complexes form large quadrangular crystals with black faces,

which appear dark red when illuminated. In dry air, solid **1** and **2** remain unchanged for ca. two hours, although their solutions are decomposed within a few minutes if air is admitted.

Their infrared spectra display the characteristic *ortho*-metalation bands at $\tilde{\nu}$ = 722 cm^{-1} (**1**) and 726 cm^{-1} (**2**), which correspond to out-of-plane CH vibrations.[3c] The ^{31}P NMR spectra (−40 °C) feature an AM_2X pattern of three signals with J(AM) = 49 Hz (**1**) and 48 Hz (**2**), which is consistent with a trigonal-bipyramidal arrangement of donor atoms with one axial (A) and two equatorial (M) trimethylphosphanes. The equatorial chelate P nucleus X displays a high-field signal characteristic of four-membered metallacycles[10] with J(AX) = 70 Hz and J(MX) = 87 Hz.

The trigonal-bipyramidal configuration of **1** has been confirmed in the crystal. Figure 1 shows the first molecular structure of an *ortho*-metalated arylcobalt complex. The bond lengths are as expected for Co^{I} centered in a trigonal bipyramid of CP_4 donor atoms.[11] The bond angles at cobalt deviate from ideal symmetry because of steric repulsions. Those of the axial P4 atom appear to be augmented by 5°, and the small chelate bite angle [C16−Co−P1 = 71.48(10)°] causes a bending of the main axis towards the chelate ring [C16−Co−P4 = 168.00(11)°]. Thus, the properties and the molecular structure prove **1** (18 metal-valence electrons) to be a true homologue of its 16-electron rhodium congener **B**.

Reaction with Carbon Monoxide

At ambient temperature under 1 bar CO, THF solutions of complexes **1** and **2** react with two molar equivalents of CO according to Equation 3. An in situ transformation also occurs after *ortho*-metallation, as described by Equations 1 or 2.

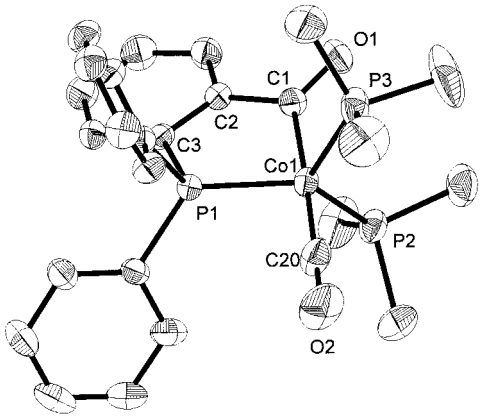
Compound **3** has previously been obtained by C,H activation of 2-diphenylphosphanylbenzaldehyde.[11] Compounds **3** and **4** show analogous infrared absorptions of their carbonyl ligands at $\tilde{\nu}$ = 1953 and 1946 cm^{-1} (C≡O) and benzoyl groups $\tilde{\nu}$ = 1916 and 1909 cm^{-1} (C=O), respectively. When compared with the ^{31}P NMR spectroscopic data for **1** and **2**, the largest difference is seen in the shift of the chelate P atom. On going from a four-membered to a five-membered metallacycle, a low-field shift of 115 ppm is found, which is of the expected order.[10] The two trimethylphosphane ligands give rise to a broad singlet at δ = 9, which splits into a doublet at −40 °C. The coupling constant [J(PP) = 81 Hz] is indicative of a P−Co−P angle of about 120°, which is in perfect agreement with the molecular structure of **3**[12] (Figure 2). The cobalt atom is centered in a trigonal bipyramid comprising three equatorial P-donor functions. The chelate bite angle [P1−Co−C1 = 85.03(9)°] is similar to that in **1**, and the metallacycle shows a normal Co−C bond length only slightly longer than in **1** [Co−C1 = 1.960(3) Å]. Surprisingly, the groups with the largest *trans* influence are almost perfectly aligned along an axis [C1−Co−C20 = 176.3(2)°].

In the observed configuration, the carbonyl ligand can be expected to dissociate freely from **3**. A further carbonyl ligand may be mobilized through a decarbonylation reaction of the acyl function, restoring the four-membered metallacycle. In an attempted ligand equilibration reaction, regarding **3** as a source and **1** as an acceptor of carbonyl groups, no exchange of ligands was observed.

In further attempts to prepare the desired compound from either $CoMe(CO)(PMe_3)_3$ [13] and triphenylphosphane or from $CoCl(CO)(PMe_3)_3$ [14] and MeLi in the presence of triphenylphosphane, no *ortho*-metalation was observed.

Hydrogenation of Metallacycles

Under ambient conditions (20 °C, 1 bar H_2) in pentane or diethyl ether, **1** undergoes a ring-opening reaction to form mixed-ligand cobalt hydrides according to Equations 4 and 5. While **5** can be crystallized from pentane, **6** may be obtained through a ligand dismutation reaction and precipitated as an orange solid as it is insoluble in diethyl ether.



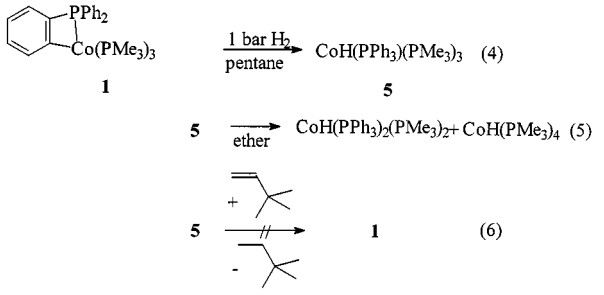


Figure 2. Molecular structure of **3** (ORTEP plot with hydrogen atoms omitted); selected bond lengths [Å] and angles [°]: Co−C1 196.0(3), Co−P1 215.02(10), Co−P2 217.38(9), Co−C3 181.7(3), Co−C20 174.3(4), C20−O2 115.3(4), C1−O1 122.1(3), C1−C2 154.0(4), C2−C3 138.2(4), P1−C3 181.7(3); C1−Co−P1 85.03(9), C1−Co−P2 83.70(9), C1−Co−P3 89.56(9), C1−Co−C20 176.3(2), P1−Co−P2 123.91(3), P1−Co−P3 115.42(4), P1−Co−C20 93.47(12), P2−Co−P3 119.23(4), P2−Co−C20 94.35(13), C20−Co−P3 94.18(13), Co−C1−C2 117.2(2), C1−C2−C3 117.9(2), C2−C3−P1 111.2(2), C3−P1−Co 104.65(9), Co−C1−O1 126.9(2), O1−C1−C2 115.9(3)

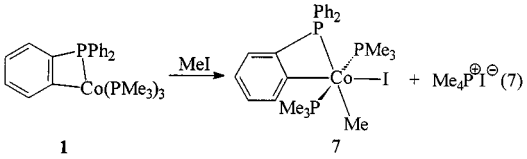


The hydrogenation reaction cannot be reversed by adding an olefin. Cyclohexene, 1-octene, and even 3,3-dimethylbut-1-ene, with its large heat of hydrogenation, remain unreactive. Such equilibria would, in principle, make the pair of compounds **1** and **5** a homogeneous hydrogenation catalyst involving *ortho*-metalated intermediates as are supposedly involved in Parshall's ruthenium system.[15] However, with (trimethylphosphane)cobalt compounds, hydrogenation reactions appear to be generally rather slow.

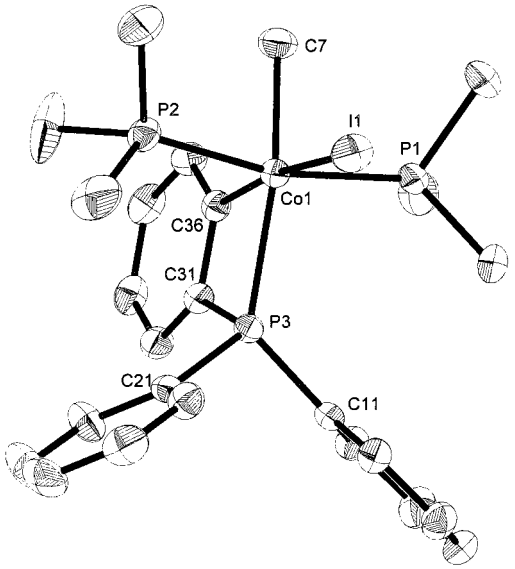
The catalytic activity of **1** and **5** in the hydrogenation of 1-octene was tested under 70 bar H_2 at 80 °C, but none was found. Hydrogen uptake was only observed with **1**, which was found to correspond to a stoichiometric reaction according to Equation 4.

Oxidative Addition and Oxidation

The ease with which it is hydrogenated under ambient conditions makes complex **1** a candidate for oxidative addition reactions. Using iodomethane as a substrate, the interesting question arises as to whether attack by the metal would proceed as a regioselective addition or promote ring-opening through a subsequent reductive C−C coupling reaction.

Within 15 h, the appearance of a light-brown coloration and a white precipitate of tetramethylphosphonium iodide indicated reaction according to Equation 7. However, trimethylphosphane was only partly quaternated in a side reaction, and addition of a second molar equivalent of iodomethane did not improve the yield of dark-brown crystals of **7** obtained from either diethyl ether or pentane. The use of a tenfold excess of iodomethane completely suppressed the formation of **7** and led to some $CoMe_2(I)(PMe_3)_3$ [16] as a product of a subsequent ring-opening reaction, as well as a cobalt-containing dark-green solid, which proved insoluble and was not identified.

In the ^{1}H NMR spectrum of **7**, the $CoCH_3$ protons resonate at δ = 0.51, which is close to the chemical shift seen for $CoMe_2(I)(PMe_3)_3$,[16] and are coupled to two *cis*-trimethylphosphane ligands [^3J(PH) = 9.5 Hz] and a *trans*-chelating phosphorus atom [^3J(PH) = 1.8 Hz], which gives rise to a high-field signal (δ(P) = −40) in the ^{31}P NMR spectrum, indicative of a four-membered metallacycle. All spec-



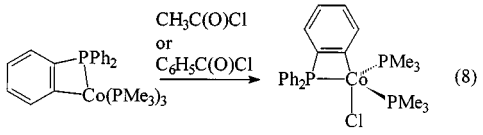


Figure 3. Molecular structure of **7** (ORTEP plot with hydrogen atoms omitted); selected bond lengths [Å] and angles [°]: I−Co 2.7099(6), Co−C36 1.942(3), Co−C7 2.039(3), Co−P1 2.2381(11), Co−P2 2.2425(11), Co−P3 2.3467(10), P3−C31 1.799(3), P3−C11 1.829(3), P3−C21 1.830(3), C31−C36 1.395(4), C31−C32 1.389(4), C32−C33 1.374(5), C33−C34 1.375 (5), C34−C35 1.384(5), C35−C36 1.398(4); C36−Co−C7 89.60(15), C36−Co−P1 94.06(10), C7−Co−P1 84.50(11), C36−Co−P2 91.88(10), C7−Co−P2 83.90(12), P1−Co−P2 166.92(4), C36−Co−P3 69.98(10), C7−Co−P3 159.57(11), P1−Co−P3 96.01(4), P2−Co−P3 96.97(4), C36−Co−I 171.33(10), C7−Co−I 98.96(11), C31−P3−C21 110.33(16), C31−P3−Co 80.77(11), C21−P3−Co 125.96(11), C11−P3−Co 127.73(11), P1−Co−I 88.17(3), P2−Co−I 87.69(3), P3−Co−I 101.46(3), C31−P3−C11 107.12(15), C31−P3−C21 110.32(16), C11−P3−C21 100.23(15), C31−P3−Co 80.77(11), C36−C31−P3 101.2(2), C31−C36−Co 108.0(2), C35−C36−Co 134.5(3)

troscopic data are thus compatible with an octahedral configuration of **7** in solution.

Crystals of **7** proved to be stable in air for more than two days and could thus be mounted on an X-ray diffractometer without inert gas protection. The molecular structure (Figure 3) confirms the configuration of **7** as derived from the spectroscopic data. The iodo and methyl ligands lie in the plane of the chelate ring, and the two carbon−cobalt bonds are mutually orthogonal [C7−Co−C36 = 89.60(15)°]. The trimethylphosphane ligands are positioned in an axis perpendicular to the chelate ring and appear slightly bent [P1−Co−P2 = 116.92(4)°] towards the $CoCH_3$ group. This bending and the small bite angle of the chelating ligand [C36−Co−P3 = 69.98(10)°] reflect the spatial requirements of the iodo ligand. The strong *trans* influence of the $CoCH_3$ group and the weak effect of the iodo ligand cause an elongation of Co−P3 by 0.1 Å compared with Co−P1 and Co−P2 and a contraction of Co−C36 by 0.045 Å compared with the corresponding Co−C16 distance in **1**. Therefore, the molecular structure of **7** appears to be the result of a regioselective *cis* addition of iodomethane.

With benzoyl chloride or acetyl chloride, oxidation is observed rather than oxidative addition, as in the rhodium system.[8]

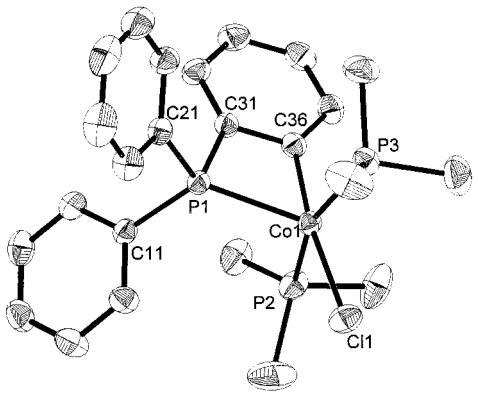
(8)

1 **8**

The cobalt(II) complex **8** (17 valence electrons) was obtained as the only cobalt-containing species in 50−60% yield, while the remaining hydrocarbon moieties have yet to be characterized.

Dark-brown quadrangular crystals could be grown from pentane or diethyl ether and proved to be stable in moist air for more than two hours. The thermal stability, color, and multitude of infrared bands in the fingerprint region are very similar to those observed for **7**, although the crystal habit is different.

The molecular structure of **8** (Figure 4) can be related to a trigonal bipyramid similar to that of **1**. The chelate bite angle [C36−Co−P1 = 71.28(12)°] has a value intermediate between those of **1** and **7**. Distances from the cobalt atoms to the trimethylphosphanes are 0.04 Å longer than those not subject to a strong *trans* influence in **1**. The chelate P atom is almost 0.15 Å farther away from the metal center, although in the opposite direction there is a methyl group in **1** and a void in **8**, which is defined by bond angles P2−Co−P3 = 157.70(5)° and Cl−Co−C36 = 170.49(12)°. This space is large enough for, although not occupied by, a hydride ligand, as indicated by the fact that there no bands in the Co−H region of the infrared spectrum (1980−1880 cm^{-1}), and solid **8** has paramagnetic properties as would be expected for a total of 17 metal-valence electrons.



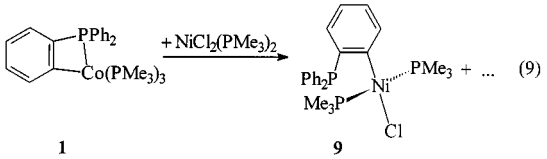


Figure 4. Molecular structure of **8** (ORTEP plot with hydrogen atoms omitted); selected bond lengths [Å] and angles [°]: Co−C36 1.926(4), Co−P1 2.3631(11), Co−P2 2.2179(12), Co−P3 2.2096(12), Co−Cl 2.3014(13), P1−C11 1.831(4), P1−C31 1.811(4), P1−C21 1.840(4), C31−C36 1.397(6), C31−C32 1.390(6), C32−C33 1.388(6), C33−C34 1.377(7), C34−C35 1.386(7), C35−C36 1.402(6); C36−Co−P1 71.28(12), C36−Co−P2 86.85(12), P3−Co−P2 157.70(5), C36−Co−Cl 170.49(12), P3−Co−Cl 88.48(5), P2−Co−Cl 89.79(5), C36−Co−P1 71.28(12), P3−Co−P1 98.53(5), P2−Co−P1 101.87(4), Cl−Co−P1 118.15(4), C31−P1−C11 109.17(19), C31−P1−C21 107.08(19), C11−P1−C21 102.53(19), C31−P1−Co 78.85(14), C11−P1−Co 118.65(13), C21−P1−Co 134.16(14), C36−C31−P1 103.1(3), C31−C36−C35 117.2(4), C31−C36−Co 106.7(3), C35−C36−Co 136.0(3)

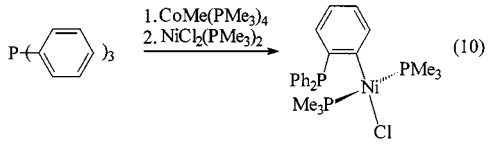
Although the actual molecular symmetries of **1**, **7**, and **8** are lower than those of idealized coordination polyhedra, the angles around the cobalt atom change in a way as to suggest a smooth transition from a trigonal bipyramid in **1** through an intermediate geometry in **8** to an approximate octahedron in **7**.

Transmetalation Reaction

In reactions of $NiCl_2(PMe_3)_2$ with one or two molar equivalents of methyllithium in the presence of triphenylphosphane, no evidence of *ortho*-metalation has been observed. Besides elemental nickel, the mixture of soluble species produced was invariably found to contain $Ni(PMe_3)_4$, $Ni(PPh_3)(PMe_3)_3$, and $Ni(PPh_3)_2(PMe_3)_2$. However, the *ortho*-metalated chelate ligand might be transferred to nickel according to Equation 9.



(9)

1 **9**

A light-green powder was obtained as a cobalt-containing residue, from which no soluble compound could be extracted. From a diethyl ether solution containing a considerable quantity of $Ni(PMe_3)_4$, honey-colored cubes of **9** were crystallized in 55% yield, which proved to be stable in air for more than two hours. The infrared spectrum features all the bands typical of *ortho*-metalated triphenylphos-

phane, while the NMR spectra show singlets indicating fast exchange of the ligands as in *trans*-NiCl(Me)(PMe_3)$_2$. At −40 °C, the ^{31}P NMR spectrum shows an A_2B pattern of resonances at δ = −5.4 (2 P) and δ = −7.0 (1 P) with a coupling constant [^2J(PP) = 21 Hz] falling in the range reported for related square-planar nickel(II) compounds.[7] These data are consistent with the presumption that the configuration of **9** is *trans*-square planar and the arylphosphane donor is uncoordinated.

(10)

The transmetalation reaction (Equation 9) provides access to an *ortho*-metalated triphenylphosphane without the need for halogenated arylphosphane precursors through a two-step synthetic procedure (Equation 10).

Conclusion

Methylcobalt(I) complexes incorporating triphenylphosphane ligands spontaneously eliminate methane forming four-membered metallacycles, which remain unchanged in oxidation or oxidative addition reactions. Ring-opening by dihydrogen occurs in a slow reaction and cannot be easily reversed. Under the conditions employed, the system is not an active hydrogenation catalyst. Insertion of carbon monoxide into the metallacycle constitutes a template synthesis of the C,P-chelating (2-diphenylphosphanyl)benzoyl ligand.

Experimental Section

General Procedures and Materials: All air-sensitive and volatile materials were handled using standard vacuum techniques and were stored under argon. − Microanalyses: Kolbe Microanalytical Laboratory, Mülheim/Ruhr, FRG. − Melting points/decomposition temperatures: Sealed capillaries, uncorrected values. − Chemicals (Merck/Schuchardt) were used as purchased, although liquids were degassed in vacuo by a freeze-pump-thaw procedure. Literature methods were followed for the preparation of CoMe(PMe_3)$_4$,[13] CoCl(PMe_3)$_3$,[14] and $NiCl_2(PMe_3)_2$.[17] − IR: Nujol mulls between KBr discs, Bruker spectrophotometer type FRA 106. − NMR: ^{1}H and ^{13}C NMR spectra (300 and 75 MHz, respectively) were recorded with a Bruker ARX-300 spectrometer, ^{31}P NMR spectra (81 MHz) with a Bruker AM-200 instrument. ^{13}C and ^{31}P resonances were obtained with broad-band proton decoupling.

[(2-Diphenylphosphanyl)phenyl-*C*^{1},*P*]tris(trimethylphosphane)cobalt (1). − Method a: CoCl(PMe_3)$_3$ (3.38 g, 11.0 mmol) in THF (60 mL) was combined with triphenylphosphane (2.75 g, 10.5 mmol) in THF (10 mL) at −70 °C to give a green solution. After 5 min, 0.9 M MeLi solution in diethyl ether (6.6 mL, 10.5 mmol) was added to afford an orange solution, which turned deep red on warming to 20 °C. After 4 h, the volatiles were removed in vacuo and the residue was extracted with toluene (50 mL) through a glass sinter disc (G3). Evaporation of the solvent from the extract and drying of the residue in vacuo afforded a black microcrystalline solid. Crude yield 5.70 g (99%) of **1**; yield after recrystallization from 30 mL of pentane 4.5 g (79%). − **Method b:** CoMe(PMe_3)$_4$ (880 mg, 2.30 mmol) in THF (50 mL) and triphenylphosphane (630 mg, 2.40 mmol) in THF (10 mL) were combined at −70 °C. On warming to 20 °C, the mixture took on a deep-red color. After 60 h, the volatiles were removed in vacuo and the residue was extracted with pentane (30 mL). Crystallization at 4 °C afforded dark-red quadrangular rods. Yield 690 mg (55%) of **1**; decomp. > 115 °C. − ^{1}H NMR ([D$_8$]THF): δ = 1.13 (br. s, 9 H, PCH_3), 1.26 (br. s, 18 H, PCH_3), 6.29 (m, 1 H, CH), 6.45 (m, 1 H, CH), 6.65 (m, 1 H, CH), 6.85 (m, 1 H, CH), 7.22 (m, 6 H, CH), 7.69 (m, 4 H, CH). − ^{13}C NMR (300 MHz, [D$_8$]THF): δ = 22.1 (m, PCH_3), 22.9 (m, PCH_3), 118.4 (m, 4-C/6-C), 119.6 (m, 6-C/4-C), 126.2 (s, 5-C), 126.4 (s, *p*-C), 126.6 (s, *m*-C), 131.8 [d, ^2J(PC) = 9 Hz, *o*-C], 140.1 [d, ^2J(PC) = 9 Hz, 2-C], 154.2 (m, *i*-C), 170.0 (m, 1-C). − ^{31}P NMR ([D$_8$]THF, 233 K): δ = −32 [dt, $^2J(P_{eq}P_{eq})$ = 87 Hz, $^2J(P_{ax}P_{eq})$ = 70 Hz, 1 P, PPh_2], −4 [dd, $^2J(P_{eq}P_{eq})$ = 87 Hz, $^2J(P_{ax}P_{eq})$ = 49 Hz, 2 P, PMe_3], 23 [dt, $^2J(P_{eq}P_{ax})$ = 70 Hz, $^2J(P_{eq}P_{ax})$ = 49 Hz, 1 P, PMe_3]. − $C_{27}H_{41}CoP_4$ (548.2): calcd. C 59.13, H 7.53, P 22.59; found C 59.21, H 7.40, P 22.68.

{2-[Bis(4-methylphenyl)phosphanyl]-5-methylphenyl-*C*^{1},*P*}-tris(trimethylphosphane)cobalt (2). − Method a: CoCl(PMe_3)$_3$ (840 mg, 2.60 mmol) in THF (50 mL) was combined with tris(4-methylphenyl)phosphane (790 mg, 2.60 mmol) in THF (10 mL) at −70 °C to give a green solution. After 5 min, 2.6 M MeLi solution in diethyl ether (1.6 mL, 2.60 mmol) was added to afford an orange solution, which turned deep red on warming to 20 °C. After 15 h, the volatiles were removed in vacuo and the residue was extracted with pentane (30 mL). Crystallization at 4 °C afforded dark-red quadrangular rods. Yield 580 mg (38%) of **2**; m.p. 142−144 °C. − ^{1}H NMR (200 MHz, [D$_8$]THF): δ = 1.10 [d, ^2J(PH) = 9 Hz, 9 H, PCH_3], 1.25 (br. s, 18 H, PCH_3), 2.01 (s, 3 H, CCH_3), 2.29 (s, 6 H, CCH_3), 6.18 (m, 2 H, CH), 6.71 (br. s, 1 H, CH), 7.04 [d, ^3J(HH) = 7 Hz, 4 H, CH], 7.56 [dd, ^3J(HH) = 8 Hz, ^3J(PH) = 8 Hz, 4 H, CH]. − ^{13}C NMR (75.4 MHz, [D$_8$]THF): δ = 19.4 (s, CH_3), 20.7 (s, CH_3), 22.1 (m, PCH_3), 22.9 (m, PCH_3), 119.2−171.6 (C). − ^{31}P NMR ([D$_8$]THF, 233 K): δ = −34 [dt, $^2J(P_{eq}P_{eq})$ = 87 Hz, $^2J(P_{ax}P_{eq})$ = 70 Hz, 1 P, PPh_2], −5 [dd, $^2J(P_{eq}P_{eq})$ = 87 Hz, $^2J(P_{ax}P_{eq})$ = 49 Hz, 2 P, PMe_3], 22 [dt, $^2J(P_{eq}P_{ax})$ = 70 Hz, $^2J(P_{eq}P_{ax})$ = 49 Hz, 1 P, PMe_3]. − $C_{30}H_{47}CoP_4$ (548.2): calcd. C 61.02, H 8.02, P 20.98; found C 60.69, H 7.80, P 21.39.

Carbonyl[2-(diphenylphosphanyl)benzoyl-*C*^{1},*P*]bis-(trimethylphosphane)cobalt (3): CoMe(PMe_3)$_4$ (880 mg, 2.30 mmol) in THF (50 mL) and triphenylphosphane (610 mg, 2.30 mmol) in THF (10 mL) were combined at −70 °C and then the resulting solution was allowed to warm to 20 °C in vacuo. After 3 h, CO was admitted, and the mixture was stirred under 1 bar CO for 15 h. The volatiles were then removed in vacuo and the residue was extracted with pentane (30 mL). Crystallization at 4 °C afforded dark-red crystals. Yield 300 mg (24%) of **3**; m.p. 141−143 °C. − IR (Nujol): $\tilde{\nu}$ = 1917 cm^{-1} (C≡O), 1582 (C=C), 1551 (C=O). − ^{1}H NMR (300 MHz, [D$_8$]THF): δ = 1.13 [t′, $|^2J(PH) + {}^4J(PH)|$ = 7.1 Hz, 18 H, PCH_3], 7.33 (m, 8 H, CH), 7.47 (m, 1 H, CH), 7.56 (m, 4 H, CH), 7.66 (m, 1 H, CH). − ^{13}C NMR (75.4 MHz, [D$_8$]THF): δ = 18.3 (m, PCH_3), 119.4−156.0 (C), 222.4 (m, C≡O), 261.1 (m, C=O). − ^{31}P NMR ([D$_8$]THF): δ = 8.7 [d, $^2J(P_{eq}P_{eq})$ = 69 Hz, 2 P, PMe_3], 83.0 (br. s, 1 P, PPh_2).

{2-[Bis(4-methylphenyl)phosphanyl]-5-methylbenzoyl-*C*^{1},*P*}carbonyl-bis(trimethylphosphane)cobalt (4): CoMe(PMe_3)$_4$ (760 mg, 2.00 mmol) in THF (50 mL) and tri-*p*-tolylphosphane (610 mg, 2.30 mmol) in THF (10 mL) were combined at −70 °C and then

the resulting mixture was allowed to warm to 20 °C in vacuo. After 3 h, CO was admitted, and the mixture was stirred under 1 bar CO for 15 h. Workup as in the case of **3** afforded dark-red crystals. Yield 300 mg (26%); m.p. 162−164 °C. − IR (Nujol): $\tilde{\nu}$ = 1909, 1863 cm^{-1} (C≡O), 1598 (C=C), 1572, 1546 (C=O). − ^1H NMR (300 MHz, [D_8]THF): δ = 1.11 [t′, $|^2J(PH) + {}^4J(PH)|$ = 7.2 Hz, 18 H, PCH_3], 2.31 (s, 6 H, CCH_3), 2.35 (s, 3 H, CCH_3), 7.12 [d, $^3J(HH)$ = 7.9 Hz, 4 H, CH], 7.16 [d, $^3J(HH)$ = 7.6 Hz, 1 H, CH], 7.26 (s, 1 H, C^6-H), 7.42 [dd, $^3J(PH)$ = 10.0 Hz, $^3J(HH)$ = 8.1 Hz, 4 H, C^2−H], 7.51 [dd, $^4J(PH)$ = 5.8 Hz, $^3J(HH)$ = 7.5 Hz, 4 H, C^3−H]. − ^{13}C NMR (75.4 MHz, [D_8]THF): δ = 15.7 (s, CH_3), 20.2 [t′, $|^1J(PC) + {}^3J(PC)|$ = 26 Hz, PCH_3], 21.3 (s, CH_3), 121.6 [d, $^2J(PC)$ = 20 Hz, 3-C], 129.5 [d, $^3J(PC)$ = 9 Hz, *m*-C], 130.6 (s, 4-C/6-C), 131.1 (s, 6-C/4-C), 132.8 [d, $^2J(PC)$ = 13 Hz, *o*-C], 137.8 [d, $^1J(PC)$ = 35 Hz, *ipso*-C], 139.3 (s, *p*-C), 140.6 [d, $^2J(PC)$ = 32 Hz, 2-C], 140.8 (s, 5-C), 158.7 [d, $^1J(PC)$ = 62 Hz, 1-C], 222.7 (m, C≡O), 263.1 (m, C=O). − ^{31}P NMR ([D_8]THF, 233 K): δ = 9.0 [d, $^2J(P_{eq}P_{eq})$ = 81 Hz, 2 P, PMe_3], 80.5 [t, $^2J(P_{eq}P_{ax})$ = 81 Hz, 1 P, PPh_2]. − $C_{29}H_{38}CoO_2P_3$ (570.1): calcd. C 61.06, H 6.71, P 16.29; found C 60.88, H 6.95, P 15.71.

Hydrogenation of 1: Hydrogenation of **1** (250 mg, 0.50 mmol) in diethyl ether (30 mL) by stirring for 15 h under 1 bar of H_2 furnished a red solid, which was isolated by decantation and washing. Yield 50 mg of **5** (27% based on PPh_3); decomp. > 158 °C. − IR (Nujol): $\tilde{\nu}$ = 1941 cm^{-1} (Co−H), 1582 (C=C). − ^1H NMR (200 MHz, [D_8]THF): δ = −17.30 (br. s, 1 H, CoH), 1.11 (br. s, 27 H, PCH_3), 7.18−7.41 (m, 15 H, CH). − ^{31}P NMR ([D_8]THF): δ = 4.8 (br. s, 3 P, PCH_3), 58.5 (br. s, 1 P, PPh_3). − $C_{27}H_{43}CoP_4$ (550.5): calcd. C 58.91, H 7.87, P 22.51; found C 57.92, H 7.34, P 21.73. − All volatiles were removed in vacuo from the light-red solution, and the solid residue was taken up in pentane (30 mL). At −25 °C, red plates crystallized. Yield 180 mg of **6** (60% based on PPh_3); decomp. > 171 °C. − IR (Nujol): $\tilde{\nu}$ = 1967 cm^{-1} (Co−H), 1582 (C=C). − ^1H NMR (300 MHz, [D_8]THF): δ = −17.70 (m, 1 H, CoH), 0.93 (br. s, 18 H, PCH_3), 7.11 (m, 18 H, CH), 7.36 (m, 12 H, CH). − ^{31}P NMR ([D_8]THF): δ = 5.5 (br. s, 2 P, PCH_3), 56.3 (br. s, 2 P, PPh_3).

[2-(Diphenylphosphanyl)phenyl-*C*^{1},*P*]iodo(methyl)bis(trimethylphosphane)cobalt (7): 1 (840 mg, 1.50 mmol) in THF (30 mL) was combined with iodomethane (0.10 mL, 210 mg, 1.50 mmol) in THF (30 mL) at −70 °C. The solution was allowed to warm to ambient temperature and within 30 min took on a light-brown color and became turbid. After 15 h at 20 °C, the volatiles were removed in vacuo and the brown solid was extracted with diethyl ether. On storage of the extract at 4 °C, dark-brown crystals were obtained. Yield 390 mg (42%); m.p. 123−124 °C. − ^1H NMR (300 MHz, [D_8]THF): δ = 0.51 [dt, $^3_{cis}J(PH)$ = 9.5 Hz, $^3_{trans}J(PH)$ = 1.8 Hz, 3 H, $CoCH_3$], 0.98 [t′, $|^2J(PH) + {}^4J(PH)|$ = 3.7 Hz, 18 H, PCH_3], 6.73 (br. s, 1 H, CH), 7.05 (m, 2 H, CH), 7.22 [d, $^3J(HH)$ = 8 Hz, 1 H, CH], 7.33 (m, 6 H, CH), 7.77 (m, 4 H, CH). − ^{13}C NMR (75.4 MHz, [D_8]THF): δ = 14.2 [t′, $|^1J(PC) + {}^3J(PC)|$ = 27 Hz, PCH_3], 121.6 [d, $^3J(PC)$ = 6 Hz, 4-C], 126.6 (s, 5-C/6-C), 127.6 [d, *J*(PC) = 8 Hz, *o*-C/*m*-C], 128.0 (s, *p*-C), 130.9 [d, *J*(PC) = 9 Hz, *m*-C/*o*-C], 134.4 [d, $^2J(PC)$ = 20 Hz, 3-C], 137.5 [d, $^1J(PC)$ = 14 Hz, *ipso*-C]. − ^{31}P NMR ([D_8]THF, 233 K): δ = 9.6 (s, 2 P, PMe_3), −40.2 (s, 1 P, PPh_2). − $C_{25}H_{35}CoIP_3$ (614.0): calcd. C 48.88, H 5.74, P 15.13; found C 48.78, H 5.62, P 15.88.

Chloro[2-(diphenylphosphanyl)phenyl-*C*^{1},*P*]bis(trimethylphosphane)cobalt (8). − Method a: 1 (310 mg, 0.6 mmol) in THF (40 mL) was combined with benzoyl chloride (80 mg) in THF (1 mL) at −70 °C. Warming to 20 °C afforded a dark-brown solution which, after stirring for 16 h, was concentrated to dryness in vacuo. The residue was extracted with pentane to remove traces of $CoCl(PMe_3)_3$ (IR control) and then with diethyl ether, from which dark-brown quadrangular rods were crystallized. Yield 150 mg (50%) of **8**. − **Method b:** At −70 °C in vacuo, acetyl chloride (210 mg, 1.50 mmol) in THF (30 mL) was condensed into a vessel containing **1** (740 mg, 1.40 mmol) in THF (30 mL). The resulting mixture was allowed to warm to ambient temperature; within 5 min a light-green solid separated, which slowly redissolved. After 15 h at 20 °C, a red-brown solution was obtained, which was concentrated to dryness in vacuo. The residue was extracted with pentane, and on storage of the extract at 4 °C dark-brown crystals were obtained. Yield 660 mg (59%) of **8**; m.p. 123−124 °C. − IR (Nujol): $\tilde{\nu}$ = 1582 cm^{-1}, 1552 (C=C). − $C_{24}H_{32}ClCoP_3$ (507.1): calcd. C 56.76, H 6.35, P 18.30; found C 56.68, H 6.35, P 18.22.

Chloro[2-(diphenylphosphanyl)phenyl]bis(trimethylphosphane)nickel (9): 1 (830 mg, 1.5 mmol) and $NiCl_2(PMe_3)_2$ (420 mg) were combined in diethyl ether (60 mL) at −70 °C. Warming to 20 °C afforded a dark-brown solution which, after 16 h, had taken on a greenish-brown appearance. It was then concentrated to dryness in vacuo. Extraction of the residue with diethyl ether afforded a greenish-brown solution, storage of which at 4 °C led to the deposition of honey-colored quadrangular rods. Yield 420 mg (55%) of **9**; m.p. 165−168 °C. − IR (Nujol): $\tilde{\nu}$ = 1581 cm^{-1}, 1554 (C=C). − ^1H NMR (300 MHz, [D_8]THF): δ = 0.89 (br. s, 1 H, 18 H, PCH_3), 6.70 [t, $^3J(PH)$ = 7.2 Hz, 1 H, CH], 6.85 [t, $^3J(PH)$ = 7.1 Hz, 1 H, CH], 6.93 [d, $^2J(PH)$ = 5 Hz, 1 H, CH], 7.31 (m, 7 H, CH), 7.44 (m, 4 H, CH). − ^{13}C NMR (75.4 MHz, [D_8]THF): δ = 13.2 [t′, $|^1J(PC) + {}^3J(PC)|$ = 30 Hz, PCH_3], 121.4, 127.3, 132.3 (s, 4-C, 5-C, 5-C), 129.0 (s, *p*-C), 129.1 [d, $^3J(PC)$ = 6 Hz, *m*-C], 134.9 [d, $^2J(PC)$ = 17 Hz, *o*-C], 136.6 [dt, $^2J(PC)$ = 25 Hz, $^4J(PC)$ = 6 Hz, 3-C], 140.4 [d, $^1J(PC)$ = 15 Hz, *ipso*-C], 137.5 (m, 2-C), 169.4 (m, 1-C). − ^{31}P NMR ([D_8]THF, 233 K): δ = −5.4 (B_2, PMe_3), −7.0 (A, PPh_2); AB_2 spin system, *J*/δ = 0.16 with $^2J(PP)$ = 21 Hz. − $C_{24}H_{32}ClNiP_3$ (506.1): calcd. C 56.79, H 6.35, P 18.31; found C 56.64, H 6.60, P 18.22.

Hydrogenation Tests: A 1-L stainless steel autoclave was charged with 1-octene (15.4 g) in pentane (130 mL) under argon. A solution of either **5** or **1** (430 mg) in pentane (10 mL) was added under hydrogen pressure, which was maintained at 70 bar by continuous feeding. The system was kept at 30 °C for 8 h until no further uptake of hydrogen was observed. The volatiles were then collected in a cold trap in vacuo and were shown to contain 1-octene and less than 1% octane (GC).

Crystal Structure Analyses: Crystal data are presented in Table 1 and Table 2. Data collection: Complex **1**: A dark-red specimen was sealed under argon in a glass capillary and mounted on a Siemens P4 diffractometer. Intensities were collected (ω scans) using graphite-monochromated Mo-K_α radiation; Lp corrections and absorption corrections based on ψ-scans were applied. The structure was solved by direct and conventional Fourier methods. All non-hydrogen atoms were treated anisotropically; hydrogen atoms were treated with a riding model in idealized positions. − Complex **3**: A dark-brown specimen was sealed and mounted as described for **1**. Data collection as for **1**. The structure was solved using Patterson and Fourier methods. Refinement as for **1**. − Complex **7**: A dark-brown specimen was sealed and mounted as described for **1**. Data collection, structure solution, and refinement as for **1**. − Complex **8**: A dark-brown specimen was sealed and mounted as described for **1**. Data collection, structure solution, and refinement as for **1**. − Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-116690 for **1**, CCDC-136410 for **3**, CCDC-116691 for **7**, and CCDC-116692 for **8**. Heteroatom-Bridged Calixarenes

Burkhard König*[a] and Maria Hechavarria Fonseca[a]

Dedicated to Prof. Dr. Martin A. Bennett on the occasion of his 65th birthday

Keywords: Macrocycles / Calixarenes / Supramolecular chemistry / Host−guest chemistry / Crown compounds

Macrocycles have always played an important role in supramolecular chemistry. Macrocycles with rigid subunits, known as calixarenes, are an important subclass of these compounds. While carbon-bridged calixarenes have been studied intensively and are used for practical applications, heteroatom-bridged calixarenes have entered the stage more recently. This review summarizes the current knowledge of synthesis and properties of heteroatom-bridged calixarenes in the year 2000.

Introduction

Macrocyclic compounds are of great importance in supramolecular chemistry whenever selective molecular recognition is desired.[1] The reason for this is obvious; selective recognition requires intermolecular forces that are strong enough to stabilize the assembly, but at the same time allow the dynamic formation and breaking of intermolecular bonds to reach the aggregate that represents the thermodynamic minimum. Weak bonds, such as hydrogen bonds, electrostatic interactions, or kinetically labile coordination to metal ions, fulfill this requirement. However, compared to covalent or metallic bonds, these interactions are usually weak and contribute only a small enthalpic stabilization energy to the aggregate. Therefore, the loss of entropy in the assembly process becomes a significant factor in determining the stability of the supramolecular structure.[2] Macrocyclic preorganization reduces the loss of entropy in aggregate formation by achieving a more restricted conformation as compared to acyclic compounds. This makes macrocycles good host compounds in recognition and self-assembly processes; indeed, this phenomenon has long been known as the macrocyclic effect.[3]

From the large number of macrocycles with potential binding abilities, compounds with rigid, aromatic or heteroaromatic subunits have received special attention. Fully or partially conjugated macrocycles of this kind, such as porphyrins **1**, are widely found in nature, with hemoglobin and chlorophyll the most common. A nonconjugated macrocycle possessing sub-heterocyclic pyrrol rings **2** was synthesized more than 100 years ago by Baeyer from pyrrol and acetone.[4] Somewhat later the formation of cyclic condensation products from *para-tert*-butylphenol and formaldehyde was discovered, but it took another 50 years before the structures of the different calixarenes were determined and protocols for their selective synthesis were developed.[5]

María Hechavarria Fonseca was born in 1974 in Cuba. She studied chemistry at the Universities of Santiago de Cuba and Havana from 1991 until 1996. In 1998 she obtained her Master's degree in the group of Prof. F. Coll at the University of Havana. Last year she received a DAAD Scholarship for her PhD studies in the group of Prof. Burkhard König. Her research interests are the synthesis of artificial receptors and the molecular recognition of natural products.

Burkhard König received his doctorate in 1991 from the University of Hamburg under the direction of Prof. de Meijere. He continued his scientific education as a postdoctoral fellow with Prof. M. A. Bennett, Canberra, Australia, and Prof. B. M. Trost, Stanford, U. S. A. In 1996 he obtained his "Habilitation" at the Technical University of Braunschweig and since 1999 he has been Professor at the University of Regensburg. His current research interests focus on intermolecular interactions, which naturally includes the chemistry of macrocycles.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

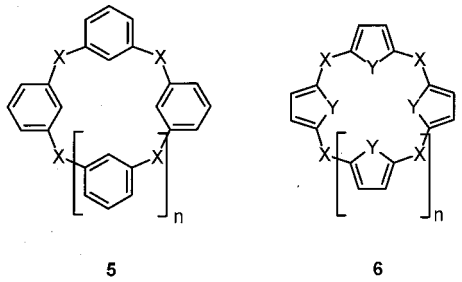
The chemistry of mainly calix[4]- (**3**, $n = 1$), calix[6]- (**3**, $n = 3$) and calix[8]arenes (**3**, $n = 5$) has been thoroughly studied, and the search for new calixarenes is still ongoing, as illustrated by the recent synthesis of calix[4]pyridines **4**.[6] The reasons for the very successful application of heteroaromatic and aromatic calixarenes as artificial receptor molecules are apparent: Depending on their conformation they provide an inner cavity for inclusion of guests, functional groups can be selectively introduced to build binding sites in three dimensions, and the parent calixarene macrocycles are in many cases available in large quantities from simple starting materials (Scheme 1).



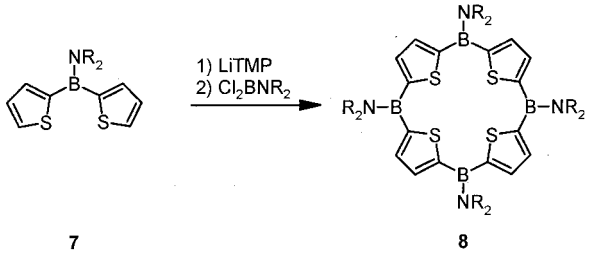
Scheme 1. Conjugated and nonconjugated macrocycles with rigid subunits: porphyrin (**1**), *meso*-octamethylcalix[4]pyrrole (**2**), *para-tert*-butylcalix[3+*n*]arene (**3**), and chlorocalix[4]pyridine (**4**)

Calixarenes in which the carbon methylene bridge between the arene or heteroarene units is replaced by a heteroatom are much less studied. For such compounds the name hetero-calixarenes will be used in this article. The introduction of a heteroatom as the bridge provides an additional opportunity to tune the ring size, conformation, and binding properties of the macrocycle. Synthetic approaches to both classes of compounds are rather different. While the main synthetic routes to carbon-bridged calixarenes are condensation reactions of arenes or heteroarenes and carbonyl compounds, this reaction is in most cases not suitable for the introduction of heteroatom bridges.

In this account we will summarize recent reports of the synthesis and the binding properties of heteroatom-bridged calixarenes that have appeared in the literature. We include our own investigations on silicon-, sulfur-, and germanium-bridged macrocycles.

Results and Discussion

Most heteroatom-bridged calixarenes discussed in this paper are described by the two general formulae **5** and **6** shown in Scheme 2. The substitution pattern of the arene rings in **5** is not restricted to *meta*-, *ortho*- and *para*-substituted rings as part of the macrocycle and mixtures of substitution patterns are included. The arene ring may contain additional heteroatoms. As a classification scheme, we will use the bridging heteroatoms X in the order of the main groups of the periodic table. As five-membered heterocyclic rigid subunits of the calixarene, furans (Y = O), thiophenes (Y = S) and *N*-methylpyrrols (Y = Me−*N*) are considered. Macrocycles with three ($n = 0$) to six ($n = 3$) rigid arene or heteroarene units are covered in this review.

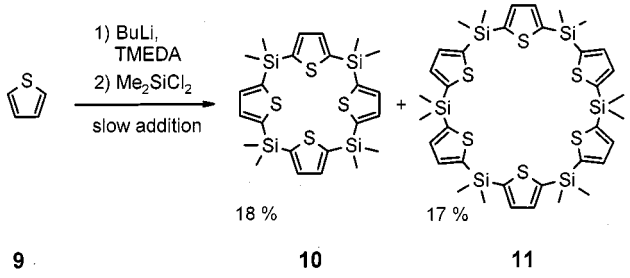


Scheme 2. General formulae of heterocalixarenes covered in this review

1. Group IIIA Elements

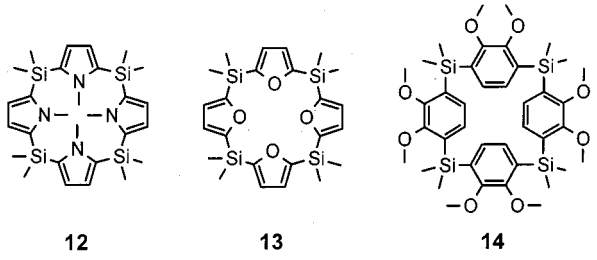
1.1 Boron

The first boron-bridged tetrathiaporphyrinogen **8** has been reported only recently.[7] The macrocycle was synthesized in remarkable 62% yield from *N*,*N*-dimethylbis(2-thienyl)borylamine **7** via the dilithio compound. No polymer formation was observed in the reaction although this was the initial objective of the experiment. The X-ray structure analysis shows that all four bridging boron atoms do not lie in a single plane, as it is the case for the analogous carbon-[8] and silicon-bridged compounds (Scheme 3).



Scheme 3. Synthesis of a boron-bridged tetrathiaporphyrinogen; LiTMP = lithium-2,2,6,6,-tetramethylpiperidid; R = *i*Pr

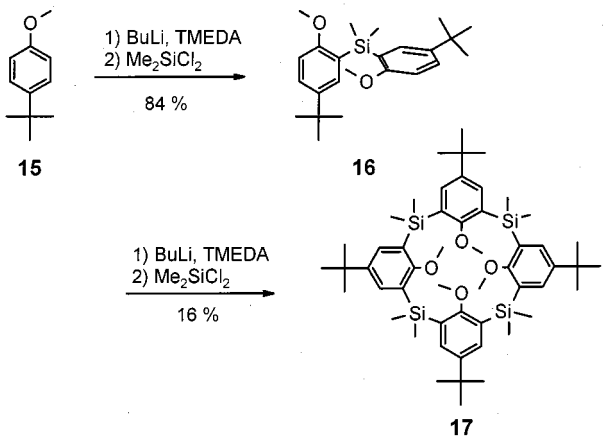
2. Group IVA Elements



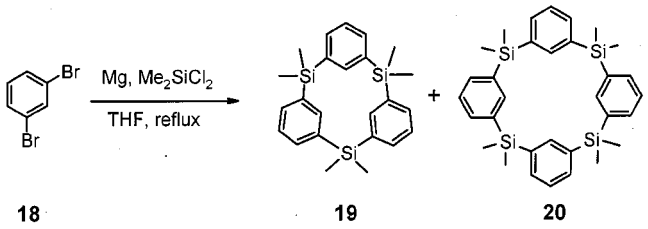
2.1 Silicon

The element closely related to carbon, silicon, has been widely used for the synthesis of macrocycles with rigid aromatic or heteroaromatic subunits. The first report appeared in 1973 by Kauffmann et al.[9] who obtained a macrocycle **10** consisting of four thiophene rings bridged by dimethylsilyl groups from the reaction of a lithiated dimethylsilyl-

bridged bis(thiophene) in 16% yield. Later silicon-bridged macrocycles, such as **10** and **11**, were reported by Corriu and Moreau as by-products in polymerization reactions (Scheme 4).[10] We have further developed protocols for silicon-bridged macrocycles, which now allow the synthesis of a wide variety of lipophilic macrocycles with weak coordination sites. In this strategy carbo- or heterocyclic dianions react with bis(electrophiles), such as Me_2SiCl_2.[11] The low solubility of the dianions in petroleum ether solvent and the very fast reaction of the slowly added bis(electrophile) generate *pseudo*-dilute conditions. The synthesis of macrocycles therefore proceeds under high substrate concentrations. Variation of the heterocyclic dianion yields the macrocyclic structures **12** and **13** (Scheme 5).



Scheme 4

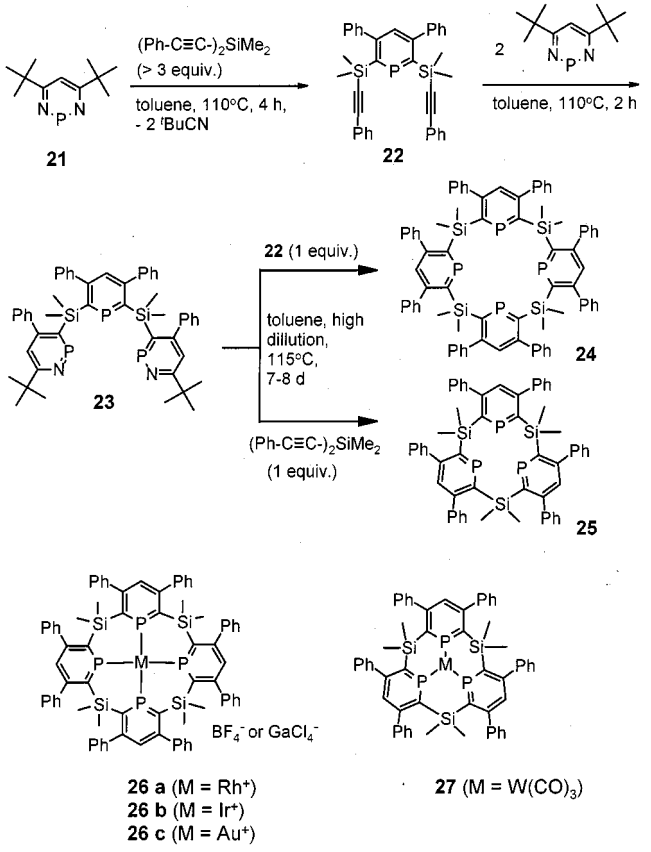


Scheme 5

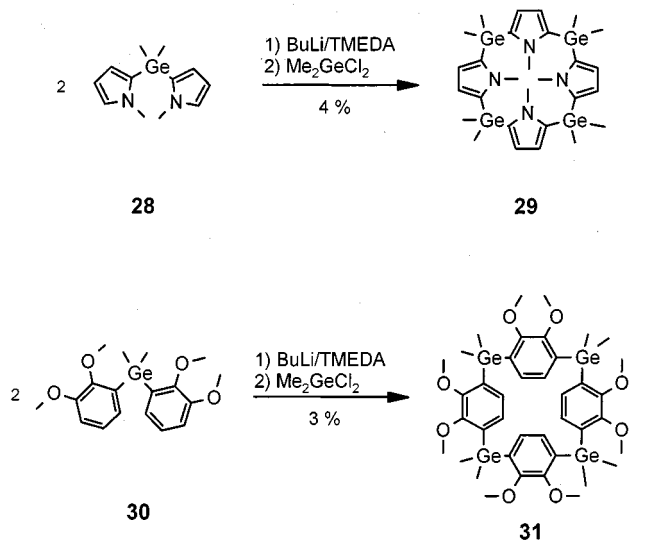
An extension of the synthesis to sila[1_4]paracyclophanes **14** or silicon-bridged calix[4]arenes **17** is possible by a two-step route: Aromatic anions, generated by *ortho*-lithiation, react with Me_2SiCl_2 to give silicon-bridged dimers **16** (Scheme 6). Double deprotonation of **16** generates the dianion for cyclization. Metal salt extraction experiments from aqueous solutions revealed a much smaller affinity towards the silicon-bridged macrocycles as compared to crown ethers. In some cases high selectivities were observed, but it was not possible to establish a rational structure-selectivity relationship.

Yoshida et al.[12] have obtained the unsubstituted parent trisilacalix[3]arene (trisila[1.1.1]*meta*-cyclophane) **19** and tetrasilacalix[4]arene **20** (tetrasila[1.1.1.1]*meta*-cyclophane) from 1,3-dibromobenzene (**18**), Me_2SiCl_2, and magnesium in 12 and 2% yield, respectively (Scheme 7). The X-ray structure analysis revealed that **19** adopts a saddle structure and **20** a 1,2-alternate structure in the solid state. An isomer of **19**, trisila[1.1.1]*ortho*-cyclophane, has been previously prepared by Sakurai et al.[13] Mass spectrometry showed that **19** and **20** do form complexes with silver cations. Association constants have not been reported.[12]

Scheme 6

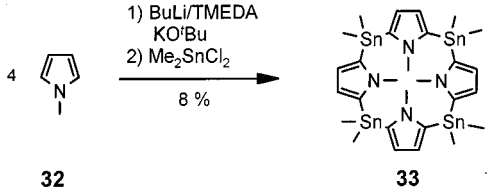


Scheme 7



A successful synthesis of silicon-bridged dicoordinate phosphorous macrocycles was reported by Mathey, Le Floch, and co-workers.[14] They used a previously established, versatile route to phosphinines[15] based on the [4+2] cycloaddition of alkynes with 1,3,2-diazaphosphanes for the synthesis. The 1,3,2-diazaphosphinine **21** was first allowed to react with a threefold excess of dialkynylsilane to give **22** in 60 to 70% yield (Scheme 8). Next, compound **22** was allowed to react with two equivalents of diazaphosphinine **21** to give **23**. Under high dilution conditions **23** reacted with one equivalent of **22** to give the calix[4] derivative **24** or the calix[3] derivative **25** under similar conditions, both in 20% yield. The macrocycles act as ligands with strong π-acceptor properties. From compound **24** the rhodium and iridium complexes **26a** and **b** have been prepared and from macrocycle **25** the $W(CO)_3$ complex **27**. Reaction of **24** with AuI gave the first macrocyclic gold(I) complex **26c**, which can be reduced with sodium or potassium to a paramagnetic gold(0) complex.[14c]

2.2 Germanium



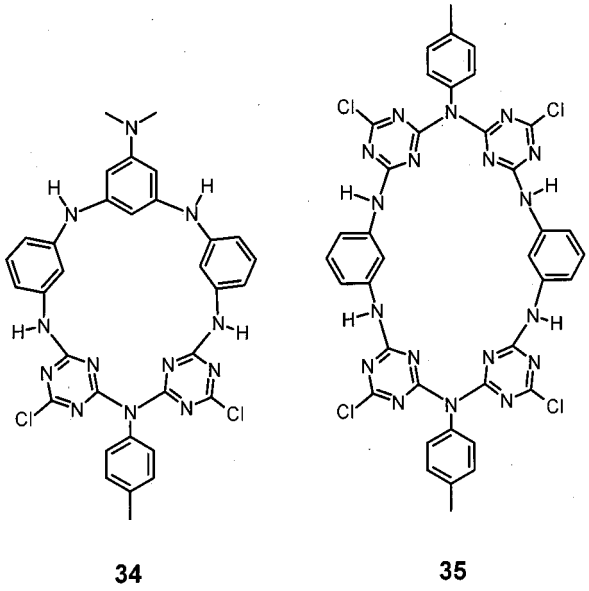
Extension of the reaction of the bis(carbanions) with Me_2SiCl_2 to Me_2GeCl_2 revealed significant differences: While the reaction of monolithiated heterocycles, such as furan, thiophene or *N*-methylpyrrole with Me_2GeCl_2 gave Me_2Ge-bridged dimers in good yield, the reaction of 2,5-dianions with Me_2GeCl_2 mostly yielded a mixture of linear oligomers instead of macrocycles. However, reaction of stoichiometric amounts of Me_2GeCl_2 with the 5,5′-dianion of **28** and **30** gave macrocycles **29** and **31**, respectively (Scheme 9), both in low yield.[16] The reaction of other dianions of Me_2Ge-bridged aromatic and heteroaromatic

Scheme 8

Scheme 9

Scheme 10

dimers yielded mixtures of linear oligomers exclusively. The size and distribution of the oligomers was investigated by gel permeation chromatography. The monomodal distribution in all cases indicates a regular, unbranched structure for the oligomers, with an average size being from 4 to 17 repeating units. The UV spectra of Me_2Ge- and Me_2Si-bridged arenes and heteroarenes show a small, but distinct bathochromic shift of λ_{max} with increasing molecule size. The extent of this shift differs only slightly for Me_2Si- and Me_2Ge-bridged molecules, which shows the similar abilities of these elements to electronically link the π-systems by σ-conjugation.[17]

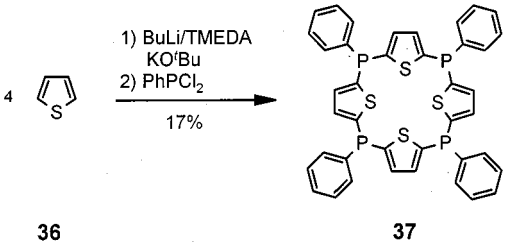


2.3 Tin

Tin can substitute for silicon or germanium in the macrocycles. Compound **33** was synthesized from the *N*-methylpyrrol dianion and Me_2SnCl_2 as described before (Scheme 10).[11b] The nearly identical NMR spectra of **33** and **12** indicate similar structures for both compounds. However, macrocycle **33** is rather unstable and decomposes rapidly if stored in air.

3. Group VA Elements

3.1 Nitrogen

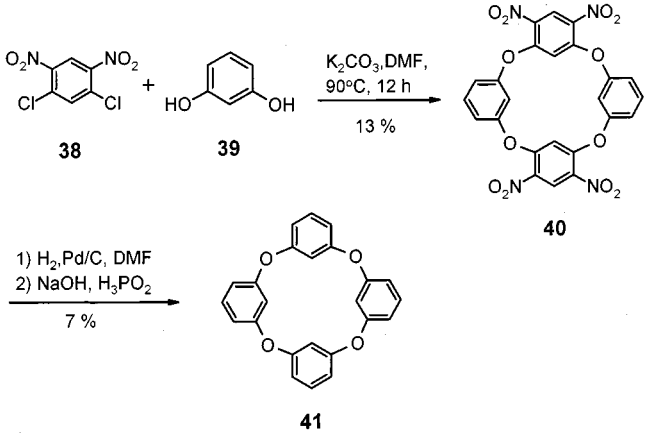


The nitrogen-bridged macrocycles **34** and **35** with aromatic subunits have been obtained from the reaction of trichlorotriazene with primary amines and diamines in stepwise procedures (Scheme 11).[18,19] The synthetic strategy allows for the incorporation of a wide variety of substituents. A first example of nitrogen-bridged calixarenes of structure **5** with X = NCH_3 (n = 1) has been reported in the literature very recently,[20] but so far no information about the binding properties is available. The advances in methods for the formation of nitrogen−carbon bonds to arenes[21] makes it likely that many more such compounds will soon be available.

Scheme 11

3.2 Phosphorus

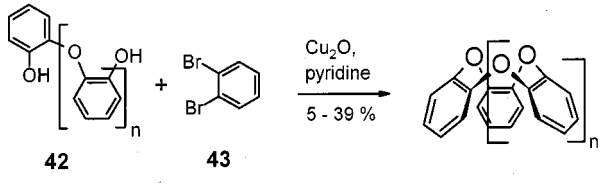
The reaction of $PhPCl_2$ with the 2,5-dianion of thiophene gave macrocycle **37** in 17% yield (Scheme 12).[11b] The ^{31}P resonance shows the formal oxidation level to be +3 for the phosphorus bridge. However, the sensitivity of the compound towards oxidation did not allow for metal extraction studies.



36 **37**

Scheme 12

4. Group VIA Elements

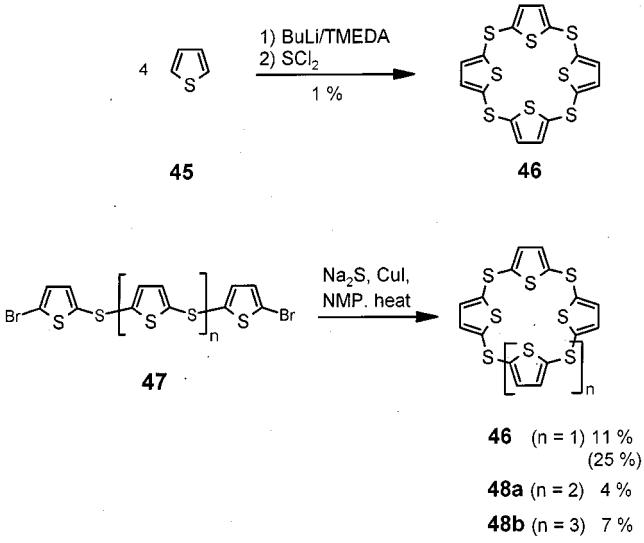


4.1 Oxygen

Several oxygen-bridged calixarenes have been prepared. Such compounds, which can be described as fully aromatic crown ethers, have been prepared to investigate the influence of a more rigid structure and less basic binding sites on the binding selectivity of crown ethers towards metal cations. The synthesis uses either nucleophilic aromatic substitution of activated arenes[22] (Scheme 13) or Ullmann-type reactions of bis(hydroxyaryl) ethers **42** with 1,2-dibromobenzene (**43**) in the presence of copper salts and pyridine (Scheme 14).[23] The structure of **44** with $n = 1$ has been determined in the solid state and was found to have a C_2-symmetric saddle form. Crown compounds **44** (n = 4,5) were tested by extraction methods for their extraction abilities, but no complexes were formed with lithium, sodium, potassium, calcium, or ammonium cations.

38 **39** **40** **41**

Scheme 13



42 **43** **44**

Scheme 14

4.2 Sulfur

A large variety of sulfur-bridged calixarenes and heterocalixarenes have appeared in the literature. A simple extension of the previously described synthesis via 2,5-dilithiothiophenes to bis(electrophiles), such as SCl_2 yields thiacalix[4]arene **46**, although in very low yield (Scheme 15).[24] The reaction of dibromo derivatives of linear sulfur-bridged thiophenes with Na_2S and copper salts in NMP as reported by Nakayama et al. gave access to **46** in higher yield and gave larger thiacalixarenes **48**.[25]

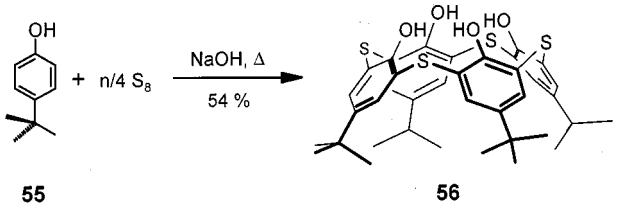
48b (n = 3) 7 %

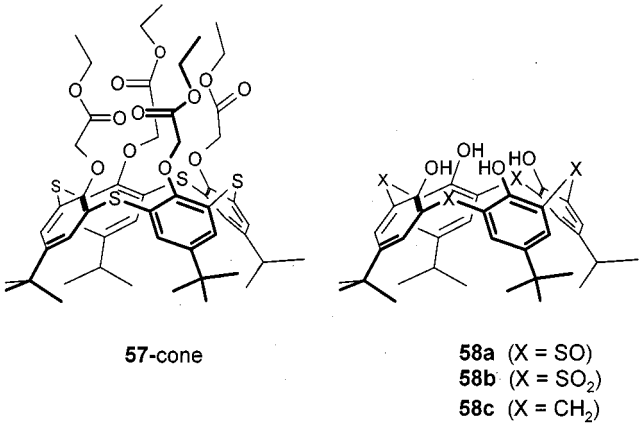
Scheme 15. Synthesis of sulfur-bridged thiacalixarenes; the yield of compound **46** increases to 25% if CuI is replaced by Cs_2CO_3



The reaction of *para*- or *meta*-dichlorobenzene or -dibromobenzene and sodium sulfide results in the formation of linear polyphenylene sulfides that contain small amounts (ca. 3%) of sulfur-bridged macrocycles of various ring sizes. From the low molecular weight fractions, several macrocycles, such as **50** or **52a**, with 3−6 benzene units have been isolated by extraction, chromatography and recrystallization, and characterized spectroscopically (Scheme 16).[26] An X-ray structure analysis has been reported for compound **52a**. The analogous thiacalix[3]pyridine **52b** was obtained from intermolecular condensation of 6-chloropyridine-2-thione in the presence of P_2S_5, but no yield was reported.[27] In 90% yield a sulfur-bridged calix[3]azine **54** was synthesized from 6-*tert*-butyl-2,4-dichloro-1,3,5-triazine (**53**) and Na_2S in dioxane. The X-ray analysis of the molecule revealed a surprisingly flat structure with each triazine

ring participating in π-stacking interactions with neighboring molecules.[28]

Scheme 16



Most reports have appeared on the synthesis and properties of tetrahydroxytetrathiacalix[4]arenes. The synthesis of tetrahydroxy-*para-tert*-butyltetrathiacalix[4]arene (**56**) starts from *para-tert*-butylphenol (**55**), as in the parent methylene-bridged system. Heating of **55** with elemental sulfur and NaOH in tetraethylene glycol dimethyl ether results in the

Scheme 17

formation of **56** in 54% yield (Scheme 17). Small amounts of the corresponding thiacalix[5]- and thiacalix[6]arenes were isolated by HPLC.[29] The synthesis of all possible isomers of *para-tert*-butylcalix[4]arenes in which methylene bridges were partly replaced by sulfur linkages has also been reported.[30] The X-ray structure analysis of **56** shows the inclusion of dichloromethane in the cavity under the conditions of crystallization. The molecule has a cone conformation in the solid state.[31] The compound is an interesting ligand for metal ion coordination. An antiferromagnetic copper complex with copper acetate is obtained in DMF. The X-ray structure analysis shows a square cluster of four copper(II) ions with phenoxy and sulfur bridges sandwiched between two fully deprotonated calixarenes, thus forming a ditopic, divergent receptor.[32] Zinc(II) ions are coordinated by the bridging sulfur atom and the phenolic oxygen atom to form a complex coordination structure.[33] The high affinity of **56** for transition metal ions was also demonstrated by quantitative extraction of Co^{2+}, Cu^{2+}, and Zn^{2+} salts from the aqueous phase into chloroform.[34] Alkylation of the hydroxy groups of tetrahydroxythiacalixarenes has been used to lock the macrocycle conformation and thereby tune complexation properties. Depending on the counterion of the base used in the alkylation reaction, the conformer distribution is altered from the cone as the major product with sodium ions to the 1,3-alternate conformation with cesium ions present. The results suggest that a template effect is the main controlling factor. X-ray structure analysis of the 1,3-alternate conformer showed the formation of channels in the solid state.[35] NMR investigations showed a higher conformational flexibility for the tetraethyl ether of thiacalix[4]arene in comparison with the methylene-bridged calixarene. The larger cavity of the sulfur-bridged macrocycle is a likely rationale for this observation.[36] Extraction studies with the different conformers of tetrakis[(ethoxycarbonyl)methoxy]-thiacalix[4]arene **57** (Scheme 18) showed a higher affinity of the cone conformer for sodium ions, whereas the 1,3-alternate conformer extracts preferentially potassium and rubidium ions. The extraction ability of the partial cone conformer was found to be lower for all metal ions.[37] The stoichiometry of the complex of cone-**57** with sodium ion was determined to be 1:1 with the stability constant of $10^{2.85}$ L mol^{-1} in 50% (v/v) $CDCl_3/CD_3OD$. For details of percentage cation extracted and experimental conditions, see ref.[37]

Water-soluble sulfonated tetrathiacalix[4]arenes have been used for the removal of small halogenated organic substances, such as CH_2Cl_2 or $CHCl_3$, from water. By formation of a ternary complex of the negatively charged thiacalixarene, an anion-exchange resin and the halogenated organic compound, almost perfect removal of organic pollutants, with removal rates of more than 99.9% from water, was achieved.[38] Thiacalix[4]arene derivatives, which are modified with di- and tridansyl moieties, have been prepared to investigate their metal-sensing abilities in aqueous solution. Such molecules with two dansyl groups are able to detect metal cations in aqueous solution by variation of the fluorescence intensity, but observed selectivities are low.[39]

Scheme 18

Oxidation of **56** with H_2O_2 in glacial AcOH yielded sulfonylcalixarene **58b** in 59% yield (Scheme 18). The X-ray analysis revealed the formation of a three-dimensional network of hydrogen bonds between the OH and SO_2 groups, whereby the calixarenes adopt a 1,3-alternate conformation.[40] Stepwise oxidation of **55** to sulfinyl- and sulfonylcalix[4]arenes was achieved with stoichiometric amounts of $NaBO_3$ in chloroform.[41] Extraction experiments (see Table 1) showed that sulfonylcalix[4]arene **58b** completely lost the ability of thiacalixa[4]arenes, such as **56**, to extract transition metal ions. With **58b**, alkaline earth metal ions, in particular Ca^{2+}, are extracted. Interestingly, sulfinylcalixarene **58a** shows affinity for both transition and alkaline earth metal ions in extraction experiments.[41]

Table 1. Percentage of extracted transition metal and alkaline earth metal cations by calixarenes from the aqueous phase into chloroform; for detailed experimental conditions, see ref.[41]

Compound	Transition metal (pH = 8.0)			Alkaline earth metal (pH = 10)			
	Co^{2+}	Ni^{2+}	Cu^{2+}	Zn^{2+}	Mg^{2+}	Ca^{2+}	Ba^{2+}
58c	5	1	1	6	0	0	3
56	99	97	99	99	1	0	7
58a	99	99	17	99	99	91	99
58b	9	2	4	10	60	100	80

Conclusion

The introduction of heteroatoms as bridging atoms in calixarene macrocycles offers additional opportunities to modify their properties, affinity and selectivity for binding ions or molecules. So far, the number of known heteroatom-bridged calixarenes is still rather limited compared with carbocyclic calixarenes, and the relation of macrocyclic structure to selectivity of binding is obvious in only very few cases. However, if ongoing research in this field will provide the knowledge to better predict binding properties, as it is the case for crown ethers and cryptands, designed heteroatom-bridged calixarenes will have the potential to serve as selective ionophores and host molecules for many applications.

Acknowledgments

Support of our own work on heteroatom-bridged macrocycles from the Fonds der Chemischen Industrie is acknowledged. M. H. F. thanks the Deutscher Akademischer Austauschdienst (DAAD) for a scholarship.

Reactivity of Copper(I) Complexes Towards Dioxygen

Siegfried Schindler*[a]

Keywords: Copper / Oxygen / Bioinorganic chemistry / Tripodal ligands / Peroxo complexes

Efforts to model the reactions of copper enzymes with dioxygen with low molecular weight complexes have been quite successful during recent years. Guided by Nature, intriguing model systems for the active sites of such proteins have been developed. In the course of these investigations, it has been discovered that a whole variety of copper–dioxygen adducts form when simple copper(I) complexes are oxidized with dioxygen. The course of these reactions depends on the temperature, the ligands present, and the solvent. The effects of these parameters (especially the effect of ligand modification) on the reactivity of copper(I) complexes towards dioxygen are discussed in detail in this review.

Introduction

Oxidations play important roles in biochemistry, industrial processes, and organic syntheses.[1] For example, controlled partial oxidation of hydrocarbons is necessary to convert petrochemical feedstock into industrial organic chemicals. For economic reasons, there is much interest in the chemical industry in the use of dioxygen as the primary oxidant. However, these processes depend greatly on metal catalysts to promote the rates and enhance the selectivities of the reactions.

Copper ions are found in the active sites of many redox-active metalloproteins that transport (hemocyanin) or transfer molecular oxygen [e.g. tyrosinase (an oxygenase), dopamine β-hydroxylase, or ascorbate oxidase].[2–9] A key step in these redox reactions is the activation of dioxygen upon binding at the active site prior to the reaction with a substrate (Equation (1)).

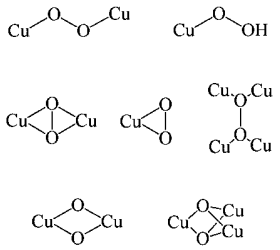
$$\text{Metalloenzyme or Metal Complex} \xrightleftharpoons{O_2} \text{Oxy-Form} \xrightarrow{\text{Substrate}} \text{Product} \qquad (1)$$

The interest in preparing low molecular weight model complexes for such copper enzymes is twofold. First, the models provide a better understanding of the biological molecules.[3,8] Second, they assist in the development of new catalysts for selective oxidations under mild conditions.[1,10] Therefore, it is of great interest to elucidate the factors that govern the (reversible) binding and activation of dioxygen in various natural oxygen transport systems, i.e. mono- and dioxygenases. Guided by Nature, intriguing model systems for the active sites of copper-containing dioxygen-binding enzymes have been synthesized. These systems are discussed here in detail.

Considerable effort has been directed towards the development of useful catalytic systems for mild and selective oxidations with dioxygen. The feasibility of this has recently been demonstrated with different model compounds for galactose oxidase. In the presence of these complexes, alcohols were catalytically oxidized to aldehydes.[11,12]

This review article gives an overview of the structurally characterized compounds that have been obtained by re-



Siegfried Schindler studied chemistry at the Technical University of Darmstadt where he received his Ph. D. with Prof. Horst Elias. He then worked as a postdoctoral fellow with Dr. Carol Creutz at Brookhaven National Laboratory, New York, USA. He began his Habilitation in the group of Prof. Rudi van Eldik supported by a DFG scholarship at the Private University of Witten/Herdecke in 1993, focussing on the activation of small molecules. In 1994, he moved to the University of Erlangen-Nürnberg where he completed his Habilitation in 1997. He was a visiting professor at the University of Odense, Denmark, in 1997 and at the University of Vienna, Austria, in 1999. His research interests are centred on synthetic and kinetic studies of the reactions of transition metal complexes with dioxygen, carbon dioxide, carbon monoxide, and nitrogen oxide.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

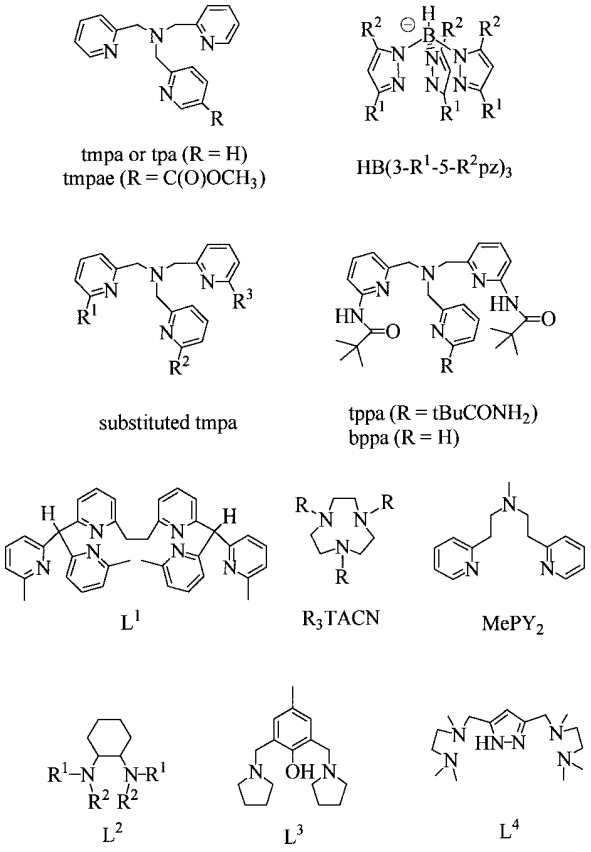
acting copper(I) complexes with dioxygen [or in some cases copper(II) complexes with hydrogen peroxide]. Coordination modes of "dioxygen" adopted in copper complexes that have been structurally characterized are shown in Scheme 1. More detailed information on these compounds can be found in the original references as well as in a series of review articles on various aspects of copper(I)/dioxygen chemistry.[3,8,10,13–15] Furthermore, this article deals with binding and activation of dioxygen in copper(I) complexes according to the first part of Equation (1). It details how this reaction can be optimized, mainly through ligand modification ("ligand tuning"), but also by varying reaction conditions such as concentration, solvent, and temperature.



Scheme 1. Dioxygen binding modes in structurally characterized copper complexes

Structurally Characterized Copper Peroxo, Superoxo, and Oxo Complexes

For a long time, copper–peroxo complexes were postulated as intermediates in the reaction of copper(I) complexes with dioxygen.[16,17] However, a structural characterization of such a complex was not available until 1988.[18] At that time, Karlin and co-workers synthesized and characterized a complex incorporating a *trans*-μ-1,2-peroxo-bridged dicopper(II) moiety.[18,19] It was obtained from the reaction of $[(tmpa)Cu(CH_3CN)]^+$ {tmpa = tris[(2-pyridyl)-methyl]amine, sometimes abbreviated as tpa; Scheme 2} with dioxygen. Shortly thereafter, a copper complex with a μ-η^2:η^2-peroxo bridge, prepared by the reaction of $[Cu\{HB(3,5\text{-}i\mathrm{Pr}_2pz)_3\}]$ [$HB(3,5\text{-}i\mathrm{Pr}_2pz)_3$ = hydrido-tris(3,5-isopropyl)pyrazolylborate anion, Scheme 2; $HB(3\text{-}R^1\text{-}5\text{-}R^2pz)_3$, $R^1 = R^2 = i\mathrm{Pr}$] with O_2 (or by careful addition of aqueous hydrogen peroxide to the μ-dihydroxo dimer complex $[Cu_2\{HB(3,5\text{-}i\mathrm{Pr}_2pz)_3\}_2(OH)_2]$) was described by Kitajima and co-workers.[3,20] Its spectroscopic features closely resembled those observed for oxy-hemocyanin, the oxygen-transport protein of arthropods and molluscs, which has a dinuclear copper center in its active site. The similarity of the model complex and the protein was confirmed soon afterwards when the crystal structure of the *oxy*-hemocyanin of *Limulus polyphemus* subunit II was solved.[2]

When $HB(3\text{-}t\mathrm{Bu}\text{-}5\text{-}i\mathrm{Pr}_2pz)_3$ [Scheme 2; $HB(3\text{-}R^1\text{-}5\text{-}R^2pz)_3$, $R^1 = t\mathrm{Bu}$, $R^2 = i\mathrm{Pr}$] was used instead of $HB(3,5\text{-}i\mathrm{Pr}_2pz)_3$ it was possible to isolate and structurally characterize a side-on bound superoxo copper complex.[21] To date, only one other X-ray crystal structure of a copper–superoxo complex has been reported by Jitsukawa, Masuda, and co-workers with a η^1 "end-on" superoxide

Scheme 2. Ligands used in structurally characterized copper–dioxygen adducts

stabilized by hydrogen-bonding interactions with the surrounding tppa ligand (tppa = tris{[6-(pivaloylamido)-2-pyridyl]methyl}amine; Scheme 2).[22] This finding was questioned by Tolman and co-workers, who showed that the published X-ray data had probably been misinterpreted.[13] It now seems more likely that a monocopper hydroxide was obtained rather than a superoxo complex.

When Jitsukawa, Masuda, and co-workers reacted $[Cu^{II}(bppa^-)]ClO_4$ or $[Cu^{II}(bppa)(CH_3COO)]ClO_4$ (bppa = bis[(6-pivaloylamido)-2-pyridylmethyl](2-pyridylmethyl)amine; Scheme 2) with hydrogen peroxide in acetonitrile, they obtained a mononuclear copper hydroperoxo complex, which was characterized by X-ray crystallography and resonance Raman spectroscopy.[23]

Recently, Kodera et al. succeeded in synthesizing and structurally characterizing a new dinuclear copper complex with a μ-η^2:η^2-peroxo bridge that proved to be unusually stable at room temperature (the half-life at 25 °C was reported to be 25.5 h).[24] This compound was obtained when the dinuclear complex $[Cu_2L^1](PF_6)_2$ (L^1 = 1,2-bis{2-[bis(6-methyl-2-pyridyl)methyl]-6-pyridyl}ethane; Scheme 2) was reacted with O_2 in dichloromethane.

An important finding with regard to understanding the reactions of copper(I) with dioxygen was reported by Tolman and co-workers.[13,14,25–29] Using substituted triazacyclononane (Scheme 2; R_3TACN), these authors showed for the first time that copper μ-η^2:η^2-peroxo-bridged complexes can undergo interconversion with bis(μ-oxo)dicopper(III)

complexes. These new species were characterized spectroscopically, and the crystal structures were solved for $[(BN_3TACN)_2Cu_2(\mu\text{-}O)_2]^{2+}$ (BN_3TACN = 1,4,7-tribenzyl-1,4,7-triazacyclononane) and $[(i\text{Pr}_4\text{-dtne})Cu_2(\mu\text{-}O)_2]^{2+}$ [$i\text{Pr}_4$-dtne = 1,2-bis(4,7-diisopropyl-1,4,7-triaza-1-cyclononyl)ethane, Scheme 4; L^7: X = *m*-xylyl].[13,14]

When copper(I)−MePY2 {MePY2 = *N,N*-bis[2-(2-pyridyl)ethyl]methylamine; Scheme 2} was reacted with dioxygen at low temperatures, $[(MePY2)Cu-(O_2)-Cu(MePY2)]^{2+}$ was obtained.[30] Its crystal structure reveals a geometry halfway between that of a side-on peroxide and that of a bis(μ-oxo) core. However, X-ray absorption and resonance Raman spectroscopy provided clear evidence that this does not describe the true structure. Thus, the crystalline material was in fact found to be a solid solution composed of approximately 20% of the bis(μ-oxo) core and 80% of the side-on peroxide isomer. A mixture of these two species was also observed in solution.[31]

Very recently, it has been shown that introduction of two 6-methylpyridyl groups into the tmpa ligand (substituted tmpa, R^1 = H, R^2, R^3 = Me; Scheme 2) prevents the formation of *trans*-μ-1,2-peroxo-bridged dicopper(II) species in a trigonal-bipyramidal structure, probably due to the steric requirements of the two 6-methylpyridyl groups. Instead, formation of a brown bis(μ-oxo)dicopper(III) complex, $[Cu_2(O)_2(Me_2\text{-tmpa})_2](PF_6)_2\cdot(CH_3)_2CO$, is observed, the crystal structure of which has been reported.[32]

Two further examples of oxo-bridged copper complexes with peralkylated 1,2-cyclohexanediamine ligands (L^2, Scheme 2; R^1 and R^2 = Me and/or Et) have been structurally characterized by Stack and co-workers.[33,34] With R^1 = Me and R^2 = Et, a $Cu_2(\mu\text{-}O)_2$ core almost isostructural with that of $[(BN_3TACN)_2Cu_2(\mu\text{-}O)_2]^{2+}$ was obtained, although the Cu···Cu distance was shorter by 0.05 Å.[34] Interestingly, with R^1 = R^2 = Me, a unique trinuclear cluster compound with two μ_3-oxide ligands and three copper ions was obtained.[33] The structure was formally described as a mixed-valence cluster of two copper(II) ions and a single copper(III) ion bridged by two μ_3-oxo ligands.

An example of an exceptionally stable copper−peroxo complex has been reported by Krebs and co-workers.[15,35,36] By reacting a mixture of 2,6-bis(pyrrolidinomethyl)-4-methylphenol (L^3, Scheme 2), copper(II) perchlorate, and triethylamine with hydrogen peroxide (or 3,5-di-*tert*-butylcatechol), these authors obtained a tetranuclear copper complex with the peroxo ligand bound end-on in a μ_4-$(\eta^1)_4$ mode. When the same reaction was performed in the absence of hydrogen peroxide (or 3,5-di-*tert*-butylcatechol), a tetranuclear copper−oxo complex with a μ_4-O^{2-} unit was formed. The crystal structures of the two complexes are closely related; there is also evidence to suggest that the two species are interconvertible.

A further new example of a tetranuclear copper complex with a slightly different μ_4-peroxo coordination has recently

been reported by Meyer and Pritzkow using a multidentate pyrazolate ligand (L^4, Scheme 2).[37]

Crystallographic and spectroscopic properties of the aforementioned copper−dioxygen adducts are summarized in Table 1.

Kinetics and Thermodynamics of Copper(I)/Dioxygen Interaction

As described above, copper superoxo, peroxo, and bis(μ-oxo) complexes are rather unstable and are therefore difficult to crystallize. Consequently, other methods have to be used to identify and characterize these species, especially when they are only short-lived oxidation intermediates. Oxidations with dioxygen can be followed by UV/Vis spectrophotometry (see below). However, this technique should not be used exclusively to characterize the complexes that are formed in these reactions. Instead, resonance Raman spectra should also be recorded. This method allows detailed insight into the binding mode of the dioxygen.[30,33,34,38]

Among the most powerful tools for detailed investigations of bioinorganic transformations are kinetic studies.[10,39] Among the first researchers to investigate the oxidation of copper(I) complexes with dioxygen in water were Zuberbühler and co-workers.[16] Although dioxygen complexes could not be detected spectroscopically at first, unstable copper−dioxygen intermediates were postulated.[16,17] In a number of cases, kinetic evidence clearly implied the intermediacy of CuO_2^+ and $Cu_2O_2^{2+}$ species.[16] However, no information concerning their stabilities, spectroscopic properties, or structures was available. This situation improved dramatically when it was discovered that $[(tmpa)Cu(CH_3CN)]^+$ reacts with dioxygen to form a copper−peroxo complex that is stable at low temperatures (see above). After detailed kinetic investigations, a mechanism for the reaction of $[(tmpa)Cu(CH_3CN)]^+$ with dioxygen was postulated (Equations (2)−(4); L = tmpa).[40] Most importantly, for the first time it was possible to spectroscopically detect the formation of a superoxo complex (Equation (2)) prior to the formation of a peroxo compound.

$$[(L)Cu(RCN)]^+ + O_2 \rightleftharpoons [(L)Cu(O_2)]^+ + RCN \quad (2)$$

$$[(L)Cu(RCN)]^+ + [(L)Cu(O_2)]^+ \rightleftharpoons [(L)Cu(O_2)Cu(L)]^{2+} + RCN \quad (3)$$

$$[(L)Cu(O_2)Cu(L)]^{2+} \longrightarrow \text{irreversible decay} \quad (4)$$

Since most of these reactions are very fast, their kinetic investigation requires special low-temperature stopped-flow instruments operating with diode-array techniques. Furthermore, data fitting of the obtained time-resolved UV/Vis spectra is only possible with modern global fitting routines (including all data sets and spectra of intermediates).[17] These methods allow the determination of multi-step kinetic mechanisms, including kinetic and equilibrium constants, and the elucidation of complete UV/Vis spectra of intermediates.

A recent review article describes the kinetics and thermodynamics of the copper(I)/dioxygen interaction.[17] Therefore, only selected aspects concerning this particular interaction are mentioned in the present article, together with some new findings.

As mentioned above, copper μ-η^2:η^2-peroxo-bridged complexes are capable of interconversion with bis(μ-oxo)-dicopper(III) compounds. A kinetic study has shown that there is a rapid equilibrium between these two species (ligand R_3TACN, R = *i*Pr; Scheme 2).[28,41] Furthermore, it has been proposed that the oxygenation involves rate-determining formation of a mononuclear superoxo complex followed by a faster reaction with a second molecule of the monomeric copper(I) complex.

Dinuclear copper(I) complexes have been synthesized by linking mononuclear units as described below, in the hope that these "pre-organized" systems would stabilize the copper−peroxo unit. Kinetic measurements showed that this could indeed be achieved, but that this approach only works when the linked mononuclear units are not under any strain.[13,14,17,29,42−45] A linker that introduces steric strain leads to intermolecular rather than intramolecular formation of copper−peroxo complexes. Consequently, the dinuclear peroxo complexes should not be more stable than those obtained from the mononuclear compounds. This was confirmed in principle, but it was also observed that intermolecular oxidation can lead to quite stable polynuclear copper−peroxo complexes.[43]

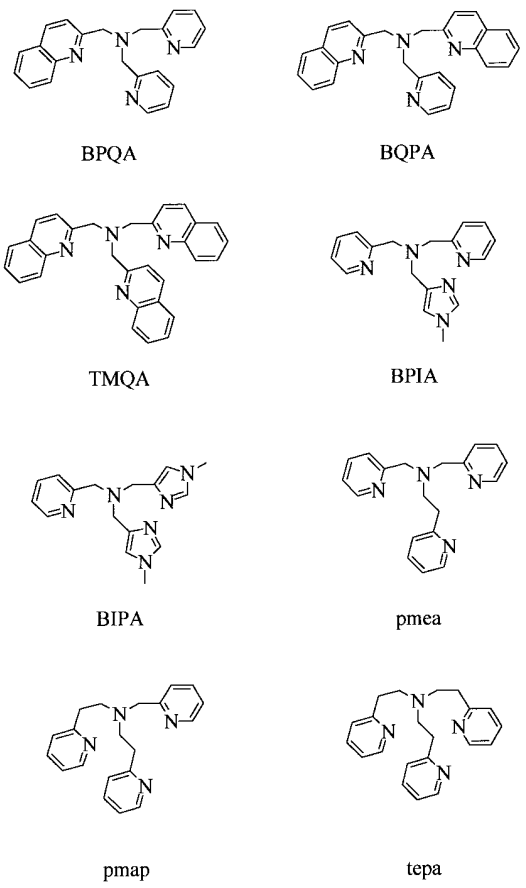
Recently, the author's group succeeded in carrying out kinetic investigations on the reaction of a dinuclear copper(I) complex, $[Cu_2-H-XYL-H]^{2+}$ (ligand H−XYL−H is shown in Scheme 8), with dioxygen under high-pressure conditions.[46] This study turned out to be quite a challenge because the reaction of the oxygen-sensitive compound could only be investigated in organic solvents at low temperatures by means of stopped-flow techniques *and* under high pressure (this was accomplished using a high-pressure stopped-flow unit assembled in-house). For the first time, activation volumes for the formation $\Delta V^{\#} = -15.0 \pm 2.5$ cm^3/mol (as well as for the back reaction, $\Delta V^{\#} = +4.4 \pm 0.5$ cm^3/mol) and the decomposition ($\Delta V^{\#} = -4.1 \pm 0.7$ cm^3/mol) of a dinuclear copper−peroxo complex were obtained. Furthermore, solvent effects on this reaction were investigated. The reaction mechanism in acetone was shown to be more complicated than that in dichloromethane owing to an additional equilibrium between the dinuclear copper(I) complex and a less reactive isomer.

It should be pointed out that while there are clearly many similarities between dinuclear copper(I) complexes and hemocyanin, there are also many differences. For example, the reaction of the dinuclear copper(I) complex $[Cu_2-H-XYL-H]^{2+}$ (Scheme 8) with dioxygen is pressure dependent while that of deoxy-Hc is not.[46,47] More importantly, the oxidation of the protein proceeds very rapidly in water, while the model complexes investigated to date could only be studied in organic solvents.[48] Moreover,

when the protein is reacted with carbon monoxide it only binds one molecule, clearly indicating that the two copper(I) sites are differently shielded towards the reaction with substrates. The model complexes studied thus far bind one carbon monoxide molecule per copper(I) ion.[49]

General Approach

To optimize the reactions of copper(I) complexes with dioxygen in order to obtain stable copper−dioxygen adducts, most research groups follow a similar general strategy.



Temperature variation offers an important means of stabilizing copper superoxo, peroxo, or bis(μ-oxo) complexes. Thus, while many of these compounds are unstable at room temperature, they can be stored at low temperatures for months and can be isolated under these conditions. For example, by working at −80 °C, Karlin and co-workers were able to isolate and structurally characterize the first copper−peroxo complex.[18] For this reason, many studies on the behavior of copper(I) complexes towards dioxygen are performed using low-temperature techniques.[14,17,28,46,50] In principle, it should also be possible to bring about some of the temperature effects through pressure changes. However, for the relevant systems it is quite difficult and often impossible to accomplish pressure changes with the given experimental set-ups.

The most important method for modulating the reaction behavior of copper(I) complexes is modification of their ligands, either by introducing different donor atoms, changing chelate ring sizes, or using substituents that can influence the ligand sterically or electronically. Moreover, mononuclear units can be linked to form larger pre-organized ligand systems. This review is mainly focussed on how these chemical modifications affect the reactivity of copper complexes towards dioxygen. Quite recently, theoretical calculations have been used to predict the structures and/or reactivities of promising copper complexes (see below). Furthermore, the solvent can play an important role in the reaction of copper(I) complexes with dioxygen.

In general, a detailed study starts with a copper(I) complex that shows an interesting reaction behavior towards dioxygen. A detailed kinetic investigation is then undertaken and, in some cases, theoretical calculations are performed. The results are used to chemically modify the ligand in order to optimize the desired transformation.

Copper(I) Complexes with Tripodal Ligands Derived from tmpa

As discussed above, the tripodal complex $[Cu(tmpa)(CH_3CN)]^+$ has proved to be very useful for studying the reactions of copper(I) complexes with dioxygen. In order to gain further insight into these transformations, tmpa has been chemically modified and the resulting effects have been investigated.

Scheme 3. tmpa and derivatives

Karlin and co-workers replaced the pyridine moieties with sterically more demanding quinolyl groups in a stepwise manner. This yielded the ligands BPQA [bis(2-pyridylmethyl)(2-quinolylmethyl)amine], BQPA [bis(2-quinolylmethyl)(2-pyridylmethyl)amine], and TMQA [tris(2-quinolylmethyl)amine] shown in Scheme 3.[40,51] On going from tmpa to TMQA, dramatic differences in the reactivities of the corresponding copper(I) complexes towards dioxygen were observed. A detailed kinetic study showed that when $[Cu(BPQA)]^+$ was reacted with dioxygen at low temperatures, only the peroxo complex $[(BPQA)Cu(O_2)Cu(BPQA)]^{2+}$ could be detected; the formation of a superoxo complex was not observed under these conditions. In contrast, although reaction of $[Cu(BQPA)]^+$ with dioxygen led initially to the peroxo complex, this then immediately formed the 1:1 adduct, i.e. the superoxo complex $[(BQPA)Cu(O_2)]^+$. In the case of $[Cu(TMQA)]^+$, no interaction with dioxygen was observed.[40] According to the authors, steric effects are the most important factors in rationalizing these variations in reactivity.

Similar effects have been observed upon the successive introduction of three methyl groups at the 6-positions of the three pyridine moieties of tmpa (Scheme 2; substituted tmpa: R^1, R^2, R^3 = CH_3 or H).[52,53] As discussed above, with Me_2tmpa as ligand a bis(μ-oxo)dicopper(III) complex was obtained.[32] However, no detailed kinetic study has yet been performed.

Furthermore, the introduction of three phenyl groups at the 6-positions of the three pyridine moieties of tmpa renders the resulting copper(I) complex (Scheme 2; substituted tmpa: R^1, R^2, R^3 = phenyl) inert towards dioxygen.[54]

The introduction of steric hindrance in the tris(pyrazolyl)borate ligand [$HB(3\text{-}R^1\text{-}5\text{-}R^2pz)_3$, Scheme 2] allowed the synthesis and structural characterization of a copper−superoxo complex (see above).[21] Using the same approach, Jitsukawa, Masuda, and co-workers introduced three pivalolylamino groups at the 6-positions of the pyridine moieties of tmpa (Scheme 2; tppa). They hoped that the increased steric hindrance would lead to the formation of a copper−superoxo (1:1 adduct) instead of a peroxo complex.[22,55,56] Although these authors claimed to have structurally characterized a superoxo complex $[(tppa)Cu(O_2)]^+$, there is strong evidence that the described compound was actually $[(tppa)Cu(OH)]^+$ (see above).[57] Using bppa (Scheme 2), the same researchers were able to isolate and structurally characterize a copper−hydroperoxo complex (see above). Here, the hydroperoxo ligand is stabilized by hydrogen bonding.[23]

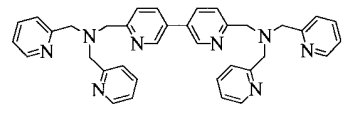
Karlin and co-workers also synthesized copper(I) complexes with tripodal ligands incorporating imidazolyl donor groups rather than pyridine (BPIA = {bis[(2-pyridyl)methyl(1-methylimidazol-2-yl)methyl]amine}; BIPA = {bis[(1-methylimidazol-2-yl)methyl]-(2-pyridyl)methylamine}, Scheme 3).[58] Interestingly, these complexes are dinuclear as solids, but dissociate into mononuclear species in solution. When $[Cu(BPIA)]^+$ was reacted with dioxygen at low temperatures, it exhibited very similar UV/Vis spectroscopic features to those of the parent $[(TMPA)Cu(RCN)]^+$, as well as of the quinolyl-containing $[Cu(BPQA)]^+$. For this reason, the formation of the peroxo complex $[(BPIA)CuO_2(BPIA)]^{2+}$ with a *trans*-(μ-1,2 peroxo) dicopper(II) moiety was postulated. This indicates that when one of the three pyridyl rings is substituted by some other donor group, the steric and electronic environment around the copper(I) center remains the same. However, when two pyridine groups are substituted by two imidazole donors, the copper−dioxygen chemistry becomes greatly altered. When $[Cu(BIPA)]^+$ was exposed to dioxygen at low temperatures in propionitrile, a red species was formed. It could not be fully characterized as it proved to be unstable under these conditions. Its UV/Vis spectrum was similar to that of the μ-η^2:η^2-peroxo compound $[\{HB(3,5\text{-}i\text{Pr}_2pz)_3\}Cu(O_2)Cu\{HB(3,5\text{-}i\text{Pr}_2pz)_3\}]$ described above. However, the molar extinction coefficients were much lower, probably owing to rapid decomposition of the red compound. In view of the lack of further evidence, these results that are based on UV/Vis measurements alone must be treated with caution.

Clearly, all these studies on Cu^I and Cu^{II} species with similar ligands show that small changes in ligand architecture can have a strong influence on the reactivity. In the active sites of enzymes, the nature of the ligand donors plays an important role in forcing the metal ions to participate in the desired biochemical transformations. Thus, further studies of ligand variations should provide valuable insights into fundamental aspects of biologically relevant coordination chemistry. With this in mind, it was decided to compare the reactivity of copper(I), copper(I)/O_2, and copper(II) complexes of other tripodal ligands derived from tmpa.[59]

On coordination of tmpa to copper ions, five-membered chelate rings are formed. If the carbon chain lengths in tmpa are increased by the introduction of pyridineethyl instead of pyridinemethyl groups, the ligands pmea {*N*,*N*-bis[(2-pyridyl)methyl]-2-(2-pyridyl)ethylamine}, pmap {*N*,*N*-bis[2-(2-pyridyl)ethyl]-(2-pyridyl)methylamine}, and tepa {tris[2-(2-pyridyl)ethyl]amine} are obtained (Scheme 3). Recently, the copper(I) and copper(II) complexes of pmea and pmap have been structurally characterized in this laboratory;[59] the copper(I) and copper(II) complexes of tmpa and tepa have been described previously.[19,60−62] In the case of tmpa and tmpae (Scheme 2), the copper(I) complex normally crystallizes in a trigonal-bipyramidal geometry with an additional acetonitrile molecule in the axial position.[19,60] This is not the case when the sterically demanding triphenylphosphane is used as an additional ligand.[19] The trigonal-bipyramidal geometry of $[(tmpa)Cu(CH_3CN)]^+$ is retained when this compound is oxidized with dioxygen to give a copper(II)−peroxo complex.[19] Furthermore, the copper(II) complex $[(tmpa)CuCl]^+$ is structurally very similar to the peroxo complex.[19,61] That the trigonal-bipyramidal geometries of the copper(II) complexes are retained in solution was confirmed by UV/Vis and EPR measurements.[19] In contrast, neither Cu^I nor Cu^{II} complexes of pmea, pmap, or tepa are trigonal bipyramidal.[59,61,62] The copper(I) complexes are best described as distorted tetrahedra without any additional ligands. The copper(II) complexes show distorted square-pyramidal geometries.

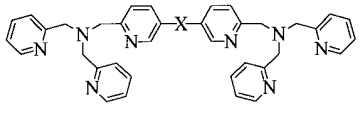
These differences are reflected in the reaction behavior towards dioxygen. While $[(tmpa)Cu(CH_3CN)]^+$ is oxidized at low temperatures to give a stable peroxo complex, this is not the case for any other compound of this series.[59] When $[(pmea)Cu]^+$ is reacted with dioxygen at low temperatures, only a very unstable peroxo complex is produced. With $[(pmap)Cu]^+$, no such intermediate is detected during oxidation; $[(tepa)Cu]^+$ does not react with dioxygen.[59] From these findings, it is clear that in this series of complexes an increase in chelate ring size leads to a dramatic destabilization of the copper−dioxygen adducts.

A similar effect has been observed on increasing the carbon chain lengths in tren [tren = tris(2-aminoethyl)amine; Scheme 5]. As discussed below, it proved impossible to isolate crystals of a copper(I) complex with tren, because at higher concentrations this compound undergoes disproportionation to copper(II) and copper metal.[50] However, using $N[(CH_2CH_2CH_2NH_2)_2CH_2CH_2NH_2]$ or $N(CH_2CH_2CH_2NH_2)_3$, the copper(I) complexes could be isolated and structurally characterized.[63] Again, it was found that in contrast to the other complexes of this series, the copper(I) complex with $N(CH_2CH_2CH_2NH_2)_3$ as ligand is stable towards dioxygen, similar to $[(tepa)Cu]^+$ de-



scribed above. Crystal structures of the copper(II) complexes of these ligands have been reported.[64]

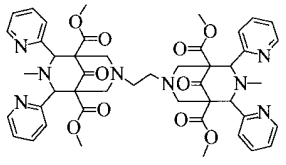
Linking Mononuclear Units and Theoretical Calculations



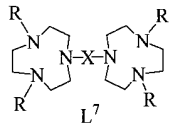
The studies on the oxidation of copper(I) complexes with tmpa-like ligands clearly demonstrate that the copper−peroxo complex with tmpa is most stable. Therefore, it should be possible to optimize this reaction by chemically connecting two tmpa units to a pre-organized dinuclear copper(I) site.

An interesting approach in this regard was the use of bipyridine as the "bridging" unit. The resulting ligand btmpa (6,6′-bis{[bis(2-pyridylmethyl)amino]methyl}-2,2′-bipyridine, also abbreviated as btpa) is shown in Scheme 4. Crystal structures of its dinuclear copper(II) complexes have been published.[65,66] When the dinuclear copper(I) complex was reacted with dioxygen, only a very slow oxidation was observed; dioxygen intermediates could not be detected.[66,67] Karlin and co-workers rationalized this finding in terms of a steric hindrance created by the chelate sites, which influences the molecular geometry around the copper ions.[66] This causes the dinuclear copper complexes to exhibit spectroscopic and electrochemical properties dissimilar to those of their parent tmpa analogues.

In the light of these findings, it became clear that the two mononuclear units had to be separated by a real spacer.



btmpa (btpa)



$D^1 = -CH_2-CH_2-$

$L^5 = -CH_2-O-CH_2-$

L^6

L^7

Scheme 4. Ligands for the synthesis of dinuclear copper complexes

This was accomplished by linking two tmpae units (Scheme 2), giving rise to the ligand D^1 shown in Scheme 4 ($X = -CH_2CH_2-$).[42,43] The crystal structure of the dinuclear copper(I) complex shows that the bond lengths and angles at each copper(I) ion are very similar to those in the mononuclear units of the copper(I) complexes of tmpa and tmpae. A detailed kinetic study on the reaction of dioxygen with these complexes showed that there was a big difference between the behavior of the copper(I) complexes of tmpa and tmpae and that of the dinuclear complex, so that different reaction pathways must exist.[42,43]

While the formation of a copper−superoxo (dinuclear complex:O_2 = 1:1) and a copper−peroxo complex (1:1) could still be observed, the formation of a 1:2 superoxo complex and intermolecular copper−peroxo complexes was also detected. The intramolecular formation of $[(D^1)Cu_2(O_2)]^{2+}$ was found to be significantly faster than the generation of the corresponding 2:1 complexes $[(tmpa)Cu(O_2)(tmpa)]^{2+}$ and $[(tmpae)Cu(O_2)(tmpae)]^{2+}$, the latter being formed in an intermolecular fashion from mononuclear precursors. However, its structure seems to be strained. Therefore, the intermolecular arrangement of oligomeric peroxo complexes is preferred; in particular, a stable cyclic trimer is observed. As the authors point out, the Cu_2-O_2 μ-peroxo complex (or complexes) containing D^1 is (or are) in fact more stable than those of the mononucleating ligands tmpa or tmpea. However, it was not the naively expected intramolecular species $[(D^1)Cu_2(O_2)]^{2+}$, but rather highly associated Cu_2-O_2 compounds that formed in an intermolecular fashion (species that cannot possibly form with ligands such as tmpa and tmpae).

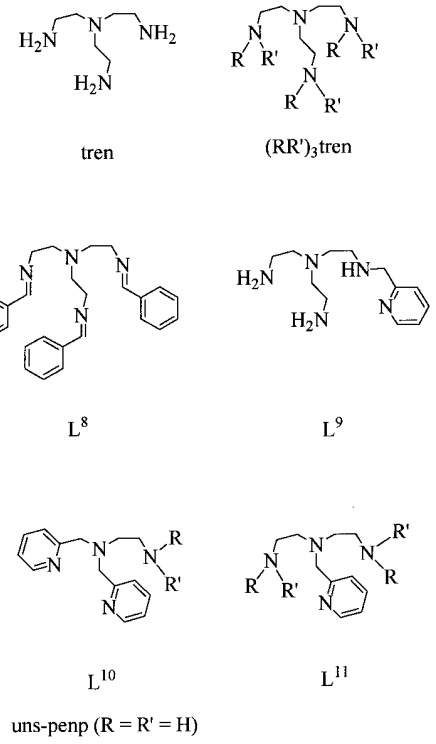
A combination of synthetic work and molecular mechanics modelling on these intramolecular copper−peroxo complexes with different spacer groups X (Scheme 4) led to the preparation of the ligand L^5 ($X = CH_2-O-CH_2$).[44][68] When the corresponding dinuclear copper complex was reacted with dioxygen, a relatively stable peroxo complex was formed, indicating that the longer linker arm in L^5 relieves the strain observed for $[(D^1)Cu_2(O_2)]^{2+}$ and significantly enhances adduct formation at room temperature.

The same approach of combining theoretical calculations with synthetic work for linking mononuclear units has been used by Comba and co-workers.[69] This group investigated the reaction of dioxygen with a mononuclear copper(I) complex {with the ligand methyl 2,4-bis(2-pyridinyl)-3,7-diazabicyclo[3.3.1]nonane-9-diol-1,5-dicarboxylate} and detected a quite stable peroxo compound. In order to further increase the stability of the oxygenation product, a linker for two of the mononuclear units had to be designed. Molecular mechanics modelling studies showed that an ethyl spacer would be most appropriate. The calculations were confirmed when a much more stable copper−peroxo complex was obtained after the dinuclear copper(I) complex of this ligand (L^6, Scheme 4) was reacted with dioxygen. In collaboration with this group, investigations of the oxidation of these complexes using low-temperature stopped-flow instrumentation have been started in this laboratory. A complex kinetic behavior has been observed, with several

dioxygen adducts being detected spectrophotometrically. As yet, these have not been unequivocally identified.[70]

Furthermore, theoretical calculations have been used to design a macrocyclic ligand (MEPY22PZ, Scheme 6) for a dinuclear copper(I) complex, which has again been shown to form a quite stable peroxo complex on reaction with dioxygen (see below).[71]

As discussed above, Kodera et al. successfully increased the stability of copper−peroxo complexes by linking mononuclear structures.[24] Indeed, they synthesized and structurally characterized the most stable dinuclear copper μ-η^2:η^2-peroxo complex (ligand L^1, Scheme 2) yet published.



The choice of the linker X in L^7 (Scheme 4) also influences the reaction pathways of the corresponding copper(I) complexes.[14] With X = $-CH_2-CH_2-$, only the bis(μ-oxo) core is obtained and there are no spectroscopic indications of the presence of a peroxo isomer. With the more expanded *m*-xylyl linker, complications occur because here again both intra- and intermolecular complex formation is observed.

Ligands Derived from tren

Because small changes in the ligand environment can have a dramatic effect on the reactivity of copper(I) complexes towards dioxygen, it is important to chemically vary the ligands in a systematic manner and to study the effects. One of the disadvantages of using tmpa and derivatives, as well as many other ligands described above, is the fact that chemical modification of these compounds can be difficult and time consuming. Therefore, a series of tripodal ligands that could be easily modified and then studied kinetically was sought.

As a starting material, tren (Scheme 5), an amine produced in industrial quantities, was chosen. It is a versatile tetradentate ligand, known to form trigonal-bipyramidal complexes with copper(II) ions in the solid state as well as in solution [similar to the copper(II) tmpa complexes discussed above]. One of the axial positions is occupied by the tertiary amine nitrogen, the other by water or some other monodentate ligand.[72−77] This geometry is important with regard to ligand substitution reactions because copper(II) complexes with tetragonal distorted geometry react very rapidly (approaching the diffusion limit), whereas copper(II) complexes with trigonal-bipyramidal geometry react much more slowly [this may be one of the reasons for the different reaction behavior of the copper(I) complexes with tmpa, pmea, and pmap discussed above].[76,78−82] Furthermore, tren can easily be modified to yield a whole family of tripodal ligands.

As yet, it has proved impossible to isolate crystals of a copper(I) complex with tren, because at higher concentrations this compound undergoes disproportionation to copper(II) and copper metal.[50] Nevertheless, dilute solutions of $[Cu(tren)]PF_6$ {or more likely $[Cu(tren)(RCN)]PF_6$} could be obtained by mixing stoichiometric amounts of $[Cu(CH_3CN)_4]PF_6$ and tren in propionitrile or acetone under inert conditions. Using low-temperature stopped-flow equipment, it was possible to detect spectrophotometrically the fast formation (faster than the mixing time of the instrument) of an unstable dioxygen adduct at −90 °C in propionitrile.[77] Its UV/Vis spectrum is very similar to that of the superoxo complex $[(tmpa)CuO_2]^+$ (characteristic absorbance at λ_{max} = 410 nm). Therefore, it is proposed that the complex $[(tren)CuO_2]^+$ had been formed. Owing to its instability, resonance Raman data that might have provided further evidence for the formation of a superoxo complex could not be obtained. The decomposition of this compound became faster on increasing the temperature; time-resolved spectra of this reaction at −70 °C are shown in Figure 1.

Scheme 5. tren and derivatives

In contrast to $[(tmpa)Cu(O_2)]^+$, which reacts with $[(tmpa)Cu(CH_3CN)]^+$ to yield $[(tmpa)Cu(O_2)Cu(tmpa)]^{2+}$ (Equation (3)), no copper tren peroxo complex could be detected under these conditions. Most probably, the superoxo complex reacts with protons provided by tren and a copper(II) complex and hydrogen peroxide are formed as final products. In tmpa copper(I) complexes, protons are not provided by the ligand and this reaction is not observed in propionitrile. In contrast, the formation of $[(tmpa)Cu(O_2)Cu(tmpa)]^{2+}$ is also dramatically disfavored when the reaction of $[(tmpa)Cu(CH_3CN)]^+$ with dioxygen is performed in methanol, a protic solvent. Furthermore, it was found that when acid was added to $[(tmpa)Cu(O_2)Cu(tmpa)]^{2+}$, a copper(II) complex and hydrogen peroxide were produced as the final products.[83] The structural characterization of a hydroperoxo complex discussed above lends further support to this alternative reaction pathway.

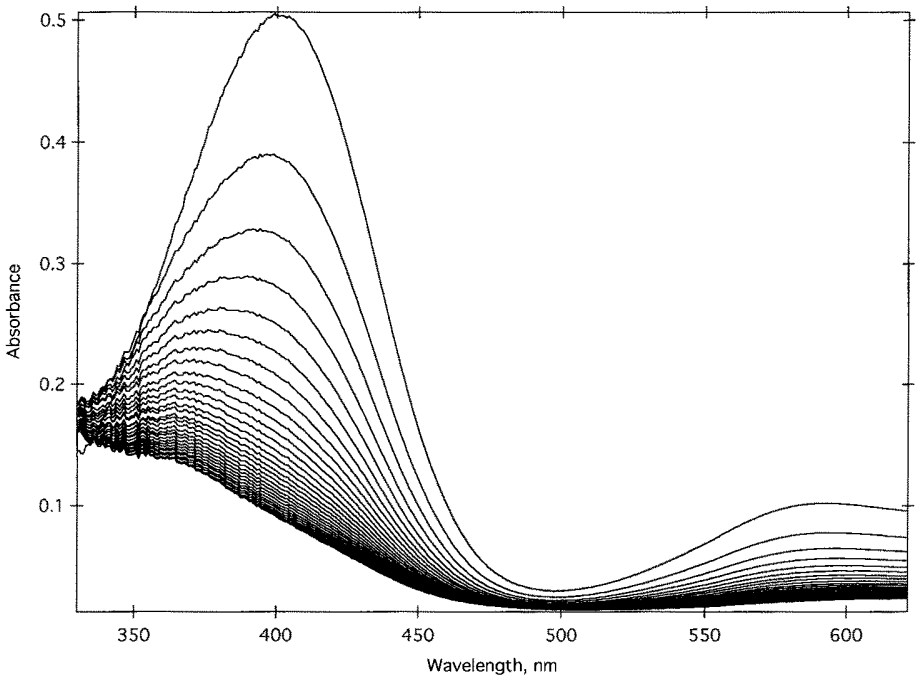


Figure 1. Reaction of $[(tren)Cu(RCN)]PF_6$ with dioxygen at −70 °C in dry propionitrile ([complex] = 0.26 mM, $[O_2]$ = 0.8 mM, Δt = 1.1 s)

To gain further insight into the reaction mechanism, Me_3tren [2,2′,2′′-tris(2-monomethylamino)triethylamine, Scheme 5; R = H, R′= Me] was synthesized. Once again, however, it proved impossible to isolate a solid copper(I) complex.[77] However, copper(II) complexes with Me_3tren could easily be synthesized and characterized.[76,77] First, the dinuclear species $[(Me_3tren)Cu-CN-Cu(Me_3tren)](ClO_4)_3$ was obtained, which is a further example of the few known $Cu^{II}-CN$ complexes.[76] Additionally, the trigonal-bipyramidal complex $[(Me_3tren)CuCl]ClO_4$ could be crystallized, which is structurally very similar to $[(tren)CuCl]ClO_4$.[77]

The reaction of a stoichiometric mixture of $[Cu(CH_3CN)_4]PF_6$ and Me_3tren in propionitrile with dioxygen at −90 °C also provided spectroscopic evidence for the superoxo complex $[(Me_3tren)Cu(O_2)]^+$. As in the oxidation of the copper(I) tren complex described above, a copper−peroxo complex was not observed under these conditions. However, there is one clear difference between the two systems. For reasons not yet understood, $[(Me_3tren)CuO_2]^+$ is much more stable than $[(tren)CuO_2]^+$. Work is currently in progress aimed at clarifying this.

As shown above, an increase in steric hindrance can facilitate the synthesis of a copper−superoxo complex. To test this approach further, the ligand Bz_3tren [tris(2-benzylaminoethyl)amine, Scheme 5; $(RR')_3tren$: R = H, R′ = benzyl] was used instead of Me_3tren.[77] As expected, it proved impossible to isolate a solid copper(I) complex because of disproportionation. Crystal structures of the copper(II) complexes $[(Bz_3tren)Cu(H_2O)](ClO_4)_2$ and $[(Bz_3tren)CuCl]ClO_4$ have been determined.[77] Both show trigonal-bipyramidal geometry, with the latter being very similar to $[(Me_3tren)CuCl]ClO_4$ and $[(tren)CuCl]ClO_4$. An ORTEP plot of $[(Bz_3tren)Cu(H_2O)]^{2+}$ is shown in Figure 2. Evidently, there

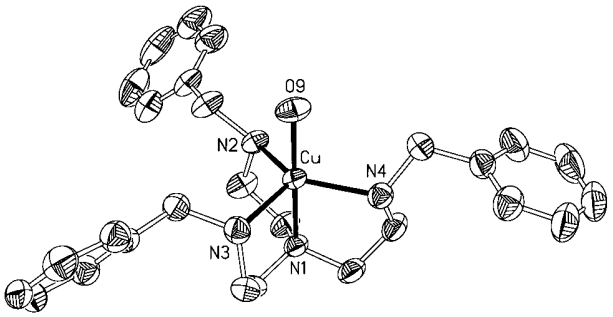

Figure 2. ORTEP view of $[(Bz_3tren)Cu(H_2O)]^{2+}$; thermal ellipsoids are drawn at a 50% probability level; hydrogen atoms are omitted for the sake of clarity

is no significant steric hindrance when only three hydrogen atoms in tren are replaced by bulky groups; the three benzyl groups are turned away sideways.

Most surprisingly, a stoichiometric mixture of $[Cu(CH_3CN)_4]PF_6$ and Bz_3tren in propionitrile showed a reaction behavior towards dioxygen different from that of Me_3tren.[77] Time-resolved spectra recorded at −70 °C are shown in Figure 3. Even though a detailed kinetic study has not yet been performed, the spectra provide evidence for the formation of $[(Bz_3tren)CuO_2]^+$ and $[(Bz_3tren)CuO_2Cu(Bz_3tren)]^{2+}$ as the spectral features are similar to the known UV/Vis spectra of copper−superoxo and −peroxo complexes.[40,51] The absorbance maxima of the superoxo $[(Bz_3tren)CuO_2]^+$ (λ_{max} = 406 nm) and peroxo $[(Bz_3tren)CuO_2Cu(Bz_3tren)]^{2+}$ (λ_{max} = 506 nm) complexes were assigned accordingly. However, resonance Raman spectra are still needed to confirm this assignment. According to these results, the reaction pathway is similar to that described for $[(tmpa)Cu(CH_3CN)]^+$ by Equations (2)−(4). The considerable differences in the behavior of the three

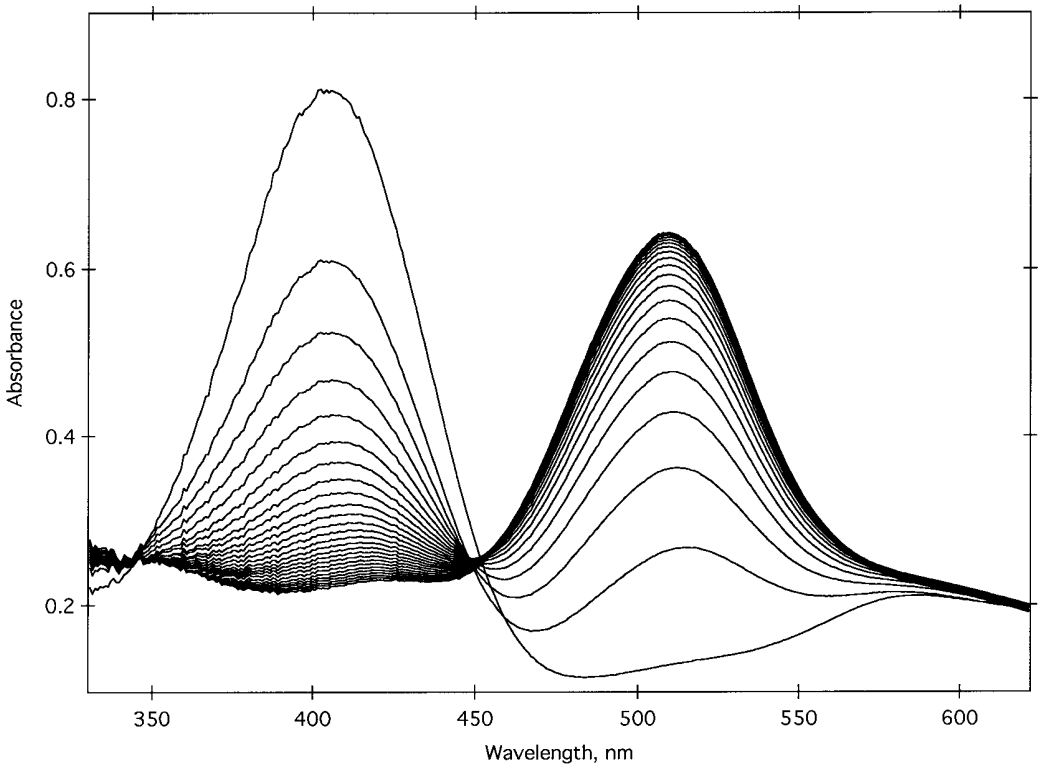

Figure 3. Reaction of $[(Bz_3tren)Cu(RCN)]PF_6$ with dioxygen at −80 °C in dry propionitrile ([complex] = 0.25 mM, $[O_2]$ = 4.4 mM, Δt = 35.2 s)

complexes $[Cu(tren)]^+$, $[Cu(Me_3tren)]^+$, and $[Cu(Bz_3tren)]^+$ towards dioxygen have yet to be explained; further investigations are necessary.

At the beginning of these investigations, the now commercially available amine Bz_3tren was synthesized by reacting benzaldehyde with tren followed by a reduction with sodium borohydride.[84] This prompted investigations of the reaction behavior of the copper(I) complex with the initially formed imine ligand (L^8, Scheme 5).[77,85,86] In contrast to tren and its derivatives, the soft imine donor groups in L^8 have a large stabilizing effect on the soft copper(I) ion. Therefore, the corresponding copper(I) complex can easily be synthesized and structurally characterized.[85,86] However, when this complex was reacted with dioxygen in a variety of solvents at different temperatures, dioxygen intermediates were not detected.[77,85] This finding is well in line with earlier results on the reaction of dioxygen with various copper imine complexes.[87−89] All kinetic investigations suggest the formation of a copper peroxo (or superoxo) complex, but it has proved impossible to detect these compounds spectroscopically. Most probably, the dioxygen intermediate immediately reacts further to yield a decomposition product (steady-state concentration of dioxygen intermediates). As yet, no explanation has been offered as to why this especially seems to be the case for copper(I) imine complexes.

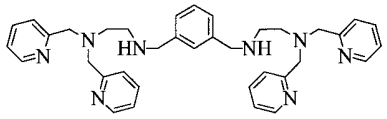
To avoid effects caused by ligand protons, Me_6tren [tris(2-dimethylaminoethyl)amine, Scheme 5; R = R′ = Me], i.e. fully methylated tren, was used.[50,90] The solutions of Me_6tren and Cu^I salts proved to be extremely sensitive towards traces of dioxygen or moisture; oxidation or disproportionation of the complex was frequently observed before the pure, crystalline copper(I) complex $[Cu(Me_6tren)]ClO_4$ could be isolated.[50]

The geometry of $[Cu(Me_6tren)]ClO_4$ is best described as trigonal pyramidal, but a weak interaction with the perchlorate anion cannot be neglected. This anion occupies the axial position of a trigonal-bipyramidal arrangement constituted by three of the four oxygen atoms and the copper(I) ion. This structure is unusual because of the weak interaction between the perchlorate anion and the copper(I) cation. After crystallizing $[Cu(Me_6tren)]ClO_4$ from acetonitrile, one would expect to find an additional acetonitrile molecule coordinated to the copper ion in the axial position (instead of perchlorate); this was found for the copper(I) complex with tmpa as discussed above. A comparison of this complex with $[Cu(Me_6tren)]ClO_4$ reveals that the bond lengths and bond angles are quite different.[50]

When $[Cu(Me_6tren)]ClO_4$ was reacted with dioxygen at low temperatures in a stopped-flow instrument, spectral changes indicative of the formation of the superoxo $[Cu(Me_6tren)O_2]^+$ and peroxo $[(Me_6tren)Cu(O_2)Cu(Me_6tren)]^{2+}$ complexes were observed; the latter was further characterized by resonance Raman measurements, $\nu(O-O) = 880\ cm^{-1}$.[50] A detailed kinetic study of this reaction is currently in progress. From the data obtained to

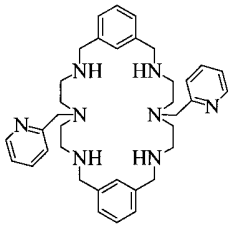
date, it is clear that the reaction pathway is similar to that described for $[(tmpa)Cu(CH_3CN)]^+$ by Equations (2)−(4). However, there is one major difference: $[Cu(tmpa)O_2]^+$ immediately undergoes further reaction to give the peroxo complex (Equation (3)), whereas $[Cu(Me_6tren)O_2]^+$ reacts much more slowly.[50]

The aforementioned findings show that copper(I) complexes with tren or its derivatives form dioxygen adducts during oxidation. Consequently, this represents an excellent approach for systematically synthesizing a series of tripodal ligands that can be used to test the differences in behavior of the corresponding copper(I) complexes towards dioxygen. In principle, combinatorial chemistry could now be used to synthesize and investigate copper(I) complexes with a large variety of tripodal ligands.



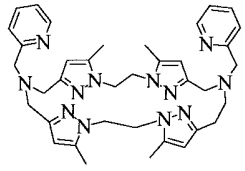
By reacting tren with aldehydes followed by reduction, a series of R_3tren ligands (Scheme 5; R′ = H) can be synthesized. Further reaction with organic chlorides or the use of aldehydes and sodium cyanoborohydride allows the preparation of a wide variety of $R_3R'_3$tren ligands (Scheme 5). When these R groups provide additional donor atoms, several copper ions can be bound by the ligand; for example, reaction of tren with picolyl chloride or 2-vinylpyridine allowed the isolation of trinuclear copper complexes.[91,92] It is also possible to chemically alter tren without modifying all three arms. An example where only one amine arm was altered has been described by Spiccia and co-workers (L^9, Scheme 5).[93]

In order to avoid ligand mixtures when only one or two additional groups were introduced into tren, the amines L^{10} and L^{11} were used (Scheme 5; R = R′ = H; ligand L^{10} is abbreviated as uns-penp[94]). Both of these amines have been known for a long time[94,95] (uns-penp was actually "rediscovered" after 10 years as a "new" ligand![96]) but surprisingly they have been little used in the synthesis of novel transition metal complexes.[94−98] The reaction of uns-penp with an aldehyde (pyridinealdehyde or salicylaldehyde, for example), followed by a reduction, allows the selective introduction of one additional donor group. Recent work has shown the modified uns-penp ligand to be extremely useful in the synthesis of iron and manganese complexes.[99−102] Ligand L^{11} permits the selective introduction of two further donor groups. Further work in this area using these new ligands for the synthesis and investigation of copper(I)/(II) complexes is ongoing in the author's laboratory.[103]

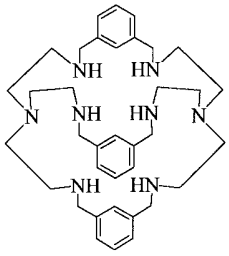


There is a further advantage in using these ligands. As discussed above, pyridine donors stabilize copper(I) complexes and facilitate their investigation. Preliminary experiments have indicated that the copper(I) uns-penp complex does not form a peroxo compound when it is reacted with dioxygen,[104] although this needs to be confirmed. In contrast, when the protons in L^{10} and L^{11} (Scheme 5; R = R′ = Me) were replaced by methyl groups, quite stable peroxo complexes could be detected as intermediates during oxidation.[103] These new ligands can be regarded as the two "missing links" between Me_6tren and tmpa.

Bridging Ligands Derived from tren and Derivatives



The use of uns-penp is also advantageous in that this ligand can be easily linked together, much more easily than tmpa itself. By reacting uns-penp with dialdehydes and reducing the imines to amines (organic chlorides can also be used), it was found that different bridging groups (or spacer molecules) could be introduced between the two units. This allowed a "tuning" of the distances between the two uns-penp units. It has been found that different xylyl linkers dramatically affect the stabilities of the corresponding copper−peroxo complexes. A peroxo complex with a *m*-xylyl spacer bridging the two uns-penp units (L^{12}, Scheme 6) proved to be the most stable.



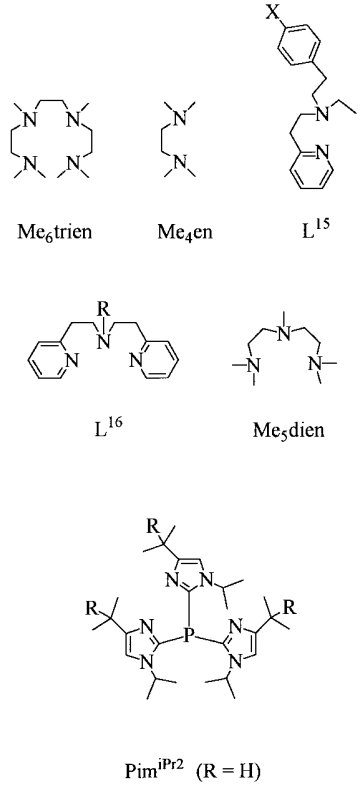
L^{12}

L^{13}

MEPY22PZ

L^{14}

Scheme 6. Ligands for the synthesis of dinuclear copper complexes



The above results suggest that the mononuclear units should be connected through more than one linker molecule. Connecting the tripodal amines with two linkers leads to macrocyclic ligands; an example currently being synthesized in the author's laboratory is shown in Scheme 6 (L^{13}). The potential of this approach has been highlighted by Bol et al., who synthesized the macrocyclic ligand MEPY22PZ (Scheme 6).[71,105] In this example, the tripodal units are connected through pyrazolyl/ethyl linkers. When the dinuclear copper(I) complex of this ligand was reacted with dioxygen, an extremely stable peroxo complex was formed. Theoretical calculations were also employed in the design of this ligand.[71]

When three linkers are used to connect two tren units, cryptands are obtained. A typical example is L^{14}, shown in

Scheme 6. However, when dinuclear copper(I) complexes of this and other cryptands with different linker molecules were reacted with dioxygen, only slow oxidation was observed and dioxygen intermediates could not be detected spectroscopically [this is similar to the reaction described above with btmpa (btpa); Scheme 4].[106]

Other Amines Related to tren

Once it had been established that aliphatic amines derived from tren are useful tools for studying copper(I)/dioxygen reactions, it was decided to investigate an additional series of amines.[48] The copper(I) complex of Me_6trien {*N*,*N*′-bis[2′-(dimethylamino)ethyl]-*N*,*N*′-dimethylethane-1,2-diamine; Scheme 7}, an isomer of Me_6tren, can be synthesized by a comproportionation reaction in water.[107] With this in mind, attempts were made to characterize a copper−dioxygen adduct in aqueous solution. However, although the copper(I) and copper(II) complexes of Me_6trien could be synthesized and characterized, no copper−dioxygen adduct could be detected when the copper(I) complex was treated with dioxygen (neither in aqueous nor organic media).[48]

Scheme 7. Various amine ligands

Me_4en (tetramethylethylenediamine; Scheme 7) can be viewed as being a part of Me_6trien or Me_6tren. The behavior of its copper(I) complex with a ratio of ligand to copper of 2:1 resembles that of the copper(I) complex of Me_6trien.[48] Crystal structures show the two compounds to be isostructural. The situation changes when Me_4en and copper(I) are used in a stoichiometric ratio of 1:1. Under these circumstances, complexes with Me_4en or other alkylated ethylenediamines become quite reactive towards dioxygen; on the basis of kinetic data, a variety of peroxo and oxo complexes have been postulated to form during oxidation.[108−112] This was proven by the fact that ligand L^2 (Scheme 2), which is very similar to the alkylated ethylenediamines, could be used to obtain the structurally characterized bis(μ-oxo) copper complexes described above.[33,34]

Furthermore, it has been shown that such bidentate ligands can be used for intramolecular aromatic and aliphatic hydroxylations.[113][114] In a recent study, copper(I) complexes of *N*-ethyl-*N*-[2-(2-pyridyl)ethyl]-2-phenylethylamine (L^{15}, Scheme 7; X = OMe, Me, H, Cl, NO_2) were investigated.[114] Time-resolved UV/Vis spectra as well as resonance Raman spectra provided strong evidence that bis(μ-oxo) complexes were formed during the oxidations.

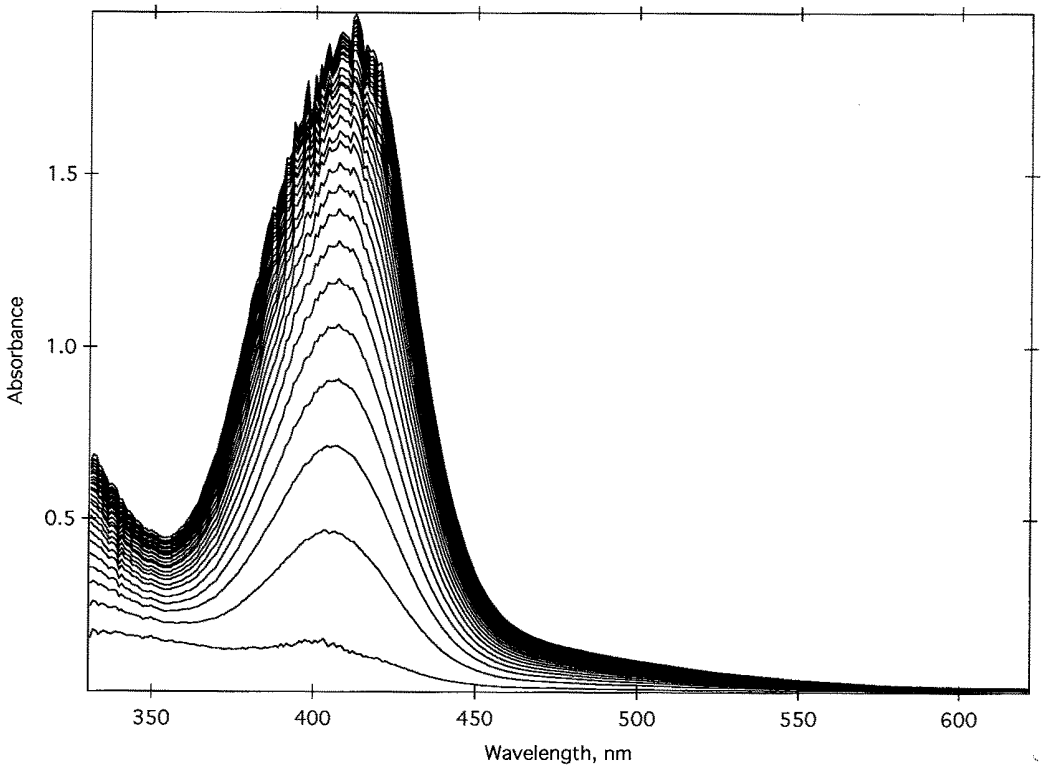
Copper complexes with bidentate and tridentate ligands have been successfully employed in investigating the oxidation of intramolecular ligands or substrates.[25,31,115−121] Copper complexes incorporating L^{16} (Scheme 7; R = Me, phenyl) provide important insight into these reactions.[31,118,119]

The above results are corroborated by investigations on tridentate ligands carried out in this laboratory. Copper(I) and copper(II) complexes of Me_5dien (1,1,4,7,7-pentamethyldiethylethylenetriamine; Scheme 7) have previously been structurally characterized.[122,123] Me_5dien can be regarded as Me_6trien or Me_6tren with one arm missing.[48,50] Time-resolved spectra of the reaction of copper(I) Me_5dien with dioxygen at −90 °C are shown in Figure 4.[104] These spectra strongly suggest that a bis(μ-oxo) complex is formed. However, as yet it has not been possible to obtain resonance Raman data to prove this. Since Me_5dien can also be regarded as an open-chain analogue of a substituted triazacyclononane (Scheme 2), it will be interesting to investigate whether increased steric hindrance in this amine will allow the observation of similar peroxo/bis(μ-oxo) equilibria as seen for the copper complexes of R_3TACN.

These results suggest that in future researchers should turn from complicated ligand systems to simple amines that can be easily modified. Combinatorial chemistry might also be considered as being potentially helpful. It should be mentioned at this point that Karlin and co-workers have already succeeded in producing peroxo complexes by reacting copper(I) complexes of the simple ligand imidazole with dioxygen.[124,125]

Many of the hitherto characterized dinuclear copper complexes have not been mentioned in this article. Most of these have been described in detail in several monographs or review articles; some more recent work is described in refs.[8,10,49,126−132] It should be pointed out that these dinuclear complexes can be described as linked mononuclear units (Scheme 8).

Ligand type (a) represents a general example of the linked tripodal units discussed above (e.g. L^{12}, Scheme 6). Reducing the number of donor atoms leads to ligands of types (b) and (c). Here, bidentate or tridentate ligands (sim-



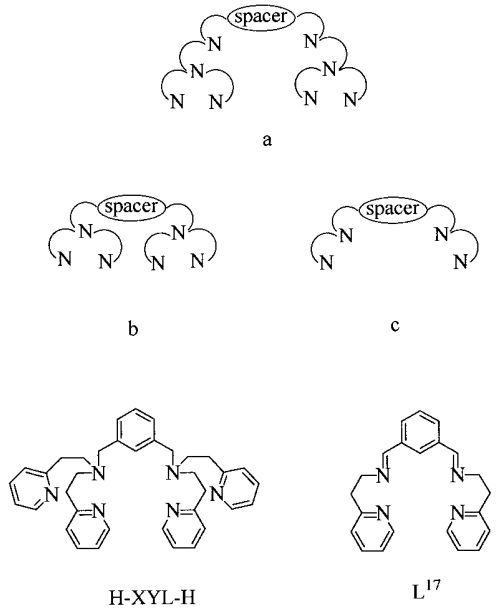


Figure 4. Reaction of $[(Me_5dien)Cu(RCN)]PF_6$ with dioxygen at −90 °C in dry propionitrile ([complex] = 0.36 mM, $[O_2]$ = 4.4 mM, Δt = 0.15 s)

Scheme 8. Ligands for the synthesis of dinuclear copper complexes

ilar to en, dien, or derivatives thereof) are connected through spacer molecules. An example of ligand type (b) is provided by H−XYL−H shown in Scheme 8 (another example would be ligand L^7 in Scheme 4, where the N donor units constitute a tridentate macrocycle).[46] The dinuclear copper complex of this ligand was discussed above. The ligand itself can be described as two L^{16} units (Scheme 7) bridged by a *m*-xylyl spacer. An example of ligand type (c) is the imine ligand L^{17} shown in Scheme 8.[8] Recently, amine ligands similar to L^{17} have been used in investigations of dinuclear copper complexes.[130,131,133]

The dinuclear copper(I) complexes of ligands of types (b) and (c) have been used to study the intramolecular benzene hydroxylation that occurs when some of these are reacted with dioxygen.[8,10,46,49,87,126−131,133] As yet, the mechanisms of such intramolecular aromatic or aliphatic hydroxylations are not well understood.[113]

Effect of Solvent

In the course of the investigations described above, it was found that the solvent played an important role in many reactions of copper(I) complexes with dioxygen. Propionitrile proved to be useful for studying the oxidations of copper(I) complexes with tripodal ligands such as tmpa or Me_6tren.[17,50] However, according to Equations (2) and (3), propionitrile is not only a solvent but a competing ligand as well, shifting the equilibria to the left. Acetone only shows weak ligating properties towards copper(I), so a dramatic effect was observed when this solvent was used instead of propionitrile.[44,50] In acetone, it proved possible to observe the copper−peroxo complexes of tmpa and Me_6tren even at room temperature. It was not possible to use dichloromethane as the copper(I) complexes of the tripodal ligands reacted with this solvent.[134] Methanol was not suitable either as it was found to have a dramatic destabilizing effect on the peroxo complexes.[50] This can probably be attributed to the protons of this solvent, similar to

the effect observed when tren was used as a ligand (see above).

Such solvent effects are not observed with other copper(I) complexes. For example, the copper(I) complex of Pim*i*Pr$_2$ (Scheme 7) produced a dioxygen adduct (evidence was found for the formation of a copper−peroxo complex) in both methanol and acetone.[135,136] Here, the protons of the solvent do not seem to have a destabilizing effect.

Dichloromethane has been used for investigating the reactions of dinuclear copper(I) complexes with dioxygen at low temperatures. For example, the oxidation of $[Cu_2-H-XYL-H]^{2+}$ (H−XYL−H; Scheme 8) has been studied in both dichloromethane and acetone.[46] While differences in the reaction behavior were observed, no dramatic stabilization of the peroxo complex was evident in either of these solvents. In contrast, nitrile solvents suppress the intramolecular hydroxylation observed in the former two solvents. Again, this may be explained in terms of the strong binding of nitrile molecules.

Furthermore, depending on the solvent, the formation of either μ-η^2:η^2-peroxo-bridged or bis(μ-oxo)dicopper(III) compounds can be favored.[28]

Decomposition Reactions

While the binding of dioxygen is not yet perfectly understood, much insight into this reaction has been gained. This is much less true for decomposition reactions. In some instances, hydrogen peroxide is probably formed while the ligand of the complex remains intact. However, oxidation of the ligand is also a possibility. Only in a few cases has selective intramolecular hydroxylation been observed, leading to products that could be characterized (examples are given above). The detailed mechanisms of these reactions are still not understood.

A very interesting reaction ensues following the oxidation of [(tmpa)Cu(CH$_3$CN)]PF$_6$, which involves a fluoride abstraction. The product, a fluoride-bridged copper(II) complex, has been isolated and structurally characterized.[137]

Conclusions

In this article, an overview of the progress that has been made concerning the activation of dioxygen with copper(I) complexes has been presented. While it is still not possible to predict the reaction pathway for a copper(I) complex and dioxygen, the studies performed in recent years allow a much better understanding of these reactions than in the past. As indicated above, a more systematic investigation on this type of oxidation is still necessary. The contribution of the author's group to this task has been the development of a ligand building block system starting from simple amines. This system (similar to Lego or Tinker Toys) allows the synthesis of a large number of new ligands for copper(I) complexes. In principle, it should also permit a combinatorial approach. Even though selective substrate oxidation with copper(I) complexes and dioxygen has not been discussed in detail here, it seems most likely that in the near future many more oxidation catalysts will be based on these systems.

Acknowledgments

I thank my co-workers Michael Becker, Markus Schatz, Florian Thaler, and Gemma Romualdo Torres, as well as my collaborators, whose names are listed in the references. They have contributed superbly to this research and their efforts are greatly appreciated. Financial support was provided by Prof. Rudi van Eldik (University of Erlangen-Nürnberg), the Deutsche Forschungsgemeinschaft, and the Volkswagen-Stiftung.

Note Added in Proof (June 20, 2000): While this microreview was accepted for publication, a summary on copper−dioxygen species and copper−oxo species was published: A. G. Blackman, W. B. Tolman, "Copper−Dioxygen and Copper−Oxo Species Relevant to Copper Oxygenases and Oxidases", in *Structure & Bonding* (Ed.: B. Meunier), Springer-Verlag, Berlin, Heidelberg, **2000**, vol. 97, p. 179−211.

Reactivity of Triosmium Carbonyl Clusters with 1,8-Diaminonaphthalene − Synthesis and Structural Characterization of Amido, Diamido, and *C*-Metalated Trinuclear Derivatives

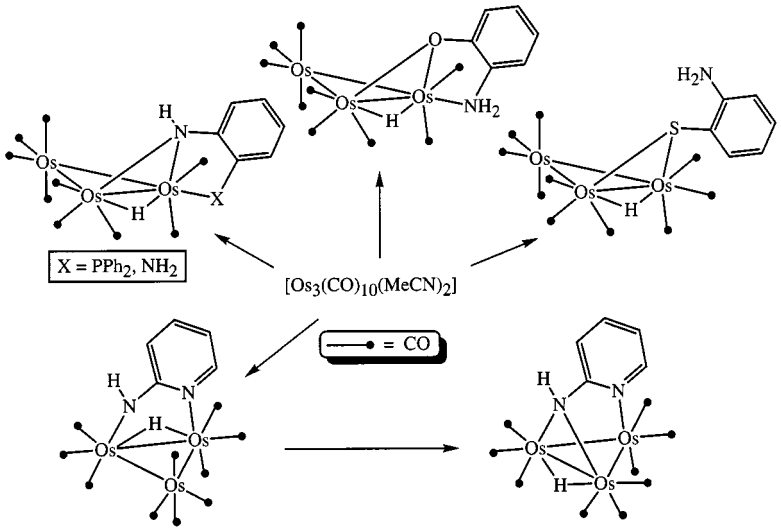
Javier A. Cabeza,*[a] Heinrich Nöth,[b] María de Jesús Rosales-Hoz,[c] and Gloria Sánchez-Cabrera[c]

Keywords: Osmium / Amido complexes / Cluster compounds / Metalation reactions / N ligands

The compounds $[Os_3(CO)_{12}]$ and $[Os_3(\mu\text{-}H)_2(CO)_{10}]$ do not react with 1,8-diaminonaphthalene (H_2dan) under thermal conditions (110 °C, 30 min). However, $[Os_3(CO)_{10}(MeCN)_2]$ reacts with H_2dan (THF, reflux temperature) to give two isomers of $[Os_3(\mu\text{-}H)(\mu\text{-}Hdan)(CO)_9]$ (**1** and **2**). In toluene at reflux temperature, these reagents afford $[Os_3(\mu\text{-}dan)(CO)_{10}]$ (**3**). Compound **2** can be converted into **3** under thermal conditions, but no interconversion between **1** and **2** has been observed. The three compounds have been characterized by X-ray diffraction methods. Compound **1** arises from the *C*-metalation of H_2dan in a position adjacent to an NH_2 group; this generates a hydride and a ligand that interacts with the three metal atoms through one of the NH_2 groups, through the metalated carbon atom (which spans an Os–Os edge), and through one of the C=C bonds of the metalated ring. In compound **2**, the hydride arises from the oxidative addition of an N–H bond of H_2dan; the resulting ligand interacts with two of the three metal atoms through the amido NH fragment (bridging position) and through the remaining NH_2 group. Compound **3** is derived from the transformation of both NH_2 groups of H_2dan into amido NH groups and consists of a 50-electron trinuclear cluster with the longest edge doubly-bridged by both amido groups.

Introduction

The last fifteen years have witnessed the renaissance of amido-metal chemistry, particularly that of the early transition metals.[1] The inert nature of the R_2N-M bond in these complexes has allowed the design of reactive metal centers specifically tailored to allow reactions in areas such as the activation of poorly reactive molecules, homogeneous catalysis, and organic synthesis.[1] The amido-metal chemistry of the late transition metals has received much less attention[2−11] as a consequence of the thermodynamically less favorable combination of "soft" metals with "hard" ligands. However, the relative lability of the R_2N-M bonds in these complexes has recently been shown to be useful in facilitating reactions such as the formation of C−N bonds through the insertion of unsaturated organic molecules into the R_2N-M bonds.[11]



The chemistry of ruthenium carbonyl amido complexes is rather well documented in the literature,[2−4] whereas in the case of osmium only a few carbonyl amido derivatives have been reported. Pentafluoroaniline reacts with $[Os_3(CO)_{12}]$ to give $[Os_3(\mu\text{-}H)(\mu\text{-}NHC_6F_5)(CO)_{10}]$.[5] *ortho*-Functionalized anilines, such as 2-diphenylphosphanylaniline,[3d,6] 1,2-diaminobenzene,[7] and 2-aminophenol[7] react with $[Os_3(CO)_{10}(MeCN)_2]$ to give $[Os_3(\mu\text{-}H)(\mu\text{-}ZC_6H_4X)(CO)_9]$ (Scheme 1). However, the reaction of $[Os_3(CO)_{10}(MeCN)_2]$ with 2-aminothiophenol gives $[Os_3(\mu\text{-}H)(\mu\text{-}SC_6H_4NH_2)(CO)_{10}]$ (Scheme 1) as a consequence of the "softer" character of the sulfur atom.[7] Some 2-amino heterocycles, such as 2-aminopyridine, give amido derivatives when treated with osmium clusters (Scheme 1).[8,9a] The reactivities of other primary and secondary amines towards trinuclear osmium clusters have also been studied.[9]

As far as amido complexes of the late transition metals derived from 1,8-diaminonaphthalene (H_2dan) are concerned, a rich derivative chemistry has been reported for binuclear compounds of ruthenium,[4] rhodium, and iridium[10] incorporating the diamido ligand dan (which is formed by the loss of two NH protons from H_2dan). In these complexes, the basicity of the diamido ligand increases the nucleophilic character of the metal atoms, enhancing their reactivity towards electrophiles (protons, metal fragments, etc.).[4c,4d,4e,10e] In addition, the *cis*-labilizing effect of the "hard" amido fragment promotes regioselective carbonyl substitution processes in positions *cis* to the amido ligand.[4a]

The hitherto obtained results summarized above prompted us to study the reactivity of osmium carbonyl clusters towards 1,8-diaminonaphthalene. We now report that this study has led to the synthesis of amido, diamido, and *C*-metalated triosmium derivatives.

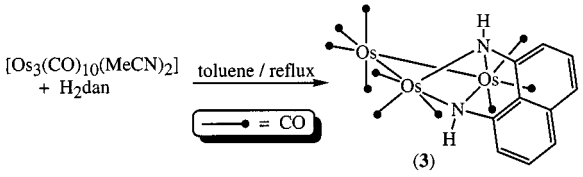
Results

Synthesis of Compounds 1−3



The compounds $[Os_3(CO)_{12}]$ and $[Os_3(\mu\text{-}H)_2(CO)_{10}]$ do not react with 1,8-diaminonaphthalene (H_2dan) under thermal conditions (toluene, reflux temperature, 30 min).

However, the activated[12a] cluster $[Os_3(CO)_{10}(MeCN)_2]$ reacts with H_2dan in THF (reflux temperature, 30 min) to give two isomers of $[Os_3(\mu\text{-}H)(\mu\text{-}Hdan)(CO)_9]$ (compounds **1** and **2** in Scheme 2), in a 1:4 mol ratio, which may be separated by chromatographic methods. The product ratio remains unchanged after longer reaction times.

Scheme 2

In an attempt to induce the reaction of two H_2dan molecules with $[Os_3(CO)_{10}(MeCN)_2]$, the latter was treated with an excess of H_2dan in refluxing toluene. A new compound, subsequently identified as $[Os_3(\mu\text{-dan})(CO)_{10}]$ (**3**) was isolated in 58% yield (Scheme 3). We later found that the excess of H_2dan is unnecessary and that the reaction temperature is the crucial factor for the formation of **3**. In fact, this compound could also be prepared, albeit in lower yield (42%), by thermolysis of **2** in refluxing toluene.

Scheme 3

Structural Characterization of Compounds 1−3

The trinuclear nature of **1**−**3** and the isomeric character of **1** and **2** were indicated by their microanalyses and mass spectra, but the information obtained from their IR and NMR spectroscopic data was insufficient to assign their molecular structures, which were determined by X-ray diffraction methods.

The structure of complex **1** is depicted in Figure 1. Selected structural parameters are listed in Table 1. The compound is formed by *C*-metalation of H_2dan in a position adjacent to an NH_2 group. This generates a hydride ligand, which spans the Os(1)−Os(2) edge, and a ligand that interacts with the three metal atoms through one of the NH_2 groups [Os(1)−N(1) = 2.12(1) Å], through the metalated carbon atom C(2), which spans an Os−Os edge, and through the carbon atom C(1). Analysis of the Os−C distances indicates a σ-type interaction with Os(2) [Os(2)−C(2) = 2.13(2) Å] and a π-type interaction with Os(3) [Os(3)−C(1) = 2.35(1); Os(3)−C(2) = 2.30(1) Å]. The ligand shell is completed by nine carbonyl ligands, three on each metal atom.

Figure 2 shows the molecular structure of complex **2**. Selected bond lengths and angles are listed in Table 1. In this compound, an Os−Os edge is doubly-bridged by a hydride ligand and by the amido fragment of an *N*-monodeprotonated H_2dan ligand [Os(1)−N(1) = 2.176(9); Os(2)−N(1) = 2.119(8) Å], of which the NH_2 group is also attached to one

of the metal atoms of the same edge [Os(2)−N(2) = 2.18(1) Å] in a position approximately *trans* to the Os(2)−Os(3) edge. The ligand shell is completed by nine carbonyl ligands, of which four are attached to Os(3), three to Os(1), and two to Os(2).

Figure 3 shows the molecular structure of complex **3**. Selected bond lengths and angles are collected in Table 1. This compound is formed by the transformation of both NH_2 groups of H_2dan into NH groups and consists of a 50-electron trinuclear cluster in which the longest (open?) edge [Os(1)−Os(2) = 3.088(1) Å] is doubly-bridged by both NH groups [av. Os−N = 2.17(1) Å]. The ligand shell of the cluster is completed by ten carbonyl ligands, of which four are attached to Os(3), three to Os(1), and three to Os(2). The naphthalene plane lies perpendicular to the Os(1)−Os(2) edge, resulting in an overall (not crystallographic) C_{2v} symmetry. This symmetry is maintained in solution, as indicated by the ^{1}H NMR spectrum, which shows only four resonances for the naphthalene and NH protons.

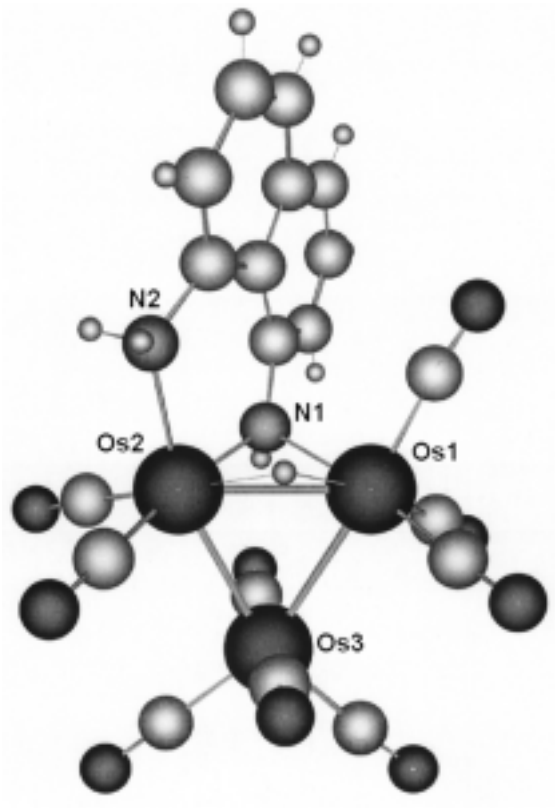

Figure 2. Molecular structure of compound **2**

Discussion

The compound $[Os_3(CO)_{12}]$ is kinetically very stable and generally requires very high temperatures to initiate its reactions, particularly those involving CO substitution.[12b] However, the fact that $[Os_3(\mu\text{-}H)_2(CO)_{10}]$ does not react with H_2dan under thermal conditions seems somewhat surprising as this unsaturated cluster is very reactive.[12c] Indeed, it has been reported that the saturated adducts $[Os_3H(\mu\text{-}H)(CO)_{10}(L)]$ (L = NH_3, NH_2R, NHR_2) can be prepared at room temperature by treating $[Os_3(\mu\text{-}H)_2(CO)_{10}]$ with ammonia gas either in the solid state[13] or in solution,[14] or with primary and secondary amines in solution.[15] In the case of H_2dan, the existence of intramolecular hydrogen bonding involving both NH_2 groups may account for its lower reactivity as compared with that of other amines.

The fact that the isomeric compounds **1** and **2** do not mutually interconvert under thermal conditions indicates that neither is an intermediate in the synthesis of the other, although they may be formed from a common intermediate {probably the product of substitution of the acetonitrile ligands in $[Os_3(CO)_{10}(MeCN)_2]$ by H_2dan}. The fact that compound **3** can be prepared by thermolysis of **2** does not necessarily imply that **2** is an intermediate in the synthesis

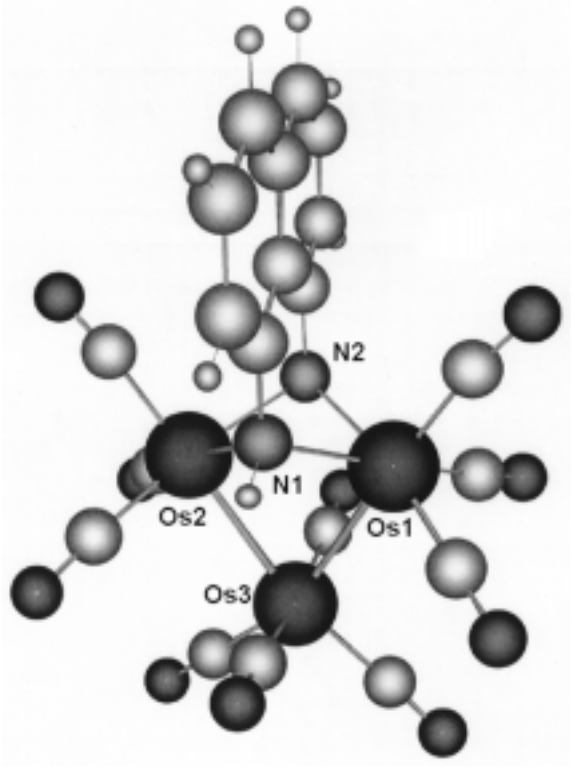

Figure 3. Molecular structure of compound **3**

of **3** from $[Os_3(CO)_{10}(MeCN)_2]$ and H_2dan. It should be noted that **3** has ten CO ligands, whereas **2** has only nine, and that some cluster decomposition occurs in refluxing toluene, since some minor products, including $[Os_4(\mu\text{-}H)_2(CO)_{13}]$, are also formed.

As far as we are aware, the *C*-metalation (as in complex **1**) and the mono *N*-metalation (as in complex **2**) of H_2dan have no precedents in the coordination chemistry of this diamine, although the structure of **2** is reminiscent of those of the ruthenium and osmium cluster complexes $[M_3(\mu\text{-}H)(\mu\text{-}HNC_6H_4X)(CO)_{10}]$ derived from 1,2-diaminobenzene (X = NH_2; M = Ru,[16] Os[7]) and 2-diphenylphosphanylaniline (X = PPh_2; M = Ru,[3d] Os[6]) (Scheme 1). The coordination mode of the dan ligand in complex **3** (symmetric, doubly-bridging six-electron donor) has previously been observed in binuclear complexes of ruthenium,[3c,4a,4b] rhodium, and iridium,[10] and in some trinuclear derivatives resulting from the addition of metallic electrophiles to these binuclear compounds;[4c,4d,10e] however, no homometallic trinuclear complexes incorporating the dan ligand as a doubly-bridging six-electron donor (as in complex **3**) have previously been reported.

It is also interesting to remark that in ruthenium carbonyl cluster chemistry, the binuclear complex $[Ru_2(\mu\text{-dan})(CO)_6]$ is the sole product of the reaction of $[Ru_3(CO)_{12}]$ with H_2dan.[4a,16] Thus, the osmium chemistry described in this article has no parallel in ruthenium chemistry. This can be rationalized by considering the low reactivity of H_2dan (as mentioned above) and the stronger metal−metal bonds of osmium as compared with those of ruthenium.[12b] Thus, H_2dan requires a high temperature for reaction with $[Ru_3(CO)_{12}]$ (toluene under reflux) and Os−Os bonds withstand this temperature whereas Ru−Ru bonds are more easily cleaved.

Experimental Section

General Remarks: Solvents were dried over sodium diphenyl ketyl (THF, hydrocarbons) or calcium hydride (dichloromethane) and distilled under nitrogen prior to use. The reactions were carried out under nitrogen using Schlenk vacuum line techniques and were routinely monitored by solution IR spectroscopy (carbonyl stretching region) and by spot TLC (silica gel). − All reagents were purchased as analytically pure samples, except for anhydrous Me_3NO, which was obtained by azeotropic distillation of $Me_3NO{\cdot}2H_2O$ in toluene. − IR: Perkin−Elmer FT 1720-X. − ^{1}H NMR: Bruker AC-200 and AC-300 spectrometers, room temperature, $SiMe_4$ as internal standard. − Microanalyses: Perkin−Elmer 2400. − MS: VG Autospec double-focusing mass spectrometer operating in the FAB+ mode; ions were produced with a standard Cs^+ gun at ca. 30 kV; 3-nitrobenzyl alcohol (NBA) was used as matrix; data quoted refer to the most abundant molecular ion isotopomer.

$[Os_3(\mu\text{-}H)(\mu\text{-}Hdan)(CO)_9]$ (Isomers 1 and 2): A solution of Me_3NO (9.5 mg, 0.127 mmol) in acetonitrile (2 mL) was added dropwise to a solution of $[Os_3(CO)_{12}]$ (50 mg, 0.055 mmol) in dichloromethane (15 mL) over a period of 15 min. After stirring for 1 h, complete conversion of $[Os_3(CO)_{12}]$ into $[Os_3(CO)_{10}(MeCN)_2]$ had occurred (IR control). The excess Me_3NO was removed by passing the solution through a short column (1 × 5 cm) of neutral alumina (activity I). The solvent was removed under reduced pressure and the solid residue was redissolved in THF (20 mL). Freshly sublimed 1,8-diaminonaphthalene (13 mg, 0.082 mmol) was added and the resulting solution was stirred at reflux temperature for 30 min. The solvent was then removed under reduced pressure and the residue was separated by preparative TLC on silica gel. Elution with hexane/dichloromethane (1:1) afforded three bands. The first band (pale yellow) was found to contain a small amount of an unidentified compound and was discarded. Workup of the second (yellow-orange) and third (yellow) bands afforded compounds **1** (6 mg, 11%) and **2** (25 mg, 46%), respectively.

Analytical and Spectroscopic Data for Compound 1: $C_{19}H_{10}N_2O_9Os_3$ (980.89): calcd. C 23.27, H 1.03, N 2.86; found C 23.52, H 1.28, N 2.75. − FAB-MS: *m*/*z* = 982 [M^+]. − IR (CH_2Cl_2): ν(CO) = 2085 (m), 2056 (s), 2024 (vs), 2002 (m), 1985 (m), 1966 (w) cm^{-1}. − ^{1}H NMR ($CDCl_3$): δ = 8.86 (br. d, *J* = 9.4 Hz, 1 H), 7.86 (d, *J* = 8.8 Hz, 1 H), 7.4−7.0 (m, 2 H), 6.69 (d, *J* = 8.8 Hz, 1 H), 4.03 (br. s, 2 H, NH_2), 3.75 (br. s, 2 H, NH_2), −14.60 (s, 1 H, μ-H).

Analytical and Spectroscopic Data for Compound 2: $C_{19}H_{10}N_2O_9Os_3$ (980.89): calcd. C 23.27, H 1.03, N 2.86; found C 23.38, H 1.27, N 2.71. − FAB-MS: *m*/*z* = 982 [M^+]. − IR (CH_2Cl_2): ν(CO) = 2089 (m), 2049 (vs), 2007 (m), 1995 (s), 1990 (s), 1978 (sh), 1965 (sh), 1918 (m) cm^{-1}. − ^{1}H NMR ($CDCl_3$): δ = 7.8−7.0 (m, 6 H), 6.48 (br. s, 1 H, NH), 5.94 (d, *J* = 12.7 Hz, 1 H of NH_2), 5.48 (d, *J* = 12.7 Hz, 1 H of NH_2), −12.31 (s, 1 H, μ-H).

$[Os_3(\mu\text{-dan})(CO)_{10}]$ (3): A solution of 1,8-diaminonaphthalene (13 mg, 0.082 mmol) and $[Os_3(CO)_{10}(MeCN)_2]$ (0.055 mmol, prepared in situ as described above) in toluene (15 mL) was stirred at reflux temperature for 30 min. The solvent was then removed under reduced pressure and the residue was separated by preparative TLC on silica gel. Multiple elution with hexane/dichloromethane (2:1)

X-ray Crystallographic Studies: Crystal data and details of the structures of compounds **1**−**3** are listed in Table 2. The selected crystal of compound **1** was covered with perfluoropolyether oil, attached to the tip of a glass fibre, and then mounted on the Euler cradle of a Siemens P4 four-circle diffractometer equipped with a CCD area detector and an LT2 low-temperature device. Unit cell dimensions were calculated from four sets of data collected at 193 K with different crystal orientations over 15 frames, each with Δψ = 0.3°. Data collection was carried out in the hemisphere mode at 193 K, at two different χ settings with Δψ = 0.3° for each series, over a total of 100 frames. Structure solution was performed by the Patterson method, followed by successive difference Fourier cycles.[18] Non-hydrogen atoms were refined anisotropically, while hydrogen positions were calculated with the exception of those bonded to the nitrogen atoms. An absorption correction was applied by empirical methods.

Crystals of complexes **2** and **3** were mounted on glass fibres and their unit cell dimensions were determined from the angular settings of 25 reflections with 10 < θ < 12° on a Nonius CAD4 diffractometer. Both structures were solved by direct methods followed by successive difference Fourier cycles using SHELXL.[19] In both cases, an empirical absorption correction was applied. Non-hydrogen atoms were refined anisotropically, while hydrogen atoms were geometrically positioned and included in the refinement with fixed isotropic values.

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-142357 (**1**), CCDC-142356 (**2**), and CCDC-142355 (**3**). Copies of the data can be obtained free of charge on application to the CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

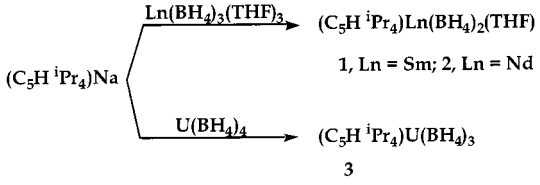
Synthesis and X-ray Crystal Structures of $(C_5HiPr_4)Ln(BH_4)_2(THF)$ (Ln = Nd and Sm), Versatile Precursors for Polymerization Catalysts

Denise Barbier-Baudry,*[a] Olivier Blacque,[a] Abderrafia Hafid,[b] Abdelaziz Nyassi,[b] Helmuth Sitzmann,[c] and Marc Visseaux[a]

Keywords: Lanthanides / Uranium / Metallocenes / Bulky ligands / Boron / Hydrides / Polymerization

The new half metallocenes $[(C_5HiPr_4)Ln(BH_4)_2(THF)]$ [Ln = Sm (**1**) and Nd (**2**)], and $[(C_5HiPr_4)U(BH_4)_3]$ (**3**) have been synthesized. The crystal structures of **1** and **2** and of the metallocenes $[(C_5HiPr_4)_2Ln(BH_4)]$ [Ln = Sm (**4**) and Nd (**5**)] have been determined. The substitution of the BH_4 groups of **1** and **2** by a nitrogen-based ligand is possible. In the presence of butyllithium, these complexes show an activity in isoprene and styrene polymerization.

Introduction



A large number of metallocene catalysts for olefin polymerization have been reported during the last decade. Nowadays, much interest has been placed in the synthesis of half metallocenes, such as, for example, amidocyclopentadienyl compounds for the stereospecific polymerization of α-olefins or styrene.[1] Lanthanide organometallic complexes are analogous to cationic zirconium derivatives and the synthesis of monocyclopentadienyl complexes of the early lanthanides could offer the opportunity to access a great variety of new catalysts. The organometallic chemistry of these elements is actually largely based on biscyclopentadienyl (or related) complexes.[2] We considered that the use of the sterically demanding ligand C_5HiPr_4 [3] could allow an easy synthesis of monocyclopentadienyl derivatives. In order to avoid the incorporation of alkali metal salts leading to the formation of undesirable anionic complexes,[4] borohydrides were used, the pseudohalide BH_4 anion being more electron donating than the chloride ion. In this preliminary communication we present the synthesis and some aspects of the reactivity of $[(C_5HiPr_4)Ln(BH_4)_2(THF)]$ [Ln = Sm (**1**) and Nd (**2**)] and $[(C_5HiPr_4)U(BH_4)_3]$ (**3**). The latter uranium complex, which is tetracoordinate, could be considered as a model of both zirconium and anionic lanthanide $[(C_5HiPr_4)Ln(BH_4)_3]^-$ moieties. Until now, no example of a lanthanide monocyclopentadienylbisborohydride has been reported.

Results and Discussion

Synthesis

Reaction of the tetraisopropylcyclopentadienyl sodium salt C_5HiPr_4Na with $[Sm(BH_4)_3(THF)_3]$, $[Nd(BH_4)_3(THF)_3]$ or unsolvated $[U(BH_4)_4]$ in toluene (or THF) at room temperature, affords the analytically pure monocyclopentadienyl complexes $[(C_5HiPr_4)Sm(BH_4)_2(THF)]$ (**1**), $[(C_5HiPr_4)Nd(BH_4)_2(THF)]$ (**2**) and $[(C_5HiPr_4)U(BH_4)_3]$ (**3**), isolated in ca. 50−60% yield (Scheme 1). These complexes are stable and melt without decomposition around 170 °C. The monomeric structure of **1** and **2** was established by an X-ray structural analysis. The easy sublimation of **3** also indicates a monomeric structure, as is usually observed for analogous uranium compounds.[5]

Scheme 1. Synthesis of complexes **1**−**3**

Monopermethylated cyclopentadienyl lanthanide complexes are less numerous than the disubstituted ones, and most of the complexes obtained from the halide compounds are hexacoordinated complexes of general formula $[Cp^*LnX_2(THF)_3]$ or $[Cp^*LnX_3M(THF)_2]$ ($Cp^* = C_5Me_5$, X = Cl or I, M = Li or Na).[6] The simultaneous use of the very bulky tetraisopropylcyclopentadienyl ligand and of the borohydrides as starting materials allows the formation of monomeric, four-coordinate complexes.

Characterisation

The IR spectra of complexes **1**, **2**, and **3** show the characteristic pattern of a tridentate BH_4 group.[7]

[a] THF: δ = −0.01 and −0.51* (**1**), −3.5* and −9.16 (**2**). * Confused with a methyl signal, separated at higher temperature.

The NMR spectra of these paramagnetic complexes were recorded in C_6D_6, at variable temperature, to differentiate overlapping signals. The large signal of the BH_4 group, the coordinated THF and the seven signals of the substituted cyclopentadienyl ligand are observed (Table 1). In the spectrum of **2,** the borohydride signal is observed at very low field, as expected in consequence of the strong contact contribution in a neodymium complex. As generally observed for analogous neodymium and samarium complexes, the signals of the H atoms with the highest contact influence (CpH and BH_4) are observed at opposite ends of the spectrum: [Sm]CpH: δ = 10.7; [Nd]CpH: δ = −15.2 (see Table 1). The line widths are similar to those usually observed for paramagnetic uranium, samarium and neodymium complexes,[8] except for two very large signals, which are shifted to much higher field, for the methyl groups of **1** and **2**. At higher temperature (70 °C), these signals are significantly sharpened and exhibit a normal line width. The broadening of these signals cannot be explained only on the basis of the paramagnetic nature of the complexes, but is more likely to be related to a dynamic process: at ambient temperature the rotation of the four methyl groups located close to the metal would be restricted.

For **3,** no significant broadening of the methyl signals was observed; the rotation appears to be free, probably because of the decreased steric hindrance when a THF molecule is replaced by a BH_4 group.

The X-ray crystallographic analyses of **1** and **2** (Figure 1, Ln = Nd) reveal the same monomeric pseudo-tetrahedral structure, with one THF molecule coordinated.[9]

Reactivity

On an NMR scale, we looked at the substitution of the borohydride groups by other ligands. We tried to obtain first the hindered biscyclopentadienyl complexes. In the presence of an excess of $C_5H_iPr_4Na$, with gentle heating (50 °C), the monocyclopentadienyl complexes **1**,**2** and **3** can be slowly (48 h) converted into the corresponding biscyclopentadienyl complexes **4**, **5** and **6**, respectively. Bulk syntheses of **4** and **5** afforded crude material which could not be obtained analytically pure, even after crystallisation. Nevertheless, crops of X-ray quality crystals of **4** and **5** were obtained, and the two compounds were found to be isostructural (Figure 2, Ln = Sm). These monomeric borohydrides are the first examples of tetracoordinated complexes of the early lanthanides; all the other early lanthanide borohydrides described are pentacoordinate,[10] dimeric,[11] or dinuclear complexes.[12]

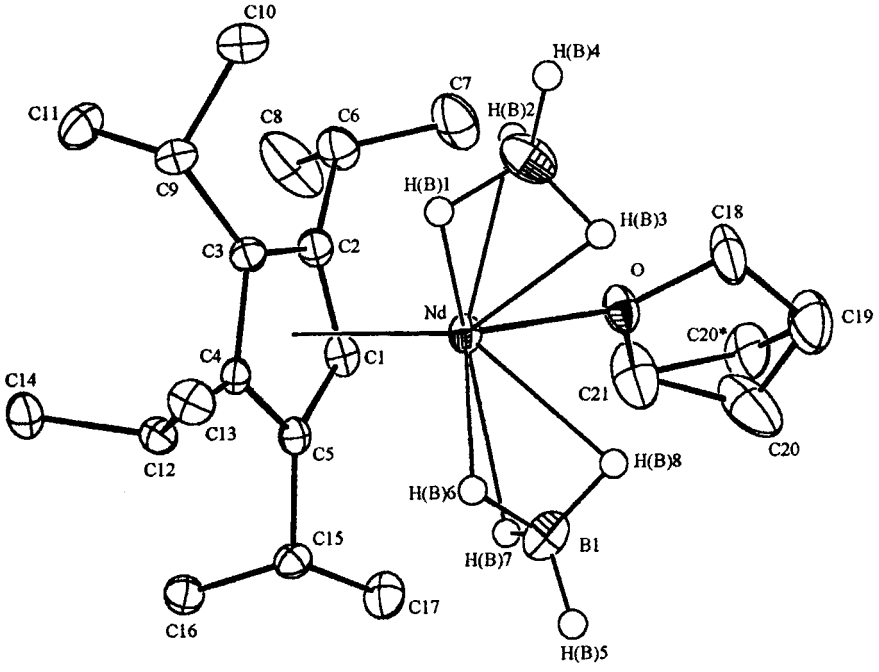

Figure 1. Molecular structure of **2**; selected interatomic distances (Å): Nd−Cp1 2.446, Nd−B1 2.605(3), Nd−B2 2.595(3), Nd−H(B)1 2.32(3), Nd−H(B)2 2.33(3), Nd−H(B)3 2.41(4), Nd−H(B)6 2.28(6), Nd−H(B)7 2.33(4), Nd−H(B)8 2.38(5); Cp1 is the geometric center of the C1−C5 ring

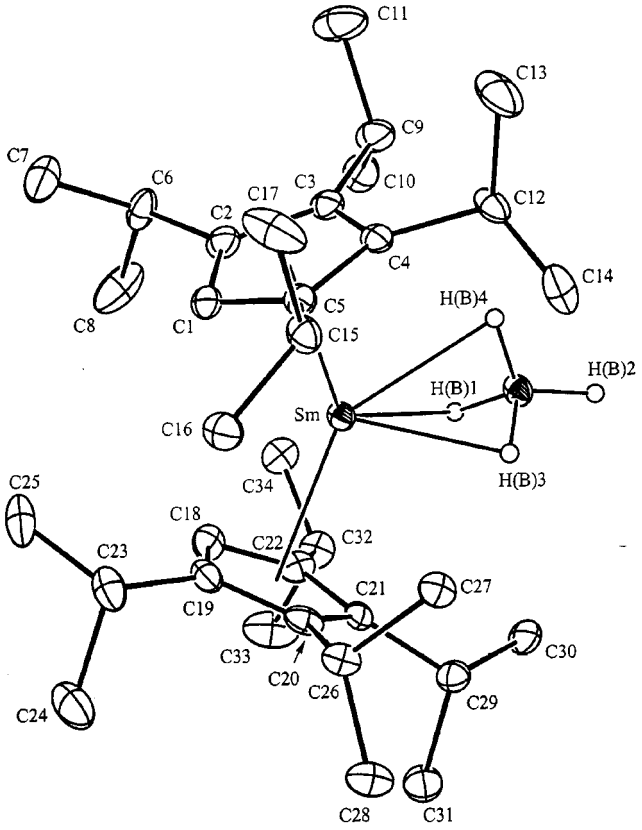

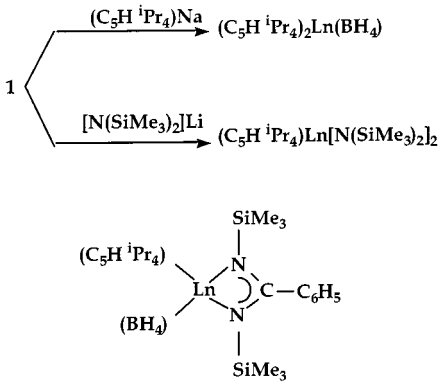

Figure 2. Molecular structure of **4**; selected interatomic distances (Å) and angles (°): Sm−Cp1 2.475, Sm−Cp2 2.436, Sm−B 2.579(3), Sm−H(B)1 2.30(4), Sm−H(B)3 2.28(4), Sm−H(B)4 2.45(4), Cp1−Sm−Cp2 138.7; Cp1 and Cp2 are the geometric centers of the C1−C5 and C18−C22 rings

Ligand exchanges are commonly observed for uranium and lanthanide complexes, but here the bulkiness of the tetraisopropylcyclopentadienyl ligand markedly slows down the exchange process: the complete equilibrium shift of a mixture of $[(C_5HiPr_4)_2Sm(BH_4)]$ **(4)** and $[Sm(BH_4)_3(THF)_3]$ to form **1** requires one week, whereas the metathesis of C_5H_4tBu derivatives requires only one day.[13]

By mixing a stoichiometric amount of **1** and $LiN(SiMe_3)_2$, a new set of signals reveals the presence of the diamido complex $[(C_5HiPr_4)Sm\{N(SiMe_3)_2\}_2]$ mixed with ca 50% of unreacted **1**. By using the more bulky chelating benzamidinate ligand $C_6H_5C(NSiMe_3)_2$, it was possible to substitute one BH_4 ligand of **1** or **3** (Scheme 2).

Scheme 2. Reactivity of compound **1**

Polymerization Experiments

The above-described experiments clearly showed that a new series of organolanthanide complexes could be synthesized from tetraisopropylcyclopentadienyllanthanide borohydrides. We are currently investigating the access to catalytic systems: After addition of one equivalent of BuLi, a benzene solution of **1** or **2** was found to be active towards the polymerization of isoprene, affording 95% of 1,4-*trans*-poly(isoprene) (5 h, 50 °C, M_n = 90 000, I_p = 1.5). These results are in good agreement with the formation of an active organolanthanide species; anionic polymerization with BuLi gives a high percentage of 1,4-*cis*-poly(isoprene).

Under the same conditions, styrene is polymerized to give syndiotactic rich (ca 75% by ^{13}C NMR) polystyrene (16 h, 50 °C, yield 90%, M_n = 300 000, I_p = 1.6).

Conclusion

We have reported the first structures of half-metallocene bisborohydrides of lanthanides. The simultaneous use of the very bulky tetraisopropylcyclopentadienyl and borohydride ligands allows the easy production of monocyclopentadienyl complexes of neodymium and samarium, with an unusually low coordination number. The stable hemimetallocene complexes **1** and **2** are convenient precursors of new catalysts for styrene and isoprene polymerization. From these complexes, one expect the development of a rich new organolanthanide chemistry.

Experimental Section

General Procedures: All reactions were performed under an argon atmosphere in a Jacomex glove box or on a vacuum line. The solvents were dried, deoxygenated and distilled from benzophenone ketyl just before use. NMR spectra were recorded on AC 80, AC 200 or DRX 500 Bruker spectrometers at 300 K. IR spectra were recorded in nujol mulls with a Bruker IFS/66V spectrometer. The syntheses of C_5HiPr_4Na,[3] $U(BH_4)_4$,[14] $Ln(BH_4)_3(THF)_n$ (Ln = Nd,[15] Sm[16]), and the benzamidinate ligand[17] were made as previously described. Polymerization experiments were performed by classical procedures,[18] and GPC analyses were carried out on a Gynkotek P580 apparatus. Elemental analyses were performed with a Fisons EA 1108 CHON apparatus. X ray Data collection: Nonius Kappa CCD diffractometer, Mo-K_α radiation (λ = 0.71073 Å), graphite monochromator.

$[(C_5HiPr_4)Sm(BH_4)_2(THF)]$ (1): $[Sm(BH_4)_3(THF)_3]$ (600 mg, 1.45 mmol) and C_5HiPr_4Na (370 mg, 1.45 mmol) were placed in a flask connected to a vacuum line, and toluene (25 mL) was added by condensation. After stirring for one hour at ambient temperature, the resulting orange solution was separated by filtration and the solvent was removed in vacuo. The crude solid was extracted with pentane and, after a slow crystallization, crystals suitable for X-ray analysis were obtained. After concentration of the mother liquor, a second crop of analytically pure crystals of **1** was obtained (yield 60%). M.p. 165 °C. − IR: $\tilde{\nu}$ = 2461 cm^{-1}, 2200, 2130 (BH_4). − $C_{21}H_{45}B_2OSm$ (486): calcd. C 51.94, H 9.34; found C 52.24, H 9.21.

[($C_5H_iPr_4$)Nd(BH_4)$_2$(THF)] (2): As described for **1**, but with THF as solvent, the dichroic blue-pink **2** was obtained in 55% yield from $Nd(BH_4)_3(THF)_3$ (104 mg, 0.26 mmol) and C_5HiPr_4Na (65.7 mg, 0.26 mmol). M.p. 170 °C. − IR: $\tilde{\nu}$ = 2457 cm^{-1}, 2193, 2127 (BH_4). − $C_{21}H_{45}B_2ONd$ (479): calcd. C 52.60, H 9.46; found C 53.36, H 10.09.

[($C_5H_iPr_4$)U(BH_4)$_4$] (3): From $U(BH_4)_4$ (260 mg, 0.872 mmol) and C_5HiPr_4Na (223 mg, 0.872 mmol), the synthesis of **3** was performed as for **1**, except that the pure compound was obtained as pale orange crystals by sublimation (100 °C, 2 Torr) of the crude material. By crystallization from cold pentane, very thin needles, unsuitable for X-ray structural determination, were obtained. M.p. 160 °C. − IR: $\tilde{\nu}$ = 2516 cm^{-1}, 2178, 2100 (BH_4). − $C_{17}H_{41}B_3U$ (516): calcd. C 39.57, H 8.01; found C 39.77, H 8.36.

[($C_5H_iPr_4$)$_2$Sm(BH_4)] (4), [($C_5H_iPr_4$)$_2$Nd(BH_4)] (5), and [($C_5H_iPr_4$)$_2$U(BH_4)$_2$] (6): Preliminary experiments on an NMR scale allowed the determination of the reaction time and the nature of the obtained products before the attempts at bulk synthesis. Typical experiment for **4**: Compound **1** (8 mg, 0.016 mmol) and C_5HiPr_4Na (4.2 mg, 0.016 mmol) were weighed in an NMR tube, 0.5 mL of C_6D_6 was added and the mixture was stirred by sonication until the two solids dissolved. After 48 h at 50° C, an orange red solution and a colorless precipitate were obtained. The volatiles were then removed in vacuo and a new aliquot of C_6D_6 was added. The spectrum of **4** (mixed with diamagnetic impurities) was observed.
Bulk synthesis allowed the production of crude **4**, **5** and **6** as pasty colored solids mixed with pale, oily, impurities. Slow crystallization from cold pentane afforded some crystals of **4** (red) and **5** (green) suitable for X ray analyses. These crystals were collected for analysis and analytically pure samples of **4** and **5** were obtained after repeating the crystallization. $C_{34}H_{62}BSm$ (631): calcd. C 64.61, H 9.88; found C 64.85, H 10.23. − $C_{34}H_{62}BNd$ (625): calcd. C 65.24, H 10.99; found C 65.49, H 10.44.

X-ray Analysis: Needles of **1** (orange), **2** (blue), **4** (red), and **5** (green) obtained from the bulk synthesis were cut and mounted on a goniometer head.[9] Compounds **1** and **2**, and compounds **4** and **5,** were found to be isostructural.

Crystallographic data (excluding structure factors) for compounds **2** and **4** have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-143895 (**2**) and CCDC-143896 (**4**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk; www: http://www.ccdc.cam.ac.uk].

Reactivity: [(C_5HiPr_4)Sm(BH_4)$_2$(THF)] (11 mg, 0.023 mmol) and Na($NSiMe_3$)$_2$ (4.2 mg, 0.023 mmol) were weighed in an NMR tube, 0.5 mL of C_6D_6 was added and the mixture was stirred by sonication until the two solids dissolved. After 3 h, a yellow-orange solution and a colorless precipitate were obtained. The volatiles were then removed in vacuo and a new aliquot of C_6D_6 was added. A mixture of **1,** Sm[$(N(SiMe_3)_2]_3$ (ca 5%) and [(C_5HiPr_4)$_2$Sm{$(N(SiMe_3)_2$}$_2$] was observed. Silylamido compound: ^{1}H NMR (C_6D_6): δ = 13.97 (HCp), 3.35 and 2.00 (H*i*Pr), 2.51, 1.86, 0.87, −0.19(Me), −4.05 ($SiMe_3$). The mixture was heated for four days at 50 °C, beside the previously observed signals, only a small set of new signals, ca 10% intensity, was observed. Similar experiments were conducted with Li[$C_6H_5C(NSiMe_3)_2$], and a new benzamidinate complex was formed: ^{1}H NMR (C_6D_6): δ = 12.50 (HCp), 10.89, 8.18, 7.99 (C_6H_5), 4.94, 3.85, 3.30, and 2.95 (H*i*Pr), 2.23, 2.06, 1.05, 1.00, 0.87, 0.10 (6 H) and −0.68 (Me), 0.28, 0.14 and −1.26 (MeSi), −2.62 ($SiMe_3$), −10.88 (BH_4).

Polymerizations: Polymerizations were performed as previously described:[18] In a glove box, the lanthanide precursor (5 mg) was introduced into the polymerization flask, a stoichiometric amount of BuLi (1 M hexane solution) was added with a syringe and the monomer (1 mL) was immediately added. The reaction mixture was kept in a thermostatic bath at 50 °C for a given time. After the polymerization was finished, the flask was opened and the solution was poured into 200 mL of ethanol. The crude polymer was washed twice with ethanol and dried under vacuum. The polymers were analyzed by ^{1}H and ^{13}C NMR spectroscopy, the molecular weights were determined by GPC with a polystyrene standard.

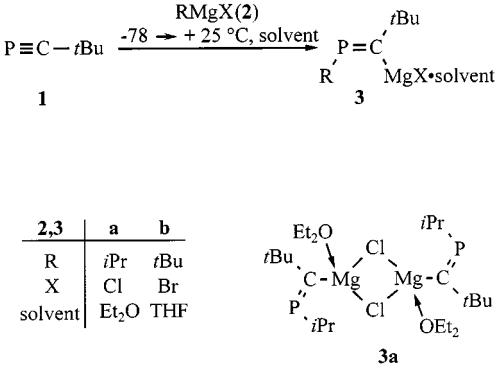
1,2-Additions of Organomagnesium Halides to Phosphaalkynes: Synthesis of 2-Phospha-1-vinylmagnesium Halides and a Novel Type of Magnesium-Phosphorus Cage Compound

Jens Renner,[a] Uwe Bergsträßer,[a] Paul Binger,*[a] and Manfred Regitz*[a]

Dedicated to Professor Marianne Baudler on the occasion of her 80th birthday

Keywords: Additions / Phosphaalkynes / Grignard reagents / Phosphavinylmagnesium halides / Cage compounds



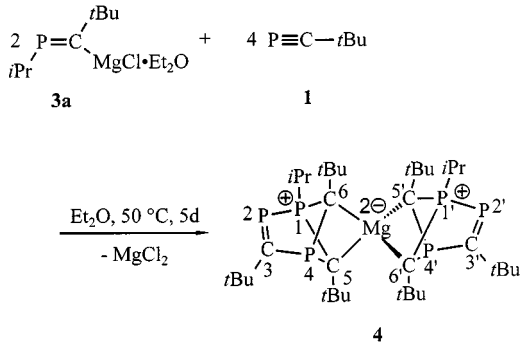
Grignard reagents such as isopropyl- and *tert*-butylmagnesium halide (**2a:** X = Cl**; 2b:** X = Br) react with *tert*-butylphosphaacetylene **(1)** in a regio- and stereoselective 1,2-addition process at –78 °C to give the 2-phospha-1-vinylmagnesium halides **3a,b** in high yields. At elevated temperatures, the phosphavinylmagnesium chloride **3a** reacts with two more equivalents of **1** to afford the previously unknown magnesium-phosphorus cage compound **4**, the structure of which has been confirmed by X-ray-analysis.

Introduction

The recent report on the synthesis of phosphavinyl-Grignard compounds by way of a regio- and stereospecific 1,2-addition of Grignard reagents to *tert*-butylphosphaacetylene **(1)**[2] prompted us to report our results in this field.

Results and Discussion

In the course of our investigations on the use of metallocene[3] and η^8-cyclooctatetraene trunk complexes[4] of zirconium and hafnium in the synthesis of new heterocyclic organophosphorus compounds, we attempted to use the di(isopropoxy)(η^2-propene)titanium complex[5] – readily accessible from titanium tetraisopropoxide and isopropylmagnesium chloride **(2a)** – as a starting material in an appropriate cyclooligomerization protocol of, for example, *tert*-butylphosphaacetylene **(1)**. In these experiments we found that the Grignard reagent reacts with **1** at least as rapidly as with titanium tetraisopropoxide with the result that an inseparable mixture was obtained from the reaction. As a logical consequence, we then performed the reaction of **1** with isopropylmagnesium chloride **(2a)** in the absence of the titanium complex in diethyl ether at −78 °C and found that the metal−carbon bond in **2a** underwent stereo- and regioselective addition to the triple bond of **1** (Scheme 1). As described by Jones et al. for other organomagnesium halides,[2] the 2-phospha-1-vinylmagnesium chloride monoetherate **(3a)** (colorless) was obtained in this case in 100% yield. In the crystalline form the compound exists as the dimer. The phosphaalkyne **1** reacted analogously with one equivalent of *tert*-butylmagnesium bromide **(2b)** to furnish orange crystals of the THF adduct **3b** in 74% yield.



Scheme 1. Synthesis of some phosphavinyl Grignard reagents

The NMR spectroscopic data of the novel phospha-1-vinylmagnesium halides are in good agreement with the values previously reported.[2] Thus, the ^{31}P NMR spectra show signals at δ = 339.4 **(3a)** and 355.1 **(3b)**. These signals, considered together with the low-field ^{13}C NMR signals of the olefinic carbon atoms at δ = 262.1 (d, $^1J_{C,P}$ = 72.1 Hz, **3a**) and 258.9 (d, $^1J_{C,P}$ = 69.6 Hz, **3b**), unambiguously illustrate the presence of the phosphaalkene moiety. An X-ray crystallographic analysis of **3a** demonstrates in this case also the regio- and stereochemistry of the 1,2-addition of isopropylmagnesium chloride, as well as the dimeric structure in the solid state.[6] As already shown by Jones and coworkers, the preparation of phosphavinylmagnesium halides is a general method with regard to the originally em-

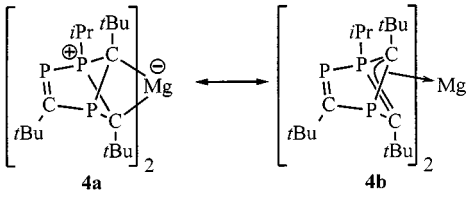


Scheme 2. Synthesis of the new magnesium phosphorus cage compound **4**

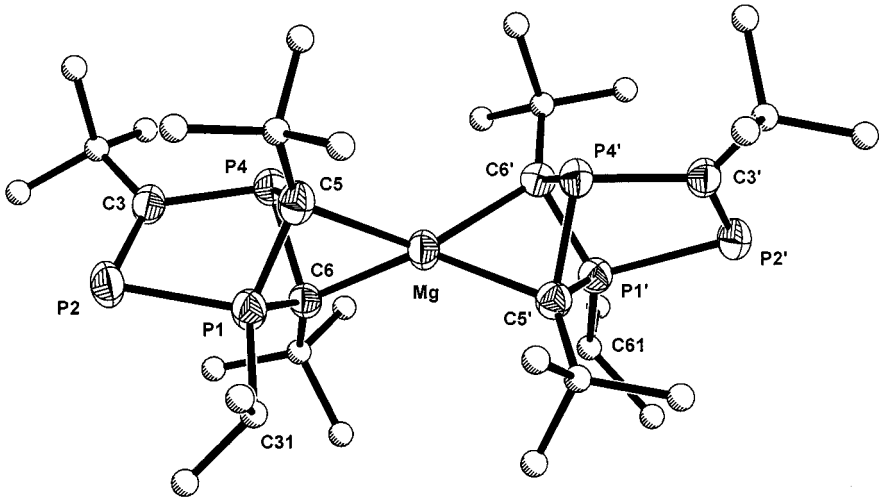
ployed Grignard reagent.[2] Preliminary experiments in our laboratory have confirmed this aspect and have also revealed that other kinetically stabilized phosphaalkynes are also amenable to this reaction.

Some phosphavinyl Grignard reagents of the type *trans*-Mes*P=C(R)MgBr (Mes* = C_6H_2-*t*Bu_3-2,4,6; R = halogen, $SiMe_3$) have previously been prepared, albeit only in situ, by other routes and used in synthesis.[7]

Compounds **3a** and **3b** are not only stable at room temperature in the solid state but also in solution. In the presence of at least two equivalents of **1**, however, **3a** undergoes further reaction even at room temperature (Scheme 2, as can be seen from the change from colorless to red. At 50 °C the reaction is complete after five days. The novel magnesium complex **4** formed by the incorporation of two equivalents of **1** is obtained as dark red crystals in 72% yield.

The structure of the complex **4** was unequivocally demonstrated by X-ray crystallography (Figure 1). This shows that the magnesium is in a tetrahedral environment linked by two Mg−C-σ bonds to each of the two 1,2,4-triphosphabicyclo[2.1.1]hexenediyl units. Compound **4** crystallizes without incorporation of solvent molecules and no longer contains chlorine atoms. Both of the bicyclic units contain a four-coordinated phosphorus atom, and accordingly the complex must have a betaine structure in which the bicyclic units each bear a formal positive charge, leaving the magnesium atom with two formal negative charges. To the best of our knowledge, organomagnesium compounds of this type have not been described before.[8] The individual atomic separations found are mostly in agreement with previously reported values. Thus, the bond lengths of between 2.247 and 2.284 Å found for the four Mg−C bonds are in agreement with the reported characteristic values for known organomagnesium compounds.[9] The two bicyclic ligands exhibit P−C, P=C, and P−P bond lengths of 1.878−1.943, 1.663−1.682, and 2.2637−2.2702 Å, respectively, which can be considered as normal.[10,11] The only exceptions are the P1−C6 and P1−C5 (as well as the P1′−C6′ and P1′−C5′) bond lengths of 1.778−1.793 Å, which are considerably shortened in comparison with the values for normal P−C single bonds. From these findings, we can deduce that the structure of the complex **4** must involve not only the betaine structure **4a** but also the η^3-structure **4b** (Scheme 3).

Scheme 3. Mesomeric structures of compound **4**



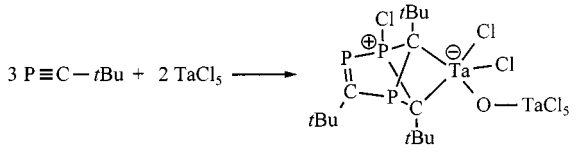


Figure 1. Molecular structure of **4**; selected bond lengths [Å] and angles [°]; H omitted for clarity, displacement ellipsoids at 50% probability: Mg−C5 2.284(3), Mg−C5′ 2.252(3), Mg−C6 2.247(3), Mg−C6′ 2.271(3), C5−P4 1.885(3), C5−P1 1.793(4), C6−P4 1.889(3), C6−P1 1.788(3), P1−P2 2.2637(14), P1−C31 1.850(3), P2−C3 1.682(3), C3−P4 1.932(3), C5′−P4′ 1.888(3), C5′−P1′ 1.778(3), C6′−P4′ 1.877(3), C6′−P1′ 1.779(3), P1′−P2′ 2.2702(12), P1′−C61 1.836(4), P2′−C3′ 1.664(4), C3′−P4′ 1.943(3); C5−Mg−C6 65.18(12), C5−Mg−C6′ 132.52(13), C5−Mg−C5′ 134.90(12), C6−Mg−C5′ 138.80(13), C6−Mg−C6′ 135.06(12), C5′−Mg−C6′ 64.71(11), Mg−C5−P4 82.08(13), Mg−C5−P1 89.3(2), Mg−C6−P4 83.01(13), Mg−C6−P1 90.60(14), Mg−C5′−P4′ 82.24(12), Mg−C5′−P1′ 91.08(13), Mg−C6′−P4′ 81.95(12), Mg−C6′−P1′ 90.42(13), P1−C5−P4 82.45(14), C5−P4−C6 80.6(2), C5−P4−C3 101.0(2), C6−P4−C3 99.10(14), P4−C6−P1 82.46(14), C6−P1−C5 85.9(2), C6−P1−P2 105.14(10), C5−P1−P2 105.50(11), P1−P2−C3 86.05(11), P2−C3−P4 115.8(2), P1′−C5′−P4′ 82.72(14), C5′−P4′−C6′ 79.99(14), C5′−P4′−C3′ 99.17(14), C6′−P4′−C3′ 100.96(14), P4′−C6′−P1′ 82.99(13), C6′−P1′−C5′ 85.7(2), C6′−P1′−P2′ 105.35(11), C5′−P1′−P2′ 104.72(11), P1′−P2′−C3′ 86.65(11), P2′−C3′−P4′ 115.5(2)

On the basis of the crystal structure analysis we were also able to assign the NMR spectroscopic data of complex **4**. As a result of the C_2-symmetry of **4**, only three signals are observed in the ^{31}P NMR spectrum for the six phosphorus atoms. The two olefinic P-atoms give a double doublet signal at δ = 174.1 with $^1J_{P,P}$ = 284.8 and $^2J_{P,P}$ = 14.2 Hz. The neighboring, four-coordinated P-atoms give a signal at δ = 67.2 with a $^2J_{P,P}$ coupling constant of 38.7 Hz. Finally, the two $\sigma^3\lambda^3$ P-atoms produce a signal (also a double doublet) at δ = 27.0 (see Experimental Section). The ^{13}C NMR spectrum reveals a signal for the vinylic C-atoms at δ = 262.0. This signal appears as a doublet of doublets of doublets and confirms the magnetic equivalence of the respective atoms in the two ligands. The carbon atoms bonded to magnesium give rise to two doubled, pseudo-triplet signals at δ = 110.1 and 109.9 with $^1J_{C,P}$ couplings of 57.1 Hz (56.2 Hz) and small $^2J_{C,P}$ couplings of 4.0 Hz each. Similarly, the ^1H NMR spectrum of **4** contains three signals for the six *tert*-butyl groups at δ = 1.57, 1.12 and 1.10, while the two isopropyl groups produce a complicated multiplet at δ = 2.76−2.58 for the two CH groups and two signals at δ = 1.71 and 1.63 for the four methyl groups.

The skeleton of the two ligands at magnesium is already known: it was first observed in the monomeric tantalum complex **5** obtained from the reaction of tantalum pentachloride with three equivalents of **1** (Scheme 4).[12] The mechanism of formation of **4** is still unknown as it has not yet been possible to isolate or identify any intermediates. It is possible that the mechanism proposed by Becker and coworkers [12] for the formation of **5** is also applicable to **4** even though other routes are feasible.

1 **5**

Scheme 4. Synthesis of the tantalum phosphorus compound **5**[12]

We are currently investigating the synthetic potential of these phosphavinylmagnesium compounds as well as the reactivity of complexes of the type **4**.

Experimental Section

All experiments were carried out under argon in anhydrous solvents. − MS: Finnigan MAT 90. − ^1H and ^{13}C NMR: Bruker AC 200 and Bruker AMX 400; chemical shifts were determined relative to solvent signals and converted into the TMS scale. − ^{31}P NMR: Bruker AC 200 (80.8 MHz); external standard H_3PO_4. − Chemicals: 2,2-dimethylpropylidynephosphane [*tert*-butylphosphaacetylene, **(1)**] was prepared according to a published procedure;[13] the Grignard reagents are commercially available.

(*Z*)-1-*tert*-Butyl-2-isopropyl-2-phosphavinylmagnesium Chloride (3a): To a solution of **1** (0.1 mL, 90% solution in hexamethyldisiloxane, 0.72 mmol) in Et_2O (2 mL) cooled to −78 °C was added dropwise a 2 M solution of isopropylmagnesium chloride **(2a)** in Et_2O (0.36 mL, 0.72 mmol). The color of the reaction solution changed spontaneously from colorless to yellow and **3a** precipitated. After stirring for 2.5 h at this temperature and a further 12 h at room temperature, a yellow solution was obtained from which **3a** crystallized out at +4 °C. − Yield 200 mg (100%) **3a** as monoetherate. − m.p. > 295 °C (dec.). − ^1H NMR (400.1 MHz, CD_2Cl_2): δ = 3.94 (q, $^3J_{H,H}$ = 7.0 Hz, 4 H, OCH_2−CH_3), 1.91 [sept, $^3J_{H,H}$ = 6.9 Hz, 1 H, CH(CH$_3$)$_2$], 1.29 (t, $^3J_{H,H}$ = 7.0 Hz, 6 H, OCH$_2$−CH_3), 1.21 [d, $^4J_{H,P}$ = 2.2 Hz, 9 H, C(CH_3)$_3$], 1.14 [dd, $^3J_{H,P}$ = 11.8 Hz, $^3J_{H,H}$ = 6.9 Hz, 6 H, CH(CH_3)$_2$]. − $^{13}C\{^1H\}$ NMR (100.6 MHz, CD_2Cl_2): δ = 262.1 (d, $^1J_{C,P}$ = 72.1 Hz, P=*C*), 65.7 (s, O*C*H$_2$CH$_3$), 43.4 [d, $^2J_{C,P}$ = 13.4 Hz, *C*(CH$_3$)$_3$], 36.5 [d, $^1J_{C,P}$ = 34.8 Hz, *C*H(CH$_3$)$_2$], 33.8 [d, $^3J_{C,P}$ = 19.1 Hz, C(*C*H$_3$)$_3$], 22.9 [d, $^2J_{C,P}$ = 15.3 Hz, CH(*C*H$_3$)$_2$], 14.2 (s, OCH$_2$−*C*H$_3$). − $^{31}P\{^1H\}$ NMR (80.8 MHz, C_6D_6): δ = 339.4 (s). − MS (EI, 35 eV); *m/z* (%): 277 (5) [M^+], 144 (39) [M^+ − MgCl − Et_2O], 101 (19) [PC*t*BuH$^+$], 87 (18) [*i*PrPCH$^+$], 74 (30) [Et_2O], 70 (30) [CH*t*Bu$^+$], 69 (55), 59 (34), 57 (71) [*t*Bu$^+$], 43 (96), 41 (100), 31 (96).

(*Z*)-1,2-Di-*tert*-butyl-2-phosphavinylmagnesium Bromide (3b): In analogy to the preparation of **3a** a solution of **1** (0.1 mL, 90% solution in hexamethyldisiloxane, 0.72 mmol) in THF (2 mL) was treated dropwise with a 1.57 M solution of **2b** in THF (0.46 mL, 0.72 mmol) to obtain 154 mg (74%) of **3b** as a solvate complex in the form of orange crystals. − m.p. > 295 °C (dec.). − ^1H NMR (400.1 MHz, CD_2Cl_2): δ = 3.95 (m, 4 H, THF), 1.90 (m, 4 H, THF), 1.26 [d, $^4J_{H,P}$ = 2.5 Hz, 9 H, C(CH_3)$_3$], 1.18 [d, $^3J_{H,P}$ = 9.3 Hz, 9 H, C(CH_3)$_3$]. − $^{13}C\{^1H\}$ NMR (100.6 MHz, CD_2Cl_2): δ = 258.9 (d, $^1J_{C,P}$ = 69.6 Hz, P=*C*), 69.6 (s, THF), 44.1 [d, $^2J_{C,P}$ = 16.7 Hz, *C*(CH$_3$)$_3$], 34.1 [d, $^1J_{C,P}$ = 20.5 Hz, P*C*(CH$_3$)$_3$], 32.2 [d, $^3J_{C,P}$ = 15.7 Hz, C(*C*H$_3$)$_3$], 31.2 [d, $^2J_{C,P}$ = 12.4 Hz, C(*C*H$_3$)$_3$], 25.6 (s, THF). − $^{31}P\{^1H\}$ NMR (80.8 MHz, C_6D_6): δ = 355.1 (s).

Bis[3,5,6-tri-*tert*-butyl-1-isopropyl-1,2,4-triphosphabicyclo[2.1.1]hex-2-ene-5,6-diyl]-magnesium (4): To a solution of **1** (0.2 mL, 90% solution in hexamethyldisiloxane, 1.44 mmol) in Et_2O (2 mL) cooled to −78 °C was added a 2 M solution of isopropylmagnesium chloride **(2a)** in Et_2O (0.72 mL, 1.44 mmol). After the mixture had been stirred for 1 h at −78 °C and a further hour at room temperature, the ^{31}P NMR spectrum of the mixture showed the presence of **3a** as the sole product. The reaction mixture was transferred to a pressure Schlenk tube, a further 2 equivalents of **1** (0.4 mL, 2.88 mmol) were added, and the mixture heated at 50 °C for 5 days. During this time a white precipitate formed and the color of the reaction solution changed to red. The solution was separated by decantation and the precipitate washed with several 1-mL portions of ether. The volume of the collected solutions was reduced under vacuum to ca. 4 mL. Cooling to +4 °C resulted in the precipitation of **4** in the form of red crystals suitable for X-ray crystallography. − Yield 740 mg (72%). − m.p. 238 °C (dec.). − ^1H NMR (200.1 MHz, CD_2Cl_2): δ = 2.76 − 2.58 [m, 1 H, CH(CH$_3$)$_2$], 1.71 [dd, $^3J_{H,P}$ = 6.9 Hz, $^3J_{H,H}$ = 5.2 Hz, 3 H, CH(CH_3)$_2$] and 1.63 [dd, $^3J_{H,P}$ = 7.1 Hz, $^3J_{H,H}$ = 5.3 Hz, 3 H, CH(CH_3)$_2$], 1.57 [d, $^4J_{H,P}$ = 1.5 Hz, 9 H, C(CH_3)$_3$], 1.12 [s, 9 H, C(CH_3)$_3$], 1.10 [s, 9H, C(CH_3)$_3$]. − ^{13}C NMR (100.6 MHz, C_6D_6, 55 °C): δ = 262.0 (ddd, $^1J_{C,P}$ = 94.8 Hz, $^1J_{C,P}$ = 47.4 Hz, $^2J_{C,P}$ = 40.5 Hz, P=*C*), 110.1 (dpt, $^1J_{C,P}$ = $^1J_{C,P}$ = 57.1 Hz, $^2J_{C,P}$ = 4.0 Hz, Mg−*C*) and 109.9 (dpt, $^1J_{C,P}$ = $^1J_{C,P}$ = 56.2 Hz, $^2J_{C,P}$ = 4.0 Hz, Mg−*C*), 44.3 [pt, $^2J_{C,P}$ = $^2J_{C,P}$ = 13.8 Hz, Mg−C−*C*(CH$_3$)$_3$] and 44.1 [pt, $^2J_{C,P}$ = $^2J_{C,P}$ = 13.8 Hz, Mg−C−*C*(CH$_3$)$_3$], 40.5 [dd, $^2J_{C,P}$ = 7.8 Hz, $^2J_{C,P}$ = 6.0 Hz, P=C−*C*(CH$_3$)$_3$], 39.1 [ddd, $^1J_{C,P}$ = 21.6 Hz, $^2J_{C,P}$ = 8.6 Hz, $^3J_{C,P}$ = 5.2 Hz, *C*H(CH$_3$)$_2$], 36.0−35.7 [m, Mg−C−C(*C*H$_3$)$_3$], 32.7 [dd, $^3J_{C,P}$ = 10.4 Hz, $^3J_{C,P}$ = 6.9 Hz, P=C−C(*C*H$_3$)$_3$], 20.2 [d, $^3J_{C,P}$ = 9.5 Hz, CH(*C*H$_3$)$_2$]. − $^{31}P\{^1H\}$ NMR (80.8 MHz, CD_2Cl_2): δ = 174.1 (dd, $^1J_{P,P}$ = 284.8 Hz, $^2J_{P,P}$ = 14.2 Hz, P2 and P2′), 67.2 (dd,

A Three-Dimensional, Cyano-Bridged Cluster−Metal Coordination Compound with Large Cavities

Vladimir P. Fedin,*[a] Alexander V. Virovets,[a] Irina V. Kalinina,[a] Vladimir N. Ikorskii,[a] Mark R. J. Elsegood,[b] and William Clegg[b]

Keywords: Tungsten / Tellurium / Cobalt / Cyanides / Crystal engineering

By very slow diffusion of aqueous solutions of $CoCl_2 \cdot 6H_2O$ and $K_6[W_4Te_4(CN)_{12}] \cdot 5H_2O$ through silica gel, single crystals of $[Co(H_2O)_4]_3[W_4Te_4(CN)_{12}] \cdot 15.38H_2O$ were obtained. A complete X-ray structure determination reveals an extremely porous, three-dimensional neutral cluster-expanded framework structure with large water-filled cuboidal cavities.

Introduction

Reactions of mononuclear aquo- and cyano-transition metal complexes lead to the formation of an extensive family of cyanide-bridged metal−metal coordination polymers.[1,2] This class of compounds has the potential for use in molecular separation because large cavities are formed in some cases.[3,4] Recently, octahedral $[Re_6E_8(CN)_6]^{4-}$ (E = S, Se, Te) cluster complexes with an outer ligand topologically equivalent to hexacyanometallates have been shown to react with transition metal ions to precipitate a range of framework solids with unprecedented structures.[5] Cluster-expanded Prussian blue analogues of the composition $M_4[Re_6E_8(CN)_6] \cdot nH_2O$ (M = Ga, Fe)[6] and $[Cd_2(H_2O)_4][Re_6S_8(CN)_6] \cdot 14H_2O$[7] with large, water-filled cavities have been obtained. In the Cd compound the volume of each water-filled cavity is 345 Å^3, and the cavities represent 62% of the total volume of the structure. Another example of a porous compound based on a cyanide cluster is $(H_5O_2)_2Zn_3[Re_6Se_8(CN)_6] \cdot 18H_2O$[8] with a hexagonal cavity of ca. 11 × 11 × 5 Å filled by hydroxonium cations and water molecules.

The synthesis and crystallization of cyanide-bridged coordination polymers with structural and functional similarity to inorganic zeolites continues to be a challenging problem. Recently we have described the syntheses, X-ray structure determination and properties of cubane-type M_4E_4 (M = Mo, W; E = S, Se, Te) water-soluble cyano complexes.[9] Here we report for the first time that cuboidal cluster complexes of T_d symmetry can be used for the preparation of framework solids with voluminous cavities.[10]

Results and Discussion

An aqueous solution of $CoCl_2 \cdot 6H_2O$ was added slowly to an aqueous solution of mixed-valence (3.5) $K_6[W_4Te_4(CN)_{12}] \cdot 5H_2O$ to give, in quantitative yield, well-formed cuboidal dark red-brown crystals of composition $[Co(H_2O)_4]_3[W_4Te_4(CN)_{12}] \cdot 8H_2O$ (**1**). The compound is X-ray amorphous after drying in air (XRD, Philips APD 1700). The compound was characterized by elemental analysis, IR spectroscopy, thermogravimetry and magnetochemical measurements. The FT-IR spectrum of **1** clearly shows the presence of H_2O and two types of cyanide ligands: the terminal W−CN fragments exhibit a sharp, intense band at 2100 cm^{-1} {compared with ν(CN) = 2097 cm^{-1} for $K_6[W_4Te_4(CN)_{12}] \cdot 5H_2O$},[9] whereas the W−CN−Co bridges exhibit a broader line shifted to higher frequency (2127 cm^{-1}). The effective magnetic moment of 4.72 μB calculated per Co atom is reasonable for three isolated high-spin Co^{2+} ions per formula unit. The N end of the cyanide ligand is a weak field ligand and thus stabilizes a high-spin state. Thermogravimetric analysis in Ar revealed complete dehydration of **1** by 150 °C, with no further significant weight loss below 450 °C. The FT-IR spectra of **1** and a dehydrated sample (150 °C, vacuum, 1 h) confirm that only minor perturbation occurs in the arrangement of the framework upon complete dehydration. The structure of X-ray amorphous compound **1** is still unknown.

Further attempts were made to prepare single crystals from the system $Co^{2+}/[W_4Te_4(CN)_{12}]^{6-}$. Very slow diffusion of aqueous solutions of $[W_4Te_4(CN)_{12}]^{6-}$ and $[Co(H_2O)_6]^{2+}$ through silica gel for eight weeks resulted in cuboidal dark red-brown crystals (**2**) suitable for an X-ray single-crystal analysis. The composition of compound **2**, according to diffraction data, is $[Co(H_2O)_4]_3[W_4Te_4(CN)_{12}] \cdot 15.38H_2O$, the calculated density being approximately half of that measured for **1**.

The local coordination environment of the Co atom and the structure of the $[W_4Te_4(CN)_{12}]^{6-}$ cluster complex are shown in Figure 1. Each Co^{2+} ion exhibits pseudo-octahedral coordination, with four water ligands and two nitrogen atoms of the cyanide ligands bound in a *trans* arrangement.

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 2000 1434−1948/00/1111−2341 $ 17.50+.50/0

The arrangement of water around Co^{2+} is disordered over two symmetrically equivalent positions. A structure determination revealed a cubic three-dimensional neutral framework of cuboidal $[W_4Te_4]^{6+}$ and $[Co(H_2O)_4]^{2+}$ fragments linked through bridging cyanide ligands (Figure 2). There are 12 cobalt atom positions around each W_4Te_4 cluster. These positions are statistically half-occupied, and therefore each cluster is linked to six cobalt atoms to give a primitive cubic lattice of ReO_3 type with clusters and cobalt atoms in the Re and O positions, respectively. The centres of the cluster anions follow a primitive cubic motif, although not face-centred as in Prussian blue. The large cavities are filled by highly disordered water molecules. Our attempts to resolve the disorder by assuming lower symmetry space groups were unsuccessful.

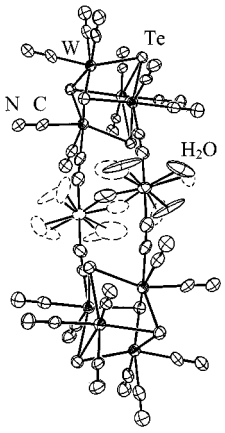

Figure 1. Fragment of structure of **2** showing the $[Co(H_2O)_4]^{2+}$ bridges between $[W_4Te_4(CN)_{12}]^{6-}$ anions, 30% probability ellipsoids; the W−W bonds are omitted for clarity; the disordered positions of Co atoms and water molecules are shown by dashed lines; main bond lengths (Å): W−W, 2.952(2), W−Te, 2.6889(17), W−C, 2.078(19), C−N, 1.20(2), Co−N, 2.096(17), Co−O, 2.15(4)−2.19(5).

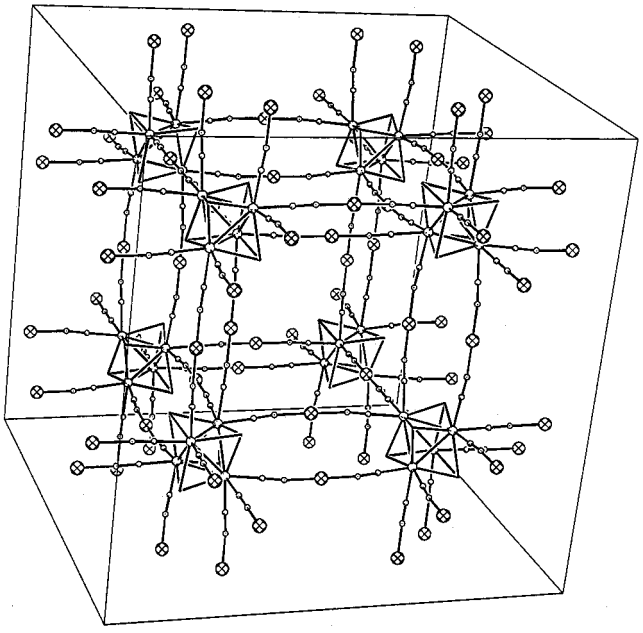

Figure 2. Crystal packing of **2**; all water molecules are omitted for clarity; all disordered positions of Co^{2+} ions are shown, but only one half of them are occupied.

The cavity in **2** of O_h symmetry has the centre at the point with coordinates (1/2, 1/2, 1/2). The O(3) atoms coordinated to the cobalt atoms form a cubic cubeoctahedron (the coordination polyhedron in the *ccp* structure) around the centre of the cavity. The diameter of the cubeoctahedron is 10.05 Å and the edges are of 5.05 Å. The calculated packing coefficient of **2** is unusually low at 0.354. The framework occupies only 27.3% of the unit cell, which means that the total Van der Waals volume of cavities and portals is 1520.1 $Å^3$ per formula unit of **2**. For comparison, the calculated void volumes per formula unit of $Na_{12}[Al_{12}Si_{12}O_{48}]$ (zeolite A) and $H_2[Al_2Si_{94}O_{192}]\cdot 24H_2O$ (zeolite ZSM-5) are 557 $Å^3$ and 2365 $Å^3$, respectively.

Our experiments show that crystals of compound **2** are very unstable. Water loss happens within a few minutes at room temperature resulting in an amorphous product which is identical to **1** according to the chemical analysis and physical measurement data. Crystals of **2** can be kept in native silica gel for a long time.

Investigations probing the electrochemistry and inclusion properties of this and related cyano-bridged cuboidal M_4E_4 (M = Mo, W; E = S, Se, Te) cluster-metal framework solids are in progress.

Experimental Section

Preparation of $[Co(H_2O)_4]_3[W_4Te_4(CN)_{12}]\cdot 8H_2O$ (1): Diffusion of 3 mL of an aqueous solution of $CoCl_2\cdot 6H_2O$ (0.076 g, 0.319 mmol) through silica gel in a narrow-diameter tube into 15 mL of an aqueous solution of $K_6[W_4Te_4(CN)_{12}]\cdot 5H_2O$ (0.100 g, 0.053 mmol) for two weeks resulted in a dark red-brown compound which was isolated by filtration, washed with water, and dried in air. Yield 0.108 g of $[Co(H_2O)_4]_3[W_4Te_4(CN)_{12}]\cdot 8H_2O$ (97%). Satisfactory elemental analyses (C, H, N, W, Te, Co) were obtained. − IR (KBr pellet): $\tilde{\nu}$ = 2127 s, ν(CN), 2100 s, ν(CN), 1600 s, br, δ(HOH), 450 m, ν(WC)/δ(WCN) cm^{-1}. − The magnetic susceptibility was measured at 300 K: $2.78\cdot 10^{-2}$ $cm^{-3}\cdot mol^{-1}$. The density of **1** was measured by microburette method: 3.34 gcm^{-3}.

Preparation of 2: Diffusion of aqueous solutions of $K_6[W_4Te_4(CN)_{12}]\cdot 5H_2O$ (0.05 $mol\cdot L^{-1}$) and $CoCl_2\cdot 6H_2O$ (0.1 $mol\cdot L^{-1}$) through silica gel in a U-tube for eight weeks resulted in cuboidal single crystals of **2** suitable for X-ray single crystal analysis.

X-ray Crystal Structure Determination of 2: The X-ray structural analysis was carried out at 160 K on a Bruker SMART CCD diffractometer (Mo-K_α, λ = 0.71073 Å, graphite monochromator, standard techniques, narrow frames of 0.3°, 40 s/frame). The crystal was covered by a frozen drop of oil to prevent decomposition. *Crystal data*: $C_{12}H_{54.76}Co_3N_{12}O_{27.38}Te_4W_4$, mol. Wt. 2228.0, cubic, space group $Fm\bar{3}m$, a = 25.577(6) $Å^3$, U = 16732(7) $Å^3$, Z = 8, D_c = 1.769 gcm^{-3}. A total of 25728 reflections were collected up to θ_{max} = 28.6°, of which 1103 were unique (R_{int} = 0.0768). Absorption corrections (μ = 7.476 mm^{-1}) were applied by the SADABS program with transmission factors ranging from 0.417 to 0.604. The structure was solved by direct methods and refined by full-matrix least-squares methods on F^2 in an anisotropic approximation using the SHELX-97 set of programs.[11] Hydrogen atoms were not located. It was found that the Co atom position has half occupancy, along with the water molecules attached to it. Some of

the uncoordinated water molecules are also disordered, and their occupancy factors and displacement parameters were refined to reasonable values. Final *R* values: *R1* = 0.0418 for 422, $F_o \geq 4\sigma(F)$, *wR2* = 0.1438, GOF = 0.931 for all unique data. The packing coefficient and the volume of the framework were calculated by the KPACK program[12] using 600 test points per 1 Å^3 and the following atomic radii (Å): C, 1.71, O, 1.40, N, 1.55, Te, 2.15, W, 1.37 (metallic).

Crystallographic data for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-144302. Copies of the data can be obtained free of charge on application to the CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

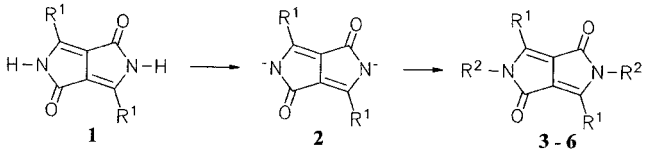
Chromophores Encapsulated in Gold Complexes: DPP Dyes with Novel Properties

Heinz Langhals,*[a] Michael Limmert,[b] Ingo-Peter Lorenz,*[b] Peter Mayer,[b] Holger Piotrowski,[b] and Kurt Polborn[a]



Dedicated to Prof. Dr. R. Huisgen on the occasion of his 80th birthday

Keywords: Gold / Copper / Dyes / Fluorescence spectroscopy / UV/Vis spectroscopy

Colour pigments of the DPP type (R^2 = H) were deprotonated and coordinated to transition metals [$R^2 = M(PPh_3)_2$ (M = Cu, Ag) and $AuPPh_3$]. Dyes were obtained with novel properties such as high solubilities, high fluorescence quantum yields and bathochromic absorptions. The crystal structures indicate a torsion of the planes of the rings of the substituents R^1 with respect to the plane of the chromophore depending on the complex fragment.

Introduction

The diaryl DPP dyes **1**[1] (DPP = **d**iketo**p**yrrolo**p**yrrol) belong to the most recently developed classes of technical pigments. Their good properties as pigments are supported by the formation of intermolecular hydrogen bond structures. However, these hydrogen bonds are also a disadvantage for the use of **1** for fluorescence applications because they diminish fluorescence quantum yields in many cases. For example, the fluorescence quantum yield[2] of **1a** was found to be only 50%. The formation of hydrogen bonds can be inhibited by an alkylation[3] or an arylation[4] at the nitrogen atoms. The coordination of the nitrogen atoms to metal ions would be a further possibility for the blocking these positions. The elements of the first subgroup would be suitable for this purpose and the formation of polymeric networks should be prevented by the coordination of at least one further coordination site by bulky substituents such as in compounds **4**–**6** (Scheme 1). The entire chromophore would be thus shielded against external influences.

R^1	C_6H_5	4-Cl-C_6H_4	3,5-di-*t*-bu.-C_6H_3
1 - 6	a	b	c

R^2	CH_3	$((C_6H_5)_3P)_2Cu$	$(C_6H_5)_3PAg$	$(C_6H_5)_3PAu$

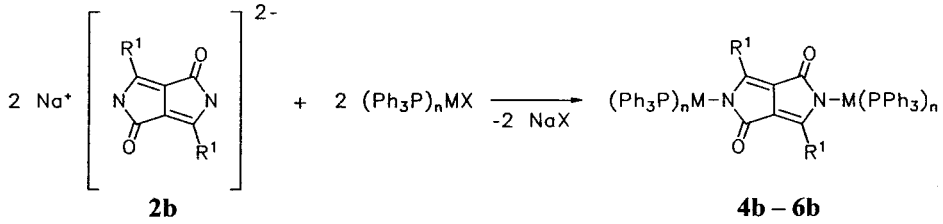
Scheme 1. Derivatives of DPP dyes

Results and Discussion



One mol DPP **(1a)** was allowed to react according to this concept with two mol hexamethyldisilazane sodium salt to give the dianion of DPP **(2a)**, and then with a mixture of two mol copper(I) chloride and two mol triphenylphosphane to obtain a violet, rather persistent, but absolutely insoluble material. A polymeric structure is probably responsible for the low solubility. An increase of the amount of triphenylphosphane to six mol or more results in partially soluble components in the reaction product. The filling of two coordination sites initially gave appreciably better results: bis(triphenylphosphane)copper(I) nitrate reacts with **2a** to give the complex **4a**. A substitution at the *p*-position of the phenyl groups in **1** with chloride **(1b)** results, after initial formation of **2b**, in the appreciably more-stable complex **4b**. Suitable single crystals of **4b** could be obtained for an X-ray single crystal structure analysis. Compound **1b** however, was preferred for the following synthesis because a higher stability was generally found for metal complexes with the chlorine derivative, see Scheme 2.

With silver(I) tetrafluoroborate and triphenylphosphane, compound **2a** forms the homogeneously soluble and brilliant violet complex **5b** with two triphenylphosphane ligands at each silver ion. However, no suitable single crystals could be obtained for a crystal structure analysis.

Even better results were obtained from the reaction of **2b** with triphenylphosphanegold(I) chloride: compound **6b** was obtained as a bright-red crystalline powder and well-

formed single crystals suitable for an X-ray crystal structure analysis were isolated. The X-ray structure shows a bond of one triphenylphosphane group with one gold(I) ion and a linear N1−Au1−P1 arrangement. Complex **6b** is completely stable under argon at room temperature and can even be stored in air for several days.

The single crystal structure analysis of **4b** (Figure 1) and **6b** (Figure 2) indicates the different composition and structures of the inversion symmetrical copper(I) and gold(I) compounds. The copper atoms in **4b** are trigonal planar, and are surrounded by the phosphorus atoms of the phosphane ligands and the N atom of the DPP dianion **2b**. The P_2CuN skeletons are planar and the Cu atoms pressed out-of-plane by 18°. The two P_2Cu planes and the planes of the rings R^1 are twisted by 70° and 25°, respectively, with respect to the central planes of the molecules. This indicates the enormous steric demand of the 12 covering phenyl groups.

The gold atoms in **6b** are linearly coordinated[5] to one N and one P atom so that a linear arrangement of all N, Au and P atoms results. The two phosphane ligands are staggered with their phenyl groups so that there is enough room

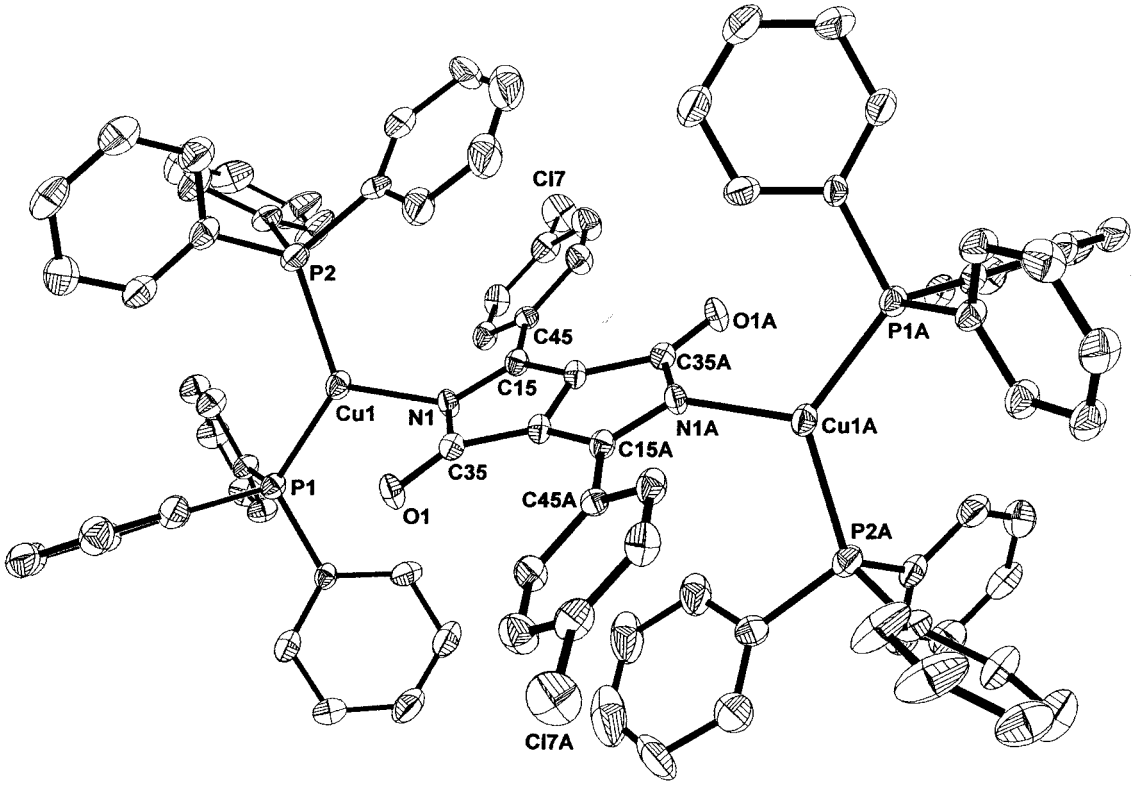

Figure 1. Crystal structure of **4b**; selected bond lengths [Å] and angles [°]: Cu1−N1 1.984(5), Cu1−P1 2.229(2), Cu1−P2 2.253(2), C15−C45 1.478(9), N1−Cu1−P1 118.7(2), N1−Cu1−P2 113.7(2), P1−Cu1−P2 127.48(7); sum of angles at N = 355.52°, sum of angles at Cu = 360°

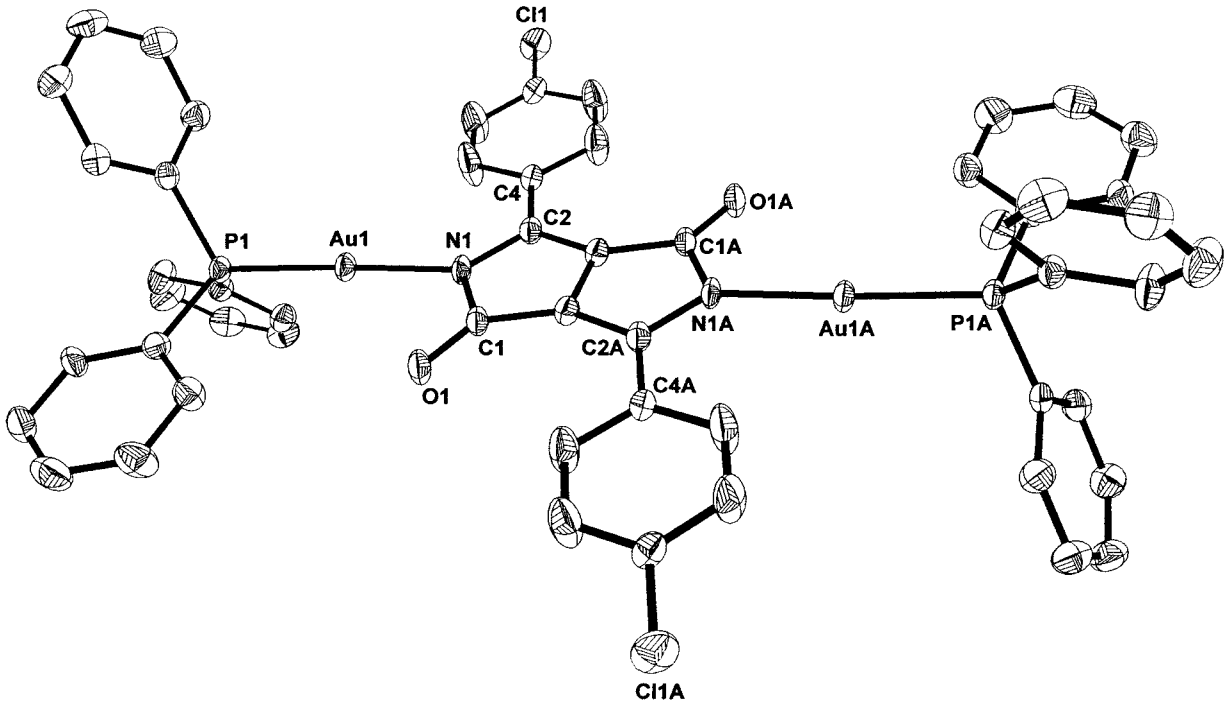

Figure 2. Crystal structure of **6b**; selected bond lengths [Å] and angles [°]: Au1−N1 2.047(5), Au1−P1 2.230(2), C2−C4 1.467(10), N1−Au1−P1 175.3(2); sum of angles at N1 = 360°

for the planarization of R^1 into the plane of the chromophore; this geometry is also preferred for electronic reasons.

Dye **1c** was used as a reference for the UV/Vis spectra of **4b−6b**, because of its sufficiently high solubility caused by the four solubilising *tert*-butyl groups in the *m*-positions of the phenyl groups.[6,7] Compound **1c** exhibits a structured UV/Vis absorption spectrum in chloroform solution (λ_{max} = 507 nm) and a mirror-type fluorescence spectrum (λ_{max} = 513 nm), see Figure 3.

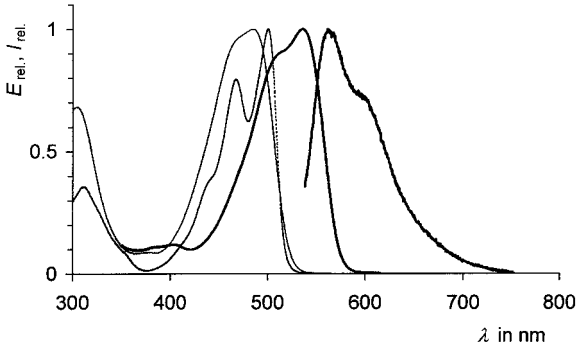

Figure 3. UV/Vis absorption and fluorescence spectrum of **6b** (—) and the absorption spectra of **1c** (···) and **3c** (—) in chloroform

A methylation of the nitrogen atoms **(3c)** will block the formation of hydrogen bonds and thus increase the fluorescence quantum yields by several percent and induce a hypsochromic shift of the UV/Vis absorption with a substantial loss of spectral structure (see Figure 3). A blocking of the nitrogen atoms by complexation with $AuP(C_6H_5)_3$ also increases the fluorescence quantum yield; however, in contrast to the former, a bathochromic shift is obtained (absorption: λ_{max} = 535.4 nm; fluorescence: λ_{max} = 561 nm; **6a** absorbs at 530 nm, see Figure 3). The changes in the UV/Vis spectra can be explained in terms of changes in the torsion angles of the aryl substituents. A torsion angle of 15° was calculated (AM1) for the phenyl groups in **1a**. This angle is probably representative of the dissolved dye. An *N*-methylation increases the torsion angle to 30° in **3c** and induces a hypsochromic shift because of the decoupling of the two π-systems. In contrast to this, the phenyl groups in the more bathochromically absorbing gold complex **6b** are completely turned into the plane of the chromophore. This corresponds to the bathochromic absorption of the planar blue dianion **2a**; a planar structure was also calculated for **2a** (AM1).

The fluorescence quantum yield of **1a** was found to be 50%. A complexation with copper **(4b)** decreases the quantum yield to 20%; this corresponds to the well-known fluorescence quenching effect of copper ions. The fluorescence quantum yield is further diminished in the silver complex **5b** to 17%. Surprisingly, the fluorescence quantum yield is strongly increased by coordination with gold ions so that 99% was obtained for **6b**. Solutions of **6b** in chloroform are bright yellow in daylight and purple in transmitted light. All complexes **4b**, **5b** and **6b** exhibit a red, solid-state fluorescence.

The high fluorescence quantum yield of **6b** indicates the efficient supporting effect of the bulky gold substituents for fluorescence. Interestingly, in contrast to alkyl groups the gold substituents allow the complete planarization of the chromophore, including the phenyl substituents (R^1 = **b**). This is a further indicator for the efficient shielding of the chromophore against aggregation because such a large planar π-system would otherwise exhibit a very high tend-

ency for aggregation. Furthermore, the fluorescence quantum yield of **6b** of nearly 100% excludes a notable intersystem crossing rate to triplet states. This is remarkable because one might expect a pronounced heavy-atom effect on the I.S.C.-rate by gold because of its high atomic weight. This will be the subject of further investigations.

Experimental Section

2b: Addition of $NaN(SiMe_3)_2$ (0.30 mL, 1.00 M solution in THF) to a well-stirred suspension of **1b** (50 mg, 0.14 mmol) in 10 mL of DMF (cf. ref [8]) yielded a blue solution of **2b**, which was used in all further reactions.

4b: Compound **2b** was added dropwise to $(PPh_3)_2CuNO_3$ (195 mg, 0.30 mmol) in 5 mL of DMF at ambient temperature and left stirring for two hours. The solvent was removed under vacuum at 60 °C, the residue dissolved in 10−15 mL $CHCl_3$ and filtered (P3). The solution was carefully diluted with *n*-hexane and stored at −20 °C for some days, after which time **4b** had precipitated as violet crystals. To improve the yield the solution can be layered with some more *n*-hexane. Yield: 111 mg (42%) of **4b** as violet crystals, m.p. 165 °C. − IR (KBr): $\tilde{\nu}$ = 3075 cm^{-1}, 3035, 1607, 1598, 1579, 1556, 1521, 1481, 1435, 1408, 1342, 1300, 1277, 1262, 1214, 1182, 1157, 1121, 1093, 1070, 1027, 1011, 998, 837, 828, 820, 773, 741, 694, 642, 628, 618, 527, 516, 507, 490, 442, 431. − ^1H NMR (270 MHz, $CDCl_3$): δ = 7.15−7.37 (m, 68 H, Ph, 4-Cl−C_6H_4). − $^{31}P\{^1H\}$ NMR (109.37 MHz, $CDCl_3$): δ = −2.4 (s, PPh_3). − UV ($CDCl_3$): λ_{max} (ε) = 547.7 nm (1), 572 sh (0.91). − Solid-state fluorescence: λ_{max} (I_{rel}) = 642. − FAB-MS: *m/z* = 1007 [M^+ − 2PPh_3], 587 [$Cu(PPh_3)_2$], 325 [$CuPPh_3$], 262 [PPh_3]. − $C_{90}H_{68}Cu_2Cl_2N_2O_2P_4$·4$CHCl_3$ (1890): calcd. C 54.93, H 3.52, N 1.33; found C 55.49, H 3.66, N 1.46.

5b: Compound **2b** was added to a stirred solution of $AgBF_4$ (58 mg, 0.30 mmol) and PPh_3 (236 mg, 0.90 mmol) in 5 mL of DMF. After 1 hour **5b** was formed as a violet solid. The solvent was removed and the residue washed with acetone (25 mL, three times) and diethyl ether (25 mL) and dried in vacuum. Soxhlet extraction of the crude product with 200 mL CH_2Cl_2 in the dark and covering the solution with a layer of *n*-hexane gave **5b** as a violet powder. Yield: 134 mg (59%), m.p. 223 °C. − IR (KBr) $\tilde{\nu}$ = 3082 cm^{-1}, 3053, 1597, 1577, 1553, 1522, 1480, 1435, 1408, 1337, 1300, 1278, 1213, 1180, 1158, 1122, 1092, 1027, 1011, 998, 839, 818, 772, 743, 715, 694, 644, 630, 618, 513, 504, 490, 437. − ^1H NMR (270 MHz, $CDCl_3$): δ = 7.15−7.45 (m, 68 H, Ph, 4-ClC_6H_4). − $^{31}P\{^1H\}$ NMR (109.37 MHz, $CDCl_3$): δ = 8.56 (s, PPh_3) . − UV ($CDCl_3$): λ_{max} (ε) = 525.8 nm (0.81), 560.1 (1.00). − Solid-state fluorescence: λ_{max} (I_{rel}) = 662. − FAB-MS: *m/z* = 1096 [M^+ − 2 PPh_3], 631 [$Ag(PPh_3)_2$], 369 [$AgPPh_3$]. − $C_{90}H_{68}Ag_2Cl_2N_2O_2P_4$ (1620): calcd. C 66.73, H 4.20, N 1.73; found C 65.09, H 4.27, N 1.93.

6b: Addition of **2b** to a stirred solution of Ph_3PAuCl (148 mg, 0.30 mmol) in 5 mL of DMF gave **6b** as a red solid. The product was purified analogously to **5b**; it was dissolved in 50 mL of warm $CHCl_3$, filtered (P3) and layered with *n*-hexane to give red crystals of **6b**. Yield: 135 mg (64%) of **6b** as a red powder, m.p. > 300 °C. − IR (KBr) $\tilde{\nu}$ = 3082 cm^{-1}, 3053, 1699, 1673, 1615, 1574, 1484, 1436, 1405, 1330, 1302, 1277, 1200, 1183, 1119 1102, 1092, 1027, 1011, 996, 836, 743, 711, 694, 545, 509, 484, 451, 440. − ^1H NMR (270 MHz, $CDCl_3$): δ = 8.71 [d, ^3J (H,H) = 8.62 Hz, 4H, 4-Cl−C_6H_4], 7.45−7.60 (m, 30 H, Ph_3P), 7.26 [d, ^3J (H,H) = 8.88 Hz, 4H, 4-Cl−C_6H_4]. − $^{31}P\{^1H\}$ NMR (109.37 MHz, $CDCl_3$): δ = 33.01 (s, PPh_3). − $^{13}C\{^1H\}$ NMR (67.5 MHz, $CDCl_3$): δ = 170, 134.99, 134.39, 134.19, 131.91, 131.86, 131.45, 129.78, 129.62, 129.39, 129.25, 128.71, 128.27. − FAB-MS: *m/z* = 1274 [M^+], 814 [M^+ − $AuPPh_3$], 721 [$Au(PPh_3)_2$], 459 [$AuPPh_3$]. − UV ($CDCl_3$): λ_{max} (ε) = 512.5 nm sh (23400), 535.4 (26000). − Fluorescence ($CHCl_3$): λ_{max} (I_{rel}) = 561 nm (1.0), 597 (0.72); solid-state fluorescence: λ_{max} (I_{rel}) = 633 nm (1.0), 690 sh (0.4). − $C_{54}H_{38}Au_2Cl_2N_2O_2P_2$·2$CHCl_3$ (1512): calcd. Synthesis and Crystal Structure of a Palladium Metallacyclic Complex: A Key Intermediate in the Carbonylation of Azobenzene to *N*-Phenyl Urethane

Andrea Sessanta o Santi,[a] Barbara Milani,*[a] Ennio Zangrando,[a] and Giovanni Mestroni[a]

Keywords: Carbonylations / Crystal structure / Metallacycles / N ligands / Palladium

The reductive carbonylation of azoxybenzene to *N*-phenyl urethane via azobenzene is promoted by the catalytic system based on palladium, bidentate nitrogen-donor chelating ligands N-N [N-N = 1,10-phenanthroline (phen) and its substituted derivatives] and the acid cocatalyst [(N-N)H][PF_6], the same catalyst as for the reductive carbonylation of nitroaromatic compounds to the corresponding carbamates. The possible key intermediate of the azobenzene → *N*-phenyl urethane transformation has been synthesised and fully characterised.

Introduction

Since 1962 the reductive carbonylation of nitroaromatic compounds has been an interesting field of research, both from the academic and industrial point of view, due to the demand for a new, phosgene-free method for the synthesis of carbamates.[1]

The industrial development of a powerful catalytic system is dependent both on its catalytic activity and on the selectivity towards the carbamate. In this system the main by-products are: aniline, *N*,*N*′-diphenylurea, azobenzene and azoxybenzene. Therefore, the comprehension of the factors which control both the formation and the transformation of these side-products are of great interest.

This reaction is homogeneously catalysed by systems based on different metals, such as ruthenium, rhodium and palladium.[1] The palladium-based system with nitrogen-donor chelating ligands, in the presence of a weak Brønsted acid as cocatalyst, is the most promising up to now.[2,3]

Mechanistic studies have been carried out based mainly on either the isolation or the spectroscopic detection of several metallacyclic derivatives, which should be directly involved in the catalytic cycle.[4−6] In particular, the structural characterization of two metallacyclic intermediates of general formula [(N-N)Pd*C*(O)N(Ar)O*C*(O)] **(1)** (**1a:** N-N = phen, Ar = Ph; **1b:** N-N = 4,4′-di(*tert*-butyl)-2,2′-bipyridyl, Ar = *p*-*tert*-butylphenyl; the italic letters indicate the atoms of the metallacyclic fragment bound to the palladium centre), which differ in the N-N ligand and the aryl group, has been reported by Osborn[4c] and by us.[5]

In this paper we report the isolation and the complete characterization, both in the solid state and in solution, of the symmetric metallacycle [(N-N)Pd*C*(O)N(Ph)N(Ph)*C*(O)] **(2)** [**2a:** N-N = phen; **2b:** N-N = 3,4,7,8-tetramethyl-1,10-phenanthroline (tm-phen)]. This complex is proposed as a "key-intermediate" for the carbonylation of azobenzene to *N*-phenyl urethane. Some preliminary catalytic results are also presented.

Results and Discussion

During the investigation of the catalytic cycle involved in the reductive carbonylation of nitroaromatic compounds to urethanes, we isolated, in high yield, the metallacyclic derivative [(phen)Pd*C*(O)N(Ph)O*C*(O)] **(1a)**, starting from [Pd(phen)($CH_3COO)_2$] in a nitrobenzene/alcohol mixture, under mild reaction conditions.[5] When the same precursor was treated with azobenzene, instead of nitrobenzene, at room temperature, in the presence of free phen and under a CO pressure of 40 atm., a pale yellow solid, formulated as [(phen)Pd*C*(O)N(Ph)N(Ph)*C*(O)], was obtained. After 24 h the yield was about 20% and this increased to 50% on prolonging the reaction time to 60 h. The addition of an excess of chelating ligand was necessary to prevent the formation of palladium metal, which occurs on increasing the reaction temperature. Moreover, no solid was isolated when the reaction was carried out under atmospheric CO pressure. The yield of the reaction is also affected by the nature of the nitrogen ligand. Actually, it further decreases when the tm-phen is used instead of phen (from 20% to 5%). All these data indicate that the formation of the metallacycle **2a** occurs with more difficulty than that of the corresponding derivative **1a**.

Yellow crystals of **2a** suitable for an X-ray analysis were obtained by slow diffusion of diethyl ether into a chloroform solution of the compound. Its molecular structure is shown in Figure 1.

The Pd centre exhibits the expected square-planar coordination geometry with Pd−N and Pd−C distances of 2.148(6) and 2.173(5) Å, and 1.947(7) and 1.963(7) Å, respectively, which are comparable to those observed in the closely related Pd metallacyclic complexes [(N-N)Pd*C*(O)N(Ar)O*C*(O)].[4c,5] The phenyl rings are structurally disor-

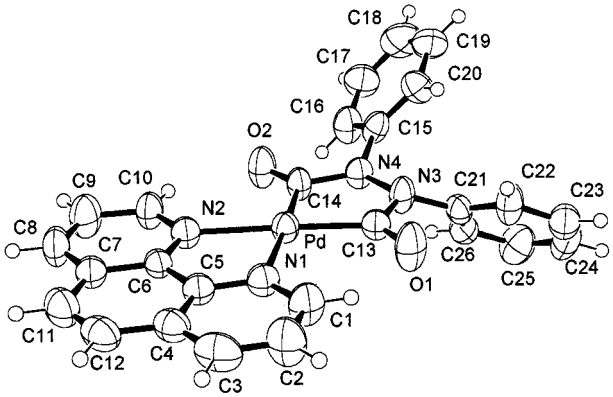

Figure 1. An ORTEP drawing (50% probability thermal ellipsoids) of the metallacycle **2a** with atom numbering scheme; selected bond lengths (Å) and angles (°): Pd−C(14) 1.947(7), Pd−C(13) 1.963(7), Pd−N(2) 2.148(6), Pd−N(1) 2.173(5), N(3)−N(4) 1.419(7); C(14)−Pd−C(13) 81.8(3), C(14)−Pd−N(2) 100.9(3), C(13)−Pd−N(2) 177.3(3), C(14)−Pd−N(1) 177.0(3), C(13)−Pd−N(1) 101.1(3), N(2)−Pd−N(1) 76.2(2), C(1)−N(1)−Pd 126.5(5), C(5)−N(1)−Pd 113.5(5), C(10)−N(2)−Pd 127.5(5), C(6)−N(2)−Pd 114.4(5)

dered over two positions since the phenanthroline and the atoms of the metallacycle Pd*C*(O)NN*C*(O) lie on a crystallographic mirror plane (see Experimental Section). In Figure 1 the rings are represented in a *trans* arrangement, which is the most likely configuration, with their mean planes forming dihedral angles of 48.7 and 45.4° with the crystallographic plane.

The N−N azo bond length of 1.419(7) Å is indicative of considerable single bond character when compared with the value of 1.26−1.27 Å measured in a series of (*E*)-azobenzenes.[7] On the other hand, the nitrogen atoms display a bonding geometry close to planarity, as shown by the summation of the bond angles about them (ca. 355°), and by the value of the torsion angle C(Ph)−N−N−C(Ph) [50.0(6)°], an aspect that may suggest a π delocalization in the azodioxo ring, although packing forces are not to be excluded in driving the observed configuration. In fact, in the crystal structure the [(phen)Pd*C*(O)NN*C*(O)] moieties stack at 3.38 Å (i.e. half of the *b* axis) in a head-to-tail arrangement.

For complexes **2** the IR spectra in the solid state show the typical band of ketonic CO stretching at 1627 cm^{-1}.

Their ^1H NMR spectra in $CDCl_3$ solution present one set of signals for the N-N ligand and one for the *C*(O)N(Ph)N(Ph)*C*(O) moiety. The number of signals of the N-N ligand and their integration confirm the equivalence of the two halves of the ligand in solution, as already observed in the solid state. All the signals of the nitrogen ligand are shifted with respect to those of the free ligand; in particular, the signals attributed to $H^{2,9}$ are deshielded by about 1.00 ppm.

The addition of one equivalent of tm-phen to a solution of [(phen)Pd*C*(O)N(Ph)N(Ph)*C*(O)], **(2a)**, resulted in an exchange of the two ligands at the palladium centre, in agreement with the higher coordinating capability of tm-phen with respect to phen. Indeed, immediately after the dissolution, the spectrum shows the signals of both coordinated and free ligands, indicating that the exchange process is slow on the NMR time scale. Although the frequencies of $H^{2,9}$ of the coordinated phen and tm-phen are quite broad, from their integration it is possible to follow the proceeding of the reaction with time. After five min, 64% of **2a** is transformed into **2b** and the equilibrium is reached after 30 min. The equilibrium mixture is formed from 83% of **2b** with the remainder being unchanged **2a**. Working in the presence of an excess of tm-phen (two equivalents with respect to Pd), the exchange process is accelerated and after five min the phen-metallacycle is completely transformed into the tm-phen derivative. In agreement with this behaviour the metallacycle [(tm-phen)Pd*C*(O)N(Ph)N(Ph)*C*(O)] **(2b)** is easily obtained by a ligand exchange reaction starting from [(phen)Pd*C*(O)N(Ph)N(Ph)*C*(O)], in chloroform, at room temperature.

We have previously reported that the catalytic system formed by $[Pd(phen)_2][PF_6]_2$ in combination with free phen and the acid cocatalyst $[(phen)H][PF_6]$ is very active in the reductive carbonylation of nitroaromatic compounds to the corresponding carbamates.[2b,8] We have now found that the same catalytic system promotes the carbonylation of both azoxy- and azobenzene to urethane (Table 1). The preliminary results reported in Table 1 show that 94% of azobenzene is converted into carbamate in two hours, with aniline as the main by-product. On the other hand, when azoxybenzene is the substrate, azobenzene is the main product. These data indicates that azoxybenzene is transformed in azobenzene, which further reacts to give the carbamate.

Table 1. Carbonylation of azoxy- and azobenzene to carbamate; catalytic system: $[Pd(phen)_2][PF_6]_2$ + phen + $[(phen)H][PF_6]$[a]

Substrate	Conv. (%)	Selectivity (%)			
		Carbamate	Aniline	Azobenzene	Other
Azobenzene	94	80	14		6
Azoxybenzene	75	29	3	41	2

[a] Reaction conditions: n_{Pd} = 0.02 mmol; $n_{free\ phen}$ = 0.08 mmol; $n_{[(phen)H][PF6]}$ = 0.12 mmol; substrate: 2.5 mmol; methanol: V = 8.0 mL; 2,2′-dimethoxypropane: V = 0.4 mL; T = 155 °C; P_{CO} = 40 atm; t = 2 h.

On the basis of the catalytic results and on the isolated metallacycles (**2**) we propose a catalytic cycle (Figure 2) which may be operative contemporary to that of the main reaction.[4] The carbonylated species **A**, which is also supposed to be the active species for the conversion of nitrobenzene to carbamate, reacts with azoxybenzene yielding the metallacycle **B**. From the latter, azobenzene is obtained and the active species **A** is restored. Azoxy- and azobenzene may compete for the intermediate **A**. When azobenzene interacts with **A** the metallacycle **C** is formed. This intermediate can follow two different pathways: in one case it reacts with methanol and protons yielding one equivalent of carbamate and aniline, which was found to be the main by-product. In the other, the insertion of carbon monoxide into the Pd−N bond is possible yielding the metallacycle **D**, which corresponds to **2**. The attack of methanol on this

species generates two equivalents of carbamate and regenerates the active species **A**.[9]

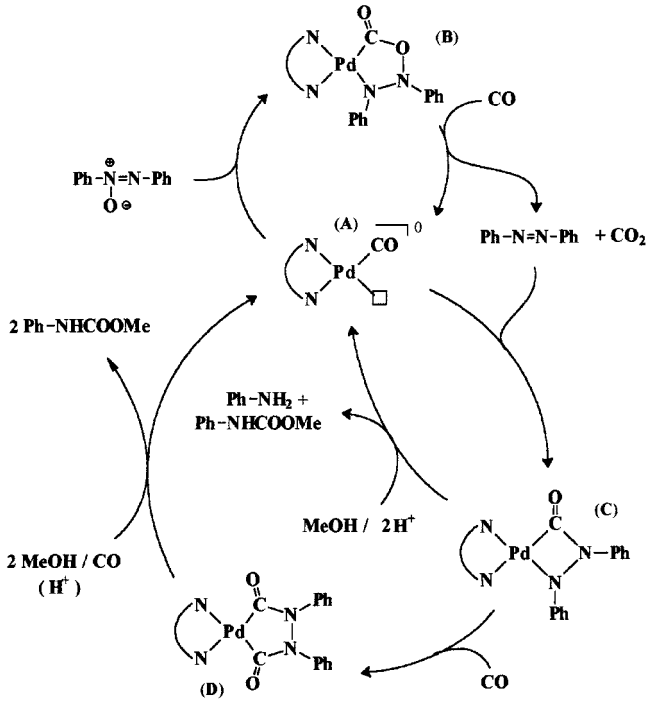

Figure 2. Proposed catalytic cycle

Conclusion

The isolation of the new metallacylic derivatives [(N-N)Pd*C*(O)N(Ph)N(Ph)*C*(O)] has allowed us to propose another catalytic cycle which should be operative contemporary to that of direct conversion of nitrobenzene to carbamate. In agreement with this hypothesis azoxy- and azobenzene are better regarded as intermediates of the reaction rather than by-products.

Moreover, a comparison of the two metallacycles [(phen)Pd*C*(O)N(Ph)O*C*(O)] **(1a)** and [(phen)Pd*C*(O)N-(Ph)N(Ph)*C*(O)] **(2a)** shows that, in the former, the N−O bond of the *C*(O)N(Ph)O*C*(O) moiety is polar, and therefore more likely to be broken than the N−N bond of the *C*(O)N(Ph)N(Ph)*C*(O) fragment of the second one. Therefore, the high amount of azobenzene obtained in the reductive carbonylation of nitrobenzene to urethane might be related to the more difficult formation and reaction of the metallacycles **2** than of **1**. The use of unsymmetrically substituted phenanthrolines, such as 3,4-dimethyl-1,10-phenanthroline, might favour the transformation of the corresponding metallacycle **2** into carbamate, increasing the selectivity of the overall reaction.

Experimental Section

The nitrogen-donor ligands were used as supplied (Aldrich). Azoxybenzene was synthesised from nitrosobenzene (Aldrich) in 0.2 M NaOH ethanolic solution. Azobenzene (Fluka) and methanol (Baker) were used without further purification. Carbon monoxide (CP grade, 99.9%) was supplied by SIAD.

IR spectra were recorded on a Perkin−Elmer 983G spectrometer as KBr pellets.

^{1}H NMR spectra were recorded at 400 MHz on a Jeol EX 400 spectrometer operating in Fourier-transform mode, with tetramethylsilane (TMS) as internal standard.

The GC analyses were conducted on a gas-chromatograph DANI 6800 on a column 10% SE 30 (2 m), equipped with a Carlo Erba DP700 data processor.

Synthesis: The complexes [Pd(N-N)($CH_3COO)_2$], [Pd(N-N)$_2$][PF_6]$_2$ and compounds [(N-N)H][PF_6] were synthesised according to the procedures reported in literature.[10,11]

Synthesis of [(N-N)Pd*C*(O)N(Ph)N(Ph)*C*(O)] [N-N = phen (2a), tmphen (2b)]: The reaction was carried out in a Berghof stainless steel autoclave (100 mL), equipped with a Teflon liner and magnetic stirrer. [Pd(phen)($CH_3COO)_2$] (0.30 g, 0.7 mmol), phen (0.27 g, 1.5 mmol), azobenzene (0.77 g, 4.2 mmol) and methanol (10 mL) were placed in the reactor, which was then pressurised at 40 atm. with CO. The system was stirred at room temperature for 24 h. After releasing the residual gas, the pale-yellow solid was filtered at reduced pressure, washed with methanol and dried under vacuum.

The same procedure was followed for the complex with the tmphen ligand.

2a: Yield: 75 mg, 20%. − $C_{26}H_{18}N_4O_2Pd$ (524.85): calcd. C 59.5, H 3.46, N 10.7; found C 58.5, H 3.26, N 10.2. − IR (KBr): ν(CO) = 1627 cm^{-1}. − ^{1}H NMR ($CDCl_3$): δ = 7.05 (t, 2 H, *p*-Ph), 7.28 (overlapped with $CDCl_3$, *m*-Ph), 7.46 (d, 4 H, *o*-Ph), 7.91 (dd, 2 H, H^{3,8}), 7.95 (s, 2 H, H^{5,6}), 8.47 (d, 2 H, H^{4,7}), 10.25 (d, 2 H, H^{2,9}).

Synthesis of [(tm-phen)Pd*C*(O)N(Ph)N(Ph)*C*(O)] (2b): A chloroform (2.5 mL) solution of [(phen)Pd*C*(O)N(Ph)N(Ph)*C*(O)] (0.05 g, 0.1 mmol) was treated with tm-phen (0.03 g, 0.12 mmol). After stirring for 3 h at room temperature, a few drops of diethyl ether were added. The solid was filtered off, washed with cold chloroform and diethyl ether and dried under vacuum.
Yield: 53 mg, 90%. − $C_{30}H_{26}N_4O_2Pd$ (580.96): calcd. C 62.0, H 4.51, N 9.64; found C 61.5, H 4.26, N 9.52. − IR (KBr): ν(CO) = 1627 cm^{-1}. − ^{1}H NMR ($CDCl_3$): δ = 2.59 (s, 6 H, CH_3 of tm-phen), 2.70 (s, 6 H, CH_3 of tm-phen), 7.05 (t, 2 H, *p*-Ph), 7.28 (overlapped with $CDCl_3$, *m*-Ph), 7.45 (d, 4 H, *o*-Ph), 8.01 (s, 2 H, H^{5,6}), 9.74 (s, 2 H, H^{2,9}).

X-ray Structure Determination: A yellow single crystal of **2a**, prism shaped (0.40 × 0.20 × 0.18 mm) was mounted on an Enraf−Nonius CAD4 diffractometer, equipped with graphite monochromator and Mo-K_α radiation. Unit cell dimensions were obtained from a least-squares fit of the setting angles of 25 reflections in the θ range 10.0−14.5°. Intensity data were corrected for Lorentz-polarisation effects and absorption by an empirical ψ-scan method. The structure was solved by conventional Patterson and Fourier techniques[12] and refined by a full-matrix anisotropic least-squares method.[13] All the calculations were performed using the WinGX System, Ver 1.61.[14]

The choice of space group $P2_1/m$ involves a structural disorder of the phenyl rings, the Pd(phen) moiety being located on a symmetry mirror. On the other hand, an attempted structure solution in the

noncentrosymmetric space group $P2_1$ did not produce satisfactory results (large correlation matrix elements and nonpositive definite thermal ellipsoids for some atoms).

$C_{26}H_{18}N_4O_2Pd$, M = 524.84, monoclinic, space group $P2_1/m$ (No. 11), a = 10.125(5), b = 6.766(2), c = 15.468(3) Å, β = 94.97(2)°, U = 1055.7(6) Å^3, Z = 2, ρ_{calcd} =1.651 g cm^{-3}, μ (Mo-K_α) = 0.912 mm^{-1}, F(000) = 528; 2902 measured reflections at room temperature ($2\theta_{max}$ = 56°, octants $-14 \le h \le 14$; $0 \le k \le 9$; $0 \le l \le 20$), 2783 unique reflections [R(int) = 0.0708], 1568 observed [$I > 2\sigma(I)$], 229 parameters, $R1$ = 0.0524, $wR2$ = 0.0939, GoF = 0.953; hydrogen atoms in idealized geometries; weighting scheme $w = 1/[\sigma^2(F_o^2) + (0.0410P)^2]$, where P = (Max (F_o^2, 0) + $2F_c^2$)/3; max positive and negative peaks in ΔF map 0.460 and −0.909 e Å^{-3}, respectively. Crystallographic data (excluding structure factors) for the structure included in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-100492. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; Email: deposit@ccdc.cam.ac.uk].

Catalysis: The carbonylation reactions were carried out in the Berghof reactor (see above). After introducing the catalyst precursor, the ligand and the acid cocatalyst the autoclave was closed. Nitrobenzene, methanol and 2,2′-dimethoxypropane were placed in a two necked flask connected both to the reactor and to the CO bomb through a PTFE tube. This solution was flushed with CO for 20 min and it was then transferred to the reactor. The autoclave was charged at 40 atm. of CO and heated to the proper temperature. At the end of the run the autoclave was cooled and the residual gas vented. The reaction mixture was filtered off over fine paper and analysed by GC.

Zinc Complexes of Condensed Phosphates, 2[‡]

Diphosphate−Zinc Complexes with Chelating Coligands

Alexandra Müller-Hartmann[a] and Heinrich Vahrenkamp*[a]

Keywords: Zinc / Phosphates / Organic pyrophosphates / Synthetic methods / Phosphatases

Zinc perchlorate, diorganodiphosphates (POP^{2-}), and chelating ligands L (L = 1,10-phenanthroline, neocuproine, 2,2′-bipyridine, oxinate) yield three types of ternary complexes. Type 1 ($L_2Zn{\cdot}POP$) contains octahedral zinc bound by the diphosphate as an OPOPO chelate ligand. Type 2 (LZn·POP) consists of dimeric complexes containing five-coordinate zinc, with the diphosphates acting as OPOPO chelate ligands for one zinc ion and as OPO bridges between two zinc ions. Type 3 ($L_2Zn_2{\cdot}POP$), observed only for oxinate, is proposed to contain two five-coordinate zinc ions bridged by the diphosphate as a tetradentate ligand.

Introduction

In the chemistry of condensed phosphates, metal ions play an important role with regard to both the stabilization of the phosphate structures in the solid state[2] and in solution[3] and the activation of the phosphates for hydrolytic cleavage, as exemplified by the many enzymes that transfer phosphate units from oligophosphates, e.g. ATPases, kinases, and pyrophosphatases.[4−7] While the typical metal ions for this purpose are magnesium, calcium, and manganese, zinc can also fulfil the role of the former and may be essential in certain enzymes.[8]

This clearly provides a motivation to study the coordination chemistry of oligophosphates, both from a structural and mechanistic standpoint as well as with regard to modeling of the bonding and reactivity patterns of enzymes that act on oligophosphates. Numerous studies have been published in this field, with a considerable emphasis on metal complexes of ATP and cyclic triphosphate.[3,9] There has been comparatively little work on soluble coordination compounds of pyrophosphate,[10−12] although a copper complex of thiamine pyrophosphate has been described.[13] In addition, structure determinations of several enzymes containing metal-bound oligophosphates, e.g. inorganic pyrophosphate,[14] ADP,[15] and thiamine pyrophosphate,[16] have been reported.

In our field, namely the biorelevant coordination chemistry of zinc, information on condensed phosphates as ligands is still scarce. We are not aware of any solution studies or syntheses of species containing zinc coordinated by simple inorganic or organic pyrophosphates or triphosphates. However, the interactions between zinc and nucleotides have been investigated in solution,[2] the species $Zn_3(ADP)_2$ and $Zn_2(ATP)$ have been isolated,[17] and the structures of zinc complexes with H_2ATP^{2-} [18] and $HATP^{3-}$ [19] have been reported. Among the many metal−oligophosphate solid-state compounds, several zinc pyrophosphate species,[2] a zinc triphosphate,[20] and a zinc tetraphosphate[21] have been obtained and structurally characterized.

Our interest in the coordination chemistry of zinc with oligophosphates stems from our observation that our "enzyme models", the pyrazolylborate−zinc hydroxide complexes, are well suited to effect hydrolytic cleavage of tetraorganopyrophosphates.[22] Our mechanistic implications for these and similar hydrolytic reactions with Zn−OH species[23,24] require that the substrate (e.g. the pyrophosphate) is attached to only one zinc ion through only one oxygen donor during the activation step, which is in contrast to common schemes for phosphate hydrolyses[3,8] that imply attachment of zinc to two P−O units or the attachment of two metal ions to one phosphate entity. We therefore embarked on a comprehensive study of the coordination chemistry of zinc with condensed phosphates.

The aim of this study was to gain an understanding of the factors that control the bonding modes (terminal, chelating, bridging) and the hapticity (monodentate to polydentate) of oligophosphates towards zinc. The measures taken to achieve this were a control of the number of available coordination sites on the zinc ion and influence on the number of donor sites on the oligophosphates. The former was accomplished by using nitrogen-containing coligands with varying donor numbers, the latter by using partially esterified oligophosphates. Thus, we used neither inorganic pyrophosphate or triphosphates nor ADP, ATP, or analogues thereof. Our "substrates" were triorgano- or diorgano-diphosphates, -triphosphates, and -methylenediphosphonates. Our coligands were bidentate and tridentate chelators or tridentate and tetradentate tripods. In accordance with the aims of this investigation, conditions favoring

the stoichiometric or catalytic hydrolysis of the oligophosphates were carefully avoided.

This paper describes the results obtained with bidentate coligands. The first paper in this series[1] dealt with oligophosphate complexes of zinc without coligands. The two succeeding papers[25,26] will deal with complexes incorporating coligands of higher donor numbers.

Phosphates and Coligands

The three dilithium diorganodiphosphates $Li_2[POP^1]$, $Li_2[POP^2]$, and $Li_2[POP^3]$ have been described previously by both ourselves[1] and others.[27] They are obtained by condensation of the appropriate organophosphoric acid with the organo(*n*-butylcarbamoyl)phosphate. They undergo hydrolytic cleavage in water only very slowly, but in some cases their reactions with zinc salts give rise to hydrolysis products in the reaction mixtures.

As coligands, we chose the classical examples listed below. Of these, neocuproine could be expected to favor lower coordination numbers than six for zinc, while oxinate, as a negatively charged O,N donor, was likely to produce complexes of a different type compared to the other three coligands.

In the following discussion, the resulting complexes are classified according to product types. Three different stoichiometries corresponding to three different structural types were observed.

Type 1 Complexes: $L_2Zn(POP)$

The complexes of this type, **1** and **2**, were obtained when the *p*-chlorophenyl-substituted diphosphate POP^3 was combined with zinc perchlorate and the coligands phen and bpy. They are the only products in this series for which the octahedral coordination of zinc and the chelating nature of the diphosphate ligands could be predicted from their compositions coupled with the mirror symmetry of the diphosphates and coligands as evidenced by NMR.

$(phen)_2Zn(POP^3)$ **1** $(bpy)_2Zn(POP^3)$ **2**

X-ray structure determinations of **1** and **2** verified their octahedral nature. Inspection of Figure 1 and 2 reveals the similarity of the two structures. Table 1 summarizes the relevant structural features. It is noticeable that the Zn−O bonds are shorter than the Zn−N bonds, indicating good zinc−phosphate bonding, and that the P=O and P−O(Zn) bond lengths are similar, pointing to a highly ionic nature of the zinc−phosphate interactions. The other structural features are normal for these types of ligands, as observed for instance in $(bpy)_2Zn(NO_3)_2$,[28] $[(phen)_2Zn(H_2O)_2]SO_4$,[29] $(NH_3)_4Co(HP_2O_7)$,[30] and $(bpy)Zn(H_2ATP)$.[18] Both structures demonstrate the stress-free attachment of the organodiphosphates as bidentate ligands forming six-membered chelate rings.

Zn−O−P	130.4−136.0(5)	132.1−137.2(1)
P−O−P	135.5(5)	136.3(1)
O−Zn−O	90.6(3)	89.0(1)

Type 2 Complexes: LZn(POP)

Irrespective of the reaction stoichiometry, all three N,N coligands (phen, neo, bpy) formed 1:1:1 complexes of type 2 with zinc perchlorate and the diphosphates POP^1 and POP^2. In addition, neo also yielded a complex of this type with POP^3. The ^1H NMR data (see Experimental Section) allow a distinction to be made between types 1 and 2, cf. **1**/**3** or **2**/**8**, but they yield no structural information other than that both the diphosphates and the coligands have mirror symmetry. The ^{31}P NMR spectra give the same indications, thereby pointing to a symmetrical bidentate coordination of the diphosphates. This would imply that in solution complex type 2 contains zinc in a tetrahedral ZnN_2O_2 environment.

L·Zn(POP)

L	POP^1	POP^2	POP^3
phen	**3**	**4**	
neo	**5**	**6**	**7**
bpy	**8**	**9**	

Structure determinations of **5** and **6** yielded the surprising information that the compounds are dimeric in the solid state. Figure 3 and 4 show that zinc is five-coordinate in the solid state, its coordination geometry being distorted trigonal-bipyramidal. In both compounds, the two mononuclear fragments are related to each other by an inversion center. Each diphosphate ligand uses two of its terminal oxygen atoms for chelate bonding to one zinc ion and another one to form the bridge linking the two complex halves.

The bonding details (see Table 2) of the coligands and of the chelating diphosphates resemble those of complexes **1** and **2** and may be compared to the same reference compounds (see above). There is, however, a wider spread of bond lengths and angles between **5** and **6** than between **1** and **2**. Overall, the Zn−O and Zn−N bonds in **5** and **6** are shorter, in agreement with the lower coordination number. A notable feature concerns the Zn−O bond lengths in the bridging vs. the chelating mode of the diphosphates. One of the two Zn−O (chelate) bonds is short while the other is 0.10−0.13 Å longer. The latter involves the monophosphate fragment that also provides the bridge bond, thus indicating a weakening of the Zn−O interaction due to the attach-

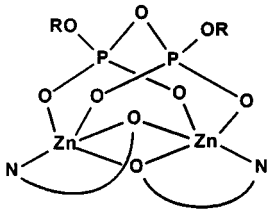
ment of a second zinc ion. In contrast, the bridging Zn−O interaction is strong, as indicated by the short bond length. Again, the P−O bond lengths, which are virtually identical for the terminal, bridging, and chelating situations, do not reflect the varying Zn−O interactions in which these P−O functions are involved.



Type 3 Complexes: $L_2Zn_2(POP)$

Only one complex of this type was obtained, and it was also the only complex that could be isolated in a pure state from reactions with oxine. Compound **10** was found to be readily soluble in methanol and hence is unlikely to be a coordination polymer.

$$(ox)_2Zn_2(POP^2)$$

10

The spectra of **10** (see below) again give no information other than that the diphosphate is bound symmetrically. It seems likely that the oxinate oxygen serves as a bridging ligand, as observed for tetrameric bis(oxinato)zinc,[31] and that zinc with oxinate ligands is five- or six-coordinate.[31,32] If one also excludes coordination polymers or solvated species, the number of possible constitutions for **10** becomes small. That depicted below is one of the possibilities, but in view of the lack of spectroscopic support, it can only be regarded as a proposal.

Spectroscopy

The ^{1}H NMR data (see Experimental Section) serve no other purpose than to confirm the compositions of the complexes. In all cases, they indicate that the diphosphates are bound in a symmetrical fashion. As has been shown for **5** and **6**, this is not the case in the solid state. Thus, it must be concluded that the complexes are labile, being characterized by the solution phenomena of solvation and/or fluxionality.

Table 3 lists the IR and ^{31}P NMR spectroscopic data. Coordination of the diphosphates leads to typical features for the very strong IR bands of the PO_2 stretches. In all cases, the two bands due to $\nu_{as}(PO_2)$ are significantly shifted to higher wavenumbers, while the band for $\nu_s(PO_2)$ is shifted by a similar amount to lower wavenumbers. However, as shown by the arrangement in Table 3, similarities within groups of the same POP ligand are more typical than similarities within groups representing the same complex type. Similar conclusions can be drawn from the ^{31}P NMR data. Coordination of the diphosphates is evident from a shift of about 2 ppm to higher field in all cases. However, there are no group trends, and the unsymmetrical nature of the diphosphates in complex type 2 is not reflected in the spectra.

Conclusions

In the preceding paper[1] it was shown that reducing the donor capacity of oligophosphates by esterification is not sufficient to produce low molecular weight zinc−oligophosphate complexes. In the present work, we have shown that this can be achieved by reducing the number of coordination sites on zinc through the use of chelating coligands. Complex types **1** and **2**, for which structural information has been obtained, contain one diphosphate ligand per zinc ion, which is bound as an O,O chelate ligand with a six-membered chelate ring. With two N,N coligands, zinc achieves octahedral ZnO_2N_4 coordination. When only one N,N coligand is attached, the diphosphates become tridentate, using one of their P=O functions as a bridging donor. The resulting dinuclear complexes contain zinc in a trigonal-bipyramidal ZnO_3N_2 coordination. Neither a monodentate attachment to one zinc ion nor a bis-monodentate bridging of two zinc ions has been observed. This has prompted us to increase the hapticity of the coligands, leading to the results presented in the two succeeding papers.

Experimental Section

General: For general working and measuring procedures, see ref.[33] The lithium salts of the diphosphates[1,27] were stored under anhydrous conditions. During the course of the reactions, no precautions were taken to prevent the access of moisture. All organic phosphates are potentially toxic and were handled accordingly.

1: A solution of $Li_2[POP^3]$ (100 mg, 0.23 mmol) in boiling methanol (80 mL) was added to a solution of phen (42 mg, 0.23 mmol) and $Zn(ClO_4)_2{\cdot}6H_2O$ (87 mg, 0.23 mmol) in boiling methanol (50 mL). The mixture was filtered while hot, slowly allowed to cool to room temp., and then slowly concentrated to a volume of 20 mL in a desiccator. 30 mg (30%) of **1**, m.p. 168 °C, was precipitated. − $C_{36}H_{24}Cl_2N_4O_7P_2Zn{\cdot}3\,H_2O$ (822.8 + 54.1): calcd. C 49.31, H 3.45, N 6.39, Zn 7.46; found C 48.86, H 3.10, N 6.70, Zn 7.85. − ^{1}H NMR ([D$_6$]DMSO): δ = 6.69 (d, *J* = 8.2 Hz, 4 H, Ph), 6.90 (d, *J* = 8.2 Hz, 4 H, Ph), 7.97 (s, 6 H, phen), 8.25 (s, 6 H, phen), 8.84 (d, *J* = 7.8 Hz, 12 H, phen).

2: Prepared in the same manner as **1** from $Li_2[POP^3]$ (100 mg, 0.23 mmol), bpy (36 mg, 0.23 mmol), and $Zn(ClO_4)_2{\cdot}6H_2O$ (87 mg, 0.23 mmol). After cooling, the mixture was filtered and the filtrate was slowly concentrated to a volume of 8 mL, yielding 35 mg (39%) of **2**; m.p. 261 °C. Water of crystallization (5 H_2O) could be removed by prolonged pumping. − $C_{32}H_{24}Cl_2N_4O_7P_2Zn$ (774.8): calcd. C 49.61, H 3.12, N 7.23, Zn 8.44; found C 48.55, H 2.91, N 6.89, Zn 8.25. − ^{1}H NMR ([D$_6$]DMSO): δ = 7.05 (d, *J* = 8.8 Hz, 4 H, Ph), 7.20 (d, *J* = 8.8 Hz, 4 H, Ph), 7.55 (m, 4 H, bpy), 8.06 (m, 4 H, bpy), 8.45 (m, 4 H, bpy), 8.71 (m, 4 H, bpy).

3: Prepared in the same manner as **1** from $Li_2[POP^1]$ (124 mg, 0.28 mmol) in methanol (25 mL) and phen (50 mg, 0.28 mmol) and $Zn(ClO_4)_2{\cdot}6H_2O$ (103 mg, 0.28 mmol) in methanol (95 mL). Upon cooling, 72 mg (43%) of **3**, m.p. 284 °C, was precipitated. − $C_{26}H_{22}N_2O_7P_2Zn$ (601.8): calcd. C 51.89, H 3.68, N 4.65, Zn 10.86; found C 51.12, H 3.66, N 4.61, Zn 10.76. − ^{1}H NMR ([D$_6$]DMSO): δ = 2.10 (s, 6 H, Me), 6.80 (m, 8 H, Ph), 8.02 (dd, *J* = 6.4, 6.4 Hz, 2 H, phen), 8.19 (s, 2 H, phen), 8.81 (d, *J* = 8.0 Hz, 2 H, phen), 9.11 (d, *J* = 4.2 Hz, 2 H, phen).

4: Prepared in the same manner as **1** from $Li_2[POP^2]$ (92 mg, 0.19 mmol) in methanol (30 mL) and phen (35 mg, 0.19 mmol) and $Zn(ClO_4)_2{\cdot}6H_2O$ (72 mg, 0.19 mmol). Yield 30 mg (23%) of **4**; m.p. 296 °C. − $C_{32}H_{34}N_2O_7P_2Zn$ (686.0): calcd. C 56.03, H 5.00, N 4.08, Zn 9.53; found C 55.43, H 5.01, N 3.89, Zn 9.65. − ^{1}H NMR ([D$_6$]DMSO): δ = 1.19 (s, 18 H, *t*Bu), 6.94 (d, *J* = 8.4 Hz, 4 H, Ph), 7.12 (d, *J* = 8.4 Hz, 4 H, Ph), 8.08 (dd, *J* = 6.4, 6.4 Hz, 2 H, phen), 8.21 (s, 2 H, phen), 8.83 (d, *J* = 8.1 Hz, 2 H, phen), 9.23 (d, *J* = 3.5 Hz, 2 H, phen).

5: Prepared in the same manner as **1** from $Li_2[POP^1]$ (148 mg, 0.33 mmol) in methanol (20 mL) and neo·H_2O (74 mg, 0.33 mmol) and $Zn(ClO_4)_2{\cdot}6H_2O$ (123 mg, 0.33 mmol) in methanol (20 mL). After cooling, the mixture was filtered and the filtrate was slowly concentrated to a volume of 35 mL, yielding 50 mg (24%) of **5**;

m.p. 282 °C. – $C_{28}H_{26}N_2O_7P_2Zn$ (629.9): calcd. C 53.39, H 4.16, N 4.45, Zn 10.38; found C 53.19, H 4.14, N 4.39, Zn 10.40. – ^{1}H NMR ([D$_6$]DMSO): δ = 2.20 (s, 6 H, Me), 2.98 (s, 6 H, Me), 6.91 (m, 8 H, Ph), 7.96 (d, J = 8.6 Hz, 2 H, neo), 8.15 (s, 2 H, neo), 8.80 (d, J = 7.6 Hz, 2 H, neo).

6: Prepared in the same manner as **1** from $Li_2[POP^2]$ (257 mg, 0.54 mmol) in ethanol (150 mL) and neo·H_2O (123 mg, 0.54 mmol) and $Zn(ClO_4)_2$·$6H_2O$ (220 mg, 0.54 mmol) in ethanol (50 mL). After cooling, the mixture was filtered and the filtrate was slowly concentrated to a volume of 150 mL, yielding 171 mg (40%) of **6**; m.p. 294 °C. – $C_{34}H_{38}N_2O_7P_2Zn$·EtOH·H_2O (714.0 + 46.1 + 18.0): calcd. C 55.57, H 5.96, N 3.60, Zn 8.40; found C 55.29, H 5.50, N 3.68, Zn 8.90. – ^{1}H NMR ([D$_6$]DMSO): δ = 1.05 (t, J = 6.9 Hz, 3 H, EtOH), 1.23 (s, 18 H, *t*Bu), 2.99 (s, 6 H, Me), 3.17 (s, 2 H, H_2O), 3.43 (q, J = 6.9 Hz, 2 H, EtOH), 6.95 (d, J = 8.7 Hz, 4 H, Ph), 7.18 (d, J = 8.7 Hz, 4 H, Ph), 7.93 (d, J = 8.1 Hz, 2 H, neo), 8.22 (s, 2 H, neo), 8.73 (d, J = 8.9 Hz, 2 H, neo).

7: Prepared in the same manner as **1** from $Li_2[POP^3]$ (138 mg, 0.32 mmol) in ethanol (100 mL) and neo·H_2O (73 mg, 0.32 mmol) and $Zn(ClO_4)_2$·$6H_2O$ (120 mg, 0.32 mmol) in ethanol (100 mL). Yield 46 mg (21%) of **7**; m.p. 235 °C. – $C_{26}H_{20}Cl_2N_2O_7P_2Zn$ (670.7): calcd. C 46.56, H 3.01, N 4.18, Zn 9.75; found C 47.00, H 3.56, N 3.98, Zn 9.60. – ^{1}H NMR ([D$_6$]DMSO): δ = 3.00 (s, 6 H, Me), 7.04 (d, J = 8.8 Hz, 4 H, Ph), 7.21 (d, J = 8.8 Hz, 4 H, Ph), 7.97 (m, 2 H, neo), 8.16 (s, 2 H, neo), 8.77 (m, 2 H, neo).

8: Prepared in the same manner as **1** from $Li_2[POP^1]$ (105 mg, 0.23 mmol) in methanol (90 mL) and bpy (36 mg, 0.23 mmol) and $Zn(ClO_4)_2$·$6H_2O$ (87 mg, 0.23 mmol) in methanol (10 mL). The mixture was filtered while hot and the filtrate was slowly concentrated to a volume of 50 mL at room temp., yielding 21 mg (16%) of **8**; m.p. 266 °C. – $C_{24}H_{22}N_2O_7P_2Zn$ (577.8): calcd. C 49.89, H 3.84, N 4.85, Zn 11.32; found C 48.82, H 3.64, N 4.76, Zn 11.14. – ^{1}H NMR ([D$_6$]DMSO): δ = 2.18 (s, 6 H, Me), 6.91 (m, 8 H, Ph), 7.71 (m, 2 H, bpy), 8.23 (m, 2 H, bpy), 8.57 (d, J = 7.5 Hz, 2 H, bpy), 8.74 (s, 2 H, bpy).

9: Prepared in the same manner as **1** from $Li_2[POP^2]$ (100 mg, 0.21 mmol) in methanol (90 mL) and bpy (33 mg, 0.21 mmol) and $Zn(ClO_4)_2$·$6H_2O$ (79 mg, 0.21 mmol) in methanol (10 mL). The mixture was filtered while hot and then slowly concentrated to a volume of 50 mL at room temp., yielding 29 mg (20%) of **9**; m.p. 296 °C. – $C_{30}H_{34}N_2O_7P_2Zn$·H_2O (661.9 + 18.0): calcd. C 52.99, H 5.34, N 4.12, Zn 9.62; found C 52.79, H 5.07, N 4.03, Zn 9.45. – ^{1}H NMR ([D$_6$]DMSO): δ = 1.22 (s, 18 H, *t*Bu), 3.17 (s, 2 H, H_2O), 6.97 (d, J = 8.7 Hz, 4 H, Ph), 7.16 (d, J = 8.7 Hz, 4 H, Ph), 7.72 (m, 2 H, bpy), 8.23 (m, 2 H, bpy), 8.58 (d, J = 7.9 Hz, 2 H, bpy), 8.78 (m, 2 H, bpy).

10: Prepared in the same manner as **1** from $Zn(ClO_4)_2$·$6H_2O$ (81 mg, 0.22 mmol) and $Li_2[POP^2]$ (103 mg, 0.22 mmol) in methanol (30 mL) and oxH (32 mg, 0.22 mmol) in methanol (5 mL). The mixture was refluxed for 15 min., filtered while hot, allowed to cool, and then slowly concentrated to a volume of 15 mL, yielding 40 mg (21%) of **10**; m.p. 206 °C. – $C_{38}H_{38}N_2O_9P_2Zn_2$ (859.5): calcd. C 53.11, H 4.46, N 3.26, Zn 15.21; found C 54.27, H 4.87, N 3.20, Zn 14.89. – ^{1}H NMR ([D$_6$]DMSO): δ = 1.23 (s, 18 H, *t*Bu), 7.03 (d, J = 8.5 Hz, 4 H, Ph), 7.08 (s, 2 H, ox), 7.22 (d, J = 8.5 Hz, 4 H, Ph), 7.41 (m, 4 H, ox), 7.56 (dd, J = 6.2, 6.2 Hz, 2 H, ox), 8.35 (d, J = 8.2 Hz, 2 H, ox), 8.83 (s, 2 H, ox).

Structure Determinations:[34] The selected crystals were taken directly from the reaction solutions and used without drying in vacuo. They were immersed in fluorinated polyether oil and immediately placed in the nitrogen stream of the diffractometer's cooling system. Diffraction data were recorded at ca. −100 °C using the ω/2θ technique with a Nonius CAD4 diffractometer fitted with a molybdenum tube (K_α, λ = 0.7107 Å) and a graphite monochromator. Empirical absorption corrections based on ψ scans were applied. The structures were solved by direct methods and refined anisotropically with the SHELX program suite.[35] Hydrogen atoms were included with fixed distances and isotropic temperature factors 1.5 times those of their attached atoms. Parameters were refined against F^2. The R values are defined as $R_1 = \Sigma|F_o - F_c|/\Sigma F_o$ and

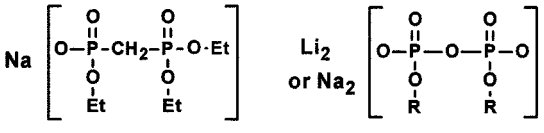
Zinc Complexes of Condensed Phosphates, 3[‡]

Diphosphate−Zinc Complexes with Tridentate Coligands

Florian Groß,[a] Alexandra Müller-Hartmann,[a] and Heinrich Vahrenkamp*[a]

Keywords: Zinc / Phosphates / Organic pyrophosphates / Methylene diphosphonates / Phosphatases

Diorganodiphosphates (POP^{2-}) and a triorgano-methylenediphosphonate (PCP^{-}) have been combined with zinc salts and the tridentate ligands L [L = bis(benzimidazolylmethyl)amine, bis(2-pyridylmethyl)amine, triazacyclononane, trimethyltriazacyclononane, and (dimethylaminoethyl)(2-pyridylmethyl)amine]. The resulting ternary complexes have been found to contain four-, five-, or six-coordinate zinc. Four-coordinate zinc has been identified in the complex types $[L{\cdot}Zn(PCP)]^{+}$ and $[L{\cdot}Zn(POP)Zn{\cdot}L]^{2+}$, containing monodentate phosphate ligands. Five-coordinate zinc has been found in the complexes [L·Zn(POP)] with chelating diphosphate ligands. Six-coordinate zinc has been observed in the complex type $[L{\cdot}Zn(POP){\cdot}H_2O]$ containing chelating diphosphates and in the complex type $[L{\cdot}Zn(POP)]_2$ in which the diphosphates act as tridentate bridging ligands. In a few cases, hydrolytic cleavage of the diphosphates resulted in the isolation of the trinuclear complexes $[(L{\cdot}Zn)_3(ROPO_3)_2]$ HPO_4 containing triply-bridging monophosphates.

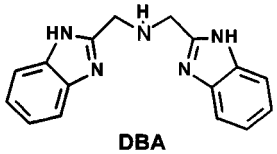


Introduction

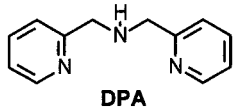
In the preceding paper[1] we outlined our motivation for studying the coordination chemistry of zinc with condensed phosphates and the associated scientific background. The main impetus is the importance of metal-containing systems (catalysts, enzymes) in the hydrolytic cleavage of oligophosphates, which is of relevance in the technical as well as in the biological world. Metal catalysis involves coordination of the substrates to the metals, and hence bonding modes of oligophosphates toward metals should provide an insight into possible catalytic pathways for their hydrolysis.

The literature on metal−oligophosphate complexes[1] is largely confined to studies of ATP and inorganic pyrophosphates. Specifically for the biologically important metal zinc, there have been only a few reports and even less structure determinations.[1] We have started to close this gap by carrying out a systematic study, in which the number of available coordination sites at zinc as well as the number of available donor functions on the phosphates have been varied. So far, we have reported on oligophosphate complexes of zinc without coligands[2] and with bidentate coligands.[1] In this paper, we present our results for zinc complexes with tridentate coligands. The succeeding paper[3] will report on systems with encapsulating tripodal coligands.

Phosphates and Coligands

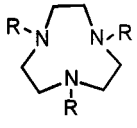


Diphosphates with both P−C−P and P−O−P linkages have been employed. The triethyl methylenediphosphonate PCP[4] was chosen to represent minimal donor qualities since it possesses only one P−O function with a formal negative charge. The diorganodiphosphates POP^1−POP^5 [2,5,6] have two negative charges. They have already[1] been shown to act as chelating bidentate as well as chelating plus bridging tridentate ligands. They could furthermore be expected to act as monodentate or bis-monodentate bridging ligands.

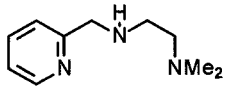


PCP

POP[1]: R = benzyl
POP[2]: R = phenyl
POP[3]: R = p-tolyl
POP[4]: R = p-t-Bu-phenyl
POP[5]: R = p-Cl-phenyl



As coligands, we chose tridentate systems containing only nitrogen donors, all of which can be derived from ethylenediamine. DBA,[7] DPA,[8] TACN,[9] and TACN*[10] are well established in coordination chemistry. PDEA was newly prepared by $NaBH_4$ reduction of the corresponding Schiff base.



DBA

DPA

As in the previous paper,[1] we sort the resulting zinc complexes according to product types rather than according to phosphates or coligands. We observed three different product types and one class of decomposition products.

Four-Coordinate Complexes

It was anticipated that the PCP ligand might only bind in a monodentate fashion. Its combination with the coligands DBA and DPA seems to verify this. With zinc perchlorate, the products **1** and **2** were obtained. While the spectroscopic data (see below) of these and all the other complexes yield no other information than the compositions of the products, support for the mononuclear nature of **1** and **2** was obtained from the ESI mass spectrum of **1**, which showed the parent ion.

$[(DBA)Zn(PCP)]ClO_4$ **1** $[(DPA)Zn(PCP)]ClO_4$ **2**

Likewise, a presumably bis-monodentate coordination was found for the POP ligands in three cases. All three involved the pyridine-containing coligands DPA or PDEA. The resulting complexes were **3**, **4**, and **5**. The main evidence for their constitutions was again provided by ESI-MS. The MS of compound **4** showed the parent ion of the dinuclear complex cation.

$[(L)Zn(POP)Zn(L)](ClO_4)_2$

3: L = DPA, POP = POP^3
4: L = DPA, POP = POP^4
5: L = PDEA, POP = POP^1

As none of the compounds proved to be suitable for X-ray structure determination, the structural assignments of **1**–**5** as tetrahedral complexes with ZnN_3O coordination are not unambiguous. As seen before,[1] the diphosphate ligands can be chelating, leading to five-coordinate zinc. They may also be bridging,[1] giving the same result. While there is some likelihood that the PCP ligand in **1** and **2** is indeed bridging, this should not be the case in **3**–**5**. The latter would require that the one POP ligand uses four of its P–O functions to generate two chelate rings. Although we have discussed this previously, it is unrealistic and would produce noticeable ^{31}P NMR shifts. The ^{31}P NMR data of **3**–**5** (see below) are, however, normal, showing the typical small shifts for the attachment of one zinc ion.

Five-Coordinate Complexes

The most typical coordination mode for the POP ligands seems to be the chelating one with six-membered Zn(O-POPO) chelate rings.[1] In combination with the tridentate coligands, this would lead to five-coordinate complexes, a very common coordination motif in zinc chemistry. Surprisingly, this could only be verified for the coligand DBA. In combination with the five POP ligands, it produced the complexes **6**–**10**. Otherwise, only DPA and POP^1 could be combined in this fashion to yield **11**. Proof of the nature of **6**–**11** as monomolecular species in solution and in the gas phase was obtained from the ESI mass spectrum of **10**, which showed a prominent peak attributable to the $[\mathbf{10}Na]^+$ ion.

$(DBA)Zn(POP^n)$ **6**–**10**: n = 1–5 $(DPA)Zn(POP^1)$ **11**

Proof of the monomolecular nature in the solid state was obtained by a structure determination of **8** (see Figure 1). The coordination of zinc in **8** is, to a good approximation, trigonal-bipyramidal; the central N atom of DBA and one O atom occupy the axial positions. While the axial Zn–N distance is typically long, the equatorial and axial Zn–O distances differ by just 0.015 Å. The essentially ionic nature of the Zn–O interactions can again[1] be derived from the fact that the P–O bond lengths for the coordinated and uncoordinated P–O functions are virtually identical. The geometrical parameters of the chelating POP ligand compare well with those in other zinc complexes (see below and ref.[1]). Otherwise, structures of trigonal-bipyramidal complexes of DBA or POP ligands are rare, two examples being the $CuCl_2$ complex of DBA[11] and a Cu complex of thiamine pyrophosphate.[12]

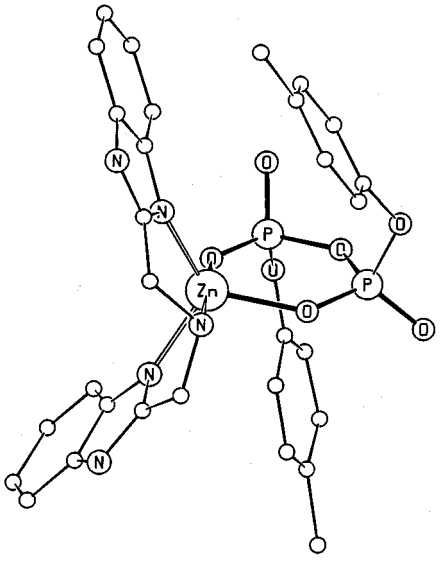

Figure 1. Molecular structure of **8**; selected bond lengths [Å] and angles [°]: Zn–O 2.020(3), 1.987(3), Zn–N 2.018(3), 2.373(3), 2.007(3), P–O(Zn) 1.473(3), 1.494(3), P=O 1.484(4), 1.473(3), P–O(P) 1.602(3), 1.590(3), P–O(C) 1.526(4), 1.594(4); Zn–O–P 134.0(2), 133.1(2), P–O–P 136.5(2), O–Zn–N(axial) 178.4(1)

Six-Coordinate Complexes

The triazacyclononane ligands are well known to form octahedral metal complexes. In this study, they were found to do so without exception. The TACN* coligand could be combined with POP^1, POP^2, and POP^3 in the 1:1:1 zinc complexes **12**–**14**. These were found to be hydrates like **6** and **7**. However, in contrast to these cases, where the water molecules are co-crystallized solvent, the complexes **12**–**14** contain coordinated water. This was shown by an X-ray

structure determination of **12**. In addition, on the basis of slightly different ^{1}H NMR patterns for the POP ligands, complexes **6**–**8** and complexes **12**–**14** can be divided into two separate groups.

$$(TACN^*)Zn(POP^n) \cdot H_2O$$

12–**14**: n = 1–3

The structure of **12** (Figure 2) contains zinc in a slightly distorted octahedral environment. The diphosphate ligand adopts the chelating mode, and all the salient structural details correspond to those discussed already (see above and ref.[1]). The features of the Zn−TACN* coordination correspond to those in the cationic complex $[(TACN^*)_2Zn_2(\mu\text{-}OAc)_2(\mu\text{-}OH)]$.[13]

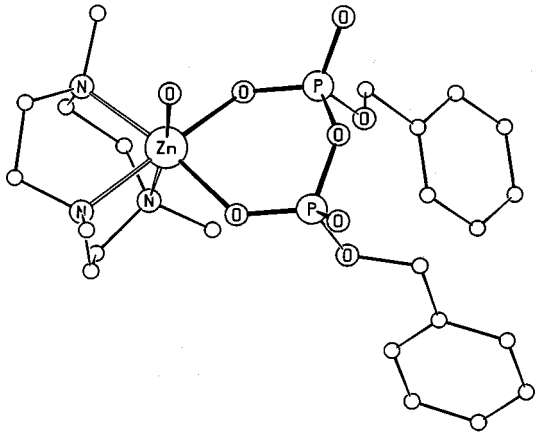

Figure 2. Molecular structure of **12**; selected bond lengths [Å] and angles [°]: Zn−N 2.206, 2.190, 2.178(2), Zn−O(P) 2.055, 2.059(2), Zn−O(H_2O) 2.115(2), P−O(Zn) 1.491, 1.490(2), P=O 1.492, 1.482(2), P−O(P) 1.599, 1.625(2), P−O(C) 1.590, 1.589(2); Zn−O−P 130.4, 131.5(1), P−O−P 131.0(1)

Two other complexes of 1:1:1 composition isolated as hydrates were **15** and **16**. On the basis of their spectral data, these might have been grouped with **12**–**14**. However, their structure determinations showed that in these cases the water molecules are not coordinated to zinc. Instead, the metal achieves octahedral coordination by using a third P−O function of each diphosphate as a bridging donor, thereby linking two molecular units to a dinuclear complex. We have observed this bonding mode before in dinuclear complexes with five-coordinate zinc.[1] It is difficult to explain why the two alternatives of octahedral coordination (coordinated water or diphosphate bridging), both of which exist in the presence of water, are preferred in specific examples.

$$(TACN)Zn(POP^1) \qquad (PDEA)Zn(POP^2)$$

15 **16**

The basic structural features of **15** (Figure 3) and **16** (Figure 4) are very similar, and they also resemble those of the previously reported complexes of this type with five-coordinate zinc.[1] The bridging makes the diphosphates tridentate ligands. The dinuclear entities have inversion centers, hence the zinc−diphosphate chelate rings are arranged in a parallel fashion, and the eight-membered rings created by the dimerization are in the chair conformation. In both cases, the Zn−O bond to the bridging oxygen is significantly shorter than the two Zn−O bonds in the chelate ring. For the diphosphate ligands, there is no noticeable change in their geometrical parameters or bond lengths as compared to the purely chelating mode. The distortion of the ZnO_3N_3 octahedra is comparably small in both the hydrate **12** and the dimers **15** and **16**. Compared to the related five-coordinate zinc complexes (see above and ref.[1]), all the Zn−O and Zn−N bonds are elongated.

Trinuclear Monophosphate Complexes

Although the pyrophosphates used in this study were found to be quite inert towards hydrolytic cleavage, in the presence of zinc salts they sometimes underwent hydrolysis.

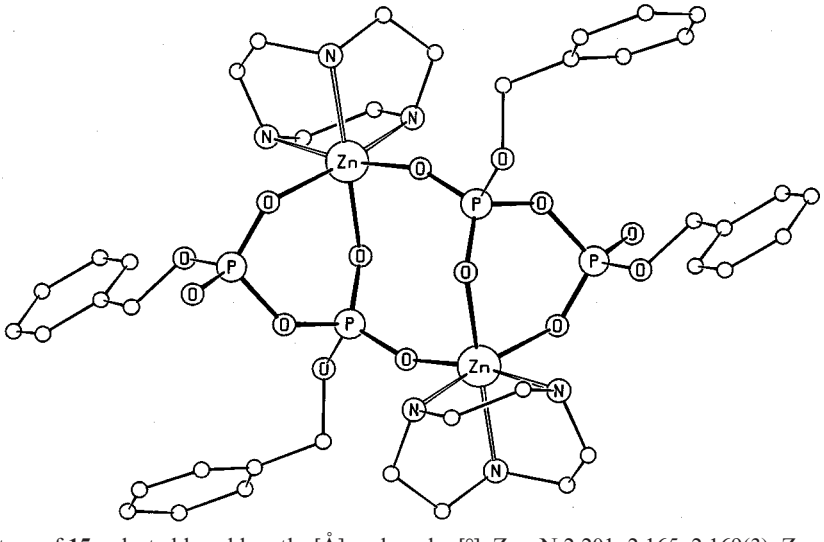

Figure 3. Molecular structure of **15**; selected bond lengths [Å] and angles [°]: Zn−N 2.201, 2.165, 2.169(3), Zn−O(br) 2.027(3), Zn−O(ch) 2.114, 2.099(3), P−O(Zn) 1.476, 1.473, 1.490(3), P=O 1.484(3), P−O(P) 1.612, 1.597(3), P−O(C) 1.600, 1.581(3); Zn−O−P 131.0, 127.8(2), P−O−P 131.5(2)

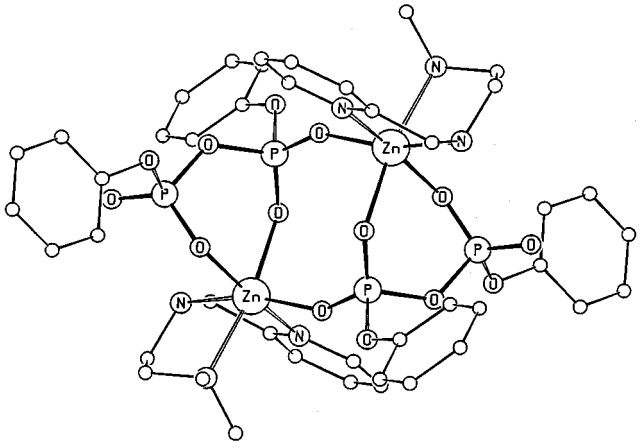

Figure 4. Molecular structure of **16**; selected bond lengths [Å] and angles [°]: Zn−N 2.171, 2.184, 2.221(2), Zn−O(br) 2.016(2), Zn−O(ch) 2.144, 2.112(2), P−O(Zn) 1.485, 1.487, 1.472(2), P=O 1.463(2), P−O(P) 1.609, 1.611(2), P−O(C) 1.603, 1.605(2); Zn−O−P 130.4, 126.1(1), P−O−P 126.8(1)

This normally meant that work-up of the reaction mixtures failed, which is the reason why the series of compounds presented here is incomplete. In two cases, however, the hydrolysis products were isolated as zinc complexes, the trinuclear nature of which was established by structure determinations. Both these complexes, **17** and **18**, were derived from the coligand DPA. They have HPO_4^{2-} counterions, as was verified by ^{31}P NMR spectroscopy.

$[(\mathbf{D}PA{\cdot}Zn)_3(TolOPO_3)_2]\,HPO_4$ **17**

$[(\mathbf{D}PA{\cdot}Zn)_3(ClC_6H_4OPO_3)_2]\,HPO_4$ **18**

Figure 5 depicts the structure of the trinuclear cation of complex **17**. The structure of **18** is quite similar, but will not be discussed here because of its mediocre quality. The $Zn_3(ROPO_3)_2$ units give rise to a structural motif that is seemingly unknown in the coordination chemistry of phosphates. The $P_2(OZnO)_3$ framework, having roughly trigonal symmetry and roughly planar POZnOP wings, is that of bicyclo[3.3.3]undecane. In contrast, the coordination of three metal−ligand units to one phosphate is not uncommon, as exemplified by the zinc complex $\{[(12\text{-ane-}N_4)Zn]_3(ROPO_3)\}^{4+}$.[14] The zinc ions in **17** and **18** are in a severely distorted trigonal-bipyramidal environment. Their Zn−O and Zn−N bond lengths fall in the characteristic ranges for ZnO_2N_3 complexes. The P−O bonds of the P−O−Zn linkages are somewhat longer than in those cases where there is only one zinc ion per phosphate unit (see above). The HPO_4^{2-} ions in the lattice lie beyond the range for coordination to zinc.

Spectroscopy

The ^1H NMR spectra (see Experimental Section) identify the coligands in the complexes and indicate that the POP ligands are bound in a symmetrical fashion in all cases. This does not conform with the solid-state structures of **15** and **16** and suggests that these complexes exist as solvated monomers or are fluxional in solution.

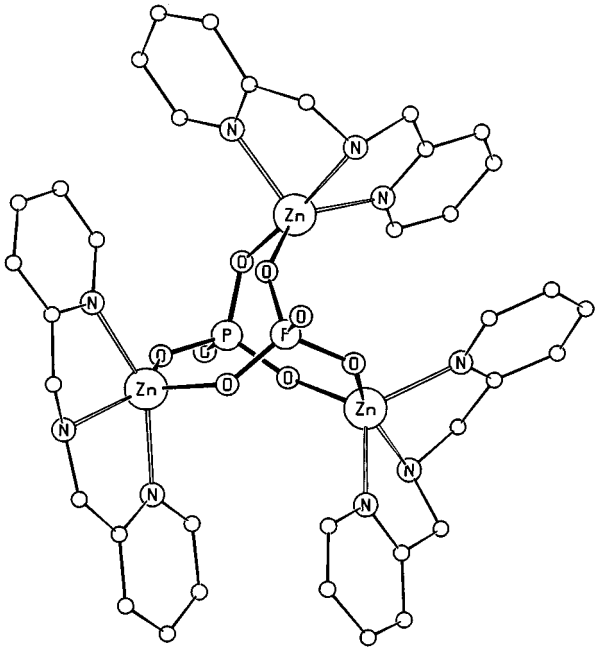

Figure 5. Structure of the zinc complex in **17** (tolyl groups omitted for clarity); important bond lengths [Å] and angles [°]: Zn−O(ax) 1.962−2.002(4), Zn−O(eq) 1.939−1.954(4), Zn−N(ax) 2.148−2.237(6), Zn−N(eq) 2.073−2.149(6), P−O(Zn) 1.493−1.520(4); O−Zn−O 96.8, 105.2, 115.0(2), Zn−O−P 123.5−156.0(3), O−P−O 112.3−114.4(3)

The IR bands in the P−O region show irregular coordination shifts (see Table 1). The $\nu_{as}(PO_2)$ bands are shifted by small amounts to either higher or lower wavenumbers. The $\nu_s(PO_2)$ bands are shifted by 20−30 cm^{-1} to lower wavenumbers. Thus, these bands are only of diagnostic value. More information can be derived from the ^{31}P NMR data. In all cases, an upfield shift is seen upon coordination. Its magnitude is around 1−2 ppm for aryl diphosphates,

Table 1. IR (KBr, cm^{-1}) and ^{31}P NMR (rel. to H_3PO_4) data

[a] PO_3 vibrations.

2−3 ppm for benzyl diphosphate, and 10−15 ppm for triethyl methylenediphosphonate. This proves that the phosphates are coordinated to zinc even in good donor solvents such as DMSO or water.

Conclusions

The reliable tridentate attachment of the coligands in this study and the fact that all the complexes contain just one coligand per zinc ion has allowed the observation of three coordination modes for the diphosphates. Monodentate attachment of PCP and bis-monodentate attachment of the POP ligands seems to yield tetrahedral $ZnON_3$ complexes. The most typical coordination mode of the POP ligands seems to be the chelating one. It has been observed in five- and six-coordinate zinc complexes with the coordination patterns ZnO_2N_3 and ZnO_3N_3. The open-chain tridentate ligands favor five-coordination, while the TACN ligands enforce octahedral coordination.

Two unusual bonding types have been found. In one of these, the POP ligands act as chelators for one zinc ion and as additional donors for the other zinc ion in dinuclear complexes. In the other, organo-monophosphates, which result from hydrolysis, act as triply-bridging ligands in trinuclear $(LZn)_3(phosphate)_2$ complexes.

With regard to the catalytic function of zinc in conventional or biological oligophosphate hydrolyses, the complexes described here and in the preceding papers[1,2] seemingly give no mechanistic information. The chelating mode of the diphosphates seems to provide stabilization rather than activation. Specifically in enzymes, steric restrictions at the active center render a chelating coordination unlikely. We therefore decided to enforce similar steric restrictions through the use of encapsulating ligands for zinc. The succeeding paper[3] describes their application in zinc−diphosphate chemistry.

Experimental Section

General: For general working and measuring procedures, see ref.[15] The lithium and sodium salts of the diphosphates[2,4−6] were stored under anhydrous conditions, as were the hygroscopic coligands.[7−10] During the course of the reactions, no precautions were taken to prevent the access of moisture. All organic phosphates are potentially toxic and were handled accordingly.

Ligand PDEA: The Schiff base PDEI (derived from pyridine-2-carbaldehyde and *N*,*N*-dimethylethylenediamine[16]) (1.50 g, 8.40 mmol) was dissolved in methanol (15 mL). $NaBH_4$ (1.60 g, 42.3 mmol) was then slowly added with stirring. After stirring for 20 h, 2 N HCl (20 mL) was added. The resulting mixture was extracted with dichloromethane (3 × 20 mL). After drying with Na_2SO_4, the combined extracts were concentrated to dryness. Chromatography of the residue on a 2 × 20 cm silica gel column (0.063−0.20 mm) eluting with cyclohexane/ethyl acetate/triethylamine (8:2:1) yielded the product PDEA; R_f = 0.29. 1.02 g (68%) of PDEA was obtained as an orange oil, which was not analytically pure. − $C_{10}H_{17}N_3$ (179.3): calcd. C 67.00, H 9.56, N 23.44; found C 64.22, H 9.30, N 21.88. − ^{1}H NMR (CD_3OD): δ = 2.21 (s, 6 H, Me), 2.39 (t, *J* = 6.7 Hz, 2 H, CH_2), 2.63 (t, *J* = 6.7 Hz, 2 H, CH_2), 3.79 (s, 2 H, py-CH_2), 7.19 (m, 1 H, py), 7.36 (d, *J* = 7.7 Hz, 1 H, py), 7.70 (m, 1 H, py), 8.40 (d, *J* = 4.9 Hz, 1 H, py).

1: Na[PCP] (70 mg, 0.25 mmol) in boiling ethanol (5 mL) was added to a solution of DBA·H_2O (73 mg, 0.25 mmol) and $Zn(ClO_4)_2$·$6H_2O$ (92 mg, 0.25 mmol) in boiling ethanol (20 mL). After refluxing for 15 min., the mixture was filtered while hot, cooled to room temp., and then slowly concentrated to one third of its original volume. 97 mg (55%) of **1** was precipitated as a colorless powder; m.p. 186 °C. − $C_{23}H_{32}ClN_5O_{10}P_2Zn$ (701.3): calcd. C 39.39, H 4.60, N 9.99, Zn 9.32; found C 38.72, H 4.58, N 9.57, Zn 8.99. − ^{1}H NMR ([D_6]DMSO): δ = 1.05 (m, 9 H, CH_3), 2.36 (t, *J* = 19.8 Hz, 2 H, PCH_2P), 3.84 (m, 6 H, CH_2), 4.27 (s, 1 H, NH), 4.36 (s, 4 H, NCH_2), 7.31 (m, 4 H, Ph), 7.58 (m, 2 H, Ph), 8.07 (m, 2 H, Ph), 13.31 (s, 2 H, NH).

2: Prepared in the same manner as **1** from Na[PCP] (108 mg, 0.37 mmol) in methanol (20 mL) and $Zn(ClO_4)_2$·$6H_2O$ (140 mg, 0.37 mmol) and DPA (75 mg, 0.37 mmol) in methanol (20 mL). Yield 117 mg (50%) of **2** as a colorless powder; m.p. 186 °C. − $C_{19}H_{30}ClN_3O_{10}P_2Zn$ (623.2): calcd. C 36.62, H 4.85, N 6.74, Zn 10.49; found C 35.95, H 4.71, N 6.63, Zn 10.72. − ^{1}H NMR (D_2O): δ = 1.20 (m, 9 H, CH_3), 2.33 (t, *J* = 20.2 Hz, 2 H, PCH_2P), 3.86 (dq, *J* = 7.2, 7.3 Hz, 2 H, OCH_2), 4.15 (d, *J* = 16.6 Hz, 2 H, NCH_2), 4.25 (dq, *J* = 7.0, 7.1 Hz, 4 H, OCH_2), 4.53 (d, *J* = 16.6 Hz, 2 H, NCH_2), 7.49 (m, 4 H, Ph), 7.93 (dd, *J* = 8.5, 8.5 Hz, 2 H, Ph), 8.54 (d, *J* = 4.6 Hz, 2 H, Ph).

3: DPA (60 mg, 0.30 mmol) and $Zn(ClO_4)_2$·$6H_2O$ (112 mg, 0.30 mmol) were combined in methanol (12 mL). Li_2[POP^3] (55 mg, 0.15 mmol) in methanol (10 mL) was then added with stirring. After stirring for 15 h, the solvent was removed in vacuo and the residue was taken up in dichloromethane (25 mL). After filtering, *n*-heptane was carefully added to the filtrate until precipitation commenced. Subsequent slow evaporation of the solvent yielded 73 mg (45%) of **3** as colorless microcrystals; m.p. 195 °C. − $C_{38}H_{40}Cl_2N_6O_{15}P_2Zn_2$ (1084.4): calcd. C 42.09, H 3.72, N 7.75, Zn 12.06; found C 40.95, H 3.71, N 7.71, Zn 11.15. − ^{1}H NMR (CD_3OD): δ = 2.14 (s, 6 H, CH_3), 3.81 (d, *J* = 16.5 Hz, 4 H, NCH_2), 4.34 (d, *J* = 16.5 Hz, 4 H, NCH_2), 6.88 (s, 8 H, Ph), 7.38 (m, 4 H, py), 7.48 (d, *J* = 7.9 Hz, 4 H, py), 7.98 (m, 4 H, py), 8.42 (d, *J* = 4.6 Hz, 4 H, py).

4: Prepared in the same manner as **3** from DPA (29 mg, 0.15 mmol), $Zn(ClO_4)_2$·$6H_2O$ (54 mg, 0.15 mmol), and Li_2[POP^4] (34 mg, 0.073 mmol) in methanol (total volume 15 mL). Yield 50 mg (59%) of **4** as a colorless powder; m.p. 150−155 °C. − $C_{44}H_{52}Cl_2N_6O_{15}P_2Zn_2$ (1168.5): calcd. C 45.23, H 4.49, N 7.19, Zn 11.19; found C 44.65, H 4.40, N 7.07, Zn 11.03. − ^{1}H NMR (CD_3OD): δ = 1.25 (s, 18 H, *t*Bu), 3.92 (d, *J* = 16.7 Hz, 4 H, NCH_2), 4.43 (d, *J* = 16.7 Hz, 4 H, NCH_2), 6.99 (d, *J* = 8.7 Hz, 4 H, Ph), 7.21 (d, *J* = 8.7 Hz, 4 H, Ph), 7.49 (m, 8 H, py), 7.99 (m, 4 H, py), 8.62 (d, *J* = 3.9 Hz, 4 H, py).

5: Prepared in the same manner as **3** from PDEA (54 mg, 0.30 mmol), $Zn(ClO_4)_2$·$6H_2O$ (112 mg, 0.30 mmol), and Na_2[POP^1] (60 mg, 0.15 mmol) in methanol (total volume 25 mL); reflux for 2 h. Yield 80 mg (51%) of **5** as a colorless powder; m.p. 95 °C. − $C_{34}H_{48}Cl_2N_6O_{15}P_2Zn_2$ (1044.4): calcd. C 39.10, H 4.63, N 8.05, Zn 12.52; found C 39.75, H 4.65, N 7.77, Zn 11.81. − ^{1}H NMR (CD_3OD): δ = 2.27 (s, 12 H, NMe_2), 2.68 (m, 8 H, C_2H_4), 3.87 (d, *J* = 17.3 Hz, 2 H, NCH_2), 4.20 (d, *J* = 17.3 Hz, 2 H, NCH_2), 4.91 (d, *J* = 7.4 Hz, 4 H, OCH_2), 7.20 (s, 10 H, Ph), 7.38 (m, 4 H, py), 7.93 (m, 2 H, py), 8.62 (d, *J* = 4.4 Hz, 2 H, py).

6: $Na_2[POP^1]$ (272 mg, 0.68 mmol) was dissolved in hot methanol (50 mL) and as much water as necessary to obtain a clear solution. The resulting solution was added to a solution of DBA (200 mg, 0.68 mmol) and $Zn(ClO_4)_2{\cdot}6H_2O$ (252 mg, 0.68 mmol) in hot methanol (50 mL). The mixture was refluxed for 8 h and then stirred at room temp. for 48 h. During this time, 310 mg (65%) of **6** was precipitated as a colorless powder; m.p. 230 °C. − $C_{30}H_{29}N_5O_7P_2Zn{\cdot}H_2O$ (689.9 + 18.0): calcd. C 50.26, H 4.36, N 9.77, Zn 9.12; found C 50.88, H 4.30, N 9.70, Zn 8.67. − ^{1}H NMR ([D$_6$]DMSO): δ = 4.27 (d, *J* = 4.8 Hz, 4 H, NCH_2), 4.83 (dd, *J* = 2.7, 2.7 Hz, 4 H, OCH_2), 7.25 (m, 14 H, Ph + Bz), 7.54 (d, *J* = 8.0 Hz, 2 H, Ph), 8.43 (d, *J* = 8.0 Hz, 2 H, Ph).

7: $Li_2[POP^2]$ (116 mg, 0.34 mmol) in hot methanol (15 mL) was added to a solution of DBA (100 mg, 0.34 mmol) and $Zn(ClO_4)_2{\cdot}6H_2O$ (126 mg, 0.34 mmol) in boiling methanol (15 mL). On cooling, 99 mg (42%) of **7** was precipitated as a colorless powder; m.p. 270 °C. − $C_{28}H_{25}N_5O_7P_2Zn{\cdot}H_2O$ (670.9 + 18.0): calcd. C 48.82, H 3.95, N 10.17, Zn 9.49; found C 48.32, H 3.79, N 9.74, Zn 9.99. − ^{1}H NMR ([D$_6$]DMSO): δ = 4.23 (s, 4 H, NCH_2), 4.91 (s, 1 H, NH), 6.91 (m, 2 H, Ph), 7.08 (m, 8 H, Ph), 7.28 (m, 4 H, Ph), 7.56 (d, *J* = 7.4 Hz, 2 H, Ph), 8.34 (d, *J* = 7.4 Hz, 2 H, Ph), 13.27 (s, 2 H, NH).

8: Prepared in the same manner as **6** from $Li_2[POP^3]$ (94 mg, 0.21 mmol), DBA (62 mg, 0.21 mmol), and $Zn(ClO_4)_2{\cdot}6H_2O$ (78 mg, 0.21 mmol) in methanol (total volume 50 mL). Slow crystallization by evaporation of the solvent yielded 44 mg (30%) of **8** as colorless crystals; m.p. 300 °C. − $C_{30}H_{29}N_5O_7P_2Zn$ (689.9): calcd. C 51.56, H 4.18, N 10.02, Zn 9.35; found C 51.18, H 4.07, N 11.16, Zn 9.37. − ^{1}H NMR ([D$_6$]DMSO): δ = 2.13 (s, 6 H, CH_3), 4.22 (d, *J* = 4.9 Hz, 4 H, NCH_2), 6.82 (d, *J* = 8.5 Hz, 4 H, Ph), 6.94 (d, *J* = 8.5 Hz, 4 H, Ph), 7.26 (m, 4 H, Ph), 7.54 (d, *J* = 7.1 Hz, 2 H, Ph), 8.31 (d, *J* = 7.3 Hz, 2 H, Ph), 13.21 (s, 2 H, NH).

9: Prepared in the same manner as **6** from $Li_2[POP^4]$ (100 mg, 0.21 mmol), DBA (62 mg, 0.21 mmol), and $Zn(ClO_4)_2{\cdot}6H_2O$ (78 mg, 0.21 mmol) in methanol (total volume 20 mL). Yield 156 mg (95%) of **9** as colorless crystals; m.p. 260 °C. − $C_{36}H_{41}N_5O_7P_2Zn$ (783.1): calcd. C 55.22, H 5.28, N 8.94, Zn 8.35; found C 54.22, H 5.23, N 8.60, Zn 8.55. − ^{1}H NMR ([D$_6$]DMSO): δ = 1.19 (s, 18 H, *t*Bu), 4.24 (d, *J* = 4.2 Hz, 4 H, NCH_2), 6.98 (d, *J* = 8.8 Hz, 4 H, Ph), 7.08 (d, *J* = 8.8 Hz, 4 H, Ph), 7.25 (m, 4 H, Ph), 7.54 (d, *J* = 7.2 Hz, 2 H, Ph), 8.38 (d, *J* = 7.2 Hz, 2 H, Ph), 13.27 (s, 2 H, NH).

10: Prepared in the same manner as **6** from $Li_2[POP^5]$ (100 mg, 0.23 mmol), DBA (69 mg, 0.23 mmol), and $Zn(ClO_4)_2{\cdot}6H_2O$ (87 mg, 0.23 mmol) in methanol (total volume 65 mL). Slow crystallization by evaporation of the solvent yielded 76 mg (44%) of **10** as colorless crystals; m.p. 320 °C. − $C_{28}H_{23}Cl_2N_5O_7P_2Zn$ (739.8): calcd. C 45.46, H 3.13, N 9.47, Zn 8.84; found C 44.99, H 3.15, N 9.49, Zn 8.75. − ^{1}H NMR ([D$_6$]DMSO): δ = 4.27 (s, 4 H, NCH_2), 7.06 (m, 8 H, Ph), 7.26 (m, 4 H, Ph), 7.45 (d, *J* = 7.0 Hz, 2 H, Ph), 8.26 (d, *J* = 7.2 Hz, 2 H, Ph), 13.27 (s, 2 H, NH).

11: A solution of $K_2[POP^1]$ (130 mg, 0.70 mmol) in methanol (8 mL) was added to a solution of DPA (60 mg, 0.30 mmol) and $Zn(ClO_4)_2{\cdot}6H_2O$ (112 mg, 0.30 mmol) in methanol (15 mL). After stirring for 15 h, the mixture was filtered and the filtrate was concentrated to dryness. The residue was taken up in dichloromethane and the resulting solution was filtered. Addition of a few mL of *n*-heptane and slow evaporation of the solvents yielded 81 mg (44%) of **11** as colorless crystals; m.p. 170 °C. − $C_{26}H_{27}N_3O_7P_2Zn$ (620.9): calcd. C 50.30, H 4.38, N 6.77, Zn 10.53; found C 49.96, H 4.57, N 6.26, Zn 10.55. − ^{1}H NMR (CD_3OD): δ = 4.27 (d, *J* = 16.6 Hz, 2 H, NCH_2), 4.72 (d, *J* = 16.6 Hz, 2 H, NCH_2), 4.80 (dd, *J* = 3.2, 3.3 Hz, 4 H, OCH_2), 7.10 (s, 10 H, Ph), 7.20 (m, 2 H, py), 7.30 (d, *J* = 7.8 Hz, 2 H, py), 7.79 (m, 2 H, py), 8.68 (d, *J* = 5.5 Hz, 2 H, py).

12: $ZnCl_2$ (51 mg, 0.37 mmol) in acetonitrile/water (10 mL) was treated with TACN* (64 mg, 0.37 mmol) and $Na_2[POP^1]$ (150 mg, 0.37 mmol) in acetonitrile/water (20 mL). After stirring at 80 °C for 15 h, the mixture was slowly concentrated to a volume of 15 mL at room temp. 90 mg (36%) of **12** was precipitated as colorless crystals; m.p. 200 °C. − $C_{23}H_{35}N_3O_7P_2Zn{\cdot}5H_2O$ (592.9 + 90.1): calcd. C 40.45, H 6.64, N 6.15, Zn 9.57; found C 40.46, H 6.63, N 6.10, Zn 9.52. − ^{1}H NMR (CD_3OD): δ = 2.63 (s, 9 H, CH_3), 2.73 (s, 12 H, C_2H_4), 5.03 (dd, *J* = 3.2, 3.2 Hz, 4 H, OCH_2), 7.36 (m, 10 H, Ph).

13: Prepared in the same manner as **11** from $K_2[POP^2]$ (140 mg, 0.30 mmol), TACN* (51 mg, 0.30 mmol), and $Zn(ClO_4)_2{\cdot}6H_2O$ (112 mg, 0.30 mmol). Crystals were obtained by slow evaporation of the solvents from a methanol/water solution. Yield 124 mg (67%) of **13** as colorless crystals; m.p. 185 °C. − $C_{21}H_{31}N_3O_7P_2Zn{\cdot}3H_2O$ (564.8 + 54.0): calcd. C 40.76, H 6.03, N 6.79, Zn 10.57; found C 41.02, H 5.97, N 6.83, Zn 10.19. − ^{1}H NMR (CD_3OD): δ = 2.60 (s, 9 H, CH_3), 2.72 (s, 12 H, C_2H_4), 7.08 (m, 2 H, Ph), 7.25 (m, 8 H, Ph).

14: Prepared in the same manner as **11** from $Li_2[POP^3]$ (110 mg, 0.30 mmol), TACN* (51 mg, 0.30 mmol), and $Zn(ClO_4)_2{\cdot}6H_2O$ (112 mg, 0.30 mmol). Yield 93 mg (50%) of **14** as colorless crystals; m.p. 145 °C. − $C_{23}H_{35}N_3O_7P_2Zn{\cdot}1.5H_2O$ (592.9 + 27.0) calcd. C 44.56, H 6.18, N 6.75, Zn 10.55; found C 44.59, H 6.13, N 6.73, Zn 10.40. − ^{1}H NMR (CD_3OD): δ = 2.28 (s, 6 H, CH_3), 2.59 (s, 9 H, CH_3), 2.73 (s, 12 H, C_2H_4), 7.07 (s, 8 H, Ph).

15: Prepared in the same manner as **11** from $K_2[POP^1]$ (109 mg, 0.25 mmol), TACN (32.2 mg, 0.25 mmol), and $Zn(ClO_4)_2{\cdot}6H_2O$ (93 mg, 0.25 mmol). Yield 36 mg (25%) of **15** as colorless crystals. − $C_{20}H_{29}N_3O_7P_2Zn{\cdot}H_2O$ (550.8 + 18.0): calcd. C 42.23, H 5.49, N 7.39, Zn 11.50; found C 41.09, H 5.29, N 6.76, Zn 11.23. − ^{1}H NMR (CD_3OD): δ = 2.47 (m, 6 H, C_2H_4), 2.97 (m, 6 H, C_2H_4), 5.01 (s, 4 H, OCH_2), 7.34 (m, 10 H, Ph).

16: Prepared in the same manner as **11** from $K_2[POP^2]$ (102 mg, 0.25 mmol), PDEA (45 mg, 0.25 mmol), and $Zn(ClO_4)_2{\cdot}6H_2O$ (93 mg, 0.25 mmol). Yield 51 mg (35%) of **16** as colorless crystals; m.p. 175 °C. − ^{1}H NMR (CD_3OD): δ = 2.38 (s, 6 H, CH_3), 2.76 (m, 4 H, C_2H_4), 3.91 (d, *J* = 17.2 Hz, 1 H, NCH_2), 4.17 (d, *J* = 17.2 Hz, 1 H, NCH_2), 7.02 (m, 2 H, Ph), 7.20 (m, 8 H, Ph), 7.49 (m, 2 H, py), 8.03 (m, 1 H, py), 8.67 (d, *J* = 5.8 Hz, 1 H, py).

17: A solution of $Li_2[POP^3]$ (180 mg, 0.40 mmol) in hot methanol (40 mL) was added to a solution of BPA (160 mg, 0.80 mmol) and $Zn(ClO_4)_2{\cdot}6H_2O$ (299 mg, 0.80 mmol) in boiling methanol (20 mL). After refluxing for 10 min, the mixture was filtered while hot and the filtrate was cooled to −24 °C. 70 mg (32%) of **17** was precipitated as colorless crystals; m.p. 235 °C. − $C_{50}H_{54}N_9O_{12}P_3Zn_3{\cdot}H_2O$ (1262.1 + 18.0): calcd. C 46.91, H 4.41, N 9.85, Zn 15.32; found C 43.01, H 3.85, N 8.96, Zn 14.55. − ^{1}H NMR (CD_3OD): δ = 2.28 (s, 6 H, CH_3), 3.78 (d, *J* = 16.2 Hz, 6 H, NCH_2), 4.33 (d, *J* = 16.2 Hz, 6 H, NCH_2), 7.05 (m, 14 H, Ph, py), 7.41 (d, *J* = 7.8 Hz, 6 H, py), 7.83 (dd, *J* = 7.2, 7.8 Hz, 6 H, py), 8.59 (d, *J* = 4.8 Hz, 6 H, py). − ^{31}P NMR ([D$_6$]DMSO): δ = −1.3 (3 P), −1.0 (1 P).

18: Prepared in the same manner as **17** from $Li_2[POP^5]$ (106 mg, 0.25 mmol), BPA (99 mg, 0.50 mmol), and $Zn(ClO_4)_2{\cdot}6H_2O$

(185 mg, 0.50 mmol) in boiling methanol (total volume 40 mL). Yield 70 mg (32%) of **18** as colorless crystals; m.p. 235 °C. – $C_{48}H_{48}Cl_2N_9O_{12}P_3Zn{\cdot}H_2O$ (1302.9 + 18.0): calcd. C 44.25, H 3.71, N 9.68, Zn 15.05; found C 40.32, H 3.30, N 8.83, Zn 13.73. – ^{1}H NMR (CD_3OD): δ = 3.81 (d, J = 16.2 Hz, 6 H, NCH_2), 4.36 (d, J = 16.2 Hz, 6 H, NCH_2), 7.04 (dd, J = 5.7, 6.1 Hz, 6 H, py), 7.18 (m, 8 H, Ph), 7.43 (d, J = 7.8 Hz, 6 H, py), 7.82 (dd, J = 7.3, 7.4 Hz, 6 H, py), 8.58 (d, J = 4.4 Hz, 6 H, py). – ^{31}P NMR ([D_6]DMSO): δ = −1.6 (3 P), −1.0 (1 P).

Structure Determinations:[17] The selected crystals were taken directly from the reaction solutions and used without drying in vacuo. They were immersed in fluorinated polyether oil and immediately placed in the nitrogen stream of the diffractometer's cooling system. Diffraction data were recorded at ca. −100 °C using the ω/2θ technique on a Nonius CAD4 diffractometer fitted with a molybdenum tube (K_α, λ = 0.7107 Å) and a graphite monochromator. Empirical absorption corrections based on ψ scans were applied. The structures were solved by direct methods and refined anisotropically with the SHELX program suite.[18] Hydrogen atoms were included with fixed distances and isotropic temperature factors 1.5 times those of their attached atoms. Parameters were refined against F^2. The R values are defined as $R_1 = \Sigma|F_o - F_c|/\Sigma F_o$ and $wR_2 = \{\Sigma[w(F_o^2 - F_c^2)^2]\Sigma[w(F_o^2)^2]\}^{1/2}$. Drawings were produced with SCHAKAL.[19] The crystallographic data are collected in Table 2.

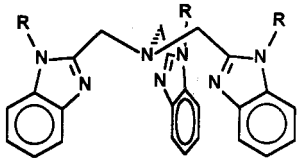
Zinc Complexes of Condensed Phosphates, 4[‡]

Diphosphate−Zinc Complexes with Encapsulating Tripodal Coligands

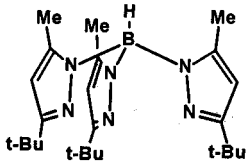
Alexandra Müller-Hartmann[a] and Heinrich Vahrenkamp*[a]

Keywords: Zinc / Phosphates / Organic pyrophosphates / Methylene diphosphonates / Phosphatases



Tris(benzimidazolylmethyl)amine (TBA) and tris(pyrazolyl)borate (Tp) ligands have been used to prepare ternary zinc complexes with triorganodiphosphates (R_3POP^-), triorganomethylenediphosphonates (R_3PCP^-), and diorganodiphosphates (R_2POP^{2-}). The complex types $[(TBA)Zn(R_3POP)]^+$ and $[(TBA)Zn(R_3PCP)]^+$ have been assigned as containing trigonal-bipyramidal zinc with monodentate diphosphate ligands. By X-ray structure determination, the complex type $[(TBA)Zn(R_2POP)]$ has been found to contain the same ZnN_4O coordination pattern, which has also been assigned to the dinuclear complexes $[(TBA)Zn(R_2POP)Zn(TBA)]^{2+}$ incorporating the diphosphates as bis-monodentate bridging ligands. The same monodentate and bis-monodentate attachment of the diphosphates, but with tetrahedral zinc in a ZnN_3O environment, has been identified in the pyrazolylborate complexes $TpZn(R_3POP)$ and $TpZn(R_2POP)ZnTp$.

Introduction

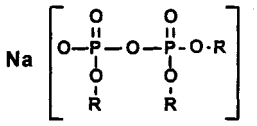


This paper is the fourth and final one in a series on zinc complexes of oligophosphates.[1−3] Our main motivation for this work has stemmed from the importance of metal-containing enzymes in biological phosphate transfer to and from inorganic pyrophosphate, ADP, ATP, and the like, which is among the most frequently observed biological processes. In the first papers of the series,[2,3] we made reference to the biochemical and biostructural background of the work and surveyed the literature on the associated coordination chemistry. While there have been numerous solution studies[4] and structure determinations[5] of metal−ATP species, literature on other metal−oligophosphate compounds is scarce. In the coordination chemistry of zinc, which is of particular interest to us, we are not aware of any studies on soluble complex species other than those of nucleotides.[4,6−8]

Our aim in this field, as before,[9,10] has been to learn about function from structure. We set out to delineate all possible coordination modes between zinc ions and oligophosphate species. In order to avoid typical lattice structures and coordination polymers, which cannot be biorelevant, we reduced the functionality of both the phosphates and the zinc species. The former was achieved by esterification, i.e. rather than pyrophosphate we used diorgano- and triorganodiphosphates. The latter was achieved by reducing the number of available coordination sites at zinc through the use of chelating coligands. We found that bidentate[3] and even tridentate coligands[1] still allow the oligophosphates to become polydentate towards one zinc ion. A further reduction in the functionality at zinc was thus deemed necessary.

In this paper, we describe the use of tripodal coligands for this purpose. As such, we used tris(benzimidazolylmethyl)amine (TBA) and its benzyl derivative TBA*, which we have previously found to be a reliable enforcer of trigonal-bipyramidal coordination in (TBA)Zn−X complexes.[11,12] Likewise, the 3-substituted tris(pyrazolyl)borate (Tp) ligands are known to be tetrahedral enforcers,[13] particularly the *tert*-butyl-substituted Tp*.[14] It thus had to be established whether the enforcing qualities of these tripodal coligands would be sufficiently strong to limit the oligophosphates to monodentate coordination towards one zinc ion.

TBA : R = H
TBA*: R = benzyl



Tp*

The oligophosphates used were the same as those used previously. The methylenediphosphonate PCP and the diphosphates PO^1 and PO^2, both having three organic substituents, were expected to be monofunctional and possibly monodentate. The diorganodiphosphates POP^1−POP^4 were expected to be difunctional, and we know[1,3] that their preferred bonding mode is as OPOPO chelate ligands, which should be unlikely in the presence of the tripodal coligands. Thus, we hoped to limit the oligophosphates to monodentate coordination towards one zinc ion and possibly bis-monodentate coordination as bridging ligands in dinuclear complexes.

PCP

(TBA)Zn Complexes of Triorganodiphosphates

Both TBA ligands were combined with zinc perchlorate and the three monofunctional phosphates PO^1, PO^2, and PCP. In all six cases, complexes with a 1:1:1 composition, **1**−**6**, were produced as perchlorate salts. While crystals of **1**−**6** suitable for X-ray analysis could not be obtained, FAB mass spectra of **1**, **2**, and **5** and an ESI mass spectrum of **3**, each showing the parent ion of the respective cationic complex as the only prominent peak, supported the assignment of the complexes as monomolecular. This makes it likely that the oligophosphates are monodentate and that the coordination geometry is trigonal-bipyramidal as indicated below.

$[(TBA)Zn(PO^1)]^+$	$[(TBA)Zn(PO^2)]^+$	$[(TBA)Zn(PCP)]^+$
1	**2**	**3**
$[(TBA^*)Zn(PO^1)]^+$	$[(TBA^*)Zn(PO^2)]^+$	$[(TBA^*)Zn(PCP)]^+$
4	**5**	**6**

The IR data for the P−O vibrations (Table 1) show a characteristic shift of the 1100 cm^{-1} band, attributable to $\nu_s(PO_2)$, to lower wavenumbers (cf. refs.[1,3]), but yield no structural information. In contrast, the ^{31}P NMR data are quite informative. All the phosphate ligands in **1**−**6** are unsymmetrical with typical shifts for the ^{31}P nuclei and typical coupling constants. Upon coordination to zinc, one of the two ^{31}P resonances is shifted upfield by 2−5 ppm while the other remains unchanged, and the coupling constants become characteristically smaller. This is in full agreement with the structural assignments. Together with the structure determinations of **8** and **10** (see below), these observations lend support to the statement that in all complexes **1**−**6** the oligophosphate ligands are monodentate.

Table 1. IR data (KBr, cm^{-1}) and ^{31}P NMR data (DMSO, rel. to H_3PO_4, ppm/Hz) of **1**−**6** and their phosphate constituents

(TBA)Zn Complexes of Diorganodiphosphates

Having established that the phosphates can be monodentate in (TBA)Zn complexes, it seemed likely that the bifunctional POP^{2-} ligands would also have this ability, being monodentate in (TBA)Zn(POP) complexes and bis-monodentate in dinuclear $[(TBA)Zn(POP)Zn(TBA)]^{2+}$ complexes. Both alternatives could be realized. Of the eight possibilities in each case, combining the given TBA and POP ligands, four could be realized for the mononuclear complexes and five for the dinuclear complexes. The mononuclear and dinuclear combinations are almost mutually exclusive, i.e. for a given set of TBA and POP only one of the two alternatives seems to be stable.

Mononuclear complexes were isolated only for the unsubstituted coligand TBP, but with all four POP ligands. Compounds **7**−**10** could be unambiguously identified as mononuclear and molecular entities, e.g. by X-ray structure determinations of **8** and **10** and through the FAB mass spectrum of **9**. Among them, **8** and **10** are the only species for which the dinuclear alternative (**11**, **12**, see below) also exists. However, **8** and **10** could not be prepared in suitably pure form from 1:1:1 mixtures of zinc salts, TBA, and $[POP]^{2-}$. They were obtained from solutions of **11** and **12** when these were left to stand for prolonged periods in attempts to obtain crystals of the latter for structure determinations.

(TBA)Zn(POP^n)

7: $n = 1$ **8**: $n = 2$ **9**: $n = 3$ **10**: $n = 4$

In those cases where the syntheses of the dinuclear complexes were successful, they proceeded straightforwardly from 2:2:1 mixtures of zinc perchlorate, the TBA ligand, and the POP salt. Proof of the dinuclear nature of complexes **11**−**15** and disproof of their existence as coordination polymers was obtained from a FAB mass spectrum of **11** and an ESI mass spectrum of **14**, both of which showed the parent ion of the complex cation as the prominent peak.

Attempts to grow crystals of **11**−**15** for structure determinations were unsuccessful.

(TBA)Zn(POP^n)Zn(TBA)

11: $n = 2$ **12**: $n = 4$

(TBA*)Zn(POP^n)Zn(TBA*)

13: $n = 2$ **14**: $n = 3$ **15**: $n = 4$

The IR and ^{31}P NMR spectra of complexes **7**−**15** (Table 2) yield less information than might have been expected. The strong and characteristic IR bands due to the P−O vibrations are shifted by small amounts, as observed previously.[1,3] A typical feature arising from the coordination of the diphosphates is the pronounced decrease in the intensity of the $\nu_s(PO_2)$ band. The ^{31}P NMR signals undergo the usual upfield shifts of 2−4 ppm upon coordination of the phosphates to zinc. Again,[1,3] in those cases where the diphosphates should be unsymmetrical (complexes **7**−**10**), there is only one ^{31}P resonance rather than two. As before, the explanation for this must be that in solution the complexes are labile and undergo rapid exchange of their coordinated and uncoordinated P−O donor functions.

Table 2. IR data (KBr, cm^{-1}) and ^{31}P NMR data (DMSO, rel. to H_3PO_4, ppm) of **7**−**15** and their phosphate constituents

	$\nu_{as}(PO_2)$	$\nu_s(PO_2)$	$\delta(^{31}P)$

[**15**]$(ClO_4)_2$	1282/1236	1161	−19.1

Structure determinations of **8** and **10** were necessary to eliminate any doubts concerning the structural assignments of the complexes in this class. They verified the monodentate coordination of the diphosphates in the 1:1:1 complexes **7**−**10**. By analogy and spectroscopic similarity, they furthermore supported the assignment of bis-monodentate coordination in the 2:2:1 complex cations **11**−**15**. The molecular structures of **8** (Figure 1) and **10** (Figure 2) are quite similar in terms of the environment of the zinc ions. However, they show conformational differences, specifically in the orientation of the phenyl rings at the phosphates. Moreover, in **8** there are two independent complex molecules in the asymmetric unit, which again differ conformationally, most notably in their non-bonding Zn···O(P) distances.

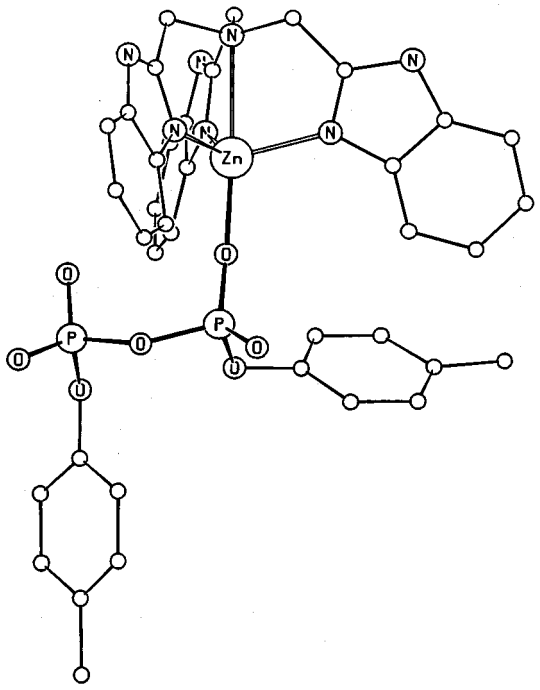

Figure 1. Molecular structure of **8**; selected bond lengths [Å] and angles [°] for both independent molecules: Zn−N(ax) 2.490(4), 2.474(4), Zn−N(eq) 2.030−2.039(4), 2.030−2.044(4), Zn−O 1.969(4), 1.979(4), Zn···O 4.109(4), 3.550(4), P−O(Zn) 1.485(4), 1.480(4), P=O 1.474−1.479(4), 1.475−1.484(4), P−O(P) 1.595−1.617(4), 1.591−1.619(4); Zn−O−P 164.0(3), 156.7(2), P−O−P 136.2(3), 135.7(2)

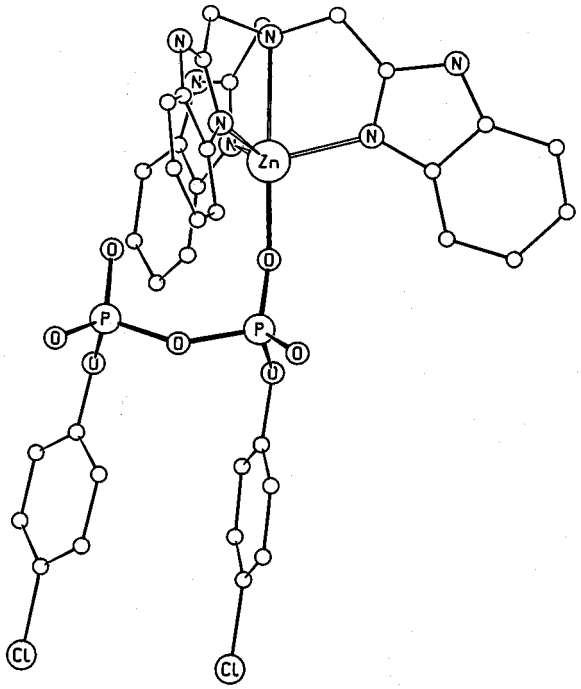

Figure 2. Molecular structure of **10**; selected bond lengths [Å] and angles [°]: Zn−N(ax) 2.49(2), Zn−N(eq) 2.01−2.03(2), Zn−O 1.97(1), Zn···O 3.48(1), P−O(Zn) 1.48(2), P=O 1.44−1.47(2), P−O(P) 1.60, 1.62(2); Zn−O−P 165(1), P−O−P 136(1)

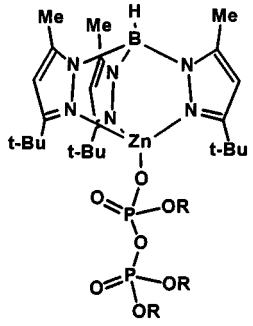
The coordination of the zinc ions in **8** and **10** can be described as trigonal-bipyramidal. As usual for TBA com-

plexes,[11,12] the elongation of the axial Zn−N bond is so pronounced and the equatorial Zn−N bonds are so clearly bent away from the Zn−O bond (102−107°) that a tetrahedral description (ignoring the axial Zn−N interaction) is also appropriate. Accordingly, the Zn−O bond is almost as short as in tetrahedral zinc−phosphate complexes.[15,16] The diphosphates are coordinated to zinc in a clearly monodentate fashion. Although one P−O donor function on the second phosphorus atom is oriented towards the zinc ion, its Zn−O distance (3.5−4.1 Å) is outside the range for bonding. Monodentate coordination of oligophosphates to zinc is unprecedented. There are, however, examples in $(NH_3)_5Co^{III}$−oligophosphate chemistry.[17,18] All bonding parameters of the diphosphates in **8** and **10** correspond to those of the same phosphates in the chelating mode and have been discussed in the preceding papers.[1,3] The most important observation in this respect concerns the formal P=O bond lengths, which do not change when one, two, or three of these P=O units are coordinated to zinc, thus indicating that the Zn−O interactions are quite ionic.

(Tp)Zn Complexes



The pyrazolylborate ligand Tp* could be expected to confine the zinc ion to a tetrahedral coordination. The products obtained following condensation reactions of Tp* Zn−OH with the diphosphoric acids $HP_2O_4(OR)_3$ and $H_2P_2O_5(OR)_2$ seemed to confirm this. The monofunctional triorganodiphosphates H[PO^1] and H[PO^2] yielded the mononuclear complexes **16** and **17**, while 2:1 reactions of Tp*Zn−OH with the difunctional diorganodiphosphates led to the dinuclear complexes **18** and **19**.

Tp*Zn(PO^1)	Tp*Zn(PO^2)
16	**17**
Tp*Zn(POP^1)ZnTp*	Tp*Zn(POP^2)ZnTp*
18	**19**

The molecular nature of **16−19** is evident from their solubilities in non-polar solvents. Their nuclearity was confirmed by a FAB mass spectrum of **17** and an ESI mass spectrum of **18**. The IR bands due to the P−O vibrations (Table 3) show little variation as compared to those of the anionic diphosphates (cf. Tables 1 and 2). The most significant information is provided by the ^{31}P NMR spectra recorded in non-polar solvents (Table 3). In all four cases, a considerable upfield shift (7−8 ppm) of the ^{31}P resonance of the zinc-coordinated phosphate unit to higher field is seen, while that of the uncoordinated phosphate unit in **16** and **17** remains practically unchanged. Thus, there is good evidence that the phosphates in **16** and **17** are indeed monodentate and that those in **18** and **19** are bis-monodentate. Together with the evidence from the structure determinations of **8** and **10**, the structural assignments given below for **16** and **17** seem appropriate.

Table 3. IR data (KBr, cm^{-1}) and ^{31}P NMR data ($CDCl_3$, rel. to H_3PO_4, ppm/Hz) of **16−19**

	ν(PO)	δ/J(^{31}P)
16	1290, 1187, 1137	−11.8, −18.3/11.2
17	1279, 1185, 1136	−11.6, −18.3/10.0
18	1278, 1186	−15.3
19	1292, 1187, 1123	−23.6

Conclusions

This paper concludes the series of investigations on the coordination of condensed phosphates to zinc. Throughout the series, phosphates with organic substituents have been employed, such that they have some relation to the most important biological oligophosphates, i.e. nucleotides. The available coordination sites at zinc have been controlled by using "naked" zinc ions,[2] bidentate,[3] tridentate,[1] and encapsulating tripodal coligands (this paper). The oligophosphates have been found to be mono-, di-, tri-, and possibly tetradentate. Three coordination sites at zinc had to be blocked in order to prevent the formation of coordination polymers. Furthermore, considerable steric hindrance had to be enforced to ensure purely monodentate coordination. The most commonly encountered coordination mode is that of an OPOPO chelate ligand.

In terms of the catalytic activation of the oligophosphates by zinc for hydrolytic reactions, the monodentate and chelating bidentate coordination modes seem to be relevant. Both provide one point of attachment per phosphate unit, thereby activating the P−O function, and leave coordination sites at the zinc or space in the coordination sphere for the hydrolytic nucleophile. We favor the monodentate attachment, as we have already presented preparative[15,16] and mechanistic[9,10] evidence in support of it. This paper has proved its existence in the environment of encapsulating ligands, which resembles most closely that in enzymes.

An aim of this series of investigations (refs.[1−3] and this paper) was to provide structural information related to catalytic events. Accordingly, conditions favoring stoichiometric or catalytic hydrolyses of the oligophosphates were carefully avoided. Nevertheless, some hydrolytic decomposition was observed, underlining the reactivity of the intermediate zinc−aqua and zinc−hydroxide species in this respect.

Thus, the natural extension of this work will be catalytic studies, in continuation of our previous work on the hydrolyses of pyrophosphates and sulfonatophosphates.[15]

Experimental Section

General: For general working and measuring procedures, see ref.[19] The lithium and sodium salts and the free acids of the triorgano-[20,21] and diorganodiphosphates,[2,20,22] as well as the TBP[11] coligands and Tp*Zn−OH,[23] were stored under inert conditions. During the course of the reactions no precautions were taken to prevent the access of moisture. All organic phosphates are potentially toxic and were handled accordingly.

1: A solution of TBA (100 mg, 0.245 mmol) and $Zn(ClO_4)_2·6H_2O$ (91 mg, 0.25 mmol) in ethanol (10 mL) was added to a solution of Na[PO^1] (115 mg, 0.245 mmol) in boiling ethanol (30 mL). After stirring for 15 min., the precipitate was filtered off and recrystallized from hot ethanol to yield 151 mg (58%) of [**1**]·ClO_4, m.p. 170 °C. − $C_{45}H_{42}ClN_7O_{11}P_2Zn·2H_2O$ (1019.5 + 36.0): calcd. C 51.20, H 4.39, N 9.29, Zn 6.19; found C 51.51, H 3.97, N 9.17, Zn 5.68. − ^{1}H NMR ([D$_6$]DMSO): δ = 3.32 (s, 4 H, H_2O), 4.53 (s, 6 H, CH_2), 5.08 (d, J = 7.4 Hz, 4 H, CH_2), 5.25 (d, J = 6.4 Hz, 2 H, CH_2), 7.12 (t, J = 8.0 Hz, 3 H, Ph), 7.28 (m, 15 H, Ph), 7.40 (m, 3 H, Ph), 7.56 (d, J = 8.4 Hz, 3 H, Ph), 8.43 (d, J = 8.4 Hz, 3 H, Ph), 14.12 (s, 3 H, NH).

2: Prepared in the same manner as **1** from TBA (58 mg, 0.14 mmol), $Zn(ClO_4)_2·6H_2O$ (53 mg, 0.14 mmol), and Na[PO^2] (100 mg, 0.14 mmol). Yield 107 mg (60%) of [**2**]·ClO_4; m.p. 142 °C. − $C_{45}H_{39}Br_3ClN_7O_{11}P_2Zn$ (1256.3): calcd. C 43.02, H 3.13, N 7.80, Zn 5.20; found C 42.76, H 3.17, N 7.30, Zn 5.30. − ^{1}H NMR ([D$_6$]DMSO): δ = 4.53 (s, 6 H, CH_2), 5.05 (d, J = 7.9 Hz, 4 H, CH_2), 5.18 (d, J = 7.3 Hz, 2 H, CH_2), 7.1−7.5 (m, 18 H, Ph), 7.56 (d, J = 8.1 Hz, 3 H, Ph), 8.38 (d, J = 7.9 Hz, 3 H, Ph), 13.53 (s, 3 H, NH).

3: Prepared in the same manner as **1** from TBA (79 mg, 0.19 mmol), $Zn(ClO_4)_2·6H_2O$ (72 mg, 0.19 mmol), and Na[PCP] (55 mg, 0.19 mmol). Yield 114 mg (72%) of [**3**]·ClO_4; m.p. 156 °C. − $C_{31}H_{38}ClN_7O_{10}P_2Zn$ (831.5): calcd. C 44.78, H 4.61, N 11.79, Zn 7.86; found C 42.90, H 4.57, N 11.02, Zn 6.29. − ^{1}H NMR ([D$_6$]DMSO): δ = 1.13 (m, 9 H, CH_3), 2.47 (m, 2 H, PCH_2P), 3.95 (q, J = 7.2 Hz, 4 H, OCH_2), 4.14 (q, J = 7.2 Hz, 2 H, OCH_2), 4.53 (s, 6 H, CH_2), 7.32 (m, 6 H, Ph), 7.56 (m, 3 H, Ph), 8.52 (m, 3 H, Ph), 13.42 (s, 3 H, NH).

4: Prepared in the same manner as **1** from Na[PO^1] (69 mg, 0.15 mmol), $Zn(ClO_4)_2·6H_2O$ (54 mg, 0.15 mmol), and TBA* (100 mg, 0.15 mmol). Yield 92 mg (48%) of [**4**]·ClO_4; m.p. 110 °C. − $C_{66}H_{60}ClN_7O_{11}P_2Zn·H_2O$ (1290.1 + 18.0): calcd. C 60.60, H 4.78, N 7.50, Zn 5.00; found C 60.13, H 4.31, N 8.16, Zn 4.23. − ^{1}H NMR ([D$_6$]DMSO): δ = 3.31 (s, 2 H, H_2O), 4.61 (s, 6 H, CH_2), 5.06 (d, J = 7.4 Hz, 4 H, OCH_2), 5.27 (d, J = 8.0 Hz, 2 H, OCH_2), 5.53 (s, 6 H, CH_2), 7.30 (m, 36 H, Ph), 7.61 (d, J = 8.8 Hz, 3 H, Ph), 8.46 (d, J = 8.8 Hz, 3 H, Ph).

5: Prepared in the same manner as **1** from Na[PO^2] (104 mg, 0.15 mmol), $Zn(ClO_4)_2·6H_2O$ (55 mg, 0.15 mmol), and TBA* (100 mg, 0.15 mmol). Yield 114 mg (51%) of [**5**]·ClO_4; m.p. 116 °C. − $C_{66}H_{57}Br_3ClN_7O_{11}P_2Zn$ (1526.7): calcd. C 51.92, H 3.76, N 6.42, Zn 4.28; found C 51.49, H 3.87, N 6.39, Zn 4.00. − ^{1}H NMR ([D$_6$]DMSO): δ = 4.60 (s, 6 H, CH_2), 5.03 (d, J = 8.1 Hz, 4 H, OCH_2), 5.18 (d, J = 6.9 Hz, 2 H, OCH_2), 5.51 (s, 6 H, CH_2), 7.1−7.5 (m, 33 H, Ph), 7.60 (d, J = 8.3 Hz, 3 H, Ph), 8.45 (m, 3 H, Ph).

6: Prepared in the same manner as **1** from Na[PCP] (13 mg, 0.05 mmol), $Zn(ClO_4)_2·6H_2O$ (17 mg, 0.05 mmol), and TBP* (31 mg, 0.05 mmol). Yield 40 mg (79%) of [**6**]·ClO_4; m.p. 200 °C. − $C_{52}H_{56}ClN_7O_{10}P_2Zn$ (1101.8): calcd. C 56.68, H 5.12, N 8.90, Zn 5.93; found C 55.72, H 5.58, N 8.62, Zn 5.93. − ^{1}H NMR ([D$_6$]DMSO): δ = 0.83 (t, J = 7.0 Hz, 6 H, CH_3), 1.22 (t, J = 7.9 Hz, 3 H, CH_3), 2.33 (t, J = 20.0 Hz, 2 H, PCH_2P), 3.65 (q, J = 7.2 Hz, 4 H, OCH_2), 4.14 (q, J = 7.0 Hz, 2 H, OCH_2), 4.62 (s, 6 H, CH_2), 5.49 (s, 6 H, CH_2), 7.1−7.3 (m, 21 H, Ph), 7.60 (m, 3 H, Ph), 8.51 (m, 3 H, Ph).

7: A solution of Na_2[POP^1] (30 mg, 0.075 mmol) in boiling methanol (40 mL) was added to a solution of TBA (30 mg, 0.075 mmol) and $Zn(ClO_4)_2·6H_2O$ (28 mg, 0.075 mmol) in boiling methanol (10 mL). The mixture was filtered while hot, slowly allowed to cool to room temp., and kept in a desiccator to allow slow removal of the solvent. 45 mg (71%) of **7**, m.p. 250 °C (dec.), was isolated. − $C_{38}H_{35}N_7O_7P_2Zn·CH_3OH$ (829.1 + 32.0): calcd. C 54.40, H 4.56, N 11.39, Zn 7.59; found C 53.47, H 4.45, N 11.26, Zn 7.50. − ^{1}H NMR ([D$_6$]DMSO): δ = 3.27 (s, 3 H, CH_3OH), 4.40 (s, 6 H, CH_2), 4.90 (m, 4 H, OCH_2), 7.19 (m, 16 H, Ph), 7.50 (d, J = 7.2 Hz, 3 H, Ph), 8.18 (d, J = 7.0 Hz, 3 H, Ph), 13.16 (s, 3 H, NH).

8: **11** (130 mg, 0.084 mmol) in a mixture of acetonitrile (30 mL), water (5 mL), and toluene (3 mL) was kept in a flask fitted with a solvent-permeable plastic seal for 2 months until most of the solvent had evaporated. A single crystal for structure determination was taken from the resulting crude precipitate. After filtration, washing with a small volume of methanol, and drying in vacuo, 85 mg (27%) of impure **8** remained; m.p. 220 °C (dec.). − $C_{38}H_{35}N_7O_7P_2Zn$ (829.1): calcd. C 55.05, H 4.26, N 11.83, Zn 7.89; found C 48.00, H 3.82, N 10.16, Zn 7.29. − ^{1}H NMR ([D$_6$]DMSO): δ = 2.12 (s, 6 H, CH_3), 4.33 (s, 6 H, CH_2), 6.84 (d, J = 8.3 Hz, 4 H, Ph), 6.99 (d, J = 8.3 Hz, 4 H, Ph), 7.22 (m, 6 H, Ph), 7.52 (d, J = 6.9 Hz, 3 H, Ph), 8.10 (d, J = 6.3 Hz, 3 H, Ph).

9: Prepared in the same manner as **7** from Li_2[POP^3] (62 mg, 0.13 mmol), TBA (107 mg, 0.26 mmol), and $Zn(ClO_4)_2·6H_2O$ (98 mg, 0.26 mmol). Yield 29 mg (24%) of **9**; m.p. 240 °C (dec.). − $C_{44}H_{47}N_7O_7P_2Zn$ (913.2): calcd. C 57.87, H 5.19, N 10.74, Zn 7.16; found C 54.32, H 4.99, N 9.57, Zn 7.00. − ^{1}H NMR ([D$_6$]DMSO): δ = 1.15 (s, 18 H, *t*Bu), 4.30 (s, 6 H, CH_2), 7.00 (d, J = 8.8 Hz, 4 H, Ph), 7.08 (d, J = 8.8 Hz, 4 H, Ph), 7.25 (m, 6 H, Ph), 7.52 (m, 3 H, Ph), 8.15 (m, 3 H, Ph).

10: Prepared in the same manner as **8** from **12** (39 mg, 0.025 mmol) within 3 months. Yield 7 mg (32%) of **10**, which, according to NMR analysis, was not pure. − ^{1}H NMR ([D$_6$]DMSO): δ = 4.42 (s, 6 H, CH_2), 7.05 (d, J = 9.1 Hz, 4 H, Ph), 7.11 (d, J = 9.1 Hz, 4 H, Ph), 7.25 (m, 6 H, Ph), 7.53 (m, 3 H, Ph), 8.10 (m, 3 H, Ph), 13.11 (s, 3 H, NH).

11: A solution of Li_2[POP^2] (55 mg, 0.12 mmol) in boiling ethanol (20 mL) was added to a solution of TBA (100 mg, 0.245 mmol) and $Zn(ClO_4)_2·6H_2O$ (91 mg, 0.25 mmol) in boiling ethanol (20 mL). After stirring for 10 min, the clear solution was slowly allowed to cool to room temp. 130 mg (70%) of [**11**]·$(ClO_4)_2$ was precipitated, which was washed with cold ethanol and dried in vacuo; m.p. 260 °C (dec.). − $C_{62}H_{56}Cl_2N_{14}O_{15}P_2Zn_2·3H_2O$ (1500.8 + 54.1): calcd. C 47.89, H 4.02, N 12.61, Zn 8.41; found C 46.94, H 3.63, N 12.18, Zn 7.77. − ^{1}H NMR ([D$_6$]DMSO): δ = 2.12 (s, 6 H, CH_3), 3.37 (s, 6 H, H_2O), 4.48 (s, 12 H, CH_2), 6.85 (d, J = 8.2 Hz, 4 H, Ph),

7.06 (d, J = 8.2 Hz, 4 H, Ph), 7.21 (t, J = 7.4 Hz, 12 H, Ph), 7.49 (d, J = 7.8 Hz, 6 H, Ph), 8.19 (d, J = 7.2 Hz, 6 H, Ph).

12: Prepared in the same manner as **11** from $Li_2[POP^4]$ (16 mg, 0.064 mmol), TBA (52 mg, 0.13 mmol), and $Zn(ClO_4)_2{\cdot}6H_2O$ (48 mg, 0.13 mmol). The precipitate was recrystallized from hot ethanol to yield 39 mg (38%) of **[12]**·$(ClO_4)_2$; m.p. 250 °C (dec.). − $C_{60}H_{50}Cl_4N_{14}O_{15}P_2Zn_2{\cdot}3H_2O$ (1541.7 + 54.1): calcd. C 45.16, H 3.54, N 12.29, Zn 8.19; found C 45.05, H 3.27, N 11.28, Zn 7.57. − ^{1}H NMR ([D$_6$]DMSO): δ = 3.42 (s, 6 H, H_2O), 4.51 (s, 12 H, CH_2), 7.2−6.9 (m, 20 H, Ph), 7.46 (d, J = 8.2 Hz, 6 H, Ph), 8.29 (d, J = 7.4 Hz, 6 H, Ph).

13: Prepared in the same manner as **11** from $Li_2[POP^2]$ (33 mg, 0.074 mmol), TBA* (100 mg, 0.15 mmol), and $Zn(ClO_4)_2{\cdot}6H_2O$ (55 mg, 0.15 mmol). The precipitate was recrystallized from hot ethanol to yield 134 mg (87%) of **[13]**·$(ClO_4)_2$; m.p. 161 °C. − $C_{104}H_{92}Cl_2N_{14}O_{15}P_2Zn_2{\cdot}2H_2O$ (2041.6 + 36.0): calcd. C 60.12, H 4.66, N 9.44, Zn 6.29; found C 59.71, H 4.43, N 9.53, Zn 6.33. − ^{1}H NMR ([D$_6$]DMSO): δ = 2.08 (s, 6 H, CH_3), 3.36 (s, 4 H, H_2O), 4.61 (s, 12 H, CH_2), 5.45 (s, 12 H, CH_2), 6.75 (d, J = 7.7 Hz, 4 H, Ph), 6.88 (d, J = 7.7 Hz, 4 H, Ph), 7.11 (m, 12 H, Ph), 7.23 (m, 30 H, Ph), 7.50 (d, J = 7.7 Hz, 6 H, Ph), 8.23 (d, J = 7.7 Hz, 6 H, Ph).

14: Prepared in the same manner as **11** from $Li_2[POP^3]$ (46 mg, 0.097 mmol), TBA* (132 mg, 0.195 mmol), and $Zn(ClO_4)_2{\cdot}6H_2O$ (73 mg, 0.19 mmol). Yield 105 mg (51%) of **[14]**·$(ClO_4)_2$; m.p. 174 °C. − $C_{110}H_{104}Cl_2N_{14}O_{15}P_2Zn_2$ (2125.7): calcd. C 62.15, H 4.93, N 9.22, Zn 6.15; found C 60.49, H 4.92, N 8.94, Zn 6.45. − ^{1}H NMR ([D$_6$]DMSO): δ = 1.22 (s, 18 H, *t*Bu), 4.60 (s, 12 H, CH_2), 5.46 (s, 12 H, CH_2), 6.9−7.2 (m, 50 H, Ph), 7.51 (d, J = 8.1 Hz, 6 H, Ph), 8.27 (d, J = 8.1 Hz, 6 H, Ph).

15: Prepared in the same manner as **11** from $Li_2[POP^4]$ (15 mg, 0.035 mmol), TBA* (47 mg, 0.070 mmol), and $Zn(ClO_4)_2{\cdot}6H_2O$ (26 mg, 0.070 mmol). Recrystallization from hot ethanol yielded 64 mg (88%) of **[15]**·$(ClO_4)_2$; m.p. 180 °C (dec.). − $C_{102}H_{86}Cl_4N_{14}O_{15}P_2Zn_2$ (2082.5): calcd. C 58.83, H 4.16, N 9.42, Zn 6.28; found C 58.63, H 4.26, N 9.44, Zn 5.62. − ^{1}H NMR ([D$_6$]DMSO): δ = 4.67 (s, 12 H, CH_2), 5.54 (s, 12 H, CH_2), 7.17 (m, 50 H, Ph), 7.53 (m, 6 H, Ph), 8.22 (m, 6 H, Ph).

16: A freshly prepared solution of $H[PO^1]$ (49 mg, 0.12 mmol) in dichloromethane (6 mL) was added to a solution of Tp*Zn−OH (56 mg, 0.12 mmol) in dichloromethane (12 mL). After stirring for 1 d, the mixture was filtered and the filtrate was concentrated to dryness. The residue was taken up in the minimum volume of dichloromethane and this solution was layered with *n*-hexane (25 mL). After a few days at 0 °C, 38 mg (34%) of **16** had separated, which was washed with cold acetonitrile (1 mL); m.p. 42 °C. − $C_{45}H_{61}BN_6O_7P_2Zn$ (936.2): calcd. C 57.74, H 6.57, N 8.98, Zn 6.98; found C 57.85, H 6.15, N 8.89, Zn 6.52. − ^{1}H NMR ($CDCl_3$): δ = 1.29 (s, 27 H, *t*Bu), 2.35 (s, 9 H, CH_3), 5.18 (d, J = 6.2 Hz, 4 H, OCH_2), 5.30 (d, J = 6.4 Hz, 2 H, OCH_2), 5.79 (s, 3 H, pz), 7.30 (m, 15 H, Ph).

17: Prepared in the same manner as **16** from $H[PO^2]$ (102 mg, 0.15 mmol) and Tp*Zn−OH (75 mg, 0.15 mmol). Yield 44 mg (25%) of **17**; m.p. 112 °C. − $C_{45}H_{58}BBr_3N_6O_7P_2Zn$ (1172.9): calcd. Structure Determinations:[24] The selected crystals were taken directly from the reaction solutions and used without drying in vacuo. They were immersed in fluorinated polyether oil and immediately placed in the nitrogen stream of the diffractometer's cooling system. Diffraction data were recorded at ca. −100 °C using the ω/2θ technique with a Nonius CAD4 diffractometer fitted with a molybdenum tube (Mo-K_α, λ = 0.7107 Å) and a graphite monochromator. Empirical absorption corrections based on ψ scans were applied. The structures were solved by direct methods and refined anisotropically with the SHELX program suite.[25] Hydrogen atoms were included with fixed distances and isotropic temperature factors 1.5 times those of their attached atoms. Parameters were refined against F^2. The R values are defined as $R_1 = \Sigma|F_o - F_c|/\Sigma F_o$ and $wR_2 = \{\Sigma[w(F_o^2 - F_c^2)^2]\Sigma[w(F_o^2)^2]\}^{1/2}$. Drawings were produced with SCHAKAL.[26] The crystallographic data are collected in Table 4.

Acknowledgments

This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We are indebted to Mrs. P. Klose and Mrs. F. Bitgül for assistance with the preparative work, Drs. W. Deck and M. Tesmer for recording the NMR spectra, and Drs. M. Ruf, B. Müller, and A. Trösch for help in solving the crystal structures.

Sulfur Compounds, 213[‡]

Geometries, Acidities, and Dissociation Reactions of the Gaseous Superacids $H_2S_2O_3$, H_2SO_5, HSO_3F, and HSO_3Cl

Ralf Steudel*[a] and André H. Otto[a]

Dedicated to Professor J. Gijs Kuenen, Delft, on the occasion of his 60th birthday

Keywords: Sulfur oxoacids / Acidity / Ab initio calculations / Thermodynamics / Structures

The gas-phase geometries, dipole moments, enthalpies, and Gibbs free energies of thiosulfuric acid $H_2S_2O_3$, peroxosulfuric acid H_2SO_5, fluorosulfuric acid HSO_3F, and chlorosulfuric acid HSO_3Cl as well as of their monoanions have been determined by ab initio MO calculations at various levels of theory. The most stable conformations of the four acid molecules are all of C_1 symmetry. The acidities, defined as $\Delta G°_{298}$ of the deprotonation reaction, obtained by the G2 method are as follows [kJ mol^{-1}]: *H*O–SO_2–SH 1251 and HO–SO_2–S*H* 1276, *H*O–SO(=S)–OH 1241, *H*O–SO_2–OOH 1239, *H*O–SO_2–F 1229, *H*O–SO_2–Cl 1219. Good agreement of the calculated acidities of HSO_3F and HSO_3Cl is observed with the experimental gas-phase acidities, which are the only experimental values available. The OH acidities of all five species are higher than that of sulfuric acid (1268 kJ mol^{-1}). Therefore, these compounds may be termed as superacids. In contrast to the liquid state, chlorosulfuric acid is a stronger proton donor than fluorosulfuric acid in the gas phase. The dissociation of the acid molecules HSO_3X (X = SH, OOH, F, Cl) into SO_3 and HX is endothermic and endergonic in all cases. The same holds for the dissociation of the anions SO_3X^- into SO_3 and X^-. From these dissociation enthalpies and literature data the enthalpies of formation of the mentioned sulfonic acids and their anions are calculated.

Introduction

According to a suggestion by R. J. Gillespie[1] superacids are those nonaqueous systems which are of higher acidity than pure sulfuric acid as far as Brønsted acids are concerned. Using the Hammett acidity scale[2] 100% H_2SO_4 has the acidity $H_o = -12$. Well-known examples of superacids (H_o in parentheses) are disulfuric acid $H_2S_2O_7$ (−14.8), chlorosulfuric acid HSO_3Cl (−13.8), and fluorosulfuric acid HSO_3F (−15.1). A 1:9 mixture of HSO_3F and SbF_5 exhibits the highest known acidity ($H_o = -27$).[3,4] This mixture is called *magic acid* since it protonates and consequently dissolves even saturated hydrocarbons.

The concept of superacids can also be applied to gaseous Brønsted acids again using the acidity of sulfuric acid as a reference value. The acidity of gaseous H_2SO_4 may be defined as the Gibbs free energy change for the deprotonation reaction [Equation (1)].

$$H_2SO_4 \rightarrow H^+ + HSO_4^- \quad (1)$$

It is obvious that this enthalpy change will always be strongly endothermic (> 1200 kJ mol^{-1}). For example, $\Delta G°_{298}$ [Equation (1)] was determined experimentally[5] as 1265±10 kJ mol^{-1} while 1268 kJ mol^{-1} was calculated by high-level ab initio MO methods.[6] As part of a systematic study of the acidities of the sulfur oxo acids we report here a detailed study of the geometries and acidities of the gaseous compounds $H_2S_2O_3$, H_2SO_5, HSO_3F, and HSO_3Cl which are of general formula HO−SO_2−X (X = SH, OOH, F, Cl).

To obtain accurate gas-phase acidities for the above-mentioned species *at identical levels of theory* we have calculated the energies of these acids HA and their corresponding anions A^- at the G2 level of theory, which has been shown to provide reliable acidity data for sulfur compounds, agreeing with the best experimental values within ca. 8 kJ mol^{-1}.[7] In addition, the CBS-Q and G2(MP2) methods were applied to all species since these more economical levels of theory will be used in an upcoming publication on several larger sulfur oxo acid molecules like polythionic acids, $H_2S_nO_6$, and polysulfuric acids, $H_2S_nO_{3n+1}$ ($n > 1$). In this way a comparison of data for different acids as well as a discussion of trends in acidities as a function of molecular structure will be possible. Since the gas-phase acidity has been defined in the literature as either $\Delta G°_{298}$ or $\Delta H°_{298}$ of the deprotonation reaction we also calculated both values for the systems investigated.

Calculations

Ab initio molecular orbital calculations were performed at the CBS-Q,[8] G2(MP2),[9] and G2[10] levels of theory us-

ing the GAUSSIAN program system.[11] The G2 method essentially implies an energy calculation at the QCISD(T)/6-311+G(3df,2p) level using geometries optimized at the MP2(fu)/6-31G(d) level. Harmonic vibrational wavenumbers were obtained at the HF/6-31G(d) level and were scaled by a factor of 0.893. The G2(MP2) method is a modified version of G2 but uses the second-order Møller–Plesset perturbation theory (MP2) for the basis set extension correction rather than the fourth order (MP4). G2(MP2) is almost as accurate as the G2 method but at a substantially reduced computational expense.

Complete Basis Set (CBS) model chemistries utilize the "dagger" 6-31G† basis set[12] in trying to overcome some deficiencies in the standard 6-31G(d) basis set. While the latter arbitrarily assigns an exponent of 0.8 to all four elements, the former uses the exponents from the d functions in the 6-311G basis set. The CBS models[10] use the asymptotic convergence of pair natural orbital expansion to extrapolate from calculations using a finite basis set to the estimated CBS limit. The CBS method consists of the following steps: geometry optimization at the HF/6-31G† level, thermal corrections using wavenumbers obtained at the same level and scaled by a factor of 0.918, reoptimization at the MP2/6-31G† level followed by energy calculations using a large basis set in combination with HF and MP2. The next steps are MP4(sdq) and QCISD(T) calculations applying medium-size basis sets. Then the CBS extrapolation is made and empirical corrections are added to obtain the final thermodynamic data.

The excellent performance of all of these methods in predicting gas-phase acidities of small molecules is well established.[13]

To obtain reliable geometries of the most stable isomers complete optimizations as well as wavenumber calculations were performed at the MP2/6-311++G(d,p) level.

For details of the quantum chemical methods see ref.[14] All calculations were carried out with a Cray J90 or a Linux workstation. A list of the absolute enthalpies $H°_{298}$ and Gibbs free energies $G°_{298}$ of all species used in this work at the levels CBS-Q, G2(MP2) and G2 is given in the Appendix (Table 12). To allow for the thermal corrections to the Gibbs free energy of the proton a value of −0.010654 hartree (−28 kJ mol^{-1}) was used.

Results and Discussion

Molecular Structures

Thiosulfuric Acid $H_2S_2O_3$

No experimental structures of $H_2S_2O_3$ or its monoanion are known since these species are thermally unstable at temperatures above −20 °C. In fact, the molecule $H_2S_2O_3$ has never been observed although this compound is mentioned in practically all inorganic chemistry textbooks. The anion $HS_2O_3^-$ is contained in the ammonium salt $NH_4[HS_2O_3]$ which is the only hydrogen thiosulfate which has ever been prepared.[15] The low-temperature Raman spectra of this salt and its deuterated derivative demonstrated that the connectivity of the anion is $HS-SO_3^-$ rather than $HO-SO_2(=S)^-$. By ab initio MO calculations at the MP4/6-311G(d,p)//HF/6-311G(d,p) + ZPE level of theory it was shown that the most stable connectivity of thiosulfuric acid is $HO-SO_2-SH$ (**1**) which is 41 kJ mol^{-1} more stable than the alternative $HO-SO(=S)-OH$ (**2**) and that the connectivity $HS-SO_3^-$ (**3**) is 20 kJ mol^{-1} more stable than the tautomer $HO-SO_2(=S)^-$ (**4**).[16] Calculations at the MP2/6-31+G(d)//HF/6-31G(d) level revealed that **1** exists as two conformers **1a** and **1b** (Figure 1).[17] The energy difference between these species was calculated as 4 kJ mol^{-1} (at 0 K) with **1a** as the global minimum.

The geometries of $H_2S_2O_3$ and its monoanion obtained at the MP2/6-311++G(d,p) level are given in Table 1; the numbering of atoms is shown in Figure 1. In accordance with the previous results the thiosulfuric acid molecule is of C_1 symmetry and two conformations **1a** and **1b** exist which differ only by the orientation of the SH and OH groups with respect to the terminal oxygen atoms. The global minimum is the conformer **1a** which has an analogous conformation to the sulfuric acid molecule. The bonds O–H and S–H point in almost opposite directions. The second conformer **1b** and the isomer **2** with two O–H bonds are less stable by 2.9 and 34.7 kJ mol^{-1}, respectively, if $\Delta G°_{298}$ at the G2 level is taken as a measure (Table 2). The anions **3** (SH) and **4** (OH) are of C_s and C_1 symmetry, respectively. The OH species **4** is by 24.7 kJ mol^{-1} less stable than the SH tautomer **3** and therefore has not been considered any further. Very similar thermodynamic data were obtained at the levels CBS-Q and G2(MP2) (see Table 2).

Compared to our previous calculations there are some significant changes in the geometrical parameters. In particular, the S–S bond lengths are now considerably longer and calculated as 210.1 and 222.6 pm for the acid and the anion while 205.7 and 215.5 pm had been obtained at the HF/6-311G(d,p) level.[16]

Peroxosulfuric Acid H_2SO_5

The molecular structure of crystalline peroxosulfuric acid is known from an X-ray diffraction study of single crystals.[18] However, the gas-phase structure seems to be unknown. The crystal structure is characterized by extensive intermolecular hydrogen bonding but there are no intramolecular hydrogen bonds (Table 3). The O–O bond length (146.4 pm) and the S–O–O–H torsion angle (104°) have values typical for covalent peroxides. The molecular symmetry is C_1 (Figure 1). The structure of the monoanion HSO_5^- is known from two independent X-ray crystal structure determinations of the potassium salt $KHSO_5 \cdot H_2O$ (Table 4).[19,20] The anion is of C_1 symmetry with the connectivity $HO-O-SO_3^-$. The O–O distance was determined as 146 pm while the S–O–O–H torsion angle was given as "ca. 90°"[19] and 87°.[20] Again, intermolecular hydrogen bonding is a characteristic feature of the structure. The structure of this anion has also been investigated by ab

initio MO calculations at the MP2/3-21+G(*) level.[21] These data will be discussed below.

As part of the acidity calculation we have optimized the structures of H_2SO_5 (**5**) and HSO_5^- (**6**) with no symmetry restrictions first at the MP2/6-31G(d) level. The vibrational eigenvalues of the structures found were all positive. After the most stable conformations of H_2SO_5 and HSO_5^- had been located on the energy hypersurface these structures were optimized at the MP2/6-311++G(d,p) level. In Table 3 and Table 4 we compare the calculated geometries with the solid-state structures.

Table 3. Structural parameters of H_2SO_5 (C_1) in the gas phase and in the crystal (internuclear distances in pm, bond angles and torsion angles in °); for numbering of atoms see Figure 1

[a] See ref.[18]

There is a remarkably good agreement between the two conformations of H_2SO_5 calculated for the free molecule and found in the crystal. This can be seen from the close agreement of the three torsion angles given in Table 3. The two O−H bonds point into practically opposite directions and the four atoms O3−S−O4−O5 (torsion angle −177.4°) are almost located in a plane. Most of the bond lengths and bond angles agree rather closely with the solid-state

structure. Exceptions are the two S−O single bonds involving O1 and O4 which are calculated to be 6−8 pm longer than observed in the crystal. Since these oxygen atoms do not take part in the hydrogen bonding network we have no explanation for the differing bond lengths. There are no intramolecular hydrogen bonds in **5** since the shortest nonbonded contact distance (O3···H1: 254.1 pm) is about equal to the sum of the van der Waals radii.

The calculated anion structure (Table 4) also agrees quite well with the crystallographically determined structure of $KHSO_5 \cdot H_2O$ despite the fact that the anion is coordinated by six cations and three water molecules. The differing H−O−O−S torsion angles (calcd. 43.2° versus 87°) may be caused by the intermolecular hydrogen bonding in the crystal on one hand and by the intramolecular hydrogen bond in the free ion. The strongest hydrogen bond in the crystal originates from the peroxide hydrogen and ends at the oxygen atom of a neighboring water molecule.[20] In the free ion the same hydrogen atom is linked to the oxygen atom O2 by a weak hydrogen bond of length 200.9 pm. The S−O single bond to the peroxide oxygen atom is calculated much longer (173.2 pm) than observed in the crystal (163.3 pm) which may be caused by the coordination of the peroxomonosulfate ion to the surrounding potassium ions. All other calculated S−O bond lengths agree within 2.6 pm with the solid-state data but the deviations always follow the same trend: The calculated distances are larger than the observed ones. The same type of deviations have been observed when the structure of HSO_5^- was calculated at the MP2/3-21+G(*) level.[21]

Attempts to optimize the structure of the isomeric anion HO_3S-O-O^- failed since its structure always rearranged to the more stable isomer $HO-O-SO_3^-$. Therefore, the acidity of the peroxide proton of H_2SO_5 could not be calculated.

Fluorosulfuric Acid HSO_3F

The molecular structure of gaseous HSO_3F seems to be unknown but the crystalline acid has been studied by X-ray diffraction at 123 K.[22] The HO−SO_2−F molecules form infinite chains via OH···O hydrogen bonds. The site symmetry is C_1. The structural parameters are given in Table 5 together with the results of our calculations at the MP2/6-311++G(d,p) level. Previous geometry calculations had been performed at the HF/6-31+G(d)[23,24] and HF/6-31G(d) levels.[17] The gas-phase symmetry is also C_1. The hydrogen atom shows no tendency to move close to the fluorine atom and there is no intramolecular O···H bond either: The closest O···H distance is 252.3 pm (with O3), which is about identical to the van der Waals distance. There is a fairly good agreement between calculated and observed bond lengths and angles taking the two different phases into account. Besides the OH bond length, which cannot be determined accurately by X-ray diffraction, the largest difference between the calculated and the solid-state structures is found for the S−OH single bond which is calculated to be too long by 8 pm. Next is the S−F bond, which is calculated to be too long by 6.6 pm. However, by comparison with a gaseous derivative of HSO_3F it can been demonstrated that the calculated structure is basically correct. The structure of the methyl ester Me−O−SO_2−F has been determined by microwave spectroscopy and electron diffraction.[25] Assuming identical lengths for the two S=O bonds of the sulfone group the following internuclear distances [pm] and bond angles [°] were obtained: S=O 141.0(2), S−O 155.8(7), S−F 154.5(6), O−S=O 109.5(6), O=S=O 124.4(7), F−S=O 106.8(5). The S−O bond length agrees within 4 pm with our data for HSO_3F while the S−F bond deviates by 6.1 pm. The three bond angles agree within 1.5°. Taking into account the fact that two different, although related molecules are being compared and that ab initio MO methods reproduce S−F and S−O single bond lengths only poorly, the agreement of the data may be considered fairly good.

Table 5. Molecular structure of HSO_3F (C_1) in the gas phase and in the crystal (internuclear distances in pm, bond angles and the torsion angle in °); for numbering of atoms see Figure 1

[a] See ref.[22]

The structure of the fluorosulfate anion has been determined, for example, by X-ray crystallography of the lithium salt.[26] The gas-phase symmetry of the anion is C_{3v} but owing to its unsymmetrical coordination by lithium cations in $LiSO_3F$ the site symmetry is C_s. The structural parameters are compared to our calculated data in Table 6. Previous geometry calculations had been performed at the HF/6-31G(d)[17] and HF/6-31+G(d)[23,24] levels.

Table 6. Molecular structure of the anion SO_3F^- in the gas phase (C_{3v}) and in the crystal of $LiSO_3F$ (internuclear distances in pm, bond angles in °); for numbering of atoms see Figure 1

Parameter	MP2/6-311++ G(d, p)	X-ray diffraction[a]
S−O1	146.1	145.5 (6)

O2−S−F	101.7	102.8 (3)

[a] See ref.[26]

The anion of $LiSO_3F$ is coordinated to eight cations through Li−O contacts. There is no Li−F contact shorter than the sum of the van der Waals radii. Therefore, the S−F bond length should not be influenced too much and should approximately agree with the value calculated for the free molecule. However, at the level MP2/6-311++G(d,p) the agreement is rather poor: the calculated S−F distance is 14.3 pm or 9% too large! The previous uncorrelated calculations with smaller basis sets reproduced the S−F bond length much better although in all cases too long (by 3.5% or more). The larger deviation between calculated and observed solid-state bond lengths, especially in anions, may be partly caused by the coordination of the lithium cations which withdraw electron density and therefore strengthen the S−O and S−F bonds in a manner similar to that what protonation of anions does: The S−F bond of HSO_3F is 9.2 pm or 6% shorter than that of SO_3F^-. Similar effects are observed with the S−Cl bonds in HSO_3Cl and SO_3Cl^-.

Chlorosulfuric Acid HSO_3Cl

The structure of chlorosulfuric acid has never been determined experimentally but a number of theoretical studies have been published. Basch and Hoz[17] as well as Otto et al.[23] and Bencivenni et al.[24] found a structure of C_1 symmetry at the HF/6-31G(d) and HF/6-31+G(d) levels. The conformation is analogous to that of fluorosulfuric acid (see above). Our results obtained for the most stable conformation of this acid and for its anion at the MP2/6-311++G(d,p) level are shown in Table 7. A comparison of these data with the previous results shows once more that the uncorrelated calculations with the smaller basis sets yield shorter internuclear distances for all three types of bonds. The only experimental data available for comparison are the geometrical parameters of the methyl ester of chlorosulfuric acid, the structure of which has been determined by electron diffraction assuming identical S=O bond lengths in the sulfonyl group.[27] The following internuclear distances [pm] and bond angles [°] were obtained: S−O 156.2(4), S=O 141.9(3), S−Cl 202.3(4), O−S=O 108.7(8), O=S=O 122.2(15), Cl−S−O 102.8(14), Cl−S=O 106.4(6). The maximum deviation of the bond lengths from our data for HSO_3Cl amounts to 4.4 pm while the bond angles agree within 2.7°.

Table 7. Molecular structures of chlorosulfuric acid HSO_3Cl and of its anion calculated at the MP2/6-311++G(d,p) level (internuclear distances in pm, bond angles and torsion angles in °); for numbering of atoms see Figure 1

Parameter	HSO_3Cl (C_1)	SO_3Cl^- (C_{3v})
H−O1	97.0	–
S−O1	160.6	146.1
S−O2	142.9	146.1
S−O3	143.7	146.1
S−Cl	206.2	224.2
O1−S−O2	106.0	116.1
O1−S−O3	109.0	116.1
O2−S−O3	124.6	116.1
O1−S−Cl	100.1	101.5
O2−S−Cl	107.7	101.5
O3−S−Cl	106.8	101.5
H−O1−S−Cl	−80.4	–
H−O1−S−O2	167.8	–
H−O1−S−O3	31.5	–

An interesting feature of the two structures shown in Table 7 are the quite different S−Cl bond lengths in HSO_3Cl (206.2 pm) and in its anion (224.2 pm). Obviously, the strengthening of the bond S−O1 on deprotonation is partly due to a simultaneous weakening of the S−Cl bond. The anion may therefore be viewed as an adduct between SO_3 and a chloride anion. Below it will be shown that the thermodynamics of this adduct formation (or of the reverse dissociation) supports this view.

The shortest intramolecular nonbonded O···H contact distance of 250.8 pm (O3···H) corresponds to the sum of the van der Waals radii.

Acidities

The gas-phase acidity data calculated for various sulfonic acids of the type $HO-SO_2-X$ like H_2SO_3,[6] H_2SO_4,[6] $H_2S_2O_3$, H_2SO_5, HSO_3F, and HSO_3Cl are given in Table 8. The acidity is defined here as either $\Delta H°_{298}$ or $\Delta G°_{298}$ of the deprotonation reaction. The Gibbs free energies obtained at the CBS-Q and G2(MP2) levels differ by only 6 kJ mol^{-1} (0.5%) or less from the G2 data.

Table 8. Gas phase acidities [kJ mol^{-1}] of the sulfonic acids $HO-SO_2-X$ (X = H, OH, SH, OOH, F, Cl)

	CBS-Q		G2(MP2)		G2	
	$\Delta H°_{298}$	$\Delta G°_{298}$	$\Delta H°_{298}$	$\Delta G°_{298}$	$\Delta H°_{298}$	$\Delta G°_{298}$
HO−SO_2−H	1303	1275	1310	1282	1307	1279
HO−SO_2−OH	1299	1264	1307	1271	1305	1268
HO−SO_2−SH	1280	1247	1286	1254	1284	1251
HO−SO_2−S*H*	1303	1271	1311	1278	1308	1276
HO−SO_2−OOH	1264	1233	1272	1241	1270	1239
HO−SO_2−F	1256	1223	1263	1232	1260	1229
HO−SO_2−Cl	1243	1213	1252	1222	1249	1219

The OH acidities presented in Table 8 obviously depend on the electronegativity and the charge capacity of the substituent X. Therefore, sulfonic acid HO−SO_2−H (X = H) is the weakest of the mentioned sulfonic acids, followed by sulfuric acid HO−SO_2−OH. Surprisingly, thiosulfuric acid and peroxosulfuric acid are considerably stronger than sulfuric acid and therefore may be termed as *superacids*. Obviously, the charge capacity of the substituents SH and OOH, i.e., the ability to accommodate an additional negative charge in the anion, is larger than that of the OH group in sulfuric acid. For the same reason, gaseous chlorosulfuric acid is stronger than fluorosulfuric acid, in contrast to the pure liquids. The experimental deprotonation enthalpy of HSO_3F at 368 K was reported as $\Delta H°_{368}$ = 1285 kJ mol^{-1} with $\Delta G°_{368}$ = 1255±10 kJ mol^{-1}.[5] Both values deviate by 26 kJ mol^{-1} from our G2 data. This deviation is much smaller than from the previously reported theoretical data[23] obtained using geometries calculated at a much lower level than in this work. It should be pointed out that the experimental acidity of sulfuric acid[5] perfectly agrees with the G2 results cited in Table 8. No experimental acidity data are known for $H_2S_2O_3$ and H_2SO_5. In the case of thiosulfuric acid we also computed the SH acidity ($\Delta G°_{298}$ = 1276 kJ mol^{-1}) which is of course much smaller than the OH acidity (1251 kJ mol^{-1}) of this compound but still comparable to the OH acidity of sulfonic acid (1279 kJ mol^{-1}) which is a tautomer of sulfurous acid. The OH acidity of the metastable tautomer of thiosulfuric acid, HO−SO(=S)−OH **2**, was calculated as $\Delta G°_{298}$ = 1241 kJ mol^{-1} at the G2 level.

The *dipole moments* of the acids calculated at the MP2/6-311++G(d,p) level are as follows (in D): H_2SO_3 3.77, H_2SO_4 3.63, $H_2S_2O_3$ (**1a**) 4.18, H_2SO_5 2.26, HSO_3F 3.15, HSO_3Cl 3.28.

Dissociation Reactions

Sulfonic acid HO−SO_2−H is unstable with respect to dissociation to H_2O and SO_2[6] and a number of the acids investigated in this work also decompose easily either at room temperature ($H_2S_2O_3$) or on heating (H_2SO_5, HSO_3Cl). Even sulfuric acid partly decomposes into H_2O and SO_3 on distillation at ambient pressure. Therefore, we have calculated the reaction enthalpies and Gibbs free reaction energies of the dissociation reactions of the most stable conformers of HO−SO_2−X into SO_3 and HX (X = H, OH, SH, OOH, F, Cl). The results are shown in Table 9.

In contrast to the instability of H_2SO_3 all other decomposition reactions are endothermic and endergonic at 298 K. However, the dissociation of HSO_3Cl requires a Gibbs free energy of only 9.8 kJ mol^{-1}. It is therefore understandable that this compound cannot be purified by distillation. In fact, chlorosulfuric acid is difficult to prepare in a pure state except by fractional crystallization.[28]

We have also studied the dissociation of the related gaseous anions SO_3X^- into X^- and SO_3 (SO_2 in the case of the sulfonate ion). Only the most stable tautomers and conformations were used. As the data in Table 10 demonstrate

$SO_3Cl^- \rightarrow Cl^- + SO_3$	202	168	196	163	199	165

all reactions are strongly endothermic and endergonic. The reverse reactions are the nucleophilic additions of the Lewis bases X^- to the strong Lewis acid SO_3. By far the lowest reaction energy is that calculated for the addition of chloride anions to SO_3, which is in agreement with the structure of the chlorosulfate anion and its rather weak S−Cl bond as discussed above.

From the G2 enthalpies in Table 9 and 10 and the published enthalpies of formation[29] of SO_2, SO_3, H_2O, H_2S, H_2O_2, HF, HCl, OH^-, OOH^-, SH^-, F^-, and Cl^- we have calculated the enthalpies of formation of the gaseous acids and their monoanions as given in Table 11. Only few experimental data[28] are available for comparison and these are often not very accurate. Nevertheless, the agreement is reasonable. In the case of the hydrogen sulfide anion two slightly different values for the enthalpy of formation have been published.[28] Therefore, two enthalpies are given for $HSSO_3^-$ in Table 11 with the second value probably being more reliable. In the case of HSO_3Cl the enthalpy of formation was calculated from $\Delta_f H°_{298}$ of the liquid substance (−597.5 kJ mol^{-1})[28] and the enthalpy of evaporation at the boiling point (53.6 kJ mol^{-1} at 150°C).[28] The result (−543 kJ mol^{-1}) perfectly agrees with the value found in the present study (−538 kJ mol^{-1}).

Conclusion

The five sulfur oxo acids HO−SO_2−SH, HO−SO(=S)−OH, HO−SO_2−OOH, HO−SO_2−F, and HO−SO_2−Cl, as well as their monoanions, were investigated by ab initio MO calculations at the CBS-Q, G2(MP2), and G2 levels of theory to obtain their structures as well as their enthalpies and Gibbs free energies, from which the thermodynamics of the deprotonation reactions at 298 K were calculated. Unexpectedly, the OH acidities of all spe-

cies are higher than that of sulfuric acid. Therefore, these species may be termed superacids. The OH acidity of acids of type $HO-SO_2-X$ obviously depends on the electronegativity as well as on the charge capacity of the substituent X (X = H, OH, SH, OOH, F, Cl). In addition, the enthalpies and Gibbs free energies of the products of the two dissociation reactions $HO-SO_2-X \rightarrow SO_3 + H-X$ and $SO_3X^- \rightarrow SO_3 + X^-$ were calculated to obtain the reaction enthalpies. All these reactions are endothermic and endergonic. In other words, both the acids and their monoanions are thermodynamically stable species in the gas phase at 298 K. From these dissociation enthalpies and literature data of the dissociation products we have calculated the enthalpies of formation of the gaseous acids H_2SO_3, $H_2S_2O_3$, H_2SO_5, HSO_3F, and HSO_3Cl.

Appendix

Enthalpies $H°$ and Gibbs free energies $G°$ of the acids $HO-SO_2-X$ (X = H, OH, SH, OOH, F, Cl), their anions, and the products of decomposition at 298 K are given in Table 12.

Synthesis and Characterization of Novel Iodine(III) Compounds; Crystal Structures of Methoxy(trifluoromethyl)iodine(III) Chloride [$CF_3I(Cl)OCH_3$] and Dimethoxy(trifluoromethyl)iodine(III) [$CF_3I(OCH_3)_2$]

Rolf Minkwitz,*[a] Michael Berkei,[a] and Ralf Ludwig[a]

Keywords: Iodine / Structure elucidation / Vibrational spectroscopy

The reactions of $CF_3I(Cl)F$ and CF_3IF_2 with $(CH_3)_3SiOCH_3$ lead to the novel iodine(III) compounds $CF_3I(Cl)OCH_3$ and $CF_3I(OCH_3)_2$, respectively. The crystal structure of $CF_3I(Cl)OCH_3$ confirms that it is a ternary, trifluoromethyl-substituted iodine(III) derivative. $CF_3I(Cl)OCH_3$ crystallizes in the triclinic space group $P\bar{1}$, with four formula units per unit cell with the dimensions $a = 8.164(1)$, $b = 8.802(1)$, $c = 10.237(1)$ Å and angles $\alpha = 97.10(1)°$, $\beta = 91.41(1)°$, $\gamma = 115.00(1)°$. $CF_3I(OCH_3)_2$ crystallizes in the monoclinic space group $P2_1/n$ with four formula units per unit cell with $a = 6.295(1)$, $b = 15.607(1)$, $c = 7.736(1)$ Å, and $\beta = 111.44(1)°$. Both molecules have been additionally characterized by Raman, IR, and NMR spectroscopy and the experimental results are compared with quantum-mechanically calculated parameters.

Introduction

The chemistry of (trifluoromethyl)iodine(III) compounds is a well-explored field of research, although crystal structures have been obtained in only a few cases. The reported structures are limited to compounds having highly electronegative ligands, such as F, Cl, or ONO_2, in the apical positions.[1−3] These compounds are more stable and can be isolated more easily than derivatives having less electronegative ligands. According to Bent's rule, the apical positions are favourably occupied by the most electronegative ligands.[4] These positions are characterized by 3-center-4-electron bonds, in which the negative charge is located at the termini.[5]

Since all attempts to synthesize $CF_3I(OH)_2$ have proven unsuccessful, we became interested in its alkyl-substituted derivatives $CF_3I(OR)_2$. The tendency of iodine to form double bonds with oxygen leads to destabilization of these compounds and favours condensation reactions leading to CF_3IO. Although methanolysis of PhIO leads to $PhI(OCH_3)_2$ and Naumann et al. supposed a similar tendency of CF_3IO to form $CF_3I(OCH_3)_2$, no experimental details of this have yet been reported.[6,7] In 1974, Oates and Winfield described the synthesis of $CF_3IF_{4-n}(OCH_3)_n$ ($n = 1-4$) by reaction of CF_3IF_4 with $(CH_3)_3SiOCH_3$.[8] All the products were identified by their mass and NMR spectra. Since no similar investigation has been carried out in the case of iodine(III), it seemed desirable to study the reaction of CF_3IF_2 with $(CH_3)_3SiOCH_3$. In this reaction, $CF_3I(F)OCH_3$ is expected to be an observable intermediate. In general, ternary iodine(III) compounds are known to decompose by symmetrization in solution, even at low temperatures, and are thus difficult to isolate.[9] In order to obtain ternary iodine(III) compounds, $CF_3I(Cl)F$ represents a good starting material.[9] In this compound, the I−F bond is elongated and the I−Cl bond is shortened. This renders it suitable for exchange reactions in which only the I−F bond is replaced.

In this work, we report the syntheses and crystal structures of $CF_3I(Cl)OCH_3$ and $CF_3I(OCH_3)_2$. As far as we are aware, this constitutes the first report of structural data for (trifluoromethyl)iodine(III) compounds substituted by methoxy groups.

Results and Discussion

Formation of $CF_3I(Cl)OCH_3$ and $CF_3I(OCH_3)_2$

The molecules were obtained by reactions of (methoxy)-trimethylsilane with $CF_3I(Cl)F$ and CF_3IF_2, respectively [Equations (1) and (2)]. This synthesis is analogous to the preparation of $CF_3IF_n(OCH_3)_{4-n}$ ($n = 1-4$) by Oates and Winfield.[8] The driving force behind these reactions is the formation of the thermodynamically favoured Si−F bond at the expense of the Si−O bond.

$$CF_3I(Cl)F + (CH_3)_3SiOCH_3 \xrightarrow{-80°C} CF_3I(Cl)OCH_3 + (CH_3)_3SiF$$

$$CF_3IF_2 + 2(CH_3)_3SiOCH_3 \xrightarrow{-50°C} CF_3I(OCH_3)_2 + 2(CH_3)_3SiF$$

The fine colourless solids proved to be stable for several months at −70 °C under nitrogen, decomposing at about −40 °C. The iodine(III) compounds were found to be soluble in sulfur dioxide at −50 °C. In solution, they start to decompose even at temperatures below −50 °C.

Vibrational Spectra

The observed Raman and IR frequencies of $CF_3I(Cl)OCH_3$ and $CF_3I(OCH_3)_2$ are summarized in

[a] Fachbereich Chemie der Universität Dortmund, 44221 Dortmund, Germany

Table 1. The vibrational spectra are assigned on the basis of C_1 symmetry for the molecules. For $CF_3I(Cl)OCH_3$, 27 fundamental vibrations are to be expected. The strongest line in the Raman spectrum at 509 cm^{-1} corresponds to the I−O stretching mode. The I−Cl stretching mode can be assigned to the line at 304 cm^{-1}. This is in good accordance with assignments made for $CF_3I(Cl)ONO_2$ (326 cm^{-1}) and $CF_3I(Cl)F$ (304 cm^{-1}).[3,9] The asymmetric CF_3 stretching modes are found in the range 1056 to 1209 cm^{-1}, while the symmetric mode is seen at about 1043 cm^{-1}. The corresponding bending modes are observed at 739 cm^{-1} (δ_{as} CF_3), 542 cm^{-1} (δ_s CF_3), and in the range 243 to 265 cm^{-1} (ρ CF_3). In the case of $CF_3I(OCH_3)_2$, the I−O stretching modes can be assigned to the strongest lines in the Raman spectrum at 532 cm^{-1} (ν_{as} IO_2) and 353 cm^{-1} (ν_s IO_2), respectively, while the IO_2 bending is seen at 236 cm^{-1}. For comparison, in $CF_3I(ONO_2)_2$, these vibrational modes are found at 705−734 cm^{-1} (ν_{as} IO_2), 332/346 cm^{-1} (ν_s IO_2), and 182/190 cm^{-1} (δ IO_2).[3] The C−I stretching mode is observed at about 277 cm^{-1}. The vibrational bands of the CF_3 and CH_3 groups were detected in the expected ranges.

Crystal Structure of $CF_3I(Cl)OCH_3$

$CF_3I(Cl)OCH_3$ crystallizes in the triclinic space group $P\bar{1}$ with four formula units per unit cell. The crystal data are summarized in Table 2. The molecule has a distorted Ψ-trigonal bipyramidal structure with chlorine and the methoxy group in the apical positions and the trifluoromethyl group and two lone pairs in the equatorial positions (Figure 1). This is in accordance with the Gillespie−Nyholm model and the structure can be described as T-shaped.[10,11] Bond lengths and selected bond angles are listed in Table 3.

The unit cell contains two crystallographically independent molecules with slightly different bond lengths. The I−Cl bonds have lengths of 2.578(2) and 2.580(2) Å, about 0.3 Å longer than the sum of the covalent radii, and are 0.1 Å longer than those found in CF_3ICl_2.[2,12] For the I−O bonds, values of 1.969(5) and 1.991(5) Å are observed, these being only slightly longer than the sum of the covalent radii of 1.94 Å.[12] The molecules are arranged in chains, due to strong intermolecular I−Cl contacts. Owing to intermolecular I−O contacts, the chains are arranged in layers, stacked along the *b* axis. All these interactions result in the formation of ribbons of twelve-membered, centrosymmetric rings (Figure 1). In these rings, I−O−I−O parallelograms are spanned by two molecules involving I−O contacts with lengths of 3.235(5) and 3.250(5) Å. On the basis of these contacts, the environment at the iodine atom can be designated as distorted square-pyramidal. Between the layers of molecules, no contacts shorter than the sum of the van der Waals radii are found.

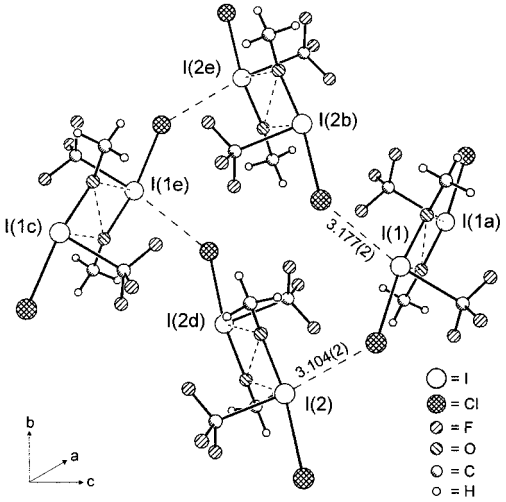

Figure 1. Fragment of the structure of $CF_3I(Cl)OCH_3$; projection of a twelve-membered ring; distances [Å]: I(1)···Cl(2b) 3.177(2), I(1)···O(1a) 3.235(5), O(1)···O(1a) 2.864(5), I(2)···Cl(1) 3.104(2), I(2)···O(2d) 3.250(5), O(2)···O(2d) 2.878(5); symmetry operations: *a*: $-x+2, -y+1, -z+1$; *b*: $x+1, y, z$; *c*: $x, y, z-1$; *d*: $-x+1, -y+1, -z$; *e*: $-x+2, -y+1, -z$

Crystal Structure of $CF_3I(OCH_3)_2$

$CF_3I(OCH_3)_2$ (Figure 2) crystallizes in the monoclinic space group $P2_1/n$ with four formula units per unit cell. The crystal data are summarized in Table 2 and bond lengths and selected angles are listed in Table 3. $CF_3I(OCH_3)_2$ has a T-shaped arrangement with two methoxy groups in apical positions. The I−O bonds have lengths of 2.019(11) Å

[a] For the sake of simplicity, the average C−F bond lengths are shown.

[I(1)−O(1)] and 2.087(11) Å [I(1)−O(2)] and are significantly longer than the sum of the covalent radii of 1.94 Å and the corresponding bonds in $CF_3I(Cl)OCH_3$ [1.969(5) and 1.991(5) Å].[12] The molecules present donors as well as acceptors for each secondary I−O bond, which points to the C−I bond. For iodine, a square-planar environment results. Taking the intermolecular contacts into consideration, the observed difference in I−O bond lengths due to weakening of the I(1)−O(2) bond becomes reasonable. The molecules are arranged in chains along the *c* axis. The CF_3 group and the methoxy group of O(1) are not involved in any intermolecular contacts and occupy the positions of side groups on the chains. A similar arrangement is found in CF_3ICl_2.[2] The C−I distance of 2.190(12) Å is comparable to those in similar compounds such as CF_3IF_2 [2.174(6) Å], CF_3ICl_2 [2.229(10) Å], and $CF_3I(ONO_2)_2$ [2.212(4) Å].[1−3] The CF_3 group is almost tetrahedral with F−C−F angles of about 108° and an average C−F bond length of about 1.31(2) Å.

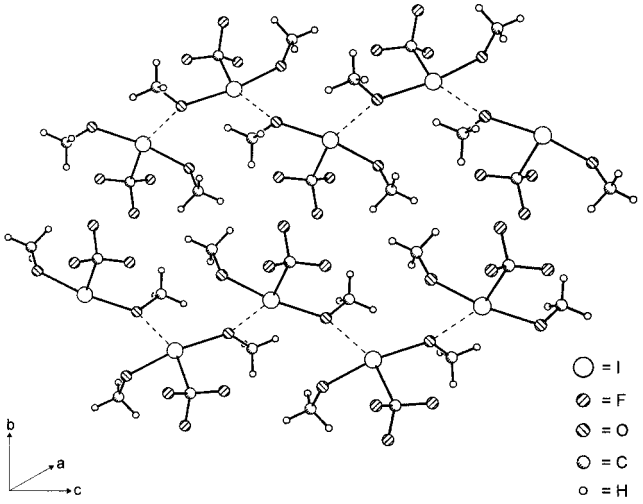

Figure 2. View of the crystal structure of $CF_3I(OCH_3)_2$ in *q* orientation; the intermolecular I−O contacts measure 2.749(9) Å

Quantum-Mechanical Calculations

Ab initio RHF and density functional B3LYP calculations were performed using the Gaussian 98 program.[13] To take relativistic effects into account, calculations were carried out with the LANL2DZ basis set, which includes D95 on first-row atoms, and a Los Alamos ECP, which puts DZ on other atoms.[14−17] Additional calculations with CEP-121G and SDD basis sets not described here yielded similar results.[18−21] To obtain optimized molecular structures, the wavefunctions were analyzed by the natural bond orbital (NBO) method, a standard program option of Gaussian 98.[22]

The optimized geometries for both systems are given in Table 3 and are compared with experimental data. Whereas the HF method overestimates the I−Cl bond length by about 8 pm, the density functional method B3LYP systematically overestimates the lengths of all iodine-containing bonds by about 10 pm. With the chosen basis set, the B3LYP approximation does not yield adequate results for iodine-containing systems. It should also be borne in mind that all calculations were performed for free molecules in the gas phase. Some deviations between the calculated and experimentally observed values can thus be attributed to the strong intermolecular cross-links in the crystalline solid state. In the case of $CF_3I(OCH_3)_2$, we could not find any explanation for the difference in symmetries calculated by the two methods.

For both compounds, NBO analyses for all methods and basis sets were performed.[22] Summarizing the calculated charges on each atom of the various ligands clearly indicates that total negative charges increase in the order: $F_3C > H_3CO > Cl$ (Table 4). The calculated charges support the assumption that the apical ligands are bound by 3-center-4-electron bonds.[5] In 1992, Boyd and Boyd reported group electronegativities calculated by the bond critical model.[23] For the CF_3 and H_3CO groups, values of 2.71 and 3.53, respectively, were calculated.[23] In accordance with Bent's

rule, this explains the apical positions of chlorine and the methoxy group in $CF_3I(Cl)OCH_3$ and of both methoxy groups in $CF_3I(OCH_3)_2$.[4]

Table 4. Calculated and summarized NBO charges of the three different ligands in $CF_3I(Cl)OCH_3$ and $CF_3I(OCH_3)_2$; charges are given in e^-

Experimental Section

Caution! $CF_3I(Cl)F$ and CF_3IF_2 are unstable at room temperature and are sensitive to moisture. Skin contact with these compounds should be avoided because their hydrolysis leads to HF or HCl, which cause burns and in some cases irreparable damage. Safety precautions should be taken when using and handling these materials.

All synthetic work and sample handling was performed using a standard glass vacuum line and standard Schlenk techniques. Nonvolatile materials were handled under dry nitrogen. The syntheses of $CF_3I(Cl)F$ and CF_3IF_2 were carried out by treating trifluoromethyl iodide (CF_3I) with trifluoromethyl hypochlorite (CF_3OCl) at −78 °C and −50 °C, respectively, based on literature methods.[1,9] (Methoxy)trimethylsilane [$(CH_3)_3SiOCH_3$] (ABCR) was used as received without any purification. Owing to the low stability of the products, we were unable to obtain reliable elemental analysis results. − The Raman spectra were recorded with a Jobin Yvon T64000 spectrometer using an Ar^+ laser (514.5 nm) from Spectra Physics. The spectra were obtained from samples in a glass cell cooled with liquid N_2.[24] − Infrared spectra were recorded with a Bruker IFS 113v spectrophotometer. Spectra were obtained from samples coated on CsBr plates placed in a low-temperature cell.[25] − NMR spectra in SO_2 solution at −50 °C were recorded with Bruker DPX 300 and Bruker DRX 400 spectrometers. − Single crystals were placed in Lindemann capillaries in a cooled stream of dry nitrogen, and X-ray diffraction data were collected using a Nonius Kappa CCD diffractometer. The crystal structures were solved by the Patterson method and successive difference Fourier syntheses. For refinement, full-matrix least-squares methods were applied. Data reduction, structure solution, and refinement were carried out with programs in the SHELXTL package, PLATON, MISSYM, and PARST.[26−30]

Quantum-Mechanical Calculations: Hartree−Fock and density functional calculations were performed with the program Gaussian 98.[13] In the density functional B3LYP,[31] the 3-parameter exchange functional by Becke[32] and the correlation functional by Lee, Yang, and Parr[33] were used. The LANL2DZ basis set contains a D95 basis[14] for elements of the first period and an effective core potential and a double-zeta basis for elements from sodium to bismuth.[15−17] For the geometry optimization, different starting coordinates were chosen. The calculation of the vibrational frequencies showed whether or not the energy-minimized structures represented stable molecules. All frequencies were positive, indicating that at least local minima on the Born−Oppenheimer hypersurface were found.

Preparation of $CF_3I(Cl)OCH_3$: In a typical reaction, $(CH_3)_3SiOCH_3$ (0.26 g, 2.50 mmol) was condensed onto $CF_3I(Cl)F$ (0.50 g, 2.00 mmol) in a dry glass vessel with greaseless stopcocks (Young). The mixture was then allowed to warm to −80 °C and was maintained at this temperature for 30 min. After removal of the volatile materials in vacuo at −70 °C, the formation of 0.39 g (1.49 mmol, 74%) of methoxy(trifluoromethyl)iodine(III) chloride, $CF_3I(Cl)OCH_3$, was observed. The resulting colourless solid was found to be stable up to −40 °C and sensitive to moisture. − NMR: ^{19}F: δ = −29.68 (s, CF_3). − ^{13}C: δ = 67.47 (s, CH_3), 83.09 (q, ^1J = 344 Hz, CF_3). − ^1H: δ = 4.13 (s, CH_3).

Preparation of $CF_3I(OCH_3)_2$: $(CH_3)_3SiOCH_3$ (0.52 g, 5.00 mmol) was condensed onto CF_3IF_2 (0.47 g, 2.00 mmol) in a dry glass vessel with greaseless stopcocks (Young). The mixture was allowed to warm to −50 °C and was maintained at this temperature for 1 h. After removal of the volatile materials in vacuo at −50 °C, the formation of 0.24 g (0.93 mmol, 48%) of dimethoxy(trifluoromethyl)iodine(III), $CF_3I(OCH_3)_2$, was observed. The resulting colourless solid was found to be stable up to −40 °C and sensitive to moisture. − NMR: ^{19}F: δ = −28.42 (s, CF_3). − ^{13}C: δ = 63.21 (s, CH_3), δ = 81.19 (q, ^1J = 344 Hz, CF_3). − ^1H: δ = 4.36 (s, CH_3).

Reduction of the Phosphododecamolybdate Ion by Phosphonium Ylides and Phosphanes

Vincent Artero[a] and Anna Proust*[a]

Keywords: Polyoxometalates / Molybdenum / Ylides / Phosphanes / Electron transfer / Heteropoly blues

The reaction of phosphonium ylides with $[PMo_{12}O_{40}]^{3-}$ consists of successive single electron transfers leading to the formation of the 1e- and 2e-reduced polyoxomolybdates $[PMo_{12}O_{40}]^{4-}$ and $[PMo_{12}O_{40}]^{5-}$. The ylide is converted into the corresponding phosphonium cation via a radical-cation intermediate. The reaction of phosphanes follows the same pathway but subsequent reactions with residual water produce protons which induce the disproportionation of $[PMo_{12}O_{40}]^{4-}$. Authentic samples of heteropoly blues in different protonation states have been obtained from the reaction of phenyllithium with $[PMo_{12}O_{40}]^{3-}$ and subsequent protonation with triflic acid. On the basis of electrochemical and spectroscopic data, the reaction product of $[PMo_{12}O_{40}]^{3-}$ with triphenylphosphane, which has been previously described as the oxygen-deficient species $[PMo_{12}O_{39}]^{3-}$, is reformulated as $[H_2PMo_{12}O_{40}]^{3-}$.

Introduction

Early transition metals in their highest oxidation states form a large class of oxo−metal cluster anions called polyoxometalates.[1] For the past ten years, our group has been involved in a systematic study of the functionalization of polyoxometalates.[2] One subclass of derivatized polyoxometalates include compounds that derive from parent polyoxometalates through the replacement of terminal oxo ligands by other multiply bonded ligands. The oxo, imido, nitrido and cyclopentadienyl groups are formally six-electron donors. Thus imido,[3] nitrido[4] and cyclopentadienyl[5] derivatives of polyoxometalates are effectively isoelectronic with the parent polyoxometalates. On the other hand, the $[MoO]^{4+}$, $[Mo(NO)]^{3+}$ and $[Mo(NNR)]^{3+}$ groups are isolobal, so that the formation of nitrosyl[6] and diazenido[7] polyoxomolybdates can easily be rationalized. The oxo ligand can also act as a four-electron donor and, as such, is isoelectronic with alkylidene groups. These considerations led us to look for alkylidene derivatives of polyoxometalates. Our aims were threefold: (i) to provide structural and spectroscopic models for metathesis reactions on oxide surfaces; (ii) to identify the reactive species when $[Mo_6O_{19}]^{2-}$ is used as a precatalyst;[8] (iii) to design new metathesis catalysts or precatalysts in a special oxo environment that could be further tuned through size, shape or charge modifications. One strategy for the functionalization of polyoxometalates relies on the analogy between oxometal units and organic functionalities. This has been established by Floriani et al. for oxovanadium groups.[9] The analogy also holds to some extent for oxomolybdenum groups. Indeed, hydrazido[4,7b,10] and imido[3a,11,12] derivatives of polyoxomolybdates have been obtained from the reactions of *N*,*N*-disubstituted hydrazines and iminophosphoranes or isocyanates with polyoxomolybdates. The formation of imido derivatives is reminiscent of the aza Wittig reaction and is thought to proceed by a net [2 + 2] cycloaddition of the P=N and Mo=O bonds.[13] Intermetal exchange of oxo, imido and alkylidene ligands has been shown to occur readily, at least at coordinatively unsaturated metal centres.[14] However, attempts to achieve the replacement of an oxo ligand by an alkylidene ligand have so far failed. For instance, the reaction of *cis*-$[MoO_2(mesityl)_2]$ with Bu_3PCH_2 has afforded the stable betaine-like $[MoO_2(mesityl)_2(CH_2PBu_3)]$.[15] We have investigated the reactions of a number of phosphonium ylides with $(nBu_4N)_3[PMo_{12}O_{40}]$ in acetonitrile and we have found that only 1e- and/or 2e-reduced derivatives of $[PMo_{12}O_{40}]^{3-}$ are formed.

Another route to functionalized polyoxometalates involves lacunary polyoxometalates. This has been widely applied to the rational synthesis of metal-substituted polyoxometalates. On the other hand, polyoxometalates with oxygen vacancies would be potential precursors for the synthesis of ligand-substituted polyoxometalates. The only oxygen-deficient polyoxometalates that have been reported so far are the species $[PMo_{12}O_{40-x}]^{3-}$ (x = 1, 2 or 3) which were obtained by Kawafune et al. by reaction of $[PMo_{12}O_{40}]^{3-}$ with PPh_3 in acetonitrile.[16] However, these results have not been confirmed by Mattes et al., who isolated $[HPMo_{12}O_{40}]^{4-}$ from Kawafune's reaction.[17] Furthermore, Bond et al. have recently shown that the similar reaction of the Dawson-type polyanion $[S_2Mo_{18}O_{62}]^{4-}$ yields plenary reduced species.[18] This led us to revisit the reaction of $[PMo_{12}O_{40}]^{3-}$ with phosphanes. We have shown that only plenary reduced anions are formed in these reactions and that the compound formulated as $(nBu_4N)_3[PMo_{12}O_{39}]$ by Kawafune et al. is actually $(nBu_4N)_3[H_2PMo_{12}O_{40}]$. Identification of the reduced species formed in the reactions of $[PMo_{12}O_{40}]^{3-}$ with phosphonium ylides or phosphanes has been based on the comparison with the samples ob-

tained by reduction of $[PMo_{12}O_{40}]^{3-}$ by phenyllithium. Thus this report deals with interrelated studies of the reactions of $[PMo_{12}O_{40}]^{3-}$ with phosphonium ylides, phenyllithium and phosphanes.

Results

From here on, the Keggin anions $[PMo_{12}O_{40}]^{3-}$, $[PMo_{12}O_{40}]^{4-}$ and $[PMo_{12}O_{40}]^{5-}$ will be designated by the numerals **0**, **I** and **II**, respectively, according to their reduction state. Unless otherwise stated, they were isolated as tetrabutylammonium salts. Other cations will be specified when appropriate. Thus, **LiII** refers to $(n\mathrm{Bu_4N})_4\mathrm{Li}[PMo_{12}O_{40}]$ while **H_2II** refers to $(n\mathrm{Bu_4N})_3[H_2PMo_{12}O_{40}]$.

1e- and 2e-Reduced Derivatives of $[PMo_{12}O_{40}]^{3-}$

In nonaqueous solvents, most often MeCN and DMF, 1e- and 2e-reduced derivatives of $[PMo_{12}O_{40}]^{3-}$ have usually been obtained by electrolysis and characterized in situ. Only in a few cases were the reduced derivatives isolated. Phenyllithium proved to be a convenient reagent for the synthesis of **I** and **LiII** from **0** in MeCN. Reduction of **0** by phenyllithium was first recognized when an excess of phenyllithium was inadvertently used in the synthesis of the benzylidene ylide, which was subsequently added to a solution of $(n\mathrm{Bu_4N})_3[PMo_{12}O_4]$ in MeCN. When the reaction of $(n\mathrm{Bu_4N})_3[PMo_{12}O_{40}]$ with PhLi in MeCN was monitored by ^{31}P NMR spectroscopy, it was found that **I** is quantitatively formed upon addition of one equivalent of PhLi, while addition of a second equivalent yields **II**. The reduction does not proceed beyond the 2e-reduced state. The 1e- and 2e-reduced derivatives were readily isolated as $(n\mathrm{Bu_4N})_4[PMo_{12}O_{40}]$ (**I**) and $(n\mathrm{Bu_4N})_4\mathrm{Li}[PMo_{12}O_{40}]$ (**LiII**). Acidification of the solution of **LiII** with triflic acid allowed the isolation of $(n\mathrm{Bu_4N})_4[HPMo_{12}O_{40}]$ (**HII**) and $(n\mathrm{Bu_4N})_3[H_2PMo_{12}O_{40}]$ (**H_2II**). In this way, a full set of spectroscopic data could be obtained for the 1e- and 2e-reduced derivatives of $[PMo_{12}O_{40}]^{3-}$. Indeed, only **0** and **I** had been previously fully characterized by IR,[19] UV/Vis,[20] ^{31}P NMR[3b,21] and (for **I**) by EPR spectroscopy.[20] IR data for **HII** and **H_2II**, UV/Vis data for **II** and **H_2II**, and ^{31}P NMR data for **II** and **H_2II** have now been obtained and are reported herein. ^{31}P NMR data are gathered in Table 1. The electrochemical behaviour of **HII** and **H_2II** in MeCN had been previously studied by Himeno et al.[22] As electrochemical data will be at the centre of the discussion, they were examined further. The results reported in Table 2 are in agreement with those reported by Himeno et al. Solution data for **HII** and **H_2II** were measured both for these species formed in situ by acidification of **LiII** and after isolation of $(n\mathrm{Bu_4N})_4[HPMo_{12}O_{40}]$ and $(n\mathrm{Bu_4N})_3[H_2PMo_{12}O_{40}]$, respectively. No significant discrepancy was observed.

The ^{31}P NMR chemical shift of **II** steadily moves to higher frequency as the proton content increases. The values characteristic of **II**, **HII** and **H_2II** are $\delta = -5.4$, -5.2 and -5.0, respectively, in CH_3CN. **I** undergoes disproportionation upon acidification. Indeed, the ^{31}P NMR spectrum of an equimolecular mixture of **I** and triflic acid displays two signals with equal intensities at $\delta = -2.3$ and -5.0 which can be unambiguously assigned to **0** and **H_2II**, respectively, indicating the full disproportionation of **I** according to Equation (1).

$$2\,[PMo_{12}O_{40}]^{4-} + 2\,H^+ \rightarrow [PMo_{12}O_{40}]^{3-} + [H_2PMo_{12}O_{40}]^{3-} \quad (1)$$

On the other hand, the ^{31}P NMR spectrum of a solution of **I** with half an equivalent of triflic acid displays three signals at $\delta = +1.4$, -2.3 and -5.2, which are respectively assigned to **I**, **0** and **HII**. Further, the same spectrum is obtained for an equimolar solution of **0** and **HII**. This

Table 1. ^{31}P NMR chemical shift of some relevant species, referenced to external 85% H_3PO_4

	$\delta_{(CH_3CN/CD_3CN)}$ [ppm]	$\delta_{(DMSO/[D_6]DMSO)}$ [ppm]		$\delta_{(CH_6CN/CD_6CN)}$ [ppm]
$[PMo_{12}O_{40}]^{3-}$	−2.3	−2.9	$Bu_3PCH_3^+$	33.5
$[PMo_{12}O_{40}]^{4-}$	1.4 [21]	0.8	Bu_3PO	47.5
$[PMo_{12}O_{40}]^{5-}$	−5.4	−5.8	Bu_3P	−30.8
$[HPMo_{12}O_{40}]^{4-}$	−5.2[a]	−	$Ph_3P{=}CHPh$	9.3
$[H_2PMo_{12}O_{40}]^{3-}$	−5.0	−5.5	$Ph_3PCH_2Ph^+$	24.2
			Ph_3PO	27.5
			Ph_3P	−4.5
			Ph_4P^+	24.4

[a] This value aggrees with that reported by Mattes et al. for $[K(18\text{-crown-6})]_2[N(PPh_3)_2]_2[HPMo_{12}O_{40}]$ when locking the value for **0** at −2.3 ppm.[17]

Table 2. Electrochemical data[22] for $[H_xPMo_{12}O_{40}]^{n-}$ species, 1 mM in MeCN, at a platinum electrode

		$E_{1/2}$ [V/SCE]	$1/2(E_{pa}+E_{pc})$	$E_{1/2}$ [V/SCE]	$1/2(E_{pa}+E_{pc})$
$[PMo_{12}O_{40}]^{4-}$	**I**	0.14 ($1e^-$, ox)[a]	0.18 (rev.)[b]	−0.28 ($1e^-$, red)	−0.24 (rev.)
$\{Li[PMo_{12}O_{40}]\}^{4-}$	**LiII**	0.17 ($1e^-$, ox)	0.22 (rev.)	−0.10 ($1e^-$, ox)	−0.11 (rev.)
$[HPMo_{12}O_{40}]^{4-}$	**HII**	0.56 ($1e^-$, ox)	irrev.	0.2 ($1e^-$, ox)	irrev.
$[H_2PMo_{12}O_{40}]^{3-}$	**H_2II**	0.56 ($2e^-$, ox)	irrev.	0.1 ($1e^-$, red)	irrev.

[a] ox and red for oxidation and reduction processes, respectively. − [b] rev. and irrev. for reversible and irreversible processes, respectively.

shows that **0**, **I** and **HII** are in equilibrium according to Equation (2).

$$2\ [PMo_{12}O_{40}]^{4-} + H^+ \leftrightarrows [PMo_{12}O_{40}]^{3-} + [HPMo_{12}O_{40}]^{4-} \quad (2)$$

It follows therefore that $[HPMo_{12}O_{40}]^{3-}$ cannot be isolated. Whether the more positive oxidation wave of $[HPMo_{12}O_{40}]^{4-}$ at 0.56 V/SCE is due to the 1e-oxidation of **HI**, as assumed by Himeno et al.,[22] or to the 2e-oxidation of $\mathbf{H_2II}$ resulting from the disproportionation of **HI**, remains to be established. Indeed, the R.D.E. voltammogram of an equimolar mixture of **I** and triflic acid is identical to that of an equimolar mixture of **0** and $\mathbf{H_2II}$ at the same overall polyanion concentration.

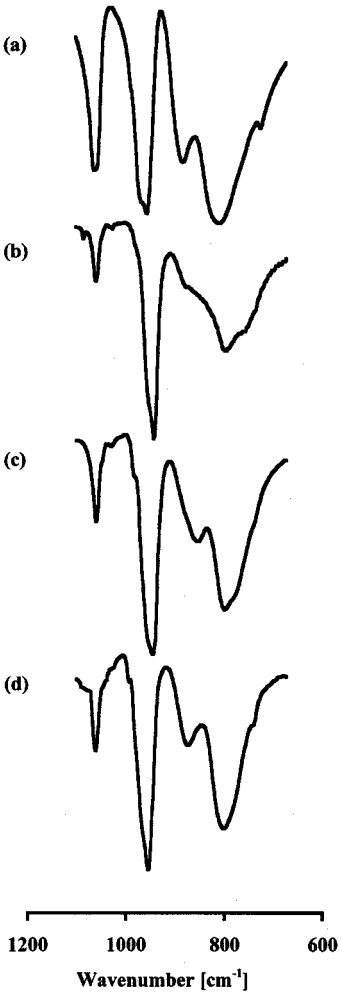

Figure 1. Infrared spectra of $(n\mathrm{Bu_4N})_3[PMo_{12}O_{40}]$ (**0**, a), $Li(n\mathrm{Bu_4N})_4[PMo_{12}O_{40}]$ (**LiII**, b), $(n\mathrm{Bu_4N})_4[HPMo_{12}O_{40}]$ (**HII**, c) and $(n\mathrm{Bu_4N})_3[H_2PMo_{12}O_{40}]$ ($\mathbf{H_2II}$, d)

The IR spectra of **0**, **LiII**, **HII**, and $\mathbf{H_2II}$ (Figure 1 and Table 3) all display the characteristic pattern of α-Keggin anions, with four bands arising from the P−O, Mo=O_t, and Mo−O−Mo stretching vibrations.[23] The progressive decrease in both the intensity and the energy of the P−O and Mo−O−Mo bands upon reduction has been fully discussed in the literature.[17,19] The energy of the Mo=O_t stretching mode also decreases upon reduction. However, the corresponding band shifts to higher frequencies upon protonation so that the values are fortuitously the same for **0** and $\mathbf{H_2II}$.

Reactions of Phosphonium Ylides with $[PMo_{12}O_{40}]^{3-}$

Various phosphonium ylides $R_3P{=}CR^1R^2$ (R = Bu, $R^1 = R^2 = H$; R = Ph, $R^1 = H$, R^2 = Ph, C(O)Me, C(O)N(Me)OMe; R = Ph, $R^1R^2 = (CH_2)_4$; R = Ph, R^1 = Me, R^2 = CHO) were used. In each case, the addition of a phosphonium ylide to a solution of $(n\mathrm{Bu_4N})_3[PMo_{12}O_{40}]$ in MeCN results in the formation of reduced species as evidenced by the strong blue colour of the resulting solutions. However, the reaction proceeds most cleanly with $Bu_3P{=}CH_2$. Immediately after the addition of one equivalent of $Bu_3P{=}CH_2$ to a solution of $(n\mathrm{Bu_4N})_3[PMo_{12}O_{40}]$ in CH_3CN, the ^{31}P NMR spectrum displays two signals, assigned to **I** and to the phosphonium cation $Bu_3PCH_3^+$, respectively (Figure 2). Subsequent addition of a second

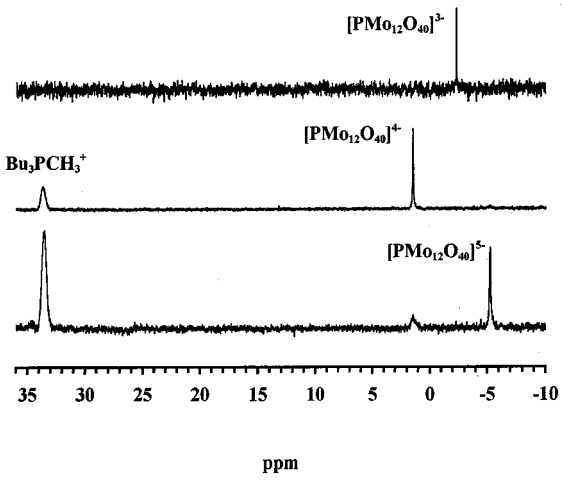

Figure 2. ^{31}P NMR spectra (referenced to external 85% H_3PO_4) in acetonitrile: $(n\mathrm{Bu_4N})_3[PMo_{12}O_{40}]$ (top); $(n\mathrm{Bu_4N})_3[PMo_{12}O_{40}]$ + 1 equiv. $Bu_3P{=}CH_2$ (center); $(n\mathrm{Bu_4N})_3[PMo_{12}O_{40}]$ + 2 equiv. $Bu_3P{=}CH_2$ (bottom)

Table 3. Spectroscopic data for $[H_xPMo_{12}O_{40}]^{n-}$ species

Anion		Electronic λ_{max} (solvent) [nm]	Infrared [cm^{-1}] $10^{-3}\varepsilon$ [$mol^{-1}\cdot L\cdot cm^{-1}$]	ν(PO)	ν(Mo=O)	ν(MoOMo)
$[PMo_{12}O_{40}]^{3-}$ [23]	**0**	–	–	1063	965sh, 956	880, 807
$[PMo_{12}O_{40}]^{4-}$ [19][20]	**I**	800 (DMF)	1.3	1058	952, 942	858, 794

equivalent of $Bu_3P{=}CH_2$ leads to the reduction of **I** to **II** with formation of another equivalent of phosphonium cation. The reduction products were further identified as **I** and **II** by R.D.E. measurements. According to ^{31}P NMR and electrochemical analyses, the reactions are quantitative. When $(Ph_4P)_3[PMo_{12}O_{40}]$ was used instead of $(nBu_4N)_3[PMo_{12}O_{40}]$, precipitation of $(Ph_4P)_4[PMo_{12}O_{40}]$ occurred after addition of one equivalent of ylide.

A similar pattern was observed for the reaction of $Ph_3P{=}CHPh$ with $(nBu_4N)_3[PMo_{12}O_{40}]$, with the exception of the initial formation of a green precipitate, which proved to be a mixture of oxidized and reduced phosphodecamolybdates containing lithium, tetrabutylammonium and phosphonium cations. This was followed by the precipitation of $(nBu_4N)_4[PMo_{12}O_{40}]$ which could be recrystallized from DMSO.

Reactions of Phosphanes with $[PMo_{12}O_{40}]^{3-}$

Phosphanes react with $(nBu_4N)_3[PMo_{12}O_{40}]$ in MeCN to yield reduced species, as indicated by the blue colour of the resulting solutions. In a typical experiment, a solution of $(nBu_4N)_3[PMo_{12}O_{40}]$ (510 mg, 0.200 mmol) and PPh_3 (52.5 mg, 0.200 mmol) in distilled MeCN (20 mL) was heated to reflux and samples were periodically analysed by ^{31}P NMR spectroscopy, which showed a progressive decrease in the signals of PPh_3 and $[PMo_{12}O_{40}]^{3-}$ at $\delta = -4.5$ and -2.3, respectively, and a concomitant increase in two new signals, one at $\delta = 27.5$, which is unambiguously assigned to Ph_3PO, the second at $\delta = -5.0$, which is consistent with $[H_2PMo_{12}O_{40}]^{3-}$. These observations are in agreement with those reported by Kawafune et al.[16] However, contrary to these authors, we found that the complete disappearance of $[PMo_{12}O_{40}]^{3-}$ in distilled acetonitrile required more than one equivalent of PPh_3. A pure product with analytical and spectroscopic features identical to those reported by Kawafune et al. for $(nBu_4N)_3[PMo_{12}O_{39}]$, was then isolated after heating a solution of $(nBu_4N)_3[PMo_{12}O_{40}]$ and a 10-fold excess of PPh_3 at reflux for 17 h (see Experimental Section). It was subsequently found that only one equivalent of phosphane is needed if the reaction is carried out in the presence of a sufficient amount of water. Analytical, spectroscopic and electrochemical data for the compounds obtained either in distilled acetonitrile, but in the presence of an excess of PPh_3, or in wet acetonitrile are identical to those of $\mathbf{H_2II}$ as well as to the analytical and spectroscopic data reported by Kawafune for $(nBu_4N)_3[PMo_{12}O_{39}]$. The latter has thus to be reformulated as $(nBu_4N)_3[H_2PMo_{12}O_{40}]$ and the reaction could be thought to proceed according to Equation (3).[24,25]

$$[PMo_{12}O_{40}]^{3-} + PPh_3 + H_2O \rightarrow [H_2PMo_{12}O_{40}]^{3-} + Ph_3PO \quad (3)$$

The reaction of tributylphosphane with $[PMo_{12}O_{40}]^{3-}$ is much faster than that of PPh_3 and proceeds according to a different stoichiometry. The reaction was monitored by ^{31}P NMR spectroscopy (Figure 3). For molar ratios less than 0.5 phosphane per polyanion, three signals are observed, which are unambiguously assigned to $[PMo_{12}O_{40}]^{3-}$ (**0**), $[H_2PMo_{12}O_{40}]^{3-}$ ($\mathbf{H_2II}$) and Bu_3PO. For ratios from 0.5 to ca. 1.0, five signals are observed: The first three are unambiguously assigned to **0**, **I** and Bu_3PO; the fourth, which shifts from $\delta = -5.0$ to $\delta = -5.2$ as the ratio increases, is tentatively assigned to a mixture of **HII** and $\mathbf{H_2II}$; the fifth, which appears as a broad doublet ($\delta = 14-35$, $J_{PH} = 400$ Hz), is assigned to Bu_3PH^+. Its chemical shift varies widely, which might be indicative of proton exchange with other species such as reduced polyoxometalates. Complete disappearance of **0** is observed for ratios in the range 1 to 1.1. Control experiments have shown that the reduction of **I** by PBu_3 is quite slow at room temperature.

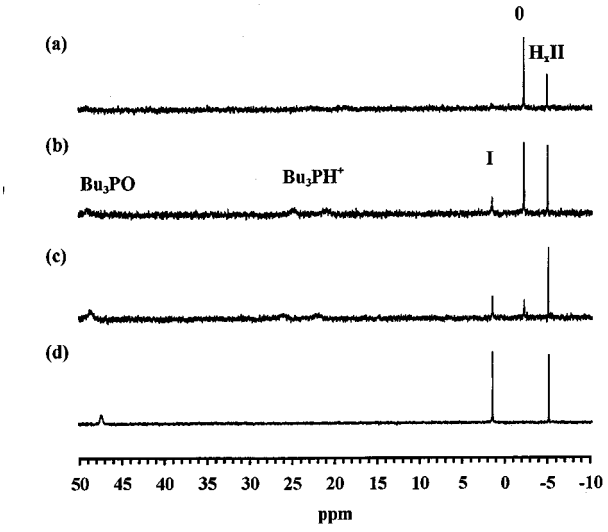

Figure 3. ^{31}P NMR spectra (referenced to external 85% H_3PO_4) in acetonitrile: (a) $(nBu_4N)_3[PMo_{12}O_{40}]$ + 0.5 equiv. PBu_3; (b) $(nBu_4N)_3[PMo_{12}O_{40}]$ + 0.75 equiv. PBu_3; (c) $(nBu_4N)_3[PMo_{12}O_{40}]$ + 1 equiv. PBu_3; (d) $(nBu_4N)_3[PMo_{12}O_{40}]$ + 2 equiv. PBu_3

Discussion

Reactions of Phosphonium Ylides with $[PMo_{12}O_{40}]^{3-}$

The addition of a phosphonium ylide to a solution of $(nBu_4N)_3[PMo_{12}O_{40}]$ in MeCN only results in the formation of reduced species **I** and **II**, whatever ylide is used. We could not obtain any evidence for the formation of an alkylidene derivative of $[PMo_{12}O_{40}]^{3-}$. The more reducing the ylide is, the cleaner the reaction. The reactions of Bu_3PCH_2 with **0** and **I** are fast. Both the reduction of **0** in **I** and that of **I** in **II** involve one equivalent of ylide and yield one equivalent of the parent phosphonium ion. The stoichiometry of the reactions is consistent with Equations (4) and (5).

$$[PMo_{12}O_{40}]^{3-} + R_3P{=}CR^1R^2 \rightarrow [PMo_{12}O_{40}]^{4-} + [R_3P{=}CR^1R^2]^{\bullet+} \quad (4)$$

$$[PMo_{12}O_{40}]^{4-} + R_3P{=}CR^1R^2 \rightarrow [PMo_{12}O_{40}]^{5-} + [R_3P{=}CR^1R^2]^{\bullet+} \quad (5)$$

The formation of ylide-derived radical-cations is known. Indeed, $[Ph_3P{=}CPh_2]^{\bullet+}$ has been obtained and characterized by electrochemical oxidation of $Ph_3P{=}CPh_2$ in MeCN in the probe of an EPR spectrometer.[26] However, direct

evidence for the formation of $[R_3P{=}CR^1R^2]^{\bullet+}$ could not be obtained. Indirect evidence for the formation of a radical is nevertheless provided by the formation of diphenyl disulfide when the reaction was carried out in the presence of thiophenol. Diphenyl disulfide was isolated by extraction with ether and characterized by TLC and IR spectroscopy. Control experiments showed that thiophenol is not oxidized by **0** on the reaction timescale.

The formation of the parent phosphonium ion $[R_3PCHR^1R^2]^+$ by reaction of the ylide with solvent can be excluded since $Ph_3P{=}CHPh$ proved to be stable in the absence of $(n\mathrm{Bu}_4\mathrm{N})_3[\mathrm{PMo}_{12}\mathrm{O}_{40}]$. Indeed, complete "spontaneous" transformation of $Ph_3P{=}CHPh$ into $[Ph_3PCH_2Ph]^+$ requires more than 12 h in MeCN at room temperature. The formation of phosphonium ions in the reactions of various ylides with dioxomolybdenum complexes in CH_2Cl_2 has been observed by Lai et al. and ascribed to transylidation between residual ylide and an oxometallabetaine initially formed.[15] However, such a pathway could not account for the complete transformation of the ylide into the parent phosphonium ion. We have reinvestigated the reactions of various ylides with $[MoO_2(dedtc)_2]$ (dedtc = diethyl dithiocarbamate) in MeCN and we have found that addition of the ylide is followed by the precipation of the purple compound $[Mo_2O_3(dedtc)_4]$. The formation of this complex most probably accounts for the violet colour observed by Lai et al. in their experiments and suggests that a redox pathway also occurs in the reaction of ylides with dioxomolybdenum complexes.

The actual source (XH) of the hydrogen atom in the formation of the phosphonium ion from the ylide-derived radical cation (Equation 6) has not been definitively established.

$$[R_3P{=}CR^1R^2]^{\bullet+} + XH \rightarrow [R_3P{-}CHR^1R^2]^+ + X^{\bullet} \quad (6)$$

It is unlikely that either the ylide or the tetrabutylammonium ion acts as XH. Indeed the ylide is quantitatively transformed into the parent phosphonium ion and the course of the reaction is not altered upon the replacement of tetrabutylammonium by tetraphenylphosphonium, which does not act as an hydrogen donor. Thus XH is most likely MeCN or residual H_2O.

Reactions of Phosphanes with $[PMo_{12}O_{40}]^{3-}$

Reactions of phosphanes with oxomolybdenum complexes have been largely investigated in relation to modelling studies of molybdenum oxotransferases.[27] Oxo transfer reaction from $[MoO_2L_n]$ to PR_3 is initiated by nucleophilic attack on an $Mo^{VI}{=}O$ unit and the formation of a $(\mu\text{-oxo})Mo^V$ dimer $[Mo_2O_3L_{2n}]$ often competes with that of the Mo^{IV} complex $[MoOL_n]$. Kawafune et al. were the first to extend such reactions to polyoxoanions by investigating the reaction of PPh_3 with $(n\mathrm{Bu}_4\mathrm{N})_3[\mathrm{PMo}_{12}\mathrm{O}_{40}]$ in MeCN.[16] They claimed to have obtained the oxygen-deficient reduced species $(n\mathrm{Bu}_4\mathrm{N})_3[\mathrm{PMo}_{12}\mathrm{O}_{40-x}]$ (x = 1, 2 or 3) by successive oxo transfer reactions. Although it is commonly accepted that oxygen-deficient species are formed in the course of heterogeneous catalytic oxidations with polyoxometalates,[28] the formation of such species in solution may be questioned. The reaction has been revisited by Mattes et al. who isolated **HII** by reaction of PPh_3 with $[K(18\text{-crown-6})][N(PPh_3)_2]_2[PMo_{12}O_{40}]$ and subsequent workup.[17] It should also be noted at this point that the UV/Vis and ^{31}P NMR spectra of $[HPMo_{12}O_{40}]^{4-}$ are not in agreement with those reported by Kawafune et al. for the so-called $[PMo_{12}O_{39}]^{3-}$ species. Mattes et al. assumed that $[PMo_{12}O_{39}]^{3-}$, once formed, reacts with residual water. Indeed we found the reaction of PPh_3 with $(n\mathrm{Bu}_4\mathrm{N})_3[\mathrm{PMo}_{12}\mathrm{O}_{40}]$ to be dependent on the residual amount of water in the solvent. The reaction did not go to completion when distilled acetonitrile was used, probably due to kinetically competitive phosphane-consuming side-reactions. Only in the presence of a sufficient amount of water did the reaction go to completion with one equivalent of PPh_3. The product obtained in this way displays all the features reported by Kawafune et al. for $(n\mathrm{Bu}_4\mathrm{N})_3[\mathrm{PMo}_{12}\mathrm{O}_{39}]$ and will be referred to as Kawafune's compound. Analytical data reasonably conform to the formula $(n\mathrm{Bu}_4\mathrm{N})_3[\mathrm{PMo}_{12}\mathrm{O}_{39}]$, but would equally be consistent with either $(n\mathrm{Bu}_4\mathrm{N})_3[\mathrm{HPMo}_{12}\mathrm{O}_{40}]$ or $(n\mathrm{Bu}_4\mathrm{N})_3[\mathrm{H}_2\mathrm{PMo}_{12}\mathrm{O}_{40}]$. IR features are clearly indicative of a reduced Keggin anion by the reduced intensity of P−O and Mo−O−Mo stretching bands. Moreover, the $Mo{-}O_t$ stretching band is almost unaltered with respect to $[PMo_{12}O_{40}]^{3-}$, which suggests that both compounds have the same charge. Again, this would be consistent with any of the three formulas above. In any case, the formation of $[PMo_{12}O_{40}]^{5-}$ (**II**) can be ruled out since this species could not coexist with $[PMo_{12}O_{40}]^{3-}$ in solution. The hypothesis of a 1e-reduced product may also be ruled out since the observed ^{31}P signal is shielded with respect to that of $[PMo_{12}O_{40}]^{3-}$. Neither does the product correspond to $[HPMo_{12}O_{40}]^{4-}$ (**HII**) as described by Mattes et al. Definitive evidence for the true nature of the product is provided by electrochemistry which shows that the behaviour of the product is identical to that of $(n\mathrm{Bu}_4\mathrm{N})_3[\mathrm{H}_2\mathrm{PMo}_{12}\mathrm{O}_{40}]$ (**H_2II**). Indeed the R.D.E. voltammogram (Figure 4) displays a 2e-oxidation wave at +0.56 V/SCE and becomes indistinguishable from those of $[HPMo_{12}O_{40}]^{4-}$ and $[PMo_{12}O_{40}]^{5-}$ upon addition of one and two equivalents of tetrabutylammonium hydroxide, respectively. Finally, electrochemical, ^{31}P NMR, IR and UV/Vis data are identical to those of $(n\mathrm{Bu}_4\mathrm{N})_3[\mathrm{H}_2\mathrm{PMo}_{12}\mathrm{O}_{40}]$. Thus, Kawafune's compound, which was postulated to be $(n\mathrm{Bu}_4\mathrm{N})_3[\mathrm{PMo}_{12}\mathrm{O}_{39}]$, is actually $(n\mathrm{Bu}_4\mathrm{N})_3[\mathrm{H}_2\mathrm{PMo}_{12}\mathrm{O}_{40}]$.

While only **H_2II** was obtained by reaction of PPh_3 with $(n\mathrm{Bu}_4\mathrm{N})_3[\mathrm{PMo}_{12}\mathrm{O}_{40}]$, **I**, **HII** and **$H_2$II** have been characterized from the products of the reaction with PBu_3, depending on the amount of phosphane. This can be explained on the basis of the mechanism postulated by Bond et al. for the reduction of $[S_2Mo_{18}O_{62}]^{4-}$ by phosphanes [Equation (7) to Equation (9)].[18]

$$[PMo_{12}O_{40}]^{3-} + R_3P \rightarrow [PMo_{12}O_{40}]^{4-} + R_3P^{\bullet+} \quad (7)$$

$$R_3P^{\bullet+} + H_2O \rightarrow R_3POH^{\bullet} + H^+ \quad (8)$$

$$[PMo_{12}O_{40}]^{3-} + R_3POH^{\bullet} \rightarrow [PMo_{12}O_{40}]^{4-} + R_3PO + H^+ \quad (9)$$

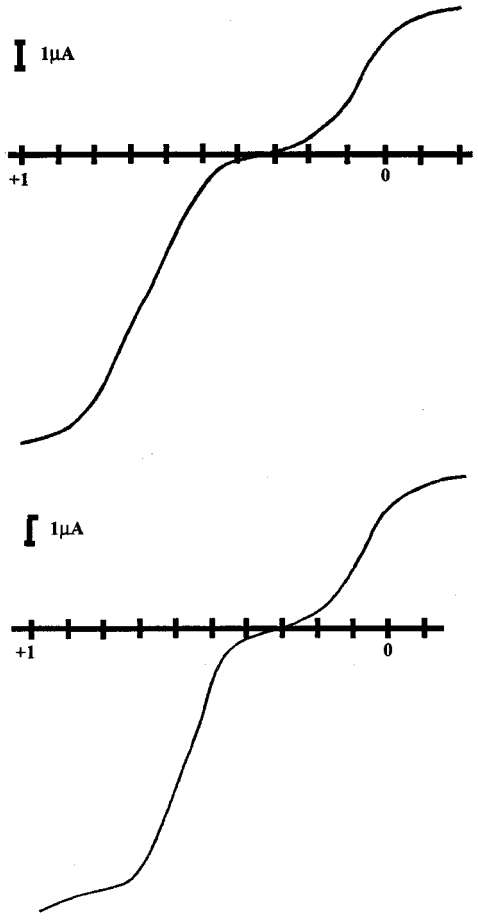

Figure 4. R.D.E. voltammogram of the reaction product of PPh_3 with $(nBu_4N)_3[PMo_{12}O_{40}]$ (top) and $(nBu_4N)_3[H_2PMo_{12}O_{40}]$ (bottom), both 1 mM in MeCN, E in Volt vs. SCE at a platinum electrode

The net reaction can then be written as Equation (10).

$$2\,[PMo_{12}O_{40}]^{3-} + R_3P + H_2O \rightarrow 2\,[PMo_{12}O_{40}]^{4-} + R_3PO + 2\,H^+ \quad (10)$$

As **I** disproportionates in the presence of protons, the final products will depend upon the relative basicities of the different species. When a strong base such as triethylamine is added to the reaction mixture, the reaction stops after addition of half an equivalent of PBu_3 and the ^{31}P NMR spectrum only displays the signal of **I**, in agreement with Equation (11).

$$2\,[PMo_{12}O_{40}]^{3-} + PBu_3 + H_2O + 2\,Et_3N \rightarrow 2\,[PMo_{12}O_{40}]^{4-} + Bu_3PO + 2\,Et_3NH^+ \quad (11)$$

In the absence of any additional base, the products depend on the basicity of the phosphane. PPh_3 is a weak base so that **I** undergoes disproportionation according to Equation (1), and the overall reaction reduces to Equation (3). On the other hand, PBu_3 is more basic than PPh_3 and competes with **I** for protonation. For low phosphane-to-polyanion ratios, $\mathbf{H_2II}$ is the only product observed while a mixture of **I**, $\mathbf{H_2II}$ and/or **HII** is found for higher ratios.

While this mechanism is consistent with the experimental results, the following alternative mechanism [Equation (12) to Equation (15)] might equally account for the stoichiometry of the reaction of $(nBu_4N)_3[PMo_{12}O_{40}]$ with PBu_3 in the presence of NEt_3.

$$[PMo_{12}O_{40}]^{3-} + R_3P \rightarrow [PMo_{12}O_{39}]^{3-} + R_3PO \quad (12)$$

$$[PMo_{12}O_{39}]^{3-} + H_2O \rightarrow [H_2PMo_{12}O_{40}]^{3-} \quad (13)$$

$$[H_2PMo_{12}O_{40}]^{3-} + 2\,NEt_3 \rightarrow [PMo_{12}O_{40}]^{5-} + 2\,Et_3NH^+ \quad (14)$$

$$[PMo_{12}O_{40}]^{3-} + [PMo_{12}O_{40}]^{5-} \rightarrow 2\,[PMo_{12}O_{40}]^{4-} \quad (15)$$

As no evidence could be obtained for either $R_3P^{\bullet+}$ or $[PMo_{12}O_{39}]^{3-}$, it is not possible to discriminate between these two mechanisms.

Concluding Remarks

Phenyllithium and phosphonium ylides act as 1e-reducing reagents towards $[PMo_{12}O_{40}]^{3-}$. The former is a convenient reagent for the millimolar-scale preparation of **I**, **LiII**, **HII** and $\mathbf{H_2II}$, which have been fully characterized. To the best of our knowledge, the only previous mention of the reduction of polyoxometalates by organometallic reagents is the report by McCann et al. of the catalytic norbornene ROMP by a single crystal of $(nBu_4N)_2[Mo_6O_{19}]$, in the presence of $EtAlCl_2$.[8] On the other hand, phosphanes act as 2e-reducing reagents, although it could not be established whether the reactions proceed through oxo transfer or via phosphane-based radical intermediates. Whatever the actual mechanism, the so-called oxygen-deficient compound $(nBu_4N)_3[PMo_{12}O_{39}]$ previously reported by Kawafune is actually $(nBu_4N)_3[H_2PMo_{12}O_{40}]$.

Experimental Section

Reagents and Solvents: Reactions were routinely carried out under inert atmospheres unless otherwise stated. Solvents were dried and freed of oxygen using standard procedures. $(nBu_4N)_3[PMo_{12}O_{40}]\cdot xH_2O$ was prepared as previously described[2,3] and further dried overnight at 80 °C under vacuum; $(Ph_4P)_3[PMo_{12}O_{40}]$ was obtained by a similar procedure, using Ph_4PBr instead of nBu_4NBr. Other chemicals were used as supplied.

Methods and Instrumentation: Infrared spectra were recorded from KBr pellets with a Bio-Rad FT 165 spectrophotometer and electronic absorption spectra on Shimadzu UV-2101 spectrophotometer. – Elemental analyses were performed at the Service Central d'Analyse of the CNRS (Vernaison, France). – ^{31}P NMR spectra (121.5 MHz, external 85% H_3PO_4) were recorded on CH_3CN/CD_3CN or DMSO/[D_6]DMSO solutions (0.3 mL – 0.1 mL) with a Bruker AC300 spectrometer equipped with a QNP probehead. – All electrochemical measurements were carried in 0.1 M $(nBu_4N)BF_4$ CH_3CN solutions under nitrogen at room temperature using a standard three-electrode cell [platinum rotating disk working electrode, auxiliary platinum wire and aqueous KCl saturated double junction calomel electrode (SCE)]. Rotating disk electrode voltammograms were recorded with a Tacussel PRG3 device at the rate of 5 $mV\cdot s^{-1}$. Cyclic voltammograms were recorded with a PAR 273A instrument at the rate of 100 $mV\cdot s^{-1}$.

Ylide Syntheses: Tributyl(methylene)phosphorane $Bu_3P{=}CH_2$ was prepared from tributyl(methyl)phosphonium iodide and butylli-

thium and distilled under vacuum.[29] − A slurry of benzyltriphenylphosphonium bromide (433 mg, 1.00 mmol) in CH_3CN (10 mL) was cooled in an ice bath. Phenyllithium solution (1 equiv.) was then added via syringe. The reaction mixture quickly turned orange and was filtered via canula after stirring for 15 min at 0 °C. The solution of benzylidenetriphenylphosphorane was then directly used in the reaction on $[PMo_{12}O_{40}]^{3-}$.

Reduced Phosphododecamolybdates. − (nBu$_4$N)$_4$[PMo$_{12}$O$_{40}$]: Phenyllithium (1.00 mmol) was added slowly to a solution of (nBu$_4$N)$_3$[PMo$_{12}$O$_{40}$] (2.55 g, 1.00 mmol) in acetonitrile (90 mL). The blue solution was filtered when necessary and (nBu$_4$N)BF$_4$ (320 mg, 1.00 mmol) was added. Cooling to −40 °C afforded a blue-green precipitate coated with a brown oil and was isolated by filtration. Pure (nBu$_4$N)$_4$[PMo$_{12}$O$_{40}$] was obtained by washing the blue-green powder with tetrahydrofuran and methanol until the filtrate was colourless. Further crops of the product can be isolated by successive additions of (nBu$_4$N)BF$_4$ (320 mg, 1.00 mmol) followed by cooling, filtration and washing. The powder can be handled in air and its solutions in MeCN, DMF or DMSO are stable towards oxidation. Yield: 2.1 g (75%). − $C_{64}H_{144}N_4PMo_{12}O_{40}$ (2792.0824): calcd. C 27.53, H 5.2, Mo 41.23, N 2.01, P 1.11; found C 27.57, H 5.23, Mo 40.86, N 2.05, P 1.19. − Recrystallization in DMSO led to dark-blue crystals of (nBu$_4$N)$_4$[PMo$_{12}$O$_{40}$]: tetragonal, $a = b = 18.72(2)$ Å, $c = 14.548(3)$ Å, $V = 5094(2)$ Å^3.[3b]

Li(nBu$_4$N)$_4$[PMo$_{12}$O$_{40}$]: The same procedure with two equivalents of phenyllithium afforded pure Li(nBu$_4$N)$_4$[PMo$_{12}$O$_{40}$]. Yield: 2.3 g (82%). − $C_{64}H_{144}LiMo_{12}N_4O_{40}P$ (2799.0234): calcd. C 27.46, H 5.19, Li 0.25, N 2, P 1.11; found C 27.46, H 5.40, Li 0.21, N 2.22, P 1.14.

(nBu$_4$N)$_4$[HPMo$_{12}$O$_{40}$]: A solution of triflic acid in acetonitrile (1.00 mL, 200 mM) was slowly added to a solution of Li(n-Bu$_4$N)$_4$[PMo$_{12}$O$_{40}$] (560 mg, 0.200 mmol) in acetonitrile (10 mL). Subsequent addition of (nBu$_4$N)BF$_4$ (320 mg, 1.00 mmol) and cooling to −40 °C afforded a blue precipitate of (nBu$_4$N)$_4$[HPMo$_{12}$O$_{40}$], which was washed with THF and dried in vacuum. Yield: 0.42 g (0.15 mmol, 75%). − $C_{64}H_{145}Mo_{12}N_4O_{40}P$ (2793.0903): calcd. C 27.52, H 5.23, Mo 41.22, N 2.01, P 1.11; found C 27.36, H 5.21, Mo 40.20, N 2.07, P 1.22.

(nBu$_4$N)$_3$[H$_2$PMo$_{12}$O$_{40}$]: The same procedure using 2.00 mL of the 200 mM solution of triflic acid in acetonitrile afforded (nBu$_4$N)$_3$[H$_2$PMo$_{12}$O$_{40}$]. Yield: 0.29 mg (57%). − $C_{48}H_{110}Mo_{12}N_3O_{40}P$ (2551.6311): calcd. C 22.59, H 4.35, N 1.65, P 1.21; found C 22.92, H 4.83, N 1.76, P 1.30.

Typical Experiment for the Reaction of (nBu$_4$N)$_3$[PMo$_{12}$O$_{40}$] with Phosphonium Ylide or Tributylphosphane: In a typical experiment, (nBu$_4$N)$_3$[PMo$_{12}$O$_{40}$] (510 mg, 0.200 mmol) was dissolved in acetonitrile (20 mL) or DMSO (5 mL) and the desired amount of reagent was added via syringe or transferred via canula (benzylidenetriphenylphosphorane solution). The reaction mixture was stirred for 10 min at room temperature. A sample (0.3 mL) was then placed in an NMR tube, purged with argon, and CD_3CN (0.1 mL) was added.

(Ph$_4$P)$_4$[PMo$_{12}$O$_{40}$]: To a solution of (Ph$_4$P)$_3$[PMo$_{12}$O$_{40}$] (1.0 g, 0.35 mmol) in acetonitrile (100 mL) was added a slight excess of Bu_3PCH_2 (85 mg, 0.40 mmol) via syringe. The solution turned dark green and a blue precipitate formed immediately. Yield: 0.6 g. Recrystallization in DMF led to dark-blue crystals of composition (Ph$_4$P)$_4$[PMo$_{12}$O$_{40}$]·2DMF: triclinic, $a = 13.973(2)$ Å, $b = 14.378(4)$ Å, $c = 15.193(2)$ Å, $\alpha = 71.17(2)°$, $\beta = 77.97(1)°$, $\gamma = 79.40(2)°$, $V = 2803$ (1) Å^3. − $C_{102}H_{94}Mo_{12}N_2O_{42}P_5$ (3325.9860): calcd. C 36.83, H 2.85, Mo 34.61, N 0.84, P 4.66; found C 37.16, H 2.8, Mo 33.85, N 0.98, P 4.59.

Reaction of (nBu$_4$N)$_3$[PMo$_{12}$O$_{40}$] with Triphenylphosphane: (nBu$_4$N)$_3$[PMo$_{12}$O$_{40}$] (510 mg, 0.200 mmol) and PPh_3 (525 mg, 2.00 mmol) were heated at reflux in acetonitrile (20 mL) for 17 h. The solvent was then evaporated in vacuum and the blue residue washed with ethyl ether and THF until the filtrate was colourless. Yield: 0.40 g (78%). − $C_{48}H_{110}Mo_{12}N_3O_{40}P$ (2551.6311): calcd. C 22.59, H 4.35, Mo 45.12, N 1.65, P 1.21; found C 23.39, H 4.37, Mo 46.45, N 1.64, P 1.26. − ^{31}P NMR (CD_3CN): $\delta = -5.0$. − IR (cm^{-1}): $\tilde{\nu} = 1062$ (m), 955(s), 880(m), 807(s). − UV/Vis (CH_3CN): $\lambda_{max} = 740$ nm ($\varepsilon = 5.4\ 10^3\ mol^{-1}\cdot L\cdot cm^{-1}$).

Acknowledgments

We are very grateful to Prof. P. Gouzerh for fruitful discussions from the very beginning of the experimental search to the final version of this manuscript.

Chiral Recognition Among Tris(diimine)−Metal Complexes, 6[‡]

Racemic Compound Formation *versus* Conglomerate Formation with $[M(bpy)_3](PF_6)_2$ (M = Ni, Zn, Ru); Molecular and Crystal Structures

Josef Breu,*[a] Holger Domel,[a] and Alexander Stoll[a]

Keywords: Molecular recognition / Chiral recognition / Conglomerate crystallization / Self-assembly / Polymorphism

Minor modifications in molecular size and shape induced by variation of the central atom drastically alter the crystallization behaviour of the hexafluorophosphate salts of $[M(bpy)_3]^{2+}$. With M = Ru, racemic solutions crystallize as true racemates in the β-type [$P\bar{3}c1$, a = 10.6453(5), c = 16.2987(9) Å, Z = 2], while for M = Zn the racemic structure cannot be obtained, as spontaneous resolution {γ-type [$P3_1$, a = 10.3873(5), c = 26.1309(16) Å, Z = 3]} is the only crystallization path observed. For $[Ni(bpy)_3](PF_6)_2$, crystals of both structural types can be obtained concomitantly from the same crystallization batch. The γ-phase is systematically twinned by merohedry. The dramatic and unpredictable change in the packing pattern of the very similar building blocks within this series arises from a delicate balance between the intermolecular forces. Distinct intermolecular interactions with different directionalities can be identified in the two structure types. Through careful analysis of the crystal and molecular structures, a trend with respect to molecular size and shape on going from $[Ru(bpy)_3](PF_6)_2$ to $[Zn(bpy)_3](PF_6)_2$ can be established. Even though one might speculate that increasing the size of the molecular cation should destabilize the β-type structure relative to the γ-type, no conclusive rationalization based solely on structural parameters can be given as regards why the relative order of the two local minima on the energy hypersurface should become inverted.

Introduction

Crystal structures of molecular solids are the result of cooperative molecular (chiral) recognition and self-assembly leading to a favourable 3D arrangement. Recognition involves the storage of information at the molecular level and its manifestation at the supramolecular level in a double-complementary fashion, taking into account energetic as well as geometrical requirements.[2,3] However, the ways in which individual noncovalent forces compete with or reinforce one another in complex systems are poorly understood.

Dunitz[4,5] succinctly described the crystal as the "*supramolecule par excellence*". Indeed, each observed packing pattern represents the culmination of highly specific and amazingly precise molecular (chiral) recognition based on noncovalent interactions. Consequently, each crystal structure contains a wealth of valuable information about the ways in which the multitude of noncovalent intermolecular interactions compete and collaborate to achieve their subtle balance.[6] Careful analysis of crystal structures, packing motifs, and distinct differences in intramolecular geometries should make available the inherent information, thereby assisting in the development of a better understanding of the "*grammar of crystal packing*".[7] Besides the more general utility of these rules in the syntheses of designed molecular materials (i.e. for "crystal engineering"), a practical application might be the development of strategies for increasing the likelihood of conglomerate crystallization.

Conglomerate crystallization is defined as the phenomenon whereby a racemic solution or melt produces a mechanical mixture of enantiomorphic, homochiral crystals, i.e. each individual crystal (or at least domain in the case of racemic twinning) contains a single enantiomer.[8,9] The phenomenon of conglomerate crystallization can be utilized for optical resolution by the so-called method of "resolution by entrainment", but it is relatively rare; its frequency has been estimated to be in the range 5−10%.[10]

Tris(chelate)−metal complexes of planar ligands, $[M(L-L)_3]^{n+}$ (e.g. L−L: phen = 1,10-phenanthroline, bpy = 2,2′-bipyridine, bpdz = 3,3′-bipyridazine, bpm = 4,4′-bipyrimidine, bpym = 2,2′-bipyrimidine, bpz = 2,2′-bipyrazine) are especially well suited for studying crystal packing phenomena.[11−13] On the one hand, these propeller-shaped, chiral molecules display a very corrugated molecular form. In Lehn's[2] notation, much information is stored at the molecular level, which will inevitably be manifested at the supramolecular level when neighbouring molecular ions interpenetrate to achieve maximum packing density. Moreover, this molecular recognition will not be obscured by gross intramolecular changes since the molecular ions are rather rigid. On the other hand, such molecular systems are extremely flexible. The central atom and its oxidation state may be varied over a wide range and this allows for a fine, systematic tuning of the component parts. Such alterations should help us to gain further insight into

the relative strengths, directionalities, and structural influences of the various noncovalent forces.

The crystal structures of the true racemate β-[Ru(bpy)$_3$](PF$_6$)$_2$ [14,15] and its closely related low-temperature polymorph α-[Ru(bpy)$_3$](PF$_6$)$_2$ [16] have been known for some time. Of the analogous molecular salts of the first-row transition metals, only the structure of [Fe(bpy)$_3$](PF$_6$)$_2$ has been reported[17] to be isomorphous with that of β-[Ru(bpy)$_3$](PF$_6$)$_2$. All others are absent from the Cambridge Structural Database (CSD),[18] probably because the structures could not be successfully refined. For example, as early as 1983, Ferguson and Herren[19] recognized that in contrast to the Ru analogue, [Zn(bpy)$_3$](PF$_6$)$_2$ undergoes spontaneous resolution upon crystallization. However, they continued: "Attempts to determine the structure by X-ray methods proved fruitless and the difficulties were consistent with perfect multiple twinning." Solution of the crystal structure was claimed in two later publications[20,21] and cell data were given, but the structural details were never published as no satisfactory structure refinement could be accomplished.[22]

After having solved the twinning problem, we are able to report herein the detailed molecular and crystal structures of the enantiomorphic structure type γ-[M(bpy)$_3$](PF$_6$)$_2$ (M = Ni, Zn, Ru) and compare them with those of the true racemate β-[M(bpy)$_3$](PF$_6$)$_2$ (M = Ni, Ru).

Results and Discussion

Braga, Grepioni, and co-workers, who have been at the forefront of developing an organometallic "branch" of crystal engineering, conclude from their experience[23] that "objects of similar shape tend to pack in a similar manner, provided that the type of noncovalent interactions at work are not significantly altered." Contrary to this, we have found that even minor modifications in molecular size and shape induced by variation of the central atom drastically alter the crystallization behaviour of the hexafluorophosphate salts of [M(bpy)$_3$]$^{2+}$. With M = Fe, Ru, the racemic solutions crystallize as true racemates in the β-type, while for M = Zn the racemic structure could not be obtained, as spontaneous resolution (γ-type) is the only crystallization path observed. Interestingly, for [Ni(bpy)$_3$](PF$_6$)$_2$, crystals of both structure types can be obtained concomitantly[24] from the same crystallization batch. Finally, since [Ru(bpy)$_3$]$^{2+}$ is inert towards racemization, the γ-type can be "forced" upon [Ru(bpy)$_3$](PF$_6$)$_2$ by chemical resolution prior to crystallization. Enantiomerically pure [Ru(bpy)$_3$](PF$_6$)$_2$ can no longer crystallize in the centrosymmetric β-type, but must crystallize in an enantiomorphic structure with a space group that contains no improper symmetry operations. The dramatic and unpredictable change in the packing arrangement of the very similar building blocks within this series arises from a delicate balance between the intermolecular forces. The following detailed analysis and interpretation of systematic changes in the molecular shapes and intermolecular parameters of the crystal packings within this series should help to establish trends for these systems and to recover some of the information concerning noncovalent forces encoded in these polymorphic modifications.

Even for these rather rigid units, the geometries observed in the solid state result from the interplay of intra- and intermolecular interactions. To explore the effect of packing forces on the intramolecular geometry, the structure of β-[Ru(bpy)$_3$](PF$_6$)$_2$ was redetermined at a low temperature (200 K) intermediate between those of the prior determinations of the α-type (105 K)[16] and the β-type (294 K).[15]

Finally, the structure of γ-[Ni(bpy)$_3$](PF$_6$)$_2$ was determined twice using two different crystals at the same temperature to get an estimate of the variance in the intermolecular and intramolecular parameters introduced by statistical errors inherent to any structure determination. Not surprisingly, the structural parameters were found to agree within experimental error, but their influence on the packing energies[25] was noticeable.

Comparison of Crystal Structures

Both the β- and γ-type structures are composed of layers of complex cations extending parallel to the *ab* plane, with the anions fully immersed in the layers (Figure 1 and Figure 2). In both structures, the cation layers are homochiral (Figure 3 and Figure 4). However, while in β-[M(bpy)$_3$](PF$_6$)$_2$ layers of complex cations with Λ and Δ configuration alternate along *c*, in the γ-type structure layers of the same chirality are stacked along *c*. The molecular cations are arranged in a hexagonal primitive array in both structures and the distances between the metal atoms in the plane are similar {e.g. 10.3809(7) Å and 10.6453(6) Å in γ- and β-[Ru(bpy)$_3$](PF$_6$)$_2$, respectively; see Table 1}.

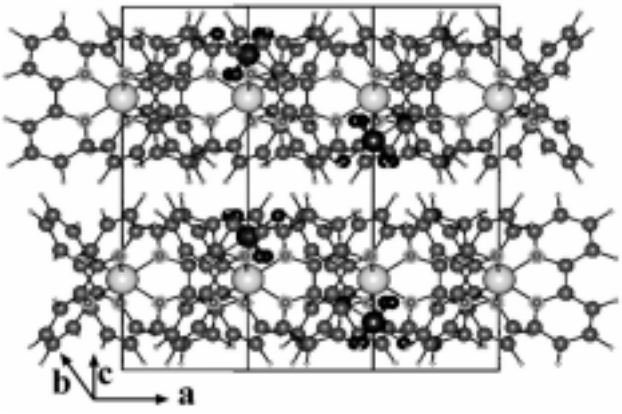

Figure 1. Crystal-packing diagram of β-[M(bpy)$_3$](PF$_6$)$_2$

In the β-phase, the complex cations occupy D_3 sites and are oriented with their C_3 axes exactly perpendicular to the layers and with their C_2 axes extending exactly along the hexagonal axes. In contrast, the cations in the γ-phase are

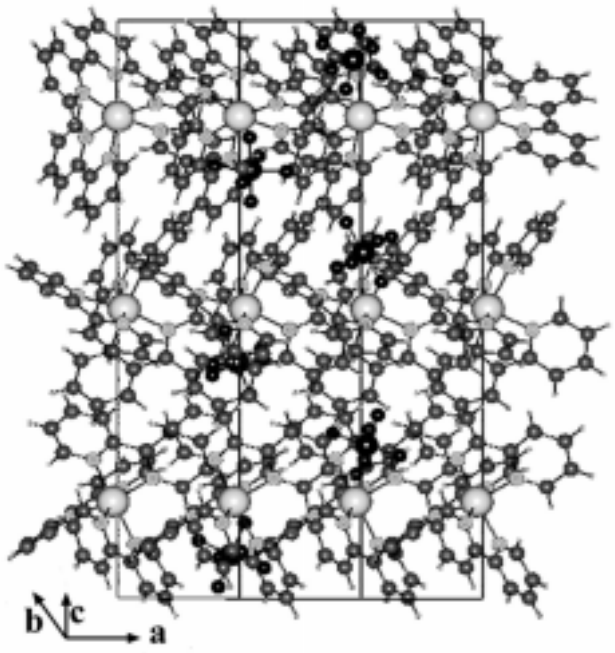

Figure 2. Crystal-packing diagram of γ-$[M(bpy)_3](PF_6)_2$

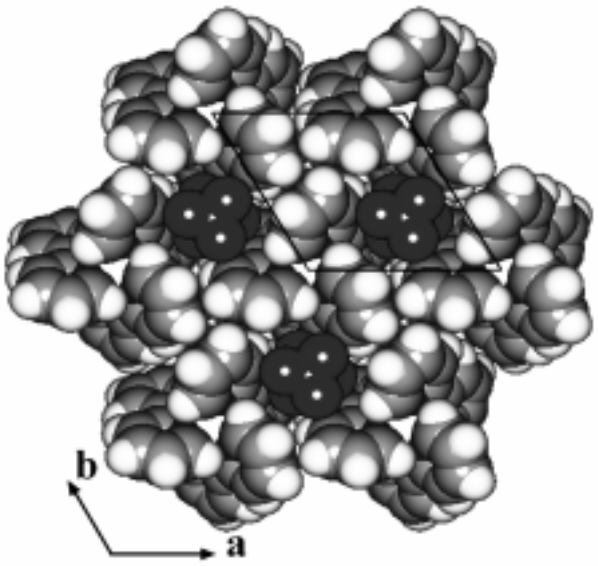

Figure 3. Space-filling packing diagram of the complex cation layer in β-$[M(bpy)_3](PF_6)_2$

effectively "tipped over". Their pseudo C_3 axes lie approximately in the *ab* plane. Moreover, the pseudo C_2 axes are not aligned along the hexagonal axes as would be required in the higher symmetry space group $P3_221$ (or $P3_121$), but rather are inclined towards the *ab* and *ac* planes (for $< C_2|ab$, $< C_2|ac$, see Table 1). The rigorous point symmetry of the cation is C_1 rather than C_2. Presumably, this slight distortion permits a more efficient packing. Furthermore, this induces a small dipole moment in the unit cell in the *c* direction, cancelling out of which might, in turn, be the reason for the systematic twinning of this structure type.

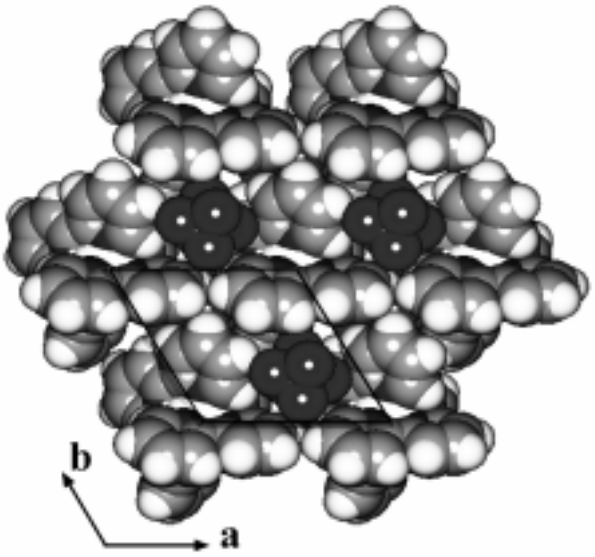

Figure 4. Space-filling packing diagram of the complex cation layer in γ-$[M(bpy)_3](PF_6)_2$

The packing coefficients (Table 1) are similar for both structure types. The absence of improper symmetry elements in the γ-structure does not hamper packing efficiency. This is in line with a study of a larger number of systems, in which no clear trends regarding the densities of true racemates and conglomerates were found either.[26] Despite the corrugated molecular shape, more than one arrangement of almost equal density is possible.

In neither of these close-packed layers do neighbouring complex cations interpenetrate. Instead, the voids are filled with anions. However, the interlocking of the corrugated van der Waals surfaces in the stacking direction (*c*) is notable and very distinct for both structure types. In the β-structure, racemic columns of complex cations with colinear C_3 axes extend along *c*. Along the columns, complexes of opposite chirality are engaged like gearwheels with the tips of the ligands interacting (Figure 5a) and relatively short cation−cation contacts arise {e.g. 8.1494(5) Å for β-$[Ru(bpy)_3](PF_6)_2$; see Table 1}. This stacking results in a T-shaped geometry of adjacent aromatic ligands.[27] In the γ-structure, homochiral columns of cations related by the 3_1 (or 3_2) screw axis are observed. The relative orientation of the C_3 axes of neighbouring cations is therefore reasonably close to the tetrahedral angle, which has been recognized as a preferred mutual orientation for an active pair of propeller-shaped molecules based on van der Waals interactions.[28,29] This mutual arrangement affords two "shifted π-stacks" of adjacent pyridine rings per complex cation (Figure 5c), which are in close contact {8.7601(6) Å for γ-$[Ru(bpy)_3](PF_6)_2$; see Table 1}. The shortest perpendicular distances between the centroid of one bipyridine ring and the plane of the second ring in the diad are, for instance, 3.689 Å and 3.496 Å in γ-$[Ru(bpy)_3](PF_6)_2$.

The intermolecular interactions along the cationic chain for both structure types appear to be controlled by so-called "π−π interactions".[30−32] Lateral interactions of this kind are commonly encountered motifs in the crystal packings

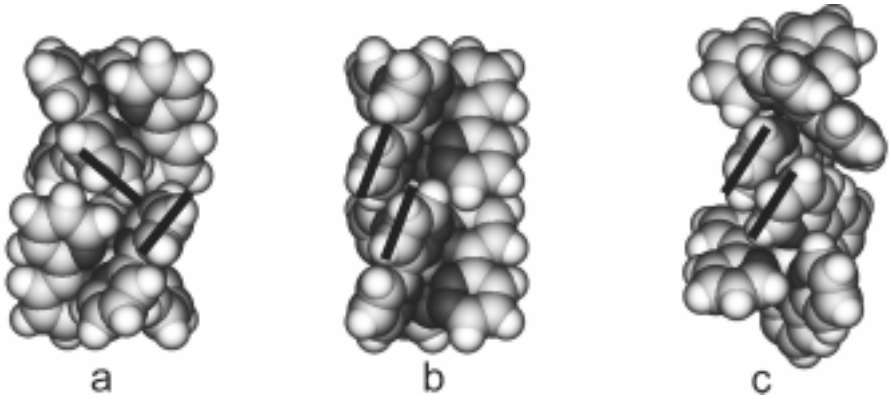

Figure 5. Space-filling packing diagram of the complex cation columns running along *c* in β-$[M(bpy)_3](PF_6)_2$ (a), $[Ni(bpdz)_3](ClO_4)_2$ [49] (b), and γ-$[M(bpy)_3](PF_6)_2$ (c) displaying the interlocking of adjacent cations in the various "π−π interactions"

of aromatic compounds[33,34] and their general importance in molecular recognition has been acknowledged.[35,36] Recent experimental[35,37−39] and theoretical[31,40−42] work has shown that both dispersion forces and electrostatic C−H···π interactions contribute towards the favourable "π−π interactions". The relative importance of these two contributions is a matter of debate,[38,39] especially for the T-shaped arrangement. The inherent polarity of aromatic systems stems from the electron-rich core being surrounded by an electron-poor torus of hydrogen atoms. This electrostatic contribution accounts for the energetic preference of both T-shaped and shifted π-stacked arrangements. Which one is preferred depends on the relative magnitude of the dispersion and C−H···π interactions and therefore on the planar extension of the aromatic system. Even for the simplest system, i.e. the benzene dimer in the gas phase, there is an ongoing dispute as to which local minimum on the potential energy hypersurface represents the more stable configuration.[41,43−47] In the solid state, the two local minima manifest themselves in herringbone and/or π-stacked crystal packing motifs.[33,34,48] These favourable "π−π interactions" may facilitate direct cation−cation contacts. However, with $[M(L-L)_3]^{n+}$, the situation is somewhat more complicated than that with simple aromatic systems since the fixing of three aromatic systems in a rigid mutual orientation imposes certain spatial requirements that also depend on the chirality of these complexes. Racemic pairs with colinear C_3 axes, as in β-$[Ru(bpy)_3](PF_6)_2$, lead to a T-shaped configuration (Figure 5a), for the analogous active pair as observed in $[Ni(bpdz)_3](ClO_4)_2$ [49] a shifted π-stack involving half of a ligand results (Figure 5b), while active pairs with tilted C_3 axes as in the γ-modification yield a shifted π-stack implying a complete ligand.

Despite the spatial restraints imposed by the coordination, "π−π interactions" are frequently observed in crystal structures of neutral {$[Ru(bpy)_3]$[50]} and, more surprisingly, charged propeller-shaped molecules of the type investigated here {$[Ru(bpym)_3](PF_6)_2 \cdot CH_3CN$,[15] $[Ru(phen)_3](PF_6)_2$ [13]}.

The "coordination" of the cations by anions is quite similar in both the γ- and β-type structures. Each cation is surrounded by six PF_6^- anions in a trigonal antiprism and the MP distances are all of comparable magnitude (Table 1). This suggests that the monopole−monopole interaction between cations and anions should be very similar in both structural types (see also ref.[25]).

Grepioni et al.[23] have shown that for hexafluorophosphate organometallic salts C−H···F interactions play a significant role among the various intermolecular interactions when assisted by the charge difference between anions and cations. In both structure types, we find bonds shorter than the van der Waals cut-off distances (Table 2), these being indicative of specific and directional interactions. However,

it is impossible to even qualitatively assess their relative energetic significance.

The racemic low-temperature polymorph (α-type) represents just a slight distortion of the packing in the β-type[16,51] and will not be discussed further here.

Comparison of Molecular Structures

The three bpy ligands form a propeller-like trigonal arrangement around the metal atoms. The coordination by the nitrogen atoms is trigonally distorted octahedral owing to the fact that the ligand bite (Figure 6, Table 3) is too short to fit a perfect octahedron. The stereochemistry is completely defined by the normalized bite of the bidentate ligand, b = N···N/M−N, and the angle of twist Θ between the upper and lower triangular faces formed by the N atoms of the bpy ligands (Table 4). The regular octahedron corresponds to Θ = 30° and $b = 2^{1/2}$. Calculations have shown that distortions from D_3 symmetry are increasingly possible as b is decreased.[52] The distortions in the γ-phase are indeed quite substantial, as manifested in variations of more than 3° in the N−M−N angles at the base of the trigonal antiprisms (ν, Figure 6). Moreover, the trigonal faces are no longer parallel and the central atoms are displaced from the midpoint between them (Table 4). Apparently, the coordination sphere is rather flexible and can be adjusted within certain limits to suit packing requirements.

Not even the ligands can be treated as rigid units. Admittedly, the bond lengths and bond angles within the pyridine moieties are consistent within experimental error in the different phases and compounds; the rings are planar, and the maximum deviations from the best planes are smaller than 0.03 Å (Δ_{max} in Table 3). However, the two pyridine rings within a ligand are deflected downwards around the midpoint of the py−py bond. This kink can be quantified by the difference between A and B (Table 3), which decreases on going from $[Ru(bpy)_3](PF_6)_2$ to $[Zn(bpy)_3](PF_6)_2$ while the ligand bite and M−N distance increase accordingly. This trend reflects the size of the central cation. The extent of the kink together with the trigonal twist determines the height of the complex cation along the C_3 axis. The smaller the kink and the trigonal twist, the "taller" the complex

[a] For labelling scheme, see Figure 6. − [b] Normalized ligand bite. − [c] Averaged in D_3 symmetry. − [d] Trigonal twist. − [e] Distances between the central atom and the centre of gravity of the trigonal faces formed by the N atoms of the bpy ligands. − [f] Edge length of the base of the trigonal antiprism.

cation. Thus, $[Ru(bpy)_3](PF_6)_2$ is shorter than $[Zn(bpy)_3](PF_6)_2$, as indicated by the height of the trigonal antiprisms formed by the N atoms of the bpy ligands (2.100 Å and 2.265 Å, respectively).

The widths of the molecular cations, i.e. their extensions perpendicular to the C_3 axis, are largely determined by the M−N distance since the ligands are pushed further away as the bond lengths increase. The mean lengths of the edges of the bases of the trigonal faces (S, Table 4) increase from 3.046 Å to 3.191 Å on going from $[Ru(bpy)_3](PF_6)_2$ to $[Zn(bpy)_3](PF_6)_2$. This suggests that the height/width ratio changes slightly in the series, with $[Zn(bpy)_3](PF_6)_2$ being relatively larger around the "waist".

Another intramolecular low-energy mode that the cation takes advantage of to adjust to the local packing environment is the torsion about the py−py bond. Lowering the temperature from 294 K to 200 K, thereby shortening the intermolecular distances, results in an increase in the dihedral angle between the two pyridine rings in the ligand from 7.90(19)° to 8.81(13)° for β-$[Ru(bpy)_3](PF_6)_2$ (Table 3) and still further to 9.0(4)−10.3(3)° for α-$[Ru(bpy)_3](PF_6)_2$.[16] The variation in the γ-phase [6.7(2)−12.7(2)°] is even more notable.

Conclusion

In the realm of organic and organometallic compounds, polymorphism has often been associated with torsional degrees of freedom of molecular fragments bound by single bonds, thus making it conformational in nature. Although the system under consideration here utilizes its very limited intramolecular degrees of freedom to optimize packing, the molecular shape of the building blocks is to a first approximation the same. A similar example of a rather rigid coordination compound crystallizing in different polymorphs has been recently found in the case of $[Pd(dmpz)_2(Hdmpz)_2]_2$ (Hdmpz = 3,5-dimethylpyrazole).[53]

The simple fact that there are coexisting polymorphs in the case of $[Ni(bpy)_3](PF_6)_2$ emphasizes the importance of kinetic aspects, but it is nevertheless expected that the non-occurrence of γ-$[Fe(bpy)_3](PF_6)_2$, γ-$[Ru(bpy)_3](PF_6)_2$, or β-$[Zn(bpy)_3](PF_6)_2$ on crystallization from the respective racemic solutions can be attributed to thermodynamic factors. At least it is hard to imagine that nucleation kinetics could be so different for these similar systems. On the one hand, careful analysis of the crystal and molecular structures has established a trend with respect to molecular size and shape (Table 4) on going from $[Ru(bpy)_3](PF_6)_2$ to $[Zn(bpy)_3](PF_6)_2$. On the other hand, distinct intermolecular interactions with different directionalities (T-shaped as opposed to shifted π-stack π−π interactions) have been identified in the two structure types. However, this gives no indication of their relative strengths, and no rationalization can be given as to why the relative order of the two local minima on the energy hypersurface becomes inverted. This requires an analysis of the packing energies, which will be dealt with in a separate paper.[25] Given the molecular structure, little can be said a priori on the likelihood of spontaneous resolution of racemic solutions upon crystallization, even though one might speculate that increasing the size of

the molecular cation should destabilize the β-type relative to the γ-type structure. However, size alone cannot give a satisfactory explanation since $[Ru(bpy)_3](PF_6)_2$ and $[Ni(bpy)_3](PF_6)_2$ are very similar in that respect and yet still display different crystallization behaviour. Evidently, other information at the molecular level, as for instance the molecular electrostatic potential, is also important.

Certainly, the presented case gives a striking example of the sensitivity of crystal packings to even tiny variations in molecular structure. Moreover, the shape of molecular building blocks alone surely does not determine the crystal structure, but rather it is the subtle balance between all the various intermolecular forces. This equilibrium balance of forces embraces many intermolecular interactions; "π−π interactions" are apparent in crystal structures of $[M(bpy)_3](PF_6)_2$ compounds. However, T-shaped and shifted π-stack arrangements compete. Unquestionably, postulation of dominance by a T-shaped arrangement, as in a report by Dance,[27] is not justified. Moreover, solely on the basis of topology, nothing can be said about the relative contributions of dispersion/repulsion forces and electrostatic C−H···π interactions to these "π−π interactions".

Experimental Section

Synthesis: All $[M(bpy)_3](PF_6)_2$ salts were obtained by metathesis of the corresponding chloride, sulfate, or bromide salts, in turn prepared according to literature procedures.[54,55] − Optical resolution of $[Ru(bpy)_3]^{2+}$, which did not occur spontaneously, was achieved by a modification of the procedure of Dwyer and Gyarfas using potassium antimonyl tartrate.[56] − Concomitant crystallization of β- and γ-$[Ni(bpy)_3](PF_6)_2$ could be achieved by slow evaporation of the solvents from an acetone/water (2:1) solution at ambient temperature. β-$[Ru(bpy)_3](PF_6)_2$ could be crystallized from the same solvent mixture, but from ethanol/water (2:1) more suitable single crystals were obtained. The best crystals of γ-$[Ru(bpy)_3](PF_6)_2$ and γ-$[Zn(bpy)_3](PF_6)_2$ were obtained by recrystallization from acetone/ethanol (5:1).

Crystal Structure Analyses: Relevant crystallographic data and details of the data collection and structure refinement are listed in Table 5. Structure solution and refinement of the β-type structures was straightforward.

All compounds crystallizing in the γ-phase are affected by systematic twinning due to merohedry. This is indicated by a gritty appearance of the crystal faces. The twin antisymmetry space group is $P3_22'1$ (or $P3_12'1$).[57] Structure solution in this space group proved impossible. In $P3_1$ (and its enantiomorphic space group $P3_2$), direct methods yielded a partial structure model, which could be completed by successive difference Fourier syntheses. However, anisotropic refinement was not feasible until the correct twinning law ([110]) was introduced. The absolute structure was assigned on the basis of the Flack *x* parameter,[58] where *x* is the fractional contribution of the inverted component of a "racemic twin". It is expected to be zero for the correct structure, unity for the inverted structure, and somewhere in between if racemic twinning is present. For the chemically resolved γ-$[Ru(bpy)_3](PF_6)_2$, the assignment is in agreement with the observed specific rotation. Surprisingly, while for γ-$[Zn(bpy)_3](PF_6)_2$ each singular crystal seems to be homochiral, for γ-$[Ni(bpy)_3](PF_6)_2$ general and racemic twinning has to be refined simultaneously.

All structures were refined in a consistent manner employing the SHELX-97 program package.[59] SHELX refines against F^2 and all data were used in the full-matrix least-squares refinement. H atoms were placed in idealized positions and were refined with fixed isotropic displacement parameters of $1.2U_{eq}$ (parent C). All other atoms were refined anisotropically. The weighting scheme recommended by the program was used and refinement was continued until complete convergence (maximum shift/esd < 0.001) was achieved. Graphics and geometrical parameters were generated using the PLATON package.[60]

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-101675 {β_{200}-[Ru(bpy)$_3$](PF$_6$)$_2$}, -101676 {γ_{200}-[Ru(bpy)$_3$](PF$_6$)$_2$}, -101677 {β_{240}-[Ni(bpy)$_3$](PF$_6$)$_2$}, -101678 {γ_{200}(1)-[Ni(bpy)$_3$](PF$_6$)$_2$}, -101679 {γ_{200}(2)-[Ni(bpy)$_3$](PF$_6$)$_2$}, and -101680 {γ_{200}-[Zn(bpy)$_3$](PF$_6$)$_2$}. Copies of the data can be obtained free of charge on application to the CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Since submission of the manuscript we have been informed that the structure of γ-[Zn(bpy)$_3$](PF$_6$)$_2$ has meanwhile also been solved by Bernal's group; the manuscript will soon be submitted to *J. Chem. Soc., Dalton Trans.*[62]

Acknowledgments

We would like to thank Prof. Dr. K.-J. Range for making equipment available and for support in various areas, the Fonds der Chemischen Industrie, and the DFG for financial support. Furthermore, we thank the Degussa AG for a donation of $RuCl_3 \cdot 3H_2O$.

Chiral Recognition Among Trisdiimine−Metal Complexes, 7[‡]

Racemic Compound Formation *versus* Conglomerate Formation with $[M(bpy)_3](PF_6)_2$ (M = Ni, Zn, Ru); Lattice Energy Minimisations and Implications for Structure Prediction

Josef Breu,*[a] Holger Domel,[a] and Per-Ola Norrby[b]

Keywords: Molecular recognition / Chiral recognition / Conglomerate crystallisation / Crystal structure prediction / Polymorphism

Polymorphism observed with $[M(bpy)_3](PF_6)_2$ (M = Ru, Ni, Zn) offers a unique opportunity to study the impact of different intermolecular packing motifs on lattice energies. Additionally, it allows us to test the accuracy of empirical intermolecular potentials, because these compounds represent an example of a system where a small change in molecular geometry already induces a qualitatively different crystal packing. Lattice energy minimisations for these three compounds applying both, rigid body and flexible body approaches, are reported. The calculations quite reasonably reproduce the crystallisation behaviour observed in this heteropolymorphic series. We conclude that the state-of-the-art approach and all four tested empirical intermolecular potentials are adequate for these organometallic compounds. However, it is crucial to input the most accurate molecular structures. Molecular structures determined by X-ray analysis need to be corrected for the apparent bond shrinkage due to librational motion. When these molecular structures are to be obtained by Molecular Mechanics or Quantum Mechanics methods the highest possible accuracy is required. Our results suggest that routine polymorph prediction may be more severely hampered by inaccuracies in molecular structures than by inadequacies in the intermolecular potentials. The key to a successful structure prediction is therefore the input of reliable molecular structures.

Introduction

The last few years have seen an increasing interest in the prediction of crystal structures for various reasons. The two main motives are, on the one hand, structure solution in real space (solving the phase problem), where interpretation of the powder diffraction intensities in reciprocal space has proved impossible;[2−5] on the other hand, exploration of the lattice energy hypersurface is driven by the need for so-far-unknown polymorphs with desired properties (shelf life, solubility, bioavailability, morphology, etc.),[6−13] or even perhaps for patenting and registration purposes.

The vast majority of search engines employ lattice energies based on some empirical intermolecular atom−atom pair potentials as the cost function,[14,15] and the systems most frequently investigated are neutral organic molecules. The basic experience is that, often, many theoretical polymorphs are identified within a lattice energy range of 10 kJ/mol[16] and that the experimentally observed structure — where known — is indeed close to the global minimum. This suggests that phase space is thoroughly covered by the different search engines, but even the most elaborate and presumably accurate potentials often fail to give the experimental crystal structure always with the lowest lattice energy as would be expected for thermodynamic product control. Observation of polymorphism at the same *p,T* conditions or even in the same crystal crop indicates that, for some substances, there may indeed be a range of energetically accessible structures, and that the kinetics and thermodynamics of nucleation — about which little is known — are responsible for selecting those which will be found experimentally. However, contrary to the experience in theoretical predictions, in the experimental world polymorphism seems to be much less pervasive.[17] No one has, for instance, ever seen acetylsalicylic acid polymorphs[18] despite the large quantities of aspirin tablets manufactured.

Polymorphs may be considered as conformers of the supramolecule which is the crystal structure itself.[19] Crystal polymorphism for any one compound is therefore already a valuable and informative phenomenon with regard to supramolecular chemistry and crystal engineering. Polymorphs are the result of the same cohesive forces and therefore they should provide better information on intermolecular forces. Moreover, since it is not expected that nucleation-induced metastability is very pronounced when growing

crystals at room temperature, polymorphism may also help to assess the quality of different empirical intermolecular potentials used in structure prediction. In that respect, it is very useful if polymorphism can be tailored and/or the crystallisation of unstable polymorphs can be enforced on the system, for example, by taking advantage of chirality or tailor-made additives. In such a way, a wider lattice-energy range should be accessible experimentally. Furthermore, it is helpful if the molecule has few internal degrees of freedom that would require a balanced and accurate treatment of intra- and intermolecular parts of a force field.

The preceding paper[1] describes such a system. With $[M(bpy)_3](PF_6)_2$ (M = Ni, Zn, Ru) three different polymorphs are observed. α-$[M(bpy)_3](PF_6)_2$ is just a slight distortion of β-$[M(bpy)_3](PF_6)_2$ and the phase transition is induced upon cooling, but the packing in the γ-polymorph is drastically different: while the α- and β-form are true racemates the γ-structure is an enantiomorph.

We have performed lattice-energy minimisations of the three compounds in the different structure types, both within the rigid body and the flexible body framework. The results are analysed with regard to the self-organisation of such propeller-shaped molecules. Additionally, more general conclusions regarding the mentioned problems in structure prediction are discussed on the basis of calculated lattice energies.

Results and Discussion

When studying the relative importance of different intermolecular contributions during the self-assembly of crystals, organometallic compounds display significant advantages over organic compounds since structural molecular parameters may be tuned to a much finer degree. With $[M(bpy)_3](PF_6)_2$ the size of the complex cations and the molecular electrostatic potential (MEP) may be delicately varied by substitution of the central atom. Moreover, this variation leads to different polymorphs, and it is possible to switch between the polymorphs by choosing the right metal. With M = Fe,[20] M = Ru,[21,22] or M = Os[23,24] the racemic solutions crystallize as true racemates in the β-type. This β-type undergoes a phase transition to the closely related low temperature α-polymorph.[25,26] For M = Zn this racemic structure is not accessible experimentally. Instead, the enantiomorphous γ-type is the only modification observed. For M = Ni, crystals of both structure types are obtained concomitantly in the very same crystallization batch. Finally, since $[Ru(bpy)_3]^{2+}$ is inert towards racemisation the γ-type can be "forced" upon $[Ru(bpy)_3](PF_6)_2$ by chemical resolution prior to crystallization.

According to thermodynamics, polymorphic modifications can be at equilibrium only at the phase-transition temperature where the ΔG curves cross. The likelihood of choosing exactly this temperature for crystallization is rather slim.[27] Moreover, Gavezzotti & Filippini[17] have shown in their systematic study of crystal polymorphism that entropy differences between polymorphs of differing packing topology are never large enough to have $300\Delta S$ exceed ΔH (Note that ΔH is also dependant on temperature). They conclude that relative stability among polymorphs at room temperature can be judged on the basis of packing energy (enthalpy) alone. Consequently, it is obvious that kinetics must have a certain impact when concomitant crystallization of two polymorphs is observed at the same temperature, in the same solvent, and at the same supersaturation level. For this to happen the nucleation rates of both modifications must be similar. However, concomitantly crystallizing polymorphic modifications as observed with $[Ni(bpy)_3](PF_6)_2$ must nevertheless have energetically equivalent structures.[27] Generally, it is thought that even polymorphs obtainable at varying crystallization conditions (solvent, temperature, supersaturation) have lattice energies within 4−12 kJ/mol.[18] It is expected that for concomitantly crystallizing polymorphs this range is even smaller. Therefore, already $[Ni(bpy)_3](PF_6)_2$ provides an excellent and very demanding benchmark for the validation of interatomic potentials as they must reproduce the near equivalency of the crystal energetics. The crystallization behaviour of the heteropolymorphic series of $[M(bpy)_3](PF_6)_2$ structures as a whole is even better suited to test the accuracy of empirical intermolecular atom−atom pair potentials: It is anticipated that the calculated lattice energies for β-$[Ni(bpy)_3](PF_6)_2$ and for γ-$[Ni(bpy)_3](PF_6)_2$ are very similar, irrespective of the unknown absolute value. For $[Ru(bpy)_3](PF_6)_2$ the racemic β-type, and for $[Zn(bpy)_3](PF_6)_2$ the enantiomorphic γ-type, should be preferred energetically.

Rigid-Body Minimisations

Lattice-energy minimisations for these three compounds applying the rigid body code MPA[9] (Molecular Packing Analysis) in combination with four popular sets of intermolecular potentials, CFF91,[28] Williams,[29] UNI,[30] and MM3,[31] yield very satisfying results (Tables 1−4).

In a first approximation, the quality of a set of intermolecular atom−atom pair potentials for crystal structure calculations can be judged by relaxing the experimental structures in the force field. When the experimental structure does not change much upon minimising, the intermolecular potentials are considered adequate. For a high quality set of potentials small shifts of 1−2% in the cell edges are reasonable, since this is the typical range of thermal expansion. Judging by this criterion, all experimentally observed crystal structures (EXPTL crystal model) of both structure types are satisfactorily reproduced by any of the four sets of intermolecular potentials. The maximum relative error in cell lengths is 2.2% (Table 1−4). Because our calculations neglect thermal vibrations, a shrinkage of cell lengths would have been expected. Actually, we observe quite a few cell expansions upon relaxation. This is due to the fact that, with the exception of β_{294}-$[Ru(bpy)_3](PF_6)_2$, all crystal structures were determined at low temperatures. Nevertheless, with "true 0 K" empirical intermolecular potentials, a shrinkage due to the effect of thermal expansion would still be expected, since the experimental temperatures are always

well above 0 K. However, although temperature is not explicitly considered, some thermal effects have been subsumed into the interatomic potentials during their fitting to experimental observables which were mostly determined at room temperature. As discussed in more detail by Gale,[32] modern-day potentials correspond to an effective temperature which is a weighted average of the temperatures at which the different pieces of data were measured. The simulations therefore should rather be called athermal, and this might explain the observed cell expansions upon relaxation.

The lattice energies calculated for the three compounds $[M(bpy)_3](PF_6)_2$ (M = Ru, Ni, Zn) in the two basic structure types (β and γ) cover only a small energy range despite the drastically differing packing topology. This result, in combination with the uncertainty in the model potential would render it impossible to estimate the relative stability of the two polymorphs of any singular compound and the reliability of such a conclusion without further evidence. However, we can take advantage of the additional observation that only the Ni compound crystallizes concomitantly in both structure types. Therefore, for $[Ni(bpy)_3](PF_6)_2$ both structure types are expected to be energetically equivalent, while for $[Zn(bpy)_3](PF_6)_2$ the γ-type, and for $[Ru(bpy)_3](PF_6)_2$ the β-type, should be energetically favoured. It is a very fortunate coincidence that, within this series of complexes, it is possible to switch between the two topologically different polymorphs by simply substituting the central metal atom. If this experimentally observed crystallization behaviour within this unique heteropolymorphic series of $[M(bpy)_3](PF_6)_2$ (M = Ru, Ni, Zn) compounds is reflected in the predicted relative stability of the two polymorphs, even small lattice-energy differences may be regarded as significant. Furthermore, since the transition between the α- and the β-structure for $[Ru(bpy)_3](PF_6)_2$ is driven by cooling and therefore by entropy, a "0 K" static lattice energy minimisation should predict the α-structure to be more stable.

Judging by this energy criterion all four sets of empirical intermolecular potentials perform well again. The maximum energy difference between the γ- and the β-structure for the Ni compound is observed with the Williams potentials (5.1 kJ/mol, Table 1−4, EXPTL crystal model). Also, all four potential sets predict the relative stability of the two polymorphs for the Ru and the Zn compound correctly. However, for the Williams, the UNI, and the MM3 potential sets, the β- and γ-structures for $[Ru(bpy)_3](PF_6)_2$ are getting almost as close in energy as for $[Ni(bpy)_3](PF_6)_2$. None of the intermolecular potential sets predicts α-$[Ru(bpy)_3](PF_6)_2$ to be lower in energy than β-$[Ru(bpy)_3](PF_6)_2$.

Although all four intermolecular force fields have been calibrated by using some experimentally determined sublimation enthalpies, the absolute values for the calculated lattice energies differ considerably (up to 15%).

It is difficult to quantify precisely the uncertainties associated with this rigid body approach. The lattice energies as defined by the intermolecular interactions are rather sensitive to the particular rigid molecular structures (see also next two sections) that are put into the starting configuration. These molecular structures may vary due to experimental errors and, more importantly, due to tiny conformational changes induced by the interplay of intramolecular and intermolecular forces, which in turn is dependant on temperature. To explore the effect of such methodical uncertainties in the molecular structures on the results of the lattice energy minimisations, the lattice energy for γ-$[Ni(bpy)_3](PF_6)_2$ was calculated for two starting structures which were determined at the same temperature (200 K) using two data sets sampled on different crystals [$\gamma_{200}(1)$ and $\gamma_{200}(2)$[1]]. The lattice energies for these two starting structures determined at the same temperature differ by less than 0.5 kJ/mol. To investigate minor modifications in the molecular shapes induced by temperature-dependant packing requirements the lattice energy for the racemic $[Ru(bpy)_3](PF_6)_2$ structures was not only calculated for the α-type (105 K, α_{105})[25] and the β-structure determined by Rillema at 294 K (β_{294}),[22] but also for a structure determined at an intermediate temperature (200 K, β_{200}),[1] that is still well above the onset of the phase transition to the low-temperature modification. The variation of the calculated lattice energies increases by up to 2 kJ/mol. Since the lattice energies are compared for structures determined at different temperatures, this may be regarded as the error in the intermolecular lattice energy inherent in this rigid body approximation.

Influence of Systematic Errors in Molecular Structures

Next, the effect of a systematic error on lattice energies calculated within the rigid body approach shall be taken into account which is contained in input molecular structures determined by X-ray structure analysis. Cruishank noted as early as 1956 that rotational oscillations of rigid molecules or moieties in crystals cause the apparent atomic positions to be slightly displaced from the true position towards the rotation axis.[33] X-ray analysis locates the centroids of atomic distributions that are undergoing vibrations. Distances calculated from these mean positions are shorter and cannot be interpreted directly as interatomic distances.

Approximately spherical molecules like $[PF_6]^-$ are especially prone to be affected by this systematic error. When comparing Ru−N distances as determined by different structure determinations of $[Ru(bpy)_3](PF_6)_2$ with the corresponding P−F bond lengths (Table 5) it is striking that the variation in bond length is up to an order of magnitude larger in the complex anion than in the cation.

From the principal axis directions and mean-square libration amplitudes (eigenvectors and eigenvalues of $\boldsymbol{L}$) calculated from the anisotropic displacement parameters reported for $LiPF_6$ [34] a true experimental bond length of 1.61 Å can be estimated for the P−F bond in $[PF_6]^-$. From a comparison with the uncorrected values a considerable shrinkage effect due to librational motion is evident. The apparent shortening of the P−F bond as observed in structure determinations of $[Ru(bpy)_3](PF_6)_2$ can be up to 0.08 Å. Thus the molecular dimension of the hexafluorophosphate anion obtained by X-ray crystal structure analysis is considerably in error unless corrected for the effect of mo-

Independ. site			A	B	C	
Ru−N [Å]	2.056	2.048	2.052 2.053	2.053 2.053	2.053 2.053	2.049 – 2.069
P−F [Å]	1.549 1.568	1.570 1.593		1.583 – 1.618		1.527 – 1.614

[a] Ref.[21,22] – [b] Ref.[1]. – [c] Ref.[25]

lecular libration. Since the complex cations are effected to a much lesser extent by molecular libration, no corrections were applied to their molecular shape. When expanding the P−F vector in the starting structures to a reasonable value of 1.61 Å (CORR crystal model) considerable shifts in the calculated lattice energies are observed (Table 1−4). The maximum shift as compared to the EXPTL crystal model is observed for γ-$[Ru(bpy)_3](PF_6)_2$ in connection with the CFF91 potentials and amounts to 11.9 kJ/mol. When recalling that 10 kJ/mol is an energy range within which, usually, many theoretical polymorphs are predicted, it becomes obvious that correction of the observed molecular structure does indeed matter and should not be neglected.

Also, calculated lattice energies are in much better agreement with the observed crystallization behaviour for the CORR crystal model than for the EXPTL crystal model. The energy differences between β-$[Ni(bpy)_3](PF_6)_2$ and $\gamma_{200}(1)$-$[Ni(bpy)_3](PF_6)_2$ become 5.4 kJ/mol, 3.1 kJ/mol, 0.3 kJ/mol and 1.6 kJ/mol for the CFF91, Williams, UNI, and MM3 potentials, respectively. All four sets of empirical intermolecular potentials predict the γ-type to be significantly lower in energy than the β-type for $[Zn(bpy)_3](PF_6)_2$. β-$[Ru(bpy)_3](PF_6)_2$ is not only predicted to be more stable than γ-$[Ru(bpy)_3](PF_6)_2$, the energy gap between the two structure types also increases after applying the correction. Moreover, the CFF91, Williams, and UNI potentials even predict α-$[Ru(bpy)_3](PF_6)_2$ to be slightly more stable (100−400 J) than β_{200}-$[Ru(bpy)_3](PF_6)_2$.

Although the dispersion/repulsion parameters used with the four tested intermolecular force fields have not been optimised for this class of organometallic compounds, the potentials yield an excellent agreement with experiment. The atom centred monopoles give an accurate enough description of the electrostatic potential, and even anisotropic electrostatic interactions, such as the important π−π interactions, are satisfactorily represented. Quadrupole−quadrupole interactions from the π electrons are not explicitly included into the electrostatic model, but they get subsumed into the monopole−monopole interactions. Also, the assumed isotropic atom−atom form for the repulsion appears to be adequate to describe the stacking of aromatic rings as observed in the γ-structure[1] even though the charge density in these regions is known not to be spherical.[35]

This satisfying result encourages further interpretation with respect to crystal engineering. Recognition of special interactions and recurring intermolecular motifs in molecular crystals offers the opportunity of classification, but quantifying the interaction strengths provides a deeper understanding than sheer geometry — there is no such thing as a pure and simple structure-defining interaction. With respect to the intermolecular interaction patterns the β- and γ-structure differ most significantly in the particular C−H···π-interaction realised. In the β-modification T-shaped π−π interaction[36−38] contacts along the racemic columns with colinear C_3 axes are observed, while in the γ-type shifted π-stacks occur along the complex cation columns running along *c* (Figure 5a and 5c in ref.[1] respectively). Since these two mutual arrangements also allow for an effective penetration of adjacent molecules, it cannot even be decided from geometry alone whether these C−H···π-interactions have to be realised or just happen to be there because of the complementarity of molecular surfaces and thus packing efficiency. It is unclear whether the dispersion/repulsion- or the electrostatic C−H···π-interactions are predominantly responsibly for these two intermolecular interaction patterns. As the implied energies are small, a sound proof of this cannot be given without quantitative calculations. The calculated lattice energies may therefore be used to examine the relative strength, energetics and structural influence of these two different intermolecular interactions.

A comparison of the relative size of the dispersion/repulsion ($\Delta E_{d/r}$) and the electrostatic ($\Delta E_{Coul.}$) contribution to the total lattice energy is revealing with respect to the relative significance of the C−H···π-interactions (Table 3, CORR crystal model). On one hand, the Coulomb energy would prefer the γ-structure for all three compounds. This is not provoked by the arrangement of the ions, which in fact is very similar in both structures and would actually give a larger Coulomb energy for the β-arrangement: putting charges of +2 and −1 at the corresponding positions of the Ru and the P atom gives Madelung energies of −1000.4 kJ/mol and −998.0 kJ/mol for the β_{200}- and γ-arrangement, respectively. Consequently, the electrostatic preference of the γ-type must be founded in local electrostatic contributions, i.e. C−H···π- or C−H···F-interactions. Unfortunately, these two cannot be further separated. The differing MEPs for the three cations contribute towards the observed differences in $\Delta E_{Coul.}$. On the other hand, the dispersion/repulsion contribution to the total lattice energy favours the β-type for all three compounds. The differing size of the complex cations is subsumed into this energy term via the repulsion. While $\Delta E_{Coul.}$ increases moderately when going from $[Ru(bpy)_3](PF_6)_2$ to $[Ni(bpy)_3](PF_6)_2$ and to $[Zn(bpy)_3](PF_6)_2$, $\Delta E_{d/r}$ drops sharply. With large cations (e.g. M = Zn) only the γ-type, and with small cations (e.g. M = Fe, Ru) only the β-type, is observed. By chance the differences happen to cancel with M = Ni and consequently both structures crystallize concomitantly. Although the

C−H···π- and C−H···F-contributions to the Coulomb energy cannot be separated, these results indicate that C−H···π-interactions have a larger relative weight in the concert of intermolecular interactions in the shifted π-stack geometry realised in the γ-structure than in the T−shaped (edge-to-face) arrangement in the β-structure. This result contradicts the importance assigned by Dance[39] to such concerted T-shaped arrangements with regard to the molecular recognition between $[M(bpy)_3]^{n+}$. This supramolecular motif was even given a distinct name, "sextuple aryl embrace". Instead, our lattice energy calculations are in line with the experimental evidence presented by Wilcox[40,41] that suggests that the electrostatic potential of the aromatic ring is *not* a dominant aspect of the edge-to-face aryl−aryl interaction, but that London dispersion forces should be the predominant driving force for this type of interaction.

However, it should be kept in mind that the experimental crystal structures cannot be explained by a single type of interaction but result from an interplay between all the different interactions, both weak and strong.

Flexible Body Minimisations

From a comparison of the lattice energies calculated for β_{200}-$[Ru(bpy)_3](PF_6)_2$ and β_{294}-$[Ru(bpy)_3](PF_6)_2$ it is already evident that even the very limited conformational flexibility inherent in $[M(bpy)_3]^{2+}$ does play some role and that the subtle interplay between the molecular structure and the crystal structure may be significant even for these rather rigid molecules. When molecules are conformationally flexible, the intramolecular energy difference between the two solid phases has to be included in the total energy, since the crystal structure molecular conformers are not necessarily the lowest energy conformers.[42,43] However, this requires an accurate balance between inter- and intramolecular potentials.

To get an idea of the significance of the intramolecular term, we have performed single-point density-functional calculations, although there are justified concerns about calculating the relative stability of conformers using ab initio methods on molecules with a fixed geometry.[42] Such single-point calculations are very sensitive to slight errors in the experimental bond lengths and angles. These errors may be of varying magnitude for different structure determinations and, consequently, this will bias the results in an unpredictable way. However, α-$[Ru(bpy)_3](PF_6)_2$ offers the rare opportunity of three crystallographically independent complex cation sites with slightly varying molecular shapes (see intramolecular parameters given in Table 6), which should be of comparable accuracy. These three sites differ most significantly in the torsional angles around the pyridine−pyridine bond (py−py). The ab initio energies for the three different crystallographic sites in the gas phase already differ by 5.3 kJ/mol which is of similar magnitude to the lattice-energy differences observed in the rigid body approach. This result suggests that one might have to worry about intramolecular contributions even though $[M(bpy)_3]^{2+}$ cations display only very limited conformational flexibility.

Unfortunately, reliable molecular mechanics parameters for Ru^{II}−polypyridyl coordination compounds have up to now only been developed within the context of the MM3* force field in MacroModel.[44] However, this package does not allow lattice-energy calculations with accelerated convergence techniques. Therefore, we derived molecular mechanics parameters within the context of the CFF91 force

field, which subsequently permits lattice energy minimisations employing Cerius−OFF.[45] This program uses Ewald summation methods for evaluation of the electrostatic- and the dispersion term yielding lattice energies of the same precision as obtained by MPA in the rigid body approach.

In order to accurately reproduce structures and energies by a molecular mechanics force field, information about the exact shape of the intramolecular potential energy surface (PSE) has to be used in the fitting of the force field.[46] Mass weighted Hessian elements calculated by Quantum Mechanics (QM) supply a wealth of information about the PSE and can be included very efficiently in parametrizations. However, it is important to realise that systematic errors in the QM method will be reproduced by the force field. This may be counteracted by simultaneous use[44,46−49] of structural information contained in experimentally determined molecular structures. Here, it should be kept in mind that these structures might be influenced by crystal packing[50] and by systematic errors caused by thermal motion, as discussed earlier. The relative weighting factors for QM and experimental "observables" employed in the fitting of the Ru force field parameters (Table S8) and the optimised parameters (Tables S9−S12) are given in the supporting information.

Unfortunately, there are not enough reliable experimental parameters available in the literature that could be used in the parametrization of the anion (see discussion in the previous section). Furthermore, density functional methods applied to $[PF_6]^-$ in the gas phase give equilibrium bond lengths that are longer (1.648 Å) than the values observed in crystal structures. Therefore, the equilibrium bond length has to be shifted after fitting (r_0 = 1.61 Å). The optimised force-field parameters for $[PF_6]^-$ are also listed in the supporting information (Table S13).

The ab initio energies calculated for the three independent sites in α-$[Ru(bpy)_3](PF_6)_2$ may be used as a first benchmark that might confirm the accuracy of the derived force field. DMol[53] and CFF91 energies are indeed consistent (Table 6), suggesting that, to a first approximation, the intramolecular potential energy landscape is adequately described by the force field. Structural overlays of molecular structures as observed in the two crystal structures and as minimised in the context of the force field show only minor deviations (Figure 2) and indicate that intra- and intermolecular interactions are quite satisfactorily balanced.

Nevertheless, the flexible-body model fails to produce the correct order in lattice energies for β_{200}-$[Ru(bpy)_3](PF_6)_2$ and γ-$[Ru(bpy)_3](PF_6)_2$. The energy difference between the γ- and the β-type drops from 16.8 kJ/mol to −8.5 kJ/mol when going from the rigid body to the flexible body model (Table 1, CORR crystal model and Table 7). At first glance the optimised unit-cell dimensions are still in satisfying agreement with those determined by experiment. Also, the experimental intramolecular parameters listed in Table 8 are well reproduced. There is only one py−py torsion in the γ-modification that stands out by differing by 8.1° from the experimental value. The valence terms of the energies are

actually very similar in both polymorphs (36.1 kJ/mol and 36.3 kJ/mol for β- and γ-type, respectively).

The decisive change when going from the rigid- to the flexible-body model happens in the intermolecular energy [note that the nonbonding energies calculated in the molecular mechanics approach (Table 7) contain intramolecular contributions!]. While the intermolecular lattice energy as calculated with MPA for the flexible body minimised β_{200}-$[Ru(bpy)_3](PF_6)_2$ structure is very similar to the one observed in the rigid body approach (−1280.4 kJ/mol versus −1283.1 kJ/mol), it changes considerably for flexible body minimised γ-$[Ru(bpy)_3](PF_6)_2$ (−1290.8 kJ/mol versus −1266.3 kJ/mol). When taking a closer look at both the intra- and the intermolecular parameter differences (Table 8 and 9), an interesting correlation becomes evident. In comparison to the experimentally observed molecular structure in the γ-type, the relaxed cation is somewhat higher along the pseudo−C_3 axis as indicated by the M−t1 and M−t2 distances (1.102 Å and 1.103 Å) and slightly thinner perpendicular to it (S = 3.012 Å). In other words, the cation is stretched out along the pseudo-C_3 axis. Since the pseudo-

C_3 axes of the complex cations in the γ-type lie approximately in the *ab* plane, the *a* and *b* axes expand upon minimisation in the context of the flexible body force field, while the *c* axis shrinks relative to the experimental values. In the rigid-body minimisation it is the other way around. As a consequence the cation−cation distance along the columns is too short by 0.2 Å (Table 9). The prominent change in one of the py−py torsions is probably the outgrowth of an intramolecular adjustment to this alteration in intermolecular geometry. Even though other small distortions occur to the molecular shape upon minimisation, it appears that changing this critical molecular parameter of relative height by a tiny amount of a few hundredths of an angström already induces a different ranking of the two polymorphs. As a consequence, one has to realize that a successful crystal structure prediction requires an accuracy in the determination of the underlying molecular shape that certainly overtaxes the best force fields and even QM methods currently available. Apparently, some force constants for intramolecular distortions are predicted to be too weak in the DFT calculations. Consequently, errors are introduced in the MM force field, since the force field cannot give better results than the data that went into its derivation. It should be noted that, due to its corrugated shape, $[Ru(bpy)_3]^{2+}$ displays quite a few intramolecular inter-ligand contacts which are less than the van der Waals separation. Therefore, the electron-density distribution in these rather remote inter-ligand regions needs to be represented accurately in order to get a realistic picture of nonbonding intramolecular contributions to the PES, which in turn greatly influence the relative positions of the ligands. It is a well-known fact that present day DFT is struggling with the long-range behaviour of the electron density.[54,55]

Conclusions

Polymorphism may be of considerable benefit to crystal engineering. Polymorphic systems provide unique opportunities to study the competition between different intermolecular interaction patterns and correlations between changes in molecular structure and crystal packing. This is especially true if concomitant crystallization is observed.

Our calculations reproduce quite reasonably the crystallization behaviour observed in this heteropolymorphic system of $[M(bpy)_3](PF_6)_2$ (M = Ru, Ni, Zn). We conclude that the state-of-the-art approach and all four tested sets of empirical intermolecular atom−atom pair potentials are adequate for this class of organometallic compounds. When starting with the most accurate crystal structures, determined at low temperature and corrected for apparent bond shrinkage due to librational motion, significantly lower lattice energies are calculated for the experimentally observed packing topologies. Where two polymorphs crystallize concomitantly, similar lattice energies result for both structures. However, since the rigid body approach requires molecular geometries from crystal structure determinations it involves no predictive power.

A comparison of the relative size of the dispersion/repulsion ($\Delta E_{d/r}$) and the electrostatic ($\Delta E_{Coul.}$) contribution to the total lattice energy suggests that the electrostatic potential of the aromatic ring is *not* a dominant aspect of the edge-to-face aryl−aryl interaction. Certainly, concerted T-

shaped arrangements are not the electrostatically favoured molecular recognition motif between $[M(bpy)_3]^{n+}$.

The essence of the crystal structure prediction difficulties is the close proximity of several possible crystal structures for the same compound. The investigated compounds represent a good example of a system where a small change in molecular geometry already induces a qualitatively different crystal packing. Changing the M−N bond length by a few hundredths of an angström is therefore relevant. Even modest changes in molecular size or shape, which only induce slightly different intermolecular distances, have a drastically amplified effect on the lattice energy in these molecular salts due to the long range interactions.

Implications to crystal structure and polymorph prediction strategies are considerable, since either known molecular structures determined by XRD or gas phase structures optimised at various levels of theory are employed as input to the packing and search algorithms used. These results suggest that routine polymorph prediction may be more severely hampered by inaccuracies in molecular structures than by inadequacies in the empirical intermolecular potentials. The key to a successful structure prediction is therefore input of the most accurate molecular structures.

In this respect it cannot be stressed too strongly that molecular dimensions obtained by X-ray crystal structure analysis in general may be considerably in error unless corrected for the effect of libration. In extreme cases, like for spherical molecular ions such as hexafluorophosphate, the bond length errors due to this effect may exceed 0.1 Å. Of course, errors of such magnitude in the molecular shape and/or size matter when trying to predict the relative stability of polymorphs.

Furthermore, X-ray structures used for deriving inter- and intramolecular force fields should be carefully checked. Low temperature determination may be given a higher weighting factor, while structures that suffer from any kind of disorder should be excluded. In the generation of molecular structures for polymorph prediction even high level ab initio calculations may not be accurate enough. Certainly, the extreme sensitivity of the lattice energy to the molecular shape in such molecular salts tests the limits of current day intramolecular force fields. Even with molecules of very limited conformational flexibility, a balanced description of intra- and intermolecular interactions proves to be a difficult task. The situation gets still more difficult with more flexible molecules where a precise balance between intra- and intermolecular interactions is required.

Aside from the problems inherent in the accuracy of input molecular structures and force fields, the purely thermodynamic approach ignores the fact that the kinetics of crystal nucleation may be actually responsible for selecting those polymorphs that will be found experimentally. This will require a deeper understanding of molecular recognition and self-organisation in the polymolecular subcritical nuclei present in supersaturated solutions[56,57] and the effect of solvent−solute interactions on nucleation.[58] It is reassuring that the presented results give confidence that modern day intermolecular potentials should be accurate enough to realistically model nucleation kinetics for these organometallic compounds.

Experimental Section

Computational Methods

Crystal Structure Models: Two types of crystal models were constructed for each polymorph of $[M(bpy)_3](PF_6)_2$ (M = Ru, Ni, Zn) using different molecular structures. The EXPTL crystal model used the experimental structures as reported in the literature and the preceding paper,[1,21,22,25] but corrected for well-recognised inadequacies of X-ray determination by positioning the hydrogen atoms at a bond length of 1.09 Å. Secondly, in the CORR crystal model the P−F bond length was also corrected for the apparent shortening caused by librational motion of the almost spherical anion. Applying the PLATON package[59] the principal axes and eigenvalues of the molecular libration tensor ***L*** and of the translation tensor ***T*** were estimated together with components of a tensor ***S*** that allows for the quadratic correlation between librational and translational motion[60] from the atomic displacement parameters (ADPs or U_{ij} tensor components). Since the polymorphs of $[M(bpy)_3](PF_6)_2$ are affected to a different extent by static and dynamic disorder, this TLS analysis was applied instead to $LiPF_6$ for which a very precise structure determination has been reported in the literature.[34]

The hypothetical starting structure for β-$[Zn(bpy)_3](PF_6)_2$, which is inaccessible experimentally, was obtained by averaging the molecular parameters of $[Zn(bpy)_3]^{2+}$ as observed in γ-$[Zn(bpy)_3](PF_6)_2$ in D_3-symmetry and importing this molecular structure into the structure of the Ru−analogue.

Electrostatic Model: The MEPs of the complex anions and cations were represented by point charges positioned at the nucleus of the atoms. As most widely used, point charges were fitted to the quantum mechanically calculated MEP[61] employing the program POL.[62] The net charge was constrained using a Lagrange multiplicator and least-squares fits were performed for points given on a rectangular grid (0.2 Å spacing) in a 0.7 Å thick layer outside the van der Waals surface. For the cation, the charge of the well-buried central atom was fixed to its Hirshfeld partition value.[63] Symmetry-equivalent atoms were averaged. The partial charges listed in the supporting information (Tables S1 and S2) reproduce the MEPs quite well, as indicated by the low relative root-mean-square values (< 3% for cations and 5.1% for $[PF_6]^-$) for the fits and should be well suited to represent the electrostatic interactions. The MEPs were calculated applying the density functional code DMol.[53] Molecular geometries for the single-point calculations were taken from X-ray structures with H atoms recalculated at idealised positions (C−H = 1.09 Å) and no symmetry restrictions were applied. We used DNP basis sets with inner cores frozen, a FINE integration grid, and the Vosko, Wilk, Nusair[64] parametrization of the correlation energy in the homogenous electron gas. The local spin-density approximation was used in SCF iterations and gradient corrections were added in a pertubative approach using the functionals proposed by Perdew and Wang[65] and Becke[66] for the correlation and exchange, respectively. The same approach was used for the single point energy calculations given in Table 6.

Rigid Body Minimisations: Within the rigid-body approach, molecules were considered to be rigid. The lattice energy was expressed as being purely intermolecular, and was calculated as the sum of intermolecular coulombic, dispersion and repulsion interactions between individual atom sites.

Applying the code MPA[9] the starting crystal models were relaxed using the method of static lattice energy minimisation with periodic boundary condition, which calculates the structure corresponding to the nearest energy minimum[9][67−69] in the context of a given set of interatomic potentials. The crystal structure was specified by six unit cell constants, three molecular rotation angles, and three *xyz* coordinates specifying the molecular centre. The site symmetry of molecules consequently needs to be lowered to C_1. Parameters related by space group or symmetry are connected by constraints.

The program calculates first (gradient) and second (Hessian) derivatives with respect to the above-mentioned variables. To remove imaginary modes from the Hessian, the program automatically selects energy minimisation by the OREM (off-ridge eigenvector minimisation[70]) method. If the Hessian is positive definite the NR (Newton−Raphson) method is used.

For evaluation of the slowly converging electrostatic and dispersion terms, accelerated convergence techniques are applied,[71] while the repulsion term is summed in real space (cut-off 15 Å).

It is a well-known fact that the lattice energy of a polar crystal, where the unit cell has a non-zero dipole moment, depends in principle on the external shape of the crystal.[72] Consequently, the lattice energy of the polar γ-modification cannot be given precisely unless the form of the crystals is specified. However, the γ-structure displays only a very small dipole moment {(e.g. −0.8008 eÅ for $\gamma_{200}(1)-[Ni(bpy)_3](PF_6)_2$}. Using the correction term derived by Smith[73] with the assumption of a spherical crystal ($2\pi p^2/3V$, with p and V being the dipole moment and the volume of the unit cell) a minor correction of 0.26 kJ/mol would apply for the total lattice energy. Therefore, no correction was applied to the values given in the Tables.

Four popular sets of empirical intermolecular potentials, CFF91,[28] Williams,[29], UNI,[30] and MM3,[31] were tested. It should be mentioned that all but the MM3 set are lacking some parameters and needed to be supplemented with parameters from other sources. Also, MPA will not allow the use of explicit parameters for mixed interactions, but instead uses combination rules to deduce these. Further, the combination rules are restricted to the common terms, $A_{ij} = (A_iA_j)^{1/2}$, $B_{ij} = (B_iB_j)^{1/2}$, $C_{ij} = (C_i + C_j)/2$, more elaborate rules as implemented in the CFF91 force field could not be used. Explicit values and details are given in the supporting information (Table S3).

Flexible Body Minimizations: The parametrization was performed according to the new method developed by Norrby and Liljefors with simultaneous use of experimental and quantum mechanical data.[44,46−49] A slightly modified *penalty function*[51] from the one used for the MM3* parametrization[44] was applied. Inverse distances were utilised instead of bond and torsion angles. The weighting factors employed are given in the supporting information (Table S8). Starting with the MM3* values, the stretching, bending, and torsional parameters involving ruthenium were optimised by minimising the penalty function using numerical NR techniques.[47] The same mass-weighted Hessian elements and structural data applied in the previous derivation of the MM3* parameters were used in the fit. Starting values involving the coordinating N−atom types (np_x, np_y, np_z) were taken from the CFF91[28] force field (np). The subscript is needed in order to be able to differentiate between *cis* and *trans* configurations in the angle-bending term, otherwise the atom types are equivalent and they are abbreviated np_{xyz}. Furthermore, the original CFF91 force field contains no appropriate atom type for the pyridyl−pyridyl bridge (cpp). This new atom type was also included in the fitting procedure. The starting values were taken from the corresponding atom type for biphenyl as contained in CFF95 (cpb).[74]

Parameters for the anion $[PF_6]^-$ were derived in a consistent way. The geometry was fully optimised in O_h symmetry, whereupon the Hessian was calculated numerically. The mass-weighted Hessian elements were used in the parametrization. Calculations employed the Gaussian94[75] program. The B3LYP[76][77] hybrid functional was used together with the 6−31G* basis set. The quantum mechanically determined P−F distance in the gas phase is much longer (1.648 Å) than the experimentally observed value in the solid state. This was noted before[52] by others even with better basis sets and is not a shortcoming of the ab initio method, but is due to the lack of an embedding environment as anions are very sensitive to this. Ideally, a perfect force field should be able to reproduce the bond shortening that will occur upon incorporation of the anion into the crystal field. Since the force field failed to fully match this appreciable bond shortening when going into the solid state the problem was "fixed" by shifting the r_0 value derived in the fitting procedure to the *TLS* corrected value (1.61 Å). Since there are not enough reliable experimental values available for the anion only QM information could be utilised in the parametrization. In the fitting procedure the same partial charges were used as in the lattice minimisations.

Supporting information for this article (Tables S1 and S2 with partial charges, Table S3 with intermolecular potentials, Tables S4−S7 with the contributions to the total lattice energy, Table S8 with waiting factors used for the penalty function, and Tables S9−S13 with intramolecular potential parameters) is available on the WWW under http://www.wiley-vch.d/home/eurjic or from the corresponding author.

Acknowledgments

We would like to thank Prof. Dr. K. -J. Range for making equipment available and for miscellaneous support, the Fonds der Chemischen Industrie, and the DFG for financial support. Also, we are grateful to Professor Caroline Röhr for kindly providing the atomic coordinates and U_{ij} values for $LiPF_6$. Furthermore, we thank the Degussa AG for a donation of $RuCl_3 \cdot 3H_2O$.

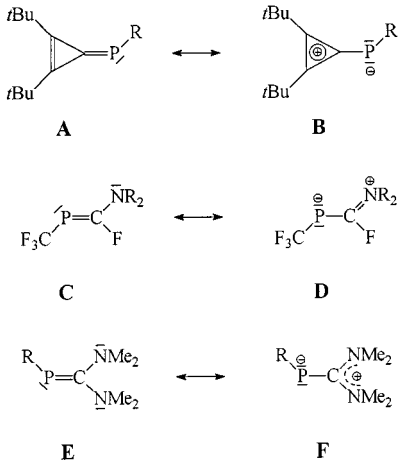
Phosphaalkenes with Inverse Electron Density

Lothar Weber[a]

Keywords: Phosphaalkenes / Electron density / Synthetic methods / Phosphorus

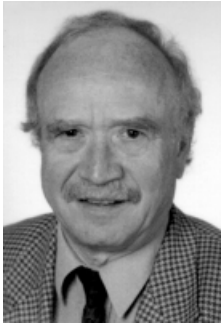


This review gives an account of the syntheses, structures, and properties of phosphaalkenes $R^1P{=}CR^2R^3$ with an inverse electron distribution at the P–C double bond ($P^{\delta-}C^{\delta+}$). The chemical reactivity of compounds of this type is novel and quite surprising compared to the chemistry of "classically polarized" phosphaalkenes ($P^{\delta+}C^{\delta-}$).

1. Introduction

The chemistry of compounds with low-coordinate phosphorus atoms involved in phosphorus−carbon multiple bonding has rapidly developed since the discovery of HC≡P by Gier in 1961.[1,2] The formal replacement of one methylene group in alkenes $R^2R^3C{=}CR^4R^5$ by the phosphanediyl unit R^1P affords the class of phosphaalkenes $R^1P{=}CR^2R^3$. Numerous papers on phosphaalkenes have highlighted the remarkable ability of phosphorus to mimic the chemistry of carbon.[3] The vast majority of phosphaalkenes feature an electron distribution $P^{\delta+}C^{\delta-}$ at the P−C double bond, as would be anticipated from the different electronegativities of carbon (2.5) and phosphorus (2.1).

About ten years ago inversely polarized phosphaalkenes were independently discovered by several research groups. Regitz et al. synthesized the first 2,3-di-*tert*-butylcyclopropylidene phosphanes and pointed out that these phosphatriafulvenes have an inverse π-electron distribution at the exocyclic P=C double bond, as depicted in the zwitterionic limiting structure **B**.[4]



A similar polarization of the π-bond was inferred from the ^{31}P NMR spectra of phosphaalkenes such as $F_3CP{=}C(F)NR_2$ (R = Me, Et, *i*Pr; NR_2 = pyrrolidino, piperidino, 2-methylpiperidino, 3-methylpiperidino, *N*-methylanilino),[5] $F_3CP{=}C(OR)NR'_2$ (R, R′ = Me, Et),[6] or $HP{=}C(Me)NMe_2$[7] where unusual high-field resonances for the dicoordinate phosphorus atom were observed (Scheme 1).

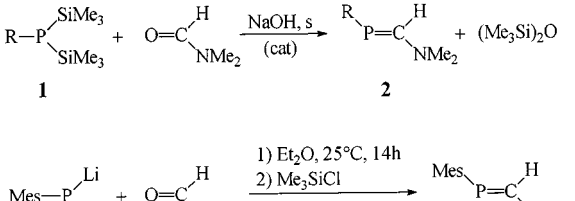
Scheme 1. Resonance structures of phosphaalkenes with an inverse π-electron density

This polarization is even more pronounced in phosphaalkenes with two amino substituents at the carbon atom of the double bond, such as $RP{=}C(NMe_2)_2$ (R = H,[8] Me_3Si,[9] alkyl,[7] aryl[10]) (Scheme 1).

[a] Fakultät für Chemie der Universität Bielefeld, Universitätsstraße 25, 33615 Bielefeld, Germany

Lothar Weber was born in 1944 in Langenöls in Schlesien. He studied at the Universität Marburg and received his doctorate there under the direction of Professor Günter Schmid in 1973. Afterwards, he carried out post-doctoral studies with Professor Barry M. Trost at the University of Wisconsin in Madison, USA. On his return to Marburg, he began the experimental work leading to his Habilitation, which was completed in 1982 at the Universität Essen. His work centered on the coordination chemistry of sulfur ylides. In 1985, he became a C2 Professor and then joined the Fakultät für Chemie der Universität Bielefeld. His research interests include the chemistry of compounds with low-coordinate elements of the fifth main group, the synthesis of homo- and heterocycles with heavy elements, new aspects in boron chemistry, and metal complex catalyzed reactions of multiply bonded systems.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

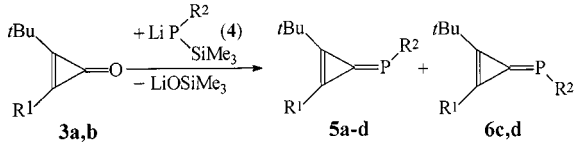


2. Syntheses

Basically, phosphaalkenes with an inverse π-electron density are available by the same synthetic methods which have been developed for phosphaalkenes with a normal π-electron distribution ($P^{\delta+}C^{\delta-}$). The most useful approaches to inversely polarized phosphaalkenes, however, involve condensations or substitution reactions at the P=C skeleton of appropriate precursors.

2.1. Condensation

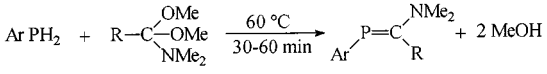
Among condensation processes the Peterson olefination plays a prominent role in the construction of P=C double bonds.



Thus, condensation of neat organobis(trimethylsilyl)phosphanes $RP(SiMe_3)_2$ (**1a**: R = Mes; **b**: Ph; **c**: *t*Bu) with excess *N*,*N*-dimethylformamide to afford the yellow phosphaalkenes $RP{=}C(H)NMe_2$ (**2a–c**, Scheme 2) was achieved in the presence of catalytic amounts of solid sodium hydroxide.[11] Without the catalyst, the reaction takes several weeks for completion.[12] An alternative high-yield synthesis of $MesP{=}C(H)NMe_2$ makes use of lithium phosphanide $LiP(Mes)(SiMe_3)$ as a starting material. Here the $LiOSiMe_3$ byproduct must be treated with Me_3SiCl prior to work up.[11]

1, 2	a	b	c
R	Mes	Ph	*t*Bu

Scheme 2. Synthesis of *C*-(dimethylamino)phosphaalkenes **2a–c**



Analogously, treatment of cyclopropenones **3a**,**b** with lithium (trimethylsilyl)phosphanides **4** led to the formation of the cyclopropanylidene phosphanes **5a–d** and **6c**,**d** (Scheme 3).[4]

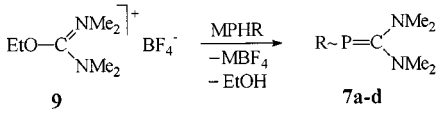
b	*t*Bu	Mes
c	1-Ad	Me_3Si
d	1-Ad	Mes

Scheme 3. Synthesis of cyclopropenylidenephosphanes **5** and **6**

Another effective route to the *P*-arylated phosphaalkenes **2a**,**b**,**d–f** makes use of the ready condensation of carboxylic amide acetals with primary arylphosphanes at 60 °C. The products were isolated as dark yellow oils, which in some cases solidified to give light yellow crystals (Scheme 4).

	2a	2b	2d	2e	2f
Ar	Mes	Ph	Ph	Mes*	Mes*
R	H	H	Me	H	Me

Scheme 4. Reaction of carboxylic amide acetals with arylphosphanes

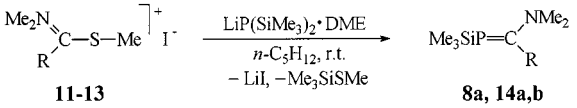


It is worth mentioning that primary alkylphosphanes do not react with these acetals.

Geminal difluorides are useful precursors for the preparation of *C*-amino-functionalized phosphaalkenes. Thus, [bis(dimethylamino)methylene](phenyl)phosphane (**7b**) and [bis(dimethylamino)methylene](trimethylsilyl)phosphane (**8a**) were obtained by gentle heating of an equimolar mixture of 1,1-difluoro-*N*,*N*,*N*′,*N*′-tetramethyldiaminomethane and either $PhP(SiMe_3)_2$ or $(Me_3Si)_3P$, respectively (Scheme 5).[9]

Scheme 5. Synthesis of **7b** and **8a**

Aryl bis(dimethylamino)methylene phosphanes such as $RP{=}C(NMe_2)_2$ [R = Mes (**7a**), Ph (**7b**)] are also conveniently accessible by combination of the carbenium salt $[EtOC(NMe_2)_2]^+BF_4^-$ (**9**) with the respective alkali metal arylphosphanide in diethyl ether[10] (Scheme 6).



7	a	b	c	d
R	Mes	Ph	*t*Bu	H
M	Li	Na	Li	K

Scheme 6. Reaction of carbenium salts with alkali metal phosphanides

This approach, however, is of only limited value, and usually fails with the more basic alkali metal alkylphosphanides. Only $tBuP{=}C(NMe_2)_2$ (**7c**) could be prepared in 30% yield from lithium *tert*-butylphosphanide and **9**.[7] A comparable yield of the phosphaalkene **7d** was achieved when the carbenium salt **9** was allowed to react with KPH_2 in THF at ambient temperature.[7]

Spontaneous condensation occurred upon mixing of lithium bis(trimethylsilyl)phosphanide · DME with the methylthiocarbenium iodides **11–13** in *n*-pentane. The

phosphaalkenes **8**, **14a**, and **14b** were formed as orange-yellow oils in moderate to good yields (Scheme 7).[15,16]

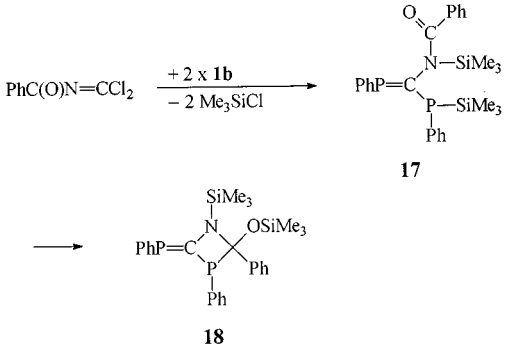
Scheme 7. Synthesis of *P*-silylphosphaalkenes **8a** (R = NMe_2), **14a** (R = Ph), and **14b** (R = *t*Bu)

2.2. Condensation and 1,3-Trimethylsilyl Migration

The transformation of organodisilylphosphanes to amino-substituted phosphaalkenes such as **16** with imidoyl chlorides formally parallels the synthesis of the oxygen-functionalized analogues $R^1P{=}C(OSiMe_3)R^2$. Thus, heating a 1:1 mixture of phenylbis(trimethylsilyl)phosphane **1b** with imidoyl chlorides at 150−160 °C led to compounds **16a−k** in 23−85% yield. Intermediates of the type **15** could not be detected by ^{31}P NMR spectroscopy.[17]



The content of Scheme 8 has to be regarded critically, as not all the phosphaalkenes **16** exhibit an inverse π-electron distribution, and in line with this, significantly shielded ^{31}P NMR absorptions. In keeping with Scheme 1, only those species where the limiting structure **D** is possible are regarded as inverse phosphaalkenes. Whenever, for steric reasons, the amino group and the C−C=P−C skeleton cannot be accommodated in the same plane, π-conjugation between the lone pair of electrons and the P=C-π bond will be precluded and the molecule will behave as a normally polarized phosphaalkene. This point will be discussed in more detail in Chapter 3 of this account.

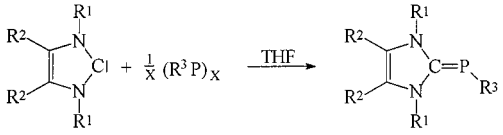
k	Ph	*p*-$MeOC_6H_4$

Scheme 8. Synthesis of phosphaalkenes **16** from imidoyl chlorides



Condensation with subsequent silatropy was also effected with *N*-(dichloromethylene)amides. Consistently, interaction of **1b** with *N*-(dichloromethylene)benzamide afforded phosphaalkene **17**, which in polar solvents at elevated temperatures underwent a rapid intramolecular insertion of the carbonyl unit into the P−Si bond with the formation of **18** (Scheme 9).[18]

Scheme 9. Reaction of *N*-(dichloromethylene)benzamide with $PhP(SiMe_3)_2$

2.3. Carbene Addition

Adducts **20** formed between imidazol-2-ylidenes **19** and phenylphosphinidene or (trifluoromethyl)phosphinidine also exhibit the structural features of phosphaalkenes with an inverse π-electron distribution (Scheme 10). They were easily synthesized from suitable stable carbenes and pentaphenylcyclopentaphosphane, or tetrakis(trifluoromethyl)cyclotetraphosphane as the sources of the phosphinidene fragments.[19,20]

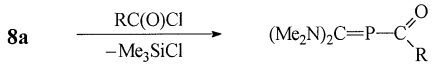
Scheme 10. Synthesis of **20a−c** by carbene addition to phosphinidenes

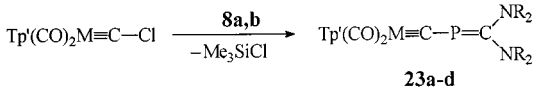
2.4. Substitution



Substitution reactions at the P=C skeleton of inversely polarized phosphaalkenes represent a valuable approach to many of the compounds under discussion. In particular, *P*-silylated phosphaalkenes proved to be appropriate targets for further functionalization.

The reaction of phosphatriafulvene **5a** with carboxylic chlorides in diethyl ether afforded the *P*-acylphosphatriafulvenes **21** in yields of 40−87% (Scheme 11).[4b]

Scheme 11. Acylation of **5a**

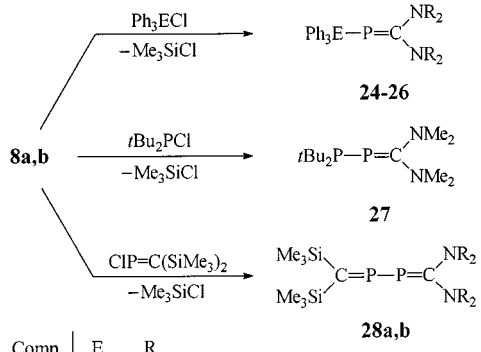


Similarly $Me_3SiP{=}C(NMe_2)_2$ (**8**) was transformed into the *P*-acyl derivatives **22a** and **22b** when allowed to react with an equimolar amount of pivaloyl or benzoyl chloride, respectively (Scheme 12).[21]

22a (R = *t*Bu)
22b (R = Ph)

Scheme 12. Acylation of **8a** by *t*BuC(O)Cl and PhC(O)Cl

Reaction of the chlorocarbyne complexes $Tp'(CO)_2M{\equiv}C{-}Cl$ [M = Mo, W; Tp′ = HB(3,5-$Me_2C_3HN_2)_3$] with two molar equivalents of **8a** in CH_2Cl_2 led to the precipitation of the red carbyne complex functionalized phosphaalkenes **23a**,**b** within 2 h (Scheme 13). The analogous conversion of the chlorocarbyne complexes into **23c**,**d** by treatment with $Me_3SiP{=}C(NEt_2)_2$ (**8b**) required 15−18 h to reach completion.[22]



23	a	b	c	d
M	Mo	W	Mo	W
R	Me	Me	Et	Et

Scheme 13. Condensation of chlorocarbyne complexes with **8a** and **8b**

Bis(amino)methylene(trimethylsilyl)phosphane **8a** underwent transsilylation when treated with equimolar amounts of chlorotriphenylsilane in benzene at 20 °C for 3 h.[23]

In contrast to this, the reactions of the phosphaalkenes with trialkylchlorosilanes were reversible as indicated by the action of $(Et_2N)_2C{=}PSiMe_3$ (**8b**) with 1.2 equiv. of $Me_2EtSiCl$ at 20 °C, which led to an 1:2 equilibrium mixture of starting material and $(Et_2N)_2C{=}PSiMe_2Et$. Treatment of **8b** with equimolar amounts of Ph_3GeCl and Ph_3SnCl in benzene at 40 °C irreversibly afforded $Ph_3GeP{=}C(NEt_2)_2$ (**25**) and $Ph_3SnP{=}C(NEt_2)_2$ (**26**), respectively (Scheme 14).[23] The replacement of the silyl function in **8a** by a di-*tert*-butylphosphanyl group with formation of $tBu_2P{-}P{=}C(NMe_2)_2$ (**27**) was effected with an equimolar amount of tBu_2PCl in diethyl ether.[9b]

28b		Et

Scheme 14. Reaction of **8a**,**b** with Ph_3ECl (E = Si, Ge, Sn), tBu_2PCl, and $ClP{=}C(SiMe_3)_2$

Reactions of *P*-silylphosphaalkenes **8a**,**b** with *P*-chlorophosphaalkenes are a valuable route to compounds **28a**,**b** with a diphosphadiene system (92−93% yield)[24] (Scheme 14).

The transition metal functionalized phosphaalkenes **29a−e** were obtained as crystalline products from the condensation of *P*-silylphosphaalkenes with $[(\eta^5\text{-}C_5Me_5)(CO)_2FeBr]$ and $[(\eta^5\text{-}C_5Me_5)(CO)_2RuBr]$[16,25] (Scheme 15).

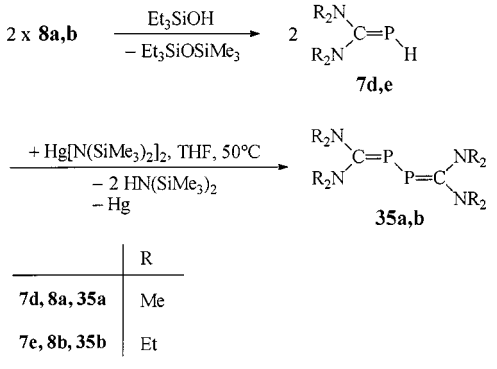
Scheme 15. Synthesis of metallophosphaalkenes **29a−e**

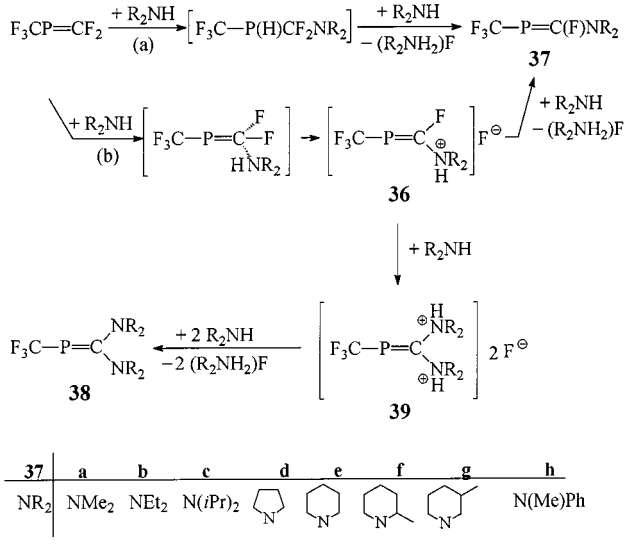


The P−Si bond of **5a** and **8a**,**b** tends to undergo 1,2 addition to the multiple bonds in alkynes and heterocumulenes

to yield compounds **30**–**34** as yellow to red crystalline solids[4,21,26] (Scheme 16).

Scheme 16. Reaction of **5a** and **8a** with $MeO_2C-C{\equiv}C-CO_2Me$ and heterocumulenes

Triethylsilanol selectively cleaved the P–Si bond in *P*-silylphosphaalkenes **8a**,**b** without affecting the P=C bond. This transformation constitutes a convenient method for the preparation of **7d** and **7e**,[27] which can be further transformed into the yellow liquid 2,3-diphosphabutadienes **35a**,**b** by treatment with $Hg[N(SiMe_3)_2]_2$ (Scheme 17).[28]

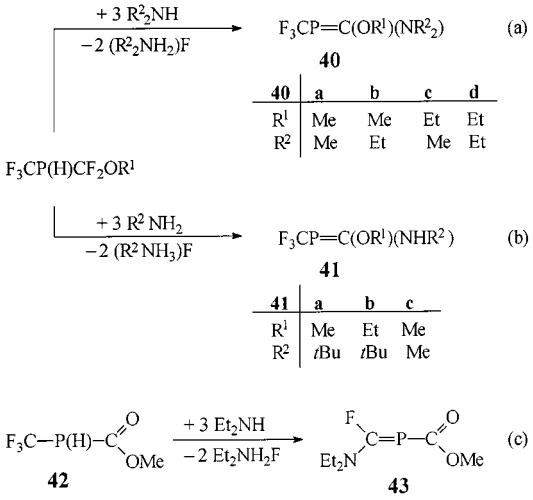


Scheme 17. Preparation of 2,3-diphosphabutadienes from **7d**,**e**

It is also possible to synthesize *C*-amino-functionalized phosphaalkenes by replacement of a fluorine substituent in phosphaalkenes such as $F_3CP{=}CF_2$ or $HP{=}CF_2$.

Perfluoro-2-phosphapropene reacted quantitatively with secondary amines in the molar ratio 1:2 at low temperature to yield the (*Z*)-configured phosphaalkenes $F_3CP{=}C(F)NR_2$ **37a**–**h**.[5]

Two possible mechanisms were discussed in rationalizing this result. In path (a) the addition of the NH function to the P=C bond was rapidly followed by the base-assisted 1,2-elimination of HF. In route (b) one molar equivalent of amine was added to the positively polarized carbon atom of the P=C bond prior to fluoride extrusion to give intermediate **36**, which was subsequently deprotonated by a second equivalent of amine (Scheme 18). During the course of this reaction small amounts of the disubstituted products $F_3CP{=}C(NR_2)_2$ (**38**) were also generated, which was explained by a second competing fluoride displacement from intermediate **36** by amine and a twofold deprotonation of the resulting dication **39**.



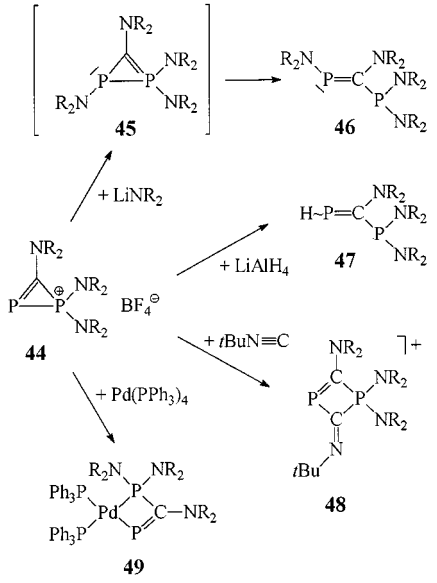
Scheme 18. Preparation of $F_3CP{=}C(F)NR_2$ and $F_3CP{=}C(NR_2)_2$ from $F_3C-P{=}CF_2$

Alternatively, the monoamino products **37** were accessible by treatment of bis(trifluoromethyl)phosphane with the secondary amine in a molar ratio of 1:3 at −40 °C via transient $F_3CP{=}CF_2$. This approach has the advantages of a one-pot reaction and the easy availability of the precursor $(CF_3)_2PH$.[5]

This synthetic principle was extended to the preparation of the yellow liquid phosphaalkenes $HP{=}C(F)NR_2$ [R = Me (**a**), Et (**b**), *i*Pr (**c**)] by the utilization of CF_3PH_2 as a starting material.[29]

Similarly, compounds $F_3CP{=}C(F)(OR^1)$ were subjected to reaction with secondary amines to yield the stable inversely polarized phosphaalkenes $F_3CP{=}C(NR^2_2)(OR^1)$ (**40a**–**d**).[6] Again it was advantageous to generate the phosphaalkene precursors $F_3CP{=}C(F)(OR^1)$ in situ from PH-functionalized phosphanes $F_3CP(H)CF_2OR^1$ by amine-induced HF elimination[6] [Scheme 19 (a)].

The employment of primary amines gave rise to the thermolabile compounds **41a**–**c**, which in CH_2Cl_2 solution at 20 °C completely decomposed within a few hours[30] [Scheme 19, (b)].



Scheme 19. Preparation of $F_3CP{=}C(OR^1)(NR^2_2)$, $F_3CP{=}C(OR^1)(NHR^2)$ and **43**

The very interesting *P*-methoxycarbonyl-functionalized phosphaalkene **43** resulted as a final product from the combination of phosphane **42** with an excess of diethylamine at −40 °C by a sequence of elimination and addition steps [Scheme 19, (c)].

The product was isolated as a yellow thermally stable oil in 65% yield.[30]

2.5. Miscellaneous

Ring opening reactions occurred when the readily available diphosphirenium salt **44** was treated with nucleophiles. After combination of a THF solution of **44** with a stoichiometric amount of lithium diisopropylamide at −78 °C, phosphaalkene **46** was isolated in 85% yield. The formation of **46** was explained by the nucleophilic attack of the lithium salt at the dicoordinate phosphorus atom of **44**, leading to a transient $\lambda^3\sigma^3,\lambda^5\sigma^4$-diphosphirene **45**, which was stabilized by ring opening[31] (Scheme 20). In a similar manner, addition of one equivalent of lithium aluminium hydride to a THF solution of **44** afforded the corresponding *P*-hydrophosphaalkene **47** as a 50:50 mixture of (*Z*) and (*E*) isomers.[32] Ring expansion of **44** was achieved by the addition of *tert*-butyl isocyanide[31] or $Pd(PPh_3)_4$[32c] to the cation. In both cases diphosphacyclobutenes with the structural features of inversely polarized phosphaalkenes were obtained.

3. Structure and Bonding

3.1. Theoretical Studies

Quantum chemical calculations were performed on the parent methylenephosphane and its amino-substituted derivatives (B3LYP/6-31g* level)[33] to substantiate the presence of an inverse π-electron density in the molecules (Scheme 21). The parent compound $HP{=}CH_2$ has a σ+π NBO charge of +0.387 e at the phosphorus and of −0.810 e at the carbon atom, whereas its P−C π-bond is essentially nonpolar (+0.030 e at P; −0.039 e at C). This agrees well with previous ab initio calculations based on Mulliken charges and a different basis set.[34a] By comparison, in the cyclopropylidenephosphane a σ+π Mulliken charge of −0.037 e at the phosphorus and of −0.177 e at the carbon atom of the exocyclic double bond were calculated (at the RHF approximation utilizing an ab initio wavefunction with a double-zeta basis set).[4] Here the P−C π-bond is clearly polarized towards the phosphorus atom as the negative end of the dipole with an excess of 0.369 e at the P atom and a deficiency of 0.084 electron at the C atom. The positive charge is stabilized by incorporation into the Hückel aromatic cyclopropenium unit. Quantum chemical calculations on the *C*-amino-substituted phosphaalkenes (B3LYP/6-31g*) predict a strong polarization of the π-bond. Only one, and to a greater extent, two amino

Scheme 21. Geometric parameters and charge distribution of $HP{=}CH_2$, cyclopropylidenephosphane, $HP{=}C(NH_2)H$ and $HP{=}C(NH_2)_2$

groups at the carbon atom induce an inverse electron density distribution at the π-bond, the charge at the phosphorus is increased in comparison to parent methylenephosphane. Alternatively, an amino group at the phosphorus atom has an opposite effect; it enhances the π-electron density at the methylene carbon atom. One may note that polarization of the P−C π-bond by amino substituents had been proposed some time ago.[34b] The quantum chemical investigations are based on the results of C_s symmetry imposed structures.[33] The calculations reveal that this holds true for the monoamino-substituted derivatives but for the *C*,*C*-diamino-substituted methylenephosphane, weak pyramidalization at the nitrogen atoms is predicted which causes a structural relaxation by 2.5 kcal/mol. However, the principal result of polarization of the P−C π-bond by the amino groups is retained.

Rotation of the amino groups lifts the π-conjugation ability of the amino group and causes a shrinking of the P−C bond. In other words the bonding features resemble more closely those of the parent methylenephosphane. Actually, the following structural parameters were obtained for the geometries with one orthogonal amino group (B3LYP/6-31g*) level:[34c] *cis*-(*trans*-)*C*-aminomethylenephosphane, P−C = 1.686 (1.686), C−N = 1.439 (1.441) Å.

3.2. Molecular Structures

Elongation of the P=C bond is the most noticeable structural change that classical phosphaalkenes undergo on replacement of one or two organic substituents at the tricoordinate carbon atom of the P=C double bond by one or two functionalities which are capable of π-donation. The P=C double bond length in nonconjugated phosphaalkenes ranges from 1.65−1.67 Å[2] whereas in *C*-amino-functionalized phosphaalkenes P−C distances of 1.70−1.76 Å are frequently measured[8] as is illustrated in **29a** [1.709(5) Å],[25] **29c** [1.717(4) Å] [Figure 1, (c)],[16] **7d** [1.740(1) Å],[5b] and **37a** [1.744(2) Å][21] [Figure 1, (a)]. A prerequisite for this bond lengthening is an effective π-interaction with (nearly) coplanar dialkylamino groups. In keeping with this, the atomic distances between the trigonal planar carbon atom and the nitrogen atoms are significantly shorter than the standard value for the C(sp^2)−N(sp^2) single bond (1.45 Å). Compound **29d**[16] represents a good example where, presumably for steric reasons, such a heteroallylic π-electron delocalization does not occur [Figure 1, (d)]. Here the P=C bond length of 1.697(3) Å is smaller and resembles that of the "classical" phosphaalkenes (η^5-C_5Me_5)$(CO)_2$Fe−P=C($SiMe_3$)Ph [1.665(6) Å][16] and (η^5-C_5Me_5)$(CO)_2$FeP=C($SiMe_3$)$_2$ [1.680(9) Å].[35] The atomic distance between the planar atom C(13) and the slightly pyramidalized nitrogen atom N(1) of 1.448(4) Å is clearly that of a single bond. The ferriophosphaalkenes with an inverse π-electron density about the P=C bond **29a** and **29c** feature significantly longer Fe−P bonds [2.325(2) and 2.316(1) Å] than **29d** [2.276(1) Å]. The latter value compares well with that of (η^5-C_5Me_5)$(CO)_2$FeP=C($SiMe_3$)$_2$ [2.269(2) Å] or (η^5-

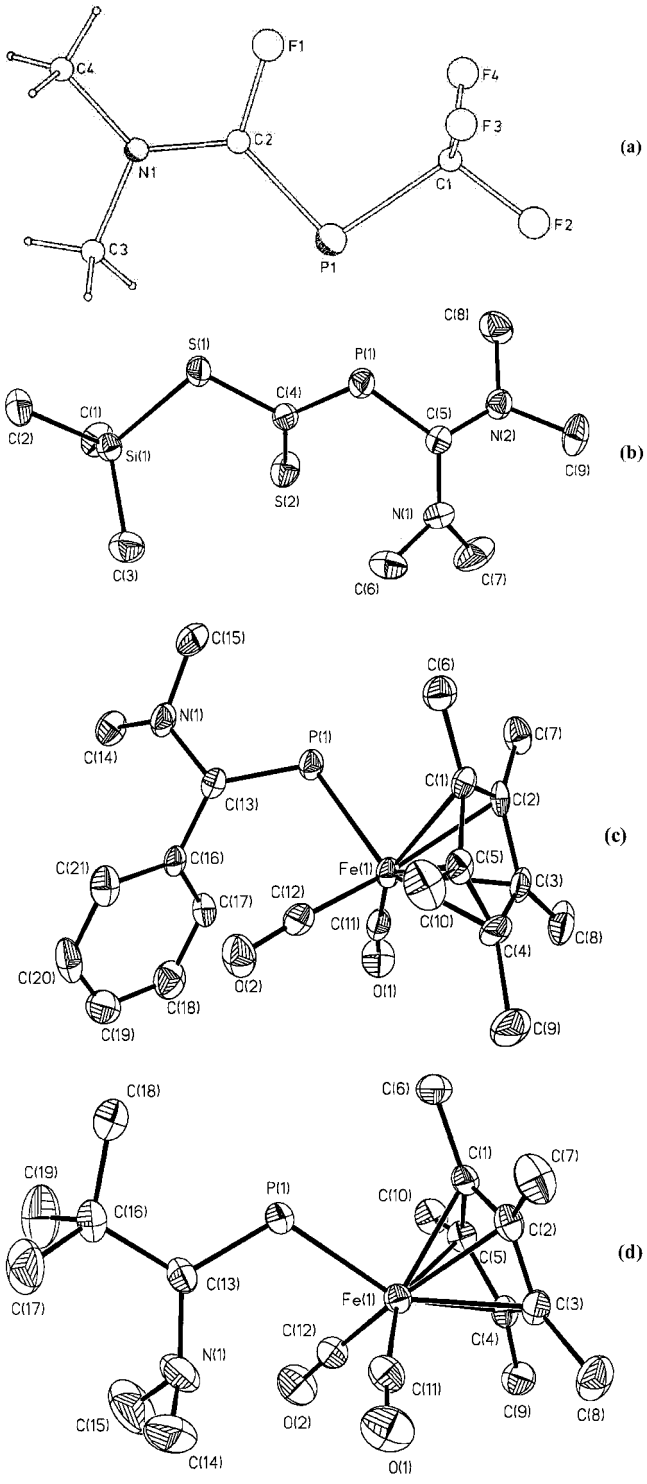

Figure 1. Molecular structures in the crystal of the phosphaalkenes **37a**, **33**, **29c**, and **29d**; selected bond lengths [Å] and angles [°]: (a) **37a**: P(1)−C(1) 1.862(2), P(1)−C(2) 1.744(2), C(2)−N(1) 1.311(2), C(1)−P(1)−C(2) 97.0(1), ΣN(1) 359.3(1); (b) **33**: P(1)−C(4) 1.748(2), P(1)−C(5) 1.826(2), C(4)−S(1) 1.801(2), C(4)−S(2) 1.673(2), C(5)−N(1) 1.341(2), C(5)−N(2) 1.338(2), N(1)−C(6) 1.458(2), C(4)−P(1)−C(5) 101.89(7), ΣN(1) 358.81(15), ΣN(2) 359.18(14); (c) **29c**: P(1)−C(13) 1.717(4), P(1)−Fe(1) 2.316(1), C(13)−N(1) 1.399(4), N(1)−C(14) 1.452(5), Fe(1)−P(1)−C(13) 118.9(1), ΣN(1) 352.6(3); (d) **29d**: P(1)−C(13) 1.697(3), Fe(1)−P(1) 2.276(1), C(13)−N(1) 1.448(4), N(1)−C(14) 1.447(5), Fe(1)−P(1)−C(13) 117.0(1), ΣN(1) 348.2(3)

$C_5Me_5)(CO)_2FeP{=}C(SiMe_3)_2$ [2.256(2) Å]. The bond lengthening in **29a** and **29c** presumably results from an electronic repulsion between the electron-rich iron atom and the negatively polarized P atom of the P=C bond. In the light of these observations the ferriophosphaalkenes **29a** and **29c** have to be considered as inversely polarized phosphaalkenes, whereas compound **29d** displays the characteristics of a normally polarized P=C bond. The molecular structure of **33** is particularly interesting [Figure 1, (b)]. Here a dithiocarboxy function successfully competes for the negative charge accumulated at the P atom of an inversely polarized phosphaalkene. Charge delocalization into the C−S double bond is evident by the bond shortening of P(1)−C(4) to 1.748(2) Å and concomitant elongation of the C=S bond to 1.673(2) Å. By comparison, a P−C single bond and a localized C=S double bond show bond lengths of 1.85 and 1.62 Å, respectively. Consistent with this, the former P−C double bond P(1)−C(5) is lengthened to 1.826(2) Å and the nearly planar nitrogen atoms N(1) and N(2) provide multiple bonding to carbon atom C(5) [N(1)−C(5) = 1.341(2) Å, N(2)−C(5) = 1.338(2) Å]. The bond angles at the P atom in **37a** [97.0(1)°], **7d** [103(1)°], and **33** [101.89(7)°] are comparable to that of the parent molecule $HP{=}CH_2$ (97.4°),[36] whereas steric congestion in **29a**, **29b**, and **29d** accounts for the more obtuse angle of ca. 118°. Thus, the valence angle at the P atom of phosphaalkenes does not reflect the polarity of the P=C π-bond.

3.3. Spectra

3.3.1. NMR Spectra

The characteristic ^{31}P and ^{13}C NMR shifts for selected compounds are summarized in Table 1. Generally, the ^{31}P NMR chemical shifts of phosphaalkenes vary in the wide range between δ = −99.9 for (*Z*)-H−P=C(F)NMe_2[29] and δ = 740.5 in the nickel complex [Cp*(PEt_3)Ni−P=$C(SiMe_3)_2$].[37] The ^{31}P NMR data of compounds containing low-coordinate phosphorus are compiled in several reviews.[2d,38,39] In spite of the large problems associated with the theoretical collation and interpretation of these large differences in shift, which generally occur for compounds containing two-coordinate phosphorus, some trends can be discerned for phosphaalkenes in general and for such representatives with an inverse π-electron density in particular. Basically, there are two major contributions to the ^{31}P chemical shift, namely a diamagnetic contribution reflecting the electron density associated with the low-coordinate P atom and another contribution, which is determined by the HOMO−LUMO gap of the molecule. Small HOMO−LUMO gaps in *P*-metallophosphaalkenes such as the aforementioned nickel compound or the complex [Cp*$(CO)_2FeP{=}C(SiMe_3)_2$] (δ = 641.5)[37] give rise to significant low-field shifts. The large valence angle at phosphorus [126.2(6)°] in the iron complex indicates that the energy of the nonbonding orbital as the HOMO is raised by sp^2-hy-

[a] $J_{P1,P2}$ = 403 Hz.

bridization, whereas the energy of the LUMO, which is the π* orbital, remains roughly unaffected. The electronic nature of the substituent at the phosphorus atom also markedly influences the chemical shift. In η^1-Cp*P=$C(SiMe_3)_2$[40] the valence angle at phosphorus was determined to be 118.7(2)°, which also agrees with sp^2-hybridization, but the ^{31}P NMR resonance appears at only δ = 370.6. The substituents at the C atom of the P=C bond in "normal" phosphaalkenes also determine the ^{31}P NMR chemical shift as evident in ClP=C(Ph)$SiMe_3$ (δ = 273) and ClP=$C(SiMe_3)_2$ (δ = 342).[2d]

In several amino- and bis(amino)-substituted representatives where π-conjugation of the nitrogen lone pair with the P=C double bond operates in addition to the paramagnetic contribution, a second component to the ^{31}P NMR shift has to be considered. As a consequence of the three-center four-π-electron system, the phosphorus atom β to the nitrogen atom experiences additional negative charge, which causes a pronounced high-field shift.

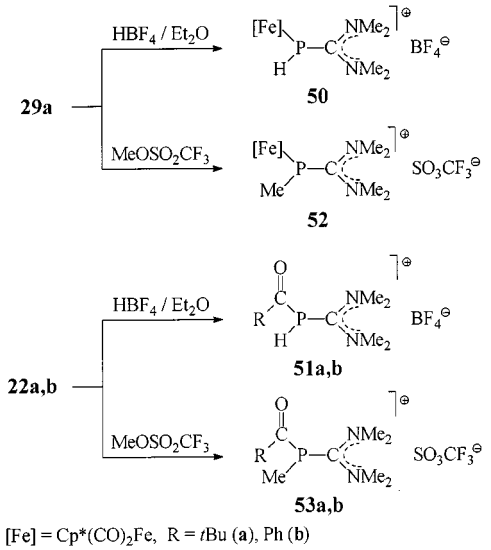
This is evident in compounds (*E*)-**16a** ($\delta^{31}P$ = 144) and (*Z*)-**16a** ($\delta^{31}P$ = 225), where presumably for steric reasons only the (*E*) isomer achieves the planar geometry required for a three-center four-electron arrangement in an inversely polarized phosphaalkene.[17]

The influence of the substituent at phosphorus on the ^{31}P chemical shift may be studied in molecules of the type X−P=$C(NMe_2)_2$. Here the compound with the highest degree of shielding at phosphorus is $Ph_3SiP=C(NMe_2)_2$ (δ = −85.1).[23] An increasing low-field shift as a function of X is observed as follows: **7d** (X = H; $\delta^{31}P$ = −62.6) > **8a** (Me_3Si; −47.1) > **23a** [Tp′$(CO)_2$Mo≡C; 62.3] > **7c** (*t*Bu; 91.9) > **29a** [Cp*$(CO)_2$Fe; 135.5]. Particularly interesting is the replacement of the hydrogen atom at phosphorus by functional groups, which are able to withdraw electron density from phosphorus by π-delocalization as observed in $MeO_2CP=C(F)NMe_2$ (**43**) ($\delta^{31}P$ = −23.4)[30] vs. (*E*,*Z*)-HP=$C(F)NMe_2$ (**39a**) ($\delta^{31}P$ = −90.0 and −99.9)[29] or in $(Me_2N)C=P-C(S)SSiMe_3$ (**32**) ($\delta^{31}P$ = 145)[21] vs. **7d**.

The introduction of a bulky and electron-releasing substituent at the phosphorus atom, such as the [Cp*$(CO)_2$Fe] group in **29a**, causes a strong low-field shift which may be due to the small HOMO−LUMO gap discussed above. Further deshielding was achieved by replacing one amino group by a phenyl ring in **29c** ($\delta^{31}P$ = 232.0), which is oriented orthogonally to the NCP four-π-electron unit. In contrast to (*E*)-**29c** in complex (*Z*)-**29d** a planar three-center four-electron arrangement is not possible for steric reasons, and consequently this compound behaves as a normal phosphaalkene with a low-field ^{31}P NMR signal at δ = 409.0.[16]

The ^{13}C NMR spectra of phosphaalkenes show characteristic doublets for the tricoordinate carbon atom of the P−C double bond at δ = 160−220. The cyclopropenylidenephosphanes are found at the lower range ranging from $\delta^{13}C$ = 163.7 (d, $^1J_{P,C}$ = 85.6 Hz) in **5b** to $\delta^{13}C$ = 178.5 (d, $^1J_{P,C}$ = 96.1 Hz) for $Cl_3C-C(O)-P=C^a-C^b(tBu)=C^c(tBu)$($C^a-C^c$) (**21o**). These values are quite typical for the cyclopropenylium system. In the cyclopropenium cation the corresponding resonances appear at δ = 176.8 whereas in the dipolar di-*tert*-butylcyclopropenone a chemical shift of δ = 159.4 was determined for the heteroatom-substituted ring carbon atom.[41] For the methylene carbon atoms of bis(amino)phosphaalkenes $XP=C(NMe_2)_2$ doublets were observed between δ = 197.0 (d, $^1J_{P,C}$ = 68.4 Hz) in **7a** (X = Mes)[10] and δ = 207.5 (d, $^1J_{P,C}$ = 70.6 Hz) in **7d** (X = H).[7] The signals of the monoamino-functionalized inverse phosphaalkenes $XP=C(R)NMe_2$ range from δ = 184.0 (d, $^1J_{P,C}$ = 54.5 Hz) for the P−C carbon atom in **2c** (X = *t*Bu; R = H) to δ = 219.7 (d, $^1J_{P,C}$ = 94.1 Hz) in **14b** (X = Me_3Si; R = *t*Bu).

3.3.2. IR Spectra



Valuable information about the polarity of the P=C bond in *P*-acylated phosphaalkenes is provided by IR spectroscopy. In *t*BuC(O)P=C$(OSiMe_3)$*t*Bu an intense band at $\tilde{\nu}$ = 1663 cm^{-1} was assigned to the IR stretching mode.[42] This value falls within the 1630−1690 cm^{-1} range usually encountered in acylphosphanes, where no electron delocalization from the phosphorus lone pair into the CO group is present. In the IR spectra of the inversely polarized phosphaalkenes **22a** and **22b**, strong bands at $\tilde{\nu}$ = 1563 and 1546 cm^{-1} respectively, indicate pronounced π-delocalization of electron density into the carbonyl group.[21] In $MeO_2C-P=C(F)NMe_2$ the ν(CO) vibration is observed at $\tilde{\nu}$ = 1685 cm^{-1} and thus at a lower wavenumber than in $MeO_2CP(H)CF_3$ [ν(CO) = 1738 cm^{-1}].[30] The CO frequencies of **21** are also bathochromically shifted (1590−1640 cm^{-1}) in comparison with monoacylated phosphanes.[4b]

4. Reactivity of Inversely Polarized Phosphaalkenes

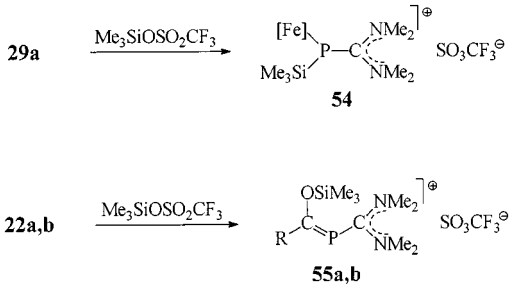
4.1. Protonation

The ferriophosphaalkene **29a** was protonated at the P atom by ethereal HBF_4 (54%) in diethyl ether at −50 to 20 °C to afford the yellow salt **50** in high yield.[43] Similarly, the reaction of the *P*-acylphosphaalkenes **22a** and **22b** with equimolar amounts of ethereal HBF_4 at −50 °C led to the formation of the phosphanyl carbenium salts $[RC(O)P(H)C(NMe_2)_2]BF_4$ **51a** (R = *t*Bu) and **51b** (R = Ph)[33] (Scheme 22).

Upon protonation, the ^{31}P NMR signal of **29a** (δ = 135.5 in C_6D_6) was shifted upfield and appeared in **50** as a broad singlet at δ = −78.4. In the ^1H NMR spectrum of **50** a doublet at δ = 2.82 ($^1J_{P,H}$ = 205.0 Hz) was attributed to the PH functionality. Interestingly, protonation of the normally polarized phosphaalkene $Cp(CO)_3W-P=C(SiMe_3)_2$ ($\delta^{31}P$ = 505.2) to give $[Cp(CO)_3WP(H)C(SiMe_3)_2]^+$ ($\delta^{31}P$ = 187.0) resulted in even stronger shielding and a much larger PH coupling ($^1J_{P,H}$ = 367 Hz),[44] which agrees with a tri-

Scheme 22. Reaction of **22a**,**b** and **29a** with HBF_4 and $MeOSO_2CF_3$

gonal-planar P atom in this cation. By analogy with the structures of the alkylated products (vide infra) it is clear that the P atom in **50** has a trigonal-pyramidal geometry. In the ^{31}P NMR spectrum, the protonated products **51a**,**b** display doublets at $\delta = -53.7$ ($^1J_{P,H} = 245$ Hz) and $\delta = -46.6$ ($^1J_{P,H} = 257.7$ Hz) which are significantly shifted to high field with respect to the corresponding signals in **22a** ($\delta = 26.4$) and **22b** ($\delta = 31.3$). In the ^1H NMR spectrum a doublet at $\delta = 6.02$ ($^1J_{P,H} = 245$ Hz) (**51a**) and at $\delta = 6.23$ ($^1J_{P,H} = 257.7$ Hz) (**51b**) accounts for the PH unit.[34]



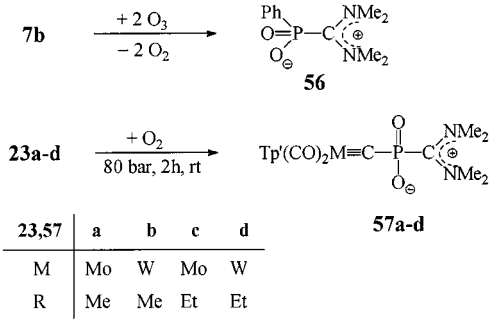
4.2. Alkylation

Alkylation of **29a** and **22a**,**b** was achieved by treatment with equimolar amounts of methyl trifluoromethanesulfonate (triflate) in diethyl ether at −60 °C. Compounds **52** and **53a**,**b** spontaneously precipitated and were isolated in good yield as orange or yellow powders[43,33] (Scheme 22).

Methylation at the phosphorus center of **22a**,**b** and **29a** was accompanied by marked shifts of the P NMR resonances to high field (**52**: $\delta = -26.4$ s; **53a**: −3.8 s; **53b**: −2.3 s). An X-ray structure analysis of the cation $[Cp^*(CO)_2FeAs(Me)C(NMe_2)_2]^+$ displayed a trigonal-pyramidal arsenic atom, analogously to **52**. From the analogous analytical and spectroscopic data it was inferred that **52** also contains a pyramidal pnicogen center.

4.3. Silylation

Reaction of **29a** with trimethylsilyl triflate in diethyl ether at −70 °C caused the precipitation of **54** as a yellow solid in 92% yield (Scheme 23). In the ^{31}P NMR spectrum of **54** a singlet was observed at $\delta = -78.4$. Here it seems appropriate to describe the cation as a η^1-complex of the phosphaalkene $Me_3SiP{=}C(NMe_2)_2$ (**8a**) ($\delta^{31}P = -47.1$) with the 16VE fragment $[(\eta^5\text{-}C_5Me_5)(CO)_2Fe]^+$. Coordination of **8a** caused a high field shift of its ^{31}P NMR signal, which in fact has been frequently encountered in the coordination chemistry of inversely polarized phosphaalkenes (vide infra).



Scheme 23. Silylation of **22a**,**b** and **29a**

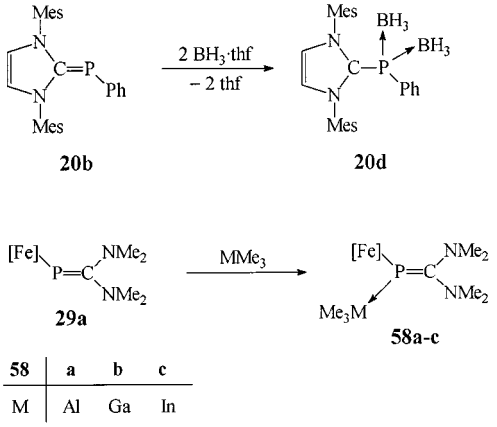
The silylation of **22a**,**b** with trimethylsilyl triflate in diethyl ether gave the extremely air- and moisture-sensitive salts **55a**,**b**. Here, in contrast to the protonation and methylation of **22a**,**b**, deshielding of the ^{31}P NMR resonances [$\delta = 109.2$ (**55a**) and $\delta = 101.0$ (**55b**)] was observed. This situation is best explained by an attack of the hard acid "Me_3Si" at the hard oxygen center of the carbonyl group with the generation of Si−O and P=C bonds. The products can be described as salts with unsymmetrical phosphaallyl cations or, alternatively, as phosphaalkenyl-functionalized carbocations.[45] Thus, the main spectroscopic evidence for an electrophilic attack at the P or O atom of *P*-acylphosphaalkenes with inverse electron density is from the direction in which the ^{31}P NMR resonances of the product are shifted.

4.4. Reaction with Chalcogens

Phosphaalkene **7b** reacted directly with ozone at ambient temperature with formation of the amidiniophosphinate **56** (Scheme 24). Compound **7b** always incorporates two atoms of oxygen. Intermediates in this process could not be detected. Product **56** appears to be inert towards excess O_3.[46]

23,57	a	b	c	d
M	Mo	W	Mo	W
R	Me	Me	Et	Et

Scheme 24. Oxidation of **7b** and **23a−d**



The related carbyne complex functionalized α-carbenium phosphinates **57** were obtained when crystalline samples of the complexes **23c** and **23d** (R = Et) were exposed to air for two weeks, whereupon a color change from deep red to orange-red occurred.

Similarly, compounds **23a** and **23b** (R = Me) were rapidly oxidized under O_2 pressure, whereas in air complete oxidation took about three weeks.[47]

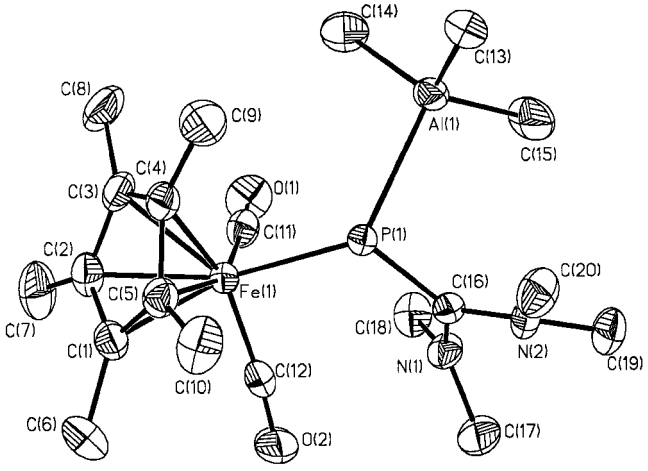
4.5. Reaction with Group 13 Electrophiles

Treatment of carbene **20b** with $BH_3 \cdot THF$ in toluene resulted in exclusive formation of the bis(borane) adduct **20g**.[20b] The ^{31}P NMR signal is shifted from $\delta = -23.0$ to $\delta = 4$. The P−C bond in **20b** [1.763(6) Å] lengthens to 1.856(2) Å in the adduct.[20b]

Combination of **29a** with equimolar amounts of $AlMe_3$, $GaMe_3$, and $InMe_3$ in *n*-pentane in the temperature range −78 °C to 20 °C afforded the trimethylmetal adducts **58a−c** as air- and moisture-sensitive solids, whereas the phosphaalkene appeared to be inert towards $Al\textit{i}Pr_3$[48] (Scheme 25).

Scheme 25. Reaction of **20b** with $BH_3 \cdot THF$, and of **29a** with $AlMe_3$, $GaMe_3$ and $InMe_3$

The ^{31}P NMR spectra of the adducts **58a−c** are characterized by singlets at $\delta = -12.1$, 14.5, and 22.2, which are strongly deshielded with respect to **29a** ($\delta = 135.5$).



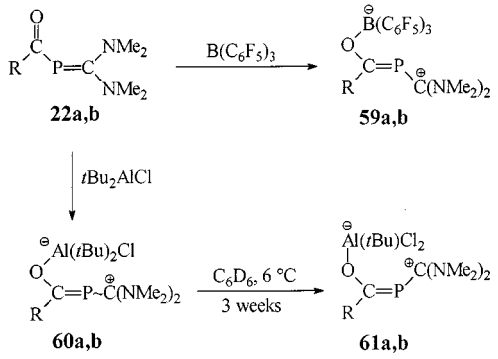


Figure 2. Molecular structure of **58a** in the crystal; selected bond lengths [Å] and angles [°]: Fe(1)−P(1) 2.317(1), Al(1)−P(1) 2.508(1), P(1)−C(16) 1.779(3), Fe(1)−P(1)−Al(1) 124.13(4), Al(1)−P(1)−C(16) 99.4(1), Fe(1)−P(1)−C(16) 116.5(1)

The X-ray structural analysis of **58a** (Figure 2) shows that coordination of **29a** to trimethylaluminium through the phosphorus lone pair results in significant distortion of the organophosphorus ligand. The P atom is now coordinated in a trigonal-pyramidal fashion (sum of angles 340.0°) and forms single bonds to the atoms Fe, Al, and C(16).

In comparison with **29a** the P−C bond is elongated from 1.709(5) to 1.779(3) Å. As in precursor **29a** the methylene carbon atom C(16) is trigonal planar.

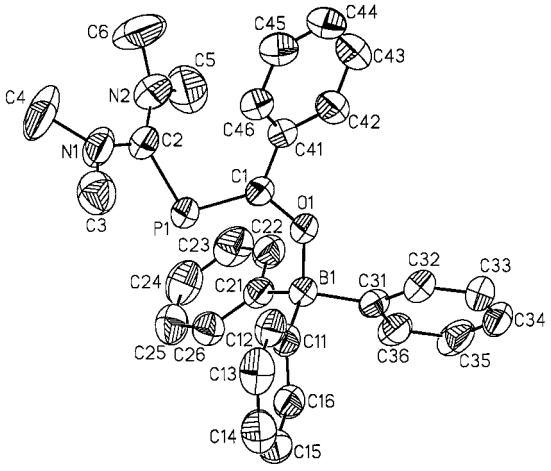
In view of the electrophilic attack of Me_3Si at the carbonyl oxygen atom of **22a**,**b** we focused our interest on the reactivity of the phosphaalkene towards the hard Lewis acids $B(C_6F_5)_3$, $t\text{Bu}_2\text{AlCl}$, and $(AlMe_3)_2$. Combination of **22a** or **22b** with tris(pentafluorophenyl)borane in toluene solution at 20 °C gave the adducts **59a** and **59b** as yellow solids (Scheme 26). Low-field shifted singlets in the $^{31}P\{^1H\}$ NMR spectra at $\delta = 68.3$ (**59a**) ($\Delta\delta = 41.9$) and 72.6 (**59b**) ($\Delta\delta = 41.5$), and the absence of ν(C=O) bands in the IR spectra of the adducts agree with the phosphaalkenes attaching to the electron-deficient boron center via the oxygen atom.[34]

Scheme 26. Reaction of **22a**,**b** with $B(C_6F_5)_3$ and $t\text{Bu}_2\text{AlCl}$

The X-ray structural analysis of **59b** confirmed the presence of a tetracoordinate boron atom, which is linked to the carbonyl group via a B−O single bond of 1.506(3) Å (Figure 3). Delocalization of the negative charge into the C=O bond is clear by its elongation from 1.240(2) Å (as measured in **22b**)[49] to 1.315(3) Å, and by the bond length P(1)−C(1) of 1.735(2) Å, which is similar to the P=C bond length in $HP{=}C(NMe_2)_2$ (**7d**) [1.740(1) Å]. The PC(N) bond in **22b** [1.800(1) Å] is lengthened to 1.838(3) Å in **59b**. The very bulky $B(C_6F_5)_3$ moiety is directed towards the P atom of the P−C multiple bond, giving rise to torsion angles B(1)−O(1)−C(1)−P(1) and B(1)−O(1)−C(1)−C(41) of 2.5° and −179.4°, respectively.

Di-*tert*-butylaluminium chloride reacted smoothly with equimolar amounts of **22a** or **22b** in toluene at −30 C° to yield the adducts **60a**,**b** as extremely moisture-sensitive orange solids. Attempts to grow crystals of **60a** and **60b** from C_6D_6 solutions at 6 C over a period of 3 weeks led to the formation of crystals of the dismutation products **61a** and **61b** instead. The $^{31}P\{^1H\}$ NMR resonances of both adducts, which appeared at lower field (**60a**: $\delta = 72.9$ s; **60b**: $\delta = 78.2$ s) than in the precursors are diagnostic for the mode of coordination, and the presence of dative Al−O bonds in the products was inferred.

The X-ray structural analysis of the dismutation product **61b** showed a (*Z*)-configured phosphaalkene with a P=C double bond of 1.728(2) Å between the phosphorus atom and the carbonyl carbon atom. The carbonyl bond is lengthened to 1.309(2) Å. The trigonal-planar amino-sub-



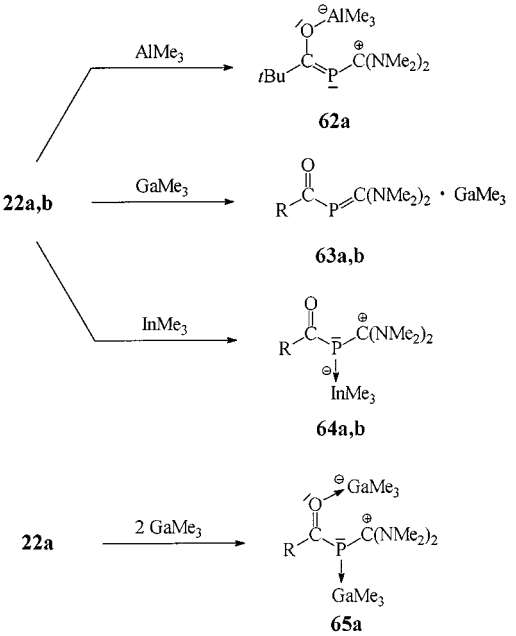


Figure 3. Molecular structure of **59b** in the crystal (fluorine atoms at the borane unit are omitted for clarity); selected bond lengths [Å] and angles [°]: P(1)−C(1) 1.735(2), P(1)−C(2) 1.838(3), O(1)−C(1) 1.315(3), O(1)−B(1) 1.506(3), C(1)−P(1)−C(2) 102.3(1), C(1)−O(1)−B(1) 130.2(2)

stituted carbon atom forms a single bond of 1.844(2) Å with the P atom.

Reaction of equimolar amounts of **22a** and trimethylaluminium in *n*-pentane yielded adduct **62a** as a pale yellow moisture-sensitive oil. The $^{31}P\{^1H\}$ NMR spectrum of the product displayed a singlet at $\delta = 62.7$, which is deshielded by $\Delta\delta = 36.3$ with respect to free **22a**. Thus, the aluminium atom is attached to the oxygen atom of the carbonyl group, as it is in the case of the adducts **60** and **61**.

Under analogous conditions one equivalent of trimethylgallium was added to **22a** and **22b** with formation of yellow **63a** and **63b**[34] (Scheme 27).

Scheme 27. Reaction of **22a**,**b** with $AlMe_3$, $GaMe_3$, and $InMe_3$

Broad singlets in the $^{31}P\{^1H\}$ NMR spectra at $\delta = 38.7$ (**63a**) or $\delta = 48.1$ (**63b**) did not allow for an unambiguous assignment of the structure, and crystals suitable for an X-ray study were not available. However, it was possible to grow yellow crystals of the 1:2 adduct **65a** from a concentrated mixture of **22a** and excess $GaMe_3$ in *n*-pentane at −30 °C. The NMR spectra of **65a** did not differ significantly from those determined for **63a**. All the three adducts **63a**,**b** and **65a** easily lose the ligated $GaMe_3$ in vacuo.

The crystal structure analysis of **65a** sheds some light in the nature of the 1:2 adduct (Figure 4). The backbone of the molecule is constituted by a *P*-acyl unit with a trigonal-pyramidal P atom (sum of angles 333.26°), which is connected to the atoms C(4), C(12), and Ga(2) via single bonds. The bond length P(1)−C(4) [1.784(3) Å] is shorter than P(1)−C(12) [1.831(3) Å]. The latter bond length was determined to be 1.800(1) Å in **22b**. A pronounced strengthening of the $P-C_{(CO)}$ bond, as observed in **59b** and **61b**, did not occur. The C−O bond length of the carbonyl group [1.249(3) Å] is similar to that of the *P*-acyl function in **2b** [1.240(2) Å]. Both $GaMe_3$ units are only weakly attached to the organophosphorus ligand as is evident from the long atomic distances Ga(2)−P [2.635(2) Å] and Ga(1)−O(1) [2.109(2) Å].

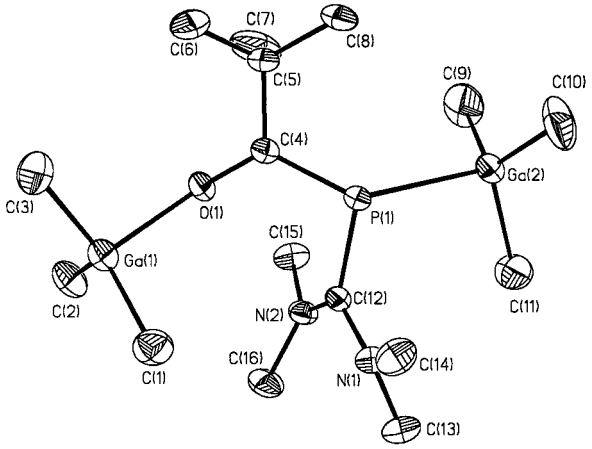

Figure 4. Molecular structure of **65a** in the crystal; selected bond lengths [Å] and angles [°]: P(1)−C(4) 1.784(3), P(1)−C(12) 1.831(3), P(1)−Ga(2) 2.635(2), O(1)−C(4) 1.249(3), O(1)−Ga(1) 2.109(2), C(4)−P(1)−C(12) 102.9(1), C(4)−P(1)−Ga(2) 127.7(1), Ga(2)−P(1)−C(12) 102.6(1)

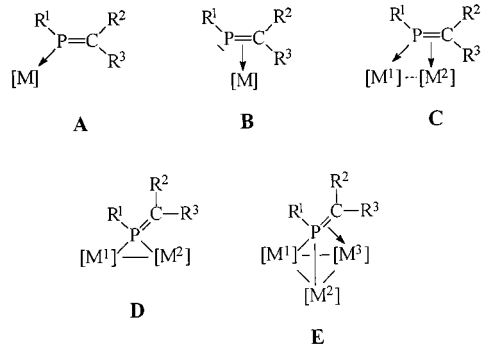
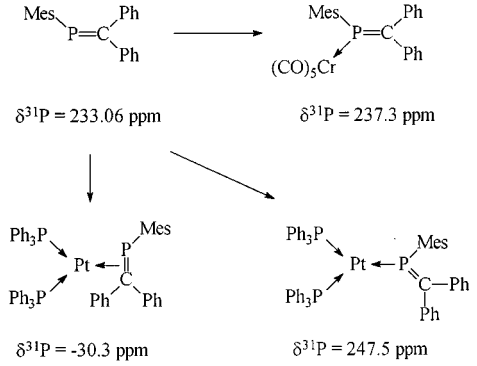
The coordination chemistry of **22a** and **22b** towards the "soft" acid $InMe_3$ is more straightforward (Scheme 27). The adducts **64a** and **64b** display singlets in their $^{31}P\{^1H\}$ NMR spectra at $\delta = 15.6$ and 36.8. A high-field coordination shift of $\Delta\delta = 10.8$ for **64a**, and a low-field shift of $\Delta\delta = 5.5$ are consistent with In−P contact rather than with the alternative In−O ligation. In the IR spectrum of **64a** strong ν(CO) bands appear at $\tilde{\nu} = 1594$ and 1546 cm^{-1}, and in the spectrum of **64b** a ν(CO) band of medium intensity at 1540 cm^{-1} with a shoulder at 1597 cm^{-1} was observed.



The X-ray structural analysis of **64a** features a *P*-acylphosphaalkene with a trigonal-pyramidal P atom, which is coordinated to the indium atom by a single bond of 2.774(4) Å.

The environment around the carbonyl carbon atom is trigonal-planar; a C=O double bond [1.238(10) Å] and a

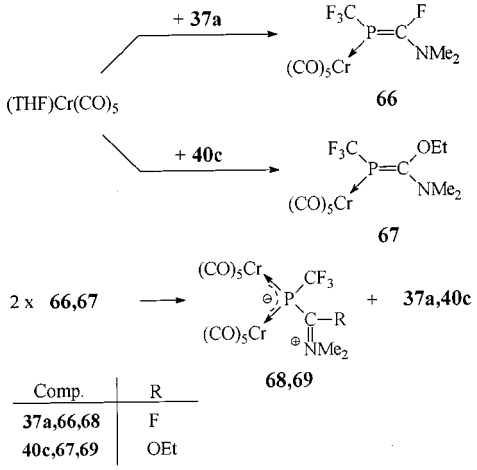
single bond to the P atom [1.851(9) Å] clearly exclude π-conjugation of the carbonyl group with the lone pair on phosphorus in **64a**. The bond between the phosphorus atom and the amino-substituted carbon atom of 1.823(8) Å is elongated with respect to the precursor.[34]



4.6. Transition Metal Complexes

Normally polarized phosphaalkenes are versatile ligands in transition metal coordination chemistry. At least five different fundamental modes of coordination of phosphaalkene ligands are known to date (Scheme 28).

Scheme 28. Modes of coordination in phosphaalkene complexes

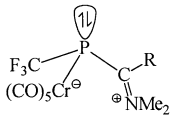


The most frequently observed types are η^1-coordination via the lone pair at phosphorus (**A**) and η^2-ligation **B**, which resembles that of alkenes in their transition metal π-complexes. In all of these complexes **A**−**E** the structural integrity of the phosphaalkene ligand is generally preserved. This particularly applies in case **A**. Here the P atom has a trigonal-planar geometry with a nearly unchanged P=C bond length with respect to the free ligand.[50] In η^2-complexes of the type **B** the P−C bond is usually elongated beyond 1.80 Å. While in η^1-complexes the ^{31}P NMR signals usually exert small coordination shifts (mostly to low field), in η^2-complexes strong high-field shifts are observed[50−52] (Scheme 29).

Scheme 29. Coordination shifts in phosphaalkene complexes

The coordination chemistry of inversely polarized phosphaalkenes is somewhat different. Pentacarbonylchromium complexes of the phosphaalkenes $CF_3P{=}C(F)NMe_2$ (**37a**)[5b] and $CF_3P{=}C(OEt)NMe_2$ (**40c**)[6] are available by treatment with equimolar amounts of $(THF)Cr(CO)_5$ in THF.

In organic solvents ($CDCl_3$, [D_8]toluene) complexes **66** and **67** were dismutated into to the binuclear complexes **68** and **69** and the free ligands **37** and **40c**, respectively (Scheme 30).



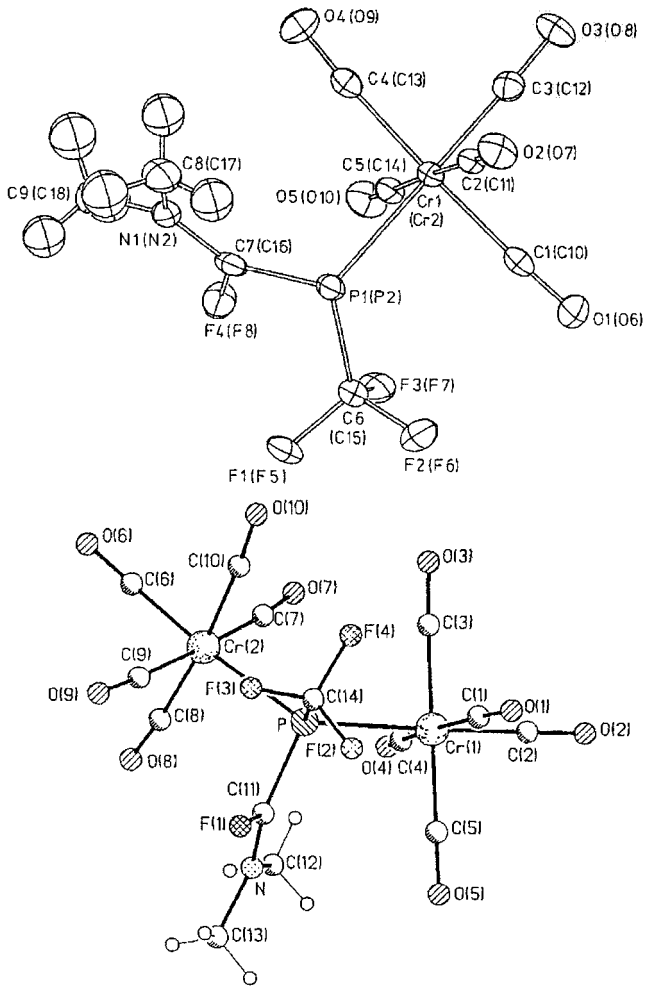
Scheme 30. Formation of the complexes **66**, **67**, **68**, and **69**

The coordination of **37a** ($\delta^{31}P = -9.0$) to one or two $[Cr(CO)_5]$ fragments via the phosphorus atom was accompanied by deshielding of the ^{31}P NMR signal to δ = 3.94 (**66**) and δ = 98.8 (**68**). On going from $CF_3P{=}C(OEt)NMe_2$ to **67** and **69** the ^{31}P NMR resonance is shifted to δ = 13.4 (**67**) and δ = 89.9 (**69**).

The molecular structures of **66**[5b] and **68**[53] are particularly interesting (Figure 5). The P=C bond length is markedly elongated from 1.744(2) Å in **37a** to 1.805(3) Å in **66** and 1.859(5) Å in **68**.

Those atomic distances are close to the average value of 1.85 Å for a P−C single bond. At the same time, the C−N separation in **66** [1.288(3) Å] and **68** [1.278(6) Å] indicates multiple bonding. In contrast with the situation in $[(CO)_5Cr]$ complexes of normally polarized phosphaalkenes having trigonal-planar P atoms, a trigonal-pyramidal phosphorus atom is observed in **66** (sum of angles: 304.8°). These observations favor a zwitterionic description of the complexes and rationalize the binding of a second $[Cr(CO)_5]$ unit at the phosphorus center.

The transfer of negative charge onto the $[Cr(CO)_5]$ building block is also reflected in bathochromically shifted CO stretching bands [**66**: $\tilde{\nu}$ = 2055 w, 1985 w, 1940 vs, 1930 s, 1912 s cm^{-1}] relative to $[(CO)_5Cr\{P(Mes){=}CPh_2\}]$ [ν(CO) ($CHCl_3$): 2068, 1955 cm^{-1}].[50a] The mode of coordination in **68** is unprecedented. Reaction of ferriophosphaalkene **29a** with an excess of $[Ni(CO)_4]$ led to the tricarbonylnickel adduct **70**.[54] This process was accompanied by a strong high-field shift of the $^{31}P\{^1H\}$ NMR signals from δ = 135.5 in **29** to δ = 15.0. A similar observation was made during the preparation of complex **71** from **29a** and [(*Z*)-



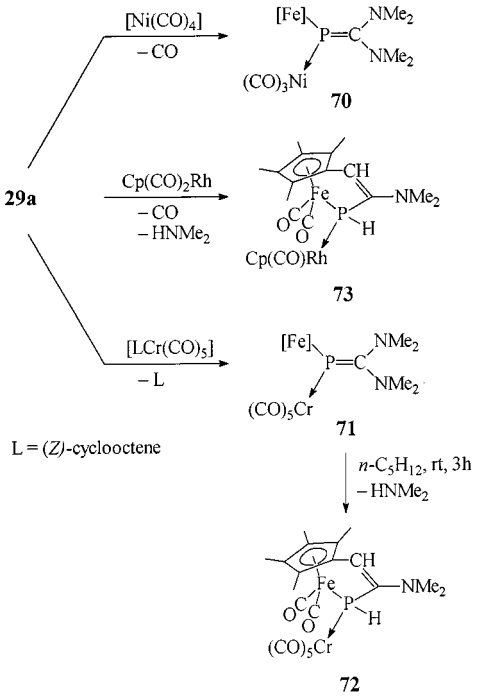


Figure 5. Molecular structures in the crystal of **66** (top) and **68** (bottom); selected bond lengths [Å] and angles[°]: **66**: Cr(1)−P(1) 2.454(1), P(1)−C(7) 1.805(1), N(1)−C(7) 1.288(3); Cr(1)−P(1)−C(6) 108.3(1), Cr(1)−P(1)−C(7) 102.4(1), C(6)−P(1)−C(7) 94.1(1); **68**: Cr(1)−P 2.459(2), Cr(2)−P 2.457(2), P−C(11) 1.859(5), C(11)−N 1.278(6); Cr(1)−P−Cr(2) 127.5(1)

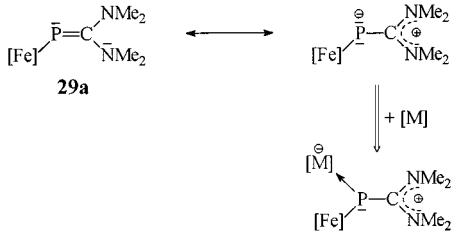
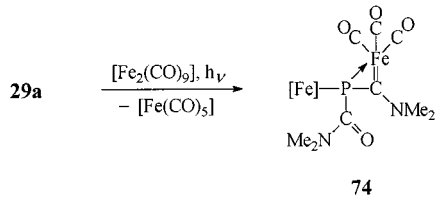
cyclooctene]$Cr(CO)_5$ in *n*-pentane. The dark violet complex ($\delta^{31}P = -1.0$) was, however, not stable. Upon prolonged stirring of the slurry in *n*-pentane it underwent condensation to give **72** and free dimethylamine.[54] A condensation product analogous to **72** resulted from the treatment of **29a** with [η^5-$Cp(CO)_2Rh$][55] in *n*-pentane. No intermediates in this transformation could be detected (Scheme 31).



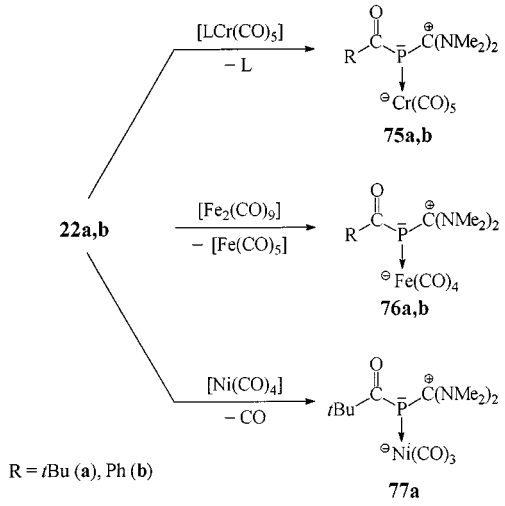
The formation of **72** and **73** is remarkable as one of the five methyl groups of the C_5Me_5 ligand behaves as a CH-acidic species which is involved in a Knoevenagel-type condensation. Usually Cp* ligands are ideal spectator ligands and insertions of metal atoms in one or more C−H bonds of methyl substituents are only observed with coordinatively and electronically unsaturated complexes.

The IR spectra of **70** and **71** display carbonyl stretching bands at remarkably low wavenumbers [e.g. **70**: ν(CO) = 2034, 1957, 1950 cm^{-1}] in comparison with [Mes*P=C=Ph_2]$Ni(CO)_3$ [ν(CO) = 2080, 2020, 1990 cm^{-1}],[56] indicating a considerable transfer of charge from the ligand onto the $[Ni(CO)_3]$ unit.



Scheme 31. Conversion of **29a** into the complexes **70**, **71**, **72**, and **73**

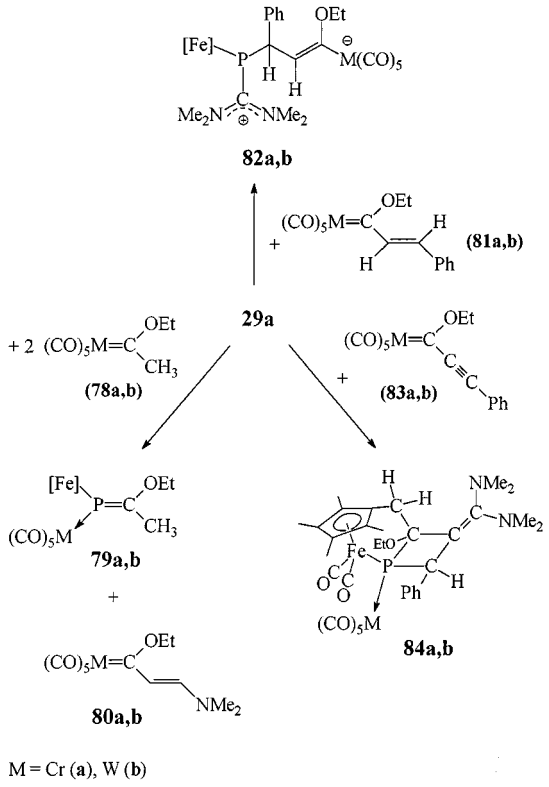
According to X-ray diffraction studies, the complexation of **29a** to an $[Ni(CO)_3]$ or $[Cr(CO)_5]$ fragment[57] leads to a severe distortion of the metallophosphaalkene skeleton (Scheme 32). Whereas the Fe(1)−P(1) distance in **70** and **71** [2.329(2) and 2.325(2) Å] remains nearly unaffected when compared with **29a** [Fe(1)−P(1) = 2.325(2) Å] the P−C bond in both complexes is significantly lengthened [**70**: 1.770(5); **71**: 1.793(5) Å. The P atoms have trigonal-pyramidal geometries with sum of angles of 335.9° (**70**) and 346.1° (**71**). In contrast to this, the carbon atom of the former P=C bond is trigonal-planar with relatively short C−N bonds [1.352(6) − 1.373(6) Å]. The electronic ground state of **29a** may be expressed by means of two canonical formulae, the which the zwitterionic form is obviously stabilized by coordination to metal fragments.



Scheme 32. Resonance structures of **29a** and its complexes

The photochemical reaction of **29a** with $[Fe_2(CO)_9]$ in *n*-pentane took a completely different course. Instead of the anticipated $[Fe(CO)_4]$ adduct, the phosphanylcarbene complex **74** was isolated as black crystals (Scheme 33).

Scheme 33. Formation of **74**



The reaction of **22a** and **22b** with carbonyl compounds of transition metals would be expected to lead to coordination compounds with metal−phosphorus bonds by the hard-soft acid-base concept (Scheme 34).

Scheme 34. Syntheses of complexes **75a**,**b**, **76a**,**b**, and **77a**

The high-field shifts of the $^{31}P\{^{1}H\}$ NMR singlets of complexes **75a**,**b**, **76a**,**b** and **77a**, in the range $\delta = -26.4$ to 1.9, agree with metal−phosphorus ligation. The X-ray structural analysis of **75a** unambiguously confirms coordination to $[Cr(CO)_5]$ of the trigonal-pyramidal phosphorus atom (sum of angles = 332.9°) with a P−Cr bond of 2.516(1) Å, which is at the upper end of P−Cr single bonds in low-valent carbonylchromium−phosphorus systems. The phosphorus−carbon distances [1.848(2) and 1.833(2) Å] are indicative of single bonds. Within the organophosphorus ligand, a localized C−O double bond of 1.225(2) Å was found.[34]

Having obtained some insight into the coordination behavior of inversely polarized phosphaalkenes toward trialkyl- and carbonylmetal compounds, the question of its reactivity towards Fischer carbene complexes became relevant. Compound **29a** was allowed to react with two molar equivalents of carbene complexes **78a** and **78b** in ether, forming the novel ferriophosphaalkene complexes **79a**,**b** and β-aminoalkenyl(ethoxy)carbene complexes **80a**,**b**[58] (Scheme 35).

Scheme 35. Reaction of **29a** with Fischer carbene complexes

The X-ray structural analysis of **79b** (Figure 6) shows an (*E*)-configured, classically polarized phosphaalkene, which is η^1-coordinated to the $[W(CO)_5]$ fragment via a remarkably long W−P bond [2.567(3) Å].[59] The P−C bond of 1.689(10) Å is typical for a P=C bond with an oxygen substituent, and the coordination geometry about P(1) and C(1) is trigonal planar. Interestingly the Fe(1)−P(1) dis-

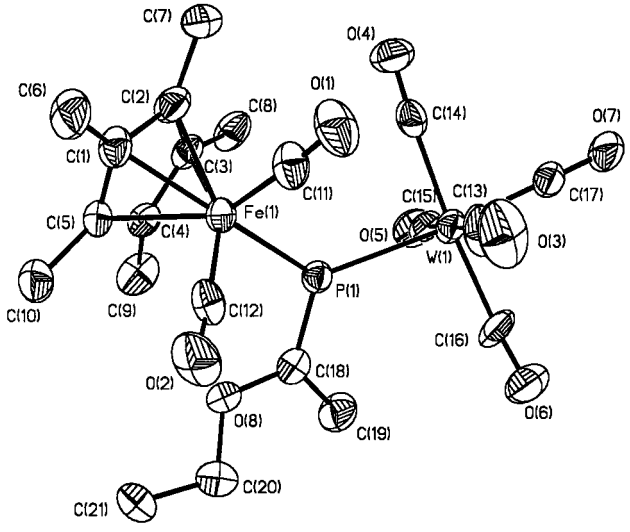


Figure 6. Molecular structure of **79b** in the crystal; selected bond lengths [Å] and angles [°]: W(1)−P(1) 2.567(3), Fe(1)−P(1) 2.262(3), P(1)−C(18) 1.689(10); Fe(1)−P(1)−C(18) 112.8(3)

tance of 2.262(3) Å is significantly shorter than in the carbonylmetal complexes of **29a**.

Combination of **29a** and the alkenylcarbene complexes **81a**,**b** in a mixture of *n*-pentane diethyl ether at −30 °C led to the precipitation of the orange zwitterionic Michael-type adducts **82a**,**b** (Scheme 35).

In sharp contrast to the synthesis of **79a**,**b** and **82a**,**b**, treatment of **29a** with an equimolar amount of the ethynyl(phenyl)carbene complexes **83a**,**b** in *n*-pentane at −60 °C afforded the yellow pentacarbonylmetal adducts **84a**,**b** of a 1-ferriophosphetane as the only tractable phosphorus-containing products (ca. 20% yield). (Scheme 35)

From the diversity of the product patterns the reactions of inversely polarized phosphaalkenes with carbene complexes display, it is clear that exploration of this fruitful area is only just beginning.

5. Conclusions and Perspectives

The "peculiarities" in the chemistry of *C*-amino-substituted phosphaalkenes, as discussed by Markovskii et al.[8] can be explained by their inverse distribution of π-electron density ($P^{\delta-}C^{\delta+}$) in comparison to the normal polarization ($C^{\delta-}P^{\delta+}$) in classical phosphaalkenes. Considering a growing body of evidence, the inverse π-electron density in a phosphaalkene may be detected from the following experimental features:

• The ^{31}P NMR signals of such molecules occur at unusually high field, whereas in normally polarized phosphaalkenes low-field ^{31}P NMR resonances are typical.

• These ^{31}P NMR signals may even be more shielded in transition metal complexes having inversely polarized η^1-phosphaalkene ligands. In η^1-complexes of normally polarized phosphaalkenes, coordination shifts to low field are usually observed.

• In η^1-complexes with inversely polarized phosphaalkene ligands, the phosphorus atom is pyramidal and the P−C bond is significantly elongated, in some cases attaining a bond order of unity, whereas in complexes with normally polarized phosphaalkenes the bond length between the trigonal planar atoms P and C is nearly unaffected upon coordination.

• The introduction of electron-withdrawing substituents at the P atom of inversely polarized phosphaalkenes results in delocalization of negative charge from the P−C unit into the substituent.

It is clear that classically and inversely polarized phosphaalkenes differ in their chemical reactivity. The latter are pronounced nucleophiles via their P atom and the systematic investigation of their synthetic potentials has just commenced. An interesting question still to be answered concerns Wittig-type reactivity of inversely polarized phosphaalkenes with organic carbonyl compounds. Little information is available on transformations with compounds which tend to liberate electron-sextet species, such as organic azides, diazoalkanes, carbenoid species etc.

The electronic situation present in inversely polarized phosphaalkenes should also be studied by electrochemical methods.

Thiomolybdates — Simple but Very Versatile Reagents

Stuart H. Laurie

Keywords: Copper / Molybdenum / Sulfur / Redox chemistry / Bioinorganic chemistry / EPR spectroscopy / Exafs spectroscopy

A large number of thiometallate anions, $MO_xS_{4-x}^{n-}$, and some of the seleno analogues, are known in which M is a transition metal in a high oxidation state. They are characterised by their strong colours arising from low energy S(Se)→M charge transfer transitions, by unusual redox properties and by their ability to act as ligands to produce a wide range of heterometal complexes. This review outlines some of these properties associated with the thiometallate anions of molybdenum(VI). These anions are prepared by passing H_2S through an alkaline molybdate solution, giving a sequential replacement of O atoms by S and ultimately MoS_4^{2-} (TTM) as product. The thiomolybdates, particularly TTM, have been the most intensively studied because of their ease of preparation, their relatively greater thermal and hydrolytic stabilities and their biological roles. Unusual redox changes which involve internal electron transfer have been shown by reaction with organic disulfides and with Cu^{II}. In the latter case insoluble polymeric products are readily formed which, from EPR and EXAFS studies, involve S-bridged reduced Cu and Mo centres. Reaction of TTM with Cu^{I}, on the other hand, produces a range of complexes in which from 1 to 6 Cu ions add across the tetrahedral faces of TTM with no redox changes. Further Cu^{I} ions can be added to the $[Cu_6(MoS_4)]$ moiety to produce cluster ions. This illustrates the ability of the thiometallates to act as building blocks for a very wide range of heterometal complexes ranging from simple linear ions to complex clusters, a prime example of the latter being the FeMo cofactor of the enzyme nitrogenase. TTM was identified sometime ago as the reactive intermediate in the Mo-induced Cu-deficiency that afflicts ruminants with serious consequences. Subsequently TTM, as its ammonium salt, has been successfully used in removing the excess Cu and then controlling the Cu levels of patients of Wilson's disease. It appears to act by blocking the intestinal absorption of Cu and by converting Cu into a metabolically inert form, and in these respects is different to the mode of action of chelating agents which can be used for treating this disease.

1. Introduction

There exists a number of thiometallate anions of general formula $MO_xS_{4-x}^{n-}$ in which M is a transition metal and $x = 0-3$ (Table 1). Because of their strong colours (mainly yellow to red) compounds of these ions have attracted attention since the very early studies by Berzelius in the 19th century. For some of these the corresponding selenide anions are also known − although generally less well studied. All these chalcogenide anions form a remarkably reactive series whose chemistry has still not been fully explored.

A full assignment of the UV/Vis and IR bands of these tetrahedral anions has been given by Müller and his coworkers.[1,2] Two remarkable features are first, all the metal centres are in their highest oxidation states — despite being

[a] Department of Chemistry, De Montfort University, The Gateway, Leicester, LE1 9BH, UK

Professor Stuart Laurie obtained his BSc(Hons) and PhD degrees in chemistry at the University College of Wales, Aberystwyth. He then spent several years as a research worker, first at Washington State University and subsequently at the Protein Chemistry Division of the CSIRO, Australia. It was at the latter institute that he first developed his research interests in bioinorganic chemistry. He then spent two years as a Senior Research Fellow with professor R. D. Gillard's bio-inorganic group at the Univerity of Kent at Canterbury. In 1969 he joined the staff of De Montfort University (then Leicester Polytechnic) as a lecturer, subsequently being promoted to Senior Lecturer and then Reader and Professor of Inorganic Chemistry. During the time at DMU he has spent sabbatical periods at the Biochemistry Division, Hospital for Sick Children, Toronto, working with Professors B. Sarkar and (the late) A. Sass-Kortsak on Wilson's Disease therapy and, more recently, at the Marine Sciences Laboratory, University of South Florida, with Professor R. H. Byrne working on aspects of aqueous metal speciation. His current research interests are still focussed on coordination chemistry with particular reference to ternary metal chalcogenides and the recovery of metals from industrial wastes.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

ReS_4^{-}	$ReOS_3^{-}$	$ReO_2S_2^{-}$	ReO_3S^{-}

coordinated to the strongly reductive S^{2-} ions. Second, the M−S bond lengths that have been determined are all very similar, 2.15−2.18 Å. The first feature accounts for their strong colours as the S→M charge transfer bands are of relatively low energy and lie in the visible region. Linear relationships in fact have been established between the energy of the longest wavelength electronic transition with the M−S stretching force constant and with the optical electronegativity of the metal centre (for closely related species). In the latter case the transition energy increases as the χ_{opt} value decreases — consistent with charge transfer being in the S→M direction.[2]

The second feature points towards some π character in the M−S bonds — as also suggested from MO calculations.[1] Electron delocalisation through π bonding also explains why these anions do not undergo a spontaneous internal redox reaction.

Of this series it is the Mo^{VI} anions, particularly MoS_4^{2-} (TTM), which have been the most studied — this can be attributed to their ease of formation and conversion into other dimolybdenum-thiol species, their greater thermal and hydrolytic stabilities and their implication and use in biological systems.

2. Preparation and Properties of the Thiomolybdates

TTM can be most easily prepared as its ammonium salt by passing H_2S through an ammoniacal molybdate solution. [3] In 15−20 minutes $(NH_4)_2MoS_4$ precipitates from the reaction mixture as red crystals of high purity and in high yield — a chemist's dream! The Na^+ and K^+ salts [3,4] are also known but are more difficult to prepare (and keep). Attempts to prepare the Ca^{2+} salt for medical use (vide infra) have been unsuccessful.[5] Alkylammonium and phosphonium salts are particularly important for studying reactions in non-aqueous media and as starting materials for many of the known heterometal complexes. The $[R_4N]_2MoS_4$ salts can be readily prepared from aqueous solutions of the ammonium salt by elimination of the ammonium ion as ammonia. $[PPh_4]_2MoS_4$ is a particularly useful starting material for dimolybdenum compounds and is readily precipitated from aqueous solutions of $[NH_4]_2MoS_4$ by the simple addition of $[PPh_4]Cl$.[6] Preparation of salts of the intermediate oxythio anions, $MoO_xS_{4-x}^{2-}$ (x = 1−3), have all been reported — these all involve passage of H_2S but require more strictly controlled conditions in order to avoid contamination with neighbouring thiomolybdates.[1,3,7]

Formation of TTM from MoO_4^{2-} clearly proceeds via successive replacement of oxygen, as evidenced from the colour sequence change in solution: MoO_4^{2-}(colourless) → MoO_3S^{2-}(yellow) → $MoO_2S_2^{2-}$(orange) → $MoOS_3^{2-}$(orange-red) → MoS_4^{2-}(red). This colour sequence is shown in the aesthetic UV/Vis absorbance spectrum of the reaction between MoO_4^{2-} and S^{2-} as a function of time, as shown in Figure 1.

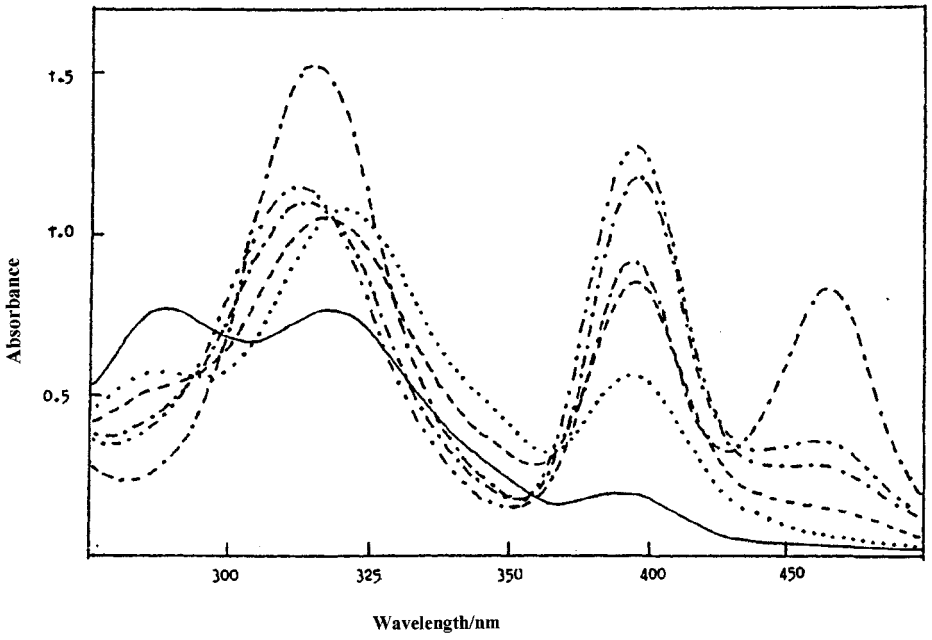

Figure 1. Formation of thiomolydate anions as a function of time (initial MoO_4^{2-} 1.3×10^{-4} M, S^{2-} 2.9×10^{-3} M, pH 7.0, 37 °C): after ——— 1 min., ····· 6 min., - - - - - - 21 min., ·-·-·-·-·- 60 min., ··-··-··-··- 110 min., --·--·--·--·--19 h; see Table 2 for assignment of the absorbance peaks)

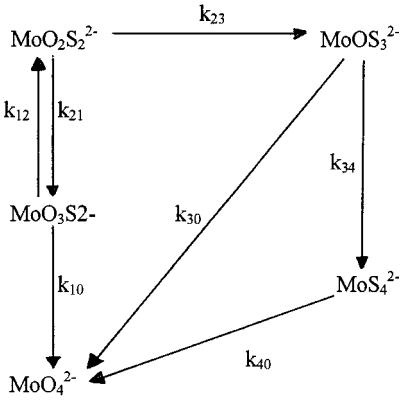

The strong UV/Vis and IR absorption bands are particularly useful diagnostic tools in determining the purity of the thiomolybdates and in following their reactions. These spectral details are given in Table 2.

Table 2. UV/Vis and IR bands of the thiomolybdate anions[a]

	UV/Vis λ/nm[b] (ε)[c]	IR[d] λ/cm^{-1} Mo−S	Mo−O
MoS_4^{2-}	316 (1.76), 465 (1.24)	476	-
$MoOS_3^{2-}$	315 (0.84), 398 (0.81), 465 (0.14)	470	860
$MoO_2S_2^{2-}$	288 (0.39), 320 (0.64), 394 (0.29)	460	860, 840
MoO_3S^{2-}	288 (−), 390 (−)[e]	476	880, 860, 840

[a] From measurements made in this laboratory. − [b] In pH 7 buffered aqueous solutions, ±2 nm. − [c] 10^4 dm^3 mol^{-1} cm^{-1}. − [d] Peak positions vary depending on the nature of the solvent and cation. − [e] Difficult to obtain accurate values.

The distinctive UV/Vis spectra of TTM and the oxythiomolybdate anions (Figure 1) have been used [8] to determine the rate constants for the formation (pseudo-first order with S^{2-} in excess) and hydrolysis of the ions as in Scheme 1.

Scheme 1

The rate constants for the thiol formation reactions follow the order:

$k_{12} > k_{23} > k_{34}$

Whilst that for the hydrolysis reactions is:

$k_{10} > k_{21} \approx k_{30} > k_{40}$

All the rates increase linearly with increase in H^+ concentration. Two important results with regard to TTM formation and existence in biological systems are that its complete formation in aqueous media requires a high S:Mo ratio and that its known increasing hydrolysis rate with increasing H^+ concentration proceeds without detectable formation of the intermediate oxythio ions in the above scheme.[8]

Earlier claims that, like MoO_4^{2-}, polymerisation of TTM occurs in lower pH solutions have not been substantiated. However, treatment with polysulfide produces dimeric and trimeric species in which the Mo centres have been reduced to oxidation states V and IV respectively,[9−11] e.g. to $(NH_4)_2[Mo_2^V(S_2)_6]\cdot 2H_2O$ and $(NH_4)_2[Mo_3^{IV}S(S_2)_6]$. Cyclic voltammetry of TTM in aqueous solution shows an irreversible reduction wave at −1.08 V,[12] whilst in dimethylformamide a reversible reduction potential of −2.50 V is observed.[13]

3. Thiomolybdates as Ligands

By far the most important property of the thiomolybdates, in particular TTM, is their role as ligands in a range of complexes, In these the $MoO_xS_{4-x}^{2-}$ moieties are mostly retained. It is the sulfide ions that play the key role as bridging ligands in which they can bridge two, three or four metal centres. The complexes formed range from simple linear structures, to small cubanes (Figure 2) to more complex clusters. In these cases the thiometallate anions act as the building blocks.

These compounds have received an enormous amount of attention over recent years because of their structural diversity and potential applications, e.g. as nonlinear optical materials, industrial catalysts and as models for the active Fe−Mo−S cluster site in the metalloenzyme nitrogenase. Consequently, they have been well reviewed.[2,14−17] Mention will be made here of only the much-studied system R/$Cu^I/MoO_xS_{4-x}^{2-}$, where R typically is a phosphane PR_3, halide (Cl^- or Br^-) or CN^-. In the absence of R, polymeric products are obtained, as in $(NH_4)CuMoS_4$ and Cu_2MoS_4, which feature alternate S-linked Cu^I and Mo^{VI} centres. In the presence of the R ligands, which preferentially occupy Cu^I sites, a range of discrete complexes can be obtained

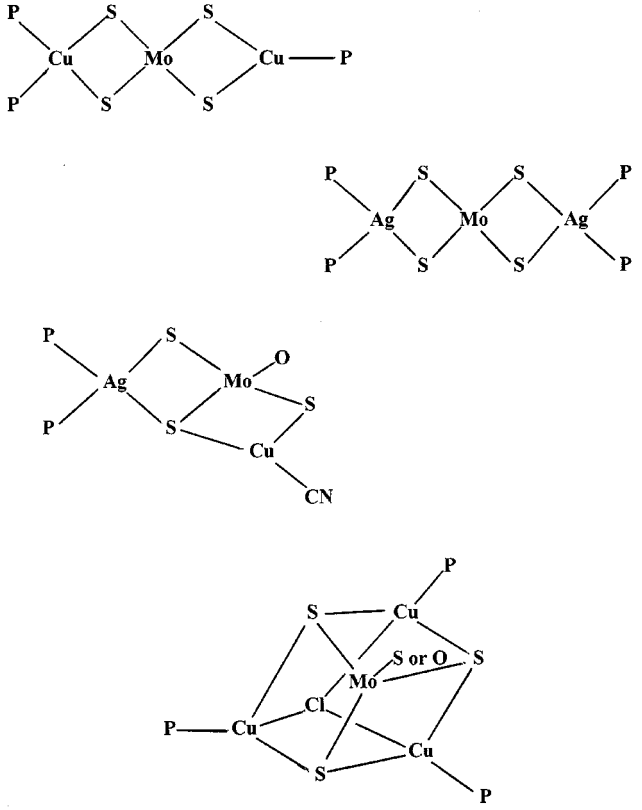

Figure 2. Some simple linear and cubane structures in schematic form illustrating the ability of thiomolybdate anions to act as ligands and as building blocks for more complex structures (P = triphenylphosphane)

depending on the reaction conditions (some examples are given in Table 3), the structures of many of these are known. Compounds have been reported from the reaction of CuCl with MoS_4^{2-} in which 1 to 6 Cu atoms occupy the six edges of the tetrahedral MoS_4^{2-} ion, i.e. of the form $[MoS_4(CuL)_n]$ ($n = 1-6$). A number of clusters with larger Cu:Mo ratios have also been synthesised, e.g. the anion $[MoS_4Cu_{10}\ Cl_{12}]^{4-}$ in which the central MoS_4^{2-} ion has six bridging Cu^I ions along its tetrahedral faces (as in the $n = 6$ case above) with the remaining four Cu^I ions forming an outer tetrahedral array linked by Cl^- bridges.[18] The formation of this latter complex from $(NH_4)_2MoS_4$ and CuCl illustrates how important the ratios of the starting reactants and the nature of the solvent are in terms of the final product(s) obtained. The structures of many of these heterometal compounds are known and illustrate the wide range of structural forms that they can exhibit.[19] Spectroscopic studies show that the IR ν(Mo−S) absorption modes in the 415−500 cm^{-1} region are diagnostic of the number of coordinated Cu^I ions.[20] For the diamagnetic heterometal complexes, ^{95}Mo NMR spectroscopy appears to provide a sensitive probe of the Mo environment;[21,22] for $[NPr_4]_2[Pt(MoS_4)_2]$ in DMF solution the observation of Pt−Mo coupling implies significant M−Mo interactions in these compounds.

Table 3. Examples of compounds isolated from R + Cu^I + (a) MoS_4^{2-}, + (b) $MoOS_3^{2-}$ or + (*c*) $MoO_2S_2^{2-}$

(*a*) $[Cl(PPh_3)_3Cu_3MoS_4]$	(*a*) $(PPh_3)_3[Cu_2(MoS_4)].0.8CH_2Cl_2$
(*a*) $(Bu_4N)_4[Cu_{12}(MoS_4)_8]$	(*b*) $(Bu_4N)_4[Mo_4Cu_{10}S_{16}O_3].H_2O$
(*a*) $(Me_4N)_5[MoS_4(CuCl)_6Cl_3]$	(*c*) $(Et_4N)_4[Mo_4Cu_4S_{12}O_4]$

A variation on the above is to use S^{2-} as the additional ligand leading to a further variation in structural types such as, $[Mo_4Cu_4S_{12}O_4]^{4-}$ (square type), $[Mo_8Cu_{12}S_{28}E_4]^{4-}$ E = S,O (cage), $[Mo_6Cu_6S_{19}O_6]^{2-}$ (cage).[23]

4. Redox Activity

Both the metal centres and the S ligands are redox active — either acting separately or, of more interest, acting in concert.[24] Oxidation of S^{2-} can result in a number of species with oxidation states ranging up to VI, e.g. S_2^{2-}, S_4^{2-}, S_8, SO_2, SO_3 as well as the various oxyanions. All of these are also potential ligands. As mentioned above, the occurrence of high metal oxidation state Mo^{VI} and low S state makes the occurrence and stability of the thiometallate ions somewhat surprising, especially for the thiomolybdate ions as the Mo and S redox potentials are fairly close. The potential redox activity has been realised in a number of reactions, e.g. in the reaction between TTM and organic disulfides elucidated by Stiefel and co-workers.[25,26]

$$2\ MoS_4^{2-} + RSSR \rightarrow Mo_2S_8^{2-} + 2\ RS^- \quad (1)$$

In this reaction the disulfide *oxidant* appears to have caused reduction of the Mo^{VI} centres to Mo^V! The required four electron donation in fact comes from the conversion of sulfides to persulfides:

$$4\ S^{2-} \rightarrow 2\ S_2^{2-} + 4e^- \quad (2)$$

The sulfide ion oxidation proceeds without M−S bond cleavage as X-ray analysis shows the persulfide ions to be coordinated to the Mo centres (Figure 3).

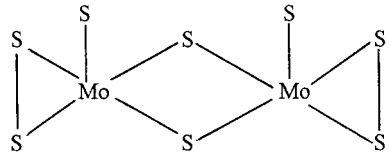

Figure 3. Structure of the anion $[Mo_2^VS_4(S_2)_2]^{2-}$ showing the coordinated persulfide ions (from ref. 25)

Under the same conditions WS_4^{2-} was found not to undergo metal reduction, but only a ligand redox reaction.[25] However, induced internal electron transfer has been observed with other tetrathiometallates. Stiefel[25] has pointed to a correlation between the ease of internal redox reactions and the lowest energy ligand-to-metal charge-transfer band (LMCT) and points to the position of the LMCT band being a "spectroscopic indicator" for such reactions. The LMCT bands in question are: ReS_4^-, 19800 cm^{-1}; MoS_4^{2-}, 21300 cm^{-1}; WS_4^{2-}, 25300 cm^{-1}. Of these ions, WS_4^{2-}, with the highest energy LMCT transition, undergoes internal redox changes the least easily. A similar intramolecular redox reaction has been reported by Coucouvanis et al.[27] involving the reaction between the oxy- and tetrathiomolybdates with elemental sulfur: under *oxidising* conditions the Mo centres were reduced to Mo^{IV} complexes with the formation of coordinated S_4^{2-} ions.

We have reported a similar redox reaction between TTM and salts and complexes of Cu^{II}, a black insoluble compound of composition $Cu_{1.6}MoS_4X_y$ was obtained (X = Cl^-, Br^-, $y = 1$; X = SO_4^{2-}, $y = 0.5$) when the Cu^{II} halide or sulfate salts were reacted with TTM in aqueous solutions.[28,29] EPR spectroscopy showed no Cu^{II} but the presence of Mo^V with a small (ca. 10%) contribution to the spectrum from an S radical species.[29] Presumably, the one electron reduction of each of the metal centres arises mainly from sulfide oxidation to persulfide, as in reactions (1) and (2) above. Some sulfide oxidation must also lead to the S radicals that were observed. EXAFS spectroscopy at the Cu and Mo K-edges show the Mo coordination to have been reduced to a trigonal MoS_3 moiety whilst the Cu is most likely a mixture of CuS_3 and CuS_4 coordination. Without some knowledge of the S species present it is difficult to predict the likely structure of this fascinating material; its insolubility does, however, suggest a multi-S bridged polymer. A further, surprising, finding was the observation that the solid irreversibly absorbs up to 2 mol O_2, with no change in either the EPR or EXAFS spectra, which suggests oxygenation at the S atoms. These EXAFS spectra are shown in Figure 4. We also found WS_4^{2-},despite its reported greater redox stability, to react with Cu^{II} identically to TTM in its reaction stoichiometry, redox changes and oxygenation.

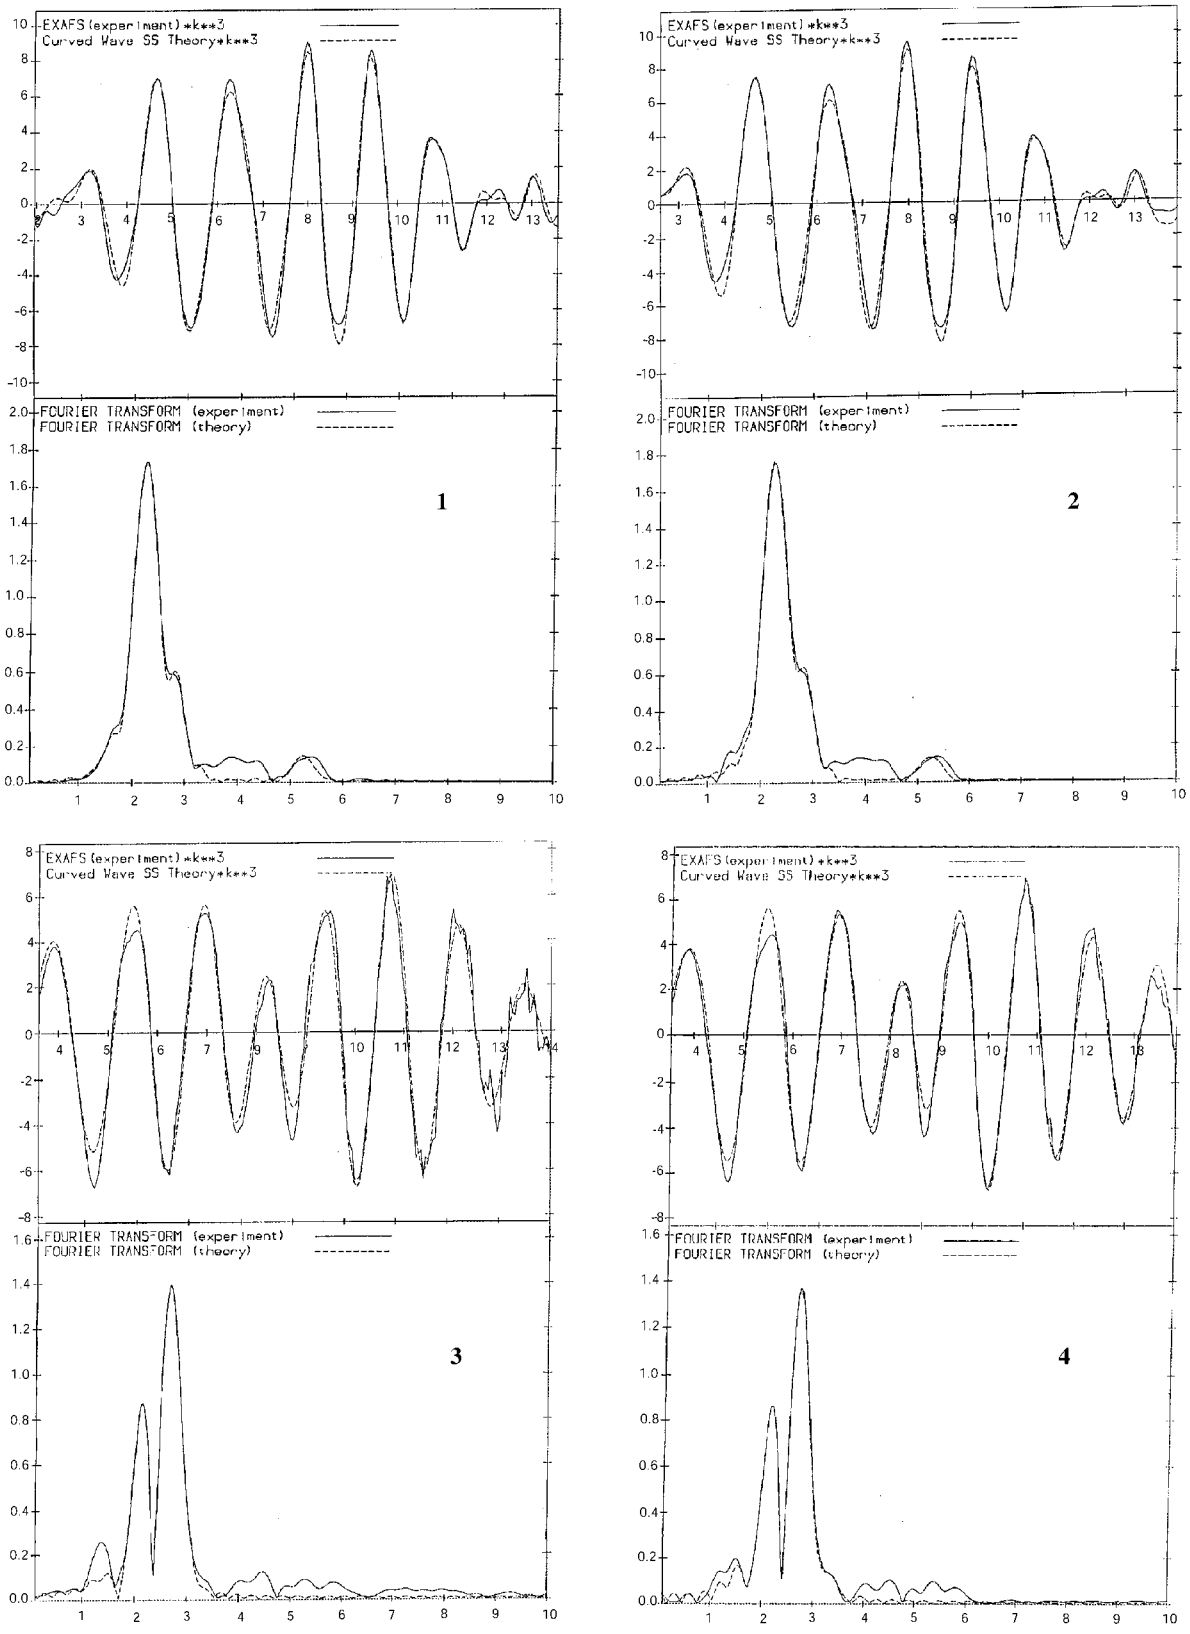

Figure 4. EXAFS spectra and Fourier transforms of $[Cu_{1.6}MoS_4Cl]$ showing retention of the metal coordination sites after O_2 uptake; **1** Cu k-edge, **2** Cu k-edge of oxygenated sample, **3** Mo k-edge, **4** Mo k-edge after oxygenation

Recently, Noble et al.[30] have shown that S coordinated at a dimolybdenum centre can undergo conversion into coordinated SO (sulfoxide) and coordinated SO_2 (sulfone). Similar oxygen capture reactions have been reported for Ni thiolates.[31] It would appear that this is a reaction with unexplored potential.

The Cu:Mo ratio in the above product is very close to that in the discrete anion $[Cu_{12}Mo_8S_{32}]^{4-}$, formed from the reaction in the solid state between TTM and CuCN. Surprisingly, the CN^- ligand is not retained in this case.[31] This anion, one of the largest known of its type, contains slightly distorted $Mo^{VI}S_4$ units linking tetrahedral Cu^IS_4 centres. A fuller description is given in reference 32 and in the review by Dance and Fisher.[15]

Reaction with the oxythioanions $MoO_xS_{4-x}^{2-}$ (x = 1,2; M = Mo, W) with Cu^{II} has also been found to lead to mutual metal reduction to Cu^I and Mo^V from the EPR spectra of the products. However, the stoichiometry in these cases is close to 1:1 Cu:Mo rather than the 1.6:1 observed with TTM.[33] Preliminary analysis of the EXAFS Cu spectra of these compounds shows a consistent trigonal CuS_3 coordination in all samples (Cu−S 2.5−2.7 Å) and a Mo atom at 2.67−2.70 Å. The EXAFS Mo spectra are consistent with $MoOS_3$ and $MoOS_2$ environments, the latter suggesting, rather surprisingly, the cleavage of one O atom from the $MoO_2S_2^{2-}$ reactant; the presence of Mo−O bonds is also evident from the strong IR absorption in the 800−900 cm^{-1} region. As with the Cu K-edge spectra there is also one neighbouring Cu atom observed in the Mo spectra at 2.67−2.70 Å. Our preliminary studies also show an oxygenation reaction occurs without any change in either the EPR or the EXAFS spectra.

5. Biological Properties

The Copper−Molybdenum Antagonism

Both Cu and Mo are well-known essential elements occurring in a range of metalloenzymes. Although their enzymatic functions primarily involve redox processes there is no evidence of any direct biological interactions between them as there is, for example, between Cu and Zn and Cu and Fe; this would be as expected from their different coordination chemistry behaviour and from their very different naturally occurring forms. However, there is one exception to this, and that is the well documented Mo-induced Cu deficiency that can afflict ruminants; more correctly this should be expressed as a Mo−S−Cu interaction.

The first component of the complex digestive system of ruminants (e.g. cattle and sheep), the rumen, has a high microbial content and is anaerobic, under these conditions both inorganic and organic sulfur are reduced to sulfide. Rumen sulfide levels of up to 6.0 ppm have been observed. High dietary Mo levels have been found to inhibit sulfide production.[34] It was recognised over 50 years ago that ruminant animals grazing pastures of high Mo content (ca. ≥2 mg/kg) develop symptoms characteristic of copper deficiency, i.e. a decline in weight gain, diarrhoea, rough and discoloured coats, and skeletal abnormalities.[35] Much research on this widespread antagonism has subsequently shown that although the dietary Cu levels may be sufficient this was indeed an induced Cu deficiency. High Mo levels themselves do not necessarily induce Cu deficiency — the Mo-induced Cu deficiency also requires a high dietary S intake. Several reviews cover this earlier work.[36−38] Mills and his co-workers subsequently showed that TTM forms from molybdate ion in rumen cultures.[39] Laboratory simulation of rumen conditions also showed that the oxythiomolybdate ions and subsequently TTM can form.[40] However, because of the low natural concentrations of molybdate in the rumen it has not been possible to directly observe the presence of any thiomolybdate within a rumen.

Addition of Cu^{II} to a solution of TTM in strained rumen contents resulted in the loss of the TTM UV/Vis spectrum, with a complete loss of spectrum at an approximately 1:1 Cu:Mo ratio.[39] Our own studies[40,41] have confirmed that a rapid reaction occurs between Cu^{II} ions and its complexes with TTM and with the oxythiomolybdates: in fact, taking into account the rapidity of the reaction and the rumen concentrations it was concluded that the oxythiomolybdate ions $MoO_xS_{x-4}^{2-}$ (x = 1,2) were the more likely reactants.[41] Studies by Mason and co-workers show that the di-, tri-, and tetrathiomolybdates all have an effect on Cu metabolism when given intravenously to ruminants and have a reversible inhibitory effect on caeruloplasmin oxidase.[42]

Despite these latter observations the majority of studies on the biological effects of the thiomolybdate ions have concentrated on TTM because of its greater aqueous stability. The Cu depletion caused by TTM appears to result from a decreased absorption from the diet and the formation of a non-bioabsorbable form. The latter has been identified as a ternary Cu−Mo protein form in both blood plasma and in liver cells, the proteins involved being albumin and metallothionein, respectively. Molybdenum-95 NMR spectroscopy shows that TTM can bind to serum albumin protein.[43] Our own studies, using membrane filtration and UV/Vis spectroscopy, suggest this association to be a relatively weak, mainly ionic, binding between albumin and TTM, there was certainly no evidence of any S cross-linking. With Cu-albumin, however, there was rapid formation of a ternary TTM-Cu-Albumin complex with similar characteristics to the polymeric compound that we isolated in vitro, i.e. EPR evidence of Cu^I and Mo^V centres.[41] While we could find no evidence of any interaction between the Zn-thionein protein and TTM, with Cu^I-thionein TTM was strongly bound; the other thiomolybdates were found to behave in a similar manner.[41]

Administration of TTM to nonruminants such as rats causes dramatic changes to the Cu distribution within plasma and reduction in the catalytic activity of the Cu enzymes, caeruloplasmin, ascorbate oxidase, superoxide dismutase and tyrosinase. The oxythiomolybdates were found to have less marked effects. From these studies it is evident that TTM may have potential as an antidote in acute Cu intoxication, animal studies have confirmed this and showed that it could also act as an antidote against Zn and Ni toxicity but not against other metals.[44]

TTM in the Treatment of Wilson′s Disease

Wilson′s disease is a relatively rare human disease first described by Kinnear Wilson in 1912 as progressive lenti-

cular degeneration, a familial disease occurring in young people. It is progressive and invariably fatal — unless treated early.[45] The cause of the disease is an accumulation of Cu resulting from a genetic defect which impairs the body′s normal excretion of dietary copper. As stated by Wilson, the disease is progressive, with severe neurological and liver deterioration. Unless treated early on, patients invariably die in their late teens or early twenties. The high Cu concentrations in the liver, low caeuloplasmin levels and Cu deposits in the cornea of the eyes (Kayser-Fleischer rings) are typical clinical symptoms used in the diagnosis of the disease. At the molecular level, free Cu ions are well-known enzyme poisons because of their potential to bind strongly to the many coordinating sites present in protein molecules. In fact, the body has well-established mechanisms for maintaining very low concentrations of free metal ions. This capacity is obviously exceeded in Wilson′s disease and the excess Cu ions are transported into the brain, the central nervous system and the liver, as well as other tissues.

Treatment of the disease is normally with chelating agents which can (a) rapidly excrete the excess Cu, and (b) over the rest of the patient′s life keep him/her in a low Cu balance. The two chelating agents of choice are D-penicillamine and triethylenetetraamine (trientine). The former is the more effective and is the usual first choice; however, penicillamine does have toxic side-effects and some patients become intolerant, in which case trientine is then used. Treatment with zinc salts has also been claimed to be beneficial, although not as effective as the above chelating agents. Another compound which is finding increasing use is TTM.

The usual criteria for successful chelation therapy is that the chelate must be nontoxic, be water soluble, resistant to metabolic degeneration, and have selective and adequate chelating ability at physiological pH. The agents and their metal chelates must be rapidly excreted by the kidneys. As shown above, TTM is very effective at removing Cu from animal tissues — even when the Cu is at normal levels — but it would not seem to fit many of the criteria for chelation therapy; it has nevertheless become another useful reagent for treating this disease. A useful summary of the prognosis of this disease and its therapy together with the related copper disorder, Menkes Disease, has recently been given by Sarkar.[46]

TTM was first used by Dr John Walshe, then at Addenbrookes Hospital, Cambridge, in 1982 on a patient who had become intolerant of all the other available treatments. She was initially treated with 50 mg twice a day, this was subsequently reduced to 30 mg twice a day and she was maintained on this regime until her death from other causes 16 years later; the longest recorded successful treatment to-date with TTM. She was initially treated with D-penicillamine but became intolerant of this, following this she responded well to trientine which reduced her liver Cu level to 90 units (ug/g wet tissue weight) but then became intolerant of this as well. She was then put on $ZnSO_4$ but after one year developed gastric problems, at this time her liver Cu level was 155 units. After a further 10 months without treatment she had deteriorated and her liver Cu level was up to 408 units. It was at this time that she was put on TTM, her health then improved and her liver Cu level decreased to 130 units. The initial follow up studies on this patient and others were reported in 1986 by Walshe.[47] TTM appears to act by blocking the intestinal absorption of Cu and by converting Cu into a metabolically inert form. The latter is most likely an S-linked Cu−Mo protein ternary complex as found in the earlier animal studies and our laboratory studies mentioned above and, more recently, in the TTM application to a rat strain that models Wilson′s disease.[48] The salt used then, and now, is the ammonium salt. Although there was some initial concern about the prolonged use of the ammonium ion there appears to have been no related adverse effect. It would have been preferable to use salts with cations such as Na^+, K^+ or Ca^{2+}, but, as noted above, these are difficult to prepare (most commercially available materials we have found to be impure, the major impurity being the highly insoluble MoS_3). The sodium salt has been found to be less toxic in rat studies than the ammonium form, LD_{50} 537 mg/kg and 176 mg/kg, respectively.[44] TTM has been successfully used by others:[44,50] in particular, a detailed study by Brewer et al. showed very promising results on using TTM as an initial treatment both to reduce Cu levels and improve neurological functions, followed by zinc administration for long term maintenance.[44] However, because of the lack of clinical data the use of TTM must still be treated as an experimental therapy. Additionally, there have been reports of it having toxic side effects,[48,49,51] although in two of these studies[48,49] the dosages used on a mg/kg body weight basis were considerably higher than those used successfully by Walshe on his patients. The applicability of some of the animal studies as models for the treatment of Wilson′s disease is also questionable. However, it is clear that continuous monitoring of a patient′s Cu and Mo tissue levels and other related clinical testing is needed during treatment with TTM.

6. Conclusions

We have shown that the unusual redox reaction between thiomolybdates and Cu^{II} occurs for a wide range of different forms of Cu^{II}. The question then arises as to how extensive this reaction is in terms of other thioanions, as listed in Table 1, and other reducible metal ions, and how common is the oxygenation reaction? I suspect that many similar reactions have previously gone undetected. Unpublished studies in our laboratory show that the thioanions of W, $WO_xS_{4-x}^{2-}$ ($x = 0-2$) undergo the same reactions with Cu^{II} as do the Mo analogues. A solid-state redox reaction between Cu^{II} and VS_4^{3-} has also been observed. The combination of EPR and EXAFS measurements has proved particularly valuable in these studies. As regards other potentially reducible metal ions to-date we have only carried out some preliminary studies with Fe^{III}. In this latter case, redox reactions have been observed but no well-defined

products have been obtained. A further area worthy of investigation is to carry out the reactions with Cu^{II} in the presence of Cu^{I} ligands so as to produce more tractable molecular species. There is also still much to be learnt about the metabolic properties of TTM and the nature of the ternary Cu-TTM-protein complex formed in the application of TTM in treating Wilson′s disease.

Electron Density and Charge Distribution around the Metal Atom in [Cp*Fe(η^5-As_5)]

Rolfe H. Herber*[a] and Otto J. Scherer[b]

Keywords: Sandwich complexes / Iron / Arsenic / Moessbauer spectroscopy / Calorimetry

^{57}Fe Mössbauer effect spectroscopy has been used to study the charge density, charge distribution, and lattice dynamics in the ferrocene-related compound [Cp*Fe(η^5-As_5)]. The isomer shift (at 90 K) is significantly more positive than that observed for the related η^5-P_5 homologue reported earlier, while the quadrupole hyperfine interaction is essentially the same in both compounds, but only about a quarter of that observed in related ferrocenes with only carbon atoms in the ring structure. The temperature dependence of the recoil-free fraction evidences a discontinuity centered at about 213 K, which is also observed in the DSC data. These data are compared to related results acquired for homologous ferrocenes with variable ring substitution.

Introduction

Due to its centrality in the development of organometallic chemistry over the past several decades, ferrocene [(η^5)$(Cp)_2$Fe] has been the subject of a multitude of physical and chemical characterizations, and is, undoubtedly, among the best characterized organometallic compounds in the chemical literature.[1] Among these characterizations have been temperature-dependent ^{57}Fe Mössbauer effect studies[2,3] designed to explore the charge density and symmetry of the charge distribution around the metal atom, and to relate these to a satisfactory description of the bonding and dynamics in this compound. In a recent study,[4] these investigations have been extended to [Cp*FeP_5] (**1**) and [$Cp^R FeP_5$] (**2**) [Cp* = $C_5(CH_3)_5$, Cp^R = $C_5(CH_3)_4(C_2H_5)$] and it was noted that the replacement of five $C(CH_3)$ ring components by the isoelectronic P atom resulted in a marked change in both the isomer shift (IS) and quadrupole splitting (QS) parameters over the temperature range $90 \leq T \leq 340$ K, compared to the parent ferrocene homologues. The recently reported synthesis[5a] and manifold chemistry[5b] of the corresponding [Cp*Fe (η^5-As_5)] (**3**) has made it possible to extend these studies to the arsenic congener, and the details of this study are the subject of the present communication. The structure of the related homologue of **3,** with Cp^R instead of Cp*[5a] is shown in Figure 1.

To overcome the pronounced nonresonant scattering by arsenic of the 14.4 keV gamma radiation accompanying the Mössbauer transition, the recent availability of strong (≈ 100 mCi) sources of ^{57}Co radiation, and the use of fast detector electronics, has made possible studies of arsenic containing iron organometallics which to date have been very limited.[6] The experimental details governing these measurements are briefly described below.

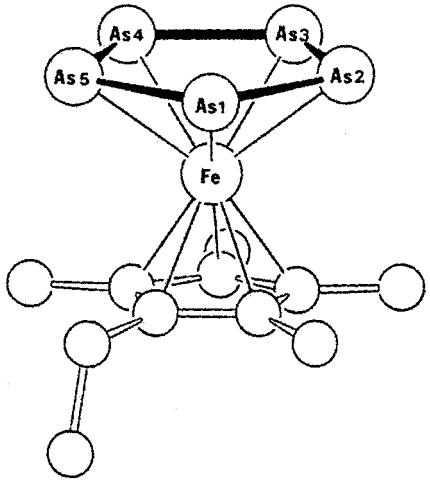

Figure 1. Structure of Cp^RFe(η^5-As_5) at 298 K; the X-ray structure of **3** with Cp* instead of Cp^R has not yet been reported

Results and Discussion

The ^{57}Fe Mössbauer spectra of all the compounds reported here consist of well-resolved doublets, and a typical spectrum is shown in Figure 2.

The IS, QS, and related parameters at 90 K are summarized in Table 1. A number of features of these data are worthy of comment. Compared to the corresponding data[4] for **1** and **2**, the IS of **3** is significantly more positive, and has nearly the same value as that of the parent ferrocene without ring substituents **6**, but is significantly smaller than that reported for [Cp*FeCp][7,8] and [Cp^*_2Fe], indicating a reduction of the s-electron density at the metal center. It is well-known that changes in the Cp ring substituents which are bonded to the carbon atoms by σ bonds have relatively little effect on the electron density at the iron atom since

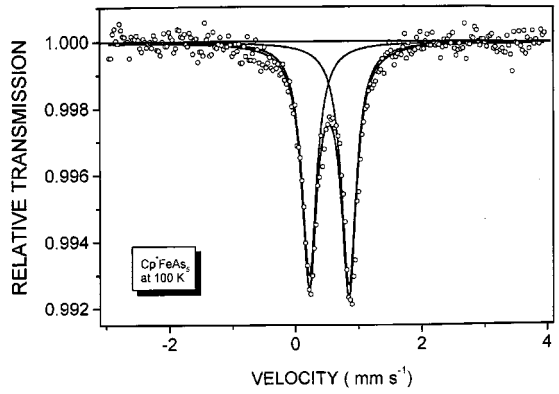

Figure 2. ^{57}Fe Mössbauer spectrum of **3** at 90 K; the velocity scale is with respect to the centroid of an α-Fe spectrum at 300 K; the small effect magnitude (even at 100 K) is a reflection of the presence of large amounts of arsenic in the sample, as discussed in the text

the latter is bonded primarily by overlap between the metal atom d-orbitals and the π density associated with the carbon atoms of the ring structure. Clearly, the effect of the presence of the electron-donating methyl groups is offset by the larger size of the As atoms constituting the ring, and presumably arises from the increase in shielding by the presence of 10 d-electrons in As compared to P and CH. This shielding reduces the s-electron density at the Fe nucleus and thus leads to the observed increase in the IS parameter. The temperature dependence of the IS is well represented by a linear regression over the range $90 \leq T \leq 273.2$ K: IS = $0.592 - (3.66 \pm 0.13) \times 10^{-4}$ T mm s^{-1}, with a correlation coefficient of 0.986 for 25 data points. This temperature dependence corresponds to an M_{eff} [9] of 113 daltons, reflecting the covalency of the metal-ligand bonding interaction.

Turning next to the QS interaction, it is seen (Table 1) that the numerical value of this parameter is essentially identical to that observed in **1** and **2**; that is, about a quarter of the size of that observed in complexes with Cp_2, Cp^*_2 and CpCp*[7] ligands. The likely explanation of this observation in the case of **1** and **2** has been discussed earlier.[4] It is to be noted, however, that going from the 3s,3p orbitals of P to the 4s,4p (and 3d) orbitals of As does not result in a further diminution of the QS. Again, it can be inferred that the electron density in the metal−ring atom overlap in latter case is − due to greater delocalization and the effect of the intervening 3d orbitals − essentially equivalent to that in the case of the P atoms, keeping in mind that the covalent atomic radii in the two cases are nearly identical (2.19 and 2.18 Å). The temperature dependence of the QS is essentially zero within the error limits of the present measurements, in contrast to the small positive value of d (QS)/ d T observed[4] for **1** and **2**. Due to the unavailability of well-formed single crystals of **3**, it is not possible to infer the sign of the QS from the presently available data (compare the intensity asymmetry shown in Figure 2 to that reported earlier for **1** at 90 K), and such an inference — in the absence of single crystal samples — would have to be based on measurements in high magnetic fields[10] to remove the (magnetic) degeneracy of the ±3/2 and ±1/2 spin levels observed in the present study.

Turning next to the dynamics of the metal atom motion in **3**, this characteristic is most clearly revealed in the temperature dependence of the area (A) under the resonance curve, which (for a thin absorber) scales directly with the recoil-free fraction, and hence with the mean-square amplitude of the metal atom relative to the center of symmetry of the molecule as a whole. It is amply clear from the temperature insensitivity of the intensity ratio R [= A(+)/ A(−)] that there is no resolvable Gol'danskii−Karyagin asymmetry[11] of the metal atom motion in this compound despite the presence of the five heavy As atoms. The temperature dependence of A over the range $90 \leq T \leq 273.2$ K is summarized graphically in Figure 3, in which the open and closed points refer to data accumulated in the warming and cooling modes, respectively, and illustrate the reversibility of these data. It is clear that there are two distinct regimes in this plot separated by a transition region centered at about 213 K. The slopes in the two regions are nearly identical [$-(7.79 \pm 0.36) \times 10^{-3}$ and $-(8.58 \pm 0.78) \times 10^{-3}$ K^{-1} in the ranges $90 \leq T \leq 205$ and $220 \leq T \leq 273.2$ K, respectively] and are very similar to the behavior reported[4] for **1** in which the mid-point of the discontinuity was observed at 195 K. As in the earlier study, the identification of this discontinuity is supported by the DSC data summarized in Figure 4.

The relatively broad endotherm at 217 K, observed at a warming rate of five degrees per minute, is in reasonable agreement (midpoint about 213 K) with the data summarized in Figure 3, which show Mössbauer data accumulated over a period of several hours at each temperature. It is tempting to identify this transition with the lambda point

Table 1. Summary of Mössbauer data for the compounds discussed in the text [Cp = η^5-C_5H_5, Cp* = η^5-$C_5(CH_3)_5$, Cp^R = η^5-$C_5(CH_3)_4(C_2H_5)$ P_5 = η^5-P_5, As_5 = η^5-As_5]

(at 169 K) reported for ferrocene, which is related[12] to a change from the triclinic (low *T*, nearly eclipsed rings) to the orthorhombic/monoclinic (high *T*, staggered rings) form, but additional support for this identification cannot be extracted from the presently available data. The gas phase (473 K) structure of [Cp*FeP_5] has been reported by Blom et al.,[13] and consists of a staggered conformation of the two five-membered rings. No comparable data for **3** have been reported to date, although the X-ray diffraction data for [Cp^RFeAs_5] have been summarized by Scherer et al.[5a]

Experimental Section

A sample of **3** was synthesized as described earlier,[5a] and, because of its (slight) light and air sensitivity, quickly mixed in subdued light with an equal weight of BN to optimize random crystallite orientation. This sample was then mounted in a standard plastic sample holder and immediately cooled to 78 K before transferring to the Mössbauer spectrometer. The other compounds cited in this study were obtained as described previously.[4]

For the gamma ray resonance measurements, a strong (≈100 mCi) ^{57}Co/Rh source was used at room temperature in connection with a fast proportional counter able to handle input rates in excess of 10^5 Hz. The problem of the efficient detection of the resonantly scattered 14.4 keV gamma radiation in the presence of As is, of course, exacerbated by the reduction in the recoil-free fraction with increasing temperature. To obtain reasonably reliable data, in excess of 5×10^7 counts per channel were scaled at the higher temperatures indicated above. Temperature control was maintained by use of a regulated proportional feedback circuit, and temperatures maintained at better than ±0.2 degrees over the data collection interval. Spectrometer calibration was effected before and after the data collection period, using a standard α-Fe foil at room temperature, and all IS values are quoted with reference to the centroids of these spectra. Data reduction was effected as detailed earlier.[3,4]

The DSC data were acquired using a Mettler Toledo Model DSC30 differential scanning calorimeter at heating and cooling rates of 2 and 5 degrees per minute over the temperature interval $173 \leq T \leq 308$ K.

Acknowledgments

The authors are indebted to Ms. Sigalit Gura of Bar Ilan University for the DSC measurements, and to Prof. I. Nowik for helpful discussions concerning data reduction. This research was supported in part by the Israel National Academy of Science.

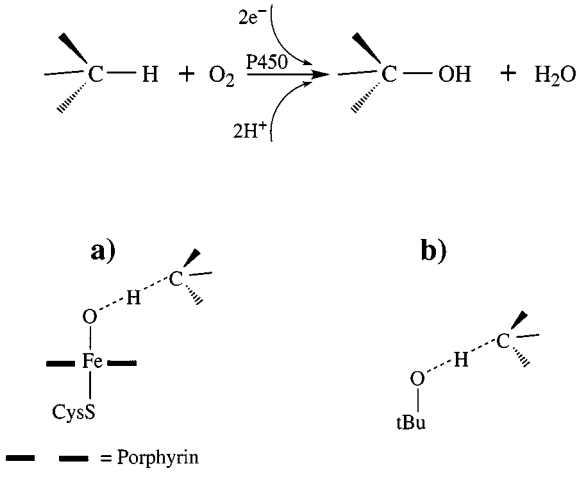
Alkane Hydroxylation by Cytochrome P450: Is Kinetic Isotope Effect a Reliable Probe of Transition State Structure?



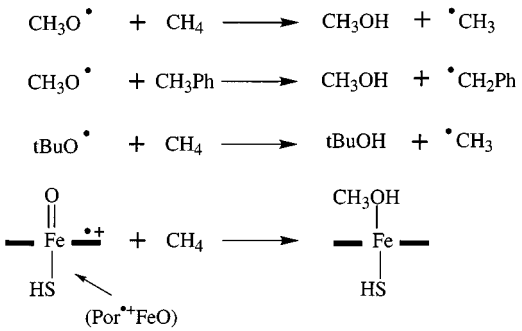
François Ogliaro,[a] Michael Filatov,[a] and Sason Shaik*[a]

Keywords: Density functional calculations / Isotope effects / Cytochrome P450 / Hydroxylation / Metalloenzymes

Computed kinetic isotope effect (*KIE*) values for methane hydroxylation by Cytochrome P450, in both high- and low-spin states, compare well with *KIE*'s for model hydrogen abstraction reactions, thereby demonstrating the utility of *KIE* as a mechanistic probe and supporting a two-state-rebound mechanism.

Introduction

Kinetic Isotope Effect (*KIE*) has been used extensively as a mechanistic probe in alkane hydroxylation by Cytochrome P450, Scheme 1.[1−5] In view of the importance of the process, and the questions which still surround its mechanism, it is deemed essential to establish the mechanistic significance of *KIE* by theoretical means in a manner that can be related to experimental measurements and mechanistic questions.



Scheme 1. Alkane hydroxylation by Cytochrome P450: **a**) and **b**) describe the proposed isostructural transition states based on kinetic isotope effect studies[6]

Let us first mention experimental data which form the primary motivation for this study. Thus, Dinnocenzo-Jones and co-workers have investigated the *intrinsic* $KIE_{H/D}$, for C−H vs. C−D hydroxylation[6] in a series of substrates undergoing P450 hydroxylation vis à vis hydrogen abstraction by the tertiary butoxyl radical. The $KIE_{H/D}$ data for the two processes were found to exhibit a good linear correlation as well as a virtual identity of the individual $KIE_{H/D}$ values for hydrogen abstraction and P450 oxidation of each substrate. These findings suggest, in agreement with earlier conclusions by Meunier et al.,[4] that the transition state for the bond activation step of P450 hydroxylation possesses a structure with a co-linear O−H−C moiety, as in a hydrogen abstraction process (**a** and **b**, Scheme 1). This structural feature of the transition state supports the "rebound" mechanism of alkane hydroxylation by P450.[1] However, since the rebound mechanism has been questioned by recent mechanistic investigations,[7,8] theoretical calculations are necessary to assess the mechanistic utility of the Dinnocenzo-Jones concept as a means to probe transition state structure.

To tackle this problem, we carried out density functional calculations of $KIE_{H/D}$ in the model hydroxylation reaction, Scheme 2, where methane is used as a substrate and the ferryl-oxene oxidant ($Por^{\bullet+}FeO$) carries a simplified thiolate ligand.[9,10] These $KIE_{H/D}$ values are compared with three model hydrogen abstraction processes by methoxyl and tertiary-butoxyl radicals, using methane and toluene as substrates. The mechanism for methane hydroxylation by ferryl-oxene was determined in recent work,[9,11] and the results are schematized in Figure 1. It was found that hydroxylation proceeds by a two-state-rebound mechanism of the high-spin (HS) quartet state and the low-spin (LS) doublet state, both nascent from the corresponding states of ferryl-oxene.[9,11] The processes exhibit two-phases with distinct atomic rearrangements; C−H bond activation and rebound. The bond activation takes place via two closely lying transition states ($^{4,2}TS_H$). Subsequently, the HS reaction proceeds to form an iron-hydroxo intermediate and a $CH_3^{\cdot}$ radical with a significant barrier for rebound. On the other hand, the ^2TS_H transition state collapses to alcohol products in a virtually barrier-free fashion, making the LS process effectively concerted.[9,11] In the present study we determine $KIE_{H/D}$ values for both HS and LS surfaces. These results are compared with the corresponding $KIE_{H/D}$ values of the radical abstraction reactions (Scheme 2), and enable us to assess the Dinnocenzo-Jones method,[6] and answer the title question.

Scheme 2. Model reactions for kinetic isotope effect calculations

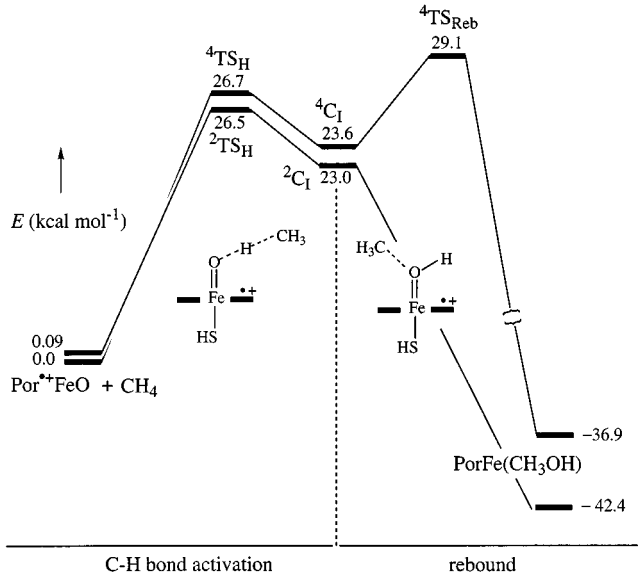

Figure 1. Calculated two-state rebound mechanism for methane hydroxylation by a model ferryl-oxene

Results and Discussion

All calculations were done with the GAUSSIAN98 package of programs.[12] The hybrid (HF/DFT) density functional UB3LYP calculations[13] was used. The Los Alamos effective core potential coupled with the double-zeta LACVP basis set[14] on iron and the 6−31G basis[12] for the rest of the atoms (hence, ECP+LACVP-6−31G). Geometries for all the species were fully optimized without symmetry constraints.[9,11] Here, the reactants, transition states, intermediates and alcohol products for all processes in Scheme 2 were ascertained by frequency calculations. Possible dependence of the KIE on the basis set was tested for the model hydrogen abstraction reaction by the alkoxyl radicals. Semiclassical *KIE* values[15] were determined from the Eyring equation using free energies of activation. Tunneling corrections[15] of the semiclassical *KIE* values were examined using three different models: the asymmetrical Eckart potential model,[15,16] the Bell model[15,16] and the Wigner model.[15,16]

Figure 2 shows essential features of the O−H−C portions of the transition states for the HS and LS bond activation, $^{4,2}TS_H$, and the model transition states for hydrogen abstraction by methoxyl and tertiary butoxyl radicals, $^2TS_{MeO}$, $^2TS_{Tol}$, and $^2TS_{tBuO}$. The latter three transition states are seen to be slightly more "central" than the P450 transition states, but otherwise the four transition states are similar. In all the structures, C−H cleavage is significant and the O−H−C portion is close to being linear. A negative spin density on the hydrogen flanked by positive densities on the heavy atoms is a mark of three-electron delocalization over three centers. The observation of such a feature in the transition states shows that all of them involve three electrons delocalized in the O−H−C portion, thereby emphasizing the common electronic structure shared by these transition states. This similarity supports the concept of Dinnocenzo-Jones and co-workers[6] that the hydrogen abstraction reaction by *t*BuO· models the bond activation in C−H hydroxylation by Cytochrome P450.

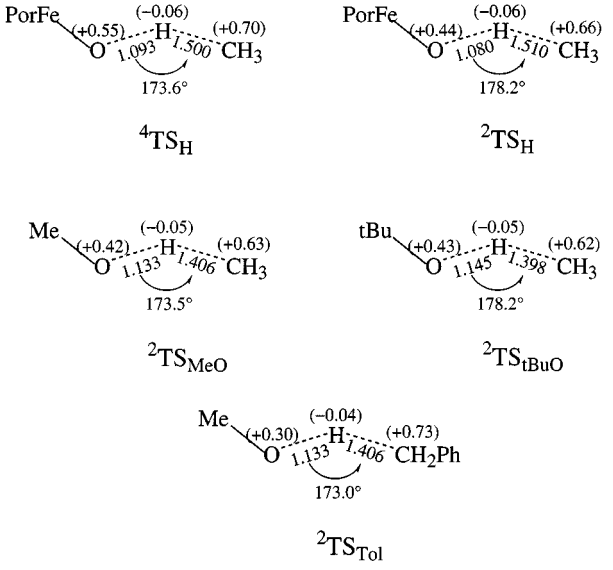

Figure 2. Transition state structures for the model reactions in Scheme 2; data in parentheses correspond to group spin densities; the spin densities on the oxygen atom P450 transition states ($^{2,4}TS_H$) are atomic spin densities and do not include the density on the rest of the species (hence the sum is not unity)

Table 1 shows computed $KIE_{H/D}$ for the four reactions; semiclassical values (3rd line), as well as tunneling corrected ones (fourth, fifth and sixth lines). As can be seen from the semiclassical values for the alkoxyl radicals, improvement of the basis set increases the $KIE_{H/D}$ values by less than 5%. Changing the substrate from methane to toluene has a small effect too (*ca* 15%). Due to the size of the problem, we cannot upgrade the frequency calculations for the P450 reactions, but the preceding comparisons indicate that the ECP+LACVP-6−31G results can be regarded with credence.

As shown in Table 1, the approximate tunneling corrections are extremely sensitive to the imaginary frequency of the transition state. All three different types of tunneling corrections agree with one another for the imaginary fre-

quencies below ca. 1000 cm^{-1}, but show strong basis set- and model dependence for higher frequencies. Apparently, such situations cannot be adequately treated by the one-dimensional tunneling corrections. Unfortunately, the size of the P450 species does not allow us to perform sophisticated calculations of the tunneling. However, for P450 situations, the tunneling correction for the three models, changes the $KIE_{H/D}$ values by less than 20% (see Table 1). Thus, tunneling has a modest effect on the $KIE_{H/D}$ values, and the semiclassical $KIE_{H/D}$ values may be used for comparison with the experiment.[6] A similar estimation of the role of tunneling in this reaction has been done by Meunier et al.[4]

The Dinnocenzo-Jones[6] $KIE_{H/D}$ values for hydrogen abstraction from toluene and *p*-xylene by *t*BuO$^{\cdot}$ are 6.0 ± 0.2 and 6.3 ± 0.3, respectively, compared with 5.9 ± 0.35 and 6.4 ± 0.90 for the corresponding P450 hydroxylations. The average computed $KIE_{H/D}$ for P450 hydroxylation is only 5−15% lower than the corresponding values for the hydrogen abstraction by alkoxyl radicals. Considering the spread of the experimental values, of 10−15%, our computed results exhibit a reasonable match between the $KIE_{H/D}$ values for hydrogen abstraction by alkoxyl groups and those for the bond activation step in P450 hydroxylation. The common features of transition state structures, discussed in Figure 2, and the similarity of $KIE_{H/D}$ values support, therefore, the mechanistic conclusion of Dinnocenzo and Jones[6] based on $KIE_{H/D}$ profiles of P450 C−H hydroxylation vis à vis a model hydrogen-abstraction reaction. The results indicate that the kinetic isotope effect can serve as a reliable probe of the transition state structure in P450 hydroxylation, and support the rebound mechanism.[1]

It is interesting to apply these results on the $KIE_{H/D}$ profiles to another situation where the deuterium substitution comes into play. Recently, Newcomb and co-workers[17−19] have shown that a substitution of the CH_3 group of **1**, Scheme 3, by CD_3, changes the regioselectivity by an order of magnitude, from a methyl to a phenyl oxidation ("metabolic switching"). However, the amount of rearrangement due to C−H hydroxylation of **1**, measured by the ratio of cyclic to acyclic products (*C*/*A*), exhibits a small isotope effect, if any.[17,18] The metabolic switching implies a large *KIE* on the C−H hydroxylation in agreement with independent measurements[1−5] of internal *KIE* values. What could then be the mechanistic significance of a small product isotope effect on the *C*/*A* ratio? Is it always going to be small, or will it change, and if so what factors govern its change?

Scheme 3. Results of oxidation of probe **1** by Cytochrome P450 [17−19]

From mutation studies, Newcomb[19] has concluded that probe **1** undergoes C−H hydroxylation mostly, if not exclusively, by ferryl-oxene. If the hydroxylation occurs by the classical rebound mechanism with a single oxidant species, where the oxidant participates with a single reactive state and produces free radicals in the first step of the reaction, a constant *C*/*A* value (subject only to secondary isotope effects) will always result. However, as already mentioned, this scenario faces difficulties to account for the trend of radical lifetimes and for the incomplete scrambling often observed.[7,8]

These difficulties can be circumvented in the two-state-rebound mechanism. In this scenario (Figure 1), rearrangement occurs only on the HS surface which exhibits a barrier for the radical rebound.[9,11] In the event where the ferryl-oxene oxidant engages primarily or exclusively in C−H hydroxylation,[20,21] the isotope effect on the *C*/*A* ratio of a probe like **1** will be gauged by the ratio of the isotope effects for the HS and LS processes.[20,21] In the extreme situations, where the kinetic isotope effects for the HS and LS processes are very different, i.e., either $(KIE_{H/D})^{HS} >> (KIE_{H/D})^{LS}$ or $(KIE_{H/D})^{HS} << (KIE_{H/D})^{LS}$, replacement of the methyl group by deuteriomethyl will considerably slow down either the HS or the LS processes, thereby causing the $(C/A)_{3D}$ ratio to either increase or decrease dramatically relative to $(C/A)_{3H}$. Thus, a significant product isotope effect is expected under such conditions. In contrast, identical $KIE_{H/D}$ values for the HS and the LS processes can lead to a constant *C*/*A* ratio (neglecting secondary isotope effect).[20] The $KIE_{H/D}$ values in Table 1 for the HS and the LS processes are not identical, however they differ by only 15% of each other. If these *KIE* results are relevant to the probe substrate **1** in Scheme 2, they would predict a small

isotope effect on the *C*/*A* ratio,[21] as is found experimentally.[17]

It is important to emphasize that the near equality, $(KIE_{H/D})^{HS} \approx (KIE_{H/D})^{LS}$, in our calculation arises due to the structural similarity of the corresponding transition-state structures for the two states (Figure 2). The HS and LS transition structures have been predicted before to depend on the donor ability of the substrate (probe) and on the binding capability of the cysteinato ligand which can introduce structural variations between the two paths.[9,11] Thus, the two-state-reactivity scenario predicts some dependence of the product isotope effect on the *C*/*A* ratio on these factors, as well as on the rates of rearrangement and rebound of the free radical clock.[20] No such dependencies will be expected when the rebound mechanism proceeds on a single state surface and with a single oxidant.

Conclusions

In summary, the combination of a small isotope effect on the *C*/*A* ratio in P450 hydroxylation, along with the match of *KIE* values to model hydrogen-abstraction reactions have jointly a clear mechanistic significance in terms of two-state reactivity.[22,23] Other scenarios are possible; for example, a large product isotope effect on the *C*/*A* ratio will indicate either a more complex mechanistic scheme of two state reactivity,[21] or two-oxidants which participate in C−H hydroxylation.[7,8] It is hoped that this work will form the incentive to further articulate the various models and elucidate the mechanistic significance of *KIE* in P450 hydroxylation.

[1.04 ± 0.24 for racemic mixture of the probe, and 0.6−0.7 (±0.1) for the pure enatiomers (*R,R*)-**1** and (*S,S*)-**1**].The data seem to show an apparent discrepancy between the *C*/*A* ratios for the racemic mixture vis à vis the pure enantiomers. However, the uncertainties of the data are of the same order as the discrepancy.
[18] The *KIE* on the *C*/*A* ratio is more reliable than the KIE values on the methyl/phenyl oxidation ratios which may reflect selective binding [ref. 5].
[19] P. H. Toy, M. Newcomb, M. J. Coon, A. D. N. Vaz, *J. Am. Chem. Soc.* **1998**, *120*, 9718−9719.
[20] Using a simple two-state C−H hydroxylation scheme[11] with spin-state crossing leads to an equal partition of the HS and LS paths, one gets the following expression for the product isotope effect on the *C*/*A* ratio, $(C/A)_{3H}/(C/A)_{3D} = (KIE_{H/D})^{LS}/(KIE_{H/D})^{HS}\{[1+\xi_H]/[1+\xi_D]\}$, where $\xi_H = (k_{HS}{}^H/k_{LS}{}^H)[k_{OH}/(k_r+k_{OH})]$ and $\xi_D = (k_{HS}{}^D/k_{LS}{}^D)[k_{OH}/(k_r+k_{OH})]$. The various terms refer to Figure 1, as follows: k_{OH}: the rebound rate on the HS surface; k_r: the rate of free radical rearrangement on the HS surface. k_{HS} and k_{LS} are the rate constants of the bond activation of the HS and LS surfaces, where the superscripts H and D refer to the hydrogenic and deuterio isotopomers. The situation in which $\xi_H \approx \xi_D$ means, necessarily, that $(KIE_{H/D})^{LS} \approx (KIE_{H/D})^{HS}$, and leads to $(C/A)_H/(C/A)_D \approx (KIE_{H/D})^{LS}/(KIE_{H/D})^{HS} \approx 1$.
[21] If, however, ferryl oxene is engaged significantly also in phenyl oxidation, the kinetic expression becomes more complex. Then the $(C/A)_{3H}/(C/A)_{3D}$ ratio can be significantly different than unity, even if the *KIE's* are the same for the HS and LS path. We thank J. P. Jones for communicating this point.

Cobalt-Assisted Condensation of 2-Butanone Oxime and Acetone: Synthesis and X-ray Structure of the Novel Acetaldiimine Complex $[CoI_2\{((CH_3CH_2)(CH_3)C{=}NO)_2C(CH_3)_2\}]$

Jean-Cyrille Hierso,[a] Dianne D. Ellis,[b] Anthony L. Spek,[b] Elisabeth Bouwman,*[a] and Jan Reedijk[a]

Keywords: Cobalt / Ketoximes / Ketones / Template synthesis / Metallacycles / Acetaldiimine

The synthesis of the first acetaldiimine cobalt complex and its full characterisation are reported. The nitrogen-bonded chelate complex $[CoI_2\{((CH_3CH_2)(CH_3)C{=}NO)_2C(CH_3)_2\}]$ is obtained in high yield from the reaction of 2-butanone oxime with cobalt iodide dihydrate in acetone, in the presence of trimethyl orthoformate as dehydrating agent. A single-crystal X-ray structure determination, infrared spectroscopy and mass spectrometry analyses confirm the formation of a new ligand in situ from the addition of an acetone molecule to two oximato species. This cobalt-mediated reaction provides an indirect proof for the existence in solution of monodentate *N*-bonded cobalt–ketoxime species.

Introduction

The chemistry of oxime/oximato transition metal complexes is rich and has shown a great variety of reactivity modes, as demonstrated in the review by Kukushkin et al.[1] Simple oxime complexes[2] (or mono-oximes as opposed to chelating dioximes) are known to form with palladium, nickel[3] or platinum, for which they have been thoroughly studied.[4] These compounds display generally a strict monodentate coordination to the metal by bonding through the nitrogen centre. To date, the analogous cobalt-ketoxime complexes still remain unknown, and only a single cobalt-aldoxime complex has been reported which displays monodentate coordination.[5] Thus, although several hundred complexes of cobalt-dioximes have been identified, the stabilisation and proper description of cobalt mono-ketoxime complexes, especially monodentate ones (either N- or O-bonded), still remains challenging. In the course of our attempts to isolate new cobalt species with simple ketoxime ligands from cobalt halide salts,[6] we have identified an as-yet-unknown reactivity of cobalt allowing the addition of 2-butanone oxime to acetone.

Results and Discussion

The title compound $[CoI_2\{((CH_3CH_2)(CH_3)C{=}NO)_2C(CH_3)_2\}]$ (**1**) was prepared from the reaction of $CoI_2{\cdot}2H_2O$ with a solution of $(CH_3CH_2)(CH_3)C{=}NOH$ in acetone, in the presence of trimethyl orthoformate. The new compound was characterised by infrared spectroscopy, elemental analysis, mass spectrometry and single-crystal X-ray crystallography. A fully labelled representation of the molecular structure of the complex is given in Figure 1. The cobalt(II) atom is surrounded by two iodide and two nitrogen atoms in a distorted tetrahedral environment. The two nitrogen atoms linked to cobalt are part of a novel chelating ligand, which has been formed in situ from two 2-butanone oxime molecules bridged by a $-C(CH_3)_2-$ unit. The six-membered ring formed by the acetaldiimine ligand at cobalt forces the N(1)−Co(2)−N(2) angle to contract to 96.31(13)°, whilst the angle I(1)−Co(1)−I(2) opens to 117.32(2)°, resulting in a distorted tetrahedron around Co. The Co−I distances [Co(1)−I(1) 2.5508(7), Co(1)−I(2) 2.5802(6) Å] are in the range of values reported for CoI_2 in a tetrahedral environment.[7] The bond distances in the acetaldiimine ligand are in very good agreement with those of the related compound previously described in the crystallographic literature [1,1-bis(1-phenylethylidenaminooxy)-ethyl]benzene.[8] The six-membered Co(1)−N(1)−O(1)−C(2)−O(2)−N(2) ring adopts a flattened boat conformation at the temperature of measurement. The chair-like conformation for this kind of metal−ligand rings is common,[9] whereas boat forms are rarely observed.[10]

The infrared measurements confirmed the chelating cyclization of the 2-butanone oxime molecules by both the disappearance of the oxime OH stretching vibration at 3214 cm^{-1}, and the large shift of the C=N stretching vibration from 1664 cm^{-1} in the free simple oxime to 1620 cm^{-1} in the bound acetaldiimine. From electrospray mass spectrometry experiments on **1**, the parent peak has been found at m/z = 215; this value corresponds to the ionic fragment $[H(CH_3CH_2)(CH_3)C{=}NO)_2C(CH_3)_2]^+$, which confirms not only the formation but also the stability of the acetaldiimine ligand.[11] Our attempts to isolate the cobalt chloride and cobalt bromide analogues of **1** have failed, producing sticky

oils which are difficult to characterise. The van der Waals volume of the iodide ions, which is considerable larger than those of the smaller halide analogues, possibly permits the crystallisation of the complex. The tetrahedral geometry around cobalt is confirmed by Vis-NIR spectroscopy (typical broad band split in three, centred around 7000 cm^{-1} and a more intense band around 15000 cm^{-1}).

The global equation for the reaction leading to the acetaldiimine can be written as:

$$2\ RR'C{=}N{-}OH + (CH_3)_2C{=}O \rightleftarrows H_2O + RR'C{=}N{-}O{-}C(CH_3)_2{-}O{-}N{=}CR'R$$

The use of trimethyl orthoformate, which reacts readily with water molecules to form methanol and methyl formate,[12] displaces the above equilibrium to the right toward the formation of the adduct. Experiments with 2-butanone oxime and acetone (four equivalents) refluxed at 80 °C for three hours in either an acidic (pH = 3), neutral, or basic (pH = 12) medium, in the absence of the cobalt salt, do not show any changes in the infrared and ^1H NMR spectra of the mixture. Similar attempts conducted in the presence of trimethyl orthoformate also failed to yield the acetaldiimine, showing the need for cobalt in order to perform the condensation of the oxime and acetone.

Oximes, being weak oxygen acids, can react with bases and undergo deprotonation. Literature reports state that the nitrogen coordination of oxime ligands to a metal centre leads to a large increase in their acidic character, and the formation of oximato ligands is favourable upon coordination. It has also been shown that oximes behave as nucleophiles towards other unsaturated species such as olefins, arenes or ketones involving nucleophilic addition by either the O or the N atom.[1] From these data the following hypothesis can be proposed concerning the global mechanism of formation of the ligand and the complex: (i) the 2-butanone oxime molecules could coordinate to the cobalt centre giving a strong acidic character at their OH hydrogen atoms, (ii) the electrophilic attack of an acetone molecule towards the activated oxygens in the coordination sphere of the metal could then take place, the formation of the adduct being favoured by the progressive consumption of water by reaction with trimethyl orthoformate (without this reactant no compound has been isolated). Following this idea, the formation of the complex should be favoured in alkaline medium and disfavoured in acidic medium. Indeed, the synthesis conducted with addition of 0.1 mL of 1 M NaOH solution in water leads to **1** precipitating quickly as a fine powder, whereas from an acidic medium (addition of 0.1 mL of HCl in water at pH = 2), compound **1** could not be isolated. It is worthwhile to note that conventional acetal formation is acid-catalysed and does not proceed under alkaline conditions, contrary to this metal-mediated reaction. The qualitative observations reported above support the

formation in solution of intermediary N-bonded monodentate cobalt-ketoxime species, explaining the OH acidic activation towards the oximato species. However, these N-bonded monodentate cobalt-ketoxime complexes still have to be isolated.

Only a few other examples of the metal-assisted addition of oximes to compounds containing double or triple bonds are described in the literature.[13,14] Amongst these the most notable one was described by Kukushkin et al.:[15] from the reaction of the platinum(II) complex $[PtCl_2((CH_3)_2C{=}NOH)_2]$ with *m*-chloroperoxybenzoic acid in acetone the *N*,*O*-chelating complex $[PtCl_2\{OC(CH_3)_2ON{=}C(CH_3)_2\}_2]$ was obtained which contains two five-membered Pt−N−O−C−O rings. The most likely explanation for the formation of the product was proposed to be the coordination of acetone molecules at vacant sites on platinum, followed by ring closure with neighbouring N-coordinated monodentate oxime ligands. Here, the isolated platinum bis(ketoxime) species is the starting product, and, similarly, a cobalt-ketoxime compound is assumed to be an intermediate in the formation of **1**.

In conclusion, this work describes a novel template reaction of acetone with two ketoxime molecules, forming a symmetric chelating diimine ligand with an acetal backbone. Applications of this template reactivity in syntheses of new diimine ligands can be of interest in comparison to the "organic" routes reported so far,[16] and might be further explored.

Experimental Section

Acetone was distilled, dried and degassed over molecular sieves under an argon atmosphere. Other reactants and solvents were used as received from commercial sources. Vis-NIR spectra were obtained on a Perkin−Elmer Lambda 900 spectrophotometer using the diffuse reflectance technique with MgO as a reference. Infrared spectra were obtained on a Perkin−Elmer Paragon 1000 FTIR spectrophotometer equipped with a Golden Gate ATR device, using the reflectance technique (4000−500 cm^{-1}, res. 4 cm^{-1}). NMR measurements were performed at 300.13 MHz on a Bruker 300 DPX spectrometer. Mass spectrometry and elemental analyses were performed in the analytical service department of the Gorlaeus laboratories.

IR of 2-Butanone Oxime: Selected bands (cm^{-1}): $\tilde{\nu}$ = 923 vs/br, 975 vs; 1072 s, 1096 s, CC stretching; 1368 s, 1458 s, CH bending; 1664 m, C=N stretching; 2880 m, 2972 m, sh, CH stretching; 3214 s, br, OH stretching.

Synthesis of $[Co\{((CH_3CH_2)(CH_3)C{=}NO)_2C(CH_3)_2\}I_2]$ (1): $CoI_2{\cdot}2H_2O$ (0.65 g, 1.9 mmol) in an Erlenmeyer flask was covered by 2.5 mL of trimethyl orthoformate and then dissolved in 10 mL of dry acetone to give a bright deep green solution. An excess of 2-butanone oxime (0.60 g, 7.3 mmol) in 15 mL of dry acetone was prepared. The two solutions were boiled and mixed, the mixture was boiled for 5−6 minutes to reduce the volume to approximately 10 mL. After 24 h standing in air, almost all the residual solvent was evaporated and bright green needles were formed. The crystals were washed with a minimum of acetone, and quickly with 2 × 1 mL of diethyl ether, then with pentane, resulting in 0.78 g of complex (yield 80%) as single crystals suitable for X-ray diffraction measurements. $C_{11}H_{22}CoI_2N_2O_2$ (527.04): calcd. C 25.07, H 4.21, N 5.32, Co 11.18; found C 24.94, H 3.96, N 5.32, Co 11.42. − IR (cm^{-1}): $\tilde{\nu}$ = 891 vs, 933 vs; 1148 s, CO stretching; 1366 s, 1377 s, 1456 s, CH bending; 1620 s, C=N stretching; 2972 m, sh, CH stretching. Vis-NIR (solid state, cm^{-1}): $\tilde{\nu}$ = 6900, 7400, 9600, 14900, 28000.

X-ray Crystal Structure Analysis of 1: $C_{11}H_{22}CoI_2N_2O_2$, M = 527.04, dark green needles (0.21 × 0.09 × 0.09 mm^3), monoclinic, $P2_1/c$ (no. 14), a = 10.9678(3), b = 12.0102(4), c = 15.7274(4) Å, β = 119.924(2)°, V = 1795.52(10) $Å^3$, Z = 4, D_c = 1.950 $g{\cdot}cm^{-3}$, $F(000)$ = 1004, μ(Mo-K_α) = 4.392 mm^{-1}, 11288 reflections measured, 4509 independent, R_{int} = 0.036. Data were collected on a Nonius Kappa CCD area detector with rotating anode, λ(Mo-K_α) = 0.71073 Å, T = 150 K, using a graphite monochromator. Absorption corrections based on multiple measured equivalent reflections were applied. The structure was solved by Patterson techniques (DIRDIF-99[17]) and refined using full-matrix least-squares on F^2 (SHELXL-97[18]). All non-hydrogen atoms were refined with anisotropic displacement parameters, hydrogen atoms were located at calculated positions and refined riding on their carrier atoms. Refinement converged at $R1$ = 0.0331 [for 3929 reflections with $F_o > 4\sigma(F_o)$], $wR2$ value of 0.0740 (S = 1.193). Geometric calculations and molecular graphics were performed with PLATON.[19] One of the butane moieties is disordered due to an exchange of the methyl, C(30), and ethyl, C(32)−C(33), groups (major site occupancy 80% is shown in Figure 1).

Crystallographic data (excluding structure factors) for the structure in this paper have been deposited at the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-144112. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax:+44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Influence of Charge Distribution on the Properties of Keggin- and Dawson-Type Heteropolyanions

Bineta Keita,[a] Yu Wei Lu,[a] Louis Nadjo,*[a] and Roland Contant[b]

Keywords: Polyoxometalates / Polyanions / Lacunary species / Cyclic voltammetry / Charge distribution / Acid-base equilibria

The cyclic voltammetric behavior of selected Keggin- and Dawson-type heteropolyanions has been studied as a function of electrolyte composition. The buffer capacity of the electrolyte is shown to be an important parameter that can be used to reveal the symmetry or dissymetry in charge distribution within each oxometalate. A fully symmetrical heteropolyanion like $[P_2W_{18}O_{62}]^{6-}$ exhibits a uniform protonability, while its α_1 and α_2 lacunary derivatives present a donor set of hard oxide ions with stepwise acid-base equilibria. The behavior of these sites is revealed readily in unbuffered or poorly buffered media at pH = 3, and is ascribed to the change in symmetry of charge distribution in the molecules. It is shown that cations other than the proton, even in very high excess, fail to give rise to the classical voltammograms of lacunary heteropolyanions. The same behavior also appears in $\alpha_2[Mo_2P_2W_{15}O_{61}]^{10-}$, $\alpha[PW_{11}O_{39}]^{7-}$, $\alpha[SiW_{11}O_{39}]^{8-}$, $[H_2P_2W_{12}O_{48}]^{12-}$, and, to a lesser extent, in $\alpha_2[Ni(H_2O)P_2W_{17}O_{61}]^{8-}$ and $\alpha_2[Zn(H_2O)P_2W_{17}O_{61}]^{8-}$. The analogy in the cyclic voltammograms of most dication-substituted heteropolyanions with those of the precursor lacunary species could thus be explained.

Introduction

Interest in the study of oxometalates remains at a high level due to their wide range of properties in several fields.[1−3] In particular, the main results from electrochemistry investigations by this group and from others, which establish unambiguously the existence of catalytic properties for heteropolyanions towards numerous chemicals in solution, have been reviewed recently.[4] New results concern the ability of one- and two-electron reduced heteropolyanions of the Keggin and Dawson series to convert quantitatively NO into N_2O in acidic aqueous media.[5] Unsubstituted and lacunary as well as transition metal cation substituted heteropolyanions of these two groups prove active for this purpose. Such achievements have stimulated our interest in the synthesis of heterometal-substituted heteropolyanions of these two families, with the aim of investigating their new electrocatalytic behavior.[6−10] Furthermore, the electrochemical characterization of these compounds reveals that most of them cannot be considered as "saturated" species and that the appropriate comparison remains between the cyclic voltammograms of the metal ion-substituted and the lacunary precursor oxometalates.[6,8−10] In the course of these comparisons, a strong sensitivity of the shapes, peak potential locations, and current intensities of the cyclic voltammograms to changes in the electrolyte was observed. On further scrutiny it was found that the influence appears to increase as the nominal charge of the heteropolyanion increases. Various lines of experimental evidence confirm the very low surface charge density, at least for symmetrical saturated Keggin- and Dawson-type heteropolyanions.[11−14] For example, a simple linear variation of the first reduction potentials of $\alpha[XW_{12}O_{40}]^{n-}$ with the anion charge is observed under conditions without protonation.[2] Extension of the preceding remarks to the corresponding lacunary species and to their first transition metal ion-substituted derivatives do not seem straightforward, possibly owing to the change in symmetry of the charge distribution in the molecules in conjunction with the increase in the overall negative charge. The lacunary heteropolyanions are known to exhibit "a donor set of hard oxide ions, while the adjacent d^0 (Mo^{VI}, W^{VI}) atoms provide acceptor orbitals".[1,15,16] In contrast, the classical symmetrical heteropolyacids like $H_6P_2W_{18}O_{62}$, $H_6Mo_3P_2W_{15}O_{62}$, $H_3PW_{12}O_{40}$, and $H_4SiW_{12}O_{40}$, which can be considered as the precursors of the species under investigation, are strong acids with a uniform acidity.[17]

The aim of the present paper is to illustrate the behavior, in cyclic voltammetry, of selected representative lacunary heteropolyanions and of the corresponding metal ion substituted species in the presence of various electrolytes.

The Selection of Experimental Conditions

The following heteropolyanions were used: $\alpha[P_2W_{18}O_{62}]^{6-}$ (abbreviated as P_2W_{18}); α_1- and $\alpha_2[P_2W_{17}O_{61}]^{10-}$ (α_1- and $\alpha_2P_2W_{17}$); $\alpha[Mo_3P_2W_{15}O_{62}]^{6-}$ ($P_2W_{15}Mo_3$); $\alpha_2[Mo_2P_2$-

$W_{15}O_{61}]^{10-}$ ($\alpha_2P_2W_{15}Mo_2$); $\alpha[PW_{11}O_{39}]^{7-}$ (PW_{11}); $\alpha[SiW_{11}O_{39}]^{8-}$ (SiW_{11}); $[H_2P_2W_{12}O_{48}]^{12-}$ (P_2W_{12}); $\alpha_2[Zn(H_2O)P_2W_{17}O_{61}]^{8-}$ ($\alpha_2P_2W_{17}Zn$); $\alpha_2[Ni(H_2O)P_2W_{17}O_{61}]^{8-}$ ($\alpha_2P_2W_{17}Ni$). The preparation and characterization of these materials have already been described in detail.[6,8,9,18–21]

A priori, at least two antagonist influences due to the supporting electrolyte can be anticipated during the reduction of heteropolyanions: on the one hand, protonation and/or ion-pair formation with other cations, which might enhance the reduction kinetics; on the other hand, the anions of the electrolyte might counteract these reduction kinetics. It is desirable to maintain one of these influences constant for the study of the second one. First, sodium salts or, occasionally, lithium salts were used to maintain a constant cation concentration [M] = 0.4 M. In the cases in which the results are known, these two cations are not completely without action on the oxidized forms of several heteropolyanions; however, the stability constants of the corresponding complexes are rather small.[18] Even if a stronger association could be anticipated with the reduced forms of the heteropolyanions, the experiments described in the following pages indicate, as anticipated, that the interaction does not depend to an appreciable extent on the nature of these alkaline cations. This observation leaves room for the identification of other effects. Furthermore, the compounds under scrutiny in this work are sensitive to the concentration of protons. The corresponding saturated species react mostly by ECE- or EEC-type processes, with the C step usually being a protonation. Therefore, a constant pH = 3 value was selected throughout; in the present work we found this proton level high enough, in sulfate media, to favor the protonation of the reduced oxometalates over their ion-pairing with Na^+ or Li^+ cations, at least as far as the first redox system of the studied heteropolyanions is concerned. A detailed examination of the competition between protonation and ion-pairing of the reduced heteropolyanions is beyond the scope of this paper. Finally, our usual experimental conditions have been maintained in the present work, which is aimed first at confirming and expanding previous observations: This point essentially concerns the glassy carbon working electrode, which we have demonstrated to be suitable for the study of the electrochemical and electrocatalytic behaviors of heteropolyanions under a variety of experimental conditions.[5–10,22,23] Indeed, the present knowledge of the interfacial properties of glassy carbon is, at best, qualitative, even though several papers suggest that this electrode material could be used for kinetic studies.[11,24,25] Gold and platinum are well characterized but cannot be used throughout in experiments spanning a large potential domain in the relatively acidic media necessary for our studies.

Voltammetric Behavior of Selected Heteropolyanions in Several pH = 3 Media

Two lacunary heteropolyanions, $\alpha_2P_2W_{15}Mo_2$ and $\alpha_2P_2W_{17}$, were selected to illustrate the basic observations. Figure 1 (1A and 1B) shows the evolution of the corresponding cyclic voltammograms for $5\cdot10^{-4}$ M heteropolyanion in the presence of appropriate concentrations of Na_2SO_4, $NaClO_4$, $NaNO_3$, and NaCl as supporting electrolytes.

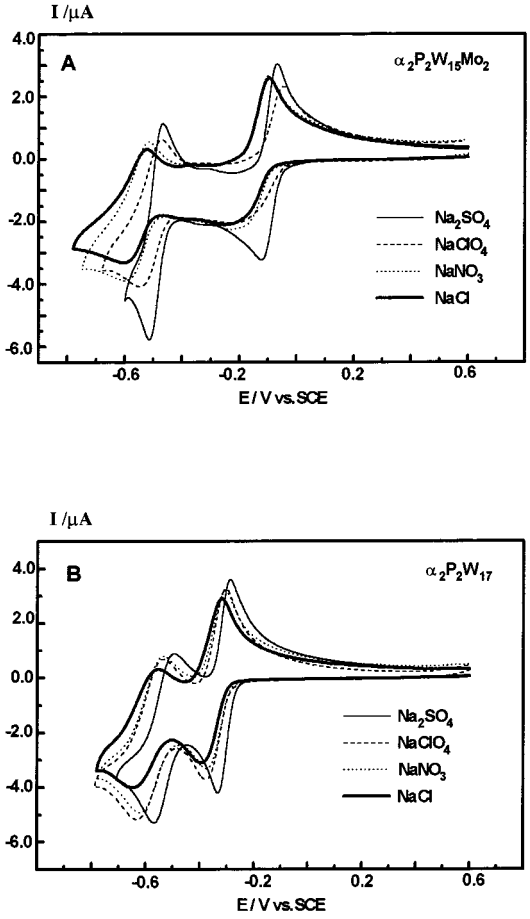

Figure 1. Cyclic voltammograms of a $5\cdot10^{-4}$ M solution of the relevant heteropolyanion in several pH = 3 media containing 0.4 M Na^+; scan rate: 10 mVs^{-1}; working electrode: glassy carbon

The potential domain is restricted to encompass the first two redox systems for each oxometalate. Figure 1 speaks for itself and only brief comments are necessary. However, the distortion is more marked in the cyclic voltammogram of $\alpha_2P_2W_{15}Mo_2$ than that of $\alpha_2P_2W_{17}$, even though qualitatively identical effects are observed. We note that the two waves are modified: taking the voltammogram in the sulfate medium as a reference, those in the presence of other salts show drawn out shapes, with smaller current intensities and peak potentials that are pushed in the negative direction. The concentration of Na^+ is 800 times that of the oxometalate. In this situation the ionic strength of the solution cannot be suspected to induce the observed phenomena. The nature of the anions of the supporting electrolyte is thus proposed as the relevant parameter. Furthermore, as these observations are made in the presence of a large excess of supporting electrolyte, it can be concluded that the effect of cations other than the proton is minimal in the reduction processes of these systems or largely counteracted by some anion effect. An attempt can be made to rationalize the difference in behavior between the two lacunary heteropolyanions by considering their respective basicities. The first

two-electron wave for $\alpha_2P_2W_{15}Mo_2$ in the sulfate medium (taken as a reference) features Mo-centered redox processes while that for $\alpha_2P_2W_{17}$ is W-centered. A report in the literature[26] suggests the reduced Mo-substituted site to be the stronger base of the two compounds. As a consequence, protonation and/or ion-pairing are easier in Mo-substituted complexes. Correlatively, a higher sensitivity of the latter compound to possible anion effects is not expected, a situation in contrast to that actually observed. Provisionally, comparison between α_1 and $\alpha_2P_2W_{17}$ shows the two compounds to behave in exactly the same way. However, not much work was carried out with the α_1 isomer due to its known relative instability under most of the conditions used in the present investigation. Further discussion of this system is postponed until the main parameters of this study emerge clearly.

Figure 2 and Figure 3 are helpful in this issue. Figure 2 shows the observations pertaining to three other lacunary species and to a Zn-substituted Dawson-type complex in the two electrolytes that give the most contrasting behavior.

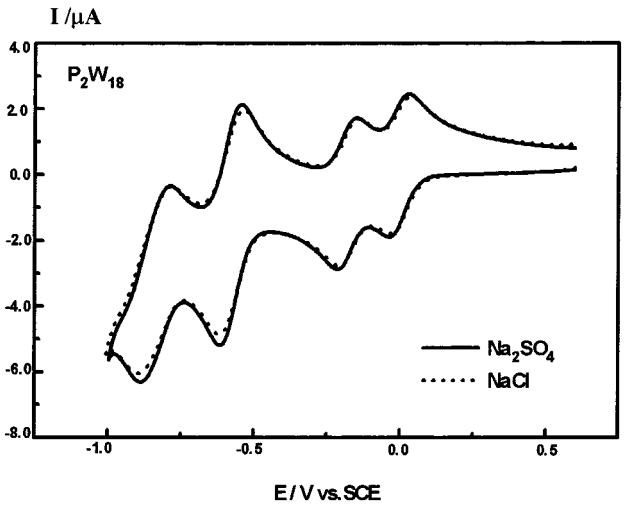

Figure 3. Cyclic voltammograms of a $5\cdot10^{-4}$ M $[P_2W_{18}O_{62}]^{6-}$ in two pH = 3 media containing 0.4 M Na^+; scan rate: 10 mVs^{-1}; working electrode: glassy carbon

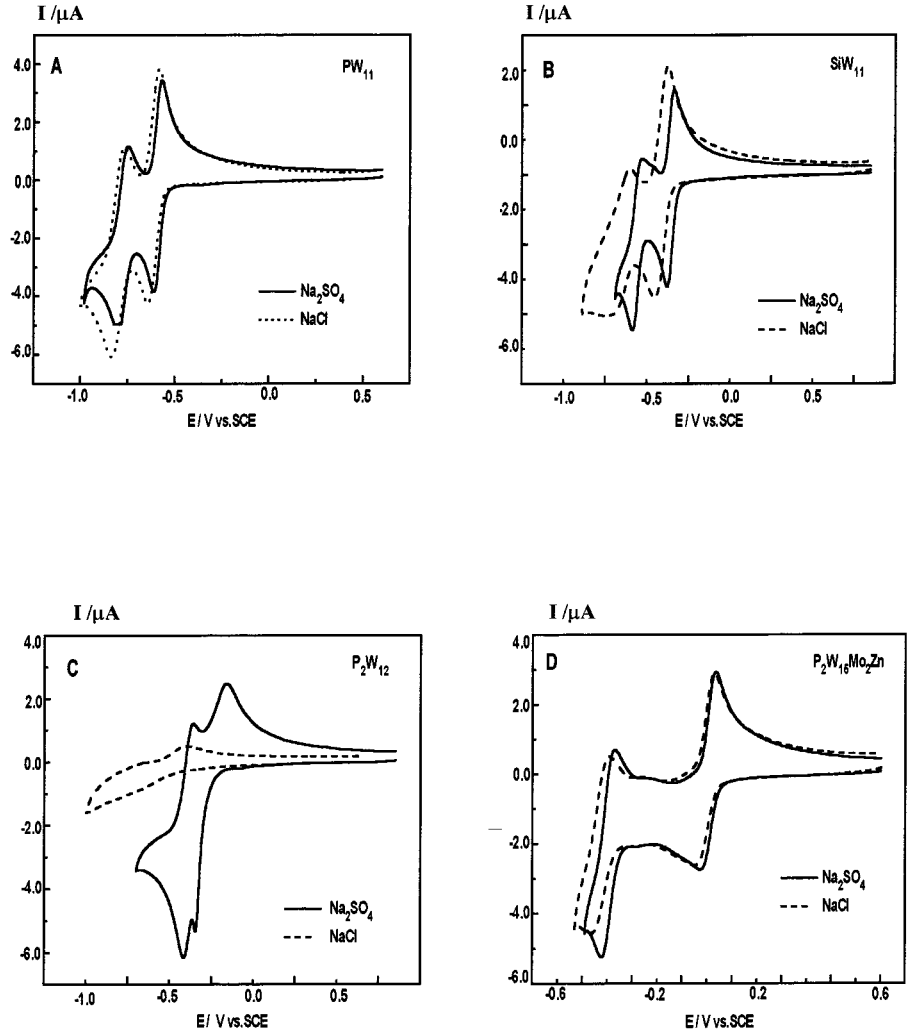

Figure 2. Cyclic voltammograms of a $5\cdot10^{-4}$ M solution of the relevant heteropolyanion in two pH = 3 media containing 0.4 M Na^+; scan rate: 10 mVs^{-1}; working electrode: glassy carbon

The previously observed effect also exists in this group, which contains two Keggin-type species. Even though the surface charge density varies from one component to the next, the structure of the heteropolyanion does not seem to constitute a relevant parameter. Strikingly, the intensity of the effect is greater as the nominal negative charge of the anion under scrutiny becomes larger. At least two details are worth noting and these will be elaborated in the following discussion: (i) the cyclic voltammogram of $[H_2P_2W_{12}O_{48}]^{12-}$ in NaCl solution vanishes almost completely; (ii) the behavior of $\alpha_2P_2W_{17}Zn$ also deserves emphasis in that as the volume increases, the nominal charge remains the same as SiW_{11} and a slightly smaller first peak potential shift is observed. Figure 3 compares the behaviors of P_2W_{18} in sulfate and chloride media and shows that no difference is observed. The same observation holds for $P_2W_{15}Mo_3$. This result is in agreement with the previously known behaviors of saturated heteropolyanions. Even though P_2W_{18} and $P_2W_{15}Mo_3$ are the less charged of the complexes in the present series, the main characteristic likely to bring about the difference in behavior in comparison with the others is the symmetry of the charge distribution in the saturated species.

The observations discussed above all converge to indicate the total nominal charge of each anion on the one hand and its distribution on the other, as two of the parameters that govern the shape and potential location of cyclic voltammetric waves. A second conclusion concerns the particular role of protons in the presence of large amounts of other cations, which failed to counteract the suggested anion effect. Could these observations be rationalized in the framework of the double layer theory? Some complementary experiments seem to contradict this possibility. For example, in a pH = 3 medium containing 0.1 M Na_2SO_4 + 0.2 M NaCl, the classical cyclic voltammograms known in sulfate media for $\alpha_2P_2W_{15}Mo_2$, $\alpha_2P_2W_{17}$, or P_2W_{12} are obtained almost exactly. More strikingly, upon addition of 0.1 M Na_2SO_4 to pH = 3 solutions containing 0.2, 0.3, or 1 M NaCl, the vanishingly small and drawn-out cyclic voltammogram of P_2W_{12} is immediately replaced by a well-defined pattern. In addition, the cyclic voltammograms depend on the concentration of the relevant heteropolyanion in solution. This behavior suggests a preeminent role for the proton and deserves further investigations, which are described in the following section.

Influence of the Proton to Heteropolyanion Concentration Ratio

To highlight the influence of this parameter, the following experiments were carried out with a proton to heteropolyanion concentration ratio from 4 down to 0.22 in most cases. Typically, the pH = 3 supporting electrolyte contains 0.2 M Na_2SO_4 and the concentration of the appropriate heteropolyanion varied from $0.25\cdot10^{-3}$ to $4.5\cdot10^{-3}$ M. Figure 4 and Figure 5 pertain to $\alpha_2P_2W_{15}Mo_2$ and $\alpha_2P_2W_{17}$, respectively. For the sake of clarity each figure is split into three parts.

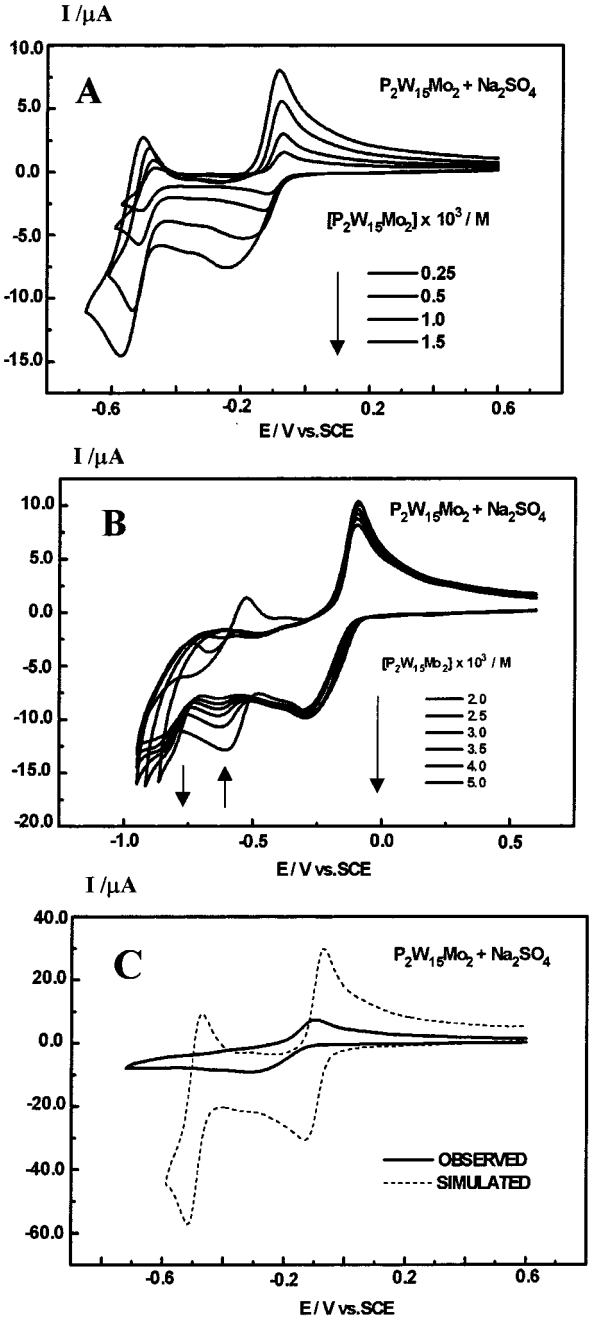

Figure 4. Cyclic voltammograms of several increasing concentrations of $\alpha_2[Mo_2P_2W_{15}O_{61}]^{10-}$ in 0.2 M Na_2SO_4 + H_2SO_4 (pH = 3 before addition of heteropolyanion); scan rate: 10 mVs^{-1}; working electrode: glassy carbon; A and B: the appropriate concentrations are indicated in the sketches; C: observed and simulated cyclic voltammograms for a concentration of $4.5\cdot10^{-3}$M $\alpha_2[Mo_2P_2W_{15}O_{61}]^{10-}$ in the initially pH = 3 medium; scan rate: 10 mVs^{-1}; working electrode: glassy carbon; for further details, see text

In Figure 4A the peak current intensities are strictly proportional to the analytical concentration of the heteropolyanion. This concentration domain is narrow, despite the presence of a high concentration of cations in the solution. Details in Figure 4B deserve particular attention. Upon in-

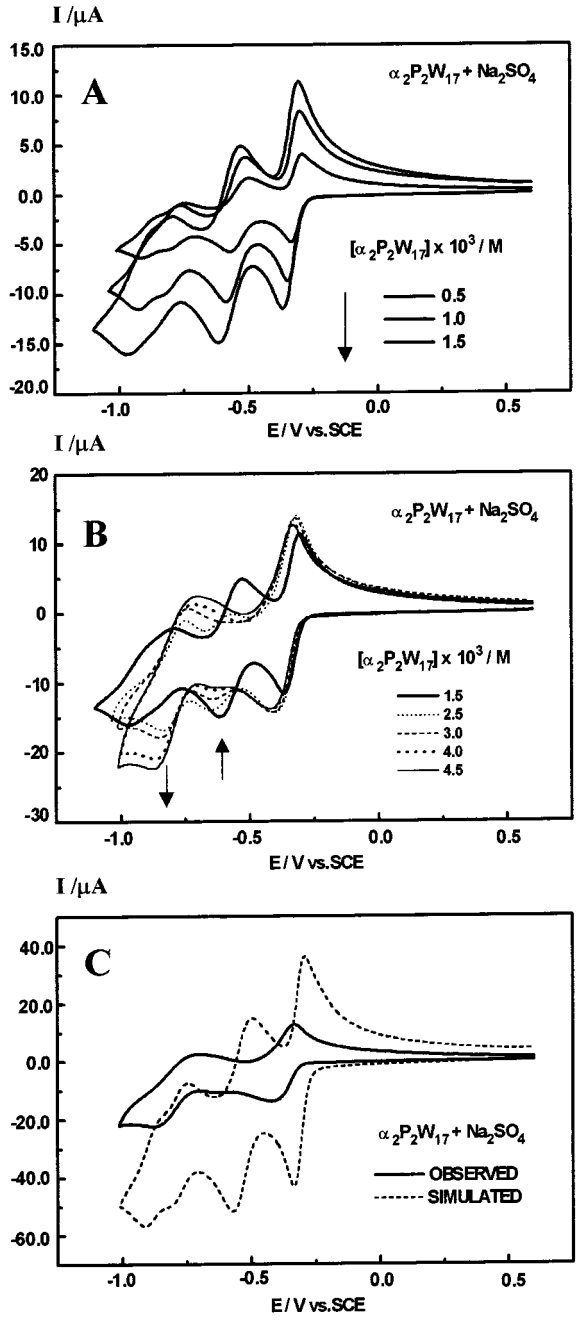

Figure 5. Cyclic voltammograms of several increasing concentrations of $\alpha_2[P_2W_{17}O_{61}]^{10-}$ in 0.2 M Na_2SO_4 + H_2SO_4 (pH = 3 before addition of heteropolyanion); scan rate: 10 mVs^{-1}; working electrode: glassy carbon; A and B: the appropriate concentrations are indicated in the sketches; C: observed and simulated cyclic voltammograms for a concentration of $4.5\cdot10^{-3}$ M $\alpha_2[P_2W_{17}O_{61}]^{10-}$ in the initially pH = 3 medium; scan rate: 10 mVs^{-1}; working electrode: glassy carbon; for further details, see text

creasing the heteropolyanion concentration, the first wave becomes roughly constant in intensity and the peak potential continues its slight shift in the negative direction; the current intensity of the second wave decreases until it becomes vanishingly small; concomitantly, a new wave appears at a more negative potential than the former second wave and grows at its expense. Figure 4 C shows a comparison between the final voltammogram observed for $4.5\cdot10^{-3}$ M $\alpha_2P_2W_{15}Mo_2$ and the voltammogram simulated from that corresponding to the lowest concentration of complex on the assumption that the peak current intensities maintain the expected proportionality and peak potentials remain constant. Figure 5 shows analogous observations for $\alpha_2P_2W_{17}$. Apart from the difference in wave shapes, which is the incentive for showing both Figure 4 and 5, exactly the same comments are applicable to the two complexes and will not be repeated.

In contrast, the addition of potassium hydrogen phthalate, which increases the buffer strength of the sulfate solution, improves drastically the observed phenomena. Figure 6 compares the observed and simulated cyclic voltammograms for $\alpha_2P_2W_{15}Mo_2$ and $\alpha_2P_2W_{17}$, respectively, under these experimental conditions.

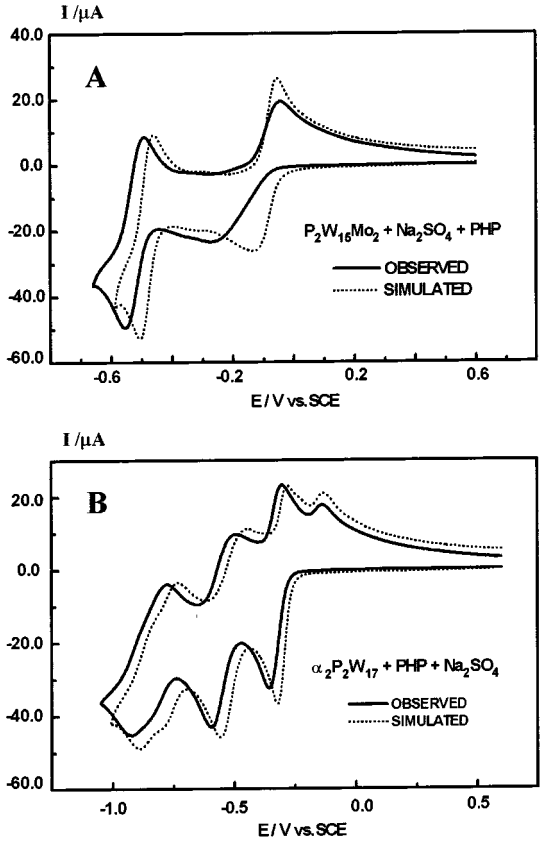

Figure 6. Observed and simulated cyclic voltammograms for $5\cdot10^{-3}$ M of the relevant heteropolyanion in 0.175 M Na_2SO_4 + $5\cdot10^{-2}$ M PHP (initial pH = 3); scan rate: 10 mVs^{-1}; working electrode: glassy carbon; for further details, see text; A: $\alpha_2[Mo_2P_2W_{15}O_{61}]^{10-}$; B: $\alpha_2[P_2W_{17}O_{61}]^{10-}$

Even with modest concentrations of the phthalate, the "expected" cyclic voltammograms are almost completely restored, as can be seen in Figure 6. Such an observation underscores the influence of the buffer capacity of the electrolyte and the special participation of the proton in the electrochemistry of the selected oxometalates. Also, comparison of the behavior of the two complexes in the same medium confirms the difference in basicity between their reduced forms.

Finally, complementary experiments were carried out. Figure 7 indicates for two metal ion substituted heteropolyanions, $\alpha_2P_2W_{17}Ni$ and $\alpha_2P_2W_{17}Zn$ selected as representative examples, the same trends as obtained for the precursor lacunary species, albeit to a lesser extent.

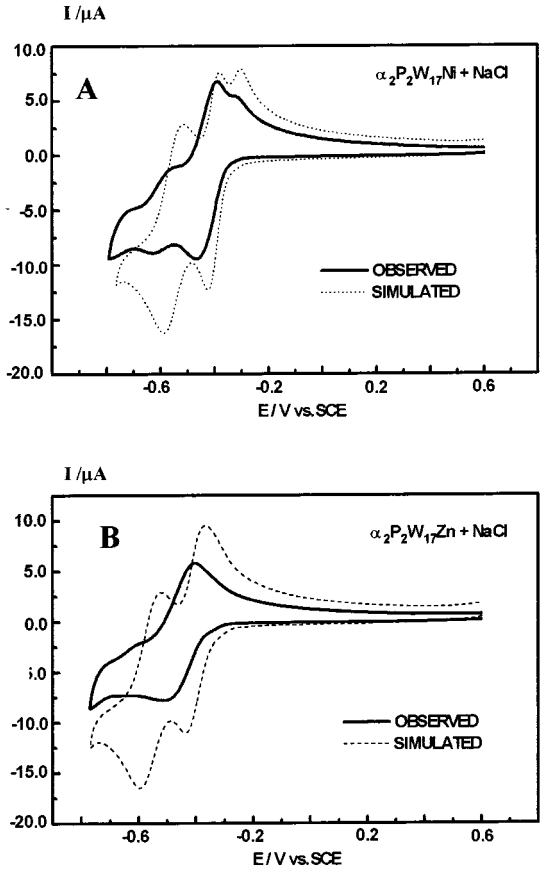

Figure 7. Observed and simulated cyclic voltammograms for $5 \cdot 10^{-3}$ M of the relevant heteropolyanion in 0.4 M NaCl + HCl (initial pH = 3); scan rate: 10 mVs^{-1}; working electrode: glassy carbon; for further details, see text; A: $\alpha_2[NiP_2W_{17}O_{61}]^{8-}$; B: $\alpha_2[ZnP_2W_{17}O_{61}]^{8-}$

Substitution of Na^+ by Li^+ in the supporting electrolyte does not change the general behavior observed for lacunary as well as for metal cation substituted heteropolyanions. Figure 8 summarizes the evolution, with the heteropolyanion concentration, of the current intensity ratio of the observed and simulated first voltammetric waves as defined previously.

It is also clear from Figure 8 that there is a slower decrease of this ratio when the ionic strength of the electrolyte increases.

With a proton-to-heteropolyanion ratio smaller than 2, all the observations suggest a reaction pathway in which two main species are in equilibrium in the solution, with their reduction featured respectively by the first and the second voltammetric waves. In this issue, it can be hypothesized that the first wave should correspond to the reduction of a protonated form of the heteropolyanion and the second wave to another protonated or to an unprotonated form.

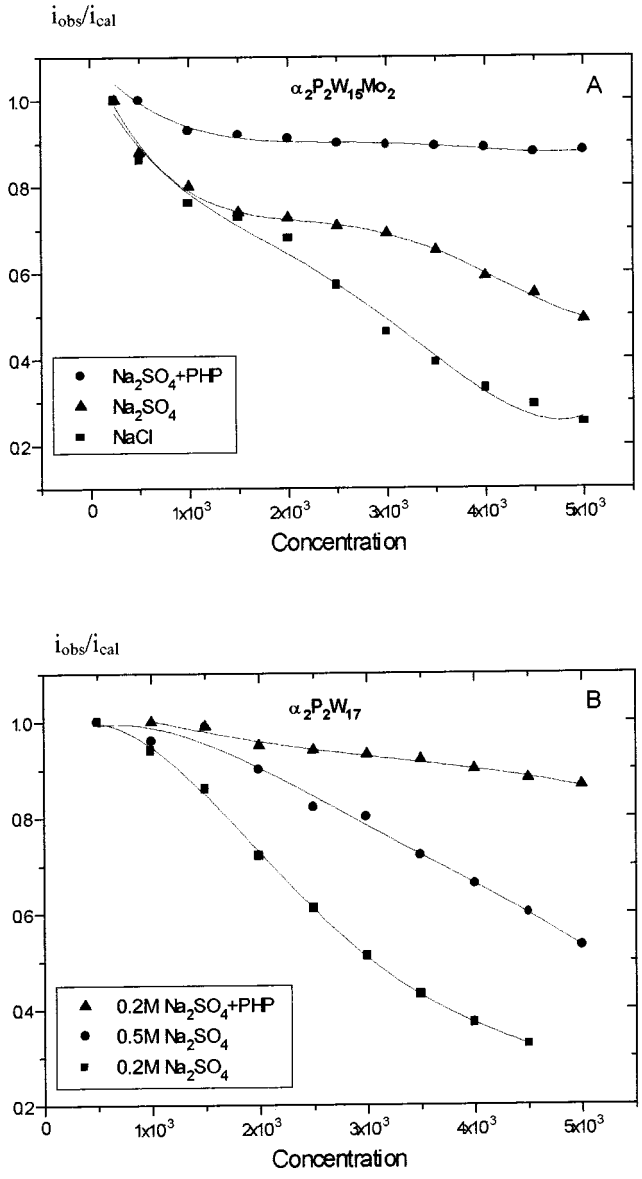

Figure 8. Normalized first reduction peak current intensity as a function of heteropolyanion concentration [M], using the calculated diffusion current as a reference; for further details, see text; A: $\alpha_2[Mo_2P_2W_{15}O_{61}]^{10-}$; B: $\alpha_2[P_2W_{17}O_{61}]^{10-}$

This distinction stems from the failure of large amounts of sodium or lithium cation to assume the role of protons and from the known polybasic behavior of $\alpha_2P_2W_{17}$,[18] which is also anticipated for $\alpha_2P_2W_{15}Mo_2$.

Acid−Base Equilibria

An attempt to rationalize the observations discussed above demands complementary experiments that can support or invalidate the basic hypothesis. The study is restricted to $\alpha_2P_2W_{15}Mo_2$ and $\alpha_2P_2W_{17}$.

Typically, several experiments were performed by starting the measurements with a pH = 3 solution containing the appropriate concentration of Na_2SO_4 + PHP, Na_2SO_4, or NaCl, which are the most representative supporting electrolytes used in this work. The pH of such solutions was then monitored accurately as a function of the added concentra-

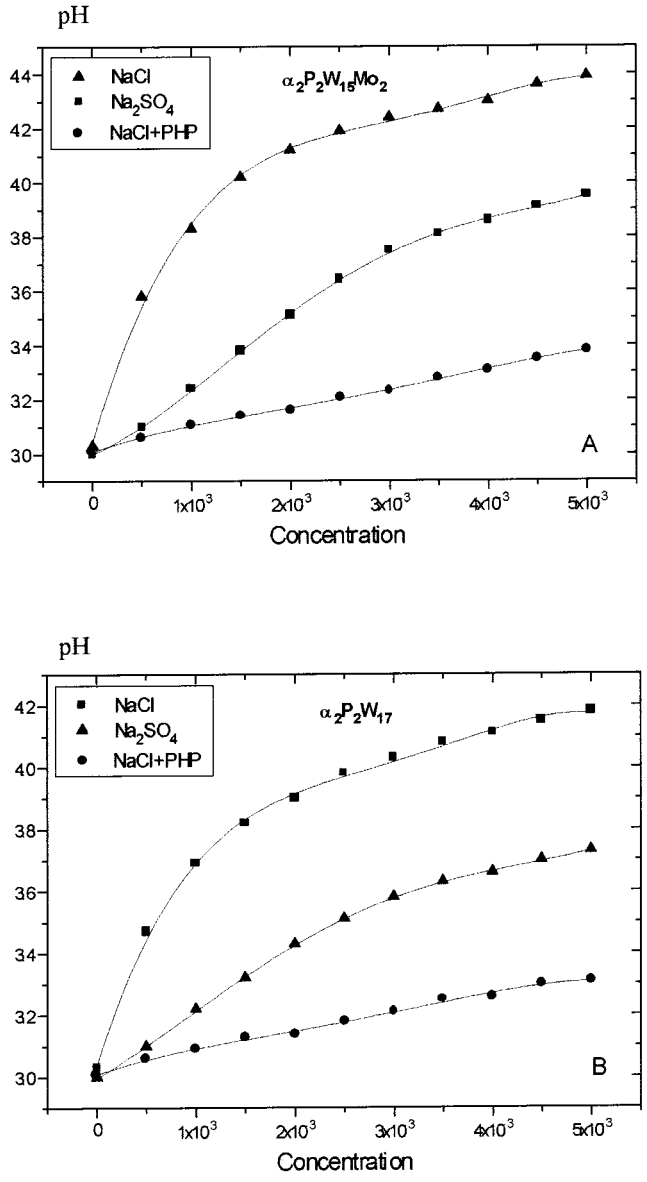

Figure 9. Variation of pH as a function of the concentration of heteropolyanion added to an initially pH = 3 solution; the composition of the electrolyte is indicated on each curve; A: $\alpha_2[Mo_2P_2W_{15}O_{61}]^{10-}$; B: $\alpha_2[P_2W_{17}O_{61}]^{10-}$

tion of the relevant heteropolyanion. The results are shown in Figure 9 and are enlightening.

Even with the smallest concentration of oxometalate used in this work, proton consumption occurs. Clearly, for both heteropolyanions, at least one of their pK_a values falls in the pH domain of the supporting electrolyte. The differences observed between the various media are easily explained in terms of their buffer capacity. The chloride medium has no buffer capacity and the consumption of protons by the heteropolyanion results in a rapid increase in the pH value. In the pure sulfate medium, $[HSO_4]^-$ is a proton donor, the presence of which confers some buffer capacity to the electrolyte. By following a literature procedure,[27] the initial concentration of hydrogen sulfate in the pH = 3 solution containing 0.2 M Na_2SO_4 can be evaluated and was found to be roughly $1.54 \cdot 10^{-2}$ M. Incidentally, it is worth noting that the increase of hydrogen sulfate species in 0.5 M Na_2SO_4 ($3.85 \cdot 10^{-2}$ M) and, to a lesser extend, the increase of cations, participate in the observed influence of ionic strength in Figure 8A. Finally, two proton donors are present in the mixture of sulfate and PHP, which can explain the small variation of pH with the concentration of heteropolyanion in that medium.

As far as the acid-base equilibria of the heteropolyanions are concerned, each of the present Dawson-type lacunary compounds is theoretically expected to fix ten protons. In fact, previous work on $\alpha_2P_2W_{17}$[18] and the present experiments on the two species under investigation indicate that the consumption of only three protons occurs. A detailed account of the accurate pK_a determinations for these compounds, as well as for several other species in the Dawson and Keggin series, under various experimental conditions will be given elsewhere along with the distribution of the various possible species in equilibrium at a given pH value.[28]

Discussion

The classical picture encountered so far in our studies for the reduction of lacunary heteropolyanions in pH = 2 or 3 media with a large enough proton-to-heteropolyanion ratio,[6–10,29] begins with two two-electron waves. At least the first peak current intensity is proportional to the analytical concentration of the oxometalate. Most, but not all, first transition metal ion substituted heteropolyanions behave similarly and show a system of two-electron waves at practically the same potential locations as those of the precursor lacunary species.[6–10,29] Hence the conclusion that most of these systems cannot actually be considered as "saturated" compounds.

Several observations in the experiments described above deserve further specific discussion. Emphasis will be placed on an attempt at the rationalization of the influence of the overall negative charge of the heteropolyanion, the partial localization of this charge, and the role of various counterions present in the solution, with particular attention paid to the remarkable behavior of the proton.

In the pH domain explored and with the heteropolyanion concentrations used in this work, the lacunary as well as the substituted compounds are stable. As a matter of fact, regardless of the starting situation, addition of acid to obtain a large proton-to-heteropolyanion ratio restores immediately the classical cyclic voltammograms with a first two-electron wave, the current intensity of which is proportional to the analytical concentration of the oxometalate. The extremely high speed of this restoration might rule out association phenomena as the origin of the observed behavior.

We consider first the situation in Figure 1 through 3. With the sulfate medium chosen as a reference, the electrolyte composition seems suitable to ensure classical behavior for the oxometalates described in this work. For this same pH but in the presence of other anions, a general negative shift in the peak potential locations is obtained with a con-

comitant decrease of the peak currents. Such behavior spans a large potential domain, roughly from +0.6 to −1 V in the present experiments. Provisionally, it must be noted that this domain encompasses two two-electron waves of the fully symmetrical heteropolyanion P_2W_{18}, and that the whole cyclic voltammogram for this compound remains unaltered by the change in anion in the supporting electrolyte. On the reasonable assumption that the added electrons are delocalized in the equatorial region or that the charge distribution remains symmetrical in the first few reduced forms of P_2W_{18}, this cyclic voltammogram would indicate that the overall charge by itself is not a main parameter in the observed behavior. In contrast, substituted heteropolyanions are sensitive to the change of anions, which lends support to the conclusion that they behave much like the precursor lacunary species. The idea emerges that charge localization is of prime importance to induce the behaviors of lacunary and lacunary-like species. The larger this charge localization, the larger the effects. It has also been confirmed by UV/Vis spectroscopy that decomposition of the oxometalates does not occur. Given this information we are left with an explanation involving anion effects and/or local pH effects. The most striking or complex behaviors are encountered with $\alpha_2P_2W_{15}Mo_2$ and P_2W_{12}. Work is still in progress on the latter compound. Therefore, focus is placed on the first compound. The anion effect in electrochemistry has been known for some time and is rationalized in terms of adsorption and double layer effects.[30−35] More specifically, the anion effect in the reduction of chromate ions has been described in detail by Gierst and co-workers.[36,37]

However, examination of Figure 8A. and Figure 9A, indicates that $\alpha_2P_2W_{15}Mo_2$ and its reduced species should fix protons irreversibly, thus raising the pH value in the reaction layer. As a consequence, the peak current intensity could be lowered and the peak potential driven in the negative direction. This possibility might appear difficult to separate from the pure double layer effect, but the present observations rule out any preeminent anion effect.

The second issue of importance concerns the role of counter cations in the reaction mixture. Even though they are active in ensuring the overall electroneutrality of the solutions, their behavior is particularly prominent when the proton to heteropolyanion ratio is low. In these circumstances, it is observed that the high cation-to-heteropolyanion ratio cannot counteract the pH variation effect. This conclusion is confirmed in Figure 4 and 5, in which it can be seen that cations other than the proton also fail to give rise to the classical cyclic voltammograms of lacunary heteropolyanions. In contrast, the efficiency of protons in these circumstances is clearly highlighted, in particular through the buffer capacity of the supporting electrolyte. The facts in this particular case are clear although their complete rationalization seems difficult at present. Therefore, the following discussion represents an attempt to sum up the main questions raised by the present observations, with an indication of the tentative ways in which these questions could be solved. At least two questions arise: (i) the extent, if any, of ion-pairing of cations with the outer surface of heteropolyanions, more specifically in the reduced states; (ii) the compensation by cations of the localized charges of the vacancy corresponding to the missing moiety. Complexation and/or ion-pairing of the lacunary[18] and the substituted[18,38,39] heteropolyanions with alkali metal cations were demonstrated and seem to be associated with the dissymetry of the molecules.[12,40] This remark suggests charge localization to some extent. As a consequence, we focus on the atoms in and around the vacancy. The complexation stability constants, in the cases in which they were measured,[18,28] have sizeable values. It can be assumed that the corresponding reduced species should be even more strongly complexed by alkali metal cations. Then, the particular role played by protons should be tentatively attributed to either or both of the following possibilities: the very fast protonation kinetics, in agreement with the p*K* values, and/or some restricted accessibility of protonable/complexable sites. This last assumption might be supported by the known bulkiness of solvated alkali metal cations:[41,42] the ionic radii are 2.35 Å for solvated Na^+, 2.08 Å for solvated Li^+, while the value of 0.74 Å for W^{6+} is generally accepted to represent also the radius of the vacancy. A new problem now arises concerning the actual state (i.e. whether they are solvated, partially solvated or unsolvated) of the cations that participate in the neutralization of the charges around the vacancy. It is known[18,28] that, among the five protonable sites, only the four outer sites have a good accessibility and that three are protonable. It is likely that solvated cations can only complex these sites in a fairly loose manner. Work in progress is aimed at clarifying several of these problems.

Concluding Remarks

The observations made for the electrochemical behavior of the oxometalates studied in this work show evidence for the influence of electrolyte composition. Despite the variety of Dawson- and Keggin-type structures, the conclusion emerges that lacunary as well as their divalent cation substituted species are sensitive mainly to the buffer capacity of the electrolytes. This influence pushes the peak potentials in the negative direction and, as a whole, increases the reduction overvoltage of the oxometalate. The intensity of the influence decreases smoothly from the lacunary species to their divalent cation substituted derivatives, and vanishes completely in the precursor-saturated compound. Furthermore, the importance of this influence turns out to follow smoothly the nominal negative charge borne by each molecule. This observation confirms and reinforces the conclusion that most divalent cation substituted heteropolyanions are not actually "saturated" compounds and that their electrochemistry should be compared with that of the corresponding lacunary species. This behavior reveals, in fact, some dissymmetry in the charge distribution in the molecules, as evidenced by the comparative study with P_2W_{18} or $P_2W_{15}Mo_3$. The possible further interference of local pH changes during reduction processes must also be considered. Thus, one remarkable outcome of this work is the pos-

sibility that electrochemical behavior governed by electrolyte composition can serve as probes of charge distribution in oxometalates.

Another issue of interest concerns the very modest role played by cations other than the proton in the electrochemical behavior of oxometalates. The series of questions raised by this observation can be partly answered by considering qualitatively the charge localization on hard oxide ions around the vacancy and the bulkiness of solvated alkali cations in competition with proton hopping. Also, the pK_a value of the various sites in the oxidized as well as in the reduced forms must be considered. These explanations cannot be extended to the known specificity of several cations in the synthesis of lacunary heteropolyanions. Work in progress aims at answering several such questions.

Experimental Section

Pure water from a Milli-RO_4 unit followed by a Millipore Q purification set was used throughout. All chemicals were of high-purity grade and were used as received. H_2SO_4, Li_2SO_4, Na_2SO_4, LiCl, NaCl, HCl, $NaClO_4$, $NaNO_3$, $C_8H_5O_4K$ (potassium hydrogen phthalate, abbreviated as PHP), CH_3COOH, CH_3COONa (Prolabo) were commercial products. In the present comparative study, only pH = 3 media were used. The heteropolyanions used in this work have been cited previously, along with appropriate abbreviations and preparations.[6,8,9,18–21] The stability of these compounds was checked in a 0.2 M Na_2SO_4 + H_2SO_4 medium (pH = 3) by UV/Vis spectroscopy over a period of at least 24 h. The solutions were deaerated thoroughly for at least 30 min with pure argon and kept under a positive pressure of this gas during the experiments.

The source, mounting and polishing of the glassy carbon (GC, Le Carbone Lorraine, France, 3 mm diameter) have been described.[5,6] The electrochemical set-up was an EG & G 273 A driven by a PC with the corresponding 270 software. Potentials are quoted against a saturated calomel electrode (SCE) in a compartment separated from the test solution by a fine-porosity glass frit. The counter electrode was platinum gauze of large surface area in a separated compartment with a medium-porosity glass frit. The UV/Vis spectra were recorded with a Perkin–Elmer Lambda 19 spectrophotometer. Experiments were performed at 23 ± 1 °C.

Hyperfine Shifts in Low-Spin Iron(III) Hemes: A Ligand Field Analysis

Ivano Bertini,*[a,b] Claudio Luchinat,[a,c] and Giacomo Parigi[a,c]

Keywords: Magnetic properties / Anisotropy / Iron / Heme proteins / Low-spin complexes / Partial orientation

The hyperfine shifts of heme nuclei in low-spin iron(III) porphyrins of known geometry are predicted from: (i) a ligand field analysis, and (ii) the Kurland and McGarvey theory (R. J. Kurland, B. R. McGarvey, *J. Magn. Reson.* **1970**, *2*, 286–301). The ligand field parameters are optimized to reproduce the experimentally available *g* values and magnetic susceptibility anisotropy, the latter being obtained from the analysis of pseudo-contact shifts. Simple known geometric relationships (I. Bertini, C. Luchinat, G. Parigi, F. A. Walker, *J. Biol. Inorg. Chem.* **1999**, *4*, 515–519; N. V. Shokhirev, F.A. Walker, *J. Biol. Inorg. Chem.* **1998**, *3*, 581–594), are used to relate the contact shifts to the various heme positions. The systems investigated are: metMyoglobin cyanide, cytochrome b_5 and cytochrome *c*. It is shown that the contact hyperfine coupling constants recalculated from this approach are different to those obtained through the simple and generally used McConnell equation, and that the deviation can be more or less severe, depending on the position on the heme and on the orientation of the axial ligands. The contact shift tensor is highly anisotropic and therefore the shift is dependent on the orientation of the molecule in a magnetic field. This theoretical analysis is necessary to interpret ENDOR spectra and NMR spectra in partially oriented systems.

Introduction

Contact shifts are generally and incorrectly assumed to be isotropic because the hyperfine coupling constant is isotropic.[1−4] However, contact shifts depend on the induced electron magnetic moment at the nucleus, and such magnetic moments are orientation-dependent because spin-orbit coupling causes anisotropy in the expected value of S_z, $<S_z>$. This effect is well-known[5] but does not show up in solution where the anisotropy is averaged out.[1−4]

Dipolar shifts due to the electron-nucleus coupling are known to be anisotropic.[2−6] They have an average value of zero in the absence of spin-orbit coupling and if all the orientations in solution are equally probable. In the presence of spin-orbit coupling, *g* and the magnetic susceptibility χ become anisotropic and the average dipolar coupling is different from zero. This effect gives rise to the well-known pseudo-contact shift.[2−6]

The interest here is in low-spin iron(III) heme systems. The *g* values of the ground state are available from EPR spectroscopy.[7−10] The magnetic susceptibility anisotropy, $\Delta\chi$, is available from the analysis of the ^{1}H pseudo-contact shifts, which are easily obtained for heme proteins [11−24]. Indeed, protons separated from the metal ion by several chemical bonds experience only pseudo-contact shifts, which then provide both magnetic susceptibility anisotropy and the principal directions of the magnetic susceptibility tensor. By fitting the *g* and $\Delta\chi$ values and directions with any ligand-field approach, the proper wave functions of the three lowest orbital levels are obtained, which are the basis set for the Kurland and McGarvey approach to determine: (i) the contact shifts for each orientation of the molecule in the external magnetic field, and (ii) the average value of isotropic rotation. The calculated contact shifts are then compared to the contact shifts of the heme methyl protons, which are estimated from the experimental hyperfine shifts by subtracting the calculated pseudo-contact shifts from the known magnetic susceptibility anisotropy tensor. Here, a simple analytical approach[9,25−29] is used. The contact shifts along the heme positions are predicted by assuming a $\sin^2\theta$ dependence for the ground state and a $\cos^2\theta$ dependence for the first excited state, where θ is the angle between the iron-proton vector and the direction of the (average) p-orbital nodal plane(s) of the π-bonding axial ligand(s)[21,30]. The analysis of the experimental contact shifts on the basis of this theoretical approach is quite instructive. The systems analyzed are: cyanometmyoglobin, rat microsomal cytochrome b_5 and horse heart cytochrome *c*.

Finally, since the technology of partial orientation is rapidly developing,[31−39] we want to address the problem of the effect of partial, but extensive, orientation on the contact (and pseudo-contact) shifts. This prediction is extremely important for the analysis of ENDOR spectroscopy and is not yet available in the literature, whereas extensive orientation in solution is not yet obtainable without severe broadening of the NMR lines.

Theory

Contact Shift

The Fermi contact contribution to the paramagnetic NMR shift can be calculated by using the Kurland and

McGarvey equation,[5] as it depends on the thermally populated electronic states:

$$\delta_i^{con} = \frac{1}{kT\sum_{\Gamma n} e^{-\varepsilon_\Gamma/kT}}\left(\sum_{\Gamma n,\Gamma m} e^{-\varepsilon_\Gamma/kT} < \Gamma n \mid \mu_i \mid \Gamma m >< \Gamma m \mid A_{Fi} \mid \Gamma n > + \right. \quad (1)$$

$$\left. - kT \sum_{\Gamma n,\Gamma m\,(\Gamma \neq \Gamma')} \frac{e^{-\varepsilon_\Gamma/kT} - e^{-\varepsilon_{\Gamma'}/kT}}{\varepsilon_\Gamma - \varepsilon_{\Gamma'}} < \Gamma n \mid \mu_i \mid \Gamma' m >< \Gamma' m \mid A_{Fi} \mid \Gamma n > \right)$$

Here i represents any of the principal directions of the molecular axes, $|\Gamma n>$ are the eigenstates of the electronic multiplets, ε_Γ is the energy of each multiplet state $|\Gamma>$, k is the Boltzmann constant and T is the temperature. Furthermore,

$$\mu_i = -\mu_B(L_i + 2S_i)$$

$$A_F = \frac{8\pi g_e \mu_B}{3}\delta(r)S$$

where δ indicates the Dirac δ operator, μ_B is the electron Bohr magneton, g_e is the electron g factor and L and S are the electron-orbital and spin operators. The eigenstates $|\Gamma n>$ can be provided by a ligand-field analysis.[9,25–29]

A pictorial scheme of the electronic levels of low-spin iron(III) heme proteins[26] is shown in Figure 1. On the left-hand side, the splitting of the d_{xy}, d_{yz}, d_{xz} orbitals (with energies E_0, E_1, E_2) is provided by the low symmetry, whereas on the right-hand side the effect of spin-orbit coupling is shown (and the orbital energy levels are labeled E'_0, E'_1, E'_2). The figure also shows the energy of the excited states, ε_1 and ε_2.

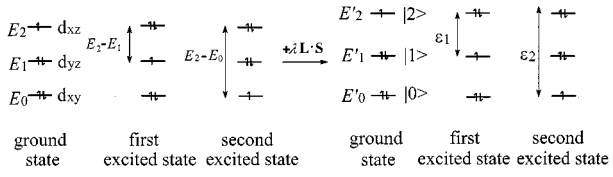

Figure 1. The low-symmetry splitting of the orbitally degenerate $^2T_2$ ground state and first and second excited states of low-spin iron(III)

This simple three-state analysis provides the g values for the ground state and the molecular χ values as follows [9,25–29]:

$$g_x = 2[2\xi_0\zeta_0 - \eta_0^2 - \sqrt{2}\eta_0(\xi_0 - \zeta_0)]$$

$$g_y = 2[-2\xi_0\zeta_0 - \eta_0^2 - \sqrt{2}\eta_0(\xi_0 + \zeta_0)] \quad (2)$$

$$g_z = 2[-2\xi_0^2 + \eta_0^2]$$

$$\chi_{ii} = -\frac{\mu_0\mu_B^2}{4\sum_{\Gamma n} e^{-\varepsilon_\Gamma/kT}}\sum_{\Gamma n}\sum_{\Gamma' m}(g_{\Gamma\Gamma'})_i^2 \frac{e^{-\varepsilon_\Gamma/kT} - e^{-\varepsilon_{\Gamma'}/kT}}{\varepsilon_\Gamma - \varepsilon_{\Gamma'}} \quad (3)$$

where μ_0 is the vacuum permeability, $(g_{\Gamma\Gamma'})_i$ are the electron g values in the ith direction[29] and ξ, η, and ζ are the coefficients of the ground and the two excited-state Kramer doublets, given by the following linear combination of the $|m_l, m_s>$ states:

$$|\Gamma,+> = \xi_\Gamma|1,-1/2> + \eta_\Gamma|0,1/2> + \zeta_\Gamma|-1,-1/2>$$

$$|\Gamma,-> = \xi_\Gamma|-1,1/2> + \eta_\Gamma|0,-1/2> + \zeta_\Gamma|1,1/2> \quad (4)$$

for $\Gamma = 0$, 1 and 2.

The fitting of the experimental data requires E_1 and E_2 of Figure 1 and the spin-orbit coupling constant. The orbital reduction parameter is taken to be 1.

By performing the calculations of Equation (1) with $|\Gamma n>$ provided by the three Kramer doublets, for external magnetic field directions along the principal directions of the g (or χ) tensor, the following components of the contact shift tensor are obtained:

$$\delta_x^{con} = a_x A_0/h + b_x A_1/h + c_x A_2/h$$

$$\delta_y^{con} = a_y A_0/h + b_y A_1/h + c_y A_2/h \quad (5)$$

$$\delta_z^{con} = a_z A_0/h + b_z A_1/h + c_z A_2/h$$

The a, b and c coefficients derive from the specific $|\Gamma n>$ functions weighted by the Boltzmann population, and $A_{0,1,2}/h$ are the hyperfine coupling constants (expressed in MHz; $\frac{A_i}{h} = \frac{\gamma_N}{2\pi}\frac{8\pi g_e\mu_B}{3}K_i$, where γ_N is the proton magnetogyric ratio and K_i represents the proportionality constant between the orbital-spin density and the electron-spin density at the nucleus[5]) for the ground and excited levels, respectively. In fact, since the hyperfine contact constants A are different for the different electronic states, three such terms are needed. The functional form of these terms has been extensively studied in previous works for the particular case of low-spin iron(III) heme systems,[17,21,30,41–49] and will be summarized below.

The average contact shift in solution is obtained by averaging over all orientations,

$$\delta_{av}^{con} = \frac{1}{3}\left[\delta_x^{con} + \delta_y^{con} + \delta_z^{con}\right] \quad (6)$$

For completeness, the equation for the average dipolar shift, which is the pseudo-contact shift, is also reported:[5,40]

$$\delta^{pc} = \frac{1}{24\pi}\frac{1}{r^3}\left\{\left[2\chi_{zz} - (\chi_{xx} + \chi_{yy})\right](3n^2 - 1) + 3(\chi_{xx} - \chi_{yy})(l^2 - m^2)\right\} \quad (7)$$

where χ_{ii} is the magnetic susceptibility of the molecule in the i direction, r is the distance of the observed nucleus from the atom bearing the unpaired electron spin, and l, m and n are the direction cosines of the metal-nucleus vector with respect to the principal directions of the χ-tensor.

Functional Form of A_0, A_1 and A_2

In low-spin heme complexes, A_0 and A_1 for heme methyl substituents are a function of the angle between the metal-pyrrole II direction and the direction of the (average) p-orbital nodal plane(s) of the π-bonding axial ligand(s)(Figure 2).[17,21,41−43] A_0 depends on the spin density according to[30]

$$A_0 = a\sin^2(\gamma_i - \varphi) \quad (8)$$

where a is a proportionality constant which depends on the amount of orbital-spin density and γ_i is the angle between the metal-*i*th-proton direction and the metal-pyrrole II axis (equal to 112.5, 22.5, 292.5 and 157.5 for methyls 1, 3, 5 and 8, respectively).

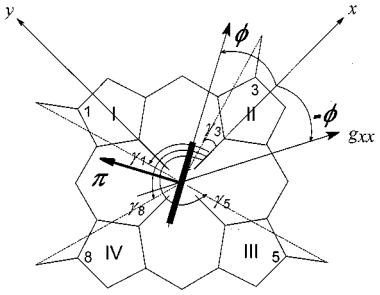

Figure 2. Schematic representation of the heme moiety; the γ_i angles for the four methyl groups are defined as the angles between the metal−methyl *i*th vector and the metal−pyrrole II direction; the Φ angle defines the direction of the average p-orbital nodal plane of the π-bonding axial ligand(s), and the -Φ angle the resulting direction of the g_{xx} and χ_{xx} axis

The second A value, A_1, is related to the heme spin-density pattern originating from the excited π-MO. It has been assumed that A_1 is equal to A_0, but shifted by 90°, and thus[30]

$$A_1 = a\cos^2(\gamma_i - \varphi) \quad (9)$$

The third A value, A_2, is related to the spin density on a MO to which iron contributes mostly with the d_{xy} orbital. Its value is given by a constant owing to the symmetry of the d_{xy} orbital. Furthermore, its contribution is small as found in those systems with a d_{xy} ground state.[44−49]

Results and Discussion

The simultaneous reproduction of the observed g values and the anisotropy of the magnetic susceptibility values, $\Delta\chi$, was obtained with the parameters reported in Table 1 for cyanometmyoglobin, cytochromes b_5 and c. The values of E_1, E_2, and λ are somewhat different to those calculated by fitting the g values only,[9,26] but the overall picture is the same. The values of E_1 and E_2 vary by about 10% when calculated through an angular overlap approach, which takes into consideration all the excited levels (program CAMMAG [50,51]). This provides a difference in the calculated contact shifts of about 5%, which is considered negligible. Therefore, the three-orbital approximation is sufficient.

In cyanometmyoglobin, the electron energy levels are 0, 692, and 915 cm^{-1} for the lowest three orbitals, d_{xy}, d_{yz}, and d_{xz}, respectively, so that the difference in energy between the ground and the two excited states is 223 and 915 cm^{-1}. These states are perturbed by spin-orbit coupling (with spin-orbit coupling constant $\lambda = 240$ cm^{-1})[52] to 0, 348, and 1023 cm^{-1} (Figure 1). These energy values provide $g_x = 0.93$, $g_y = 1.86$, $g_z = 3.40$ (see Table 1), in good agreement with the experimental values,[8,53] and $\chi_x = 3.12\cdot10^{-32}$, $\chi_y = 4.15\cdot10^{-32}$, $\chi_z = 7.35\cdot10^{-32}$ m^3, at 298 K, which provide $\Delta\chi_{ax} = 3.71\cdot10^{-32}$ m^3 and $\Delta\chi_{rh} = -1.03\cdot10^{-32}$ m^3, again in good agreement with the experimental values (see Table 1). The values of $\delta^{con}_{x,y,z}$, for external magnetic field directions along the principal directions of the g (or χ) tensor, have thus been calculated (in ppm):

$$\delta_x^{con} = 14.7A_0/h + 9.9A_1/h + 0.5A_2/h$$

$$\delta_y^{con} = 19.9A_0/h + 7.7A_1/h + 0.6A_2/h$$

$$\delta_z^{con} = 36.3A_0/h + 0.7A_1/h + 0.9A_2/h$$

at 298 K, where $A_{0,1,2}/h$ are expressed in MHz. Since A_2 is reasonably much smaller than A_0 and A_1,[44−49] and since the coefficients for the second excited state are usually smaller than the others, we will neglect the second excited state contribution hereafter.

The average solution values of the calculated contact and pseudo-contact shifts for the methyl protons, found by setting a fixed value for the a parameter in Equations (8) and (9), are reported in Table 2. It can be seen that the shift pattern is well reproduced for both the contact and the pseudo-contact contributions. For cyanometmyoglobin, for instance, the calculated contact shifts for the 1, 3, 5, and 8 methyl protons are 21.5, 8.2, 26.3, and 12.0 ppm, respectively, in comparison with the experimental values 18.4, 6.7, 27.8, and 15.8 ppm, and the calculated pseudo-contact shifts for the 1, 3, 5, and 8 methyl protons are −3.0, −5.8, −3.0, and −5.6 ppm, respectively, in comparison with the experimental values −3.4, −5.7, −3.3, and −6.5 ppm.[12] It should be noted that the angular dependence of the contact constants is of the same type as that of the pseudo-contact shift. Therefore, the sum of contact and pseudo-contact shifts is provided by an equation which contains the linear combination of $\sin^2$ and $\cos^2$ terms. This justifies the use of a recently proposed heuristic equation.[30]

Similarly, satisfactory results were obtained for cytochrome b_5 and cytochrome c (Table 2). In cytochromes b_5 and c the φ angle in Equations (8) and (9)[43] is determined by the presence of two histidines or a histidine and a methionine as axial ligands.[54] The a values needed to best reproduce the experimental shifts are within ±25% from those found for MetMbCN.

A comparison between the contact hyperfine constants calculated with the Kurland and McGarvey equation and the McConnell equation is reported in Table 3. It is interesting to compare the analysis of the contact shifts through

Table 1. Energy values of the excited orbitals, E_1 and E_2, obtained by fitting the experimental g and χ values of MetMbCN, cytochrome b_5 and cytochrome c. ε_1 and ε_2 are the energies of the excited states; the energy values are expressed in cm^{-1}, the values of the magnetic susceptibility are expressed in m^3; the a, b, and c coefficients of Equation (5) are provided for the three proteins;[a] the experimental data are from: MetMbCN, for g see ref.[8,53] and for $\Delta\chi$ see ref.[18]; cytochrome b_5: for g see ref.[9] and for $\Delta\chi$ see ref.[20]; cytochrome c:for g see ref.[26] and for $\Delta\chi$ see ref.[19,21]

MetMbCN		Experimental	Calculated	Experimental	Calculated			
$E_1 = 692$	$\varepsilon_1 = 348$	$g_x = 0.93$	$g_x = 0.93$	$\Delta\chi_{ax} = 3.78\cdot10^{-32}$	$\Delta\chi_{ax} = 3.71\cdot10^{-32}$	$a_x = 14.7$	$b_x = 9.9$	$c_x = 0.5$

		$g_z = 3.06$	$g_z = 3.06$			$a_z = 35.0$	$b_z = 0.5$	$c_z = 1.4$

[a] In the present work, the theoretical treatment always results in labeling g_x as the smallest of the three g-tensor components (in absolute value). The same holds for the χ-tensor components. Therefore, $\Delta\chi_{rh}$ values are always negative.

Table 2. Calculated and experimental contact and pseudo-contact shifts for MetMbCN [12], cytochrome b_5 [20] and cytochrome c;[19] the shifts (in ppm) are reported for methyl protons 1, 3, 5, and 8; the methyl proton shifts were corrected for an average higher shift value of the protons of methyls 5 and 8 and an average lower shift value of the protons of methyls 1 and 3 (±1 and ±2.4 ppm for cytochrome c and for cytochrome b_5 and MetMbCN, respectively);[30,43] the empirical a values in Equations (8) and (9) are 1.2, 0.9 and 1.4 for MetMbCN, cytochrome b_5 and cytochrome c, respectively

	Contact shift calculated	experimental	Pseudo-contact shift calculated	experimental
MetMbCN	21.5/8.2/26.3/12.0	18.4/6.7/27.8/15.8	−3.0/−5.8/−3.0/−5.6	−3.4/−5.7/−3.3/−6.5
Cytochrome b_5	6.3/13.5/11.2/6.2	8.6/16.0/17.7/2.0	−0.9/−5.9/−0.9/−2.3	−1.5/−4.7/−1.5/−2.8
Cytochrome c	9.9/29.6/11.9/33.0	7.7/30.1/11.0/35.4	−5.9/−1.2/−5.9/−1.6	−4.4/−1.1/−4.9/−1.9

the Kurland and McGarvey approach and the McConnell approach. In the latter case, the contact shift is given by[1]

$$\delta^{con} = \frac{g_e \mu_B S(S+1)}{3kT\gamma_N}\frac{A'}{\hbar} \quad (10)$$

where A' is the McConnell hyperfine coupling constant. The data reported in Table 3 show that the value of A'/h is not directly correlated to the values of A_0/h and A_1/h, and the deviation is different for the different methyl protons. Data reported in Table 3 provide an indication of the error inherent in use of the simple McConnell equation. If the difference in energy between the ground and excited states increases, the spin-orbit coupling does not efficiently mix the different d orbitals, the g anisotropy decreases and A' approaches A_0. It should be noted that A' differs from A_0 even in the limits of zero and infinite temperatures (Table 3). In the first case, this is because $<S_z>$ contains an orbital contribution which makes it different from the Curie value used in the McConnell equation. In the second case, the contact coupling constants of each level differ from one another. Only in a case where $A_0 = A_1 = A_2$, which is unrealistic for methyl protons in heme porphyrins, would A' coincide with A_0.

Figure 3 shows how anisotropic the contact shift of methyl protons in cyanometmyoglobin is predicted to be. The contact shift is reported for different orientations of the external magnetic field in either the xy, xz, or yz planes. NMR experimentalists of low-spin hemeproteins have always ignored this anisotropy, because they are dealing with an averaged shift in solution and only the average contact contribution to the hyperfine interaction is obtained. It is obvious, however, that in the case of partially oriented systems, the average should be calculated by providing a different weighting in the different directions, and therefore anisotropy must be considered.

In Table 4 the contributions to the contact shift along the three main directions have been reported for the methyl protons. Data show that the anisotropy can be very large, so that such an effect must be taken into account in the presence of partial orientation. Appropriate equations are reported in the Appendix.

It should be noted that, since contact shifts are usually larger than pseudo-contact shifts, the effects originating from the anisotropy in the contact term are similarly expected to be larger than those related to the anisotropies in the dipolar term. Therefore, such dependencies should be carefully considered in ENDOR spectroscopy, where any

Table 3. Contact shifts of the methyl protons, δ^{con}, of MetMbCN, cytochrome b_5 and cytochrome c, obtained with the Kurland and McGarvey equation with the values of A_0/h and A_1/h calculated from Equations (8, 9) and the resulting coupling constant A'/h back-calculated from the values of δ^{con} and from the McConnell equation, for three different temperatures; A/h values are expressed in MHz, and the shifts in ppm; note that in the table the heuristic correction made in Table 2, and suggested in ref.[43] was not made

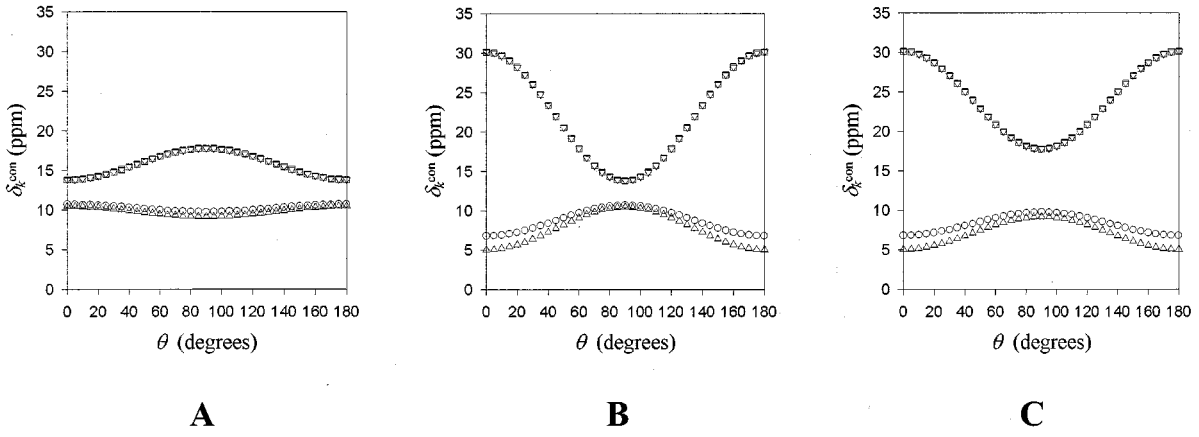

Figure 3. Contact shift calculated for different k orientations of the molecule in a magnetic field for the four methyl protons (□ = 1-CH_3, ○ = 3-CH_3, ▽ = 5-CH_3, Δ = 8-CH_3); panel A shows the shifts for the magnetic field B_0 in the xy plane, where θ is the angle between B_0 and the metal-pyrrole(II) direction; in panels B and C, θ is the angle between B_0 and the z axis, with B_0 in the xz (B) or yz (C) planes; φ is set to −2°, as found experimentally for MetMbCN[60,61]

angular dependence is usually ascribed to the dipolar interaction, and assuming an isotropic contact contribution would be erroneous.

Concluding Remarks and Perspectives

The McConnell equation (Equation 10) is generally used to analyze contact shift patterns. As outlined on several occasions,[5,55] such an equation only holds for one unpaired electron in a single orbital with g near to 2. Low-spin Ru^{III} and Fe^{III} have g values very different from 2, and also have low-lying excited levels.[28,29,53] In these cases a much more complex analysis is needed. In the case of heme proteins, the hyperfine shifts are provided by both contact and pseudocontact contributions. The latter are absolutely dominant for protons several bonds away from the metal ion, and allow for the determination of magnetic susceptibility anisotropies (according to Equation 7) together with the

Table 4. Anisotropic contributions to the contact shifts (in ppm), calculated for MetMbCN, cytochrome b_5, and cytochrome *c*

Methyl		MetMbCN[12,59]	Cytochrome b_5[20]	Cytochrome *c*[19,21]

principal direction of the χ tensor and a refinement of the solution structure.[19,20,40,56] From the knowledge of the *g* and Δχ values, the contact shift of the heme protons can be estimated. A ligand-field analysis, together with the Kurland and McGarvey approach, allows for a detailed and instructive analysis of the contributions of the various electronic levels. Such an analysis is absolutely necessary when the hyperfine coupling is analyzed by ENDOR spectroscopy and when proton hyperfine shifts are analyzed in partially oriented systems.

Finally, magnetically anisotropic molecules in a high magnetic field experience partial orientation, which should result in a variation in the hyperfine shifts due to residual dipolar coupling between the unpaired electron(s) and the resonating nucleus. When the contact shift is anisotropic, there is also a variation in the contact contribution. This is the first time that such an effect has been accurately calculated for heme proteins, although dipolar coupling in those systems is well known in ENDOR spectroscopy.[57] When contact shift occurs, its anisotropy also contributes to the change in hyperfine shifts in partially oriented systems. This has always been neglected in ENDOR and NMR spectroscopy, despite the warnings of McGarvey,[5,55] which have largely been ignored.

Residual electron-nucleus dipolar couplings are a new class of structural constraints and may become significant when systems with $S > 1/2$ and/or more efficient orienting solvents are used. When the contact interaction is operative, further details of the electronic structure of the systems under investigation become available.

Appendix

In the presence of partial orientation, an orientational *D* tensor should be defined, with principal components D_x, D_y, and D_z. The residual contact shift, i.e. the difference between the averaged contact shift in the absence and in the presence of partial orientation, $\Delta\delta^{con}$, is given by

$$\Delta\delta^{con} = \tilde{\delta}_x^{con} D_x + \tilde{\delta}_y^{con} D_y + \tilde{\delta}_z^{con} D_z \qquad (A.2)$$

In general, the *D* and *g* tensors are not diagonal in the same frame. Therefore, the shifts must be calculated by evaluating the weighted average between the shifts along the main directions of the orientational *D* tensor, so that in Equation A.1

$$\tilde{\delta}_i^{con} = \delta_x^{con} \sin^2\alpha\cos^2\beta + \delta_y^{con} \sin^2\alpha\sin^2\beta + \delta_z^{con} \cos^2\alpha \qquad (A.2)$$

where $\tilde{\delta}_i^{con}$ are provided by Equation (5), with α and β equal to the polar angles that define the position of the $i = x, y, z$ axes of the *D* tensor in the frame of the *g* tensor.

Analogously, the residual dipolar shift contribution is provided by the following equation

$$\Delta\delta^{dip} = \tilde{\delta}_x^{dip} D_x + \tilde{\delta}_y^{dip} D_y + \tilde{\delta}_z^{dip} D_z \qquad (A.3)$$

with[4]

$$\tilde{\delta}_i^{dip} = \frac{1}{4\pi r^3}\left[3\left(\chi_{zz}\cos\alpha\cos\vartheta + \chi_{xx}\sin\alpha\cos\beta\sin\vartheta\cos\varphi + \chi_{yy}\sin\alpha\sin\beta\sin\vartheta\sin\varphi\right)\right.$$
$$\left(\cos\alpha\cos\vartheta + \sin\alpha\cos\beta\sin\vartheta\cos\varphi + \sin\alpha\sin\beta\sin\vartheta\sin\varphi\right) - \qquad (A.4)$$
$$\left.\left(\chi_{zz}\cos^2\alpha + \chi_{xx}\sin^2\alpha\cos^2\beta + \chi_{yy}\sin^2\alpha\sin^2\beta\right)\right]$$

where α and β are the polar angles that define the position of the main axis *i* of the *D* tensor in the frame where χ is diagonal, and are the polar angles that define the position of the electron−proton direction in the same frame (see Figure 4). Integration of Equation (A.4) over all space gives Equation (7). Equations (A.1−A.2) and (A.3−A.4) may prove useful whenever extensive orientation in solution

without too severe broadening in the NMR lines is obtained.

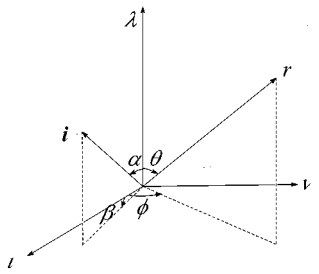

Figure 4. Schematic representation in the χ frame of the α and β polar angles defining the position of the *i* direction and of the θ and φ polar angles defining the proton-electron *r* direction

For completeness, we mention the limit values of Equations (A.1−A.2) and (A.3−A.4) when the *D*, *g* and χ tensors are diagonal in the same frame. This may be the case for molecules experiencing partial orientation in a field as a result of the anisotropy of the χ tensor itself.[58] For the residual contact shift, $\tilde{\delta}_i^{\mathrm{con}}$ in Equation (A.1) are provided by Equation (5). For the residual dipolar shifts, $\tilde{\delta}_i^{\mathrm{dip}}$ in Equation (A.3) reduce to:

$$\tilde{\delta}_x^{\mathrm{dip}} = \frac{\chi_{xx}\left(3l^2-1\right)}{4\pi r^3} \qquad \tilde{\delta}_y^{\mathrm{dip}} = \frac{\chi_{yy}\left(3m^2-1\right)}{4\pi r^3} \qquad \tilde{\delta}_z^{\mathrm{dip}} = \frac{\chi_{zz}\left(3n^2-1\right)}{4\pi r^3}$$

In the axial case and in the hypothesis that the components of the *D* tensor are proportional to those of the χ tensor, the following relationships can be derived:

$$D_{\parallel} = \frac{1+\frac{B_0^2}{2\mu_0 kT}\chi_{\parallel}}{3+\frac{B_0^2}{2\mu_0 kT}\chi_{\parallel}+2\frac{B_0^2}{2\mu_0 kT}\chi_{\perp}} \qquad D_{\perp} = \frac{1+\frac{B_0^2}{2\mu_0 kT}\chi_{\perp}}{3+\frac{B_0^2}{2\mu_0 kT}\chi_{\parallel}+2\frac{B_0^2}{2\mu_0 kT}\chi_{\perp}}$$

so that $D_{\parallel} + 2D_{\perp} = 1$. Substituting into Equation (A.3) provides the pseudo-contact shift

$$\delta^{\mathrm{pc}} = \frac{1}{3+\frac{B_0^2}{2\mu_0 kT}\chi_{\parallel}+2\frac{B_0^2}{2\mu_0 kT}\chi_{\perp}} \cdot \frac{1}{4\pi r^3}\left[\left(3\chi_{\parallel}\cos^2\theta-\chi_{\parallel}\right)\left(1+\frac{B_0^2}{2\mu_0 kT}\chi_{\parallel}\right)+2\left(\frac{3}{2}\chi_{\perp}\sin^2\theta-\chi_{\perp}\right)\left(1+\frac{B_0^2}{2\mu_0 kT}\chi_{\perp}\right)\right]$$

where θ is the angle between *r* and $\chi_{\parallel}$. To first order, the above equation can be approximated as

$$\delta^{\mathrm{pc}} = \frac{(3\cos^2\theta-1)(\chi_{\parallel}-\chi_{\perp})}{12\pi r^3}\left(1+\frac{B_0^2}{6\mu_0 kT}(2\chi_{\parallel}+\chi_{\perp})\right) \quad (A.5)$$

A similar equation has already been reported.[58] A remarkable feature of this equation is that the correction to the pseudo-contact shifts owing to orientation $\left(\frac{B_0^2}{6\mu_0 kT}(2\chi_{\parallel}+\chi_{\perp})\right)$ depends on the magnitude of the magnetic susceptibility but is independent of its anisotropy.

Acknowledgments

We thank Professor Bruce McGarvey for the enlightening discussions on the factors determining the anisotropy of contact shift during his stay as visiting professor in Florence in 1998. He has given us the correct perception of the importance of such effects. For financial support, we thank Murst ex 40%, Italy, the European Union, TMR-LSF contract ERB FMGE CT950033, and CNR, Progetto Finalizzato Biotecnologie, Italy.

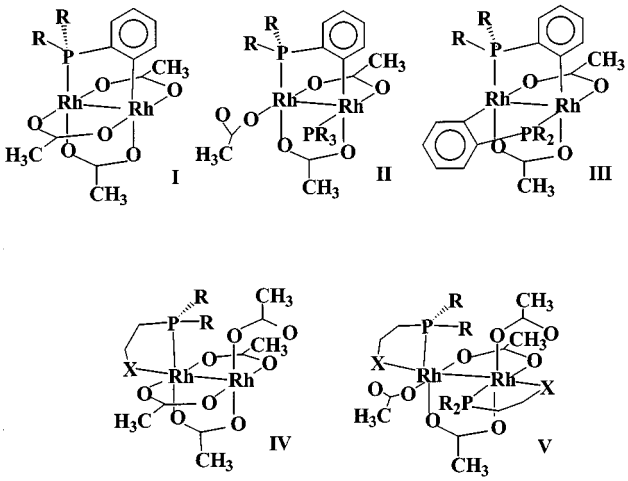
Diastereospecific Control in the Synthesis of Enantiomerically Pure Bis-Equatorial Rhodium(II) Catalysts by Chiral Phosphanes

Pascual Lahuerta,*[a] Eduardo Moreno,[a] Angeles Monge,[b] Guillermo Muller,[c] Julia Pérez- Prieto,*[d] Mercedes Sanaú,[a] and Salah-Eddine Stiriba[a][‡]



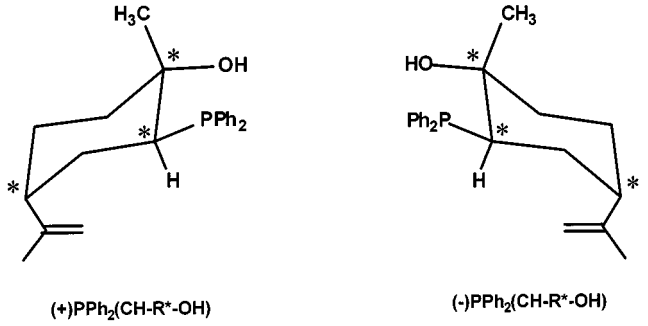
Keywords: Carboxylato complexes / Chirality / Diazo compounds / P ligands / Rhodium

The reaction of $Rh_2(O_2CR)_4$ [R = CH_3, CF_3] with the chiral phosphane (1*S*,2*S*,5*R*)-(2-hydroxy-5-isopropenyl-2-methylcyclohexyl)(diphenyl)phosphane, (+)PPh_2(CH–R*–OH) or its enantiomer (1*R*,2*R*,5*S*)-(2-hydroxy-5-isopropenyl-2-methylcyclohexyl)(diphenyl)phosphane, (–)-PPh_2(CH–R*–OH), results in the specific formation of the products (*P*)-$Rh_2(\mu\text{-}O_2CR)_2(\eta^1\text{-}O_2CR)_2\{\eta^2\text{-}(+)PPh_2(CH–R^*–OH)\}_2$ [**P(+)1**, R = CH_3; **P(+)2** R = CF_3] and (*M*)-$Rh_2(\mu\text{-}O_2CR)_2(\eta^1\text{-}O_2CR)_2\{\eta^2\text{-}(–)PPh_2(CH–R^*–OH)\}_2$ [**M(–)1**, R = CH_3; **M(–)2**, R = CF_3] in a high yield. Their synthesis, characterisation and catalytic behaviour in metal–carbenoid reactions are reported. X-ray analysis of **P(+)2** and **M(–)2** shows, in each case, a Rh_2^{4+} unit supported by two bridging and two monodentate trifluoroacetates; two phosphanes, (+)PPh_2(CH–R*–OH) or (–)PPh_2(CH–R*–OH) respectively, acting as chelating equatorial (P) and axial (O) donor ligands, complete the coordination sphere. These compounds are a pair of enantiomers. The crystallographic parameters are as follow: for **P(+)2**, space group $P3_121$ (trigonal) with $a = b = 13.0366(8)$, $c = 29.756(2)$ Å, $Z = 6$ and $R = 0.0499$; for **M(–)2** space group $P3_2$ (trigonal) with $a = b = 12.9751(9)$, $c = 29.685(3)$ Å, $Z = 3$ and $R = 0.0747$.

Introduction

The current interest in the development of rhodium(II) compounds recently observed[1] is due to their applications in catalytic metal−carbene transformations.[2] Most rhodium(II) compounds are formulated as $[Rh_2(ABC)_4L_2]$ and have the lantern-type structure characteristic of dimetal tetracarboxylate compounds.[1a] Cotton[3] and others[4] have reported that rhodium(II) carboxylate compounds with arylphosphanes afford compounds of the type $[Rh_2(\mu\text{-}O_2CR)_{4-x}(\mu\text{-PC})_x]$ (x = 1,2; R = CH_3 or CF_3; PC = metalated arylphosphane).

The great variety of these structures[3,4] and the possibility of modifying these compounds for specific purposes ensure continued emphasis on synthesis, characterisation and catalytic studies.[5] Cyclometalated rhodium(II) compounds with structures of type **I**−**III** (Scheme 1) have been characterised by X-ray methods,[3a][4a][4b] and some of them have shown chemoselectivity in diazo transformations.[4f]



Scheme 1. Rhodium compounds type **I**−**V**

Related compounds with *ortho*-functionalised phosphanes and structures **IV**[6] and **V**, [5] have also been reported. It should be noted that structures **III** and **V** have C_2 symmetry and consequently are inherently chiral. Compounds with the formula $Rh_2(O_2CCH_3)_2[(C_6H_4)P(C_6H_5)_2]_2$, with structure **III**, have been isolated as pure enantiomers by conventional resolution methods.[7] The resolved enanti-

omers induce moderate enantioselectivity in a C−H insertion reaction.

Compounds of type **V**, with acetate groups and X = Cl, OCH_3, have shown catalytic activity in cyclopropanation reactions.[5] Considering the potential interest of these type of compounds as pure enantiomers, we explored their selective synthesis by using the chiral phosphanes (*1S*,2*S*,5*R*)-(2-hydroxy-5-isopropenyl-2-methylcyclohexyl)(diphenyl)-phosphane, (+)-PPh_2(CH−R*−OH)[8] or its enantiomer (1*R*,2*R*,5*S*)-(2-hydroxy-5-isopropenyl-2-methylcyclohexyl)(diphenyl)-phosphane, (−)-PPh_2(CH−R*−OH) (Scheme 2).

Scheme 2. (1*S*,2*S*,5*R*)-(2-hydroxy-5-isopropenyl-2-methylcyclohexyl)(diphenyl)phosphane (+)PPh_2(CH−R*−OH) and its enantiomer, (−)PPh_2(CH−R*−OH)

We describe in this paper the diastereospecific synthesis of compounds **P(+)1** and **P(+)2** from the reaction of (+)-PPh_2(CH−R*−OH) with rhodium acetate or trifluoroacetate (Scheme 3). Similar reactions with the phosphane (−)-PPh_2(CH−R*−OH) produced **M(−)1** and **M(−)2**. We also report on the X-ray structure of the trifluoroacetate derivatives **P(+)2** and **M(−)2**, as well as the catalytic behaviour of several of these compounds.

Scheme 3. Synthesis of bis equatorial rhodium(II) catalysts by reaction of chiral phosphanes with rhodium tetracarboxylates

Results

Synthetic Aspects

Addition of 2 equivalents of (+)-PPh_2(CH−R*−OH) to a solution of $Rh_2(O_2CCH_3)_4$·2MeOH in refluxing toluene/acetic acid (3:1), resulted in the formation of a green solution from which the complex (*P*)-$Rh_2(\mu\text{-}O_2CCH_3)_2(\eta\text{-}O_2CCH_3)_2\{\eta^2\text{-}(+)\text{-}PPh_2(CH-R^*-OH)\}_2$ **[P(+)1]** was easily isolated in a high yield. The same reaction with the phosphane (−)-PPh_2(CH−R*−OH) yielded the corresponding enantiomer (*M*)-$Rh_2(\mu\text{-}O_2CCH_3)_2(\eta\text{-}O_2CCH_3)_2\{\eta^2\text{-}(-)\text{-}PPh_2(CH-R^*-OH)\}_2$ **[M(−)1]**.

Addition of 2 equiv. of (+)-PPh_2(CH−R*−OH) to a solution of $Rh_2(O_2CCF_3)_4$ in diethyl ether at room temperature, yielded the complex (*P*)-$Rh_2(\mu\text{-}O_2CCF_3)_2(\eta\text{-}O_2CCF_3)_2\{\eta^2\text{-}(+)\text{-}PPh_2(CH-R^*-OH)\}_2$ **[P(+)2]** in a high yield. The same reaction with the phosphane (−)-PPh_2(CH−R*−OH) yielded the corresponding enantiomer (*M*)-$Rh_2(\mu\text{-}O_2CCF_3)_2(\eta\text{-}O_2CCF_3)_2\{\eta^2\text{-}(-)\text{-}PPh_2(CH-R^*-OH)\}_2$ **[M(−)2]**.

X-ray Analysis

The crystal structures for compounds **P(+)2** and **M(−)2** have been determined by X-ray procedures. ORTEP diagrams, with the corresponding atom-labelling schemes are shown in Figure 1 and 2 for both the compounds together with selected bond lengths and angles.

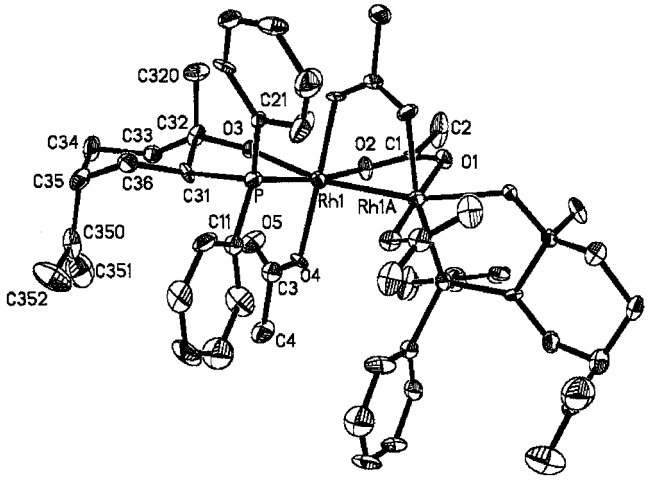

Figure 1. ORTEP diagram of the complex (*P*)-$Rh_2(\mu\text{-}O_2CCF_3)_2(\eta^1\text{-}O_2CCF_3)_2\{\eta^2\text{-}(+)PPh_2(CH-R^*-OH)\}_2$ **[P(+)2]** with the F and H atoms omitted for clarity; selected bond lengths [Å] and angles [°]: Rh1−Rh1A 2.5873(13), Rh1−O3 2.250(5), Rh1−P 2.252(3), Rh1−O2 2.148(8); O1−Rh1−O4 176.4(3), O2−Rh1−P 168.9(2), O3−Rh1−Rh1A 165.8(2), O4−Rh1−P 92.6(2)

The structure of **P(+)2** consists of an Rh_2^{4+} unit supported by two bridging and two monodentate trifluoroacetates; two (+)PPh_2(CH−R*−OH) phosphanes, acting as chelating equatorial (P) and axial (O) donor ligands, complete the coordination sphere around the metal atoms.

The two bridging trifluoroacetate groups are in a *cisoid* configuration and the phosphorous atoms exhibit a (*P*) configuration.

The Rh−Rh bond length, 2.5873(13) Å, is slightly longer than the distance [2.5605(11) Å] found in a structurally related compound with the formula $[Rh_2(\mu\text{-}O_2CCH_3)_2(\eta\text{-}Cl)_2\{\eta^2\text{-}(o\text{-}CH_3OC_6H_4)P(C_6H_5)_2\}_2]$.[5]

One interesting feature of **P(+)2** is that the axial Rh−O bond length, 2.250(5) Å, is shorter than that observed in the analogous $[Rh_2(\mu\text{-}O_2CCH_3)_2(\eta\text{-}Cl)_2\{\eta^2\text{-}(o\text{-}CH_3\text{-}$

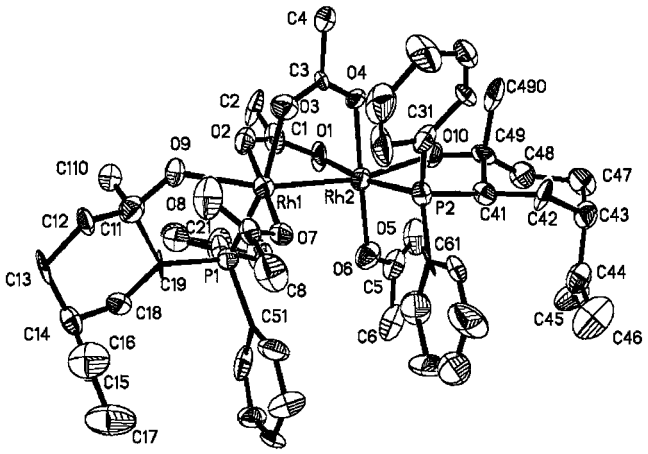

Figure 2. ORTEP diagram of the complex $(Rh_2(\mu\text{-}O_2CCF_3)_2(\eta^1\text{-}O_2CCF_3)_2\ \{\eta^2\text{-}(-)PPh_2(CH-R^*-OH)\}_2$ [**M(−)2**] with the F and H atoms omitted for clarity; selected bond lengths [Å] and angles [°]: Rh1−Rh2 2.6011(18), Rh1−O9 2.255(13), Rh1−P1 2.246(5), Rh1−O3 2.170(12); O2−Rh1−O7 176.0(5), O3−Rh1−P 169.1(4), O9−Rh1−Rh2 166.6(3), O7−Rh1−P 93.0(3)

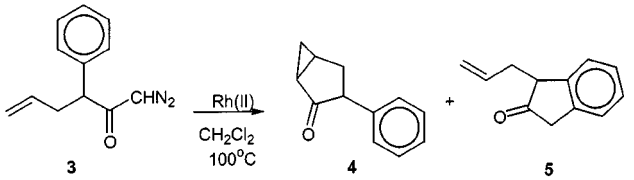
$OC_6H_4)P(C_6H_5)_2\}_2$, 2.342(7) Å].[5] This distance is also shorter than the average Rh−O distance observed for rhodium(II) bis-adduct complexes with oxygen donor ligands.[1a][3a,4]

Compound **M(−)2** has the same overall structure as **P(+)2**, but has an (*M*) configuration. The Rh−Rh distance of 2.602(8) Å, is typical for such a type of species.

NMR-Spectroscopic Data

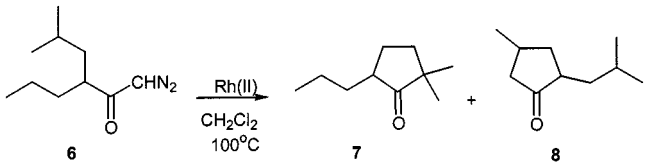


The spectroscopic data recorded for all the isolated compounds, support that the solid-state structure is maintained in solution. The ^{31}P NMR spectra show a second-order signal, with a very similar chemical shift for all the isolated compounds ($\delta \approx 46$), that corresponds to the AA′ part of an AA′XX′ system. This high value of the chemical shift is characteristic of nonmetalated phosphanes in an equatorial coordination.[5] The signals from the protons of the OH groups of the phosphanes appear at a remarkable low field, ($\delta \approx 10-12$), in agreement with the axial Rh−O coordination observed in the X-ray data. In particular, the homonuclear shift correlated 2D NMR spectrum of **P(+)2** confirms the coupling between the proton of the OH group (at 10.1 ppm) with the CH_3 group at $\delta = 1.4$ ppm, and also the coupling between the olefinic protons ($\delta = 4.2$ and 4.6) and the methyl group ($\delta = 1.1$).

The NMR-spectroscopic data also confirms the existence of two different types of carboxylate groups in each compound. Thus, compounds **P(+)2** and **M(−)2**, with trifluoroacetate groups, show two resonance signals in the corresponding ^{19}F NMR spectra. For the corresponding compounds with acetate groups, **P(+)1** and **M(−)1**, the ^1H NMR spectra show four resonance signals of equal intensity; two of these signals, at $\delta = 1.4$ and 1.1, correspond to the phosphane while the others, at $\delta = 1.0$ and 1.2, correspond to the acetate groups.

Catalytic Studies

The X-ray structural analysis provides evidence for the relatively strong coordination of the OH groups of the phosphanes to the axial site of the rhodium centre. This data suggests a low reactivity of these rhodium dimers toward diazo compounds; in order to confirm this assumption, control experiments were performed. Thus, the reaction of ethyl diazoacetate with compound **P(+)2** in dichloromethane, was carried out in a sealed tube at different temperatures in the 45−100 °C temperature range. We only observed a transformation of the diazo compound at temperatures close to 100 °C; at lower temperatures the substrate was recovered unchanged after extensive heating. ^{31}P and ^1H NMR spectra confirm that no decomposition of the rhodium compound occurred during this heating.



Studies of chemo- and regioselectivity of compounds **P(+)1** and **P(+)2** in diazo compound transformation were performed by using model substrates. Diazo ketone **3**[9] was used to study the competition between the cyclopropanation reaction and aromatic substitution (Scheme 4), while diazo ketone **6**[10] was used for similar studies in tertiary versus secondary C−H insertion reaction (Scheme 5). It is remarkable that these compounds led to a similar selectivity as rhodium acetate. Not surprisingly, these rhodium compounds exhibited poor enantioselectivity in the cyclopropanation of 1-diazo-5-phenyl-2-pentanone[11] (enantiomeric excess less than 6%).

Discussion

The above results confirm that it is possible to induce diastereospecificity in the synthesis of compounds of type **V**, $Rh_2(\mu\text{-}O_2CR)_2(\eta\text{-}O_2CR)_2(\eta\text{-}P{-}X)_2$, using the OH-functionalised chiral phosphanes (+)PPh_2(CH−R*−OH) and (−)PPh_2(CH−R*−OH). As the formation of these compounds occurs by coordination of the phosphane to one axial coordination site, followed by migration from the axial to the equatorial position, this highly chiral induction could be rationalised in terms of the steric effects in some of the steps of this process. Thus, in Scheme 6 the reaction intermediate is represented with the axial ligand (−)PPh_2(CH−R*−OH) in the two extreme orientations leading to each diastereoisomer. It also shows how the repulsive interaction between the methyl group of the entering phosphane and the monodentate carboxylate group is especially important in the intermediate that leads to the diastereoisomer **P(−)1**, justifying the selective formation of the **M (−)1** isomer. The same applies to the reaction with the phosphane (+)PPh_2(CH−R*−OH), where the only isomer formed is **P(+)1**.

R = isopropenyl
P*= (-)PPh_2(CH-R*-OH)

Scheme 6. Proposed origin of the diastereospecificity

The low activity and selectivity of these catalysts must be a consequence of the relatively strong Rh−O axial ligation. The high temperature needed to reach catalytic activity suggests that, under such thermal conditions, Rh−O bond dissociation can take place supplying free active catalytic sites.

The high temperature needed to liberate the active catalytic site produces the carbene transfer reaction in relatively drastic conditions and precludes the selective diazo transformation. In fact, the selectivities shown by these compounds are similar to those reported for the poorly selective rhodium acetate.[9]

Conclusion

These results confirm the ability of a functionalised chiral phosphane, to induce diastereospecificity in the synthesis of chiral rhodium(II) compounds. The above described catalytic results prove that the relatively strong axial Rh−O coordination lowers the activity of the synthesised species of structural type **V**. In general, this strong axial coordination must be considered as a negative effect in the design of a catalyst. However, we suggest that this property might be used in a beneficial way in the case of complexes of type **II**. In this case the functionalised phosphane could be used to block one axial coordination site, leaving the other metal centre open for interaction with the diazo compound. Thus, the use of this sort of functionalised phosphanes in the synthesis of chiral complexes of type **II**, appears as a useful strategy for obtaining enantiomerically pure species with only one available position for catalytic purposes.

Experimental Section

General Considerations: Commercially available $Rh_2(O_2CCH_3)_4{\cdot}2MeOH$ was purchased from Pressure Chemical Com. $Rh_2(O_2CCF_3)_4$ $2(Me_2CO)$,[12] the phosphanes (+)PPh_2(CH−R*−OH),[8] and (−)PPh_2(CH−R*−OH)[8] and the diazo compounds **3**,[9] **6**,[10] and **9**[11] were prepared according to literature procedures. − Solvents were distilled prior to use. − ^1H, $^{13}C\{^1H\}$, $^{31}P\{^1H\}$ and ^{19}F NMR spectra were recorded with a Varian−300 Unity and with a Bruker AM-250 instrument; spectra were obtained as solutions in $CDCl_3$. − Elemental analyses were performed at Centro de Microanálisis Elemental (Universidad Complutense de Madrid). − Optical rotations were measured with a Perkin−Elmer 241 polarimeter at the Na-D line in 10-cm quartz cuvettes. − The UV/Vis measurements were performed with a Varian Cary 1 spectrophotometer.

X-ray Crystallographic Procedures: Single crystals of compounds **P(+)2** or **M(−)2** were obtained by slow diffusion of hexane into an ethyl ether solution of each compound at room temperature. X-ray diffraction experiments were carried out with a Siemens Smart diffractometer with a CCD detector using Mo-K_α radiation. Unit cell dimensions were determined by a least fit of 50 reflections, ($2.73° < \theta < 23.31°$). All calculations were done using SMART software for data collection.[13] Empirical absorption correction was applied on compound **P(+)2**. The structures were solved by direct methods, and refined on F^2 with the program SHELXTL.[14] The positions of the remaining atoms were located after an alternating series of least-squares cycles and difference Fourier maps. Anisotropic displacement parameters were assigned to all nonhydrogen atoms, except to C51 on **M(−)2**, which was refined isotropically. Hydrogen atoms were placed in geometrically generated positions and refined riding on the carbon atom to which they are attached. Crystal Data: **P(+)2**: $C_{26}H_{26}F_6O_5PRh{\cdot}1/2CHCl_3$, M = 728.05, trigonal, $a = b = 13.0366(8)$, $c = 29.756(2)$ Å, V = 4379.6(5) Å^3, T = 293 K, space group $P3_121$, Z = 6, μ(Mo-K_α) = 0.851 mm^{-1}, 6335 reflections measured, 2615 unique (R_{int} = 0.0426) which were used in all calculations. Data/parameters

2615:351. The final R was 0.0499 ($wR2$ = 0.098). − **M(−)2**: $C_{52}H_{52}F_{12}O_{10}P_2Rh_2{\cdot}2H_2O$, M = 1358.69, trigonal $a = b$ = 12.9751(9), c = 29.685(3) Å, V = 4328.0(6) Å^3, T = 173 K, space group $P3_2$, Z = 3, μ(Mo-K_α) = 0.723 mm^{-1}, 6662 reflections measured, 4751 unique (R_{int} = 0.0547) which were used in all calculations. Data/parameters 4751:715. The final R was 0.0747($wR2$ = 0.1762). − Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publications nos. CCDC-139657 **[P(+)2]** and CCDC-139658 **[M(−)2]**. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

General Procedure for Rhodium(II)-Catalysed Reactions of Diazo Compounds: The rhodium(II) compound (1%) was added under argon to a solution containing a diazo compound (0.5 mmol) in dry dichloromethane (4 mL). The mixture was heated at 100 °C in a sealed tube. The extent of reaction was monitored by TLC, using hexane/ethyl acetate as the eluent, until the diazo starting material was consumed. The solution was filtered through a 1-cm plug of silica gel, followed by washing with CH_2Cl_2 (20 mL). The filtrate was concentrated in vacuum and the residue was directly chromatographed with a mixture of hexane/ethyl acetate (10:1).

(*P*)-Rh$_2$(μ-O$_2$CCH$_3$)$_2$(η^1-O$_2$CCH$_3$)$_2${η^2-(+)PPh$_2$(CH−R*−OH)}$_2$ [P(+)1]: $Rh_2(O_2CH_3)_4{\cdot}2$(MeOH) (0.15 g, 0.3 mmol) was refluxed with (+)PPh$_2$(CH−R*−OH) (0.22 g, 0.65 mmol) in toluene/acetic acid (3:1) (30 mL) for 1 h. The resulting green solution was concentrated to dryness to yield a green solid that was crystallised from CH_2Cl_2/hexane giving **P(+)1** (0.30 g, 80%). − $[\alpha]_D$ = −39 (c = 0.125, $CHCl_3$). −^{1}H NMR ($CDCl_3$): δ = 12.0 (s, 2 H, OH), 7.8 (m, 4 H, aromatic protons), 7.0−7.5 (m, 16 H, aromatics), 4.5 (s, 2 H, HC=C), 4.0 (s, 2 H, HC=C), 2.6 (m, 2 H, HC−P), 2.3−1.5 (m, 14 H, cyclohexyl protons), 1.4 (s, 6 H, CH_3), 1.2 (s, 6 H, acetate), 1.1 (s, 6 H, CH_3), 1.0 (s, 6 H, acetate). − ^{13}C{^{1}H} NMR ($CDCl_3$): δ = 21.6 (CH_3C=C), 23.0 (CH_3, acetate), 23.7 (CH_3COH), 26.2, 29.6, 38.3, 38.6 (cyclohexyl carbons), 55.1 (HC−P), 75.3 (COH), 111.5 (CH_2=C), 127.4, 127.7, 129.5, 129.9, 132.7, 134.5 (aromatic carbons), 143.9 (C=CH_2), 184.6 (OOC acetate), 188.5 (O_2C acetate). − ^{31}P{^{1}H} NMR ($CDCl_3$): δ = 46 ($^1J_{Rh-P}$ = 163 Hz, $^2J_{Rh-P}$ = −5 Hz, J_{Rh-Rh} = 20 Hz). − UV/Vis ($CHCl_3$): $\lambda_{max}(\varepsilon)$ = 321 nm (41690), 258 nm (32370). − $C_{52}H_{66}O_{10}P_2Rh_2$ (1118.94): calcd. Organometallic Complexes of Uracil and Orotic Acid Derivatives: Coordination Mode, Structure, and Reactivity

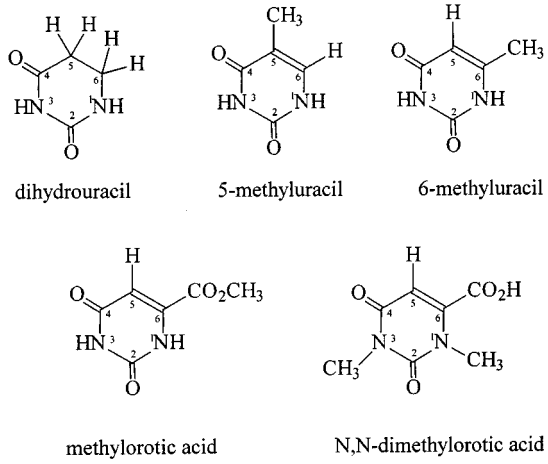
Donald J. Darensbourg,*[a] Brian J. Frost,[a] David L. Larkins,[a] and Joseph H. Reibenspies[a]



Keywords: Carbonyl complexes / Uracil / Pyrimidines / Kinetics

Carbonyltungsten derivatives of uracilates and orotates, where the metal center is bound to a nitrogen atom of the pyrimidine ring, are described. There organometallic complexes were synthesized by the reaction of either $W(CO)_5THF$ or $W(CO)_5MeOH$ with the tetraethylammonium salt of the deprotonated monoanion of dihydrouracil (**1**), 5-methyluracil (**2**), 6-methyluracil (**3**), methylorotic acid (**4**), and *N*,*N*-dimethylorotic acid (**5**). The complexes were all characterized in solution by IR and ^{13}C NMR spectroscopy, and in select instances in the solid-state by X-ray crystallography. The structures of complexes **1** and **3** consist of octahedrally coordinated anions of pentacarbonyltungsten uracilate, where the uracilate ligand is bound to the metal center by the N3 atom of the pyrimidine ring, and the tetraethylammonium cation for charge balance. In contrast, the anion of complex **2** reveals that the uracilate ligand is bound to the $W(CO)_5$ fragment by the N1 atom of the pyrimidine ring. The ν(CO) vibrational modes and ^{13}C NMR chemical shifts for the carbonyl ligands of complexes **1** and **3** indicate that the metal centers are more electron-rich than those of complex **2**. This conclusion is further substantiated by the rates of intermolecular CO exchange in these carbonylmetal anions with ^{13}CO. The facile CO exchange observed in complexes **1** and **3** is faster than that seen in complex **2**. The rapid CO dissociation process measured in these derivatives is attributed to the π-donation of electron density from the pyrimidine ring to the tungsten center in the transition state as the M–CO bond is broken.

Introduction

The coordination chemistry of pyrimidine bases has been a subject of interest for many years, and has been studied from a variety of perspectives by many different research groups.[1−4] Pyrimidine derivatives of thymine and uracil, such as AZT (3′-azido-3′-deoxythymidine), have been shown to be effective antiviral drugs.[5,6] Metal complexes of pyrimidines have been shown to be useful as biological carriers for some of these drugs such as AZT,[7−10] others have demonstrated anti-cancer/tumor activity.[11,12] Despite the plethora of coordination complexes of pyrimidines, the organometallic chemistry involving these ligands has received limited attention, with most efforts coming from the laboratory of Beck and co-workers.[13,14] Recently, we have examined the coordination modes of uracils and orotic acid derivatives to zero-valent group-6 carbonylmetal compounds, focusing our studies on the ability of the ring nitrogen atoms to serve as π-donor ligands and to facilitate CO dissociation.[15,16] Previously, investigations of the coordination chemistry of uracils have revealed a wide range of metal-dependent binding modes, including via N1, N3, the exocyclic oxygen atoms,[1,2] both an endocyclic nitrogen and an exocyclic oxygen (or sulfur) atom,[15,17] and finally, though less common, through C5.[18]

Herein, we wish to communicate a continuation of our studies of organometallic derivatives of uracils and orotic acid derivatives. Specifically, this study will examine the various coordination modes and π-donor abilities of a series of tungsten-bound uracilate and orotate derivatives, in particular dihydrouracil, 5-methyluracil (thymine), 6-methyluracil, methylorotic acid, and *N*,*N*-dimethylorotic acid (Scheme 1). Also discussed are the electronic effects of different pyrimidine derivatives as examined by IR and ^{13}C NMR spectroscopy, and CO exchange kinetics.

Scheme 1

Results and Discussion

A series of $[Et_4N][W(CO)_5L]$ complexes, where L = dihydrouracilate (**1**), 5-methyluracilate (**2**), 6-methyluracilate (**3**), methylorotate (**4**), and *N*,*N*-dimethylorotate (**5**), were synthesized in good yields by the labile-ligand displacement of THF or methanol from $W(CO)_5(THF)$ or $W(CO)_5(MeOH)$

[a] As the tetraethylammonium salt. − [b] Spectra determined in CH_3CN. − [c] Ref.[15]

[prepared in situ by photolysis of $W(CO)_6$ in THF or meth-1anol] by the tetraethylammonium salt of the deprotonated monoanion of the corresponding uracil or orotic acid derivative. All complexes were characterized by IR and ^{13}C NMR spectroscopy in the carbonyl region, elemental analysis, and X-ray crystallography for complexes **1**−**3**. In addition, the product of the reaction of **1** with methanol, $[Et_4N]_2[W_2(CO)_8(OMe)_2]$ (**6**), was also characterized by X-ray crystallographic analysis and ^{13}C NMR spectroscopy.

The IR spectra in the ν(CO) stretching region of complexes **1**−**5** consist of three bands of the appropriate intensity pattern for a $W(CO)_5$ fragment of C_{4v} local symmetry. Table 1 contains the ν(CO) values for these, and closely related, derivatives. Since the ν(CO) stretching vibrational modes are such good probes of the electron-donating ability of the ancillary ligands bound to the metal center in the carbonylmetal derivatives, it is clear from a close scrutiny of the ν(CO) spectra of complexes **2** and **3** (Figure 1) that the uracilate ligands are coordinated differently in these instances. That is, there is a significant difference in the low-frequency A_1 modes of these two derivatives, where the electronic effects of the uracilate-binding mode should be most evident. Similarly, the pyrimidine carbonyl stretches are also quite different, with the $\Delta\nu(CO_2)$ for the asymmetric and symmetric vibrations being 23 and 92 cm^{-1} for **2** and **3**, respectively. Furthermore, based on the similarity of the ν(CO) spectra of complexes **1**, **3**, and **4**, it is reasonable to suggest that in these derivatives the pyrimidine ligands are bonded in a similar fashion. It is also evident from the ν(CO) IR data listed in Table 1 that complex **2** and the structurally characterized $[Et_4N][W(CO)_5$(uracilate)] derivative[15] share a common structure. The *N*,*N*′-dimethylorat-

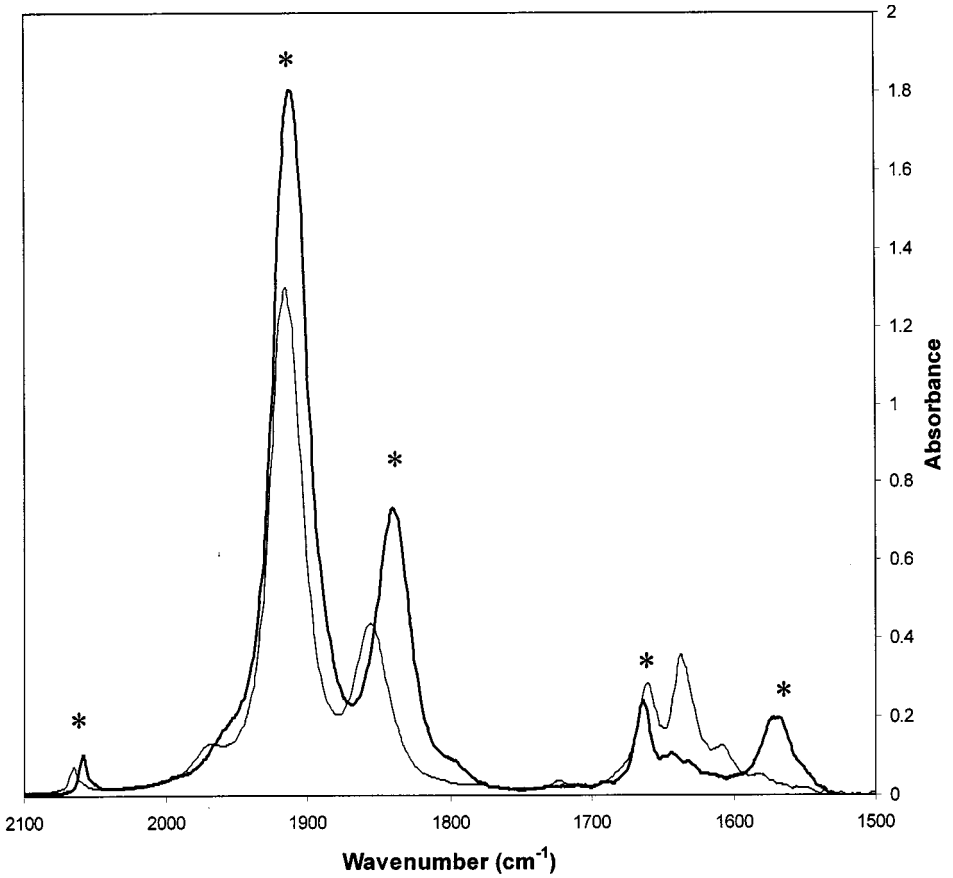

Figure 1. Infrared spectra in the ν(CO) and ν(CO_2) regions of $[Et_4N][W(CO)_5$(5-methyluracilate)] (**2**) and $[Et_4N][W(CO)_5$(6-methyluracilate) (**3**) in acetonitrile solvent; peaks marked with asterisks are those due to complex **3**

ate derivative, complex **5**, exhibits ν(CO) IR bands typical of carboxylates bound in a monodentate fashion containing electron-withdrawing substituents in anionic complexes of the type $W(CO)_5$(carboxylate)$^-$. For example, the $W(CO)_5(O_2CCF_3)^-$ anion has ν(CO) vibrational modes at 2066, 1916, and 1857 cm^{-1} in THF solution.[19]

^{13}C NMR spectroscopic data for the carbonyl ligands were compiled for complexes **1**−**6**, and are listed in Table 2. Complexes **1**−**5** exhibit the anticipated two ^{13}C resonances of intensity ratio 1:4, with the more intense upfield signal corresponding to that of the four *cis* carbonyl ligands. Complex **2** displays ^{13}C NMR signals for the equatorial and axial CO ligands at δ = 200.6 and 205.7, respectively, which are quite similar to values previously reported for the carbonyl ligands of the $W(CO)_5$(uracilate)$^-$ anion.[15] On the other hand, complexes **1**, **3**, and **4** exhibit ^{13}C NMR resonances which are measurably different from complex **2** and $[Et_4N][W(CO)_5$(uracilate)], again suggesting a different coordination mode for these latter two pyrimidine derivatives.

Table 2. ^{13}C NMR data for the carbonyl ligands in complexes **1**−**6**

Complex[a]	^{13}C resonance, δppm ($^1J_{W-C}$ [Hz]) CO (equatorial)	CO (axial)
$[W(CO)_5$(dihydrouracilate)]$^-$ (**1**)	203.0 (130)	208.5 (149)[b]
$[W(CO)_5$(5-methyluracilate)]$^-$ (**2**)	200.7 (131)	205.8[c]
$[W(CO)_5$(6-methyluracilate)]$^-$ (**3**)	202.0 (131)	204.8[c]
$[W(CO)_5$(methylorotate)]$^-$ (4)	201.7 (131)	207.9[c]

In order to address the question of the coordination modes of the pyrimidines definitively, the structures of complexes **1**−**3** were determined in the solid state by X-ray crystallography. The structures of all three derivatives are quite similar with five of the octahedral coordination sites occupied by carbonyl ligands and the sixth position occupied by a pseudo-amido donor from the pyrimidine base. Indeed, the differences in these structures lie in the pyrimidine ring/coordination mode. That is, in complexes **1** and **3** the pyrimidine ligand is bound through the deprotonated N3 nitrogen atom of the pyrimidine ring. In contrast, complex **2** contains a pyrimidine ring bound to the tungsten center through the deprotonated N1 nitrogen atom in a manner analogous to that previously reported for the $W(CO)_5$(uracilate)$^-$ anion.[15] Coordination through the N3 nitrogen atom of the pyrimidine ring places the exocyclic oxygen atoms in close proximity to the metal center, thereby assisting in the loss of a CO ligand with concomitant formation of a tetracarbonyl derivative containing a chelating uracilate ligand. For example, the tetracarbonyl derivative of complex **3** has been characterized by ν(CO) IR: 1991(w), 1865(s), 1840(m), and 1808(m) in THF; and by ^{13}C NMR: δ = 208.1 (2 *C*O), 217.7 (1 *C*O), and 218.3 (1 *C*O) in CD_3CN.

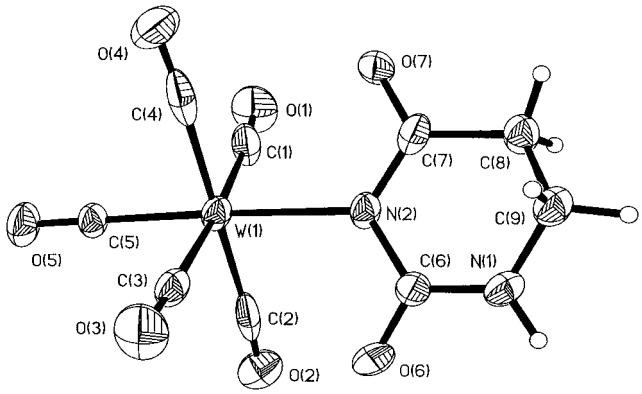

Figure 2. Thermal ellipsoid representation of the anion of complex **1**, $W(CO)_5$(dihydrouracilate)$^-$

Crystals of complex **1** suitable for X-ray analysis were obtained by the slow diffusion of hexane into a THF solution of the complex maintained at 0 °C. A thermal ellipsoid drawing of the monoanion, $W(CO)_5$(dihydrouracilate)$^-$, is depicted in Figure 2 along with the atomic numbering scheme. Selected bond lengths and bond angles are listed in Table 3. The crystal lattice of complex **1** contains a tetraethylammonium cation (for charge balance), as well as a diethyl ether molecule of solvation. The octahedral environment about the tungsten center consists of a dihydrouracilate anion bound to the metal center through the N3 atom of the pyrimidine ring at a distance of 2.263(8) Å. This bond length compares well with other related W−N bond lengths which are summarized in Table 4.[20−22] The *trans*-CO ligand exhibits a slightly shorter W−C bond length [1.967(10) Å] than the average W−C distance for the four *cis*-CO ligands [2.061(16) Å]. As anticipated, the pyrimidine ring in complex **1** is non-planar (Figure 3), unlike those in complexes **2** and **3** (vide supra) where the ring is pseudoaromatic.

The solid-state structure of complexes **2** and **3** were determined by crystallographic analysis on crystals obtained from the slow diffusion of hexane into a THF solution of the respective complex at ambient temperature. Thermal ellipsoid drawings of the anions of complexes **2** and **3** are shown in Figure 4 and Figure 5, respectively. Table 5 and Table 6 compile selected bond lengths and bond angles for these derivatives.

In complex **2**, the pyrimidine ligand is bound through the deprotonated N1 position of the ring like that observed in the parent $W(CO)_5$(uracilate)$^-$ anion.[15] On the other hand, the $[W(CO)_5]$ fragment in complex **3** is bound through the deprotonated N3 position of the pyrimidine ring, much like that seen in complex **1**. The choice of binding modes appears to be mainly a consequence of steric interactions. As is apparent from the space-filling models for the anions of complexes **2** and **3** (Figure 6), the methyl substituent on the pyrimidine ring precludes binding at the N1 site in complex **3**.

On the other hand, for all other structures we have determined herein and elsewhere,[15] binding occurs at the N1

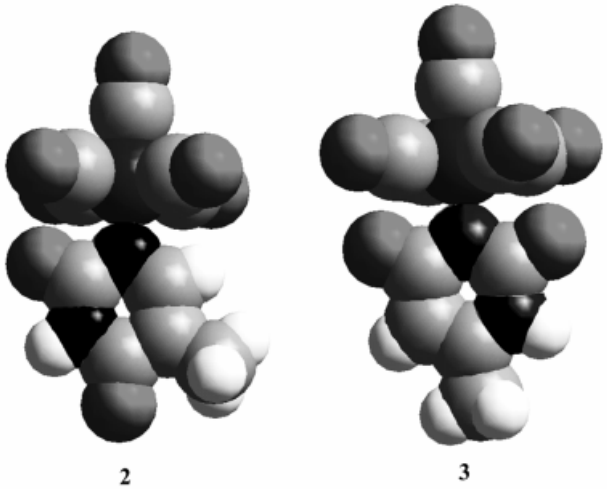

Figure 6. Space-filling models of the anions of complex **2** (left) and **3** (right)

N1. The tungsten−nitrogen distances are 2.236(15) Å and 2.276(4) Å, respectively, in complexes **2** and **3**. The W−C distances in the two derivatives are similar as expected, with both exhibiting a *trans* effect. That is, the W−C distance *trans* to the pyrimidine ligand is shorter than the average W−C distance *cis* to the pyrimidine ligand. For example, in complex **3**, the W−C *trans* distance is 1.952(5) Å, whereas the average W−C *cis* bond length is 2.040(6) Å. The packing diagrams of complexes **1**−**3** reveal that there is substantial amount of hydrogen bonding that is prevalent in the crystal structures of these complexes, as might be anticipated for pyrimidine derivatives. This is illustrated in Figure 7, which depicts the base-pairing observed in complex **3**, where the average O···N distance is 2.754 Å.

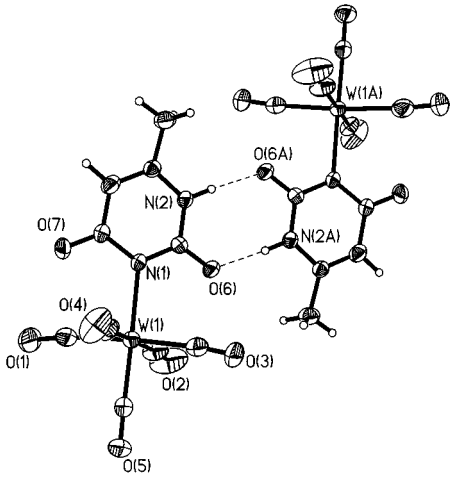

Figure 7. Thermal ellipsoid representation of the anions of complex **3**, $W(CO)_5$(6-methyluracilate)$^-$, showing the hydrogen-bonding motif between base pairs

These pyrimidine derivatives of carbonyltungsten are unstable in protic solvents. For example, on dissolving complex **1** in methanol the solution rapidly underwent a color change from orange to bright red and back to orange. Crystals of complex **6**, $[Et_4N]_2[W(CO)_4OMe]_2$ were isolated from a sample of **1** dissolved in CD_3OD in an NMR tube. We have characterized this derivative in the solid state by X-ray crystallography and in solution by ^{13}C NMR spectroscopy (δ = 208.5 and 220.1), thereby demonstrating that it is identical to the methoxide-bridged dimer we reported previously.[23] Presumably, this complex results from pro-

[a] Kinetic data on all complexes were obtained as Et_4N^+ salts to avoid significant ion-pairing effects (M. W. Payne, D. L. Leussing, S. G. Shore, *Organometallics* **1991**, *10*, 574). − [b] In THF. − [c] In CH_3CN.

tonation of the dihydrouracilate ligand by methanol to initially afford the $W(CO)_5OMe^-$ anion. This methoxide derivative has been shown to readily undergo CO dissociation and aggregation to the anions $[W(CO)_4(OMe)]_2^{2-}$ and $[W_2(CO)_6(OMe)_3]^{3-}$, or $[W(CO)_3OMe]_4^{4-}$.[23]

The CO lability in complexes **1**−**5** was examined by monitoring CO exchange (Equation 1) using in situ spectroscopy in the ν(CO) region. The decrease in absorbance of the highest frequency ν(CO) band was measured as a function of time with an IR probe inserted directly into an acetonitrile solution of the respective complex maintained at constant temperature with a thermostated water bath. The reactions were performed in the presence of a large excess of ^{13}CO in order to avoid having to consider the reverse process. Table 7 compiles the first-order rate constants for the CO exchange for the various complexes as a function of temperature. Table 8 lists the derived activation parameters for these processes obtained from the data in Table 7 and Figure 8, along with the corresponding values for the $W(CO)_5(uracilate)^-$ anion previously reported.

$$W(CO)_5(uracilate)^- + n^{13}CO \underset{k_2}{\overset{k_1}{\rightleftharpoons}} W(CO)_{5-n}(^{13}CO)_n(uracilate)^- + nCO \quad (1)$$

As is evident from the Eyring plots in Figure 8 for ^{13}CO exchange in complex **1**−**3** and the parent uracilate derivative, there are two distinct regions, one for the N1-bound complexes (**2** and the parent uracilate) and one for the N3-bound derivatives (**1** and **3**). The two complexes bound through the deprotonated N3 center are slightly more reactive towards CO exchange than the two complexes ligated by way of the deprontonated N1 group. Furthermore, within each grouping the presence of an electron-donating methyl substituent in the pyrimidine ring results in a somewhat enhanced rate (factor of 2−3) of CO lability. In other words, this facile CO exchange is attributed to π-donation of electron density from the deprotonated N1 or N3 atoms of the uracilate ligands, thereby stabilizing the developing 5-coordinate metal intermediate. Previously, we have demonstrated for the uracilate derivative that it is the *cis*-carbonyl ligands that are selectively exchanged. Nevertheless, these pyrimidine ligands bound through their endocyclic ni-

trogen atoms are *considerably less* CO-labilizing than the good π-donating phenolate ligands,[23] and *slightly less* CO-labilizing than the Cl^- ion or the exocyclic sulfur donors in thiouracilate derivatives.[16,23]

The rate constant for CO exchange ($1.88 \cdot 10^{-5}$ s^{-1} at 25 °C) in complex **4**, the closely related methylorotate derivative, is similar to those determined for the other pyrimidine complexes examined herein. The corresponding activation parameters, $\Delta H^{\neq} = 69.6 \pm 3.6$ kJ/mol and $\Delta S^{\neq} = -101.8 \pm 11.6$ J/molK, were derived from the temperature-dependent rate constant data. On the other hand, attempts to determine the kinetic parameters for intermolecular CO exchange in the carboxylate-bound derivative, $[Et_4N][W(CO)_5(N,N\text{-dimethylorotate})]$ (**5**), lead to extensive ligand loss with the formation of ^{13}CO-labeled $W(CO)_6$. Concomitantly, when the substitution reaction was carried out with $P(OEt)_3$ as an incoming ligand the principal product was the neutral complex $W(CO)_5P(OEt)_3$, resulting from displacement of the carboxylate ligand.

Conclusion

Stable tetraethylammonium salts of pentacarbonyltungsten anions of pyrimidine bases have been synthesized from the reactions of $W(CO)_5$(solvent), where solvent = THF or MeOH, with the deprotonated monoanion of the corresponding uracil or orotic acid derivative. Crystal structures of $[Et_4N][W(CO)_5$(dihydrouracilate)] (**1**) and $[Et_4N][W(CO)_5$(6-methyluracilate)] (**3**) reveal that the uracilate ligands are bonded to the tungsten center through the deprotonated N3 atom, whereas $[Et_4N][W(CO)_5$(5-methyluracilate)] (**2**) is bound to the metal fragment by the deprotonated N1 nitrogen atom of the ring. This disparity in binding mode appears to be dictated by steric considerations. In the absence of steric hindrance preferential binding at the N1 position is anticipated.

This difference in metal-binding sites is evident as well, by both IR and ^{13}C NMR spectroscopy. The ν(CO) and $\nu(CO_2)$ vibrational modes of complexes **1** and **3** are quite similar and occur at lower frequencies than the corresponding parameters of complex **2**. This is indicative of a less electron-donating nitrogen center in the latter derivative. This conclusion is also consistent with the more downfield positions of the ^{13}C resonances for the carbonyl ligands in complexes **1** and **3**.

Concomitantly the rates of CO dissociation in the complexes ligated through the deprotonated N3 center (complexes **1** and **3**), are slightly more facile than the corresponding rate in the N1 ligated derivative (complex **2**). This facile CO exchange with labeled ^{13}CO, which is comparable to that seen in the $W(CO)_5Cl^-$ anion but less than that observed in the alkoxide or aryloxide analogs, is attributed to π-donation of electron density from the nitrogen atom of the pyrimidine bases to the tungsten center in the transition state as the CO bond is broken.

Experimental Section

Methods and Materials: All manipulations were performed in a double manifold Schlenk vacuum line under argon or in an argon-filled glovebox. Solvents were freshly distilled under nitrogen from sodium/benzophenone ketyl (tetrahydrofuran, hexane, diethyl ether), magnesium iodide (methanol), or phosphorous pentoxide followed by calcium hydride (acetonitrile). − Photolysis experiments were performed using a mercury arc 450-W UV immersion lamp purchased from Ace Glass Co. − Routine IR spectra were recorded with a Matteson 6022 spectrometer with DTGS and MCT detectors, using a 0.10-mm CaF_2 cell. − Kinetic measurements were monitored with an ASI REACT IR™ 1000 system equipped with an MCT detector and 30 bounce SiCOMP™ in situ probe. − ^{13}C NMR spectra were obtained with a Varian Unity XL-300 spectrometer. − ^{13}CO was purchased from Cambridge Isotopes and used as received. $W(CO)_6$ was purchased from Fluka, and used without further purification. Dihydrouracil, 6-methyluracil, 5-methyluracil, and orotic acid methyl ester were purchased from Aldrich Chemical and used as received. 1,3-dimethylorotic acid was synthesized according to a previously published procedure.[24] − Microanalyses were performed by Canadian Microanalytical Service, Ltd., Delta, B.C.

Synthesis of $[NEt_4][W(CO)_5$(dihydrourcilate)] (1): In a typical synthesis dihydrouracil (0.163 g, 1.43 mmol) was placed in a Schlenk flask with a 25% w/w Et_4NOH solution in methanol (0.85 g, 1.44 mmol), along with 10 mL of THF. This solution was stirred for 45 min and concentrated for about 12 h to provide a white solid. $W(CO)_5THF$ was prepared by photolysis of $W(CO)_6$ (0.50 g, 1.44 mmol) in 60 mL of THF for 45 min. This yellow solution was then transferred to the $[Et_4N]$[diydrouracilate] and 1.5 mL methanol was added to dissolve the salt. The solution turned dark orange red on addition of the methanol. The solution was stirred for 10 min and concentrated to dryness leaving an orange powder. This powder was dissolved in CH_3CN and filtered through Celite leaving a clear orange solution, which was washed with 2 × 20 mL of hexane to remove excess $W(CO)_6$, and a white solid (unchanged $[Et_4N]$[diydrouracilate]). The product was precipitated with diethyl ether and vacuum-dried yielding 0.61 g (75% yield) of an analytically pure orange powder. − $C_{17}H_{25}O_7N_3W$ (567.3): calcd. C 36.00, H 4.44, N 7.41; found C 35.22, H 4.48, N 7.38. − IR (CH_3CN): $\tilde{\nu}$ = 2058 (w), 1911 (s), 1838 (m) cm^{-1}. − ^{13}C NMR (CD_3CN): δ = 202.3 (4 *cis*-CO), 208.0 (*trans*-CO). − Orange block crystals of **1** were obtained by slow diffusion of hexane into a THF solution of $[Et_4N][W(CO)_5(C_4H_5N_2O_2)]$ at 0° C.

Synthesis of $[NEt_4][W(CO)_5$(5-methyluracilate)] (2): In a typical synthesis 5-methyluracil (thymine) (0.179 g, 1.42 mmol) was placed in a Schlenk flask with tetraethylammonium hydroxide (25% w/w in methanol) (0.842 g, 1.43 mmol) and 10 mL of methanol. This solution was stirred for 1 h and vacuum-dried for about 12 h, yielding a white solid. $W(CO)_5THF$ (1.44 mmol), generated as in **1**, was added to this white solid, and 3 mL of methanol was also added to aid in the solubility of the salt. This yellow solution was stirred for 1 h and concentrated to dryness. The resulting yellow/brown solid was redissolved in THF and filtered through Celite leaving a yellow solution and a brown solid. The remaining yellow solution was layered with hexane and 0.49 g (57% yield) of an analytically pure bright yellow powder was obtained. − $C_{18}H_{25}O_7N_3W$ (579.3): calcd. C 37.32, H 4.35, N 7.25; found C 37.39, H 4.38, N 7.19. − IR (CH_3CN): $\tilde{\nu}$ = 2065 (w), 1915 (s), 1855(m) cm^{-1}. − ^{13}C NMR (CD_3CN): δ = 200.7 (4 *cis*-COs), 205.8 (*trans*-CO). − Yellow crystals of **2** were obtained by slow diffusion of hexane into a THF solution of **2** at room temperature over 4 d.

Synthesis of [NEt$_4$][W(CO)$_5$(6-methyluracilate)] (3): The synthesis of **3** was carried out in a manner analogous to that of **2**. 6-methyluracil (0.181 g, 1.44 mmol) was placed in a Schlenk flask with 1 equiv. of tetraethylammonimum hydroxide (25% w/w in methanol), and 10 mL of methanol. This solution was stirred for 2 h and vacuum dried for about 12 h, yielding a white solid. W(CO)$_5$THF (1.44 mmol), generated photochemically, was added to this and 2 mL of methanol was added to aid in its solubility. The resulting cloudy orange solution was filtered through Celite, leaving a clear orange solution. This solution was layered with hexane yielding 0.58 g (66% yield) of an analytically pure yellow powder. − $C_{18}H_{25}O_7N_3W$ (579.3): calcd. C 37.32, H 4.35, N 7.25; found C 37.39, H 4.35, N 7.25. − IR (CH_3CN): $\tilde{\nu}$ = 2059 (w), 1912 (s), 1840 (m) cm^{-1}. − ^{13}C NMR (CD_3CN): δ = 202.0 (4 *cis*-CO), 204.8 (*trans*-CO) cm^{-1}. − Yellow diffraction-quality crystals of **3** were grown by slow diffusion of hexane into a THF solution of **3** at room temperature over 3 d.

Synthesis of [Et$_4$N][W(CO)$_5$(methylorotate)] (4): In a typical synthesis a Schlenk flask was charged with the methyl ester of orotic acid (0.242 g, 1.44 mmol), slurried in 10 mL of THF and deprotonated with a 25% w/w Et$_4$NOH solution in methanol (0.85 g, 1.44 mmol). This solution was stirred for 30 min and the solvent was removed under vacuum, leaving a pale yellow solid. W(CO)$_5$THF was prepared photochemically, starting with W(CO)$_6$ (0.50 g, 1.44 mmol) in 60 mL of THF. This was photolyzed for 45 min. The resulting yellow solution was transferred via a cannula into the flask containing the deprotonated ester. The resulting solution changed color from yellow to a dark yellow-brown. The solution was stirred for 45 min and then concentrated to dryness overnight. The resulting solid was dissolved in CH_3CN and filtered through Celite affording a clear brownish-yellow solution which was washed with hexane to remove any residual W(CO)$_6$. The product was obtained in < 80% yield by the removal of solvent under reduced pressure to give a sticky brown solid. − $C_{19}H_{25}N_3O_9W$ (623.2712): calcd. C 36.61, H 4.04, N 6.74; found C 35.72, H 3.94, N 6.88. − IR (CH_3CN): $\tilde{\nu}$ = 2060 (w), 1914 (s), 1846 (m) cm^{-1}.

Synthesis of [Et$_4$N][W(CO)$_5$(*N*,*N*-dimethylorotate)] (5): A Schlenk flask was charged with *N*,*N*-dimethylorotic acid (0.261 g, 1.44 mmol), slurried in 10 mL of THF and deprotonated with a 25% w/w Et$_4$NOH solution in methanol (0.85 g, 1.44 mmol). This solution was stirred for 30 min and the solvent was removed under vacuum, leaving a white solid. W(CO)$_5$THF was prepared photochemically, starting with W(CO)$_6$ (0.50 g, 1.44 mmol) in 60 mL of THF. This was photolyzed for 45 min. The resulting yellow solution was transferred via a cannula into the flask containing the deprotonated acid. The resulting solution changed color from yellow to a dark orange-yellow. The solution was stirred for 45 min and then concentrated to dryness overnight. The sticky solid was dissolved in CH_3CN and filtered through Celite affording a clear brownish-orange solution which was washed with hexane to remove any residual W(CO)$_6$. The product was obtained in < 80% yield by the removal of solvent under reduced pressure to give a brown-orange solid. − $C_{20}H_{27}N_3O_9W$ (637.3): calcd. C 37.69, H 4.27, N 6.59; found C 37.65, H 4.56, N 6.62. − IR (CH_3CN): $\tilde{\nu}$ = 2067 (w), 1920 (s), 1853 (m) cm^{-1}.

Reaction of 1 with Methanol: Approximately 0.05 g of **1** was placed in an NMR tube with 1 mL of CD_3OD. The orange solution was then placed under ^{13}CO and inserted into an NMR probe. On removal of the tube from the NMR spectrometer, red block crystals of [Et$_4$N]$_2$[W(CO)$_4$(OMe)]$_2$ (**6**) were found. − ^{13}C NMR (CD_3OD): δ = 208.5 (4 *cis*-CO), 220.1 (4 *trans*-CO).

X-ray Crystallography

[Et$_4$N][W(CO)$_5$(dihydrouracilate)] (1): Crystal data and details of data collection are given in Table 9. An orange block of **1** was mounted on a glass fiber with epoxy cement, at room temperature. Preliminary examination and data collection were performed with a Rigaku AFC5R X-ray diffractometer (Cu-K_α, λ = 1.54178 Å radiation) for **1**. Cell parameters were calculated from the least-squares fitting of the setting angles for 24 reflections; ω scans for several intense reflections indicated acceptable crystal quality. Data were collected for 7.62° ≤ 2θ ≤ 120.12°. Three control reflections, collected every 97 reflections, showed no significant trends. Background measurements by stationary-crystal and stationary-counter techniques were taken at the beginning and end of each scan for half of the total scan time. Lorentz and polarization corrections were applied to 3873 reflections for **1**. A semiempirical absorption correction was applied to **1**. A total of 3873 unique reflections with $|I| \geq 2.0\sigma(I)$ were used in further calculations. The structure of **1** was solved by direct methods (SHELXS program package, Sheldrick, **1993**). Full-matrix least-squares anisotropic refinement for all non-hydrogen atoms yielded R = 0.0598, R_w = 0.0634, and S = 1.085 for **1**. Hydrogen atoms were placed in idealized positions with

the isotropic thermal parameters fixed at 0.08. Neutral-atom scattering factors and anomalous scattering correction terms were taken from the *International Tables for X-ray Crystallography.* Crystallographic data (excluding structure factors) for the structure(s) reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-148932 (**1**), -148933 (**3**), -148934 (**6**), and -148935 (**2**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

$[Et_4N][W(CO)_5(L)]$ [L = 5-Methyluracilate (2), 6-Methyluracilate (3)]: Crystal data and details of data collection are given in Table 9. A yellow needle of **2** and a yellow block of **3** were mounted on a glass fiber with epoxy cement at room temperature, and cooled in a cold stream of liquid nitrogen. Preliminary examination and data collection were performed with a Rigaku AFC5R X-ray diffractometer (Cu-K_α, λ = 1.54178 Å radiation) for **2**, and a Siemens P4 X-ray diffractometer (Mo-K_α, λ = 0.71073 Å radiation) for **3**. Data collection and parameters are identical to those described for complex **1**. Data were collected for $6.36° \leq 2\theta \leq 100.00°$ for **2** and $4.06° \leq 2\theta \leq 50.00°$ for **3**. Lorentz and polarization corrections were applied to 2437 reflections for **2** and 3887 reflections for **3**. A total of 2437 unique reflections for **2** and 3886 unique reflections for **3** were used in further calculations. Anisotropic refinement for all non-hydrogen atoms yielded R = 0.0665, R_w = 0.1466, and S = 0.920 for **2**, and R = 0.0274, R_w = 0.0704, and S = 0.786 for **3**.

$[Et_4N]_2[W_2(CO)_8(OMe)_2]$ (6): Crystal data and details of data collection are given in Table 9. A red block of **6** was mounted on a glass fiber with epoxy cement at room temperature, and cooled in a cold stream of liquid nitrogen. Preliminary examination and data collection were performed with a Siemens P4 X-ray diffractometer (Mo-K_α, λ = 0.710 73 Å radiation). Data collection and parameters are identical to that described for complex **1**. Data were collected for $4.08° \leq 2\theta \leq 50.00°$ for **6**. Lorentz and polarization corrections were applied to 8614 reflections. A total of 8614 unique reflections were used in further calculations. Anisotropic refinement for all non-hydrogen atoms yielded R = 0.0473, R_w = 0.0706, and S = 1.006.

Kinetic Measurements: The rates of ^{13}CO exchange in complexes **1**−**5** were determined at a variety of temperatures; ^{13}CO was placed over the solution of 0.1 g of the complex in 15 mL of THF or CH_3CN, which was situated in a thermostated temperature bath. The solutions were magnetically stirred and placed in a temperature bath at a variety of temperatures for **1** (35.0, 40.0, 45.0, 50.0, 57.0 °C), **2** (20.0, 30.0, 40.0, 50.0 °C), **3** (5.0, 15.0, 30.0, 40.0 °C), **4** (20, 35, 41, 45, 50 °C), and **5** (30, 40, 50 °C). The kinetics were monitored using ASI ReactIR in situ IR probe, by following the decrease in absorbance of the highest frequency A_1 band in the ν(CO) region of the IR spectrum as a function of time.

Investigation of the Structure of New Gallium Phosphonate Based Hybrid Materials by ^{31}P, ^{71}Ga, and ^{1}H Solid-State NMR

Martine Bujoli-Doeuff,[a] Michel Evain,[a] Franck Fayon,[b] Bruno Alonso,[b] Dominique Massiot,[b] and Bruno Bujoli*[c]

Keywords: Phosphonate complexes / Gallium / NMR spectroscopy / Homonuclear proton decoupling

Modern high-resolution solid-state NMR is a powerful tool for probing the structure of phosphonate-based hybrid materials, in the organic as well as in the inorganic region. This is illustrated in the case of a series of new gallium phosphonates [$Ga(OH)(O_3PCH_3) \cdot x\,H_2O$ [x = 1 (**1**); x = 0 (**1′**)] and $Ga(OH)(O_3PCH_2C_6H_5)$ (**2**)], that were characterized by X-ray diffraction and FTIR, and then studied using ^{71}Ga, ^{31}P, and ^{1}H NMR.

Introduction

Metal phosphonates are organic-inorganic hybrid materials in which the structure can be tuned by the choice of the organic moiety covalently bonded to the inorganic portion.[1] These materials are attracting increasing interest because of the large variety of applications they can offer, among which supported catalysis has particularly attracted our attention.[2] For a better understanding of the structure/property relationships in these solids, modern high-resolution solid-state NMR offers a wide variety of methods that can selectively examine the inorganic part, the organic part, and their connection, provided NMR-observable nuclei are present. In this paper we describe a new series of gallium phosphonates and their study by recently developed experimental NMR techniques which demonstrate the potential of these methods to give access to detailed structural information. Layered phosphonates are now well documented,[1] but to date, only one example of the gallium series has been reported;[3] in this study, two new layered gallium phosphonates [$Ga(OH)(O_3PCH_3) \cdot H_2O$ (**1**) and $Ga(OH)(O_3PCH_2C_6H_5)$ (**2**)] were prepared under hydrothermal conditions. The metal/PO_3 arrangement within the slabs of compound **1** can be described as edge-sharing octahedra (made of four phosphonate oxygen atoms and two μ-2 hydroxide groups) forming infinite chains parallel to the *b* axis.

These chains are connected via the PO_3 groups, thus leading to a 2D network (Figure 1), with the methyl substituents oriented perpendicular to the layers, and the non-coordinated water molecules located between the sheets, weakly hydrogen-bonded to some phosphonate and hydroxide oxygen atoms (Figure 2).

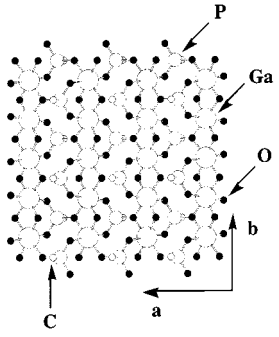

Figure 1. Schematic representation of a $Ga(OH)(O_3PCH_3) \cdot H_2O$ (**1**) layer viewed down the *c* axis; selected interatomic distances [Å]: Ga−O: 1.967(3) [X 2], 2.006(3) [X 2], 1.941(3) [X 2−OH]

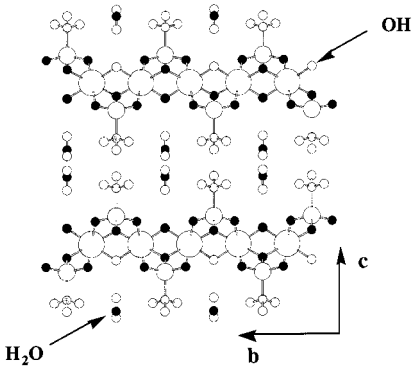

Figure 2. Schematic representation of the layered arrangement of **1** shown perpendicular to the *a* axis

No modification of the inorganic network occurs after the loss of the water molecule [performed by heating **1** at 100 °C for 1 h to yield **1′**] since the infrared spectrum is not modified, except in the ν(OH) region. As FTIR is very sensitive to the metal−O_3P arrangement in metal phosphonates, the strong similarities observed in the IR data

collected for **2** and **1′** (for the OH and PO_3 absorptions − see Experimental Section) give clear evidence that the structural features in these three products are quite similar.

As far as the inorganic component in these materials is concerned, the six-coordinate nature of the gallium atoms is clearly evident from the isotropic chemical shift measured from the ^{71}Ga VOCS NMR[3,4] spectra [$\delta_{iso} = -13 \pm 10$ for **1** and **1′**, and 10 ± 10 for **2**] shown in Figure 3.

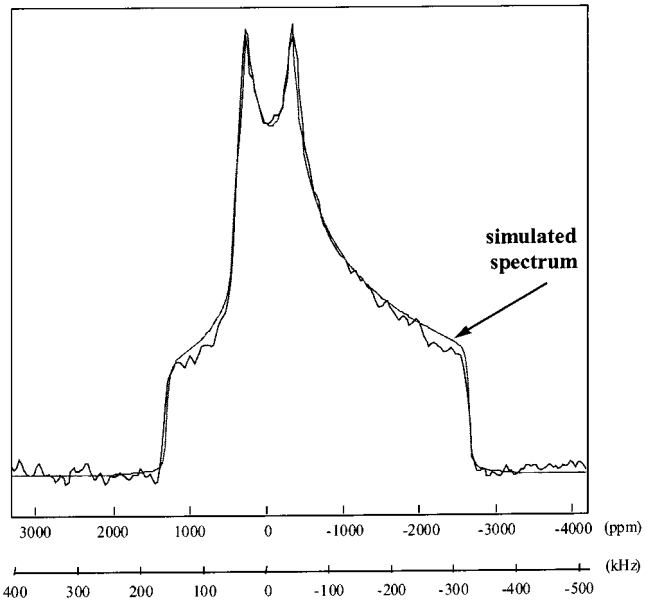

Figure 3. Experimental ^{71}Ga static NMR spectrum of **1**, and simulated spectrum with second-order quadrupolar broadened shape, according to parameters described in Table 1

On the other hand, as previously demonstrated in the case of zinc phosphonates,[5] it appears that the connectivity of the PO_3 groups (i.e. the number of metal atoms connected to each of the three oxygen atoms bound to the phosphorus atom) can be deduced from the ^{31}P MAS NMR spectra, by the chemical shift asymmetry parameter κ (skew) of the individual phosphorus sites (reported in Table 1). Interestingly, in the previously described gallium phosphonate $Ga(OH)(O_3PC_2H_4CO_2H) \cdot H_2O$[3] (and more generally in the case of aluminum phosphonates with well-established structures[6]) the highest connectivity observed for the PO_3 groups was (111) and the range of variation of the κ value for the P sites was then [−0.3, −0.5]. As evidenced by the X-ray structure of **1**, a (112) connectivity is found for the first time in such compounds, with a markedly different κ value observed for the P sites: $\kappa = 0$ for **1** and +0.2 for **1′** and for **2**.

Resolved ^1H NMR solid-state spectra cannot be obtained using simple acquisition sequences, due to dominant homonuclear couplings between the protons. We acquired 2D $\{^1H\}$-^1H correlation spectra using the Phase Modulated Lee−Goldburg (PMLG) experiment recently proposed by Vinogradov and co-workers.[7] In this experiment a better resolved proton (homonuclear decoupled under Lee−Goldburg excitation) spectrum is obtained in the indirect dimension of a 2D experiment and is correlated with the usual low-resolution MAS spectrum.

The resulting 2D spectrum of **1** is presented in Figure 4. We observe two resolved signals at $\delta = 4.6$ and 1.5 in **1** in a ca. 1:1 ratio. The most deshielded signal ($\delta = 4.6$) is ascribed to water molecules and hydroxide groups (H_2O + OH) and the signal at $\delta = 1.5$ to CH_3 units. In the case of the water-free compound **1′**, these signals at $\delta = 4.5$ and 1.7 are in a ca. 1:3 ratio and correspond to hydroxide and methyl groups respectively, in agreement with the stoichiometry. Under similar acquisition conditions, the broad MAS spectrum of **2** splits in two resolved contributions ascribed to (OH + CH_2) at $\delta = 4.5$ and C_6H_5 at $\delta = 7$.

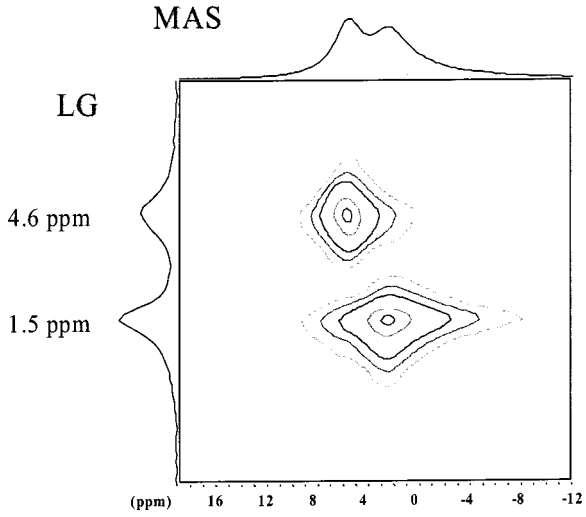

Figure 4. 2D PMLG/MAS $\{^1H\}/^1H$ spectrum of **1**

Table 1. Experimental values for ^{71}Ga chemical shift and electric field gradient, and for ^{31}P chemical shift tensor, for compounds **1**, **1′**, and **2**

$Ga(OH)(O_3PCH_3) \cdot H_2O$ (**1**)	^{71}Ga ^{31}P	δ_{iso}[a] = −13 δ_{iso}[d] = 32.2	C_Q[b] = 16.2 MHz Ω[e] = 60.4	η_Q[c] = 0.8 κ[f] = 0
$Ga(OH)(O_3PCH_3)$ (**1′** from dehydration of **1**)	^{71}Ga ^{31}P	Same values as for **1** δ_{iso}[d] = 30.5	 Ω[e] = 69.7	 κ[f] = 0.2
$Ga(OH)(O_3PCH_2C_6H_5)$ (**2**)	^{71}Ga ^{31}P	δ_{iso}[a] = 10 δ_{iso}[d] = 25.6	C_Q[b] = 17.5 MHz Ω[e] = 89.4	η_Q[c] = 0.8 κ[f] = 0.2

[a] Chemical shifts are referenced to ^{71}Ga resonance in a 1 M gallium nitrate solution; error in the measured value: ±10 ppm. − [b] Quadrupolar coupling constant ($C_Q = e^2qQ/h$); error in the measured value: ±0.25 MHz. − [c] Asymmetry factor. − [d] Chemical shifts are referenced to ^{31}P resonance in 85% H_3PO_4. − [e] Chemical shift span defined as $\delta_{11} - \delta_{33}$ with $\delta_{11} \geq \delta_{22} \geq \delta_{33}$. − [f] Chemical shift skew defined as $3(\delta_{22} - \delta_{iso})/\Omega$.

In conclusion, solid-state NMR appears to be an efficient tool to provide accurate insights into the local environments of P, Ga, and H present in these hybrid (organic/inorganic) compounds. Work is in progress to investigate a wider range of model gallium phosphonate compounds which should allow us to establish a stronger correlation between NMR parameters and local structure: δ_{iso} and skew of chemical shift anisotropy of ^{31}P, δ_{iso} and quadrupolar tensor of ^{71}Ga and δ_{iso} for resolved ^{1}H. This approach should easily be transferred to the case of aluminum phosphonates using the recently established correlation between ^{27}Al and ^{71}Ga NMR parameters.[4] The improved resolution obtained in the Lee−Goldburg decoupled ^{1}H spectra opens the possibility of exploring the whole material on different scales using spin diffusion between protons with possible encoding through the other NMR active nuclei. These experiments are expected to be very fruitful in the case of polycrystalline or amorphous materials involving phase-separated domains as well as organic/inorganic interfaces.

Experimental Section

Syntheses of 1 and 2: A mixture of gallium nitrate (1 mmol) and methylphosphonic (**1**) or benzylphosphonic (**2**) acid (10 mmol) in water (20 mL) was placed in the PTFE cell of an autoclave, which was sealed and kept at 160 °C (**1**) or 170 °C (**2**) in a drying oven for 8 (**1**) or 5 d (**2**). Compound **1** was obtained in 32% yield (64 mg) as white crystals, used for the X-ray structure determination, while **2** was isolated as a white powder in 45% yield (115 mg). − **1:** CH_6GaPO_5 (198.7): calcd. C 6.04, H 3.04, P 15.58; found C 6.12, H 2.94, P 15.29. − FTIR (KBr): $\tilde{\nu}$ = 3589 m, 3512 s, 3453 m, 3382 m, 1324 m, 1099 vs, 1058 vs, 995 vs, 912 s cm^{-1}. − TGA (25−300 °C): 8.90% (calcd. 9.05%; $-H_2O$, 35 °C). − After dehydration of **1** (performed by heating at 100 °C for 1 h to yield **1′**), the infrared spectrum was unchanged, except in the ν(OH) region where only a strong (3515 cm^{-1}) and a broad band (3400 cm^{-1}) remained. − **2:** $C_7H_8GaPO_4$ (256.8): calcd. C 32.73, H 3.14, P 12.06; found C 32.89, H 3.10, P 12.18. − FTIR (KBr): $\tilde{\nu}$ = 3519 s, 3400 b, 1151 m, 1100 vs, 1060 vs, 990 vs, 910 s cm^{-1}. − TGA (25−300 °C): 0%.

Solid-State NMR Experiments: NMR solid-state spectra of ^{71}Ga, ^{31}P, and ^{1}H have been acquired with a Bruker DSX400 spectrometer operating at 9.4 T. The wide ^{71}Ga spectra extend over several hundreds of kHz and have been acquired in static following the VOCS protocol[8] (Magic Angle Spinning would not provide any gain in resolution). The ^{31}P spectra have been acquired using CP-MAS $\{^{1}H\}$-^{31}P excitation, as previously described[3] with a typical contact time of 1.5 ms and 1 s of recycle time. The Lee−Goldburg/MAS $\{^{1}H\}/^{1}H$ correlation spectra have been acquired using the Phase Modulated Lee−Goldburg decoupling scheme[7] with a ^{1}H radio-frequency field of 50 kHz. The two-dimensional spectra were typically obtained within 10 mins with two transients per slice and up to 256 slices, depending on resolution. Spectra were simulated using a modified version of the Bruker Winfit program.[9]

Structure Determination of 1: Data collection was carried out with a single crystal approximately 0.3×0.2×0.04 mm in size with a STOE Imaging Plate Diffraction System,[10] using graphite-monochromatized Mo-K-$L_{2,3}$ radiation (λ = 0.71073 Å). Data intensities were corrected for Lorentz polarization and absorption (Gaussian analytical correction) and subsequently merged according to the *mmm* point group (R_{int} = 0.051), giving rise to a set of 409 independent reflections at a 2σ level. Although the systematic extinctions suggested *Pnmn* as the most probable space group, *Pnma* was found to be the correct space group, both at the residue factor and the structure coherence level. A starting model was found with the Shelxtl V5.0 direct method program[11] and refined (F^2, all reflections included) with the Jana2000 program.[12] All subsequent calculations were carried out with the Jana2000 program package. Missing atoms, including hydrogen atoms, were found in difference Fourier synthesis maps. Non-hydrogen atoms were refined with anisotropic displacement parameters and hydrogen atoms were kept at fixed positions with a common fixed isotropic displacement parameter. At the last stage of the refinement, a secondary extinction coefficient[13] was introduced and the residue factor smoothly converged with R/R_w = 0.0303/0.0681 for 409 reflections with $I/\sigma(I) > 2$ and 47 parameters. − Crystal Data: $Ga(OH)(O_3PCH_3) \cdot H_2O$; orthorhombic *Pnma*; a = 4.5193(7), b = 5.9965(7), c = 19.556(2) Å, V = 530.0(2) $Å^3$ from 3096 reflections collected with the STOE IPDS; monochromatized Mo-K-$L_{2,3}$ radiation; Z = 4; M = 198.75; $\rho_{calcd.}$ = 2.490 $g \cdot cm^3$; μ = 54.25 cm^{-1}; residual electron density [−0.84/+0.62] $e \cdot Å^3$. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no.CCDC-142094. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Organoamido- and Aryloxo-Lanthanoids, 23[‡]

Aryl Ether C−O Bond Activation by Organoamidolanthanoid(II) Complexes

Glen B. Deacon,*[a] Craig M. Forsyth,[a] and Natalie M. Scott[a]

Dedicated to Prof. Dr. Herbert Schumann on the occasion of his 65th birthday

Keywords: N ligands / Ytterbium / C−O activation / O ligands / Lanthanoids

The reaction of ytterbium metal, $HgPh_2$ and *N*-(2-methoxyphenyl)-*N*-(trimethylsilyl)amine (L^1H) or *N*-(2-phenoxyphenyl)-*N*-(trimethylsilyl)amine (L^2H) in tetrahydrofuran (thf) unexpectedly yielded the ytterbium(III) complexes $[Yb(L^1)_2(\mu\text{-OMe})]_2$ **(1)** and $[Yb(L^2)_2(OPh)(thf)]$ **(2)**, the structures of which were established by X-ray crystallography. These are considered to be derived from C–O bond cleavage of the ligand aryl ether moiety by an initially formed Yb^{II} species, e.g. the thermally unstable, but crystallographically authenticated $[Yb(L^1)_2(thf)_2]$ **(3)**, which was independently prepared from $[Yb\{N(SiMe_3)_2\}_2(thf)_2]$ and L^1H.

Introduction

Divalent lanthanoid complexes react with a number of oxygen-containing substrates due to the oxophilicity of these metals and the large $Ln^{3+} \rightarrow Ln^{2+}$ reduction potentials (Ln = Yb,Sm).[2] For example, tetrahydrofuran (thf) solutions of SmI_2 have found extensive applications in organic synthesis as a selective reducing agent for ketones.[2−4] Other LnL_2 species are capable of stoichiometric reactions with ketones, forming metal-bound ketyl radical anions,[5,6] and the reductive coupling of carbon dioxide by $Sm(C_5Me_5)_2$ complexes has been reported.[7] Whilst $Sm(C_5Me_5)_2$-induced deoxygenation of epoxides is facile, yielding $[Ln(C_5Me_5)_2(\mu\text{-O})]_2$,[8] transformations of unstrained carbon−oxygen single bonds occur only under unusual circumstances. For example, thermolytic cleavage of diethyl ether by very low coordinate ytterbium(II) complexes has been reported[9,10] and photolysis of 1,2-dimethoxyethane (dme) solutions of YbI_2 gives the methoxide complex $[YbI_2(\mu\text{-OMe})(dme)]_2$.[11] Furthermore, cleavage of dme by highly novel La^{II} or Ce^{II} organometallic complexes was recently reported.[12−14] These few examples of C−O cleavage of alkyl ethers contrast the numerous stable coordination complexes of divalent lanthanoids with these ligands.[15,16]

In this contribution, we report the unexpected cleavage of the aryl ether C−O single bond of the anionic bidentate N,O-ligands L^1, L^2 [L^1 = $N(SiMe_3)C_6H_4$-2-OMe, L^2 = $N(SiMe_3)C_6H_4$-2-OPh] by a ytterbium(II) centre and the characterisation of the lanthanoid(III) products $[Yb(L^1)_2(\mu\text{-OMe})]_2$ **(1)** and $[Yb(L^2)_2(OPh)(thf)]$ **(2)**. The latter is the first structurally authenticated lanthanoid complex with an unsubstituted phenoxide ligand; surprisingly, for a sterically undemanding ligand, it is nonbridging. The synthesis and characterisation of the thermally unstable, proposed ytterbium(II) precursor $[Yb(L^1)_2(thf)_2]$ **(3)** are also described.

Results and Discussion

We initially attempted to prepare novel ytterbium(II) complexes of the bidentate N,O-ligands L^1 and L^2 (for preparations and the X-ray crystal structure of L^1H see Experimental Section) by a redox transmetallation/ligand exchange reaction (Equation 1).

$$Ln^0 + HgPh_2 + 2LH \longrightarrow Ln(L)_2 + 2PhH + Hg^0 \quad (L = L^1 \text{ or } L^2) \qquad (1)$$

This route has previously been utilised for the preparation of $Ln(NRR')_2$ species including $[Ln\{N(SiMe_3)Ar\}_2(thf)_2]$ (Ar = C_6H_3-2,6-*i*Pr_2, Ln = Sm, Yb).[17] The current reactions afford moderate to low yields of red-orange crystals after workup. The presence of L^1 or L^2 was evident from the infrared spectra, but the products were shown to contain Yb^{III} by the observation of *f*←*f* transitions near 1000 nm[18] in the electronic spectra. Furthermore, the analytical data did not fit the compositions $Yb(L^1)_3$ or $Yb(L^2)_3$ and thus the formation of heteroleptic Yb^{III} species was indicated. X-ray crystallography subsequently revealed that the products were the alkoxide and aryloxide complexes $[Yb(L^1)_2(\mu\text{-OMe})]_2$ **(1)** and $[Yb(L^2)_2(OPh)(thf)]$ **(2)** (Figure 1 and 2).

Complex **1** crystallises as two virtually identical, but independent, dimers each having two bridging methoxide ligands, chelating L^1 coordination and hexacoordinate ytterbium atoms of an irregular geometry. Both molecules are sited on crystallographic twofold axes through the methox-

ORTEP view of one molecule of $[Yb(L^1)_2(\mu\text{-}OMe)]_2$ **(1)** drawn with 30% thermal ellipsoids; hydrogen atoms have been omitted for clarity; selected bond lengths (Å) and angles (°): Yb(1)−O(1) 2.346(2), Yb(1)−O(2) 2.355(2), Yb(1)−N(1) 2.250(3), Yb(1)−N(2) 2.245(3), Yb(1)−O(11) 2.221(2), Yb(1)−O(12) 2.217(2); O(1)−Yb(1)−O(2) 171.09(8), N(1)−Yb(1)−N(2) 112.7(1), N(2)−Yb(1)−O(1) 106.24(9), N(1)−Yb(1)−(O2) 102.03(9), N(2)−Yb(1)−O(2) 71.16(9), N(1)−Yb(1)−O(1) 70.80(9), O(12)−Yb(1)−O(11) 72.5(1), O(12)−Yb(1)−N(2) 91.12(9), O(11)−Yb(1)−N(2) 147.90(7), O(12)−Yb(1)−N(1) 149.79(8), O(11)−Yb(1)−N(1) 93.2(1), O(12)−Yb(1)−O(1) 85.27(6), O(11)−Yb(1)−O(1) 99.85(6), O(12)−Yb(1)−O(2) 103.17(6), O(11)−Yb(1)−O(2) 85.60(6), Yb(1)−O(11)−Yb(1A) 107.4(1), Yb(1)−O(12)−Yb(1A) 107.6(1); symmetry transformation: −x, y, −z + 3/2

ide ligands, hence the four-membered Yb_2O_2 rings are planar. The geometry of the methoxide bridges, with larger O−Yb−O than Yb−O−Yb angles is virtually identical to that of $[CeCp''_2(\mu\text{-}OMe)]_2$ [Cp" = $\eta\text{-}C_5H_3\text{-}1,3\text{-}(SiMe_3)_2$].[12] The near equal Yb−OMe distances are comparable with the *longer* of the two Yb−OMe distances 2.210(6), 2.152(4) Å,[11] in $[YbI_2(\mu\text{-}OMe)(dme)]_2$, where the Yb−OMe bond lengthening was attributed to the *trans* influence of the iodide ligand.[11] In **1**, the two methoxide ligands have the same relative dispositions to the amide nitrogens. One nitrogen is *transoid* to each methoxide and hence exerts a *trans* influence. However, the present lengthening may also be attributed to steric crowding, since the Yb−O(ether) distances approach values expected for crowded systems.[19] The ether oxygen atoms of the L^1 ligands are approximately *trans*, with Yb−O bond lengths somewhat larger than those of the dme ligands in $[\{YbI_2(\mu\text{-}OMe)(dme)\}_2]$, 2.317(6) and 2.308(5) Å.[11] Surprisingly, the angle between the nitrogens of the bulky aryl(trimethylsilyl)amide groups is *cisoid* [c.f. *transoid* O(ether)−Yb−O(ether)], although this is consistent with the *fac*-coordination of the alkyl(trimethylsilyl)amide groups in tris(*N*,*N*-dimethyl-*N'*-trimethylsilylethane-1,2-diaminato)lanthanoid(III) complexes.[20] In a similar manner, the bulky carbazolate (cbz) ligands are *cisoid* in six coordinate $[Ln(cbz)_2(thf)_4]$ (Ln = Yb and Sm).[21,22] The Yb−N distances are nearly identical with those of six coordinate $[YbL_2(\mu\text{-}Cl)_2Li(thf)_2]$ [L = $Me_2Si(OtBu)(NtBu)$], 2.247(5) and 2.225(5) Å,[23] implying a similar steric congestion.

In contrast to **1**, complex **2** crystallises as discrete monomers with two independent, but similar, molecules comprising the asymmetric unit, one being displayed in Figure 2. The ytterbium atoms are hexacoordinate, each with an irregular coordination sphere provided by two chelating L^2 ligands, a terminal phenoxide and a coordinated thf. The relative orientation of the L^2 ligands, with the ether-OPh groups coordinated in an approximately *cis* arrangement, is different from that of L^1 in **1**. One of the Yb−O(ether) bond lengths is significantly longer than the other, attributable to its *trans* disposition relative to the phenoxide oxygen. A meaningful *trans*-influence for aryloxide ligands in lanthanoid complexes has been reported.[19] Both the shorter Yb−O(ether) and the Yb−O(thf) bond lengths are of a similar magnitude to the mutually *trans* Yb−O(ether) distances in **1**. As with **1**, the bulky silylamide groups are *cisoid*, and whilst the N−Yb−N angle is marginally smaller than in **1**, there is no significant change in the Yb−N distances. The Yb−OPh distance is comparable to, albeit marginally smaller than, those of terminal 2,6-disubstituted aryloxide ligands bound to six coordinate ytterbium(III) {e.g.

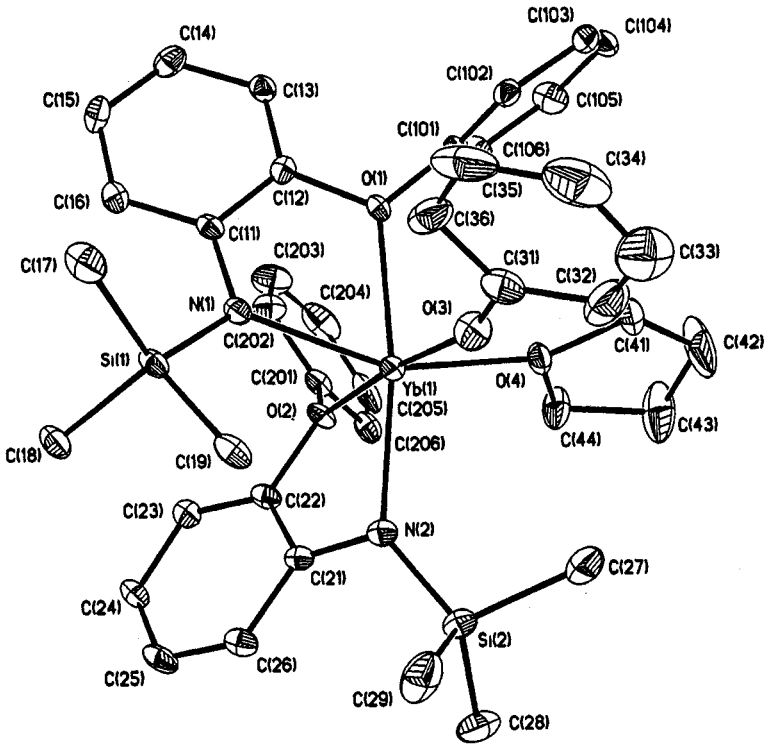

Figure 2. ORTEP view of one molecule of $[Yb(L^2)_2(OPh)(thf)]$ **(2)** drawn with 30% thermal ellipsoids; hydrogen atoms have been omitted for clarity; selected bond lengths (Å) and angles (°): Yb(1)−O(1) 2.380(4), Yb(1)−O(2) 2.459(5); Yb(1)−O(3) 2.023(6), Yb(1)−O(4) 2.357(4), Yb(1)−N(1) 2.250(5), Yb(1)−N(2) 2.247(5), O(3)−Yb(1)−N(2) 108.4(2), O(3)−Yb(1)−N(1) 104.3(2), N(2)−Yb(1)−N(1) 107.0(2), O(3)−Yb(1)−O(4) 86.1(2), N(2)−Yb(1)−O(4) 95.6(2), N(1)−Yb(1)−O(4) 150.3(2), O(3)−Yb(1)−O(1) 95.9(2), N(2)−Yb(1)−O(1) 155.2(2), N(1)−Yb(1)−O(1) 70.7(2), O(4)−Yb(1)−O(1) 80.7(2), O(3)−Yb(1)−O(2) 173.2(2), N(2)−Yb(1)−O(2) 69.9(2), N(1)−Yb(1)−O(2) 82.5(2), O(4)−Yb(1)−O(2) 87.5(2), O(1)−Yb(1)−O(2) 85.4(2)

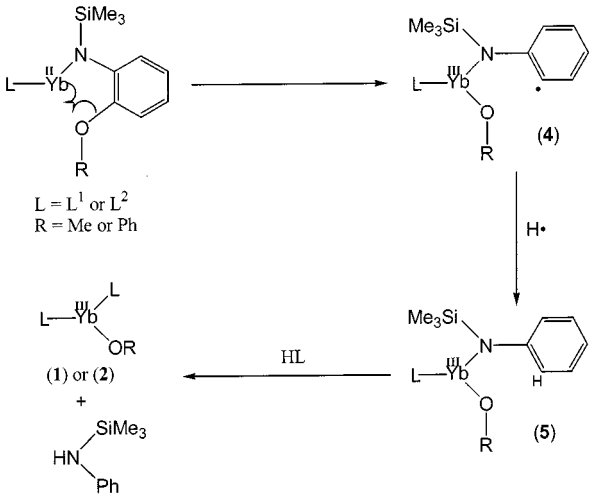

in $[Yb(MeC_5H_4)(OAr)_2(thf)]$, 2.040(4) and 2.078(4) Å[24] and $[Yb(OAr)Cl_2(thf)_3]$, 2.083(5) Å;[25] Ar = C_6H_2–2,6-tBu$_2$-4-Me}, consistent with reduced crowding in **2**. The structure of **2** is novel as the first authenticated example of an unsubstituted phenoxide bound to a lanthanoid centre.[16,26] There must be a fine balance between formation of a six coordinate μ-OPh (thf-free) species and the observed thf-coordinated structure **2**, since OPh is only marginally bulkier than thf.[27]

The methoxide and phenoxide groups in **1** and **2** are derived from the ligands L^1 and L^2, respectively. There was some ambiguity arising from the use of dme as a recrystallisation solvent in our initial isolation of **1**, since dme could be a OMe source.[11−14] However, the same product is formed in similar yield in the absence of dme (Experimental Section), i.e. where the crude product of the redox transmetallation/ligand exchange was treated with diethyl ether and recrystallised from hexane. We propose that the formation of **1** and **2** occurs by a one-electron transfer from Yb^{II} to an L^1 or L^2 ligand, Ar−O bond cleavage, formation of a Yb^{III}−OR (R = Me or Ph) bond, and then protolysis of the intermediate **5** by L^1H or L^2H (Scheme 1) present as reactants (Equation 1). In confirmation, we have shown that $[Yb(L^1)_2(thf)_2]$ **(3)** (see below) is converted into **1** in the presence of an excess of L^1H in hexane (see Experimental Section). A GC-MS analysis of the hydrolysed filtrate after the isolation of **2** showed the presence of phenol, *o*-phenoxyaniline and aniline, the last consistent with hydrolysis of the proposed product $HNPh(SiMe_3)$ and hence with prior proton abstraction (probably from the solvent[28]) by the aryl radical **4** (Scheme 1). The first two are the expected products of hydrolysis of the isolated $[Yb(L^2)_2(OPh)(thf)]$ **(2)**. Instability of *N*-trimethylsilylamines to hydrolysis in the present systems was established by partial conversion of L^1H into *o*-methoxyaniline on exposure to air. Whilst a mechanism involving reduction of the aryl ether by ytterbium metal (analogous to alkali metal cleavage of ethers)[29] may also be plausible, it would seem less likely since, under similar conditions, we have previously utilised methoxy-substituted aryloxide ligands in the presence of Yb metal without detection of ether cleavage.[30]

We have also prepared the thermally unstable divalent ytterbium complex $[Yb(L^1)_2(thf)_2]$ (**3**), by a ligand exchange reaction of $[Yb\{N(SiMe_3)_2\}_2(thf)_2]$[17] with L^1H in toluene at −78 °C (Equation 2).

$$Yb\{N(SiMe_3)_2\}_2 + 2L^1H \longrightarrow Yb(L^1)_2 + HN(SiMe_3)_2 \quad (2)$$

The divalent complex **3** was characterised by spectroscopic methods and a single crystal structure determination. Satisfactory elemental analyses were not obtained, even for single crystals, presumably due to the instability of the complex, but the ^1H NMR spectrum is consistent with the proposed composition. The structure of **3** (Figure 3), determined at 123 K, shows a monomeric complex with the ytterbium atom situated on a twofold axis and surrounded

Scheme 1

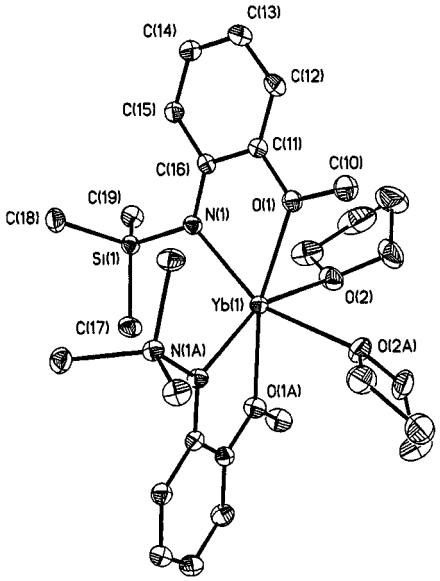

Figure 3. ORTEP view of $[Yb(L^1)_2(thf)_2]$ **(3)** drawn with 30% thermal ellipsoids; hydrogen atoms have been omitted for clarity; selected bond lengths (Å) and angles (°): Yb(1)−O(1) 2.458(2), Yb(1)−O(2) 2.494(2); Yb(1)−N(1) 2.386(2), N(1A)−Yb(1)−N(1) 108.81(12), N(1A)−Yb(1)−O(1) 121.79(8), N(1)−Yb(1)−O(1) 67.71(8), N(1)−Yb(1)−O(1A) 121.79(8), O(1)−Yb(1)−O(1A) 165.43(11), N(1A)−Yb(1)−O(2) 154.33(9), N(1)−Yb(1)−O(2) 89.45(9), O(1)−Yb(1)−O(2) 81.36(9), O(1A)−Yb(1)−O(2) 87.48(8), N(1A)−Yb(1)−O(2A) 89.48(8), O(1A)−Yb(1)−O(2A) 81.35(9), O(2)−Yb(1)−O(2A) 80.01(14); symmetry transformation: −x + 1, y, −z + 3/2

by two chelating L^1 ligands and two *cis* thf molecules with an irregular six-coordinate geometry. The orientation of the L^1 ligands is similar to that found in **1** above, with comparable *transoid* O(ether)−Yb−O(ether) and *cisoid* N−Yb−N angles (Figure 3). The Yb−N distance of **3** is comparable with or shorter than those of $[Yb(cbz)_2(thf)_2(dme)]$ [2.43(3), 2.45(2) Å][30] and **3** has a similar N−Yb−N angle to that of the unidentate carbazolyl ligands (107.3(7) °).[31] The Yb−O(thf) distance is longer than <Yb−O(thf)> of the six coordinate complex $[Yb\{PhC(NSiMe_3)_2\}_2(thf)_2]$ (2.415 Å)[32] which has *trans* thf ligands since each thf oxygen of **3** is *transoid* to an amide nitrogen. Further, the *cis* thf coordination geometry in **3** is similar to that of $[Yb(cbz)_2(thf)_2(dme)]$ [Yb−O(thf) 2.41(2), 2.48(2) Å; O(thf)−Yb−O(thf) 87.6(6) °].[31] It is noteworthy that there are only a few examples of bidentate, ether supported, amide ligands attached to a divalent lanthanoid, e.g. deprotonated 4,13-diaza-18-crown-6[33] and $Me_2Si(O\textit{t}\text{-}Bu)(N\textit{t}Bu)$.[23]

Compounds **1** and **2** are unique examples of the products of O−C(Ar) bond activation by a lanthanoid(II) centre. The ligands L^1 and L^2 also show the ability to stabilise heteroleptic lanthanoid(III) complexes with sterically undemanding co-ligands e.g. OMe, OPh.

Experimental Section

All reactions were carried out under dry nitrogen using dry box and standard Schlenk techniques. Solvents were dried by distillation from sodium wire/benzophenone. IR data (4000−650 cm^{-1}) were recorded for Nujol mulls sandwiched between NaCl plates with a Perkin−Elmer 1600 FTIR spectrometer. NMR spectra were obtained with a Bruker AC 300 MHz (^{1}H) spectrometer. The ytterbium(III) complexes gave unresolvable, uninterpretable, broadened spectra. Mass spectra were recorded with a VG Trio-1 GC mass spectrometer. Each listed *m*/*z* value for Yb-containing ions is the most intense peak of a cluster pattern in good agreement with the calculated pattern. GC-MS measurements were carried out using helium as a carrier gas and run on a Hewlett-Packard 5890A instrument interfaced to a VG Trio-1 GC mass spectrometer using a XTI-5 column (30m, 0.32 mm id) (bonded 5% phenyl − 95% dimethylpolysiloxane). The temperature program started at 50 °C (2 min) and then was increased by 10 °C/min to 280 °C. Retention times are measured in minutes from injection. Elemental analyses (C,H,N) were determined by the Campbell Microanalytical Service, University of Otago, New Zealand. Ytterbium analyses of digested samples were by complexiometric titration with $[Na_2EDTA]$.[1,34] $[Yb\{N(SiMe_3)_2\}_2(thf)_2]$ was prepared according to a reported procedure.[17] Commercial $HgPh_2$ (Aldrich) and lanthanoid powders (Rhône-Poulenc) were used as received.

[L^1H]: To a stirred solution of *o*-methoxyaniline (18 mL, 0.16 mol) in ether (100mL) at 0 °C was slowly added *n*BuLi (100 mL, 0.16 mol). After complete addition a white solid was obtained which was stirred and warmed to room temperature (ca. 1 h). Following cooling to 0 °C, Me_3SiCl (18.5 mL, 0.16 mol) was slowly added and the reaction mixture was allowed to warm to room temperature (ca. 1 h). The solvent volume was then reduced in vacuo until a residual oil remained which was vacuum distilled and upon cooling formed a colourless moisture-sensitive (see below) crystalline solid (26.7 g, 85%). − m.p. 25−27 °C − IR: $\tilde{\nu}$ = 3401 vs, 3043 s, 2956 vs, 2901 s, 2884 s, 1599 vs, 1504 vs, 1460 s, 1446 s, 1386 vs, 1322 vs, 1289 vs, 1238 vs, 1215 vs, 1174 s, 1113 vs, 1050 s, 1031 vs, 902 vs, 842 vs, 776 s, 735 vs, 689 s, 620 w, 590 w cm^{-1}. − MS: *m*/*z* (%) = 195 (80) [M^+], 180 (50) [$(L^1)^+$ − Me], 165 (100) [$(L^1)^+$ − 2Me], 150 (60) [$(L^1)^+$ − 3Me], 135 (45) [$C_6H_5ONSi^+$], 108 (19) [$C_6H_4OMe^+$], 73 (75) [$SiMe_3^+$], 58 [$SiMe_2^+$]. − ^{1}H NMR (300 MHz, C_6D_6, 298 K): δ = 0.16 [s, 9 H, $Si(CH_3)_3$], 3.31 [s, 3 H, OCH_3], 4.26 [br s, 1 H, N*H*], 6.57 [dd, ^3J = 7.4 Hz, ^4J = 1.1 Hz, 1 H, H-6], 6.74 [ddd, 1 H, H-5], 6.88 [m, 2 H, H-3, H-4]. − $C_{10}H_{17}NOSi$, (195.34): calcd. C 61.49, H 8.77, N 7.17; found C 61.66, H 8.89, N 7.29.

A sample of L^1H was exposed to air for 5 h, diluted with $CHCl_3$, and analysed by GC-MS: R_t (rel. int.) = 9.73 (100), *m*/*z* (%) = 123

(90) [$CH_3OC_6H_4NH_2^+$]; R_t = 12.51 (25), *m/z* (%) = 195 (20) [L^1H^+]; no $SiMe_3$-containing decomposition products, e.g. Me_3SiOH, were observed.

[L^2H]: As for L^1H above, 16.9 mL of a solution of *n*BuLi (1.6 M in hexanes) was added dropwise to a stirred solution of *o*-phenoxyaniline (5 g, 27 mmol) in ether (50 mL) at 0 °C. After complete addition a white solid was obtained which was stirred and warmed to room temperature (ca. 1 h) and Me_3SiCl (3.5 mL, 27 mmol) was slowly added. The reaction mixture was stirred for another 5 h. The reaction solution was decanted from the LiCl formed and the solvent volume was then reduced in vacuo until a residual oil remained. This was vacuum distilled and upon cooling formed a colourless moisture-sensitive crystalline solid (5.3 g, 76%). − m.p. 33−35 °C − IR: $\tilde{\nu}$ = 3401 vs, 1606 vs, 1589 s, 1583 s, 1499 s, 1307 vs, 1253 vs, 1240 vs, 1217 s, 1161 s, 1099 vs, 1072 s, 1038 s, 912 vs, 841 s, 750 vs, 689 vs. cm^{-1}. − MS: *m/z* (%) = 257 (60) [M^+], 242 (61) [$(L^2)^+ - Me$], 226 (15) [$(L^2)^+ - Me_2H$], 211 (5) [$(L^2)^+ - Me_3H$], 165 (100) [$OC_6H_4NHSiMe_2^+$], 150 (40) [$C_6H_4ONHSiMe^+$], 135 (30) [$C_6H_4OSiNH^+$], 73 (35) [$SiMe_3^+$], 58 (10) [$SiMe_2^+$]. − ^{1}H NMR (300 MHz, C_6D_6, 298 K): δ = 0.07 [s, 9 H, $Si(CH_3)_3$], 4.14 [br s, 1 H, NH], 6.57−6.63 [ddd, 1 H, H-4], 6.76−6.80 [tt, 1 H, H-5], 6.82−6.88 [dd, 1 H, H-3], 6.90−7.02 [m, 6 H, H-6, H-2′,H-3′,H-4′,H-5′,H-6′] − $C_{15}H_{19}NOSi$ (257.41): calcd. [a] The asymmetric unit comprises two independent, similar, well separated (no H-bonding), molecules. Bond lengths and angles were as expected,[36] and the details are available in the supplementary data.

C_6D_6 was shown to convert into a paramagnetic species upon heating at 60 °C for 24h by ^1H NMR spectroscopy.

To **3** (0.47 g, 0.66 mmol) in hexane (30 mL) was added L^1H (0.13 g, 0.66 mmol). The resulting mixture was heated to 60 °C for 12h. The reaction mixture was then allowed to stand for 3 weeks at room temperature and the solvent volume was reduced to 3 mL under vacuum giving crystals of **1** which was identified by a unit cell determination and an IR spectrum.

X-ray Crystal Structure Analysis: Crystals were mounted under viscous oil onto a glass fibre. Low temperature (≈123 K) data were collected on an Enraf−Nonius CCD area-detector diffractometer (Mo-K_α radiation, λ = 0.71073 Å, frames comprised 1.0° increments in φ and ω yielding a sphere of data) using proprietary software (Nonius B.V., 1998). Each data set was merged (R_{int} as quoted) to N unique reflections and the structures were solved by conventional methods and refined, with anisotropic thermal parameter forms for the non-hydrogen atoms, by full-matrix least-squares on all F^2 data using the SHELX 97 software package.[35] Hydrogen atoms were included in calculated positions and allowed to ride on the parent carbon atom with isotropic thermal parameters. For **1**, the methoxide carbon atoms lie on crystallographic twofold axes and therefore two sets of hydrogens atoms, each with occupancies of 0.5, were placed on each carbon, disordered about the axes. Crystal and refinement data are listed in Table 1.

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-146332 (L^1H), -143939 **(1)**, -143940 **(2)**, -143941 **(3)**. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

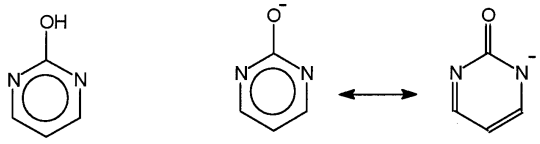
Thermally Robust Metal Coordination Polymers: The Cobalt, Nickel, and Zinc Pyrimidin-2-olate Derivatives

Norberto Masciocchi,*[a,b] G. Attilio Ardizzoia,*[b,c] Girolamo LaMonica,[b,c] Angelo Maspero,[b,c] and Angelo Sironi[a]



Keywords: X-ray powder diffraction / Coordination chemistry / Nitrogen heterocycles / Polymers

A number of coordination polymers of the pymo ligand (Hpymo = 2-hydroxypyrimidine) have been prepared and fully characterized by chemical, spectroscopic, and thermal analyses. Their complete crystal structures have been solved ab initio from laboratory X-ray powder diffraction data and ultimately refined by the Rietveld method. The $M(pymo)_2$ species (M = Co, Ni, Zn) consist of structurally related three-dimensional frameworks of very high thermal stability (decomposing under N_2 only at $T > 550$ °C), with the metal atoms, linked by μ_2-η^1-η^1 (*N*;*N*′) (Co, Zn) or μ_2-η^2-η^1 (*N*,*O*;*N*′) bridges, about 5.4–5.7 Å apart. The hydrated species $Ni(pymo)_2(H_2O)_{2.5}$ is based on a two-dimensional array of $Ni(pymo)_2$ stoichiometry, containing both coordinated and clathrated water molecules, and can be selectively transformed into $Ni(pymo)_2$ by thermal treatment, through an amorphous intermediate, recrystallizing at $T > 315$ °C. In contrast, one dimensional chains are found in the three hydrazine adducts, $M(pymo)_2(N_2H_4)_2$, which show unique bis(μ_2-hydrazine) bridges (M···M ca. 4.0 Å) and terminally *O*-bonded pymo ligands.

Introduction

Coordination polymers containing metal ions in their backbones have been widely investigated, and found to possess a variety of interesting electrical, electrochemical and optical properties.[1] In particular, metal polymers containing azoles and azolates have very recently shown remarkable magnetic,[2] anticorrosion,[3] and even antimicrobial[4] activity. In order to design stable, coordinatively saturated systems, a number of metal ions have been therefore treated with polydentate ligands, either neutral (such as 4,4′-bipyridine or longer spacers[5]) or negatively charged. In the latter group, pyrazolates[6,7] and imidazolates[8] have been found to afford binary species which could be structurally characterized only by X-ray powder diffraction (XRPD) methods.

Recently, we have shifted our interests to the less known pyrimidin-2-olate (pymo) ligand (Scheme 1), which afforded, with silver(I) ions, one-dimensional (hydrated) polymeric species[9] and cyclic hexamers,[10] and, with copper(I) ions, a surprising crystal phase containing, simultaneously, hexamers and infinite helical polymers.[11] In our search for polymers of higher dimensionality and higher thermal stability, we focused on cobalt(II), nickel(II), and zinc(II) ions, i.e. on metals with different electronic requirements, larger coordination numbers and lower redox propensities than copper and silver.

Hpymo pymo

Scheme 1

Therefore, in this paper we report on the syntheses, thermal, and spectroscopic characterization of a number of polymeric species of the M/pymo type (outlined below), which have been structurally characterized by the newly emerging ab initio XRPD technique,[12] pioneered by us in the field of coordination chemistry, from conventional laboratory equipment.[13] The following numbering scheme has been used throughout the paper: **1a** = $Co(pymo)_2$; **1b** = $Ni(pymo)_2$; **1c** = $Zn(pymo)_2$; **2b** = $Ni(pymo)_2(H_2O)_{2.5}$; **3a** = $Co(pymo)_2(N_2H_4)_2$; **3b** = $Ni(pymo)_2(N_2H_4)_2$; **3c** = $Zn(pymo)_2(N_2H_4)_2$.

Results

Syntheses

The reaction of 2-hydroxy-pyrimidine with cobalt, nickel, and zinc dichlorides in water, in the presence of a base such as NH_3, affords, in high yield, the corresponding metal pyrimidinolate derivatives $Co(pymo)_2$, **1a**, $Ni(pymo)_2(H_2O)_{2.5}$,

2b, and $Zn(pymo)_2$, **1c**. The water content in complex **2b** has been verified by TGA analyses, which indicated that all the water molecules are lost in a one-step process at relatively low temperature (200 °C, vide infra) giving rise to the anhydrous species $Ni(pymo)_2$, **1b**.

The synthesis of the hydrazine derivatives $M(pymo)_2(NH_2NH_2)_2$ (M = Ni, Co, Zn) originally derives from the failure in attempting the synthesis of cobalt(I) species by one electron reduction of cobalt(II) in the $Co(pymo)_2$ derivative **1a** with NH_2NH_2. The formation of the unexpected $Co(pymo)_2(NH_2NH_2)_2$ species, **3a**, prompted us to thoroughly investigate this complex and to verify if such a reaction could also occur for the nickel and zinc pyrimidin-2-olate derivatives. Consistently, all three species $M(pymo)_2$ easily react with NH_2NH_2 in acetonitrile, giving rise to derivatives of general formula $M(pymo)_2(NH_2NH_2)_2$ (M = Co, **3a**; Ni, **3b**; Zn, **3c**).

Crystal Structures of $Co(pymo)_2$ (1a) and $Zn(pymo)_2$ (1c)

The isomorphous crystals of **1a** and **1c** contain tetrahedrally coordinated metal(II) ions (lying on a −4 symmetry site, *a* in Wyckoff notation), which are linked to four nitrogen atoms of distinct pymo ligands [Co−N = 2.032(4) Å, Zn−N = 2.086(4) Å]. A schematic drawing of the crystal packing, viewed approximately down [001], is shown in Figure 1. As already observed in several group 11 derivatives, pymo ligands coordinate in the common *N,N′*-exobidentate mode (μ_2-η^1-η^1 coordination), bridging metal atoms which are 5.65 (Co) or 5.70 Å (Zn) apart.[14] In the crystals, all ligands lie about twofold axes (*d* in Wyckoff notation), passing through the C=O vector and parallel to *a* (and *b*).

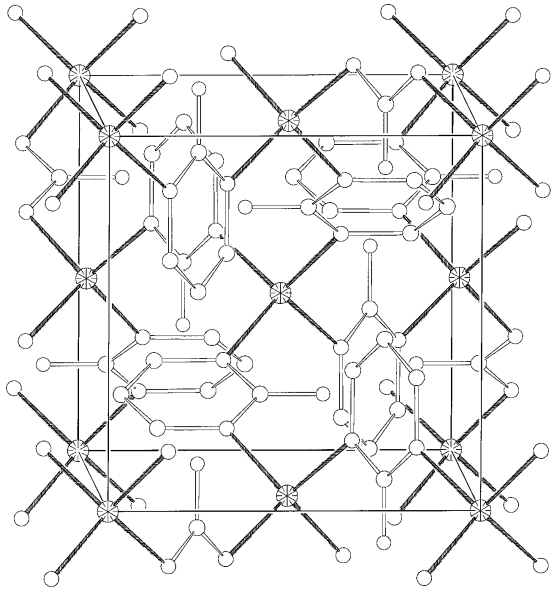

Figure 1. Crystal packing of species **1a**, viewed approximately down [001]; metal atoms are cross-hatched

Disregarding the actual shape of the ligands, the topology of the overall connectivity is far from unusual, since a non-interpenetrated diamond-like framework can be easily recognized. However, it is rather surprising that simple(r) metal diazolates, which contain tetrahedral ions and N,N′ exobidentate C_{2v} anionic heterocycles (i.e. ligands of similar steric, electronic, and symmetry requirements) do not afford the highly symmetric structure found for **1a**; indeed, up to eight crystallographically independent imidazolate (imz) ligands (average Co−N distance: 1.984 Å) are found in $Co(imz)_2$.[15] Similarly, cobalt and zinc pyrazolates (pz), where much shorter M···M contacts are present,[16] do not afford three-dimensional diamondoid structures, but, albeit maintaining tetrahedral coordination, only exist as linear chain (1-D) polymers. However, it must be noted that many of these species are prone to extended polymorphism [see for example Cu(pz),[6] Ag(pz),[6] $Cu(imz)_2$[17] and $Pt(pz)_2$[18]], and that the occurrence of one crystal phase cannot rule out the possibility of a different polymorph.

Crystal Structure of $Ni(pymo)_2$ (1b)

A schematic drawing of the crystal packing of **1b**, viewed down [001] is shown in Figure 2. Bearing in mind that a body-centered tetragonal cell can be always described by a F-centered tetragonal lattice with twice the volume, one can see that the structure of **1b**, in the observed *Fdd*2 space group (after axis relabelling) bears a proper subgroup relation to that of **1a**, (*I*-42*d*) and, therefore, suggests that **1b** can be obtained by removing a symmetry element (in this case, the −4 improper rotation) from the highly symmetric crystals of **1a**. Indeed, crystals of **1b** contain nickel(II) ions (lying on twofold axes, *a* in Wyckoff notation) connected to four distinct pymo ligands, with Ni−N values of 2.135(4) and 2.172(4) Å. The removal of the −4 symmetry element is here tentatively explained by the higher tendency of nickel(II), vs. cobalt(II), to hexacoordination,[19] which distorts the original tetrahedral geometry found in **1a** to a NiN_4 fragment of approximate saw-horse geometry [*trans* N−Ni−N value: 150.3(9)°], leaving two open coordination sites, now occupied by oxygen atoms of two already coordinated pymo ligands [Ni−O 2.288(6)Å]. Thus, while maintaining the overall (diamondoid) three-dimensional topology found in **1a**, pymo ligands are here found in the *new* μ_2-η^1-η^2 coordination mode, i.e. N,O chelating on one side, and purely N donor on the other; the Ni···Ni interatomic distance, bridged by such a tridentate pymo ligand, is only 5.46 Å. The overall coordination geometry of each nickel ion is, therefore, best described by *cis*-NiN_4O_2 pseudooctahedral fragments, their refined bond lengths and angles being reported in the caption of Figure 2. It is noteworthy that the coexistence of N and η^2-*N,O* coordination at the same metal has been previously found for the $[Cu(Hpymo)_4]^{2+}$ cation,[20] with the notable difference that, although maintaining crystallographically imposed C_2 symmetry, the oxygen atoms in the latter occupy *trans*, rather than *cis*, positions.

Crystal Structure of $Ni(pymo)_2(H_2O)_{2.5}$ (2b)

Crystals of **2b** contain octahedrally coordinated nickel(II) ions (lying on a crystallographic −1 site symmetry position, *e* in Wyckoff notation), bonded to four nitrogen atoms of four distinct pymo ligands and two mutually *trans* water

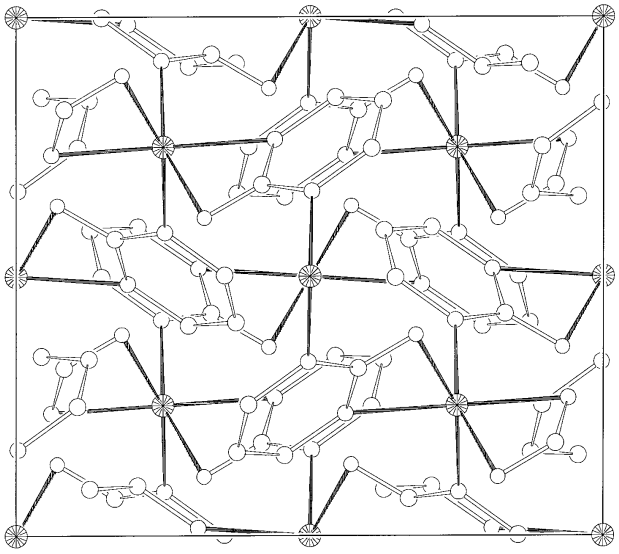

Figure 2. Crystal packing of species **1b**, viewed down [001]; metal atoms are cross-hatched

molecules. Additional water molecules, not involved in metal coordination [lying on *2m m* . (Wyckoff's *c*) positions] fill the cavities of the whole framework. Therefore, species **2b** is best represented by the $Ni(pymo)_2(H_2O)_2 \cdot {}^1/_2H_2O$ formulation. A schematic drawing of the crystal packing, viewed approximately down [1−49] is shown in Figure 3. As depicted therein, the pymo ligands act in the *N*,*N*′-exobidentate mode, connecting Ni ions which are 6.33 Å apart (inter alia, the largest distance ever found within such a class of compounds).

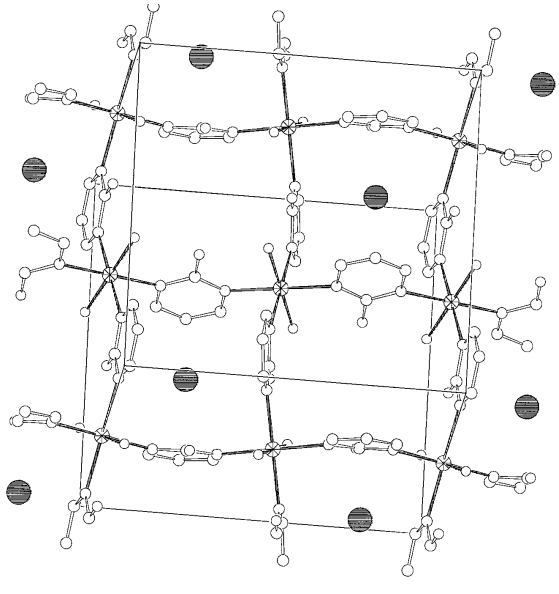

Figure 3. Crystal packing of species **2b**, viewed approximately down [1−49]; metal atoms are cross-hatched, while non-coordinated water molecule are depicted by solid black circles; hydrogen bonds are present, with O···O distances of 2.506(5) and 2.576(3) Å

Neglecting terminally bonded and non-framework water molecules, the overall topology of **2b** can be described by a stack (along *c*) of *two-dimensional* arrays of $Ni(pymo)_2$ squares, thus intrinsically different from the $Co(pymo)_2$ 3-D array described above for **1a**. Interestingly, loosely H-bonded water molecules (O···O >3.0 Å) occupy the cavities of the framework, while much stronger (intralayer, thus "intramolecular") C=O···H−O−H bonds (O···O 2.51−2.58 Å), connecting the pymo oxygens to the coordinated water molecule, are found [and reflected by the significant lowering of the ν(CO) absorption frequency, vide infra].

Crystal Structures of $Co(pymo)_2(N_2H_4)_2$ (3a), $Ni(pymo)_2(N_2H_4)_2$ (3b), and $Zn(pymo)_2(N_2H_4)_2$ (3c)

Species **3a**, **3b**, and **3c** are strictly isomorphous and contain octahedrally coordinated metal ions. A schematic drawing of the crystal packing, viewed approximately down [108] is shown in Figure 4. Each metal(II) ion lies on a crystallographic *2/m* position (*a* in Wyckoff notation) and is bonded to two (mutually *trans*) oxygen atoms of *mono*dentate (μ_1-η^1) pymo ligands (slightly off the mirror plane, see Experimental Section) and, equatorially, to four nitrogen atoms of four distinct hydrazine molecules, which bridge metal atoms separated by ca. 4.0 Å (the *b* vector). It is notable that such M···M distances correlate well with the shrinking of the apparent ionic radii on passing from cobalt(II) to zinc(II) ions.

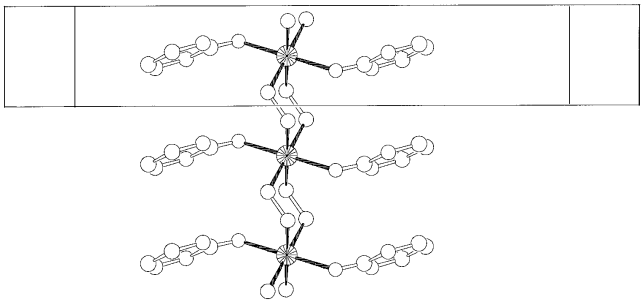

Figure 4. Crystal packing of species **3b**, viewed approximately down [108]; metal atoms are cross-hatched; relevant bond lengths [Å] and angles [°]: Ni−N 2.105(6)−2.111(5), Ni−O 2.208(25); N−Ni−N 89.7(6)−90.3(6), N−Ni−O 89.7(11)−90.3(8)

With reference to Figure 4, one can envisage the existence of linear chains of metal(II) atoms, doubly bridged by μ_2-N_2H_4 molecules (in the very same manner as the pyrazolate anion does) and bearing axial monodentate ligands: such a structural pattern is well-known in coordination chemistry, and accounts for a large portion of the known MX_2L_2 structures, where M = an octahedrally coordinated dication, X = a bridging anionic ligand (halide, hydroxide, azide) and L = a nitrogen donor neutral ligand.[21]

The most interesting structural features of these species are the monodentate nature of the pymo ligand and the unexpected poly(hydrazine) bridges, which, apparently successfully compete with the propensity of pymo to act as a strong *exo*-bidentate ligand. While the first of these anomalies can be partially understood upon analyzing in detail the environment of the "swinging" end of pymo, for which a number of (weak) N···H−N(hydrazine) bonds is detected (see caption to Figure 4), the formation (and stability) of the μ_2-N_2H_4 bridges need more subtle comments.

Hydrazine is known to afford μ_2-bridges, mostly with second and third row transition metals (Ru, Mo, W, Pt), the only structurally characterized species containing a lighter metal being for Fe^{III}.[22] Among the known species, a *transoid* form (ideal value of the M−N−N−M torsion angle of 180°) is by far the most commonly observed one. On the other hand, *cis*-M−N−N−M forms are likely to be disfavored by the presence of eclipsed H···H contacts, even if isosteric (and isoelectronic) peroxo fragments bridging octahedrally coordinated metal atoms at distances as low as 4.01 Å are known.[23] These observations, therefore, seem to suggest that there should not be anything special in the formation of a *staggered* M−N−N−M bridge, either *trans* or *gauche* (like in the present case, with a torsion angle near 77°). The peculiar feature in species **3abc** is, however, the presence of an unprecedented[24] bis-dihydrazine link, leading to six-membered M−N−N−M−N−N− *spiro*-rings with chair-like conformation.

Thermal Stability of Cobalt Derivatives

Powders of **1a** are rather stable and, if heated in a nitrogen atmosphere, only decompose at T > 500 °C, a strongly endothermic peak being observed in the DSC trace near 560 °C. This behaviour is clearly in good agreement with the three-dimensional nature of such coordination polymer, as well as with the negligible tendency of cobalt(II) to display solid-state redox chemistry. In contrast, the much poorer coordination strength of hydrazine speaks for a labile product: indeed, powders of **3a** lose N_2H_4 ($t_{1/2}$ a few hours at room temp.), and, surprisingly, quantitatively transform, in the solid, into polycrystalline **1a**. Note that, as discussed below, such transformation requires a dramatic change in the coordination mode of the pymo ligand with heavy shifts (several Å's) of the metal atom locations; nevertheless, it appears to occur without the formation of an (XRPD detectable) intermediate crystalline, or amorphous, material.

Thermal Stability of Nickel Derivatives

Powders of **2b** lose all water molecules upon heating to almost 200 °C, in a single, nonstructured event, affording a turquoise amorphous powder. Further heating promotes its crystallization (exothermic DSC peak with onset near 315 °C, ca. 26 kJ mol^{-1}), forming **1b** in a quantitative manner. Thus the loss of water leaves empty coordination sites and is not immediately accompanied by the 2-D to 3-D structural rearrangement (**2b** => **1b**) which requires extra energy. Interestingly, this transformation leads, from (originally) centrosymmetric crystals, to a conglomerate of enantiomorphic, acentric crystals. Obviously, additional cooling and heating cycles of powders of **1b** (in the 50−400 °C range), did not show any of the aforementioned features. Heating of **1b** at ca. 450 °C in vacuum promotes a *reversible* change of color (green to brown), which may be associated to the formation of tetrahedral nickel(II) ions by labilization of the Ni−O contacts, possibly leading to a tetragonal high-temperature crystal phase isomorphous to **1a** and **1c**, through an easy crystal-to-crystal phase transformation (vide infra).

Species **3b** is rather stable and can be stored under nitrogen indefinitely at room temperature. Contrasting the cobalt analogue, when heated for several hours at 150 °C, **3b** slowly transforms, with hydrazine loss, into a green amorphous material and *does not* form the binary species **1b**, which is, however, restored, as described above for **2b**, upon heating above 320 °C.

Thermal Stability of Zinc Derivatives

Very similarly to **1a**, and sharing the same crystal structure, species **1c**, upon heating, is rather stable and decomposes near 570 °C, a slightly higher temperature than **1a**. In contrast, species **3c** is rather labile and very rapidly loses N_2H_4 ($t_{1/2}$ < 15 min at room temp.) and, as observed for the cobalt analogue, transforms into polycrystalline **1c**. Consistently, this fast loss of hydrazine resulted in an

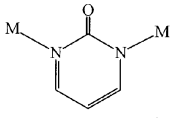
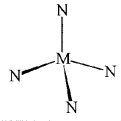
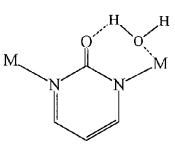
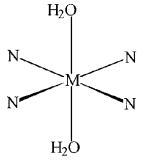
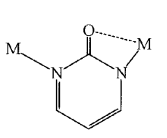
[a] For **3abc**, the site symmetry of an *ideally ordered* crystal phase is quoted (see *Experimental*). − [b] Structures not refined (isomorphous with **3b**). − [c] Subjected to restraints.

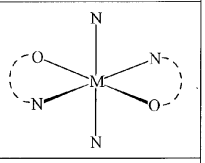


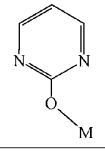


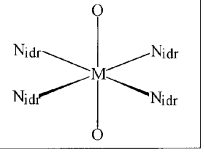












XRPD pattern of low(er) quality, for it shows a multiphase system (evolving with time), measured, in order to avoid complete decomposition, over a short time.

Infrared Spectroscopy

Infrared spectra of complexes **1abc**, **2b**, and **3abc** display the versatility of the coordination features of the pymo ligand. In particular, the position of the ν(CO) band of the lactamic form can be employed as a useful diagnostic tool in order to establish the coordination mode of the ligand (see Table 1).

Derivatives **1a** and **1c** show ν(CO) absorptions at relatively high wavenumbers (1630 and 1633 cm^{-1}, respectively), in agreement with the *N*,*N* coordination of the pyrimidin-2-olate ligand and the absence of any interaction between the exocyclic oxygen and the metal centers.[25] Complex **2b** exhibits such a ν(CO) absorption at 1605 cm^{-1}. The shift can be justified by the presence of strong hydrogen-bonds between coordinated water and the carbonyl moiety. Moreover, complex **2b** also shows two strong and broad absorptions centered at 2900 and 2250 cm^{-1}. These bands are often found in species possessing strong *intra-* or *inter*-molecular hydrogen bonds, e.g. in a large series of pyrazole/pyrazolate derivatives.[26] After removal of coordinated and clathrated water from **2b** (obtaining **1b)**, the aforementioned bands disappear and the ν(CO) absorption shifts at 1586 cm^{-1}, in agreement with the presence of the M···O=C interaction depicted above.

Given the poor stability at ambient conditions of species **3a** and **3c**, only the hydrazine adduct of the Ni(pymo)$_2$ species can give spectroscopic information about the coordination mode of pymo. Indeed, in **3b**, the aforementioned ν(C=O) bands near 1600 cm^{-1} are absent, while a strong absorption, not present in **1abc** or **2b**, is found at 1223 cm^{-1}, which can be attributed to the C−O stretching (of single-bond character) of the pymo ligand coordinating as a phenolate (vide supra).

METAL (M)	ENVIRONMENT AROUND THE METAL		
Co, (**1a**) Zn, (**1c**)	$M(N)_4$		
Ni, (**2b**)	$M(N)_4(O_W)_2$		
Ni, (**1b**)	$M(N,O)_2(N)_2$		
Co, (**3a**) Ni, (**3b**) Zn, (**3c**)	$M(O)_2(N_{idr})_4$		

Scheme 2

Finally, complex **3b** shows a ν(CO) absorption at 1223 cm^{-1}, which is typical of the C−O stretching of a phenolate group, in agreement with the coordination mode of the pymo ligand.

A schematic summary of the structural and spectroscopic information discussed above is pictorially drawn in Scheme 2.

Discussion

All M(pymo)$_2$ phases presented above crystallize in non-centrosymmetric space groups and contain aromatic *dipolar* fragments of idealized C_{2v} symmetry with highly delocalized π electrons. Therefore, in agreement with recent studies on C_{2v} DCM laser dye derivatives[27] and diazaaromatic metal complexes,[28] they are ideal candidates for testing NLO properties, such as second harmonic generation activity.[29] Preliminary measurements (λ_{exc} = 1064 nm) by the Kurtz−Perry technique[30] have indeed shown SHG efficiencies of about 5, 8, and 0.2% (urea as standard) for **1a**, **1b**, and **1c**, respectively.

In addition, they all display rather stable three-dimensional frameworks, which do not decompose or melt upon heating at 500 °C; compared to the other known metal(II) diazolates, they show the highest stabilities: indeed, only Zn(pz)$_2$ was found to sustain rather high temperatures (although decomposing near 440 °C to crystalline zinc dicyanide, with selective CH_3CN extrusion), while accessibility to redox reactions [such as cyanogen formation for Cd(pz)$_2$ or ring mercuriation for Hg(pz)$_2$] dramatically lowers the thermal stability of such species,[16b] including Cu(4X-pz)$_2$. (X = H, Br, Cl, CH_3)[31] and Cu(imz)$_2$.[17] That pymo ligands form rather stable metal adducts was already observed for copper(I) and silver(I) ions: indeed, Cu(pymo)[32] decomposes 70 °C higher than α-Cu(pz)[33] (dec. 270 °C) and *hexameric* Ag(pymo) is stable up to 300 °C,[34] about 40 °C higher than the Ag(pz)[33] and Ag(imz)[35] *polymers*.

Interestingly, while in the previously known silver and copper pyrimidinolates, the pymo ligand was exclusively found to coordinate in the μ_2-η^1-η^1 (*N*,*N*′) mode, the structures reported in this paper demonstrate its coordination versatility. Indeed, within a homogeneous class of compounds, pymo acts either as a (μ_1-η^1-*O*) monodentate or as a (*N*,*N*′) polydentate ligand, with (μ_2-η^2-η^1) or without (μ_2-η^1-η^1) ancillary oxygen coordination.[36] In contrast, the isostructural pyrimidin-2-thiolato ligand, which, owing to the biological importance of its derivatives,[37] has been extensively characterized in a large number of metal complexes, has never been found in the pure μ_2-η^1-η^1 (*N*,*N*′) mode, but, in the rare cases where both N atoms were involved in metal coordination,[38] the (larger and softer) sulfur atom was invariably found in the coordination sphere of one metal.

The different bridging modes of the pymo ligand also influence the distances at which nearest M···M contacts are found: they surprisingly range from 5.46 to 5.70 Å for the binary species up to ca. 6.33 Å for the octahedrally coordinated nickel(II) ions in the hydrated species **2b**. Consistently, the flexibility of such links affects not only the different

connectivity patterns described above, but also the actual values of the M−N and M−N−C bond lengths and angles (see Table 1).

Conclusions

In this paper we have demonstrated that reaction of metal ions with deprotonated diazaaromatic ligands can afford rather stable coordination polymers, which can be heated without decomposition up to ca. 550 °C. When pymo and Co, Ni, and Zn ions are employed, three-dimensional diamondoid networks are formed, in contrast with the 1-D nature of all known $M(pz)_2$ polymers (M = Cu, Zn, Cd, Hg). Such stereochemical features, together with the low(er) propensity of Co, Ni and, particularly, Zn toward redox reactions, are thought to heavily influence the stability of such crystal phases. In the process of developing suitable syntheses for such species, a number of water and hydrazine adducts have been prepared, the structural characterization of which showed the extreme versatility of the pymo ligands, as well as the formation of 2-D (for **2b**) and 1-D (**3abc**) polymers.

Since all these species could only be obtained as microcrystalline samples, their full structural analyses was performed through the ab initio XRPD technique (see Appendix); as recently shown by us in the field of coordination chemistry for metal pyrazolates and metal diazaaromatic halides, this method has become a powerful laboratory tool for the complete characterization of *entire* classes of compounds and not only, as often appeared in the recent literature, for fortunate, isolated or benchmark cases bearing methodologically important aspects.

Experimental Section

General: 2-Hydroxypyrimidine hydrochloride and metal salts were used as supplied (Aldrich Chemical Co.). − Infrared spectra were recorded on a BIO RAD FTIR 7 instrument. − Thermogravimetric analyses were performed on a Perkin−Elmer TGA-7 system. DSC traces were obtained with the aid of a Perkin−Elmer DSC 7 calorimeter. − X-ray powder diffraction was used to characterize the phases formed upon heating the powders in the DSC furnace. − Elemental analyses (C, H, N) were carried out at Microanalytical Laboratory of the University of Milan.

Synthesis of Cobalt(II), Nickel(II), and Zinc(II) Derivatives: Complexes **1a**, **2b**, and **1c** have been prepared following the same synthetic route: ten mmol of the appropriate metal chloride ($CoCl_2{\cdot}6H_2O$, 2.38 g, $NiCl_2{\cdot}6H_2O$, 2.38 g and $ZnCl_2$, 1.36 g) were dissolved in distilled water (30 mL) and 2-hydroxypyrimidine hydrochloride (3.31 g, M/Hpymo ratio = 1:2.5) was added under stirring. The clear solutions were kept at room temperature for about 20 min., then the temperature was raised to 90 °C and aqueous ammonia (25% w/w) was added dropwise, adjusting the pH of the solution to a value near 10. The pink $Co(pymo)_2$, **1a**, and the white $Zn(pymo)_2$ species, **1c**, suddenly precipitate, whereas turquoise $Ni(pymo)_2(H_2O)_{2.5}$, **2b**, separates from a deep blue solution in about 10 minutes. The suspensions were stirred at 90 °C for an additional half hour, the solids were then filtered, washed with hot water and dried under vacuum.

Anhydrous $Ni(pymo)_2$, 1b, (amorphous phase) was obtained upon heating the hydrated $Ni(pymo)_2(H_2O)_{2.5}$ species **2b** at 200 °C for 10 min under vacuum. A microcrystalline powder of **1b**, suitable for the XRPD study (vide infra), was obtained after over-heating the solid at ca. 550 °C under vacuum. All preparations gave quantitative (>95%) yields. Analyses: **1a**: $C_8H_6CoN_4O_2$: calcd. C 38.57, H 2.41, N 22.49; found C 38.51, H 2.47, N 22.41; **1b**: $C_8H_6N_4NiO_2$: calcd. C 38.60, H 2.41, N 22.52; found C 38.53, H 2.45, N 22.45; **1c**: $C_8H_6N_4O_2Zn$: calcd. C 37.59, H 2.35, N 21.93; found C 37.47, H 2.43, N 21.86; **2b**: $C_8H_{11}N_4NiO_{4.5}$: calcd. C 32.69, H 3.75, N 19.07; found C 31.91, H 3.85, N 18.85.

Synthesis of the Hydrazine Adducts: Complexes **1a** (or **1b/1c**) (500 mg, about 2 mmol) were suspended in acetonitrile (7 mL) and hydrazine (160 μL, 80% water solution) was added with stirring. A rapid change in color was observed when cobalt or nickel pyrimidin-2-olate derivatives were employed (from pink to white and from turquoise to very light violet, respectively). The suspensions were stirred for 4 h, the solids were then filtered under nitrogen (to avoid atmospheric moisture) and dried under a flow of dry nitrogen. The nickel derivative $Ni(pymo)_2(N_2H_4)_2$, can also be obtained employing $Ni(pymo)_2(H_2O)_{2.5}$ in place of $Ni(pymo)_2$. A longer reaction time is in this case required (about 12 h). Analysis for **3b**: $C_8H_{14}N_8NiO_2$: calcd. C 30.70, H 4.48, N 35.82; found C 30.77, H 4.41, N 35.73; due to thermal instability, the chemical analyses for **3a** and **3c** are erratic (see text).

X-ray Powder Diffraction Analysis of 1abc, 2b, and 3abc: The powders were gently ground in an agate mortar, than cautiously deposited in the hollow of an aluminium holder equipped with a zero background plate (supplied by The Gem Dugout, State College, PA) with the aid of glass slide. Diffraction data (Cu-K_α, λ = 1.5418 Å) were collected on a vertical scan Philips PW1820 diffractometer, equipped with parallel (Soller) slits, a secondary beam curved graphite monochromator, a Na(Tl)I scintillation detector and pulse height amplifier discrimination. The generator was operated at 40 KV and 40 mA. Slits used: divergence 1.0°, antiscatter 1.0° and receiving 0.2 mm. Nominal resolution for the present setup is 0.12° 2θ (FWHM) for the Si(111) peak at 28.44° (2θ). Long overnight scans were performed for **1abc**, **2b**, and **2c** with $5<2\theta<95°$, with t = 10 s and $\Delta 2\theta$ = 0.02°, while the low stability of the zinc hydrazine adduct required a much faster scan ($5<2\theta<35°$, t = 1s, approximately 30 min long).

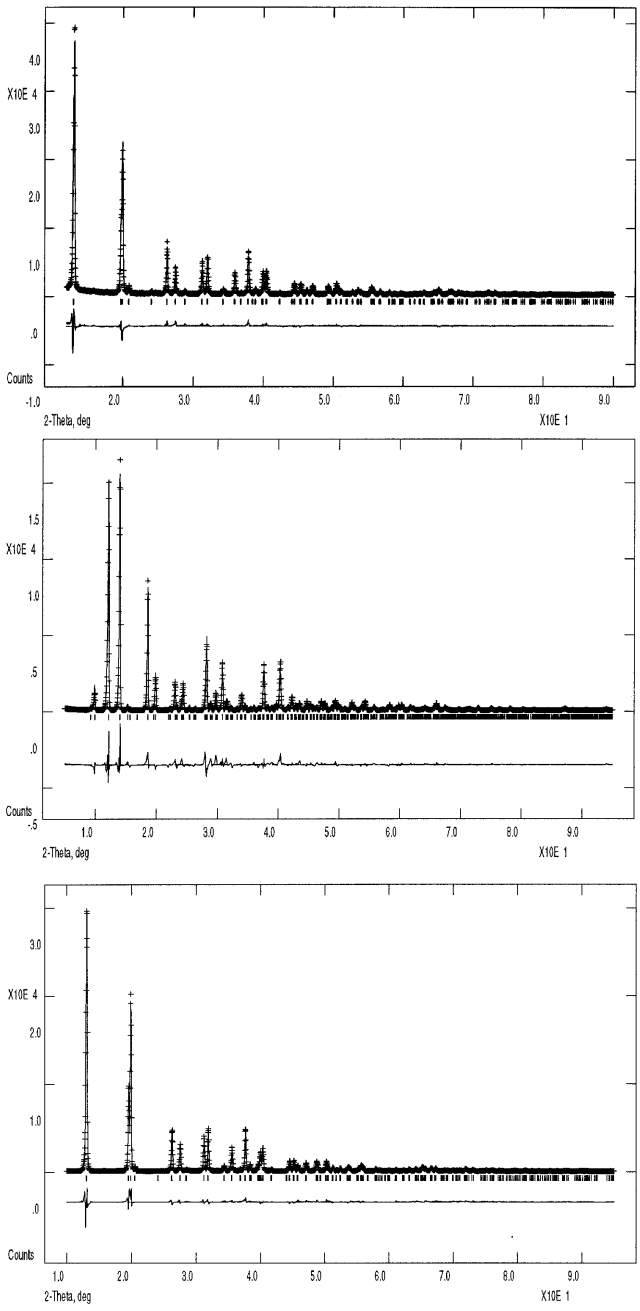
Indexing, using TREOR,[39] of the low angle peaks suggested, for **1a** and **2b**, tetragonal unit cells of approximate dimensions a = 7.39, c = 17.03 Å for **1a** [M(20)[40] = 19; F(20)[41] = 25 (0.016, 51), I-centered] and a = 12.62, c = 14.54 Å for **2b** [M(10) = 32; F(10) = 38 (0.012, 22), primitive]; in contrast, the unit cell determination of **3a** lead to a triclinic cell [a = 4.04, b = 6.04, c = 15.42 Å, α = 64.3, β = 113.3 and γ = 90.4°; M(13) = 24; F(13) = 35 (0.015, 24)], which could be successfully transformed into a C-centered monoclinic lattice with a = 25.04, b = 4.04, c = 6.04 Å, β = 92.8°; indexing of **1b** suggested, as probable unit cell, an orthorhombic lattice with a = 11.02, b = 9.60 Å, c = 16.21, [M(11) = 23; F(11) = 29 (0.006, 67); F-centered]. Systematic absences indicated (among others) *I−42d*, *C2/m*, *$P4_2$/nmc*, and *Fdd2* as the probable space group, for **1a**, **3a**, **2b**, and **1b**, respectively, later confirmed by successful solution and refinement; **3b** and **3c** were found to be strictly isomorphous with **3a** (and **1c** to **1a**), and, therefore, not solved ab initio.

Structure solutions of **1a**, **1b**, and **2b** were initiated by EXPO[42] [108 ($2\theta<85°$), 147 and 84 ($2\theta < 65°$) independent F_o's, respectively]

which afforded all metal and N atom locations, as well as the positions of a few other light atoms. With the help of difference Fourier syntheses and geometrical modeling, approximate coordinates for the remaining non-hydrogen atoms were easily obtained. Approximate lattice constants and atomic coordinates for **1c** were taken from those of the isomorphous species **1a**.

In contrast, the structure of **3abc** could not solved by this method; therefore, we resorted to the ′brutal force′ program ESPOIR,[43] which combines direct space search and a reverse Monte Carlo algorithm; rather efficiently, using 134 F_o's extracted by EXPO, this program succeeded in finding the Ni atom in **3b** and approximate location and orientation of the (crystallographically unique) pymo ligand. Difference Fourier and geometric modeling later afforded the location of μ_2-bridging hydrazine. However, the original location of the pymo and hydrazine ligands, bisected by crystallographic mirror planes, afforded reasonable profile agreement factors (wR_p and R_p: 0.175 and 0.132, respectively), but a poor R_F value (0.184) and a rather strained hydrazine molecule, possessing an implausible *eclipsed* conformation and N−N−Co angles near 135°. Therefore, we suspected the presence of local disorder of the hydrazine bridges and simulated the diffraction pattern for ordered and disordered C-1 and C2 models. Comparison of the Rietveld refinements, of the resulting stereochemistries and evaluation of the overall (intramolecular + packing) steric energy by a locally developed molecular mechanics programs (based on the MM3 force field and capable of dealing with crystal lattices and polymeric systems[44]), revealed that *disordered* bis-hydrazine bridges, with M−N−N−M−N−N rings in chair conformation, and pymo ligands slightly off the mirror plane, are present, with the strict stereochemical condition that, within each polymeric chain, a rather perfect order is maintained, and that the average *C2/m* space group symmetry stems from the order loss in the lateral packing of chains. Therefore, the final model described in the following, as well in Table 1 and Table 2, Figure 5 and in the Supporting Information, show split ligands with atomic fractional occupancy of 0.5.

The final refinements were performed with the aid of the GSAS suite of programs,[45] by imposing steric restraints to chemically stiff and known fragments: pymo rings were idealized with average literature values (C−C and C−N: 1.38 Å; C=O: 1.25 Å; all angles set at 120°). A soft restraint was also applied to hydrazine N−N distance [1.44(1) Å in **3b**]. The peak shapes were best described by the Thompson/Cox/Hastings formulation[46] of the pseudo Voigt function, with GV and LY set to zero. The experimental background was modeled by a cosine Fourier series, while systematic errors were corrected with the aid of a sample-displacement angular shift. Metal atoms were given a refinable isotropic displacement parameter [U_{iso}(M)], while lighter atoms *U*'s were arbitrarily given [U_{iso}(M) + 0.02] Å^2 values. The contribution of the hydrogen atoms to the scattered intensity was neglected. Scattering factors, corrected for real and imaginary anomalous dispersion terms, were taken from the internal library of GSAS. Final R_p, R_{wp}, and R_F agreement factors, together with details of the data collections and analyses for the seven crystal phases can be found in Table 2. Figure 5 shows the final Rietveld refinement plots. The multiphase nature *and* the variable composition of the XRPD data for species **3a** and **3c** prevented a full structural refinement; therefore, the data reported in Table 2 refer to a LeBail (**3a**) and multiple peak positions (**3c**), rather than Rietveld, fit. Final fractional coordinates and full lists of bond lengths and angles are supplied as Supporting Information. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-141485−141489. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [fax: (+44)1223 336−033; E-mail: deposit@ccdc.cam.ac.uk].



Appendix

X-ray powder diffraction is known to afford very good estimates of the lattice parameters, but only approximate values for atomic position and thermal displacement parameters. Also, in the formulation of the ′correct′ structural model for complex structures, *external* knowledge, such as chemical composition and stereochemical rules, must be introduced by the sagacious use of restraints. We

have recently demonstrated that packing energy evaluation within the crystal lattice may discriminate among similar models, thus acting as a lens for rescuing subtle details at spatial resolution higher that that affordable by XRPD data alone.[47] Accordingly, the final structural model for species **3b** has been derived after *overall* steric energy minimization, stereochemical considerations and a number of parallel refinements had been performed, with the aim of identifying the most likely (i.e. correct?) structural model. While the figures reported hereafter in Table 3 cannot be straightforwardly used as in standard single-crystal diffractometry (apart from the "unobservable" R_F value), it is only their internal comparison and the stereochemical features associated to the different cases that guarantee successful results even from XRPD data.

[14] In contrast to that observed in previous XRPD studies, all M···M separations reported in this paper are rather accurately estimated, since, owing to the special location of the metal atoms, they only depend on the lattice metrics which, from PD experiments, typically possess e.s.d.'s lower than in conventional single-crystal diffractometry.

Synthesis and Structure of Siloxy-Substituted ZnO Aggregates Having $(ZnO)_n$ (n = 2, 4) and Zn_3O_4 Cores

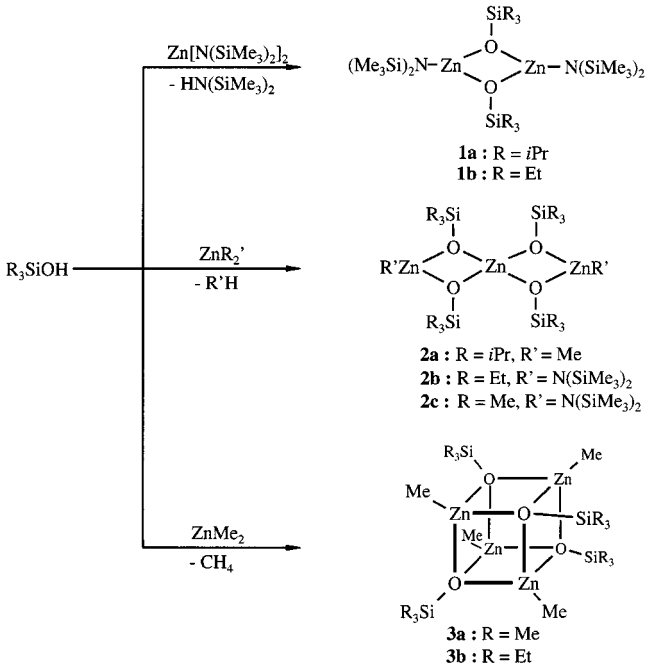
Matthias Driess,*[a] Klaus Merz,[a] and Stefan Rell[a]

Keywords: Clusters / Metal oxides / Siloxides / Zinc

Convenient syntheses and X-ray crystallographic characterizations of the first bis(trimethylsilyl)amido-, methyl-, and iodozinc triorganosiloxide aggregates **1**–**5** are described. They are accessible by the simple reaction of ZnR'_2 [R = Me, $N(SiMe_3)_2$] with the respective silanols R_3SiOH (R = Me, Et, *i*Pr), which affords the dimeric $[(Me_3Si)_2NZnOSiR_3]_2$ (**1a**: R = *i*Pr; **1b**: R = Et), trinuclear $[(MeZn)_2Zn(OSi{\it i}Pr_3)_4]$ (**2a**), $\{[(Me_3Si)_2NZn]_2Zn(OSiR_3)_4\}$ (**2b**: R = Et; **2c**: R = Me), and tetranuclear heterocubanes $[MeZnOSiR_3]_4$ (**3a**: R = Me; **3b**: R = Et), respectively. The latter were oxidized with four equivalents of elemental iodine to form the tetraiodo derivatives $[IZnOSiR_3]_4$ (**4a**: R = Me; **4b**: R = Et) in 82 and 88% yield, respectively. Due to the higher polarity of the Zn–I vs. Zn–C σ-bond, the Zn–O distances of the almost regular Zn_4O_4 core in **4a** are 2–6 pm shorter than those observed in the less Lewis-acidic cluster **3b**. However, the Zn–O distances in **3b** and **4a** are ca. 10–15 pm longer than those in **1a**, **2a**, and **2c**, due to different coordination numbers at Zn and the effects of ring strain. Remarkably, the iodo derivatives **4a**,**b** undergo dissociation in THF to give the respective dimeric THF solvates $[IZn(THF)OSiR_3]_2$ (**5a**: R = Me; **5b**: R = Et), whereas the Zn_4O_4 cores in **3a** and **3b** are retained even in aprotic polar solvents.

Introduction

Molecular single-source precursors for the formation of metal oxides such as metal alkoxides and siloxides[1] have attracted wide interest in the fields of material science and catalysis. While many fascinating applications have been developed in the series of homo- and heterometallic alkoxides and siloxides[1,2] relating to most s-, p-, d-, and f-block elements, the precursor chemistry of molecular zinc alkoxide aggregates[3] and related systems (siloxides, phosphonates)[4] has received much less attention. Remarkably, in contrast to molecular zinc thiolate/sulfide clusters, which consist of structural subunits of sphalerite with six-membered Zn_3S_3 rings comprised of alternating zinc and sulfur atoms,[5] zinc alkoxide aggregates possess single or edge-fused, four-membered Zn_2O_2 cores. This is evident from the rare examples of structurally characterized Zn_4O_4 heterocubanes, edge-shared Zn_7O_8 double-cubanes, and spirobicyclic Zn_3O_4 aggregates.[3] The formation of other types of aggregates or substitution of the exocyclic organic ligands at zinc without degradation of the Zn_xO_y framework seems very limited, due to the high polarity of the Zn−O bond. Since the degree of aggregation and reactivity of such clusters is strongly influenced by the steric and electronic properties of the substituents at oxygen, siloxy-substituted derivatives can be expected to be even more versatile building blocks than their alkoxide analogues due to the convenient leaving-group properties of silyl groups. Whereas only two types of siloxy-substituted ZnO aggregates have been described previously, 35 years ago by Schmidbaur et al.,[6] no information is yet available concerning the influence of the size of the triorganosilyl group at O or of the substituent at Zn on the degree of aggregation of molecular zinc siloxides. We report herein on the synthesis and structural characterization of the siloxy-substituted di-, tri-, and tetranuclear ZnO clusters **1**, **2**, and **3**, which represent potentially useful precursors for the synthesis of ZnO nanoparticles. Remarkably, the methyl groups at Zn in **3a**,**b** can easily be replaced by iodine atoms, ultimately leading to the respective tetraiodides **4a**,**b**, which are promising starting materials for the synthesis of other nonorgano-substituted (Zn−X) Zn_4O_4 heterocubanes.



Results and Discussion

Different siloxy-substituted ZnO aggregates are accessible simply by the Brønsted acid/base reaction of triorganosilanols with dialkyl- and diamidozinc compounds. Thus, conversion of the triorganosilanols R_3SiOH (R = Me, Et, *i*Pr) with the zinc bases ZnR_2' [R′ = Me, $N(SiMe_3)_2$] furnishes, depending on the steric demand of the substituents, di-, tri-, and tetranuclear ZnO aggregates of types **1**−**3**. Reaction of the sterically congested silanol iPr_3SiOH with $ZnMe_2$ leads exclusively to the trinuclear, spirobicyclic Zn_3O_4 aggregate **2a** in 76% yield, while its analogous conversion with the bulky zinc diamide $Zn[N(SiMe_3)_2]_2$ affords only the dimer **1a** in 84% yield (Scheme 1). However, reaction of Et_3SiOH with $Zn[N(SiMe_3)_2]_2$ furnishes a 1:1 mixture of the dimeric and trinuclear species **1b** and **2b**, respectively. Apparently, the size of the silyl group has a stronger influence on the rate of deprotonation and the degree of

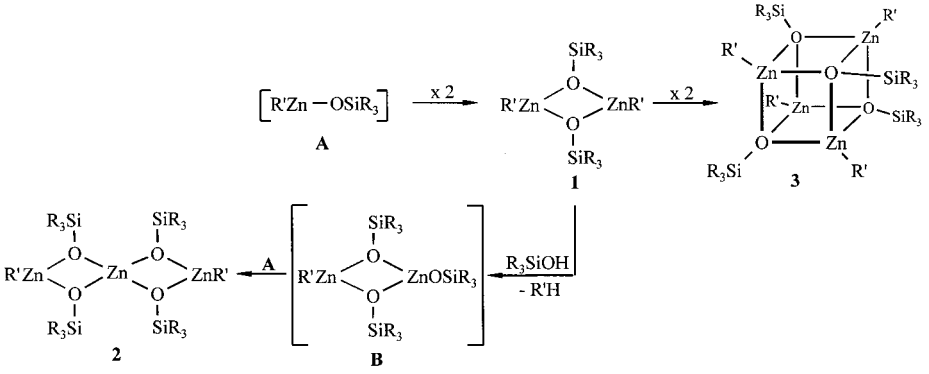
aggregation than the steric or electronic situation at the zinc center.



Scheme 1. Synthesis of **1**–**3**

Consequently, a higher degree of aggregation can be expected by employing sterically less congested silyl groups. This is confirmed by the reaction of R_3SiOH (R = Me, Et) with Me_2Zn, which leads to the tetranuclear heterocubanes **3a** and **3b**, respectively, in > 90% yield. Compound **3a** has already been prepared and structurally characterized by Schmidbaur et al.[6] The formation of tetrameric ZnO heterocubanes has also been observed for a few appropriate alkoxides, but in these cases the zinc atoms bore relatively bulky organo groups implying a relatively low reactivity of the cluster.[5] Although the mechanism of aggregation is still unknown, we propose that the initial step of the reaction of R_3SiOH with ZnR'_2 involves the formation of monomeric $R'ZnOSiR_3$ moieties **A**, which subsequently dimerize to a derivative of type **1** (Scheme 2).

$R'ZnOSiR_3$. Appropriate substitution favors dimerization of **1** to **3**, while additional Brønsted acid/base reaction (siloxylation) with one molecule R_3SiOH affords the polar, coordinatively unsaturated intermediate **B**. The latter can either undergo a rearrangement or association with **A** to form derivatives of type **2**. The siloxy derivatives **1**–**3** were found to be well soluble on warming in aliphatic and aromatic solvents, and their structures were also found to be retained in aprotic polar solvents such as ethers and tertiary amines. The relatively high stability of the Zn_4O_4 core in **3a** and **3b** permits oxidative exchange of the substituents at the zinc centers. While attempts to achieve Me/X exchange (X = halogen) at zinc on the intact Zn_4O_4 skeleton in **3a**,**b** with Ph_2PX as a potential halogenating agent failed,[7] we obtained the colorless, crystalline tetraiodo derivatives **4a** and **4b** in 88 and 82% yield, respectively, through direct iodination of **3a**,**b** with four molar equivalents of I_2 in toluene. This iodination was found to proceed in a stepwise manner, the rate of the reaction decreasing with increasing number of iodine atoms in the reaction intermediates, and complete conversion required about 48 h.

While **4b** is only sparingly soluble even in boiling toluene, **4a** dissolves in hexane and toluene at room temperature without dissociation. Because of the greater polarity of the terminal Zn–X bonds in the heterocubane core of **4a**,**b** (X = I) compared to those in **3a**,**b** (X = C), the Zn_4O_4 core in **4a**,**b** decomposes in aprotic polar solvents or in the presence of donor molecules, affording two molar equivalents of solvated Zn_2O_2 dimers. Thus, the dimers **5a** and **5b**

Scheme 2. Proposed mechanism for the formation of **1**–**3** via **A** and **B**

Apparently, the fate of **1** depends decisively on the steric demand of the substituents and the reactivity of the terminal Zn–X bond (X = C, N) toward R_3SiOH and

are formed quantitatively in THF solution. The compositions of compounds **1**–**5** have been verified by correct combustion analyses, whereas mass spectrometric analyses (EI,

FAB) resulted only in the detection of fragment ions. Since most of the compounds discussed here give rise to relatively simple ^{1}H NMR spectra, their structures could only be unequivocally corroborated by single-crystal X-ray diffraction analysis, as discussed below.

Structural Descriptions

The dinuclear aggregate **1a** crystallizes in the monoclinic space group *C*2/*c* and consists of a planar Zn_2O_2 core (Figure 1). The coordination of the Zn and O centers is trigonal-planar with uniform Zn−O distances that resemble the values observed in other dimers.[5b] Due to the steric requirements of the *i*Pr$_3$Si and amino groups, the N(SiMe$_3$)$_2$ groups at Zn cannot be oriented in a coplanar fashion in relation to the Zn_2O_2 plane. However, this configuration permits significant Zn−O π-interactions, which lower the high Zn−O σ-bond polarity (difference in Pauling electronegativities = 1.78).

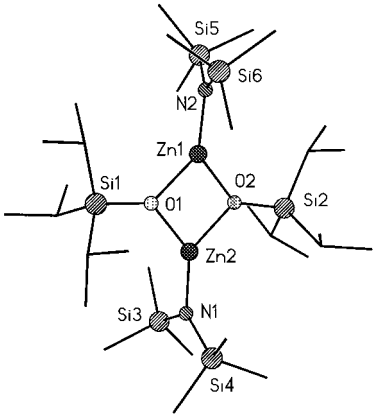


Figure 1. Solid-state structure of **1a**; H atoms are omitted for clarity

The average Zn−N distance of 1.871 Å is practically identical to values found for analogous dinuclear systems bearing terminal N(SiMe$_3$)$_2$ substituents,[7,8] but is significantly shorter than in the tris(amido) complex anion Zn[N(SiMe$_3$)$_2$]$_3^-$ (1.957 and 1.985 Å).[9] The topologically identical spirobicyclic Zn_3O_4 aggregates **2a** and **2c** crystallize in monoclinic (*C*2/*c*) and orthorhombic (*Pbcn*) space groups, respectively, and consist of an almost linear array of three Zn centers bridged by four siloxide ligands. The coordination of both the two terminal Zn and the O centers is trigonal-planar, whereas the central zinc atom has a distorted tetrahedral geometry (Figure 2 and Figure 3). Similar to the situation in **1a**, the amido groups at Zn in **2c** are almost perpendicularly oriented with respect to the Zn_2O_2 planes. Although the terminal and central Zn atoms have different coordination numbers, their respective Zn−O distances are almost uniform (Table 1), reflecting a relatively strong Zn−O σ-bond polarity within the Zn_3O_4 backbone.

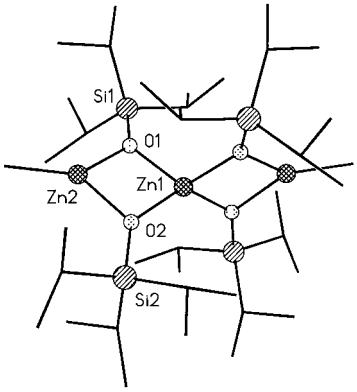

Figure 2. Molecular structure of **2a**; H atoms are omitted for clarity

In contrast, the Zn−O distances in the tetrameric ZnO aggregates **3b** and **4a**, which crystallize in monoclinic space groups (*C*2/*c* and *P*2$_1$/*n*, respectively) are, for steric reasons, ca. 10−15 pm longer than those in **1a**, **2a**, and **2c** (see Table 1). It is noteworthy that the Zn−O distances in the tetraiodo derivative **4a** are ca. 2−6 pm shorter than those in **3b**, probably because of the greater polarity of the Zn−I bond compared to the Zn−C bond. The heterocubane Zn_4O_4 cores in **3b** and **4a** (Figure 4 and Figure 5) are almost regular and therefore resemble very closely the structures observed for related Zn_4O_4 derivatives.[5b,6]

The Zn−I distances in **4a** are almost identical and are unremarkable, comparing well with the values observed for other iodozinc complexes.[7c,10] Slightly longer Zn−I distances, and concomitantly shorter endocyclic Zn−O1 distances are observed, as expected, in the THF solvate **5b**, which crystallizes in the orthorhombic space group *Pbca* (Figure 6). The terminal Zn−O2 distance, i.e. that between the zinc atom and the oxygen center of the THF ligand, is 10 pm longer than the endocyclic Zn−O1 distance, while the elongation of the Zn−I distance is caused by the stabilizing dative Zn−O(THF) bond. Apparently, the driving force behind the facile decomposition of heterocubanes **4a**,**b** in polar solvents can be interpreted in terms of coordination effects and the release of ring strain. Finally, it is worthy of note that the structures of the Zn(OSiR$_3$) aggregates **1**−**4** show a striking similarity to those of the isoelectronic Zn(NPR$_3$) clusters (phosphoraneimidinato complexes).[7] However, the Zn centers in the latter are much more electronically stabilized by π-donation from the N=P moiety and therefore, in contrast to **4a** and **4b**, the aggregates resist degradation even in donor solvents.

Experimental Section

General Remarks: All reactions were performed under anaerobic conditions using modified Schlenk techniques. Solvents were freshly distilled from Na and saturated with Ar prior to use. − ^{1}H NMR spectra were recorded at 250 MHz, ^{13}C NMR spectra at 63 MHz, and ^{29}Si NMR spectra at 50 MHz with samples in C_6D_6

solution with a Bruker WP250 spectrometer; chemical shifts are quoted in δ values relative to $SiMe_4$ as an internal standard.

$[(Me_3Si)_2NZnOSi\mathit{i}Pr_3]_2$ (1a): A solution of $Zn[N(SiMe_3)_2]_2$ (Aldrich) (1.43 g, 3.71 mmol) in toluene (30 mL) was allowed to react with $\mathit{i}Pr_3SiOH$ (0.65 g, 3.71 mmol) at −78 °C. After stirring, the clear mixture for 6 h at room temperature, the volatile components were removed under reduced pressure (10^{-3} Torr, 40 °C) and the residue was redissolved by gently heating in a small volume of hexane. Colorless crystals of **1a** were deposited at room temperature. Yield: 1.24 g (1.55 mmol, 84%); m.p. 186−189 °C (decomp.). − ^{1}H NMR (C_6D_6): δ = 0.42 (s, 36 H, SiMe), 1.29 (sept, 6 H, C*H*Me$_2$), 1.35 (d, 36 H, CH*Me*$_2$). − ^{13}C NMR (C_6D_6): δ = 5.7 [q, 12 C, $SiMe_3$, ^1J(C,H) = 117 Hz], 16.3 [d, 6 C, *C*HMe$_2$, ^1J(C,H) = 116 Hz], 19.3 [q, 12 C, CH*Me*$_2$, ^1J(C,H) = 126 Hz]. − ^{29}Si NMR (C_6D_6): δ = −1.5 [dec, 4 Si, $SiMe_3$, ^2J(Si,H) = 3.8 Hz], 15.3 (m, 2 Si, Si$\mathit{i}Pr_3$). − $C_{30}H_{78}N_2O_2Si_6Zn_2$ (798.2): calcd. C 45.14, H 9.85; found C 44.98, H 9.83.

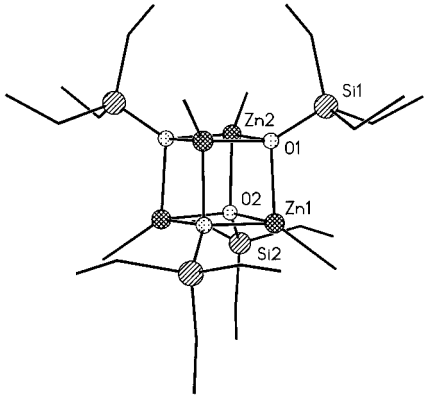

Figure 4. Molecular structure of **3b**; H atoms are omitted for clarity

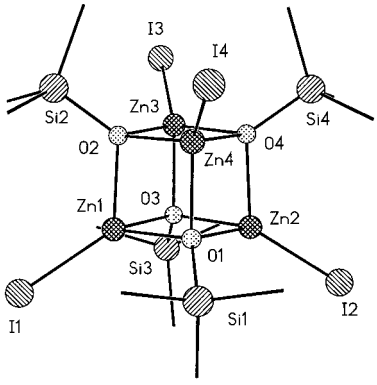

Figure 5. Solid-state structure of **4a**

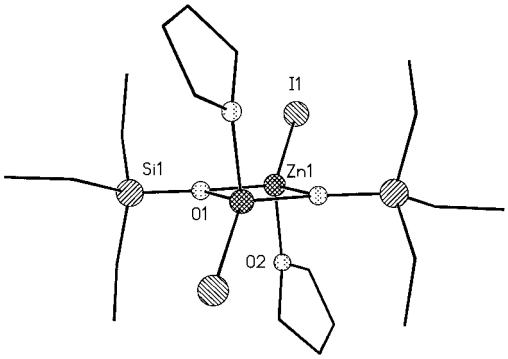

Figure 6. Molecular structure of **5b**; H atoms are omitted for clarity

$[(Me_3Si)_2NZnOSiEt_3]_2$ (1b), $\{[(Me_3Si)_2NZn]_2Zn(OSiEt_3)_4\}$ (2b): The product **1b** was prepared in a similar manner as **1a**. However, from common organic solvents, **1b** could only be crystallized in the form of a 1:1 mixture with **2b**. Reaction of a solution of zinc diamide (1.37 g, 3.55 mmol) in toluene (20 mL) with Et_3SiOH (0.47 g, 3.55 mmol) afforded colorless plates. Yield: 1.03 g; m.p. 167−170

Table 2. Details of the crystal structure determinations of **1a**, **2a**, **2c**, **3b**, **4a**, and **5b**

°C (decomp.). The structure of this mixture was established by X-ray crystallography, which confirmed the presence of equimolar amounts of **1b** and **2b**. The moderate crystal quality did not permit a satisfactory refinement of the data.

[(MeZn)$_2$Zn(OSi*i*Pr$_3$)$_4$] (2a): At −78 °C, a solution of $ZnMe_2$ (1.44 g, 15.2 mmol, 2 M solution in toluene; Aldrich) in toluene (ca. 100 mL) was slowly treated with a solution of *i*Pr$_3$SiOH (3.52 g, 20.3 mmol) in toluene (10 mL), which resulted in the immediate evolution of methane. The solution was then allowed to warm to room temperature and all volatiles were removed in vacuo (10^{-3} Torr). Colorless plates were obtained after recrystallization of the residue from a small volume of hexane at 25 °C. Yield: 3.53 g (3.84 mmol, 76%); m.p. 211−214 °C (decomp.). − ^{1}H NMR (C_6D_6): δ = −0.05 (s, 6 H, ZnMe), 1.12 [sept, 12 H, C*H*Me$_2$, ^3J(H,H) = 6.8 Hz], 1.20 [d, 72 H, CH*Me*$_2$, ^3J(H,H) = 6.8 Hz]. − ^{13}C{1H} NMR (C_6D_6): δ = −11.9 (s, 2 C, ZnMe), 15.6 (s, 12 C, *C*HMe$_2$), 19.2 (s, 24 C, CH*Me*$_2$). − ^{29}Si{^{1}H} NMR (C_6D_6): δ = 14.9 (s). − $C_{38}H_{90}O_4Si_4Zn_3$ (919.6): calcd. C 49.63, H 9.86; found C 49.19, H 9.85.

{[(Me$_3$Si)$_2$NZn]$_2$Zn(OSiMe$_3$)$_4$} (2c): Product **2c** was prepared in a similar manner as **2a**, starting from Zn[N(SiMe$_3$)$_2$]$_2$ (1.01 g, 2.62 mmol) and Me$_3$SiOH (0.31 g, 3.49 mmol). Recrystallization of the residue from hexane (10 mL) afforded colorless cubes. Yield: 0.60 g (0.069 mmol, 79%); m.p. 218−222 °C (decomp.). − ^{1}H NMR (C_6D_6): δ = 0.31 (s, 36 H, OSiMe), 0.44 (s, 36 H, NSiMe), 1.27 (sept, 6 H, C*H*Me$_2$), 1.34 (d, 36 H, CH*Me*$_2$). − ^{13}C{^{1}H} NMR (C_6D_6): δ = 3.1 (s, 12 C, OSiMe$_3$), 5.7 (s, 12 C, NSiMe$_3$), 16.0 (s, 6 C, *C*HMe$_2$), 19.4 (s, 12 C, CH*Me*$_2$). − ^{29}Si{^{1}H} NMR (C_6D_6): δ = −1.5 (s, 4 Si, NSiMe$_3$), 19.6 (s, 4 Si, OSiMe$_3$). − $C_{24}H_{72}N_2O_4Si_8Zn_3$ (873.6): calcd. C 32.99, H 8.30; found C 32.34, H 8.28.

[MeZnOSiMe$_3$]$_4$ (3a): This compound was prepared and characterized according to a literature procedure.[6]

[MeZnOSiEt$_3$]$_4$ (3b): At −78 °C, a solution of $ZnMe_2$ (0.90 g, 11.11 mmol, 2 M solution in toluene; Aldrich) in toluene (ca. 80 mL) was treated with Et$_3$SiOH (1.46 g, 11.11 mmol). After methane evolution had ceased, the clear solution was concentrated to dryness in vacuo. Recrystallization of the residue from hexane afforded colorless plates. Yield: 2.23 g (2.63 mmol, 95%). − ^{1}H NMR (C_6D_6): δ = 0.01 (s, 12 H, ZnMe), 0.96 [q, 24 H, CH_2Me, ^3J(H,H) = 7 Hz], 1.08 [t, 36 H, CH_2*Me*, ^3J(H,H) = 7 Hz]. − ^{13}C{^{1}H} NMR (C_6D_6): δ = −8.30 (s, 4 C, ZnMe), 7.97 (s, 12 C, CH$_2$*Me*), 8.70 (s, 12 C, *C*H$_2$Me). − ^{29}Si{^{1}H} NMR (C_6D_6): δ = 23.8 (s). − $C_{28}H_{72}O_4Si_4Zn_4$ (846.7): calcd. C 39.71, H 8.57; found C 39.11, H 8.50.

$[IZnOSiMe_3]_4$ (4a): A solution of **3a** (1.37 g, 2.02 mmol) was treated with I_2 (4.90 g, 8.08 mmol) at room temperature. The violet color of the mixture slowly disappeared in the course of about 48 h. Evaporation of all volatile components in vacuo (10^{-3} Torr) afforded a solid residue, which was redissolved by gently heating in a small volume of hexane. The product **4a** crystallized in the form of colorless cubes. Yield: 2.00 g (1.70 mmol, 88%). – ^{1}H NMR (C_6D_6): δ = 0.62 (s, SiMe). – ^{13}C NMR (C_6D_6): δ = 4.20 [q, SiMe, ^1J(C,H) = 119 Hz]. – ^{29}Si{^{1}H} NMR (C_6D_6): δ = 37.7 (s). – $C_{12}H_{36}I_4O_4Si_4Zn_4$ (1126): calcd. C 12.80, H 3.22; found C 12.47, H 3.19.

$[IZnOSiEt_3]_4$ (4b): Derivative **4b** was prepared in a similar manner as **4a**, starting from **3b** (1.01 g, 1.19 mmol) and I_2 (1.21 g, 4.76 mmol). Recrystallization of the residue from hot benzene afforded colorless cubes. Yield: 1.15 g (0.97 mmol, 82%). – ^{1}H NMR (C_6D_6): δ = 0.91 [q, C*H*$_2$Me, ^3J(H,H) = 7 Hz], 1.01 [t, CH$_2$*Me*, ^3J(H,H) = 7 Hz]. – ^{13}C{^{1}H} NMR (C_6D_6): δ = 7.97 (s, CH$_2$*Me*), 8.70 (s, *C*H$_2$Me). – ^{29}Si{^{1}H} NMR (C_6D_6): δ = 23.2 (s). – $C_{24}H_{60}I_4O_4Si_4Zn_4$ (1294): calcd. C 22.27, H 4.67; found C 22.04, H 4.61.

$[IZn(THF)OSiMe_3]_2$ (5a) and $[IZn(THF)OSiEt_3]_2$ (5b): The heterocubanes **4a** (1.00 g, 0.88 mmol) and **4b** (1.10 g, 0.93 mmol) were dissolved in THF at room temperature. Complete evaporation of the solvent in vacuo (10^{-3} Torr) and recrystallization of the residue from hexane afforded colorless cubes in quantitative yield. – **5a:** ^{1}H NMR (C_6D_6): δ = 0.65 (s, 18 H, SiMe), 1.32 (m, 8 H, THF), 3.50 (m, 8 H, THF). – ^{29}Si{^{1}H} NMR (C_6D_6): δ = 36.7 (s). – $C_{14}H_{34}I_2O_4Si_2Zn_2$ (707.1): calcd. C 23.78, H 4.84; found C 23.23, H 4.80. – **5b:** ^{1}H NMR (C_6D_6): δ = 0.99 [q, 12 H, C*H*$_2$Me, ^3J(H,H) = 7 Hz], 1.01 [t, 18 H, CH$_2$*Me*, ^3J(H,H) = 7 Hz], 1.28 (m, 8 H, THF), 3.44 (m, 8 H, THF). – ^{29}Si{1H} NMR (C_6D_6): δ = 23.7 (s). – $C_{20}H_{46}O_4I_2Si_2Zn_2$ (791.3): calcd. C 30.35, H 5.86; found C 30.11, H 5.84.

X-ray Structure Determinations: Experimental details relating to the X-ray crystal structure determinations of **1a**, **2a**, **2c**, **3b**, **4a**, and **5b** are listed in Table 2. The intensities were measured with a Bruker-axs-SMART 1000 diffractometer. The structures were solved by direct methods (SHELXS-97). Refinements were carried out using the SHELXL-97 package. All nonhydrogen atoms were refined with anisotropic temperature factors. The hydrogen atoms were placed in calculated positions and refined isotropically in riding mode. All refinements were made by full-matrix least-squares methods on F^2. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-143075 (**1a**), -143076 (**2c**), -143077 (**4a**), -143078 (**2a**), -143079 (**5b**), and -143080 (**3b**). Copies of the data can be obtained free of charge on application to the CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Keywords: Palladium / Allyl complexes / Tridentate ligands / Fluxionality

The potentially tridentate ligands 2,2′:6′,2"-terpyridine (terpy) and 2,6-bis(diphenylphosphanylmethyl)pyridine (PNP) have been used to prepare novel palladium–allyl complexes of general formula [(terpy)Pd(CH_2CHCRR')](BF_4) [R = R′ = H (**1**); R = H, R′ = Me (**2**); R = R′ = Me (**3**)] and [(PNP)Pd(CH_2CHCRR')](BF_4) [R = R′ = H (**4**); R = H, R′ = Me (**5**); R = R′ = Me (**6**)], which were characterized by elemental analysis, IR spectroscopy, and ^{13}C, ^{31}P and variable-temperature ^1H NMR spectroscopy. The low-temperature ^1H NMR spectra show that the configuration of the complexes in solution depends strongly on the nature of the ligand. The terpy complexes **1**–**3** are η^3-allyl species, where terpy is dihapto and one pyridine ring remains uncoordinated, whereas the PNP complexes **4**–**6** occur as η^1-allyl compounds with a trihapto PNP ligand. All complexes are fluxional through η^3-η^1 exchange processes. Energy barriers of 47.5–48.6 kJ·mol^{-1} (243–262 K) are reported for the interconversion of terminal allylic protons (complexes **2**–**4**). $\Delta G^{\ddagger}$ is higher (71.1 kJ·mol^{-1} at 350 K) for the interconversion of the methyl groups in complex **6**. A lower-barrier oscillatory mechanism involving terpy ($\Delta G^{\ddagger}$ = 43.9 kJ·mol^{-1} at 231 K) is also involved in complex **1**. The X-ray structures of complexes [(η^3-terpy)Pd(η^1-C_5H_9)](BF_4) (**3a**) and [(η^3-PNP)Pd(η^1-C_4H_7)](BF_4) (**5a**) are reported; the structure of **3a** corresponds to a species that is not observed in solution.

Introduction

Palladium−allyl complexes have been much studied in the last thirty years, and have recently attracted even more attention because of their importance as intermediates in palladium-catalyzed allylic substitution (e.g. alkylation) reactions. Attack of the nucleophile on a cationic palladium η^3-allyl complex is at present conventionally accepted as the crucial step in the catalytic cycle.[1] One major goal in allylic alkylation catalysis is to achieve regio-, stereo- or enantioselectivity, especially by modifying the nature of the spectator ligand. Up to now, few examples have been reported concerning the use of potentially meridional tridentate ligands in palladium allyl chemistry[2−5] or in palladium-catalyzed allylic alkylation.[5,6] This type of ligand is prone to stabilize a η^1-allyl palladium complex, which was proposed in some cases as another possible intermediate in allylic substitution.[7]

We have lately been interested in the use of potentially tridentate ligands, such as the mixed-P,N-donor ligand 2,6-(diphenylphosphanylmethyl)pyridine (PNP) and its derivatives, in coordination chemistry and catalysis.[8] We have also reported preliminary results in palladium allyl chemistry with 2,2′:6′,2"-terpyridine (terpy).[9] Therefore we decided to investigate the influence of the nature of the tridentate ligand and the allyl ligand on the structure of the corresponding complex.

We report here the synthesis and complete characterization, especially by X-ray diffraction analysis and variable-temperature NMR spectroscopy, of palladium allyl complexes bearing the terpy and PNP ligands.

Results and Discussion

The complexes **1**−**6** were prepared in good chemical yields (73−92%) by abstraction of Cl^- from the corresponding chloride-bridged allylpalladium dimers with a silver salt, followed by coordination of palladium(II) with the appropriate ligand (Table 1). They were obtained as air-

stable, yellow to red powders, which were soluble in dichloromethane or acetonitrile. If we assume that these palladium complexes are square planar, we can consider that they can adopt five possible configurations (Scheme 1). It is the purpose of our study to determine which configuration is adopted by each complex in solution and/or in the solid state.

Scheme 1. Potential isomeric forms of complexes **1**–**6**

Variable-Temperature ^{1}H NMR Spectroscopy

The room-temperature ^{1}H NMR spectra of most of the synthesized complexes show some broad resonances, which is a hint that they are fluxional. Variable-temperature NMR analysis indicates that this is actually the case for all of them. It was necessary to record the spectra at low temperature (184–200 K) in order to detect the frozen species, except for complex **6**. Selected ^{1}H signals and H-H or H-P coupling constants of complexes **1**–**6** at low temperature and high or room temperature are given in Table 2 and Table 3.

The low-temperature ^{1}H NMR spectra of complexes **1**, **2**, and **3** display eleven terpy signals and five signals belonging to the allylic moiety. This pattern is characteristic of η^3-allylpalladium complexes with an unsymmetrical terpy ligand, of which only two nitrogen atoms coordinate to the metal center, viz. under the form **c** or **d** (Scheme 1). A thorough analysis shows that the actual configuration is **c**, which is also the less sterically constrained one (Scheme 2;

Scheme 2. Complexes present in solution according to low-temperature NMR spectroscopic data

The assignment of all signals could be made with the help of proton-decoupling experiments and/or NOE and scalar-coupling cross-peaks in 2D-ROESY NMR experiments. In fact, the aromatic pattern presents close similarities concerning both multiplicities and chemical shifts to the spectra of other bidentate terpy metal complexes analyzed in detail in the literature (Table 2, Figure 1).[10,11] The aromatic signals of complexes **1**−**3** generally appear at the same chemical shift within ±0.02 ppm at 190−200 K (Table 2). However, two protons do not follow this trend; the chemical shift of H^4 and, to a lesser extent, of H^5 are affected by the nature of the substituents R and R′. For instance, H^4 is shielded by 0.22 ppm and H^5 is deshielded by 0.1 ppm when one changes from **1** (R = R′ = H) to **3** (R = R′ = Me). This can be explained by their proximity to the R and R′ groups.

At 188 K, the H^{1anti} and H^{15} signals of **1** appear broadened; this is probably the result of a fluxional process with a very low energy barrier, i.e. the restricted rotation of the dangling pyridine. In comparison, both analogous frozen rotamers could be clearly observed by low-temperature NMR spectroscopy in the (η^2-terpy)$PtIMe_3$ complex,[10b] where the rotation is more hindered than in complex **1**. The H^1 and H^{15} signals of complexes **2** and **3** undergo the same broadening when the temperature is decreased (see Figure 1 and Figure 2); furthermore, the H^1 protons are shielded by the pendant pyridine (δ = 2.11−2.57) as they are in complex **1**.[9] These observations allow us to rule out the form **d** in favor of form **c** for the terpy complexes (Scheme 1). In the case of complex **2**, the value of the H^2-H^3 coupling constant (12.3 Hz) infers that the methyl group is in the *syn* position, which is common in η^3-allyl palladium complexes.[12]

With an increase in temperature, most of the NMR signals of complexes **1**−**3** broaden, then sharpen to give simplified spectra at or above ambient temperature. We observe the coalescence of pairs of aromatic signals H^4/H^{18}, H^5/H^{17}, H^6/H^{16}, H^7/H^{15}, and H^{10}/H^{12} characteristic of the exchange between the uncoordinating and the coordinating lateral pyridines of terpy (Table 2, Figure 1). The corresponding energy barriers were estimated from the coalescence of the clearly distinguishable H^5 and H^{17} with the help of the Eyr-

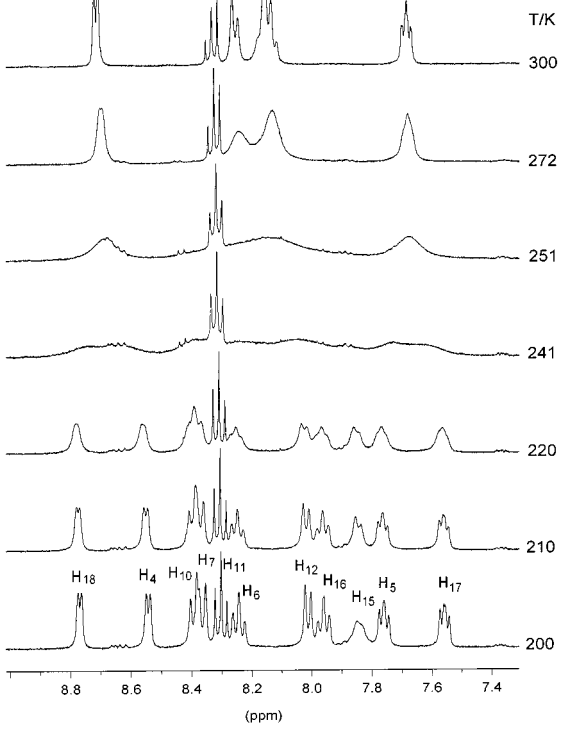

Figure 1. 400 MHz ^{1}H NMR spectra (aromatic region) of [(terpy)$Pd(CH_2CHCMe_2)$](BF_4) **(3)** in CD_2Cl_2 in the range 200−300 K; see Scheme 2 for hydrogen labelling

6[f]	78	350	71.1	Me^{cis}/Me^{trans}

[a] For the adopted numbering scheme, see Scheme 2. − [b] Spectra recorded in CD_2Cl_2 at 300 MHz. − [c] Spectra recorded in CD_2Cl_2 at 400 MHz. − [d] Spectra recorded in CD_2Cl_2 at 500 MHz. − [e] Difference between the average chemical shift of H^{3cis} and H^{3trans}, and the chemical shift of H^1. − [f] Spectra recorded in [D$_6$]DMSO at 400 MHz.

The four signals corresponding to the terminal allylic protons of complex **1** coalesce into one doublet with an average coupling constant of 9.6 Hz.[9] A close examination of the NMR spectra on raising the temperature first shows a coalescence of the H^{1syn} and H^{3syn} signals and another coalescence of the H^{1anti} and H^{3anti} signals, related to a fast chemical exchange between both ends of the allyl moiety. This leads to two very large superimposed signals, which then sharpen into a doublet through a slower *syn-anti* chemical exchange. From the coalescence of both H^{anti} signals, a $\Delta G^{\ddagger}$ value of 43.9 kJ·mol^{-1} can be estimated for the first exchange; this infers that it is concerted with the exchange of the terpy hydrogens (43.5 kJ·mol^{-1}; see Table 4). This is explained by the oscillatory or "tick-tock" twist fluxional motion (Scheme 3), which was introduced by Orrell et al. for similar terpy metallic complexes[10,11] and has been the object of thorough studies and discussions.[13] In the second process, the *syn* and *anti* protons exchange through a classical η^3-η^1-η^3 mechanism,[1b] where the intermediate is probably the form **a** (Scheme 4).

Scheme 3

Scheme 4

A phase-sensitive 2D NMR ROESY spectrum of **1** recorded at 200 K confirms our analysis (Figure 3). Strong H^{1syn}/H^{3syn} and H^{1anti}/H^{3anti} exchange positive cross-peaks are displayed, whereas H^{syn}/H^{anti} exchange cross-peaks are not observed, perhaps because they are hidden under the geminal H^{syn}/H^{anti} NOE cross-peaks of the opposite sign. Thus the *syn*/*anti* exchanges must be slower than the *syn*/*syn* and *anti*/*anti* exchanges, otherwise the corresponding cross-peaks would probably have appeared on the ROESY spectrum in spite of the NOE effect.

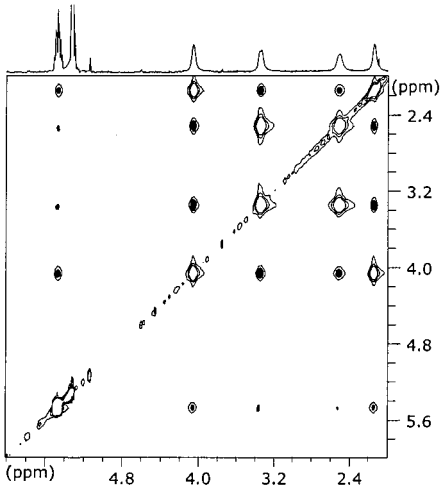

Figure 3. Section of the ^{1}H phase-sensitive ROESY spectrum of [(terpy)Pd(CH_2CHCH_2)](BF_4) **1** (CD_2Cl_2, 200 K, 500 MHz), showing exchange cross peaks and NOE (darkened) cross peaks within the allyl signals

In the spectra of complexes **2** and **3**, the two upfield H^{1syn} and H^{1anti} signals coalesce into a doublet with an average coupling constant; the H^2 signal changes from a doublet of doublets to a triplet (Figure 2). This *syn*/*anti* interconversion also takes place through the mechanism given in Scheme 4 and the corresponding energy barriers agree with the values calculated for the terpy signals (Table 4). These barriers are roughly the same for both complexes (ca.

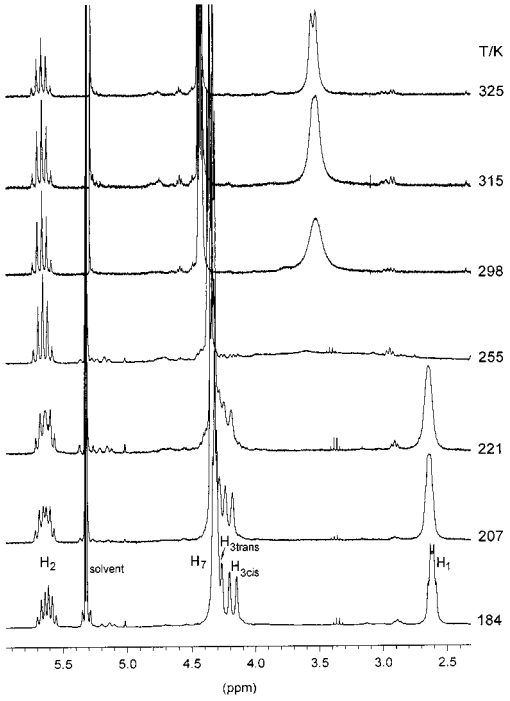
48.6 kJ·mol^{-1}). This is not surprising if we consider that the number of substituents on the C^3 allylic carbon does not modify the steric hindrance in the intermediate involved in the fluxional process (Scheme 2). It ensues that the energy barrier of the *syn*/*anti* exchange in **1** is very likely to be approximately the same, and thus superior to the "tick-tock" barrier.

The methyl signal of **2** also undergoes some modifications over this temperature range: it broadens and sharpens several times, and this is an indication of additional fluxional processes. We believe that there are equilibria between the major isomer **c** (Me *syn*) and minor ones: isomer **c** (Me *anti*) (via the intermediate **b**) and/or isomer **d** (through the "tick-tock" mechanism) (Scheme 1). Yet the small methyl signals corresponding to these minor isomers could not be clearly distinguished in the NMR spectra. On the contrary, the methyl signals of **3** do not undergo any modification up to 340 K.

The ^{1}H NMR pattern of the PNP ligand in complexes **4**−**6** does not vary with temperature and is indicative of a tridentate coordinating mode. Apart from the aromatic signals, the methylene signal appears as a virtual triplet at δ = 4.3−4.7 (depending on the solvent and the temperature) with a $|^2J_{HP} + {}^4J_{HP'}|$ value of approximately 9 Hz. Such virtual triplets are commonly observed in the same region for other PNP palladium complexes in which the phosphorus atoms are mutually *trans*.[14,15,16]

In contrast to the terpy complexes, the allyl ligand in the frozen complexes **4**−**6** is η^1 (form **a**; see Scheme 1) according to their low-temperature (**4**,**5**) or room-temperature (**6**) NMR spectroscopic data (Table 3, Figure 4). The NMR spectra display four signals for the allyl ligand at the expected chemical shifts that one would expect by comparison with other η^1-allyl palladium complexes reported in the literature.[3,17,18] The value of the H^2-H^3 coupling constant (14.7 Hz) in complex **5** at 220 K indicates that the C−C double bond is in the thermodynamically preferred *trans* form. However, we detect a small methyl doublet at δ = 0.83 at that temperature which probably belongs to the *cis* isomer (ca. 10% according to the signal integration).

When the temperature is increased from 184 K to 325 K, the three allyl signals H^1, H^{3cis} and H^{3trans} of complex **4** coalesce into a doublet at δ = 3.55 (Figure 4). This results from a η^1-η^3-η^1 fluxional process, with an energy barrier of 47.5 kJ·mol^{-1} comparable to the ones estimated for the terpy complexes (Table 4). In complex **5**, the coalescence of the two methyl signals (T_c = 281 K) reveals that the *trans* and *cis* isomers are in equilibrium. The energy barrier calculated for the *trans* to *cis* transformation following the Shanan-Atidi and Bar-Eli method[19] reaches 60.8 kJ·mol^{-1}. We note that at high temperatures, the H^2-H^3 coupling constant is not significantly modified (ca 14 Hz, see Table 3), which suggests that the *cis* form is still minor. The methyl groups of complex **6** also exchange to give rise to a singlet at δ = 1.07 in [D_6]DMSO at high temperature; the coalescence temperature and the energy barrier are then higher (350 K and 71.1 kJ·mol^{-1}, respectively). We propose that η^3-allyl complexes and the η^1-allyl form **b** are involved as intermediates in the chemical exchanges of both complexes (see the mechanism depicted in Scheme 5). The progression of the energy barriers from **4** to **5** and **6** reflects the increasing steric hindrance within the intermediates of the fluxional processes, owing to the proximity of the methyl group(s) and the coordination sphere.



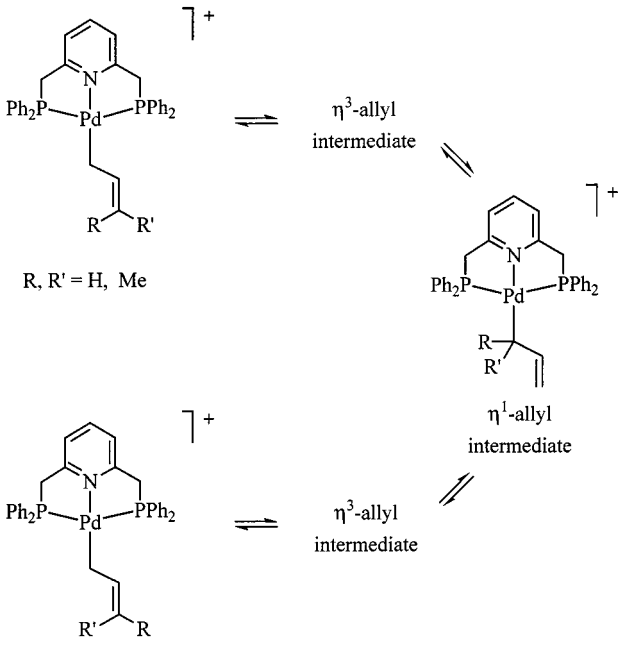


Figure 4. 300 MHz ^{1}H NMR spectra (allylic region) of [(PNP)Pd(CH_2CHCH_2)](BF_4) **(4)** (range 188−255 K: solvent CD_2Cl_2; range 298−325 K: solvent $CDCl_3$); see Scheme 2 for hydrogen labelling

^{13}C and ^{31}P NMR Spectroscopy

In general, the proton-decoupled ^{31}P and ^{13}C NMR spectra recorded at room temperature are in agreement with the room-temperature ^1H NMR spectra, i.e. that of dynamic species (except for **6**). The ^{31}P NMR spectra of complexes **4**−**6** exhibit singlets at δ = 26.0, 25.2, and 25.1, respectively. These values are close to that found by Vasapollo and coworkers for $(PNP)PdCl_2$ (δ = 24.35), and are therefore consistent with the form **a**.[16] The room-temperature ^{13}C NMR spectroscopic data are given in Table 5. The rapidly exchanging C^1 and C^3 nuclei of **1** show a common signal at δ = 63.7. The chemical shifts for **1**, **2**, and **3** are typical of palladium η^3-allyl complexes with nitrogen-donor ligands.[20] In contrast, the vinylic carbons of the η^1-allyl complexes **4**−**6** are deshielded (δ = 121.4−142.8), whereas the C^1 signal (δ = 16.1−18) is typical of a metal-bonded carbon atom.[3c][17f] We can probably not detect the C^1/C^3 signal of **4** because the corresponding temperature of coalescence is very close to room temperature. Besides, the values found for the ^{13}C chemical shifts of the PNP ligand are consistent with the assignment proposed by Taube et al.[15]

Solid-State Analysis

We have previously reported the X-ray structures of the isomeric $[(\eta^3\text{-terpy})Pd(\eta^1\text{-}C_3H_5)]^+$ and $[(\eta^2\text{-terpy})Pd(\eta^3\text{-}C_3H_5)]^+$ cations.[9] Single crystals of **3** and **5** suitable for X-ray diffraction analysis were obtained under a nitrogen atmosphere from dichloromethane solutions by vapor-phase diffusion of diethyl ether (**3**) or pentane (**5**). Their solid-state structures are depicted in Figure 5 and Figure 6, respectively, and selected bond lengths and angles are given in Table 6 and Table 7. They crystallize as monocationic, square-planar palladium complexes and separate noncoordinating anions, and appear as the forms **3a** and **5a**, where the terpy or PNP ligand is tridentate and the allyl ligand monohapto. On the contrary, we note that the X-ray structure of the complex $[(SNS)Pd(CH_2CHCMe_2)]^+$ (SNS = 2,6-bis(dimethylthiomethyl)pyridine), resolved by Canovese et al., reveals a η^3-allyl complex with a noncoordinating sulfur.[4a] We observe a striking resemblance between the structures of $[(\eta^3\text{-terpy})Pd(\eta^1\text{-}C_3H_5)]^+$ and **3a**, which are nearly mirror images of each other, except for the C19 and C20 atoms of **3a**. The bond lengths and bond angles within the (terpy)Pd fragment are of the same order of magnitude, as well as the Pd−C16 bond length.

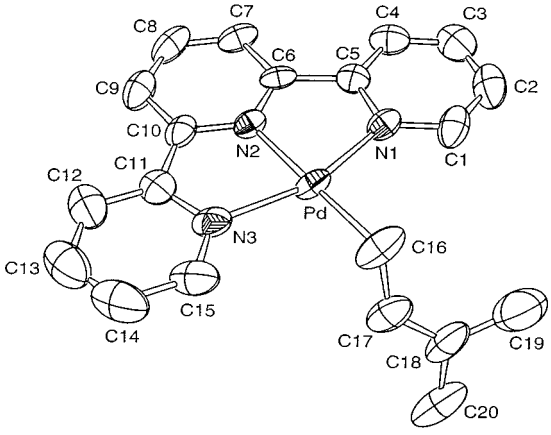

Figure 5. ORTEP drawing of **3a** showing 50% probability thermal ellipsoids and the atom-numbering scheme; hydrogen atoms and the BF_4^- anion are omitted for clarity

Two structures of **5a** are drawn in Figure 6; as long as crystallographic disorder is observed in the allyl ligand, the vinylic carbons C33 and C34 occupy two positions each. However, in both cases the allyl is in the *trans* configuration, which is also the case in the major isomer detected in solution by NMR spectroscopy (vide supra). The dihedral angles P1−Pd−C32−C33 and P1−Pd−C32−C33′ are −115.5° and −79.8°, respectively. Furthermore, the N−Pd−P1 and N−Pd−P2 bond angles are smaller than 90° [81.41(6)° and 81.61(6)°, respectively], owing to the constrained five-membered metallacycles. The palladium, nitrogen and phosphorus atoms are all nearly coplanar, with deviations of less than 0.04 Å. In general, the bond lengths and angles related to PNP and Pd compare well with the data reported for complexes $[(PNP)Pd(PEt_3)](BF_4)_2$[14] and $[(PNP)Pd(styrene)](BF_4)_2$,[15] except for the Pd−N bond length which is longer [2.137(2) Å vs. 2.107(4) and 2.058(4)

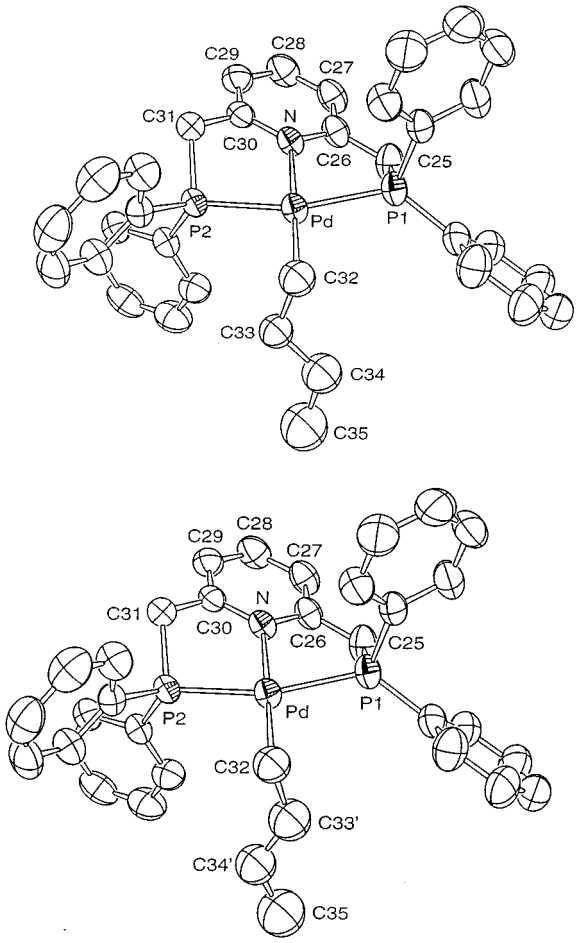

Figure 6. ORTEP drawings of both forms of **5a** showing 50% probability thermal ellipsoids and the atom-numbering scheme, the occupancy ratios for (C33, C34) and (C33′, C34′) being 50%/50%; hydrogen atoms and the BF_4^- anion are omitted for clarity

Å] because of the strong *trans* influence of the η^1-allyl ligand.[21]

The bonds lengths and bond angles of the η^1-allyl fragments of **3a** and **5a** are comparable to other examples of transition metal η^1-allyl complexes.[22] The palladium−carbon bond lengths (2.036−2.075 Å) agree with the moderate *trans* influence of pyridine.[23] We also note that the angle between the plane defined by the three allylic carbons and the coordination plane (mean plane defined by the four coordinating atoms) is roughly the same

Table 7. Selected bond lengths [Å] and bond angles [°] for **5a**

Pd−P1	2.3017(7)	C32−C33′	1.53(1)

for both complexes [**3a**: 109.6(6)°; **5a**: 111.9(2)° and 109.1(3)°].

Finally, a distinct medium-intensity $\nu_{C=C}$ band can be detected at approximately 1630 cm^{-1} in the IR spectra of both dimethylallyl complexes (**3**: 1629 cm^{-1}; **6**: 1634 cm^{-1}), which is characteristic of an η^1-allyl complex.[17c,24] This is consistent with the results depicted above for **6** from NMR analysis, and for **3** from X-ray diffraction studies. In addition, two bands are observed at 1599 and 1565 cm^{-1} in the spectra of complexes **4**−**6**; this confirms that the nitrogen atom of PNP actually coordinates with the palladium atom in the solid state.[25]

Conclusion

According to low-temperature NMR spectra, the complexes **1**−**3** are η^2-terpy, η^3-allyl complexes (form **c**) and the complexes **4**−**6** η^3-PNP, η^1-allyl complexes (form **a**). In no case were both forms detected together in solution (although a solution of $[(terpy)Pd(C_3H_5)]^+$ led to monocrystals of each form[9]). In comparison, Werner et al. have reported that the two isomers $[(\eta^5\text{-Cp})Pd(\eta^1\text{-}C_3H_5)]$ and $[(\eta^1\text{-Cp})Pd(\eta^3\text{-}C_3H_5)]$ coexist in solution.[18] On the basis of the six complexes studied here, the existence of one form or the other depends solely on the nature of the ancillary, potentially tridentate ligand. In contrast, whether the allyl ligand bears two, one or no methyl groups makes no difference for a given ancillary ligand.

Vrieze et al. found that $[(terpy)Pd(allyl)]^+$ adopts form **a** when the allyl bears an acetyl group in the 2 position,[3a] and that it is also the case for the (PNN)Pd(allyl) cationic complex.[3b][3c] The latter can be compared with our PNP complexes **4**−**6**, where both phosphanyl groups also show a good coordinating ability towards palladium. The presence of the form **c** is rather unexpected for our terpy complexes because of the rigidity of this ligand.[26] Indeed, the steric constraints within $[(\eta^2\text{-terpy})Pd(\eta^3\text{-}C_3H_5)]^+$ are important,[9] as indicated by various data taken from the X-ray diffraction study; thus steric factors do not seem to play a major role in the predominance of one isomeric form or another.

All complexes proved to be fluxional, as indicated by variable-temperature NMR experiments, either through a "tick-tock" mechanism or through the η^3-allyl/η^1-allyl

mechanism, which is well-known in palladium allyl chemistry. The latter reflects the competition between one donor atom of the tridentate ligand and the allylic C=C double bond to coordination to the palladium center. In our complexes, the energy barriers associated with H^{syn}/H^{anti} exchanges are lower than 50 kJ·mol^{-1}, whereas it has generally been found to be higher for allyl palladium complexes bearing mono- or bidentate ligands.[27] This is probably the effect of the tridentate nature of the ligand.

We note that only the η^3-allyl forms **1c** and **3c** could be seen in solution at 200 K, whereas the corresponding η^1-allyl isomers **1a** and **3a** were only intermediates involved in the fluxional processes. However, those intermediates can indeed be isolated in the solid state, as shown by their X-ray structures.

Experimental Section

General Remarks: All experiments were carried out under a nitrogen or argon atmosphere, using a vacuum line or Vacuum Atmospheres glovebox equipped with Dri-Train HE-493 inert gas purifier. Pentane and diethyl ether were distilled with sodium and benzophenone, and dichloromethane with calcium hydride under nitrogen immediately before use. Bis[(η^3-allyl)chloropalladium],[28] bis[(η^3-1-methylallyl)chloropalladium],[28] bis[(η^3-1,1-dimethylallyl)chloropalladium],[28] and 2,6-bis(diphenylphosphanylmethyl)pyridine[25] were prepared as described in the literature. 2,2′:6′,2"-terpyridine was purchased from Aldrich and used as received. − The NMR spectra were obtained at room temperature (unless otherwise indicated) on Bruker spectrometers, at a concentration of ca 0.02 M. ^{1}H NMR spectra were recorded at 300.16 MHz (AC-300 instrument), 400.13 MHz (AM-400) or 500.13 MHz (ARX-500) and referenced to $SiMe_4$. ^{13}C NMR{^{1}H} (broadband decoupled) spectra were recorded at 50.32 MHz (AC-200) or 75.48 MHz (AC-300) and referenced to $SiMe_4$. ^{31}P{^{1}H} (broadband decoupled) spectra were recorded at 121.51 MHz (AC-300) and referenced to 85% aqueous H_3PO_4. The assignments given are supported by irradiations or 2D NMR analysis, and/or were in agreement with ref.[29] For variable-temperature spectra, the probe temperature was controlled (±1 K) by a B-VT 2000 unit calibrated with a methanol (low-temperature) or ethylene glycol (high-temperature) NMR tube. The $\Delta G^{\ddagger}$ values were calculated with the Eyring equation[30] $\Delta G^{\ddagger} = RT_c(22.96 + \ln T_c/\Delta\nu)$ [J·mol^{-1}] where T_c (K) is the temperature of coalescence of two given signals and $\Delta\nu$ (Hz) is the difference in their chemical shifts at low exchange temperature; the error is estimated to be ±0.4 kJ·mol^{-1}. The ^{1}H phase-sensitive 2D-ROESY spectrum[31] was recorded on the ARX-500 spectrometer using a mixing time of 0.3 s. − FT-IR spectra were recorded on a Perkin−Elmer 1600 Series spectrometer on KBr pellets. − FAB MS spectra and elemental analyses were carried out by the respective facilities at the Centre de Recherche de Chimie, Université Louis Pasteur, Strasbourg.

Preparation of Complexes 1−6. Typical Procedure: To a solution of $[Pd(\eta^3\text{-}C_3H_5)Cl]_2$ (100 mg, 0.273 mmol) in CH_2Cl_2 (10 mL) was added dropwise under nitrogen and in the dark a solution of $AgBF_4$ (2.1 equiv.) in CH_2Cl_2 (2 mL). The resulting suspension was stirred at room temperature for 15 min, then filtered through celite. A solution of terpy (2.1 equiv.) in CH_2Cl_2 (2 mL) was added to the filtrate, after which the solution turned from yellow to orange. After stirring at room temperature for 15 min, the solution was evaporated to dryness and the resulting complex **1** recrystallized from CH_2Cl_2/diethyl ether as an air-stable solid.

The other complexes were prepared in a similar manner starting from the corresponding allylpalladium chloride dimer (100 mg), replacing terpy with PNP (**4**−**6**, in which case the color changed from yellow to red upon addition of the ligand) and CH_2Cl_2 with CH_3CN (**2**, **4**, **5**).

[(terpy)Pd(CH_2CHCH_2)](BF_4) (1): Orange crystals; yield 232 mg (91%). − $C_{18}H_{16}BF_4N_3Pd$ (467.55): calcd. Collection of the X-ray Data and Structure Determination for 3a and 5a: For compound **3a**, a Philips PW100/16 diffractometer was used with Cu-K_α graphite monochromated radiation (λ = 1.5418 Å). For compound **5a**, the data were collected on a Nonius CAD4 or MACH3 diffractometer using Mo-K_α graphite monochromated radiation (λ = 0.7107 Å). The structures were solved by direct methods and refined against |*F*|. Hydrogen atoms were introduced as fixed contributors. Absorption corrections were derived from psi scans of 7 reflections. For all computations, the Nonius OpenMoleN package[32] was used. The crystal and refinement data are summarized in Table 8. The C32, C33, C33′, C34, C34′, and C35 atoms of **5a** were refined isotropically. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-140659 (**3a**) and -140660 (**5a**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk).

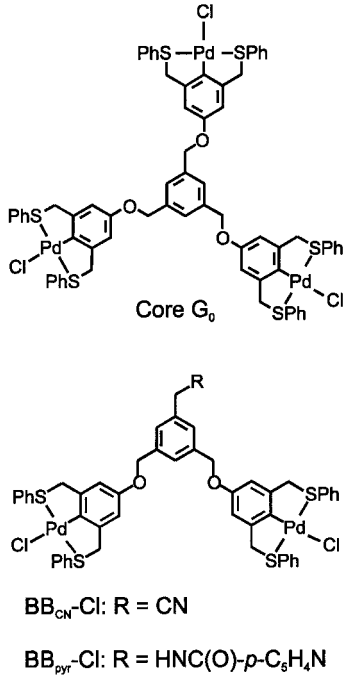
Coordination Chemistry of SCS Pd^{II} Pincer Systems

Henk-Jan van Manen,[a] Kazuaki Nakashima,[a,b] Seiji Shinkai,[b] Huub Kooijman,[c] Anthony L. Spek,[c][‡] Frank C. J. M. van Veggel,*[a] and David N. Reinhoudt*[a]

Keywords: Coordination chemistry / N ligands / P ligands / Palladium / Tridentate ligands

We have studied the coordination of substituted pyridines, and phosphorus- and sulfur-containing ligands to an SCS Pd^{II} pincer system. These ligands coordinate to Pd^{II} (*trans* to the cyclopalladated aryl group) by quantitative substitution of the labile acetonitrile ligand in complex **1**. Competition experiments showed that both electronic and steric effects influence the strength of coordination to the Pd^{II} pincer of the substituted pyridines. A quantitative analysis of the substituent effect was achieved by a Hammett correlation. Phosphorus-containing ligands also coordinate to this SCS Pd^{II} motif, as evidenced by NMR spectroscopy and single-crystal X-ray diffraction studies. They are much stronger ligands than the pyridines. The coordination strength of the thioureas falls in between those of the pyridines and phosphanes/phosphites. Our results lead therefore to the following order of ligand strength towards Pd^{II} in SCS Pd^{II} pincers: $PR_3 > P(OR)_3 > N,N'$-disubstituted thiourea > (substituted) pyridines > MeCN.



Introduction

meta-Xylene derivatives in which the two methylene groups carry suitable donor atoms (e.g. N, P, or S), so-called pincer ligands,[1] are used for the complexation of a wide range of transition metals.[2] Cyclometallation gives rise to a variety of systems displaying rich coordination chemistry.

A number of stable Pd^{II} complexes containing SCS pincer systems have been reported to date,[3] with recent examples mainly related to supramolecular chemistry.[4] We have been exploiting the SCS Pd^{II} pincer motif in the noncovalent synthesis of nanosize metallodendrimers.[5] Representative dendritic building blocks used in our investigations are depicted in Scheme 1.

Controlled metallodendrimer assembly up to generation 5 has been achieved by *divergently* growing from the core $\mathbf{G_0}$.[6] In these metallodendritic structures, the coordination of nitrile ligands is used as the assembling principle. Large self-assembled hyperbranched organopalladium spheres (100−400 nm) have also been synthesized divergently by an uncontrolled one-pot strategy.[7]

By employing ligands of different coordination strengths, it is also possible to synthesize metallodendrimers in a *convergent* manner.[8] This growth strategy commences by coordinating the strongest ligands first (at the periphery). Subsequent growth proceeds inwards using building blocks of decreasing coordination strength. This order is imperative in preventing ligand scrambling. We have demonstrated this type of growth in the synthesis of a third generation metallodendrimer containing cyano- and pyridine-based building blocks. In order to broaden the scope of this metallodendrimer synthetic method, other ligands with different binding strengths are needed. Therefore, we have studied the relative coordination strengths of a series of ligands towards

the SCS Pd^{II} pincer system. We report here our results for the parent Pd^{II} pincer. Moreover, a dipincer has been synthesized which could be used as a new rigid core for metallodendrimer synthesis.

Results and Discussion

Synthesis and Characterization of Model SCS Pd^{II} Pincer Complexes

The SCS Pd^{II} complexes **1** and **2** were prepared in two and three steps, respectively (Scheme 2). After alkylation of the previously reported[7b] SCS pincer ligand **4** with *n*-butyl bromide (77% yield), cyclopalladation of the resulting ligand **5** was achieved by reaction with $[Pd(CH_3CN)_4][BF_4]_2$.

Scheme 2. Synthesis of SCS Pd^{II} pincer complexes; a) *n*BuBr, *t*BuOK, CH_3CN

The cationic acetonitrile complex **1** (containing the noncoordinating BF_4^- counter anion) was obtained in 90% yield by precipitation with Et_2O from CH_3CN solution after completion of the cyclopalladation. The neutral chloro complex **2** was isolated (in 94% yield) by stirring a solution of **1** in CH_2Cl_2/CH_3CN with saturated NaCl, followed by column chromatography.

Similarly, dipincer **3** was prepared in two steps from 1,2,4,5-tetrakis(bromomethyl)benzene by first allowing the benzyl bromides to react with *tert*-butylthiophenol using K_2CO_3 as base and 18-crown-6 as catalyst (81% yield), followed by cyclopalladation of the resulting dipincer ligand **6** using $[Pd(CH_3CN)_4][BF_4]_2$ in CH_3CN. The bis(acetonitrile) complex was purified by precipitation from CH_3CN solution with Et_2O (60% yield). Complexes **1**, **2** and **3** were isolated as air- and moisture-stable yellow solids. All spectroscopic and analytical data are consistent with cyclopalladation. Compared to the free ligands **5** and **6**, the ^1H NMR resonances for the diastereotopic CH_2S protons in the palladium complexes are shifted downfield by ca. 0.5 ppm and are broadened due to slow conformational interconversion of the Pd^{II}-containing five-membered rings. At lower temperatures the coupling of the two diastereotopic CH_2S protons results in the broad signal splitting into a pair of doublets (vide infra). Further, the signals for the *ortho*-protons at $\delta = 6.80$ (in **5**) or $\delta = 6.92$ (in **6**) are absent from the ^1H NMR spectra, indicating complete cyclopalladation. In the ^{13}C NMR spectra of the acetonitrile complexes **1** and **3**, the signal of the carbon atom directly linked to Pd^{II} is too weak to be observed (probably due to long relaxation times), whereas in the chloro complex **2** it is present at $\delta = 150.9$ (30 ppm downfield compared to ligand **5**). In the positive FAB-MS spectrum of **2**, a signal corresponding to $[M - Cl + H]^+$ ($m/z = 499.6$) is present, whereas in the negative FAB-MS spectrum the chloride ion remains coordinated to Pd^{II}, resulting in a signal at $m/z = 533.7$ ($[M]^+$). Loss of the acetonitrile ligand is observed in both the positive and negative FAB-MS spectra of **1**, resulting in signals corresponding to $[M - MeCN - BF_4]^+$ ($m/z = 499.0$) and $[M - MeCN + BF_4]^-$ ($m/z = 671.6$) respectively, while both acetonitriles are lost in the positive FAB-MS spectrum of **3** ($m/z = 1001.1$ for $[M - 2MeCN - 2BF_4 + H]^+$).

X-ray Structure of 1

Besides the analytical evidence discussed above, structural proof of the acetonitrile complex **1** is provided by an X-ray analysis. A drawing of the acetonitrile complex **1** is shown in Figure 1. The following bond lengths for the atoms bonded to Pd^{II} have been obtained: Pd−S(1) 2.2992(8) Å, Pd−S(2) 2.2961(9) Å, Pd−N 2.110(2) Å, Pd−C(1) 1.975(2) Å.

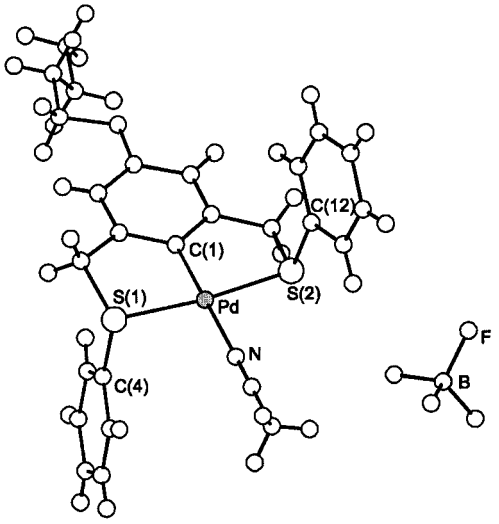

Figure 1. Structure of the acetonitrile complex **1**

The Pd atom adopts a slightly distorted square-planar geometry [S(1)−Pd−S(2) 171.11(2)° and N−Pd−C(1) 178.26(11)°] and the two five-membered chelate rings possess somewhat distorted envelope conformations in which the two phenyl rings (oriented *anti* with respect to the square plane) are in axial positions [Pd−S(1)−C(4) 100.51(9)° and Pd−S(2)−C(12) 103.17(9)°]. It should be noted that complex **1** is chiral in the solid state (prepared as a racemate) due to the lack of symmetry elements.

Substitution of the Labile MeCN Ligand by Pyridine

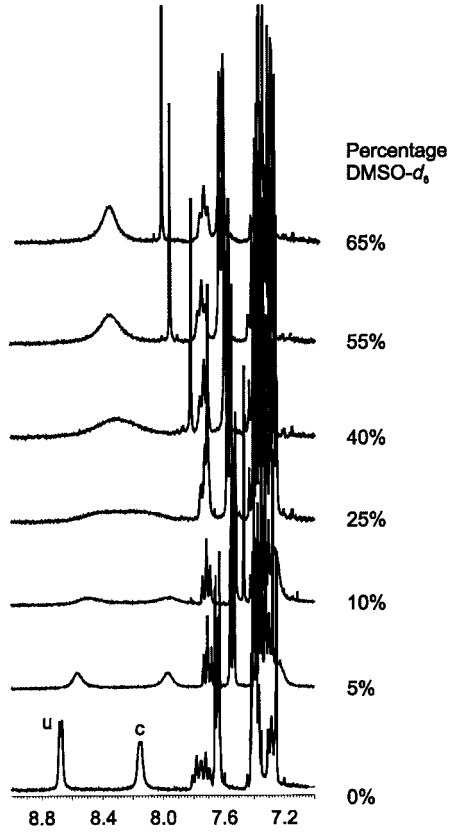
Substitution of the labile acetonitrile ligand of complex **1** by stronger ligands such as pyridine is facile. Upon treat-

ment of **1** with 1 equiv. of pyridine (in $CDCl_3$), fast and quantitative substitution was observed. In the ^1H NMR spectrum of the pyridine adduct, the resonance of the pyridine α-protons is shifted *upfield* from δ = 8.60 (free pyridine) to δ = 8.15 (coordinated pyridine). This is different from the pyridine complexes of SCS Pd^{II} pincers reported by Loeb and co-workers[9] for which a *downfield* shift of the pyridine α-protons was observed upon coordination. This difference must be due to the presence of the phenyl rings attached to the sulfur atoms in our system. The ring current of these aromatic rings will have a shielding effect on the pyridine protons (mostly the α-protons). The α-proton signal is also considerably broadened, indicating hindered rotation of the pyridine ligands with respect to the plane of coordination. The CH_2S proton signal shifts downfield by 0.15 ppm, and the aromatic proton signal by 0.05 ppm, upon substitution of MeCN by pyridine. The greater coordination strength of the pyridine ligand as compared to acetonitrile is also evident from the positive FAB-MS spectrum, in which a small, but significant peak corresponding to the molecular ion $[M - BF_4]^+$ is observed at *m*/*z* = 578.4, in addition to a large signal at *m*/*z* = 499.2 from $[M - pyr - BF_4]^+$.

Upon adding excess pyridine, two separate NMR signals for free and bound pyridine are observed. This observation can be explained by either slow exchange of pyridine on the NMR timescale or a kinetically stable pyridine complex. Exchange of pyridine was indeed evidenced by treatment of the pyridine complex with an excess (5 equiv.) of $[D_5]$pyridine. The signal at δ = 8.15 disappeared and a new peak appeared at δ = 8.6, indicating free pyridine. This kinetic lability is consistent with other pyridine−Pd^{II} complexes.[10]

The pyridine exchange rate is dependent on the solvent. In $CDCl_3$ two separate signals for bound and free pyridine were observed up to 50 °C. However, when acetonitrile complex **1** was treated with 2 equiv. of pyridine in $[D_6]$DMSO, a coordinating solvent, only one broad signal for the pyridine α-protons was observed in the ^1H NMR spectrum, indicating fast exchange on the NMR timescale. When $[D_6]$DMSO was titrated into a $CDCl_3$ solution of the pyridine complex containing 1 equiv. of excess pyridine (Figure 2), the rate of pyridine exchange varied with the concentration of $[D_6]$DMSO.

It is known that the kinetics of substitution in d^8 square-planar complexes depends on two factors, one related to direct ligand attack (associative-dissociative mechanism) and the other to an associative solvolysis pathway, in which the leaving group is first displaced by a solvent molecule and which is subsequently substituted by the incoming ligand (dissociative-associative mechanism).[11] The observed pyridine exchange rate can be rationalized in this way. With increasing $[D_6]$DMSO concentration, the pyridine exchange increasingly follows the solvolysis pathway. In $CDCl_3$ this pathway is not possible and only slow direct pyridine attack occurs.



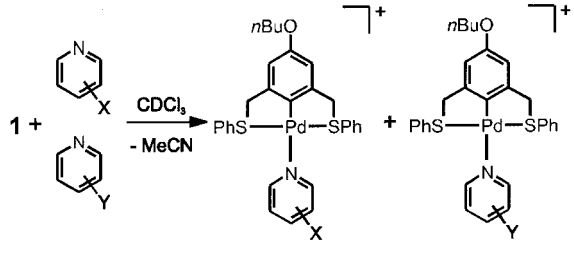


Figure 2. ^1H NMR spectra (298 K) of the titration of $[D_6]$DMSO to a $CDCl_3$ solution of the pyridine complex of the SCS Pd^{II} pincer system containing an excess of 1 equiv. pyridine; the designations u and c correspond to the pyridine α-proton signals of uncoordinated and coordinated pyridine, respectively

Substituent Effects on Pyridine Complex Stability

Within a series of substituted pyridines, we anticipated that subtle differences in nitrogen electron density would control the coordination strength towards Pd^{II}. When two different pyridines (each 1 equiv.) were mixed with 1 equiv. of the acetonitrile complex **1** in $CDCl_3$ (Scheme 3), the α-proton signals of the two pyridines in the ^1H NMR spectra were used as a probe to determine the extent of coordination of each pyridine (e.g. see Figure 3).

Scheme 3. Competition experiments between substituted pyridines

Table 1 shows that electron-donating pyridines bind more strongly than pyridine, whereas electron-withdrawing pyridines are weaker ligands than pyridine. The stability of these pyridine complexes follows the Hammett equation using the σ^+ constant of Brown and Okamoto.[13] This modified substituent constant applies to reactions in which strong ac-

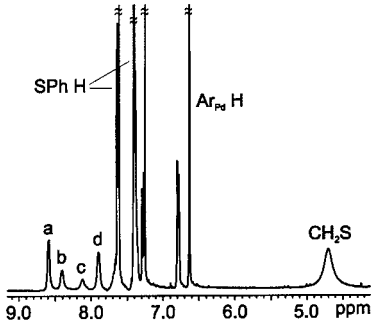

Figure 3. Part of the ^{1}H NMR spectrum ($CDCl_3$, 298 K) for a competition experiment between pyridine and 4-methoxypyridine. The designated signals correspond to the pyridine α-proton signals of: a) free pyridine, b) free 4-methoxypyridine, c) bound pyridine, d) bound 4-methoxypyridine

ceptor character develops at the aromatic ring, e.g. solvolysis of tertiary halides in which ionization is rate-determining. Using the selectivities reported in Table 1 (only the data of the 4-substituted pyridines are analyzed), a Hammett plot as shown in Figure 4 is obtained with a ρ^+ value of -1.0.

Table 1. Results of coordination competition experiments between substituted pyridines

X	Y	% bound pyr−X/pyr−Y	Selectivity[a]
4-H	4-NH_2	17:83	4.88
4-H	4-MeO	32:68	2.13
4-H	4-*t*Bu	40:60	1.50
4-H	4-Me	45:55	1.22
4-H	4-Ph	44:56	1.27
4-H	4-Ac	62:38	0.61
4-H	4-CO_2Me	64:36	0.56
2-Me	4-Me	43:57	1.33
2-Me	3-Me	57:43	0.75

[a] Ratio of bound pyridine−Y over bound pyridine−X.

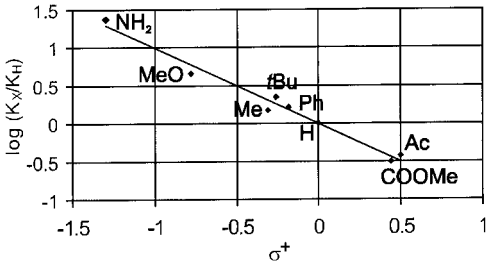

Figure 4. Hammett plot of the stability of 4-substituted pyridine complexes with the SCS Pd^{II} pincer system against the Brown−Okamoto σ^+ substituent constant

Usually in systems obeying the Brown−Okamoto equation, the values of ρ^+ are much more negative. However, in those cases a full positive charge develops in the rate-determining step instead of the partial positive charge developing on nitrogen in pyridine−Pd^{II} coordination.

The effect of steric hindrance was investigated in the picoline series. On the basis of electronic effects alone, it would be expected that 2-picoline would bind stronger than 3-picoline. However, as the reverse is found experimentally, it must be concluded that steric hindrance between the 2-methyl group and the aryl groups of the Pd^{II} pincer system overrules electronic effects in this case.

Coordination of Triphenylphosphane to Pd^{II}

The coordination of phosphorus-containing ligands to SCS Pd^{II} pincers has, to the best of our knowledge, not been investigated. Only phosphanes coordinated to transition metal pincer systems of the PCP[14] and NCN[15] type, and a phosphane coordinated to an SCS Pt^{II} pincer[3] have been reported. Upon addition of 1 equiv. of PPh_3 to **1**, several distinct spectroscopic features evidenced phosphane coordination to Pd^{II}. Firstly, in the ^{1}H NMR spectrum a broad peak corresponding to the CH_2S protons is present. The signal is sharper and is shifted downfield (± 0.25 ppm) when compared to the MeCN complex. Furthermore, the signal from the aromatic protons is a doublet (J = 2.9 Hz) due to proton-phosphorus coupling. In the ^{31}P NMR spectrum, the phosphorus signal shifts from δ = −5.6 (free PPh_3) to δ = 13.6 upon coordination. These combined results prove the coordination of PPh_3 *trans* to the cyclometallated aryl group. Opening of the S−Pd chelate ring, as suggested by Shaw et al.,[16] does not occur.

X-ray Structure of 3·$(PPh_3)_2$

The *dipincer* complex **3**, which is more soluble in organic solvents than reported dipincers[17] due to its *tert*-butyl groups, was mixed with 2 equiv. of PPh_3. Crystals were grown by vapor diffusion of diethyl ether into a $CHCl_3$ solution of the bis(PPh_3) complex (Figure 5).

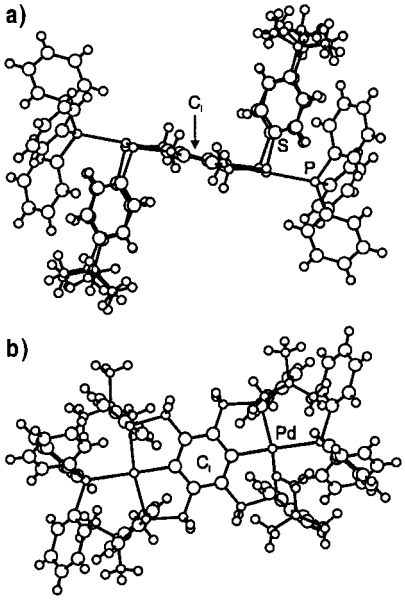

Figure 5. Structure of 3·$(PPh_3)_2$; a) side view, b) top view

In the bis(triphenylphosphane) complex, the Pd atoms are in a distorted square-planar environment: S(1)−Pd(1)−S(2) 167.15(3)° and P(1)−Pd(1)−C(1) 178.53(9)°. The following bond lengths for the atoms bon-

ded to Pd^{II} were obtained: Pd−S(1) 2.3075(10) Å, Pd−S(2) 2.3057(9) Å, Pd−P 2.3785(9) Å, Pd−C(1) 2.032(3) Å. The Pd^{II}−C bond is substantially longer than in complex **1** (2.03 vs. 1.98 Å). The complex has C_i symmetry (inversion point at the center of the bispalladated ring) in which the two *tert*-butyl phenyl groups attached to the metal-bound sulfur atoms of the same SCS Pd^{II} pincer moiety are oriented towards the same side of the square plane.

Stability of Coordinated PPh_3 Complexes

In transition metal inorganic complexes, PPh_3 is in general a stronger ligand than pyridine. This is expressed in their respective nucleophilicity parameters, for example, which differ substantially (n^0_{Pt} = 3.19 for pyridine and 8.93 for PPh_3, respectively).[11] In the ^1H NMR spectrum of a mixture of 1 equiv. of PPh_3 and the pyridine complex of compound **1** (Scheme 2: X = pyridine), quantitative substitution of pyridine by PPh_3 is shown. The spectrum is a superposition of the spectra of free pyridine and the PPh_3 complex. Heating the PPh_3 complex in refluxing $CHCl_3$ with a 10-fold excess of pyridine did not result in any detectable exchange.

As mentioned before, ring opening of the S−Pd chelate by PPh_3 has been suggested. Upon adding 5 equiv. of PPh_3 to *acetonitrile* complex **1**, no changes were observed in either the ^1H or ^{31}P NMR spectra. The situation was different when PPh_3 was added to the *chloro* complex **2**. Increasing amounts (0.25, 0.5, 1.0, 1.5, 2.5 and 5.0 equiv.) of PPh_3 were added to **2**. The ^1H and ^{31}P NMR spectra show that an equilibrium is established after each addition because in every case two signals are observed in the ^{31}P NMR spectrum, one corresponding to free PPh_3 ($\delta = -5.6$), and the other indicating coordination of PPh_3 *different from that described for the substitution of acetonitrile above* because the signal of coordinated PPh_3 now appears at $\delta = 21.9$ instead of $\delta = 13.6$. In the ^1H NMR spectrum a signal appears that corresponds to "free" CH_2S protons. This means that *the S−Pd chelate ring opens upon PPh_3 addition*. It also seems that both chelate rings open together, as the opening of only one would destroy the symmetry of the system. Substitution of the chloro ligand by PPh_3 is also unlikely, as can be inferred from the ^{31}P NMR spectra (i.e. no signal observed at $\delta = 13.6$). Therefore it is concluded that 2 molecules of PPh_3 displace the sulfur atoms as ligands. This only occurs quantitatively with a large excess (> 4−5 equiv.) of PPh_3.

Coalescence Temperatures of Different SCS Pd^{II} Pincer Complexes

The two five-membered chelate rings of the cyclopalladated pincer system display slow conformational interconversion, which is reflected in the ^1H NMR spectrum by the broadening of the CH_2S proton signal of the pincer complexes. Different ligands have a different influence on the conformational interconversion of the chelate rings. This phenomenon is reflected in the coalescence temperature T_c where the two *separate* signals of the CH_2S protons coalesce into a broad singlet.

As can be seen from Table 2, the coalescence temperature decreases in the order acetonitrile > pyridine > chloride > triphenylphosphane. For the neutral ligands this order corresponds to the lone pair electron donation (the nucleophilicity) towards Pd^{II}. In the case of PPh_3, no unambiguous coalescence temperature could be observed. NMR experiments at low temperatures reveal multiple signals for the CH_2S protons for all the complexes mentioned above. On one hand, freezing out the ring puckering results in loss of the apparent C_{2v} symmetry of the complex that exists at higher temperatures in solution. On the other hand, in the PPh_3 complex one very broad signal is observed, ranging from $\delta = 4.3$ to $\delta = 5.2$ at −10 °C. Splitting of the signal into two doublets is not observed, suggesting that besides lowering the rate of ring interconversion, rotation of the bulky PPh_3 ligand around the Pd^{II}−P bond is also restricted, leading to different conformational isomers. Moreover a long range coupling to ^{31}P cannot be excluded a priori.

Table 2. Coalescence temperatures and free energies of activation for ring interconversion of SCS Pd^{II} pincer complexes

Ligand X	Coalescence temperature T_c [K]	Free energy of activation $\Delta G^{\ddagger}_c$ [kJ/mol] at T_c
MeCN	289 ± 2	57.5 ± 0.3
Pyridine	286 ± 2	56.5 ± 0.3
Cl^-	271 ± 2	54.8 ± 0.5
PPh_3	< 268[a]	−

[a] No unambiguous coalescence temperature was observed, see also text.

From the coalescence temperature the free energy of activation for ring puckering can be estimated.[12] The free energies of activation for ring puckering vary between 55 and 58 kJ/mol in the ligand order chloride < pyridine < acetonitrile. From Table 2 it is evident that higher coalescence temperatures correspond to higher free energies of activation at T_c for ring puckering in this system.

Coordination of Other Phosphorus-Containing Ligands

Besides triphenylphosphane other phosphorus-containing ligands were investigated as ligands for the SCS Pd^{II} pincer system. Coordination of these ligands to Pd^{II} was shown by ^1H and ^{31}P NMR spectroscopy and by FAB mass spectrometry (Table 3).

As with the substituted pyridines competition experiments were employed, establishing that the relative coordination strengths of these ligands increase in the order $PCy_3 > PPh_3 > P(OMe_3) > P(OPh)_3$. The relative differences in coordination strengths are quite high, as in all cases [PCy_3 vs. PPh_3, PPh_3 vs. $P(OMe)_3$ and $P(OMe)_3$ vs. $P(OPh)_3$] the selectivity exceeds a 4:1 ratio. Further competition experiments revealed that all the phosphorus containing ligands coordinate much more strongly than pyrid-

Table 3. Complexes of phosphorus-containing ligands with the SCS Pd^{II} pincer system

Complex **1** with X =	^{1}H NMR Ar H[a] (ppm)/*J* (Hz)	^{31}P NMR coord/free ligand (ppm)	FAB-MS $[M]^+$ found/calcd
$P(OMe)_3$	6.72/4.8	122.7/141.0	623.2/623.1
$P(OPh)_3$	6.64/5.1	114.7/127.9	809.1/809.1
PCy_3	6.66/2.9	24.0/11.5	779.5/779.3

[a] Aromatic protons of cyclopalladated ring.

ine. Only a minor amount of pyridine complex was found in competition experiments with the weakest phosphite ligand [$P(OPh_3)$].

In the case of PCy_3 and $P(OPh)_3$, addition of excess ligand to their respective phosphane or phosphite complexes had no effect on the complex stability, as was the case for PPh_3 (vide supra). However, upon addition of excess $P(OMe)_3$ to complex **1** [X = $P(OMe)_3$], the SPh ligands were substituted by $P(OMe)_3$ to form a complex containing three phosphite ligands. This was evidenced by ^{1}H (the CH_2S protons give a sharp signal at $\delta = 4.2$) and ^{31}P NMR spectroscopy (the two *trans* phosphite ligands couple to the *cis* phosphite ligand and vice versa to give one triplet and one doublet, $J = 73$ Hz). In the other cases the presence of one bulky ligand apparently prevents the coordination of additional ligands.

The observed order of phosphorus ligand strengths matches the order of χ_i values [$\chi_i = 0.1$ (Cy), 4.3 (Ph), 7.7 (OMe) and 9.7 (OPh)], which is regarded as a parameter measuring substituent contribution to the σ donor and π acceptor abilities of phosphorus-containing ligands.[18] On the other hand, the cone angle θ (the ligand bulkiness) increases in the order $P(OMe)_3$ (107°) < $P(OPh)_3$ (128°) < PPh_3 (145°) < PCy_3 (170°).[18] Obviously in our case steric effects can be ignored, as the ligand strength order is the same as the electronic parameter χ_i and not the steric parameter θ.

Coordination of Sulfur-Containing Ligands

Finally, we have investigated the coordination of sulfur-containing ligands to the SCS Pd^{II} pincer. Thioureas have high nucleophilicity values ($n^0_{Pt} = 7.17$ for unsubstituted thiourea),[11] so they are possible ligands.[19] *N*-Benzyl-*N'*-butylthiourea was prepared from butyl isothiocyanate and benzylamine. Upon addition of this thiourea to the acetonitrile complex **1**, the ^{1}H NMR spectrum indicated thiourea coordination. Firstly, the acetonitrile signal was present at $\delta = 1.99$, indicating the release of acetonitrile (coordinated MeCN gives rise to a signal at $\delta = 2.08$). Secondly, significant changes in the chemical shifts of the thiourea NH protons and the adjacent CH_2 protons were observed. Finally, the broad signals of the SPh protons of the pincer and essentially all protons of the thiourea indicated restricted thiourea rotation. Moreover, the FAB-MS spectrum displayed an intense signal at $m/z = 721.2$ corresponding to the thiourea complex.

From their n^0_{Pt} values we can expect that thioureas are stronger ligands than pyridine but weaker ligands than phosphanes. This was confirmed experimentally by competition experiments. The ^{1}H NMR spectra show that the ratio of coordinated thiourea to coordinated pyridine is higher than 95:5. In the presence of PPh_3 the thiourea did not coordinate significantly, as was inferred from ^{1}H and ^{31}P NMR spectroscopy. FAB mass spectrometry only showed the PPh_3 complex of the SCS Pd^{II} pincer system in such mixtures. This means that the order of ligand strength is PPh_3 > thiourea > pyridine.

Conclusions

In this paper, a study of the coordination strengths of various ligands towards a SCS Pd^{II} pincer system has been reported. Several *para*-substituted pyridines have been coordinated to this pincer system, and the differences in coordination strengths found to arise from electronic and steric effects. The effect of *para* substituents was quantitatively analyzed by correlation with the Brown−Okamoto σ^+ substituent constants. Moreover, it was demonstrated that phosphorus- and sulfur-containing ligands are stronger ligands than pyridines. These results allow for the *convergent* metallodendrimer assembly methodology to be extended. Investigations concerning these topics are currently underway and the results will be described elsewhere.

Experimental Section

General: Melting points were determined with a Reichert melting point apparatus and are uncorrected. CH_2Cl_2 and hexane were freshly distilled from $CaCl_2$. CH_3CN (p.a. from Merck) was stored over molecular sieves (4 Å). Other solvents (EtOH, $CHCl_3$, acetone) were used as received (p.a. from Merck). All reagents were purchased from Aldrich and used without further purification. Solutions containing phosphanes or phosphites were degassed prior to use. − NMR spectra were recorded in $CDCl_3$ (unless stated otherwise) at 298 K with a Varian Unity 300 locked to the deuterated solvent. Chemical shifts are given relative to tetramethylsilane (TMS). − FAB-MS spectra were recorded with a Finnigan MAT 90 spectrometer with *m*-nitrobenzyl alcohol (NBA) as the matrix. − Elemental analyses were performed using a Carlo Erba EA1106. − Column chromatography was performed using silica gel (SiO_2, E. Merck, 0.040−0.063 mm, 230−240 mesh).

1-(*n*-Butoxy)-3,5-bis(phenylthiomethyl)benzene (5): To a solution of 3,5-bis(phenylthiomethyl)phenol (**4**) (1.40 g, 4.1 mmol) in CH_3CN (200 mL) was added *t*BuOK (0.93 g, 8.3 mmol) and the resulting mixture was stirred at room temperature for 1 h. A solution of *n*-butyl bromide (0.44 mL, 4.1 mmol) in CH_3CN (20 mL) was added

dropwise, and the mixture was stirred overnight at 40 °C. After evaporation of the solvent in vacuo, the residue was taken up in CH_2Cl_2 (100 mL), washed with 1 M HCl (100 mL), saturated $NaHCO_3$ (100 mL) and brine (100 mL). The dried ($MgSO_4$) organic layer was concentrated to dryness and the crude product was purified by column chromatography (SiO_2; eluent: CH_2Cl_2/hexane, 1:1, v/v) to afford a colorless oil. Yield: 1.26 g (77%). − ^{1}H NMR: δ = 0.94 (t, J = 7.3 Hz, 3 H, CH_3), 1.36−1.51 (m, 2 H, CH_2CH$_3$), 1.63−1.74 (m, 2 H, OCH$_2$CH_2), 3.83 (t, J = 6.6 Hz, 2 H, OCH$_2$), 4.01 (s, 4 H, CH_2S), 6.68 (s, 2 H, Ar H), 6.80 (s, 1 H, Ar H), 7.12−7.29 (m, 10 H, SPh). − ^{13}C NMR: δ = 13.3, 18.7, 30.7, 38.5, 67.1, 113.4, 121.1, 125.8, 128.3, 129.4, 135.8, 138.5, 158.8. − FAB-MS; *m/z*: 395.1 [M + H]$^+$, calcd. for $C_{24}H_{26}OS_2$: 395.1.

Acetonitrile Complex of Pd Pincer 1: Ligand **5** (233 mg, 0.6 mmol) was dissolved in CH_3CN (50 mL) and the solution was placed under argon. Pd[MeCN]$_4$(BF$_4$)$_2$ (262 mg, 0.6 mmol) was added in one portion, and the mixture was stirred at room temperature for 2 h. After evaporation of the solvent in vacuo, the yellow paste was taken up in CH_3CN (3 mL) and the product was precipitated by dropwise addition of diethyl ether. Yield: 334 mg (90%). − M.p. 68−70 °C. − ^{1}H NMR: δ = 0.95 (t, J = 7.3 Hz, 3 H, CH_3), 1.37−1.52 (m, 2 H, CH_2CH$_3$), 1.67−1.76 (m, 2 H, OCH$_2$CH_2), 2.08 (s, 3 H, CH_3CN), 3.88 (t, J = 6.4 Hz, 2 H, OCH$_2$), 4.57 (br s, 4 H, CH_2S), 6.59 (s, 2 H, Ar H), 7.48−7.50 (m, 6 H, SPh), 7.77−7.81 (m, 4 H, SPh). − ^{13}C NMR (CD_3CN): δ = 13.6, 19.4, 31.4, 50.3, 68.2, 110.2, 130.6, 131.3, 131.5, 132.1, 151.8, 158.2. − FAB-MS; *m/z*: 499.0 [M − BF_4 − CH_3CN]$^+$, calcd. 499.0. − $C_{26}H_{28}BF_4NOPdS_2$·H_2O: calcd. C 48.35, H 4.68, N 2.17, S 9.93; found C 48.18, H 4.50, N 2.25, S 9.92.

Chloro Complex of Pd Pincer 2: Acetonitrile complex **1** (0.75 g, 1.2 mmol) was dissolved in a mixture of CH_2Cl_2 (75 mL) and CH_3CN (25 mL). After the addition of brine (100 mL), the mixture was stirred vigorously overnight. After separation of the layers, the organic phase was concentrated in vacuo and the residue was purified by column chromatography (SiO_2; eluent: CH_2Cl_2/Et_2O, 95:5, v/v) to afford a yellow solid. Yield: 0.60 g (94%). − M.p. 63−64 °C. − ^{1}H NMR: δ = 0.94 (t, J = 7.3 Hz, 3 H, CH_3), 1.40−1.48 (m, 2 H, CH_2CH$_3$), 1.66−1.75 (m, 2 H, OCH$_2$CH_2), 3.85 (t, J = 6.4 Hz, 2 H, OCH$_2$), 4.53 (br s, 4 H, CH_2S), 6.56 (s, 2 H, Ar H), 7.32−7.37 (m, 6 H, SPh), 7.78−7.83 (m, 4 H, SPh). − ^{13}C NMR: δ = 13.3, 18.7, 30.8, 51.2, 67.3, 108.3, 129.1, 129.2, 130.9, 131.9, 149.6, 150.9, 156.5. − FAB-MS; *m/z*: 499.6 [M − Cl + H]$^+$, calcd. 500.0. − $C_{24}H_{25}ClOPdS_2$: calcd. C 53.83, H 4.71, S 11.98; found C 53.90, H 4.70, S 11.88.

Dipincer Ligand 6: A mixture of 1,2,4,5-tetrakis(bromomethyl)benzene (3.00 g, 6.7 mmol), 4-*tert*-butylthiophenol (5.00 g, 30.1 mmol), K_2CO_3 (9.20 g, 66.6 mmol) and 18-crown-6 (1.80 g, 6.8 mmol) in acetone (150 mL) was heated at reflux overnight under argon. After evaporation of the solvent, the residue was taken up in CH_2Cl_2 (250 mL) and washed with brine (250 mL). After drying the organic layer with $MgSO_4$ and evaporation of the solvent in vacuo, the crude product was recrystallized from EtOH/$CHCl_3$ to afford a white solid. Yield: 4.30 g (81%). − M.p. 185−186 °C. − ^{1}H NMR:

Yield: 203 mg (60%). − M.p. > 280 °C (dec.). − ^{1}H NMR (CD_3CN): δ = 1.33 [s, 36 H, $C(CH_3)_3$], 4.61 (br s, 8 H, CH_2S), 7.56 (d, *J* = 8.8 Hz, 8 H, SAr H), 7.74 (d, *J* = 8.8 Hz, 8 H, SAr H). − ^{13}C NMR (CD_3CN): δ = 30.8, 35.2, 50.0, 127.8, 127.9, 132.0, 145.8, 155.2. − FAB-MS; *m/z*: 1001.1 [M − 2MeCN − 2BF_4 + H]$^+$, calcd. 1001.2. − $C_{52}H_{65}B_2F_8NOPd_2S_4$·2$H_2O$: calcd. C 49.15, H 5.47, N 1.10 S 10.09; found C 48.86, H 5.14, N 1.25, S 10.00 (the found values for the elemental composition correspond to the substitution of one acetonitrile ligand by water, which probably occurs upon prolonged standing).

Crystal Structure Determinations of 1 and 3·$(PPh_3)_2$: Crystals suitable for X-ray structure determination were mounted on a Lindemann-glass capillary and transferred into the cold nitrogen stream of the diffractometer. Data were collected with a Nonius Kappa CCD diffractometer on rotating anode (Mo-K_α radiation, graphite monochromator, λ = 0.71073 Å, *T* = 150 K, φ and ω scans). Pertinent data for the structure determinations are collected in Table 4. Structures were solved with automated Patterson and subsequent difference Fourier methods for structure **1** and direct methods for structure **3**·$(PPh_3)_2$, using SHELXS86[20] for both structures. Full-matrix refinement on F^2 was performed with SHELXL-97−2.[21] The hydrogen atoms of structure **1** were located on a difference Fourier map and their coordinates were included as parameters in the refinement; the hydrogen atoms of **3**·$(PPh_3)_2$ were included in the refinement on calculated positions riding on their carrier atoms. The nonhydrogen atoms were refined with anisotropic displacement parameters. The hydrogen atoms were refined with a fixed isotropic displacement parameter related to the value of the equivalent isotropic displacement parameter of their carrier atoms. The *t*Bu groups of **3**·$(PPh_3)_2$ were refined with a disorder model involving two sites. The BF_4^- counteranions and the chloroform solvent molecules of this compound were also disordered. Since no satisfactory disorder model could be obtained the contribution of the disordered region to the structure factors was taken into account using the SQUEEZE procedure as incorporated in PLATON.[22] A total of 219 e^- were found in a cavity of 537 Å^3, located at the inversion center on (0,0,0). Neutral atom scattering factors and anomalous dispersion corrections were taken from the International Tables for Crystallography.[23] Geometrical calculations were performed with PLATON.[22] Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-141832 [for **3** · $(PPh_3)_2$] and -141833 (for **1**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

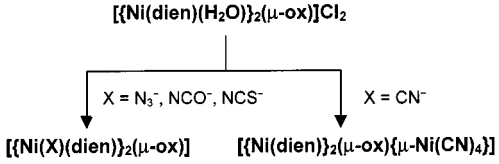
Keywords: Nickel / Binuclear complexes / Density functional calculations / Structure elucidation / Magnetic properties

Nickel(II) molecular complexes were obtained by water displacement reactions of $[\{Ni(dien)(H_2O)\}_2(\mu\text{-ox})]Cl_2$ and the corresponding pseudohalide. The three nickel(II) compounds $[\{Ni(N_3)(dien)\}_2(\mu\text{-ox})]$ (**1**), $[\{Ni(NCO)(dien)\}_2(\mu\text{-ox})]\cdot H_2O$ (**2**) and $[\{Ni(NCS)(dien)\}_2(\mu\text{-ox})]$ (**3**) are almost isostructural. The structure determinations reveal the presence of a binuclear complex with C_{2h} symmetry, where the oxalate ligand is coordinated in a bis(bidentate) fashion to the twofold related nickel atoms. The distorted octahedral environment of each nickel atom is completed by the three nitrogen atoms of the diethylenetriamine ligand in a *fac* arrangement and one nitrogen atom from a pseudohalide ligand. Magnetic susceptibility data in the temperature range 4.2–300 K shows intramolecular antiferromagnetic coupling.

Introduction



The design and synthesis of molecular magnetic compounds has attracted increasing attention over the past two decades or so.[1] A significant amount of magnetostructural research work during the last twenty five years has been devoted to analysing the remarkable ability of the oxalate bridge to mediate exchange coupling between first-row transition metal ions separated by more than 5 Å in both homo- and heteropolynuclear compounds.[2] The simple binuclear geometry involving symmetric, in-plane bridging with a single oxalate ion binding through two oxygen atoms to each of two metal centres has been observed in the chemistry of copper,[3] nickel,[4] and less frequently, the remaining first transition series metal ions.[5] Magnetostructural data of oxalato-bridged Ni^{II} complexes have revealed that J varies from -22 to -39 cm^{-1}.[6] This value is strongly dependent on the nature of the donor atoms in the peripheral ligands. The present contribution is devoted to the analysis of this factor in oxalato-bridged octahedral nickel(II) complexes with an NiN_4O_2 environment. We have succeeded in synthesising a related series of nickel(II) complexes of general formulation $[\{Ni(X)(dien)\}_2(\mu\text{-ox})]\cdot n H_2O$ ($X = N_3^-$, NCS^-, $n = 0$; $X = NCO^-$, $n = 1$). This work has allowed us to study the influence of the water of crystallization on the crystal packing and thermal behaviour of these compounds.

Results and Discussion

Synthesis

In the synthesis of the three molecular compounds, the binuclear complex $[\{Ni(dien)(H_2O)\}_2(\mu\text{-ox})]Cl_2$[2c] was used as a precursor owing to the lability of its water molecules, which may be substituted by pseudohalide ligands. The preparation of the compound was performed as follows: the sodium or potassium salt of the corresponding pseudohalide dissolved in a small amount of water was added to a hot aqueous solution of $[\{Ni(dien)(H_2O)\}_2(\mu\text{-ox})]Cl_2$. When we used cyanide as pseudohalide, a neutral trinuclear complex was obtained where the two water molecules were replaced by two cyano groups belonging to a square planar $[Ni(CN)_4]^{2-}$ unit,[7] (Scheme 1).

Scheme 1

Description of the Crystal Structures

The three compounds crystallize in the same monoclinic space group $C2/m$ and could be considered almost isostructural. Single crystal structure analyses were performed for the neutral $[\{Ni(N_3)(dien)\}_2(\mu\text{-ox})]$ (**1**) and $[\{Ni(NCO)(dien)\}_2(\mu\text{-ox})]\cdot H_2O$ (**2**) complexes. These analyses reveal the presence of a binuclear complex of C_{2h} symmetry, with nickel atoms and pseudohalide ligands contained in the symmetry plane. The twofold axis is defined by the C−C bond of the oxalate ligand which is coordinated in a bis(bidentate) fashion to the twofold related nickel atoms.

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 2000 1434−1948/00/1212−2541 $ 17.50+.50/0

The distorted octahedral environment of each nickel atom is completed by three nitrogen atoms from a diethylenetriamine ligand in a *fac* arrangement and one nitrogen atom from a pseudohalide ligand (Figure 1). The Ni−oxalato−Ni fragments adopt a chair conformation with a Ni−Ni distance of 5.397 Å for **1** and 5.491 Å for **2**. The nickel atoms are displaced by 0.021 Å for **1** and 0.198 Å for **2** out of the oxalate plane towards the N atom of the pseudohalide. The dihedral angle between the oxalato group and the equatorial mean plane is 2.37° for **1** and 3.98° for **2**. Bond lengths and angles involving non-hydrogen atoms are listed in Table 1. The Ni−O (oxalate) distances are 2.081 Å for **1** and 2.108 Å for **2**, whereas the Ni−N bonds vary in the range 2.08−2.16 Å. These distances agree with those observed in other oxalato-bridged nickel(II) complexes.

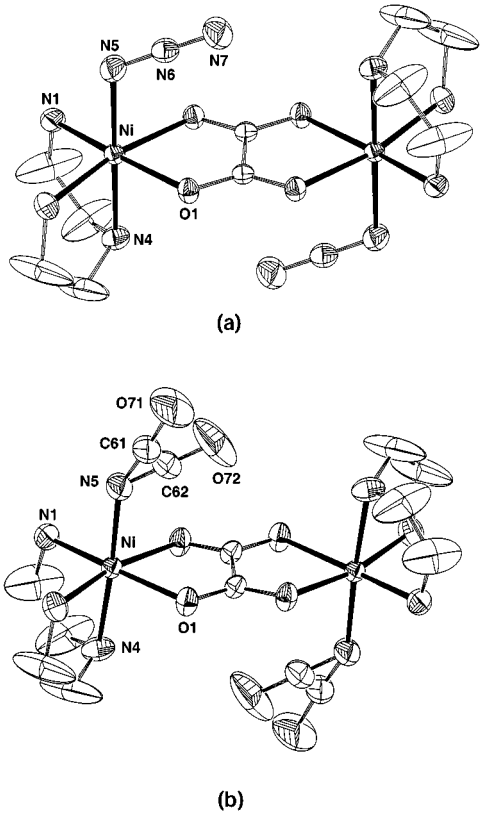

Figure 1. ORTEP views of compound **1** (a) and compound **2** (b) with atom labelling

The thermal analysis of the compound **2** confirms the presence of one water molecule, which is found to be disordered around an inversion centre in the crystal structure determination.

The different coordination modes of the pseudohalide ligands are remarkable. In compound **1** the azide ligand coordinates with an Ni−N5−N6 angle of 113.3°, while in compound **2** the cyanate ligand shows two coordination modes, with different values of the Ni−N5−C6 angle, 152.0° (64%) and 121.4° (36%). In order to check if this behaviour is due to electronic or packing effects, theoretical calculations were performed on a mononuclear model compound of general formula $[Ni(X)(NH_3)_3(CH_2O_2)]^+$ where $X = N_3^-$, NCO^-. Both structures were fully optimised and only one minimum was found for each, with a coordination angle of 109.9° for the azide and 124.8° for the cyanate ligand. Both values agree quite well with experimental ones. As there is no energy minimum with (quasi)linear coordination of the cyanate ligand, the experimental value of 152° observed for 64% of the molecules in the crystal must be due to the formation of hydrogen bonds with the water molecule present in compound **2** but absent in compound **1** (vide infra). The water molecule plays an important role in the thermal behaviour of this compound. Just before the end of the dehydration process (210 °C) the heat flow curve shows a sharp endothermic peak superimposed on the broad peak associated with water loss (Figure 2). Preliminary studies indicate a disorder-order phase transition. The loss of the water molecule destabilises the cyanate coordination mode having the higher angle and all cyanate ligands should coordinate with an angle of ≈120°.

Based on the high accuracy of the above-mentioned DFT calculations on model monomers, the geometry of the dimers has been optimized at the same level. The combination of the BPW91 functional with the 6-31G* basis set seems a good choice for studies of coordination compounds.[8] A summary comparison of the experimental and theoretical geometrical parameters is given in Table 1, which show good agreement.

In both compounds the dinuclear units are held together by means of an extensive two-dimensional hydrogen bonding network, involving the amino groups as donors and the oxygen atoms of the oxalate ligand and nitrogen atoms of the pseudohalide ligand as acceptors, such that each dimeric unit is connected to its neighbours through eight N1−H11···O1 and eight N1−H12···N5 hydrogen bonds

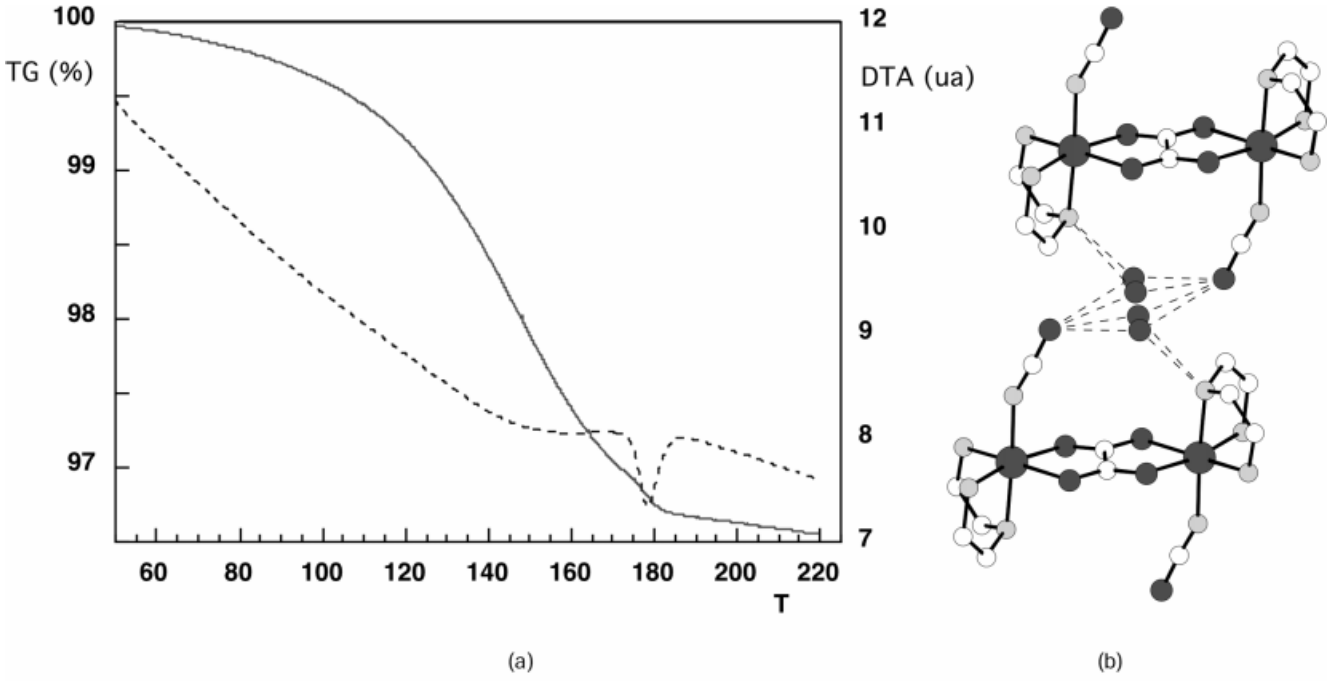

Figure 2. (a) Thermal analysis of the dehydration process and (b) disordered water molecule environment in compound **2**

(Table 2), leading to an infinite two-dimensional arrangement along the *xy* plane (Figure 3). However, they differ in the connections between layers, which in compound **1** are held together through hydrophobic interactions involving the CH_2 groups of dien ligand, but in compound **2** such connections are through hydrogen bonding of the water molecule, the oxygen atom of NCO^- and the secondary nitrogen atom of the dien ligand (Figure 2b). The presence of this water molecule in the structure causes an increase of about 1 Å in the value of the unit cell *c* parameter with respect to that of compound **1**, corresponding with the layer packing direction.

Besides these intermolecular hydrogen bonds, two intramolecular N4−H41···N7 interactions are also present in compound **1**.

Magnetic Properties

The molar magnetic susceptibility, χ_M, vs. temperature curves for compounds **1−3** are depicted in Figure 4. The susceptibility curve for these complexes increases when the compound is cooled until a maximum is reached (T_{max} = 46.4, 42.0 and 48.7 K, for **1−3**, respectively) and then decreases very quickly. The ground state of nickel(II) ion in an octahedral environment is orbitally nondegenerate, and as such, it is possible to represent the intradimer magnetic interaction, *J*, with the isotropic spin Hamiltonian $H = -JS_A \cdot S_B$. The molar magnetic susceptibility for a nickel(II) dimer (local spins $S_A = S_B = 1$) may be expressed by Equation 1, where *N*, β, *k*, *g* and *T* have their usual meaning.

$$\chi_M = \frac{2N\beta^2 g^2}{kT} \times \frac{\exp(J/kT) + 5\exp(3J/kT)}{1 + 3\exp(J/kT) + 5\exp(3J/kT)}$$

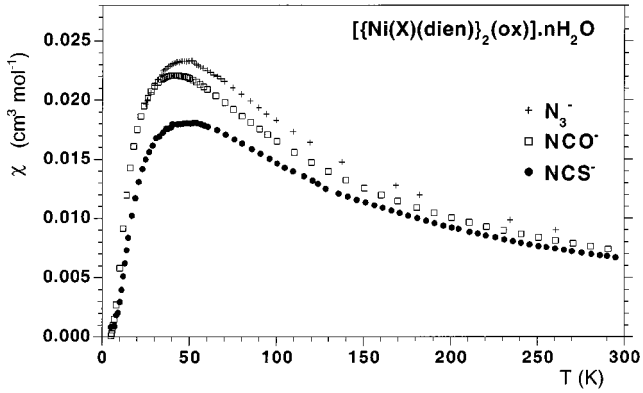

Figure 4. Thermal dependence of the molar magnetic susceptibility for compounds **1**−**3**

Although nickel(II) with axial symmetry can have a large zero-field splitting *D*, the magnetic behaviour of nickel(II) dimers closely follows Equation 1 when a relatively strong antiferromagnetic interaction is operative.[9] This is the case for complexes **1**−**3** where least-squares analysis of the experimental data with Equation 1 leads to $J = -31.4$ cm^{-1}, $g = 2.25$ and $R = 1{\cdot}10^{-4}$ for **1**; $J = -28.5$ cm^{-1}, $g = 2.14$ and $R = 5{\cdot}10^{-5}$ for **2**; $J = -33.0$ cm^{-1}, $g = 2.08$ and $R = 1.6{\cdot}10^{-5}$ for **3**. *R* is the agreement factor defined as $R = \Sigma(\chi_M^{obs} - \chi_M^{calc})^2/\Sigma(\chi_M^{obs})^2$. Previously reported *J* values for μ-oxalato bridged nickel(II) binuclear complexes are close to those of compounds **1**−**3**. This information is summarized in Table 3 for dinuclear Ni^{II}-oxalato systems in an NiO_2N_4 environment. It is well known that structural distortions (distance Ni−O_{ox}, bite angle O−Ni−O, deviation from the planarity of the nickel ion respect to mean plane of the oxalate bridging ligand) can play a key role in the fine-tuning of exchange coupling and the influence of apical pseudohalide ligands on the *J* values is similar in the three compounds since all are N-donor ligands.

A graphical representation of the four DFT magnetic orbitals of compound **2** is given in Figure 5, with those for compound **1** being very similar. As expected for the case of octahedral nickel centres, the unpaired electrons are mainly located in the d_{z^2} and d_{xy} orbitals, with a noticeable contribution to the d_{z^2} magnetic orbital of the pseudohalide orbital.

Conclusions

The reaction between pseudohalogen species and the cationic complex $[\{Ni(dien)(H_2O)\}_2(\mu\text{-ox})]^{2+}$ results in water displacement when the pseudohalides are N_3^-, NCO^-, and NCS^-, leading to the corresponding neutral binuclear complexes. However, in the case of cyanide anion, the trinuclear species $[\{Ni(dien)\}_2(\mu\text{-ox})\{\mu\text{-}Ni(CN)_4\}]$ is obtained due to the high stability of the $[Ni(CN)_4]^{2-}$ complex which is initially formed when the cyanide salt is added. The tetracyanonickelate(II) acts a template for the formation of the trinuclear unit.

The three compounds are almost isostructural, but differ in the degree of hydration. Compound **2** is monohydrated

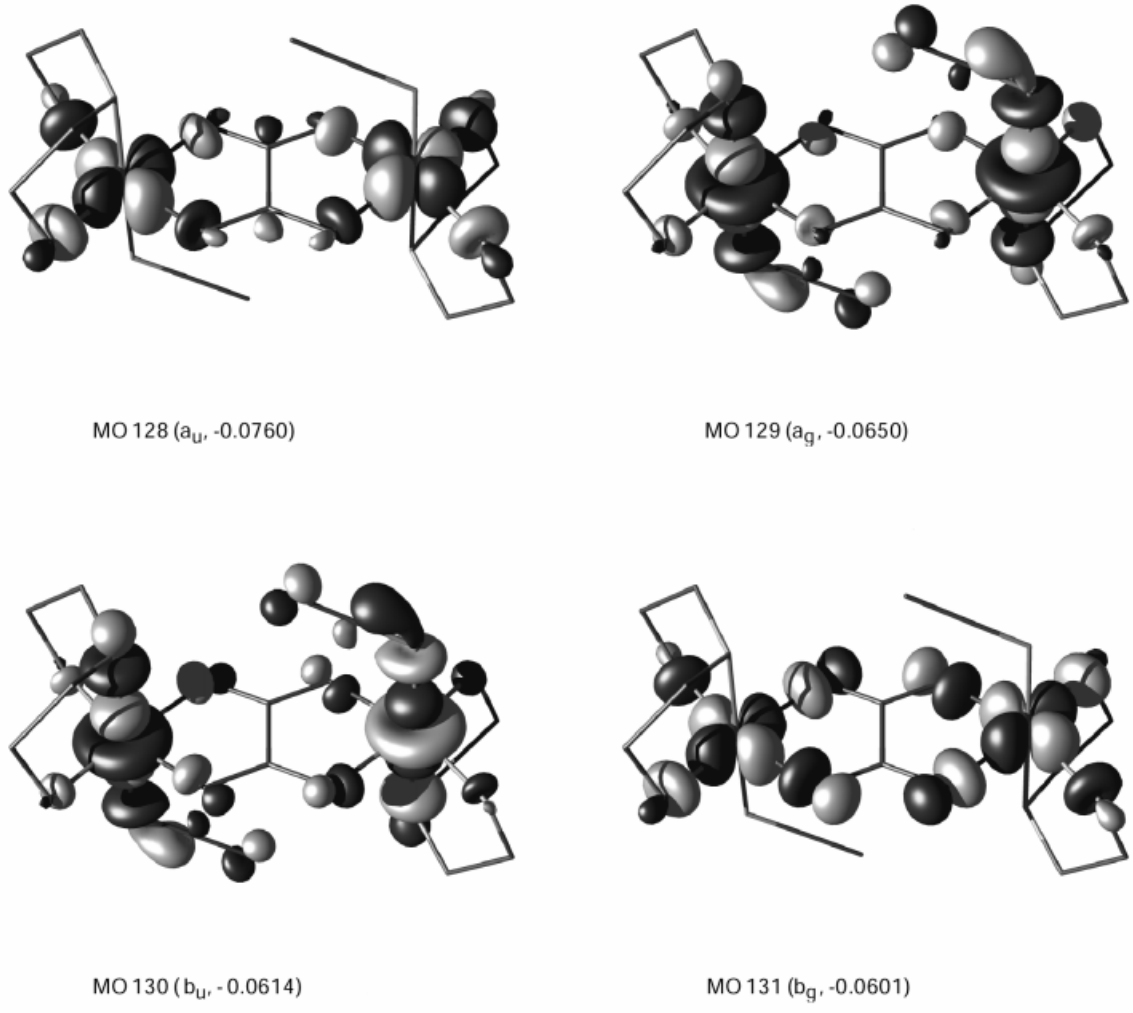

Figure 5. Magnetic orbitals for compound **2** (symmetry, energy)

but compound **1** and **3** are anhydrous. Although the dinuclear units in both compounds are held together by means of an extensive two-dimensional hydrogen bonding network, they differ in the connection between layers. In anhydrous compound **1** the layers are held together through hydrophobic interactions, but in hydrated compound **2** such connections are via hydrogen bonding involving the water molecule. This fact confirms that hydrogen bonds of type O−H···O are stronger than possible O−H···N or O−H···S ones, and are strong enough to force 64% of NCO^- ligands to adopt a coordination fashion which according to the DFT calculations is less stable.

DFT calculations on the binuclear complexes confirm the nature of the magnetic orbital previously reported in these kinds of compounds,[2c] although the energetic order is different.

Experimental Section

General: Microanalyses of carbon, nitrogen, hydrogen, and sulfur were performed on a LECO CHNS-932 analyser. −IR: NICOLET 740 FT-IR. − TG: SETARAM TAG 24 S16. The thermal experiments were performed in synthetic dry air atmosphere (100 $mL{\cdot}min^{-1}$) and a heating rate of 2 $°C{\cdot}min^{-1}$ in the temperature range 25−250 °C. All chemicals were procured commercially and used without subsequent purification.

Synthesis of [{Ni(N_3)(dien)}$_2$(μ-ox)] (1): Obtained from [{Ni(dien)(H_2O)}$_2$(μ-ox)]Cl_2 (0.360 g, 0.707 mmol) in water (40 mL) and NaN_3 (0.114 g, 2.25 mmol) in water (5 mL), as blue crystals in 60% yield (0.210 g, 0.424 mmol). − $C_{10}H_{26}N_{12}Ni_2O_4$ (495.80): calcd. C 24.23; H 5.29; N 33.90; found C 24.2; H 5.4; N 34.0. − IR (KBr): $\tilde{\nu}$ = 2036 cm^{-1} (N_3^-).

Synthesis of [{Ni(NCO)(dien)}$_2$(μ-ox)]·H_2O (2): [{Ni(dien)(H_2O)}$_2$(μ-ox)]Cl_2 (0.231 g, 0.448 mmol) in water (70 mL) and NaNCO (0.110 g, 1.69 mmol), as blue crystals in 55% yield (0.120 g, 0.244 mmol). $C_{12}H_{26}N_8Ni_2O_6{\cdot}H_2O$ (513.81): calcd. C 28.05; H 5.49; N 21.81; found C 28.1; H 5.6; N 21.9. − IR (KBr): $\tilde{\nu}$ = 2210, 2169 cm^{-1} (NCO^-).

Synthesis of [{Ni(NCS)(dien)}$_2$(μ-ox)] (3): [{Ni(dien)(H_2O)}$_2$(μ-ox)]Cl_2 (0.230 g, 0.440 mmol) in water (50 mL) and KSCN (0.115 g, 1.18 mmol), as blue spherulites in 75% yield (0.174 g, 0.330 mmol). − $C_{12}H_{26}N_8Ni_2O_4S_2$ (527.91): calcd. C 27.30; H 4.96; N 21.23; found C 27.3; H 4.96; N 21.23. − IR (KBr): $\tilde{\nu}$ = 2049 cm^{-1} (NCS^-).

Magnetic Susceptibility Measurements: Magnetic susceptibility measurements were carried out on polycrystalline samples in the temperature range 4.2−300 K, with a pendulum type susceptometer/magnetometer (Manicsd DSM8) equipped with a helium continuous flow cryostat. The diamagnetic contribution was calculated from Pascal's constants.

X-ray Crystallographic Studies: Data collection for the prismatic blue single crystals of **1** and **2** was performed on an Enraf−Nonius CAD4 and a Philips PW1100 diffractometer, respectively, with graphite monochromated Mo-K_α radiation (λ = 0.71069 Å). Intensities were collected by the ω-2θ scan technique. A Lorentz-polarization (Lp) correction was applied. The experimental details and crystal data are listed in Table 4. The atomic scattering factors were taken from the International Tables for X-ray Crystallography.[10] The structures were solved by direct methods (DIRDIF92[11]). The non-hydrogen atoms were anisotropically refined by the full-matrix least-squares method. In compound **2**, C

and O pseudohalide atoms were found to be distributed over two positions. Hydrogen atoms bonded to nitrogen atoms were located in a difference Fourier synthesis and refined isotropically. Most calculations were performed using XRAY76 System.[12]

For compound **3** the powder X-ray diffraction pattern was collected on a STOE diffractometer using Cu-$K_{\alpha 1}$ radiation (λ = 1.54059 Å). Data were collected by scanning in the 2θ range 5−70° with increments of 0.02°. The structure was refined by the Rietveld method using the FULLPROF program.[13]

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-140558 (**1**), -140559 (**2**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (E-mail: deposit@ccdc.cam.ac.uk).

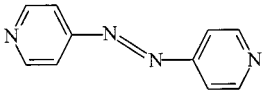
Syntheses and Structures of Silver and Copper Coordination Polymers with 4,4′-Azopyridine − Effect of Counter Anions and π−π Interactions on the Network Systems



Cheng He,[a] Bing-Guang Zhang,[b] Chun-ying Duan,*[a] Ji-hui Li,[a] and Qing-Jin Meng*[a]

Keywords: Anions / Stacking interactions / Polymers / Silver / Copper

The syntheses and structures of $[Ag(azpy)](NO_3)(H_2O)(CH_3OH)$ (**1**), $[Cu(azpy)_2](ClO_4)$ (**2**), $[Cu(azpy)_2(H_2O)_2](NO_3)_2(H_2O)_2$ (**3**) and $[Cu(azpy)_2(H_2O)_2](ClO_4)_2(C_2H_5OH)_2$ (**4**), where azpy = trans-4,4′-azopyridine, are reported to test the dependence of network topology on counter anions and π–π interactions. Complex **1** contains pairs of linear chains of alternating Ag^I ions and azpy ligands, resembling a ladder structure in which the ligands form π–π interactions (with a distance of 3.53 Å) and AgAg interactions (with a distance of 3.30 Å). Complex **2** exists as a 3D adamantoid polymer in which each Cu^I center is coordinated to four azpy ligands in a tetrahedral geometry, the ligands are in turn coordinated to four other Cu^I centers. The cavities are filled with four other adamantoid units forming five interpenetrating networks. Complexes **3** and **4** are composed of two-dimensional sheets in which the Cu^{II} atom is coordinated in an octahedral geometry to two water molecules and four ligands. The ligands are in turn coordinated to four other Cu^{II} centers. While the sheets in complex **3** display inclined 2D interpenetration, the sheets in complex **4** are all parallel and isolated, with an intersheet separation of ca. 4.7 Å.

Introduction

Much interest at present is focused on the deliberate construction of coordination polymers by self-assembly of the component metal complexes. These solid materials with well-defined, discrete network topologies are attractive to chemists not only for aesthetic reasons, but also for their potential applications in many areas.[1−3] A large amount of these research works have used the 4,4′-bipyridine (4,4′-bipy) ligand and its analogues.[4−5] The coordination polymers observed can be predicted to a certain extent and this led to the development of a wide variety of architectures related to common models such as the honeycomb,[6] ladder,[7] grid,[8] and adamantoid network,[9] or to less common ones exhibiting different degrees of interpenetrations.[1b,10] Although the overall structure is predominantly controlled by the coordination preferences of the transition metal and the ligand building blocks, more subtle effects such as anion control[11] and π−π stacking interactions[12] have been seen to have a profound effect upon network topology. Here we report on the syntheses of some silver and copper complexes, by reaction of the potentially bridging ligand 4,4′-azopyridine (Scheme 1) and metal salts with different anions. A few compounds which exhibit quite novel structures with this ligand have been reported.[13−15] As a result of the different conformations exhibited by this type of ligand, its capability of forming hydrogen bonds with the anions and solvent molecules, as well as the potential π−π stacking interactions between ligands, it was anticipated that the products would present interesting structural features.

Results and Discussion

Structure of $[Ag(azpy)](NO_3)\cdot(CH_3OH)\cdot(H_2O)$

The structure contains pairs of linear chains (Figure 1) of alternating Ag^I ions and azpy ligands, resembling a ladder structure in which the ligands form π−π interactions (with a distance of 3.53 Å) and weak AgAg interaction (with a distance of 3.30 Å). Each Ag^I ion coordinates to two azpy ligands in a linear arrangement [Ag(1)−N(1) 2.147(8) Å, Ag(1)−N(4A) (A: 1 + *x*, *y*, 1 + *z*) 2.180(9) Å, N(1)−Ag(1)−N(4A) 173.0(3)°], giving an infinite chain of alternating Ag^I separated by 14.65 Å, and azpy ligands which align themselves along the (101) direction. The pairs of chains are linked together by π−π interactions between the azpy ligands and in which the ligands lie parallel to each other at a distance of 3.36 Å forming a two-dimensional sheet. Chains, ladders and sheets of (bipyridine)silver(I) complexes have been reviewed by A. J. Blake et. al.[2a] It is said that the π−π stacking interaction had a profound effect upon the solid-state packing of Ag−bipyridine chains. From the simple linear chains of [Ag(4,4′-bipy)](BF_4), to the ladders of [Ag(pybut)](PO_2F_2) [pybut = 1,4-bis(4-pyridyl)butadiyne],[2a] and to the 2D sheets of [Ag(diaz)](BF_4) (diaz = 2,7-diazapyrene[10b]), it can be seen

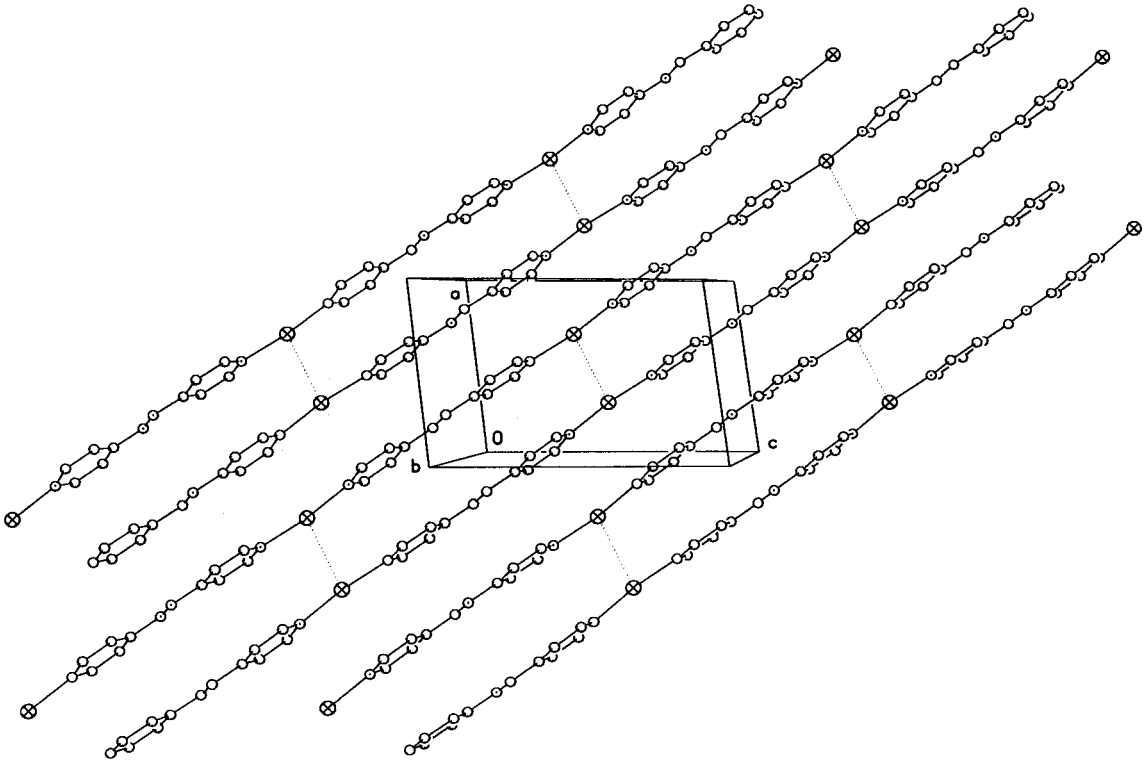

Figure 1. View of the pairs of linear chains observed in complex **1**, in which the ligands form π−π interactions (with a distance of 3.53 Å) and AgAg interactions (with a distance of 3.30 Å)

that by increasing the ability of the ligand to form π−π interactions, the construction of long-range arrays is be encouraged. The increased ability of azpy to form π−π interactions compared with 4,4′-bipy and pybut, encourages not only the formation of pairs of chains, or ladders, but also the formation of a sheet structure with extended π−π stacking interactions.

Structure of $[Cu(azpy)_2]ClO_4$

The reaction of $[Cu(MeCN)_4]ClO_4$ with azpy in MeCN/CH_2Cl_2 affords black crystal suitable for X-ray analysis. The crystal structure shows that the complex exists as a three-dimensional adamantoid polymer in which each Cu^I is coordinated in a tetrahedral geometry to four azpy ligands, which are in turn coordinated to four other Cu^I centers, Cu(1)-N, 2.054(7) Å, Cu(2)-N, 2.025(10) Å. The 3D structure is built through the formation of edge-sharing adamantoid units. The CuCu separation is 12.98 Å creating large cavities within this first 3D lattice. These cavities are filled with four other $[Cu(azpy)_2]^+$ lattices so that a total of five independent adamantoid lattices, related by translation symmetry, interpenetrate throughout the 3D structure, as illustrated in a simplified form by the five adamantoid units (Figure 2).

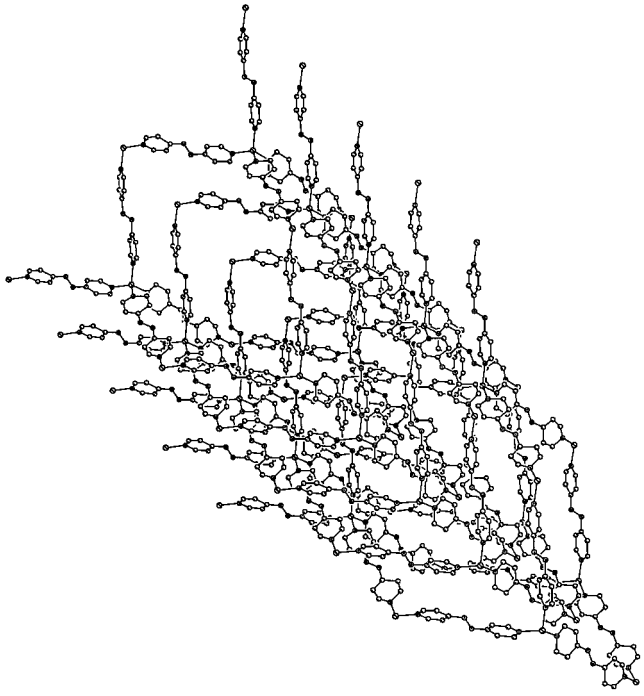

Figure 2. The five independent interpenetrating adamantoid lattices of complex **2**

The channels running through the structure are parallel to the translation vector relating the five networks and accommodate the ClO_4^- counter anions (Figure 3).

Adamantoid networks based on bifunctional linear ligands have been studied for some Cu^I and Ag^I complexes. In general, the lengths of the bridging ligands and the lateral bulk of the ligands are possible factors in controlling the degree and type of interpenetration in adamantoid lattices. Comparing this structure with two other isomorphous structures $[Cu(bpe)_2](BF_4)\cdot 0.5CH_2Cl_2$[9b] and $[Cu(bpe)_2](BF_4)(CH_3CN)$[16] [bpe = *trans*-1,2-bis(4-pyridyl)ethene], it

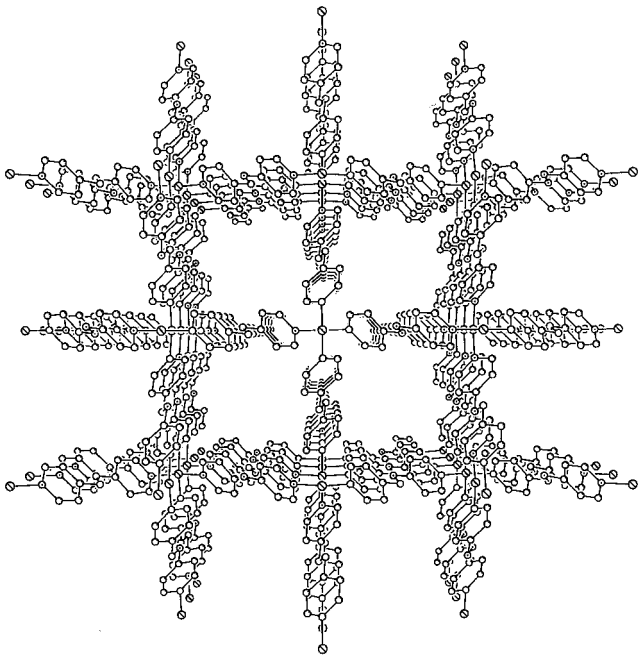

Figure 3. View of the complex **2** network illustrating the channels that run through the accommodating counter ions

is interesting to find that the structure remains essentially the same with different ligands and anions. The implications of this are that the solvent and the counter anion have little or no templating effects.

Structures of $[Cu(azpy)_2(H_2O)_2](NO_3)_2\cdot 2H_2O$ and $[Cu(azpy)_2(H_2O)_2](ClO_4)_2\cdot 2EtOH$

The Cu^{II} complexes **3** and **4** are obtained as large black crystals by treating $Cu(NO_3)_2$ or $Cu(ClO_4)_2$ in water with the azpy ligand in an ethanol solution in a 1:2 molar ratio. One of the aims of this research was to compare the behavior of azpy with that of the shorter 4,4′-bipyridine ligand. These ligands give both interpenetrated[17] and noninterpenetrated structures when treated with $ZnSiF_6$.[8a] Another aim was to assess the effect of the counter anion on the crystal packing of the sheets.

The structure of **3** contains two-dimensional layers of squares (Figure 4). The Cu^{II} atoms are octahedrally coordinated to four equatorial azpy ligands (Cu−N distance ca. 2.02 Å) and two axial water molecules (Cu−O distance ca. 2.50 Å). Each azpy unit is attached to two copper centers to form an infinite sheet. The Cu^{II} cations within a sheet are coplanar and form a grid of edge-shared squares, the average CuCu distance along the edge is ca. 12.95 Å. Parallel sheets, stacked on top of each other, are laterally displaced so that the copper centers of the first sheet, viewed in the horizontal plane, are vertically above those of the 3rd, 5th, 7th etc. sheets, and are vertically above the midpoints of the Cu_4 squares of the 2nd, 4th, 6th etc. sheets. An equivalent stack of sheets is found in planes perpendicular to the first, giving rise to the interpenetrating pattern represented in Figure 5. Hydrogen bonds are apparent between the coordinated water molecules and the disordered NO_3^- anions.

The structure of **3** is isomorphous with the structure of $[Zn(azpy)_2(H_2O)_2]\ SiF_6\cdot H_2O$,[13b] the size of the cavity is almost equivalent (166 vs. 165 Å^2). An interesting feature of this structure is the fact that the structure remains essentially unchanged whether the metal center is Cu^{II} or Zn^{II} and the anion is SiF_6^{2-} or NO_3^-. The implications of this are that either SiF_6^{2-} and NO_3^- behave similarly as templates for the interpenetrating structure, or they have little or no template effect. In both structures the counter anions and water molecules are contained in the tetrahedral channels, although there is twice as much NO_3^- included as there is SiF_6^{2-}. It was anticipated that when the perchlorate counter anion was used instead of the nitrate counter anion, the expected structure would be similar to that proposed for **3** and $[Zn(azpy)_2(H_2O)_2]SiF_6\cdot H_2O$. However, after synthesizing and studying the crystal structure of the perchlorate salt of **3** (i.e. **4**), it was surprising to find that the structure of **4** is quite different.

Compound **4** crystallizes in the tetragonal space group $P4_2/mnm$ with $Z = 2$. The skeleton structure of the two-dimensional sheet 2 (in **4**) is the same as that in **3** (CuCu distance along the edge is 13.06 Å, and the Cu−N, Cu−O distances ca. 2.02 Å, 2.68 Å, respectively). However, the sheets subsequently stack along *c* in a close-packed staggered manner, as described above, with interplane separations 4.7 Å. Such short inter-plane separations certainly

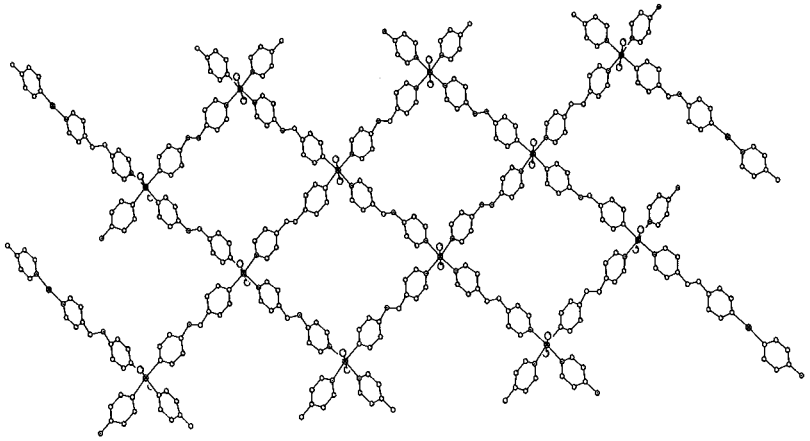

Figure 4. View of the two-dimensional sheets of complex **3**

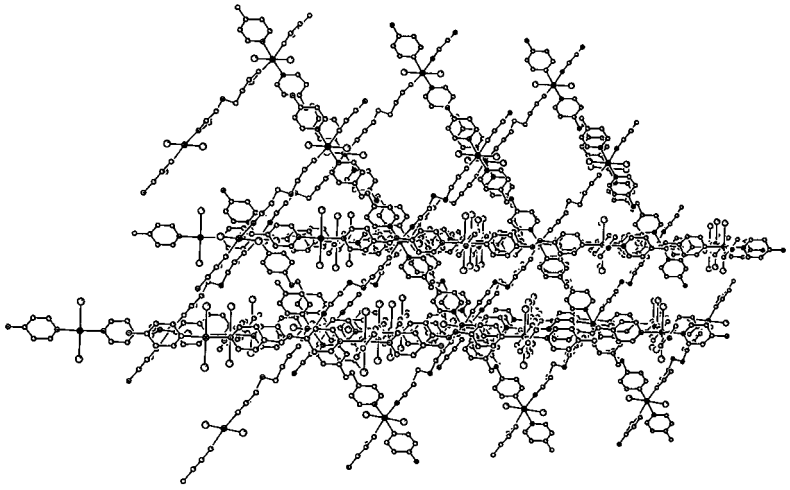

Figure 5. A schematic view of the interpenetration of the layers, showing its inclined nature, and the channels of complex **3**; the anions and the solvent molecules are omitted for clarity

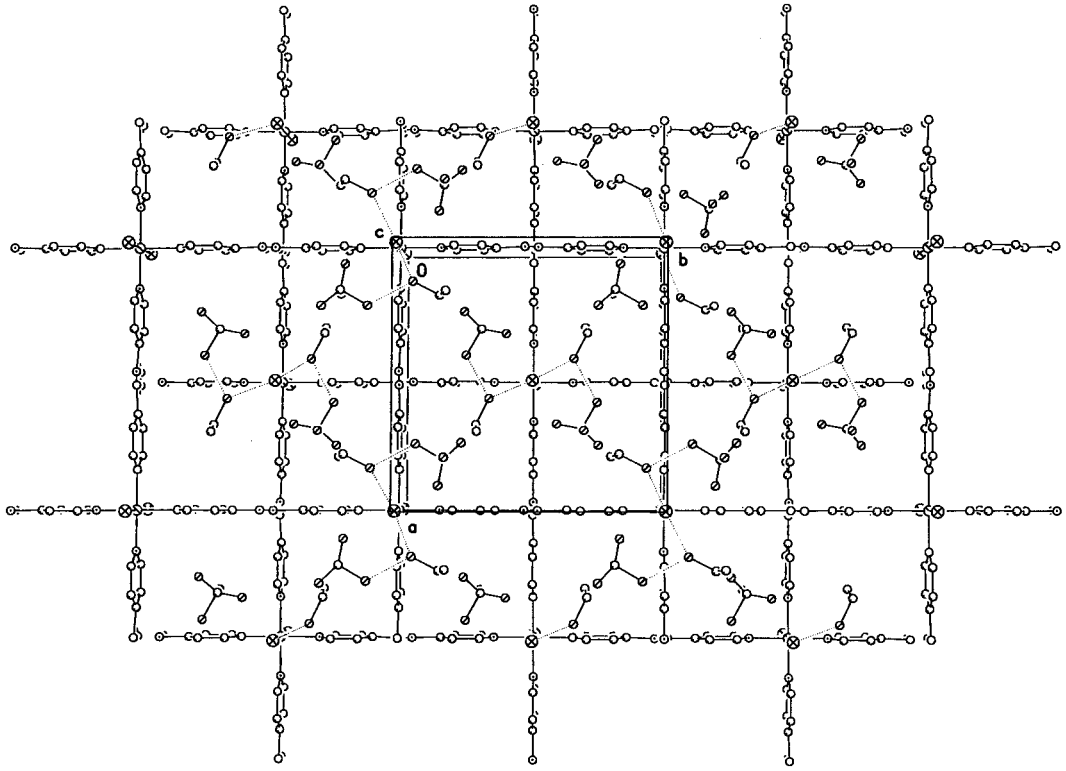

Figure 6. View of the square cavities of a single sheet in complex **4**, showing the ClO_4^- anions and ethanol molecules in the clathrates

preclude the possibility of interpenetration. The square cavities are enclosed by the azpy ligands. Two ClO_4^- anions and two ethanol molecules occupy the square cavity within the clathrate (Figure 6). There is significant hydrogen bonding between the ethanol molecules and the ClO_4^- anions.

It is interesting to find that the water molecules coordinated to the Cu^{II} atom extend to the center of the cavity on the adjacent layer and interact with the two ethanol molecules in the clathrate by hydrogen bonding, to form one-dimensional chains along the *c* axis (Figure 7).

The fact that the counter anions can influence the final structure of coordinated complexes has been noted. It is clearly indicated that noncoordinating counter anions can play an important role in the crystal engineering of coordination complexes. The result of this study illustrates the fine balance between interpenetrated and noninterpenet-

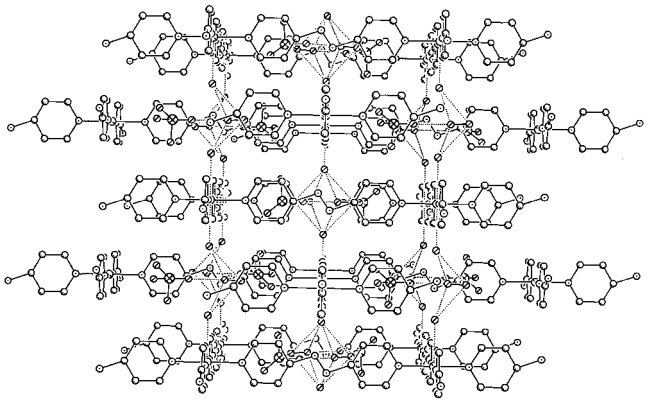

Figure 7. View through the *ac* plane in complex **4**, showing the one-dimensional hydrogen-bonding chains on the *c* axis

rated structures. Although the mechanism of the structural change is unpredictable, understanding the features may be a clue to the design of self-assembly network compounds.

Experimental Section

General: All starting materials were purchased from Aldrich and used as received. The ligand 4,4′-azopyridine[18] and $Cu(MeCN)_4ClO_4$[19] were prepared by literature procedures. − The IR spectra were recorded with a Nicolet 170SX FT-IR spectrophotometer with KBr pellet in the 4000−400cm^{-1} region. − ^{1}H NMR spectra were recorded with Am5600 Bruker spectrometers at 298 K using TMS as an internal standard.

[Ag(azpy)](NO$_3$)(CH$_3$OH): A solution of $AgNO_3$ (0.10 g, 0.59 mmol) in water (5 mL) was added to a stirred solution of azpy (0.11 g, 0.60 mmol) in methanol (10 mL). A pale red precipitate formed and was filtered off and dried under vacuum(0.16 g, yield 69%). − $C_{11}H_{12}AgN_5O_4$ (386.1133): calcd. C 34.2, H 3.1, N 18.1; found C 34.7, H 2.7, N 18.2. − ^{1}H NMR [$(CD_3)_2SO$]: δ = 8.88 (d, J = 5.0 Hz, 4 H, py], 7.84 [d, J = 5.6 Hz, 4 H, py]. − IR (KBr): $\tilde{\nu}$ = 1594 cm^{-1} (m), 1587 (m), 1565 (m), 1486 (w), 1414 (s), 1384 (s), 1317 (m), 1238 (w), 1222 (m), 1051 (w), 1006 (w), 989 (w) and 836 (s). Crystals were obtained by slow concentration of an acetonitrile/ethanol solution at ambient temperature.

[Cu(azpy)$_2$](ClO$_4$): Solutions of $Cu(CH_3CN)_4ClO_4$ (0.10 g, 0.31 mmol) in CH_2Cl_2 (10 mL) and azpy (0.12 g, 0.65 mmol) in CH_3CN (10 mL) were mixed. After concentrating the solution to a small volume, black crystals of **2** were obtained and were filtered off (0.09 g, yield 55%). − $C_{20}H_{16}ClCuN_8O_4$ (531.3950): calcd. C 45.2, H 3.0, N 21.1; found C 45.6, H 3.2, N 21.3. − IR (KBr): $\tilde{\nu}$ = 1595 (s), 1563 (m), 1486 (m), 1467 (w), 1416 (s), 1324 (w), 1241 (w), 1224 (m), 1101 (s), 1083 (s), 1051 (s), 1010 (m), 962 (m), 932 (w), 867 (w), 846 (s), 831 (s).

[Cu(azpy)$_2$(H$_2$O)$_2$](NO$_3$)$_2$2H$_2$O: Solutions of $Cu(NO_3)_26H_2O$ (0.10 g, 0.33 mmol) in water (10 mL) and azpy (0.12 g, 0.65 mmol) in ethanol (10 mL) were mixed. After slow concentration of the solution to a small volume, black crystals were formed and were filtered off. − IR (KBr): $\tilde{\nu}$ = 3431 (w), 3102 (w), 1608 (s), 1570 (w), 1513 (m), 1480 (s), 1424 (s), 1384 (s), 1352 (s), 1327 (m), 1293 (s), 1274 (s), 1231 (m), 1194 (m), 1094 (w), 1051 (m), 1034 (w), 1013 (m), 995 (m), 850 (s), 803 (m) .

[Cu(azpy)$_2$(H$_2$O)$_2$](ClO$_4$)$_2$2CH$_3$CH$_2$OH: Solutions of $Cu(ClO_4)_26H_2O$ (0.10 g, 0.27 mmol) in water (10 mL) and azpy (0.10 g, 0.54 mmol) in ethanol (10 mL) were mixed. Black crystals were obtained by slowly concentrating the solution in air. They were filtered off. − IR (KBr): $\tilde{\nu}$ = 3449 (w), 3111 (w), 1609 (s), 1568 (w), 1494 (w), 1423 (s), 1229 (m), 1184 (s), 1043 (s), 989 (m), 928 (m), 846 (s), 621 (s).

X-ray Crystallography: Parameters for data collection and refinement of the crystals are summarized in Table 1. Intensities were collected with a Siemens P4 four-circle diffractometer with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) using the ω-2θ scan mode. Data were corrected for Lorentz polarization effects during data reduction using XSCANS,[20] and a semi-empirical absorption correction from ψ scans was applied. The structures were solved by direct methods and refined on F^2 by full-matrix least-squares methods using SHELXTL version 5.0.[21] Anisotropic thermal parameters were refined for the non-hydrogen atoms. For complex **1**, the nitrate anion, and the H_2O and CH_3OH molecules were found to be disordered into two occupied sites. The site occupancy factor (SOF) of the atoms of the NO_3^- anion were refined using

free variables, the SOF of the atoms in the methanol molecules, however, were fixed at 0.5. To assist in the refinement, several restraints were applied for the nitrate anion: 1) all N-O bonded and all OO nonbonded distances were restrained to be similar; 2) thermal parameters on adjacent atoms were restrained to be similar for the disordered pairs. For complex **2**, the perchlorate anion was disordered with the SOF of the atoms fixed at 0.5. The ClO_4^- was refined to the idealized tetrahedron with Cl−O distance fixed at 1.43(1) Å, and OO separation fixed at 2.32(2) Å. For complex **3**, hydrogen atoms of the water molecules were found from the difference Fourier maps, however, they were refined using the riding model. The ligands were disordered along the direction of the Cu−azpy−Cu chains, the ligands and the nitrate anions were also affected. The SOF was fixed at 0.5 for each ligand. In order to make the refinement stable, many restrains such as distance restrains on the atoms in the ligands and thermal parameter restrains were used in the refinement of the nitrate anions. For complex **4** the oxygen atoms of the perchlorate anion were found to be disordered, the site occupancy factors for them were fixed at 0.25. The atoms of the ethanol molecules were also found to be disordered, the SOF for them were also fixed at 0.25, the C−O and C−C distances were fixed at 1.45(1) Å. Crystallographic data for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Center: CCDC-145343 (**1**), CCDC-145344 (**2**), CCDC-145346 (**3**), CCDC-145345 (**4**). Neutral and Cationic Methyl Complexes of Platinum(II) with 6-Substituted 2,2′-Bipyridines: Synthesis, Characterisation and Reactivity with Carbon Monoxide − Molecular Structures of [PtCl(methyl)(6-ethyl-2,2′-bipyridine)] and of [Pt(methyl)(acetonitrile)(6-ethyl-2,2′-bipyridine)][BF_4]

Angelino Doppiu,[a] Maria Agostina Cinellu,[a] Giovanni Minghetti,*[a] Sergio Stoccoro,[a] Antonio Zucca,[a] Mario Manassero,*[b] and Mirella Sansoni[b]

Keywords: Platinum / N ligands / Methyl complexes / Crystal structure / Hydrogen bonds

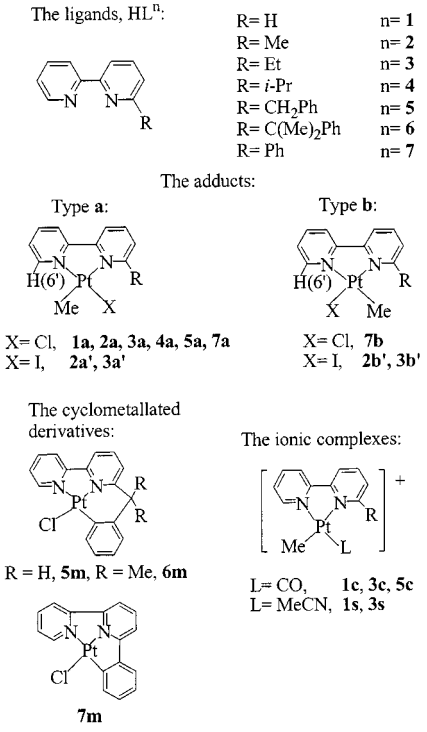
The complex *trans*-[PtCl(Me)(SMe_2)$_2$] reacts with 6-R-substituted 2,2′-bipyridine, HL^n (n = 1, R = H; n = 2, R = Me; n = 3, R = Et; n = 4, R = *i*Pr; n = 5, R = CH_2Ph; n = 7, R = Ph), to afford the neutral complexes [PtCl(Me)(HL^n)]. Only one isomer is formed (R *cis* to Cl) with all the ligands, but one (R = Ph). When R = $C(Me)_2Ph$ (HL^6), only an (N–N–C) cyclometallated species is formed. The stereoselectivity observed is interpreted in terms of the nature of the substituent R, and of the hydrogen bond formed between H–C(α) of the R substituent and the chloride ion bound to the platinum center. The molecular structure of [PtCl(Me)(HL^3)] has been resolved by an X-ray analysis and shows that the above-mentioned hydrogen bond length is 2.28 Å. The reactivity of three representative complexes (R = H, Et, CH_2Ph) with carbon monoxide has been studied. The reaction affords the ionic species [Pt(Me)(CO)(HL^n)]$^+$[$PtCl_2$(Me)(CO)]$^-$ and the free ligand. There is evidence of the formation of an acyl species, which does not contain the bipyridine ligand, only when working at high pressures of CO. The above cations are also obtained by direct carbonylation of the solvent species, [Pt(Me)(MeCN)(HL^n)][BF_4], achieve by halide abstraction from the neutral complexes. The molecular structure of [Pt(Me)(MeCN)(HL^3)][BF_4] has been resolved by an X-ray analysis.

Introduction

Palladium complexes [PdX(R)(N−N)], where X is a halide, R an alkyl or aryl group and (N−N) a bidentate nitrogen ligand, have been widely studied because of their potential in organic syntheses.[1] Many studies have focused their attention on the reaction of these Pd complexes with carbon monoxide. This is of fundamental interest in industrial processes, e.g., hydroformylation and copolymerisation of olefins and carbon monoxide.[2] As a result, there is a lot of experimental and theoretical data available on the insertion of carbon monoxide, as well as of alkenes, into the palladium−carbon σ bonds.[3] The analogous platinum complexes [PtX(R)(N−N)] also have been the subject of many studies concerning intra- and intermolecular C−H activation,[4] oxidative addition reactions[5] and addition of neutral ligands to give coordinatively saturated 18-electron species.[6] Great efforts have been devoted to the electronic and steric requirements which could stabilise pentacoordinated derivatives: in this context, in the case of bipyridine or phenanthroline derivatives, reactions with olefins have been widely investigated.[7] Surprisingly, reactions with CO, as well as the related migratory−insertion reactions into metal−carbon σ bonds, have been less investigated in spite of the extensively developed chemistry of alkylplatinum(II) and -platinum(IV) compounds[8] with nitrogen donors and being interesting as models for the catalytic species in the palladium systems.

Herein we report the synthesis and the spectroscopic characterisation of a series of alkylplatinum(II) derivatives of the type: [PtX(Me)(HL^n)] (X = Cl or I, HL^n = unsymmetric 2,2′-bipyridine 6-alkyl-, benzyl- or aryl-substituted), as well as their reactivity with carbon monoxide. Furthermore, some X-ray structural determinations are given.

Results and Discussion



Synthesis of the Adduct Species

The ligands HL^n and the platinum complexes are depicted in Scheme 1; the index n indicates the ligand.

The complex **1a** (HL^1 = 2,2′-bipyridine) is well known, it can be prepared in an almost quantitative yield by reaction of [PtCl(Me)(COD)] (COD = 1,5-cyclooctadiene) with HL^1 in CH_2Cl_2.[9] The 6-substituted-2,2′-bipyridines HL^{2-7} show a different reactivity, in spite of several attempts under a variety of experimental conditions, we were unable to achieve displacement of COD. Nevertheless, the adducts of all the ligands but one (HL^6, see later), can easily be obtained by reaction of *trans*-[PtCl(Me)(SMe_2)$_2$], an intermediate used in the synthesis of other species with (N−N) ligands.[5b,7b] The adducts can be isolated in good yields, they

Scheme 1

are stable in the solid state and in all cases but one (**5a**) also in solutions of chlorinated solvents at room temperature. They are not electrolytes in acetone. Owing to the ligand asymmetry, two stereoisomers are possible (Scheme 1).

In the case of the alkyl- or benzyl-substituted ligands HL^{2-5} only one isomer is formed. ^1H NMR spectroscopic data are consistent with isomer **a**; in particular the assessment relies on the chemical shift of H(6′) proton and its coupling constant to ^{195}Pt. The resonance is known to be influenced by the neighbouring ligands,[10] halides having a stronger deshielding effect than a methyl ligand. The values observed for **2a**−**5a** and **7a** (see Table 1) indicate that the methyl group is in close proximity to H(6′). This is supported by NOE difference experiments on **2a** and **3a** ($CDCl_3$ solution), irradiation of the H(6′) resonance gives enhancement of the signal of the methyl group bound to the platinum center, and vice versa. The extent of the coupling between H(6′) and ^{195}Pt is related to the nature of the ligand *trans* to the nitrogen atom N(1) of the unsubstituted pyridine ring. The relatively high values of $^3J_{Pt-H}$ indicate that the ligand has a low *trans* influence, like a chloride ligand.[11] It is worth noting that in **1a**, one H(6) is close to the chloride ion and the other to the methyl group. Indeed, one of the resonances is strongly deshielded ($\delta = 9.65$) with $^3J_{Pt-H} \approx 17$ Hz, whereas the other one ($\delta = 9.23$) has a larger $^3J_{Pt-H}$ value (60.3 Hz). The latter values are very similar to those found for **2a**−**5a** and **7a**.

As stated above, two stereoisomers **7a** and **7b** (ca. 1:1) are formed, only in the case of the ligand HL[7]. Evidence for the formation of two isomers is given by ^1H NMR spectra. There are two methyl signals at $\delta = 1.26$ ($^2J_{Pt-H} = 82.3$ Hz) and $\delta = 0.32$ ($^2J_{Pt-H} = 77.2$ Hz) and two H(6′) resonances. The upfield methyl signal can be assigned to **7b**, taking into account the anisotropic shielding effect of the phenyl substituent. The H(6′) resonance in **7b** ($\delta = 9.58$) is, as expected, more deshielded than in **7a** ($\delta = 9.10$); the extent of the $^{195}Pt-^1H$ coupling reflects the difference in the *trans* influence between the chloride ($^3J_{Pt-H(6')} = 60.0$ Hz, **7a**) and the methyl group (coupling not observable, **7b**). One of the isomers, **7b**, can be isolated in a pure form from the mixture by column chromatography, the other one is converted during elution through the column to the cyclometallated species **7m** (see later). The structure of **3a** has been resolved by an X-ray analysis.

Molecular Structure of [PtCl(Me)(HL^3)] (3a)

The structure consists of the packing of discrete [PtCl(Me)(HL^3)] molecules. An ORTEP[12] view of the molecule is shown in Figure 1. Selected bond lengths and angles are reported in Table 2.

Table 1. ^1H NMR spectroscopic data of the adduct and the cyclometallated species, room temperature, solvent $CDCl_3$ unless otherwise stated, coupling constants in Hz, J_{Pt-H} in brackets, J_{H-H} in parentheses, chemical shift in ppm from internal TMS.

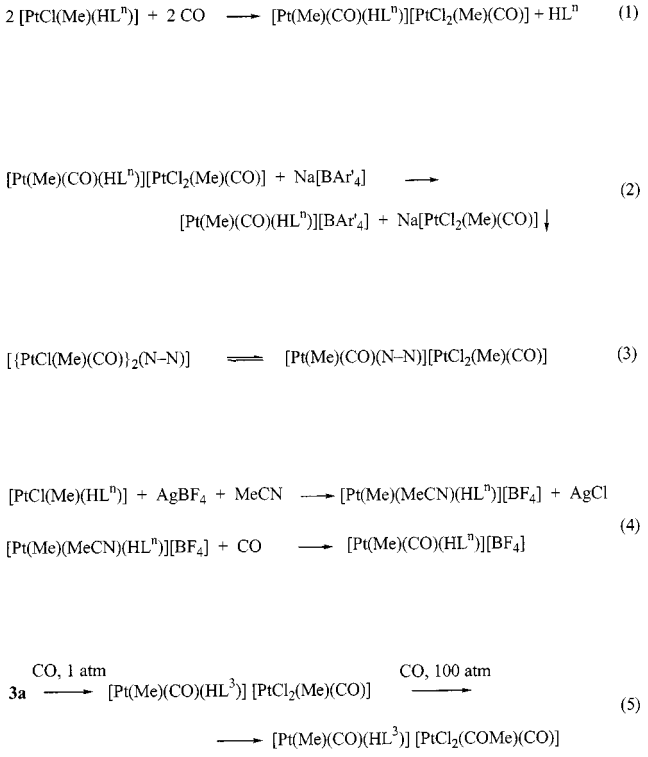
The platinum atom displays a square-planar coordination with a slight square-pyramidal distortion; maximum deviations from the best plane are +0.033(1) and −0.034(4) Å for Pt and N1, respectively. The Pt−Cl and Pt−N1 bond lengths, 2.299(2) and 2.022(4) Å, respectively, are normal and in good agreement with the corresponding values, 2.289(2) and 2.030(6) Å found in $[PtCl_2(HL)]$[13] [HL = diphenyl(2-pyridylmethyl)phosphane oxide]. The Pt−N2 distance, 2.188(4) Å, is rather long even after taking into account the *trans* influence of the Me ligand; compare Pt−N1 = 2.117(7) Å in [PtCl(L)][14] (HL = 6-*tert*-butyl-2,2′-bipyridine), where the pyridine N atom is *trans* to an alkyl group. The Pt−C13 bond length, 2.043(6) Å, is in good agreement with the corresponding value, 2.037(3) Å, found in $[Pt\{HOB(C_6F_5)_3\}(Me)(HL)]$[8b] (HL = 4,4′-di-*tert*-butyl-2,2′-bipyridine). The Cl−Pt−N2 angle, 103.1(1)°, is very large and is probably a result of the steric hindrance of the ethyl substituent on the bipyridine ligand. However, it must be observed that there is a clear intramolecular hydrogen bond between H8, bonded to C11, and the Cl atom (see Figure 1, Cl···H8 = 2.28 Å, C11−H8···Cl angle = 160.4°). The two pyridine rings are strictly planar and are twisted 9.8(2)° with respect to each other. A rather short distance (2.78 Å) between the chlorine atom of one molecule and the hydrogen atom H2, bonded to C2, of a neighbouring molecule, suggests the possibility of a weak intermolecular hydrogen bond.

The isolation of only one isomer (type **a**) for the adducts of the ligands HL^{1-5} deserves comments. Several factors can play a role in making isomer **a** the preferred one: *i*) in **a**, the Me group, more bulky than Cl, is far away from the R substituent; *ii*) owing to the higher *trans* influence of the methyl group with respect to the chloride ion, a methyl group *trans* to N2 can lengthen the Pt−N2 bond, thus relieving the steric effects of the R substituent; *iii*) the **a**-type isomer can be more stable due to the hydrogen bond between the chloride ion and the hydrogen atom on C(α) of the R substituent. The hydrogen bond could be responsible, at least in part, also for the deshielding of the α-hydrogen signals observed in the solution ^1H NMR: $[\delta_{complex} - \delta_{ligand}]$ = 0.54 (**2a**, 3 α-H), 0.82 (**3a**, 2 α-H), 1.92 (**4a**, 1 α-H), 0.92 (**5a**, 2 α-H).

The ligand HL^7 (R = Ph) lacks α-hydrogen atoms on the substituent, thus preventing the formation of a hydrogen bond with the chloride ion. Furthermore, the phenyl ring is sterically less demanding, owing to the ability of setting itself perpendicular to the coordination plane. Indeed, in this case both isomers **a** and **b** are formed in about a 1:1 ratio.

In order to obtain an insight into the role of the α-hydrogen atoms in driving the reaction selectively towards isomer **a**, several attempts were carried out to obtain the adduct of the *tert*-butyl-substituted ligand. No adduct was isolated and no evidence was provided by ^1H NMR spectra for its existence in solution. Actually, the reaction affords an unusual C(3)-metallated (C−N) species, $[PtCl(SMe_2)(L)]$ (HL = 6-*tert*-butyl-2,2′-bipyridine), with the loss of methane. The X-ray structure of this complex has recently been reported.[15]

Replacement of the chloride by an iodide ion has been carried out on **2a** and **3a** by reaction with LiI. Alternatively, these products can be obtained by reaction of the ligands HL^2 and HL^3 with *trans*-$[PtI(Me)(SMe_2)_2]$. The two procedures give the same products, the latter one in lower yield. Both isomers are obtained, **2a′**, **2b′** and **3a′**, **3b′**, the **a**-type isomers being the major products (77% for **2a′** and 79% for **3a′**). Therefore, it seems that both *α*-hydrogen atoms and a chloride ligand are required to make isomer **a** the more favoured isomer.



Cyclometallated Species

The synthesis of the adduct species is straightforward with all the ligands but HL^6 (R = $C(Me)_2Ph$). It behaves like an (N−N−C) tridentate ligand, affording only the cyclometallated species **6m** which arises from aromatic C−H activation and elimination of methane. Similar cyclometallated species are also obtained with HL^5 and HL^7 (Scheme 1). The adduct **5a** is not stable in chlorinated solvents, and slowly converts at room temperature to the cyclometallated species **5m**; **7m** is formed during the chromatographic separation of the mixture of isomers **7a** and **7b**.

Reaction with Carbon Monoxide

The reaction of the neutral adducts **1a**, **3a** and **5a** with carbon monoxide (p_{CO} = 1 atm) did not afford the corres-

ponding acyl derivatives, either at room temperature, or in refluxing chloroform. Only when working under high pressures of CO (ca. 100 atm) there is some evidence for slow formation of an acyl species (see later). Under mild conditions, the reaction proceeds to give the ionic species in accordance with Equation (1) of Scheme 2.

Scheme 2

The free ligand was recovered almost quantitatively from the reaction mixture. The ionic nature of the products was confirmed, by conductivity measurements in dichloromethane and acetone, and by FAB mass spectroscopy (positive and negative ions). The IR spectra show two strong absorptions at ca. 2100 and 2060 cm^{-1} due to the stretching vibrations of the terminal carbonyl groups (Table 3). The lower frequency can be assigned to the CO ligand of the anionic complex. The ^1H NMR spectra (Table 3) show two methyl signals; the more shielded one at $\delta = 0.87$ [$(CD_3)_2CO$ solution] is assigned to the anion and is unaffected by the type of the cation (**1c**, **3c**, **5c**), further supporting the hypothesis of two independent ions, one of which does not contain the (N−N) ligand. Indeed, the cations **1c**, **3c** and **5c** could be isolated as $[BAr'_4]^-$ salts {$[BAr'_4]^-$ = tetrakis[3,5-bis(trifluoromethyl)phenyl]borate} by exchange with Na[BAr'_4] [Equation (2), Scheme 2] in CH_2Cl_2 solution. The sodium salt of the anion could not be isolated owing to rapid decomposition.

It is worth noting that [**1c**] $[PtCl_2(Me)(CO)]$ is obtained in two forms that differ in colour, one is yellow and the other one red. Analytical and spectroscopic (^1H NMR, IR and MS) data support their identical composition, while UV spectra ($CHCl_3$ solution) show that the colour difference is due to an absorption at 410 nm (λ_{max}, $\varepsilon \approx 1500$ M^{-1} cm^{-1}) present in the red form. The absorption is concentration-dependent and disappears upon dilution, thus supporting stacking interactions between the anion and the cation and leading to charge-transfer phenomena.[16] Unfortunately, in spite of several attempts, we were unable to grow crystals suitable for X-ray determinations.

Tetraalkylammonium salts of $[PtCl_2(Me)(CO)]^-$ have previously been described[17] as having a *cis* configuration for the anion and our experimental data confirm this arrangement. In particular, the IR spectra show two Pt−Cl stretching frequencies at ca. 320 and 260 cm^{-1}.

A behaviour somewhat reminiscent of that observed in our complexes is described in the literature.[18] In the case of a complex with a 6-R-pyridine-2-carbaldehyde imine, carbonylation of pentacoordinated [PtCl(Me)(ethylene)-(N−N)] (N−N = 6-Me-py-2-CH=NPh) gave a mixture of products, in which free (N−N) and square-planar mono- and dinuclear complexes were detected. The main species is described as a dinuclear complex having a bridging (N−N) ligand; it is not an electrolyte in chloroform, but does dissociate in nitromethane according to the equilibrium shown in Equation (3), Scheme 2.

Cationic Species

The cationic complexes $[Pt(Me)(CO)(HL^n)]^+$ can also be obtained by halide abstraction from the neutral complexes with $AgBF_4$ and subsequent carbonylation of the solvent species [Equation (4), Scheme 2].

The ^1H NMR spectra of the cations obtained in this way are "exactly" superimposable on the spectra of the products obtained by direct carbonylation of the neutral complexes (Table 3), except for the methyl resonance of the anion $[PtCl_2(Me)(CO)]^-$. Although two isomers are possible for **3c** and **5c**, the carbonylation reaction is stereospecific affording only the **a**-type isomer, as confirmed by NOE difference experiment on **3c**[BF_4] (CD_3CN solution). Irradiation of H(6′) at $\delta = 8.90$ gives enhancement of the signal at $\delta = 1.40$ (Me) and vice versa. The linear structure of CO, which does not cause steric hindrance, most likely favours isomer **a**. The solvent species are obtained in good yields and can be isolated and characterised in the solid state. The structure of **3s**[BF_4] has been resolved by an X-ray analysis.

Molecular Structure of [Pt(Me)(MeCN)(HL^3)][BF_4] (**3s**[BF_4])

The structure consists of the packing of $[Pt(Me)(MeCN)(HL^3)]^+$ cations and $[BF_4]^-$ anions in the molar ratio 1:1. An ORTEP view of the molecule is shown in Figure 2. Selected bond lengths and angles are reported in Table 4.

The platinum atom displays a square-planar coordination with a slight square-pyramidal distortion; maximum deviations from the best plane are +0.011(1) and −0.005(4) Å for atoms Pt and C13, respectively. The Pt−N1, Pt−N2 and Pt−C13 bond lengths, 2.013(2), 2.173(3) and 2.036(4) Å, respectively, are very similar to the corresponding values, discussed above, observed in **3a**, 2.022(4), 2.188(4) and 2.043(6) Å. The Pt−N3 distance, 1.971(3) Å, can be com-

Table 3. ^{1}H NMR and selected IR data [cm^{-1}] of the ionic species

pared with the Pt−NCMe bond length, 1.955(4) Å, found in the cation $[Pt(Me)(MeCN)(Ar_2DAB)]^+$ [19] (Ar_2DAB = diaryldiazabutadiene). It is interesting also to observe that the N2−Pt−N3 angle, 103.7(1)°, is very similar to the N2−Pt−Cl angle, 103.1(1)°, found in **3a**, thus confirming the hypothesis that it is a result of the bulkiness of the ethyl substituent on the bipyridine ligand. The existence of intramolecular hydrogen bonds in this cation is more dubious, because the two hydrogen atoms bonded to C11 are 2.51 and 2.72 Å apart from atom N3, whereas one of the hydrogen atoms bonded to C13 lies 2.35 Å from N3. The two pyridine rings are strictly planar and are twisted 3.9(1.2)° with respect to each other. Four rather short interionic F···H interactions in the range 2.41−2.48 Å suggest the possibility of weak interionic hydrogen bonds.

A plausible reaction pathway that accounts for Equation (1) is shown in Scheme 3. The reaction implies (*i*) Addition of CO with displacement of a coordinated nitrogen and (*ii*) isomerisation of **A** to species **B**, having the chloride *trans* to the methyl group. Isomer **B** can re-establish the pentacycle with the bipyridine (*iii*) loosing a chloride ion or (*iv*) detach completely the bipyridine in the presence of chloride produced in step *iii*. Partial evidence for the formation of the

Scheme 3

cation **nc** and the anion $[PtCl_2(Me)(CO)]^-$ through **B** is provided by the reaction of **3c**$[BF_4]$ with LiCl in acetone, monitored by NMR spectroscopy. With excess LiCl, the ^1H NMR spectrum shows the total conversion of **3c** into $[PtCl_2(Me)(CO)]^-$ and free ligand, in an equimolecular ratio. If the reaction is carried out in the absence of excess LiCl, only the stoichiometric amount of **3c** reacts and there is no evidence of the presence of the species **B**, which seems to be very labile.

High-Pressure Carbonylation

As stated previously, we observe formation of an acyl species only when working under high pressures of CO. The acylation is indeed very slow, for example, in the case of complex **3a**, partial conversion (ca. 80%) of the ionic intermediate to an acyl species is obtained after 20 d [$p_{CO} \approx 100$ atm, Equation (5), Scheme 2].

The ^1H NMR spectra ($CDCl_3$ solution) clearly indicate that only the anion is involved in the acylation. In fact, the signals due to the cation species are not changed, while the intensity of the methyl signal (of the anion) is reduced and a new signal with satellites ($^3J_{Pt-H} = 10.3$ Hz) appears at $\delta = 2.49$; the intensities of the latter two resonances integrate to 3 protons. The IR spectra, in addition to strong bands in the region of terminal carbonyl groups, show a strong absorption at 1650 cm^{-1} and a new Pt−Cl stretch at 347 cm^{-1}.

Experimental Section

General: The unsymmetric 6-R-2,2′-bipyridine HL^{3-7} ligands were obtained through not trivial syntheses according to a procedure previously described,[20] the ligand HL^2 according to Kauffmann et al.[21] The compounds *trans*-$[PtCl(Me)(SMe_2)_2]$,[22] *trans*-$[PtI(Me)(SMe_2)_2]$[22] and $Na[BAr'_4]$[23] {sodium tetrakis[3,5-bis(trifluoromethyl)phenyl]borate} were prepared as reported elsewhere. All solvents were freshly distilled prior to use. Reactions with CO under pressure were performed with a Pyrex bottle in a stainless steel autoclave. − Elemental analyses were performed with a Perkin−Elmer Elemental Analyzer 240B by Mr A. Canu (Dipartimento di Chimica, Università di Sassari). − Conductivities were measured with a Philips PW 9505 conductimeter. − Infrared spectra (Nujol mull or CH_2Cl_2 solution) were recorded in the range 4000−180 cm^{-1} with a Perkin−Elmer 983 spectrophotometer. − UV spectra ($CHCl_3$ solution) were determined with a Hitachi 2010 spectrophotometer. − ^1H NMR spectra were recorded with a Varian VXR 300 spectrometer operating at 299.9 MHz and the selected data are collected in Table 1 and Table 3; the chemical shifts are given in ppm relative to internal TMS and were determined by reference to the residual ^1H solvent peaks. − Mass spectra were obtained with a VG 7070EQ instrument operating under FAB conditions with 3-nitrobenzyl alcohol as a supporting matrix.

[PtCl(Me)(HL^1)] (1a): A solution of the ligand (46.4 mg, 0.297 mmol) in CH_2Cl_2 (10 mL) was added to a solution of *trans*-$[PtClMe(SMe_2)_2]$ (100.0 mg, 0.270 mmol), in the same solvent (20 mL). The solution was stirred for 3 h and then concentrated under vacuum to a small volume, hexane was added dropwise affording a yellow solid adduct. Yield 102.0 mg (94%); m.p. 250 °C. − $C_{11}H_{11}ClN_2Pt$: calcd. C 32.88, H 2.77, N 6.97; found C 32.55, H 2.89, N 6.72. − FAB-MS; *m/z*: 401 $[M]^+$, 386 $[M - Me]^+$, 366 $[M - Cl]^+$, 351 $[M - Cl - Me]^+$. − IR (Nujol): $\tilde{\nu}$ = 1599 s, 1555 m, 333 s cm^{-1}.

The other adduct species were obtained according to the same procedure but with different reaction times.

[PtCl(Me)(HL^2)] (2a): 30 min, orange. Yield 97%, m.p. 176−177 °C. − $C_{12}H_{13}ClN_2Pt$: calcd. C 34.66, H 3.16, N 6.74; found C 34.43, H 3.05, N 6.38. − FAB-MS; *m/z*: 415 $[M]^+$, 400 $[M - Me]^+$, 380 $[M - Cl]^+$, 365 $[M - Cl - Me]^+$. − IIR (Nujol): $\tilde{\nu}$ = 1600 s, 1556 m, 320 s cm^{-1}.

[PtI(Me)(HL^2)] (2a′+2b′): LiI (43.4 mg, 0.325 mmol) was added to a solution of **2a** (45.0 mg, 0.108 mmol) in acetone (20 mL). The solution was stirred for 20 h at room temperature. It was then concentrated to dryness and the residue dissolved in CH_2Cl_2, filtered and concentrated to a small volume. Addition of hexane gave an orange analytical sample. Yield 45.0 mg (82%); m.p. 134−136 °C (mixture). The reaction between *trans*-$[PtIMe(SMe_2)_2]$ and the ligand in CH_2Cl_2 gave the products in 32% yield. − $C_{12}H_{13}ClN_2Pt$: calcd. C 28.41, H 2.59, N 5.52; found C 28.25, H 2.35, N 5.30. − IR (Nujol): $\tilde{\nu}$ = 1597 s, 1556 m cm^{-1}.

[PtCl(Me)(HL^3)] (3a): 30 min, yellow. Yield 84%; m.p. 142−144 °C. − $C_{13}H_{15}ClN_2Pt$: calcd. C 36.32, H 3.52, N 6.52; found C 35.95, H 3.64, N 6.27. − FAB-MS; *m/z*: 414 $[M - Me]^+$, 379 $[M - Cl - Me]^+$. − IR (Nujol): $\tilde{\nu}$ = 1599 s, 1565 m, 321 s cm^{-1}.

[PtI(Me)(HL^3)] (3a′ + 3b′): The title compounds were prepared according to the two procedures described for **2a′** and **2b′**. Orange. Yields: 80−40%; m.p. 97−100 °C (dec., mixture). − $C_{13}H_{15}IN_2Pt$: calcd. C 29.95, H 2.91, N 5.38; found C 30.08, H 2.76, N 5.32. − IR (Nujol): $\tilde{\nu}$ = 1595 s, 1556 m cm^{-1}.

[PtCl(Me)(HL^4)] (4a): 4.5 h. Pale yellow. Yield 68%; m.p. 85−89 °C (dec. with gas evolution). − $C_{14}H_{17}ClN_2Pt$: calcd. C 37.88, H 3.87, N 6.31; found C 37.60, H 3.55, N 5.95. − FAB-MS; *m/z*: 443 $[M]^+$, 428 $[M - Me]^+$, 393 $[M - Cl - Me]^+$. − IR (Nujol): $\tilde{\nu}$ = 1599 s, 1562 m, 317 s cm^{-1}.

[PtCl(Me)(HL^5)] (5a): 30 min. Orange. Yield 73%; m.p. 147−150 °C. − $C_{18}H_{17}ClN_2Pt$: calcd. C 43.95, H 3.49, N 5.70; found C 43.69, H 3.38, N 5.52. − FAB-MS; *m/z*: 476 $[M - Me]^+$, 456 $[M - Cl]^+$, 441 $[M - Cl - Me]^+$. − IR (Nujol): $\tilde{\nu}$ = 1596 s, 1562 m, 702 s, 322 s cm^{-1}.

[PtCl(L^5)] (5m): A solution of **5a** in CH_2Cl_2 was stirred at room temperature for 4 d. It was then concentrated under vacuum to a small volume and diethyl ether was added dropwise, affording the title complex in a quantitative yield. The product was a yellow solid; m.p. 247−249 °C. − $C_{17}H_{13}ClN_2Pt$: calcd. C 42.91, H 2.76, N 5.89; found C 42.71, H 2.51, N 5.67. − FAB-MS; *m/z*: 475 $[M]^+$, 440 $[M - Cl]^+$. − IR (Nujol): $\tilde{\nu}$ = 1600 s, 340 s, 319 s cm^{-1}.

[PtCl(L^6)] (6m): A solution of the ligand (89.8 mg, 0.327 mmol) in CH_2Cl_2 (10 mL) was added to a solution of *trans*-[PtClMe(SMe_2)$_2$] (110.0 mg, 0.297 mmol), in the same solvent (20 mL). The solution was stirred for 2 h and then concentrated under vacuum to a small volume. Hexane was added dropwise to afford the cyclometallated species as an orange solid. Yield 94.4 mg (63%);. m.p. stable at 280 °C. − $C_{19}H_{17}ClN_2Pt$: calcd. C 45.28, H 3.41, N 5.56; found C 45.00, H 3.51, N 5.34. − FAB-MS; *m/z*; 503 $[M]^+$, 468 $[M - Cl]^+$. − IR (Nujol): $\tilde{\nu}$ = 1595 s, 1568 m, 339 s cm^{-1}.

[PtCl(Me)(HL^7)] (7a + 7b): 4 h. Orange. Yield 84%; m.p. 258 °C (mixture). − $C_{17}H_{15}ClN_2Pt$: calcd. C 42.72, H 3.17, N 5.86; found C 42.45, H 3.07, N 5.71. − IR (Nujol): $\tilde{\nu}$ = 1595 s, 1573 s, 697 s, 337 s cm^{-1}.

[PtCl(L^7)] (7m): The two isomers, **7a + 7b**, were separated by chromatography on neutral Al_2O_3 (activity II) by elution with dichloromethane. **7b** was recovered in the first fraction, whereas **7a** underwent a decomposition affording the cyclometallated species **7m**: red-orange; m.p. stable at 280 °C. − $C_{16}H_{11}ClN_2Pt$: calcd. C 41.61, H 2.41, N 6.07; found C 41.53, H 2.33, N 6.08. − IR (Nujol): $\tilde{\nu}$ = 1590 s, 1570 m, 328 s cm^{-1}.

1c[PtCl$_2$(Me)(CO)]: CO was bubbled through a stirred orange solution of **1a** (110.0 mg, 0.274 mmol) in CH_2Cl_2 (20 mL) at room temperature. After 2.5 h, the solution became pale yellow. It was concentrated under vacuum to a small volume, diethyl ether was then added dropwise affording a yellow solid which was filtered and collected (67.0 mg, m.p. 149 °C). The filtrate was concentrated to dryness and the oily residue washed with diethyl ether several times to give a red solid which was recrystallised from CH_2Cl_2/diethyl ether (14.0 mg, m.p. 148 °C). Yield 81.0 mg (84%). From the mother liquor, some ligand was recovered (20.0 mg, 0.128 mmol). − $C_{14}H_{14}Cl_2N_2O_2Pt_2$: calcd. C 23.91, H 2.01, N 3.98; found C 23.75, H 2.12, N 4.36. (the microanalysis refers to the yellow form, the one of the red form is very similar). − FAB-MS; *m/z*: 394 $[M]^+$, 379 $[M - Me]^+$, 366 $[M - CO]^+$, 351 $[M - Me - CO]^+$, 308 $[N]^-$, 293 $[N-Me]^-$, 280 $[N-CO]^-$, 265 $[N-Me-CO]^-$. − IR (CH_2Cl_2): $\tilde{\nu}$ = 2104 vs, 2060 vs; (Nujol) 2093 vs, 2045 vs, 1602 s, 318 m, 262 m cm^{-1}(the spectroscopic data are identical for the yellow and the red form). − UV ($CHCl_3$): λ_{max} (yellow form) = 335 nm ($c = 10^{-3}$ M); red form: 335 nm, 410 nm ($c = 10^{-3}$ M), 300 nm ($c = 2{\cdot}10^{-5}$ M).

1s[BF$_4$]: A solution of $AgBF_4$ (48.5 mg, 0.249 mmol) in MeCN (5 mL) was added dropwise to a stirred orange solution of **1a** (100.0 mg, 0.249 mmol) in CH_2Cl_2 (10 mL). The mixture was stirred in the absence of light for 0.5 h at room temperature, it was then filtered through a Celite filter aid, affording a yellow filtrate. The solvent was removed in vacuo to give an orange-yellow solid, which was recrystallised from CH_2Cl_2/diethyl ether, affording a brick-red solid. Yield 110.7 mg (90%); m.p. 218−226 °C (dec.). − $C_{13}H_{14}BF_4N_3Pt$: calcd. C 31.60, H 2.86, N 8.50; found C 31.49, H 2.81, N 8.25. − FAB-MS; *m/z*: 407 $[M]^+$, 392 $[M - Me]^+$, 366 $[M - MeCN]^+$, 351 $[M - Me - MeCN]^+$. − IR (Nujol): $\tilde{\nu}$ = 2359−2303 vw, 1600 m, 1058 vs cm^{-1}.

1c[BF$_4$]: CO was bubbled through a stirred orange solution of **1s**[BF_4] (200.0 mg, 0.405 mmol) in CH_2Cl_2 (50 mL) at room temperature. After 20 h, the solution was lemon-yellow, it was concentrated under vacuum to a small volume and diethyl ether was then added dropwise, affording a pale yellow solid in a quantitative yield (193.7 mg); m.p. 260−270 °C (dec.). − $C_{12}H_{11}BF_4N_2OPt$: calcd. C 29.95, H 2.31, N 5.82; found C 29.60, H 2.11, N 5.59. − IR (Nujol): $\tilde{\nu}$ = 2119 vs, 1598 s, 1060 vs cm^{-1}.

1c[BAr′$_4$]: Na[BAr′$_4$] (62.9 mg, 0.071 mmol) was added to a stirred solution of **1c**[$PtCl_2$(Me)(CO)] (50.9 mg, 0.072 mmol) in CH_2Cl_2 (5 mL). After a few minutes, the solution was filtered through a Celite filter aid, concentrated to dryness and then dried in vacuo. The off-white solid was recrystallised from CH_2Cl_2/hexane. Yield 89.3 mg (quantitative). m.p. 139−141 °C. − $C_{44}H_{23}BF_{24}N_2OPt$: calcd. C 42.02, H 1.85, N 2.23; found C 41.70, H 1.67, N 2.38. − FAB-MS; *m/z*: 394 $[M]^+$, 379 $[M - Me]^+$, 366 $[M - CO]^+$, 351 $[M - Me - CO]^+$, 863 $[N]^-$. − IR (Nujol): $\tilde{\nu}$ = 2100 s, 1600 m, 1120 vs cm^{-1}.

3c[PtCl$_2$(Me)(CO)]: CO was bubbled through a deep yellow solution of **3a** (52.0 mg, 0.121 mmol) in CH_2Cl_2 (20 mL) at room temperature. After 1 h, the resulting pale yellow solution was concentrated to dryness and the oily residue washed with diethyl ether to afford a pale-yellow solid which was recrystallised from CH_2Cl_2/diethyl ether. The free ligand (9.9 mg, 0.054 mmol) was recovered from the mother liquor. Yield 41.1 mg (93%). m.p. 153 °C (dec.). − $C_{16}H_{18}Cl_2N_2O_2Pt_2$: calcd. C 26.27, H 2.48, N 3.83; found C 26.37, H 2.16, N 3.64. − FAB-MS; *m/z*: 422 $[M]^+$, 407 $[M - Me]^+$, 379 $[M - Me - CO]^+$, 308 $[N]^-$, 293 $[N-Me]^-$, 280 $[N-CO]^-$, 265 $[N-Me-CO]^-$, 258 $[N-Me-Cl]^-$. − IR (CH_2Cl_2): $\tilde{\nu}$ = 2099 vs, 2059 vs; (Nujol) 2084 vs, 2043 vs, 1601 s, 1568 m, 320 s, 262 m cm^{-1}.

3s[BF$_4$]: The title complex was prepared in the same manner as **1s**[BF_4]. A bright-yellow solid was obtained (the dropwise addition of diethyl ether caused the precipitation of a bright-red solid which was rapidly converted into a bright-yellow one). Yield 81%. m.p. 215 °C (dec.). − $C_{15}H_{18}BF_4N_3Pt$: calcd. C 34.49, H 3.48, N 8.05; found C 34.41, H 3.32, N 7.97. − FAB-MS; *m/z*: 435 $[M]^+$, 420 $[M - Me]^+$, 394 $[M - MeCN]^+$, 379 $[M - Me - MeCN]^+$. − IR (Nujol): $\tilde{\nu}$ = 2358−2332 vw, 1600 m, 1563 m, 1052 vs cm^{-1}

3c[BF$_4$]: The title complex was prepared in the same manner as **1c**[BF_4]. 10 h, colourless solution. Quantitative yield; m.p. 235−238 °C. − $C_{14}H_{15}BF_4N_2OPt$: calcd. C 33.02, H 2.98, N 5.50; found C 32.74, H 2.60, N 5.39. − FAB-MS; *m/z*: 422 $[M]^+$, 407 $[M - Me]^+$, 394 $[M - CO]^+$, 379 $[M - Me - CO]^+$. − IR (CH_2Cl_2): $\tilde{\nu}$ = 2100 vs, (Nujol) 2109 vs, 1599 s, 1566 m, 1057 vs cm^{-1}.

3c[BAr′$_4$]: The title complex was prepared in the same manner as **1c**[BAr′$_4$]. Yield: quantitative; m.p. 129 °C. − $C_{46}H_{27}BF_{24}N_2OPt$: calcd. C 42.97, H 2.12, N 2.18; found C 42.64, H 2.02, N 2.38. − FAB-MS; *m/z*: 422 $[M]^+$, 407 $[M - Me]^+$, 394 $[M - CO]^+$, 379 $[M - Me - CO]^+$. − IR (Nujol): $\tilde{\nu}$ = 2100 s, 1600 m, 1120 vs cm^{-1}.

5c[PtCl$_2$(Me)(CO)]: The title complex was prepared in the same manner as **3c**[$PtCl_2$(Me)(CO)]. Pale-yellow. Yield 90%; m.p. 154−158 °C (dec.). − $C_{21}H_{20}Cl_2N_2O_2Pt_2$: calcd. C 31.78, H 2.54, N 3.53; found C 32.04, H 2.29, N 3.74. − FAB-MS; *m/z*: 484 $[M]^+$, 468 $[M - CH_4]^+$, 440 $[M - CH_4 - CO]^+$, 308 $[N]^-$, 293 $[N-Me]^-$, 280 $[N-CO]^-$, 265 $[N-Me-CO]^-$, 258 $[N-Me-Cl]^-$. − IR (CH_2Cl_2): $\tilde{\nu}$ = 2100 vs, 2060 vs; (Nujol) 2081 vs, 2055 vs, 1605 s, 1568 m, 702 s, 323 s, 274 s cm^{-1}.

X-ray Data Collections and Structure Determinations: Crystal data and other experimental details are summarised in Table 5. The diffraction experiments were carried out with a Siemens SMART CCD area detector diffractometer at room temperature using Mo-K_α radiation (λ = 0.71073 Å) with a graphite crystal monochromator in the incident beam. Cell parameters and orientation matrices were obtained from the least-squares refinement of 83 (for **3a**) and 52 (for **3s**[BF_4]) reflections measured in three different sets of 15 frames each, in the range $3° < \theta < 23°$. At the end of the data collections the first 50 frames, containing 251 (for **3a**) and 180 (for **3s**[BF_4]) reflections, were recollected in order to monitor the crystal

Table 5. Crystallographic data

Compound	**3a**	**3s**[BF_4]
Empirical formula	$C_{13}H_{15}ClN_2Pt$	$C_{15}H_{18}BF_4N_3Pt$
M	429.82	522.23

μ (Mo-K_α) [cm^{-1}]	109.6	83.6
Min. and max. transm. factors	0.50−1.00	0.50−1.00
Scan mode	ω	ω
Frame width [°]	0.30	0.30
Time per frame [s]	15	20
No. of frames	2450	2450
Detector−sample distance [cm]	5.00	5.00
θ range [°]	3−26	3−26
Reciprocal space explored (*h*, *k*, *l*)	±9, ±13, ±24	±10, ±12, ±17
No. of reflections (total; independent)	15516; 3192	9996; 3987
R_{int}	0.051	0.033
Final R_2 and R_{2w} indices[a] (F^2, all reflections)	0.042, 0.054	0.035, 0.044
Conventional R_1 index [$I > 2\sigma(I)$]	0.024	0.020
Reflections with $I > 2\sigma(I)$	2735	3265
No. of variables	154	217
Goodness of fit[b]	1.06	0.95

[a] $R_2 = [\Sigma(|F_o^2 - kF_c^2|)/\Sigma F_o^2]$, $R_{2w} = [\Sigma w(F_o^2 - kF_c^2)^2/\Sigma w(F_o^2)^2]^{1/2}$. − [b] $[\Sigma w(F_o^2 - kF_c^2)^2/(N_o - N_v)]^{1/2}$, where $w = 4F_o^2/\sigma(F_o^2)^2$, $\sigma(F_o^2) = [\sigma^2(F_o^2) + (0.04F_o^2)^2]^{1/2}$, N_o is the number of observations and N_v the number of variables.

decay, which was not observed, so that no time-decay correction was needed. The 2450 (for both **3a** and **3s**[BF_4]) collected frames were processed with the software SAINT,[24] and an empirical absorption correction was applied (SADABS[25]) to the 15516 collected reflections of **3a**, 3192 of which are unique with $R_{int} = 0.051$ ($R_{int} = \Sigma|F_o^2 - F_{mean}^2|/\Sigma F_o^2$), and to the 9996 collected reflections of **3s**[BF_4], 3987 of which are unique with $R_{int} = 0.033$. Scattering factors and anomalous dispersion corrections were taken from ref.[26] The calculations were performed with an AST Power Premium 486/33 computer using the Personal Structure Determination Package[27] and the physical constants tabulated therein. The structures were solved by Patterson and Fourier methods and refined by full-matrix least squares, using all reflections and minimising the function $\Sigma w(F_o^2 - k|F_c^2|)^2$ (refinement on F^2). Anisotropic thermal factors were refined for all the non-hydrogen atoms. The hydrogen atoms of the methyl group bonded to the platinum center and those of the methyl group belonging to the acetonitrile ligand were detected in the final Fourier maps and not refined. All the other hydrogen atoms were placed in their ideal positions (C−H = 0.97 Å, *B* 1.10 times that of the carbon atom to which they are attached) and not refined. For the noncentrosymmetric compound **3a**, full refinement of the reported structure model led to $R_2 = 0.042$ and $R_{2w} = 0.054$, full refinement of the structure enantiomorph led to $R_2 = 0.056$ and $R_{2w} = 0.094$. The final Fourier maps show maximum residuals of 1.7(4) e/Å^3 at 0.85 Å from Pt for **3a**, and of 0.88(30) e/Å^3 at 1.06 Å from Pt for **3s**[BF_4]. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-142180 (**3a**) and -142181 (**3s**[BF_4]). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

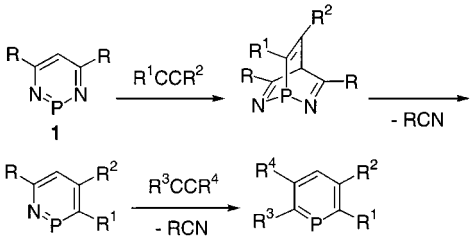
Syntheses of Phosphinine-Based Tripodal Ligands

Ute Rhörig,[a] Nicolas Mézailles,[a] Nicole Maigrot,[a] Louis Ricard,[a] François Mathey,*[a] and Pascal Le Floch*[a]

Keywords: Phosphorus heterocycles / Phosphinines / Cycloadditions / Tungsten / Tripodal ligands

The syntheses of several tripodal phosphinine-based ligands are presented. 1,3,2-Diazaphosphinine **(1)** undergoes Diels–Alder reactions with tris-(propynyl)phenylsilane to yield tris-(1,2-azaphosphinine)phenylsilane **6**. This intermediate serves as precursor for the preparation of two tripodal ligand. First, tris(phosphinine)phenylsilane **(7)** is obtained from the reaction with trimethylsilylacetylene. Under more drastic conditions, compound **6** reacts with 4-octyne to yield the tripodal ligand **8** containing six *n*-propyl groups. Reaction of **8** with $[W(CO)_5(THF)]$ affords the corresponding $W(CO)_3$ complex **9** whose structure was confirmed by an X-ray crystallographic study. The synthesis of two extended tripodal ligands **12** and **13** containing three phosphinine units each connected to the same CH linker by dimethylsilyl groups was also studied. As a prerequisite, the precursor tris(propynyldimethylsilyl)methane **(10)** was synthesized by reaction of three equivalents of propynyllithium with tris(bromodimethylsilyl)methane. Reaction of excess **1** with **10** yielded the corresponding tris(dimethylsilyl-1,2-azaphosphinine)methane **(11)** as an intermediate. The formation of ligands **12** and **13** was achieved by reacting **11** with trimethylsilylacetylene or 4-octyne, respectively, in excess. The reaction of ligand **13** with $[W(CO)_5(THF)]$ in toluene yielded the corresponding $W(CO)_3$ complex **14** which was structurally characterized.



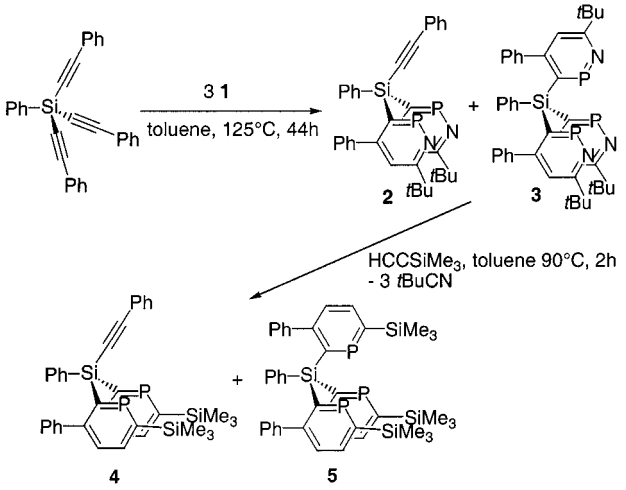
Introduction

Polydentate phosphane ligands continue to attract a lot of interest from both coordination and organometallic chemists. This is mainly due to their unique structural and electronic properties which allow the stabilization of many metallic centers with various oxidation states and geometries.[1] Furthermore, transition metal complexes of such ligands have shown an interesting potential in many catalytic processes of importance. Indeed, tripodal systems have been successfully used in the hydrogenation of alkynes, alkenes and nitriles, hydroformylation and isomerization reactions of alkenes, oligomerization and polymerization of alkynes,[2] C−H activation of unsaturated substrates[3] and, very recently, Bianchini et al. have reported the use of soluble metal complexes for hydrogenation, hydrogenolysis and desulfurization of thiophenic substrates.[4] For synthetic reasons most of these ligands usually bear *P*-alkyl or *P*-aryl groups as binding sites and tripodal structures incorporating strong π-acceptor phosphane groups are still rather rare.[5]

In the course of our studies on phosphinines we became interested in synthesizing analogs of these tripodal ligands. Phosphinines are known to be excellent π-acceptor ligands which significantly increase the Lewis-acidity of the metal centers to which they are coordinated.[6] Furthermore, they have shown a strong ability to stabilize very electron-rich metallic centers,[7] and recently, the synthesis of a remarkably stable gold(0) complex in which a phosphinine-based macrocycle acts like a "CO matrix" was reported.[8] Though some sp^2-based tridentate ligands with phosphaalkenes[9] and phosphinines[10] are known, tri- or tetrapodal ligands including P=C bonds are still unknown. Herein we wish to report on a simple synthetic methodology which allows the assembly of these phosphinine-based tripodal structures.

Results and Discussion

Synthetic approaches allowing the connection of phosphinines are rare and often require multi-step sequences. To circumvent this limitation, we developed a simple strategy relying on the reactivity of 1,3,2-diazaphosphinines.[11] As shown below, these heterocycles react with one equivalent of alkyne to give 1,2-azaphosphinines, which can subsequently be transformed into phosphinines at higher temperatures when a second equivalent of alkyne is reacted (Scheme 1). These thermally promoted transformations involve two successive [4+2] cycloaddition/cycloreversion sequences with the concomitant release of two molecules of nitrile. In a series of articles we showed that this approach was indeed particularly efficient for building sophisticated



Scheme 1. Reactivity of 1,3,2-di- and 1,2-azaphosphinines towards alkynes

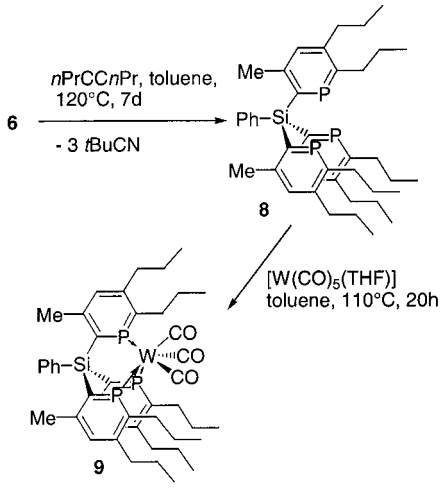
structures such as 2,3,5,6-tetrafunctionalized rings,[10] bis- and tris-phosphinines and phosphinine-based macrocycles.[12]

Quite logically we attempted to see whether this method could be transferred to the synthesis of tripodal structures with triynes. In all our experiments, the readily available 4,6-di-*tert*-butyl-1,3,2-diazaphosphinine **(1)** was used as precursor.[11] As the regioselectivity in the cycloaddition reaction can be a problem, we focused on silyl-substituted alkynes which usually react regiospecifically. Previous studies have indeed shown that the silyl-substituted carbon atom of the alkyne reacts exclusively at phosphorus, and therefore the silicon group is always located at the α-carbon atom in the final compound.[10–12] A first series of experiments demonstrated that the bulkiness of the alkyne is of utmost importance. Thus, the reaction of tris(phenylethynyl)phenylsilane with four equivalents of **1** in toluene at 125 °C yields a mixture of two compounds whose structures were ascribed, on the basis of their ^{31}P NMR spectroscopic data, to the bis(1,2-azaphosphinine)silane **(2)** (80%) (δ = 308.3) and the expected tris(1,2-azaphosphinine)silane **(3)** (20%) (δ = 307.5). Whatever the experimental conditions used (temperature, ratio of precursors, heating time), the formation of **3** never exceeded 20%: the presence of a phenyl group at the β-position of the phosphinine very likely hampers the third cycloaddition leading to **3**. To confirm our hypothesis about the structures of **2** and **3**, trimethylsilylacetylene was reacted with the mixture of compounds. After two hours of heating at 90 °C in toluene, the bis(phosphinine)phenylethynylsilane **(4)**, the desired tripodal ligand **5** and traces of the 2,6-bis(trimethylsilyl)phosphinine[11] resulting from the reaction of the excess of **1** with the alkyne were formed. Whereas this latter could easily be eliminated by chromatographic purification, complete separation of **4** and **5** turned out to be impossible and only compound **4** was isolated in pure form. Nevertheless, mass spectroscopy measurements carried out on a mixture of both compounds allowed us to confirm the proposed structure for ligand **5** {*m*/*z* (%) = 823 (10) [M]} (Scheme 2).

Scheme 2. Synthesis of ligands **4** and **5**



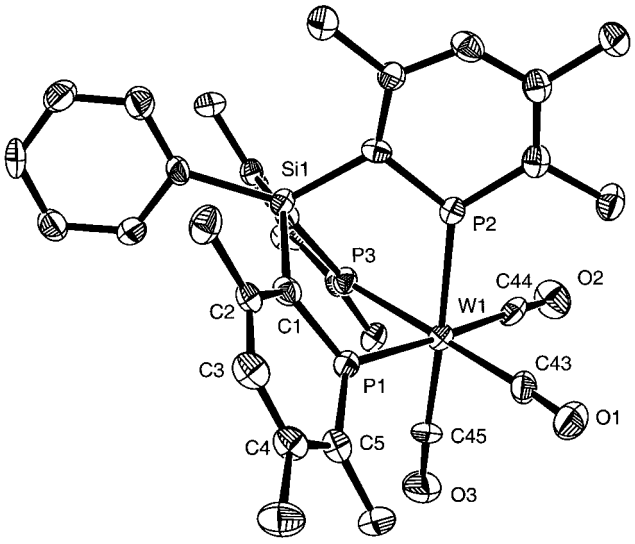
Better results were obtained simply by replacing the phenyl group of the alkyne moiety by a methyl group. Tris(propynyl)phenylsilane reacts with four equivalents of **1** to yield, after 20 hours at 100 °C, a mixture of **1** and a compound which gives a singlet in the ^{31}P NMR spectrum at δ = 308.0. On the basis of this chemical shift, which compares well with those of other 3-silyl-substituted-1,2-azaphosphinines, its formula was ascribed to that of the expected intermediate, the tris(1,2-azaphosphinine)phenylsilane **(6)**. In a subsequent step, **6** was reacted with trimethylsilylacetylene in excess. After 2 hours at 90 °C, the tripodal ligand **7** was formed together with traces of the 2,6-bis(trimethylsilyl)phosphinine.[11] The formulation of **7** was elucidated by conventional NMR spectroscopy and mass spectrometry. A significant piece of information is found in the ^{13}C NMR spectrum of **7**: the signal of the C2-carbon atom appears as a doublet of triplets due to the coupling to the neighboring P atom (^1J = 87.5 Hz) and to the two other magnetically equivalent P atoms of the other rings (^3J = 5.5 Hz) (Scheme 3).

Scheme 3. Synthesis of ligand **7**

Unfortunately, although somewhat predictably, the presence of three peripheral silyl groups in ligand **7** preclude complexation to non-sterically demanding $M(CO)_3$ fragments {M = Cr, Mo, W, with $[Cr(CO)_4(CH_3CN)_2]$, $[Mo(CO)_4(nbd)]$, $[W(CO)_5(THF)]$ or $[W(CO)_4(CH_3CN)_2]$ as precursors}. To alleviate the steric bulk around the cavity, we therefore decided to replace these silyl substituents by alkyl groups. To avoid the formation of many isomers, we decided to use the symmetrical 4-octyne. As previously observed, the use of a nonpolar alkyne dramatically decreases the rate of the reaction and seven days of heating at 120 °C were necessary to ensure the complete formation of ligand **8**, which was isolated as a yellow oil in 76% yield (Scheme 4).

Unequivocal evidence for the proposed structures were provided by NMR spectroscopy and mass spectrometry. As a result of alkyl substitution, the ^{31}P NMR chemical shift of **8** appears at rather high field (δ = 247.0) compared to that of phosphinine **7** (δ = 272.6). As postulated, the introduction of smaller groups at the α-positions frees the access to the cavity and complexation can now be achieved. Reaction of $[W(CO)_5(THF)]$ with **8** yields the expected $W(CO)_3$

Scheme 4. Synthesis of ligand **8** and complex **9**



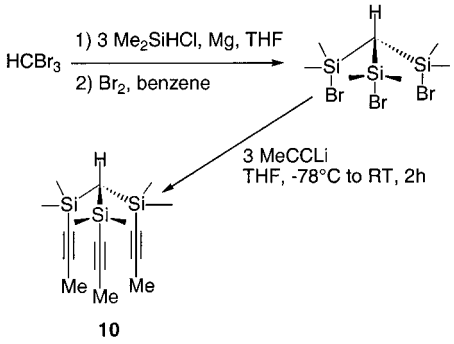


Figure 1. ORTEP drawing of **9** as determined by a single-crystal X-ray diffraction analysis; ellipsoids are drawn to enclose 50% of the electron density; the hydrogen atoms of the CH_2CH_3 grouping of the *n*-propyl substituent have been omitted for clarity[a]
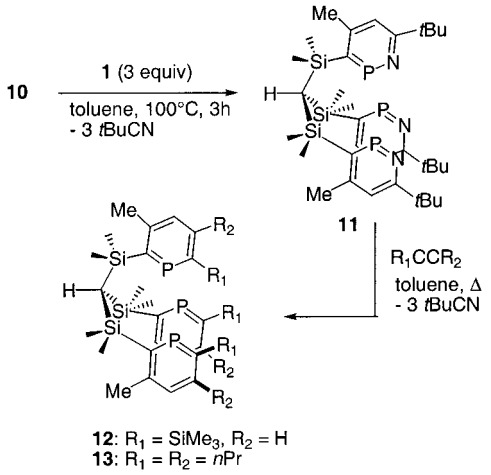
[a] Selected bond lengths [Å] and angles [°]: W−P1 2.437(2), W−P2 2.502(2), W−P3, 2.427(2), W−C43, 2.00(1), W−C44, 2.02(1), W−C45 1.998(8), Si1−C1, 1.907(8), P1−C1 1.723(8), C1−C3, 1.40(1), C2−C3, 1.39(1), C3−C4 1.39(1), C4−C5 1.38(1), C5−P1 1.733(8), P1−W−P2, 84.76(7), P1−W−P3 84.56(7), P3−W−P1, 88.47(6), P1−W−C44 176.8(2), P2−W−C45 177.3(3), P3−W−C43 179.3(3), C5−P1−C1, 107.4(4), C6−C16 131.24(3), C1−C16, 100.93(3), C11−C16 101.62(3)

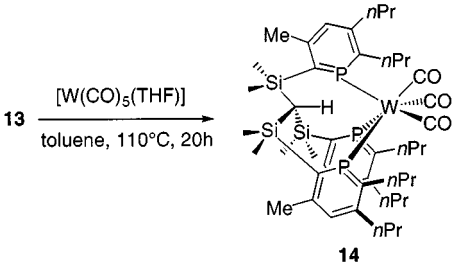
complex **9** after refluxing for 20 hours in toluene (Scheme 4).

Complex **9** was characterized by conventional NMR techniques, IR spectroscopy and elemental analysis. As frequently observed with phosphinines, coordination to a tungsten carbonyl fragment induces a significant upfield shift ($\delta = 213.1$, $\Delta\delta = -34$). In the ^{13}C NMR spectrum, the very characteristic doublet of triplets at $\delta = 210$, assignable to three magnetically equivalent carbonyl ligands, is found. Indeed, each carbonyl group is located *trans* to one phosphorus atom ($^2J = 29.0$ Hz) and *cis* to the other two ($^2J = 7.0$ Hz). Finally, as expected for strong π-acceptor ligands, the bands in the IR spectrum are shifted towards higher frequencies (1950 and 1875 cm^{-1}) than for "analogous" phosphane complexes[13a] {1930 and 1834 in $[MeC(CH_2PPh)_3W(CO)_3]$}.[13b] Slow diffusion of methanol (or pentane) into a dichloromethane solution of **9** furnished crystals suitable for an X-ray study. An ORTEP view of the structure is shown in Figure 1. The crystallographic labelling used is arbitrary and differs from the numbering utilized for NMR spectral assignments. As expected from NMR and IR spectroscopic data, the tripodal ligand occupies one face of the octahedron leaving three structurally equivalent carbonyls ligands. As previously observed in the X-ray structure of $[W(CO)_3$(silacalix-3-phosphinine)],[12a] a strain is found in the coordination sphere of tungsten, and the P−W−P angles are slightly smaller than the ideal value of 90° [ranging from 84.46(7) to 88.47(6)]. On the other hand, the internal bond lengths in the three phosphinine subunits are close to those recorded for free 2-substituted silylphosphinines,[12] thus indicating that aromaticity is not significantly perturbed. A similar observation has been made for $[W(CO)_5$(2-chlorophosphinine)].[14] The most surprising feature concerns the geometry around the silicon atom, where a significant deviation from the ideal tetrahedral geometry can be observed. Whereas four C−Si−C angles are "normal" [100.9(3) to 103.2(3)°], C1−Si1−C6 [119.3 (3)°] and C16−Si1−C11 [131.2(3)°] are strongly widened. This phenomenon very likely reflects a strong steric crowding between the hydrogen atoms of the phenyl substituent and those of the three methyl groups which point towards the top of the ligand. With this particular arrangement, the shortest through-space H(phenyl)−H(methyl) interaction measured is 2.29 Å.



Being encouraged by these first results, we then attempted to enlarge the scope of our method to the preparation of more sophisticated polydentate species, such as extended tripodal ligands. We selected tris(propynyldimethylsilane)methane **(10)** as the starting material. Preparation of this molecule was readily achieved by reaction of three equivalents of propynyllithium with one equivalent of tris(bromodimethylsilyl)methane, whose synthesis was reported by Gade and Becker (Scheme 5).[15]

Scheme 5. Synthesis of triyne **10**



Reaction of this precursor with an excess of **1** for 30 hours at 100 °C yields intermediate **11**, which was characterized by ^{31}P NMR spectroscopy only ($\delta = 305.8$). Subsequent reaction with trimethylsilylacetylene in a large ex-

cess then led to the desired ligand **12** which was formed together with the 2,6-bis(trimethylsilyl)phosphinine as by-product. These two compounds were readily separated by column chromatography, and **12** was isolated as a white solid. All NMR spectroscopic data, as well as mass spectrometry, confirm the proposed structure. Despite the extension of each arm of the tripod resulting, supposedly, both in a larger size of the cavity and a greater flexibility, ligand **12** has the same coordinating behavior as **7**: the three $SiMe_3$ groups prevent the approach of $M(CO)_3$ fragments. Following the above-mentioned strategy we investigated the replacement of bulky $SiMe_3$ groups by linear alkyl groups. As shown in Scheme 6, the intermediate **11** can be reacted with 4-octyne in excess to yield ligand **13**. Heating at 120 °C for 13 days was necessary to ensure complete consumption of **11**. This very long heating period was somewhat detrimental to the overall yield (35%). All NMR spectroscopic data, as well as mass spectroscopy, confirm the proposed structure. The ^{31}P NMR chemical shift is found at δ = 242.6 as expected for an α-alkyl-substituted phosphinine.

Scheme 6. Syntheses of ligands **12** and **13**

As expected, the reaction of this extended tripod with $[W(CO)_5(THF)]$ in toluene at 110 °C for 20 h yield complex **14** as a red oil which slowly crystallizes (Scheme 7). Coordination to tungsten is obvious in the ^{31}P NMR spectrum. Coupling of ^{183}W (14% abundance) with three magnetically equivalent phosphorus atoms gives rise to the expected satellites at δ = 211.6 ($^1J_{P,W}$ = 227.7 Hz). In the ^{13}C NMR, the signal of the three carbonyl ligands appears as a "doublet of triplets" because each CO couples with one *trans* ($^2J_{P,C}$ = 21.2 Hz) and two *cis* ($^2J_{P,C}$ = 9.2 Hz) phosphorus atoms. The most surprising feature is found in the ^1H NMR spectrum. Whereas the signal for the H−C in the free ligand appears at about δ = 0 as a broad singlet, it is found in the complex at δ = +6 as a quadruplet ($^4J_{H,P}$ = 8.5 Hz). Surprisingly, no such effect in the chemical shift of the C−H was observed in the ^{13}C NMR spectrum. It thus seems that the strong downfield shift of the hydrogen results from a geometrical constraint. This hydrogen must be located in the anisotropy cone created by the three aromatic phosphinine moieties. This blocked conformation is also responsible for the magnetic inequivalence of the two methyl groups of the $SiMe_2$ linkers. The difference in their chemical shift of 0.5 ppm clearly shows that they have a very different electronic environment. In order to verify these assumptions, an X-ray crystal study was carried out.

Scheme 7. Complexation of ligand **13** with $[W(CO)_5(THF)]$

The complex crystallized as red blocks of almost millimeter size from a diffusion of MeOH into a chloroform solution of **14**. An ORTEP plot of the structure is shown in Figure 2. A number of very peculiar features are found in the structure. First, the apex carbon appears very flattened. The three Si−C−Si angles range between 114.93 and 118.17°. The sum of these angles at C (349.76°) is much closer to a C sp^2 hybridized than expected. Second, confirming the NMR findings, the hydrogen atom is located inside the cavity. This very peculiar arrangement prompted us to have a closer look at the bond lengths between C−H and H···W. In fact the C−H bond length is not elongated (0.979 Å) and the H···W distance of 2.683 Å indicates only a weak interaction between the metal center and the hydrogen. As expected for a coordinatively saturated metallic center there is no indication of an agostic interaction.

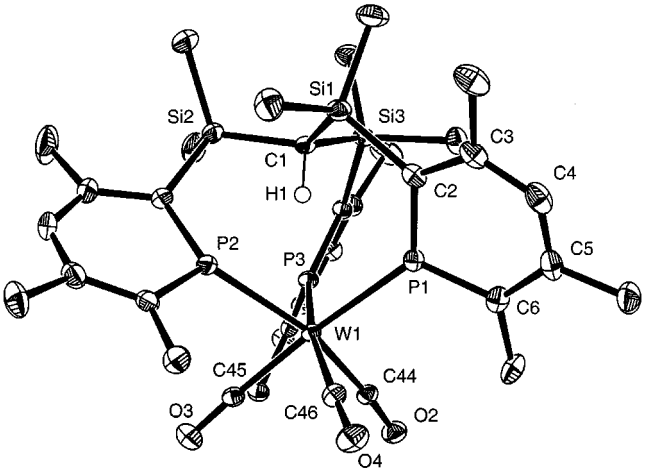


Figure 2. ORTEP drawing of **14** as determined by a single-crystal X-ray diffraction analysis; ellipsoids are drawn to enclose 50% of the electron density; the hydrogen atoms of the CH_2CH_3 grouping of the *n*-propyl substituents have are omitted for clarity[a]
[a] Selected bond lengths [Å] and angles [°]: W1−P1 2.5551(8), W1−P2 2.559(1), W1−P3 2.5700(8), W1−C44 1.967(2), W1−C45 1.975(3), W1−C46 1.970(2), P1−C2 1.741(3), C2−C3 1.408(3), C3−C4 1.398(4), C4−C5 1.389(4), C5−C6 1.403(3), C6−P1 1.747(3), C2−Si1 1.903(3), Si1−C1 1.871(3), C1−Si2 1.878(2), C1−Si3 1.881(3), C1−H1 0.979; P1−W1−P2 98.18(2), P2−W1−P3 98.63(3), P3−W1−P1, 99.15(3), P1−W1−C44 97.22(7), P1−W1−C46 80.46(8), P1−W1−C45 165.57(7), C6−P1−C2 106.7(1), P1−C2−Si1 119.1(1), Si1−C1−Si3 116.7(1), Si3−C1−Si2 114.9(1), Si1−C1−Si2 118.2(1)

Therefore the particularities of the structure are just a consequence of the coordination. The value of the dihedral angles $C_{ring}-C_{ring}-P-W$ (for example $C_3-C_2-P_1-W$ = 154.2°) should be 180° and they are found between 145 and 160° in the structure. As it appears in the ORTEP plot, the three phosphinine rings do not experience this strain and are not significantly distorted (if one excepts small deviations from planarity). This phenomenon is obvious from the ORTEP plot and this confirms the strain in the complex.

In conclusion, we have developed a simple access to the first phosphinine-based tripodal ligands using a "one pot sequence" from 1,3,2-diazaphosphinines. This simple synthetic scheme seems to be flexible enough to allow the introduction of various functional groups on phosphinines and should provide an access to more sophisticated cavities incorporating, for example, other heteroatom-based ligands which can serve as a hemilabile moiety. These developments as well as those concerning the coordinating behavior of ligands such as **8** and **13** and are currently under investigation and will be reported in due course.

Experimental Section

General: All reactions were routinely performed under nitrogen using Schlenk techniques and dry, oxygen-free solvents. Dry toluene and hexane were obtained by distillation from sodium/benzophenone and dry CH_2Cl_2 was obtained by distillation from P_2O_5. Dry celite was used for filtration. − NMR: Bruker AC-200 SY operating at 200.12 MHz for ^1H, 50.32 MHz for ^{13}C, and 81.01 MHz for ^{31}P; chemical shifts (ppm) are relative to TMS (^1H and ^{13}C) or 85% H_3PO_4 (^{31}P). List of abbreviations used: s, singlet, d, doublet, t, triplet, q, quadruplet, p, pseudo, m, multiplet. − Elemental analyses: "Service d'analyse du CNRS", Gif-sur-Yvette, France. Phosphinine **1** was prepared according to a published method.[11]

Synthesis of Ligand 4: A solution of diazaphosphinine **1** (0.63 g, 3.0 mmol) and tris(phenylethynyl)phenylsilane (0.29 g, 0.7 mmol) in toluene (25 mL) was heated at 125 °C for 44 hours. After this period, ^{31}P NMR analysis showed the presence of intermediates **2** and **3**. Trimethylsilylacetylene (0.78 g, 7.9 mmol) was then added and the resulting reaction mixture was heated at 90 °C for 2 hours. After cooling the flask to room temperature, celite (0.5 g) was added and the volatiles were evaporated. The resulting brown powder was then poured onto the top of a silica-gel column for chromatography. A first fraction, eluted with hexane, yielded the 2,6-bis(trimethylsilyl)phosphinine which is formed as a by-product. A second fraction, eluted with a mixture of toluene/hexane (70:30), yielded ligand **4**. The tripodal ligand **5** was recovered (mixture with **4**) in an additional fraction with a mixture of toluene/hexane (65:35). After evaporation of solvents, **4** was recovered as a yellow oil (0.19 g, 40% based on silane). − ^1H NMR ($CDCl_3$): δ = 0.30 (s, 18 H, $SiMe_3$), 6.90−7.50 (m, 20 H, C_6H_5), 7.73−8.20 (dd, 4 H, H-5 and H-4). − ^{13}C NMR ($CDCl_3$): δ = 0.7 (s, $SiMe_3$), 92.8 (s, C*C*−Si), 110.8 (s, C*C*−Ph), 125.0−135.0 (m, C_6H_5), 137.4 (s, C-5), 138.6 (d, ^3J = 5.0 Hz, C-4), 145.6 (s, Cq of C_6H_5), 154.7 (d, ^2J = 8.6 Hz, C-3), 162.2 (dd, ^1J = 91.5 Hz, ^3J = 7.8 Hz, C-2), 167.1 (d, ^1J = 84.5 Hz, C-6). − ^{31}P NMR ($CDCl_3$): δ = 269.6 (s). − MS ; *m/z* (%): 692 (100) [M]. − $C_{42}H_{42}P_2Si_3$ (693.0): calcd. C 72.79, H 6.11; found C 72.95, H 6.20.

Synthesis of Ligand 7: A solution of diazaphosphinine **1** (0.63 g, 3.0 mmol) and tris(propynyl)phenylsilane (0.16 g, 0.7 mmol) in toluene (25 mL) was heated at 100 °C for 20 hours. After this period a ^{31}P NMR control indicated the complete formation of intermediate **6**. Trimethylsilyacetylene (0.78 g, 7.9 mmol) was then added and the resulting reaction mixture was heated at 90 °C for 3.5 hours. After cooling the flask to room temperature, celite (0.5 g) was added and volatiles were evaporated. The resulting brown powder was then poured on to the top of a silica-gel column for chromatography. A first fraction, eluted with hexane, yielded the 2,6-bis(trimethylsilyl)phosphinine formed as a by-product. A second fraction, eluted with a mixture of toluene/hexane (70:30), yielded ligand **7**. After evaporation of solvents, **7** was recovered as a yellow oil (0.32 g, 70% based on the silane). − ^1H NMR ($CDCl_3$): δ = 0.20 (s, 27 H, $SiMe_3$), 2.16 (s, 9 H, Me of phosphinine), 7.07−7.27 (m, 5 H, C_6H_5), 7.53 (d, ^3J = 6.5 Hz, 3 H, H-4), 7.84−7.93 (m, 3 H, H-5). − ^{13}C NMR ($CDCl_3$): δ = 0.7 (d, ^3J = 4.0 Hz, $SiMe_3$), 29.9 (s, Me of phosphinine), 126.0−129.7 (C_6H_5), 131.1 (d, ^3J = 25.0 Hz, C-4), 138.4 (s, Cq of C_6H_5), 139.3 (d, ^2J = 10.0 Hz, C-5), 151.9 (d, ^2J = 10.5 Hz, C-3), 163.6 (td, ^1J = 87.50 Hz, ^3J = 5.5 Hz, C-2), 166.7 (d, ^1J = 83.0 Hz, C-6). − ^{31}P NMR ($CDCl_3$): δ = 272.5 (s). − MS ; *m/z* (%): 648 [M] (100), 575 (31) [M − $SiMe_3$]. − $C_{33}H_{47}P_3Si_4$ (649.0): calcd. C 61.07, H 7.30; found C 61.25, H 7.28.

Synthesis of Ligand 8: A solution of intermediate **6** in toluene (20 mL), prepared as described above from diazaphosphinine **1** (0.50 g, 2.40 mmol) and tris(propynyl)phenylsilane (0.12 g, 0.56 mmol), was heated with 4-octyne (1.10 g, 10 mmol) at 120 °C for one week. Celite (0.5 g) was then added and toluene and the excess of alkyne were evaporated yielding a brown solid, which was purified by chromatography. A fraction eluted with a mixture of hexane/toluene (50:50) yielded **8** which was isolated as a brown oil after evaporation of solvents (0.29 g, 76% based on the silane). − ^1H NMR ($CDCl_3$): δ = 0.92−1.03 (m, 18 H, 6 C*H*$_3$−CH$_2$), 1.52−1.71 (m, 12 H, 6 CH$_3$−C*H*$_2$), 2.17 (s, 9 H, Me of phosphinine), 2.61−2.68 (m, 6 H, CH$_2$−C-5), 2.79−2.91 (m, 6 H, CH$_2$−C-6), 7.16−7.32 (m, 5 H, C_6H_5), 7.62 (d, ^3J = 8.0 Hz, 3 H, H-4). − ^{13}C NMR ($CDCl_3$): δ = 15.0 and 15.1 (2s, 2 Me of *n*-propyl groups), 25.3 (s, Me of phosphinine), 27.7 (d, ^3J = 8.0 Hz, *C*H$_2$−CH$_2$−C-6), 29.1 (s, *C*H$_2$−CH$_2$−C-5), 36.9 (s, *C*H$_2$−C-5), 37.6 (d, ^2J = 36.5 Hz, *C*H$_2$−C-6), 126.0−129.7 (C_6H_5), 135.2 (d, ^3J = 19.0 Hz, C-4), 138.4 (s, Cq of C_6H_5), 147.3 (d, ^2J = 10.0 Hz, C-5), 149.5 (d, ^2J = 12.5 Hz, C-3), 161.3 (dt, ^1J = 76.0 Hz, ^3J = 5.5 Hz, C-2), 167.8 (d, ^1J = 60.0 Hz, C-6). − ^{31}P NMR ($CDCl_3$): δ = 247.0 (s). − MS ; *m/z* (%): 685 (92) [M + 1], 491 (100) [M − $C_{12}H_{18}P$], 299 (37) [M − 2 $C_{12}H_{18}P$]. − $C_{42}H_{59}P_3Si$ (684.9): calcd. C 73.65, H 8.68; found C 73.80, H 8.82.

Synthesis of Complex 9: A solution of ligand **8** (0.27 g, 0.39 mmol) in toluene (5 mL) was added to a solution of [W(CO)$_5$(THF)] (0.31 g, 0.78 mmol) in toluene (10mL). The resulting mixture was then heated at 110 °C for 20 hours. After cooling to room temperature, celite (0.5 g) was added and the mixture was evaporated to dryness yielding a brown powder which was purified by chromatography over silica gel. A first fraction, eluted with hexane, yielded traces of $W(CO)_6$. A second fraction, eluted with a mixture of hexane/toluene (80:20), yielded complex **9** as a red oil after evaporation of solvents (0.20 g, 56% based on the ligand). Microcrystals suitable for an X-ray analysis study were obtained by slow diffusion of methanol in a toluene solution of the complex. − ^1H NMR ($CDCl_3$): δ = 0.77−1.18 (m, 18 H, 6 C*H*$_3$−CH$_2$), 1.71−1.84 (m, 12 H, 6 CH$_3$−C*H*$_2$), 2.08 (s, 9 H, Me−C-3), 2.47 (t, ^3J = 7.9 Hz, 6 H, C*H*$_2$−C-5), 2.80−2.99 (m, 6 H, CH$_2$−C-6), 7.17−7.31 (m, 5

H, C_6H_5), 7.80−7.84 (m, 3 H, H_4). − ^{13}C NMR ($CDCl_3$): δ = 15.1 (s, 2 CH_3CH_2), 25.5 (s, *Me*−C-3), 27.4 (d, ^3J = 6.0 Hz, CH_2−CH_2−C-5), 29.9 (d, ^4J = 7.5 Hz, CH_2−CH_2−C6), 25.3 (d, ^2J = 23.5 Hz, CH_2−C-6), 37.3 (d, ^2J = 3.0 Hz, CH_2−C-5), 128.6−129.7 (C_6H_5), 131.0 (d, ^3J = 27.0 Hz, C-4), 136.7 (s, Cq of C_6H_5), 148.4 (d, ^2J = 9.0 Hz, C-5), 149.7 (d, ^2J = 15.0 Hz, C-3), 149.7 (signal of C-2 which is partially masked), 157.3 (s, C-6), 210.4 (dt, ^2J = 29.0 Hz, ^2J = 7.0 Hz, CO). − ^{31}P NMR ($CDCl_3$): δ = 213.1 (s). − IR (KBr): ν (CO) = 1950, 1875 cm^{-1}. − $C_{45}H_{59}0_3P_3SiW$ (952.8): calcd. C 56.73, H 6.24; found C 56.70, H 6.20.

Synthesis of Triyne 10: Tris(bromodimethylsilyl)methane was synthesized following a reported procedure.[15] This compound (4.55g, 10.6 mmol) was added to three equivalents of MeCCLi (1.47g, 32.0 mmol) suspended in THF (60 mL) cooled to −78 °C. The mixture was stirred at −78 °C for 30 minutes and at room temperature for an additional two hours. After evaporation of the volatiles, the mixture was purified by column chromatography on silica gel with hexanes as eluent. The title compound was obtained as a viscous oil in 55% yield (nonoptimized). − ^{1}H NMR ($CDCl_3$): δ = −0.50 (s, 1 H, CH), 0.34 (s, 18 H, 3 $SiMe_2$), 1.87 (s, 9 H, Me). − ^{13}C NMR ($CDCl_3$): δ = 3.1 (s, $SiMe_2$), 3.2 (s, CH), 5.6 (s, C−Me), 86.4 (s, C−Si), 104.3 (s, *C*−Me). − MS (CI, NH_3); *m*/*z* (%): 306 (10) [M + 1], 291 (15) [M − CH_3+1].

Synthesis of Ligand 12: A solution of diazaphosphinine **1** (0.53 g, 2.5 mmol) and ligand **10** (0.17 g, 0.56 mmol) in toluene (20 mL) was heated at 100 °C for 30 hours. After this period a ^{31}P NMR control indicated the complete formation of intermediate **11**. Trimethylsilylacetylene (0.99 g, 10 mmol) was then added and the resulting reaction mixture was heated at 90 °C for 5 hours. After cooling the flask to room temperature, celite (0.5 g) was added and the volatiles were evaporated. The resulting brown powder was then purified by column chromatography on silica gel. A first fraction, eluted with hexane, yielded the 2,5-bis(trimethylsilyl)phosphinine as by-product. A second fraction, eluted with a mixture of hexane/CH_2Cl_2 (90:10), yielded ligand **12**. After evaporation of solvents, **12** was recovered as a white solid (0.32 g, 75% based on the silane). − ^{1}H NMR ($CDCl_3$): δ = 0.06 (br. s, 1 H, CH), 0.30 (s, 18 H, $SiMe_2$), 0.50 (d, ^4J = 2.0 Hz, 27 H, $SiMe_3$), 2.36 (s, 9 H, Me of phosphinine), 6.93 (d, ^3J = 8.1 Hz, 3 H, H-4), 7.78 (dd, ^3J = 8.1 Hz, 3 H, H-5). − ^{13}C NMR ($CDCl_3$): δ = 0.8 (d, ^3J = 5.5 Hz, $SiMe_3$), 3.0 (br. s, CH), 5.0 (d, ^3J = 16.5 Hz, $SiMe_2$), 27.1 (s, Me of phosphinine), 130.2 (d, ^3J = 25.0 Hz, C-4), 138.7 (d, ^2J = 11.5 Hz, C-5), 149.3 (d, ^2J = 12.5 Hz, C-3), 166.0 (d, ^1J = 83.5 Hz, C-2), 168.9 (d, ^1J = 89.0 Hz, C-6). − ^{31}P NMR ($CDCl_3$): δ = 263.0 (s). − MS ; *m*/*z* (%): 731 (8) [M], 549 (100) [M − phosphinine]. − $C_{34}H_{61}P_3Si_6$ (731.3): calcd. C 55.84, H 8.41; found C 55.69, H 8.38.

Synthesis of Ligand 13: A solution of diazaphosphinine **1** (0.69 g, 3.25 mmol) and ligand **10** (0.22 g, 0.72 mmol) in toluene (20 mL) was heated at 100 °C for 30 hours. After this period a ^{31}P NMR control indicated the complete formation of intermediate **11**. 4-Octyne (1.20 g, 11 mmol) was then added and the resulting reaction mixture was heated at 120 °C for 13 days. After cooling the flask to room temperature, celite (0.5 g) was added and the volatiles were evaporated. The resulting brown powder was then purified by column chromatography on silica gel. A first fraction, eluted with hexane, yielded the 2,3,4,5-tetrapropylphosphinine as by-product. A second fraction, eluted with a mixture of hexane/toluene (50:50), yielded ligand **13**. After evaporation of solvents, **13** was recovered as a viscous oil (0.18 g, 35% based on the silane). − ^{1}H NMR ($CDCl_3$): δ = 0.08 (br. s, 1 H, CH), 0.45 (d, ^4J = 2.0 Hz, 18 H, $SiMe_2$), 0.95−1.05 (m, 18 H, 6 CH_3−CH_2), 1.56−1.65 (m, 12 H, 6 CH_3−CH_2), 2.35 (s, 9 H, Me of phosphinine), 2.52−2.58 (m, 6 H, CH_2−C-5), 2.72−2.90 (m, 6 H, CH_2−C-6), 6.77 (d, ^4J = 1.3 Hz, 3 H, H-4). − ^{13}C NMR ($CDCl_3$): δ = 3.0 (br. s, CH), 4.7 (d, ^3J = 15.3 Hz, $SiMe_2$), 15.0 (s, Me), 25.3 (s, C-5−CH_2−CH_2−CH_3), 26.5 (s, Me of phosphinine), 27.6 (d, ^3J = 10.0 Hz, C-6−CH_2−CH_2−CH_3), 36.8 (s, CH_2−C-5), 37.6 (d, ^2J = 34.5 Hz, CH_2−C-6), 134.4 (d, ^3J = 20.0 Hz, C-4), 146.5 (d, ^2J = 11.5 Hz, C-5 or C-3), 147.2 (d, ^2J = 14.5 Hz, C-3 or C-5), 166.4 (d, ^1J = 78.0 Hz, C-2 or C-6), 166.8 (d, ^1J = 58.3 Hz, C-6 or C-2). − ^{31}P NMR ($CDCl_3$): δ = 242.6 (s). − MS ; *m*/*z* (%): 767 (8) [M], 573 (100) [M − phosphinine]. − $C_{43}H_{73}P_3Si_3$ (767.2): calcd. C 67.32, H 9.59; found C 67.45, H 9.70.

Synthesis of Complex 14: A solution of ligand **13** (0.15 g, 0.20 mmol) in toluene (5 mL) was added to a solution of [$W(CO)_5$(THF)] (0.16 g, 0.40 mmol) in toluene (10mL). The resulting mixture was then heated at 110 °C for 20 hours. After completion, celite (0.5 g) was added and the mixture was evaporated to dryness,yielding a red-brown powder, which was purified by chromatography over silica gel. A first fraction, eluted with hexane, yielded traces of $W(CO)_6$. A second fraction, eluted with a mixture of hexane/toluene (80:20), yielded complex **14** as a red oil after evaporation of solvents (0.11 g, 56% based on **13**). This oil turned into a red solid after trituration in methanol. − ^{1}H NMR ($CDCl_3$): δ = 0.00 (s, 9 H, CH_3 of $SiMe_2$), 0.50 (s, 9 H, CH_3 of $SiMe_2$), 0.86 (t, ^3J = 7.3 Hz, 9 H, 3 CH_3−CH_2), 0.97 (t, ^3J = 7.3 Hz, 9 H, 3 CH_3−CH_2), 1.40 (m, 6 H, 3 CH_3−CH_2−CH_2), 1.63 (m, 6 H, 3

X-Ray Structural Analysis: For compounds **9** and **14**, data were collected on a KappaCCD diffractometer. Mo-K_α (λ = 0.71073 Å) radiation and a graphite monochromator were used in all cases. The crystal structures were solved and refined using SIR-97[16a] and refined with SHELXL-97.[16b] Other experimental details are given in Table 1. The ORTEP drawings reported in this article were generated using the winGX program created by Professor L. J. Farrugia (ORTEP III for Windows, available on the internet as a freeware at louis@chem.gla.ac.uk, Department of Chemistry at the University of Glasgow).

Crystallographic Data (excluding structure factors) for the structures reported have been deposited with the Cambridge Data Centre as supplementary publication nos. CCDC-142208 (**9**) and CCDC-142209 (**14**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Multinuclear NMR Study and Crystal Structure of *trans*-[$PtCl_2(PHtBu_2)_2$]

Roberto Giannandrea,[a] Piero Mastrorilli,*[a] Mariangela Palma,[a] Francesco Paolo Fanizzi,[b] Ulli Englert,[c] and Cosimo Francesco Nobile[a]

Keywords: Platinum / Phosphanes / Bridging ligands / Force field calculations / Conformational equilibrium

trans-[$PtCl_2(PHtBu_2)_2$] **(1)** was thoroughly characterised by ^1H, $^{31}P\{^1H\}$ and $^{195}Pt\{^1H\}$ NMR spectroscopy. Two rotational conformers were found to be stable in solution at room temperature. Force field calculations confirmed that these two conformers are very similar in energy. They co-crystallise in the tetragonal space group *P*4bar as revealed by X-ray diffraction studies. The dynamics of *trans*-[$PtCl_2(PHtBu_2)_2$] is here reported together with spectroscopic evidence of a phosphido-bridged reduction product.

Introduction

As part of our continuing interest in the chemistry of low-valent transition metal complexes, we recently became interested in the coordination chemistry of metals with secondary bulky phosphanes, such as $PHtBu_2$, $PHCy_2$ and $PHPh_2$, in phosphorus-bridged binuclear systems.[1]

With the aim of investigating the behaviour of platinum(II) complexes towards alkali metal-promoted reduction we have synthesised *trans*-[$PtCl_2(PHtBu_2)_2$] (**1**) and reacted it with metallic sodium.

Results and Discussion

trans-[$PtCl_2(PHtBu_2)_2$] **(1)** was first prepared by Shaw et al. who extracted the main NMR features of the $[AMX_{18}]_2$ system from its ^1H spectrum.[2] Moreover, it was noticed that **1** exists in solution as a mixture of two conformational isomers even at room temperature[2] (Figure 1).

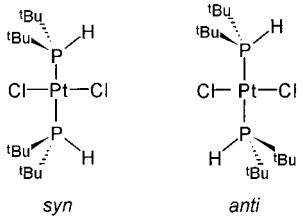

Figure 1

More recently, Goel and Ogini[3] claimed a new synthesis of **1** (as a white solid) from the reaction of K_2PtCl_4 with $PtBu_3$ in a 1:3 ratio in refluxing DMF. Contrary to Shaw's findings they observed only a broad peak (with satellites) in the $^{31}P\{^1H\}$ NMR spectrum at ambient temperature (δ = 56.8, CH_2Cl_2) which was resolved into two peaks at 183 K.

By reaction of $PtCl_2(PhCN)_2$ with $PHtBu_2$ in a Pt:P ratio of 1:2 we have obtained **1** as a pale yellow solid. Its ^1H NMR spectrum is consistent with that reported by Shaw[2] and shows two overlapped spin systems of the $[AMX_{18}]_2$ type, where A is the phosphorus atom, M is the hydrogen directly bound to the phosphorus, X_{18} are the *tert*-butyl hydrogens. Figure 2 shows the M part of this spectrum. The analysis of such a system, developed by Mann,[4] allowed us to obtain the spectroscopic features reported in Table 1 along with ^1H, ^{31}P, ^{13}C and ^{195}Pt chemical shifts.

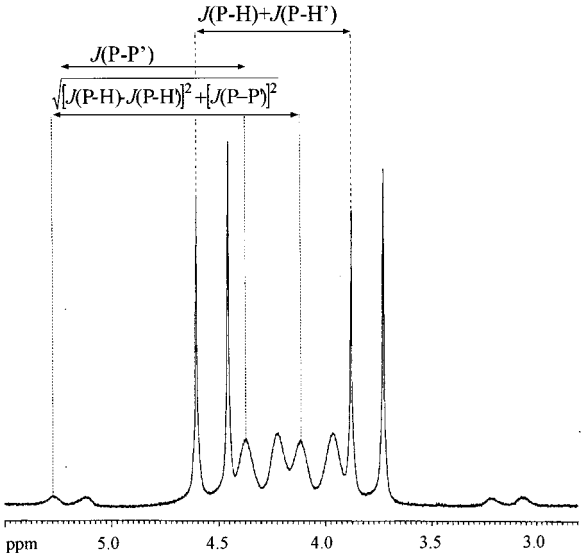

Figure 2. P-H region of the ^1H NMR spectrum of *syn* and *anti* conformers of complex **1** ($CDCl_3$, 295 K); see ref.[4] for the analysis of the $[AMX_{18}]_2$ spin system

δ(Pt)	−3738	−3767

[a] Solvent C_6D_6, 298 K.

The $^{31}P\{^1H\}$ NMR spectrum of **1** recorded in $CDCl_3$ at ambient temperature shows the presence of two signals with satellites at δ = 49.4 and 56.5 ascribable to the *syn* and *anti* conformers of **1**. Their *anti*/*syn* ratio, as assessed by the integrals in the ^{31}P NMR spectrum, was found to be equal to 1.2.

The $^{31}P\{^1H\}$ dynamic NMR spectrum shows the expected broadening of the signals with increasing temperature (Figure 3). A line-shape analysis[5] allowed an estimation of a lower limit of ΔG for the interconversion of the conformers equal to 18 ± 2 kcal/mol.

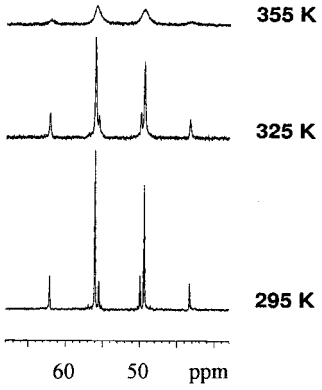

Figure 3. Variable temperature $^{31}P\{^1H\}$ NMR spectra of complex **1** ([D_8]toluene)

The $^{195}Pt\{^1H\}$ spectrum (Figure 4) shows the expected two triplets with Pt-P direct couplings of 2429 Hz (*syn* isomer) and 2421 Hz (*anti* isomer).

The resonance of the methyl carbons in the $^{13}C\{^1H\}$ NMR spectrum was found as a doublet ($^2J_{P-C}$ = 12 Hz) centred at δ = 31.3. The quaternary carbons of the coordinated phosphanes give a pseudotriplet arising from the AXX′ system (A = ^{13}C; X,X′ = ^{31}P) when $J_{XX'} >> J_{AX}$.[6] The chemical shift is δ = 34.9, and the value of $|^1J_{P-C} + {}^3J_{P-C}|$ directly obtainable from the spectrum is 23.4 Hz.

In order to gain insight into the structure of the two (or at least of the most stable) conformers we probed the energy hypersurface with respect to the torsional position of the phosphane ligands. Molecular mechanics calculations were

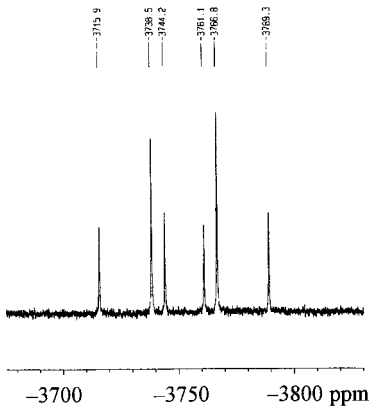

Figure 4. $^{195}Pt\{^1H\}$ NMR spectrum of complex **1** ($CDCl_3$, 295 K)

performed with an augmented MM2[7] force field. The torsion angles between the Cl−Pt and the P−H bonds in the P*H*$t$$Bu_2$ ligands were independently varied in steps of three degrees, and for each step all other intramolecular degrees of freedom were allowed to relax. The energy profile and four selected conformers are shown in Figure 5. The two geometries with both PH groups in the coordination plane of the metal centre, i.e. the *anti* (A) and the *syn* isomer (D), have almost the same energy, whereas the geometries with one (B) or two (C) P−H bonds perpendicular to the plane of coordination are energetically less favourable.

In addition to the force field calculations a crystallographic analysis was undertaken. X-ray diffraction studies were carried out on three single crystals of **1**. A ^1H NMR analysis of these crystals redissolved in $CDCl_3$ showed the immediate presence of both conformers.

The X-ray diffraction study revealed that **1** crystallises in the space group $P\bar{4}$ with the metal atom on the twofold axis (Wyckoff position 2*g*) and a fractional *z* coordinate of approximately 0.25**.** Due to this position of the most prom-

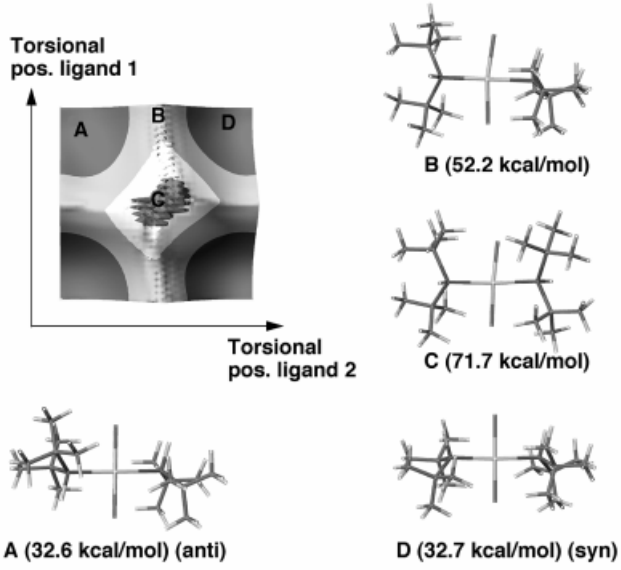

Figure 5. Profile of the energy hypersurface of **1** as a function of the torsional orientation of the phosphane ligands and the geometry of four selected conformers

inent scatterer, the intensity statistics resemble that of an *I* centred lattice: over 95% of the scattered intensity may be attributed to reflections of the type *hkl*, $h + k + l = 2n$.

Location of the metal, chlorine, and phosphorus atoms was straightforward. After refinement of this initial model a Fourier-difference synthesis showed electron density above and below the Pt coordination plane attributable to the carbon atoms of the phosphane ligands. Two alternative strategies were followed to deal with the electron density above and below this plane:

a) Tentative refinement as carbon positions resulted in highly anisotropic displacement parameters. Rigid bond and distance restraints had to be applied to ensure physically and chemically reasonable refinement results. In view of the site symmetry of the Pt central atom this procedure necessarily leads to an *anti* geometry although the NMR spectrum suggested the presence of both conformers in the crystal. Furthermore, the resulting angles around phosphorus were much larger than expected and in conflict with both the above mentioned force-field results and comparable structures of the $PHtBu_2$ ligand[8] drawn from the CSD database.[9]

b) It was observed that the electron density closely matched the situation depicted in Figure 6 and could be explained by superposition of *anti* and *syn* (shaded) conformers, corresponding to geometries A and D, respectively, in Figure 5.

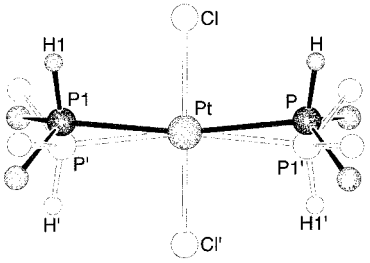

Figure 6. SCHAKAL[12] representation of the alternative orientations of **1** in the crystal; all methyl groups have been omitted, primed atoms are related to unprimed ones by the symmetry operation $1 - x, -y, z$; a possible *syn* conformer has been emphasized by shading

The $PHtBu_2$ ligand geometry was extracted from the molecular mechanics model and introduced as a rigid group in two alternative orientations. In addition to the parameters regarding Pt, Cl, and P only two overall isotropic displacement parameters for the methyl C and the phosphorus-bonded carbon atoms were refined. Despite the much smaller number of variables this second approach gave better convergence results. Figure 7 shows a PLATON view of the

anti conformer and lists selected interatomic angles and distances.

trans-[$PtCl_2(PHtBu_2)_2$] was reacted with excess sodium metal to obtain a complex mixture of compounds as revealed by ^{31}P NMR spectroscopy. Among the signals present in the ^{31}P NMR spectrum of the reaction solution a triplet centred at $\delta = 278.7$ with satellites ($J_{P-P} = 43$ Hz; $J_{P-Pt} = 2588$ Hz) was clearly evident in the low field region (Figure 8). The values of the chemical shift and coupling constants are typical for *tert*-butyl phosphides bridging two platinum(I) atoms linked by a metal−metal bond.[7a] The presence, in the region of terminally bonded phosphanes, of a sharp triplet centred at $\delta = 62.0$, with a coupling constant as high as 43 Hz, strongly suggests the formation of the binuclear phosphido-bridged platinum(I) complex [Pt(μ-$PtBu_2$)($PHtBu_2$)]$_2$ **(2)**.

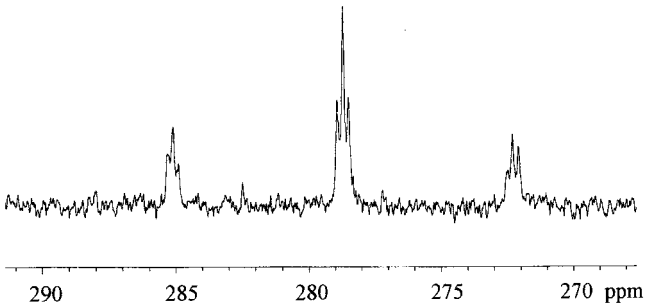

Figure 8. Phosphide resonance in the $^{31}P\{^1H\}$ NMR spectrum of complex **2** ([D_8]toluene, 295 K)

The synthesis of **2** has already been reported by Leoni, Pasquali et al. by hydride abstraction from [Pt(μ-$PtBu_2$)(H)($PtBu_2H$)]$_2$ but no NMR spectroscopic data were reported, due to its low solubility.[8a] Prolonged reaction times of **1** with sodium led to decomposition into free phosphane, NaCl and platinum metal.

Experimental Section

General: All manipulations were carried out under a pure dinitrogen atmosphere, using freshly distilled and oxygen-free solvents. Di-*tert*-butylphosphane was purchased from Fluka and used as received.

Infrared spectra were recorded on a Perkin−Elmer 883 spectrometer. Elemental analyses were carried out by using a Carlo Erba model EA 1108 elemental analyser.

NMR spectra were recorded on a Bruker Avance DRX500 spectrometer; chemical shifts are referenced to Me_4Si (^1H and ^{13}C), 85% H_3PO_4 (^{31}P), and H_2PtCl_6 (^{195}Pt).

***trans*-Bis(di-*tert*-butylphosphane)dichloroplatinum(II) (1):** A suspension of [$PtCl_2(PhCN)_2$][10] (1.3 g, 2.8 mmol) and di-*tert*-butylphosphane (0.88 g, 6.0 mmol) in toluene (20 cm^3) was stirred at 70 °C. After a few minutes a clear yellow solution was obtained, which was cooled to room temperature and concentrated in vacuo. It was then filtered and washed three times with petroleum ether and dried in vacuo (1.3 g, 85% yield). − IR (nujol mull): $\tilde{\nu}_{max} = 2351$m (P−H), 1365vs, 1181vs, 1023s, 901s, 813vs, 468s, 333vs (Pt−Cl) cm^{-1}. − UV/Vis (CH_2Cl_2, 1.61×10^{-4} mol dm^{-3}): λ_{max} (ε/dm^3 mol^{-1} cm^{-1}) = 240.0 (6180), 267 (8260) and 301.0 (sh) nm.

Crystallography

Crystals of compound **1** were obtained by crystallisation from toluene. Intensity data were collected with Mo-K_α radiation (λ = 0.71073 Å, graphite monochromator) on an ENRAF-Nonius CAD4 diffractometer at 243 K on a crystal of approximate dimensions 0.13 × 0.13 × 0.13 mm.

Crystal data: a = 8.906(1), c = 14.337(4) Å; V = 1137.2(4) Å^3, Z = 2, d(calcd.) = 1.63 g·cm^{-3}, μ = 6.605 mm^{-1}, F(000) = 552. 3977 Reflections were collected with the $\omega-2\theta$ scan method in the range $3.2 < \theta < 25.1$ deg. After merging symmetry equivalent data [R(int) = 0.062], 2032 independent reflections remained for structure solution by direct methods.[11] The final structure model was based on rigid-group refinement of the force field optimised PHtBu$_2$ ligand in two alternative orientations with full-matrix least-squares on F^2.[10] Convergence was reached for 2032 reflections and 50 variables at agreement factors of $wR2$ = 0.0997 (all data), $R1$ = 0.0431 [observations with $I > 2\sigma(I)$]. Max. and min. from a final Fourier map were 1.506 and −0.461 e·Å^{-3}.

Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-141698. Copies of the data can be obtained free of charge on application to The Director, CCDC 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Reduction of 1 with Sodium: A suspension of *trans*-[PtCl$_2$(PHtBu$_2$)$_2$] (0.5 g, 0.9 mmol) and sodium sand (0.3 g, 13 mmol) in toluene (10 cm^3) was vigorously stirred at room temperature until a dark green suspension was obtained (about 10 h). Unreacted metallic sodium, NaCl and small amount of platinum metal were filtered off and the solution concentrated in vacuo and used for ^{31}P NMR analysis. The ^{31}P{^{1}H} NMR spectrum of the obtained orange solution showed two triplets with satellites [^{31}P{^{1}H} NMR ([D$_8$]toluene): δ = 62.0 (t, J_{P-P} = 43 Hz, J_{P-Pt} = 4775 Hz, P$_t$), 278.7 (t, J_{P-P} = 43 Hz, J_{P-Pt}= 2588 Hz, P$_\mu$), along with less-intense signals ascribable to uncharacterised species.

Structural Patterns and Forms of Aggregation of Metallated Diamido Donor Ligands upon Going from Lithium to Thallium(I)

Christian H. Galka,[a] Dominique J. M. Trösch,[a] Martin Schubart,[b] Lutz H. Gade,*[a] Sanja Radojevic,[c] Ian J. Scowen,[c] and Mary McPartlin[c]

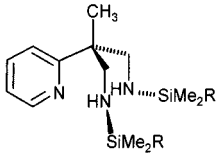
Dedicated to Professor Max Schmidt on the occasion of his 75th birthday

Keywords: Lithium / Amides / Thallium / N ligands / Structure elucidation

Two polyfunctional lithium amides, $[(2\text{-}C_5H_4N)C(CH_3)\{CH_2N(Li)SiMe_2R\}_2]_2$ [R = Me (**3**), *t*Bu (**4**)], have been synthesized and structurally characterized by X-ray crystallography. They were found to have dimeric structures containing ladder-type Li–N arrangements in which the form of aggregation and thus folding of the ladder appears to be influenced by the steric demand of the *N*-bonded silyl groups. Substitution of the lithium ions by thallium(I) was achieved in two steps, yielding the mixed metal amide $[(2\text{-}C_5H_4N)C(CH_3)\{CH_2N(Li)SiMe_3\}\{CH_2N(Tl)SiMe_3\}]_2$ (**5**) and the thallium(I) diamide $[(2\text{-}C_5H_4N)C(CH_3)\{CH_2N(Tl)SiMe_3\}_2]_2$ (**6**). X-ray diffraction studies of both compounds revealed a dimeric ring structure through Li–N links for the former, while the latter is monomeric and only weakly aggregated in the crystal structure through a short, unsupported thallium(I)–thallium(I) contact of 3.500(2) Å.

Introduction

Alkali metal amides derived from polyfunctional amines display molecular structures and forms of aggregation which are largely dictated by the relative orientation of the functional groups joined by the ligand framework.[1,2] This reduction of the structural degrees of freedom may lead to patterns of aggregation which are different from those of simple monofunctional amides.[3,4] More significantly, the integration of several functional groups within a ligand system enables systematic control of their role in the assembly of metallated derivatives. This provides an alternative to the well-established co-aggregation of alkali metal amides and neutral ligands or donor solvents.[1,2]



We recently reported the synthesis of a novel dianionic tripodal ligand in which two amido functions are combined with a neutral pyridyl unit.[5,6] This ligand system provides the key to stabilizing a whole range of early transition metal complexes, among these a series of imido complexes.[7,8] Whereas the role of this polydentate ligand in transition metal chemistry is clearly the protection of a large part of the coordination sphere around the metal centre and the masking of potentially accessible coordination sites by the displaceable neutral pyridyl function, the latter may play the part of a "capping" functionality in aggregates of its main group derivatives. While the structures of the group-1 metal amides may be viewed as resulting from primarily ionic interactions between the N-functions and the metal cations,[1] we and others have previously shown that monovalent thallium amides display structures which are markedly different.[9–12]

In this paper we present a systematic study of the forms of aggregation adopted by the lithium amides containing the ligand $[(2\text{-}C_5H_4N)C(CH_3)(CH_2NR)_2]^{2-}$, their thallium analogues and the mixed lithium–thallium species. It will be shown that stepwise replacement of the alkali metal ions by thallium(I) is feasible under appropriate reaction conditions, thus enabling the synthesis of a mixed metal species. The aim will be not only to demonstrate how the ligand enforces the relative arrangement of the metal atoms but also to elucidate the way interactions between the monovalent metal ions themselves determine the structural patterns.

Results and Discussion

Synthesis and Structural Characterization of $[(2\text{-}C_5H_4N)C(CH_3)\{CH_2N(Li)SiMe_2R\}_2]_2$ [R = Me (3), *t*Bu (4)]

Reaction of the pyridyl diamines $(2\text{-}C_5H_4N)C(CH_3)(CH_2NHSiMe_2R)_2$ [R = Me (**1**), *t*Bu (**2**)] with two

molar equivalents of *n*-butyllithium and subsequent workup yields the corresponding lithium amides. Whereas the ^{1}H, ^{13}C, ^{29}Si, and ^{7}Li NMR spectra of **4** in C_6D_6 display structural patterns consistent with a C_s-symmetric monomeric structure, the NMR spectra of **3** indicate aggregation of the lithium amide. The inequivalence of the signals assigned to the methyl groups of the $SiMe_3$ substituents and the patterns of the signals from the protons and carbon nuclei in the ligand framework indicate dimerization of the lithium amide and thus reduction of the local symmetry of the diamidopyridine ligand. This postulated dimerization is supported by a cryoscopic study of **3** in benzene, which also indicated a degree of aggregation lower than two for the analogous compound **4** containing the bulkier ligand periphery. It is assumed that the solution NMR data of the latter are those of the monomeric species. In order to obtain more specific information of the structures of the aggregates, an X-ray crystallographic study of both complexes was clearly essential.

Large colourless single crystals of **3** and **4** were obtained by cooling solutions of the lithiated amines in toluene and pentane, respectively. X-ray structure analyses of both compounds established their dimeric structures in the solid state, which are depicted in Figure 1 and 2 along with selected lengths and inter-bond angles.

The only available crystals of **4** diffracted poorly, leading to relatively high ESDs for all parameters in this structure, but although bond lengths have to be treated with caution, the overall structure is well established and it is interesting to compare the ladder arrangement in the two dimeric molecules. The dilithium diamide units are aggregated in both structures forming four-rung ladders which are terminated by coordination of the neutral pyridyl functions. In compound **3** this lithium amide ladder adopts a boat-type arrangement which is derived from the $(LiN)_4$ cube previously observed in difunctional lithium amides such as $[CH_2\{CH_2N(Li)SiMe_3\}_2]_2$,[13] $[\{t\text{BuN(Li)}\}_2SiMe_2]_2$ [14] and $[\{rac\text{-N}(t\text{Bu})\text{CH(Me)CH(Me)N}t\text{Bu}\}\text{Li}]_2$.[15] Coordination of the neutral donor function has led to opening of one face of the cubic structure to generate the ladder arrangement with crystallographic C_2 symmetry. In **3**, the three Li_2N_2 parallelograms are each planar to within 0.006 Å, and the two symmetry-related outer Li_2N_2 units are folded by 62.3° towards cubic from a possible co-planar arrangement with the central unit. In contrast, in the dimeric ag-

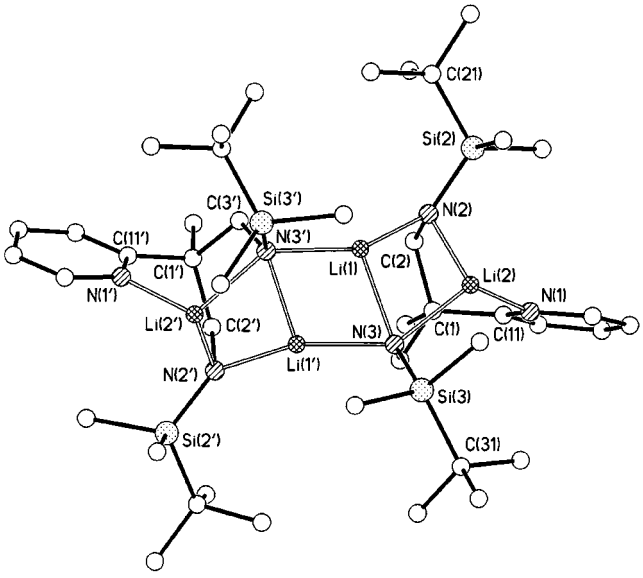

Figure 2. Molecular structure of **4**, which has virtual C_2 symmetry, showing the almost linear arrangement of the lithium amide ladder; mean values of selected bond lengths [Å] and angles [°]: Li(1)−N(2) 1.93(1), Li(1)−N(3) 2.11(1), Li(1)−N(3′) 2.11(2), Li(2)−N(1) 1.85(1), Li(2)−N(2) 1.97(1); N(1′)−Li(1)−N(2) 151(1), N(2)−Li(1)−N(3) 94(1), N(3)−Li(1)−N(3′) 109(1), N(2)−Li(2)−N(3) 105(1), N(3)−Li(2)−N(1) 109(1), N(3)−Li(2)−N(2) 97(1), Li(1)−N(2)−Li(2) 79(1), Li(2)−N(3)−Li(1) 71(1), Li(2)−N(3)−Li(1′) 140 (1)

gregate of compound **4**, unlike the arrangement in **3**, the lithium amide ladder is stepped in the normal way (Figure 2). Six atoms of the Li_4N_4 ladder in **4** show only a small "bowing" from planarity [maximum deviations: Li(1), Li(1′): 0.19 Å and Li(2), Li(2′): −0.19 Å], but the two outer amido nitrogen atoms, N(2) and N(2′), each lie out of this plane by 1.0 Å in the same direction. The mean dihedral angle between the best planes of the inner and each of the outer Li_2N_2 unit, which fold towards each other, is only 20.5° in **4**.

Compound **3** has exact C_2 symmetry, and although compound **4** has only virtual C_2 symmetry, all chemically equivalent bond lengths and angles are equal within experimental error, so the mean values are used (with the atomic symbols for one half of the molecule) in the caption to Figure 2 and in the following discussion. The two lithium atoms in each half of the molecules of **3** and **4** are three-coordinate with Li(1) connected to three amido functions, and Li(2) to two amide groups and one pyridyl group. The amido−N−Li distances of 1.964(8)−2.111(8) Å in **3**, and 1.93(1)−2.11(1) Å in **4**, lie in the expected range for lithium amides.[16] The structure of **4** is readily envisaged as two similar dinuclear monomeric units in which Li(1) and Li(2) are bridged by both amido groups N(2) and N(3) of one ligand, with a third bond from N(3) to a lithium atom, Li(1′), of the second dinuclear unit forming the only bridge between the virtually identical monomer units. In contrast the structure of **3** is intrinsically tetranuclear with the two amido groups of each ligand spanning all four lithium atoms, so that N(2) bridges Li(2) and Li(1A) and N(3) bridges Li(1) and Li(2A) and also forms a bridge to Li(1A) to complete the ladder arrangement. These solid-state structural features are consistent with the observed differences in the NMR spectra of these two compounds, **4** giving a C_s spectrum characteristic of the dinuclear monomer, and **3** giving the less symmetric spectrum characteristic of the Li_4 aggregate. The more linear arrangement in **4** leads to a greater spatial separation of the silyl groups, which are considerably bulkier than those in **3**. It is probable that steric interaction of the peripheral *N*-bound substituents in **4** favours the more open form of aggregation.

Synthesis and Structural Characterization of [(2-C_5H_4N)-$C(CH_3)\{CH_2N(Li)SiMe_3\}\{CH_2N(Tl)SiMe_3\}]_2$ (5) and [(2-C_5H_4N)$C(CH_3)\{CH_2N(Tl)SiMe_3\}_2]_2$ (6)

We have recently established the crystal structures of several polyfunctional thallium(I) amides and found patterns of aggregation which differ markedly from those of the alkali metal derivatives.[11,12] A polyfunctional system containing both neutral and anionic donor atoms has not been studied to date. In view of the results described above, it was of interest to find out how the analogous thallium(I) amides aggregate in the solid.

Reaction of $[(2\text{-}C_5H_4N)C(CH_3)\{CH_2N(Li)SiMe_3\}_2]_2$ (**3**) with two molar equivalents of TlCl (per monomeric unit) in pentane over a period of four days led to the exchange of the lithium ions by Tl^+. After workup, two types of crystalline solid, **5** and **6**, were obtained by cooling the pentane solution of the reaction product(s). Colourless crystals (**5**) were collected along with a deep orange crystalline solid (**6**) and were separated by hand. Whereas the orange product did not contain any lithium and was analyzed as the dithallium(I) diamide $[(2\text{-}C_5H_4N)C(CH_3)\{CH_2N(Tl)SiMe_3\}_2]_2$ (**6**) the colourless product was found to be a mixed lithium−thallium amide and was formulated as $[(2\text{-}C_5H_4N)C(CH_3)\{CH_2N(Li)SiMe_3\}\{CH_2N(Tl)SiMe_3\}]_2$ (**5**). Repeated runs of this metal exchange under the same reaction conditions gave both compounds in every case as described above whereas use of 1,4-dioxane as solvent exclusively led to formation of the dithallium(I) diamide **6**.

In order to establish their patterns of aggregation in the solid single-crystal X-ray structure analyses of both compounds were carried out. Their molecular structures are displayed in Figure 3 and 4 along with selected bond lengths and angles.

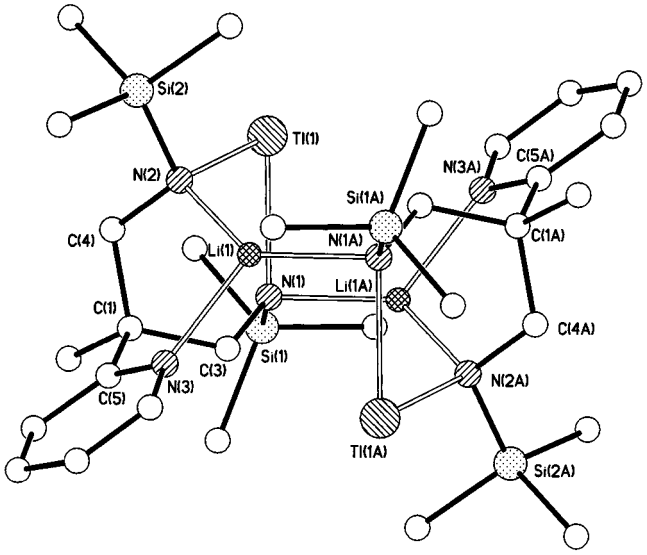

Figure 3. Molecular structure of **5**; selected bond lengths [Å] and angles [°]: Li(1)−N(1A) 2.044(12), Li(1)−N(2) 1.998(12), Li(1)−N(3) 2.102(12), Tl(1)−N(1) 2.483(5), Tl(1)−N(2) 2.455(5); N(2)−Li(1)−N(1A) 135.0(6), N(2)−Li(1)−N(3) 99.3(5), Tl(1)−N(2)−Li(1) 111.4(4), Li(1A)−N(1)−Tl(1) 88.9(3), N(1)−Tl(1)−N(2) 83.29(17), N(3)−Li(1)−N(1A) 123.1(6)

The structural centrepiece of **5** is a $Li_2Tl_2N_4$ macrocycle in which the thallium atoms occupy intramolecular bridging positions and the lithium atoms link the two metallated diamidopyridine ligands. The centre of this cyclic structure coincides with a crystallographic centre of inversion which relates the two halves of the molecule. Whereas the dicoordinate thallium centres adopt the typically exposed positions, the lithium atoms are three-coordinate due to additional bonding of the pyridyl units. The Tl−N distances of Tl(1)−N(2) [2.455(5) Å] and Tl(1)−N(1) [2.483(5) Å] lie in the usual range observed for thallium(I) amides.[10−12,17] The amido-N−Li bond lengths of Li(1)−N(2) [1.998(12) Å] and Li(1)−N(1A) [2.044(12) Å] are significantly shorter than the corresponding value for the pyridyl-N−Li bond of 2.102(12) Å.

In contrast to the dimeric mixed metal amide **5**, the homometallic species $[(2\text{-}C_5H_4N)C(CH_3)\{CH_2N(Tl)$-

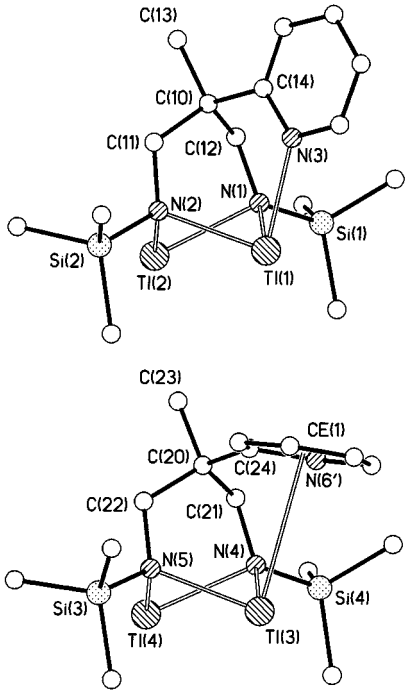

Figure 4. Molecular structure of the monomeric dithallium compound **6**: a) (top) fully ordered monomer unit of **6**, which is one half of the asymmetric unit in the crystal; b) (bottom) second isomer **6′**, present as a 30% component disordered in the second "molecule" of the asymmetric unit of **6**; selected bond lengths [Å] and angles [°]: Tl(1)−N(1) 2.470(14), Tl(1)−N(2) 2.406(15), Tl(1)−N(3) 2.468(15), Tl(2)−N(1) 2.445(13), Tl(2)−N(2) 2.434(14); N(2)−Tl(1)−N(1) 72.4(5), N(3)−Tl(1)−N(1) 80.0(5), N(3)−Tl(1)−N(2) 84.1(5), Tl(1)−N(3)−C(18) 119.2(14), Tl(1)−N(3)−C(14) 121.8(11), Tl(1)−N(2)−Tl(2) 90.4(5), Tl(1)−N(1)−Tl(2) 88.6(4)

$SiMe_3\}_2]_2$ (**6**) is monomeric in the solid state with two independent molecules in the asymmetric unit. The structure of the first molecule, which is fully ordered, is shown in Figure 4 (a); disorder present in the second molecular unit involves two orientations of the pyridyl ring which corresponds to 30% occupancy by a second isomer [Figure 4 (b)], in which rotation of the pyridyl ring gives a π-interaction of this ring with a thallium atom [Tl(3)−centroid: 3.524 Å]. The ordered monomer unit of **6** has one three-coordinate [Tl(1)] and one two-coordinate thallium centre [Tl(2)] and possesses almost exact molecular mirror symmetry, the virtual mirror plane containing the pyridyl ring, the ligand backbone atoms C(10) and C(13) as well as the two thallium atoms Tl(1) and Tl(2). With respect to Tl(1), the ligand adopts the typical tripod arrangement previously established for the early transition metal derivatives of this system.[6−8] Remarkably, the Tl−N distances to Tl(1) of the two anionic amido functions [Tl(1)−N(1) 2.470(14) Å and Tl(1)−N(2) 2.406(15) Å] and the neutral pyridyl function [Tl(1)−N(3) 2.468(15) Å] lie in the same range and thus do not allow for differentiation between the two types of metal−ligand interactions.

The orientation of the two monomeric units in the crystal corresponds to a weak association to dimeric aggregates

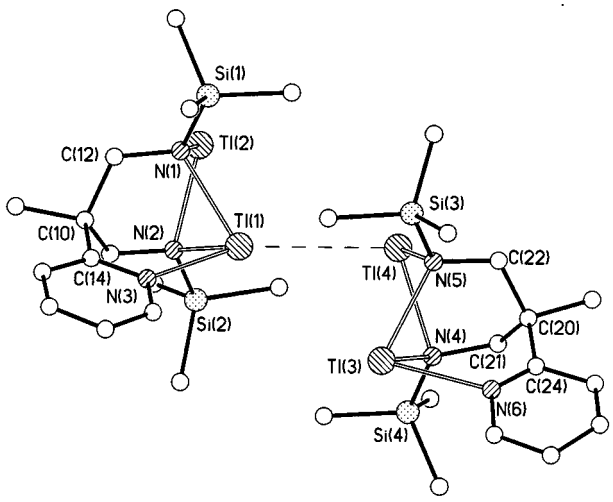

Figure 5. The asymmetric unit of **6** showing the aggregation of the two monomers via weak Tl−Tl interactions [Tl(1)Tl(4) 3.500(2) Å]

(Figure 5) of the type previously established for several other thallium amides, with an unsupported Tl−Tl contact.[9−12] This involves the three-coordinate thallium centre of one monomer and the two-coordinate metal atom of a neighbouring molecule ("head-to-tail" arrangement). The intermetallic distance of Tl(1)−Tl(4) [3.500(2) Å] is significantly shorter than the sum of the van der Waals radii (ca. 4.0 Å) and is thought to reflect a weakly attractive dispersive interaction between the metal centres.

Comparison of the Crystal Structures of 3−6: Variation of the Patterns of Aggregation upon Replacement of Lithium by Thallium(I)

The progression from the lithium amides via the mixed metal amide **5** to the homometallic thallium species **6** may be viewed as a gradual opening of a molecular cage. This is best represented if the cubic dimeric structure of the simple dilithium diamide $[CH_2\{CH_2N(Li)SiMe_3\}_2]$, which we reported recently,[13] is added to the series (Figure 6). If we begin with the cube, addition of the neutral pyridyl units first leads to an opening to form a ladder structure, either of the boat-type arrangement found in **3** or the stepped arrangement found for **4**. Replacement of lithium by thallium leads to a reduction in the nitrogen−metal interaction and breakdown of the dimer to give the weakly associated structure found for the thallium complex **6**.

Conclusions

In this study we have presented the first systematic structural investigation of lithium and thallium(I) derivatives of a polydentate amido donor ligand. The combination of these two different metal monocations leads to disparate forms of aggregation in the solid, ranging from the principally electrostatic amido−metal interaction in the alkali metal derivatives to the weakly dispersive metal attraction found for the thallium complex. Current work is aimed at extending the structural chemistry of mixed alkali

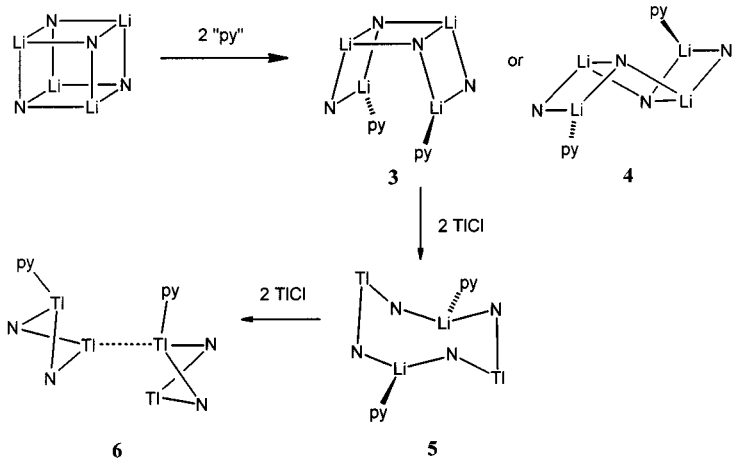

Figure 6. Opening of the heterocubane structure of bidentate lithium amides upon integration of neutral donors and substitution of lithium by thallium(I)

metal−thallium amides in order to gain further insight into the interactions defining their aggregation in the solid state.

Experimental Section

All manipulations were performed under dried argon in standard (Schlenk) glassware, which was flame-dried with a Bunsen burner prior to use. Solvents were dried according to standard procedures and saturated with Ar. The deuterated solvents used for the NMR-spectroscopic measurements were degassed by three successive "freeze-pump-thaw" cycles and dried over 4-Å molecular sieves. − The ^{1}H, ^{13}C, ^{29}Si, and ^{7}Li NMR spectra were recorded with a Bruker AC 200 spectrometer equipped with a B-VT-2000 variable-temperature unit (at 200.13, 50.32, 39.76, and 77.77 MHz, respectively) with tetramethylsilane or LiI/H_2O (1 M) as reference. − The IR spectra were recorded with a Bruker IFS 25 FT-IR spectrometer. − Elemental analyses were carried out in the microanalytical laboratory of the chemistry department at Würzburg. − The compounds (2-C_5H_4N)$C(CH_3)(CH_2NH_2)_2$ and (2-C_5H_4N)$C(CH_3)$-$(CH_2NHSiMe_3)_2$ (**1**) were prepared as reported previously.[6] All other chemicals used as starting materials were obtained commercially and used without further purification.

Preparation of (2-C_5H_4N)$C(CH_3)(CH_2NHSiMe_2tBu)_2$ (2): To a stirred solution of of (2-C_5H_4N)$C(CH_3)(CH_2NH_2)_2$ (9.01 g, 54.5 mmol) in thf (250 mL), NEt_3 (16.0 mL, 114.8 mmol), and then *t*$BuMe_2SiCl$ (16.4 g, 109.0 mmol) in thf (50 mL) was added in small portions at 0 °C. The mixture was warmed to room temperature and stirred for 3 h. After filtration, the solvent was removed under reduced pressure. Compound **2** was obtained as a colourless liquid after distillation under reduced pressure (yield: 20.6 g, 96%). − B.p.: 150 °C/3 mbar. − ^{1}H NMR (200.13 MHz, C_6D_6, 295 K): δ = −0.3, −0.1 [s, 12 H, $Si(CH_3)_2$], 0.73 (m, 2 H, NH), 0.91 [s, 18 H, $SiC(CH_3)_3$], 1.33 [s, 3 H, $C(CH_3)$], 3.09 {dd, 2 H, $^{2}J_{HH}$ = 12.5 Hz, $^{3}J_{HH}$ = 8.5 Hz, C[C*H*HNHSi$(CH_3)_2]_2$}, 3.31 {dd, 2 H, $^{3}J_{HH}$ = 8.1 Hz, C[CH*H*NHSi$(CH_3)_2]_2$}, 6.58 (m, 1 H, H^5, C_5H_4N), 7.06 (m, 1 H, H^3, C_5H_4N), 7.10 (m, 1 H, H^4, C_5H_4N), 8.46 (m, 1 H, H^6, C_5H_4N). − $\{^{1}H\}^{13}C$ NMR (50.32 MHz, C_6D_6, 295 K): δ = −4.8, −4.7 [$Si(CH_3)_3$], 18.7 [$SiC(CH_3)_3$], 21.2 [$C(CH_3)$], 26.8 [$SiC(CH_3)_3$], 48.6 [$C(CH_3)$], 51.2 {C[$CH_2NHSi(CH_3)_2]_2$}, 120.9 (CH, C^5, C_5H_4N), 121.9 (CH, C^4, C_5H_4N), 135.7 (CH, C^3, C_5H_4N), 149.2 (CH, C^6, C_5H_4N), 166.4 (C, C^2, C_5H_4N). − $\{^{1}H\}^{29}Si$ NMR (39.76 MHz, C_6D_6, 295 K): δ = 8.3. − IR (film): $\tilde{\nu}$ = 3396 w, 2952 vs, 2927 vs, 2982 s, 2854 vs, 1588 s, 1569 w, 1471 vs, 1431 s, 1401 vs, 1360 s, 1254 vs, 1110 vs, 1084 vs, 1006 s, 829 vs, 811 s, 777 s, 746 s, 662 s cm^{-1}. − $C_{21}H_{43}N_3Si_2$ (393.8): calcd. X-ray Crystallographic Study of 3−6: Data of **3** and **4** were collected using a Siemens P4 diffractometer at a temperature of 198(2) K (**3**) and 305(2) K (**4**), respectively, with oil-coated crystals mounted in Lindemann tubes. Data of **5** and **6** were collected using an Enraf−Nonius CAD4 diffractometer at a temperature of 133(2) K (**5**) and 193(2) K (**6**), respectively, with oil-coated shock-cooled crystals[18] mounted on the top of a glass pin under nitrogen. Crystal data and experimental details for the crystals of **3−6** are given in Table 1. All data for the structures **5** and **6** were corrected for absorption using Ψ-scans. No absorption correction was applied for structure **3** and **4**. Structure **5** was solved by Patterson methods, structures **3**, **4**, and **6** by direct methods (SHELXS-86: **3**, **5**, **6**; SHELXS-97: **4**) and refined on F^2 (SHELXL-93: **3**; SHELXL-97: **4−6**).[19] The comparatively high residual electron density in **5** and **6** was in the vicinity of the thallium atoms. Due to extremely poor diffraction by the only crystals of **4** available, data was collected in a very limited θ range (θ < 18°) and the chemically equivalent bond lengths in the two halves of the molecule were constrained in the refinement to be equal within an esd of 0.03 Å, because of the shortage of data. In the case of **5** a solvent molecule (*n*-pentane) was disordered across the inversion centre. In the case of **6**, disorder of the pyridine ring in one molecule in the asymmetric unit corre-

sponds to a random distribution at this site, throughout the crystal, of two isomers **6** and **6′** (differing only in the orientation of this pyridine ring) in a 70:30% ratio. In the final cycles of refinement all non-hydrogen atoms of **3**−**6** were assigned anisotropic displacement parameters. Hydrogen atoms were included in idealized positions riding on the parent atoms and were assigned isotropic displacement parameters of 1.2 U_{eq} (=CH, CH_2) and 1.5 U_{eq} (CH_3) of the parent atom. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-142874 (**3**), -142875 (**4**), -142876 (**5**), -142877 (**6**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

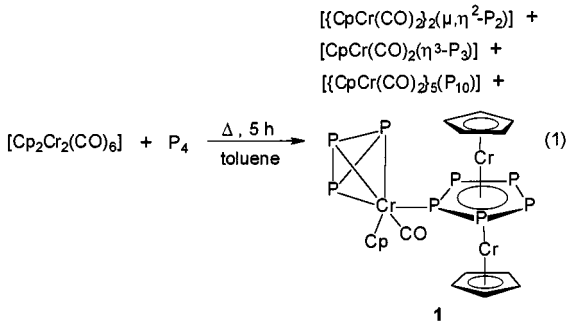
Synthesis and Properties of Novel Metal-Linked P_n Ligand Complexes

Perumal Sekar,[a] Shubhangi Umbarkar,[a] Manfred Scheer,*[a] Andreas Voigt,[b] and Reinhard Kirmse[b]

Dedicated to Professor Herbert Schumann on the occasion of his 65th birthday

Keywords: Phosphorus / Chromium / Molybdenum / Cyclopentadienes / Sandwich complexes



The reaction of $[CpCr(CO)_3]_2$ with P_4 in toluene at 90 °C for 5 h affords the triple-decker sandwich complex $[CpCr(CO)(\eta^3\text{-}P_3)(CpCr)_2(\mu,\eta^1\text{:}\eta^5\text{:}\eta^5\text{-}P_5)]$ (**1**) as a new product, along with the previously described products with P_2, P_3, and P_{10} units. The structure of the paramagnetic complex **1** has been established by single-crystal X-ray diffraction methods. A novel complex $[\{CpCr(CO)_2\}_2(\mu,\eta^1\text{:}\eta^1\text{:}\eta^2\text{-}P_2)\{Mo(CO)_4\}_2\{(\mu,\eta^1\text{:}\eta^1\text{:}\eta^5\text{:}\eta^5\text{-}P_5)(CpCr)_2\}]$ (**2**) has been obtained from the reaction of $[\{CpCr(CO)_2\}_2(\mu,\eta^2\text{-}P_2)]$ with $[Mo(CO)_4(NBD)]$ (NBD = norbornadiene). The X-ray structure of **2** reveals a six-membered Mo_2P_4 ring combining a Cr_2P_2 tetrahedral core and a triple-decker sandwich Cr_2P_5 moiety. The EPR spectra of the paramagnetic ($S' = 1/2$) complexes **1** and **2** are reported. A noticeable hyperfine interaction with two ^{31}P nuclei is observed for **2**.

Introduction

Research in the area of complexes with "naked" Group-15 elements as ligands has recently undergone a dynamic and exciting development.[1] The majority of publications in this field deal with the synthesis and structural features of E_n (E = P, As, Sb, Bi) containing complexes. However, during the last decade, various groups[2–5] have started to investigate the reactivities of such species, especially those of P_n ligand complexes. In continuation of our activities aimed at exploring unusual reactivity features of E_n-containing complexes, we have focussed our interest on studying the reactivity pattern of $[\{CpCr(CO)_2\}_2(\mu,\eta^2\text{-}P_2)]$, which was first obtained by Goh et al.[6] In one of our projects in this field, our interest lies in the synthesis of oligomers of such P_2 ligand complexes linked by transition metal moieties. In this context, we tried to obtain an Mo-bridged dimer of $[\{CpCr(CO)_2\}_2(\mu,\eta^2\text{-}P_2)]$ tetrahedral units by using the lone pairs of the phosphorus atoms. The surprising results are reported herein.

Results and Discussion

Goh et al. have described the isolation of $[\{CpCr(CO)_2\}_2(\mu,\eta^2\text{-}P_2)]$, $[CpCr(CO)_2(\eta^3\text{-}P_3)]$, $[(CpCr)_2(\mu,\eta^5\text{:}\eta^5\text{-}P_5)]$, and $[\{CpCr(CO)_2\}_5(P_{10})]$ from the thermolysis of $[CpCr(CO)_3]_2$ with P_4.[6] Additionally, from the same reaction we have obtained $[CpCr(CO)(\eta^3\text{-}P_3)(CpCr)_2(\mu,\eta^1\text{:}\eta^5\text{:}\eta^5\text{-}P_5)]$ (**1**) as a new product in good yields by stirring the reaction mixture for 5 h at 90 °C [Equation (1)].

Complex **1** was isolated along with $[\{CpCr(CO)_2\}_2(\mu,\eta^2\text{-}P_2)]$, $[CpCr(CO)_2(\eta^3\text{-}P_3)]$, and $[\{CpCr(CO)_2\}_5(P_{10})]$ after column chromatographic work-up. The ^{31}P NMR spectrum of the crude reaction mixture showed no signal attributable to the complex $[(CpCr)_2(\mu,\eta^5\text{:}\eta^5\text{-}P_5)]$. On the basis of this observation, one may speculate that **1** is formed by the subsequent reaction of $[CpCr(CO)_2(\eta^3\text{-}P_3)]$ with $[(CpCr)_2(\mu,\eta^5\text{:}\eta^5\text{-}P_5)]$, which are initially formed in the reaction of $[CpCr(CO)_3]_2$ with P_4. Complex **1** is insoluble in *n*-hexane but moderately soluble in toluene, CH_2Cl_2, and THF. Its infrared spectrum shows a broad absorption at 1897 cm^{-1} attributable to a terminal CO group. Due to the paramagnetic nature of **1**, no signal could be detected in its ^{31}P NMR spectrum. The mass spectrum of **1** shows peaks due to the parent ions $[CpCr(CO)(\eta^3\text{-}P_3)]$ and $[(CpCr)_2(\mu,\eta^5\text{:}\eta^5\text{-}P_5)]$ and fragmentation products thereof.

The molecular structure of **1** is shown in Figure 1. It consists of a triple-decker sandwich with a *cyclo*-P_5 middle deck, of which one of the P atoms coordinates to the Cr atom of the distorted $[CpCr(CO)(\eta^3\text{-}P_3)]$ tetrahedral moiety. The P–P distances in the P_5 middle deck fall into long [2.331(2) and 2.437(2) Å] and short [2.180(3) and 2.198(3) Å] categories, reflecting a lengthening of the P–P bonds around the atom P(4) due to its additional coordination to the Cr atom of the CrP_3 unit. This also leads to a slight

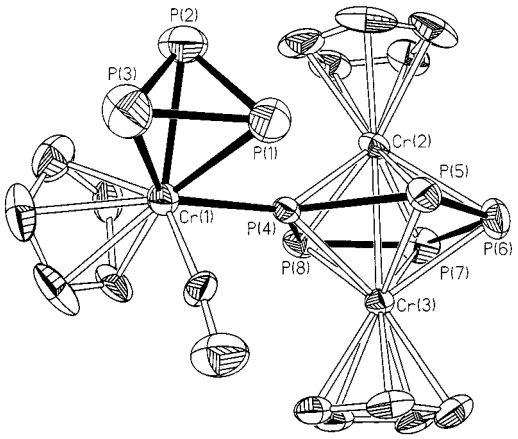

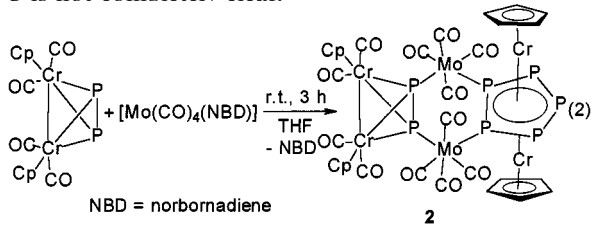

Figure 1. Molecular structure of **1** (ellipsoids drawn at a 50% probability level, H atoms of the Cp ligands are omitted for clarity); selected bond lengths [Å] and angles [°]: Cr(1)−P(1) 2.483(2), Cr(1)−P(2) 2.420(2), Cr(1)−P(3) 2.431(2), Cr(1)−P(4) 2.309(2), Cr(2)−Cr(3) 2.727(13), P(1)−P(2) 2.138(3), P(2)−P(3) 2.169(3), P(3)−P(1) 2.132(3), P(4)−P(5) 2.331(2), P(5)−P(6) 2.180(3), P(6)−P(7) 2.197(3), P(7)−P(8) 2.198(3), P(8)−P(4) 2.437(2); Cr(1)−P(4)−Cr(2) 141.18(8), P(4)−Cr(1)−P(1) 77.82(7), P(4)−Cr(2)−Cr(3) 53.54(5), P(1)−P(2)−P(3) 59.63(10)

shortening of the other P−P bonds within the *cyclo*-P_5 ring as compared to those in the *cyclo*-P_5 unit in $[(CpCr)_2(\mu,\eta^5{:}\eta^5\text{-}P_5)]$ [*d*(P−P) = 2.276(2)−2.206(3) Å],[6b] which is not additionally coordinated. In contrast, the P−P bond lengths in the *cyclo*-P_3 unit in **1** are slightly longer [2.132(3)−2.169(3) Å] than those in the *cyclo*-P_3 unit in $[CpCr(CO)_2(\eta^3\text{-}P_3)]$[6a] [2.118(3)−2.127(3) Å]. Due to this effect, a shortening of the Cr−P bond lengths in the tetrahedral CrP_3 unit of **1** is observed. These Cr−P bond lengths are in the range 2.420(2)−2.483(2) Å, thus making them slightly shorter than the corresponding distances observed in the complex $[CpCr(CO)_2(\eta^3\text{-}P_3)]$ [2.432(2)−2.494(1) Å]. The Cr−Cr distance in **1** [2.727(3) Å] is very similar to those in other triple-decker complexes reported in the literature, e.g. $[(CpCr)_2(\mu,\eta^5{:}\eta^5\text{-}P_5)]$ [2.738(1) Å] and $[(Cp^*Cr)_2(\mu,\eta^5{:}\eta^5\text{-}P_5)]$ [2.727(5) Å].[7]

Reactivity of $[\{CpCr(CO)_2\}_2(\mu,\eta^2\text{-}P_2)]$

Reaction of $[\{CpCr(CO)_2\}_2(\mu,\eta^2\text{-}P_2)]$ with one equivalent of $[Mo(CO)_4(NBD)]$ in THF at room temperature and subsequent column chromatographic work-up led to the isolation of $[\{CpCr(CO)_2\}_2(\mu,\eta^1{:}\eta^1{:}\eta^2\text{-}P_2)\{Mo(CO)_4\}_2\text{-}\{(\mu,\eta^1{:}\eta^1{:}\eta^5{:}\eta^5\text{-}P_5)(CpCr)_2\}]$ (**2**). In a further fraction, a paramagnetic complex − referred as **3** − was isolated as a minor product. In the mass spectrum of **3**, a small peak attributable to $[\{CpCr(CO)_2\}(\mu,\eta^1{:}\eta^1{:}\eta^3\text{-}P_3)\{Mo(CO)_4\}_2\text{-}\{(\mu,\eta^1{:}\eta^1{:}\eta^5{:}\eta^5\text{-}P_5)(CpCr)_2\}]$ was detected. All attempts to isolate suitable crystals for X-ray structure analysis failed, thus with only the mass spectral data available the nature of **3** is not completely clear.

The reddish-brown complex **2** was found to be insoluble in *n*-hexane but soluble in CH_2Cl_2. Its ^{31}P NMR spectrum features only a singlet at δ = 61.7, which can be assigned to the Cr_2P_2 part of the molecule.

The molecular structure of **2** is shown in Figure 2. It consists of a triple-decker sandwich and a tetrahedral Cr_2P_2 core bridged by two $[Mo(CO)_4]$ moieties, which results in a planar, six-membered Mo_2P_4 ring. Each Mo atom resides in a sixfold coordination environment made up of two P atoms, one from each of the $[\{CpCr(CO)_2\}_2(\mu,\eta^2\text{-}P_2)]$ and $[(CpCr)_2(\mu,\eta^5{:}\eta^5\text{-}P_5)]$ fragments, along with four carbonyl groups. This molecule represents the first example of a complex containing a tetrahedron as well as both five- and six-membered rings. The P_4Mo_2 and *cyclo*-P_5 moieties are coplanar and are connected by a shared P_2 edge. Scherer et al. have reported the complex $[\{[CpMo(CO)_2]_2(\mu,\eta^2{:}\eta^1{:}\eta^1\text{-}P_2)\}_2\{Re(CO)_3Br\}_2]$,[8] in which the two Re atoms and the P_2 units of two tetrahedral $[\{CpMo(CO)_2\}_2(\mu,\eta^2\text{-}P_2)]$ fragments form a planar six-membered ring. Due to the coordination to the $[Mo(CO)_4]$ moieties in **2**, the P(2)−P(2A) distance [2.438(5) Å] in the P_5 ring is lengthened as compared to those in $[(CpCr)_2(\mu,\eta^5{:}\eta^5\text{-}P_5)]$ [*d*(P−P) = 2.276(2)−2.206(3) Å]. The bond lengths and angles in the coordinated Cr_2P_2 tetrahedron in **2** differ very little from those in the uncoordinated molecule. The Mo−P bond lengths in **2** [2.517(2) and 2.541(2) Å] are slightly longer than that in $[\{CpCr(CO)_2\}_2(\mu,\eta^2{:}\eta^1{:}\eta^1\text{-}P_2)\{Mo(CO)_5\}_2]$ (2.506 Å).[9]

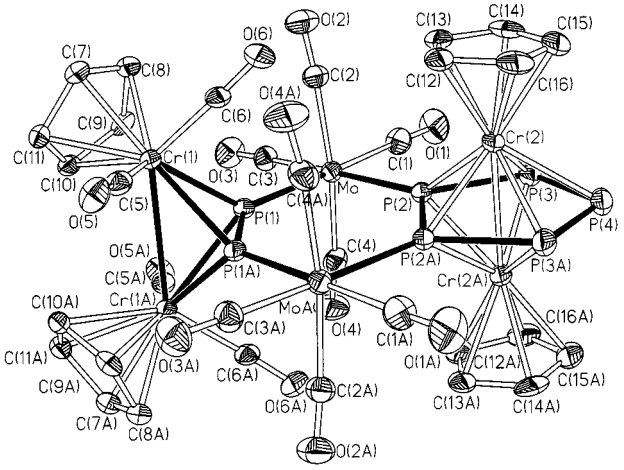

Figure 2. Molecular structure of **2** (ellipsoids drawn at a 30% probability level, H atoms of the Cp ligands are omitted for clarity); selected bond lengths [Å] and angles [°]: Mo−P(1) 2.517(2), Mo−P(2) 2.541(2), Cr(1)−Cr(1A) 3.019(1), Cr(2)−Cr(2A) 2.728(3), Cr(1)−P(1) 2.329(2), Cr(1)−P(1A) 2.514(2), Cr(1A)−P(1) 2.514(2), Cr(1A)−P(1A) 2.329(2), P(1)−P(1A) 2.087(4), P(2)−P(2A) 2.438(5), P(2)−P(3) 2.276(3), P(3)−P(4) 2.206(3), P(4)−P(3A) 2.206(3), P(4)−P(2A) 2.276(3); P(1)−Mo−P(2) 88.39(7), Cr(1)−P(1)−Mo 137.54(9), Cr(2)−P(2)−Mo 144.33(9), P(1A)−P(1)−Mo 138.87(5), P(2A)−P(2)−Mo 132.66(5)

EPR Investigations

The room-temperature X-band EPR spectrum of a CH_2Cl_2 solution of **1** consists of one line with a linewidth of $\Delta B_{pp} \approx 5$ mT and shows no hyperfine interactions. At low temperatures (T = 130 K), an EPR spectrum character-

ized by an axially symmetric $\boldsymbol{g}$ tensor is observed. Again, no hyperfine interactions can be detected. This spectrum is reproduced in Figure 3. The g values detected are given in Table 1.

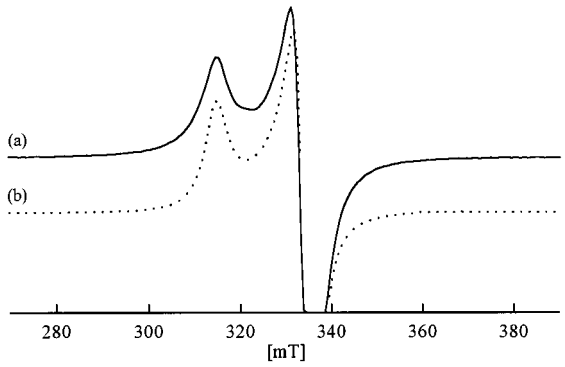

Figure 3. Experimental (a) and simulated (b) X-band EPR spectrum of **1** in CH_2Cl_2 at $T = 130$ K

Table 1. EPR parameters of **1** and **2**; hyperfine coupling constants are given in [10^{-4} cm^{-1}]

	1[a]		**2**[a]
$g_\perp$	2.018	g_1	1.991
$g_\parallel$	2.145	g_2	2.021
g_{av}[b]	2.060	g_3	2.048
g_0	2.073	g_{av}[c]	2.020
A^P_1	[d]	A^P_1	17.2
A^P_2	[d]	A^P_2	16.0
A^P_3	[d]	A^P_3	24.6
$A^P{}_{av}$[c]	–	$A^P{}_{av}$[c]	19.3

[a] Experimental error: $g_i \pm 0.003$; $A^P{}_i \pm 1.0$. – [b] $g_{av} = (2g_\perp + g_\parallel)/3$. – [c] $g_{av} = (g_1 + g_2 + g_3)/3$; $A^P{}_{av} = (A^P{}_1 + A^P{}_2 + A^P{}_3)/3$. – [d] Not resolved.

For compound **2**, the EPR spectrum recorded in THF at room temperature shows a 1:2:1 triplet of lines (the linewidth of $\Delta B_{pp} \approx 0.5$ mT is considerably smaller than that observed in the case of **1**), as expected for the interaction of one unpaired electron with two $I = 1/2$ nuclei (^{31}P). The derived isotropic parameters are: $g_0 = 2.022 \pm 0.002$ and $a^P_0 = (18.0 \pm 1.0) \times 10^{-4}$ cm^{-1}. The frozen-solution EPR spectrum of **2** is given in Figure 4 together with its simulation. For the simulation, the aforementioned isotropic parameters were taken into account. The main features of the spectrum can be rationalized by assuming a spin system consisting of one unpaired electron and its interaction with two equivalent ^{31}P nuclei. The derived parameters are listed in Table 1. However, the spectrum also shows some smaller splittings, possibly due to hyperfine interactions with neighbouring protons or phosphorus nuclei. Since no other signals could be detected in the accessible spectral range (neither for **1** nor for **2**), the spectra as described above were interpreted with the following "effective" spin Hamiltonian [Equation (3)].

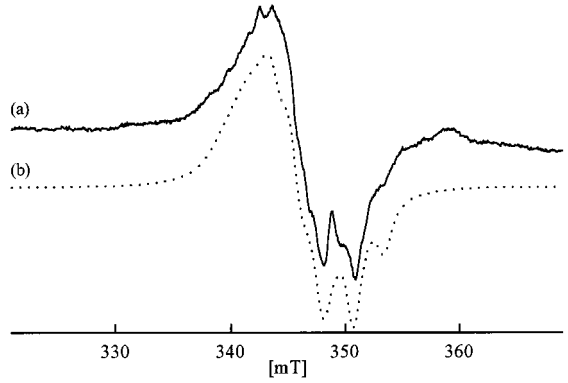

Figure 4. Experimental (a) and simulated (b) X-band EPR spectrum of **2** in THF at $T = 130$ K

$$\boldsymbol{H}_{sp} = \mu_B \cdot \boldsymbol{g} \cdot \boldsymbol{B}_0 \cdot \boldsymbol{S}' + \boldsymbol{S}' \cdot \boldsymbol{A}^P \cdot \boldsymbol{I}^P \quad (3)$$

In Equation (3), S' denotes $S = 1/2$; for compound **2**, two equivalent ^{31}P nuclei were taken into account. It should be noted that in spite of the aforementioned ^{31}P hyperfine interactions, no other hyperfine interactions (e.g. ^{53}Cr, $^{95,97}Mo$) could be detected.

The ^{31}P hyperfine parameters derived for **2** can be used to estimate the spin density on these nuclei. For this, the isotropic component A^P_{av} and the dipolar component b^P ($b^P = A^P_\perp - A^P_{av}$) of the ^{31}P coupling are needed. According to the nearly axially symmetric ^{31}P hyperfine tensor, A^P_1 and A^P_2 can be averaged to $A^P_\perp = 16.6 \cdot 10^{-4}$ cm^{-1}. Using the previously reported procedure[2c,10,11] and the atomic parameters calculated by Morton and Preston,[10] 0.5% and 2.2% of the spin density was calculated to reside in the 3s and 3p orbitals of P, respectively. Thus, 5.4% of the overall spin density is located on the two P atoms observed in the spectra. Since no other hyperfine interactions (e.g. $^{95,97}Mo$) could be successfully analysed for the $Cr_4Mo_2P_7$ unit of **2**, the bulk of the electron spin density seems to be localized in a $Cp_2Cr_2P_2$ unit, thereby accounting for the observed ^{31}P hyperfine interactions with the bridging P atoms of the P_5 ring.

Conclusions

Although the initial goal of the synthesis of a metal-linked dimer of tetrahedral Cr_2P_2 complexes has not been achieved, the interesting reactivity of [{$CpCr(CO)_2$}$_2$(μ,η^2-P_2)] has led to the generation of the unexpected product **2**. The formation of **1** and **2** under mild conditions is suggestive of preferential transformation to a triple-decker sandwich complex [$(CpCr)_2$(μ,η^5:η^5-P_5)], even when this forms a part of more complex molecules, giving rise to novel structural features. This characteristic has previously been observed in the reaction of [{$CpCr(CO)_2$}$_2$(μ,η^2-P_2)] with $LiBEt_3H$, where the complex [{[$CpCr(CO)_2$]$_2$(μ-PH)}{$(CpCr)_2$(μ,η^1:η^1:η^5:η^5-P_5)}] [2c] was formed as a side-product. In contrast to the situation in the analogous tetrahedral M_2P_2 ligand complexes of molybdenum and tungsten, the weaker Cr–Cr bond in [{$CpCr(CO)_2$}$_2$(μ,η^2-P_2)]

has been shown to be largely responsible for the unusual reactivity behaviour of this species. The formation of a triple-decker sandwich complex in **2** is one of its consequences. This effect is also observed in the reactions of $[\{CpCr(CO)_2\}_2(\mu,\eta^2\text{-}P_2)]$ with ECl_3 (E = P, As, Sb), which furnish the corresponding mixed *cyclo*-P_2E ligand complexes under elimination of $[CpCrCl_2]_2$.[2d] Further investigation of this interesting behaviour of $[\{CpCr(CO)_2\}_2(\mu,\eta^2\text{-}P_2)]$ is part of our ongoing research.

Experimental Section

General Techniques: All reactions and manipulations were performed under dry argon using standard Schlenk techniques. Solvents were dried and distilled under argon prior to use, toluene and THF with Na/benzophenone, hexane with $LiAlH_4$, dichloromethane with P_2O_5. – IR spectra were recorded with a Bruker IFS 28 FT-IR spectrometer, mass spectra with a Finnigan MAT 711 spectrometer at 70 eV. Satisfactory elemental analyses were obtained with an Elementar Vario EL at the Institute of Inorganic Chemistry, University of Karlsruhe.

Reaction of $[\{CpCr(CO)_3\}_2]$ with P_4: Dry P_4 (0.92 g, 7.45 mmol) was added to a deep-green solution of $[\{CpCr(CO)_3\}_2]$ (3.0 g, 7.45 mmol) in toluene (75 mL) and the resulting mixture was stirred at 90 °C for 5 h. The reddish-brown solution was then filtered through silica gel and the filtrate was concentrated to dryness in vacuo. The unchanged P_4 was removed by sublimation prior to chromatography. Chromatographic workup on a silica gel column (40 × 3.0 cm) eluting with *n*-hexane yielded a trace amount of unchanged P_4 followed by a yellowish-brown fraction containing $[CpCr(CO)_2(\eta^3\text{-}P_3)]$ (0.3 g, 1.13 mmol, 7.5%). Elution with *n*-hexane/toluene (2:1) gave a yellow fraction that turned brown, from which black crystals of $[CpCr(CO)(\eta^3\text{-}P_3)(CpCr)_2(\mu,\eta^1{:}\eta^5{:}\eta^5\text{-}P_5)]$ (**1**) (1.0 g, 1.59 mmol, 33% yield) crystallized. Using *n*-hexane/toluene (1:1) as eluent, a magenta-coloured fraction containing $[\{CpCr(CO)_2\}_2(\mu,\eta^2\text{-}P_2)]$ (1.1 g, 2.69 mmol, 36%) followed by a golden-brown fraction containing $[\{CpCr(CO)_2\}_5P_{10}]$ (1.2 g, 1.02 mmol, 7%) were obtained (yields are calculated on the basis of $[\{CpCr(CO)_3\}_2]$).

1: IR [KBr, ν(CO)/cm^{-1}]: 1897 (s, br). – ^{1}H NMR (250.13 MHz, CD_2Cl_2, TMS, 301 K): δ = 4.21 (br. s, $CpCrP_3$), 19.48 [br. s, $(CpCr)_2P_5$]. – EI-MS (70 eV, 150 °C): *m*/*z* (%) = 389 (100) $[Cp_2Cr_2P_5]$, 327 (86) $[Cp_2Cr_2P_3]$, 262 (6) $[CpCr_2P_3]$, 238 (24) $[CpCr(CO)P_3]$, 210 (59) $[CpCrP_3]$, 200 (12) $[CpCr_2P]$, 182 (74) $[CrCp_2]$, 135 (6) $[Cp_2Cr]$, 124 (33) $[P_4]$, 117 (60) [CrCp]. – $C_{16}H_{15}Cr_3OP_8$ (627.1): calcd. C 30.65, H 2.41; found C 30.05, H 2.61.

Reaction of $[\{CpCr(CO)_2\}_2(\mu,\eta^2\text{-}P_2)]$ with $[Mo(CO)_4(NBD)]$: $[\{CpCr(CO)_2\}_2(\mu,\eta^2\text{-}P_2)]$ (100 mg, 0.245 mmol) and $[Mo(CO)_4(NBD)]$ (74 mg, 0.245 mmol) were dissolved in THF (40 mL) and the resulting mixture was stirred at room temperature for 3 h. The solvent was then removed in vacuo. Chromatographic workup on a silica gel column (35 × 2.5 cm) eluting with *n*-hexane/CH_2Cl_2 (1:1) gave a magenta-coloured solution of unchanged $[\{CpCr(CO)_2\}_2(\mu,\eta^2\text{-}P_2)]$ (25 mg, 25%), a trace amount of $[Mo(CO)_4(NBD)]$, followed by a reddish-brown fraction containing $[\{CpCr(CO)_2\}_2(\mu,\eta^1{:}\eta^1{:}\eta^2\text{-}P_2)\{Mo(CO)_4\}_2\{(\mu,\eta^1{:}\eta^1{:}\eta^5{:}\eta^5\text{-}P_5)(CpCr)_2\}]$ (**2**) (50 mg, 34%). Elution with *n*-hexane/CH_2Cl_2 (1:3) yielded a dark-brown fraction containing **3** (20 mg).

2: IR [CH_2Cl_2, ν(CO)/cm^{-1}]: 2070 (w), 2023 (w), 1942 (s, br). – ^{31}P NMR (101.256 MHz, C_6D_6, 85% H_3PO_4): δ = 61.7 (s). – ^{1}H NMR (250.13 MHz, CD_2Cl_2, TMS, 301 K): δ = 3.38 (br. s, Cr_2P_2). – EI-MS (70 eV, 350 °C): *m*/*z* (%) = 989 (1) $[M^+ - 8CO]$, 840 (5) $[M^+ - Cp - 11CO]$, 676 (2) $[Cp_3Cr_4P_7(CO)_2]$. – **3**: IR [CH_2Cl_2, ν(CO)/cm^{-1}]: 2072 (w), 2020 (s), 1977 (s), 1940 (vs, br). – ^{31}P NMR (101.256 MHz, C_6D_6, 85% H_3PO_4): δ = −58.9 (s). – EI-MS (70 eV, 370 °C): *m*/*z* (%) = 1071 (0.02) $[Cp_3Cr_3P_8Mo_2(CO)_8]$,

X-ray Structure Determination and Details of the Refinement: Data were collected with a STOE IPDS area detector diffractometer using Mo-K_α (λ = 0.71069 Å) radiation. Machine parameters, crystal data, and data collection parameters are summarized in Table 2. The structures were solved by direct methods using SHELXS-86[12a] and refined by full-matrix least-squares methods on F^2 using SHELXL-93[12b] with anisotropic displacement factors for non-H atoms; hydrogen atoms were placed in idealized positions and refined isotropically according to the riding model. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-142655 and -142656. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk.

EPR Measurements: EPR spectra were recorded in the X-band ($\nu \approx 9.5$ GHz) with a Bruker ESP 300E spectrometer in the temperature range 295−130 K using ca. 10^{-2}−10^{-3} M solutions of **1** (CH_2Cl_2) and **2** (THF). After cooling the samples, the formation of a good "glass" was proven. The EPR parameters were obtained using a modified version of the computer program written by White and Belford.[13,14]

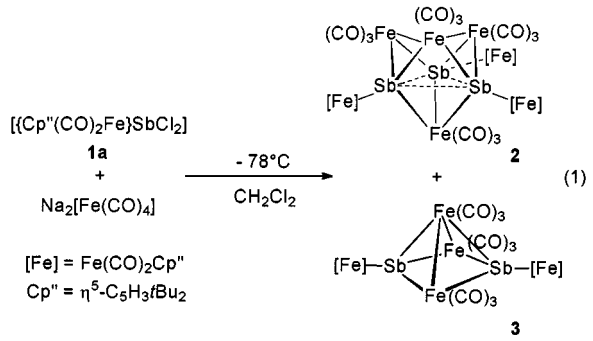
Novel Main Group-Transition Metal Cluster Compounds Incorporating Antimony, Iron and Cobalt

Thomas Gröer,[a] Tobias Palm,[a] and Manfred Scheer*[a]

Dedicated to Professor Herbert W. Roesky on the occasion of his 65th birthday

Keywords: Antimony / Iron / Cobalt / Cluster / Polyhedra

The reaction of [{$Cp^x(CO)_2Fe$}$SbCl_2$] [**1a**: $Cp^x = \eta^5$-$C_5H_3tBu_2$-1,3 (Cp"); **1b**: $Cp^x = \eta^5$-C_5Me_5 (Cp*)] with $Na_2[Fe(CO)_4]$ or $K[Co(CO)_4]$ affords the novel antimony-transition metal cluster compounds [{μ_3-$SbFe(CO)_2Cp"$}$_3${$Fe(CO)_3$}$_4$] **(2)**, [{$Fe_3(CO)_9$}{μ_3-$SbFe(CO)_2Cp"$}$_2$] **(3)** and [{μ_4-$SbFe(CO)_2$-Cp^*}$_2${$Co_4(CO)_{10}(\mu$-CO)}] **(4)**. All products were characterised by X-ray structure analyses and other methods. Cluster **2** reveals a novel Sb_3Fe_4 core, which does not follow the Wade–Mingos rules. Cluster **3** forms a square-pyramidal *nido*-cluster. The Sb_2Co_4 cluster core of **4** derives from a pentagonal bipyramid and consists of apical Sb and equatorial Co atoms with one missing pentagonal core atom.

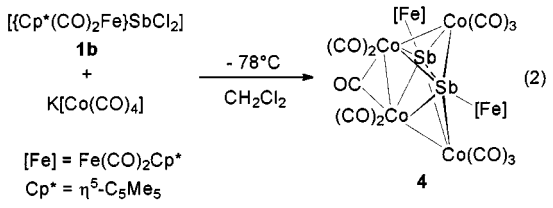


Introduction

Clusters which incorporate main group elements and transition metals together in a core framework have been of wide interest in the last years.[1] We are particularly interested in complexes which contain the heavy group 15 elements Sb and Bi. Amongst those, only a few examples of antimony-rich complexes have been prepared, e.g. [{$Mo(CO)_3Cp^x$}$_2$(μ,η^2-Sb_2)] (Cp^x = Cp,[2] Cp*[3]) [(μ,η^2-Sb_2){$W(CO)_5$}$_3$],[4] and [{$Mo(CO)_2Cp^x$}(η^3-Sb_3)][3] (Cp^x = Cp, Cp*). The synthetic approach to these clusters is versatile: they can be prepared either by metalation of $SbCl_3$, reaction of elemental antimony with transition metal complexes or from cyclic organo-antimony precursors.

Even though there is a large variety of synthetic methods to yield these cluster compounds, a rational way of preparing them is still missing. Recently, we reported the synthesis and structure of transition metal-substituted dichlorides of antimony and bismuth of the formula [{$Cp"(CO)_2Fe$}ECl_2] [E = Sb **(1a)**, Bi].[5] These complexes have interesting properties for the building-up of main group element-transition metal clusters of varying composition in a straightforward manner. This might be feasible by either using reducing agents (e.g. Mg) to yield (μ_3-E) bridged binary compounds[5] or by incorporating other transition metals from a reaction with metalates. This latter reaction was successfully used to prepare phosphorus rich complexes starting from $[Cp(CO)_3WPCl_2]$.[6] We herein report the synthesis and structures of novel antimony-containing main group-transition metal cluster compounds.

Results and Discussion



The reaction of [{$Cp"(CO)_2Fe$}$SbCl_2$] **(1a)** with $Na_2[Fe(CO)_4]$ yields the novel cluster compound [{μ_3-$SbFe(CO)_2Cp"$}$_3${$Fe(CO)_3$}$_4$] **(2)** as the main product and smaller amounts of [{μ_3-$SbFe(CO)_2Cp"$}$_2${$Fe_3(CO)_9$}] **(3)** [Equation (1)]. While it was possible to isolate **2** as a pure compound by fractional crystallisation, the minor product **3** always co-crystallises with **2**. Attempts to separate these mixtures by column chromatography on silica gel or aluminium oxide failed due to the decomposition of the products. The complex [{$Cp^*(CO)_2Fe$}$SbCl_2$] **(1b)** reacts with two equivalents of $K[Co(CO)_4]$ to form [{μ_4-$SbFe(CO)_2$-Cp^*}$_2${$Co_4(CO)_{10}(\mu$-CO)}] **(4)** [Equation (2)] and some $[Cp^*(CO)Fe(\mu\text{-}CO)_2Co(CO)_3]$ **(5)**. The occurrence of **5** is a hint that, as a side-reaction, a metal-antimony bond cleavage occurs — as it was also reported for the reaction of **1a** with magnesium.[5] Complex **5** has already been structurally characterised,[7] and our X-ray[8] and spectroscopic data are similar to the reported values.

All complexes were isolated as red crystalline compounds, which are readily soluble in *n*-hexane or toluene. In the IR spectra of compounds **2**–**4**, the CO stretching frequencies for terminal CO groups are detected, whereas for cluster **4** an addition band at 1779 cm^{-1} for a bridging

CO group is found. In the ^{1}H NMR spectrum of **2** at ambient temperature the *t*Bu groups and the protons on the Cp" rings are inequivalent. At a temperature of 368 K the two signals of the methyl protons coalesce indicating the free rotation of the Cp" ligands. The free activation enthalpy of this process at the coalescence temperature (T_c = 368 K) is calculated to be $\Delta G^{\#}_{Tc}$ = 80 kJ/mol.

An X-ray structure analysis of **2** reveals a central Sb_3Fe tetrahedron, the Sb_3 and two Sb_2Fe planes of which are capped by three $Fe(CO)_3$ groups (Figure 1). The Fe atom of the tetrahedron additionally coordinates to three carbonyl ligands, whereas each antimony atom binds to an $Fe(CO)_2Cp"$ fragment. Within the Sb_3 unit two different kinds of Sb···Sb distances are observed: long distances are found around the Sb(3) atom [3.2412(9) and 3.2574(10) Å] and are much longer than known Sb−Sb single bonds as, for example, in Sb_7^{3-} [2.717(2)−2.906(2) Å],[9] $[\{Mo(CO)_2Cp^*\}(\eta^3\text{-}Sb_3)]$[3] [2.7397(9)−2.7682(8) Å], (*t*BuSb)$_4$ [2.822(1)−2.878(1) Å[10a]] or in $[(Me_3Si)_2CHSb]_3$ [2.8188(6)−2.8453(6) Å].[10b] However, the shortest distance in **2** [Sb(1)−Sb(2) = 3.0259(9) Å] is still within the range of long, bonding Sb−Sb distances as found in the compound $[\{Cp(CO)_2Fe\}\{Cr(CO)_5\}SbBr]_2$,[11] possessing the longest known Sb−Sb single bond length of 3.069(6) Å. Intermolecular Sb···Sb distances within the structure of **2** are in the range of 3.678(1)−4.271(1) Å, as found for Me_4Sb_2 [12] and $[(\eta^3\text{-}Sb_3)\{Mo(CO)_2Cp^x\}]$ (Cp^x = Cp, Cp*).[3]

The Sb_3Fe_4 cluster core of **2** is close to C_s symmetry with the symmetry plane defined by the atoms Sb(3), Fe(6) and Fe(7), which becomes evident by the similarity in the bond lengths of Fe(6)−Sb(1) and Fe(6)−Sb(2) [2.6686(14) vs. 2.6672(15) Å], and Fe(6)−Fe(5) and Fe(6)−Fe(4) [2.844(2) vs. 2.8466(18) Å] (Figure 2). Due to the steric hindrance of the bulky Cp" ligands, the molecule might not be able to adopt an overall C_s symmetry. Describing the Sb_3Fe_4 cluster core of the 20 skeletal electrons by the Wade−Mingos rules does not lead to a satisfactory explanation of the adopted polyhedron. An explanation can be given using the concept of "Topological Electron Counting" (TEC), as suggested by Teo[13] for the relation between cluster geometry and valence electrons in transition metal clusters. Using this relation with mixed transition metal-main group element clusters, the number of bonding orbitals (CVMO) will count to $CVMO = 8X + 3N - F + 2$ (X = number of transition elements; N = number of main group elements; F = number of polyhedral faces). In the case of the cluster core in compound **2** this results in a CVMO of 34 on assuming bonding Sb−Sb interactions. Calculating the number of cluster electrons by EAN rules leads to 68, which fits with the number of bonding cluster orbitals. To the best of our knowledge this polyhedron is so far unique for a main group transition metal cluster.

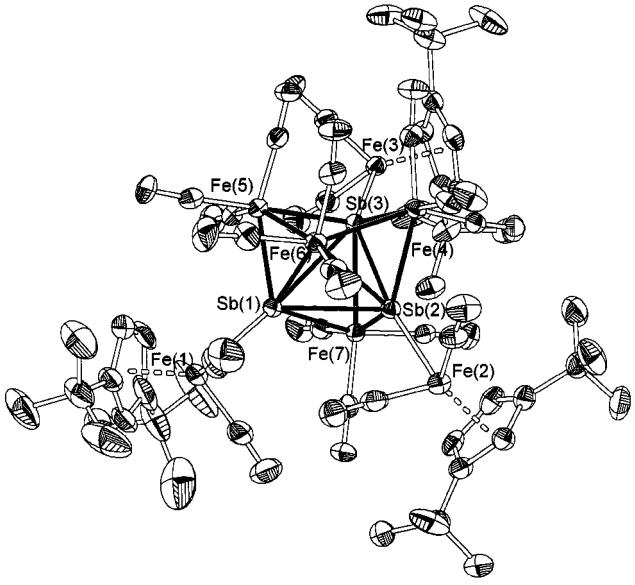

Figure 1. Molecular structure of $[\{\mu_3\text{-}SbFe(CO)_2Cp"\}_3\{Fe(CO)_3\}_4]$ **(2)** showing 30% probability ellipsoids; hydrogen atoms are omitted for clarity; selected bond lengths [Å]: Sb(1)−Sb(2) 3.0259(9), Sb(1)−Sb(3) 3.2412(9), Sb(2)−Sb(3) 3.2574(10), Sb(1)−Fe(1) 2.5917(14), Sb(1)−Fe(5) 2.5170(14), Sb(1)−Fe(6) 2.6686(14), Sb(1)−Fe(7) 2.6337(13), Sb(2)−Fe(2) 2.5921(16), Sb(2)−Fe(4) 2.5311(13), Sb(2)−Fe(6) 2.6672(15), Sb(2)−Fe(7) 2.6076(14), Sb(3)−Fe(3) 2.6415(14), Sb(3)−Fe(4) 2.6312(14), Sb(3)−Fe(5) 2.6157(13), Sb(3)−Fe(7) 2.6833(12), Fe(6)−Fe(5) 2.844(2), Fe(6)−Fe(4) 2.8466(18)

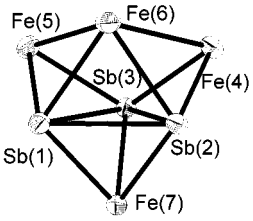

Figure 2. Sb_3Fe_4 cluster core in **2**

The structure of the compound $[\{\mu_3\text{-}SbFe(CO)_2Cp"\}_2\{Fe_3(CO)_9\}]$ **(3)** is built up of a tetragonal pyramid of three Fe and two Sb atoms, with the two Sb and two of the Fe atoms alternately building the base square (Figure 3). The third Fe atom is at the top of the pyramid. Each Sb atom is additionally bound to a $Fe(CO)_2Cp"$ moiety. On using the Wade−Mingos rules on the Sb_2Fe_3 cluster core, an electron count comes to 14 skeletal electrons, which is the same number as in *nido*-pentaborane B_5H_9, which also forms a square pyramid. A similar cluster framework has been found for the lighter congeners of Sb within $[\{Fe_3(CO)_9\}\{\mu_3\text{-}PFe(CO)_2Cp\}_2]$[14] and $[\{Fe_3(CO)_9\}\{\mu_3\text{-}AsMo(CO)_3Cp\}_2]$.[15] The Fe−Fe distances within the $Fe_3(CO)_9$ fragment in **3** are 2.823(2) Å and 2.814(2) Å. The Fe−Fe bond length is dependent on the atomic radius of the pnicogenido atom, and decreases from **3** through $[\{Fe_3(CO)_9\}\{\mu_3\text{-}AsMo(CO)_3Cp\}_2]$ [2.726(2) and 2.750(2) Å] to $[\{Fe_3(CO)_9\}\{\mu_3\text{-}PFe(CO)_2Cp\}_2]$ [2.704(3) and 2.718(4) Å]. In compound **3** there is no bonding interaction

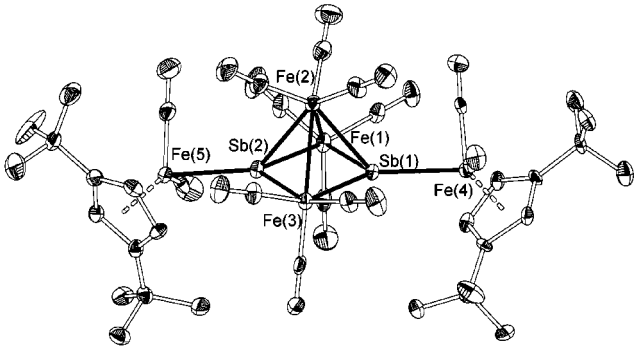

Figure 3. Molecular structure of $[\{\mu_3\text{-SbFe}(CO)_2Cp''\}_2\{Fe_3(CO)_9\}]$ **(3)** showing 30% probability ellipsoids; hydrogen atoms are omitted for clarity; selected bond lengths [Å] and angles [°]: Sb(1)−Fe(1) 2.5075(19), Sb(1)−Fe(2) 2.543(2), Sb(1)−Fe(3) 2.530(2), Sb(1)−Fe(4) 2.5518(19), Sb(2)−Fe(1) 2.512(2), Sb(2)−Fe(3) 2.5240(18), Sb(2)−Fe(2) 2.5529(18), Sb(2)−Fe(5) 2.5607(18), Sb(1)···Sb(2) 3.1705(15), Fe(1)−Fe(2) 2.823(2), Fe(2)−Fe(3), 2.814(2); Fe(1)−Sb(1)−Fe(3) 101.94(7), Fe(1)−Sb(2)−Fe(3) 101.97(7), Sb(1)−Fe(1)−Sb(2) 78.34(6), Sb(2)−Fe(3)−Sb(1) 77.71(6), Fe(1)−Sb(1)−Fe(4) 121.74(6), Fe(3)−Sb(1)−Fe(4) 136.28(6), Fe(2)−Sb(1)−Fe(4) 128.54(6), Fe(1)−Sb(2)−Fe(5) 125.27(6), Fe(2)−Sb(2)−Fe(5) 135.23(7), Fe(3)−Sb(2)−Fe(5) 131.87(6), Fe(3)−Fe(2)−Fe(1) 87.92(7)

between Fe(1) and Fe(3) [Fe(1)···Fe(3) = 3.913(2) Å]. All Sb−Fe bond lengths are within the small range of 2.5075(19) [Sb(1)−Fe(1)] and 2.5607(18) Å [Sb(2)−Fe(5)] and are therefore shorter than the Sb−Fe bond lengths in **2**. The Sb···Sb distance is 3.1705(15) Å. The folding angle between the two planes defined by Sb(1), Fe(1) and Sb(2), and Sb(1), Fe(3) and Sb(2), respectively, is 178.29(2)° and hence close to planarity. It is similar to that of the dianionic *nido*-cluster $[\{Fe_3(CO)_9\}(\mu_3\text{-SbFe}(CO)_4)_2]^{2-}$ [174.54(3)°].[16a] At first sight, the structures of this compound and of its homologues $[\{Fe_3(CO)_9\}(\mu_3\text{-EFe}(CO)_4)_2]^{2-}$ (E = As,[16b] Bi[16c]) seem to be similar to **3**; however, in these dianionic complexes the lone pair of the pnicogens coordinates to an exocyclic $Fe(CO)_4$ group,[16d] whereas in **3** a σ-bond exists to exocyclic $CpFe(CO)_2$ moieties.

The X-ray structure analysis of **4** (Figure 4) shows a central Sb_2Co_2 tetrahedron, two planes of which are capped by one $Co(CO)_3$ group each. The Co−Co edge of the tetrahedron is bridged by a carbonyl ligand. Each antimony atom additionally binds to an $Fe(CO)_2Cp^*$ fragment. The Sb−Sb distance in **4** is 2.986(2) Å and hence is shorter than the distances in compound **2** [3.0259(9)−3.2574(10) Å]. The Sb−Co bond lengths [2.605(4)−2.651(3) Å] are in the known range for single bonds [2.480(1)−2.690(1) Å].[17−19]

The anionic cluster compounds $[E_2Co_4(CO)_{10}(\mu\text{-CO})]^{n-}$ (E = Sb, Bi; n = 1, 2), possessing a E_2Co_4 core similar to **4**, were first described by Whitmire[20] and Martinengo,[21] respectively. In contrast to these compounds, compound **4** is uncharged, and the electrons of the charges in the former compounds are in **4** formally located in the Sb−Fe bonds to the $Fe(CO)_2Cp^*$ fragments. This results in a longer Sb−Sb distance in **4** [2.986(2) Å] than that in $[Sb_2Co_4(CO)_{10}(\mu\text{-CO})]^{2-}$ [2.882(2) Å] and a concomitant shortening of the Co−Co bond lengths within the cluster core [2.598(5)−2.683(4) Å] compared to those in

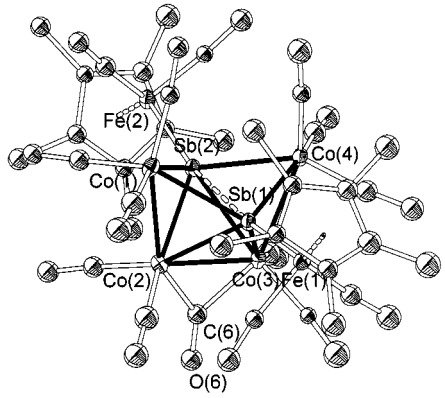

Figure 4. Molecular structure of $[\{\mu_4\text{-SbFe}(CO)_2\text{-}Cp^*\}_2\{Co_4(CO)_{10}(\mu\text{-CO})\}]$ **(4)** showing 30% probability ellipsoids; hydrogen atoms are omitted for clarity; selected bond lengths [Å] and angles [°]: Sb(1)−Sb(2) 2.986(2), Sb(1)−Fe(1) 2.599(4), Sb(2)−Fe(2) 2.606(3), Co(1)−Co(2) 2.658(5), Co(2)−Co(3) 2.598(5), Co(3)−Co(4) 2.683(4), Sb(1)−Co(1) 2.628(3), Sb(1)−Co(2) 2.653(4), Sb(1)−Co(3) 2.605(4), Sb(1)−Co(4) 2.608(4), Sb(2)−Co(1) 2.611(4), Sb(2)−Co(2) 2.614(3), Sb(2)−Co(3) 2.651(3), Sb(2)−Co(4) 2.621(4), Co(2)−C(6) 1.84(3), Co(3)−C(6) 1.93(3), C(6)−O(6) 1.20(3); Sb(1)−Co(2)−Sb(2) 69.07(9), Sb(1)−Co(3)−Sb(2) 69.23(10), Co(1)−Co(2)−Co(3) 104.78(15), Co(2)−Co(3)−Co(4) 104.47(15)

$[Sb_2Co_4(CO)_{10}(\mu\text{-CO})]^{2-}$ [2.645(5)−2.717(5) Å]. The same tendency is visible for the Sb−Co bond lengths [2.605(4)−2.653(4) Å in **4** compared to 2.616(4)−2.676(4) Å]. The Sb−Sb bond length in the monoanionic compound $[Sb_2Co_4(CO)_{10}(\mu\text{-CO})]^-$ [2.911(1) Å][20] is still shorter than in **4**, whereas the Co−Co distances in $[Sb_2Co_4(CO)_{10}(\mu\text{-CO})]^-$ tend to fall in a wider range [2.510(3)−2.725(3) Å], as do Sb−Co distances [2.605(2)−2.692(2) Å]. As for the Sb_3Fe_4 polyhedron in **2**, a description of the Sb_2Co_4 cluster core of **4** following the Wade−Mingos rules fails. A thorough MO-theoretical discussion of charged 18-electron clusters of this type and a discussion as to whether $[E_2Co_4(CO)_{10}(\mu\text{-CO})]^{2-}$ clusters are best expressed as a bicapped tetrahedron or derived from a pentagonal bipyramid was previously described by Whitmire and co-workers.[20] On this basis, for **4** we tend towards the explanation of the pentagonal bipyramid with a missing pentagonal core atom. Assuming that the structure of **4** derives from a bicapped tetrahedron, angles of 109.5° are expected, whereas only 108° is necessary for a pentagonal bipyramid. Angles of 104.78(15) and 104.47(15) for Co(1)−Co(2)−Co(3) and Co(2)−Co(3)−Co(4), respectively, are found within **4** and are even smaller than necessary, whereas the angles of the tetrahedral faces Sb(1)−Co(2)−Sb(2) [69.07(9)°] and Sb(1)−Co(3)−Sb(2) [69.23(10)°] are larger than the expected 60° for a bicapped tetrahedron.

Conclusions

In contrast to reactions of $[\{Cp^x(CO)_2Fe\}SbCl_2]$ [Cp^x = Cp" **(1a)**; Cp^x = Cp* **(1b)**] with magnesium, which yield (μ_3-Sb) bridged binary antimony-transition metal complexes, these compounds react with transition metalates

with incorporation of a main group element moiety within a transition metal cluster framework. Only a small tendency to Sb−Sb bond formation was observed, as found for the complexes **2** and **4**. For similar reactions of phosphorus-containing starting materials of the formula $[L_nMPCl_2]$,[6] a higher tendency of P−P bond formation was discovered. The reason for this can probably be found in the stronger metallic character of Sb, and hence in the higher tendency of element−metal bond formation.

Generally, the compounds **1a,b** open a facile and rational way to generate novel main group-transition metal clusters. Starting from halogenated main group elements which already bear a transition metal function, they might even serve as a good starting point for preparing cluster compounds with different main group elements and different transition metals in a specific manner.

Experimental Section

General Techniques: All manipulations were performed under an atmosphere of dry Ar using standard Schlenk techniques. All solvents were dried by common methods and freshly distilled prior to use. NMR spectra were recorded on a Bruker AC 250 using TMS as external standard. Mass spectra were done with a Varian MAT 711. IR spectra were recorded on a Bruker IFS 28 FT-IR spectrometer. Elemental analyses were performed on a Elementar Vario EL of the institute.

Reagents: $K[Co(CO)_4]$[22] and $Na_2[Fe(CO)_4]$[23] were prepared according to literature methods. The synthesis of $[\{Cp^x(CO)_2Fe\}SbCl_2]$ (**1a:** $Cp^x = \eta^5$-$C_5H_3tBu_2$-1,3; **1b:** $Cp^x = \eta^5$-C_5Me_5) has been described previously.[5]

Synthesis of $[\{\mu_3$-$SbFe(CO)_2Cp''\}_3\{Fe(CO)_3\}_4]$ (2) and $[\{\mu_3$-$SbFe(CO)_2Cp''\}_2\{Fe_3(CO)_9\}]$ (3). To a solution of $[\{Cp''(CO)_2Fe\}SbCl_2]$ **(1a)** (0.42 g, 0.87 mmol) in 50 mL of THF at −78 °C was added $Na_2[Fe(CO)_4]$ (0.19 g, 0.87 mmol in one portion). After one hour, the solution was allowed to warm up to room temperature. The solvent was then evaporated in vacuo. Subsequently, the brown residue was dissolved in 50 mL of hexane and filtered through a column of dry SiO_2 (10 cm × 2 cm). The solution was concentrated to 30 mL and red crystals of **2** (120 mg, 23%) were obtained at 0 °C. Further concentration of the solution to 10 mL gave a mixture of **2** and **3** (457 mg).

2: IR (KBr): ν̃(CO) = 2012(m), 1997(vs), 1985(s), 1961(m), 1942(m), 1932(m), 1925(m), 1911 (m), 1897(m), 1879(s). − ^{1}H NMR (C_7D_8, 300 K): δ = 1.05 (s, 9 H), 1.10 (s, 9 H), 4.10 (dd, J = 1.9 Hz, 1 H) 5.17 (dd, J = 1.9 Hz, 1 H), 5.53 (dd, J = 1.9 Hz, 1 H); 368 K: 1.10 (s, 9 H), 4.20 (br, 1 H) 5.13 (br, 1 H), 5.30 (br, 1 H). − $C_{57}H_{63}Fe_7O_{18}Sb_3$ (1792.30): calcd. C 38.20, H 3.54; found C 37.94, H 3.23.

Synthesis of $[\{\mu_4$-$SbFe(CO)_2Cp^*\}_2\{Co_4(CO)_{10}(\mu$-$CO)\}]$ ($Cp^* = \eta^5$-C_5Me_5) (4): To a solution of $[\{Cp^*(CO)_2Fe\}SbCl_2]$ **(1b)** (0.44 g, 1 mmol) in 50 mL of THF at −78 °C was added $K[Co(CO)_4]$ (0.42 g, 2 mmol) at one go. After 1 h of stirring at this temperature the solution was allowed to warm up to room temperature. After another hour of stirring at room temperature all volatiles were evaporated in vacuo. The brown residue was dissolved in 20 mL of CH_2Cl_2 and subsequently filtered through a column of dry SiO_2 (10 cm × 2 cm). The resulting solution was reduced in vacuo to 10 mL. At 0 °C red crystals of **4** were obtained. Isolated yield: 860 mg (67%, based on **1b**). After reducing the solution to a volume of 2 mL 50 mg of $[Cp^*(CO)Fe(\mu$-$CO)_2Co(CO)_3]$ **(5)** was isolated.

4: IR (KBr): ν̃(CO) = 2004(vs), 1971(s), 1949(sh), 1779(m). − ^{1}H NMR ($CDCl_3$, 300 K): δ = 1.90 (s, 15 H). − EI-MS (70 eV): *m/z* (%) = 1281.6 (1.4) [M^+], 494.1 (10.6) [$Cp^*_2Fe_2(CO)_4^+$], 341.0 (3.3)

X-ray Structure Determination and Details of Refinement: Data were collected on a STOE IPDS area-detector diffractometer using Mo-K_α (λ = 0.71069 Å) radiation. Machine parameters, crystal data and data collection parameters are summarised in Table 1. The structures were solved by direct methods using SHELXS-86,[24a] full-matrix least-squares refinement on F^2 in SHELXL-97[24b] with anisotropic displacement for non-H atoms (**2** and **3**), hydrogen atoms placed in idealised positions and refined isotropically according to the riding model. Due to the low crystal quality of **4**, only the heavy atoms Fe, Co and Sb were anisotropically refined, which causes relatively large values for R_1 and wR_2.

Crystal Data for [Cp*(CO)Fe(μ-CO)$_2$Co(CO)$_3$] (5): Cell dimensions: a = 8.1836(16) Å, b = 9.1759(18) Å, c = 12.139(2) Å, α = 90.51(3)°, β = 90.67(3)°, γ = 110.50(3)°, V = 853.7(3) Å^3, Z = 2, $d_{calcd.}$ = 1.626 g cm^{-3}, μ = 1.848 mm^{-1}, space group $P\bar{1}$, 6655 reflection collected, of which 3082 independent (R_{int} = 0.0389), 2656 with $I > 2\sigma(I)$. $R1$ = 0.0289, $wR2$ = 0.0789, max./min. residual electron densities 0.455 and −0.496 e Å^{-3}.

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-143869 to -143871 (**2**–**4**) and CCDC-143985 for **5**. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

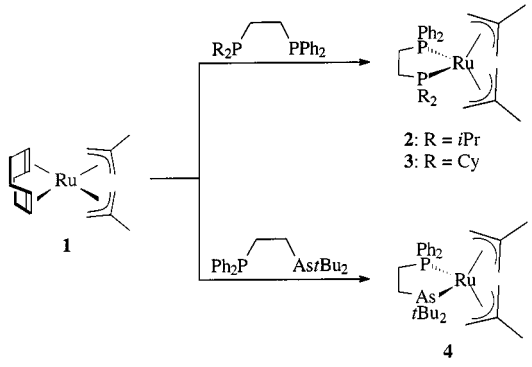
Keywords: Acetylacetonato complexes / Allyl complexes / Ruthenium / Chelates / Phosphorus / Arsenic

The bis(η^3-2-methallyl)ruthenium(II) complexes [Ru(η^3-2-MeC_3H_4)$_2$(κ^2-$Ph_2PCH_2CH_2PR_2$)] [R = *i*Pr (**2**), Cy (**3**)] were prepared from the cycloocta-1,5-diene derivative [Ru(η^3-2-MeC_3H_4)$_2$(η^4-C_8H_{12})] (**1**) and the unsymmetrical 1,2-bis(phosphanyl)ethanes $Ph_2PCH_2CH_2PR_2$. The As,P analogue [Ru(η^3-2-MeC_3H_4)$_2$(κ^2-$Ph_2PCH_2CH_2AstBu_2$)] (**4**) was obtained by the same route. The reaction of **2** with hexafluoroacetylacetone afforded the chelate compound [Ru(κ^2-[F_6]-acac)$_2$(κ^2-*i*$Pr_2PCH_2CH_2PPh_2$)], whereas treatment of **2** and **3** with pentachlorophenol gave the related, more labile complexes [Ru(κ^2-*O*,*Cl*-OC_6Cl_5)$_2$(κ^2-$R_2PCH_2CH_2PPh_2$)] [R = *i*Pr (**6**), Cy (**7**)]. Preparation of the parent bis(acac) compound [Ru(κ^2-acac)$_2$(κ^2-*i*$Pr_2PCH_2CH_2PPh_2$)] (**8**), which could not be obtained from **2** and acacH, was achieved by ligand exchange of **6** and acetylacetone. The molecular structures of **2** and **6** were determined by X-ray crystallography.

Introduction



By attempting to modify the donor/acceptor properties of bidentate ligands with P, As, and Sb as donor atoms, we recently described two new synthetic methodologies for unsymmetrical bis(phosphanyl)methanes and 1,2-bis(phosphanyl)ethanes as well as for their As,P analogues.[1,2] While the methane derivatives $R_2PCH_2ER'_2$ were prepared from the stannylated phosphanes $R_2PCH_2SnR''_3$ by metalation with MeLi or PhLi in the presence of tetramethylethylenediamine followed by treatment with R'_2PCl or R'_2AsCl,[1] the corresponding disubstituted ethanes $R_2PCH_2CH_2ER'_2$ were obtained in a one-pot reaction from the cyclic sulfate $C_2H_4O_2SO_2$ by stepwise addition of R'_2ELi and R_2PLi, respectively. The latter method is also suitable for the preparation of *chiral* bidentate P,P donors of the general composition $R_2PCH_2CH(Me)PPh_2$ and $R_2PCH_2CH_2CH(Me)PPh_2$ where the substituent R is a bulky alkyl or cycloalkyl group such as *i*Pr, *t*Bu, or C_6H_{11}.[2,3]

In the initial phase of these studies, we tested the coordination properties of the new ligands toward rhodium(I) and isolated a series of square-planar and half-sandwich-type complexes including [Rh(η^4-C_8H_{12})(κ^2-*R*-$Ph_2PCH(Me)CH_2PCy_2$)]PF_6[3] and [(η^6-C_6H_5R)Rh(κ^2-$Cy_2PCH_2Pi Pr_2$)]PF_6 (R = H, Me).[1] In this paper we report the synthesis of a series of ruthenium(II) compounds with both $Ph_2PCH_2CH_2PR_2$ and $Ph_2PCH_2CH_2AstBu_2$ as chelating ligands and η^3-2-methallyl, pentachlorphenolate, and acetylacetonates as ancillary bidentate units. Some preliminary results of this work have already been communicated.[2]

Results and Discussion

The preparation of the chelate complexes **2** and **3** (Scheme 1) followed the route which was used by Holle, Jolly, and Kuhnigk to obtain the related bis(η^3-allyl)ruthenium(II) compounds with $iPr_2P(CH_2)_nPiPr_2$ (n = 1, 2, and 3) as ligands.[4] The reaction proceeds in hexane under reflux conditions and affords the products as yellow solids in about 70% isolated yield. Compounds **2** and **3** are only slightly air-sensitive and, apart from pentane and ether, readily soluble in most common organic solvents. The ^{31}P NMR spectra of both **2** and **3** display two sharp doublets for the nonequivalent phosphorus nuclei with ^{31}P-^{31}P coupling constants of 8.5 and 7.6 Hz, respectively. Due to the presence of the unsymmetrical 1.2-bis(phosphanyl)ethane ligand, the ^1H NMR spectra of **2** and **3** are rather complex, thus making an exact assignment of the signals for the CH_2 allyl protons difficult.

Scheme 1

The molecular structure of compound **2**, of which single crystals were obtained from a saturated solution in hexane, was determined by X-ray crystallography. The molecular

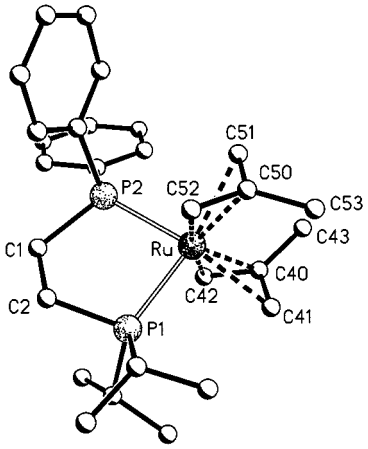
diagram (Figure 1) reveals that the coordination geometry around the metal center can be described as a distorted tetrahedron with the two phosphorus atoms P1 and P2 and the two central carbon atoms C40 and C50 of the allylic moieties at the corners of the tetrahedron. The bond lengths Ru−C40 and Ru−C50 are somewhat shorter than those from the ruthenium center to the terminal carbon atoms of the 2-methallyl ligands. This results in dihedral angles of 37.7(1)° and 34.9(1)° between the planes [C40,C41,C42] and [C50,C51,C52] of the π-allyl units and the plane of the five-membered chelate ring [Ru,P1,C2,C1,P2]. The distances Ru−P1 and Ru−P2 differ only slightly to those in similar phosphaneruthenium(II) complexes[5−7] while the bite angle P1−Ru−P2 of 85.32(3)° is nearly identical to that in $[Ru(\eta^3\text{-}2\text{-}MeC_3H_4)_2(\kappa^2\text{-}Cy_2PCH_2CH_2PCy_2)]$ [85.03(4)°].[5]



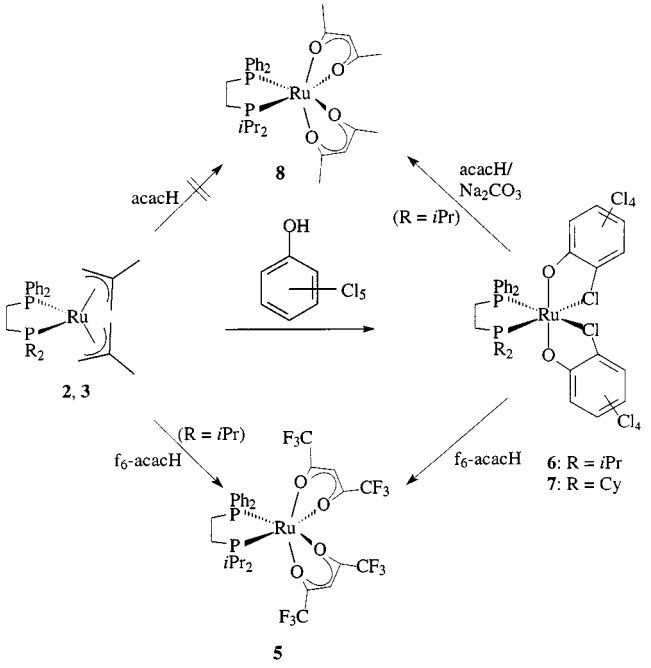


Figure 1. Molecular structure of compound **2**; selected bond lengths [Å] and angles [°]: Ru−P1 2.3278(9), Ru−P2 2.2981(8), Ru−C40 2.178(3), Ru−C41 2.237(4), Ru−C42 2.232(4), Ru−C50 2.181(3), Ru−C51 2.247(3), Ru−C52 2.230(4), P1−C2 1.854(3), P2−C1 1.851(3); P1−Ru−P2 85.32(3), C1−P2−Ru 110.07(11), C2−P1−Ru 107.03(11), C1−C2−P1 111.9(2), C2−C1−P2 110.1(2), C41−C40−C42 116.4(3), C51−C50−C52 117.9(3)

In contrast to $iPr_2PCH_2AstBu_2$, which does not react with the starting material **1** by substitution of the cyclooctadiene ligand,[3] the reaction of the ethane derivative $Ph_2PCH_2CH_2AstBu_2$ with **1** affords the chelate complex **4** (see Scheme 1) as a yellow solid in 51% isolated yield. While the ^{31}P NMR spectrum of **4** displays, in agreement with the proposed structure, a single resonance at δ = 79.4, the ^1H NMR spectrum is very complex and shows several overlapping signals between δ = 2.95 and 0.51, which originate from the allyl, the *tert*-butyl and the CH_2 protons of the coordinated As,P donor unit. In the ^{13}C NMR spectrum of **4**, the CH_2 carbon atoms of the 2-methallyl units give rise to four doublets at δ = 39.6, 36.9, 36.3, and 33.4, thus confirming the presence of an additional unsymmetrical bidentate ligand.

Similarly to the starting material **1**, the substituted compounds **2** and **3** are also quite reactive towards Brönsted acids. However, in contrast to **1** which reacts cleanly with CF_3CO_2H to give $[Ru(\eta^4\text{-}C_8H_{12})(\mu\text{-}O_2CCF_3)_2]_2$,[8] treatment of **2** or **3** with trifluoroacetic acid leads to a mixture of products which could not be separated by conventional techniques.

The reaction of **2** with two equivalents of hexafluoracetylacetone affords, by protonation of both 2-methallyl ligands (and elimination of isobutene), the chelate complex **5** (Scheme 2) as a red air-stable solid in almost quantitative yield. Due to the coordination of the unsymmetrical 1,2-bis(phosphanyl)ethane, the two [F_6]acac units are nonequivalent and therefore the ^{13}C NMR as well as the ^{19}F NMR spectrum of **5** display four resonances for the carbon and fluorine nuclei of the CF_3 groups. The appearance of four quadruplets for the CF_3CO and of two singlets for the $COCHCO$ carbon atoms equally illustrates the stereochemical nonequivalence of the [F_6]acac ligands.

Scheme 2

In contrast to the hexafluoro derivative [F_6]acacH, the parent compound acacH does not react, even in refluxing toluene, with the starting material **2**. The lower acidity of acetylacetone (pK_a = 9.0) compared to the hexafluoro analogue (pK_a = 5.3)[9] presumably causes the difference in the reactivity of the two diketones toward the η³-2-methallylruthenium(II) complex **2**.

However, the bis(acac) compound **8** is accessible in a stepwise route via the intermediate bis(pentachlorophenolato) complex **6**. Both **6** and **7** are obtained in excellent yield as orange, moderately air-sensitive solids upon treatment of **2** and **3** with two equivalents of C_6Cl_5OH in toluene at room temperature. With regard to the spectroscopic data of **6** and **7**, the interesting feature is that the ^{13}C NMR spectra (in [D_8]toluene) display at both 295 K and 188 K only one signal for the *ortho*- and one signal for the *meta*-carbon atoms of the OC_6Cl_5 units. This observation indicates that a fluxional process takes place in solution, which involves (on the NMR time scale) rapid coordination/decoordination of the chlorine atoms in *ortho* position of the six-membered rings to the metal center. There is good reason to believe that the stability of the chelating bonding mode (via

oxygen and chlorine) of the pentachlorophenolato ligands to the ruthenium center depends significantly on the coordination sphere since the tris(chelate) complexes [Ru(κ^2-OC_6Cl_5)$_2$(κ^2-$Ph_2PCH_2PR_2$)] (R = *i*Pr, Cy) are fluxional at 295 K but rigid at 188 K,[10] while the hydrido compound [RuH(κ^2-OC_6Cl_5)(CO)(P*i*Pr$_3$)$_2$] is nonfluxional on the NMR timescale even at room temperature.[11]

The X-ray crystal structure analysis of **6** (Figure 2) confirms the existence of weak Ru−Cl interactions comparable to those between transition metals and other C−Cl bonds.[12] The Ru−Cl distances of 2.498(1) Å and 2.524(1) Å are significantly longer than in *trans*-[RuCl$_2$(κ^2-$Ph_2PCH_2CH_2PPh_2$)$_2$] [2.4325(12) Å][13] and *trans*-[RuCl$_2$(κ^2-$Ph_2PCH_2PPh_2$)$_2$] [2.426(1) Å,[14] where "normal" covalent Ru−Cl bonds are present. The coordination geometry around the metal center in **6** is a distorted octahedron with a bite angle P1−Ru−P2 of 84.32(5)° that is almost identical to that in compound **2**. The bond angles Ru−O1−C1 [120.6(3)°] and Ru−O2−C7 [119.3(3)°] are considerably smaller than in the hydrido complex *trans*-[RuH(OC_6H_4-4-Me)(κ^2-$Me_2PCH_2CH_2PMe_2$)$_2$] [137.58(16)°][15] where no additional interaction between the C−H units of the phenolato ligand and the metal exists.

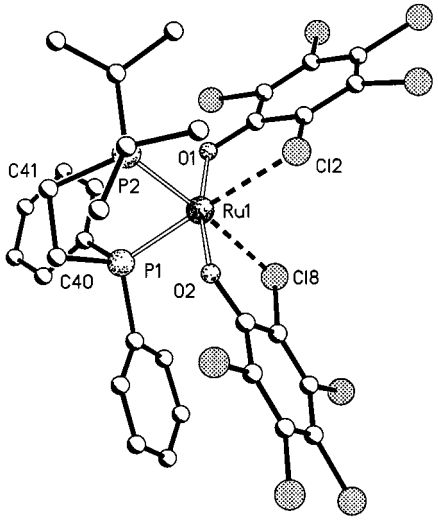

Figure 2. Molecular structure of compound **6**; the THF molecule is omitted for clarity; selected bond lengths [Å] and angles [°]: Ru−P1 2.2341(13), Ru−P2 2.2578(13), Ru−O1 2.088(3), Ru−O2 2.078(3), Ru−Cl2 2.5240(13), Ru−Cl8 2.4978(13); P1−Ru−P2 84.32(5), P1−Ru−O1 99.45(9), P1−Ru−O2 89.24(9), P1−Ru−Cl2 176.70(4), P1−Ru−Cl8 94.03(5), P2−Ru−O1 94.51(9), P2−Ru−O2 93.00(8), P2−Ru−Cl2 98.90(5), P2−Ru−Cl8 174.32(4), O1−Ru−O2 169.03(11), O1−Ru−Cl2 79.60(9), O1−Ru−Cl8 91.12(9), O2−Ru−Cl2 91.34(9), O2−Ru−Cl8 81.53(8), Cl2−Ru−Cl8 82.85(4)

In contrast to **2**, compound **6** reacts with acetylacetone in the presence of Na_2CO_3 to afford the bis(acac) complex **8** as a yellow air-stable solid in 89% isolated yield. Moreover, the bis(pentachlorophenolato) derivative **6** affords the bis([F$_6$]acac) complex **5** almost instantaneously upon treatment with [F$_6$]acacH in toluene. This pattern of reactivity indicates that **6** (and equally **7**) could be considered as a masked 14-electron species in which the additional interaction between the chlorine atoms in *ortho* position of the OC_6Cl_5 units and the metal center prevents a subsequent oligomerization or decomposition process. We note that quite recently Baratta et al. reported another example of a ruthenium(II) complex with a formal 14-electron configuration; in this case two strong agostic RuHC interactions relieve part of the electronic unsaturation at the metal center.[16]

Experimental Section

All operations were carried out under argon using Schlenk techniques. The starting material **1**[17] as well as the ligands $Ph_2PCH_2CH_2PR_2$ (R = *i*Pr, Cy) and $Ph_2PCH_2CH_2AstBu_2$[2,3] were prepared as described in the literature. − IR: Perkin−Elmer 1320. − NMR: Bruker AC 200 and AMX 400. − Melting points determined by DTA.

1. Preparation of [Ru(η^3-2-MeC_3H_4)$_2$(κ^2-$Ph_2PCH_2CH_2P$*i*Pr_2)] (2): A suspension of **1** (261 mg, 0.8 mmol) in hexane (8 mL) was treated with $Ph_2PCH_2CH_2P$*i*Pr_2 (252 mg, 0.8 mmol) and heated at reflux for 12 h. After cooling to room temperature, the solvent was evaporated in vacuo, the residue was washed with pentane (10 mL) and dried. A yellow microcrystalline solid was obtained; yield 308 mg (72%); m.p. 114 °C. − ^{1}H NMR (400 MHz, C_6D_6): δ = 7.96 (m, 2 H, C_6H_5), 7.30 (m, 4 H, C_6H_5), 7.00 (m, 4 H, C_6H_5), 2.93 (br m, 1 H, one H of PCH_2), 2.48, 2.25 (both s, 3 H each, CH_3 of 2-MeC_3H_4), 2.42−2.15 (br m, 5 H, PCH_2 and CH_2 of 2-MeC_3H_4), 2.10 [sept, 2 H, *J*(PH) = 1.7 Hz, PC*H*CH$_3$], 1.73−1.52 (br m, 4 H, CH_2 of 2-MeC_3H_4), 1.47 [dd, 3 H, *J*(PH) = 14.2, *J*(HH) = 7.2 Hz, PCHC*H*$_3$], 1.24 [dd, 3 H, *J*(PH) = 11.3, *J*(HH) = 7.2 Hz, PCHC*H*$_3$], 1.13 [dd, 1 H, *J*(PH) = 15.1, *J*(HH) = 4.8 Hz, one H of 2-MeC_3H_4], 0.92 [dd, 3 H, *J*(PH) = 9.4, *J*(HH) = 7.3 Hz, PCHC*H*$_3$], 0.89 [dd, 3 H, *J*(PH) = 9.6, *J*(HH) = 7.3 Hz, PCHC*H*$_3$], 0.50 [d, 1 H, *J*(PH) = 13.5 Hz, one H of 2-MeC_3H_4]. − ^{13}C NMR (100.6 MHz, C_6D_6): δ = 140.5 [d, *J*(PC) = 40.5 Hz, *ipso*-C of C_6H_5], 138.9 [d, *J*(PC) = 21.0 Hz, *ipso*-C of C_6H_5], 133.8 [d, *J*(PC) = 10.5 Hz, *ortho*-C of C_6H_5], 131.3 [d, *J*(PC) = 6.7 Hz, *ortho*-C of C_6H_5], 129.2 [d, *J*(PC) = 1.9 Hz, *para*-C of C_6H_5], 126.9 (s, *para*-C of C_6H_5), 126.7 [d, *J*(PC) = 8.6 Hz, *meta*-C of C_6H_5], 126.3 [d, *J*(PC) = 7.6 Hz, *meta*-C of C_6H_5], 95.2 (s, *C*CH$_3$ of 2-MeC_3H_4), 94.2 [d, *J*(PC) = 1.9 Hz, *C*CH$_3$ of 2-MeC_3H_4], 41.6 [dd, *J*(P^{1}C) = 19.1, *J*(P^{2}C) = 1.9 Hz, CH_2 of 2-MeC_3H_4], 38.0, 36.8 (both m, CH_2 of 2-MeC_3H_4), 34.2, 34.0 [both d, *J*(PC) = 1.9 Hz, C*C*H$_3$ of 2-MeC_3H_4], 32.7 [dd, *J*(P^{1}C) = 25.3, *J*(P^{2}C) = 18.1 Hz, PCH_2], 31.1 [dd, *J*(P^{1}C) = *J*(P^{2}C) = 21.9 Hz, PCH_2], 26.8 [d, *J*(PC) = 28.6 Hz, P*C*HCH$_3$], 26.6 [d, *J*(PC) = 18.6 Hz, P*C*HCH$_3$], 21.2 [d, *J*(PC) = 4.8 Hz, PCH*C*H$_3$], 20.7, 19.8 (both s, PCH*C*H$_3$), 19.6 [d, *J*(PC) = 2.9 Hz, PCH*C*H$_3$]. − ^{31}P NMR (162.0 MHz, C_6D_6): δ = 81.4 [d, *J*(PP) = 8.5 Hz, *i*Pr$_2$P], 73.9 [d, *J*(PP) = 8.5 Hz, Ph_2P]. − $C_{28}H_{42}P_2Ru$ (541.4): calcd. 3. Preparation of [Ru(η^3-2-MeC$_3$H$_4$)$_2$(κ^2-Ph$_2$PCH$_2$CH$_2$As*t*Bu$_2$)] (4): Analogous to the procedure described for **2**, using **1** (281 mg, 0.9 mmol) and Ph$_2$PCH$_2$CH$_2$As*t*Bu$_2$ (355 mg, 0.88 mmol) as starting materials. Yellow microcrystalline solid; yield 275 mg (51%); m.p. 99 °C. – ^{1}H NMR (400 MHz, C$_6$D$_6$): δ = 7.89 (m, 2 H, C$_6$H$_5$), 7.22–7.09 (br m, 4 H, C$_6$H$_5$), 6.87 (m, 4 H, C$_6$H$_5$), 2.95–0.51 (br m, 36 H, CH$_2$ and CH$_3$ of 2-MeC$_3$H$_4$, PCH$_2$, and AsCCH$_3$). – ^{13}C NMR (100.6 MHz, C$_6$D$_6$): δ = 140.4 [d, *J*(PC) = 37.2 Hz, *ipso*-C of C$_6$H$_5$], 139.3 [d, *J*(PC) = 22.9 Hz, *ipso*-C of C$_6$H$_5$], 134.1 [d, *J*(PC) = 11.4 Hz, *ortho*-C of C$_6$H$_5$], 131.7 [d, *J*(PC) = 6.7 Hz, *ortho*-C of C$_6$H$_5$], 129.2 [d, *J*(PC) = 1.9 Hz, *para*-C of C$_6$H$_5$], 126.9 (s, *para*-C of C$_6$H$_5$), 126.5 [d, *J*(PC) = 9.5 Hz, *meta*-C of C$_6$H$_5$], 126.3 [d, *J*(PC) = 6.7 Hz, *meta*-C of C$_6$H$_5$], 95.0, 91.2 (both s, *C*CH$_3$ of 2-MeC$_3$H$_4$), 39.6, 36.3 [both d, *J*(PC) = 2.9 Hz, CH$_2$ of 2-MeC$_3$H$_4$], 39.1, 39.0 (both s, As*C*CH$_3$), 36.9 [d, *J*(PC) = 4.8 Hz, CH$_2$ of 2-MeC$_3$H$_4$], 33.4 [d, *J*(PC) = 2.3 Hz, CH$_2$ of 2-MeC$_3$H$_4$], 32.8 [d, *J*(PC) = 24.8 Hz, PCH$_2$], 32.2, 31.5 (both s, AsC*C*H$_3$), 25.9, 25.7 (both s, C*C*H$_3$ of 2-MeC$_3$H$_4$), 21.6 [d, *J*(PC) = 20.2 Hz, AsCH$_2$]. – ^{31}P NMR (162.0 MHz, C$_6$D$_6$): δ = 79.4 (s). – C$_{30}$H$_{46}$AsPRu (613.7): calcd. C 58.72, H 7.56; found C 58.37, H 7.06.

4. Preparation of [Ru(κ^2-[F$_6$]acac)$_2$(κ^2-Ph$_2$PCH$_2$CH$_2$P*i*Pr$_2$)] (5): a) A solution of **2** (104 mg, 0.2 mmol) in toluene (5 mL) was treated at –78 °C with hexafluoroacetylacetone (88 μL, 0.4 mmol), which led to a rapid change of color from yellow to dark red. After warming to room temperature and stirring the solution for 20 min, the solvent was evaporated in vacuo and the residue was dissolved in pentane (2 mL). The solution was chromatographed on Al$_2$O$_3$ (basic, activity grade I, height of column 10 cm). With pentane a red fraction was eluted, from which a dark red microcrystalline solid was obtained upon removal of the solvent; yield 147 mg (92%). – b) A solution of **6** (164 mg, 0.2 mmol) in toluene (5 mL) was treated with hexafluoroacetylacetone (71 μL, 0.4 mmol), which led to a rapid change of color from orange to dark red. The solvent was evaporated in vacuo, the residue was washed with pentane (5 mL, –20 °C) and dried. Orange microcrystalline solid; yield 133 mg (93%); m.p. 148 °C. – IR (CH$_2$Cl$_2$): ν([F$_6$]acac) = 1611, 1522 cm^{-1}. – ^{1}H NMR (400 MHz, CDCl$_3$): δ = 7.97 (m, 2 H, C$_6$H$_5$), 7.63 (m, 3 H, C$_6$H$_5$), 7.46–7.34 (br m, 3 H, C$_6$H$_5$), 7.18 (m, 2 H, C$_6$H$_5$), 6.37, 5.67 (both s, 1 H each, CH of acac-f$_6$), 3.40–2.76 (br m, 2 H, PCH$_2$), 2.64–2.52 (br m, 1 H, PC*H*CH$_3$), 2.48–2.34 (br m, 2 H, PCH$_2$), 2.28–2.12 (br m, 1 H, PC*H*CH$_3$), 1.49 [dd, 3 H, *J*(PH) = 9.4, *J*(HH) = 7.0 Hz, PCHC*H*$_3$], 1.45 [dd, 3 H, *J*(PH) = 10.4, *J*(HH) = 7.2 Hz, PCHC*H*$_3$], 1.18 [dd, 3 H, *J*(PH) = 14.1, *J*(HH) = 7.0 Hz, PCHC*H*$_3$], 1.07 [dd, 3 H, *J*(PH) = 14.2, *J*(HH) = 7.2 Hz, PCHC*H*$_3$]. – ^{13}C NMR (100.6 MHz, CDCl$_3$): δ = 175.1, 174.0, 172.1, 171.3 [all q, *J*(FC) = 34.3 Hz, CO of acac-f$_6$], 134.9 [d, *J*(PC) = 42.9 Hz, *ipso*-C of C$_6$H$_5$], 133.3 [d, *J*(PC) = 10.5 Hz, *ortho*-C of C$_6$H$_5$], 132.0 [d, *J*(PC) = 43.9 Hz, *ipso*-C of C$_6$H$_5$], 130.6 [d, *J*(PC) = 9.5 Hz, *ortho*-C of C$_6$H$_5$], 129.2 [d, *J*(PC) = 2.9 Hz, *para*-C of C$_6$H$_5$], 128.3 [d, *J*(PC) = 9.5 Hz, *meta*-C of C$_6$H$_5$], 118.5, 117.7, 116.3, 116.1 [all q, *J*(FC) = 284.2 Hz, CF$_3$], 91.2, 89.9 (both s, CH of acac-f$_6$), 27.8 [dd, *J*(P^{1}C) = 34.3, *J*(P^{2}C) = 8.6 Hz, PCH$_2$], 25.3 [d, *J*(PC) = 22.9 Hz, P*C*HCH$_3$], 25.0 [d, *J*(PC) = 23.8 Hz, P*C*HCH$_3$], 23.9 [dd, *J*(P^{1}C) = 38.6, *J*(P^{2}C) = 12.4 Hz, PCH$_2$], 18.3, 18.3, 18.2, 18.0 (all s, PCH*C*H$_3$). – ^{19}F NMR (376.5 MHz, CDCl$_3$): δ = –75.7, –75.4, –74.6, –74.2 (all s). – ^{31}P NMR (162.0 MHz, CDCl$_3$): δ = 90.4 [d, *J*(PP) = 25.4 Hz, *i*Pr$_2$P], 79.1 [d, *J*(PP) = 25.4 Hz, Ph$_2$P]. – C$_{30}$H$_{30}$F$_{12}$O$_4$P$_2$Ru (845.6): calcd. C 42.61, H 3.58; found C 42.30 H 3.22.

5. Preparation of [Ru(κ^2-*O*,*Cl*-OC$_6$Cl$_5$)$_2$(κ^2-Ph$_2$PCH$_2$CH$_2$P*i*Pr$_2$)] (6): A solution of **2** (135 mg, 0.3 mmol) in toluene (5 mL) was treated at –30 °C with a solution of pentachlorophenol (133 mg, 0.5 mmol) in toluene (5 mL). After warming to room temperature and stirring for 10 min, the solvent was evaporated in vacuo. The residue was washed with pentane (5 mL) and dried. An orange microcrystalline solid was obtained; yield 221 mg (92%); m.p. 165 °C. – ^{1}H NMR (400 MHz, C$_6$D$_6$): δ = 8.09 (m, 2 H, C$_6$H$_5$), 7.19 (m, 3 H, C$_6$H$_5$), 6.87 (m, 2 H, C$_6$H$_5$), 6.69 (m, 3 H, C$_6$H$_5$), 2.17–1.96 (br m, 2 H, PCH$_2$), 1.72 (m, 1 H, PC*H*CH$_3$), 1.60–1.49 (br m, 2 H, PCH$_2$), 1.43–1.29 (br m, 1 H, PC*H*CH$_3$), 1.21 [dd, 3 H, *J*(PH) = 14.1, *J*(HH) = 7.0 Hz, PCHC*H*$_3$], 1.15 [dd, 3 H, *J*(PH) = 13.9, *J*(HH) = 7.7 Hz, PCHC*H*$_3$], 0.60 [dd, 3 H, *J*(PH) = 11.4, *J*(HH) = 7.0 Hz, PCHC*H*$_3$], 0.56 [dd, 3 H, *J*(PH) = 11.7, *J*(HH) = 7.0 Hz, PCHC*H*$_3$]. – ^{13}C NMR (100.6 MHz, C$_6$D$_6$): δ = 163.6, 162.7 (both s, *ipso*-C of C$_6$Cl$_5$), 134.6 [d, *J*(PC) = 10.5 Hz, *ortho*-C of C$_6$H$_5$], 133.8 [d, *J*(PC) = 47.7 Hz, *ipso*-C of C$_6$H$_5$], 132.6 [d, *J*(PC) = 45.8 Hz, *ipso*-C of C$_6$H$_5$], 131.7 [d, *J*(PC) = 8.6 Hz, *ortho*-C of C$_6$H$_5$], 131.3, 129.4 [both d, *J*(PC) = 1.9 Hz, *para*-C of C$_6$H$_5$], 128.6 [d, *J*(PC) = 10.5 Hz, *meta*-C of C$_6$H$_5$], 127.5 [d, *J*(PC) = 9.5 Hz, *meta*-C of C$_6$H$_5$], 125.7, 125.4, 118.0, 117.8, 116.4, 115.6 (all s, C$_6$Cl$_5$), 28.1 [dd, *J*(P^{1}C) = 36.2, *J*(P^{2}C) = 7.2 Hz, PCH$_2$], 26.7, 26.2 [both d, *J*(PC) = 24.8 Hz, P*C*HCH$_3$], 20.9 [dd, *J*(P^{1}C) = 30.0, *J*(P^{2}C) = 11.0 Hz, PCH$_2$], 19.3, 18.5, 18.1, 18.0 (all s, PCH*C*H$_3$). – ^{31}P NMR (162.0 MHz, C$_6$D$_6$): δ = 99.2 [d, *J*(PP) = 28.8 Hz, *i*Pr$_2$P], 84.8 [d, *J*(PP) = 28.8 Hz, Ph$_2$P]. – C$_{32}$H$_{28}$Cl$_{10}$O$_2$P$_2$Ru (962.2): calcd. C 39.95 H 2.91; found C 40.04 H 3.22.

6. Preparation of [Ru(κ^2-*O*,*Cl*-OC$_6$Cl$_5$)$_2$(κ^2-Ph$_2$PCH$_2$CH$_2$PCy$_2$)] (7): Analogous to the procedure described for **6**, using **3** (246 mg, 0.5 mmol) and pentachlorophenol (245 mg, 1.0 mmol) as starting materials. Orange microcrystalline solid; yield 221 mg (92%); m.p. 208 °C. – ^{1}H NMR (200 MHz, C$_6$D$_6$): δ = 8.10–6.60 (br m, 10 H, C$_6$H$_5$), 2.32–0.38 (br m, 26 H, PCH$_2$ and C$_6$H$_{11}$). – ^{13}C NMR (50.3 MHz, C$_6$D$_6$): δ = 162.6, 162.5 (both s; *ipso*-C of C$_6$Cl$_5$), 135.1 [d, *J*(PC) = 43.2 Hz, *ipso*-C of C$_6$H$_5$], 134.8 [d, *J*(PC) = 39.8 Hz, *ipso*-C of C$_6$H$_5$], 133.8 [d, *J*(PC) = 14.1 Hz, *ortho*-C of C$_6$H$_5$], 131.3 [d, *J*(PC) = 8.0 Hz, *ortho*-C of C$_6$H$_5$], 129.9, 128.0 [both d, *J*(PC) = 1.9 Hz, *para*-C of C$_6$H$_5$], 128.4, 127.3 [both d, *J*(PC) = 7.1 Hz, *meta*-C of C$_6$H$_5$], 125.6, 125.4, 118.7, 118.0, 116.7, 116.1 (all s, C$_6$Cl$_5$), 43.3 [dd, *J*(P^{1}C) = 12.1, *J*(P^{2}C) = 5.8 Hz, CH of C$_6$H$_{11}$], 38.4 [d, *J*(PC) = 6.1 Hz, CH of C$_6$H$_{11}$], 32.5 [dd, *J*(P^{1}C) = 24.2, *J*(P^{2}C) = 16.7 Hz, PCH$_2$], 31.0 [dd, *J*(P^{1}C) = 22.5, *J*(P^{2}C) = 18.9 Hz, PCH$_2$], 30.8, 30.0, 26.5, 26.4 (all s, CH$_2$ of C$_6$H$_{11}$), 30.4, 29.9 [both d, *J*(PC) = 4.3 Hz, CH$_2$ of C$_6$H$_{11}$], 29.0 [d, *J*(PC) = 9.7 Hz, CH$_2$ of C$_6$H$_{11}$], 26.9 [d, *J*(PC) = 9.4 Hz, CH$_2$ of C$_6$H$_{11}$], 26.8 [d, *J*(PC) = 6.9 Hz, CH$_2$ of C$_6$H$_{11}$], 26.7 [d, *J*(PC) = 10.6 Hz, CH$_2$ of C$_6$H$_{11}$]. – ^{31}P NMR (81.0 MHz, C$_6$D$_6$): δ = 91.3 [d, *J*(PP) = 28.7 Hz, Cy$_2$P], 85.4 [d, *J*(PP) = 28.7 Hz, Ph$_2$P]. – C$_{38}$H$_{36}$Cl$_{10}$O$_2$P$_2$Ru (1042): calcd. C 43.78 H 3.48; found C 44.08 H 3.45.

7. Preparation of [Ru(κ²-acac)₂(κ²-Ph₂PCH₂CH₂P*i*Pr₂)] (8): A solution of **6** (189 mg, 0.2 mmol) in toluene (8 mL) was treated with acetylacetone (55 mg, 0.6 mmol) and Na_2CO_3 (69 mg, 0.7 mmol) and then heated for 1 h at 65 °C. After cooling to room temperature, the solvent was evaporated in vacuo. The residue was dissolved in pentane (5 mL), the solution filtered and the filtrate was brought to dryness in vacuo. A yellow microcrystalline solid was obtained; yield 112 mg (89%); m.p. 157 °C. – IR (CH_2Cl_2): ν(acac) = 1580, 1518 cm^{-1}. – ^1H NMR (200 MHz, $CDCl_3$): δ = 7.88–7.76 (br m, 2 H, C_6H_5), 7.30–6.95 (br m, 8 H, C_6H_5), 5.14, 4.55 (both s, 1 H each, CH of acac), 2.62–2.50, 2.24–2.12 (both br m, 2H each, PCH_2), 1.99–1.83 (br m, 2 H, PC*H*CH_3), 1.86, 1.68, 1.62, 1.20 (all s, 3H each, CH_3 of acac), 1.24–1.18 (br m, 6 H, PCHC*H*$_3$), 0.86–0.76 (br m, 6 H, PCHC*H*$_3$). – ^{13}C NMR (100.6 MHz, $CDCl_3$): δ = 184.7, 183.9, 183.3, 182.7 (all s, CO of acac), 138.6 [d, *J*(PC) = 37.6 Hz, *ipso*-C of C_6H_5], 136.3 [d, *J*(PC) = 36.6 Hz, *ipso*-C of C_6H_5], 134.0, 131.1 [both d, *J*(PC) = 8.1 Hz, C_6H_5], 129.1, 127.7, 127.3 (all s, C_6H_5), 127.2 [d, *J*(PC) = 8.4 Hz, C_6H_5], 97.1, 96.6 (both s, CH of acac), 27.9 [dd, $J(P^1C)$ = 34.8, $J(P^2C)$ = 8.6 Hz, PCH_2], 27.8, 27.6, 27.3, 27.1 (all s, CH_3 of acac), 25.2 [d, *J*(PC) = 18.9 Hz, P*C*HCH$_3$], 25.0 [d, *J*(PC) = 23.8 Hz, P*C*HCH$_3$], 22.9 [dd, $J(P^1C)$ = 29.6, $J(P^2C)$ = 10.4 Hz, PCH_2], 18.4, 18.3, 18.2, 18.0 (all s, PCH*C*H$_3$). – ^{31}P NMR (81.0 MHz, $CDCl_3$): δ = 91.2 [d, *J*(PP) = 23.4 Hz, *i*Pr_2P], 82.5 [d, *J*(PP) = 23.4 Hz, Ph_2P]. – $C_{30}H_{42}O_4P_2Ru$ (629.7): calcd. C 57.22 H 6.73; found C 56.89 H 7.03.

X-ray Structure Determination of Compounds 2 and 6:[18] Single crystals of **2** were grown from hexane at 25 °C and those of **6** from THF at 25 °C. Crystal data collection parameters for these structures are presented in Table 1. The data were collected with an Enraf–Nonius CAD4 diffractometer using monochromated Mo-K_α radiation (λ = 0.71073 Å). Intensity data were corrected for Lorentz and polarization effects. An empirical absorption correction was applied for both structures [Ψ scans; T_{min} = 0.90, T_{max} = 1.00 (**2**); T_{min} = 0.59, T_{max} = 0.80 (**6**)]. The structures were solved by Patterson methods with SHELXS-97.[19] All structures were refined by full-matrix least-squares procedures on F^2, using SHELXL-97.[20] The positions of all hydrogen atoms were calculated according to ideal geometry and refined by employing the riding method, except for H41a, H41b, H42a, H42b, H51a, H51b, H52a, and H52b of **2**, which were found in a differential Fourier synthesis and refined without restraints.

2-[Ethyl-(2-methallyl)amino]indenyllithium: Structural Characterization of a Base-Free Oligomeric Supersandwich Indenyllithium Compound

Jean-Luc Fauré,[a] Gerhard Erker,*[a] Roland Fröhlich,[a][+] and Klaus Bergander[a][++]

Keywords: Lithium / Sandwich complexes / Polymers / 2-Aminoindenyllithium

Treatment of the enamine **2**, formed by condensation of 2-indanone and ethyl(2-methallyl)amine, with *n*-butyllithium yields 2-[ethyl(2-methallyl)amino]indenyllithium (**3**), whose structure was determined by X-ray single crystal diffraction. Complex **3** exhibits an oligomeric supersandwich structure in the solid state, characterized by a linear string of alternating μ-η^5:η^5-indenyl anion and lithium cation moieties along which the substituents are found attached in a helical conformational arrangement.

Introduction

The alkali metal cyclopentadienides and their benzoanellated analogues are important reagents in organic and organometallic synthesis, but have also attracted a great deal of interest in themselves due to their unique structural properties. The high electrostatic component of the carbon−alkali metal bond[1] has made a variety of specific structural arrangements possible for the family of the ^{R}CpM^{I} systems, ranging from neutral (^{R}Cp)ML$_n$ monomers to cationic [M−^{R}Cp−M^{+}, "inverse sandwich"] and anionic [^{R}Cp−M−^{R}Cp^{-}, sandwich] arrangements, and to neutral-ligand-capped dimeric [^{R}Cp−M−^{R}Cp−ML$_n$] or oligomeric [^{R}Cp−M−^{R}Cp−M]$_n$ "supersandwich" structures.[2] The latter polymers are frequently encountered in ^{R}Cp sodium or potassium chemistry, but so far the lithium analogues have seldom been unambiguously characterized. The first example, [($C_5H_4SiMe_3$)Li]$_n$, was only recently described,[3−6] and its structure was solved by a single crystal X-ray diffraction analysis. Oligomeric (CpLi)$_n$ was recently characterized by high resolution X-ray powder diffraction.[7] The same technique was used for the determination of the oligomeric supersandwich structure of (η^5-indenyl-Li)$_n$ in the solid state [with Li-indenyl five-membered ring distances ranging between 2.304(3) Å and 2.350(3) Å].[8] Oligomeric (indenyl-Li)$_n$, characterized by X-ray powder diffraction, exhibits local internal C_s-symmetry. We describe here the structure of a related (2-aminoindenyl)Li reagent (**3**), whose oligomeric supersandwich structure was determined by single crystal X-ray diffraction.

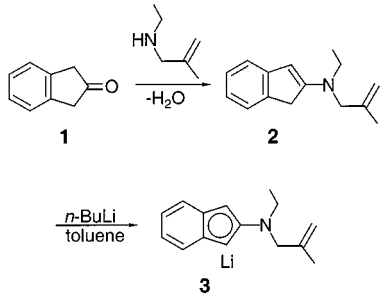
Results and Discussion

Preparation and Structure of the 2-[Ethyl(2-methallyl)-amino]indenyllithium Oligomer

The title compound **3** was prepared in the following way: 2-indanone was treated with a ca. threefold excess of ethyl(2-methallyl)amine in toluene in the presence of 3 Å molecular sieves to yield the corresponding enamine **2** (85% isolated).[9] Treatment of **2** with *n*-butyllithium in toluene/hexane resulted in the formation of the amino-substituted indenyllithium compound **3** in almost quantitative yield. The NMR spectra of **3** in [D_8]THF solution show the signals of a conformationally averaged, 2-substituted indenyl ligand (1-/3-H NMR signal at δ = 5.35; arene resonances at δ = 6.35 and 7.05). Single crystals of this specifically substituted indenyllithium example were obtained by slowly concentrating a solution of **3** in a mixture of toluene/ether (90:10) in a stream of argon at −20 °C during 48 h. The obtained single crystals of **3** were free of the donor ligand and suitable for characterization by an X-ray crystal structure analysis.



In the crystal the indenyllithium compound **3** adopts a polymeric supersandwich structure composed of alternating η^5-(2-aminoindenyl) units and intercalating lithium atoms. There are three crystallographically independent Li(R_2N-indenyl) subunits present in the solid, which represent chemically equivalent moieties. The planes of the individual 2-[ethyl(2-methallyl)amino]indenyl units are oriented almost parallel to each other [angles between the individual Cp planes: 15.9° ("Cp1"/"Cp21"), 16.6° ("Cp21"/"Cp41"), and 10.3° ("Cp41"/"Cp1")]. The lithium atoms are symmetrically η^5-coordinated from either side of the indenyl five-membered ring systems. Within all three independent subunits the minimum/maximum Li−C indenyl values amount to 2.237(7) Å (Li3−C1$^{\#}$) and 2.389(7) Å (Li1−C8). The Li1−C1,2,7−9(av.) values, averaged over the three inde-

pendent molecules, are within a narrow range between 2.288(7) and 2.321(7) Å; the corresponding Li1−C21,22,27−29(av.) values are found between 2.284(7) and 2.313(7) Å. The overall averaged Li−C bond lengths to either side of the Cp sections of the indenyl ligands in the supersandwich structure amount to 2.305 Å [Σ Li1−C1,2,7−9(av.)/5] and 2.297 Å [Σ Li1−C21,22,27−29(av.)/5], which illustrates the symmetrical bonding of the lithium atoms between adjacent η^5-indenyl ligands along the oligomeric chain in the crystal of **3** (see Figure 1). Both these averaged Li−C(av.) distances of **3** are smaller than the respective value determined in the recent X-ray powder diffraction study of $(\text{indenyl-Li})_n$ (2.320 Å).[8] The Li−C(av.) values found for **3** are close to the average Li−C(Cp) values obtained from the X-ray powder diffraction study of the parent $(\text{CpLi})_n$ oligomer (2.307 Å).[7]

The framework of the 2-[ethyl(2-methallyl)amino]indenyl ligand in **3** is completely planar (sum of averaged C−C−C bond angles inside the five-membered ring: 539.9°; inside the six-membered ring: 720.0°). The C−C bond lengths inside the five-membered ring are in a narrow range between 1.439(5) Å (C2−C7) and 1.411(5) (C8−C9)/1.413(4) (C1−C9). The pronounced contact of the lithium atoms to all five carbon atoms of the indenyl five-membered ring has a marked influence on the bonding features of the anellated planar arene system, which exhibits a marked bond alternation: the C3−C4(av.) [1.364(5) Å] and C5−C6(av.) [1.367(5) Å] bonds (see Figure 1) are noticeably shorter than the adjacent C4−C5(av.) [1.400(5) Å] bonds, as expected for an overall bonding situation of **3** as indicated in Scheme 1.

The coordination geometry of the nitrogen atom N10 in **3** is very close to trigonal planar (sum of C−N−C bond angles: 356.7°), and the amino-substituent is oriented in the central ligand plane. The C9−N10(av.) linkage is short {1.387(4) Å, the adjacent N10−C11(av.) [1.450(4) Å] and N10−C13(av.) [1.444(5) Å] bonds being much longer}, which indicates an enamine-like interaction at the aminoin-

Side view of the oligomeric supersandwich chain of **3** with unsymmetrical atom numbering scheme, containing two pairs of the set of three independent monomeric subunits found in the crystal; averaged (av.) bond lengths (Å) and angles (°): Li1−C1(av.) = (Li1−C1 + Li2−C21 + Li3−C41)/3 = 2.289(7), Li1−C2(av.) 2.288(7), Li1−C7(av.) 2.317(7), Li1−C8(av.) 2.321(7), Li1−C9(av.) 2.308(7), Li1−C21(av.) 2.285(7), Li1−C22(av.) 2.284(7), Li1−C27(av.) 2.297(7), Li1−C28(av.) 2.313(7), Li1−C29(av.) 2.306(7), C1−C2(av.) 1.424(5), C1−C9 1.413(4), C2−C7(av.) 1.439(5), C7−C8(av.) 1.423(5), C8−C9(av.) 1.411(5), C2−C3(av.) 1.412(5), C3−C4(av.) 1.364(5), C4−C5(av.) 1.400(5), C5−C6(av.) 1.367(5), C6−C7(av.) 1.406(5), C9−N10(av.) 1.387(4), N10−C11(av.) 1.450(4), C11−C12(av.) 1.523(6), N10−C13(av.) 1.444(5), C13−C14(av.) 1.480(6), C14−C15(av.) 1.330(6); C9−C1−C2(av.) 108.2(3), C1−C2−C3(av.) 133.1(3), C1−C2−C7(av.) 107.5(3), C3−C2−C7(av.) 119.3(3), C2−C3−C4(av.) 119.4(3), C3−C4−C5(av.) 121.3(4), C4−C5−C6(av.) 121.3(4), C5−C6−C7(av.) 119.5(4), C6−C7−C8(av.) 133.5(3), C6−C7−C2(av.) 119.2(3), C2−C7−C8(av.) 107.3(3), C7−C8−C9(av.) 108.5(3), C8−C9−C1(av.) 108.4(3), C8−C9−N10(av.) 125.8(3), C1−C9−N10(av.) 125.7(3), C9−N10−C11(av.) 119.8(3), C9−N10−C13(av.) 119.2(3), C11−N10−C13(av.) 117.7(3), N10−C13−C14(av.) 115.2(4), C13−C14−C15(av.) 120.8(4), C13−C14−C16(av.) 117.0(3), C15−C14−C16(av.) 122.1(6)

denyl unit,[10] probably resulting in an increased electron density at carbon inside this anionic ligand system.

The conformational arrangement of the indenyl anions along the $[-Li-Cp(centroid)-]_n$ vector is such that the amino substituents are arranged almost ideally staggered along the chain (see Figure 2) which is characterized by dihedral angles of close to 120° between the corresponding N−C(Cp) vectors. There are subtle differences in the conformational arrangement of the rather large methallyl substituents at the three independent Li−2-[ethyl(2−methallyl)amino]indenyl subunits [one $-CH_2-C(CH_3)=CH_2$ group pointing "up", one "down" and one being arranged in the ligand plane] that lead to the observed marginal deviation of the overall chain from ideal linearity (see Figure 1).

Conclusions

We conclude that compound **3** seems to represent the first example of a base-free oligomeric (μ-η^5:η^5-indenyl) lithium supersandwich system that was characterized by an X-ray single crystal structure analysis. The amino-functionalized (η^5-indenyl)Li structure **(3)** exhibits shorter bonds between the lithium atom and the carbon atoms of the indenyl five-membered ring than in the recent high resolution X-ray powder diffraction analysis of the (η^5-indenyl-Li) structure.[8] Like the parent $(indenyl\text{-}Li)_n$, the amino-substituted compound **3** exhibits an organometallic oligomeric structure in the solid state. The 2-[ethyl(2-methallyl)amino]indenyllithium polymer **(3)** is characterized by a regularly alternating arrangement of η^5-aminoindenyl anion moieties and lithium cations, probably formed by dominant electrostatic metal−carbon interactions. The helical conformational arrangement of the substituents at the resulting oligomeric chain indicates that such systems possess well-defined stereochemical features in the crystal. The use of such substituted indenyllithium reagents is currently being studied in our laboratory.

Experimental Section

All reactions were carried out under argon using Schlenk-type glassware or in a glovebox. Solvents (including deuterated solvents used for the NMR spectroscopic characterization) were dried and distilled under argon prior to use. For additional general information see ref.[4] and ref.[5a] NMR experiments were carried out on a Varian Unity Plus 600 NMR spectrometer. The ^1H and ^{13}C NMR assignments were confirmed by GCOSY, GHSQC, GHMBC and DPFGSE-NOE experiments. The $\delta(^{15}N)$ determination was performed by indirect detection by the $^1H,^{15}N$-GHMBC experiment [preparation delay: $1/(2J) = 0.1$ s)]. Compound **2** was synthesized in analogy to a literature method.[9]

Preparation of 2-[Ethyl(2-methallyl)amino]indene (2): 2-Indanone (**1**, 3.2 g, 24.2 mmol) was added to a stirred suspension (3 g) of activated 3 Å molecular sieves in 40 mL of toluene. Ethyl(2-methallyl)amine (7.02 g, 72.6 mmol) was added, and the reaction mixture was stirred for 1 day at 70 °C. The mixture was filtered and the remaining molecular sieves washed with toluene (20 mL). Volatiles were removed from the combined organic solutions in vacuo to yield **2** as a liquid (4.31 g, 85%). HRMS (ESI): calcd. for $C_{15}H_{19}NH^+$: m/z = 214.1596; found m/z = 214.1572. − ^1H NMR (599.1 MHz, [D$_8$]toluene, 298 K): indene: δ = 7.04 (dd, 1 H, 5-H), 7.01 (d, 1 H, 7-H), 6.93 (d, 1 H, 4-H), 6.76 (dd, 1 H, 6-H), 5.19 (s, 1 H, 3-H), 3.00 (s, 2 H, 1-H); 2-methallyl: δ = 4.66 (s, 2 H, $=CH_2$), 3.28 (s, 2 H, CH_2), 1.43 (s, 3 H, CH_3); ethyl: δ = 2.87 (q, 2 H, CH_2), 0.85 (t, 3 H, CH_3). − ^{13}C NMR (150.7 MHz, [D$_8$]toluene, 298 K): indene: δ = 156.0 (C2), 148.7 (C3a), 136.8 (C7a), 126.9 (C5), 122.8 (C7), 119.9 (C6), 116.9 (C4), 96.6 (C3); 2-methallyl: δ = 142.0 (quat.-C), 111.3 ($=CH_2$), 56.1 (CH_2), 56.1 (CH_2), 19.9 (CH_3); ethyl: δ = 45.1 (CH_2), 12.0 (CH_3). − ^{15}N NMR (60.7 MHz, [D$_8$]toluene, 298 K): δ = −306.

Preparation of 2-[Ethyl(2-methallyl)amino]indenyllithium (3): *n*-Butyllithium (17.0 mmol, 9.8 mL of a 1.75 M solution in hexane) was slowly added at −78 °C to a stirred solution of 2-[ethyl(2-methallyl)amino]indene (**2**, 3.46 g, 16 mmol) in toluene (30 mL). The reaction mixture was allowed to warm to room temperature and then stirred for 16 h. The resulting solid was recovered from the suspension by filtration, washed with pentane (2 × 10 mL) and dried in vacuo to yield 3.50 g (98%) of **3** as a white solid. ^1H NMR (599.1 MHz, [D$_8$]THF, 298 K): indene: δ = 7.02 (m, 2 H, 4-H, 7-H), 6.31 (m, 2 H, 5-H, 6-H), 5.33 (s, 2 H, 3 H); 2-methallyl: δ = 4.91 (s, 1 H) and 4.76 (s, 1 H, $=CH_2$), 3.74 (s, 2 H, CH_2), 1.73 (s, 3 H, CH_3); ethyl: δ = 3.26 (2 H, CH_2), 1.08 (t, 3 H, CH_3). − ^{13}C NMR (150.7 MHz, [D$_8$]THF, 298 K): indene: δ = 151.1 (C2), 131.5 (C3a, C7a), 119.2 (C4, C7), 115.5 (C5, C6), 80.5 (C1, C3); 2-methallyl: δ = 148.7 (quat.-C), 113.5 ($=CH_2$), 61.3 (CH_2) 23.5 (CH_3); ethyl: δ = 48.5 (CH_2), 14.8 (CH_3). − ^{15}N NMR (60.7 MHz, [D$_8$]THF, 298 K): δ = −326.

X-ray Crystal Structure Analysis of 3: Single crystals were obtained from a toluene/ether (9:1) solution, that was concentrated under argon at −20 °C. $C_{15}H_{18}NLi$, M = 219.24, a = 16.447(1), b = 11.611(1), c = 21.706(1) Å, β = 101.01(3)°, V = 4068.8(5) Å^3, μ = 0.61 cm^{-1}, Z = 12, monoclinic, space group $P2_1/c$ (No. 14), λ = 0.71073 Å, T = 198 K, 9655 reflections collected ($\pm h$, $\pm k$, $\pm l$), 5336 independent (R_{int} = 0.075) and 2864 observed reflections [$I \geq 2\,\sigma(I)$], R = 0.065, wR^2 = 0.139. The data set was collected with a Nonius KappaCCD diffractometer, equipped with a rotating anode generator Nonius FR591. Programs used: data collection COLLECT (Nonius B.V., 1998), data reduction Denzo-SMN (Z. Otwinowski, W. Minor, *Methods Enzymol.* **1997**, *276*, 307−326), absorption correction SORTAV (R. H. Structural and Theoretical Studies of *ortho*-Substituted Triphenylphosphane Ligands and Their Rhodium(I) Complexes

Pekka Suomalainen,[a] Sirpa Jääskeläinen,[a] Matti Haukka,[a] Riitta H. Laitinen,[b] Jouni Pursiainen,[b] and Tapani A. Pakkanen*[a]

Keywords: Structure elucidation / P ligands / Rhodium / Molecular modeling

The triarylphosphanes, (*o*-thiomethylphenyl)diphenylphosphane (SP, **1**), (*o*-*N*,*N*′-dimethylaminophenyl)diphenylphosphane (NP, **2**), and (*o*-methoxyphenyl)diphenylphosphane (OP, **3**) have been structurally characterized. Detailed information on the stereochemistry of the ligands was gathered by spectroscopic (^{1}H, ^{31}P, ^{13}C NMR) and X-ray crystallographic studies. Molecular modeling methods for investigation of the structures were also applied. It is shown that the geometrical optimization of the ligand can be performed accurately by the ab initio Hartree–Fock method. Furthermore, the steric contribution of the coordinated ligands can be estimated by studying the different conformational states of the free ligands. The coordination abilities of the ligands were studied in reactions with the rhodium compounds $Rh_2(CO)_4Cl_2$ and $Rh(NO_3)_3$ under different reaction conditions. The SP and NP ligands yielded mononuclear chelate complexes, while the OP ligand coordinated solely in a monodentate fashion through the phosphorus atom. The crystal structures of the ligands **1**–**3** and the rhodium(I) complexes [RhCl(CO)(NP)] (**5**) and [RhCl(CO)(OP)$_2$] (**6**) are reported.

Introduction

Increasing research is being done to rationalize the design of homogeneous catalysts for specific industrial applications. The demand for higher selectivity of the several homogenous catalytic reactions has inspired research on the effects of modifying the metal sphere with various ligands. The development of tertiary phosphane ligands began with Wilkinson′s catalyst.[1] Since then, many sterically and electronically enhanced PX_3 ligands have been investigated, and useful tools have been developed for measuring the properties of these ligands.[2,3] Polydentate phosphorus ligands have attracted much interest in the field of homogeneous catalysis. Mixed ligands containing phosphorus together with oxygen, nitrogen or sulfur have been studied in a number of applications including polymerization and oligomerization of olefins,[4] carbonylation of methanol,[5] and hydroformylation of olefins.[6] With the possible hemilabile character of these ligands, a more weakly coordinated donor site may appear between the coordinated/uncoordinated equilibrium, allowing an interesting setup for catalytic reactions. Hemilabile character has earlier been reported for several mixed heteroatom-phosphorus ligands, including ether-phosphanes,[7] hydroxyphenyl phosphanes,[8] phosphonate-phosphanes,[9] and amido-diphosphanes.[10] The fluxional behavior of this type of ligand around the metal center is considered to activate CO and H_2 molecules, thus improving the oxo-reactions such as carbonylation and hydroformylation. Recently, Reinius et al. studied the hydroformylation of methyl methacrylate (MMA) in the presence of SP, NP, and OP ligands. Exceptional selectivity towards branched methyl-α-formylisobutyrate was found when the SP ligand was used in situ with $Rh(NO_3)_3$.[11]

This paper describes structural and complexation studies on three *ortho*-substituted triphenylphosphane derivatives: (*o*-thiomethylphenyl)diphenylphosphane (SP, **1**), (*o*-*N*,*N*′-dimethylaminophenyl)diphenylphosphane (NP, **2**), and (*o*-methoxyphenyl)diphenylphosphane (OP, **3**). In addition to spectroscopic and crystallographic studies, theoretical investigations of the ligand structures have been carried out to obtain a better understanding of the stereochemistry. We were particularly interested to know whether the steric requirements of the coordinated ligands could be estimated by ab initio calculations of the ligands in the gas phase. The coordination modes of the ligands were studied in reactions with the rhodium compounds $Rh_2(CO)_4Cl_2$ and $Rh(NO_3)_3$. Syntheses at a higher synthesis gas pressure and temperature were carried out to investigate the behavior of the ligands in a catalytic environment.

Results and Discussion

Synthesis and Characterization of Substituted Triarylphosphane Ligands

The mono-substituted triphenylphosphane derivatives SP, NP, and OP were prepared according to literature methods.[11–13] The X-ray crystal structures of the ligands are reported for the first time. Crystallographic data are given in Table 1. Figure 1 shows an Ortep drawing of the SP ligand. Selected bond parameters for ligands **1**–**3** are compiled in Table 2. The labeling scheme for the NP and OP ligands is the same as for the SP ligand.

* Global minimum.

Conformational Flexibility of the Ligands

The equilibrium geometries of the SP, OP, and NP ligands were first determined by optimizing the structures with the ab initio Hartree−Fock method using a 3−21G* basis set. Starting from the initial geometries, a conformational analysis was carried out by rotating the torsional angles of the three phenyl rings. Several local minima were identified and subsequently optimized with the HF/3−21G* method. The energies of the minima relative to the ground state are shown in Table 3.

The steric crowding of the free ligands was measured using Tolman's semi-cone angle concept.[2] The cone angles of the free ligands were calculated for the ground states and for low lying conformations. As shown in Table 3, the cone angles are widest for the ground states and narrow for the higher energy conformers, giving an indication of the en-

ergy demands of the steric repulsion. In the lowest energy conformations, the maximum semi-cone angles are always determined by the *m*-hydrogen atoms of the phenyl rings and by one of the hydrogen atoms in the -XCH_3 group. In this manner, the ligands can be arranged in decreasing order of bulkiness: SP = OP < NP. For the higher energy conformations of the ligands, the cone angles diminish because the substituted phenyl ring(s) rotates in such a way that the -XCH_3 group becomes located inside the cone and no longer directly affects the maximum semi-cone angle. This eventually leads to identical values of cone angles.

Synthesis and Characterization of Rhodium Phosphane Complexes

Two different rhodium sources, $Rh_2(CO)_4Cl_2$ and $Rh(NO_3)_3$, were used to prepare the complexes. Variations in atmosphere, temperature, pressure, and solvent, were introduced to clarify the various possibilities for the reaction pathways, and to proceed step-by-step from milder reaction conditions to a more severe, actual catalytic environment. At room temperature, the syntheses were carried out in an atmosphere of either nitrogen or carbon monoxide. Conditions nearer to a catalytic environment were obtained when the reactions were carried out in autoclaves that were heated to 100 °C and pressurized to 20 bar with carbon monoxide or synthesis gas (CO/H_2). The reaction time in the pressurized synthesis reactions was 4 h, after which the autoclaves were allowed to cool to room temperature.

Reactions With the SP Ligand

A yellow precipitate was isolated after $Rh_2(CO)_4Cl_2$ and the SP ligand were allowed to react in a methanol solution at room temperature and under an atmosphere of nitrogen. The product was identified crystallographically as the square-planar rhodium compound [Rh(CO)Cl(SP)] **(4)** with the SP ligand chelating through the sulfur and phosphorus atoms. The IR spectrum of **4** shows a CO stretching vibration at 2010 cm^{-1}, while the ^{31}P NMR spectrum gives a doublet at $\delta = 67.2$ with $J_{Rh-P} = 152$ Hz. Dilworth et al.[14] have previously reported the synthesis of a brown precipitate, which they proposed on the basis of spectroscopic investigation to be compound **4**. More recently, Steeg et al.[15] published a crystallographic characterization of the same compound, which was, however, reached by a different route.

Compound **4** was again formed under an atmosphere of carbon monoxide in toluene solution. Likewise the formation of **4** was observed under syngas pressure (CO/H_2 20bar) and at high temperature (100 °C), but another doublet in the ^{31}P NMR spectrum was found at $\delta = 48.9$ with a smaller coupling constant of 77 Hz. This new signal was assigned to an isomeric form of complex **4** with the carbonyl group *trans* to phosphorus, since such coordination gives a lower shift and coupling constant than the corresponding orientation with phosphorus *trans* to chloride.[16]

The reaction between $Rh(NO_3)_3 \cdot 2H_2O$ and SP in a catalytic environment gave peaks at 2034 and 1873 cm^{-1} in the IR spectrum, as well as a broad line at $\delta = 28$ in the ^{31}P NMR spectrum. Resemblance of the spectroscopic data to those of the rhodium diphosphane compounds $HRh(CO)_x(P)_y$ prepared under similar reaction conditions can be seen.[17] In addition, the fluctuation of the SP coordination is possible. Furthermore, the formation of polynuclear carbonyl compounds is possible as a result of degradation of the ligand under severe reaction conditions.[18]

Reactions With the NP Ligand

Methanol solutions of $Rh_2(CO)_4Cl_2$ and NP were mixed at room temperature under an atmosphere of nitrogen to form a yellow precipitate. The product was identified crystallographically as the monometallic chelate species, [Rh(CO)Cl(NP)] (**5**), bonded through nitrogen and phosphorus (Figure 2). The structure shows a planar geometry around the rhodium atom with a slight deviation from ideal. The largest discrepancy is along the axis P(1)−Rh(1)−Cl(1) where the angle is 174.7 (2) Å. A shorter Rh−C(4) distance than in complex **4** indicates the stronger

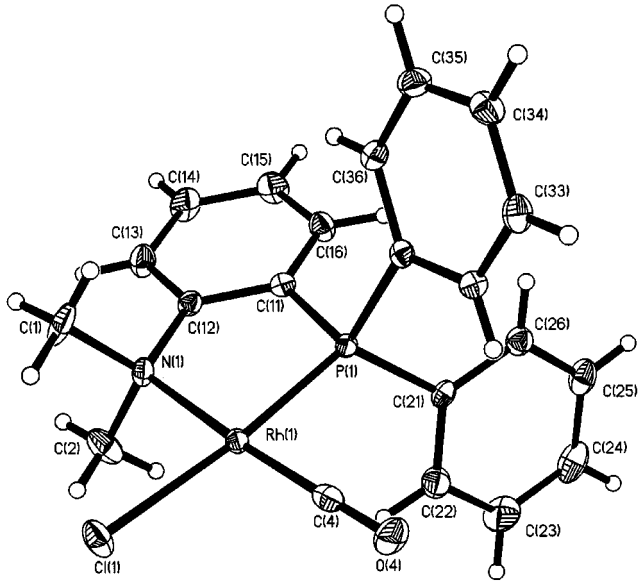

Figure 2. Ortep drawing of Rh(CO)ClNP with thermal ellipsoids at 50% level

Table 4. Selected bond angles and distances for Rh(CO)Cl(NP) (**5**)

Atoms	Bond lengths (Å)
Rh(1)−P(1)	2.3308(10)
Rh(1)−P(2)	2.3335(10)
Rh(1)−Cl(1)	2.4131(10)
Rh(1)−C(4)	1.827(5)
C(4)−O(4)	0.989(5)
Atoms	**Bond angles (deg)**
C(4)−Rh(1)−P(1)	87.26(10)
C(4)−Rh(1)−P(2)	92.21(9)
P(1)−Rh(1)−P(2)	179.39(4)
C(4)−Rh(1)−Cl(1)	178.40(11)
P(1)−Rh(1)−Cl(1)	92.89(3)
P(2)−Rh(1)−Cl(1)	87.63(3)

electron-donor character of the NP ligand. The flow of electron density to the rhodium increases π-back donation to the carbonyl. This is further observed in the CO stretching frequencies of 2010 cm^{-1} and 1995 cm^{-1} for **4** and **5**, respectively. The ^{31}P spectrum of **5** shows a doublet at δ = 56.8 with a Rh−P coupling of 171 Hz.

When the same reactants were allowed to react in the autoclave (toluene, 100 °C, 20 bar CO, 4 hours), species **5** was again isolated and characterized by its IR stretching vibration and elemental analysis. The same product was observed when a CO/H_2 atmosphere was applied to the reaction. An IR absorption at 1995 cm^{-1} was found, but also an additional peak at 2071 cm^{-1} appeared in the spectrum, suggesting the formation of a $Rh_6(CO)_{16}$ cluster. The synthesis and stereochemistry of **5** has previously been discussed by Roundhill et al.[19,20]

The strong chelating ability of the NP ligand was also observed in the reaction with $Rh(NO_3)_3 \cdot 2H_2O$ at room temperature under a CO atmosphere. From the assignment of a doublet at δ = 57.9 (141 Hz) in the ^{31}P NMR spectrum and an IR absorption at 1995 cm^{-1}, we deduced that a chelate compound was formed with the NP ligand. Under more severe reaction conditions, the product from the reaction with $Rh(NO_3)_3 \cdot 2H_2O$ and NP afforded similar spectroscopic data to those obtained with the SP ligand, suggesting corresponding species.

Reactions With the OP Ligand

$Rh_2(CO)_4Cl_2$ and the OP ligand were allowed to react under nitrogen at room temperature in a methanol solution to form a yellow precipitate. The compound, *trans*-[Rh(CO)-$Cl(OP)_2$] (**6**), was characterized crystallographically as a tetracoordinate monocarbonyl complex with two phosphorus ligands bonded in a monodentate fashion (Figure 3). Analogous $[RhX(CO)(PAr_3)_2]$ (X = Cl, I, Br) structures have been reported previously.[21−23] Compound **6** gives a strong CO stretching vibration at 1974 cm^{-1} and the ^{31}P NMR spectrum shows a doublet at δ = 23.2 with a Rh−P coupling constant of 129 Hz. The crystallographic data for **6** are given in Table 1. Selected bond lengths and angles are given in Table 5. Under similar reaction conditions in dichloromethane, the reaction proceeds differently, resulting in strong IR absorptions at 2090 and 2010 cm^{-1}, characteristic of either monometallic *cis*-dicarbonyl or dimeric, doubly five-coordinated phosphane derivatives.[24] At an elevated pressure and temperature, complex **6** was again the main product.

Table 5. Selected bond angles and distances for $Rh(CO)Cl(OP)_2$ (**6**)

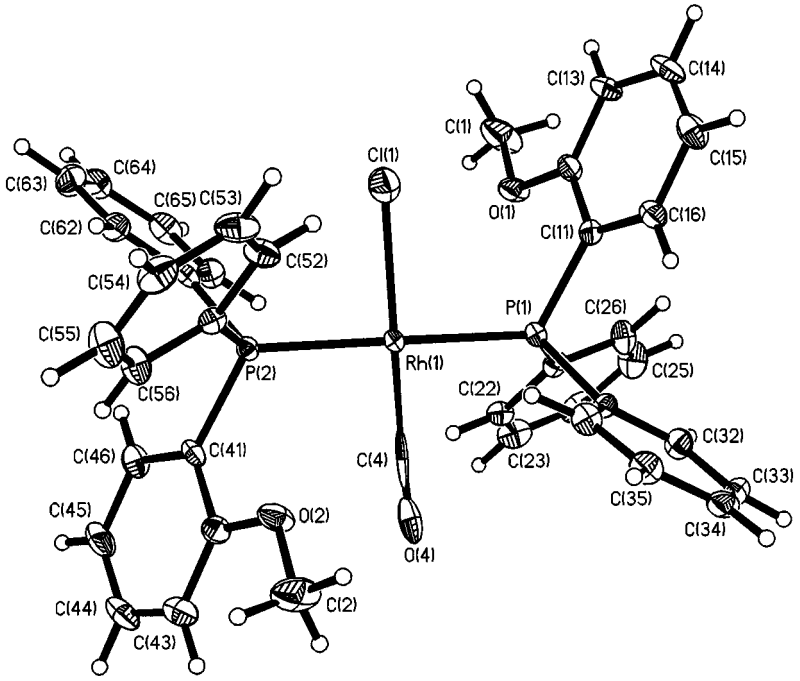

Figure 3. Ortep drawing of $Rh(CO)Cl(OP)_2$ with thermal ellipsoids at 50% level

The reaction between $Rh(NO_3)_3 \cdot 2H_2O$ and the OP ligand in a methanol solution under an atmosphere of CO resulted in a greenish-yellow solid. This compound gives a strong IR absorbance at 1974 cm^{-1}, indicating a geometry similar to that of complex **6**. Crystallization from dichloromethane led to a mixture of yellow and green crystals. The yellow crystals turned out to be species **6**, evidently formed through exchange of an NO_3 group for the chlorine atom. The green crystals have a linear P−Rh−P skeleton, as in complex **6**, with a bidentate NO_3 ligand attached by two oxygen atoms. However, the remaining ligands were disordered, and crystallization of two different species also seemed probable. In the ^{31}P NMR spectrum, the green crystals give rise to a doublet at $\delta = 20.2$ with $J_{Rh-P} = 153$ Hz.

The presence of **6** was again observed at elevated temperature and 20 bar syngas pressure. Additional absorptions were detected at 2034 and 1873 cm^{-1} in the IR spectrum, and there is a broad line at $\delta = 28$ in the ^{31}P NMR spectrum. Similar species as observed with the SP and NP ligands are proposed.

No evidence was found for the chelating character of the OP ligand. The monodentate binding mode of the OP ligand has also been observed by Trzeciak et.al.[8] However, they found that substitution of a methoxy group for a hydroxyl group changes the reactivity of the ligand, resulting in stable chelate complexes.

Comparison Between Solid State and Calculated Structures

Reliable predictions of ligand geometries were obtained using the Hartree−Fock method. The geometries of the ground-state structures and the X-ray structures of the ligands deviate by only a few hundredths of an angstrom in bond lengths and one degree in bond angles. The cone angle values based on the solid state structures of the free ligands fall within the cone angle range measured for the different gas-phase conformers. Only the SP ligand was found to have a greater angle in the solid state. The cone angle data for the ligands are shown in Table 6. A closer investigation of the coordinated OP ligand in complex **6** revealed a similar geometry to its lowest energy conformation. Being in the *trans* position to each other, the two OP ligands can lie near the low energy conformation. We can assume that the phosphane does not encounter a significant amount of steric interaction from the CO or Cl ligands. A comparison of the structures of the free and bonded OP ligand is shown in Figure 4. The presence of a bidentate coordination mode in compounds **4** and **5** makes a similar examination of these compounds more difficult.

Table 6. Cone angle values based on different structural data

Ligand	Free ligand (X-ray)	Flexibility range (HF 3−21G*)	Coordinated ligands (X-ray) $Rh(CO)Cl(L)_2$ **(6)**
SP	164	153−158	-
NP	176	153−180	-
OP	162	153−166	154, 155

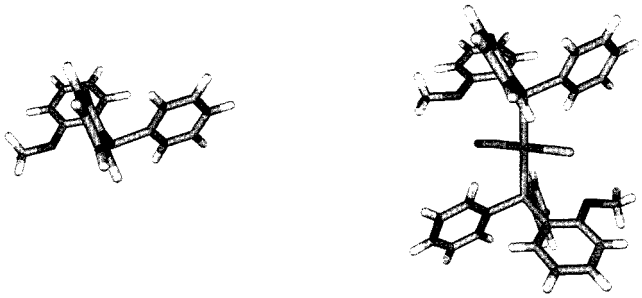

Figure 4. Comparison of the lowest energy conformations of (*o*-methoxyphenyl)diphenylphosphane and the coordinated ligand

Conclusion

Through a detailed examination of the conformational variations of the free ligand structures in the gas phase, we were able to estimate the steric requirements of the solid-state structures of the free and coordinated ligands. However, the multiple binding sites of the ligands may lead to highly strained conformations, which are hard to predict on the basis of the free ligand structures.

The coordination preference of the ligand in the prepared rhodium complexes was influenced by the type of donor atom in the *ortho* position of the phenyl ring. The strong σ-donor ligands, SP and NP, both yielded chelate species independently of the reaction conditions. In contrast, the OP ligand was found to coordinate in a monodentate fashion.

Experimental Section

General: All the syntheses were carried out using standard Schlenk techniques under an atmosphere of nitrogen. Other gases, carbon monoxide and synthesis gas (CO/H_2), were of high purity grade (99.997%) and were purchased from AGA and MG, respectively. The solvents, methanol and toluene (p.a. grade), were deoxygenated with nitrogen prior to use. $Rh_2(CO)_4Cl_2$ was prepared according to a literature method[25] and $Rh(NO_3)_3 \cdot 2H_2O$ was purchased from Alfa. NMR spectra were recorded on a Bruker AM250 spectrometer. ^{31}P spectra were referenced to 85% H_3PO_4. Elemental analyses were done with a Perkin−Elmer 2400 Series II CHNS/O analyzer. High-pressure synthesis reactions were conducted in 100 mL Berghof autoclaves with a 60 mL Teflon liner. In a typical run, the autoclave was charged in a glovebox with the rhodium compound, ligand, and solvent (toluene). The autoclaves were then sealed and pressurized with either H_2/CO (1:1) or CO to 20 bar. The autoclaves were heated to 100 °C, with the temperature controlled and monitored by an internal thermocouple. After four hours reaction time, the autoclaves were cooled slowly and brought to normal atmospheric pressure. The Gaussian 94[26]and Sybyl[27] programs were used in modeling. The 3−21G* basis set was used for geometric optimizations at the Hartree−Fock level. In the conformational analyses, the single point energies were calculated with the grid-search method of Sybyl, and the final geometries were determined with the HF/3−21G* method. The phenyl rings were rotated 180° and the substituted phenyl ring was rotated 360° in increments of 20°. For cone angle determinations, the metal−phosphorus distance was fixed at 2.28 Å. A dummy atom was used for free ligands.

Rh(CO)ClSP (4): $Rh_2(CO)_4Cl_2$ (25 mg, 0.064 mol) and SP (40 mg, 0.129 mol) were dissolved in methanol in separate flasks. The ligand solution was added dropwise to the solution of the rhodium compound. The yellow precipitate that formed was filtered, washed with methanol, and quickly dried under vacuum. Yellow crystals for X-ray studies were crystallized from CH_2Cl_2. – $C_{20}H_{17}ClPRhS$ (474.73): calcd. C 50.60, H 3.61, S 6.75; found C 50.67, H 3.62, S 6.89. – IR (CH_2Cl_2): ν(CO) = 2010cm^{-1}. – ^{31}P NMR: δ = 67.5 [d, J(Rh–P) = 152 Hz].

Rh(CO)ClNP (5): $Rh_2(CO)_4Cl_2$ (100 mg, 0.257 mol) and NP (80 mg, 0.262 mol) were dissolved in methanol in separate Schlenk flasks. The ligand solution was added dropwise to the solution of the rhodium compound. Rapid formation of a yellow precipitate was observed and the reaction was allowed to continue for 2 hours. The precipitate was filtered, washed with methanol and dried under vacuum. Yellow crystals for X-ray studies were obtained from a CH_2Cl_2/hexane solution. – $C_{21}H_{20}ClPRhS$: calcd. C 53.47, H 4.27, N 2.97; found C 53.27, H 4.31, N 3.14. – IR (CH_2Cl_2): ν(CO) = 1995cm^{-1}. – ^{31}P NMR: δ = 56.8 [d, J(Rh–P) = 171 Hz].

Rh(CO)Cl(OP)$_2$ (6). Method 1: $Rh_2(CO)_4Cl_2$ (100 mg, 0.257 mol) and OP (150 mg, 0.3763 mol) were dissolved in methanol in separate flasks. The ligand solution was added dropwise to the precursor solution. The yellow precipitate that formed was filtered, washed with methanol, and quickly dried under vacuum. Yellow crystals for X-ray studies were crystallized from a CH_2Cl_2/hexane solution. – $C_{39}H_{34}ClO_3P_2Rh$: calcd. C 62.37, H 4.56; found C 62.07, H 4.54. – IR (CH_2Cl_2): ν(CO) = 1974cm^{-1}. – ^{31}P NMR: δ = 23.5 [d, J(Rh–P) = 130 Hz].
Method 2: $Rh_2(CO)_4Cl_2$ (25 mg, 0.064 mol) and OP (55 mg, 0.3763 mol) were packed into the autoclave together with 5 mL of toluene. The autoclave was pressurized to 20 bar (CO/H_2) and heated to 100 °C. After four hours the autoclave was cooled and brought to normal atmospheric pressure. The yellow precipitate that formed was filtered, washed with toluene, and dried under vacuum.

X-ray Crystallographic Study: X-ray diffraction data were collected with a Nonius KappaCCD diffractometer using Mo-K_α radiation (λ = 0.71073 Å) and φ-scan or combined φ/ω-scan data collection mode with a Collect[28] data collection program. The Denzo and Scalepack[29] programs were used for cell refinements and data reduction. All structures were solved by direct methods using the SHELXS97[30] program with the WinGX[31] graphical user interface or by using the SHELXTL v5.1[32] program package. The structure refinements were carried out with SHELXL97.[33] For compounds OP, NP, Rh(CO)Cl(SP), and Rh(CO)Cl(OP)$_2$, hydrogen atoms were constrained to ride on their parent atom. [aromatic hydrogens: C–H = 0.93Å, U_{iso} = 1.2(C_{eq}) at 293 K and C–H = 0.95Å, U_{iso} = 1.2(C_{eq}) at 120 K; methyl hydrogens: C–H = 0.96 Å, U_{iso} = 1.5(C_{eq}) at 293 K and C–H = 0.95Å, U_{iso} = 1.2(C_{eq}) at 120 K]. For compound **5** and SP, all atoms were located from the difference Fourier map. In the former case, the hydrogen atoms were refined isotropically, and in the latter case with constant U_{iso} = 0.08. The structure of [Rh(CO)Cl(OP)$_2$] (**6**) was solved as a racemic twin (Flack parameter 0.48952) in the acentric space group *Pn*.

Crystallographic data are summarized in Table 1 and selected bond lengths and angles for the ligands are presented in Table 2, Table 4 and Table 5.

Crystallographic data (excluding structure factors) for the structure(s) reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-140374 **(3)**, -140375 **(1)**, -140376 **(2)**, -140377 **(6)**, -140378 **(5)**. Osmium Complexes of the 5,10,15,20-Tetrakis(4-phosphonomethylphenyl)-porphyrin Anion, A New Water-Soluble Tetraphenylporphyrinate System

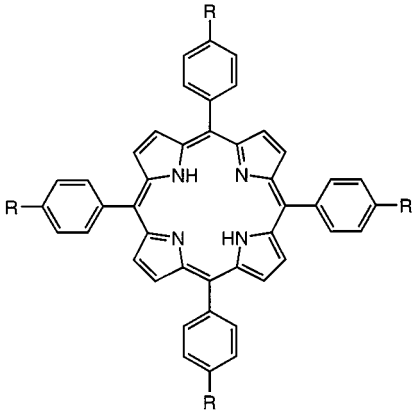
Johann W. Buchler[a] and Joachim R. Simon*[b]

Keywords: Osmium / Porphyrinates / Anions / Autoxidation / Electrophoresis



The synthesis of a new class of water-soluble osmium tetraphenylporphyrinates, complexes of the tetrakis(4-phosphonomethylphenyl)porphyrin anion $[H_2(tP_4O_8\{OH\}_4mpp)]^{4-}$ **(5)**, is described. Starting from OsCO(tmecpp)thf **(1a)** and OsO_2(tmecpp) **(1b)**, the new complexes **5a–c** were synthesized by a four-step reaction with Os(t{OH}$_4$mpp)LL′ **(2a–b)**, Os(tBr_4mpp)LL′ **(3a–b)**, and Os(tP_4O_4{OEt}$_8$mpp)LL′ **(4a–c)** as intermediates. The new complexes were characterized by UV/Vis, IR, ^{1}H NMR, and ^{31}P NMR spectroscopy, as well as by cyclic voltammetry and electrophoresis.

Introduction

Only a few water-soluble porphyrin systems with anionic functional groups are known. Besides the tetrakis(4-sulfonatophenyl)porphyrin anion $[H_2(tpps_4)]^{4-}$ **(6)**, tetrakis(4-carboxyphenyl)porphyrin $H_2(tH_4cpp)$[2] **(7)**, and tetrakis(4-boronatophenyl)porphyrin **(8)**[3] are mentioned exclusively. Additionally, the tetrakis(4-phosphonophenyl)porphyrin is reported,[4] however, its synthesis is difficult. As compared with **6**, **7** and **8** are soluble only in alkaline media. All in all the tetrakis(4-sulfonatophenyl)porphyrin anion **6** is the only water-soluble porphyrin system that can be synthesized easily, and is soluble in aqueous media over the full pH range.

Anionic porphyrin systems are very interesting, due to their behaviour.[5–11] As the number of these porphyrins are limited, researchers look out for further possibilities of synthesizing new porphyrin systems with anionic functional groups. By a four-step reaction starting from H_2(tmecpp) **(1)**, Katzenmeier[12] was able to extend the number of anionic porphyrin systems. A new porphyrin, the tetra-sodium salt of 5,10,15,20-tetrakis(4-phosphonomethylphenyl)porphyrin anion $[H_2(tP_4O_8\{OH\}_4mpp)]^{4-}$ **(5)** was described. Like tetrakis(4-sulfonatophenyl)porphyrin anion **(6)**, compound **5** shows no reactions in alkaline or acidic media. The excellent solubility over almost the full pH-range must be noted.

With the exception of complexes with carbonic[13a,13b] or sulfonic[13] functional groups, no other water-soluble osmium porphyrin complexes are known. Attempts to synthesize cationic osmium porphyrin complexes have been described,[13b] although it was not possible to obtain the desirable products.

Water-soluble osmium(II) porphyrinates with sulfonate groups in the *para*-position of the phenyl rings can undergo reversible redox reactions,[13] and because of this behaviour are good cytochrome models. The aim of this work was to prove whether other hydrophilic osmium(II) porphyrinates show the same redox behaviour. Based on the results of Katzenmeier,[12] we were able to synthesize a new class of

Synthesis

As shown previously,[13b] water-soluble osmium(II) porphyrin complexes cannot be synthesized directly by reaction of K_2OsCl_6 with the ionic porphyrin system: they must be synthesized by a four-step reaction with water-insoluble osmium porphyrin complexes as intermediates. Based on these results we decided to synthesize the osmium complexes of the tetrakis(4-phosphonomethylphenyl)porphyrin anion $[H_2(tP_4O_8\{OH\}_4mpp)]^{4-}$ **(5)** by metallation of $H_2(tP_4O_4\{OEt\}_8mpp)$ **(4)**, followed by saponification. Unfortunately, we were not able to obtain the product by the method described for metallation of H_2(tmecpp).[13] Indeed, complete metallation was confirmed by UV/Vis spectroscopy. However, some ester groups were saponified during the reaction. Also, several experiments in the presence of EtOH yielded only the diester $A_2[OsCO(tP_4O_6\{OEt\}_2\{OH\}_4mpp)thf]$ **(4d)**, as seen in the ^1H NMR spectra. Compound **4d** was saponified, for standardization. Neither saponification with CH_3SiBr/KOH,[12,14,15] nor KOH (4%)[13b,16] yielded the expected product, but instead a water-soluble residue was characterized as $K_2[OsCO(tP_4O_6\{OEt\}_2\{OH\}_4mpp)thf]$ **(5d)** by NMR spectroscopy and elemental analysis. Reaction of **5d** with 1-methylimidazole or MeOH, resulted in the axial ligand (thf) being substituted to yield $K_2[OsCO(tP_4O_6\{OEt\}_2\{OH\}_4mpp)MEOH]$ **(5e)** or $K_2[OsCO(tP_4O_6\{OEt\}_2\{OH\}_4mpp)(1\text{-meim})]$ **(5f)**, respectively. The new axial ligands were established by IR spectroscopy.

In agreement with Künzel,[13b] it was not possible to synthesize the water-soluble osmochromes $K_4[Os(tP_4O_8\{OH\}_4mpp)LL']$ **(5h)** by oxidation of **5d** or by the reduction of the intermediate dioxo complex **5g**. As shown by the UV/Vis and IR spectra, either no reaction was observed, or **5g** was contaminated with decomposition compounds that could not be separated by chromatography or ultrafiltration. As a result, a different method of synthesis of **5h** was sought. The most important reference was given by the retro-synthetic work of Katzenmeier.[12] He was able to show that the tetrakis(4-phosphonomethylphenyl)porphyrin anion $[H_2(tP_4O_8\{OH\}_4mpp)]^{4-}$ **(5)** can be synthesized in a four-step reaction starting from the well-known tetrakis(4-methoxycarbonylphenyl)porphyrin H_2(tmecpp) **(1)**. Indeed, the corresponding osmium complexes are well-known too.[13b,16] We decided to synthesize the osmochromes $[Os(tP_4O_8\{OH\}_4mpp)LL']^{4-}$ **(5h)**, starting from **1a** and **1b**, by substitution in the porphyrin periphery.

Reduction of [OsCO(tmecpp)thf] **(1a)** or $[OsO_2$(tmecpp)] **(1b)** with $LiAlH_4$ in anhydrous THF yielded the complexes **2a** and **2b**. During this procedure only the ester groups in the porphyrin periphery were reduced, and the osmium was not affected. This is shown by the characteristic Os=O oscillation of **2b** at 834 cm^{-1}. Partial reduction of the hydroxyl to the methyl groups was prevented by the thin layer chromatography control and hydrolysis of excess $LiAlH_4$.[17] Compound **2a** was transformed into $[OsCO(tBr_4mpp)thf]$ **(3a)** by nucleophilic substitution with PBr_3. The highest yields were obtained with CH_2Cl_2 as the solvent, whereas reactions in $CHCl_3$ mainly led to polymerization and decomposition products. Reaction of $[OsO_2(t\{OH\}_4mpp)]$ **(2b)** with PBr_3 did not yield the expected dioxo-complex $[OsO_2(tBr_4mpp)]$ **(3c)**, but the paramagnetic bis(bromo) complex $[Os(tBr_4mpp)Br_2]$ **(3b)**. Hitherto analogous bis(-bromo)osmium(IV)porphyrin complexes were synthesized exclusively by reaction of bis(ligand)osmium(II)porphyrin complexes with CCl_4.[18] Presumably, the osmium is reduced from the +6 to the +4 oxidation state by the H_3PO_3 formed from the reaction with PBr_3. Reaction of **3b** in the presence of 1-methylimidazole yielded the osmichrome $[Os(tBr_4mpp)(Br)(1\text{-meim})]$ **(3c)**. During this procedure the substitution of Br^- by 1-meim is followed by a reduction step with 1-methylimidazole as the reducing agent. Attempts to synthesize the analogous bis(1-methylimidazole) complex $[Os(tBr_4mpp)(1\text{-meim})_2]$ **(3d)** by adding further amounts of $N_2H_4{\cdot}H_2O$ and 1-methylimidazole were not successful.

Following the Michaelis–Arbuzov-reaction,[19,20] compounds **3a** and **3b** were transformed into the tetrakis(4-diethylphosphonomethylphenyl)porphyrin complexes by adding $P(OEt)_3$. As shown by the NMR and IR spectra, the substitution in the porphyrin periphery occurred in conjunction with the substitution of the axial ligands. Reaction of **3a** with $P(OEt)_3$ yielded $[Os(tP_4O_4\{OEt\}_8mpp)\{P(OEt)_3\}_2]$ **(4a)**. Presumably, the weakly

bound thf ligand is displaced by $P(OEt)_3$. Furthermore, back-bonding from the *trans*-CO ligand is weakened by this π-acceptor ligand and CO is finally displaced by $P(OEt)_3$. Satisfactory observations were made by Kokisch[21] for the osmium porphyrin complexes $[Os(oep)\{P(OMe)_3\}_2]$ and $[OsCO(oep)\{P(OMe)_3\}_2]$. As for **3b**, the ligand substitution is followed by reduction of osmium from the +4 to +3 oxidation state with $P(OEt)_3$ as the reducing agent,[22] to yield $[Os(tP_4O_4\{OEt\}_8mpp)\{P(OEt)_3\}Br]$ **(4b)**, which can be transformed into $[Os(tP_4O_4\{OEt\}_8mpp)\{P(OEt)_3\}(1\text{-meim})]$ **(4c)** by reaction with 1-methylimidazole in the presence of $N_2H_4{\cdot}H_2O$. Compound **4c** can also be obtained by ligand substitution of **4a** with 1-methylimidazole.

The tetrakis(4-phosphonomethylphenyl)porphyrin complexes **5a−c** were synthesized as described for **5**,[12] by saponification of the complexes **4a−c** by silylation with CH_3SiBr and subsequent addition of KOH (4%). The new water-soluble osmium porphyrin anions $[Os(tP_4O_8\{OH\}_4mpp)\{P(OEt)_3\}_2]^{4-}$ **(5a)**, $[Os(tP_4O_8\{OH\}_4mpp)\{P(OEt)_3\}Br]^{4-}$ **(5b)** and $[Os(tP_4O_8\{OH\}_4mpp)\{P(OEt)_3\}(1\text{-meim})]^{4-}$ **(5c)** were obtained in good yields. Indeed, **5c** can be obtained by reaction of **5a** and **5b** with 1-methylimidazole in the presence of $N_2H_4{\cdot}H_2O$.

Analytical Characterization

All compounds were identified by UV/Vis, IR, and ^1H NMR spectroscopy. The phosphorous containing complexes were also characterized by ^{31}P NMR spectroscopy (for individual data, see protocols 1−11). The new water-soluble complexes **5a−d** were also characterized by cyclic voltammetry and electrophoresis.

UV/Vis Spectra

A special feature of the lipophilic osmochromes is their acid-induced autoxidation, which has been shown to proceed via superoxide formation.[21,23] Contrary to these results, compound **4c,** as well as the water-soluble complexes **5a** and **5c,** are oxidized to the osmichrome salts [**4c**, **5a**, **5c**]$^+$, also in the absence of acid (Equation 1, Figure 1, and Table 1). Indeed, the osmochromes can be restored by adding small amounts of $N_2H_4{\cdot}H_2O$ to the solution. As **4c**, **5a**, **5c** can perform this reversible redox reaction, these osmochromes are cytochrome models under these spectroscopic and functional aspects.[24]

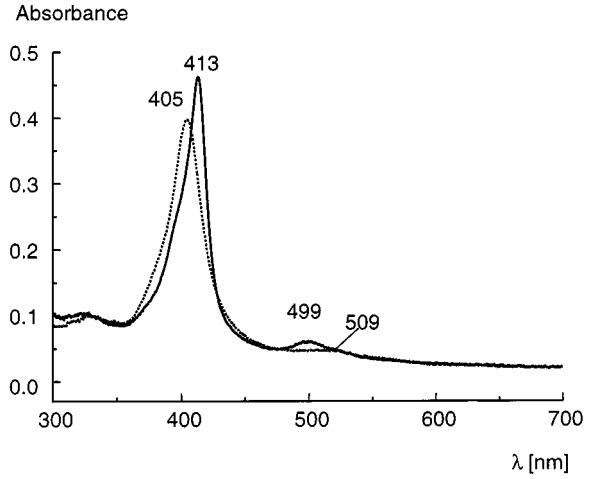

Figure 1. UV/Vis spectra of $[Os(tP_4O_8\{OH\}_4mpp)\{P(OEt)_3\}(1\text{-meim})]^{4-}$ (**5c**$^-$) (full line) and $[Os(tP_4O_8\{OH\}_4mpp)\{P(OEt)_3\}(1\text{-meim})]^{3-}$ (**5c**) (dotted line) in H_2O

Cyclic Voltammetry

In the voltage range from −1.5 to +1.5 V, osmochromes usually show two reversible oxidations (E_1 and E_2), both occurring at the metal centre and producing the osmium(III) and the osmium(IV) porphyrin complex, respectively.[13,21,22] Contrary to this result we observed only one quasi-reversible redox step (E_1) when studying the complexes **4a** and **4c** by cyclic voltammetry. In comparison with analogous complexes of the type Os(tmecpp)LL′,[25] the redox potentials of **4a** and **4c** are shifted to lower potentials, hence the $(tP_4O_4\{OEt\}_8mpp)$ system is characterized as a weaker π-acceptor ligand (Table 2).

Table 2. Comparison of the redox potentials of the complexes **4a**, **4c**, **5a**, and **5c** [**4a**, **4c**: CH_2Cl_2; **5a**, **5c**: DMF/H_2O (9:1); 25 °C, NBu_4PF_6 as supporting electrolyte, potentials versus saturated calomel electrode (SCE)]

Complex	No.	E_1 [V]	E_2 [V]
$Os(tP_4O_4\{OEt\}_8mpp)\{P(OEt)_3\}_2$	**4a**	0.147[a]	1.123[b]

$[Os(tP_4O_8\{OH\}_4mpp)\{P(OEt)_3\}_2]^{3-}$	**5a**	0.078[a]	–
$[Os(tP_4O_8\{OH\}_4mpp)\{P(OEt)_3\}(1\text{-meim})]^{3-}$	**5c**	[c]	–

[a] Quasireversible. – [b] Irreversible. – [c] Not analyzable.

Indeed, analysis of the complexes **5a** and **5c** by cyclic voltammetry was difficult. The complexes were completely insoluble in DMF and as a result the addition of small amounts of water to the suspension was necessary. To our disappointment, only broad quasi-reversible voltammograms (E_1) were seen under these conditions. Thus, a comparison with the redox potentials of water-soluble osmium porphyrin complexes published elsewhere[1,13,25] was neither sensible, nor possible.

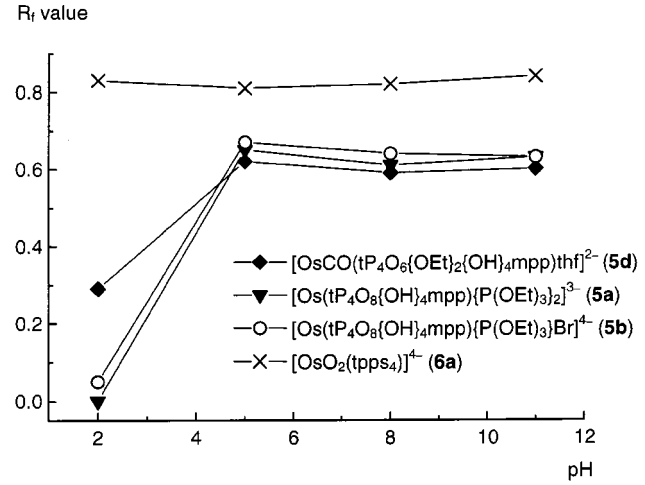

Figure 2. R_f values of the osmium porphyrin complexes $[Os(tP_4O_8\{OH\}_4mpp)LL']^{n-}$ **5a−5d** and their pH dependence {agarose gel, R_f values versus $K_4[InS_4]$ (R_f = 1)}

Electrophoresis

In accordance with the results of Katzenmeier,[12] **5a−d** showed no dependence on pH in the range from pH 3 to pH 11 (see Figure 2). Electrophoretic measurements at pH 12 could not be observed. This is due to the change of the total charge of the benzylphosphonate groups from −4 to −8.[12]

Compared with $[OsO_2(tpps_4)]^{4-}$ **(6a)** as an internal standard, we observed much smaller R_f values for the osmichromes **5a** and **5c**. This effect can be explained by the formation of a so called "inner salt".[13b] In accordance with the complexes of the type $[Os(tpps_4)LL']^{3-}$, the positive charge of the osmium(III) ion is neutralized by one of the four anionic benzylphosphonate groups.

To our surprise, the R_f values of **5a−d** were not influenced by a change in the effective charge n of the osmium porphyrin complexes (Table 3). As demonstrated in Figure 2, compounds **5a−d** showed similar R_f values in the pH range from 3 to 11, although the effective charges varied from n = −4 **(5b)** to n = −2 **(5d)**.

Table 3. R_f Values of the osmium porphyrin complexes $[Os(tP_4O_8\{OH\}_4mpp)LL']^{n-}$ **5a−5d** and their pH dependence {agarose gel, R_f values versus $K_4[InS_4]$ (R_f = 1)}

Ligands L	L′	n	No.	R_f values pH 2	pH 5	pH 8	pH 11
CO	thf[a]	2−	**5d**	0.29	0.62	0.59	0.60

[a] Diester $[OsCO(tP_4O_6\{OEt\}_2\{OH\}_4mpp)thf]^{2-}$. − [b] *trans*-Dioxoosmium(VI) porphyrin complex $[OsO_2(tpps_4)]^{4-}$ [13b,25] as internal standard.

At pH < 3 the benzylphosphonate groups are protonated, hence no electrophoretic measurements were obtained for **5a−c** at pH 2. A broad spot was observed for $[OsCO(tP_4O_6\{OEt\}_2\{OH\}_4mpp)thf]^{2-}$ **(4d)** at 0.29. Satisfactory observations were made by Katzenmeier[12] for $[H_2(tP_4O_8\{OH\}_4mpp)]^{4-}$ **(4)**.

Methods and Materials: UV/Vis: spectrometers Hewlett-Packard HP 8451A "Diode Array" and Bruins-Instruments Omega 10, programme SPECTRA CALC (Galactic Industries Corporation). − IR: Nicolet IMPACT 400 FT-IR-spectrometer, (KBr, 4000−400 cm^{-1}), programme Omnic (Nicolet Analytical Instruments). − NMR: spectrometers Bruker WM 300 and Bruker AM 200. − MS: Varian MAT 311 A, field desorption method. − Elemental analyses: Analytical Laboratories, P.O.B. 1106, D-51779 Lindlar. − Electrochemistry: Princeton Applied Research potentiostat M 173 controlled by an interface 175 with the software M 270/250; conditions: 25 °C, redox potentials versus SCE (Ingold), working electrode: platinum electrode (Beckman), reference electrode: platinum (Metrohm). − Ultrafiltration: Stirred cell 8400 and Diaflow ultrafiltration membranes YM1 from Amicon. − Electrophoresis: horizontal slab gel system type Desaphor HE 200 (Desaga), voltage multiplier Pherograph type 74 (Vetter KG). − Conductivity measurements: conductometer type CD 78 with cell CM 0.5/88 G from Tacussel, France. − K_2OsCl_6 was obtained from Degussa-Hüls; potassium indigo 5,5′,7,7′-tetrasulfonate ($K_4[InS_4]$) from Aldrich; Agarose, Tris, Glycin, DEGE, HCOOH 100%, $N_2H_4{\cdot}H_2O$, DMF, DMSO, $LiAlH_4$, PBr_3, $P(OEt)_3$, KBr p.a., CH_3SiBr from Fluka; DEGE from Acros; all other chemicals and solvents from Merck or Merck Schuchardt. − Al_2O_3 W 200 neutral (super I) was obtained from ICN Biomedicals, the lower activity grades were adjusted by adding adequate portions of water. − Analytical thin layer chromatography was performed on commercial aluminium sheets coated with silica gel 60 F_{254}, alumina 60 F_{254} Typ E and alumina RP-18F_{254s} (Merck). − 1,2,4-Trichlorobenzene (TCB) from Fluka was chromatographed on an alumina column (activity grade super I, basic, 40 × 3 cm) before use. All other solvents were distilled before use. − DMF for electrochemistry was prepared by a literature method.[26] 5,10,15,20-Tetrakis(4-methoxycarbonylphenyl)porphyrin (**1**)[27], as well as **1a** and **1b**[13b,25] were prepared by literature methods.

Protocol 1: General Procedure of Synthesis of Bis(ligand)-[5,10,15,20-tetrakis(4-hydroxymethylphenyl)porphyrinato]-osmium (2a, 2b): $LiAlH_4$ (325 mg, 8563 μmol) was added in small portions to a solution of **1a** (299 mg, 263 μmol) or **1b** (233 mg, 218 μmol) in 200 mL of anhydrous THF, and the solutions were stirred for 30 min at 20 °C. Addition of 40 mL of hydrous THF destroyed the excess $LiAlH_4$ and the resulting slurry strained with silica gel. The silica gel containing residues of the product was put in an Twisselmannaufsatz and allowed to reflux in 70 mL of anhydrous THF for 2 h. After cooling the solvent of the combined filtrates was evaporated and the residue dried at 80 °C. The products $[OsCO(t\{OH\}_4mpp)thf]$ **(2a)**, and $[OsO_2(t\{OH\}_4mpp)]$ **(2b)** were isolated as blue-violet powders.

Carbonyl(tetrahydrofuran)[5,10,15,20-tetrakis(4-hydroxymethylphenyl)porphyrinato]osmium(II) (2a): 239 mg (89%). − UV/Vis (DMSO): λ_{max} (lg ε) = 411 nm (5.34), 521 (4.06), 594 (3.71). − IR (KBr): $\tilde{\nu}$ = 1899 cm^{-1} (CO), 1351, 1074 (thf), 1351, 1203, 1043 (CH_2OH). − ^1H NMR ([D_6]DMSO): δ = 1.42 (m, 4 H, OH), 4.41 (m, 4 H, thf), 4.84 (m, 8 H, CH_2R), 5.53 (m, 4 H, thf), 7.71 (m, 8 H, phenyl-H), 7.98 (m, 4 H, phenyl-H), 8.14 (m, 4 H, phenyl-H), 8.46 (s, 8 H, pyrrole-H). − MS (FD); *m/z* (%): 947 (100) [M^+ − thf, − 3 H].

***trans*-Dioxo[5,10,15,20-tetrakis(4-hydroxymethylphenyl)porphyrinato]osmium(VI) (2b):** 138 mg (66%). − UV/Vis (DMSO): λ_{max} (lg ε) = 399 nm (4.80), 513 (3.91), 584 (3.67), 638 (3.45). − IR (KBr): $\tilde{\nu}$ = 834 cm^{-1} (Os=O), 1205, 1131, 1051 (CH_2OH). − ^1H NMR ([D_6]DMSO): δ = 1.42 (m, 4 H, OH), 4.92 (s, 8 H, CH_2R), 7.85 (m, 8 H, *m*-phenyl-H), 8.30 (m, 8 H, *o*-phenyl-H), 9.17 (m, 8 H, pyrrole-H).

Protocol 2: Carbonyl(tetrahydrofuran)[5,10,15,20-tetrakis(4-bromomethylphenyl)porphyrinato]osmium(II) (3a): PBr_3 (1.2 mL, 12.72 mmol) was added dropwise to a suspension of [OsCO(t{OH}$_4$mpp)thf] **(2a)** (361 mg, 352 μmol) in 700 mL of $CHCl_3$, and the suspension was refluxed for 1 h. After cooling and neutralization with saturated aqueous sodium carbonate solution the suspension was washed three times with 100 mL of water and dried by adding sodium sulfate. Evaporation of the solvent in vacuo and drying at 40 °C yielded 290 mg (65%) of **3a** as a blue-violet powder. − UV/Vis (CH_2Cl_2): λ_{max} (lg ε) = 409 nm (5.11), 520 (4.11). − IR (KBr): $\tilde{\nu}$ = 1898 cm^{-1} (CO), 1350, 1073 (thf), 608 (CH_2Br). − ^1H NMR ($CDCl_3$): δ = 4.10 (m, 4 H, thf), 4.80 (s, 8 H, CH_2R), 5.62 (m, 4 H, thf), 7.67 (m, 8 H, phenyl-H), 7.93 (m, 4 H, phenyl-H), 8.18 (m, 4 H, phenyl-H), 8.49 (m, 8 H, pyrrole-H).

Protocol 3: Dibromo[5,10,15,20-tetrakis(4-bromomethylphenyl)porphyrinato]osmium(IV) (3b): PBr_3 (0.9 mL, 9540 μmol) was added dropwise to a suspension of [OsO_2(t{OH}$_4$mpp)] **(2b)** (250 mg, 261 μmol) in 400 mL of CH_2Cl_2, and the suspension was allowed to reflux for 1 h. After cooling and neutralization with saturated aqueous sodium carbonate solution the suspension was washed three times with 100 mL water and dried by adding sodium sulfate. Evaporation of the solvent in vacuo and drying at 40 °C in high vacuo yielded 143 mg (41%) of **3b** as a green-black powder. − UV/Vis (CH_2Cl_2): λ_{max} (lg ε) = 332 nm (4.01), 407 (4.58), 453 (3.99), 514 (3.69), 605 (3.38). − IR (KBr): $\tilde{\nu}$ = 619 cm^{-1}, 600 (CH_2Br).

Protocol 4: [5,10,15,20-Tetrakis(4-diethylphosphonomethylphenyl)-porphyrinato]bis(triethyl phosphite)osmium(II) (4a): A solution of [OsCO(tBr_4mpp)thf] **(3a)** (242 mg, 189 μmol) in 30 mL of $P(OEt)_3$ was allowed to reflux for 6 h. After standing without stirring for 24 h, the solvent was removed in vacuo. 257 mg (78%) of **4a** was obtained as a blue-violet powder after chromatography on an alumina column (activity grade III, neutral, 10 × 2.5 cm, isolation of the first brown-red fraction) with CH_2Cl_2/EtOH (9:1). − UV/Vis (CH_2Cl_2): λ_{max} (lg ε) = 328 nm (4.44), 421 (5.26), 509 (4.12). − IR (KBr): $\tilde{\nu}$ = 2978 cm^{-1}, 1528, 1028, 772, 727, 536 {$P(OEt)_3$}, 1260 (P=O), 1052 (P−O−R). − ^1H NMR (CD_2Cl_2): δ = 0.01 (m, 12 H, P{OCH_2CH_3}$_3$), 1.16 (m, 18 H, P{OCH_2CH_3}$_3$), 1.35 (m, 24 H, CH_3), 3.40 (m, 8 H, CH_2P), 4.14 (m, 16 H, OCH_2), 7.57−7.88 (m, 24 H, phenyl-H and pyrrole-H). − ^{31}P NMR ($CDCl_3$): δ = 25.44 (s), 27.56 (s). − MS (FD); *m/z* (%): 1734 (100) [M^+].

Protocol 5: Bromo[5,10,15,20-tetrakis(4-diethylphosphonomethylphenyl)porphyrinato](triethyl phosphite)osmium(III) (4b): A solution of [Os(tBr_4mpp)Br_2] **(3b)** (124 mg, 92 μmol) in 25 mL of $P(OEt)_3$ was allowed to reflux for 7 h. After standing without stirring for 10 h, the solvent was removed in vacuo. The remaining oil was treated with 15 mL of THF and the product isolated by adding 60 mL of water. Drying at 60 °C in high vacuo yielded 51 mg (33%) of **4b** as a red-violet powder. − UV/Vis (CH_2Cl_2): λ_{max} (lg ε) = 330 nm (4.29), 406 (5.03), 515 (3.88). − IR (KBr): $\tilde{\nu}$ = 2980 cm^{-1}, 1525, 1026, 771, 736, 556 {$P(OEt)_3$}, 1234 (P=O), 1051 (P−O−R). − ^1H NMR (CD_2Cl_2, + N_2H_4·H_2O): δ = −0.07 (m, 6 H, P{OCH_2CH_3}$_3$), 1.16 (m, 9 H, P{OCH_2CH_3}$_3$), 1.26 (m, 24 H, -CH_3), 3.41 (m, 8 H, -CH_2P), 4.19 (m, 16 H, OCH_2-), 7.58 (m, 8 H, *m*-phenyl-H), 7.94 (m, 8 H, *o*-phenyl-H), 8.06 (m, 8 H, pyrrole-H). − ^{31}P NMR ($CDCl_3$): δ = 25.25 (s), 27.24 (s).

Protocol 6: (1-Methylimidazole)[5,10,15,20-tetrakis(4-diethylphosphonomethylphenyl)porphyrinato](triethyl phosphite)osmium(II) (4c): A) Reaction of 4a with 1-Methylimidazole: A solution of [Os(tP_4O_4{OEt}$_8$mpp){$P(OEt)_3$}$_2$] **(4a)** (50 mg, 28 μmol) in 25 mL of CH_2Cl_2 and 1 mL of 1-methylimidazole were allowed to reflux under argon for 15 min. After standing without stirring for 12 h, the solvent was removed in high vacuo. The residue was treated with 10 mL of CH_2Cl_2 and chromatographed on an alumina column (activity grade III, neutral, 8 × 2.5 cm). Fractions were obtained as follows: with CH_2Cl_2 the red fraction of [Os(tP_4O_4{OEt}$_8$mpp){$P(OEt)_3$}(1-meim)] **(4c)** and with CH_2Cl_2/EtOH (2:1) the orange fraction of the oxidized complex [Os(tP_4O_4{OEt}$_8$mpp){$P(OEt)_3$}(1-meim)]$^+$ **(4c$^+$)**. N_2H_4·H_2O (0.1 mL) was added to the combined fractions and the solution stirred for 15 min at 20 °C. Evaporation of the solvent and drying at 50 °C in high vacuo yielded 41 mg (85%) of **4c** as a blue-violet powder.

B) Reaction of 4b with 1-Methylimidazole: N_2H_4·H_2O (0.1 mL) was added to a solution of Os(tP_4O_4{OEt}$_8$mpp){$P(OEt)_3$}Br (**4b**) (15 mg, 9 μmol) in 15 mL of CH_2Cl_2 and 1 mL of 1-methylimidazole, at 60 °C. After stirring for 4 h at 60 °C, the solution was cooled and the solvent removed in high vacuo. Drying at 50 °C in high vacuo yielded 9 mg (60%) of **4c** as a blue-violet powder. − UV/Vis (CH_2Cl_2): λ_{max} (lg ε) = 328 nm (4.03), 416 (4.82), 501 (3.81). − IR (KBr): $\tilde{\nu}$ = 2963 cm^{-1}, 1529, 1024, 737 {$P(OEt)_3$}, 3124, 1529, 1399, 1095 (1-meim), 1261 (P=O), 1052 (P−O−R). − ^1H NMR (CD_2Cl_2 and N_2H_4·H_2O): δ = 0.06 (m, 6 H, P{OCH_2CH_3}$_3$), 1.27 (m, 9 H, P{OCH_2CH_3}$_3$), 1.36 (m, 24 H, CH_3), 1.91 (s, 1-meim), 2.32 (m, 1-meim), 3.45 (m, 8 H, CH_2P), 3.67 (s, 1-meim), 4.15 (m, 16 H, OCH_2), 7.58−8.05 (m, 24 H, phenyl-H and pyrrole-H). − ^{31}P NMR ($CDCl_3$): δ = 25.83 (s), 27.33 (s).

Protocol 7: General Procedure of Saponification of Bis(ligand)-[5,10,15,20-tetrakis(4-diethylphosphonomethylphenyl)porphyrinato]osmium (4a,4b): CH_3SiBr (0.25 mL, 1950 μmol) was added to a solution of **4a** (50 mg, 28 μmol) or **4b** (28 mg, 16 μmol) in 25 mL of anhydrous CH_2Cl_2, and the mixture was stirred for 14 h at 20 °C. After neutralization with 25 mL of KOH (4%) the aqueous phase was washed twice with 40 mL of CH_2Cl_2, separated and cleaned via ultrafiltration. Evaporation of the solvent in vacuo and drying at 60 °C yielded the complexes K_3[Os(tP_4O_8{OH}$_4$mpp){$P(OEt)_3$}$_2$] **(5a-K)** and K_4[Os(tP_4O_8{OH}$_4$mpp){$P(OEt)_3$}Br] **(5b-K)** as blue-violet powders.

Tripotassium [{5,10,15,20-Tetrakis(4-phosphonomethylphenyl)-porphyrinato}bis(triethyl phosphite)osmate(III)], K_3[Os(tP_4O_8{OH}$_4$mpp){$P(OEt)_3$}$_2$] (5a-K): 40 mg (86%). − UV/Vis (H_2O): λ_{max} (lg ε) = 329 nm (4.41), 403 (5.10), 511 (4.00), 555 (3.82). − IR (KBr): $\tilde{\nu}$ = 2978 cm^{-1}, 1043, 776, 552 {$P(OEt)_3$}, 1181, 1164 (P=O). − ^1H NMR (CD_3OD, + N_2H_4·H_2O): δ = 0.01 (m, 12 H, P{OCH_2CH_3}$_3$), 1.24 (m, 18 H, P{OCH_2CH_3}$_3$), 3.92 (m, 8 H, CH_2P), 7.59 (m, 8 H, phenyl-H), 7.81 (m, 8 H, phenyl-H), 8.01 (m, 4 H, pyrrole-H), 8.08 (m, 4 H, pyrrole-H). − ^{31}P NMR (CD_3OD): δ = 16.98 (s), 18.17 (s).

Tetrapotassium [(Bromo){5,10,15,20-tetrakis(4-phosphonomethylphenyl)porphyrinato}(triethyl phosphite)osmate(III)], K_4[Os(tP_4O_8{OH}$_4$mpp){$P(OEt)_3$}Br] (5b-K): 22 mg (82%). − UV/Vis (H_2O): λ_{max} (lg ε) = 329 nm (4.36), 403 (5.06), 511 (3.91), 557 (3.74). − IR (KBr): $\tilde{\nu}$ = 2978 cm^{-1}, 1522, 1048, 776, 553 {$P(OEt)_3$}, 1181, 1161 (P=O). − ^1H NMR (CD_3OD, + N_2H_4·H_2O): δ = 0.01 (m, 6 H, P{OCH_2CH_3}$_3$), 1.28 (m, 9 H, P{OCH_2CH_3}$_3$), 3.96 (m, 8 H, CH_2P), 7.68−8.11 (m, 24 H, phenyl-H and pyrrole-H). − ^{31}P NMR (CD_3OD): δ = 16.54 (s), 18.08 (s).

Protocol 8: Tripotassium [(1-Methylimidazole){5,10,15,20-tetrakis(4-phosphonomethylphenyl)porphyrinato}(triethyl phosphite)-osmate(III)] (5c-K): A) Saponification of 4c: CH_3SiBr (0.3 mL, 2340 μmol) was added to a solution of **4c** (30 mg, 18 μmol) in 25 mL of anhydrous CH_2Cl_2, and the mixture was stirred for 10 h at 20 °C. After neutralization with 25 mL of KOH (4%) the aqueous phase was washed twice with 40 mL of CH_2Cl_2, separated and cleaned by ultrafiltration. Evaporation of the solvent in vacuo and drying at 60 °C in high vacuo yielded 19 mg (68%) of $K_3[Os(tP_4O_8\{OH\}_4mpp)\{P(OEt)_3\}(1\text{-meim})]$ **(5c-K)** as a red-violet powder.

B) Reaction of 5a-K with 1-Methylimidazole: $N_2H_4{\cdot}H_2O$ (0.1 mL) was added to a solution of $K_3[Os(tP_4O_8\{OH\}_4mpp)\{P(OEt)_3\}_2]$ **(5a-K)** (19 mg, 11 μmol) in 15 mL of Glycin-buffer pH 11[12,24] and 1 mL of 1-methylimidazole, at 70 °C. The solution was stirred for 4 h at 70 °C. After cooling, the solution was cleaned via ultrafiltration. Evaporation of the solvent in vacuo and drying at 60 °C in high vacuo yielded 17 mg (94%) of **5c-K** as a red-violet powder.

C) Reaction of 5b-K with 1-Methylimidazole: A solution of $K_4[Os(tP_4O_8\{OH\}_4mpp)\{P(OEt)_3\}Br]$ **(5b-K)** (3 mg, 1.9 μmol) in 5 mL of H_2O and 0.5 mL of 1-methylimidazole was stirred for 2 h at 60 °C. After cooling, the solvent was removed in vacuo. Drying at 120 °C in high vacuo yielded 2 mg (69%) of **5c-K** as a orange-red powder. – UV/Vis (H_2O): λ_{max} (lg ε) = 327 nm (4.34), 405 (5.01), 509 (3.94), 560 (3.75). – IR (KBr): $\tilde{\nu}$ = 2973 cm^{-1}, 1048, 734, 552 {$P(OEt)_3$}, 3129, 1539, 1403, 1096 (1-meim), 1181, 1161 (P=O). – ^1H NMR (CD_3OD, + $N_2H_4{\cdot}H_2O$): δ = 0.05 (m, 6 H, $P\{OCH_2CH_3\}_3$), 1.25 (m, 9 H, $P\{OCH_2CH_3\}_3$), 1.90 (m, 1-meim), 3.70 (s, 1-meim), 3.96 (m, 8 H, CH_2P), 5.46 (m, 1-meim), 6.99–8.10 (m, 24 H, phenyl-H and pyrrole-H). – ^{31}P NMR (CD_3OD): δ = 17.17 (s), 18.28 (s).

Protocol 9: Reaction of K_2OsCl_6 with 5,10,15,20-Tetrakis(4-diethylphosphonomethylphenyl)porphyrin (4): A solution of K_2OsCl_6 (66 mg, 132 μmol) in 10 mL formic acid was allowed to reflux under argon for 4 h. After cooling, the solvent was removed in high vacuo. The remaining residue was dissolved in 8 mL of TCB and 30 mL of DEGE, $H_2(tP_4O_4\{OEt\}_8mpp)$ **(4)** (122 mg, 100 μmol) was added and the solution was refluxed under CO for 18 h. After cooling, the solvent was removed in high vacuo and the residue dried in vacuo for 2 h at 80 °C.

As shown by the analytical thin layer chromatography, the ester groups of the porphyrin were partially saponified during metallation. For standardization, the residue was dissolved in an anhydrous mixture of 30 mL of CH_2Cl_2/THF/EtOH (1:1:1). After adding CH_3SiBr (0.7 mL, 5460 μmol), the solution was stirred for 15 h at 25 °C. A further 50 mL of KOH (4%) was added and the aqueous phase was washed twice with 70 mL of CH_2Cl_2. The aqueous phase was separated and cleaned via ultrafiltration. Evaporation of the solvent in vacuo and drying at 60 °C yielded 141 mg (97%) of $K_2[OsCO(tP_4O_6\{OEt\}_2\{OH\}_4mpp)thf]{\cdot}2\ H_2O$ **(5d-K)** as a blue-violet powder. – UV/Vis (0.01 N NaOH): λ_{max} (lg ε) = 409 nm (5.18), 5.21 (4.01), 555 (3.74), 589 (3.55), 644 (3.38). – IR (KBr): $\tilde{\nu}$ = 1897 cm^{-1} (CO), 1351, 1070 (thf), 1206, 1188 (P=O). – ^1H NMR (CD_3OD): δ = 1.40 (m, 6 H, $-CH_3$), 3.17 (m, 4 H, thf), 3.56 (m, 8 H, $-CH_2P$), 4.10 (m, 4 H, thf), 4.21 (m, 4 H, OCH_2-), 7.78–8.88 (m, 24 H, phenyl-H and pyrrole-H). – ^{31}P NMR (CD_3OD): δ = 19.83 (m), 27.47 (m). – $C_{57}H_{54}K_2N_4O_{14}OsP_4$ (1411.36): calcd. C 48.60, H 4.93, N 4.08, P 8.86, K 5.72; found C 48.51, H 3.86, N 3.97, P 8.78, K 5.54.

Protocol 10: Reaction of $K_2[OsCO(tP_4O_6\{OEt\}_2\{OH\}_4mpp)thf]$ (5d-K) with MeOH: A solution of $K_2[OsCO(tP_4O_6\{OEt\}_2\{OH\}_4mpp)thf]$ **(8d-K)** (60 mg, 41 μmol) in 15 mL of MeOH was stirred for 2 h at 60 °C. Evaporation of the solvent in vacuo and drying at 60 °C yielded 50 mg (81%) of $K_2[OsCO(tP_4O_6\{OEt\}_2\{OH\}_4mpp)MeOH]$ **(5e-K)** as a blue-violet powder. The new axial ligand MeOH was confirmed by IR spectroscopy. – UV/Vis (0.01 N NaOH): λ_{max} (lg ε) = 4.11 nm (5.06), 521 (3.96), 555 (3.67), 589 (3.46), 646 (3.32). – IR (KBr): $\tilde{\nu}$ = 1889 cm^{-1} (CO), 1352 (MeOH), 1205, 1186 (P=O).

Protocol 11: Reaction of $K_2[OsCO(tP_4O_6\{OEt\}_2\{OH\}_4mpp)thf]$ (5d-K) with 1-Methylimidazole: A solution of $K_2[OsCO(tP_4O_6\{OEt\}_2\{OH\}_4mpp)thf]$ **(5d-K)** (86 mg, 59 μmol) in 10 mL H_2O and 2 mL 1-methylimidazole were stirred for 2 h at 80 °C. Evaporation of the solvent in vacuo and drying at 120 °C in high vacuo yielded 63 mg (69%) $K_2[OsCO(tP_4O_6\{OEt\}_2\{OH\}_4mpp)(1\text{-meim})]$ **(5f-K)** as a blue-violet powder. The new axial ligand 1-methylimidazole was confirmed by IR spectroscopy. – UV/Vis (0.01 N NaOH): λ_{max} (lg ε) = 411 nm (5.02), 5.22 (3.92), 555 (3.68), 588 (3.48), 646 (3.31). – IR (KBr): $\tilde{\nu}$ = 1899 cm^{-1} (CO), 3127, 1527, 1401, 1097 (1-meim), 1239, 1211, 1186 (P=O).

Acknowledgments

Financial support by the BASF AG, Bayer AG, Hoechst AG, Aventis AG, Fonds der Chemischen Industrie, and the Deutsche Forschungsgemeinschaft is gratefully acknowledged. The authors thank Prof. Dr. J. J. Veith and Mr. M. Fischer for performing mass spectra, Dr. S. Braun, K. Jungk, K.-O. Runzheimer, Dr. U. Möller, and J. Wendlig for performing NMR spectra.

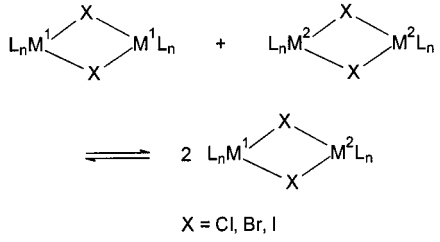
Asymmetric Halogeno-Bridged Complexes of the Late Transition Metals − A Computational and Experimental Study

Margarita Öhm,[a] Axel Schulz,*[a] and Kay Severin*[a]



Keywords: Density functional calculations / Dinuclear complexes / Bridging ligands / Transition metals / halides

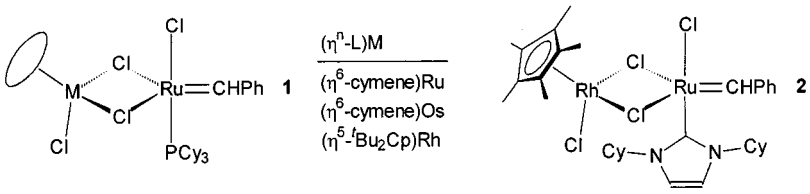
Metathesis reactions of dinuclear halo-bridged complexes of the late transition metals have been studied by NMR. For selected combinations of 15 different complexes, it has been shown that asymmetric complexes are formed in a dynamic equilibrium. The equilibrium constants have been calculated and the trends therein are discussed. A theoretical analysis of halo-bridged complexes containing $(C_3H_5)MX$, $(H_3P)MX_2$, $[(H_3P)_2MX]^+$, and $(ppy)_2RhCl$ fragments (M = Pd, Pt; X = Cl, Br, I; ppy = anion of 2-phenylpyridine) has been carried out to gain further insight into (i) the influence of the bridging halogen atoms on the equilibrium, (ii) the electron transfer, (iii) the thermodynamic stability and the dynamic equilibrium behaviour, and (iv) structural differences between symmetric and asymmetric halo-bridged complexes.

Introduction

Dinuclear complexes in which two identical metal fragments are connected through halo bridges are versatile starting materials in organometallic chemistry. They readily react with neutral or anionic ligands to form mononuclear complexes. Due to their intrinsic reactivity, they are often used as catalyst precursors. Asymmetric complexes on the other hand, i.e. complexes in which two different metal fragments are joined through halo bridges, have been described only rarely.[1] The reactivity of this class of compounds has just started to be explored. Grubbs and co-workers have reported that asymmetric complexes such as **1** are extremely active catalysts for alkene metathesis, being more active than the original "Grubbs catalyst" $[(PCy_3)_2Ru(=CHPh)Cl_2]$.[2] Furthermore, it has been shown that the activity is modulated by the second metal fragment, which itself is catalytically inactive. Similar results have been obtained by Herrmann and co-workers, who have investigated catalysts such as **2**.[3] These findings clearly show that asymmetric chloro-bridged complexes are an interesting class of compounds, among which highly active catalysts showing co-operative effects between the two metal centres can be found.

In previous publications, we have reported that in some cases heterobimetallic and mixed-valence chloro-bridged complexes can be obtained in almost quantitative yield by metathesis reactions of the appropriate symmetrical complexes.[4] This kind of reaction has provided easy access to a variety of different complexes, several of which have been structurally characterized. In this paper, we provide experimental evidence that halo-bridged complexes of the late transition metals generally undergo metathesis reactions with one another. In chlorinated organic solvents, an equilibrium between symmetrical and asymmetrical halo-bridged complexes is rapidly established (Scheme 1). Factors determining the position of this equilibrium are discussed herein. The experimental results have been supplemented by a computational study, performed to gain further insight into the stabilities, electronic character, and structural features of asymmetric halo-bridged complexes.

Scheme 1



Results and Discussion

NMR Studies

The mixed-valence complex $[(azb)_2Rh(\mu\text{-}Cl)_2Rh(CO)_2]$ (azb = *ortho*-metallated azobenzene) (**3**) was among the first asymmetric chloro-bridged complexes to be isolated[5] and structurally characterized.[6] Although other methods of preparation were initially investigated, it was realized that this compound could also be obtained by metathesis of $[(azb)_2Rh(\mu\text{-}Cl)]_2$ with $[(OC)_2Rh(\mu\text{-}Cl)]_2$.[5c] The first systematic analysis concerning the dynamic behaviour of chloro-bridge metathesis was carried out by Masters and co-workers.[7] They studied the reaction of $[(R_3P)ClPd(\mu\text{-}Cl)]_2$ with $[(R_3P)ClPt(\mu\text{-}Cl)]_2$ (R = Pr, Bu) in chloroform by means of ^{31}P NMR. The two symmetrical complexes were shown to be in a dynamic equilibrium with the heterobimetallic compound $[(R_3P)ClPd(\mu\text{-}Cl)_2PtCl(PR_3)]$. In contrast to the above-mentioned rhodium complex, only a slight thermodynamic preference for the asymmetric complex was observed (K = 5.3 for R = Bu). These results were later confirmed by Clark and co-workers, who also carried

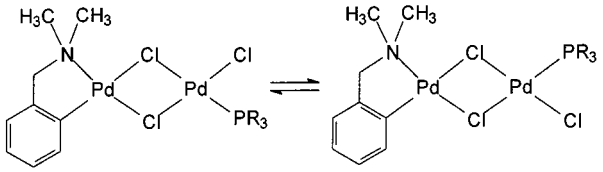
out a crystal structure analysis of $[(Et_3P)ClPd(\mu\text{-}Cl)_2PtCl(PEt_3)]$.[8] In recent publications, we have reported on investigations of the reactions of $[(C_{10}H_{16})ClRu(\mu\text{-}Cl)]_2$, $[(R_3P)_2M(\mu\text{-}Cl)]_2(BF_4)_2$ (M = Pd, Pt), and $[(\text{“N}-\text{C”})_2M(\mu\text{-}Cl)]_2$ (M = Rh, Ir; “N−C” = 2-phenylpyridine anion, benzo[*h*]quinoline anion) with various chloro-bridged complexes of the late transition metals.[4] In almost all cases, the corresponding asymmetric complexes were found to be formed in virtually quantitative yields ($K > 100$). In order to gain further insight into the scope and limitations of metathesis as a method for preparing asymmetric dinuclear complexes, we have now performed a comprehensive NMR study with selected combinations of 15 different halo-bridged complexes of the late transition metals.[9] Equimolar amounts of two symmetrical complexes were dissolved in $CDCl_3$ or CD_2Cl_2. An approximation of the equilibrium constant was then determined by integration of suitable NMR signals. The results, supplemented by data from the literature, are summarized in Table 1.



In all cases, asymmetric halo-bridged complexes could be detected by NMR. Side reactions or mononuclear species were not observed. The temperature-independent equilibrium distribution was reached within seconds and remained constant thereafter. For some complexes, dynamic behaviour led to significant line broadening at room temperature. Therefore, the spectra were generally recorded at temperatures below 0 °C. Depending on the symmetry of the dinuclear product, two different dynamic processes responsible for line broadening can be distinguished. Firstly, the complexes $[(dmb)Pd(\mu\text{-}Cl)_2MCl(PBu_3)]$ (M = Pd, Pt; Table 1, Entries 5 and 11) exist as mixtures of two isomers. For $[(dmb)Pd(\mu\text{-}Cl)_2PdCl(PBu_3)]$, the interconversion of these isomers is fast compared to the NMR time scale (Scheme 2). From the coalescence temperature T_c and the difference in chemical shifts of the ^{31}P NMR signals, a $\Delta G^{\ddagger}$ value of 14.0 (± 0.2) kcal/mol was calculated.[10] Interestingly, for the corresponding platinum complex $[(dmb)Pd(\mu\text{-}Cl)_2PtCl(PBu_3)]$, a coalescence of the ^{31}P NMR signals was

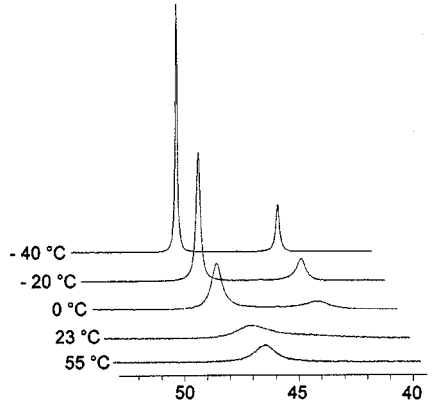
[a] cod = 1,5-cyclooctadiene. – [b] dmb = *ortho*-metallated dimethylbenzylamine.

not observed under similar conditions. A "*cis*−*trans*" isomerization has also been observed for heterodimeric complexes with a significantly higher equilibrium constant, such as $[(ppy)_2Rh(\mu\text{-}Cl)_2PtCl(PBu_3)_2]$ (Table 1, Entry 18), or for symmetrical complexes such as $[(Ph_3P)(CO)Rh(\mu\text{-}Cl)]_2$.[11] Recently, the same fluxional process was detected for mixed-valence rhodium complexes of the formula $[(Ph_3P)_2H_2Rh(\mu\text{-}X)_2Rh(CO)(PPh_3)]$ (X = Cl, I).[12] A plausible mechanism for this isomerization is a dissociative opening of one halide bridge, followed by rotation about the remaining bridge and subsequent reformation of the second one.

Scheme 2

Secondly, the metathesis reaction itself can be fast compared to the NMR time scale. If this is the case, a coalescence of the signals due to the symmetrical and asymmetrical complexes is observed. Such behaviour was found for $[(C_3H_5)Pd(\mu\text{-}Cl)_2PdCl(PEt_3)]$ (Table 1, Entry 3). At −40 °C, the ^{31}P NMR spectrum shows two distinct signals due to $[(Et_3P)PdCl(\mu\text{-}Cl)]_2$ and $[(C_3H_5)Pd(\mu\text{-}Cl)_2PdCl(PEt_3)]$ in a ratio of 100:34 ($K = 1.2 \cdot 10^{-1}$). At temperatures above 20 °C, on the other hand, only one broad signal is detected (Figure 1).



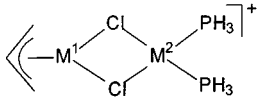


Figure 1. ^{31}P NMR spectra of $[(C_3H_5)Pd(\mu\text{-}Cl)_2PdCl(PEt_3)]$ (in $CDCl_3$) at various temperatures

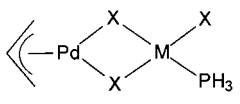
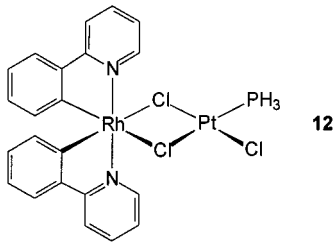


From the data summarized in Table 1, some trends regarding the stabilities of the asymmetric complexes can be deduced. In all cases investigated, the metathesis reaction between two d^8 complexes gave equilibrium constants close to $K = 1.0$, the value expected for a statistical distribution. Complexes with $(R_3P)PtCl$ fragments generally proved to be more stable than those with $(R_3P)PdCl$ fragments (Table 1, Entries 3/9, 4/12, 10/17). The nature of the halo bridge is seen to have only a small effect on the position of the equilibrium with $K_{Cl} > K_{Br} > K_I$ (Table 1, Entries 1−3). The highest equilibrium constants were found for complexes containing metals in different oxidation states such as Ru^{IV}, Rh^{III}, or Ir^{III} in combination with metal ions in oxidation state II, or for complexes with positively charged metal fragments such as $[(R_3P)_2PtCl]^+$. Other asymmetric halo-bridged complexes not synthesized by metathesis and for which an equilibrium with the corresponding homodimeric complexes has not been discussed, such as **3** ($Rh^{III}-Rh^{I}$),[5,6] **4** ($Ir^{III}-Pd^{II}$),[13] **5** ($Pt^{IV}-Pt^{II}$),[14] and **6** (a combination of formally negative and positive fragments),[15] share the same characteristic.

Computational Study



To complement the experimental results, a computational study was carried out on five different asymmetric complexes (**7**−**11**) together with the corresponding symmetrical complexes using density functional theory at the B3LYP level with effective core potentials for the heavy metals. Complexes **7**−**11** were chosen because structural, vibrational, and NMR data are available for several closely related chloro compounds (in the computational model species, PH_3 was used instead of PR_3). These data were used to validate the computational results.[16]

	M^1	M^2	X

11	Pd	Cl, Br, I

12

In Table 2, selected structural data for some of the computed species are compared with the experimental data. The molecular structures of all the species were fully optimized at the B3LYP level and characterized as minima by a frequency analysis. For $[(H_3P)MCl(\mu\text{-}Cl)]_2$ (M = Pd, Pt), two different isomers (*cis* and *trans*) were obtained. The *trans* isomer was found to be stabilized by ca. 3 kcal/mol at the HF and B3LYP levels. This is in agreement with the experimental results, which show that the *trans* isomer is favoured both in solution as well as in the crystal.[27,46,48] An exception is the triphenylphosphane complex $[(Ph_3P)PtCl(\mu\text{-}Cl)]_2$, for which the *cis* form can be isolated.[17] Two isomers were also found for the allyl complexes $[(C_3H_5)M(\mu\text{-}Cl)]_2$ (M = Pd, Pt): a planar *trans* isomer with a centre of symmetry and a *cis* form with a bent chloro bridge (Pt: θ = 157.4°; Pd: θ = 167.5°). The pairs of isomers are very similar in energy [$\Delta E_{B3LYP}(Pt_{cis/trans}) = -2.60$ kcal/mol; $\Delta E_{B3LYP}(Pd_{cis/trans}) = +0.04$ kcal/mol]. This result is confirmed by the observation that both isomeric forms have been reported for substituted allylpalladium complexes.[18]

[a] (C_3H_5) *trans* to (C_3H_5). − [b] dppb = 1,4-bis(diphenylphosphanyl)butane. − [c] Cl *trans* to PR_3. − [d] Cl *trans* to Cl. − [e] M = $M(C_3H_5$. − [f] M = $M(PR_3)$.

A more complicated situation is encountered with the rhodium complex $[(ppy)_2Rh(\mu\text{-}Cl)]_2$ (**12**). Not only the size of the ligands (as a consequence of which only the HF method was utilized) but also different isomers of the complexes need to be considered. Since the rhodium atoms are stereogenic centres, diastereoisomers are observed: the homochiral complexes ΔΔ and ΛΛ, as well as the *meso* complex ΔΛ. The homochiral complexes are energetically favoured by 7.77 kcal/mol at Hartree−Fock level. On the basis of molecular modelling studies of $[(ppy)_2Rh(\mu\text{-}Cl)]_2$[19] and closely related complexes,[20] it has previously been suggested that the *meso* form is less stable due to interligand steric repulsion. Accordingly, for this class of compounds only ΔΔ/ΛΛ complexes have been structurally characterized.[20,21]

A common feature of all the symmetrical complexes is a planar $M(\mu\text{-}Cl)_2M$ unit (Table 2, Entries 1−11), the only exception being $[(PPh_3)_2Pd(\mu\text{-}Cl)]_2^{2+}$, which displays a slightly bent chloro bridge in the crystal. This characteristic is also observed for most other halo-bridged complexes of d^8 transition metal ions.[22] For all asymmetric complexes, on the other hand, a bent chloro bridge (θ = 152−174°) and two significantly different Cl^1M^1 and Cl^1M^2 bond lengths are found (Table 2, Entries 12−17). This striking property is in agreement with the experimental results; e.g. a bent chloro bridge (θ = 164°) was found for the optimized structure of **7** and an angle of 168° was observed for $[(C_3H_5)Pd(\mu\text{-}Cl)_2Pt(PBu_3)_2](BF_4)$ in the crystal. To determine the energy difference between the planar and bent forms, the bending potentials of **7** in the range 230° to 130° were investigated. Apparently, the potential is very flat [$\Delta E(180°-164°) \approx 0.1$ kcal/mol] and, as expected, is not symmetrical (Figure 2). The bent chloro bridges observed for asymmetric complexes are thus a direct consequence of the reduced symmetry of these compounds. Moreover, the very flat bending potential indicates that Coulomb and packing forces may be of great relevance to the structure upon crystallization.

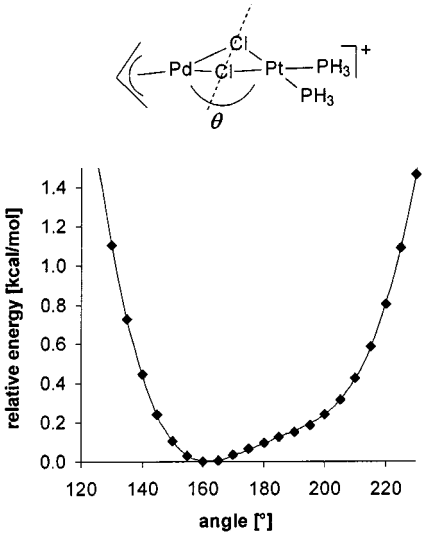

Figure 2. Relative energy of $[(C_3H_5)Pd(\mu\text{-}Cl)_2Pt(PH_3)_2]^+$ as a function of the bending angle θ

Overall, the calculated structural parameters are in good agreement with the experimental data. It should be noted that the computation was carried out for single, isolated (gas-phase) molecules with PH_3 ligands instead of bulky PR_3 ligands. Therefore, small differences between the gas-phase and solid-state data are to be expected.

In a second step of our investigation, the thermodynamics of the equilibrium reactions (Scheme 1) of the asymmetric complexes **7**−**11** was studied. The total energies and zero-point vibrational energies, the molecular free enthalpies, and the equilibrium constants of all the reactions are summarized in Table 3. From these data, and in excellent agreement with the experimental findings, it can be stated that in the case of equilibrium reactions with the mono-

cationic phosphane complexes **7**−**9**, only the metathesis products should be observed. These reactions are fairly exothermic (−65 to −75 kcal/mol) and therefore have very large equilibrium constants associated with them. Apparently, the nature of the metal ion (Pd or Pt) has only a very small influence on the energetics. Thus, formation of the homodimeric Pt complex **8** is only slightly more exothermic than that of the corresponding Pd complex **9**. The situation changes dramatically when neutral d^8 complexes undergo the same reaction (**10** and **11**). Here, the free enthalpy of the metathesis lies on the borderline between exothermic and endothermic reactions. Therefore, the formation of the asymmetric complexes (regardless of whether they are homo- or heterodinuclear) represents an observable equilibrium with a very small equilibrium constant (compared to the formation of **7**−**9**). Again, this fact represents a nice agreement between experiment and theory. Furthermore, we looked at the influence of the bridging halo ligand. Like the effect of the metal centre, changing the halogen was found to have only a small influence on the thermodynamic stabilities of the asymmetric complexes, the equilibrium constants increasing in the order $K_{Cl} < K_{Br} \approx K_I$ (Table 3).

The entropy terms of all the considered metathesis reactions are fairly small (Table 3). Consequently, the temperature is found not to have any great influence on the equilibrium. This finding is in agreement with our NMR studies.

Finally, the metathesis reaction of $[(ppy)_2Rh(\mu\text{-}Cl)]_2$ with $[(PH_3)(Cl)Pt(\mu\text{-}Cl)]_2$ was investigated. Although this reaction results in a neutral product complex, it is essentially quantitative (Table 1, Entry 18). At HF level, we were able to confirm this experimental observation. For the homochiral rhodium complex an equilibrium constant of ca. 10^{29} ($\Delta E = -39.9$ kcal/mol) was estimated, while that for the *meso* complex was estimated to be ca. 10^{23} ($\Delta E = -32.1$ kcal/mol).

In order to investigate the electronic situation in the asymmetric complexes **7**−**11**, we calculated the partial charges[16] as well as the charge transfer that occurs upon metathesis (Table 3). The total amount of charge transfer, q_{ct}, lies in the range 0.20 to 0.17e for the cationic complexes **7**−**9** and 0.06 to 0.10e for the neutral complexes **10** and **11**. It is interesting to note that a considerable proportion of the values for **7**−**9** stems from the allyl ligand and is mainly "received" by the PH_3 ligand, e.g. for **7** 0.162e is donated by the allyl ligand and 0.150e is accepted by the two PH_3 ligands (0.075e per PH_3) with a total electron transfer of 0.203e between the two different monomers. As the allyl ligand acts as a donor and therefore possesses a much smaller negative charge in the metathesis product, a dramatic change in the chemical reaction behaviour towards nucleophilic attack on the allyl group is to be expected. This is especially interesting since allylpalladium complexes are versatile catalysts for allylic substitutions.[23]

Investigation of the reaction of $[(ppy)_2Rh(\mu\text{-}Cl)]_2$ with $[(PH_3)(Cl)Pt(\mu\text{-}Cl)]_2$ leading to **12** supports the hypothesis that charge transfer within the complex upon metathesis plays an important role with regard to the thermodynamic stability of such metathesis complexes. For this reaction, a large charge transfer was found (0.268e), even though only neutral complexes are involved.[24] The phenylpyridine ligand system constitutes a very good electron donor, but the PH_3 group does not act as the main electron acceptor (0.061e). Most of the redistributed charge density is transferred to the chloro bridge (0.103e) and to the central platinum atom (0.074e).

Table 3. Total energies (E_{tot}/a.u.), zero-point vibrational energies (zpe/kcal mol^{-1}), enthalpies (ΔH_{298}/kcal mol^{-1}), free enthalpies (ΔG_{298}/kcal mol^{-1}), equilibrium constants (K), and charge transfer (Δq_{ct}/e; negative sign means acceptor, positive sign means donor)

11	I	0.25	0.82	−2.86	124	−	−	−	−	−	−	−

[a] b = bridging, t = terminal. − [b] $\Delta q(Cl_b) = [q_1(Cl_b, \text{product}) + q_2(Cl_b, \text{product})]*0.5 - q(Cl_b, \text{starting material})$. − [c] $\Delta q_{ct} = [\Delta q(C_3H_5) + \Delta q\text{M}(C_3H_5) + \Delta q(Cl_b)] = \Delta q_{ct}(\text{fragment 1}) = -\Delta q_{ct}(\text{fragment 2})$

Overall, a correlation between q_{ct} and the exothermicity of the metathesis reaction is evident for the reactions investigated. The often discussed linear relationship between ΔG and q_{ct} for Lewis acid−Lewis base complexes arises from a model in which charge transfer is only allowed between donor and acceptor centres and the effects of charge redistribution and changes in structure are ignored.[25] This may account for the observed differences.

Conclusions

The NMR data presented in this paper indicate that in organic solvents such as chloroform, halo-bridged complexes of the late transition metals generally undergo metathesis reactions to form asymmetric homo- or heterobimet-

allic complexes. This hypothesis is wholly consistent with previously published results relating to this class of compounds.[26] The possibility that asymmetric halo-bridged complexes are in dynamic equilibrium with the corresponding symmetric complexes should therefore be considered even if the relevant compounds have not been prepared by metathesis reactions (e.g. **1**, **2**, and **4−6**). Due to the high lability of the halo bridge, the metathesis reaction is very fast, in some cases even fast compared to the NMR time scale. The position of the equilibrium strongly depends on the nature of the participating metal fragments. For combinations of two neutral d^8 complexes, only small equilibrium constants close to the statistical value of $K = 1.0$ have been observed. For charged metal fragments or complexes in different oxidation states, however, the equilibrium may lie completely on the side of the asymmetric complex.

These findings have been confirmed by the results of theoretical investigations. Interestingly, the difference between the metathesis reactions of neutral complexes vs. cationic complexes or complexes with different oxidation states is to some extent correlated with the charge redistribution that occurs upon metathesis. The charge transfer has consequences regarding the reactivities of compounds of this class, which are expected to differ from those of the corresponding symmetrical complexes. We are currently investigating possible applications of asymmetric halo-bridged complexes in homogeneous catalysis and the first results will be reported in due course.

Experimental Section

General Remarks: NMR spectra were recorded with JEOL EX 400 or GSX 270 spectrometers taking the solvent signal as an internal standard. The complexes $[(PR_3)MX(\mu\text{-}X)]_2$ (M = Pd, Pt; R = Et, Bu; X = Cl, Br, I),[27] $[(cod)Rh(\mu\text{-}Cl)]_2$,[28] $[(cod)Ir(\mu\text{-}Cl)]_2$,[29] $[Cp^*MCl(\mu\text{-}Cl)]_2$ (M = Rh, Ir),[30] $[(cymene)RuCl(\mu\text{-}Cl)]_2$,[31] $[(C_3H_5)_2Rh(\mu\text{-}Cl)_2]_2$,[32] $[(dmb)Pd(\mu\text{-}Cl)]_2$,[33] and $[(C_3H_5)Pd(\mu\text{-}Cl)_2]_2$ [34] were prepared according to literature procedures.

NMR Experiments: $CDCl_3$ or CD_2Cl_2 (600 μL) was added to equimolar amounts (30 μmol each) of two different halo-bridged complexes. Once the compounds had dissolved, the solution was transferred to an NMR tube. Spectra were recorded at −40 °C, except where otherwise indicated.

Computational Details: The structural and vibrational data of the species under consideration were calculated by means of density functional theory using the program package Gaussian 98.[35] For Br and I (I: ECP46MWB; Br: ECP28MWB)[36] as well as for Pt and Pd (Pd: ECP28MWB; Pt: ECP60MWB),[37] quasi-relativistic pseudopotentials of the Stuttgart group[38] were utilized. The use of this pseudopotential facilitates the treatment of major relativistic effects such as Darwin and mass velocity terms. Spin-orbit interaction is not included. For H, C, P, and Cl, a standard 6-31G(d,p) basis set was used, for Br and I a (5s5p1d)/[3s3p1d] DZ+P basis set,[39] and for Pt and Pd an (8s7p6d)/[6s5p3d] basis set.[36] − The computations were carried out at the HF level (pre-optimization) and at the DFT level using the hybrid method B3LYP, which includes a mixture of Hartree−Fock exchange with DFT exchange correlation. Becke's 3-parameter functional, where the non-local correlation is provided by the LYP expression (Lee, Yang, Parr correlation functional), was used as implemented in Gaussian 98. For a concise definition of the B3LYP functional, see ref.[40] − The theoretically predicted vibrational frequencies[16] for all the species were calculated with the harmonic approximation. It was found that the deviation from the experimentally obtained frequencies could be partly be compensated by using scaling factors. The frequencies may also be different for various vibrational modes accessible to the molecules.[41] − The metathesis energies were corrected for zero-point vibrational energies obtained at the same level of theory from unscaled harmonic vibrational frequencies. Thermal corrections were also made to allow estimation of the molecular free enthalpies of metathesis and equilibrium constants. Atomic charges (NPA) and the extent of charge transfer were determined by means of NBO analysis.[42,43] It should be emphasized that the computation was carried out for a single, isolated (gas-phase) molecule. There may well be significant differences between gas-phase and solid-state data. In addition, to save CPU time PH_3 was used instead of PPh_3 in our model species.

Acknowledgments

K. S. and A. S. thank Prof. Dr. W. Beck (LMU München) and Prof. Dr. T. M. Klapötke (LMU München) for their generous support and E. Karaghiosoff for technical assistance. Financial funding from the Bayerischer Habilitations-Förderpreis (K. S.) is gratefully acknowledged. We also wish to thank the Leibniz Rechenzentrum (München) for a generous allocation of CPU time.

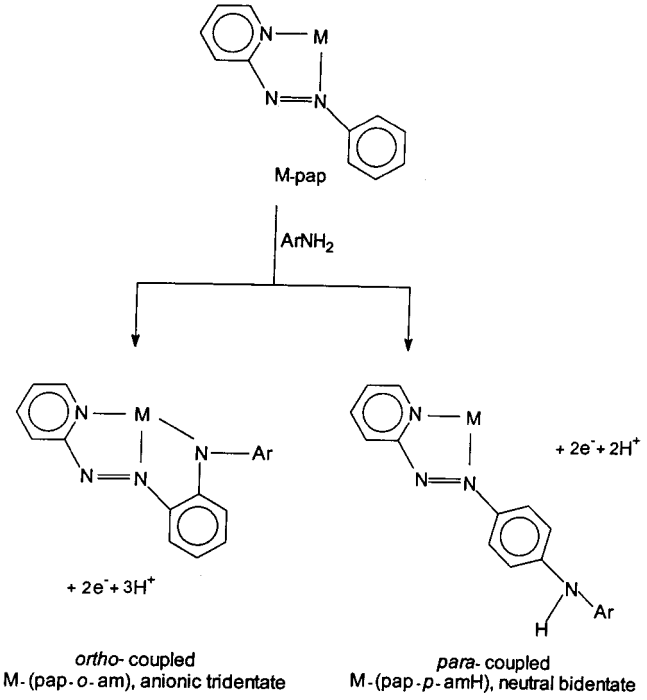
Transition-Metal-Promoted C−N Bond-Formation Processes − Low-Spin Fe^{III}, Fe^{II}, and Ni^{II} Complexes of 2-[(Arylamido)phenylazo]pyridine − X-ray Structure, Redox- and Spectroelectrochemistry

Amrita Saha,[a] Partha Majumdar,[a] Shie-Ming Peng,[b] and Sreebrata Goswami*[a]

Dedicated to Professor Animesh Chakravorty on the occasion of his 65th birthday



Keywords: Transition-metal-promoted reactions / Aminations / Iron / Nickel / Electrochemistry / N ligands

The metal-promoted amination of an aromatic ring of coordinated L^1 [L^1, pap = 2-(phenylazo)pyridine] is described. Whereas the labile cobalt complex $[Co(L^1)_3]^{2+}$ prefers *ortho*-amination, yielding L^2H {2-[2-(arylamino)phenylazo]-pyridine}, the corresponding $[Fe(L^1)_3]^{2+}$ complex produces the *para*-aminated product L^3H {2-[4-(arylamino)-phenylazo]pyridine}. Both L^2H and L^3H have been isolated in the pure state and were fully characterised. They have low pK_a values, for example pK_a(L^{2a}H) = 8.5 ± 1 and pK_a(L^{3a}H) = 9.1 ± 1. Upon deprotonation, the ligand L^2H behaves as a potential tridentate N,N,N donor. It reacts with anhydrous $FeCl_3$ and $NiCl_2{\cdot}6H_2O$ to produce cationic $[Fe(L^2)_2]^+$ (**1**$^+$) and neutral $[Ni(L^2)_2]$ (**2**), respectively. The cationic ferric complex has been isolated as its perchlorate salt, which is paramagnetic with one unpaired electron (1.66 μ_B). It shows a rhombic EPR spectrum with g_1 = 2.11, g_2 = 2.08, g_3 = 1.93. The room-temperature magnetic moment of the nickel complex is 2.89 μ_B, which confirms the presence of two unpaired electrons. The representative X-ray structures of [**1**]ClO_4 and **2** are reported. In both cases the azo nitrogen atoms of the coordinated ligand, $[L^2]^-$ approach the metal centres more closely, and there is a significant degree of ligand backbone conjugation. The complexes display multiple redox responses. Chemical reduction of **1**$^+$ with dilute hydrazine affords the corresponding ferrous complex $[Fe(L^2)_2]$ (**1**) in almost quantitative yield. The spectral changes upon electrolysis of the above couples have been recorded in an OTTLE cell.

Introduction

Reactions of coordinated ligands belong to an important class of chemical transformations,[1−5] as they provide facile synthetic routes for the formation of many novel molecules that are otherwise difficult, or even impossible, to synthesise by conventional synthetic procedures. We are interested in the aromatic ring amination of coordinated azoarene ligands. In this respect, we have recently described[6,7] cobalt- and rhodium-promoted amination processes of the coordinated 2-(phenylazo)pyridine ligand (pap, L^1). Upon coordination, the phenyl ring of the ligand L^1 is activated, and as a result, both *ortho*- and *para*-amination processes were observed (Scheme 1). The *ortho*-aminated product L^2H can act as a monoanionic tridentate N,N,N donor with the dissociation of the amine proton.

The *para*-aminated product L^3H, on the other hand, binds as a neutral bidentate N,N-donor.[6] The tridentate ligand $[L^2]^-$ has a unique combination of hard as well as soft donor sites. The strong acceptor ability of the azopyridine moiety[8] is capable of stabilising low oxidation states of the metal centre, while the strong electron donor

amido part is expected to stabilise the high-valent metal centre. Thus, tunable donor-acceptor properties of this ligand that depend on the oxidation state of the metal centre may be found. It should be noted here that the anionic ligand $[L^2]^-$ reacts readily with the respective metal salts to produce[9] octahedral low-spin complexes of Mn^{II} and Co^{III}.

Two interrelated aspects, viz. metal-promoted reactions of the coordinated azopyridine ligand and the coordination chemistry thereof, are of great interest in this area. As a logical continuation of this project, we report here the first isolation of the *para*-aminated ligand L^3H, together with the coordination chemistry of $[L^2]^-$ involving low-spin Fe^{II} and Fe^{III} ions, and Ni^{II} ion. It may be worth noting that examples of stable and structurally characterised low-spin ferric complexes are rare in the literature.[10–12]

Results and Discussion

Iron- and Nickel-Promoted Aromatic Ring Amination of Coordinated 2-(Phenylazo)pyridine (L^1)

The neutral ligand, L^1 is known to form cationic tris(chelates) of the type $[M(L^1)_3]^{2+}$ (M = Co^{II}, Fe^{II}, and Ni^{II}) with the respective metal ions.[13] The labile cobalt complex $[Co(L^1)_3]^{2+}$ reacts smoothly with primary aromatic amines ($ArNH_2$), without solvent, to produce[6] green, crystalline complexes $[Co^{III}(L^2)_2]^+$. The free ligand $[L^2H]$ has been isolated[9] by the removal of the metal ion from $[Co(L^2)_2]^+$ (Scheme 2). Similarly, the corresponding Fe^{II} and Ni^{II} complexes $[M(L^1)_3]^{2+}$ react with $ArNH_2$ to produce blue or blue-violet mixtures. Unfortunately, these compounds could not be purified. They decompose rapidly in solution and give inconsistent analyses. The blue iron intermediate is diamagnetic, but the nickel compound is paramagnetic. The iron intermediate is thus an Fe^{II} complex. However, the transformed organic ligands can be isolated from these crude mixtures by the removal of the metal ions (Scheme 3).

$$[Co^{II}(L^1)_3]^{2+} \xrightarrow{ArNH_2} [Co^{III}(L^2)_2]^+ \xrightarrow{N_2H_4/(NH_4)_2S_x} [L^2H] + CoS + \text{Other products}$$

$$[Ni^{II}(L^1)_3]^{2+} \xrightarrow{ArNH_2} [\text{Intermediate}] \xrightarrow{(NH_4)_2S_x} [L^2H] + [L^3H] + NiS + \text{Other products}$$
Green Blue-violet Organge Yellow

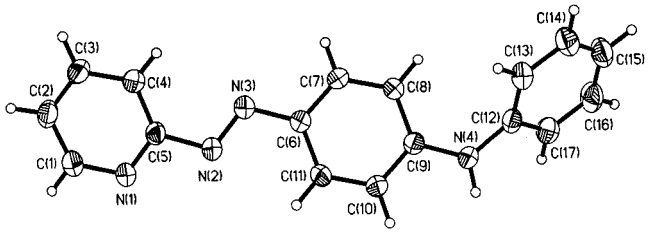
Scheme 3. Isolation of the ligands L^2H and L^3H

While only *ortho*-amination was observed in the case of $[Co(L^1)_3]^{2+}$, the *para*-aminated ligand L^3H is the only product obtained from $[Fe(L^1)_3]^{2+}$. In contrast, the corresponding nickel compound $[Ni(L^1)_3]^{2+}$ produced a mixture of $[L^2H]$ and $[L^3H]$ in almost equal proportions. The actual reasons for the regioselectivity of these amination processes are yet to be established. It has been shown, however, that prior coordination of the amine residue to the metal centre is an important prerequisite for an *ortho*-amination process of the above type, which is favoured in the case of a labile metal complex.[6] Of the three (pap)metal complexes mentioned above, $[Co(pap)_3]^{2+}$ is kinetically most labile and readily dissociates one pap moiety in solution. These amination reactions are ($2\,e^- + 2\,H^+$) transfer processes and occur in the presence of air, which is the source of the oxidising agent.

Isolation and Characterisation of $[L^3H]$

A methanolic solution of the blue mixture obtained from the reaction of $[Fe(L^1)_3]^{2+}$ and $ArNH_2$ on treatment with NH_3(aq.) precipitated brown hydrated ferric oxide and the solution became yellow. Upon work-up $[L^3H]$ was obtained as orange crystals (Scheme 3). Two such compounds viz. $[L^{3a}H]$ and $[L^{3b}H]$ ($L^{3a}H$: $ArNH_2$ = aniline and $L^{3b}H$: $ArNH_2$ = *p*-toluidine) were isolated. Both the ligands show highly resolved ^1H NMR spectra in $CDCl_3$. The N–H resonance appears as a broad singlet at $\delta = 6.12$. This is in marked contrast to the corresponding *ortho* ligand, where the N–H resonates at $\delta = 10.58$. In the *ortho* isomer, intramolecular hydrogen bonding is expected which is absent in the *para* isomer. For the ^1H NMR spectrum of $[L^{3b}H]$ see Supporting Information. The reagent ammoniacal polysulfide was used to decompose the nickel intermediate.

The ligand $[L^{3a}H]$ formed crystals suitable for a single-crystal X-ray structure determination. The structure confirms the formation of $[L^{3a}H]$ from coordinated L^1 and aniline. The ORTEP and atom numbering scheme are shown in Figure 1. The geometry of this ligand is *trans* about the diazo fragment. The N–N distance is 1.264(2) Å, which is indicative of a double bond. For comparison, this distance[14] in $[L^1H]ClO_4$ is 1.258(5) Å. All other bond lengths are within the range of normally observed values. The pyridyl ring, diazo function, phenyl ring, and amine nitrogen atoms are all coplanar. The terminal phenyl group is out of this plane by ca. 44°. The tetrahedral nature of the amine



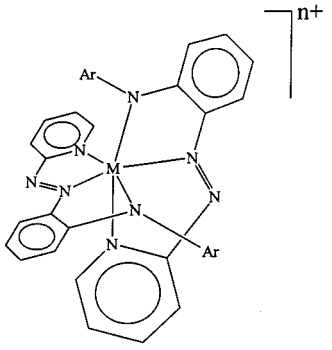


Figure 1. Molecular structure and atom numbering scheme for $[L^{3a}H]$; selected bond lengths [Å]: N(1)–C(5) 1.337(2), N(2)–C(5) 1.427(2), N(2)–N(3) 1.264(2), N(3)–C(6) 1.408(2), C(6)–C(10) 1.394(3), C(10)–C(11) 1.370(2), C(9)–C(10) 1.401(2), N(4)–C(9) 1.383(2), N(4)–C(12) 1.405(2), C(12)–C(13) 1.382(3)

nitrogen atom N(4) may be assessed by the nonplanarity of the two phenyl rings attached to it.

The Iron and Nickel Complexes of $[L^2]^-$

The 1:2 reaction of anhydrous $FeCl_3$ with $[L^2H]$ in methanol in the presence of dilute NEt_3 produced a brown solution at room temperature. Subsequent addition of dilute aqueous $NaClO_4$ afforded crystalline $[Fe(L^2)_2]ClO_4$, **[1]**ClO_4 in excellent yields. The green nickel(II) complexes, $[Ni(L^2)_2]$ (**2**) were obtained directly from the reaction of hydrated nickel(II) chloride with $[L^2H]$ in the presence of dilute NEt_3 (Scheme 4).

$M = Fe^{III}$; $n = 1$

$M = Ni^{II}$; $n = 0$

Scheme 4. Schematic diagram of the metal complexes, $[M(L^2)_2]^{n+}$

In solution, the bivalent nickel complex behaves as a non-electrolyte, whereas the complex $[Fe(L^2)_2]ClO_4$ is a 1:1 electrolyte[15] (Λ = 135−140 $\Omega^{-1}cm^2M^{-1}$ in MeCN). The room-temperature (298 K) magnetic moments of solid $[Fe(L^2)_2]ClO_4$ and $[Ni(L^2)_2]$ lie in the ranges 1.66−1.73 μ_B and 2.89−2.93 μ_B, respectively. Thus, the iron compound is in a low-spin state, $t_2^5(Fe^{III})$. For comparison, the magnetic moments of the corresponding low-spin manganese(II) complex $[Mn(L^2)_2]$ are observed[9] in the range 1.65−1.70 μ_B. In frozen (77 K) dichloromethane/toluene solution the ferric complexes display rhombic spectra with g_1 = 2.11, g_2 = 2.08, and g_3 = 1.93. The rhombic nature of EPR spectra in the present case indicates the asymmetry of the electronic environment around Fe^{III}. The spectrum may be considered as pseudo-axial, consisting of a rather isolated signal g_3 (g_{II} in the true axial case) and two relatively close signals g_1 and g_2 (rhombic components of $g_\perp$). Accordingly, the axial distortion (Δ) that splits the t_2 levels into a and e components is expected to be larger[16] than the rhombic distortion (V) that splits e. The EPR spectral pattern further confirms[11] the low-spin state of iron in $[Fe(L^2)_2]^+$.

Structures

Figure 2 and Figure 3 show the ORTEP and atom numbering schemes for **[1a]**$^+$ and **2a**, respectively.

Figure 2. The structural analysis of cationic $[Fe(L^{2a})_2]^+$ reveals the presence of two ligands, each of which acts as an N,N,N-tridentate donor with deprotonation of the amine nitrogens, viz. N(4) and N(8). Its geometry is meridional and the Fe atom sits on an imposed C_2 axis bisecting the angles

N(1)−Fe−N(5) and N(4)−Fe−N(8). The two azo nitrogen atoms of the anionic tridentate ligands approach the metal centre more closely [Fe−N(3)/N(7) ≈ 1.88 Å] than the other four Fe−N bonds. There is an indication of significant backbone conjugation in the coordinated anionic ligand. Notably, the N=N azo distances in these complexes are appreciably elongated. For example, this bond length in [**1a**]ClO_4 (1.299 Å) is much longer than in $L^{3a}H$ (1.264 Å). This change is reflected in the reduction of $\nu_{N=N}$ in [**1a**]ClO_4, which appears at 1370 cm^{-1}. In the infrared spectrum of $L^{2a}H$, the $\nu_{N=N}$ stretching is observed at 1420 cm^{-1}. Moreover, the bond length N(azo)−C(phenyl) (1.377 Å) is shorter than the value of 1.421 Å found for the corresponding distance[14] in the salt [Hpap]ClO_4. Similarly, the amido nitrogen atom of $[L^{2a}]^-$ binds to the phenyl group of pap at a shorter distance than is observed for a N−C(phenyl) single bond. These are all in agreement with the notion of extensive electron delocalisation along the ligand backbone. Some degree of conjugation along the ligand backbone of this bis(chelate) system could be implicated in the shortening of Fe−N(azo) bonds, either through an increase in the electron density on N(azo) and a concomitant increased basicity or through an enhanced π-bonding capability of the more conjugated ligand.

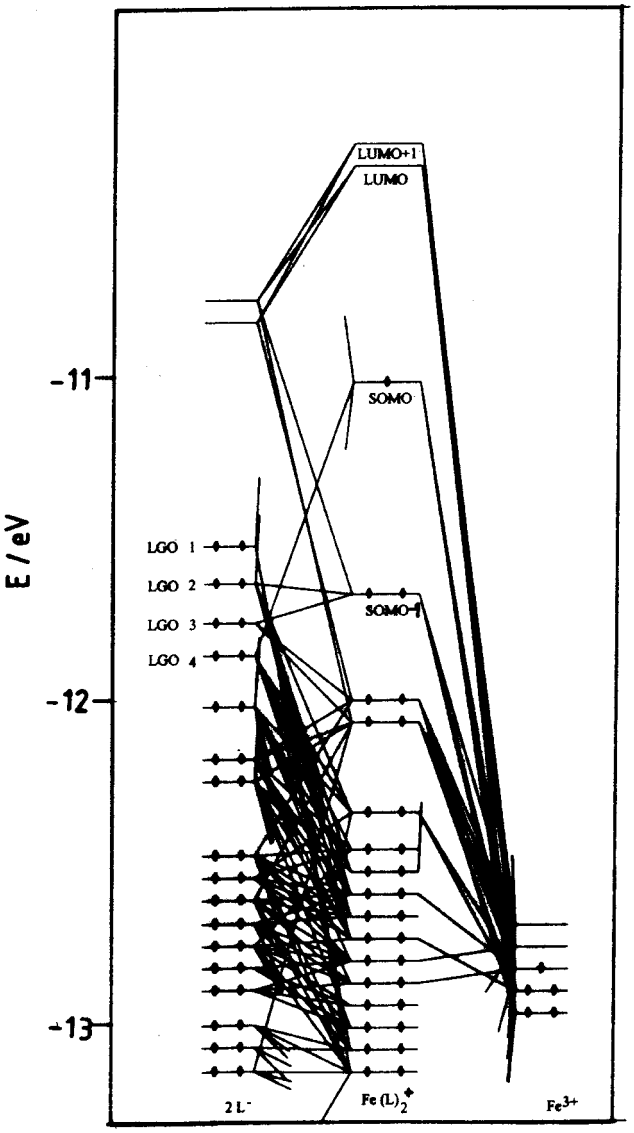

Figure 4. Partial energy level diagram of $[Fe(L^{2a})_2]^+$; for pictorial representations of the ligand group orbitals (LGO) see Supporting Information

The main features of the structure of the molecular complex $[Ni(L^{2a})_2]$ (**2a**) are very similar to those for **1a**$^+$. The two anionic ligands $[L^{2a}]^-$ bind the metal ion in an N_6 fashion using pairs of pyridyl-N, azo-N, and deprotonated arylamido-N atoms. The relative orientations within the pairs are *cis*, *trans*, and *cis*, respectively. The chelate bite angles are dissimilar, and are considerably less than the ideal octahedral value (90°). Extensive electron delocalization along the ligand backbone has also been observed in this case. As a result, the N−N(diazo) distances are longer than the usual N=N distance, and the average of the two Ni−N(azo) distances is shorter than the other Ni−N distances in this molecule.

From the crystallographic data it is obvious that the metal complexes under consideration may best be described as delocalised systems. In order to have some insight into the nature of redox and spectroscopically relevant orbitals, a standard extended Hückel MO calculation using the crystallographic parameters was performed on $[Fe(L^{2a})_2]^+$ using the CACAO programme by Mealli and Proserpio.[17] A partial energy level scheme for $[Fe(L^{2a})_2]^+$ is shown in Figure 4. In this complex the SOMO is strongly delocalised. It has 40% metal d-character with significant contributions from both amide and azo functions. The next lower orbital, SOMO-1, is a ligand orbital where the metal contribution is only 11%. There are two closely spaced LUMO and LUMO+1 orbitals which are predominantly ligand π-acceptor orbitals (−N=N− + phenyl rings) with an admixture of 18−19% metal d-character. For pictorial presentation of the above four MOs see Supporting Information.

Redox Properties and Behaviour

The redox properties of the iron and nickel complexes have been studied by cyclic voltammetry (CV) with a platinum working electrode. Voltammetric data are collected in Table 1 and representative voltammograms are displayed in

Table 1. Cyclic voltammetric data

Compound	Oxidation $E_{1/2}$ [V][a]	Reduction $E_{1/2}$ [V][a]
$[Fe(L^{2a})_2]ClO_4$	1.1, 1.75[b]	0.18, −0.97, −1.45
$[Fe(L^{2b})_2]ClO_4$	1.05, 1.73[b]	0.16, −1.01, −1.49
$[Ni(L^{2a})_2]$	0.56, 0.85[c], 1.48[b]	−1.10, −1.26[d]
$[Ni(L^{2b})_2]$	0.54, 0.84[c], 1.45[b]	−1.13, −1.28[d]
$L^{2a}H$	1.00,[b] 1.30[b]	−1.15

[a] Experiments were carried out in CH_3CN at 298 K using TEAP as supporting electrolyte. The reported data corresponds to a scan rate of 50 mVs^{-1}. − [b] Irreversible anodic response, the potential corresponds to E_{pa}. − [c] $i_{pa} > i_{pc}$. − [d] Irreversible cathodic response, the potential corresponds to E_{pc}.

Figure 5. In all cases acetonitrile was used as solvent. The nature of the voltammograms of the complexes under consideration do not change in dichloromethane. However, due to the relatively limited potential window of dichloromethane, acetonitrile was commonly used for voltammetric studies.

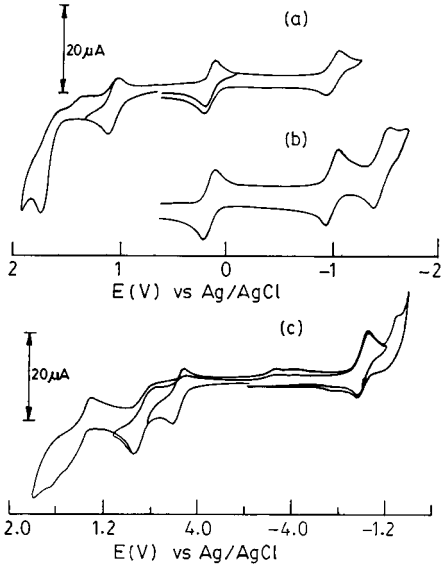

Figure 5. Cyclic voltammograms (scan rate 50 mVs^{-1}, solvent CH_3CN, 0.1 M TEAP) of (a) $[Fe(L^{2a})_2]ClO_4$ (platinum), (b) $[Fe(L^{2a})_2]ClO_4$ (glassy carbon), and (c) $Ni(L^{2a})_2$ (platinum)

The ferric complexes show four responses in the range +1.5 to −1.6 V. Three of these are cathodic, while the fourth one, occurring at ca. 1.0 V, is an anodic response. The free ligand $L^{2a}H$ displays[9] two irreversible anodic responses and a reversible cathodic response at 1.00, 1.30, and −1.15 V, respectively. The cathodic response in free $L^{2a}H$ is due to the reduction of the diazo function. For comparison, the parent ligand pap undergoes two successive step reductions at −1.31 and −1.57 V. Thus, the two cathodic responses in $\mathbf{1}^+$ at −0.97 and −1.45 V may be logically assigned to ligand reductions, centred mainly at the azoamide chromophore. The reductive response at +0.18 V and the oxidative response at 1.1 V both occur presumably at SOMO, which has almost equal metal and ligand contributions. These two responses may formally be assigned to Fe^{III}/Fe^{II} and Fe^{III}/Fe^{IV} couples. Presence of a hard donor site like $[ArN]^-$ in the deprotonated $[L^2]^-$ ligand helps in stabilisation of higher valent states of iron. For comparison, the ferrous state is highly stabilised in the parent $[Fe(pap)_3]^{2+}$ complex. The irreversible anodic response in $[\mathbf{1}]^+$ at > 1.7 V mainly concerns the oxidation of the amido function (SOMO-1).

Such low potentials for the Fe^{III}/Fe^{II} couple in $\mathbf{1}^+$ persuaded us to try and isolate the corresponding ferrous complex **1** in the pure state. Fortunately, with hydrazine as the reducing agent, we were able to isolate pink **1** in almost quantitative yield. This compound is thermally stable, but air-sensitive and is slowly reoxidised to $\mathbf{1}^+$ in the presence of air. In solution, the ferrous complex is a nonelectrolyte and is diamagnetic. Diamagnetism in this case confirms a low-spin state (t_2^6), which shows a highly resolved ^1H NMR spectrum. The nature of the ^1H NMR spectrum is similar to that observed for $[Co^{III}(L^2)_2]^+$.[6] The most notable feature in the infrared spectrum of **1a** is a large shift of $\nu_{N=N}$ to lower wavenumber (1300 cm^{-1}), indicating very strong $d_\pi - p_\pi$ interactions between the metal and ligand orbitals. For comparison, this vibration in the corresponding $[Fe(pap)_3]^{2+}$ complex is observed at 1350 cm^{-1}.[13] Our attempts to isolate the oxidized product, $[Fe(L^2)_2]^{2+}$ have so far been unsuccessful. Multiple electron-transfer responses are also the main features for the nickel complexes. These show two adjacent oxidative responses at ca. 0.56 and 0.85 V. The first one of these is reversible and the second one is only partly chemically reversible ($i_{pa} > i_{pc}$). Another high potential ligand-based irreversible oxidation process at > 1.4 V was also observed. The isolation of corresponding cationic $[\mathbf{2}]^+$ by chemical oxidation has been unsuccessful.

Spectroelectrochemistry

In order to study the spectra of the parent as well as other stable members of the redox series, two representative examples viz. $[Fe(L^{2a})_2]ClO_4$, $[\mathbf{1a}]ClO_4$, and $[Ni(L^{2a})_2]$ (**2a**) were chosen for spectroelectrochemical studies. These were performed in an OTTLE cell.[18] In both cases dichloromethane was used as solvent to take advantage of the higher solubilities of the complexes. The spectral data are collected in Table 2.

Figure 6 shows the solution spectra of the parent $\mathbf{1a}^+$ along with electrogenerated $\mathbf{1a}^{2+}$, **1a**, and $\mathbf{1a}^-$. The starting complex $\mathbf{1a}^+$ shows a very broad transition at 2125 nm (ε = 1070 $M^{-1}cm^{-1}$) in the NIR region. There are also two ill-defined shoulders at 1170 and 1055 nm. High-intensity multiple CT transitions ($\varepsilon \geq 10{,}000$ $M^{-1}cm^{-1}$) in the visible and UV range are the characteristics of all the above spectra. Upon oxidation, $\mathbf{1a}^+ \rightarrow \mathbf{1a}^{2+}$, the above broad NIR transition in $\mathbf{1a}^+$ is shifted to 2050 nm (ε = 2950 $M^{-1}cm^{-1}$), which is associated with a less-intense transition at 1635 nm (ε = 535 $M^{-1}cm^{-1}$). The intensities of NIR transitions for the present examples are too intense for a d−d transition. The lowest energy transition in $\mathbf{1a}^{2+}$ presumably involves two molecular orbitals that are ligand (SOMO-1, donor) and metal-ligand (SOMO, acceptor) orbitals. Hence, this transition is formally a ligand-to-metal charge-transfer (LMCT) transition. Notably, the corresponding Mn complex, $[Mn(L^{2a})_2]^+$, also shows[9] a similar transition at 2250 nm. The NIR region transitions in the case of **1a** appear at 1240 and 1440 nm. Upon further reduction to $\mathbf{1a}^-$, the NIR transitions completely disappear. The highly intense visible-range transitions may be due to SOMO→LUMO transitions. The rest of the high-energy transitions are assigned as intra-ligand transitions. It should be noted here that the free ligand $L^{2a}H$ shows[9] an intense transition at 490 nm, which is due to amido→azo charge transfer. All the above redox processes viz. $\mathbf{1a}^+ \rightleftarrows \mathbf{1a}^{2+}$, $\mathbf{1a}^+ \rightleftarrows \mathbf{1a}$ and $\mathbf{1a} \rightleftarrows \mathbf{1a}^-$ are reversible, and the spectrum of each of them

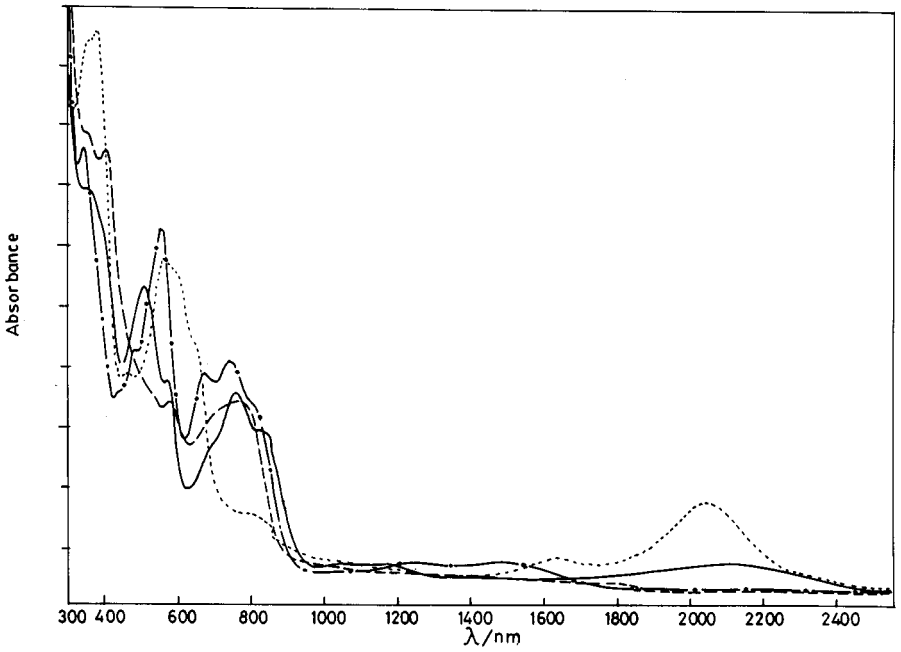

Figure 6. Solution spectra of $[Fe(L^{2a})_2]^+$ (—), $[Fe(L^{2a})_2]^{2+}$ (·····), $[Fe(L^{2a})_2]$ (– · – · –), and $[Fe(L^{2a})_2]^-$ (- - - - -).

may be quantitatively generated by application of the appropriate potential.

A spectroelectrochemical study on $[Ni(L^{2a})_2]$ (**2a**) was confined only to one reversible oxidation process, viz. **2a** $\rightleftarrows$ $\mathbf{2a}^+$ (see Supporting Information). The other redox processes are not chemically reversible, and these are not reported. Like the other transition metal complexes of this ligand system, the starting nickel(II) complex **2a** also shows multiple allowed CT transitions in the visible and UV region. Upon oxidation of the complex to $\mathbf{2a}^+$ the two low-energy transitions at 1570 and 1210 nm appear.

Conclusions

Metal-promoted amination of the pendant aromatic ring of a coordinated diazo ligand together with the chemistry of the transformed ligands involving iron and nickel are the two major aspects of this report. This work further demonstrates that, upon coordination, the ligand pap is susceptible to a fascinating metal-mediated chemical transformations. Earlier it was demonstrated that the pendant phenyl group of pap can be hydroxylated[4a] and thiolated[4b] by C–H activation. In the present study we have been able to isolate the aminated ligands that show interesting modifications of properties as ligands. The *ortho* fusion of the above type results in the formation of a potent N,N,N donor, which stabilises the rare low-spin state of both Fe^{III} and Fe^{II}. This anionic ligand has a unique combination of hard and soft donor sites. Extensive charge delocalisation plays a crucial role in the stabilization of low-spin state of the iron(III) complex. The study of coordination chemistry of both L^2H and L^3H involving heavier transition elements is in progress.

Experimental Section

Materials: The starting complexes $[Co(L^1)_3](ClO_4)_2$, $[Fe(L^1)_3](ClO_4)_2$, $[Ni(L^1)_3](ClO_4)_2$, and L^2H were prepared by reported

methods.[9,20] The solvents and chemicals used for synthesis were of analytical grade. The supporting electrolyte tetraethylammonium perchlorate (TEAP) and solvents for electrochemical work were obtained as before.[21]

Caution: Perchlorate salts of metal complexes were generally explosive. Although no detonation tendencies have been observed, care is advised and handling of only small quantities is recommended.

Physical Measurements: A Shimadzu UV 2100 UV/Vis spectrophotometer was used to record electronic spectra. − The IR spectra were recorded with a Perkin-Elmer 783 spectrophotometer. − ^{1}H NMR spectra in $CDCl_3$ were recorded with a Bruker Avance DPX300 spectrophotometer. $SiMe_4$ was used as an internal standard. − A Perkin−Elmer 240C elemental analyser was used to collect microanalytical data (C,H,N). − Electrochemical measurements were performed under dry nitrogen with an EG&G PARC Model 273A Potentiostat/Galvanostat based electrochemistry system. All potentials reported in this work are referenced to the Ag/AgCl electrode and are uncorrected for junction contribution. − The pH measurements were made with a μ-pH system 361 Systronics pH meter, standardised with buffers of pH = 7.0 and 9.2. − Electrical conductivities were measured by using a Systronics Direct Reading Conductivity meter 304. The pK_a values of the ligands were determined pH-metrically as described before.[21] − EPR measurements were made with a Varian 109C E-line X-band spectrometer fitted with a flat cell. Spectra were calibrated with the help of DPPH (g = 2.0037). − Magnetic moment measurements were carried out by using a PAR 155 vibrating sample magnetometer fitted with a Walker Scientific L75FBAL magnet. − Spectroelectrochemical studies were carried out in an OTTLE cell mounted in the sample compartment of a Perkin−Elmer Lambda 19 spectrophotometer, as described earlier.[18]

Isolation of 2-[4-(Arylamino)phenyl]azopyridine, L^3H: The reaction of neat $ArNH_2$ ($ArNH_2$ = aniline or *p*-toluidine) with $[Fe(L^1)_3](ClO_4)_2$ produced a blue mixture from which no pure product could be isolated. However, this crude product was used to isolate L^3H in the pure state. Details are given below. − The above crude product (0.10 g, $ArNH_2$ = aniline) was dissolved in methanol (30 mL) and NH_3(aq) (5 mL) was added. The mixture was then stirred for 30 min at a room temperature. The resulting yellow solution was concentrated to dryness under vacuum. The residue was then extracted with benzene and subjected to column chromatography on a silica gel (1 × 15 cm) column. A yellow band of $L^{3a}H$ was eluted with a benzene/chloroform mixture (3:1, v/v). The yellow extract was taken to dryness under vacuum. X-ray quality crystals were obtained at room temperature by slow diffusion of a benzene solution of the compound into hexane. Yield:0.06 g (60%). − UV/Vis (CH_2Cl_2): λ_{max} (ε, $M^{-1}cm^{-1}$) = 270 (10400), 415 (20800), 545(sh) nm. − IR (KBr): $\tilde{\nu}$ = 1575 (C=N), 1450 cm^{-1} (N=N). − ^{1}H NMR ($CDCl_3$): δ = 6.12 (s, N−H), 7.02 (d, J = 8.92 Hz, 2 H, 9-H and 11-H), 7.16 (4 H, 14-H,18-H and 15-H,17-H), 7.29 (t, J = 8.36 and 7.39 Hz, 1 H, 5-H), 7.72 (d, J = 8.0 Hz, 1 H, 3-H), 7.80 (t, J = 8.06 and 7.20 Hz, 1 H, 4-H), 7.93 (d, J = 8.86 Hz, 2 H, 8-H and 12-H), 8.64 (d, J = 4.73 Hz, 1 H, 6-H) (Figure 7). − pK_a = 9.1 ± 1. − $C_{17}H_{14}N_4$ (274.32): calcd. C 74.37, H 5.10, N 20.41; found C 74.02, H 5.63, N 20.04. − Similarly $L^{3b}H$ ($ArNH_2$ = *p*-toluidine) was isolated as orange needles following the above procedure. Yield: 58%. − UV/Vis (CH_2Cl_2): λ_{max} (ε, $M^{-1}cm^{-1}$) = 275 (11400), 410 (19000), 550(sh) nm. − IR (KBr): $\tilde{\nu}$ = 1595 (C=N), 1455 cm^{-1} (N=N). − ^{1}H NMR ($CDCl_3$): δ = 6.09 (s, N−H), 7.02 (d, J = 8.90 Hz, 2 H, 9-H and 11-H), 7.17 (4 H, 14-H,18-H and 15-H,17-H), 7.35 (t, J = 7.85 and 7.12 Hz, 1 H, 5-H), 7.79 (d, J = 7.94 Hz, 1 H, 3-H), 7.85 (t, J = 8.06 and 7.16 Hz, 1 H, 4-H), 7.97 (d, J = 8.85 Hz, 2 H, 8-H and 12-H), 8.70 (d, J = 3.67 Hz, 1 H, 6-H). − pK_a = 9.5 ± 1. − $C_{18}H_{16}N_4$ (288.32): calcd. C 74.92, H 5.55, N 19.42; found C 75.38, H 5.68, N 19.49.

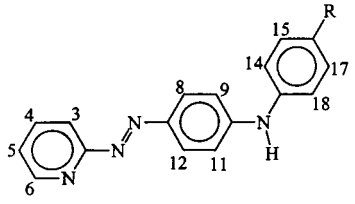

Figure 7. Numbering scheme for the protons of ligand L^3H

Synthesis of Bis[2-(2-phenylamido)phenyl)azopyridine]iron(III) Perchlorate, $[Fe(L^{2a})_2]ClO_4$, [1a]ClO_4: The ligand $L^{2a}H$ (0.11 g, 0.41 mmol) was dissolved in 25 mL of methanol and 1−2 drops of triethylamine were added. To this deprotonated ligand solution was added a methanolic solution of anhydrous $FeCl_3$ (0.03 g, 0.20 mmol) and the mixture was stirred for 1 h at a room temperature. The colour of the solution changed from orange yellow to reddish brown. The resulting solution was filtered and 5 mL of a dilute aqueous solution of $NaClO_4$ (ca. 1 M) was added. X-ray quality crystals were obtained at room temperature by slow diffusion of a dichloromethane solution of the compound into hexane. Yield: 0.12 g (85%). − IR (KBr): $\tilde{\nu}$ = 1595 (C=N), 1370 (N=N), 1100, 625 cm^{-1} (ClO_4^-). − Λ_M = 135 $\Omega^{-1}cm^2mol^{-1}$ (1 × 10^{-3} M in CH_3CN). − μ_{eff} (298 K) = 1.66 μ_B. − $C_{34}H_{26}ClFeN_8O_4$(701.93): calcd. C 58.13, H 3.70, N 15.96; found C 58.53, H 3.94, N 15.17. − Similarly, anhydrous $FeCl_3$ was treated with $L^{2b}H$ in a 1:2 ratio in methanolic solution in the presence of 1−2 drops of triethylamine as base. Subsequent addition of aqueous $NaClO_4$ to the reaction mixture produced crystalline $[Fe(L^{2b})_2]ClO_4$ (**1b**). Yield: 80%. − IR (KBr): $\tilde{\nu}$ = 1595 (C=N), 1365 (N=N), 1100, 625 cm^{-1} (ClO_4^-). − Λ_M = 140 Ω^{-1} cm^2mol^{-1} ($1{\cdot}10^{-3}$ M in CH_3CN). − μ_{eff} (298 K) = 1.68 μ_B. − $C_{36}H_{30}ClFeN_8O_4$ (729.93): calcd. C 59.18, H 4.11, N 15.34; found C 59.32, H 4.45, N 15.98.

Chemical Reduction of $[Fe^{III}(L^{2a})_2]ClO_4$ {[1a]ClO_4} to $[Fe^{II}(L^{2a})_2]$ {[1a]}: A dichloromethane solution of [**1a**]ClO_4 (0.10 g in 20 mL) was stirred with 5 mL of dilute aqueous hydrazine solution at room temperature for 30 min. The colour of the solution changed from reddish-brown to pink. The above mixture was extracted with dichloromethane (2 × 10 mL), which was then dried with anhydrous sodium sulfate. The dried solution was concentrated to half of its initial volume. Slow addition of hexane to the above pink solution precipitated dark microcrystals of **1a**. This was further crystallised from a dichloromethane/hexane solvent mixture. The compound is diamagnetic. Yield: 95%. − IR (KBr): $\tilde{\nu}$ = 1595 (C=N), 1300 cm^{-1} (N=N). − $C_{34}H_{26}FeN_8$ (602.43): calcd. C, 67.73, H 4.32, N 18.59; found C 67.46, H 4.73, N 18.30.

Synthesis of Bis[2-{2-(phenylamido)phenyl}azopyridine]nickel(II), $[Ni(L^{2a})_2]$, [2a]: The ligand $L^{2a}H$, (0.20 g, 0.74 mmol) was dissolved in 25 mL of methanol and 1−2 drops of triethylamine were added. To the deprotonated ligand solution was added a methanolic solution of $NiCl_2{\cdot}6H_2O$ (0.09 g, 0.37 mmol), and the mixture was stirred for 1 h at room temperature. The colour of the solution changed from orange yellow to green. The resultant mixture was filtered and the solvent was evaporated under vacuum. The compound thus obtained was finally crystallised from a dichlorome-

thane/hexane mixture. X-ray quality crystals were obtained at room temperature by slow diffusion of a dichloromethane solution of the compound into hexane. Yield: 0.19 g (85%). − IR (KBr): $\tilde{\nu}$ = 1595 (C=N), 1370 cm^{-1} (N=N). − μ_{eff} (298 K) = 2.89 μ_B. − $C_{34}H_{26}N_8Ni$ (605.34): calcd. C 67.40, H 4.30, N 18.50; found C 67.67, H 4.80, N 18.32. − Similarly, $NiCl_2{\cdot}6H_2O$ was treated with $L^{2b}H$ in a 1:2 ratio in methanolic solution in the presence of 1−2 drops of triethylamine as base to produce crystalline [Ni(L^{2b})$_2$] (**2b**). Yield: 80%. − IR (KBr): $\tilde{\nu}$ = 1595 (C=N), 1375 cm^{-1} (N=N). − μ_{eff} (298 K) = 2.92 μ_B. − $C_{36}H_{30}N_8Ni$ (633.34): C 68.21, H 4.74, N 17.68; found C 68.92, H 5.03, N 17.53.

Crystal Structure Determination: The crystallographic data for the compounds $L^{3a}H$, Fe(L^{2a})$_2ClO_4$, [**1a**]ClO_4, and Ni(L^{2a})$_2$ (**2a**) are collected in Table 3. The data were corrected for Lorentz and polarisation effects. All the structures were solved by using SHELXS-86 package of programme.[22] These revealed the positions of all non-hydrogen atoms and refined by full-matrix least-squares techniques against F^2 (SHELXL-93).[23] Absorption corrections were made with the SADABS package of programs. Hydrogen atoms were placed at the calculated positions. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-141470, -141471, -141472. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

Financial support received from the Department of Science and Technology, New Delhi, is acknowledged. We are grateful to Professor J. A. McCleverty, Dr. M. D. Ward, University of Bristol, and Dr. S. Bhattacharya for their help. S. G. thanks the RSC for its financial support, which allowed him to visit the University of Bristol. We are thankful to the referees for suggestions.
