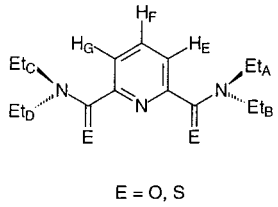
These spectral changes can be interpreted in terms of the exchanges depicted in Schemes 2 (i) – (iii) (E = O; R = Me).

Rate data for these schemes were obtained by bandshape analysis of the *N*-methyl region spectra in the temperature range 303–353 K for the C–N rotation rates (for coordinated and pendant groups) and the pyridyl hydrogen region spectra in the range 343–413 K for the 1,4-metallotropic shifts.

Scheme 2. Three types of internal dynamic process in the diamide ligand complexes

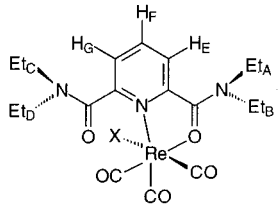
The room temperature ^{1}H NMR spectra of the complexes [ReX(CO)$_3$tmpdt] (X = Cl, Br) exhibited three *N*-methyl signals in the intensity ratio 6:3:3. The signal of intensity 6 was due to the *N*-methyl groups of the coordi-

nated thioamide group which rotates rapidly on the NMR timescale, while the signals of intensity 3 were due to the chemically distinct *N*-methyls of the uncoordinated -C(S)NMe_2 group where C−N rotation was slow on the NMR timescale, as was observed in the free ligand tmpdt. The rates of C−N rotation in the coordinated thioamide group were measured from spectra taken in the temperature range 263−313 K, with band coalescence occurring at ca. 288 K. Measurement of C−N rotation rates in the pendant -C(S)NMe_2 group required above-ambient temperature studies. Spectra measured in the range 383−413 K showed line broadenings but band coalescence was clearly above 413 K, the upper temperature limit of the solvent $(CDCl_2)_2$. Bandshape analysis of these line broadenings was dependent on the two rate constants k_{RRP} and k_{MS} (Scheme 2, E = S; R = Me); the latter, however, were most accurately measured from the effect of the metallotropic shifts on the H_E and H_G pyridyl hydrogens.



(iii) Ligands tepdc, tepdt and Complexes [ReX(CO)$_3$tepdc] (X = Cl, Br)

These ligands are the *N*,*N*,*N*′,*N*′-tetraethyl analogues of tmpdc and tmpdt and they behave in a very similar fashion. Their ^{1}H NMR characteristics are given in Table 4 where it will be observed that distinction within each of the pairs of *N*,*N*′-diethyl groups is seen in both the CH_2 and CH_3 signals.



For tepdc unambiguous assignments of the CH_2 and CH_3 signals were made by NOE difference experiments. Irradiation of the CH_2 signal at δ = 3.35 caused a weak enhancement of the pyridyl hydrogens at the 3- and 5-positions whereas irradiation at the other CH_2 signal (δ = 3.55) caused no enhancement. The weakness of the enhancement indicated that the NEt_2 groups were considerably out of the pyridyl ring plane with the Et_A and Et_C groups shielded (relative to Et_B/Et_D) by the aromatic ring current. The NOEs of the methyl signals provided firm assignments of these signals also. It should be noted that all these assignments are rather at variance with those previously reported for tepdc[5] but in that study only a planar structure for this ligand was considered. However, molecular mechanics calculations on tepdc[8] have shown that the carbonyl groups of the carboxamide functions are twisted relative to the pyridine ring by ca. 64°. Such a twist accounts for the NOE effects between the methyl groups of Et_A and Et_C and the pyridyl hydrogens H_E and H_G being small, with these ethyl groups being shielded relative to Et_B and Et_D, since the latter are more remote from the effects of the pyridyl ring current. On raising the solution temperature of tepdc from 303 to 413 K, dynamic broadening occurs with coalescences at ca. 353 K (CH_3 signals) and ca. 360 K (CH_2 signals). Bandshape fittings of both sets of signals were made for six spectra in the temperature range 333−383 K, and provided reliable rate data.

The 2D-EXSY method had to be applied to the thioamide analogue tepdt to obtain rate data. Accordingly, 2D-EXSY spectra of tepdt were measured at 353, 373 and 393 K with mixing times of 0.8 s, 0.1 s and 0.01 s, respectively, and rate data obtained with the D2DNMR program.[27]

[a] Measured in $(CDCl_2)_2$ at 303 K. − [b] Measured in $(CDCl_2)_2$ at 273 K. − [c] Signals at δ = 4.25, 3.95*, 3.73*, 3.64*, 3.62*, 3.30, 3.27 and 3.08 (* coordinated side). − [d] Signals at δ = 4.24, 3.96*, 3.69*, 3.61*, 3.61*, 3.32, 3.29 and 3.08 (* coordinated side).

The ambient temperature ^{1}H NMR spectra of the complexes [ReX(CO)$_3$ tepdc] (X = Cl, Br) revealed some interesting features. Four distinct ethyl environments were identified as expected for a static bidentate chelate complex. These were represented by four methyl signals, two of which were sharp 1:2:1 triplets and two were broad, unsplit signals. On cooling to 273 K all four signals became sharp triplets (Figure 2).

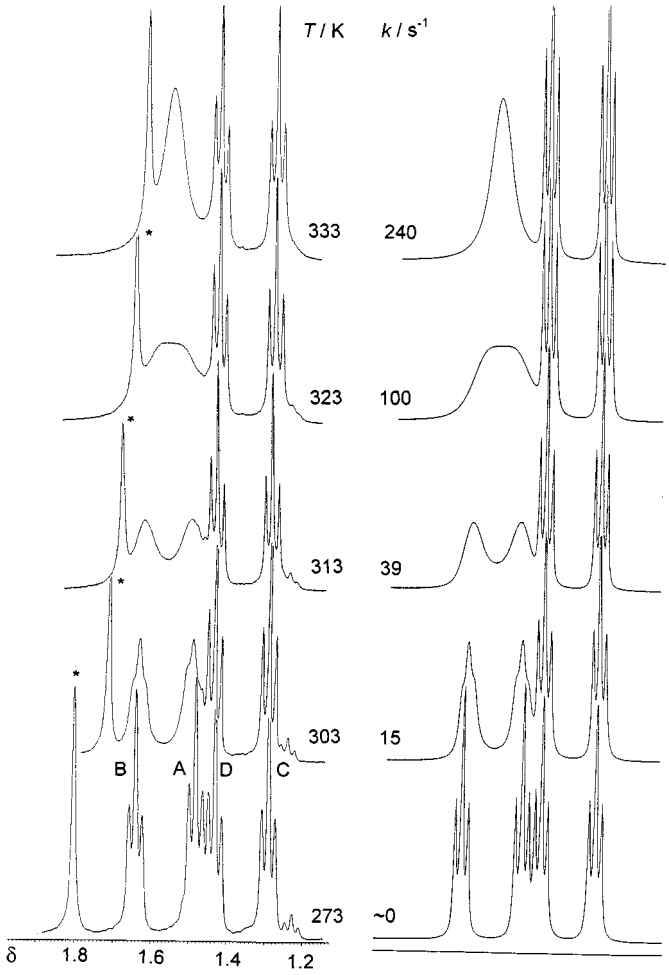

Figure 2. Variable temperature 400 MHz ^{1}H NMR spectra of [ReBr(CO)$_3$tepdc] in $(CDCl_2)_2$ showing the effects of restricted C−N rotation in the coordinated C(O)NEt$_2$ on the methyl signals; computer simulated spectra with "best-fit" rate constants are shown alongside. * solvent band

At 303 K the methylene hydrogens were represented by eight signals, four of which showed dynamic broadening and four which were sharp sextuplets. On cooling to 273 K all eight signals showed this same multiplet splitting which was interpreted as a combination of two-bond geminal methylene couplings and weaker three-bond couplings to the adjacent methyl hydrogens. The sextuplets resulting from partial overlap of the expected doublet of quadruplets had lines in the intensity ratio 1:3:4:4:3:1 and were the result of the $^2J_{HH}$ values being approximately twice the magnitude of the $^3J_{HH}$ values, (*viz*. $|^2J_{HH}| \approx 14$ Hz, $|^3J_{HH}| \approx 7$ Hz). The observation of spin-spin coupling between the geminal methylene hydrogens arises from the diastereotopic nature of these groups, which is not apparent in the free ligand.

The broadened signals in both the methyl and methylene regions of the spectra at room temperature are due to the ethyl environments A and B associated with the Re-coordinated -C(O)NEt$_2$ group. On warming, the broad methyl signals coalesced (at ca. 323 K for X = Br) and then the averaged signal sharpened. The four broadened methylene signals exhibited coalescences at ca. 313 K and 333 K, (X = Br). Bandshape analysis was performed on the methyl signals in the temperature range 273−373 K and excellent fits of experimental and theoretical spectra obtained (Figure 2), which led to activation energies for the restricted C−NEt$_2$ rotation on the metal-coordinated side.

On raising the temperature beyond 333 K additional dynamic broadenings involving all methyl and all methylene signals occurred. This was the result of fluxional shifts of the Re moiety between the N/O donor pairs and rotation of the NEt$_2$ group on the pendant side of the ligand. The relatively slow rates of magnetisation transfer arising from these processes were measured by 2D-EXSY as well as by 1D-bandshape analysis. The 2D-EXSY spectrum of [ReBr(CO)$_3$tepdc] at 343 K is shown in Figure 3.

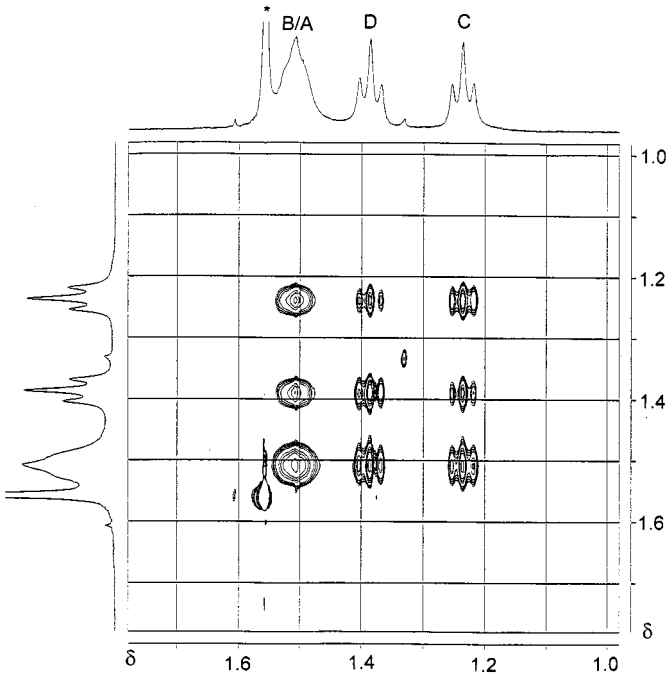

Figure 3. 400 MHz ^{1}H 2D-EXSY spectrum of [ReBr(CO)$_3$tepdc] at 343 K in $(CDCl_2)_2$ solution. Mixing time was 0.4 s. Cross peaks indicate restricted rotation in the pendant −C(O)NEt$_2$ group and 1,4-metallotropic shifts

At this temperature the methyl signals of the coordinated carboxamide moiety have coalesced, and cross peaks are observed between all three methyl signals. Cross peaks between the two lowest frequency signals (C and D) associated with the pendant carboxamide moiety, were due to restricted C−N rotation in this moiety, whereas the cross peaks between the signals C and D and the coalesced signal B/A was due to the metallotropic shift.

Table 5. Activation energy data for $C-NR_2$ restricted rotation in the pyridine-carboxamide and -thioamide ligands

Ligand	Temp range/K	Method[a]	$\Delta H^{\neq}$ /kJ mol^{-1}	$\Delta S^{\neq}$ /J K^{-1} mol^{-1}	$\Delta G^{\neq}$ [b] /kJ mol^{-1}
dmpc	323−373	BSA	81.2 ± 2.2	19.8 ± 6.7	75.3 ± 0.3[c]
tmpdc	333−373	BSA	72.7 ± 1.5	-7.3 ± 4.2	74.9 ± 0.2[d]

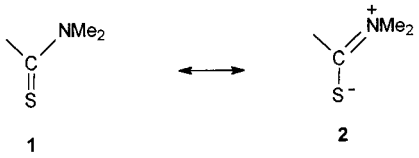
tmpdt	353−393	EXSY	107.8 ± 9.4	49.3 ± 25.3	93.2 ± 1.9
tepdt	353−393	EXSY	87.1 ± 0.5	-2.9 ± 1.3	88.0 ± 0.1

[a] BSA -^{1}H bandshape analysis, EXSY - ^{1}H exchange spectroscopy. − [b] At 298.15 K. − [c] Ref.[12] gives 74.9 kJ mol^{-1} (BSA); Ref.[16] gives 73.4 kJ mol^{-1} (coalescence 361 K).

Rate data for the restricted C−N rotation of the pendant -C(O)NEt$_2$ group (k_{RRP}) were obtained from the 2D-EXSY spectrum at 343 K and from the 1D spectra at 343, 353 and 363 K.



Rate constants for the metallotropic shifts (k_{MS}) were most accurately extracted from the 1D spectra of the pyridyl hydrogens, since this process interconverts the hydrogen atoms at the 3- and 5-position, but leaves that at the 4-position unaffected. Bandshape analysis of seven spectra in the temperature range 293−353 K provided reliable rate data for this fluxional process.

Discussion

Activation energy data for $C-NR_2$ restricted rotation in all six free ligands are collected in Table 5. Gibbs free energy values, $\Delta G^{\neq}$ (298.15 K), have the lowest associated uncertainties and it is most meaningful to make comparisons with this parameter. The 2-pyridine-carboxamide and 2,6-pyridine dicarboxamide, dmpc and tmpdc, have been studied previously, albeit rather less accurately in one case, and the present $\Delta G^{\neq}$ values of 75.3 and 74.9 kJ mol^{-1} are in moderately good agreement with the previous values of 74.9[12] and 73.4[16] kJ mol^{-1}.

These results imply that there is negligible electronic influence between the two amide groups in these systems. Replacement of the NMe_2 groups by NEt_2 appears to cause a slight rise in the C−N rotational barrier with the value for tepdc being 79.8 kJ mol^{-1}.

Replacement of the carbonyl oxygen of the amides by a sulfur atom in the thioamides causes a very significant increase in the C−N rotation barrier as can be seen by comparing $\Delta G^{\neq}$ data for the ligand pairs dmpc/dmpt, tmpdc/tmpdt and tepdc/tepdt, where increases of 13.1, 18.3 and 8.2 kJ mol^{-1}, respectively, occur. These increases are of similar magnitude to the increase of 9.6 kJ mol^{-1} which occurs on going from *N*,*N*-dimethylbenzamide[17] to the corresponding thioamide.[18] These increases may be attributed primarily to increased conjugation of the C−N bond(s) with the aromatic rings in the thioamide systems relative to the carboxamide systems, or alternatively to an increased contribution of the resonance form **2** below.

1 **2**

Such rationalisation is supported by the observation that in nonaromatic analogues such as *N*,*N*-dimethylcarbamoyl chloride $ClC(O)NMe_2$, and its thiocarbamoyl analogue $ClC(S)NMe_2$, the increase in the rotation energy barrier is only 5.4 kJ mol^{-1}.[19] However, recent ab initio calculations on formamide/thioformamide[20] and acetamide/thioacetamide[21] systems have implied that conjugation effects may not be the dominant contributors to C−N rotational barriers, but that the nitrogen lone pair may play a crucial role. For instance, a valence-bond study[20] suggests that the preferred orientation of the N lone pair perpendicular to the molecular plane may lead to resonance stabilisation of planar conformers which is responsible for about one half of the rotational barrier of formamide and two thirds of the barrier for thioformamide, the large magnitude of the latter being due to greater conjugation effects. An MO study[21] of acetamide and thioacetamide ascribes even greater importance to the N lone pair and the preference of the N atom for pyramidalization.

The full set of activation energy data for the various motional processes occurring in the $[ReX(CO)_3L]$ (X = Cl, Br) complexes is listed in Table 6.

For the complexes where L = tmpdc, tepdc and tmpdt, there appears to be no significant changes in the $\Delta G^{\neq}$ data for a change of halogen. The effect of Re coordination of the ligand on the C−N rotational characteristics of the $-C(E)NR_2$ groups is, however, particularly significant. This is highlighted in Table 7 where $\Delta G^{\neq}$ values for this process in both the coordinated and pendant portions of the complex are compared with the values for the free ligand.

Rhenium coordination of the amide oxygen reduces the -$C-NR_2$ rotation barriers by 2−13 kJ mol^{-1}, whereas coordination of the sulfur atom in the thioamide moieties greatly reduces the barrier by 28−33 kJ mol^{-1}. Metal σ-coordination acts as an electron drain on the carboxamide or thioamide functions, which will destabilise the zwit-

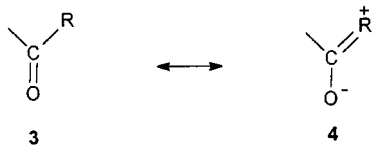
[a] Not measurable, complex thermally unstable.



terionic form of the function leading to a decrease in the energy barrier to C−N rotation. This effect appears to be much stronger for the sulfur atom with its greater *p* electron complement compared to oxygen. Not unexpectedly, the barriers for the pendant portions of the ligands in the complex are of similar magnitude to those of the free ligand. For O coordination there is a small increase of 3−4 kJ mol^{-1} in the complex, and for S coordination there is a slight decrease of 0.8 kJ mol^{-1}.

Metallotropic shifts involving interchange of bidentate, chelate bonding between adjacent donor pairs in N_3 ligands have been reported for a variety of metal moieties, but data for the moiety $ReX(CO)_3$ where X is halogen, are most widely available. Much fewer data are available for metallotropic shifts in O, N, O and S, N, S ligands. However, Table 8 contains the activation energies [$\Delta G^{\ddagger}$ (298.15 K)] for a variety of complexes of general type [$ReBr(CO)_3L$] (L = 2,6-disubstituted pyridines where the substituents are either amides, thioamides, ketones or esters) from both published and unpublished work. $\Delta G^{\ddagger}$ values lie in the range 60−89 kJ mol^{-1}.

An increase in magnitude of ca. 5 kJ mol^{-1} on changing from a dicarboxamide to a dithioamide ligand mirrors somewhat the relative energies of C−N rotation of the analogous free ligands, and can again be related to increased conjugation of the -C=S function as opposed to the -C=O function with the pyridyl aromatic ring, thus increasing the donor strength of the S atoms.

Energy barriers for the -C(O)R groups also vary appreciably with the nature of R, being in the range 60−84 kJ mol^{-1}. The highest values, 79−84 kJ mol^{-1}, are associated with the strong electron donors NMe_2, NEt_2, and lower values, in the range 60−64 kJ mol^{-1}, with the weaker electron donors OMe, OEt, Me and *t*Bu. This can be rationalised in terms of the strength of the oxygen donor being increased by the extent to which its electron density is enhanced by donation from the R group, i.e. the extent to

which resonance form **4** (below) contributes to the overall structure.

3 **4**

The mechanism of 1,4 metallotropic shifts has been the subject of some controversy as to whether it has a dissociative or associative mechanism.[3] The present study does not provide further insight into this matter as no investigation was made into whether the rearrangement interchanged the equatorial carbonyl environments or not. This would have required variable temperature ^{13}C studies of the type performed on the E = O; R = Me complex.[22] This earlier study showed exchange broadening of the equatorial CO environments accompanying the metal fluxion, which lent support to an associative mechanism involving pairwise breaking and making of both metal coordinate bonds in a "windscreen wiper" or "tick-tock twist" process.[3] It would be surprising if the same mechanism was not operating in the present complexes

Experimental Section

Materials: The carboxamide ligands, *N*,*N*-dimethyl-2-pyridinecarboxamide (dmpc), *N*,*N*,*N*′,*N*′-tetramethyl-2,6-pyridinedicarboxamide (tmpdc) and *N*,*N*,*N*′,*N*′-tetraethyl-2,6-pyridinedicarboxamide (tepdc) were prepared by adapting literature methods.[8][24] The thioamides *N*,*N*-dimethyl-2-pyridinethioamide (dmpt), *N*,*N*,*N*′,*N*′-tetramethyl-2,6-pyridinedithioamide (tmpdt) and *N*,*N*,*N*′,*N*′-tetraethyl-2,6-pyridinedithioamide (tepdt) were prepared by treating the corresponding carboxamide with Lawesson′s reagent.[25]

Measurements: Elemental analyses were carried out by Butterworth Laboratories Ltd., Teddington, Middlesex, UK. − Melting temperatures were recorded on a Gallenkamp apparatus and are uncorrected. Infrared spectra were measured with a Nicolet Magna FT-IR instrument. − ^1H NMR spectra were recorded on a Bruker DRX400 instrument operating at 400.13 MHz. A standard B-VT2000 variable temperature unit was used to control the probe temperature, the calibration of this unit being checked periodically against a Comark digital thermometer. The temperatures are considered to be accurate to ±1 °C. Rate data were derived from band-shape analysis of the ^1H spectra using a version of the DNMR3 program,[26] or from 2D-EXSY spectra using volume integration data in the authors D2DNMR program.[27] − Activation parameters based on experimental rate data were calculated using the THERMO program.[28] − Two-dimensional exchange (EXSY) spectra were obtained using the standard Bruker program NOESY-PH.AU.

Synthesis of Complexes: All preparations were carried out using standard Schlenk techniques under purified nitrogen using freshly distilled and degassed solvents. Synthetic and analytical data are given in Table 1. The preparation of the complex [$ReBr(CO)_3$(dmpc)] is described by way of illustration.

Bromotricarbonyl(*N*,*N*-dimethyl-2-pyridinecarboxamide)rhenium(I): The compounds [$ReBr(CO)_5$] (0.23 g, 0.57 mmol) and dmpc (0.1 g, 0.67 mmol) were dissolved in benzene (15 cm^3) with gentle warming to produce a colourless solution. The solution was heated under reflux for 4 h and then hexane (20 cm^3) was added to the hot solution. After allowing the solution to stand at ambient temperature for 9 h the solvent was decanted off and the yellow solid washed with hexane (3 × 20 cm^3). The sample was then dried in vacuum for 7 h. Yield 0.27 g (93%).

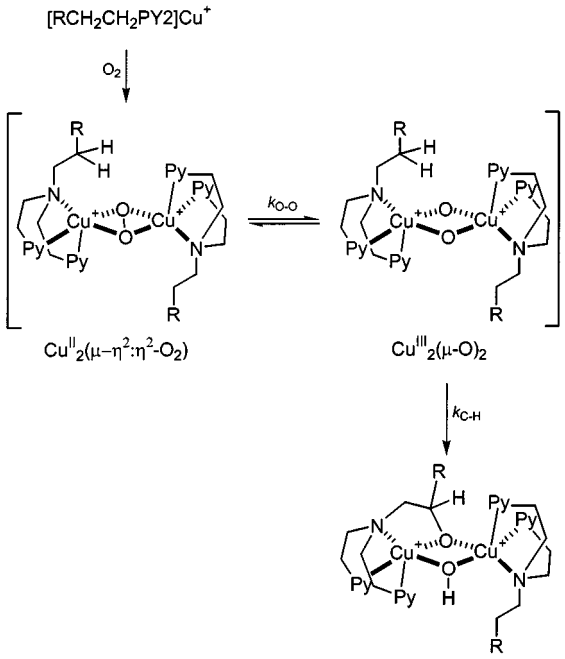
Substrate-Binding Ligand Approach in Chemical Modeling of Copper-Containing Monooxygenases, 1 Intramolecular Stereoselective Oxygen Atom Insertion into a Non-Activated C–H Bond



Ingrid Blain,[a] Michel Giorgi,[a] Innocenzo De Riggi,[b] and Marius Réglier*[a]

Keywords: Copper / Oxygenase / Copper–oxygen radical species / RPY2 ligand / Oxygenation

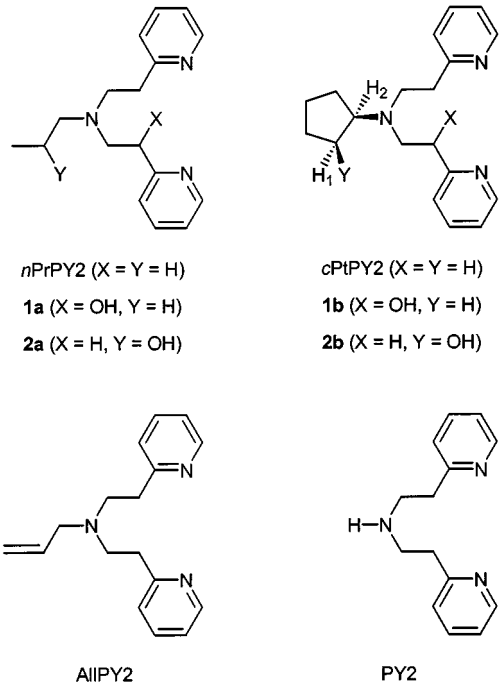
We describe the reactivity of new copper AlkylPY2 type complexes which react with dioxygen and thus hydroxylate an aliphatic C–H bond of the ligand in the same manner as copper-containing monooxygenases.

Introduction

Copper-containing monooxygenases[1] are involved in important biological reactions and copper-dioxygen chemistry has been the subject of important recent investigations.[2] It has been shown that copper(I) coordinated to tridentate ligands {HB(3,5-*i*Pr$_2$pz)$_3$,[3] RPY2,[4,5] P(2,4-*i*Pr$_2$im)$_3$[6] and *i*Pr$_3$tacn[7] leads to $[Cu^{II}_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}O_2)]^{2+}$ species upon reaction with dioxygen. More recently, Tolman et al.[8] reported that these species can exist in equilibrium with a bis(μ-oxo)dicopper species in a formal $[Cu^{III}_2(\mu\text{-}O)_2]^{2+}$ oxidation state. Whereas the structure of these copper-dioxygen adducts is now well documented, few examples of exogenous substrate oxidation mediated by these species are known.[4] In some cases, these peroxo species are capable of inserting an oxygen atom into a C−H bond of the ligand.[5−7,9,10] Taking advantage of this behavior, we described in previous papers,[10] the *substrate-binding ligand approach*, which involves the study of copper complexes derived from RPY2-type ligands. In these compounds a substrate is covalently bound to the ligand′s tertiary amino group in such a way that an intramolecular oxygen-atom transfer from the copper center to the ligand is favored. The chemio-, regio- and stereoselectivities of the oxygen atom transfer, as revealed by the structure of the hydroxylated ligands, are used to gain more information on the nature of the hydroxylating species and the exact oxidation mechanism. When using such complexes, benzylic hydroxylation (DBH functional model)[5,10c] and hydroxylation at the α-position of the amido group (PHM functional model)[10a] were described. Herein, we report the reactions of a new RPY2 ligand in which we chose to attach a propyl or cyclopentyl group as the substrate in order to find out if copper-oxygen species are capable of inserting an oxygen atom into a nonactivated C−H bond.

Scheme 1. Substrate-binding ligand approach

Results and Discussion



The new RPY2 ligands were synthesized from simple organic reactions. Thus, Michael addition of primary amines to freshly distilled 2-vinyl pyridine in a methanol/acetic acid mixture yielded the ligands *n*PrPY2 and *c*PtPY2. The copper(II) complexes [*n*PrPY2]Cu(OTf)$_2$ and [*c*PtPY2]Cu(OTf)$_2$ (OTf = OSO_2CF_3) were obtained in methanol in nearly quantitative yields by complexation of the corresponding ligands with Cu(OTf)$_2$. Recrystallization from dichloromethane using the diethyl ether vapor diffusion technique afforded blue crystals of [*n*PrPY2]Cu(OTf)$_2$ which were suitable for an X-ray diffraction analysis (Table 1, Figure 1).

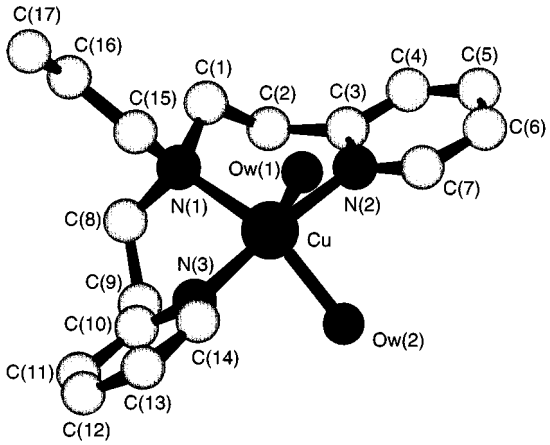

Figure 1. Perspective view of the copper(II) complex [*n*PrPY2]-Cu(OTf)$_2$ emphasizing the central coordination sphere; selected bond distances (Å): Cu−Ow(1), 2.224 (3), Cu−Ow(2), 2.045 (3), Cu−N(1), 2.088 (3), Cu−N(2), 1.994 (3), Cu−N(3), 1.990 (4); bond angles (°): Ow(1)−Cu−Ow(2), 102.8 (1), Ow(1)−Cu−N(2), 86.9 (2), Ow(1)−Cu−N(1), 106.8 (2), Ow(1)−Cu−N(3), 93.5 (2), Ow(2)−Cu−N(2), 87.8 (2), Ow(2)−Cu−N(1), 150.2 (2), Ow(2)−-Cu−N(3), 86.4 (2), N(2)−Cu−N(1), 96.4 (2), N(2)−Cu−N(3), 174.1 (2), N(1)−Cu−N(3), 89.1 (2).

The copper complex [*n*PrPY2]CuPF$_6$, was prepared in situ by interaction (under argon) of the corresponding ligand *n*PrPY2 with 1 equiv. of $(CH_3CN)_4CuPF_6$ in degassed dichloromethane. When it was placed in a dioxygen atmosphere the clear yellow solution rapidly turned green and a copper(II) complex was obtained. Demetallation with 35% aqueous ammonia and analysis of the organic products indicated the complete recovery of the starting ligand *n*PrPY2 with no products resulting from an oxygen-atom transfer to the ligand. More interesting were the results obtained by treatment of [*n*PrPY2]Cu(OTf)$_2$ with 2 equiv. of benzoin/NEt$_3$ in dichloromethane at 25°C. Under argon, reduction to a copper(I) state by 2 equiv. of benzoin/NEt$_3$ occurred in less than two hours. After exposure to a dioxygen atmosphere for 18 hours and demetallation with 35% aqueous ammonia, analysis of the organic products indicated the presence of compounds **1a**, **2a** and AllPY2 in addition to recovered ligand *n*PrPY2 and small amounts of secondary amine PY2 resulting from an *N*-dealkylation reaction (Table 2, entry 2).[11] A thorough analysis of the spectral data indicated that the main product **1a** was the result of hydroxylation at the benzylic position of one pyridine ring. This is clearly evident from the ^{13}C NMR spectra which show the splitting of all pyridine signals and the appearance of two new signals at δ = 61.5 and 70.8, attributable to the N−*C*H$_2$−*C*HOH−pyr sequence, and from the ^{1}H NMR spectra which show a doublet of doublets at δ = 4.75 corresponding to N−CH$_2$−C*H*OH−pyr. Compound **2a** as revealed by NMR analysis and confirmed by comparison with an authentic sample was the result of a β-hydroxylation of the *n*-propyl group.[12]

In order to study the stereoselectivity of the oxygen-atom transfer to the alkyl part of the ligand, we then studied the reactivity of *c*PtPY2-derived copper complexes. As already mentioned for [*n*PrPY2]CuPF$_6$, we did not observe any hydroxylation products by reaction of [*c*PtPY2]CuPF$_6$, prepared in situ, with dioxygen. However two equiv. of

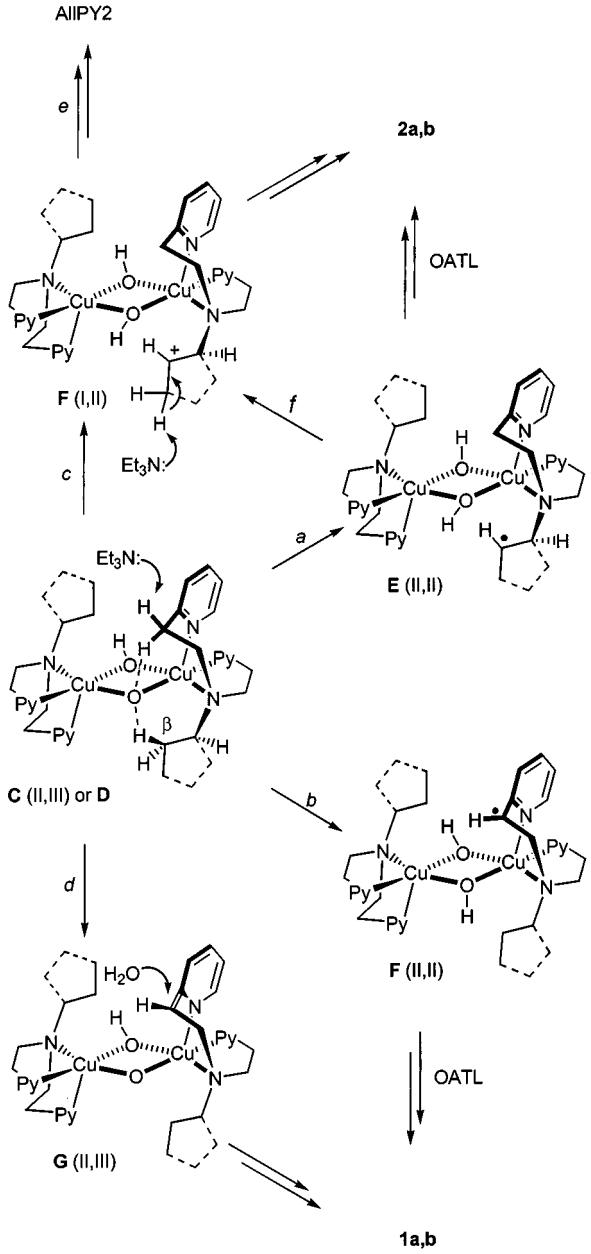
benzoin/NEt_3 in dichloromethane at 25°C transformed [*c*PtPY2]Cu(OTf)$_2$ into the hydroxylated compounds **1b** and **2b** (Table 2, entry 5). Compound **1b**, which showed the same spectroscopic features as **1a** (^{13}C NMR: splitting of all pyridine signals and appearance of two new signals at $\delta = 71$ and 59; ^{1}H NMR: dd at $\delta = 4.76$), was the result of a hydroxylation at a benzylic position. An NMR structural analysis of compound **2b** revealed that it was the result of a β-*cis* hydroxylation of the cyclopentane ring. The *cis* stereochemistry could be assigned by a two dimensional NOESY sequence showing a Nuclear Overhauser Effect (NOE) between protons H-2 and H-1.[13]



In one of our previous papers the higher deuterium kinetic isotope effect observed for reaction of [IndPY2]CuPF$_6$/O_2 relative to that of [IndPY2]Cu(OTf)$_2$/benzoin/NEt_3/O_2 (11 vs. 7.6) was rationalized as being due to the occurrence of two different copper-oxygen intermediates.[10c] The absence of Oxygen Atom Transfer to the Ligand (OATL) during the reaction of [RPY2]CuPF$_6$ with dioxygen confirms this suggestion. At this time it is difficult to provide any evidence for the oxygenated copper species responsible for the hydroxylation. Nevertheless, on the basis of the observed products we can formulate several hypotheses concerning the structure of the active oxygen species. Itho,[5] and more recently Karlin,[4a] with [PhenPY2]CuPF$_6$ and [MePY2]CuPF$_6$ complexes, respectively, have shown that such complexes lead to $\{[RPY2]Cu^{II}_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}O_2)\}^{2+}$ by oxygenation, and that a homolytic cleavage of the peroxy bond occurs (at least partially) to give, in the first step of the reaction, a $\{[RPY2]Cu^{III}_2(\mu\text{-}O_2)\}^{2+}$ species (Scheme 3). In this context, it is reasonable to assume the formation of species **A** and/or **B** upon reaction with dioxygen (Scheme 3). Except with complexes derived from PhenPY2 and IndPY2 ligands where activated benzylic hydrogen are present, such species do not transfer an oxygen atom to the AlkylPY2 ligand. In a recent study on pMMO, Chan et al. proposed that a $Cu^{III}_2(\mu\text{-}O_2)^{2+}$ species is not reactive enough to abstract a hydrogen atom from methane.[1d] Nevertheless, these authors suggested that transfer of an additional electron, probably from another copper atom, and the occurrence of the mixed valence $Cu^{II}Cu^{III}(\mu\text{-}O_2)^{2+}$ species,[14] may enhance the reactivity of the copper-oxygen core. This hypothesis is very attractive for the hydroxylation of complexes derived from an AlkylPY2 ligand, which only occurs when benzoin is present. Thus, we propose that benzoin acts in the monoelectronic reduction of **A** and/or **B** to give a mixed valence species **C** which, as suggested by Chan, could be active in transferring one oxygen atom to the ligand to give $\{[HORPY2]Cu^{II}\}^{2+}$. This process is accompanied by the formation of a copper(I) complex, which can participate again after reaction with dioxygen in a monooxygenase-like cycle.[15] According to this mechanism, the transformation of copper(II) complexes [RPY2]Cu(OTf)$_2$ in such a cycle needs two electrons (one equiv. of benzoin). We observed that the transformation of the original copper(II) complexes into the observed products consumed a four-fold excess of benzoin (Table 2, entry 4). Benzoin is a strong reducing agent that can participate in a second electron addition to **C** (and/or **D**) in a competitive reaction to give a different copper(II) species which is unreactive in the hydroxylation reaction (oxydase like cycle). The two competitive processes (oxydase vs. monooxygenase) may explain why the complete transformation of [RPY2]Cu(OTf)$_2$ needs more than one equiv. of benzoin.

The OATL mechanism needs some comments. Scheme 4 illustrates possible pathways whereby hydroxylation can occur *via* the dimeric species **C** (or monomer **D**). The first explanation for the formation of **1a** or **1b** is to consider that the electrophilic Cu^{III} core in **B** (or **C**) increases the acidity of the benzylic hydrogen of pyridine, thus facilitating the deprotonation with triethylamine (path *d*). This mechanism can be dismissed as increasing the amount of triethylamine did not increase the amount of **1a** in the [nPrPY2]Cu(OTf)$_2$/Benzoin/O_2 reaction (Table 2, entry 3). From our results two observations are in favor of a mechanism occurring in the coordination sphere of the copper core: (1) hydroxylation exclusively in the β position of the tertiary amino group, and (2) exclusive *cis* hydroxylation of the aminocyclopentane moieties of [*c*PtPY2]Cu(OTf)$_2$. While we cannot definitively exclude a concerted mechanism, several examples in the literature are in favor of a two step mechanism where the abstraction of a β hydrogen atom occurs in the partially rate determining step. Since AllPY2 is not the result of the dehydration of a copper(II) complex of [**2a**],[16] the isolation of AllPY2 can be considered as being indicative of a two-step mechanism where a carbenium ion is formed. The question which arises now is to know if this intermediate is formed directly by abstraction of a H^- by an electrophilic oxygen (path *c*) or by oxidation of the radical **E** (path *f*). At the moment, it is difficult to answer this fundamental question. More experiments are needed, notably using a radical clock fixed on the tertiary amino group

Scheme 3. Oxydase *vs.* monooxygenase-like cycles

of the ligand. However, initial radical formation from a hydrogen atom abstraction by the Cu−O core seems to be more reasonable since Mayer has recently shown that metal-oxo complexes oxidize hydrocarbons by a hydrogen-atom abstraction mechanism which is attributed to their thermodynamic affinity for a hydrogen atom (≡ $H^+ + e^-$).[17]

Scheme 4. Mechanism proposed for β-hydroxylations

Conclusion

While benzylic hydroxylation is the easier process, we have now demonstrated that copper-oxygen species are able to functionalise aliphatic C−H bonds probably *via* a two-step process. Once again, it is possible to show that the substrate binding ligand approach gives valuable information about the active species involved in the copper-dioxygen activation. This organic chemistry approach is complementary to that of inorganic chemists who are more interested in the structural study of copper-oxygen species

Experimental Section

General: Solvents were freshly distilled under argon: MeOH from Mg, Et_2O from sodium benzophenone ketyl and CH_2Cl_2 from P_2O_5. Deoxygenation of solvents and solutions was carried out by three vacuum/purge cycles. Standard Schlenk techniques were used in the preparation and handling of air-sensitive compounds. Commercial starting materials were used without further purification, except for 2-vinylpyridine, which was distilled prior to use. NMR spectra were recorded on Bruker AC-200 or AMX-400 spectrometers. Chemical shifts are reported in ppm as δ values downfield from an internal standard (TMS). Elemental analyses were obtained on a CHN Technicon microanalyser.

RPY2: To absolute MeOH were added freshly distilled 2-vinylpyridine, the primary amine and acetic acid. After refluxing for 2−5 days, MeOH and the excess 2-vinylpyridine were evaporated under vacuum. The crude product was dissolved in CH_2Cl_2, washed with a saturated solution of $NaHCO_3$ and dried over Na_2SO_4. Evaporation of CH_2Cl_2 under reduced pressure (18 Torr) and flash chro-

matography (Silica gel, CH_2Cl_2/MeOH 85/15) afforded ligands RPY2.

***n*PrPY2:** Yield: 610 mg (2.3 mmol, 38%) [from *n*-propylamine (354 mg, 6 mmol), 2-vinylpyridine (3.88 mL, 36 mmol), CH_3COOH (420 mL, 7.5 mmol), MeOH (8 mL), 2 day reflux]. − ^{1}H NMR (200 MHz, $CDCl_3$): δ = 0.83 (t, *J* = 7.5 Hz, 3 H), 1.52 (hex, *J* = 7.5 Hz, 2 H), 2.63−2.56 (m, 2 H), 3.00 (s, 8 H), 7.16−7.07 (m, 4 H), 7.57 (td, *J* = 7.5 and 1.7 Hz, 2 H), 8.51 (ddd, *J* = 4.8, 1.7 and 1 Hz, 2 H). − ^{13}C NMR (50.32 MHz, $CDCl_3$): δ = 11.47 (CH_3), 19.64 (CH_2), 34.99 (CH_2), 53.48 (CH_2), 55.46 (CH_2), 120.96 (CH), 123.18 (CH), 136.10 (CH), 148.82 (CH), and 159.86 (C).

***c*PtPY2:** Yield: 1.18 g (4 mmol, 40%) [*c*-pentylamine (850 mg, 10 mmol), 2-vinylpyridine (10 mL, 0.1 mol), CH_3COOH (2.3 mL, 40 mmol), MeOH (10 mL), 5 day reflux]. − ^{1}H NMR (200 MHz, $CDCl_3$): δ = 1.32−1.74 (m, 6 H), 1.75−1.85 (m, 2 H), 2.90−3.10 (m, 9 H), 7.00−7.10 (m, 4 H), 7.52 (td, *J* = 7.7 and 1.8 Hz, 2 H), 8.46 (dd, *J* = 4.8 and 0.9 Hz, 2 H). − ^{13}C NMR (50.32 MHz, $CDCl_3$): δ = 23.93 (CH_2), 30.10 (CH_2), 35.71 (CH_2), 51.80 (CH_2), 63.71 (CH), 121.11 (CH), 123.38 (CH), 136.27 (CH), 149.13 (CH), and 160.70 (C).

[RPY2]Cu(OTf)$_2$: To a solution of $Cu(OTf)_2$ (694 mg, 1.9 mmol) in CH_2Cl_2 (5 mL) was added dropwise a solution of ligand RPY2 (1.9 mmol) in CH_2Cl_2 (5 mL). The mixture was allowed to stir for 2 h, and Et_2O was added until precipitation. The precipitate obtained was centrifuged, washed with Et_2O and dried in vacuo to give [RPY2]Cu(OTf)$_2$.

[*n*PrPY2]Cu(OTf)$_2$: blue solid. − Yield: 1.10 g (1.66 mmol, 87%) − $C_{19}H_{23}CuF_6N_3O_6S_2$ (631.06): calcd. C 36.16, H 3.67, N 6.66; found C 35.16, H 3.88, N 6.47.

[*c*PtPY2]Cu(OTf)$_2$: blue solid. − Yield 1.23 g (1.78 mmol, 94%) − $C_{21}H_{25}CuF_6N_3O_6S_2$ (657.10): calcd. C 38.39, H 3.83, N 6.39; found C 37.36, H 4.03, N 6.22.

Oxidation of [RPY2]CuPF$_6$ With O$_2$: To a solution of $[CH_3CN]_4CuPF_6$ (0.1 mmol) in degassed CH_2Cl_2 (50 mL), was added dropwise a solution of RPY2 (0.1 mmol) in CH_2Cl_2 (50 mL). The mixture was stirred under argon for 1 h, and then exposed to an O_2 atmosphere for 24 h. The CH_2Cl_2 was subsequently evaporated in vacuo, Et_2O (50 mL) was added, and the precipitate thus obtained was filtered off, washed with Et_2O, and dried in vacuo to give a mixture of copper(II) complexes. This mixture was dissolved in CH_2Cl_2 (20 mL), washed with 35% NH_4OH (5 mL) and brine (3 × 5 mL), and dried over Na_2SO_4. Evaporation of the CH_2Cl_2 under reduced pressure (18 Torr) gave the crude product. Flash chromatography (SiO_2, CH_2Cl_2/MeOH, 90:10) afforded the recovered ligands RPY2.

Oxidation of [RPY2]Cu(OTf)$_2$ With O$_2$ in the Presence of Benzoin: To a solution of [RPY2]Cu(OTf)$_2$ in degassed CH_2Cl_2 were added benzoin (1 equiv.) and NEt_3 (1 equiv.). This mixture was stirred under argon for 2 h and then exposed to an O_2 atmosphere for 24 h. The CH_2Cl_2 was subsequently evaporated in vacuo and Et_2O was added. The precipitate thus obtained was filtered off, washed with Et_2O, dissolved in CH_2Cl_2, washed with 35% NH_4OH and brine, and dried over Na_2SO_4. Evaporation of the CH_2Cl_2 under reduced pressure (18 Torr) gave a mixture of recovered ligands RPY2 and compounds **1a**,**b**, **2a**,**b** and AllPY2 which were separated by flash chromatography (SiO_2, CH_2Cl_2/MeOH, 90:10).

1a: ^{1}H NMR (200 MHz, $CDCl_3$): δ = 0.75 (t, *J* = 7 Hz, 3 H), 1.4 (m, 2 H), 2.4−2.7 (m, 3 H), 3.1−2.85 (m, 5 H), 4.75 (dd, *J* = 9 and 3.4 Hz, 1 H), 6.95 (d, *J* = 7.5 Hz, 1 H), 7.2−7.05 (m, 4 H,), 7.4−7.7 (m, 3 H), 8.50 (m, 2 H). − ^{13}C NMR (50.32 MHz, $CDCl_3$): δ = 11.6 (CH_3), 20.0 (CH_2), 35.6 (CH_2), 54.1 (CH_2), 56.2 (CH_2), 61.5 (CH_2), 70.8 (CH), 121.4 (CH), 120.5 (CH), 123.4 (CH), 122.2 (CH), 136.7 (CH), 136.6 (CH), 149.1 (CH), 148.6 (CH), 162.1 (C), 160.2 (C).

1b: ^{1}H NMR (200 MHz, $CDCl_3$): δ = 1.20−1.80 (m, 8 H), 2.60 (dd, *J* = 13 and 10 Hz, 1 H), 2.90−3.08 (m, 5 H), 3.14−3.32 (m, 1 H), 4.76 (dd, *J* = 10 and 3 Hz, 1 H), 7.05−7.20 (m, 3 H), 7.50−7.72 (m, 3 H), 8.50 (m, 2 H). − ^{13}C NMR (50.32 MHz, $CDCl_3$): δ = 29.8 (CH_2), 27.6 (CH_2), 24.0 (CH_2), 23.9 (CH_2), 36.2 (CH_2), 52.3 (CH_2), 59.0 (CH_2), 63.5 (CH), 71.0 (CH), 121.3 (CH), 120.4 (CH), 123.4 (CH), 122.2 (CH), 136.7 (CH), 136.5 (CH), 149.0 (CH), 148.6 (CH), 162.4 (C), 160.3 (C).

2a: ^{1}H NMR (200 MHz, $CDCl_3$): δ = 1.08 (d, *J* = 6.2 Hz, 3 H), 2.35 (dd, *J* = 12.9 and 9.9 Hz, 1 H), 2.48 (dd, *J* = 12.9 and 3.1 Hz, 1 H), 2.70−3.10 (m, 8 H), 3.66 (dqd, *J* = 9.9, 6.2 and 3.1 Hz, 1 H), 4.09 (br. s, 1 H), 6.97 (d, *J* = 7.5 Hz, 2 H), 7.07 (ddd, *J* = 7.5, 5.1 and 1.0 Hz, 2 H), 7.51 (td, *J* = 7.5 and 1.7 Hz, 2 H), 8.48 (ddd, *J* = 5.1, 1.7 and 1.0 Hz, 2 H). − ^{13}C NMR (50.32 MHz, $CDCl_3$): δ = 19.5 (CH_3), 35.6 (CH_2), 53.9 (CH_2), 62.1 (CH_2), 63.5 (CH), 120.8 (CH), 123.9 (CH), 135.9 (CH), 148.7 (CH), 160.0 (C).

2b: ^{1}H NMR (200 MHz, $CDCl_3$): δ = 1.53−1.62 (m, 1 H), 1.78−1.90 (m, 4 H), 1.95 (br. t, *J* = 10 Hz, 1 H), 3.05−3.19 (m, 4 H), 3.23 (br. s, 1 H), 3.41−3.50 (m, 4 H), 4.35 (br. s, 1 H), 7.10 (ddd, *J* = 8, 5 and 2 Hz, 2 H), 7.58 (td, *J* = 8 and 2 Hz, 2 H), 7.16 (d, *J* = 8 Hz, 2 H), 8.38 (br. d, *J* = 5 Hz, 2 H). − ^{13}C NMR (50.32 MHz, $CDCl_3$): δ = 20.7 (CH_2), 26.6 (CH_2), 31.8 (CH_2), 32.5 (CH_2), 68.3 (CH), 51.0 (CH_2), 70.4 (CH), 121.9 (CH), 123.7 (CH), 137.0 (CH), 149.0 (CH), 158.5 (C). Two-dimensional NMR experiments were carried out on an AMX Bruker 400 MHz spectrometer. COSY gradient, HMQC and HMBC experiments were performed with 5 mm inverse broadband probehead incorporating a shielded z-gradient coil. These correlations allowed the total assignment of all the protons and carbon atoms of the compound **3b**. A 5 mm DUAL ^{1}H/^{13}C probehead was used to acquire the 2D phase-sensitive NOESY data.

AllPY2: ^{1}H NMR (200 MHz, $CDCl_3$): δ = 2.90 (br. s, 8 H), 3.25 (d, *J* = 6 Hz, 2 H), 5.10 (br. d, *J* = 10 Hz, 1 H), 5.18 (br. d, *J* = 17 Hz, 1 H), 5.80 (ddt, *J* = 17, 10 and 6 Hz, 1 H), 7.10−6.90 (m, 4 H), 7.50 (td, *J* = 8 and 2 Hz, 2 H), 8.50 (dt, *J* = 5 and 1 Hz, 2 H). − ^{13}C NMR (50.32 MHz, $CDCl_3$): δ = 35.7 (CH_2), 53.3 (CH_2), 58.8 (CH_2), 116.9 (CH_2), 120.7 (CH), 123.0 (CH), 135.5 (CH), 135.8 (CH), 146.8 (CH), 160.3 (C).

X-ray Structure Analysis: Crystal data for [*n*PrPY2]Cu(OTf)2 together with details of the X-ray diffraction experiment, are reported in Table 1. Crystallographic data for the structure reported in this paper has been deposited at the Cambridge Crystallographic Data Center as supplementary publication no. CCDC 113535. Second Coordination Sphere Water Molecules and Relaxivity of Gadolinium(III) Complexes: Implications for MRI Contrast Agents

Mauro Botta[a]

Keywords: Relaxivity / Nuclear magnetic relaxation dispersion / Imaging agents / NMR spectroscopy / MRI contrast agents

Dipolar interaction between the metal ion and proximate water molecules represents an efficient mechanism for solvent relaxation in Gd^{3+} complexes currently employed as MRI contrast agents. Besides *inner sphere* (metal bound) and *outer sphere* hydration molecules, a well-defined second coordination shell may provide an additional mechanism for paramagnetic relaxation leading to a strong enhancement of the relaxivity of the complexes. Through a careful choice of hydrogen-bond-acceptor groups on the ligand we may: (1) promote the formation of a strong interaction; (2) increase the number of water molecules in the second hydration shell; (3) decrease their average distance from the paramagnetic metal center. These possibilities have been explored by considering complexes bearing phosphinate, phosphonate and carboxoamide pendant arms, by exploiting the formation of ion-pairs with cationic substrates and inclusion compounds of these adducts with β-cyclodextrin. Finally, the contribution of this relaxation mechanism to the relaxivity of the commercially available MRI contrast agents is discussed and the NMRD data reevaluated and compared with crystallographic data.

Introduction

The emergence of MRI as an important clinical tool has fostered the development of agents designed to enhance tissue differentiation.[1] These drugs, mainly complexes of Gd^{3+} and Mn^{2+}, are useful for increasing the image contrast between normal and diseased tissue and/or providing dynamic tissue function. Unlike the contrast agents (CAs) used in other clinical imaging studies, these paramagnetic complexes are not themselves directly imaged but rather enhance contrast indirectly by affecting the nuclear magnetic relaxation times of the water protons in surrounding tissues. Because Gd^{3+} has particularly favorable magnetic properties, complexes of this ion have been the primary focus for MRI contrast agent development.[2] The clinically approved CAs are stable, highly water soluble poly(aminocarboxylate) derived complexes (Gd^{3+} complexes with ligands **1–4**, Scheme 1). The requirements to design a practical, general, MRI CA can be summarized as follows:

Mauro Botta was born in Cuneo in 1958. He studied chemistry at the University of Torino where he received the Laurea degree in 1985. After three years spent as a research assistant in the Department of Chemistry working in the group of Prof. Silvio Aime, he held a tenure of Researcher (1990–1998) at the faculty of Pharmacy of the University of Torino and was nominated associate Professor (1998) at the University of Piemonte Orientale "Amedeo Avogadro." In 1998 he was awarded the Nasini Medal of the Inorganic Chemistry Division of the Italian Chemical Society. His research has mainly focused on the application of NMR spectroscopy to investigate solution and solid state properties of metal carbonyl clusters and coordination complexes for biomedical applications.

Scheme 1

(1) *High stability.* The injection of gram amounts of gadolinium into patients presents some potential toxicity problems which requires strong metal complexation by the parent ligand.

(2) *Good water solubility and low osmolality of the solutions used clinically.* Injection of relatively small volumes of a fairly concentrated solutions of the metal complex is required. Neutral complexes have been developed with the goal of lessening the discomfort from injection of high osmolality salt solutions (Gd-**3** and Gd-**4**).

(3) *High relaxivity.* The relaxivity (r_{1p}) is an intrinsic property of a paramagnetic complex that characterize its ability to enhance the nuclear magnetic relaxation rates (R_i, i = 1,2) of nearby protons and is defined as the increase in R_i per millimolar concentration of the CA.[1–3]

The dependence of the relaxivity on structural features of the paramagnetic compounds has represented an important area of research in the field of inorganic chemistry over the last ten years. These studies have made significant contributions towards a rational design of MRI CAs, opened new perspectives in the use of paramagnetic complexes as diagnostic probes and increased our knowledge of the coordination chemistry of lanthanide ions. The general properties of MRI CAs,[1b] the determinants of the relaxivity,[2] the crucial role of the water exchange rate,[4] and the perspectives for attaining high relaxivities[5] have been recently reviewed. Here I will discuss recent results that have allowed us to pinpoint a direct role of the second coordination shell water molecules in determining the relaxivity of the paramagnetic complexes, the strategies used for optimizing this contribution and the implications for the analysis of relaxation data for MRI CAs.

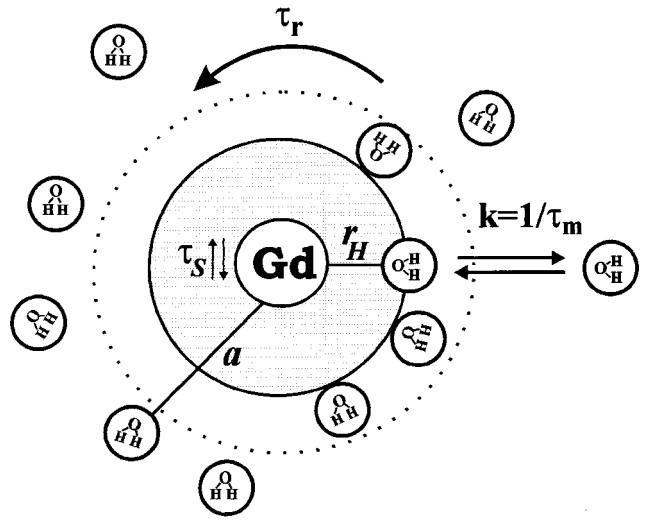

Figure 1. Schematic representation of the three types of hydration layers around a Gd^{3+} complex and the most relevant parameters of paramagnetic relaxation

Relaxivity: Contributions and Parameters

The relaxivity enhancement of water protons in aqueous solutions of Gd^{3+} complexes arises from time fluctuation of the dipolar coupling between the electron magnetic moment of the metal ion and the nuclear magnetic moment of the solvent nuclei.[6] This interaction is traditionally described with a model that considers two contributions (Figure 1): *inner sphere* (*IS*), due to water molecules present in number q in the coordination sites of the Gd^{3+} ion, and *outer sphere* (*OS*), which involves all the solvent molecules diffusing by the complex:

$$R_1^{obs} = R_{1p}^{IS} + R_{1p}^{OS} + R_1^W \quad (1)$$

where R_1^{obs} is the measured relaxation rate and R_1^W the relaxation rate of the solvent in the absence of the paramagnetic complex.

Inner Sphere

This term represents the most important contribution to r_{1p} and thus the efforts towards contrast agents of improved efficacy have been directed mainly towards its optimization. The large number of experimental data recorded over the last 15 years on small Gd^{3+} chelates have been interpreted on the basis of the Solomom-Bloembergen-Morgan approach,[7] and have provided a good understanding of the role played by the different relaxation parameters, of their mutual relationship, and of their dependence on the structural features of the complexes.[1–5,8] The relevant Equations are:

$$R_{1p}^{IS} = \frac{[M]q}{55.6}\frac{1}{T_{1M}+\tau_M} \quad (2)$$

$$\frac{1}{T_{1M}} = \frac{2}{15}\frac{\gamma_H^2 g^2 S(S+1)\beta^2}{r_H^6}\left[\frac{3\tau_{C1}}{1+\omega_H^2\tau_{C1}^2}+\frac{7\tau_{C2}}{1+\omega_S^2\tau_{C2}^2}\right] \quad (3)$$

$$\frac{1}{\tau_{Ci}} = \frac{1}{\tau_R} + \frac{1}{\tau_M} + \frac{1}{\tau_{Si}} \quad (4)$$

where M is the concentration of the CA, T_{1M} the longitudinal relaxation time of the bound water protons, S is the electron spin quantum number (7/2 for Gd^{3+}), γ_H is the proton nuclear magnetogyric ratio, β is the Bohr magneton, g is the Landè factor for the free electron, r_H is the distance between the metal ion and the bound water protons; ω_H and ω_S are the proton and electron Larmor frequencies, respectively, and τ_{Ci} (i = 1,2) are the correlation times of the modulation of the dipolar electron-proton coupling. The overall correlation times τ_{Ci} receive contributions from the reorientation of the paramagnetic species, τ_R, by the residence lifetime of the bound water protons, τ_M and by the electronic relaxation times of the metal ion, τ_S. A marked enhancement of r_{1p} at the magnetic fields currently employed clinically has been obtained primarily by slowing down the molecular tumbling (increasing τ_R) by different approaches.[9–15] However, the expected increase of r_{1p} has not been observed because of the limiting effect of the mean water residence lifetime τ_M.[2,4,11,12] A fine tuning of this parameter has emerged as a primary objective of the current research in this field, as only values around 30 ns would allow the full exploitation of the decrease of T_{1M} induced by the lengthening of τ_R.

Outer Sphere

This contribution accounts for about 40% of the relaxivity of monoaquo Gd^{3+} complexes at the imaging fields and arises from the modulation of the dipolar interaction by diffusion of the solvent molecules next to the paramagnetic center:

$$R_{1p}^{OS} = C^{OS}\left(\frac{1}{aD}\right)\left[7J(\omega_S) + 3J(\omega_H)\right] \quad (5)$$

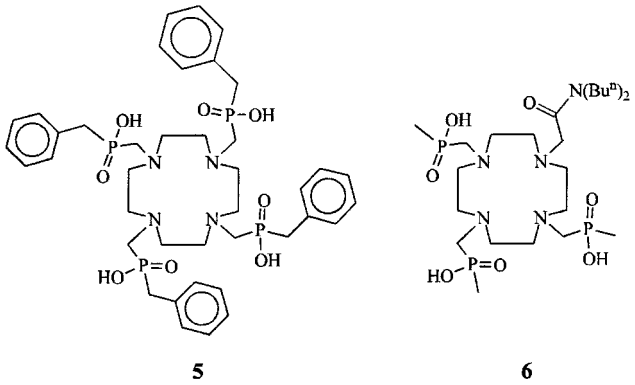
$$J(\omega) = Re\left[\frac{1 + 1/4\left(i\omega\tau_d + \frac{\tau_d}{\tau_{Si}}\right)^{1/2}}{1 + \left(i\omega\tau_d + \frac{\tau_d}{\tau_{Sj}}\right)^{1/2} + 4/9\left(i\omega\tau_d + \frac{\tau_d}{\tau_{Sj}}\right) + 1/9\left(i\omega\tau_d + \frac{\tau_d}{\tau_{Sj}}\right)^{3/2}}\right] \quad (6)$$

$$with \quad j = 1,2; \quad \tau_d = \frac{a^2}{D}$$

where C^{OS} is a constant (5.8×10^{-13} s^{-2} M^{-1}) and the non-Lorentzian spectral density functions $J(\omega_i)$ contain the dependence on τ_S. At the magnetic fields of interest it depends primarily on the distance of closest approach a, related to the molecular dimension and charge distribution of the complex, and on the relative diffusion coefficient of solute and solvent D. It follows that r_{OS}^{1p} assumes a comparable value (above 10 MHz) for all the small gadolinium chelates of clinical interest.

Second Coordination Sphere: A Third Contribution to Relaxivity

In principle the outer sphere relaxivity can also receive contributions by another mechanism: fluctuation of the dipolar electron-nuclear coupling involving water molecules held in the second coordination shell of the paramagnetic ion by hydrogen bonding interactions with polar groups of the ligand (Figure 1). This term (2S) has to be distinguished from the traditional diffusion-controlled outer-sphere relaxivity only when the residence lifetime of the structured water in the second shell is longer than the diffusional correlation time τ_D ($\tau_D = a^2/D$). In this latter case the quantitative description of the effects on the relaxivity is analogous to that of the inner sphere water molecules (Equation 2), as clearly pointed out by Lauffer.[1b] Firm experimental evidence for the occurrence of this solvent/metal complex interaction is difficult to obtain and, in most cases, its consideration may only represent a negligible correction to the inner- and outer-sphere relaxivities in the traditional model. However, in several cases, a careful analysis of the relaxation rate of the solvent as a function of magnetic field, pH and temperature allowed the evaluation of this contribution and the extraction of more useful and correct information from the data analysis.



In 1981 Koenig et al. reported that replacement of the iron(III)-bound water molecule in methemoglobin by fluoride ion increases the relaxation rate drastically.[17] It was shown by variable temperature relaxivity data that the heme-iron-coordinated water molecule in met-Hb is kinetically inert as it is stabilized by a hydrogen bond with a proximate hystidine residue, and that the relaxivity enhancement upon fluoride binding can be attributed to a labile water molecule hydrogen bonded to the coordinated anion. Such structural arrangement brings a proton of this second sphere water molecule close enough to the paramagnetic center to be strongly relaxed. Recently this interpretation was confirmed by a crystallographic study that revealed the presence of a water molecule hydrogen bonded to the fluoride anion at a distance of 2.71 Å.[18] In 1984 Kushnir and Navon investigated the water relaxation-rate enhancement by Mn^{2+} bound to macromolecules and found the presence of an additional contribution to r_{1p}^{IS} which dominated the observed relaxivity at high fields and originated from outer sphere solvent molecules.[19] This additional contribution could not be explained on the basis of a spin-diffusion mechanism from the protein protons or of the usual dipolar interaction with the diffusing solvent molecules. A good quantitative account was obtained by considering water molecules bound outside the first hydration shell with an average lifetime of 0.3 ns.

The possible contribution of r_{1p}^{2S} to the overall relaxivity of small paramagnetic complexes has seldom been considered in the past. Oakes and Smith studied the proton relaxation properties of $[Mn(EDTA)(H_2O)]^{2-}$ and attributed the outer sphere contribution to the presence of

four water molecules hydrogen bonded to the four coordinated carboxylate groups.[20] The calculated Mn–H distance for these water molecules is 3.7 Å, a value that seems reasonable even though the validity of this very simple model is questionable, and it has not been checked by a magnetic field- and temperature-dependent study. More recently, Merbach et al. reported a detailed ^{17}O NMR and computer modeling study on the structure and dynamics of the second coordination shell water molecules around the Cr^{3+} hexaaqua ion.[21] In the case of this ion, which is endowed with a kinetically inert first hydration shell, where the bonding occurs through the O-atom of the water molecules, the authors were able to assess the presence of 13 water molecules in the second shell with an average lifetime of 128 ps. On the other hand no evidence was found for a well defined second shell in the case of a cation of larger ionic radius like Ln^{3+}.[22] It is worth noting that only in these latter two cases, characterized by an isotropic disposition of the ligand molecules around the metal ion, is the term "second sphere" strictly applicable. In the polyamminopolycarboxylate(-polyphosphonate) complexes considered here, the widely used definition of second sphere can be misleading as it refers exclusively to water molecules hydrogen-bonded to polar groups of the ligand present on the hydrophilic side of the metal complex.

Gd^{3+} Complexes

The lanthanide complexes with the macrocyclic tetrabenzylphosphinate ligand **5** (Scheme 2) have been characterized both in the solid state and in solution, where they are present as a single diastereoisomer with an inverted square antiprismatic coordination polyhedron.[23]

5 **6**

Scheme 2

Unlike the case of the carboxylate analogues, the higher steric bulk of the phosphinate groups prevents the access to the metal ion of the water molecules and the complexes have $q = 0$. Therefore, the relaxivity of [Gd-**5**]$^-$ does not present the complications of the inner sphere component and its NMRD (**N**uclear **M**agnetic **R**elaxation **D**ispersion, i.e. the magnetic field dependence of the relaxivity) profile is rather simple and characterized by a shape and an amplitude as predicted by the translational diffusion model of pure outer sphere relaxivity (Figure 2). Fitting of the data yields a value of 4.35 Å for the distance a of closest approach of the protons of the solvent molecules, in good agreement with the value estimated from the X-ray structure.[23]

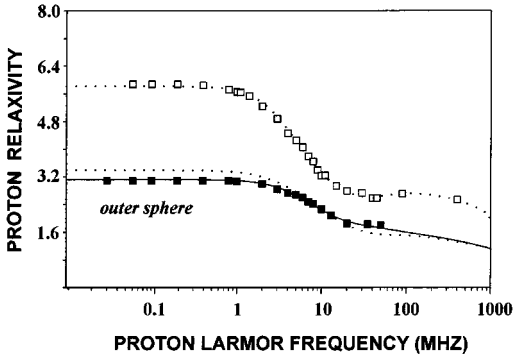


Figure 2. NMRD profiles (25 °C) of [Gd-**5**]$^-$ (filled squares) and Gd-**6** (open squares) and best-fit curves; the dotted line at the bottom is the calculated outer-sphere contribution for [Gd-**6**]$^-$

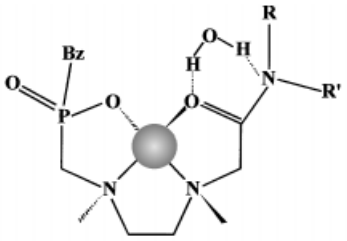
By substituting one phosphinate group with a less bulky carboxoamide **6** we obtain neutral Gd^{3+} complexes, of potential interest as low osmolality MRI CA, and furthermore we favor the access of water to the paramagnetic center by releasing part of the steric encumbrance.[24] The NMRD profile has the typical shape of $q = 1$ complexes such as [Gd-**1**]$^{2-}$, [Gd-**2**]$^-$ and Gd-**4**, but its magnitude is significantly lower. On the other hand, assuming $q = 0$ would imply for Gd-**6** either an a value shorter than the molecular radius or a dramatic change of the diffusional dynamics of its aqueous solution. The profile shows a small hump of relaxivity around 100 MHz, particularly evident at lower temperatures, which suggests a dependence of the relaxivity upon the rotational dynamics of the complex (τ_R), which substantiates the hypothesis of the presence of an "inner sphere" contribution. This increase in relaxivity observed on passing from pure outer-sphere complexes such as [Gd-**5**]$^-$ to Gd-**6** can be quantitatively explained on the basis of the presence of a tightly bound water molecule in the second coordination sphere of the metal ion at a distance of ca. 3.6 Å and with a sufficiently long lifetime. This interaction is likely to involve a hydrogen bond between the carboxoamide oxygen atom and a water molecule, which results in a metal–proton distance short enough to affect the solvent relaxation (Figure 3). Interestingly, a good correlation has been found in a series of related complexes between the r_H values derived from NMRD analysis and the average hydration state q ($0 < q < 1.3$) obtained by luminescence measurements on the Eu^{3+} derivatives.[24b]

This suggested the hypothesis that, besides the pure outer- ($q = 0$) and inner-sphere ($q = 1$) limiting cases, complexes with octadentate ligands may assume in solution any intermediate value depending on the number and nature of the hydrogen-bond acceptor groups of the ligand. In other words, this implies that fractional q values (and long r_H distances) can be correlated to the existence of a well-defined second hydration shell of the metal ion.[24b,25]



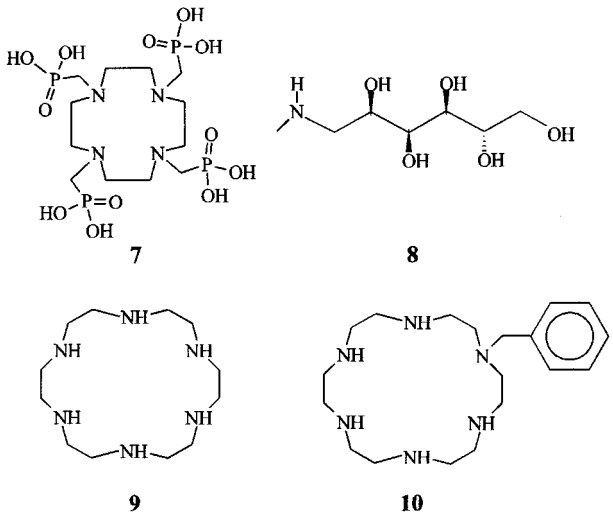


Figure 3. Schematic view of Gd-**6** showing the possible location of the second sphere water molecule

These results caused the reconsideration of the case of the anionic tetraphosphonate macrocyclic complex [Gd-**7**]$^{5-}$, whose solution structure is strictly related to that of the complexes [Ln-**5**]$^{-}$.[26] In recent years Ln^{3+} complexes of **7** (Scheme 3) have been extensively investigated as effective shift reagents for metal cations (Dy^{3+}, Tb^{3+} and Tm^{3+}), relaxation agents for MRI and probes of the charged regions of protein surfaces.

Scheme 3

The relaxation properties of [Gd-**7**]$^{5-}$ present unusual features whose interpretation has originated conflicting explanations: formation of oligomers,[27] fractional number q of coordinated waters (mixture of isomers differing in the q value),[27] one coordinated water molecule ($q = 1$) with an unusually long r_H distance.[28] The NMRD profile shows an anomalous behavior: on the basis of considerations of symmetry, rigidity and molecular dimension [Gd-**7**]$^{5-}$ is expected to show relaxivity values greater than the structurally similar [Gd-**2**]$^{-}$ over the entire frequency range. Nevertheless, the NMRD profile of [Gd-**7**]$^{5-}$ falls well below that of [Gd-**2**]$^{-}$ (but well above that of Gd-**6**) and the best-fitting analysis of the experimental data to the established theory of inner- and outer-sphere relaxivity components yielded a distance $r_H = 3.26$ Å for the inner sphere water molecule.[28] This value is significantly longer than that obtained by X-ray analysis of related macrocyclic Ln^{3+} complexes or derived from NMRD analysis and is therefore appears disputable. By considering that the phosphinate complexes of the type [Gd-**5**]$^{-}$ and Gd-**6** have $q = 0$ and that the high negative charge distributed over the eight uncoordinated oxygen atoms of the phosphonate groups may promote the formation of strong hydrogen bonds with the solvent molecules, we could interpret the relaxivity of [Gd-**7**]$^{5-}$ by considering a strong second-sphere contribution. By adopting values for a and D similar to those found for [Gd-**5**]$^{-}$ and Gd-**6**, and by allowing for the second-sphere water molecules an average distance in the range 3.3–4.0 Å, an excellent fit of the NMRD data is obtained for two solvent molecules localized at a distance of 3.89 Å. This result, although in good agreement with the available structural data for related complexes, represents only a rough estimation since there is probably an array of hydrogen-bonded solvent molecules characterized by different distances r_H and residence lifetimes τ_M. Moreover, these water molecules may present different rotational mobilities and the assumption of a single τ_R appears unlikely. What does seem reasonable is to attribute the nearly 50% increase of relaxivity of [Gd-**7**]$^{5-}$ versus [Gd-**5**]$^{-}$ to structured solvent molecules in the second coordination shell of the metal ion involved in a relatively strong bonding interaction with the oxygen atoms of the phosphonate groups. A strong support for this hypothesis was found by the measurement of the ^{17}O transverse relaxation rate (R_2^Q) as a function of temperature, a well-recognized method for obtaining information on the dynamics of the metal-bound water molecule(s). The profile of R_2^Q with temperature is typical of a $q = 0$ complex and thus confirms the absence of any *IS* water molecule for [Gd-**7**]$^{5-}$.[29] The case of [Gd-**7**]$^{5-}$ is particularly striking as it shows that a few solvent molecules held in the vicinity of the paramagnetic center through hydrogen-bonding interactions with polar groups on the ligand in a suitable geometrical arrangement provide a contribution to r_{1p} similar to that of a metal-bound water molecule. The second coordination sphere relaxation pathway depends on the same parameters as the *IS* term, and thus its efficacy is enhanced by slowing down the rotational mobility of the complex, as shown by the increase of r_{1p} by decreasing the temperature. There are some distinct features though that must be considered for optimizing r_{1p}^{2S}:

1) The value of τ_M for the currently used MRI CAs is about one or two orders of magnitude longer than the optimal value and this represents a serious obstacle to the achievement of the high relaxivity expected for dendrimeric or macromolecular derivatives and required by the new and emerging applications of MRI. Conversely, the mean lifetime of the interaction of the 2*S* water molecules, although only roughly estimated by relaxometry, is much shorter and can play a negative role in determining τ_C (Equations 3–4). Longer values of τ_M imply stronger interaction through a proper choice of the hydrogen-bond acceptor groups of the ligand and their suitable mutual spatial disposition on the Gd^{3+} complex;

2) The r_H values for *IS* water molecules show a negligible variation among Ln^{3+} chelates of different charge, coordination number and hydration state. The distance of 2*S* water molecules is a far more flexible parameter, which may assume values in the range 3.2 (*IS*) – 4.5(*OS*) Å. Because

of the $1/r_H^6$ dependence of r_{1p}, a control of this parameter, which is determined by the type and geometry of the interaction, would be of primary importance for attaining high relaxivities.

3) Unlike the *IS* case, the number of water molecules in the second shell can in principle be increased without altering the number of the donor atoms of the ligand and compromising the thermodynamic stability of the complex.

This latter possibility has been explored through the formation of ion-pair adducts between anionic Gd^{3+} chelates and positively charged organic bases. [Gd-**7**]$^{5-}$ was found to be particularly useful for this purpose: its negative charges localized on the oxygen atoms of the phosphonate groups directed outwards from the coordination cage favor multiple electrostatic interactions and formation of strong ion-pairs in solution with a variety of substrates.[29][30] It has been found that *N*-methyl-glucamine (**8**, Scheme 3) interacts with [Gd-**7**]$^{5-}$ and induces a marked relaxation enhancement of the bulk water protons that, at pH = 9 and 25 °C, is as large as 3.5 and corresponds to r_{1p} of about 15 $mM^{-1}s^{-1}$ (at 20 MHz), a value comparable to that of Gd^{3+} chelates linked to macromolecular substrates.[28] This effect was originally explained by a contribution of the exchangeable protons of the organic base maintained in the close proximity of the metal ion by the chelate-type structural organization of the substrate in the supramolecular adduct.[31] In light of the above considerations we can attribute the relaxivity gain to a high number of water molecules involved in a network of H-bonding interactions with the phosphonate groups of the complex and the hydroxyl groups of the substrate. Moreover, the coordination polyhedron of [Gd-**7**]$^{5-}$, an inverted square antiprism where the negative charges are localized about the O_4 square plane above the metal ion, suggests that the effects associated with the ion-pairing interaction could be further optimized by choosing polyammonium macrocycles of suitable size and charge as the anion receptor substrates. This hypothesis was verified in the case of exacyclen (**9**, Scheme 3). The large cavity size of **9** matches very well the square plane of [Gd-**7**]$^{5-}$ and results in a strong interaction ($K_A = 1 \times 10^4$ M; pH = 6) that is pH dependent as it depends on the protonation of both the anionic and cationic species. In the ion-pair adduct the average distance between the ring carbons of the macrocycle and the Gd^{3+} has been estimated to be 6.1 Å by ^{13}C NMR T_1 data, thus suggesting the possible presence of a number of water molecules sandwiched between the two planes, with the hydrogen atoms directed towards the paramagnetic center at a distance short enough for optimal relaxation effects (Figure 4).[29]

As pointed out above, the 2*S* relaxation mechanism is governed by the same type of parameters as *IS* and, in particular, depends strongly on rotation (τ_R). Thus, the increase of τ_R by increasing the molecular size of the complexes should provide a further relaxivity gain. This has been observed when a benzyl group is introduced into **9**. The substituted exacyclen (**10**, Scheme 3), interacts with [Gd-**7**]$^{5-}$ just as strongly but now the supramolecular adduct can be further involved in the formation of an inclusion compound

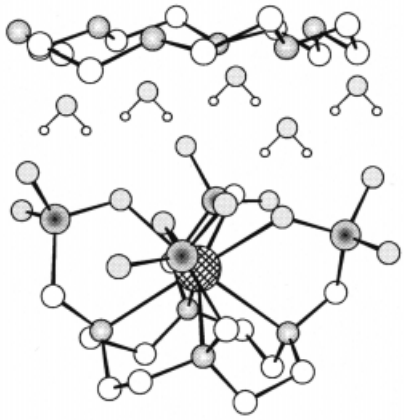

Figure 4. Model of the ion pair adduct between [Gd-**7**]$^{5-}$ and **9** showing the "sandwiched" water molecules of the second hydration shell

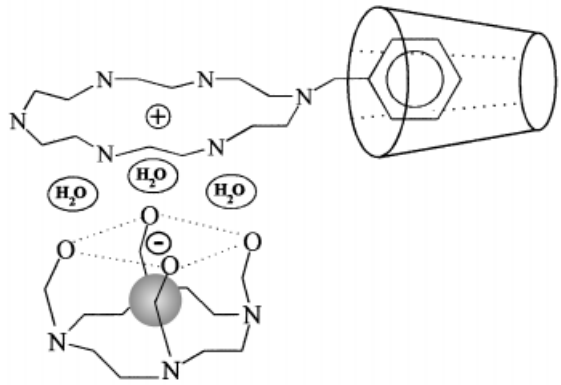
with β-cyclodextrin (β-CD), as shown in Figure 5. The noncovalent ternary complex presents a remarkably high relaxivity ($q = 0$!) of 18 $mM^{-1}s^{-1}$ at 20 MHz and 25 °C, which is entirely attributable to an optimized contribution of 2*S* hydration.[29]



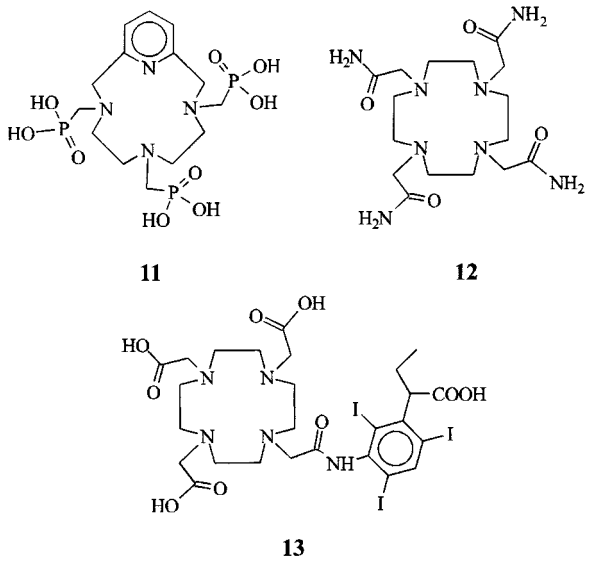


Figure 5. Schematic view of the noncovalent ternary complex between [Gd-**7**]$^{5-}$, **10** and β-cyclodextrin

From all these studies it appears evident that a very good candidate for a relaxation reagent of improved efficacy should be a complex where all the three relaxation mechanisms are operating, thus combining the properties of [Gd-**2**]$^-$ and [Gd-**7**]$^{5-}$. This interesting approach has been explored by investigating the relaxometric properties of the Gd^{3+} complex with **11**, a heptadentate macrocyclic ligand which features only three pendant arms bearing phosphonate groups (Scheme 4). As expected, the decreased denticity of the ligand allows a water molecule to occupy a coordination site of Gd^{3+}, and the relaxivity was measured to be as high as 7.7 $mM^{-1}s^{-1}$ (20 MHz, 25 °C).[32,33]

This high value of r_{1p}, about 50% higher than that of the commercial MRI CA, was shown to arise from comparable contributions of the three mechanisms: *OS*, *IS*, 2*S*. A quantitative analysis of the NMRD profile was performed under this hypothesis and an excellent fit of the data was obtained in the presence of a single *IS* water molecule at a distance of 3.06 Å from the metal ion. Moreover, in this octacoordinate complex, the exchange rate of the metal-

Scheme 4

bound water molecule is much faster than those found for enneacoordinated Gd^{3+} complexes. [Gd-**11**]$^{3-}$ represents the first example that clearly shows the feasibility and the potential of this strategy for relaxation enhancement.

Unusual, pH-dependent relaxation effects produced by second coordination shell water molecules have been observed also in the case of cationic Gd^{3+} complexes of macrocyclic tetraamide ligands such as **12** (Scheme 4).[34,35] The complexes are nine-coordinate, being bound to one water molecule, the four ring nitrogen and the amide carbonyl oxygen atoms, with a geometry corresponding to a monocapped square antiprism. At ambient pH and temperature the *IS* water exchange-lifetime, as determined by ^{17}O NMR spectroscopy, is long enough (19 μs) to strongly limit the *IS* contribution to r_{1p} and to allow a detailed study of the hydration structure and exchange dynamics. In the pH region above 7, despite the deprotonation of the bound water, which decreases the effective q value from 1 to 0.5, the relaxivity increases as a result of a base-catalyzed prototropic exchange taking place at the water coordination site. In fact, at high pH the rate of this process becomes faster than the rate of exchange of the whole water molecule, thus decreasing the effective τ_M and increasing the relaxivity. However, at pH 11, the relaxivity reaches a value (about 6 $mM^{-1}s^{-1}$) which is too high to be explained on the basis of prototropic exchange catalysis. This increase is associated with the deprotonation of the amide nitrogen (pK_a = 11.02 and 11.89) and has been shown to depend on the formation of a well-defined second hydration sphere consisting of water molecules bridging the amide group and the bound hydroxyl group through hydrogen-bond interactions (Figure 6). The profile of r_{1p} versus pH could be nicely fitted by considering two water molecules at a distance r_H = 3.6 Å.[35]

An analogous behavior was observed more recently in related macrocyclic tetra- and triamide derivatives.[36] Other examples of second coordination sphere water molecules tightly interacting with a negatively charged functional

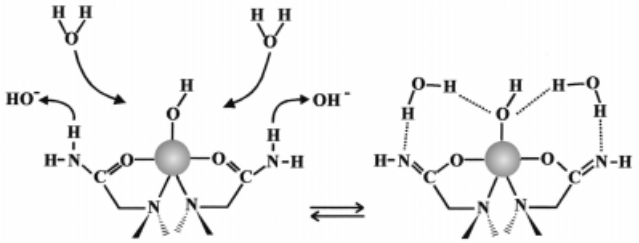

Figure 6. Deprotonation of the amide NH protons on [Gd-**12**]$^{3+}$ favors the formation of a second hydration sphere leading to a relaxivity enhancement

group of the ligand are the Gd^{3+} complexes with ligands **4** and **13** (Scheme 4). The monoaquo neutral complex [Gd-**4**] features a coordinated hydroxyl group that deprotonates at basic pH (pK_a = 11.36) with a concomitant structural rearrangement involving the loss of the coordinated water molecule. Surprisingly, this coordination equilibrium is not followed by a decrease of relaxivity which, at pH 12 (q = 0), assumes almost the same value as when measured at pH 7 (q = 1). It was concluded that the new contribution to r_{1p} measured at basic pH arises from a second coordination sphere water molecule hydrogen bonded to the alkoxide functional group whose protons were estimated to be at an average distance of 3.2 Å from Gd^{3+}.[4] Similarly, the monoamide neutral complex [Gd-**13**] presents a fairly acidic amidic proton ($pK_a \simeq 9$) and the profile of r_{1p} with pH is sensitive to this equilibrium: it passes from a value of 6.7 $mM^{-1}s^{-1}$ at pH 7 to 8.5 $mM^{-1}s^{-1}$ at pH > 10. This high relaxivity is again a consequence of the concomitant occurrence of all three relaxation mechanisms due to: one water coordinated to Gd^{3+} (*IS*) contributing about 50% of the overall relaxivity, one water molecule hydrogen bonded to the negatively charged nitrogen in the second coordination shell (2*S*, 20%), and the closely diffusing water molecules in the outer hydration sphere (*OS*, 30%).[4] It must be stressed that the relative contributions of the three mechanisms are not given as a direct result of experiments but rather derive from an analysis of the data based on a more plausible model, and therefore are to be considered as a qualitative interpretation.

Implications for MRI Contrast Agents

The relatively large body of data presented here clearly shows that 2*S* relaxation plays an important role in determining the relaxivity of aqueous solution of Gd^{3+} complexes bearing phosphonate or anionic groups next to the coordination sites of the metal ion. Can these effects be of more general importance and also partly affect the relaxivity of the currently available poly(aminocarboxylate) MRI CAs? Or can the contribution of 2*S* relaxation for these compounds be safely neglected as has so far been implicitly assumed? Some insights to correctly address these questions have recently been gained. Chen et al. have investigated the complexes of vanadyl (VO^{2+}) in order to exploit the absence of inner-sphere water molecules and analyze the re-

laxation data only in terms of *OS* and 2*S* contributions.[37–38] The rotational correlation times τ_R, one of the most important parameters for 2*S* relaxation, and τ_V were determined by ESR measurements and used to interpret the NMRD profiles. A large 2*S* contribution, predominant in the case of the DTPA complex, was found for all the compounds investigated. By making several assumptions the results from this study were then used to aid the interpretation of the NMRD profiles for the Gd^{3+} complexes with **1** and its ethoxybenzyl derivative. In the case of [Gd-**1**]$^{2-}$ the authors estimated a 2*S* contribution of roughly 25% to the overall relaxivity at the imaging fields. Though providing a qualitatively convincing interpretation of the relative role of inner-, outer- and second-sphere mechanisms to the relaxivity of the Gd^{3+}-based MRI CAs, the best-fitting procedure used yields poor values for the *IS* parameters τ_R (about two times larger than the value calculated for related complexes of similar molecular weight or estimated from ^{13}C T_1 data on diamagnetic derivatives), r_H (3.36, much longer than the values obtained from X-ray and ^{17}O NMR spectroscopic studies) and τ_M (20.9 ns, about one order of magnitude shorter than the value measured by a variable temperature ^{17}O $1/T_2$ data). We used a more direct approach to evaluate the 2*S* contribution of MRI CAs, involving a greatly reduced number of assumptions and fitting parameters, by taking advantage of a new X-ray crystal structure of [Yb-**1**]$^{2-}$ which clearly shows the three types of hydration shells of the complex.[39] In particular, a water molecule was located at a distance r_H = 3.28 Å from the ytterbium ion, strongly hydrogen bonded to the carboxylate oxygen atoms, and clearly belonging to the second coordination sphere. Six water molecules were also found in the outer coordination sphere surrounding the anionic complex, at an average r_H distance of 4.5 Å, a value in excellent agreement with that derived for the distance of closest approach *a* from NMRD analysis for the Gd^{3+} complexes with **5**, **6** and **7**. On the basis of the solid-state data we reanalyzed the NMRD profile of [Gd-**1**]$^{2-}$ on the basis of a model considering contributions from the water molecules in the three different environments (Figure 7).

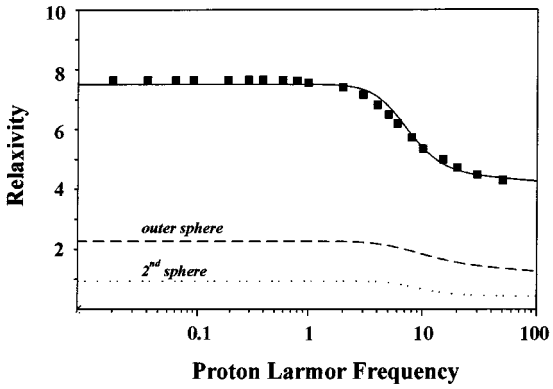

Figure 7. NMRD profile of [Gd-**1**]$^{2-}$ at 25 °C and pH = 7 showing the calculated outer- and second-sphere contributions

An excellent fitting of the relaxation data was obtained with relaxation parameters that are in very good agreement with crystallographic and NMR spectroscopic data and where: (1) the *IS* water molecule is located at 2.93 Å; (2) the 2*S* water molecule is hydrogen-bonded to the carboxylate oxygen atoms with a residence lifetime of 94 ps (at 25 °C) and at a distance of 3.28 Å, giving a contribution of about 10% to the total relaxivity at high fields; (3) the *OS* water molecules diffuse near the complex at a minimum distance of 4.5 Å.[39]

Conclusions

The qualitative picture which emerges from these data recognizes the importance of the structured water around the complexes and the potential of relaxometry to study the effects and test different hypotheses. 2*S* Solvation plays a small role in determining the relaxivity of the commonly used small poly(aminocarboxylate) Gd^{3+} chelates but its consideration is very important for a correct and more realistic interpretation of the relaxation data and for a better understanding of the structure-relaxivity relationship. Furthermore, large relaxation enhancements due to the 2*S* relaxation mechanism are possible through a careful ligand design and by exploiting strong interactions with suitable substrates (Figure 8).

Finally, the study of these effects has a direct implication in the understanding of the relaxivity changes occurring when a small Gd^{3+} chelate interacts with a macromolecule. We found that q = 0 complexes such as [Gd-**5**]$^{-}$, or its aryl methoxy-substituted derivatives, interact strongly with *bovine serum albumin* (BSA) leading to a marked relaxivity

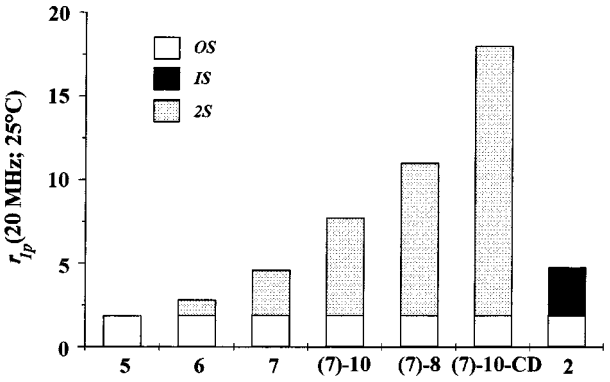

Figure 8. Plot of the relaxivity for some of the Gd^{3+} complexes discussed in this work showing the large relaxation enhancement achieved by exploiting the 2*S* mechanism

enhancement which cannot be accounted for either with an optimization of the outer sphere component of r_{1p} or with a change in the coordination number of the metal ion upon interaction with the protein.[23][40] Rather, it arises from exchangeable protons on the protein close to the interaction site of the complex and from a network of hydrogen-bonded water molecules in the second coordination sphere of Gd^{3+}. This contribution is only detected in the presence of the protein because of the reduced mobility of its well-structured hydration layer. A higher relaxation enhancement is observed in the case of the adduct of [Gd-**7**]$^{5-}$ with

BSA,[29,32] and the NMRD profile (Figure 9) is rather similar both in shape and in amplitude to those measured for $q = 1$ complexes, which shows that, even in this latter case, the 2*S* mechanism plays a major role, probably as a consequence of the limiting effect of the long τ_M value on r_{1p}^{IS}.

Acknowlegdments

I am very grateful to Prof. Silvio Aime and his group (University of Turin) for the invaluable contribution given to the work presented here. I would also like to thank Prof. David Parker (University of Durham) for a fruitful and productive collaboration. Financial support from CNR (Legge 95/95) and a travel grant from the NATO Science Program are gratefully acknowledged.

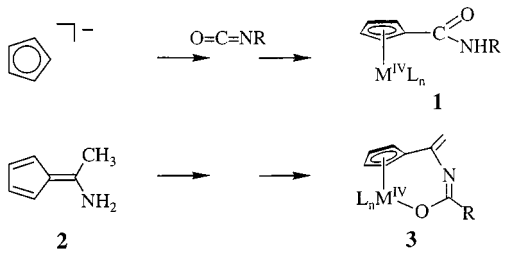
Reactions of Functional Groups at the Periphery of Group 4 Metallocene Frameworks: Selective Formation of a Cp-Bonded Azaboretidine Derivative by a Hydroboration Route

Doris Kunz,[a] Gerhard Erker,*[a] Roland Fröhlich,[a] and Gerald Kehr[a]



Dedicated to Professor Dirk Walther on the occasion of his 60th birthday

Keywords: Functionalized zirconocenes / Half-sandwich complexes / Hydroboration / Propene polymerization / Homogeneous catalysis

6-Amino-6-methylfulvene has been coupled with benzoic acid by treatment with 7-azahydroxybenzotriazole and DCC. Subsequent two-fold deprotonation, at the NH and 6-methyl groups, generated the vinylidene-bridged Cp/benzoylamido ligand **5**. Treatment of **5** with $ZrCl_4(THF)_2$ gave the *spiro*-metallocene complex **3a** (characterized by X-ray crystal structure analysis), while reaction of **5** with $(Et_2N)_2ZrCl_2(THF)_2$ yielded the bridged half-sandwich complex **3b**. Treatment of **3a** with two molar equivalents of the strongly electrophilic borane $HB(C_6F_5)_2$ resulted in hydroboration of the exocyclic C=C double bond with concomitant intramolecular N–B adduct formation to yield the azaboretidine-type systems **7** (three diastereoisomers, one of which has been characterized by X-ray diffraction analysis). Similarly, hydroboration of **3b** with $HB(C_6F_5)_2$ yielded the azaboretidine derivative **9**. Activation of the complexes **7** and **9** with methylalumoxane led to active homogeneous Ziegler-type propene polymerization catalysts.

Introduction

The chemistry of functional groups attached to Group 4 metallocene frameworks is important, e.g. for extending the structural scope of the "constrained geometry" Ziegler catalysts,[1] but as yet remains little developed. The introduction of functionalities typically used in organic chemistry is often difficult to accomplish by the conventional methods employed in organic synthesis due to the sensitivity of the organometallic Group 4 metal systems to hydrolytic conditions as well as to acidic or basic reaction environments. However, that increased efforts are being made to find suitable conditions and methods to overcome this apparent deficiency in the organic chemistry of Group 4 metallocenes is evident from recent literature.[2,3]

Scheme 1. Syntheses of functionalized Group 4 metal Cp-complexes

We have recently described several ways of introducing carboxamide-derived functional groups at the Cp rings of zirconocene or titanocene complexes (see Scheme 1).[4] A fulvene route has made functionalized systems such as **3** readily available.[5] It was conceivable that the azadiene moiety in **3**, the framework of which is perpendicularly oriented with respect to the metallocene backbone, could be used as a target for a hydrometallation reaction.[6] This posed the question as to whether the two parts of this conjugated metallocene side-chain would react independently or jointly with a suitable H–[M] reagent. Examples of zirconium complexes incorporating this ligand system have now been treated with the strongly electrophilic borane $HB(C_6F_5)_2$ (**6**, "Piers' borane"),[7] which has opened a simple route to novel organometallic azaboretidine derivatives exhibiting interesting structural and stereochemical properties as well as useful features in catalysis.

Results and Discussion

The synthesis of the ligand system used in this study started from 6-amino-6-methylfulvene (**2**), which, in turn, was prepared by amine exchange of 6-dimethylamino-6-methylfulvene by treatment with NH_3.[8] The aminofulvene **2** was then *N*-benzoylated. This was cleanly achieved by employing a coupling method used in peptide chemistry.[9] In a series of experiments it was found that benzoic acid was best activated for this purpose by treatment with 7-aza-hydroxybenzotriazole with subsequent addition of dicyclohexylcarbodiimide.[9b] The resulting active ester was then treated with 6-amino-6-methylfulvene **2** and triethylamine to cleanly afford the benzoylated product **4** in $> 60\%$ isolated yield. Double deprotonation of **4**, at the NH group and at the 6-CH_3 substituent,[5,10] was achieved by reaction with two molar equivalents of LDA in diethyl ether. The corresponding dianionic reagent **5** was not isolated but was

generated in situ and used directly for the preparation of the respective zirconium complexes.

Treatment of the dianion **5** with zirconium tetrachloride resulted in replacement of all four chloride ligands at the metal center with the formation of the *spiro*-metallocene product **3a**. In solution, complex **3a** shows the spectroscopic features of a C_2-symmetric, and hence chiral, framework. This leads to the observation of signals due to four pairs of diastereotopic cyclopentadienyl CH units in the ^{1}H- and ^{13}C-NMR spectra ([D$_6$]benzene, ^{1}H: δ = 5.74, 5.65, 5.61, 5.47; ^{13}C: δ = 120.9, 112.7, 108.3, 105.4). The ^{1}H-NMR signals of the *exo*-methylene group (C=CH$_2$) appear at δ = 5.38 and 5.00 (^2J = 1.1 Hz).

The organometallic *spiro*-complex **3a** was characterized by X-ray crystal structure analysis. It shows an approximately C_2-symmetric framework. Two monosubstituted η^5-Cp ligands and two imidato oxygen atoms are coordinated to zirconium in a pseudo-tetrahedral arrangement. The Zr–O bonds are rather long at 2.032(2) Å (Zr–O9) and 2.047(2) Å (Zr–O19). It would seem that the cyclic structure effectively prevents any pronounced metal–oxygen π-interaction.[11] The corresponding Zr–O9–C8 and Zr–O19–C19 angles are thus rather small [132.2(2)° and 134.2(2)°, respectively] for such a situation.[12] The adjacent C8–N7 bond length [1.277(5) Å] is in the appropriate range for a nitrogen–carbon double bond [C18–N17: 1.281(5) Å], while the adjacent C–O linkages [C8–O9: 1.327(4) Å; C18–O19: 1.335(4) Å] are in the typical C(sp^2)–O σ-bond range.[13] Characterization of **3a** as an *O*-bonded Zr-iminocarboxylate thus seems warranted (see Scheme 2 and Figure 1).

Scheme 2. Synthesis of the hydroboration compounds **7** and **9**

Treatment of the salt **5** with the reagent (Et$_2$N)$_2$ZrCl$_2$(THF)$_2$[14] resulted in selective replacement of the two chloride ligands to form the half-sandwich complex **3b**. The spectral data of **3b** indicate analogous bonding of the ligand system to zirconium as that seen in **3a**, i.e. through both the C$_5$H$_4$ moiety and the pendant imidato substituent, the latter being κ-*O*-bonded. The Cp–C(=CH$_2$)–N=C(Ph)–O ligand gives rise to characteristic NMR signals at δ = 160.7 (^{13}C of the imidato carbonyl carbon) and at δ = 5.38, 5.10 (^{1}H of the =CH$_2$ group, ^2J = 1.5 Hz). In complex **3b**, only two CH resonances of the monosubstituted Cp ligand are seen (^{1}H: δ = 5.97, 5.95; ^{13}C: δ = 110.64, 110.56). The complex is prochiral at the pseudotetrahedral zirconium center. Therefore, a single set of NCH$_2$CH$_3$ NMR resonances is observed, although the NCH$_2$ protons are diastereotopic.

The organometallic *spiro*-complex **3a** was treated with two molar equivalents of the electrophilic borane HB(C$_6$F$_5$)$_2$ in benzene solution. The reaction reached completion within 2 days at ambient temperature and a product fraction of low solubility (ca. 16%) precipitated from the reaction medium. Crystallization from [D$_6$]benzene gave single crystals of this material suitable for X-ray crystal structure analysis. This showed the crystals to be composed of a single isomerically pure 2:1 adduct of the borane with **3a**, resulting from addition of the borane to the exocyclic carbon–carbon double bonds of the pendant –C(=CH$_2$)–N=C(Ph)–O moiety. This hydroboration proceeded with complete *anti*-Markovnikov orientation, as is usual. Thus, the B(C$_6$F$_5$)$_2$ group was attached at the former olefinic methylene group, while the hydrogen was attached at C$_α$. The most remarkable structural feature of the hydroboration product **7a** is the strong coordination of the =N(R)

nitrogen atom to the adjacent electrophilic boron center.[15] This leads to the formation of two four-membered heterocycles in the approximately C_2-symmetric metallocene product. The corresponding bond lengths (in Å) at the substituted azaboretidine-type ring systems are 1.597(10) (B1–N13), 1.492(9) (N13–C14), 1.640(12) (B1–C20), 1.301(9) (N13–C12). The corresponding bond angles measure 83.9(5)° (C20–B1–N13), 92.0(5)° (B1–N13–C14), 126.8(6)° (C12–N13–C14), 138.7(6)° (C12–N13–B1), and 90.8(5)° (N13–C14–C20) (the approximately symmetry-equivalent second azaboretidine ring shows similar values, see Figure 2). The remaining bonding parameters of the framework of complex **7a** resemble those of its immediate precursor **3a**. In **7a**, the O11–Zr–O51 angle measures 98.3(2)°. The bond angles at the two oxygen atoms are 144.4(5)° (Zr–O11–C12) and 143.4(5)° (Zr–O51–O52) and the corresponding metal–oxygen bond lengths were determined as 2.041(5) Å (Zr–O11) and 2.043(5) Å (Zr–O51), respectively.

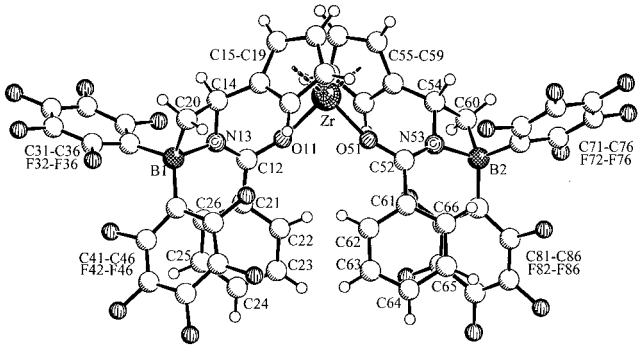

Figure 2. Molecular structure of **7a** showing the non-systematic atom numbering scheme; selected bond lengths [Å] and angles [°]; additional values are given in the text: Zr–O11 2.041(5), Zr–O51 2.043(5), Zr–$C_{Cp(15–19)}$ 2.485(8), Zr–$C_{Cp(55–59)}$ 2.479(8), C12–O11 1.300(8), C52–O51 1.305(7), C12–N13 1.301(9), C52–N53 1.278(8), C12–C21 1.473(10), C52–C61 1.493(9), N13–C14 1.492(9), N53–C54 1.493(8), C14–C20 1.548(10), C54–C60 1.539(10), C14–C15 1.483(10), C54–C55 1.498(9), N13–B1 1.597(10), N53–B2 1.602(9), C20–B1 1.640(12), C60–B2 1.647(11), B1–C31 1.634(12), B2–C71 1.617(11), B1–C41 1.621(11), B2–C81 1.619(11); O11–Zr–O51 98.3(2), Zr–O11–C12 144.4(5), Zr–O51–C52 143.4(5), O11–C12–N13 122.0(6), O51–C52–N53 123.4(6), O11–C12–C21 116.8(6), O51–C52–C61 114.7(6), C21–C12–N13 121.2(6), C61–C52–N53 121.8(6), C12–N13–C14 126.8(6), C52–N53–C54 126.9(5), N13–C14–C20 90.8(5), N53–C54–C60 91.8(5), N13–C14–C15 118.7(5), N53–C54–C55 118.2(5), C15–C14–C20 117.6(7), C55–C54–C60 117.7(7), C12–N13–B1 138.7(6) C52–N53–B2 141.2(5), C14–N13–B1 92.0(5), C54–N53–B2 90.7(5), C14–C20–B1 88.3(6), C54–C60–B2 87.4(6), N13–B1–C20 83.9(5), N53–B2–C60 84.2(5), N13–B1–C31 112.5(7), N53–B2–C71 110.8(6), N13–B1–C41 113.3(6), N53–B2–C81 113.4(6), C20–B1–C31 107.5(6), C60–B2–C71 107.4(6), C20–B1–C41 118.5(7), C60–B2–C81 118.2(7), C31–B1–C41 116.7(7), C71–B2–C81 117.9(6)

The stereochemistry of the complexes **7** is interesting. The *spiro*-metallocene framework of **7** (and also that of **3a**) is axially chiral. The hydroboration reaction introduced two new chiral centers at the carbon atoms α to the Cp rings (C14 and C54 in Figure 2). Therefore, a mixture of four chiral diastereomers could, in principle, have been formed (2^3 stereoisomers), each of course as a racemate. However, in the specific system **7** under consideration here, the two newly formed chiral carbon centers are topologically equivalent. Therefore, two of the four possible diastereomers are in fact identical. It thus remains that three diastereoisomers could possibly be formed upon hydroboration of the *spiro*-metallocene **3a**, their relative configurations being (a*R*,*S*,*S*)* (**7a**), (a*R*,*R*,*S*)* [**7b**, identical to (a*R*,*S*,*R*)*], and (a*R*,*R*,*R*)* (**7c**).[16] The single isomer found in the crystal conformed to the first case, i.e. the (a*R*,*S*,*S*)* diastereoisomer **7a** was characterized by X-ray diffraction analysis.

The hydroboration reaction of **3a** with $HB(C_6F_5)_2$ was, however, far from diastereoselective. Workup of the mother liquor after removal of the first batch of precipitated product gave a major fraction (ca. 40% yield) that was found to contain all three products **7a**, **7b**, and **7c** in a 2:10:3 ratio. This ratio may not accurately reflect the actual diastereoselectivity of the hydroboration reaction under the employed reaction conditions due to the separation of isomers during the workup, but it is rather close to the expected statistical ratio. This probably indicates that the two new stereogenic centers are formed independently of one another. The C_1-symmetric (a*R*,*R*,*S*)* isomer **7b** could readily be distinguished from its C_2-symmetric counterparts **7a** and **7c** by the characteristic splitting of the respective pairs of $^1H/^{13}C$-NMR resonances. For instance, complex **7b** shows a total of eight equally intense cyclopentadienyl methine proton ^1H-NMR signals (at δ = 7.16, 6.89, 6.60, 6.56, 6.51, 6.41, 6.29, 6.24 in [D_2]dichloromethane), whereas for **7a** and **7c** only four such resonances are seen in each case (**7a**: δ = 6.81, 6.55, 6.46, 6.37; **7c**: δ = 7.32, 7.27, 6.54, 6.19).

Hydroboration of the cyclic half-sandwich complex **3b** with $HB(C_6F_5)_2$ proceeds in a similar manner, but is of course stereochemically much simpler because, as expected, only a single isomerically pure product is obtained. H–[B] addition occurs cleanly (and regioselectively) at the *exo*-methylene functionality of the organometallic ring system, and the product **9** again contains a strong N–B interaction. This is evident from the characteristic ^{11}B-NMR shift at δ = –2.2 (**7a**: δ = –1.1). Moreover, ^{15}N-NMR data have proved very useful in characterizing the obtained structural type.[17] Complex **9** shows the ^{15}N-NMR resonance of the planar tricoordinate $=N^+$ nitrogen atom of the azaboretidine ring at δ = –205, very similar to the corresponding signal of complex **7a** (δ = –209). In contrast, the ^{15}N-NMR signals of the sp^2-hybridized dicoordinate nitrogen atoms in the starting materials **3a** and **3b** are seen at δ = –148 and δ = –145, respectively.

Complex **9** contains a single chiral center, i.e. at the tertiary carbon atom of the azaboretidine ring. Therefore, a set of four separated methine CH resonances due to the monosubstituted Cp ring are observed in the ^1H-NMR spectrum (at δ = 6.32, 6.15, 5.89, 5.82). The two metal-bonded $–N(CH_2CH_3)_2$ groups are diastereotopic, and thus give rise to two ^{15}N-NMR signals at δ = –171 and –187 and two ^1H-NMR methyl signals at δ = 0.85 and 0.73. The ethyl groups at each of the apparently trigonal-planar nitrogens behave homotopically, but the protons of each $–N(CH_2–)$ group are diastereotopic, giving rise to a total of four separated *AB*X_3 multiplets (at δ = 3.24, 3.04, 2.97, and 2.95 in [D_6]benzene at 298 K).

Under carefully controlled conditions, we were able to observe experimentally the formation of a 1:1 adduct (**8**) between the strongly electrophilic borane $HB(C_6F_5)_2$ and the metal complex **3b**. The addition product **8** was obtained in [D_8]toluene solution after mixing the two components at low temperature (–78 °C), allowing them to react briefly at ambient temperature (1 min), and then cooling the mixture to ca. 5 °C to record the NMR spectra. Under these conditions, complex **8** is relatively stable and is only slowly converted into the final product **9**. In **8**, the C=CH_2 double bond conjugated to the Cp ring remains intact [^{1}H NMR: δ = 5.41, 5.04; ^{13}C NMR: δ = 141.3, 109.6 (C=CH_2)]. The ^{13}C-NMR resonance of the C=N moiety is seen at δ = 177.5, i.e. downfield shifted relative to the starting material **3b** (δ = 160.7)[15] and no proton is attached to this carbon. The ^{15}N-NMR signal of **8** is found to be considerably shifted (**8**: δ = –204; **3b**: δ = –145). The broad ^{11}B-NMR signal at δ = –10.9 is indicative of the presence of a tetravalent borane adduct. The combined spectroscopic evidence indicates simple adduct formation between $HB(C_6F_5)_2$ and the imidato nitrogen atom of **3b** to give **8**. Complex **8** slowly undergoes conversion into the final hydroboration product **9**. Geometrically, this could take place by an intramolecular rearrangement process, since the large bending of the Cp–C(=CH_2)–N=C 2-azadiene unit from planarity [θ C61–C6–N7–C8 in the related system **3a** is –48.1(4)°] would probably allow H-transfer from boron to the trisubstituted sp^2 carbon. However, on electronic grounds, we regard it as more likely that the final hydroboration to give **9** may simply be preceeded by a reversible formation of the $HB(C_6F_5)_2$ adduct **8**.

The organometallic hydroboration products **7** and **9** are quite stable and can be used as homogeneous Ziegler-type catalyst precursors. Exploratory propene polymerization experiments were carried out by activating the respective catalyst precursors by treatment with a large excess of methylalumoxane (see Table 1).[18] Under the typical reaction conditions (for details, see the Experimental Section), the mixture of diastereomers **7a**–**c** gave a medium activity propene polymerization catalyst upon such MAO activation. A similar activity was obtained by employing the pure diastereoisomer **7a** as a precursor. It is clear that the Zr–O linkage in **7** must be cleaved during its conversion into an active catalyst. Consequently, pre-activation with excess MAO solution in toluene resulted in a slightly increased catalyst activity in these cases. Atactic polypropylene was generated in the experiments employing **7**.

Table 1. Propene polymerization experiments with the **3**, **7**, **9**/MAO systems

Precursor (mg/μmol)	Al/Zr ratio	PP[a]	activity[b]	σ[c]
3a (20/39)	0.82×10^3	[d]	–	–
3a (21/41)[e]	0.78×10^3	[d]	–	–
3b (23/52)	0.62×10^3	[d]	–	–
7 (20/17)	1.9×10^3	0.71	11	0.55
7 (15/12)[e]	2.6×10^3	0.71	14	0.57
7a (16/13)	2.4×10^3	0.66	12	0.50
7a (17/14)[e]	2.3×10^3	1.3	23	0.55
9 (20/25)	1.3×10^3	2.4	24	0.20

[a] g of polypropylene isolated. – [b] a in g polymer/mmol [Zr]·bar·h. – [c] Probability of obtaining an m diad under chain-end control. – [d] Traces. – [e] Pre-activation of the precursor with 2.5 mL of a 10% (1.6 M) methylalumoxane solution in toluene for 15 min.

The diethylamido ligands of **9** are seemingly more readily displaced during the activation process with MAO. Without pre-treatment, polypropylene was obtained with a medium activity (a = 24). In this case, the obtained polypropylene turned out to be slightly syndiotactic [with σ = 0.2 (where σ expresses the probability of having an m diad formed at the catalyst center by stereochemical chain-end control)], which probably just represents another example of an ordinary behavior of such a catalyst system in the high temperature regime.[19]

In contrast to **7** and **9**, similar treatment of their unsaturated precursors **3a** and **3b** did not produce active Ziegler-type catalysts for propene polymerization under the applied conditions. This may be due to the dominant role played by the nucleophilic imidato nitrogen center in these complexes, which renders them liable to form reasonably strong adducts with Lewis acidic reagents [for example, the $HB(C_6F_5)_2$ adduct described above]. One might speculate that such complex formation takes place preferentially upon treatment of **3a** or **3b** with the bulky MAO Lewis acid, leading to strong steric shielding of the potential catalytic centers in these adducts. On the basis of our observations, we conclude that hydroboration of these systems leading to azaboretidine formation very effectively inhibits the catalyst deactivation. We have thus, in effect, employed the $HB(C_6F_5)_2$ reagent as an organometallic protecting group that has facilitated conversion of the functionalized (CpX)Zr systems to active homogeneous Ziegler-type catalyst systems without complete loss of the pendant functional groups at the central organometallic framework. We are hopeful that the use of such protective groups might open ways of using a variety of functionalized Group 4 metal complexes in homogeneous Ziegler catalysis and related catalytic processes. Such studies are being actively pursued in our laboratory.

Experimental Section

All the described compounds (other than **4**) are air- and moisture-sensitive. They were thus prepared and handled under argon atmosphere using Schlenk-type glassware or in an argon-filled glovebox. Solvents (including deuterated solvents) were dried and distilled under argon prior to use. – NMR spectra were recorded on Varian Unity Plus, Bruker AMX 400, Bruker ARX 300, and Bruker AC 200 P-FT-NMR spectrometers. Spectroscopic characterization usually included ^{1}H,^{1}H GCOSY, ^{1}H,^{13}C (G)HMBC, and (G)HMQC experiments, even where not explicitly stated. – IR spectra were recorded on a Nicolet 5 DXC FT-IR spectrometer in KBr pellets or from films between NaCl plates. – Elemental analyses were carried out using a Foss Heraeus CHN-O-Rapid analyser, while DSC measurements were made on a Texas Instruments DSC 2010. – X-

ray crystal structure analyses: Data sets were collected with Enraf–Nonius CAD4 and Nonius KappaCCD diffractometers. Programs used: data collection: Express and Collect; data reduction: MolEN or Denzo-SMN; structure solution: SHELXS-86; structure refinement: SHELXL-93 and SHELXL-97; graphics: SCHAKAL.[20] – 7-Aza-hydroxybenzotriazole (HOAt),[9b] 6-amino-6-methylfulvene,[8] $ZrCl_4(thf)_2$,[21] $ZrCl_2(NEt_2)_2(thf)_2$,[14] and $HB(C_6F_5)_2$[7] were prepared according to literature procedures.

Preparation of 6-Amido-*N*-benzoyl-6-methylfulvene (4): To a yellow suspension of benzoic acid (2.44 g, 20.0 mmol) and 7-aza-hydroxybenzotriazole (2.72 g, 20.0 mmol) in dichloromethane (50 mL) at 0 °C was added dicyclohexylcarbodiimide (4.13 g, 20.0 mmol). The resulting suspension was stirred for 30 min at 0 °C until the active ester and dicyclohexylurea had been formed and the yellow colour of the suspension had turned to white. The suspension was then filtered into a cold (0 °C) solution of 6-amino-6-methylfulvene (2.14 g, 20.0 mmol) and triethylamine (7.0 mL, 50 mmol) in dichloromethane (30 mL). The filter cake was washed with 30 mL of dichloromethane and the filtrate was combined with the fulvenic solution. The resulting brown reaction mixture was allowed to warm to room temperature and then stirred for 3 days. It was subsequently washed with 5% aq. sodium bicarbonate solution (3 × 50 mL) and with water (3 × 30 mL). The organic phase was dried with magnesium sulfate and the solvent was removed in vacuo. The residual brown oil was purified by chromatography on silica gel 60, eluting with a mixture of diethyl ether/pentane (1:3), to which 1% (*v*/*v*) of *N*,*N*-dimethylethylamine had been added. Removal of the solvent in vacuo afforded 2.78 g (66%) of the product in the form of orange needles. DSC: 78 °C (m.p.), 131 °C (dec.). – $C_{14}H_{13}NO$ (211.26): calcd. C 79.59, H 6.20, N 6.63; found C 79.32, H 6.38, N 6.35. – IR (KBr): $\tilde{\nu}$ = 3304, 1659, 1633 cm^{-1}. – ^1H NMR (400.1 MHz, [D$_2$]dichloromethane, 300 K): δ = 8.62 (br. s, 1 H, NH), 7.87 (m, 2 H, *o*-Ph), 7.62 (m, 1 H, *p*-Ph), 7.53 (m, 2 H, *m*-Ph), 6.65, 6.53 (each m, each 1 H, α-Fulv), 6.49, 6.43 (each m, each 1 H, β-Fulv), 2.81 (s, 3 H, CH_3). – ^{13}C NMR (100.6 MHz, [D$_2$]dichloromethane, 300 K): δ = 166.0 (C=O), 146.4 (C-6), 135.1 (*i*-Ph), 133.3 (*p*-Ph), 130.8, 129.5 (β-Fulv), 130.3 (C-1), 129.7 (*m*-Ph), 128.0 (*o*-Ph), 122.6, 115.2 (α-Fulv), 15.9 (CH_3).

Preparation of Bis{η^5:κ*O*-1-(*N*-benzoylamido)ethenylcyclopentadienyl}zirconium (3a): Compound **4** (1.30 g, 6.15 mmol) and lithium diisopropylamide (1.32 g, 12.3 mmol) were weighed into a Schlenk vessel, which was subsequently cooled to –78 °C, whereupon diethyl ether (100 mL) was added. The cooling bath was removed and the suspension was stirred for 2 h while slowly warming to room temperature. The reaction was seen to be complete by the appearance of a light-yellow precipitate of the dilithium salt. The suspension was then cooled to –50 °C and a suspension of tetrachlorozirconium–bis(tetrahydrofuran) (1.16 g, 3.07 mmol) in diethyl ether (50 mL) was added. The cooling bath was removed once more, allowing the suspension to warm to room temperature, and stirring was continued for 12 h. The resulting yellow suspension was then concentrated to dryness and the remaining yellow powder was extracted with diethyl ether (5 × 100 mL). The ethereal solution was filtered and the filtrate was concentrated in vacuo. The product was isolated as a deep-yellow solid; yield 641 mg (41%). – DSC: 189 °C (m.p., followed by decomp.). – IR (KBr): $\tilde{\nu}$ = 1616, 1590, 1560 cm^{-1}. – ^1H NMR (599.9 MHz, [D$_6$]benzene, 298 K): δ = 8.31 (m, 4 H, *o*-Ph), 7.15 (m, 6 H, *m,p*-Ph), 5.74 (m, 2 H, 2-H), 5.65 (m, 2 H, 5-H), 5.61 (m, 2 H, 3-H), 5.47 (m, 2 H, 4-H), 5.38 (d, $^2J_{HH}$ = 1.1 Hz, 2 H, C=CH_2^{cis}), 5.00 (d, $^2J_{HH}$ = 1.1 Hz, 2 H, C=CH_2^{trans}). – ^{13}C NMR (gated decoupled) (150.8 MHz, [D$_6$]benzene, 298 K): δ = 162.9 (s, OC=N), 146.1 (s, *C*=CH_2), 135.6 (m, *i*-Ph), 130.8 (dm, $^1J_{CH}$ = 160 Hz, *p*-Ph), 128.9 (dm, $^1J_{CH}$ = 159 Hz, *o*-Ph), 128.3 (dm, $^1J_{CH}$ = 160 Hz, *m*-Ph), 120.9 (dm, $^1J_{CH}$ = 175 Hz, C-3), 112.7 (dm, $^1J_{CH}$ = 174 Hz, C-2), 108.3 (dm, $^1J_{CH}$ = 173 Hz, C-4), 105.4 (dm, $^1J_{CH}$ = 173 Hz, C-5), 104.8 (ps. t, $^1J_{CH}$ = 159 Hz, C=*C*H$_2$), the resonance of C-1 is obscured by the solvent signal. – ^{15}N,^1H GHMBC (60.8/599.9 MHz, [D$_6$]benzene): δ^{15}N/δ^{1}H = –148/5.38 (C=N/C=CH_2^{cis}), –148/5.00 (C=N/C=CH_2^{trans}).

X-ray Crystal Structure Analysis of 3a: Formula $C_{28}H_{22}N_2O_2Zr$, M_r = 509.70, yellow crystal, 0.35 × 0.25 × 0.10 mm, *a* = 23.282(2) Å, *b* = 11.318(1) Å, *c* = 17.345(3) Å, β = 96.11(1)°, *V* = 4544.5(10) Å^3, ρ_{calcd} = 1.490 g cm^{-3}, *F*(000) = 2080 e, μ = 5.12 cm^{-1}, empirical absorption correction based on ψ scan data (0.951 ≤ *C* ≤ 0.999), *Z* = 8, monoclinic, space group *C*2/*c* (No. 15), λ = 0.71073 Å, *T* = 223 K, 4771 reflections collected (±*h*, –*k*, +*l*), $[(\sin\theta)/\lambda]_{max}$ = 0.62 Å^{-1}, 4610 independent and 3377 observed reflections [$I \geq 2\sigma(I)$], 298 refined parameters, *R* = 0.037, wR^2 = 0.106, max. residual electron density 0.68 (–0.63) eÅ^{-3}.

Preparation of Bis{dimethylamido}{η^5:κ*O*-1-(*N*-benzoylamido)-ethenylcyclopentadienyl}zirconium (3b): Compound **4** (1.10 g, 5.21 mmol) and lithium diisopropylamide (1.12 g, 10.4 mmol) were weighed into a Schlenk vessel, which was then cooled to –78 °C, whereupon diethyl ether (100 mL) was added. The cooling bath was removed and the suspension was stirred for 2 h while slowly warming to room temperature. The suspension was then cooled to –50 °C, whereupon $(Et_2N)_2ZrCl_2(THF)_2$ (2.35 g, 5.21 mmol) in 50 mL of diethyl ether was added. The cooling bath was then removed once more, allowing the mixture to warm to room temperature, and stirring was continued for 12 h. The solvent was evaporated in vacuo from the resulting brown suspension and the residual brown oil was extracted with 150 mL of pentane. The light-brown suspension thus obtained was filtered and the filtrate was concentrated in vacuo to leave 1.88 g (81%) of a very viscous red-brown oil. – $C_{22}H_{31}N_3OZr$ (444.73): calcd. C 59.42, H 7.03, N 9.45; found C 58.92, H 6.93, N 9.39. – IR (NaCl): $\tilde{\nu}$ = 1609, 1591, 1558 cm^{-1}. – ^1H NMR (599.9 MHz, [D$_6$]benzene, 298 K): δ = 8.50 (m, 2 H, *o*-Ph), 7.23 (m, 2 H, *m*-Ph), 7.18 (m, 1 H, *p*-Ph), 5.97, 5.95 (each m, each 2 H, Cp), 5.38 (m, 1 H, C=CH_2), 5.10 (ps. d, $^2J_{HH}$ = 1.5 Hz, 1 H, C=CH'$_2$), 3.16 (ABX_3, $^{2/3}J_{HH}$ = 7.2 Hz, 4 H, C*H*$_2$CH$_3$), 3.12 (ABX_3, $^{2/3}J_{HH}$ = 6.6 Hz, 4 H, C*H'*$_2$CH$_3$), 0.89 (t, $^3J_{HH}$ = 6.9 Hz, 12 H, CH$_2$C*H*$_3$). – ^{13}C NMR (gated decoupled) (150.8 MHz, [D$_6$]benzene, 298 K): δ = 160.7 (t, $^3J_{CH}$ = 4 Hz, OC=N), 147.1 (s, *C*=CH_2), 136.6 (t, $^3J_{CH}$ = 7 Hz, *i*-Ph), 130.4 (dm $^1J_{CH}$ = 159 Hz, *p*-Ph), 129.0 (dm, $^1J_{CH}$ = 161 Hz, *o*-Ph), 128.1 (dm, $^1J_{CH}$ = 159 Hz, *m*-Ph), 126.0 (m, *i*-Cp), 110.64, 110.56 (each dm, each $^1J_{CH}$ = 171 Hz, Cp), 104.4 (ps. t, $^1J_{CH}$ = 159 Hz, C=*C*H$_2$), 44.1 (t, $^1J_{CH}$ = 131.7 Hz, N*C*H$_2$CH$_3$), 15.7 (qt, $^1J_{CH}$ = 125 Hz, $^2J_{CH}$ = 3 Hz, NCH$_2$*C*H$_3$). – ^{15}N,^1H GHMBC (60.8/599.9 MHz, [D$_6$]benzene, 298 K): δ^{15}N/δ^{1}H = –145/5.10 (C=*N*/C=C*H'*$_2$), –192/0.89 (*N*CH$_2$CH$_3$/C*H*$_2$CH$_3$).

Reaction of 3a with $HB(C_6F_5)_2$ – Formation of 7: Compound **3a** (255 mg, 500 μmol) and bis(pentafluorophenyl)borane (346 mg, 1.0 mmol) were weighed into a Schlenk vessel, which was then cooled to 0 °C, whereupon benzene (10 mL) was added. The resulting orange solution was allowed to warm to room temperature and stirred for 2 days. The yellow suspension obtained was filtered and the collected light-yellow precipitate was dried in vacuo yielding 102 mg (16%) of isomer **7a**. Concentration of the filtrate to dryness afforded a yellow powder (235 mg, 40% overall yield), which was found to contain the three diastereomers **7a**, **7b**, and **7c** in a ratio of 2:10:3.

Isomer 7a: $C_{52}H_{24}B_2F_{20}N_2O_2Zr \cdot C_6H_6$ (1279.70): calcd. C 54.44, H 2.36, N 2.19; found C 54.07, H 2.44, N 1.98. – DSC: 257 °C (m.p.), 267 °C (dec.). – ^1H NMR (599.9 MHz, [D$_2$]dichloromethane, 298 K): δ = 7.44 (ps. d, $^3J_{HH}$ = 7.78 Hz, 4 H, *o*-Ph), 7.34

(ps. t, $^3J_{HH}$ = 7.5 Hz, 2 H, *p*-Ph), 7.07 (m, 4 H, *m*-Ph), 6.81 (m, 2 H, Cp_β), 6.55 (m, 2 H, Cp_α), 6.46 (m, 2 H, Cp_α), 6.37 (m, 2 H, Cp_β), 5.20 (ps. t, $^3J_{HH}$ = 9.0 Hz, 2 H, NCH), 1.80 (ps. t, $^{2/3}J_{HH}$ = 10.5 Hz, 2 H, CH_2B), 1.67 (ps. t, $^{2/3}J_{HH}$ = 10.5 Hz, 2 H, CH'_2B). – ^{13}C NMR (gated decoupled) (150.8 MHz, [D$_2$]dichloromethane, 298 K): δ = 166.2 (s, OC=N), 136.6 [br. m, obscured by the carbon resonance of $B(C_6F_5)$, *i*-Cp], 133.1 (dt, $^1J_{CH}$ = 161 Hz, $^3J_{CH}$ = 8 Hz, *p*-Ph), 129.5 (d ps. t, $^1J_{CH}$ = 161 Hz, $^3J_{CH}$ = 7 Hz, *o*-Ph), 128.9 (t, $^3J_{CH}$ = 7 Hz, *i*-Ph), 128.1 (dd, $^1J_{CH}$ = 162 Hz, $^3J_{CH}$ = 7 Hz, *m*-Ph), 121.6 (dm, $^1J_{CH}$ = 175 Hz, Cp_β), 113.4 (dm, $^1J_{CH}$ = 175 Hz, Cp_α), 111.5 (dm, $^1J_{CH}$ = 175 Hz, Cp_β), 107.6 (dm, $^1J_{CH}$ = 174 Hz, Cp_α), 59.1 (d, $^1J_{CH}$ = 145 Hz, NCH), 27.2 (tm, $^1J_{CH}$ = 126 Hz, CH_2B). – ^{11}B NMR (64.2 Hz, [D$_2$]dichloromethane, 300 K): δ = –1.1 ($\nu_{1/2}$ = 670 Hz). – ^{15}N,^{1}H GHMBC (60.8 MHz/599.9 MHz, [D$_2$]dichloromethane, 298 K): $\delta^{15}N/\delta^1H$ = –209.3/5.20 (*N*C*H*), –209.3/1.67 (*N*CH/C*H'*$_2$B). – ^{19}F NMR (564.3 MHz, [D$_2$]dichloromethane, 298 K): δ = –133.3 [m, 2 F, *o*-$B(C_6F_5)$], –135.9 [m, 2 F, *o*-$B(C_6F_5)$'], –158.2 [t, $^3J_{FF}$ = 20.1 Hz, 1 F, *p*-$B(C_6F_5)$], 159.4 [t, $^3J_{FF}$ = 20.1 Hz, 1 F, *p*-$B(C_6F_5)$'], –164.5 [m, 2 F, *m*-$B(C_6F_5)$], –164.6 [m, 2 F, *m*-$B(C_6F_5)$'].

X-ray Crystal Structure Analysis of 7a: Crystals from C_6D_6, formula $C_{62.5}H_{34.5}B_2F_{20}N_2O_2Zr$, M_r = 1338.26, light-yellow crystal, 0.25 × 0.20 × 0.20 mm, *a* = 12.621(2) Å, *b* = 14.907(2) Å, *c* = 15.900 (2) Å, α = 73.28(1)°, β = 80.74(1)°, γ = 83.67(1)°, *V* = 2821.2(7) Å^3, ρ_{calcd} = 1.575 g cm^{-3}, *F*(000) = 1339 e, μ = 3.09 cm^{-1}, empirical absorption correction based on SORTAV (0.927 ≤ *T* ≤ 0.941), *Z* = 2, triclinic, space group $P\bar{1}$ (No. 2), λ = 0.71073 Å, *T* = 198 K, 14406 reflections collected (±*h*, ±*k*, ±*l*), $[(\sin\theta)/\lambda]_{max}$ = 0.59 Å^{-1}, 8208 independent and 6373 observed reflections [$I \geq 2\sigma(I)$], 820 refined parameters, R = 0.088, wR^2 = 0.194, max. residual electron density 1.33 (–0.58) e Å^{-3}; the asymmetric unit contains two half-molecules of benzene and one three-quarter-molecule of benzene.

Reaction of 3b with $HB(C_6F_5)_2$. – Formation of 9: To a solution of compound **3b** (190 mg, 427 μmol) in toluene (20 mL) was added bis(pentafluorophenyl)borane (148 mg, 427 μmol). After stirring of the orange solution for 1 day, the solvent was removed in vacuo to provide 293 mg (87%) of the product as an orange solid. – DSC: 99 °C (dec.). – $C_{34}H_{32}BF_{10}N_3OZr$ (790.67): calcd. C 51.65, H 4.08, N 5.31; found C 51.64, H 4.34, N 4.46. – IR (KBr): $\tilde{\nu}$ = 1645, 1599, 1516 cm^{-1}. – ^{1}H NMR (599.9 MHz, [D$_6$]benzene, 298 K): δ = 7.69 (m, 2 H, *o*-Ph), 6.82 (m, 2 H, *m*-Ph), 6.77 (m, 1 H, *p*-Ph), 6.32 (m, 1 H, Cp_α), 6.15 (m, 1 H, Cp_β), 5.89 (m, 1 H, Cp_α), 5.82 (m, 1 H, Cp_β), 5.15 (ps. t, $^3J_{HH}$ = 9.1 Hz, 1 H, NCH), 3.24 (ABX_3, $^{2/3}J_{HH}$ = 7.0 Hz, 2 H, NCH_2CH_3), 3.04 (ABX_3, $^{2/3}J_{HH}$ = 7.0 Hz, 2 H, $N'CH_2CH_3$), 2.97 (ABX_3, $^{2/3}J_{HH}$ = 6.9 Hz, 2 H, NCH'_2CH_3), 2.95 (ABX_3, $^{2/3}J_{HH}$ = 7.0 Hz, 2 H, $N'CH'_2CH_3$), 2.22 (ps. t, $^{2/3}J_{HH}$ = 10.6 Hz, 1 H, CH_2B), 1.73 (ps. t, $^{2/3}J_{HH}$ = 10.3 Hz, 1 H, CH'_2B), 0.85 (t, $^3J_{HH}$ = 7.0 Hz, 6 H, $N'CH_2CH_3$), 0.73 (t, $^3J_{HH}$ = 6.9 Hz, 6 H, NCH_2CH_3). – ^{1}H TOCSY (599.9 MHz, [D$_6$]benzene, 298 K, irradiation at/response at): δ = 7.69 (o-Ph)/6.82 (*m*-Ph), 6.77 (*p*-Ph); 6.32 (Cp_α)/6.15 (Cp_β), 5.89 (Cp_α), 5.82 (Cp_β); 5.15 (NC*H*)/2.22 (C*H*$_2$B), 1.73 (C*H'*$_2$B); 3.24 (NCH_2CH_3)/2.97 (NCH'_2CH_3), 0.73 (NCH_2CH_3); 1.73 (C*H'*$_2$B)/5.15 (NC*H*), 2.22 (C*H*$_2$B); 0.85 ($N'CH_2CH_3$)/3.04 ($N'CH_2CH_3$), 2.95 ($N'CH'_2CH_3$); 0.73 (NCH_2CH_3)/3.24 (NCH_2CH_3), 2.97 (NCH'_2CH_3). – ^{13}C NMR (gated decoupled) (150.8 MHz, [D$_8$]toluene, 298 K): δ = 166.0 (s, OC=N), 149.0 (dm, $^1J_{CF}$ = 243 Hz) and 148.1 (dm, $^1J_{CF}$ = 238 Hz) [*o*-$B(C_6F_5)$, *o*-$B(C_6F_5)$'], 139.8 [ps. d, $^1J_{CF}$ = 247 Hz, *p*-$B(C_6F_5)$, *p*-$B(C_6F_5)$'], 137.7 (dm, $^1J_{CF}$ = 251 Hz) and 137.4 (dm, $^1J_{CF}$ = 251 Hz) [*m*-$B(C_6F_5)$, *m*-$B(C_6F_5)$'], 132.0 (dm, $^1J_{CH}$ = 161 Hz, *p*-Ph), 131.4 (s, *i*-Ph), 123.6, 118.8 [each m, *i*-$B(C_6F_5)_2$], 113.7 (dm, $^1J_{CH}$ = 171 Hz, Cp_α), 113.1 (dm, $^1J_{CH}$ = 174 Hz, Cp_β), 110.2 (dm, $^1J_{CH}$ = 171 Hz, Cp_α), 109.2 (dm, $^1J_{CH}$ = 172 Hz, Cp_β), 60.2 (d, $^1J_{CH}$ = 144 Hz, NCH), 44.0 (t, $^1J_{CH}$ = 132 Hz, $N'CH_2CH_3$), 43.3 (t, $^1J_{CH}$ = 132 Hz, NCH_2CH_3), 27.8 (tm, $^1J_{CH}$ = 134 Hz, CH_2B), 15.8 (q, $^1J_{CH}$ = 126 Hz, $N'CH_2CH_3$), 15.2 (t, $^1J_{CH}$ = 126 Hz, NCH_2CH_3). – ^{11}B NMR (64.2 MHz, [D$_6$]benzene, 300 K): δ = –2.4 ($\nu_{1/2}$ = 420 Hz). – ^{15}N,^{1}H GHMBC (60.8/599.9 MHz, [D$_6$]benzene, 298 K): $\delta^{15}N/\delta^1H$ = –171/0.85 (NCH_2CH_3), –187/0.73 ($N'CH_2CH_3$), –205/5.15 (*N*C*H*). – ^{19}F NMR (282.4 MHz, [D$_6$]benzene, 298 K): δ = –132.5 [m, 2 F, *o*-$B(C_6F_5)$], –136.4 [m, 2 F, *o*-$B(C_6F_5)$'], –158.2 [ps. t, $^3J_{FF}$ = 21 Hz,

1 F, *p*-B(C_6F_5)], –159.0 [ps. t, $^3J_{FF}$ = 21 Hz, 1 F, *p*-B(C_6F_5)'], –163.7 [m, 2 F, *m*-B(C_6F_5)'], –164.4 [m, 2 F, *m*-B(C_6F_5)].

Reaction of 3b with $HB(C_6F_5)_2$ at Low Temperature. – Generation of the Adduct 8: 30 mg (67 μmol) of **3b** was dissolved in [D_8]toluene (0.4 mL) and this solution was cooled to –78 °C and then added to an NMR tube containing a suspension of bis(pentafluorophenyl)borane (23 mg, 67μmol) in [D_8]toluene (0.1 mL) at –78 °C. While warming to room temperature, the NMR tube was shaken until all of the solid had dissolved. After 1 min under ambient conditions, the solution was cooled to 0 °C. Simultaneous formation of compound **9** could not be avoided. At 5 °C, however, the subsequent reaction to **9** is very slow and the adduct **8** could still be detected after 3 weeks. – ^{1}H NMR (599.8 MHz, [D_8]toluene, 273 K): δ = 7.55 (m, 2 H, *o*-Ph), 6.89 (m, 2 H, *m*-Ph), 6.83 (m, 1 H, *p*-Ph), 6.06, 5.77 (each m, each 2 H, Cp), 5.41 (ps. s, 1 H), 5.04 (d, $^2J_{HH}$ = 0.90 Hz, 1 H, C=CH_2), 2.95–2.86 (each m, each 4 H, N$CH_2$$CH_3$, N$CH'_2$$CH_3$), 0.63 (ps. t, $^3J_{HH}$ = 6.9 Hz, 12 H, NCH_2CH_3). – ^{13}C NMR (gated decoupled) (150.8 MHz, [D_8]toluene, 273 K): δ = 135.3 (t, $^2J_{CH}$ = 8 Hz, *i*-Cp), 130.6 (dm, $^1J_{HH}$ = 162 Hz, *p*-Ph), 127.1 (dm, $^1J_{HH}$ = 163 Hz, *o*-Ph), 111.5 (d, $^1J_{CH}$ = 175 Hz, Cp), 110.6 (d, $^1J_{CH}$ = 171 Hz, Cp), 43.6 (t, $^1J_{CH}$ = 130 Hz, NCH_2CH_3), 15.3 (q, $^1J_{HH}$ = 127 Hz, NCH_2CH_3); the *m*-Ph and *i*-Cp signals are obscured by those of the solvent. – ^{11}B NMR (64.2 MHz, [D_6]benzene, 300 K): δ = –11.6 (d, $^1J_{BH}$ = 60 Hz, $\nu_{1/2}$ = 390 Hz). – ^{15}N,^{1}H GHMBC (60.8/599.8 MHz, [D_8]toluene, 273 K): $\delta^{15}N/\delta^1H$ = –204/5.04 (OC=*N*/C=CH_2), –173/0.63 (*N*CH_2CH_3). – ^{19}F NMR (564.3 MHz, [D_6]benzene, 298 K): δ = –133.3 [br. ps. s, 4 F, *o*-B(C_6F_5)$_2$], –159.7 [ps. t, $^3J_{FF}$ = 20.6 Hz, 2 F, *p*-B(C_6F_5)$_2$], –164.8 [br. ps. s, 4 F, *m*-B(C_6F_5)$_2$].

Propene Polymerization Reactions. – General Procedure: A thermostated Büchi glass autoclave (25 °C) was charged with toluene (300 mL) and 20 mL of a 10% (1.6 M) methylalumoxane solution in toluene. Propene was introduced at a pressure of 2.0 bar. After 0.5 h, a solution of the organometallic catalyst precursor in 5 mL of toluene was added and the polymerization reaction allowed to proceed for 2.0 h. The system was then vented and its contents were quenched by treatment with aqueous HCl/CH_3OH (1:1). The layers were separated and the aqueous phase was extracted with toluene (3 × 100 mL). The combined organic layers were then washed with aqueous HCl (3 × 100 mL) and with water (3 × 100 mL) to remove inorganic salts. Evaporation of the solvent afforded the polymers as very viscous oils (see Table 1).

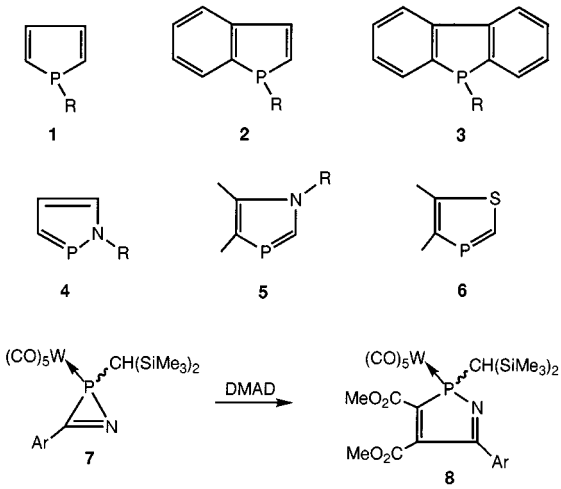
2*H*-1,2-Azaphosphindoles – Synthesis and Characterization

Victorio Cadierno,[a] Bruno Donnadieu,[a] Alain Igau,[a] and Jean-Pierre Majoral*[a]



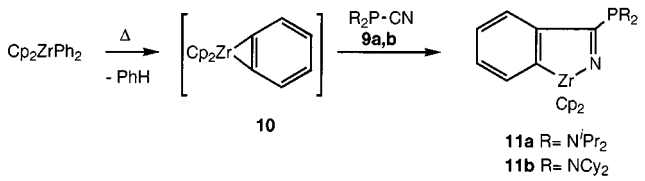
Keywords: Phosphorus / Benzynezirconocenes / Azazirconacyclopentenes / Exchange reactions / 1,2-Azaphosphindole

The first 1,2-azaphosphindoles **14a,b**, **15a,b** were obtained in a straightforward manner upon heating diphenylzirconocene in the presence of a cyanophosphane, which afforded azazirconacyclopentenes **11a,b** which can be reacted with various dichlorophosphanes. The use of the tetrachlorodiphosphane $Cl_2P(CH_2)_2PCl_2$ instead of a dichlorophosphane allowed the preparation of the bis(1,2-azaphosphindoles) **19**, **19′**. The monosulfur adduct of the azaphosphindole **14a**, i.e. **16a**, was characterized by X-ray structure analysis. Alkylation of **14a** or **16a** with methyltrifluoromethane sulfonate occurred selectively on the intracyclic phosphorus atom or on the sulfur atom, giving the salts **20** or **21**, respectively.

Introduction

Chemistry of 1*H*-phospholes **1** and of the corresponding fused-ring systems phosphindoles **2** (phosphorus analogs of indoles) and dibenzophospholes **3** has attracted considerable attention in the past two decades and is now well-documented.[1] The chemical behavior of these phosphorus heterocycles appeared to be quite different from that of the common heterocyclopentadiene systems such as furan, pyrrole and thiophene, and was the source of a rich and versatile chemistry.[1]

In marked contrast, synthesis and properties of analogous systems containing both phosphorus and one additional heteroatom are quite undeveloped and only a very few examples of 1*H*-1,2-azaphospholes **4**,[2a] 1*H*-1,3-λ^3-azaphospholes of type **5** or 1,3-λ^3-thiaphospholes of type **6** were reported.[2b,2c] Moreover, in all these derivatives the phosphorus atom is dicoordinated and not tricoordinated as in compounds **1–3**. Indeed, only recently was reported the formation of unique 2*H*-1,2-azaphosphole tungsten-complexes **8** by the thermal decomposition of 2*H*-azaphosphirene **7** in toluene at 75 °C in the presence of DMAD[3] (Scheme 1). However, such a method suffers from two main drawbacks: 2*H*-azaphosphirenes are not easy to prepare, and yields of isolated complexes **8** are poor (5–12%).



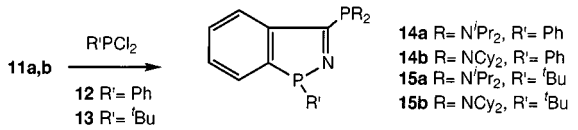
Scheme 1. Synthesis of 2*H*-1,2-azaphosphole tungsten complexes **8**

To our knowledge the preparation of free 1,2-azaphospholes and 1,2-azaphosphindoles has not yet been reported. We now present the facile synthesis of a number of azaphosphindoles, the X-ray characterization of an azaphosphindole, as well as preliminary studies concerning their reactivity.

Results and Discussion

Thermolysis of diphenylzirconocene in the presence of a wide variety of nitriles has previously been shown to generate azazirconacyclopentenes as dimers in the solid state in good to excellent yields.[4] A similar reaction was undertaken with the bisamino-cyanophosphanes **9a,b**[5] and diphenylzirconocene (Scheme 2). The transient zirconocene–benzyne complex **10** was trapped by **9a,b** to give the new azazirconacyclopentenes **11a,b** in 95% and 93% yield respectively. The reaction can be monitored by ^{31}P NMR spectroscopy, which shows the disappearance of the signal of the starting phosphane (**9a:** $\delta = 29.5$, **9b:** $\delta = 33.7$), which is replaced by a new signal at $\delta = 45.5$ (**11a**) or $\delta = 55.8$ (**11b**). Mass spectrometry (FAB) is in agreement with the expected compounds **11a** and **11b**.

Scheme 2. Synthesis of azazirconacyclopentenes **11a, b**



Infrared spectroscopy ($\tilde{\nu}_{C=N} = 1581–1583\ cm^{-1}$), and ^{13}C NMR [**11a:** $\delta_{C=N} = 191.3$ (d, $^1J_{CP} = 19.0$ Hz); **11b:** $\delta_{C=N} = 191.2$ (d, $^1J_{CP} = 19.5$ Hz)] corroborated the presence of an imino group. All the other NMR data are in agreement with the proposed azazirconacyclopentene structure.

Treatment of **11a** or **11b** with phenyldichlorophosphane **12** or *tert*-butyldichlorophosphane **13** at room temperature

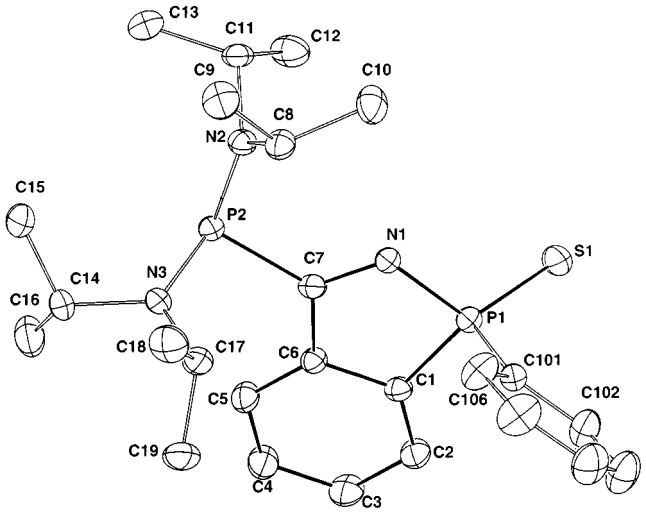
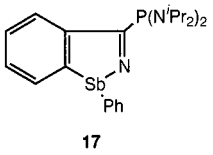
led to elimination of Cp_2ZrCl_2 to form the unprecedented 1,2-azaphosphindoles **14a,b** or **15a,b** as yellow solids obtained in 69–86% yield after workup (Scheme 3). The ^{31}P NMR spectrum exhibited, as expected, two doublets for compounds **14a**, **14b**, and **15b** {**14a:** δ = 41.1 [P(N*i*Pr$_2$)$_2$], 77.0 (PPh), J_{PP} = 6.7 Hz; **14b:** δ = 44.1 [P(NCy$_2$)$_2$], 76.5 (PPh), J_{PP} = 13.7 Hz; **15b:** δ = 44.9 [P(N*i*Pr$_2$)$_2$], 99.0 (P*t*Bu), J_{PP} = 6.5 Hz}; only two singlets were detected for **15a** at δ = 43.8 [P(N*i*Pr$_2$)$_2$] and at δ = 100.2 (P*t*Bu). Both 1,2-azaphosphindoles were further characterized by ^1H and ^{13}C NMR, IR, mass spectrometry and elemental analyses. Addition of sulfur to **14a** afforded selectively the monosulfide **16a** {δ = 39.8 (PN*i*Pr$_2$)$_2$ and 81.9 [P(S)Ph], J_{PP} = 6.5 Hz} (Scheme 4). Confirmation of the identity of **16a** and as a consequence of **14a** and the other 1,2-azaphosphindoles was achieved by a single-crystal X-ray study. The representation of the structure of **16a** is shown in Figure 1 , and the most representative bond lengths and angles are summarized.

Scheme 3. Synthesis of 1,2-azaphosphindoles **14a,b, 15a,b**

Scheme 4. Synthesis of the monosulfide adduct **16a**





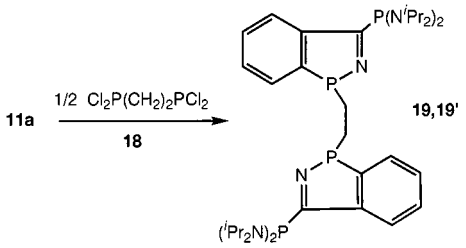


Figure 1. Molecular structure of **16a** with crystallographic numbering scheme; selected bond lengths (Å) and bond angles (°): P(1)–N(1) 1.702 (3), P(1)–C(1) 1.791 (4), C(7)–N(1) 1.300 (4), C(6)–C(7) 1.498 (5), C(6)–C(1) 1.393 (5), P(2)–N(3) 1.674 (3), N(1)–P(1)–C(1) 94.94 (15), C(7)–N(1)–P(1) 110.0 (2)

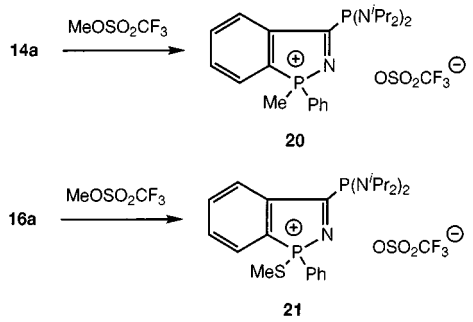
It appears therefore that such a one-pot reaction involving diphenylzirconocene, a cyanophosphane then by a dichlorophosphane, constitutes a very efficient method for the preparation of the first 3-phosphanyl-1,2-azaphosphindoles. A similar exchange reaction involving **11a** and phenyldichlorostilbene led to the formation of the corresponding 1,2-azastilbindole **17** obtained in 72% yield after workup. The ^{31}P chemical shift of **17** (δ = 83.8) as well as the $^1J_{CP}$ coupling constant of the imino carbon atom (J_{CP} = 0 Hz) differ notably from the values detected for the azaphosphindoles described above. However, such a variation of chemical shift and very small $^1J_{CP}$ values were already observed in different systems incorporating a bis(diisopropylamino)-phosphanyl group. Mass spectrometry (*m*/*z*: 532 [M + H]$^+$) and the other NMR data corroborate the proposed structure.

Such a methodology can be applied to the preparation of derivatives incorporating more than one 1,2-azaphosphindole unit. As an example, treatment of a solution of the complex **11a** in toluene with the phosphane $Cl_2P(CH_2)_2PCl_2$ **18** at 0 °C for 15 min afforded the expected bis 1,2-azaphosphindole in 91% yield as two diastereoisomers **19** and **19'** in a 2:1 ratio (Scheme 5). The formation of these two diastereoisomers can be detected mainly by ^{31}P NMR spectroscopy, where two singlets were observed for the P(N*i*Pr$_2$)$_2$ group at δ = 41.4 and 42.6.



Scheme 5. Synthesis of bis(1,2-azaphosphindoles)

A preliminary study of the reactivity of these new phosphorus heterocycles was undertaken. Alkylation of **14a** by means of methyltrifluoromethane sulfonate selectively occurred on the intracyclic phosphorus atom leading to **20**. The signal of this phosphorus atom was deshielded ($\Delta\delta$ = 8.2) while the signal of the P(N*i*Pr$_2$)$_2$ unit was shielded ($\Delta\delta$ = 6.9). ^1H and ^{13}C NMR spectroscopy clearly indicated that the methyl group was linked to the P(Ph) group [^1H NMR: δ_{CH3} = 2.69 (d, J_{HP} = 14.6 Hz); ^{13}C NMR: δ_{CH3} = 8.7 (dd, J_{CP} = 61.0 Hz, J_{CP} = 4.0 Hz]. Alkylation of the sulfur adduct **16a** with methyltrifluoromethane sulfonate also took place selectively on sulfur, giving **21**

(Scheme 6). Alkylation did not occur on nitrogen or on the bis(diisopropylamino)phosphanyl group.

Scheme 6

Conclusion

In conclusion a simple and efficient way for the preparation of a new type of phosphorus heterocycles, namely 1,2-azaphosphindole, can be proposed through the thermolysis of benzynezirconocene in the presence of a cyanophosphane, followed by an exchange reaction involving the resulting azazirconacyclopentene and various dichlorophosphanes, or a tetrachlorodiphosphane. Taking into account the fascinating versatile chemistry of classical phospholes, azaphosphindoles should be reagents of choice to develop new applications of phosphorus heterocycles in different areas such as coordination and heterocyclic chemistry, and catalysis, to name a few. Such studies are under active investigation.

Experimental Section

General Remarks: All manipulations were conducted under a dry argon atmosphere using standard Schlenk techniques. All reagents were purchased from commercial suppliers and used without further purification. Solvents were dried by standard methods and distilled under argon before use. Nuclear magnetic resonance (NMR) spectra were recorded on Bruker AC-200, AM-250 or MSL 400 spectrometers. Chemical shifts are reported in ppm relative to $SiMe_4$ (^{1}H, ^{13}C) or H_3PO_4 (^{31}P). IR spectra were recorded on a Perkin–Elmer FT 1725x spectrometer. Mass spectrum analyses and elemental analyses were performed by the analytical service of the Laboratoire de Chimie de Coordination (LCC) of the CNRS.

General Procedure for the Synthesis of Compounds 11a,b: To a solution of Cp_2ZrPh_2 (0.410 g, 1.09 mmol) in toluene (5 mL) was added at room temperature the corresponding cyanophosphane $(R_2N)_2PC{\equiv}N$ [R = iPr (**9a**), Cy (**9b**)] (1.09 mmol). The mixture was heated at reflux for 45 min, and then evaporated to dryness. The resulting solid residue was washed with pentane (3 mL) to give compounds **11a**,**b** as red solids.

Compound 11a: 95% yield. – IR (KBr): $\tilde{\nu}_{(C=N)}$ = 1581 cm^{-1}. – ^{31}P{^{1}H} NMR (C_6D_6): δ = 45.5 (s). – ^{1}H NMR (C_6D_6): δ = 1.29 (d, J_{HH} = 2.2 Hz, 12 H, CH_3), 1.32 (d, J_{HH} = 2.4 Hz, 12 H, CH_3), 3.56 (m, 4 H, NCH), 5.94 (s, 10 H, CH_{Cp}), 6.95–7.12 (m, 3 H, CH_{arom}), 7.91 (m, 1 H, CH_{arom}). – ^{13}C{^{1}H} NMR (C_6D_6): δ = 24.7 (d, J_{CP} = 5.6 Hz, CH_3), 25.2 (d, J_{CP} = 6.5 Hz, CH_3), 48.9 (d, J_{CP} = 9.3 Hz, NCH), 111.6 (s, CH_{Cp}), 124.4, 126.5, 126.8 and 138.7 (s, CH_{arom}), 166.2 (d, J_{CP} = 51.7 Hz, ZrC*C*), 191.3 (d, J_{CP} = 19.0 Hz, C=N), 192.0 (d, J_{CP} = 7.7 Hz, ZrC). – MS (FAB.); *m*/*z*: 554 [M + H]$^+$, 453 [M – *i*Pr$_2$N]$^+$ – $C_{29}H_{42}N_3PZr$ (554.86): calcd. Synthesis of Compound 16a: To a solution of compound **14a** (0.150 g, 0.339 mmol) in toluene (5 mL) was added at room temperature S_8 (0.128 g, 0.5 mmol). The mixture was stirred at room temperature for 2 h and then evaporated to dryness. The resulting solid residue was dissolved in THF (3 mL) and transferred to a silica gel chromatography column. Elution with pentane gave a yellow band from which compound **16a** was isolated after removal of the solvent (78% yield). – M.p. 121–122 °C (decomp.). – IR (KBr): $\tilde{\nu}_{(C=N)}$ = 1511 cm^{-1}. – $^{31}P\{^1H\}$ NMR (C_6D_6): δ = 39.8 [d, J_{PP} = 6.5 Hz, P(N*i*Pr$_2$)$_2$], 81.9 [d, J_{PP} = 6.5 Hz, P(S)Ph]. – ^1H NMR (C_6D_6): δ = 1.12 (d, J_{HH} = 6.6 Hz, 18 H, CH$_3$), 1.18 (d, J_{HH} = 6.6 Hz, 6 H, CH$_3$), 3.54 (m, 4 H, NCH), 6.95–7.17 (m, 5 H, CH$_{arom}$), 7.48 (m, 1 H, CH$_{arom}$), 7.88 (m, 2 H, CH$_{arom}$), 8.15 (d, J_{HH} = 7.6 Hz, 1 H, CH$_{arom}$). – $^{13}C\{^1H\}$ NMR (C_6D_6): δ = 24.5 (d, J_{CP} = 5.9 Hz, CH$_3$), 24.7 (d, J_{CP} = 7.5 Hz, CH$_3$), 25.0 (d, J_{CP} = 7.0 Hz, CH$_3$), 48.9 (d, J_{CP} = 11.2 Hz, NCH), 49.6 (d, J_{CP} = 10.3 Hz, NCH), 126.0 (pt, J_{CP} = 12.4 Hz, J_{CP} = 12.4 Hz, CH$_{arom}$), 128.8 (d, J_{CP} = 11.9 Hz, CH$_{arom}$), 128.9 [d, J_{CP} = 12.7 Hz, *o*-P(S)Ph], 131.5 [d, J_{CP} = 11.6 Hz, *m*-P(S)Ph], 131.8 (d, J_{CP} = 9.8 Hz, CH$_{arom}$), 132.2 [s, *p*-P(S)Ph], 132.6 (d, J_{CP} = 2.0 Hz, CH$_{arom}$), 142.3 [dd, J_{CP} = 82.0 Hz, J_{CP} = 2.6 Hz, CP(S)Ph], 144.3 [dd, J_{CP} = 43.9 Hz, J_{CP} = 37.3 Hz, *C*CP(S)Ph], 192.8 (pt, J_{CP} = 21.7 Hz, J_{CP} = 21.7 Hz, C=N). *i*-P(S)Ph not observed. – $C_{25}H_{37}N_3P_2S$ (473.59): calcd. C 63.40, H 7.87, N 8.87; found C 63.23, H 7.92, N 8.99.

Synthesis of Compound 17: To a solution of complex **11a** (0.345 g, 0.623 mmol) in toluene (5 mL) was added at room temperature $PhSbCl_2$ (0.168 g, 0.623 mmol). The mixture was stirred at room temperature for 15 min and then evaporated to dryness. The resulting solid residue was washed with pentane (3 × 20 mL) and diethyl ether (3 × 5 mL) to give compound **17** as a yellow solid (72% yield). – IR (KBr): $\tilde{\nu}_{(C=N)}$ = 1591 cm^{-1}. – $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = 83.8 (s). – ^1H NMR (CD_2Cl_2): δ = 1.08 (d, J_{HH} = 5.9 Hz, 6 H, CH$_3$), 1.19 (d, J_{HH} = 6.9 Hz, 6 H, CH$_3$), 1.37 (d, J_{HH} = 6.9 Hz, 6 H, CH$_3$), 1.47 (d, J_{HH} = 6.9 Hz, 6 H, CH$_3$), 3.94 (m, 2 H, NCH), 4.25 (m, 2 H, NCH), 7.12–8.05 (m, 9 H, CH$_{arom}$). – $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 24.7 (br s, CH$_3$), 25.2 (br s, CH$_3$), 50.9 (d, J_{CP} = 6.3 Hz, NCH), 51.2 (d, J_{CP} = 6.5 Hz, NCH), 123.8, 127.4, 128.3, 128.6, 129.8, 136.3 and 141.7 (s, CH$_{arom}$), 134.0 (s, *i*-Ph), 144.7 (d, J_{CP} = 26.1 Hz, *C*CSbPh), 146.9 (d, J_{CP} = 10.3 Hz, *C*SbPh), 194.6 (s, C=N). – MS (DCI/CH_4); *m*/*z*: 532 $[M + H]^+$. – $C_{25}H_{37}N_3PSb$ (532.30): calcd. C 56.42, H 7.00, N 7.89; found C 56.30, H 7.11, N 7.95.

Synthesis of Compounds 19, 19': To a solution of complex **11a** (0.417 g, 0.753 mmol) in toluene (8 mL) was added at 0 °C $Cl_2PCH_2CH_2PCl_2$ (**18**) (0.056 mL, 0.376 mmol). The mixture was stirred at room temperature for 15 min and then evaporated to dryness. The resulting solid residue was extracted with pentane (15 mL) and filtered. The volatiles were removed from the solution to give a yellow solid containing an inseparable mixture of two diastereoisomers **19** and **19'** in a ratio of *ca.* 2:1 (91% yield). – IR (KBr): $\tilde{\nu}_{(C=N)}$ = 1566 cm^{-1}. – $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 41.4 [s, P(N*i*Pr$_2$)$_2$ major isomer], 42.6 [s, P(N*i*Pr$_2$)$_2$ minor isomer], 81.5 (s, PCH$_2$). – ^1H NMR ($CDCl_3$): δ = 1.00–1.66 (m, 52 H, CH$_3$ and CH$_2$), 3.52 (m, 8 H, NCH), 7.25–7.65 (m, 6 H, CH$_{arom}$), 8.20 (m, 2 H, CH$_{arom}$). – $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 23.0 (dd, J_{CP} = 28.5 Hz, J_{CP} = 3.9 Hz, CH$_2$), 23.9 (br s, CH$_3$), 24.1 (d, J_{CP} = 7.1 Hz, CH$_3$), 24.3 (d, J_{CP} = 7.2 Hz, CH$_3$), 47.9 (d, J_{CP} = 10.8 Hz, NCH), 48.3 (d, J_{CP} = 8.5 Hz, NCH), 48.4 (d, J_{CP} = 8.0 Hz, NCH), 125.5 (d, J_{CP} = 10.3 Hz, CH$_{arom}$), 126.5 (dd, J_{CP} = 14.9 Hz, J_{CP} = 10.7 Hz, CH$_{arom}$), 127.2 and 127.4 (s, CH$_{arom}$), 145.4 (dd, J_{CP} = 41.4 Hz, J_{CP} = 31.6 Hz, *C*CPCH$_2$), 151.7 (m, *C*PCH$_2$), 187.0 (pt, J_{CP} = 19.7 Hz, J_{CP} = 19.7 Hz, C=N). – $C_{40}H_{68}N_6P_4$ (756.91): calcd. C 63.47, H 9.05, N 11.10; found C 63.22, H 9.13, N 11.30.

Synthesis of Compound 20: To a solution of compound **14a** (0.115 g, 0.260 mmol) in dichloromethane (5 mL) was added at 0 °C CF_3SO_3Me (0.029 mL, 0.260 mmol). The mixture was stirred at room temperature for 15 min and then evaporated to dryness. The resulting solid residue was washed with pentane (3 × 15 mL) and dried in vacuo to give compound **20** as a red solid (81% yield). – IR (KBr): $\tilde{\nu}_{(C=N)}$ = 1631 cm^{-1}. – $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = 49.2 [d, J_{PP} = 2.7 Hz, P(N*i*Pr$_2$)$_2$], 70.1 [d, J_{PP} = 2.7 Hz, P(Me)Ph]. – ^1H NMR (CD_2Cl_2): δ = 1.14–1.32 (m, 24 H, CH$_3$), 2.69 (d, J_{HP} = 14.6 Hz, 3 H, PCH$_3$), 3.60 (m, 4 H, NCH), 7.66–8.59 (m, 9 H, CH$_{arom}$). – $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 8.7 (dd, J_{CP} = 61.0 Hz, J_{CP} = 4.0 Hz, PCH$_3$), 23.9 (br s, CH$_3$), 49.5 (d, J_{CP} = 11.1 Hz, NCH), 49.6 (d, J_{CP} = 13.1 Hz, NCH), 117.8 [dd, J_{CP} = 93.3 Hz, J_{CP} = 5.0 Hz, *C*P(Me)Ph], 127.6 (pt, J_{CP} = 12.6 Hz, J_{CP} = 12.6 Hz, CH$_{arom}$), 130.3 (d, J_{CP} = 12.9 Hz, CH$_{arom}$), 131.8 [d, J_{CP} = 11.0 Hz, *o*-P(Me)Ph or CH$_{arom}$], 131.9 [d, J_{CP} = 8.9 Hz, *o*-P(Me)Ph or CH$_{arom}$], 133.5 [d, J_{CP} = 9.3 Hz, *m*-P(Me)Ph], 135.5 and 135.8 [s, CH$_{arom}$ and *p*-P(Me)Ph], 146.8 [dd, J_{CP} = 42.3 Hz, J_{CP} = 32.2 Hz, *C*CP(Me)Ph], 208.5 (dd, J_{CP} = 29.6 Hz, J_{CP} = 18.2 Hz, C=N). *i*-P(Me)Ph not observed. – $C_{27}H_{40}N_3O_3F_3P_2S$ (605.64): calcd. C 53.54, H 6.65, N 6.93; found C 53.42, H 6.59, N 7.10.

Synthesis of Compound 21: To a solution of compound **16a** (0.100 g, 0.211 mmol) in dichloromethane (5 mL) was added at room temperature CF_3SO_3Me (0.023 mL, 0.211 mmol). The mixture was stirred at room temperature for 15 min and then evaporated to dryness. The resulting solid residue was washed with pentane (2 × 15 mL) and dried in vacuo to give compound **21** as a red

solid (93% yield). – IR (KBr): $\tilde{\nu}_{(C=N)}$ = 1521 cm^{-1}. – $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = 55.6 [s, $P(NiPr_2)_2$], 82.9 [s, P(SMe)Ph]. – ^1H NMR (CD_2Cl_2): δ = 1.28 (d, J_{HH} = 6.6 Hz, 12 H, CH_3), 1.34 (d, J_{HH} = 6.5 Hz, 12 H, CH_3), 2.21 (d, J_{HP} = 15.9 Hz, 3 H, SCH_3), 3.61 (m, 4 H, NCH), 7.44–8.50 (m, 9 H, CH_{arom}). – $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 18.4 (s, SCH_3), 23.6 (br s, CH_3), 47.9 (br s, NCH), 50.1 (br s, NCH), 117.2 [dd, J_{CP} = 96.3 Hz, J_{CP} = 4.0 Hz, *C*P(SMe)Ph], 128.3 (dd, J_{CP} = 14.6 Hz, J_{CP} = 9.6 Hz, CH_{arom}), 130.9 [d, J_{CP} = 14.1 Hz, *o*-P(SMe)Ph or CH_{arom}], 131.2 [d, J_{CP} = 9.9 Hz, *o*-P(SMe)Ph or CH_{arom}], 132.1 (d, J_{CP} = 10.5 Hz, CH_{arom}), 134.5 [d, J_{CP} = 10.1 Hz, *m*-P(SMe)Ph], 136.6 and 137.0 [s, CH_{arom} and *p*-P(SMe)Ph], 146.8 [dd, J_{CP} = 48.6 Hz, J_{CP} = 30.7 Hz, *C*CP(SMe)Ph], 210.2 (dd, J_{CP} = 28.5 Hz, J_{CP} = 23.4 Hz, C=N). *i*-P(SMe)Ph not observed. – $C_{27}H_{40}N_3O_3F_3S_2P_2$ (637.70): calcd. C 50.85, H 6.32, N 6.58; found C 50.91, H 6.40, N 6.71

X-ray Crystallographic Study of 16a: $C_{25}H_{37}N_3P_2S$. M=473.58; tetragonal, space group *P*, 42/*n*; *a* = 15.743(2) Å, *b* = 15.746(2) Å, *c* = 21.684(3) Å; *V* = 5375.4(12) $Å^3$; D_{calcd} = 1.170 g cm^{-3}; graphite-monochromated Mo-$K_($ radiation (λ = 0.71073 Å); μ = 0.256 mm^{-1}; *T* = 293(2) K. – Data collection was performed at room temperature on a STOE Imaging Plate Diffraction System (I.P.D.S) and corrected for Lorentz and polarisation effects: 3868 unique data in the range 2.05°< θ <23.26°, final unit cell parameters were obtained by a least-squares refinement on a set of 5000 reflections equally distributed in reciprocal space; crystal decay was monitored by measuring two hundred reflections per image. Any fluctuations in the intensity were observed over the course on the data collection. – Structure was solved by Direct Methods using (SIR92),[6] and refined by least-squares procedures on a F^2 with the aid of (SHELXL-97).[7] Final $R1 = \Sigma \| F_o | - | F_c \| / \Sigma | F_o | = 0.0441$ for 3868 $F_o > 4\sigma F_o$ and 0.1002 for all data, $wR2 = [\Sigma w(F_o^2 - F_c^2)^2 / \Sigma w(F_o^2)^2]^{1/2} = 0.0988$, 0.1238 for all data, G.O.F = $[\Sigma w(F_o^2 - F_c^2)^2 / (n-p)]^2 = 0.853$ for 289 parameters and with a Scheme of ponderation following: Weight = $1/[\sigma^2(F_o^2) + (0.0696P)^2]$ where $P = (F_o^2 + 2F_c^2)/3$. Residual electron density extrema are: 0.444 and –0.273e $Å^{-3}$. Drawing of molecules were performed using the program ZORTEP[8] with a 50% probability displacement ellipsoids for non-hydrogen atoms. – Crystallographic data for the structure reported in this paper have been deposited at the Cambridge Crystallographic Data Centre as supplementary information number CCDC-132612. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK, E-mail: deposit@ccdc.cam.ac.uk.

Methyl(2-phosphanylphenolato[*P*,*O*])nickel(II) Complexes – Synthesis, Structure, and Activity as Ethene Oligomerization Catalysts

Joachim Heinicke,*[a] Mengzhen He,[a] Attila Dal,[a,b] Hans-Friedrich Klein,*[b] Olaf Hetche,[b] Wilhelm Keim,*[c] Ulrich Flörke,[d] and Hans-Jürgen Haupt[d]

Keywords: Methylnickel complexes / 2-Phosphanylphenolate / Chelates / Homogeneous catalysis / Oligomerization

Reactions of various substituted 2-phosphanylphenols **1a–f** with half-molar amounts of *cis*-[MeNi(μ-OMe)(PMe_3)]$_2$ have been found to yield square-planar methyl(2-phosphanylphenolato)(trimethylphosphane)nickel(II) complexes **2a–f**. $^2J_{PP}$ coupling constants of 305–316 Hz at low temperature indicate a *trans*-configuration for the products, while broad ^{31}P-NMR signals at room temperature can be attributed to rapid dissociation of PMe_3. Reaction with excess **1** gave rigid bis(2-phosphanylphenolato)nickel(II) complexes as exemplified by **3e**, whereas addition of PMe_3 to **2a** led to the pentacoordinate methyl(2-phosphanylphenolato)bis(trimethylphosphane)nickel(II) complex **4a**. Higher yields of **4a** and **4d** were obtained by reactions of **1a** and **1d** with $Me_2Ni(PMe_3)_3$. Single-crystal X-ray diffraction analyses of **3e** and **4a** have revealed the structures as square-planar *trans*-bis- and trigonal-bipyramidal mono(2-phosphanylphenolato)nickel(II) P∩O-chelate complexes, respectively. The methylnickel complexes **2** and **4** have been found to be effective one-component catalysts for the oligomerization of ethene. High conversions (> 96%) were achieved with the P-basic derivatives **2e**, **2f**, and **4d** bearing one or two branched alkyl groups (isopropyl, *tert*-butyl), whereas the diphenylphosphanyl derivatives were less active; **4d** gave shorter oligomers than **2e** or **2f**.

Introduction

P∩O-chelate complexes are of crucial importance in the oligomerization of ethene to give linear α-olefins by the Shell Higher Olefins Process.[1] In order to tune the catalyst properties, various P∩O-nickel complexes of varying ring sizes and bearing different functional groups have been investigated.[2,5] In early studies of the oligomerization of ethene, using in situ generated catalysts obtained from 2-diphenylphosphanylphenol and bis(1,5-cyclooctadiene)nickel or nickel salts in the presence of $NaBH_4$, mainly polymers were obtained.[6] Oligomers of ethene were, however, formed using phenyl(2-diphenylphosphanyl-4-hydroxyphenolato)(triphenylphosphane)nickel(II), obtained by phenyl migration from α-benzoyl phosphorus ylides.[2b,7] A recent study of the influence of various auxiliary phosphane ligands on the activity and selectivity of analogously prepared phenyl(2-diphenylphosphanylphenolato)(phosphane)nickel(II) catalysts established that high activity is seen with PPh_3, P(4-X–C_6H_4)$_3$ (X = Cl > Me > F), and PPh_2Me, whereas PCy_3 (Cy = cyclohexyl), which has a strong enhancing effect on the activity of the related phenyl(2-diphenylphosphanyl-1-phenylenolato)(phosphane)nickel(II) catalysts, induces only moderate activity. Generally, a marked tendency to produce higher oligomers, from $C_{10=}$ to $C_{90=}$, and only minor amounts of the desired $C_{4=}$ to $C_{10=}$ oligomers is observed. Exceptions are complexes with PMe_3 and $PPhMe_2$ ligands, which give α-olefins of low molecular weight ($C_{4=}$ to $C_{24=}$), although with lower catalytic activity.[3d] In view of the recently reported access to variously substituted 2-phosphanylphenols[8,9] and their high tendency to form P∩O-chelates,[8,10,11] we turned our attention to the synthesis of catalytically active (2-phosphanylphenolato[*P*,*O*])nickel(II) complexes and the tuning of their activity and selectivity by variation of substituents at the phosphorus and the phenolate group. We report here on methyl(2-phosphanylphenolato)nickel complexes, which differ from cyclopentadienyl(2-phosphanylphenolato)nickel(II) complexes[8b,11] in that they are active oligomerization catalysts.

Results and Discussion

Synthesis

Selected 2-phosphanylphenols **1a**–**f** were synthesized either by dilithiation of 2-bromophenols, reaction with the respective chlorophosphane and acid workup,[9c,10i] or, in analogy to the procedure of Rauchfuß,[8b] by *ortho*-metallation of the corresponding phenolmethoxymethyl

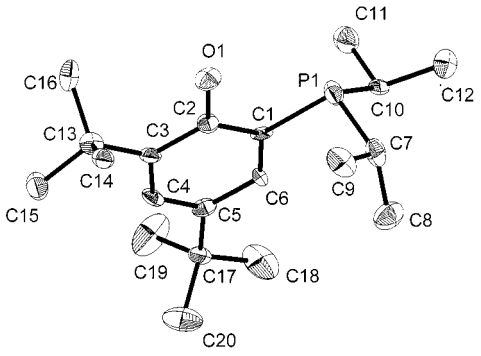
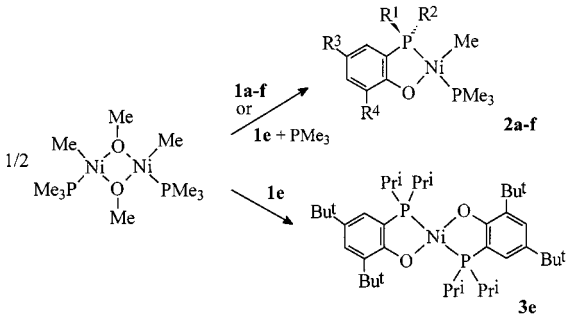
Scheme 1. Synthesis of 2-phosphanylphenols

The chosen substitution pattern, i.e. diphenyl, alkylphenyl, and dialkyl groups at phosphorus, 4,6-di-*tert*-butyl-, 4-methyl-6-*tert*-butyl-, and 4-fluoro-substituents at the phenoxy group, provided ligands with widely differing basicities at phosphorus and oxygen, allowing a qualitative appraisal of electronic effects on the oligomerization of ethene by the corresponding nickel P∩O-chelate complexes. Branched alkyl groups were selected since 2-isopropylphenylphosphanyl- and, in particular, 2-*tert*-butylphenylphosphanylcresol have been found to exhibit a lower tendency to form the thermodynamically preferred bis(P∩O-chelates) than 2-methylphenylphosphanyl- or 2-diphenylphosphanyl derivatives[11b] upon reaction with equimolar amounts of nickelocene in toluene. The 6-*tert*-butyl group stabilizes the P∩O-chelate complexes through its steric effect on the periphery, but does not significantly shield the metal center. The steric effect causes a bending of the substituents at oxygen towards the phosphorus, as is evident from the unusual formation of a 2-phosphanylphenolate P∩O-chelate complex with the hard titanium cation,[10h] an extremely increased $^4J_{PSn}$ in a 2-phosphanylphenolstannyl ether, and the presence of P···H–O hydrogen bonds in **1c** and **1d**.[9c] In **1e**, the presence of a P···H–O hydrogen bond is evident from a large $^4J_{PH}$ coupling constant of 12.4 Hz for the hydroxyl proton, whereas in **1f** this proton gives rise to a broad singlet. An X-ray structure analysis of single crystals of **1e**, performed at –100 °C, reveals a *trans*-eclipsed conformation (Figure 1), which means that the lone electron pair is also directed towards the hydroxyl group in the solid state. The lack of evidence for any such P···H–O hydrogen bond in **1f** underlines the role of the bulky 6-substituent in inducing such interactions.

Reactions of **1a–c** and **1f** with half-molar and of **1d** with equimolar amounts of $[NiMe(PMe_3)(\mu\text{-}MeO)]_2$ in diethyl ether, THF, or pentane solution proceeded via red intermediates and led to the yellow or red-brown methyl(2-phosphanylphenolato)(trimethylphosphane)nickel(II) complexes **2a–d** and **2f**. However, when the P-basic **1e** was used in slight excess relative to the half-molar amount of $[NiMe(PMe_3)(\mu\text{-}MeO)]_2$, the air-stable *trans*-bis(P∩O-chelate) complex **3e** was formed in high yield. This can be mainly attributed to the more facile dissociation of PMe_3 from **2e**.





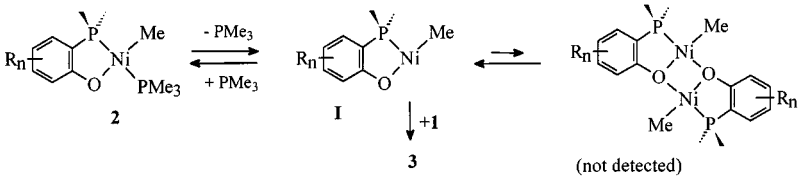


Figure 1. ORTEP plot of the molecular structure of **1e**; selected distances [Å] and angles [°]: P1–C2 1.847(9), P1–C7 1.877(10), P1–C10 1.838(10); P1–C1–C2 118.7(8), P1–C1–C6 122.1(8), O1–C2–C1 119.9(9), O1–C2–C3 116.9(10)

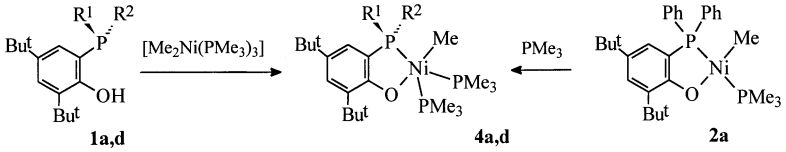
When the reaction was carried out in the presence of one equivalent of PMe_3, **2e** was isolated (Scheme 2). The complexes **2** were purified by fractional extraction of the crude products with pentane.



Scheme 2. Synthesis of the nickel complexes **2a**–**f** and **3e**

Whereas the room-temperature NMR spectra of *cis*- and *trans*-bis(2-phosphanylphenolato[*P,O*])nickel(II) chelate complexes **3** feature sharp signals and multiplets showing couplings to both phosphorus atoms for a number of ^1H as well as ^{13}C nuclei,[11,12] the room-temperature spectra of **2a–f** reveal couplings of the corresponding ^1H and ^{13}C nuclei to only one phosphorus atom, and in the ^{31}P-NMR spectra broad doublets or singlets are observed. At low temperature (–25 to –70 °C), the phosphorus signals of **2a–f** appear as sharp doublets with $^2J_{PP}$ couplings in the range 305–316 Hz, indicating a *trans* configuration. These values are similar to the $^2J_{PP}$ values of 245–290 Hz recently observed in phenylnickel-*o*-diphenylphosphanylphenolate phosphane complexes.[3d] The ^1H and ^{13}C signals of the NiMe groups in **2a**–**f** are split by couplings with both the phosphorus atoms, whereas the multiplicity of the ^1H and ^{13}C signals of the P∩O-ligand (at –25 to –30 °C) arises from coupling with the *o*-phosphorus nucleus only when PH or PC coupling is observed. These observations are indicative of rapid dissociation of the monodentate phosphane at room temperature, whereas exchange reactions of the P∩O-ligands, as indicated, e.g., by the different configurations of a bulky substituted bis(2-phosphanylphenolato)nickel complex in solution and in the solid state,[12] are slow on the NMR time scale. The decreased line-widths of the room-temper-

Scheme 3. Dissociation equilibria of **2**

Scheme 4. Syntheses of the nickel complexes **4a**, **d**

ature phosphorus resonances of the diisopropylphosphanyl complexes **2e** and **2f** and the lower temperature necessary for obtaining sharp doublets (–70 °C) indicate enhanced dissociation in the case of P$^{\frown}$O-ligands with increased donor and diminished acceptor strengths. The dissociation products, the tricoordinate 14-electron nickel intermediates **I**, undergo a rapid back-reaction with PMe_3 (Scheme 3). The presence of excess **1** disrupts this equilibrium by trapping **I**, thereby yielding the more stable bis(P$^{\frown}$O-chelates) **3**. The high reactivity of **I** prevents the observation of equilibrium concentrations. The concentrations of free trimethylphosphane and of dimers of **I** also fall below the limit of detection by NMR, suggesting a rapid association–dissociation equilibrium of PMe_3 with a small equilibrium constant. Dissociation of PMe_3 also seems to be responsible for the rapid aerial oxidation of solutions of **2a** since the solid material is stable in air for several hours.

In order to ascertain whether trimethylphosphane may be scavenged by the 16-electron complexes **2**, generation of the pentacoordinate complex **4a** was attempted by adding excess trimethylphosphane to **2a**. However, this method gave only a low yield (ca. 30%) of the red product. It was found that **4a** and **4d** could be obtained much more readily by reaction of **1a** and **1d**, respectively, with dimethyl tris(trimethylphosphane)nickel(II) in diethyl ether (Scheme 4). Complexes **4a** and **4d** were found to be stable under ambient conditions but lose trimethylphosphane on heating and decompose at around 106–109 °C. As expected for pentacoordinate nickel complexes, **4a** and **4d** are highly fluxional and exhibit two broad phosphorus singlets in their ^{31}P-NMR spectra, even at –30 °C, indicating rapid pseudo-rotation and dissociation of PMe_3. The ^{1}H and ^{13}C nuclei of the P$^{\frown}$O-ligand and the Ni methyl group only show coupling with the rigid chelate-bound phosphorus. As in the case of **2**, the dissociation equilibria account for the fact that solutions of **4** are rapidly oxidized, whereas the isolated complexes can be exposed to air for a short time.

Structural Aspects

In addition to the dynamic effects, the ^{1}H-, ^{13}C-, and ^{31}P-NMR chemical shifts and coupling constants of the rigid phosphanylphenolate ligands confirmed the configurations of **2**–**4**. Further structural information was provided by single-crystal X-ray structure analyses of **3e** and **4a**. In this regard, we will now discuss some trends by comparison of selected data (Table 1). The coordination chemical shifts of the *ortho*-phosphorus atoms (*o*-P) in complexes of types **4**, *cis*-**3**, and *trans*-**3** reveal a greater deshielding in the more highly alkylated P–alkyl$_n$Ph$_{2-n}$ derivative in each case, due to the lower acceptor strength. The same trend is observed for **2a** to **2d**, but the more P-basic diisopropylphosphanyl complexes **2e** and **2f** show smaller than expected values for $\Delta\delta$(*o*-P). Similarly, the coordination chemical shifts of PMe_3 in **2e** and **2f**, which approach those in **4a** and **4d**, are markedly lower than $\Delta\delta(PMe_3)$ in **2a**–**d**. This indicates a higher electron density at nickel(II) and an increased electron-repelling effect due to the lack of back bonding, which is also responsible for the noticeable high-field shifts of the NiMe carbon resonances in **2e** and **2f** as compared with those in **2a**–**d**, the lower $^{1}J_{PC2}$ and slightly lower $^{2}J_{PC1}$ coupling constants, and the aforementioned higher rate of dissociation in **2e** and **2f**. Comparison of the phosphorus coordination shifts of P$^{\frown}$O,P nickel complexes **2** with those of bis(P$^{\frown}$O-chelates) **3** having similar substitution patterns at phosphorus reveals smaller or slightly smaller $\Delta\delta$ values for the *trans* isomers of **3**, but significantly larger deshielding in *cis*-**3**. An even more clear-cut distinction of *cis* and *trans* isomers follows from the different $^{1}J_{PC2}$ (*Jcis* > *Jtrans*) and $^{2}J_{PC1}$ (*Jcis* < *Jtrans*) values, which indicate different electronic situations. The latter observation would suggest that substituent effects influence the configuration. Whereas this is true for the rigid bis(P$^{\frown}$O-chelates) **3**,[8a,11,12] monochelate P$^{\frown}$O,P nickel complexes **2** such as acyclic bis(phosphane)bis(phenolate)nickel complexes[13] always preferentially adopt a *trans* configuration. *cis*-Isomers of **2** would be expected to exhibit $^{2}J_{PNiP}$ coupling constants in the range 60–90 Hz.[11b,14,15] Such signals could not be detected, neither for P(R)–aryl nor for dialkylphosphanyl derivatives. Traces of impurities giving rise to sharp phosphorus doublets (J_{PP} = 14–16 Hz) were detected in the spectra of **2a**,**b**,**d**, the nature of which has not yet been established.

A single-crystal X-ray structure analysis of **3e** (Figure 2) confirmed the *trans* configuration and provided the first such data for a *trans*-bis(phosphanylphenolato[*P*,*O*])-nickel(II) complex. Like acyclic *trans*-bis(phosphane)bis-

(phenolato)nickel(II) complexes,[13] **3e** possesses an almost ideal square-planar geometry about the nickel center, with O–Ni–O and P–Ni–P angles of 180°. This is in marked contrast to the distorted structures of *cis*-**3**, where O–Ni–O angles of 85.0 to 87.5° and P–Ni–P angles of 97.9 to 107.1° are found.[11b,12] The latter value relates to **3d**, which occurs in the *cis* form in the solid state, but in the kinetically preferred (*trans* effect) *trans* configuration in solution[12] and may thus represent the degree of steric congestion at the borderline of *cis*- and *trans*-bis(2-phosphanylphenolato)nickel(II) complexes. The Ni–P bond lengths in **3e** are somewhat longer [2.1997(8) Å] while the Ni–O [1.857(2) Å] distances are a little shorter as compared to the values in *cis*-bis(2-phosphanylphenolato)nickel(II) moieties, i.e. 2.1432(13) to 2.172(2) Å (the latter in *cis*-**3d**) and 1.869(10) to 1.889(3) Å, respectively. The angles within the chelate ring are as those in *cis*-**3** and underline the rigidity of the five-membered Ni–P∩O-chelate ring.

Although single crystals of *trans*-**2a**–**f** suitable for structure determinations could not be obtained, their structures are believed to be similar to those of phenyl(2-diphenylphosphanylenolato)(triphenylphosphane)nickel(II) complexes.[2a,3b] X-ray structure analysis of **4a** reveals an almost ideal trigonal-bipyramidal geometry with the three phosphorus atoms in equatorial positions and the oxygen and the methyl group in axial positions (Figure 3). The Ni–P(1) distance is markedly longer than the Ni–P bond lengths in *cis*-**3**, but is comparable to the corresponding distances in **3e** and phenyl(2-phosphanylenolato)(phosphane)nickel(II) complexes. The axial Ni–O bond is longer than Ni–O bonds in *cis*- and *trans*-**3**, but is comparable to the longer distances found in the (2-phosphanylenolato)(phosphane)nickel or pentacoordinate *o*-benzoyl(trimethylphosphane)nickel complexes.[16] The Ni–C(Me) and Ni–P(2) or Ni–P(3) distances fall in the usual ranges of bond lengths in methylnickel-trimethylphosphane complexes.[17]

Ethene Oligomerization

Toluene solutions of the methylnickel phosphane complexes **2c**,**e**,**f** and **4a**,**d** (ca. 0.1 mmol) were treated with

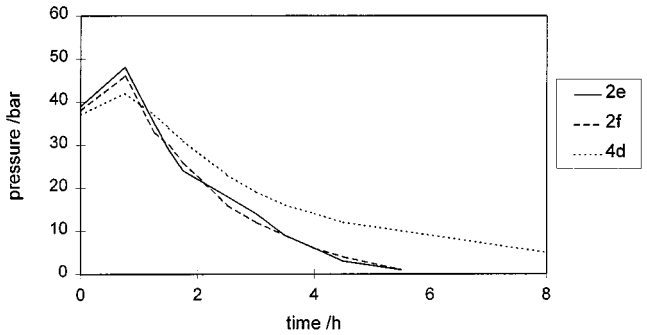

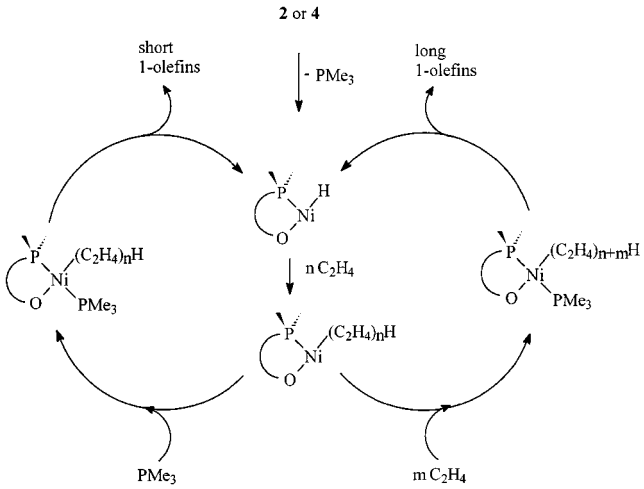

Figure 4. Conversion of ethene at 80 °C in the presence of **2e**, **2f**, and **4d**

ethene (ca. 7.7 g) at 80 °C in a 75 mL autoclave (Table 2). After an initial increase of the starting pressure (35 bar) to 45–50 bar during the induction period (about 30–45 min), the pressure fell at a rate that depended on the one-component catalyst (Figure 4). The bulk of the ethene reacted within ca. 4 h, whereas an almost quantitative conversion required 6 h in the case of **2e** and **2f**, and 10 h in the case of **4d**. The less P-basic diphenylphosphanyl- and alkylphenylphosphanyl representatives of **2** and **4** were much less active. This has a parallel in the low oligomerization activity of phenyl(2-diphenylphosphanylphenolato)(trimethylphosphane)nickel(II) as compared to phenylnickel complexes of this type with other, mainly P-arylated monodentate phosphane ligands.[3d] This is believed to be due to the greater stability of "push-pull" *trans*-diphosphane nickel complexes with a good donor on one side and a good acceptor ligand on the other as compared with the easily dissociating P-basic complexes **2e**, **2f**, and **4d** or phenyl(2-diphenylphosphanylphenolato)(triarylphosphane)nickel(II) species[3d] with similar phosphane ligands on either side.

The products of the catalytic conversion of ethene were oligomers (Scheme 5), mainly linear α-olefins (Table 3). The selectivity decreased somewhat with increasing chain length, from C4 to C12, as detected by GC. The unusually high content of a hexene isomer in II (11.5%) may be attributed to a competing reaction with 1-butene. With **4d**, lower oligomers with a Schultz–Flory distribution[18] and large amounts of 1-butene, 1-hexene, and octenes were observed. The mono-PMe_3 complexes form longer chain oligomers with broad, flat maxima in their molar weight distributions. In experiment I using the catalyst **2c**, the maximum was

Scheme 5. Proposed mechanism of oligomerization of ethene catalyzed by **2** or **4**

found in the range C10 to C14 by GC and C12 to C18 by mass spectrometry (based on abundance of $[M^+]$ using direct inlet). The most abundant oligomers (by GC) in experiments II and III using the diisopropylphosphanylphenolate catalysts **2e** and **2f** were 1-hexene and 1-octene, followed by either 1-decene (II/**2e**) or 1-butene (III/**2f**). Besides these, greater amounts of C14+ oligomers ($n > 7$) (33 and 51 mass%) were observed. Interestingly, the mass spectrum of the oligomer mixture of II revealed low abundance maxima due to the molecular ions of oligomers $n = 10$–12 and $n = 23$–25. The higher conversion and the occurrence of longer olefins using the diisopropylphosphanylphenolate catalysts **2e** and **2f** may be explained by the higher degree of dissociation allowing, over time, a proportionally faster uptake of ethene. Since diisopropylphosphanylphenolate catalysts, prepared in situ from **1e** or **1f** and $Ni(COD)_2$ and free of monodentate phosphanes, give higher polyethenes than diphenyl- or alkylphenyl-substituted species,[19] the lower-oligomer maxima seen in the catalysis using **2e** and **2f** might be induced by stronger promotion of β-hydride elimination in the alkyl(2-diisopropylphosphanylphenolato)(phosphane)nickel(II) intermediates than in intermediates formed using **2c**. This is in line with the higher electron density at nickel in **2e** and **2f** as compared with that in **2a**–**d**, which is reflected in a high-field shift of the methyl group ^{13}C resonance by ca. 4 ppm (Table 1). Coordination of an alkylphos-

phane ligand will accelerate β-hydride transfer in the case of C_{2n}-alkyl chains at nickel. A small proportion of active centers, depending on the equilibrium concentration of PMe_3, may produce somewhat longer chains, promoted by a decreasing association of PMe_3 with increasing chain length.

Conclusions

Tertiary 2-phosphanylphenols **1** bearing phenyl and alkyl groups at phosphorus react with $[MeNi(\mu\text{-}OMe)(PMe_3)]_2$ to give 16-electron methyl(2-phosphanylphenolato)(trimethylphosphane)nickel(II) complexes **2** with *trans*-square-planar structures. Complex **2** reacts with excess **1** to give nickelbis(P$^\cap$O-chelates) **3** or adds PMe_3 to form 18-electron trigonal-bipyramidal methyl(2-phosphanylphenolato)bis(trimethylphosphane)nickel(II) complexes **4**. Higher yields of **4** are obtained from **1** and $Me_2Ni(PMe_3)_3$. Both **2** and **4** are fluxional molecules, particularly their dialkylphosphanyl derivatives. This is attributed to rapid dissociation–association equilibria; **4** may additionally undergo rapid pseudorotation. Both the expected unsaturated 14-electron species **I** (or dimers thereof) and free PMe_3 escape detection by NMR because of their low concentrations (low equilibrium constants). Nevertheless, alkylphenyl- or dialkylphosphanyl derivatives of **2** and **4** have proved to be effective one-component catalysts in the oligomerization of ethene. Since addition of ethene to **2** will be much less favorable than addition to **I**, and since electron-rich 2-dialkylphosphanylphenolates **2**, which bind trimethylphosphane in a *trans* fashion less tightly than 2-diphenylphosphanyl derivatives, form the more efficient catalysts, **I** can be regarded as the active species, which may even be formed by dissociation of **4**. The short chain lengths of the oligomers obtained with **2** as compared to those of the polymers produced with catalysts prepared in situ from **1** and $Ni(COD)_2$[6a,11b,19] and the even lower molecular weights of the oligomers formed with **4** suggest that β-hydride elimination is favored by coordination of PMe_3 at a free coordination site of the catalyst.

Experimental Section

General Procedures and Materials: All procedures were carried out under an atmosphere of purified argon using standard vacuum line or Schlenk techniques. Solvents (THF, diethyl ether, pentane) were dried with sodium (ketyls) and freshly distilled prior to use. $[NiMe(PMe_3)(\mu\text{-}OMe)]_2$,[16,17] *trans*-$Me_2Ni(PMe_3)_3$,[20] and the 2-phosphanylphenols **1a**,[9c] **1b**,[10i] and **1c**[9c] were prepared according to known procedures; iPr_2PCl was purchased from Aldrich and used without further purification. – IR spectra were recorded on a Nicolet Impact 400 FT-IR spectrometer. – NMR spectra were recorded on Bruker AM 200, WM 300, or ARX 300 multinuclear Fourier transform spectrometers and are referenced to tetramethylsilane for ^1H and ^{13}C and to H_3PO_4 (85%) for ^{31}P. The measuring temperature was 298 K unless otherwise stated. For resonances that are part of an AXX' spin system (X,X' = ^{31}P), vc and τ denote "virtual coupling" and the triplet appearance of the A resonance, respectively. – Melting points were determined in sealed capillaries (Büchi type 510) and are uncorrected. – Elemental analyses were carried out using CHN 240 A (Perkin–Elmer) or CHNS-932 (LECO) analyzers.

Ligand Preparation

4,6-Di-*tert*-butyl-2-(diisopropylphosphanyl)phenol (1e): At –40 °C, a hexane solution of *n*BuLi (21.0 mL, 1.6 N, 33.6 mmol) was slowly added to 2,4-di-*tert*-butylphenyl methoxymethyl ether (8.3 g, 33.2 mmol) in Et_2O (60 mL). After stirring for 4 h at 20 °C, chlorodiisopropylphosphane (5.0 g, 32.8 mmol) was rapidly added at 0 °C, the suspension was stirred for 1 h at room temperature, and then filtered. The filtrate was concentrated to dryness and the residue was treated with degassed 2 N HCl (200 mL) at 60 °C. After heating for 5 h, the volatiles were removed in vacuo and the residue was crystallized from methanol. Yield 7.8 g (73%) of **1e** as white crystals; m.p. 67–68 °C. – IR (Nujol): $\tilde{\nu}_{OH}$ = 3322 cm^{-1} s. – ^1H NMR (C_6D_6): δ = 0.86 (dd, $^3J_{PH}$ = 12.2, $^3J_{HH}$ = 6.9 Hz, 6 H, CH*Me*), 1.00 (dd, $^3J_{PH}$ = 16.5, $^3J_{HH}$ = 7.0 Hz, 6 H, CH*Me*), 1.34 (s, 9 H, CMe_3), 1.60 (s, 9 H, CMe_3), 1.94 (m, $^3J_{HH}$ = 7, $^2J_{PH}$ = ca. 3.5 Hz, 2 H, CH), 7.22 (ps. t, $^4J_{HH}$ = 2.4, $^3J_{PH}$ = ca. 2.6 Hz, 1 H, 3-H), 7.55 (d, $^4J_{HH}$ = 2.4 Hz, 1 H, 5-H), 7.76 (d, $^4J_{PH}$ = 12.4 Hz, 1 H, OH). – ^{13}C NMR (75.5 MHz, C_6D_6): δ = 18.6 (d, $^2J_{PC}$ = 7.0 Hz, CH*Me*), 20.0 (d, $^2J_{PC}$ = 17.9 Hz, CH*Me*), 23.1 (d, $^1J_{PC}$ = 6.9 Hz, C*H*Me), 29.8 (CMe_3), 31.8 (CMe_3), 34.5 (CMe_3), 35.4 (d, $^4J_{PC}$ = 2.0 Hz, CMe_3), 117.8 (d, $^1J_{PC}$ = 5.2 Hz, C-2), 125.6 (C-5), 127.1 (d, $^2J_{PC}$ = 1.1 Hz, C-3), 135.2 (d, $^3J_{PC}$ = 1.7 Hz, C-6), 141.2 (C-4), 158.1 (d, $^2J_{PC}$ = 18.8 Hz, C-1). – $^{31}P\{^1H\}$ NMR (121.5 MHz, C_6D_6): δ = –24.3. – MS (EI, 70 eV): *m/z*: 323 [M^+],

307 [$M^+ - CH_3$], 281 [$M^+ - C_3H_6$], 266 [$M^+ - t$Bu], 239 [$M^+ - 2\,C_3H_6$], 57 [tBu]. – $C_{20}H_{35}OP$ (322.47): calcd. C 74.49, H 10.94; found C 74.19, H 10.97.

4-Fluoro-2-(diisopropylphosphanyl)phenol (1f): At –40 °C, *n*BuLi (38.5 mL 1.6 N in hexane, 61.5 mmol) was added to 9.6 g (61.5 mmol) of 4-fluorophenyl methoxymethyl ether in Et_2O (100 mL) and the mixture was allowed to warm to room temperature. After 2 h, chlorodiisopropylphosphane (9.4 g, 61.6 mmol) was added. The resulting suspension was stirred for 1 h at 20 °C and then filtered. The filtrate was concentrated to dryness and the residue was treated with degassed aqueous 2 N HCl solution as above. After 5 h at 60 °C, the volatiles were removed in vacuo. The residue was crystallized from methanol to give 4.9 g (35%) of **1f** as white needles; m.p. 61–64 °C. – IR (Nujol): $\tilde{\nu}_{OH}$ = 3302 cm^{-1} s. – ^{1}H NMR (300.1 MHz, C_6D_6): δ = 0.70 (dd, $^3J_{PH}$ = 12.5, $^3J_{HH}$ = 6.9 Hz, 6 H, CH*Me*), 0.89 (dd, $^3J_{PH}$ = 16.5, $^3J_{HH}$ = 7.0 Hz, 6 H, CH*Me*), 1.68 (m, $^3J_{HH}$ = 7, $^2J_{PH}$ = ca. 3.5 Hz, 2 H, CH), 6.73 (m, $^3J_{HH}$ = 9.0, $^3J_{FH}$ = 8.1, $^4J_{HH}$ = 3.1 Hz, 1 H, 5-H), 6.82 (m, $^3J_{HH}$ = 9.0, $^4J_{FH}$ = 5.1, $^4J_{PH}$ = 3.9 Hz, 1 H, 6-H), 6.91 (m, $^3J_{FH}$ = 8.3, $^4J_{HH}$ $^3J_{PH}$ 2.8 Hz, 1 H, 3-H), 7.02 (br. s, 1 H, OH). – ^{13}C NMR (75.5 MHz, C_6D_6): δ = 19.3 (d, $^2J_{PC}$ = 7.6 Hz, CH*Me*), 20.5 (d, $^2J_{PC}$ = 18.0 Hz, CH*Me*), 23.8 (d, $^1J_{PC}$ = 7.7 Hz, *C*HMe), 117.2 (dd, $^3J_{FC}$ = 7.2, $^3J_{PC}$ = 1.7 Hz, C-6), 119.0 (dd, $^2J_{FC}$ = 21.1, $^2J_{PC}$ = 1.7 Hz, C-3), 119.0 (d, $^2J_{FC}$ = 23.1 Hz, C-5), 120.8 (dd, $^1J_{PC}$ = 4.5, $^3J_{FC}$ = 12.4 Hz, C-2), 157.6 (d, $^1J_{FC}$ = –239.7 Hz, C-4), 158.7 (dd, $^2J_{PC}$ = 18.7, $^4J_{FC}$ = 1.7 Hz, C-1). – ^{31}P{^{1}H} NMR (121.5 MHz, C_6D_6): δ = –21.8. – MS (EI, 70 eV): *m*/*z*: 228 [M^+], 186 [$M^+ - C_3H_6$], 144 [$M^+ - 2\,C_3H_6$], 111 [$M^+ - P$*i*Pr_2]. – $C_{12}H_{18}FOP$ (228.25): calcd. Complex-Catalyzed Oligomerization of Ethene. – General Procedure: A solution of the appropriate nickel complex **2** or **4** (ca. 0.1 mmol) in toluene (12 mL) was transferred at room temperature into an argon-filled stainless steel autoclave (75 mL) equipped with a magnetic stirrer. Ethene was introduced with stirring until the pressure remained constant at 35 bar (7.5–7.8 g by weight difference), then the valve was closed and the autoclave was heated at 80 °C for 6–10 h. After cooling to ca. 20 °C and weight control, the valve was opened and the gases were passed through a cooling trap (–60 °C) to condense gaseous butenes. The remaining material was flash distilled at 25–30 °C/10^{-2} Torr to separate volatile oligomers (condensed at –60 °C) and waxes. The former were analyzed by GC and in some cases by GC/MS. The results are summarized in Table 2 and 3.

Crystal Structure Analysis

1e: A crystal of **1e** was sealed under argon in a glass capillary, mounted on a Siemens R3m/V diffractometer, and examined using graphite-monochromated Mo-K^{α} radiation, λ = 0.71073 Å. Lattice parameters were determined from 25 selected reflections. The structure was solved by a full-matrix least-squares refinement (SHELXL-97). Non-hydrogen atoms were treated anisotropically, hydrogen atoms were fixed in idealized positions. Crystal data are presented in Table 4; selected bond lengths and angles are indicated in Figure 1.

3e: A green crystal of **3e** was sealed under argon in a capillary; data were collected as above on a Bruker P4 diffractometer. Lattice parameters were refined from 28 reflections in the range 15 ≤ 2Θ ≤ 40°. During data collection, 3 standard reflections were checked every 397 intensities and were found to show only random deviations. Lorentz and polarization corrections were applied, as well as an absorption correction based on psi-scans. The structure was solved by direct and conventional Fourier methods, with full-matrix least-squares refinement based on F^2. All atoms other than the H-atoms and disordered C-atoms were refined anisotropically. The *tert*-butyl group C7–C102 and the isopropyl group C19–C21 were each found to be disordered over two sites and were refined with a split model. Site occupancy factors were refined to 0.43(1) and 0.57(1) for the *tert*-butyl group and to 0.29(1) and 0.71(1) for the isopropyl group, respectively. Hydrogen atoms were refined at idealized positions with a riding model. Further crystallographic and refinement data are given in Table 4; selected bond lengths and angles are indicated in Figure 2.

4a: A red crystal of **4a** was sealed under argon in a glass capillary. Data collection was performed as described for **3e**. Lattice parameters were refined from 25 reflections in the range 17 ≤ 2Θ ≤ 34°. Standard reflections showed a decrease of 7%. Lorentz, polarization, and absorption corrections were applied as above. Structure solution and refinement and the positioning of the hydrogen atoms was as described above. Further crystallographic and refinement data are given in Table 4; selected bond lengths and angles are indicated in Figure 3.

Crystallographic data (excluding structure factors) have been deposited with the Cambridge Crystallographic Data Centre. Copies of the data [CCDC-136785 (**1e**)], [CCDC-135904 (**3e**)], [CCDC-135905 (**4a**)] can be obtained free of charge on application to the CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) +44 (0)1223/336033; E-mail: deposit@chemcrys.cam.ac.uk].

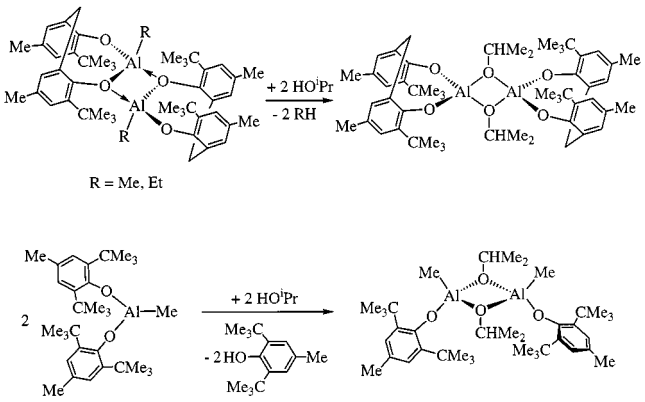
Alcoholysis of Aluminum Alkyls Supported by Bulky Phenoxide Ligands: Synthesis, Characterization, and ε-Caprolactone Polymerization Activity of Two Dimeric Aluminum Isopropoxides

Insa Taden,[a] Hak-Chul Kang,[b] Werner Massa,[b] Thomas P. Spaniol,[a] and Jun Okuda*[a]

Keywords: Aluminum / Alkoxides / Lactone / Ring-opening / Polymerization



Reaction of trialkylaluminum Al_2R_6 (R = Me, Et) with 2,2′-methylenebis(6-*tert*-butyl-4-methylphenol) ($mbmpH_2$) gives the dimeric mono(alkyl) complex $[Al(mbmp)R]_2$ with bridging oxygen atoms. Reaction of $[Al(mbmp)R]_2$ with one equiv. of 2-propanol results in the formation of the dimeric isopropoxide $[Al(mbmp)(\mu\text{-O}i\text{Pr})]_2$. Single-crystal X-ray analysis shows a C_{2h}-symmetric structure with a planar Al_2O_2 core. Monomeric methylbis(2,6-di-*tert*-butyl-4-methylphenolato)aluminum, $AlMe(OC_6H_2\text{-}2,6\text{-}t\text{Bu}_2\text{-}4\text{-Me})_2$ (MAD), was found to react with one equiv. of 2-propanol to give a dimeric isopropoxide $[AlMe(OC_6H_2\text{-}2,6\text{-}t\text{Bu}_2\text{-}4\text{-Me})(\mu\text{-O}i\text{Pr})]_2$ in which the bulky phenolate, instead of the methyl group, has been displaced. According to the single-crystal X-ray structure analysis, the molecule contains a similar Al_2O_2 core, but the two 2,6-di-*tert*-butyl-4-methylphenolato ligands are *cis*- and orthogonally arranged to each other. ε-Caprolactone is polymerized at 50 °C in toluene in a controlled manner by $[Al(mbmp)(\mu\text{-O}i\text{Pr})]_2$, to give poly(ε-caprolactone) with high molecular weights and narrow molecular weight distributions ($M_w/M_n < 1.50$). The low efficiency values (number of polymer chains initiated per aluminum atom) imply that $[Al(mbmp)(\mu\text{-O}i\text{Pr})]_2$ exists in a monomer–dimer equilibrium. The polymerization of ε-caprolactone by $[AlMe(OC_6H_2\text{-}2,6\text{-}t\text{Bu}_2\text{-}4\text{-Me})(\mu\text{-O}i\text{Pr})]_2$ is faster, but somewhat less controlled.

Introduction

Aluminum tri(isopropoxide) is a readily available compound that, among various applications in organic synthesis, has been employed as an efficient initiator for the ring-opening polymerization of aliphatic cyclic esters such as ε-caprolactone.[1] In the crystalline state it is a tetranuclear aggregate in which one six-coordinate aluminum center is surrounded by three bridging $Al(O\textit{i}Pr)_4$ units.[2] In solution, several other species including a trimer are present and the thermodynamics as well as the kinetics of their interconversion evidently complicates the polymerization mechanism.[1d,e] We anticipated that a *monomeric* aluminum alkoxide supported by bulky phenoxide ligands[3] would furnish a structurally well-defined initiator for ring-opening polymerization, and be amenable to mechanistic investigation. By employing the mono(alkyl) complexes with the chelating mbmp ligand [mbmp: 2,2'-methylenebis(6-*tert*-butyl-4-methylphenolato)] and its nonchelating analog 2,6-di-*tert*-butyl-4-methylphenolato, we attempted the synthesis of mono(isopropoxide) complexes. We present here the somewhat unexpected outcome of the alcoholysis reactions as well as the reactivity of the resulting products.[4]

Results and Discussion

When the sterically demanding chelating bisphenol $mbmpH_2$ [2,2'-methylenebis(6-*tert*-butyl-4-methylphenol)] was treated with trimethylaluminum in hexane, vigorous evolution of methane was observed and the monomethyl complex $[Al(mbmp)Me]_2$ was formed in high yields as air- and moisture-sensitive colorless crystals. The aluminum-bound methyl group occurred as broad signals in the ^1H and ^{13}C NMR spectra at $\delta = -0.39$ and -7.36, respectively. The resonances of the mbmp ligand are all doubled, suggesting an unsymmetric structure in which the two halves of the mbmp ligand are inequivalent. We propose that a centrosymmetric dimer forms in which the Lewis-acidic aluminum center is coordinated to one phenoxy oxygen of the neighboring mbmp ligand (Scheme 1). By engaging in a bridging mode, for which the lone pair of the phenoxy oxygen is well suited, the coordinative unsaturation at the aluminum center is alleviated. Although, to the best of our knowledge, this bonding mode is unprecedented for the

bulky bisphenolato ligand mbmp,[5] this type of bridging has been frequently observed in aluminum compounds with phenoxy[6] and chelating ligands in which at least one alkoxy function is present.[7] Addition of a Lewis base such as diethyl ether, THF, and pyridine, results in the formation of a mononuclear adduct with a four-coordinate aluminum center, as observed by NMR spectroscopy. The ethyl derivative [Al(mbmp)Et]$_2$ can be obtained in an analogous fashion from triethylaluminum, and isolated as colorless crystals. Due to the diastereotopicity, the methylene protons of the ethyl groups appear as a high-order multiplet, but give rise to a binomial quadruplet upon formation of the C_s-symmetric pyridine adduct [Al(mbmp)Et(py)]. The ethylene-linked bisphenol ebmpH$_2$[8] also forms a dimeric methyl complex [Al(ebmp)Me]$_2$ with NMR spectroscopic features similar to that of [Al(mbmp)Me]$_2$.

When precisely two equiv. of 2-propanol is added to an ethereal solution of the alkyl [Al(mbmp)R]$_2$ (R = Me, Et), the isopropoxide [Al(mbmp)(μ-O*i*Pr)]$_2$ is formed with concomitant alkane evolution and can be isolated as colorless crystals in 79% yield (Scheme 1). This compound can be independently prepared by reacting commercially available aluminum tri(isopropoxide) with one equiv. of mbmpH$_2$. The ^{1}H and ^{13}C NMR spectra indicate a molecule with a mirror plane bisecting the mbmp ligand, while the parent ion in the EI mass spectrum suggests a dimeric structure.

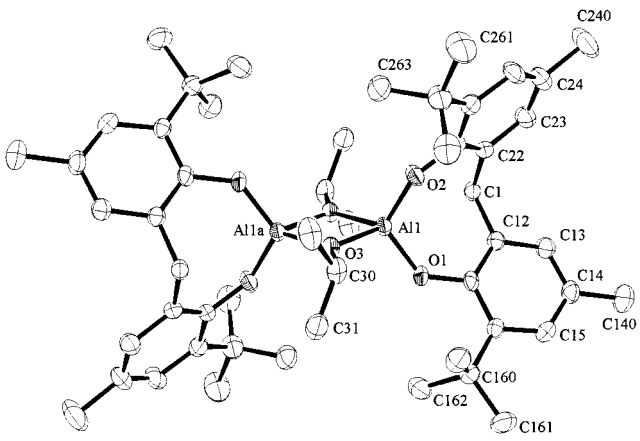

Figure 1. ORTEP diagram of the molecular structure of [Al(mbmp)(μ-O*i*Pr)]$_2$. Thermal ellipsoids are drawn at 50% probability level. Hydrogen atoms are omitted for the sake of clarity; selected bond lengths [Å] and angles [°]: Al1–O1 1.698(2), Al1–O2 1.694(3), Al1–O3 1.822(2), Al1–O3a 1.813(2); Al1–O1–C11 134.8(2), Al1–O2–C21 141.0(2), O1–Al1–O2 116.4(1), O1–Al1–O3 112.2(1), O3–Al1–O3a 81.1(1), Al1–O3–Al1a 99.0(1).

The single-crystal X-ray diffraction (Table 1, Figure 1) confirms the centrosymmetric dimeric structure with pseudo C_{2h} symmetry. The average Al–O bond lengths of 1.696(2) Å for the chelate is somewhat longer than those observed in AlMe(OC$_6$H$_2$-2,6-*t*Bu$_2$-4-Me)$_2$ (MAD) (1.686 Å), and the angles at the phenoxy oxygens of 134.8(2) and 141.0(2)° are

[a] Efficiency is defined as the fraction of active initiators, calculated from the observed number of polymer chains relative to the theoretical ones, assuming that each aluminum initiates one polymer chain.

smaller [average 143.6(2)° in MAD].[3a] These features may reflect the diminished double-bond character of the aluminum-oxygen bond within the mbmp chelate ring.[9] The two Al(mbmp) moieties with tetrahedrally-coordinated aluminum centers are linked by two isopropoxide groups. The geometry of the planar Al_2O_2 ring [average Al–O distance 1.818(2) Å; O–Al–O angle 81.1(1)°] corresponds to that of similar dimeric aluminum alkoxides such as [Al(OC$_6$H$_2$-2,4,6-*t*Bu$_3$)$_2$(μ−OEt)]$_2$ with Al–O distance of 1.845(2) Å and O–Al–O = 77.7(1)°,[10a] [AlH$_2$(μ−O*t*Bu)]$_2$ [Al–O = 1.810(3) Å and O–Al–O = 81.0(2)°],[10b] or [(η^1-C$_5$H$_5$)$_2$Al(μ-O-*i*Pr)]$_2$ [Al–O = 1.829(1) Å and O–Al–O = 80.85(1)°].[10c]

Molecular weight measurements in nonpolar solvents were inconclusive, probably due to the presence of a monomer–dimer equilibrium. As expected, molecular weight determination by vapor-pressure osmometry in THF indicated a mononuclear structure. By ^{1}H NMR spectroscopy, the formation of a 1:1 adduct with Lewis bases such as pyridine and γ-butyrolactone Al(mbmp)(O*i*Pr)(L) can be observed.

When monomeric AlMe(OC$_6$H$_2$-2,6-*t*Bu$_2$-4-Me)$_2$ is treated with 2-propanol, methane formation does not occur. Rather, under kinetic control, one equiv. of the bulky phenol HOC$_6$H$_2$-2,6-*t*Bu$_2$-4-Me is displaced to give [AlMe(OC$_6$H$_2$–2,6-*t*Bu$_2$-4-Me)(μ-O*i*Pr)]$_2$ as colorless crystals in high yields. The methyl group at the aluminum is recorded in the ^{1}H NMR spectrum at δ = –0.48. In the ^{13}C NMR spectrum the corresponding signal could not be detected, probably due to excessive broadening. Over the temperature range of +80 to –80 °C there is no significant change in the signal pattern. Molecular weight measurements in nonpolar solvents were inconclusive, but the dimeric structure can be inferred from the parent ion in the EI mass spectrum.

Single-crystal X-ray structural analysis (Table 1, Figure 2) showed a dimeric structure with two isopropoxo bridges and the ligands at the two aluminum centers arranged in a *cis* fashion. Metrical parameters such as Al–CH$_3$ [1.938(4), 1.945(4) Å] and Al–O distances of the phenoxy ligands [1.708(2), 1.698(2) Å] are within the expected ranges,[3a,10a,11] as are the values for the Al_2O_2 ring [average Al–O distance = 1.842(2) Å; O–Al–O angle = 99.1(1)°]. Most notably, the phenyl ring of one OC$_6$H$_2$-2,6-*t*Bu$_2$-4-Me ligand is turned in such a way as to bisect the plane formed by the Al_2O_2 lozenge [angle between the planes 82.4(1)°]. The other phenyl ring is in an almost orthogonal arrangement, the angle between the two aromatic rings amounting to 80.4(1)°. The two isopropyl groups of both of the bridging ligands are turned so that the methine hydrogens point toward the aluminum bearing the orthogonal aromatic ring. Evidently, the two aluminum fragments have to undergo substantial "gear-meshing" to alleviate the steric strain caused by the dimerization.

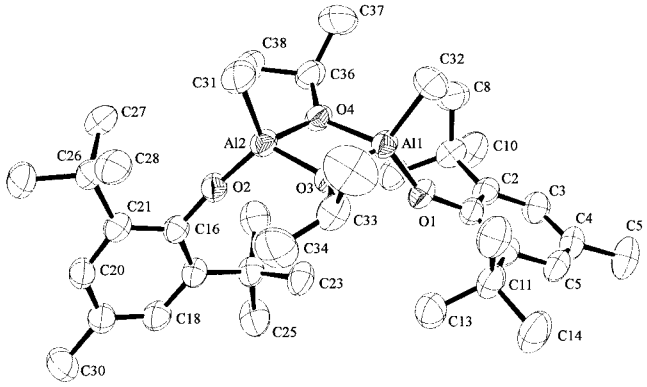

Figure 2. ORTEP diagram of the molecular structure of [AlMe(OC$_6$H$_2$–2,6-*t*Bu$_2$-4-Me)(μ-O*i*Pr)]$_2$. Thermal ellipsoids are drawn at 50% probability level. Hydrogen atoms are omitted for the sake of clarity; selected bond lengths [Å] and angles [°]: Al1–C32 1.938(4), Al1–O1 1.708(2), Al1–O3 1.839(2), Al1–O4 1.855(2), Al2–C31 1.945(4), Al2–O2 1.698(2), Al2–O3 1.837(2), Al2–O4 1.835(2); Al1–O1–C1 149.2(2), Al2–O2–C16 167.5(2), O1–Al1–C32 116.0(2), O1–Al1–O3 112.0(1), O3–Al1–O4 80.1(1), Al1–O3–Al2 99.3(1), Al1–O4–Al2 98.8(1), O2–Al2–C31 120.5(2), O2–Al2–O3 116.0(1).

Both the isopropoxo complexes are highly active initiators for the ring-opening polymerization of ε-caprolactone.[1] As summarized in Table 2, high molecular weights can be achieved in toluene at 50 °C, [AlMe(OC$_6$H$_2$–2,6-Bu$_2$-4-Me)(μ-O*i*Pr)]$_2$ being particularly active (complete conversion of a 2.0 M solution of monomer within 30 min). Moreover, the chelate complex [Al(mbmp)(μ-O*i*Pr)]$_2$ behaves in a controlled manner, as judged by the low molecular weight distribution values. The number-averaged molecular weights increase linearly with conversion, as well as with monomer to initiator ratio. Notably, since the effici-

ency, reflecting the number of chains started per aluminum, has a value of about 0.36 (run no. 1–4), we suggest that, under the conditions studied, the equilibrium between the dimer and the monomer Al(mbmp)(μ-O*i*Pr) is not completely on the side of the monomer.[12] The equilibrium constant for the dissociation in the presence of γ-butyrolactone as a nonpolymerizable lactone at 50 °C can be estimated to be K_{eq} = 0.15 mol L^{-1}. However, we cannot exclude the possibility that the dimeric species is also capable of initiating polymerization. Polymerization initiated by $[AlMe(OC_6H_2$–2,6-*t*Bu_2-4-Me)(μ-O*i*Pr)$]_2$ is noticeably less controlled, as can be judged by the higher molecular weight distribution values as well as by the rather erratic efficiencies. We suspect that initiation may occur both at the Al-Me and Al-O*i*Pr function.[13,14]

Experimental Section

General Considerations: All experiments were performed under argon using standard Schlenk or glovebox techniques. – THF, pentane, and hexane were purified by distillation from sodium/benzophenone ketyl. Toluene was distilled over sodium sand. ε-Caprolactone was dried over calcium hydride and distilled. Commercially available $mbmpH_2$ (Aldrich), trimethyl-, and triethylaluminum (WITCO) were used as received. $AlMe(OC_6H_2$–2,6-*t*Bu_2-4-Me$)_2$ was prepared according to a literature procedure.[3a] – NMR spectra were recorded on a Bruker DRX 400 spectrometer (^{1}H, 400 MHz; ^{13}C, 101 MHz) in $CDCl_3$ at 298 K, unless otherwise stated. Chemical shifts for ^{1}H and ^{13}C spectra were referenced internally using the residual solvent resonances and reported relative to tetramethylsilane. – Mass spectra were recorded on a Finnigan 8230 spectrometer. – Elemental analyses were performed by the microanalytical laboratory of this department. – Gel permeation chromatographic (GPC) analyses of the polymers were performed using a SpectraSeries P100 pump, a SDV 5μ 60 cm column, two 100 A 5 μ columns, with lengths of 5 cm and 30 cm, respectively, and a Shodex-RI-71 detector. THF was used as eluent; flow rate: 1 mL/min. – Molecular weights were corrected by universal calibration relative to polystyrene standards.

[Al(mbmp)Me]$_2$: To a suspension of $mbmpH_2$ (10.0 g, 29.5 mmol) in 40 mL of hexane was slowly added a 2.0 M solution of trimethylaluminum in hexane (14.75 mL, 29.5 mmol). Instantaneous and vigorous evolution of methane and heat was observed. Upon cooling the reaction mixture, a colorless precipitate formed that was filtered off, washed with cold hexane (2 × 10 mL), and dried in vacuo to give colorless microcrystals; yield 10.76 g (95%). – ^{1}H NMR: δ = –0.39 (s, 3 H, $AlCH_3$), 1.14 [s, 9 H, $C(CH_3)_3$], 1.28 [s, 9 H, $C(CH_3)_3$], 2.15 (s, 3 H, 4-CH_3), 2.24 (s, 3 H, 4-CH_3), 3.34 (d, $^2J_{HH}$ = 13.7 Hz, 1 H, CH_2), 4.27 (d, $^2J_{HH}$ = 13.7 Hz, 1 H, CH_2), 6.88 (d, $^4J_{HH}$ = 2.0 Hz, 1 H, 5-H), 6.91 (d, $^4J_{HH}$ = 2.0 Hz, 1 H, 5-H), 6.96 (d, $^4J_{HH}$ = 2.0 Hz, 1 H, 3-H), 7.01 (d, $^4J_{HH}$ = 2.0 Hz, 1 H, 3-H). – ^{13}C{^{1}H} NMR: δ = –7.4 ($AlCH_3$), 21.2, (4-CH_3), 21.3 (4-CH_3), 29.7 [$C(CH_3)_3$], 32.1 [$C(CH_3)_3$], 34.7 [$C(CH_3)_3$], 35.2 [$C(CH_3)_3$], 36.3 (CH_2), 126.6 (C-3), 127.5 (C-3'), 127.7 (C-5), 128.1 (C-5'), 130.7 (C-4), 130.9 (C-4'), 133.1 (C-2), 134.7 (C-2'), 138.1 (C-6), 141.3 (C-6'), 144.7 (C-1), 151.6 (C-1'). – EI MS; *m*/*z* (%): 760 (48) [M^+], 380 (100) [$M/2^+$], 57 (78) [$C_4H_9^+$]. – $C_{24}H_{33}AlO_2$ (380.5): calcd. C 75.76, H 8.74; found C 76.71, H 9.64.

[Al(mbmp)Et]$_2$: This compound was synthesized in a manner analogous to that described for $[Al(mbmp)Me]_2$ using triethylaluminum and isolated as colorless microcrystals in 86% yield. – ^{1}H NMR: δ = 0.42 (m, 2 H, $AlCH_2CH_3$), 0.84 (t, $^3J_{HH}$ = 7.0 Hz, 3 H, $AlCH_2CH_3$), 1.26 [s, 9 H, $C(CH_3)_3$], 1.36 [s, 9 H, $C(CH_3)_3$], 2.20 (s, 3 H, 4-CH_3), 2.31 (s, 3 H, 4-CH_3), 3.56 (d, $^2J_{HH}$ = 14.0 Hz, 1 H, CH_2-bridge), 4.56 (d, $^2J_{HH}$ = 14.0 Hz, 1 H, CH_2-bridge), 6.95 (d, $^4J_{HH}$ = 1.8 Hz, 1 H, 5-H), 7.09 (d, $^4J_{HH}$ = 1.8 Hz, 1 H, 3-H), 7.21 (d, $^4J_{HH}$ = 1.8 Hz, 1 H, 3-H). – ^{13}C{^{1}H} NMR: δ = 8.0 ($AlCH_2CH_3$), 21.3 ($AlCH_2CH_3$), 30.2, (4-CH_3), 30.3 (4'-CH_3), 32.3 [$C(CH_3)_3$], 35.0 [$C(CH_3)_3$], 35.6 [$C(CH_3)_3$], 35.9 (CH_2-bridge), 126.8 (C-3), 127.85 (C-3'), 128.3 (C-5), 129.9 (C-5'), 130.3 (C-4), 131.2 (C-4'), 133.5 (C-2), 134.9 (C-2'), 138.2 (C-6), 140.9 (C-6'), 152.9 (C-1). – EI MS; *m*/*z* (%): 788 (17) [M^+], 394 (74) [$M/2^+$]. – $C_{25}H_{35}AlO_2$ (394.5): calcd. C 76.11, H 8.94; found C 76.42, H 9.23.

Upon adding 10 equiv. of pyridine, the pyridine adduct Al(mbmp)Et(py) was formed. – ^{1}H NMR: δ = –0.41 (q, $^3J_{HH}$ = 6.4 Hz, 2 H, $AlCH_2CH_3$), 0.79 (t, $^3J_{HH}$ = 6.4 Hz, 3 H, $AlCH_2CH_3$), 1.13 [s, 18 H, $C(CH_3)_3$], 1.95 (s, 6 H, 4-CH_3), 3.08 (d, $^2J_{HH}$ = 14.0 Hz, 1 H, CH_2-bridge), 3.52 (d, $^2J_{HH}$ = 14.0 Hz, 1 H, CH_2-bridge), 6.42 (d, $^4J_{HH}$ = 1.6 Hz, 2 H, 5-H), 6.64 (d, $^4J_{HH}$ = 1.6 Hz, 2 H, 3-H), 6.98 (m, 2 H, py), 7.38 (m, 1 H, py), 8.33 (m, 2 H, py); – ^{13}C NMR: δ = 10.7 ($AlCH_2CH_3$), 16.1 ($AlCH_2CH_3$), 22.8 (4-CH_3), 31.9 [$C(CH_3)_3$], 35.4 [$C(CH_3)_3$], 36.8 (CH_2-bridge), 125.3 (C-3), 125.9 (py), 127.6 (C-5), 128.4 (py), 130.9 (C-4), 132.6 (C-2) 140.1 (C-6), 151.6 (py), 155.2 (C-1).

[Al(ebmp)Me]$_2$: This compound was synthesized in a manner analogous to that described for $[Al(mbmp)Me]_2$ and isolated as colorless microcrystals in 79% yield. – ^{1}H NMR: δ = –0.81 (s, 3 H, $AlCH_3$), 1.11 [s, 9 H, $C(CH_3)_3$], 1.43 [s, 9 H, $C(CH_3)_3$], 2.24 (s, 3 H, 4-CH_3), 2.31 (s, 3 H, 4'-CH_3), 2.71 (m, 3 H, CH_2CH_2), 3.27 (m, 1 H, CH_2CH_2), 6.81 (d, $^4J_{HH}$ = 1.8 Hz, 1 H, 5-H), 6.89 (d, $^4J_{HH}$ = 1.8 Hz, 1 H, 5-H), 6.93 (d, $^4J_{HH}$ = 1.8 Hz, 1 H, 3-H), 7.10 (d, $^4J_{HH}$ = 1.8 Hz, 1 H, 3-H). – ^{13}C NMR: δ = –5.5 ($AlCH_3$), 20.8 (4-CH_3), 20.9 (4-CH_3), 30.8 [$C(CH_3)_3$], 31.6 [$C(CH_3)_3$], 33.1 [$C(CH_3)_3$], 34.6 [$C(CH_3)_3$], 36.0 (CH_2-bridge), 37.9 (CH_2-bridge), 126.4 (C-6), 126.6 (C-3), 127.5 (C-6), 128.3 (C-4), 128.5 (C-4), 128.9 (C-4), 129.3 (C-5), 134.1 (C-2), 135.9 (C-2), 140.5 (C-1), 144.4 (C-1). – EI MS; *m*/*z* (%): 789 (100) [M^+], 774 (65) [$M^+ - C_4H_9$], 380 (24) [$M/2^+ - CH_3$]. – $C_{25}H_{35}AlO_2$ (394.5): calcd. C 76.11, H 8.94; found C 76.19, H 8.43.

[Al(mbmp)(μ-O*i*Pr)]$_2$: A suspension of $[Al(mbmp)Me]_2$ (4.66 g, 6.1 mmol) in 20 mL of diethyl ether was treated dropwise under vigorous stirring at room temperature with 2-propanol (0.9 mL, 12.1 mmol). After some minutes an exothermic gas evolution began. Upon cooling, a precipitate formed which was filtered, washed with hexane, and dried in vacuo; yield 4.07 g (79%) of colorless microcrystals. – ^{1}H NMR: δ = 1.39 [s, 18 H, $C(CH_3)_3$], 1.58 [d, $^3J_{HH}$ = 6.4 Hz, 6 H, $CH(CH_3)_2$], 2.18 (s, 6H, 4-CH_3), 3.69 (d, $^2J_{HH}$ = 14.0 Hz, 1 H, CH_2), 3.89 (d, $^2J_{HH}$ = 14.0 Hz, 1 H, CH_2), 4.66 [septet, $^3J_{HH}$ = 6.4 Hz, 1 H, $CH(CH_3)_2$], 6.97 (d, $^4J_{HH}$ = 2.0 Hz, 2 H, 5-H), 7.11 (d, $^4J_{HH}$ = 2.0 Hz, 2 H, 3-H). – ^{13}C{^{1}H} NMR: δ = 19.2 (4-CH_3), 23.4 [$CH(CH_3)_2$], 28.6 [$C(CH_3)_3$], 33.4 (CH_2), 69.7 [$CH(CH_3)_2$], 124.8 (C-3), 126.5 (C-5), 127.1 (C-4), 127.4 (C-6), 136.7 (C-2), 149.7 (C-1). – EI MS; *m*/*z* (%): 848 (6) [M^+]. – $C_{26}H_{37}AlO_3$ (424.6): calcd. C 73.55, H 8.78; found C 73.18, H 8.55.

Upon adding 10 equiv. of pyridine, the pyridine adduct Al(mbmp)(O*i*Pr)(py) was formed. – ^{1}H NMR: δ = 1.11 [d, $^3J_{HH}$ = 6.4 Hz, 6 H, $CH(CH_3)_2$], 1.56 [s, 18 H, $C(CH_3)_3$], 2.14 (s, 6 H, 4-CH_3), 3.31 (d, $^2J_{HH}$ = 14.1 Hz, 1 H, CH_2-bridge), 3.99 (d, $^2J_{HH}$ = 14.1 Hz, 1 H, CH_2-bridge), 4.81 [s, $^3J_{HH}$ = 6.4 Hz, 1 H, $CH(CH_3)_2$], 6.97 (d, $^4J_{HH}$ = 1.6 Hz, 2 H, 5-H), 7.18 (d, $^4J_{HH}$ = 1.8 Hz, 2 H, 3-H), 7.22 (m, 2 H, py), 7.62 (m, 1 H, py), 8.55 (m, 2

H, py). – ^{13}C NMR: δ = 21.3 (4-CH_3), 27.7 [$CH(CH_3)_2$], 30.4 [$C(CH_3)_3$], 34.2 (CH_2-bridge), 35.1 [$C(CH_3)_3$], 64.3 [$CH(CH_3)_2$], 125.3 (C-3), 126.0 (C-5), 126.2 (py), 129.4 (C-4), 130.7 (C-2), 138.21 (py), 40.1 (C-6), 149.9 (C-1), 153.8 (py).

[AlMe(OC$_6$H$_2$-2,6-*t*Bu$_2$-4-Me)(μ-O*i*Pr)]$_2$: To a suspension of MAD (2.63 g, 4.8 mmol) in 10 mL of diethyl ether was added over a period of 2 h 2-propanol (0.37 mL, 4.8 mmol) at room temperature. The reaction mixture was stirred overnight and the solvent volume reduced to half, resulting in a precipitate of a colorless solid. In order to complete the precipitation, hexane was added. The supernatant was filtered off, the precipitate washed with diethyl ether (2 × 10 mL), and dried in vacuo; yield 1.10 g (72%) of colorless crystals. – ^{1}H NMR: δ = –0.48 (s, 3 H, $AlCH_3$), 1.41 [s, 18 H, $C(CH_3)_3$], 1.44 [d, 6 H, $^3J_{HH}$ = 6.2 Hz, $CH(CH_3)_2$], 2.27 (s, 6 H, 4-CH_3), 4.93 [septet, $^3J_{HH}$ = 6.2 Hz, 1 H, $CH(CH_3)_2$], 7.03 (s, 2 H, C-3,5). – ^{13}C NMR: δ = 21.4 [$CH(CH_3)_2$], 25.3 (4-CH_3), 31.7 [$C(CH_3)_3$], 35.3 [$C(CH_3)_3$], 69.9 [$CH(CH_3)_2$], 126.5 (C-3,5), 126.9 (C-4), 139.0 (C-2,6), 153.4 (C-1). – EI MS; *m/z* (%): 640 (6) [M^+], 365 (61) [$Al(OC_{15}H_{24})(OC_3H_7)_2^+$]. – $C_{19}H_{33}AlO_2$ (320.4): calcd. C 71.21, H 10.38; found: C 71.19, H 10.43.

Polymerization of μ-Caprolactone: An appropriate amount of the initiator was dissolved in toluene (5 mL) and heated to 50 °C. ε-Caprolactone was added to give a ca. 2 M solution of the monomer, and the polymerization initiated. The reaction mixture was worked up after complete conversion by dropwise adding it to a tenfold volume of methanol. The poly(ε-caprolactone)s were filtered off and dried in vacuo until the weight remained constant.

X-Ray Crystal Structure Analysis of [Al(mbmp)(μ-O*i*Pr)]$_2$ and [AlMe(OC$_6$H$_2$–2,6-*t*Bu$_2$-4-Me)(μ-O*i*Pr)]$_2$: Relevant crystallographic data for [Al(mbmp)(μ-O*i*Pr)]$_2$ and [AlMe(OC$_6$H$_2$-2,6-*t*Bu$_2$-4-Me)(μ-O*i*Pr)]2 are summarized in Table 1. Single crystals suitable for X-ray crystal structure analysis were obtained by slow cooling of concentrated pentane solutions. Data collections were performed on an Enraf–Nonius CAD-4 diffractometer with graphite-monochromated Cu-K_α radiation. Data reductions were carried out using the program system XCAD4[15a] for [Al(mbmp)(μ-O*i*Pr)]$_2$ and MolEN[15b] for [AlMe(OC$_6$H$_2$-2,6-*t*Bu$_2$-4-Me)(μ-O*i*Pr)]$_2$. From the measured reflections, all independent reflections were used and the parameters were refined by full-matrix least-squares against all F_o^2 data (SHELXL-93).[15c] The structure was solved using direct methods (SHELXS-86)[15d] and difference-Fourier syntheses and refined with anisotropic thermal parameters for nonhydrogen atoms. The hydrogen atoms in [Al(mbmp)(μ-O*i*Pr)]$_2$ were calculated at their idealized positions, whereas those in [AlMe(OC$_6$H$_2$-2,6-*t*Bu$_2$-4-Me)(μ-O*i*Pr)]$_2$ were located and refined with isotropic parameters. Crystallographic data for the structures have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-104970 for [Al(mbmp)(μ-O*i*Pr)]$_2$ and –133689 for [AlMe(OC$_6$H$_2$-2,6-*t*Bu$_2$-4-Me)(μ-O*i*Pr)]$_2$. Copies of the data can be obtained free of charge from the Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44 (1223)336–033 or E-mail: deposit@ccdc.cam.ac.uk or http://www.ccdc.cam.ac.uk].

Effect of Substitution on the ESR Spectra and Electronic Ground State of ZnTPP Cation Radicals

Paresh C. Dave[a] and D. Srinivas*[b]

Keywords: Zinc / Metalloporphyrins / Porphyrins / Cations / Radicals / ESR

Zinc(II) complexes of substituted tetraphenylporphyrins, Zn[T(X–P)P], where X = H, *p*-F, *p*-Cl, *m*-Cl, *p*-CH_3O, and *m*-CH_3O, have been synthesized and characterized. Peripheral substitution shows marked changes in the chemical shifts of the phenyl proton resonances and $E_{1/2}$ values of the redox couples in the anodic region while the UV/Vis spectra are unaffected. The monocation radicals of these complexes are generated by chemical oxidation with bromine. The ESR spectra reveal the formation of two types of radical species, $Zn[T(X–P)P]^{+\cdot}Br^-$ (species **I**) and $Zn[T(X–P)(Br_n–P)]^{+\cdot}Br^-$ (species **II**): Species **I** at 298 K shows a spectrum, with well-resolved bromine hyperfine features, characteristic of a $^2A_{2u}$ electronic ground state while species **II**, except for the complex with X = *m*-CH_3O, shows a featureless, isotropic resonance attributable to a $^2A_{1u}$ state. $Zn[T(m\text{-}CH_3O–P)(Br_n–P)]^{+\cdot}Br^-$, on the other hand, exhibits nine resolved nitrogen hyperfine features corresponding to a $^2A_{2u}$ state. Variable temperature ESR spectra (77–298 K) indicate reduction in the bromine and nitrogen hyperfine coupling constants and an increase in the g value of species **I** from 2.0049 to 2.0060 with lowering temperature and suggest a labile electronic ground state for species **I**. The *p*-CH_3O substituted complex exhibits an electronic transformation from $^2A_{2u}$ to $^2A_{1u}$ while the remaining complexes, including *m*-CH_3O, show a transformation from $^2A_{2u}$ to an admixed $^2A_{1u}/^2A_{2u}$ state. The effect of substitution on the variable temperature ESR spectra are discussed.

Introduction

Porphyrin π-cation radicals play a crucial role in the mechanisms of various biocatalytic reactions, including oxygen activation by heme proteins,[1–9] and in the electron-transfer processes at the photosynthetic reaction centre.[10,11] Based on the electronic ground state, the π-cation radicals have been categorised into those possessing a $^2A_{1u}$ or a $^2A_{2u}$ ground state.[9] The two highest occupied molecular orbitals of metalloporphyrins (a_{1u} and a_{2u}) are nearly degenerate and their relative energies are dictated by many factors, including the nature and position of the porphyrin peripheral substitution, the central metal ion, the identity and disposition of the axial ligand, environment, temperature and symmetry of the molecule.[12–18] Compound **I** of catalase and chloroperoxidase enzymes belong to the former category of radicals.[7] The electronic ground state of compound **I** of horseradish peroxidase enzyme is still to be conclusively determined. ENDOR and magnetic circular dichroism studies have indicated a $^2A_{2u}$ ground state for HRP-I[19,20] while more recent NMR[21,22] and Resonance Raman (RR)[23,24] studies show a $^2A_{1u}$ state. A correlation between the electronic structure and functionality is interesting, but so far not conclusive and therefore needs further work.[2]

Generally, among the synthetic metalloporphyrins, the cation radicals of the octaethylporphyrins $M\{OEP\}^{+\cdot}$ possess a $^2A_{1u}$ ground state while those of the tetraphenylporphyrins $M\{TPP\}^{+\cdot}$ possess a $^2A_{2u}$ state ($M = Zn^{2+}$ and Mg^{2+}).[1,9,25,26] However, it was found that $Co\{OEP\}^{+\cdot}$ and $Ru\{OEP\}^{+\cdot}$ have a $^2A_{1u}$ ground state with Br^- as the counter ion and $^2A_{2u}$ with ClO_4^- as the counter ion.[21,27] The electron density is greater at the *meso* carbon atoms in the case of the $^2A_{2u}$ configuration, and hence electron-withdrawing substituents on the tetraphenyl groups of $M\{TPP\}^{+\cdot}$ affect the energetics of a_{2u} while a_{1u} is unaltered. On the other hand, for radicals with a $^2A_{1u}$ electronic ground state, the electron density is greater at the β carbon atoms of the pyrrole ring while the *meso* carbons lie in the nodal plane, and hence substitution on the pyrrole ring alters the position of the a_{1u} level while a_{2u} is hardly affected. Therefore, by a rational substitution it is possible, in principle, to design a molecule with a desired property.

Gross and co-workers have reported an admixed ground state for zinc complexes of halogen-substituted tetraphenylporphyrin cation radicals.[28,29] The quantum admixture of $^2A_{1u}$ and $^2A_{2u}$ states was also reported by Kalsbeck et al.[30] for $Zn[T(Cl_2–P)P]^{+\cdot}$ and $Mg\{T(Cl_2–P)P]^{+\cdot}$ radicals where $T(Cl_2–P)P$ = tetrakis(*o*-dichlorophenyl)porphyrin. Theoretical studies on the π-cation radicals of metalloporphyrins have shown that electron-withdrawing substituents in the *meso* position lead to a $^2A_{1u}$ ground state while electron-donating substituents result in a $^2A_{2u}$ state.[31] Density functional calculations have revealed that electron-withdrawing substituents in the *meta* and *para* positions should exert significantly stronger electronic effects than with *ortho* substitution.[32] Our recent studies using variable temperature ESR spectroscopy indicated, for the first time, a labile electronic ground state for $Zn[T(H–P)P]^{+\cdot}Br^-$ with a $^2A_{2u}$

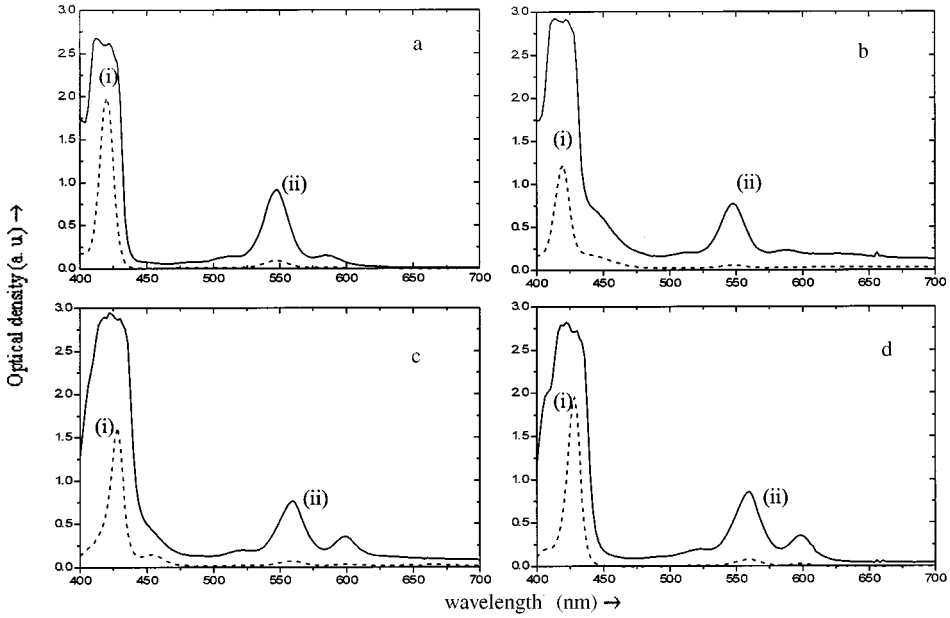

Figure 1. UV/Visible spectra for Zn[T(*m*-CH_3O–P)P] in CH_2Cl_2: (a) neutral species, (b) cation radical, (c) cation radical + pyrazine, and (d) neutral species + pyrazine; (i) spectrum for 10 times lower concentration and (ii) for higher concentrations; optical density is in units of mol·cm

ground state at 298 K changing to a $^2A_{1u}$ state at 77 K.[33] In the course of understanding the factors influencing the electronic structure and structure-reactivity correlations, we here report the effect of peripheral substitution (X) on the ESR spectral properties and ground state configuration of $Zn[T(X–P)P]^{+\cdot}Br^-$ radical cations generated by chemical oxidation with bromine. Two types of radical species viz., $Zn[T(X–P)P]^{+\cdot}Br^-$ (**I**) and $Zn[T(X–P)(Br_n–P)]^{+\cdot}$, $n = 8$ or 4 (**II** and **II'**, respectively) are observed on oxidation with bromine. Irrespective of the nature of the peripheral substitution (X = *p*-CH_3O, *p*-Cl, *p*-F, *m*-CH_3O, *m*-Cl), species **I** showed a labile electronic ground state ($^2A_{2u}$ at 298 K and $^2A_{1u}$ or admixed $^2A_{1u}/^2A_{2u}$ at 77 K). Species **II**, however, is $^2A_{1u}$ throughout the temperature range 77–298 K, although species **II'** exhibits ground state lability similar to that of species **I**. The changes in the electronic structure are proposed to be associated with the changes in the conformational geometry of the porphyrin skeleton. It is to be noted that the notations $^2A_{1u}$ and $^2A_{2u}$ assume D_{4h} symmetry for the porphyrin cores. These notations are used here only for simplicity as the porphyrin cores of the molecules studied in this work have a symmetry lower than D_{4h}.

Results and Discussion

A typical UV/Vis spectrum for Zn[T(*m*-CH_3O–P)P] is shown in Figure 1 a. Substituents have little effect and showed similar UV/Vis spectra for all the complexes. In strong donor solvents and in the presence of nitrogenous ligands, such as pyridine, imidazole and pyrazine (Figure 1 d), the Soret and Q-bands are red shifted indicating a change in molecular conformation, probably due to solvation and axial ligand coordination. The cation radicals of Zn[T(X–P)P], generated by chemical oxidation with bromine, showed a blue-shift and reduced intensity for the Soret band and broad, diffused, overlapping Q-bands in the region 500–700 nm (Figure 1 b). These spectral features are characteristic of a $^2A_{2u}$ ground state of the porphyrin cation radical.[25,26] Upon adding nitrogenous ligands to the radical solution, a spectrum typical of the neutral species was observed, indicating the instability of cation radicals in the presence of coordinating ligands (Figure 1 c). This agrees well with the RR results on some iron tetraphenylporphyrin cation radicals.[34]

The effect of substitution is clearly manifested on the chemical shifts of the phenyl proton resonances; the signals due to the β-protons are unaffected. These resonances were shifted up-field due to the substitution. This shift, with *para* substitution, was marginal for the *ortho* protons and varies in the sequence H < F < Cl < OCH_3 while it was significant for the *meta* protons where it varies in the order H < Cl < F < OCH_3. Similar trends were also observed with *meta* substitution. The ^{1}H-NMR spectroscopic data for all the complexes are listed in Table 1. The trends described for the chemical shifts are completely in line with what is expected for phenyl protons and simply show that there is practically no conjugation between the porphyrin and the phenyl groups, as they are probably perpendicular to one other.

Cyclic voltammograms (CVs) of the complexes showed two quasi-reversible redox couples in the range 0 to +2.0 V, corresponding to $Zn[T(X–P)P]^{+\cdot}/Zn[T(X–P)P]$ and $Zn[T(X–P)P]^{2+}/Zn[T(X–P)P]^{+\cdot}$, respectively. Representative CV and differential pulse voltammograms (DPV) for Zn[T(*m*-CH_3O–P)P] are shown in Figure 2 and the electrochemical data are provided in Table 2. Ferrocene was used as the reference. The $E_{1/2}$ values vary with the substituents in the order F > Cl > H > OCH_3. Electron donating

Table 1. ^{1}H NMR spectroscopic data for Zinc(II) complexes of substituted tetraphenylporphyrins Zn[T(X–P)P] in $CDCl_3$

X	Pyrrole	*o*-	*m*-	*p*-
H	8.95	8.27, 8.25, 8.18	7.78, 7.76, 7.72	–

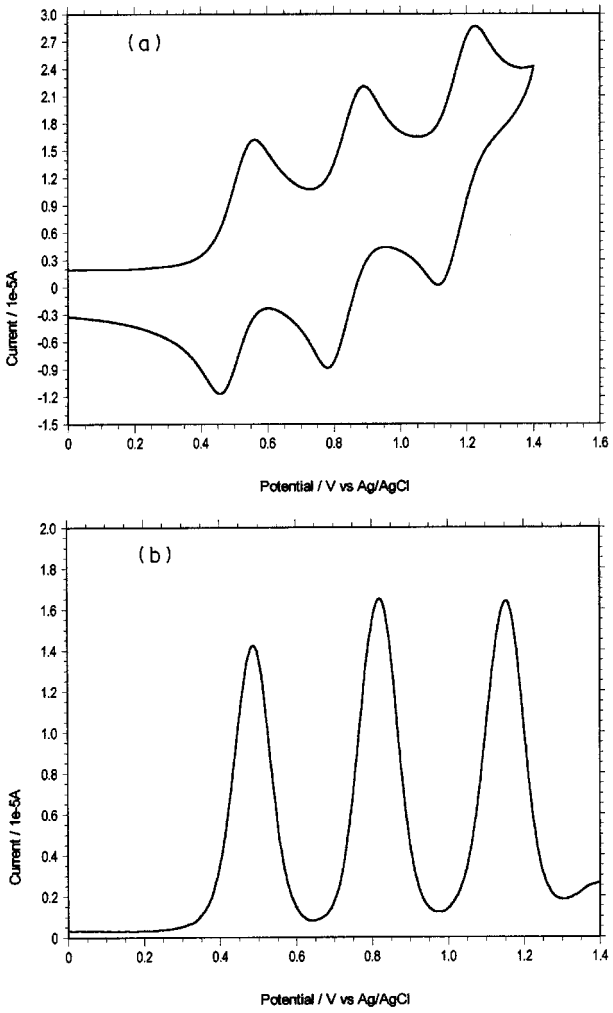

Figure 2. (a) CV (b) DPV of Zn[T(*m*-CH_3O–P)P] in CH_2Cl_2; working electrode: glassy carbon; reference electrode: Ag/AgCl; auxiliary electrode: Pt wire; supporting electrolyte: tetrabutylammonium hexafluorophosphate; scan rate: 100 mV/s; the first couple at $E_{1/2}$ = 0.51 V corresponds to the redox couple of ferrocene used as an internal reference

Table 2. Electrochemical data for 0.1 M Zn[T(X–P)P] in CH_2Cl_2

Compex	$E^1_{1/2}$	$E^2_{1/2}$
Zn[T(*p*-F–P)P]	0.95	1.42
Zn[T(*m*-Cl–P)P]	0.95	1.26
Zn[T(*p*-Cl–P)P]	0.93	1.2
Zn[T(H–P)P]	0.89	1.35
Zn[T(*m*-OCH_3–P)P]	0.84	1.17
Zn[T(*p*-OCH_3–P)P]	0.82	1.23

CH_3O substitution means that the oxidation is easier than with the electron-withdrawing halogen groups. The $E_{1/2}$ of the *meta*-substituted porphyrins is larger than that of the *para*-substituted porphyrins. The $E_{1/2}$ for couple **II**, $Zn[T(X–P)P]^{2+}/Zn[T(X–P)P]^{+\cdot}$ is more affected by the substitution than couple **I**, $Zn[T(X–P)P]^{+\cdot}/Zn[T(X–P)P]$. The trends in $E_{1/2}$ are as expected, as are the chemical shifts.

The ESR spectra of the cation radicals, in general, consist of four equally spaced resolved hyperfine (h.f.) features. The intensity of the third h.f. feature is greater than expected. Spectral simulations indicate the presence of two types of paramagnetic radical species; species **I** showing the characteristic four line h.f. pattern due to interaction of electron spin ($S = {}^1/_2$) with the nuclear spin (I) of ${}^3/_2$ and species **II** exhibiting an isotropic resonance. For species **I**, the coupling is due to coordinated bromide ion.[35] The intensity of the signal due to species **II** increased with excess bromine. Species **I** could be attributed to $Zn[T(X–P)P]^{+\cdot}Br^-$ and **II** to brominated cation radicals, $Zn[T(X–P)(Br_n–P)]^{+\cdot}Br^-$. Depending on the type of substitution (X) and its location (*para*/*meta*) the value of "*n*" can be 8 or 4.[36] Figure 3 shows a schematic representation of various oxidation products and their nomenclature. Two types of tetrabromotetraphenylporphyrin cation radicals (species **II'**) are possible, as shown in Figure 3 , one with one bromine substituent per pyrrole ring and the others with two bromine substituents on the two opposing pyrrole rings. ^{1}H-NMR spectroscopic studies by Crossley et al. favour the formation of the latter species with two bromine substituents on the two opposing pyrrole rings in the reaction of metal-free tetraphenylporphyrin with *N*-bromosuccinimide.[37]

The UV/Visible spectrum and the resolved h.f. coupling features of species **I** at ambient temperatures are characteristic of a $^2A_{2u}$ electronic ground state while the featureless isotropic signal for species **II** is characteristic of a $^2A_{1u}$ state. Upon sudden lowering of the temperature to 77 K, the h.f. features disappeared and, instead, only two overlapping isotropic resonances for species **I** and **II** or **II'** were visible. Representative spectra for the cation radicals of Zn[T(*p*-CH_3O–P)P] and Zn[T(*m*-CH_3O–P)P] at 298 and 77 K along with the simulated results are shown in Figure 4 and Figure 5 , respectively.

The spin Hamiltonian parameters for all the radicals are listed in Table 3. Except for Zn[T(*m*-CH_3O–P)P], the peak-to-peak linewidth (ΔH) increased from 5.5 to 8.0 G for species **II** while it decreased from 8.9 to 8.0 G for species **I** with lowering of the temperature. The g value increased from 2.0048 to 2.0057 and A_{Br} increased from 7.61 to 8.30

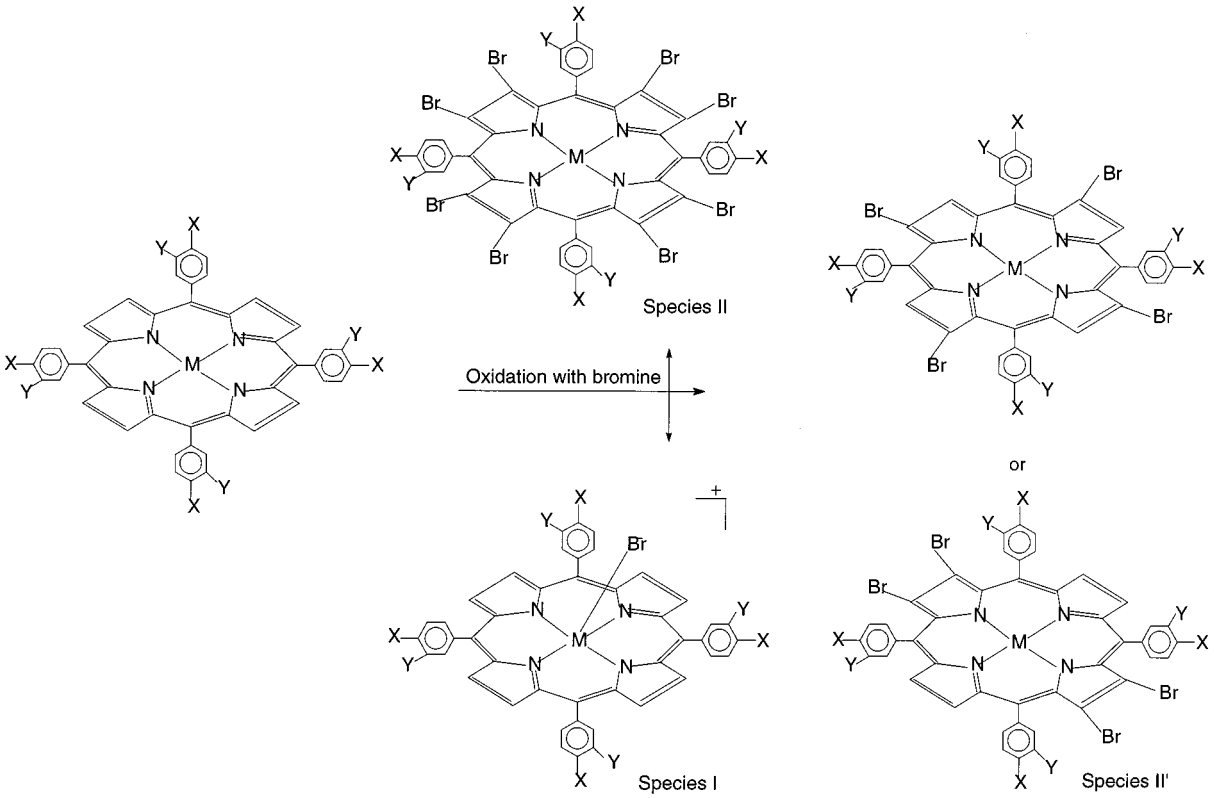

Figure 3. Schematic representation of various oxidation products of Zn[T(X–P)P]

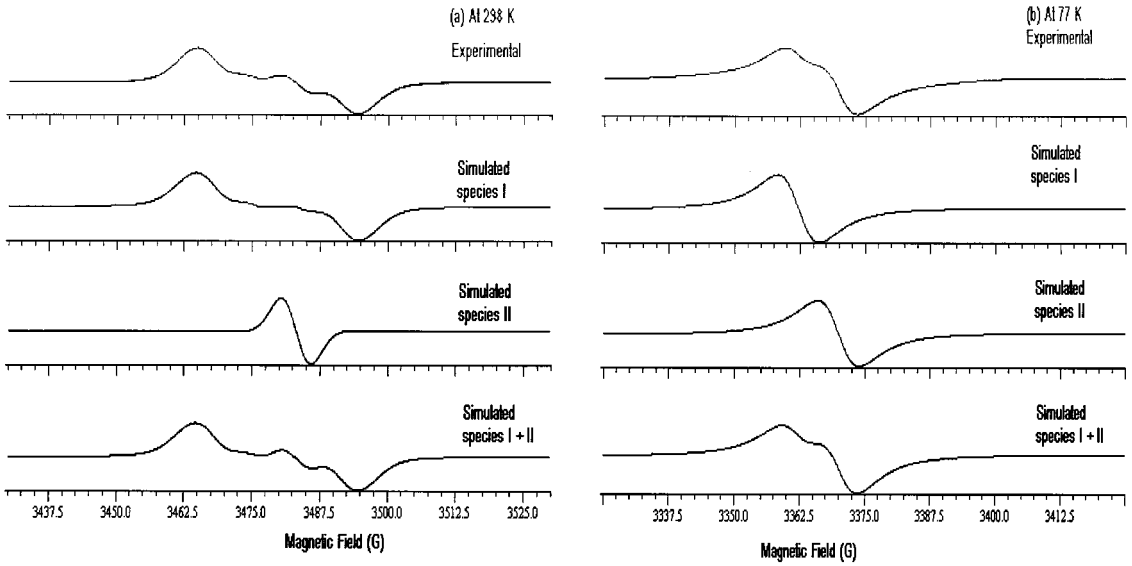

Figure 4. Experimental and simulated ESR spectra of Zn[T(*p*-CH_3O–P)P] in CH_2Cl_2 at 298 and 77 K; receiver gain = $5.02 \cdot 10^3$, modulation amplitude = 0.6 G, power = 2 mW, time constant = 81.92 ms, ν = 9.76 GHz (for 298 K) 9.46 GHz (for 77 K) and resolution in X = 1024

G with the increasing electron-withdrawing capacity of the substituent. The location of the substituent (*para* or *meta*) has a considerable effect on the A_{Br} value. This value increased from 7.61 to 8.20 for CH_3O substitution and decreased from 8.30 to 8.10 G for chloro substitution. The disappearance of the bromine h.f. coupling features at 77 K is attributed to a change in the electronic ground state from $^2A_{2u}$ to $^2A_{1u}$ for species **I**. A systematic variation of temperature in the range 298 K to 77 K, discussed below, for the cation radicals of Zn[T(*p*-CH_3O–P)P] and Zn[T(*m*-CH_3O–P)P], provides a deeper insight into the transition behaviour.

Figure 6 shows the variable temperature ESR spectra for the cation radicals of Zn[T(*p*-CH_3O–P)P] and Zn[T(*m*-CH_3O–P)P]. Bromine h.f. coupling constant (A_{Br}) for species **I** decreased gradually as the temperature was lowered

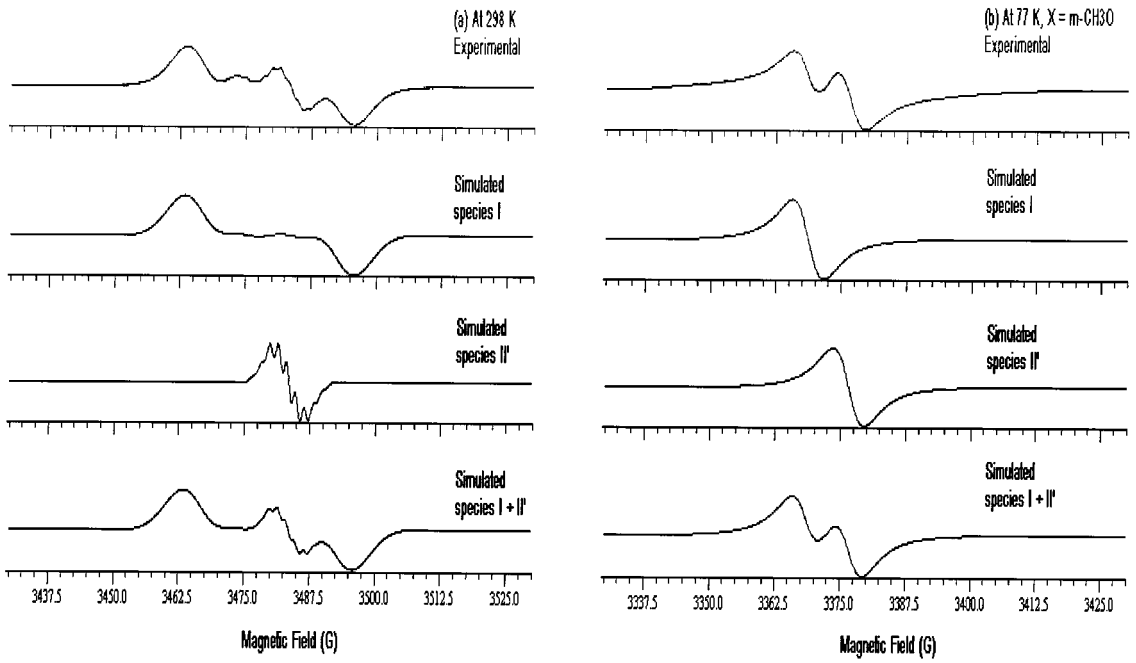

Figure 5. Experimental and simulated ESR spectra of Zn[T(*m*-CH_3O–P)P] in CH_2Cl_2 at 298 and 77 K; receiver gain = $5.02 \cdot 10^3$, modulation amplitude = 0.6 G, power = 2 mW, time constant = 81.92 ms, ν = 9.76 GHz (for 298 K) 9.46 GHz (for 77 K) and resolution in X = 1024

Table 3. Simulated EPR data for monocation radicals of Zinc(II) substituted tetraphenylporphyrins, $Zn[T(X–P)P]^{+\cdot}$, in $CHCl_3$

X	Temp. [K]	[g]	Species **I** A(Br) [G]	Δ*H* [G]	[g]	Species **II** Δ*H* [G]
p-CH_3O	298	2.0048	7.61	8.5	2.0028	5.5

	77	2.0076	–	8.4	2.0039	7.4

from 298 to 190 K, in steps of 10 K and from then onwards showed a featureless isotropic resonance.

However, distinct changes were observed for species **II** with the *p*-CH_3O and *m*-CH_3O substituted complexes. The former, like the rest of the complexes, showed a featureless isotropic resonance throughout the temperature range, the latter complex with *m*-CH_3O substitution, on the other hand, showed nine well-resolved hyperfine features (Δ*H* = 1.70 G) due to interaction of the electron spin with the nuclear spin of four equivalent nitrogen atoms (*I* = 1). The spectral behaviour and the A_N value (1.56 G) are consistent with those of TPP radicals with ClO_4^- as the counterion.[26] Theoretical calculations for the $^2A_{2u}$ ground state revealed a larger electron density at the pyrrole nitrogen and meso carbon atoms and negligible electron density at the β pyrrole position. For the $^2A_{1u}$ ground state the pyrrole nitrogens and the meso carbons are in the nodal plane and the electron density is greater at the β-pyrrole position. Hence, a resolved, hyperfine-rich spectrum is observed for the cation radical with a $^2A_{2u}$ ground state while a featureless isotropic signal is observed for the $^2A_{1u}$ ground state. Variable temperature ESR results in the present study therefore indicate a $^2A_{2u}$ electronic ground state for species **II'** with *m*-CH_3O substitution and $^2A_{1u}$ for the rest of the complexes. As the temperature is lowered the h.f. resolution is lost. Figure 7 shows the variation of A_{Br} and $\Delta H/A_{Br}$ with temperature for Zn[T(*m*-CH_3O–P)P] cation radicals.

The former radical shows an abrupt change around 180 K while for the latter the bromine hyperfine coupling is reduced gradually up to 77 K. The rate of cooling has an effect on the nature of the spectrum. Sudden cooling to 77 K gives an overlapping two line spectrum for *p*-CH_3O substitution (Figure 5) whereas slow cooling shows a single resonance. However, such a behaviour is not observed for the complexes with X = *m*-CH_3O and H. These observations clearly indicate that the cation radical of Zn[T(*p*-CH_3O–P)P] (species **I**) undergoes an electronic transition from $^2A_{2u}$ to $^2A_{1u}$ at 180 K while the rest of the complexes exhibit a transition from $^2A_{2u}$ to an admixed $^2A_{1u}/^2A_{2u}$ state as the temperature is lowered. The reduction in the bromine hyperfine coupling constant at lower temperatures indicates a change in the degree of binding of the bromine ion in the $Zn[T(X–P)P]^{+\cdot}Br^-$ complex. Our earlier studies[33] revealed that the Zn–Br bond is labile and the Br^- could be replaced by ClO_4^-, PF_6^-, and BF_4^- ions. The perchlorato anion forms an axial coordination and shows a typical spectrum with a nine line hyperfine pattern due to interaction with the four equivalent nitrogen atoms of the pyrrole rings. With noncoordinating PF_6^- and BF_4^- ions, however, only a single line is observed.

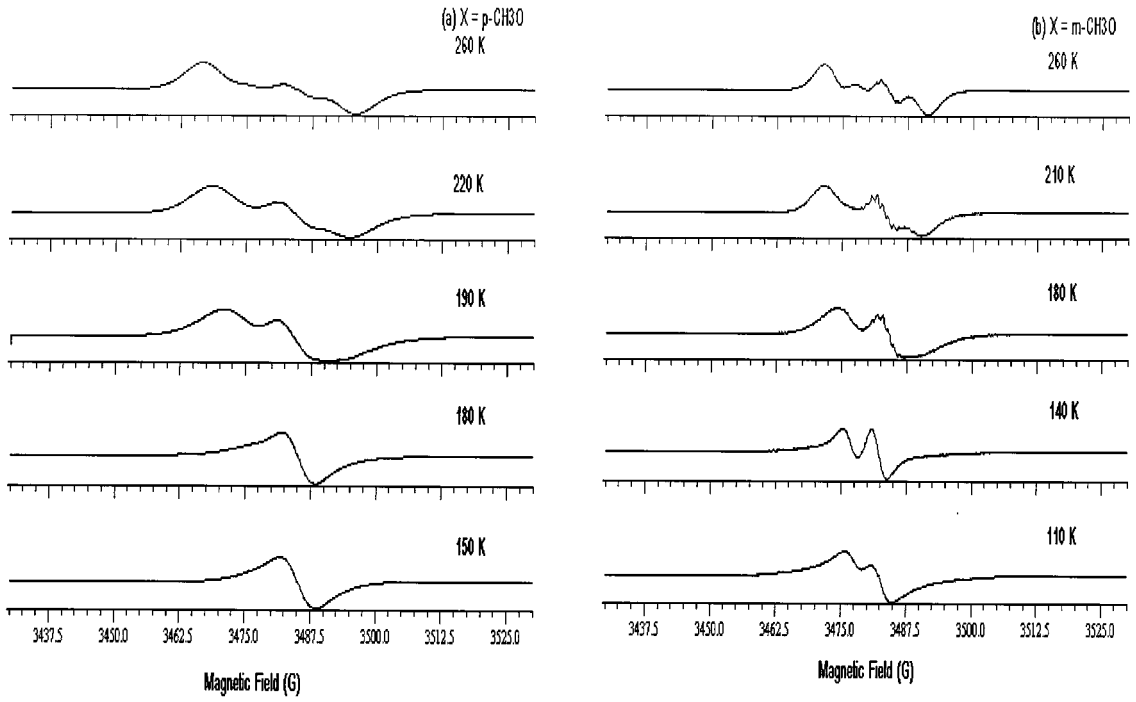

Figure 6. Variable temperature ESR spectra for (a) Zn[T(*p*-CH_3O–P)P] and (b) Zn[T(*m*-CH_3O–P)P] in CH_2Cl_2 showing the effect of substitution on the lability of the electronic ground state; species **II** shows resolved nitrogen hyperfine coupling for *m*-CH_3O (b) while a featureless signal is seen for *p*-CH_3O (a) substituted complexes; receiver gain = $5.02 \cdot 10^3$, modulation amplitude = 1.60 G, time constant = 163.84 ms, ν = 9. 46 GHz, resolution in X = 1024

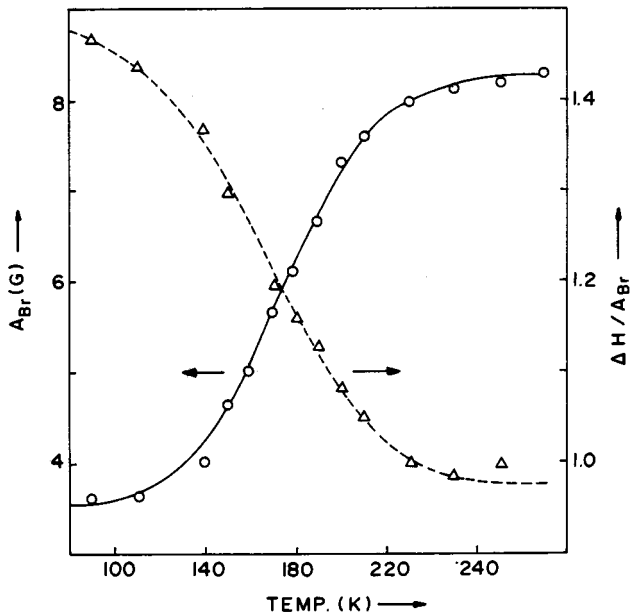

Figure 7. Variation of A_{Br}, $\Delta H/A_{Br}$ with temperature for Zn[T(*m*-CH_3O–P)P]$^{+\cdot}Br^-$

Species **II**, as mentioned earlier, is attributed to a brominated species, Zn[T(X–P)(Br_n –P)]$^{+\cdot}Br^-$.[36] The difference in the spectral features of the *m*-CH_3O substituted complex (showing resolved nitrogen hyperfine coupling) from the rest of the complexes is attributed solely to the location of the substituent and its electronic and steric effects. During chemical oxidation both the β-pyrrole positions can be brominated resulting in species **II**. However, bulkier CH_3O substitution in the *meta* position probably imposes a degree of steric hindrance and thereby forms a tetrabrominated cation radical (species **II'**) instead of the octabrominated species **II**. The former, with an electron-donating CH_3O group in the *meta* position and electron-withdrawing tetrabromo groups in the β-pyrrole position, stabilizes the $^2A_{2u}$ ground state while the rest of the substituted complexes with octabromo substitution in the β-pyrrole position stabilize the $^2A_{1u}$ state for species **II**. As for all the structures of the octabrominated tetraphenylporphyrin complexes studied so far, species **II** most probably possesses an S_4 symmetry and displays a saddle-shaped or ruffled conformation.[38] Such a nonplanar conformation probably stabilizes a $^2A_{1u}$ electronic ground state. As reported earlier,[38] the symmetry of the tetrabrominated cation radical (species **II'**) is expected to be, at least, C_i with slightly distorted chair-like conformation and such a geometry probably stabilizes a $^2A_{2u}$ state. With lowering of temperature, the conformational geometries of species **I** and **II'** change and this results in a transition in the electronic ground state from $^2A_{2u}$ to $^2A_{1u}$. Hence, it can be concluded that the lability in the electronic structure is associated with a change in the conformational geometry of the TPP moiety.

Conclusions

Chemical oxidation of zinc(II) substituted tetraphenylporphyrins with bromine generated two types of cation radicals, Zn[T(X–P)P]$^{+\cdot}Br^-$ (species **I**) and Zn[T(X–P)(Br_n–

P)]$^{+\cdot}$Br$^-$ (species **II** or **II'**). Species **I** for all the complexes exhibits a labile electronic ground state with a *p*-CH_3O substituted radical ion showing an electronic transition from $^2A_{2u}$ to $^2A_{1u}$ while the rest of the radical ions show a transition from $^2A_{2u}$ to an admixed $^2A_{1u}/^2A_{2u}$ state. Species **II** with octabromo substitution at β-pyrrole position possesses a $^2A_{1u}$ state throughout the temperature range (298–77 K), while the *m*-CH_3O complex with tetrabromo substitution (species **II'**) exhibits a labile $^2A_{2u}$ electronic state. The lability in the electronic state is associated with changes in the conformational geometry of the porphyrin macrocyclic moiety. Metal complexes with labile electronic ground states and flexible ligand geometries are potential materials for molecular devices. By and large the present study reveals that by incorporating an appropriate substitution into the porphyrin macrocycle it is possible to fine-tune the electronic structure to design a desired material.

Experimental Section

Materials: Aldehydes and other chemicals (E. Merck) were used as received. Solvents (A.R. grade) were purified and dried before use. Freshly distilled pyrrole (Aldrich) was used for the condensation.
Physical Measurements: Elemental (C,H,N) analysis was carried out on a Perkin–Elmer PE-2400 Series **II** analyzer. – FT-IR spectra were recorded as KBr pellets on a Biorad FTS 40 spectrophotometer. – Electronic spectra for solutions were measured on a HP 8452 Diode array UV/Visible spectrophotometer. – ^{1}H-NMR measurements were conducted on a Bruker DPX 200 MHz spectrometer using TMS as the internal standard. – Cyclic voltammetric studies were conducted on BAS CV-27 and CH 660 A USA instruments. Glassy carbon was used as a working electrode, Ag/AgCl as a reference electrode, Pt wire as an auxiliary electrode and 0.1 M tetrabutylammonium hexafluorophosphate as a supporting electrolyte. – ESR investigations were carried out on a Bruker EMX spectrometer (ν = 9.75 GHz) using 100 kHz field modulation. Frequency was monitored using a microwave frequency counter inbuilt in the Bruker ER 041 XD-G microwave bridge. DPPH was used a field marker (g = 2.0036). Temperature variation experiments were performed using a Bruker BVT-3000 set-up and liquid nitrogen temperature (77 K) measurements using a quartz inserting Dewar. – ESR spectral simulations were done using a Simfonia software package.

Synthesis: Zinc(II) tetraphenylporphyrin and its derivatives were prepared following the procedure of Adler et al.[39] Purification of the porphyrins was carried out by following the method of Barnett et al.[40] The π-cation radicals were generated by chemical oxidation of deoxygenated CH_2Cl_2 solutions of metalloporphyrins with 0.5 equivalents of bromine in carbon tetrachloride.[33]

The complexes were characterised by various physico-chemical techniques such as elemental analysis, UV/Visible, FT-IR, FT NMR, and ESR spectroscopy, and electrochemistry. The analytical data for the various complexes are as follows:

Zn[T(H–P)P]: $C_{44}H_{28}N_4Zn$: calcd. C 77.95, H 4.13, N 8.27; found C 77.20, H 3.99, N 8.00. – FT-IR: $\tilde{\nu}$ = 1486 (m, C–H bend), 1339 (s, C=N stretch), 1068 (s, *p*-subst. phenyl), 1002 (vs, C–H pyrrole rock), 798 (vs, C–H out-of-plane defor.), 717 (s, mono subst. C_6H_5) cm^{-1}. – UV/Vis: λ (ε), nm ($cm^{-1}\cdot mol^{-1}$): 420 (545000), 512 (3700), 548 (25200), 586 (4600).

Zn[T(*p*-CH_3O–P)P]: $C_{44}H_{36}N_4O_4Zn$: calcd. C 72.20, H 4.51, N 7.02; found C 69.54, H 5.33, N 6.75. – FT-IR: $\tilde{\nu}$ = 1490 (m, C–H bend), 1338 (s, C=N stretch), 1246 (vs, *p*-subst. C_6H_5), 1106 (s, *p*-subst. phenyl), 996 (vs, C–H pyrrole rock), 801 (vs, C–H out-of-plane defor.), 718 (s, mono subst. C_6H_5) cm^{-1}. – UV/Vis: λ (ε), nm ($cm^{-1}\cdot mol^{-1}$): 422 (368000), 514 (4200), 550 (22500), 590 (8100).

Zn[T(*m*-CH_3O–P)P] · CH_2Cl_2: $C_{45}H_{38}Cl_2N_4O_4Zn$: calcd. C 66.77, H 4.34, N 6.35; found C 67.39, H 5.07, N 8.10. – UV/Vis: λ (ε), nm ($cm^{-1}.mol^{-1}$): 420 (397200), 512 (2700), 548 (18300), 584 (3100).
Zn[T(*p*-Cl–P)P]: $C_{44}H_{24}N_4Cl_4Zn$: calcd. C 64.69, H 2.96, N 6.86; found C 62.03, H 3.36, N 7.88. – FT-IR: $\tilde{\nu}$ = 1480 (m, C–H bend), 1338 (s, C=N stretch), 1091(s, *p*-subst. phenyl), 1000 (vs, C–H pyrrole rock), 799 (vs, C–H out of plane defor.), 723 (s, mono subst. C_6H_5) cm^{-1}. – UV/Vis: λ (ε), nm ($cm^{-1}\cdot mol^{-1}$): 420 (431300). 512 (2200), 548 (16100), 586 (2800).

Zn[T(*m*-Cl–P)P]: $C_{44}H_{24}Cl_4N_4Zn$: calcd. C 64.69, H 2.96, N 6.86; found C 63.29, H 3.13, N 7.08. – UV/Vis: λ (ε), nm ($cm^{-1}\cdot mol^{-1}$): 420 (349800), 512 (3100), 548 (14300), 584 (2700).

Zn[T(*p*-F–P)P]: $C_{44}H_2F_4N_4Zn$: calcd. C 70.40, H 3.20, N 7.47; found C 69.80, H 3.85, N 8.31. – FT-IR: $\tilde{\nu}$ = 1489 (m, C–H bend), 1337 (s, C=N stretch), 1231 (vs, *p*-subst. C_6H_5), 1092 (s, *p*-subst. phenyl), 1003 (vs, C–H pyrrole rock), 793 (vs, C–H out of plane defor.), 720 (s, mono subst. C_6H_5) cm^{-1}. UV/Vis: λ (ε), nm ($cm^{-1}\cdot mol^{-1}$): 420 (453400), 512 (4600), 548 (24000), 586 (4600).

Tetraazido Complexes of Aluminium, Gallium, and Indium

Harald Sussek,[a] Frank Stowasser,[a] Hans Pritzkow,[b] and Roland A. Fischer*[a]

Keywords: Aluminium / Gallium / Indium / Azide / Rietveld

The new tetraazido complexes of aluminium, gallium, and indium $[thf_2Na][thf_2Al(N_3)_4]$ (**1**), $[py_2Na][py_2In(N_3)_4]$ (**2**), and $Na[Ga(N_3)_4]$ (**3**) have been synthesized from MCl_3 and NaN_3 by salt metatheses and characterized by X-ray diffraction analysis. In compounds **1** and **2**, the Group 13 metal atom and the sodium atom are each hexacoordinated by four azido groups and two additional solvent molecules. The azido groups act as μ(1,3)-bridging ligands between the Group 13 metal and sodium, thereby forming network structures. In contrast, complex **3** is solvent-free and exhibits a tetracoordinated gallium centre and a heptacoordinated sodium atom. The structure of **3** has also been investigated by means of X-ray powder data and the Rietveld method and the results are compared with the single-crystal data.

Introduction

Organometallic and inorganic azide derivatives of the Group 13 metals (M = Al, Ga, In), including the compounds $[X_2Ga(N_3)]_3$ (R = Et, H, Cl),[1] $[(\mu\text{-}NMe_2)\text{-}Ga(N_3)(NMe_2)]_2$,[2] $(N_3)_aM[(CH_2)_3NMe_2]_{3-a}$ (M = Al, Ga, In; a = 1, 2), and $Ga(N_3)_3(L)$ (L = NMe_3, NEt_3)[3] have been studied as precursors of the respective Group 13 nitride materials. Gallium nitride, as well as the ternary alloys $Al_xGa_yIn_zN$ ($x + y + z = 1$), are wide-band-gap semiconductors that exhibit a unique combination of properties making them useful for a number of advanced applications in optoelectronics and various other fields.[4] The azido unit would appear to be an interesting choice for the introduction of the nitrogen component in metal nitride synthesis. The commonly used precursors, e.g. MR_3 and ammonia or alkylamines, contain M−C, C−H, N−H, and N−C bonds, fragmentation of which leads to the incorporation of impurities into the nitride material. However, a drawback to the use of metal azide derivatives as precursors of nitrides is their inherent tendency to undergo exothermic decomposition. Nitrogen-rich compounds such as $[H_2Ga(N_3)]_3$ and $Ga(N_3)_3L_n$ may even detonate under certain circumstances.[1][5] Intramolecular adduct formation has, however, proved to be a reliable method for stabilizing Group 13 metal azides against explosive decomposition.[3] In the context of potential applications as electronic materials, the purity of nonexplosive azide precursors with regard to contamination by dangerous explosive species is a very important issue. We were thus interested in characterizing all the possible species involved when Group 13 metal halides are treated with alkali azides, e.g. NaN_3. We report herein on the synthesis and structural chemistry of the previously unknown tetraazido complexes of aluminium, gallium, and indium, **1−3**.

Syntheses and Properties

During the course of our investigations of Group 13 metal azide complexes containing various donor ligands $M(N_3)_3L_n$ (L = NR_3, n = 1; L = py, n = 3), the three new complexes of aluminium, gallium, and indium **1−3** have been isolated (Scheme 1). When the Group 13 chlorides MX_3 are treated with precisely stoichiometric amounts of sodium azide in a toluene/pyridine mixture, the tripyridine compounds $M(N_3)_3py_3$ are formed, which can be isolated in high yields.[3b,3c,3d,6] However, only use of a significant excess of sodium azide (> 5 equiv.) and an appropriate combination of solvent and additional ligands selectively gives **1−3**. A large excess of sodium azide is generally required in order to avoid halide contamination of Group 13 azide derivatives due to incomplete Cl^-/N_3^- exchange.[6] The donor-stabilized triazidogallium complexes $Ga(N_3)_3(NR_3)$ (**4**) are thus typically synthesized from compound **3** as an (isolated) intermediate. This intermediate is also important in the synthesis of the donor-free parent compound $[Ga(N_3)_3]_\infty$ (**5**), which can be extracted with toluene as an unstable thf adduct $Ga(N_3)_3(thf)_x$, in a similar manner as in the synthesis of compound **4**.[6] However, the isolation of the pure tetraazides **1−3** requires special precautions since they are explosive compounds and will detonate spontaneously when heated above 200°C at rates greater than 2 K/min, or when exposed to mechanical shock. The enthalpy of detonation of compound **2** was measured as 2.3 $MJ\cdot kg^{-1}$ (607 $kJ\cdot mol^{-1}$) using a special sealed calorimeter.[7] This value compares well with that of 1.54 $MJ\cdot kg^{-1}$ (450 $kJ\cdot mol^{-1}$) found for $Pb(N_3)_2$.

Crystal Structures

Different representations of the structure of **1** in the solid state, showing the coordination at the metal centres as well as the packing in the crystal, are given in Figures 1a−b. Compound **1** crystallizes from saturated thf solutions in the triclinic space group $P\bar{1}$. Each metal cation is octahedrally coordinated by four azido groups in equatorial positions

Scheme 1. Synthesis and chemistry of donor-stabilized triazido complexes and tetraazido complexes

and two apical thf molecules. The azido groups act as μ(1,3) bridging ligands between the aluminium and sodium octahedra, thereby forming a two-dimensional layer structure with the metal atoms and the azido groups in the *ab* plane of the unit cell. The thf molecules show a disordering, which could not be resolved. These positions were refined by assuming equivalent interatomic distances. The metal−O bond lengths were fixed at 201.3 pm for aluminium and at 235.9 pm for sodium. The Na−N bond lengths were found to be very similar to those in compound **3** and other related ionic sodium azides.[8][9] The $Na-N_\alpha-N_\beta$ angles were found to vary between 127.6(1)° (Na−N6−N5) and 150.0(2)° (Na−N3−N2). The corresponding values at the aluminium centre range from 129.3(1)° (Al−N1−N2) to 132.8(1)° (Al−N4−N5), which are similar to the angles found in other covalent metal azides and are thus indicative of sp^2 hybridization at the N_α atoms. An alternation of the N−N bond lengths, i.e. a longer $N_\alpha-N_\beta$ bond [119.7(2) pm and 119.2(2) pm] and a shorter $N_\beta-N_\gamma$ bond [114.2(2) pm and 114.7(2) pm] is found, which is a typical feature of covalent azides.[10a,10b] These features indicate the presence of a more covalently bonded tetraazidoaluminium moiety and a more ionic interaction with the sodium cation. Compound **1** consists of layers made up of sodium and aluminium atoms interconnected by azido groups, which are oriented parallel to each other in the *ab* plane of the unit cell.

Representations of the structure of compound **2** in the solid state, showing the coordination at the two metal centres as well as the packing in the crystal, are given in Figures 2a−c. Compound **2** is obtained from pyridine solution in the form of needles, which are monoclinic with space group *C*2/*c*. As in the case of **1**, the structure in the crystal resembles that of a coordination polymer. The metal centres are surrounded by four azido groups and two pyridine ligands in an octahedral arrangement. Each indium atom is connected to four sodium atoms through the terminal nitrogen atoms (N_α or N_γ) of the azido ($N_\alpha-N_\beta-N_\gamma$) groups and vice versa. At the indium centre, the azido groups occupy the *equatorial* positions and the pyridine ligands the *apical* positions. At the sodium centre, the pyridine ligands are *cis* orientated. The general features of the azide coordination and bonding properties compare well with the situation discussed for compound **2** and with the situations in

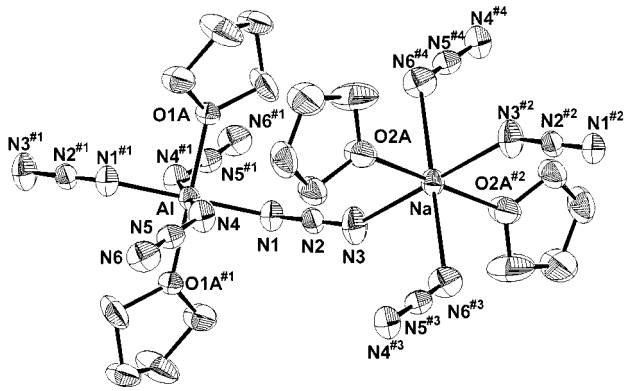

Figure 1a. Perspective view of the structure of **1** showing the coordination spheres of the aluminium and sodium atoms (ZORTEP[15] plot with 50% probability thermal ellipsoids); selected bond lengths [pm] and angles [°]: Al−N1 195.0(2), Al−N4 194.1(1), Al−O1A 201.3(9), Na−N3 249.9(2), $Na-N6^{\#3}$ 255.3(2), Na−O2A 235.9(1), N1−N2 119.7(2), N2−N3 114.2(2), N3−N4 119.2(2), N5−N6 114.7(2); Al−N1−N2 129.3(1), N1−N2−N3 175.3(2), Al−N4−N5 132.8(1), N4−N5−N6 176.0(2), $Na-N3-N2$ 150.0(2), $Na-N6^{\#3}-N5^{\#3}$ 127.7(1)

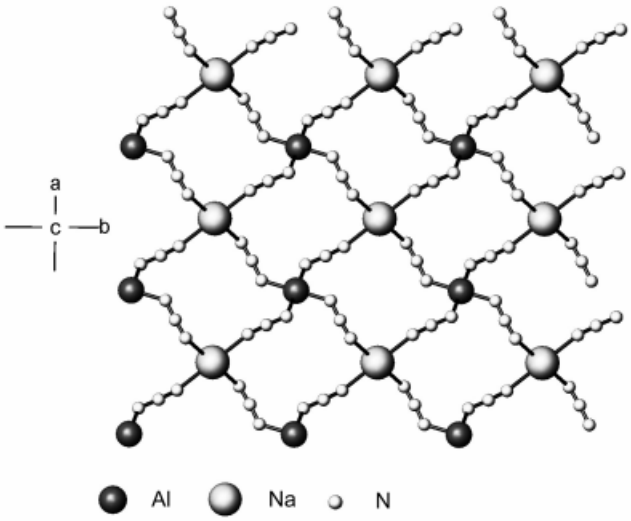

Figure 1b. Packing diagram of compound **1** in the solid state (projection along the *c* axis on the *ab* plane) showing an almost flat, two-dimensional network built-up of sodium and aluminium atoms interconnected by azido groups; the thf ligands, which are stacked between the metal azide layers, are omitted for the sake of clarity

other known covalent indium azides.[3b] The $M-N_{py}$ distances measure 230.7(2) pm for M = In and 247.5(2) pm for M = Na. The $In-N_{py}$ values are close to those in the related triazido compound $In(N_3)_3(py)_3$.[3b] The organic ligands do not show any unusually short intra- or intermolecular distances or any remarkable angles. Indeed, the structural parameters of compound **3** are rather similar to those of the isostructural compound $[(py)_2Na][(py)_2Cr(N_3)_4]$.[8] Because of the mutual *cis* orientation of the py ligands at the sodium atom, in contrast to the *trans* orientation of the thf ligands in the case of the related aluminium compound **1**, complex **2** forms a different type of coordination network. Whereas in **1** each metal atom in the layers parallel to the *ab* plane is interconnected through the

μ(1,3) azido groups (Figure 1b), in **2** the metal atoms in the layers parallel to the *ac* plane are only partly interconnected through μ(1,3) groups (Figure 2b). Every second sodium centre is connected through μ(1,3) azide bridges with the adjacent layers above and below (Figure 2c). Thus, a three-dimensional network is built-up. The py ligands occupy the holes in the packing in a similar fashion as the thf ligands of complex **1**.

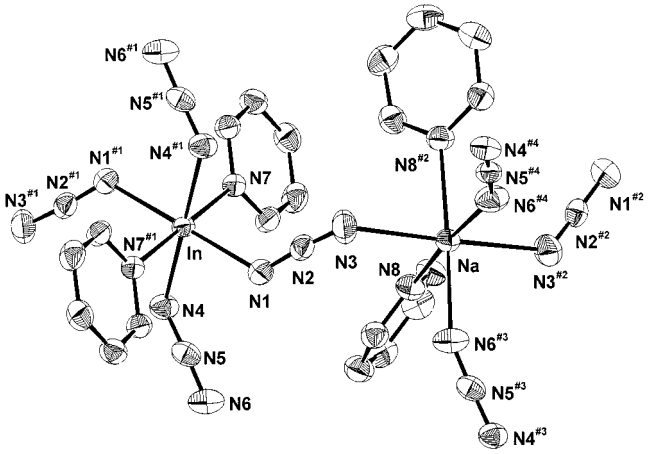

Figure 2a. A perspective view of the structure of **2** showing the coordination spheres of the indium and sodium atoms (ZORTEP plot with 50% probability thermal ellipsoids); selected bond lengths [pm] and angles [°]: In−N1 218.0(2), In−N4 222.6(2), In−N7 230.7(2), Na−N3 253.2(2), Na−N6 247.8(2), Na−N8 247.5(2), N1−N2 117.5(3), N2−N3 116.0(3), N3−N4 117.4(3), N5−N6 159.3(3); In−N1−N2 124.8(2), N1−N2−N3 176.2(2), Al−N4−N5 121.6(2), N4−N5−N6 176.5(2), Na−N3−N2 128.2(2), Na−N6−N5 151.6(2)

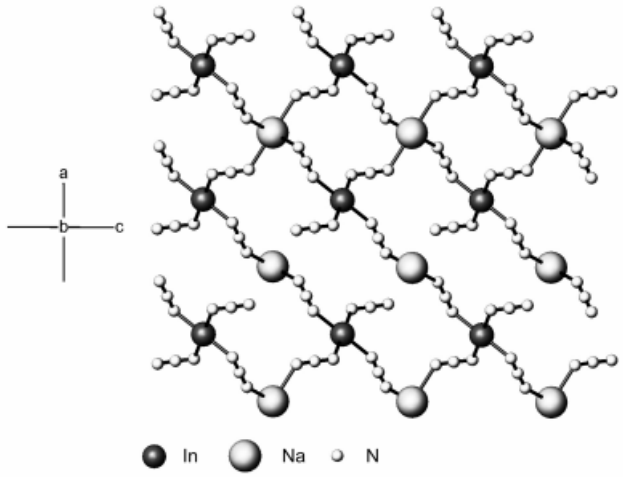

Figure 2b. Packing diagram of compound **2** in the solid state (projection along the *b* axis on the *ac* plane) showing a three-dimensional network with wave-like (in direction *b*) areas built-up of sodium and indium atoms interconnected by azido groups; the pyridine ligands, which are stacked between the metal azide layers, are omitted for the sake of clarity

Representations of the structure of **3** in the solid state, showing the coordination at the metal centres and the packing in the crystal, are given in Figures 3a−c. In contrast to **1** and **2**, compound **3** crystallizes from saturated THF solutions as a solvent-free complex in the orthorhombic

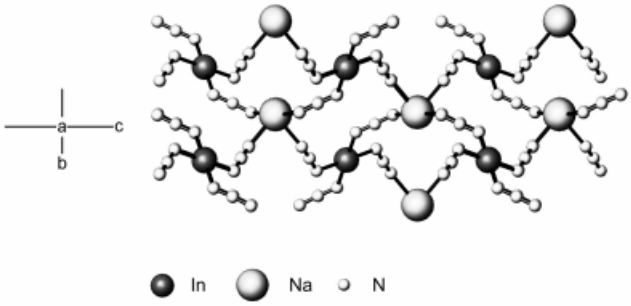

Figure 2c. Packing diagram of compound **2** in the solid state (projection along the *a* axis on the *bc* plane) showing the wave-like (in direction *b*) network built-up of sodium and indium atoms interconnected by azido groups; the pyridine ligands, which are stacked between the metal azide layers, are omitted for the sake of clarity

space group $P2_12_12_1$. The gallium atom is coordinated by azido groups in a tetrahedral fashion. Four of the six N−Ga−N angles are quite close to the ideal angle of 109°, while two show a stronger deviation [N10−Ga−N7: 93.7(1)°, N1−Ga−N7: 116.5(1)°]. The Ga−N bond lengths measure about 190(±2) pm, values that compare well with the bond lengths in other tetracoordinated gallium azides such as $(N_3)_2Ga[(CH_3)_3NMe_2]$ and $Ga(N_3)_3(NR_3)$.[5][6] The bending of the $Ga-N_\alpha-N_\beta$ units of 113.2(2)° (Ga−N1−N2) and 131.1(2)° (Ga−N7−N8) again indicates sp^2-hybridization at the N_α atom, which is typical for covalent metal azides. Three azido groups simultaneously bridge two different sodium atoms: one $Ga-N_\alpha-Na$ bridge and one head-to-tail $Ga-N_\alpha-N_\beta-N_\gamma-Na$ bridge. The azido group N10−N11−N12 is N_α-connected through N10 to the same sodium atom as N7. Interestingly, this azido group is *not* coordinated through the terminal atom N12, which is manifested in a higher temperature factor for this nitrogen. The sodium atoms are surrounded by seven azido groups, resulting in a rather asymmetric pentagonal bipyramid. Four azido groups bridge gallium and other sodium ions through their terminal nitrogen atom N_γ, while two azido groups are N_α-connected to gallium and N_γ-connected to other sodium ions. The N10−N11−N12 azide is only N_α bridged to gallium through N10. The $Na-N_{azide}$ bond lengths measure 250−260 pm, except for the Na−N7 bond, which is unusually long at 274.4(3) pm, probably as a result of steric requirements arising from the packing in the crystal. The series of $Na-N_\alpha-N_\beta$ angles are distinctly nonuniform and vary from 113.2(2)° (Na−N1−N2) to 170.5(3)° (Na−N6−N5), as expected for more ionic interactions. Each azido group exhibits the expected alternation in the N−N bond lengths, which is more pronounced than in the aluminium compound **1**, e.g. a short N2−N3 distance of 113.4(3) pm and a long N1−N2 distance of 122.9(3) pm. In this respect, the azide bonding to the gallium centre is rather similar to that in the covalent, neutral triazido congeners $Ga(N_3)_3(NR_3)$.[5][11] The packing of compound **3** (Figure 3c) can also be rationalized as a layer structure with cross-linking through μ(1,3) azido groups. The density of the packing is much higher than that in **1** and **2** due to the absence of the solvent ligands thf or py. As discussed above,

the N10−N11−N12 azide does not act as a μ(1,3) bridge. In the projection of Figure 3b, these groups point upwards and downwards along the *c* direction in an alternating fashion, into the empty space between the metal azide layers parallel to the *ab* plane.

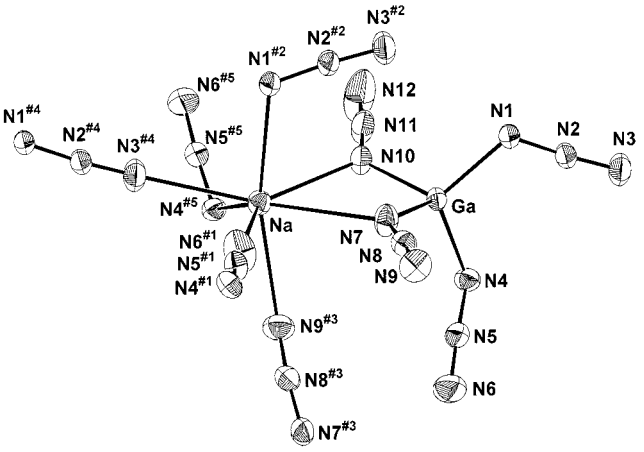

Figure 3a. A perspective view of the structure of **3** showing the coordination spheres of the gallium and sodium atoms (ZORTEP plot with 50% probability thermal ellipsoids); selected bond lengths [pm] and angles [°]: Ga−N1 189.6(2), Ga−N4 190.9(3), Ga−N7 190.9(2), Ga−N10 189.7(2); Ga−N1−N2 113.2(2), Ga−N4−N5 118.8(2), Ga−N7−N8 131.1(2), Ga−N10−N11 126.1(2); Na−$N1^{\#2}$ 251.8(3), Na−$N3^{\#4}$ 254.6(3), Na−$N4^{\#5}$ 258.5(3), Na−$N6^{\#1}$ 250.0(3), Na−$N9^{\#3}$ 252.3(3), Na−N7 274.4(3), Na−N10 258.9(3); N1−Ga−N4 110.1(1), N1−Ga−N7 116.5(1), N1−Ga−N10 112.6(1), N10−Ga−N4 111.6(1), N10−Ga−N7 93.7(1), N4−Ga−N7 111.5(1)

X-ray Powder Diffraction and Rietveld Analysis of 3

As described above, compound **3** is a valuable intermediate in the synthesis of donor-stabilized gallium triazides $Ga(N_3)_3L_m$ (**4**) and other gallium azides, even for the parent

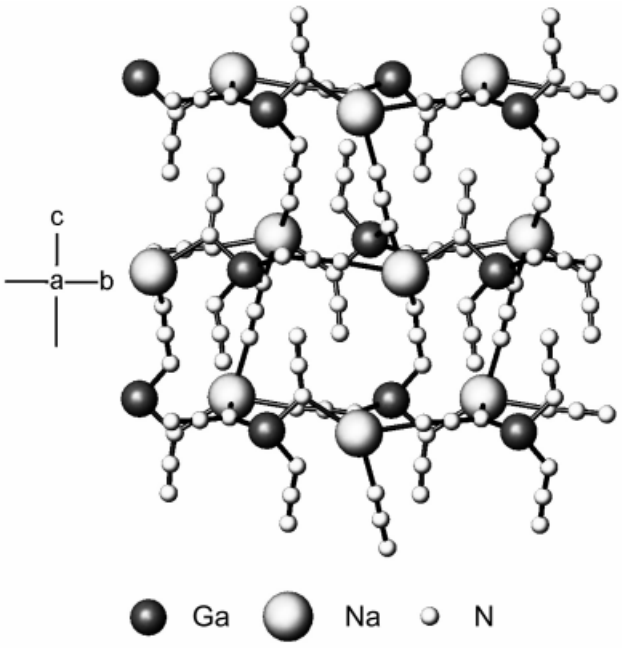

Figure 3c. Packing diagram of compound **3** in the solid state (projection along the *a* axis on the *bc* plane) showing a three-dimensional network built-up of sodium and gallium atoms interconnected by azido groups

compound $[Ga(N_3)_3]_\infty$ (**5**), which can all serve as percursors in the preparation of nanocrystalline GaN powders.[5] To verify the purity of the compounds **1−5**, it is necessary to check for the presence of sodium azide, gallium chloride, sodium chloride, and other possible inorganic impurities and side products. Reliable elemental analysis data are very difficult to obtain on a routine basis because of the explosive nature of the compounds. Consequently, we investigated X-ray powder diffraction patterns in detail using the Rietveld method so as to establish a routine tool to check the purities of **1−5** that could also be used for similar metal azide complexes and related problems. Compound **3** was selected for this study, because it is a likely and dangerous impurity in compounds of the type $Ga(N_3)_3L_m$ (**4**). Compound **3** is usually obtained as a microcrystalline powder. Figure 4 shows the measured and calculated XRD patterns. The difference curve exhibits only small deviations, thus indicating a very good agreement. The reflections induced by the beryllium window were fitted independently and have no influence on the overall structure refinement of the tetraazide. The general features of the structure of **3** are reproduced using the powder data, but details concerning bond lengths and angles differ to some extent. For example, the environment at the gallium centre shows a more marked deviation from tetrahedral in the case of the powder data and the obtained $Ga-N_{azide}$ bond lengths, which range from 201.4 pm to 216.2 pm, are longer. The $Ga-N_\alpha-N_\beta$ angles are close to the single-crystal data to within ±5°, with the exception of the Ga−N1−N2 angle where the powder data value of 130.5° is unusually large as compared with the single-crystal value of 113.2(2)°. Other deviations become apparent upon analyzing the bond lengths and angles in the

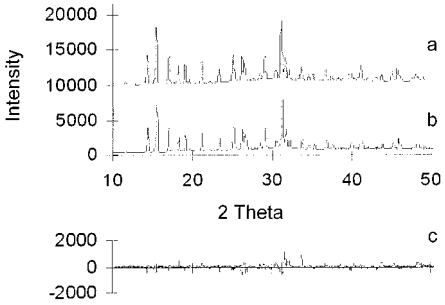

Figure 4. Detail of the X-ray patterns obtained for $NaGa(N_3)_4$ (**3**): (a) experimental data obtained with an aluminium sample holder and a beryllium window, (b) calculated data for the Rietveld structure refinement, (c) difference curve between observed and calculated data

plane containing the Na, Ga, N7, and N10 atoms. While the single-crystal data show the largest angle of 103.1(1)° located at N10 (Ga−N10−Na) and the smallest angle of 62.68(8)° at the Na atom (N7−Na−N10), the powder data show a largest angle of 106.3° for N7−Ga−N10 and a smallest angle of 81.3° at the Na centre (N7−Na−N10). Nevertheless, the constitution of the compound, the coordination features at the metal centres, and the packing mode in the crystal are reproduced quite well using X-ray powder diffraction analysis with Rietveld refinement. The deviations of the more specific structural parameters from the single-crystal reference (bond lengths and angles) are most likely attributable to the intrinsic limitations of the powder diffraction data. Moreover, the conditions of the two experiments were somewhat different. The powder data had to be collected at room temperature, while the single-crystal data were obtained at 203 K. Because of this difference in the conditions, a temperature-dependent phase transition also had to be taken into account. However, in view of the explosive nature of pure crystalline **3**, we decided not to pursue this matter further. Anyway, X-ray powder diffraction in combination with Rietveld analysis of the diffraction pattern constitutes a reliable method for establishing the identity and purity of compounds such as **3** and **4**, especially if single crystals are difficult to obtain. This is particularly true for $[Ga(N_3)_3]_\infty$ (**5**), the structure of which is still unknown due to the very poor X-ray powder diffraction data obtained to date. The work reported herein has shown that samples of **5** synthesized according to ref.[6] are essentially free of compound **3** and other likely by-products.

Experimental Section

General Procedures: All manipulations were performed using thoroughly oven-dried reaction vessels (Schlenk techniques) under an inert atmosphere of purified argon in a glove box (argon; O_2 and H_2O < 1 ppm). Solvents were dried and distilled according to standard procedures[12] and were stored over 4 Å molecular sieves (residual water < 1 ppm, Karl-Fischer). − The IR spectra were recorded in solution (thf, toluene, pyridine) using 0.1 mm CaF_2 or NaCl cells or freshly prepared KBr plates with a Perkin−Elmer 1650 FT-IR or a Bruker IFS-66 spectrometer. − Elemental analyses were provided by the Microanalytical Laboratory of the Chemical Institute at the University of Heidelberg. The metal content was determined by back-titration of excess EDTA solution (complexometric determination with Titriplex®, Merck KGaA, Darmstadt). − Melting points (uncorrected) were determined with a Gallenkamp hot-air melting point apparatus or a Seiko TG/DTA 6300

SII thermobalance (DTA data). ***NOTE:*** Working with the described Group 13 azides requires strict adherence to special security precautions, i.e. the use of protective face shields, special gloves (metal net), and thick leather body protection. The compounds are shock-sensitive and detonate upon rapid heating (> 2 K/min) to temperatures above 200°C.

[Bis(tetrahydrofuran)sodium] [Tetraazidobis(tetrahydrofuran)aluminate], [thf_2Na][$thf_2Al(N_3)_4$] (1): A solution of anhydrous, freshly sublimed $AlCl_3$ (0.75 g, 5.63 mmol) in 25 mL of thf was slowly added to a suspension of sodium azide (1.45 g, 22.30 mmol) in 25 mL of THF at −78°C. After allowing the mixture to warm to room temperature, it was stirred for 15 h, then filtered, and the filtrate was concentrated to dryness in vacuo. The product was obtained in the form of colourless crystals. Yield: 2.43 g (4.8 mmol, 85.3% based on $AlCl_3$). − IR (KBr): $\tilde{\nu}(N_3)_{max}$ = 2122 cm^{-1} (vs), 2037 (vs), 1261 (w). − ***NOTE:*** The substance detonates vigorously on rapid heating (> 2 K/min) beyond 220°C! Decomposition at 200°C without melting. − $C_{16}H_{32}AlN_{12}NaO_4$ (506.48): calcd. Al 5.33; found Al 6.01. This large discrepancy may be attributed to evaporation of the coordinated thf and also to the very small amount of sample used for the analysis in view of the explosion risk.

[(Dipyridine)sodium] [Tetraazido(dipyridine)indate], [py_2Na][$py_2In(N_3)_4$] (2): A solution of anhydrous, freshly sublimed $InCl_3$ (1.0 g, 4.52 mmol) in 20 mL of pyridine was slowly added to a suspension of 1.3 g (20 mmol) of sodium azide in 10 mL of pyridine at −78°C. After allowing the mixture to warm to room temperature, it was stirred for 15 h, then filtered, and the filtrate was concentrated to dryness in vacuo. The product was obtained in the form of colourless crystals. Well-defined single crystals could be obtained by warming a saturated solution to 80°C and slowly cooling to room temperature. Yield: 2.43 g (3.93 mmol; 87% based on $InCl_3$). − IR (KBr): $\tilde{\nu}(N_3)_{max}$ = 2083 cm^{-1} (sh), 2067 (vs), 2037 (vs). − ***NOTE:*** The substance detonates vigorously on rapid heating (> 2 K/min) above 250°C! Decomposition at 200°C without melting. − $C_{20}H_{20}InN_{16}Na$ (622.33): calcd. C 38.60, H 3.24, N 36.01, In 18.45; found C 37.73, H 3.41, N 32.90, In 20.20.

Sodium Tetraazidogallate, Na[$Ga(N_3)_4$] (3): A solution of anhydrous, freshly sublimed $GaCl_3$ (1.05 g, 5.96 mmol) in 15 mL of thf was slowly added to a suspension of sodium azide (1.47 g, 22.61 mmol) in 25 mL of thf at −78°C. After allowing the mixture to warm to room temperature, 50 mL of toluene was added and the resulting solution was stirred for 15 h. It was then filtered and the filtrate was concentrated in vacuo. The product was obtained in the form of colourless crystals. Yield: 1.43 g (5.48 mmol; 92.0% based on $GaCl_3$). M.p. 122°C. − IR (KBr): $\tilde{\nu}(N_3)_{max}$ = 2094 cm^{-1} (sh), 2075 (s), 2064 (vs). − ***NOTE:*** The substance detonates vigorously on fast heating (> 2 K/min) above 150°C! − $GaN_{12}Na$ (260.83): calcd. Ga 26.73; found Ga 27.21.

X-ray Structure Determination: Experimental details relating to the X-ray crystal structure determinations of **1**, **2**, and **3** are listed in Table 1. Intensity data were collected with a Siemens−Stoe AED2 four-circle diffractometer using Mo-K_α radiation in ω-scan mode; an absorption correction was applied on the basis of φ scans. The structures were solved by direct methods (SHELXS-86)[13] and refined by full-matrix least-squares methods based on F^2 using all measured reflections (SHELXL-93)[13] with anisotropic temperature factors for all nonhydrogen atoms. X-ray powder diffraction data were collected with Cu-$K_{\alpha1/2}$ radiation employing a Siemens D500 instrument equipped with a secondary monochromator and a scintillation counter. In Table 2, the crystallographic data and parameters relating to the refinement are summarized. Data were collected in the Θ/2Θ mode with a step width of 0.02° and 15 s per step. The powder sample of **3** was carefully prepared in an aluminium sample holder for bulk measurements, which was covered by a beryllium window (0.25 mm) and sealed with epoxy resin to prevent decomposition by air or moisture. The measured data were refined using the program TOPAS.[14] The intensities were corrected for absorption by the beryllium window. The azido groups were defined as rigid bodies with five degrees of freedom (3 translation, 2 rotation). The isotropic temperature factors for sodium (0.5) and nitrogen (2.0) were fixed. The refined temperature factor for gallium was 0.3(1). The obtained R_{Bragg} factor of 3.2, which gives an indication of the refinement quality, is very good. Crystallographic data for the structures of **1**−**3** reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-119351, -119352, and -119353. Copies of the data can be obtained free of charge on application to the CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Potentially Tridentate Hydrazonic Ligands in the Synthesis of Methyl and Acetyl Palladium(II) Complexes

Paolo Pelagatti,[a] Mauro Carcelli,[a] Francesca Franchi,[a] Corrado Pelizzi,*[a] Alessia Bacchi,[a] Andrea Fochi,[a] Hans-Werner Frühauf,[b] Kees Goubitz,[c] Kees Vrieze[b]

Keywords: Palladium / Insertion reactions / Tridentate ligands / Hydrazones

Potentially tridentate hydrazonic ligands of the type HNNO have been used in the synthesis of some methyl palladium(II) complexes. Depending on the applied experimental conditions two different kinds of complexes are obtained. Thus, the reactions between **HL1–HL5** and (COD)PdMeCl in diethyl ether led to the formation of bidentate methyl complexes of the type Pd(HNN)MeCl (**1–5**), where the ligands maintain a neutral character. However, in the presence of a base such as Et_3N or NaOMe, the ligands are deprotonated with the consequent formation of tridentate methyl complexes of the type Pd(NNO)Me (**7–10**). In solution, complexes **1–5** tend to lose the hydrazonic proton with elimination of methane and formation of a tridentate chloride complex Pd(NNO)Cl (**6**); this tendency can be correlated with the acidity of the free ligands, which has been determined. On bubbling carbon monoxide through solutions of **1–5**, the corresponding acetyl complexes Pd(HNN)[C(O)Me]Cl (**11–15**) are formed, in which both the *cis* and *trans* isomers are present. Their molar ratio is rationalised from the results of a molecular modelling study on the basis of electronic considerations. A remarkably different reactivity has been found in the carbonylation of the tridentate complexes **7–10**: they decompose rapidly and quantitatively to palladium black and an organic product corresponding to the ligand with an acetyl group bonded to the hydrazonic nitrogen. The X-ray structures of a methyl complex (**3**) and its corresponding acetyl (**13**) derivative have been determined.

Introduction

The use of potentially tridentate ligands in the synthesis of organometallic compounds has received much attention since tridentate metal complexes are expected to exhibit interesting catalytic properties, such as better stereoselective or chemoselective control of the reactions.[1] We have been interested in the study of the coordinating behaviour of tridentate hydrazonic ligands towards palladium(II) for some years,[2] and more recently our interest has been focused on the capability of the isolated complexes to activate a simple molecule like hydrogen.[3]

With the aim of studying the reactivity towards other simple molecules, we have investigated the insertion of CO into the Pd–C bond, this reaction being a key step in many palladium-mediated processes, such as the hydroxy- or alkoxycarbonylation of alkenes[4] and the copolymerisation of alkenes and CO.[5]

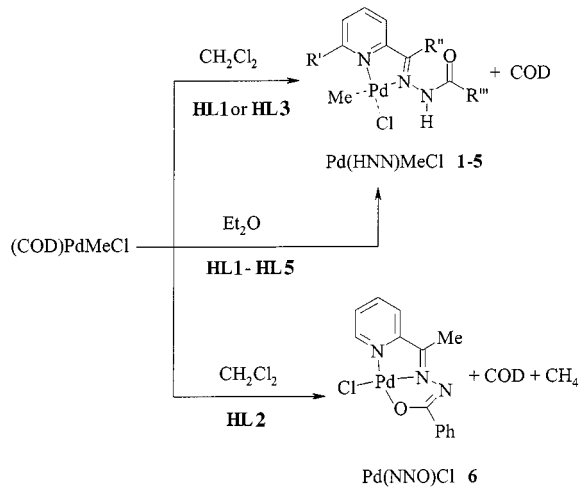
In this field much work has been done with both symmetrical[6] and unsymmetrical bidentate ligands.[7] Recently complexes with rigid bidentate nitrogen ligands showed faster CO and alkene insertion than those with flexible bidentate nitrogen ligands.[8] Moreover, as opposed to complexes containing phosphorous ligands, the insertion of CO into the Pd–Me bond was not prevented by either the flexible or the rigid tridentate nitrogen ligands,[9] and kinetic studies have shown that the insertion rate of CO and strained alkenes increases with increasing rigidity of the ligand.[10]

Asymmetric tridentate ligands have been scarcely studied in the synthesis of methyl and acetyl palladium(II) complexes and, importantly, only neutral ligands have been employed.[11] Although mechanistic details have not been reported, the rupture of a coordinative bond seems to be a prerequisite for CO coordination and insertion. The breaking of a Pd–N or Pd–O coordinating bond has been proposed also by us as a key step in the homogeneous hydrogenation of terminal alkenes and alkynes catalysed by palladium(II) complexes with tridentate ligands.[3] In the present work, we have prepared methyl palladium(II) complexes with acylhydrazones, HNNO (Scheme 1), which can behave as either neutral bidentate, or as anionic tridentate ligands, placing the metal in diverse electronic and steric environments.



In relation to the experimental conditions, complexes with both coordination modes have been obtained, namely bidentate Pd(HNN)MeCl, and tridentate Pd(NNO)Me (see Scheme 2).

Scheme 1. The hydrazonic ligands **HL1–HL5**

Scheme 2. Synthesis of the complexes **1–6**

We now report on the synthesis and characterisation of these complexes, and on their reactivity towards CO insertion into the Pd–Me bond. The reactivity of the methyl complexes towards CO has also been investigated considering the coordination mode and steric hindrance of the ligand and, for the Pd(HNN)MeCl complexes, the acidity of the hydrazonic proton.

Results and Discussion

Synthesis and Characterisation of Ligands HL1–HL5

The acyl hydrazonic ligands **HL1–HL5** were obtained by condensation between a 2-pyridyl-carbonylic system and a hydrazide, in the presence of a catalytic amount of glacial acetic acid. All the ligands are colourless solids, readily soluble in common organic solvents. The N–H bond is visible in their IR spectra with a band at about 3200 cm^{-1}, whereas the C=O group gives rise to a strong band at about 1650 cm^{-1}. The hydrazonic chain is represented by two intense bands centred at about 1550 cm^{-1} and 1300 cm^{-1}, assigned to the AMIDE II and AMIDE III systems, respectively. With the exception of **HL5**, two different sets of signals are present in the ^{1}H-NMR spectrum of the ligands, showing the presence of both (*E*) and (*Z*) isomers (Scheme 1).[12]

Table 1. Selected ^{1}H-NMR ($CDCl_3$) data for ligands **HL1**–**HL5**

	δ[a] N–H	R′	H^1	H^2	H^3
HL1 (*E*)	8.89(s)	8.58(d)	7.26(t)	7.69(t)	8.07(d)
(*Z*)	9.04(s)	8.67(d)	7.32(t)	7.84(t)	7.51(d)
HL2 (*E*)	9.14(s)	8.59(d)	7.27(t)	7.70(t)	–[b]
(*Z*)	15.78(s)	8.71(d)	7.39(t)	7.91(t)	7.62(d)
HL3 (*E*)	11.15(s)	8.54(d)	7.33(t)	7.79(t)	8.13[b]
(*Z*)	15.48(s)	8.76(d)	7.41(t)	7.93(t)	8.02(d)
HL4 (*E*)	8.33(s)	8.59(d)	7.50(m)	7.68(t)	7.58(d)
(*Z*)	9.24(s)	8.75(d)	7.47(m)	7.93(t)	7.66(d)
HL5 (*E*)	9.67(s)	2.55(s)	7.13(d)	7.59(t)	7.88(d)

[a] For simplicity the coupling constants are not reported. – [b] Overlapping with other signals,

These can be distinguished from the signal of the hydrazonic proton (Table 1), which is more deshielded in the (*Z*) isomer, owing to the formation of an intramolecular hydrogen bond with the N_{py}.

Starting from the upper signal, the sequence shown by the pyridine protons of the (*E*) isomer is R′ > H^3 > H^2 > H^1, while in the (*Z*) isomer, and in the palladium complexes, the sequence becomes R′ > H^2 > H^3 > H^1. This indicates that the interaction between H^3 and the iminic nitrogen, present in the (*E*) form, is removed by rotation around the py–C(R″)N bond upon hydrogen-bond formation or coordination to the metal.[8a] Taking into account these observations, an initial predominance of the (*E*) isomer was established, with an (*E*/*Z*) ratio of about 1:0.3 for ligands **HL1**–**HL4**. After 24 hours in chloroform solution at room temperature, **HL2** and **HL3**, containing R‴ = Ph, showed a practically inverted ratio, whereas no change was observed for **HL1**, in agreement with the capacity of the phenyl group to support isomerisation around a C=N bond.[12a] For **HL5** the low deshielding of the hydrazonic proton and the sequence of the pyridinic signals are in favour of the *E* isomer and no changes were observed in a chloroform solution at room temperature after 24 hours.

Synthesis and Characterisation of the Bidentate Methyl Complexes Pd(HNN)MeCl (1–5)

Depending on the solvent, the ligands **HL1**–**HL5** showed a different reactivity towards (COD)PdMeCl. In dichloromethane, **HL1** and **HL3** gave the methyl complexes of formula Pd(HNN)MeCl (**1** and **3**), where the neutral ligand coordinates in a bidentate mode through the pyridinic and the iminic nitrogens, excluding the carbonyl oxygen from the coordination sphere (Scheme 2). The neutral character of the ligand is supported by both the IR and NMR spectra (presence of the N–H bond signals), whereas a strong IR band at about 1700 cm^{-1} indicates an uncoordinated C=O group. In the ^{1}H-NMR spectra of **1** and **3** (Table 2), the methyl group bonded to the metal gives rise to a singlet at 0.97 ppm and 1.01 ppm, respectively, which are typical values for a methyl group σ-bonded to palladium.[8a,c,9] The chemical shift of the R′ proton is useful in establishing the disposition of the methyl ligand with respect to the C=N

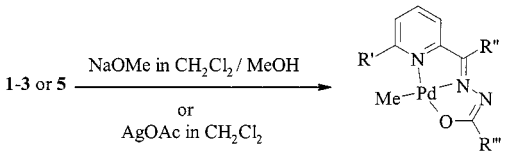
[a] For simplicity the coupling constants are not reported. – [b] Overlapping with other signals. – [c] Solvent: CD_2Cl_2.

bond. In fact when the alkyl group is *trans* to the C=N, R′ shows a resonance similar to that observed in the free ligand, while in a *cis* disposition, R′ resonates at higher ppm values as it is deshielded by the electron-withdrawing effect of the chlorine atom.[8a] On the basis of NMR spectroscopic data, a *trans* disposition was inferred for both **1** and **3**.

The assumed structures for **1** and **3** are confirmed by an X-ray analysis conducted on a single crystal of **3** obtained from a dichloromethane/diethyl ether mixture (1:1), as reported in the Crystallographic Section.

The reaction between **HL2** and (COD)PdMeCl in dichloromethane followed a different pathway (Scheme 2). No traces of the expected Pd(HNN)MeCl complex were observed, but only the formation of a tridentate chloride complex Pd(NNO)Cl (**6**). This reaction involves the deprotonation of the ligand with the consequent formation of methane. The loss of the hydrazonic proton forces the carbonylic oxygen to coordinate to the metal, as demonstrated by the disappearance of the stretching band of the C=O group in the IR spectrum.

The bidentate methyl complex **2** can be selectively obtained by addition of (COD)PdMeCl to an ethereal suspension of **HL2** (Scheme 2). The ^{1}H-NMR spectrum of **2** indicates the presence of both *cis* and *trans* isomers in a ratio of 0.07:1. The use of diethyl ether in the preparation of the Pd(HNN)MeCl complexes was extended to the synthesis of **1** and **3** with ligands **HL1** and **HL3**. The predominant *trans* configuration found in the Pd(HNN)MeCl complexes is probably due to steric factors, as previously reported.[8a,9b,13] In this way, the methyl ligand is kept far from the bulky hydrazonic chain. Furthermore, the *trans* configuration allows for the formation of a hydrogen bond between the chlorine atom and the hydrazonic proton, as shown by the molecular modelling study (see molecular modelling in the Crystallographic Section), and this may be considered as a further stabilising effect. This intramolecular interaction is clearly seen in the ^{1}H-NMR spectra of **2**, where the N–H signal of the *trans* isomer is more deshielded than that of the *cis* isomer (10.38 ppm for the *trans*, and 9.78 ppm for the *cis* isomer). As inferred from the molecular modelling study, the tendency to form the N–H···Cl hydrogen bond decreases with increasing bulkiness of R′′; with the aim of confirming this outcome, the reaction between **HL4** and (COD)PdMeCl in diethyl ether was carried out and, as expected, the resulting complex **4** showed a *cis*/*trans* ratio of 0.27:1, on the basis of the NMR integrals.



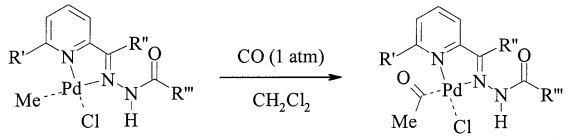
The different reactivity observed towards (COD)PdMeCl in dichloromethane for **HL2** relative to that of **HL1** and **HL3**, may be traced back to the different acidity of the hydrazonic proton, which was experimentally measured by spectrophotometric titration of the dissolved ligands with potassium hydroxide.[3b,e] These analyses established that **HL2** bears the most acidic proton and its acidity seems to be sufficient to cause the methane elimination in dichloromethane solution. On the other hand, when diethyl ether is used as solvent, complex **2** immediately precipitates, and deprotonation is prevented. On dissolution in deuteriochloroform, **2** appears to be rather unstable, and at room temperature its ^{1}H-NMR spectrum changes to that of the chloride complex **6** within a few hours. A similar behaviour was also found for complex **4**, whereas for complexes **1** and **3** only after several days was the transformation into the chloride complex complete (the full characterisation of the chloride complexes was not done, except for **6**).

One might suspect that the small amount of the *cis* isomer present in **2** and **4** could be responsible for their faster transformation into the chloride complexes, since the closeness of the methyl ligand to the hydrazonic proton should facilitate the methane formation. As this transformation happens in a quantitative way, an isomerisation around the metal centre would be required, whereby the methyl group shifts from a *trans* position to the more reactive *cis* one. In order to test this hypothesis, the reaction between the hindered ligand **HL5** and (COD)PdMeCl was carried out in diethyl ether. The presence of the methyl substituent on the aromatic ring forces the alkyl ligand to take a *cis* position,[8a,9b,14] so eventually favouring a faster methane elimination. Contrary to our expectations the stability of **5** in solution at room temperature was found to be higher than that of **2** under the same conditions; thus the acidity of the ligand must be considered decisive for the stability of complexes **1–5**. Furthermore, the ^{1}H-NMR spectra of **1–5** show very narrow resonance lines, indicating the absence of dynamic behaviour with respect to *cis*-*trans* isomerisation on the NMR time scale. Complexes **1–5** are stable in the solid state for months without releasing palladium black.

Synthesis and Characterisation of the Tridentate Methyl Complexes Pd(NNO)Me (7–10)

By adding an excess of a strong base like NaOMe to a solution of **1–3** or **5** at room temperature, or by stirring at

room temperature a dichloromethane solution of the same complexes in the dark overnight with a fivefold excess of silver acetate, the corresponding tridentate methyl complexes Pd(NNO)Me (**7–10** in Equation 1) were obtained as yellow-orange solids.



Pd(NNO)Me **7-10**

The addition of a base caused the deprotonation of the ligand and the consequent formation of a covalent Pd–O bond. Complexes **7–10** show a spectroscopic pattern similar to that of complex **6**, except for the presence of a Pd–Me resonance in the ^{1}H NMR spectra. This signal is generally more shielded than in the corresponding bidentate complexes (Table 2), owing to the increased electron density around the metal centre due to the higher chelating effect exerted by the tridentate ligands. A second significant difference with the ^{1}H-NMR spectrum of **6** is the stronger shielding of the R′ proton due to the absence of the electron-withdrawing effect of the chlorine atom; this proton, in fact, resonates at about 0.1–0.2 ppm lower (Table 2). To our knowledge these complexes represent the first example of methyl complexes where palladium is coordinated in a tridentate fashion by an anionic ligand; in fact the use of anionic chelating agents in this type of chemistry has so far been restricted to some bidentate systems.[15] Complexes **7–10** are stable for months in the solid state but only for some hours in solution, resulting in the formation of palladium black. The stability in solution of complex **10** is remarkably lower than that of complexes **7–9**, as expected from the encumbrance generated by the closeness of the alkyl ligand to the methyl substituent of the pyridine.

Carbonylation Reactions With Complexes Pd(HNN)MeCl

On bubbling CO for a few minutes through dichloromethane solutions of complexes **1** or **3–5** at room temperature, an insignificant amount of palladium black was formed. After filtration of the solution through celite and addition of an excess of *n*-hexane, the acetyl complexes Pd(HNN)[C(O)Me]Cl **11** and **13–15** were obtained in good yields (Equation 2).

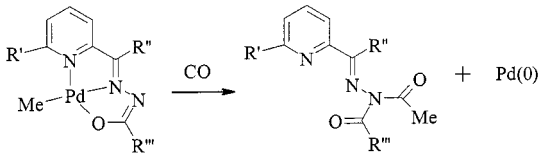
1-5 Pd(HNN)(C(O)Me)Cl **11-15**

The CO insertion is clearly demonstrated in their ^{1}H-NMR spectra by the disappearance of the Pd–Me singlet in favour of a new singlet at about 3 ppm, a characteristic value for an acetyl group σ bonded to Pd.[8a,8c,9] The IR spectrum is not as helpful as usually reported in establishing the insertion as the stretching band of the carbonyl group of the ligand is partially overlapped by the same signal of the acetyl group bonded to palladium, and only a strengthening of the band at about 1700 cm^{-1} was observed. However, the persistence of the stretching band of the C=O group of the ligand, together with the IR and NMR signals of the N–H bond, indicates that the ligand behaviour in **11** and **13–15** is analogous to that in the methyl precursors. The ^{1}H NMR spectra of the four acetyl complexes show two sets of signals (Table 2), indicating the presence of the *cis* as well as the *trans* isomer.

Some difficulties have been found in the isolation of the acetyl complex of **2**. In fact by carrying out the reaction at room temperature in chloroform, dichloromethane or acetonitrile, the fast degradation of the complex to palladium black was observed. When the reaction was repeated in an NMR tube, the signals of the chloride complex **6** were found, together with other signals due to uncharacterised products. By bubbling CO into a dichloromethane solution of **2** at 0 °C, the decomposition was much slower, and two different acetyl isomers could be obtained, in good yields (**12**), where the ligand has the same chelating behaviour as observed in the other acetyl complexes. For **11–15** the separation of the two different isomers was not successful either by chromatographic techniques or by crystallisation. As already reported for the methyl complexes, no fluxional behaviour was found in their NMR spectra.

The amount of the *cis* isomer found in the acetyl complexes is much greater than that found in the methyl precursor. In fact, for complex **13** the *cis*/*trans* ratio is 0.41:1, but for **11**, **12** and **14** it becomes 1:0.57, 1:0.50, and 1:0.56, respectively. For complex **15** only the *cis* isomer was found which is in agreement with the encumbrance created in the coordination plane by a methyl R′ group. Usually an increase of the *cis*/*trans* ratio is observed from the methyl to the corresponding acetyl complexes,[8a,13] and this is generally justified by the tendency of the acetyl group to arrange itself perpendicularly to the coordination plane, thus reducing steric interactions. However the nature of the R′′ group also has a great deal of influence on the *cis*/*trans* ratio, as can be seen from the molecular modelling study (see Crystallographic Section). Thus whenever R′′ is an alkyl group (Me or Et) the *cis* isomer is the predominant one because of the formation of the N–H···O$_{acetyl}$ hydrogen bond; this intramolecular interaction is also corroborated by the deshielding of the hydrazonic proton in the ^{1}H NMR spectra (Table 2).

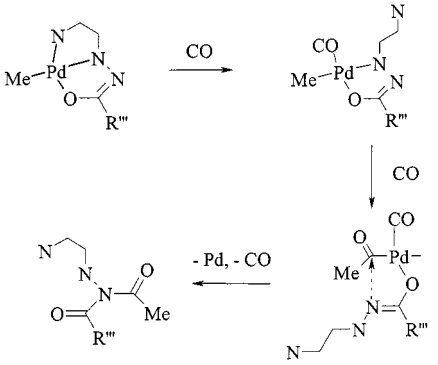
An X-ray diffraction analysis carried out on a crystal of **13**, showed that only the *trans* isomer is present in the crystalline state but, interestingly, in the ^{1}H-NMR spectrum of the same crystals both isomers were present in the same *cis*/*trans* ratio seen for the powdery product.



The fast formation of palladium black, observed when CO was bubbled into a solution of **2** at room temperature, can be related to the highly acidic character of the ligand, which is also responsible for the instability of **2** in solution.

The hydrazonic proton probably reacts with the acetyl ligand although, unfortunately, it was not possible to detect the presence of acetaldehyde by GC-MS or ^{1}H NMR analyses.

Owing to the high reaction rate, in no case could mechanistic information be obtained by monitoring the carbonylation reactions by ^{1}H NMR, even when conducting the reaction at –20 °C. At this temperature only the disappearance of the methyl resonance and the simultaneous appearance of the acetyl resonance was detected, without observing any signals attributable to an intermediate species. On the basis of literature data,[8a,16] we propose that the CO coordination occurs with the breaking of the Pd–py bond. The formation of both *cis* and *trans* isomers can be understood considering the possibility of rotation around the Pd–N_{iminic} bond after pyridine dissociation, a step which would involve a unidentate intermediate.



Carbonylation Reactions with Complexes Pd(NNO)Me

Contrary to what is usually reported in the literature for neutral tridentate ligands, the isolation of the tridentate acetyl palladium complexes of the type Pd(NNO)[C(O)Me] was unsuccessful owing to the fast formation of palladium black when CO was bubbled through a dichloromethane or THF solution of complexes **7–10** at 25, 0 or –40 °C. The formation of palladium black was accompanied by bleaching of the solutions. After removal of the metallic palladium, an MS analysis of the solution revealed the presence of a new organic species with a molecular weight corresponding to the acylated ligand. The spectroscopic data suggest that the acetyl group is bonded to the hydrazonic nitrogen, as depicted in Equation 3, giving rise to a bi(acyl) hydrazone derivative.

As a further confirmation, the same product i.e. 2-pyridylaldehyde *N*-acetylbenzoylhydrazone, was isolated by refluxing a mixture of **HL3** and acetylchloride in pyridine, following a known procedure.[17]

The course of the carbonylation reaction strongly resembles that of the palladium catalysed carbonylation of organic halides to form amides.[18] In this process an external nucleophile (usually a secondary amine in the presence of a base) directly attacks the acetyl group bonded to palladium or a pre-coordinated carbon monoxide molecule in a cationic intermediate.[19] Both pathways are followed by a reductive elimination step which leads to the formation of the amide and Pd^0. In our case, even if a plausible mechanism was not determined owing to the high reaction rate observed even at low temperatures, it is reasonable to suppose that the hydrazonic nitrogen acts as a nucleophile towards the acetyl group σ bonded to palladium, as depicted in Scheme 3; this attack is possible only if the formation of an oxygen-monodentate intermediate with a dangling ligand is supposed, the breaking of both Pd–N bonds being justified by the large excess of CO present in the reaction vessel.

Scheme 3. Proposed mechanism for the carbonylation with Pd(NNO)Me

In the attempt to isolate the tridentate acetyl complexes Pd(NNO)[C(O)Me] in the absence of CO, the corresponding bidentate acetyl complexes **11–15** were deprotonated by treatment with sodium methoxide in dichloromethane or THF. Rapid formation of palladium black was again observed and the ^{1}H-NMR spectra of the isolated product revealed the presence of the acylated ligand along with traces of the tridentate methyl complexes Pd(NNO)Me. This unexpected result can be rationalised by the presence of both *cis* and *trans* isomers in the solutions of **11–15**. In the case of the *cis* isomer it is plausible to suppose that, after deprotonation of the ligand, the hydrazonic nitrogen attacks the electrophilic acetyl group bonded to palladium, bringing about the formation of the acylated ligand, metallic palladium and NaCl. In the case of the *trans* isomer, the intramolecular nucleophilic attack is unlikely because of the distance of the acetyl group from the hydrazonic chain and, consequently, the deprotonation of the ligand may result only in the formation of the expected product Pd(NNO)-[C(O)Me]. This compound seems to lose CO rapidly, forming the corresponding tridentate methyl complex. A similar decarbonylation process undergone by the tridentate acetyl complexes has already been observed with tridentate ligands, both in solution and in the solid state.[9b,10,11b,11c]

Crystallographic Section

X-ray Crystal Structures of 13 and 3

In the neutral complex **13**, shown in Figure 1, the bidentate neutral ligand coordinates to the metal by the pyridinic and the iminic nitrogen atoms, while the carbonylic oxygen O1 does not participate in the chelation.

The square planar coordination around the palladium atom is completed by a chloride, *trans* to the pyridinic nitrogen, and by an acetyl group *trans* to the iminic nitrogen; the coordinated atoms are coplanar to the metal within 0.04 Å. A list of the most relevant bond lengths and angles is given in Table 3.

The entire ligand, with the exception of the terminal phenyl C8–C13, is coplanar within 0.22 Å, and the atoms which deviate most from this plane are the protonated hydrazonic N3 and the carbonyl O1, involved in the intramolecular hydrogen bonds N3–H···Cl [N3···Cl = 3.218(4) Å, H···Cl = 2.58(3)Å, N3–H···Cl = 145(3)°] and C6–H···O1 [C6···O1 = 2.806(5)Å, C6–H···O1 = 116(3)°]. The terminal phenyl C8–C13 makes a dihedral angle of 34° with the average molecular plane. The plane of the acetyl ligand is tilted by 63° with respect to the coordination plane. A search of the Cambridge Structural Database has shown that the corresponding values for acetyl groups coordinated to square-planar palladium or platinum atoms range from 68° to 90°. The bond Pd–C14 [1.947(3) Å] is the shortest ever observed among the seven palladium-acetyl complexes structurally characterised, whose bond lengths range between 1.948 and 2.001 Å. The influence of the acetyl group on the Pd–N bond lengths can be analysed by comparing **13** with acetyl(2,2′-bipyridine)chloropalladium[8a] and acetylchloro-[2-(*N*-isopropyl)carbaldiminopyridine]palladium.[8a] The coordination geometry of **13** is very close to that observed in the former (Pd–acetyl = 1.948, Pd–N1 = 2.067, Pd–N2 = 2.162 Å, with the acetyl group *trans* to N2). On the contrary, in acetylchloro[2-(*N*-isopropyl)carbaldiminopyridine]palladium the acetyl group is *trans* to the pyridine nitrogen, causing the elongation of the Pd–N1 bond (2.171 Å), while the bond length between palladium and the iminic nitrogen (2.062 Å), *trans* to a chloride, is shorter than in **13** and similar to the Pd–pyridine distances of **13** and acetyl(2,2′-bipyridine)chloropalladium.

The geometry of compound **3** (Figure 2) is identical to that of **13** (see Table 4); the coordinated atoms are coplanar with the metal within 0.06 Å. Also, the entire ligand is coplanar within 0.18 Å to the coordination plane. There are two intramolecular hydrogen bonds N3–H···Cl [N3···Cl =

3.183(8) Å, H···Cl = 2.43(12) Å, N3–H···Cl = 131(13)°] and C6–H···O [C6···O = 2.779(11) Å, C6–H···O = 118(6)°]. The terminal phenyl C8–C13 makes a dihedral angle of 27° with the average molecular plane.

Molecular Modelling

As shown by NMR spectroscopy, the proportion of *cis*/*trans* isomers in solution for compounds Pd(HL)(R)Cl (HL = **HL1–HL5**) [R = Me, C(O)Me] is related to the nature of the R group coordinated to the metal and to the steric hindrance of the substituent R′′ attached to the iminic carbon. Some factors that can affect the preference for one or the other forms involve the different *trans* influence of the pyridinic and iminic nitrogens, the steric hindrance of the ligand *cis* to the hydrazonic N–H group, and the repulsion between the carbonylic oxygen and the alkyl substituents on the iminic carbon. In order to elucidate the relative importance of these factors on the observed isomer distributions, we analysed the conformational energy of different model systems by semi-empirical calculations. The systems considered in the analysis are shown in Scheme 4: they comprise the *cis* and *trans* isomers, referring to the hydrazonic N–H, of methyl- and acetyl- derivatives of complexes containing the ligands **HL1** and **HL3′**. [**NB** The ligand HL3′ is modelled by replacing the terminal phenyl of HL3 with a methyl group (see Experimental Section)].

These differ in the presence of a hydrogen or a methyl on the iminic carbon. The simultaneous effect of the *cis* ligand and of the iminic substituent on the NH–C=O system has been studied by calculating the energetic profile for the rotation of the rigid terminal NH–C(O)Me group around the N–N single bond. The C6–N2–N3–C7 torsion angle (for labelling see Figure 1 and Figure 2) has been varied from –120° to +120°, in increments of 5°, and at each step the torsion angle has been held fixed, and the other parameters have been released to minimise the energy. Then, the most stable conformations have been found by minimising the energy of the molecular geometries close to the minima in the path.

Methyl Complexes

Figure 3 shows the energetic profile for molecules TMH, CMH, TMM, and CMM.

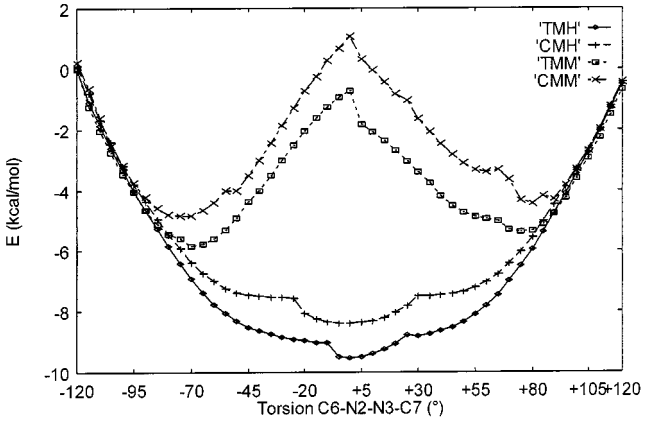

Figure 3. Energetic profiles for the rotation of the terminal NH(CO)–Me group around the N–N bond for methyl complexes TMH, CMH, TMM, and CMM; all energies have been rescaled referring to the value found for TMH at torsion = –120°

TMH and CMH do not present any steric obstacle for the carbonyl oxygen to lie in the ligand plane, and for both *cis* and *trans* isomers the conformation with minimum energy is planar, with the hydrazonic group practically coplanar to the coordination plane (C6–N2–N3–C7 = –19 and –11°, respectively), and the N–H group pointing towards the *cis* ligand. The *trans* form is about 1.2 kcal/mol more stable than the *cis* form due to the intramolecular hydrogen-bond N–H···Cl (H···Cl = 2.47 Å). This interaction is effective in the torsion angle window between –70° and +70° where the N–H dipole detects the stabilising attraction of the chloride, as shown by the fact that the curves for the two isomers coincide when the N–H group is oriented almost perpendicularly to the coordination plane (as for C6–N2–N3–C7 <–70° and >+70°). The introduction of a methyl group on the iminic carbon produces a remarkable destabilisation (about 9.3 kcal/mol) of the planar conformation, due to the repulsion between the carbonyl and the methyl (O···C = 2.76 and 3.15 Å for the most stable conformations of TMM and CMM, respectively). Two equivalent minima are found in the energy profile (Figure 3), corresponding to

torsion angles C6–N2–N3–C7 of –58° and +58° for TMM and –73° and +73° for CMM. Again, the molecule with the chloride *cis* to the N–H (TMM) is about 1 kcal/mol more stable than the molecule with the methyl close to the N–H (CMM), because of the N–H···Cl hydrogen bond (H···Cl = 2.52 Å), that can also explain the difference of about 15° between the positions of the energy minima for the two configurations. The optimisation of this interaction is favoured by a slight pyramidalisation of the bonding geometry for N3, expressed as the sum of the bond angles around it, which works out to 348.5° and 342.8° for TMM and CMM, respectively, whereas it is close to 360° for the sp^2-hybridized N3 in TMH and CMH (357.9° and 359.2°, respectively).

Acetyl Complexes

The oxygen of the acetyl group bound to the metal can compete with the chloride as a hydrogen-bond acceptor towards the N–H group. The acetyl complexes have an additional degree of freedom, represented by the orientation of the acetyl group around the Pd–C bond. The analysis of the energetic profile for the rotation shows that for the *trans* complex TAH there is a broad range of favoured orientations lying in a shallow minimum, with values of N1–Pd–C14–O2 ranging between –90° and +90°. For these conformations the acetyl oxygen is oriented towards the pyridine, and does not feel the repulsion of the negative charge localised on the chloride. Within this range two local minima are found, corresponding to –60° and +60°, as observed in the crystal structure of **13**, separated by a rotational barrier of about 5 kcal/mol, at N1–Pd–C14–O2 = 0° (with the acetyl in the square coordination plane). When the acetyl is bonded *cis* to the N–H group (CAH), the preferred orientations are situated in a shallow minimum with the torsion angle N2–Pd–C14–O2 ranging between –30° and +30° (Figure 4), which brings the acetyl oxygen close to the coordination plane and in proximity to the N3–H dipole.

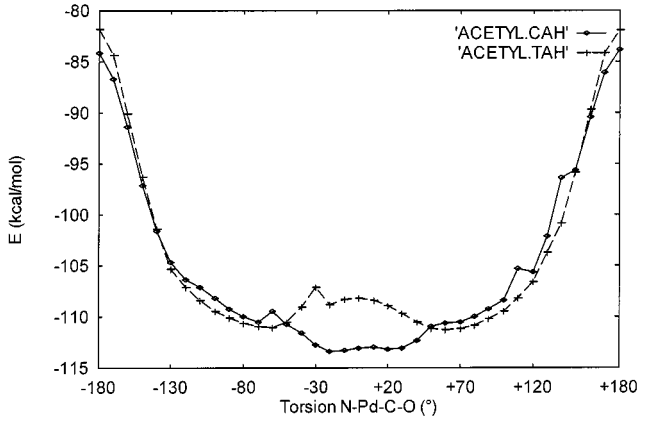

Figure 4. Energetic profiles for the rotation of the acetyl ligand around the Pd–C bond for TAH and CAH; torsion N–Pd–C–O refers to N2 for CAH and to N1 for TAH

These data suggest that the interaction between the acetyl and the N–H can stabilise the *cis* isomer. The relative stability of the *cis* and *trans* isomers when the steric hindrance on the iminic carbon is varied have been studied for compounds TAH, CAH, TAM, and CAM (Scheme 4), with the same procedure as in the case of the methyl complexes. The results are shown in Figure 5.

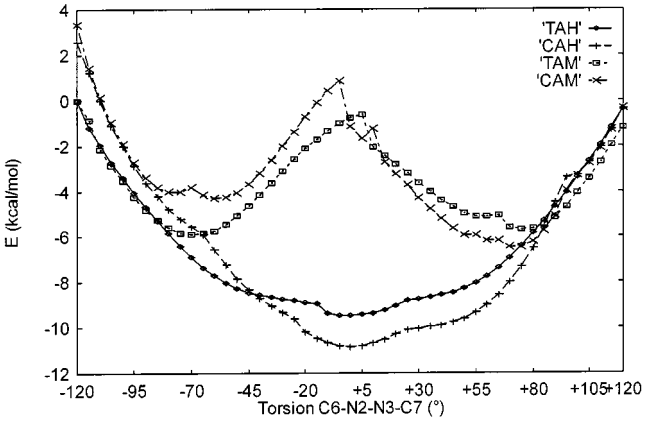

Figure 5. Energetic profiles for the rotation of the terminal NH(CO)–Me group around the N–N bond for acetyl complexes TAH, CAH, TAM, and CAM; all energies have been rescaled referring to the value found for TAH at torsion = –120°

As already observed for the methyl complexes, in the absence of steric hindrance for O1, for the most stable conformations the plane containing the NH–C(O)Me terminal group is coplanar with the metal coordination plane, and the N–H points towards the *cis* ligand (C6–N2–N3–C7 = –15° and –9° for TAH and CAH, respectively). However, the hydrogen-bond acceptor capabilities of the acetyl ligand produce a relevant inversion in the stability of the *cis* and *trans* isomers: when the terminal group is almost perpendicular to the coordination plane (C6–N2–N3–C7 < –50°) the *trans* isomer TAH is slightly more stable than the *cis* isomer CAH, but, as the N–H dipole enters in the range of interaction of the *cis* acetyl, at C6–N2–N3–C7 = –45°, the *cis* isomer CAH gains stability by the incipient formation of the N–H···O hydrogen bond (H···O = 1.80 Å at the minimum), which is much stronger than the N–H···Cl hydrogen bond present in the *trans* isomer TAH (H···Cl = 2.48 Å). The asymmetry of the profile relative to the *cis* isomer is due to the fact that the acetyl orientation is held fixed at N2–Pd–C14–O2 = –30°, meaning that at C6–N2–N3–C7 = –45° the N–H is on the opposite side of the acetyl oxygen with respect to the coordination plane, while at C6–N2–N3–C7 = +45° it is on the same side. The asymmetry of the energetic profile for the rotation of the torsion angle C6–N2–N3–C7 is even more significant for CAM and TAM, where the orientations with the hydrazonic group coplanar with the coordination plane are destabilised by the repulsion between O1 and C16 (Figure 5). Both molecules have two preferred conformations, as seen for CMM and TMM, but in the case of the acetyl complexes the *cis* complex CAM (with N2–Pd–C14–O2 = –30°) is about 1.9 kcal/mol less stable than the *trans* complex when the NH is oriented on the opposite side of the acetyl oxygen with respect to the coordination plane (C6–N2–N3–C7 = –56°). The stabilisation of TAM is due to the interaction N–H···Cl (H···Cl = 2.50Å), as found for TMM. The relative stability

of TAM and CAM is inverted when the torsion angle C6–N2–N3–C7 has positive values: in CAM the optimisation of the hydrogen bond to the *cis* group involves a gain of about 0.9 kcal/mol, relative to TAM, for the most stable conformation (C6–N2–N3–C7 = 66°, N2–Pd–C14–O2 = –31°, H···O = 1.79Å). This conformation is also the global minimum for CAM, and is about 2.0 kcal/mol more stable than the one with C6–N2–N3–C7 = –56°. For TAM the two minima are energetically equivalent, due to the local symmetry of the NH···Cl system with respect to the coordination plane.

These results show that the conformational preferences for compounds in Scheme 4 are mainly influenced by the hydrogen bond between the NH group and the *cis* ligand. When the choice is between Cl and Me, the hydrogen bond with the former is favoured in all cases (CMH, TMH, CMM, TMM). In TAH, CAH, CAM, TAM, the chloride must compete with the acetyl, and it has been seen that the latter is generally more suited to optimise the hydrogen bond, provided that it is correctly oriented.

Conclusions

We have shown that HNNO tridentate hydrazonic ligands can form two different kinds of methyl palladium(II) complexes, depending on the experimental conditions. Thus, in the absence of a basic medium, the ligands adopt a neutral bidentate HNN coordination, whereas in the presence of a base a tridentate NNO behaviour is preferred. In solution the bidentate complexes tend to eliminate methane in relation to the acidic character of the ligand. The reactivity towards CO of the bidentate and tridentate complexes is drastically different. The bidentate complexes form the corresponding acetyl complexes, where the ligand maintains a neutral bidentate HNN behaviour. On the contrary, the carbonylation of the tridentate complexes results in their fast and complete decomposition to palladium black together with the formation of the acylated ligand, the acetyl group being bonded to the hydrazonic nitrogen.

A molecular modelling study indicates that not only steric effects determine the isomeric *cis*/*trans* distribution observed in both bidentate methyl and acetyl complexes, but also that electronic considerations must be taken into account. Thus, for the methyl complexes the possibility of formation of a N–H···Cl hydrogen bond favours the *trans* isomer, whereas in the acetyl complexes the formation of a N–H···O_{acyl} hydrogen bond favours the *cis* isomer.

Experimental Section

General: All the manipulations were carried out under a purified dry nitrogen atmosphere, using standard Schlenk techniques. Solvents were dried prior to use and stored under nitrogen. 2-Acetylpyridine and 2-pyridinecarboxaldehyde were purchased (Aldrich), whereas 6-methyl-2-pyrdinecarboxaldehyde was synthesised by the oxidation of 6-methyl-2-pyridinemethanol with SeO_2 in dioxane.[20] The hydrazides were synthesised by reaction between the corresponding methyl or ethyl esters and hydrazine monohydrate (Fluka). (COD)PdMeCl was synthesised following literature methods.[11a] Silver acetate was purchased (Aldrich).

Proton NMR spectra were recorded on a Bruker 300 FT spectrometer, with $SiMe_4$ as internal standard, at 25 °C. IR spectra were obtained by a Nicolet 5PCFT-IR spectrophotometer in the 4000–400 cm^{-1} range with KBr disks. Mass spectra were recorded on a FINNIGAN SSQ 710 spectrometer. Elemental analysis (C,H,N) were performed by using a Carlo Erba Model EA 1108 apparatus. GC-MS spectra were obtained with a Hewlett–Packard 5890 series II gas chromatograph with a Gerstel CIS III temperature-controllable injector, an HP 5971A mass-selective detector with electron-impact ionisation at 70 eV, and an HP Ultra-2 column (25 m, 0.20 mm inner diameter, 0.33 μm film thickness).

Synthesis of Ligands HL1–HL4. – General Procedure: Ligands **HL1**–**HL4** were synthesised by refluxing a solution containing the ketone or the aldehyde (0.5 g) with a stoichiometric amount of the corresponding hydrazide, in the presence of a few drops of glacial acetic acid. The end of the reaction was determined by TLC, monitoring the disappearance of the stain corresponding to the pyridinic system. After concentration and cooling of the solution, the pure ligands crystallised as colourless needles which were washed with a few millilitres of diethyl ether and dried in vacuum.

Methyl 2-Pyridyl Ketone Acetylhydrazone (HL1): Yield: 0.571 g (78%). – M.p. 153 °C. – IR (cm^{-1}): ν(N–H) = 3198 m, ν(C=O) = 1678 vs, AMIDE II $\tilde{\nu}$ = 1580 s, AMIDE III = 1371 s. – ^{1}H NMR ($CDCl_3$): (*E*) isomer δ = 2.40 [s, 3 H, MeC(O)], 2.36 [s, 3 H, C(Me)=N]; (*Z*) isomer δ = 2.37 [s, 3 H, MeC(O)], 2.33 [s, 3 H, C(Me)=N]. – MS (C.I.): 178 [M^+ + 1]. – $C_9H_{11}N_3O$ (177.21): calcd. C 61.00, H 6.26, N 23.71; found C 60.88, H 6.23, N 23.81. – log β_1^H = 12.51(1).

Methyl 2-Pyridyl Ketone Benzoylhydrazone (HL2): Yield: 0.741 g (75%). – m.p.: 150–152 °C. – IR (cm^{-1}): ν(N–H) = 3180 br, ν(C=O) = 1654 vs, AMIDE II $\tilde{\nu}$ = 1544 s, AMIDE III = 1282 s. – ^{1}H NMR ($CDCl_3$): (*E*) isomer δ = 7.90 [d, 2 H, Ph *o*–C(O)], 7.51–7.46 [m, 4 H, H^3 + Ph *m* and *p*-C(O)], 2.49 [s, 3 H, C(Me)=N]; (*Z*) isomer δ = 7.95 [dd, 2 H, Ph *o*-C(O)], 7.52–7.43 [m, 3 H, Ph *m* and *p*-C(O)], 2.50 [s, 3 H, C(Me)=N]. – MS (C.I.): 240 [M^+ + 1]. – $C_{14}H_{13}N_3O$ (239.28): calcd. C 70.35, H 5.47, N 17.56; found C 70.36, H 5.67, N 17.86. – log β_1^H = 11.35(1).

2-Pyridyl Carboxaldehyde Benzoylhydrazone (HL3): Yield: 0.864 g (78%). – m.p.: 107–109 °C. – IR (cm^{-1}): ν(N–H) = 3193 w, ν(C=O) = 1662 vs, AMIDE II $\tilde{\nu}$ = 1553 vs, AMIDE III = 1286 vs. – ^{1}H NMR ($CDCl_3$): (*E*) isomer δ = 7.97 [d, 3 H, H^3 + Ph *o*-C(O)], 7.27 [s, 1 H, C(H)=N]; (*Z*) isomer δ = 8.02 [d, 3 H, H^3 + Ph *o*-C(O)], 7.61–7.50 [m, 5 H, Ph *m* and *p*-C(O)], 7.27 [s, 1 H, C(H)=N]. – MS (C.I.): 226 [M^+ + 1]. – $C_{13}H_{11}N_3O$ (225.25): calcd. C 69.32, H 4.92, N 18.66; found C 69.35, H 4.97, N 18.64. – log β_1^H = 11.48(1).

Ethyl 2-Pyridyl Ketone Benzoylhydrazone (HL4): Yield: 0.500 g (53%). – m.p.: 146 °C. – IR (cm^{-1}): ν(N–H) = 3174 m, ν(C=O) = 1653 vs, AMIDE II $\tilde{\nu}$ = 1548 s, AMIDE III = 1300 s. – ^{1}H NMR ($CDCl_3$): (*E*) isomer δ = 7.90 [d, 2 H, Ph *o*-C(O)], 7.53–7.48 [m, 3 H, Ph *m*- and *p*-C(O)], 3.04 (q, 2 H, Et), 1.25 (t, 3 H, Et). – (*Z*) isomer δ = 7.97 [d, 2 H, Ph *o*-C(O)], 7.49–7.45 [m, 3 H, Ph *m*- and *p*-C(O)], 2.94 (q, 2 H, Et), 1.31 (t, 3 H, Et). – MS (C.I.): 254 [M^+ + 1]. – $C_{13}H_{15}N_3O$ (229.28): calcd. C 71.13, H 5.97, N 16.59; found C 71.16, H 6.03, N 16.52.

Synthesis of Ligand HL5: The synthesis was carried out in situ introducing the correct amount of benzoylhydrazide into the solu-

tion coming from the synthesis of 6-methyl-2-pyridylcarboxyaldehyde. The solution was then refluxed for 30 minutes. After cooling a pale pink solid was filtered and washed with diethyl ether.

6-Methyl-2-pyridyl Aldehyde Benzoylhydrazone (HL5): Yield: 0.593 g (60%). – m.p.: 108 °C. – IR (cm^{-1}): ν(N–H) = 3187 m, ν(C=O) = 1653 vs, AMIDE II $\tilde{\nu}$ = 1560 s, AMIDE III = 1296 s. – ^1H NMR ($CDCl_3$): (*E*) isomer δ = 8.30 [s, 1 H, C(H)=N], 7.88 [d, 2 H, Ph *o*-C(O)], 7.45 [t, 2 H, Ph *m*-C(O)], 7.54 [t, 1 H, Ph *p*-C(O)]. – MS (C.I.): 240 [M^+ + 1]. – $C_{14}H_{13}N_3O$ (239.28): calcd. C 70.28, H 5.48, N 17.56; found C 70.31, H 5.53, N 17.60. – log β_1^H = 11.61(1).

Synthesis of the Bidentate Methyl Complexes Pd(HNN)MeCl 1–5. – General Procedure: To a vigorously stirred ethereal ligand suspension (0.100 g) was added a stoichiometric amount of (COD)PdMeCl. Instantaneously a pale yellow solid precipitated and the resulting mixture was stirred for two hours at room temperature. After filtration the isolated solid was repeatedly washed with diethyl ether and then dried in vacuum.

Complexes **1** and **3** can also be prepared with CH_2Cl_2 as solvent by the following procedure: 0.100 g of ligand are dissolved in 20 mL of CH_2Cl_2 and a stoichiometric amount of (COD)PdMeCl is added. The yellow solution is stirred at room temperature for two hours. Concentration of the solution and precipitation with *n*-hexane gives the desired products as a yellow powder, which is filtered off, washed with *n*-hexane and then dried under vacuum for several hours. The yields are lower then those obtained using diethyl ether (65%).

The yields reported below are those from the synthesis carried out in diethyl ether.

[PdMeCl(HL1)] (1): Yield: 0.106 g (92%). – IR (cm^{-1}): ν(N–H) = 3291 s, ν(C=O) = 1699 vs, AMIDE II $\tilde{\nu}$ = 1478 m, AMIDE III = 1374 m. – ^1H NMR ($CDCl_3$): δ = 2.26 [s, 3 H, MeC(O)], 2.20 [s, 3 H, C(Me)=N]. – $C_{10}H_{14}ClN_3OPd$ (334.09): calcd. C 35.95, H 4.22, N 12.58; found C 35.86, H 4.08, N 12.68.

[PdMeCl(HL2)] (2): Yield: 0.155 g (93%). – IR (cm^{-1}): ν(N–H) = 3195 w, ν(C=O) = 1673 vs, AMIDE II $\tilde{\nu}$ = 1499m–1460 s, AMIDE III = 1271 m. – ^1H NMR ($CDCl_3$): *trans* isomer δ = 7.99 [d, 2 H, Ph *o*-C(O)], 7.60–7.50 [m, 4 H, H^1 + Ph *m* and *p*-C(O)], 2.37 [s, 3 H, C(Me)=N]; *cis* isomer δ = 2.42 [s, 3 H, C(Me)=N]. – $C_{15}H_{16}ClN_3OPd$ (396.17): calcd. C 45.48, H 4.07, N 10.61; found C 45.51, H 4.01, N 10.60.

[PdMeCl(HL3)] (3): Yield: 0.153 g (91%). – IR (cm^{-1}): ν(N–H) = 3247 w, ν(C=O) = 1669 vs, AMIDE II $\tilde{\nu}$ = 1506vs–1485 s, AMIDE III = 1266 vs. – ^1H NMR (CD_2Cl_2): δ = 9.96 [s, 1 H, C(H)=N], 7.96 [d, 2 H, Ph *o*-C(O)], 7.52 [t, 3 H, Ph *m*- and *p*-C(O)]. – $C_{14}H_{14}ClN_3OPd$ (382.14): calcd. C 44.00, H 3.69, N 11.00; found C 43.99, H 3.53, N 10.85.

[PdMeCl(HL4)] (4): Yield: 0.115 g (91%). – IR (cm^{-1}): ν(N–H) = 3206 w, ν(C=O) = 1668 vs, AMIDE II $\tilde{\nu}$ = 1466 m, AMIDE III = 1268 m. – ^1H NMR ($CDCl_3$): *trans* isomer δ = 8.02 [d, 2 H, Ph *o*-C(O)], 7.50 [m, 3 H, Ph *m* and *p*-C(O)], 2.84 (q, 2 H, Et); *cis* isomer δ = 7.99 [d, 2 H, Ph *o*-C(O)], 2.89 (s, 2 H, Et). The triplets of the Et groups are fused in a multiplet centred at δ = 1.25 – $C_{16}H_{18}ClN_3OPd$ (410.19): calcd. C 46.85, H 4.42, N 10.24; found C 46.800, H 4.29, N 10.46.

[PdMeCl(HL5)] (5): Yield: 0.141 g (85%). – IR (cm^{-1}): ν(N–H) = 3234 w, ν(C=O) = 1674 vs, AMIDE II $\tilde{\nu}$ = 1483 m, AMIDE III = 1263 m. – ^1H NMR ($CDCl_3$): δ = 7.96 [d, 2 H, Ph *o*-C(O)], 7.60 [t, 1 H, Ph *p*-C(O)], 7.47 [t, 2 H, Ph *m*-C(O)], 9.96 [s, 1 H, C(H)=N]. – $C_{15}H_{16}ClN_3OPd$ (396.17): calcd. C 45.48, H 4.10, N 10.61; found C 45.45, H 4.08, N 10.46.

Synthesis of the Chloride Complex Pd(NNO)Cl 6: HL2 (0.020 g, 0.084 mmol) was dissolved in 30 mL of CH_2Cl_2 and (COD)PdMeCl (0.022 g, 0.084 mmol) was added. Immediately a yellow solution was formed from which a yellow solid precipitated within 20 minutes of stirring at room temperature. After two hours of reaction the solid was filtered, repeatedly washed with diethyl ether and then dried in vacuum.

[PdCl(L2)] (6): Yield: 0.260 g (82%). – IR (cm^{-1}) $\tilde{\nu}$: AMIDE II = 1498 s, AMIDE III = 1364 s. – ^1H NMR ($CDCl_3$): δ = 8.11 [d, 2 H, Ph *o*-C(O)], 7.38–7.30 [m, 4 H, H^3 + Ph *m*- and *p*-C(O)], 2.46 [s, 3 H, C(Me)=N]. $C_{14}H_{12}ClN_3OPd$ (380.12): calcd. C, 44.24, H 3.18, N 11.05; found C 44.43, H 2.99, N 11.12.

Synthesis of the Tridentate Methyl Complexes Pd(NNO)Me 7–10: i): Compound **1**, **2**, **3**, or **5** (0.050 g) was dissolved in 20 mL of THF together with a threefold excess of NaOMe. Soon after the base had been added, a colour change of the solution from yellow to orange was observed. The solution was then stirred at room temperature for two hours. The unchanged NaOMe and the formed NaCl were removed by filtration and the resulting solution was concentrated in vacuum. By adding *n*-hexane an orange powder precipitated which was filtered off and dried in vacuum for several hours. ii): Compound **1**, **2**, **3**, or **5** (0.050 g) was dissolved in 20 mL of CH_2Cl_2 and a fivefold excess of silver acetate was added. The resulting mixture was stirred in the dark overnight. After removal of the silver salts the solution was concentrated in vacuum and the product precipitated by adding diethyl ether. For both methods the yields vary from 55% to 75%.

[PdMe(L1)] (7): IR (cm^{-1}) $\tilde{\nu}$: AMIDE II = 1582 vs, AMIDE III = 1370 m. – ^1H NMR ($CDCl_3$): δ = 2.31 [s, 3 H, MeC(O)], 2.28 [s, 3 H, C(Me)=N]. $C_{10}H_{13}N_3OPd$ (297.63): calcd. C 40.35, H 4.40, N 14.12; found C 40.30, H 4.46, N 14.10.

[PdMe(L2)] (8): IR (cm^{-1}) $\tilde{\nu}$: AMIDE II = 1499 s, AMIDE III = 1365 s. – ^1H NMR (CD_2Cl_2): δ = 8.06 [d, 2 H, Ph *o*-C(O)], 7.30–7.26 [m, 3 H, Ph *m* and *p*-C(O)], 2.41 [s, 3 H, C(Me)=N]. $C_{15}H_{15}N_3OPd$ (359.70): calcd. C 50.09, H 4.20, N 11.68; found C 49.99, H 4.15, N 11.50.

[PdMe(L3)] (9): IR (cm^{-1}) $\tilde{\nu}$: AMIDE II = 1501 s, AMIDE III = 1380 s. – ^1H NMR ($CDCl_3$): δ = 9.21 [s, 1 H, C(H)=N], 8.19 [d, 2 H, Ph *o*-C(O)], 7.33–7.30 [m, 3 H, Ph *m* and *p*-C(O)]. $C_{14}H_{13}N_3OPd$ (345.68): calcd. C 48.64, H 3.79, N 12.16; found C 48.61, H 3.82, N 12.10.

[PdMe(L5)] (10): IR (cm^{-1}) $\tilde{\nu}$: AMIDE II = 1462 m, AMIDE III = 1366 vs. – ^1H NMR ($CDCl_3$): δ = 9.06 [s, 1 H, C(H)=N], 8.13 [d, 2 H, Ph *o*-C(O)], 7.41–7.33 [m, 3 H, H^2 + Ph *m* and *p*-C(O)].

Carbonylation Reactions of the Bidentate Methyl Palladium Complexes Pd(HNN)MeCl. General Procedure for the Preparation of Complexes 11, 13, 14, and 15: Compound **1**, **3**, **4**, or **5** (0.050 g) was placed in a 50 mL Schlenk tube and dissolved in about 10 mL of CH_2Cl_2; CO was then bubbled through this solution for about 5–10 minutes through a glass capillary. After filtration of the solution through celite the acetyl complexes were precipitated by addition of *n*-hexane.

{Pd[C(O)Me]Cl(HL1)} (11): Yield: 0.024 g (45%). – IR (cm^{-1}): ν(N–H) = 3174 s, ν(C=O) = 1692br, ν{Pd[C(O)Me]} = 1670 sh–1646 s, AMIDE II $\tilde{\nu}$ = 1501 s, AMIDE III = 1371 m. – ^1H NMR

($CDCl_3$): *trans* isomer δ = 2.28 [s, 3 H, MeC(O)], 2.20 [s, 3 H, C(Me)=N]; *cis* isomer δ = 2.48 [s, 3 H, MeC(O)], 2.19 [s, 3 H, C(Me)=N]. – $C_{11}H_{13}ClN_3O_2Pd$ (361.10): calcd. C 36.49, H 3.90, N 11.60; found C 36.43, H 3.54, N 11.43.

{Pd[C(O)Me]Cl(HL3)} (13): Yield: 0.043 g (80%). – IR (cm^{-1}): ν(N–H) = 3266 w, ν(C=O) + ν{Pd[C(O)Me]} = 1692 vs, AMIDE II $\tilde{\nu}$ = 1503 vs–1486 s, AMIDE III = 1250 s. – ^{1}H NMR ($CDCl_3$): *trans* isomer δ = 9.90 [s, 1 H, C(H)=N], 7.96 [d, 2 H, Ph *o*-C(O)], 7.67–7.51 [m, 5 H, H^1+H^3 + Ph *m* and *p*-C(O)]; *cis* isomer δ = 10.24 [s, 1 H, C(H)=N], 8.11 [d, 2 H, Ph *o*-C(O)]. – $C_{15}H_{14}ClN_3O_2Pd$ (410.15): calcd. C 43.93, H 3.44, N 10.24; found C 44.00, H 3.52, N 10.26.

{Pd[C(O)Me]Cl(HL4)} (14): Yield: 0.033 g (62%). – IR (cm^{-1}): ν(N–H) = 3206 m, ν(C=O) = 1692 vs, ν[Pd(C(O)Me)] = 1668 sh–1645 s, AMIDE II $\tilde{\nu}$ = 1462 s, AMIDE III = 1368 m. – ^{1}H NMR ($CDCl_3$): *trans* isomer δ = 2.92 (q, 2 H, Et); *cis* isomer δ = 2.98 (q, 2 H, Et). The low resolution of the spectrum does not allow a correct attribution of the signals of the pyridine and phenyl rings. For both isomers the Pd–Me signals are overlapped with the triplets generated by the methyl group of the R substituent in a multiplet centred at 1.27 ppm. – $C_{17}H_{18}ClN_3O_2Pd$ (438.20): calcd. C 47.14, H 3.03, N 9.70; found C 47.10, H 3.00, N 9.75.

{Pd[C(O)Me]Cl(HL5)} (15): Yield: 0.016 g (45%). – IR (cm^{-1}): ν(N–H) = 3234 m, ν(C=O) + ν(Pd(C(O)Me)] = 1700 vs, AMIDE II $\tilde{\nu}$ = 1509 s, AMIDE III = 1262 s. – ^{1}H NMR ($CDCl_3$): δ = 7.96 [d, 2 H, Ph *o*-C(O)], 7.61 [t, 1 H, Ph *p*-C(O)], 7.52 [t, 2 H, Ph *m*-C(O)], 6.94 [s, 1 H, C(H)=N]. – $C_{15}H_{16}ClN_3O_2Pd$ (412.16): calcd. C 45.31, H 3.80, N 9.91; found C 45.25, H 3.71, N 9.89.

Procedure for the Preparation of 12: Compound **2** (0.060 g, 0.150 mmol) was placed in a 50 mL schlenk tube and dissolved in 20 mL of cold CH_2Cl_2 (0 °C). The reactor was evacuated and filled with CO for three consecutive times. The solution was stirred for 15 minutes maintaining the temperature at 0 °C and then the solvent was removed in vacuum without varying the temperature. The solid residue was re-dissolved in CH_2Cl_2, filtered through celite and dried again in vacuum.

{Pd[C(O)Me]Cl(HL2)} (12): Yield: 0.042 g (78%). – IR (cm^{-1}): ν(N–H) = 3200 w, ν(C=O)+ν[Pd(C(O)Me)] = 1689 vs, AMIDE II $\tilde{\nu}$ = 1474 s, AMIDE III = 1261 s. – ^{1}H NMR ($CDCl_3$): *trans* isomer δ = 2.38 [s, 3 H, C(Me)=N]; *cis* isomer δ = 2.52 [s, 3 H, C(Me)=N]. In both isomers the residual protons are overlapped with other signals.

Carbonylation Reactions of the Tridentate Methyl Palladium Complexes Pd(NNO)Me. – General Procedure: Complexes **7–10** (0.020 g) were dissolved in 20 mL of CH_2Cl_2 in a 50 mL schlenk tube. CO was bubbled through the solution at room temperature for 5 minutes through a glass capillary. Immediately palladium black was formed. The solution was stirred under CO atmosphere until it was completely colourless and then filtered through celite. After evaporation of the solution a pale yellow solid was filtered off.

The characterisation of the formyl 2-pyridyl aldehyde *N*-acetyl benzoylhydrazone is reported: Yield: 0.015 g (complete conversion). – m.p: 116 °C. – IR (cm^{-1}) $\tilde{\nu}$: AMIDE II = 1459s–1421 m, AMIDE III = 1262 m. – ^{1}H NMR (CD_2Cl_2): δ = 8.63 (d, 1 H, R′), 7.78 (td, 1 H, H^2), 7.34 (td, 1 H, H^1), 7.88 [dd, 2 H, Ph *o*-C(O)], 7.55–7.43 [m, 4 H, H^3 + Ph *m* and *p*-C(O)], 7.02 [s, 1 H, C(H)=N], 2.33 [s, 3 H, C(O)Me]. – MS (CI): 268 (M^+ + 1). – $C_{15}H_{13}N_3O_2$ (267.29): calcd. C 67.41, H 4.90, N 15.72; found C 67.45, H 5.01, N 15.77.

Synthesis of Formyl 2-Pyridyl Aldehyde *N*-acetyl Benzoylhydrazone: Compound **HL3** (0.500 g, 2.220 mmol) was dissolved in 20 mL of pyridine under a nitrogen atmosphere. The obtained solution was stirred in an ice bath and acetyl chloride (0.871 g, 11.100 mmol) was added dropwise to the solution. Immediately pyridinium hydrochloride precipitated. The mixture was refluxed for 24 hours after which 30 mL of water was slowly added. From the solution a brown solid precipitated which was filtered off and dried in vacuum. Recrystallisation from ethanol gave 0.400 g (67%) of microcrystalline product.

X-ray Structure Determination of 13 and 3:[21] A single crystal of **13** suitable for X-ray analysis was glued to a glass fibre and mounted on a Philips PW100 diffractometer employing Mo-K_α radiation. The instrument was equipped with a graphite monochromator. Intensities were collected at room temperature, and corrected for absorption using the ψ-scan method. During data collection, no intensity decay was observed. Corrections for Lorenz and polarisation effects were applied. Relevant data collection and structure refinement parameters are summarised in Table 5.

Table 5. Crystal data and structure refinement for compounds **3** and **13**

Compound	**3**	**13**

[a] $R = \Sigma\| F_o | - | F_c \| / \Sigma | F_o |$. – [b] $R_w = \{\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma [w(F_o^2)^2]\}^{1/2}$.

The phase problem was solved by direct methods employing SIR97.[22] Atom coordinates and anisotropic thermal parameters were refined for all non-hydrogen atoms by full-matrix least-squares on F^2 with the SHELXL97 program.[23] All hydrogen atoms were located in the difference Fourier maps and refined isotropically. The final geometry was analysed with the program PARST97.[24] The calculations were performed on a DIGITAL Alpha255 workstation at the "Centro di Studio per la Strutturistica Diffrattometrica del C.N.R." in Parma.

A wedge-shaped crystal of compound **3** was used for data collection on an Enraf–Nonius CAD-4 diffractometer with graphite-monochromated Cu-Kα radiation. Corrections for Lorentz and polarisation effects were applied. During data collection, no intensity decay was observed. The structure was solved by the PATTY op-

tion of the DIRDIF96 program system.[25] The hydrogen atoms were calculated and restrained so that the distance to their carrier remained constant at approximately 1.0 Å. Structure was refined by full-matrix least-squares on *F*, using anisotropic thermal parameters for non-hydrogen atoms and isotropic thermal parameters for hydrogen atoms. The DIFABS empirical absorption correction[26] was applied with coefficients in the range of 0.64–2.02. The secondary isotropic extinction coefficient[27] refined to $R = 70.(2)$. A final difference Fourier map revealed a residual electron density between –1.8 and 1.2 eÅ^{-3}, in the vicinity of the heavy atoms. Scattering factors were taken from Cromer and Mann,[28a] International Tables for X-ray Crystallography (1974).[28b] The anomalous scattering of Cl and Pd was taken into account.[29] The calculations were performed with XTAL.[30] All drawings were made with ZORTEP[31] an extensive use was made of the Cambridge Structural Database software.[32]

Molecular Energy Calculations: All the calculations were performed with the program MOPAC 6.00[33] running on a Pentium 200 MHz personal computer. The model compounds (Scheme 4) were built based on the geometry of the crystal structure of **3** (Figure 2, Table 4), which presented a *trans* configuration. In all cases the terminal phenyl has been replaced by an idealised methyl group. The atomic labelling refers to Figure 2. The acetyl derivatives were built by inserting the acetyl group on the metal, with geometry taken from the X-ray structure of **13**. The atomic labelling refers to Figure 1. The *cis* derivatives were built by exchanging the –R and –Cl ligands, preserving the original bond lengths. The iminomethyl molecules (TMM, CMM, TAM, CAM) have been built by substituting the H atom with an idealised methyl group. All hydrogen atoms were introduced in idealised geometry with the exception of the iminic and hydrazonic ones, which were taken from the crystal structure. The geometries of all models have been optimised by minimising the molecular energy using the PM3 Hamiltonian.[34] The metal was treated as a dummy bivalent cation, and the geometry of the molecular core around the metal was held fixed, as observed in the crystal (Table 4 indicates all the parameters which were not modified in the minimisation). The geometric parameters which were optimised are all the bond lengths, angles and torsions starting from the N2–N3 bond and proceeding towards the terminal methyl. The geometries of the iminic hydrogen and methyl, the NH group, and the rotation of the coordinated methyl and acetyl groups around the Pd–C bonds were also optimised.

The energetic profiles for the rotation of the terminal NH–C(O)–Me group around the N–N bond, and for the rotation of the acetyl around the Pd–C bond have been calculated by varying the torsion considered (C6–N2–N3–C7 for the former and N1–Pd–C14–O3 and N2–Pd–C14–O3 for the latter, *trans* and *cis*, respectively) in steps of 5° and 10°, respectively, and by optimising the rest of the molecule at each step, with the constraints described above. The acetyl was also constrained to remain planar during its rotation. In all cases a correction of 14*sin(τ) kcal/mol was applied to the rotational barrier for the N–C(O) bond, introducing an additional molecular mechanics energetic contribution due to the partial double-bond character of the amidic bond as implemented in MOPAC, depending on the torsion angle τ = C6–N2–N3–C7.

Acknowledgments

This work has been partially supported by a grant from C.N.R. (Rome). The C.I.M. (Centro Interfacoltà di Misure "Giuseppe Casnati") of the University of Parma is thanked for the technical support. Particular thanks are due to Prof. Mirco Costa for the helpful discussions.

Low-Coordinate Arsenic Chemistry: Studies of Amino(iminoarsanes) Using UV Photoelectron Spectroscopy and Density Functional Theory

Karinne Miqueu,[a] J.-M. Sotiropoulos,[a] G. Pfister-Guillouzo,*[a] and V. Romanenko[b]

Keywords: Arsenic / UV photoelectron spectroscopy / Ab initio calculations

In this paper, we report the gas-phase characterization of two differently substituted amino(iminoarsanes), TmpAs=$NSiMe_3$ and $(SiMe_2tBu)_2NAs=N(SiMe_2tBu)$, by coupling flash vacuum thermolysis (FVT) with UV photoelectron spectroscopy (PES). Quantum chemical calculations, using the DFT method (B3LYP) with the basis set 6-311G(d,p), have also been carried out on the $R_1As=NR_2$ unit with R_1 = H, NH_2, $N(CH_3)_2$, $N(SiH_3)_2$ and R_2 = H, SiH_3, in order to study the effect of substitution on the electronic properties and the thermodynamic stability of the As=N skeleton. Similarities with phosphorus analogues are also discussed.

Introduction

In recent years, photoelectron spectroscopic (PES) investigation of multiple bond systems involving heavy main-group elements has been the subject of a great deal of experimental effort.[1] While low-coordinate phosphorus compounds have been extensively studied, the chemistry of related species containing dicoordinated arsenic remains practically unexplored. In parallel with the first studies of arsaalkenes,[2] we have envisaged the possibility of similarly characterizing the iminoarsanes. A small number of these compounds with bulky substituents have been unequivocally isolated and characterized.[3] To date, all their structures have been found to be *anti*, although only a few details concerning their geometrical parameters are as yet available.

A preliminary theoretical approach[4] showed that, as for iminophosphanes, the σ-push-pull substitution effect considerably modifies the structures and stabilities of the iminoarsanes. The As=N double-bond character is strengthened when the arsenic is substituted with an electron-withdrawing group (halogen) and the nitrogen with a σ-electron-releasing group (SiH_3). The substitution of arsenic with an amino group is more complex. In the present case, two effects operate concurrently: the electronegativity of the amino group nitrogen and the interactions of various kinds that depend on the orientation of the amino group.

The $\sigma^2\lambda^3$-iminophosphanes, in which a phosphorus atom is substituted with an amino group, represent an extensively studied[5] class of compounds. On the contrary, the preparation of amino(iminoarsanes) still represents a substantial challenge. Our purpose was to synthesize amino(iminoarsanes) bearing substituents of various degrees of bulkiness and to characterize them by UV photoelectron spectroscopy using our specially designed equipment to detect and analyse short-lived species by utilizing the band pattern as a "molecular fingerprint".[6] By generating these species by flash vacuum thermolysis in the proximity of the photoionization zone, we were able to avoid rearrangement and/or polymerization reactions. We have also carried out a theoretical study in order to define the stabilities of the isomers and rotamers, as well as to estimate the energies of the first two ionic states; considering the envisaged isomers or rotamers, these states were expected to be well-separated.

Results and Discussion

Our initial attempts to generate fully silylated amino(iminoarsane), $(Me_3Si)_2N–As=NSiMe_3$, by employing a synthetic approach similar to that used previously to synthesize its phosphorus analogue, met with little success. In accordance with preliminary results reported in the literature,[7] the decomposition of $\{[(Me_3Si)_2]_2N\}_2AsCl$ in the gas phase under flash vacuum thermolysis (FVT) conditions was found to commence at temperatures above 823 K and involves the elimination of $(Me_3Si)_3N$ instead of the expected Me_3SiCl. The PE spectrum observed is too complex to be interpreted.

In accordance with the hypothesis that on increasing the steric bulk of the substituent R in the R_2N ligand the elimination of R_2NSiMe_3 from the molecule $R_2NAs(Cl)N(SiMe_3)_2$ should become disfavoured compared to that of Me_3SiCl, we turned our attention to 2,2,6,6-tetramethylpiperidino (Tmp)-substituted chloroarsane $TmpAs(Cl)N(SiMe_3)_2$ (**1**). It is noteworthy that no *N*-

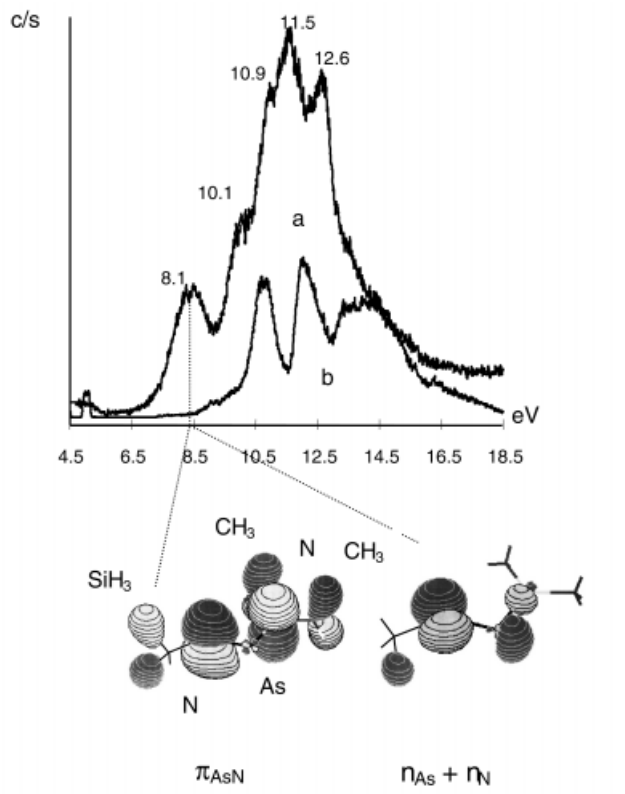

Figure 1. Photoelectron spectra at 813 K of (a) TmpAs=$NSiMe_3$ (**2**) with Me_3SiCl and (b) pure Me_3SiCl

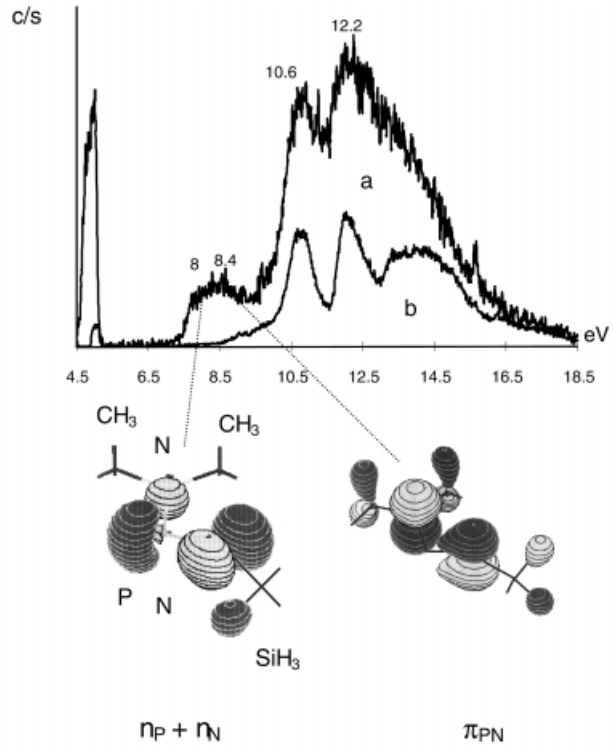

Figure 2. Photoelectron spectra of (a) TmpP=$NSiMe_3$ (**4**) and (b) Me_3SiCl

trialkylsilylated 2,2,6,6-tetramethylpiperidine has yet been characterized. The chloroarsenic precursor **1** was prepared by reaction of $TmpAsCl_2$ with $(Me_3Si)_2NLi$ and subjected to short-path internal FVT. As predicted, the replacement of one $(Me_3Si)_2N$ group in the compound $[(Me_3Si)_2N]_2$-AsCl by a Tmp substituent led to a different reaction pattern. The FVT/PES coupling indicated quite clearly that thermolysis of **1** at 813 K led to the formation of chlorotrimethylsilane and an arsenic species. The superposition of the spectra of Me_3SiCl and of the product obtained after thermolysis (see Figure 1) clearly shows the presence of a broad band centered at 8.1 eV. This band, which probably relates to two ionizations, could be assigned to TmpAs=$NSiMe_3$ (**2**). In order to confirm this hypothesis, a further experimental study was performed on the phosphorus analogue TmpP=$NSiMe_3$ (**4**). This species was obtained from $TmpPClN(SiMe_3)_2$ (**3**). The loss of Me_3SiCl was very rapid and did not require thermolysis, in contrast to $TmpAsClN(SiMe_3)_2$. This experimental observation can be attributed to the greater thermal stability of the precursor; its longer As–N and As–Cl bonds compared to their P–N and P–Cl counterparts retard the loss of Me_3SiCl.

The respective spectra obtained for TmpAs=$NSiMe_3$ and TmpP=$NSiMe_3$ (Figure 1 and Figure 2) show numerous similarities. The main ionization potentials (IP) are centered at 8.1 eV for **2** and at 8.0 eV and 8.4 eV for **4**.

In order to confirm that the bands observed at low energies (< 10 eV) in the PE spectra were indeed attributable to monomeric amino(iminoarsane), we studied the thermally induced decomposition of chlorobis(amino)arsane $\{[Me_2tBu)_2Si]_2N\}_2AsCl$ (**5**) bearing the sterically demanding Me_2tBuSi group. As in the case of the chloroarsane **1**, it was again hypothesized that the elimination of a silylamine from this arsane precursor would be sterically unfavorable. In fact, under FVT conditions (160–190 °C/0.5 Torr), compound **5** was found to decompose to furnish $Me_2tBuSiCl$ and the amino(iminoarsane) $(Me_2tBuSi)_2$-NAs=$NSiMe_2tBu$ (**6**), which proved sufficiently stable to be isolated by trapping at low temperature and subsequent revaporization. Moreover, in preparative experiments, we succeeded in high-vacuum redistillation of the product, which could then be immediately characterized by mass spectrometry. The spectrum of $(SiMe_2tBu)_2NAs=N(SiMe_2tBu)$ (Figure 3) features two characteristic bands at 8.4 eV and 9.5 eV.

Theoretical Results

Method Used

Ab initio calculations were performed using Gaussian 94/DFT.[8,9] The density functional theory method[10] was used in view of the non-trivial number of atoms present in the compounds under study. In this way, calculation times were shortened. Moreover, we have previously shown that this method correctly predicts the ionization energies of alkenes, alkynes, and heteroalkenes.[11] Nevertheless, we verified that the estimation of the first two ionic states of the *anti* form of MeP=NMe [A': 8.6 eV ($n_P + n_N$) and A": 10 eV ($\pi_{P=N}$), respectively] was indeed congruous with the spectrum observed by Elbel and Niecke for *t*BuP=N*t*Bu.[12] The calculations were performed using the hybrid Becke 3LYP

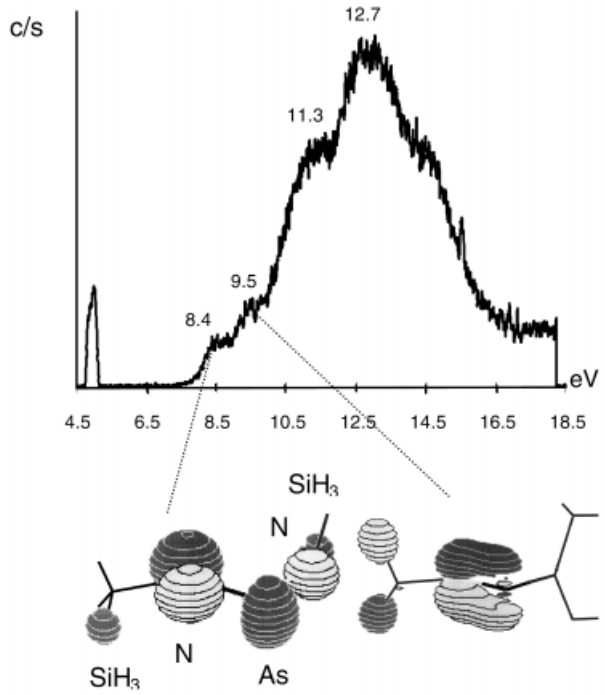

Figure 3. Photoelectron spectrum of (tBuMe$_2$Si)$_2$NAs=NSiMe$_2$$t$Bu (**6**)

functional[13] in conjugation with the basis set 6-311G(d,p). The structures were optimized at the resulting geometries and second-order derivatives were calculated in order to ascertain whether a minimum or a saddle point had been obtained. In order to calculate vertical ionization energies, the energy difference between the neutral molecule and the ion (both at the optimum geometry of the neutral molecule) was used. The obtained geometrical parameters are indicated in Figure 4.

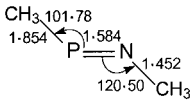

Figure 4. Geometrical parameters calculated for *anti*-CH$_3$P=NCH$_3$ [B3LYP, 6-311G(d,p)]; bond lengths in Å, bond angles in degrees

The experimental PE spectrum features two separated low-energy PE bands at 8.11 eV and 9.70 eV, attributable to ionizations from the bonding combination between the phosphorus and nitrogen lone pairs ($n_P + n_N$) and the $\pi_{P=N}$ orbital, respectively. Taking into account the destabilizing effect of the tBu group, the calculated data are in agreement with the experimentally determined ionizations. These observations encouraged us to use the latter method to carry out all the calculations on the As=N double bond systems that are described below.

Favoured Structures of the Amino(iminoarsanes) R$_1$As=NR$_2$ [R$_1$ = NH$_2$, N(CH$_3$)$_2$, N(SiH$_3$)$_2$; R$_2$ = H, SiH$_3$]

The *anti* form of the parent compound HAs=NH is slightly more stable than its *syn* form (by 0.4 kcal/mol). In both structures, the As=N bond length measures around 1.7 Å, but is slightly shorter in the *syn* isomer (1.712 Å: *syn*; 1.722 Å: *anti*), which is in agreement with the opening of the bond angles. The two bond angles H–As–N and As–N–H are larger in the *syn* conformation (103.37° and 113.41°, respectively) than in the *anti* form (H–As–N: 95.84° and As–N–H: 107.47°).

For the amino(iminoarsanes), two minima were found on the potential energy surface. These corresponded to the *syn* and *anti* isomers, in which the nitrogen of the amino group is sp^2 hybridized (except in the case of R$_1$ = H$_1$,H$_2$, where it is sp^3 hybridized in the favored *anti* isomer; ΣN = 341.51°) and is coplanar with the As=N moiety. The *anti* form is slightly favored compared to the *syn* form (Table 1).

Taking into account the electronegativity of silicon, the attachment of an SiH$_3$ group on the imino nitrogen gives the lone pair a considerable degree of p character. In fact, we observe an opening of the angle at nitrogen (imino), especially in the case of *syn*-(NH$_2$)As=NSiH$_3$ (140.48°) and *syn*-(CH$_3$)$_2$NAs=NSiH$_3$ (165.13°). This leads to a lowering of the inversion barrier (to around 2 kcal/mol vs. 14 kcal/mol for the non-silylated compounds). Only the *anti* isomer is found for (SiH$_3$)$_2$NAs=NSiH$_3$. The stabilization of the *anti* form can be rationalized in terms of electronic and repulsion energies. For NH$_2$As=NSiH$_3$, the weak nuclear energy governs the stability of the *anti* form, whereas for NH$_2$As=NH and N(CH$_3$)$_2$As=NSiH$_3$ it is the electronic energy (Table 1). It is interesting to note that for these two compounds the *syn* isomers have electronic energies lower than those of the *anti* forms, in spite of the more significant antiplanar stabilizing interactions (see NBO analysis, Table 2).[14] It is likely that highly destabilizing interactions involving four electrons counterbalance the stabilizing interactions.

In the two isomers of NH$_2$As=NSiH$_3$ and (CH$_3$)$_2$NAs=NSiH$_3$, as well as in (SiH$_3$)$_2$NAs=NSiH$_3$, the amino nitrogens are sp^2 hybridized and are coplanar with the AsNSi system, resulting in a maximized $n_N^{\pi}\,\pi^*_{As=N}$ interaction. In the course of the rotation process (Table 3), two saddle points are found (TS$_1$, TS$_2$), which correspond to an sp^3 hybridization of the amino nitrogen. For the *anti* isomer, the lower saddle point (TS$_2$) corresponds to the rotamer where the nitrogen sp^3 lone pair and that on arsenic are in a *syn* arrangement (Figure 5). In the particular case of (SiH$_3$)$_2$NAs=NSiH$_3$, the nitrogen remains sp^2 hybridized (one transition state), the barrier to rotation being 10.41 kcal/mol. For the *syn* isomers, substitution at the amino nitrogen reverses the nature of the lower saddle point (arsenic and nitrogen lone pairs antiperiplanar).

On analyzing the geometrical parameters presented in Table 1, it can be noted that a planar amino group at nitrogen makes the As=N double bond shorter as compared to that in the unsubstituted molecule. Comparison with the parent molecule also reveals a slight opening of the arsenic bond angle when this atom is substituted with an amino group (by up to 7°) and a more pronounced opening of the nitrogen bond angle (by up to 52°). This is understandable when the s character shown by natural bond orbital (NBO)

analysis is considered; in fact, it is almost identical for the arsenic lone pair in all these compounds, whereas for the nitrogen the sp^2 character changes considerably.

Comparison of the geometries of the iminoarsanes and iminophosphanes reveals the same features. Indeed, detailed quantum chemical calculations have shown that changing the substituents on phosphorus or nitrogen may lead to a considerable change in geometry. The P=N double bond shortens when the phosphorus is substituted with π-donors (e.g. NH_2),[15] due to the effect between n^{π}_N and π*; the σ-effect counteracts the π-effect.

Discussion of the Results: Interpretation of the Photoelectron Spectra

The Kohn–Sham energies and the two first ionization energies of the two forms (*syn* and *anti*) are presented in Table 4. For the *anti* isomer, the ionic state A' corresponds to the ejection of an electron from the orbital described as a bonding combination between the arsenic and nitrogen lone pairs, whereas for the *syn* conformation it corresponds to ionization from the antibonding combination orbital between these lone pairs.

When the arsenic atom was substituted with an amino group, the energy of the A'' ionic state clearly decreased compared to that of the parent molecule, in the same way for both the *syn* and *anti* isomers. The associated molecular orbital is seen to be strongly localized on the amino and imino nitrogens since it indicates an interaction between the amino lone pair and the $\pi_{As=N}$ and $\pi^*_{As=N}$ orbitals. This is shown in Figure 1 by means of the MOLDEN representations. X-ray analysis of $TmpP{=}NN(SiMe_3)_2$[16] reveals that the amino nitrogen is sp^2 hybridized (ΣN = 358.95°) and that the Tmp group is almost planar (dihedral angles $CN_{amino}PN_{imino}$ = 8.24° or 156.36°). Accordingly, it seems reasonable to use the fragments $(CH_3)_2NP{=}NSiH_3$ and $(CH_3)_2NAs{=}NSiH_3$ composed of an sp^2 hybridized amino nitrogen coplanar with As–N (or P–N) to model the experi-

[a] Italic values correspond to the phosphorus analogous.

mentally examined compounds. Taking into account the steric requirement of the Tmp substituent, the *syn* isomer can be excluded. Only calculations relating to the *anti* form may be used to interpret the PE spectra of $TmpAs{=}NSiMe_3$ and $TmpP{=}NSiMe_3$. For the two first ionic states of the respective systems $(CH_3)_2NAs{=}NSiH_3$ and $(CH_3)_2NP{=}NSiH_3$, we calculated a reverse order. The A' state, corresponding to a bonding combination between arsenic (phosphorus) and nitrogen lone pairs, was calculated at 8.47 eV (8.49 eV); the A'' state was calculated at 8.18 eV (ionization from the $\pi_{As=N}$ orbital) and 8.58 eV (ionization from the $\pi_{P=N}$ orbital). The values observed for $TmpP{=}NSiMe_3$ are similar to those described by Niecke[6] and we interpret them in the same way. The above result is interesting because it allows an interpretation of the different shapes of the two spectra (Figure 1 and Figure 2). The first broad band in the spectrum of $TmpAs{=}NSiMe_3$ is composed of two overlapping ionizations, the first associated with the A'' ionic state and the second with the A' state. For $TmpP{=}NSiMe_3$, the band at low energy corresponds to the A' ionic state and the broad feature at 8.4 eV is associated with the A'' ionic state.

The $2p_\pi$-$4p_\pi$ overlap is weaker than the $2p_\pi$-$3p_\pi$ overlap; it induces an energetic destabilization of the $\pi_{As=N}$ orbital as compared to the $\pi_{P=N}$ orbital as a result of the more diffuse character of the former. It also leads to a reduction in the contribution from the stabilizing $n^{\pi}_{Namino}\,\pi^{*}_{AsN}$ interaction. This difference between the phosphorus and arsenic derivatives is clearly apparent from the 3D MO plots shown in Figure 1 and Figure 2, which reveal more extensive delocalization for the phosphorus compound. The spectrum of $(SiMe_3)_2NP{=}NSiMe_3$ obtained by Niecke,[6] showed the first two ionizations at 8.10 eV (n) and 8.75 eV (π). The pronounced shift of the second ionization towards higher energy is due to the effect of the $SiMe_3$ group on the ionization energy of the lone pair of the amino nitrogen through its interaction with the π system. Considering the arsenic derivatives, calculations are indicative of the same tendency. Compared with a CH_3 substituent, the SiH_3 group stabilizes the $\pi_{As=N}$ orbital (0.76 eV) more than it does the n

orbital (0.31 eV). Ionic state energy calculations on $(SiH_3)_2NAs{=}NSiH_3$, in which the amino group is coplanar with the As=N system, show approximately the same values for the A''(π) and A'(n) states. The experimental spectrum observed for $(SiMe_2tBu)_2NAs{=}NSiMe_2tBu$ features two bands with a gap of 1 eV; it does not seem to correspond to an iminoarsane system having an sp^2 amino group interacting with the π system. The steric requirement of the $SiMe_2tBu$ substituent could modify the orientation of the amino group, as observed for *trans*-$(SiMe_2tBu)_2NP{=}PN(SiMe_2tBu)_2$, for which a bis-orthogonal conformation is seen[17] (the two amino groups are orthogonal to the π system). In contrast to the piperidino derivatives, in this case it seems possible to envisage a *gauche* form corresponding to a minimization of the steric demand.

The $(SiH_3)_2NAs{=}NSiH_3$ form, in which the amino group is orthogonal to the π system (to minimize steric hindrance), corresponds to TS_1. The relevant geometrical parameters are given in Figure 6. The first ionic state (A') is calculated at 8.87 eV. It is associated with an ionization from the bonding combination ($n_N + n_{As}$). The energy of the A'' state, corresponding to the ejection of an electron from the $\pi_{As=N}$ orbital, is calculated as 9.98 eV. Taking into account the destabilizing effect of the *tert*-butyl group as compared to a methyl group, the experimentally observed bands at 8.4 eV and 9.5 eV can be assigned to the amino(iminoarsane) $(SiMe_2tBu)_2NAs{=}N(SiMe_2tBu)$ with the amino group in a *gauche* orientation. In compound **6**, the steric effect leads to a rupture of the bond between the amino nitrogen lone pair and the $\pi_{As=N}$ system.

Conclusion

The study described in this paper represents the first effort to characterize amino(iminoarsanes). The diffuse character of the $\pi_{As=N}$ bonding, akin to that already known for iminophosphanes, made it difficult to isolate an As=N moiety that did not bear bulky substituents. Substitution at nitrogen by an electropositive SiR_3 group increases the s character of the As–N (P–N) bonding and induces stabilization of these reactive π systems through negative hyperconjugation. Likewise, for the σ skeleton, the attachment of an amino group at the arsenic strengthens the σ_{AsN} bond. The π electronic delocalization, induced by the coplanar amino group, would also lead to a stabilization of the system (interaction between the n_N^{π} and the $\pi_{P/AsN}^{\pi}$). Nevertheless, in spite of the non-existence of this delocalization, the attachment of a substituent with substantial steric bulk allows the isolation of amino(iminoarsanes) as a result of kinetic stabilization.

Experimental Section

General Remarks: All manipulations were carried out under nitrogen atmosphere using Schlenk techniques. Diethyl ether and pentane were distilled from sodium/benzophenone shortly prior to use. $TmpAsCl_2$, Tmp–P=$NSiMe_3$, and $(Me_2tBuSi)_2NH$ were prepared according to published methods.[18] – ^{1}H-NMR spectra were recorded on a Bruker AC80 spectrometer; chemical shifts are reported in ppm relative to Me_4Si as an external standard.

UV Photoelectron Spectra: The photoelectron spectra were recorded on a Helectros 0078 instrument equipped with a 127° cylindrical analyser and were monitored by means of a microcomputer supplemented with a digital analogue converter. The spectra were calibrated against the known autoionization of helium at 4.98 eV and nitrogen ionization at 15.59 eV. Our short-path thermolysis system has been described elsewhere.[19]

Chloro(2,2,6,6-tetramethylpiperidido)bis(trimethylsilyl)amidoarsenite (1): A freshly prepared solution of $(Me_3Si)_2NLi$ (20 mmol) [obtained by treatment of $(Me_3Si)_2NH$ in 25 mL of Et_2O with an equimolar amount of BuLi (1.6 M in hexane)] was added dropwise to a stirred solution of 2,2,6,6-tetramethylpiperidinodichloroarsenite (20 mmol) in pentane (20 mL) at 0 °C under nitrogen. The resulting mixture was stirred for 24 h and then the deposited LiCl was removed by filtration through a fine-pore glass frit under nitrogen. The filtrate was concentrated and the crude product was purified by low-temperature crystallization (–20 °C) from pentane. Yield 63%. – ^{1}H NMR ($CDCl_3$): δ = 0.36 (s, 18 H, Me_3Si), 1.45 (s, 12 H, CH_3), 1.25–1.48 (m, 6 H, CH_2). – $C_{15}H_{36}AsClN_2Si_2$: calcd. C 43.83, H 8.83; found C 49.19, H 8.65.

Chloro[bis(*tert*-butyldimethylsilyl)amido]arsenite (5): At 0 °C, a solution of $(Me_2tBuSi)_2NLi$ (15 mmol) in diethyl ether (35 mL) was added dropwise to a stirred solution of $AsCl_3$ (7.5 mmol) in diethyl ether (20 mL). The reaction mixture was stirred for a further 48 h and then the volatiles were removed in vacuo. Extraction of the residue with pentane, filtration of the extracts, concentration, and crystallization afforded the product as a colorless oil, which solidified on cooling. Yield 92%. – ^{1}H NMR ($CDCl_3$): δ = 0.21 (s, 24 H, Me), 1.15 (s, 36 H, *t*Bu). – $C_{24}H_{60}AsClN_2Si_4$: calcd. C 48.09, H 10.09; found C 48.45, H 10.61.

[Bis(*tert*-butyldimethylsilyl)amino][(*tert*-butyldimethylsilyl)imino]arsane (6): Vacuum distillation of chloroarsenite **5** obtained following short-path Arbusov FVT (160–190 °C, 0.5 Torr) gave 43% of crude **6** as a yellow oil. At this stage, the product was found to be contaminated with a small amount of $Me_2tBuSiCl$. Redistillation of the crude product afforded pure amino(iminoarsane) **6**; b.p. 130–135 °C (0.02 Torr). Yield 28%. – ^{1}H NMR (C_6D_6): δ = 0.31 (s, 18 H, Me_2Si), 0.93 (s, 27 H, *t*Bu). – $C_{18}H_{45}AsN_2Si_3$: calcd. C 48.18, H 10.10; found C 47.61, H 10.04. – EI-MS: *m*/*z* = 448 [M^+].

[14] Natural bond orbital analysis, which represents ab initio molecular wavefunctions in terms of localized Lewis structures, was applied in order to provide a quantitative analytical framework for the interpretation of molecular orbital interactions. The NBO population analysis shows the presence of antiperiplanar stabilizing interactions between an occupied orbital (lone pair on arsenic and/or nitrogen) and a vacant one (σ^*_{AsR1}, σ^*_{NR2}); these are more important for the *syn* isomer (Table 2). – [14a] A. On the Nature of Arene η^6 Interactions in the Solid State and the Use of Cylindrophanes as Ligands for Sandwich Complexation of Metals with Longer-Range Interactions with the Benzene Ring

Mark Mascal,*[a] Jean-Luc Kerdelhué,[a] Alexander J. Blake,[a] Paul A. Cooke,[a] Roger J. Mortimer,[b] and Simon J. Teat[c]

Keywords: Coordination modes / Cyclophanes / Macrocycles / Sandwich complexes / Solid-state structures

A novel mode of containment for metal ions which participate in longer-range interactions with aryl rings (≥ 2.5 Å) is demonstrated in the preorganized cylindrical host **1**. Three equatorial sulfur atoms in **1** hold metals in a trigonal planar ligand field between two apical benzene centroids at an M–Ar distance of about 3 Å. Evidence of an interaction between the π electrons and the metals is gained by ^{1}H NMR spectroscopy of the complexes, and support for the general description of metal–arene contacts in the 2.5–3.5 Å range as "bonds" is derived from a statistical study of η^6-coordination in the solid state. Crystal structures of $[Ag(\mathbf{1})]BF_4$ and $[Cu(\mathbf{1})]BF_4$ confirm the first examples of arene Ag^I and Cu^I sandwich complexation and indeed the only structurally characterized Cu^I-aryl centroid interaction. The two isomeric *tris*-sulfoxides derived from **1** show less tendency to interact with metals ions.

Introduction

Since the discovery of ferrocene and transition metal-benzene complexes in the 1950's, there has been a constant fascination with the way metals interact with aromatic rings. The paradigmatic interaction involving neutral arenes is the η^6 mode of complexation, in which most group 3–10 metals participate.[1] We recently noted the bimodal nature of the arene–metal distance histogram generated from solid-state structures in the Cambridge Structural Database (CSD), which neatly divides this interaction into two categories, i.e. classic, short-range η^6 bonding, and longer-range aryl centroid–metal contact.[2] The *sym*-[5.5.5]trithiacyclophane macrobicycle **1**[3] was designed to take advantage of the fact that the mean value for the latter is around 3 Å (corresponding to the distance between the midpoint of the cavity and the center of each ring), which made possible the first structural characterization of the Ag^I and Cu^I arene sandwich complexes **2**. A divalent heteroatom (O, S) is required at the "equatorial" positions in ligands such as **1** because hydrogens occupy the cavity in the NH and hydrocarbon analogs,[4] but since the longer-range metal–arene interaction is weak, the complexes **2** owe their overall stability to the consequent trigonal-planar heteroatom ligand set. The analysis and reasoning which led to the design of "cylindrophane" **1**, and the subsequent preparation of novel cryptates **2**, are now presented in full.

1 **2**

Results and Discussion

Statistical Analysis of η^6-Metal Complexation

To appreciate the design principles behind **1**, it is first instructive to look in some detail at the nature of the interactions of metals with benzene rings. Although an account of η^6-benzene and arene complexes was included in Orpen et al.'s general analysis of coordination complexes in the CSD,[5] the study only tabulated data for 15 η^6-bonded *d*-block metals (vs. 29 in this analysis), with the longer-range noncovalent metal–arene contacts outside its remit.

The sampling of a cylindrical volume 0.5 Å in radius extending from the centroid of any benzene or aryl ring in the CSD was accomplished by constructing a query in QUEST3D[6] as follows: Three points were defined on a six-membered ring; point *x*, one C-atom of the ring; point *o*, the centroid of the ring; and point *y*, the centroid of one of the C–C bonds parallel to *xo* (Figure 1).

and "cyclohexatriene" arguments for the bonding in the ring. A metal atom at point *m* would have *x*,*y* coordinates $x_m = om \times \cos(x\hat{o}m)$ and $y_m = om \times \cos(y\hat{o}m)$. The radius of the cylinder (*r*) was defined by the relationship $x_m^2 + y_m^2 \leq r^2$, and the height of the cylinder was simply limited by constraining *om*. Choosing an arbitrary value of 5 Å for *om* produced a total of 2525 observations of metal atoms occupying this space. The *om* vs *xôm* scattergram (Figure 2a) reveals a massive data island centered around *om* = 1.7 Å corresponding to the plethora of η^6-complexes of the central transition metals. A discontinuity then precedes a second, more diffuse set of observations between ca. 2.5–3.5 Å. Subtracting the Bondi half-thickness of the benzene ring (1.77 Å) from this range of values gives a difference which is less than the van der Waals radius of the metal in most cases,[7] hence interactions of some description are indicated in this region (vide supra). Finally, the upward trend in the plot towards the 5 Å limit arises from the fixed

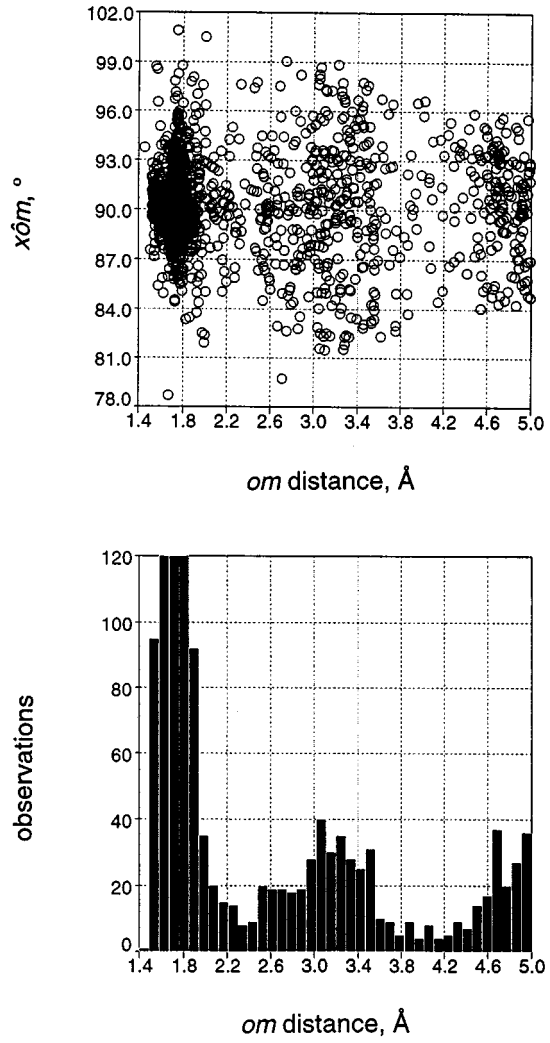

Figure 2. (a: top) *xôm* angle vs *om* distance scatterplot. (b: bottom) *om* distance histogram; the off-scale histogram bins between ca. 1.6–1.8 Å represent a total of 1648 observations

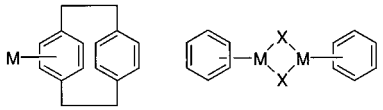

Figure 3. Increasing observations beyond 4.5 Å in the data presented in Figure 2 are due to relationships between metals and the *more distant* benzene rings in the above structures

relationships between metals and proximal rings in the numerous [2.2]paracyclophane η^6-metal complexes and μ-bridged bis(η^6-metal) species in the Database (Figure 3).

While statistical arguments are useful for generally characterizing the second maximum as a "bonding" region, individual cases are open to interpretation. Clearly, a sound basis for a cohesive electrostatic interaction can be derived from numerous gas phase studies between metal ions and aromatic systems, where bond energies on the order of 100 kJ mol^{-1} are typical.[8] Inspection of the datapoints individually gives valuable insights into the nature of the species involved. Analysis of both maxima by elemental composition, for example, leads to a reorganization of at least some of the data based on observed trends. Hence it becomes evident that the lanthanides and uranium, although formally in the second maximum in the plots in Figure 2, belong to the "short-range" bonding curve in the graphical representation of the data (Figure 4) taken from Tables 1 and 2. Likewise, some of the observations of Li–Ar contacts are contained within the first peak. After manual removal of redundant data arising from redeterminations, there are 1972 observations of short-range η^6 bonding to transition metals where the π-system can be counted in the valence electron set, and 328 other contacts which will simply be referred to as "longer-range."[9]

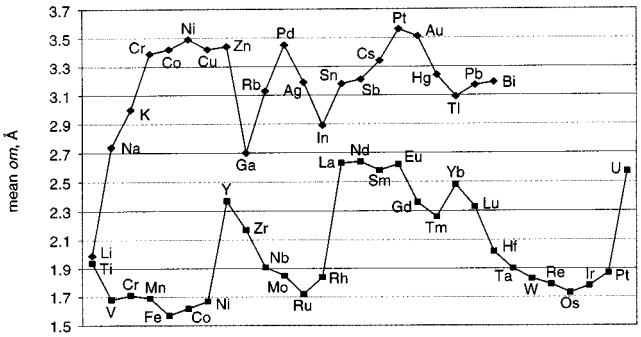

Figure 4. Mean longer-range (upper curve) and short-range (lower curve) Ar centroid–metal contact distances (*om*) by element with increasing atomic number

Certain elements appear to participate in both modes of complexation, i.e. divalent Cr, Co, Ni, and Pt, which in coordinatively unsaturated, square-planar complexes include a long-range arene contact over the vacant orbital. These, however, represent a total of only 18 observations and, in general, the longer-range complexes involve more-or-less exclusively main-group metals and some transition metals with filled *d*-shells. Indeed, apart from Ag^{I} and Hg^{II}, the case for including any transition metal among the longer-range complexes is debatable.

Trends in the lower curve in Figure 4 are periodic and consistent with the electronic nature of the metals involved. The upper curve, on the other hand, shows the anticipated progression within the alkali metal series, although a conspicuous discontinuity occurs at gallium, indium, and thallium. This evidence of a comparatively strong interaction in these cases is consistent with the anomalous solubility of monovalent group 13 salts in aromatic hydrocarbons. This phenomenon was examined in detail by Schmidbaur in the 1980s and rationalized in terms of a particularly effective overlap of the empty LUMO set of *p*-orbitals on the metal with the HOMO of the arene.[10]

Since the issue at hand is sandwich complexation in **1**, the dataset for longer-range contacts was also scrutinized for other occurrences of this mode of assembly. Twenty three examples of metals simultaneously coordinated to two or more aryl rings are found, most involving the alkali and group 13 metals, but in all but a few cases the *o···m···o* angle was considerably less than 180°. One notable exception was $[Cs(p\text{-xylene})_2]^+$, with a mean *om* distance of 3.4 Å and $o\hat{m}o$ = 176.7°.[11] Also relevant here are the π-cation complexes between 1,3-alternate calix[4]arenes and metal ions, four examples of which meet the general search criteria set out in the present work, although again, $o\hat{m}o$ ranges from 138.8 to 159.8°.[12]

Finally, two examples of other purpose-designed, mixed π-heteroatom ligands also emerge in this search. In the first, a crown ether incorporates a single aromatic ring whose centroid is involved in longer-range bonding to either Tl^{I} (*om* = 2.96 Å)[13] or Ag^{I} (*om* = 2.89 Å).[14] The second involves a tripodal *tris*(pyrazoylmethyl)benzene ligand for ruthenium.[15]

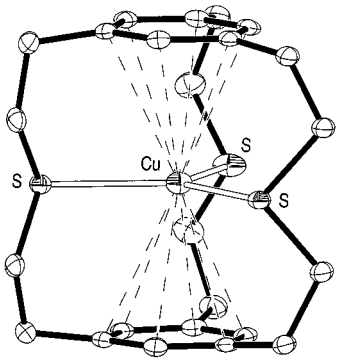
Cylindrophane 1 and Complexes 2

As mentioned above, the utility of a receptor such as **1** derives from its Ar···Ar bisector distance, which coincides approximately with the second maximum of the histogram in Figure 2. This provides an opportunity to study metals residing in a trigonal planar heteroatom ligand field and their interactions with the apical benzene centroids. Although **1** was designed to possess a high degree of conformational stability, molecular dynamics simulations indicate an accordion-like flexibility along the axis which runs through the rings, which gives the ligand the potential to accommodate metals throughout a range of preferred *om* distances.[16]

Preorganization in cylindrophanes such as **1** is achieved through careful regard for the conformational preferences of chains which link aromatic rings together, and the structural arguments in the design of these molecules have been discussed in detail.[4] The synthesis of **1** was carried out as described[2] and the stable complexes $[Ag(\mathbf{1})]BF_4$ and $[Cu(\mathbf{1})]BF_4$ were prepared by simple mixing of **1** with the tetrafluoroborate salts of the respective metals. The ^{1}H-NMR spectra ($CDCl_3$) of the complexes indicated no loss of symmetry and gave evidence of a substantial interaction between the metals and the ligand by the marked shifts of the S–CH_2 signal (+0.6–0.7 ppm). Most interesting, however, was the downfield shift of the aromatic protons (+0.20 ppm in $[Ag(\mathbf{1})]BF_4$, 0.12 ppm in $[Cu(\mathbf{1})]BF_4$), supporting the view that the phenyl rings in $[M(\mathbf{1})]^+$ do not simply block the apical positions but actually coordinate to the metal center.

Final proof of the structure was gained by X-ray crystallography of the complexes. Because $[Ag(\mathbf{1})]BF_4$ and $[Cu(\mathbf{1})]BF_4$ are isostructural, only the latter is shown in Figure 5. Relevant angles and distances for each complex are presented in Table 3.[17] A mirror plane passes through the

metal and the three sulfur atoms which surround it with molecular C_3 symmetry. While trigonal planar coordination is unusual for Ag^I and Cu^I,[18] the bis(η^6)-complexation of the metals presented here is unique. Even simple η^6-coordination is unprecedented in the case of Cu^I, although this species is known to participate in η^1-complexation to arenes,[19] which is also the preferred mode of interaction for Ag^I.[20]



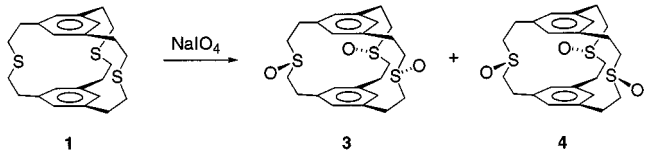


Figure 5. A view of the complex cation in the crystal structure of [Cu(**1**)]BF_4

Table 3. Selected geometric parameters for [Ag(**1**)]BF_4 and [Cu(**1**)]BF_4

	[Ag(**1**)]BF_4	[Cu(**1**)]BF_4
S–M, Å	2.577(2)	2.370(2)
	2.578(2)	2.380(3)
	2.631(2)	2.412(3)
S–M–S, °	117.72(5)	119.00(9)
	119.98(6)	119.91(9)
	122.31(5)	121.08(9)
M–centroid, Å	2.92	2.97
M–centroid–M, °	177.5	178.4

Cyclic voltammetry of [Cu(**1**)]BF_4 in $MeCN/CH_2Cl_2$ (1:1) gave a CV reminiscent of a metal deposition/stripping wave, with sharp oxidation and reduction peaks at E_{pa} = –0.61 V and E_{pc} = –0.87 V vs. Fc/Fc^+. When the solvent was switched to neat CH_2Cl_2, little if any current was measured up to the working limit of the platinum electrode. This result implied sufficient dissociation of the complex in the presence of acetonitrile to give a measurable concentration of electrochemically active, "free" Cu^I, whereas in the less-polar solvent system the cylindrophane effectively shields the metal and thus prevents redox activity. Analogous experiments with the silver complex had a similar outcome, with E_{pa} = –0.28 V and E_{pc} = –0.72 V and an irreversible anodic wave at 0.60 V vs Fc/Fc^+ in 1:1 $MeCN/CH_2Cl_2$.

Perhaps the most obvious modification of **1** is oxidation to the *tris*-sulfoxide. Modelling shows that in conformers where the three oxygens point into the cavity, the distance from these sites to the center of the trigonal plane they define is a convenient 2.3 Å, compared, for example, to 3.1 Å in the trioxa analog of **1**.[4] Thus, reaction of **1** with sodium periodate in aqueous THF provided the isomeric sulfoxides

Scheme 1. Synthesis of *tris*-sulfoxide cylindrophanes **3** and **4**

3 (12%) and **4** (62%) (Scheme 1). Even after chromatography, both of these compounds showed substantial $[M + Na]^+$ peaks in the FAB mass spectra, attributed to the presence of Na^+ in the oxidation reaction. However, sulfoxide **3** showed no noteworthy changes in the ^1H NMR spectrum during titration with a range of metal ions (in CD_3OD), while the unsymmetric **4** interacted only weakly and non-specifically with Na^+, Ag^+, and Cu^+.

Attempts to crystallize **3** or **4** in the presence of $NaBF_4$ led in one instance to the observation of very small crystals (of **4**), the structure of which could be determined using synchrotron radiation, but which did not include the metal (Figure 6). As might have been predicted, the sulfur lone pairs occupy the cavity in preference to the oxygens, which renders the complexation of metals in the cavity less favorable, despite the potentially more appropriate heteroatom-metal distance. The Ar···Ar separation in **4** is 5.66 Å in the crystal, i.e. slightly closer than in the metal complexes of **1** (cf. Table 3).

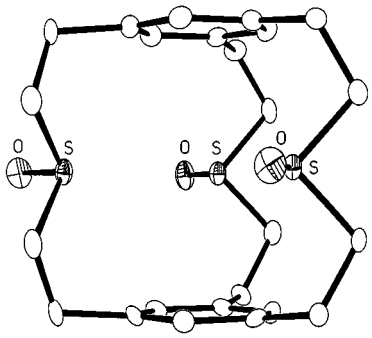

Figure 6. X-ray crystal structure of **4**

Conclusion

The encapsulation of metal ions in cylindrophane **1** provides a general approach to effective metal sandwich complexation in cases where longer (> 2.5 Å) aryl centroid–metal contacts are required. Two complexes, [Ag(**1**)]BF_4 and [Cu(**1**)]BF_4, have been prepared and characterized by NMR spectroscopy and X-ray crystallography. Together they constitute uncommon examples of Cu^I and Ag^I coordination in a trigonal-planar ligand field, a rare example of η^6-coordination to Ag^I, the first example of η^6-coordination to Cu^I, and, of course, the only examples of Cu^I and Ag^I sandwich complexes.[21] A detailed statistical analysis of metal-η^6 species in the solid state establishes a context for the study, and the population of metals in longer-range contact to the benzene ring supports the general characterization of such interactions as bonding. Although this me-

ans of association is energetically inferior to short-range η^6-complexation, this work nevertheless draws awareness to its availability as a noncovalent "design principle."

The metal–arene distances of ca. 3 Å in [Ag(**1**)]BF_4 and [Cu(**1**)]BF_4 invite speculation as to which other metals in Table 2 might give stable cylindrophane complexes, or indeed whether the lanthanides in Table 1, with metal–arene distances as great as 2.7 Å, might, as trivalent ions, complete their valence shell with the 18 electrons present in **1**. Basic modifications to the cylindrophane framework also suggest themselves, among them the use of phosphorus as the equatorial heteroatom, the transformation of which into the corresponding phosphane oxide would force the three O sites into the cavity between the rings (in preference certainly to any alkyl/aryl group on P). Work along these lines continues.

Experimental Section

[Ag(1)]BF_4: To a solution of the ligand **1** (51 mg, 0.12 mmol) in CH_2Cl_2 (5 mL) was added $AgBF_4$ (24 mg, 0.12 mmol) and the solution was stirred in the dark for 24 h. The solvent was evaporated and the residue dissolved in acetonitrile, preabsorbed onto silica and chromatographed (10% MeOH/$CHCl_3$) to give a white solid (48 mg, 64%), m.p. 270 °C (dec). – ^{1}H NMR (250 MHz, $CDCl_3$): δ = 2.95 (t, 12 H), 3.24 (m, 12 H), 6.93 (s, 6 H). – ^{13}C NMR (67.8 MHz, $CDCl_3$): δ = 34.0, 37.6, 127.4, 141.0; – MS (FAB): *m*/*z* 521 (23) [M^+]; elemental analysis calcd for $C_{24}H_{30}S_3AgBF_4$: C, 47.31, H, 4.96; found: C, 47.36, H, 4.90.

[Cu(1)]BF_4: To a solution of the ligand **1** (37 mg, 0.089 mmol) in a mixture of CH_2Cl_2 (1.5 mL) and MeCN (0.5 mL) was added [Cu(MeCN)$_4$]BF_4 (28 mg, 0.089 mmol) and the solution was stirred overnight. The solvent was evaporated and the residue chromatographed (5% MeOH/$CHCl_3$) to give a white solid (41 mg, 82%), m.p. 240 °C (dec). – ^{1}H NMR (250 MHz, $CDCl_3$): δ = 2.90 (t, 12 H), 3.16 (br s, 12 H), 6.85 (s, 6 H). – ^{13}C NMR (67.8 MHz, $CDCl_3$): δ = 33.4, 36.7, 126.3, 140.8. – HRMS (ES-TOF): *m*/*z* calcd. for $C_{24}H_{30}S_3Cu$: 477.0806; found 477.0780 (M^+).

***Tris*-sulfoxides 3 and 4:** To a solution of the sulfide **1** (274 mg, 0.661 mmol) in a mixture of THF (30 mL) and water (2 mL) was added sodium periodate (0.465 g, 2.17 mmol). The reaction was stirred for 12 h, filtered and the solvent evaporated. The residue was dissolved in methanol, preabsorbed onto silica gel, and chromatographed (12% MeOH/$CHCl_3$) to give **3** (37 mg, 12%) and **4** (190 mg, 62%), both as a white solids.

3: m.p. 300 °C (dec.). – ^{1}H NMR (250 MHz, $CDCl_3$): δ = 2.59–2.71 (m, 6 H), 2.92–3.15 (m, 18 H), 6.88 (s, 6 H). – ^{13}C NMR (67.8 MHz, $CDCl_3$): δ = 29.2, 55.7, 128.1, 139.4. – HRMS (FAB): *m*/*z* calcd. for $C_{24}H_{31}S_3O_3$: 463.1435; found: 463.1437 (M^+ + H).

4: m.p. 280 °C (dec.). – ^{1}H NMR (250 MHz, $CDCl_3$): δ = 2.47–2.63 (m, 7 H), 2.83–3.09 (m, 19 H), 6.73 (s, 2 H), 6.86 (s, 2 H), 7.02 (s, 2 H). – ^{13}C NMR (67.8 MHz, $CDCl_3$) δ = 28.2, 29.1, 54.1, 55.2, 55.4, 126.0, 127.9, 129.3, 139.7, 139.9, 140.5. – HRMS (FAB): *m*/*z* calcd. for $C_{24}H_{31}S_3O_3$ 463.1435; found: 463.1432 (M^+ + H).

Cyclic Voltammetry of [Ag(1)]BF_4 and [Cu(1)]BF_4: Cyclic voltammograms (CVs), 100 mV s^{-1}, were recorded at 22±2°C in the solvent indicated using an EG & G Princeton Applied Research (PAR) Model 173 potentiostat. The supporting electrolyte was tetraethylammonium tetrafluoroborate (0.2 M). A three-compartment electrochemical cell was employed using nitrogen-purged solutions, with a platinum wire working electrode, a platinum-mesh counter electrode, and a sodium chloride saturated calomel reference electrode. The platinum wire working electrode was pre-treated before measurements by anodisation, then cathodisation, (1 min each at 100 mA in 1 M sulfuric acid) followed by washing with deionised water, then acetonitrile and finally air dried.

Crystal Data for 4: Colorless needle from methanol, $C_{24}H_{30}O_3S_3$, M = 462.7, monoclinic, a = 8.891(2), b = 14.763(3), c = 17.928(4) Å, β = 100.695(6)°, U = 2312.3(9) Å^3, T = 150(2) K, space group $P2_1/c$ (no. 14), Z = 4, μ(Mo-$K\alpha$) = 0.344 mm^{-1}, 15450 reflections measured of which the 4904 unique to $2\theta_{max}$ 52° (R_{int} = 0.088) were used in all calculations. The final $wR(F^2)$ was 0.328, R_1 = 0.116. Data were collected on the Bruker SMART CCD area detector diffractometer on Station 9.8 at CLRC Daresbury Laboratory, using synchrotron radiation with a wavelength of 0.6917 Å. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-132651. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

The financial support of the University of Nottingham and the use of the EPSRC's Chemical Database Service at Daresbury[6b] is acknowledged. We also thank the CLRC for the provision of beamtime on Station 9.8 of the SRS. The author is indebted to Dr. Richard Wheatley for helpful discussions and Mr. Neil Brooks for experimental assistance.

[1] With the apparent exception of Tc and Pd; scandium(0) η^6-complexes have been prepared (see F. G. N. Cloke, *Chem. Soc. Rev.* **1993**, *22*, 17–24), but do not appear in the present study since no X-ray crystal structures have been published.

Stabilization of Carbenium Ions Derived from Ethynylestradiol by Different Adjacent Organometallic Moieties. Implication in the Inactivation of the Estrogen Receptor

Domenico Osella,*[a] Mauro Ravera,[a] Carlo Nervi,[b] Giorgio Cavigiolio,[b] Marco Vincenti,[c] Anne Vessières,[d] and Gérard Jaouen*[d]

Keywords: Clusters / Steroids / Protonation / Carbocations / Immunoassay

The stabilization of carbenium ions by an adjacent organotransition metal moiety has been evaluated using the classical Deno's method as well as a new procedure based on DCI-MS spectrometry. The ability of transition metal clusters to enhance the stability of a proximate carbocationic center in 17α-alkynylestradiol–[OM] derivatives {[OM] = $Co_2(CO)_6$; $Co_2(CO)_4$(dppm); $Mo_2Cp_2(CO)_4$; $M_3(CO)_{10}$, M = Ru, Os; $HRu_3(CO)_9$} has been related to their capacity to inactivate the estrogen receptor (affinity marker properties).

The stabilization of carbenium ions by an adjacent organotransition metal moiety is a well documented phenomenon.[1,2] The study of the hexacarbonyldicobalt unit as a protecting group for the C≡C triple bond[3] led Nicholas et al. to discover the fast acid-promoted hydration/dehydration equilibrium, (Figure 1) which generates the $[(propargyl)Co_2(CO)_6]^+$ cation as an intermediate.[4]

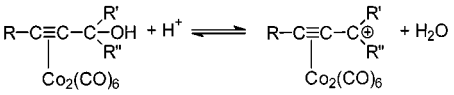

Figure 1. Hydration/dehydration equilibrium involving a $[(propargyl)Co_2(CO)_6]$-like compound

A large variety of propargyl cations coordinated to many different organometallic fragments have been investigated to date.[5–8] The major interest in these compounds is based on the possibility of employing them as electrophilic synthons. In this context, 17α-alkynylestradiol organometallic derivatives (Figure 2) may be regarded as analogous to the propargylic alcohol complexes.

Several examples of transition-metal carbonyl fragments, used as labeling agents for 17α-alkynylestradiol, have been reported in the literature {[OM] = $Co_2(CO)_6$; $Mo_2Cp_2(CO)_4$; $M_3(CO)_{10}$, M = Ru, Os}.[9] An appreciable

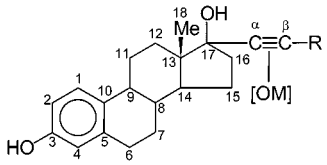

Figure 2. Conventional representation of the [OM]-steroidal ring system, showing the numbers used to identify the carbon atoms

recognition level for the receptor, evaluated in terms of the *relative binding affinity (RBA)*, is maintained even when relatively bulky groups are linked to a 17α-alkynylestradiol.[10] This particular labeling of steroids has been used in a new non-isotopic immunoassay (*carbonylmetalloimmunoassay, CMIA*) for assaying circulating hormones such as cortisol[9] or in receptorology for studying the interaction between the hormone and its receptor.

The synthesis of a large number of organometallic labeled hormones led to the discovery of a new family of *affinity markers* for the estrogen receptor, i.e. molecules able to bind irreversibly to the receptor, probably through a direct covalent bond. This unusual behavior may be attributed to the stability of the associated organometallic carbenium ion, as previously discussed. The 17β-OH group is essential for inactivation of the receptor.[11] The presence of cysteine acid residues near the association site of the receptor can account for the formation of the carbocation through an acid-promoted dehydration reaction on the OH group at the 17β position (Figure 3). Unfortunately, the recently published X-ray structure for the Ligand Binding Domain (LBD) of the α-estradiol receptor was obtained after chemical modification of the cysteines.[12] Therefore, this hypothesis cannot be proven for the moment, although these organometallic markers may help in the elucidation of the structure of the receptor binding site.[13,14,15]

The aim of this work is to investigate both the relationship between the ability of transition metal clusters to enhance the stability of the neighboring carbocationic center in 17α-alkynylestradiol derivatives, and also to investigate their affinity marker properties. Breast cancers that retain estrogen receptor (ER) can usually be treated effectively by endocrine therapy, such as by the use of the antiestrogen tamoxifen. Moreover, by labeling estradiol with cytotoxic metal derivatives one could expect to synthesize a new family of anticancer drugs able to use the receptor system as a vector to reach the target cells and remain attached for a period sufficient to damage the cancerous tissue.

Results and Discussion

Several 17α-alkynylestradiol organometallic derivatives **1–6** and the corresponding propargylic model complexes **1a–6a** have been synthesized (Figure 4).

Compound **6a** [$HRu_3(CO)_9(–C{\equiv}CCH_2OH)$] was obtained in good yield by thermolysis of $Ru_3(CO)_{10}(HC{\equiv}CCH_2OH)$ (**4a**). In contrast, the direct reaction of $Ru_3(CO)_{12}$ and $HC{\equiv}CCH_2OH$ gave compound **6a** only in trace amounts; the major product was metallacyclopentadiene $Ru_2(CO)_6(alkyne)_2$.[16]

The relative binding affinities of these complexes for the ER were determined in a competition binding assay using lamb uterine cytosol as a source of ER, and [^{3}H]estradiol as the tracer. The values found range between 2.5 and 33% (estradiol itself being taken as 100%), indicating moderate recognition. Roughly, RBA values are inversely proportional to the steric bulk of the organometallic graft.

The possible existence of a covalent bond between the hormone derivatives and the receptor was investigated by receptor inactivation (RI) studies. The RI procedure involves a preliminary incubation of the organometallic tracer with the cytosol receptor after which the free organometallic tracer is removed by means of charcoal-dextran treatment. The remaining reversible estrogen binding activity of the tracer-receptor adduct is then measured by an exchange reaction of [^{3}H]estradiol with the organometallic tracer not covalently bound to the estrogen binding site. The quantification of the [^{3}H]estradiol specifically bound to the ER was then performed by protamine sulfate precipitation as previously described.[17] The residual radioactivity

on the precipitate is related to the remaining estrogen binding activity: the higher the radioactivity, the lower the receptor inhibition (RI% = 0 for estradiol itself).[18]

Carbenium ions can be generated in presence of strong acids. The pK_{R+} values for ionization of alcohols in aqueous sulfuric acid were determined spectrophotometrically. The position of the alcohol–carbenium ion equilibrium (Equation 1):

$$R^+ + H_2O \rightleftharpoons ROH + H^+ \quad (1)$$

was studied as a function of sulfuric acid concentration, using the empirical acidity function (C_0) proposed by Deno.[19] The Deno's method is a facile way of obtaining the thermodynamic stability of the carbenium ions, provided that a sharp change in the UV/Vis spectrum is produced upon acid addition. However, the strongly acidic conditions required by this method may induce rearrangements of the steroid skeleton to give several enyne complexes (Figure 5), a possibility proposed in a previous study.[6]

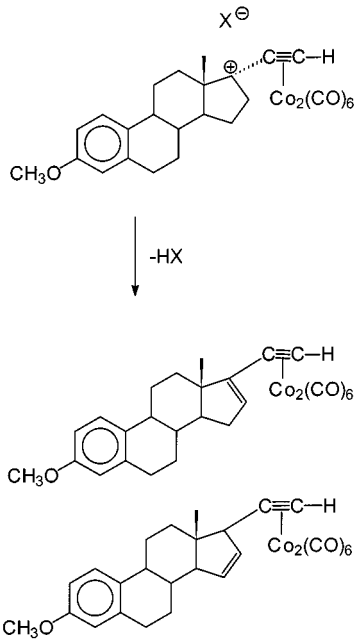

Figure 5. Proposed mechanism for the formation of enyne complexes through rearrangements of the steroid skeleton

Since the $[R^+]/[ROH]$ ratio is evaluated from the UV/Vis absorptions of both species, any chemical transformation of either is likely to alter the overall spectrum profile and, consequently, the pK_{R+} value. To prevent misinterpretations, several measurements have been carried out on the corresponding propargylic alcohol as models. This simplification is reasonable, as the pK_{R+} values measured for the propynylestradiol complexes **1** and **3** proved to be similar to those of the model propargyl complexes.[6]

To overcome the limitations inherent in the Deno's method, we propose an alternative gas phase procedure for evaluating carbocation stability with respect to the parent alcohol. This procedure utilizes chemical ionization mass spectrometry in combination with the fast thermal vaporization of the organometallic complex (DCI-MS). A relatively high pressure of reagent gas (i.e. isobutane) and a low pressure of analyte (M) are simultaneously present in the ionization chamber. The reagent gas is ionized by electron impact, and fragments in a conventional manner. Several collisions occur between ions and neutral isobutane molecules yielding the *tert*-butylcarbonium ion $[(CH_3)_3C]^+$ as a stable species. This may subsequently react with the analyte (M) by proton transfer to generate the quasi-molecular ion $[M + H]^+$. The facility of such a process, and thus the intensity of the quasi-molecular ion peak $[M + H]^+$, depends on the acid-base properties of the species involved in the equilibrium (Equation 2):

$$[(CH_3)_3C]^+ + M \rightleftharpoons (CH_3)C{=}CH_2 + [M{+}H]^+ \quad (2)$$

In the present case, the protonated ion $[M + H]^+$ can eliminate H_2O, provided the corresponding carbocation is sufficiently stable (Figure 6). Thus, the ratio, $[M - OH]^+/[M + H]^+$, between ion peak intensity represents a good estimate of the corresponding carbocation stability in the gas phase.

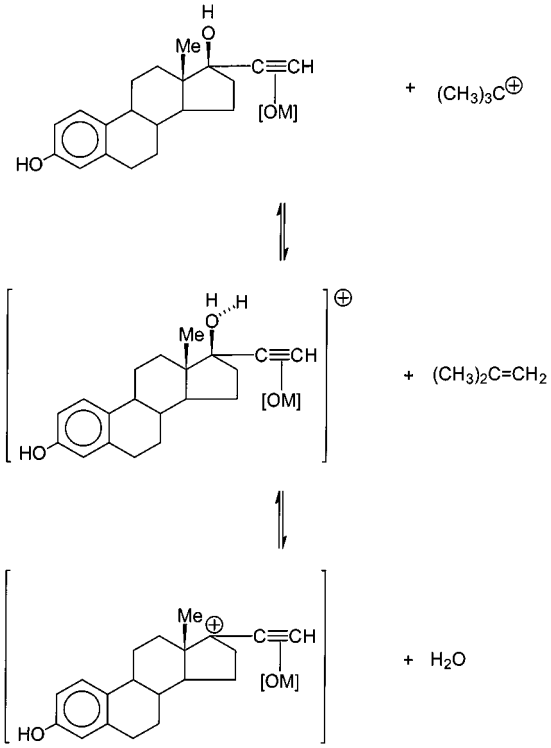

Figure 6. Water elimination reaction on the organometallic estradiol

The DCI method is experimentally simpler than the (chemical) Deno's method. Furthermore, the ionization process and ion detection is so rapid that elimination reactions on the carbenium ion do not occur, allowing a meaningful measure on real estradiol-organometallic derivatives.

The presence of the 17β-OH group is essential for carbocation formation; in fact, the DCI-MS spectrum of estrone (C=O group in lieu of the OH group) does not exhibit the $[M - OH]^+$ peak. The contribution of the phenolic OH in position 3 to the protonation-dehydratation process is negligible: $[M - OH]^+/[M + H]^+$ ratios of 17α-ethynylestradiol and 3-methoxy-17α-ethynylestradiol are identical, within error.

Compounds **4** and **5** show a fragmentation pathway different to all the other complexes. Since the major process is the loss of a CO ligand, a reaction previously found in solution,[20] the $[M + H]^+$ and $[M - OH]^+$ peaks are too small to be evaluated properly. For this reason, the mass ratio has been evaluated by the relative abundance of the daughter ions $[(M - CO) - OH]^+/[(M - CO) + H]^+$.

The DCI-MS data for the propargyl models **1a–6a** are similar to those of the estradiol homologues: the $[M - OH]^+/[M + H]^+$ ratios of the former are always higher than those of the latter. This result can be explained by postulating that the $[M + H]^+$ internal energy for estradiol derivatives is distributed over a much larger number of chemical bonds than for propargyl derivatives. Less energy is therefore available to induce the loss-of-water fragmentation process.

Complexes **1–6** may be separated into three categories:

(i) Complex **2** has a pK_{R+} value of –11 and a DCI-MS ratio of 0.87, indicating a highly unstable carbenium ion, and gives no alkylation of receptor at all (RI% = 0);

(ii) Compounds **1** and **4–6** have pK_{R+} values in the –6.0 to –1.4 range and DCI-MS ratios from 7.2 to 1.4, indicating the formation of moderately stable but still reactive carbocations; they efficiently inactivate the estradiol receptor ($80 < RI\% < 60$);

(iii) Complex **3** shows the highest pK_{R+} and DCI-MS values (+2.7 and 12.0, respectively) indicating a very stable but almost unreactive carbocation, associated with a low inactivation of the receptor (RI% = 22).

The best affinity marker was found to be compound **1**, which has a pK_{R+} around –6. With smaller or higher pK_{R+} values this phenomenon of receptor inactivation is not so apparent. Although 17α-propynylestradiol shows the same pK_{R+} value as **1**, it does not reveal any detectable RI effect. This implies that the C≡C triple bond in the α position is itself able to stabilize the adjacent carbocation, although the metal core should play a further active role in establishing a covalent bond with the receptor, for instance with the thiol groups of cysteine residues present in the LBD. In this context, it is known that cobalt carbonyls are able to react with thiol functionalities, giving rise to a plethora of compounds.[21]

Table 1. Relative binding affinity (RBA%) of the estradiol receptor, inactivation of the receptor (RI%), pK_{R+} and DCI-MS ($[M - OH]^+/[M + H]^+$) ratio

	Compound	RBA	RI%	pK_{R+}	$[M - OH]^+/[M + H]^+$

6a	$HRu_3(CO)_9(-C{\equiv}CCH_2OH)$	–	–	[d]	2.8[b]

[a] Values by definition. – [b] This work. – [c] ref. [10]. – [d] No shape change in the UV/Vis spectrum occurred upon acid addition. This prevented the correct evaluation of pK_{R+} values. – [e] ref.[6] – [f] Calculated as the ratio $[(M–Co)–OH]^+/[(M–CO) + H]^+$.

The experimental results are summarized in Table 1.

There is a rough correlation between pK_{R+} and DCI-MS values, although the metallic grafts are very different throughout the series. Higher (less negative) pK_{R+} values correspond to higher DCI-MS ratios; both results point to a higher stabilization of the corresponding carbocations.

As previously mentioned, an approximate correlation exists between the affinity marker properties of estradiol organometallic derivatives (evaluated by their RI% value) and the carbenium ions stabilization (evaluated from both pK_{R+} and DCI-MS values).[9] However, the interactions in a sophisticated biological system are always more complex than in our simple model experiment.

As mentioned above, compound **1** shows the highest RI value (80%). Replacement of one carbonyl group on hexacarbonyldicobalt-coordinated propargyl cations by phosphane is expected to increase the stability, and hence the pK_{R+} values of these compounds. This would occur by increasing the electron density on the Co_2 moiety, in the manner qualitatively described by Nicholas.[22] Kuhn et al. quantified this effect in a kinetic study on the electrophilic reactivity of $[Co_2(CO)_5(PPh_3)(HC{\equiv}CPh)]^+$ cation.[23] Thus, the replacement of two carbonyls by diphosphanes in compound **1** (to give **2**) is expected to increase the carbocation

stability. Surprisingly, compound **2** gave a pK_{R+} value of –11 and a mass ratio of 0.87, both indicating a highly unstable cation. This unexpected behavior can be explained in terms of steric hindrance.

The build-up of a positive charge results in a shift of the cationic center towards one of the Co atoms. It has to be recognized that the mechanism of carbocation stabilization involves rearrangements on the overall skeleton which facilitate the metal–$C(17)^+$ interaction. Melikyan et al. resolved the structure of a $Co_2(CO)_6$-complexed propargyl cation showing that the C^+ atom is no longer equidistant from Co atoms.[24] The same behavior was observed in $\mathbf{3}^+$, where the organometallic moiety shifts below the estradiol D ring, enabling a Mo–$C(17)^+$ interaction to be established.[6] In the case of $\mathbf{3}^+$ this interaction is weaker than that reported for $\mathbf{3a}^+$, and interestingly, this difference has been attributed to the conformational constraints imposed by the bioligand.

In **2** the steric repulsion should be enhanced by the presence of two bulky diphosphane and the large steroidal skeleton. In order to investigate this hypothesis, we compared the size of **2** with respect to **1**, by representing them using the molecular modeling program PC Model.[25] The organometallic fragments were derived from the X-ray structure of $Co_2(CO)_6(PhC{\equiv}CPh)$[26] and $[Co_2(CO)_4(dppm)]_2[PhC{\equiv}C{-}C{\equiv}CPh]$.[27] The steroidal moiety structure was taken from the crystallographic data of the estradiol-propanol adduct.[28] The fragments were combined according to **1** and **2**. After adjusting the new bond distances to normal values, the resulting structures were energy-minimized by rotating the steroidal fragment around the C(17)–Cα bond (fixed at 1.50 Å). This procedure was repeated several times. Lastly, by allowing small oscillations of all atoms (except those in the organometallic moiety), the overall energy minimum was obtained. Although the approximation inherent to this procedure should be recognized (e.g. the organometallic fragment is considered as a frozen unit), this method provides a reasonable model of the overall molecular geometries of **1** and **2**. The molecular surfaces were obtained by simply considering the atomic radii of their constituents (CPK surface). The resulting space-filling models of **1** and **2** (Figure 7) suggest that the large size of the diphosphane ligand buries the cobalt metals and therefore hinders any $C(17)^+$–Co interaction, in the corresponding carbocation $\mathbf{2}^+$, that is responsible for carbocation stabilization.

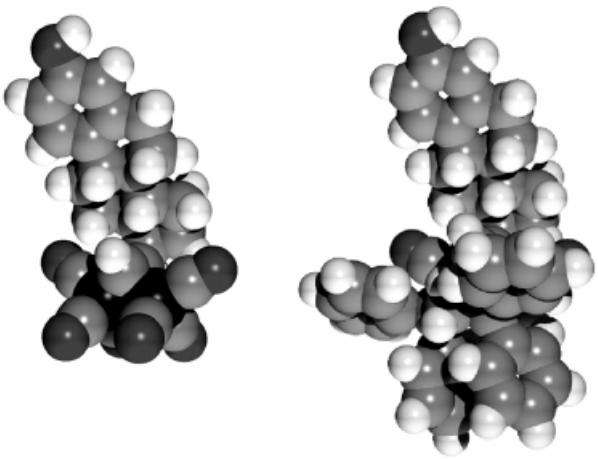

Figure 7. Space-filling models of **1** (left) and **2** (right). The picture was obtained by using molecular modeling program to graft the steroidal fragment onto the organometallic moiety

Experimental Section

General Chemical Procedures and Materials: All reactions were carried out under an atmosphere of dry nitrogen with standard Schlenk techniques. Solvents were distilled under nitrogen from appropriate drying agents. Published procedures were employed for the synthesis of 17α-propynylestradiol, **1** and **3**,[29] **4–6**,[10] and model complex **3a**.[30] Model complexes **1a**, **2a**, **4a**, and **5a** were synthesized by reaction of $Co_2(CO)_8$, $Co_2(CO)_6$(dppm),[31] or $M_3(CO)_{10}(NCCH_3)_2$,[32] (M = Ru for **7a** and Os for **8a**) with propargyl alcohol. Their purity was checked by IR, MS, and NMR spectroscopy. All elemental analyses are within ±0.5% of the theoretical values. Solution infrared spectra were recorded on a Bruker Equinox 55 in matched air-free cells with NaCl windows. ^{1}H-, ^{13}C-, and ^{31}P-NMR spectra were acquired on a JEOL EX-400 spectrometer operating at 400 MHz for ^{1}H, 100.6 MHz for ^{13}C, and 161.9 MHz for ^{31}P. Chemical shifts are reported downfield, positive with respect to the reference standard $SiMe_4$ (δ = 0) using the residual H signals as internal standard (^{1}H) or the characteristic resonances of the solvent nuclei (^{13}C); for ^{31}P, 85% H_3PO_4 was used as reference. ^{31}P and ^{13}C data are proton decoupled. DCI-MS spectra were recorded on a Finnigan-MAT 95Q instrument with magnetic and electrostatic analyzers. Isobutane was used as the reagent gas at 0.5 mbar pressure. The ion source temperature was kept at 50 °C, the electron emission current at 0.2 mA, and the electron energy at 200 eV. Positive ion spectra were collected. A computer program provides a digital readout of peak intensity and their comparison with the simulated isotopic pattern. The fit was excellent for all of the compounds under investigation.

Synthesis of $Co_2(CO)_4$(dppm)(EC≡CH) (2): Stoichiometric amounts of 17α-ethynylestradiol and $Co_2(CO)_6$(dppm), prepared according to the literature procedure,[33] were heated at reflux in benzene for 2 h, under nitrogen. The hot reaction mixture was filtered over a short silica column to remove any insoluble impurities and eluted with ethyl acetate/cyclohexane (40:60). The filtrate was dried under vacuum, and the complex was then purified by recrystallization from hexane/CH_2Cl_2 at –20 °C. Yields 60%. – IR (CH_2Cl_2): $\tilde{\nu}_{CO}$ = 2022 s, 1991 sh, 1989 vs, 1966 s cm^{-1}. – ^{1}H NMR ($CDCl_3$): δ = 8.12 (s, 1 H, C3–OH), 7.50–7.20 (m, 20 H, Ph), 7.10 (s, 1 H, C1–H), 6.62 (dd, 1 H, C2–H), 6.56 (d, 1 H, C4–H), 5.65 (t, ≡C21–H, $^3J_{HP}$ = 7.7 Hz), 4.69 (s, C17–OH), 3.62 and 3.22 (each m, 1 H, P–CH_2–P)[35], ca. 3.0–1.3 (all the remaining resonances heavily overlapped), 1.11 (s, 3 H, Me-18). – ^{13}C NMR ($CDCl_3$): δ = 204.42 (br, CO), 153.25 (C3), 138.34 (C5), 136–128 (Ph), 132.90 (C10), 126.42 (C1), 115.14 (C4), 112.51 (C2); 110.73 (C20), 85.04 (C17), 75.12 (C21), 48.21 (C13), 41.62 (t, P–CH_2–P, J_{CP} = 20.2 Hz), 42–20 (all the remaining resonances heavily overlapped); 15.73 (Me-18). – ^{31}P NMR ($CDCl_3$): δ = 42.5 (s).

Synthesis of $HRu_3(CO)_9$(–C≡C–CH_2OH) (6a): A solution of **6** in cyclohexane was heated at 75 °C under nitrogen for 45 min. The mixture was allowed to reach room temperature and purified by chromatography on a silica column. Cyclohexane first eluted some

adventitious $Ru_3(CO)_{12}$; pure CH_2Cl_2 then eluted the desired compound. Yield 50%. – IR (CH_2Cl_2): $\tilde{\nu}_{CO}$ = 2100 w, 2074 vs, 2054 vs, 2022 vs, 1989 m cm^{-1}. – ^1H NMR ($CDCl_3$): δ = 4.89 (d, 2 H, –CH_2–, J_{HH} = 6.1 Hz), 2.07 (t, 1 H, –OH), –21.03 (s, 1 H, hydride). – ^{13}C NMR ($CDCl_3$): δ = 197.15 and 188.19 (Ru–CO),[36] 160.58 (≡C–Ru), 102.64 (≡C–CH_2), 61.05 (CH_2).

pK_{R+}: Aliquots of a 10^{-3} M solution of the compound under investigation in acetonitrile (50 μL) were added to 450 μL of H_2SO_4/H_2O solutions of increasing acid concentration. The wavelength of maximum absorption was sought by scanning the 190–600 nm range and the approximate concentration of H_2SO_4 required to achieve 50% ionization of organometallic hormone determined by comparing the maximum UV/Vis absorbance for the different H_2SO_4/H_2O solutions.

A minimum of four aqueous H_2SO_4 solutions, whose concentrations were around the roughly estimated value, were prepared. Thirty minutes after the initial injection of acetonitrile solution into the acid solutions, a spectroscopic determination of the ratio [R^+]/[ROH] was performed. The final pK_{R+} value was calculated by use the following Equation (Equation 3):

$$pK_{R+} = C_0 + \log\frac{[R^+]}{[ROH]} \quad (3)$$

where C_0 is the Deno acidity function for H_2SO_4/H_2O solutions.[34]

Biochemical Materials and Methods: Estradiol, 17α-ethynylestradiol, charcoal (Norit A), and protamine sulfate (from salmon, grade X) were from Sigma. [6,7-^{3}H]Estradiol (specific activity 70 Ci/mmol) was purchased from C.E.A. (Saclay, France).

Preparation of Lamb Uterine Cytosol and Binding Assays: Lamb uteri, used as a source of estrogen receptor, were obtained from the slaughterhouse of Mantes-la-Jolie, France and kept frozen in liquid nitrogen until used. The lamb uteri were thawed, and the minced tissues homogenized with an Ultra-Turrax in buffer A (0.05 M Tris–HCl, sucrose 0.25 M, 0.1% 3β-mercaptoethanol, pH 7.4). The homogenate was centrifuged at 40,000 r.p.m. for 35 min in the TFT 65-13 rotor of a Kontron T-1160 ultracentrifuge. Aliquots (200 μL) of the supernatant (usually called cytosol) were incubated for 3 h at 0 °C with [^{3}H]estradiol ($6\cdot10^{-9}$ M) in presence of nine different concentrations (ranging from $1\cdot10^{-8}$ M to $1\cdot10^{-6}$ M) of the compound under investigation, acting as the competitor. An equivalent incubation, containing the same aliquots of cytosol and the same concentration of [^{3}H]estradiol, was prepared with nine different concentrations (ranging from $1\cdot10^{-8}$ M to $1\cdot10^{-6}$ M) of non-radioactive estradiol as the competitor. A blank (without competitors) was added to the incubation set to evaluate the maximum receptor binding capacity. At the end of the incubation, separation of the bound fractions of the steroids was achieved by using protamine sulfate precipitation.[17] The bound fractions were collected on glass fiber paper (Whatman GF/C) under a light vacuum and washed extensively with phosphate buffer (pH = 7.2). The filters were then transferred into a vial containing 10 mL of scintillation fluid (A.C.S., Amersham) and the radioactivity was measured in an LKB-1211 Rack-Beta scintillation counter. The percentage reduction in binding of [^{3}H]estradiol (Y) was calculated using the logit transformation of Y, where logit Y = ln(Y/1 – Y), vs. the log of the mass of competing steroid. The concentration of competitor required to displace 50% of the bound [^{3}H]estradiol was calculated for the compound under investigation (C_{50}) and for non-radioactive estradiol (C_{50e}); the result was expressed as the relative binding affinity [RBA = (C_{50e}/C_{50})×100].

Receptor Inactivation Assays: Aliquots (3 × 200 μL) of lamb uterine cytosol were first incubated for 2 h at 0 °C in the presence of $1\cdot10^{-8}$ M of compound under investigation (estradiol, 17α-ethynylestradiol**,** 17α-propynylestradiol, or **1–6)**, then [^{3}H]estradiol (final concentration $2.65\cdot10^{-9}$ M) was added to each fraction, which was again incubated for 1 h at 25 °C. At the end of this second incubation, the fraction of [^{3}H]estradiol specifically bound to its receptor was measured by protamine sulfate precipitation (vide supra). This value corresponds to the fraction of the estradiol receptor reversibly bound to the organometallic hormone in the first incubation. This value is compared to that of a control, i.e. aliquots of uterine cytosol (3 × 200 μL) incubated under the same conditions of time and temperature, but in the presence of tritiated estradiol only.

Acknowledgments

We thank Johnson Matthey Ltd. for a generous loan of $RuCl_3$ and OsO_4 and Ministero dell'Università e della Ricerca Scientifica e Tecnologica (MURST, Rome) for financial support (COFIN-98).

[35] The CH_2 group shows two multiplets readily interpreted as an ABX_2 ($X = {}^{31}P$) system. This support an equatorial (pseudoaxial) coordination mode of the dppm ligand as found in the solid state structure of $Co_2(CO)_4$(dppm)(PhC≡CPh), see: P.H. Bird, A. R. Fraser, D. N. Hall, *Inorg. Chem.* **1977**, *16*, 1923–1930.
[36] These resonances, with an integrated intensities ratio of 1:2 from low to high field, are assigned to one axial and two equatorial carbonyl groups of the $Ru(CO)_3$ unit π-bonded to the alkyne; the remaining carbonyls are involved in a moderately fast exchange process at room temperature so that their resonances are too broad to be observed. They eventually merge in a single peak at higher temperature, see: D. Osella, O. Gambino, C. Nervi, M. Ravera, G. Jaouen, *Inorg. Chim. Acta* **1992**, *192*, 65–70.

Reactivity of 2-(Diphenylphosphanyl)thiophenol ($HSC_6H_4PPh_2$) with Ruthenium and Osmium Carbonyl Complexes; Breaking of $HSC_6H_4PPh_2$ into Sulfide, Phenyl and Diphenylphosphanyl Ligands on a Triruthenium Cluster

Javier A. Cabezza,*[a] M. Angeles Martínez-García,[a] Victor Riera,[a] Diego Ardura,[b] and Santiago García-Granda[b]

Keywords: Ruthenium / Osmium / Phosphane-thiolate ligands / C−P activation / C−S bond activation

2-(Diphenylphosphanyl)thiophenol ($HSC_6H_4PPh_2$) reacts with the carbonyl clusters $[Ru_3(CO)_{12}]$ and $[Os_3(CO)_{10}(MeCN)_2]$ to give mixtures of products, the composition of which depends upon the reaction conditions and the ratio of the reactants. The derivatives $[M_3(\mu\text{-}H)(\mu\text{-}\eta^2\text{-}SC_6H_4PPh_2)(CO)_9]$ (**1a**: M = Ru; **1b**: M = Os), $[Ru_3(\mu_3\text{-}S)(\mu\text{-}\eta^2\text{-}Ph)(\mu\text{-}PPh_2)(PPh_3)(CO)_6]$ (**2**), and $[Ru_2(\mu\text{-}\eta^2\text{-}SC_6H_4PPh_2)_2(CO)_4]$ (**3**) have been isolated. The $SC_6H_4PPh_2$ ligand of compounds **1a** and **1b** has the sulfur atom spanning the same M−M edge as the hydride ligand and the phosphorus atom attached to one of the bridged metal atoms. Compound **2**, which contains sulfide, phenyl, diphenylphosphanyl and triphenylphosphane ligands that arise from $HSC_6H_4PPh_2$, has the Ru_3 triangle capped by the sulfide and two Ru−Ru edges spanned by bridging phenyl and diphenylphosphanyl ligands. In complex **3**, the two $SC_6H_4PPh_2$ ligands have the same coordination behavior as in **1a** or **1b**; this binuclear complex is more conveniently prepared by treating $[Ru_2(\mu\text{-}\eta^2\text{-}MeCO_2)_2(CO)_4(MeCN)_2]$ with $HSC_6H_4PPh_2$.

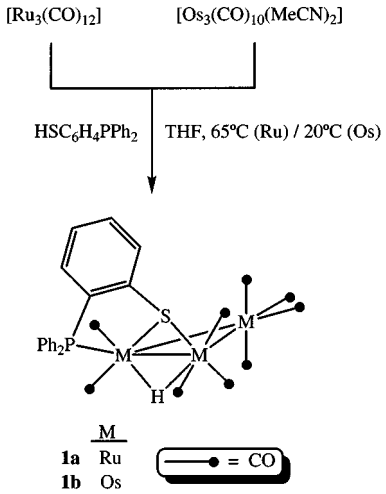
Introduction

The reactivity of unfunctionalized arenethiols with ruthenium[1][2] and osmium[3−7] carbonyl clusters has been studied in detail. Most of these investigations have attempted to shed light on the fundamental steps of catalytic hydrodesulfurization (HDS) reactions[8] in which sulfur is removed from thiols and other organosulfur compounds in fossil fuels.[9] However, despite the widespread use of HDS processes and their economic and environmental significance, the nature of the interaction of the organosulfur compounds with the catalysts and the mechanisms of the catalytic processes are still far from being well-known.[9]

Both $[Ru_3(CO)_{12}]$ and $[Os_3(CO)_{12}]$ react with thiophenol to give $[M_3(\mu\text{-}H)(\mu\text{-}SPh)(CO)_{10}]$ (M = Ru,[2] Os[3]) as primary products. However, these compounds undergo facile C−S bond activation reactions, under thermal and/or photochemical conditions, leading to the sulfide derivatives $[M_3(\mu_3\text{-}S)(\mu_3\text{-}CO)(CO)_9]$ (M = Ru,[2] Os[4][5]), $[Os_3(\mu_3\text{-}S)_2(CO)_9]$,[3b,4,6] $[M_3(\mu\text{-}H)_2(\mu_3\text{-}S)(CO)_9]$ (M = Ru,[2] Os[4]), $[Ru_4(\mu_4\text{-}S)(\mu\text{-}CO)_2(CO)_9]$[2] $[Os_4(\mu_3\text{-}S)_2(CO)_{13}]$,[3b] $[Os_4(\mu_3\text{-}S)_2(CO)_{12}]$,[3b] and $[Os_6(\mu_4\text{-}S)_2(CO)_{17}]$.[5] It has also been reported that $[Os_3(CO)_{11}(MeCN)]$ reacts with *m*- and *p*-thiocresol to give $[Os_3(\mu\text{-}H)(\mu\text{-}SC_6H_4Me)(CO)_{10}]$ and that this reaction proceeds *via* the intermediate $[Os_3(CO)_{11}(HSC_6H_4Me)]$, in which both the sulfur and the hydrogen atoms of the thiol group interact with an osmium atom.[7]

Despite this interesting reactivity of thiophenols with ruthenium and osmium carbonyl clusters, only a limited number of studies involving functionalized thiophenols have been published. We have previously reported that 1,2-benzenedithiol reacts with $[Ru_3(CO)_{12}]$ and $[Os_3(CO)_{12}]$ to give the binuclear derivatives $[M_2(\mu\text{-}\eta^2\text{-}S_2C_6H_4)(CO)_6]$ (M = Ru, Os),[10] and that treatment of 2-aminothiophenol with $[Ru_3(CO)_{12}]$ gives $[Ru_3(\mu\text{-}H)(\mu\text{-}\eta^2\text{-}SC_6H_4NH_2)(CO)_9]$.[11] However, the reaction of 2-aminothiophenol with $[Os_3(CO)_{10}(MeCN)_2]$ gives $[Os_3(\mu\text{-}H)(\mu\text{-}SC_6H_4NH_2)(CO)_{10}]$,[12] in which the NH_2 group is not coordinated. It is also known that $[Os_3(CO)_{10}(MeCN)_2]$ reacts with 2-mercaptobenzoic acid to give the hexanuclear compound $[\{Os_3(\mu\text{-}H)(CO)_{10}\}_2(\mu\text{-}\eta^3\text{-}SC_6H_4CO_2)]$,[13] in which the $SC_6H_4CO_2$ ligand connects two triangles of osmium atoms through the thiolate and the carboxylate groups, each group bridging one edge of the corresponding trimetal fragment.

We report herein the reactivity of 2-(diphenylphosphanyl)thiophenol ($HSC_6H_4PPh_2$) with $[Ru_3(CO)_{12}]$ and $[Os_3(CO)_{10}(MeCN)_2]$.



Results and Discussion

Treatment of a THF solution of $[Ru_3(CO)_{12}]$ with $HSC_6H_4PPh_2$, in a 1:1 ratio, at reflux temperature for 1.5 h gave $[Ru_3(\mu\text{-}H)(\mu\text{-}\eta^2\text{-}SC_6H_4PPh_2)(CO)_9]$ (**1a**) as the major component of a mixture of at least three products. The compound was isolated in 56% yield after a chromatographic workup. On the other hand, the osmium derivative $[Os_3(\mu\text{-}H)(\mu\text{-}\eta^2\text{-}SC_6H_4PPh_2)(CO)_9]$ (**1b**) was isolated in 48% yield after a chromatographic separation from a mixture of at least four compounds, formed from the reaction of $[Os_3(CO)_{10}(MeCN)_2]$ with $HSC_6H_4PPh_2$, in a 1:1 ratio, in THF at room temperature.

In both cases, longer reaction times, higher temperatures or the use of larger amounts of $HSC_6H_4PPh_2$ resulted in lower yields of **1a** or **1b** and in the formation of complex mixtures. In the case of the ruthenium reactions, we managed to isolate and characterize some of these products (vide infra), but the osmium reactions did not allow the identification of more products, since they afforded a plethora of compounds in very small amounts as soon as the temperature was raised.

Scheme 1. Synthesis of compounds **1a** and **1b**

The structure depicted for compounds **1a** and **1b** in Scheme 1 is based on their analytical and spectroscopic data and on an X-ray diffraction study on the ruthenium derivative **1a**. Both compounds give molecular ions in their FAB MS corresponding to the proposed formulation. Their ^1H NMR spectra contain a hydride resonance as a doublet with a small J_{H-P} coupling constant (8.3 Hz for **1a** and 8.1 Hz for **1b**), which indicates a *cis* arrangement of the hydride and the phosphorus atom in the clusters.[14−16] All these data, in addition to their microanalyses and IR spectra, indicate that both compounds have analogous structures. In order to precisely assign the coordination of the $SC_6H_4PPh_2$ ligand to the clusters, the structure of the ruthenium derivative **1a** was determined by X-ray diffraction methods.

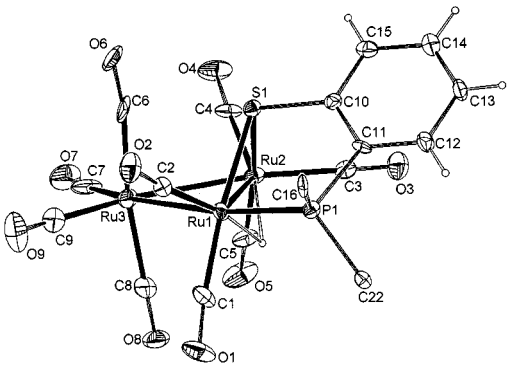

Figure 1. Molecular structure of complex **1a**; the atoms C(16) and C(22) are part of phenyl groups which have been omitted for clarity

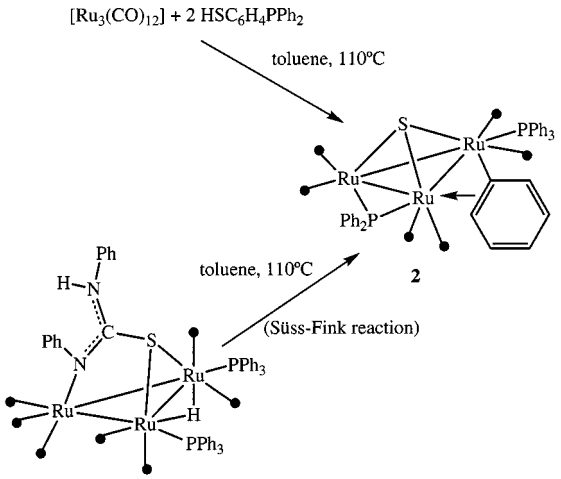

Table 1. Selected structural parameters of complex **1a**

Bond Lengths [Å]		Bond Angles [°]

Ru(3)−C(7)	1.94(2)	Ru(1)−Ru(3)−Ru(2)	60.29(5)
Ru(3)−C(8)	1.94(2)	C(10)−S(1)−Ru(1)	105.2(6)
Ru(3)−C(9)	1.97(2)	C(10)−S(1)−Ru(2)	105.0(5)
		Ru(1)−S(1)−Ru(2)	72.8(1)

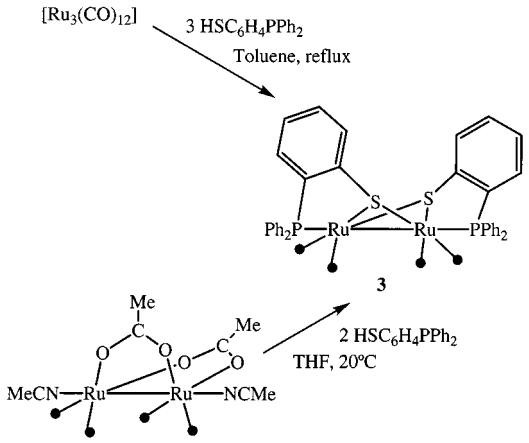
Figure 1 shows the molecular structure of compound **1a**. A selection of bond lengths and angles is given in Table 1. The cluster consists of an irregular triangle of ruthenium atoms in which the longest edge [Ru(1)−Ru(2) 2.841(2) Å], is spanned by the sulfur atom of a $SC_6H_4PPh_2$ ligand [Ru(1)−S(1) 2.381(4) Å, Ru(2)−S(1) 2.404(4) Å] and by a hydride ligand. The phosphorus atom of the $SC_6H_4PPh_2$ ligand is also attached to one of the ruthenium atoms of the same edge [Ru(1)−P(1) 2.309(4) Å] in a position approximately *trans* to the Ru(1)−Ru(3) edge [P(1)−Ru(1)−Ru(3) 166.7(1)°]. The cluster shell is completed by nine CO ligands, four of which are attached to Ru(3), three to Ru(2), and two to Ru(1). An analogous structure has been reported for the aminothiolate derivative $[Ru_3(\mu\text{-}H)(\mu\text{-}\eta^2\text{-}SC_6H_4NH_2)(CO)_9]$.[11] The structures of the ruthenium and osmium compounds $[M_3(\mu\text{-}H)(\mu\text{-}\eta^2\text{-}HNC_6H_4PPh_2)(CO)_9]$ (M = Ru,[15] Os[16]), derived from 2-(diphenylphosphanyl)aniline, have also been determined by X-ray diffraction methods and they are also similar to that of **1a**, although their bridged edges are shorter than the unbridged ones, in contrast to that of **1a**, probably as a consequence of the different sizes of the bridgehead atoms (N *vs* S).[17]

Treatment of THF or toluene solutions of $[Ru_3(CO)_{12}]$ with $HSC_6H_4PPh_2$, in 1:2 mol ratio, at reflux temperature, resulted in complex mixtures of products from which compounds **1a** and **2** could be separated by chromatographic means and subsequently identified. The best yield of complex **2** (13%) was obtained from a 1 h reaction in toluene at reflux temperature.

The structure depicted for compound **2** in Scheme 2 is based on an X-ray diffraction study, since little structural information was obtained from its analytical (microanalysis, FAB MS) and spectroscopic data (IR, ^1H and ^{31}P NMR). After having determined the structure, we found that Süss-Fink′s group had previously synthesized the same compound by thermolysis of $[Ru_3(\mu\text{-}H)(\mu\text{-}\eta^2\text{-}SCNHPhNPh)(CO)_7(PPh_3)_2]$ in refluxing toluene (Scheme 2), in the course of a study of the reactivity of $[Ru_3(CO)_{12}]$ with *N,N′*-disubstituted thioureas.[18] They also reported its

Scheme 2. Synthesis of compound **2**

X-ray structure. Consequently, we will not describe the structural details here.



It should be noted that all the non-CO ligands of complex **2**, i.e. sulfide, phenyl, diphenylphosphanyl and triphenylphosphane, arise in our case from the degradation of 2-(diphenylphosphanyl)thiophenol, implying the cleavage of P−C, S−C, and S−H bonds and the formation of C−H bonds. To our knowledge, this is the first example in which such important processes occur in the same ligand in a metal complex.

As mentioned in the introduction, the reactions of arenethiols with carbonyl metal clusters often lead to stoichiometric desulfurization of the thiols, to give the arenes and sulfide-metal derivatives.[1−8] However, apart from compound **2**, few examples of cluster compounds containing phenyl ligands arising from the degradation of arylphosphane ligands have been reported, but in all of them the phenyl groups are η^1-coordinated in terminal[19] or bridging[20] modes. Cluster **2** is a rare example of a complex containing a bridging phenyl ligand which interacts in a monohapto manner with one metal atom and in a dihapto manner with the other metal atom. This type of coordination is frequently observed for bridging alkenyl ligands.

The reaction pathway by which complex **2** is formed appears to be quite intricate, since it involves the breaking and the formation of many bonds. The composition of **2** suggests that it may be formed from **1a** and two equivalents of $HSC_6H_4PPh_2$, but a sulfur atom is in excess from a stoichiometric point of view. This is in accordance with the fact that the formation of complex **2** is accompanied by the formation of other products which could not be characterized.

As a part of several attempts to shed light on the mechanism of formation of complex **2**, compound **1a** was thermolyzed in refluxing toluene for 1 h, both in the absence and presence of $HSC_6H_4PPh_2$. In the former case, a $^{31}P\{^1H\}$ NMR spectrum of the crude reaction mixture revealed the presence of **2**, in low yield, among many other products with high ^{31}P chemical shifts ($\delta > 200$). In the latter case, compound **2** was formed in a greater amount, being the major component (*ca.* 15%) of a mixture of many products ($^{31}P\{^1H\}$ NMR spectrum of the crude reaction mixture). These data suggest that compound **1a** may be an early intermediate in the formation of **2** from $[Ru_3(CO)_{12}]$ and $HSC_6H_4PPh_2$, although other possibilities excluding the intermediacy of **1a** cannot be ruled out.

In a further attempt to shed light on the mechanism of formation of complex **2**, $[Ru_3(CO)_{12}]$ was heated with three equivalents of $HSC_6H_4PPh_2$ in refluxing THF for 2 h. In this case, complex **2** was also formed in a small amount, but the major component of the mixture (*ca.* 20%) was a complex that could be separated by TLC and subsequently identified as the binuclear derivative $[Ru_2(\mu\text{-}\eta^2\text{-}SC_6H_4PPh_2)_2(CO)_4]$ (**3**). Similar results were obtained carrying out the reaction in refluxing toluene for 1 h.

Scheme 3. Synthesis of compound **3**

The microanalysis and FAB MS data of **3** support its binuclear formulation. Its $^{31}P\{^1H\}$ NMR spectrum, which only contains a singlet at $\delta = 75.3$, and its IR spectrum, which shows four absorptions in the carbonyl region, confirm the C_2 symmetry shown in Scheme 3 for this complex.

Complex **3** can be more efficiently prepared (45% yield) by treatment of the binuclear acetate dimer $[Ru_2(\mu\text{-}\eta^2\text{-}MeCO_2)_2(CO)_4(MeCN)_2]$[21] with $HSC_6H_4PPh_2$ (1:2 mol ratio) in THF at room temperature. The carboxylate bridges of $[Ru_2(\mu\text{-}\eta^2\text{-}RCO_2)_2(CO)_4(MeCN)_2]$ are labile in the presence of acids (HX) whose conjugate bases (X) are able to act as bridging ligands, the carboxylate bridge being released as the corresponding carboxylic acid. This synthetic method has previously been used to prepare some ligand-bridged diruthenium complexes, such as $[Ru_2(\mu\text{-}SR)_2(CO)_4(PPh_3)_2]$[22] or $[Ru_2(\mu\text{-}pz)_2(CO)_4(PPh_3)_2]$[23] (pz = pyrazolate). The preparation of complex **3** by this method, which starts from a binuclear precursor, also supports its binuclear nature.

In conclusion, the present work describes the synthesis of some bi- and trinuclear ruthenium and osmium carbonyl complexes derived from the reactions of $[Ru_3(CO)_{12}]$ and $[Os_3(CO)_{10}(MeCN)_2]$ with 2-(diphenylphosphanyl)thiophenol. We have shown that these reactions are not selec-

tive, since this thiol is very fragile once it is coordinated to a metal cluster, being liable to undergo a series of S−H, S−C and P−C bond cleavage reactions that often lead to mixtures of many products, as has been proven with the isolation and characterization of compound **2**

Experimental Section

General: Solvents were dried over sodium diphenyl ketyl (THF, diethyl ether, hydrocarbons) or CaH_2 (dichloromethane) and distilled under nitrogen prior to use. − Unless otherwise stated, the reactions were carried out under nitrogen, using standard Schlenk techniques, and were routinely monitored by solution IR spectroscopy (carbonyl stretching region) and by spot TLC on silica gel. − The compounds $[Ru_3(CO)_{12}]$,[24] $[Os_3(CO)_{12}]$,[25] $[\{Ru_2(\mu\text{-}\eta^2\text{-}MeCO_2)_2(CO)_4\}_n]$[21] and $HSC_6H_4PPh_2$[26] were prepared as described in the literature. Anhydrous Me_3NO was prepared by azeotropic distillation of a toluene solution of $Me_3NO{\cdot}2H_2O$ and was stored under nitrogen. $RuCl_3{\cdot}nH_2O$ and OsO_4 were purchased from Pressure Chemicals, all other reagents were purchased from Aldrich. − Microanalyses: University of Oviedo Analytical Service. − FAB MS (positive ion): Finnigan Mat-95 spectrometer, nitrobenzyl alcohol as matrix, cesium as bombarding gas. − IR: Perkin−Elmer FT 1720-X. − NMR: Bruker AC-200 and AC−300, 23°C, $SiMe_4$ (internal, for ^1H) or 85% H_3PO_4 (external, for ^{31}P) as standards ($\delta = 0$).

Synthesis of 1a: A solution of $[Ru_3(CO)_{12}]$ (100 mg, 0.156 mmol) and $HSC_6H_4PPh_2$ (50 mg, 0.158 mmol) in THF (15 mL) was stirred at reflux temperature for 1.5 h. The color changed from orange to deep red. After addition of neutral alumina (*ca.* 100 mg) to the solution, the solvent was removed under vacuum. The solid residue was poured on top of a column (2 × 15 cm) of neutral alumina (activity I) packed in hexane. Elution with dichloromethane/hexane (1:6) afforded to yellow bands. A dark residue remained uneluted at the top of the column. The second band was very weak and was discarded. The first band gave compound **1a**, as a yellow/orange solid, when the solvent was evaporated under vacuum. − Yield: 75 mg (56%). − $C_{27}H_{15}O_9PRu_3S$: calcd. C 38.17, H 1.78; found C 37.98, H 1.72. − IR (THF): ν(CO) = 2086 (m), 2050 (s), 2017 (m), 2005 (s), 1988 (m), 1961 (w), 1944 (w). − ^1H NMR ($CDCl_3$): δ = 7.86−7.10 (m, 14 H), −15.76 (d, J_{H-P} = 8.3 Hz, 1 H). − $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 69.8 (s). − FAB MS: *m*/*z* = 850 $[M]^+$.

Synthesis of 1b: A solution of $[Os_3(CO)_{12}]$ (50 mg, 0.055 mmol) and anhydrous Me_3NO (10 mg, 0.14 mmol) in dichloromethane (15 mL) and acetonitrile (2 mL) was stirred at room temperature for 1 h. The resulting solution, containing the complex $[Os_3(CO)_{10}(MeCN)_2]$[27] (IR identification) was evaporated to dryness under vacuum. The residue was extracted into THF (10 mL) and was treated with $HSC_6H_4PPh_2$ (16 mg, 0.055 mmol). After stirring for 1 h at room temperature, the solution was concentrated to *ca.* 2 mL and was applied onto preparative silica gel TLC plates. Elution with dichloromethane/hexane (2:5) afforded four bands. The major band, yellow, was extracted with dichloromethane to give compound **1b**, as a yellow solid, after crystallization from dichloromethane/hexane. − Yield: 30 mg (48%). − $C_{27}H_{15}O_9Os_3PS$: calcd. C 29.03, H 1.35; found C 29.31, H 1.38. − IR (CH_2Cl_2): ν(CO) = 2110 (w), 2091 (m), 2052 (s), 2010 (s), 1990 (m), 1970 (w), 1951 (w). − ^1H NMR ($CDCl_3$): δ = 7.84−7.18 (m, 14 H), −17.42 (d, J_{H-P} = 8.1 Hz, 1 H). − $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 43.8 (s). − FAB MS: *m*/*z* = 1117 $[M]^+$.

Synthesis of 2: A solution of $[Ru_3(CO)_{12}]$ (100 mg, 0.156 mmol) and $HSC_6H_4PPh_2$ (97 mg, 0.330 mmol) in toluene (20 mL) was stirred at reflux temperature for 1 h. The color changed from orange to deep red. The solution was concentrated to *ca.* 2 mL and the concentrate was applied onto preparative silica gel TLC plates. Elution with dichloromethane/hexane (2:5) afforded five bands and a residue at the base line. The major band, pink, was extracted with dichloromethane to give compound **2**, as a dark pink solid, after crystallization from dichloromethane/hexane. − Yield: 21 mg (13%). − $C_{42}H_{30}O_6P_2Ru_3S$: calcd. C 49.08, H 2.94; found C 49.03, H 2.87. − IR (THF): ν(CO) = 2002 (vs), 1977 (s), 1943 (m), 1927 (w). − ^1H NMR ($CDCl_3$): δ = 8.10 (d, J_{H-P} = 8.0 Hz, 1 H), 7.80−7.20 (m, 26 H), 7.06 (t, J_{H-P} = 8.0 Hz, 1 H), 6.52 (t, J_{H-P} = 8.0 Hz, 1 H), 6.09 (d, J_{H-P} = 8.0 Hz, 1 H) − $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 215.1 (s, 1 P) 40.0 (s, 1 P). − FAB MS: *m*/*z* = 1028 $[M]^+$.

Synthesis of 3: A suspension of $[\{Ru_2(\mu\text{-}\eta^2\text{-}MeCO_2)_2(CO)_4\}_n]$ (100 mg, 0.231 mmol) was stirred in acetonitrile (20 mL) at reflux temperature for 15 min to give a yellow solution containing $[Ru_2(\mu\text{-}\eta^2\text{-}MeCO_2)_2(CO)_4(MeCN)_2]$[21] (IR identification). The solvent was removed under reduced pressure, and $HSC_6H_4PPh_2$ (136 mg, 0.463 mmol) and THF (20 mL) were added. The resulting solution was stirred at room temperature for 6 h. The color changed from orange to red. The solution was concentrated to *ca.* 2 mL and the concentrate was applied to preparative silica gel TLC plates. Elution with dichloromethane/hexane (1:5) afforded four bands. The first and major band, yellow, was extracted with dichloromethane to give compound **3**, as a yellow solid, after crystallization from dichloromethane/hexane. − Yield: 95 mg (45%). − $C_{40}H_{28}O_4P_2Ru_2S_2$: calcd. C 53.33, H 3.13; found C 53.71, H 3.33. − IR (hexane): ν(CO) = 1999 (w), 1978 (vs), 1940 (s), 1924 (w). − ^1H NMR ($CDCl_3$): δ = 7.84−7.06 (m) − $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 75.3 (s). − FAB MS: *m*/*z* = 901 $[M]^+$.

Crystal Structure Determination of 1a: Crystal data and details of the structure determination are listed in Table 2. The unit cell dimensions were determined from the angular settings of 25 reflections with 10° < Θ < 15°. The orthorhombic space group *P*bca

was determined from systematic absences and confirmed by the structure determination. The intensity was checked throughout data collection by monitoring three standard reflections every 60 min. Final drift correction factors were between 0.99 and 1.02. Profile analysis[28] was performed on all reflections. Lorentz and polarization corrections were applied and data were reduced to $|F_o|^2$ values.

The structure was solved by Patterson interpretation using the program DIRDIF92.[29] Anisotropic least-squares refinement, using a local version of SHELX,[30] was followed by an empirical absorption correction[31] (maximum and minimum correction factors 1.00 and 0.28, respectively). Full matrix anisotropic least squares refinement on F^2, using the program SHELXL92,[32] followed by a difference Fourier synthesis allowed the location of all the hydrogen atoms. Positional parameters and anisotropic thermal parameters of the nonhydrogen atoms were refined. All hydrogen atoms, except the bridging hydride ligand, were geometrically placed, and were isotropically refined. The function minimized was $\Sigma w(|F_o|^2-|F_c|^2)^2$, $w = 1/[\sigma^2(F_o^2) + (0.0236P)^2]$, with $\sigma(F_o)$ from counting statistics and $P = (F_o^2 + 2F_c^2)/3$. Atomic scattering factors were taken from the literature.[33] The plot in Figure 1 was made with the EUCLID package.[34] Geometrical calculations were made with PARST.[35] All computations were performed on an Alpha AXP3000 workstation.

Crystallographic data (excluding structure factors) for compound **1a** have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-133011. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk; www: http://www.ccdc.cam.ac.uk].

Ion Chemistry in XH_4/Allene (X = Ge, Si) Gaseous Mixtures – Formation of X–C Bonds

Paola Benzi,[a] Lorenza Operti,*[a] and Roberto Rabezzana[a]

Keywords: Ion-molecule reactions / Mass spectrometry / Allene / Germanium / Silicon

The gas-phase ion chemistry of germane/allene and silane/allene mixtures has been studied, with the aim of obtaining information on the experimental conditions leading to the formation of clusters of increasing size containing Ge or Si bonded to carbon atoms. Mechanisms of ion/molecule reactions have been elucidated by ion-trap mass spectrometry using single and multiple isolation steps. Rate constants for the most important reactions have been determined experimentally and compared with collisional rate constants. The germane/allene mixtures display a low reactivity and the most abundant germanium and carbon containing ion is $GeCH_3^+$. However, chain propagation proceeds after the first nucleation step, even if rather slowly, with the formation of large clusters such as $Ge_4C_3H_3^+$ at low abundance. In contrast, the silane/allene mixtures are very reactive and many different processes are observed, with the formation of several silicon and carbon containing ions with appreciable efficiency. Chain propagation proceeds mainly through reactions of silicon-containing ions with allene molecules and the subsequent formation of large clusters such as $Si_3C_3H_5^+$ and $Si_4C_3H_7^+$.

Introduction

In the last few years, hydrogenated amorphous compounds of elements of the Group 14 have been extensively studied for their possible applications in electronic and optoelectronic devices.[1] Amorphous semiconductors based on germanium carbides, a-GeC:H, or silicon carbides, a-SiC:H, have recently been considered[2] in order to obtain collectors of wide range light.

The preparation of these materials is generally carried out by laser-assisted, X-ray-assisted, or other assisted chemical-vapour deposition (CVD) techniques, starting from suitable mixtures of gaseous hydrides containing germanium or silicon with hydrocarbons. It has been observed that the amount of Ge and C, or Si and C in the final solid is a function of the molar composition of the gaseous system, but it does not depend on it in a direct or predictable way. Therefore, it is very important to know which are the main processes taking place in the mixtures under examination, and which occur more rapidly, contributing to a larger extent to the growth of the polymer containing carbon bonded to germanium or silicon atoms. These results provide information on the relationship between the partial pressure of the gaseous reactants and the abundance of the corresponding elements in the solid material.

In previous studies, the mechanisms and kinetics of ionic reactions involved in radiolytically assisted CVD of volatile silicon and germanium hydrides in different mixtures (SiH_4/NH_3, SiH_4/PH_3, CH_3SiH_3/NH_3, CH_3SiH_3/PH_3, GeH_4/NH_3, GeH_4/PH_3, CH_3GeH_3/NH_3, CH_3GeH_3/PH_3) were determined by ion-trap mass spectrometry.[3] Germane or methylgermane/hydrocarbon mixtures, including GeH_4/allene and CH_3GeH_3/allene systems, were also studied by Fourier transform and chemical-ionisation mass spectrometry under different experimental conditions from the present work.[4] More recently, systems containing silane with propane or propene,[5] ethane or ethyne,[6] and ethene,[7] have been studied in an ion-trap instrument with the aim of investigating the formation of ion species containing Si–C bonds.

In this paper we report on the mechanisms of ion/molecule reactions in silane/allene and germane/allene mixtures studied by ion-trap mass spectrometry. Self-condensation processes in allene have also been investigated. The results are interesting both for fundamental and applied chemistry, as they give insights on pathways leading to the formation of silicon-carbon or germanium-carbon containing ions as possible precursors of amorphous silicon or germanium carbides.

The rate constants of the first steps of the chain propagation have been experimentally determined and compared with the collisional rate constants, calculated according to the Langevin theory.[8] A comparison can be also drawn on the gas-phase reactivity of germane and silane towards allene.

Results and Discussion

Tables 1–6 report experimental and collisional rate constants (Langevin theory) of the ion/molecule reactions taking place in the systems studied, and reaction efficiencies calculated as their ratio. When heats of formation were available,[9–17] enthalpies at 298 K were calculated to confirm the feasibility of the observed processes. The most

stable isomer for every species was considered in the calculations of the reaction enthalpies.

Allene Self-Condensation

The ion chemistry of allene has been previously studied by different mass spectrometric techniques.[18] Overall rate constants have been reported for reactions of the $C_3H_n^+$ (n = 1–4) ions with neutral allene,[18f] and are generally higher than those reported in the present paper (see Table 1). Such discrepancy is probably due to the different conditions of sample pressure at which the instruments operate, and to the presence of a buffer gas in the ion-trap mass spectrometric experiments, giving a lower population of excited ions with respect to other methods.

Ionisation of allene gives rise to the $C_3H_n^+$ (n = 1–4) and $C_2H_n^+$ (n = 2–4) ion families. Formation of $C_2H_3^+$ and $C_2H_4^+$ involves hydrogen migration before the fragmentation process. If stored for suitable periods of time, all the above-mentioned ions react with neutral allene to yield heavier ion species such as protonated allene ($C_3H_5^+$), $C_4H_n^+$ (n = 3–5), and $C_5H_5^+$ ions.

Many different reactions are observed (Table 1) taking place with elimination of different neutral moieties. Rather common paths involve loss of an ethyne molecule or, to a lesser extent, of an ethene molecule or a C_3H_3 fragment. Elimination of a hydrogen atom or molecule is also observed, but is limited to $C_3H_n^+$ (n = 2–5) and $C_4H_n^+$ (n = 4, 5) ions.

Efficiencies of reaction are rather high for all primary ions and protonated allene, except for $C_3H_3^+$, which reacts very slowly. Reactions of the $C_4H_n^+$ (n = 3–5) ion family show a lower efficiency, which further decreases for the stable $C_5H_5^+$ ion.

Germane/Allene Mixture

Table 2 reports the most significant ion/molecule reactions occurring in a germane/allene mixture. During ionisation, the GeH_n^+ (n = 0–3) ion family is formed, besides primary ions of allene as described above. The main reaction pathway shown by all the $C_2H_n^+$ (n = 2–4) ions, as well as C_3H^+, consists of charge transfer to GeH_4 with successive fragmentation to form ions of the GeH_n^+ (n = 0–3) family. It is worth noting that $GeCH_3^+$ ions are formed by almost all primary and secondary ions of allene, even if these processes are generally rather slow and only in two cases the reaction rate constants are in the 10^{-10} $cm^3molecule^{-1}s^{-1}$ order of magnitude. The exceptions are $C_3H_4^+$, $C_4H_4^+$, and

$C_5H_5^+$, which not only do not give the $GeCH_3^+$ product, but are unreactive towards germane.

Efficiencies of reaction of the primary $C_2H_n^+$ (n = 2–4) and $C_3H_n^+$ (n = 1–4) ion families decrease with increasing number of hydrogen atoms within the same family. Moreover, ions containing two carbon atoms are more efficient than the $C_3H_n^+$ species. Besides $GeCH_3^+$, which is unreactive under the experimental conditions used here, only two ion species, $GeC_2H_3^+$ and $GeC_3H_3^+$, contain Ge–C bonds and are interesting for the chain propagation towards germanium carbide. It is also worth noting that in previous studies on GeH_4/allene mixtures, performed by Fourier transform mass spectrometry, only these three Ge/C containing ions ($GeCH_3^+$, $GeC_2H_3^+$, and $GeC_3H_3^+$) were observed.[4a] Among the germane primary ions, GeH_3^+ is not included in the table as it is unreactive in the reaction times examined here. Germane self-condensation reactions are not reported as they have been already shown in previous papers.[3f,21] All reactions of GeH_n^+ (n = 0–2) ions with allene yield ion products containing germanium and carbon together. Again, $GeCH_3^+$, $GeC_2H_3^+$, and $GeC_3H_3^+$ ions are observed, together with $GeCH_2^+$ and $GeC_3H_5^+$, which are not formed from allene ions reacting with germane.

Unfortunately, mixed ions containing both Ge and C, as well as two-germanium containing ions, generally originate in very slow processes. It follows that, in the time range considered here, their abundance is too low to perform selective isolation with reproducible results. Moreover, as previously also observed in CH_3GeH_3/allene systems,[4b] in which $GeCH_3^+$ is a primary ion displaying a very high abundance, mixed Ge/C ions react very slowly and do not seem to be the precursors of higher order clusters. In particular, they do not react with germane in the reaction time considered, as all mixed ions show a unique germanium atom and up to six carbon atoms in high pressure chemical ionisation experiments.[4b]

However, as the main interest in these systems relies on the catenation of germanium and carbon atoms together to give mixed cluster ions of increasing size, experiments were carried out with isolation and reaction of the whole $Ge_2H_n^+$ (n = 2–4) ion family in the GeH_4/C_3H_4 ($4.7 \times 10^{-7}/1.9 \times 10^{-7}$ Torr) mixture. The mass spectra recorded immediately after the isolation (a), and after 0.5 s (b), 0.9 s (c), and 2 s (d) of reaction are reported in Figure 1. These data do not allow the calculation of the rate constants, nevertheless they give valuable information about $Ge_2H_n^+$ ions reactivity with allene.

At zero reaction time, signals in the mass spectra cover the range of m/z values due to $Ge_2H_2^+$, $Ge_2H_3^+$, and $Ge_2H_4^+$ germane secondary ions, the first one being the most abundant. Increase of the reaction time up to 2 s allowed us to detect several multiplets. Because of the low abundance of some signals, the identification of the number of hydrogen atoms contained in some of the ion species was not straightforward. Therefore, these ions are written with an 'x' as coefficient for hydrogen atoms. Anyway, it is interesting to note that with increasing reaction time the

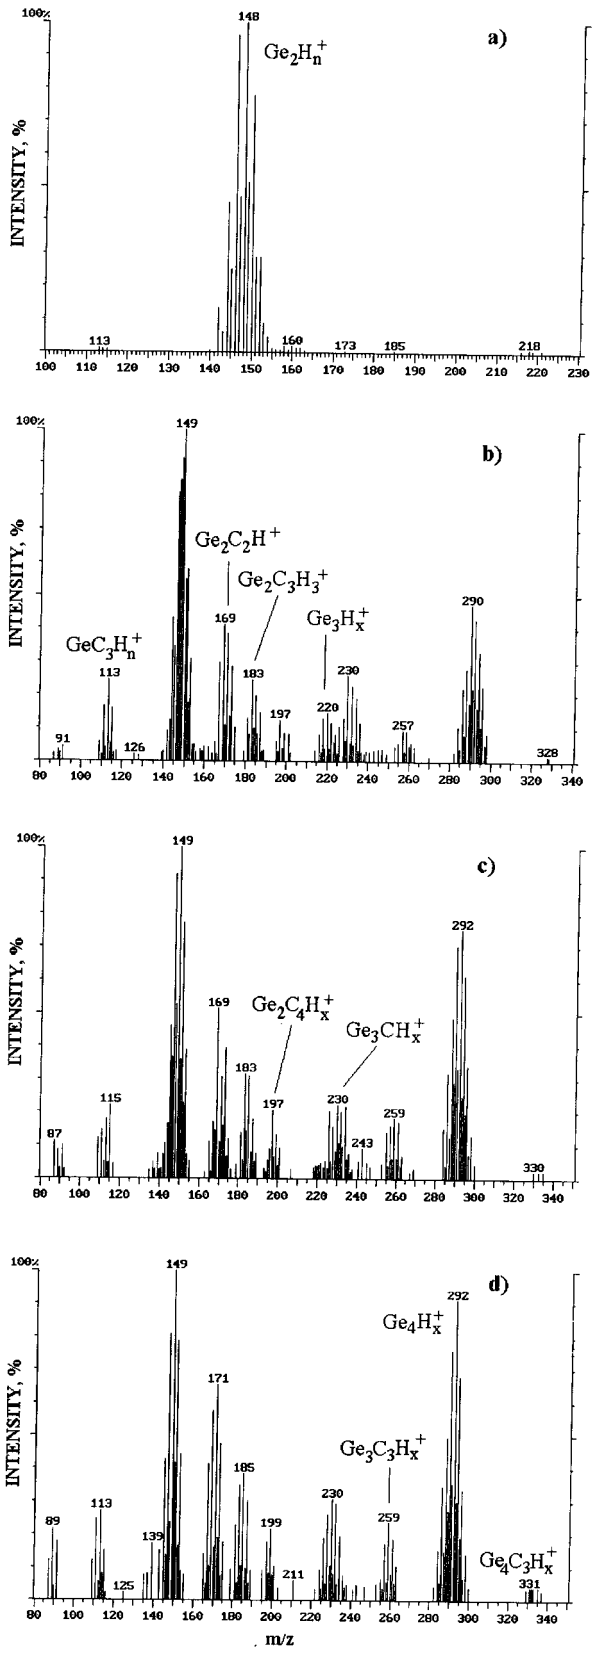

Figure 1. Mass spectra obtained after isolation of the $Ge_2H_n^+$ (n = 2–4) multiplet ions at 0 s (a), 0.5 s (b), 0.9 s (c), and 2 s (d) reaction times.

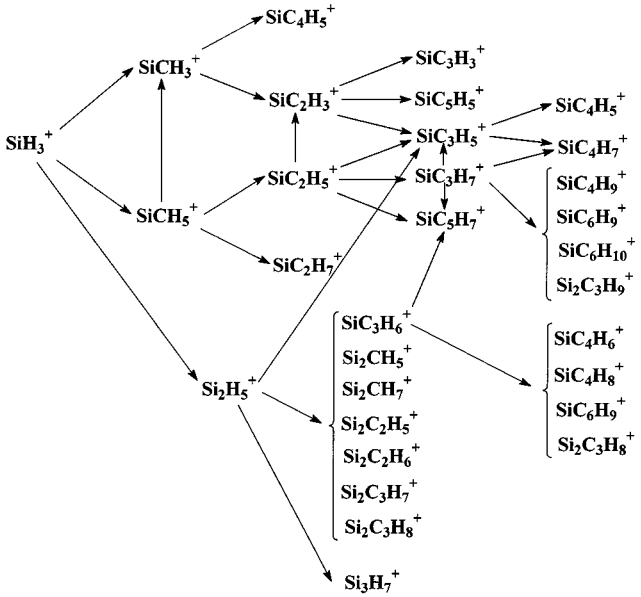

$Ge_2H_n^+$ multiplet reduces to the one corresponding to the $Ge_2H_3^+$ species only. It means that this ion is less reactive than the $Ge_2H_n^+$ (n = 2, 4) species, whose abundance decreases rapidly due to ion/molecule reactions occurring in the mixture. Therefore, the products observed are mainly formed from the $Ge_2H_2^+$ and $Ge_2H_4^+$ ion species reacting with allene, and in particular from $Ge_2H_2^+$, which is the most abundant ion at zero reaction time.

On the basis of the lower and upper limits and of the most intense signal of each multiplet in the spectra, $GeC_3H_n^+$ (n = 3–5), $Ge_2C_2H^+$, $Ge_2C_3H_3^+$, and $Ge_3H_x^+$ (x = 2 for the most abundant species in the multiplet) ion species are formed. Weak signals due to the $Ge_2C_4H_x^+$ (x = 5 for the most abundant species in the multiplet) ions are also observed. As it contains four carbon atoms, it cannot be directly formed from $Ge_2H_n^+$, but it can only originate from $Ge_2C_2H^+$ or $Ge_2C_3H_3^+$. After about 0.9 s reaction time, the signals due to the $Ge_3H_x^+$ ions almost disappear from the mass spectra, while the intensities of higher mass multiplets, assigned to the $Ge_3CH_x^+$ (x = 0 and 2 for the most abundant species in the multiplet), $Ge_3C_3H_x^+$ (x = 5 for the most abundant species in the multiplet), and $Ge_4H_x^+$ (x = 0 and 2 for the most abundant species in the multiplet) ion species, increase remarkably. If the reaction time is further increased, a weak multiplet due to the $Ge_4C_3H_x^+$ ions becomes detectable, the possible precursors being $Ge_3C_3H_x^+$ and $Ge_4H_x^+$ ions.

In separate and successive experiments, some of these ion families were in turn isolated and reacted, in order to determine their direct products. In particular, $Ge_2C_2H^+$ and $Ge_2C_3H_3^+$ ions were isolated together, and the main products of reaction observed after 2 s are $GeC_5H_x^+$ and $GeC_6H_x^+$. These ions were obtained by substitution of a Ge atom by two or three carbons. Moreover, small amounts of $Ge_2C_4H_x^+$ and $Ge_3H_x^+$ ions are also found. Isolation and reaction of the $Ge_3H_x^+$ ion family shows that it produces $Ge_3CH_x^+$ and $Ge_4H_x^+$ ions, but a partial contribution of other species, such as $Ge_2C_2H^+$ or $Ge_2C_3H_3^+$, cannot be ruled out. Finally, it was possible to isolate the $Ge_3CH_x^+$ multiplet, which leads to the formation of the $Ge_3C_3H_x^+$ ion species.

Silane/Allene Mixture

Three different mixtures were considered, which consist of silane and allene in the approximate ratios 1:5 ($1.8 \times 10^{-7}/8.5 \times 10^{-7}$ Torr), 1:1 ($5.0 \times 10^{-7}/4.6 \times 10^{-7}$ Torr), and 5:1 ($8.6 \times 10^{-7}/1.7 \times 10^{-7}$ Torr). Ionisation of the two reacting molecules again produces the allene primary ions and the SiH_n^+ (n = 0–3) ion species from silane. They are trapped in the cell of the mass spectrometer and react with both neutral species with increasing reaction times up to 2 seconds. During this time, several ion families are formed in successive reactions, and products that are obtained after four reaction steps are detected. As an example, Scheme 1 shows the paths of ion/molecule reactions starting from SiH_3^+ primary ion of silane, reacting with silane and allene neutral molecules.

Scheme 1. Paths of ion/molecule reactions starting from SiH_3^+ in a SiH_4/C_3H_4 mixture.

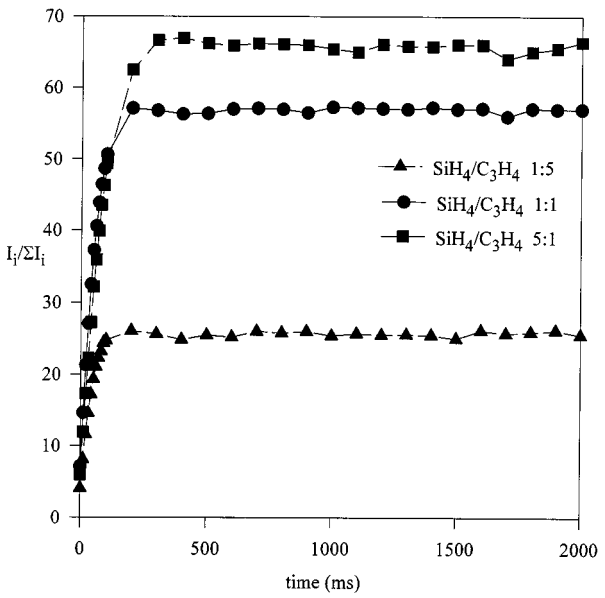

Figure 2. Variation of the total abundances of silicon and carbon containing ions as a function of reaction time for the 1:5, 1:1, and 5:1 silane/allene mixtures.

Figure 2 reports the variation of the total ion abundance of mixed ions as a function of reaction time for the three silane/allene mixtures. In all cases, the abundance rapidly increases to a maximum value, which remains constant up to two seconds of reaction. The highest yield is given by the SiH_4/C_3H_4 5:1 mixture, which is more than twice that of the 1:5 mixture. However, it is worth noting that the behaviour of the 1:1 silane/allene system is rather similar to that of the 5:1 one. Such a trend can be due to the involvement of allene as neutral reagent.

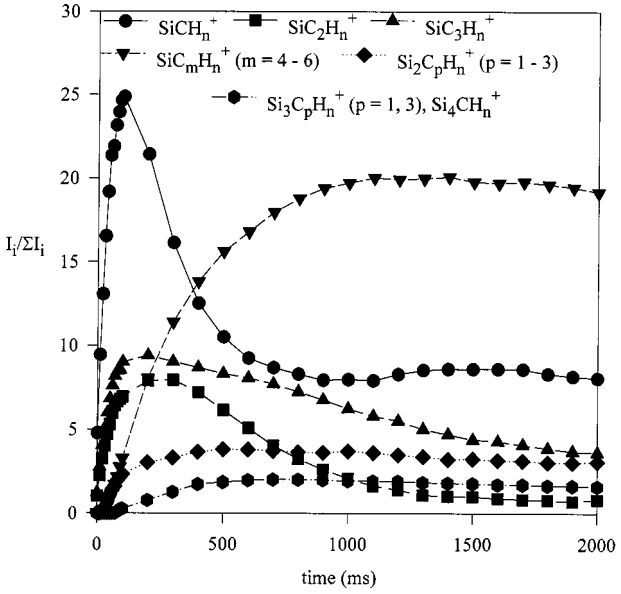

Figure 3. Variation of the abundances with reaction time of the $SiCH_n^+$, $SiC_2H_n^+$, $SiC_3H_n^+$, $SiC_mH_n^+$ (m = 4–6), $Si_2C_pH_n^+$ (p = 1–3), and $Si_3C_pH_n^+$ (p = 1, 3) with $Si_4CH_n^+$ ion families for the 1:1 silane/allene mixtures.

reason, Si^+ is not shown. Allene primary and secondary ions react with silane through different pathways, in which loss of small hydrocarbon molecules (C_2H_2, C_2H_4, C_3H_4), fragments (CH_3, C_2H_3), or H atom, with or without a molecule of hydrogen,occurs. Rate constants are generally low for all reaction paths considered. As observed for the germane/allene mixtures, efficiencies of reaction decrease with increasing number of hydrogen atoms in the families of primary $C_2H_n^+$ (n = 2, 3) and $C_3H_n^+$ (n = 1–4) ions.

Table 4 shows the ion/molecule reactions of the SiH_n^+ (n = 1–3) and $Si_2H_n^+$ (n = 2–5) ions with allene. Self-condensation reactions of silane are not reported, as already discussed in previous papers.[3a,21] Generally, many different products are detected and the reaction efficiencies are high. However, rate constants of single reactions are rather low and the high efficiencies are mainly due to the great number of pathways observed. The only two exceptions are the SiH^+ and SiH_3^+ ions, which yield $SiCH_3^+$with high rate constants, through loss of the stable neutrals, C_2H_2 and C_2H_4, respectively.

As a general remark, reactions with loss of hydrocarbon molecules are the most frequently observed paths. Addi-

Table 3. Reactions of $C_2H_n^+$, $C_3H_n^+$ and $C_4H_n^+$ ions with silane in a SiH_4/C_3H_4 mixture

[a] Rate constants are expressed as 10^{-10} $cm^3molecule^{-1}s^{-1}$; experiments were run at 333 K; uncertainty is within 20%. – [b] Rate constants have been calculated according to the Langevin theory taking polarizability of SiH_4 from ref.[20] – [c] Efficiency has been calculated as the ratio $\Sigma k_{exp}k_L$.

Variation of the abundances of the $SiCH_n^+$, $SiC_2H_n^+$, $SiC_3H_n^+$, $SiC_mH_n^+$ (m = 4–6), $Si_2C_pH_n^+$ (p = 1–3), and $Si_3C_pH_n^+$ (p = 1–3) together with $Si_4CH_n^+$ ion families are reported in Figure 3 for the 1:1 silane/allene mixture. The total abundance of ions formed in the first reaction step ($SiCH_n^+$, $SiC_2H_n^+$, and $SiC_3H_n^+$) reaches a maximum value after about 100–200 ms of reaction, and then decreases to a rather constant value.

The other ion species show a slower increase, which is as high as 20% for the $SiC_mH_n^+$ ion family, whereas ions produced in successive reaction steps never exceed 4%. However, it is remarkable that the abundance of each ion family examined here does not change substantially after 1 s of reaction.

The rate constants of ion/molecule reactions occurring in the silane/allene system are displayed in tables 3–6. In Table 3, reactions of the $C_2H_n^+$ (n = 2, 3), $C_3H_n^+$ (n = 1–5), and $C_4H_n^+$ (n = 3, 4) ions with silane are listed. The $C_2H_4^+$ ion is not reported, as it has the same nominal mass of the Si^+ species formed from silane, and no experiment was possible that allowed its selection alone. For the same tions of C_3H_4 and losses of an atom of hydrogen together, or without a molecule of hydrogen are very frequent processes too, with rate constants that are generally lower than the previous ones. Every $Si_2H_n^+$ (n = 2–5) ion shows at least one process characterised by substitution of a neutral fragment containing only silicon and hydrogen by a moiety originating from allene. In fact, loss of a silyl radical is displayed by all the $Si_2H_n^+$ (n = 2–5) ions, except $Si_2H_3^+$, which loses a silylene group. The $Si_2H_n^+$ (n = 4, 5) ions also undergo substitution of a silane by an allene molecule.

In order to follow the growth of ions containing silicon and carbon already bonded together, reactions of the $SiCH_n^+$ (n = 2–5) ion family with both allene and silane are reported in Table 5. As already noticed for ions containing only silicon and hydrogen, reactions of the $SiCH_n^+$ (n = 2–5) species with allene proceed through loss of various neutral molecules (H_2, CH_4, C_2H_2, C_2H_4, and C_3H_6) or by elimination of a variety of hydrocarbon fragments or hydrogen atoms. In contrast, the reactivity of this ion family towards silane is remarkably low, as only $SiCH_2^+$ and $SiCH_4^+$ react

Table 4. Reactions of SiH_n^+ and $Si_2H_n^+$ ions with allene in a SiH_4/C_3H_4 mixture

with SiH_4 through loss of a hydrogen molecule with rather low rate constants.

The reaction of $SiCH_4^+$ to give $SiCH_5^+$ is an hydrogenation process which can involve both silane and allene as neutral reagent. Similarly, ions at nominal mass 58 and 59, could be formed by $SiCH_4^+$ reacting with both silane[5] ($Si_2H_2^+$ and $Si_2H_3^+$) and allene ($SiC_2H_6^+$ and $SiC_2H_7^+$). The hydrogenation process was observed in the SiH_4/C_3H_6 system previously studied,[5] and the use of a pulsed valve allowed us to state that both neutrals react with $SiCH_4^+$ to give $SiCH_5^+$. The procedure was repeated in this SiH_4/C_3H_4 system, isolating and reacting $SiCH_4^+$ in experiments with allene at a constant pressure and pulsing silane into the trap. In this way, it was found that the $SiCH_5^+$ ion is formed from $SiCH_4^+$ and allene, as well as $SiC_2H_6^+$ and $SiC_2H_7^+$ and the corresponding formation rate constants were calculated.

The propagation of the processes leading to cluster ions of increasing size was further studied and results are reported in Table 6. In this table, the reactions of the $Si_3H_5^+$,

$Si_4H_7^+$, $SiC_2H_n^+$ (n = 3, 5) and $SiC_3H_n^+$ (n = 5–7) ions with allene are shown, together with rate constants of reactions of $SiC_3H_n^+$ (n = 6, 7) with silane.

The $Si_3H_5^+$ and $Si_4H_7^+$ ions were chosen as an example of the behavior of tertiary and quaternary silane ions, as they are the most abundant within their corresponding families. Hence, it was possible to isolate and select them. Also the reactivity of the $Si_3H_4^+$ ion was studied, which reacts very slowly to give the $Si_3CH_4^+$ and $Si_3CH_8^+$ products. Unfortunately their abundance was too low to allow the determination of their formation rate constants. The $Si_3H_5^+$ and $Si_4H_7^+$ ions show a very similar behaviour towards allene.

The $SiC_2H_n^+$ (n = 3, 5) ions react only with allene with loss of hydrocarbon and H_2 molecules with rather low rate constants. A similar behaviour is displayed by the $SiC_3H_n^+$ (n = 5–7) ions. Within this family, the number of reactions with allene and the reaction efficiencies increase with increasing number of hydrogen atoms in the reacting ion. Only the $SiC_3H_n^+$ (n = 6, 7) ions react with silane and yield the large clusters $Si_2C_3H_{n+2}^+$ via loss of a hydrogen molecule characterised by low rate constants.

The present results may be compared with those obtained in the SiH_4/C_3H_8 and SiH_4/C_3H_6 systems previously studied.[5] The reactivity of the SiH_4/C_3H_8 system was found to be remarkably low, and hence the comparison may be limited to the SiH_4/C_3H_6 and SiH_4/C_3H_4 mixtures. Silane primary ions show a similar behaviour towards propene and allene. In fact, reaction efficiencies are quite high and the most favourable neutral losses are almost the same in the two systems. However, when allene is the neutral reagent, the number of different reaction paths is high. In contrast, reactions of the SiH_n^+ (n = 1–3) ions with propene proceed through a lower number of paths, but generally with higher rates. A similar trend is displayed by the $Si_2H_n^+$ (n = 2–5) ions in the comparison of the two systems. Because of the several different processes starting from silane ions, the number of Si, C, and H containing ion species formed in the SiH_4/C_3H_4 system is higher than in the SiH_4/C_3H_6 one. Among these, some ions are common to the two systems: $SiCH_n^+$ (n = 4, 5), $SiC_2H_5^+$ and $SiC_3H_7^+$. Their reactivity towards silane is supposed to be the same; nevertheless, reactions of $SiCH_5^+$ and $SiC_2H_5^+$ ions could not be studied in the SiH_4/C_3H_4 system, the reason being the lower abundance of the reacting ions in the SiH_4/C_3H_4 mixture. In fact, $SiCH_5^+$ is formed through fewer processes and with lower rate constants in the presence of allene than with propene. $SiC_2H_5^+$ has a higher number of precursors in the SiH_4/C_3H_4 system, but formation rate constants are remarkably low. Mixed ions, containing silicon, carbon and hydrogen, that are present in both the systems react with comparable efficiencies with allene and propene, the number of reaction paths being higher in the silane/allene mixture as already observed for silane ions. Finally, several hydrocarbon ions are common to the two mixtures: $C_2H_3^+$, $C_3H_n^+$ (n = 1–5), rate constants of their reactions with silane being in good agreement among the two systems.

Conclusions

In the comparison of the two mixtures studied in this paper, the great difference of reactivity between silane and germane towards allene is remarkable. In fact, neutral germane as well as ions originated by its ionisation are considerably less reactive than the corresponding silicon containing species. Primary and secondary ions of silane react with allene through many different paths and with appreciable reaction efficiencies to yield mixed ion clusters of growing size, such as $Si_4C_3H_7^+$ or $SiC_6H_{10}^+$. In contrast, germane primary ions react with allene to give only one product for each ion, the only exception being GeH_2^+ which gives several mixed ions but with low rate constants. Moreover, the distribution of the signal due to an ion species containing two Ge atoms and the consequent overlapping of different multiplets make the single selection procedures difficult. Anyway, the isolation of the whole $Ge_2H_n^+$ (n = 2–4) ion family and its reaction (with reaction times as long as 2 s) allowed the detection of mixed clusters, up to $Ge_4C_3H_x^+$ ions, although in low abundance.

Hydrocarbon ions, formed in self-condensation processes of allene, mainly reacted with germane by charge-exchange processes to give ion products containing Ge and H only, together with a few mixed ion clusters. To the contrary, allene ions react with silane to yield a great number of different products containing Si, C, and H atoms. These ion species react further, preferentially with allene, in successive steps, to give large clusters with increasing number of carbon atoms.

Finally, it appears clear that the cationic mechanism does not give a high contribution to the growth of materials, starting from gaseous mixtures in the GeH_4/C_3H_4 system, while it is more efficient in the SiH_4/C_3H_4 one. Moreover, in the silane/allene mixture, the largest cluster ions are generally formed in reactions of silicon containing ions with allene and the highest yield are observed in mixtures containing silane in excess.

Experimental Section

Allene and silane were commercially supplied in high purity and germane was prepared and purified as described in the literature.[22] Prior to use, each of the reagent gases was dried by means of anhydrous sodium sulfate. Helium was supplied at an extra-high degree of purity, and no further purification was necessary. The experiments were performed on a ITMS Finnigan mass spectrometer and the pressure was measured by a Bayard Alpert ionisation gauge. The read pressures were corrected for the relative sensitivity of the ion gauge with respect to different gases[23,24] and for a calibration factor, calculated as previously reported,[21] in order to get the real pressure in the trap. Helium buffer gas was admitted to the trap at a pressure of about 4×10^{-4} Torr (1 Torr = 133 Pa), and allene, germane and silane at pressures in the 2.0×10^{-7}–10.0×10^{-7} Torr range. The trap temperature was 333 K in order to avoid thermal decomposition of reagents and to obtain results comparable with systems studied previously. In all experiments, ions were detected in the mass range of 14–400 u . In order to prevent side

reactions with water background, the manifold and the lines for introduction of reagent gases and helium were frequently baked-out.

The scan modes used to isolate selected ion species or ranges of ions for the determination of reaction mechanisms and rate constants, as well as the procedures for calculations, were previously described in detail.[3,21,25] Ionic species that were selectively isolated from silane contained the ^{28}Si isotope, whereas those isolated from germane contained the ^{70}Ge (Ge^+, GeH^+) or ^{76}Ge (GeH_2^+, GeH_3^+) isotope. Selection of ions at a specific *m*/*z* value was performed by using dc voltages and by resonance ejection, as in previous studies.[25] The latter method, applying rf voltages only, is expected to cause a lower excitation of the selected ions with respect to the method in which a dc voltage is used. The rate constants obtained with the two different methods were very similar and this behaviour is consistent with the hypothesis that ions are thermalized by unreactive collisions with the buffer gas. The single exponential decays of the abundance of the reacting ions observed in the kinetic experiments further confirm this hypothesis.

Formation of ions was obtained with an electron beam at about 35 eV for ionisation times in the range 1–20 ms. A reaction time suitable to maximise the abundance of ions to be stored was applied after the ionisation event. Isolation of the selected ions, their reactions with neutrals present in the trap for convenient reaction times (50 ms for rate constants calculation and up to 2 s for mechanisms determination) and acquisition were the successive steps.

In the silane/allene mixture, where Si is isobaric with C_2H_4, some experiments were performed by introducing one reagent gas via a pulsed valve in order to determine the neutral species involved in the ion/molecule reaction under examination and, as a consequence, the composition of the product ion. A General Valve Corporation's Iota One pulse valve was used,[26] and the experimental procedures have been already described.[4] Briefly, the introduction into the ion trap of one of the reactants through a pulsed valve allows us to react selected ions with only the other gas which is continuously leaked into the trap. The pressure of the gas to be pulsed was set behind the valve to about 1×10^{-6} Torr, the valve opening time was 0.1 ms and the time required for the pressure of the pulsed gas to decrease to zero was about 1.5 s.

Multinuclear 1D and 2D NMR Investigations on the Interaction between the Pyrimidic Nucleotides 5'-CMP, 5'-dCMP, and 5'-UMP and Diethyltin Dichloride in Aqueous Medium

Laurent Ghys,[a,b] Monique Biesemans,[b,c] Marcel Gielen,[c] Achilleas Garoufis,[d] Nick Hadjiliadis,[e] Rudolph Willem,*[b,c] José C. Martins[b]

Keywords: Tin / Nucleotides / NMR spectrometry / Mass spectroscopy

The interactions between diethyltin dichloride and 5′-CMP, 5′-dCMP, and 5′-UMP in aqueous solution were investigated by multinuclear 1D and 2D NMR techniques including ^{119}Sn, ^{15}N and ^{31}P nuclei. These studies were combined with electrospray mass spectrometry, infrared spectroscopy, solid state ^{13}C, ^{31}P and ^{117}Sn CP-MAS NMR, and elemental analysis. As demonstrated by ^{31}P-^{1}H HOESY spectroscopy, the diethyltin moiety interacts with the phosphate group of the pyrimidic mononucleotides in the pH range 0.5–3.5. Compound **8** (X = Cl), the solid isolated in this pH range from 5′-CMP, contains two tin atoms bridged by one oxygen and one chlorine atom, each tin atom being linked to the phosphate group of a nucleotide moiety. For 5′-UMP the solid isolated (**12**) has a dimeric structure with two different tin atoms; it can be formed by dimerization of compound **11** with the elimination of two water molecules. As demonstrated by ^{1}H-^{119}Sn HMQC correlation NMR data and the $^{2}J(^{119}\text{Sn–O–}^{117}\text{Sn})$ coupling constant of 156 Hz, the diethyltin moiety reacts with the O(2′) and O(3′) oxygen atoms of the nucleotides to form a dimeric diethyldioxastannolane at pH > 9.0. Between pH 5.0 and 9.0, no evidence for any interaction between the diethyltin moiety and the nucleotides was found.

Introduction

Many organometallic compounds exhibit interesting antitumoural activity against several human cancer cell lines.[1] The well-known complex cisplatin, $Pt(NH_3)_2Cl_2$, clinically used in cancer chemotherapy, proved to interact mainly with the N7 atoms of two adjacent guanines in the same DNA strand.[2–5] For several years, we have been interested in the synthesis and characterisation of organotin complexes which, in some cases, display higher antitumour activities in vitro than cisplatin.[6] In contrast to platinum compounds, very little is known about the origin of the antitumoural activity of organotin compounds although, as for cisplatin, DNA was proposed to be the target.[7] Some work has already been performed on the interactions between organotins and DNA or its precursors. Barbieri et al. have investigated the solid resulting from the reaction of ethanolic organotins [$SnR_2Cl_2(EtOH)_2$ and $SnR_3Cl(EtOH)$] with aqueous DNA or mononucleotide solutions. However, only ^{119}Sn Mössbauer spectroscopy was used.[8–10] The condensate was assumed to be a diorganotin species interacting with two vicinal phosphate groups of DNA. Li et al. have investigated the interaction of $(C_2H_5)_2SnCl_2$(phen) (phen = phenanthroline) with 5'-dGMP in aqueous medium using [*trans*-$en_2Os(\eta\text{-}H_2)](CF_3SO_3)_2$, a versatile ^{1}H NMR probe. They also studied solid mixtures of the same diethyltin dichloride complex with 5'-AMP, 5'-CMP, and 5'-GMP dissolved in DMSO, using ^{1}H and ^{31}P NMR and UV spectroscopy.[11a] More recently, Hadjiliadis et al.[11b] studied the interaction of the purine nucleotides 5'-IMP and 5'-GMP with Et_2SnCl_2 using various techniques, including ^{1}H, ^{13}C and ^{31}P 1D NMR and Mössbauer spectroscopy. Finally, a very recent paper described the investigation of the interaction between dimethyltin dichloride and 5'-GMP, 5'-ATP and 5'-$d(CGCGCG)_2$ by potentiometric titrations and ^{1}H and ^{31}P NMR spectroscopy.[11c] All these authors concluded that the organotin moiety reacts with the phosphate group of the nucleotides. However, these interactions have not been investigated further using spectroscopic techniques that provide more detailed structural data, such as ^{119}Sn NMR spectroscopy. Potentially, this technique is an ideal tool of investigation, comparable to ^{195}Pt NMR spectroscopy for platinum compounds.[12]

This study investigates the interaction between a diorganotin dichloride, Et_2SnCl_2, and pyrimidic nucleic acid precursors within a wide pH range in aqueous medium. The three mononucleotides investigated, cytidine-5'-monophosphate (5'-CMP), 2'-deoxycytidine-5'-monophosphate (5'-dCMP) and uridine-5'-monophosphate (5'-UMP), were selected on the basis of their increased solubility when they are complexed to tin (Figure 1).

First, we monitored the ^{31}P chemical shift of the mononucleotides in aqueous solution as a function of pH in the presence or absence of diethyltin dichloride and the ^{119}Sn chemical shift of a mixture of the latter with the mononu-

cleotides. The differences in ^{31}P chemical shift titration profiles are used as indicators for an interaction between diethyltin dichloride and the mononucleotides. Subsequently, the structural features of the interaction are characterised by 1D and 2D NMR correlation techniques involving ^{1}H, ^{13}C, ^{15}N, ^{31}P and ^{119}Sn nuclei, completed by ^{35}Cl NMR data where appropriate. Proton detected ^{1}H-^{119}Sn HMQC[13–15] and phosphorus detected ^{31}P-^{1}H HOESY[16,17] have been reported to be very efficient for the characterisation of organotin complexes in solution.[18] Whenever precipitation occurs, the solid is isolated and characterised by solid state ^{13}C, ^{31}P, and ^{117}Sn CP-MAS NMR and IR spectroscopy as well as elemental analysis. None of the solids isolated provided crystals suitable for X-ray diffraction analysis.

Results and Discussion

Aqueous Chemistry of Diethyltin Dichloride

Figure 2 shows the different intermediates (in their monomeric form, for convenience) generated upon hydrolysis of Et_2SnCl_2 as mentioned in the literature.[19–21] The NMR data collected during this preliminary investigation are suitable references for the interpretation of data obtained in the presence of nucleotides.

441	**2** + H^+
277	$[Et_2SnCl(CH_3OH)_2]^+$
245	$[Et_2SnCl(CH_3OH)]^+$

Table 2. Experimental elemental analysis data for the solid compound isolated from an aqueous solution of Et_2SnCl_2 at pH 2.8 as well as calculated data for the proposed structure

	%C	%H	%Cl	%Sn
Et_2SnCl_2 isolated at pH 2.8	21.8	4.3	14.0	52.2
$[ClEt_2SnOSnEt_2Cl]$ (**2**)	21.8	4.6	16.1	53.9

The pH of a 0.5 M aqueous solution of Et_2SnCl_2 is ca. 2.2. A precipitate is generated when the pH of the supernatant is raised above 2.2 with aqueous NaOH. Below pH 2.2, a clear solution is observed. An electrospray mass spectrum of a mixture obtained by adding methanol to an aqueous solution of Et_2SnCl_2 (pH 2.2) with a final MeOH/H_2O ratio of 90/10 reveals two species. On the basis of data from Dakternieks et al.[22a] these species can be assigned to compounds **5** and **2** (Table 1). The fragment detected at *m/z* 441 in the electrospray mass spectrum is the protonated form of intermediate **2** (Figure 2).

The other fragment ions correspond to $[Et_2SnCl]^+$ solvated by one or two methanol molecules or to hydrated **5** (Table 1). These results clearly indicate that in solution at pH 2.2 only one chloride anion dissociates from diethyltin dichloride.

The precipitate obtained at pH 2.8 was isolated. Its elemental analysis data (Table 2) indicate that it basically corresponds to compound **2**, probably contaminated by **3**, considering the slight chlorine deficit.

The ^{117}Sn NMR spectrum of this sample in $CDCl_3$ at 89.150 MHz displays eight resonances between $\delta = -87$ and $\delta = -182$. They can be divided into two pairs of equally intense resonances **B** and **C** and one set of four equally intense resonances **A**. Set **B** ($\delta = -91.7$ and -139.9) displays one pair of satellites with a coupling of 67 Hz. It is assigned to intermediate **2** which is described by Otera[22b] as a dimer for R = Me, Et and Bu with similar ^{119}Sn parameters for R = Et:[22b] $\delta(^{119}Sn1) = -140.6$; $\delta(^{119}Sn2) = -91.8$; $^{2}J(^{119}Sn–O–^{117/119}Sn) = 73$ Hz. Set **C** ($\delta = -157.0$ and -176.2) displays at least one pair of $^{2}J(^{117}Sn–O–^{117/119}Sn)$ satellites with a coupling of 212 Hz, others being unclear due to a low signal-to-noise ratio. The ^{117}Sn resonances of

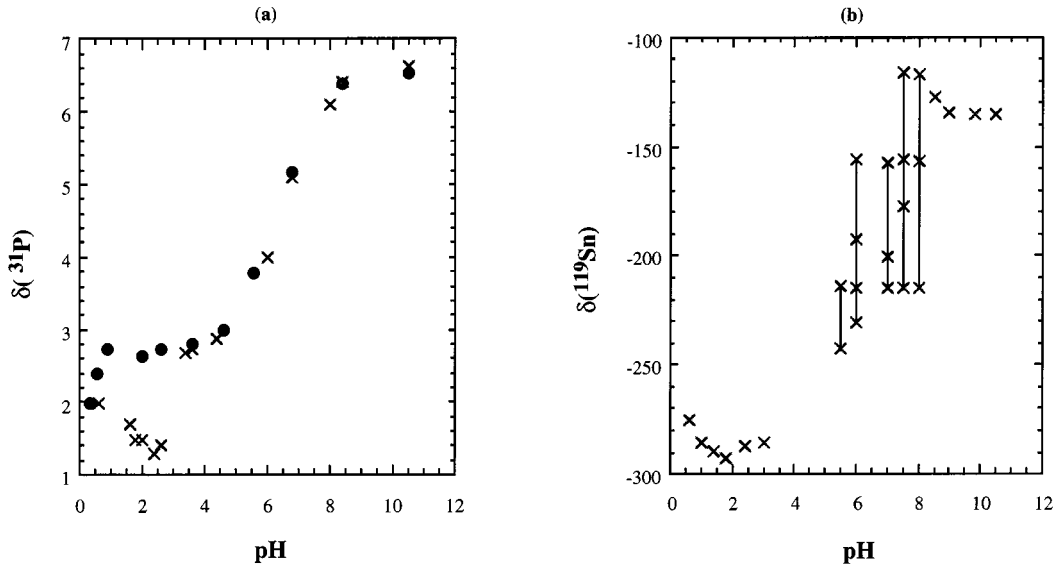

Figure 3. (a) ^{31}P NMR titration curve of 5'-CMP and a mixture of 5'-CMP and Et_2SnCl_2; full circles represent free 5'-CMP; crosses correspond to 5'-CMP/Et_2SnCl_2; (b) ^{119}Sn NMR titration curve for 5'-CMP/Et_2SnCl_2; multiple points related by straight lines for a given pH value account for the presence of multiple resonances

set **A** (δ = –87.9, –130.9, –151.8, and –181.8) display a pair of signals with a coupling constant of 98 Hz and another pair with a coupling constant of 175 Hz. Although the species generating **A** and **C** cannot be identified, these NMR data point to a mixture of intermediates including **3** and **4**, possibly aggregated to various degrees during hydrolysis of Et_2SnCl_2 depicted in Figure 2.

Interactions of Diethyltin Dichloride with the Nucleotides in Acidic Medium

Above pH 2.2, precipitation occurs from the solutions of the three 2:1 mixtures of 5'-CMP/Et_2SnCl_2, 5'-dCMP/Et_2SnCl_2, and 5'-UMP/Et_2SnCl_2. Consequently, samples for NMR experiments in solution are obtained from the supernatant of this precipitate. Because in acidic medium the three nucleotides behaved similarly in the presence of Et_2SnCl_2, only the mixture 5'-CMP/Et_2SnCl_2 is discussed in detail.

In the pH range 0.5–3.5, the addition of 0.5 equivalent of diethyltin dichloride to 5'-CMP, 5'-dCMP and 5'-UMP causes the ^{31}P resonance of the phosphate group of the nucleotides to shift to lower frequencies, with the maximum change in chemical shift in the pH range 2.0–2.5. The titration curve of the ^{31}P chemical shift is displayed in Figure 3a for 5'-CMP and 5'-CMP/Et_2SnCl_2.

This ^{31}P chemical shift modification can be traced back to an interaction of diethyltin dichloride with the phosphate group of the three nucleotides. ^{1}H-^{119}Sn, ^{1}H-^{31}P, ^{31}P-^{119}Sn, and ^{13}C-^{31}P HMQC experiments[23,24] performed on 5'-CMP/Et_2SnCl_2 at pH 2.2 failed to show any correlation peaks between the resonances of the organotin moiety and those of 5'-CMP. However, this does not formally exclude the interaction between diethyltin dichloride and the phosphate group of 5'-CMP. Indeed, the coupling can be very small or even nonexistent and undetectable depending on the bond strength.[25] The ^{31}P-^{1}H HOESY (^{31}P detected Heteronuclear Overhauser Spectroscopy) technique[16–18] which correlates nuclei through dipolar couplings was previously used by Barnham et al.[26] to characterise the Pt–NH···5'-phosphate intermolecular interaction in the complex [Pt(en)(5'-GMP–N7)$_2$]·9H_2O. This technique provided a 2D spectrum of 5'-CMP/Et_2SnCl_2 at pH 2.2 with four ^{31}P-^{1}H NOE cross-peaks, two from the CH_2 and CH_3 protons of diethyltin dichloride and two from the H5' and H6 protons of 5'-CMP. Similar results were obtained for the mixtures of the two other nucleotides with Et_2SnCl_2, i.e. 5'-dCMP/Et_2SnCl_2 and 5'-UMP/Et_2SnCl_2 at pH 2.2. With the ratio ($\gamma^1H/\gamma^{31}P$) > 2.38 in mind, the distances between the ethyl protons and the phosphorus atom of the three nucleotides cannot exceed 4 Å, proving that the tin moiety interacts with the phosphate group of the nucleotide. ^{31}P-^{1}H-NOE's are always positive, irrespective of the correlation time.[27] Hence, weak or missing NOE's cannot be assigned to a zero cross point of the NOE effect. The observed cross peak between the H6 proton and the ^{31}P nucleus of 5'-CMP, 5'-dCMP, and 5'-UMP arises from the *anti* conformation of the base relative to the sugar unit which is also known for free 5'-GMP.[28]

As assessed by the ^{119}Sn chemical shifts and the $^{1}J(^{13}C$–$^{119}Sn)$ values,[29,30] the tin atom is six-coordinated in all three mixtures, i.e. 5'-CMP/Et_2SnCl_2, 5'-dCMP/Et_2SnCl_2, and 5'-UMP/Et_2SnCl_2 at pH 2.2 (Table 3). Empirical correlations between C–Sn–C angles and coupling constants involving the ^{119}Sn nucleus[31] (Table 3) provide C–Sn–C angle values typically ranging from 150° to 170°, which are in agreement with distorted *trans*-octahedral, six-coordinate geometries at the tin atom.

As shown by ^{13}C, ^{31}P, and ^{117}Sn CP-MAS NMR, the solid isolated from the mixture 5'-CMP/Et_2SnCl_2 (2:1) at pH 2.2 contains both Et_2Sn and 5'-CMP moieties. The ^{31}P CP-MAS NMR spectrum exhibits 5'–CMP two resonances at δ = –11 and δ = –12 which are low frequency shifted

with respect to the single one in solution at ca. $\delta = 1$. The assignment of the resonances in the ^{13}C CP-MAS spectrum is made by comparison with the solution ^{13}C chemical shifts of 5'-CMP/Et_2SnCl_2 at pH 2.2. In solution, ^{1}H-^{13}C HMBC and HMQC[23,24,32] spectra allowed the assignment of the ^{13}C and ^{1}H resonances that is further supported by literature data.[33]

Table 4 shows that some of the solid state ^{13}C resonances are duplicated, one is even triplicated; this is a result of the nucleotide moieties being nonequivalent, possibly because of chirality, packing effects, and/or polymorphism. The ^{13}C chemical shifts of the tin ethyl CH_2 group, the pyrimidic and the C5' carbons deviate most from those in the liquid state. For the pyrimidic carbons, this variation can be explained by a different H-bonding network in the solid state, as previously seen for several nucleotides by IR spectroscopy.[34] The ^{117}Sn NMR CP-MAS spectrum exhibits a single isotropic shift at $\delta = –274$ in the range typical for six-coordinate tin atoms in solution. These CP-MAS NMR data, combined with the solution NMR data, suggest that the tin environments in the solid and solution states are similar.

The vibrational data (Table 5) account exclusively for the existence of a tin–phosphate interaction, the ring vibration frequencies not being affected by the addition of Et_2SnCl_2. As suggested above for the variation of the pyrimidic ^{13}C chemical shifts, the shift of the ν(C(2)=O) frequency [$\Delta\nu$ = ν(5'-CMP/Et_2SnCl_2) – ν(5'-CMPNa_2) = 23 cm^{-1}] can be explained by different H-bonding networks.[34] The Raman spectrum displays two characteristic bands at 434 and 568 cm^{-1} that were tentatively assigned to the $\tilde{\nu}$(Sn–O–P) and $\tilde{\nu}$(Sn–O–Sn) vibration frequencies, respectively.[35–37]

On the basis of all previous data, four tin–phosphate complexes (Figure 4) are conceivable for the solid-state structure obtained from mixing 5'-CMP and Et_2SnCl_2. Unexpectedly, elemental analysis data from samples of the complex depend on the acid (HCl or HBr) used for the adjustment of the pH of the supernatant from which this solid precipitates; nevertheless, these data are self-consistent and reproducible (Table 6). With HCl, the chlorine detected originates not only from Et_2SnCl_2 but also, and even predominantly, from the excess HCl. However, chlorine is also detected when HBr is used in excess. In the latter case, the solid analysed contains two complexes, one only with bromine (ca. 80%) and one only with chlorine (ca. 20%). Structures **6**, **7** (X = Cl, OH), as well as structure **9** (X = OH) (Figure 4) can easily be rejected on the basis of the chlorine elemental analysis. Structure **8** (X = Cl) is favoured over structure **9** (X = Cl) because the calculated carbon and tin elemental data match the experimental data better for the former than for the latter (Table 6). A thermogravimetric analysis of the solid detects a weight loss of ca. 7% up to 170 °C, prior to a more substantial and continuous loss above 190 °C. The initial low weight loss is compatible with the expected loss of one equivalent of HCl and two equivalents of water, an observation which again matches structure **8** better than **9** (X = Cl). Structure **8** is proposed as a hydrochloric salt with a Sn–Cl–Sn bridge, which is known for various organotin oxides,[38,39] and a hydrogen bond between the chloride anion and the oxygen bridging the two

Table 5. IR data of free 5'-CMP and 5'-UMP as well as IR and Raman (*) data of the mixtures 5'-CMP/Et_2SnCl_2 and 5'-UMP/Et_2SnCl_2 in the solid state in KBr pellets (cm^{-1})

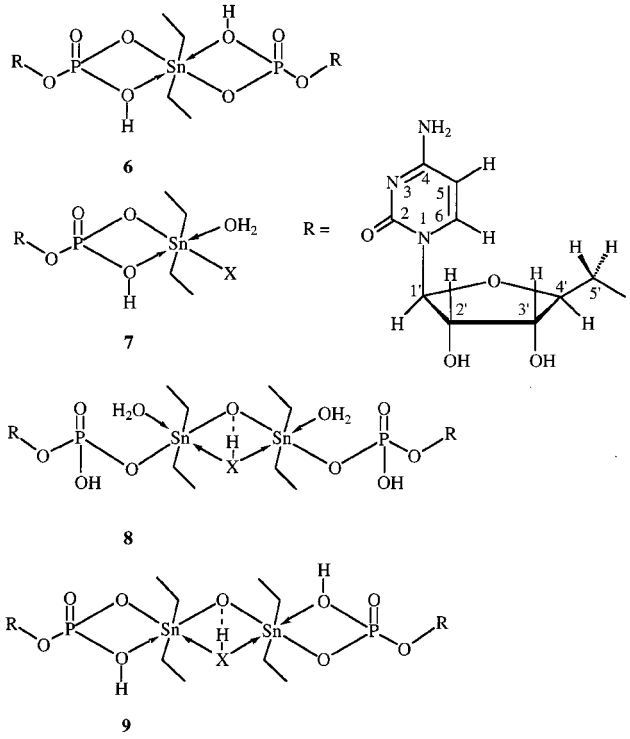

Figure 4. Potential structures for the solid isolated from the mixture 5'-CMP/Et_2SnCl_2 at pH 2.2 and assessed against the data (X = OH, Cl, or Br)

tin atoms. When prepared from the HBr solution, the compounds appear to be of type **8** with X being either Cl or Br.

As supported by similar ^{13}C and $^{117/119}Sn$ CP-MAS and solution NMR data, the environments of the tin atom in solution and in the solid state are proposed to be similar for 5'-CMP/Et_2SnCl_2. Thus, the structure of the complex in solution should be closely related to structure **8** (X = Cl), even if some differences between the solution and solid state ^{31}P and ^{13}C chemical shifts of the CH_2 group suggest local structure differences, possibly due to different H-bridge network or packing effects.

The ^{35}Cl solution NMR data of the supernatant shed some further, albeit indirect light on this proposal. It is well-known that the ^{35}Cl NMR signal of the chloride anion is very sharp and displays a chemical shift around $\delta = 0$.[40] In contrast, covalently bound chlorine generally fails to provide a useful ^{35}Cl signal since it is smeared out in the noise. The supernatant of the solid with proposed structure **8** falls into the latter category. Provided that **8** has identical structures in the supernatant and the solid, this structure implies that one chloride ion has been split off from the initial Et_2SnCl_2, while the second is covalently bound. The absence of any visible ^{35}Cl resonance in a solution of **8** implies the presence of covalently bound chlorine (as indicated by elemental analysis), necessarily being in fast exchange with the ionic chloride which must also be present.

Mixtures of Et_2SnCl_2 with the nonphosphorylated analogue of 5'-CMP, cytosine, also give rise to precipitates at pH 2–5; this occurs to an even larger extent than for 5'-CMP/Et_2SnCl_2. Indeed, the ^1H NMR spectra of the supernatants show that only small amounts of compounds containing a diethyltin moiety are present in solution, as assessed from a comparison of the integrations of the H6 and Et_2Sn protons. The precipitate was isolated; its ^{13}C CP-MAS NMR spectrum presents only ^{13}C resonances from the diethyltin moieties and none from the nucleobase. The ^{117}Sn CP-MAS NMR spectrum of the cytosine-derived

Table 7. Experimental elemental analysis data for the solid compound isolated from cytosine/Et_2SnCl_2 at pH 2.2 as well as calculated data for the proposed structure

	%C	%H	%Cl
cytosine/Et_2SnCl_2	23.1	5.0	8.4
$[(OH)Et_2SnOSnEt_2Cl]$	22.8	5.0	8.4

sample displays two isotropic ^{117}Sn chemical shifts of comparable intensities at $\delta = -164$ and $\delta = -178$. In agreement with this, the elemental analysis data of this sample as well as the two equally intense ^{117}Sn resonances observed match the formula $[(OH)Et_2SnOSnEt_2Cl]$ (Table 7) that corresponds to intermediate **3** in the hydrolysis scheme of Figure 2. In line with Otera's finding on 3-chloro-1-hydroxytetraorganodistannoxanes (R = *n*Bu), this structure should be dimeric.[22b] In fact this compound, which is also soluble in $CDCl_3$, has a ^{117}Sn NMR spectrum which displays the same eight resonances as species A, B, and C, albeit with different relative populations, as in the sample isolated by precipitation at pH 2.8 from pure aqueous Et_2SnCl_2. Therefore, it probably includes intermediates **2**, **3** and **4**. Since essentially the same hydrolysis products are observed as with pure Et_2SnCl_2, it can be concluded that at least no peculiar interaction between the Et_2Sn moiety and cytosine occurs (Figure 2). In particular, this rules out any interaction between the Et_2Sn moiety and the nucleobase functionalities.

A solid was also isolated from a mixture of 5'-UMP and Et_2SnCl_2 at pH 2.2. The ^{31}P CP-MAS NMR spectrum exhibits two resonances at $\delta = -7$ and $\delta = -12$; they are shifted to low frequency with respect to the single one in solution at ca. 0.2 ppm. The ^{117}Sn CP-MAS NMR spectrum exhibits two isotropic resonances of equal intensity at $\delta = -262$ and $\delta = -281$ in the range corresponding to six-coordinate tin atoms. The vibrational data of 5'-UMP/Et_2SnCl_2 also unambiguously reflect a tin–phosphate interaction (Table 5). In contrast to 5'-CMP/Et_2SnCl_2, the elemental analysis data of 5'-UMP/Et_2SnCl_2 (Table 6) are independent of the acid used for adjusting the pH of the solution from which the solid originates, no chlorine or bromine being detected. These data are fairly consistent with structure **10** and even better for structure **11** (Table 6 and Figure 5). Unlike **8**, the thermogravimetric analysis of this solid does not indicate loss of H_2O or HCl, supporting structure **11** rather than **10**. However, the two different isotropic chemical shifts observed in the ^{117}Sn CP-MAS spectrum are in disagreement with both structures **10** and **11**; therefore, structure **12** can be proposed (Figure 5). It contains two different tin atoms and can be formed by dimerization of structure **11** with elimination of two water molecules. Among the three structures proposed, **12** agrees best with the elemental analysis data (Table 6) and is the only one to fit all the NMR data.

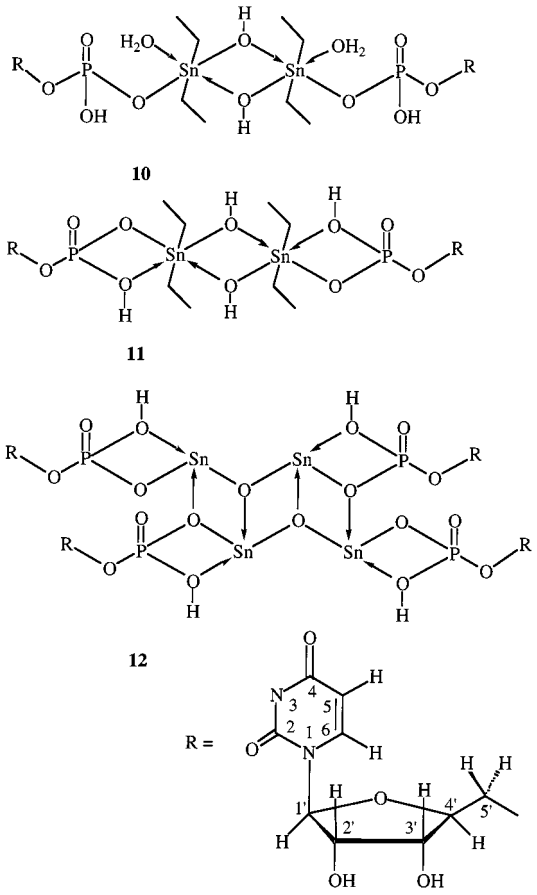

Figure 5. Potential structures for the solid isolated from the mixture 5'-UMP/Et_2SnCl_2 at pH 2.2 and assessed against the data; in structure **12**, the ethyl groups bonded to the tin atoms have been omitted for clarity

The tendency of the 5'-dCMP/Et_2SnCl_2 mixtures to precipitate is lower than that of 5'-CMP and 5'-UMP, with precipitation only occurring at higher pH's. Moreover, no reproducible elemental composition and solid state NMR data could be obtained as the solid appears to contain hydrolysis products of Et_2SnCl_2 as well as free and complexed 5'-dCMP with $\delta(^{31}P) = 0.6$ and –9.2.

Interaction of Diethyltin Dichloride with the Nucleotides at pH > 9.0

At pH 9.0, the 1D ^{119}Sn NMR spectrum of the mixture 5'-CMP/Et_2SnCl_2 (2:1) exhibits a single ^{119}Sn resonance at $\delta = -137$ (Figure 4), characteristic of R_2SnO_2 compounds in the presence of a donor giving rise to a five-coordinate tin.[31,41] The ^{13}C NMR spectrum exhibits a pair of signals for each carbon atom of the sugar unit, one ^{13}C resonance of each pair arising from free 5'-CMP. Upon addition of one more equivalent of diethyltin dichloride (5'-CMP/Et_2SnCl_2 = 1:1) the ^{13}C resonances corresponding to free 5'-CMP disappear but the 1D ^{119}Sn NMR spectrum displays a second very small ^{119}Sn signal at $\delta = -202$. The latter increases as the amount of Et_2SnCl_2 is further increased. The mixture 5'-UMP/Et_2SnCl_2 displays similar behaviour; in contrast, the mixture 5'-dCMP/Et_2SnCl_2 in any

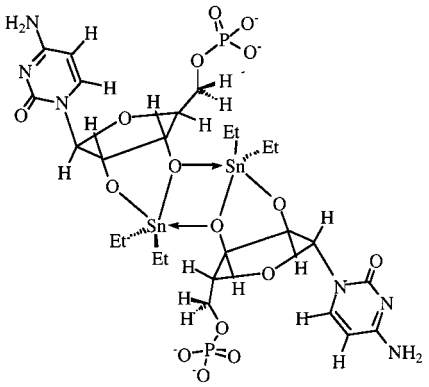

Figure 6. Structure proposed for the complex generated in mixture 5'-CMP/Et_2SnCl_2 at pH 10.5

Table 8. Chemical shifts (ppm) and coupling constants (Hz) for the three nucleotides studied at pH 10.5 in the presence of Et_2SnCl_2

	$\delta(^{119}Sn)$	$^1J(^{13}C–^{119/117}Sn)$	$^2J(^1H–^{119/117}Sn)$
5'-CMP/Et_2SnCl_2	–137	667	81
5'-dCMP/Et_2SnCl_2	–202	757	[a]
5'-UMP/Et_2SnCl_2	–137	665	79

[a] Nonobservable due to broad signal.

ratio exhibits a single ^{119}Sn resonance at δ = –202. Furthermore, the ^{119}Sn nuclei associated with the two ^{119}Sn resonances (δ = –137 and –202) are in chemical exchange, as demonstrated by the presence of intense cross-peaks in the 2D ^{119}Sn EXSY spectrum[42,43] recorded from the mixture 5'-CMP/Et_2SnCl_2. A 2D ^1H-^{119}Sn HMQC spectrum of this mixture reveals no correlations between the ^{119}Sn resonance at δ = –202 and the proton resonances of the 5'-CMP moiety. In contrast, the ^{119}Sn resonance at δ = –137 displays ^1H-^{119}Sn HMQC correlations with the H2' and H3' proton resonances of the sugar unit, as well as satellites corresponding to a $^2J(^{119}Sn–O–^{117/119}Sn)$ coupling constant of 156 Hz.

These ^1H-^{119}Sn HMQC correlations result from $^3J(^1H–^{119}Sn)$ couplings through the pathways H2'–C2'–O2'–Sn and H3'–C3'–O3'–Sn and can be traced to the formation of bonds between the tin atom and the O(2') and O(3') oxygen atoms of the sugar unit (Figure 6). The ^{119}Sn chemical shift of δ = –137, the $^1J(^{13}C–^{119}Sn)$ of 667 Hz (Table 8), and the $^2J(^{119}Sn–O–^{117/119}Sn)$ of 156 Hz, combined with the ^1H-^{119}Sn HMQC data, are consistent with a five-coordinate tin atom in a dimeric R_2SnO_2 diethyldioxastannolane as shown in Figure 6, one oxygen atom of the diol group of the sugar unit being tricoordinated.[41] Similarly, dimeric dibutylstannylene acetals have ^{119}Sn chemical shifts between δ = –115 and –150 in five-membered rings with pentacoordination at the tin atom (Table II of ref.[41b]).

A ^{35}Cl NMR spectrum of the mixture at pH 10.5 confirms that no covalently bonded chlorine is involved, as supported by the very narrow ^{35}Cl resonance at δ = 0[40] which indicates that this element is only present as a chloride anion. The ^{119}Sn resonance at δ = –202 starts appearing when the tin to nucleotide ratio exceeds 1:1 in a mixture of Et_2SnCl_2 with substrates which contain a diolic sugar unit, i.e. 5'-CMP, 5'-UMP, cytidine, and D-ribose. All of these substrates display a resonance around δ = –135 to –138, arising from the tin diolate complex being formed first. In contrast, the δ = –202 signal is the only resonance observed for a mixture of Et_2SnCl_2 with substrates which do not contain a diolic sugar unit, i.e. 5'-dCMP and cytosine. These observations unambiguously rule out that the second ^{119}Sn resonance at δ = –202 is due to any interaction between the tin moiety and functional groups of the pyrimidic unit, with or without a hydrogen bonding network. This is confirmed by ^{15}N NMR data obtained from ^{15}N enriched 5'-CMP/Et_2SnCl_2 mixtures (2:1, 1:1, 1:2) which did not reveal any deviation of the ^{15}N chemical shift of the N3, NH_2 or N1 atoms in the presence of diethyltin dichloride, with respect to free 5'-CMP. By way of an example, the titration curve of the $^{15}N3$ resonance of such a mixture is shown in Figure 7.

As in the acidic medium, the ^{119}Sn resonance at δ = –202 can only originate from some hydrolysed species on the hydrolysis pathway of Et_2SnCl_2 (Figure 2). Further evidence for this is the fact that the ^{119}Sn NMR spectrum of the supernatant of the mixture obtained from Et_2SnCl_2 in D_2O at pH 10.5 exhibits the very same resonance at δ = –202. By comparing the ^{117}Sn CP-MAS NMR spectrum with the one of pure Et_2SnO (δ = –166), the precipitate that was isolated from this mixture was identified as Et_2SnO (δ = –165), the anisotropy patterns being identical. As expected, the supernatant of this mixture exhibits a ^{35}Cl

resonance at a slightly higher chemical shift (δ = 4) than for completely anionic chloride (δ = 0, NaCl). This can originate from an equilibrium between intermediate **3**, with one chlorine atom covalently bonded to the tin atom, and intermediate **4**, from which chlorine can only be released as chloride. Compound **4** is the direct precursor of Et_2SnO which is indeed the solid detected; it can be formed directly by simple loss of a water molecule. Therefore, the species at δ = –202 is most likely intermediate **4** in the hydrolysis scheme of Et_2SnCl_2 (Figure 2).

Interaction of Diethyltin Dichloride with 5'-CMP, 5'-dCMP and 5'-UMP at pH 5.5–9.0

Several ^{119}Sn resonances appear in the ^{119}Sn NMR spectra of 5'-CMP/Et_2SnCl_2 in this pH range (Figure 3). These resonances are all very broad, needing a long acquisition time to obtain a reasonable signal-to-noise ratio. Due to the broadness of the resonances, ^1H-^{119}Sn HMQC correlations could not be detected between the proton resonances of the 5'-CMP moiety and the ^{119}Sn resonance. Attempts to reduce the line width of the ^{119}Sn resonances by recording a ^{119}Sn spectrum at lower temperatures failed, the resonances remaining still too broad. Likewise, 5'-CMP/Et_2SnCl_2 mixtures prepared in CD_3OD/D_2O (50:50) turned cloudy below 273 K.

Similar ^{119}Sn resonance frequencies, at least within experimental error, are found for all three nucleotides investigated in the pH range 5.5–9.0. For 5'-dCMP/Et_2SnCl_2, the ^{119}Sn resonance around δ = –202 is observed at pH 6.5.

These findings again suggest that all the ^{119}Sn resonances arise from hydrolysis products of Et_2SnCl_2, rather than from Et_2SnCl_2 interacting with the nucleotides. The broad ^{119}Sn resonances are in agreement with the associated species being in moderately slow exchange on the ^{119}Sn NMR time scale, since no evidence for multiple species was found in the ^1H and ^{13}C spectra (this indicates that these species, whatever they maybe, are in fast exchange on the ^1H and ^{13}C NMR time scales but in slow exchange on the ^{119}Sn NMR time scale). Unfortunately, 2D ^{119}Sn EXSY experiments which were aimed at supporting the presence of exchange were unsuccessful; this was due to broad linewidths and/or a low signal-to-noise ratio.

The solid isolated from the mixture 5'-CMP/Et_2SnCl_2 (1:1) around pH 7.0 mainly reveals a single isotropic ^{117}Sn chemical shift at δ = –167 in its CP-MAS spectrum. A comparison of its chemical shift anisotropy pattern with that of a pure sample of Et_2SnO reveals that this solid is the latter compound. However, a CP-MAS ^{117}Sn pattern from another unidentified minor species with much lower intensity (ca. 10%) is also observed at pH 7.0.

Conclusions

From pH 2.0–3.0, the Et_2Sn moiety from Et_2SnCl_2 is involved in bonding with the phosphate group of the three nucleotides studied. This interaction was characterised by a ^{31}P-^1H HOESY spectrum. At the same pH, the precipitated solid was isolated and structurally characterised. Among several possible structures, only one satisfied all data including the elemental analysis. This structure contains two tin atoms bridged by one oxygen and one chlorine atom, each tin atom being linked to the phosphate group of the nucleotide. Between pH 3.0 and 5.5 the absence of visible ^{119}Sn resonances precludes a conclusion.

Around neutral pH (5.5–9.0), no evidence for the Et_2Sn moiety interacting with the nucleotide was found, Et_2SnCl_2 giving rise to several hydrolysis products that are in mutual chemical exchange with one another.

In a 1:1 nucleotide/Et_2SnCl_2 mixture at pH > 9.0, Et_2SnCl_2 reacts with the O(2') and O(3') oxygen atoms of the sugar unit of the nucleotide as demonstrated by the presence of two HMQC cross-peaks H2'–Sn and H3'–Sn. With an excess of Et_2SnCl_2, a second ^{119}Sn resonance appears at δ = –202, which, however, does not correlate with any proton resonance of the nucleotides. This species is one of the hydrolysis products of Et_2SnCl_2, as further indicated by the absence of any ^{15}N chemical shift effect on the pyrimidic moieties that should have originated from the presence of a tin unit in the neighbourhood of nitrogen atoms.

The corresponding pH value limits for the interactions of the purine nucleotides 5'-IMP and 5'-GMP with Et_2SnCl_2 were: pH < 4 for the interaction through the phosphate group, pH > 9.5 for the interaction through the O(2') and O(3') oxygen atoms, and no observed interaction for pH 4–9.5.[11b]

These results are in contrast to the mode of interaction of cisplatin that interacts with the nitrogen atoms of purines (N7 of guanosine) and pyrimidines (N3 of cytidine).[44] However, they are similar to those reported for vanadium complexes which have been shown to interact with the phosphate group of mononucleotides at acidic pH, to hydrolyse at neutral pH and to react with the O(2') and O(3') oxygen atoms of the sugar unit of mononucleotides at basic pH.[45]

Experimental Section

Preparation of NMR Samples: The samples were typically prepared by dissolving the nucleotides (0.1 mmol) in D_2O (0.2 mL, 99.9% D, Aldrich). A solution of diethyltin dichloride (0.05 mmol) in D_2O (0.3 mL) was added dropwise. This resulted in a clear solution with a pH of approximately 6. The pH was adjusted by the dropwise addition of deuterated hydrochloric acid or sodium hydroxide solutions (0.1 M). Whenever generated, the precipitate was filtered and thoroughly washed with water and diethyl ether prior to drying in vacuum over P_2O_5 and further analysis (see Results and Discussion). The elemental analyses were performed by the "Laboratoire Central d'Analyse du CNRS", Vernaison, France. ^{15}N enriched (98% isotopic purity) 5'-CMP was purchased from CIL (MA).

NMR Experiments: All spectra were recorded at 303 K on a Bruker AMX500 spectrometer equipped with a digital lock and operating at 500.13, 202.46, 125.77, 186.50, 50.68, and 49.00 MHz for ^1H, ^{31}P, ^{13}C, ^{119}Sn, ^{15}N, and ^{35}Cl nuclei, respectively. ^{31}P chemical shifts were referenced to an aqueous solution of H_3PO_4 (85%). The ^{119}Sn chemical shifts were referenced to Ξ = 37.290665 MHz.[46a] The

^{35}Cl chemical shifts were referenced to a solution of NaCl (1 M, $\delta = 0$). The ^{15}N chemical shifts were referenced to $\Xi = 10.136767$ MHz.[46b]

Broad band ^{1}H-decoupled ^{13}C and ^{119}Sn spectra were recorded using the Bruker pulse sequences with standard delays. The 1D and 2D ^{1}H-^{119}Sn HMQC experiments consisted of gradient enhanced-versions of the standard HMQC pulse sequence processed in the magnitude mode and implemented as described elsewhere.[32] The 2D ^{31}P-^{1}H HOESY[16,17] experiments were performed by recording 128 FIDs of 1 K data points, 144 scans each, with an acquisition time of 0.2 s, a relaxation delay of 1.6 s and a mixing time of 1 s. The 2D ^{1}H-^{15}N HMQC spectra were typically obtained by recording 64 FIDs of 4 K data points, 32 scans each, with an acquisition time of 0.5 s and a relaxation delay of 1.5 s. The 2D ^{119}Sn EXSY spectra were typically obtained by recording 24 FIDs of 4 K data points, 3,200 scans each, with an acquisition time of 0.1 s, a relaxation delay of 1 s and a mixing time of 10 ms.

All CP-MAS NMR spectra[47] were recorded on a Bruker AC250 and, in later stages, on a Bruker DRX250 spectrometer operating at 101.26, 62.90, and 89.15 MHz for ^{31}P, ^{13}C, and ^{117}Sn nuclei, respectively. The spectrometer was equipped with a 7 or 4 mm MAS broad-band probe. The matching conditions for Hartmann-Hahn cross-polarization[47] (pulse length 5 μs) and the chemical shift reference for the ^{117}Sn nucleus were set with (*cyclo*-$C_6H_{11})_4Sn$ [$\delta = -97.35$ relative to $(CH_3)_4Sn$]. The ^{13}C chemical shift reference frequency was set with adamantane. The ^{117}Sn spectra were typically obtained by acquiring 32 K data points over a spectral width of 166.7 kHz, a 2 ms contact time and a relaxation delay of 2 s with 10,000 to 20,000 scans. The isotropic chemical shifts were identified by recording two spectra with sufficiently different spinning rates.[47] The ^{13}C CP-MAS spectra were obtained by acquiring 4 K data points over a spectral width of 17 kHz, a 2 ms contact time and a relaxation delay of 4 s with 1,000 to 10,000 scans. The ^{1}H-decoupled ^{31}P MAS spectra were obtained by acquiring 4 K data points over a spectral width of 20 kHz and a relaxation delay of 4 s with 100 to 1,000 scans.

Infrared Spectroscopy: Infrared spectra were acquired from KBr pellets in the Fourier transform mode from a Perkin–Elmer System 2000 FT-IR spectrometer. The Raman spectra were acquired in the Fourier-transform mode from a Perkin–Elmer System 2000 NIR FT-RAMAN spectrometer using a Raman dpy2 beam with 310 mW power.

Electrospray Mass Spectrometry: The electrospray mass spectra were recorded in the cationic and anionic modes on a Micromass Quattro II instrument coupled to a Masslynx system (ionisation in an electric field of 3.5 kV; source temperature 80 °C; source pressure 1 atm.; analyser pressure 10^{-5} mbar).[48] Cone voltages were 15 V. Calculated and experimental isotopic distributions were compared using the shareware program MassCluster v.2.1. for Apple Macintosh. The *m*/*z* ratios reported in Table 1 and Figure 3 correspond to the peak with the highest intensity of the isotopic distribution patterns.

Thermogravimetric Analysis: The thermogravimetric analysis was made on a Perkin–Elmer TGA-7 thermogravimetric analyser by heating the sample from 40 to 500 °C at 10 °C/min under a nitrogen atmosphere.

Acknowledgments

We thank Mrs I. Verbruggen for recording some of the NMR spectra, Dr. G. Laus and Mr. M. Desmet for recording the electrospray mass spectra, and Prof. Dr. Ir. B. Van Mele and Dr. Ir. H. Rahier for access to the IR, Raman and thermogravimetric analysis facilities. J. C. M. is a postdoctoral research associate of the Fund for Scientific Research Flanders (Belgium). η^4-Coordination of Dienes and Heterodienes to the TripodCobalt(I) Template $[CH_3C(CH_2PPh_2)_3Co]^+$: Synthesis, Structure, and Dynamics

Rolf Rupp,[a] Axel Frick,[a] Gottfried Huttner,*[a] Peter Rutsch,[a] Ute Winterhalter,[a] Annette Barth,[a] Peter Kircher,[a] and Laszlo Zsolnai[a]

Dedicated to Prof. Dirk Walther on the occasion of his 60th birthday

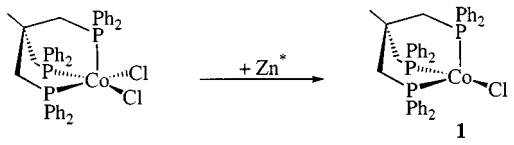
Keywords: Tripol ligands / Dienes / Heterodienes / η^4-Coordination / Hindered rotation / Line-shape analysis

$CH_3C(CH_2PPh_2)_3CoCl$ (**1**) is easily accessible from $CH_3C(CH_2PPh_2)_3CoCl_2$ by reduction with activated zinc powder. Upon dehalogenation with $TlPF_6$, **1** reacts with dienes to give $[tripodCo^I\text{-}(\eta^4\text{-diene})]^+$ (**2**). The heterodienes acrolein and methyl vinyl ketone produce the analogous η^4-heterodiene compounds **3**. When crotonaldehyde is used as the potential η^4-diene ligand, decarbonylation is observed leading to $[tripodCo^I\text{-}(CO)_2]^+$ (**4**). Reaction of $[tripodCo_{aq}](BF_4)_2$ with allyl mercaptan produces $[tripodCo^I\text{-}(\eta^4\text{-thioacrolein})]^+$ (**3a**) through dehydrogenation of the ligand precursor. 1,2-Diketones such as benzil and phenanthrenequinone do not coordinate in a η^4 fashion but rather generate η^2-coordinate enediolato ligands by an electron-transfer process, resulting in compounds of the type $\{tripodCo^{III}\text{-}[\eta^2\text{-RC(O)=C(O)R}]\}^+$ (**5**). All the compounds have been characterized by standard analytical and spectroscopic techniques, including X-ray analysis in some cases. Compounds **4** and **5** show trigonal-bipyramidal coordination in the solid state, whereas the coordination polyhedra in compounds **2** and **3** are better described as square-pyramidal. While a minimum of two phosphorus resonances might be expected for each of these coordination geometries, only one time-averaged signal is normally observed. Only with the η^4-coordinated heterodienes acrolein, methyl vinyl ketone, and thioacrolein present in **3** is there a resolution of the signals of the three chemically distinct phosphorus nuclei at low temperatures. By ^{31}P-NMR line-shape analysis, the activation barriers for the rotational reorientation of the heterodienes are found to be around $\Delta H^{\neq} = 47$ kJmol^{-1} for all three compounds **3**.

Introduction

The chemistry of *tripod*cobalt templates $[CH_3C(CH_2Ph_2)_3Co]$ has been extensively studied. Largely due to the efforts of Sacconi and his group, the very special properties of this kind of template have been documented through the isolation of many types of compounds that are not accessible with any other type of $[L_3Co]$ template.[1] However, the chemistry of this highly valuable template $[CH_3C(CH_2PPh_2)_3Co]$ is hampered by the fact that the initial oxidation state of cobalt is generally Co^{II} and the [*tripod*Co] compounds are formed by addition of the *tripod* ligand and an appropriate coligand to the inorganic salt. The products of such reactions may well contain cobalt in the oxidation states of Co^I, Co^{II}, and Co^{III}, depending on the coligand and the reaction conditions.[2–4]

A systematic approach to the chemistry of the $[CH_3C(CH_2PPh_2)_3Co]^+$ template containing cobalt in the oxidation state (+I) has not yet been developed, even though a 14-electron species such as $[tripodCo]^+$ might be expected to provide a highly promising access to a novel type of coordination chemistry of the [*tripod*Co] entity. This expectation arises, in part, from consideration of the chemistry of the CpCo template, which has rapidly developed since the generation of this template by reductive decyclopentadienylation was reported by Jonas.[5][6] Moreover, since there are relatively few methods available for the generation of 14-electron species with late 3d transition metals, the development of suitable methods for the generation of a $[tripodCo]^+$ reagent would seem particularly worthwhile.



In this paper, we report on several methods for the in situ generation of $[tripodCo]^+$ and its reactions with unsaturated compounds.

Results and Discussion

Amongst the compounds containing the $[CH_3C(CH_2PPh_2)_3Co^I]$ template, the chloride $CH_3C(CH_2PPh_2)_3CoCl$ (**1**) appeared to be the most logical starting material for probing the chemistry of the $[CH_3C(CH_2PPh_2)_3Co]^+$ entity. **1** has been known for a long time and its preparation by $NaBH_4$ reduction of $CH_3C(CH_2PPh_2)_3CoCl_2$ has been reported by Sacconi et al.[2a] Its structure and its complicated equilibrium with respect to the starting material $CH_3C(CH_2PPh_2)_3CoCl_2$ have recently been described.[2b] While it is possible to prepare **1** by the method described by Sacconi et al., the accompanying formation of $\{[CH_3C(CH_2PPh_2)_3Co]_2H_3\}^+$ complicates this procedure and a simpler, cleaner preparation pathway remains desirable.[2a,2c,3a] We have found that $CH_3C(CH_2PPh_2)_3CoCl_2$ undergoes a clean reduction to **1** when treated with activated zinc powder in THF (Scheme 1).

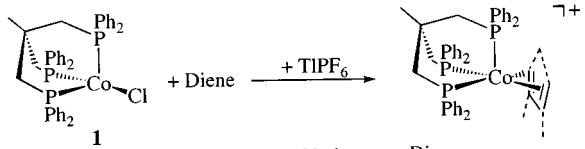
Scheme 1



After filtration and evaporation of the THF, **1** is obtained as a microcrystalline beige powder in almost quantitative yield. While freshly prepared **1** dissolves in CH_2Cl_2 to produce a clear orange-brown solution, dissolution of samples of **1** left at room temperature for more than 6 h leads to green solutions, indicating different degrees of decomposition. The nature of the green products has not yet been established.

[TripodCo^{I}] Derivatives of Dienes

Freshly prepared **1** reacts with dehalogenating agents in the presence of 4-electron donors L_2 such as conjugated dienes to produce the corresponding [*tripod*Co^{I}-L_2]$^+$ species **2**. When **1** was treated with $(CH_3)_3SiOSO_2CF_3$, a colour change from orange-brown to red-brown was observed. Addition of 2,3-dimethyl-1,3-butadiene resulted in a colour change to orange and, after evaporation of the solvent, an orange microcrystalline powder was obtained. By comparison with authentic spectroscopic data for the corresponding compound [*tripod*Co^{I}-(η^4-2,3-dimethyl-1,3-butadiene)]$^+$ (**2b**; see below), the data obtained following this reaction clearly showed that the η^4-diene derivative had been formed. The product obtained this way was, however, found to be contaminated with some paramagnetic impurities, which could not be separated. While the ^{31}P-NMR spectrum of the product clearly showed the characteristic signals of **2b**, the ^{1}H-NMR spectrum featured only very broad signals, as befits the presence of some paramagnetic contamination. Mass spectra of the product showed the characteristic fragmentation pattern of **2b** as the dominant pattern, as well as the characteristic *m*/*z* peak of [*tripod*Co^{I}-(triflate)]. It is thus probable that the paramagnetic contamination was, in fact, due to [*tripod*Co^{I}-(triflate)] which, in analogy to [*tripod*Co^{I}-(formate)]$^+$, should be a 16-electron paramagnetic species.[2d] If this interpretation is correct, the coordinative power of the triflate anion is evidently still too high to allow for its complete exchange by the diene under the applied conditions.[7]

When a solution of **1** in CH_2Cl_2 was treated with an equimolar amount of $GaCl_3$, a colour change from orange-brown to red-brown was observed. When this solution was treated with 2,3-dimethyl-1,3-butadiene, a further colour change to orange was observed. Mass spectra showed the fragmentation pattern of **2b**. In contrast to the product obtained by dehalogenation with $(CH_3)_3SiOSO_2CF_3$ (see above), no paramagnetic contamination was apparent and both the ^{1}H- and ^{31}P-NMR spectra of the product were in complete agreement with those obtained for authentic **2b** (see below). While it is clear from these results that **2b** was indeed formed under the described conditions, elemental analysis data for the product were less than satisfactory. Carbon and hydrogen values were too low, indicating that the anionic part of the salt was not in fact $GaCl_4^-$, which had been assumed to constitute the counteranion.

$AgBF_4$ and $AgPF_6$, while also acting as dehalogenating agents, proved not to be appropriate for this reaction since they led to concomitant oxidation. The problems were finally overcome by using $TlPF_6$ as the dehalogenating agent (Scheme 2).

2a	2-Methylbutadiene
2b	2,3-Dimethylbuta-1,3-diene
2c	Cyclopentadiene

Scheme 2

The orange PF_6 salts of **2a**−**2c** were obtained in good yields after purification by chromatography (Table 1, Table 4, Table 9). *Tripod*Co^{I} derivatives of conjugated dienes of type **2** are known.[2e] [*Tripod*Co^{I}-(η^4-butadiene)]$^+$, [*tripod*Co^{I}-(η^4-isoprene)]$^+$ (**2a**), [*tripod*Co^{I}-(η^4-1,3-cyclohexadiene)]$^+$, [*tripod*Co^{I}-(η^4-1,3,5,7-cyclooctatetraene)]$^+$, and [*tripod*Co^{I}-(η^4-1,3,5-cycloheptatriene)]$^+$ have previously been obtained by treating solutions of *tripod*Co^{II} precursors with propan-2-ol as the reductant in the presence of the appropriate olefinic ligand.[2e] A standard procedure for reactions of this type has not yet been established, nor have the products been completely characterized, although the structures of the products are known from a reported X-ray analysis of [*tripod*Co^{I}-(η^4-1,3,5-cycloheptatriene)]ClO_4.[2e] The type of coordination observed in this η^4-coordinated triene derivative remains essentially unchanged when dienes are coordinated to the [*tripod*Co]$^+$ entity. The general features already described by Sacconi et al. for the cycloheptatriene derivative apply equally well to the structure of **2c**, which has been determined in the case of its PF_6 salt (Figure 1, Figure 6; Table 5, Table 10).

The ^{31}P-NMR spectra of compounds **2**, besides the characteristic septet due to the PF_6 counteranion, show one sharp signal, the shape of which does not change significantly on cooling from 303 K to 193 K (Table 1). Irrespective of the specific coordination geometry (trigonal bipyramidal *vs.* square pyramidal), for a static structure arising from the combination of an entity with constitutional C_3-symmetry (*tripod*Co) and a coligand with at most C_{2v}-symmetry, a minimum of two different ^{31}P-NMR signals can be expected. This expectation is indeed borne out by the spectroscopic behaviour of the related compounds [L_3Co^{I}-(η^4-diene)]$^+$ (L = PMe_3, PMe_2Ph, PPh_2H) containing three isolated phosphane donors, where − depending on the symmetry of the diene coligand and the temperature of observation − up to three ^{31}P-NMR signals are observed.[8−10]

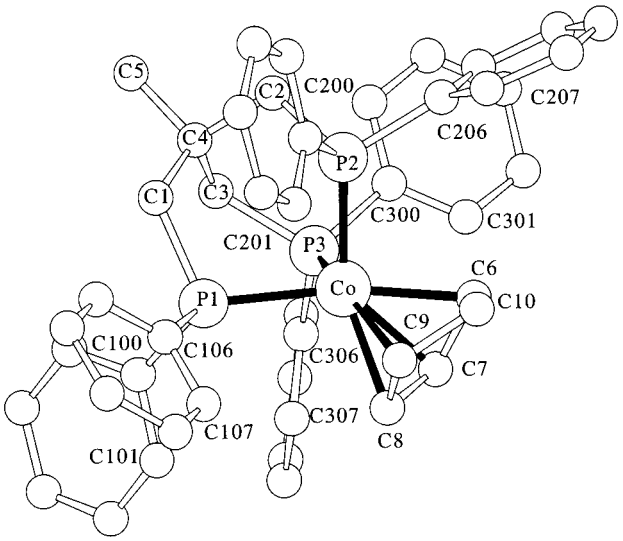

Figure 1. X-ray structure of **2c**

The fact that **2a**−**2c** show only one sharp signal for the three phosphorus nuclei of the coordinated ligand can only be rationalized by assuming that some dynamic process is operative, which renders the time-averaged environments of the phosphorus nuclei equivalent. This process must have a rather low activation energy, since not even a broadening of this ^{31}P-NMR signal is observed on cooling to 193 K. The most easily envisaged dynamic process is a tumbling of the diene coligands about the idealized C_3-axis of the [*tripod*Co] template. Such a tumbling motion would, of course, involve the transition of idealized square-pyramidal and idealized trigonal-bipyramidal coordination geometries. The ^{1}H-NMR spectra (Table 1) are in full agreement with the assigned constitutions, as are the mass spectra, which show the molecular ions as the most prominent peaks (Table 4). High-resolution mass spectra (**2a**−**2c**) and microanalytical data (**2b**) are also in agreement with the given formulae (Table 1).

When the procedure for the dehalogenation of **1** was performed in the presence of ethylene instead of a conjugated diene, $[tripodCo^{I}\text{-(ethylene)}_2]^+$ was formed, as was evident from the ^{31}P-NMR spectrum and mass spectroscopic data (see Experimental Section). However, it was not possible to purify the compound by chromatography, nor was it possible to obtain an analytically pure specimen by crystallization.

When non-conjugated dienes such as bicyclo[2.2.1]hepta-2,5-diene (2,5-norbornadiene) or 1,5-cyclooctadiene were used, PF_6 salts containing $[tripodCo^{I}\text{-(diene)}]^+$ as the cationic part were formed in high yields. Again, the compounds could not be purified by chromatography without significant decomposition (see Experimental Section). Even though the aforementioned compounds incorporating non-conjugated dienes or two ethylene ligands were invariably obtained with contamination by minor amounts of paramagnetic impurities, they were the only detectable products by ^{31}P-NMR and mass spectrometry. The species $[tripodCo^{I}\text{-(ethylene)}_2]^+$ is found to be thermodynamically far more stable than its isoelectronic equivalent CpCo(ethylene)$_2$.[5][6] While this latter compound starts to decompose at 323 K, [*tripod*Co(ethylene)$_2$]PF_6 is indefinitely stable at 343 K under an inert atmosphere.

On the other hand, the reactions of **1** described above show that, upon activation with $TlPF_6$, this compound constitutes a clean source for the intermediate generation of $[tripodCo]^+$. With regard to ease of handling, a method involving in situ reduction of $[tripodCo]^{2+}$ to $[tripodCo]^+$ would be desirable. It is in fact observed that a solution of $Co_{aq}(BF_4)_2$ and *tripod* in ethanol/CH_2Cl_2 reacts with conjugated dienes when treated with activated zinc powder in an ultrasonic bath. Compounds **2a**−**2c** are also accessible by this method (Scheme 3). They may be isolated as PF_6 salts by metathesis with KPF_6 in acetone following workup as described.

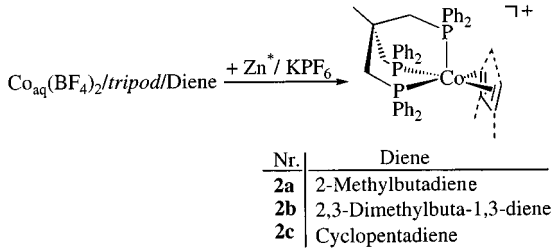
The yields of **2a**−**2c** achieved using this method were somewhat lower than those obtained starting from **1** (Table 9).

[TripodCo^{I}] Derivatives of Heterodienes

It has been observed that treatment of $Co_{aq}(BF_4)_2$ with 2-propene-1-thiol (allyl mercaptan) in the presence of $NaBPh_4$ and *tripod* produces the thioacrolein compound **3a** (Scheme 4).[2f]

In order to obtain this compound in a reproducible manner, it is necessary to keep the reaction mixture in a Schlenk tube sealed with a rubber stopper, presumably to keep the oxygen concentration at a very low but significant level. The BPh_4 salt of **3a** was obtained as a spectroscopically and analytically pure, dark-green, crystalline material consisting of single crystals suitable for X-ray analysis (Figure 2, Figure 5; Table 4, Table 5, Table 10).

When $Co_{aq}(BF_4)_2$ was treated with 2-propen-1-ol (allyl alcohol) instead of 2-propene-1-thiol (allyl mercaptan), a smooth colour change was again observed, leading to a red-brown solution. Evaporation of the solvent afforded a red-brown powder, the mass spectrum of which showed the molecular ion of the acrolein derivative **3b** as the most prominent peak. The ^{31}P-NMR data of the product were also identical with the data obtained for the analytically pure η⁴-acrolein compound **3b** (see below). However, it proved impossible to obtain an analytically pure compound using this reaction procedure.



Based on the observation that **1** reacts with dienes in an almost quantitative manner, the procedure used for the activation of **1** in the presence of dienes was applied with heterodienes as the potential coligands. It was found that 2-propenal (acrolein) and its methylated derivative 3-buten-2-one (methyl vinyl ketone) became η⁴-coordinated at the $[tripodCo]^+$ template in the same way as observed for carbon-centred diene ligands (Scheme 5).

Compounds **3b** and **3c** were produced in yields comparable to those obtained in the synthesis of **2** (Table 9). Chromatographic workup of the PF_6 salts of **3b** and **3c** resulted in claret microcrystalline powders, which proved to be analytically and spectroscopically pure (Table 2, Table 4).

[a] CH_3, CH_2, CH, and C carbons were assigned by means of a 135° DEPT experiment. − [b] Satisfactory microanalytical data could only be obtained for **2b**. The problems encountered with **2a** and **2c** may be traced to inappropriate handling of these air-sensitive compounds during microanalytical workup.

Scheme 3

Scheme 4

The reaction that was found to proceed cleanly in the case of acrolein and methyl vinyl ketone, leading to the η^4-coordinate heterodiene compounds **3b** and **3c**, could not be carried out with 2-butenal (crotonaldehyde) as the heterodiene. Reaction of this specific unsaturated aldehyde with **1** in the presence of $TlPF_6$ was found to produce the dicarbonyl compound **4** (Scheme 6).

The dicarbonyl compound **4** was isolated as its BPh_4 salt. **4** itself has previously been described by Ellermann et al. as the product of the reaction of *tripod* with $Co_2(CO)_8$.[2g] **4** could also be obtained from **1** in the presence of $TlPF_6$ and CO (see Experimental Section). The structure of **4**·$(BPh_4)^-$,

Scheme 6

as determined by X-ray analysis, is shown in Figure 3 (Table 6, Table 10).

The approximate idealized trigonal-bipyramidal coordination is evident from Figure 3, as well as from the data in Table 6.

In view of the clean reactions giving **3b** and **3c** as compounds with η⁴-coordinated heterodienes, the comparatively clean reaction of the linear C_4-heterodiene crotonaldehyde to produce the dicarbonyl compound **4** is remarkable. It appears that decarbonylation of α,β-unsaturated aldehydes is the predominant reaction pathway when allylic intermediates can be formed, which is possible by a simple hydrogen migration process with crotonaldehyde, thereby producing **4**, but cannot occur with the heterodienes leading to **3b** and **3c**.

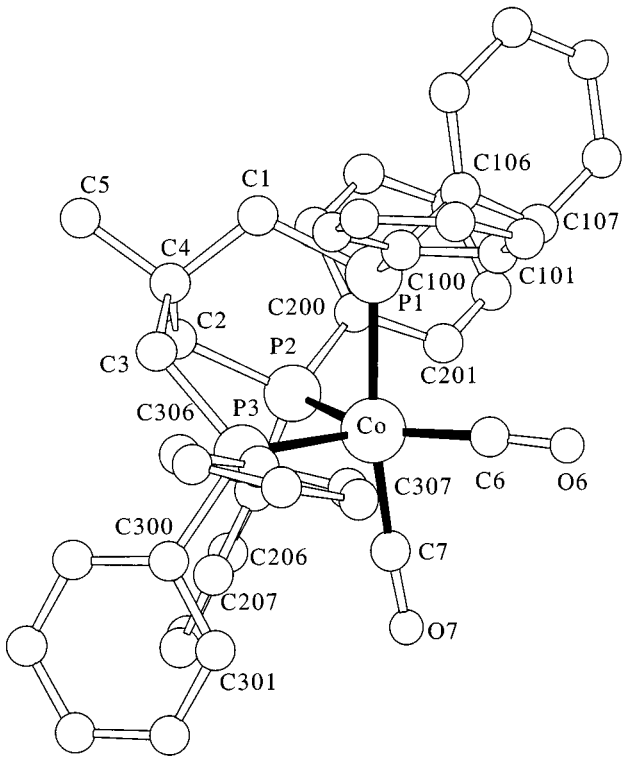

Figure 3. X-ray structure of **4**

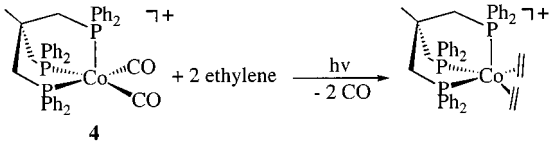

4 itself might represent a precursor for the generation of the [*tripod*Co]⁺ species if its carbonyl groups could be dis-

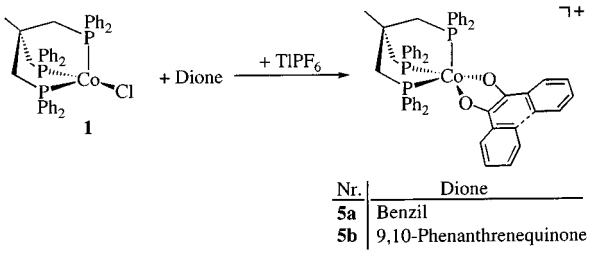
placed. Considering the cationic [*tripod*Co]$^+$ template to which the carbonyl groups are coordinated, the cobalt−CO bonds should not be prohibitively strong. Indeed, the ν_{CO} IR absorptions of **4** are observed at rather high energies (2025 cm^{-1}, 1965 cm^{-1}; Table 4), indicating that the CO bond order is high with the consequence that the Co−C_{CO} bond order should be low. With this in mind, **4** was irradiated in the presence of ethylene, whereupon complete replacement of its CO groups by ethylene ligands was observed (Scheme 7).



4

Scheme 7

Although the product formed in this reaction could not be obtained in analytically pure form, its mass spectrum and ^{31}P-NMR data leave no doubt as to its identity. The spectroscopic data obtained were in quantitative agreement with the data found for the same cation prepared from **1** (see Experimental Section).

The fact that not only carbon-centred dienes but also conjugated mono-heterodienes coordinate to the [*tripod*Co]$^+$ template in a η^4 fashion indicates that this template is ideally suited for the coordination of ligands containing a 4-centre 4π-system. In this respect, the template behaves as expected for an isoelectronic equivalent of $Fe(CO)_3$ and CpCo. The $Fe(CO)_3$ template is known to form stable derivatives with dienes, and is the only known template that also allows the η^4-coordination of heterodienes.[11−13] In fact, to the best of our knowledge, η^4-coordination of dienes and thioacrolein has hitherto only been achieved using this type of iron-centred template.[14]

By generating [*tripod*Co]$^+$ in the presence of 1,2-diketones, the question was addressed whether these 4-centre 4π-systems would bind in a η^4-coordination mode or whether, by electron-transfer processes, they would be transformed into η^2-coordinating enediolato-type ligands. The coordination of a dialdehyde to the Cp*Co template, in a fashion where at least one CO group of the ligand forms a π-bond with the other one acting as a σ-donor, has recently been reported by Brookhart et al., and hence the η^4-coordination of 1,2-diketones cannot a priori be excluded.[15] However, reaction of benzil or phenanthrenequinone with **1** in the presence of $TlPF_6$ produces the enediolato derivatives **5** (Scheme 8).

1

Nr.	Dione
5a	Benzil
5b	9,10-Phenanthrenequinone

Scheme 8

Formal oxidation of Co^I to Co^{III} thus took place, with a corresponding formal two-electron reduction of the diketones to produce enediolato ligands. It appears that the propensity of the [*tripod*Co]$^+$ template to acquire an 18-electron configuration − which it would have if the dione were to have bound as a η^4-diene ligand − is not sufficiently strong to counterbalance the formation of the stable five-membered cycles present in **5** accompanied by a 16-electron configuration at the cobalt centre. Many compounds showing the same type of bonding of 1,2-dioxo ligands as found in **5** are known, and an alternative synthesis of **5b** has been mentioned in the literature.[4a−4c] A characteristic feature of such compounds is that they show a prominent long-wavelength absorption at around 800 nm, which has been interpreted in terms of an LMCT band.[4c] This type of band is also seen for compounds **5** (Table 4). The η^4-binding mode of the dienes present in **2** and **3** gives rise to a distinctly different electronic absorption pattern (Table 4).

The η^2-bonding mode of the ligands in **5**, which, as outlined above, could be established on the basis of the electronic spectra, was further corroborated by the observation that the ^{13}C resonances of the carbon atoms in the 2,3-positions of the unsaturated ligands are at distinctly different δ values for the η^4-coordinated dienes (**2**, **3**) as compared to the corresponding shifts for the η^2-coordinated ligands in **5** (Table 1, Table 2, Table 3). Moreover, the ^{31}P resonances of **5** (Table 3) appear in a range characteristic of [*tripod*Co(diolato)]$^+$ compounds (δ = 30−36), which is again distinctly different from the range in which the corresponding resonances for the η^4-diene derivatives **2** and **3** are seen (Table 1, Table 2).[4a−4c]

Compounds **5** were obtained in microcrystalline form as the intense cornflower-blue PF_6 salt (**5a**) or as the blue-green BPh_4 salt (**5b**). The results of an X-ray structure analysis of single crystals of **5b** were in complete agreement with the constitution established on the basis of spectroscopic data, clearly showing the η^2-binding mode of the enediolato ligand (Figure 4; Table 6, Table 10).

Structure and Dynamics

While the structure of **5b** needs no further comment since it is in very good agreement with the many well-documented and discussed structures of the [*tripod*Co(enediolato)]$^+$ type, the structures of the compounds containing η^4-coordinated dienes merit further discussion.[4a−4c]

If the geometries of these compounds (Figure 1, Figure 2, Figure 5, Figure 6; Table 5) are described as square-pyramidal, then the axial Co−P bond lengths (Co−P2) might be expected to be different from the equatorial distances. However, it is found that in all the compounds mentioned in this paper, **2c**, **3a**, and in the literature, [*tripod*Co^I-(η^4-C_7H_8)]$^+$ (**A**, **B**, Figure 6; Table 5), [$(Me_3P)_3Co^I$-(η^4-C_7H_8)]$^+$ (**C**, Figure 6; Table 5), the Co−P bonds are of approximately equal length.[2e,10] In **2c**, the equatorial bond Co−P1 [228.5 (1) pm] is some 7 pm longer than the Co−P2 [221.2

[a] CH_3, CH_2, CH, and C carbons were assigned by means of a 135° DEPT experiment. − [b] The rather poor data obtained for **5b**·BPh_4^- may be attributed to inappropriate handling of this sensitive compound during microanalytical workup. Moreover, with the equipment used, carbon values tend to be too low in the presence of boron.

(1) pm] and Co−P3 [221.4 (1) pm] bonds. An explanation for this difference might be found in the interaction between the phenyl groups at P1 and the cyclopentadiene ligand. A comparison of the structures shown in Figure 5 and Figure 6 shows that the orientation of these phenyl groups is distinctly different in **2c** (Figure 6) from the observed orientations in **3a** (Figure 5) and **A**, **B** (Figure 6). The torsion angles given in Table 5 quantify this difference. Comparing the positions of the diene ligands relative to the [*tripod*Co] entities in Figure 5 and Figure 6, it can be seen that the diene ligand in **2c** is positioned such as to reduce this interaction. In all the compounds examined (Figure 5, Figure 6; Table 5, Table 10), the cobalt−carbon bonds to the central carbon atoms of the diene systems are shorter than those to the terminal carbon atoms. This corresponds to a general rule.[9,10,16]

The cobalt−sulfur bond to the sulfur atom of the thioacrolein ligand in **3a** measures 231.3(4) pm. Since the heterodiene is approximately planar (C9−C8−C7−S6: 5°), this indicates a shift of the diene ligand relative to the [*tripod*Co] entity (Figure 5; Table 5, Table 10). The bond lengths within the diene ligands are as expected, as are the angles and torsion angles within the [*tripod*Co] cages (Table 5, Table 10).

The description of the compounds as idealized square-pyramidal is perhaps rather too simplistic. The rotational positions of the diene ligands relative to a pseudo C_3-axis of the [*tripod*Co] entity, vertical in relation to the P1−P2−P3 plane and centred at the cobalt atom, are rather

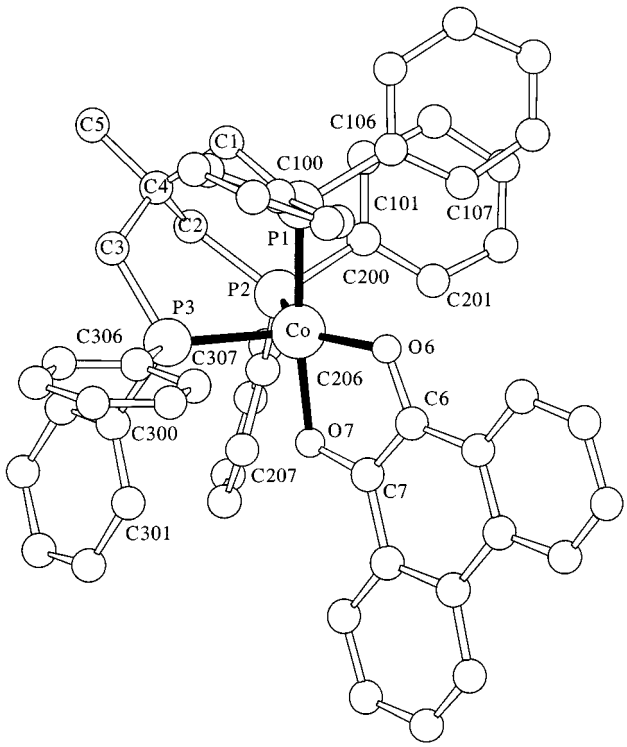

Figure 4. X-ray structure of **5b**

different. As a point of reference for describing this rotation with respect to the diene system, the midpoint of the central bond C7−C8 of this system was chosen. The point of reference with respect to the [*tripod*Co] template was chosen as P1. The angle φ describing the rotation of these reference points with respect to the pseudo axis was found to lie between 27° and 84° in the *tripod* derivatives and to be 40° in the PMe_3 derivative (Figure 5, Figure 6; Table 5, Table 10). It thus appears that the rotational position is rather flexible.

If the rotational positions were fixed, the phosphorus nuclei would reside in different environments even in solution, such that, depending on the symmetry of the arrangement, three or at least two different phosphorus signals could be expected to be observed by ^{31}P-NMR spectroscopy. In fact, it is observed that compounds **2** give rise to only one ^{31}P-NMR signal in CD_2Cl_2 solution, which shows no broadening even on cooling to 193 K. Since it is improbable that all three nuclei − given a static structure − are isochronous, it must be concluded that the all-carbon diene ligands in **2** are free to rotate even at low temperatures, such that a time-averaged ^{31}P-NMR signal is observed. This is in contrast to observations made for other compounds of the type $[L_3M(\eta^4\text{-diene})]$.[8−10,17] In these cases, the ligands L were non-chelating phosphorus donors. For compounds of this type, rotation − even at temperatures close to ambient − is generally sufficiently slow to result in resolution into dis-

crete signals in the ^{31}P-NMR spectra as well as in the ^{1}H-NMR spectra for the groups which are symmetrically non-equivalent in a static arrangement.[8−10,17]

At first glance, it is difficult to understand why this type of rotation of the diene ligands should have a lower associated activation energy in the [*tripod*Co] compounds as compared to the non-chelate $[L_3Co]$ derivatives. Comparing the structure of $[(Me_3P)_3Co^I\text{-}(\eta^4\text{-}C_7H_8)]^+$ (Figure 6; Table 5, Table 10) with those of the [*tripod*Co] compounds (Figure 5, Figure 6; Table 5, Table 10), it appears that the P−Co−P angles in the *tripod* derivatives are somewhat smaller than those in the $[(Me_3P)_3Co]$ compound. This would leave more space between the coordinated diene and the phosphorus nuclei in the *tripod* compounds as compared to that in the $[(Me_3P)_3Co]$ derivative (Figure 6; Table 5, Table 10). However, it would appear that the dominant repulsive interactions between the *tripod* ligand and the dienes are those between the substituents on phosphorus and the dienes and not those between the dienes and the phosphorus nuclei. Space-filling models of $[tripodCo^I\text{-}(\eta^4\text{-}C_7H_8)]^+$ (**A**) and $[(Me_3P)_3Co^I\text{-}(\eta^4\text{-}C_7H_8)]^+$ (**C**) are shown in Figure 7.[2e,9] For the *tripod* compound **A**, no ^{31}P-NMR data are available, but in view of the findings for compounds **2** it is probable that the diene ligand is free to rotate in this compound as well.[2e]

For $[(Me_3P)_3Co^I\text{-}(\eta^4\text{-}C_7H_8)]^+$, the NMR data reveal a static structure even at room temperature.[10] Figure 6 and Figure 7 suggest that the incorporation of methyl substituents at the phosphorus donors in $[(Me_3P)_3Co^I\text{-}(\eta^4\text{-}C_7H_8)]^+$ leads to a more congested steric situation than that in [*tri-*

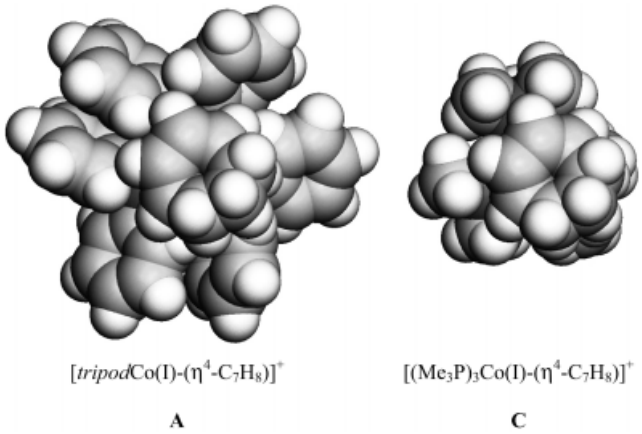

Figure 7. Space-filling models of **A** [*tripod*Co^{I}-(η^4-C_7H_8)]$^+$ and **C** [$(Me_3P)_3Co^{I}$-(η^4-C_7H_8)]$^+$

podCo^{I}-(η^4-C_7H_8)]$^+$, where a rotation of the phenyl groups may open up an almost unimpeded rotational pathway for the diene ligand.

The finding that there is still free rotation of the diene ligands in **2** at 193 K must mean that the electronic contribution to this barrier is rather low and hence the electronic preference for one orientation over the other must be small. This electronic contribution to the barrier might be expected to be higher with heterodiene ligands and indeed it is found that the heterodiene compounds **3** show three different phosphorus signals in their low-temperature ^{31}P-NMR spectra (Table 7). On warming to 303 K, exchange processes become apparent such that for **3a** and **3b** only one time-averaged ^{31}P-NMR signal is observed. In the case of **3c**, coalescence remains incomplete at 303 K. The spectra obtained at different temperatures have been analysed by line-shape analysis.[18] The quality of fit obtained by this procedure is shown for **3a** as a representative example, as is the Eyring plot obtained from the individual line-fitting procedures (Figure 8).

An activation enthalpy of 47 kJmol^{-1} was determined for **3a** (Table 8). The activation enthalpies similarly derived for **3b** and **3c** were 46 kJmol^{-1} and 48 kJmol^{-1} (Table 8).

The activation entropies were found to be negative throughout the series of compounds **3a**−**3c** (Table 8). While the entropy value derived for **3b** (−22 ± 6 Jmol^{-1}K^{-1}) was not too accurate, the activation entropy found for **3c** was definitely negative, more so than that determined for **3a** (Table 8). The entropy data thus suggest that the transition state associated with the rotational process is sterically more

congested than the ground state. The activation enthalpies were found to be approximately equal for all three compounds **3a**–**3c**, despite the fact that the ligand in **3a** contains sulfur as the heteroatom while the ligands in **3b** and **3c** contain oxygen.

Conclusion

Simple and straightforward procedures for the synthesis of $[tripodCo^{I}\text{-}L_2]^+$ have been described, where L_2 is a diene (isoprene, 2,3-dimethylbuta-1,3-diene, cyclopentadiene) (**2**) or heterodiene (acrolein, methyl vinyl ketone, thioacrolein) (**3**), coordinated in a η^4 fashion. While the idealized square-pyramidal coordination geometry observed for **2** and **3** in the solid state might be expected to give rise to chemically different phosphorus nuclei, only one sharp time-averaged ^{31}P-NMR signal is observed for **2**. Only with **3** is the rotational reorientation process sufficiently slow to allow the observation of three different ^{31}P-NMR signals at low temperatures. Line-shape analysis has allowed the estimation of $\Delta H^{\neq}$ in these cases, for which values close to 47 kJmol^{-1} have been obtained for all the compounds analysed (**3a** thioacrolein, **3b** acrolein, **3c** methyl vinyl ketone).

Experimental Section

General Remarks: Unless noted otherwise, all manipulations were carried out under argon using standard Schlenk techniques. All solvents were dried by standard methods and distilled under argon.[19] The zinc powder (Merck) used in some of the reactions was activated by stirring it under argon by means of a magnetic bar for 12 h. The solvents CD_3NO_2, [D_6]acetone, [D_8]THF, and CD_2Cl_2 used for NMR spectroscopic measurements were degassed by three successive "freeze-pump-thaw" cycles and dried with 4 Å molecular sieves. – Photochemical reactions were carried out with a Hanau TQ high-pressure mercury lamp in a Duran glass 50 irradiation apparatus equipped with a cooling system. – NMR: Bruker Avance DPX 200 at 200.12 MHz (^{1}H), 50.323 MHz (^{13}C{^{1}H}), 81.015 MHz (^{31}P{^{1}H}); T = 303 K, unless stated otherwise; chemical shifts (δ) in ppm with respect to (residual protons in) CD_3NO_2 (^{1}H: δ = 4.33; ^{13}C: δ = 62.8), [D_6]acetone (^{1}H: δ = 2.05; ^{13}C: δ = 29.8, 206.2), [D_8]THF (^{1}H: δ = 1.72, 3.57; ^{13}C: δ = 25.3, 67.4), and CD_2Cl_2 (^{1}H: δ = 5.32; ^{13}C: δ = 53.8) as internal standards. ^{31}P chemical shifts (δ) in ppm with respect to 85% H_3PO_4 (^{31}P: δ = 0) as external standard. – IR: Bruker IFS-66; KBr discs. – UV/vis: Perkin–Elmer Lambda 19 – Fast-atom bombardment (FAB) MS: Finnigan MAT 8230; xenon atom beam; matrix: 4-nitrobenzyl alcohol. – HR-MS (FAB): JEOL JMS 700; matrix: 4-nitrobenzyl alcohol. – Elemental analyses: Microanalytical Laboratory of the Organisch-Chemisches Institut, Universität Heidelberg. – Melting points: Gallenkamp MFB-595 010; uncorrected values. – Cyclic voltammetry: Metrohm "Universal Meß- und Titriergefäß", Metrohm GC electrode RDE 628, platinum electrode, SCE electrode, Princeton Applied Research potentiostat model 273; 10^{-3} M substrate in 0.1 M nBu$_4$NPF$_6$/CH_2Cl_2.

Preparation of *Tripod*CoCl (1): 1 mmol (130 mg) of $CoCl_2$ and 1 mmol (624 mg) of $CH_3C(CH_2PPh_2)_3$ (*tripod*) were dissolved in 25 mL of THF to give a blue-green solution of *tripod*$CoCl_2$.[2b] An excess of activated zinc powder was then added to the solution, and the mixture was treated for 10 min. in an ultrasonic bath. When the reaction was complete, the mixture had become orange-beige in colour. The solvent was evaporated and the residue was redissolved in CH_2Cl_2. The solution was filtered to remove $ZnCl_2$ and excess zinc powder. The solvent was then evaporated once more to leave *tripod*CoCl (**1**) in analytically pure form. – $C_{41}H_{39}ClCoP_3$ calcd. C 68.48, H 5.47; found C 68.57, H 5.61.

A: General Procedure for the Synthesis of [*Tripod*Co^{I}-(η^4-diene)]$^+$ Complexes or [*Tripod*Co^{III}-diolato]$^+$ Compounds from 1,3-Dienes and Heterodienes [Diene = Isoprene (2a), 2,3-Dimethylbuta-1,3-diene (2b), Cyclopentadiene (2c), Acrolein (3b), Methyl Vinyl Ketone (3c), Benzil (5a), Phenanthrenequinone (5b)]: 1 mmol (718 mg) of freshly prepared *tripod*CoCl (**1**) and 1 mmol (349 mg) of $TlPF_6$ were suspended in 20 mL of THF to give a yellow solution, from which a fine white precipitate was deposited. 1 mmol of the appropriate ligand (Table 9) was then added to this suspension and the reaction mixture was treated in an ultrasonic bath for 10 min. During the course of this procedure, the reaction mixture underwent a colour change to orange in the case of the carbon-centred dienes, to claret in the case of acrolein and methyl vinyl ketone, to cornflower blue with benzil, and to blue-green with phenanthrenequinone. The solvent was subsequently evaporated in vacuo and the residue was redissolved in CH_2Cl_2. This solution was filtered to remove the TlCl produced. The solvent was then evaporated once more and the residue (except in the case of **5b**) was purified by chromatography on silica gel (ICN Biomedicals, 32–63 μm, 60 Å),

Table 9. Analytical data for compounds **2** to **5**

Compound	Coligand	Eluent mixture	Colour	Yield [%] (method)	m.p. [°C][a]
2a	68 mg (1 mmol) isoprene	Et_2O/CH_2Cl_2 (2:1)	orange	78 (A) 64 (B)	141 (dec.)
2b	82 mg (1 mmol) 2,3-dimethylbutadiene	Et_2O/CH_2Cl_2 (2:1)	orange	71 (A) 61 (B)	150 (dec.)
2c	66 mg (1 mmol) cyclopentadiene	Et_2O/CH_2Cl_2 (2:1)	orange	76 (A) 69 (B)	155 (dec.)
3a	108 mg (1.5 mmol) 2-propenethiol	–	brown-green	35	130 (dec.)
3b	56 mg (1 mmol) acrolein	Et_2O/CH_2Cl_2 (3:1)	claret	81	125 (dec.)
3c	70 mg (1 mmol) methyl vinyl ketone	Et_2O/CH_2Cl_2 (3:1)	claret	78	130 (dec.)
4	116 mg (2 mmol) 2-butenal	Et_2O/CH_2Cl_2 (3:1)	orange	76	175 (dec.)
5a	210 mg (1 mmol) benzil	Et_2O/CH_2Cl_2 (4:1)	cornflower blue	85	180 (dec.)
5b	208 mg (1 mmol) phenanthrenequinone	–	blue-green	91	185 (dec.)

[a] dec. = decomposition.

eluting with the solvent mixture indicated in Table 9, to afford the PF_6 salts of **2a**–**c**, **3b**, **3c**, and **5a**. In order to obtain the crystalline BPh_4 salt of **5b**, a solution of **5b**·PF_6 in THF was treated with a three-fold excess of $NaBPh_4$. The solvent was evaporated, the residue was redissolved in CH_2Cl_2, and this solution was filtered to remove $NaPF_6$ and excess $NaBPh_4$. Removal of the solvent afforded **5b**·BPh_4. For analytical data of the compounds, see Table 1, Table 2, Table 3, Table 4.

B: General Procedure for the Synthesis of [*Tripod*Co^I-(η^4-diene)]PF_6 Complexes [Diene = Isoprene (2a), 2,3-Dimethylbutadiene (2b), Cyclopentadiene (2c)]: 1 mmol (342 mg) of $Co_{aq}(BF_4)_2$ and 1 mmol (624 mg) of *tripod* were dissolved in 30 mL of CH_2Cl_2/ethanol (1:1) to give a brown-red solution. 1 mmol of the appropriate diene (Table 9) and a five-fold excess of zinc powder were then added. The reaction mixture was treated in an ultrasonic bath for 5 min. The solvent was then removed in vacuo, the residue was redissolved in CH_2Cl_2, and this solution was filtered to remove $ZnCl_2$ and excess zinc powder. The filtrate was then concentrated to dryness, the residue was redissolved in THF, and treated with a three-fold excess of KPF_6. The solvent was again removed in vacuo, the residue was redissolved in CH_2Cl_2, and this solution was filtered to remove excess KPF_6 and KBF_4. The filtrate was concentrated to dryness and the residue was purified by chromatography on silica gel (ICN Biomedicals, 32–63 μm, 60 Å), eluting with the solvent mixture indicated in Table 9. After workup of the appropriate fractions, the PF_6 salts of **2a**–**c** were obtained as microcrystalline powders. For analytical data of the compounds, see Table 1, Table 4.

Preparation of [*Tripod*Co^I-(η^4-thioacrolein)]BPh_4 (3a·BPh_4^-): 1 mmol (342 mg) of $Co_{aq}(BF_4)_2$ and 1 mmol (624 mg) of *tripod* were dissolved in 30 mL of THF/ethanol (1:1) to give a brown-red solution. Addition of 1.5 mmol (108 mg) of allyl mercaptan and 3 mmol (1026 mg) of $NaBPh_4$ led to an immediate colour change to dark brown. After filtration through silanized silica gel (Merck), the filtrate was concentrated in vacuo to a volume of 20 mL. The Schlenk tube was then flushed with argon and sealed with a rubber stopper. After 3 days, a brown-green precipitate had been deposited, which was washed with Et_2O (3 × 10 mL). The product, which could reproducibly be obtained, was identified as analytically and spectroscopically pure **3a**·BPh_4 (Table 2, Table 4).

Preparation of [*Tripod*Co^I-$(CO)_2$]BPh_4 (4·BPh_4^-): (a) From 2-Butenal: 1 mmol (718 mg) of freshly prepared *tripod*CoCl (**1**) and 1 mmol (349 mg) of $TlPF_6$ were suspended in 20 mL of THF to give a yellow solution, from which a fine white precipitate was deposited. 2 mmol (116 mg) of 2-butenal (commercial *E*/*Z* mixture) was added to this suspension and the reaction mixture was treated in an ultrasonic bath for 10 min. During the course of this procedure, the reaction mixture underwent a colour change to orange. The solvent was then evaporated in vacuo and the residue was redissolved in CH_2Cl_2. This solution was filtered to remove the TlCl produced. After concentration of the filtrate, the residue was redissolved in THF and this solution was treated with a three-fold excess of $NaBPh_4$. The solvent was evaporated, the residue was redissolved in CH_2Cl_2, and this solution was filtered to remove $NaPF_6$ and excess $NaBPh_4$. Concentration of the filtrate and purification of the residue by chromatography on silica gel (ICN Biomedicals, 32–63 μm, 60 Å), eluting with the solvent mixture indicated in Table 9, gave the BPh_4 salt of [*tripod*Co^I-$(CO)_2]^+$. For analytical data of the compound, see Table 3, Table 4.

(b) From CO: 1 mmol (718 mg) of freshly prepared *tripod*CoCl (**1**) and 1 mmol (349 mg) of $TlPF_6$ were suspended in 20 mL of THF to give a yellow solution, from which a fine white precipitate was deposited. CO was then bubbled through this solution for 10 min., leading to a colour change to orange. The solvent was then evaporated in vacuo and the residue was redissolved in CH_2Cl_2. This solution was filtered to remove the TlCl produced. After concentration of the filtrate, the residue was redissolved in THF and this solution was treated with a three-fold excess of $NaBPh_4$. The solvent was evaporated, the residue was redissolved in CH_2Cl_2, and this solution was filtered to remove $NaPF_6$ and excess $NaBPh_4$. Concentration of the filtrate and purification of the residue by chromatography on silica gel (ICN Biomedicals, 32–63 μm, 60 Å), eluting with the solvent mixture indicated in Table 9, gave the BPh_4 salt of [*tripod*Co^I-$(CO)_2]^+$. For analytical data of the compound, see Table 3, Table 4.

Preparation of [*Tripod*Co^I-(norbornadiene)]PF_6 and [*Tripod*Co^I-(1,5-cyclooctadiene)]PF_6: 1 mmol (718 mg) of freshly prepared *tripod*CoCl (**1**) and 1 mmol (349 mg) of $TlPF_6$ were suspended in 20 mL of THF to give a yellow solution, from which a fine white precipitate was deposited. 1 mmol of the appropriate ligand was then added to this suspension and the reaction mixture was treated in an ultrasonic bath for 10 min. During the course of this procedure, the reaction mixture underwent a colour change to brown-

orange. The solvent was evaporated in vacuo and the residue was redissolved in CH_2Cl_2. This solution was filtered to remove TlCl. Evaporation of the solvent from the filtrate afforded the PF_6 salts as dark-orange powders. – ^{31}P NMR (CD_2Cl_2): [*tripod*Co^I-(norbornadiene)]$^+$: δ = 23.8 (s), −144.2 (sept, $^1J_{PF}$ = 713 Hz); [*tripod*Co^I-(1,5-cyclooctadiene)]$^+$: δ = 24.1 (s), −144.2 (sept, $^1J_{PF}$ = 713 Hz). – IR (KBr): [*tripod*Co^I-(norbornadiene)]$^+$: ṽ (PF): 849 cm^{-1} vs; [*tripod*Co^I-(1,5-cyclooctadiene)]$^+$: ṽ (PF): 837 cm^{-1} vs. – FAB-MS: [*tripod*Co^I-(norbornadiene)]$^+$: *m*/*z* = 775 [M^+]; [*tripod*Co^I-(1,5-cyclooctadiene)]$^+$: *m*/*z* = 792 [M^+].

Preparation of [*Tripod*Co^I-(ethylene)$_2$]PF_6: 1 mmol (718 mg) of freshly prepared *tripod*CoCl (**1**) and 1 mmol (349 mg) of $TlPF_6$ were suspended in 20 mL of THF to give a yellow solution, from which a fine white precipitate was deposited. Ethylene was then bubbled through this solution for 15 min., leading to a colour change to brown-orange. The solvent was subsequently evaporated in vacuo and the residue was redissolved in CH_2Cl_2. This solution was filtered to remove the TlCl produced. Evaporation of the solvent from the filtrate afforded the PF_6 salt as a brown-orange powder. – ^{31}P NMR (CD_2Cl_2): δ = 22.5 (br. s), −144.2 (sept, $^1J_{PF}$ = 713 Hz). – IR (KBr): ṽ (PF): 839 cm^{-1} vs. – MS-FAB: *m*/*z* = 739 [M^+].

The BPh_4 salt of [*tripod*Co^I-(ethylene)$_2$]$^+$ could also be obtained by irradiation of [*tripod*Co^I-$(CO)_2$]BPh_4 (**4**) while bubbling ethylene through the reaction mixture for 1 h. – ^{31}P NMR (CD_2Cl_2): δ = 22.5 (br. s). – MS-FAB: 739 [M^+].

X-ray Crystallographic Study: The measurements were made on a Siemens P4 four-circle diffractometer (**3a** and **5b**) or on a Nonius-Kappa CCD diffractometer (**2c** and **4**), using graphite-monochromated Mo-K_α radiation throughout. In the case of the measurements on the Siemens P4 four-circle diffractometer, the intensities of three check reflections (measured every 100 reflections) remained constant throughout the data collection, thus indicating crystal and electronic stability. The data collected on this instrument were corrected in the usual manner, including an experimental absorption correction. The data from the Nonius-Kappa CCD device were processed using the standard Nonius software.[20] All calculations were performed using the SHELXT-PLUS software package. Structures were solved by direct methods using the SHELXS-97 program and refined with SHELXL-97.[21][22] Graphical handling of the structural data during solution and refinement was performed with XPMA.[23] Atomic coordinates and anisotropic thermal parameters of the non-hydrogen atoms were refined by full-matrix least-squares calculations. Data relating to the structure determinations are compiled in Table 10. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-127496 to CCDC-127498. Copies of data can be obtained free of charge on application to the CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) +44 (0)1223/336033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

We are indebted to the Deutsche Forschungsgemeinschaft (SFB 247) and the Fonds der Chemischen Industrie for financial support. One of us (R.R.) is indebted to the Graduiertenkolleg "Selektivität in der organischen und metallorganischen Synthese und Katalyse" for a scholarship. The unselfish cooperation of Dr. J. Groß and Mr. T. Jannack (mass spectrometric measurements), Mr. D. Günauer (cyclic voltammetry), and Mrs. A. Dittes, Mrs. C. Vetter, Mrs. E. Weiß and Mr. F. Liebscher (elemental analysis) is gratefully acknowledged.

Keywords: Pyrrolizinato complexes / Tetracyanoethylene / Phthalocyanines

Complexes of Ni^{II}, Cu^{II}, Zn^{II}, and Co^{III} containing the 1,2,6,7-tetracyano-3,5-dihydro-3,5-diiminopyrrolizinide (L) and the 2,4-*tert*-butylacetylacetonide (DPM) ligands have been synthesized and characterized. The absorption optical spectra of these species and of the corresponding ML_2 complexes in coordinating solvents are compared with those of metal-phthalocyanines (MPc) and hydrogen-phthalocyanine (H_2Pc), respectively. The comparison shows a close similarity, especially for the nickel-containing species, in the low-energy spectral region where the first $\pi\rightarrow\pi^*$ transitions occur (Q band). The Q band position of the pyrrolizinato complexes is much more dependant on the metal than is the case for MPc. For the same metal, the Q band position is also dependant on the M–N bond lengths in the molecular plane. For M = Ni, a reduction of this distance causes a red-shift of the Q band and a decrease of its maximum intensity. These conclusions are based on the X-ray molecular structure of the solvent-free NiL(DPM) complex and its pyridine solvate NiL(DPM)$(Pyr)_2 \cdot 2$ Pyr and on their solvatochromism. A symmetry-based correlation diagram between the frontier orbitals of the pyrrolizinato-complexes and the phthalocyanines is proposed.

Introduction

During the last ten years, we have been investigating the metal(II) complexes of the ligand (L) 1,2,6,7-tetracyano-3,5-dihydro-3,5-diiminopyrrolizinide, a derivative of tetracyanoethylene (TCNE) (Scheme 1). Our attention was mainly concentrated on the structurally characterized bis-pyrrolizinates ML_2 (ML_2 = Fe,[1] Co,[1] Ni,[2] Cu,[3] Zn,[4] and Pd[5]). An important feature of these species is the surprisingly strict similarity of their optical spectra (due to the $\pi\rightarrow\pi^*$ transitions), especially in the low-energy region (Q band), with those of metal-phthalocyanines (-tetraazatetrabenzoporphyrins, MPc). This allows ML_2 complexes to be used as spectroscopic models, potentially for better understanding the electronic structure of porphyrinic systems. This is in spite of the deep structural dissimilarities and differences in the number of π-orbitals and π-electrons between the two systems. Recently, the optical spectrum of FeL_2 was assigned in D_{2h} symmetry by using polarized specular reflectance measurements on single crystals of its tetrahydrofuran (THF) adduct, $FeL_2 \cdot 4$ THF.[6] Well-resolved solid-state optical spectra, in close agreement with the solution spectra, were obtained. Interestingly, it was found that the Q band in this system originates from four different electronic transitions [$Q_{(x)}$, $Q'_{(y)}$, $R_{(x)}$, $R'_{(y)}$]. So, it was concluded by analogy that the same band in the MPc's (D_{4h}) should be composed of two electronic transitions [$Q_{(x,y)}$, $R_{(x,y)}$]. This conclusion is in contrast with the widely accepted and supposedly well-established assignment, based on Gouterman's model, where the Q band in MPc's is due to a single electronic transition plus a vibronic component.[7–9] We sometimes also isolated a few monopyrrolizinates (ML), specifically [Cl_2PdL^-][10] and CH_3HgL,[11] but because of the lack of suitable single crystals, we were not able to characterize them using X-ray analysis. However, the optical spectrum of these species are also close to those of the corresponding MPc, even closer than the analogous ML_2. On these grounds, we were interested in synthesizing and characterizing a series of homologous monopyrrolizinates, and to compare their optical spectra with those of the series ML_2 and MPc in order to define

more precisely the significant spectral similarities within the ML series in comparison to the others and, at the same time, to provide further experimental data for an overall rationalization based on molecular orbital calculations. We then found that the acetylacetonide ligand (acac) may coexist with L in coordinating the same metal center for several metals (M = Co, Ni, Cu, Zn). More importantly, the 2,4-*tert*-butyl-derivative of acac (or dipivaloylmethanide, DPM) made it possible to isolate single crystals, suitable for the X-ray structure determination, of the complexes NiL(DPM) and the corresponding pyridine (Pyr) solvate NiL(DPM)$(Pyr)_2 \cdot 2$ Pyr. Furthermore, NiL(DPM) shows an exceptional solvatochromism in solution, varying the coordination properties of the solvent. The available structural data of these nickel complexes suggest that this phenomenon is due to a variation of the Q band in both energy and intensity, and is related to the variation of the Ni–N equatorial distances. We report here on all these findings.

Results and Discussion

Synthesis and Structures of ML(DPM)

The monopyrrolizinates are readily formed from the reaction between LH and the bisacetylacetonates. This is not the case when using ML_2 as the pyrrolizinido source for the same reaction. Nevertheless, they are fairly stable towards the ligand metathesis, so that they could all be purified by recrystallization from hot saturated solutions. In any case, the pyrrolizinide moiety is planar and, with respect to DPM, either coplanar as in the Ni^{II} complexes (see later) or rotated by 90° as in ZnL(DPM) · 3 NAPH.[12] The complex CoL(DPM), if it exists, was not isolated. The reaction between LH and $Co(DPM)_2$, even under a rigorously controlled inert atmosphere, always gives a mixture of Co^{II} and Co^{III} complexes, characterized by a visible spectrum with two intense absorption maxima at 636 and 714 nm, respectively. Therefore, only the Co^{III} complex can be isolated as a pure species from the above reaction, provided that this is carried out under the appropriate conditions. A mild oxidizing agent (air) in a poorly Co^{II}-coordinating solvent (acetonitrile) was enough to achieve this. The complex $CoL(DPM)_2$ was therefore synthesized, and it could be recrystallized as a solvent-free species from hot toluene in air without decomposition.

X-ray Structure of the Solvent-Free NiL(DPM)

The molecular structure is shown in Figure 1. Selected bond lengths and angles are reported in Table 1. The nickel

atom is four-coordinate as NiN_2O_2 in a slightly distorted square-planar geometry with two imino-groups from the pyrrolizinido ligand (L) and two oxygen atoms from DPM. The Ni–N and Ni–O mean distances, of 1.889(8) and 1.840(9) Å respectively, are very close to the corresponding ones in the parent bis-chelate square-planar complexes NiL_2[13] and $Ni(DPM)_2$.[14] Also, the geometrical parameters within the two ligands L and DPM are similar to those of the above mentioned bis-chelates. This is different for the bis-pyrrolizinato NiL_2 complexes, in which two donor solvent molecules, doubly hydrogen-bonded to the chelating imino groups in the equatorial plane, are always present,[2,13] and no "equatorial adduct" is formed.

The NiL(DPM) molecule is essentially planar, the best plane being orthogonal to the (010) plane and is almost coincident with the crystallographic (–103) plane. The major molecular axis **x**, defined as the line passing through N(1), Ni, and C(21) atoms, makes angles of 35 and 62° with the *a* and *c* axes respectively, while the minor molecular axis **y**, normal to **x** through Ni in the plane, is parallel to *b*. The crystal structure of NiL(DPM) consists therefore of parallel, iso-oriented, solvent-free complex units, with only weak intermolecular interactions: symmetry-related molecular units weakly interact via –CN···HN– hydrogen bonds (N···H distances in the range 2.18–2.32 Å) developing along the *y* crystallographic direction.

X-ray Structure of NiL(DPM)(Pyr)$_2$ · 2 Pyr

The molecular structure is shown in Figure 2' and is strictly related to **1** decribed above. The nickel atom is in a distorted octahedral geometry NiN_4O_2, with two pyridine molecules axially coordinated at a distance Ni–N_{ax} of 2.117(9) Å (av.), whose planes are rotated 90° with respect to each other, bisecting the N(8)–Ni–N(14) and N(8)–Ni–O(19) angles, respectively. The Ni–N and Ni–O equatorial distances, of 2.084(12) and 2.004(11) Å respectively, are similar to those found in analogous octahedral nickel(II) complexes,[2,15] and longer by ca. 0.19 and 0.16 Å respectively than the corresponding values in the square-planar NiL(DPM). Also, the geometrical parameters of the two ligands L and DPM, although affected by high e.s.d.'s because of the presence of two interstitial solvent pyridine molecules in the asymmetric unit (each one disordered at two slightly different positions), are very similar to those found in **1** (see Table 2). As regards the crystal packing, it is noteworthy that the Ni–N_{ax} vector, the major molecular axis **x**, and the minor molecular axis **y** are parallel to *b*, *a*, and *c* respectively. Therefore, parallel iso-oriented molecular units are therefore also found, with weak intermolecular hydrogen-bonds (–CN···HN– in the range 2.56–2.64 Å) forming a monodimensional network along the *z* direction.

We may note that both complexes **1** and **2**, because of their crystallographic features, are good candidates for a spectroscopic investigation using polarized light on single crystals in order to have valuable information on the electronic structure of porphyrins in addition to the data already known from $FeL_2 \cdot 4$ THF.[6]

Optical Spectra of ML(DPM)

These spectra (Figure 3 and Table 3) are characterized by intense bands due to $\pi \rightarrow \pi^*$ electronic transitions localized on the planar system formed by the pyrrolizinido moiety and the adjacent chelate ring including the metal. The low-energy portion of these spectra from the window centered at 500 nm is very similar to that of the corresponding MPc's spectra, except for an enhanced band intensity in the latter. In particular, the Q band profile is amanzingly alike for the

nickel-containing species. It is to be noted, however, that the Q band maximum in the monopyrrolizinates shows a comparatively large dependence on the nature of the metal ion, varying by 47 nm from ZnL(DPM) to $CoL(DPM)_2$. In fact, for MPc's such a trend is almost negligible, being at most 9 nm. More interestingly, in the monopyrrolizinato series, the effect on the Q band can be examined by varying the M–N bond length in the molecular plane for the same M, as detailed in the following section.

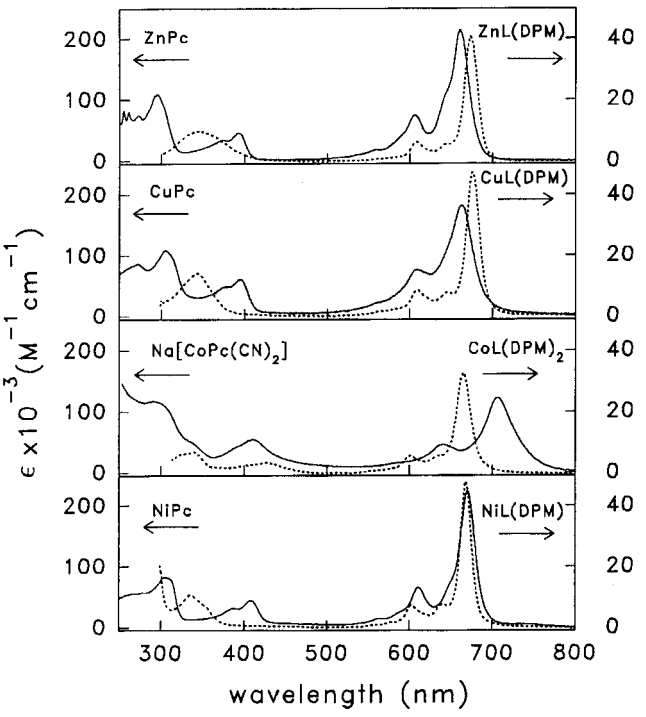

Figure 3. Solution optical spectra of the monopyrrolizinato metal complexes (—— in THF) and the corresponding metalphthalocyanines (- - - - NiPc and CuPc in 1,2,4-trichlorobenzene, Na-[$CoPc(CN)_2$] in acetone, ZnPc in dimethylacetamide)

Solvatochromism and Thermochromism of NiL(DPM)

NiL(DPM) shows an exceptional solvatochromism: its colour is pale-green in an uncoordinating solvent (CH_2Cl_2 or acetone) but becomes an intense blue in a coordinating solvent (THF) or on adding a coordinating species to the uncoordinating solvents, as for examples adding pyridine to CH_2Cl_2 or water to acetone. In Figure 4a, the pertinent spectral changes in question are reported for CH_2Cl_2/pyridine as a solvent system. These changes, being the same for the several solvent systems tested, can be interpreted as resulting from a perturbation of the frontier π orbitals of NiL(DPM) by axial coordination to the nickel atom. From the X-ray molecular structural parameters available, we can state that an elongation of the Ni–N bond in the molecular plane causes a sharpening, a blue shift, and an increase of the maximum intensity of the Q band. The change of the coordinating properties of the solvent also results in a different coordination geometry around the nickel ion, from square planar to octahedral, with an associated different optical metal d→d transition pattern.[16] However, such transitions are comparatively much weaker than the π→π* transitions, since their molar absorbitivities are in the range 1–100 $M^{-1}\cdot cm^{-1}$.[17] So, it can be concluded that the observed solvatochromism, which involves optical bands with molar absorbitivities in the range 10^4 $M^{-1}\cdot cm^{-1}$ (Table 3), originates from a conformational change of the π electron systems rather than by the difference in the metal coordination.

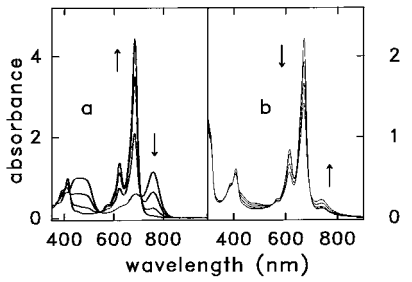

Figure 4. (**a**) Spectral changes of a dichloromethane solution of NiL(DPM) (3.0 mL, $C = 9.91\cdot10^{-5}$ M, pathlength = 1 cm) on adding increasing amounts (0.7, 1.7, 4.7 mL) of pyridine in CH_2Cl_2 (0.005 M). (**b**) Spectral changes of a THF solution of NiL(DPM) ($C = 6.03\cdot10^{-5}$ M, pathlength = 1 cm) on heating: 22, 40, 60, 75 °C. In both **a** and **b**, the arrows indicate the direction of the spectral changes

Moreover, NiL(DPM) in a coordinating solvent (e.g. THF) is thermochromic (Figure 4b). This phenomenon can be reasonably explained as solvatochromism. That is, by decreasing the temperature, the equilibrium in solution, NiL(DPM) · 2 THF $\rightleftarrows$ NiL(DPM) + 2 THF, shifts to the left. Therefore, the resulting spectral changes parallel those occurring on adding pyridine to NiL(DPM) in CH_2Cl_2.

For completeness, we ascertained that all other monopyrrolizinato complexes are neither solvatochromic nor thermochromic, including the isomorphous CuL(DPM). In this case, the reason for the absence of any solvatochromism, despite the well-known tendency of square-planar Cu^{II} complexes to increase the metal-coordination number, might be that the Cu–N_{eq} distances do not lengthen significantly, due to the large Jahn–Teller effect normally observed in these type of compounds,[3,18] on going from square-planar to tetragonally elongated hexa-coordination.

Optical Spectra of ML_2

We previously[1–4] reported the solution optical spectra of ML_2 complexes, but, for the reasons given below, most of these data actually referrred to ML species. Here, the correct spectra of the pertinent ML_2 species are presented for the first time (Figure 5 and Table 3). The resemblance of these spectra, particularly that of NiL_2, to the spectrum of H_2Pc is to be noted, within the limits already outlined in comparing ML(DPM) and MPc. This resemblance is now less surprising than in the previous interpretation, given that the two systems display the same symmetry (D_{2h}). We therefore conclude that the spectral changes occurring upon lowering the symmetry from D_{4h} to D_{2h} in tetraazatetrabenzoporphyrins are the same as those occurring when going from ML to ML_2, and that the resulting Q-band splitting is similar (0.8–1.0 Kk) in either case for M = Ni.

We now explain why the previously reported spectra of ML_2 were not interpreted correctly. Actually, the previous spectra were those of ML since they were recorded in solution with excess metal ion (M). Recently, we ascertained that an excess of free metal ion in solution in the presence of L' or ML_2 stabilizes the mono-pyrrolizinato species as a consequence of the reaction: ML_2 + M $\rightleftarrows$ 2 ML. The spectral changes associated with this reaction were recorded for M = Ni in methanol and methanol/THF as solvents. In both solvent systems, the initial and final spectra are the same, while the dynamics are different. The process is slower in methanol and can be easily followed at room temperature (Figure 6). From the presence of several isosbestic points it is clear that only one clean reaction occurs, and that the reaction product is the monopyrrolizinato-complex NiL, since the final spectrum is the same as that of NiL(DPM) (see Figure 3), except for the $\pi\rightarrow\pi^*$ electronic transitions (falling below 320 nm) localized on DPM in the latter.

Other noteworthy features of ML_2 spectra are, as in the ML(DPM) series, the dependence of the Q band maximum both on the metal ion (Table 3) and on the M–N bond length for constant M. Again, for M = Ni the consequent solvatochromism and thermochromism have been observed

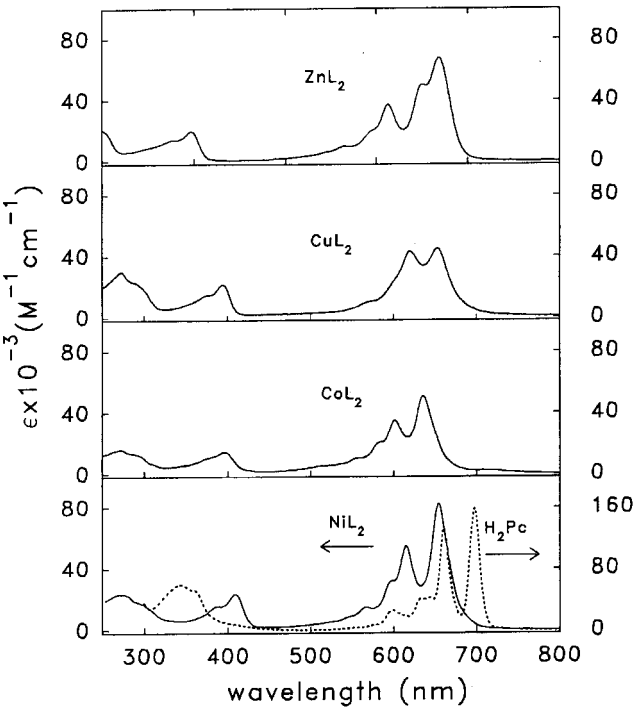

Figure 5. Solution optical spectra of bis-pyrrolizinato metal complexes (—— NiL_2 in CH_3OH, CoL_2, CuL_2, and ZnL_2 in THF) and of hydrogenphthalocyanine (- - - - in 1,2,4-trichlorobenzene)

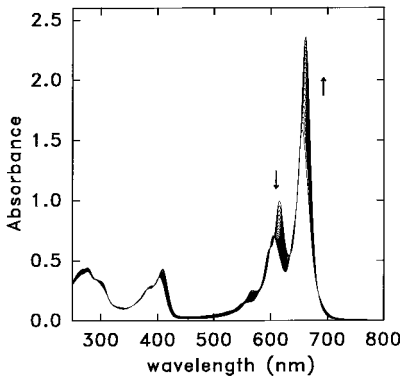

Figure 6. Spectral changes with time (every 5 min) undergone by a CH_3OH solution of NiL_2 (C = 1.96·10^{-4} M) after addition of 200 molar equivalents of $NiCl_2 \cdot 6\,H_2O$

in nitrobenzene/pyridine and ethyl acetate[19] as the solvent system, respectively.

Hypothesis on the Electronic Structure of ML Complexes

On the basis of the current solution spectral data, together with those from FeL_2, for which a close agreement between solution and solid state spectra was found, a correlation diagram of the frontier orbitals can be constructed for the MPc, H_2Pc, ML_2, and ML series, (Figure 7) and a reasonable hypothesis about the electronic structure of ML complexes can be put forward. This correlation diagram is presented in Figure 7. In ML_2 or H_2Pc (D_{2h}), four transitions give rise to the Q band. In MPc (D_{4h}) these transitions are reduced to two by symmetry.

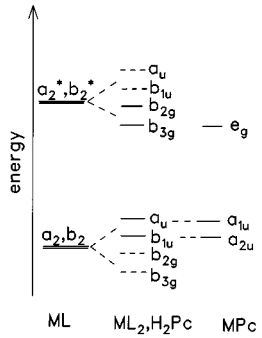

Figure 7. Qualitative scheme of the frontier orbitals for the systems ML, ML_2 or H_2Pc, and Mpc

Now, because of the similarity between ML and MPc, we must also suppose that the Q band is in ML is also composed of two electronic transitions involving MPc-like orbitals. In a C_{2v} molecule such as ML (Scheme 1), the π-molecular orbitals are of a_2 or b_2 symmetry and there is no forbidden π→π* transition, being $a_2 \rightarrow a_2$ or $b_2 \rightarrow b_2$ *x*-allowed and $a_2 \rightarrow b_2$ *y*-allowed. So, the frontier orbitals of ML could be two HOMO's (a_2, b_2) and two LUMO's (a_2^*, b_2^*), both nearly degenerate. The four excited electronic states, 2 A_1 and 2 B_1, originating from the transitions among these orbitals could be reduced to two after a configuration interaction: A_1 and B_1, consisting of the mixed configurations $a_2 \rightarrow a_2^*/b_2 \rightarrow b_2^*$ and $a_2 \rightarrow b_2^*/b_2 \rightarrow a_2^*$, respectively. Furthermore, this orbital pattern in ML is consistent with the frontier orbitals in ML_2. Here, the π-ligand orbitals can be considered as the symmetric and antisymmetric combinations of the corresponding orbitals of two ML weakly interacting fragments. As a matter of fact, the b_{3g} and a_u in D_{2h} are the symmetric and antisymmetric combination of a_2 in C_{2v}, while b_{1u} and b_{2g} are the corresponding combinations of b_2, respectively.

Conclusions

The optical spectra similarity between the pyrrolizinates and the phthalocyanines has been further studied: the spectra of ML_2 are similar to H_2Pc, and the increase of symmetry by switching from H_2Pc to MPc is spectrally equivalent to removing a pyrrolizinato moiety from ML_2. The origin of such similarity, in spite of the many differences between the two systems, still awaits an explanation and it will probably be accounted for only with appropriate molecular orbital calculations based mainly on the current experimental data. In the pyrrolizinates, the metal ion effect on the optical spectrum is much larger than in the phthalocyanines, so that the closest resemblance occurs for M = Ni and when Ni–N is relatively long (2.08 Å), in both ML and ML_2 series. The Ni-pyrrolizinates made it possible to see the effect on the electronic spectrum while varying the Ni–N bond length in the molecular plane. This effect is responsible for both the solvatochromism and the thermochromism in these species, while is not seen in the phthalocyanines because of the rigidity of the metal-coordinating hole size. Both title Ni–monopyrrolizinato species display a crystal structure suitable for spectroscopic investigation with polarized light, which is in progress. Therefore, additional experimental information on the electronic structure of these systems, valuable also for porphyrinic systems, will be available in the near future.

Experimental Section

Materials: Our procedures were followed for the synthesis of LH[20] and ML_2 (M = Co,[1] Ni,[2] Cu,[3] Zn[4]), while $M(DPM)_2$ (M = Co, Ni, Cu, Zn),[21] $Co(DPM)_3$[21] and $Na[CoPc(CN)_2]$[22] were prepared as described in the literature. Commercial H_2Pc, NiPc, CuPc, and ZnPc were purified by sublimation. Pyridine, CH_3CN, CH_3OH, THF, toluene, acetone, and CH_2Cl_2 were dried and freshly distilled before use. 1-Chloronaphthalene (NAPH) was used as received from Fluka.

General Procedures: Microanalyses were by Malissa and Reuter Analytische Laboratorien, Elbach, Germany, and by Servizio Microanalisi del CNR, Area della Ricerca di Roma. – Solution optical spectra were recorded on a Cary 5 and IR spectra on a Perkin–Elmer 16F PC FT spectrometer on Nujol mulls. – The magnetic measurements were carried out by using the Gouy method at room temperature. Molar susceptibilities were corrected for intrinsic diamagnetism estimated from Pascal's constants. – Suitable single crystals of ML for X-ray crystallography were grown in a sealed vial from a hot saturated solution of the sample in the appropriate solvent, followed by slow cooling, over several days, from the reflux temperature of the solvent down to room temperature (RT) in an ASCON M710 thermostatic oven.

Preparation of NiL(DPM): $Ni(DPM)_2$ (0.420 g, 0.985 mmol) was dissolved in methanol (60 mL) and LH (0.174 g, 0.746 mmol) added. After 1 h stirring a grey microcrystalline solid precipitated leaving a light-blue solution behind. After filtration, the solid was washed with methanol and dried in air. Yield 0.313 g (0.66 mmol, 88%). Diamagnetic: $\chi_M = -237 \cdot 10^{-6}$ e.m.u. – $C_{22}H_{21}N_7NiO_2$: calcd. C 55.73, H 4.46, N 20.68, Ni 12.38, O 6.75; found: C 56.77, H 4.30, N 21.10. Single crystals were obtained in a vial from a toluene/acetone (7:3) mixture, on cooling from 70 °C to room temp. over 15 d.

Crystal Growth of NiL(DPM)(Pyr)$_2$ · 2 Pyr: A suspension of NiL(DPM) (0.1 g) in a toluene/pyridine mixture (90:10, 30 mL) was heated under reflux, under N_2 for 30 min. The hot saturated solution was filtered and sealed in a vial under vacuum. On cooling the vial from 95 °C to room temp. over 20 h purple needle-like crystals of the NiL(DPM)–tetrapyridinate separated. This compound loses pyridine quite rapidly in air so that all the solid-state measurements on it were not reproducible, apart from the single crystal X-ray diffraction data, provided that the crystals were exposed to a saturated vapour of their mother liquor.

Preparation of CuL(DPM): $Cu(DPM)_2$ (1.930 g, 4.48 mmol) was dissolved in CH_3CN (80 mL) and LH (0.500 g, 2.15 mmol) added. An intense blue coloured solution was immediately formed. This solution was left 4 h at room temp. and then chilled down to –20 °C. A purple microcrystalline solid separated, which was filtered at low temperature and then dried in air. Yield 0.620 g, (1.29 mmol, 60%). Paramagnetic: $\mu_{eff} = 1.72\ \mu_B$. – $C_{22}H_{21}CuN_7O_2$: calcd. C 55.18, H 4.42, N 20.47, Cu 13.25, O 6.68; found: C 55.09, H 4.29,

N 21.51. Single crystals were obtained in a vial from a toluene/CH_3CN (7:3) mixture, on cooling from 90 °C to room temp. over 3 d and then leaving the sample at this temperature for another 10 d. This compound is isomorphous to the analogous NiL(DPM).[23]

[a] $R_{merge} = \Sigma_h \Sigma_i(\mid Ih,i - \langle Ih \mid \rangle)/\Sigma_h \Sigma_i Ih,i$ where Ih,i is the intensity value of the i^{th} measurement of h and $\langle Ih$ is the corresponding mean value of h for all i measurements of h. – [b] $R = \Sigma(\mid F_o - F_c \mid)/\Sigma|F_o|$. $R_w = [\Sigma_w(F_o - F_c)^2/\Sigma_w \mid F_o \mid ^2]^{1/2}$.

Preparation of ZnL(DPM) · 3 NAPH: $Zn(DPM)_2$ (1.119 g, 2.58 mmol) was dissolved in NAPH (40 mL). This solution was filtered and then LH (0.3 g, 1.29 mmol) added. After stirring the resulting suspension overnight under N_2, the microcrystalline solid in the reaction mixture changed colour from golden (LH) to purple. This solid was collected, washed with light petroleum and dried in air. It was then recrystallized from hot (120 °C) NAPH. The elemental analysis of this compound was not reproducibile, due to the partial loss of NAPH on drying it. Nevertheless, it was possible to ascertain its true composition by means of X-ray crystallography.[12]

Preparation of CoL(DPM)$_2$ $Co(DPM)_2$ (0.712 g, 1.67 mmol) was dissolved in CH_3CN (100 mL) and LH (0.400 g, 1.72 mmol) added. After stirring in air for 5 d at room temp., the resulting dark-green solution was evaporated to dryness. The residue was dissolved in boiling toluene. After filtration and cooling to room temp. the toluene solution afforded dark-green needle-like crystals. Yield 0.600 g (0.91 mmol, 55%). Diamagnetic: $\chi_M = -455 \cdot 10^{-6}$ e.m.u. – $C_{33}H_{40}CoN_7O_4$: calcd. C 60.27, H 6.13, N 14.91, Co 8.96, O 9.73; found: C 60.23, H 6.37, N 14.74, Co 9.02, O 9.95. Attempts to synthesize this compound from $Co(DPM)_3$ were unsuccessful due to the kinetic inertness of this species.

X-ray Crystallography of NiL(DPM) (1) and NiL(DPM)$(Pyr)_2 \cdot 2$ Pyr (2): Compound **1** crystallizes as dark-green needle-like platelets, stable in air, with one of the crystal dimensions being only some microns. In order to obtain a diffraction data set utilizable for an X-ray analysis, it was necessary to use high intensity synchrotron radiation. A well-formed crystal of dimensions 1.0 × 0.1 × 0.01 mm, fixed on a glass fiber, was therefore mounted on the Hard X-Ray Diffraction (HRD) beam-line of ELETTRA (Trieste).[24] Intensity data were collected by using a 16 keV radiation (λ = 0.775 Å) and a 180 mm MAR Image Plate Area Detector, and processed by DENZO[25] and CCP4[26] programs. Unit cell dimensions were determined by mounting the crystal on the Huber four-circle automated diffractometer of the same beam-line and refined from the setting angles of 15 selected high-angle reflections.

The crystals of **2** are unstable in air, leading to the loss of crystallization solvent: a selected crystal was therefore fixed inside a Lindemann capillary in the presence of the mother liquor. Data were collected on a rotating anode AFC5R Rigaku automated diffractometer (Cu-K_α radiation) with a graphite monochromator and corrected for absorption (psi-scan method), Lorentz and polarization effects. Cell constants were refined from setting angles of 22 reflections in the 2θ range 40–80°.

Both structures were solved by direct methods by using the SIR97 programs[27] and refined by full-matrix least-squares methods (248 and 405 variables segmented into two and four blocks for **1** and **2** respectively) by using the SHELXTL programs.[28]

Details of data collection and refinements are given in Table 42. Hydrogen atoms were included using a riding model.

Additional structural diagrams and tables listing atomic coordinates, bond lengths, bond angles, and anisotropic thermal parameters have been deposited with the Cambridge Crystallographic Data Centre under the numbers CCDC-130259 (**1**) and CCDC-130260 (**2**).Copies may be obtained without charge from: CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [fax: +44-1223/336033, E-mail: deposit@ccdc.cam.ac.uk, www: http//www.ccdc.cam.ac.uk].

Quantitative 2D EXSY and Dynamic ^{19}F-NMR Studies of the Dynamic Behaviour of the Bidentate Chelate Complex Ga(fox)$_3$ (fox = 5-fluoro-8-hydroxyquinoline)

Marina Gromova,[a] Olivier Jarjayes,[a] Sylvain Hamman,[a] Robert Nardin,[b] Claude Béguin,*[b] and Rudolph Willem[c]

Keywords: Coordination chemistry / Gallium(III) / Dynamik ^{19}F NMR / EXSY / Kinetics of ligand exchange / Bailar and Rây–Dutt mechanisms

The rates of intramolecular rearrangement of the *meridional* isomer of the metal *tris*-chelate complex [Ga(fox)$_3$, fox = 5-fluoro-8-hydroxyquinoline] in DMF solution were measured using 1D NMR line shape analysis and 2D EXSY spectra. The rates of exchange k_{ab}, k_{bc} and k_{ac} between the three non-equivalent ligands **a**, **b** and **c** were determined. The values of the activation parameters were obtained. ΔH^{+} was 70.6 kJ mol^{-1} for all the rate constants. ΔS^{+} was different in each of the three cases: ΔS^{+}_{ab}, ΔS^{+}_{bc} and ΔS^{+}_{ac} were 27.7, 28.5 and 34.6 J K^{-1} mol^{-1} respectively. The interpretation of these data was related to the discrimination of different twist processes (Bailar and Rây–Dutt) for intramolecular rearrangement of the *tris*-chelate complex.

Introduction

The elucidation of the mechanisms of intramolecular rearrangements of metal chelate complexes, especially those involving metal *tris*-chelate complexes, has been studied in depth but remains a problem of continuous significance in coordination chemistry.[1] *Tris*-chelate complexes with three identical unsymmetrical bidentate ligands can exist as two *facial* (*fac*) and *meridional* (*mer*) stereoisomers, each of which exists as enantiomers Δ and Λ. Changes in stereoisomers can be observed such as inversion or racemisation ($\Delta \rightleftarrows \Lambda$) and isomerisation (*fac* $\rightleftarrows$ *mer*). In the literature, two categories of intramolecular mechanism have been proposed, namely those involving temporary rupture of a metal-ligand bond and those that involve ligand twisting without any bond rupture. Among the different bond rupture mechanisms, Holm et al. showed that the most probable mechanism was the one with a square-pyramidal axial transition state.[2] For those processes with concerted non-bond-breaking geometrical changes, symmetry selection rules lead to the identification of four possible mechanisms named push-through, cross-over, Bailar (transition state with D_{3h} group of symmetry for symmetrical bidentate ligands) and Rây–Dutt (transition state with C_{2v} group of symmetry for symmetrical bidentate ligands).[3–7]

Several examples in the literature show that NMR spectroscopy is well adapted for kinetic measurements of such molecular rearrangements in complexes of appropriate metal cations:[1] chromium(III) complexes with the unsymmetrical bidentate (*S*)-tryptophan (^{1}H NMR),[7] ruthenium hydrides with triphenylphosphanes as other ligands (^{31}P NMR)[8] and several *tris*(unsymmetrical bidentate ligand)-metal(III) complexes of group 13 metals such as *tris*(trifluoroacetylacetonato)-Ga(III) complexes (^{19}F NMR),[9] *tris*-(substituted-tropolonato)metal(III) complexes (^{1}H NMR),[10] *tris*[2-(2'-hydroxyphenyl)-2-oxazolino]metal(III) complexes (^{1}H and ^{27}Al NMR),[11] *tris*(2-thienoyltrifluoroacetonato)metal(III) complexes (^{1}H and ^{19}F NMR),[12] *tris*(substituted-catecholato)metal(III) complexes (^{1}H NMR).[13]

Previously, we studied a new tripodal iron chelator, *O*-Trensox, based on 8-hydroxyquinoline.[14] Subsequently, we studied, as a model, the coordination chemistry of Ga(III) [the diamagnetic analogue of Fe(III)] with a fluorine-labelled sub-unit, the 5-fluoro-8-hydroxy-quinoline (fox).[15] The presence of only one fluorine atom per ligand leads to simplified ^{19}F-NMR studies. Recently, for the Ga(fox)$_3$ species, we were able to observe the minor *facial* isomer with its C_3 axis of symmetry and the more abundant *meridi-*

onal isomer with no elements of symmetry. In this case, the three ligands are chemically nonequivalent.[16] In addition, we were able to assign the three corresponding ^{19}F-NMR signals (using low temperature NOE experiments) as shown in Figure 1: **a** (the signal at higher frequency) assigned to the ligand perpendicular to the NGaN octahedral axis (or *antiperiplanar* to two oxygen atoms), **b** the signal at intermediate frequency, assigned to the ligand perpendicular to the OGaN axis, the first priority axis using Sloan's notation (or *antiperiplanar* to oxygen and nitrogen atoms), and **c** (the signal at lower frequency) assigned to the ligand perpendicular to the OGaO axis (second priority axis) (or *antiperiplanar* to two nitrogen atoms).[16,17]

The aim of this paper is to describe, very precisely, the stereochemical non-rigidity of the Ga(fox)$_3$ complex from the kinetic point of view and to analyse the nature of the intramolecular rearrangement mechanisms in dimethylformamide (DMF) solutions.

Results

The ^{19}F-NMR chemical shift values in ppm at low temperature (255 K, ^{1}H decoupled signals) in DMF for each fluorine of the ligands **a**, **b**, **c** in the *mer* complex were: $\delta_a = 22.80_5$, $\delta_b = 22.51_3$, $\delta_c = 21.83_8$. The corresponding chemical shift for the *fac* isomer was: $\delta = 22.28_9$.

1D Measurements versus Temperature

The line shapes of the ^{19}F Ga(fox)$_3$ signals at several temperatures are shown in Figure 2A. The exchange rates were determined by complete line shape analysis for a three-sites system (**a**, **b** and **c**). Calculated spectra are shown in Figure 2B.

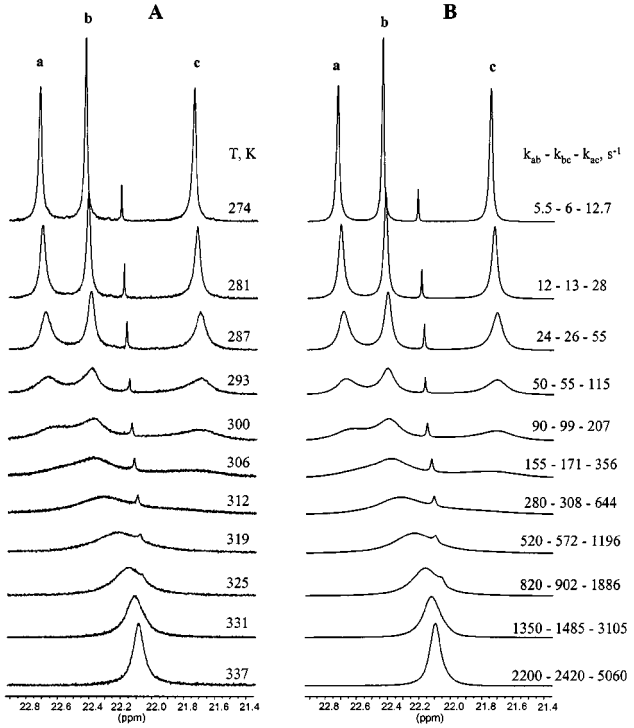

Figure 2. Variable temperature ^{19}F NMR spectra of Ga(fox)$_3$ in DMF (using ^{1}H decoupling): A – experimental, B – computer-simulated

A major problem for the refinement between experimental and calculated spectra is that the static NMR parameters were temperature dependent (chemical shifts and linewidths). Since the three populations for the different sites of exchange were equal and since all the coupling constants are suppressed, the temperature has no influence on these parameters. We also observed that the *fac* isomer intensity (5%) did not change in the explored temperature range.

(i) The temperature dependence of δ was not similar for the three signals **a**, **b** and **c**. We have recorded a set of spectra in a temperature range where the exchange effects were negligible. Assuming a linear variation of δ versus T we extrapolated the δ values at higher temperatures.

(ii) The linewidth was also an important parameter to determine in order to obtain accurate rate constants from the simulated spectra. The low temperature spectra allowed the determination of the relationship between the Ga(fox)$_3$ and C_6F_6 signals linewidth (lw). This ratio lw(*Ga(fox)$_3$*)/lw(*C_6F_6*) was approximately 1.6 in DMF. So, we evaluated the natural Ga(fox)$_3$ line from the C_6F_6 linewidth measured for each temperature, assuming that this pertinent ratio was constant for all the temperature range. We were comforted by the observation that the ratio between the width of the free ligand (fox) line and that of the C_6F_6 line was constant over the temperature range.

The exchange rates between the three ligands of the Ga(fox)$_3$ complex were determined by complete lineshape analysis for the 3-sites system through the " WIN-DYNAMICS " software (see Experimental Section). We differentiated three different exchange rates: k_{ab}, k_{bc} and k_{ac} corresponding to the **a** ⇄ **b**, **b** ⇄ **c** and **a**<->**c** ligand exchange respectively. The kinetics of exchange involving the *fac* isomer only occurred for temperatures higher than 319 K, so, its contribution in the main range was negligible. All the values are reported for the 262–350 K temperature range, along with their standard errors on the fit, in Table 1.

2D Measurements versus Temperature

2D EXSY experiments with appropriate mixing times were carried out. Figure 3 shows a contour plot of the spectra obtained in DMF at 273 K with $\tau_m = 30$ ms as a mixing time. From the volume of the cross-peaks, according to the methodology developed in the Experimental Section, we obtained a new set of reaction rates for three temperatures (249, 255 and 268 K). These values, with standard deviation higher than with 1D measurements, are also reported in Table 1. The aim of these experiments was to extend towards the low temperature range and to show clearly that the exchange rate k_{ac} was larger than the other rates, thus demonstrating the greater efficiency of the transfer of magnetization between **a** and **c**.

Table 1. Values of rate constants (s^{-1}) for exchange derived from 1D (lineshape analysis) and 2D EXSY ^{19}F-NMR spectra as a function of temperature (K)

T, K	k_{ab}, s^{-1}	k_{bc}, s^{-1}	k_{ac}, s^{-1}
249	0.17 (± 0.04)[a]	0.19 (± 0.04)[a]	0.39 (± 0.08)[a]

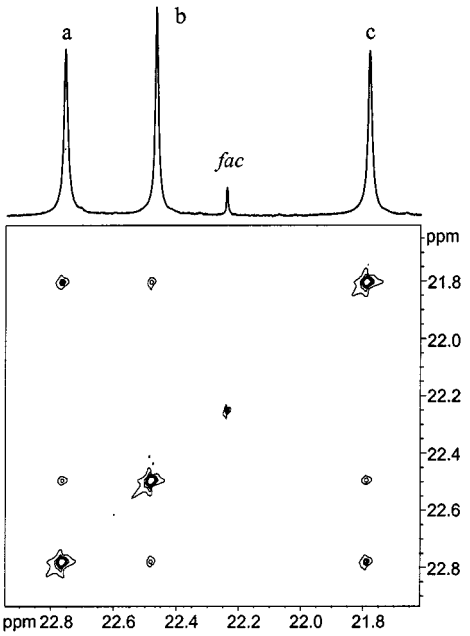

Figure 3. Contour plot of 2D EXSY ^{19}F NMR spectrum of $Ga(fox)_3$ in DMF obtained at 273 K with 30 ms as a mixing time

Rate Constants versus Temperature

For each temperature, the **a** ⇄ **b** exchange is the slowest, **b** ⇄ **c** is slightly faster and the **a** ⇄ **c** is the fastest (ratio of the rate constants k_{ab}, k_{bc} and k_{ac} were 1, 1.1 and 2.3 respectively).

The plots of $\log(kij/T)$ of these rate constants versus the reciprocal of temperature gave three straight lines (for the three lines, $r = 0.9997$) according to the Eyring formula (Figure 4):

$$\log(k/T) = \log(k_B/h) - \Delta H^{\#}/RT + \Delta S^{\#}/R$$

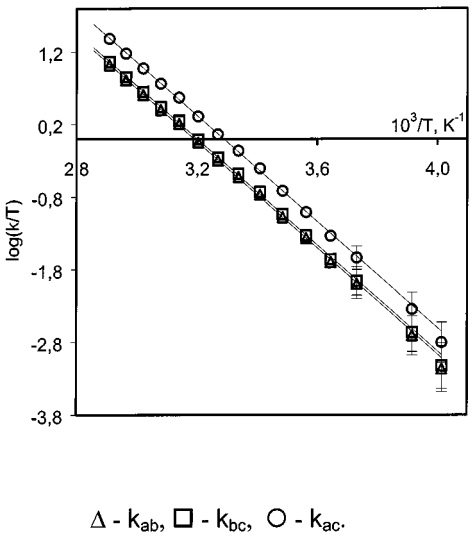

Figure 4. Eyring plot of $\log(k_{ij}/T)$ *versus* 1/T for ligand exchanges in $Ga(fox)_3$ in DMF

The activation parameters (enthalpy, entropy and free enthalpy at 293 K) are reported in Table 2.

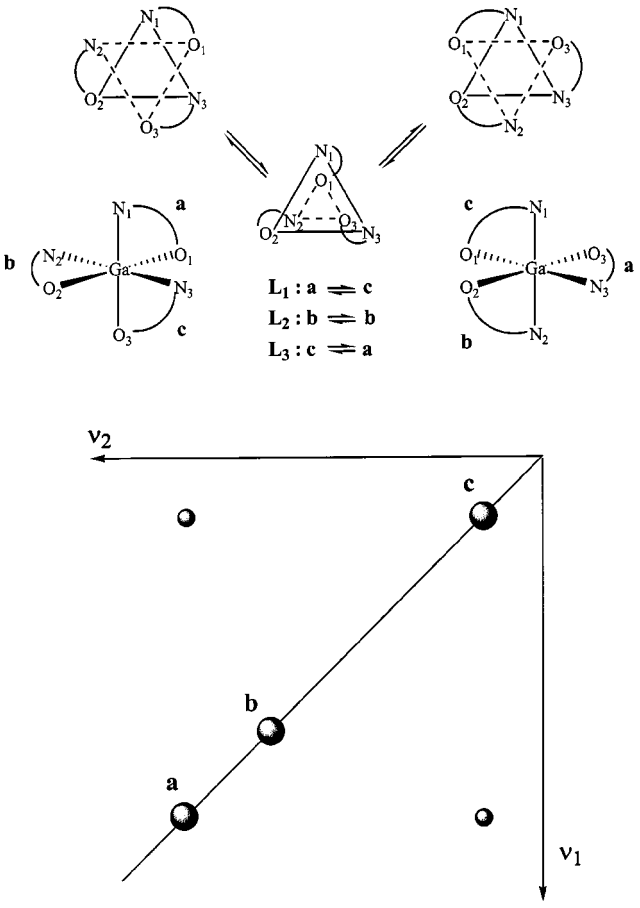
Table 2. Activation parameters for the ligand exchanges for $Ga(fox)_3$ in DMF

Exchange	$\Delta H^{\#}$, kJ mol^{-1}	$\Delta S^{\#}$, J K^{-1} mol^{-1}	$\Delta G^{\#}$, kJ mol^{-1} (293 K)
a ⇄ b	70.6 ± 0.5	27.7 ± 2	62.3 ± 1.5
b ⇄ c	70.6 ± 0.5	28.5 ± 2	62.1 ± 1.5
a ⇄ c	70.6 ± 0.5	34.6 ± 2	60.2 ± 1.5

The slopes of the Eyring plot are, within the experimental errors, the same. The ratio ($k_{ac}/k_{ab} = 2.3$) between the fastest and the slowest rate constants can be described as an "extra" entropy effect of about 6.5 J mol^{-1} K^{-1}.

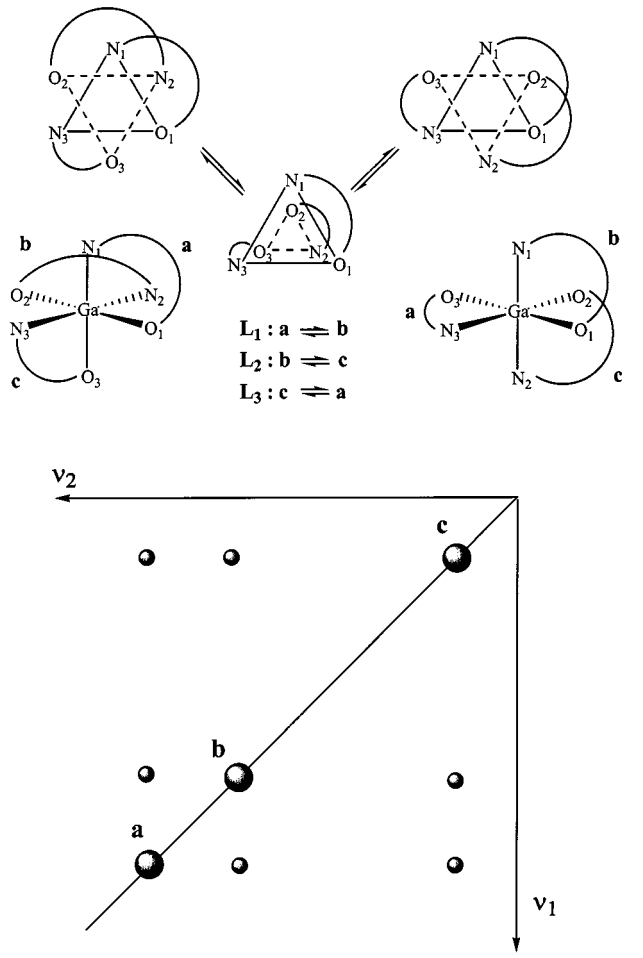
Discussion

The three main features of our kinetic results are:



(i) For each temperature, the ratio of the exchange reaction rates between the three sites are 1:1.1:2.3 for $k_{ab}/k_{bc}/k_{ac}$ respectively. This effect is particularly clear as shown in Figure 3 where the cross-peak from the **a** and **c** signals was larger than the two others involving the ligand **b**.

(ii) The kinetics of exchange involving the *fac* isomer among the exchange between the three sites of the *meridional* isomers was negligible.



(iii) The enthalpies of activation are, within the experimental errors, the same (70.6 kJ mol^{-1}) and the value of k_{ac} in comparison of the k_{bc} and k_{ab} can be described as an "extra" entropy effect of about 6.5 J mol^{-1} K^{-1}.

The intramolecular rearrangement processes of the $Ga(fox)_3$ complex are described as an inversion without isomerisation. The inversion proceeds by two energetically favourable twist mechanisms that are easily discriminated through the structure of their transition state:[1]

(i) Bailar's transition state, which has a C_3 axis of symmetry (trigonal prismatic geometry, Scheme 1). There is only one such transition state, and

Scheme 1. Intramolecular rearrangement through a Bailar transition state and predicted cross-peak intensity in a 2D EXSY experiment

Scheme 2. Intramolecular rearrangement through a Rây–Dutt transition state and predicted cross-peak intensities in a 2D EXSY experiment

(ii) Rây–Dutt's transition state, which has no element of symmetry (the group of symmetry for the corresponding complex with a symmetrical bidentate ligand would be C_{2v} with the C_2 axis perpendicular to the ligand joining the two planes in Scheme 2). There are three such transition states depending on the nature of the ligand (1, 2 or 3) perpendicular to the plane of the drawing.

If the internal rearrangement only consisted of a Bailar-type mechanism then Scheme 1 shows that ligand 1 (with the heteroatoms N and O labelled as 1 in the starting structure), which has an environment **a** (from the electronic distribution in the neighbourhood and has a high frequency ^{19}F chemical shift named site **a**), is moving to give, in the final structure, the site **c**. From the same scheme, ligand 2 (site **b**) and ligand 3 (site **c**) move to sites **b** and **a** respectively. We can predict that the transfer of magnetization occurs only between **a** and **c** as shown in the bottom part of Scheme 1. If the internal rearrangement consisted only of a Rây–Dutt type mechanism, Scheme 2 shows that ligand 1 with the environment **a** (named site **a**) is moving to give, in the final structure, the site **b**. Similarly, from Scheme 2, sites **b** and **c** move to **c** and **a** sites respectively. We can predict that the transfer of magnetization occurs as a permutation between **a**, **b** and **c**. The same permutation occurs for the two other Rây–Dutt transition states. The prediction of the cross-peak intensities is shown in the lower part of Scheme 2. So, as we observe non-equal magnetization transfers between the three **a**, **b** and **c** signals, we suggest that two mechanisms for internal rearrangement occur: a Rây–Dutt mechanism giving equal magnetization transfers between the three signals (at the origin of the almost equal k_{ab} and k_{bc} reaction rates) and an almost equal contribution (1.3) by a Bailar mechanism, at the origin of the higher k_{ac} reaction rate value (~ 2.3 k_{ab}).

The activation parameters of the two mechanisms seem to be the same. The $\Delta H^{\neq}$ value was 70.6 kJmol^{-1}, which is of the same order of magnitude as values obtained in dipolar aprotic solvents and reported in the literature.[13] A positive moderate $\Delta S^{\neq}$ value (28.1 J K^{-1} mol^{-1}) for the two processes (Bailar and Rây–Dutt) implies more disorder in the transition states than in the initial states. The apparent increase of entropy of 6.5 J K^{-1} mol^{-1} is only due to the contribution of the two mechanisms ($2.2 = e^{6.5/8.32}$). The activation parameters for the two processes were almost the same as no predominance of one of the two mechanisms was evidenced at one of the edges of the temperature range.

This fact suggests that the bond modifications from the initial state to the transition state are almost the same around the C_3 axis for the Bailar twist or the *pseudo*-C_3 axis for the Rây–Dutt twists. The same types of interactions of the initial and transition states with the solvent are at the origin of the same activation entropy values. These facts also confirm that a bond-rupture mechanism with a pendant axial ligand did not occur, as the entropy of activation should not be the same for a mechanism with temporary rupture of a metal-ligand bond and those with twisting without any bond rupture.[4,12]

The relative importance of the Bailar mechanism can also be interpreted in relation with the metal-chelating heteroatom distances in the complex. We were unable to obtain sufficiently good crystals of $Ga(fox)_3$ for X-ray crystallography, but in the literature we have data for closely related complexes $Fe(ox)_3$ and $Ga(ox)_3$ (where ox is for 8-hydroxyquinoline or oxine).[18,19] Table 3 gives selected values of metal-oxygen, metal-nitrogen and oxygen-nitrogen bond lengths for these two complexes. We can see that the metal-nitrogen$_b$ bonds are the shortest in relation with the **b** site, which "sees" no change in the Bailar-type process. More precisely, as discussed in several papers,[4,7] the pertinent parameter for these studies is the bite size (also called the normalised bite), defined as the ratio of the distance between the donor atoms of the chelate ring divided by the metal-donor atom distance. When this value is less than 1.5, the Bailar twist is energetically preferred over a Rây–Dutt twist.[4,7] From literature data in Table 3, this bite value is included in 1.244 to 1.384 values for the gallium complex and 1.212 and 1.360 for the iron one. These values are calculated as: the higher ratio for gallium (1.384) was obtained as the ratio of the highest distance between the donor atoms (265.8 pm) divided by the smallest metal-donor atom distance (192.1 pm); the lowest ratio (1.244) was obtained as the ratio of the shortest distance between the donor atoms (263.3 pm) divided by the largest metal-donor atom distance (211.6 pm), and the same for the iron case. Arguments developed by Rodger and Johnson show that a Bailar twist was energetically preferred over a Rây–Dutt twist for bite values less than 1.5.[4] We suggest that both mechanisms are plausible because the bite values for our system are not too far from 1.5.

Table 3. Selected bond lengths (pm) for $M(ox)_3$ complexes [M = Ga(III) or Fe(III)] from the literature[18,19]

Bond	Distance (pm) for Ga[19]	Distance (pm) for Fe[18]
M–Oa	192.9	195.6
M–Ob	195.6	199.6
M–Oc	192.1	193.6
M–Na	211.6	216.6
M–Nb	206.7	212.5
M–Nc	209.1	217.2
Oa–Na	263.3	262.5
Ob–Nb	264.8	262.8
Oc–Nc	265.8	263.3

We were also able to undertake experiments on the same complex in methanol as a solvent instead of DMF. The data obtained were not as detailed, especially from evaluation of the experimental errors, as linewidths for the complex were not so easily related to those of C_6F_6 as they were in DMF. Nevertheless, we can make some comments on the data. Assignment of the fluorine signals is the same for site **c** but the reverse for sites **a** and **b**. The enthalpies of activation are almost the same ($\Delta H^{\neq} = 72.5$ kJ mol^{-1}) as in DMF, but the entropies of activation are much lower ($\Delta S^{\neq}$ about 22 J K^{-1} mol^{-1}) than for DMF as the reaction rates at the same temperatures were slower in methanol than in DMF. This smaller positive entropy value in methanol than in DMF can be related with closer interactions between the transition state and the highly ordered protic solvent methanol. More work has to be done using this solvent for more detailed analysis of the rate constants for exchange between the three sites.

Conclusion

To our knowledge, this work constitutes one of the first measurements of three different rates of exchange between the three sites **a**, **b** and **c** in this type of complex. We were able to discriminate, from the kinetic point of view, the different twist processes (Bailar and Rây–Dutt) for intramolecular rearrangement in *tris*-chelate complexes of metal cations such as Ga(III) in solution, using 1D NMR line shape analysis and 2D EXSY measurements.

Experimental Section

Preparation of $Ga(fox)_3$: To a solution of 5-fluoro-8-hydroxyquinoline (denoted fox) (0.05 g, 0.31 mmol) in methanol (10 mL) was added $Ga(NO_3).9\ H_2O$ (0.36 g, 0.088 mmol) in methanol/water (10:1), followed by slow addition of 3.3 equivalents of sodium hydroxide (1 M). The resulting mixture was stirred for 15 min and evaporated to dryness.

Apparatus: The 1D ^{19}F- and 2D phase-sensitive ^{19}F-EXSY-NMR spectra of $Ga(fox)_3$ in DMF were recorded at 376.42 MHz on a Bruker AM 400 spectrometer at various temperatures. The ^{19}F chemical shifts are expressed in ppm with respect to the C_6F_6 line used as the internal reference. The ^{19}F-NMR chemical shifts for ^1H decoupled signals at 255 K in DMF were: $\delta = 22.80_5$ (s, F_a), $\delta = 22.51_3$ (s, F_b), $\delta = 21.83_8$ (s, F_c), $\delta = 22.28_9$ (s, F_{fac}). The variable-temperature accessories were calibrated with methanol and ethylene glycol samples. The measurement was repeated three times for each point of calibration. The NMR tubes were left in the probe during at least 20 minutes in order to obtain an equilibrium and were not spinning.

1D ^{19}F-NMR Spectra: The temperature range variations were 224–368 K for DMF (with a variation of 6 K by step). The ^{19}F spectra of $Ga(fox)_3$ were acquired with ^1H decoupling in Waltz mode, using a spectral width of 11.6 kHz, 32 K memory size, 3.4 s total recycling delay and 256 scans. The series of spectra were realised at low temperatures (without chemical exchange effects) in order to study the chemical shift variations as a function of temperature. For the control of the magnetic field stability, an accurate measurement of the linewidth of the C_6F_6 signal was carried out for each temperature. We evaluated the $Ga(fox)_3$ linewidth from the measured C_6F_6

linewidth multiplied by the ratio lw($Ga(fox)_3$)/lw(C_6F_6) (approximately evaluated to be 1.6). The final spectra were obtained after Fourier transformation using "1D Win-NMR" software. The simulation of 1D NMR exchange spectra was performed using the Bruker "Win-Dynamics" software.[20] We treated the data with the model of three exchanging sites on only one non-coupled spin 1/2.

2D ^{19}F-EXSY Spectra: 2D ^{19}F-EXSY spectra were recorded in DMF at 258, 263 and 273 K using a conventional NOESY *90° – t1 – 90° – τ_m – 90° – acq* phase sensitive pulse sequence[21] with time-proportional phase incrementation (TPPI). The 90° pulse length was calibrated at low temperature. The following parameters were used: spectral width 1104 Hz, with a size of 512 × 1024 data points, 512 time incrementations, 56 scans, total recycling delay of 2.9 s. The used mixing times (τ_m) were 0.2, 0.4, 0.6, 0.8 and 1 s at 258 K; 40, 60, 80 ms at 263 K and 10, 20, 30, 40, 50 ms at 273 K. Each EXSY spectrum required approximately 20 h of accumulation. Both FID's were apodized by a shifted sine-bell window function, with a shift of 2 to minimise the truncature, and was zero filled in t_1 dimensions to build a 1024 × 1024 points matrix. The auto- and cross-peak volumes were determined using "2D Win-NMR" Bruker software after phase and baseline corrections in both dimensions. The calculations of matrix elements were performed with "Mathematica" software on a Unix computer.

Rate Constant Calculation for Treatment of 2D Data: To calculate the rate constants we used the method of Perrin, Gipe and Dwyer,[22,23] improved on several examples by Willem,[24,25] which consists of determining the matrix of exchange (**L**) from all peak volumes obtained from an experiment at a single mixing time: $\mathbf{L} = (1/\tau_m)\ln\mathbf{A} = (1/\tau_m)\mathbf{U}\ln\ \mathbf{U}^{-1}$, where the elements of the matrix **A** are defined as $A_{kj}(\tau_m) = V_{kj}(\tau_m)/x_j$ (**U** and λ are the matrices of the eigenvectors and eigenvalues of **A**). $V_{kj}(\tau_m)$ represents the integrated auto-peak (k = j) or cross-peak (k ≠ j) volume and x_j is the molar chemical equilibrium fraction of the species associated with resonance j (in our case of intramolecular exchange $x_a = x_b = x_c$). We prefer to use this method rather than the one with matrix $A_{kj}(\tau_m) = V_{kj}(\tau_m)/M_j^0$, where M_j^0 is the volume of the corresponding auto-peak for $\tau_m = 0$). The substitution of M_j^0 by x_j affects only the exchange matrix **L** diagonal part and leads to the loss of the information about the longitudinal relaxation rate (containing in L_{jj} diagonal elements calculated with M_j^0). This method, however, allows the avoidance of comparison between auto- and cross-peak volumes from different EXSY spectra with important error in the case of instrumental instabilities during the rather long times of experiments (instability accentuated by necessity of work at low temperature). The same calculations were performed with replacement of cross-peak volumes V_{kj} and V_{jk} in matrix **A** by symmetrical value $(V_{kj} + V_{jk})/2$ in order to "smooth out" experimental error.[24–26] The rate constant obtained for each temperature was averaged from the data obtained at different mixing time and given with its standard deviation.

Acknowledgments

We thank Bruker Ltd for access to " Win-Dynamics " program and Dr. Ursula Weber (Bruker) for fruitful discussions. We thank Marie-Françoise Foray and Claude Gey for help on treatment of the data from AM 400 Bruker spectrometer and Marie-Christine Brochier for help on the simulations (centre Grenoblois de Résonance Magnétique Nucléaire). We also thank the Chemistry Department of the C.N.R.S. for providing a position of associated researcher for one of us (M. G.).

Structural Studies and Catalytic Activity of MCM-41 and MCM-48 Modified With the Titanocenophane $[SiMe_2(\eta^5\text{-}C_5H_4)_2]TiCl_2$

Paula Ferreira,[a] Isabel S. Gonçalves,[a] Fritz E. Kühn,[b] Martyn Pillinger,[a] João Rocha,*[a] Ana M. Santos,[b] and Alan Thursfield[a]

Keywords: Mesoporous materials / MCM-41 / MCM-48 / Immobilisation / Solid-state NMR / Heterogeneous catalysis / Titanium / Titanocenes

Titanium(IV)-grafted mesoporous silicas have been prepared by diffusion of an excess of the *ansa*-bridged titanocene $[SiMe_2(\eta^5\text{-}C_5H_4)_2]TiCl_2$ into the channels of hexagonal MCM-41 and cubic MCM-48 in dichloromethane or tetrahydrofuran at room temperature. The choice of solvent determines the course of the reaction and hence the activity of the resulting materials as catalysts in the catalytic epoxidation of cyclooctene with *tert*-butylhydroperoxide. Magic-angle spinning (MAS) NMR (^{13}C, ^{29}Si) spectroscopy was used to characterise the local environment of the surface-bound titanium active sites. When dichloromethane is used, the dominant species anchored to the surface are isolated *ansa*-bridged titanocene fragments. When THF is used, the $[SiMe_2(\eta^5\text{-}C_5H_4)_2]$ unit is lost with the concomitant formation of surface-bound Ti^{IV} species coordinated by THF molecules. These materials showed the best catalytic performance per Ti atom for the conversion of cyclooctene. All materials were further characterised by means of elemental analysis, powder X-ray diffraction (XRD), N_2 adsorption and FTIR spectroscopy.

Introduction

The confinement of redox-active metal centres on the surface of an inorganic oxide support matrix is a recognised route to heterogeneous catalysts for liquid-phase oxidations.[1] In the early Seventies the Shell Ti^{IV}/SiO_2 catalyst was developed for the epoxidation of propylene with ethylbenzene hydroperoxide.[2] An organic peroxide has to be used as the oxygen source in this process because the catalyst is sensitive to deactivation by water. This gives rise to toxic side products. A major step forward came with the discovery of titanium(IV) silicalite-I (TS-1),[3] obtained by the isomorphous substitution of titanium for silicon in the tetrahedral framework sites of silicalite-I, a hydrophobic molecular sieve possessing a three-dimensional system of intersecting elliptical pores with diameters of 5.3 × 5.5 and 5.1 × 5.5 Å. TS-1 is a catalyst for selective oxidations under very mild conditions with aqueous H_2O_2. Its remarkable activity is due to site isolation of Ti^{IV} centres in the hydrophobic pores of silicalite which allows for the simultaneous adsorption of the hydrophobic substrate and the oxidant. Site isolation is important because it prevents the oligomerisation of the Ti^{IV} centres to unreactive μ-oxo species.

TS-1 is a medium pore molecular sieve and its use is restricted to substrate molecules with kinetic diameters 5.5 Å. Thus, new materials with larger pore sizes and different coordination environments have always been sought. Examples include the hydrophilic Ti-doped zeolite β (pore diameter 7 × 7 Å),[4] and the recently discovered ETS-10 (Engelhard Corporation Titanium Silicate) containing tetrahedrally coordinated Si^{4+} and octahedrally coordinated Ti^{4+}.[5] A breakthrough into the mesoporous regime came with the discovery by researchers at the Mobil Corporation of a new generation of surfactant-templated (alumino)silicates (M41S) with very high surface areas (1000 $m^2\ g^{-1}$), high pore volumes (1 $cm^3\ g^{-1}$) and very narrow pore size distributions, tuneable in the range 16–100 Å.[6] The M41S family includes the thermally stable hexagonal MCM-41 and cubic MCM-48 phases. They have properties intermediate between those of SiO_2 and Al_2O_3, and microporous crystalline molecular sieves. Ti-substituted M41S, and related materials, have been prepared directly by either treating Ti alkoxides with silicon compounds, or mixing TiO_2 with silica.[7] One problem with these materials as catalysts is that access by the reactants to the Ti active centres is still somewhat limited as the latter are buried within the inner walls of the mesoporous solid.

An alternative strategy for the incorporation of redox-active metal centres into the internal surface of M41S materials is the covalent attachment of organometallic complexes by reaction with pendant silanol (Si–OH) groups.[1,8] Thomas and co-workers have prepared a heterogeneous titanium(IV) catalyst by diffusing a solution of Cp_2TiCl_2 in chloroform into the mesopores of MCM-41, followed by treatment with Et_3N to activate the Si–OH groups to form Si–O–Ti linkages.[9] The final catalyst is obtained by calcination to remove the organic ligands. An extension of this synthetic methodology comprises the functionalisation of the walls of MCM-41 with ferrocenyl end-groups by a ring-opening reaction of the strained metallocenophane $[Fe(\eta^5\text{-}C_5H_4)_2SiMe_2]$.[10] We followed up this work to show that

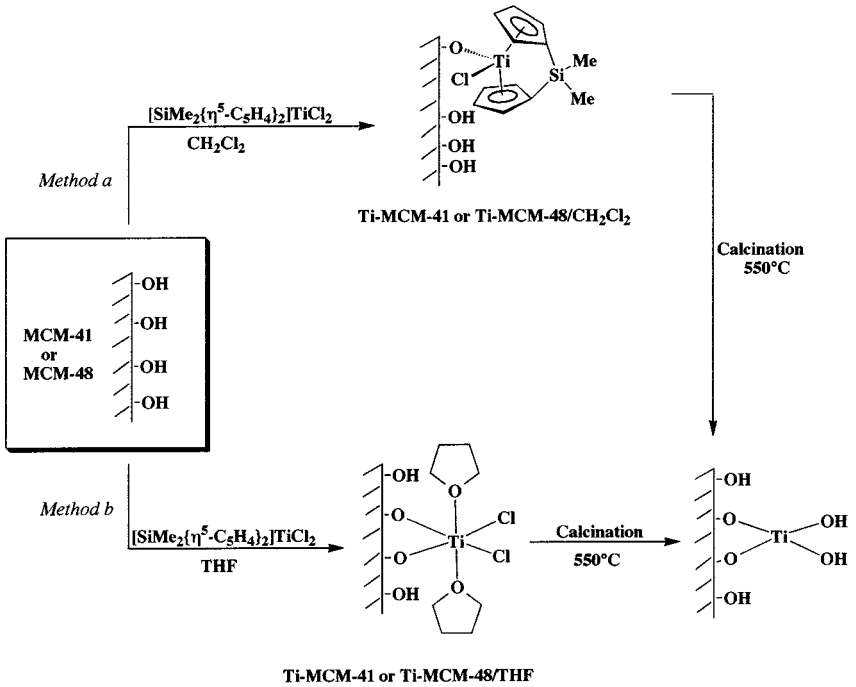
the organometallic complex reacts in a similar way with the surface silanols of MCM-48 to give a $C_5H_4SiMe_2$–O linkage.[11] We now wish to report studies on the derivatisation of MCM-41 and MCM-48 by direct reaction with the titanocenophane complex $[SiMe_2(\eta^5\text{-}C_5H_4)_2]TiCl_2$. All materials have been characterised by elemental analysis, powder XRD, N_2 adsorption and MAS NMR spectroscopy (^{13}C, ^{29}Si). The derivatised materials are catalysts for the epoxidation of cyclooctene.

Results and Discussion



Synthesis and Spectroscopic Characterisation

The introduction of an interannular bridge in titanocene dichloride alters its reactivity considerably, particularly in relation to reduction. A comparison of the redox behaviour of Cp_2TiCl_2 and the dialkylsilyl-bridged derivatives $[SiR_2(\eta^5\text{-}C_5H_4)_2]TiCl_2$ showed that the bridged compounds exhibit a single one-electron reversible reduction whereas the unbridged compound exhibits several reduction waves.[12] The stability of the one-electron reduced d^1 Ti^{III} monoanion of the bridged compounds has been rationalised on the basis of the ability of the SiR_2 ligand to restrict the mobility of the Cp rings and to maintain their original canted arrangement. As mentioned above, titanocene dichloride grafted onto mesoporous MCM-41 is a precursor to an active and selective heterogeneous epoxidation catalyst. Detailed spectroscopic and computational studies have confirmed that $(\equiv Si\text{–}O)_3TiCp$ is more likely to form than $(\equiv Si\text{–}O)_2TiCp_2$.[13] To the best of our knowledge, no studies have yet been made of the effect of the presence of an interannular bridge on the anchoring process, or the catalytic properties, of the grafted product.

The Ti-modified mesoporous materials are designated as Ti-MCM-41/(CH_2Cl_2 or THF) and Ti-MCM-48/(CH_2Cl_2 or THF), and were prepared as depicted in Scheme 1. MCM-41 and MCM-48 were treated with an excess of $[SiMe_2(\eta^5\text{-}C_5H_4)_2]TiCl_2$ in either dichloromethane (method a) or THF (method b). The products were isolated by filtration and washed thoroughly with the relevant solvent to remove excess organometallic before drying in vacuo at room temperature.

Method a gave grey/dark-brown, air-sensitive products which transformed to light brown powders after exposure to air for several hours. The products from method b were pale pink/beige powders and not visibly air-sensitive. Elemental analysis indicated that the materials contained approximately 4.2 mass% Ti (method a) or 1.2 mass% Ti (method b). This is consistent with a coverage of titanium atoms of 8.8×10^{-25} mol/nm^2 (0.5 Ti atoms per nm^2) and 2.5×10^{-25} mol/nm^2 (0.15 Ti atoms per nm^2), respectively. The former value is similar to the concentration of surface silanol groups in parent calcined MCM-41, reported to be in the range 1 to 3 per nm^2.[14] Grafted samples were subsequently calcined in air at 550 °C for 10 hours to remove organic components.

After treatment of the mesoporous materials with the titanocenophane complex in CH_2Cl_2 or THF the infrared band of the OH groups at 3742 cm^{-1} was noticeably reduced in intensity. In addition the spectra of MCM-41/CH_2Cl_2 or MCM-48/CH_2Cl_2 show bands at 2962 and 2930 cm^{-1}, representing the asymmetric and symmetric CH_3 stretching vibrations. The IR spectra of these anchored materials and of the starting material show that the C=C stretching modes in the region of 1400 cm^{-1} are similar. The bands assigned to the Cp ring, appearing at 1456 cm^{-1} and

Scheme 1. Modification of MCM-41 and MCM-48 using $[SiMe_2(\eta^5\text{-}C_5H_4)TiCl_2]$

1375 cm^{-1} for the free organometallic, are not shifted to different frequency on anchoring, indicating a similar interaction between the titanium centre and the Cp_2SiMe_2 group.

The powder X-ray diffraction (XRD) patterns of the parent calcined MCM-41 and MCM-48 can be indexed on a hexagonal unit cell (using the strongest reflection, d_{100}, a = 40 Å) and cubic unit cell (using the strongest reflection, d_{211}, a = 88.62 Å), respectively. The data for the as-synthesised and calcined Ti-modified MCM materials are consistent with retention of the hexagonal and cubic mesoporous structures throughout the grafting and calcination process (Figure 1 and 2).

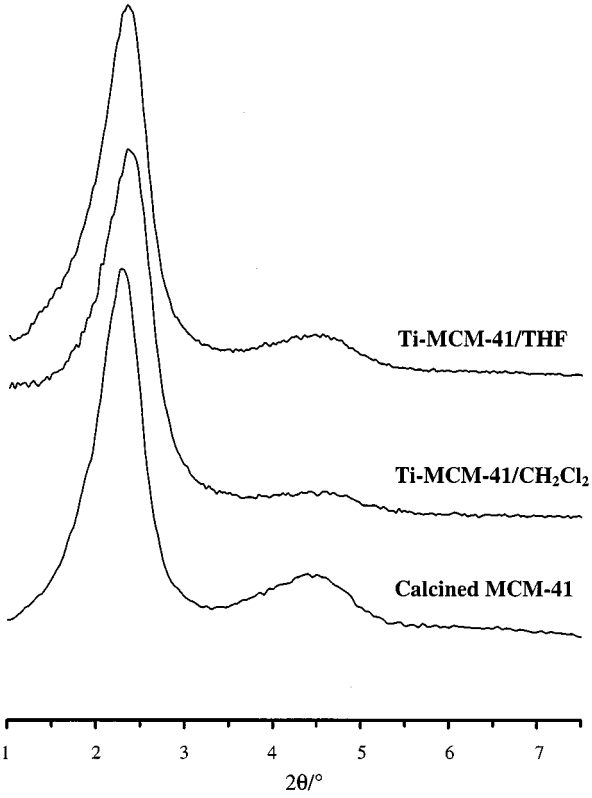


Figure 1. Powder XRD patterns of MCM-41 materials

Figure 3 and 4 show the ^{29}Si CP MAS and MAS NMR spectra for Ti-MCM-41 and Ti-MCM-48 prepared in dichloromethane, respectively. The ^{29}Si CP MAS NMR spectrum of Ti-MCM-41/CH_2Cl_2 exhibits two broad convoluted resonances, at δ = –108.4 and –100.3 assigned to Q^4 and Q^3 species, respectively [$Q^n = Si(OSi)_n(OH)_{4-n}$], together with a shoulder at δ = –92.8 ascribed to Q^2 species. The signal at δ = –3.8 can be assigned to asymmetric $[\mathbf{Si}Me_2(\eta^5\text{-}C_5H_4)_2]TiClO\text{–}Si$ in agreement with the ^{29}Si MAS NMR spectrum for $[\mathbf{Si}Me_2(\eta^5\text{-}C_5H_4)_2]TiCl_2$ (δ = –4.0). The other poorly defined broad resonances, at δ = 2.4 and δ = –16.2, are attributed to symmetric $[\mathbf{Si}Me_2(\eta^5\text{-}C_5H_4)_2]Ti(O\text{–}Si)_2$ species or to organic decomposition products. A similar result was obtained for Ti-MCM-48/CH_2Cl_2 (Figure 4). A comparison with the ^{29}Si CP MAS and MAS NMR spectra of the original mesoporous silicate showed that the intensity of the Q^2 and Q^3 species had decreased significantly.

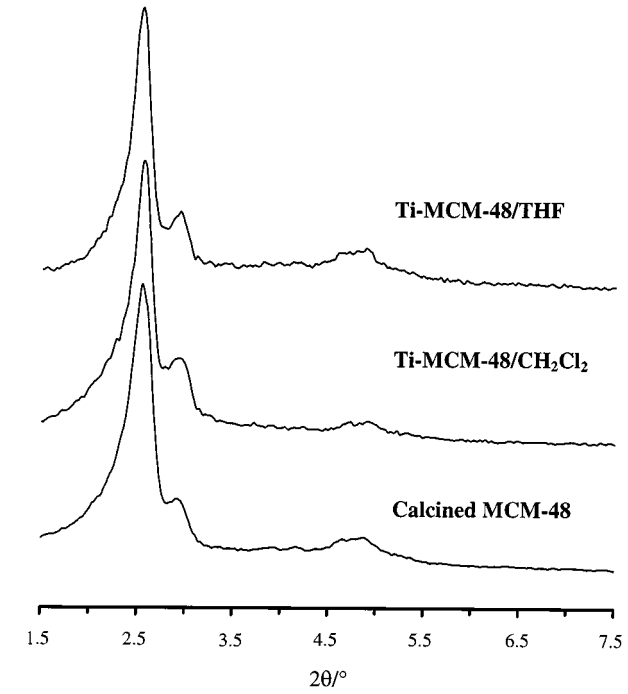

Figure 2. Powder XRD patterns of MCM-48 materials

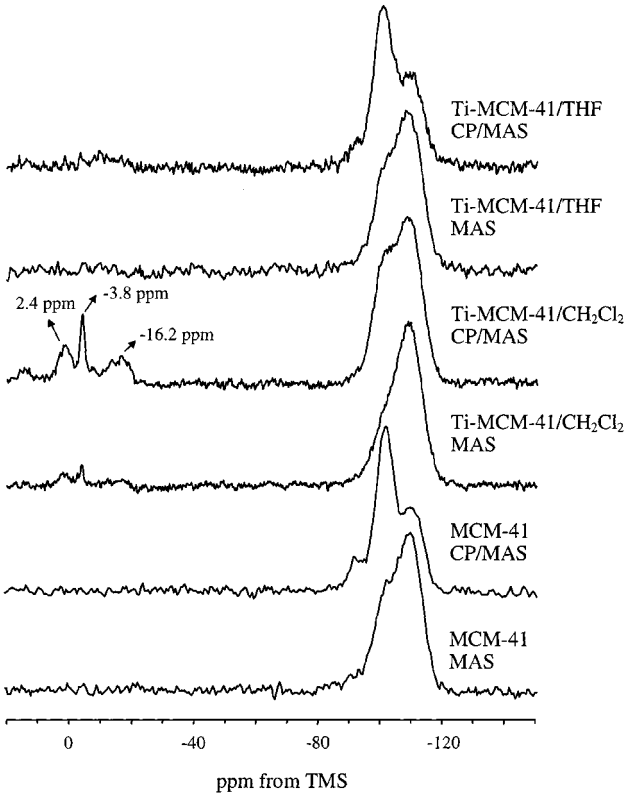

Figure 3. ^{29}Si CP MAS and MAS NMR at room temperature of MCM-41 materials

The ^{29}Si CP MAS NMR spectra of Ti-MCM-41/THF and Ti-MCM-48/THF only exhibited two broad, convo-

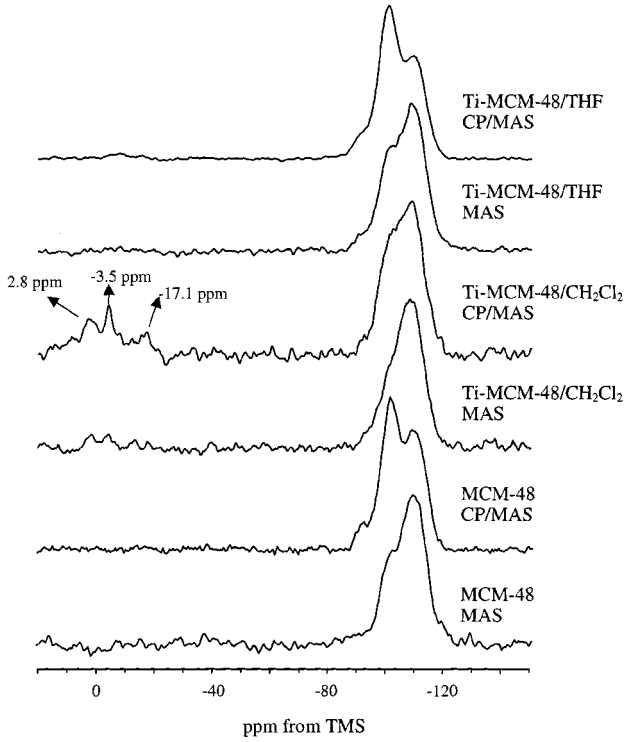

Figure 4. ^{29}Si CP MAS and MAS NMR at room temperature of MCM-48 materials

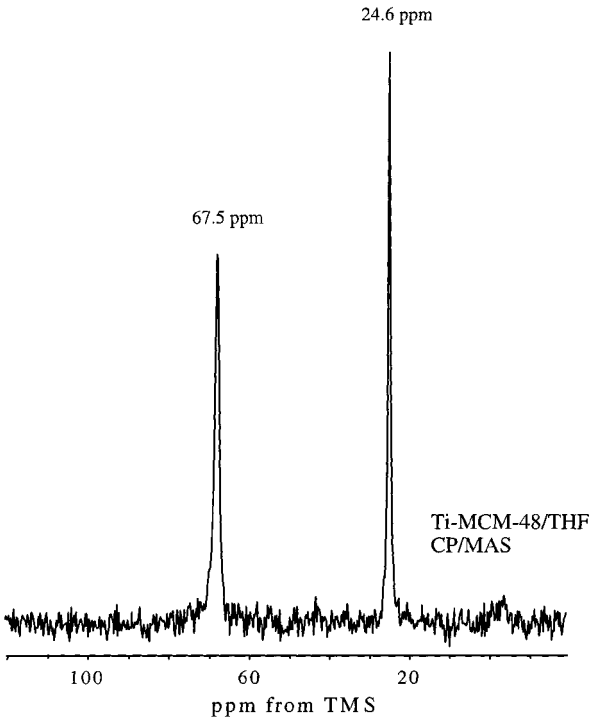

Figure 5. ^{13}C CP MAS NMR at room temperature

luted low-frequency resonances at δ –109.5 (Q^4) and at δ –101.0 (Q^3) together with a shoulder at δ –91 ppm (Q^2) (Figure 3 and 4). These results are consistent with the absence in the IR spectra of bands assignable to the Cp ring. Reaction of the organometallic with MCM-41 and MCM-48 in tetrahydrofuran replaces the Cp_2SiMe_2 group (Scheme 1). Alcohols are known to react with CpTi compounds with the replacement of the cyclopentadienyl group.[15]

Calcination of all these materials (Ti-MCM-41/CH_2Cl_2, Ti-MCM-48/CH_2Cl_2, Ti-MCM-41/THF, and Ti-MCM-48/THF) removes the organic ligand [$SiMe_2(\eta^5\text{-}C_5H_4)_2$ or THF] and these sites are probably occupied by an OH group (Scheme 1). After calcination all these materials give a similar ^{29}Si MAS NMR spectrum. Both the ^{29}Si CP MAS and MAS NMR spectra clearly show the diminished intensity of the Q^2 and Q^3 peaks relative to the Q^4 peak, indicating the esterification of the free hydroxyl groups. The presence of Ti-oxide species anchored to the silica surface is revealed by an IR absorption at around 950 cm^{-1} which has been assigned to the asymmetric stretching mode of Ti–O–Si groups.[7b]

The ^{13}C CP MAS NMR spectra of Ti-MCM-41/CH_2Cl_2 and Ti-MCM-48/CH_2Cl_2 are similar. The signals of the $SiMe_2$ and Cp ligands are slightly affected by immobilisation. Four broad resonances are observed, all of which are broader than those of the related crystalline titanocenophane [$SiMe_2(\eta^5\text{-}C_5H_4)_2$]$TiCl_2$. This broadening is due to the range of chemically different environments in which the molecules are located, giving rise to an envelope of peaks with very similar chemical shifts. The spectrum of Ti-MCM-41/CH_2Cl_2 exhibits four broad resonances at δ = 133.6, 120.6, 115.5 and –1.8 attributed to $(C_5H_4)_2Si$ and $SiMe_2$, respectively. These resonances can be compared with those given by the solid [$SiMe_2(\eta^5\text{-}C_5H_4)_2$]$TiCl_2$ (see Experimental Section). However, immobilisation takes place by elimination of one or more of the original chlorides with the hydrogen atoms from the silanol groups (Si–OH) in the MCM's and the spectrum appears more complicated. The low value of Cl/Ti suggests that the Ti–Cl bonds are involved in the reaction between the metallocene precursor and the MCM-41 or MCM-48 (Scheme 1). Analogous bipodal anchoring of the unbridged Cp_2Ti fragment has also been suggested for the very recently reported titanocene dichloride grafted ITQ-2,[16] a high surface area layered silica.

The ^{13}C MAS NMR spectra of Ti-MCM-41/THF and Ti-MCM-48/THF (Figure 5) only present two peaks at δ = 67.7 and 25.3 attributed to the THF coordinated to the titanium (Scheme 1).

N_2 Adsorption Studies

Figure 6 shows the N_2 isotherms of the parent and modified MCM-41 and -48 materials recorded at 77 K. The parent materials both gave a type IV isotherm with a small hysteresis, the A_{BET} specific surface areas were calculated to be 1035 m^2 g^{-1} for MCM-41 and 950 m^2 g^{-1} for MCM-48. The modified samples exhibit a lower uptake of N_2 than the parent solids as expected for successful incorporation of the organometallic within the pore systems. Adsorption of N_2 on the Ti-MCM-48/CH_2Cl_2 (Figure 6d) and Ti-MCM-41/THF (Figure 6e) samples was found to be very slow re-

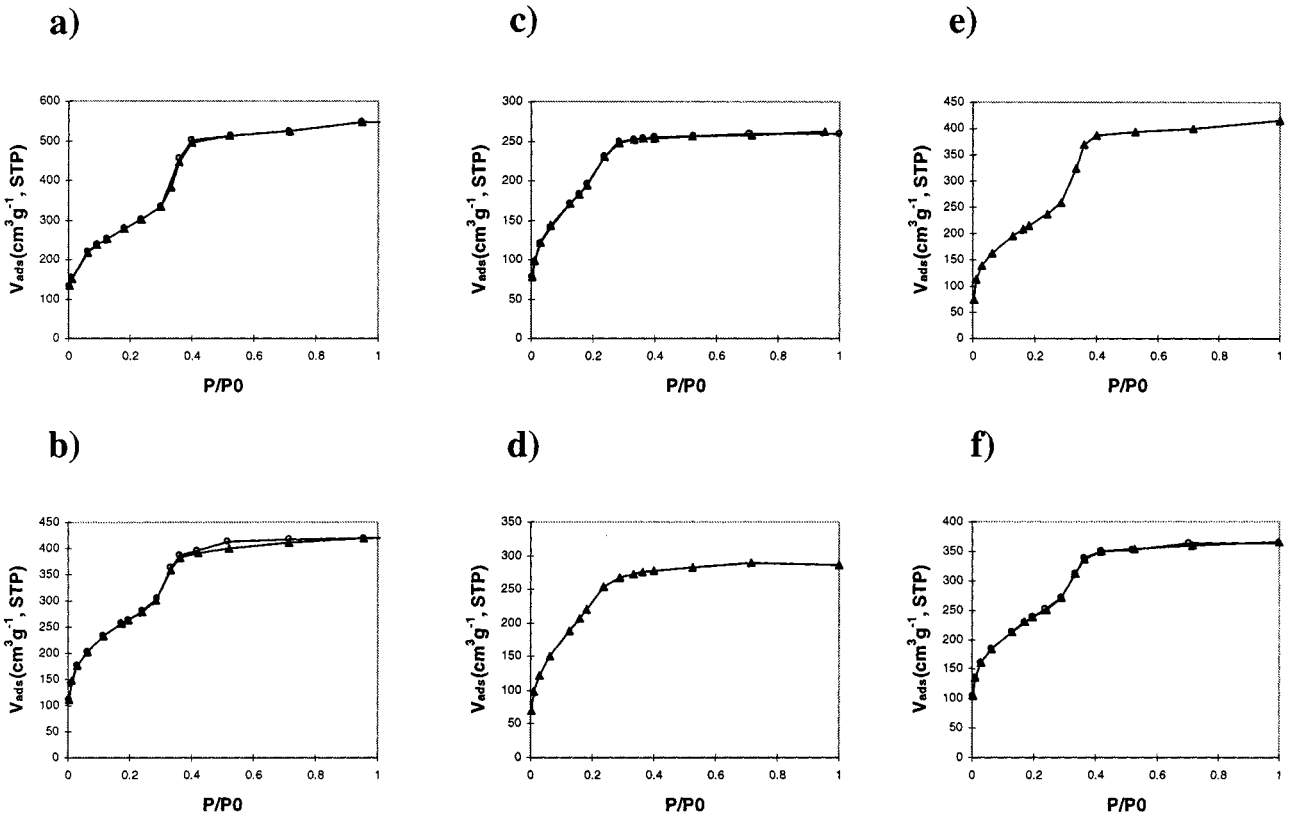

Figure 6. Isotherm of: (a) N_2 adsorption and desorption on MCM-41; (b) N_2 adsorption and desorption on MCM-48; (c) N_2 adsorption and desorption on Ti-MCM-41/CH_2Cl_2; (d) N_2 adsorption on Ti-MCM-48/CH_2Cl_2; (e) adsorption of N_2 on Ti-MCM-41/THF; (f) adsorption and desorption of N_2 on Ti-MCM-48/THF

sulting in nonequilibrium isotherms. The desorption part was not recorded for these two samples.

Inspection of the isotherms reveals that the materials produced using THF as the solvent exhibit a higher uptake of N_2 than those prepared using CH_2Cl_2 indicating that CH_2Cl_2 is superior in the task of promoting incorporation of the organometallic, in agreement with the elemental analysis results. The two samples produced using CH_2Cl_2 also have poorly defined capillary condensation regions as a result of the higher loadings. The incorporation of the organometallic appears to depend on the solvent employed and not on the pore system and pore diameters of the parent solids which are significantly different.

MCM-41 and MCM-48 Derivatives in Oxidation Catalysis

Reports have shown that Ti-MCM-41 materials are active and selective catalysts to perform the epoxidation of olefins by organic hydroperoxides.[7,9] Two distinct kinds of catalysts have been described, as mentioned above. The first accommodates the titanium ions within the walls of the mesoporous silica[7] and the second has the tetracoordinated Ti^{IV} ions grafted onto the inner surface of the mesoporous host.[9] The second catalyst is prepared via a titanocene dichloride-grafted precursor.[9] Surface-grafted Ti-MCM-41 catalysts have been shown to be more active than lattice-embedded Ti-MCM-41 materials in terms of activity per Ti centre, due to a large concentration of accessible, isolated and structurally well-defined active sites.[17]

The Ti-modified mesoporous silicas prepared in this work were screened as catalysts for the epoxidation of cyclooctene at 323 K with TBHP. The experimental details are given in the Experimental Section and results are shown in Figure 7.

It is evident that the materials prepared in CH_2Cl_2 show a higher conversion of cyclooctene after any given period than those prepared in THF. However, the materials prepared in THF are considerably more active in terms of conversion of cyclooctene per mol of titanium atoms. For example, after reacting for four hours, 55% conversion was observed for Ti-MCM-41/CH_2Cl_2 (25 mol cyclooctene per mol of titanium atoms) and 39% for Ti-MCM-41/THF (69 mol cyclooctene per mol of titanium atoms). Conversion was 88% for the former material after 24 h reacting.

As a general observation it can be concluded that $[SiMe_2(\eta^5\text{-}C_5H_4)_2]TiCl_2$ reacts in a similar way with the internal surfaces of MCM-41 and MCM-48 to give materials with similar titanium loadings, structurally similar monomeric Ti^{IV} species and similar catalytic activities. This is despite the fact that MCM-41 and MCM-48 possess very different mesoporous surfaces.

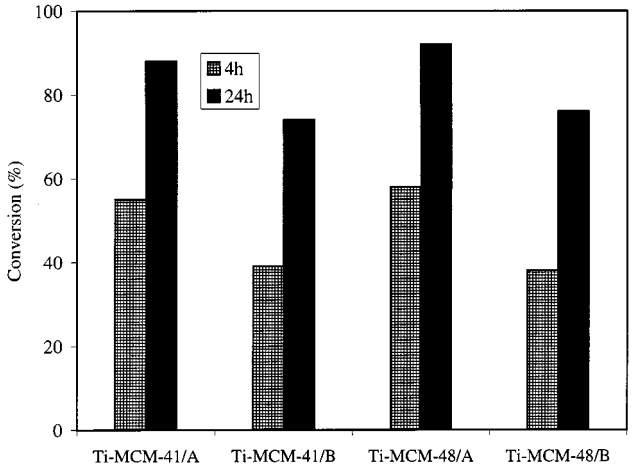

Figure 7. Conversion after 4 h and 24 h reacting in the catalytic oxidation of cyclooctene with TBHP on Ti-MCM materials (A, CH_2Cl_2); (B, THF); see text and Experimental Section for reaction details

Experimental

General: All preparations and manipulations were performed using standard Schlenk techniques under an oxygen- and water-free nitrogen atmosphere. Commercial grade solvents were dried and deoxygenated by refluxing for at least 24 h over appropriate drying agents under a nitrogen atmosphere and freshly distilled prior to use.

Powder X-ray diffraction (XRD) data were collected on a Phillips X'pert diffractometer using Cu-K_α radiation filtered by Ni. Microanalyses were performed at the TU Munich. Infrared spectra were recorded on a Unican Mattson Mod 7000 FTIR spectrophotometer using KBr pellets and/or solutions. ^{29}Si and ^{13}C NMR spectra were recorded at 79.49 and 100.62 MHz, respectively, on a (9.4 T) Bruker MSL 400P spectrometer. ^{29}Si magic-angle spinning (MAS) NMR spectra were recorded with 40° pulses, spinning rates 5.0–5.5 kHz and 60 s recycle delays. ^{29}Si CP MAS NMR spectra were recorded with 5.5 μs ^{1}H 90° pulses, 8 ms contact time, a spinning rate of 5.0 kHz and 4 s recycle delays. Chemical shifts are quoted in parts per million from TMS. ^{13}C CP MAS NMR spectra were recorded with a 4.5 μs ^{1}H 90° pulse, 2 ms contact time, a spinning rate of 8 kHz and 4 s recycle delays. Chemical shifts are quoted in ppm from TMS.

Nitrogen adsorption isotherms were recorded using a CI electronics MK2-M5 microbalance connected to a vacuum manifold line. The parent calcined MCM-41 and MCM-48 solids were dehydrated overnight at 723 K to an ultimate pressure of 10^{-4} mbar and then cooled to room temperature prior to adsorption. Extra care with the functionalised materials was necessary due to the possibility of aerial oxidation and therefore transfer to the balance and outgassing of the system was rapid. A lower dehydration temperature of 413 K was used with these samples to further minimise destruction of the functionalities. Nitrogen isotherms were then recorded at 77 K. Equilibration of each data point was monitored using CI electronics' Labweigh software and the pressure monitored using an Edwards Barocel pressure sensor. Specific surface areas, A_{BET}, were determined from the linear part of the BET plot (P/P_o = 0.05–0.3) assuming the average area occupied by a N_2 molecule in the monolayer to be 16.2 Å^2.

$[SiMe_2(\eta^5\text{-}C_5H_4)_2]TiCl_2$ was prepared as described previously.[12] ^{13}C CP MAS NMR (25 °C): δ = 132.6 [$(C_5H_4)_2Si$], 120.8 [$(C_5H_4)_2Si$], 116.2 [$(C_5H_4)_2Si$], –1.2 (SiMe_2). – ^{29}Si MAS NMR δ = –4.0 [$SiMe_2(\eta^5\text{-}C_5H_4)_2$]

The hexagonal channel host MCM-41 was synthesised from $[(C_{14}H_{29})NMe_3]Br$ according to published procedures.[18] After calcination (540 °C/6 h), the material was characterised by powder XRD, N_2 adsorption and FTIR spectroscopy.

The cubic channel host MCM-48 was synthesised from $[(C_{16}H_{33})NMe_3]Cl$ according to published procedures.[19] After calcination (540 °C/6 h), the material was characterised by powder XRD, N_2 adsorption and FTIR spectroscopy.

Preparation of Ti-MCM-41. Method A: Calcined MCM-41 (0.5 g) was activated at 180 °C under high vacuum for 2 hours and then treated with an excess of $[SiMe_2(\eta^5\text{-}C_5H_4)_2]TiCl_2$ in CH_2Cl_2 (20 mL). The mixture was stirred at room temperature for 4 days. The solution was filtered off and the grey solid washed three times with 15 mL portions of CH_2Cl_2 before drying under high vacuum at room temperature for several hours. Found: Ti 4.24, Cl 5.38, C 12.37, H 2.60. – IR (KBr): $\tilde{\nu}$ = 3428 vs, 2962 m, 2930 m, 2858 w, 1637 s, 1456 w, 1402 m, 1380 w, 1236 vs, 1172 w, 1080 vs, 955 m, 807 s, 586w, 453 s cm^{-1}. – ^{29}Si MAS NMR: δ = –108.6 (br.), –3.4 [$SiMe_2(\eta^5\text{-}C_5H_4)_2$], 3.1 (br.). – ^{29}Si CP MAS NMR: δ = –100.3 (br., Q^3), –108.4 (br., Q^4), –92.8 (weak, Q^2), –3.8 [$SiMe_2(\eta^5\text{-}C_5H_4)_2$], –16.2 (br.), 2.4 (br.). – ^{13}C CP MAS NMR (25 °C) δ = 133.6 [br., $(C_5H_4)_2Si$], 120.6 [br., $(C_5H_4)_2Si$], 115.5 [br., $(C_5H_4)_2Si$], –1.8 (br., SiMe_2).

Method B: Calcined MCM-41 (0.5 g) was activated at 180 °C under vacuum for 2 hours and then treated with an excess of $[SiMe_2(\eta^5\text{-}C_5H_4)_2]TiCl_2$ in THF (15 mL). The mixture was stirred at room temperature for 66 hours. The solution was filtered off and the pale pink solid washed three times with 10 mL portions of THF before drying under vacuum at room temperature for several hours. Found: Ti 1.10, Cl 2.00. – IR (KBr): $\tilde{\nu}$ = 3461 vs, 2976 w, 2932 w, 1637 s, 1383 w, 1235 vs, 1081 vs, 964 m, 801 m, 571 w, 458 s cm^{-1}. – ^{29}Si MAS NMR: δ = –107.9 (br.). – ^{29}Si CP MAS NMR: δ = –100.4 (br., Q^3), δ = –110.2 (br., Q^4), –91.0 (weak, Q^2). – ^{13}C MAS NMR (25 °C) δ = 67.7 (THF), 25.3 (THF).

Preparation of Ti-MCM-48. Method A: Calcined MCM-48 (0.5 g) was activated at 180 °C under vacuum for 3 hours and then treated with an excess of $[SiMe_2(\eta^5\text{-}C_5H_4)_2]TiCl_2$ in CH_2Cl_2 (20 mL). The mixture was stirred at room temperature for 4 days. The solution was filtered off and the grey solid washed three times with 15 mL portions of CH_2Cl_2 before drying under vacuum at room temperature for several hours. Found: Ti 4.10, Cl 5.20, C 11.33, H 2.70. – IR (KBr): $\tilde{\nu}$ = 3437 vs, 2965 m, 2929 m, 2858 m, 1636 s, 1457 w, 1395 m, 1375 w, 1238 vs, 1076 vs, 956 m, 807 s, 452 s cm^{-1}. – ^{29}Si MAS NMR: δ = –108.2 (br.), –3.6 [$SiMe_2(\eta^5\text{-}C_5H_4)_2$], 1.9 (br.). – ^{29}Si CP MAS NMR: δ = –101.6 (br., Q^3), –108.5 (br., Q^4), –91.9 (weak, Q^2), –3.5 [$SiMe_2(\eta^5\text{-}C_5H_4)_2$] –17.1 (br.), 2.8 (br.). – ^{13}C CP MAS NMR (25 °C) δ = 132.0 [br., $(C_5H_4)_2Si$], 124.5 [br., $(C_5H_4)_2Si$], 115.2 [br., $(C_5H_4)_2Si$], –2.0 (br., SiMe_2).

Method B: Calcined MCM-48 (0.5 g) was activated at 180 °C under vacuum for 2 hours and then treated with an excess of $[SiMe_2(\eta^5\text{-}C_5H_4)_2]TiCl_2$ in THF (20 mL). The mixture was stirred at room temperature for 66 hours. The solution was filtered off and the pale pink solid washed three times with 20 mL portions of THF before drying under vacuum at room temperature for several hours. Found: Ti 1.30, Cl 2.12. – IR (KBr): $\tilde{\nu}$ = 3481 vs, 1636 s, 1230 s, 1082 vs, 957 m, 804 m, 564 w, 455 s cm^{-1}. – ^{29}Si MAS NMR: δ = –101.2 (br., Q^3), δ = –108.2 (br., Q^4). – ^{29}Si CP MAS NMR: δ = –100.6 (br., Q^3), δ = –109.2 (br., Q^4). – ^{13}C CP MAS NMR (25 °C) δ = 67.5 (THF), 24.6 (THF).

Preparation of Calcined Samples: As-synthesised Ti-MCM-41 and Ti-MCM-48 were dried in air at 110 °C for 1 h prior to calcination in air at 550 °C for 10 h (heating rate 1 °C/min). The resultant materials have the same textural and structural characteristics as the parent calcined materials.[16]

Catalytic Reactions With Ti-MCM-41 and Ti-MCM-48: *cis*-Cyclooctene (800 mg, 7.3 mmol), *n*-dibutyl ether (800 mg, internal standard), Ti-MCM-41/(CH_2Cl_2 or THF) or Ti-MCM-48/(CH_2Cl_2 or THF) (180 mg) and 5.5 M *t*-butyl hydroperoxide in decane (2 mL) were added to a thermostated reaction vessel and stirred for 24 h at 50 °C. The course of the reaction was monitored by quantitative GC-analysis. Samples were taken every thirty minutes, diluted with dichloromethane, and chilled in an icebath. For the destruction of hydroperoxide and removal of water a catalytic amount of manganese dioxide and magnesium sulfate was added. After the gas evolution ceased the resulting slurry was filtered over a filter-equipped Pasteur pipette and the filtrate injected onto the GC column. The conversion of cyclooctene and formation of cyclooctene oxide was calculated from a calibration curve ($r^2 = 0.999$) recorded prior to the reaction course.

Study of Copper(II) Polyazamacrocyclic Complexes by Electronic Absorption Spectrophotometry and EPR Spectroscopy

Carlos F. G. C. Geraldes,*[a] M. Paula M.Marques,[b] Baltazar de Castro,*[c] and Eulália Pereira[c]

Keywords: Macrocyclic ligands / Copper / EPR spectroscopy / Electronic spectrophotometry

Copper(II) mononuclear complexes with the polyazamacrocyclic ligands NOTA (1,4,7-triazacyclononane-*N*,*N*′,*N*″-triacetate), DOTA (1,4,7,10-tetraazacyclo-dodecane-*N*,*N*′,*N*″,*N*‴-tetraacetate), NOTP [1,4,7-triazacyclononane-*N*,*N*′,*N*″-tris(methylenephosphonate)] and DOTP [1,4,7,10-tetraazacyclododecane-*N*,*N*′,*N*″,*N*‴-tetrakis(methylenephosphonate)] were characterised in aqueous solution by electronic absorption spectrophotometry and electron paramagnetic resonance (EPR) spectroscopy. While two isomeric species were detected by EPR spectroscopy in frozen samples of the polycarboxylate complexes, only one complex form was found for the poly(methylenephosphonate) systems. The results obtained are in accordance with a six-coordinate pattern for the metal centre, yielding tetragonally distorted complexes in solution, in agreement with previously reported studies on Cu^{II} complexes, both in solution and in the solid state.

Introduction

In the past two decades there has been a growing interest in the study of metal complexes with macrocyclic polyfunctional ligands, as they have found use in a wide variety of applications, ranging from analytical chemistry[1–4] to biochemistry and medicine.[5–7] A knowledge of the conformational preferences of these systems in aqueous solution is thus of the utmost importance in predicting their coordination behaviour and understanding their mechanism of action.

Among the numerous macrocyclic ligands known, the coordination chemistry of many transition metal ions with the *N*-substituted polyazamacrocycles NOTA (1,4,7-triazacyclononane-*N*,*N*',*N*''-triacetate), DOTA (1,4,7,10-tetraazacyclododecane-*N*,*N*',*N*'',*N*'''-tetraacetate), NOTP [1,4,7-triazacyclononane-*N*,*N*',*N*''-tris(methylenephosphonate)] and DOTP [1,4,7,10-tetraazacyclododecane-*N*,*N*',*N*'',*N*'''-tetrakis(methylenephosphonate)] (Figure 1), due to their remarkable chelating properties, has been the object of numerous studies. Complexes of the above ligands with Cu^{II} are well characterised, but no studies by electron paramagnetic spectroscopy (EPR) have been reported to date on Cu^{II} complexes with the tri- and tetraaza-polyphosphonate ligands. Furthermore, even though there is a reported EPR study on the Cu^{II}/DOTA system,[8] the effect of the pH on the EPR pattern of these macrocyclic complexes in aqueous solution was never investigated.

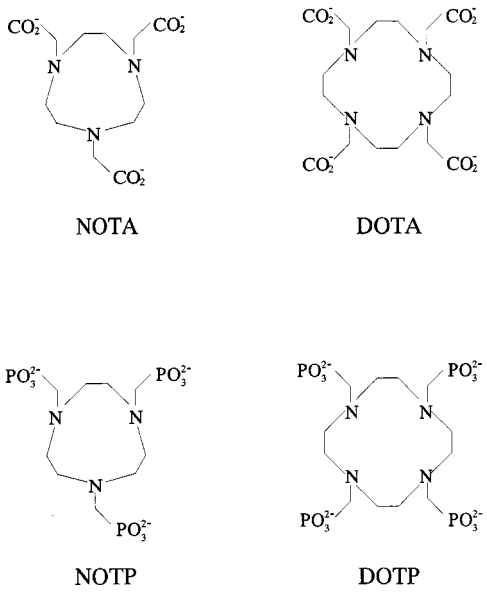

Figure 1. Schematic representation of the macrocyclic ligands investigated in this work

The solid-state structures of Cu^{II} complexes with NOTA,[9] NOTP,[10] DOTA,[11] and analogous tetraazamacrocyclic ligands,[12–20] have been obtained by X-ray diffractrometry. The NOTA complex in $Na[Cu(NOTA)] \cdot 2\,NaBr \cdot 8\,H_2O$ was found to have a distorted pseudoprismatic geometry, with the metal ion bound to all donor atoms of the ligand (three carboxylate oxygen atoms and three ring nitrogen atoms).[9] In the methylenephosphonate analogue Cu^{II}/NOTP the metal ion is bound to only two oxygen atoms from the pendant arms of the macrocycle and to the three ring nitrogen atoms in a dis-

torted square-pyramidal structure; the axial position is occupied by a ring nitrogen atom, for which the usual long axial Cu–N bond length is observed.[10]

In the mononuclear Cu^{II} complex with the tetraaza ligand DOTA, the metal ion exists in a distorted octahedral geometry, coordinated to all ring nitrogen atoms and to two (opposite) carboxylate oxygen atoms; the other two carboxylate groups are protonated.[11] The two coordinated oxygen and two nitrogen atoms (in the *trans* positions in the macrocycle) occupy the equatorial positions, while the other two nitrogen atoms are axially bound. The axial bonds are elongated, as expected from the Jahn-Teller effect, but this elongation is not as pronounced as in other copper(II) complexes, probably as a consequence of steric constraints imposed by the cyclic structure of the ligand.

The stability constants in aqueous solution (at 298 K) of copper(II) complexes with polyaza ligands have been determined by several authors: NOTA, $\log K_{ML}$ = 21.63 (1 M $NaClO_4$);[21] DOTA, $\log K_{ML}$ = 22.25 [0.1 M $(CH_3)_4NNO_3$],[22–24] 22.72 (0.1 M KCl);[25] NOTP, $\log K_{ML}$ = 21.3 (1 M KNO_3);[26] DOTP, $\log K_{ML}$ = 25.4 (1 M KNO_3).[27] The presence of protonated species in aqueous solution (MH_nL, n is typically 1 or 2), along with the more stable nonprotonated form (ML), has been detected for some Cu^{II} macrocyclic chelates.[25,28,29] Although the formation of binuclear complexes (M_2L) has been observed in some cases in the solid state,[23] it appears to be negligible in solution.[20–22]

Most of the Cu^{II} tri- and tetraazamacrocyclic complexes present in aqueous solution are thus mononuclear and five- or six-coordinate, with the metal ion probably bound to all the nitrogen atoms of the macrocyclic ring and to two or three carboxylate oxygens of its pendant arms. These Cu^{II} complexes often display strong tetragonal distortions that normally result in a lengthening of the axial metal–ligand bonds and an associated compression of the four equatorial ones.

In the present work, Cu^{II} complexes with the polyazapolycarboxylate ligands NOTA and DOTA, and with the polyazapolymethylenephosphonate macrocycles NOTP and DOTP were studied in aqueous solution at different pH values and in the presence of distinct electrolytes, by electronic absorption spectrophotometry (visible region) and electron paramagnetic resonance spectroscopy (EPR). Whilst these techniques are not especially good indicators of the geometry of the copper(II) complexes, by taking into account the known solid-state structures of the NOTA, DOTA, and NOTP complexes, and those of other closely related compounds, it was possible to get some insight into the solution behaviour of these systems.[30]_[32]

Results and Discussion

Visible Spectrophotometry

The electronic absorption spectra (visible region) of the complexes studied exhibit an asymmetric band in the wavelength region between 500 and 850 nm (Table 1), with molar absorptivity coefficients that are typical of *d–d* transitions in highly symmetric Cu^{II} complexes with tetragonal Jahn–Teller distortion.[33] The cyclic nature of these chelating ligands, however, imposes limits on the extent of this distortion, and the difference in length between the axial and equatorial bonds to copper is smaller in Cu^{II} triaza and tetraazamacrocyclic chelates than in Cu^{II} complexes with noncyclic ligands.[34]

Table 1. Electronic transitions (visible region) for several Cu^{II} complexes with some polyazapoly-carboxylate/polymethylenephosphonate macrocycles, in aqueous solution at pH 7.0. The experiments were run at 298 K, for a sample concentration of $4 \cdot 10^{-3}$ mol·dm^{-3}

Cu/NOTA: Previous potentiometric and spectroscopic studies[21] have shown that two distinct complex species are present in aqueous solution. In the pH range 2.0 to 2.5, [Cu(HNOTA)] is present at concentrations higher than 60% of total copper, while for pH values above 3.5 the predominant form is $[Cu(NOTA)]^-$. These complexes exhibit different spectra: that of [Cu(HNOTA)] has a *d–d* band at 660 nm, which is bathochromically shifted to 750 nm in the deprotonated species.[21] The solid state geometry of $Na[Cu(NOTA)] \cdot 2\,NaBr \cdot 8\,H_2O$ is intermediate between pure octahedral and trigonal prismatic, and a distortion from octahedral geometry is expected to cause a decrease in ligand field strength and thus an increase in λ_{max}. Protonation of one of the carboxylate groups, and subsequent substitution by a solvent molecule, is accompanied by either a release of strain or a reorientation of the metal-to-ligand bonds, which leads to an increase in ligand field strength and thus explains the high energy for the *d–d* band in [Cu(HNOTA)]. These observations suggest that the ligand is five-coordinate in acidic solutions, but six-coordinate at high pH.

Cu/DOTA: Several copper complexes are present in solution: in the pH range 2.4 to 3.2, the fully protonated $[Cu(H_2DOTA)]$ complex is the most abundant, but at higher pH $[CuHDOTA]^-$ and $[Cu(DOTA)]^{2-}$ are also present in significant amounts, the former reaching its maximum concentration (ca. 30%, based on total Cu^{II} concentration) at pH 3.8, and the latter being the predominant form at pH higher than 4.6. However, the spectra now obtained were found to be insensitive to pH changes, thus suggesting that protonation does not impose severe structural changes in the coordination sphere. As the molecular struc-

ture of $[Cu(H_2DOTA)]$[11] reveals two nonbound carboxylate groups, deprotonation of these distant nonbonding carboxylate groups is not expected to exert a marked influence in the electronic structure of the metal complex. The spectrum of the crystalline form has one *d–d* band centred at 715 nm,[11] a value quite similar to that found in solution (Table 1); the small difference in band maxima is most probably due to solvation or solid-state effects. It should be noted that the energy of this *d–d* band is lower than that usually found for copper(II) complexes with tetragonally distorted octahedral geometry and an N_2O_2 equatorial plane. Nevertheless, the crystal structure shows that the tetragonal distortion is unusually small in this complex,[11] a consequence of the conformation adopted by the ligand, and this is expected to cause a decrease in the equatorial ligand field and thus in the energy of the *d–d* band. The similarity in the values of λ_{max} in the solid and in solution suggests that the ligand is mainly six-coordinate in solution.

Cu/NOTP: The band detected in the spectrum appears at energies similar to those of [Cu(HNOTA)][21] and $[Cu([9]aneN_3)(H_2O)_3]^{2+}$ in aqueous solution,[21,35] implying that the coordination mode of this macrocyclic polyphosphonate ligand is different from that of the similar complex, $[Cu(NOTA)]^-$. This is in accordance with the crystal structure reported for the NOTP complex, in which one of the phosphonate groups is not bound to the metal centre.[10] The distinct coordination behaviour of NOTP and NOTA may be attributed to their different charges. In fact, in Cu/NOTP a very high negative charge would be localised at the metal centre should the three available phosphonate groups bind to Cu^{II}, and thus NOTP is five-coordinate here.

Cu/DOTP: In this complex, the four nitrogen atoms of the cyclic structure are expected to be involved in bonding, leaving only two coordination sites of the metal centre available, either for pendant phosphonate groups or for solvent molecules. The spectra of the complexes with DOTP are significantly different from those with DOTA, implying distinct structures for these complexes in solution. However, the *d–d* band for Cu/DOTP is in the same energy range as that of the corresponding copper(II) complex with the ligand $[12]aneN_4$, which has a square-pyramidal geometry in solution, with the four ring nitrogen atoms defining the equatorial plane and one axial position occupied by a solvent molecule.[36] The present results support a similar structure for the Cu/DOTP complex, in which the axial position of the pyramid is probably occupied by an oxygen from one phosphonate side-arm, in analogy with the solid state geometry reported for the copper(II) complex with the similar ligand *N*,*N*',*N*'',*N*'''-tetrakis(2-diphenylphosphorylethyl)-1,4,7,10-tetraazacyclododecane.[37]

EPR Spectroscopy

The EPR spectra of frozen aqueous solutions (77 K) of the complexes under study are shown in Figures 2 and 3, and the corresponding anisotropic parameters are summarised in Table 2.

Cu/NOTA: The EPR spectrum of Cu/NOTA at pH 7 shows two different signals, corresponding to two distinct Cu^{II} complex species, in a 3:2 concentration ratio (Figure 2A, Table 2). Both signals are typical of Cu^{II} complexes in a tetragonal ligand field, with a $d(x^2 - y^2)$ ground state.[30] In order to check if the two species detected are pH dependent, EPR spectra were also recorded at pH 3 and pH 9. In alkaline solution the spectrum is identical to the one at pH 7, thus excluding the formation of hydroxo-complexes in this pH region. Under acidic conditions, however, it is possible to perceive at least one more Cu^{II} signal superimposed on the two signals observed at pH 7. Based on the stability constants reported in the literature[21] the additional signal detected at pH 3 must be due to [Cu(HNOTA)], while the other two signals observed in all the samples studied probably reflect the presence of two geometric isomers for $[Cu(NOTA)]^-$. Simulation of the spectrum obtained at pH 3 was unsuccessful, due to its poor resolution and to the existence of at least three different signals. To try to improve resolution, spectra were obtained in the presence of inert electrolytes: NaCl (1 M), $NaClO_4$ (0.1 and 1 M), and $(CH_3)_4NNO_3$ (0.1 M); however, no significant differences were obtained, either in resolution or in the overall signal pattern.

Several hypotheses concerning the occurrence of two isomeric forms of $[Cu(NOTA)]^-$, excluding protonation equilibria, may be advanced, but the large difference between the $g_\parallel$ and $A_\parallel$ values of the two signals observed at pH 7 clearly points to different coordination environments. The signal with $g_\parallel = 2.287$ and $A_\parallel = 149.5 \cdot 10^{-4}$ cm^{-1} is typical of a six-coordinate complex with a distorted octahedral structure similar to that observed in the solid state.[9] The smaller $g_\parallel$ and larger $A_\parallel$ values of the other signal, in turn, point to a significant decrease in the axial ligand field for the second isomer. This decrease in axial interaction may be caused either by substitution of one axial ligand by a solvent molecule, or simply by breaking of an axial ligand bond with formation of a five-coordinate square-pyramidal structure. The latter hypothesis is supported by the similarity between the EPR parameters of the system under discussion and those of Cu^{II} square-pyramidal complexes with the macrocyclic ligands $[12]aneN_4$,[36] 1,4,7,10-tetrabenzyl-2,5,8,11-tetraethyl-1,4,7,10-tetraazacyclododecane[39] and 7,11-bis(carboxymethyl)-1,4-dioxa-7,11-diazacyclotridecane.[40]

Cu/DOTA: The EPR spectrum of $[Cu(DOTA)]^{2-}$ in aqueous solution was previously obtained by other authors at pH 9 for a metal-to-ligand ratio of 1:2,[8] and the reported parameters are included in Table 2. The spectra obtained in the present work for a metal-to-ligand ratio of 1:1 and at pH 3, 7, and 9, are poorly resolved both at room temperature and in frozen solution (77 K). In order to improve spectral resolution several different electrolytes were added to the solutions; however, it was found that those electrolytes containing Na^+ interact with the copper(II) complexes studied (see below).

At pH 3 and in the absence of Na^+ ions, the spectra obtained either without electrolyte or in the presence of

[8], 9.28 GHz, pH 9.

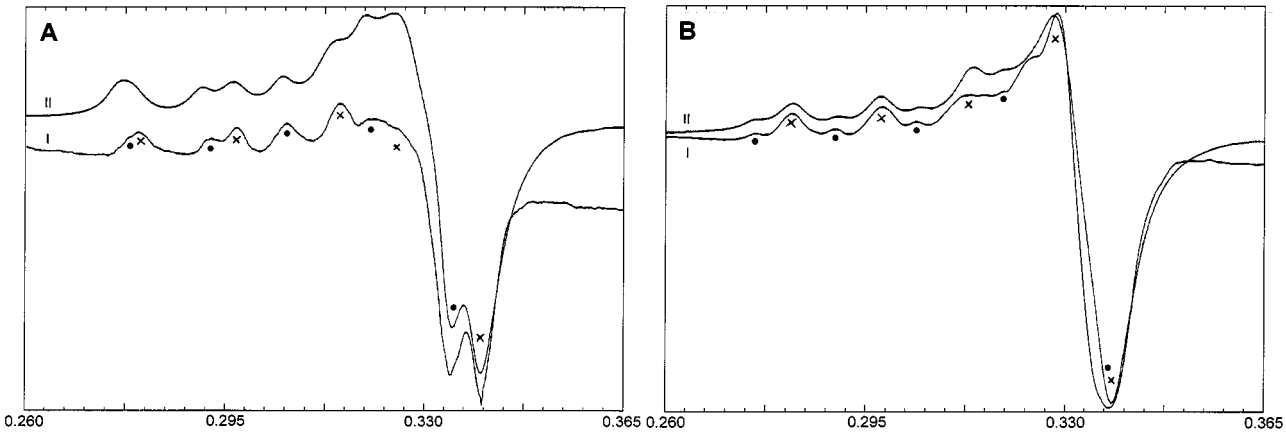

Figure 2. EPR spectra (X-band, 0.34 T, 9.5 GHz), at 77 K, of the Cu^{II} complexes (1:1) with the macrocyclic polyaza-polycarboxylate ligands NOTA (A) and DOTA (B), in aqueous solution at pH 7, in the presence of $1 \cdot 10^{-1}$ M Na^+: I – Experimental spectra; II – Simulated spectra; [complexes] = $1 \cdot 10^{-3}$ M; the symbols × and • refer to the major and minor complex species of each of the systems studied, respectively

$(CH_3)_4NNO_3$ (0.5 M) exhibit more than one signal but, due to their low resolution, no accurate EPR parameters could be obtained. Addition of $NaClO_4$ or NaCl caused significant spectral changes, namely the appearance of a new EPR signal superimposed on those observed for solutions without added electrolyte, and for $[Na^+] \geq 1$ M only this new signal was observed (see Figure 3).

Similar experiments were carried out for solutions at pH 7 and pH 9, but since the results obtained were identical for these two pH values they will be discussed together. In the absence of Na^+ the spectra, although poorly resolved, exhibit only one signal. Addition of NaCl or $NaClO_4$ induces clear changes in the spectra, with the appearance of a new copper(II) signal (Figure 2B). For these pH values, however, even for $[Na^+] = 1$ M, the new signal appears superimposed on the one detected without the electrolyte. The difference in EPR parameters for the two signals observed in solutions containing Na^+ is significant enough to indicate that the corresponding species have distinct coordination environments, thus implying that in the presence of high concentrations of Na^+ the Cu/DOTA complex undergoes a structural reorganisation.

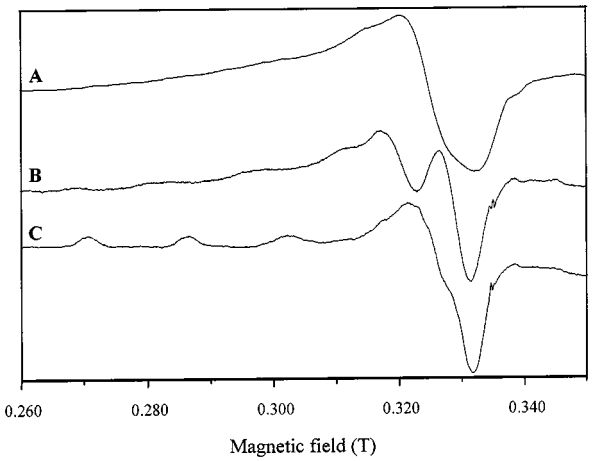

Figure 3. EPR spectra (X-band, 0.34 T, 9.5 GHz), at 77 K, of the Cu^{II} complex (1:1) with the macrocyclic polyaza-polycarboxylate ligand DOTA, in aqueous solution at pH 3, as a function of the concentration of Na^+ ion: A – $[Na^+] = 0$; B – $[Na^+] = 1 \cdot 10^{-1}$ M; C – $[Na^+] = 1$ M; [complex] = $1 \cdot 10^{-3}$ M

Analysis of the EPR parameters obtained in this work can yield additional information about the interaction of

the Cu/DOTA complex with Na^+. The signal obtained without added electrolyte at pH 7 was found to have unusual EPR parameters ($g_\perp = 2.10$, $g_\parallel = 2.30$ and $A_\parallel = 150 \cdot 10^{-4}$ cm^{-1}) for a tetragonally distorted octahedral chelate with a N_2O_2 equatorial plane, namely high $g_\parallel$ and low $A_\parallel$ values. These values can be accounted for by taking into consideration the crystallographic structure of this system,[11] that shows a small tetragonal distortion compared to what is usually found in other copper(II) complexes. A decrease in tetragonal distortion is expected to increase $g_\parallel$ and decrease $A_\parallel$, and also to decrease the anisotropy of the EPR spectra.[24] Thus, it is quite reasonable to assume that the spectrum observed at pH 7 without added Na^+ is due to $[Cu(DOTA)]^{2-}$, with a geometry similar to that observed in the solid state.

The new signals observed in the solutions containing Na^+, at both pH 3 and 7 are not significantly different. Comparison of the corresponding EPR parameters with those obtained from the spectrum at pH 7 in the absence of Na^+ shows that these new species have significantly lower $g_\parallel$ and higher $A_\parallel$ values. These values are similar to those commonly found for six-coordinate copper(II) complexes displaying a N_2O_2 equatorial plane. This seems to imply that these new complexes have a different structure, for which the steric constraints that impose a low axial distortion to copper coordination in $[Cu(DOTA)]^{2-}$ have been lost. This may be attributed either to partial solvolysis of $[Cu(DOTA)]^{2-}$ or to a rearrangement of the ligand around the metal, leading to a distinct coordination pattern. This structural reorganisation induced by Na^+ points to a strong interaction between the alkali metal ion and the copper(II) complex, either (a) by binding to the ligand free acetate groups, or (b) by competition of the sodium ions with Cu^{II} for the coordinated acetate side-arms.

A precedent for the former hypothesis is provided by noting that Na^+ binds to the free ligand ($\log K_{Na/DOTA} = 4.38$, $[(CH_3)_4NNO_3] = 0.1$ M).[16] However, against this it should be noted that if Na^+ only interacts significantly with the free acetate groups of the complex, its effect would be more important for negatively charged species; it was found that at pH 7 and $[Na^+] = 1$ M, where the predominant complex species would have a –2 charge, the presence of $[Cu(DOTA)]^{2-}$ is still detected, while at pH 3, where the Cu^{II} complexes are expected to be protonated, either neutral or with a +1 charge, only the signal due to the Na^+/Cu/DOTA complex was observed. Our results thus seem to support the second hypothesis, despite the large stability constants in aqueous solution of these Cu^{II} macrocyclic chelates. The observed pH dependence for the formation of Na^+/Cu/DOTA complexes may result from the lower stability of the protonated complexes, due to the smaller negative charge of the protonated ligand, which favours the release of at least one acetate group which would promptly bind to Na^+. It is worth noting, however, that the EPR signals detected at pH 3 and 7 (Figure 2 and Figure 3) in the presence of Na^+ are slightly different, which implies that they are not due to identical species but to structurally very similar complexes. These small differences are probably a consequence of differing degrees of protonation of the complex.

Analysis of the EPR parameters for the Na^+/Cu/DOTA system show that these new complexes seem to have very different structures to that of $[Cu(DOTA)]^{2-}$ in the solid state, an observation that also favours the hypothesis of release of at least one of the carboxylate pendant arms of the macrocyclic ligand, either yielding a five-coordinate complex or merely leading to substitution by a solvent molecule in the coordination sphere of the metal ion. In either case, breaking of one M−O(carboxylate) bond would release some of the steric strain imposed by the ligand, as present in the solid state, which would facilitate decoordination.

Cu/NOTP and Cu/DOTP: The frozen solution EPR spectra of Cu/NOTP and Cu/DOTP at pH 7 reflect the axial symmetry of these systems (with $g_\parallel >> g_\perp$). Hyperfine structure due to the copper nuclei (^{63}Cu and ^{65}Cu, $I = 3/2$) is detected in the parallel region (Table 2), whereas the perpendicular region is not sufficiently resolved to allow the observation of any such splitting. These data are typical of Cu^{II} complexes in a tetragonal field, with a $d(x^2 - y^2)$ ground state.[24] The band patterns at pH 3, 7, and 9 are very similar, which indicates that protonation of these complexes does not induce significant structural or electronic changes. This observation may be taken as an indication that protonation of these systems probably takes place at the unbound phosphonate side-arms.

The influence of added electrolytes [NaCl, $NaClO_4$, and $(CH_3)_4NNO_3$] was also checked, but no appreciable changes in the EPR spectra were detected, either in the overall signal pattern or in band width.

Based on the spectrophotometric results discussed above, a *trans* coordination of DOTP to the metal centre has been proposed, implying an N_4 equatorial plane. The EPR parameters obtained for this system support that hypothesis, although the $g_\parallel$ value is higher, and the $A_\parallel$ value smaller, than typical values found for other complexes with this coordination environment. These differences, however, may be a consequence of a strong axial bond with the oxygen atom of a phosphonate side-arm, similar to the one reported for the related complex with *N*,*N*',*N*'',*N*'''-tetrakis(2-diphenylphosphorylethyl)-1,4,7,10-tetraazacyclododecane.[37]

For Cu/NOTP, the $g_\parallel$ value is larger than that of DOTA, in agreement with the N_2O_2 equatorial plane expected for this complex. As in Cu/DOTP, the $A_\parallel$ value is smaller than expected for a square-pyramidal structure. This may also be rationalised by a strong axial metal–ligand interaction, since a low tetragonal distortion is expected in this case due to the facial coordination of the cycle, which imposes a short axial bond to the nitrogen atom.

Conclusion

One important result that emerged from the present study is that the polyphosphonate ligands NOTP and DOTP always coordinate to copper(II) in a pentadentate mode, although the corresponding complexes may be five- or six-coordinate by binding a solvent molecule. This behaviour is to be contrasted with that of the polycarboxylate

ligands NOTA and DOTA, which is more complex. Firstly, the coordination mode of the ligands was found to be pH dependent: (a) in copper(II) complexes with NOTA the ligand is five-coordinate in acidic solutions, through protonation of one carboxylate group, but at pH 7 two complexes were observed in solution, probably with the ligand being six- and five-coordinate; (b) in those complexes with DOTA, the ligand is essentially six-coordinate, although at low pH the possibility of protonation of one bound carboxylate group could not be ruled out. Secondly, the DOTA coordination mode was also found to be dependent on the presence of sodium ions in solution, which are capable of competing with Cu^{II} for coordinating carboxylates; in fact, with $[Na^+] = 1$ M and at pH 3 only complexes in which DOTA acts as a five-coordinate ligand could be detected by EPR, whereas at pH 7, two species – displaying a six-coordinate and five-coordinate DOTA – were observed. Once the presence of sodium ions was found not to affect the coordination equilibria of the other three macrocyclic ligands, it is likely that the steric constraint imposed by DOTA when acting in a six-coordinate mode eases by decoordination of one carboxylate group when in the presence of a large excess of sodium ions.

Experimental Section

General: The ligands were synthesised and purified as described elsewhere (NOTA,[41] DOTA,[23,42] NOTP and DOTP[43,44]). The purity of the ligands was checked by ^{1}H-NMR spectroscopy (Varian XL-200 and Varian Unity-500 spectrometers).

Preparation of Copper(II) Complexes: The concentration of the ligand solutions was determined by complexometric titration, using a copper chloride solution and murexide (5,5'-nitrilodibarbituric acid) as an indicator. The copper chloride solution was previously titrated with standard EDTA, with Black Sulphon F [1-hydroxy-8-(2-hydroxynaphthylazo)-2-(sulfonaphthylazo)-3,6-disulfonic acid] as an indicator. Stock aqueous solutions of the complexes ($1\cdot10^{-3}$ M) were prepared by adding stoichiometric amounts of the macrocyclic ligand to a solution of copper chloride (Aldrich). The pH of the solutions was adjusted with HCl and CO_2-free NaOH (using a Crison MicropH 2002 pH-meter with an Ingold 405-M5 combined electrode).

Spectroscopic Studies: The electronic spectra (visible region) were obtained in a double beam JASCO-7800 spectrometer (cell with 1 cm optical path). The experiments were run at 298 K, in the pH range between 2.0 and 10.0, for sample concentrations of $1\cdot10^{-3}$ and $1\cdot10^{-5}$ M. No changes in spectra were observed upon repeating the measurements one week after the first run.

The EPR spectra (X-band, 0.34 T, 9.5 GHz), were obtained in a continuous wave BRUKER ESP-300E spectrometer, with a microwave power of 15.9 mW and a modulation frequency of 100 kHz. The experiments were performed at pH 3.0, 7.0, and 9.0, both at 298 K and at 77 K (frozen samples). DPPH (2,2-diphenyl-1-picrylhydrazil radical) was used as an internal reference ($g = 2.0037$). Simulation of experimental EPR spectra, in order to obtain the corresponding anisotropic parameters, were performed using a modified version of the program developed by Pilbrow.[45] This program assumes a purely Lorentzian shape for the EPR bands, and does not account for changes in signal width with external magnetic field. The simulation was carried out ignoring the isotopic mixture of the copper nuclei and nuclear quadrupole effects.

Synthesis, Characterization and Electrochemistry of Complexes Derived from $[(1),2,3\text{-}P_2Mo_2W_{15}O_{61}]^{10-}$ and First Transition Metal Ions

Roland Contant,*[a] Mostefa Abbessi,[a][+] Jacqueline Canny,[a] Martine Richet,[a] Bineta Keita,[b] Abderrahmane Belhouari,[b] and Louis Nadjo*[b]

Keywords: Polyoxometalates / Heteropolyanions / Dawson-type structures / Transition metal cations / Electrochemistry

The complexes formed by $[(1)\text{-}2,3\text{-}P_2Mo_2W_{15}O_{61}]^{10-}$ with vanadium(IV), manganese(II), cobalt(II), nickel(II), copper(II), and zinc(II) were synthesized. They were characterized by elemental analysis, IR, UV/Vis and ^{31}P NMR spectroscopy. Their electrochemical studies are complemented by those of the previously synthesized iron(III)- and Mo(VI)-substituted complexes. Among the main conclusions from the electrochemistry of all these compounds, it can be pointed out that only the iron(III) and the copper(II) ions within the complexes are reducible in the same potential domain as the molybdenum(VI) moieties. In the case of the iron(III) complex, it has been possible to obtain a reversible overall three-electron process on the first wave of the oxometalate by varying the pH of the solution. In contrast, copper can be deposited from the corresponding complex. Substitution of $[(1)\text{-}2,3\text{-}P_2Mo_2W_{15}O_{61}]^{10-}$ with vanadium(IV), manganese(II), iron(III), cobalt(II), nickel(II), copper(II), zinc(II) and molybdenum(VI) gives a series of complexes in which the trimetallic moiety constituting one of the "caps" of the polyoxometalate contains cations different from the remaining tungsten skeleton. The electrochemical properties of these complexes are modulated by this particular constitution.

Introduction

In recent articles,[1,2] we described the syntheses, characterization and the electrochemical properties of some monoferro-heptadecatungsto-diphosphates and pentadecatungsto-dimolybdo-diphosphates. This work constitutes a first step in our systematic examination of parameters and combination of parameters which could favor or counteract the merging of the first several waves in heteropolyanion (HPA) electrochemistry. As a matter of fact, it turns out that most energetically favorable electro-reductive catalytic processes triggered by HPAs require more than one electron and are thus, usually accomplished at fairly negative potentials where the necessary number of electrons could be accumulated and delivered by the framework. In the above-mentioned articles from this group, three complexes of the present series have already been studied, with M = Mo^{VI}, V^{V}, Fe^{III}. The electrochemistry of $\alpha_2P_2Mo_3W_{15}$ has been described briefly.[2,3] In a pH = 2 medium, its cyclic voltammogram begins with three well-behaved one-electron diffusion waves. In contrast, with V^{V} as a substituent instead of Mo^{VI}, the molybdenum centers are easily reduced through an apparently direct two-electron process. Still more striking, the substitution by Fe^{III}, combined with pH effects, allows for an approach to an overall three-electron process on the first voltammetric wave of the corresponding complex in a pH = 2 medium. Such results stimulated the need for the present study. Furthermore, as another incentive, it is anticipated that the presence of two molybdenum atoms in the "cap" near the substituent heterocation might substantially influence the electronic communication between the various sites in this trimetallic moiety, especially during redox processes. In this context, we describe here the syntheses, characterization and electrochemical properties of the complexes formed by $[(1)\text{-}2,3\text{-}P_2Mo_2W_{15}O_{61}]^{10-}$ with some first transition metal ions and with the Zn dication.

Results and Discussion

All the polyanions to be studied here can be considered as being primarily derived from $[\alpha P_2W_{18}O_{62}]^{6-}$, abbreviated as P_2W_{18}. In Figure 1, the tungsten atoms in αP_2W_{18} are

numbered according to the IUPAC recommendations.[4] The two P atoms are numbered (1) and (2) for the upper and the lower halves of the molecule, respectively. Considering the upper half of the molecule and taking into account the numbering, the metal atoms in the "cap" occupy what will be termed α_2 positions and those in the "belt", α_1 positions. In the lacunary species, the vacancies (missing W atoms) are numbered in the same way and represented by □ in the formula of the anion. Any heterometal filling the vacancy will keep the same index.

Syntheses

The metal cation substituted species were elaborated under the same conditions as the iron(III)-substituted one. However, the ^{31}P NMR spectra have shown that there was an isomerically pure compound with V, Ni and Cu, but two compounds with Mn, Co and Zn. With heated Co sample, two main compounds and several isomeric impurities were observed. Such a behavior has been described by T. L. Jorris et al.[5] on metallo-heptadecatungsto-diphosphates. and was interpreted as $\alpha_2 \rightarrow \alpha_1$ isomerization. In our case the migration of molybdenum atoms may give numerous other isomers. The number and the nature and the ratio of isomers depend on preparation conditions. To obtain more than 90% of the α_2 isomer, the synthesis must be performed in acidic solution without heating.

UV/Vis and IR Characterization

The formation constants of the complexes have been measured. The logβ values are fairly large; they are shown in brackets for the various substituent metal cations: V^{IV} (>18); Mn^{II} (6.5); Fe^{III} (17.2); Co^{II} (7.4); Ni^{II} (7.5); Cu^{II} (7.9); Zn^{II} (7.5). The electrochemical behavior to be discussed in a subsequent section, has been studied essentially at pH 3 and 5 for all the complexes. Their stability in these media and, occasionally in others when necessary, has been checked by monitoring their UV/Vis spectra at least over a period of 24 h. The only slight instability was detected with the cobalt-substituted compound, which shows decreasing absorbance, even though the decrease is not fast enough to preclude an electrochemical study.

^{31}P NMR

The NMR study of paramagnetic elements containing HPAs was performed by Jorris et al.[5] on P_2W_{17}. They found no isomerically pure compound but a mixture of α_1 and α_2 isomers. They observed with the α_2 isomer that the chemical shifts of the P atom far from the paramagnetic elements were unaffected by the nature of the element. There is an exception: Co^{II}. The same observation, with the same exception, appears in Table 2 and in Figure 2. This

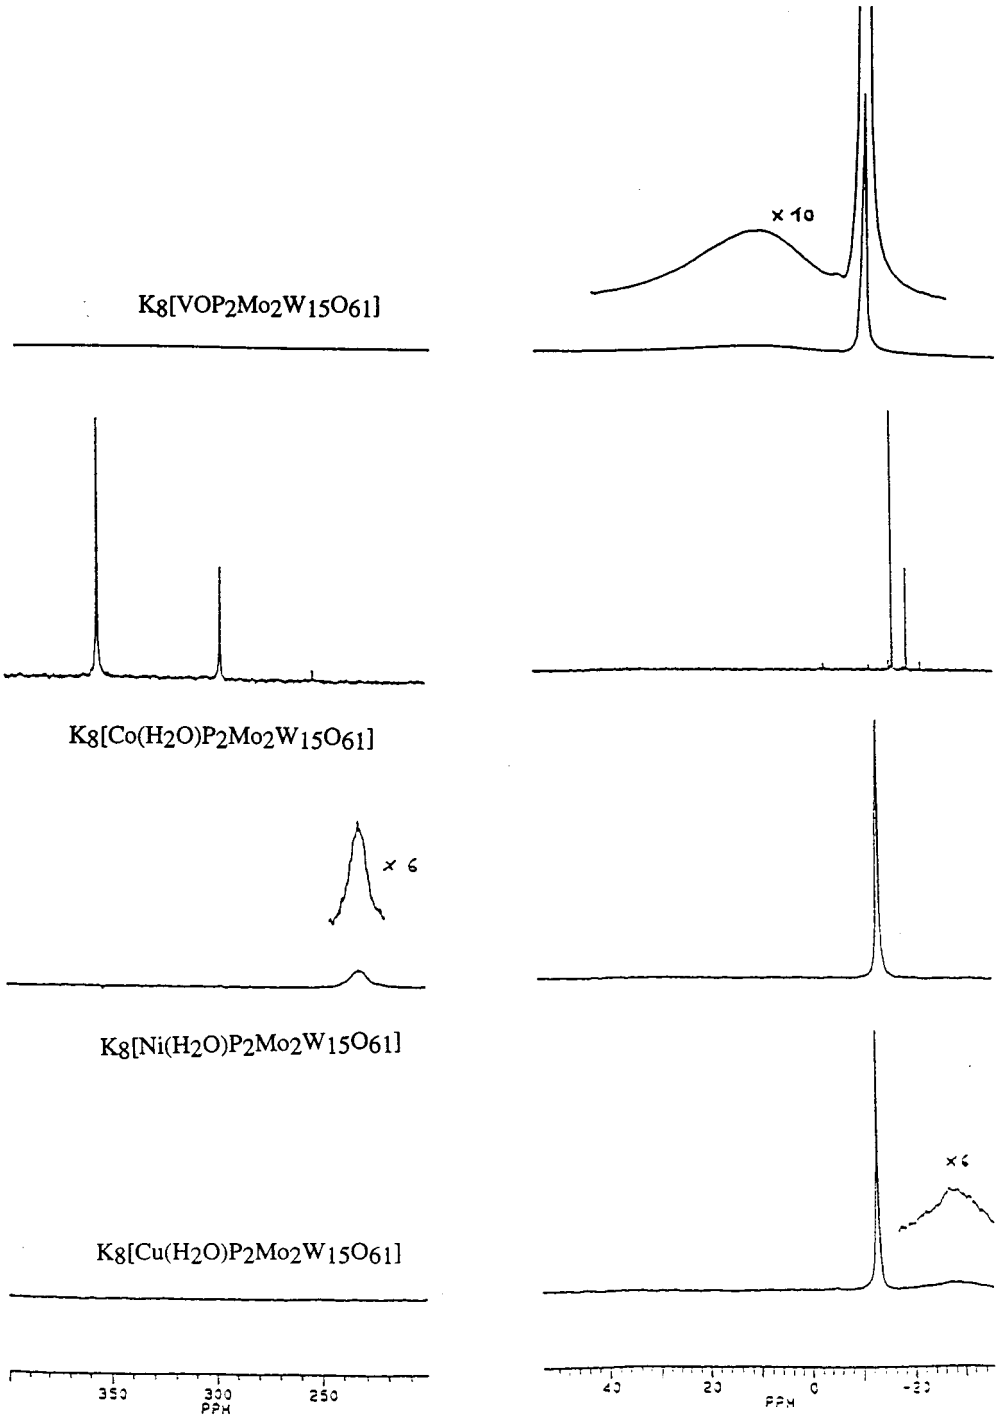

Figure 2. Selected representative ^{31}P NMR spectra. The appropriate compound formula is indicated on each spectrum

Figure shows spectra representative of the whole series. Such an observation confirms the stereospecificity of the syntheses. Under the same standard conditions used for all the other compounds, only one ^{31}P NMR line is observed for the V^{IV}-substituted species. Therefore, particular attention has been exercised to obtain a satisfactory ^{31}P NMR spectrum for this complex. A fairly concentrated solution of the lithium salt of this compound was prepared. With such a solution, it has been possible to observe the NMR line corresponding to the phosphorus atom in the close vicinity of the magnetic atom. This line appears at around $\delta = 8.3$ ppm and is roughly 2500 Hz broad.

Electrochemistry

The following studies are restricted either to the first or to the first few chemically reversible redox processes of the substituted complexes, and to their changes with pH. As a matter of fact, we are interested in controlling the number

of electrons which could be accumulated on the first wave of HPAs. This restriction also avoids any derivatization of the electrode surface as observed previously, albeit under different conditions.[9] In this study, the focus will be directed mainly on the reduction of molybdenum centers up to the first wave corresponding to the reduction of the tungsten framework. The redox behavior of the "substituent" metallic center will be considered simultaneously when it happens to appear in the potential domain of interest for the reduction of molybdenum centers. Otherwise, this behavior will be described separately.

Well-separated redox behaviors for the substituent cation and for the HPA framework: This situation is encountered with V^{IV}-, Mn^{II}-, Co^{II}-, Ni^{II}-, and Zn^{II}-substituted compounds. Figure 3 shows representative examples of the main features observed, throughout this work, for most of the complexes at pH = 3 and pH = 5. The Ni^{II} and V^{IV} complexes have been chosen. The cyclic voltammogram of the parent lacunary complex has been added for comparison. In Figure 3A, two well-behaved redox systems are observed. In line with previous work,[1,2,10] the first wave is assigned to the reduction of the molybdenum centers. Whatever the substituted complex, only very modest peak potential and peak current intensity variations are observed compared to the same parameters for the lacunary species, provided comparable concentrations are used. It must be concluded that for the pH = 3 medium, the Ni^{II}- and V^{IV}-substituted complexes behave in the same way as the lacunary compound, at least where the reduction of the molybdenum centers is concerned. No reduction of the substituent "heterometallic" cation has been detected in the potential domain studied. In Figure 3A, the wave corresponding to the reduction of the tungsten framework appears to be more discriminating among the complexes. Starting with the lacunary compound, the potential location of this "tungsten wave" is pushed to more and more negative values when passing to the Ni^{II}- and the V^{IV}-substituted complexes. It is worth noting that the trend is the same, but much more pronounced here than for the reduction of molybdenum centers. In this pH = 3 medium, exactly the same general behavior as observed for the Ni^{II}- and V^{IV}-substituted complexes is seen with Mn^{II}, Co^{II}, and Zn^{II} as substituents.

Figure 3B, obtained at pH = 5 for the lacunary species and for the Ni^{II}- and V^{IV}-substituted complexes displays more contrasted behaviors. We focus first on the cyclic voltammogram of the lacunary species. The cathodic pattern is composed of a system of drawn-out, presumably close-spaced two waves, followed by a well-defined two-electron wave. By continuity with the observations performed in the pH = 3 and the pH = 4 (not shown) media, the first system should be attributed to the reduction of molybdenum centers, while the last wave should feature the reduction of the tungsten framework. It is worth noting that on potential reversal, the respective anodic traces are well-behaved. In particular, a single anodic wave is observed for the reoxidation of the molybdenum centers. This result would suggest that no intrinsic electron-transfer "slowness" should actually exist for the reduction of molybdenum moieties. So, the

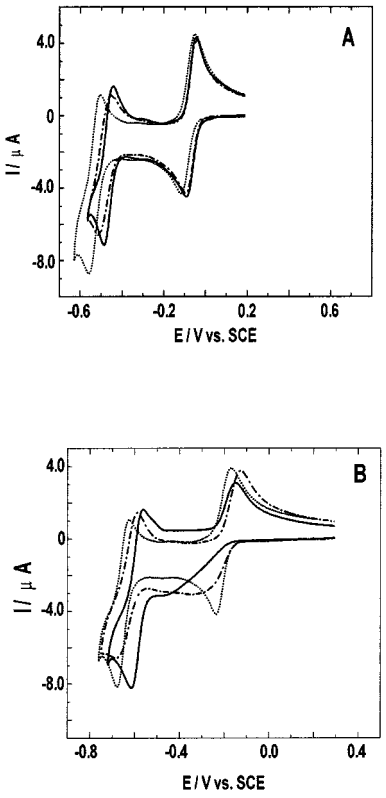

Figure 3. Comparison of the cyclic voltammograms observed for 5 × 10^{-4} M solutions of the lacunary heteropolyanion [(1)-2,3-$P_2Mo_2W_{15}O_{61}$]$^{10-}$ and the corresponding Ni^{II}- and V^{IV}-substituted complexes. Scan rate: 10 mV s^{-1} .(A) pH = 3 (0.2 M Na_2SO_4 + H_2SO_4): *solid line curve*: $P_2\square Mo_2W_{15}$; *dot and dash curve*: $P_2W_{15}Mo_2Ni$; *short dot curve*: $VP_2Mo_2W_{15}$. (B) pH = 5 (0.2 M CH_3COONa + CH_3COOH): *solid line curve*: $P_2\square Mo_2W_{15}$; *dot and dash curve*: $P_2W_{15}Mo_2Ni$; *short dot curve* $P_2VMo_2W_{15}$. For further details, see text.

observation might be traced to one or several of the following effects: condensation, pH and/or cation effects in the solution. The cyclic voltammetric patterns for Ni^{II}- and V^{IV}-substituted compounds can be considered as featuring a modulation, to different extents, of the observed sluggishness in the lacunary complex. For the V^{IV} complex, the first wave remains peak-shaped while a rather plateau current is obtained for the Ni^{II} complex. It must be noted that the "slowness" is less pronounced for these complexes than for the lacunary compound. Also, the tungsten wave can no longer be considered as a fingerprint to distinguish between the Ni^{II} and V^{IV} compounds, as their potential locations are now roughly the same.

The observations in the pH = 4 medium show a smooth transition of wave shapes and potential locations from the pH = 5 medium**.** The complexes substituted by the other metallic cations selected in this work, have also been examined in the same pH media. Due to the smooth evolution already mentioned, emphasis is put here only on the pH = 5 medium. The main qualitative difference is the extent of "slowness" observed from one complex to the next. In this series, it was found that the first wave of the V^{IV}-substituted complex has kept a sharp peak shape. All other complexes show plateau currents, with the same limiting current. For

this purpose, due care has been exercised concerning the reproducibility of the working electrode surface area and the concentrations of the complexes in solution. Incidentally, the results for pH = 3 prove that the diffusion coefficients remain very close to each other in these complexes. We arbitrarily chose the only well-defined peak potential value as the reference point for which the current intensities are measured for all the other complexes. Then, as no current crossing is observed between the various ''polarograms'' up to their common limiting value, the measured current intensities feature a qualitatively good index of the relative ''slowness'' among complexes. In the order of increasing slowness, the scale is then: V^{IV}(0.62), Ni^{II}(0.69), Co^{II}(0;72), Zn^{II}(0.74), Mn^{II}(0.80) and □, where this symbol represents the vacancy. Provisional crystal ionic radii of the various ions in Å are given in brackets.[11]

Considering all the results together, it becomes evident that a large number of parameters or combinations of parameters govern the electrochemical behaviors of the present complexes as revealed by cyclic voltammetry. Only qualitative aspects can be considered here as possible guidelines in an attempt at rationalization of the observed behaviors. Despite this really entangled situation, a simple electrostatic consideration might explain qualitatively the difference between the metal cation substituted complexes and the lacunary species. The substitution lowers the negative charge on the heteropolyanion and facilitates its reduction. Then, the differences between the potential locations of the various substituted complexes are more difficult to rationalize. As a matter of fact, it is probably more difficult to take several possible parameters into account. The size of each ion, its electronic configuration, its favorite geometry, should contribute to fix the extent of its penetration in the vacancy of the lacunary HPA. The possibility and extent of the Jahn–Teller effect should not be neglected. Furthermore, there is no change in the oxidation state of the heterometallic cation during the redox processes studied in this section, which could have modified the abovementioned considerations substantially. Also, it must be anticipated that the presence of the two MoO_6 octahedra next to the vacancy should render the latter more flexible than in a skeleton comprised totally of tungsten. The interplay of these various influences should determine the extent of ''effective'' lowering of the negative charge on the heteropolyanion due to substituent metallic cation, relative to the initial charge of the lacunary species. It should also determine, at least partly, the possibility and extent of electronic ''communication'' between neighbor redox centers in the complex, and, more specifically, between the heterometal substituent and the molybdenum moieties. A more important parameter in this last issue is the distribution of the redox potentials of the possibly interacting centers. Although no clear conclusions can be drawn, it is worth noting provisionally that it is now widely accepted that P_2W_{18} is initially reduced at one of the twelve equivalent tungsten atoms.[3,12,13] Here, the molybdenum centers, which are more easily reducible than the tungsten moieties, are situated in the "cap". On the basis of the foregoing discussion, no simple correlation is expected unless a single parameter overrides all others and/or several parameters show the same trend. However, the results in Figure 3B and the corresponding results for the other complexes would suggest that the ''slowness'' observed for the reduction of molybdenum centers is strictly larger as the crystal ionic radius of the substituent cation increases. But such an explanation would not include the results in Figure 3A, in which such a possible size effect could not be distinguished. Finally, in the present qualitative discussion, the pH appears as a decisive parameter. As a matter of fact, ECE-type mechanisms are known to intervene frequently in the redox behaviors of heteropolyanions.[14,15]

The redox behaviors of the substituent metal cations have been studied briefly. In the potential domains explored, no electrochemical activity has been detected for Ni^{II} or Zn^{II}. The Co^{II} center is oxidized to Co^{III}, with a peak potential observed at +1.120 V vs. SCE during the first positive potential scan. This wave disappears on subsequent runs. Even during the very first run, no reduction of Co^{III} back to Co^{II} is obtained. Such a behavior should be traced to the abovementioned lability of the cobalt-substituted complex rather than to an electrode material effect. In contrast, a well-behaved, reversible one-electron wave is observed for the oxidation of V^{IV} to V^{V} and the subsequent reduction of V^{V} to V^{IV} with E_0 around +0.412 V vs. SCE at pH = 5. This wave seems slightly pH-dependent. The case of Mn^{II} is more striking, as at least two fairly stable states are obtained, featuring the Mn^{II}/Mn^{III} and Mn^{III}/Mn^{IV} steps.

Mixed redox behaviors for the substituent cation and for the HPA framework: This situation, encountered with Fe^{III} and Cu^{II} as substituents in the present work, is the one likely to make the first wave of the corresponding HPAs involve *n* electrons (*n* □ 2). The case of the Fe^{III} complex has been described briefly,[1,2] and is mentioned here for completeness and for the sake of comparison with the Cu^{II} complex. Typically, the presence of the Fe^{III} cation in [$\alpha_2Fe(OH_2)P_2Mo_2W_{15}$]$^{7-}$, abbreviated as $\alpha_2FeP_2Mo_2W_{15}$, modifies substantially the electrochemical behavior of this heteropolyanion compared to the behavior of $\alpha_2P_2Mo_3W_{15}O_{62}^{6-}$·($\alpha_2P_2Mo_3W_{15}$). In a pH = 2 medium, the cyclic voltammogram of $\alpha_2P_2Mo_3W_{15}$ begins with three diffusion-controlled one-electron waves. In contrast, the iron(III)-substituted complex displays a cyclic voltammogram nearly identical in potential locations to that of the corresponding lacunary species. Comparison of current intensities as well as controlled potential coulometry indicate the consumption of roughly three electrons per molecule on the first wave of $\alpha_2FeP_2Mo_2W_{15}$. This result is consistent with the merging of the molybdenum and iron waves at pH = 2. The combined wave remains chemically reversible upon cycling. A study of this pattern as a function of pH allows the Fe^{III} wave to be separated from the molybdenum reduction, thus confirming the merging mechanism.

Figure 4 shows representative examples of the cyclic voltammograms obtained with the Cu^{II} substituted complex. In Figure 4A, the ''first'' wave of the system is displayed for pH = 3 and pH = 5. The pH-dependence is obvious for

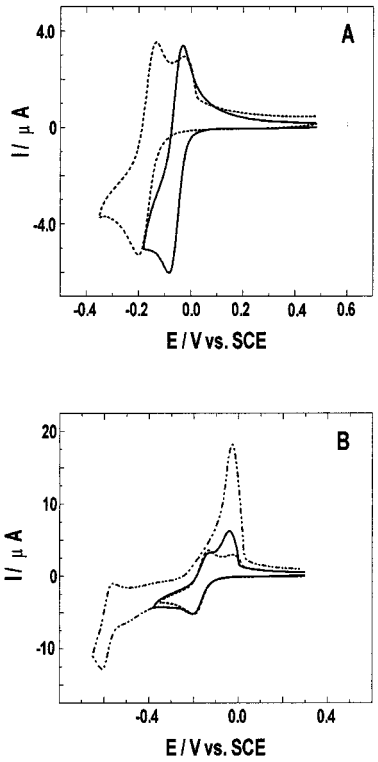

Figure 4. Cyclic voltammograms observed for [1,2,3-$P_2CuMo_2W_{15}$) under various conditions. Scan rate: 10 mV s^{-1}. – (A) *Solid line curve*: pH = 3 (0.2 M Na_2SO_4 + H_2SO_4). Use of an acetate medium does not modify the results. – *Short dot curve* pH = 5 (0.2 M CH_3COONa + CH_3COOH). The voltammograms are restricted to the "first" wave of the system. – (B) pH = 5 (0.2 M CH_3COONa + CH_3COOH): The negative going scan is reversed at different potential values.

the cathodic wave, concerning its potential location as well as its current intensity. A rough estimate would indicate a peak potential shift of 52 mV/pH-unit. These observations must be traced mainly to the electrochemical behavior of molybdenum centers. On potential reversal, two well-defined and well-separated oxidation peaks are observed at pH = 5. The same pattern is obtained at pH = 3, but with poorer separation. This result suggests that one of the two oxidation components is hardly pH-dependent, if at all. It has been checked that no splitting of the oxidation wave associated with the reduced molybdenum centers is observed at pH = 3 and at pH = 5 for the lacunary species α_2P_2 Mo_2W_{15}. A reasonable outcome is the hypothesis that the reduction of the Cu^{II} center mixes up, at least partly, with that of the molybdenum moieties. Support for such a possibility appears in Figure 4B. The well-behaved cathodic trace of the "molybdenum wave" is followed by an ill-defined series of waves. The potential excursion is reversed just past the first other well-behaved wave. Comparison of the cyclic voltammogram of Figure 4B with that of $\alpha_2P_2Mo_2W_{15}$ indicates that this last wave must be associated with the first tungsten-centered redox process of the heteropolyanion framework. The anodic trace associated with the ill-defined zone and the molybdenum wave is clearly composite. The more anodic wave of this composite trace is the larger and the sharper, the more cathodic is the value selected to reverse the potential during the negative going scan. In short, the anodic trace reveals the reduction of copper within the heteropolyanion. The electrochemical behavior of the Cu^{II} in $\alpha_2CuP_2Mo_2W_{15}$ deserves some comments. In the pH domain which could be explored in the present experiments, the copper reduction mixes up partly with the molybdenum reduction. A controlled potential coulometry is performed at E = –0.176 V vs. SCE, a potential just negative of the peak of the "molybdenum wave" in a pH = 3 medium, where no obvious reduction of Cu^{II} is observed on the cyclic voltammogram. Substantially more than two electrons per molecule of complex are consumed. Provisionally, it is worth noting that this electrolysis results in a red deposit, visible to the naked eye on the electrode surface. Preliminary XPS analyses indicate mainly the presence of copper in the deposit.

Concluding Remarks

One of the main ideas behind the present work is to take a further step in our systematic study of parameters which could favor several electron processes on the first wave of HPAs. The introduction of two molybdenum atoms in the "cap" of the framework of $\alpha P_2W_{18}O_{62}^{6-}$, with the possibility of varying the nature of the third metallic atom in the corresponding trimetallic moiety, has given interesting results. The molybdenum centers are reducible in a fairly positive potential domain, and their redox behaviors are pH-dependent. Another outcome worth noting is the importance of those heterometallic centers which are easily reduced in the same potential domain as the molybdenum centers. The Fe^{III}- and Cu^{II}-substituents appear to be two excellent illustrations of this conclusion. In the case of Fe^{III}, the interplay between the potential location of the iron-centered reduction and the pH effect on the potential location of the molybdenum moieties reduction, has permitted the observation of a three-electron first wave for $\alpha_2FeP_2Mo_2W_{15}$. For the Cu^{II} complex, a deposition process has been demonstrated, and further details are under scrutiny. For the other metallic cations used in this work, the comparison of their cyclic voltammograms with that of $\alpha_2P_2Mo_2W_{15}$ indicates unambiguously that the influence of all these substituents, in combination with the known pH effect, favors the two-electron reduction of the molybdenum centers. However, the first redox process of the corresponding heteropolyanion remains, at most, limited to the two-electron uptake of the molybdenum centers. Furthermore, some of the metallic substituents do not show any electrochemical activity within the heteropolyanion. Possibly, substitution at the α_1 position rather than at the α_2 position explored here, might be beneficial to circumvent some of the present difficulties. Work is in progress in this direction.

Experimental Section

Preparations: The potassium salt of [(1)-2,3-$P_2\square Mo_2W_{15}O_{61}$]$^{10-}$ was prepared by published methods.[1,3,16,17]

$K_8[VOP_2Mo_2W_{15}O_{61}]\cdot 16H_2O$: A sample of $K_{10}[P_2Mo_2W_{15}O_{61}]\cdot 19H_2O$ (9.4 g, 2 mmol) was dissolved in a stirred solution of LiCl (6.8 g), glacial acetic acid (3.7 mL) and lithium hydroxide (1.64 g) in water (220 mL). A sample of vanadyl sulfate, $VOSO_4\cdot 5H_2O$ (0.51 g, 2 mmol), was added and the whole solution was treated with saturated KCl solution (170 mL). After 30 min, the precipitate was filtered on a sintered glass frit, washed with ethanol and diethyl ether, and dried in air. $K_8[VOP_2Mo_2W_{15}O_{61}]\cdot 16H_2O$**:** calcd. K 6.72, V 1.10, Mo 4.12, W 59.2, H_2O 6.19; found: K 6.64, V 1.09, Mo 4.1, W 59.0, H_2O 6.25.

$K_8[Mn(H_2O)P_2Mo_2W_{15}O_{61}]\cdot 16H_2O$: To a stirred solution of $Mn(NO_3)_2\cdot 6H_2O$ (0.63 g, 2.2 mmol) in water (80 mL), acidified with HNO_3 (1 M, 0.5 mL), was added $K_{10}[P_2Mo_2W_{15}O_{61}]\cdot 19H_2O$ (9.4 g, 2 mmol). The solution was treated with saturated KCl solution (40 mL). The precipitate was filtered on a sintered glass frit, washed with ethanol and diethyl ether and air-dried. $K_8[Mn(H_2O)P_2Mo_2W_{15}O_{61}]\cdot 16H_2O$**:** calcd. K 6.71, Mn 1.18, Mo 4.12, W 59.2, H_2O 6.56; found: K 6.65, Mn 1.16, Mo 4.06, W 59.0, H_2O 6.49.

$K_8[CO(H_2O)P_2Mo_2W_{15}O_{61}]\cdot 15H_2O$: Prepared by the same method as the manganese(II) salt. $K_8[Co(H_2O)P_2Mo_2W_{15}O_{61}]\cdot 15H_2O$**:** calcd. K 6.73, Co 1.27, Mo 4.12, W 59.1, H_2O 6.20; found: K 6.60, Co 1.27, Mo 4.35, W 59.5, H_2O 6.19.

$K_8[Zn(H_2O)P_2Mo_2W_{15}O_{61}]\cdot 14H_2O$: Prepared by the same method as the manganese(II) salt. $K_8[Zn(H_2O)P_2Mo_2W_{15}O_{61}]\cdot 14H_2O$**:** calcd. K 6.75, Zn 1.41, Mo 4.12, W 59.2, H_2O 5.82; found: K 6.74, Zn 1.37, Mo 4.1, W 59.5, H_2O 5.71

$K_8[Ni(H_2O)P_2Mo_2W_{15}O_{61}]\cdot 15H_2O$: A sample of $Ni(NO_3)_2\cdot 6H_2O$ (0.73 g, 2.5 mmol) was added to water (80 mL) with stirring, and $K_{10}[P_2Mo_2W_{15}O_{61}]\cdot 19\ H_2O$ (9.4 g, 2 mmol) was added. The mixture was warmed up until dissolution occurred, and the solution was then left at 5 °C for a few hours. The pale yellow crystals were filtered off, washed with ethanol and diethyl ether, and then air-dried. $K_8[Ni(H_2O)P_2Mo_2W_{15}O_{61}].15H_2O$**:** calcd. K 6.73, Ni 1.25, Mo 4.12, W 59.2, H_2O 6.20; found: K 6.65, Ni 1.26, Mo 4.06, W 59.0, H_2O 6.12.

$K_8[Cu(H_2O)P_2Mo_2W_{15}O_{61}]\cdot 15.5H_2O$: Prepared by the same method as the nickel(II) salt. $K_8[Cu(H_2O)P_2Mo_2W_{15}O_{61}].15.5H_2O$**:** calcd. K 6.71, Cu1.36, Mo 4.12, W 59.2, H_2O 6.37; found: K 6.65, Cu 1.34, Mo 4.07, W 59.9, H_2O 6.34.

NMR, IR and UV Visible and Potentiometric Measurements: ^{31}P NMR spectra were recorded in 10 mm optical density tubes on a Bruker VM 250 apparatus operating at 101.2 MHz, in the Fourier transform mode. The ^{31}P chemical shifts were measured on 0.02 M solutions of the polyanions in aqueous 1 M LiCl (10% D_2O) solutions, and were referenced to external 85% H_3PO_4 by the substitution method. – IR spectra were recorded on a Bio-Rad FTS 165 FTIR spectrophotometer. – UV/Vis spectra were recorded on a 555 Perkin–Elmer spectrophotometer. – Potentiometric measurements were made on a Tacussel LPH 430T pH meter. The apparent formation constant β_{app} for the Fe^{III}-substituted compound was determined potentiometrically in 1M HNO_3, considering that in this medium, the lacunary polyoxometalates of this work do not complex Fe^{2+} ions.[1] The formation constant for the V^{IV}-substituted complex has been evaluated by comparison with the value obtained for the iron complex. For all the other compounds, a procedure derived from that described in detail for the stability constant measurements of Ce^{III} and Ce^{IV} complexes of both the α_1 and α_2 $[P_2W_{17}O_{61}]^{10-}$ isomers[18] was used. A detailed account of these measurements for each complex will be given elsewhere.[19] In the present work, the Co^{II} derivative of α_2 $[P_2W_{17}O_{61}]^{10-}$ was selected as the central species worked out in detail in an acid medium, and with which all the others are then compared. In an acid medium, the lacunary species is known[20] to be in the protonated form α_2 $[H_3P_2W_{17}O_{61}]^{7-}$. The determination of the three acidity constants of this species and that of the substituted complex are the main sources of error. An average estimation of the total error on the logβ values is in the range of ± 0.3.

Electrochemical Experiments; Chemicals, Equipment and Apparatus: Pure water was used throughout. It was obtained by passing through a Milli-RO_4 unit and subsequently through a Millipore Q water purification set. All the chemicals were of high-purity grade and were used as received. H_2SO_4, Na_2SO_4, CH_3COONa, CH_3COOH and NaOH were commercial products (Prolabo). The appropriate compositions of the various supporting electrolytes are indicated in the figure captions.

The solutions were purged thoroughly for at least 30 min. with pure argon and kept under a positive pressure of this gas during the experiments.

The source, mounting and polishing of the glassy carbon (GC, Tokai, Japan) electrodes has been described.[21] The glassy carbon samples had a diameter of 5 mm. The electrochemical set-up was an EG G 273 A driven by a PC with the 270 software. The data were recorded in the computer. Potentials are quoted against a saturated calomel electrode (SCE). The counter electrode was a platinum gauze of large surface area. Spectroelectrochemical experiments were performed in a three-compartment cell comprising a 1 cm optical path quartz cuvette. The working electrode was a sheet of glassy carbon (V25, Le Carbone Lorraine). The whole cell remained inserted in the spectrometer cavity and kept under continuous argon bubbling and stirring during the electrolysis. A second 1 cm quartz cell was matched with that of the electrochemical cell and served as a reference. The UV/Vis spectra were recorded with a Perkin–Elmer Lambda 19 spectrophotometer. All experiments were performed at the laboratory temperature.

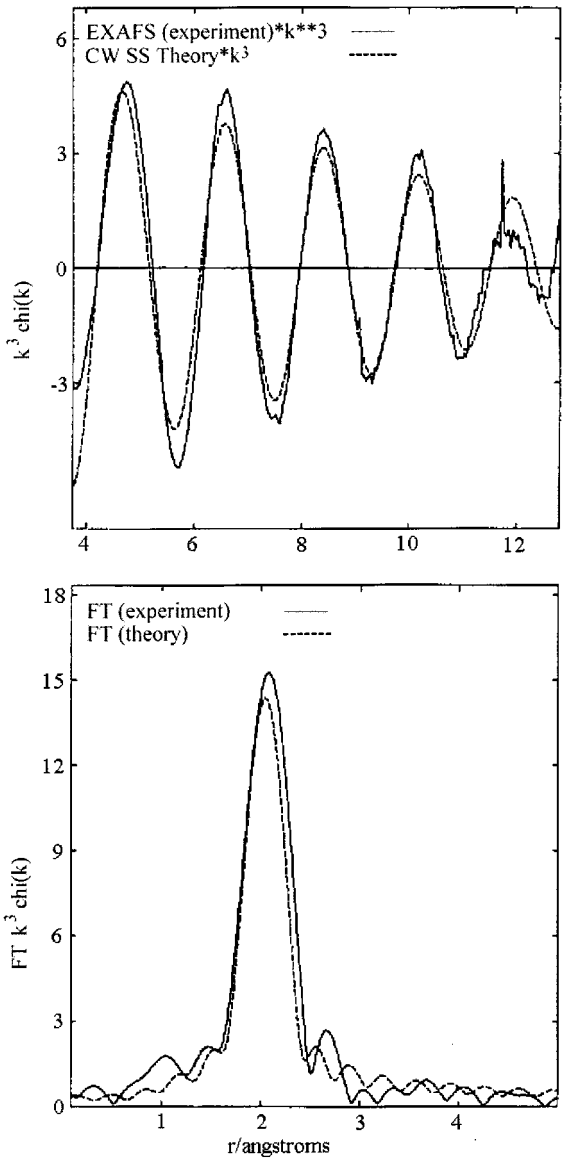

Figure 6. Fe K-edge k^3-weighted EXAFS spectrum and Fourier transform, phase-shift corrected for carbon (—— experimental; ------- curved wave theory, fit B in Table 1), of [Fe{(η-$C_5H_4)_2SiMe_2$}] at 298 K

were very large: *R* factor 45.5%, E° −1.8 eV, *r*(Fe−C) 2.023(5) Å, 2 σ^2 0.0236(17) Å^2, *r*(Fe···Si) 2.736(33) Å, 2 σ^2 0.0176(83) Å^2. A better fit to the experimental data was obtained by starting from fit A and refining the coordination number (fit B, Table 1, Figure 6). The final value was 4.3 but the error in this value must be much higher than 20% for the reasons outlined above.

Conclusion

The pore walls of mesoporous siliceous MCM-48 have been successfully derivatized with (1,1′-ferrocenediyl) dimethylsilane. The organometallic complexes react with the MCM-48 surface silanols (particularly of the Q^3 type) to give a $C_5H_4SiMe_2$−O linkage to the silica surface. Despite the fact that MCM-48 and MCM-41 possess very different mesoporous surfaces, this process strongly resembles the process previously reported for the functionalization of the latter by strained ferrocenophanes.

Experimental Section

General: All preparations and manipulations were performed using standard Schlenk techniques under an oxygen-free and water-free argon atmosphere. Pentane was dried by reflux over Na/benzophenone ketyl, distilled under argon, and kept over 4-Å molecular sieves. − Powder X-ray diffraction (XRD) data were collected on a Philips Xpert diffractometer using Cu-K_α radiation filtered by Ni. − Microanalyses were performed at the TU Munich. − Infrared spectra were recorded on a Unican Mattson Mod 7000 FTIR spectrophotometer using KBr pellets and/or solutions. − ^{29}Si- and ^{13}C-NMR spectra were recorded at 79.49 and 100.62 MHz, respectively, on a (9.4 T) Bruker MSL 400P spectrometer. ^{29}Si-MAS NMR spectra were recorded with 40° pulses, spinning rates of 5.0−5.5 kHz, and 60 s recycle delays. ^{29}Si-CP MAS NMR spectra were recorded with 5.5 μs pulses, a spinning rate of 5.0 kHz and 5 s recycle delays. Chemical shifts are quoted in parts per million relative to TMS. ^{13}C-CP MAS NMR spectra were recorded with 4.5 μs pulses, a spinning rate of 8 kHz, and a 4 s recycle delay. Chemical shifts are quoted in ppm relative to TMS. − Nitrogen adsorption isotherms were recorded using a CI electronics MK2-M5 microbalance connected to a vacuum manifold line. The as-made MCM samples (typically around 0.02 g) were dehydrated overnight at 723 K to an ultimate pressure of 10^{-4} mbar, and then cooled to room temperature prior to adsorption. Extra care with the functionalized materials was necessary and so the samples were dehydrated at 423 K to prevent the destruction of the functionalities. Nitrogen isotherms were then recorded at 77 K. Equilibration of each data point was monitored using CI electronics Labweigh software, and the pressure monitored using an Edwards Barocel pressure sensor. Specific surface areas, A_{BET}, were determined from the linear part of the BET equation (P/P_o = 0.05−0.3). − Fe K-edge X-ray absorption spectra were collected at room temperature in transmission mode on station 9.2 [double crystal Si(220) order-sorting monochromator, 50% harmonic rejection] of the Synchrotron Radiation Source at the Daresbury Laboratory, operating at 2 GeV in single bunch mode, with typical currents of 13−19 mA. Solid samples, diluted if necessary with boron nitride, were held between layers of mylar film in 0.5 mm thick aluminium plates. Two spectra were recorded for each sample and summed using the program EXCALIB, available on the Daresbury computer XRSSERV1. The program EXBACK was used to extract the raw EXAFS, $\chi^E(k)$, and curve-fitting analyses, by least-squares refinement of the non-Fourier filtered k^3-weighted EXAFS data, were carried out within EXCURVE (version EXCURV98[13]) using spherical wave methods.[14] Phase shifts were calculated using Von Bart ground state and H. Lundqvis exchange potentials.

[Fe{(η-$C_5H_4)_2SiMe_2$}] was prepared by the method reported by Wrighton[15] and purified by sublimation under vacuum.

MCM-41 was synthesized according to the literature employing [($C_{14}H_{29}$)NMe_3]Br as a templating agent.[16] After calcination (540 °C/6 h) and dehydration (200 °C under a vacuum 10^{-4} Torr for 8 h) the material was characterized by XRD, N_2 adsorption and IR spectroscopy.

MCM-41/[Fe{(η-$C_5H_4)_2SiMe_2$}] was prepared as described in the literature.[4] Elemental analysis indicated 8.33 mass-% Fe. − IR

(KBr): $\tilde{\nu}$ = 3574 vs cm^{-1}, 3096 m, 2963 m, 1645 s, 1365 m, 1234 vs, 1169 vs, 901m, 816 s, 798 s, 667 m. − (^1H, ^{13}C, ^{29}Si) NMR spectroscopic data are in agreement with ref.[4]

MCM-48 was synthesized according to the literature employing $[(C_{16}H_{33})NMe_3]Cl$ as a templating agent.[17,10b] After calcination (540°C/6 h) and dehydration (220°C at 10^{-4} Torr for 6 h) the material was characterized by XRD, N_2 adsorption and IR spectroscopy.

Preparation of MCM-48/[Fe{(η-C_5H_4)$_2$$SiMe_2$}]: A suspension of MCM-48 (0.5 g) in pentane (15 mL) was treated with a solution of [Fe{$(C_5H_4)_2SiMe_2$}] (0.35 g) in pentane. After 24 h at room temperature, the resulting suspension was filtered off and the remaining orange solid was washed several times with pentane, and dried under an oil-pump vacuum. The pentane washings contained trace amounts of the starting material [Fe{(η-C_5H_4)$_2$$SiMe_2$}] and ferrocene, identified by solution ^1H-NMR spectroscopy. − Elemental analysis indicated 8.18 mass-% Fe. − IR (KBr): $\tilde{\nu}$ = 3454 vs cm^{-1}, 3103 m, 2960 m, 1637 s, 1423 m, 1234 vs, 1169 vs, 1081 vs, 968 m, 900 m, 822 s, 798 s, 667 m, 453 s.

Zwitterionic Organometallates

Remi Chauvin[a]

Keywords: Organometallate complexes / Zwitterionic states / Transition metals / Coordination modes / Electrostatic interactions / Ion pairs

Whereas ion-pairing has been long recognized as playing a key role in organometallic chemistry, the zwitterionic feature of organotransition metal complexes has only recently become an influential factor in the design of cationic metal catalysts. The prospective situation of reversed polarity, with metal fragments formally bearing an integral negative charge, may be envisaged. Besides the well-documented zwitterionic complexes derived from phosphonium ylides, other examples of zwitterionic organometallate complexes, formulated as such on the basis of structural, spectroscopic, or chemical evidence, have been reported in the recent literature and are reviewed here. They are classified according to the nuclearity of the anionic core and the nature of the cationic moiety, which can be a phosphonium, an ammonium, an iminium, a sulfonium, or a cationic organometallic fragment. The stabilization of the non-solvated charge separation is shown to arise from resonance and partial hapticity effects, hydrogen-type bonding, and tight intramolecular ion-pairing made possible by a back-folding of the ligand onto the metal center.

Introduction

Whereas dative bonds are generally assumed to govern the structures and reactivities of organometallic transition metal complexes as well as their catalytic properties, electrostatic interactions govern those of biochemical systems and enzymes. Of course, the borderline between the two realms is not quite so clear-cut. Indeed, metalloenzymes belong to the electrostatically-governed realm, whereas their models and biomimetic catalysts tend to rely on the auxiliary roles of dative interactions involving mainly electronegative atoms (O, N, S, etc.).[1] Conversely, electrostatic interactions play a definite albeit auxiliary role in organometallic complexes involving less electronegative atoms (C, P, H, etc.). Significantly, ion-pairing effects in organometallic species of both main group[2] and transition metals[3] have been widely studied. Nevertheless, intermolecular ion-pairing in solution remains a somewhat intangible phenomenon which is difficult to assess experimentally. In contrast, the intramolecular situation is chemically more relevant and is more easily appraised. Since the entropic effect is prone to favor rearrangements leading to the disappearance of the charge separation, the a priori fragile zwitterionic complexes merit special consideration. The purpose of this review is to classify a number of stable zwitterionic complexes selected from the recent literature, with particular emphasis on metallate species. In addition to the electrostatic energy of the intramolecular charge separation, the presence of a formal negative integral charge at an electropositive transition metal atom is apparently an intriguing feature of Lewis structures that are supposed to represent stable molecules (elusive zwitterionic excited states will not be discussed).[4] This misleading paradox can be rationalized by considering that the negative charge is actually more or less delocalized over the metal fragment and its auxiliary ligands (CO, X, Ph, etc.). Nevertheless, the *formal* presence of *integral* opposite charges linked through a path of covalent and dative bonds, located at the metal fragment and in a definite region of

The author obtained his Ph. D. in 1988 under the supervision of Prof. H. B. Kagan in Orsay (France). He then pursued in the field of asymmetric organometallic synthesis and catalysis as a postodoctoral fellow with Prof. K. B. Sharpless at M.I.T. (Cambridge, MA), and then with Prof. A. Vasella at Zürich University (Switzerland). From 1991 to 1993 he worked as an organic chemist at the Roussel Uclaf Company in Romainville (France). He then moved back to academic research at the C.N.R.S. in Toulouse (France). In 1998, he was appointed as a Professor at Toulouse University, and launched new research axes ("carbomer" structures, and search for electrostatic effects in asymmetric catalysis). In the recent past, his general interests have focused on the problem of the quantification of chirality and on chiral organophosphorus complexes, especially chiral zwitterionic ones.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

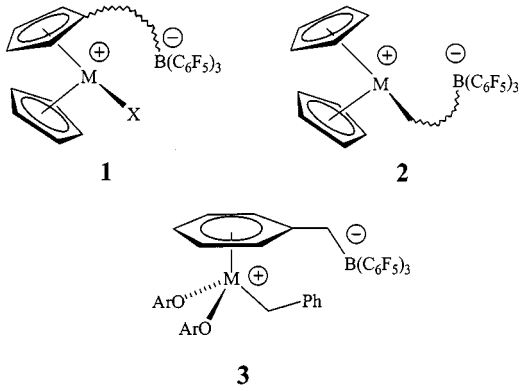
the organic ligands, respectively, is explicitly emphasized as a peculiar feature by many authors: it is shown here to be a unifying feature of complexes designed for very different purposes.

Neglecting orbital components, the through-space electrostatic interaction corresponds to the energy of a formal point charge subjected to the isotropic electrostatic potential of the other. A number of cases may be distinguished depending on the relative positions of the formal charges. Firstly, if no non-zwitterionic connected Lewis structure can be drawn by resonance of the π-electrons, the complex will be classified as "mesoionic" or "truly zwitterionic". Secondly, if the opposite integral formal charges of the ion can be cancelled out by resonance in a non-zwitterionic mesomeric form, the complex will merely be partially zwitterionic. Three main situations are encountered:

(i) α-Dipole: This trivial situation corresponds to ionic ($M^{\pm}$,$X^{\mp}$) and semi-polar ($M^{\pm}$–$L^{\mp}$) bonds. It is trivially rendered degenerate by non-zwitterionic resonance forms (M–X, M=L, M↔L); the charge separation is thus weak and very formal.

(ii) β-Dipole: This situation can be mesoionic (M^{-}–X–Y^{+}) or otherwise ($M^{\pm}$=X–$Y^{\mp}$ ↔ M–X=Y) and corresponds to that of the well-studied derivatives of phosphonium ylide complexes M^{-}–CH_2–$^{+}PR_3$.[5]



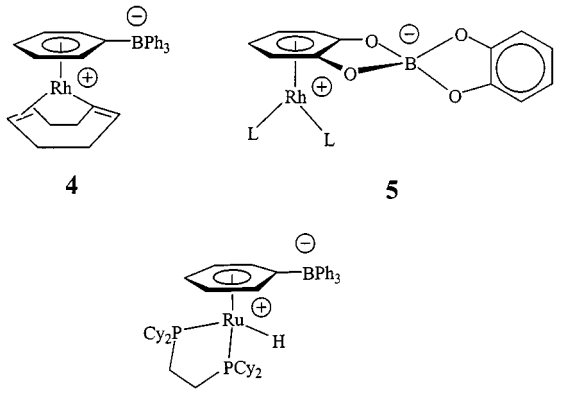
(iii) ω-Dipole: Here, the greater topological charge separation should a priori enhance the destabilization. Many push-pull transition metal complexes where the metal center plays the role of a donor or an acceptor have been prepared, particularly with a view to studying electron-transfer phenomena and to test their second-order nonlinear optical responses.[6] The ground states of such complexes can, however, essentially be described by the non-zwitterionic resonance form. In contrast, only zwitterionic complexes formulated by a main zwitterionic resonance form and stabilized by a secondary contribution from a non-zwitterionic resonance form will be dealt with here. Emphasis will be placed on stabilization stemming from inductive delocalization through σ-bonds, as well as from geometrical shortening of charge separation (back-folding of the ligand charge onto the metal charge).

After a brief overview of zwitterionic organometallic complexes of cationic metals that are currently the subject of growing interest for catalysis purposes, the review will then provide a survey of zwitterionic organometallic complexes exhibiting reversed polarity, i.e. with anionic transition metals, classified according to the nuclearity of the anionic fragment and the nature of the cationic terminus.

I. Zwitterionic Organometallic Complexes with Cationic Metals: A Brief Overview

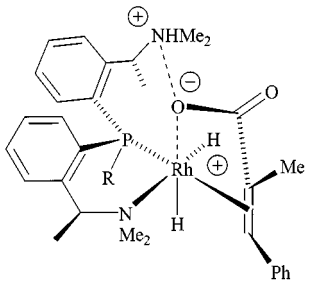
Numerous neutral complexes containing a cationic transition metal center covalently bound to anions usually classified as weakly- or non-coordinating have been prepared, especially for catalysis purposes.

Catalysis in aqueous media is an active field of research of both industrial and academic relevance.[7] Water-soluble catalysts are obtained by tethering ionic functions to phosphane ligands of catalysts previously known to be effective in organic media. In this regard, the coordination sphere of the metal must be preserved, and the anion must be repelled at the periphery of the complex where it mainly interacts with the aqueous solvent. Although cationic functions such as ammonium can be used,[8] most water-solubilizing ligands bear anionic functions (carboxylate, sulfonate, etc.). Although the latter are often locally neutralized by a sodium cation, some cationic metal complexes such as the hydroformylation catalyst $Na_5[Co(CO)_3(P\{(CH_2)_nC_6H_4$-$p$-$SO_3\}_3)_2]$ can be formulated as zwitterionic.[9] Generally, however, the metal in the active species can be viewed as being formally neutral, ionicity being more important than zwitterionicity.



Besides water-solubilization effects, anionic end-groups can have more significant effects on catalytic activities. This is nicely illustrated by the design of efficient Group 4 metal catalysts for olefin polymerization. Since the pioneering work of Hlatky and Turner,[10] many research groups have focussed on the design of zwitterionic titanium, zirconium, and hafnium complexes bearing a borate functionality and acting as single-component polymerization catalysts. The state-of-the-art in cyclopentadienyl-containing zwitterionic catalysts (e.g. of types **1** or **2**) has periodically been reviewed.[11]

The active 14-electron cationic species must preserve its Lewis acidity as a target for the olefin, but as in the intermolecular situation, a sufficient degree of stabilization is required. Provided that it is allowed by the geometry, this is achieved by tight intramolecular $Zr^{+}\cdots H_2CB^{-}(C_6F_5)_3$ ion-pairing,[12] eventually assisted by α agostic interactions.[13] When the geometry enforces a large intramolecular charge separation, weak ArH→Zr^{+} or $^{-}$BArF:→Zr^{+} interactions serve to stabilize the structure. Zwitterionic complexes with a phenyl (instead of cyclopentadienyl) ancillary ligation (**3**) have also been reported, but proved to be poor polymerization catalysts owing to the π-donor properties of the aryloxy ligands.[14]



More generally, phenyl rings tethered to anionic borate centers can act as η^6-ligands towards other metals. Of par-

ticular relevance is Alper's zwitterionic rhodium(I) tetraphenylborate complex (**4**), which exhibits well-defined catalytic activity in various reactions (hydroformylation, hydrogenation, polymerization, etc.)[15] and, in particular, in the carbonylation of benzylic and allylic bromides under phase-transfer conditions.[16] Bis(catecholato)borate also acts as a η^6-coordinating anion in 18-electron cationic rhodium catalysts **5** for the hydroboration and diboration of alkenes.[17] Related hydridoruthenium complexes, such as **6**, have also been described, in which the boron atom of the η^6-tetraphenylborate ligand is even tilted away from the cationic ruthenium hydride.[18]

4 **5** **6**

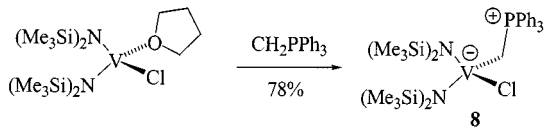
The subtle effects of ion-pairing phenomena in catalysis have been the topic of several studies, e.g. in the case of palladium-catalyzed allylic alkylation,[19] and zwitterionic intermediates have been shown to play a key role in stereoselective catalysis. Thus, in order to achieve enantioselective hydrogenation of substituted acrylic acid derivatives, Yamagishi and co-workers designed rather oxophilic rhodium complexes of chiral ω-aminophosphane ligands: the non-chelating amino group acted as a basic center that could deprotonate the carboxylic group of the substrate.[20] A separation of three formal charges was assumed to occur in the cationic intermediate **7**, and the intramolecular electrostatic interaction was claimed to enhance the facial selectivity of the alkene coordination.

7

Similarly, Brunner et al. designed chiral rhodium complexes bearing chiral ligands where a ligand–substrate charge-transfer was found to control the stereoselectivity in asymmetric catalysis.[21]

Besides these applications in catalysis, the syntheses, structures, and properties of many zwitterionic organometallic complexes with cationic metal fragments have been studied. Consequently, the more rare situation of reversed polarity will now be considered in more depth.

II. Zwitterionic Organometallic Complexes with an Anionic Metal

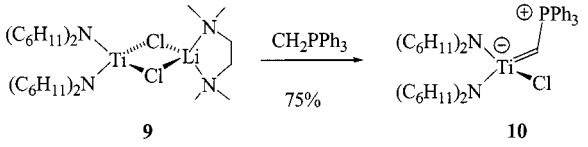


Among zwitterionic metallate complexes, a distinction can be made between mononuclear and dinuclear species.

II.1. Mononuclear Anionic Fragments

II.1.a. Phosphonium Complexes

Most zwitterionic representations of organometallic complexes with an anionic metal center encountered in the literature correspond to the coordination of a phosphonium ylide or a conjugated equivalent. In these complexes, the charge separation is weak and corresponds to a β-dipole (M^-–CH_2–$^+PR_3$). It is remarkable that the metal–phosphorus distance is non-bonding: despite the possibility of adopting a formally non-zwitterionic Lewis topology [phosphorane alkylidene complex M(η^2-CH_2=PR_3)], this limiting dative bonding resonance form (which might be called a "haptomer form" by reference to a limiting π bonding resonance form called a "mesomer form") makes a negligible or very low contribution to actual equilibrium ground-state structures. The M^-–(η^1-CH_2–P^+) sequence can be regarded as a homologue of the simple M^-–$^+PR_3$ semi-polar or M←PR_3 dative bond. Along the same lines, phosphoniocarbene metallate (M^-=CH–$^+PR_3$), phosphoniovinyl metallate (M^-–CH=CH–$^+PR_3$), and phosphonioacetylide metallate (M^-–C≡C–$^+PR_3$)[22a] structures are found to predominate over the non-zwitterionic mesomer forms in the descriptions of equilibrium ground-state complexes. Greater charge separations are also encountered in higher homologues of simple phosphane complexes M←PR_3. The chemistry of these complexes has been thoroughly reviewed on several occasions,[5] hence only a few recent illustrative examples will be outlined here.

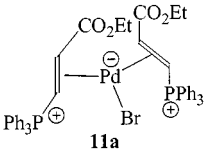


Phosphonium Ylide Complexes: The simplest method of preparation involves the substitution of a labile 2-electron ligand by the anionic end of an ylide. This is illustrated by the synthesis of the paramagnetic vanadium(III) zwitterionic complex **8** by substitution of a THF ligand by CH_2PPh_3 (Scheme 1).[22b] Despite the electrostatic attraction and the possibility of η^2-bonding, the V–C–P angle (128.6°) and the $V^-\cdots P^+$ distance (≈ 3.55 Å) are large. The analogous titanium(III) complex displays the same features.

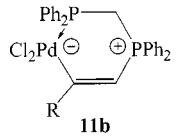
8

Scheme 1

Phosphoniocarbene Metallate Complexes: The diamagnetic titanium(IV) complex **10** was obtained by oxidative coupling of an ylide with a titanium(III) complex **9** (Scheme 2).[22b] Analysis of the bond lengths by X-ray crystallography suggests that the non-zwitterionic phosphoranevinylidenyl limiting form $[(R_2N)_2(Cl)Ti–CH=PPh_3]$ makes only a minor contribution. This can be related to the pre-existence of a formal negative charge on the titanium atom in **9**, which can also be formulated as $[(R_2N)_2TiCl_2]^-[Li(NMe_2CH_2)_2]^+$.

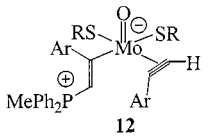


9 **10**

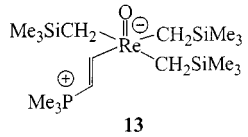


Scheme 2

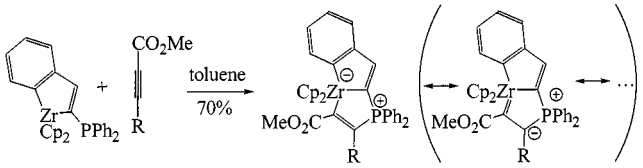
Phosphoniovinyl Metallate Complexes: η^2-Phosphonioalkene complexes such as **11a**,[23a] and η^1-β-phosphoniovinyl complexes such as **11b**,[23b] **12**,[24] or **13**,[25] among many others, are stabilized by a non-polar resonance form and often adopt a *trans* configuration across the C=C bond.



A *cis* configuration, as in **11b**, is enforced in metallacycles.[26] Stable 18-electron organometallic phosphonium zirconate complexes (**14**) have recently been described by Majoral and co-workers.[27] These were prepared by [3+2] cycloadditions of zirconaindene with alkynes (Scheme 3). The complexes were found to exhibit both an α- and a β-phosphonium configuration. Thus, several π-resonance paths can be envisaged, but the non-metallate resonance forms make only negligible contributions.

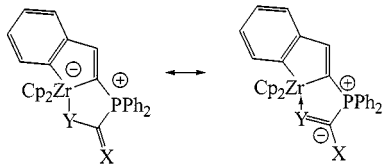


11a

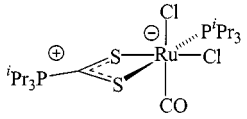


11b

12



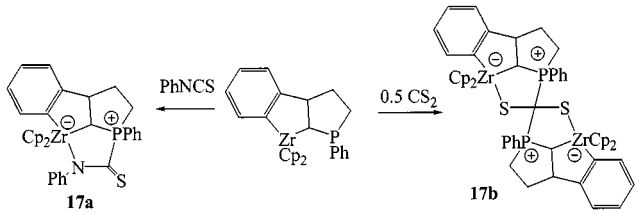
13



14

Scheme 3

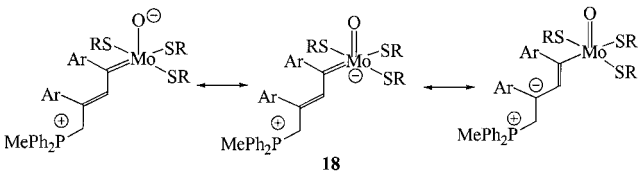
This synthetic strategy has been extended to heteroallenes X=C=Y (X, Y = S, O, NR), leading to α-phosphoniovinyl complexes of type **15**.[28] Here, the Zr–Y bond lengths (Y = S, NR) were found to be longer than any known Zr–Y single bonds, thus indicating their dative character. A related type of covalent-dative zwitterionic ruthenate complex, **16**, has been obtained by insertion of CS_2 into a $iPr_3P\rightarrow Ru$ bond.[29]



15 X = O, S; Y = S, NR

16

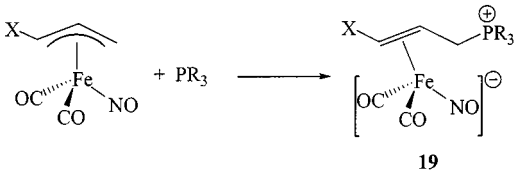
Finally, it must be pointed out that the phosphoniovinyl function is not necessary for stabilizing the zwitterionic structure. Reaction of X=C=S (X = S, NPh) with α-phospholane zirconaindane leads to either the tetracyclic phosphonium zirconate **17a** or to the spirocyclic bis-zwitterionic complex **17b** (Scheme 4).



17a **17b**

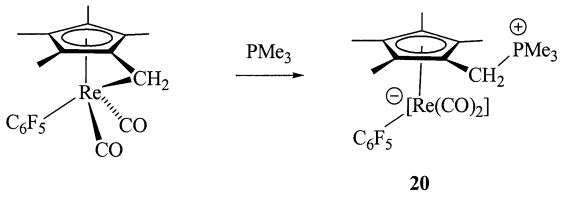
Scheme 4

In all these cyclic phosphonium zirconate complexes, the $Zr^-\cdots P^+$ distances are in the typical range of 3.5–3.7 Å found in non-cyclic derivatives such as **8**.



Other Phosphonium Metallates: Zwitterionic mononuclear phosphonium metallate complexes with a large intrinsic charge separation can be stabilized by resonance. This is illustrated by comparing the phosphonium carbene-molybdate complex **18** (where the shortness of the Mo–C bond length is indicative of strong alkylidene character) with the related **12**, which has neither non-zwitterionic nor α-ylide resonance forms.[24]

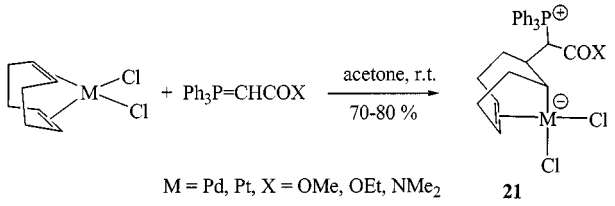
18



The γ-charge separation in allyl-type configurations is not greatly stabilized, as has previously been emphasized

for the η^2-allylphosphonium ferrate complexes **19**,[30] but many related complexes have been isolated (Scheme 5).

Scheme 5

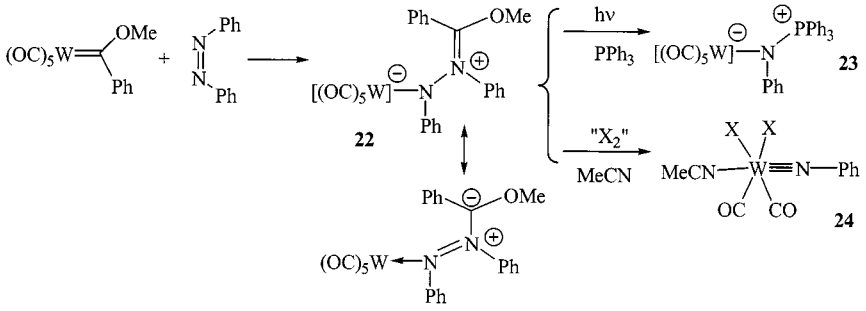


The principle of the above reaction (cleavage of a metal–CH_2 bond by a phosphane) can be applied to the preparation of zwitterionic phosphonium rhenate complexes,[31] e.g. **20** (Scheme 6), where the link between the charges contains a cyclopentadienyl ligand as in $[^{-}Cr(CO)_3\{\eta^5\text{-}C_5H_4(CH_2P^{+}Et_3)\}]$[32] or in the bimetallic complex $[Fe\{\eta^5\text{-}C_5H_4M^{-}(CO)_5\}(\eta^5\text{-}C_5H_4P^{+}Ph_2Me)]$.[33]

Scheme 6

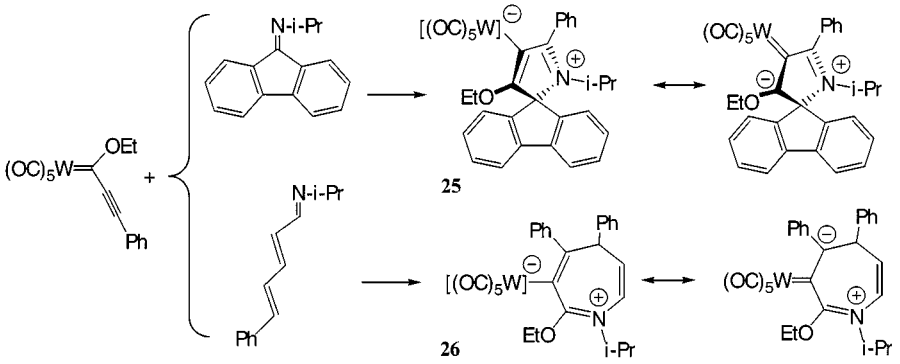
In a similar process, cleavage of an Rh–C bond in a carborane-rhodium complex by nucleophiles leads to γ-zwitterionic phosphonium complexes.[34a] Owing to the fact that the $C_2B_9H_{11}^{2-}$ carborate is considered as an L_2X^{-} equivalent of the $C_5H_5^{-}$ ligand, the starting 18-electron Rh^{III} complex $[\{\sigma,\eta^5\text{-}10\text{-}[CH(p\text{-tol})]\text{-}7,9\text{-}C_2B_9H_{10}^{-}\}Rh^{+}(CO)(PPh_3)]$ is zwitterionic with a positive charge on the rhodium atom and a negative charge on the $C_2B_9H_{10}$ framework.[34b] Reductive cleavage by PEt_3 leads to the zwitterionic 18-electron Rh^{I} complex $[\{\eta^5\text{-}10\text{-}[Et_3P^{+}\text{–}CH(p\text{-tol})]\text{-}7,9\text{-}C_2B_9H_{10}^{-}\}Rh(CO)(PPh_3)]$, where no formal charge resides on the rhodium atom. The latter complex is therefore not a formal metallate.

Very recently, zwitterionic phosphonium organopalladate and organoplatinate complexes **21** with a δ non-conjugated charge separation were described. They were obtained through an unusual vinylogous nucleophilic attack of stabilized α-phosphonium ylides at a cyclooctadiene ligand in an *exo* fashion (Scheme 7).[35] Although the chloride ligands may be displaced by non-coordinating anions, the Pt–Cl 8distances in the crystal (2.3 or 2.4 Å depending on the *trans* effect of the facing ligand) are definitely bonding. IR and NMR data confirmed the formal zwitterionic nature of the complexes in solution.



Scheme 7

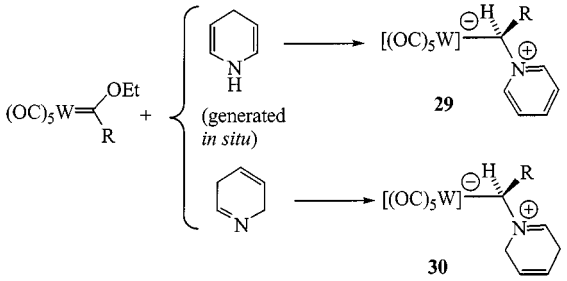
II.1.b Mononuclear Ammonium and Iminium Metallate Complexes



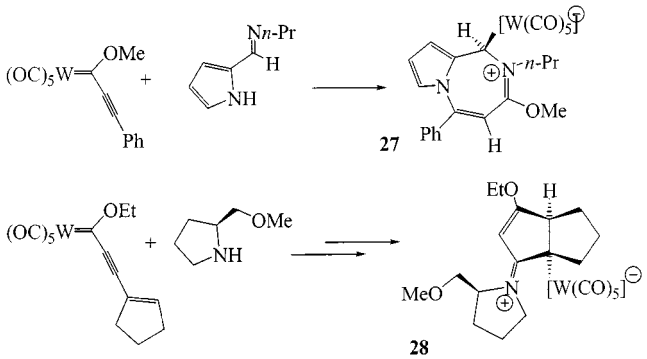
Interesting zwitterionic complexes, where the metal exhibits both a negative charge and a low formal oxidation state, are accessible from Fischer carbene complexes. This tendency is consistent with the analogy between the $(CO)_nM{=}C(R')\text{–}OR$ fragment and the ester $O{=}C(R')O\text{–}R$ fragment,[36] considering the resonance $O{=}C(R')O\text{–}R \leftrightarrow O^{-}\text{–}C(R'){=}{}^{+}OR$ to translate to $(CO)_nM{=}C(R')O\text{–}R \leftrightarrow (CO)_nM^{-}\text{–}C(R'){=}{}^{+}OR$. Such resonance arguments have been invoked to account for the α-CH acidities of Fischer-type carbene complexes $(CO)_5M{=}C(OR)(CH_2R')$.[37]

Unlike phosphonium ylides, "hydrazonium aza-ylides" are mesoionic. Their complexes have been prepared by formal metathesis of tungsten Fischer carbene complexes with *cis*-azobenzene.[38] The stereochemistry of complex **22** was deduced from its crystal structure, where the amido nitrogen atom was seen to be perfectly planar.[39] This planarity does not result from a p_π N:⇒W donation, but rather from steric constraints. The presence of the negative charge on the metal was supported by photochemical arguments, in particular by a shoulder in the UV/vis spectrum of the complex, which was interpreted as an MLCT transition. Under thermal or photochemical activation, complex **22** represents a source of the nitrene complex $(CO)_5W{=}NPh$, which can be trapped by PPh_3 to give the β-zwitterionic complex **23**, the zwitterionic (as opposed to apolar phosphinime) structure of which is suggested by its IR and ^{31}P-NMR data.[40] Under oxidative conditions, the zwitterionic amide complex **22** represents a precursor of imido tungsten complexes such as **24**, exhibiting various oxidation states.[41] The disappearance of the formal charge separation in the zwitterionic complex contributes to the driving force of the reaction (Scheme 8).

Scheme 8



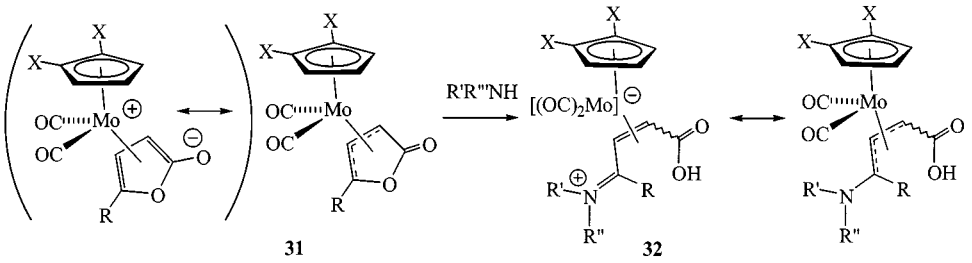
The formation of the zwitterionic amido complex **22** involves nucleophilic attack of the nitrogen atom of azobenzene at the carbenic center, followed by a 1,3-shift of the $W(CO)_5$ fragment. Zwitterionic chromium complexes have also been generated from chromium carbene electrophiles,[42] and from other nitrogen nucleophiles such as ketenimines.[43] α,β-Unsaturated Fischer carbene complexes are susceptible to 1,2- or 1,4-attack by nitrogen nucleophiles, and subsequent rearrangements lead to zwitterionic iminium carbonylmetallate complexes **25–28**.[44] When the nucleophile contains an imino but not an amino group, the final complexes **25** or **26** may be mesoionic, although not necessarily at the metal center: the metal fragment is indeed bonded to an sp^2 carbon atom and the negative charge can be delocalized by π-resonance from the metal to the organic ligand (Scheme 9).[45]



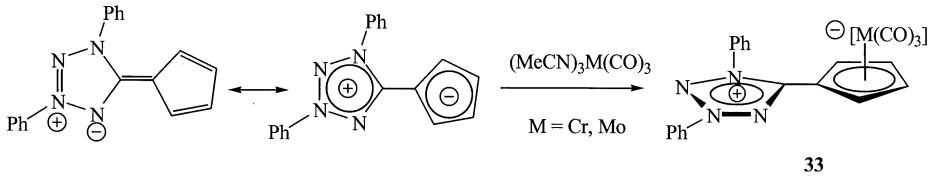
Scheme 9

In contrast, when the nucleophile contains a secondary amino group (Scheme 10), the metal in the iminium carbonylmetallate products **27** or **28** is bonded to an sp^3 carbon atom and the negative charge remains on the carbonyl-metal fragment (as reflected in the corresponding C–Cr^- or C–W^- and C=N^+ bond lengths in the crystal structures).[46][47] The zwitterionic complexes are readily formed at room temperature and exhibit an astonishing degree of hydrolytic and thermal stability. The $W^-\cdots N^+$ separation can involve two bonds (iminium ylide complexes) or three bonds, but the positive charge of the exocyclic or endocyclic nitrogen atom is stabilized by resonance with α,β-conjugated C=C bonds and α- or γ-C–OR bonds. Nonetheless, the charge localization in complexes of type **28** also requires the support of electron-donating substituents at the nitrogen atom. Analogous dialkylphospheniums are unstable and rearrange to non-zwitterionic tungsten vinylphosphane complexes.

Pyridinium ylide complexes of pentacarbonyltungsten, **29**, are true β-zwitterionic complexes where the metal fragment is bonded to an sp^3 carbon atom and retains its anionic charge in all possible π-resonance structures with the organic ligand. Such complexes are produced by the reaction of $(CO)_5M{=}C(OEt)R$ (M = Cr, W) with 1,4-dihydropyridine, formed in situ from 1-methoxycarbonyl-1,2-dihydropyridine and methyllithium (Scheme 11).[48] The stability of the zwitterionic complex might be ascribed to the aromaticity of the pyridinium product. However, non-aromatic 2,5-dihydropyridine analogues **30** have also been structurally characterized, demonstrating the presence of 2,5-dihydropyridine derivatives along with 1,4-dihydropyridine in the in situ formed reactant (Scheme 11).[49] The positive charge delocalization in **30** is restricted, and an X-ray analysis did not indicate any increased delocalization of the negative charge over the carbonyl ligand.



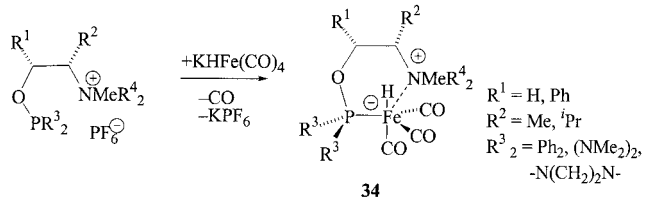
Scheme 11



Scheme 10

In a reaction related to that leading to complex **19**, π-allyl ligands at $(CO)_2XMo^{II}$ centers undergo nucleophilic attack to afford zwitterionic intermediates.[50] In the case of η^3-lactonoyl ligands, despite the possible contribution of the reverse zwitterionic "haptomeric" structure in the electrophilic starting complex **31** (which has been explicitly invoked in related acyl π-allyl complexes),[51] the metal center is not directly attacked. The zwitterionic structure resulting from amine attack stabilizes by undergoing ring-opening (Scheme 12). According to IR spectroscopy and X-ray crystallography, the complexes **32** are better described by an iminium molybdate picture than by a non-zwitterionic structure.[52] The stability of **32** is somewhat surprising; the

Scheme 12



Scheme 13

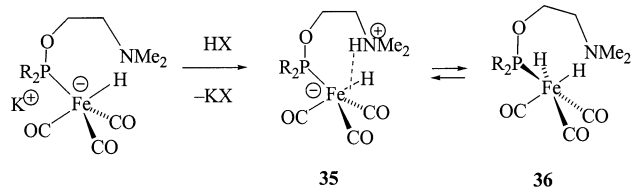
anionic metal neither deprotonates the carboxylic acid function nor reacts with CH_3I.

Tetrazole is a cyclic imine that can act as an *N*-donor ligand in zwitterionic cationic metal tetrazolate complexes,[53] but it also provides the framework for a delocalized cationic moiety in zwitterionic complexes of reversed polarity (Scheme 13). The mesoionic character of olate, thiolate, selenolate, or cyclopentadienide 5-substituted tetrazolium can be transferred to zwitterionic Cr and Mo complexes **33**.[54] In the case of the cyclopentadienide derivative, the high-field shifts of the ^{1}H- and ^{13}C-NMR signals of the nuclei of the Cp ring and the decrease in the pivotal C–C stretching frequency in the IR spectrum upon complexation indicate that the resonance form with the shortest charge separation (N^+–N^-) tends to disappear in the complex. The latter is therefore truly zwitterionic. A similar conclusion can be drawn for olate, thiolate, and selenolate derivatives.

Zwitterionic metallate complexes with a positive charge completely localized at a quaternary ammonium center are not stabilized by resonance, but are less likely to lose the charge separation by a rearrangement of high-energy π-electrons. The intramolecular ion-pairing is thus expected to be very tight. Zwitterionic analogues of ammonium salts of phosphite and phosphinite hydridocarbonylferrates[55] have been studied in order to examine the possibility of a putative "chiral zwitterionic control strategy" in asymmetric reduction of prochiral ketones by chiral iron hydrides.[56] Chiral ammonium phosphinite ligands based on ephedrine or valinol skeletons ("ephosium", "valphosium", etc.) have thus been synthesized and reacted with $KHFe(CO)_4$ to give stable zwitterionic hydridotricarbonylferrate complexes **34** (Scheme 14).[57]

Scheme 14

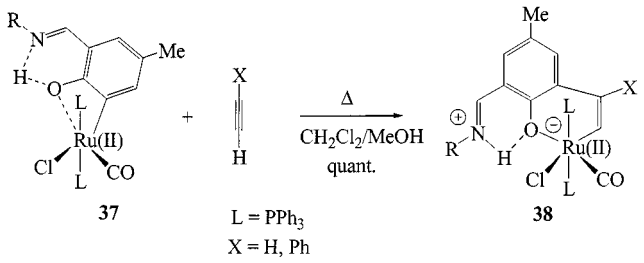
An unusual *cis*-H–Fe–P arrangement was suggested by IR and NMR data in solution, and was confirmed in the crystal. It was proposed that this rare feature was dictated by a stabilizing electrostatic back-folding of the $[NMeR^4_2]^+$ terminus onto the $[FeH]^-$ center. Indeed, a precise intramolecular $N^+Me_3\cdots{}^-HFe$ van der Waals contact between hydrogen atoms of the two moieties has been observed in the crystal. For steric reasons (hindrance of the equatorial carbonyl ligands), this dative-electrostatic chelation is not possible in a *trans*-H–Fe–P isomer. The intramolecular pairing was shown to be retained in solution, by a ^{1}H-^{1}H NOE between NMe_3^+ and HFe^-, and by the variation of the $|^2J(H,P)|$ coupling constant with the dielectric constant of the solvent, which also increases with temperature.[58] The latter correlation was proposed to reflect the effect of the dielectric constant on the average opening of hemilabile electrostatic edge $[HFe]^-\cdots{}^+[N]$ in the equilibrium:



open-[$^+$N~PFeH$^-$···solvent] ⇄ *closed*-[~N$^+$···$^-$HFeP~] + solvent

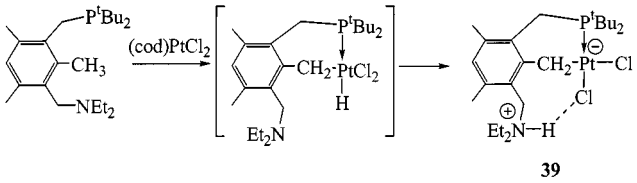
Ammonium cations were shown to form intermolecular contact ion-pairs with $[HFe(CO)_3L]^-$ anions, and a multisite docking of Me_4N^+ onto the external $[HFe(CO)_3P]^-$ anion was proposed to occur in THF in the vicinity of the [FeCO] and the [Fe–H] sites.[59] An intramolecular contact of this type has been found in the solid-state structure of **34**. It is also entropically favored in solution, even in polar solvents such as acetonitrile and dimethyl sulfoxide.

In conclusion, the true zwitterionicity and the flexibility of these complexes allow for stabilization through the adoption of otherwise rare structural and dynamic features. The chiral zwitterionic complexes are capable of reducing activated ketones, but do not give significant enantiomeric excesses. Chiral phosphonium phosphanes ("diopium", "binapium") have been devised as alternative ligands, but their higher basicities have so far prevented the isolation of the corresponding zwitterionic hydridocarbonylferrate complexes.[60][61]



Hydrogen or dihydrogen bonds $A^{\delta'-}\cdots{}^{\delta+}HX^{\delta-}$ involving transition metal centers (X = N, O, F; A = M, MY, MH), although electrostatic in nature, do not generally involve

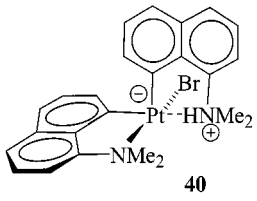
integral formal charges on both A and HX,[62] but some examples are worthy of mention. Transition metal complexes with a bond between a "proton" and a "hydride" $^{\delta-}$MH···HX$^{\delta+}$ are fascinating species corresponding to a heterolytic predissociation state of the dihydrogen molecule. In most cases, however, the charge on the metal is not formally –1 (the H ligands of neutral or even cationic transition metal hydrides are still refered to as "hydrides").[63] Protonation of an ω-aminophosphane hydridoferrate anion occurs at both nitrogen and iron sites (Scheme 15). In polar solvents at low temperatures, the zwitterionic structure **35** has been detected by ^{1}H-NMR, and measurements of the T_1 relaxation times for the NH$^+$ and FeH$^-$ ^{1}H nuclei at low temperatures allowed an estimation of the H···H distance of ca. 1.71 Å.[64] This value is typical for a dihydrogen bond, and was reproduced as the optimized distance in DFT calculations using the B3PW91 functional.[65] In less polar solvents and at higher temperatures, an equilibrium between the zwitterionic ammonium hydride structure **35** and the non-zwitterionic dihydride structure **36** was observed. DFT calculations showed the non-zwitterionic complex **36** to be more stable than **35** by 8 kcal mol^{-1} in vacuo, but that the order of stability is reversed on taking into account the dielectric constant of a polar solvent.



Scheme 15

More classically, hydrogen-type bonding can involve a halide or an oxygen atom instead of a hydride,[66] and occurs as a source of stabilization in truly zwitterionic complexes. The zwitterionic character of complex **38** arises from strain release following insertion into the four-membered metalla-oxetane ring of **37** (Scheme 16). Thus, the cyclic Ru–O bond in complex **37** is quite long (≈ 2.24 Å) and undergoes facile cleavage by ligands. The insertion of an alkyne into the adjacent Ru–C cyclic bond leads to a complex that features a much shorter Ru–O bond length (2.10 Å) with a definitely protonated nitrogen atom. This complex could be described by the zwitterionic structure **38**, featuring an NH···O hydrogen bond.[67]

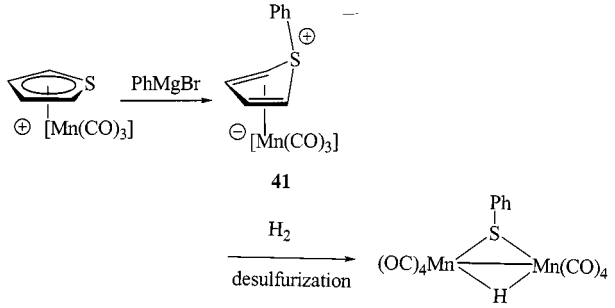
Scheme 16



Milstein and co-workers reported that a non-zwitterionic Pt^{IV} complex produced by intramolecular C–H activation of a neutral Pt^{II} complex undergoes spontaneous stabilization through intramolecular proton-transfer to a pendant amino group to give the zwitterionic Pt^{II} complex **39** (Scheme 17).[68]

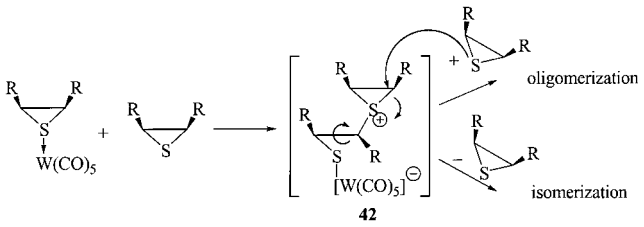
Scheme 17

The zwitterionic nature of **39** was established by X-ray crystallography. Thus, the chlorine atom involved in the hydrogen-bonding is tightly bound to the platinum atom (NH···ClPt ≈ 2.41 Å), the corresponding Pt–Cl bond being shorter (≈ 2.38 Å) than the others (≈ 2.41 Å).



This coordination mode represents the alkylplatinum analogue of the zwitterionic arylplatinum complexes described by van Koten and co-workers.[69] The authors showed that ammonium protons of zwitterionic platinate complexes can interact with either a Pt–Br bond or the formally anionic platinum atom. In the latter situation, the formal charge separation is shorter, but is still present in the platinate(II) structure **40**. The non-zwitterionic hydridoplatinum(IV) structure was ruled out on the basis of NMR data (downfield shift of the proton resonance, small coupling constants between the *ortho*-aromatic protons of the ligand and ^{195}Pt) and by its X-ray crystal structure (N–H ≈ 0.88 Å, Pt···HN ≈ 2.11 Å >> classical Pt–H bond lengths). The stability of the zwitterionic structure of **40** is not only due to the hydrogen bonding, but also to steric shielding of both the platinate center (from strong electrophiles such as MeI) and the ammonium center (from D_2O exchange).

Borderline examples of zwitterionic ammonium metallate complexes are worthy of mention. Thus, zwitterionic 16-electron rhodium-carborate complexes have been prepared by substituting two 2-electron ligands of a neutral rhodium precursor {e.g. [RhBr(PPh$_3$)$_3$]} with a zwitterionic *nido*-carborate ligand (e.g. *nido*-7-*t*BuH$_2$N$^+$–7-CB$_{10}$H$_{10}^-$).[70] The product might a priori be formulated as an 18-electron rhodium(I) complex [(η^5-7-*t*BuH$_2$N$^+$–7-CB$_{10}$H$_{10}$)Rh$^-$Br(PPh$_3$)]. However, since the metallacarborane is not distorted from a triangular *closo*-icosahedral framework, the complex is actually a 16-electron cationic rhodium(III) complex [(η^5-7-*t*BuH$_2$N$^+$–7-CB$_{10}$H$_{10}^{2-}$)Rh$^+$Br(PPh$_3$)], in which both the Rh and N atoms are cationic and a double negative charge is delocalized over the carborane framework.

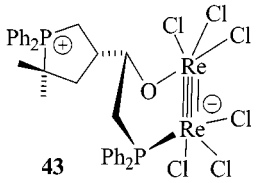


II.1.c. Sulfonium Metallate Complexes

Sulfonium metallate structures are of great relevance to the industrial challenge of petroleum desulfurization. Thus, thiophene derivatives can be hydrodesulfurized via zwitterionic sulfonium manganate(0) complexes **41** obtained by nucleophilic attack at the S atom of cationic η^5-thiophene species. A model of the above zwitterionic intermediate has been characterized by X-ray crystallography. Its structure reveals activation of both the manganese and sulfur atoms, which allows hydrogenolysis of the C–S^+ bonds (Scheme 18).[71]

Scheme 18

Zwitterionic sulfonium metallates occurring in catalytic processes cannot be isolated, but can be invoked as key intermediates. $W(CO)_5$(NCMe) and $W(CO)_5$(thiirane) complexes have been found to catalyze desulfurization, ring-opening oligomerization, and isomerization of thiiranes $S(CHR)_2$ (R = H, Me),[72] and the intermediacy of zwitterionic species **42** resulting from an S_N2 reaction of a free thiirane sulfur atom at a coordinated thiirane carbon atom has been postulated (Scheme 19).



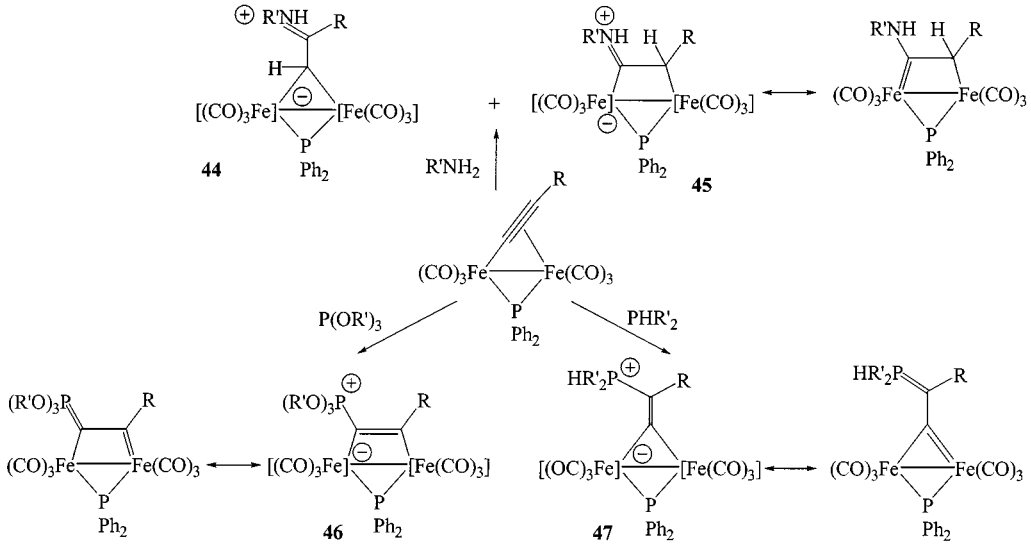
Scheme 19

II.1.d. Zwitterionic Oxonium Complexes

nido-Carborane complexes such as $[Mn(CO)_3\{\eta^5\text{-}7,8\text{-}C_2B_9H_{10}\text{–}10\text{-}O(CH_2)_4\}]$ have been described as zwitterionic. This representative complex has been characterized by X-ray crystallography, and has been shown to react with various nucleophiles to afford phosphonium and ammonium zwitterionic complexes with large charge separations. However, the dianion $C_2B_9H_{11}^{2-}$ is a complexing equivalent of the monoanion $C_5H_5^-$ and since the formally neutral manganese atom in $[Mn(CO)_3\{\eta^5\text{-}C_5H_5\}]$ obeys the 18-electron rule, the negative charge compensating the positive charge of the oxonium substituent is delocalized over the $C_2B_9H_{10}$ framework and not over the metal atom. Therefore, although the complex is indeed zwitterionic, it should not be regarded as a formal metallate species.[73]

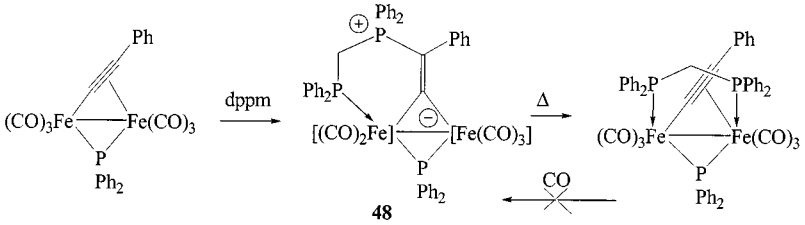
II.2. Dinuclear Anionic Fragments

A negative charge can be delocalized over two or more metal fragments. Owing to the electropositivity of metals, this is a priori a destabilizing factor, but the metal–metal bond permits delocalization of the excess electron over twice as many auxiliary ligands (CO, Cl, etc.) on the anionic metals as in the corresponding mononuclear species. For example, in the nice zwitterionic complex of the chiral phosphonium ligand "isodiop", **43**,[74] the negative charge is delocalized through a quadruple rhenium–rhenium bond. Here, the X-ray crystal structure does not reveal any back-folding of the P^+ center onto the anionic metal.



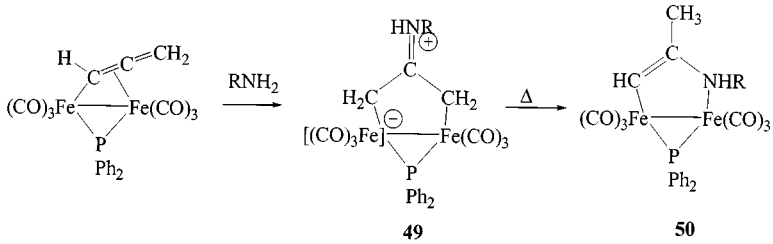
Homo- and heterobimetallic transition metal allenyl complexes with single metal–metal bonds provide frameworks for interesting zwitterionic organometallate complexes,[75] particularly in the case of diiron complexes. Nucleophilic additions at the μ-σ,π-acetylide ligand of $Fe_2(CO)_6(\mu\text{-}PPh_2)(\mu\text{-}C_2R)$ afford various kinds of zwitterionic complexes, in which a negative charge is delocalized over the two iron centers (Scheme 20).

Short β charge separations, also shadded off by minor contributions from non-dipolar resonance forms,[76] occur in **45**–**47**, but γ charge separation occurs in the truly zwitterionic complex **44**.[77] The negative charge can also reside on (and polarize) substituted $Fe_2(CO)_5P$ cores as in the C_β-phosphonio-phosphane complex **48**[78] (Scheme 21) or in related C_α-phosphonio-phosphane complexes.[79]

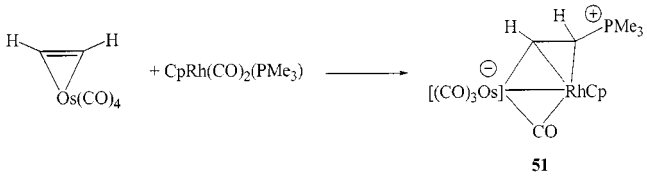


Related μ-σ,π-allenyl precursors generate similar phosphonium complexes,[80] but can also lead to a new type of mesoionic μ-η^2-propylene complex **49**,[81] which isomerizes to the non-dipolar complex **50** (Scheme 22).

Dinuclear phosphonium complexes with three-bond charge separation have long been characterized.[82] The X-ray crystal structure of complex **51** shows that the hydrocarbyl ligand adopts a μ-η^1:η^2 coordination mode (Scheme 23). The high-field shift of the ^{13}C-NMR signal of the C_α–Os center confirms the 18-electron rule and indicates that the osmium atom bears the negative charge which is no longer delocalized over the neutral 18-electron rhodium atom.[83]

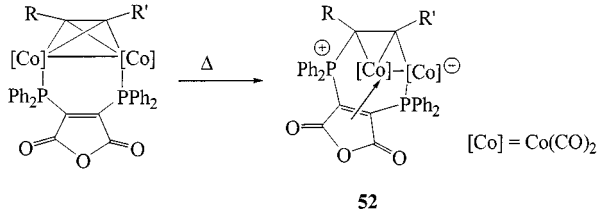


Among the Group 9 homodinuclear metallates, a complex of 2,3-bis(diphenylphosphanyl)maleic acid has been found to stabilize through formation of a zwitterionic cobaltate complex **52** at elevated temperatures (Scheme 24).[84] An 18-electron count for both the metal atoms indicates that the formal charges are separated by three bonds. This



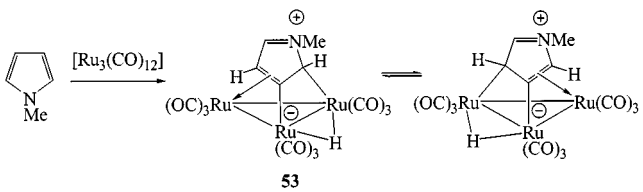
Scheme 20

Scheme 21



Scheme 22

Scheme 23

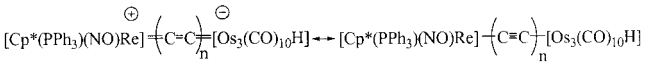


example does not represent a C-η^1-ylide complex, but rather a C,C-η^2-β-phosphoniovinyl complex, the non-coordinated analogue of which corresponds to complexes of types **12** and **13**.

Scheme 24

II.3. Trinuclear Anionic Fragments

Zwitterionic metallates of higher homonuclearity ($[Fe]^{-}_{3}$, $[Ti]^{-}_{3}$, $[Ru]^{-}_{3}$, etc.) have also been described, where the cationic charge is borne by either an appended metal fragment,[85] an iminium,[86] a phosphonium, or an ammonium group.[87] For example, the charge separation on the ruthenium cluster **53** has been evidenced by spectroscopy (ν_{CO} IR frequencies are lower than those found for classical non-zwitterionic related clusters) and by a strong solvent effect on the thermal stability the cluster. The charge delocalization over the three metal atoms also takes place dynamically in solution through rapid interconversion of isomers by

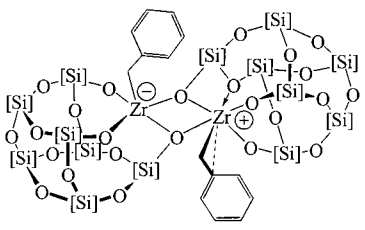


Scheme 25

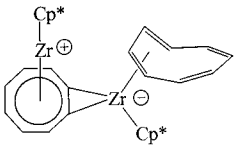
concerted hydride shifts and small geometric displacements (Scheme 25).

III. Zwitterionic Complexes with both Anionic and Cationic Metals

Transition metals linked by a "wire" of sp carbon atoms are attracting a great deal of interest in the context of studies of electron-transfer between metals under various physicochemical stimuli. When the two metallic groups are different in electronegativity, a zwitterionic form can make a significant contribution to the ground state of the complex. For instance, in the rhenium–osmium bimetallic complex **54**, the zwitterionic cumulenic form is seen to make a significant contribution as opposed to the polyacetylenic form.[88]



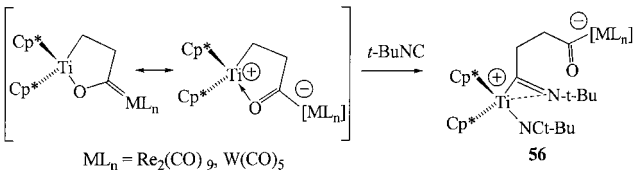
54



It is not the aim of this review to cover this large field; this section merely gathers together several examples of types of zwitterionic dinuclear complexes that can simply be described in terms of a static two-electron transfer from one metal to another on the basis of structural and spectroscopic data.

III.1. Zwitterionic Group 4 Metallates with an Appended Cationic Metal

It has previously been mentioned that both zwitterionic cationic zirconium and anionic zirconate complexes are known. The two charge states have been postulated as being present in the zirconium complexes **55a** and **55b**. Indeed, the dimeric silsesquioxane **55a** exhibits an asymmetric structure in the solid state.[89] A negative charge has been assigned to the zirconium atom bearing five oxygen ligands and one η^2-benzyl ligand. However, the comparable Zr–O bond lengths suggest that a non-zwitterionic limiting structure also contributes to the description of the complex. For the organo-bridged complex **55b**, the zwitterionic formulation was suggested by a reasonable electron count, showing two 16-electron Zr^{IV} and Zr^{II} atoms, and was confirmed by the diamagnetism of the complex.[90]



55a [Si] = c-C_5H_9Si

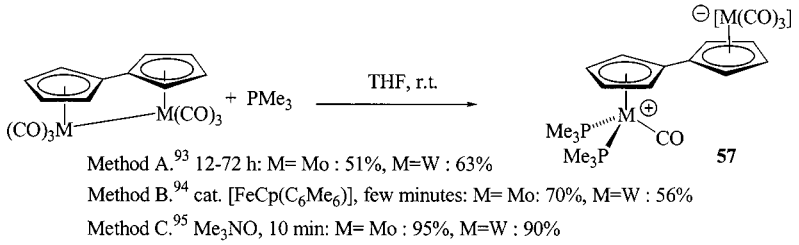
55b

III.2. Zwitterionic Group 5 Metallates with an Appended Cationic Metal

Alkyltitanium-rhenium and -tungstene complexes undergo insertion of *tert*-butylisocyanide to afford truly zwitterionic complexes of type **56**, in which the 18-electron metals are separated by a butanedioic bridge (Scheme 26). The reaction is favored by the existence of a zwitterionic resonance form of the starting complex.[91]

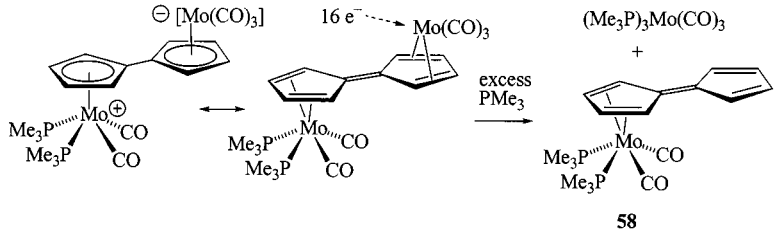
$ML_n = Re_2(CO)_9$, $W(CO)_5$

56



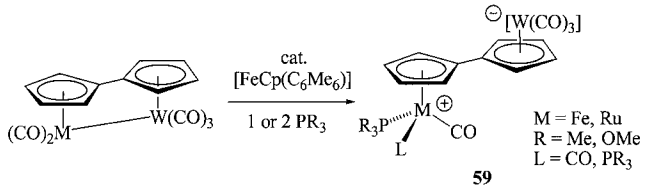
Scheme 26

1II.3. Zwitterionic Group 6 Metallates with an Appended Cationic Metal



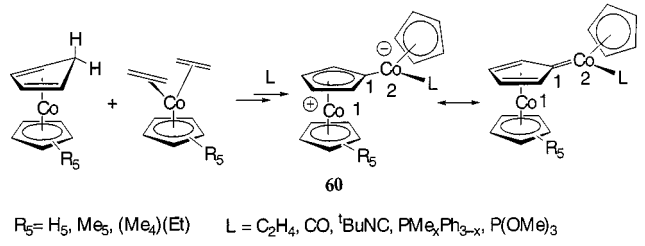
Besides metal-substituted (π-arene)chromium complexes polarized by subtle resonance and inductive effects (e.g. [{η^1:η^6-$C_6H_5(TiCp_2Cl)$}$Cr(CO)_3$]),[92] zwitterionic bimetallic complexes of Group 6 metals are found in the fulvalene series. Homodinuclear complexes, in which the metals exhibit different CO vs. phosphane substitution patterns, can be prepared by several methods (A,[93] B,[94] or C[95]) from (fulvalene)$Mo_2(CO)_6$ and basic phosphanes. After metal–metal bond cleavage, the steric repulsion between the metal centers overrides the electrostatic attraction and results in a 180° rotation of the cyclopentadienyl metal moieties, which, in turn, leads to a *trans* arrangement of the opposite charges with respect to the cyclopentadienyl plane. The zwitterionic nature of these complexes, e.g. **57**, is evident from comparisons of their IR and NMR spectroscopic data, X-ray crystal structures, and chemical reactivity with those of related separated anionic and cationic complexes (Scheme 27).

Most notably, the molybdenum zwitterionic complex undergoes ring-slippage to give the neutral mononuclear η^4-fulvalene complex **58**, probably via an intermediate in which one of the molybdenum atoms has a 16-electron configuration (Scheme 28). This intermediate structure might also be regarded as a non-zwitterionic "haptomer" form of the complex, accounting for its stability and the electron communication between the two metals.



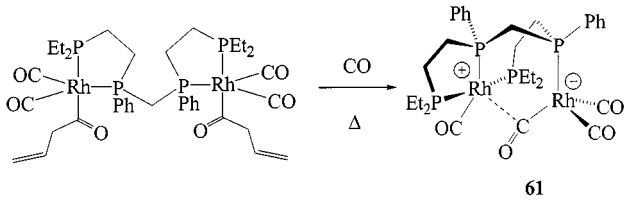
The use of electron-reservoir complexes such as [FeCp(arene)] can also serve to prepare heterodinuclear $^-$[Mo,W]–[Fe,Ru]$^+$-type zwitterions (**59**). Here, phosphane ligands selectively bind to the cationic Group 8 metal. The enhanced rate and selectivity of this reaction (Scheme 29) as compared with those of their homodinuclear counterparts can be rationalized in terms of the dissymmetry of the heterodinuclear system and has been verified by cyclic voltammetry experiments.

Scheme 27



Scheme 28

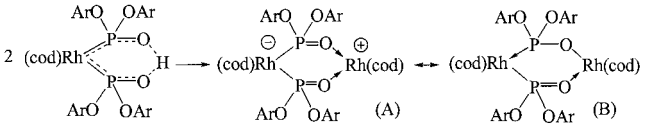
Scheme 29



III.4. Zwitterionic Group 9 Metallates with an Appended Cationic Metal

Twofold C–H activation of the η^4-cyclopentadiene ligand in complexes by the homologous bis(ethylene) complex (Jonas' reagent) leads to dinuclear Co^{I}–Co^{III} complexes (**60**) (Scheme 30). X-ray crystal data ruled out the possibility of a metal–metal bond and the formal assignment of the oxidation states can be interchanged between the two metals by simple "haptomeric resonance". The relative contributions of these limiting structures have been carefully analyzed in terms of the π-acceptor vs. σ-donor character of the ligand L.[96] The C(1)–Co(2) distance is extremely short (average 1.87 Å) while the C(1)–Co(1) distance (average 2.20 Å) is longer than all the other (Cp)C–Co(1) distances (average 2.04 Å). Thus, although the occurrence of a cobaltocenium fragment is expected to be favored, the zwitterionic character is not pure. It nevertheless becomes quite important when L is an acceptor ligand.

Scheme 30

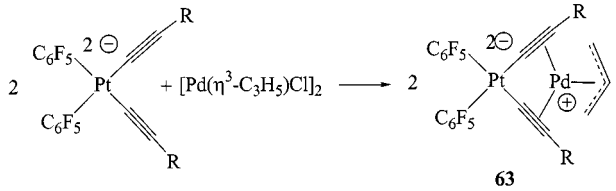


Potentially symmetrically bridged dinuclear complexes can exist as rearranged zwitterionic complexes. Thus, thermal activation of a symmetrical tetraphosphane diacyl dirhodium complex under CO pressure unexpectedly led to the disymmetrical dirhodium complex **61** (Scheme 31).[97] The zwitterionic character of **61** was ascertained by X-ray crystallography, which revealed a tetrahedrally coordinated anionic tricarbonylrhodium center facing a geometrically distorted cationic triphosphane rhodium center without an Rh–Rh bond. A semi-bridging carbonyl ligand accounts for the stability of the zwitterionic structure. This feature also results in an 18-electron count for both rhodium atoms in the $^{-}Rh{\approx}Rh^{+}$ structure without an Rh–Rh bond. The structure is also supported in solution by ν_{CO} IR and ^{31}P-NMR data.

Scheme 31

Dinuclear rhodium complexes can be formulated as zwitterionic on the basis of reactivity arguments. The acidic proton of a phosphito-phosphonato rhodium complex $[Rh^{I}]^{-}[H]^{+}$ can be removed by NaOH, but also by the basic Rh^{I} center of another identical molecule to give an intermediate $[Rh^{I}]^{-}[Rh^{III}H]^{+}$ salt, which reacts further to give the molecular salt $\{[Rh^{I}]^{-}[Rh^{I}]^{+}\}$, **62** (Scheme 32). The latter complex can therefore be regarded as a disymmetrical zwitterionic species, in which two "hard" oxygen atoms of the two equivalent phosphonate ligands point towards the hard cationic Rh atom, while the two "softer" phosphorus atoms point towards the softer anionic Rh atom. However, the

driving force of the reaction relates to the participation of two equivalent non-zwitterionic forms (B).



62

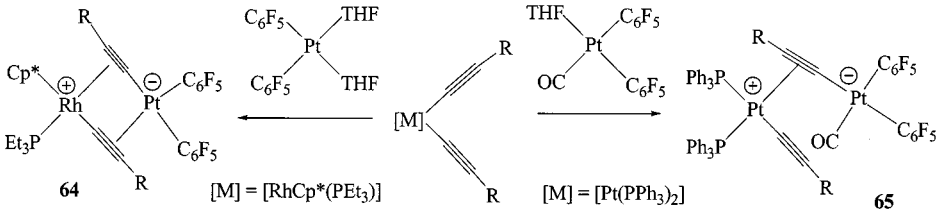
Scheme 32

III.5. Zwitterionic Group 10 Metallates with an Appended Cationic Metal

Cationic π-allyl complexes of palladium and platinum react with dianionic platinate to give stable anionic bimetallic complexes **63** with a 2–/+ charge separation (Scheme 33).[98] X-ray, IR, and NMR analyses indicate that the metals communicate through π-bonds.

63

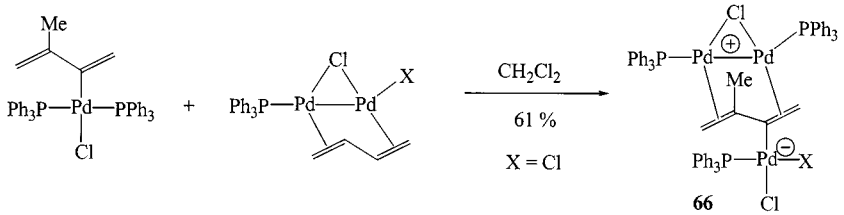
Scheme 33



However, when the reactant is the twofold cationic $[Cp^*Ir(PEt_3)(acetone)_2]^{2+}$ complex, the expected 2–/2+ charge separation is unstable and a non-zwitterionic product results from a migration of the σ-alkynyl ligands to the iridium atom.[99] In contrast, migration of alkynyl ligands from neutral bis(alkynyl)platinum complexes to neutral platinum or rhodium reactants can occur in the presence of suitable ligands, thereby leading to charge separation in complexes **64**[100] and **65** (Scheme 34).[101]

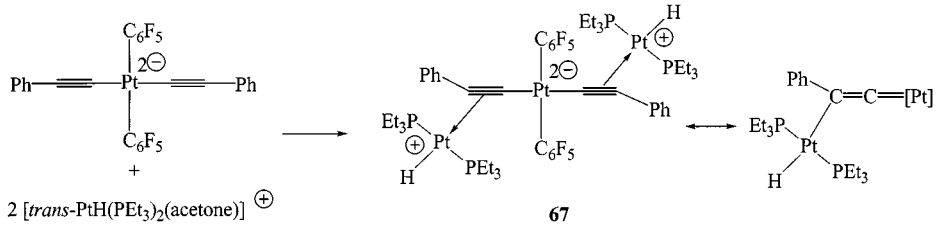
A similar process of migration of a chlorine ligand between two neutral complexes leads to the trimetallic zwitterionic complex **66**, in which the positive charge is delocalized over a dimetallic core (Scheme 35).[102]

A zwitterionic monoanionic platinate complex with a cationic charge delocalized over a trinuclear platinum core has also been reported.[103] Trinuclear zwitterionic metallate complexes with a –2/+1/+1 charge separation on the metals may be prepared from a *trans*-dialkynylplatinate. The latter reacts with two equivalents of the cationic platinum reagent $[trans\text{-}PtH(PEt_3)_2]^+$ to give the neutral zwitterionic trinuclear complex **67**, in which the doubly negative platinate center acts as a bridging unit (Scheme 36). Although low stability in solution prevented characterization by ^{13}C-NMR, the zwitterionic nature could be ascertained from IR and X-ray diffraction data, although a contribution of a "haptomer" vinylidene structure has been suggested.[104]



Conclusion

Besides the relative electronegativity of the formally charged fragments tuned by suitable auxiliary ligands, many complexes claimed to be zwitterionic are in fact stabilized by non-zwitterionic π-electron resonance or by partial hapticity. Although these forms have often been regarded



64 [M] = [RhCp*(PEt$_3$)] [M] = [Pt(PPh$_3$)$_2$] **65**

Scheme 34

66

Scheme 35

67

Scheme 36

as making only minor contributions, they play the role of a stabilizing force equilibrating the electrostatic destabilization due to charge separation. True zwitterionic complexes, in which the opposite charges are separated by two or more sp^3 carbon atoms (as in **28**, **34**, **35**, **39**, **43**, **56**), are less common, and multinuclear anionic cores and hydrogen-type bonding are found to be present as additional sources of stabilization.

The ''zwitterionic metallate'' feature may become a fundamental consideration in the design of mixed valence, push-pull or donor–acceptor complexes, for applications in nonlinear optics, molecular electronics, molecular conductivity, etc. Furthermore, just as zwitterionic cationic metal complexes are bringing new perspectives in catalysis, zwitterionic metallates might play a role in governing the activity or selectivity of catalytic reactions through specifically designed hybrid dative-electrostatic interactions in the coordination spheres of reduced metal centers.[56][57]

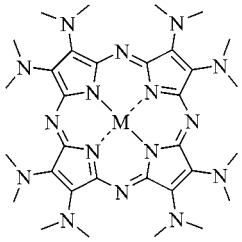
C_i Symmetric and Non-Centrosymmetric Crystalline Complexes of [60]Fullerene with Octakis(dimethylamino)porphyrazinato-Copper(II) and -Nickel(II)

Detlev H. Hochmuth,*[c] Sarah L. J. Michel,[b] Andrew J. P. White,[a] David J. Williams,[a] Anthony G. M. Barrett,*[a] and Brian M. Hoffman*[b]

Keywords: Porphyrazines / Fullerenes



X-ray structural analysis of octakis(dimethylamino)porphyrazinato-metallo(II)·[60]fullerene complexes (M = Cu^{2+} and Ni^{2+}) surprisingly revealed two totally different supramolecular structures, the first exhibiting a C_i symmetric sandwich complex of two slightly dished porphyrazine units enclosing one fullerene sphere, the other featuring a noncentrosymmetric 1:1 complex with a strongly warped porphyrazine unit.

Introduction

In continuation of our previous studies[1] on charge-transfer complexes of porphyrazines we herein report on the syntheses and structures of two donor-acceptor crystals formed from [60]fullerene and metallated porphyrazines. These complexes are considered possible precursors for much sought-after three-dimensional molecular magnets[2] and possible structures with superconducting properties. For structurally related complexes see those of fullerenes with metallated octaethylporphyrines.[3,4]

Results and Discussion

The syntheses of octakis(dimethylamino)porphyrazinato-metallo(II) (Scheme 1, M-Pz, with M = Ni^{2+}, Cu^{2+}, $2H^+$) and of the $(2H\text{-}Pz)_2\text{-}C_{60}$ complex have been reported previously.[5] The complexes were synthesised by incubation of fullerene and excess of porphyrazine (M-Pz) under an argon atmosphere and subsequent isolation and purification by repeated extraction-evaporation-dissolution cycles. Slow evaporation of the benzene or toluene solution afforded nonconducting black needles which were subsequently handled in air.

Scheme 1. Oktakis(dimethylaminoporphyrazinato)-metal(II), the porphyrazine unit of the fullerene complexes **1**, **2**, and **3**; (M = Ni, Cu, 2H).

$(CuPz)_2\text{-}C_{60}$ (1)

The X-ray analysis of **1** (see Experimental Section) revealed the formation of a C_i symmetric 2:1 Cu(Pz):C_{60} complex (Figure 1) which at the molecular level is very similar to that formed between 2H-Pz and C_{60} (**3**), though in the latter the symmetry is C_2 and crystallisation occurred in a noncentrosymmetric space group. Here in **1**, each C_{60} molecule is sandwiched between pairs of dished Cu(Pz) units (Figure 1), the copper atom lying 0.06 Å out of the N_4 coordination plane, and 0.18 and 0.48 Å out of the planes of the four "pyrrole-linking" *meso*-N-atoms, and the eight peripheral dimethylamino N-atoms, respectively. The distance from the centroid of the C_{60} molecule to the N_4 coor-

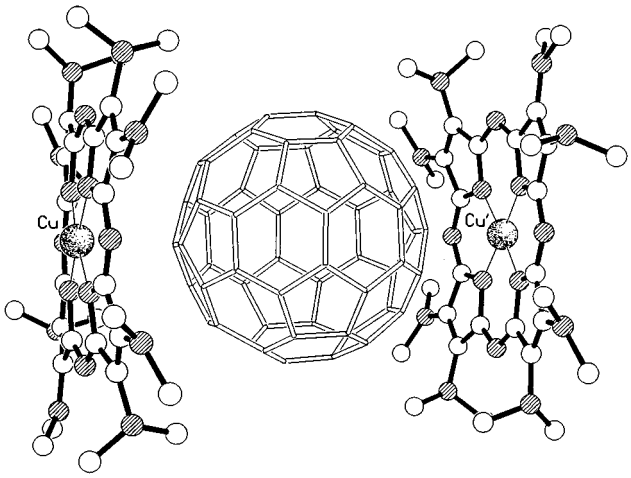

Figure 1. The 2:1 complex **1** formed between Cu(Pz) and C_{60}. The Cu–N distances are in the range 1.939(4) to 1.945(4) Å.

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 2000 1434–1948/00/0404–0593 $ 17.50+.50/0

dination planes is 6.32 Å, (this parameter, and others given in this communication, refer to the low temperature structural determinations) a value identical to that observed in **3**. The copper atom lies 0.18 and 0.48 Å out of the planes of the four ''pyrrole-linking'' N-atoms, and the eight peripheral dimethylamino N-atoms, respectively. A feature of particular interest is a short approach of 2.89 Å between the copper and one of the C_{60} carbon atoms, the carbon being positioned almost directly above the centre of the copper coordination plane. Although, as in **3**, the crystals contain aromatic solvent molecules (S) positioned between C_{60} units, the overall supramolecular structure is distinctly different. The pattern of -Pz-C_{60}-Pz-Pz-C_{60}-Pz- and -C_{60}-S-C_{60}-S- sandwiches is retained (Figure 2), but in the third direction (into the plane of the paper in Figure 2) adjacent sheets are offset so that the linear -C_{60}-C_{60}-C_{60}- sequence seen (Figure 3) running horizontally in **3** is no longer present. The shortest inter-sheet $C_{60}\cdots C_{60}$ separation is 13.9 Å.

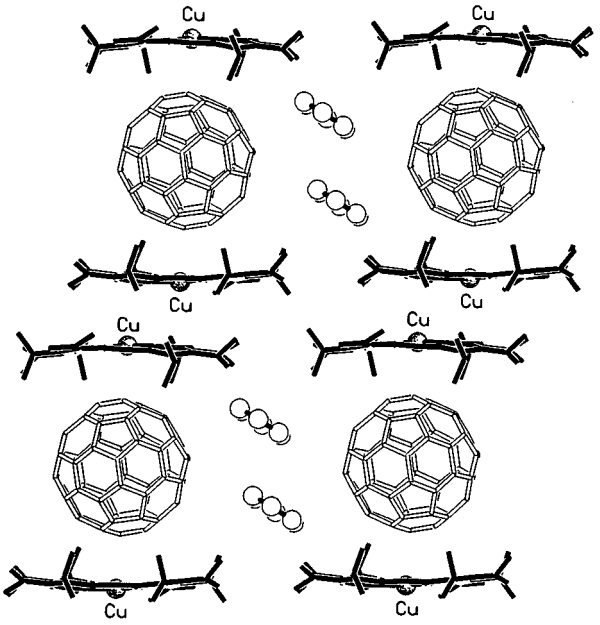

Figure 2. Part of one of the 2D sheets of C_{60}, Cu(Pz) and benzene solvent molecules in the structure of **1**. The back-to-back Cu···Cu separation is 4.67 Å, the lateral displacement being 3.31 Å. The interplanar separation between the Cu(Pz) units is ca. 3.4 Å. The lateral $C_{60}\cdots C_{60}$ distance is 15.1 Å.

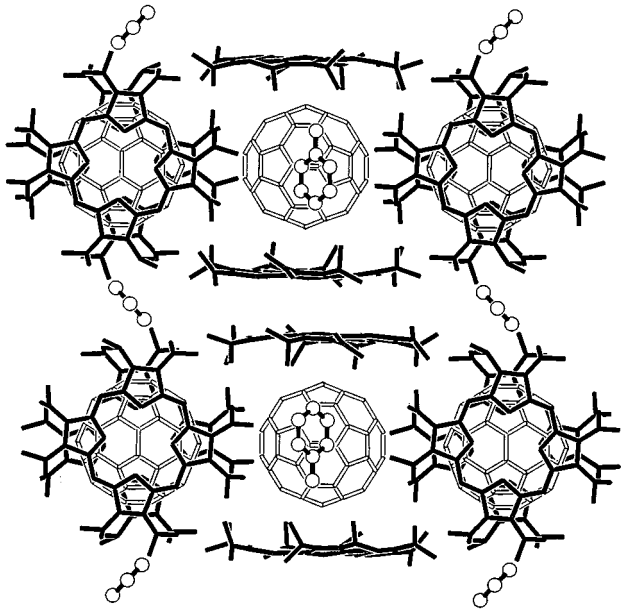

Figure 3. Part of the 3D network of Pz, C_{60} and toluene (S) molecules present in the structure of **3**. The centroids of the back-to-back Pz molecules are laterally displaced by 1.14 Å. The horizontal $C_{60}\cdots C_{60}$ centroid···centroid separation is 10.5 Å and the vertical and out of the plane $C_{60}\cdots S\cdots C_{60}$ distances are 15.9 Å.

NiPz-C_{60} (2)

Crystals of the complex formed between Ni(Pz) and C_{60} (**2**) (for crystal data see in the Experimental Section) were found to have a 1:1 stoichiometry and a totally different supramolecular structure. The Ni(Pz) unit has a distinctly warped conformation with the plane of diametrically opposite pyrrole rings being rotated by ca. 30° with respect to each other about their N···N vectors; the nickel and the four coordinated nitrogen atoms are coplanar to within 0.006 Å. In this complex each C_{60} unit lies within a cleft formed by

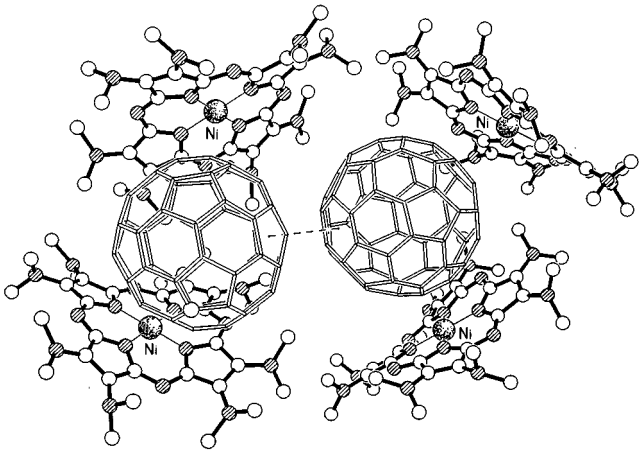

Figure 4. The partial encapsulation of a pair of π-stacked C_{60} units in the 1:1 Ni(Pz):C_{60} complex **2**. The Ni–N distances are in the range 1.859(4) to 1.870(4) Å. The N_4 plane···C_{60} centroid distances are 6.31 and 6.40 Å, and the $C_{60}\cdots C_{60}$ centroid···centroid separation is 9.95 Å.

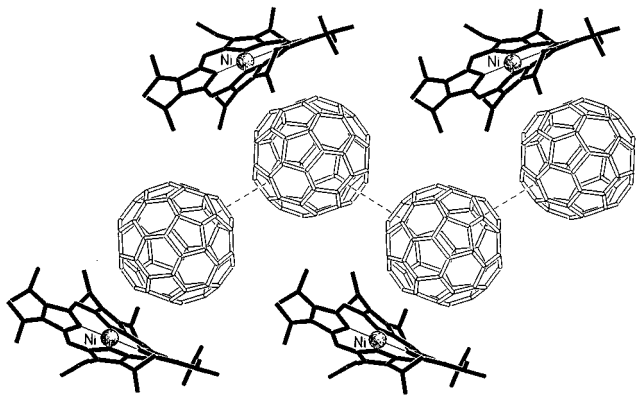

Figure 5. Part of one of the continuous zigzag chains of π-stacked, 2_1 screw related, C_{60} units in the structure of **2**. The $C_{60}\cdots C_{60}$ face-to-face and centroid···centroid separations are 3.39 and 9.95 Å respectively.

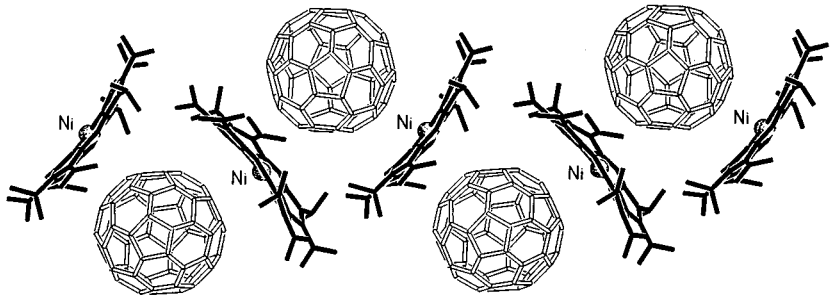

Figure 6. Part of one of the -C_{60}-Pz-C_{60}-Pz- zigzag chains in the structure of **2**.

two steeply inclined (by ca. 72°) Ni(Pz) molecules (Figure 4), the shortest Ni···C(C_{60}) distances being 3.29 and 3.64 Å. Two supramolecular features predominate; i) the formation in one direction of continuous zigzag chains of π-stacked, 2_1 screw related, C_{60} units (Figure 5) with a C_5···C_6 ring centroid···ring centroid separation of 3.39 Å, and ii) the formation in another direction of continuous -C_{60}-Pz-C_{60}-Pz- zigzag sandwiches (Figure 6). Perhaps the most important feature of interest of this 1:1 complex **2** is that, like **3**, crystallisation occurs in a noncentrosymmetric space group, thereby offering the potential for the complex to exhibit nonlinear optical properties.

Electron Paramagnetic Resonance

The electron paramagnetic resonance spectra at 77 K of the solid compound (**1**), and of the parent Cu(Pz) in dichloromethane solution are shown in Figure 7. The spectrum of this parent porphyrazine is characteristic of a monomeric square-planar Cu^{II} complex with axial g tensor ($g_\parallel = 2.15$, $g_\perp = 2.05$) and with ^{63,65}Cu hyperfine coupling of $A_\parallel = 210$ G.[6,7] Further hyperfine splittings from the four equivalent ligating ^{14}N are also resolvable both at $g_\parallel$ and $g_\perp$. The spectrum of **1** (Figure 7, inset) is characteristic of a binuclear triplet state ($S = 1$) species,[8,9] associated with the "back-to-back" Cu(Pz) pairs. The separation of the center fields of the two most intense peaks corresponding to $g_\perp$ in Figure 7 is 414 G and corresponds to $D_\perp$, the standard zero-field splitting parameter. Copper hyperfine splitting ($A_\parallel/2$) for the porphyrazine pairs is resolved for $g_\parallel$ as a seven-line pattern with a splitting half that for the porphyrazine monomer, which indicates that exchange coupling is larger than the Larmor energy. The expected "$\Delta M = 2$" transition at half field also is observed (not shown). If the system is treated with the point dipole model,[10,11] the Cu–Cu distances may be estimated as $R = (0.650 g_\perp^2/D_\perp\ [\mathrm{cm}^{-1}])^{1/3}$. The measured $D_\perp$ for the Cu(Pz)–C_{60} (**1**) complex gives $R =$ 4.3 Å. This approximates the crystal X-ray data of 4.78, the deviation likely arises from other contributions to $D_\perp$.[2]

Magnetic Properties

To determine the exchange coupling within the Cu "back to back" porphyrazine pairs, the molar magnetic susceptibility, χ_m, for **1** was measured over the temperature range of 2–300 K. Figure 8 plots $\chi_m T$ versus T with a plot of χ_m versus T as the inset. The value $\chi_m T = 0.71$–0.73 emu mol^{-1} K observed between 300 K and 10 K is expected from the Curie law for two uncoupled Cu porphyrazine pairs per mol of **1** (S = 1/2). The rapid decrease in $\chi_m T$ at temperatures below 10 K reflects antiferromagnetic coupling within the dimer. A least squares fit of the data

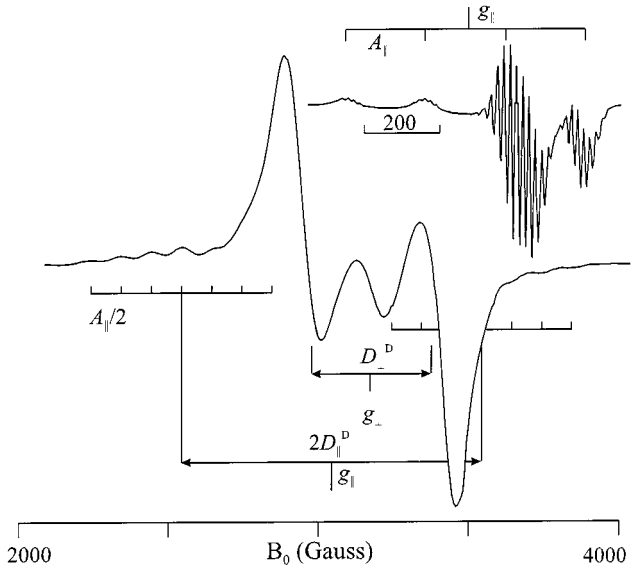

Figure 7. Electron paramagnetic resonance spectra of **1** and Cu(Pz).

to the Van Vleck Equation [$\chi_m T = [(2Ng^2\beta^2/3k)(3e^{-Jk/T}/(1+3e^{-J/kT})]$ for the thermally excited triplet state gave an exchange coupling of $J = 1.61$ cm^{-1}, such a small value being expected from the noncovalent nature of the intradimer interaction.

Conclusion

Two new octakis(dimethylaminoporphyrazinato)metal(II) fullerene complexes have been synthesised, their interesting different supramolecular structures have been investigated by X-ray crystallography, and the electromagnetic properties of the copper derivative have been characterised by EPR and SQUID measurements. Further investigations on the potential of the nonlinear optical properties of the nickel(porphyrazine) fullerene complex are being carried out.

Experimental Section

A toluene solution of three equivalents of M-Pz and one equivalent of [60]fullerene was incubated under argon in a sealed tube for 24 h at 130 °C. After evaporation of toluene the excess of M-Pz was washed out with pentane and the complex subsequently extracted with small amounts of benzene. After evaporation, the pentane-benzene extraction cycle was repeated three times. Slow evaporation of the benzene or toluene solution, respectively, afforded non-conducting black needles which were subsequently handled in air.

How to Predict Activation Barriers − Conformational Transformations of Compounds $CH_3C(CH_2PPh_2)_{3-n}[CH_2P(oTol)_2]_nMo(CO)_3$ (n = 1−3): Force Field Calculations versus NMR Data

Stefan Beyreuther,[a] Axel Frick,[a] Johannes Hunger,[a] Gottfried Huttner,*[a] Björn Antelmann,[a] Peter Schober,[a] and Rainer Soltek[a]

Dedicated to Prof. Wolf-Peter Fehlhammer on the occasion of his 60th birthday

Keywords: *Tripod* molybdenum tricarbonyl compounds / Conformational analysis in solution / Dynamic NMR / Force field calculations / Activation barriers

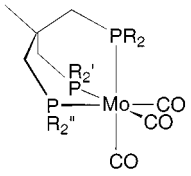
Tripod metal entities *tripod*M are sterically congested systems. The conformations adopted by compounds $CH_3C(CH_2PPh_2)_{3-n}[CH_2P(oTol)_2]_nMo(CO)_3$ (n = 1: **1**, n = 2: **2**, n = 3: **3**) will thus be largely determined by the repulsive forces acting in these molecules. The steric demand of the *o*-tolyl groups impedes their free rotation and enantiomerization processes referring to the compounds as a whole are sufficiently slow to permit their analysis by NMR techniques. Through a combination of line-shape analysis, EXSY methods, and coalescence experiments, the $\Delta G^{\ddagger}$ values for these conformational enantiomerization processes have been determined as $\Delta G^{\ddagger}_{298K}$ = 54.3, 57.9, 65.5 kJ·mol^{-1} for compounds **1**, **2**, and **3**, respectively. By an exhaustive search on a force field generated hypersurface, activation energies of 53, 57 and 69 kJ·mol^{-1} have been calculated. Thus, the force field approach correctly reproduces the dependence of the activation energy on the degree of *o*-tolyl substitution. Moreover, the force field simulation also gives an insight into the individual microsteps of the enantiomerization pathways.

Introduction

In any attempt to understand the reactivity of molecules, the shape of the reactants will play an important role. Thus, as far as we know, the reactivity as well as the outstanding selectivity of biological catalysts can, to a large extent, be attributed to the specific shape of the pocket in which the reactive center is embedded. Given appropriate electronic conditions for bond making and bond breaking in a specific catalyst system, the surrounding of the reactive center determines whether or not a substrate will be transformed through its secondary interactions with the latter. In the study of coordination compounds with potential catalytic applications, the electronic situation may nowadays be understood in part by quantum mechanical methods.[1][2]

The secondary interactions, which govern the specific shape of the catalyst as well as of the reactive entity formed upon approach of the substrate at the active site, are not so easy to handle by quantum chemical methods, one problem still being the size of the aggregate formed by a real catalyst and a real substrate. As far as those secondary interactions that are usually referred to as "steric" are concerned, force field methods appear to offer a solution to this problem.[3−7]

There remains a problem, however, when these methods are applied to coordination compounds. Reliable parameters for modelling the interactions involving the metal are generally not available and the only way to obtain an appropriate set of parameters is to gather as much experimental information as possible. If it is desired to develop a force field approach for a specific family of compounds, the structures of the members of this family constitute a valuable piece of information, not only because this information is quite detailed but also because in most cases it is easy to obtain and amply available. It has been shown how this type of information may be systematically analyzed and how, by the application of a combination of statistical tools, including pattern recognition by neural networks, it may be shown for a given family of compounds that, even though the structures have been determined in the solid state, the conformations are almost exclusively determined by the inner molecular potential.[8][9] It has also been shown how this information relating to the molecular potential, intrinsically embedded in these structures, may be extracted in an unbiased way by the use of Genetic Algorithms.[10][11] It has been found that in the specific case of *tripod* metal templates [*tripod* = $RCH_2C(CH_2X)(CH_2Y)(CH_2Z)$; X, Y, Z = $PR'R''$] this two-step process − systematic analysis of the structural database and algorithmic extraction of force field parameters therefrom − makes the force field approach a reliable means of prediction as far as stationary structures are concerned.



It has also been found that the properties of a conformational ensemble, as present for a specific *tripod* metal compound in solution, are adequately reproduced by such a force field approach, in so far as observed NOE distances

compare favorably with the values predicted on the basis of the force field model.[12] In order to predict NOE distances, a Boltzmann weighted sum has to be taken over all possible conformations and the fact that the observed distances are well reproduced by these model calculations would appear to be supportive of the notion that the relative energies as calculated by the model should be somehow on scale with the experimental reality. NOE measurements thus provide a further valuable piece of information in validating a force field approach.[12]

Experimental data more directly related to the relative energies would provide yet further information. If it were possible to measure the height of the barrier associated with transmutation of a pair of conformers of a given molecule into one another, this barrier height could be compared with the corresponding value calculated by the force field approach.

Figure 1. Compounds **1**−**3**

This approach is taken in this paper: It is found that the three molecules $CH_3C(CH_2PPh_2)_{3-n}[CH_2P(oTol)_2]_nMo(CO)_3$, $n = 1$: **1**, $n = 2$: **2**, $n = 3$: **3** (Figure 1) exist in the form of two necessarily isoenergetic conformational enantiomers in solution. These conformers transform into each other by a process that is sufficiently slow to be energetically analyzed by NMR techniques and hence the activation barriers for this process are known for all three compounds. A force field approach, as developed previously,[10,11,12] is used to model these transformations and a highly satisfying agreement between the observed and the calculated energies is found.

Results and Discussion

NMR Analysis

Compounds **1**−**3** (Figures 2, 3, 4) were synthesized by procedures akin to those well-established for the preparation of compounds of this type (see Experimental Section).

Single crystals of sufficient quality could not be obtained for **1** and **2**, so that only the structure of **3** could be determined by X-ray crystallography.[10] NMR data for the compounds were obtained from solutions (**1**, **2**: CD_2Cl_2; **3**: $CDCl_3$) in sealed NMR tubes under argon. An almost complete assignment of all the protons and carbon atoms was achieved by a combination of one- and two-dimensional NMR techniques including DQF-COSY,[13] TOCSY,[14] NOESY,[15] HSQC,[16] and HMBC[17] experiments (Figure 20 and Tables 13 and 14) show the assignment of the

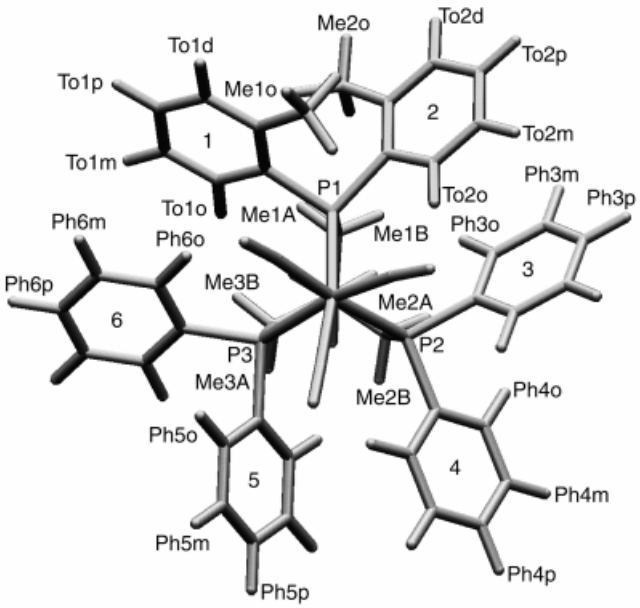

Figure 2. Projection of **1** onto the plane defined by its 3 P atoms; the numbering scheme given here is used throughout in the text

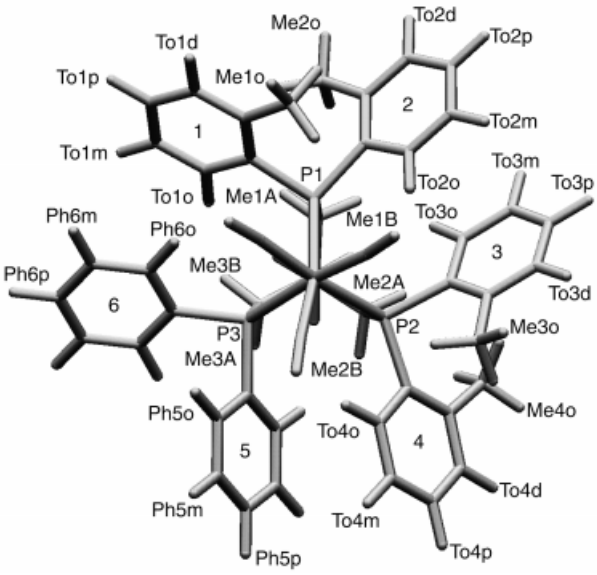

Figure 3. View of the structure of **2** in a projection onto the plane defined by the 3 P atoms; the numbering scheme given here is used throughout the text and tables

^1H and ^{13}C resonances as well as the NOESY, EXSY, and HMBC cross-peaks; see Experimental Section).

It is observed that the phenotype of the spectra changes with temperature. This is exemplified in Figure 5 by focussing on the phosphorus signals of **1** at a few selected temperatures.

At 313 K, only one triplet and one doublet are observed, in accord with the presence of one $P(oTol)_2$ group and two PPh_2 groups. At lower temperatures (Figure 5), a more complicated pattern evolves with the triplet transforming into a doublet of doublets and the doublet splitting into

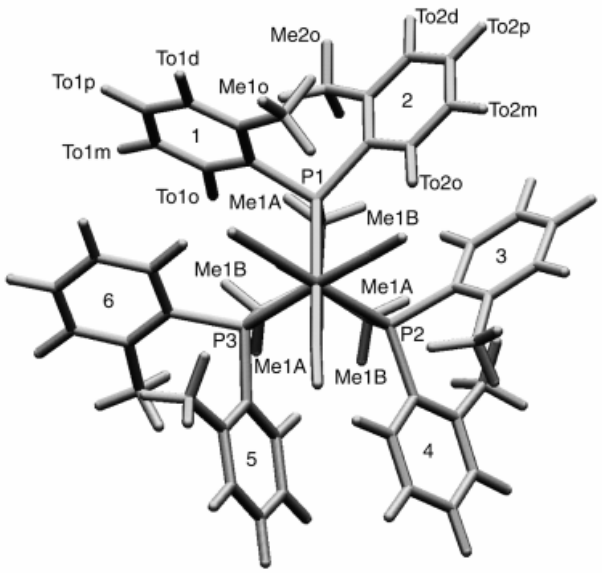

Figure 4. The structure of **3** as projected onto the plane of its 3 P atoms; according to the constitutional C_3 symmetry of the compound, only a subset of atom designators is given; designators for the symmetrically dependent atoms are defined through appropriate reference to the numbers assigned to the phosphorus atoms and the aryl rings as shown in this figure; this numbering scheme is used throughout in the text and tables

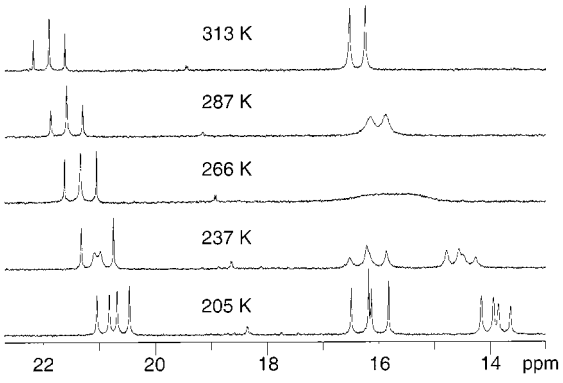

Figure 5. Temperature dependence of the $^{31}P\{^1H\}$-NMR spectrum of **1**; of the 21 spectra collected over the temperature range between 166 K and 313 K, only a few salient examples are shown in the figure; measuring frequency: 81.014 MHz

two such doublet of doublets patterns (Figure 5). The low-temperature spectrum is in accord with a structure of **1** where chiral differentiation between the two PPh_2 groups is static on the NMR time scale. With the shifts and coupling constants given for this type of structure in the legend of Figure 6, the spectrum at the low-temperature limit is correctly reproduced.

The NMR data thus show that there is only one compound present in solution at low temperatures. There remains, however, the possibility that this compound exists as a racemic mixture of two enantiomeric forms.

The ^{1}H-NMR spectra behave accordingly (Figure 7). While the methylene protons, for instance, give rise to a broad unresolved signal at around $\delta = 2.4$ at 293 K, this signal coalesces on cooling and reappears in the form of a

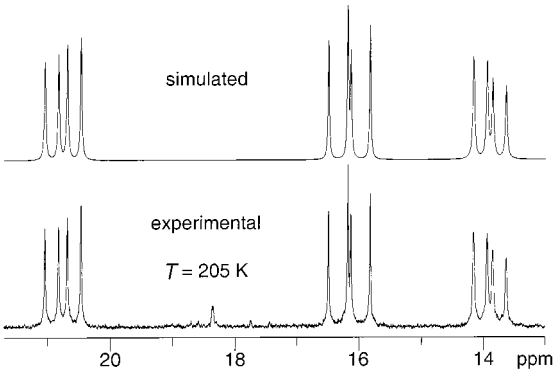

Figure 6. Experimental and simulated $^{31}P\{^1H\}$-NMR spectra of **1** at the low-temperature limit; experimental (bottom) and simulated (top) $^{31}P\{^1H\}$-NMR spectra of **1** at 205 K; $\delta(P1) = 20.75$, $\delta(P2) = 13.91$, $\delta(P3) = 16.15$, $^2J_{P1P2} = 17.8$ Hz, $^2J_{P1P3} = 29.0$ Hz, $^2J_{P2P3} = 25.0$ Hz

complicated multiplet between $\delta = 1.8$ and 2.8. Upon ^{31}P decoupling, this simplifies to a pattern with a minimum of 12 well-resolved lines (Figure 7).

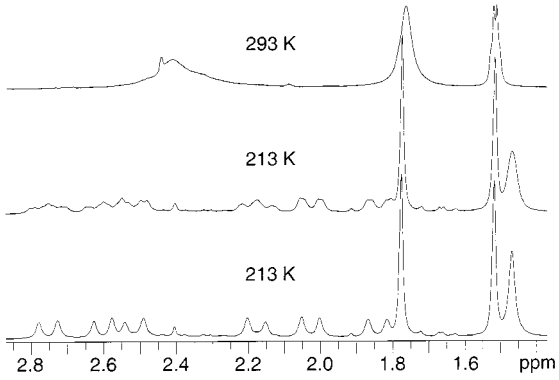

Figure 7. Temperature dependence of the aliphatic region of the ^{1}H-NMR spectrum of **1**; of the 21 spectra collected over the temperature range between 166 K and 313 K, only 3 are shown in the figure; measuring frequency: 300.13 MHz; ^{1}H-NMR spectrum of **1** at 293 K (top), 213 K (middle), and $^1H\{^{31}P\}$-NMR spectrum at 213 K (bottom)

The signal due to the *o*-tolylic methyl groups (Me1o, Me2o, Figure 2) appears as a singlet at around $\delta = 1.8$ at 293 K, which after coalescence is seen as two well-separated sharp singlets at 213 K (Figure 7; from the temperature dependence of these shifts, the center of these two lines can be placed at around $\delta = 1.65$ at 213 K). From this last finding, together with the aforementioned findings from the ^{31}P-NMR data, it is clear that the two methyl groups are in a chemically different environment in the low-temperature structure. Analogous observations have also been made for compounds **2** and **3**, with the different constitutional symmetries of the compounds leading to different appearances of the spectra, although clearly corresponding to the same phenomena. For instance, due to the constitutional equivalence of all three of its $P(o\text{Tol})_2$ groups the ^{31}P-NMR spectrum of **3** shows only one ^{31}P-NMR signal over the entire temperature range. On the other hand, the *o*-tolylic methyl groups as well as the methylene protons of **3** give rise to the

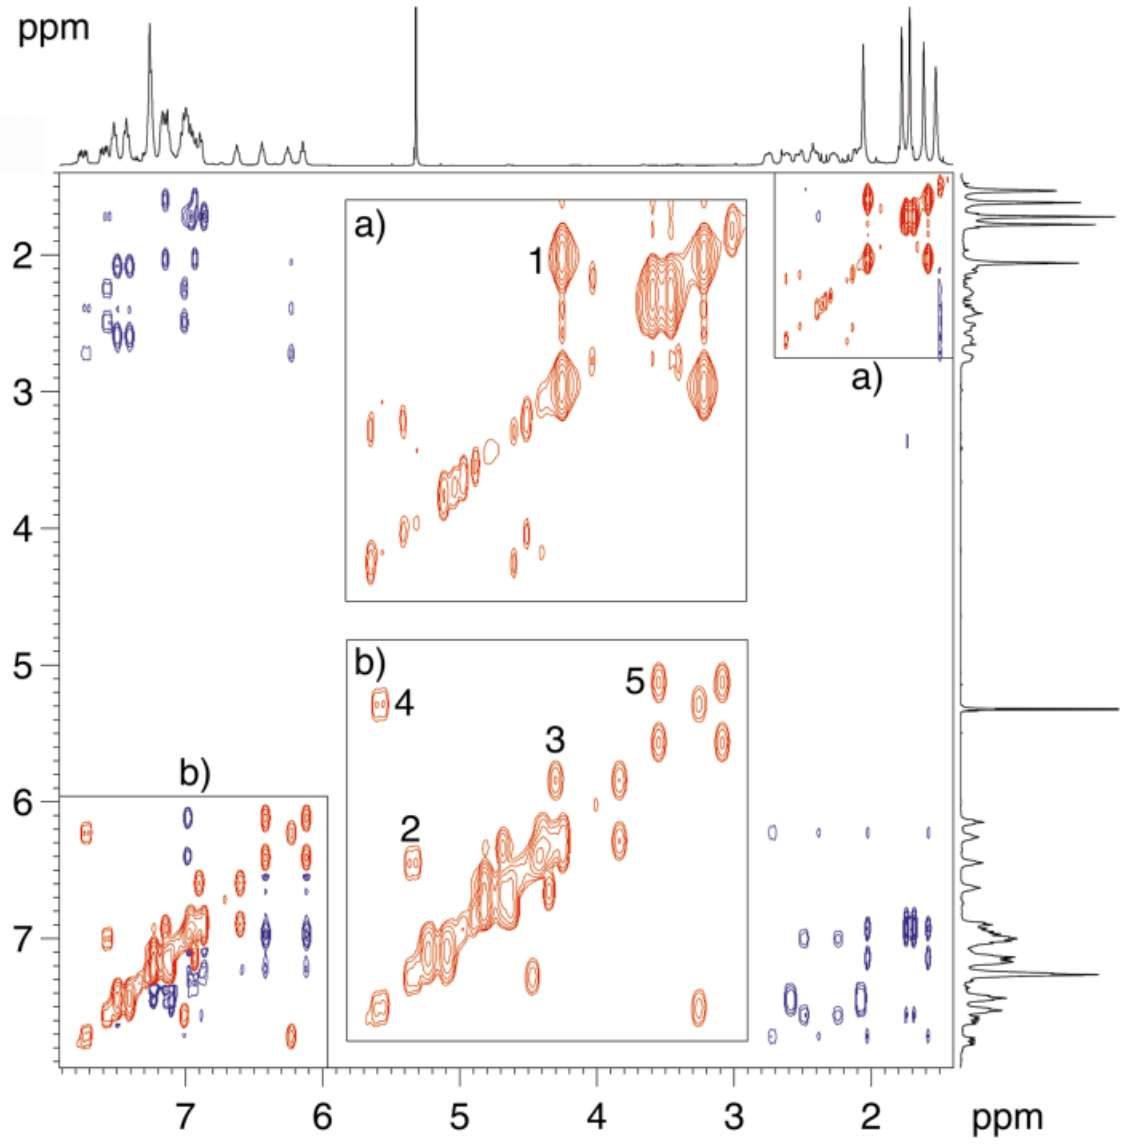

Figure 8. NOESY/EXSY spectrum of **2** at 246 K with a mixing time of 700 ms; measuring frequency: 500.13 MHz; NOESY peaks in blue, EXSY and autocorrelation peaks in red; EXSY peaks are apparent in the methyl, methylene, and arene regions; the EXSY parts of the spectrum between ca. $\delta = 1.5-2.8$ (a) and $\delta = 6.0-8.0$ (b) are shown as enlarged insets; the numbers in these insets refer to the following exchange polarization transfers: 1: Me1o−Me4o, 2: To4o−To1o, 3: To1m−To4m, 4: To2o−To3o, 5: To3m−To2m; designators are as given in Figure 3

same sequence of patterns as seen in the ^{1}H-NMR spectrum of **1**.

If the spectra of **1**−**3** are analyzed for cross-peaks due to dynamic exchange (EXSY) it is observed that the same type of exchange phenomena is present in all cases. This is exemplified by the case of **2** in Figure 8.

The EXSY cross-peaks observed for compounds **1**−**3** are given in Figure 20 and Tables 13 and 14 (see Experimental Section). It can be seen that the *o*-tolyl substituents of each P(*o*Tol)$_2$ group are involved in a mutual exchange. The protons of the CH_2 groups of the backbone of the chelate cage are likewise in a dynamic exchange.

The findings reported thus far show that in each case only one constitutional isomer is present. The observed exchange phenomena must therefore be due to a dynamic exchange between two conformational isomers such that in compound **3**, for instance, Me2o and Me1o as well as Me1A and Me1B etc. (Figures 4, 20) are interchanged in the two different conformeric forms. The most plausible process to account for these observations is a conformational racemization of the compounds, where the torsional arrangement of the aryl groups and the torsion of the chelate cage switch between the image and the mirror image. Figure 9 illustrates this kind of process for the compounds **1**−**3**.

The energy associated with this enantiomerization process has been deduced from relevant NMR observations by three different approaches: (i) Measurement of the coalescence temperature at different field strengths. (ii) Line-shape analysis at different temperatures and field strengths. (iii)

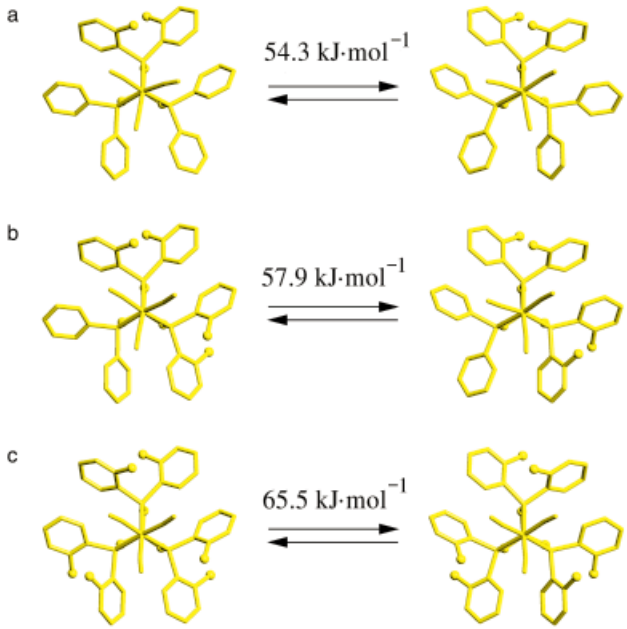

Figure 9. Inversion processes for compounds **1** (a), **2** (b), and **3** (c) and the corresponding experimental $\Delta G^{\neq}_{298K}$ values

Quantification of EXSY data at different temperatures and field strengths. Coalescence experiments have been performed for all three compounds **1**−**3**. Using the phosphorus nuclei as a probe, only **1** and **2** can be analyzed since only one ^{31}P signal is seen for **3** (see Table 12 in the Experimental Section). It is possible, however, to use the ^{1}H signal of the methyl groups of the *o*-tolyl substituents as the analytical tool for all three compounds (**1**−**3**) (Table 1).

Using the methyl protons as the probe, coalescence experiments were performed at various field strengths (Table 1), yielding closely similar results in terms of $\Delta G^{\neq}$ for all the independent experiments in each case (Table 1).

Line-shape analysis[18] of the ^{31}P-NMR data could only be performed for **1** and **2** for the reasons indicated above. As already evident from the case of compound **1** (Figure 5), the shifts are found to be strongly temperature dependent. In order to correct for this temperature dependence, a linear interpolation was used,[19] as is the usual practice. Only very minor additional corrections were found to be necessary for correcting the shift values during refinement.

The quality of fit obtained by the simulation procedure is shown in the insets of Figure 10 for compound **2** at two selected temperatures. The rate constants determined by this procedure should produce a linear plot in an $\ln(k/T)$ vs. $1/T$ diagram (Figure 10), with the slope of the line indicating $\Delta H^{\neq}$ and the abscissa value at $(1/T) = 0$ indicating the activation entropy $\Delta S^{\neq}$.[20] The $\Delta G^{\neq}$ values at 298 K were evaluated as 54.3 kJ·mol^{-1} for **1** ($\Delta H^{\neq}$ = 45.3 kJ·mol^{-1}, $\Delta S^{\neq}$ = −30 J·K^{-1}·mol^{-1}) and 57.9 kJ·mol^{-1} for **2** ($\Delta H^{\neq}$ = 51.8 kJ·mol^{-1}, $\Delta S^{\neq}$ = −20 J·K^{-1}·mol^{-1}) (Table 1).

EXSY spectroscopy constitutes yet another appropriate tool. The exchange phenomena observed pertain to the so-called "equally populated two-site exchange" case, which lends itself to a straightforward analysis by EXSY[15] methods if groups of signals are found which are related to each other solely by exchange and not by coupling.[21] The methyl signals of the *o*-tolyl groups give rise to such sets of signals, so that activation energies can also be derived from EXSY experiments.

If instead of the methyl signals Me1o−Me4o (1, Figure 8) the clearly resolved pairs of signals in the aromatic region e.g. To2m−To3m are used as a probe (5, Figure 8; signals labelled 2, 3, 4 in Figure 8 could also be used), the values

calculated for the activation barriers remain unchanged as expected.

The activation barriers associated with the conformational enantiomerization of compounds **1**, **2**, **3** are found to increase in the sequence $\Delta H^{\neq} \approx 45,\ 52,\ 59\ kJ{\cdot}mol^{-1}$ (Table 1). On increasing the number of *o*-tolyl groups, the steric congestion increases, making the isomerization process more energy consuming. The activation entropies are found to be negative throughout (**1**: −30; **2**: −20; **3**: −21 $J{\cdot}K^{-1}{\cdot}mol^{-1}$; Table 1). Even though the determination of these activation entropies is based on an extrapolation to $1/T = 0$ in the Eyring diagrams and, owing to the long distance over which this extrapolation has to be taken, is subject to considerable uncertainty, the quality of the data collected suffices to show that the activation entropies are definitely negative. This indicates that the transition state conformations will be even more sterically congested than the ground state conformations. It definitely precludes the hypothesis that the conformational racemization process might occur through decoordination of one of the "legs" of the *tripod* ligand. If this hypothesis were to apply, positive activation entropies would necessarily be observed.

Force Field Model

The force field used to describe compounds **1**−**3** has been derived by global optimization of the relevant force field parameters on the basis of the molecular structures of ten different compounds *tripod*$Mo(CO)_3$ [*tripod* = $RCH_2C(CH_2X)(CH_2Y)(CH_2Z)$; X, Y, Z = PR′R″].[10][11] It has been shown that the conformations adopted by these molecules in the solid state are equilibrium conformations, which are not disturbed to any great extent by the crystal forces.[8][9] In order to derive the relevant force field parameters, those parameters involving contributions from the metal were varied such as to reproduce the observed conformations as local minima on the corresponding energy hypersurfaces. Scaling of the energy was implicitly achieved by using standard MM2* values for all those parameters to which the metal makes no direct contribution. It was not obvious from the outset whether or not the energy scale implicitly defined by the force field parameters would also be appropriate for making energy-based predictions. However, an indication that this is approximately so was provided by the observation that NOE distances are correctly predicted by using the force field generated energies in the exponential terms of a Boltzmann weighting scheme.[12] More direct evidence would be obtained if it were possible to calculate the activation barriers associated with the enantiomerization processes of **1**−**3** and if these values were then found to be close to those observed experimentally in each case.

The experimentally determined activation energies for the conformational racemization processes of compounds **1**−**3** do, in fact, allow a comparison of the energy scale intrinsic to the force field approach with the real world. To this end, a complete reconstruction of the molecular hypersurface by the force field is necessary in order to delineate the least-energy pathway and to finally calculate the activation barrier predicted by this model. Whereas the equilibrium struc-

ture of **3** is more reliable since it has been established by X-ray analysis,[10] the least-energy conformations of **1** and **2** have to be inferred from the force field calculations themselves. This does not, however, appear to be a serious drawback since the structure of **3** as determined by X-ray methods is well reproduced by the force field approach, even as the global minimum on the hypersurface,[10] and since other structures have been predicted with high accuracy by the force field approach taken here.[10] The minimum energy conformations calculated for **1** and **2** are shown in Figures 2 and 3, respectively.

Analysis of 3

With regard to the search for a global minimum on the hypersurface relating to **3**, a complete conformational search has already been carried out, the details of which have been described.[10] It was found that from a starting set of 1376 symmetrically independent conformers, only 262 survived as local minima after refinement based on the *mm2f* parameter set.[10] The conformational space used for the grid search was defined by the six rotations of the aryl groups about their respective P−C_{ipso} bonds.

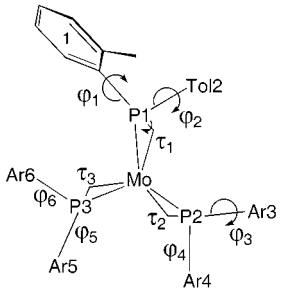

Figure 11. Definition of the six aryl rotations $\varphi_1-\varphi_6$ and the three cage torsions $\tau_1-\tau_3$ used to define the conformational space of compounds **1**−**3**; for the definition of $\varphi = 0°$ see Figure 14; $\tau = 0°$ means that the carbon atom of the bridging CH_2 group would be obscured by the Mo−P line in the diagram

The definition of these rotations denoted as φ is as shown in Figure 11 and is in accord with the definition used previously.[10] The technique used to set these rotations at the values defined by the grid points has also been described previously.[10] The torsion of the chelate cage as described by τ,[8] defined as indicated in Figure 11, was set at a uniform starting value of 20° for all three "legs" of the ligand and it was found that the strain imposed on it by the forced rotation of the aryl groups is sufficiently strong to produce negative as well as positive torsions after refinement.

The energies of the local minima obtained after refinement are distributed as shown in Figure 12a. There are only a few low-energy conformations in the energy band of 20−30 kJ·mol^{-1} above the global minimum. The three conformations with the lowest energy are qualitatively identical (the arrangement of the heavy atoms is designated as 3.1 in Figure 13); the main difference between them stems from a slightly different orientation of the methyl groups of the *o*-tolyl moieties and the energy difference between these almost identical conformers is correspondingly small.

The conformation at position four on the energy scale is already more than 10 kJ·mol^{-1} above the global minimum, with a geometry as shown in Figure 13 (designated as 3.2). This result is well in accord with the observation that in the solid state **3** adopts a conformation corresponding to the global minimum.[10]

The spread of the φ and τ values characterizing the conformations of the different energy minima has been analyzed in a global way. Cumulating all six independent φ values to obtain just one average representative as well as averaging the three individual τ values found for each conformer through the minimization process to a mean value of this torsion, the distributions shown in Figure 12b/c are obtained. There are clear preferences at around 40° and 140° for the rotational positions of the aryl groups and, of course, by the very symmetry of the problem, at around −40° and −140° (Figure 12b). The spread of the τ values is more uniform with a slight preference for torsions of around 0° and ±30° (Figure 12c). If the rotational positions of the aryl groups are analyzed individually, pronounced regularities are observed.[22]

The distinct types of mutual orientation at each specific P(*o*Tol)$_2$ group have been systematically labelled using the scheme shown in Figure 13. To describe the aforementioned regularities, the orientations are classified according to the direction in which the two methyl groups are pointing. If, for the sake of definition, "inward" means that in the projection shown (Figure 13) the methyl group lies within the sector defined by the two P−C_{ipso} bonds and outward means that it lies outside, then three classes of arrangements may be defined. Firstly, for an arrangement where both methyl groups point inward, we use the term "syn" (Figure

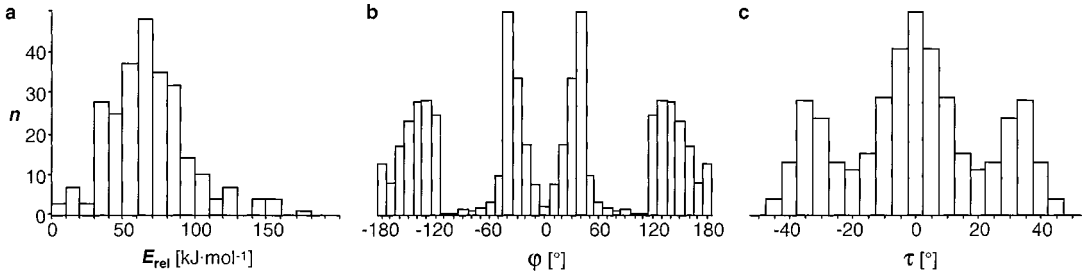

Figure 12. Histograms showing the distributions of the energies (a) and of the parameters φ (b) and τ (c) relating to the local minima found for compound **3**

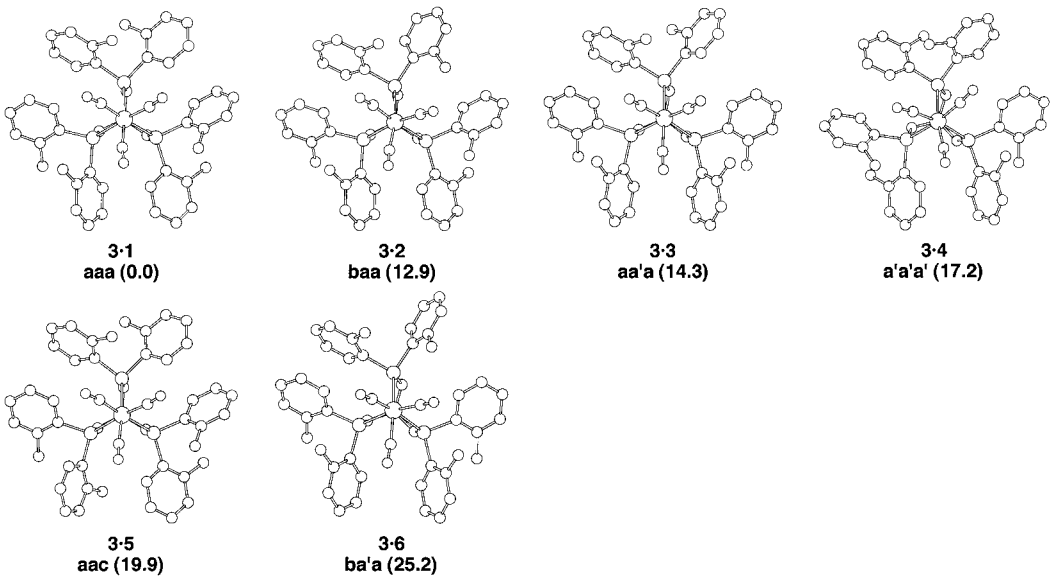

Figure 13. Conformations of **3** corresponding to local minima on the energetic hypersurface

13, 3.1). Secondly, where both methyl groups point outward, the arrangement shall be classified as "anti". The final arrangement, where one methyl group points inward and the other points outward, is referred to as "peri" (Figure 13, 3.2). For each class of orientation thus defined, there are further subclasses depending on whether a specific methyl group is on the left-hand or on the right-hand side and whether it points forwards or backwards. Designator *a* denotes a "syn" orientation with the left-hand *o*-tolyl group pointing forward and the right-hand one pointing backwards (Figure 13, 3.1). A "peri" arrangement of the methyl groups with both of them pointing forward is denoted as *b* (Figure 13, 3.2). Finally, a "peri" arrangement with both methyl groups pointing backwards is denoted as *c* (Figure 13, 3.5). These designators are combined to give the three-letter codes indicated in Figure 13, which describe the orientations adopted by the three P(*o*Tol)$_2$ groups in the sequence P1/P2/P3 (for the numbering scheme, see the definition in Figure 11). An orientation not shown in Figure 13, but referred to in Figure 14a and throughout the text, in which the left-hand methyl group points backwards and the right-hand one points forward while being in a mutual "anti" arrangement, is designated *d*.

For each of these local conformations, classified as *a*, *b*, *c*, or *d* as outlined above, an obverse conformation exists with forward and backward directions exchanged. These conformations are encoded by a prime (see, for instance, *a*′ in Figure 13, 3.4). The resulting eight designators suffice to characterize all the conformations up to calculated relative energies of around 60 kJ·mol^{-1}.

Analyzing the ensemble of conformers with respect to the specific classes to which their PAr$_2$ groups can be assigned, it is found that up to an energy of 27 kJ·mol^{-1} all these low-energy conformations have at least two local conformations

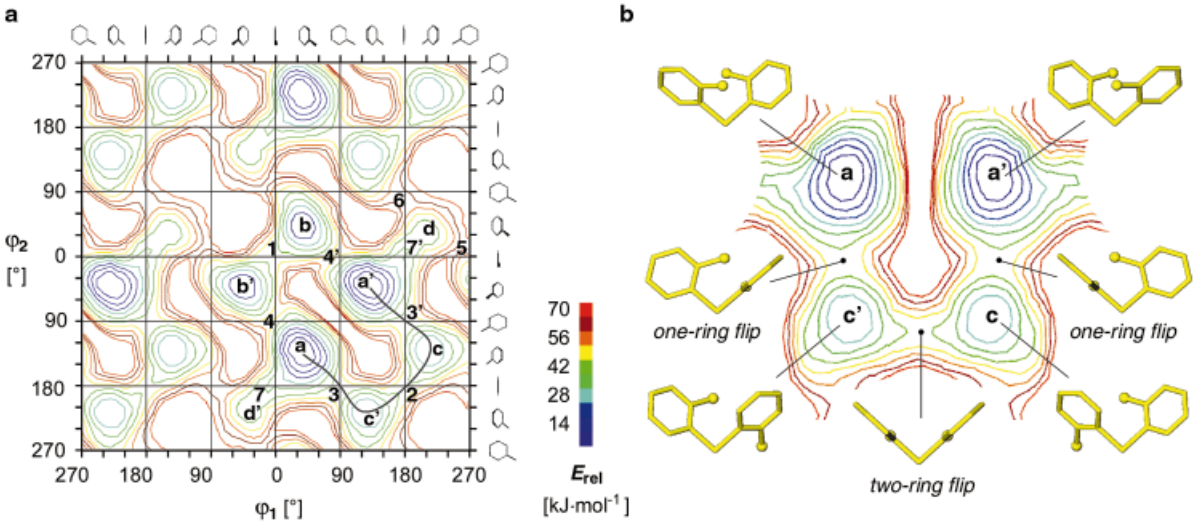

Figure 14. Contour diagram showing the enantiomerization pathway of **3**

corresponding to *a* or *a′* as defined above. This type of local orientation appears to be of peculiar stability.

The observation that conformations in which two of the P(*o*Tol)$_2$ groups remain in the orientation characterizing the arrangement of all three of these groups in the global minimum allows for a simplification of the conformational search. Selecting just one P(*o*Tol)$_2$ group and driving the rotational positions of its *o*-tolyl groups through the whole range of values from 0° to 360° should be sufficient to delineate the pathway of the overall isomerization process. The two remaining P(*o*Tol)$_2$ groups, which are not driven, will adopt the appropriate orientations during the minimization process. To allow for the torsional flexibility of the chelate scaffolding, these scans were made at two different settings of the torsion angle τ. To generate the starting conformations, all three torsion angles of one conformer were set at the same value and two complete scans of φ values were made, one at τ = 10° and the other at τ = 31°. These starting values were selected because analyses of similar compounds[8] have shown the τ values to cumulate around these values. The search was only performed with positive starting values of τ owing to the fact that all conformations must exist in isoenergetic enantiomeric pairs such that for every conformation with a given set of τ and φ values, an inverted conformation exists where the τ and φ values each have opposite signs. To allow for the torsional flexibility of the P(*o*-Tol)$_2$ groups that are not actively driven, the starting conformations of these groups were set according to the optimum arrangement (φ values) found to be characteristic for each value of τ. Initially, for small τ values an orientation as found for the global minimum (Figure 13, 3.1) was chosen, while for large τ values an orientation as shown in 3.4 (Figure 13) was used.

The subspace thus defined for the grid search has three dimensions; two aryl rotations φ_1 and φ_2 at the selected P(*o*Tol)$_2$ group and τ as a third dimension. While the τ space was only probed at two levels, the φ space was analyzed by a full rotation of both *o*-tolyl groups with an initial increment of 10°. To illustrate the result of these computations, a projection onto the subspace defined by the two aryl torsions φ_1 and φ_2 is shown in Figure 14.

Of the two energy values available at each grid point, resulting from the two values of τ assigned to it, the lower one was selected for this projection in each case. To generate the contour plot, we applied a symmetry expansion reflecting (i) the 360° translational symmetry along the φ axes, and (ii) the symmetry equivalence of enantiomeric pairs in each case. This second symmetry is evident from the diagram as a diagonal mirror plane from top left to bottom right (Figure 14).

There are three symmetrically independent energy minima apparent in this diagram. Position *a* (Figure 14; the designators *a*, *b*, *c*, *d* as used here are in accord with the definition given above in relation to Figure 13) corresponds to the global minimum. The minimum corresponding to the enantiomeric conformation is designated as *a′*. The local minima designated as *b*/*b′* correspond to an enantiomeric pair of conformations, as do the minima designated as *c*/*c′*. The positions *d*/*d′* correspond to another local minimum albeit a very flat one. The local minima *b*/*b′* (ca. 33 kJ·mol^{-1}) and *c*/*c′* (ca. 35 kJ·mol^{-1}) as well as the flat minimum *d*/*d′* (ca. 54 kJ·mol^{-1}) are all well above the energy of the global minimum *a*/*a′* (0.0 kJ·mol^{-1}). The diagram is thus consistent with the observation that only the enantiomeric conformations corresponding to the global minimum (*a*/*a′*) are seen in the NMR experiments. Although the local minima are relatively high in energy with respect to the equilibrium conformation *a*/*a′* and do thus not make a significant contribution to the conformational ensemble on thermodynamic grounds, the question still remains as to whether, once formed, they might survive due to the height of the relevant activation barriers. If this were to be the case, a thermodynamic equilibrium would not be established.

A rough estimate of the different activation barriers may be made simply by analyzing the diagram (Figure 14). The activation barriers associated with processes transforming *b′* back to *a* and *c′* back to *a* should be about 30 and 35 kJ·mol^{-1}, respectively, which are lower than those for the inverse processes, i.e. for transforming the conformation corresponding to the global minimum into the conformations characterizing the local minima *b′* and *c′*, respectively. A very rough estimate of the barriers associated with the latter transformations, as taken from the diagram, would be of the order of 50 kJ·mol^{-1} or higher. From these estimates of the relative energies of the activation barriers, it follows that the system as a whole should be in thermodynamic equilibrium under the conditions of the NMR experiments.

As far as the racemization process itself is concerned, only two plausible alternatives are suggested by the diagram: a trajectory along *a*−*b′*−*b*−*a′* or, alternatively, a transformation along *a*−*c′*−*c*−*a′*, which ever has the lower activation energy. By a more detailed analysis (see below), it is found that the latter pathway is in fact the important one.

The section of the diagram corresponding to this pathway is reproduced at the right-hand side of Figure 14 as an enlarged inset. Around this inset, the conformations characteristic of some selected points on the φ_1, φ_2 diagram are shown. It can be seen that following the pathway *a*−*c′*−*c*−*a′* corresponds to the transition of three saddle-points, which characterize one-ring, two-ring, and one-ring flip transitions in this sequence.[23]

In order to model the possible transformation pathways in a more accurate way, which would ultimately allow the extraction of reliable estimates of activation barriers, the following procedure was adopted. Starting with the ground state conformation, the P(*o*Tol)$_2$ group at P1 was selected for active rotation of its *o*-tolyl groups. A rotational increment of 2° was used throughout this analysis. The forward and backward rotations of these two *o*-tolyl groups have a different physical meaning due to the chirality of the system (this is even true at points in conformational space which, like the global minimum, correspond to C_3-symmetric arrangements).

To analyze the consequence of these rotations, each of these *o*-tolyl groups was actively driven and after each step the molecule as a whole was allowed to relax with the actively driven ring being fixed at the set position. It was found that − over a large range − the other *o*-tolyl group at P1 monotonically adopted its own rotational position in response to that of the driven group. Referring to the diagram in Figure 14, rotation of φ_1 in a negative direction, as well as independently starting with rotations of φ_2 in a positive direction, led to a route along the valley in the direction $a-b'$. Starting with φ_1 as the active rotator caused the system to follow the valley leading from *a* to *c'*. When the search was started by incrementing the rotation φ_1 in a negative sense, entry into a valley leading to *d'* was opened. Stepwise rotation in all four of these starting directions, with the appropriate relaxation after each step, led to the minima *b', c'*, and *d'* without further manipulation.

The saddlepoint 4 (Figure 14) was found at 79 kJ·mol^{-1}, irrespective, of course, of how it was arrived at. The saddlepoint 3 (Figure 14) connecting *a* and *c'* was found at 55.8 kJ·mol^{-1}, while that close to 7, separating *d'* from *a*, was found at 75 kJ·mol^{-1}.

With the analysis driven so far, a transformation following the direction *a* to *c'* is the most probable one and, as long as the saddlepoints separating *c'* from *c* and *c* from *a'* are lower in energy than the saddlepoints along the routes $a-b'$ or $a-d'$, this route is necessarily the best one. Accordingly, on driving φ_1 from its position at *c'* further in the positive direction, the local minimum *c* was reached without further interference. The saddlepoint between *c'* and *c* (2, Figure 14) was found at 52.1 kJ·mol^{-1}. If φ_1 was then further driven in a positive direction, a transition to the symmetry equivalent of *c'* was observed. Therefore, in order to delineate the route from *c* to *a'*, φ_2 was driven from this point on. In this way, *a'* was reached, the saddlepoint being found at 69.2 kJ·mol^{-1}. This is the maximum energy required for the conformational enantiomerization of the selected P(*o*Tol)$_2$ group along the route $a-c'-c-a'$. Since the saddlepoints separating *a* from *b'* as well as from *d'* are higher in energy, the routes via *b'* and *d'* do not need to be considered further.

The analysis described so far is not yet complete. There remain the other two P(*o*Tol)$_2$ groups, the rotational positions of which might, in principle, have a strong influence on the barrier height. During the optimization process described so far, the conformation at these groups remained essentially the same as in the starting conformation, with only minor undulations around the starting positions. On the one hand, this shows that coupling between neighboring P(*o*Tol)$_2$ groups is weak as compared to that dominating the interactions between two *o*-tolyl groups at one and the same phosphorus atom. Nevertheless, on the other hand, it has to be analyzed to ascertain whether any other rotational position of these neighboring P(*o*Tol)$_2$ groups would lead to a more favorable transition energy.

To simplify this problem, the following assumption was made. The lowest energy pathway for a rotational enantiomerization at each of these groups should be analogous to that already delineated for the group at P1. This assumption is well supported by the observation of almost decoupled behavior for the individual P(*o*Tol)$_2$ groups. To produce the analogous transitions, the rotations φ_3 (at P2) and φ_5 (at P3), respectively, were driven in a positive direction. This led directly to minima corresponding to *c'* with activation barriers of 73.6 kJ·mol^{-1} and 65.4 kJ·mol^{-1}. Due to the C_1 symmetry of the problem, the two routes are distinctly different and it is energetically more feasible to rotate the groups at P3 first. Driving φ_5 further in the positive direction led over a saddlepoint at 48.8 kJ·mol^{-1} to a minimum analogous to *c*. Driving φ_5 in the negative direction from this point on led to a minimum conformation locally enantiomeric to the starting conformation at P3 and thus analogous to *a'*. The saddlepoint for this last transition was found to be at 60.3 kJ·mol^{-1}. The same procedure was then applied to the rotation of the *o*-tolyl groups at P2. The saddlepoints in a sequence corresponding to the positions $a-c'-c-a'$ were found at 49.5, 44.7, and 43.6 kJ·mol^{-1}. Taking all the values together, it emerged that the energetically most costly step is the conformational enantiomerization of the first P(*o*Tol)$_2$ group (there is only one such "first" group due to the C_3 symmetry of the ground state conformation). Within the scope of the model, the value of 69.2 kJ·mol^{-1} (*mm2f*) or 61.1 kJ·mol^{-1} (*mm2t*) thus characterizes the activation energy for the racemization of the compound. The sequence of individual rotations taking place over the whole process is illustrated in Figure 15, which shows the conformations of all the minima encountered along this route.

The labels *a*,*a'* and *c*,*c'* correspond to the labels in Figure 13. The three-letter code refers to the local conformation at the phosphorus atoms P1, P2, and P3 in this sequence. The relative energies, together with the values quantifying the conformations, are given in Table 2, as are the energies calculated for the intervening saddlepoints. The energy profile given in Figure 16 summarizes the energetics of the pathway in a condensed form.

Analysis of 2

The structure of **2** is not known from crystallography. In order to model the low-energy structures, it was − in view of the knowledge already acquired with compounds of this type[12] − not considered necessary to carry out a full conformational search. Starting conformations, which should be close to the global minimum, were constructed either from low-energy conformations of $CH_3C(CH_2PPh_2)_3Mo(CO)_3$ by adding methyl groups at the appropriate positions to transform the phenyl groups into *o*-tolyl groups, or from low-energy conformations of $CH_3C[CH_2P(oTol)_2]_3Mo(CO)_3$ (**3**) by the reverse operation. Starting conformations with both types of helicity with respect to the arrangement of the aryl groups and with high (ca. 30°) and low (ca. 10°) values of the torsional arrangement of the chelate cage were analyzed. Refinement of all these conformations led to two analogous minima in each case. A con-

A conformation with relatively large τ values is only around 6 kJ·mol^{-1} higher in energy (Figure 17, *2lf*). It is predicted that one of these conformations (as quantified in Table 3) would be found if the structure of **2** were to be accessible to X-ray crystallography. This result was obtained using the *mm2f* parameter set.[10] On applying the *mm2t*[10] parameter set, qualitatively identical conformations were obtained (Figure 17, 2*st*, 2*lt*). With the force field approach *mm2t*, the conformation with the large values for the torsion angles of the cage was found at the absolute minimum, while the other one, corresponding to small cage torsions τ, was calculated to lie 6 kJ·mol^{-1} above it. The relative energies of the two lowest-energy conformations of **2**, as calculated by the two parameter sets, are

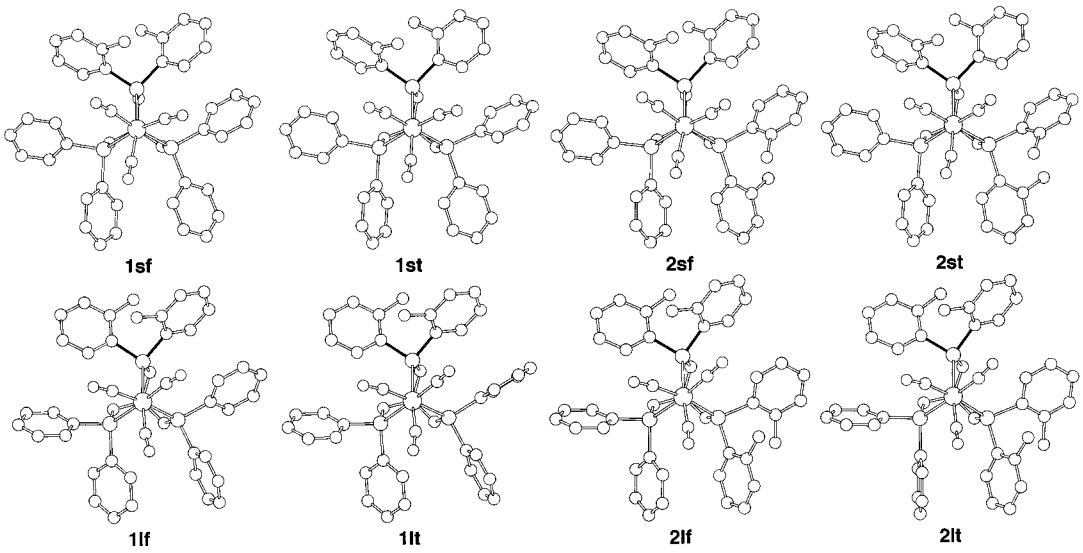

Figure 17. Lowest-energy conformations of **1** and **2** as calculated with the force field parameter sets *mm2f* and *mm2t*; the extensions *f* and *t* are used to designate the force field parameter set *mm2f* and *mm2t*, while the designators *s* and *l* refer to small and large torsions of the chelate cage

given in Table 3, together with the values quantifying these conformations.

Analysis of the racemization of the conformation corresponding to the global minimum was carried out in a similar manner as described in detail for compound **3**. The contour diagram obtained for the rotational inversion of the first P(*o*Tol)$_2$ group is very similar to that shown for **3** in Figure 14. The same types of minima and saddlepoints are observed. The energetic differentiation is, however, less pronounced than in the case of **3**. In the case of **2**, it is of relevance which of the two P(*o*Tol)$_2$ groups is selected as the first one to be subjected to the forced rotation process. Once one P(*o*Tol)$_2$ group is selected, its neighboring PAr$_2$ groups are no longer equivalent. The PPh$_2$ group is either on the left-hand or on the right-hand side of the selected fragment. This situation is reflected in the contour plot, which is no longer strictly symmetrical with respect to an idealized mirror plane lying along the diagonal.

The least-energy pathway from the global minimum coded as *aaa* in Figure 18 to its enantiomer *a′a′a′* traverses the local minima shown in Figure 18, where the meaning of the three-letter code is the same as that used for the description of **3**; due to the C_2 symmetry of the phenyl groups, only the two designators *a* and *a′* are necessary to describe the arrangement of the PPh$_2$ groups.

There is no need to actively rotate the phenyl groups; they are found to automatically orientate themselves during the minimization processes. Their reorientation is characterized by a two-ring flip transition (Figure 18, *aca*−*aa′a*). The relative energies of the corresponding minima, together with their corresponding conformational parameters and the energies of the saddlepoints en route from *aaa* to *a′a′a′* according to Figure 18, are given in Table 4.

The assignment of the individual transition processes in terms of one-ring and two-ring flip transitions given in Table 4 is also apparent from Figure 18. It is found that the highest barrier is associated with inversion of the second P(*o*Tol)$_2$ group; a barrier height of 56.5 kJ·mol^{-1} (*mm2f*) or 57.1 kJ·mol^{-1} (*mm2t*) is calculated for this step, which, within the model, characterizes the activation barrier.

Analysis of 1

The structure of **1** is not known experimentally. The low-energy conformations for **1** were calculated on a similar basis as discussed above in the case of **2**. Irrespective of the starting geometries, which were also refined as discussed for **2**, two low-energy conformations were found (*mm2f* [10]), energetically very close together (2.1 kJ·mol^{-1}) and structurally differentiated in the same way as described for **2**. These conformations were also found with *mm2t* as the force field, albeit with interchanged relative energies.

One of the calculated low-energy conformations of **1** has small torsions τ of the chelate cage and a left helical arrangement of the aryl groups (Figure 17, 1*sf*, 1*st*; Table 3). The other one has large τ values with the helicity of the aryl "propeller" being, in principle, right-handed (Figure 17, 1*lf*, 1*lt*; Table 3). The contour plot for the local enantiomerization of the P(*o*Tol)$_2$ group is again qualitatively similar to that shown for **3** and is of course symmetrical due to the mirror plane along the diagonal of this type of diagram. The calculated energies are somewhat lower than those obtained for **2**, which are in turn lower than those calculated for **3**. This is a consequence of the decreasing steric strain on descending the sequence **3**, **2**, **1**. Detailed analysis of the racemization pathway was performed as extensively as described for **3**. In contrast to the observations made for **2**, the phenyl groups do not completely adapt to the rearrangement at the P(*o*Tol)$_2$ group and have hence to be actively driven in the final step. The lowest-energy pathway for the racemization of **1** is qualitatively analogous to those described for **3** and **2**.

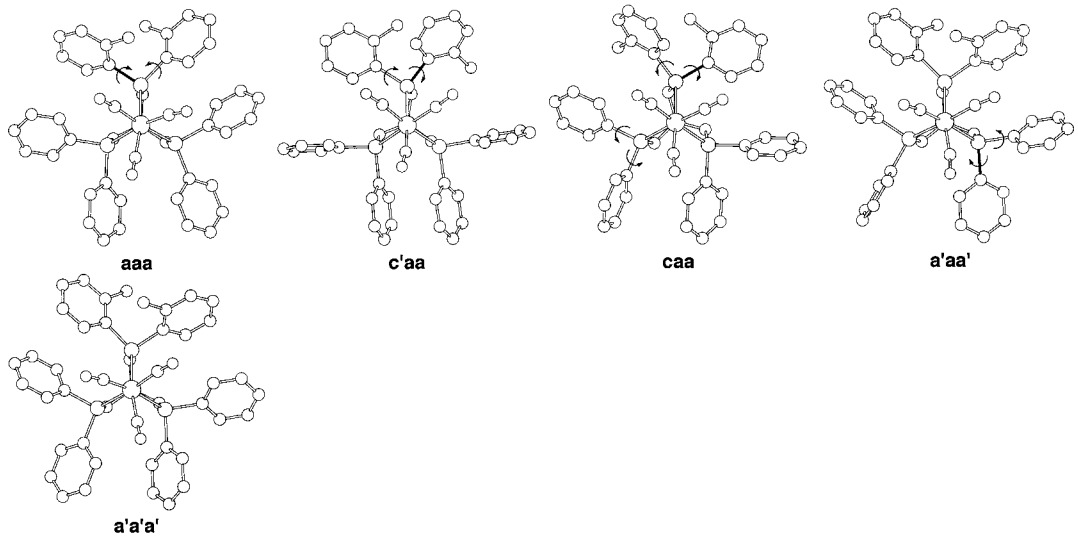

Figure 19. Sequence of rotational processes along the enantiomerization pathway of **1**

Figure 19 illustrates the local minima encountered along this pathway. The energies of these minima, together with those of the saddlepoints separating them, are given in Table 5. The highest barrier dominating the process as a whole is found at 53.1 kJ·mol^{-1} (*mm2f*) or 44.0 kJ·mol^{-1} (*mm2t*).

Comparison of Calculated and Measured Activation Barriers

Comparison of the calculated activation barriers with those observed for **1**–**3** provides a means of assessing the quality of the force field approach and especially of assessing the appropriateness of the energy scale produced by the force field approach.[24] It has previously been shown that the force field approach used is capable of correctly reproducing NOE distances in a series of compounds.[12] The best one can do in this respect is to use the energies calculated by the force field as the basis to produce a Boltzmann weighted average. Even though $\Delta G^{\neq}$ values would be necessary to make this approach a physically correct one, $\Delta H^{\neq}$ values, as obtained by the force field approach, are still the best and only choice one has. The fact that the NOE distances calculated by this approach are in close agreement with the observed values indicates that the calculated $\Delta H^{\neq}$ values are somehow on scale with the $\Delta G^{\neq}$ values.[12]

The results obtained for the activation energies of **1**–**3** using the force field approach appear highly satisfying in this respect (Table 6). Irrespective of the type of force field used (*mm2f*, *mm2t*), the activation energies are predicted to increase with increasing steric congestion on ascending the series **1**, **2**, **3**. The energies given by the force field approach do not contain entropy terms and thus have to be compared with the $\Delta H^{\neq}$ values as the experimental counterpart. Using the *mm2f* parameter set, the predicted energies are equal to the experimental values with a maximum deviation of 10 kJ·mol^{-1}; based on the *mm2t* set of parameters, the maximum deviation is only around 5 kJ·mol^{-1} (Table 6). With either parameter set, the ranking of the compounds in order of increasing activation barriers is correctly predicted. Indeed, the agreement between calculated and experimental values is as good as might be hoped for using a force field approach. This may be taken as a further confirmation of the validity of the approach taken to derive the force field parameters.

Conclusion

1. *Tripod* compounds $CH_3C(CH_2PPh_2)_{3-n}[CH_2P(o\text{-}Tol)_2]_nMo(CO)_3$ ($n = 1-3$) undergo conformational enantiomerization with activation barriers $\Delta H^{\neq}$ between 45 and 59 kJ·mol^{-1}. The barriers increase with increasing number of P(oTol)$_2$ groups present.

2. Using a force field approach, for which the force field parameters were derived by global optimization on the basis of all the structural information available,[10] reaction pathways for these enantiomerization processes have been delineated. The activation barriers predicted by this approach are in close agreement with the experimental values.

3. The approach of deriving force field parameters by global optimization over a complete basis of molecular structures[10][11] is capable of predicting conformations and conformational energy differences in agreement with experimental findings.

Experimental Section

General Remarks: All manipulations were carried out under an argon atmosphere at 20°C by means of standard Schlenk techniques, unless mentioned otherwise. All solvents were dried by standard methods and distilled under argon. The solvents used for the NMR spectroscopic measurements were degassed by three successive "freeze-pump-thaw" cycles and were dried over 4 Å molecular sieves. The silica gel (Kieselgel p.A. 0.06–0.02 mm, J. T. Baker Chemical B.V.) used for chromatography and the Kieselgur (Kieselgur, washed, heat-treated, Erg. B.6, Riedel de Haen AG) used for filtration were degassed at 1 mbar at 20°C for 48 h and then saturated with argon. – IR: Bruker FT-IR IFS-66; CaF_2 cells. – MS(EI): Finnigan MAT 8400. – Elemental analysis: Microanalytical laboratory of the Organisch-Chemisches Institut, Universität Heidelberg. Under the conditions employed, the carbon content is often found to be too low for molybdenum-containing compounds due to the formation of non-combustible molybdenum carbide. – Melting points: Gallenkamp MFB-595 010; uncorrected values. – All chemicals were obtained commercially and were used without further purification.

NMR: NMR spectra were recorded on Bruker NMR spectrometers operating at 200, 300, and 500 MHz, respectively. Two-dimensional spectra were recorded with quadrature detection in both dimensions; TPPI was used in F_1. All information about sizes and data points of the spectra is given in real points. ^{1}H- and ^{13}C-NMR spectra were calibrated internally using the residual solvent signals (CD_2Cl_2, $\delta_H = 5.32$, $\delta_C = 53.8$; $CDCl_3$, $\delta_H = 7.24$, $\delta_C = 77.0$) and tetramethylsilane (TMS, $\delta = 0$) as an external standard; ^{31}P-NMR chemical shifts are given in ppm relative to 85% H_3PO_4 ($\delta = 0$) as an external standard. Assignment of all the ^{1}H, ^{13}C, and ^{31}P resonances was accomplished by a combination of 1D and 2D NMR experiments (DQF-COSY,[13] TOCSY,[14] NOESY,[15] {^{1}H-^{13}C}-HSQC,[16] {^{1}H-^{13}C}-HMBC,[17] {^{1}H-^{31}P}-HMBC;[17] see Tables 12−14, Figure 20). For NMR analysis, saturated solutions of the compounds in CD_2Cl_2 (**1**, **2**) and $CDCl_3$ (**3**) were prepared in precision NMR tubes on a vacuum line; the tubes were flame-sealed after deoxygenation by repeated evacuation followed by readmission of argon (minimum of three freeze/pump/thaw cycles). The experimental set-ups for the various experiments are outlined in Tables 7 and 8. While compounds **1** and **2** were analyzed by a combination of all the available methods (Table 7), analysis of **3** had to be limited to a subset of these methods as indicated in Table 8.

The temperature was calibrated using a [D_4]methanol (99.8%) NMR thermometer[25] in the low-temperature range (−100°C to 30°C) and ethylene glycol at higher temperatures (20−180°C).[26] Temperatures were kept constant to within ±0.2 K (DRX500) and ±1 K (DRX300, DPX200, AC200). As judged from the calibration with [D_4]methanol, the actual sample temperatures were accurate to within approximately ±1 K. Various parameters relating to the equipment used and the experimental set-ups are given in Tables 9−11, while ^{31}P-NMR data of **1**−**3** are given in Table 12.

A matrix representation of the different types of cross-correlation signals observed for **3** is presented in Figure 20.

Tables 13 and 14 show ^{13}C- and ^{1}H-NMR data of **1** and **2**, together with the correlations used for assignment and analysis.

Experiments and Analyses: The assignments were made according to standard procedures, the salient details of which are given in Tables 12−14 and Figure 20. Rate constants were estimated using three different approaches, the most straightforward of these involving determination of the coalescence temperature. This type of experiment was performed at different field strengths and by using both ^{1}H- and ^{31}P-NMR spectroscopy (Tables 1 and 10). A somewhat more extended range of temperatures was covered by EXSY experiments based on exchange signals between pairs of different types of protons; these were also performed at different field strengths (Tables 1 and 11). The most extensive range of temperatures was covered by line-shape analysis of the ^{31}P-NMR signals. This type of experiment was, of course, limited to compounds **1** and **2** owing to the constitutional C_3 symmetry of **3**. Again, different field strengths were used for these experiments (Tables 1, 10, and 12). The quality of fit obtained is exemplified by the case of **2** in Figure 10. All the rate constants for **1** and **2** obtained by line-shape analysis were used to construct an Eyring plot in each case. Considering the error statistics, the enthalpy and entropy values obtained by this procedure would seem to be quite accurate (**1:** $R^2 = 0.998$, $\Delta H^{\neq} = 45.3 \pm 0.4$ kJ·mol^{-1}, $\Delta S^{\neq} = -30 \pm 1$ J·K^{-1}·mol^{-1}; **2:** $R^2 = 0.995$, $\Delta H^{\neq} = 51.8 \pm 0.7$ kJ·mol^{-1}, $\Delta S^{\neq} =$

[a] 3 spectra were taken with mixing times of 100, 150, and 200 ms. − [b] 6 spectra were taken with mixing times of 10, 20, 50, 100, 200, and 300 ms.

-20 ± 2 J·K^{-1}·mol^{-1}; the limits given refer to the estimated standard deviation σ in each case; Table 1). Since ^{31}P-NMR line-shape analysis was not possible for **3**, the basis for estimating activation parameters was inferred from coalescence and EXSY data (Tables 1, 10, and 11). With only six available data points (Table 1), the statistical accuracy of the estimated parameter values is somewhat lower than those obtained for **1** and **2** on the basis of the data obtained by line-shape analysis (**3**: $R^2 = 0.986$, $\Delta H^{\neq} = 59.3 \pm 3.5$ kJ·mol^{-1}, $\Delta S^{\neq} = -21 \pm 12$ J·K^{-1}·mol^{-1}; limits refer to σ; Table 1). In order to get some appraisal of the mutual agreement between the data obtained by the three different techniques, the complete set of data obtained for **1** and **2**, irrespective of the acquisition procedure (line-shape analysis, EXSY spectroscopy, coalescence measurements) was also used to construct Eyring plots. Based on the complete set of data, $\Delta H^{\neq}$ and $\Delta S^{\neq}$ as estimated for **1** ($R^2 = 0.995$, $\Delta H^{\neq} = 45.7 \pm 0.5$ kJ·mol^{-1}, $\Delta S^{\neq} = -29 \pm 2$ J·K^{-1}·mol^{-1}; limits refer to σ; Table 1) are in excellent agreement with the values obtained from line-shape analysis alone (see above, Table 1). Apply-

[a] The numbering scheme refers to Figure 3 with the following addenda: MeX denotes the carbon atom of the methyl group on the ligand backbone; Npq refers to the quaternary carbon atom of the neopentane backbone; Meαo_{ipso} refers to the carbon atoms of the *o*-tolyl group α (α = 1−4) bearing the methyl substituent; Toα_{ipso} denotes the corresponding *ipso* carbon atom of the *o*-tolyl groups, while Phβ_{ipso} (β = 5−6) analogously denotes the *ipso* carbon atoms of the phenyl groups. − [b] $^nJ_{CP}$ in Hz is given in brackets. − [c] $^{2/3}J_{HH}$ in Hz is given in brackets. − [d] $^1J_{CH}$ = 127.1 Hz. − [e] $^1J_{CH}$ = 127.8 Hz. − [f] $^nJ_{HP}$ = 5.1 Hz (Me3B); 8.7 Hz (Me2B); 8.4 Hz (Me1B); 5.9 Hz (Me1A); 10.4 Hz (Me3A); 6.7 Hz (Me2A); 8.3 Hz (To3o); 7.7 Hz (To1o); 8.8 Hz (Ph5o); 7.9 Hz (Ph6o); 17.3 Hz (To4o); 17.5 Hz (To2o). − [g] Signals of individual groups overlap; $^3J_{HH}$ coupling constants were determined by DQF-COSY experiments.

ing an analogous procedure to the complete set of data for **2** leads to an estimate of $\Delta H^{\neq}$ (R^2 = 0.990, $\Delta H^{\neq}$ = 48.7 ± 0.7 kJ·mol^{-1}; limits refer to σ; Table 1) in satisfying agreement with the value derived from the line-shape analysis data alone. The estimated activation entropy, however, is about 10 J·K^{-1}·mol^{-1} more negative ($\Delta S^{\neq}$ = −31 ± 3 J·K^{-1}·mol^{-1}; limits refer to σ; Table 1) than that obtained by using data solely from the line-shape analysis (see above, $\Delta S^{\neq}$ = −20 ± 2 J·K^{-1}·mol^{-1}; limits refer to σ; Table 1). This discrepancy between the $\Delta S^{\neq}$ values estimated on the basis of the two different data sets (line-shape analysis data alone vs. augmented data set) is close to the three σ limit, which is conventionally used to discriminate between equality or inequality of the statistical distribution that two items are subject to. It is thus found that, within the appropriate confidence interval, the two different approaches used generate estimates which, as expected, can be taken as equal. As judged from the scatter of data, the activation parameters derived from line-shape analysis alone are the most reliable, and hence these data have been quoted for **1** and **2** wherever appropriate in the text; Table 1 contains both types of estimates. To sum up, it appears that the line-shape analysis produces the most reliable data. It is felt that the data derived from EXSY measurements are less reliable, where different types of biases may result from overlap of peaks along the diagonal, NOE contributions, and loss of polarization during different delays. Likewise, coalescence data do not appear to be as reliable as the data obtained from line-shape analysis in the specific cases studied. Estimating the coalescence temperature is a procedure which is subject to personal judgement. Coupling between the coalescing nuclei makes this process even more subject to human error.

Finally, it is felt that the NMR work reported herein has some importance beyond the specific chemistry studied in this paper since the utility and reliability of three NMR techniques for the assessment of rate constants have been compared in the analysis of one and the same problem.

Force Field Calculations: Programs and parameters have been described previously,[10] as have the protocols of the individual computational procedures.[12] Details relating to the scanning of the hypersurface are given explicitly in the text. All computations were performed on a Silicon Graphics Indigo^2 MIPS R4400 workstation, 200 MHz, 128 MB RAM, operating under IRIX 5.3. Graphical representations of hypersurfaces were obtained using the *plot2D* option of MacroModel.[27]

Synthetic Procedures

1-[Bis(*o*-tolyl)phosphanyl]-3-(diphenylphosphanyl)-2-(diphenylphosphanylmethyl)-2-methylpropane (1a): To a solution of 1.3 g (2.8 mmol) of 1-chloro-2-bis(diphenylphosphanylmethyl)propane[28] in DMSO (50 mL), 730 mg (3.4 mmol) of bis(*o*-tolyl)phosphane and 380 mg (3.4 mmol) of KO*t*Bu were added and the mixture was stirred for 3 h at 130°C. The reaction mixture was worked-up hydrolytically by adding water (50 mL) and then neutralizing

Table 14. ^{1}H- and ^{13}C{^{1}H}-NMR data of **1**; the meaning of symbols is as in Figure 2

[a] The numbering scheme refers to Figure 2 with the following addenda: MeX denotes the carbon atom of the methyl group at the backbone of the ligand; Npq refers to the quaternary carbon atom of the neopentane backbone; Meαo$_{ipso}$ refers to the carbon atoms of the *o*-tolyl group α (α = 1−2) bearing the methyl substituent; Toα$_{ipso}$ denotes the corresponding *ipso* carbon atom of the *o*-tolyl groups, while Phβ$_{ipso}$ (β = 3−6) analogously denotes the *ipso* carbons of the phenyl groups. − [b] $^nJ_{CP}$ in Hz is given in brackets. − [c] $^{2/3}J_{HH}$ in Hz is given in brackets. − [d] $^1J_{CH}$ = 126.9 Hz. − [e] $^nJ_{HP}$ = 2.6 Hz (Me3A); 2.2 Hz (Me2A); 12.7 (Me1B); 4.8 Hz (Me1A); 10.7 Hz (Me2B); 11.2 Hz (Me3B); 8.2 Hz (To1o); 4.2 Hz (To1d); 10.4 Hz (Ph5o); 9.7 Hz (Ph3o/Ph6o); 17.7 Hz (To2o). − [f] Signals of individual groups overlap; $^3J_{HH}$ coupling constants were determined by DQF-COSY experiments.

with 37% aq. HCl. The product was extracted with diethyl ether (4 × 50 mL) and the combined organic phases were dried and concentrated in vacuo. The resulting pasty residue was purified by column chromatography on silica gel (20 cm, Ø = 5 cm) using petroleum ether (40/60)/diethyl ether (9:1) as eluent (TLC control, R_f = 0.50) to yield 1.7 g (2.7 mmol, 95%) of ligand **1a** as a colorless oil.

1-[Bis(*o*-tolyl)phosphanyl]-3-(diphenylphosphanyl)-2-(diphenylphosphanylmethyl)-2-methylpropanetricarbonylmolybdenum (1): To a solution of 1.7 g (2.7 mmol) of **1a** in CH_2Cl_2 (50 mL), 815 mg (2.7 mmol) of solid $(MeCN)_3Mo(CO)_3$[29] was added and the mixture was stirred for 2 h at room temperature. During the course of the reaction, the $(MeCN)_3Mo(CO)_3$ slowly dissolved and the color of the solution turned from light-yellow to yellow-brown. The solvent was then removed to leave a brown solid. The crude product was purified by column chromatography on silica gel (10 cm, Ø = 4 cm) using a mixture of petroleum ether (40/60)/CH_2Cl_2 (1:3) as eluent (TLC control: R_f = 0.75) to afford 1.5 g (1.8 mmol, 67%) of **1** as a light-yellow microcrystalline solid. The product was recrystallized from CH_2Cl_2. − IR (CH_2Cl_2): $\tilde{\nu}$ = 1936 (s, CO), 1844 (br. s, CO). − MS(EI); *m/z* (%): 834 (10) [M^+], 806 (12) [M^+ − CO], 778 (40) [M^+ − 2 CO], 750 (30) [M^+ − 3 CO].

1,1,1-Tris[bis(*o*-tolyl)phosphanylmethyl]ethane (3a): 3.87 g (18 mmol) of bis(*o*-tolyl)phosphane[30] was dissolved in DMSO (25 mL) and deprotonated at 0°C by adding 2.02 g (18 mmol) of KO*t*Bu. After warming to room temperature, the deep-red solution was stirred for 1 h. A solution of 0.92 g (5.25 mmol) of 1-chloro-2,2-dichloromethylpropane in DMSO (25 mL) was then slowly added and the resulting mixture was refluxed for 5 h. The mixture was then cooled to room temperature and the DMSO was evaporated in vacuo. The residue was hydrolyzed by adding degassed water (50 mL). After stirring for 16 h, **3a** was extracted with diethyl ether (4 × 50 mL). The combined organic phases were dried over $MgSO_4$ and filtered. Evaporation of the solvent afforded 2.3 g (3.2 mmol, 62%) of **3a** as a white powder; m.p. 176°C. − ^{1}H NMR ($CDCl_3$): δ = 1.1 (s, 3 H, CqCH_3), 2.4 (m, 24 H, ArCH_3, CH_2P), 7.10−7.33 (m, 24 H, arom. H). − ^{13}C NMR ($CDCl_3$): δ = 20.8 (s, Ar*C*H$_3$), 21.3 (s, Ar*C*H$_3$), 42.5 (m, Cq), 125.0−142.2 (m, arom. C). − ^{31}P NMR ($CDCl_3$): δ = −50.9 (s). − MS (FAB); *m/z* (%): 708 (32) [M^+], 617 (100) [M^+ − (*o*-tolyl)], 495 (16) [M^+ − P(*o*-tolyl)$_2$].

1,1,1-Tris[bis(*o*-tolyl)phosphanylmethyl]ethanetricarbonylmolybdenum (3): 708 mg (1 mmol) of the ligand **3a** was dissolved in CH_2Cl_2 (30 mL) and this solution was added to 333 mg (1.1 mmol) of solid $(CH_3CN)_3Mo(CO)_3$[29] at 20°C. The resulting mixture, which immediately turned dark, was stirred for 48 h. Petroleum ether (40/60) (6 mL) was then added and the mixture was filtered through silica gel (2 cm) and Kieselgur (1 cm), resulting in a yellow eluent. Evaporation of the solvent and drying of the residue in vacuo for 48 h afforded 835 mg (0.94 mmol, 94%) of **3** as a pale-yellow powder. A reagent tube filled with a concentrated solution of **3** in CH_2Cl_2 was placed in a Schlenk tube containing a bottom layer of diethyl ether. Vapour diffusion of the diethyl ether at room temperature yielded pale-yellow crystals suitable for X-ray structural analysis within one day.[10] − IR ($CHCl_3$): $\tilde{\nu}$ = 1932 (s, CO), 1835 (br. s, CO). − ^{1}H NMR ($CDCl_3$): δ = 1.65 (m, 3 H, CqCH_3), 1.75−2.0 (m, 18 H, ArCH_3), 2.0−3.0 (br. m, 6 H, CH_2P), 6.5 (m, 6 H, arom. H), 6.8−7.5 (m, 18 H, arom. H). − ^{13}C NMR ($CDCl_3$):

δ = 22.31 (m, Ar*C*H$_3$), 23.22 (m, Ar*C*H$_3$), 38.9 (m, *C*H$_2$P), 42.0 (m, Cq), 125.0−141.3 (m, arom. C), 220 (s, CO). − ^{31}P NMR (CDCl$_3$): δ = 20.0 (s).

Acknowledgments

The financial support by the Deutsche Forschungsgemeinschaft (SFB 247, Normalverfahren HU 151/24-1, /29-1) and the Fonds der Chemischen Industrie is gratefully acknowledged. We are indebted to Mr. T. Jannack for performing mass spectrometric measurements and to the staff of the Microanalytisches Labor of the Organisch-Chemisches Institut, Heidelberg, for providing microanalyses. We wish to acknowledge the early inspiration by the Deutsches Museum, München.

[23] For the meaning of the terms "one-ring flip" and "two-ring flip", see ref.[8]
[24] The approach used (*mm2f*, *mm2t*) makes use of the well-scaled force constants of the MM2*[3] force field for the organic part of the molecules. On the other hand, the force constants describing the "inorganic interactions" have been deduced by a minimization procedure based wholly on structural information.[10][11] There is, of course, no direct reference to energetic terms in such a structural database and if the force constants derived from this database are still appropriate on the energy scale, this must result from the indirect constraints imposed on them in the course of their refinement by the dominant force field contribution of the organic part. It was expected that the force constants used for the organic part might automatically force the refinement of the inorganic force field constants to the appropriate scale, as is indeed found.[12]

Sulfur Compounds, 211[‡]

Gas-Phase Acidities of Nine Sulfur Oxoacids of Composition [H_2,S,O_n] (n = 1–4)

André H. Otto[a] and Ralf Steudel*[a]

Keywords: Sulfur oxo acids / Acidity / Ab initio calculations

The gas-phase acidities of the most stable conformations of nine sulfur oxo acids were determined by ab initio MO calculations at the CBS-Q, G2(MP2), and G2 levels of theory. The most accurate G2 results are as follows ($\Delta G°_{298}$ of the deprotonation reaction in kJ mol^{-1}): H–S–O–*H* 1468, *H*–S–O–H 1449, $(HO)_2S$ 1426, *H*–S(=O)OH 1406, H_2S=O 1394, H–S(=O)O*H* 1361, $(HO)_2S$=O 1324, $H_2S(=O)_2$ 1321, H_2O→S 1294, *H*–$S(=O)_2OH$ 1287, H–$S(=O)_2O$*H* 1279, $(HO)_2S(=O)_2$ 1268. These values are in excellent agreement with the few experimental data that can be considered reliable. For molecules of analogous structure, the acidity increases with increasing oxidation number of the sulfur atom. While sulfenic acid, HSO*H*, is as weak an acid as HOCl, sulfurous acid, $(HO)_2SO$, is as strong a proton donor as nitric acid, HNO_3, and sulfonic acid, *H*$S(O)_2OH$, is even stronger than hydrogen iodide, HI, surpassed only by sulfuric acid, H_2SO_4. These results are of relevance to phenomena such as acid rain and aerosol formation in the earth's atmosphere.

Introduction

Sulfur forms a large number of oxo acids, $H_xS_yO_z$, because: (a) the oxidation number(s) of the S atom(s) can vary between –1 and +6 and (b) sulfur–sulfur bonds may occur if $y > 1$.[1–3] Most of these compounds are too unstable to be isolated in pure form. Consequently, the physical and chemical properties of these nevertheless important species are not well-known, and this also holds for their acidities. Only a few experimental and theoretical data are available for the acidities in water and/or in the gas phase.

The most simple ("mononuclear") oxo acids of sulfur are of composition H_2SO_n with n ranging from 1 to 4. However, even in these cases, several isomeric forms are sometimes possible. For example, the oxidation of hydrogen sulfide, H_2S (sulfane), by oxygen atoms (produced by photolysis of ozone) in an argon matrix yields the sulfane oxide H_2S=O as well as the isomeric sulfenic acid H–S–O–H ("oxadisulfane").[4] The latter molecule was shown by ab initio MO calculations to be more stable than the former.[5] The energy barriers for the isomerisations H_2S=O → HSOH and HSOH → H_2S=O were calculated at the HF/6-31G(d) level of theory as 225 and 361 kJ mol^{-1}, respectively.[5f] The acidities of HSOH and H_2S=O, defined as the standard enthalpy change for the deprotonation reactions, were calculated at the MP4/6-311++G(d,p)//MP2(fu)/6-311++G(d,p) level of theory.[5d] At 298 K the following results were obtained (kJ mol^{-1}): 1536 for HSO*H*, 1492 for *H*SOH and 1430 for H_2S=O. The same authors determined the SH acidity of *H*SOH by mass spectrometry as 1481 ± 15 kJ mol^{-1} in very good agreement with the theoretical value.

The energy hypersurface of [H_2,S,O_2] shows stationary points for at least six structures: two conformers of the chain-like sulfur dihydroxide HOSOH, sulfinic acid HS(=O)OH, sulfane dioxide $H_2S(=O)_2$, the chain-like peroxide HSOOH, the branched superoxide H_2S→O=O and the cyclic thiadioxirane H_2S–O^a–O^b(S–O^b).[6a][6b] At the MP4/6-31G(d)//MP2(fu)/6-31G(d) level of theory, the two first-mentioned isomers are considerably more stable than all the others and the chain of C_2 symmetry is the global minimum of what is usually termed as "sulfoxylic acid". The only reliable experimental information on [H_2,S,O_2] is the mass spectrometric observation of the molecule HOSOH, which had been generated by dissociative ionisation of dimethyl sulfate, followed by neutralisation and reionisation.[7] An earlier report on the matrix isolation of sulfinic acid as a photolysis product of an HI–SO_2 mixture in solid argon[8] has been disputed because the reported infrared spectrum of the product mixture does not match the spectra calculated for various [H_2,S,O_2] isomers.[6a] The gas-phase acidities of these isomers were studied at the MP4/6-31G(d)//MP2/3-21G(*) + ZPVE level[6c] and the following $\Delta H°_{298}$ values were obtained: 1444 kJ mol^{-1} for HS(O)O*H* and 1467 kJ mol^{-1} for *H*S(O)OH. Several authors reported the absolute energies both for the acids and the corresponding anions;[6a][6h] this allows the enthalpy change for the deprotonation reaction to be calculated. From the more recent and more reliable data obtained at the MP4/6-31G(d)//MP2(fu)/6-31G(d) level,[6a] the following $\Delta H°_{298}$ values for the deprotonation may be calculated (in kJ mol^{-1}): HOSOH (C_2) 1530, HOSOH (C_s) 1519, *H*S(=O)OH 1477, HS(=O)O*H* 1450, and $H_2S(=O)_2$ 1377.

On the energy hypersurface of [H_2,S,O_3], the well-known molecules of sulfurous acid $(HO)_2S$=O and sulfonic acid

H–S(=O)$_2$OH were identified as structures of minimal energy but, in addition, a 1:1 adduct of H_2O with SO_2 exists which has also been characterised by infrared and microwave spectroscopy.[9] This adduct will not be discussed further. Here we are mainly interested in the acidities of the two mentioned acids of composition H_2SO_3. Several ab initio MO calculations have shown that gaseous sulfurous acid is more stable than sulfonic acid.[6h][10] At the G2 level of theory, including ZPE correction, the energy difference at 0 K is 41 kJ mol^{-1}.[10c] However, both acids are unstable with respect to the decomposition products H_2O and SO_2. The reaction enthalpies for this decomposition at 298 K are –18 kJ mol^{-1} for (HO)$_2$SO and –53 kJ mol^{-1} for HS(O)$_2$OH at the G2 level[10c] but –45 kJ mol^{-1} were calculated for HS(O)$_2$OH (at 270 K) at the QCISD(T)/6-311++G(d,p)//MP2/6-31G(d) level.[10d] Sulfurous acid was nevertheless observed in the vapour phase by neutralisation–reionisation mass spectrometry.[11] The molecule was generated by ionisation-induced decomposition of diethyl sulfite which loses two molecules of ethene to give (HO)$_2$SO. The fragmentation pattern on collisional activation demonstrated the connectivity of sulfurous acid.

Sulfonic acid has never been observed but its anion H–SO_3^- is well-known from salts such as $CsHSO_3$ and from aqueous solutions. The rational nomenclature for this anion containing an S–H bond is sulfonate ion but it is often termed as hydrogen sulfite or as bisulfite ion, especially in the industrial literature. The name hydrogen sulfite ion should be restricted to the isomer with the connectivity HO–SO_2^-. While solid $CsHSO_3$, according to an X-ray diffraction analysis, contains the sulfonate ion,[12] aqueous solutions of the sodium salt exhibit ^{17}O-NMR signals which can be attributed to both tautomers.[13] From the peak areas, the equilibrium quotient c(HO–SO_2^-)/c(H–SO_3^-) was found to be 4.9 ± 0.1 at 298 K in solutions of ion strength 1.0 M. These results were later confirmed by a Raman spectroscopic investigation of aqueous $NaHSO_3$ solutions.[14] Ab initio MO calculations on the two ions of composition [H,S,O$_3$]$^-$ have been carried out.[6h][15] At the G2 level, the sulfonate ion of C_{3v} symmetry is more stable, by 16 kJ mol^{-1}, than the hydrogen sulfite ion, which surprisingly is of C_1 symmetry.[10c] However, if lower levels of theory are applied, the order of stabilities may be reversed, especially if the symmetry of the hydrogen sulfite ion is restricted to C_s, as has been done in some earlier publications on this subject. Attempts to model the impact of solvation on the stability of the two anions indicated that they are still of very similar energy if dissolved in water.[15c]

The gas-phase acidities of sulfurous and sulfonic acids were studied by various authors.[6h,10b,10c] At the G2 level the deprotonation enthalpies $\Delta H°_{298}$ were calculated as follows (in kJ mol^{-1}): (HO)$_2$SO 1358, *H*S(O)$_2$OH 1323, HS(O)$_2$O*H* 1308.[10c]

Sulfuric acid, H_2SO_4, is the only sulfur oxo acid whose vapour-phase structure was determined experimentally. According to a microwave spectroscopic investigation,[16] the molecule is of C_2 symmetry which was confirmed by a number of ab initio MO calculations.[17] Several conformational (torsional) isomers were theoretically identified at higher energies. In addition, the adduct $SO_3 \cdot H_2O$ was observed by infrared spectroscopy (in matrix isolation experiments),[18] and its gas-phase structure was determined both by microwave spectroscopy[19] and by ab initio MO calculations.[17b,17c] The gas-phase acidity of sulfuric acid was derived from an investigation of the proton transfer in certain ion–molecule reactions as $\Delta G°_{368}$ = 1265 kJ mol^{-1} ($\Delta H°_{368}$ = 1295 kJ mol^{-1}).[20] This value is in excellent agreement with the results of an ab initio MO calculation: At the MP2/6-311++G(d,p)//HF/6-31+G(d) level of theory the deprotonation enthalpy ($\Delta H°$) of H_2SO_4 at 0 K was obtained as 1300 kJ mol^{-1}.[17e]

To obtain accurate gas-phase acidities for the most important of the above-mentioned species *at identical levels of theory*, we calculated the energies of nine acids HA and their corresponding anions A$^-$ at the G2 level of theory, which had formerly been shown to provide reliable acidity data for sulfur compounds, and agree with the best experimental values within ca. 8 kJ mol^{-1}.[21] In addition, the CBS-Q and G2(MP2) methods were applied to all species, since these more economical levels of theory will be used exclusively in two upcoming publications on several larger sulfur oxo acid molecules such as thiosulfuric acid, polythionic acids and polysulfuric acids. In this way a comparison of data for different acids will be possible, as well as a discussion of trends in acidities as a function of molecular structure. Since the gas-phase acidity has been defined in the literature as either $\Delta G°_{298}$ or $\Delta H°_{298}$ of the deprotonation reaction, we also calculated both values for the systems investigated.

Calculations

Ab initio molecular orbital calculations were performed at the CBS-Q,[22] G2(MP2),[23] and G2[24] levels of theory with the GAUSSIAN program system.[25] The G2 method essentially implies an energy calculation at the QCISD(T)/6-311+G(3df,2p) level using geometries optimised at the MP2(full)/6-31G(d) level. Harmonic vibrational wavenumbers were obtained at the HF/6-31G(d) level and were scaled by a factor of 0.8929. All the vibrational eigenvalues of all the molecules investigated were positive. The G2(MP2) method is a modified version of G2 but uses the second-order Møller–Plesset perturbation theory (MP2) for the basis set extension correction rather than the fourth order (MP4). The G2(MP2) method is almost as accurate as the G2 method, but at a substantially reduced computational expense. The excellent performance of these methods and also of CBS-Q in predicting gas-phase acidities of small molecules is well established.[26]

In some cases {[H$_2$,S,O$_3$] and [H$_2$,S,O$_4$]} geometries were calculated with MP2 in combination with the 6-311++G(3df,2p) basis sets. The thermal corrections (no scaling) were obtained using even this level for [H$_2$,S,O$_3$] and less expensive MP2/6-311G++(d,p) calculations for [H$_2$,S,O$_4$]. Then the energies were improved by QCISD(T)/

6-311++G(3df,2p) single point calculations. In addition to the procedures described above, the MP4/6-311++G(d,p) level of theory was applied to the smallest system [H_2,S,O] to optimise the structures.

For details of the quantum chemical methods, see ref.[27] All calculations were carried out on a Cray J90 or on a Linux workstation. To allow for the thermal corrections to the Gibbs free energy of the proton, a value of –0.010654 hartree (–28 kJ mol^{-1}) was used.

Compounds of Composition [H_2,S,O]

To obtain reliable geometries of the three acids H–S–O–H, $H_2S{=}O$, and $H_2O{\rightarrow}S$, as well as of their anions H–O–S$^-$ and H–S–O$^-$, these structures were optimised at the MP4/6-311++G(d,p) level; the results are shown in Table 1. The absolute enthalpies and Gibbs free enthalpies of the species mentioned were calculated by the CBS-Q method based on MP2/6-31G(d′) geometries as well as by the G2(MP2) and G2 methods based on MP2/6-31G(d) geometries. Vibrational wavenumbers and thermal energies were obtained at the HF/6-31G(d′) [CBS-Q] and HF/6-31G(d) [G2(MP2) and G2] levels, respectively. The results are presented in Table 2, and the relative stabilities are shown in Table 3. The stabilities of the acids decrease in the order HSOH > H_2SO > H_2OS. In the case of the anions, HOS$^-$ is more stable than HSO$^-$.

Table 1. Geometries of the acids HSOH, H_2SO, and H_2OS and of their anions HOS$^-$ and HSO$^-$, optimised at the MP4/6-311++G(d,p) level (internuclear distances in pm, bond angles and torsion angles in degrees)

Species	Symmetry	*d*(SH)	*d*(SO)	*d*(HO)	α(OSH)	α(SOH)	τ(HOSH)
HSOH	C_1	134.3	170.1	96.4	97.4	106.7	94.0

HOS$^-$	C_s	–	182.4	96.1	–	101.2	–
HSO$^-$	C_s	137.7	162.1	–	105.9	–	–

Table 2. Enthalpies and Gibbs free energies (negative a. u.) of the acids HSOH, H_2SO, and H_2OS and of their anions at 298 K

	Species	CBS-Q	G2(MP2)	G2
H°	HSOH	474.044601	474.027258	474.035959
	H_2SO	474.018747	474.001229	474.008258
	H_2OS	473.983262	473.966092	473.976418
	HOS$^-$	473.483768	473.463909	473.474246
	HSO$^-$	473.475996	473.457653	473.466741
G°	HSOH	474.072204	474.054902	474.063603
	H_2SO	474.045904	474.028399	474.035427
	H_2OS	474.011289	473.994117	474.004443
	HOS$^-$	473.510585	473.490747	473.501084
	HSO$^-$	473.502920	473.484578	473.493666

All geometrical parameters listed in Table 1 have reasonable values. The most stable isomer HSOH is an intermediate between disulfane, HSSH, and hydrogen peroxide, HOOH, and in fact the torsional angle of HSOH (τ = 94°) has a value intermediate between those which have been determined for HSSH (90°)[28] and HOOH (112°).[29] The S–O bond length of 170 pm agrees reasonably well with the experimental value in gaseous CH_3–O–S–S–O–CH_3 (165.3 pm),[30] whose S–O bonds may be considered to be standard single bonds. As expected, the SO bond in the sulfoxide $H_2S{=}O$ (151.1 pm) is much shorter, but, surprisingly, in the "water sulfide" H_2OS (196.6 pm) it is much longer. The latter may therefore be considered to be a donor–acceptor complex of a water molecule and a sulfur atom, symbolised by $H_2O{\rightarrow}S$. Remarkably, the OH bond lengths of $H_2O{\rightarrow}S$ (96.6 pm) and HSOH (96.4 pm) are practically identical, while the SH bond lengths of HSOH (134.3 pm) and $H_2S{=}O$ (137.9 pm) differ substantially. Otherwise, the pyramidal structures of H_2SO and H_2OS are similar, as can be seen from the similar bond angles HSO (109.3°) versus HOS (107.9°). The angles HSH (86.6°) and HOH (105.8°) are similar to those in H_2S (92.1°) and H_2O (104.5°).

Table 3. Relative enthalpies and Gibbs free energies (kJ mol^{-1}) of the acids HSOH, H_2SO, and H_2OS and of their anions HOS$^-$ and HSO$^-$

Species	CBS-Q		G2(MP2)		G2	
	$\Delta H°_{298}$	$\Delta G°_{298}$	$\Delta H°_{298}$	$\Delta G°_{298}$	$\Delta H°_{298}$	$\Delta G°_{298}$
HSOH	0	0	0	0	0	0
H_2SO	68	69	68	70	73	74
H_2OS	161	160	161	160	156	155
HOS$^-$	0	0	0	0	0	0
HSO$^-$	20.4	20.1	16.4	16.2	19.7	19.4

The two isomeric anions differ remarkably in their SO bond strength as indicated by the differing S–O bond lengths of 182.4 pm for the more stable isomer HOS$^-$ and 162.1 pm for HSO$^-$. The latter value suggests that the SO bond has some double-bond character.

Table 4. Gas-phase acidities (kJ mol^{-1}) of HSOH, H_2SO, and H_2OS at 298 K

Species	CBS-Q		G2(MP2)		G2	
	$\Delta H°_{298}$	$\Delta G°_{298}$	$\Delta H°_{298}$	$\Delta G°_{298}$	$\Delta H°_{298}$	$\Delta G°_{298}$
HSO*H*	1499	1467	1502	1469	1501	1468
*H*SOH	1479	1447	1485	1453	1481	1449
H_2SO	1431	1398	1433	1400	1428	1394
H_2OS	1318	1287	1325	1294	1325	1294

The acidities of the three compounds of composition [H_2,S,O] are given in Table 4, both as the reaction enthalpies and the Gibbs free reaction enthalpies of the deprotonation at 298 K. The acidities increase in the order HSO*H* < *H*SOH < H_2SO < H_2OS. The value of $\Delta H°_{298}$ = 1481 kJ mol^{-1}, obtained for *H*SOH at the G2 level, perfectly agrees with the only available experimental value (see Introduction). The fact that *H*SOH is a stronger acid than HSO*H* is due to the stronger OH bond of the latter, but also due to the higher stability of the anion HOS$^-$ which is formed on deprotonation of *H*SOH. On the other hand, H_2OS is a much stronger acid than H_2SO since the rather weak SO bond of H_2OS is turned into the rather strong SO bond in HOS$^-$. In contrast, the strong SO bond of H_2SO

changes on deprotonation to the weaker SO bond in HSO^-. Therefore, H_2SO ($\Delta G°_{298}$ = 1394 kJ mol^{-1}) is as strong a proton donor as nitrous acid HNO_2 ($\Delta G°_{298}$ = 1396 kJ mol^{-1}) while H_2OS ($\Delta G°_{298}$ = 1294 kJ mol^{-1}) is as strong as hydrogen iodide HI ($\Delta G°_{298}$ = 1294 kJ mol^{-1}).[31] The acidities obtained at the CBS-Q and G2(MP2) levels (Table 4) differ by 0.5% or less from the G2 data.

Compounds of Composition [H_2S,O_2]

The geometries of the four most stable acids of composition [H_2,S,O_2], HOSOH (C_2), HOSOH (C_s), HS(O)OH, and $H_2S(O)_2$, are well-known at the MP2(full)/6-31G(d) level[6a] and have not been refined any further in this work. The absolute enthalpies and Gibbs free enthalpies of these species of their anions $HS(O)O^-$ and $HOSO^-$ are given in Table 5; the relative stabilities are presented in Table 6. Compared to the previous work, the order of relative stabilities has not changed. The acidities of the three representative structures are shown in Table 7.

Table 5. Enthalpies and Gibbs free energies (negative a. u.) of the acids HOSOH, $H_2S(O)_2$, and HS(O)OH, and of their anions $HOSO^-$ and HSO_2^-, at 298 K

Table 7. Gas-phase acidities (kJ mol^{-1}) of HOSOH, $H_2S(O)_2$, and HS(O)OH at 298 K

Species	CBS-Q		G2(MP2)		G2	
	$\Delta H°_{298}$	$\Delta G°_{298}$	$\Delta H°_{298}$	$\Delta G°_{298}$	$\Delta H°_{298}$	$\Delta G°_{298}$
HOSOH	1465	1426	1468	1430	1465	1426
$H_2S(O)_2$	1359	1324	1359	1325	1356	1321
HS(O)O*H*	1391	1359	1395	1363	1393	1361
*H*S(O)OH	1447	1412	1449	1414	1442	1406

The most stable isomer HOSOH (C_2 symmetry) is of lowest acidity ($\Delta G°_{298}$ = 1426 kJ mol^{-1}), comparable to hydrogen cyanide, HCN ($\Delta G°_{298}$ = 1420 kJ mol^{-1}). The chain of C_s symmetry is by only 3 kJ mol^{-1} less stable and therefore of practically identical acidity. The asymmetric species HS(O)OH is, by 23 kJ mol^{-1}, less stable than HOSOH (C_2). The OH acidity of this acid ($\Delta G°_{298}$ = 1361 kJ mol^{-1}) is, by 45 kJ mol^{-1}, higher than its SH acidity. This is because the anion $HS(O)O^-$ is more stable than $HOSO^-$. The least stable of the isomers considered here, the tetrahedral molecule $H_2S(=O)_2$ ($\Delta G°_{298}$ = 1321 kJ mol^{-1}) is as strong an acid as trifluoroacetic acid, CF_3COOH ($\Delta G°_{298}$ = 1324 k] mol^{-1}). No experimental acidity data on [H_2,S,O_2] compounds are available for comparison, but it is obvious now that the acidities based on the earlier MP4/6-31G(d)//MP2(fu)/6-31G(d) calculations which were mentioned in the Introduction are too low by 55–90 kJ mol^{-1}.

Sulfurous Acid, $(HO)_2SO$, and Sulfonic Acid, $HS(O)_2OH$

Although sulfurous acid is mentioned in all inorganic chemistry textbooks, its gas-phase geometry has never been studied on a correlated level of theory. The best previous data for $(HO)_2SO$ and $HS(O)_2OH$ are those by Squires,[10b] calculated with the HF/6-31++G(d,p) basis set. The situation for the anions is better: their geometries were determined at the MP2/6-311+G(2df,p) level.[10c] Therefore, we have optimised the structures of the two acids and their anions at the MP2/6-311++G(3df,2p) level. The results are shown in Table 8 The bond lengths of the acids differ by up to 2%, the bond angles by up to 3° and the torsion angles by up to 6° from the best previous data.

The molecule $(HO)_2SO$ can exist as two conformers which both have positive vibrational eigenvalues at all levels of theory investigated. These species are termed as *syn,syn* (**1a**) and *syn,anti* (**1b**) to indicate the orientation of the OH groups (see Figure 1). Their molecular symmetries are C_s and C_1, respectively. The cage-like molecule **1a** represents the global minimum on the energy hypersurface, but **1b** is only slightly less stable (Table 9).

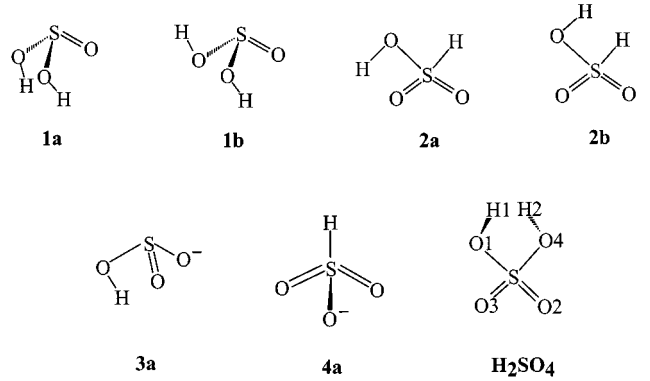

Figure 1. Conformation of the acids of composition [H_2,S,O_3] and of their anions, as well as numbering of atoms in the H_2SO_4 molecule

In a similar fashion, the molecule $HS(O)_2OH$ exists as a *syn* (**2a**) and an *anti* conformer (**2b**) which both are of C_1 symmetry. However, **2b** has one negative eigenvalue of the

Hesse matrix if the vibrational data are calculated at the MP2(full)/6-31G(d) level. At the MP2/6-311++G(d,p) level all eigenvalues are positive, but the lowest wavenumber is only 12 cm^{-1}. Furthermore, the MP2/6-311++G(3df,2p) energy of **2b** was found to be higher, by 6 kJ mol^{-1}, than that of **2a** (at 0 K without ZPE correction). Therefore, the species **2b** will not be considered further. The relative enthalpies and Gibbs free enthalpies are listed in Table 10.

Deprotonation of **1a** and **1b** may theoretically result in two conformations of the anion $HOSO_2^-$, but only one (**3a** in Figure 1) has all eigenvalues positive. This species is of C_1 symmetry. Deprotonation of **2a** at the oxygen atom results in the C_{3v} symmetric anion HSO_3^- (**4a**) which is more stable than **3a** (Table 10).

The gas-phase acidities of sulfurous and sulfonic acids were calculated before,[6h][10] but only ΔH values were given. Our data in Table 11 agree with the previous results, but in addition we present $\Delta G°$ values as well as the results obtained at the QCISD(T) level. There is a very good agreement between these different levels of theory. We therefore trust that the theoretical data are reliable; the following data of sulfurous acid **1a** seem to be the best: $\Delta H°_{298} = 1361$, $\Delta G°_{298} = 1326$ kJ mol^{-1}. An experimental deprotonation enthalpy of $\Delta G°_{298} = 1377 \pm 13$ kJ mol^{-1} was reported by Squires.[10b] However, this author already discussed the possibility that the decomposition of sulfurous acid during the mass spectrometric measurement may be responsible for the deviation of the experimental value from his theoretical result ($\Delta H°_{298} = 1380$ kJ mol^{-1}) obtained at the MP4(sdq)/6-31++G(d,p)//HF/6-31++G(d,p) level.

Table 11. Gas-phase acidities (kJ mol^{-1}) of $(HO)_2SO$ and $HS(O)_2OH$ at 298 K

Species	CBS-Q		G2(MP2)		G2		QCISD(T)	
	$\Delta H°_{298}$	$\Delta G°_{298}$	$\Delta H°_{298}$	$\Delta G°_{298}$	$\Delta H°_{298}$	$\Delta G°_{298}$	$\Delta H°_{298}$	$\Delta G°_{298}$
$(HO)_2SO$	1355	1320	1361	1327	1358	1324	1361	1326
$HS(O)_2O\mathit{H}$	1303	1275	1310	1282	1307	1279	1312	1284
$\mathit{H}S(O)_2OH$	1326	1287	1327	1290	1322	1287	1328	1291

As the data in Table 11 show, the acidity of sulfurous acid matches that of trifluoroacetic acid ($\Delta G°_{298} = 1324$ kJ mol^{-1}) and that of nitric acid HNO_3 ($\Delta G°_{298} = 1330$ kJ mol^{-1}), while sulfonic acid is even stronger: the SH acidity is comparable to that of hydrogen iodide, HI, ($\Delta G°_{298} = 1294$ kJ mol^{-1}) and the

OH acidity is close to that of metaphosphoric acid, HPO_3 ($\Delta G°_{298}$ = 1270 kJ mol^{-1}).[31]

Sulfuric Acid, H_2SO_4

The highest level of theory at which the acidity of H_2SO_4 has been studied previously was MP2/6-311++G(d,p)//6-31+G(d).[17e] Structure calculations were carried out at the MP2(full)/6-31+G(d)[17c] and MP2/6-311+G(d,p)[32] levels of theory. In addition, density functional calculations at the B3LYP/6-311++G(2d,2p) level were published.[33] We have recalculated the structure at the MP2/6-311++G(3df,2p) level, and compare the results with the experimental structure in Table 12. There is a remarkably good agreement between the two sets of data. The bond lengths differ by less than 1%, and the bond angles by less than 1.5°. Only the two torsion angles HOSO deviate by ca. 8° from the experimental values. The geometrical parameters of the hydrogen sulfate anion calculated at the same level are also given in Table 12.

Table 12. Calculated geometry of H_2SO_4 (C_2) and of its anion HSO_4^- (C_s, *trans*) optimised at the MP2/6-311++G(3df, 2p) level; comparison with the experimental structure (internuclear distances in pm, bond angles and torsion angles in degrees); for numbering of atoms, see Figure 1

[a] Ref.[16]

The energies of H_2SO_4 and its monoanion were calculated by the standard CBS-Q, G2(MP2), and G2 methods (Table 13). However, it was found that the minimal energy conformation of the anion depends on the basis set. At the MP2(fu)/6-31G(d) [G2] level a conformation of C_1 symmetry was found as the global minimum. At the higher levels MP2/6-31G(d′) [CBS-Q], MP2/6-311++G(d,p), and MP2/6-311++G(3df,2p), the only energy minimum found was that of a structure of C_s symmetry, characterised by a *trans* configuration of the four atoms HOSO located in the plane of symmetry. Therefore, the energies of H_2SO_4 and HSO_4^- were also calculated at these levels. To check whether the calculated acidities can be improved further, we carried out QCISD(T)/6-311++G(3df,2p) energy calculations. However, the results were practically identical with those at the G2 and G2(MP2) levels. These calculated acidities of H_2SO_4 at 298 K perfectly agree with the experimental value measured at 368 K (Table 14).

Discussion

In Figure 2, the acidities of the nine investigated oxo acids of sulfur are listed and compared with the acidities of well-known inorganic and simple organic proton donors. The weakest of the

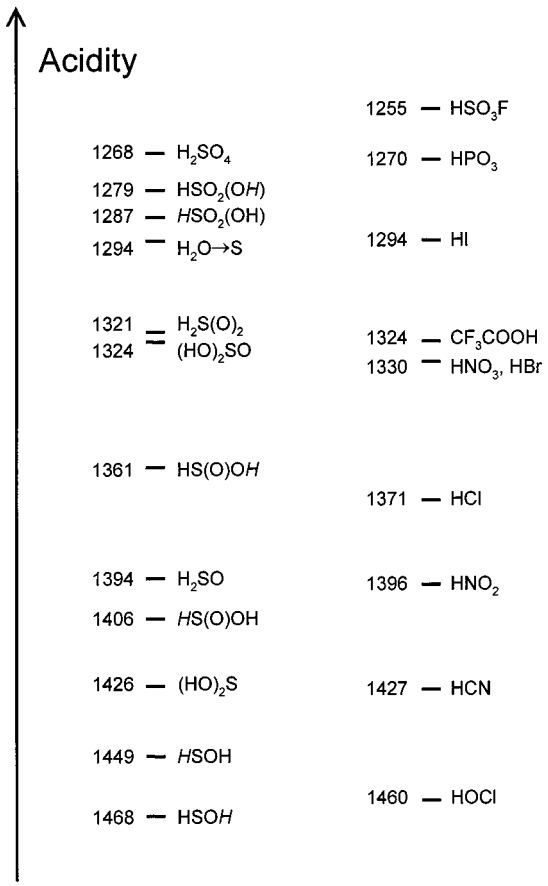

Figure 2. Gas-phase acidities of the sulfur oxo acids [$H_2S_nO_n$] (n = 1–4) relative to the acidities of other inorganic and organic proton donors; the values of $\Delta G°_{298}$ (kJ mol^{-1}) for the deprotonation reaction are given

sulfur acids (sulfenic acid HSO*H*) is as weak a proton donor as HOCl, while sulfuric acid is the strongest of the sulfur oxo acids investigated in this work.

From Figure 2 it can be seen that there is no simple relationship between the oxidation number of the sulfur atom and the OH or SH acidities. The oxidation numbers vary between 0 and +6. However, if only compounds that are structurally related are compared, a clear trend is seen, namely that higher acidities are found with increasing sulfur oxidation number (or number of oxygen atoms). This is demonstrated by the examples shown in Table 15.

Table 15. Influence of the number of oxygen atoms on the gas-phase acidities of sulfur oxo acids

Series (n = 0–2)	Species	$\Delta G°_{298}$ [kJ mol^{-1}]
$H_2S(=O)_n$	H_2S	1443
	$H_2S{=}O$	1394
	$H_2S(=O)_2$	1321
$(HO)_2S(=O)_n$	$(HO)_2S$	1426
	$(HO)_2S{=}O$	1324
	$(HO)_2S(=O)_2$	1268
$HS(=O)_nOH$	*H*SOH	1449
	*H*S(=O)OH	1406
	*H*S(=O)$_2$OH	1287

A surprising result of this study is the rather high acidities of some of the so-called lower oxo acids of sulfur, such as sulfurous acid $(HO)_2SO$ and, in particular, of sulfonic acid, $HS(O)_2OH$, which is almost as strong as sulfuric acid. Even the S*H* acidity of this acid is higher than that of all the hydrogen halides. In the vapour phase these two oxo acids are unstable with respect to H_2O and SO_2, but their formation in the earth′s atmosphere (acid rain) and in certain industrial processes is out of question, since the anions $HOSO_2^-$ and HSO_3^- are stable and these must be in equilibrium with the corresponding acids. If any of the two acids is formed from the corresponding anion, its decomposition into H_2O and SO_2 may be hindered by a substantial energy barrier, as the mass spectrometric observation of $(HO)_2SO$[11] demonstrates.

Several authors have tried to model the behaviour of sulfur oxo acids in water by calculating these molecules inside of or connected to a cluster of water molecules.[33][34] It seems that this is a promising procedure to obtain acidities for aqueous solutions by purely theoretical methods. We will report such calculations on the lower oxo acids of sulfur in a separate publication.

Summary

Nine sulfur oxo acids of composition $[H_2,S,O_n]$ with n = 1–4 were investigated by ab initio MO calculations at the CBS-Q, G2(MP2), and G2 levels of theory, to obtain the enthalpies and Gibbs free energies of the deprotonation reactions in the gas phase at 298 K. As expected, sulfuric acid is the strongest and sulfenic acid HSO*H* is the weakest proton donor. The OH acidity of sulfonic acid, $HS(O)_2OH$, is only slightly lower than that of sulfuric acid, while sulfurous acid, $(HO)_2SO$, is about as strong as nitric acid, $HONO_2$, or hydrogen bromide, HBr. The elusive water → sulfide, $H_2O \rightarrow S$, is also a strong proton donor, comparable to hydrogen iodide, HI. These results are of relevance to the chemistry of sulfur compounds in the earth's atmosphere, where species such as H_2S are oxidised by oxygen atoms, hydrogen peroxide or ozone to give various oxo acids of sulfur. Their acidity then determines the interaction with water molecules which may result in the formation of acid rain and aerosols.[35]

Sulfonamide-Functionalized Gadolinium DTPA Complexes as Possible Contrast Agents for MRI: A Relaxometric Investigation

Pier Lucio Anelli,[a] Ivano Bertini,*[b] Marco Fragai,[b] Luciano Lattuada,[a] Claudio Luchinat,[c] and Giacomo Parigi[c]

Keywords: NMRD / MRI / Contrast agents / Carbonic anhydrase / Sulfonamides

A novel Gd-DTPA derivative with a built-in sulfonamide (SA) was synthesized as a contrast agent for MRI. The complex was designed to selectively target the enzyme carbonic anhydrase. It is shown that the longitudinal relaxation rates of aqueous solutions of Gd-DTPA-SA in the presence of carbonic anhydrase increase significantly. The binding constant is determined to be 15,000 ± 5,000 M^{-1}. This value ensures substantial formation of the carbonic anhydrase adduct at imaging concentrations of Gd-DTPA-SA. The complex interacts with erythrocytes, presumably due to a high affinity for the carbonic anhydrase present on the outer surface of the latter. This takes place even though the enzyme has a low abundance and is easily saturated by small amounts of Gd-DTPA-SA. The interaction of Gd-DTPA-SA with serum proteins is negligibly small. Therefore, the complex could potentially be tested as a selective contrast agent for compartments outside the blood pool.

Introduction

Contrast agents for MRI are characterized by their large nuclear relaxation capability for the protons of water molecules. In general, a complex of a paramagnetic metal ion, typically gadolinium(III) with seven unpaired electrons, is bound to at least one water molecule, which exchanges rapidly with bulk water. In imaging fields, the gadolinium complex relaxes the protons of the coordinated water at rates ranging from 10^5 s^{-1} for small molecules to 10^6 s^{-1} for macromolecules, whereas the protons of bulk water relax at about 0.4 s^{-1}. If the coordinated water exchanges at a rate of the order of 10^6 s^{-1} or faster, it transfers significant relaxation enhancements to bulk water. This enhancement is what is measured in relaxometry and determines the properties of the contrast agent.[1–3]

Besides low-toxicity requirements, the development of a good contrast agent aims at achieving two major objectives: (i) the increase of the rotational correlation time, τ_r, with respect to the value relative to small complexes, in order to increase the relaxation rates of protons in the perfused tissues, and (ii) the localization of the contrast agent with a larger concentration in some compartments with respect to others nearby. Both requirements can be satisfied by synthesizing a molecule with an efficient targeting system that is able to provide interactions between the agent and specific macromolecular receptors. Such interactions will be regulated by a binding constant, that should be high enough to maximize the effect of the contrast agent even if administered in low doses. Binding constants of the order of 10^4 M^{-1} are large enough to ensure good affinity. The ideal binding constant should also ensure a residence time that is long enough for the MRI acquisition but not so long as to appreciably increase toxicity, as it might happen if the binding constant were much higher.[4]

Organic moieties attached to the complex favor the interaction of the contrast agent with biological molecules or tissues. Three important examples of contrast agents of this class are Gd-BOPTA,[5,6] Gd-EOB-DTPA,[7] and MS-325,[8] which are able to bind noncovalently to serum albumin and can thus highlight the uptake of the gadolinium complex by hepatocytes. Contrast agents have also been proposed to be used as reagents for quantitative in vitro assays, as, for example, Gd-DTPA derivatives containing boronic residues, which should be able to bind to glycated proteins.[9]

Another strategy was used to detect regions in the body or cells where certain enzymes are concentrated. For example, if a gadolinium complex is covalently bound to a galactopyranose residue, so that the access of water to the paramagnetic center is sterically blocked, β-galactosidase, if present, cleaves this bond and thus may expose gadolinium to the solvent.[10] Wherever β-galactosidase is present, the magnetic resonance image is then improved by the contrast agent. If a contrast agent is functionalized with a molecule that is able to specifically react with an enzyme, the contrast agent targets the enzyme and any enzyme-rich tissue. Examples are sulfonamides, which are known to be specific inhibitors of carbonic anhydrase (CA) and have been widely used in medical therapy.[11,12] Carbonic anhydrase is a zinc enzyme present in various tissues in variable amounts.[11] Therefore, different tissues may exhibit different behavior depending on the presence of the enzyme and its accessibility, which could be altered during pathologic processes.[13] Therefore, by synthesizing a Gd-DTPA contrast agent with a sulfonamide (SA) at-

tached, binding to carbonic anhydrase and relaxation enhancement may be expected.

In this paper, we describe the synthesis of a contrast agent functionalized with the sulfonamide ethylene sulfanilamide (Gd-DTPA-SA). The molecule is shown to bind carbonic anhydrase effectively in vitro with a suitable binding constant and to display a sizable relaxation enhancement. Although not designed as a blood-pool reagent, Gd-DTPA-SA shows a small relaxation enhancement in intact blood with respect to serum, probably as a consequence of its interaction with the small amount of carbonic anhydrase bound to the outside of the erythrocyte membranes.[14]

Results and Discussion

NMRD Characterization of the Gd-DTPA-SA Complex

The paramagnetic relaxivity profile of Gd-DTPA-SA in an aqueous solution at 298 K is shown in Figure 1 (open circles). It is obtained by subtracting the diamagnetic contribution of the solvent relaxation rate in the absence of the paramagnetic compound, R_{1dia}, from the total relaxation rate of the solution, R_1, and normalizing to 1 mM Gd-DTPA-SA.

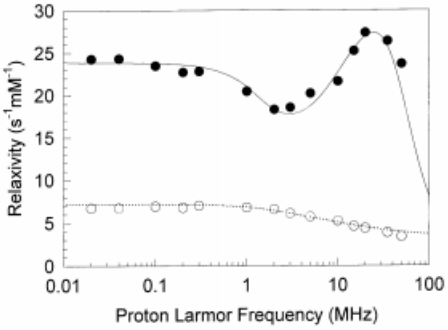

Figure 1. Proton ^{1}H-NMRD profiles of a Gd-DTPA-SA solution at 298 K in the absence (open circles) and in the presence (filled circles) of carbonic anhydrase (1.36 mM); the dotted and the solid lines represent the best fit profiles of the two sets of data

The relaxivity profile of Gd-DTPA-SA appears to be qualitatively and quantitatively very similar to the relaxivity profile of Gd-DTPA.[1] Only one inflection is present, centered at about 10 MHz, corresponding to the ω_s dispersion (where ω_s is the electron Larmor frequency in rad s^{-1}). The data were fitted by taking into account both the outer- and inner-sphere contributions; for comparative purposes, the resulting parameters are reported together with those of Gd-DTPA[1,15,16] (Table 1). The best fit profile is reported as a dotted line in Figure 1. The fit was made by keeping the parameters determining the outer-sphere contribution (the distance of closest approach, d, and the diffusion coefficient, D_{diff}) constant. Two protons were fitted at a distance of about 3 Å, the values of the other parameters being in agreement with those expected from the results of similar complexes,[5,7,15–22] including the increase in the exchange time between bulk and coordinated protons, τ_m, on passing from the binegative Gd-DTPA to the mononegative Gd-DTPA-SA complex.[23]

NMRD Characterization of the Gd-DTPA-SA–Carbonic Anhydrase Complex

Increasing concentrations of CA were added to the Gd-DTPA-SA solution in order to estimate the binding capability of the Gd-DTPA-SA complex. Relaxation measurements of such solutions were performed at 0.02, 0.15, 10, and 15 MHz. Monitoring the field dependence of water proton relaxation allows a better characterization of the parameters responsible for relaxation. Figure 2 shows the water proton longitudinal relaxation rates for solutions with different CA concentrations at 0.02 MHz. A 1:1 binding is assumed as sulfonamides are well known to interact specifically with the catalytic metal ion and the active site of the enzyme in a 1:1 fashion.[13] The data were fitted according to Equations 4–6, and a value for the binding constant of 15,000 ± 5000 M^{-1} was found. The relaxivity of the adduct, R_{add}, was found to be 25.8 s^{-1} mM^{-1} at 0.02 MHz.

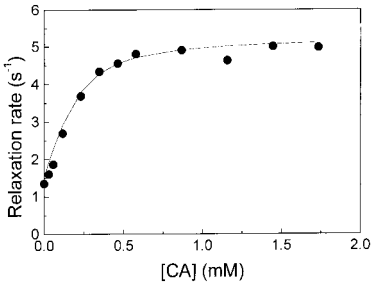

Figure 2. Titration curve of a solution of Gd-DTPA-SA (0.2 mM) with carbonic anhydrase at 0.02 MHz and 298 K

Then, the NMRD profile of a 0.2 mM Gd-DTPA-SA solution with a CA concentration of 1.36 mM (pH 8.1, 298 K) was obtained. This CA concentration ensured that the gadolinium complex was fully bound to CA. The relaxation rate values, after subtraction of the diamagnetic contribu-

[Gd-DTPA-SA]-CA	12,000	18	0.56	0.017	2	3.0	0.008	3.6	2.6

[a] In the adduct, this value is estimated from the Stokes' equation and kept constant in the fitting procedure. – [b] This value is kept constant in the fitting procedure. – [c] The transient ZFS parameter was introduced to fit the NMRD profile of the adduct only, as it was found not necessary to fit the free complex profile. – [d] From refs. [1, 15, 16]

tion of CA at the same temperature and normalization to 1 mM, are reported in Figure 1 (filled circles). The introduction of CA both increases the relaxivity values and modifies the shape of the profile. The profile now exhibits three inflections: the first (centered at about 1 MHz) can be attributed to the ω_s dispersion, the second (centered at about 10 MHz) is the result of the field-dependent electron relaxation (see below), and the third inflection, for frequencies greater than 30 MHz, is related to the ω_I dispersion (ω_I indicates 2π times the proton Larmor frequency). This behavior is due to a dramatic change in the correlation time for the proton relaxation, given by the shortest time among rotational (τ_r), exchange (τ_m), and electron relaxation (τ_e) time, according to Equation 1.[24]

$$\tau_c^{-1} = \tau_r^{-1} + \tau_m^{-1} + \tau_e^{-1} \quad (1)$$

The rotational correlation time can be estimated from the Stokes-Einstein equation (Equation 2).

$$\tau_r = \frac{4\pi a^3 \eta}{3kT} \quad (2)$$

where a is the radius of the spherical-modeled molecule, η is the viscosity of the solvent, k is the Boltzmann constant and T indicates the temperature. The value of τ_r varies from $\simeq$70 ps for the free complex to $\simeq$12,000 ps for the bound complex (MW $\simeq$30,000). Therefore, τ_r is the dominant correlation time for the nuclear relaxation (according to Equation 1) in the Gd-DTPA-SA solution,[21,25] but it loses its influence when the CA adduct is formed.[21,25] τ_m is likely to be longer, as verified a posteriori (see below). In this case, τ_c is given by the electron relaxation time only and is calculated according to the Bloembergen-Morgan equation (Equation 3).[15,26,27]

$$\tau_e^{-1} = \frac{2\Delta_t^2 (4S(S+1)-3)}{50}\left(\frac{\tau_v}{1+\omega_s^2\tau_v^2} + \frac{4\tau_v}{1+4\omega_s^2\tau_v^2}\right) \quad (3)$$

where ω_s is the electron Larmor frequency, S is the electron spin quantum number, τ_v is the correlation time for electron relaxation and Δ_t^2 is the average quadratic transient zero field splitting.[28] The decay of the electron relaxation rate as a function of the magnetic field is responsible for the peak relaxivity in the 10–50 MHz region of the proton relaxation rate. Therefore, the occurrence of this peak in the high field part of the NMRD profile confirms the presence of binding between Gd-DTPA-SA and CA. The profile was fitted (solid line in Figure 1) and the resulting best-fit parameters are reported in Table 1. With τ_r being fixed at such a large value that it is negligible in the calculation of the correlation time, the fitting procedure provides values of τ_v, τ_m, and Δ_t close to those obtained for other Gd-DTPA derivatives bound to HSA.[7,21,29,30] It should be noted, in particular, that the value of τ_m is almost the same after binding and, in any case, is longer than τ_e. From the fitting, τ_m is the limiting factor for the relaxivity peak between 10–50 MHz. As required for many protein–Gd complex adducts, the effect of a small static zero-field splitting (D) was introduced so that the profile could be reproduced better.[21]

The NMRD measurements show a good binding capability of Gd-DTPA-SA with carbonic anhydrase. The binding constant is 15,000 M^{-1}, compared to 300 M^{-1} for Gd-BOPTA and HSA, 700 M^{-1} for Gd-DTPA-EOB and HSA, or 1,700 for Gd-DOTA-$(BOM)_3$ and HSA.[30] This binding constant ensures that the carbonic anhydrase adduct is largely formed at imaging concentrations. As previous studies have shown,[13] the large value of the binding constant of sulfonamides for CA is accompanied by favorable life times of the gadolinium complex–protein adduct of the order (of a few hours).

The relaxivity of the gadolinium complex at 1 T increases from about 3.5 $mM^{-1}s^{-1}$ when free to about 25 $mM^{-1}s^{-1}$ when bound to the protein. Such an increase is comparable to that of other Gd complexes when they are completely bound to the HSA present in solution.[29] However, such an increase does not occur at the imaging concentration of other Gd complexes (Gd-BOPTA, Gd-EOB-DTPA) because of their relatively small binding constants.[6]

Measurements in Intact Blood

Experiments on human blood were performed to test whether it was possible to detect binding of Gd-DTPA-SA to the small amount of carbonic anhydrase present on the surface of the red cells. Different concentrations of Gd-DTPA-SA were added to human blood samples (and to human serum samples as controls) and relaxation measure-

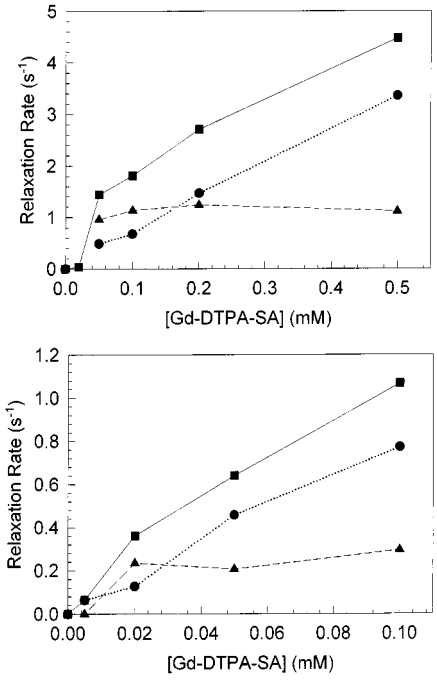

Figure 3. Paramagnetic enhancement in the proton relaxation rate measured in human blood (solid lines) and in serum (dotted lines) as a function of the Gd-DTPA-SA concentration at 0.02 MHz (A) and 50 MHz (B) at 298 K; the differences in relaxation rate between blood and serum are reported as dashed lines

ments at proton Larmor frequencies of 0.02, 0.15, 1.2, 35, and 50 MHz (corresponding to about 0.0005, 0.004, 0.03, 0.8, and 1.2 T) were performed. A small enhancement in proton relaxation was observed. The results obtained at two frequencies (0.02 and 50 MHz), decreased by the diamagnetic contributions, are shown in Figure 3, together with the difference between the paramagnetic enhancements in blood and serum. The low field measurements are more reliable, since the differences detected are much larger with respect to the instrumental precision. The measurements performed at the imaging fields are affected by larger errors, but provide the same indications as the low field experiments. The plots indicate that the Gd complex is bound in the blood sample, while it is free in the serum sample. This is shown by the higher initial increase of relaxation in the blood sample compared to the serum sample. The difference in the two samples levels off to an approximately constant value above Gd concentrations of 0.02–0.04 mM, where the increase in the relaxation rates is linear with the concentration in both blood and serum samples. Presumably, this behavior is a consequence of the saturation of the available carbonic anhydrase on the membranes of the red cells.

Conclusions

We have shown that a Gd-DTPA derivative targeted to bind to carbonic anhydrase in vivo has the desired fundamental properties in terms of binding constant and relaxation enhancements. We have also shown that the compound does not appreciably interact with any soluble macromolecule in serum, and that the amount of carbonic anhydrase present on the outer erythrocyte membranes is too small (although detectable through its enhancement) to block this reagent in the blood pool. Therefore, Gd-DTPA-SA is a potential candidate for in vivo tests for specificity in various tissues outside the blood pool.

Experimental Section

Materials: Carbonic Anhydrase (lyophilized powder from bovine erythrocytes, MW 30000) was purchased from Sigma. *N,N*-Bis(2-{bis[2-(1,1-dimethylethoxy)-2-oxoethyl]amino}ethyl)glycine was supplied by Bracco S.p.A. Human blood and serum were treated with lithium-heparin to prevent coagulation.

Synthesis of Ligands: A schematic summary of the synthesis of Gd-DTPA-SA is reported in Figure 4. *p*-Ethylaminesulfonamide II (236 mg, 1.18 mmol) was added to 20 mL of a DMF solution of *N,N*-bis(2-{bis[2-(1,1-dimethylethoxy)-2-oxoethyl]amino}ethyl)-glycine I (730 mg, 1.18 mmol). Upon the dropwise addition of 0.2 mL of DEPC [$(EtO)_2P(O)CN$] (215 mg, 1.32 mmol), the reaction mixture was maintained at 3 °C using an ice bath. Triethylamine (0.204 mL, 149 mg, 1.48 mmol) was then added slowly to the solution. The reaction was followed by TLC by observing the depletion of the free sulfonamide (R_f = 0.1) and the appearance of the product (R_f = 0.45) with the eluent $CH_2Cl_2/CH_3OH/NH_4OH$ (9:1:0.1). After 10 minutes the amine had fully reacted and the solution was warmed up and allowed to stand at room temperature for 30 minutes. DMF was then removed by vacuum evaporation. The crude product was washed and phase separated in ethyl acetate (33 mL) with a sodium bicarbonate (2 × 25 mL) and saturated sodium chloride solution (2 × 20 mL). Product III (838 mg, yield 89%) was obtained. Its purity was confirmed by using TLC (R_f = 0.45). Its ^{1}H-NMR spectrum was recorded in $CDCl_3$. – ^{1}H NMR: δ = 1.40 (s, 36 H, tBu), 2.4–2.7 (m, 8 H, N–CH_2–CH_2–N), 2.95 (s, 2 H, Ph–CH_2), 3.05 (s, 2 H, N–CH_2–CO), 3.3 (s, 8 H, N–CH_2–COO), 3.5–3.6 (m, 2 H, N–CH_2), 5.6 (s, 2 H, SO_2NH_2), 7.3–7.9 (m, 4 H, Ph), 8.2–8.3 (m, 1 H, NH).

Product III (838 mg, 1.05 mmol) was dissolved in 6 N HCl (8 mL). The mixture was stirred at room temperature for 1 hour and was then washed with CH_2Cl_2 (2 × 10 mL). The aqueous solution was dried and 671 mg (0.98 mmol, yield 93%) of pure compound IV were obtained. An ^{1}H-NMR spectrum was recorded in D_2O. – ^{1}H NMR: δ = 2.8–2.9 (m, 4 H, N–CH_2–CH_2–N), 3.1–3.0 (m, 4 H, N–CH_2–CH_2–N), 3.4–3.3 (m, 2 H, CH_2–Ph), 3.4–3.6 (m, 4 H, N–CH_2–CO–N–CH_2), 4.0 (s, 8 H, N–CH_2–CO), 7.4–7.9 (m, 4 H, Ph).

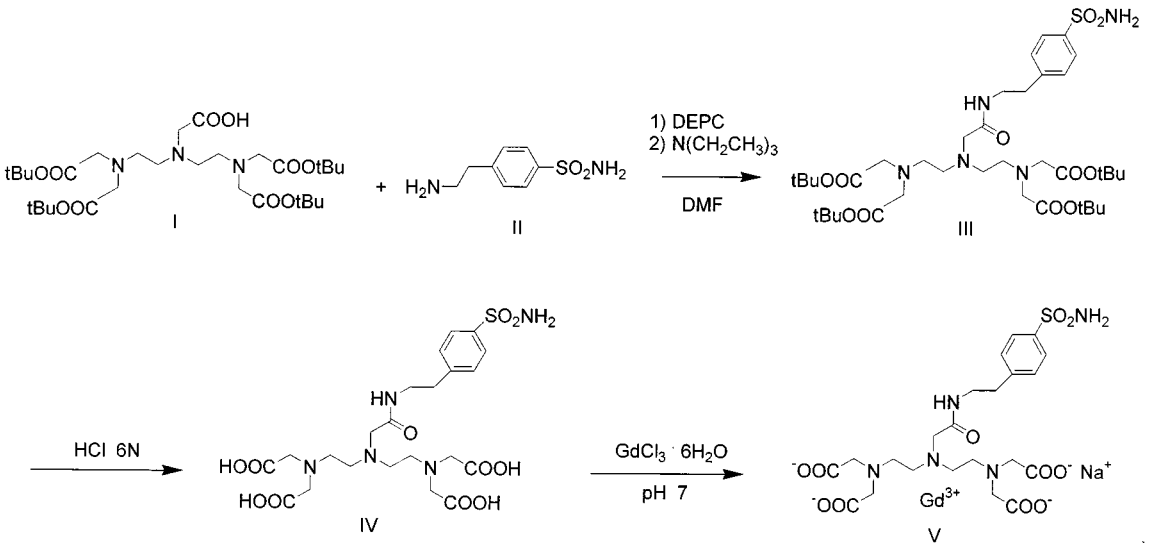

Figure 4. Schematic summary for the synthesis of Gd-DTPA-SA

Complexation and Purification of IV: The complexation and purification procedures follow a protocol already reported.[31] Compound IV (671 mg, 0.98 mmol) was dissolved in 27 mL of distilled water. To this solution 1 N NaOH was added until pH 7 was reached. An aqueous solution (5 mL) of $GdCl_3 \cdot 6H_2O$ (379 mg, 0.98 mmol) was then added slowly, maintaining a pH of 7 by addition of further aliquots of 1 N NaOH. The final crude product V (1.0 g) was obtained by evaporating the solution.

It was dissolved in 10 mL of distilled water and then loaded onto an Amberlite® XAD 1600 resin column (100 mL) and eluted with a CH_3CN/H_2O (9:1) gradient. The fractions containing the complex were evaporated to give 674 mg (0.86 mmol, yield 88%) of the crystalline white product V [negative ion FAB 729 $(M - Na)^-$].

The data collected on a large number of mono and bisamide derivatives of DTPA indicate that these compounds are remarkably stable with respect to dissociation in vivo. Therefore, the same stability is expected for our compound.[4]

Nuclear Magnetic Relaxation Dispersion Experiments: ^1H Nuclear Magnetic Relaxation Dispersion (NMRD) profiles were obtained by plotting the proton relaxation rates, R_1, as a function of the applied magnetic field. The NMRD profiles and all longitudinal water-proton relaxation rate measurements were collected with a Stelar prototype fast field cycling relaxometer or with a Koenig-Brown field cycling relaxometer[25,32] in the 0.01–50 MHz proton Larmor frequency range. Both instruments provide measurements with an error of about ±1%.

NMRD data, with the diamagnetic contribution subtracted, were analyzed according to existing theories, using a program described in ref.[33]

Determination of the Binding Constant: The observed relaxivity R_{obs} is the sum of the contributions from the free GdL complex and the GdL-CA adduct[30,34]

$$R_{obs} = \frac{C_{GdL} - [GdL - CA]}{C_{GdL}} R_{free} + \frac{[GdL - CA]}{C_{GdL}} R_{add} \quad (4)$$

with

$$[GdL\text{-}CA] = \frac{1 + K_A(C_{GdL} + C_{CA}) - \sqrt{(1 + K_A(C_{GdL} + C_{CA}))^2 - 4K_A^2 C_{GdL} C_{CA}}}{2K_A} \quad (5)$$

and

$$K_A = \frac{[GdL\text{-}CA]}{(C_{GdL} - [GdL\text{-}CA])(C_{CA} - [GdL\text{-}CA])} \quad (6)$$

where K_A is the binding constant, C_{GdL} and C_{CA} represent the initial concentrations of both GdL and CA, and R_{free} and R_{add} are the relaxivity of the free complex and the fully bound complex, respectively. Both K_A and R_{add} have been obtained through a two-parameter fitting of the R_{obs} data measured at various CA concentrations. The concentration of the gadolinium complex was 0.2 mM at pH 8.1.

[28] It is possible that some restricted motion of the bound complex characterized by a correlation time shorter than τ_e may contribute another spectral density term (see ref.[36]) However, the satisfactory fitting performed assuming negligible restricted motion (see below) suggests that this effect, if present, is minor.

Second Harmonic Generation and Two-Photon Fluorescence as Nonlinear Optical Properties of Dipolar Mononuclear Sesquifulvalene Complexes

Hans Wong,[a] Timo Meyer-Friedrichsen,[a] Tony Farrell,[a] Christoph Mecker,[a] and Jürgen Heck*[a]

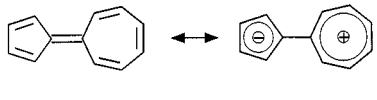
Dedicated to Prof. Dr. Dr. eh. Dr. h.c. H. Sinn on the occasion of his 70th birthday

Keywords: NLO materials / Second harmonic generation / Two-photon fluorescence / Solvatochromism / Electrochemistry / Sesquifulvalene / Sandwich complex

In order to investigate nonlinear optical properties, in particular second harmonic generation (SHG) of organometallic complexes, numerous dipolar monocationic sesquifulvalene complexes of the general form $[Mc-Z-C_7H_6]^+$ have been synthesised (Mc = metallocenyl), wherein the metallocenyl moiety Mc acts as an electron donor, and the tropylium cation $C_7H_6^+$ as an electron acceptor. The mutual electronic influence of the donor and the acceptor groups is warranted by a linking spacer Z, which is a single bond [Mc = $CpFeC_5H_4$ (**4a**); Mc = $CpRuC_5H_4$ (**4b**)], an unsaturated bridge containing olefins [Z = $(E\text{-CH=CH})_n$: n = 1, Mc = $CpFeC_5H_4$ (**25a**); Mc = $CpRuC_5H_4$ (**25b**); n = 2, Mc = $CpFeC_5H_4$ (**26**); n = 3, Mc = $CpFeC_5H_4$ (**27**)], or thiophene units [Z = 2,5-C_4H_2S, Mc = $CpFeC_5H_4$ (**28**); Z = 5,5′-(2,2′-$C_4H_2S)_2$, Mc = $CpFeC_5H_4$ (**29**); Z = 2-(5-*E*-CH=CH)C_4H_2S, Mc = $CpFeC_5H_4$ (**30**)]. For the salts of **4a**·BF_4, **4b**·PF_6 and **25a**·PF_6 X-ray structure determinations have been performed [**4a**·BF_4: orthorhombic, *P*nma, a = 21.75(2), b = 9.900(2), c = 6.881(3) Å, V = 1482.0(15) Å^3, Z = 4; **4b**·PF_6: monoclinic, $P2(1)/c$, a = 8.104(3), b = 18.206(14), c = 11.228(4) Å, β = 107.59(3), V = 1579.1(15) Å^3, Z = 4; **25a**·PF_6: triclinic, $P\bar{1}$, a = 10.067(6), b = 10.496(6), c = 11.418(6) Å, α = 94.07(4), β = 110.96(4), γ = 102.88(5)°, V = 1083.1(11) Å^3, Z = 2]; the solid state structures indicate an almost coplanar arrangement of the organic π-system. Cyclic voltammetry studies reveal an irreversible one-electron reduction and an electrochemically reversible one-electron oxidation step for the ferrocenyl derivatives, whereas the ruthenocenyl derivatives demonstrate an irreversible two-electron oxidation. The redox potentials clearly indicate that the oxidation occurs at the metallocene unit, and the reduction is localised on the tropylium entity. In the electronic absorption spectra two intense bands are observed in the region $400 < \lambda < 900$ nm which undergo strong negative solvatochromic shifts. The origin of the high-energy absorption band is assumed to be an interligand charge-transfer (LL−CT) transition, and the low-energy absorption band is assigned to a donor-acceptor charge-transfer (DA−CT) transition. Whereas the LL−CT is continuously shifted to lower energy with increasing spacer length, the energy of the DA−CT approaches a limiting value. A comparable phenomenon is also observed for the difference between the oxidation and reduction potentials obtained from electrochemical studies. Investigations concerning the nonlinear optical properties of the dipolar cationic sesquifulvalene complexes by means of hyper-Rayleigh scattering (HRS) indicate that the ferrocenyl derivatives fluoresce due to two-photon absorption whereas the ruthenocenyl congeners exhibit second harmonic generation with considerably large first hyperpolarizability which is partly resonance-enhancement based.

Introduction

Materials showing nonlinear optical (NLO) properties have potential applications in photonic devices i.e. for optical data acquisition, storage, transmission and processing. The most prominent NLO features are frequency doubling or even tripling [second and third harmonic generation (SHG and THG)] of incident light, the linear electro-optical effect (Pockels effect) which describes the change of the refractive index of matter with the strength of an applied external electric field, and photorefractivity.[1]



An important class of compounds capable of frequency doubling is composed of an electron donor (D), an acceptor (A) and a π-bridge providing the electronic communication between the donor and acceptor. Such D-π-A compounds are highly polarizable and experimental NLO studies on this kind of organic compounds in a molecular arrangement, incorporated in a polymer, or used as a self-assembled monolayer indeed reveal large SHG effects.[1−3] Our approach to NLO chromophores has been to synthesise organometallic sesquifulvalene-type complexes suitable for SHG, whose NLO properties are characterised by the first hyperpolarizability β. The special features of organometallic complexes have been well documented,[4−6] and include fine-tuning of the molecular polarisation, tailoring of the crystal formation, or fixing additional functional groups as docking spots in supramolecular chemistry.

Very often the change-transfer (CT) states which are very important to achieve high β values (vide infra), can be represented by polar resonance forms[1a] and this also holds for sesquifulvalene (**1**). Although it can be described in terms

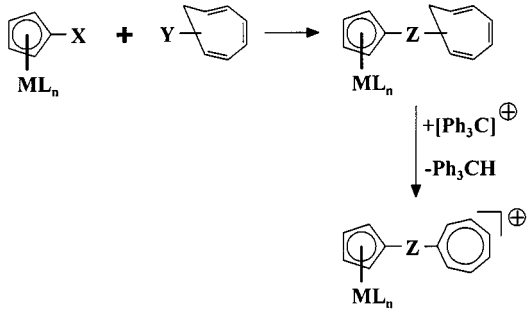
of two resonance forms of different polarities (Scheme 1), sesquifulvalene behaves like a polyene with alternating bond lengths,[7] and its ground state is thus best described by the nonpolar resonance form **A**. Upon excitation charge separation occurs and the resulting structure is likely to be related to the polar resonance form **B**.

1

Scheme 1. Resonance forms of sesquifulvalene (**1**)

Calculation of the first hyperpolarizability β[8][9] of **1** confirms a change in the dipole moment on excitation, but the high reactivity of **1**[10] prevents the experimental determination of its NLO properties. In previous papers we reported the NLO properties of sesquifulvalene-type complexes wherein both aromatic termini of the resonance form **B** are coordinated to metal centres (**2a**, **2b**).[11]



The objective of the present work was to stabilise only the five-membered ring of the aromatic units in **1** by coordination to (η^5-cyclopentadienyl)iron and -ruthenium. Hence, the neutral five-membered ring moiety of the sesquifulvalene complex would act as an electron donor whereas the uncoordinated tropylium cation would behave as an electron accepting group. Such a molecular arrangement creates a dipolar structure in the ground state, which could change upon excitation. Additionally, it was proposed to introduce various bridging functions Z, i.e. olefins and thiophenes, in order to modulate the interaction between the five- and seven-membered ring (**3**). Thiophenes are often used because of their superior thermal stability, and because of their lower resonance stabilisation energy relative to other aromatic spacers. The former HRS studies on the ethenediyl bridged heterodinuclear complex **2b** revealed a large first hyperpolarizability β.[11] It is well-known from dipolar organic NLO chromophores that increasing the number of π-bonds by one between the donor and acceptor increases the experimental β value by a factor of 1.5−2. Therefore the introduction of additional double bonds between the five- and seven-membered ring of the sesquifulvalene complexes appeared to be a very promising endeavour to improve the NLO properties. Just recently, NLO results of related mononuclear sesquifulvalene complexes with a cymantrenyl entity [ML_n = $Mn(CO)_2L$; L = CO, PR_3] instead of MCp as the electron donating group have been published wherein the donor is directly coupled to the tropylium cation or separated by an ethynediyl linker.[12] Thus it would be worthwhile to compare the two families of mononuclear sesquifulvalene complexes concerning their NLO properties.

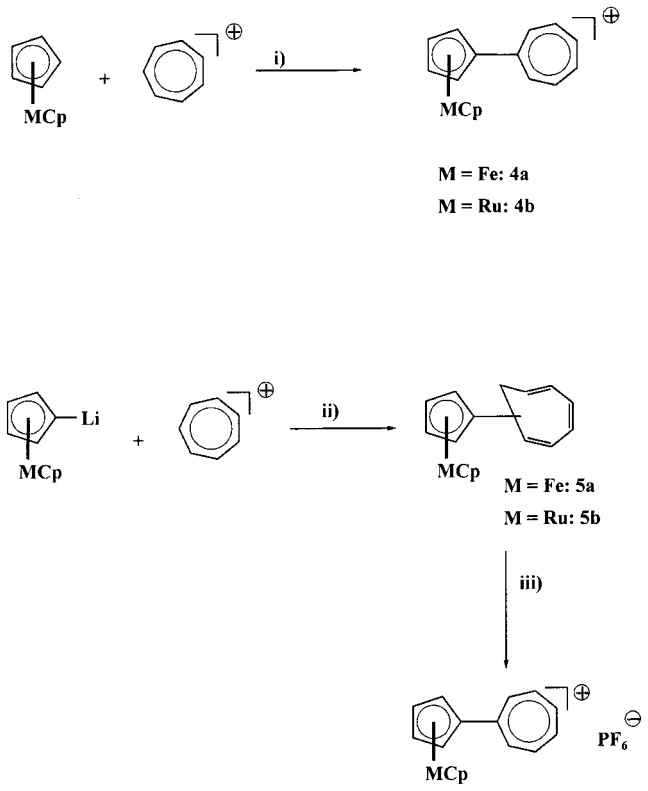
Results and Discussion

Synthesis

The general strategy to form the desired cationic mononuclear sesquifulvalene complexes was the coupling of functionalised metallocenes with the corresponding cycloheptatriene derivatives to obtain the neutral mononuclear monohydro-sesquifulvalene precursor. The monohydro-sesquifulvalene complexes were converted into the mononuclear cationic sesquifulvalene species by hydride abstraction (Scheme 2).

Scheme 2. General strategy for the synthesis of cationic mononuclear sesquifulvalene complexes

Complexes Without a π-Linker (Z = Single Bond)



The first published route to the archetypal mononuclear sesquifulvalene complex with the metallocenyl substituent directly linked to the tropylium cation (Z = single bond: **4a**, **4b**) was the electrophilic substitution reaction of ferrocene with the tropylium cation (Scheme 3, i).[13] This method is also applicable to ruthenocene under more vigorous conditions.

However, our experience with the electrophilic substitution reaction revealed difficulties in the purification of the products **4a** and **4b** which were polluted with $[C_7H_7]^+$. Additionally, **4a** was contaminated with paramagnetic impurities which were not easy to remove. Therefore, the nucleophilic addition of monolithiated metallocene[14] to the tropylium cation was preferred yielding the neutral complexes **5a** and **5b** (Scheme 3, ii). The formation of the cationic complexes **4a** and **4b** was subsequently achieved by the reaction of **5a** and **5b** with $[Ph_3C][PF_6]$ (vide infra).

Complexes With Olefinic Linkers [Z = (*E*-CH=CH)$_n$, *n* = 1, 2, 3]

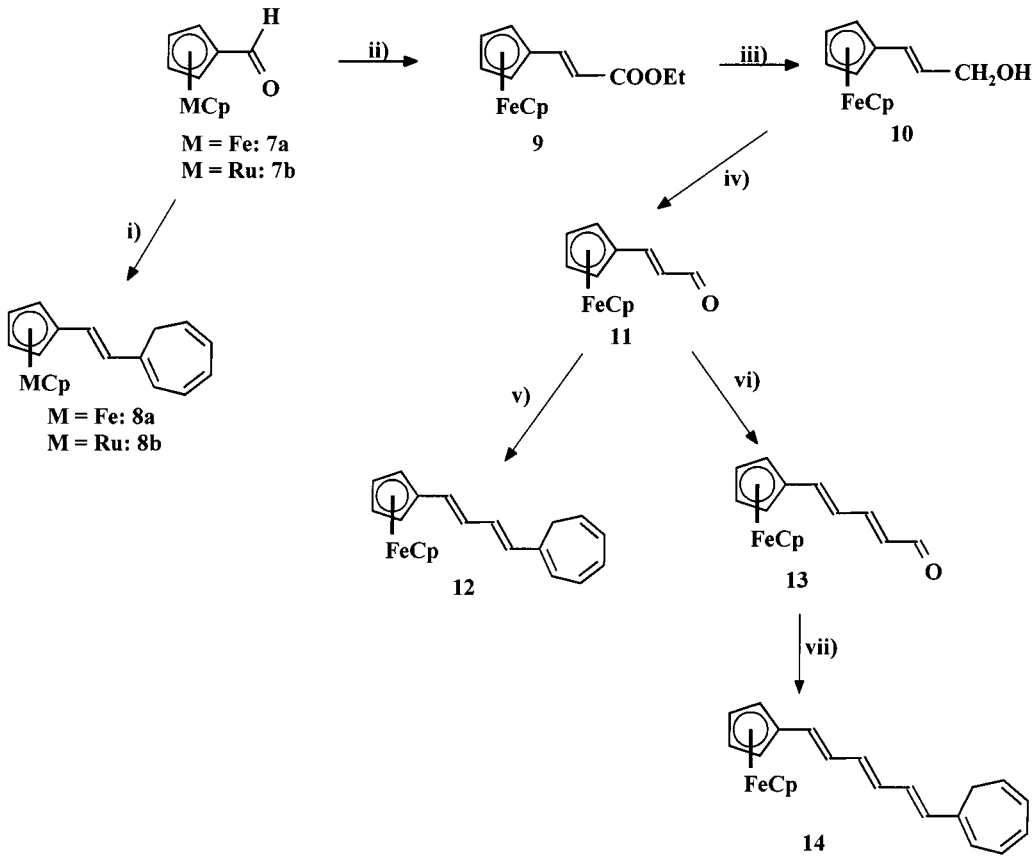
The introduction of one, two or three double bonds between the five- and seven-membered rings was afforded by

Wittig-type reactions of different formyl metallocenes with nucleophiles of the corresponding cycloheptatrienes. Since deprotonated phosphonates are known to react more stereoselectively than phosphoranes in the formation of *E*-olefins,[15] (cycloheptatrienylmethyl)diethylphosphonate (**6**) was prepared in a Michaelis-Arbuzov reaction from 1-chloromethyl-1,3,5-cycloheptatriene.[16] For $n = 1$ the phosphonate **6** underwent a Wittig-Horner-Wadsworth-Emmons (WHWE) reaction in the presence of NaH with the formyl metallocene (M = Fe: **7a**; M = Ru: **7b**[17]) to form the neutral compounds **8a** and **8b** (Scheme 4, i). The elongation of the olefinic bridge (Scheme 4, ii−vii) could be performed by the reaction of the formyl metallocenes **7a** and **7b** with (ethoxycarbonylmethyl)diethylphosphonate in a WHWE reaction. The reduction of the formed ester **9** by $LiAlH_4$ yielded the alcohol **10** which was oxidised with $BaMnO_4$[18] to the vinylogous metallocenyl carbaldehyde **11**. The aldehyde **11** was reacted either with **6**, yielding the cycloheptatrienyl derivative **12**, or was further subjected to the elongation sequence to form the dienyl formyl derivative **13**, which was then linked to the seven-membered ring to give the neutral complex **14**.

Scheme 3. Formation of the monometallic sesquifulvalene complexes **4a** and **4b**: (i) M = Fe, MeCN, reflux; M = Ru, 1,2-$C_2H_4Cl_2$, reflux; (ii) Et_2O, −20°C; (iii) CH_2Cl_2, $[Ph_3C][PF_6]$

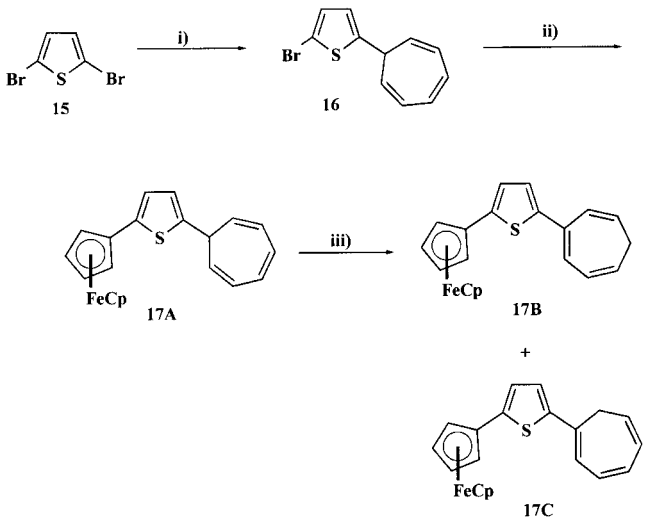
Complexes With Thiophene Linkers {Z = 2,5-C_4H_2S or 5,5′-[2,2′-$(C_4H_2S)_2$]}

Another preparatively convenient method to warrant the electronic interaction in dipolar NLO chromophores upon elongation of the dipole is the use of thiophenes as π-linkers.[19−21] These types of complexes have been synthesised starting from 2,5-dibromothiophene[22] (**15**) (Scheme 5). Lithium-bromine exchange and subsequent nucleophilic addition to the tropylium cation led to the formation of 2-bromo-5-cycloheptatrienylthiophene (**16**).[23] Compound **16** was allowed to react with ferrocenyl zinc chloride[24] in a cross-coupling reaction[25] affording a mixture of isomers **A**, **B** and **C** of the monothiophene species **17** (Scheme 5). Thermolysis of the mixture only revealed the isomers **B** and **C** (40:60), which facilitated the final hydride abstraction (vide infra).



The elongation of the 2,5-thienylene bridge by an additional thiophene unit has been achieved in a Ni-catalysed cross-coupling reaction[26] of the Grignard reagent 2-thienyl magnesium bromide (**18**) with **16** resulting in the formation of the bithiophene derivative **19**[27] (Scheme 6). The bithiophene **19** was lithiated, followed by a zinc-lithium exchange and cross-coupled with iodoferrocene,[14] subsequently yielding the bithiophene bridged monohydro-sesquifulvalene complex **20** as the isomer **A**, which was thermally isomerized to **B**.

Complexes With a Vinylenethienylene Linker [Z = 2-(5-*E*-C_2H_2)C_4H_2S]



A third way to extend the π-bridge was the combination of an olefinic bond and a thiophene forming a vinylenethienylene bridge.[28] These types of bridges between the donor and an acceptor moiety are easy to synthesise by the formylation[29] of 2-cycloheptatrienylthiophene (**21**),[25] to form compound **22**. Subsequent Wittig reaction of **22** with (ferrocenylmethyl)triphenylphosphorane (**23**)[30][31] afforded the vinylenethienylene-bridged mononuclear monohydro-sesquifulvalene complex **24** (Scheme 7) as a mixture of *E* and *Z* isomers, each of which consisted of two further isomers differing in the position of the sp^3-carbon atom in the seven-membered ring. The isomers were not isolated as, after the hydride abstraction, only one isomer was formed (vide infra).

Formation of the Cationic Sesquifulvalene Complexes

All the sesquifulvalene complexes described above were subjected to hydride abstraction by adding trityl cation to a solution of the neutral complexes (Scheme 8), and was accompanied by a dramatic change in colour from orange-red to deep violet-blue indicating a strong enhancement in the electronic communication between the metallocene and the cationic tropylium entity. All the cations were fully characterised except the cationic sesquifulvalene complex **27** which suffers from a limited stability in solution and in solid state which prevented complete analysis.

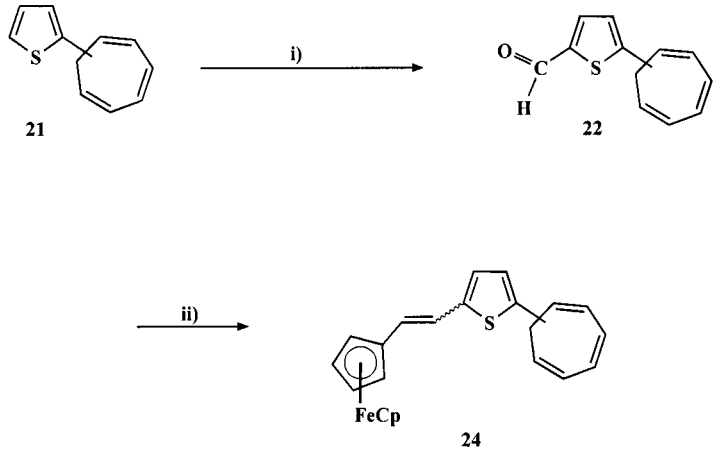
Structural Results

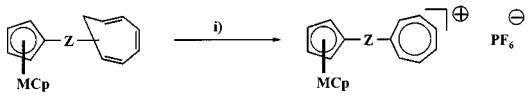


A very important conclusion of the studies on the structural parameters and molecular factors governing the NLO properties, in particular the first hyperpolarizability β, is the correlation between the bond length alternation (BLA) of olefinic bridged D-π-A systems and (i) the dipole change $\Delta\mu_{eg}$ between the ground and the excited CT state, (ii) the electronic transition moment M^2 of the CT transition, and (iii) the energy ΔE of the CT transition.[32][33]

From the sesquifulvalene complexes **4a**, **4b** and **25a** X-ray structure analyses were performed (Figure 1), although for **25a** the accuracy of the structural analysis, which is absolutely necessary for the discussion of a structure-property relationship, suffered from molecular disorder. Two different molecules in the ratio 70:30 lie in almost identical positions and the uncoordinated carbon-carbon double bonds between the five- and seven-membered rings are in a crossed position to each other (Figure 1). The result of an X-ray structure analysis of **4a** has already been published[34] but with less accuracy than obtained in the present work.

The complexes **4a**, **4b** and **25a** all crystallise in centrosymmetric space groups and hence could not be used in the crystalline state for NLO studies to evaluate the SHG. The crystal structures of **4a**, **4b** and **25a** all reveal a virtually coplanar arrangement of the π-termini of the sesquifulvalene ligand (Figure 1, Table 1) as has already been observed in the cymantrenyl congeners.[12][35] The interplanar angle between the five- and seven-membered ring is less than 5°. Within experimental error, the C−C and C−metal dis-

Scheme 6. Formation of the 5,5′-bithienylene bridged monohydro-sesquifulvalene complex **20**: (i) THF, 2-(C_4H_3S)MgBr (**18**), $NiCl_2$dppe; (ii) 1. THF, −78°C, *n*BuLi, 2. $ZnCl_2$; (iii) THF FcI, $Pd(PPh_3)_4$; (iv) toluene, reflux



Scheme 7. Synthesis of the vinylenethienylene bridged monohydro-sesquifulvalene complex **24**: (i). 1. THF, −78°C, *n*BuLi, 2. DMF; (ii) THF, *n*BuLi, [$FcCH_2PPh_3$]I

tances in the metallocene moieties are very similar to the corresponding structural data of other metallocene derivatives. The C−C bond lengths of the seven-membered ring in **4a** and **4b** show a small but distinct bond alternation suggesting a slight contribution of the polyene resonance structure **A** (vide supra) to the ground state. Concomitantly the C−C bond linking the five- and seven-membered rings is somewhat shorter than expected for a sp^2-sp^2 carbon-carbon bond. Additionally, it is worth mentioning that the vector of the connecting bond between the two π-termini in **4a** and **4b** is slightly tilted towards the metal centre indicating the electron-withdrawing property of the tropylium part[36] (Table 1).

Redox Properties

The ferrocenyl-containing compounds reveal an electrochemically reversible one-electron oxidation (Figure 2) which is anodically shifted with respect to ferrocene. The amount of the anodic shift depends on the length of the π-linker (Table 2). The reduction of the sesquifulvalene complexes occurs in an irreversible one-electron transfer and at very similar potentials as reported for the unsubstituted tropylium cation.[37] The peak potential E_{pc} also depends on the length of the π-connection. Comparable trends in the redox behaviour are observed for the ruthenocenyl-containing complexes, although the oxidation step is normally

Scheme 8. Synthesis of the cationic mononuclear sesquifulvalene complexes by hydride abstraction: (i) CH_2Cl_2, $[Ph_3C][PF_6]$

Electronic Absorption Spectra

The UV/Vis spectra of the complexes under study are comparable in that the spectra consist of two strong absorption bands in the visible region (Figure 3) with the exception of the ruthenocenyl derivatives in which the high energy absorption bands are shifted towards the near-UV. As can be seen from Table 3 the electronic excitations are governed by a strong blue-shift on increasing the solvent polarity. This strong negative solvatochromism indicates that in the ground state the positive charge is more or less localised on the tropylium moiety of the complexes, whereas upon excitation the positive charge is delocalized or even localised on the opposite part of the complex.

Figure 3 demonstrates the influence of the length of the π-bridge on the electronic absorption spectra: whereas the high energy absorption band is still considerably red shifted, when the π-linker is elongated the longer wavelength absorption band moves to a certain value which may be regarded as the merocyanine limit[39][40] of these mononuclear sesquifulvalene complexes. This behaviour is in accordance with the assignment of the low energy absorption

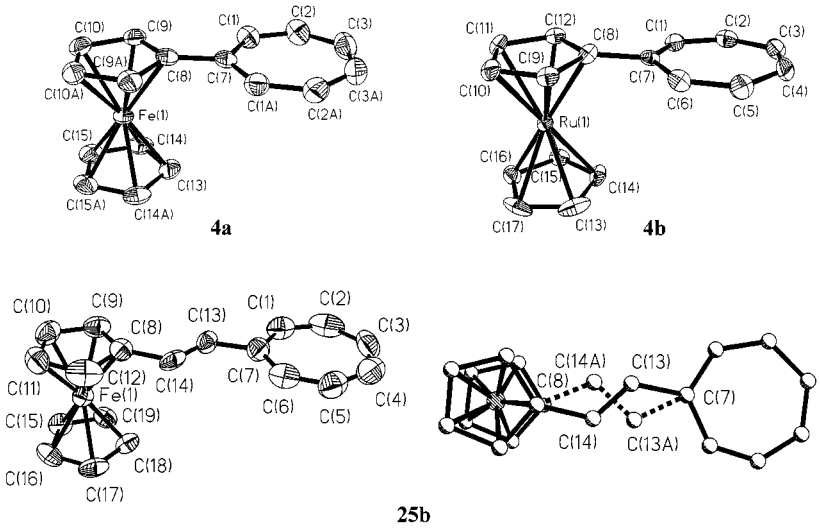

Figure 1. Molecular structures of **4a**, **4b** and **25a** (50% ellipsoids; for **25a** the disordered double bonds are additionally shown (right); the hydrogen atoms, counter ions (BF_4^- and PF_6^-, respectively) and solvent molecules are omitted for clarity)

400−700 mV more anodically shifted (Table 2), and includes an irreversible two-electron transfer.[38] As the π-bridge between the electrophores is extended, the difference of the potentials ΔE between the oxidation and reduction resembles more and more the ΔE value between the oxidation of the free metallocene and the reduction of the unsubstituted tropylium cation.

The electrochemical data make clear that in these sesquifulvalene complexes the nature of the HOMO is still dominated by the neutral donating sandwich units, whereas the character of the LUMO is determined by the cationic tropylium moiety. This combination favours a dipole change upon electronic excitation from the HOMO to the LUMO; ΔE is a relative measure of the energy gap between the HOMO and the LUMO.

band to a donor-acceptor charge transfer (DA−CT) transition. As can be deduced from the electrochemical data the oxidation potential of the ferrocenyl donor continuously approaches the potential of free ferrocene as the π-bridge is extended; similarly, the reduction potential of the acceptor tends towards that of the unsubstituted tropylium cation. Therefore, the energy difference between the donor (HOMO) and the acceptor (LUMO) orbitals has to reach a constant value with increasing π-bridge length, and thus the excitation energy must also reach a limiting value. The close relationship between the electrochemical data and the UV/Vis spectroscopic results is demonstrated by a graphical representation of the ΔE values of the ferrocene-containing complexes as a function of the λ_{max} value of the DA−CT transition (Figure 4).

the organic dye studies in that unusually long-wavelength absorptions are to be expected when the HOMO and the LUMO are located in different parts of the molecule.[40] Additionally, this assignment is corroborated by the relationship of the positions of the absorption bands on the nature of the donor: the absorption band at higher energy is considerably less influenced than the low lying absorption band upon changing the donating capability as demonstrated for **4a**, **4b** and **25a**, **25b**. It is therefore supposed that the higher-lying absorption band is due to an interligand π-π* transition (LL−CT), which also agrees with the dramatic bathochromic shift of this absorption band when the number of double bonds between the five- and seven-membered ring increases. Several theoretical models[2] have been proposed in an attempt to understand and relate the electronic structure of metallocenyl chromophores to their spectroscopic properties. Our assignment of the absorption bands is in excellent agreement with the latest theoretical treatment[2c] and is based on experimental results.

Non-Linear Optical Studies

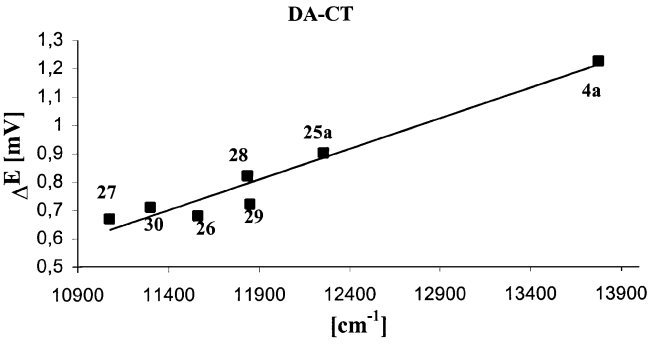

Figure 4. Correlation between the difference of the redox potentials and the λ_{max} values of the DA−CT bands of the ferrocenyl containing sesquifulvalene complexes

and acceptor orbitals, respectively, make sesquifulvalene type complexes most promising NLO candidates. Therefore these complexes were subjected to HRS studies. However, an intrinsic shortcoming of this method may be fluorescence due to two-photon absorption.[41−43]

Using the two-level approximation (Equation 1)[44] to calculate the first hyperpolarizability β indicates that β increases when the energy difference $\Delta E = h\omega_{eg}$ between the ground and the excited states decreases. Nevertheless, in an HRS experiment, the excited state will not be populated although the uptake of two photons of the irradiating frequency ω, and the instantaneous emission of one photon of 2ω will be more probable as the energy $E_{2\omega}$ approaches the energy of the excited state (E_{eg}).[45] When $E_{2\omega}$ equals E_{eg}, the CT state can be populated by the absorption of two photons, whereupon relaxation can occur by means of fluorescence, which may affect considerably the intensity of the measured frequency of the HRS signal (Figure 5).

Since the realisation of the problem of multiphoton absorption-induced fluorescence concerning the determination of first hyperpolarizabilities using the HRS method, several techniques to overcome this problem have been in-

$$\beta\ (-2\omega,\omega,\omega) = \frac{3\Delta\mu g M_{eg}^2}{(\hbar\omega)^2} \cdot \frac{\omega_{eg}^2}{(1-4\omega/\omega_{eg}^2)\cdot(\omega_{eg}^2-\omega^2)} \quad (1)$$

vestigated. These include long wavelength measurement,[47a,47b] time resolved HRS[47c] and the measurement of the two-photon fluorescence spectrum to abstract the fluorescence contribution to the HRS signal.[47d] Recently, Persoons et al.[47e] reported a high frequency demodulating technique to suppress the multiphoton fluorescence contribution to the HRS signal.

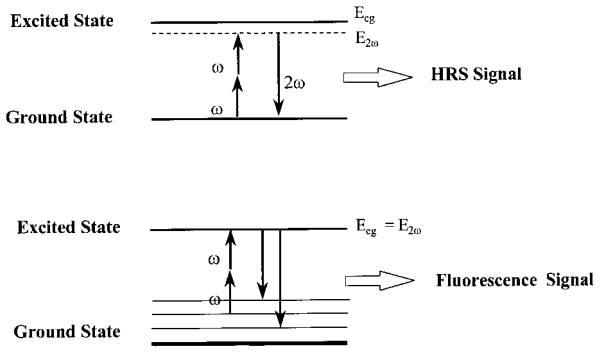

Figure 5. Schematic drawing of the origin of the HRS and the fluorescence signal

In order to check for fluorescence enhancement of the complexes under study we introduced bandpass filters with peak transmittances at different wavelengths in front of the photomultiplier of the HRS set-up.[46] A fluorescence signal should have a very broad line width and a maximum of the emission band which occurs at $\lambda/2$ only by chance.[47d] In sharp contrast to this the line width of the HRS signal is narrow and the maximum has to be fixed. In our investigations we used a Q-switched Nd:YAG laser with λ =

1064 nm, and detected the intensity of the scattered light at $\lambda = 532$ nm to determine the first hyperpolarizability as well as at $\lambda = 400$, 450, 500, 560, 600, 650 and 700 nm to obtain indications of fluorescence.

In Figure 6 the corresponding absorption and emission spectra of the reference *p*-nitroaniline (pNA) are shown corroborating the emission characteristics of the HRS signal of the second harmonic. Comparable HRS signals were recorded for the ruthenocenyl-containing sesquifulvalene complexes **4b** and **25b** as shown in Figure 7, whereas most of the ferrocene derivatives reveal broader emission spectra with a maximum not at $\lambda = 532$ nm (Figure 8), indicating that these ferrocene derivatives exhibit fluorescence. In some cases the solutions of the compounds under study were irradiated at the wavelength of the absorption bands. The failure of any subsequent fluorescence is a strong indication that the fluorescence for the ferrocene derivatives originates from a two-photon absorption.

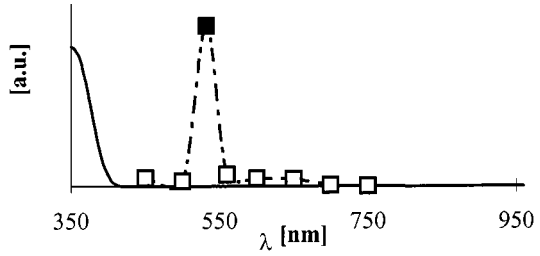

Figure 6. Absorption and emission spectra of the HRS reference *p*-nitroaniline (pNA) (irradiation wavelength $\lambda = 1064$ nm) [squares: λ of measured emission intensities; filled square: position of the HRS signal ($\lambda = 532$ nm)]

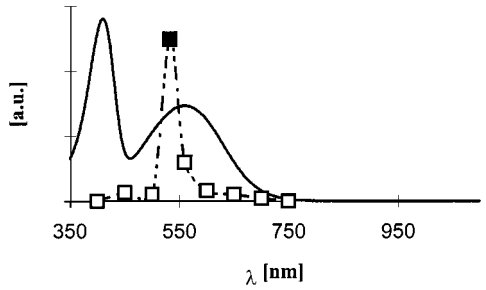

Figure 7. Absorption and emission spectra of the ruthenium sesquifulvalene complex **4b** (irradiation wavelength $\lambda = 1064$ nm; squares: λ of measured emission intensities; filled square: position of the HRS signal ($\lambda = 532$ nm))

In Table 4 the determined β values of the nonfluorescent complexes **4b** and **25b** are shown. Comparing the experimental first hyperpolarizability β and the calculated static hyperpolarizability β_0[50] of **4b** and **25b** it is obvious that the β_0 values are less reliable as the DA−CT maximum approaches the position of the HRS signal. Several features of the estimated β and β_0 values are remarkable:

• As expected from organic NLO chromophores, the first hyperpolarizability increases with increasing chain length (compare **4b** and **25b**). The β and β_0 value of **25b** determined from CH_2Cl_2 and $MeNO_2$ solutions confirm the long wavelength absorption as the DA−CT absorption band and its greater contribution to the first hyperpolarizability. Upon changing the solvent from CH_2Cl_2 to $MeNO_2$ both absorption bands undergo a distinct blue shift, which brings the low energy donor-acceptor absorption band closer to the HRS signal, whereas the LL−CT absorption band is shifted further away; thus, the resonance enhancement is greater for **25b** in $MeNO_2$ than in CH_2Cl_2 solution.

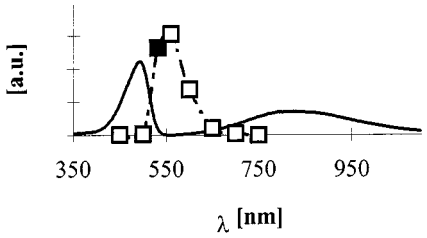

Figure 8. Absorption and emission spectra of the ferrocenyl-containing sesquifulvalene complex **25a** (irradiation wavelength $\lambda = 1064$ nm; squares: λ of measured emission intensities; filled square: position of the HRS signal ($\lambda = 532$ nm))

• These results illustrate that the metallocenes are stronger electron donors than cymantrenyl derivatives.

• Compared to other organometallic mononuclear NLO chromophores with extended π-linkers the results are very promising with regard to the short donor-acceptor distance in the sesquifulvalene-type complexes.

A comparison of the SHG effect between other ferrocenyl complexes[1d,2,36,49] and the corresponding mononuclear sesquifulvalene congeners (**4a**, **25a**, **26**−**30**) is not possible since the latter ferrocene derivatives all show fluorescence. However, our results demonstrate the necessity to check the ferrocenyl-containing D-π-A complexes for fluorescence. Much less work has been performed on NLO chromophores with a ruthenocenyl unit as a donor.[2a, 49] The published data have been obtained from EFISH-measurements at 1.907 μm. In addition to the problem of comparing EFISH and HRS data[41][42] a very recent paper show that first hyperpolarizabilities obtained at different fundamental wavelengths can hardly be compared. However, the β and β_0 values of **25b** listed in Table 4 correspond to values obtained for other sesquifulvalene complexes with ferrocenyl donor units.[11a,51,52]

Conclusions

Various synthetic routes to different dipolar cationic, mononuclear sesquifulvalene complexes, whose application as NLO chromophores appears to be successful, have been reported. Despite the relatively short dipole lengths, strong NLO effects can be obtained which are very promising with respect to longer π-linkers between the neutral donating sandwich and the cationic acceptor group of the seven-membered ring moiety.

Modification of the electronic properties of the donors and acceptors, and of the π-bridge, by chemical means presents the possibility of modulating the NLO properties in-

volving the results of the first hyperpolarizability β and of the influence on the two-photon absorption. The two-photon fluorescence is observed in particular for mononuclear ferrocenyl derivatives possessing low-lying DA–CT and LL–CT transitions, and is not necessarily a disadvantage because of its potential use in devices for NIR detectors and optical data storage.[53]

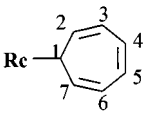
Since the chemical modification of metallocenes, particularly ferrocene, is straightforward,[54] the linkage of the sesquifulvalene-type NLO chromophores to polymers or liquid crystalline phases is quite obvious. On the other hand the presented cationic complexes are amphiphilic; hence, they may also have some potential applications for Langmuir–Blodgett films.

Experimental Section

Manipulations were carried out under a N_2 atmosphere and solvents were saturated with N_2. Tetrahydrofuran (THF), diethyl ether (Et_2O), dimethoxyethane (DME), hexane and toluene were freshly distilled from the appropriate alkali metal or metal alloy. Nitromethane ($MeNO_2$), acetonitrile (MeCN) and dichloromethane (CH_2Cl_2) were dried over CaH_2 and distilled under N_2. NMR: Bruker AM 360 and Varian Gemini 200 BB; UV/Vis: Perkin–Elmer Model 554; IR nujol mull, KBr cells, FT-IR 1720X (Perkin–Elmer); EI-MS: 70 eV, Finnigan MAT 311 A; elemental analysis: Heraeus CHN-O-Rapid, Institut für Anorganische und Angewandte Chemie, Universität Hamburg. Formylferrocene, formylruthenocene,[17] chloromethylcycloheptatriene,[16] $BaMnO_4$,[18] 2-bromo-5-cyclohepta-2′,4′,6′-trien-1-ylthiophene (**16**),[22] 2-cycloheptatrienyl-2′,5-bithiophene (**19**)[26] and 2-formyl-5-cycloheptatrienylthiophene (**22**)[30] were synthesised according to literature procedures.

Ferrocenyltropylium Hexafluorophosphate (4a) and Ruthenocenyltropylium Hexafluorophosphate (4b). – Method A

4a: Ferrocene (1.22 g, 6.56 mmol) and tropylium hexafluorophosphate (0.62 g, 2.62 mmol) were stirred in MeCN (30 mL) for 65 h at room temperature. The reaction mixture was filtered and the deep blue-green filtrate was evaporated to dryness. The residue was extracted with toluene to remove the unreacted metallocene, and redissolved in CH_2Cl_2. The product 4a was precipitated by the addition of diethyl ether. Yield: 0.77 g (69.8%). Generally, the product was contaminated by paramagnetic impurities and $[C_7H_7][PF_6]$. Recrystallisation to obtain pure 4a lowers the yield considerably (for spectroscopic data: see below)



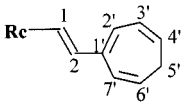
4b: Ruthenocene (0.32 g, 1.4 mmol) and tropylium hexafluorophosphate (0.20 g, 0.85 mmol) were stirred in 1,2-$C_2H_4Cl_2$ (30 mL) at 85°C for 50 h. The workup procedure as described for **4a** yielded 0.25 g (62.8%) of deep blue-violet crystals (for spectroscopic data: see below).

Method B

(Cyclohepta-2,4,6-trien-1-yl)ferrocene (5a): The synthesis of **5a** has been described elsewhere.[11a]

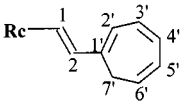
(Cyclohepta-2,4,6-trien-1-yl)ruthenocene (5b): Tropylium hexafluorophosphate (2.60 g, 11 mmol) was added portionwise to a suspension of ruthenocenyl lithium (2.37 g, 10 mmol) in Et_2O (50 mL) at −20 to −30°C. The reaction mixture was allowed to warm slowly to room temperature. After stirring for an additional three hours the solvent was evaporated and the colourless residue extracted with *n*-hexane. The product **5b** was obtained as slightly yellow crystals upon concentration of the hexane extracts. Yield: 2.41 g (75%).

5b: ^1H NMR ($CDCl_3$): δ = 2.28 (t, *J* = 5 Hz, 1 H, H-1), 4.56 (t, 2 H, C_5H_4), 4.57 (s, 5 H, Cp), 4.67 (t, 2 H, C_5H_4), 5.27 (dd, *J* = 3 Hz, *J* = 5 Hz, 2 H, H-2,7), 6.16 (m, 2 H, H-3,6), 6.68 (t, *J* = 3 Hz, 2 H, H-4,5). – ^{13}C NMR ($CDCl_3$): δ = 38.2 (C1), 70.0, 70.6 (C_5H_4, Cp), 94.7 (C_5H_4), 123.6 (C4,5), 127.4 (C2,7), 130.9 (C3,6).



5b

– UV/Vis (CH_2Cl_2): λ_{max}[nm] (ε [M^{-1} cm^{-1}]) 288 (1530), 335 (sh). – EI-MS: *m/z* (%) 322 (80) [M^+ + 1], 321 (100) [M^+]. – $C_{17}H_{16}Ru$ (321.4): calcd. C 63.53, H 5.02; found C 63.45, H 5.13.



(Cyclohepta-1,3,5-trien-1-ylmethyl)diethylphosphonate (6): 1-Chloromethyl-1,3,5-cycloheptatriene[16](10.0 g, 71 mmol) was stirred in triethylphosphite (13.4 mL, 78 mmol) at 166°C for 8 h. After cooling, the reaction mixture was distilled at 2×10^{-2} mbar. Unreacted 1-chloromethylcyclohepa-1,3,5-triene was recovered at 30°C, and the product **6** obtained at 80°C as a yellow oil. Yield: 13.07 g (76%). – ^{1}H NMR (200 MHz, $CDCl_3$): δ = 1.36 (t, 6 H, CH_2CH_3), 2.48 (d, 2 H, C_7H_7), 2.81 (d, J_{PH} = 23 Hz, 2 H, CH_2P), 4.07 (m, 4 H, CH_2CH_3), 5.38–5.49 (m, 1 H, C_7H_7), 6.12 (m, 2 H, C_7H_7), 6.42–6.62 (m, 2 H, C_7H_7). – EI-MS: *m/z* (%) 242 (12) [M^+], 213 (19) [M^+ – Et], 185 (10) [M^+ – 2Et], 105 (40) [$C_8H_9^+$], 104 (100) [$C_8H_8^+$], 91 (23) [$C_7H_7^+$].

1-(Ferrocenyl)-2-(cycloheptatrienyl)ethene (8a): Complex **7a** was first synthesized by a Wittig reaction of formylferrocene[17] with $Ph_3PCH_2C_7H_7$ to yield a *Z*/*E* mixture of products.[11] Pure *E* isomers could be obtained from the WHWE reaction of formylferrocene with the phosphonate **6** as described for the ruthenocenyl derivative below.

1-Ruthenocenyl-2-(cycloheptatrienyl)ethene (8b): To a solution of the phosphonate **6** (0.57 g, 2.3 mmol) in 2 mL THF at –78°C was added *n*BuLi (1.6 mL of a 1.66 M hexane solution). The reaction mixture was allowed to warm to room temperature, stirred for 1 h and cooled down again to –78° C. Subsequently a solution of formylruthenocene (0.53 g, 2 mmol) in 20 mL of THF was added. The reaction mixture was allowed to warm slowly to room temperature. When the reaction, the course of which was monitored by TLC, had finished, the solvent was evaporated in vacuo, and the residue extracted with hexane. The product **8b** was purified by column chromatography (SiO_2/5% H_2O; hexane/Et_2O 1:1). Yield: 514 mg (75%) of **8b**. As can be deduced from the ^{1}H NMR spectra, the product is a mixture of two isomers which differ in the position of the sp^3-carbon atom in the seven-membered ring. The minor isomer (30%) is 1-ruthenocenyl-2-(cyclohepta-1′,3′,6′-trien-1′-yl)-ethene (isomer A), and the main product is 1-ruthenocenyl-2-(cyclohepta-1′,3′,5′-triene-1′-yl)ethene (isomer B). Both isomers are discernible by the splitting pattern of the high field signal of the sp^3 carbon bound protons between 2 and 3 ppm.

A

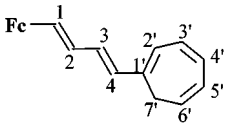
B

^{1}H NMR (200 MHz, $CDCl_3$): δ = 2.32 (t, *J* = 6.6 Hz, 2 H, H-5, isomer A), 2.60 (d, *J* = 7.1 Hz, 2 H, H-7′, isomer B), 4.52 (s, 5 H, C_5H_5), 4.58 (m, 2 H, C_5H_4), 4.79 (m. 2 H, C_5H_4), 5.36–5.54 (m, C_7H_7), 6.12–6.56 (m, C_7H_7, H-1, H-2). – EI-MS: *m/z* (%): 260 (67) [M^+], 232 (100) [$C_{10}H_{10}Ru^+$], 167 (56) [$C_5H_5Ru^+$]. – $C_{19}H_{18}Ru$ (347.4): calcd. C 65.69, H 5.22; found C 65.52, H 5.55.

1-Ferrocenyl-2-(ethoxycarbonyl)ethene (9): To a solution of (ethoxycarbonylmethyl)diethylphosphonate (2.78 g, 12 mmol) in toluene (100 mL) at 0°C was added *n*BuLi (7.8 mL of a 1.6 M hexane solution). Stirring was continued for 1 h, and then the reaction mixture was allowed to warm to room temperature. Subsequently it was cooled to 0°C, and a solution of formylferrocene (2.88 g, 14 mmol) in toluene (20 mL) was slowly added. After stirring for 1 h at room temperature the reaction mixture was hydrolysed and extracted with diethyl ether. The organic layer was dried over $MgSO_4$ and the solvent evaporated in vacuo. The residue was purified by column chromatography (Al_2O_3, neutral, 5% H_2O, hexane/diethyl ether 10:1). Yield: 3.15 g (90%). – ^{1}H NMR (200 MHz, C_6D_6): δ = 1.05 (t, *J* = 7.1 Hz, 3 H, CH_3), 3.48 (s, 5 H, C_5H_5), 3.90–4.10 (m, 2 H, C_5H_4), 4.10–4.20 (m, 4 H, CH_2, C_5H_4), 6.24 (d, *J* = 15.8 Hz, 1 H, H-1), 7.81 (d, *J* = 15.8 Hz, 1 H, H-2).

3-Ferrocenyl-2-propenol-1 (10): To a suspension of $LiAlH_4$ (0.4 g, 11 mmol) and $AlCl_3$ (0.40 g, 3 mmol) in diethyl ether (10 mL) at –10°C was added a solution of 1-ferrocenyl-2-(ethoxycarbonyl)ethene (**9**) (2.56 g, 9 mmol) in 8 mL diethyl ether. After stirring at room temperature for 1 h the reaction mixture was hydrolyzed at 0°C and acidified with dilute sulfuric acid. The product **10** was isolated by extraction with diethyl ether. Yield: 2.01 g (99%). – ^{1}H NMR (200 MHz, C_6D_6): δ = 3.9 (m, 2 H, CH_2OH), 3.98 (s, 5 H, C_5H_5), 4.04 (m, 2H. C_5H_4), 4.19 (m, 2 H, C_5H_4), 5.82 (dt, 1 H, H-2), 6.21 (d, 1 H, H-1).

3-Ferrocenylpropenal (11): Barium manganate(VI) (13.9 g, 54 mmol) was added to a solution of 3-ferrocenylpropenol (**10**) (2.01 g, 8.3 mmol) in dichloromethane (50 mL). After 30 min stirring the suspension was filtered and the filtrate evaporated to dryness. The residue was purified by column chromatography (Al_2O_3, neutral, 5% H_2O, hexane/diethyl ether 5:1). Yield: 1.63 g (82%). – ^{1}H NMR (200 MHz, C_6D_6): δ = 4.17 (s, 5 H, C_5H_5), 4.53 (m, 4H. C_5H_4), 6.34 (dd, $J_{1,2}$ = 7.6 Hz, $J_{2,3}$ = 15.4 Hz, 1 H, H-2), 7.42 (d, $J_{2,3}$ = 15.4 Hz, 1 H, H-3), 9.56 (d, $J_{1,2}$ = 7.6 Hz, H-1).

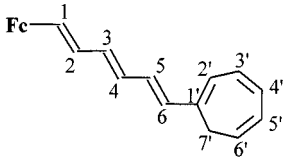


1-Ferrocenyl-4-(ethoxycarbonyl)-1,3-butadiene: The synthesis of 1-ferrocenyl-4-(ethoxycarbonyl)butadiene-1,3 was performed under the same conditions as the synthesis of 1-ferrocenyl-2-(ethoxycarbonyl)ethene (**9**). Quantities used: 1.02 g (4.22 mmol) of (ethoxycarbonylmethyl)diethylphosphonate, 30 mL of toluene, 2.64 mL (4.22 mmol) of *n*BuLi (15% solution in hexane), 1.01 g (4.22 mmol) of 3-ferrocenylpropenal (**11**) in 10 mL of toluene. Yield: 1.10 g (84%). – ^{1}H NMR (200 MHz, C_6D_6): δ = 1.06 (t, *J* = 7.2 Hz, 3 H, CH_3), 3.88 (s, 5 H, C_5H_5), 4.00–4.15 (m, 6 H, CH_2, C_5H_4), 5.99 (d, *J* = 15.2 Hz, 1 H, H-1), 6.32 (m, 2 H, H-2, H-3), 7.55–7.62 (m, 1 H, H-4).

5-Ferrocenyl-2,4-pentadienal (13): To a suspension of $LiAlH_4$ (0.135 g, 3.56 mmol) and $AlCl_3$ (0.158 g, 1.18 mmol) in 5 mL of diethyl ether at 10°C was added a solution of 1-ferrocenyl-4-(ethoxycarbonyl)butadiene (1.0 g, 3.22 mmol) in 4 mL of diethyl ether over 20 minutes. After stirring at room temperature for 1 h, the reaction mixture was hydrolysed with dilute sulfuric acid. Subsequently, the reaction mixture was extracted with diethyl ether. The organic layer was dried over Na_2SO_4 and the solvent was removed in vacuo. The residue of 1-ferrocenyl-1,3-pentadien-1-ol (0.78 g, 2.91 mmol) was dissolved in dichloromethane (20 mL) and oxidised by the addition of $BaMnO_4$ (6.1 g, 24 mmol). After stirring for 30 min the reaction mixture was filtered, the filtrate dried in vacuo and the product purified by column chromatography (Al_2O_3, neutral, 5% H_2O hexane/diethyl ether 5:3). Yield: 0.63 g (81%). – ^{1}H NMR (200 MHz, C_6D_6): δ = 3.89 (s, 5 H, C_5H_5),

4.08 (m, 2 H, C_5H_4), 4.13 (m, 2 H, C_5H_4), 6.00−6.65 (m, 4 H, H-2 − H-5), 9.54 (d, J = 7.8 Hz, 1 H, H-1).

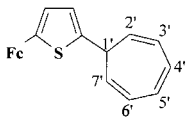
General Procedure for the Synthesis of Mononuclear Monohydrosesquifulvalene Complexes Containing Two or Three Conjugated Double Bonds: A mixture of NaH, phosphonate **6** and the corresponding aldehyde in dimethoxyethane was slowly warmed to 85° C and stirred for 24 h. After cooling to room temperature the reaction mixture was hydrolyzed and extracted with Et_2O. The organic layer was dried with $MgSO_4$ and the product purified by column chromatography.



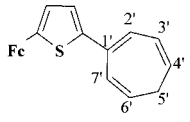
1-Ferrocenyl-4-(cyclohepta-1′,3′,5′-trien-1′-yl)-1,3-butadiene (12): 3-Ferrocenylpropenal (**11**) (1.0 g, 4.42 mmol), phosphonate **6** (1.07 g, 442 mmol), dimethoxyethane (20 mL) and NaH (0.1 g, 4.42 mmol). Column chromatography: Al_2O_3/5% H_2O, hexane/diethyl ether (5:1). Yield: 0.941 g (65%) of **12**.

12

^{1}H NMR (360 MHz, C_6D_6): δ = 2.70 (d, J = 7.2 Hz, 2 H, H-7′), 4.1 (s, 5 H, C_5H_5), 4.11 (m, 2 H, C_5H_4), 4.28 (m, 2 H, C_5H_4), 5.34 (m, 1 H, H-6′), 6.16 (m, 2 H, C_7H_7), 6.28 (m, 1 H, olefinic bridge) 6.43−6.65 (m, 5 H, C_7H_7 and olefinic bridge). − EI-MS: *m*/*z* (%) 328 (100) [M^+], 263 (10) [$M^+ - C_5H_5Fe^+$]. − $C_{21}H_{20}Fe$ (328.2): calcd. C 76.84, H 6.14; found C 75.45, H 6.27.

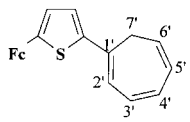


1-Ferrocenyl-6-(cyclohepta-1′,3′,5′-trien-1′-yl)-1,3,5-hexatriene (14): 5-Ferrocenyl-2,4-pentadienal (0.80 g, 3.0 mmol), THF (10 mL), phosphonate **6** (0.73 g, 3 mmol), NaH (0.073 g, 3 mmol). Column chromatography: Al_2O_3/5% H_2O, toluene. Yield: 0.45 g (63%) of **14**.



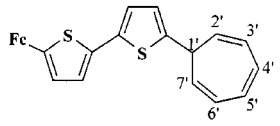
14

^{1}H NMR (360 MHz, C_6D_6): δ = 2.65 (d, J = 7.0 Hz, 2 H, H-7′), 4.00 (s, 5 H, C_5H_4), 4.11 (t, 2 H, C_5H_4), 4.29 (t, 2 H, C_5H_4), 5.31 (m, 1 H, H-6′), 6.13−6.18 (m, 2 H, C_7H_7), 6.29−6.66 (m, 8 H, olefinic bridge, C_7H_7). − EI-MS: *m*/*z* (%): 354 (100) [M^+], 289 (19) [$M^+ - C_5H_5$], 263 (15) [$M^+ - C_7H_7$], 250 (10), 225 (25), 199 (27), 186 (67) [$C_{10}H_{10}Fe^+$], 121 (65) [$C_5H_5Fe^+$]. − $C_{23}H_{22}Fe$ (354.3): calcd. C 77.98, H 6.26; found C 77.04, H 6.34.

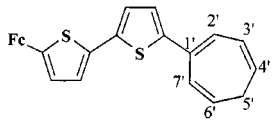


2-Ferrocenyl-5-(cycloheptatrienyl)thiophene (17): A solution of $ZnCl_2(THF)_2$ (3.37 g, 12 mmol) in THF (20 mL) was added to a solution of lithioferrocene[14] at −78°C. After 20 min stirring at −78°C the solution was allowed to warm slowly (40 min) to room temperature and a solution of 2-bromo-5-(cyclohepta-2′,4′,6′-trien-1′-yl)thiophene[22] (2.53 g, 10 mmol) and $Pd(PPh_3)_4$ (0.17 g, 0.1 mmol) in THF (40 mL) was added. After 15 h stirring at room temperature the reaction mixture was quenched with water (2 mL). The solvent was evaporated, the residue extracted with Et_2O (200 mL) in the presence of water (100 mL), and the ether layer was washed two times with 100 mL H_2O. The organic layer was dried over $MgSO_4$ and the product was isolated by column chromatography (Al_2O_3/5% H_2O/diethyl ether). Yield: 1.86 g (52%). The product **17** was a mixture of three isomers in the ratio 73% (**17A**), 14% (**17B**), 12% (**17C**). The composition of this mixture can be changed to 40:60 of isomers **17B** and **17C** by thermolysis in xylene (30 mL) under reflux for 33 h. The isomerisation was monitored by the disappearance of the proton signal H-1′ (2.94) of the isomer **17A**.

17A



17B

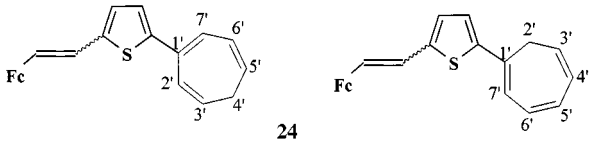


17C

^{1}H NMR (200 MHz, $CDCl_3$): **17A:** δ = 2.94 (t, 1 H, H-1′),), 4.10 (s, 5 H, C_5H_5) 4.26 (m, 2 H, C_5H_4), 4.54 (m, 2 H, C_5H_4), 5.53 (dd, 2 H, H-2′, H-7′), 6.27 (m, 2 H, H-3′, H-6′), 6.74 (m, 2 H, H-4′, H-5′), 6.80 (d, 1 H, C_4H_2S), 6.87 (d, 1 H, C_4H_2S). **17B**, **17C:** δ = 2.39 (t, J = 6.8 Hz, H-5′, **17B**), 2.81 (d, J = 6.8 Hz, H-7′, **17C**), 4.10 (s, C_5H_5), 4.11 (s, C_5H_5), 4.30 (m, C_5H_4), 4.58 (m, C_5H_4), 5.47−5.59 (m, 2 H, C_7H_7), 6.26 (dd, J = 9.4 Hz, J = 6.2 Hz, C_7H_7), 6.48 (d, J = 9.5 Hz, C_7H_7), 6.56−6.64 (m, C_7H_7), 6.86−7.06 (m, C_4H_2S, C_7H_7), 7.14 (d, J = 3.7 Hz, C_4H_2S), 7.20−7.42 (m, C_7H_7), 7.58−7.64 (m, C_4H_2S). − EI-MS: *m*/*z* (%) 358 (100) [M^+], 293 (3) [$M^+ - C_5H_5$], 202 (25) [$M^+ - C_{12}H_{12}$], 121 (21) [$C_5H_5Fe^+$]. − $C_{21}H_{18}FeS$ (358.3): calcd. C 70.40, H 5.06; found C 71.10, H 5.61.

5-Ferrocenyl-5′-(cycloheptatrienyl)-2,2′-bithiophene (20): To a cooled solution (−78°C) of 5-(cycloheptatrienyl)-2,2′-bithiophene (**19**) (1.43 g, 5.6 mmol) in 50 mL of THF was added *n*BuLi (3.5 mL of a 1.6 M hexane solution). The reaction solution was allowed to warm to room temperature, stirred for 40 min and cooled again to −78°C. A $ZnCl_2(THF)_2$ (1.56 g, 5.6 mmol) solution in THF (10 mL) was then added from a syringe. After warming to room temperature and additional stirring for 10 min this reaction mixture was added to a solution of iodoferrocene (1.73 g, 5.6 mmol) and $Pd(PPh_3)_4$ (0.06 g, 0.05 mmol) in THF (20 mL). The red coloured reaction mixture was stirred for 15 h, hydrolyzed with water (1 mL) and dried in vacuo. The solid residue was extracted with Et_2O, the organic layer was washed with water and dried over $MgSO_4$. The pure product was isolated after column chromatography (Al_2O_3/5% H_2O, hexane/ether 8:2). Yield: 1.36 g (55%) of **20** as the isomer A.

20A



20B

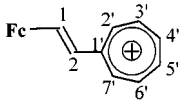
20A: ^{1}H NMR (360 MHz, C_6D_6): δ = 3.09 (dt, J = 5.6 Hz, J = 1.0 Hz, 1 H, H-1′), 3.98 (s, 5 H, C_5H_5), 4.06 (t, 2 H, C_5H_4), 4.46 (t, 2 H, C_5H_4), 5.46 (dd, J = 8.7 Hz, J = 5.7 Hz, 2 H, H-2′, H-7′), 6.06 (m, 2 H, H-3′, H-6′), 6.52 (m, 2 H, H-4′, H-5′), 6.65 (dd, J = 1.0 Hz, J = 3.6 Hz, 1 H, C_4H_2S), 6.75 (d, J = 3.7 Hz, 1 H, C_4H_2S), 6.94 (d, J = 3.6 Hz, 1 H, C_4H_2S), 6.98 (d, J = 3.6 Hz, 1 H, C_4H_2S).

Thermal Rearrangement of the Isomer 20A: A solution of **20A** (0.77 g, 1.75 mmol) dissolved in toluene (8 mL) was refluxed for 24 h. The solution was evaporated to dryness yielding isomer **20B** quantitatively.

20B: ^{1}H NMR (200 MHz, $CDCl_3$): δ = 2.16 (t, *J* = 6.9 Hz, 2 H, H-5′), 3.97 (s, 5 H, C_5H_5), 4.06 (t, 2 H, C_5H_4), 4.46 (t, 2 H, C_5H_4), 5.27 (m, 2 H, H-4′, H-6′), 6.10 (dd, *J* = 9.2 Hz, *J* = 6.1 Hz, 1 H, H-3′), 6.44 (d, *J* = 9.1 Hz, 1 H, H-7′), 6.74 (d, *J* = 3.7 Hz, 1 H, C_4H_2S), 6.85 (d, *J* = 3.7 Hz, 1 H, C_4H_2S), 6.95 (d, *J* = 3.7 Hz, 1 H, C_4H_2S), 6.98 (d, *J* = 3.7 Hz, 1 H, C_4H_2S), 7.00 (d, *J* = 6.1 Hz, 1 H, H-2′). − EI-MS: *m*/*z* (%) 440 (100) [M^+], 121 (21) [$C_5H_5Fe^+$].

1-Ferrocenyl-2-(5′-cycloheptatrienylthien-2′-yl)ethene (24): To a solution of (ferrocenylmethyl)triphenylphosphonium iodide (4.3 g, 7.4 mmol) in THF (70 mL) was added *n*BuLi (4.63 mL of 1.6 M hexane solution). After stirring for 30 min a solution of a 1:2.5 mixture of 2-(cyclohepta-1,3,5-trien-1-yl)-5-formylthiophene and 2-(cyclohepta-1,3,6-trien-1-yl)-5-formylthiophene (**22**) (1.5 g, 7.4 mmol) in THF (10 mL) was added to the Wittig reagent and subsequently stirred for 14 h. The solvent was evaporated in vacuo, and the residue extracted with hexane. The product was purified by column chromatography (Al_2O_3/5% H_2O, hexane). Yield: 1.87 g (66%) of **24**. The product is a mixture of four isomers composed of two pairs of *Z*-and *E*-isomers which differ in the position of the sp^3-carbon atom of the seven-membered ring corresponding to the isomers **22** used as starting material.

24



^{1}H NMR (200 MHz, $CDCl_3$): δ = 2.36 and 2.38 (t, *J* = 6.8 Hz, 2 H, H-5′, *E* and *Z* isomer of **24B**), 2.77 and 2.81 (d, *J* = 7.2 Hz, 2 H, H-5, *E* and *Z* isomer of **24A**), 4.13 (s, Cp), 4.26 (m, C_5H_4), 4.44 (m, C_5H_4), 5.51 (m, 2 H, C_7H_7), 6.20−7.10 (C_7H_7 and olefinic bridge). − $C_{23}H_{20}FeS$ (384.3): calcd. C 71.88, H 5.25; found C 71.94, H 5.51.

General Procedure for the Formation of the Cationic Mononuclear Sesquifulvalene Complexes by Hydride Abstraction: To a solution of the corresponding neutral monohydro-sesquifulvalene complex in dichloromethane was added an equimolar amount of trityl hexafluorophosphate dissolved in CH_2Cl_2. The reaction mixture was stirred for 30 min, and the cationic sesquifulvalene complex was precipitated by diluting the dark blue (M = Fe) or dark blue-violet (M = Ru) solution with Et_2O. Recrystallisation was performed by diffusion of Et_2O into a CH_2Cl_2 solution of the sesquifulvalene complexes.

4a·PF_6: Starting material: 0.352 g (1.16 mmol) of **5a** in 20 mL of dichloromethane, and 0.450 g (1.16 mmol) of trityl hexafluorophosphate in 10 mL of dichloromethane. Yield: 0.324 g (63%). ^{1}H NMR (200 MHz, CD_3NO_2): δ = 4.40 (s, 5 H, C_5H_5), 5.45 (t, *J* = 2 Hz, 2 H, C_5H_4), 5.51 (t, *J* = 2 Hz, 2 H, C_5H_4), 8.49−8.78 (m, 6 H, C_7H_6). − ^{13}C NMR (50 MHz, CD_3NO_2): δ = 73.4 (C_5H_4), 75.7 (C_5H_5), 81.8 (C_5H_4), 84.5 (C_q-C_5H_4), 147.9 (C_7H_6), 148.1(C_7H_6), 148.8 (C_7H_6), 175.8 (C_q-C_7H_6). − UV/Vis (CH_2Cl_2): λ_{max} [nm] (ε [$M^{-1}cm^{-1}$]) = 400 (14710), 725 (3570); (CH_3NO_2): λ_{max} [nm] (ε [$M^{-1}cm^{-1}$]) = 395 (13360), 700 (3330). − EI-MS: *m*/*z* (%) 276 (100), [M^+ − PF_6], 186 (25) [M^+ − C_7H_6 − PF_6]. − $C_{17}H_{15}F_6FeP$ (420.1): calcd. C 48.60, H 3.60; found C 48.24, H 3.76.

4b·PF_6: Starting material: 0.643 g (2.00 mmol) of **5b** in 10 mL of dichloromethane, and 0.777 g (2.00 mmol) trityl hexafluorophosphate in 10 mL of dichloromethane. Yield: 62%. − ^{1}H NMR (200 MHz, CD_3NO_2): δ = 4.74 (s, 5 H, C_5H_5), 5.48 (t, *J* = 1 Hz, 2 H, C_5H_4), 5.74 (t, *J* = 1 Hz, 2 H, C_5H_4), 8.44−8.31 (m, 4 H, C_7H_6), 8.67−8.57 (m, 2 H, C_7H_6). − ^{13}C NMR (50 MHz, CD_3NO_2): δ = 73.9 (C_5H_4), 76.8 (C_5H_5), 80.5 (C_5H_4), 88.4 (C_q-C_5H_4), 147.1 (C_7H_6), 149.2 (C_7H_6), 149.4 (C_7H_6), 173.5 (C_q-C_7H_6). − UV/Vis (CH_2Cl_2): λ_{max} [nm] (ε [$M^{-1}cm^{-1}$]) = 410 (14020), 560 (7360); (CH_3NO_2): λ_{max} [nm] (ε [$M^{-1}cm^{-1}$]) = 398 (6655), 536 (3245). − EI-MS: *m*/*z* (%) 322 (10), [M^+ − PF_6], 232 (20) [M^+ − C_7H_6 − PF_6]. − $C_{17}H_{15}F_6PRu$ (465.3): calcd. 25a·PF_6: Starting material: 0.352 g (1.16 mmol) of **8a** in 20 mL of dichloromethane, and 0.450 g (1.16 mmol) of trityl hexafluorophosphate in 10 mL of dichloromethane. Yield: 0.324 g (63%).

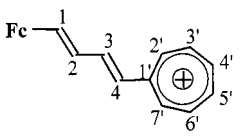
25a

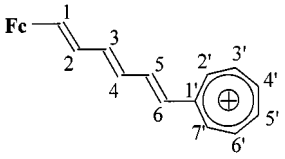
^{1}H NMR (200 MHz, CD_3NO_2): δ = 4.43 (s, 5 H, C_5H_5), 5.03 (t, 2 H, C_5H_4), 5.17 (t, 2 H, C_5H_4) 7.10 (d, *J* = 15.4 Hz, 1 H, H-2), 8.39 (d, *J* = 15.3 Hz, 1 H, H-1), 8.30−8.59 (m, 4 H, H-3′,6′, H-4′,5′) 8.62 (d, *J* = 10.4 Hz, 2 H, H-2′,7′). − ^{13}C NMR (50 MHz, CD_3NO_2): δ = 72.9 (C_5H_4), 73.6 (C_5H_5) 78.6 (C_5H_4), 83.8 (C_q-C_5H_4), 126.7 (C2), 147.9 (C_7H_6), 148.5 (C_7H_6), 148.9 (C_7H_6), 156.0 (C1), 164.7 (C_q-C_7H_6). − UV/Vis (CH_2Cl_2): λ_{max} [nm] (ε [$M^{-1}cm^{-1}$]) = 490 (39440), 816 (10460); (CH_3NO_2): λ_{max} [nm] (ε [$M^{-1}cm^{-1}$]) = 470 (24360), 765 (9510). − $C_{19}H_{17}F_6FeP$ (446.2): calcd: C 51.15, H 3.84; found C 51.17, H 3.93.



25b·PF_6: Starting material: 0.480 g (1.38 mmol) of **8b** in 20 mL of dichloromethane, and 0.538 g (1.38 mmol) of trityl hexafluorophosphate in 10 mL of dichloromethane. Yield: 0.52 g (77%).

25b

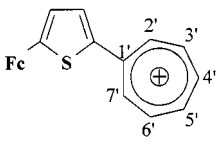
^{1}H NMR (200 MHz, CD_3NO_2): δ = 4.78 (s, 5 H, C_5H_5), 5.20 (t, 2 H, C_5H_4), 5.31 (t, 2 H, C_5H_4) 7.08 (d, *J* = 15.4 Hz, 1 H, H-2), 8.23 (d, *J* = 15.4 Hz, 1 H, H-1), 8.32−8.40 (m, 4 H, H-3′,6′, H-4′,5′) 8.61 (d, *J* = 9.7 Hz, 2 H, H-2′,7′). − ^{13}C NMR (50 MHz, CD_3NO_2): δ = 73.5 (C_5H_4), 74.8 (C_5H_5), 77.7 (C_5H_4), 125.0 (C2), 147.6 (C_7H_6), 148.6 (C_7H_6), 149.3 (C_7H_6), 152.3 (C1). − UV/Vis (CH_2Cl_2): λ_{max} [nm] (ε [$M^{-1}cm^{-1}$]) = 477 (16270), 642 (22560); (CH_3NO_2): λ_{max} [nm] (ε [$M^{-1}cm^{-1}$]) = 455 (12040), 600 (20345). − $C_{19}H_{17}F_6PRu$ (491.4): calcd: C 46.44, H 3.49; found C 45.86, H 3.74.



26·PF_6: Starting material: 0.392 g (1.2 mmol) of **12** in 20 mL of dichloromethane, and 0.466 g (1.2 mmol) trityl hexafluorophosphate in 10 mL of dichlorohexane. Yield: 0.429 g (76%).

26

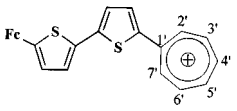
^{1}H NMR (200 MHz, CD_3NO_2): δ = 4.43 (s, 5 H, C_5H_5), 4.85 (s, 2 H, C_5H_4), 4.89 (s, 2 H, C_5H_4), 6.97 (dd, $J_{1,2}$ = 14.7 Hz, $J_{2,3}$ = 3.5 Hz, 1 H, H-2), 6.95 (d, $J_{3,4}$ = 14.7 Hz, 1 H, H-4), 8.06 (dd, $J_{3,4}$ = 14.7 Hz, $J_{2,3}$ = 3.4 Hz, 1 H, H-3), 8.26−8.44 (m, 4 H, H-3′,6′, H-4′,5′), 8.53 (d, $J_{1,2}$ = 14.9 Hz, 1 H, H-1), 8.62 (d, J = 10.1 Hz, 2 H, H-2′,7′). − ^{13}C NMR (50 MHz, CD_3NO_2): δ = 71.9 (C_5H_4), 73.2 (C_5H_5), 76.5 (C_5H_4), 78.6 (C_q-C_5H_4), 128.4 (C2), 130.6 (C4), 148.1 (C_7H_6), 148.9 (C_7H_6), 149.0 (C_7H_6), 152.2 (C1), 155.5 (C3), 166.6 (C_q-C_7H_6). − UV/Vis (CH_2Cl_2): λ_{max} [nm] (ε [$M^{-1}cm^{-1}$]) = 560 (37380), 865 (18090); (CH_3NO_2): λ_{max} [nm] (ε [$M^{-1}cm^{-1}$]) = 520 (24860), 780 (12770). $C_{21}H_{19}F_6FeP$ (472.2): calcd. C 53.42, H 4.06; found C 52.73, H 4.31.



27·PF_6: Starting material: 0.668 g (1.89 mmol) of **14** in 20 mL of dichloromethane, and 0.732 g (1.89 mmol) of trityl hexafluorophosphate in 10 mL of dichloromethane. yield: 0.51 g (54%).

27

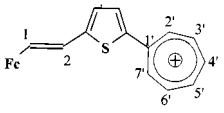
^{1}H NMR (360 MHz, CD_2Cl_2): δ = 4.62 (s, 5 H, C_5H_5), 5.18 (m, 4 H, C_5H_4), 6.34 (t, J = 12.7 Hz, 1 H, H-2), 6.47 (t, J = 12.9 Hz, 1 H, H-4), 6.68 (d, J = 14.3 Hz, 1 H, H-6), 7.01 (d, J = 14.5 Hz, 1 H, H-1), 7.27 (t, 1 H, J = 12.7 Hz, H-3), 7.98 (dd, J = 10.0, J = 3.7 Hz, 2 H, C_7H_6), 8.08 (dd, J = 14.6, 11.85 Hz, 1 H, H-5), 8.13 (m, 2 H, C_7H_6), 8.35 (d, J = 10.7 Hz, 2 H, C_7H_6).



28·PF_6: Starting material: 0.260 g (0.673 mmol) of **17** in 20 mL of dichloromethane, and 0.261 g (0.673 mmol) trityl hexafluorophosphate in 5 mL of dichloromethane. Yield: 0.20 g (60%).

28

^{1}H NMR (200 MHz, CD_3NO_2): δ = 4.25 (s, 5 H, C_5H_5), 4.84 (s, 2 H, C_5H_4), 5.03 (s, 2 H, C_5H_4), 7.45 (d, J = 4.5 Hz, 1 H, C_4H_2S), 8.24 (d, J = 4.4 Hz, 1 H, C_4H_2S), 8.28−8.47 (m, 4 H, H-3′,6′, H-4′,5′), 8.79 (d, J = 10.6 Hz, 2 H, H-2′,7′). − ^{13}C NMR (50 MHz, CD_3NO_2): δ = 70.8 (C_5H_4), 73.5 (C_5H_5), 75.1 (C_5H_4), 78.4 (C_q-C_5H_4), 129.9 (C_4H_2S), 140.6 (C_4H_2S), 141.1 (C_q-C_4H_2S), 146.2 (C_7H_6), 149.4 (C_7H_6), 150.4 (C_7H_6), 160.3 (C_q-C_4H_2S), 168.4 (C_q-C_7H_6). − $C_{21}H_{17}F_6FePS$ (502.2): calcd: C 50.22, H 3.41; found C 50.27, H 3.80.



29·PF_6: Starting material: 0.305 g (0.69 mmol) of **20** in 15 mL of dichloromethane, and 0.269 g (0.69 mmol) trityl hexafluorophosphate in 10 mL of dichloromethane. Yield: 0.222 g (55%).

29

^{1}H NMR (200 MHz, CD_3NO_2) δ = 4.37 (s, 5 H, C_5H_5), 5.14 (s, 2 H, C_5H_4), 5.90 (s, 2 H, C_5H_4) 8.13−8.54 (10 H, C_4H_2S and C_7H_6). − ^{13}C NMR (50 MHz, CD_3NO_2): δ = 69.5 (C_5H_4), 72.9 (C_5H_5), 73.1 (C_5H_4), 126.4 (C_4H_2S), 129.4 (C_4H_2S), 131.1 (C_4H_2S), 140.4 (C_4H_2S), 146.4 (C_7H_6), 150.0 (C_7H_6) 150.8 (C_7H_6), (signals of quaternary ^{13}C not observed). − $C_{25}H_{19}F_6FePS$ (552.3): calcd. C 51.39, H 3.28; found C 52.34, H 3.91.

30·PF_6: Starting material: 0.238 g (0.62 mmol) of **24** in 2 mL of dichloromethane, and 0.240 g (0.62 mmol) trityl hexafluorophosphate in 2 mL of dichloromethane. Yield: 0.258 g (79%).

30

^{1}H NMR (200 MHz, CD_2Cl_2) δ = 4.28 (s, 5 H, C_5H_5), 4.70 (m, 4 H, C_5H_4), 6.91 (d, J = 15.6 Hz, 1 H, H-2), 7.34 (d, J = 4.4 Hz, 1 H, C_4H_2S), 7.39 (d, J = 15.4 Hz, 1 H, H-1), 8.17 (d, J = 4.6 Hz, 1 H, C_4H_2S), 8.05 (dd, J = 7.1 Hz, J = 4.1 Hz, 2 H, H-4′,5′), 8.20 (m, 2 H, H-3′,6′), 8.53 (d, J = 10.8 Hz, 2 H, H-2′,7′. − ^{13}C NMR (50 MHz, CD_2Cl_2): δ = 69.7 (C_5H_4), 71.2 (C_5H_5), 73.6 (C_5H_4), 81.8 (C_q-C_5H_4), 117.0 (C2), 130.8 (C_4H_2S), 140.2 (C_4H_2S), 142.1 (C1), 144.3 (C_7H_6), 147.1 (C_7H_6), 148.1 (C_7H_6), 163.4 (C_q-C_7H_6). − $C_{23}H_{19}F_6FePS$ (528.3): calcd. C 52.29, H 3.63; found C 52.28, H 3.95.

X-ray Structure Determination : Crystals suitable for an X-ray structure analysis were obtained by diffusion of Et_2O from the gas phase into CH_2Cl_2 solutions of **4a**, **4b** or **25a**. The data were collected on a four-circle diffractometer Hilger & Watts, Mo-K_α, λ = 0.71073 Å. The structures were solved by direct methods (SHELXS-86).[55] Refinement on F^2 were carried out by full-matrix least-square techniques (SHELXL-93).[56] All non-hydrogen atoms were refined with anisotropic thermal parameters. The hydrogen atoms were refined with a fixed isotropic thermal parameter related by a factor of 1.2 to the value of the equivalent isotropic thermal parameter of their carrier atoms. Weights were optimised in the final refinement cycles (Table 5).

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-133669 (**4a**), -133670 (**4b**) and -133671 (**25a**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Cyclic Voltammetry: An Amel System 5000 was used. The measurements were performed in CH_2Cl_2 and $MeNO_2$ with 0.4 M [N(*n*-Bu)$_4$]ClO_4 as supporting electrolyte, ca. 10^{-3} M solutions of the complexes, a Pt wire as working electrode and a Pt plate (0.6 cm^2) as auxiliary electrode. The given potentials were measured against Ag/Ag^+ and are referenced against $E_{1/2}([FeCp_2]/[FeCp_2]^+)$ = 0 V.

Hyper-Rayleigh Scattering: For experimental set-up see ref.[46]; the measurements were performed at a fundamental wavelength of λ = 1064 nm with a Q-switched Nd:YAG laser; CH_2Cl_2 and $MeNO_2$ solutions were used for the measurements, with concentrations of 10^{-4} to 10^{-6} concerning the complexes under study; *p*-nitroaniline was used as reference [$\beta(CH_2Cl_2) = 21.6 \times 10^{-30}$ esu, $\beta(MeNO_2) = 34.6 \times 10^{-30}$ esu].[46]

Table 5. Crystallographic data of **4a**, **4b** and **25a**

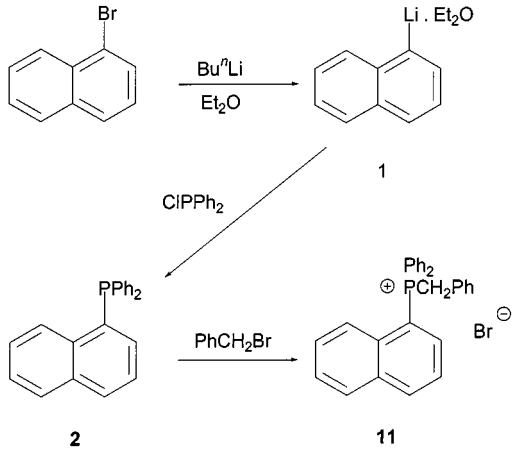
Preparation And Structure Of Phosphonium Ions With Intramolecular P ← N Coordination; Novel Diphosphonium Salts And Ionomer Containing Backbone Hypervalent Phosphorus

Francis H. Carré,[a] Claude Chuit,[a] Robert J. P. Corriu,*[a] William E. Douglas,[a] Daniel M. H. Guy,[a] and Catherine Reyé[a]

Keywords: Hypercoordinated phosphorus / Hypervalent phosphorus / Phosphorus / Diphosphonium compounds / Ionomers

Starting from $R'R_2P$ (R′ = 8-dimethylamino-1-naphthyl) containing a donor dimethylamino group, the new phosphonium salts $[R'R_2P(CH_2Ph)]^+Br^-$ [R = Me (**9**) or Ph (**10**)] and $[R'R_2P(p\text{-}CH_2C_6H_4CH_2)PR_2R']^{2+}[2Br]^{2-}$ [R = Ph (**12**)] have been prepared. An interaction between the N and P atoms is evident from the X-ray crystal structure of **10** the N–P distance being less than the sum of the van der Waals radii of the 2 atoms. The geometry of **10** is that of a monocapped tetrahedron whereas the X-ray crystal structure determination shows essentially regular tetrahedral geometry for the analogous compound without the donor amino group, $[(1\text{-}Np)Ph_2P(CH_2Ph)]^+Br^-$ (**11**). Treatment of 1,5-bis(dimethylamino)-2,6-dilithionaphthalene with chlorodiphenylphosphane gave 1,5-bis(dimethylamino)-2,6-bis(diphenylphosphanyl)-naphthalene (**8**) which in the presence of methyl iodide afforded the diphosphonium salt [1,5-bis(dimethylamino)-2,6-bis(diphenylmethylphosphonium)naphthalene]$^{2+}$[2I]$^{2-}$ (**13**). Similarly, treatment of **8** with 1 equivalent of benzyl bromide gave the monophosphonium salt [1,5-bis(dimethylamino)-2-diphenylbenzylphosphonium-6-diphenylphosphanyl-naphthalene]$^+$[Br]$^-$ (**14**) whereas in the presence of 2 equivalents of the same reagent [1,5-bis(dimethylamino)-2,6-bis(diphenylbenzylphosphonium)naphthalene]$^{2+}$[2 Br]$^{2-}$ (**15**) was obtained. The ionomer poly([(1,5-bis{dimethylamino}-2,6-bis{diphenylphosphonium}naphthalene)-(P,P-*p*-xylylene)]$^{2+}$[2 Br]$^{2-}$) (**16**), soluble in liquid SO_2, was prepared by treatment of **8** with α,α′-dibromo-*p*-xylene.



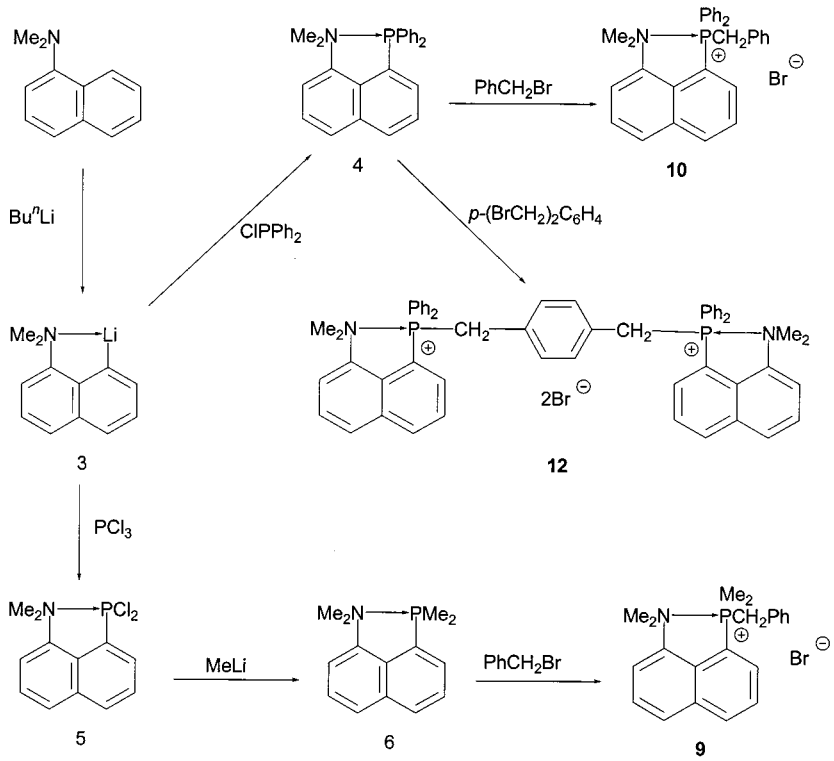
Introduction

Extension of coordination has been widely investigated for phosphoranes[1,2] and silicon compounds[3] but very rarely in the case of phosphanes and phosphonium ions.[4] It has been argued that there is no need to invoke d-orbital participation in the bonding in such hypervalent phosphorus compounds.[5] We have described the preparation, structures and some properties of various phosphanes (and also some phosphonium salts) showing extension of coordination by P←N interactions,[6–8] incorporating in particular the 8-dimethylamino-1-naphthyl ligand first used many years ago for the stabilization of hypercoordinated species[9] and widely applied in silicon chemistry.[3] Here, some new types of such phosphonium salts are reported including those containing two phosphorus atoms, prepared from the 4,8-bis(dimethylamino)-1,5-naphthylidene ligand,[10] in which there are two P←N interactions. The crystal structure of one of the phosphonium salts is compared to that of the corresponding salt without an amine group. We also describe the preparation from this same ligand of a novel ionomer containing hypervalent phosphorus in the backbone.

Results and Discussion

Preparation of Starting Phosphanes

Naphthyllithium (**1**) was prepared by treatment of bromonaphthalene in diethyl ether with *n*-butyllithium[11] (Scheme 1). The presence of one molecule of diethyl ether for each molecule of lithium reagent was shown by the proton NMR spectrum of the hydrolysis product. Naphthyldiphenylphosphane (**2**) was prepared by treatment of **1** with chlorodiphenylphosphane (Scheme 1).



Scheme 1. Preparation of **11**

The hypercoordinate phosphanes were obtained starting from the 8-(dimethylamino)-1-lithionaphthalene (**3**), the latter being prepared quantitatively by treatment of 1-dimethylaminonaphthalene with *n*-butyllithium (Scheme 2).[9] The preparation and the properties of phosphane **4** prepared by treatment of **3** with chlorodiphenylphosphane (Scheme 2) have been previously described;[8,12] a dynamic proton NMR investigation and the X-ray crystal structure determination showed that the geometry of this phosphane

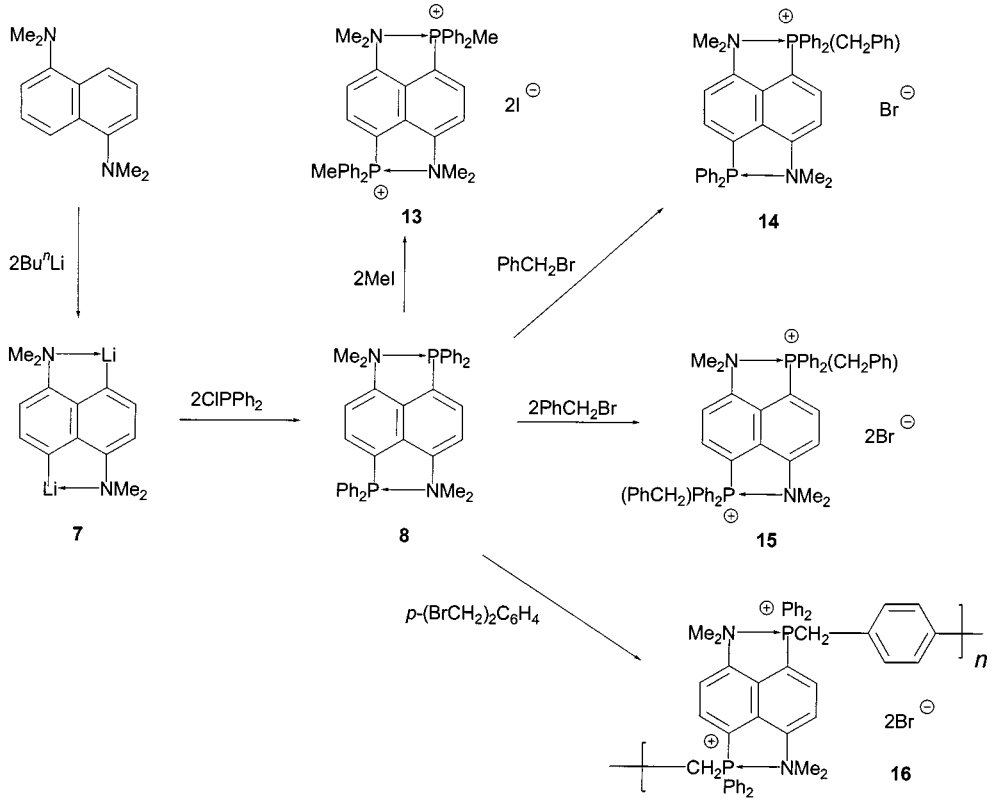
Scheme 2. Preparation of hypervalent phosphorus compounds containing the 8-dimethylamino-1-naphthyl ligand

is not symmetric and that the distance between the nitrogen and the phosphorus atoms (2.7 Å) is smaller than the sum of the van der Waals radii of the two atoms (3.4 Å[13]).[8] The geometry of **4** can be described as a monocapped tetrahedron in which the P atom is pseudo-[4+1]-coordinate (taking into account the electron lone pair).[8]



The intermediate dichlorophosphane derivative **5** was obtained by addition of the lithium reagent **3** to a large excess of trichlorophosphane (Scheme 2) at –80 °C. Treatment of **5** with methyllithium gave the dimethylphosphane derivative **6** (Scheme 2). The latter, like **4**, shows a singlet for the amine methyl protons in the proton NMR spectrum at room temperature. However, whereas for **4** this signal is split into two at –95 °C, in the case of **6** at –110 °C (250 MHz) it is merely broadened the permutational isomerization being of lower energy due to the difference in bulk of the phenyl and methyl groups.

Treatment of 1,5-bis(dimethylamino)naphthalene with two equivalents of *n*-butyllithium affords the dilithio reagent **7** (Scheme 3), as we have previously described.[10] Subsequent treatment of **7** with chlorodiphenylphosphane gives the diphosphane **8** containing two hypercoordinate phosphorus atoms (Scheme 3). A dynamic proton NMR study of this compound showed that at –95 °C the singlet corresponding to the amine protons is split into two signals. By use of the Eyring equation the energy of the permutational isomerisation was calculated[14] to be $\Delta G^{\ddagger} = 36.8$ kJ mol^{-1}, a value similar to that previously found for **4**.[8] We have not been able to determine the X-ray crystal structure of **8** but the geometry is most probably similar to that of the corresponding phosphane **4** with a monocapped tetrahedral arrangement of the ligands around each phosphorus.[8]

Preparation of Phosphonium Salts

The very air sensitive hypercoordinate phosphonium salt **9** with methyl groups at P was prepared by treatment of **6** with benzyl bromide (Scheme 2). The analogous stable salt **10** with phenyl groups at P was obtained by reaction of **4** with benzyl bromide. The X-ray crystal structure of **10** (Figure 1) shows a monocapped tetrahedral geometry in which the P atom is [4+1]-coordinate; selected bond lengths and angles are to be found in Table 1 and details of the crystal structure determination in Table 2. The distance between the nitrogen and the phosphorus atoms (2.83 Å) is less than the sum of the van der Waals radii of the 2 atoms (3.4 Å[13]),[8] thus showing that they interact. Indeed, this distance is comparable to the N–N distance (2.79 Å) in 1,8-bis(dimethylamino)naphthalene[15] despite phosphorus being much larger than nitrogen. Moreover, it should be noted that the naphthalene ring in **10** is distorted out of the plane by only *ca.* 17° (dihedral angle between the C9–C1–C2 and C7–C8–C9 planes) whereas for 1,8-bis(dimethylamino)naphthalene[15] the corresponding angle can be evaluated at 28°.

For comparison, the analogous phosphonium salt without the donor nitrogen, $[(1\text{-Np})Ph_2P(CH_2Ph)]^+Br^-$ (**11**), was synthesized by treatment of **2** with benzyl bromide in refluxing toluene (Scheme 1). The X-ray crystal structure analysis of **11** (Figure 2) shows a tetrahedral geometry in

Scheme 3. Preparation of hypervalent phosphorus compounds containing the 4,8-bis(dimethylamino)-1,5-naphthylidene ligand

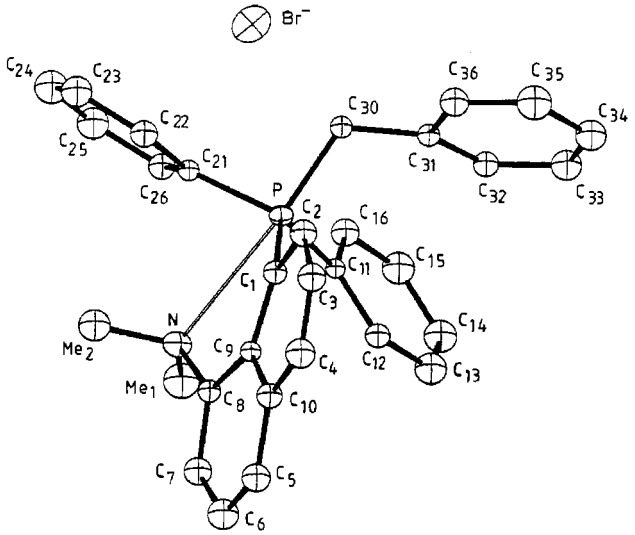


Figure 1. Molecular structure of **10**; hydrogen atoms have been omitted for clarity

which the P atom is 4-coordinate; selected bond lengths and angles are to be found in Table 1 and details of the crystal structure determination in Table 2. Comparison of the angles in **10** and **11** (Table 1) shows that the nitrogen in **10** is opposite to the benzyl group [C(30)] and has little effect on angles C(1)–P–C(30) and C(1)–P–C(11) which remain essentially tetrahedral. However, the presence of the amine group results in a reduction of C(21)–P–C(30) by ca. 9° and C(11)–P–C(30) by ca. 6°, and an enlargement of C(11)–P–C(21) and C(21)–P–C(1) by 5–6°.

The ^{1}H NMR resonances for the methylene protons in the hypercoordinate salts **9** (δ_H = 4.4) and **10** (δ_H = 4.7) occur at higher field than in the tetracoordinate salt **11** (δ_H = 5.35). This can be explained by the electron-donating effect of the dimethylamino group coordinated to the phosphorus atom. However, the ^{31}P NMR chemical shift remains essentially unchanged with increase in the coordination number from four (**11**) to five (**9** or **10**) as has previously been observed for hypercoordinated silicon compounds containing the 8-dimethylamino-1-naphthyl ligand.[16]

The analogous compound **12** containing two positively-charged phosphorus atoms was prepared by treating two

equivalents of **4** with one equivalent of α,α'-dibromo-*p*-xylene (Scheme 2). As expected the chemical shifts of the proton and ^{31}P NMR resonances for **12** are very similar to those for **10**, the ^{31}P NMR resonances for these compounds containing phenyl groups occurring at higher field than that for **9** containing methyl groups.

Phosphonium salts containing two hypercoordinate phosphorus atoms were obtained from the diphosphane **8** (Scheme 3). The reactions were followed by ^{31}P NMR, the spectra showing the disappearance of the signal corresponding to the starting phosphane (δ_P = 1.9) and the appearance of the signal corresponding to the phosphonium salt at δ ≈ 23. Salt **13** was prepared by treatment of phosphane **8** with a large excess of methyl iodide in toluene under reflux, the reaction being complete after 4.5 h (Scheme 3).

The compound **14** containing both phosphanyl and phosphonium centres was obtained by treatment of **8** with one equivalent of benzyl bromide the reaction being complete after 60 hours under reflux in toluene (Scheme 3). The ^{31}P NMR spectrum shows a signal at δ 22 characteristic of the phosphonium ion and another at δ = 5 corresponding to the phosphanyl atom, the latter being downfield of that for the starting material **8** (δ_P = 1.9). The proton resonances for the dimethylamino group *peri* to the phosphonium centre (δ_H = 1.7) are shifted upfield compared to those for **8** (δ_H = 2.3) whereas the proton resonances for the dimethylamino group *para* to the phosphonium centre are shifted downfield (δ_H = 2.5).

The analogous salt **15** containing two phosphonium centres was prepared by treatment of **8** with two equivalents of benzyl bromide the reaction being complete in this case after 120 hours under reflux in toluene (Scheme 3). As expected only one ^{31}P NMR signal is observed (δ_P = 24.8) characteristic of the phosphonium ion. The proton NMR spectrum shows all the amine protons to be equivalent (δ_H = 2.08) this signal being upfield of that for **8** (δ_H = 2.3).

The ionomer **16** was prepared by heating **8** with one equivalent of α,α'-dibromo-*p*-xylene in toluene under reflux for 10 d (Scheme 3), the product being insoluble except in

liquid SO_2. The solid state ^{31}P NMR spectrum shows a signal at $\delta = 16$. The conductivity of a compacted disc of the powdered ionomer was found to be 10^{-5} S cm^{-1} (4-point method), and that of a SO_2 solution at –30 °C was 53 S cm^{-1}.

In conclusion, we have shown that an intramolecular donor-acceptor interaction exists in the phosphonium ion **10** and therefore most probably also in the other new phosphonium ions of this type reported here (**9**, **12**, **13–15** and the ionomer **16**). This confirms that the phosphonium ion is able to undergo an extension of coordination. In particular, it should be noted that, as has been previously observed for the analogous silicon compounds,[16] incorporation of the 8-dimethylamino-1-naphthyl ligand to give pentacoordinate phosphane species does not give rise to any substantial change in NMR chemical shift. This independence of NMR chemical shift on coordination number is due to the specific geometry of the ligand and in no way throws doubt[17] on the existence of an N←P (or N←Si) coordinative interaction. On the contrary, a completely coherent picture is found for the structures and chemical behaviour of the totality of penta- and hexacoordinate derivatives formed by intramolecular coordination of either Si or P.

Experimental Section

All reactions were performed using standard Schlenk-tube techniques under an atmosphere of dry argon. Solvents were distilled from appropriate drying agents and degassed before use. ^1H and ^{13}C NMR spectra were obtained using a Bruker DPX-200 spectrometer at 200 MHz and 50.288 MHz, respectively, and ^{31}P NMR spectra on a Bruker 250 AC spectrometer at 101.202 MHz. ^1H and ^{13}C NMR chemical shifts are reported relative to Me_4Si, and ^{31}P chemical shifts relative to H_3PO_4. Infrared spectra were obtained in the region 500–4000 cm^{-1} using a Perkin–Elmer 1600 FT spectrophotometer. Elemental analyses were carried out by the Service Central de Microanalyse du CNRS. Phosphane **4** was prepared from **3** as previously described.[8]

Preparation of 1: Diethyl ether (130 mL) was added at 0 °C to 1.9 M *n*-butyllithium solution in hexane (85 mL, 160 mmol) and the resulting solution was cooled to –20 °C. 1-Bromonaphthalene (20 mL, 140 mmol) was added drop by drop and the mixture was stirred at 0 °C for 1 h and then filtered. The precipitate was washed with pentane and dried under vacuum affording 24.65 g of a white pyrophoric solid ($C_{10}H_7Li \cdot Et_2O$) isolated in 85% yield.

Preparation of 2: Chlorodiphenylphosphane (18 mL, 100 mmol) was added drop by drop to a suspension of **1** (16 g, 76.92 mmol) in diethyl ether (100 mL) at –50 °C. The mixture was then allowed to warm to room temp. and was stirred for 16 h. The resulting white suspension was heated under reflux for 5 h, and was then hydrolysed with 10% NaOH solution (50 mL). The precipitate was washed successively with water, acetone and diethyl ether before being dried under vacuum. The crude product was recrystallized from ethanol to give 13.25 g of the desired product, m.p. 122.3–124.0 °C (yield 55%). – ^1H NMR ($CDCl_3$): δ_H = 7–8.6 (m, aromatic protons). – ^{13}C-{^1H} NMR ($CDCl_3$): δ_C = 126–137 (aromatic carbons). – ^{31}P-{^1H} NMR ($CDCl_3$): δ_P = –13.6 (s). – IR (CCl_4): $\tilde{\nu}$ (cm^{-1}) = 3056 s, 1588 w, 1504 m, 1482 m, 1434 vs, 1386 m, 1329 w, 1094 w, 1027 w. – $C_{22}H_{17}P$ (312.34): calcd. C 84.60, H 5.48, P 9.91; found C 85.01, H 5.48, P 9.78.

Preparation of 3: *n*-Butyllithium in hexane (40 mL, 110 mmol) was added drop by drop to a solution of 1-(dimethylamino)naphthalene (16.54 g, 96.7 mmol) in 250 mL of diethyl ether at room temp. After the mixture had been stirred for 3 d the resulting yellow suspension was filtered and the precipitate was washed thrice with diethyl ether before being dried under vacuum to afford 16.8 g of a yellow pyrophoric fine powder (yield 98%).

Preparation of 5: A suspension of **3** (5.67 g, 32.03 mmol) in 150 mL of diethyl ether was added drop by drop to a solution of trichlorophosphane (12 mL, 137 mmol) in 150 mL of diethyl ether at –80 °C. The mixture was stirred at room temp. overnight. The resulting yellow suspension was filtered and the filtrate was concentrated to give 5.43 g of a yellow solid (yield 62%). – ^1H NMR ($CDCl_3$): δ_H = 2.87 [s, 6 H, $N(CH_3)_2$], 7.5–8.9 (m, 6 H, aromatic protons). – ^{13}C-{^1H} NMR ($CDCl_3$): δ_C = 47.6 (CH_3), 112–148 (aromatic carbons). – ^{31}P-{^1H} NMR ($CDCl_3$): δ_P = 130.85 (s).

Preparation of 6: A 1.25 M solution of methyllithium (28.2 mL, 35.22 mmol) in diethyl ether was added to a suspension of **5** (4.79 g, 17.61 mmol) in 100 mL of diethyl ether. The mixture was stirred at room temperature overnight and then heated under reflux for 3 h. The suspension was hydrolysed by addition of degassed 10% NaOH solution (40 mL). The aqueous layer was extracted with diethyl ether. The combined organic phases were washed with degassed water and dried with $MgSO_4$ before removal of the solvent to give a yellow liquid. Vacuum distillation gave 1.63 g of the desired product (40% yield), b.p. 118–120 °C/0.4 Torr. – ^1H NMR ($CDCl_3$): δ_H = 1.35 [d, $^2J_{1H,31P}$ = 5.7 Hz, 6 H, $P(CH_3)_2$], 2.75 [s, 6 H, $N(CH_3)_2$], 7.3–7.9 (m, 6 H, aromatic protons). – ^{31}P-{^1H} NMR ($CDCl_3$): δ_P = –37.8 (s). – IR (CCl_4): $\tilde{\nu}$ (cm^{-1}) = 3054 m, 2945 s, 2902 s, 2864 s, 2828 vs, 2786 s, 1929 w, 1710 w, 1563 vs, 1500 w, 1477 m, 1453 vs, 1366 vs, 1330 s, 1289 m, 1204 m, 1183 s, 1143 s, 1081 s, 1048 m, 1030 m.

Preparation of 7: *n*-Butyllithium in hexane (110 mL, 310 mmol) was added drop by drop to a solution of 1,5-bis(dimethylamino)naphthalene (30.04 g, 140 mmol) in 500 mL of diethyl ether at room temp.. After the mixture had been stirred for 10 d the resulting yellow suspension was filtered and the precipitate was washed thrice with diethyl ether before being dried under vacuum to afford 30.97 g of a white pyrophoric fine powder (yield 98%).

Preparation of 8: Chlorodiphenylphosphane (10.83 mL, 60 mmol) was added drop by drop to a suspension of **7** (8.52 g, 38 mmol) in 100 mL of diethyl ether at –80 °C. The mixture was then allowed to warm to room temp. and was stirred overnight. The resulting white suspension was heated under reflux for 9 h, and it was then hydrolysed with 10% NaOH solution (100 mL). The precipitate was washed successively with water, acetone and diethyl ether before being dried under vacuum. The crude product was recrystallized from benzene to give 9.6 g of the desired product, m.p. 259.4–263.7 °C (yield 55%). – ^1H NMR ($CDCl_3$): δ_H = 2.3 [s, 12 H, $N(CH_3)_2$], 6.7–7.4 (m, 24 H, aromatic protons). – ^{13}C-{^1H} NMR ($CDCl_3$): δ_C = 46.18 [$N(CH_3)_2$], 118–152 (aromatic carbon atoms). – ^{31}P-{^1H} NMR ($CDCl_3$): δ_P = 1.9 (s). – IR (Nujol): $\tilde{\nu}$ (cm^{-1}) = 3059 m, 2853 vs, 2822 s, 2776 m, 1954 w, 1882 w, 1823 w, 1773 w, 1677 w, 1653 w, 1578 m, 1506 m, 1451 s, 1401 w, 1368 s, 1311 m, 1275 w, 1202 m, 1181 s, 1152 m, 1109 m, 1087 m, 1068 w, 1042 s, 976 vs, 836 m, 826 m, 748 s, 738 vs, 717 m, 697 vs, 668 w, 650 m, 613 s. – $C_{38}H_{36}N_2P_2$ (582.66): C 78.32, H 6.23, N 4.81; found C 78.28, H 6.01, N 4.92.

Preparation of 9: A mixture of **6** (0.33 g, 1.43 mmol) and benzyl bromide (0.17 mL, 1.43 mmol) was heated under reflux in toluene (50 mL) for 3 h. The solvent was removed under vacuum to give 0.53 g of a very air-sensitive white powder (yield 93%). – ^{1}H NMR ($CDCl_3$): δ_H = 2.45 [d, $^2J_{1H,31P}$ = 10 Hz, 6 H, $P(CH_3)_2$], 2.75 [s, 6 H, $N(CH_3)_2$], 4.4 (d, $^2J^1_H{}^{31}_P$ = 15 Hz, 2 H, CH_2), 6.8–8.2 (m, 11 H, aromatic protons). – ^{31}P-{^{1}H} NMR ($CDCl_3$): δ_P = 24.26 (s).

Preparation of 10: A mixture of **4** (2 g, 5.63 mmol) and benzyl bromide (0.67 mL, 5.63 mmol) was heated under reflux in toluene (100 mL) for 9 d. The solvent was then removed under vacuum to give a white solid. The crude product was recrystallized from a mixture of dichloromethane and heptane to give 2.84 g of the desired product, m.p. 281.3–282.5 °C (yield 96%). – ^{1}H NMR ($CDCl_3$): δ_H = 1.5 [s, 6 H, $N(CH_3)_2$], 4.7 (d, $^2J_{1H,31P}$ = 14 Hz, 2 H, CH_2), 6.3–9 (m, 21 H, aromatic protons). – ^{13}C-{^{1}H} NMR ($CDCl_3$): δ_C = 36.14 (d, $^1J_{31P,13C}$ = 48.36 Hz, CH_2), 46.44 (CH_3), 111–151 (aromatic carbons). – ^{31}P-{^{1}H} NMR ($CDCl_3$): δ_P = 22.12 (s). – IR (Nujol): $\tilde{\nu}$ (cm^{-1}) = 3052 w, 2796 w, 1715w, 1694 w, 1570 w, 1497 m, 1438 s, 1412 w, 1376 m, 1338 m, 1286 w, 1209 w, 1195 w, 1152 m, 1114 s, 1105 s, 1081 m, 1036 m, 1023 m, 995 w, 958 w, 929 w, 879 m, 839 s, 831 s, 802 w, 776 vs, 757 s, 727 m, 699 vs, 660.

Preparation of 11: A mixture of naphthyldiphenylphosphane (**2**) (2 g, 6.41 mmol) and benzyl bromide (0.76 g, 6.41 mmol) was heated under reflux in toluene (100 mL) for 6 d. The solvent was removed under vacuum to give a white powder. The crude product was recrystallized from ethanol to give 1.81 g of the desired product, m.p. 329.5–331.2 °C (yield 58%). – ^{1}H NMR ($CDCl_3$): δ_H = 5.35 (d, $^2J_{1H,31P}$ = 15 Hz, 2 H, CH_2), 6.8–8.6 (m, 22 H, aromatic protons). – ^{13}C-{^{1}H} NMR ($CDCl_3$): δ_C = 30.53 (d, $^1J_{13C,31P}$ = 42.78 Hz, CH_2), 112–138 (aromatic carbon atoms). – ^{31}P-{^{1}H} NMR ($CDCl_3$): δ_P = 22.45 (s). – IR (nujol): $\tilde{\nu}$ (cm^{-1}) = 2783 m, 2362 w, 1602 w, 1586 w, 1502 m, 1496 m, 1440 vs, 1377 s, 1338 m, 1318 w, 1262 w, 1214 w, 1166 m, 1110 s, 1074 w, 1033 w, 997 w, 986 w, 921 w, 877 w, 832 m, 800 m, 777 s, 751 s, 717 m, 698 s, 690 s, 664 w, 586 s. – $C_{29}H_{24}BrP$ (483.39): C 72.06, H 5.00; found C 72.06, H 5.09.

Preparation of 12: A mixture of α,α'-dibromo-*p*-xylene (0.74 g, 2.81 mmol) and **4** (2 g, 5.63 mmol) was heated under reflux in toluene (100 mL) for 7 d. The solvent was removed under vacuum to give a white powder. The crude product was recrystallized from a mixture of dichloromethane and pentane to give 1.6 g of the desired product, m.p. 309.9–311.4 °C (yield 58%). – ^{1}H NMR ($CDCl_3$): δ_H = 1.5 [s, 12 H, $N(CH_3)_2$], 4.55 (d, $^2J_{1H,31P}$ = 16 Hz, 4 H, CH_2), 7–9 (m, 36 H, aromatic protons). – ^{13}C-{^{1}H} NMR ($CDCl_3$): δ_C = 38.25 (d, $^1J_{13C,31P}$ = 47.44 Hz, CH_2), 46.4 (CH_3), 110–150 (aromatic carbons). – ^{31}P-{^{1}H} NMR ($CDCl_3$): δ_P = 22.77 (s). – IR (Nujol): $\tilde{\nu}$ (cm^{-1}) = 3053 w, 2854 vs, 2808 w, 1622 w, 1566 w, 1497 w, 1437 s, 1375 s, 1336 m, 1288 w, 1212 w, 1168 m, 1151 w, 1110 s, 1100 m, 1080 w, 1034 w, 1024 w, 995 w, 954 w, 880 w, 826 m, 773 m, 756 s, 724 m, 697 m, 658 w.

Preparation of 13: A mixture of methyl iodide (1.74 g, 28.0 mmol) and **8** (2 g, 3.44 mmol) was heated under reflux in toluene (20 mL) for 4.5 h. The solvent was removed under vacuum to give a white powder. The crude product was recrystallized in a mixture of ethanol and benzene to give 2.48 g of the desired product, m.p. 323.7–324.9 °C (yield 83%). – ^{1}H NMR ($CDCl_3$): δ_H = 2.1 [s, 12 H, $N(CH_3)_2$], 3.1 (d, $^2J_{1H,31P}$ = 13.4 Hz, 6 H, PCH_3), 7.2–7.8 (m, 24 H, aromatic protons). – ^{13}C-{^{1}H} NMR ($CDCl_3$): δ_C = 11.84 (d, $^1J_{13C,31P}$ = 65.17 Hz, PCH_3), 46.67 [$N(CH_3)_2$], 111–157 (aromatic carbon atoms). – ^{31}P-{^{1}H} NMR ($CDCl_3$): δ_P = 23.76 (s). – IR (Nujol): $\tilde{\nu}$ (cm^{-1}) = 1585 w, 1567 m, 1499 s, 1438 vs, 1376 vs, 1318 s, 1211 w, 1155 m, 1121 s, 1101 m, 1038 w, 1012 w, 996 w, 972 m, 914 m, 895 m, 830 w, 785 w, 774 w, 750 s, 715 s, 693 s.

Preparation of 14: A mixture of benzyl bromide (0.61 mL, 5.15 mmol) and **8** (3 g, 5.15 mmol) was heated under reflux in toluene (50 mL) for 60 h. The solvent was removed under vacuum to give a yellow solid, m.p. 275.8–276.5 °C (yield 83%). – ^{1}H NMR ($CDCl_3$): δ_H = 1.7 [s, 6 H, $N(CH_3)_2$ *peri* to P^+], 2.5 [s, 6 H, $N(CH_3)_2$ *para* to P^+], 4.7 (d, $^2J_{1H,31P}$ = 14 Hz, CH_2), 6–7.8 (m, 29 H, aromatic protons). – ^{13}C-{^{1}H} NMR ($CDCl_3$): δ_C = 38.6 (d, $^1J_{13C,31P}$ = 47.23 Hz, CH_2), 45.72 [$N(CH_3)_2$], 46.16 [$N(CH_3)_2$], 119–150 (aromatic carbon atoms). – ^{31}P-{^{1}H} NMR ($CDCl_3$): δ_P = 4.3 (P), 21.91 (P^+). – IR (Nujol): $\tilde{\nu}$ (cm^{-1}) = 3045 w, 1584 w, 1558 w, 1498 m, 1376 vs, 1322 m, 1303 m, 1261 w, 1185 m, 1151 m, 1116 s, 1073 m, 1046 w, 1033 m, 998 m, 971 m, 904 m, 860 m, 837 m, 753 s, 723 m, 697 s.

Preparation of 15: A mixture of benzyl bromide (1.22 mL, 10.30 mmol) and **8** (3 g, 5.15 mmol) was heated under reflux in toluene (50 mL) for 120 h. The solvent was removed under vacuum to give a yellow powder. The crude product was recrystallized from a mixture of ethanol and benzene to give 4.52 g of the desired product, m.p. 294.0–294.6 °C (yield 95%). – ^{1}H NMR ($CDCl_3$): δ_H = 2.08 [s, 12 H, $N(CH_3)_2$], 4.87 (d, $^2J_{1H,31P}$ = 16 Hz, 4 H, CH_2), 6.5–9 (m, 34 H, aromatic protons). – ^{13}C-{^{1}H} NMR ($CDCl_3$): δ_C = 38.8 (d, $^1J_{13C,31P}$ = 47.66 Hz, CH_2), 46.06 (CH_3), 119–150 (aromatic carbons). – ^{31}P-{^{1}H} NMR ($CDCl_3$): δ_P = 24.78 (s). – IR (Nujol): $\tilde{\nu}$ (cm^{-1}) = 2786 w, 1574 w, 1498 s, 1439 vs, 1376 s, 1315 m, 1260 w, 1175 w, 1112 m, 1074 w, 1037 m, 1010 w, 973 w, 904 w, 851 m, 838 m, 786 w, 761 m, 750 s, 726 m, 696 s.

Preparation of 16: A mixture of α,α'-dibromo-*p*-xylene (0.73 g, 2.78 mmol) and **8** (1.62 g, 2.78 mmol) was heated under reflux in toluene (50 mL) for 10 d. The solvent was removed under vacuum to give an orange powder (d 300 °C) which is soluble in liquid SO_2. Solid-state ^{31}P-NMR HPDEC MAS: δ_P = 16. – IR (Nujol): $\tilde{\nu}$ (cm^{-1}) = 2722 w, 1614 w, 1568 m, 1498 s, 1438 vs, 1377 vs, 1315 m, 1261 m, 1211 m, 1157 m, 1110 s, 1033 m, 998 m, 968 m, 899 w, 837 s, 749 m, 720 w, 694 s, 634 w.

X-ray Structure Determinations of 10 and 11: The crystal of **10** used was found to produce only moderate diffraction intensities. The direct methods (SHELXS-86[18]) failed to give the solution of the structure with space groups *P*–1. However, an attempt to solve the structure with the non-centrosymmetric space group *P*1 gave the positions of the bromine anion, the phosphorus atom and four carbon atoms from the naphthyl group. The space group *P*–1 was again assumed to be the correct group and two subsequent Fourier syntheses and a difference Fourier map gave the positions of the remaining atoms. Owing to the small number of observed data, only the bromine, phosphorus and nitrogen atoms were refined anisotropically. The calculated hydrogen atoms[19] were included in the last stages of the refinement. Convergence occurred for the *R* value of 0.0690 (*Rw* = 0.0705). – In the case of **11** the systematic absences revealed the space group $P2_1/c$. Direct methods (SHELXS-86[18]) gave the positions of the bromine anion, the phosphorus atom and the phenyl and some of the naphthyl carbons. Two Fourier maps revealed the remaining carbon atoms. The hydrogen atoms were positioned by calculation[19] and taken into account in the next refinements. After ten cycles of least-squares refinement with anisotropic thermal parameters for all non-hydrogen atoms, the final *R* value was 0.0396 (*Rw* = 0.0409). – The crystal structure data (excluding structure factors) have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-114826 (**10**) and -114825 (**11**). Copies

of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, G.B. [Fax: int. code + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

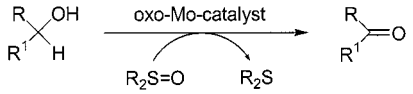
Selective and Environmentally Benign Aerobic Catalytic Oxidation of Alcohols by a Molybdenum-Copper System

Christian Y. Lorber,[a][+] Sebastian P. Smidt,[a] and John A. Osborn*[a]



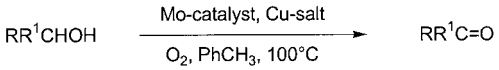
Keywords: Molybdenum / Copper / Oxidation / Alcohols / Catalysis

The oxidation of activated primary and secondary alcohols to the corresponding aldehydes and ketones can be carried out with molecular oxygen, in the presence of the bimetallic molybdenum–copper system $MoO_2(acac)_2$–$Cu(NO_3)_2$ as catalyst.

Introduction

The oxidation of primary and secondary alcohols to aldehydes and ketones, respectively, is a fundamental transformation in organic synthesis, that can be now accomplished by several oxidizing reagents. However, in most cases these reagents are very toxic and must be used in stoichiometric amounts.[1] Considering cost and environmental factors, the development of "green" catalytic processes is an important goal.[2]

During the last few years we have been interested in using high oxidation state oxo complexes of transition metals as catalysts for the oxidation and/or isomerisation of alcohols,[3,4] and we recently discovered the catalytic oxidation of primary and secondary alcohols with *cis*-dioxomolybdenum(VI) complexes with sulfoxides or *N*-oxides as co-oxidants (Scheme 1).[5]



Scheme 1

Although DMSO is a cheap oxidizing agent, DMS would be an unpleasant side-product in large-scale applications. Here we wish to report the selective catalytic oxidation of alcohols by a new heterobimetallic molybdenum-copper system that uses molecular oxygen as the oxidizing source.

Results and Discussion

In our previous catalytic system, $R_2S{=}O$ was used to re-oxidize the molybdenum-dioxo catalyst.[5] Initial investigations showed that substituting $R_2S{=}O$ by dioxygen gave only stoichiometric amount of benzaldehyde for the oxidation of benzylic alcohol. Knowing the capability of copper(I) for the fixation and/or activation of molecular oxygen,[6] we introduced a catalytic amount of copper(I/II) salt in place of the sulfoxide. As we expected, the oxidation of $PhCH_2OH$ was effective with this new heterobimetallic Mo–Cu–O_2 catalytic system in toluene at 100 °C (Scheme 2). Table 1 shows blank experiment results proving that both molybdenum and copper catalysts are essential to oxidize $PhCH_2OH$ to PhCHO under a molecular oxygen atmosphere.

Scheme 2

Table 1. Comparative blank and catalytic experiment results on $PhCH_2OH$ oxidation

Catalyst[a]	t[b] (h)	PhCHO (%)[c]
Mo^{VI}	5	5
Mo^{VI}/O_2	3	6
Cu^{II}	3	0
Cu^{II}/O_2	3	< 2
Fe^{II}/O_2	5	0
Mo^{VI}/Cu^{II}	3	6
$Mo^{VI}/Cu^{II}/O_2$[d]	3	98
$Mo^{VI}/Fe^{II}/O_2$[d]	5	75

[a] Mo^{VI} = 1 equiv. $MoO_2(acac)_2$, Cu^{II} = 1 equiv. $Cu(NO_3)_2$, Fe^{II} = 1 equiv. $FeBr_2$. – [b] 20 equiv. $PhCH_2OH$, 5 equiv. 4-toluic acid, molecular sieves (4 Å), toluene, 100 °C. – [c] GC determination. – [d] Catalytic run.

Typically, a great variety of Mo complexes can be used (e.g. alkoxides, chlorides, dithiocarbamates...), but further studies showed that the nature of the ligands around the molybdenum center is critical to the success of the reaction, with acetylacetonate ($acac^-$) proving the most effective.[7] On the other hand, varying the nature of the copper(II) counterion had little effect on the rate/yield of the reaction, for example $CuSO_4$, $Cu(OAc)_2$, $CuCl_2$, $Cu(NO_3)_2$, $Cu(acac)_2$ and copper(I) salts such as CuCl can also be used. Other transition metals salts known to activate O_2, such as Co^{II}, Fe^{II} and Mn^{II} have also been tested. With $Co(acac)_2$, $MnBr_2$, or $FeBr_2$ instead of a Cu^{II} salt we observed a slower oxidation of $PhCH_2OH$ with selectivities ranging from 75–94%. The Mo–Fe system, although less active, behaved sim-

ilarly to the Mo–Cu system, i.e. no oxidation is observed without the Mo catalyst (cf. blank experiments in Table 1); however, we verified that Co^{II} or Mn^{II} alone (i.e. without Mo catalyst) is responsible for some of the alcohol oxidation.[9]

The addition of 5 equivalents of a carboxylic acid (e.g. 4-toluic acid) to the molybdenum-copper system improved the rate and yields of the reaction; stronger acids such as *p*-TsOH have the opposite effect.[10] For similar reasons, we used powdered molecular sieves (4 Å) to trap the water formed during the alcohol oxidation, which improved the catalyst lifetime.[2a,2c,5] Therefore, our typical catalytic system consists of $MoO_2(acac)_2$ (1 equiv.), $Cu(NO_3)_2$ (1 equiv.), 4-toluic acid (5 equiv.), substrate (alcohol, 20 equiv.), powdered activated molecular sieves (4 Å), 1 atm of O_2 in toluene[11] at 100 °C.

The catalytic oxidation of various alcohols takes place under these conditions, and a few results are presented in Table 2. Primary benzylic alcohols are oxidized with nearly total selectivity to aldehydes with no further oxidation to the corresponding acid (Entries 1–5). Secondary benzylic alcohols are oxidized to ketones with good selectivity but at lower rates (Entry 6). Allylic alcohols are oxidized by this method with poor selectivity (Entries 7–8), a common side-reaction being isomerisation[5] to an allylic alcohol or dehydration leading to formation of an ether. Longer periods of reaction are needed for the oxidation of aliphatic alcohols, with only moderate selectivity (Entries 9–12), and in the case of tBuCH$_2$OH further oxidation into tBuCO$_2$H was observed at 120 °C (Entry 11). Attempts to oxidize more than 20 equivalents of substrate lead to lower rates due to deactivation of the catalyst by the water formed. Therefore, the activity of the Mo–Cu system appears to be lower than that of Ru–Cu systems,[2b,2c,4] and is limited to the oxidation of benzylic alcohols.

Studies on the oxidation of a series of *para*-substituted benzylic alcohols (R = Me, H, Cl, CF_3, NO_2) show no correlation with Hammett σ parameters and little variation in rate on the *para* substituent. Hence, benzyl radicals would appear not to be involved in the rate determining step of the oxidation process,[12,13] a conclusion which is further supported by the observation that radical traps such as 2,4,6-tri-*tert*-butylphenol or galvinoxyl have no effect on the rate of the oxidation. The catalytic oxidation of PhCH(D)OH with the Mo–Cu system at 100 °C gives a product ratio of PhCDO/PhCHO = 3.0. In parallel experiments, the overall rate of the catalytic oxidation of PhCH$_2$OH and PhCD$_2$OH at 100 °C gives a value of k_H/k_D = 1.8. Overall, these results support the direct involvement of the benzylic C–H bond in the rate-determining step.

Table 2. Oxidation of various alcohols with the Mo–Cu–O_2 catalytic system

Entry	Substrate[a]	t (h)	Product	Yield %[b]	Conversion %[b]	Selectivity %[b]

[a] 20 equiv. alcohol, 1 equiv. $MoO_2(acac)_2$, 1 equiv. $Cu(NO_3)_2$, 5 equiv. 4-toluic acid, MS 4 Å, toluene, 100 °C, 1 atm O_2. – [b] GC determination. – [c] Solvent: 1,2-dichlorobenzene, side-reaction: isomerisation into 2-methyl-3-buten-2-ol (32%). – [d] Side-reaction: etherification into ROR (R = cyclohexene) (30%). – [e] At 120 °C. – [f] Selectivity in aldehyde + acid: 66%.

Although the complete mechanism of oxidation with this new catalytic system is not yet fully understood, we propose the catalytic cycle depicted in Figure 1 based on the above observations for the oxidation of PhCH$_2$OH. An initiation would first result in the formation of an alkoxide complex (**a**) by displacement of the acac ligand, as already seen in the oxidation of alcohols with other molybdenum catalysts[5] and by previous experiments carried out in our laboratory, which show that such exchange processes occur

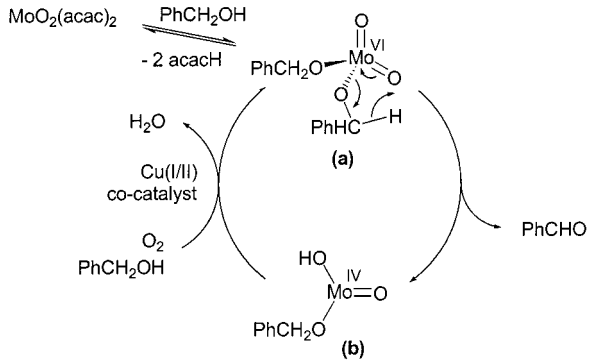

Figure 1. Proposed mechanism for the Mo–Cu–O_2-catalysed oxidation of $PhCH_2OH$; apparently low coordinate species **b** represented in this figure will have additional neutral ligands, such as alcohol, which have been omitted for simplicity

readily at electrophilic Mo^{VI} centers.[3,14] This point is further consistent with the higher rate of oxidation of $PhCH_2OH$ vs. PhCH(Et)OH which may result from the fact that prior coordination of the alcohols to the metal would be disfavored for the latter. A concerted process involving the transfer as a hydride of a β-hydrogen atom of the alkoxo ligand to one of the molybdenum-oxo entities via a five-membered cyclic transition state follows in a rate-determining step, with formation of PhCHO and a Mo^{IV} species (**b**). This transfer would result in the observed moderate primary kinetic isotope effect and is similar to the hydride transfer in other Mo-catalysed systems for the oxidation of alcohols.[5] The reoxidation of (**b**) into (**a**) by the copper salt in the presence of molecular oxygen is unclear. We can exclude a mechanism in which a copper(II) species may serve as the sole oxidant for the molybdenum by a pure redox Wacker-type process,[15] because the oxidation of $PhCH_2OH$ in the absence of molecular oxygen but with a twofold excess of Cu^{II} salt relative to the substrate (i.e. Mo/Cu/substrate = 1:40:20) proceeds with different characteristics (slow rate and very low selectivity in benzaldehyde) than the normal catalytic system under dioxygen atmosphere (Mo/Cu/substrate = 1:1:20).[16] In consequence, the regeneration of the Mo^{VI} active species (**a**) most certainly involves the activation of dioxygen by the copper co-catalyst.[17]

Further studies are needed to clarify the molybdenum reoxidation pathway and the exact function of the copper and carboxylic acid co-catalysts.

Conclusion

In conclusion, we describe a new, ecologically benign, Mo–Cu catalytic system for the aerobic oxidation of alcohols. Although so far limited to the oxidation of benzylic alcohols and with only moderate activities, this catalytic system remains very interesting from a mechanistic point of view and has been extended to the oxidation of alcohols by other oxo-metal complexes with higher activities.[4,21]

Experimental Section

General: All the substrates were purchased from Aldrich or Lancaster and were carefully dried over a suitable drying agent before use, distilled and stored under nitrogen (over molecular sieves 4 Å for liquids) in a glove box. 4-Toluic acid (Aldrich) was dried over P_2O_5 under vacuum. Molecular sieves (4 Å) were activated at 150 °C under vacuum, powdered and stored in a glove box. Toluene was dried over sodium, distilled and stored over molecular sieves in a glove box. $MoO_2(acac)_2$ was purchased from Aldrich or prepared following a literature procedure.[22] $Cu(NO_3)_2$ was obtained by drying $Cu(NO_3)_2{\cdot}2.5H_2O$ under vacuum at 100 °C for 48 hours and stored under nitrogen. $PhCD_2OH$ was prepared by treating ethyl benzoate with $LiAlD_4$ in diethyl ether, followed by hydrolysis with sodium hydroxide (10%), and distillation from CaH_2. PhCH(D)OH was prepared by treating PhCHO with $LiAlD_4$ in THF, followed by hydrolysis with $Na_2SO_4{\cdot}10H_2O$, dried with anhydrous $MgSO_4$, and distilled from CaH_2. The analyses of the catalytic reactions were carried out with a Hewlett–Packard 5890 Series II Gas Chromatograph equipped with a flame ionisation detector (FID) and a Hewlett–Packard HP-1 methyl silicon gum column of length 10 m, diameter 0.53 mm and 2.65 μm film thickness.

General Procedure for the Oxidation of $PhCH_2OH$: In a typical oxidation experiment, under nitrogen (glove box), $PhCH_2OH$ (257 mg, 20 equiv.), $MoO_2(acac)_2$ (39 mg, 1 equiv.), $Cu(NO_3)_2$ (23 mg, 1 equiv.), 4-toluic acid (81 mg, 5 equiv.), powdered molecular sieves (4 Å) (400 mg), and 2 g of toluene were placed in a 5- or 10-mL flask equipped with a stir bar and a reflux condenser. The reaction flask was connected to a molecular oxygen vacuum Schlenk line and heated at 100 °C for 3 h under 1 atm of O_2. Yield of PhCHO: 98% (determined by GC).

[10] Strong acids like *p*-TsOH have a detrimental effect on the catalysis, therefore the beneficial effect observed with a carboxylic acid may not come from its acidic proton character (as previously seen with other alcohols oxidation catalysts[5]) but from the coordinating properties of its carboxylate anion.

[11] 1,2-Dichlorobenzene can also be used, but we observed in some cases unwanted side-products. With donor solvents such as DMF and MeCN, rates are strongly decreasing, probably by inhibition of the copper function.

[16] In a Wacker-type process, to convert one equivalent of $PhCH_2OH$ to PhCHO, the catalytic system would need two equivalents of Cu catalyst in order to reoxidize the Mo center. To check the possibility of a pure redox Wacker-type process we performed the oxidation of $PhCH_2OH$ (20 equiv.) in the absence of O_2 with 1 equivalent of $MoO_2(acac)_2$ and 40 equiv. of copper(II) salt [$Cu(NO_3)_2$ or $Cu(OAc)_2$], at 100 °C for 3 hours. The reaction was carried out both in the absence of 4-toluic acid and with 5 equivalents of 4-toluic acid. In the reaction performed in the absence of carboxylic acid, we observed only the formation of 2% of PhCHO (instead of 29% with the "normal" Mo–Cu–O_2 system). In the presence of carboxylic acid, we observed the formation of 30% of PhCHO, but with a low selectivity (selectivity was only 60%, instead of 98% for the Mo–Cu–O_2 system). We believe that most of the PhCHO formed in anaerobic conditions in presence of 4-toluic acid results from a Cu-catalysed oxidation of $PhCH_2OH$ because in a blank experiment (40 equivalents Cu^{II}, 5 equivalents 4-toluic acid, but no Mo catalyst) we formed ca. 18% of PhCHO. We also noticed the same behavior with our Mo–Fe system when performing the same kind of experiments with an excess of Fe^{III} salt under argon [$MoO_2(acac)_2$ 1 equivalent, $FeCl_3$ 40 equivalents, 4-toluic acid 5 equivalents, $PhCH_2OH$ 20 equivalents 100 °C, 5 hours] with formation of only 3% PhCHO (with a selectivity in PhCHO of only 4%) which is in contrast to 75% PhCHO (selectivity in PhCHO: 75%) with the Mo–Fe system under O_2 (Mo/Fe 1:1).

[17] Copper(I) and iron(II) complexes are well known to coordinate, activate and transfer molecular oxygen.[6,18–20] We believe the Mo^{IV} complex is first oxidized to Mo^{V} by a redox process induced by the Cu^{II} salt which would generate a Cu^{I} species. The Cu^{I} species is essential for the next step which would involve the activation of O_2 and would result in the oxidation of the Mo^{V} complex with regeneration of the Mo^{VI} catalytic species **a**, possibly through a heterobimetallic μ-peroxo- or μ-oxo-Mo^{VI}–Cu^{II} complex.

Structural and Electrical Characterization of the Series $La_{1.33}Na_xMn_xTi_{2-x}O_6$

Ana Isabel Ruiz,[a] María Luisa López,*[a] María Luisa Veiga,[a] and Carlos Pico[a]

Dedicated to Prof. Gaitán on the occasion of his 70th birthday

Keywords: Perovskite phases / Mixed conductors / Materials science / Neutron diffraction / X-ray diffraction

A new series of perovskite-type materials of general formula $La_{1.33}Na_xMn_xTi_{2-x}O_6$ (x = 0.66, 0.55 and 0.44) was obtained and characterized. The common structure is rhombohedral (space group $R\bar{3}c$) although a transition to orthorhombic (space group *Ibmm*) is observed between 400 and 600 K for the x = 0.66 phase. Complex impedance techniques and charge/discharge cycles show a different electrical behavior that varies from a purely electronic conductor (x = 0.66) to a mixed electronic-ionic behavior for the other phases.

Introduction

Complex oxides with a perovskite or perovskite-type structure offer a wide range of interesting electrical properties, e.g. giant magnetoresistance, superconductivity and fast ion conductivity. In this context, complex oxides showing ion-electron conducting properties have received much attention due to their use as electrode materials in solid state batteries.

Perovskite-type oxides based on elements of the first transition series display a wide variety of defect-related phenomena which have their origin in the unfilled 3d electron shell. The relative ease with which electrons can be removed from or added to some metal cations, especially Fe and Mn, means that they often exist in different valence states, depending on the temperature and oxygen partial pressure. This fact also gives rise to a potentially large number of phases, which themselves may deviate from exact stoichiometry in terms of both cation and oxygen contents.[1] On the other hand, defects in perovskite oxides can arise from cation deficiency and the resulting vacancies often form ordered superstructures.

Among the mixed oxides with the perovskite structure, those containing Mn cations have recently attracted a great deal of interest due to their giant negative magnetoresistance effects.[2−4] The parent compound $LaMnO_3$ is an antiferromagnetic insulator in which an orbital ordering is established by means of the cooperative Jahn-Teller effect breaking the degeneracy of the electronic configuration of Mn^{3+} ($t_{2g}^3\ e_g^1$).[5] This order seems to be responsible for an orthorhombic to rhombohedral phase transition at about 873 K which is similar to other structural transitions that take place at elevated temperatures in some related systems.[6,7] It was previously reported[8] that as the orthorhombic (space group *Pbnm*) distortion of the perovskite arrangement decreases, the rare-earth, O1 and O2 atoms approach the ideal positions at (0 0 1/4), (0 1/2 1/4) and (1/4 1/4 0), respectively.

We have recently reported some results on ionic conductors, especially in perovskites of general formula $Ln_{1.33-x}Na_{3x}Ti_2O_6$.[9−10] The partial substitution of titanium by manganese in these compounds could lead to mixed conductors showing high ionic and electronic conductivity. The measurement and control of mixed ionic-electronic conductivities has become recognized as being of technological importance in an increasing number of systems. Therefore, the aim of this paper is to report both the structural and electrical behaviors of $La_{1.33}Na_xMn_xTi_{2-x}O_6$ ($0.66 \geq x \geq 0.44$). A detailed investigation of the phase $La_{1.33}Na_{0.66}Mn_{0.66}Ti_{1.34}O_6$ has been undertaken in order to clarify the parameters controlling the crystal structure of this material. An orthorhombic to rhombohedral transition was found as in $LaMnO_3$. Nevertheless, the orthorhombic space group is different, *Ibmm*, and only a rhombohedral symmetry, $R\bar{3}c$, was found for the remaining compositions. Conductivity measurements were performed and the results are interpreted on the basis of the compositional features.

Results and Discussion

For the series $La_{1.33}Na_xMn_xTi_{2-x}O_6$, pure phases were found in the compositional domain $0.66 \leq x \leq 0.44$. All samples have the characteristic X-ray diffraction patterns of the perovskite structure, in which some reflections are split

Table 1. *R* factors agreement obtained in the refinements by XRD and ND

indicating a noticeable distortion from the ideal cubic symmetry. For $x = 0.66$, the refinement was carried out in the rhombohedral space group $R\bar{3}c$, giving the unit cell parameters $a = 5.488$ Å and $c = 13.451$ Å; the R factors obtained in the refinement are gathered in Table 1.

On the other hand, an orthorhombic symmetry (whose parameters are related to the ideal perovskite ones as follows: $a_o \approx b_o \approx \sqrt{2}\, a_p$ and $c_o \approx 2\, a_p$) could be taken into account if we consider the Goldschmidt[11] factor, $t = [d(A-O)]/[\sqrt{2}\, d(B-O)]$, which is generally used as a tool for studying the perovskite structure. In our case, the value of $t = 0.97$, is compatible with an orthorhombic distortion. The XRD refinements were carried out in the space groups *Pbnm* and *Ibmm,* and the *R* factors obtained are included in Table 1. However these space groups give quite similar values and the results do not allow us to determine which is the more reliable structural model.

Neutron diffraction (ND) data were collected for the phase $La_{1.33}Na_{0.66}Mn_{0.66}Ti_{1.34}O_6$ in order to clarify the space group assignment. The *R* factors obtained by means of ND for the different space groups are also given in Table 1 and these results clearly suggest that the structure is accurately described in the *Ibmm* space group.

Neutron diffraction data were also collected for the same phase ($x = 0.66$) at different temperatures and were refined in an orthorhombic cell (space group *Ibmm*) at temperatures below 400 K that changes to a rhombohedral symmetry (space group $R\bar{3}c$) at higher temperatures (between 600 and 700 K).

The refined atom positions, lattice parameters and *R* factors obtained are listed in Table 2. The agreement between the observed and calculated integrated intensities of both orthorhombic and rhombohedral phases are considered as satisfactory with values of the crystal structure model indicators $R_B \leq 4.35$. The values of R_P and R_{WP} were ≤ 8.21 showing the reliability of the structure analysis.

To illustrate graphically the matches between the complete observed and calculated data, neutron diffraction patterns and difference plots for the orthorhombic (300 K) and the rhombohedral (700 K) forms of $La_{1.33}Na_{0.66}Mn_{0.66}Ti_{1.34}O_6$ are plotted in Figures 1a and 1b, respectively. We will discuss the main characteristic features of both structures separately.

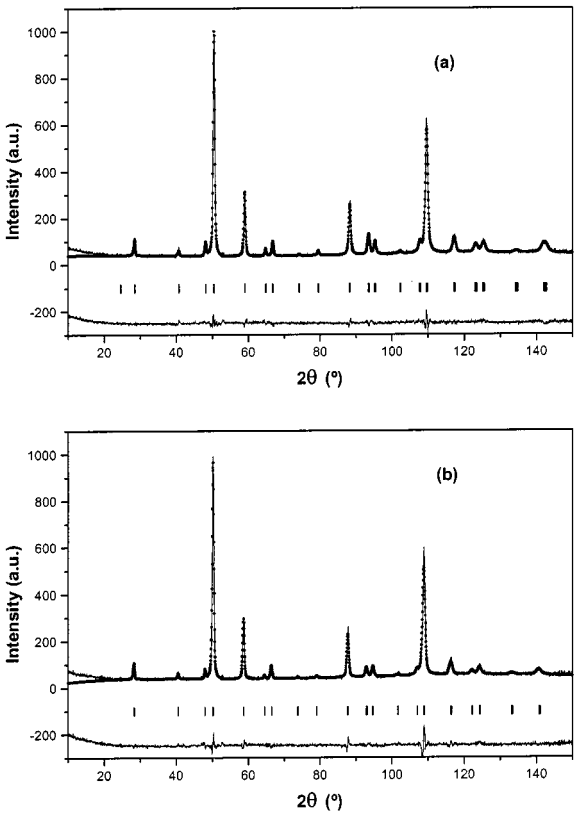

Figure 1. Calculated (full line) and observed (dots) ND patterns and difference spectrum for $La_{1.33}Na_{0.66}Mn_{0.66}Ti_{1.34}O_6$: (a) orthorhombic (300 K) and (b) rhombohedral (700 K)

Orthorhombic $La_{1.33}Na_{0.66}Mn_{0.66}Ti_{1.34}O_6$

The room temperature phase was refined in the orthorhombic space group *Ibmm*. Previous fits of the experimental results in the space group *Pbnm*, that frequently appears in orthorhombic perovskites, give higher *R* factors. In the inner-centered unit cell the Mn and Ti atoms are fixed at the 4b sites, and the La and Na atoms are located at the 4e, the O1 at the 4e and the O2 atoms at the 8g sites. The structure refinement for the title compounds, obtained separately from XRD and ND, are in good agreement and for the remaining compositions only XRD results will be discussed. An examination of the refined atomic coordinates, listed in Table 2, shows that Mn and Ti are placed on the ideal sites and the other atoms are only slightly displaced from their respective ideal positions. A comparison of the atomic coordinates obtained at 300 and 400 K shows that La, Na, O1 and O2 atoms remain nearly unchanged with temperature. Cations in the A-perovskite sites (La/Na) and

in the B ones (Mn/Ti) will be noted in the following discussion as A and B, respectively.

To study the distortion around the Mn and Ti atoms which are in a BO_6 octahedral coordination, the interatomic distances, O−B−O angles and standard deviations have been calculated and are listed in Table 3. There are two different B−O sets of bond lengths in the octahedra, the average of which scarcely varies (from 1.948 to 1.949 Å) with increasing temperature. The average B−O distances are in good agreement with the sum of the Shannon ionic radii.[12] There are four different O−B−O angles with small deviations from the ideal 90° angle for a cubic perovskite. As can be seen from the interatomic distances and angles, the distortion within the BO_6 octahedron is rather small and the values are closer to ideal ones.

The orthorhombic distortion with respect to a cubic structure can be viewed as the BO_6 octahedra having faces tilted towards or away from each other and therefore the values of the B−O−B angles can be used to study the octahedra tilting. As shown in Table 3, the B−O1−B and B−O2−B angles for the orthorhombic phase $La_{1.33}Na_{0.66}Mn_{0.66}Ti_{1.34}O_6$ are significantly different from 180°, which is the expected value for an ideal cubic perovskite, and the octahedra tilting is ≈12.5°.

Lanthanum and sodium are located in the A sites and inside a twelve-coordinated polyhedron; the respective values of the A−O interatomic distances are gathered in Table 3. In comparison with those of the BO_6 octahedra, the A−O bond lengths vary over a wide range, indicating that these later polyhedra are quite distorted. An inspection of the twelve interatomic distances does not show any discontinuity in the increasing distances, and a division between the eight first-nearest and the four second-nearest oxygen atoms cannot be made, suggesting that it would be a good approximation to assign coordination number 12 to La and Na. The mean A−O distances are of the same order as the Shannon ones.

Rhombohedral $La_{1.33}Na_{0.66}Mn_{0.66}Ti_{1.34}O_6$

The high temperature phase is described as rhombohedral in the space group $R\bar{3}c$. From the hexagonal axes of reference, the A and B atoms are fixed at the 6a and 6b sites, respectively, and the O atoms are located at the 18e ones. The refined atomic coordinates, listed in Table 2, show that only the O atoms are slightly displaced from the ideal positions (1/2 0 1/4) with $\Delta x \approx 0.03$. The refined lattice parameters referring to hexagonal cell coordinates are also given in Table 2 (columns 600 and 700 K), the actual displacement of the O atoms from the ideal positions being about 0.16 Å. The respective values of the rhombohedral unit cell parameters, a_R and α_R, are 5.4990 Å and 60.08° (at 600 K) and 5.5093 Å and 60.10° (at 700 K), respectively.

The refined interatomic distances and angles of the BO_6 octahedron for this high temperature phase are also listed in Table 3, and show that each B atom is surrounded by six almost equidistant O atoms. The O−B−O angles are slightly deviated (± 0.3°) from the ideal value of 90° indicating that the distortion within a BO_6 octahedron is very small. However, the B−O−B angles are significantly different from the ideal angle of 180°, showing that octahedral tiltings remain in the rhombohedral phase. A structural model is depicted in Figure 2, in which the slight nonlinearity of the B−O−B bonds, which are deviated by around 10°, is denoted by the full lines.

The rhombohedral distortion can be viewed as being derived from a rotation of the BO_6 octahedra around the

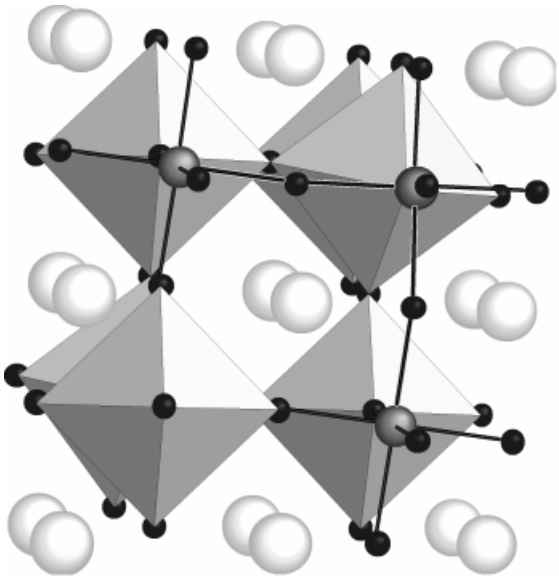

Figure 2. Structural model for compounds with rhombohedral symmetry

three-fold axis by an angle ω from the ideal perovskite position. The angle of rotation ω may be calculated from the oxygen position using $x = (\sqrt{3} - \text{tg}\ \omega)/\sqrt{12}$. The values of ω calculated at 600 and 700 K are 6.03° and 5.46°, respectively. There are different types of A−O distances for the rhombohedral phase of $La_{1.33}Na_{0.66}Mn_{0.66}Ti_{1.34}O_6$. In the absence of a sharp discontinuity in the increasing A−O distances we have assigned a coordination number 12 for the oxygen distorted polyhedra around these A atoms.

As stated above, the phase $LaMnO_3$ shows a cooperative Jahn-Teller effect that seems to be responsible for the orthorhombic to rhombohedral phase transition. Nevertheless, in our material ($x = 0.66$) only a third of the octahedral B-sites are effectively occupied by Mn^{3+}, with Ti^{4+} in the remaining ones, and any cooperative distortion must be excluded. This fact is supported by the similar B−O bond lengths that were encountered. Moreover, in the following phases ($x = 0.55$ and 0.44) only a rhombohedral symmetry appears in the whole range of temperatures studied, and therefore the adoption of such a symmetry in these systems with lower Mn^{3+} content cannot be attributed to a cooperative Jahn-Teller effect.

Rhombohedral $La_{1.33}Na_{0.55}Mn_{0.55}Ti_{1.45}O_6$ and $La_{1.33}Na_{0.44}Mn_{0.44}Ti_{1.56}O_6$

X-ray diffraction data for the phases $x = 0.55$ and 0.44, were tentatively refined on the basis of the space groups *Pbnm* and *Ibmm,* but the best fits were found in a rhombohedral symmetry (space group $R\bar{3}c$). Table 4 gathers the crystal parameters and *R* factors obtained for these compounds and a plot of the final observed, calculated and difference profiles is given in Figure 3 (for the composition $x = 0.44$). The agreements between profiles and *R* factors seem to confirm the validity of the proposed structural model. The basic features of the rhombohedral phases have been confirmed, and the results may be compared with those obtained in our neutron diffraction study.

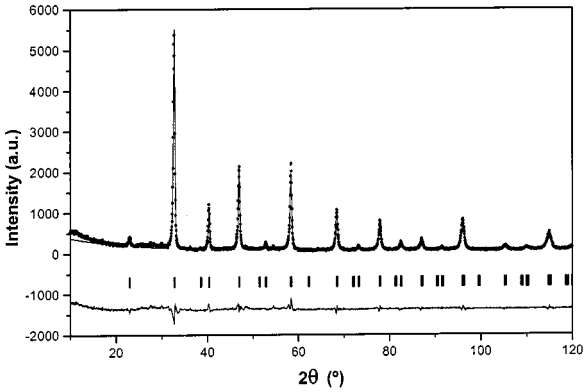

Figure 3. Calculated (full line) and observed (dots) XRD patterns and difference spectrum for $La_{1.33}Na_{0.44}Mn_{0.44}Ti_{1.56}O_6$ (rhombohedral)

On this basis, no differences in B−O bond lengths are encountered (1.952 Å for $x = 0.55$ and 1.948 Å for $x = 0.44$) and all the octahedra are regular. In consequence, the possible presence of a cooperative Jahn-Teller distortion, if it exists at a local level in the MnO_6 octahedra, is undetectable in the structure.

Electrical Properties

Measurements of a.c. impedance spectra have been carried out by alternating current techniques from the complex impedance (Z) plots. Experimental graphs at various temperatures show a semicircle and a spike. An apparent change in the nature of the charge carriers take place from electronic to electronic-ionic mixed conductors when x decreases, and this fact seems to be related to the higher number of cation vacancies in the structure.

Figure 4 shows the Z'' (imaginary part) vs. Z' (real part) plots for $x = 0.66$ at 300 and 326 K; it can be seen that the semicircle is somewhat depressed at this latter temperature.

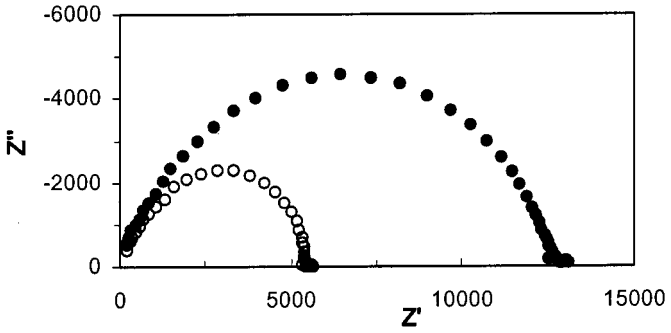

Figure 4. Complex impedance plots at 300 and 326 K for $La_{1.33}Na_{0.66}Mn_{0.66}Ti_{1.34}O_6$

However, for the samples $La_{1.33}Na_{0.55}Mn_{0.55}Ti_{1.45}O_6$ and $La_{1.33}Na_{0.44}Mn_{0.44}Ti_{1.56}O_6$ at temperatures between 298 and 333 K, a semicircle and a spike at low frequencies which is inclined by about 40° with respect to the Z′ axis were observed, and these could be associated with an electrode-electrolyte response (Figure 5, for $x = 0.55$).

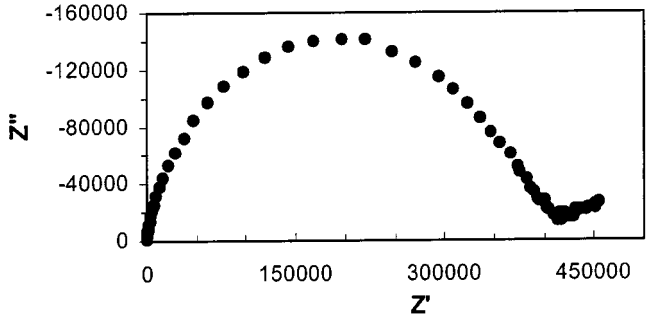

Figure 5. Complex impedance plots at 313 K for $La_{1.33}Na_{0.55}Mn_{0.55}Ti_{1.45}O_6$

Conductivity values for all samples were determined from the complex impedance plots over a wide range of temperatures and they can be fitted to an Arrhenius equation of the form: $\sigma = \sigma_o \times \exp(-Ea/kT)$. Figure 6 shows the linear plots of log σ vs. 1000/T for the three compositions. Conductivity values decrease with decreasing x, this fact being related to the total number of mobile sodium cations in the structure, although the respective activation energies remain almost constant.

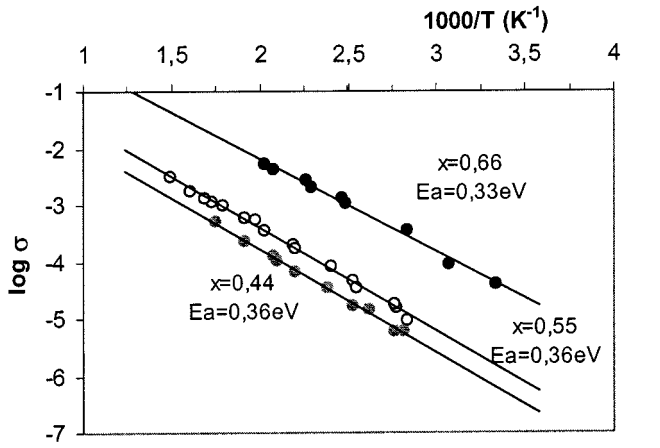

Figure 6. Arrhenius plots for the system $La_{1.33}Na_xMn_xTi_{2-x}O_6$

Charge/discharge experiments on cells consisting of pellets sandwiched between blocking platinum electrodes, showed that significant amounts of current could be passed on the charging cycle but another considerable amount is also detected on subsequently placing the cell in the discharge mode.[13] This phenomenon suggests that the products of charging were stored in the vicinity of the electrodes and were subsequently recovered on discharge, thereby indicating that a certain amount of ionic conduction occurs.

For purely ionic transport, where all the charge passed is stored and released on discharging, the ratio Q_d/Q_c (where Q_d and Q_c are the quantities of charge passed on the discharging and charging mode, respectively) should have the ideal value of unity. In a mixed ionic/electronic conductor, this ratio gives an approximate estimation of the ionic transport number, if one assumes that the reactions occur at the electrode-electrolyte interface during charging. For

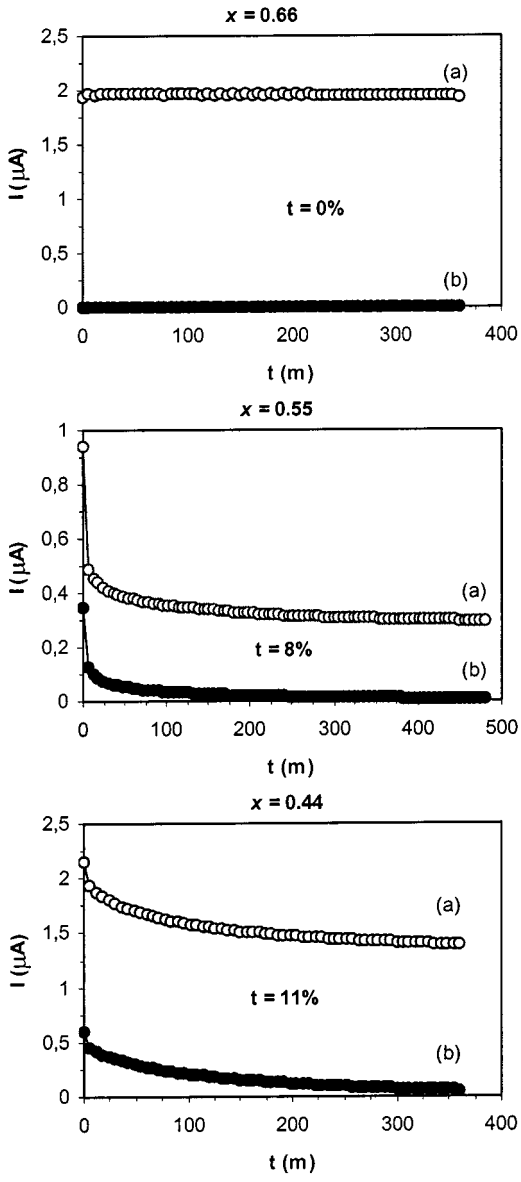

Figure 7. Current vs. time curves for charging/discharging for $x = 0.66$, 0.55 and 0.44 at 313 K (a) charging (b) discharging

purely electronic transport, the discharge current should be zero and the ratio Q_d/Q_c must also be zero. The following results of charging/discharging experiments have been interpreted in terms of these hypotheses.

The experimental results of charge/discharge processes at 313 K for all compositions are summarized in Table 5, and the respective curves are shown in Figure 7. The total charge passed through the system was calculated from the area under the I vs. t curves.

Table 5. Results of charging/discharging experiments at 313 K for $La_{1.33}Na_xMn_xTi_{2-x}O_6$

Composition	Q_c (C)[a]	Q_d (C)[b]	$t \approx Q_d/Q_c$[c]
0.66	7.04×10^{-4}	1.08×10^{-7}	1.53×10^{-4}
0.55	1.61×10^{-4}	1.29×10^{-5}	8.05×10^{-2}
0.44	5.53×10^{-4}	6.04×10^{-5}	1.09×10^{-1}

[a] Amount of charge passed during charging mode. – [b] Amount of charge recovered during discharging mode. – [c] Ionic transport number.

These results seem to confirm the different electric behavior of the materials as a function of their composition. The sample $x = 0.66$ (in which La and Na cations occupy all the A sites in the perovskite structure) behaves as a purely electronic conductor because ionic contribution is hindered. The samples $x = 0.55$ and 0.44 possess a relatively low number of A vacancies to which Na cations can move, and they show a mixed electronic-ionic conduction behavior.

Conclusion

In order to investigate materials with mixed ionic-electronic properties for their use as electrodes in solid-state batteries, some phases of general composition $La_{1.33}Na_x$-$Mn_xTi_{2-x}O_6$ have been obtained. From neutron powder diffraction data a structural transition between the orthorhombic (space group *Ibmm*) and rhombohedral (space group $R\bar{3}c$) symmetries is seen for $x = 0.66$. A similar transition from *Pbnm* to $R\bar{3}c$ symmetry is known for $LaMnO_3$ which is accompanied by an increase in the coordination number of A-cations from 8 to 12. In this respect, the space group *Ibmm* can be considered as a distorted intermediate that maintains the higher coordination number but shows a wide range of A–O bond lengths. The phases $x = 0.55$ and 0.44 adopt the rhombohedral $R\bar{3}c$ symmetry in which the BO_6 octahedra are clearly isolated and do not show any cooperative Jahn-Teller distortion.

All these phases behave as good conductors, on the basis of the relatively low activation energies, and, bearing in mind the absence of vacancies in the A sites when $x = 0.66$, this phase is a pure electronic conductor. The charge/discharge results can be interpreted as a function of the structural features.

Experimental Section

General Remarks: Polycrystalline samples of general composition $La_{1.33}Na_xMn_xTi_{2-x}O_6$ ($x = 0.66$, 0.55 and 0.44) were prepared by a classical ceramic method, from powdered mixtures of La(NO3)3·6H2O, $NaNO_3$, $C_{15}H_{21}MnO_6$ [manganese(III) acetylacetonate] and $C_{10}H_{14}O_5Ti$ (titanyl acetylacetonate), in a stoichiometric ratio, at 973 K for several days.

X-ray diffraction patterns were recorded with a Philips X′Pert-MPD diffractometer and a PW 3050/00 goniometer, using Ni-filtered Cu-K_α radiation and 2θ step size of 0.05°, with a counting time of 12.5 s for each step. The goniometer was connected to a PC controlled by the commercial program PC-APD (Analytical Powder Diffraction Software, 4.0).

The neutron powder diffraction data were recorded at four different temperatures on the D1A high-resolution powder diffractometer ($\lambda = 1.9110$ Å) at the Institut Laue-Langevin (Grenoble, France). The neutron and X-ray diffraction patterns were analyzed through the Rietveld method by the Fullprof program.[14] A pseudo-Voigt function was chosen to generate the line-shape of the diffraction peaks.

Electrical measurements were carried out with a Solartron 1260 Impedance/Gain Phase Analyzer with a frequency range of 0.1 Hz – 10 MHz. Samples were pressed into pellets and then sintered in air at 973 K for 48 h. Blocking electrodes were deposited on two faces of the pellets with platinum paint.

Polarization experiments in dc were carried out at 313 K with a charging voltage of 1 V for the compositions $x = 0.66$, 0.55 and 0.44. These samples and electrodes were the same as those used for conductivity measurements. The equipment includes a standard resistor that was in series with the sample during the charging and discharging cycles.

Cathodic Reactions Involved in Corrosion Processes Occurring in Concentrated Nitric Acid at 100 °C

Fanny Balbaud,*[a] Gérard Sanchez,[a] Gérard Santarini,[a] and Gérard Picard[b]

Keywords: Autocatalysis / Cyclic voltammetry / Nitric acid / Nitrogen oxides / Reduction mechanism

In order to explain and analyze the corrosion process of AISI 304 L stainless steel in the presence of nitric acid condensates, the reduction mechanism of nitric acid was studied on a platinum electrode in various nitric acid solutions (4 mol·L^{-1}, 8 mol·L^{-1} and 12 mol·L^{-1}) at 100 °C. Classical electrochemical techniques were used: cyclic voltammetry, chronoamperometry on a stationary electrode as well as on a rotating disk electrode. A reduction mechanism is proposed; this mechanism is autocatalytic and involves a charge-transfer step and a heterogeneous chemical reaction which regenerates the electroactive species at the electrode surface. The electroactive species is assumed to be nitrous acid which is a soluble species. The other compounds involved in the reduction mechanism are NO and NO_2, which are supposed to be adsorbed. The nitric acid concentration influences the major product of the reduction process: NO for concentrations lower than 8 mol·L^{-1} and NO_2 for higher concentrations.

Introduction

Nuclear fuel reprocessing is achieved in France using nitric acid as the dissolution reaction medium. The corrosiveness of nitric acid mixtures leads to the use of corrosion-resistant materials such as austenitic stainless steels or zirconium.

Some potential cases of intergranular corrosion have been identified in experimental devices and studied on non-sensitized stainless steels, for example, in confined and non-renewed nitric acid.[1] However in some specific conditions, uncertainties about the mechanisms involved remain. Corrosion in the presence of nitric acid condensates is one of these cases and can be encountered in any installation handling boiling nitric acid. A specific loop, named ECORCE (Etude de la CORrosion sous Condensat d'Evaporation), designed at the laboratory, revealed a much more severe corrosion of stainless steels by nitric acid condensates than in the liquid bulk under similar conditions of concentration and temperature.[2] In fact, the condensate medium can lead to such highly oxidizing conditions that the corrosion potential of the steel can reach the transpassive domain.

Very few literature data have been found on this phenomenon and no thorough study has been performed. Therefore, in order to understand and analyze the corrosion mechanism of AISI 304 L stainless steel in the presence of nitric acid condensates, a research project was performed in this laboratory. The first step of this study consisted in a thermodynamic analysis of the chemical and electrochemical properties of nitric acid media.[3] This analysis led to a representation of concentrated nitric acid at 100 °C. One of the results of this study concerns the influence of the nitric acid concentration on the reduction species of nitric acid. Major species liable to be found when nitric acid is reduced at potentials close to the equilibrium potential were determined: nitrogen monoxide for nitric acid concentrations lower than 8 mol·L^{-1} and nitrogen dioxide for higher concentrations.[3]

This paper presents the second step of the research project which is the electrochemical investigation of the reduction process of nitric acid at 100 °C occurring on a platinum electrode. The platinum electrode was used as working electrode in order to avoid the oxidation of the electrode material and to focus the research on the reduction process. This electrochemical study appeared necessary as previous corrosion studies performed on AISI 304 L stainless steel in nonrenewed and confined liquid nitric acid[1] revealed the necessity of investigating the cathodic part of the corrosion process by suggesting a major role of the reduction mechanism on the increase in the corrosion rate.

The working temperature in the thermodynamic study[3] and in the electrochemical study was fixed at 100 °C as the metallic wall temperature is close to this value in the condensation zones.

In a last step, it will be necessary to perform a similar electrochemical study on a stainless steel electrode in order to compare the reduction process obtained with the one observed on a platinum electrode and, secondly, to link these results to the results of the corrosion tests performed in the laboratory.[4] The final aim of this research is to ex-

plain the corrosion mechanism of AISI 304 L stainless steel in the presence of nitric acid condensates.

Literature Data

The Reduction Mechanism of Nitric Acid on a Platinum Electrode

This process has been widely studied over many years.[5–13] All the authors agree on its autocatalytic nature, characterized by the predominant role of the reduction products. It is also generally believed that the nitric acid molecule is not the electroactive species.

In nitric acid solutions of concentrations from 1 to 10 mol·L^{-1}, at 25 °C, containing nitrous acid,[5–12] two different autocatalytic mechanisms have been formulated respectively by Vetter and Schmid.

According to Vetter the mechanism is heterogeneous, as the chemical regeneration of NO_2, assumed to be the electroactive species, occurs at the electrode surface. NO_2 is formed at the interface according to a previous slow heterogeneous chemical reaction. In that case, the stirring of the solution has no influence on the current density.[5–7] This mechanism is described as:

$$(HNO_2)_{ads.} + H^+ = (NO^+)_{ads.} + H_2O$$
$$(NO_3^-)_{ads.} + (NO^+)_{ads.} = (N_2O_4)_{ads.}$$
$$(N_2O_4)_{ads.} = 2(NO_2)_{ads.}$$
$$(NO_2)_{ads.} + e^- = (NO_2^-)_{ads.}$$
$$(NO_2^-)_{ads.} + H^+ = (HNO_2)_{ads.}$$

According to Schmid the mechanism is homogeneous, as the chemical regeneration of NO^+, assumed to be the electroactive species, occurs in the bulk. NO^+ (equivalent to HNO_2) is obtained from the nitrous acid formed in the layer near the electrode. In that case the stirring of the solution provokes a decrease of the current density.[8–12] This mechanism is described as:

$$HNO_2 + H^+ = NO^+ + H_2O$$
$$NO^+ + e^- = NO$$
$$2NO + NO_3^- + H^+ + H_2O = 3HNO_2$$

These two mechanisms, for a long time opposed, have both been validated by Razygraev who worked in a large range of concentrations and temperatures.[13] He supposed that both mechanisms occur on a platinum electrode, but for different potentials, leading to NO_2 (heterogeneous mechanism) or NO (homogeneous mechanism).

The Reduction Mechanism of Nitric Acid on a Stainless Steel Electrode

The same study was performed on stainless steels and alloys by Razygraev.[14] He concluded that an identical sequence of reactions was taking place on the different materials as on the platinum electrode, except that both mechanisms occurred simultaneously on stainless steels.

A recent study on the effect of dissolved chromium species on the corrosion of stainless steel in nitric acid confirmed the autocatalytic characteristic of the reduction of nitric acid on a gold electrode as well as on a stainless steel electrode.[15] This study revealed the lack of influence of Ar, N_2 and N_2O on the corrosion rate of stainless steel and the effect of a continuous bubbling of NO and NO_2, which leads to an increase in the corrosion rate by a catalytic mechanism. However, no reduction mechanism of nitric acid was proposed and the role of the different nitric acid species was not clearly specified.

Conclusions from Literature Data

The knowledge of the corrosion mechanism of AISI 304 L stainless steel in the presence of nitric acid condensates involves the understanding and the analysis of the reduction process of nitric acid.[1]

Literature data on the reduction process of nitric acid occurring on a platinum electrode are very numerous and sometimes contradictory. However, the studies presented in the literature agree on two major points: the reduction mechanism is autocatalytic and the electroactive species is not nitric acid.

The major uncertainties remaining are:

- the identity of the electroactive species at low overvoltages (potential range investigated for the corrosion study): HNO_2, NO^+, NO_2,
- the regeneration site of the electroactive species: electrode surface, solution,
- the influence of the concentration of nitric acid on the reduction process,
- the relationship between the reduction process and the thermodynamic behavior of nitric acid.

In this paper, our aim is to clarify these uncertainties, to identify the major species involved in the reduction process of nitric acid, and to propose a sequence of reactions explaining the experimental facts observed.

Results and Discussion

Various electrochemical techniques have been used: cyclic voltammetry, chronoamperometry with a stationary electrode as well as with a rotating disk electrode.

The values of the Open Circuit Potential (OCP) of the platinum electrode in the nitric acid solutions are given in Table 1. The values of the nitrous acid concentrations are estimated from thermodynamic calculations.[3]

Table 1. Experimental values of the Open Circuit Potential of the platinum electrode in the three nitric acid solutions at 100 °C – corresponding calculated nitrous acid concentration

$[HNO_3]$ [mol·L^{-1}]	OCP [V/SSE][a]	$[HNO_2]$ [mol·L^{-1}]
4	0.550	3.1×10^{-5}
8	0.630	7.5×10^{-6}
12	0.680	7.5×10^{-6}

[a] SSE: $Hg/Hg_2SO_{4(sat.)}$, $K_2SO_{4(sat.)}$.

The electroactivity domain of a solution of nitric acid 4 mol·L^{-1} is presented in Figure 1. The potentials were investigated between 0.400 V/SSE and 1 V/SSE. For higher overvoltages a gaseous evolution occurs.

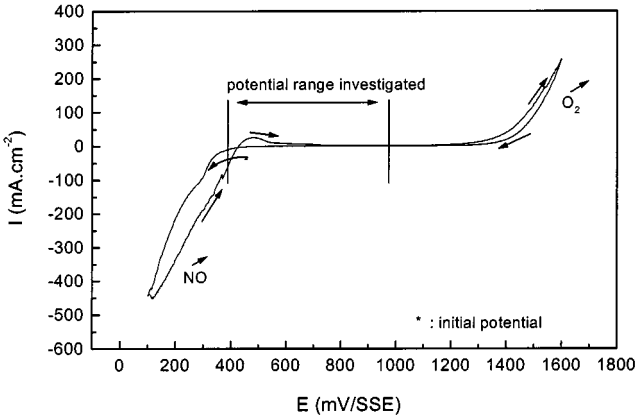

Figure 1. Electroactivity domain of HNO_3 4 mol·L^{-1} at 100 °C at a scan rate of 10 mV·s^{-1}; in reduction, NO evolution; in oxidation, O_2 evolution

Nitric Acid Solutions With No External Additions

Current-Potential Curves at a Low Scan Rate

Figures 2 and 3 show voltammograms obtained on a stationary electrode for nitric acid concentrations of 4 mol·L^{-1}, 8 mol·L^{-1} and 12 mol·L^{-1} at a scan rate of 10 mV·s^{-1}. The curves are presented in a log scale.

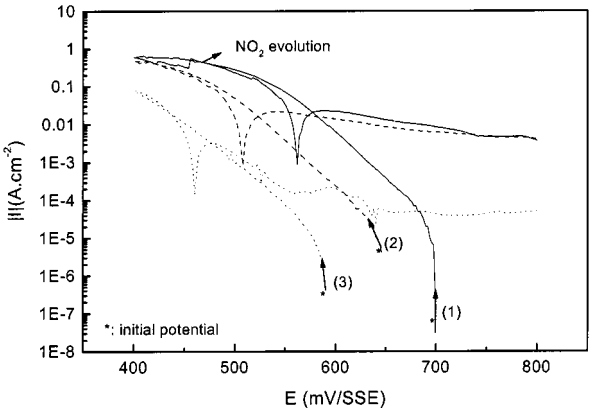

Figure 2. Cyclic voltammograms for HNO_3 solutions of different concentrations at 100 °C at a scan rate of 10 mV·s^{-1}. (1): 12 mol·L^{-1} (2): 8 mol·L^{-1} (3): 4 mol·L^{-1}

For the three solutions, the scans were performed from the OCP to the same potential of 0.400 V/SSE and then reversed (Figure 2). For HNO_3 4 mol·L^{-1}, another curve was placed on the diagram for which the scan was performed down to 0.250 V/SSE (Figure 3).

The oxidation peak is assigned to the oxidation of species formed during the reduction of nitric acid, which is confirmed by the absence of this peak when a scan is performed directly on oxidation.

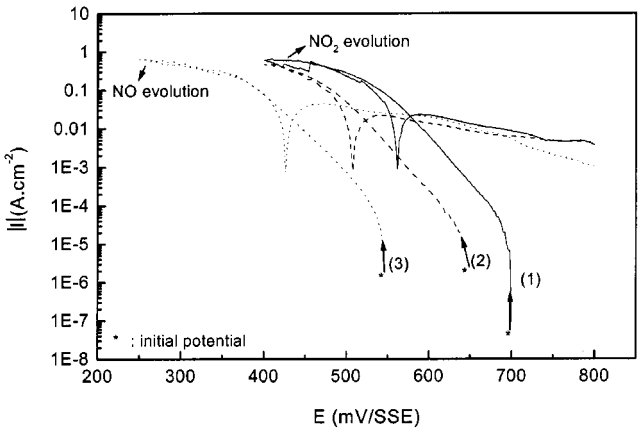

Figure 3. Cyclic voltammograms for HNO_3 solutions of different concentrations at 100 °C at a scan rate of 10 mV·s^{-1}. (1): 12 mol·L^{-1} (2): 8 mol·L^{-1} (3): 4 mol·L^{-1}

The analysis of the experiments and the visual observations show that:

– for the three concentrations, the voltammograms are similar: current densities are almost equal for the same overvoltage (taken from the OCP);
– a red gaseous evolution of NO_2 is observed for HNO_3 12 mol·L^{-1} and 8 mol·L^{-1};
– a colorless gaseous evolution (probably NO) is observed for HNO_3 4 mol·L^{-1} for a potential of 0.250 V whereas no evolution is observed for 0.400 V/SSE.

Figure 4 shows the representation [log$p$(O_2)] versus [–log$p$(HNO_3) and pH] of nitric acid at 100 °C established previously.[3] The curves represent the calculated values of the oxygen pressure for which the partial pressures of NO and NO_2 are equal to 1 bar and the concentration of nitrous acid to 10^{-2} mol·L^{-1}. The links between the oxygen pressure and the experimental potential values are determined by potentiometric measurements for 4 mol·L^{-1}, 8 mol·L^{-1} and 14.4 mol·L^{-1} solutions (determination of the potential for p_{NO2} = 1 bar at the different concentrations) and by considering that $\Delta\log p(O_2) = 1$ for $\Delta E = 2.303RT/4F = 18.5$ mV.[3] For a given potential, the oxygen pressure varies with the nitric acid concentration.

At 100 °C, the electroactivity domain of nitric acid in reduction (nonhatched domain) under a pressure of one bar is divided into two parts. The formation of NO limits the stability domain for concentrations lower than 8 mol·L^{-1} and the formation of NO_2 for higher concentrations. With this diagram, the voltammetric results can be analyzed:

– for HNO_3 12 mol·L^{-1} and 8 mol·L^{-1}, a potential of 0.400 V/SSE applied to the platinum electrode corresponds to oxygen pressures far outside the stability domain of nitric acid and an evolution of NO_2 occurs;
– for HNO_3 4 mol·L^{-1}, the potential of 0.400 V is very near the stability domain of HNO_3. Thus, no gaseous evolution occurs. However, the potential of 0.250 V is located far outside the stability domain and then a gaseous evolution of NO is observed.

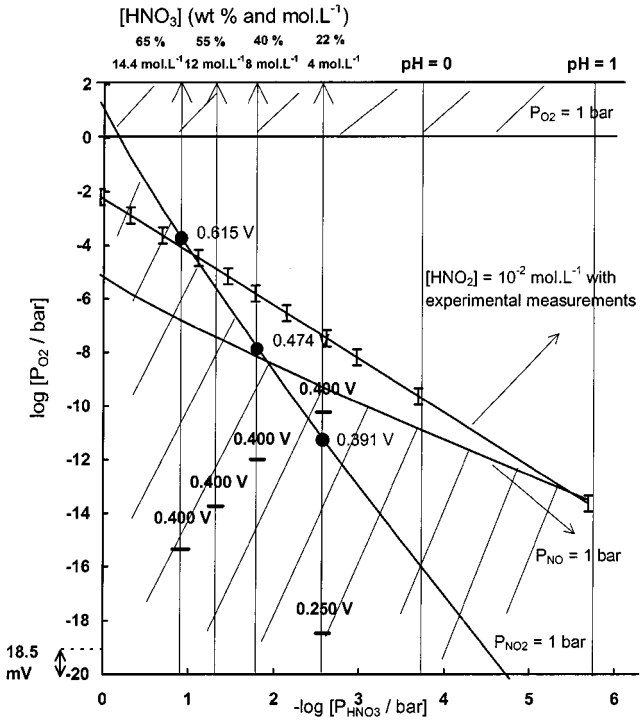

Figure 4. Representation of the chemical and electrochemical properties of concentrated nitric acid at 100 °C. •: Potential values for p_{NO2} = 1 bar (V/SSE at 25 °C); –: potential limits of the electrochemical investigations (V/SSE at 25 °C)

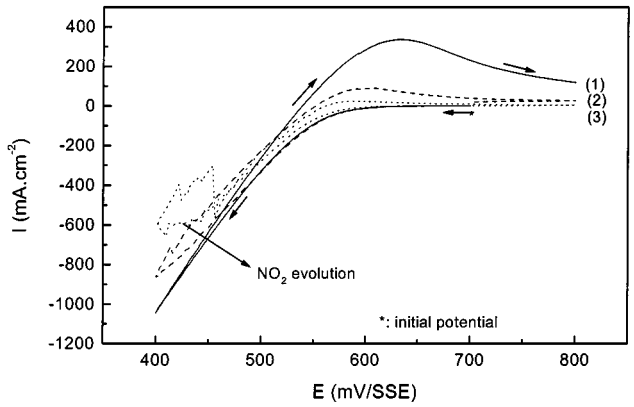

Figure 5. Cyclic voltammograms for HNO_3 12 mol·L^{-1} at 100 °C at different scan rates. (1): 500 mV·s^{-1} (2): 100 mV·s^{-1} (3): 10 mV·s^{-1}

These first results show the dependence of the reduction process on the nitric acid concentration.

Voltammetry

Figure 5, Figure 6 and Figure 7 show, for 12 mol·L^{-1}, 8 mol·L^{-1} and 4 mol·L^{-1} solutions, the voltammograms obtained for scan rates varying from 10 mV·s^{-1} to 500 mV·s^{-1}.

The results obtained are the following:

– for HNO_3 12 mol·L^{-1}, a regular variation of the voltammograms with the scan rate is obtained;

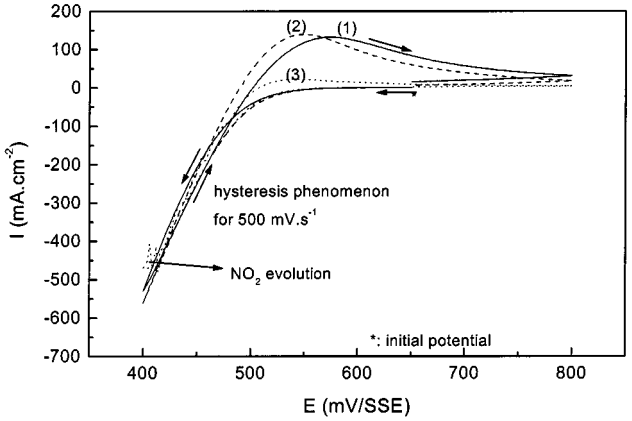

Figure 6. Cyclic voltammograms for HNO_3 8 mol·L^{-1} at 100 °C at different scan rates. (1): 500 mV·s^{-1} (2): 100 mV·s^{-1} (3): 10 mV·s^{-1}

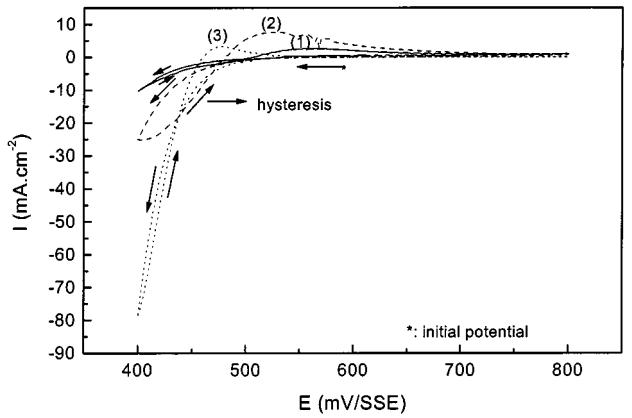

Figure 7. Cyclic voltammograms for HNO_3 4 mol·L^{-1} at 100 °C at different scan rates. (1): 500 mV·s^{-1} (2): 100 mV·s^{-1} (3): 10 mV·s^{-1}

– for HNO_3 8 mol·L^{-1}, a slight hysteresis phenomenon appears for 500 mV·s^{-1};

– for HNO_3 4 mol·L^{-1}, a sharp hysteresis phenomenon appears and the current density in reduction decreases when the scan rate increases;

– for a given scan rate, the current density increases with the nitric acid concentration.

These observations suggest the existence of a relatively slow reaction in the reduction process which is promoted by a high nitric acid concentration.

The analysis of the charges (Table 2) shows that, during the reduction process, some matter is lost: at all concentrations the ratio $|Q_{ox}/Q_{red}|$ is lower than 1 and increases when the scan rate increases. For high nitric acid concentrations, this phenomenon is more marked; the overvoltage applied in reduction is high and the stability domain of nitric acid is exceeded: the small ratio (0.04) obtained at a low scan rate is due to a gaseous evolution (NO_2).

For HNO_3 4 mol·L^{-1}, the overvoltage imposed in reduction is relatively low, the stability domain of nitric acid is not exceeded: no gaseous evolution occurs and the ratio $|Q_{ox}/Q_{red}|$ tends towards 1 for high scan rates.

Chronoamperometry

Experiments on the influence of the nitric acid concentration were performed using chronoamperometry. This tech-

Table 2. Oxidation charge, $Q_{ox.}$ [mC·cm^{-2}], reduction charge, $Q_{red.}$ [mC·cm^{-2}], and ratio $|Q_{ox.}/Q_{red.}|$, as a function of the nitric acid concentration and of the scan rate

nique was used to determine the influence of the stirring of the solution. A reduction potential (near the equilibrium potential) is imposed and when the current is stabilized, the electrode is stirred. The stirring is regulated with a rotating disk electrode (ω = 2000 rpm).

Figure 8 shows the variation of the current density with time for a potential of 0.400 V/SSE and for the different nitric acid concentrations.

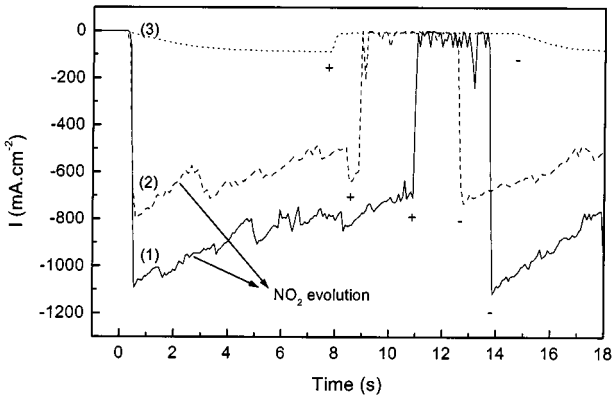

Figure 8. Influence of the stirring on the limiting current density of different nitric acid solutions at 100 °C for a potential of 0.400 V/SSE. ω = 2000 rpm; +: stirring; −: no stirring. (1): 12 mol·L^{-1} (2): 8 mol·L^{-1} (3): 4 mol·L^{-1}

An evolution of nitrogen dioxide is observed for HNO_3 8 mol·L^{-1} and 12 mol·L^{-1}. For all the concentrations the rotation of the electrode leads to a sharp decrease (it becomes nearly equal to zero) of the current density (in magnitude). This inverse dependence of the current density vs. stirring shows that the electroactive species is a soluble species formed at the electrode which diffuses into the solution. When the solution is stirred, the electroactive species is expelled from the electrode. This result is in agreement with Schmid's observations.[8–12] From these first experiments, it is possible to conclude that nitric acid is reduced indirectly through a mechanism involving at least a charge-transfer step and a chemical reaction which regenerates the electroactive species. The electroactive species is a soluble species produced at the electrode by a chemical reaction which is promoted by a high nitric acid concentration.

Influence of the Addition of Nitrous Acid in Solution and of a Flow of Nitrogen Monoxide in the Cell

In order to clarify the species involved, some voltammetric experiments were performed in nitric acid solutions containing reduction products of nitric acid at a significant concentration. The first series was performed with an addition of nitrous acid (nitrites) in solution and the second series with a flow of nitrogen monoxide in the cell.

Current-Potential Curves at a Low Scan Rate

The same experiments (as with nitric acid solutions with no external additions) were performed with an initial nitrite concentration of 10^{-2} mol·L^{-1} in solution. Table 3 gives the OCP of the platinum electrode in the different solutions for a nitrite concentration of 10^{-2} mol·L^{-1}. The values are lower than without nitrites according to the Nernst law:

$$E = E^{0'} - RT/2F \ln[HNO_2]$$

Table 3. Experimental values of the Open Circuit Potential of the platinum electrode in the three nitric acid solutions at 100 °C for a nitrite concentration of 10^{-2} mol·L^{-1}

$[HNO_3]$ [mol·L^{-1}]	OCP [V/SSE]
4	0.457
8	0.514
12	0.564

The experimental values of the apparent standard potentials, for the different nitric acid solutions at 100 °C, have been determined previously.[3]

The influence of the nitric acid concentration was studied for a scan rate of 10 mV·s^{-1} (Figure 9).

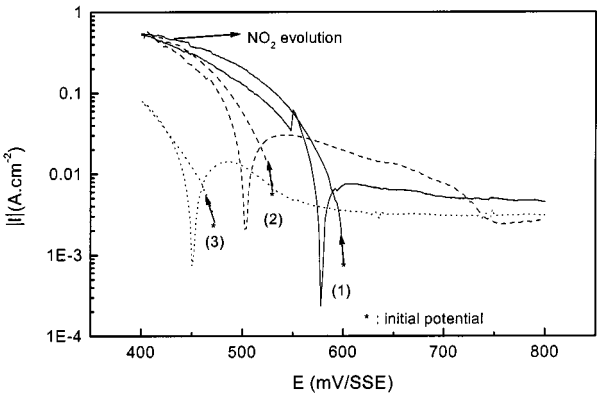

Figure 9. Cyclic voltammograms for HNO_3 solutions of different concentrations at 100 °C containing $[HNO_2] = 10^{-2}$ mol·L^{-1} at a scan rate of 10 mV·s^{-1}. (1): 12 mol·L^{-1} (2): 8 mol·L^{-1} (3): 4 mol·L^{-1}

If the voltammograms are compared with the ones without nitrites, no major differences are observed. The current

densities in reduction are nearly the same with or without nitrites for this scan rate. In oxidation, an increase of the oxidation peak is observed for HNO_3 4 mol·L^{-1} and 8 mol·L^{-1}, which is easily explained as nitrites present in solution undergo oxidation into nitric acid. For HNO_3 12 mol·L^{-1}, a slight decrease of the oxidation current is observed; this phenomenon cannot be readily explained at the moment.

Voltammetry

Figure 10, Figure 11 and Figure 12 show, for 12 mol·L^{-1}, 8 mol·L^{-1} and 4 mol·L^{-1} solutions containing nitrites, respectively, the voltammograms obtained for scan rates varying from 10 mV·s^{-1} to 500 mV·s^{-1}.

The influence of nitrites is more marked for low nitric acid concentrations and high scan rates. The results obtained are:

– for HNO_3 4 mol·L^{-1}, the charge in reduction is multiplied by 1.5 for 50 mV·s^{-1} and by 4 for 500 mV·s^{-1}. Moreover, in the presence of nitrites, the hysteresis disappears even for high scan rates; the evolution of the reoxidation peak current density becomes regular and charges in oxidation are multiplied by 20 for all the scan rates. The chemical regeneration reaction of the active species is slow and limits

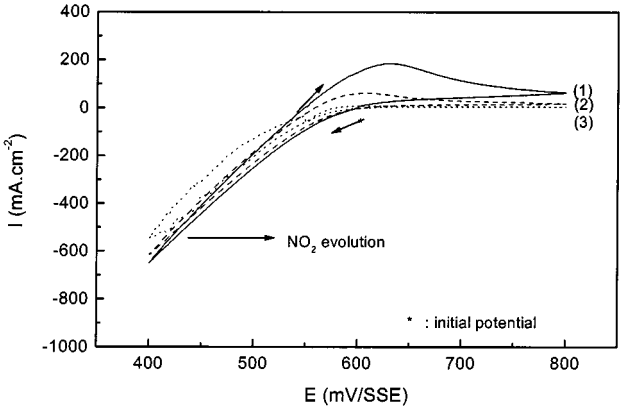

Figure 10. Cyclic voltammograms for HNO_3 12 mol·L^{-1} at 100 °C containing [HNO_2] = 10^{-2} mol·L^{-1} at different scan rates. (1): 500 mV·s^{-1} (2): 100 mV·s^{-1} (3): 10 mV·s^{-1}

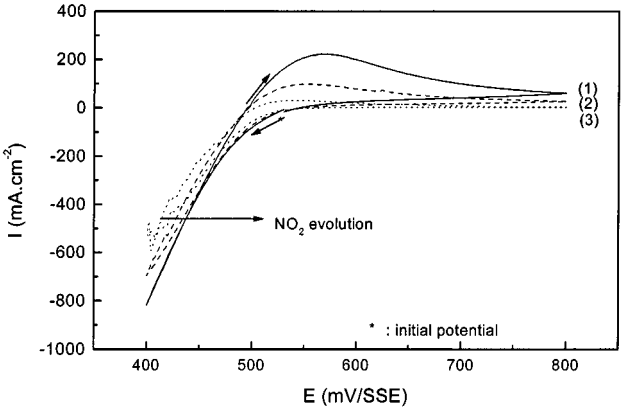

Figure 11. Cyclic voltammograms for HNO_3 8 mol·L^{-1} at 100 °C containing [HNO_2] = 10^{-2} mol·L^{-1} at different scan rates. (1): 500 mV·s^{-1} (2): 100 mV·s^{-1} (3): 10 mV·s^{-1}

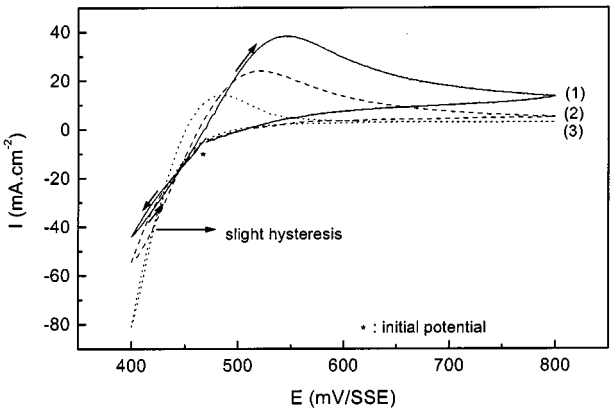

Figure 12. Cyclic voltammograms for HNO_3 4 mol·L^{-1} at 100 °C containing [HNO_2] = 10^{-2} mol·L^{-1} at different scan rates. (1): 500 mV·s^{-1} (2): 100 mV·s^{-1} (3): 10 mV·s^{-1}

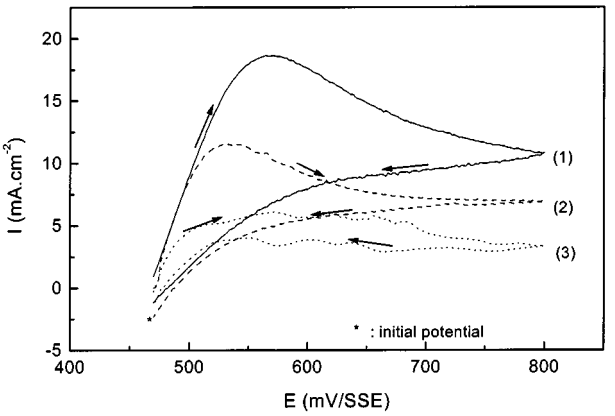

Figure 13. Voltammograms in oxidation for HNO_3 4 mol·L^{-1} containing [HNO_2] = 10^{-2} mol·L^{-1} at 100 °C at different scan rates. (1): 500 mV·s^{-1} (2): 100 mV·s^{-1} (3): 10 mV·s^{-1}

the reduction process. Therefore, the presence of nitrites in solution accelerates the chemical reaction and provokes the disappearance of the hysteresis and the increase in the reduction current densities for high scan rates;

– for HNO_3 8 mol·L^{-1}, the charges in reduction are multiplied by 1.5 for scan rates higher than 30 mV·s^{-1}; in oxidation they are multiplied by 2 for scan rates higher than 300 mV·s^{-1};

– for HNO_3 12 mol·L^{-1}, no major differences are observed with nitrites.

The presence of nitrites promotes the establishment of the steady state in reduction: nitrites in the bulk accelerate the attainment of the concentration in active species near the electrode to reduce nitric acid. For concentrated nitric acid, this concentration is reached rapidly as the chemical regeneration of the active species proceeds easily and therefore a supplementary addition of nitrites does not influence the reduction process.

Direct scans were also performed in oxidation. Figure 13 shows the voltammograms obtained for different scan rates in HNO_3 4 mol·L^{-1}. The same experiments performed in pure nitric acid display a voltammogram without peak which means that the oxidation peak is attributable to the

oxidation of nitrites into nitric acid; this is confirmed by literature data.[16]

If the current density of the oxidation peak is plotted versus the square root of the scan rate for HNO_3 4 mol·L^{-1}, 8 mol·L^{-1} and 12 mol·L^{-1} (Figure 14), a linear variation is obtained in a large range. Thus it is possible to assume that the current is diffusion controlled.

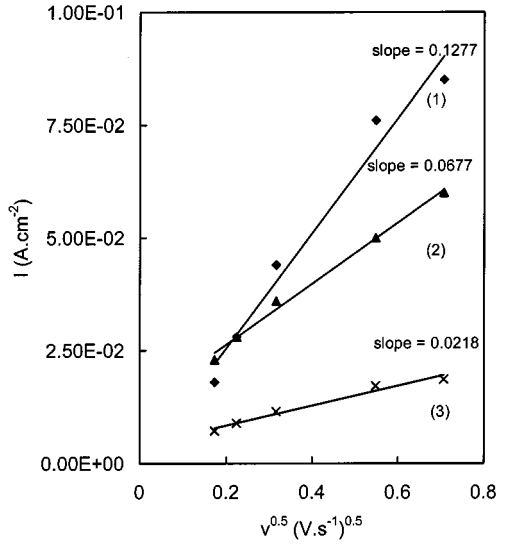

Figure 14. Influence of the scan rate on the variation of the oxidation peak current density for different nitric acid solutions at 100 °C containing approximately [HNO_2] = 10^{-2} mol·L^{-1}. (1): 12 mol·L^{-1} (2): 8 mol·L^{-1} (3): 4 mol·L^{-1}

A diffusion coefficient has been deduced according to:[17a]

$I_p = (2.40 \times 10^5) n^{3/2} D_0^{1/2} v^{1/2} C_0^*$

where

I_p = peak current density [A·cm^{-2}]

n = number of electrons involved in the oxidation charge transfer step

D_0 = diffusion coefficient [cm^2·s^{-1}]

v = scan rate (V·s^{-1})

C_0^* = nitrite concentration [mol·cm^{-3}]

The value of n is $n = 2$, as the oxidation reaction is supposed to be the oxidation of nitrites into nitric acid:

$$HNO_2 + H_2O = HNO_3 + 2H^+ + 2e^-$$

Table 4 shows the diffusion coefficients obtained for a nitrous acid concentration of approximately 10^{-2} mol·L^{-1}, in the different nitric acid solutions.

Table 4. Diffusion coefficient of nitrous acid in nitric acid solutions at 100 °C as a function of nitric acid concentration

[HNO_3] [mol·L^{-1}]	D_0 [cm^2.s^{-1}] and interval of error
4	3×10^{-5} [$8 \times 10^{-6} - 9 \times 10^{-5}$]
8	2×10^{-5} [$5 \times 10^{-6} - 6 \times 10^{-5}$]
12	7×10^{-4} [$2 \times 10^{-4} - 2 \times 10^{-3}$]

The interval of error of the diffusion coefficient is calculated from the error in the value of the concentration of nitrous acid in solution. The concentration of nitrous acid was not directly measured in these experiments. It was calculated from the OCP according to the thermodynamic data obtained previously.[3] The error in the OCP is supposed to be ± 10 mV. The error in the nitrous acid concentration and the error in the diffusion coefficient can then be deduced.

Table 4 shows higher diffusion coefficients for more concentrated HNO_3. This variation may be due to a difference in the chemical form of the diffusing species: for example HNO_2 in less concentrated medium and NO^+ in more concentrated medium. The uncertainty in the measurement minimizes this interpretation and supplementary measurements would be necessary to confirm this result.

Chronoamperometry

Figure 15 shows the variation of the current density with time for a potential of 0.400 V/SSE for the different nitric acid concentrations.

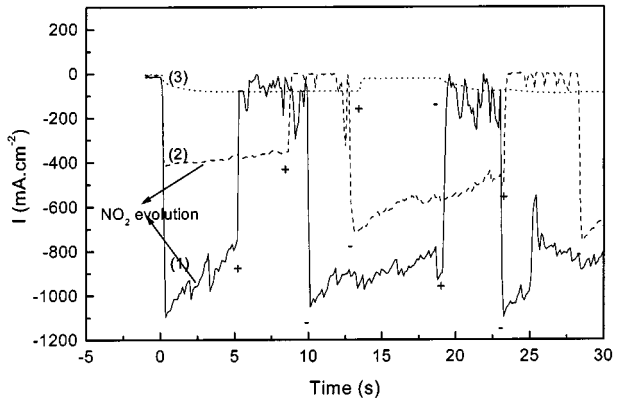

Figure 15. Influence of the stirring on the limiting current density of different nitric acid solutions at 100 °C containing [HNO_2] = 10^{-2} mol·L^{-1} for a potential of 0.400 V/SSE. ω = 2000 rpm; +: stirring; −: no stirring. (1): 12 mol·L^{-1} (2): 8 mol·L^{-1} (3): 4 mol·L^{-1}

The current densities are the same as when there are no nitrites in solution and the stirring of the solution provokes a similar decrease of the current density. Nitrites do not influence the stationary current densities (without stirring) as was already observed with the voltammograms performed at low scan rates.

For HNO_3 4 mol·L^{-1}, the stirring of the electrode provokes a decrease of the stationary current density which stabilizes at a value different from zero: this current is due to the nitrites present in solution.

For HNO_3 8 mol·L^{-1} and 12 mol·L^{-1}, the stirring of the electrode provokes a decrease of the current density similar to when there were no nitrites initially present in solution: the value of the current becomes nearly equal to zero. This result can be explained by the fact that in concentrated nitric acid, nitrites are less stable and an evolution of NO_2 occurs.

Influence of a Flow of Nitrogen Monoxide for HNO_3 4 mol·L^{-1} at 100 °C

The influence of a flow of nitrogen monoxide (flow rate = 1 L·h^{-1}) on the reduction process was studied in

HNO_3 4 mol·L^{-1}. A pressure of p_{NO} = 0.8 bar was imposed by fixing the flow rates of nitrogen monoxide and of an inert gas.

In Figure 16, the voltammograms obtained in the presence of NO and nitrites are compared with the voltammogram obtained without any addition, at a scan rate of 100 mV·s^{-1}. The presence of NO has the same influence as the addition of nitrites: it provokes an increase in the current densities in oxidation and in reduction and the disappearance of the hysteresis. The slight increase in the current densities with NO relative to nitrites is due to the fact that the pressure of NO imposed fixes a concentration in nitrites in solution higher than the concentration added in the other experiments: [HNO_2] = 3.5×10^{-2} mol·L^{-1} (experimental measurement) for p_{NO} = 0.8 bar.

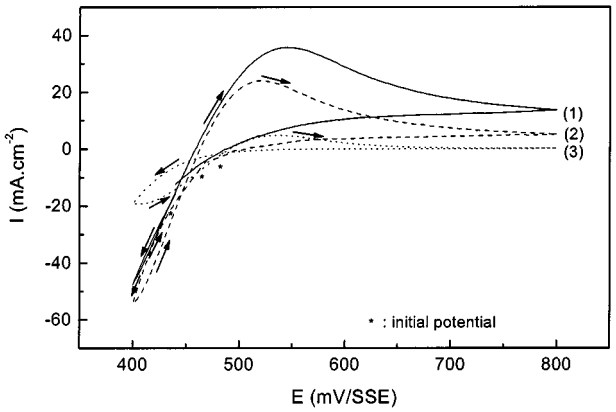

Figure 16. Cyclic voltammograms for HNO_3 4 mol·L^{-1} at 100 °C under different conditions at a scan rate of 100 mV·s^{-1}. (1): p_{NO} = 0.8 bar (2): [HNO_2] = 10^{-2} mol·L^{-1} (3): no addition

Voltammograms were performed at different scan rates in oxidation. Figure 17 presents the results obtained. If the current density of the oxidation peak is plotted versus the square root of the scan rate (Figure 18), a linear variation is obtained similar to the variation obtained in the presence of nitrites.

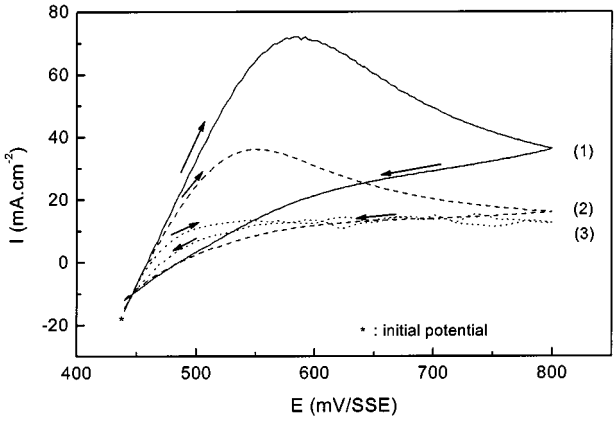

Figure 17. Voltammograms in oxidation for HNO_3 4 mol·L^{-1} under p_{NO} = 0.8 bar at 100 °C at different scan rates. (1): 500 mV·s^{-1} (2): 100 mV·s^{-1} (3): 10 mV·s^{-1}

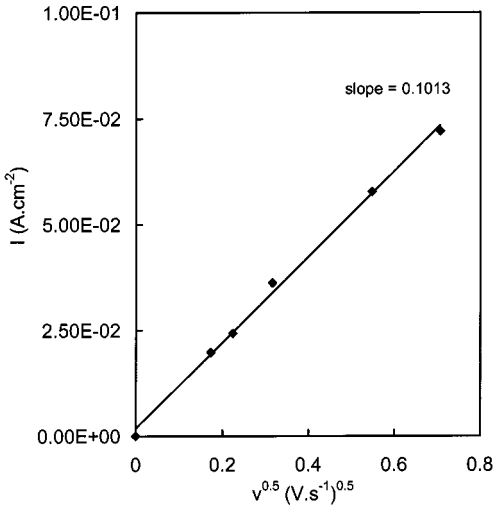

Figure 18. Influence of the scan rate on the variation of the oxidation peak current density for HNO_3 4 mol·L^{-1} at 100 °C under p_{NO} = 0.8 bar

The diffusion coefficient of nitrous acid can be calculated (the interval of error is estimated as in section 'voltammetry'), assuming that the reoxidation peak observed is attributed to the oxidation of nitrites into nitric acid:

$$D_0 = 2 \times 10^{-5}\ \text{cm}^2\cdot\text{s}^{-1}\ [5 \times 10^{-6} - 6 \times 10^{-5}]$$

Chronoamperometric measurements were also performed (Figure 19). The influence of the stirring causes a decrease in the reduction current which stabilizes for a value different from zero. This current is due to the presence of nitrites in solution.

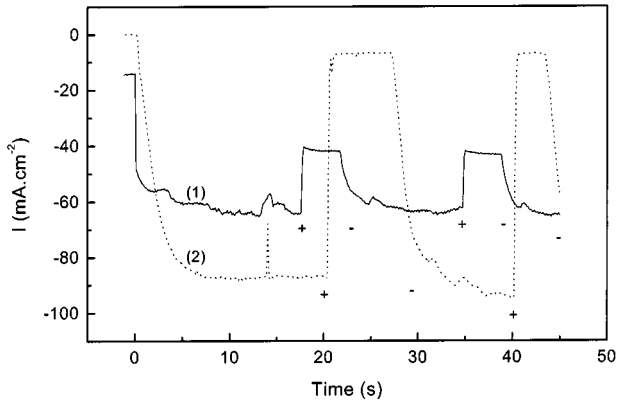

Figure 19. Influence of the stirring on the limiting current density of HNO_3 4 mol·L^{-1} at 100 °C under different conditions for a potential of 0.400 V/SSE. ω = 2000 rpm; +: stirring; −: no stirring. (1): p_{NO} = 0.8 bar (2): no addition

In fact, without stirring, at the steady state, the nitrous acid concentration at the electrode is much higher than in the bulk and this difference is larger for low nitric acid concentrations. When the solution is stirred, the nitrous acid concentration at the electrode is equal to the concentration in solution.

Mechanism of Reduction of Nitric Acid at a Platinum Electrode at 100 °C

It appears from this study that the major parameters for explaining the reduction of nitric acid are firstly the concentration range of nitric acid, and secondly the concentration of nitrous acid. The nitric acid molecule is not directly reduced; it is reduced through an autocatalytic mechanism involving an electrochemical step and a chemical reaction regenerating the active species. The electroactive species is formed at the electrode and diffuses into the solution: this explains the influence of the stirring on the current density. Moreover, it is possible to assume that the electroactive species is a soluble compound. The regeneration reaction is rapid for high HNO_3 concentrations and slow for low concentrations; this provokes the appearance of the hysteresis phenomenon. The electroactive species is believed to be nitrous acid which is the major soluble species present in nitric acid. This is confirmed by the increase in the current densities in reduction in the presence of nitrous acid in solution: this increase is sharp for low nitric acid concentrations and high scan rates and becomes nonexistent for HNO_3 12 mol·L^{-1}. Moreover nitrous acid suppresses the hysteresis phenomenon.

The influence of nitrogen monoxide was shown to be the same as nitrous acid. Therefore it is possible to assume that nitrogen monoxide reacts partly with nitric acid to form nitrous acid. The reduction of nitric acid leads to the formation of NO or NO_2 depending on the potential and the nitric acid concentration.

These conclusions, along with the literature data, allow us to propose a unique reduction mechanism of nitric acid valid for the whole nitric acid concentration range with reaction rates depending on the nitric acid concentration. This mechanism can be divided into two limiting cases, one for the lower concentrations and one for the higher concentrations. In all cases, the charge transfer step is the reduction of nitrous acid into nitrogen monoxide:

$$(HNO_2)_{el.} + H^+ + e^- + s = (NO)_{ads.} + H_2O \quad (1)$$

where 's' represents a free adsorption site.

Then, the chemical regeneration of the active species occurs; this reaction is heterogeneous and produces the electroactive species, HNO_2. It also produces nitrogen dioxide (reduction product for high nitric acid concentrations):[3]

$$HNO_3 + (NO)_{ads.} = (HNO_2)_{el.} + (NO_2)_{ads.} \quad (2)$$

The rate of reaction (2), which is the regeneration reaction, depends on the nitric acid concentration and on the nitrogen monoxide pressure. The rate of the charge transfer step (1) is also influenced, and usually promoted, by a high nitric acid concentration.

A third reaction (3) also occurs:

$$HNO_3 + (HNO_2)_{el.} + 2s = 2(NO_2)_{ads.} + H_2O \quad (3)$$

Reactions(1), (2), (3) are the elementary reactions of the reduction mechanism of nitric acid valid over the whole concentration range. For HNO_3 4 mol·L^{-1}, the regeneration reaction (2) is slow: this causes the hysteresis phenomenon appearing for high scan rates. Therefore, NO formed during the charge transfer step can accumulate and eventually evolve. Reaction (3), in low concentrated medium, promotes the formation of HNO_2, as NO_2 is not stable for concentrations lower than 8 mol·L^{-1}.

Finally, for nitric acid concentrations lower than 8 mol·L^{-1}, the reduction mechanism of nitric acid can be expressed as:

$$(HNO_2)_{el.} + H^+ + e^- + s = (NO)_{ads.} + H_2O \quad (1)$$

$$HNO_3 + 2(NO)_{ads.} + H_2O = 3(HNO_2)_{el.} + 2s \quad (4)$$

where (4) = 2 × (2) – (3)

$$(NO)_{ads.} = (NO)_{g.} + s \quad (5)$$

$$(HNO_2)_{el.} \rightarrow (HNO_2)_{sol.} \quad (6)$$

In the case of HNO_3 12 mol·L^{-1}, the chemical regeneration, reaction (2), promoted by a high nitric acid concentration, is fast and leads to an evolution of NO_2, the stable reduction product for high nitric acid concentrations. The overall reduction mechanism can be described as:

$$(HNO_2)_{el.} + H^+ + e^- + s = (NO)_{ads} + H_2O \quad (1)$$

$$HNO_3 + (NO)_{ads} = (HNO_2)_{el.} + (NO_2)_{ads} \quad (2)$$

$$(NO_2)_{ads} = (NO_2)_{g.} + s \quad (7)$$

$$(HNO_2)_{el.} \rightarrow (HNO_2)_{sol.} \quad (6)$$

Reaction (3) also occurs and is supposed to be at equilibrium. The gaseous species NO and NO_2 are supposed to be adsorbed at the electrode surface, and nitrous acid is a soluble compound formed at the electrode which diffuses into the solution. Therefore, in the reduction mechanism, desorption steps of gaseous species and a diffusion step for nitrous acid have to be added.

Conclusion

The major species involved in the reduction process of nitric acid at low overvoltages have been determined to be HNO_2, NO and NO_2. A mechanism has been proposed, which takes into account the literature data and the experimental results of this paper. It has been shown that: – nitric acid is not the electroactive species; it is reduced indirectly through an autocatalytic process; – nitrous acid is the electroactive species which is reduced into nitrogen monoxide; – nitrous acid is regenerated at the electrode according to a heterogeneous chemical reaction involving nitrogen monox-

ide and nitric acid; – a reduction mechanism for the whole nitric acid concentration range has been proposed depending on the nitric acid concentration: for concentrations higher than 8 mol·L^{-1}, the reduction of nitric acid leads to an evolution of NO_2 and for lower concentrations, it leads to an evolution of NO.

This electrochemical study of the reduction process of nitric acid on a platinum electrode allows us to propose a unique reduction mechanism valid over the whole concentration range. In the next step of our work, similar electrochemical experiments will be performed on a stainless steel electrode to compare the reduction mechanism observed on both materials and then to link the final reduction mechanism with the results of the corrosion tests performed in the laboratory.[4] This last step will be presented in a subsequent paper.

Experimental Section

Reactor Cell: The reactor containing 50 mL of solution was regulated at 100 °C. The working electrode consisted of a platinum disk electrode (area 0.0314 cm^2) polished to a mirror finish. The following circuit was set up for measuring the electrode potential: working electrode/HNO_3, solution 100 °C/HNO_3 solution, 25 °C/saturated KNO_3 solution, 25 °C/saturated K_2SO_4 solution, 25 °C/mercurous sulfate electrode, 25 °C. The reference electrode was a mercurous sulfate electrode (SSE) and is described as: $Hg/Hg_2SO_{4(sat.)}$, $K_2SO_{4(sat.)}$. The potential of this reference electrode versus the standard hydrogen electrode at 25 °C is E_{SSE} = 0.640 V/SHE.[17b]

Electrochemical Apparatus and Procedure: The potential measurements were made with an EGG PAR Model 273 potentiostat. A rotating disk electrode Tacussel EDI 101 T was used to evidence the hydrodynamic effect on the reduction process. Experiments were carried out in 4 mol·L^{-1}, 8 mol·L^{-1}, and 12 mol·L^{-1} nitric acid solutions at 100 °C. The influence of nitrous acid was studied by adding sodium nitrite at a concentration of about 10^{-2} mol·L^{-1} in the solution. The influence of nitrogen monoxide was investigated by imposing a pressure of p_{NO} = 0.8 bar in the cell. The concentration of nitrous acid (nitrite ions) in solution was measured by colorimetry with a Perkin–Elmer UV/Visible spectrometer according to the Griess method.[18]

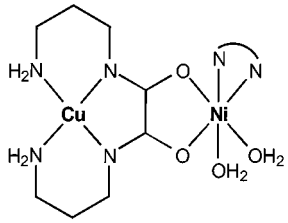
Reactions Between Dinuclear Cu^{II}–Ni^{II} Complexes and the Nitrito Ligand: A New One-Dimensional Complex $[Cu(oxpn)Ni(\mu\text{-}NO_2)(trimen)]_n(ClO_4)_n$ with Nitrite Acting as a Tridentate Bridging Ligand and Ferro- and Antiferromagnetic Alternation



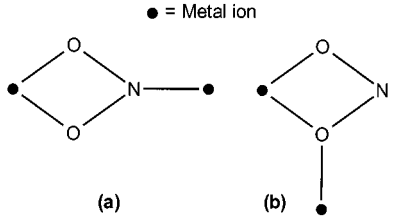
Carmen Diaz,*[a] Joan Ribas,[a] Ramon Costa,[a] Javier Tercero,[a] Mohamed Salah El Fallah[a] Xavier Solans,[b] Mercé Font-Bardía[b]

Keywords: Bridging ligands / Nitrito bridge / Copper / Nickel / Magnetic properties / Supramolecular chemistry

The reaction of $NiX_2 \cdot 6\,H_2O$ (X = NO_3^-, ClO_4^-), bidentate amine, [Cu(oxpn)] [oxpn = *N,N′*-bis(3-aminopropyl)oxamide] and sodium nitrite in ethanolic solution, leads to the formation of new Cu^{2+}–Ni^{2+} complexes of general formula $[Cu(oxpn)Ni(NO_2)(aa)]_n(X)_n$ [**1**, X = ClO_4^-, aa = *N,N,N′*-trimethylethylenediamine (trimen); **2**, X = ClO_4^-, aa = *N,N,N′N′*-tetramethylethylenediamine (tmen); **3**, X = ClO_4^-, aa = *N,N*-dimethyl-*N′*-ethylethylenediamine (dmeten); **4**, X = PF_6^-, aa = trimen; **5**, X = PF_6^-, aa = dmeten]. The structure of complex **1** consists of [Cu(oxpn)Ni(trimen)]$^{2+}$ units linked by a nitrite group acting as a tridentate ligand, giving a one-dimensional system separated by ClO_4^- anions. In contrast, the structure of complex **2** consists of isolated $[Cu(oxpn)Ni(NO_2)(tmen)]^+$ dinuclear units and uncoordinated ClO_4^- anions. The nitrite group acts as a bidentate ligand. Variable-temperature magnetic susceptibility studies were performed on **1–5**. The *J* value through the oxamidato bridge is close to –110 cm^{-1} in all five cases. For complex **1**, considered as a chain, a simulation of the $\chi_M T$ vs *T* was performed with the CLUMAG program. These calculations revealed the influence of the magnetic interactions between the dinuclear entities through the nitrito bridging ligand, on the susceptibility curves at low temperatures.

Introduction

In one-dimensional supramolecular self-assembly processes, we have found that very few complexes starting from polynuclear building blocks have been reported to date. McAuley et al.[1] reported the synthesis of a chloro-bridged polymeric copper(II) complex. Ribas et al., using (S,Se)CN^- bridging ligands, reported a one-dimensional system with Cu_3 entities,[2] and tetranuclear systems starting from Cu^{2+}–Ni^{2+} entities.[3] A one-dimensional structure has been reported from the self-assembly reaction between $[Fe(CN)_6]^{3-}$ and a Mn^{3+} Schiff-base derivative, in which the 1-D architecture is due to hydrogen bonds between trinuclear Mn^{3+}–Fe^{3+}–Mn^{3+} entities.[4] With [Cu(oxpn)], where oxpn is the dianion of *N,N′*-bis(3-aminopropyl)oxamide, the magnetic coupling in Cu–Cu, Cu–Ni or Cu–Mn dinuclear entities is strongly antiferromagnetic, owing to the broad overlap between the magnetic orbitals of the two metal ions through the corresponding molecular orbital of the oxamidato bridge.[5–10] Thus, we started with the dinuclear species $[Cu(oxpn)Ni(H_2O)_2(diamine)]^{2+}$ (Scheme 1) in an attempt to link these molecules ferro- or antiferromagnetically in order to study the spin topology of the final system.



Scheme 1. Structural formula of $[Cu(oxpn)Ni(H_2O)_2(aa)]^{2+}$

The ligand chosen for this was the nitrite group because of the number of different ways in which it can coordinate to a metal centre.[11] The factors influencing the type of nitrite coordination adopted are often delicately balanced. As a monodentate ligand it can bond through either nitrogen or oxygen, while as a bidentate ligand it can chelate or bridge either through nitrogen and oxygen or through oxygen only.[12] Very few examples of tridentate behaviour are known. This coordination mode may be accomplished in two ways. In the first case,[13] the NO_2^- ion is chelated to one metal through the two oxygens and bridged to a second metal ion through the nitrogen atom (Scheme 2a). In the second case,[14] the two metal ions are bridged through a

single oxygen atom while the second oxygen chelates to one of the metal ions (Scheme 2b).

Scheme 2. Trideutate coordination modes for the nitrite ion

Few studies have examined the magnetic exchange mediating properties of the bridging nitrite. Two polymeric Ni^{2+} complexes involving a two atom O,N-bridging mode show a moderate antiferromagnetic interaction ($J \approx -60$ cm^{-1}).[15] A Ni–Mn–Ni trinuclear complex involving the same coordination mode but also with azido bridging ligand has been reported.[12b] An interaction of the same sign and order of magnitude characterises a dinuclear Ni^{2+} complex with a combination of chelation and bridging through a single oxygen atom.[14] A weak ferromagnetic interaction (J = 8 cm^{-1}) is found in a dinuclear Cu^{2+} complex with a single O atom bridging mode[16] and a very weak one (J = 1.33 cm^{-1}) is found in a Mn–Ni bimetallic chain[13b] with nitro coordination at the Ni^{2+} centre and a bidentate nitrito coordination at Mn^{2+}. We report here five compounds of a new family of heterobimetallic polynuclear compounds obtained from Cu(oxpn)–Ni(diamine)–NO_2 with the counteranion ClO_4^- or PF_6^- (diamine = tmen, trimen, dmeten). The crystal structures of $[Cu(oxpn)Ni(\mu\text{-}NO_2)(trimen)]_n(ClO_4)_n$ (**1**), and $[Cu(oxpn)Ni(NO_2)(tmen)]ClO_4$ (**2**) are described. The crystal structure of complex **1** is found to be a chain of dimeric [Cu(oxpn)Ni(trimen)] units linked by the nitrite group acting as a tridentate ligand. The crystal structure of complex **2** is found to be dinuclear with isolated $[Cu(oxpn)Ni(NO_2)(tmen)]^+$ ions. We also report the magnetic properties of the five compounds. The magnetic behaviour of complexes **1** and **2** is markedly different at low temperatures; the other three complexes have an intermediate magnetic behaviour. For all complexes, the magnetic interactions were studied assuming only the strong antiferromagnetic coupling within the dinuclear Cu–Ni entity. Complex **1** was also studied using the ITO method, which reduces the size of the matrices.

Results and Discussion

Crystal Structures

The X-ray crystal structure of **1** consists of dimeric $[Cu(oxpn)Ni(trimen)]^{2+}$ units linked by the nitrite group acting as a tridentate ligand giving a one-dimensional system, separated by ClO_4^- anions. This tridentate nitrite coordination between Cu^{2+} and Ni^{2+}, which has not been reported previously, is a combination of chelation through the two oxygen atoms and bridging through a single oxygen atom (Scheme 2b). Selected bond lengths and angles are listed in Table 1 and the molecular structure and atom labelling is shown in Figure 1. The molecular structure of **2** consists of isolated $[Cu(oxpn)Ni(NO_2)(tmen)]^+$ dinuclear units and uncoordinated ClO_4^- anions. Selected bond lengths and angles are listed in Table 1 and the molecular structure and atom labelling is shown in Figure 2.

For both complexes, the Ni atoms are in a distorted octahedral environment. The four positions coplanar to the oxamidato bridge are occupied by the two oxygen atoms of this ligand [Ni–O = 2.030, 2.050 Å (**1**) and 2.008, 2.067 Å (**2**)], one nitrogen of the bidentate amine [Ni–N = 2.066 Å (**1**) and 2.119 Å (**2**)] and one oxygen of the nitrite ligand [Ni–O = 2.110 Å (**1**) and 2.124 Å (**2**)]. The other oxygen of the nitrite ligand occupies one of the two remaining positions [Ni–O = 2.152 Å (**1**) and 2.153 Å (**2**)] and the other nitrogen atom of the bidentate amine [Ni–N = 2.119 Å (**1**) and 2.102 Å (**2**)] occupies the other. The coordination polyhedron of Cu^{2+} is different for the two complexes. For complex **1** it can be considered as a square pyramid with apical elongation (4 + 1), the four nitrogen atoms of the oxpn organic ligand are placed in the basal position and the Cu–N

Magnetic Behaviour

Variable temperature (2–300 K) magnetic susceptibility data were collected for microcrystalline samples of compounds **1–5**. From room temperature down to ca. 25 K the $\chi_M T$ vs T plots correspond to the classical behaviour for an isolated Cu–Ni entity coupled antiferromagnetically. From ca. 25 K to 2 K we found two different behaviours: complex **1** shows a clear decrease in $\chi_M T$ from 20 K (0.46 cm^3 mol^{-1} K) to 2 K (0.40 cm^3 mol^{-1} K) and complex **2** shows the typical plateau for a dinuclear Cu–Ni complex, with no decrease in $\chi_M T$ in this zone (Figure 5), while complexes **3**, **4** and **5** show an intermediate behaviour.

The first fit was made from 300 K to ca. 20 K to study only the interaction within each Cu–Ni dinuclear moiety. The spin Hamiltonian that describes the isotropic magnetic exchange interaction in a Cu–Ni dinuclear complex is $H = -JS_{Cu}S_{Ni}$. There are two spin states, $S = 1/2$ and 3/2. Assuming antiferromagnetic coupling, the ground state is $S = 1/2$ ($E = 0$) and the low-lying excited state is $S = 3/2$ ($E = -3J/2$). The g values for each state are related to those of the ions: $g_{3/2} = (1/3g_{Cu} + 2/3g_{Ni})$ and $g_{1/2} = (-1/3g_{Cu} + 4/3g_{Ni})$.[17] By substituting these values in the Van Vleck equation, a typical expression of the molar susceptibility can be deduced. The experimental and theoretical curves of χ_{MT} for complexes **1** and **2** are shown in Figure 5. The J and g values for the five new complexes are listed in Table 2. The J values for the five complexes (close to –110 cm^{-1}) agree with those reported in the literature for the Cu–Ni heterodinuclear complexes with the oxpn bridge.[7]

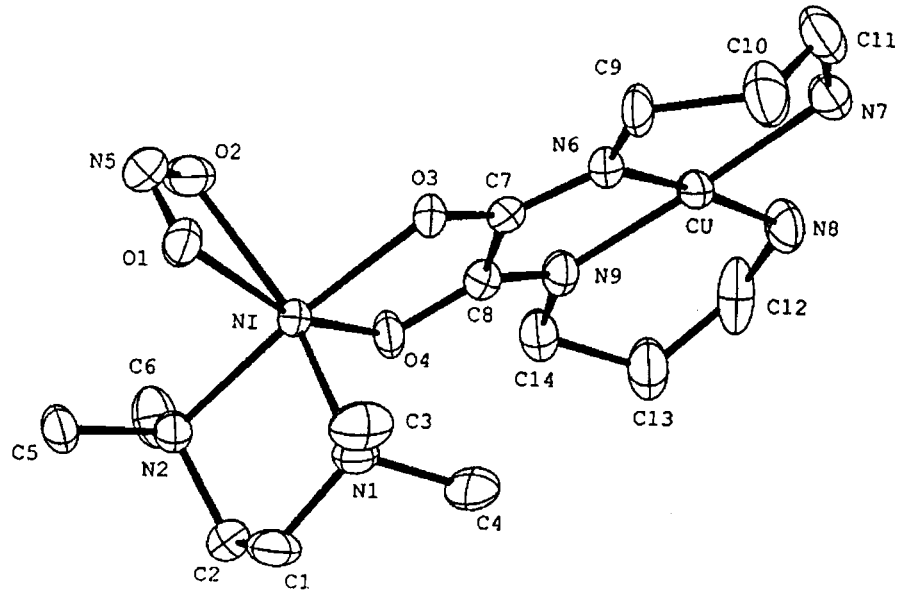

Figure 2. Drawing of the $[Cu(oxpn)Ni(NO_2)(tmen)]ClO_4$ (**2**) with atom labelling scheme; methyl groups have been omitted for clarity

distances are close to 2.0 Å; the coordination is completed by one oxygen of the nitrite bridge (Cu–O = 2.609 Å). For complex **2** the copper atom is coordinated to the four nitrogen atoms of the oxpn organic ligand in a distorted square-planar geometry; the Cu–N distances are close to 2.0 Å. The Cu–Ni distances through the oxamidato bridge are 5.303 Å for complex **1** and 5.293 Å for **2**. The Cu–Ni separation within the dinuclear entities is 4.415 Å for **1** and 6.426 Å for **2**. Schematic representations of the packing for **1** and **2** are given in Figure 3 and Figure 4, respectively.

Study of the Exchange of the Whole Chain for Complex 1

As can be seen from the crystal structure, the chain is formed by dinuclear entities linked by the bridging NO_2^- ligand (Figure 1). Such a ligand can transmit an additional interaction between the Ni–Cu entity causing two different

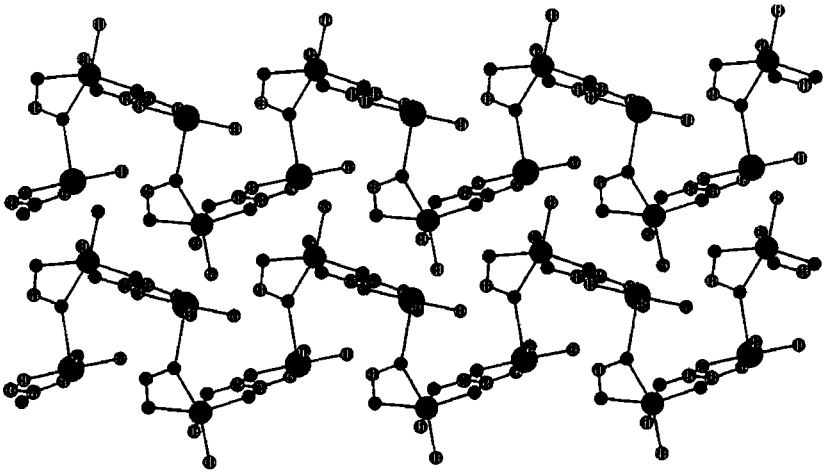

Figure 3. Schematic representation of the packing of $[Cu(oxpn)Ni(\mu\text{-}NO_2)(trimen)]_n(ClO_4)_n$ (**1**)

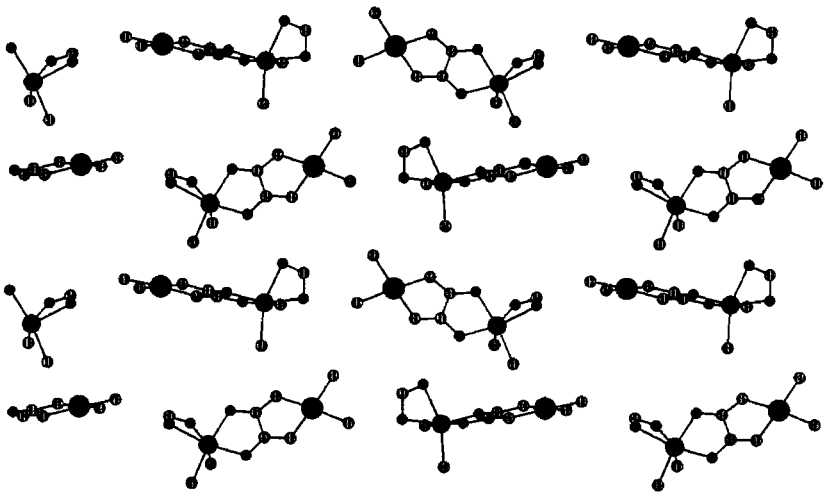

Figure 4. Schematic representation of the packing of $[Cu(oxpn)Ni(NO_2)(tmen)]ClO_4$ (**2**)

forms of the ground state at low temperature. These two forms are shown in Figure 6. If the magnetic interactions between these two entities are weakly ferromagnetic, the resulting total spin value will tend to zero at low temperatures, so the $\chi_M T$ curve would decrease and also tend to zero at these temperatures. In contrast, if the coupling were weakly antiferromagnetic $\chi_M T$ would tend to infinity at low temperatures.

In order to compare the theoretical magnetic behaviour for these extreme cases, a simulation of $\chi_M T$ vs. T for a ring of twelve atoms with alternate $S = 1$ and $S = 1/2$ spins was performed with the CLUMAG program.[18] The J_1 (coupling through the oxamidato bridge) value was fixed at –106 cm^{-1} and g was set at 2.25. The value of J_2 (coupling through the nitrite bridging ligand) was simulated between –20 and 20 cm^{-1}. As expected, with these small J_2 values the variation of $\chi_M T$ vs. T is observed only at low temperatures. The theoretical $\chi_M T$ vs. T curves are shown in Figure 7. When the J_2 coupling is antiferromagnetic $\chi_M T$ increases with decreasing temperature, tending to the six electrons value; when the J_2 coupling is ferromagnetic, $\chi_M T$ decreases with decreasing temperature, tending to zero.

From the magnetic point of view, all these aspects indicate that in this new 1-D complex the antiferromagnetic coupling through the oxamidato bridge is dominant. The coupling through the nitrito bridge is small but positive ($J_2 = 1.1$ cm^{-1} in complex **1** and is lower in the other complexes). A schematic representation of the orthogonality of the magnetic orbitals centred on the metal ions is shown in Figure 8.

The EPR spectra of the five complexes show a single band centred at $g = 2.24$. This band is sharp at low temperature (4 K) and becomes broader at higher temperature (77 and 298 K). This can be assigned to a transition between $|1/2,–1/2\rangle$, $|1/2,1/2\rangle$ of the $S = 1/2$ ground state of the dinuclear entity.

ine (dmeten) were purchased from Aldrich and used without further purification. [Cu(oxpn)], where oxpn is the dianion of *N,N'*-bis(3-aminopropyl)oxamide, was synthesised as previously described.[19] Ethanol was distilled before use.

Caution: *Although no incidents were recorded in this study, perchlorate salts containing organic ligands are potentially explosive. They should be prepared in small quantities and handled with extreme care.*

***catena*-[Cu(oxpn)Ni(μ-NO_2)(trimen)]ClO_4 (1):** $NaNO_2$ (2.73 mmol) was added to an ethanolic solution (30 mL) of [Cu(oxpn)Ni(H_2O)$_2$-(trimen)](ClO_4)$_2$ (2.73 mmol), prepared in situ by mixing [Cu(oxpn)] (2.73 mmol), Ni(ClO_4)$_2 \cdot x$ H_2O (2.73 mmol) and trimen (2.73 mmol), with constant stirring. The resulting blue solution was left to evaporate slowly at room temperature. Blue monocrystals suitable for an X-ray determination were collected after one week (yield ca. 70%). – $C_{13}H_{30}ClCuN_7NiO_8$ (570.14): calcd. C 27.38, H 5.30, N 17.20; found C 27.4, H 5.3, N 17.1.

[Cu(oxpn)Ni(NO_2)(tmen)](ClO_4) (2): This complex was prepared in the same way as **1** but with *N,N,N',N'*-tetramethylethylenediamine (tmen) instead of *N,N,N'*-trimethylethylenediamine (trimen). Blue monocrystals suitable for X-ray determination were collected after 10 days (yield ca. 60%). – $C_{14}H_{32}ClCuN_7NiO_8$ (584.15): calcd. C 28.78, H 5.52, N 16.78; Cl, 6.07; found C 28.7, H 5.5, N 16.7; Cl, 6.2.

[Cu(oxpn)Ni(NO_2)(dmeten)](ClO_4) (3): This complex was prepared in the same way as **1** but with *N,N*-dimethyl-*N'*-ethylethylenediamine (dmeten) instead of *N,N,N'*- trimethylethylenediamine (trimen) (yield ca. 65%). – $C_{14}H_{32}ClCuN_7NiO_8$ (584.15): calcd. C 28.78, H 5.52, N 16.78; Cl, 6.07; found C 28.8, H 5.6, N 16.8; Cl, 6.1.

[Cu(oxpn)Ni(NO_2)(trimen)](PF_6) (4): $NaNO_2$ (2.73 mmol) and an ethanolic solution (7 mL) of $(NH_4)PF_6$ (1.36 mmol) were added to an ethanolic solution (30 mL) of [Cu(oxpn)Ni(H_2O)$_2$(trimen)](NO_3)$_2$ (2.73 mmol), prepared in situ by mixing [Cu(oxpn)] (2.73 mmol), Ni(NO_3)$_2$·xH_2O (2.73 mmol) and trimen (2.73 mmol), with constant stirring. The resulting blue solution was left to evaporate slowly at room temperature (yield ca. 70%). – $C_{13}H_{30}CuF_6N_7NiO_4P$ (615.64): calcd. C 25.36, H 4.91, N 15.92; found C 25.2, H 5.1, N 15.8.

[Cu(oxpn)Ni(NO_2)(dmeten)](PF_6) (5): This complex was prepared in the same way as **4** but with *N,N*-dimethyl-*N'*-ethylethylenediamine (dmeten) instead of trimen (yield ca. 60%). – $C_{14}H_{32}CuF_6N_7NiO_4P$ (629.67): calcd. C 26.70, H 5.12, N 15.57; found C 26.8, H 5.2, N 15.4.

Despite all efforts no crystals suitable for X-ray determination were obtained for complexes **3**, **4**, or **5**.

X-ray Crystallography. - [Cu(oxpn)Ni(μ-NO_2)(trimen)]$_n$(ClO_4)$_n$ (1) and [Cu(oxpn)Ni(NO_2)(tmen)]ClO_4 (2): Prismatic crystals (0.1 × 0.2 × 0.2 mm) for **1** and (0.1 × 0.1 × 0.2 mm) for **2** were selected and mounted on an Enraf–Nonius CAD4 four-circle diffractometer. Unit cell parameters were determined from automatic centring of 25 reflections ($12 < \theta < 21°$) and refined by least-squares methods. Intensities were collected with graphite monochromated Mo-K_α radiation, using ω/2θ scan-technique. For **1**, 3522 reflections were measured in the range $2.01 \leq \theta \leq 29.97°$, 3474 of which were nonequivalent by symmetry [R_{int} (on I) = 0.009]; 1763 reflections were assumed as observed applying the condition $I > 2\sigma(I)$. For **2**, 4757 reflections were measured in the range $2.16 \leq \theta \leq 29.94°$, 4710 of which were nonequivalent by symmetry [R_{int} (on I) = 0.017]; 3896 reflections were assumed as observed applying the condition $I > 2\sigma(I)$. Three reflections were measured every 2 h as orientation and intensity controls; significant intensity decay was not observed. Lorentz-polarisation but not absorption corrections were made. The structure was solved by Direct Methods, using SHELXS[20] and refined by full-matrix least-squares method with SHELX93[21] using 3031 reflections for **1** and 4660 reflections for **2** (very negative intensities were not assumed). The function minimised was $\Sigma w \mid F_o \mid^2 - \mid F_c \mid^2 \mid^2$, where $w = [\sigma^2(I) + (0.0795P)^2]^{-1}$ for **1** and $w = [\sigma^2(I) + (0.0842\ P)^2]^{-1}$ for **2**, and $P = (\mid F_o \mid^2 + 2 \mid F_c \mid^2)/3$, f, f' and f'' were taken from ref.[22] The extinction coefficient was 0.0002(2) for **1** and 0.0001(9) for **2**. The chirality of the structure was defined from the Flack coefficient,[23] which is equal to 0.01(3) for **1** for the results given. For complex **1** a carbon atom of the propanediamine moiety and the four O atoms of the perchlorate ion were located in disordered positions; an occupancy factor of 0.5 was assigned according to the height of the Fourier synthesis. 19 H atoms were located from a difference synthesis and refined with overall isotropic temperature factors, using a riding model. The final R (on F) factor was 0.057, wR (on $\mid F_o \mid^2$) = 0.122 and goodness of fit = 1.107 for all observed reflections. The number of parameters refined was 287. Maximum shift/esd = 0.06, mean shift/esd = 0.00. Maximum and minimum peaks in the final difference synthesis were 0.494 and –0.660 eÅ^{-3}, respectively. For complex **2** a carbon atom, C(13), of the oxpn ligand was located in a disordered position. 18 H atoms were located from a difference synthesis and refined with overall isotropic temperature factors and 12 H atoms were computed and refined with an overall isotropic temperature factor, using a riding model. Final R (on F) factor was 0.055, wR (on $\mid F_o \mid^2$) = 0.127 and goodness of fit = 1.115 for all observed reflections. The number of parameters refined was 372. Maximum shift/esd = 0.0, mean shift/esd = 0.00. The maximum and minimum peaks in the final difference synthesis were 0.629 and –0.589 eÅ^{-3}, respectively. Crystallographic data for **1** and **2** are shown in Table 3.

Table 3. Crystallographic data and experimental parameters for [Cu(oxpn)Ni(μ-NO_2)(trimen)]$_n$(ClO_4)$_n$ (**1**) and [Cu(oxpn)Ni(NO_2)(tmen)]ClO_4 (**2**)

Atomic positional and thermal parameters, a complete list of bond lengths and angles, and F_o/F_c values are available as supplementary material from one of the authors. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-101760 **(1)** and CCDC-118817 **(2)**. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44–1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Spectral and Magnetic Measurements: Magnetic measurements were carried out on polycrystalline samples with a Quantum Design MPMS SQUID susceptometer operating at a magnetic field of 0.5 T, between 2 and 300 K. EPR spectra were recorded on powder samples at X-band frequency with a Bruker 300E automatic spectrometer. EPR measurements were carried out in the "Servei de Magnetoquímica" (University of Barcelona).

Acknowledgments

We are very grateful for the financial support given by the Dirección General de Investigación Científica y Técnica (Spain) (Grant PB96/0163). We also thank the group of Dr. D. Gatteschi (Università degli Studi di Firenze) for the providing us with the CLUMAG program and Dra. Núria Clos for recording the EPR measurements.

Complexation of Cobalt(II) at the Upper Rim of Two New Calix[4]arene/Bipyridine-Based Podands

Jean-Olivier Dalbavie,[b] Jean-Bernard Regnouf-de-Vains,*[a] Roger Lamartine,[b] Sylvain Lecocq,[c] and Monique Perrin[c]

Keywords: Calix[4]arenes / Bipyridines / Podands / Cobalt complexes

Introduction of one or two 2,2′-bipyridine units at the upper rim of the calix[4]arene platform was performed by means of the Wittig reaction. The resulting alkenes were hydrogenated to give two new bipyridyl-based calixarene podands, which were studied as ligands for Co^{II} cation. The mono-bipyridyldichlorocobalt complex was notably fully characterised by ^{1}H-NMR and X-ray crystal structure analyses, which confirmed the tetrahedral coordination mode involving the bipyridyl subunit and the two chlorine atoms around the cobalt centre.

Introduction

As recently reviewed by Matt et al.,[1] the calixarenes display interesting properties for transition metal chemistry, via their own binding sites (oxygens, aryl rings), or by their ability to act as carriers and spatial organisers of various types of chelating agents, such as esters, phosphanes, or heterocycles. In this domain, our contribution resulted in the synthesis and study of the complexation properties of various podands incorporating 2,2'-bipyridine and 2,2'-bithiazole chelating units at the lower rim of the tetra-*p*-*tert*-butylcalix[4]arene platform.

In order to develop a similar approach at the upper rim, but in a different way than through the potentially coordinating amide links developed by Beer and coll.,[3] we found that the Wittig reaction could be an interesting synthetic tool for building a new family of lipophilic ligands in which the chelating units would be attached by a stable and non-coordinating ethylenic linkage to the calixarene platform.

As a first step, this reaction was applied on the mono[*p*-(formyl)]tris[*p*-(*tert*-butyl)]calix[4]arene model, leading to the conjugated phenol-bipyridyl system **1**.[4] The relative instability of this ligand and its copper(I) complex ([**1**/Cu/**1**]PF_6),[5] especially on chromatographic supports, limited the interest of this family of unsaturated ligand in our field of investigations, and led us to develop the complexation studies of the corresponding saturated podands.

We thus present here the syntheses and some complexation properties towards Cobalt(II) of two new calixarene-based bipyridine ligands, in which the chelating units are bound by an ethylenic linkage to the upper rim of the calixarene platform.

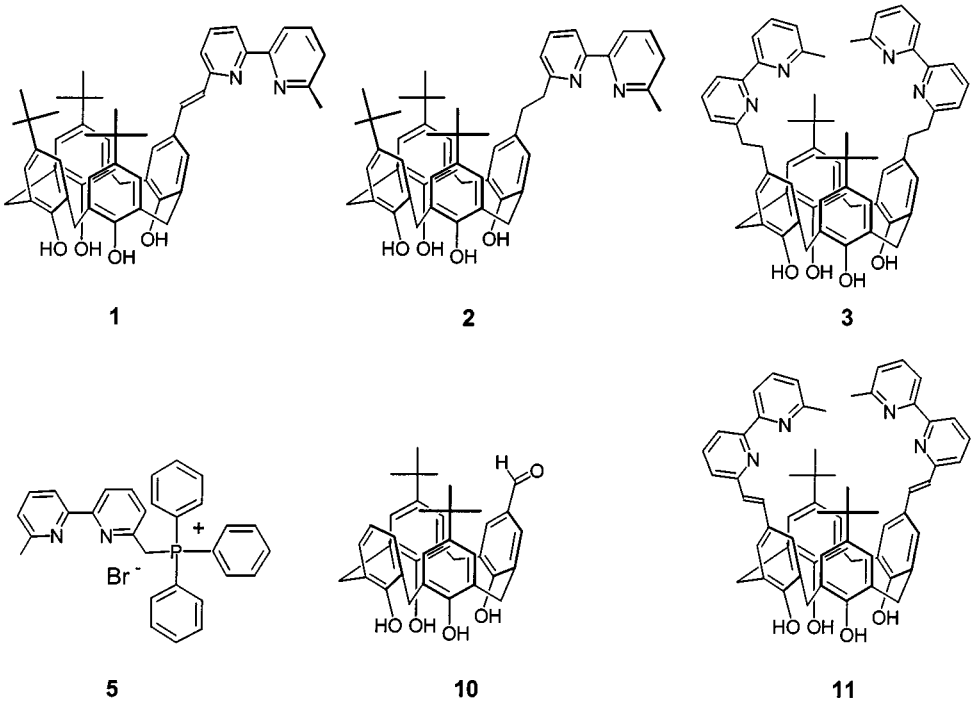
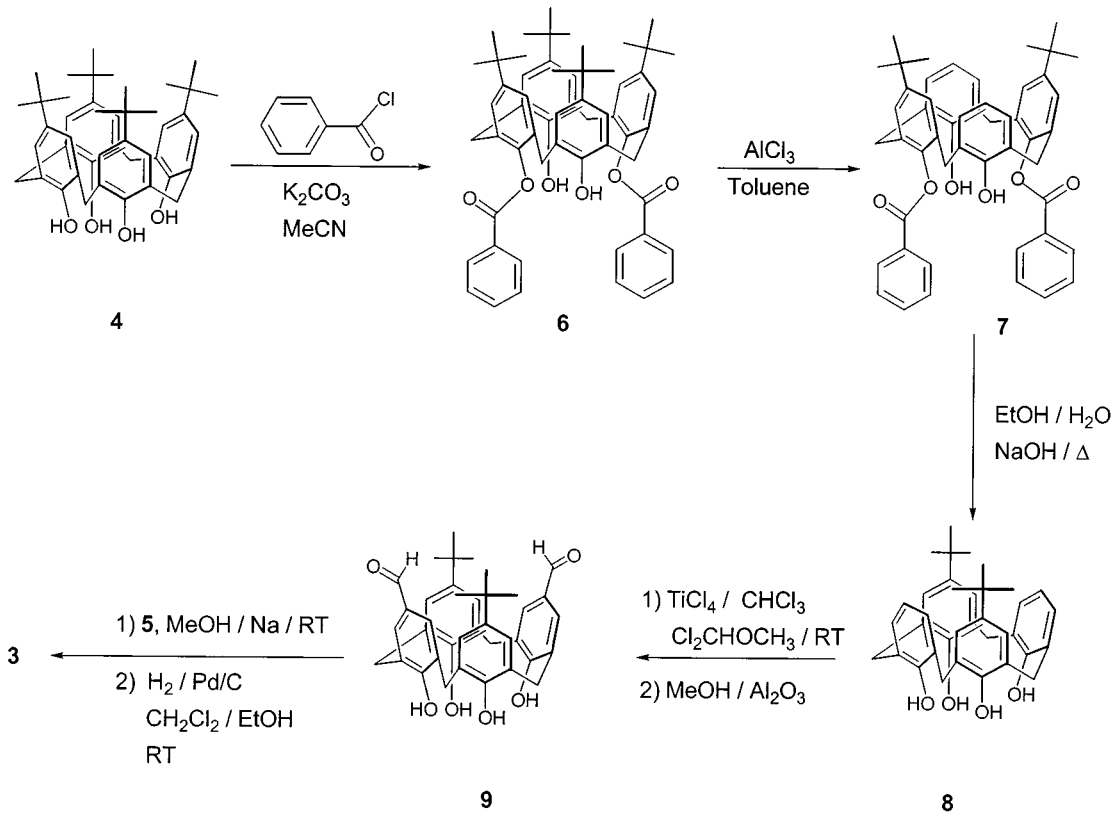
Results and Discussion



Syntheses of ligands (Scheme 1 *and Scheme* 2*)*. Ligand **2** was obtained quantitatively by catalytic hydrogenation of **1**, but we found it better to reduce the raw Wittig material directly, in order to eliminate the loss of **1** during chromatography. In this way, **2** was obtained in a yield of 40% *vs* the formylcalixarene platform, instead of 27% with isolation of **1**.

The synthetic strategy developed for the disubstituted podand **3** was similar to **1** and **2**, and involved a selective double deterbutylation of the tetra-*p*-*tert*-butylcalix[4]arene **4**, followed by a double Gross formylation[6] applied on the unprotected calixarene platform. The resulting aldehyde was then treated in alcoholic basic conditions with the monophosphonium salt of bipyridine **5** to give the corresponding diene which was directly catalytically hydrogenated into the desired armed calixarene.



The selective introduction of two chelates at the 5th and 17th positions of the calix[4]arene platform **4** involved a preliminary retro-Friedel and Crafts di-deterbutylation step developed by Gutsche and coll.[7] *via* a selective protective dinitrobenzoylation of two hydroxyl groups in diametrical positions. The resulting diester was obtained in three different acylation media, namely dichlorophenylphosphate/dinitrobenzoic acid/DMF/ pyridine, $AlCl_3$/dinitrobenzoyl chloride/DMF, or dinitrobenzoyl chloride/pyridine systems, with yields of 75, 67, and 95%, respectively. More recently, Huang and coll.[8] described the formation of the dibenzoyl analogue **6** in a benzoyl chloride/$CHCl_3$/NEt_3 medium with a yield of 68%. We found that **6** could easily be synthesised from **4** and benzoyl chloride using MeCN as solvent and K_2CO_3 as base, with a good yield of 91%.

The subsequent retro-Friedel and Crafts deterbutylation step was carried out in toluene using only five equivalents

Scheme 1

Scheme 2

of $AlCl_3$ relative to **6**. The reaction was initiated by a gentle warming and was completed in ca. 1–2 hours, giving **7** with a yield of 80%. Based on the recent work of Magrans and coll., dedicated to the conformational study of 1,3-di-*O*-benzoylated calix[4]arenes,[9] the ^{13}C-NMR analyses of compounds **6** and **7** show that they should not be in a pure cone conformation. The resonance signals of the Ar–CH_2-Ar groups appear at δ = 33.39 and 33.84, respectively, between the standard δ = 31 and 37 values observed for the pure *syn* and *anti* conformations. This suggests that a rapid exchange between the conic and the 1,3-alternate conformations takes

place in solution. Nevertheless, for legibility, **6** and **7** are drawn in the conic conformation in Scheme 2.

The benzoate groups were then removed in alcoholic NaOH at reflux. The 11,23-di-*p*-*tert*-butylcalix[4]arene **8** was thus obtained in an almost quantitative yield.

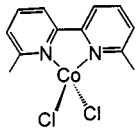
Introduction of the two formyl groups at the upper rim of **8** failed when the previously described conditions were employed. The use of $TiCl_4$ instead of $SnCl_4$ was successful, affording the bis-aldehyde **9** and some mono-aldehyde **10,** in yields of 65 and 19%, respectively. It is interesting to note that, as previously mentioned,[4] a treatment of the raw electrophilic substitution material over Al_2O_3 was mandatory to liberate the formylated species.

Reaction of **9** with two equivalents of **5**[4] in the presence of an excess of NaOMe in MeOH afforded a mixture of compounds from which only low amounts of pure bis(alkene) **11** were isolated. For this reason, we preferred to hydrogenate the raw Wittig material directly. From the resulting mixture, the bisalkane **3** was isolated after chromatography in a yield of 22%.

Complexation Studies

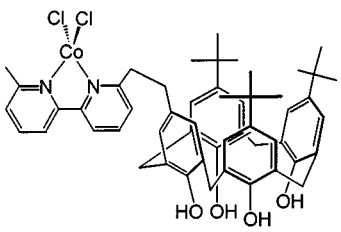
Cobalt(II) Complex of 2

The reactivity of 6,6'-dimethyl-2,2'-bipyridine (dmbpy) towards Co^{II} cation has notably been studied by Newkome and coll., who prepared, based on UV/Vis spectroscopy and elemental analysis, the neutral tetrahedral $Co(dmbpy)Cl_2$ complex **12**.[10] The same approach applied to an octobipyridylcalix[4]resorcinarene ligand allowed us to prepare, based on UV/Vis spectroscopy, elemental and ES-MS analyses, the corresponding octodichlorocobalt species,[2b] which demonstrated that the presence of a bulky substituent close to the chelating site was not limiting the complexation process.



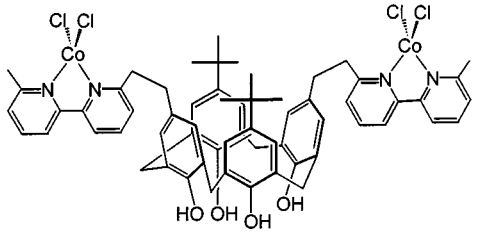
In **2** or **3**, the presence of the ethylenic linkage should give a more pronounced (dimethyl)bipyridine character to the chelating site than in the above-mentioned example, and therefore facilitate the coordination process of Co^{II}.

Thus, reacting **2** with one equivalent of anhydrous $CoCl_2$ in a $MeOH/CH_2Cl_2$ mixture at room temperature gave the light-blue complex **13** (Scheme 3), which was purified by chromatography on Sephadex LH20, and then crystallised as fine needles from a hexane/CH_2Cl_2 mixture. Unfortunately these were unsuitable for X-ray analysis. Elemental analysis was consistent with the presence of 0.2 equivalent of CH_2Cl_2.



The latter was found in the standard ^{1}H-NMR spectrum of **13**, which also did not display the resonance pattern of the bipyridyl group, thereby confirming the paramagnetic nature of the complex subunit. The remaining part of the molecule, out of the sphere of direct influence of Co^{II}, displayed resonance signals in the expected regions. In $CDCl_3$, at 300 MHz, two singlets assigned to *tert*-butyl groups were found at δ = 1.24 (9 H) and δ = 2.15 (18 H); four broad singlets located at δ = 2.50, 2.95, 3.34, and 3.94 (2 H each) were assigned to the Ar–CH_2-Ar groups, considering that the ethylenic bridge, which supports the effect of the cobalt cation, did not give resonance signals. Changing $CDCl_3$ for CD_2Cl_2 resulted in the transformation of these four singlets into two well-separated broad AB systems, confirming our previous assignment and suggesting a probable rigidification due to a specific interaction between this solvent and the macrocycle.

In the aromatic part, two sharp singlets at δ = 6.92 and 7.06, and a broad one at δ = 7.82, each integrating 2H, were assigned to the aromatic protons of the unsubstituted phenol rings. Finally, a broad singlet located at δ = 9.32 was assigned to the four hydroxyl groups.



The fact that the resonance signals of protons close to the metallic centre, with regards to the supposed structure of complex **13**, are absent in these classical analytical conditions led us to seek them in a larger frequency domain. Recording data over 65000 Hz (216 ppm at 300 MHz) allowed the exhibition of ten new signals: six relatively sharp singlets ($\Delta\nu_{1/2}$ = 30–38 Hz) integrating for 1 H each, at δ = 70.71, 69.92, 49.10, 46.67, –14.77, and –15.72 that we suspect correspond to the bipyridine protons; a larger singlet

12

13

14

Scheme 3

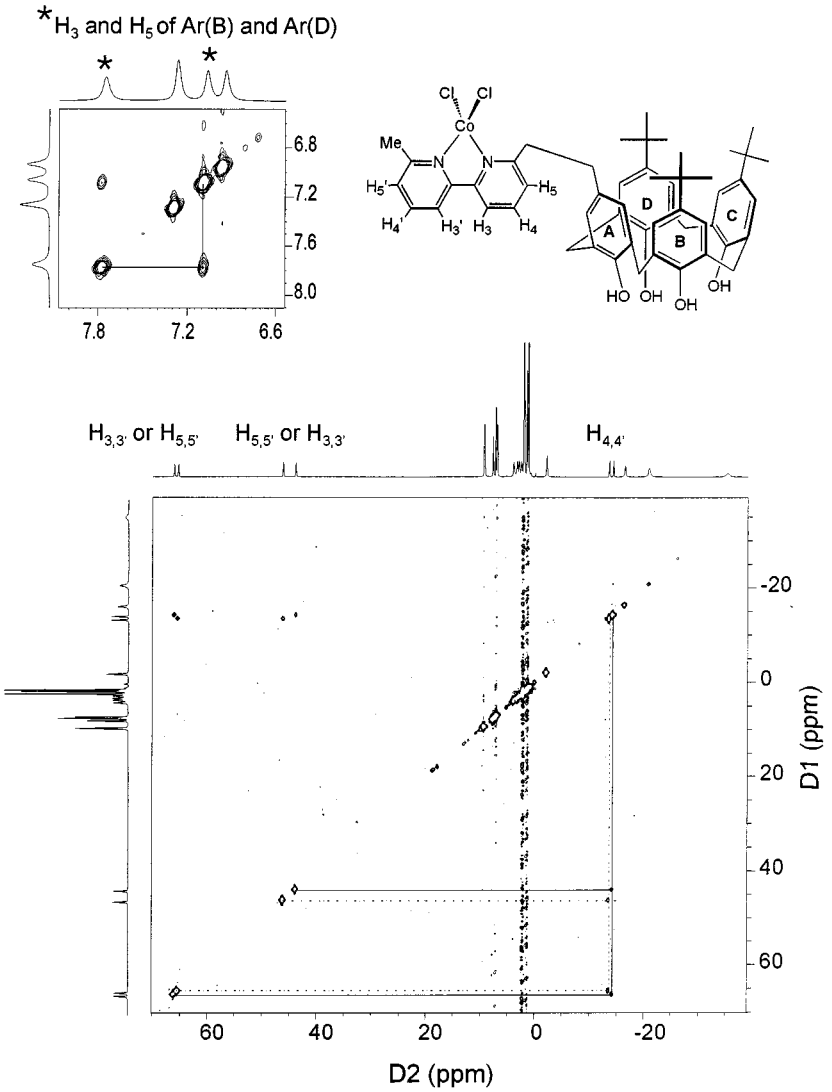


Figure 1. COSY correlations between protons of complex **13** ($CDCl_3$, 500 MHz, 293 K) (main spectrum: bipyridine resonance pattern; offset: aryl resonance pattern)

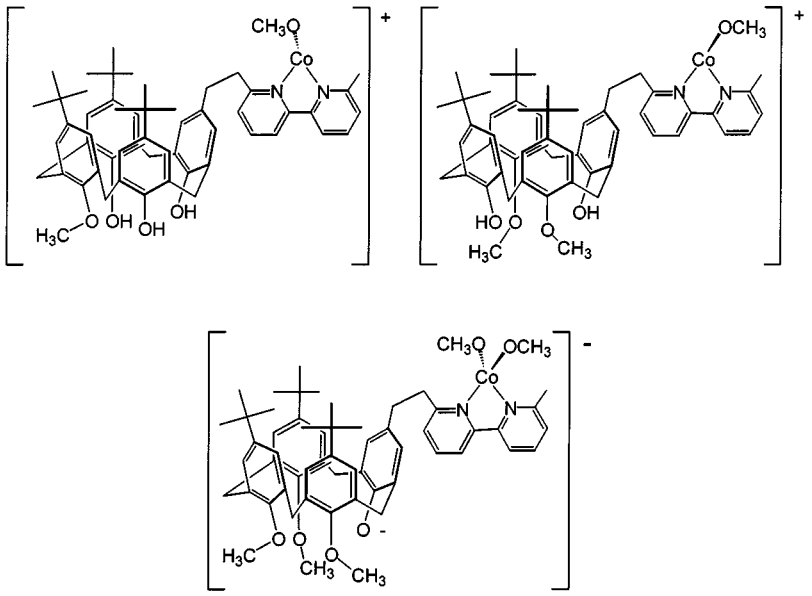

at δ = –2.63 ($\Delta\nu_{1/2}$ = 48 Hz) integrating for 2 H, which was assigned to the substituted phenol ring protons, and three large singlets, one integrating for 2 H ($\Delta\nu_{1/2}$ = 92 Hz) at δ = –17.21, another one integrating for 3 H ($\Delta\nu_{1/2}$ = 169 Hz) at δ = –21.68, and the last singlet integrating for 2 H ($\Delta\nu_{1/2}$ = 300 Hz) at δ = –37.73, which were assigned to the CH_2-phenol, the CH_3-bpy and the CH_2-bpy groups, respectively.

Working at 500 MHz resulted in slight changes in chemical shifts (see Experimental Section). 500-MHz COSY experiment (58000 Hz, 116 ppm) (Figure 1) confirmed the attribution of the bipyridine protons, with two groups of signals at δ = 66.06, 43.87, –14.30, and δ = 65.35, 46.17, –13.52, the negative signals corresponding to the H(4) and H(4') spin systems. Another scalar correlation was found in the calixarene aromatic region between the singlets at δ = 7.75 and δ = 7.07, which were thus assigned to the two lateral phenol rings.

UV/Vis spectroscopy of **13** in CH_2Cl_2 showed a complex ligand-centred absorption pattern associated with a metal-centred transition at 655.5 nm with a molar extinction coefficient of ca. 530 $dm^3.mol^{-1}.cm^{-1}$, identical to the values reported for **12** and corresponding to a tetrahedral coordination mode.[10]

ES-MS analysis confirmed the formation of **13**. The preliminary measurements were performed in CH_2Cl_2 containing some MeOH as proton source. In the positive mode, three peaks corresponding to species containing the native ligand **13** were observed at 846.5, 811.6 and 789.7 a.m.u. and were attributed to the mono-charged cations [**13** – $2Cl^-$ – H^+]$^+$, [**13** – $CoCl_2$ + Na^+]$^+$, and [**13** – $CoCl_2$ + H^+]$^+$, respectively. They were accompanied by compounds of higher molecular weights which were analysed as complex **13** in which one or two phenol groups were *O*-methylated and one chlorine was exchanged with a methoxy anion: 906.6 a.m.u. [$(CH_3O)_2$ **13**–$2Cl^-$ + CH_3O^-]$^+$ and 892.6 a.m.u. [(CH_3O) **13**–$2Cl^-$ + CH_3O^-]$^+$ (Scheme 4).

In the negative mode, which usually gives, in the calixarene family, the mono- or polyphenate anions, the same phenomenon was observed at –50 V, but with a much lower

Scheme 4

intensity, the base peak at 787.6 a.m.u. corresponding to the deprotonated ligand **2**. The molecular peak was observed at 916.6 a.m.u. [**13** – H^+]$^-$, accompanied by the mono- and the bis-dehalogenated species at 880.5 a.m.u. [**13** – Cl^- – $2H^+$]$^-$ and 844.5 a.m.u. [**13** –$2Cl^-$ – $3H^+$]$^-$, respectively. Three peaks at 950.6, 940.6, and 926.6 a.m.u. were attributed to complexes containing one tris-, one bis-, and one monomethylated ligand with a double or single anion metathesis, i.e. [$(CH_3O)_3$**13** –$2Cl^-$ + $2CH_3O^-$ – H^+]$^-$ (Scheme 4), [$(CH_3O)_2$**13** – Cl^- + CH_3O^- – H^+]$^-$, and [(CH_3O) **13** – Cl^- + CH_3O^- – H^+]$^-$. We found in fact, that these methylation reactions and anion metatheses occurred during the analysis: changing the solvent for alcohol-free CH_2Cl_2 (stabilised with 2-methyl-2-butene), gave, in the positive mode (+ 80 V), peaks at 882.5, 846.6, and 789.9 5 a.m.u. which were attributed to [**13** – Cl^-]$^+$, [**13** –$2Cl^-$ – H^+]$^+$, and [**13** – $CoCl_2$ + H^+]$^+$, respectively.

Blue single crystals of complex **13**, suitable for X-ray diffraction analysis, were obtained in a closed tube by liquid diffusion of Et_2O into a solution of **13** in CH_2Cl_2. This study confirmed the presence of the expected dichlorocobalt-bipyridine complex subunit attached by an ethylene link to the upper rim of the tri-*tert*-butylcalix[4]arene platform (Figure 2). The cobalt cation is coordinated in a distorted tetrahedral mode to the two bipyridyl nitrogen atoms and to the two chlorine anions (Table 1), confirming the hypothesis of Newkome et al.[10] The bipyridyl group is parallel to the supporting phenol ring **A**, making with it an angle of only 4.25°.

The cyclic tetramer is in a boat-shaped cone conformation, with the expected usual hydrogen bonds between the hydroxyl groups (2.608–2.731 Ä). The angles between the phenol rings **A**, **B**, **C**, and **D**, and the mean plane defined by the methylene bridges amount to 122.7(2), 118.0(2), 132.7(1), and 117.1(2)°, respectively. Surprisingly, the presence of the bulky complex substituent do not result in the leaning of the supporting phenol ring **A**, while **C**, in the alternate position, is strongly inclined. The *tert*-butyl group of the latter occupies two positions, differing by a rotation of about 60°, with occupancies of 51% and 49%.

Each complex unit is associated with a molecule of Et_2O and one of CH_2Cl_2. The former, which is not shown in Figure 2, is located between the macrocycles, while the latter is trapped into the calixarene cavity, on the level of the *tert*-butyl groups (Figure 3).[11] This molecule of CH_2Cl_2 is found in disordered positions called Cl20–C100–Cl10 (73%) (Figure 2), and Cl30–C200–Cl40 (27%); Cl20 and C200 on one part, Cl40 and C100 on the other part, are positioned on the same sites. The interactions between dichloromethane and calixarene are found between C100 and ring **C** (3.46 Å) and C200 and ring **A** (3.34 Å).

This specific complexation found in the solid state can be correlated with the modifications of the ^{1}H-NMR spectrum of complex **13**, which were previously observed between its $CDCl_3$ and CD_2Cl_2 solutions.

According to the proposal for classification and nomenclature of host-guest type compounds given by Weber and Josel,[12] compound **13** can be defined as a cryptato-tubulato clathrate.

Cobalt(II) Complex of 3

In a similar way, ligand **3** was reacted with two equiv. of $CoCl_2$ to give the dinuclear grey-blue complex **14**. The expected M_2L stoichiometry was verified by UV/Vis spectroscopy in CH_2Cl_2, with an ε value of 1030 dm^3 mol^{-1} cm^{-1} at 656.5 nm, twice the value of **13**, and by C, H, and N elemental analyses. Positive- or negative mode ES-MS analysis of **14** showed methylation reactions and anion metatheses similar to those observed with **13** when methanolic CH_2Cl_2 was used as the solvent (*see Experimental Section*). In the negative mode (–50 V), in alcohol-free CH_2Cl_2, the complex exhibited a single mass of peaks at 1185.5–1189.3

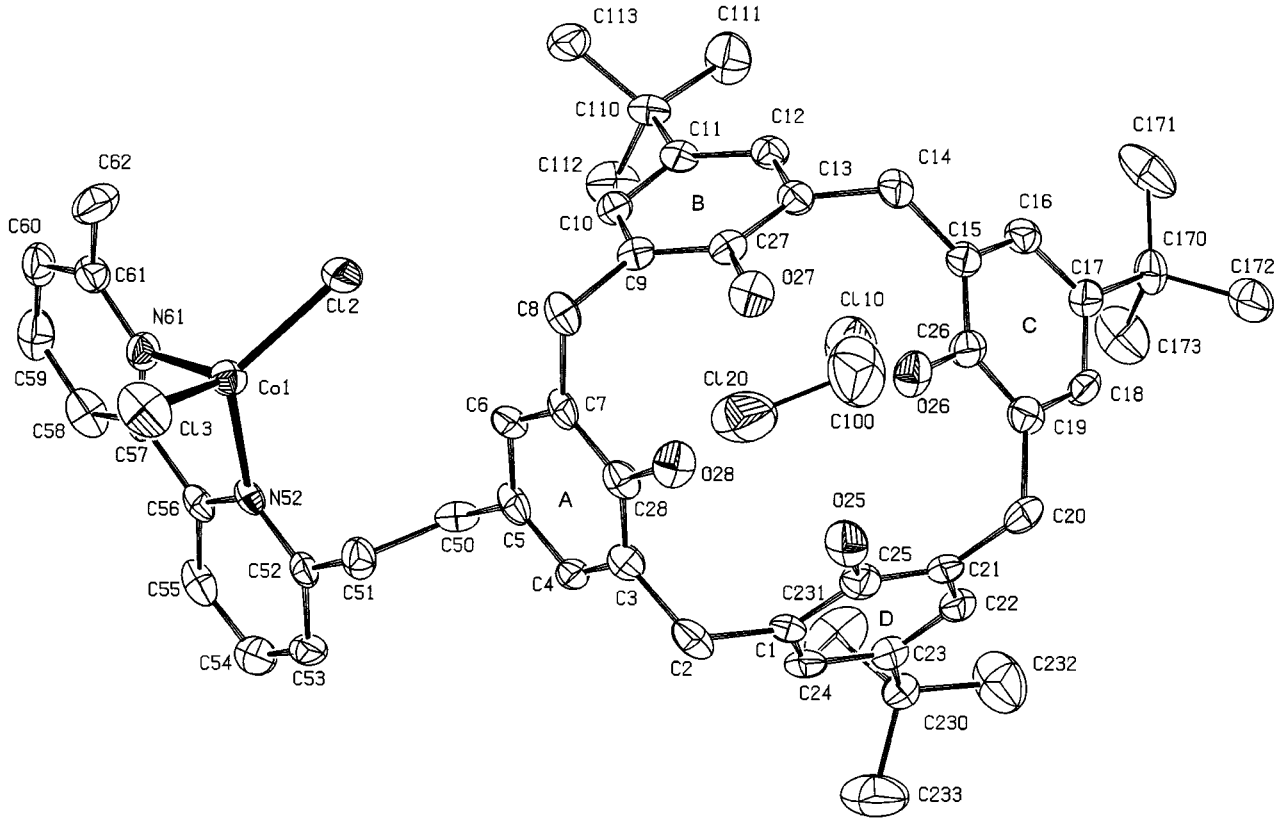

Figure 2. Numbering scheme and ORTEP underside-view of complex **13**

Table 1. Selected geometric parameters around the cobalt centre

Bond lengths [Å]			
Co–N52	2.021(5)	Co–N61	2.027(6)
Co–Cl2	2.213(2)	Co–Cl3	2.222(2)
Bond angles [°]			
Cl2–Co–Cl3	118.4(9)°	N52–Co–N61	82.3(2)
Cl2–Co–N52	119.6(2)°	Cl3–Co–N61	110.1(2)
N52–Co–Cl3	108.7(2)°	N61–Co–Cl2	112.0(2)

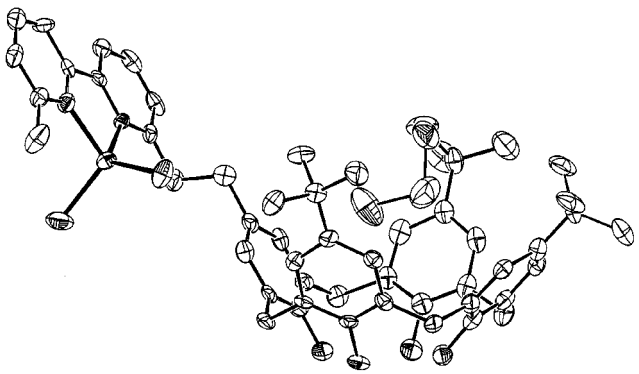

Figure 3. ORTEP side-view of complex **13**

a.m.u. which was attributed to the monophenate species [**14** – H^+]$^-$, confirming the results of UV/Vis and elemental analyses.

Unfortunately, the lack of solubility of **14** did not allow us to verify the ^{1}H-NMR results obtained with **13**.

Conclusion

By a Wittig reaction *plus* hydrogenation process, we have selectively incorporated one and two bipyridine units at the upper rim of *p*-(*tert*-butyl)calix[4]arene platforms. The two new ligands thus obtained displayed coordinating behaviour towards cobalt(II), and the resulting mono- and dinuclear complexes were fully characterised. With the monometallic species, ^{1}H-NMR COSY experiment performed on a large frequency domain allowed us to recover and to assign the bipyridine resonance signals, and X-ray analysis confirmed the tetrahedral coordination of the bipyridine and the two chlorine atoms around the cobalt centre. The complexation studies of other transition metal cations and the building of the tris- and tetra-substituted analogues are now under investigation.

Experimental Section

General: Melting points (°C, uncorrected) were determined on an Electrothermal 9100 in Capillary apparatus. – ^{1}H and ^{13}C NMR spectra were recorded on a Bruker AM 300 or DRX 300 and DRX 500 ($CDCl_3$, TMS as internal standard, chemical shifts in ppm). – Mass spectra (electrospray, ES) were recorded on a Platform Mic-

romass apparatus at the Service Central d'Analyse du CNRS, Solaize. – Infrared spectroscopy was performed on a Mattson 5000 FT apparatus (KBr, $\tilde{\nu}$ in cm^{-1}). – UV spectra were recorded on a Shimadzu UV 2401 PC or a SAFAS UV mc^2 apparatus, λ_{max} in nm, ε in $dm^3\ mol^{-1}\ cm^{-1}$. – Elemental analyses were performed at the Service Central de Microanalyse, Ecole Supérieure de Chimie, Montpellier. – Macherey–Nagel TLC plates were used for chromatography analysis (SiO_2, Polygram SIL G/UV254, ref.805021). All commercially available products were used without further purification unless otherwise specified.

Calix[4]arene-25,26,27,28-tetrol 2. – Indirect Method: To a solution of 0.05 g of **1**[3] ($0.063 \cdot 10^{-3}$ mol) in 5 mL of EtOH/CH_2Cl_2, was added 0.01 g of 5% Pd/C, and H_2 was bubbled through the solution for 1 min. The mixture was stirred at room temp. overnight under H_2 and then filtered over Celite. Evaporation of the filtrate to dryness afforded 0.045 g of pure **2** (90%).

Direct Method: The raw Wittig material obtained from 0.5 g (0.8 mmol) of monoformylcalixarene was neutralised with 1 M HCl and evaporated to dryness. The resulting glassy material was dissolved in 50 mL of CH_2Cl_2, dried over Na_2SO_4 and concentrated to ca. 20 mL. EtOH (30 mL) and 0.2 g of 5% Pd/C were added, and the resulting mixture was stirred under H_2 overnight. The suspension was filtered over Celite and evaporated to dryness. The residue was dissolved in CH_2Cl_2 and addition of MeOH resulted in the precipitation of a raw material which was purified by chromatography (Al_2O_3, CH_2Cl_2/hexane, then CH_2Cl_2/MeOH 99:1) to give 0.25 g of **2** (40%). –UV/Vis (CH_2Cl_2): λ (ε) = 281.0 (23390), 289.0 (24180), 304.0 (10400). – ^{1}H NMR ($CDCl_3$): δ = 1.198 (s, 9 H, *Me*$_3$C); 1.205 (s, 18 H, *Me*$_3$C); 2.62 (s, 3 H, *Me*bpy); 2.80–3.20 (*ABm*, 4 H, C*H*$_2$–C*H*$_2$); 3.45, 4.22 ("q", *AB*, *JAB* = 13 Hz, 4 H, Ar–C*H*$_2$-Ar); 3.45, 4.22 ("q", *AB*, *JAB* = 13 Hz, 4 H, Ar–C*H*$_2$-Ar); 6.93 (s, 2 H, Ar); 7.01–7.07 (m, 7H, 6 H of Ar, 1 H of bpy); 7.02 (d, *J* = 7.6 Hz, 1 H, bpy); 7.64 (t, *J* = 7.6 Hz, 1 H, bpy); 8.19 (*d*, *J* = 7.7 Hz, 1 H, bpy); 8.20 (d, *J* = 7.7 Hz, 1 H, bpy); 10.28 (s, 4H, O*H*). – ^{13}C NMR ($CDCl_3$): δ = 24.67 (*Me*bpy); 31.40, 31.46 (*Me*$_3$C); 32.34, 32.51 (Ar–CH$_2$-Ar); 33.98, 34.03 (Me$_3$*C*); 34.95, 40.07 (*C*H$_2$–CH$_2$); 118.19, 118.53, 122.69, 123.05, 136.97 (C-3, C-4, C-5, C-3', C-4', C-5' of bpy); 125.71, 125.86, 126.03, 129.00 (CH of Ar); 127.41, 127.71, 127.90, 128.31, 135.36, 144.44, 146.37, 146.70, 147.10 (C_o, C_p, C_{ipso} of Ar); 155.90, 155.98, 157.78, 160.67 (C-2, C-2', C-6, C-6', bpy). – ES-MS (neg. mode; –50V); *m*/*z*: 787.7–788.7 [**2** – H$^+$]$^-$. – $C_{53}H_{60}N_2O_4 \cdot 0.25\ CH_2Cl_2$ (810.31): calcd. C 78.93, H 7.53, N 3.46, O 7.90; found C 79.09, H 7.58, N 3.31, O 7.98.

Calix[4]arene-26,28-diol 6: A mixture of finely powdered K_2CO_3 (2.33 g, 17 10^{-3} mol) and 5 g of *p-tert*-butylcalix[4]arene **4** (7.7 10^{-3} mol) in 250 mL of acetonitrile was stirred at 80 °C for 30 min. Benzoyl chloride (1.8 mL, 15.4 10^{-3} mol) was then added by syring, and heating was maintained for 4 h. After cooling, the solvent was evaporated to dryness and the residue dissolved in 100 mL of CH_2Cl_2. The resulting solution was washed with water (3×50 mL), dried over Na_2SO_4, then concentrated to 40 mL on a Rotavapor. The residue was then mixed with 300 mL of EtOH and the resulting cloudy solution was concentrated in vacuo to give 6 g of **6** (91%), white precipitate, m.p. 320–330 °C (dec.). – UV/Vis (CH_2Cl_2): λ (ε) = 278.5 (6100). – IR: $\tilde{\nu}$ = 1735 (C=O). – ^{1}H NMR ($CDCl_3$): δ = 1.01 (s, 18 H, *Me*$_3$C); 1.15 (s, 18 H, *Me*$_3$C); 3.49, 3.97 ("q", *AB*, *JAB* = 14.1 Hz, 8 H, Ar–C*H*$_2$-Ar); 6.91 (s, 4 H, Ar); 7.02 (s, 4 H, Ar); 7.52 (t, *J* = 7.4 Hz, 4 H of C_6H_5); 7.70 (t, *J* = 7.4 Hz, 2 H of C_6H_5); 8.33 (d, *J* = 7.1 Hz, 4 H of C_6H_5). – ^{13}C NMR ($CDCl_3$): δ = 31.53, 31.09 (*Me*$_3$C); 33.39 (Ar–CH$_2$-Ar); 33.86, 34.06 (Me$_3$*C*); 133.71, 130.50, 128.99, 126.12, 125.64 (CH of Ar and C_6H_5); 150.43, 148.87, 143.34, 142.61, 131.92, 127.78, 129.38 (C_o, C_p, C_{ipso} of Ar; C_{ipso} C_6H_5); 165.01 (*C*=O). – ES-MS (neg. mode); *m*/*z*: 855.7 [**6** – H]$^-$; (pos. mode): 857.6 [**6** + H]$^+$. – $C_{58}H_{64}O_6$ (857.15): calcd. C 81.27, H 7.53, O 11.20; found C 81.08, H 7.90, O 11.16.

Calix[4]arene-26,28-diol 7: A mixture of **6** (6 g, $7 \cdot 10^{-3}$ mol) and $AlCl_3$ (4.7 g, 35 10^{-3} mol) in 300 mL of toluene was heated until a red colouration persisted, and then stirred at room temp. for 2 h. H_2O (100 mL) was added, and the resulting emulsion was stirred for 30 min. The toluene phase was washed with water (3×100 mL), the latter extracted with CH_2Cl_2, and the combined organic phases evaporated to dryness. The yellow residue was dissolved in a mixture of CH_2Cl_2 (50 mL) and MeOH (250 mL) and then concentrated in vacuo to ca. 100 mL to give 4.2 g of **7** (80%) as a white precipitate; m.p. 320 °C(dec). – UV/Vis (CH_2Cl_2): λ (ε) = 275.0 (9480), 282.0 (sh, 8330). – IR: $\tilde{\nu}$ = 1735 (C=O). – ^{1}H NMR ($CDCl_3$): δ = 1.08 (s, 18 H, *Me*$_3$C); 3.87, 3.57 ("q", *AB*, *JAB* = 14.1 Hz, 8 H, Ar–C*H*$_2$-Ar); 6.59 (t, *J* = 7.4 Hz, 2 H, Ar); 6.93 (d, *J* = 7.4 Hz, 4 H, Ar); 7.00 (s, 4 H, Ar); 7.52 (t, *J* = 7.7 Hz, 4 H, C_6H_5); 7.72 (t, *J* = 7.4 Hz, 2 H, C_6H_5); 8.22 (d, *J* = 7.0 Hz, 4 H, C_6H_5). – ^{13}C NMR ($CDCl_3$): δ = 31.19 (*Me*$_3$C); 33.84 (Ar–CH$_2$-Ar); 34.15 (Me$_3$*C*); 119.62, 130.70, 129.27, 128.68, 126.31, 133.75 (CH of Ar and C_6H_5); 128.05, 131.95, 144.05, 149.04, 152.91 (C_o, C_p, C_{ipso} of Ar, C_{ipso} of C_6H_5); 164.76 (*C*=O). – ES-MS (neg. mode); *m*/*z*: 535.5 [**7**– H]$^-$. – $C_{50}H_{48}O_6$ (744.94): calcd. C 80.62, H 6.50, O 12.88; found C 80.57, H 6.73, O 12.81.

Calix[4]arene-25,26,27,28-tetrol (8): A mixture of **7** (4.2 g, 5.6 10^{-3} mol) and NaOH (8 g, 200 10^{-3} mol) in a mixture of EtOH (120 mL) and H_2O (40 mL) was heated under reflux for 12 h. After cooling, the solution was acidified to pH 5–6 with HCl to give a white precipitate which was collected by filtration, and then dissolved in CH_2Cl_2. Addition of MeOH resulted in the precipitation of 3 g of **8** (99%), m.p. 300 °C. – UV/Vis (CH_2Cl_2): λ (ε) = 277.5 (10000), 282.5 (sh, 8600). – ^{1}H NMR ($CDCl_3$): δ = 1.25 (s, 18 H, *Me*$_3$C); 4.26, 3.56 ("q", 8 H, Ar–C*H*$_2$-Ar); 6.73 (t, *J* = 7.7 Hz, 2 H, Ar); 7.08 (d, *J* = 7.7 Hz, 4 H, Ar); 7.09 (s, 4 H, Ar); 10.29 (s, 4 H, O*H*). – ^{13}C NMR ($CDCl_3$): δ = 31.52 (*Me*$_3$C); 32.22 (Ar–CH$_2$-Ar); 34.12 (Me$_3$*C*); 129.02, 125.91, 122.37 (CH of Ar); 148.72, 146.77, 144.66, 128.5, 127.56 (C_o, C_p, C_{ipso} of Ar). – ES-MS (neg. mode); *m*/*z*: 535.5 [**8** – H]$^-$. – $C_{36}H_{40}O_4 \cdot 0.9\ CH_2Cl_2$ (613.15): calcd. C 72.28, H 6.87, O 10.44; found C 72.35, H 6.97, O 10.58.

Calix[4]arene-25,26,27,28-tetrol (9) and Calix[4]arene-25,26,27,28-tetrol (10): $TiCl_4$ (1.25 mL, 11.2 10^{-3} mol) was syringed into a soln. of **8** (0.4 g, 0.65 10^{-3} mol) in 10 mL of $CHCl_3$. The resulting red solution was stirred under N_2 during 30 min. Dichloromethylmethyl ether (1 mL, 11.2 10^{-3} mol) was then added dropwise. After 2 h, 25 mL of water was added and stirring was continued for 1 h. After separation, the aqueous phase was washed with CH_2Cl_2 (3×20 mL). The combined organic phases were dried over Na_2SO_4, then concentrated to dryness. The residue was dissolved in 1:1 MeOH/CH_2Cl_2 and 2 g of aluminium oxide were added to give, after ca. 12 h, the raw aldehyde which was purified by chromatography (SiO_2, CH_2Cl_2) to give 0.08 g of the mono aldehyde **10** (19%) and 0.25 g of **9** (64%). – **Compound 9:** m.p. >350 °C. – UV/Vis (CH_2Cl_2): λ (ε) = 281.0 (18300). – IR: $\tilde{\nu}$ = 1680 (C=O). – ^{1}H NMR ($CDCl_3$): δ = 1.24 (s, 18 H, *Me*$_3$C); 4.27,3.69 (br. *AB*, 8 H, Ar–C*H*$_2$-Ar); 7.15 (s, 4 H, Ar); 7.61 (s, 4 H, Ar); 9.74 (s, 2 H, C*H*O); 10.30 (s, 4 H, O*H*). – ^{13}C NMR ($CDCl_3$): δ = 31.50 (*Me*$_3$C), 31.99 (Ar–CH$_2$-Ar); 34.28 (Me$_3$*C*); 126.41, 131.16 (CH of Ar), 126.83, 129.15, 131.30, 145.87, 146.14, 154.70 (C_o, C_p, C_{ipso} of Ar); 190.56 (*C*HO). – ES-MS (pos. mode); *m*/*z*: 615.4 [**9** + Na]$^+$. – $C_{38}H_{40}O_6 \cdot 0.1\ CH_2Cl_2$ (601.23): calcd. C 76.11, H 6.74, O 15.97;

found C 76.20, H 7.18, O 15.58. – **Compound 10:** m.p. > 350 °C. – UV/Vis (CH_2Cl_2): λ (ε) = 280.0 (13500). – IR: ν̃ = 1685 (C=O). – ^{1}H NMR ($CDCl_3$): δ = 1.27 (s, 18 H, *Me*$_3$C); 3.60, 4.29 (br. *AB*, 8 H, Ar–C*H*$_2$-Ar); 6.74 (t, *J* = 7.5 Hz, 1 H, Ar); 7.06 (d, *J* = 7.5 Hz, 2 H, Ar); 7.13 (s, 4 H, Ar); 7.64 (s, 2 H, of Ar); 9.77 (s, 1 H, ArC*H*O); 10.30 (br. s, 4 H, O*H*). – ^{13}C NMR ($CDCl_3$): δ = 31.47 (*Me*$_3$C), 32.06 (Ar–CH_2-Ar); 34.16 (Me$_3$*C*); 122.55, 125.93, 126.29, 129.00, 131.15 (CH of Ar), 125.81, 126.53, 127.82, 128.17, 129.35, 131.12, 145.21, 146.41, 148.53, 154.92 (C$_{o,}$ C$_{p,}$ C$_{ipso}$ of Ar); 190.67 (*C*=O). – ES-MS (pos. mode); *m*/*z*: 587.5 [**10** + Na]$^+$. – $C_{37}H_{40}O_5$·0.8 CH_2Cl_2 (632.67): calcd. C 71.76, H 6.63, O 12.64; found C 71.82, H 6.89, O 12.51.

Calix[4]arene-25,26,27,28-tetrol (3): The bipyridinephosphonium salt **5** (0.585 g, 0.5 10^{-3} mol) was dissolved in a solution of NaOMe in MeOH [10 ml; from 0.097 g of Na (4.05 10^{-3} mol)]. To the resulting yellow solution was added 0.3 g of **9** (0.5 10^{-3} mol). The solution was stirred at room temp. for 6 h and then evaporated to dryness. The raw material was dissolved in CH_2Cl_2 and then washed with 1 M HCl and H_2O. Evaporation of CH_2Cl_2 afforded a glassy material which was dissolved in 10 mL of EtOH and 10 mL of CH_2Cl_2. 30 mg of 5% Pd/C was added and the solution was stirred under a blanket of H_2 overnight. Solid material was filtered over Celite and rinsed with CH_2Cl_2 followed by acetone. The filtrate was evaporated to dryness and the residue was dissolved in 1 mL of CH_2Cl_2. Addition of 10 mL of MeOH resulted in the formation of a white precipitate which was recovered and purified by chromatography (Al_2O_3, CH_2Cl_2/MeOH 97/3) to give 0.105 g of **3** (22%); m.p: 274 °C. – UV/Vis (CH_2Cl_2): λ (ε) = 289.5 (43200). – ^{1}H NMR ($CDCl_3$): δ = 1.21 (s, 18 H, *Me*$_3$C); 2.62 (s, 6 H, *Me*-bpy); 3.06, 2.90 (*ABm*, 8 H, C*H*$_2$C*H*$_2$); 4.24, 3.46 ("q", *AB*, J_{AB} = 13.0 Hz, 8 H, Ar–C*H*$_2$-Ar); 6.91 (s, 4 H, Ar); 7.04 (s, 4 H, Ar); 7.05 (d, *J* = 7.0 Hz, 2 H, bpy); 7.13 (d, *J* = 7.4 Hz, 2 H, bpy); 7.65 (t, *J* = 7.0 Hz, 4 H, bpy); 8.19 (t, *J* = 5.7 Hz, 4 H, bpy); 10.3 (br. s, 4 H, OH). – ^{13}C NMR ($CDCl_3$): δ = 24.68 (*Me*–bpy); 31.47 (*Me*$_3$C); 32.26 (Ar–CH_2–Ar); 34.04 (Me$_3$*C*); 34.95, 40.07 (*C*H$_2$*C*H$_2$); 125.83, 128.98 (CH of Ar); 118.18, 118.49, 122.67, 123.06, 136.98 (CH of bpy); 127.56 128.24, 135.43, 144.48, 146.76 (C$_{o,}$ C$_{p,}$ C$_{ipso}$ of Ar); 155.90, 155.99, 157.80, 160.74 (C(2), C(2'), C(6), C(6') of bpy). – ES-MS (pos. mode); *m*/*z*: 929.5 [**3** + H]$^+$. – $C_{62}H_{64}N_4O_4$·0.1 CH_2Cl_2 (937.72): calcd. C 79.54, H 6.90, N 5.97, O 6.82; found C 79.27, H 6.92, N 5.99, O 6.60.

Calix[4]arene-25,26,27,28-tetrol Cobalt(II) (13): A solution of anhydrous $CoCl_2$ (0.0145 g, 0.111 × 10^{-3} mol) in 3 mL of MeOH was added to a solution of **2** (0.09 g, 0.111 × 10^{-3} mol) in 15 mL of CH_2Cl_2. The resulting blue solution was stirred at room temp. for 3 h and then evaporated to dryness. The blue residue was dissolved in 3 mL of CH_2Cl_2 and purified by chromatography over Sephadex LH20 (CH_2Cl_2). The middle fractions were collected and concentrated; precipitation by hexane gave 0.096 g of **13** (92%), light-blue solid. – UV/Vis (CH_2Cl_2): λ (ε) = 254.5 (12300), 280.0 (16500), 287.5 (14960), 308.0 (10420), 317.0 (11440), 341.0 (6208), 570.5 (284), 655.5 (530). – ^{1}H NMR (500 MHz, $CDCl_3$): δ = –35.24 (br. s, Δν$_{1/2}$ = 300 Hz, 2 H, CH_2–C*H*$_2$-bpy); –20.85 (br. s, Δν$_{1/2}$ = 169 Hz, 3 H, *Me*-bpy); –16.39 (br. s, Δν$_{1/2}$ = 92 Hz, 2 H, C*H*$_2$–CH_2-bpy); –14.30 [s, Δν$_{1/2}$ = 30.50 Hz, 1 H, H(4) or H(4') of bpy]; –13.53 [s, Δν$_{1/2}$ = 30.12 Hz, 1 H, H(4) or H(4') of bpy]; –2.08 [br. s, Δν$_{1/2}$ = 48 Hz, 2 H, Ar(**A**)]; 1.27 (s, Δν$_{1/2}$ = 21.14 Hz, 9 H, *Me*$_3$C); 2.10 (s, Δν$_{1/2}$ = 21.93 Hz, 18 H, *Me*$_3$C); 2.54 (br. s, Δν$_{1/2}$ = 109 Hz, 2 H, Ar–C*H*$_2$–Ar); 3.03 (br. s, Δν$_{1/2}$ = 104.50 Hz, 2H, Ar–C*H*$_2$-Ar); 3.34 (br. s, Δν$_{1/2}$ = 98.70 Hz, 2 H, Ar–C*H*$_2$–Ar); 3.95 (br. s, Δν$_{1/2}$ = 85.25 Hz, 2 H, Ar–C*H*$_2$-Ar); 6.94 [s, Δν$_{1/2}$ = 22.00 Hz, 2 H, Ar(**C**)]; 7.07 [s, Δν$_{1/2}$ = 22.86 Hz, 2 H, H(3) or H(5) of Ar(**B**) and Ar(**D**)]; 7.75 [s, Δν$_{1/2}$ = 26.24 Hz, 2 H, H(5) or H(3) of Ar(**B**) and Ar(**D**)]; 9.33 (s, Δν$_{1/2}$ = 39.60 Hz, 4H, O*H*); 43.87 [s, Δν$_{1/2}$ = 36.50 Hz, 1 H, H(5 or 5') or H(3 or 3') of bpy]; 46.17 [s, Δν$_{1/2}$ = 35.20 Hz, 1 H, H(5' or 5) or H(3' or 3) of bpy]; 65.35 [s, Δν$_{1/2}$ = 36.80 Hz, 1 H, H(3 or 3') or H(5 or 5') of bpy]; 66.06 [s, Δν$_{1/2}$ = 38.62 Hz, 1 H, H(3' or 3) or H(5' or 5) of bpy]. – ES-MS, for $C_{53}H_{60}CoCl_2N_2O_4$ (918.91; 918): *CH_2Cl_2 + amylene, positive mode:* 882.6, 883.6, 884.6, 885.6 [**2** + $CoCl_2$ – Cl$^-$]$^+$; 846.6, 847.7 [**2** + $CoCl_2$ – 2 Cl$^-$ – H$^+$]$^+$; 789.7, 790.7, 791.8 [**2** + H$^+$]$^+$. *CH_2Cl_2 + amylene + MeOH as ionising agent, positive mode*: 906.6, 907.7, 908.8, 909.9 [**2**·(OCH$_3$)$_2$ + $CoCl_2$ – 2 Cl$^-$ + CH_3O^-]$^+$; 892.6, 893.6, 894.6, 895.5 [**2**·(OCH$_3$) + $CoCl_2$ – 2 Cl$^-$ + CH_3O^-]$^+$; 846.5, 847.6, 848.6 [**2** + $CoCl_2$ – 2 Cl$^-$ – H$^+$]$^+$; 811.6, 812.6, 813.6 [**2** + Na$^+$]$^+$; 789.7, 790.7, 791.7 [**2** + H$^+$]$^+$; *negative mode*: major peaks 787.6, 788.6, 789.7 [**2** – H$^+$]$^-$; minor peaks 950.6, 951.6, 952.6 [**2**·(OCH$_3$)$_3$ + $CoCl_2$ – 2 Cl$^-$ + 2 (CH_3O^-) – H$^+$]$^-$; 940.6, 941.6, 942.6 [**2**·(OCH$_3$)$_2$ + $CoCl_2$ – Cl$^-$ + CH_3O^- – H$^+$]$^-$; 926.6, 927.6, 928.6, 929.5 [**2**(OCH$_3$) + $CoCl_2$ – Cl$^-$ + CH_3O^- – H$^+$]$^-$; 916.6, 917.6, 918.6, 919.6 [**2** + $CoCl_2$ – H$^+$]$^-$; 880.5, 881.6, 882.6 [**2** + $CoCl_2$ – Cl$^-$ – 2 H$^+$]$^-$; 844.5, 845.5, 846.6 [**2** + $CoCl_2$ – 2 Cl$^-$ – 3 H$^+$]$^-$. – $C_{53}H_{60}CoCl_2N_2O_4$·0.2 CH_2Cl_2 (935.90): calcd. X-ray Crystallographic Study of Complex 13: $C_{53}H_{60}Cl_2Co_1N_2O_4$, CH_2Cl_2, $C_4H_{10}O$, crystal system monoclinic, space group *P*2(1)/*c* with *a* = 24.747(5) Å, *b* = 9.1648(18) Å, *c* = 24.231(5) Å, β = 93.12(3)°, *V* = 5487.5(19) Å^3, $D_{calcd.}$ = 1.305 g/cm^3 and *Z* = 4. The data were collected at 173 K by X-ray diffraction on an Enraf–Nonius Kappa-CCD diffractometer. Full sphere of data was collected by axis rotation with 1°.0 increments over 180°, with 30 s exposures per frame. The crystal to detector distance was 30 mm. Data were analyzed using Kappa-CCD Software.[13] Cell dimensions were refined with HKL Scalepack.[14] The structure was solved with direct methods using the SHELXS programme.[15] Refinement by SHELXL [16] leads to an *R* factor of 0.077 for 3345 F_o > 4 (F_o) and a goodness of fit of 0.947. All nonhydrogen atoms were given anisotropic displacement parameters. All hydrogen atoms were located at their theoretical position and refined as a riding model. EXYZ and EADP instructions were used for the study of the CH_2Cl_2 disorder. The final electron density difference map showed a maximum of 1.23 e.Å^{-3} and a minimum of –0.51 eÅ^{-3}. Molecular graphics were drawn with ORTEP.[17]

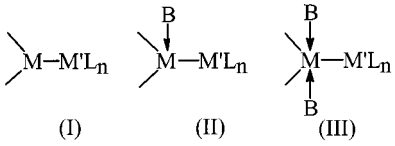
Transition Metal Complexes of (Schiff Base)Divalent Group 14 Element Species $[(salen)M]_n{=}M'(CO)_{6-n}$ (n = 1, 2; M = Ge, Sn, Pb; M′ = Cr, W)

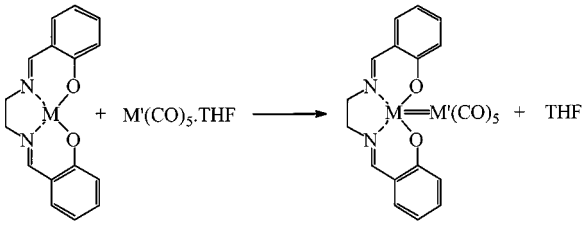


Dominique Agustin,[a] Ghassoub Rima,[a] Heinz Gornitzka,[a] and Jacques Barrau*[a]

Keywords: Germylene / Stannylene / Plumbylene / Schiff base / Transition metal complexes of M_{14} divalent species

The syntheses, characterization, and reactivities of the new stable mono- and *cis*-disubstituted Group 14 metal(II) chromium and tungsten carbonyl complexes (salen)M=M′$(CO)_5$ [salen = 2,2′-*N,N′*-bis(salicylidene)ethylenediamine; M′ = Cr, M = Ge (**4**), Sn (**5**), Pb (**6**); M′ = W, M = Ge (**7**), Sn (**8**), Pb (**9**)] and $[(salen)M]_2$=M′$(CO)_4$ [M′ = W, M = Ge (**10**), Sn (**11**), Pb (**12**); M′ = Cr, M = Sn (**14**), Ge (**15**)] are described. Complexes **4–9** were obtained in high yields by treatment of the M′$(CO)_5 \cdot$ THF intermediates with the stable divalent species (salen)M^{II} [M = Ge (**1**), Sn (**2**), Pb (**3**)]. Direct irradiation of mixtures of (salen)M^{II} and M′$(CO)_6$ resulted in formation of the monosubstituted compounds **4–9** together with the disubstituted species **10–12**, **14**, and **15** in ratios depending on the nature of both M and M′. Pure complexes **10–12** were obtained by two different synthetic approaches starting from the (salen)M^{II} species or the (salen)M=M′$(CO)_5$ complexes. Each of the new complexes has been characterized by ^{1}H- and ^{13}C-NMR, and by ^{119}Sn-NMR in the case of **5**, **8**, **11**, and **14**, as well as by IR spectroscopy in all cases. The molecular structures of **5**, **8**, **11**, and **14**, determined by X-ray structure analyses, reveal a pentacoordinated tin atom. The tin–chromium distances are among the shortest (in particular that in **5**, 2.557 Å) observed for transition metal divalent tin complexes and the tin lies about 0.99 Å above the plane defined by the O_2N_2 atoms of the salen ligand. All these complexes have been found to be unreactive towards water and organic acids. Simple phosphane monosubstitution of carbonyl in **8** using Ph_3P led to the new complex **13**. Reactions with 1,2-bis(diphenylphosphanyl)ethane and 3,5-di-*tert*-butyl-1,2-benzoquinone resulted in displacement of the divalent species from the carbonyl complexes **5** and **8**.

Introduction



Heavier analogs of carbenes can be used as ligands in transition metal chemistry. They can play an important role in the synthesis of precursors of new materials, and various metallic analogs of carbenic complexes of transition metals have been used or postulated as catalysts in reactions involving the formation or cleavage of M–M bonds. The majority of characterized complexes involve four-coordinate M atoms with type II structures; with bulky or donor substituents, a few structures with a three-coordinate M atom (structure I) have been isolated. Only a few examples of complexes with structures of type III having a five-coordinate M atom have been observed.

(I) (II) (III)

The earlier chemistry of these transition metal complexes with divalent species of Group 14 elements has been summarized in various review articles;[1–5] recent investigations concern mainly tin–Group 6 transition metal complexes.[6–14]

Recently, we reported the synthesis and characterization of new stable divalent germanium, tin, and lead homoleptic species L^2M [L^2 = 2,2′-*N,N′*-bis(salicylidene)ethylenediamine (salen), (*R,R*)-(–)-*N,N′*-bis(3,5-di-*tert*-butylsalicylidene)-1,2-cyclohexanediamine, and *N*-methyl-2,2′-iminobis(8-hydroxyquinoline); M = Ge, Sn, Pb].[15] These compounds are monomeric and feature twofold N···M intramolecular coordination, which lowers the Lewis acidity of the metal atom (characteristic of the free divalent species). Nevertheless, they are efficient σ donors and can be used as monodentate ligands in transition metal chemistry. In this work, we consider the salen compounds (salen)M (M = Ge, Sn, Pb) as precursors of new $L^2M{=}M'(CO)_5$ and $(L^2M)_2{=}M'(CO)_4$ complexes (M = Ge, Sn, Pb; M′ = Cr, W). The syntheses, crystal structures, and some chemical properties of these bimetallic compounds are presented herein.

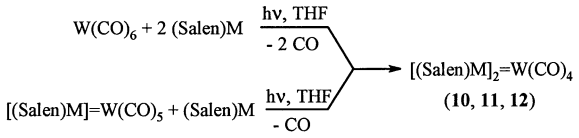
Results and Discussion

Synthesis of Complexes of Divalent Species (salen)M= M′(CO)$_5$ and [(salen)M]$_2$=M′(CO)$_4$ (M = Ge, Sn, Pb; M′ = Cr, W)



Treatment of the photochemically produced M′(CO)$_5$ · THF intermediates with the (salen)M compounds in THF led to the expected monosubstituted complexes **4–9** in high yields (Scheme 1).

These complexes were obtained as yellow-orange crystalline solids in yields in excess of 80% by recrystallization from $CHCl_3$. They were found to be soluble only in polar and protic solvents (THF, $CHCl_3$, CH_2Cl_2, DMSO, DMF, MeOH). Direct irradiation at room temperature of mixtures of the divalent compounds (salen)M and the hexacarbonyl complexes M′(CO)$_6$ (M′ = Cr, W) also resulted in the formation of the expected monometal(II) complexes in yields depending on the nature of both the Group 14 atom M and the transition metal M′ (Scheme 2). With (salen)germylene and -stannylene, the mono compounds **4** and **5** were produced in high yields when the reactions were carried out using Cr(CO)$_6$. Using W(CO)$_6$ under similar reaction conditions, substitution of more than one carbonyl was observed and the disubstituted compounds **10–12** with the ligands in a *cis* arrangement were formed alongside the monosubstituted species **7–9** (Scheme 2). Extension of this procedure to the reactions of (salen)plumbylene with Cr(CO)$_6$ and W(CO)$_6$ led to complexes **6** in 70% yield and to a mixture of **9** and **12** (30:70, as determined by ^{1}H-NMR), respectively. In contrast, attempts to prepare the (salen)M=M′(CO)$_5$ (M′ = Cr, W) complexes simply by heating mixtures of the starting materials at 80 °C for 24 h proved unsuccessful.

Scheme 2

In view of the particular sensitivity of the tungsten system and the difficulties encountered in separating the mono- and disubstituted tungsten products, we investigated alternative synthetic methods to confirm the structures of **10–12**. Thus, syntheses of pure **10** and **11** were achieved in up to 70% yield by irradiation of a mixture of (salen)M and (salen)M=W(CO)$_5$ or by irradiation of a mixture of two equivalents of (salen)M and one of W(CO)$_6$ (Scheme 3).

Scheme 3

It is interesting to note that under UV irradiation, the *cis*-[(salen)M]$_2$=M′(CO)$_4$ complexes were converted into the *trans* isomers. Such conversions have been particularly well-studied in the case of **11**; irradiation of a solution of *cis*-[(salen)Sn]$_2$=W(CO)$_4$ (**11**) for 6 h resulted in 50% conversion to *trans*-[(salen)Sn]$_2$=W(CO)$_4$ (**11′**). Crystals of **11′** suitable for X-ray structural analysis could not be obtained but its ^{1}H- and ^{13}C-NMR data, a ^{119}Sn-NMR resonance at δ = –374, an IR band at ν_{CO} = 1999 cm^{-1}, and mass spectroscopic data were consistent with the *trans* structure.

Such *cis*/*trans* photochemical isomerizations, as well as thermal reverse conversions, have previously been reported in the case of (carbene)$_2$=W(CO)$_4$.[16] In our case, it has not been possible to unambiguously observe reversion to the thermodynamically favoured *cis* isomer by heating a mixture of **11** and **11′** in the solid state or in solution. When a solid-state 50:50 *cis*/*trans* mixture was maintained at 180 °C for 12 h, the subsequently recorded ^{119}Sn-NMR spectrum featured only resonances due to the *cis* isomer (δ = –348) and due to an unidentified product (δ = –410).

Compounds **4–12** were found to be soluble in polar and protic solvents and insoluble in pentane. All these compounds proved to be stable to moisture.

Physicochemical and Structural Studies of the (salen)M= M′(CO)$_5$ and [(salen)M]$_2$=M′(CO)$_4$ Complexes (M = Ge, Sn, Pb; M′ = Cr, W)

Molecular weight determinations (cryoscopy in benzene) showed **4**, **5**, **7**, and **8** to be monomeric in solution. Compounds **4–12** have been characterized by ^{1}H-, ^{13}C-, and ^{119}Sn-NMR (for the complexes **5**, **8**, and **11**), as well as by IR spectroscopy. ^{1}H- and ^{119}Sn-NMR and IR spectroscopic data are collected in Table 1. The thermal stabilities of these complexes were found to be high; they decompose only on melting, but the germanium and tin complexes proved sufficiently volatile to allow recording of their mass spectra.

The ^{1}H-NMR spectra of complexes **4–12** show different shifts for the signals of the salen ligand relative to those seen for the divalent compounds **1–3**. The most noticeable shifts are seen in the methine proton resonances, which appear at lower field strengths as compared to those of the parent divalent species. For compounds **10–12**, NMR cannot distinguish between the two tin species complexed on the tungsten since the NMR signals of the various protons are similar and therefore non-resolvable. In all cases, as in **1–3**, the chemical shifts and splitting patterns of the CH_2N protons are consistent with the presence of N→M intramolecular coordination in these molecules.

		2047	2047	2048	2067	2063	2060	2009	1954	2015
								2060	2062	2060

The ^{13}C-NMR spectra of **4–12** feature signals with the characteristic chemical shifts of the carbon atoms of the salen ligand, shifted slightly downfield from those in the (salen)M compounds,[15] along with two carbonyl resonances for the monosubstituted complexes **4–9** (relative intensity 1:4) and for the disubstituted complexes **10–12** (relative intensity 1:1).

The ^{119}Sn-NMR spectra of **5**, **8**, and **11** feature singlets at δ = –137, –328, and –348, respectively, which fall within the range of shift values appropriate for pentacoordinate tin compounds; the shift variations between the signal of (salen)Sn and those of the corresponding (salen)Sn=M′(CO)$_5$ complexes reflect the electron-withdrawing effect of the M′(CO)$_5$ groups. The ^1J(^{119}Sn-^{183}W) coupling constants are very similar to those observed in four-coordinate tin(II)–tungsten compounds.[16]

The IR spectra of compounds **4–9** show strong absorptions in the range 1620–1640 cm^{-1} attributable to the $\nu_{C=N}$ stretching frequency under the influence of the N→M intramolecular coordination; these bands are shifted toward higher frequencies by 5–20 cm^{-1} in comparison with the spectra of the free ligands but are not affected to any appreciable extent compared to those observed for the (salen)M compounds. In the metal carbonyl region, three carbonyl bands (A′′$_1$ + A′$_1$ + E) are seen, with an intensity pattern characteristic of C_{4v} local symmetry at chromium or tungsten. Since the unique CO *trans* to the metal M is involved in the A′$_1$ mode, the position of this band [1970 (**4**), 1978 (**5**), 1976 cm^{-1} (**6**)] is indicative[18] of the π-acceptor ability of the (salen)M groups *trans* to the axial carbonyl. IR and ^{13}C-NMR data show that the (salen)M ligands are stronger donors of electron density, but are also π-acceptors. For complexes **10–12**, the appearance of four bands due to the CO groups is compatible with C_{2v} symmetry (*cis* geometry).

The five-coordinate environment about the M atom was confirmed structurally for **5**, **8**, and **11**. Compound **11** represents the first distannylene–tungsten complex [L^{2}Sn]$_2$=W(CO)$_4$ to be structurally characterized. Figure 1, Figure 2, and Figure 3 show solid-state structures of **5**, **8**, and **11**, respectively, together with the numbering scheme adopted. In the case of **11**, the three $CHCl_3$ solvating molecules are omitted for the sake of clarity. Crystal data of **5**, **8**, and **11** are presented in Table 6. Relevant bond lengths and angles in **5**, **8**, and **11** are given in Table 2, Table 3, and Table 4, respectively. In all three compounds, the tin resides in a distorted square-pyramidal geometry with the salen ligand occupying the base plane at Sn–N_2O_2 plane distances of 0.948 Å in **5**, 0.996 Å in **8**, and 1.005 Å and 1.024 Å in **11**. The observed σ Sn–O distances [2.039(3)–2.074(3) Å] are a little longer than classical σ Sn–O bonds (1.94–2.03 Å).[19] The lengths of the Sn←N bonds [2.230(5)–2.288(4) Å] appear to be normal. On going from **5** to **8** and **11**, these Sn–N and Sn–O distances increase as a result of the decreased inductive effect of the transition metal fragment. The tin–chromium or tin–tungsten bonds, which are shorter than typical Sn–M′ (M′ = Cr, W) single bonds,[20] are among the shortest ever observed in transition metal–divalent tin

complexes, the Sn–Cr distance [2.558(1) Å] in complex **5** being particularly short. These distances reflect a lower electron density at the tin atom in these complexes and may be indicative of double-bond character in the Sn–M′ unit (typical Sn=Cr: 2.60 Å,[7,21,22] Sn=W: 2.74 Å[10,17,23,24]). Thus, it seems that despite its tetradentate capacity the salen ligand does not cancel out the electronic deficiency at the tin atom through N···Sn intramolecular coordination thereby reducing the back-donation by the transition metal. Conversely the solid-state structures suggest that the peculiar arrangement resulting from the structure of the salen ligand maximizes the possibility of [d(M′)-d(p)(Sn)] π overlap.

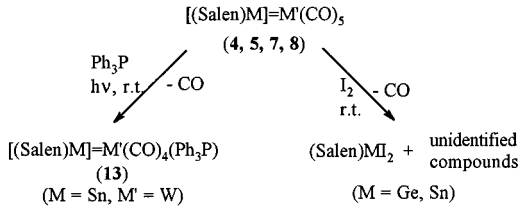
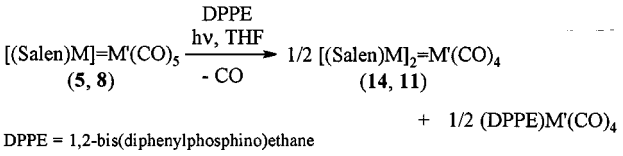
The Sn–W distances in **8** [2.712(1) Å] and **11** [2.711(1) Å and 2.703(1) Å] are very similar, which shows that the strength of the π interaction between the transition metal and the tin atom is not influenced by the number of divalent species on the transition metal. In **5**, **8**, and **11**, the coordination about the Cr or W atom is almost perfectly octahedral. In each compound, the M′–C distances are very similar; the M′–C bonds *trans* to Sn are the shortest, but do not differ significantly from the M′–C equatorial bonds. This suggests that the (salen)Sn ligand is comparable to or slightly poorer than CO as a π acceptor.



The mass spectra of complexes **4**, **5**, **7**, and **8** exhibit peaks corresponding to molecular ions M^+ [weak (**4** and **7**) or very weak (**5** and **8**) intensity] and to the characteristic fragmentations of such structures (particularly loss of carbonyl groups and of substituents on the Ge and Sn atoms).

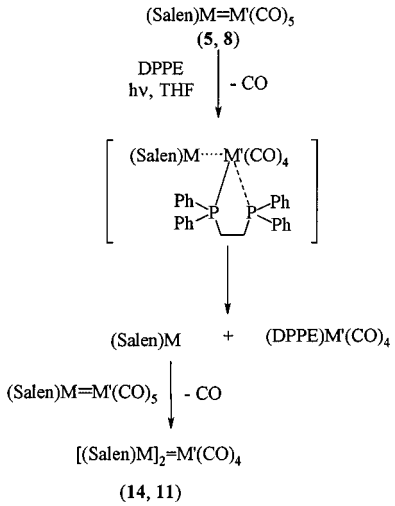
Chemical Reactivity of the (salen)M=M′(CO)$_5$ Complexes

Due to their "transition metal–carbene-like" character, the (salen)M=M′(CO)$_5$ complexes would appear to have interesting potential in organometallic chemistry. However, as observed previously, the chemistry of the complexes $L^2M{=}M'(CO)_5$ differs markedly from that of their carbene counterparts despite the many structural similarities.



In contrast to their parent compounds (**1–3**) and various $L^2M{=}M'(CO)_5$ complexes, the (salen)M=M′(CO)$_5$ and $[(salen)M]_2{=}M'(CO)_4$ complexes **4–12** were found to be totally unreactive towards water and organic acids (Scheme 3). This lack of reactivity may be attributed to electronic and particularly steric factors, most notably about the tin atom.

With iodine, we observed the expected reactions for compounds with Group 14 metal–transition metal bonds (Scheme 4).



Scheme 4

Since ligands having a lone pair, such as Ph_3P, are able to substitute one or more of the CO groups of metal carbonyls, the monotriphenylphosphane complex of **8** (or **13**, respectively) could easily be prepared by UV irradiation (λ = 254 nm) or by heating (Scheme 4). In contrast, attempted substitution of two CO groups by the chelating ligand 1,2-bis(diphenylphosphanyl)ethane (diphos) were unsuccessful; reactions of this doubly chelating phosphane with **5** and **8** surprisingly led to the distannylene–metal carbonyl complexes **14** and **11**, respectively (Scheme 5).

Scheme 5

Since compounds **5** and **8** are stable towards UV irradiation, it seems that in these cases entry of a second phosphane group into the coordination sphere about M′ causes displacement of the (salen)Sn ligand, which reacts in situ with remaining **5** or **8** to give **14** or **11**, respectively (Scheme 6).

Scheme 6

Complex **14** could be separated from the reaction mixture in the form of orange crystals, by virtue of its low solubility in pentane. The ^{13}C-NMR spectrum and IR data relating to the ν_{CO} region were in agreement with an octahedral coordination sphere about the chromium center and a *cis* geometry. This conclusion was confirmed by an X-ray crystal structure determination (Figure 4, Table 5). The struc-

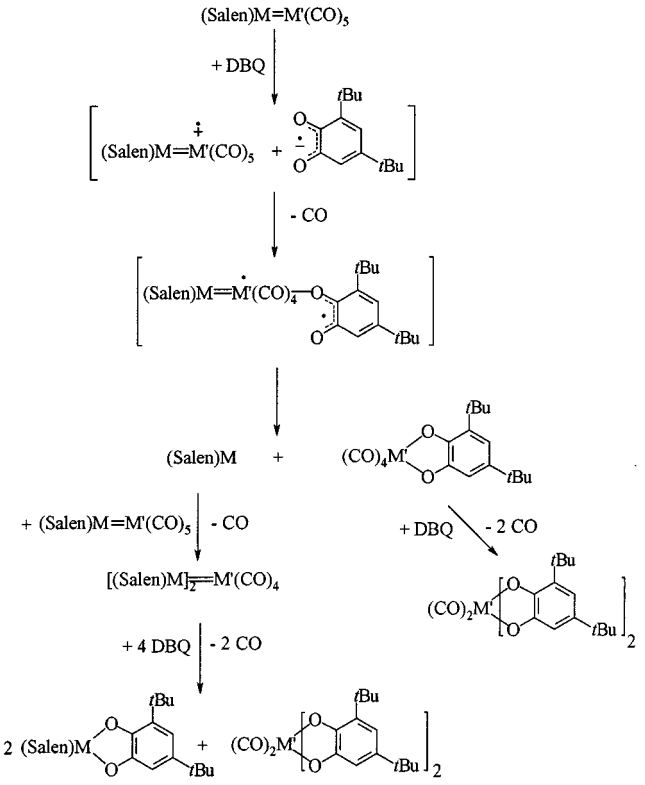

Scheme 7

ture shows similarities to that of **11**; the two *cis*-stannanediyl fragments (salen)Sn, in which the tin atoms show distorted square-pyramidal geometries, are bonded to a $Cr(CO)_4$ fragment with an octahedral environment about the chromium atom. The Cr–Sn distances [2.555(1) and 2.568(1) Å] are indicative of double-bond character in the Cr–Sn unit.

Complexes **4**, **5**, **7**, and **8** were found to react similarly with equimolar amounts of 3,5-di-*tert*-butyl-1,2-benzoquinone (DBQ), leading to **15**, **14**, **10**, and **11**, respectively, along with the $M'(CO)_2(DBCat)_2$ complexes (Scheme 7).

This reaction is consistent with a mechanism involving initial interaction of the quinone with the transition metal atom causing labilization of the M–M′ bond as a result of decreased π-back-bonding (this effect is amplified by chelate ring formation as in the case of the reaction of diphos). The resulting (salen)M ligand then primarily reacts with $(salen)M{=}M'(CO)_5$, leading to the bis-(divalent species)–transition metal complexes $[(salen)M]_2{=}M'(CO)_4$ rather than with the quinone to give the corresponding catecholate **16** (Scheme 8). Supporting evidence for this explanation was obtained by studying the relative reactivities of (salen)Sn towards coordination to the transition metal in $(salen)Sn{=}Cr(CO)_5$ and towards addition to the quinone. Starting with a 1:1:1 mixture of (salen)Sn/DBQ/$(salen)Sn{=}Cr(CO)_5$, the distannylene–chromium complex $[(salen)Sn]_2{=}Cr(CO)_4$ was by far the favored product (ratio 97:3). No evidence of a stable semiquinone intermediate was observed in this reaction. Using two equivalents of 3,5-di-*tert*-butyl-1,2-benzoquinone in addition to the disubstituted complexes, we observed substantial formation of the previously characterized (salen)Sn^{II}-3,5-di-*tert*-butyl-1,2-benzoquinone adduct **16**.[15]

Scheme 8

Conclusion

Several new stable mono- and *cis*-disubstituted Group 14 metal(II)–chromium and tungsten carbonyl complexes have been prepared and their reactivities towards phosphane and 3,5-di-*tert*-butyl-1,2-benzoquinone have been studied. Physicochemical and structural studies have shown that the Group 14 metal resides in a five-coordinate environment.

The Sn–M′ bond lengths observed in the tin complexes are shorter than the typical single-bond lengths and are among the shortest ever observed (in particular the Sn–Cr bond). This indicates that in these complexes, in spite of N→M intramolecular coordination, the divalent species (salen)M behave as σ-donors with π-acceptor properties. These results underline the influence of the stabilizing ligand (bound to the Group 14 element) on the magnitude of the M=M bonding interaction. In short, the (salen)Sn group, with its square-pyramidal geometry, seems to favor the π interaction between the Group 14 element and the chromium or tungsten atom.

Substitution of one CO group has been observed upon reaction with PPh_3. Interestingly, reactions with diphos and 3,5-di-*tert*-butyl-1,2-benzoquinone have been found to lead to the corresponding distannylene metal carbonyl complexes; displacement of the (salen)Sn ligand seems to be the key step in such reactions.

Experimental Section

General: All manipulations were performed under inert atmospheres of nitrogen or argon using standard Schlenk and high-vacuum-line techniques. Dry, oxygen-free solvents were employed throughout. All solvents were distilled from sodium benzophenone or P_2O_5 prior to use. ^{1}H-NMR spectra were recorded on a Bruker AC 80 spectrometer operating at 80 MHz (chemical shifts are reported in ppm relative to internal Me_4Si); ^{13}C-NMR spectra were recorded on an AC 200 spectrometer; the multiplicities of the ^{13}C-NMR signals were determined by the APT technique. ^{1}H-decoupled ^{119}Sn-NMR spectra were recorded on Bruker AC 200 or 400 instruments (chemical shifts are reported in ppm relative to external Me_4Sn). Mass spectra were obtained under electron impact (EI) or chemical ionization (CH_4) conditions at 70 eV and 30 eV, respectively using Hewlett Packard 5989 and Nermag R10-10H spectrometers. IR spectra were recorded on a Perkin–Elmer 1600 FT-IR spectrophotometer. Irradiations were carried out at room temperature using a low-pressure immersion lamp in a quartz glass immersion tube. Molecular weight determinations were carried out with a custom-built apparatus. Melting points (uncorrected) were obtained on a Leitz Biomed hot-plate microscope apparatus. Elemental analyses (C, H, N) were performed at the Microanalysis Laboratory of the Ecole Nationale Supérieure de Chimie de Toulouse.

X-ray Measurements of 5, 8, 11, and 14: Crystal data for all the structures are presented in Table 6. All data were collected at T = 173 K using an oil-coated shock-cooled crystal[25] in each case on

a Stoe-IPDS diffractometer employing Mo-K_α (λ = 0.71073 Å) radiation. The structures were solved by direct methods by means of SHELXS-97[26] and refined with all data on F^2 using SHELXL-97.[27] All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were placed in geometrically ideal positions and refined using a riding model. Selected bond lengths and angles in **5**, **8**, **11**, and **14** are presented in tables 2, 3, 4, and 5, respectively. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-136101 (**5**), 136102 (**8**), 136103 (**11**), and 136104 (**14**). Copies of the data can be obtained free of charge on application to the CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) +44 (0)1223/336033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis of (salen)Ge=Cr(CO)$_5$ (4). – Procedure 1: A mixture of (salen)Ge[15b] (0.51 g, 1.50 mmol) and Cr(CO)$_6$ (0.33 g, 1.50 mmol) in THF (50 mL) was irradiated for 2 h, during which a red color developed. The solvent was then removed under reduced pressure and the residual solid was treated with pentane. The resulting suspension was filtered and the collected solid was dried in vacuo to afford **4** (0.64 g, 80%) as an orange powder.

Procedure 2: A solution of Cr(CO)$_6$ (0.33 g, 1.50 mmol) in THF (30 mL) was irradiated for 1.5 h. The solution was then purged of CO by passing a stream of nitrogen through it for 15 min., and then a suspension of (salen)Ge (0.51 g, 1.50 mmol) in THF (20 mL) was added. Complex **4** (0.65 g, 83%) was obtained following the same work-up procedure as outlined above; m.p. 280–285 °C (dec.). – ^{1}H NMR (CDCl$_3$): δ = 3.90 (m, 4 H, CH$_2$), 6.50–7.80 (m, 8 H, Ar), 8.32 (s, 2 H, CH=N). – ^{13}C NMR (CDCl$_3$): δ = 59.83 (CH$_2$), 117.03 (CH$_{Ar}$), 118.60 (C$_q$), 118.78 (CH$_{Ar}$), 131.60 (CH$_{Ar}$), 132.49 (CH$_{Ar}$), 161.08 (C$_q$–O), 167.88 (CH=N), 217.08 (C=O *trans*), 218.41 (C=O), 222.47 (C=O), 224.62 (C=O). – IR (Nujol, KBr): $\nu_{C=N}$ 1630; ν_{CO} 1910, 1970, 2047 cm^{-1}. – MS (EI, 70 eV): *m*/*z* = 532 [M$^{+\cdot}$], 504 [M – CO]$^+$, 476 [M – 2 CO]$^+$, 448 [M – 3 CO]$^+$, 420 [M – 4 CO]$^+$, 392 [M – 5 CO]$^+$. – $C_{21}H_{14}CrGeN_2O_7$ (531.94): calcd. C 47.37, H 2.65, N 5.26; found C 47.58, H 2.70, N 5.10.

Synthesis of (salen)Sn=Cr(CO)$_5$ (5). – Procedure 1: A mixture of (salen)Sn[15b] (0.26 g, 0.67 mmol) and Cr(CO)$_6$ (0.15 g, 0.67 mmol) in THF (50 mL) was irradiated for 2 h, during which a red color developed. After removal of the solvent, the crude product was treated with pentane and the resulting suspension was filtered. Crystallization of the collected solid from chloroform afforded **5** (0.31 g, 80%) as red-orange crystals.

Procedure 2: Following a procedure similar to that described for **4**, compound **5** (0.30 g, 83%) was obtained from (salen)Sn (0.24 g, 0.62 mmol) and Cr(CO)$_5$THF (0.17 g, 0.62 mmol); m.p. 270–280 °C (dec.). – ^{1}H NMR ([D$_6$]DMSO): δ = 4.01 (m, 4 H, CH$_2$), 6.50–7.50 (m, 8 H, Ar), 8.42 (s, 2 H, CH=N). – ^{13}C NMR ([D$_6$]DMSO): δ = 52.86 (CH$_2$), 117.77 (CH$_{Ar}$), 118.97 (C$_q$), 122.32 (CH$_{Ar}$), 134.58 (CH$_{Ar}$), 135.90 (CH$_{Ar}$), 165.65 (C$_q$–O), 169.41 (CH=N), 218.54 (C=O), 230 (C=O). – ^{119}Sn{^{1}H} NMR ([D$_6$]DMSO): δ = –149.5. – IR (Nujol, KBr): $\nu_{C=N}$ 1638; ν_{CO} 1917, 1978, 2047 cm^{-1}. – MS (EI, 70 eV): *m*/*z* = 438 [M – 5 CO]$^+$. – $C_{21}H_{14}CrN_2O_7Sn$ (577.92): calcd. C 43.60, H 2.44, N 4.85; found C 43.71, H 2.50, N 4.90.

Synthesis of (salen)Pb=Cr(CO)$_5$ (6): To a suspension of (salen)Pb[15b] (0.15 g, 0.32 mmol) in THF (30 mL) a solution of Cr(CO)$_5$ · THF (0.09 g, 0.32 mmol) in THF (20 mL) was added dropwise. The reaction mixture was stirred at room temperature for 1 h and then the solvent was evaporated under reduced pressure. The residual maroon-orange solid was washed with pentane and dried to afford **6** (0.15 g, 70%); m.p. > 300 °C (dec.). – ^{1}H NMR

([D$_6$]DMSO): δ = 3.80 (m, 4 H, CH$_2$), 6.20–7.40 (m, 8 H, Ar), 8.24 (s, 2 H, CH=N). – IR (Nujol, KBr): $\nu_{C=N}$ 1620; ν_{CO} 1915, 1976, 2048 cm^{-1}. – $C_{21}H_{14}CrN_2O_7Pb$ (665.99): calcd. C 37.84, H 2.12, N 4.21; found C 38.01, H 2.20, N 4.03.

Synthesis of (salen)Ge=W(CO)$_5$ (7): A solution of W(CO)$_5$ · THF (0.15 g, 0.35 mmol) in THF (30 mL) was added dropwise to a suspension of (salen)Ge (0.12 g, 0.35 mmol) in THF (20 mL) and the resulting mixture was stirred at room temperature for 1 h. The solvent was then removed in vacuo and the residual orange solid was washed with pentane. Filtration of the washings and drying of the collected solid gave **7** (0.22 g, 92%) in the form of orange crystals; m.p. 260–270 °C (dec.). – ^{1}H NMR (CDCl$_3$): δ = 3.93 (m, 4 H, CH$_2$), 6.72–7.60 (m, 8 H, Ar), 8.25 (s, 2 H, CH=N). – ^{13}C NMR (CDCl$_3$): δ = 57.25 (CH$_2$), 57.40 (CH$_2$), 118.74 (CH$_{Ar}$), 121.00 (CH$_{Ar}$), 131.87 (CH$_{Ar}$), 133.11 (CH$_{Ar}$), 134.70 (CH$_{Ar}$), 135.22 (CH$_{Ar}$), 138.29 (CH$_{Ar}$), 139.85 (CH$_{Ar}$), 160.92 (C$_q$–O), 167.98 (CH=N), 168.78 (CH=N), 196.37 (C=O), 198.92 (C=O). – IR (Nujol, KBr): $\nu_{C=N}$ 1620; ν_{CO} 1916, 1972, 2067 cm^{-1}. – MS (EI, 70 eV): *m/z* = 662 [M$^{+\cdot}$], 634 [M – CO]$^+$, 608 [M – 2 CO]$^+$, 580 [M – 3 CO]$^+$, 522 [M – 5 CO]$^+$. – $C_{21}H_{14}GeN_2O_7W$ (663.95): calcd. C 37.95, H 2.13, N 4.22; found C 38.20, H 2.29, N 4.10.

Synthesis of (salen)Sn=W(CO)$_5$ (8): A suspension of (salen)Sn (0.11 g, 0.28 mmol) in THF (20 mL) was added dropwise to a solution of W(CO)$_5$ · THF (0.12 g, 0.28 mmol) in the same solvent. The reaction mixture was stirred for a further 30 min, during which an orange color developed. The volatiles were then removed in vacuo and the residual solid product was washed with pentane and purified by crystallization from chloroform to give **8** (0.18 g, 92%) in the form of yellow crystals; m.p. 280–285 °C (dec.). – ^{1}H NMR ([D$_6$]DMSO): δ = 3.99 (m, 4 H, CH$_2$), 6.70–7.00 (m, 8 H, Ar), 8.73 (s, 2 H, CH=N). – ^{13}C NMR ([D$_6$]DMSO): δ = 52.71 (CH$_2$), 117.75 (CH$_{Ar}$), 118.87 (C$_q$), 122.32 (CH$_{Ar}$), 134.55 (CH$_{Ar}$), 135.83 (CH$_{Ar}$), 165.50 (C$_q$–O), 166.99 (CH=N), 197.06 (C=O), 201.16 (C=O). – ^{119}Sn{^{1}H} NMR ([D$_6$]DMSO): δ = –328 ($^2J_{Sn-W}$ = 1458 Hz). – IR (Nujol, KBr): $\nu_{C=N}$ 1641; ν_{CO} 1913, 1977, 2063 cm^{-1}. – MS (EI, 70 eV): *m/z* = 568 [M – 5 CO]$^+$. – $C_{21}H_{14}N_2O_7SnW$ (709.93): calcd. C 35.50, H 1.99, N 3.94; found C 35.70, H 2.12, N 4.00.

Synthesis of (salen)Pb=W(CO)$_5$ (9): In a similar manner, reaction of (salen)Pb (0.15 g, 0.32 mmol) with W(CO)$_5$ · THF (0.13 g, 0.32 mmol) afforded **9** (0.20 g, 79%); m.p. > 300 °C (dec.). – ^{1}H NMR ([D$_6$]DMSO): δ = 3.87 (s, 4 H, CH$_2$), 6.30–7.30 (m, 8 H, Ar), 8.27 (s, 2 H, CH=N). – IR (Nujol, KBr): $\nu_{C=N}$ 1630; ν_{CO} 1914, 1970, 2060 cm^{-1}. – $C_{21}H_{14}N_2O_7PbW$ (798.00): calcd. C 31.58, H 1.77, N 3.51; found C 31.64, H 1.92, N 3.30.

Synthesis of *cis*-[(salen)Ge]$_2$=W(CO)$_4$ (10). – Procedure 1: A mixture of (salen)Ge (0.12 g, 0.36 mmol) and W(CO)$_6$ (0.13 g, 0.36 mmol) in THF (50 mL) was irradiated for 3 h, during which a red-orange color developed. After removal of the solvent, the crude product was washed with pentane and dried to afford a mixture of **10** (85%*) and **7** (15%*) as a red-maroon powder (* relative %).

Procedure 2: A mixture of (salen)Ge (0.25 g, 0.73 mmol) and W(CO)$_6$ (0.13 g, 0.36 mmol) in THF (50 mL) was irradiated for 2.5 h, during which the solution became orange. After removal of the solvent, the crude product was washed with pentane and dried to afford pure **10** (0.65 g, 92%) as an orange powder.

Procedure 3: A mixture of **7** (0.48 g, 0.73 mmol) and (salen)Ge (0.25 g, 0.73 mmol) in THF (50 mL) was irradiated for 4 h. After removal of the solvent, the residue was washed with pentane, the washings were filtered, and the collected solid was dried to give pure **10** (0.62 g, 87%) as orange powder; m.p. 230–240 °C (dec.). – ^{1}H NMR (CDCl$_3$): δ = 3.93 (m, 8 H, CH$_2$), 6.50–7.50 (m, 16 H, Ar), 8.17 (s, 2 H, CH=N). – ^{13}C NMR (CDCl$_3$): δ = 59.79 (CH$_2$), 117.00 (CH$_{Ar}$), 116.43 (C$_q$), 117.10 (CH$_{Ar}$), 131.55 (CH$_{Ar}$), 132.45 (CH$_{Ar}$), 160.91 (C$_q$–O), 166.56 (CH=N), 196.08 (C=O), 196.38 (C=O). – IR (Nujol, KBr): $\nu_{C=N}$ 1620; ν_{CO} 1892, 1980, 2009, 2060 cm^{-1}. – MS (EI, 70 eV): *m/z* = 608 [M – Ge(salen) – 2 CO]$^+$, 522 [M – Ge(salen) – 5 CO]$^+$. – $C_{36}H_{28}Ge_2N_4O_8W$ (975.98): calcd. C 44.26, H 2.89, N 5.74; found C 44.50, H 2.95, N 5.68.

Synthesis of [(salen)Sn]$_2$=W(CO)$_4$ (11). – Procedure 1: A mixture of (salen)Sn (0.27 g, 0.70 mmol) and W(CO)$_6$ (0.25 g, 0.70 mmol) in THF (50 mL) was irradiated for 3 h, during which a red-maroon color developed. The volatiles were then removed in vacuo and the crude product was washed with pentane and dried to afford a mixture of **11** (90%*) and **8** (10%*) as a yellow-orange powder (* relative % as determined by ^{1}H-NMR).

Procedure 2: A mixture of (salen)Sn (0.27 g, 0.70 mmol) and W(CO)$_6$ (0.13 g, 0.35 mmol) in THF (50 mL) was irradiated for 3 h, during which the solution turned pale-orange. After removal of the solvent, the crude product was washed with pentane and dried to afford pure **11** (0.69 g, 92%) as an orange powder.

Procedure 3: A mixture of (salen)Sn (0.55 g, 1.40 mmol) and W(CO)$_6$ (0.26 g, 0.70 mmol) in THF (50 mL) was irradiated for 4 h, during which the solution again turned pale-orange. After removal of the solvent, the crude product was washed with pentane and dried to afford an orange powder consisting of a 30:70 *cis*/*trans* (**11/11′**) mixture, which was characterized by ^{1}H-, ^{13}C-, and ^{119}Sn-NMR and IR spectroscopy.

Procedure 4: As Procedure 2, but after irradiation for 8 h, a 50:50 mixture of **11/11′** was obtained from (salen)Sn (0.55 g, 1.40 mmol) and W(CO)$_6$ (0.26 g, 0.70 mmol).

Procedure 5: According to the previous procedure, pure **11** was obtained from (salen)Sn (0.27 g, 0.70 mmol) and **8** (0.49 g, 0.70 mmol); yield: 0.67 g, 90%. Crystallization from CHCl$_3$ gave **11** · 3 (CHCl$_3$) as orange crystals.

11 (*cis*): m.p. 250–260 °C (dec.). – ^{1}H NMR ([D$_6$]DMSO): δ = 3.78 (s, 4 H, CH$_2$), 6.50–7.50 (m, 16 H, Ar), 8.43 (s, 2 H, CH=N). – ^{13}C NMR ([D$_6$]DMSO): δ = 52.50 (CH$_2$), 116.94 (CH$_{Ar}$), 118.96 (C$_q$), 122.17 (CH$_{Ar}$), 134.37 (CH$_{Ar}$), 135.37 (CH$_{Ar}$), 165.69 (C$_q$–O), 169.32 (CH=N), 202.19 (C=O), 207.30 (C=O). – ^{119}Sn{^{1}H} NMR ([D$_6$]DMSO): δ = –348 ($^2J_{Sn-W}$ = 1456 Hz). – IR (Nujol, KBr): $\nu_{C=N}$ 1638; ν_{CO} 1902, 1929, 1954, 2062 cm^{-1}. – MS (EI, 70 eV): *m/z* = 568 [(salen)SnW$^+$]. – $C_{36}H_{28}N_4O_8Sn_2W$ (1067.94): calcd. C 40.45, H 2.64, N 5.24; found C 40.61, H 2.72, N 5.14.

11′ (*trans*): ^{1}H NMR ([D$_6$]DMSO): δ = 3.82 (s, 4 H, CH$_2$), 6.30–7.50 (m, 16 H, Ar), 8.19 (s, 2 H, CH=N). – ^{13}C NMR ([D$_6$]DMSO): δ = 51.96 (CH$_2$), 115.97 (CH$_{Ar}$), 118.96 (C$_q$), 122.06 (CH$_{Ar}$), 131.56 (CH$_{Ar}$), 132.25 (CH$_{Ar}$), 134.17 (CH$_{Ar}$), 165.82 (C$_q$–O), 167.99 (CH=N), 211.23 (C=O). – ^{119}Sn{^{1}H} NMR ([D$_6$]DMSO): δ = –374. – IR (Nujol, KBr): $\nu_{C=N}$ 1640; ν_{CO} 1999 cm^{-1}.

Synthesis of *cis*-[(salen)Pb]$_2$=W(CO)$_4$ (12). – Procedure 1: A mixture of (salen)Pb (0.15 g, 0.32 mmol) and W(CO)$_6$ (0.11 g, 0.32 mmol) in THF (50 mL) was irradiated for 3 h, during which a maroon color developed. After filtration, the volatiles were removed under reduced pressure. The residue was washed with pentane and dried in vacuo to afford a mixture of **12** (70%*) and **9** (30%*) as a red-brown powder (* relative % as determined by ^{1}H-NMR).

Procedure 2: A mixture of (salen)Pb (0.54 g, 1.14 mmol) and W(CO)$_6$ (0.20 g, 0.57 mmol) in THF (50 mL) was irradiated for 2.5 h, during which the solution turned maroon. After work-up as described in the previous procedure, **12** (0.51 g, 72%) was obtained as an orange powder.

Procedure 3: According to the previous procedure, pure **12** (0.42 g, 60%) was obtained from (salen)Pb (0.27 g, 0.57 mmol) and **9** (0.45 g, 0.57 mmol); m.p. > 300 °C (dec.). – ^{1}H NMR ([D$_6$]DMSO): δ = 4.07 (s, 4 H, CH$_2$), 6.25–7.35 (m, 8 H, Ar), 8.03 (s, 2 H, CH=N). – IR (Nujol, KBr): $\nu_{C=N}$ 1625; ν_{CO} 1906, 1930, 2015, 2060 cm^{-1}. – $C_{36}H_{28}N_4O_8Pb_2W$ (1244.09): calcd. C 34.72, H 2.27, N 4.50; found C 34.90, H 2.40, N 4.32.

Reactions of 4 and 7 with Iodine: To a solution of **4** (0.05 g, 0.10 mmol) or **7** (0.06 g, 0.10 mmol) in DMSO (10 mL) was added iodine (0.03 g, 0.10 mmol). CO was immediately evolved and the solution turned orange. The mixture was stirred at room temperature for 3 h. Subsequent analysis by ^{1}H- and ^{13}C-NMR and by mass spectroscopy revealed that (salen)GeI$_2$ had been produced.[15b]

Reactions of 5 and 8 with Iodine: According to the same procedure as above, reactions of **5** (0.06 g, 0.10 mmol) and **8** (0.07 g, 0.10 mmol) with iodine (0.03 g, 0.10 mmol) afforded (salen)SnI$_2$.[15b]

Synthesis of *cis*-(salen)Sn=W(CO)$_4$(PPh$_3$) (13): A solution of **8** (0.22 g, 0.31 mmol) and triphenylphosphane (0.08 g, 0.31 mmol) in THF (30 mL) was irradiated for 1.5 h. The solvent was then removed in vacuo affording a maroon-orange powder, which was washed with pentane and dried under reduced pressure to give **13** (0.26 g, 90%); m.p. 250–260 °C (dec.). – ^{1}H NMR ([D$_6$]DMSO): δ = 3.77 (s, 4 H, CH$_2$), 6.72–7.60 (m, 23 H, Ar), 8.44 (s, 2 H, CH=N). – ^{13}C NMR ([D$_6$]DMSO): δ = 57.95 (CH$_2$), 122.37 (CH$_{Ar}$), 124.33 (C$_q$), 127.62 (CH$_{Ar}$), 134.18 (CH$_{Ar}$), 134.40 (CH$_{Ar}$), 134.48 (CH$_{Ar}$), 137.41 (CH$_{Ar}$), 137.91 (CH$_{Ar}$), 139.82 (CH$_{Ar}$), 140.80 (CH$_{Ar}$), 171.16 (C$_q$–O), 174.77 (CH=N), 202.34 (C=O), 202.53 (C=O), 207.64 (C=O), 212.74. – ^{119}Sn{^{1}H} NMR ([D$_6$]DMSO): δ = –347.5 (d, $^3J_{Sn-P}$ = 2088 Hz). – ^{31}P{^{1}H} NMR ([D$_6$]DMSO): δ = –16.2 ($^3J_{Sn-P}$= 2088 Hz). – IR (Nujol, KBr): $\nu_{C=N}$ 1639; ν_{CO} 1876, 1977, 2011, 2055 cm^{-1}. – MS (EI, 70 eV): *m*/*z* = 502 [Ph$_3$PW(CO)$_2$]$^+$, 446 [Ph$_3$PW]$^+$, 386 [(salen)Sn]$^{+\cdot}$. – $C_{38}H_{29}N_2O_6PSnW$ (944.03): calcd. C 48.30, H 3.10, N 2.97; found C 48.70, H 3.30, N 2.90.

Reaction of 5 with 1,2-Bis(diphenylphosphanyl)ethane: A solution of **5** (0.22 g, 0.38 mmol) in THF (30 mL) containing 1,2-bis(diphenylphosphanyl)ethane (0.15 g, 0.38 mmol) was irradiated for 2.5 h. The solvent was then removed in vacuo, affording a maroon-orange powder, which was washed with pentane and dried under reduced pressure to give a mixture of **14** and (DPPE)Cr(CO)$_4$. The product was characterized by ^{1}H-, ^{31}P-, and ^{119}Sn-NMR and by IR. Crystallization from CHCl$_3$ gave orange crystals of **14** · 3 (CHCl$_3$). – ^{1}H NMR (CDCl$_3$): δ = 3.99 (m, 4 H, CH$_2$), 6.60–7.50 (m, 10 H, Ar), 8.10 (s, 2 H, CH=N). – ^{13}C NMR (CDCl$_3$): δ = 48.70 (CH$_2$), 118.56 (CH$_{Ar}$), 119.22 (Cq$_{Ar}$), 123.98 (CH$_{Ar}$), 134.37 (CH$_{Ar}$), 136.64 (CH$_{Ar}$), 164.03 (C$_q$–O), 166.66 (C$_q$–O), 170.12 (CH=N), 211.68 (CO *cis*), 218.43 (CO *cis*), 224.99 (CO *trans*). – ^{119}Sn{^{1}H} NMR (CDCl$_3$): δ = –144. – IR (CDCl$_3$, KBr): $\nu_{C=N}$ 1621, ν_{CO} 1931, 1982, 2052 cm^{-1}. – $C_{36}H_{28}CrN_4O_8Sn_2$ (935.93): calcd. C 46.16, H 3.02, N 5.98; found C 46.40, H 3.15, N 5.54.

Reaction of 8 with 1,2-Bis(diphenylphosphanyl)ethane: A solution of **8** (0.22 g, 0.31 mmol) in THF (30 mL) containing 1,2-bis(diphenylphosphanyl)ethane (0.13 g, 0.31 mmol) was irradiated for 2.5 h. The solvent was then removed in vacuo, affording a maroon-orange powder, which was washed with pentane and dried under reduced pressure to give a mixture of **11** and (DPPE)W(CO)$_4$. The product was characterized by ^{1}H-, ^{31}P-, and ^{119}Sn-NMR and by IR.

Reaction of 5 with One Equivalent of DBQ: A mixture of **5** (0.03 g, 0.05 mmol) and DBQ (0.01 g, 0.05 mmol) was dissolved in CHCl$_3$ (5 mL). The color of the solution immediately darkened. The volatiles were subsequently removed under reduced pressure. The crude product was washed with pentane and dried in vacuo to afford **14** (0.02 g, 85%)

Reaction of 7 with One Equivalent of DBQ: A mixture of **7** (0.05 g, 0.10 mmol) and DBQ (0.02 g, 0.10 mmol) was dissolved in CHCl$_3$ (5 mL). The color of the solution immediately darkened and evolution of CO was observed. After stirring for 8 h, the volatiles were removed in vacuo. The crude product was washed with pentane and dried in vacuo to afford **10** (0.04 g, 82%).

Reaction of 8 with One Equivalent of DBQ: A mixture of **8** (0.09 g, 0.12 mmol) and DBQ (0.03 g, 0.12 mmol) was dissolved in CHCl$_3$ (5 mL). The solution immediately turned dark-red. The volatiles were subsequently removed under reduced pressure and the crude product was washed with pentane and dried in vacuo to afford **11** (0.05 g, 78%).

Reaction of 8 with Two Equivalents of DBQ: A mixture of **8** (0.09 g, 0.12 mmol) and DBQ (0.06 g, 0.24 mmol) was dissolved in CHCl$_3$ (5 mL). The solution immediately turned intensely red. The volatiles were subsequently removed under reduced pressure. The crude product was washed with pentane and dried in vacuo to afford a mixture of **11** and **16** (ratio 1:2, as determined by ^{1}H-NMR).

Reaction of 8 with Four Equivalents of DBQ: A mixture of **8** (0.09 g, 0.12 mmol) and DBQ (0.12 g, 0.48 mmol) was dissolved in CHCl$_3$ (10 mL). The solution immediately turned red. The volatiles were subsequently removed in vacuo. The crude product was washed with pentane and dried in vacuo to afford **16** (0.06 g, 83%)

Reaction of 4 with DBQ: A mixture of **4** (0.03 g, 0.05 mmol) and DBQ (0.01 g, 0.05 mmol) was dissolved in CHCl$_3$ (5 mL). The color of the solution immediately darkened and the volatiles were subsequently removed in vacuo. The crude product was washed with pentane and dried in vacuo to afford **15**. – ^{1}H NMR (CDCl$_3$): δ = 4.21 (m, 4 H, CH$_2$), 6.40–7.70 (m, 10 H, Ar), 8.40 (s, 2 H, CH=N). – ^{13}C NMR (CDCl$_3$): δ = 54.50 (CH$_2$), 119.09 (CH$_{Ar}$), 120.89 (Cq$_{Ar}$), 120.13 (CH$_{Ar}$), 134.03 (CH$_{Ar}$), 136.54 (CH$_{Ar}$), 164.20 (C$_q$–O), 161.81 (C$_q$–O), 172.2 (CH=N), 211.70 (CO cis), 217.23 (CO). – $C_{36}H_{28}N_4O_8Ge_2Cr$ (843.97): calcd. C 51.19, H 3.34, N 6.64; found C 51.40, H 3.51, N 6.23.

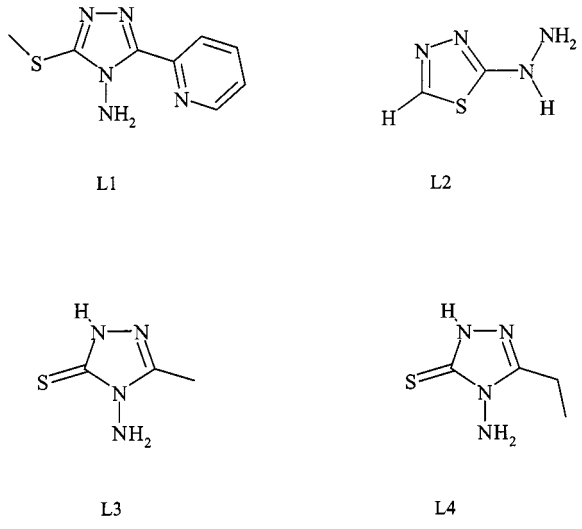
Synthesis, Spectroscopic and Structural Characterization of New Ru^{II} and Ru^{III} Complexes Containing Triazole- and Thiadiazole-Type Ligands

Marina Biagini Cingi,[a] Maurizio Lanfranchi,*[a] Maria Angela Pellinghelli,[a] and Matteo Tegoni[a]



Keywords: Ruthenium / *s*-Triazole / *s*-Triazoline / Oxidations / Crystal structure

The chemical behavior of triazole, thiadiazole, and triazoline derivatives of thiocarbonohydrazide towards *cis*-$[RuCl_2(DMSO)_4]$ (**2**) was studied. Reaction of 4-amino-5-methylthio-3-(2-pyridyl)-1,2,4-triazole (L1) with **2** gave two diastereomeric complexes, *trans,cis*-$[RuCl_2(DMSO)_2(L1)]$ (**3**) and chiral *cis,cis*-$[RuCl_2(DMSO)_2(L1)]$ (**4**). Reaction of **2** with 2-(2-formylhydrazino)-1,3,4-thiadiazole in MeOH gave the complex *trans,cis*-$[RuCl_2(DMSO)_2(L2)]$ (**5**) with concomitant deformylation of the starting ligand. The process was catalyzed by Ru^{II} in very low yield. Synthesis of the Ru complexes of 4-amino-3-methyl-1,2,4-Δ^2-triazoline-5-thione (L3) and 4-amino-3-ethyl-1,2,4-Δ^2-triazoline-5-thione (L4) resulted in an interesting oxidation of the metal promoted by DMSO. Reaction of **2** with these ligands in a 6 N HCl solution led to the isolation of the complexes *mer*-$[RuCl_3(DMSO)(L3)]\cdot 1/2\ H_2O$ (**6**) and *mer*-$[RuCl_3(DMSO)(L4)]\cdot 1/2\ H_2O$ (**7**). The complex *mer*-$[RuCl_3(DMSO)(L4)]\cdot CH_3COOH\cdot H_2O$ (**7'**) was obtained by recrystallization of **7** from ethyl acetate. The complexes **6**, **7**, and **7'** were highly stable in HCl solutions and acetone but not in neutral aqueous solution. To the best of our knowledge this is the first report of Ru^{III} complexes with an N–N–C–S chelating system.

Introduction

Cyclic derivatives of thiocarbonohydrazide and carbonohydrazide are a class of compounds rarely investigated from a structural point of view. They can exhibit analgesic properties[1] and some transition metal complexes have been studied for their pharmacological properties (such as fungicides, acaricides, insecticides, nematicides).[2] The 4-amino-5-thioxo-*s*-triazoline derivatives are known for their capability of complexing a number of soft metal ions.[3] They are also used in fixer compositions for silver halide photographic materials, as corrosion inhibitors, for rapid gravimetric determination of copper, and selective microevaluation of Au^{III}, Tl^{I}, and Ag^{I}.[4] We have previously prepared and structurally characterized complexes of Cu^{II}, Cu^{I}, $Cu^{II/I}$, and Au^{I} with 4-amino-3-methyl-1,2,4-Δ^2-triazoline-5-thione, which may be considered a good stabilizing agent of the low oxidation state.[3,5] This ligand is a weak monoprotic acid which exhibits thione-thiol tautomerism[5] in solution and undergoes an interesting desulfuration reaction promoted by copper(II).[6] In this paper we report our studies on the complexing capability of these ligands towards Ru^{II} and Ru^{III} ions.

Werner-type complexes of ruthenium with cyclic derivatives of thiocarbonohydrazide are a new class of compounds that are of interest for the development of transition metal coordination chemistry. The chloride–dimethyl sulfoxide–ruthenium derivatives containing a nitrogen ligand are of great interest for their potential as non-platinum inorganic antitumor drugs.[7] Moreover the N–N–C–S chelating system is similar to that of thiosemicarbazides and thiosemicarbazones, which constitute an important class of *N,S* donor ligands due to their interesting biological properties.[8] The ligands that we have considered are depicted in Scheme 1. In this report we describe the synthesis and the single-crystal X-ray structures of L1 **1**, L1·HCl **1'**, *trans,cis*-$[RuCl_2(DMSO)_2(L1)]$ (**3**), *cis,cis*-$[RuCl_2(DMSO)_2(L1)]$ (**4**), *trans,cis*-$[RuCl_2(DMSO)_2(L2)]$ (**5**), *mer*-$[RuCl_3(DMSO)(L3)]\cdot 1/2H_2O$ (**6**), *mer*-$[RuCl_3(DMSO)(L4)]\cdot 1/2H_2O$ (**7**) and *mer*-$[RuCl_3(DMSO)(L4)]\cdot CH_3COOH\cdot H_2O$ (**7'**).

Scheme 1. Structures of the ligands

Results and Discussion

Synthesis and Characterization

All complexing reactions were studied using *cis*-$[RuCl_2(DMSO)_4]$ (**2**). The ligands we have considered can

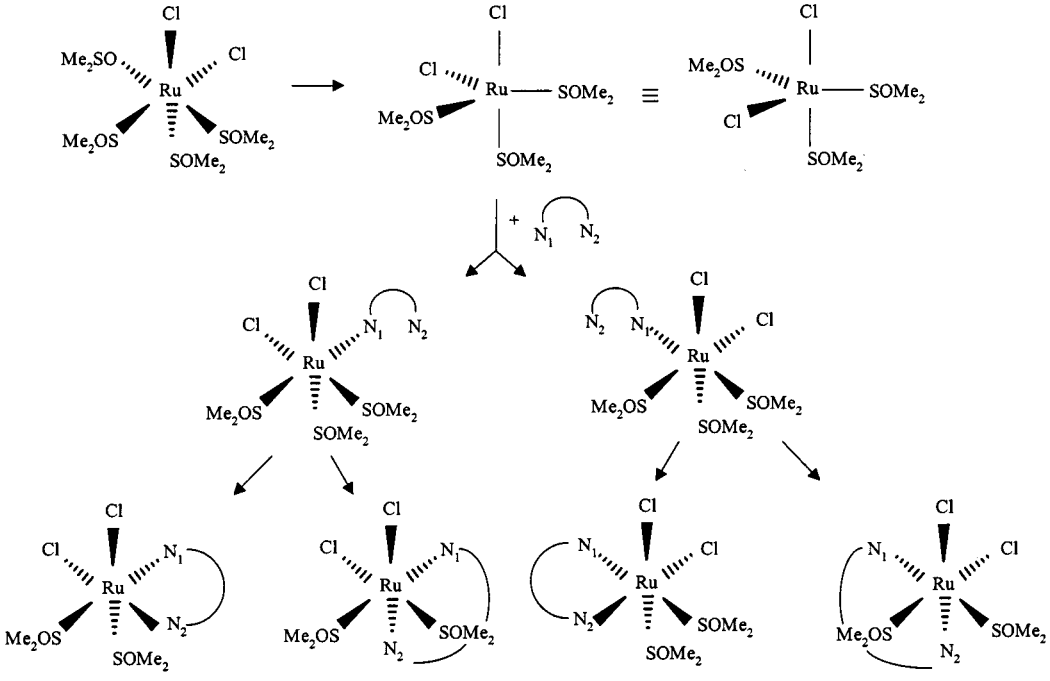
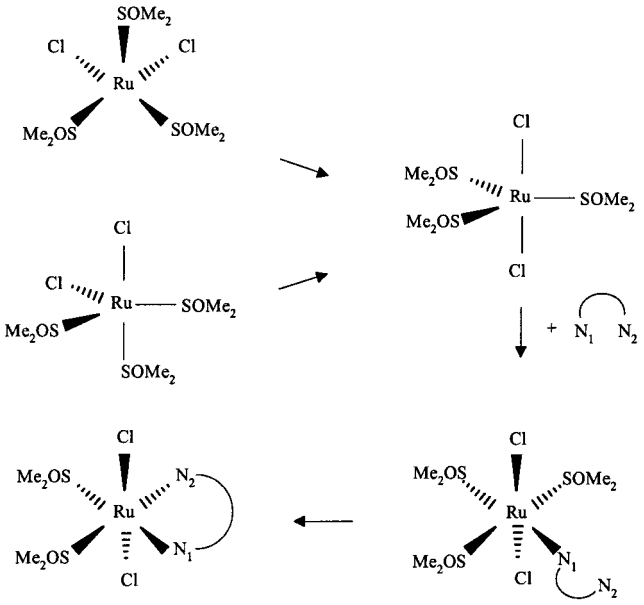
act as monodentate or bidentate *N,N* (L1, L2) or *N,S* (L3, L4) chelating agents; moreover they can interact with the metals through other donating atoms to form polymeric species.[3,5] In L1 the triazole and pyridine fragments are coplanar and can adopt two conformations with the pyridine nitrogen atom on the same side of the exocyclic amine nitrogen atom (**1**) or on the opposite side, as found in **1'**.



Reaction of **2** with L1 in MeOH produces two diastereomeric complexes, *trans,cis*-[$RuCl_2(DMSO)_2(L1)$] (**3**) and *cis,cis*-[$RuCl_2(DMSO)_2(L1)$] (**4**). The reaction conditions leading to **4** are probably governed by kinetic factors; in fact the complex was obtained only once despite many attempts that led invariably to the formation of **3**. It is well-known that Ru^{II}, a low spin d^6 system, undergoes substitution by a dissociative mechanism.[9] The leaving group in complex **2** is the *O*-coordinated DMSO molecule that lies *trans* to *S*-coordinated DMSO.[10] For steric reasons the trigonal bipyramidal intermediate (TBP) (Scheme 2) will lead to the formation of 100% *cis* isomer **4**, as is also the case of a square pyramid intermediate (SP) (Scheme 3). To explain the formation of **3** we hypothesize a rearrangement of the intermediates TBP or SP to the more stable TBP with three DMSO ligands in equatorial positions, leading to 100% of the *trans*-isomer **3** (Scheme 4). To correctly explain the formation of **4** it is necessary to hypothesize that the first binding of the ligand L1 proceeds through the pyridine nitrogen atom, due to the greater basicity of this atom than that of the triazole [see structure of L1·HCl (**1'**)] even if basicity and nucleophilicity are not equivalent concepts.

Reaction of **2** with 2-(2-formylhydrazino)-1,3,4-thiadiazole in MeOH forms the complex *trans,cis*-[$RuCl_2(DMSO)_2(L2)$] (**5**) in which the ligand is deformylated. This process is catalyzed by Ru^{II} and the yield is very low. A similar deformylation process of [2-(2-formylhydrazino)-1,3,4-thiadiazole] occurs in a 12 M solution of NH_4OH only if Zn^{2+} is added. In an acidic medium rearrangement of the ligand to form 4-amino-1,2,4-Δ^2-triazoline-5-thione was observed. The *trans,cis* isomer may arise through the same mechanism proposed for **3**. In all three complexes **3**, **4**, **5** the *S*-coordinated DMSO molecules are oriented in the same manner with the oxygen atoms lying on an equatorial plane.



The synthesis of the Ru complexes with L3 and L4 as ligands revealed an interesting oxidative process of the metal. In fact upon treatment of **2** with these ligands in a 6 N HCl solution, Ru^{III} complexes were obtained. This mech-

Scheme 3. Proposed formation pathway of **4** via the SP intermediate

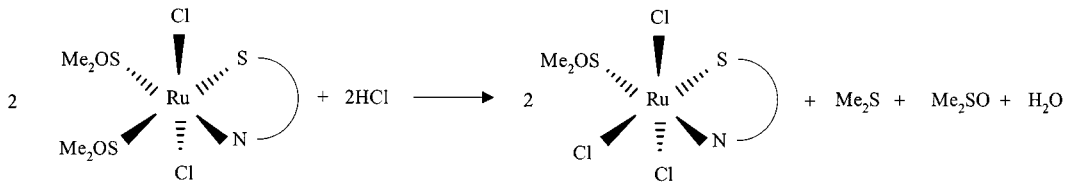
Scheme 2. Proposed formation pathway of **4** via the TBP intermediate

Scheme 4. Proposed formation pathway of **3**

anism does not involve molecular oxygen, as the reaction also proceeds under nitrogen atmosphere. It is well-known that L3 and L4 can act as reducing agents, so the oxidative process has to be due to the presence of DMSO. The oxidizing properties of DMSO in acidic solutions were tested in the presence of Ru^{II}, leading us to hypothesize an equilibrium:

$$2\,Ru^{II} + (CH_3)_2SO + 2\,H^+ \rightleftarrows 2\,Ru^{III} + (CH_3)_2S + H_2O$$

Dimethylsulfide complexes have been synthesized from acidic DMSO solutions,[11] and a similar equilibrium is probably involved in our reaction. In order to detect the dimethylsulfide produced from the reduction of DMSO in our system, the gases evolved during the reaction were allowed to flow through ethylene glycol for 8 h. This solution was analyzed by gas chromatography, showing an appropriate amount of $(CH_3)_2S$. The mechanism we propose involves the formation of a complex having formula $[RuCl_2(DMSO)_2(L)]$ (L = L3 or L4) in which the metal atom undergoes an oxidation process as shown in Scheme 5.



It is probable that during the oxidation, a DMSO molecule coordinated to one ruthenium atom can act as an *S,O* bridging ligand to a second Ru^{II} complex. A simultaneous inner sphere electron transfer mechanism of one electron from each Ru^{II} atom to the bridging DMSO can then occur. The complexes **6**, **7**, and **7'** are not stable in neutral aqueous solutions, whereas they are highly stable in HCl solutions and acetone. Conductivity experiments performed in acetone did not show any increase in molar conductivity, but when a small amount of water was added, the molar conductivity increased dramatically over three hours.

All three complexes synthesized and structurally characterized show a *mer* configuration and to the best of our knowledge this is the first report of Ru^{III} complexes with an N–N–C–S chelating system.

Spectroscopic Investigations

The ^{1}H-NMR spectrum of the complex **3** shows the CH_3 signal of L1 at $\delta = 2.75$, whereas the methyl groups of the two coordinated DMSO ligands give a signal at $\delta = 3.17$. This is in accordance with the assignments for free L1, and of DMSO coordinated to Ru^{II}.[10] The aromatic region shows three multiplets integrating for 1 H in the range $\delta = 7.73$–8.75. The mean shift of these signals with respect to free L1 is about 0.5 ppm, with the exception of the hydrogen atom *ortho* to the pyridine nitrogen atom which gives a signal at $\delta = 10.48$ as compared to $\delta = 8.70$ in free L1. The exocyclic amino group gives signal at $\delta = 6.84$ showing a shift towards higher field of about 0.3 ppm.

Several spectra of the paramagnetic complexes **6** and **7** were collected in different solvents in order to assign the signals and collect data regarding substitution of the DMSO ligand. A spectrum of both complexes in $[D_6]$acetone/$[D_6]$DMSO was collected between $\delta = +50$ and -50 although all the signals were observed between $\delta = +10$ and -12. In some ruthenium(III) complexes,[7] the signal of the methyl groups of the sulfur-coordinated DMSO is observed around $\delta = -14$ as a broad peak. A similar signal near $\delta = -11$ is present in the spectra of **6** and **7**. The signals of the hydrogen atoms of the coordinated amino groups were not located. This is probably due to both the paramagnetic shift and line broadening caused by the presence of the nearby paramagnetic centre. In the complex **6** the signal of the methyl group of L3 was observed as a broad peak at around $\delta = 6.4$. After 14 days this signal became narrower and shifted to $\delta = 5.64$; in the free ligand L3 the methyl group gives a signal at $\delta = 2.23$. In a freshly prepared sample of the analogous complex **7** the signal of the methylene group was observed at $\delta = 5.01$ and neither a shift nor a narrowing of the peak were observed after 16 days, while the signal of the methyl group was observed at $\delta = -0.12$. The signals of these two groups in free L4 are at $\delta = 2.63$ and $\delta = 1.17$, respectively. We have no explanation for the shift of the methyl group signal in the spectrum of **6**, but another important feature arises from these spectra. As the

Scheme 5

distance between the alkyl group and the triazole ring increases, the chemical shifts of the alkyl groups become more similar to those observed in the free ligand. This is probably due to the presence of a non-zero spin density on the triazole ring as a result of back-bonding from the metal to the sulfurous ligand.[12] This may also be the reason why the thioamide hydrogen atom cannot be located between $\delta = +50$ and -50. It should be noted that in the case of the complex **6** the solvent used was a mixture of acetone and DMSO. After 14 days at nearly 300 K no substitution of the coordinated DMSO was observed, strongly suggesting that the ruthenium complex is substitutionally inert. To identify the signal of the acidic thioamide hydrogen atom, a small portion of D_2O was added to the sample of **6** and a spectrum was collected immediately but no change was observed. A week after the addition of D_2O to the sample, the colour of the solution had changed from green to pale yellow. A new spectrum was collected between $\delta = +50$ and -50 but no paramagnetic peaks were observed.

Conductivity Measurements

The complexes **6** and **7** were synthesized in aqueous solution, with the pH maintained around 0 using highly concentrated hydrochloric acid. NMR experiments revealed that when dissolved in anhydrous solvents such as acetone or DMSO, the complex is quite stable for several days. On addition of small portions of water, a dramatic change in the nature of the complex occurs (Figure 1).

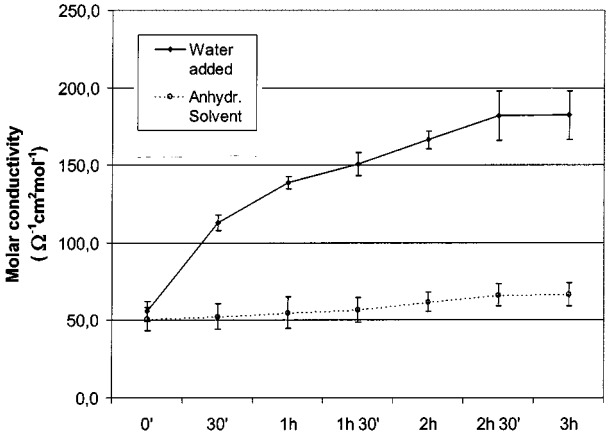


Figure 1. Conductivity measurements of **6**; measurements were made using a $1.016 \cdot 10^{-4}$ M solution of $[RuCl_3(DMSO)(L3)] \cdot 1/2\ H_2O$ in acetone; to follow the reaction, water (0.2 mL) was added to the complex solution (2 mL)

X-ray Structure Analysis

The crystal structures of the ligand L1 (**1**) and of its hydrochloride derivative **1'** are depicted in Figure 2 and Figure 3, respectively. Selected bond lengths and angles are provided in Table 1. The triazole and pyridine rings are essentially coplanar in both compounds {τ[N(1)–C(2)–C(3)–N(5)] = 169.3(2)° for **1** and –0.1(5)° for **1'**} but the molec-

C(1)–N(3)–C(2)	105.5(2)	105.1(3)	106.8(6)	105.6(4)
C(1)–N(3)–N(4)	123.2(2)	128.3(3)	121.3(7)	128.6(4)
C(2)–N(3)–N(4)	131.2(2)	126.6(3)	131.9(7)	125.7(4)
C(3)–N(5)–C(7)	117.7(2)	123.8(3)	116.7(7)	117.8(4)

ules are in different conformations. In both compounds the methyl carbon atoms are synperiplanar with respect to the imine nitrogen atom N(2) (τ[N(2)–C(1)–S–C(8)] = –1.8(2) and –4.2(3)° for **1** and **1'**, respectively). The pyramidal exocyclic amine nitrogen atom N(4) shows the lone pair oriented towards the sulfur atom in **1** and towards the hydrogen atom of the pyridine C(4) atom in **1'**. The most significant differences concerning the bond angles are the C(2)–N(3)–N(4) [131.2(2) and 126.6(3)° for **1** and **1'**, respectively] and the C(2)–C(3)–C(4) [119.1(3)° (**1**), 128.5(3)° (**1'**)] angles, probably due to the different conformations of the amine hydrogen atoms. The larger endocyclic N(5) angle in **1'** is due to the protonation of the pyridine nitrogen atom [123.8(3)° (**1'**), 117.7(2)° (**1**)].

The two Ru^{II} octahedral constitutional isomers *trans*,*cis*-(**3**) and *cis*,*cis*-[$RuCl_2(DMSO)_2$(L1)] (**4**) are shown in Figure 4 and Figure 5, respectively. Selected bond lengths and angles are reported in Table 1. In both complexes the ligand, with N(1) and N(5) synperiplanar, acts as *N*,*N* chelating agent. The torsion angles τ[N(1)–C(2)–C(3)–N(5)] [–8.6(8) and –6.6(8)° for **3** and **4**, respectively] are slightly larger than in **1'**; the S–C_{Me} bond lies on the triazole ring plane in **3** whereas it is out of the plane in **4** due to intramolecular steric hindrance {τ[N(2)–C(1)–S(1)–C(8)] = –2.2(8) and –26.6(7)°}. The conformation of the N(4) amine nitrogen atom in **3** is similar to that found in **1** while in **4** it is similar to that found in **1'**, with the same interaction C(4)–H···N(4) and same trend in the C(2)–N(3)–N(4) bond angles [131.9(7)° (**3**) and 125.7(4)° (**4**)]. In both diastereomeric complexes the DMSO molecules show S=O bonds oriented in the same direction and lying roughly on a coordination plane [N(1)N(5)S(2)S(3)Ru (**3**), N(5)S(2)S(3)-Cl(1)Ru (**4**)] which consequently nearly bisects the C–S–C DMSO bond angles. The *cis*,*cis* isomer is chiral but owing to the centrosymmetric space group both enantiomers are present in the crystal. The OC-6–32-*C* enantiomer is depicted in Figure 5. In both complexes the Ru–N(1) bond lengths involving the imine triazole nitrogen atoms are shorter than the Ru–N(5) ones involving the pyridine N atoms [2.066(5), 2.163(6) Å for **3** and 2.032(4), 2.135(4) Å for **4**, respectively]. The distance Ru–N(1) is longer in **3** than in **4** due to the *trans* influence of the DMSO–*S* ligand.

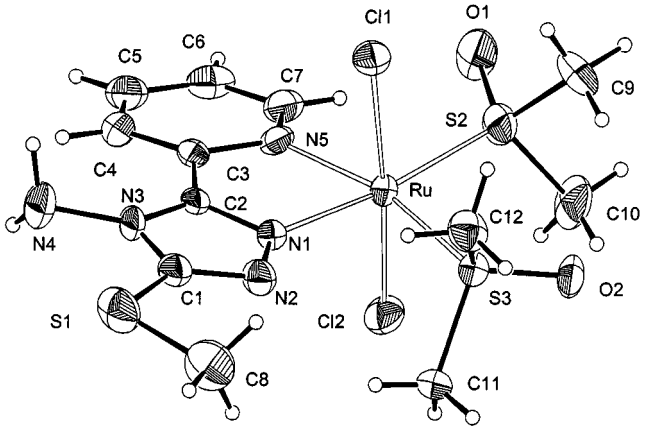

Figure 4. Molecular structure and numbering scheme of complex**3**; thermal ellipsoids are drawn at the 30% probability level

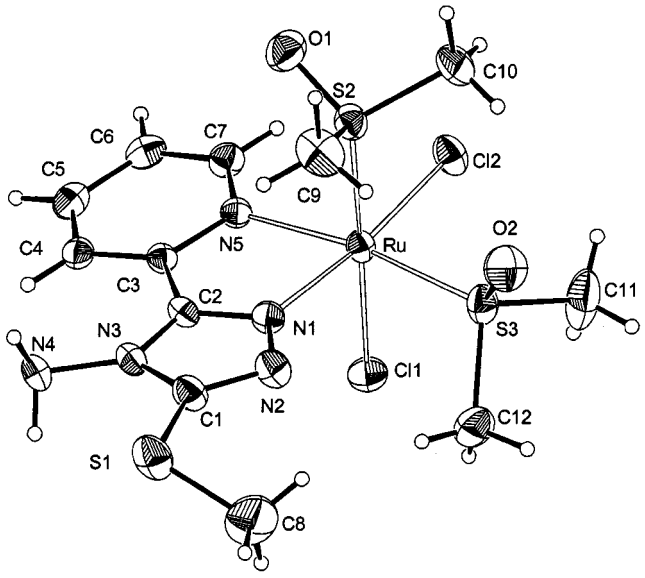

Figure 5. Molecular structure and numbering scheme of complex **4**; thermal ellipsoids are drawn at the 30% probability level

In the octahedral Ru^{II} complex *trans*,*cis*-[$RuCl_2$-$(DMSO)_2$(L2)] (**5**) (Figure 6) the 2-hydrazino-1,3,4-thiadiazole ligand L2 binds via the amine N(4) and the imine N(2) nitrogen atoms. The organic moiety and the ruthenium, sulfur, and oxygen atoms of the two DMSO ligands lie on a crystallographic mirror plane, so that the S=O bonds are oriented in exactly the same direction. The Ru–N(4) bond length involving the amine nitrogen atom is slightly longer than the Ru–N(2) one involving the imine N atom [2.130(6), 2.096(7) Å]. In this case the bite angle [79.3(3)°] is larger than in **3** [75.8(2)°] and **4** [76.7(2)°]. In the coordinated organic ligand the N(3)–C(1) bond length [1.315(12) Å] reveals a high degree of conjugation of the N(3) π orbitals with the heterocyclic ring and consequently a decrease of the double-bond character of the C(1)–N(2) [1.354(11) Å] bond.

In the complexes of Ru^{III} *mer*-[$RuCl_3$(DMSO)-(L3)]·1/2 H_2O (**6**), *mer*-[$RuCl_3$(DMSO)(L4)]·1/2 H_2O (**7**), and *mer*-[$RuCl_3$(DMSO)(L4)]·CH_3COOH·H_2O (**7'**) the 3-substituted 4-amino-Δ^{2-}1,2,4-triazoline-5-thione molecules act as *N*,*S* chelating ligands and the DMSO ligands are *trans* to the amine nitrogen atoms with the S=O bonds in the plane of the chelating ligands and oriented towards the thione S atoms. All complexes show a pseudo-C_s symmetry (Figure 7, Figure 8) except for the C(4) methyl carbon atoms of the ethyl groups in **7** and **7'**. In the three Ru^{III} complexes the Ru–$S(2)_{DMSO}$ bond lengths are ca. 0.05 Å shorter than the Ru–S(1) ones and the Ru–N(4) bond lengths *trans* to S(2) are equivalent (Table 2). The equatorial Ru–Cl(3) bonds are longer than the axial Ru–Cl ones due to the S-*trans* influence of the thione groups. The Ru–S(1) bond length in the three complexes shows some variability but as the bond strength increases a lengthening of the *trans* Ru–Cl(3) bond is observed [Ru–S(1) = 2.326(3) Å (**7**), 2.319(1) Å (**6**), 2.309(1) Å (**7'**), Ru–Cl(3) = 2.375(3) Å (**7**),

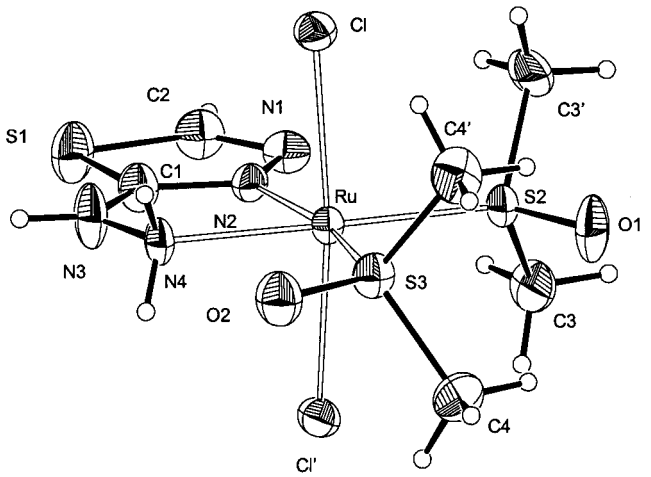

Figure 6. Molecular structure and numbering scheme of complex **5**; thermal ellipsoids are drawn at the 30% probability level; selected bond lengths [Å] and angles [°]: Ru–N(2) 2.096(7), Ru–N(4) 2.130(6), Ru–S(2) 2.242(2), Ru–S(3) 2.253(2), Ru–Cl 2.400(2), S(1)–C(2) 1.702(11), S(1)–C(1) 1.731(11), N(1)–C(2) 1.312(12), N(1)–N(2) 1.355(10), N(2)–C(1) 1.354(11), N(3)–C(1) 1.315(12), N(3)–N(4) 1.413(11); N(2)–Ru–N(4) 79.3(3), N(2)–Ru–S(2) 97.6(2), N(4)–Ru–S(3) 88.3(2), N(2)–Ru–Cl 87.46(4), N(4)–Ru–Cl 87.36(4), C(2)–S(1)–C(1) 86.9(4), C(2)–N(1)–N(2) 109.3(8), C(1)–N(2)–N(1) 114.9(7), C(1)–N(2)–Ru 110.7(6), N(1)–N(2)–Ru 134.4(6), C(1)–N(3)–N(4) 117.1(7), N(3)–N(4)–Ru 110.2(5), N(3)–C(1)–N(2) 122.8(9), N(3)–C(1)–S(1) 125.8(7), N(2)–C(1)–S(1) 111.4(7), N(1)–C(2)–S(1) 117.5(7)

2.386(1) Å (**6**), 2.395(1) Å (**7'**)]. A lengthening of the C(1)–S(1) bonds for the three complexes with respect to the free ligand L3[6] is observed [C(1)–S(1) = 1.705(11), 1.720(6), 1.716(3) and 1.674(6) Å for **7**, **6**, **7'** and L3 respectively]. The coordination alters significantly the double-bond character of the C–S group as is observed to a smaller extent in the copper complexes[3,6] $[CuCl_2(L3)] \cdot H_2O$ [1.693(6), 1.687(6) Å], $[Cu_2Cl_4(L3)]_n \cdot nH_2O$ [1.697(12) Å] and $[Cu_3Cl_5(OH_2)(L3)_2]_n \cdot 2nH_2O$ [1.699(5), 1.694(5) Å].

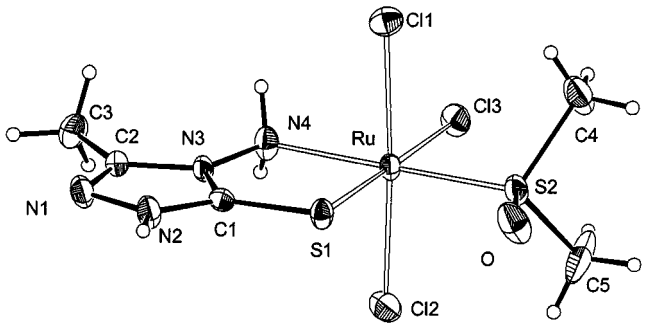

Figure 7. Molecular structure and numbering scheme of complex **6**; the H_2O molecule is omitted for clarity; thermal ellipsoids are drawn at the 30% probability level

To the best of our knowledge the only ruthenium complexes with a neutral ligand and a similar N–N–C–S chelating system are $[(\eta^6\text{-}p\text{-cymene})RuCl(taz)]PF_6$ (taz = 4-amino-2,6-dimethyl-5-oxo-3-thioxo-2,3,4,5-tetrahydro-1,2,4-triazine),[13] $[Ru(HL)(PPh_3)_2Cl]Cl \cdot CH_2Cl_2$ and $[Ru(HL)(PPh_3)(mpi)]Cl_2 \cdot CH_2Cl_2 \cdot 3H_2O$ [HL = methyl 2-pyridyl ketone 4-(4-tolyl)thiosemicarbazone, mpi = methyl(2-pyridyl)methyleneimine],[14] in which the metal has an oxidation state of +2. In the taz complex the C–S distance [1.687(3) Å] supports the double-bond character of the 3-thioxo group[15] and the C–S group is not significantly altered by coordination. In the two HL complexes the C–S bonds, 1.707(6), 1.698(7) Å, are similar to those found in **6**, **7**, and **7'**. In these Ru^{II} cationic complexes the Ru–S bond lengths [2.354(1) Å,[13] 2.386(2), 2.358(2) Å,[14]] are greater than those found in our Ru^{III} complexes, due to the lower oxidation state of the metal.

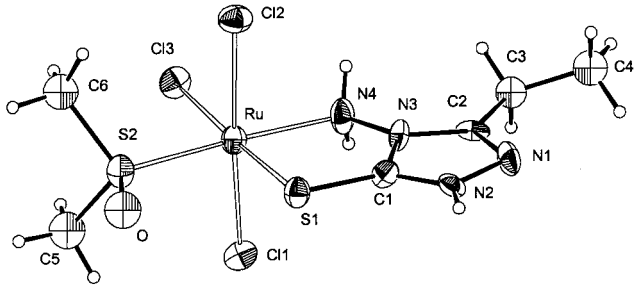

Figure 8. Molecular structure and numbering scheme of complex **7**; the H_2O molecule is omitted for clarity; thermal ellipsoids are drawn at the 30% probability level

Table 2. Selected bond lengths [Å] and angles [°] for **6**, **7**, and **7'**

	6	**7**	**7'**

N(4)–Ru–Cl(1)	84.9(2)	85.0(3)	88.99(7)
S(1)–Ru–Cl(1)	92.88(5)	91.9(1)	91.04(3)
N(4)–Ru–Cl(3)	92.2(1)	90.5(2)	88.86(7)
C(1)–S(1)–Ru	96.2(2)	96.4(4)	95.8(1)
C(2)–N(1)–N(2)	104.9(5)	103.1(8)	105.3(2)
C(1)–N(2)–N(1)	112.1(5)	114.3(9)	112.2(3)
C(1)–N(3)–C(2)	108.7(5)	109.7(9)	108.7(2)
C(1)–N(3)–N(4)	121.4(5)	123.0(8)	121.6(2)
C(2)–N(3)–N(4)	129.8(5)	126.4(8)	129.6(2)
N(3)–N(4)–Ru	111.9(3)	110.0(5)	110.5(2)

Water molecules of solvation are present in the three Ru^{III} complexes, while in **7'** a free molecule of ethanoic acid cocrystallizes. A broad network of hydrogen bonds is present in every compound structurally characterized.

All Ru complexes display a distorted octahedral coordination and in the *trans*–Cl complexes the axial Cl–Ru–Cl angles [173.95(7)° (**3**), 173.28(9)° (**5**), 173.35(6)° (**6**), 174.13(11)° (**7**), 176.00(3)° (**7'**)] show a significant deviation from linearity forced by the steric hindrance of the DMSO methyl groups. The *trans* Ru–Cl bond lengths in the Ru^{II}

complexes [2.390(2)–2.413(2) Å] compare well with the values found in other *trans*-Cl DMSO Ru^{II} complexes[10,16–21] [2.397(1)–2.432(1) Å]. The lengthening of the Ru–Cl(1) in **4** [2.454(1) Å] reflects the strong *trans* influence of the DMSO ligand, whereas the Ru–Cl(2) bond [2.412(1) Å] *trans* to N(1) agrees with the value found in *cis*,*cis*,*cis*-$[RuCl_2(Me_2SO)_2(py)(Me_3Bzm)]$[22] [2.4148(7) Å] ($Me_3Bzm$ = 1,5,6-trimethylbenzimidazole, py = pyridine). In the Ru^{III} complexes **6**, **7**, **7'**, the *trans* Ru–Cl bond lengths [2.353(2)–2.370(2) Å] are close to the upper limit of the range [2.308(2)–2.366(4) Å] found in other DMSO Ru^{III} complexes.[7,16,23]

Experimental Section

Materials and Instrumentation: Thiocarbonohydrazide, iodomethane, and ruthenium trichloride hydrate were purchased from Aldrich and Fluka. Unless otherwise specified, all reagents and solvents were AR grade and used without further purification. The syntheses of 4-amino-3-methyl-1,2,4-Δ^2-triazoline-5-thione,[24] 4-amino-3-ethyl-1,2,4-Δ^2-triazoline-5-thione,[25] 2-(2-formylhydrazino)-1,3,4-thiadiazole,[25] 4-amino-3-(2-pyridyl)-1,2,4-Δ^2-triazoline-5-thione,[25] and *cis*-dichlorotetrakis(dimethyl sulfoxide)ruthenium(II) [10] (**2**) were performed following reported procedures. – IR spectra were collected on an FT-IR Nicolet 5PC spectrometer using KBr pellets. – ^1H NMR spectra were collected on Bruker WM 300 MHz, AC 300 MHz or AC 100 MHz spectrometers. – Mass spectra were collected on a Finnigan 1020 spectrometer equipped with a MATSSQ 710 quadrupole revealer. – GC analyses were performed with a Carlo Erba MFC 500 equipped with a FID revealer and a CPSIL5CB 100% polysiloxane column (10 m × 0.32 mm, 1.20 μm) (Chrompack, Middleburg, Holland). Helium (purity 99,9%) was used as the carrier gas with a flow rate of 10 mL/min under isothermal conditions (40° C). Elemental analyses were performed using a Carlo Erba Elemental Analyzer EA 1108. – Conductivity measurements were performed using a CRISON microCM 2202 conductimeter equipped with a temperature probe. – Melting points were collected on a Gallenkamp apparatus.

4-Amino-5-methylthio-3-(2-pyridyl)-1,2,4-triazole (1): In a double necked 100 mL round bottomed flask equipped with a condenser NaOH (0.208 g, 5.2 mmol) was dissolved in DMSO (2 mL). A warm solution of 4-amino-3-(2-pyridyl)-1,2,4-Δ^2-triazoline-5-thione (1 g, 5.17 mmol) in DMSO (5 mL) was added dropwise into the flask while stirring. Iodomethane (0.65 mL, 1.48 g, 10.4 mmol) was added dropwise into the flask while stirring and the solution obtained stirred at room temperature for 1.5 h (exothermicity is observed). The solution was added dropwise into water (50 mL) at 0–5 °C. The product was extracted with CH_2Cl_2 (5 × 15 mL), the organic phase washed with water (2 × 15 mL), dried (Na_2SO_4), and concentrated to 1/3 volume under reduced pressure. White crystals of **1** were collected by slow evaporation; the product can also be recrystallized from ethanol. Yield 0.641 g (60%). – m.p. 108–109 °C. – IR (KBr, cm^{-1}): $\tilde{\nu}$ = 3260 (NH_2 asym. str.), 3171 (NH_2 sym. str.), 2923, 1659, 1463, 1420, 1416 (S–CH_3 asym. def.), 1011, 786 (CH_{py} oop def.). – ^1H NMR ([D_6]DMSO): δ = 8.70 (1 H, CH_{py}), 8.07 (1 H, CH_{py}), 8.00 (1 H, CH_{py}), 7.53 (1 H, CH_{py}), 6.55 (2 H, NH_2), 2.65 (3 H, CH_3). – $C_8H_9N_5S$ (207.26): calcd. C 46.36, H 4.38, N 33.79, S 15.47; found C 46.26, H 3.87, N 32.40, S 16.20.

4-Amino-5-methylthio-3-(2-pyridinium)-1,2,4-triazole Chloride (1'): The compound was synthesized by dissolving L1 (0.5 g 2.41 mmol) in a minimum amount of a water:ethanol (1:1) solution. The pH was lowered to ca. 3 by the addition of several drops of ca. 1 N HCl solution. L1' is easily crystallizable as white needles. Yield 0.410 g (70%). – IR (KBr, cm^{-1}): $\tilde{\nu}$ = 3187 (NH_2 str.), 3114 (CH_{py} str.), 1617 (triazole ring def.), 1603, 1541 (NH_2 def.), 1295 (S–CH_3 sym. def.), 1223, 1084, 797 (CH_{py} oop def.), 676 (CH_{py} oop def.), 506. – ^1H NMR ([D_6]DMSO): δ = 8.75 (1 H, CH_{py}), 8.16 (1 H, CH_{py}), 8.03 (1 H, CH_{py}), 7.61 (1 H, CH_{py}), 4.39 (3 H, NH_2 and NH_{py} mediated peak), 2.66 (3 H, CH_3). – $C_8H_{10}ClN_5S$ (297.16): calcd. C 39.42, H 4.16, N 28.73, S 13.15; found C 39.06, H 3.97, N 29.16, S 13.21.

***trans,cis*- (3) and *cis,cis*-Dichlorobis(dimethyl sulfoxide-*S*)(4-amino-5-methylthio-3-(2-pyridyl)-1,2,4-triazole-*N,N'*)ruthenium(II) (4):** The synthesis was performed under nitrogen atmosphere in a three necked 250 mL round bottomed flask equipped with a condenser. **1** (0.064 g, 0.31 mmol) was dissolved in dry methanol (5 mL) and the solution was heated slightly while stirring. A solution of **2** (0.15 g, 0.31 mmol) in dry methanol (10 mL) was added dropwise into the flask and the solution was heated at reflux for 1.5 h. The red-orange solution obtained was poured in a crystallizer and orange crystals of product were collected by slow evaporation. Yield of **3** 0.101 g (60%). – *trans,cis* isomer: IR (KBr, cm^{-1}): $\tilde{\nu}$ = 3273 (NH_2 asym. str.), 3167 (NH_2 sym. str.), 2922 (CH_3 str.), 1620, 1451, 1418 (S–CH_3 asym. def.), 1384, 1092 (S–O DMSO *S*-coord),1069, 1015 (CH_3 DMSO rock),781, 679 (C–S_{DMSO} str.), 426 (Ru–S str.). – ^1H NMR ([D_6]DMSO): δ = 10.48 (1 H, CH_{py}), 8.75 (1 H, CH_{py}), 8.20 (1 H, CH_{py}), 7.73 (1 H, CH_{py}), 6.84 (2 H, NH_2), 3.17 (CH_3 DMSO *S*-coord), 2.75 (3 H, CH_3). – $C_{12}H_{21}Cl_2N_5O_2RuS_3$ (535.49): calcd. C 26.92, H 3.95, N 13.08, S 17.96; found C 27.62, H 4.70, N 12.61, S 17.48. – *cis,cis* isomer: IR (KBr, cm^{-1}): $\tilde{\nu}$ = 3270 (NH_2 asym. str.), 3159 (NH_2 sym. str.), 2919 (CH_3 str.), 1635, 1450, 1411 (S–CH_3 asym. def.), 1096 (S–O DMSO *S*-coord), 1066, 1013 (CH_3 DMSO rock), 780, 678 (C–S_{DMSO} str.), 425 (Ru–S str.). – $C_{12}H_{21}Cl_2N_5O_2RuS_3$ (535.49): calcd. C 26.92, H 3.95, N 13.08, S 17.96; found C 27.37, H 4.24, N 12.76, S 17.63.

***trans,cis*-Dichlorobis(dimethyl sulfoxide-*S*)(2-hydrazino-1,3,4-thiadiazole-*N,N'*)ruthenium(II) (5):** The synthesis was performed under nitrogen atmosphere in a three necked 250 mL round bottomed flask equipped with a condenser. **2** (0.07 g, 0.14 mmol) and 2-(2-formylhydrazino)-1,3,4-thiadiazole (0.041 g, 0.28 mmol) were dissolved in methanol (15 mL) and the solution was heated at reflux while stirring for 1.5 h. The red-orange solution obtained was poured into a crystallizer and red crystals of the product were collected by slow evaporation. Yield 0.012 g (20%). – IR (KBr, cm^{-1}): $\tilde{\nu}$ = 3239 (NH str.), 3180 (NH_2 asym. str.), 3149 (NH_2 sym. str.), 1619 (NH_2 def.), 1216, 1095 (S–O DMSO *S*-coord), 1069, 1013, 687 (C–S_{DMSO} str.), 429 (Ru–S str.). – $C_6H_{16}Cl_2N_4O_2RuS_3$ (444.38): calcd. C 16.21, H 3.62, N 12.60, S 21.64; found C 16.04, H 3.83, N 12.76, S 21.58.

***mer*-Trichloro(dimethyl sulfoxide-*S*)(4-amino-3-methyl-1,2,4-Δ^2-triazoline-5-thione-*N,S*)ruthenium(III) Hemihydrate (6):** In a 100 mL round-bottomed flask, **2** (0.15 g, 0.31 mmol) was added to a suspension of L3 (0.04 g, 0.31 mmol) and HCl (ca. 6 N, 20 mL) while stirring. The mixture was stirred for 0.5 h at room temperature, then the mixture was warmed on a heating plate for 1 h. The green solution obtained was poured into a crystallizer. Dark-green crystals of the product were obtained by slow evaporation. Yield 0.059 g (45%). – IR (KBr, cm^{-1}): $\tilde{\nu}$ = 3449 (OH str.), 3197 (NH str.), 3102 (NH_2 str.), 1610, 1505 (Thioam I), 1124, 1089 (S–O DMSO *S*-coord), 1024, 688 (C–S_{DMSO} str.), 433 (Ru–S str.). – ^1H NMR ([D_6]acetone): δ = 6.4 (br, CH_3), –10.42 (br, CH_3 DMSO *S*-

coord). – $C_5H_{13}Cl_3N_4O_{1.5}RuS_2$ (424.73): calcd. C 14.14, H 3.08, N 13.19, S 15.10; found C 14.32, H 2.83, N 12.83, S 15.30.

***mer*-Trichloro(dimethyl sulfoxide-*S*)(4-amino-3-ethyl-1,2,4-Δ²-triazoline-5-thione-*N,S*)ruthenium(III) Hemihydrate (7):** The procedure was the same as for the synthesis of the previous complex, but using L4 (0.045 g, 0.31 mmol). Green crystals of the product were obtained. Yield 0.061 g (45%). – IR (KBr, cm^{-1}): $\tilde{\nu}$ = 3441 (OH str.), 3194 (NH_2 str.), 1608, 1498 (Thioam I), 1386 (CH_3 rock), 1124 (S–O DMSO *S*-coord), 1029, 684 (C–S_{DMSO} str.), 434 (Ru–S str.) – ^1H NMR ([D_6]acetone): δ = 5.01 (br 2 H, CH_2), –0.12 (3 H, CH_3), –11.15 (br, CH_3 DMSO *S*-coord). – $C_6H_{15}Cl_3N_4O_{1.5}RuS_2$ (438.76): calcd. Experimental Procedure for Conductivity Measurements: Four samples of a solution of **7** in dry acetone ($1.016\ 10^{-4}$ M, 2 mL) were prepared. Distilled water (0.2 mL) was added to two of the four samples, and seven measurements were made (every 30 min), the first immediately after the addition of water. The colour of the samples to which water was added changed from green to pale yellow in 3 h.

X-ray Crystal Structure Determinations: Diffraction data were recorded at 293(2) K with the φ/2φ technique on a Siemens AED (**1**, **5**, **7**), a Philips PW 1100 (**1'**, **3**, **7'**), and an Enraf–Nonius CAD4 diffractometer (**4**, **6**). The individual profiles were analyzed following the method of Lehmann and Larsen.[26] Corrections were made for Lorentz and polarization effects. The structures were solved by direct methods [SIR92][27] and refined by full-matrix least-squares methods based on F^2 using the SHELXL-97[28] program. All the non-hydrogen atoms were refined anisotropically except the ethyl carbon atoms and the oxygen and the methyl carbon atoms of the DMSO ligand in compound **7**. In **1** the hydrogen atoms, taken from a difference Fourier map, were refined freely. In the other compounds, the hydrogen atoms were placed in calculated positions and refined with a riding model, except those of the non-coordinated amine groups, the solvated water hydrogens and the carboxylic hydrogen atoms which were freely refined for the most part. Empirical absorption corrections were applied for compounds **4**, **5**, and **6**.[29] Crystal data and some details of the structure determinations are listed in Table 3 and Table 4. Further details of the crystal structures (excluding structure factors) have been deposited with the Cambridge Crystallographic Data Centre, and can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, England [Fax: (internat.) +44 (0)1223/336-033; E-mail: deposit@ccdc.cam.ac.uk] on quoting the reference number CCDC-121951–121958, the names of the authors, and the full journal citation. All calculations were carried out on the DIGITAL AlphaStation 255 of the "Centro di Studio per la Strutturistica Diffrattometrica'' del CNR, Parma. The programs PARST[30] and ORTEP[31] were also used.

Stoichiometric Homo-Aldol Coupling of Acetone, Cyclohexanone, and Acetophenone by the [(η^5-Cp^R)Co] (R = Me_5, 1,2,4-tri-*tert*-butyl) Moiety

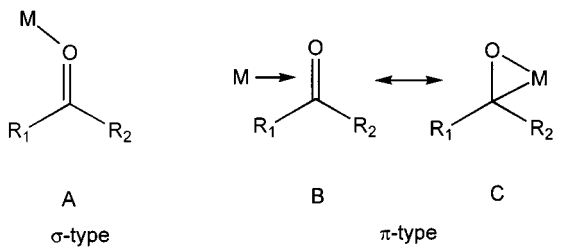
Jörg J. Schneider,*[a] Dirk Wolf,[a] Dieter Bläser,[a] and Roland Boese[a]

Keywords: Cobalt / Sandwich complexes / Aldol reactions / Ketones / C_{sp3}−H activation

Acetone, cyclohexanone, and acetophenone react with the toluene-bridged triple-decker complexes [{(η^5-Cp^R)Co}$_2$-μ-(η^4:η^4-toluene)] (R = Me_5 **3**; 1,2,4-tri-*tert*-butyl **4**) by toluene substitution and homo-aldol coupling of two ketone molecules to form the first oxadiene cobalt complexes. These reactions may involve a C_{sp3}–H activation step of the ketones by 14 e$^-$ [(η^5-Cp^R)Co] fragments generated from the triple-decker complexes **3** and **4**. If no acidic protons are present in the position α to the carbonyl carbon position in the ketone, no C_{sp3}–H activation occurs. In agreement with this, benzophenone does not react with complex **3**.

Introduction

During the last decade or so it has been well established, both spectroscopically and crystallographically, that carbonyl compounds are able to coordinate to transition metal fragments and, consequently, metal-mediated reactions, which are stoichiometric or even catalytic in nature, have been studied extensively.[1] The aldol reaction is generally regarded as one of the most powerful carbon–carbon bond forming reactions. The primary metal coordination site is at the C=O group, resulting in three different bonding situations A–C towards the transition metal center (Figure 1).[2] Recent results by Brookhart, who observed selective coordination of phthalaldehyde over acetone with the bis({trimethylsilyl}alkene)(η^5-Me_5C_5)Co complex **1** are striking.[3a] The bis-aldehyde complex **2**, which simultaneously displays coordination modes A and B is formed as the exclusive product from the activation of phthalaldehyde even though acetone was used as the reaction solvent (Scheme 1).[3a] Other examples of similar aldehyde over ketone reactivity are documented for the cobalt complex **1** by the same authors.[3b][3c]



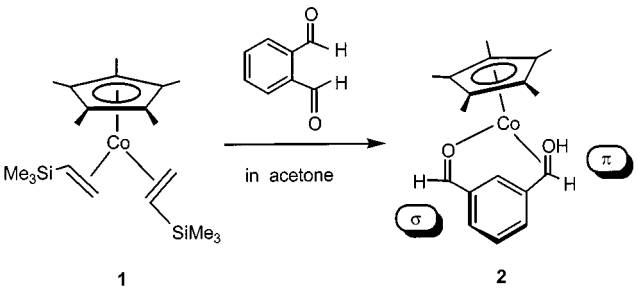


Figure 1. σ- and π-coordination modes of a transition metal fragment M to a ketone; $R_{1,2}$ = H or alkyl

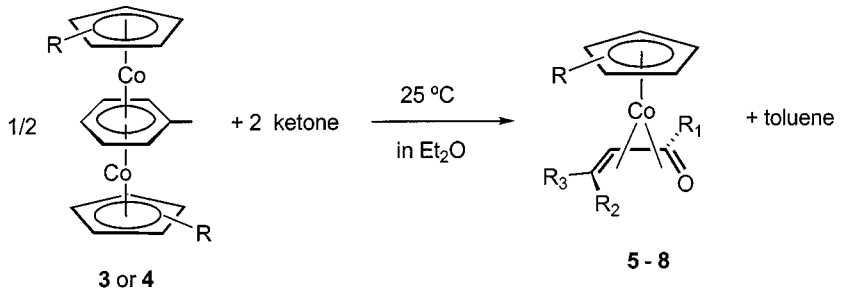
Scheme 1

Herein we report on our studies on the synthesis and structure of cobalt-oxadiene complexes which are formed via a stoichiometric homo-aldol coupling reaction of acetone, cyclohexanone, and acetophenone mediated by 14-e [(η^5-Cp^R)Co] fragments.

Results and Discussion



Reaction of [{(η^5-Me_5C_5)Co}$_2$-μ-(η^4:η^4-toluene)] (3) and [{(η^5–1,2,4-tri-*tert*-butyl-C_5H_2)Co}$_2$-μ-(η^4:η^4-toluene)] (4) with Ketones

Reaction of the triple-decker compound [{(η^5-Me_5C_5)Co}$_2$-μ-(η^4:η^4-toluene)] (**3**) either in neat acetone as solvent or with a tenfold excess of acetone in ether results in the formation of the *s-cis*-oxadiene cobalt complex **5** (Scheme 2). No *s-trans* regioisomer was observed. The question of whether the product selectively adopts one of the regioisomers (Figure 2) is of interest since the two arrangements expose different faces of the α, β-unsaturated carbonyl moiety which may lead to different enantioselective additions to this complex.

The reaction of **3** with acetone proceeds stoichiometrically and no free 2-oxo-4-methylpent-3-ene was observed as the organic aldol coupling product resulting from a catalytic reaction sequence. The η^2-keto coordination is characterized by a significant ^{13}C high-field coordination shift of the carbonyl C-atom resonance of $\Delta\delta$ = –72 ppm relative to free acetone.

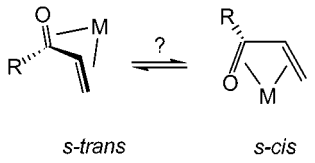
Scheme 2. General reaction scheme for the formation of Co-oxadiene complexes **5–8** via homo-aldol coupling of acetone, cyclohexanone and acetophenone. The characteristic η^4-oxadiene unit of **5–8** is depicted in bold.



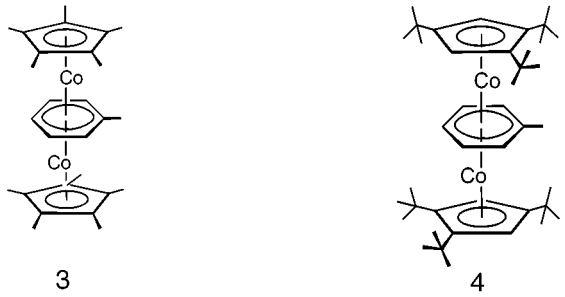


Figure 2. *s-cis* versus *s-trans* arrangement of a metal-oxadiene unit

A tenfold excess of acetophenone in diethyl ether reacts with **3** within 30 minutes to give the oxadiene cobalt complexes [{(η^5-Me_5C_5)Co(η^4-(*E,Z*)-3-methyl-1-oxo-1,3-diphenylbut-2-ene)} **(6)** as a mixture of *cis* and *trans* isomers (ratio 2:3) (Scheme 2). As in the case of **5**, a significant high-field coordination shift of $\Delta\delta$ = –49.2 ppm for the resonance of C1 characterizes the η^2-keto coordination of the [(η^5-Me_5C_5)Co] fragment of **6**. The complete set of ^{13}C-NMR signals for both isomers is not observed probably just due to a low concentration of the sample studied.

When **3** is dissolved in neat cyclohexanone a reaction occurred within two days as judged from the color change from brown red to green black. The oxadiene cobalt complex [(η^5-Me_5C_5)Co(η^4-2-cyclohexylidenecyclohexane-1-one)] **7** is formed in moderate yields. (Scheme 2). ^{1}H- and ^{13}C-NMR spectroscopy shows the formation of only the *s-cis* isomer (assignment via 1D- and 2D-NMR techniques). In the ^{13}C-NMR spectrum the η^2-keto coordination is characterized by a coordination shift of $\Delta\delta$ = –75 ppm for the resonance of C1 relative to free cyclohexanone.

To study the influence of the steric bulk of the [(Cp^R)Co] fragment on the homo-aldol coupling reaction we studied the reaction of acetone with the triple-decker complex **4**. The 1,2,4 tri-*tert*-butyl Cp ligand has already proven its versatility in kinetically stabilizing unusual metal coordination environments.[4,5] When **4** is dissolved together with a tenfold excess of acetone in diethyl ether the reaction proceeds within 12 hours to give the oxadiene complex [{(η^5-$tBu_3C_5H_2$)Co(methyl-2-oxo-pent-3-ene)}] (**8**) whose structure is confirmed by its mass, IR and ^{1}H- and ^{13}C-NMR spectra (see Experimental Section) (Scheme 2). In **8**, as well as in the other oxadiene Co complexes **5–7**, the ν(C=O) stretching frequencies of the complexed η^2-carbonyl moieties are unfortunately obscured by the strong intensity of the stretching frequencies of the Me and 1,2,4-*tert*-butyl residues of the Cp ring ligands.

Molecular Structure of 5

An X-ray crystal structure determination[6] (Figure 3) of **5** reveals the *s-cis*-arrangement of the oxadiene moiety in agreement with the solution NMR results. The C1–O1 distance [1.310(5) Å] of the π-coordinated carbonyl group is in the same range as for the η^2-coordinated C=O group of the dialdehyde complex **1**[3a] as well as for other η^2 bound ketones.[1,7] This suggests a significant amount of π-backbonding from the Co^I d-orbitals into the π^* orbitals of the carbonyl C atom. The Co–O [1.985(3) Å] and the Co1–C2 [1.994(4) Å] distances are in agreement with a symmetrical

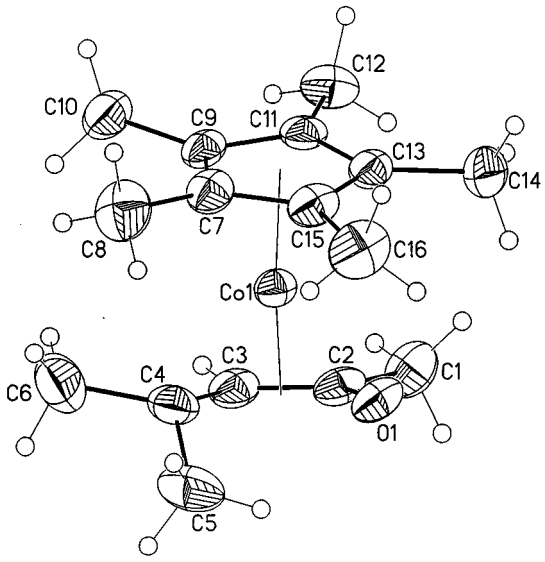

Figure 3, Molecular structure of **5** in the solid state; selected bond length [A] and angles [°]: C(2)–O(1) 1.310(5),C(2)–C(3) 1.396(6), C(3)–C(4) 1.437(6),C(1)–C(2) 1.497(6), C(4)–C(5) 1.503(7), C(4)–C(6) 1529(6), Co(1)–C(2) 1.994(4), Co(1)–O(1) 1.985(3), Co(1)–C(3) 1.985(4), Co(1)–C(4) 2.041(5) O(1)–C(2)–C(3) 116.9(4), C(2)–C(3)–C(4) 119.0(4)

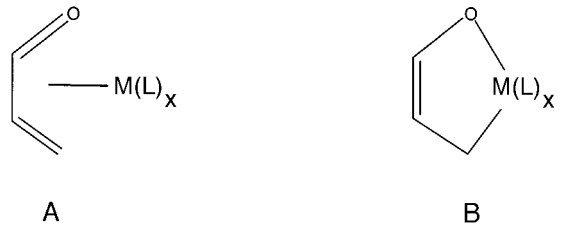
η^2-bonding of the [Co(η^5-C_5Me_5)] fragment to the keto group. The atoms C2, C3, C4, and O1 define an almost ideal plane. The bond length deviation Co–C2 [1.994(4) Å], Co1–C3 [1.985(4) Å], Co1–C4 [2.041(5) Å], and Co1–O [1.985(3) Å] is within experimental error, thus the bonding can be regarded as symmetrical η^4. However, the distance C3–C4 [1.437(6) Å] within the planar oxadiene unit is significantly longer than C2–C3 [1.396(6) Å]. This indicates an intermediate bonding situation between a pure π-coordination mode **A** and a metallacyclic type coordination **B** for **5** in the solid state (Figure 4). **A** and **B** represent the two extremes of coordination for an $M(L)_x$ fragment to a oxadiene ligand system.



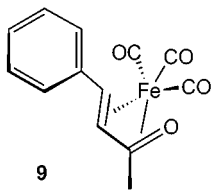


Figure 4. π-Metal coordination **A** versus σ-metallacycle formation **B** in an oxadiene complex

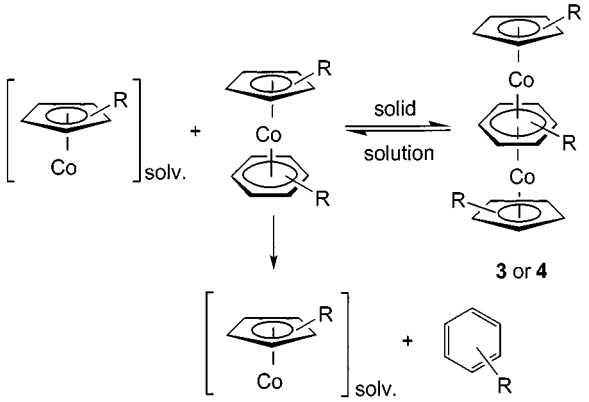
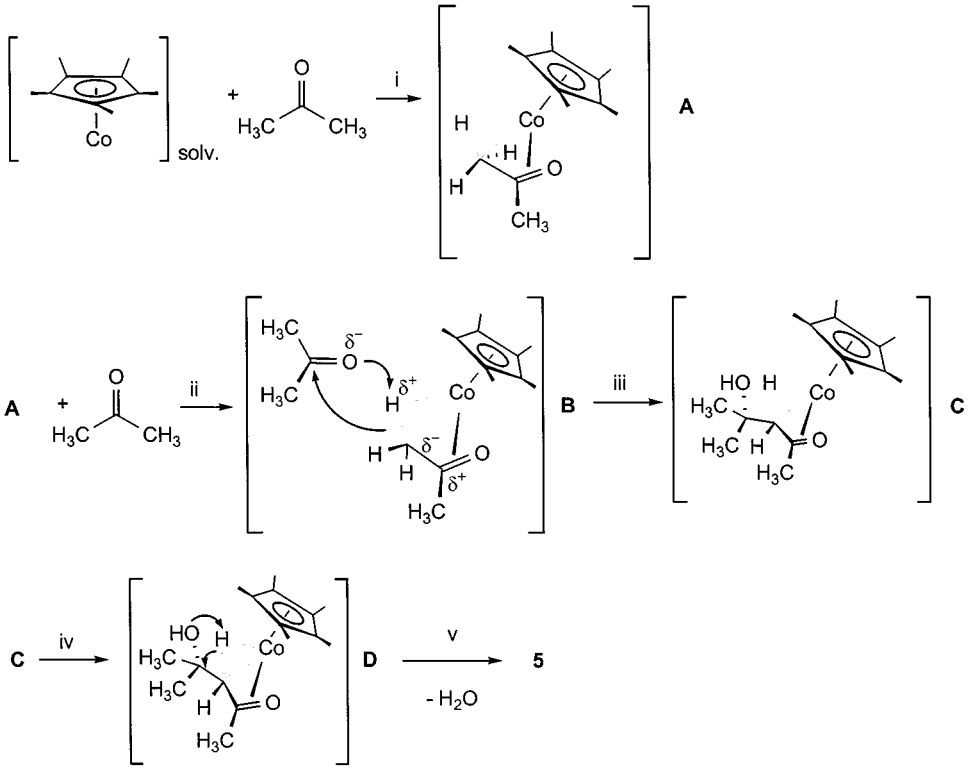


Discussion

Compounds **5–8** belong to a group of organometallic oxadiene complexes of which [(4-phenylbut-3-ene-2-one)-$Fe(CO)_3$] **(9)** represents the first example.[8] This and other enone complexes of a similar bonding type are accessible by standard complexation procedures.[9] In contrast, **5–8** are formed via a Co-mediated aldol-type coupling initiated by reactive 14 e [(η^5-Cp^R)Co] (R = Me_5, 1,2,4-tri-*tert*-butyl) fragments. Their formation from the triple-decker complexes **3** and **4** was verified by detailed mechanistic studies.[5,10] Complexes **3** and **4** are valuable sources of either one or two [(η^5-Cp^R)Co] fragments. The decay of **3** and **4** into [(η^5-Cp^R)Co] (R = Me_5, 1,2,4-tri-*tert*-butyl) fragments (Scheme 3) proceeds in any common donor solvent and is especially fast in the presence of ketones (e.g. acetone).

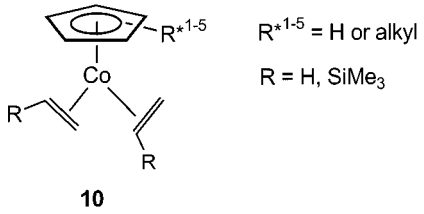
9

There has been quite intense research on the C–H bond activation by various transition metal complexes especially of the iron group triad which may be followed by functionalization of the activated substrate.[11] A process which combines C–H and C–C coupling reactions is the catalytic



Cp^R = Me_5 or 1,2,4,-tri-*tert*-butyl

Scheme 3. Solid state versus solution equilibrium of the triple-decker complexes **3** and **4**[10]



hydroacylation of olefins to form ketones at Rh^I centers studied by Bosnich.[12] However, such reactivity is usually not in the realm of first row transition metal chemistry and only a few cases are reported for organo cobalt complexes but to the best of our knowledge none so far for a C_{sp3}–H bond activation mediated by Co fragments. Extensive studies by Bergman[13], Jones,[14] and Graham[15] have established that 16 e species of the type [(η^5-R_5C_5)ML] (M = Rh, Ir) generated in situ, undergo facile oxidative addition reactions with the C–H bonds of saturated hydrocarbons and arenes. For Co, Brookhart[3a,16] demonstrated facile oxidative addition of aldehydes via the 16 e [(η^5-Me_5C_5)CoL] fragment. However, it is noteworthy with respect to our work that no activation of the less reactive acetone used as solvent is reported by these authors for the [(η^5-Cp^R)CoL] fragment which is derived from **1**. Wadepohl[17] observed facile C_{sp2}–H activation processes of cycloalkenes in the course of the formation of polynuclear [(η^5-Cp^R)Co]-based clusters which are derived from the Jonas complex [(η^5-Cp)Co(ethene)$_2$]. Crucial for the ability of Co centers to participate in C–H-bond activation processes is the generation of reactive sites, especially the formation of either coordinatively unsaturated, electron deficient 16 e [(η^5-Cp^R)Co(L_x)] or even 14 e [(η^5-Cp^R)Co] fragments.[18] C–H activation is assumed to be a significant step in the homo-aldol coupling reaction of the ketones under study herein. This is based on results obtained from the reaction of benzophenone with **3**. Benzophenone contains no acidic protons at the α-carbon position, thus no homo-aldol coupling can be observed with benzophenone which is recovered unchanged from a reaction with **3**. A possible reaction pathway invoking C_{sp3}–H bond activation of acetone, cyclohexanone and acetophenone as crucial reaction step, leading to the oxadiene cobalt complex **5–8** is outlined in Scheme 4 exemplified for the reaction of **3** and acetone.

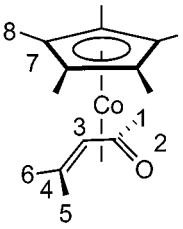
Reactive 14 e [(η^5-Me_5C_5)Co]$_{solv}$ fragments are generated from **3**. These can first coordinate the keto group of acetone followed by an activation of the hydrogen atoms of the neighboring α-methyl group giving intermediate **A**. Reaction of intermediate **A** with the "acidic" carbonyl carbon

Scheme 4. Proposed reaction scheme for the Co-mediated homo-aldol coupling of acetone

atom of another acetone molecule forms (ii), **B** results in a C–C coupling, leading to intermediate **C** (iii). Finally **C** can eliminate water (v), **D** to yield complex **5**. This elimination of water parallels the classical base catalyzed aldol type coupling reaction.[19]

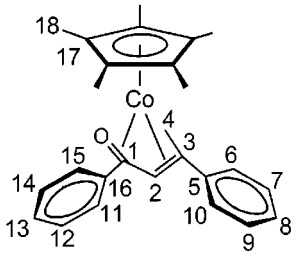
10

Conclusions



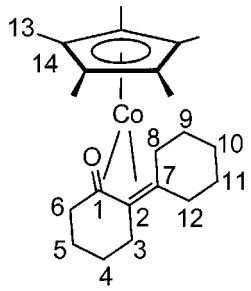
Our findings presented here indicate a pronounced reactivity enhancement of the arene triple-decker type complexes **3** and **4** over half sandwich complexes of type **10**, which in contrast to **3** and **4** do not show similar carbonyl coupling reactions and not even a reactivity towards acetone under similar conditions. This points to the fact that 14 e [(η^5-Cp^R)Co] fragments derived from the triple-deckers **3** and **4** in contrast to 16 e [(η^5-Cp^R)CoL] derived from **10** are able to activate ketones at their C_{sp3}-α-carbon atom under mild conditions. This is to the best of our knowledge the first C_{sp3}–H bond activation of ketones by an organocobalt compound leading to a C–C coupling under neutral and ambient conditions. It remains to be studied if this coupling proceeds regio- and/or stereospecifically with other ketones and if it can be tuned from stoichiometric to catalytic reactivity. Such investigations may open up new synthetic routes with respect to cobalt mediated cycloaddition reactions offering access to complex organic products as in the case of oxadiene complexes of Mo and W.[20]

Experimental Section



Compounds **3**[21] and **4**[5] were prepared according to published procedures. All ketones were commercial products (purity 99%), they were distilled prior to use and stored under nitrogen in the dark. – The NMR spectra were recorded on a Bruker AC 300 spectrometer (300 MHz for ^{1}H, 75 MHz for ^{13}C) and referenced against the residual protons of the deuterated solvent. – MS spectra were recorded on a MAT 8200 instrument under standard conditions (EI, 70 eV) and the fractional sublimation technique for compound inlet. – T_{vap} gives the individual vaporization temperature of the sublimation process during the MS experiment.

[(η^5-Me_5C_5)Co(η^4-4-methyl-2-oxopent-3-ene)] (5): Complex **3** (0.41 g, 0.85 mmol) was dissolved together with acetone (0.5 g, 8.6 mmol) in 30 mL of diethyl ether. Continued stirring for 24 hours resulted in a color change from red brown to greenish brown. Removal of all volatiles under vacuum gave a semi-solid residue which was dissolved in a minimum amount of pentane. Cooling to –78 °C afforded **5** (0.38 g, 1.31 mmol, 77%) as brown material. The same material resulted when the reaction was performed in acetone only. – MS (EI, 70 eV, T_{vap} 250 °C); *m/z* (%): 292 (100)



$[M^+]$, 277 (3) $[M^+ - CH_3]$, 249 (20) $[M^+ - CH_3CO]$, 209 (13) $[M^+ - (CH_3)_2C{=}CHCO]$, 192 (70) $[(Me_5C_5)Co]$. – ^1H NMR ($[D_6]$benzene, 300 MHz, 27 °C): δ = 0.95 (s, 3 H), 1.17 (s, 3 H), 1.50 (s, 15 H), 2.13 (s, 3 H), 4.03 (s, 1 H). – $^{13}C\{^1H\}$ NMR ($[D_6]$benzene, 75.1 MHz, 27 °C): δ = 9.4 (C7), 20.9 [C6(5)], 21.8 [C5(6)], 28.2 (C1), 77.9 (C3), 89.1 (C8), 127.2 (C4), 134.9 (C2). – IR (KBr): $\tilde{\nu}$ = 1473, 1448, 1431, 1385, 1351, 1364 (all vs, Me_5C_5), 1236, 1155, 1140, 1065, 1027, 911, 862, 602 (all vs) cm^{-1}. – $C_{16}H_{25}CoO$ (292.29): calcd. C 70.95, H 8.93, Co 20.16; found C 71.03, H 9.05.

[{(η⁵-*t*$Bu_3H_2C_5$)Co(4-methyl-2-oxopent-3-ene)}] (8): Synthetic procedure fas described for **5**; crystallization from pentane at –78 °C affords **8** as a brown solid. – MS (EI, 70 eV, T_{vap} = 120 °C); *m*/*z* (%): 390 (32) $[M^+]$, 333 (100) $[M^+ - t\text{Bu}]$, 57 (33) [*t*Bu]. – ^1H NMR ($[D_6]$benzene, 300 MHz, 27 °C): δ = 0.99 [s, 9 H, C11], 1.08 [s, 3 H, C5(6)], 1.18 [s, 3 H, C6(5)], 1.44 [s, 9 H, C7(9)], 1.77 [s, 9 H, C9(7)], 2.29 [s, 3 H, C1], 3.39 [s, 1 H, C13(14)], 4.14 [s, 1 H, C14(13)], 4.69 [s, 1 H, C3], in addition signals due to $[\{(\eta^5\text{-}t\text{Bu}_3H_2C_5)_2Co]$[22] were present in a 1:2 ratio. – $^{13}C\{^1H\}$ NMR ($[D_6]$benzene, 75.1 MHz, 27 °C): δ = 22.2 [C5(6)], 22.7 [C6(5)], 31.3 [C7(9,11)], 31.4 (C1), 32.7 [C9(7,11)], 33.2, 33.4, 35.1 [C11(7,9)], 76.3, 78.1, 79.21, 148.50 (CO). – IR (KBr): $\tilde{\nu}$ = 1486, 1458, 1391, 1242 (all vs, all *t*Bu), 1199, 1163, 1020, 990, 824, 668 (all m) cm^{-1}. – No satisfactory elemental analysis could be obtained due to trace amounts of $[\{(\eta^5\text{-}t\text{Bu}_3C_5)_2Co]$[22] already contained in the starting material **4**.

Reaction of 3 with Benzophenone: Complex **3** (0.31 g, 0.64 mmol) and benzophenone (0.46 g, 2.52 mmol) were dissolved in 30 mL of diethyl ether and stirred for 48 h. Although the color of the solution changed during this time from red-brown to orange-brown, removal of all volatiles gave mainly unchanged benzophenone. However, **3** was no longer present.

Keywords: Copper / Oxygen / Bioinorganic chemistry / Oxidations / Coordination chemistry

Copper(I) and copper(II) complexes of the ligand *N*,*N*′-bis[2′-(dimethylamino)ethyl]-*N*,*N*′-dimethylethane-1,2-diamine (Me_6trien) were synthesized and structurally characterized. In the solid state the complex cation $[Cu(Me_6trien)]^+$ (**1**) adopts a distorted tetrahedral configuration. Crystallography, EPR measurements, and UV/Vis spectroscopy indicate that the analogous copper(II) complex $[Cu(Me_6trien)Cl]^+$ has a square pyramidal geometry in the solid state as well as in solution. The reaction of **1** with dioxygen was investigated in different solvents. No copper dioxygen intermediates could be detected spectrophotometrically during these reactions.

Introduction

The dioxygen carrier protein hemocyanin (Hc) as well as many other metalloenzymes involved in important biological oxygen transfer reactions contain copper ions in their active sites.[1,2] A fundamental step in metalloenzyme redox reactions is the activation of dioxygen, upon binding at the active site, prior to the reaction with a substrate. Many low molecular weight model complexes for copper proteins have been synthesized and their reactions with dioxygen have been investigated.[1–23] A better understanding of these reactions will assist in the development of new homogeneous catalysts for selective oxidations under mild conditions.[24,25]

In contrast to enzymes, which react in aqueous solutions (although the copper ions are located in a relatively hydrophobic environment) at ambient conditions, the reactions of model complexes with dioxygen usually have to be investigated in organic solvents at low temperatures.[7,10,11,26] Therefore, in order to better model the reactivity of the biological systems, one should ideally study the oxidations of copper(I) complexes by dioxygen in water. This endeavor has been hampered because copper(I) complexes have a great tendency to disproportionate in aqueous solution. However, it is well-known that tertiary amine ligands can stabilize copper(I) in water; for example the copper(I) complex of the macrocyclic ligand 1,4,5,7,7,8,11,12,14,14-decamethyl-1,4,8,11-tetraazacyclo-tetradecane is stable towards oxidation in aqueous solution.[27] Tertiary amines in general have proven to be useful in stabilizing metal complexes in low oxidation states,[28,29] and the thermodynamic properties of a series of Cu^I and Cu^{II} complexes with the tertiary amines Me_6trien, L(1) and L(2) as ligands (Scheme 1) were investigated earlier.[27,29–34] If dioxygen is excluded, dilute solutions of the copper(I) complexes of these amines can easily be synthesized in water by a comproportionation reaction. As an example, the formation of the copper(I) complex of Me_6trien is shown in Equation 1.[31,35]

Scheme 1. Me_6trien = *N*,*N*′-bis[2′-(dimethylamino)ethyl]-*N*,*N*′-dimethylethane-1,2-diamine, L(1) = *N*,*N*′-bis(2′-(dimethylamino)-ethyl)-*N*,*N*′-dimethyl-propane-1,3-diamine, L(2) = *N*,*N*′-bis(2′-(dimethylamino)propyl)-*N*,*N*′-dimethylethane-1,2-diamine, Me_4en = tetramethylethylenediamine, Me_6tren = tris(2-dimethylamino-ethyl)amine), Me_5dien = 1,1,4,7,7-penta methyldiethylethylenetriamine

These solutions are stable under inert conditions, but are oxidized immediately to the analogous Cu^{II} complexes by dioxygen.[31,35] As part of our ongoing investigation of the reactions of copper(I) complexes with dioxygen[26,36–42] we therefore investigated these oxidations with the copper(I) complexes of the tertiary amines Me_6trien, L(1) and L(2) in more detail.

Results and Discussion

Synthesis and Crystal Structure of [Cu(Me_6trien)][$CuCl_2$] (1-[$CuCl_2$])

The comproportionation reaction shown in Equation 1 did not allow the synthesis of highly concentrated aqueous solutions of copper(I) complexes. Nevertheless, white crystals were obtained from the reaction of Me_6trien with CuCl in methanol. The molecular structure of the cation of this new complex is shown in Figure 1.

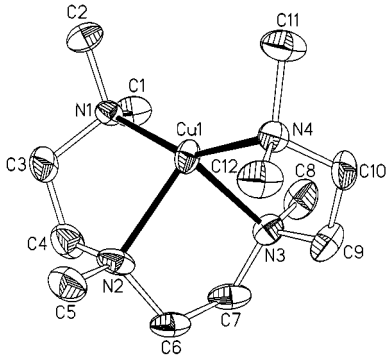

Figure 1. An ORTEP view of **1**; the thermal ellipsoids are at the 30% probability level and the hydrogen atoms are omitted for clarity

Although we had expected to obtain [CuMe_6trien]Cl (**1**-Cl) when mixing the ligand and CuCl in a stoichiometric ratio, it is obvious that the presence of the strong coordinating chloride prevents the reaction with the ligand from completing. Instead, **1**-[$CuCl_2$] is formed. In addition to the complex cation **1**, the asymmetric structural unit contains two halves of dichlorocopper(I) anions. Each of these holds a crystallographically imposed center of symmetry at the copper ion with one independent chloride. The anions are linear with Cu–Cl distances of 2.107(4) and 2.086(2) Å. These are very similar to the values that have been reported in the literature for $[CuCl_2]^-$ complexes.[43–46]

The tertiary amine tetramethylethylenediamine (Me_4en) can be regarded as one half of Me_6trien; the syntheses and structural characterizations of copper(I) complexes with Me_4en in a ratio of 1:2 were reported earlier.[28,45] The complex [Cu(Me_4en)$_2$][$CuCl_2$][45] (**2**-[$CuCl_2$]) is isostructural with **1**-[$CuCl_2$], and both complex cations adopt a distorted tetrahedral configuration. Nevertheless, close inspection of the Cu–N distances in **1** and **2** reveals significant differences. While for **2** the Cu–N bonds are consistent within the 3σ criterion [distances from 2.13(1) to 2.16(1) Å],[45] the two terminal Cu–N bonds in **1** are shorter [2.009(5) and 2.015(5) Å] than the other two Cu–N bonds [2.202(6) and 2.218(6) Å]. This clearly shows that Me_6trien in **1** is under more steric strain than Me_4en in **2**.

It is interesting to compare the molecular structure of **1** to the cation of the copper(I) complex [Cu(Me_6tren)]ClO_4 [**3**-ClO_4, Me_6tren = tris(2-dimethylaminoethyl)amine].[26] Me_6tren is an isomer of Me_6trien. In contrast to the distorted tetrahedral configuration of **1**, the geometry of **3** is best described as trigonal pyramidal (trigonal bipyramidal if the weakly coordinated perchlorate ion in the axial position is included); the copper ion is surrounded by the four amine nitrogen atoms with distances of 2.122(7) Å for the equatorial Cu–N and 2.200(14) Å for the axial Cu–N bonds.

Furthermore, bond lengths and angles in **1** are comparable to those of the complex cation of [Cu(Me_5dien)(CH_3CN)]ClO_4 (Me_5dien = 1,1,4,7,7-pentamethyldiethylethylenetriamine).[47] This compound [bond lengths for Cu–N = 2.04, 2.19, and 2.18 Å, and bond angles for N(1)–Cu–N(2) = 87.2(4) and N(2)–Cu–N(3) = 84.6(4)°] is even more distorted than **1**; its geometry was described as irregular. Me_5dien can be regarded as Me_6trien missing one arm, with the missing arm in the copper(I) complex being substituted by an acetonitrile molecule.

While it is possible to prepare dilute aqueous solutions of **1** by a comproportionation reaction (Equation 1), neither **2**, **3**, or [Cu(Me_5dien)]$^+$ could be obtained under the same conditions. However, we could prepare solutions of **3** in acetonitrile by a comproportionation reaction if Me_6tren was reacted with $CuCl_2 \times 2\ H_2O$ and copper powder under inert conditions. This reaction did not occur if Me_6trien or Me_4en were used as ligands under these conditions.

Reaction of 1 with Dioxygen

Thus far, the reactions of dioxygen with model compounds for copper proteins have been investigated mainly in organic solvents because of the disproportionation of Cu^I to Cu^0 and Cu^{II} in aqueous solutions.[1–4,24,48] For the same reason, knowledge on the kinetics of the oxidation of Cu^I complexes in water is rather limited; usually acetonitrile is chosen as a cosolvent.[39,49–55] Using the tertiary amines Me_6trien, L(1) and L(2) we tried to overcome these difficulties in order to study the formation of copper dioxygen adducts in aqueous solution, which would be similar to the oxidation of deoxy-Hc.

We successfully prepared dilute aqueous solutions of copper(I) complexes according to Equation 1. The kinetic behavior of all three amine complexes was similar; a representative example for the time resolved spectra of the reaction of dioxygen with **1** is shown in Figure 2

During the reaction, only the buildup of the product [Cu(Me_6trien)]$^{2+}$ (**4**) could be observed spectrophotometrically. No intermediate – neither a copper superoxo nor a peroxo complex – was detected. A change in pH from 7.0 to 10.0 did not alter the reaction rates significantly. Also, the rates did not depend on the concentration of dioxygen or the ionic strength. But they increased when the pressure was raised. However, these observations must be treated with caution since a detailed kinetic analysis was not possible. Computational fitting of the absorbance vs. time traces demonstrated that several reaction steps were in-

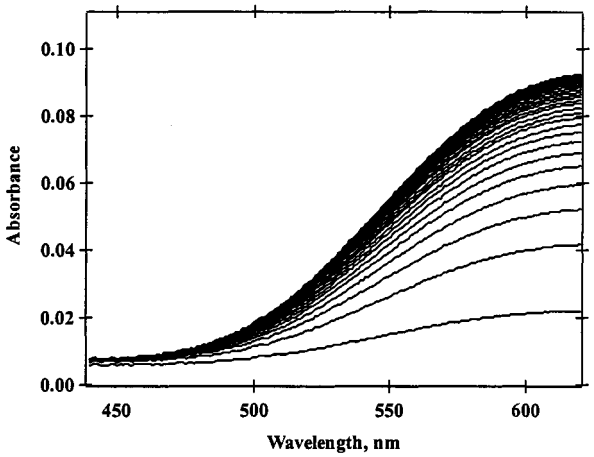

Figure 2. Reaction of **1** with dioxygen at 25 °C in water; the complex was prepared by the comproportionation reaction shown in Equation 1 ([**1**] = 0.5 mM, $[O_2]$ = 0.6225 mM, Δt = 20 s and pH = 8.0)

volved which presumably included higher order terms. To resolve these kinetic traces the spectra of intermediates and broader concentration windows for both reactants would be required.

This behavior was not unexpected because earlier investigations, mainly by Zuberbühler et al., showed that the kinetics of the reactions of copper(I) complexes with dioxygen in water are generally very complicated.[49–53,56–59] Most of these studies were performed in the presence of acetonitrile using the initial-rate treatment for the data analysis. Similar to our measurements, no copper peroxo intermediates were detected spectrophotometrically; often hydrogen peroxide was observed as a product.

To test whether hydrogen peroxide gave rise to additional reaction paths during the oxidation of **1** with dioxygen we investigated the reaction of H_2O_2 with **1** [as well as the copper(I) complexes of L(1) and L(2)]. The oxidation proceeded smoothly, but again complex kinetic behavior was observed and acceptable fitting of the data was not possible.

When small amounts of H_2O_2 were added to an aqueous solution of the copper(II) complexes, changes in the UV/Vis spectrum were not detected. When larger amounts were added (> tenfold excess) bubbles of dioxygen resulting from decomposition of H_2O_2 were observed.

A comparison between the oxidation of **1** and of deoxy-Hc shows clear differences in the reaction behavior. Deoxy-Hc reacts much faster than **1** (ca. 10000 times) with dioxygen (this rate is not dependent on pressure).[60,61] Furthermore, in contrast to the oxidation of **1**, the reaction of the protein is reversible. A major reason for these differences is the fact that the active site of deoxy-Hc is a preorganized dinuclear copper(I) site while **1** is mononuclear. In accordance with this, it has been shown earlier that a preorganized dinuclear copper(I) complex reacted extremely fast with dioxygen in organic solvents.[62] Presently, we are designing new dinuclear copper(I) complexes with tertiary amines in order to develop a system that will react similarly to the protein.

Recently, we found that **3** reacts reversibly with dioxygen in propionitrile or acetone at low temperatures, forming copper superoxo and peroxo complexes.[26][40] This reaction cannot be investigated in aqueous solution because disproportionation of **3** occurs. An investigation in methanol demonstrated that the peroxo complex is not stable in the presence of protons.[26]

The assumption that **1**, an isomer of **3**, would form dioxygen adducts in organic solvents as well, could not be confirmed. The only effect observed when **1** was reacted with dioxygen in methanol, acetone, or propionitrile was a decrease of the overall reaction rate compared to the studies in aqueous solutions. Lowering the temperature to –90 °C also slowed down the oxidation rate. No dioxygen intermediates could be observed spectrophotometrically under these conditions.

For comparison we also investigated the reaction of dioxygen with **2** (prepared in situ from $[Cu(CH_3CN)_4]PF_6$ and Me_4en) in propionitrile or acetone. The kinetic measurements did not provide evidence for the reversible formation of a peroxo intermediate and again an acceptable fitting of the data was not possible. However, it is known (also from kinetic studies) that peroxo and oxo-bridged dinuclear copper species are formed when copper(I) complexes of Me_4en, Et_4en and similar ligands (in a stoichiometric ratio of 1:1) are reacted with dioxygen in organic solvents.[63–70] Recently, a bis μ-oxo-copper complex and a trinuclear cluster with two μ_3-oxide ligands were obtained (and structurally characterized) from the reaction of copper(I) complexes of peralkylated-1,2-cyclohexanediamines with dioxygen.[18,71]

Synthesis and Crystal Structure of $[Cu(Me_6trien)Cl]ClO_4$ (4-Cl–ClO_4)

Copper(II) complexes of Me_6trien were easily prepared. The molecular structure was solved for **4**-Cl–ClO_4; its cation, with a square pyramidal geometry, is shown in Figure 3.

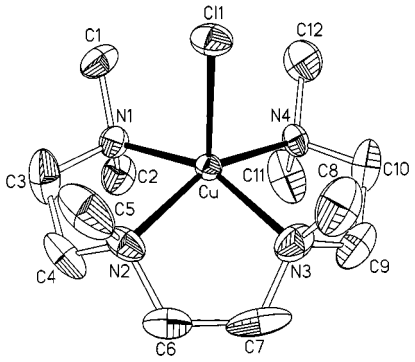

Figure 3. An ORTEP view of the cation of **4**-Cl–ClO_4; the thermal ellipsoids are at the 30% probability level and the hydrogen atoms are omitted for clarity

Structural characterization of copper complexes with Me_6trien or the related amines L(1) and L(2) (Scheme 1) was not available until recently, when the structure of the Cu^{II} complex $[CuL(1)](ClO_4)_2$ [L(1) = *N*,*N*′-bis[2′-(dimethylamino)ethyl]-*N*,*N*′-dimethylpropane-1,3-diamine]

Table 1. Selected bond lengths and bond angles with standard deviations in parentheses for **1**-[$CuCl_2$], **4**-Cl–ClO_4 and **5** × 2 H_2O

was reported.[72] L(1) differs from Me_6trien by an additional –CH_2– group. The bond lengths for Cu–N in **4**-Cl–ClO_4 (Table 1) are similar to those generally found for other tertiary amine copper(II) complexes, and differ only slightly from those for [CuL(1)]$(ClO_4)_2$.[72] The main difference between the two structures is that [CuL(1)]$(ClO_4)_2$ has a tetragonally elongated *trans*-CuN_4O_2 coordination sphere with Cu–O distances of 2.562(7) Å while **4**-Cl–ClO_4 is clearly square pyramidal with a Cu–Cl bond length of 2.420(2) Å. No interaction between copper and the perchlorate anion was observed. A direct structural comparison of [CuL(1)]-$(ClO_4)_2$ with **4**-$(ClO_4)_2$ was not possible since the obtained crystals of the latter were not suitable for X-ray crystallography. The Cu–N bond lengths in **4**-Cl–ClO_4 are slightly longer than those in the analogous copper complex [Cu(trien)(SCN)](SCN), with the nonmethylated amine [Cu–N bond length from 2.008(7)–2.030(5) Å].[73] Similarly, the Cu–N bond lengths of [CuL(1)]$(ClO_4)_2$ are longer than in the analogous nonmethylated complex [Cu(2,3,2-tet)]-(ClO_4), (Cu–N bond length from 2.016(6)–2.032(6) Å).[74]

The molecular structure of [Cu(Me_5dien)(H_2O)($OCMe_2$)] was described as distorted square pyramidal [bond lengths Cu–N = 2.036, 2.034, and 2.022 Å, and bond angles for N(1)–Cu–N(3) = 158.8(3) and O(1)–Cu–N(2) = 172.1(4)°] with the acetone molecule in the axial position [bond length Cu–O = 2.222(6) Å].[47] All Cu–ligand bond lengths in this complex are shorter than in **4**-Cl–ClO_4.

The bond lengths for the two isomeric complexes **4**-Cl–ClO_4 and **3**-Cl–ClO_4 [Cu–N_{axial} = 2.040(6) and Cu–$N_{equatorial}$ = 2.186(2) Å] are similar with the exception of the Cu–Cl bond length, which is shorter in **3**-Cl–ClO_4 [2.234(2) Å].[26] Bond angles are different for the two complexes. Complex **4**-Cl–ClO_4 has square pyramidal geometry, while the molecular structure of **3**-Cl–ClO_4 must be described as trigonal bipyramidal.

The different solid state geometries of the two complexes, **4**-Cl–ClO_4 and **3**-Cl–ClO_4, are retained in solution. An absorbance maximum for **4**-Cl–ClO_4 in water at 643 nm (ε = 248 $cm^{-1}M^{-1}$) is typical for a tetragonal distorted copper(II) complex; this coordination is further confirmed by the EPR spectrum [g values: $g(x)$ = 2.042, $g(y)$ = 2.066, $g(z)$ = 2.229; nuclear hyperfine coupling constants: $A(x)$ = 20 G, $A(y)$ = 18 G, $A(z)$ = 168 G]. The same behavior was observed for **4**-$(ClO_4)_2$ [λ_{max} = 643 nm (ε = 248 $cm^{-1}M^{-1}$); g values: $g(x)$ = 2.039, $g(y)$ = 2.064, $g(z)$ = 2.241; nuclear hyperfine coupling constants: $A(x)$ = 19 G, $A(y)$ = 26 G, $A(z)$ = 169 G]. These data are in accord with the results of our earlier measurements with solutions of **4**-SO_4.[29] Furthermore, they are comparable to those reported for [CuL(1)]$(ClO_4)_2$ as discussed above.[72] In contrast, **3**-Cl–ClO_4 represents a

typical trigonal bipyramidal complex with an absorbance maximum at 876 nm (ε = 447 $cm^{-1}M^{-1}$). The trigonal bipyramidal geometry was confirmed by EPR measurements [*g* values: *g*(x) = 2.170, *g*(y) = 2.187, *g*(z) = 2.010; nuclear hyperfine coupling constants: *A*(x) = 88 G, *A*(y) = 96 G, *A*(z) = 81 G]; the spectral parameters are consistent with those measured in the solid state.[75]

Synthesis and Crystal Structure of $[Cu_2(Me_4en)_2(OH)_2](ClO_4)_2 \times 2\ H_2O$ (**5** × 2 H_2O)

Crystalline salts of $[Cu(Me_4en)_2Cl]ClO_4$ could not be synthesized. This was expected since it was previously suggested that the Cu^{II} ion is too small to form a 1:2 complex with Me_4en.[76] When we reacted Me_4en with a mixture of $CuCl_2$ and $Cu(ClO_4)_2$ in the same way as **4**-Cl–ClO_4 was synthesized, we obtained $[Cu_2(Me_4en)_2(OH)_2](ClO_4)_2$ (**5**) instead. The molecular structure of **5** is shown in Figure 4 (bond lengths and angles are given in Table 1).

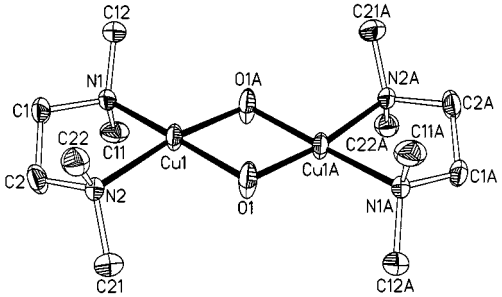

Figure 4. An ORTEP view of the cation of **5** × 2 H_2O; the thermal ellipsoids are at the 30% probability level and the hydrogen atoms are omitted for clarity

A crystal structure of **5** was described earlier by Pavkovik and co-workers.[77] It is not identical with the structure we report here because the latter holds two additional water molecules. This leads to significant differences in the dimensions and the volume of the unit cell. Furthermore, bond lengths and angles in the coordinated Me_4en of the complex described by Pavkovik (bond length C–C 1.377 Å and bond angles of 116.2° and 115.9° around the carbon atoms) do not correspond to the expected C–C bond lengths in this ligand. The authors do not discuss this, but possibly it is due to a disorder in the CH_2–CH_2 group. In contrast to these findings, we obtained a bond length of 1.493(3) Å for the two carbon atoms and bond angles of 109.2(5)° and 109.6(5)°, which are typical for a C–C bond in Me_4en.[78]

Conclusion

The study has shown that copper(I) complexes with related polymethylated aliphatic amines react very differently with dioxygen. Even though it was possible to oxidize **1** [or the copper(I) complexes of L(1) and L(2)] or **2** with dioxygen in different solvents, no dioxygen complexes could be observed as intermediates during these reactions. In contrast, it was shown earlier that the reaction of **3** with dioxygen at low temperatures in nitrile solvents allowed the observation of copper-superoxo and -peroxo complexes as intermediates.[26]

The reason for the different behavior towards dioxygen can be explained by the different geometries of the copper(I)/copper(II) complexes of these ligands. While **3** has a trigonal bipyramidal geometry; in solution a nitrile molecule replaces the weakly coordinated perchlorate,[26] **1** and **2** are best described as pseudo-tetrahedral. The coordination geometry of **3** already closely resembles that of the copper(II) complex, the peroxo product.[26] This is not the case for **1** and **2**. When the pseudo-tetrahedral **1** is oxidized it is turned into the distorted square pyramidal **4**. Evidence for the retention of the coordination geometry in solution is provided by UV/Vis and EPR spectroscopy. Thus, **1** has to undergo a geometrical rearrangement during the reaction with dioxygen; it may even be necessary for one arm of the four dentate ligand to open up before the copper(I) complex can react with dioxygen. Furthermore, the dioxygen ligand in a tetragonal elongated copper complex is kinetically more labile to substitution than in a trigonal bipyramidal geometry. This may be an important reason for the difference in behavior.[79]

It was also found that the nature of the ligand affects the stability of the copper(I) or copper(II) complexes. It was also responsible for the different behavior concerning comproportionation. Furthermore, the study clearly demonstrates that the reactions of copper(I) complexes with dioxygen vary with the solvent used.

The present findings fit well with recent reports on different copper(I) complexes that showed the influence of the ligand and the solvent on the formation of copper complexes with different peroxide binding modes; hereby an equilibrium of a peroxo complex with a bis μ-oxo copper species was discovered.[4,5,7,19–23] While it is still not possible to exactly predict the pathway for the reaction of a copper(I) complex with dioxygen, the findings presented here allow a better understanding of these reactions.

Experimental Section

General Remarks: Reagents and solvents used were of commercially-available reagent-grade quality. Distilled water was used for the preparation of aqueous solutions. The ligand Me_6trien was either synthesized as the free amine,[80] as a hydrochloride salt similar to a published procedure[81] or purchased from Aldrich. $[Cu(CH_3CN)_4]^+$ salts were synthesized and characterized according to literature methods.[82,83] CuCl was either synthesized according to a published procedure[84] or purchased from Aldrich. It was purified in a glove box under an inert atmosphere by washing the light green crystals with methanol until the solid was uniformly white. Preparation and handling of air-sensitive compounds was carried out in a glove box filled with argon (Braun, Garching, Germany; water and dioxygen less than 1 ppm). Air sensitive aqueous solutions were handled by Schlenk techniques or in a glove bag. UV/Vis spectra were measured on a CARY 5G UV/Vis-NIR spectrophotometer. Electron spin resonance measurements at X-band frequency were obtained using a Bruker EMX-113 spectrometer. Samples in methanol/DMF (3:1 mixtures) were measured at 100 K. Time resolved spectra of the reactions of dioxygen with copper(I)

[a] $R_1 = \Sigma| F_o| - | F_c || / \Sigma| F_o|$; $wR_2 = \{\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]\}^{1/2}$; $w = 1/[\sigma^2(F_o^2) + (q \times P)^2 + r \times P]$ where $P = (F_o^2 + 2F_c^2)/3$.

complexes were recorded on a modified Hi Tech SF-3 L low temperature stopped-flow unit (Salisbury, UK) equipped with a JM TIDAS 16–500 diode array spectrophotometer (JM, Aalen, Germany). Data fitting was performed using the integrated JM software Kinspec or the program Specfit (Spectrum Software Associates, Chapel Hill, USA). Dioxygen saturated solutions for the kinetic measurements were obtained by passing dioxygen through the solvent for 20 minutes described earlier.[7,10,11,26] Concentration of dioxygen was varied by mixing dioxygen saturated solutions with argon saturated solutions in syringes.

Caution! *Perchlorate salts are potentially explosive and should be handled with great care.*

[Cu(Me_6trien)][$CuCl_2$] (1-[$CuCl_2$]): In a glove box, a solution of Me_6trien (1 g, 4.34 mmol) in 10 mL of methanol was added, with stirring, to a suspension of CuCl (0.42 g, 4.34 mmol) in 10 mL of methanol. The solution turned slightly green and a small amount of red copper metal deposited. After filtration, diethyl ether was added to precipitate the complex. The white solid was filtered off and washed with diethyl ether. Drying in vacuum yielded 0.4 g (43%). – $Cu_2C_{12}H_{30}N_4Cl_2$: calcd. C 33.64, H 7.07, N 13.07; found C 33.89, H 7.14, N 13.13. Colorless crystals of **1**-[$CuCl_2$] were obtained from vapor diffusion of diethyl ether into a methanol solution of CuCl and Me_6trien.

[Cu(Me_6trien)Cl]ClO4 (4-Cl–ClO_4): To a solution of Me_6trien (1.152 g, 5 mmol) in 15 mL of methanol was added a solution of $CuCl_2 \times 2\ H_2O$ (0.42 g, 2.5 mmol) and $Cu(ClO_4)_2 \times 6\ H_2O$ (0.92 g, 2.5 mmol) in 20 mL of water. The solution was stirred for 15 minutes and filtered. After several days turquoise crystals formed suitable for X-ray analysis. Yield 1.4 g (65%). – $CuC_{12}H_{30}N_4Cl_2O_4$: calcd. C 33.61, H 7.05, N 13.06; found C 33.57, H 7.38, N 12.99.

[Cu(Me_6trien])(ClO_4)$_2$ [4-(ClO_4)$_2$]: To a solution of Me_6trien (0.576 g, 2.5 mmol) in 15 mL of methanol was added a solution of $Cu(ClO_4)_2 \times 6\ H_2O$ (0.92 g, 2.5 mmol) in 20 mL of water. Crystals immediately formed and more water was added, while heating the solution on a water bath, until most of the solid material was dissolved. After filtering the solution, deep blue crystals formed on standing for one day. Yield 0.65 g (50%). – $CuC_{12}H_{30}N_4Cl_2O_4 \times 1\ CH_3OH$: calcd. C 29.75, H 6.53, N 10.67; found C 29.67, H 6.52, N 10.93.

[Cu_2(Me_4en)$_2$($OH)_2$](ClO_4)$_2$ (5): To a solution of Me_4en (1.16 g, 10 mmol) in 25 mL of methanol was added a solution of $Cu(ClO_4)_2 \cdot 6H_2O$ (0.92 g, 2.5 mmol) and $CuCl_2 \times 2\ H_2O$ (0.42 g, 2.5 mmol) in 25 mL of water. The solution was stirred for 10 min and filtered. Soon afterwards crystals began to form which were suitable for X-ray analysis. Yield 0.55 g (35%). – $Cu_2C_{12}H_{38}N_4Cl_2O_{12}$: calcd. C 22.93, H 6.09, N 8.92; found C 23.03, H 5.73, N 8.83.

X-ray Crystallographic Study: Crystal data and experimental conditions for **1**-[$CuCl_2$], **4**-Cl–ClO_4 and **5** × 2 H_2O are listed in Table 2. The molecular structures are illustrated in Figures 1, 3, and 4. Selected bond lengths and bond angles with standard deviations in parentheses are presented in Table 1. Intensity data were collected with graphite monochromated Mo-K_α radiation (λ = 0.71073 Å). The collected reflections were corrected for Lorentz and polarization effects (but not for absorption). The structures were solved by direct methods [85,86] and refined by full matrix least squares methods on F^2.[85,87] Hydrogen atoms of **4**-Cl–ClO_4 were calculated for idealized geometries and allowed to ride on their preceding atoms, their isotropic displacement parameters were tied to those of the adjacent atoms by a factor of 1.5. For **1**-[$CuCl_2$] and **5** × 2

H_2O the positions of all hydrogen atoms were localized in a difference Fourier synthesis. The positions and a common isotropic displacement parameter were kept fixed during the refinement of **1**-[$CuCl_2$]. The high residual electron density of **1**-[$CuCl_2$] (3.426 e A^{-3}) is located near the copper atom (0.877 Å), and can be attributed to absorption effects. For **5** × 2 H_2O the positional parameters were refined with a fixed common isotropic displacement parameter. Crystallographic data (excluding structure factors) have been deposited with the Cambridge Crystallographic Data Center as supplementary publication no. CCDC-107373 (**1**-[$CuCl_2$]), –130856 (**4**-Cl–ClO_4), –130857 (**5** × 2 H_2O). Copies of the data can be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ (Fax: int. code + 1223/336-033; E-mail: deposit@ccdc.cam.ac.uk).

Acknowledgments

The authors gratefully acknowledge financial support from the Deutsche Forschungsgemeinschaft (S. S.), the Volkswagen-Stiftung (S. S.) and Deutscher Akademischer Austauschdienst (G. G.). Furthermore they would like to thank Dr. Jens Z. Pedersen (University of Odense, Denmark) for the EPR-measurements, and Prof. Dieter Sellmann and Prof. Rudi van Eldik (University of Erlangen-Nürnberg) for their support of this work.

Trinuclear Palladium(II) Complexes with 2-Hydroxy-4-methoxyacetophenone N^4-Dimethylthiosemicarbazone: Synthesis, Spectral Studies and Crystal Structure of a Tripalladium Complex

Dimitra Kovala-Demertzi,*[a] Nikolaos Kourkoumelis,[a] Mavroudis A. Demertzis,[a] John R. Miller,[b] Christopher S. Frampton,[c] John K. Swearingen,[d] and Douglas X. West[d]

Keywords: Palladium / S ligands / One-dimensional extended networks / Structure elucidation

The synthesis and spectral characterization of a new *triangular,* trinuclear palladium(II) complex with the dianion of 2-hydroxy-4-methoxyacetophenone N^4-dimethylthiosemicarbazone, 4MeOAp4Me$_2^{2-}$ is reported. The X-ray crystal structure determination of [Pd(4MeOAp4Me$_2$)]$_3$·DMSO shows it to contain a chair-type hexagon of alternating Pd and S atoms which form a molecular bowl. The crystal structure of $H_2$4MeOAp4Me$_2$ shows that it is the *E* isomer with respect to the imine bond of the thiosemicarbazone moiety.

Introduction

Metallic palladium, and its mononuclear and trinuclear palladium(II) compounds, are the catalysts of choice for many reactions.[1] For example, palladium acetate is employed as a homogeneous catalyst in a large number of organic syntheses.[2] Palladium acetate, $Pd_3(\mu\text{-}OAc)_6$, is trinuclear with a triangular arrangement of nonbonded palladium atoms,[3a] and $[Pd_3(\mu\text{-}O_2CMe)_3(\mu\text{-}MeSCHR)_3]$[3b] is a mixed-sphere palladium complex in which the solid state nuclearity and the palladium acetate structure are retained. The structures of both triangular and linear trinuclear palladium(II) complexes have been determined.[3]

Thiosemicarbazones of salicylaldehyde and 2-hydroxyacetophenone have recently attracted considerable attention because of their potential biological properties[4] and catalytic activity.[5] Binuclear copper(II)[6] and nickel(II)[7] complexes of these N^4-substituted thiosemicarbazones have phenoxide bridges. Recently, a trinuclear palladium complex[8] with sulfur bridges, and a trinuclear nickel(II) complex with both Ni–O,O–Ni and Ni–S,O–Ni bridging patterns have been reported.[9] Palladium(II) complexes of 2-formylpyridine, 2-acetylpyridine and 2-benzoylpyridine N^4-substituted thiosemicarbazones have also been studied with regard to their structural and biological properties, and some of them have shown remarkable antitumor activity.[10] Therefore we decided to expand our studies of palladium(II) complexes to include other potentially tridentate thiosemicarbazone ligands and report here the structure of [Pd(4MeOAp4Me$_2$)]$_3$·DMSO (where 4MeOAp4Me$_2$ is the dianion of 2-hydroxy-4-methoxyacetophenone N^4-dimethylthiosemicarbazone), which has Pd–S–Pd bridging. Also included is the crystal structure of the uncomplexed 2-hydroxy-4-methoxyacetophenone N^4-dimethylthiosemicarbazone, $H_2$4MeOAp4Me$_2$.

Results and Discussion

The negative charge distribution on the atoms in a molecule with several donor centers can be used to study the formation of donor-acceptor bonds with a metal. From our

[a] In the gas phase. – [b] The dipole moment and the ΔH_f are 4.62 Debye and 1.90 kcal/mol and 15.82 Debye and –24.97 kcal/mol for $H_2$4MeOAp4Me$_2$ in the gas state and in methanol, respectively. – [c] In CH_3OH. – [d] The dipole moment and the ΔH_f are 3.12 Debye and –17.88 kcal/mol and 7.43 Debye) and –223.65 kcal/mol for 4MeOAp4Me$_2^{2-}$ in the gas state and in methanol, respectively.

results the sulfur atom with maximum electron density and negative charge is predicted to be the preferred metal binding site; this agrees with the structural studies. The high effective charge and the high electron density value for the phenolic oxygen O1 and the imine nitrogen N1, also indicate strong electron-donor properties. The effective charges on the nitrogen atoms explain the conjugation of the thiosemicarbazonato moiety. The calculated molecular structures of the neutral $H_2$4MeOAp4Me$_2$ both in the gas phase and methanol are shown in Figure 1. The optimized geometry in methanol is *ZEZ* and is similar to that observed by X-ray diffraction for $H_2$4MeOAp4Me$_2$, the differences being attributable to packing effects. The data in Table 1 show the charge, electron densities for the various atoms, ionization potential, total dipole moment and enthalpy of formation of neutral $H_2$4MeOAp4Me$_2$ and the dianion 4MeOAp4Me$_2^{2-}$, in the gaseous state and in methanol, that have been calculated using MOPAC93.[11] As is evident from these data, the configuration in methanol is the preferred one over the configuration in the gas phase for $H_2$4MeOAp4Me$_2$ and 4MeOAp4Me$_2^{2-}$. The values obtained in methanol solution can be considered as a good approximation of the relative stability of the species in CH_3OH/H_2O. For 4MeOAp4Me$_2^{2-}$ a dramatic difference in stability is seen in methanol and in other polar solvents. The relative stability was computed as 23 and 206 kcal.mol^{-1} for the neutral and dianionic species, respectively.

The interaction of K_2PdCl_4 with $H_2$4MeOAp4Me$_2$ in basic solution (aqueous methanolic ammonia, pH ≈ 9) afforded the trinuclear complexes **1**, **2** and **3** according to the reactions:

$$K_2PdCl_4 \text{ with } H_2\text{4MeOAp4Me}_2 \longrightarrow [Pd(\text{4MeOAp4Me}_2)]_3 \cdot 3\,H_2O\ (\mathbf{1}) + 6\,KCl + 6\,HCl \quad (1)$$

$$\mathbf{1} \longrightarrow [Pd(\text{4MeOAp4Me}_2)]_3\ (\mathbf{2}) + 3\,H_2O \quad (2)$$

$$\mathbf{2} + DMSO \longrightarrow [Pd(\text{4MeOAp4Me}_2)]_3 \cdot DMSO\ (\mathbf{3}) \quad (3)$$

The stoichiometry of the complexes indicates that palladium(II) is coordinated by the doubly charged anion 4MeOAp4Me$_2^{2-}$ formed on the loss of the two protons from the phenolic oxygen and thioamide nitrogen, N2.

Molecular Structures

The structure of the uncomplexed thiosemicarbazone, $H_2$4MeOAp4Me$_2$, with two crystallographically different molecules per unit cell is shown in Figure 2 and the crystallographic data in Table 2, the bond lengths in Table 3 and bond angles in Table 4. The ligand has a *ZEZ* configuration about the bonds C1–C2, N1–C7 and N2–C8. N2H (and N5H) form an intermolecular hydrogen bond to a thione sulfur of an adjacent molecule, and the N2H (and N5H) groups of this molecule form hydrogen bonds to the sulfur atom of the first molecule, resulting in a dimer analogous to the dimer found for a number of heterocyclic thioureas.[12] The crystal packing is stabilized by intermolecular hydrogen bonds of the type C–H···O, O(3a)···H–C(2),[13] and by intramolecular hydrogen bonds. O1H and O3H form bifurcated intramolecular hydrogen bonds with their imine nitrogens, N1 and N3, and sulfur atoms, S1 and S2,

respectively. The various distances and angles for the intramolecular and intermolecular hydrogen bonding of both forms of $H_2$4MeOAp$_4$Me$_2$ are listed in Table 5.

The two crystallographical forms of the $H_2$4MeOAp$_4$Me$_2$ molecules have the greatest differences in the following bond lengths in the thiosemicarbazone moieties: S1–C10, 1.65(2) Å and S2–C22, 1.71(2) Å; N3–C10, 1.29(3) Å and N6–C22, 1.37(2) Å; and N1–C8, 1.27(2) Å and N4–C20, 1.32(2) Å. The bond angles in the thiosemicarbazone moieties having the greatest differences are N3–C10–S1, 126.6(12)° and N6–C22–S2, 122.2(11)°; N1–N2–C10, 121.4(12)° and N4–N5–C22, 116.8(13)° and C8–N1–N2, 121.1(11)° and C20–N4–N5, 115.4(13)°. The phenoxy and methoxy bond lengths and angles are also significantly different suggesting that the differences in the two $H_2$4MeOAp4Me$_2$ molecules are due to packing effects.

The palladium complex **3** crystallizes with a dimethyl sulfoxide solvate molecule. A perspective view of [Pd(4MeOAp4Me$_2$)]$_3$·DMSO with the atomic numbering scheme is shown in Figure 3. The crystallographic data are summarized in Table 2 and selected bond lengths and angles are listed in Table 3 and Table 4, respectively. The core of **3** consists of a six-membered ring of alternating Pd^{II} and S atoms in a chair-like configuration. The remaining two sites of each square planar Pd^{II} center are occupied by the imine nitrogen and the phenoxy oxygen. The dianionic, tridentate ligand has a *ZEZ* configuration about the bonds C1–C6, N1–C8 and N2–C10 for the oxygen, nitrogen and sulfur donor centers. The whole structure forms into a type of bowl with the (3Pd–3S) ring as the base. The bowl almost has a non-crystallographic threefold symmetry except for the disposition of the methoxyphenyl group, C(7)–O(2), on the rim. This type of core has been reported previously for palladium complexes.[14] The dihedral angles between the planes of the two chelate rings (Pd–S–C–N–N) **A** and (Pd–N–C–C–O) **B** are 8.73(13), 0.58(15) and 4.39(17)° for Pd1,

[a] Symmetry operations: i: 1 – *x*, 2 – *y*, –*z*; ii: *x*, 1 + *y*, *z*; iii: 1 – *y*, –*z*. – [b] Symmetry operations: i: –1 + *x*, *y*, *z*; ii: –1 + *x*, –1 + *y*, *z*; iii: –*x*, 2 – *y*, 1 – *z*; iv: 1 + *x*, *y*, *z*; v: *x*, –1 + *y*, *z*. Cg1 and Cg3 are referred to the centroids Pd1–S1–C10–N2–N1 and Pd3–S3–C34–N7–N8, respectively, and Cg6 and Cg9 are referred to the centroids Pd2–N4–C20–C18–C13–O3 and C13–C14–C15–C16–C17–C(18), respectively.

Pd2 and Pd3, respectively, indicating that there is some deviation from planarity by the ligands. The plane **A** of Pd1 is tilted by 83.46(14) and 73.58(14)° with respect to the plane **A** of Pd2 and Pd3, respectively.

The distances between the palladium centers [Pd1–Pd2, 3.4118(5) Å; Pd2–Pd3, 3.4746(5) Å; and Pd1–Pd3, 3.6528(5) Å] indicate that there is no direct bond between the palladium atoms. However, a very weak interaction can be postulated in agreement with the reported values for polynuclear palladium complexes [2.549(2)–3.539(1) Å].[3][8][15] The three bond angles involving bridging sulfur atoms are as follows: Pd1–S1–Pd2, 95.29(4)°; Pd2–S2–Pd3, 104.18(5)°; Pd1–S3–Pd3, 98.43(4)°. The Pd–N bond lengths range from 2.004(4) to 2.012(4) Å, the Pd–O distances from 1.987(4) to 2.000(3) Å, and the Pd–S distances from 2.2536(12) to 2.3579(12) Å and are similar to those found in other palladium complexes.[8][10] The greater *trans* influence of the iminic nitrogens can be observed in the lengthening of the *trans* Pd–S distances [2.3579(12)–2.3347(13) Å] with respect to the Pd–S distances *trans* to the phenoxy oxygens [2.2536(12)–2.2713(12) Å]. A comparison of the palladium-donor atom and thiosemicarbazonato moiety bond lengths of **3** and a related palladium complex[8] is shown in Table 6. The negative charge of the dianionic ligand is delocalized over the thiosemicarbazonato moiety and the S–C bond lengths are consistent with increased single bond character, while the imine C–N distances and both thioamide C–N distances indicate considerable double bond character.

The C–S bond length increases from an average of 1.68(2) Å in $H_2$4MeOAp4Me$_2$ to an average of 1.803(5) Å in **3** consistent with this bond's change from a conventional double bond to a single bond. Coordination of the imine nitrogen and phenoxy oxygen causes much smaller changes in the C–N and C–O bond lengths. The thioamide C–N bond (e.g., N2–C10), which formally changes from a single bond to a double bond on coordination, decreases from an average of 1.37(2) Å in $H_2$4MeOAp4Me$_2$ to 1.299(7) Å in **3**. The other thiosemicarbazone bonds' average distances also undergo modest changes on coordination, but the changes are not more than three times the combination of the estimated standard deviations of the bonds in the two compounds. The average bond angles also change on coordination to the palladium centers with most bond angles in the thiosemicarbazone moiety and the phenoxy function increasing or decreasing by at least 5°.

The dimethyl sulfoxide molecule appears to be linked via a three-center hydrogen bond (i.e., bifurcated). This bifurc-

[a] Ref.[6], where Ap4E is the dianion of 2-hydroxyacetophenone N^4-ethylthiosemicarbazone. – [b] This work.

ated hydrogen bond involves O7 on dimethyl sulfoxide and the hydrogens on the carbon atom of one trimer, C17···H17A, as well as C31′···H31B′ of an adjacent trimer.[13] Further C–H π interactions[13b] and intramolecular bonds stabilize this structure. Although it is remarkable that there are many contacts, and of different types, the interactions themselves are consistent with the known guidelines for hydrogen bond formation.[13c] For $[Pd(MeOAp4Me_2)]_3$·DMSO, molecular recognition of the hydrogen bonds leads to aggregation and a supramolecular assembly. These interactions are listed in Table 6 and are shown in the packing diagram in Figure 4. The high effective charge on methoxy oxygen atoms and on the sulfoxide oxygen atom help to rationalize the extended network of hydrogen bonding contacts in **3**.

Spectroscopy

The significant IR bands of $H_2$4MeOAp4Me$_2$ and the three forms of the palladium(II) complex are close in energy to those found in other compounds with tridentate coordination.[9][16] The bands assigned in the spectrum of $H_2$4MeOAp4Me$_2$ shift in the spectrum of the palladium complexes as follows: ν(C=N), from 1556 cm^{-1} to 1541 cm^{-1}; ν(NN), from 1026 cm^{-1} to 1089 cm^{-1}; and ν(CS) (i.e., thioamide IV), from 836 cm^{-1} to 787 cm^{-1}. The palladium-donor atom stretching frequencies are as follows: ν(PdN, imine), 511 cm^{-1}; ν(PdS), 387 cm^{-1}; and ν(PdO), 338 cm^{-1}. Complex **2** exhibits a broad band at 3400 cm^{-1} attributed to the presence of lattice water. The DMSO adduct **3** shows a very strong S–O stretching vibration at 1023 cm^{-1}. This frequency is lower than that for free DMSO (1100–1055 cm^{-1}), suggesting the interaction of DMSO with the trimer complex through oxygen[16] as detailed above.

The main differences between the ^{1}H NMR spectrum of the free $H_2$4MeOAp4Me$_2$ and the trimer complexes are the disappearance of the downfield O1H (and O3H and N2H and N5H) signals. These changes confirm that loss of both hydrogens and metallation occurs, and that the structure of the complex in the solid state persists in $(CD_3)_2SO$ and $CDCl_3$ solutions. The appearance of the OH peak downfield at δ = 13.191 and 12.525 in $(CD_3)_2SO$ and $CDCl_3$, respectively, for $H_2$4MeOAp4Me$_2$ indicates that OH is hydrogen-bonded to $(CD_3)_2SO$ and intramolecularly hydrogen-bonded to the imine nitrogen N1 (and N4) in $CDCl_3$. The position for N2H (and N5H) is downfield at δ = 9.780 and 10.962 in $(CD_3)_2SO$ and $CDCl_3$, respectively, suggesting that this proton is also involved in hydrogen bonding, with more interaction of this proton in $CDCl_3$ solution.[16b] This suggests that a tautomer may exist in solution, similar to that found in 2-acetylpyridine N^4-substituted thiosemicarbazones,[17] and more recently in 2-pyridineformamide N^4-thiosemicarbazones.[18] This would involve N2H (and N5H) shifting to N1 (and N4) to form a bifurcated hydrogen bond with the phenoxy oxygen and thione sulfur.

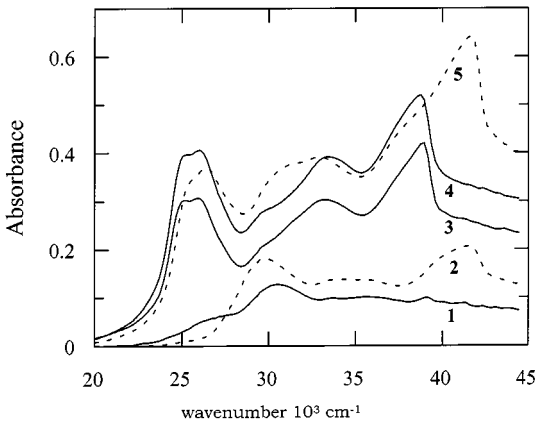

Figure 5. Electronic absorption spectra of $H_2$4MeOAp4Me$_2$; in DMSO (1); in $CHCl_3$ (2); of [Pd(4MeOAp4Me$_2$)]$_3$·3H_2O in DMSO (3); of [Pd(4MeOAp4Me$_2$)]$_3$ in DMSO (4) and of [Pd(4MeOAp4Me$_2$)]$_3$·3H_2O in $CHCl_3$ (5)

The bands of the $H_2$4MeOAp4Me$_2$ at ca. 30000 and 33500 cm^{-1} in the UV/Vis spectrum are due to n → π* transitions of the imine portion of the TSC moiety, and the aromatic ring, respectively.[19] The energies of these two bands are affected by changes in organic solvents due to differences in the mode of hydrogen bonding. The electronic spectrum of the trimer is shown in Figure 5 . Three spin-allowed singlet–singlet d → d transitions are predicted in the visible region of square planar complexes of palladium(II). However, strong charge transfer transitions for [Pd(4MeOAp4Me$_2$)]$_3$ interfere and prevent the observation of all the expected bands. The band at ca. 25000 cm^{-1} is intense and is assigned to a HOMO → LUMO transition.

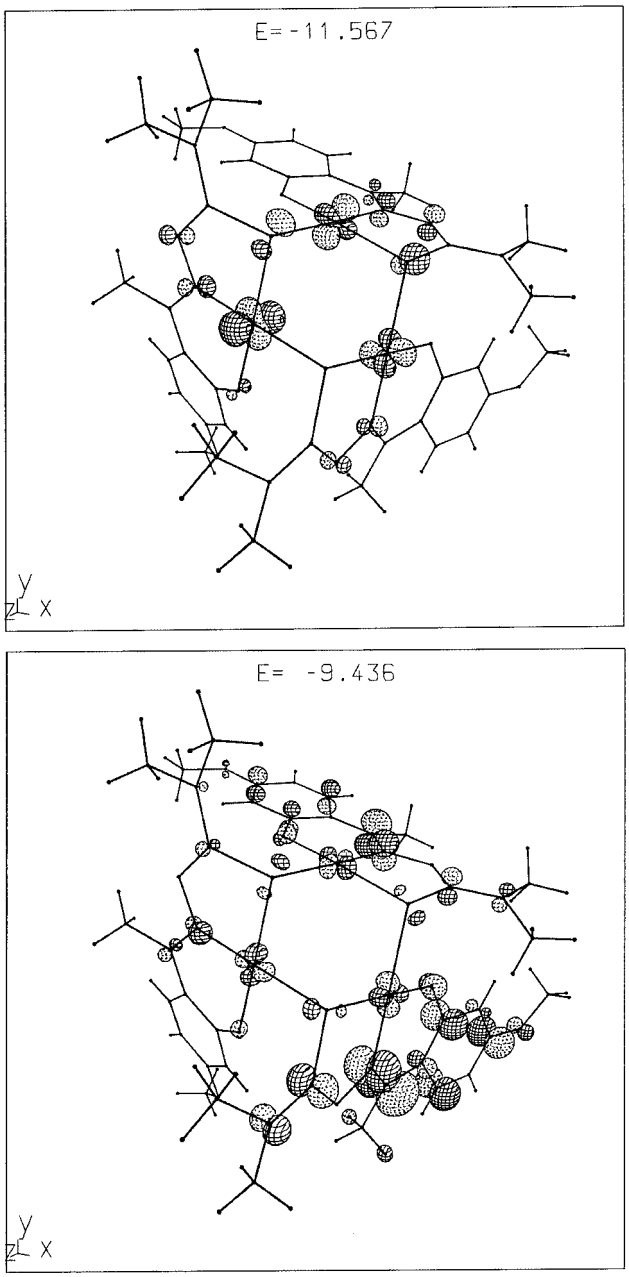

Figure 6. Representation of lowest unoccupied molecular orbital (LUMO: bottom) and highest occupied molecular orbital (HOMO: top) for complex [Pd(4MeOAp4Me$_2$)]$_3$·DMSO

The HOMO and LUMO orbitals are "d"- and π-centered on the metal and on the ligand, respectively. The bands at 25000 and 26000 cm^{-1} are assignable to a combination of d → d and charge transfer transitions.[19] The band at ca. 33000 cm^{-1} is due to the n → π* transition of the thiosemicarbazone moiety (imine, thioamide) and charge transfer involving the TSC moiety (L → M). The maxima at 20000–22000 cm^{-1} and at 26000–28000 cm^{-1} are affected by the nature of the solvent consistent with them having charge-transfer character.

The trinuclear complex was studied by the extended-Hückel method using the CACAO PC Beta-Version 5.0 package.[20] The molecular geometry was established from the crystallographic coordinates of the trinuclear complex. The highest occupied molecular orbital (HOMO; –11.567 eV, Figure 6) is mostly composed of dz2, dxy and dyz and has high percentages of the dz2 (25 %) orbital from Pd1, the dxy (8 %), dyz (10 %) orbitals from Pd2, and dxy (8 %) and dyz (9 %) from Pd3; the lowest unoccupied orbital (LUMO; –9.436 eV, Figure 6) is mostly composed of px orbitals from C32 (–18%), C29 (5%) and N7 (9%). The HOMO's energy is well isolated, strongly suggesting that the assignment of the lowest energy electronic transition can unambiguously be assigned to the computed HOMO–LUMO. This is experimentally addressed. The HOMO–n (n = 1–10) levels are similar in energy, and are more stabilized by ca. 0.5 eV relative to the HOMO. The molecular orbital $HOMO_{-10}$ has components of dxz (20%) from Pd1, dyz (–5%) from Pd2 and p (π) atomic orbitals from N2, N3, N1, C6. This is consistent with a back donation from the metal to π* orbitals from the ligand moieties.[19d]

Experimental Section

General: Solvents were purified and dried according to standard procedures. The palladium(II) complexes were analyzed for C, H and N at the European Environmental Research Institute (Ioannina). Infrared and far-infrared spectra were recorded with a Perkin–Elmer Spectrum GX FT-IR spectrophotometer using KBr (4000–400 cm^{-1}) and polyethylene pellets (400–40 cm^{-1}). Electronic spectra were recorded on a JASCO V-570 spectrophotometer UV/Vis/NIR.

Preparation of the Compounds: 2-Hydroxy-4-methoxyacetophenone N^4-dimethylthiosemicarbazone ($H_2$4MeOAp4Me_2), was prepared by stirring at room temperature a 1:1 ethanol solution (50 mL) of 2-hydroxy-4-methoxyacetophenone (0.05 mol) and N^4-dimethylthiosemicarbazide (0.05 mol) with 3 drops of conc. H_2SO_4 added. N^4-dimethylthiosemicarbazide was prepared following the procedure described by Scovill.[21] The complex Pd(4MeOAp4Me_2)]$_3$·3H_2O (**1**) was prepared directly from the reaction of K_2PdCl_4 (0.392 g, 1.2 mmol) in H_2O (5 mL) and $H_2$4MeOAp4Me_2 (0.267 g, 1 mmol) in CH_3OH (5 mL), with the pH adjusted to ca. 9 with a few drops of a 1.5 M NH_3 solution. After stirring for 24 h at room temperature, the resulting brown powder was filtered off, washed with cold methanol and ether and dried in vacuo over silica gel (yield 70%). – [Pd(MeOAp4Me_2)]$_3$·3H_2O (1169.14): calcd. C 36.98, H 4.39, N 10.78, S 8.23; found C 36.80, H 4.27, N10.95, S 8.40. – Compound **2** was obtained by drying the trihydrate at 40° C initially, and finally at 80° C for 1 h over P_4O_{10} to afford the dehydrated complex [Pd(MeOAp4Me_2)]$_3$. – **2** (1017.07): calcd. C 38.78, H 4.04, N 11.30, S 8.63; found C 38.90, H 4.00, N 11.20, S 8.73. – Slow evaporation of **1** from dimethyl sulfoxide solution yielded dark red crystals of the complex [Pd(MeOAp4Me_2)]$_3$·DMSO (**3**) suitable for X-ray structural analysis. – **3** (1193.40): calcd. C 38.25, H 4.30, N 10.56, S 10.75; found C 38.30, H 4.35, N 10.48, S 10.60.

Crystal Structure Determination of H24MeOAp4Me2 and Complex 3: Crystals of $H_2$4MeOAp4Me_2 were grown by slow concentration of a 1:1 by volume mixture of anhydrous ethanol/acetone and the selected crystal mounted on a glass fiber and used for data collection on a Nonius MACH3 diffractometer. The structure was solved by direct methods[22a] that revealed the positions of all non-hydrogen atoms, and refined on F by a full-matrix least-squares procedures using anisotropic displacement parameters.[22b] The hydrogens attached to nitrogen and oxygen were located by difference Fourier maps and were refined isotropically (U_{iso} = 0.05 Å^2). The remaining hydrogens were located in their calculated positions (C–H 0.96 Å). – A red needle-like crystal, (ca. 0.02 × 0.04 × 0.40 mm) of **3** was mounted on a glass fiber and analyzed with a Bruker SMART 1 K CCD diffractometer equipped with an Oxford Cryosystems Cryostream cooler,[23a] running at 123 K. The data collection nominally covered a sphere of reciprocal space by a combination of five sets of exposures; each exposure set had a different φ angle for the crystal and each exposure covered 0.3° in ω in 30 s. The crystal-to-detector distance was 4.909 cm. Coverage of the unique set was over 98% complete to φ = 26.37° (data truncated at 0.80Å). Data reduction was performed with the program SAINT V4.05.[23b] Crystal decay was monitored by repeating the first 50 frames of data at the end of data collection and analyzing the duplicate reflections. Area detector scaling and absorption corrections were performed by SADABS.[23b] This correction was used to scale the frames of data and to correct for absorption of the primary beam by the crystal support using the method of Blessing.[23c] A correction for absorption of the primary beam by the crystal was not applied. All calculations were performed with SHELXTL.[23d] Crystallographic data for $C_{36}H_{45}N_9O_6Pd_3S_3·C_2H_6OS$ (CCDC-132172) and $C_{12}H_{17}N_3O_2S$ (CCDC-132400) have been deposited with the Cambridge Crystallographic Data Centre. Copies of available material can be obtained, free of charge, on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Calculations: A computational study with a PM3 parameterization scheme[11a] utilizing the eigenvector-following algorithm,[11b] as implemented in the MOPAC93 program,[11c] was used to investigate the prevailing isomer of free $H_2$4MeOAp4Me_2, the monodeprotonated anion, H4MeOAp4Me_2^-, and the diprotonated anion, 4MeOAp4Me_2^{2-}, in the gas phase and simulated solvent bulk (COSMO model[11d]). The complex molecule **3** was studied by the extended-Hückel method using the CACAO PC Beta-Version 5.0 package. The crystallographic coordinates of the complex were used.[20]

Adducts of *o*-Silaborane With Water and Methanol

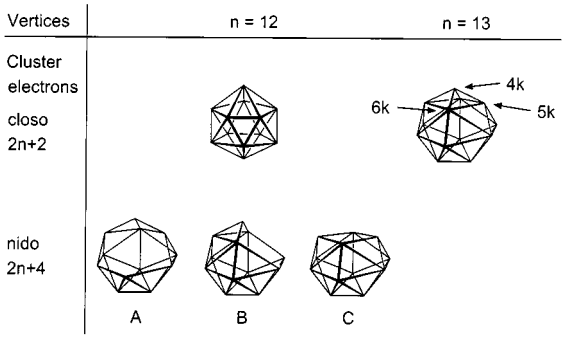
Lars Wesemann,*[a] Michael Trinkaus,[b] Yves Ramjoie,[b] Beate Ganter,[b] Ulli Englert,[b] and Jens Müller*[b]

Keywords: Silaboranes / Cluster compounds / Siloxanes / Silicon / Boranes

The synthesis of alkoxide adducts of *o*-silaborane $[(TMPDAH)_2][(Me_2Si_2B_{10}H_{10})_2O]$ (**3**) and $[TMPDAH][(Me_2Si_2B_{10}H_{10})OMe]$ (**4**) are presented (TMPDA = tetramethylpropylenediamine). For both silaborate clusters **3** and **4** the results of the NMR spectroscopic investigations together with the X-ray single crystal structure determinations are discussed. The geometries of ab initio calculations (HF and B3LYP methods) on the hydroxide adduct $[Si_2B_{10}H_{12}(OH)]^-$ are compared with the structures of **3** and **4**. The dynamic behaviour of the adducts **3** and **4** in solution is discussed with respect to the calculated energy profile for the rotation of the HSi(OH) group.

Introduction

Wade and Williams have developed a classification for borane and heteroborane clusters into groups of different numbers of skeleton electron pairs depending on the number of skeleton atoms.[1,2] On the basis of these rules the structure of a cluster with known composition can often be predicted. A *closo* cluster with n vertices can be transformed into a *nido* cluster by increasing the number of cluster electrons by two. The geometry of this *nido* cluster can be derived from the skeleton of the next higher *closo* cluster ($n + 1$ vertices). Figure 1 shows the thirteen vertex deltahedra and the three primary fragments that result from the removal of a single 4k, a selected 5k, and one of the 6k vertices.



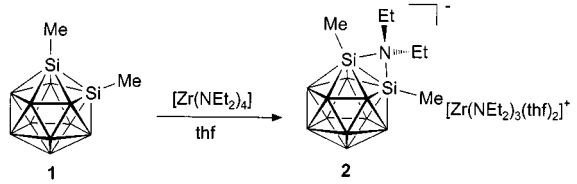


Figure 1. *closo* Clusters with 12 and 13 vertices and *nido* clusters with 12 vertices; in A the 6k vertex, in B the 5k vertex, and in C the 4k vertex is removed

Hawthorne et al. have found a cluster-opening reaction with the reduction of *o*-carborane (geometry A).[3] Examples for geometry B have been published by Paetzold et al. with the adducts of aza-*closo*-dodecaborane(12).[4] So far, 12-vertex *nido* clusters with geometry C, exhibiting a quadrangle as the open cluster face, are unknown.[1] However, *nido* 12-vertex clusters with a geometry other than the primary fragments are known. In the case of the fluxional tetracarbon cluster $R_4C_4B_8H_8$ a variety of cluster geometries has been determined by crystal structure analysis or NMR spectroscopy.[5–7] Depending on the substituents present at the carbon vertices, cluster skeletons exhibiting two neighboring quadrangles or a hexagonal open face have been characterized in the solid state. Adducts of *closo*-heterodicarbaboranes ($MC_2B_9H_{11}$ or $MC_2B_4H_6$) show opened-cluster frameworks, which have been considered as slip distorted geometries with respect to the central heteroatom.[8]

The reaction of the *commo*-cluster $[Si(C_2B_9H_{11})_2]$ with PMe_3 or pyridine results, in both cases, in an opened-cluster geometry.[9] Interestingly, the phosphane removes a boron vertex from the framework and pyridine attacks the silicon resulting in η^1-coordination of the silicon at the cluster.
The first studies on the nucleophilic degradation of 1,2-dimethyl-1,2-disila-*closo*-dodecaborane(12) (*o*-silaborane) (**1**)[10] have resulted in the isolation of a surprising adduct between the *closo*-cluster and dialkylamides.[11] Adducts of this type have been isolated in the case of dimethyl- and diphenyl-*o*-silaborane.[11,12] Regarding the cluster electron count of these adducts, an opened *arachno*-cluster geometry is expected according to the cluster rules. Surprisingly, the adducts show a structure which is closely related to the starting material and is not in agreement with Williams topological systematics (Scheme 1).

Scheme 1

The crystallographically determined structure and the NMR chemical shifts (^{11}B, ^{29}Si) of **1** and **2** have been repro-

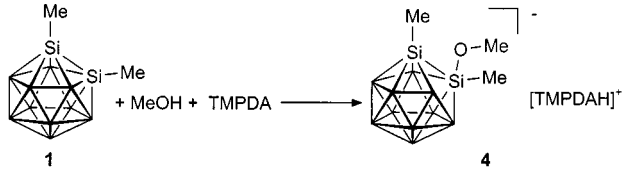
duced by ab initio calculations. The LUMO of the *o*-silaborane should be responsible for the interesting acceptor abilities. This empty orbital is essentially concentrated on the two silicon atoms and shows bonding character with respect to the silicon–silicon distance. In order to get further insight into the acceptor abilities of *o*-silaborane we studied the reaction with other nucleophiles.

Results and Discussion



Synthesis, NMR Spectroscopy, and X-ray Diffraction Studies

In this publication we present oxide *o*-silaborane adducts exhibiting a hitherto unknown cluster geometry. By accident we found a reaction of the *closo*-silaborane with water. During our studies on the reactivity of the icosahedral cluster **1** towards tertiary amines, the remaining moisture in the inert gas was found to be the source of water. One equivalent of *o*-silaborane (**1**) reacts with water and one equivalent of tetramethylpropylenediamine (TMPDA) to give the oxide adduct **3** in quantitative yield (Scheme 2).

Scheme 2

The silaborane could be completely recovered after addition of aqueous HCl to a THF solution of the dianion **3**, indicating the reversibility of this acid-base reaction. Exclusion of water from the inert gas enabled us to introduce other less-acidic reagents into this reaction. Thus methanol reacts with TMPDA and one equivalent of *o*-silaborane to give the methoxide adduct **4** (Scheme 3). This adduct formation is also reversible, as is shown by the complete recovery of *o*-silaborane after acidification of a solution of the methoxide adduct **4**.

Scheme 3

Compounds **3** and **4** have been characterized by elemental analysis, multinuclear/multidimensional NMR spectroscopy, and X-ray structure analysis. In both cases crystals suitable for X-ray diffraction were obtained by slow diffusion of hexane into a THF solution of the salts **3** and **4**. Perspective views of the cluster anions of **3** and **4** are depicted in Figure 2 and Figure 3, respectively. Selected interatomic distances are listed in Table 1 and Table 2.

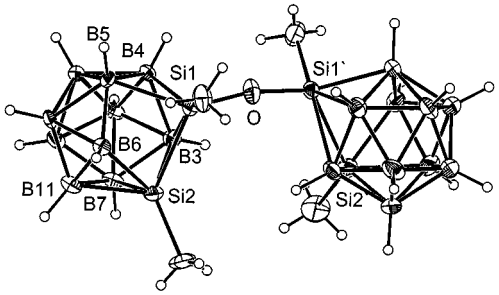


Figure 2. Structure of the anion of **3** in the crystal (PLATON representation,[16] ellipsoids at 30% probability level)

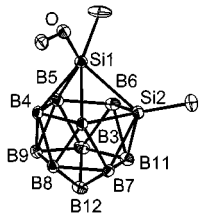

Figure 3. Structure of the anion of **4** in the crystal (PLATON representation,[16] ellipsoids at 30% probability level)

Table 2. Selected bond angles in the anion of **3** and **4** [°]

	Anion of **3**	Anion of **4**
Si2–Si1–O	120.3(1), 121.0(1) 156.8(1), 123.3(1)	125.0(1)
Si–O–Si	164.2(2), 154.6(2)	–
Si–O–C	–	132.3(3)
Si1–Si2–C2	127.4(3), 127.3(2) 123.4(3), 128.9(1)	126.6(2)
Si2–Si1–C1	114.1(3), 113.7(3) 87.7, 123.3(3)	109.1(3)
O–Si1–B12–B9	84.1(4), 87.2(3), 33.3(4), 98.4(4)	80.9(3)

Two equivalents of the salt $[(TMPDAH)_2][(Me_2Si_2B_{10}H_{10})_2O]$ (**3**) were found to crystallize independently in the asymmetric unit, thus allowing the interatomic parameters of two different Si–O–Si bridged clusters to be discussed. The variations of the Si–O–Si angles [Si1–O1–Si3 164.2(2), Si5–O2–Si7 154.6(2)] and the Si–O bond lengths [Si1–O1 1.629(3), Si3–O1 1.647(3), Si5–O2 1.643(3), Si7–O2 1.651(3)] in the two dianions suggests flexibility of this linkage. This phenomenon has been well-established by several structural and theoretical studies on molecules bear-

ing disiloxane moieties.[17] Thus, an increase in the Si–O–Si angle causes a decrease in the Si–O distance. The presented structural data of the oxide bridged silaboranes are in agreement with this tendency.

The cluster geometries of the oxide and methoxide adducts show a high degree of similarity. In both cases the Si–B distances are in the range of 2.3–2.0 Å. The longest distances between silicon and boron are found in each cluster between Si1, the silicon atom carrying the alkoxide, and B3, the boron atom which is still coordinated to both silicon atoms [2.254(5), 2.255(6), 2.281(6), 2.229(6), 2.301(5) Å]. This adduct formation is also a cluster-opening reaction. The silicon atom attacked by the nucleophile is coordinated to only three boron atoms. Obviously, the bond to the boron atom opposite to the entering nucleophile was broken during adduct formation (see Table 1 Si1–B6). Therefore, the adduct features a quadrangle consisting of two silicon atoms and two boron atoms (Type C in Figure 1). Overall the coordination number of Si1 remains as six. The silicon atom not attached to the oxygen atom is embedded in the cluster framework as in the starting material. The geometry of the oxygen adducts of *o*-silaborane can be derived from the 13-vertex *closo* skeleton by removal of the four-coordinate vertex (4k).

The static geometries of the silaborate derivatives **3** and **4** in the solid state are not compatible with the NMR spectroscopic studies at room temperature. Instead, the number of signals in the ^{1}H-, ^{11}B-, ^{13}C-, and ^{29}Si-NMR spectra equals the number observed for *o*-silaborane, possessing C_{2v} symmetry. A dynamic process involving migration of the oxygen between the neighboring silicon atoms accounts for the smaller number of signals than would be expected for the static compounds. This fluxional process is too rapid on the NMR time scale to be quenched at room temperature.

Ab Initio Calculations

In order to get further insights into the dynamic behavior we studied the oxygen adducts by ab initio calculations.[18] Instead of the anion of compound **4**, we conducted the calculations with the parent compound $[Si_2B_{10}H_{12}(OH)]^-$. Figure 4 shows the relative energies at the HF/6-31G(d) level dependent on the rotation of the SiH(OH) group (see Experimental Section). We chose Si1–B12 as the axis of rotation; i.e., we varied the O–Si1–B12–B9 (Figure 3) torsion angle in steps of 10° and optimized the resulting 19 geometries. We checked that Figure 4 describes an internal reaction path by frequency analyses. This surface scan (Figure 4) clearly shows two minima, **M1** and **M2**, and two transition states, **TS1** and **TS2**. Moreover, we conducted full optimizations for the two equilibrium geometries and the transition state highest in energy (**TS2**), both at the HF/6-31G(d) and the B3LYP/6-31G(d) levels of theory. The calculated structures are depicted in Figure 5 and selected bond lengths and additional data are compiled in Table 3.

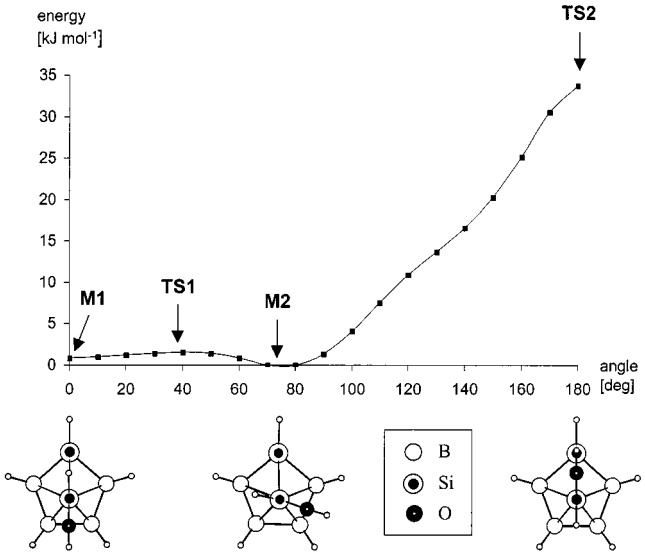

Figure 4. Surface scan for the rotation of the SiH(OH) group in $[Si_2B_{10}H_{12}(OH)]^-$ at the HF/6-31G(d) level

Besides **M1**, **M2**, and **TS2**, Figure 5 shows the two additional geometrical conformers, **M3** and **TS3**. The transition state **TS3** has the OH group symmetrically bound to both Si atoms (C_s point group). This transition state connects two enantiomers of **M3** (C_1 point group) and corresponds to an exchange of the OH group between the two Si atoms. The barrier for this process is only 29.9 kJ mol^{-1} [B3LYP/6-31G(d)].

The major difference between the structures of **M1**, **M2**, **TS1**, and **TS2** on the one side, and **M3** and **TS3** on the other, is the conformation of the OH group. Whereas for **M1**–**TS2** the H atom of the hydroxy group is directed towards the surface of the cluster (torsion angle H–O–Si1–B12 = 180°), for **M3** and **TS3** the H atom is directed in the opposite direction (Figure 5). Obviously, the two reaction coordinates **M1**–**TS1**–**M2**–**TS2** (Figure 4) and **M3**–**TS3** are related by the rotation of the OH group along the Si1–O bond. Therefore, we took several geometries from the surface scan of Figure 4 and rotated the OH group by 180° to give a new set of starting geometries. These optimizations led to two minima at the HF/6-31G(d) level which were similar to **M3**; i.e., 17.4 and 18.8 kJ mol^{-1} higher in energy than **M2**. The barrier for SiH(OH) rotation is just 30.7 kJ mol^{-1} at the B3LYP/6-31G(d) level (Figure 5).

The geometry corresponding to the minimum **M2**, and the structure of the anion of **4**, are very similar. In particular, the calculated and measured torsion angle O–Si1–B12–B9 is 75.3° (75.6°) and 80.9(3)°, respectively. The corresponding torsion angles of the two independent anions of **3** in the solid state are 84.1(4) and 87.2(3)° for one molecular unit, and 33.3(4) and 98.4(4)° for the other molecular unit. These torsion angles are in the flat region of the calculated surface (Figure 4) showing the high degree of flexibility.

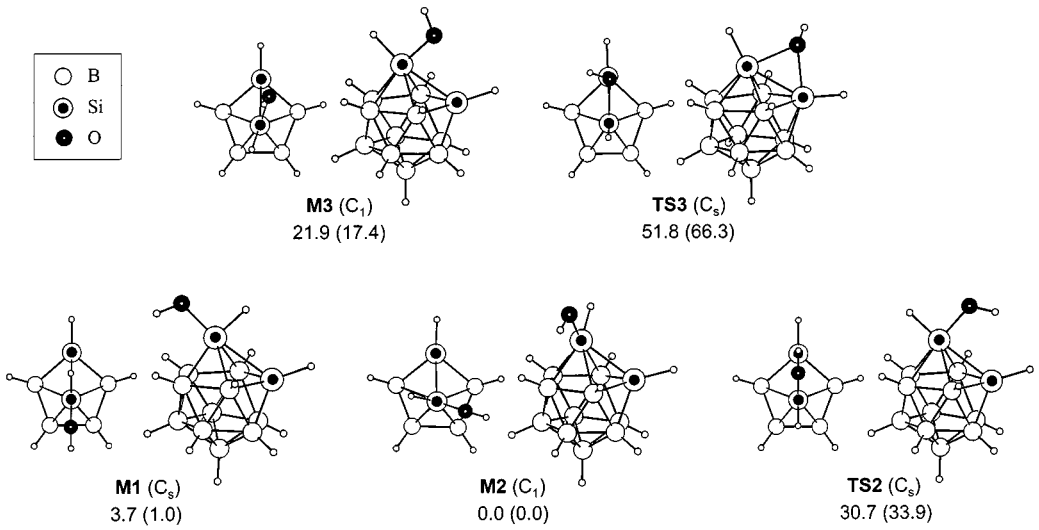

Figure 5. Minimum structures and transition states of $[Si_2B_{10}H_{12}(OH)]^-$; relative energies in kJ mol^{-1} at the B3LYP/6-31G(d) and the HF/6-31G(d) level (in parentheses); two views are depicted for each molecule

Table 3. Bond lengths in Å calculated at the B3LYP/6-31G(d) and the HF/6-31G(d) level (in parentheses)

	M1	M2	M3	TS2	TS3
Si1–Si2	2.492 (2.502)	2.377 (2.377)	2.422 (2.424)	2.461 (2.462)	2.329 (2.315)
Si1–O	1.706 (1.684)	1.708 (1.686)	1.732 (1.708)	1.723 (1.702)	1.996 (1.970)
Si1–B3	2.279 (2.278)	2.288 (2.283)	2.255 (2.257)	2.258 (2.250)	2.103 (2.102)
Si1–B4	2.082 (2.085)	2.112 (2.116)	2.077 (2.083)	2.107 (2.112)	2.066 (2.075)
Si1–B5	2.082 (2.085)	2.116 (2.123)	2.111 (2.116)	2.107 (2.112)	2.071 (2.079)
Si1–B6	2.279 (2.278)	2.391 (2.387)	2.199 (2.197)	2.258 (2.250)	2.111 (2.108)

The geometry corresponding to the transition state **TS3** compares well with the structure of the dimethylamide adduct **2** (Scheme 1).[11]

Experimental Section

General Considerations: All manipulations were carried out under an atmosphere of nitrogen using standard Schlenk techniques. THF was distilled from sodium/benzophenone, and hexane from potassium, and each was stored under nitrogen. – Elemental analyses were performed by the Mikroanalytisches Labor Pascher (Remagen) or the Analytischen Laboratorien (Lindlar). – NMR spectroscopy was performed on a Varian Unity 500 MHz spectrometer (^{1}H: 500 MHz, ^{11}B: 164 MHz, ^{13}C: 125 MHz, ^{29}Si: 100 MHz).

[(TMPDAH)$_2$][(Me$_2$Si$_2$B$_{10}$H$_{10}$)$_2$O] (3): A solution of **1** (264.2 mg, 1.29 mmol) in THF (15 mL) was treated with TMPDA (1.0 g, 7.68 mmol) and H_2O (0.015 mL, 0.94 mmol). The colorless solution was stirred overnight. All volatiles were removed and the remaining colorless solid was characterized by NMR spectroscopy to be almost quantitatively **3**. Crystalline material was obtained by slow diffusion of hexane into a THF solution of **3** (Yield: 426 mg, 0.62 mmol, 96%). – ^{1}H{^{11}B} NMR (500 MHz, TMS, CD_2Cl_2): δ = 0.84 (s, 6 H, SiCH_3), 1.25 (s, 2 H, H9/12), 1.39 (s, 2 H, H4/5/7/11), 1.67 (s, 2 H, H8/10), 1.86 (quin., 2 H, NCH$_2$CH_2CH$_2$N), 1.86 (s, 2 H, H3/6), 2.59 (s, 12 H, NCH_3), 2.98 (t, 4 H, NCH_2CH$_2$CH_2N), 11.19 (s, 1 H, N*H*N). – ^{11}B NMR (160 MHz, $BF_3 \cdot Et_2O$): δ = –11.6 (d, ^1J = 122 Hz, B3/6), –14.5 (d, ^1J = 134 Hz, B8/10), –17.3 (d, ^1J = 122 Hz, B4/5/7/11), –21.1 (d, ^1J = 122 Hz, B9/12). – ^{13}C{^{1}H} NMR (125.6 MHz, TMS): δ = 6.6 (MeSi), 21.7 (s, NCH$_2$*C*H$_2$CH$_2$N), 44.7 [s, N(CH$_3$)$_2$], 60.1 (s, N*C*H$_2$CH$_2$*C*H$_2$N). – ^{29}Si NMR (MHz, TMS): δ = –73.7. – $C_{18}H_{70}B_{20}N_4OSi_4$ (687.35): calcd C 31.46, H 10.27, N 8.15, O 2.33; found C 31.27, H 10.51, N 8.03, O 2.12.

X-ray Crystallographic Analysis of 3: $C_{18}H_{70}B_{20}N_4OSi_4$, ENRAF-Nonius CAD4; Mo-$K_\alpha$ radiation, λ = 0.71073 Å, graphite monochromator; data collection with ω-2θ scan at 203 K, Colorless translucent platelet 0.7 × 0.5 × 0.1 mm, triclinic space group $P\bar{1}$ (no. 2); a = 8.451(2), b = 22.697(3), c = 22.992(3) Å, α = 97.42(1), β = 100.01(1), γ = 100.32(1)°, U = 4214(1) Å^3, Z = 4, ρ_{calcd} = 1.083 gcm^{-3}, μ(Mo-K_α) = 1.60 cm^{-1}, F(000) = 1480; 15805 reflections in the range 2 < θ < 26°, 15226 independent reflections. Structure solution by direct methods[13] and refinement[14] on F^2 for 1366 variables; all nonhydrogen atoms refined isotropically. Convergence at R = 0.074 for 7172 observations with $F_o > 4\sigma F_o$, $wR2$ = 0.154 for all reflections, $w^{-1} = \sigma^2(F_o^2) + \{0.052[\max(F_o^2,0) + 2F_c^2]/3\}^2$, GOF = 0.929.

[TMPDAH][(Me$_2$Si$_2$B$_{10}$H$_{10}$)OMe] (4): A solution of **1** (330.0 mg, 1.61 mmol) in THF (15 mL) was treated with TMPDA (255.3 mg, 1.21 equiv.). After stirring for 30 min CH_3OH (55 mg, 1.07 equiv.) was added. The colorless solution was stirred overnight. All volatiles were removed and the remaining colorless solid was characterized by NMR spectroscopy to be almost quantitatively **4**. Crystalline material was obtained after slow diffusion of hexane into a THF solution of **4** (yield: 572 mg, 1.56 mmol, 97%). – ^{1}H{^{11}B} NMR (500 MHz, TMS, THF): δ = 0.76 (s, 6 H, SiCH_3), 1.22 (s, 2 H, H9/12), 1.37 (s, 4 H, H4/5/7/11), 1.72 (s, 4 H, H3/6/8/10), 1.88 (quin., 2 H, NCH$_2$CH_2CH$_2$N), 2.61 (s, 12 H, NCH_3), 2.97 (t, 4 H, NCH_2CH$_2$CH_2N), 11.04 (s, 1 H, N*H*N). – ^{11}B NMR (160 MHz, $BF_3 \cdot Et_2O$): δ = –13.8 (d, ^1J = 140 Hz, B3/6/8/10), –17.5 (d, ^1J = 128 Hz, B4/5(7/11), –20.5 (d, ^1J = 128 Hz, B9/12). – ^{13}C{^{1}H} NMR (125.6 MHz, TMS): δ = 3.6 (MeSi), 21.2 (NCH$_2$*C*H$_2$CH$_2$N), 44.5 [–N(*C*H$_3$)$_2$], 60.2 (N*C*H$_2$CH$_2$*C*H$_2$N). – ^{29}Si NMR (MHz, TMS): δ = –69.3. – $C_{10}H_{38}B_{10}N_2OSi_2$ (366.71): calcd C 32.75, H 10.45, N 7.64; found C 32.53, H, 10.24, N 7.79.

X-ray Crystallographic Analysis of 4: $C_{10}H_{38}B_{10}N_2OSi_2$, ENRAF-Nonius CAD4; Cu-$K_\alpha$ radiation, $\lambda = 1.54184$ Å, graphite monochromator; data collection with ω-2θ scan at 180 K. Colorless platelet $0.36 \times 0.24 \times 0.08$ mm, monoclinic space group $P2_1/c$ (no. 14); $a = 8.808(1)$, $b = 9.139(1)$, $c = 28.218(7)$ Å, $\beta = 94.24(2)°$, $U = 2265.(1)$ Å^3, $Z = 4$, $\rho_{calcd} = 1.078$ gcm^{-3}, μ(Cu-K_α) = 14.10 cm^{-1}, $F(000) = 792$; 5639 reflections in the scan range $4 < \theta < 70°$, 2599 independent observations with $I > \sigma(I)$ in structure solution with direct methods[13] and refinement[15] on F for 306 variables; all nonhydrogen atoms refined with anisotropic replacement parameters, hydrogen atoms refined isotropically. Convergence at $R = 0.066$, $Rw = 0.063$, $w^{-1} = \sigma^2(F_o)$, $GOF = 1.094$.

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-114742 (**3**) and CCDC-114741 (**4**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44–1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Ab Initio Calculations: The Gaussian 94 package,[18] run on a cluster of workstations (*Rechenzentrum der RWTH Aachen*), was applied for all ab initio calculations. The calculations were conducted in redundant internal coordinates. The surface scan of Figure 4 was performed by a step-by-step change of the torsion angle O–Si1–B12–B9 by 10° followed by an optimization of all other geometrical parameters. All full geometry optimizations were conducted without any symmetry restrictions (Figure 5). The total energies E_h (in Hartrees; B3LYP/6-31G(d) and HF/6-31G(d) in parentheses) and ZPVE calculated at HF/6-31G(d) level (in kJ mol^{-1}; in square brackets) are as follows: **M1**: –910.812603 (–907.220984) [483.2], **M2**: –910.814022 (–907.221375) [483.4], **M3**: –910.805689 (–907.214743) [482.1], **TS2**: –910.802310 (–907.208467) [481.8], **TS3**: –910.794274 (–907.196112) [481.4].

Acknowledgments

We are grateful to the Deutsche Forschungsgemeinschaft (DFG-Schwerpunktprogramm "Polyeder") for generous financial support and to the Rechenzentrum der RWTH Aachen for providing generous computer time. Especially, we would like to thank T. Eifert and J. Risch for their support.

Bis(terpyridyl)-Ruthenium(II) Units Attached to Polyazacycloalkanes as Sensing Fluorescent Receptors For Transition Metal Ions

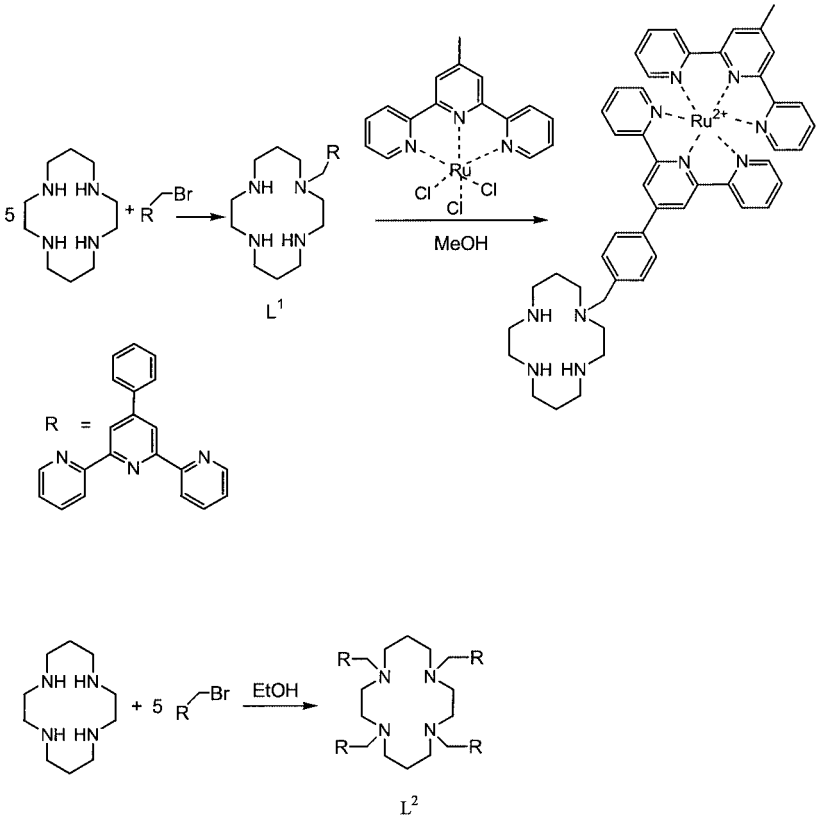
Miguel E. Padilla-Tosta,[a] José Manuel Lloris,[a] Ramón Martínez-Máñez,*[a] Angel Benito,[a] Juan Soto,[a] Teresa Pardo,[a] Miguel A. Miranda,[a] and M. Dolores Marcos[b]

Keywords: Terpyridine / Copper sensing / Cyclam / Fluorescence / Solution studies

A synthetic strategy has been devised for the preparation of new compounds in which terpyridyl fragments are linked to 1,4,8,11-tetraazacyclotetradecane (cyclam). Reaction of excess cyclam with 4′-[(4-bromomethyl)phenyl]-2,2′:2″,6′-terpyridine afforded the ligand 1-[4′-*p*-tolyl-(2,2′:6′,2″-terpyridyl)]-1,4,8,11-tetraazacyclotetradecane (L^1) in which the tetraaza macrocycle was covalently attached to one benzyl-terpyridyl fragment. Under similar conditions reaction of cyclam with excess 4′-[(4-bromomethyl)phenyl]-2,2′:2″,6′-terpyridine gave the tetra substituted cyclam derivative 1,4,8,11-[4′-*p*-tolyl-(2,2′:6′,2″-terpyridyl)]-1,4,8,11-tetraazacyclotetradecane (L^2). The multidentate ligand L^2 was crystallographically characterised by single-crystal X-ray diffraction techniques. Reaction of L^1 with $[Ru(mtpy)Cl_3]$ gave the heteroleptic ruthenium(II) complex $[Ru(L^1)(mtpy)][PF_6]_2$ (mtpy = 4′-methyl-2,2′:6′2″-terpyridine). The fluorescent intensity of the metallo-receptor $[Ru(L^1)(mtpy)][PF_6]_2$ was quenched selectively in the presence of copper(II) in an aqueous environment. To gain insight into the nature of this interaction, potentiometric titrations on $[Ru(L^1)(mtpy)]^{2+}$ in the presence of Cu^{2+} were carried out. The quenching of the emission intensity was associated with the presence of the copper $\{Cu[Ru(L^1)(mtpy)]\}^{4+}$ complex in solution. The receptor 1-[4′-methyl-(2,2′:6′,2″-terpyridyl)]-1,4,8,11-tetraazacyclotetradecane (L^3), in which the cyclam fragment is separated from the terpyriyl by a methylene group, has also been synthesised by reaction of 4′-bromomethyl-2,2′:2″,6′-terpyridine and cyclam. With L^3 as starting material, the ruthenium complex $[Ru(L^3)(mtpy)]^{2+}$ was prepared in order to evaluate the effect that the nature of the spacer has on the quenching of the fluorescence upon addition of Cu^{2+}.

Introduction

The assembly of oligopyridyl groups with Ru^{II} or some other transition metals ions to yield polymetallic species has been studied for both practical and fundamental reasons.[1,2] Some examples are: (a) the investigation of energy and electron-transfer processes,[3–8] (b) the exploitation of spectroscopic properties for testing the sensing ability of appended groups towards protons, cations and anions[9,10] and (c) the building up of dendritic species comprising several metal centres for light-harvesting and energy-collection purposes.[11,12] The investigation on these area has mainly been concentrated on building covalently linked metal complexes,[3,5,13] with the building of noncovalent links between components being an alternative pathway.[14] Few examples of these metallo-receptors have demonstrated sensor properties.[15]



We have synthesised terpyridine-functionalised cyclam ligands and formed complexes with the photoactive Ru^{II} metal ion. The domains of the macrocyclic cavity could allow for the binding of an appropriate guest that might trigger a change in the luminescence of the appended ruthenium metal centre. One of the best known metallo-fluorophores is the tris(2,2'-bipyridyl)-ruthenium(II) core, however the related bis(2,2':6',2''-terpyridine)-ruthenium(II) group has been much less studied as a luminescent signalling subunit.[9,16] We report here that the incorporation of the Cu^{2+} cation into the macrocyclic cavity appended to a bisterpyridyl ruthenium centre changes the emission properties of the $[Ru(tpy)_2]^{2+}$ core, allowing for access to new potential chemosensors based on the fluorophore–spacer–receptor concept.

Results and Discussion

The attachment of polypyridyl fragments to secondary amines in polyazacycloalkanes can be carried out by the use of a polypyridyl fragment containing a CH_2Br substituent. 4'-[(4-Bromomethyl)phenyl]-2,2':6',2''-terpyridine was synthesised following literature procedures.[17] The terpyridine-functionalised cyclam receptor was readily prepared by reaction of the terpyridine derivative with an excessof cyclam in dichloromethane in the presence of NEt_3 at 30° C for 24 hours and further column chromatography in alumina with a mixture of CH_2Cl_2/MeOH (99:1 v/v) as eluent obtaining a ca. 50% yield of L^1 (see Scheme 1). The ^1H NMR spectrum of L^1 shows pyridyl protons in the range of 7.2–8.8 ppm. The proton signals were fully assigned by using $^1H,^1H$ correlation (COSY) spectroscopy. The spectrum is completed by one singlet at 3.7 ppm of the methyl-

enic protons of the tolyl spacer, several overlapped signals in the range 2.40–2.90 of CH_2 groups attached to the nitrogen atoms in the macrocycle and two quintuplets at 1.6–1.8 ppm corresponding to the two nonequivalent central CH_2 groups from the propylene chains in the cyclam macrocycle.

Reaction of cyclam with an excess of 4'-[(4-bromomethyl-)phenyl]-2,2':6',2''-terpyridine in ethanol in the presence of NEt_3 gave L^2 as the unique product (see Scheme 1). The ^1H NMR spectrum of L^2 shows pyridyl protons in the range 7.25–8.70 ppm. The protons of the cyclam moiety appear in the range 1.8–2.8 ppm, whereas the benzylic protons give rise to a singlet at 3.52 ppm.

L^2 has also been characterised by single-crystal X-ray diffraction techniques. Suitable crystals for diffraction purposes were obtained by slow diffusion of diethyl ether into a solution of L^2 in dichloromethane. Some selected bond lengths and angles are listed in Table 1. Figure 1 shows the molecular structure of L^2. The structure consists of a cyclam core substituted with four benzyl-terpyridyl groups, giving a multidentate molecule with a promising geometry containing a central tetraaza and four peripheral terpyridine binding sites. Cyclic tetraamines can exist in several conformations depending on the relative position of the *N*-substituted groups with respect to the N4 plane.[18] Of the five possible conformations for a tetra-substituted cyclam derivative, the crystal structure of L^2 shows that the conformation with two substituents above and two below the mean N4 plane is adopted, the two benzyl-terpyridyl groups above the plane being separated by an ethylene chain. The 2,2':6',2''-terpyridine adopts the usual trans–trans conformation through the C–C interannular bond as has been found in related structures.[19] The terpyridine groups adopt a near-planar conformation with dihedral angles between the planes N(2)–C(10) and N(1)–C(5), N(3)–C(11) and N(2)–C(10), N(5)–C(38) and N(4)–C(45), N(6)–C(40) and N(5)–C(38) of 7.2°, 3.4°, 9.6°, and 13.7°, respectively. The angles between the planes C(16)–C(21) and N(2)–C(11), C(29)–C(34) and N(5)–C(38) are 26.6° and 10.5°, respectively.

Reaction of equimolar quantities of L^1 with $Ru(mtpy)Cl_3$ [mtpy = 4'-methyl-2,2':6',2''-terpyridine] in methanol with

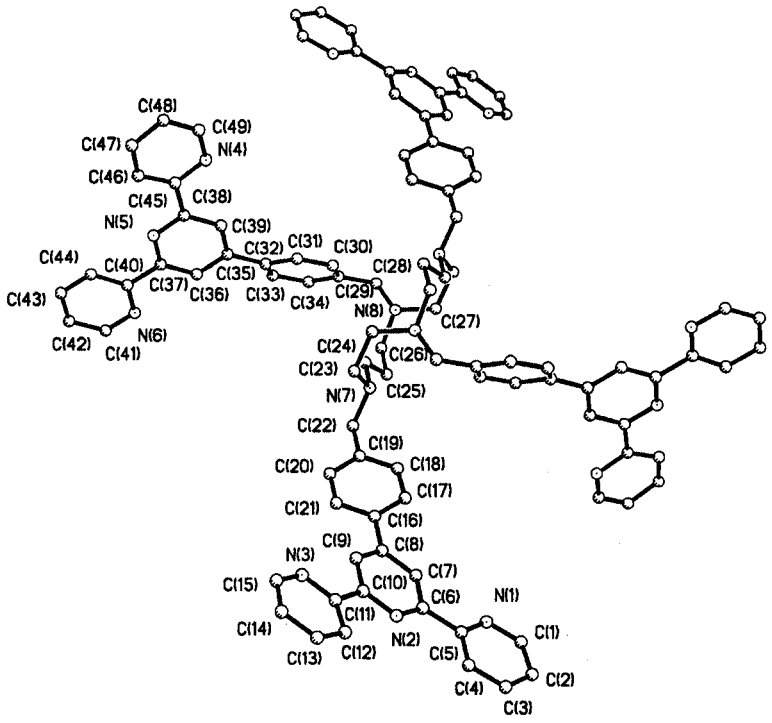

Figure 1. Molecular structure of L^2

the addition of *N*-ethyl-morpholine as mild reductant, afforded the receptor $[Ru(L^1)(mtpy)][PF_6]_2$ after column chromatography in silica using a mixture of acetonitrile/water/saturated aqueous solution of KNO_3 (17:1:2 v/v) as eluent and further precipitation with ammonium hexafluorophosphate (see Scheme 1). The FAB mass spectrum of the bis-terpyridyl ruthenium(II) complex $[Ru(L^1)(mtpy)][PF_6]_2$ showed peaks at m/z = 1161, 1015 and 869 corresponding to $[Ru(L^1)(mtpy)][PF_6]_2$, $[Ru(L^1)(mtpy)][PF_6]^+$ and $Ru(L^1)(mtpy)^{2+}$, respectively. The ^1H NMR spectrum shows the expected signals for the aromatic protons in the range 7.2–9.0 ppm, with two non-equivalent terpyridine groups. The spectrum also contained poorly defined overlapping signals in the 2.8–4 ppm range. The CH_3 of the terminal group appears at 2.93 ppm. Owing to the presence of the acetonitrile signal, the corresponding signal for the central CH_2 groups of the propylene chain in the cyclam cycle were not observed.

The synthesized ruthenium(II) complex contains a polyamine as the "receptor" part of the molecule and a bis(2,2':6',2''-terpyridine)-ruthenium(II) group able to act as signalling subunit. The following study has been carried out mainly to detect the effect that the coordination of the cyclam fragment has on the emission properties of the signalling ruthenium-terpyridine unit. The electronic spectrum of the complexes is as expected for a $[Ru(tpy)_2]^{2+}$ chromophore, with the principal $Ru[d(\pi)] \rightarrow tpy(\pi^*)$ MLCT transition at 484 nm, and the usual intense ligand-centred transitions in the UV region.[20] We have investigated the fluorescence behaviour of acetonitrile/water solutions of the receptor $[Ru(L^1)(mtpy)]^{2+}$ in the presence of transition metal ions M^{2+} (M^{2+} = Ni^{2+}, Cu^{2+}, Zn^{2+}, Cd^{2+}, Hg^{2+} and Pb^{2+}) as a function of the pH (see Figure 2) by luminescence spectroscopy. The continuous protonation of the poly- amine enhanced the emission intensity of the ruthenium core only slightly, indicating that the photoinduced electron transfer mechanism between the lone pair of the amines and the $Ru(tpy)_2^{2+}$ fluorophore is poor. The presence of the transition metals Ni^{2+}, Zn^{2+}, Cd^{2+}, Hg^{2+} and Pb^{2+} does not modify the fluorescence versus pH profile of the free receptor. In contrast, the coordination of Cu^{2+} in the macrocyclic cavity is accompanied by substantial quenching of the luminescence intensity with a minimum centred at pH = 6.9 (see Figures 2 and3).

Figure 2. Relative intensity versus pH for the L and $L-M^{2+}$ systems (L = $[Ru(L^1)(mtpy)][PF_6]_2$; M^{2+} = Cu^{2+}, Ni^{2+}, Zn^{2+}, Cd^{2+}, Pb^{2+}, Hg^{2+}) (λ_{ex} = 484 nm, λ_{em} = 664 nm)

To gain insight into the nature of the interaction of Cu^{2+} with the $Ru(tpy)_2$ fluorophore, two additional studies were carried out: (i) potentiometric titrations on an acetonitrile/water solution of $[Ru(L^1)(mtpy)]^{2+}$ in the presence of Cu^{2+}, and (ii) the synthesis of a parent fluorophore–spacer–receptor multicomponent system where the nature of the spacer was varied.

The protonation and coordination behaviour of L^1 and $[Ru(L^1)(mtpy)]^{2+}$ was studied by potentiometric titrations with KOH of previously acidified solutions in acetonitrile/

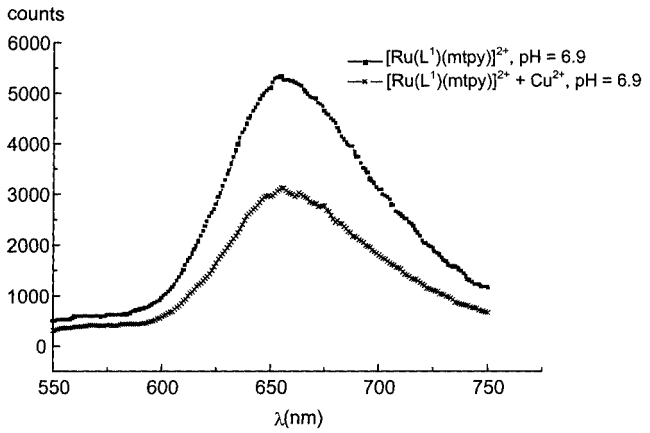

Figure 3. Emission spectra of the $[Ru(L^1)(mtpy)]^{2+}$ cation at pH = 6.9 with and without Cu^{2+}

water (70:30 v/v, 0.1 mol dm^{-3} tetrabutylammonium perchlorate). Additionally the protonation constants of cyclam in acetonitrile/water were also determined. Table 2 shows that $\log K_2 - \log K_3$ for the cyclam is 7.5, but only 3.85 for L^1 and 3.17 for $[Ru(L^1)(mtpy)]^{2+}$. The need to break a hydrogen bond to enable the third proton to become attached has been suggested as an explanation for the large difference between the values of $\log K_2$ and $\log K_3$ in the cyclam. Similar behaviour for cyclam has been observed in water or in THF/water (70:30 v/v).[21] However, this effect disappears in substituted derivatives such as L^1 and $[Ru(L^1)(mtpy)]^{2+}$. Five protonation steps were determined for L^1: the first two protonations probably took place at the macrocyclic moiety; the last three protonations either took place at the terpyridine or at the cyclam. For the $[Ru(L^1)(mtpy)]^{2+}$ complex and cyclam only three protonation constants were observed, the four being too acidic to be determined. Remarkably the $[Ru(L^1)(mtpy)]^{2+}$ complex does not show

substantial basicity difference from L^1 for the first three protonation constants, despite the existence of a positively charged $Ru(tpy)_2^{2+}$ core.

Table 3 shows the stability constants for the formation of Cu^{2+} complexes of $[Ru(L^1)(mtpy)]^{2+}$ in acetonitrile/water (70:30 v/v). The distribution diagram of the $[Ru(L^1)(mtpy)]^{2+}$–H^+–Cu^{2+} is depicted in Figure 4. The receptor $[Ru(L^1)(mtpy)]^{2+}$ forms the complex $\{Cu[Ru(L^1)(mtpy)]\}^{4+}$ existing in the neutral pH range. These species undergo two protonation processes upon lowering of the pH, whereas two additional hydroxo complexes were found to exist at basic pH. The logarithm of the stability constant for the formation of the complex $\{Cu[Ru(L^1)(mtpy)]\}^{4+}$ is 13.30. This value can be compared with that found for the formation of $[Cu(tmfcyclam)]^{2+}$ ($\log K = 19.06$)[22] (where tmfcyclam = 1,4,8,11-tetrakis(ferrocenylmethyl)-tetraazacyclotetradecane), or with that of $[Cu(cyRubipy)]^{10+}$ ($\log K = 6.01$)[23] (where cyRubipy stand for a tetramethyl-$Ru(bipy)_3$-substituted cyclam). In the latter, the Cu^{2+} cation is brought within the range of the electrostatic repulsion from all four of the pendent $[Ru(bipy)_3]^{2+}$ groups while in $Cu[Ru(L^1)(mtpy)]^{4+}$ the Cu^{2+} cation only experiences the electrostatic repulsion of one tolyl-distanced $[Ru(tpy)_2]\}^{2+}$ core. The above could explain the difference in the stability constants of $\{Cu[Ru(L^1)(mtpy)]\}^{4+}$ and $\{Cu[cyRu(bipy)_3]\}^{10+}$ ($\log K$ of $\{Cu[Ru(L^1)(mtpy)]\}^{4+}$ – logK of $\{Cu[cyRu(bipy)_3]\}^{10+}$ = 7.29). Effects of the electrostatic repulsion could also be observed when comparing the stability constants for the formation of the complexes $[Cu(tmfcyclam)]^{2+}$ and

Table 3. Stability constants (log K) for the formation of copper(II) complexes of $[Ru(L^1)(mtpy)]^{2+}$

Reaction	logK
$Cu^{2+} + 2H^+ + L^{2+} \rightleftarrows [Cu(H^2L)]^{6+}$	24.84(5)[a]
$Cu^{2+} + H^+ + L^{2+} \rightleftarrows [Cu(HL)]^{5+}$	19.77(8)

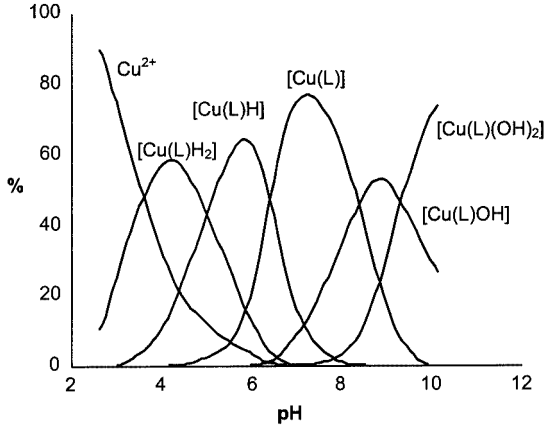
[a] Values in parentheses are standard deviations in the last significant figure.



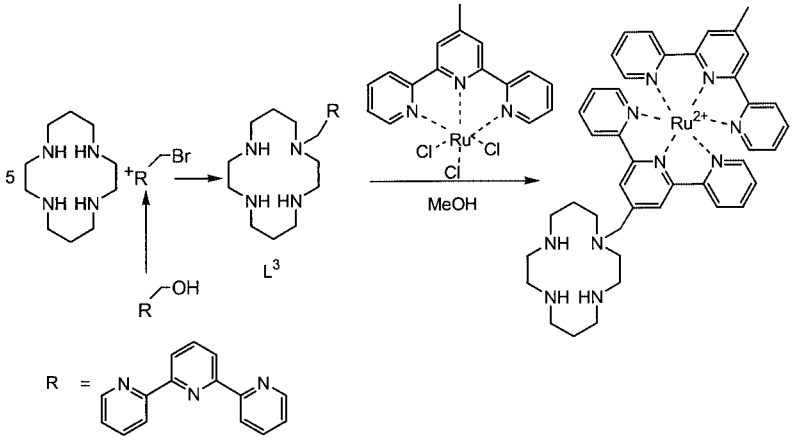


Figure 4. Distribution diagram of the species for the system $[Ru(L^1)(mtpy)]$–Cu^{2+}–H^+

$\{Cu[Ru(L^1)(mtpy)]\}^{4+}$. Despite the existence of the constraints imposed by the tmfcyclam ligand in their interaction with Cu^{2+}, the formation constant for $[Cu(tmfcyclam)]^{2+}$ is larger that that found for $\{Cu[Ru(L^1)(mtpy)]\}^{4+}$ (logK of $[Cu(tmfcyclam)]^{2+}$ – logK of $\{Cu[Ru(L^1)(mtpy)]\}^{4+}$ = 5.76), indicative of the electro-

static repulsion induced by the $[Ru(tpy)_2]^{2+}$ core on the macrocyclic cavity.

Comparison between the distribution diagram in Figure 4 and the I vs. pH curve in Figure 2 provides information about the stoichiometry and the nature of the complexes existing in the pH range where the luminescence is decreased. The quenching of the emission of the $Ru(tpy)_2^{2+}$ fluorophore is related to the presence of the $\{Cu[Ru(L^1)(mtpy)]\}^{4+}$ complex in solution, whereas further coordination of OH^- to the copper metal ion, or protonation of the amine groups in cyclam hinder the quenching.

In order to evaluate the role played by the spacer groups we have also synthesised a parent cyclam terpyridine ligand containing a CH_2 group as spacer instead of a tolyl one as in the case of L^1. For this purpose, the synthesis of the 4'-bromomethyl-2,2':6',2''-terpyridine using the 4'-methyl-2,2':6',2''-terpyridine as starting material was tested using two different routes: (i) by simple bromination of the methyl groups with *N*-bromosuccinimide, or (ii) reaction of CBr_4 with 4'-hydroxymethyl-2,2':6',2''-terpyridine obtained from the methyl derivative. When *N*-bromosuccinimide and catalytic amounts of dibenzoyl peroxide react with 4'-methyl-2,2':6',2''-terpyridine, three products were obtained: monobrominated, dibrominated and starting material. However, the mixture is not amenable to chromatographic separation. In our hands, silica or alumina did not give a very satisfactory separation of the products. The second procedure involves the reaction of 4'-(hydroxymethyl)-2,2':6',2''-terpyridine (OHmtpy) with carbon tetrabromide and triphenylphosphane to give 4'-bromomethyl-2,2':6',2''-terpyridine as the only product in 40% yield (see Scheme 2). 4'-Methyl-2,2':6',2''-terpyridine was reacted with selenium dioxide to give 4'-carbaldehyde-2,2':6',2''-terpyridine which was reduced with $NaBH_4$ to yield the corresponding 4'-(hydroxymethyl)-2,2':6',2''-terpyridine. OHmtpy has been mentioned, but to the best of our knowledge, full experimental information has not been given for its synthesis, so details are included in this paper.

Scheme 2. Synthesis of L^3 and the corresponding ruthenium complex

Reaction of the 4'-bromomethyl-2,2':6',2''-terpyridine with excess cyclam afforded the corresponding L^3 molecule in a 50% yield (see Scheme 2). As expected, the ^1H NMR spectrum of L^3 is very similar to the one of L^1 showing the pyridyl protons in the range 7.2–8.65 ppm. The spectrum is completed by one singlet at 3.62 ppm of the methylenic protons of the spacer, several overlapped signals in the range 2.40–3.10 ppm for the CH_2 groups attached to the nitrogen atoms in the macrocycle and two quintuplets at 1.8–1.95 ppm corresponding to the two nonequivalent central CH_2 groups of the propylenic chains in the cyclam macrocycle. Synthesis of $[Ru(L^3)(mtpy)][PF_6]_2$ ruthenium(II) complex was carried out by a similar method to that used in the synthesis of $[Ru(L^1)(mtpy)][PF_6]_2$ (see Scheme 2). The FAB spectrum of this complex shows peaks at m/z = 1085, 940 and 794, corresponding to $\{[Ru(L^3)(mtpy)]_2[PF_6]\}$, $\{[Ru(L^3)(mtpy)][PF_6]\}^+$ and $\{Ru(L^3)(mtpy)\}^{2+}$, respectively. The ^1H NMR spectrum shows the expected signals for the aromatic protons in the range of 7.2–8.7 ppm with two nonequivalent terpyridine groups. The spectrum also contains poorly defined overlapping signals in the 2.9–3.9 ppm range. The CH_3 of the terminal group appears at 2.93 ppm. As in the spectrum of $[Ru(L^1)(mtpy)]^{2+}$, the presence of the acetonitrile signal hampers the observation of the corresponding signal for the central CH_2 groups of the propylenic chain in the cyclam cycle.

The fluorescence behaviour of acetonitrile/water solutions of the receptor $[Ru(L^3)(mtpy)]^{2+}$ in the presence of transition metal ions M^{2+} (M^{2+} = Ni^{2+}, Cu^{2+}, Zn^{2+}, Cd^{2+}, Hg^{2+} and Pb^{2+}) as a function of the pH has also been studied. The behaviour of the ruthenium complex containing L^3 as ligand is similar to the behaviour observed for the ruthenium complex of L^1. There is a poor enhancement of the emission intensity of the ruthenium core upon protonation of the polyaza macrocycle and whereas the presence of Ni^{2+}, Zn^{2+}, Cd^{2+}, Hg^{2+} and Pb^{2+} does not modify the fluorescence versus pH profile of the free receptor, the coordination of Cu^{2+} quenches the luminescence intensity with a minimum centred at pH = 6.2 (see Figure 5). However, despite the shorter spacer between the cyclam and the $Ru(tpy)_2^{2+}$ core in complex $[Ru(L^3)(mtpy)]^{2+}$ than in $[Ru(L^1)(mtpy)]^{2+}$, a larger quenching is observed for the latter than for the former in the presence of Cu^{2+}.

With regard to the quenching mechanism, preliminary results suggest that the quenching of the fluorescence of the

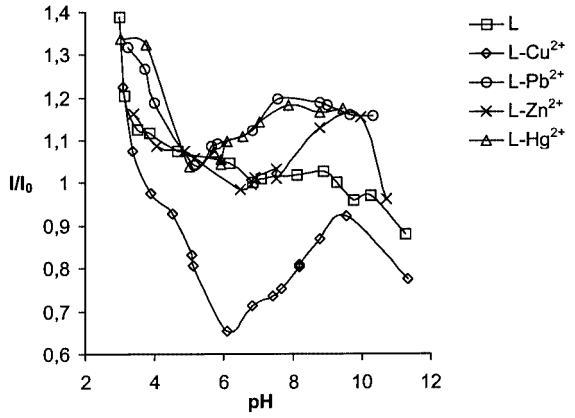

Figure 5. Relative intensity versus pH for the L and L–M^{2+} systems (L = $[Ru(L^3)(mtpy)][PF_6]_2$; M^{2+} = Cu^{2+}, Ni^{2+}, Zn^{2+}, Cd^{2+}, Pb^{2+}, Hg^{2+}) (λ_{ex} = 484 nm, λ_{em} = 625 nm)

$[Ru(L^1)(mtpy)]^{2+}$ and $[Ru(L^3)(mtpy)]^{2+}$ metallo-receptors upon Cu^{2+} binding most likely occurs predominantly by means of an energy transfer, bearing in mind that the electron transfer is unlikely due to the difficulty of oxidation or reduction of $[Cu(cyclam)]^{2+}$.[24] We have calculated the free energy associated with an electron-transfer mechanism by using the emission band intensity, the Ru^{II}/Ru^{III} oxidation potential of the ruthenium bis-terpyridine core ($E_{Ru(III)/Ru(II)}$ = + 1.3 V and the reduction potential for the Cu^{II}/Cu^{I} process ($E_{Cu(II)/Cu(I)}$ = – 1.05 V) in the cyclam environment, and have found a thermodynamically unfavourable ΔG value of +0.45 V for an electron transfer process. Energy-transfer mechanisms would require a close proximity between the fluorophore and the copper metal ion. In this sense, it is remarkable that the quenching is more pronounced in $[Ru(L^1)(mtpy)]^{2+}$ than in $[Ru(L^3)(mtpy)]^{2+}$. In $[Ru(L^1)(mtpy)]^{2+}$, the $Ru(tpy)_2^{2+}$ is separated by a tolyl spacer from the macrocyclic cavity, while in L^3 the spacer is a CH_2 group. The tolyl spacer in L^1 probably favours the movement of the Cu-cyclam core in search of a better overlap between the metal cation in the tetraamine and the $Ru(tpy)_2^{2+}$ fluorophore while in L^3 the CH_2 spacer diminishes this possibility.

Conclusion

We have developed new cyclam receptors functionalised with fluorescent $Ru(tpy)^{2+}$ signalling subunits and have demonstrated that the presence of copper(II) selectively quenches the fluorescence of the ruthenium(II) core more than other common metal ions in an aqueous environment at neutral pH. We have determined that the $\{Cu[Ru(L^1)(mtpy)]\}^{4+}$ complex is responsible for the quenching of the emission of the $[Ru(tpy)_2]^{2+}$ core, whereas further amine protonation or OH^- coordination to the complex hinders the quenching process. Additionally the $[Ru(L^3)(mtpy)]^{2+}$ receptor has also been synthesised and confirmed that Cu^{2+} produces a smaller decrease in fluorescence. An energy-transfer mechanism is suggested. We are currently extending our approach by attaching several macrocyclic structures to ruthenium-terpyridine units and continuing our study on the multireceptor L^2 to obtain dendritic species with several metal centres in order to construct assemblies with tuneable luminescence properties.

Experimental Section

General Remarks: The complexes $[Ru(mtpy)Cl_3]$, 4'-[4-(bromomethyl)phenyl]-2,2':6'.2''-terpyridine (Brmphtpy),[17] 4'-(4-methylphenyl)-2,2':6'.2''-terpyridine (mphtpy) and 2,2':6'.2''-terpyridinyl-4'-carboxaldehyde (CHOtpy), [25] were prepared according to published methods; all other reagents were commercially available and used as received. Photochemical data were obtained with a FS900CDT steady state T-Geometry Fluorometer, Edinburgh Analytical Instruments. All solutions for photophysical studies were rigorously degassed. Concentration of the ligand and metal ion was *ca.* 1.0×10^{-4} mol dm^{-3}. ^1H NMR spectra were recorded with a Varian Gemini spectrometer. Potentiometric titrations were carried out in acetonitrile/water (70:30 v/v, 0.1 mol dm^{-3} tetrabutylammonium perchlorate) using a water-thermostatted reaction vessel at 25.0 ± 0.1 °C under nitrogen. The titrant was added by a Crison microburette 2031. Experimental potentiometric details have been published previously.[26] The concentration of the metals ions was determined using standard methods. The computer program SUPERQUAD[27] was used to calculate the protonation and stability constants. The titration curves for each system (ca. 250 experimental points corresponding to at least three titration curves, pH range investigated 2.5–10.2, concentration of the ligand and metal ion was *ca.* 1.0×10^{-3} mol dm^{-3}) were treated either as a single set or as separate entities without significant variations in the values of the stability constants. Finally the sets of data were merged together and treated simultaneously to give the stability constants.

Synthesis of 4'-(Hydroxymethyl)-2,2':6'.2''-terpyridine (OHmtpy): To a mixture of CHOtpy (1.0 g, 3.8 mmol) in THF (10 mL) was added $NaBH_4$ (200 mg, 5.3 mmol) and the resulting mixture was stirred for 15 min at 0 °C. The reaction mixture was extracted with EtOAc (70 mL), and washed with water (3 × 3 mL) and brine (3 mL). The extract was dried over $MgSO_4$ and evaporated under reduced pressure. The residue was purified by column chromatography on silica gel. Yield 841 mg, 85%.

Synthesis of 4'-(Bromomethyl)-2,2':6'.2''-terpyridine (Brmtpy): To a mixture of OHmtpy (1 mmol) and carbon tetrabromide (2 mmol) in CH_2Cl_2 (5 mL) was added triphenylphosphane (1.1 mmol) at 0 °C in several portions over 15 min. The mixture was stirred for 0.5 h at the same temperature and for 0.5 h at room temperature. In order to remove triphenylphosphane oxide, the mixture was passed through a short silica gel column (10 g) and eluted with CH_2Cl_2. Compound Brmtpy was obtained as a yellow oil that solidified on prolonged drying. Yield 130 mg, 40%. – ^1H NMR (300 MHz, $CDCl_3$): δ = 4.48 (s, 2 H, CH_2Br), 7.29–7.31 [2 H, tpy H(5, 5'')], 7.78–7.81 [2 H, tpy H(4, 4'')], 8.42 [s, 2 H, tpy H(3', 5')], 8.54–8.56 [2 H, tpy H(6, 6'')] and 8.63–8.66 [2 H, tpy H(3, 3'')]. – $C_{16}H_{12}N_3Br.CH_2Cl_2$: calcd. C 49.8, H 3.4, N 10.3; found C 49.6, H 3.1, N 10.3. – FAB-MS: *m/z* (%): 327(30), 325(65), 247(80).

Synthesis of 1-[4'-*p*-Tolyl-(2,2':6',2''-terpyridyl)]-1,4,8,11-tetraazacyclotetradecane (L^1): A mixture of 4'-[4-(bromomethyl)phenyl]-2,2':6'.2''-terpyridine (0.5 mmol) in CH_2Cl_2 (20 mL) was added dropwise to a solution of cyclam (500 mg, 2.5 mmol) in CH_2Cl_2 (20 mL). Et_3N (5 drops) was added, and the solution was heated at 30°C for 24 h. The reaction mixture was washed with water (3

× 3 mL). The organic phase was dried over $MgSO_4$ and evaporated under reduced pressure. The residue was purified by column chromatography on alumina with CH_2Cl_2/CH_3OH (99:1 v/v) as eluent. A pale yellow oil was obtained which solidified on scratching. Yield: 130 mg, 50%. – **L^1**: ^{1}H NMR (300 MHz, $CDCl_3$): δ = 1.60–1.80 (4 H, $CH_2CH_2CH_2$), 2.3–2.9 (16 H, CH_2–N), 3.52 (2 H, Cy–CH_2-tpy), 7.20–7.22 [2 H, tpy H(5, 5'')], 7.34–7.36[2 H, Ph H_m), 7.70–7.72 [2 H, tpy H(4, 4'')], 7.73–7.73 (2 H, Ph H_o), 8.54–8.56 [2 H, tpy H(6, 6'')], 8.57–8.59 [2 H, tpy H(3, 3'')], and 8.62 [s, 2 H, tpy H(3', 5')]. – ^{13}C NMR ($CDCl_3$): δ = 26.17 (CH_2), 28.60 (CH_2), 46–60 (8 CH_2), 71.53 (CH_2), 118.53 (CH, tpy), 121.2 (CH, tpy), 123.64 (CH, tpy), 126.91 (CH, C_6H_4), 129.55 (CH, C_6H_4), 136.82 (CH, tpy), 140.4 (C, tpy), 148.96 (CH, tpy), 149.92 (CH, tpy), 155.8 (C, tpy), 156.14 (C, tpy). – $C_{32}H_{39}N_7.CH_2Cl_2.H_2O$: calcd. C 63.5, H 6.9, N 15.7; found C, 63.0; H, 6.9; N, 15.4. – FAB-MS: *m/z* (%): 522 (100), 323 (40), 212 (50).

Synthesis of 1,4,8,11-[4'-*p*-Tolyl-(2,2':6',2''-terpyridyl)]-1,4,8,11-tetraazacyclotetradecane (L^2): A mixture of Brmphtpy (650 mg, 1.6 mmol) and cyclam (54 mg, 0.27 mmol) in ethanol (50 mL) and in the presence of Et_3N was heated at reflux for 24 h. Yellow crystals were obtained. The residue was purified by column chromatography on alumina using CH_2Cl_2/CH_3OH (97:3 v/v) as eluent. Yield: 70 mg, 20%. **L^2:**. ^{1}H NMR (300 MHz, $CDCl_3$): δ = 1.85 (2 H, $CH_2CH_2CH_2$), 2.62 (8 H, CH_2–N), 2.71 (8 H, CH_2–N), 3.52 (8 H, Cy–CH_2-phtpy),7.25–7.30 [8 H, tpy H(5, 5'')], 7.45–7.50 [8 H, ph), 7.73–7.74 [8 H, ph), 7.75 [8 H, tpy H(4, 4'')], 8.59 [8 H, tpy H(6, 6'')], 8.63–8.66 [8 H, tpy H(3, 3'')] and 8.66 [s, 8 H, tpy H(3', 5')]. – ^{13}C NMR ($CDCl_3$): δ 30.5 (CH_2), 50.5 (4 CH_2), 51.6 (4 CH_2), 59.0 (4 CH_2), 118.8 (CH, tpy), 121.3 (CH, tpy), 123.8 (CH, tpy), 127.0 (CH, C_6H_4), 129.5 (CH, C_6H_4), 136.8 (CH, tpy), 149.0 (CH, tpy), 155.72 (C, tpy), 156.3 (C, tpy). – $C_{98}H_{84}N_{16}{\cdot}2CH_2Cl_2{\cdot}H_2O$: calcd. C 72.5, H 5.3, N 13.5; found C 72.3, H 5.1, N 12.9. – FAB-MS: *m/z* (%): 1487 (100), 1164 (45).

Synthesis of 1-[4'-Methyl-(2,2':6',2''-terpyridyl)]-1,4,8,11-tetraazacyclotetradecane (L^3): L^3 was prepared in the same manner as L^1, by the reaction of cyclam and 4'-(bromomethyl)-2,2':6'.2''-terpyridine. Yield: 110 mg, 50%. **L^3:** ^{1}H NMR (300 MHz, $CDCl_3$): δ = 1.82–1.97 (4 H, $CH_2CH_2CH_2$), 2.4–3.1 (16 H, CH_2–N), 3.62 (2 H, Cy–CH_2-tpy), 7.22–7.24 [2 H, tpy H(5, 5'')], 7.78–7.80 [2 H, tpy H(4, 4'')], 8.40 [s, 2 H, tpy H(3', 5')], 8.53–8.56 [2 H, tpy H(6, 6'')] and 8.60–8.63 [2 H, tpy H(3, 3'')]. – ^{13}C NMR ($CDCl_3$): δ 23.9 (CH_2), 24.2 (CH_2), 45–59 (8 CH_2), 72.38 (CH_2), 121.2 (2 CH, tpy), 123.9 (CH, tpy), 136.9 (CH, tpy), 148.0 (CH, tpy), 150.1 (C, tpy), 155.5 (2 C, tpy). – $C_{26}H_{35}N_7.CH_2Cl_2.H_2O$: calcd. C 59.1, H 7.1, N 17.9; found C 60.0, H 6.9, N 17.4. – FAB-MS: *m/z* (%): 446 (35), 247 (80), 213 (80).

Synthesis of $[Ru(L^1)(mtpy)][PF_6]_2$ and $[Ru(L^3)(mtpy)][PF_6]_2$: These ruthenium complexes were prepared in the same way. A mixture of the appropriate ligand (L^1 105 mg, L^3 89 mg; 0.2 mmol), with $[Ru(mtpy)Cl_3]$ (90 mg, 0.2 mmol) and three drops of *N*-ethylmorpholine as a mild reductor in MeOH (20 mL) was heated at reflux with stirring for 1 h. The resulting deep-red solution was filtered through celite to remove any unchanged $[Ru(mtpy)Cl_3]$ and excess methanolic ammonium hexafluorophosphate was added to the filtrate to precipitate the ligand complexes. Further purification was achieved by chromatography over silica using 17:2:1 acetonitrile/water/saturated aqueous KNO_3 solution. The complexes were isolated as their PF_6^- salts.

$[Ru(L^1)(mtpy)][PF_6]_2$:. Yield: 40 mg, 20%. – ^{1}H NMR (300 MHz, CD_3CN): δ = 2.90 (s, 3 H, CH_3), 3.0–3.5 (16 H, CH_2–N), 3.78–3.82 (2 H, tpy–CH_2–Cy), 7.18–7.20[4 H, tpy H(5,5'')^{1,2}], 7.37–7.39[2 H, tpy H(6,6'')^1], 7.42–7.44[2 H, tpy H(6,6'')^2], 7.74–7.76 (2 H, ph H_m), 7.94–7.96 [4 H, tpy H(4, 4'')^{1,2}], 8.20–8.22 (2 H, ph H_o), 8.48–8.50 [2 H, tpy H(3, 3'')^1], 8.68–8.70 [2 H, tpy H(3, 3'')^2] 8.70 [s, 2 H, tpy H(3', 5')^1] and 9.01 [s, 2 H, tpy H(3', 5')^2].^{1} = mtpy; ^{2} = Cy–spacer–tpy (spacer = tolyl). – $C_{48}H_{52}N_{10}Ru(PF_6)_2.2CH_2Cl_2$: calcd. C 45.1, H 4.2, N 10.5; found C 45.3, H 3.8, N 10.3. – FAB-MS: *m/z* (%): 1161 (8), 1015 (20), 869 (45), 327 (60), 281 (100). – **$[Ru(L^1)(mtpy)][PF_6]_2$:** Yield 30 mg, 15%. – ^{1}H NMR (300 MHz, CD_3CN): δ = 2.97 (s, 3 H, CH_3), 3.0–3.3 (16 H, CH_2–N), 3.7–3.9(2 H, tpy–CH_2–Cy), 7.16–7.18[2 H, tpy H(5,5'')^1], 7.22–7.24 [2 H, tpy H(5, 5'')^2], 7.24–7.26[2 H, tpy H(6,6'')^2], 7.37–7.39[2 H, tpy H(6,6'')^1], 7.92–7.94 [4 H, tpy H(4, 4'')^{1,2}], 8.44–8.46 [2 H, tpy H(3, 3'')^2], 8.50–8.52 [2 H, tpy H(3, 3'')^1] 8.66 [s, 2 H, tpy H(3', 5')^2] and 8.68 [s, 2 H, tpy H(3', 5')^1].^{1} = mtpy; ^{2} = Cy–spacer–tpy (spacer = methylene) – FAB-MS: *m/z* (%): 1085 (20), 939 (26), 793 (45), 595 (60).

X-ray Crystallographic Study: $C_{106}H_{104}N_{16}O_5$, M = 1682.05, triclinic, space group $P\bar{1}$, a = 12.303(4), b = 13.440(5), c = 15.618(6) Å, α = 106.60(3), β = 90.71(3), γ = 101.96(3), Z = 1, U = 2414(2) Å^3, Dc = 1.157 g cm^{-3}, λ(Mo-K_α) = 0.71069 Å, T = 296(2) K, μ(Mo-K_α) = 0.073 mm^{-1}. Measurements were made using a Siemens P4 diffractometer with graphite monochromated Mo-K_α radiation on a yellow crystal of L^2, of dimensions 0.26 × 0.20 × 0.23 mm. A total of 6429 reflections were collected, of which 6090 were unique (R_{int} = 0.0551). Lorentz, polarisation and semi-empirical from psi-scan absorption (Max. and min. transmission 0.4322 and 0.2287) corrections were applied. The structure was solved by direct methods (SHELXTL)[28] and refined by full-matrix least-squared analysis on *F2* (SHELXTL). The refinement converged at R_1 = 0.1077 ($F > 4\sigma(F)$) and wR_2 = 0.3120 (all data). Largest peak and hole in the final difference map +0.44, –0.35 e Å^{-3}. Crystallographic data for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-132890. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.)+ 44–1223/336–033; E-mail: deposit@ccdc.cam.ac.uk].

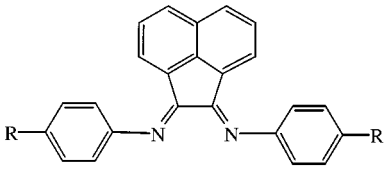
Non-Luminescent 1,2-Diiminetricarbonylrhenium(I) Chloride Complexes – Synthesis, Electrochemical and Spectroscopic Properties of $Re(DIAN)(CO)_3Cl$ with DIAN = *p*-Substituted Bis(arylimino)acenaphthene



Günther Knör,*[a] Markus Leirer,[a] Tia E. Keyes,[b] Johannes G. Vos,[c] and Arnd Vogler*[a]

Keywords: Rhenium / Diimine ligands / Charge transfer / Solvatochromism / Substituent effects

$Re(1,2\text{-diimine})(CO)_3Cl$ compounds containing the *p*-substituted bis(arylimino)acenaphthene derivatives DIAN-R with R = H, Me, OMe, Br, and Cl were prepared and characterized. The diimine ligands of this series provide unoccupied orbitals at rather low energies and display a pronounced π-accepting strength. This feature determines the electrochemical and spectroscopic properties of the $Re(DIAN\text{-}R)(CO)_3Cl$ complexes. All compounds show rhenium(I) to π*(diimine) metal-to-ligand charge transfer (MLCT) absorptions in the visible spectral region. The maxima of these CT bands systematically shift upon modification of the substituents R and are sensitive to variations of the solvent polarity (negative solvatochromism). $Re(DIAN\text{-}R)(CO)_3Cl$ complexes are non-luminescent both in fluid solution at 298 K and in solvent glass at 77 K.

Introduction

Electronic spectra of complexes of the composition $Re^I(1,2\text{-diimine})(CO)_3(L)$ with L = e.g. halide, CO, phosphane or amine have been studied extensively in recent years.[1,2] These efforts were stimulated by the luminescence behaviour of such compounds, which are characterized by long-lived ^{3}MLCT (triplet metal-to-ligand charge transfer) states. The excited state properties can be utilized for a variety of different purposes such as electron transfer, energy transfer, photochemical CO_2 reduction and the development of optical sensors.[1–4] While mainly polypyridines have been used as 1,2-diimines, ligands with imino groups that are not part of a heterocyclic aromatic system were largely neglected. Since the latter ligands provide π* orbitals at rather low energies,[5–7] the corresponding MLCT absorptions are shifted to much longer wavelengths. Although such complexes may be no longer luminescent owing to the low energy of the MLCT states (energy gap law[8]), they nevertheless could show other useful properties. For example, the charge transfer behaviour might be exploited for nonlinear optical (NLO) devices.[9] For several other applications (e.g. NIR absorbers) photochemical stability is a desireable feature. On the contrary, long-lived excited states tend to participate in bimolecular processes such as the generation of singlet oxygen, which promote photochemical decomposition. It follows that the absence of luminescence from $Re^I(1,2\text{-diimine})(CO)_3(L)$ complexes may present advantages in certain applications. We explored this possibility and selected substituted bis(arylimino)acenaphthenes (DIAN-R)[10] as ligands for the present study (Scheme 1).

Scheme 1. Structural formula of the DIAN-R ligands

These compounds are accessible by standard organic synthesis and can be systematically modified by a variation of the substituents R at the *para* position of their phenyl groups. Owing to the terminal imino groups, the π* energies of these ligands should be rather low. Moreover, since the diimine function is attached to the larger delocalized π-electron system of the acenaphthene moiety, it may be expected to display a high π-accepting strength.

Results and Discussion

The complexes $Re^I(DIAN\text{-}R)(CO)_3Cl$ with R = H, Me, OMe, Br, and Cl have been prepared and characterized by elemental analysis and a variety of spectroscopic techniques. All results are consistent with a pseudooctahedral structure of the compounds and a facial (*fac*) coordination of the carbonyl ligands in agreement with previous studies of other complexes of this type.[1,2]

The absorption spectra of $Re^I(DIAN\text{-}R)(CO)_3Cl$ show various bands below 400 nm and a pronounced absorption in the visible spectral region (Figure l, Table 1). The shorter wavelength bands include certainly intraligand (IL) transitions of the diimines, which absorb as free ligands in the same spectral region. The longer-wavelength band dominating the visible spectrum is assigned to the MLCT transition from rhenium(I) to the π* orbitals of DIAN-R. The charge

transfer character of this transition is supported by the fact that the corresponding absorption maxima of all complexes shift to higher energies with increasing solvent polarity (negative solvatochromism). This effect can be evaluated quantitatively by applying different solvent polarity scales such as the empirical E_T parameters[11] or the E^*_{MLCT} values[12] (Figure 2). Generally a linear correlation is observed, although smaller deviations are noticed as previously reported for related complexes.[12] The substituent R of the DIAN-R ligands should also affect the MLCT energy. However, the π* energy of the ligands is only slightly dependent on the nature of R because the phenyl groups at the nitrogen atoms are not coplanar with the diimine moiety.[10] Indeed, a Hammett plot (Figure 3) shows a linear correlation of the σ_p-parameter with the MLCT energies, but the slope (930 cm^{-1}) is rather small. A much stronger dependence on *p*-substituents has been observed for *meso*-tetraphenylporphyrins.[13] In this case the phenyl groups at the *meso* positions are also not coplanar with the porphyrin plane, but the ππ* transitions are more significantly shifted.

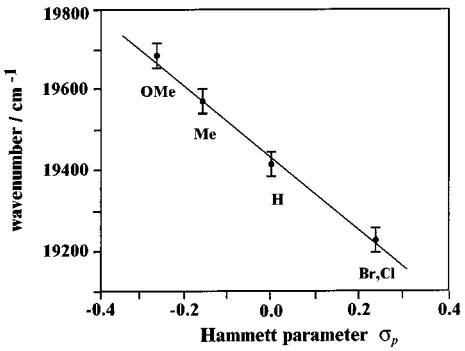

Figure 3. Substituent effects on the MLCT absorption maxima of Re(DIAN-R)$(CO)_3$Cl complexes in benzene at 298 K

To obtain further information about the π-acceptor properties of the bis(arylimino)acenaphthene ligands, electrochemical and spectroelectrochemical experiments were performed with the unsubstituted derivative Re^I(DIAN-H)$(CO)_3$Cl. The first reduction of this compound occurs in cyclic voltammetry as a reversible one-electron step at a redox potential of −0.65 V vs SCE at 298 K in dry DMF containing 0.1 M tetraethylammonium tetrafluoroborate. The reversible spectral changes associated with this process suggest that the first reduction takes place at the DIAN-H ligand. An approximate value of +1.4 V vs SCE can be estimated for the corresponding reaction in the MLCT excited state. These redox potentials reflect the much higher π-acceptor strength of bis(phenylimino)acenaphthene compared to many other frequently used diimine ligands. For example, the compound Re^I(bpy)$(CO)_3$Cl (bpy = 2,2-bipyridyine) displays its first ligand based reduction at the rather negative potential of −1.64 V vs SCE (−1.74 V vs ferrocene/ferrocenium[14]) in the electronic ground state. With exception of the initial reduction wave, the voltammetric response obtained for Re^I(DIAN-H)$(CO)_3$Cl between 1.7 and −2.0 V vs SCE indicates the occurrence of chemical reactions coupled to the heterogeneous electron transfers. Recently, a complex sequence of fragmentation and dimerization steps has been proposed for a related Re^I(1,2-diimine)$(CO)_3$Cl species under similar conditions.[15] A detailed investigation of such processes, however, was not attempted in the present study.

The complexes Re^I(DIAN-R)$(CO)_3$Cl do not show any luminescence at 298 K or 77 K. In general, the emission quantum yields of Re^I(1,2-diimine)$(CO)_3$(L) decrease with decreasing energy of the emitting MLCT state. This behaviour has been attributed to the energy gap law.[1,2,5,8] The same explanation may also apply to the absence of emission from the Re^I(DIAN-R)$(CO)_3$Cl series, since these compounds show their MLCT absorption at distinctly longer wavelength compared to corresponding complexes with polypyridyls as diimine ligands. However, it is surprising that Re^I(DIAN-R)$(CO)_3$Cl complexes do not emit at all, while $[Os(bpy)_3]^{2+}$ and some of its derivatives are luminescent, although their MLCT absorptions appear at similar or longer wavelengths[2] than those of Re^I(DIAN-R)$(CO)_3$Cl. Therefore it cannot be excluded that other effects contribute to the lack of emission from Re^I(DIAN-R)$(CO)_3$Cl.

A decrease of the π* energy of the diimine ligand usually is accompanied by a red-shift of the MLCT absorption. Moreover, a large contribution of the N atomic orbitals to the π* acceptor orbital causes a large overlap stabilization and may lead to an increased mixing of rhenium dπ and ligand Lπ* orbitals.[6] Indeed, the solvatochromism of the Re^{I}(DIAN-R)$(CO)_3Cl$ complexes (average slope = 2860 cm^{-1}) is significantly smaller than that of complexes with polypyridyl ligands[2] [e.g. Re^{I}(bpy)$(CO)_3Cl$, slope = 3120 cm^{-1}], since the "MLCT" transition of the DIAN complexes has less CT character owing to an enhanced delocalization of the participating orbitals. In contrast to polypyridyl complexes, the MLCT transitions of DIAN complexes occur then between strongly bonding dπ and antibonding Lπ* orbitals. The concomittant geometrical changes and the associated skeletal vibrations could facilitate an efficient nonradiative decay.[5,6]

Moreover, a further effect may account for the absence of luminescence from Re^{I}(DIAN-R)$(CO)_3Cl$. The increased back-bonding results in a stabilization of the dπ orbitals, which may drop below the π-orbitals of the chloride ligand.[16] The $Cl^- \rightarrow$ Lπ* diimine LLCT (ligand-to-ligand charge transfer) and MLCT transitions could now be of comparable energies. If the LLCT state is not emissive, its population might provide a new efficient channel for radiationless deactivation.

Experimental Section

Materials and Instrumentation: All starting materials were commercially available and used without further purification. The bis(arylimino)acenaphthene ligands were obtained from acenaphthene quinone and the corresponding *p*-substituted anilines.[10] – Electronic absorption spectra were recorded on a Kontron Uvikon 932 double-beam spectrophotometer and a Shimadzu 3100 UV-VIS/NIR spectrophotometer. – Emission properties were investigated with a Hitachi 850 spectrofluorometer equipped with a Hamamatsu 928 photomultiplier. – The electrochemistry was conducted at a teflon shrouded glassy carbon electrode with SCE reference and platinum mesh auxillary electrode in dry DMF containing 0.1 M tetraethyltetrafluoroborate as electrolyte. – Spectroelectrochemical measurements were carried out with equipment described elsewhere.[17] – IR spectra were measured on a Beckman Acculab 6 spectrometer. – Mass spectra were obtained using Finnigan MAT 95 and Varian MAT 311 instruments. – ^{1}H-NMR data were recorded with a Bruker AC 250 (250 MHz) spectrometer with TMS added as internal standard.

Preparation of the Complexes Re(DIAN-R)$(CO)_3Cl$: A suspension of 181 mg (0.50 mmol) of $Re(CO)_5Cl$ and the equimolar amount of the corresponding bis(arylimino)acenaphthene in 10 mL of toluene was refluxed for 30 min. After cooling the reaction mixture to room temperature and addition of *n*-hexane, the products were obtained as red microcristalline precipitates. The compounds with R = Br and Cl were further purified by chromatography on silica gel using dichloromethane as eluent.

Re(DIAN-H)$(CO)_3Cl$: Yield 289 mg (0.45 mmol, 91%). – IR (KBr): $\tilde{\nu}$ = 3050 cm^{-1} (CH), 2020, 1915, 1890 (CO), 1580 (aromatic rings). – ^{1}H NMR ($CDCl_3$): δ = 8.06 (d, 2 H), 7.00 (d, 2 H), 7.74–7.36 (m, 12 H). – MS (FD^+, $CHCl_3$): *m/z* (%): 638 (100) [M^+]. – $C_{27}H_{16}ClN_2O_3Re$ (638.10): calcd. C 50.82, H 2.53, N 4.39; found: C 50.35, H 2.82, N 4.11.

Re(DIAN-Me)$(CO)_3Cl$: Yield 306 mg (0.46 mmol, 92%). – IR (KBr): $\tilde{\nu}$ = 3030, 2920 cm^{-1} (CH), 2040, 1930, 1890 (CO), 1630, 1600 (aromatic rings). – ^{1}H NMR ($CDCl_3$): δ = 8.09 (d, 2 H), 7.09 (d, 2 H), 7.56–7.28 (m, 10 H), 2.52 (s, 6 H). – MS (FD^+, $CHCl_3$): *m/z* (%): 666.0 (100) [M^+]. – $C_{29}H_{20}ClN_2O_3Re$ (666.15): calcd. C 52.29, H 3.03, N 4.20;. found: C 52.34, H 3.33, N 4.12.

Re(DIAN-OMe)$(CO)_3Cl$: Yield 289 mg (0.45 mmol, 91%). – IR (KBr): $\tilde{\nu}$ = 3070, 3015, 2980, 2850 cm^{-1}(CH), 2040, 1920, 1890 (CO), 1630, 1600 (aromatic rings). – ^{1}H NMR ($CDCl_3$): δ = 8.06 (d, 2 H), 7.17 (d, 2 H), 7.90–7.36 (m, 8 H), 7.19–7.10 (m, 2 H), 3.94 (s, 6H). – MS (FD^+, $CHCl_3$): *m/z* (.%): 698.0 (100) [M^+]. – $C_{29}H_{20}ClN_2O_5Re$ (698.15): calcd. C 49.89, H 2.89, N 4.01; found: C 48.73, H, 2.96, N, 3.81.

Re(DIAN-Br)$(CO)_3Cl$: Yield 111 mg (0.14 mmol, 28%). – IR (KBr): $\tilde{\nu}$ = 2020, 1915, 1885 cm^{-1} (CO). – ^{1}H NMR ($CDCl_3$): δ = 8.11 (dd, 2 H), 7.10 (dd, 2 H), 7.78–7.23 (m, 10 H). – MS (FD^+, $CHCl_3$): *m/z* (%): 796.0 (100) [M^+]. – $C_{27}H_{14}Br_2ClN_2O_3Re$ (795.89): calcd. C 40.75, H 1.77, N 3.52; found: C 40.78, H 2.36, N, 3.20.

Re(DIAN-Cl)$(CO)_3Cl$: Yield 312 mg (0.44 mmol, 88%). – IR (KBr): $\tilde{\nu}$ = 3050, 2960, 2920 cm^{-1} (CH), 2030, 1920, 1890 (CO), 1620, 1595 (aromatic rings). – ^{1}H NMR ($CDCl_3$): δ = 8.06 (dd, 2 H), 7.10 (dd, 2 H), 7.70–7.31 (m, 10 H). – MS (FD^+, $CHCl_3$): *m/z* (%): 706.0 (100) [M^+]. – $C_{27}H_{14}Cl_3N_2O_5Re$ (706.98): calcd. C 45.87, H 2.00, N 3.96; found: C 46.12, H 2.78, N 3.48.

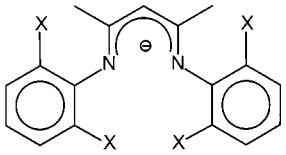
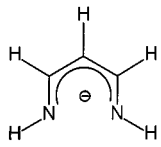
Rhodium and Iridium β-Diiminate Complexes – Olefin Hydrogenation Step by Step

Peter H. M. Budzelaar,*[a] Nicolle N. P. Moonen,[a] René de Gelder,[a] Jan M. M. Smits,[a] and Anton W. Gal[a]



Keywords: Hydrogenation / Isomerization / Rhodium / Iridium / Hydrides

The bulky β-diiminate ligands $[(2,6\text{-}C_6H_3X_2)NC(Me)CHC(Me)N(2,6\text{-}C_6H_3X_2)]^-$ (X = Me, L_{Me}; X = Cl, L_{Cl}) have been found to be effective in stabilizing low coordination numbers (CN) in Rh and Ir complexes. The 14-*e* complex L_{Me}Rh(COE) (COE = cyclooctene) has a three-coordinate T-shaped Rh environment and is nonagostic. Coordinative unsaturation is avoided by incorporation of a small ligand (e.g. N_2, MeCN, olefins), by the intramolecular coordination of a chlorine atom in L_{Cl}Rh(COE), or by an agostic interaction in L_{Me}Rh(norbornene). In solution at room temperature, L_{Me}Rh(COE) undergoes rapid isomerization according to the allyl hydride mechanism; the corresponding 2,3-dimethylbutene complex actually prefers the allyl hydride structure. Rhodium(I) complexes of L_{Me} and L_{Cl} catalyze olefin hydrogenation; hydrogenation of 2,3-dimethylbutene has been shown to be preceded by isomerization. The shielding properties of the bulky β-diiminate ligands allow direct observation of a number of reactive intermediates or their iridium analogues, including an olefin–dihydrogen complex (with Rh) and an olefin dihydride (with Ir). These observations, together with calculations on simple model systems, provide us with snapshots of a plausible hydrogenation cycle. Remarkably, hydrogenation according to this cycle appears to follow a 14-*e*/16-*e* path, in contrast to the more usual 16-*e*/18-*e* paths.



Introduction

Coordinatively unsaturated species are key intermediates in most catalytic cycles. Because of their high reactivity, they can rarely be isolated or even observed directly. Therefore, it is necessary to rely on indirect information (e.g. from trapping experiments or kinetics) to deduce the characteristic properties of such species. Obviously, isolable unsaturated species are of interest because they present an opportunity to study the reactivity of key intermediates *directly*.

We recently found that β-diiminate ligands can be effective in stabilizing low coordination numbers. With early transition metals, this has led to the isolation of stable four-coordinate Ti^{III} and V^{III} dialkyls.[1] In our recent work on late transition metals, we isolated a stable (but still highly reactive) 14-*e* rhodium(I) olefin complex.[2] We now describe the synthesis, characterization, and reactivity of Rh and Ir complexes of two bulky β-diiminate ligands, L_{Me} and L_{Cl}. The Rh complexes have proved to be active in olefin isomerization and hydrogenation. More importantly, we have found that the shielding properties of these ligands allow the direct observation of a number of species that can be envisaged as intermediates in isomerization and hydrogenation cycles, including a rhodium olefin–dihydrogen complex and an iridium olefin–dihydride complex. As an aid to interpretation of the results, B3LYP calculations have been performed on complexes of the model ligand L.

L_{Me} X = Me
L_{Cl} X = Cl

L

Other examples of coordinatively unsaturated species stabilized by bulky ligands have been reported. Some relevant examples are three-coordinate 14-*e* rhodium(I) complexes L_2RhX (L = bulky phosphane)[3] and the remarkable 14-*e* iridium dihydride complex $[P(t\text{Bu})_2Ph]_2IrH_2^+$ described by Caulton.[4] However, we are not aware of any example of a 14-*e* Rh or Ir complex bearing a labile and easily displaceable olefin ligand.

Results and Discussion

Ethene and Cyclooctadiene Complexes

The β-diimine ligand $L_{Me}H$ may easily be prepared by condensation of 2,4-pentanedione and 2,6-dimethylaniline. Reaction with $LiN(i\text{Pr})_2$ in THF produces the lithium salt L_{Me}Li(THF), which is obtained from hexane in the form of off-white crystals. The ligand $L_{Cl}H$ and its lithium salt may be prepared similarly; L_{Cl}Li(THF) forms large yellow crystals from toluene/hexane, which slowly turn reddish on exposure to light.

Reaction of L_RLi(THF) (L_R = L_{Me} or L_{Cl}) with $[Rh(COD)Cl]_2$ (COD = 1,5-cyclooctadiene) produces the

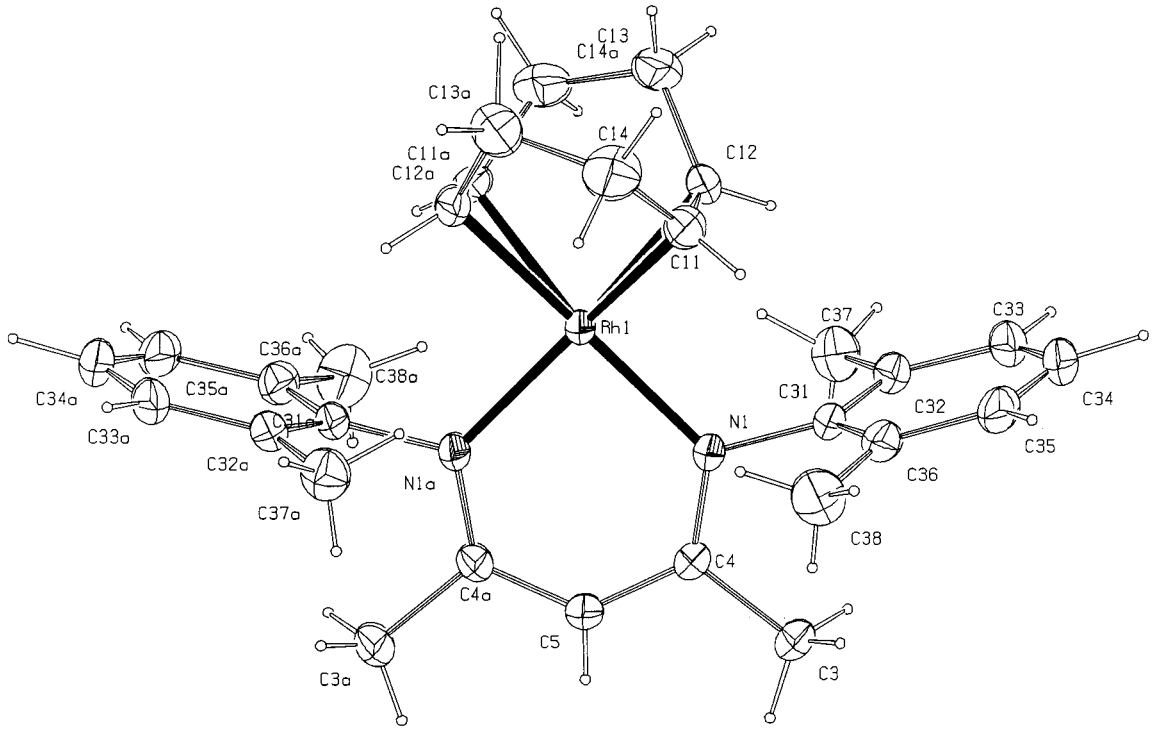

Figure 1. X-ray structure (30% ellipsoids) of $L_{Me}Rh(COD)$; atoms labelled *a* are related to original atoms by a twofold axis through Rh1 and C5; selected bond lengths (Å): Rh1–C11 2.138(2), Rh1–C12 2.169(2), Rh1–N1 2.0953(15)

very stable 16-*e* complexes $L_RRh(COD)$; ethene complexes $L_RRh(C_2H_4)_2$ can be obtained in a similar manner from $[Rh(C_2H_4)_2Cl]_2$. The X-ray structures of $L_{Me}Rh(COD)$ (Figure 1) and $L_{Me}Rh(C_2H_4)_2$ (Figure 2, A) show the expected square-planar coordination geometries. The bis(ethene) complex has perpendicular ethene ligands, which are tilted slightly out of the coordination plane in opposite directions. Distortions of this kind have been observed for *cis*-bis(ethene) complexes containing a chiral ligand; theoretical studies indicate that such structures are relatively easily deformed.[5]

The optimized structure of model complex $LRh(C_2H_4)_2$ shows a regular four-coordinate Rh atom. The calculated Rh–N distance (2.03 Å) is shorter than those observed for $L_{Me}Rh(C_2H_4)_2$ (av. 2.09 Å) and $L_{Me}Rh(COD)$ (av. 2.10 Å), while the Rh–C distances are longer (av. 2.28 Å vs. 2.15 Å). It is possible that the main cause of these discrepancies lies in the choice of model system: the aryl substituents on the L_{Me} ligand will weaken the N–Rh coordination and hence strengthen the Rh–olefin bond relative to the situation in the unsubstituted model ligand L. This means that we can also expect an underestimation of the calculated interaction strength of the LRh fragment with other added ligands.

In the calculated structure of $LRh(C_2H_4)_2$, the centers of the olefin ligands lie exactly in the coordination plane. If, however, the N–Rh–olefin angles are constrained to the value of 94° observed in the X-ray structure of $L_{Me}Rh(C_2H_4)_2$, a nonplanar structure is obtained. This suggests that the nonplanarity in the L_{Me} complex is caused by repulsion between the ethene hydrogens, as a result of the steric demand of the ligand aryl groups. A space-filling model of $L_{Me}Rh(C_2H_4)_2$ indeed shows interlocking of the ethene hydrogens and close contacts between the olefins and the aryl groups (Figure 2, B). Accordingly, the NMR spectra show that ethene rotation is blocked at room temperature. Crowded [bis(oxazolinyl)methanate]Rh(ethene)$_2$ complexes also show hindered rotation,[5] but in relatively open bis(ethene) complexes of β-diketonates and β-ketoiminates ethene rotation is usually fast at room temperature.[6]

Cyclooctene Complexes

The above results suggested that two molecules of a bulkier olefin, e.g. a *cis*-disubstituted olefin, would not fit into the cleft between the aryl groups: the substituents at the double bond of one olefin would interfere either with the arene ring or with the other olefin ligand. Indeed, reaction of $L_{Me}Li(THF)$ with $[Rh(COE)_2Cl]_2$ (COE = cyclooctene) was found to produce the deep-purple *mono*-olefin complex $L_{Me}Rh(COE)$ in moderate yield (70%). This complex proved to be extremely air-sensitive, but otherwise stable at room temperature. The X-ray structure[2] showed the molecule to be disordered over a twofold symmetry axis; this disorder could be refined satisfactorily (Figure 3). The coordination geometry about Rh is roughly T-shaped, but the olefin is shifted somewhat towards the center of the open cleft (N–Rh–olefin = 112°). Remarkably, there are no short agostic interactions.

Unfortunately, the disorder prevents us from obtaining individual distances for the two types of Rh–N bond. In the model compound $LRh(C_2H_4)$, we see a shortening of the Rh–C and Rh–N distances (by 0.07 and 0.04 Å, respectively) relative to those in the bis(ethene) complex. Accord-

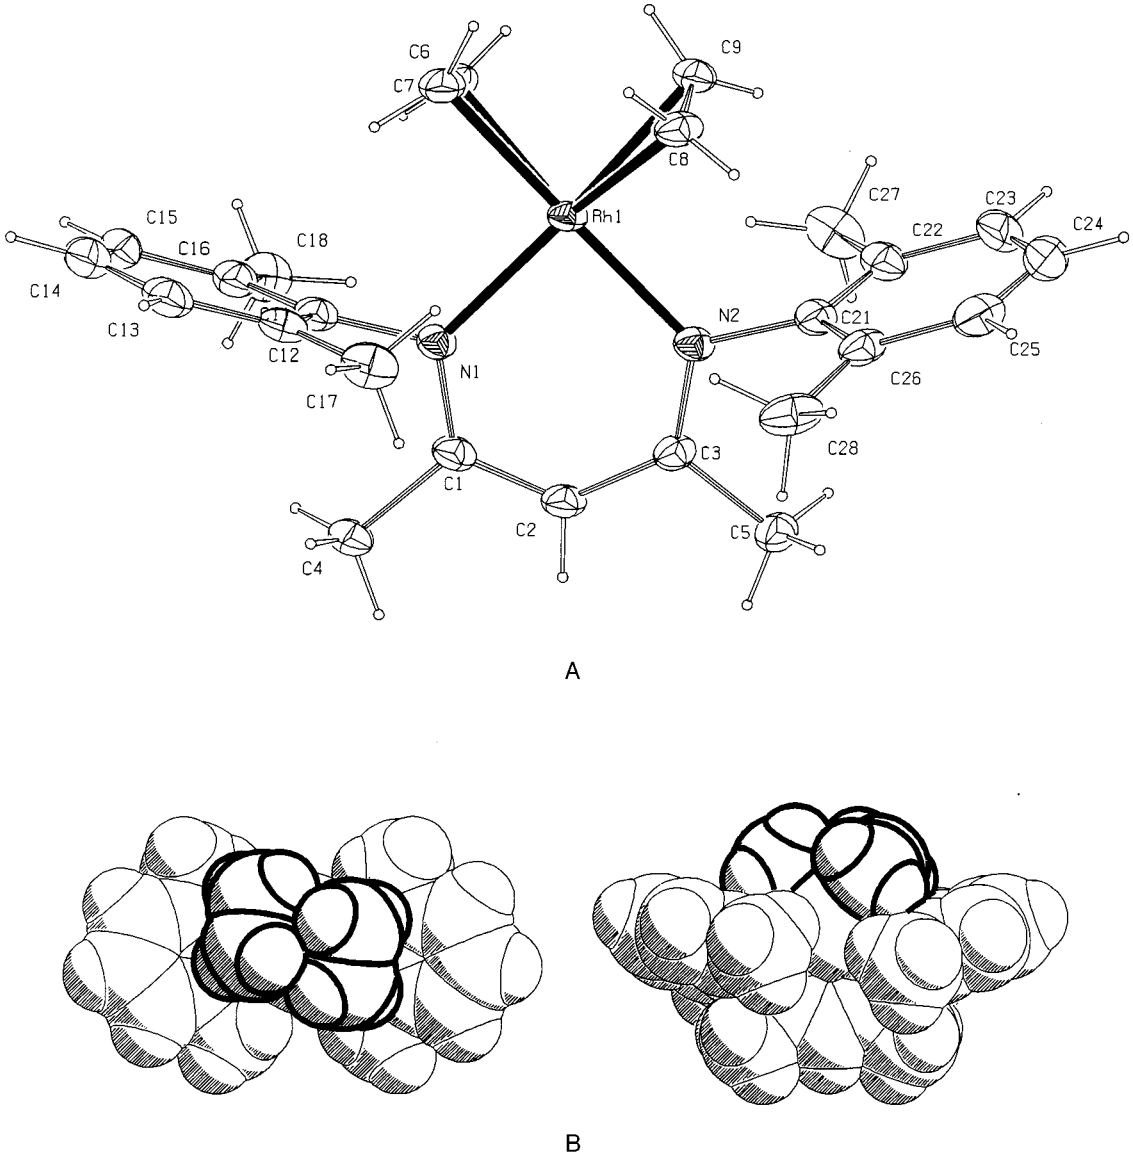

Figure 2. A: X-ray structure (30% ellipsoids) of $L_{Me}Rh(C_2H_4)_2$; B: space-filling model, outline of the ethene ligands emphasized; selected bond lengths (Å) and angles (°): Rh1–C6 2.131(4), Rh1–C7 2.155(4), Rh1–C8 2.133(4), Rh1–C9 2.160(4), Rh1–N1 2.093(3), Rh1–N2 2.086(3), C6–C7 1.390(7), C8–C9 1.367(7); N1–Rh1–N2 89.11(12)

ing to the X-ray data, the Rh–C bonds in $L_{Me}Rh(COE)$ are about 0.08 Å shorter than those in $L_{Me}Rh(C_2H_4)_2$ and $L_{Me}Rh(COD)$, while the Rh–N bonds are about 0.13 Å shorter. However, the X-ray bond lengths obtained for the COE complex must be treated with caution since the two alternative Rh positions, which differ by as much as 0.1 Å, could not be resolved in the structure determination. The N–Rh–olefin angle of 94° calculated for $LRh(C_2H_4)$ is larger than the 88° calculated for $LRh(C_2H_4)_2$, but much smaller than the value of 112° observed in $L_{Me}Rh(COE)$. The calculated barrier associated with ethene transfer between the two vacant sites of $LRh(C_2H_4)$ is only 11 kcal/mol. Thus, we attribute the distortion of $L_{Me}Rh(COE)$ towards a trigonal geometry to the steric demand of the aryl groups, coupled with a low barrier for movement of the olefin.[7]

Solution NMR data at –60 °C[8] are consistent with the solid-state structure, showing discrete resonances for the diiminate halves *cis* and *trans* to the olefin. At room temperature, however, the L_{Me} ligand has effective C_{2v} symmetry, and only two broadened resonances are observed for the cyclooctene ligand in the ^1H spectrum, corresponding to 6 and 8 protons, respectively. We attribute this dynamic behavior to rapid equilibration between olefin and allyl hydride isomers.[9] This scrambles the COE hydrogens in two groups: (i) all *endo* hydrogens (6 H) and (ii) all *exo* hydrogens together with the vinylic hydrogens (8 H). Any intermolecular process would result in complete scrambling of all 14 COE hydrogens.

Owing to the complicated nature of the spectrum, we could not extract the activation energy, but the temperature region in which coalescence is observed (–50 to –20 °C) in-

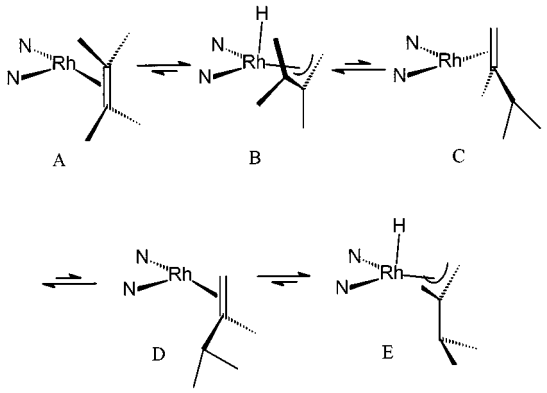
dicates a barrier of ca. 12 kcal/mol. B3LYP calculations confirm that the olefin complex LRh(propene) is more stable than the isomeric LRh(allyl)(H),[10] but the calculated energy difference is rather large (15 kcal/mol), and the calculated barrier of 24 kcal/mol is much larger than the experimental value for $L_{Me}Rh(COE)$. The difference of 12 kcal/mol between calculated and observed barriers might be attributable to deficiencies in the theoretical methods used[11] and/or to an absence of steric effects in the model system.[12] Figure 4 shows the calculated structures for the

two isomers and the transition state. The allyl hydride complex has a square-pyramidal structure, with the hydride occupying the apical position and the two outer allyl carbons in equatorial positions.



Reaction of $L_{Me}Li(THF)$ with $[Ir(COE)_2Cl]_2$ proceeded more slowly than in the Rh case, and the product was found to be unstable at room temperature (vide infra). Therefore, only a low yield (ca. 10%) of orange "$L_{Me}Ir(COE)$" could be obtained from this reaction. The ^1H- and ^{13}C-NMR spectra of this complex unambiguously establish a static allyl hydride structure $L_{Me}Ir(H)$(cyclooctenyl) ($\delta_H = -46.2$).[13] Repeated attempts to crystallize the product resulted only in poor crystals, which nevertheless allowed the connectivity to be established; this connectivity was consistent with the calculated structure shown in Figure 4. B3LYP calculations indicate that on going from Rh to Ir the relative stabilities of the olefin and allyl hydride isomers are indeed inverted (Figure 4).[14]

In the hope of obtaining a 14-*e* complex with a disorder-free structure, we also prepared red $L_{Cl}Rh(COE)$. The X-ray structure shows coordination of one of the chlorine atoms of the diiminate ligand to the metal (Figure 5). The rhodium atom is displaced out of the diiminate plane to allow close approach to the chlorine. In solution, this complex shows the same allyl hydride dynamic behavior as $L_{Me}Rh(COE)$, although the coalescence temperature is slightly higher. At –60 °C, the allyl hydride exchange is completely frozen out, but exchange of the two chlorine atoms of the chelating dichlorophenyl group remains rapid. The facile dissociation of the Rh–Cl bond in solution, as observed by NMR, does not imply that this is an intrinsically weak interaction. It merely shows that the diiminate ligand deformation needed to achieve Rh–Cl coordination requires nearly as much energy as is gained through formation of the coordination bond.

2,3-Dimethyl-2-butene Complex

When a solution of $L_{Me}Rh(COE)$ in 2,3-dimethyl-2-butene is stirred under hydrogen for a few minutes, all cyclooctene is lost as cyclooctane. After removal of the volatiles, the ^1H-NMR spectrum of the residue in $[D_8]$THF or C_6D_{12} shows strongly broadened signals attributable to a 2,3-dimethylbutene complex.[15] Apparently, *all* olefinic hydrogens in this complex are exchanging on the NMR timescale. Cooling of a $[D_8]$THF solution to –30 °C results in decoalescence of the diiminate 3-H signal into two signals of relative intensity 4:1 and considerable sharpening of the rest of the spectrum. At this temperature, the major component of the mixture (corresponding to the largest 3-H signal) gives rise to fairly sharp isopropyl group resonances (δ = 1.85 and 1.24) and a broad resonance at $\delta = -2.45$, which integrates for approximately 5 protons. Further cooling results in broadening of the resonance at $\delta = -2.45$, but at –60 °C (just above the melting point of THF) the static limit still has not been reached. Because of the multitude of peaks due to the major component and the oxidation product,[15] we cannot assign any peaks due to the minor component in the region δ = 0–2.5. However, below –40 °C, a clear hydride signal is seen at $\delta = -12$ with the appropriate intensity for 1 H of the minor component. In the ^{13}C spectrum, all peaks due to the major component and some peaks due to the minor component can be assigned.

Scheme 1 illustrates the interconversion of the isomers that can be formed from $L_{Me}Rh$(2,3-dimethyl-2-butene). The major component in the low-temperature spectrum must correspond to allyl hydride isomer **E** in equilibrium with olefin complex **D**. The observed average shift of $\delta = -2.45$ for the five protons not belonging to the isopropyl group is compatible with structure **E** but not with **D**. Thus, in contrast to cyclooctene, the equilibrium for this olefin lies on the side of the allyl hydride isomer. The minor component, which gives rise to a hydride resonance below –40 °C, must therefore be allyl hydride isomer **B**. In the olefin complexes **A**, **C**, and **D**, at least one of the substituents at the double bond points towards the diiminate aryl groups. It seems likely that steric repulsion makes the olefin complexes less stable than the allyl hydride isomers **B** and **E**.

Scheme 1. Proposed mechanism for the dynamic behavior of "$L_{Me}Rh$(2,3-dimethyl-2-butene)"

Norbornene Complex

The facile allyl hydride isomerization of cyclooctene and 2,3-dimethylbutene complexes made us wonder whether olefin complexes not containing any available allylic hydrogens would be prone to a similar C–H activation of more remote C–H bonds. Therefore, we tried to prepare a norbornene (NBE) analog of $L_{Me}Rh(COE)$ starting from $[Rh(NBE)_2Cl]_2$. This reaction invariably produced a very dark-colored mixture of complexes. ^1H-NMR showed the presence of a small amount (ca. 10%) of a compound giving signals at $\delta = -10.2$ (dd) and $\delta = -1.2$ (d), but we were not successful in isolating it from the mixture. However, treatment of $L_{Me}Rh(COE)$ with a threefold excess of NBE in hexane resulted in clean formation of the same compound in the form of red-brown crystals. The X-ray structure (Figure 6) shows that it is indeed a close analog of $L_{Me}Rh(COE)$, with a similarly distorted T-shaped coordination geometry. In this case, however, there is a clear agostic interaction with an Rh–H distance of less than 2 Å[16] [RhC = 2.531(4) Å]. This pronounced agostic interac-

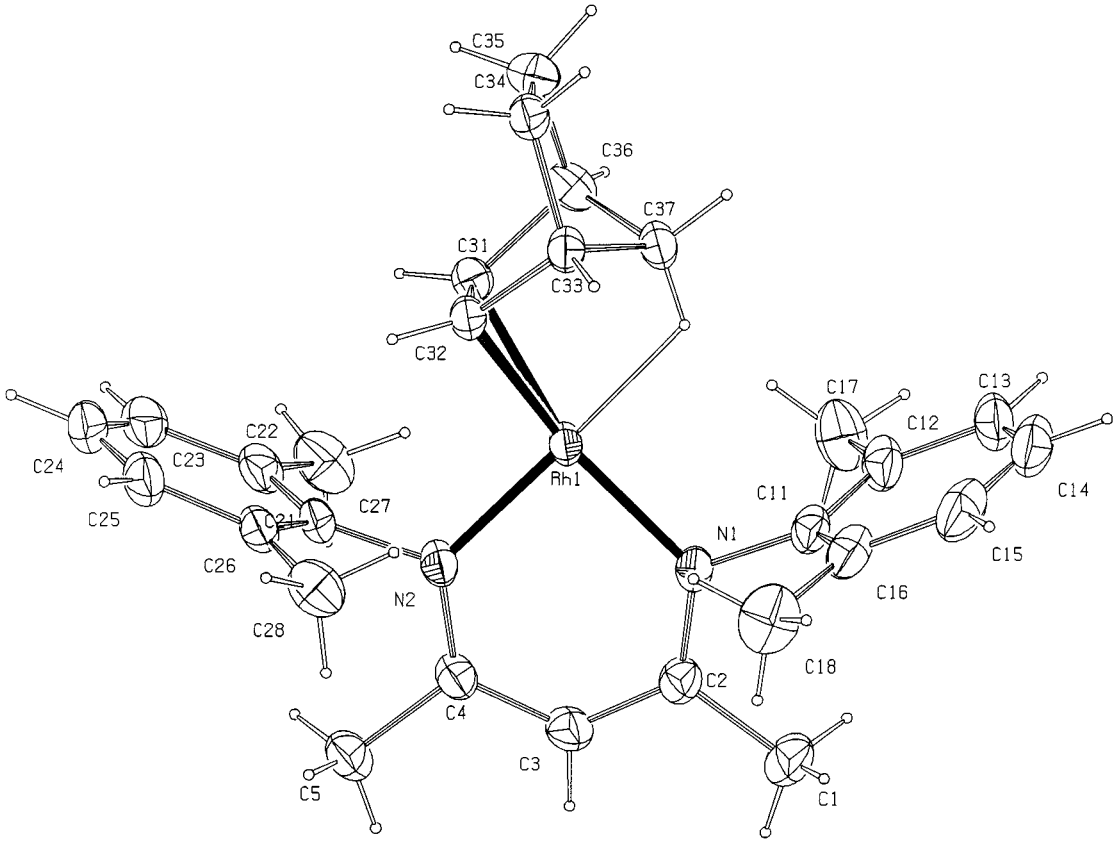


Figure 6. X-ray structure (30% ellipsoids) of $L_{Me}Rh(NBE)$; selected bond lengths (Å) and angles (°): Rh1–C31 2.115(4), Rh1–C32 2.095(4), Rh1–C37 2.531(4), Rh1–N1 2.021(3), Rh1–N2 1.985(3), C31–C32 1.395(6); N1–Rh1–N2 91.12(13)

tion accounts for the unusual high-field shift (δ = –10.2) of the bridge proton, which would more typically be associated with metal-bound hydrides. The alternative formulation as a cyclometallated olefin complex can be ruled out as the RhC distance is much too great for a single bond. Moreover, the methylene carbon is seen to be coupled to both hydrogens (J = 108 and 141 Hz), but shows no measurable coupling to Rh. Close approach of an NBE methylene hydrogen to a metal has also been observed in $(dien)Cu(NBE)^+$ [CuC = 2.78(1) Å, CuH = 2.01(15) Å],[17] but in the three other NBE complexes for which X-ray structures have been reported the distances between the metal and the methylene bridges are much larger: $[(t\text{Bu})_2P(CH_2)_2P(t\text{Bu})_2]Pt(NBE)$ (PtC = 3.18 Å, PtH = 2.75 Å),[18] $Pt(NBE)_3$ (PtC = 3.20/3.13/3.16 Å, PtH = 2.65/2.80/3.01 Å),[19] and a dicopper complex (CuC = 2.96/2.97 Å, CuH = 2.50/2.51 Å).[20]

The observation of a pronounced agostic interaction in $L_{Me}Rh(NBE)$ provides little information concerning the *strength* of this interaction. In fact, the NBE ligand appears to be predisposed towards such an agostic interaction; in the absence of any (repulsive or attractive) Rh–H forces, one would expect a structure very similar to the one observed. One observation that disfavours a strong agostic bond is the fact that such a bond is not observed at all in $L_{Me}Rh(COE)$, despite the fact that only a modest deformation of either the COE or the diiminate ligand would be required to obtain a short Rh–H contact.

In order to clarify this point, we carried out calculations on LRh(NBE). These reproduced most of the features of the X-ray structure of $L_{Me}Rh(NBE)$, although the shortening of Rh-C distances relative to those in the corresponding bis(ethene) complex was overestimated (calcd. 0.09 Å, obsd. 0.04 Å), while that of the Rh-N distances was underestimated (calcd. 0.02 Å, obsd. 0.09 Å). The agostic interaction is somewhat weaker in the calculated structure [RhH = 2.20 Å, RhC = 2.77 Å vs. 2.531(4) Å]; the agostic C–H bond is only slightly elongated (1.108 Å vs. 1.094 Å for the nonagostic bond). The angles about the methylene carbon are normal and there is no significant tilting of the NBE ligand towards the Rh atom. The calculated structure of LRh(NBE) is closer to T-shaped (N−Rh−olefin = 96°) than that observed for $L_{Me}Rh(NBE)$ (N−Rh−olefin = 102°); again, this may probably be attributed to the absence of steric constraints (vide supra) in the model. Fixing the N−Rh−olefin angle at 102° in the calculations costs only 0.7 kcal/mol and results in a slightly longer Rh−olefin bond (2.100 vs. 2.075 Å) and a more pronounced agostic interaction (RhC = 2.72 Å, RhH = 2.13 Å, C−H = 1.110 and 1.095 Å). Nevertheless, there are still no indications that the agostic interaction corresponds to a strong bond.[21]

$L_{Me}Rh(NBE)$ was found to be much less sensitive to air than $L_{Me}Rh(COE)$: a solution in THF had to be shaken in air for several minutes to effect complete oxidation, which was accompanied by liberation of NBE and formation of uncharacterizable rhodium complexes. We assume that the

relative inertness of the NBE complex reflects the inability (for steric reasons) of the NBE ligand to allow access to the fourth coordination site through rotation, and is not related to a large direct agostic bonding energy.

Complexes with Added Ligands

Because of its vacant coordination site, $L_{Me}Rh(COE)$ can be expected to be reactive towards added donor ligands. Indeed, reaction with excess acetonitrile gives yellow $L_{Me}Rh(COE)(MeCN)$, which has the expected square-planar structure (Figure 7). In THF or cyclohexane solution, $L_{Me}Rh(COE)$ reacts with dinitrogen to form brown $L_{Me}Rh(COE)(N_2)$ ($\tilde{\nu}_{NN}$ = 2172 cm^{-1}), from which the N_2 is lost in vacuo. NMR data indicate that the dinitrogen complex also has the expected static square-planar structure. In view of the weakness of the N_2 complexation in $L_{Me}Rh(COE)(N_2)$, it is hardly surprising that agostic $L_{Me}Rh(NBE)$ and 4-coordinate $L_{Cl}Rh(COE)$ do not react with N_2. Reaction of $L_{Me}Rh(COE)$ with excess 1-hexene results in a brown solution, presumably containing $L_{Me}Rh(COE)(hexene)$. On evacuation, this complex loses olefin to give a mixture of $L_{Me}Rh(COE)$ and $L_{Me}Rh(hexene)$ (ca. 4:1 by NMR).

No reaction was observed with TMEDA. NMR spectra of $L_{Me}Rh(COE)$ in cyclohexane, benzene, toluene, and THF are virtually identical, showing the same olefin–allyl hydride dynamic behaviour. Thus, it is evident that THF does not coordinate either.[8] Steric factors may be involved, or it may be that interaction with pure σ-donors such as ethers and amines is weak. Table 1 lists the calculated binding energies for various simple donor molecules at the $LRh(C_2H_4)$ and $LIr(C_2H_4)$ fragments. Bonds to Ir are consistently stronger than those to Rh; for both metals, the order is $H_2 < C_2H_4 \approx$ MeCN $\approx Me_2O \approx N_2 <$ CO. Ligands allowing strong back-donation, such as H_2 and CO, show the largest differences

Table 1. Calculated ligand binding energies of $LRh(C_2H_4)$ and $LIr(C_2H_4)$ fragments [kcal/mol]

Ligand	$LRh(C_2H_4)$	$LIr(C_2H_4)$
CO	40.6	71.2
N_2	30.5	48.2
Me_2O	29.9	35.3
MeCN	28.4	44.7
C_2H_4	24.4	46.3
H_2	11.1	33.2

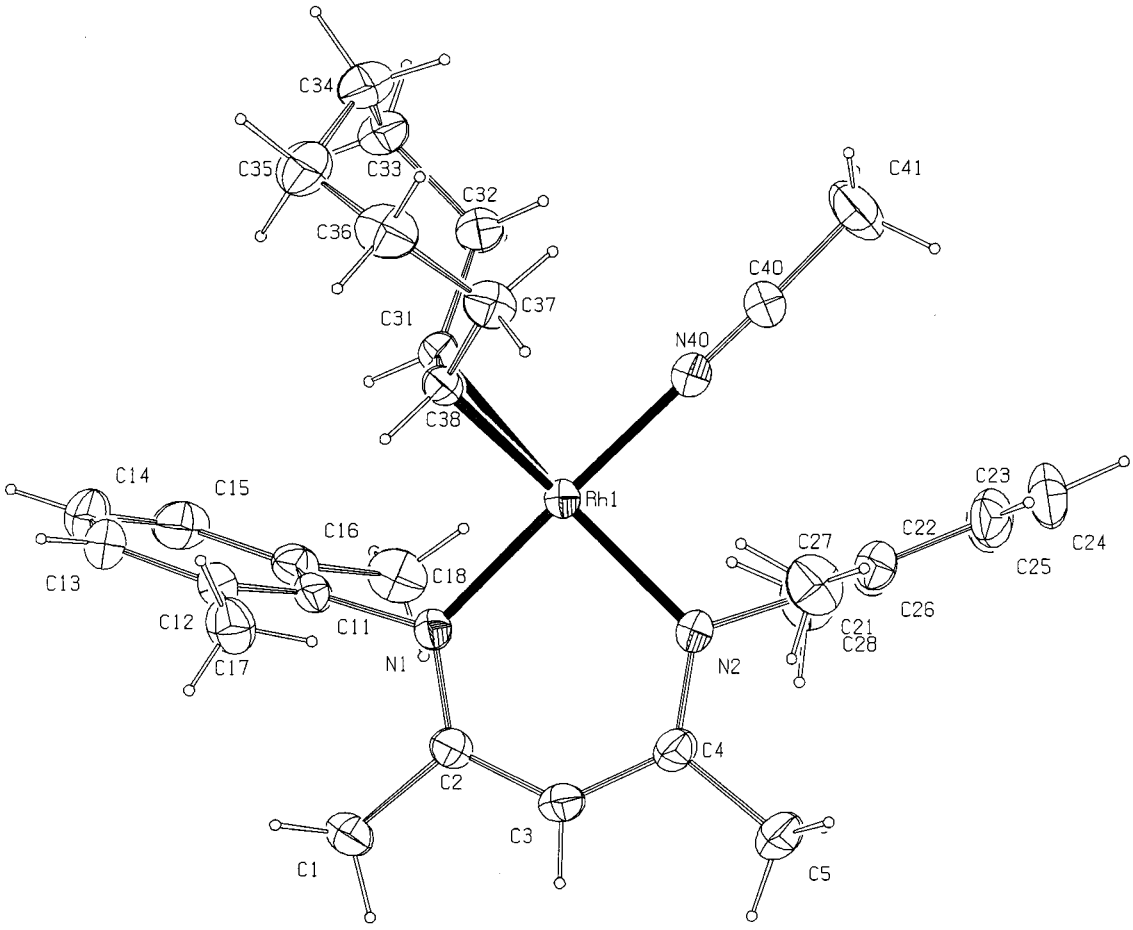

Figure 7. X-ray structure (30% ellipsoids) of $L_{Me}Rh(COE)(MeCN)$; selected bond lengths (Å) and angles (°): Rh1–C31 2.175(2), Rh1–C38 2.115(2), Rh1–N1 2.0598(16), Rh1–N2 2.0821(18), Rh1–N40 1.9899(19), C31–C38 1.399(3), N40–C40 1.136(3); N1–Rh1–N2 89.93(7), N2–Rh1–N40 88.72(7)

between Rh and Ir. The calculated coordination strengths of σ-donors (Me_2O, MeCN) are not much smaller than those of π-acceptors, which suggests that the lack of strong THF coordination is mainly due to steric factors.

Hydrogen Complexes

Reaction of $L_{Me}Rh(COE)$ with hydrogen at –40 °C in [D_8]THF produces $L_{Me}Rh(COE)(H_2)$ (characterized by ^{1}H- and ^{13}C-NMR), the large linewidth of the hydride signal of which is suggestive of a dihydrogen complex (T_1 = 10 ms at –30 °C).[22] If the solution is allowed to warm from –40 °C to 0 °C under a hydrogen atmosphere, kept at 0 °C for a few seconds, and then cooled to –40 °C once more, the dihydrogen complex is no longer present and the dominant species (ca. 50% of the total) is a dinuclear hydride (δ_H = –24.4, J_{RhH} = 25.3 Hz), to which we tentatively assign the composition $(L_{Me}Rh)_2H_4$. This compound decomposes on attempted removal of the solvent at low temperature, and on standing in solution at room temperature, hence it could not be isolated. Deactivation of low-coordinate cationic Ir hydrogenation catalysts has also been shown to involve the formation of hydride cluster complexes.[23]

The iridium complex $L_{Me}Ir(H)$(cyclooctenyl) reacts instantaneously with hydrogen at room temperature to form the stable complex $L_{Me}Ir(COE)H_2$ (δ_H = –22.7), which does not react further with olefins and/or H_2. The X-ray structure of this complex shows a regular T-shaped coordination geometry about Ir (Figure 8). The hydrogens bound to Ir could not be located, but the narrow hydride resonance suggests that in this case we are dealing with a classical dihydride. Surprisingly, $L_{Me}Ir(COE)H_2$ is also one of the decomposition products of $L_{Me}Ir(H)$(cyclooctenyl) in solution at room temperature in the *absence* of H_2. If this decomposition is carried out in a deuterated solvent ([D_8]THF, C_6D_6), a moderate amount of the mono-deuterated complex $L_{Me}Ir(COE)HD$ is formed.[24] The H–D coupling constant of 5.6 Hz is too small for a hydrogen complex, but rather large for a dihydride.[25] The NMR spectra show effective C_{2v} symmetry at room temperature, hence the molecule must be fluxional.

The surprisingly different behaviour of the Rh and Ir complexes towards H_2 is corroborated by the calculated structures of $LRh(C_2H_4)(H_2)$ and $LIr(C_2H_4)H_2$. In both cases, only a single minimum could be located. The Rh

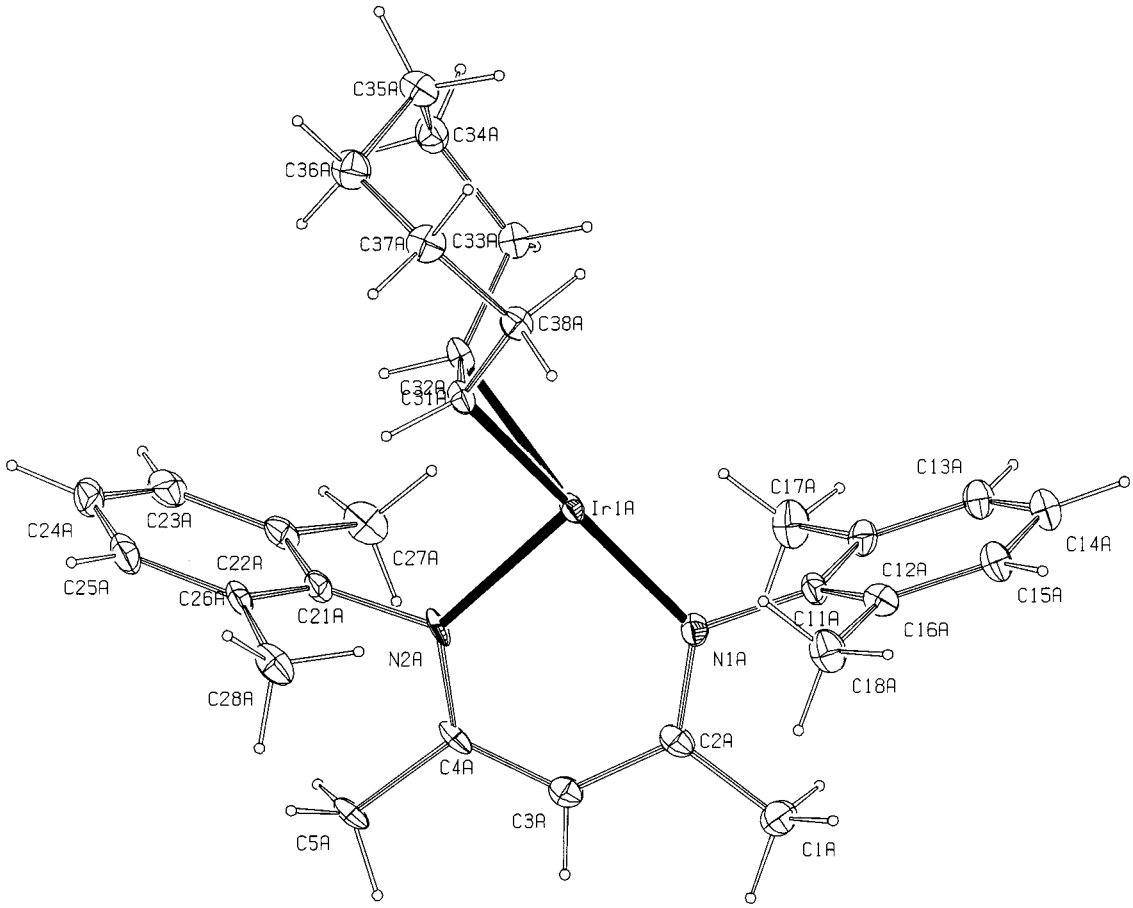

Figure 8. X-ray structure (30% ellipsoids) of $L_{Me}Ir(COE)(H_2)$; only one of the two independent molecules is shown; the hydrides were not located; selected bond lengths (Å) and angles (°): Ir1A–C31A 2.147(4), Ir1A–C32A 2.158(5), Ir1A–N1A 2.036(4), Ir1A–N2A 2.113(4), C31A–C32A 1.411(6), Ir1B–C31B 2.154(6), Ir1B–C32B 2.158(6), Ir1B–N1B 2.036(4), Ir1B–N2B 2.102(4), C31B–C32B 1.421(7); N1A–Ir1A–N2A 89.79(17), N1B–Ir1B–N2B 89.95(17)

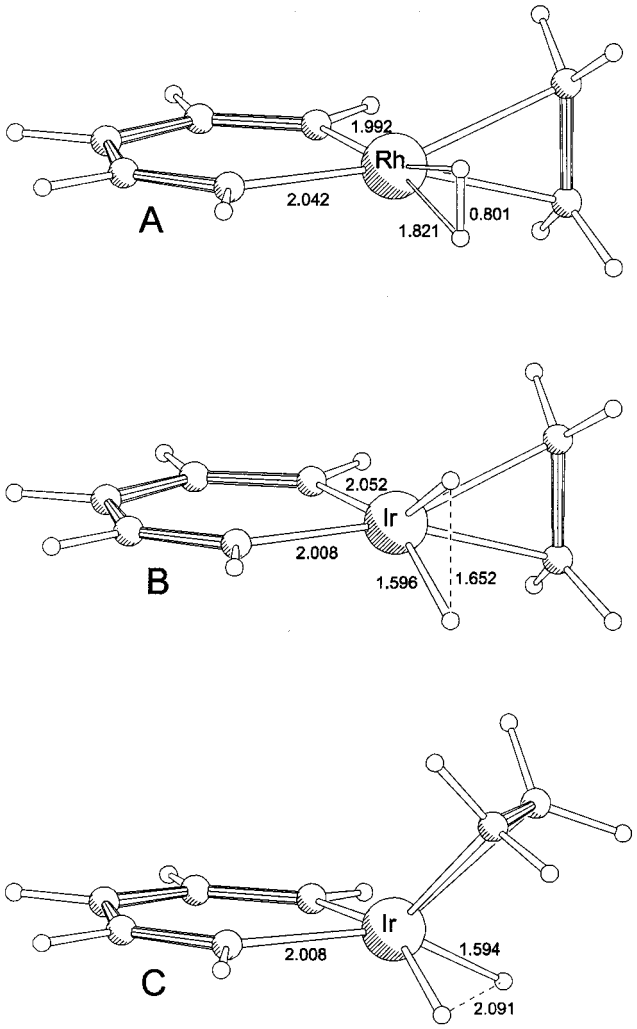

Figure 9. Calculated structures of (A) $LRh(C_2H_4)(H_2)$, (B) $LIr(C_2H_4)H_2$, and (C) the transition state for its left–right isomerization

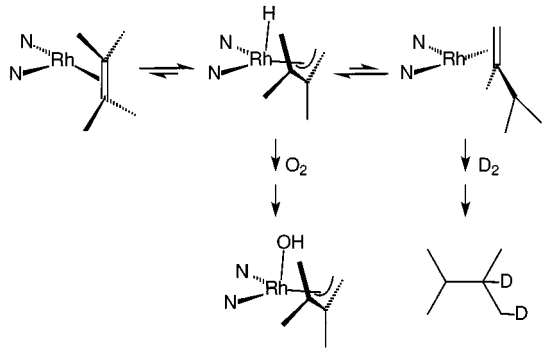
complex (Figure 9, A) is a loosely bound (11 kcal/mol) square-planar Rh^I dihydrogen complex, in which the H–H bond is only slightly elongated (0.80 Å vs. 0.75 Å in H_2). In contrast, the Ir complex (Figure 9, B) is a strongly bound (33 kcal/mol) trigonal-bipyramidal Ir^{III} dihydride with a nonbonding (but nevertheless rather short) H–H distance of 1.65 Å. The observed fluxionality of $L_{Me}Ir(COE)H_2$ must involve a left–right shift of the olefin. The corresponding calculated transition state for $LIr(C_2H_4)H_2$ (Figure 9, C) has a square-pyramidal structure with an apical olefin ligand and an increased H–H distance of 2.09 Å. The calculated activation energy of 14 kcal/mol is compatible with this rearrangement being fast at room temperature.

Olefin Hydrogenation

$L_{Me}Rh(COE)$ is active as a catalyst in olefin hydrogenation; activity data for a few representative olefins are given in Table 2. Surprisingly, turnovers are comparable for both simple (1-hexene, cyclooctene) and highly substituted (1-methylcyclohexene, 2,3-dimethyl-2-butene) olefins. Bis(cyclohexylidene) is also hydrogenated, albeit with low turnover, but 1-*tert*-butylcyclohexene is not. The catalyst is very sensitive to impurities in the olefin or hydrogen; the turnover numbers in the table are limited by catalyst deactivation. For this reason, we have not tried to obtain kinetic data. The turnovers are not very sensitive to catalyst or olefin concentration, but do show a significant dependence on temperature (COE at 0 °C: 38 turnovers after 2 h, 49 after 4 h) and hydrogen pressure (COE at 20 bar H_2: 170 turnovers after 2 h).

In the case of cyclooctene hydrogenation, the main deactivation product was identified by NMR as $L_{Me}Rh(1,4\text{-COD})$, presumably formed from traces of 1,4-COD in the COE substrate.[26]



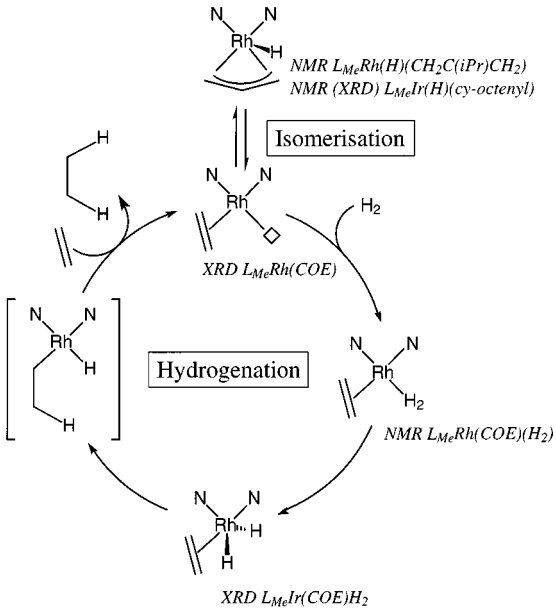
With 2,3-dimethyl-2-butene, the main catalyst deactivation product (ca. 90%) was a deep-green compound, which was identified as $L_{Me}Rh(OH)[\eta^3\text{-}CH_2C(Me)CMe_2]$ by NMR. Its formation can probably be attributed to trapping of an allyl hydride intermediate by traces of oxygen in the hydrogen used. Reduction of 2,3-dimethyl-2-butene with D_2 led to exclusive 1,2-deuteration; no higher deuterated species were detected. This demonstrates that olefin isomerization precedes hydrogenation. Since both cyclooctene and dimethylbutene undergo rapid isomerization according to the olefin–allyl hydride mechanism, it is reasonable to assume that this mechanism is also responsible for the isomerization during catalytic hydrogenation (Scheme 2). Hydrogenation of the trisubstituted olefin 1-methylcyclohexene might also involve an initial isomerization step.

Use of $L_{Me}Rh(COE)$ in hydrogenation is awkward because of its extreme sensitivity. However, less sensitive precursors such as $L_{Me}Rh(C_2H_4)_2$ and $L_{Me}Rh(COE)(MeCN)$ were found to give similar turnovers (see Table 2). Presumably, the active species is the same in all cases. $L_{Me}Rh(COD)$ could not be used as a precursor as it is too stable and does not react with hydrogen even at 100 °C. Catalysts derived from the L_{Cl} ligand give comparable turn-

Table 2. Olefin hydrogenation by β-diiminate Rh complexes

	Total turnover[a]		
Catalyst	cyclooctene	1-methyl-cyclohexene	2,3-dimethyl-2-butene[b]
$L_{Me}Rh(C_2H_4)_2$	77	70	43
$L_{Me}Rh(COE)$	89	44	42
$L_{Me}Rh(COE)(MeCN)$	89	n.d.	42
$L_{Cl}Rh(C_2H_4)_2$	73	42	11

[a] Neat olefin, olefin/catalyst = 125:1, 1 bar H_2, 2 h, room temperature; the catalyst was deactivated at the end of the experiment. – [b] After workup, a small amount of 2,3-epoxy-2,3-dimethylbutane was detected by GC/MS.



Scheme 2. Hydrogenation of 2,3-dimethyl-2-butene

overs with cyclooctene, but with the more hindered substrates the turnovers are significantly lower. We attribute this to catalyst decomposition through C–Cl oxidative addition,[27] which is able to compete with the coordination of an incoming olefin in the course of hydrogenation.

L_{Me}Ir(H)(cyclooctenyl) does not catalyze olefin hydrogenation, but merely reacts with hydrogen to form the stable dihydride L_{Me}Ir(COE)H_2, as mentioned earlier.

It is tempting to put together a catalytic cycle based on the Rh species (and their Ir analogues) observed in this work. Such a cycle is illustrated in Scheme 3. In the absence of any kinetic data, such a cycle must of course remain speculative.[28] However, it is hard to think of any realistic possibilities for ligand dissociation that would produce alternative active species. Moreover, the marginal stability of the dihydrogen complex L_{Me}Rh(COE)(H_2) is certainly compatible with its involvement in the relatively slow hydrogenation at room temperature. Here, the rate-determining step would probably be the conversion of the dihydrogen complex to a dihydride or its subsequent olefin insertion.

Scheme 3. Proposed cycles for olefin hydrogenation and isomerization based on the species observed; some of the steps of the hydrogenation cycle may be reversible

The cycle in Scheme 3 conforms to the "olefin route", in which the olefin is bound *before* the hydrogen.[29] This certainly happens on initiation, and, in view of the large excess of olefin and the higher calculated olefin binding energy, it most likely happens during propagation as well. However, we cannot exclude that – particularly at high conversions – a hydrogen route might become important. The precise nature of the alkane elimination step (associative or dissociative) also remains unclear.[30]

Most hydrogenation cycles involving Rh or Ir alternate between 16-*e* and 18-*e* species.[28,31] Even in cases where several active species are involved, they all go through intermediates with the same electron count. In our case, the catalysis appears to involve a 14-*e*/16-*e* mechanism, at least for the more hindered olefins, which may be attributed to steric factors.

Conclusions

Bulky β-diiminate ligands (such as L_{Me} and L_{Cl}) are good at stabilizing low coordination numbers, as demonstrated by the present work and by recent reports in the area of early transition metal chemistry. The ligand L_{Me} is particularly useful because its complexes nearly always crystallize well.[32] The ligand L_{Cl} tends to form even better crystallizing complexes, but the reactivity of the C–Cl bonds sometimes introduces complications.

The stabilization of low CN complexes by steric hindrance has allowed us to isolate a number of complexes that would normally be considered as reactive intermediates. Moreover, the use of Ir as a "model" for Rh[33] allows the direct observation of M^{III} species that for Rh would be transient intermediates in conversions between stable M^{I} species. This has allowed us to construct plausible catalytic cycles for hydrogenation and isomerization. Remarkably, the present hydrogenation appears to follow a 14-*e*/16-*e* path instead of the more usual 16-*e*/18-*e* path.

We attribute the observed stabilization of low CN complexes to the shielding of the metal atom by the vertical "walls" of the diiminate aryl groups. A perpendicular orientation of these groups is favoured by the 2,6-disubstitution pattern, which results in a strong repulsive interaction with the backbone methyl groups in a planar conformation. Indeed, work on early transition metal compounds has demonstrated dramatically increased reactivity of a low CN complex on removal of one or both of the substituents on the aryl groups.[1] However, the structure of L_{Cl}Rh(COE) shows that even 2,6-disubstituted aryl groups still have considerable freedom of movement.

One final point of interest is the observation of a pronounced agostic interaction in the L_{Me}Rh(NBE) species but not in L_{Me}Rh(COE). On the basis of both experimental and theoretical evidence, we conclude that in the former system close Rh–H contacts can easily form but do not correspond to strong bonds. Thus, caution should be exercised in equat-

ing small distances with large interaction energies. Such a conclusion is only justified in cases where the ligand undergoes considerable distortion to create the short contact.

Experimental Section

Calculations: All calculations were carried out using the Gaussian program[34] on SGI workstations. The small split-valence 3–21G basis was used for the first-row atoms.[35] For Rh and Ir, relativistic effective core potentials were used for the inner core orbitals and the LanL2DZ basis was used for the valence and outer core electrons;[36] the most diffuse *d* function in this basis was replaced by two components with exponents 1.4142 times higher and lower than the original exponent. Geometries were optimized at the RB3LYP[37] level without any constraints, unless stated otherwise.

Syntheses: All reactions were carried out under Ar. Solvents were distilled from Na/benzophenone prior to use. $[Rh(COD)Cl]_2$,[38] $[Rh(C_2H_4)_2Cl]_2$,[39] $[Rh(COE)_2Cl]_2$, and $[Ir(COE)_2Cl]_2$[40] were prepared according to literature methods.

$L_{Me}H$: A mixture of 2,6-dimethylaniline (30.5 mL, 30 g, 0.25 mol), 2,4-pentanedione (12.7 mL, 12.4 g, 0.12 mol), and *p*-toluenesulfonic acid (21.3 g) in toluene (350 mL) was refluxed for 24 h in a Dean-Stark apparatus. The toluene was then decanted off, and the solid residue was treated with diethyl ether (250 mL), water (200 mL), and $Na_2CO_3 10\ H_2O$ (53 g). After stirring for 25 min, the ether layer was separated, dried with $MgSO_4$, and the solvent was removed in vacuo. The residue was dried in vacuo (10^{-2} bar) at 100 °C for 6 h to remove any remaining free 2,6-dimethylaniline, to give 28.5 g (75%) of $L_{Me}H$. – $C_{21}H_{26}N_2$ (306.45): calcd. C 82.31, H 8.55, N 9.14; found C 81.82, H 8.71, N 8.97. – ^{1}H NMR ($CDCl_3$, 200 MHz): δ = 1.72 (1-H), 4.91 (3-H), 6.96–7.09 (m, *m*- + *p*-H), 2.19 (*o*-CH_3), 12.2 (br., NH). – $^{13}C\{^1H\}$ NMR (75.5 MHz): δ = 20.8 (C-1), 161.2 (C-2), 94.1 (C-3), 144.2 (*i*-C), 132.5 (*o*-C), 128.3 (*m*-C), 124.9 (*p*-C), 18.9 (*o*-CH_3).

$L_{Me}Li(THF)$: To a solution of LH (10 g) in THF (100 mL) was added a solution of $LiN(iPr)_2$ in THF [prepared from 1.6 M *n*-BuLi/hexane (20.5 mL) and diisopropylamine (4.6 mL)]. The solvent was subsequently removed in vacuo and the residue was crystallized from a hot toluene/hexane mixture to give 8.2 g (65%) of LLi(THF). – $C_{25}H_{33}N_2OLi$ (384.49): calcd. C 78.10, H 8.65, N 7.29; found C 78.36, H 8.52, N 7.45. – ^{1}H NMR (C_6D_6, 200 MHz): δ = 1.84 (1-H), 5.00 (3-H), 7.12 (d, *m*-H), 6.96 (t, *p*-H), 2.25 (*o*-CH_3); 2.86, 0.89 (THF). – $^{13}C\{^1H\}$ NMR (50.3 MHz): δ = 22.7 (C-1), 163.2 (C-2), 92.9 (C-3), 152.7 (*i*-C), 130.5 (*o*-C), 128.0 (*m*-C), 121.9 (*p*-C), 18.8 (*o*-CH_3); 67.7, 24.9 (THF).

$L_{Cl}H$: A mixture of 2,6-dichloroaniline (40.5 g, 0.25 mol), 2,4-pentanedione (12.7 mL, 12.4 g, 0.12 mol), and *p*-toluenesulfonic acid (21.3 g) in toluene (350 mL) was refluxed for 24 h in a Dean-Stark apparatus. The toluene was then decanted off, and the solid residue was treated with diethyl ether (250 mL), water (200 mL), and $Na_2CO_3 10\ H_2O$ (53 g). After stirring for 25 min, the ether layer was separated, dried with $MgSO_4$, and the solvent was removed in vacuo. The residue was dried in vacuo (10^{-2} bar) at 100 °C for 6 h to remove any remaining free 2,6-dichloroaniline, and the residue was crystallized from heptane to give 34 g (70%) of $L_{Cl}H$. – $C_{17}H_{14}N_2Cl_4$ (388.12): calcd. C 52.61, H 3.64, N 7.22, Cl 36.54; found C 52.74, H 3.67, N 7.38, Cl 36.43. – ^{1}H NMR ($CDCl_3$, 200 MHz): δ = 1.71 (1-H), 4.94 (3-H), 7.17 (d, *m*-H), 6.86 (t, *p*-H), 12.0 (NH). – $^{13}C\{^1H\}$ NMR (50.3 MHz): δ = 21.4 (C-1), 163.1 (C-2), 95.9 (C-3), 141.1 (*i*-C), 131.7 (*o*-C), 128.6 (*m*-C), 126.2 (*p*-C).

$L_{Cl}Li(THF)$: To a solution of $L_{Cl}H$ (12.6 g) in THF (100 mL) was added a solution of $LiN(iPr)_2$ in THF [prepared from 1.6 M *n*-BuLi/hexane (20.5 mL) and diisopropylamine (4.6 mL)]. The solvent was subsequently removed in vacuo, and the residue was crystallized from a hot toluene/hexane mixture to give 12.2 g (80%) of yellow $L_{Cl}Li(THF)$. – $C_{21}H_{21}N_2OCl_4Li$ (466.16): calcd. C 54.11, H 4.54, N 6.01, Cl 30.42; found C 54.06, H 4.59, N 6.13, Cl 30.54. – ^{1}H NMR (C_6D_6, 200 MHz): δ = 1.82 (1-H), 4.93 (3-H), 7.02 (d, *m*-H), 6.32 (t, *p*-H); 2.96, 0.82 (THF). – $^{13}C\{^1H\}$ NMR (50.3 MHz): δ = 23.5 (C-1), 165.6 (C-2), 95.6 (C-3), 149.5 (*i*-C), 130.7 (*o*-C), 128.7 (*m*-C), 123.0 (*p*-C); 68.2, 25.2 (THF).

$L_{Me}Rh(1,5\text{-}COD)$: A solution of $L_{Me}Li(THF)$ (1.0 g) in THF (10 mL) was added to a suspension of $[Rh(1,5\text{-}COD)Cl]_2$ (0.64 g) in THF (5 mL). The resulting mixture was stirred at room temperature for 2 h, and then the solvent was removed in vacuo. The residue was crystallized from benzene/hexane (2:1) (the hot solution was filtered to remove LiCl) to give yellow crystals of $L_{Me}Rh(1,5\text{-}COD)$ (1.2 g, 88%). – $C_{29}H_{37}N_2Rh$ (516.53): calcd. C 67.43, H 7.22, N 5.42; found C 67.42, H 7.38, N 5.42. – ^{1}H NMR ($CDCl_3$, 200 MHz): δ = 1.55 (1-H), 5.10 (3-H), 6.97–7.11 (m, *m*- + *p*-H), 2.31 (*o*-CH_3), 3.01 (br., CH=CH), 2.12, 1.60 (CH_2). – $^{13}C\{^1H\}$ NMR (50.3 MHz): δ = 25.5 (C-1), 159.3 (C-2), 97.8 (C-3), 150.9 (*i*-C), 132.9 (*o*-C), 128.7 (*m*-C), 124.9 (*p*-C), 19.3 (*o*-CH_3), 79.8 (CH=CH, J_{RhC} = 13 Hz), 31.1 (CH_2).

$L_{Cl}Rh(1,5\text{-}COD)$: A solution of $L_{Cl}Li(THF)$ (0.5 g) in THF (10 mL) was added to a suspension of $[Rh(1,5\text{-}COD)Cl]_2$ (0.26 g) in THF (5 mL). The resulting mixture was stirred at room temperature for 4 h, and then the solvent was removed in vacuo. The residue was crystallized from toluene (70/–20 °C; the hot solution was filtered to remove LiCl) to give yellow crystals of $L_{Cl}Rh(1,5\text{-}COD)$ (0.32 g, 50%). – $C_{25}H_{25}N_2Cl_4Rh$ (598.20): calcd. C 50.20, H 4.21, N 4.68, Cl 23.71; found C 50.14, H 4.12, N 4.69, Cl 23.57. – ^{1}H NMR (C_6D_6, 200 MHz): δ = 1.72 (1-H), 5.28 (3-H), 7.14 (d, *m*-H), 6.45 (t, *p*-H), 3.61 (br., CH=CH), 2.33, 1.56 (m, CH_2). – $^{13}C\{^1H\}$ NMR (50.3 MHz): δ = 25.1 (C-1), 160.9 (C-2), 99.3 (C-3), 147.8 (*i*-C), 132.9 (*o*-C), 128.5 (*m*-C), 125.8 (*p*-C), 78.8 (CH=CH, J_{RhC} = 13 Hz), 30.8 (CH_2).

$L_{Me}Rh(C_2H_4)_2$: A solution of $L_{Me}Li(THF)$ (1.0 g) in THF (10 mL) was added to a suspension of $[Rh(C_2H_4)_2Cl]_2$ (0.51 g) in THF (5 mL). The resulting mixture was stirred at room temperature for 2 h, and then the solvent was removed in vacuo. The residue was crystallized from diethyl ether (30/–20 °C; the warm solution was filtered to remove LiCl) to give very large, dark brown-yellow crystals of $L_{Me}Rh(C_2H_4)_2$ (0.68 g, 50%). Small crystals or powdered material are yellow. – $C_{25}H_{33}N_2Rh$ (464.45): calcd. C 64.54, H 7.16, N 6.03; found C 64.77, H 7.22, N 6.16. – ^{1}H NMR (C_6D_6, 200 MHz): δ = 1.65 (1-H), 5.30 (3-H), 7.04–7.12 (m, *m*- + *p*-H), 2.41 (*o*-CH_3), 2.62, 2.01 (m, C_2H_4). – $^{13}C\{^1H\}$ NMR (50.3 MHz): δ = 25.9 (C-1), 159.5 (C-2), 98.9 (C-3), 150.4 (*i*-C), 133.0 (*o*-C), 129.2 (*m*-C), 125.7 (*p*-C), 19.8 (*o*-CH_3), 63.3 (C_2H_4, J_{RhC} = 11 Hz).

$L_{Cl}Rh(C_2H_4)_2$: A solution of $L_{Cl}Li(THF)$ (0.5 g) in THF (10 mL) was added to a suspension of $[Rh(C_2H_4)_2Cl]_2$ (0.21 g) in THF (5 mL). The resulting mixture was stirred at room temperature for 2 h, and then the solvent was removed in vacuo. The residue was crystallized from diethyl ether (30/–20 °C; the warm solution was filtered to remove LiCl) to give dark-red crystals of $L_{Cl}Rh(C_2H_4)_2$ (0.22 g, 36%). – $C_{21}H_{21}N_2Cl_4Rh$ (546.13): calcd. C 46.19, H 3.88, N 5.13, Cl 25.97; found C 46.21, H 3.89, N 5.25, Cl 25.85. – ^{1}H NMR (C_6D_6, 200 MHz): δ = 1.73 (1-H), 5.29 (3-H), 7.05 (d, *m*-

H), 6.44 (t, *p*-H), 2.88, 2.02 (m, C_2H_4). – $^{13}C\{^1H\}$ NMR (125.76 MHz): δ = 24.2 (C-1), 159.9 (C-2), 98.1 (C-3), 146.1 (*i*-C), 131.8 (*o*-C), 127.4 (*m*-C), 125.0 (*p*-C), 60.8 (C_2H_4, J_{RhC} = 12 Hz).

L_{Me}Rh(COE): A solution of L_{Me}Li(THF) (3.24 g) in THF (10 mL) was added to a suspension of $[Rh(COE)_2Cl]_2$ (3.03 g) in THF (5 mL). The resulting mixture was stirred at room temperature for 1 day, and then the solvent was removed in vacuo. The residue was extracted with two 50 mL portions of warm hexane (60 °C), the combined extracts were concentrated to a volume of 15 mL, and cooled to –20 °C. The next day, a crop of dark-violet crystals had formed. These crystals were recrystallized from fresh hexane to give 3.0 g (66%) of L_{Me}Rh(COE). Crystals suitable for X-ray diffraction analysis were obtained by slow crystallization from cyclohexane. – $C_{29}H_{39}N_2Rh$ (518.55): calcd. C 67.17, H 7.58, N 5.40; found C 67.04, H 7.41, N 5.57. – ^1H NMR (200 MHz, C_6D_{12}, room temp.): δ = 1.72 (1-H), 5.18 (3-H), 7.0–7.1 (m, *m*- + *p*-H), 2.65 (*o*-CH_3), 1.87 (br. s, 8 H), 0.34 (br. s, 6 H) cyclooctene. – ^1H NMR (500 MHz, $[D_8]$THF, –80 °C): δ = 1.55, 1.39 (1-,1′-H), 4.95 (3-H), 7.16, 7.10 (*m*-,*m*′-H), 7.06, 7.05 (*p*-,*p*′-H), 2.70, 2.39 (*o*,*o*′-CH_3), 2.48 (CH=CH), 2.08, 1.5, 1.2, 1.0 (br., CH_2). – $^{13}C\{^1H\}$ NMR (125.7 MHz, $[D_8]$THF, –80 °C): δ = 24.1 (C-1), 26.5 (C-1′, superimposed by solvent signal), 158.6, 156.3, 154.3, 150.9 (C-2, C-2′, *i*-,*i*′-C), 100.4 (C-3, J_{RhC} = 39 Hz), 134.6, 134.5 (*o*-,*o*′-C), 129.9, 129.5 (*m*-,*m*′-C), 126.2, 125.8 (*p*-,*p*′-C), 21.1, 20.4 (*o*,*o*′-CH_3), 64.8 (br., CH=CH), 31.6 (br., CH_2); remaining CH_2 groups not observed.

L_{Me}Ir(cyclooctenyl)(H): A solution of L_{Me}Li(THF) (1.0 g) in diethyl ether (10 mL) was added to a suspension of $[Ir(COE)_2Cl]_2$ (1.16 g) in diethyl ether (5 mL). The resulting mixture was stirred at room temperature for 4 h, and then the solvent was removed in vacuo. The residue was extracted with two 20 mL portions of hexane, the combined extracts were concentrated to a volume of 8 mL, and cooled to –20 °C. After 3 days, orange-red crystals had formed. Concentration of the mother liquor to 3 mL and cooling to –20 °C produced a second crop of crystals. The crystals were dried in vacuo and stored at –20 °C. – $C_{29}H_{39}N_2Ir$ (607.86): calcd. C 57.30, H 6.47, N 4.61; found C 57.08, H 6.56, N 4.74. – ^1H NMR ($[D_8]$THF, –20 °C, 400 MHz): δ = 1.70 (1-H), 5.37 (3-H), 7.20, 7.18 (d, *m*- + *m*′-H), 6.99 (t, *p*-H), 2.16, 2.21 (*o*,*o*′-CH_3), 5.40 (t, 1 H), 2.54 (br. q, 2 H, cyclooctenyl CH), 1.90, 1.27, 1.05, 0.82, 0.25 (br. m, CH_2), –46.19 (IrH). – $^{13}C\{^1H\}$ (100.6 MHz): δ = 23.9 (C-1), 157.6 (C-2), 103.2 (C-3), 157.2 (*i*-C), 132.7, 130.9 (*o*-,*o*′-C), 130.2, 129.8 (*m*-,*m*′-C), 126.0 (*p*-C), 20.3, 20.0 (*o*,*o*′-CH_3), 84.9, 49.6 (cyclooctenyl CH), 32.8, 30.3, 19.9 (CH_2). – IR (KBr): $\tilde{\nu}_{Ir-H}$ = 2122 cm^{-1}.

L_{Cl}Rh(COE): A solution of L_{Cl}Li(THF) (2.0 g) in THF (10 mL) was added to a suspension of $[Rh(COE)_2Cl]_2$ (1.54 g) in THF (10 mL). The resulting mixture was stirred at room temperature for 1 h, and then the solvent was removed in vacuo. The residue was extracted with two 50 mL portions of hexane, the combined extracts were concentrated to dryness in vacuo, and the residue was redissolved in diethyl ether (50 mL). This solution was filtered and then concentrated to a volume of 4 mL and stored overnight at –20 °C. Thereafter, fine red needles had formed, which were filtered off and dried in vacuo to give 0.77 g (30%) of L_{Cl}Rh(COE). – $C_{25}H_{27}N_2Cl_4Rh$ (600.22): calcd. C 50.03, H 4.53, N 4.67, Cl 23.63; found C 49.86, H 4.54, N 4.80, Cl 23.63. – ^1H NMR (200 MHz, C_6D_6, 25 °C): δ = 6.96 (d, 4 H, *m*-H), 6.34 (t, 2 H, *p*-H), 5.36 (s, 1 H, 3-H), 2.2 (v. br., 8 H, COE *exo* ± vinylic), 1.89 (s, 1-H), 1.47 (br., 6 H, COE *endo*). – ^1H NMR (500.13 MHz, $[D_8]$THF, –53 °C[8]): δ = 7.48, 7.39 (m, 2 H each, *m*-,*m*′-H), 7.22, 6.90 (m, 1 H each, *p*-,*p*′-H), 5.30 (s, 1 H, 3-H), 2.20, 1.58 (s, 3 H each, 1-,1′-H), 1.1–2.6 (overlapping multiplets, 14 H, COE). – $^{13}C\{^1H\}$ NMR (125.76 MHz, $[D_8]$THF, –53 °C[8]): δ = 162.5, 162.2 (2-C, 2′-C), 151.7, 146.5 (*i*-,*i*′-C), 133.5, 130.4 (*o*-,*o*′-C), 129.9 (*m*-,*m*′-C), 128.8, 123.7 (*p*-,*p*′-C), 106.6 (C-3), 32.6, 28.2 (COE), 24.6 (C-1); C-1′ and remaining COE resonances not observed.

L_{Me}Rh(C_2Me_4): A suspension of L_{Me}Rh(COE) (0.15 g) in C_2Me_4 (7 mL) was stirred under a hydrogen atmosphere (1 bar) until the solid had completely dissolved (ca. 3 min), giving a dark-brown solution. All volatiles were then removed in vacuo, and the residue was redissolved in $[D_8]$THF for NMR studies (see Results Section). The solution gave rise to small but sharp peaks due to the oxidation product $L_{Me}Rh[\eta^3\text{-}CH_2C(Me)CMe_2](OH)$ (see below); resonances due to the main product were found to be broad at room temperature. At 243 K, all peaks due to the main component $L_{Me}Rh[\eta^3\text{-}CH_2C(iPr)CH_2](H)$ could be assigned: ^1H NMR ($[D_8]$THF, 500 MHz, 243 K): δ = 1.56 (obscured by cyclooctane signal; 1-H), 5.04 (3-H), 7.02, 7.04 (d, *m*-H), 6.90 (t, *p*-H), 2.53, 2.23 (*o*-CH_3), 1.85 (br. sept, H*i*Pr), 1.24 (br. d, CMe_2), –2.45 (br., CH_2 + Rh–H). – $^{13}C\{^1H\}$ NMR (125.7 MHz): δ = 23.4 (C-1), 157.6 (C-2), 99.6 (C-3), 156.8 (*i*-C), 135.0, 131.3 (*o*-C), 129.5 (*m*-C), 126.1 (*p*-C), 19.9, 21.2 (*o*-CH_3), 97.1 (C*i*Pr, J_{RhC} = 11 Hz) (CH_2 obscured by THF), 36.0 (CMe_2), 23.8 (CMe_2). In addition, some peaks due to the minor component $L_{Me}Rh[\eta^3\text{-}CH_2C(Me)CMe_2](H)$ could be tentatively assigned: ^1H NMR (500 MHz, 218 K): δ = 5.03 (3-H), –12.17 (RhH). – $^{13}C\{^1H\}$ NMR (125.7 MHz, 243 K): δ = 158.4 (C-2), 156.4, 155.9 (*i*-,*i*′-C), 133.1 (*o*-C), 130.0, 129.7, 129.3 (*m*-C), 126.4 (*p*-C), 100.0 (C-3), 21.9, 21.1, 20.5 (*o*-CH_3).

L_{Me}Rh(NBE): To a solution of L_{Me}Rh(COE) (0.7 g) in hexane (5 mL) was added NBE (0.5 g). The resulting mixture was stirred at room temperature for 15 min. All volatiles were then removed in vacuo, and the residue was crystallized from hexane (50/–20 °C) to give 0.56 g (83%) of brown-red L_{Me}Rh(NBE). – $C_{28}H_{35}N_2Rh$ (502.50): calcd. C 66.93, H 7.02, N 5.57; found C 66.68, H 6.82, N 5.42. – ^1H NMR (200 MHz, C_6D_{12}): δ = 1.40, 1.60 (1-H), 4.96 (3-H), 6.8–6.9 (m, *m*- + *p*-H), 2.31, 2.61 (*o*-CH_3), 2.55, 2.71 (vinylic and bridgehead H), 0.75 (CH_2CH_2), –0.82 (d, $^2J_{HH}$ = 14.5 Hz, nonagostic HCH), –10.2 (dd, $^2J_{HH}$ = 14.5, J_{RhH} = 11.7 Hz, agostic HCH). – $^{13}C\{^1H\}$ NMR (50.4 MHz, C_6D_{12}): δ = 23.5, 20.9 (C-1), 156.9, 155.7 (C-2), 99.2 (C-3), 158.6, 156.3, 153.3, 150.3 (*i*-C), 133.2 (*o*-C), 128.7, 128.6 (*m*-C), 125.5, 125.2 (*p*-C), 19.9, 19.4 (*o*-CH_3), 65.7 (d, C=C, J_{RhC} = 15 Hz), 47.5 (bridgehead), 29.6 (CH_2CH_2), 16.0 (CH_2). – ^{13}C NMR (125.7 MHz, C_6D_{12}): $^1J_{CH}$ = 108 and 141 Hz for the NBE CH_2. The infrared spectrum (KBr and Nujol mull) did not show any distinct peaks attributable to the agostic C–H bond.

L_{Me}Rh(COE)(N_2): Solutions of L_{Me}Rh(COE)(N_2) were generated by preparing NMR samples of L_{Me}Rh(COE) under nitrogen atmosphere. – ^1H NMR ($[D_8]$THF, 500 MHz): δ = 1.56, 1.75 (1-,1-H′), 5.24 (3-H), 7.16, 7.15 (d, *m*-,*m*′-H), 7.04, 7.09 (t, *p*-,*p*′-H), 2.50, 2.32 (*o*,*o*′-CH_3), 3.04 (CH=CH), 2.14, 1.59, 1.2 (br., CH_2). – $^{13}C\{^1H\}$ NMR (125.7 MHz): δ = 26.6, 23.8 (C-1, C-1′), 160.3, 159.1 (C-2, C-2′), 99.9 (C-3, J_{RhC} = 11 Hz), 156.2, 150.0 (*i*-,*i*′-C), 134.8, 133.3 (*o*-,*o*′-C), 130.1, 29.8 (*m*-,*m*′-C), 127.1, 126.6 (*p*-,*p*′-C), 20.6, 20.1 (*o*,*o*′-CH_3), 76.7 (CH=CH, J_{RhC} = 11 Hz), 32.5, 30.8, 28.1 (CH_2). Essentially pure solid L_{Me}Rh(COE)(N_2) was prepared by dissolving L_{Me}Rh(COE) (0.1 g) in hexane (1 mL) under nitrogen, concentrating the solution to a volume of 0.3 mL in vacuo, and connecting the Schlenk tube to another one containing 6 mL of paraffin oil. After 6 weeks, the hexane had diffused into the paraffin oil and the oily residue had solidified. – IR (Nujol mull): $\tilde{\nu}_{N-N}$ = 2172 cm^{-1}.

$L_{Me}Rh(COE)(MeCN)$: A solution of $L_{Me}Li(THF)$ (0.51 g) in THF (6 mL) was added to a suspension of $[Rh(COE)_2Cl]_2$ (0.48 g) in THF (3 mL) and MeCN (0.75 mL). The resulting mixture was stirred for one day and then the solvents were removed in vacuo. The residue was extracted with two 20 mL portions of cyclohexane. The combined extracts were concentrated to a volume of 10 mL and stored for overnight at 6 °C, which led to the deposition of a yellow powder (0.56 g, 75%). Crystals suitable for X-ray diffraction were obtained by slow crystallization at room temperature. – $C_{31}H_{42}N_3Rh$ (559.60): calcd. C 66.54, H 7.56, N 7.51; found C 66.32, H 7.91, N 7.48. – ^{1}H NMR (C_6D_6, 293 K, 200 MHz): δ = 6.93 (m, *m*-,*p*-H), 5.19 (3-H), 2.80, 2.25, 1.52, 1.27 (m, COE), 2.54, 2.42 (*o*,*o*′-CH_3), 1.69, 1.52 (1-,1′-H), 0.45 (MeCN). – $^{13}C\{^1H\}$ NMR (50.4 MHz): δ = 158.0, 156.0 (C-2, C-2′), 154.3, 149.4 (*i*-,*i*′-C), 133.1, 132.8 (*o*-,*o*′-C), 128 (superimposed by solvent signal, *m*-H), 124.5, 123.2 (*p*-,*p*′-C), 116.1 (CH_3CN), 98.0 (C-3), 66.9 (d, J_{RhC} = 14 Hz, CH=CH), 31.0, 29.7, 26.9 (COE), 25.3, 23.08 (1-,1′-C), 19.5, 19.0 (*o*,*o*′-CH_3), 1.4 (CH_3CN).

$L_{Me}Rh(1,4\text{-}COD)$: $L_{Me}Rh(COE)$ (0.3 g) was dissolved in 1,3-COD (2 mL) and the solution was stirred for 10 min. The solvent was then removed in vacuo, leaving essentially pure $L_{Me}Rh(1,4\text{-}COD)$, which was characterized only by NMR. Heating of the solution in 1,3-COD to 40 °C for 10 min prior to workup resulted in formation of $L_{Me}Rh(1,5\text{-}COD)$. – ^{1}H NMR (C_6H_6, 293 K, 200 MHz): δ = 7.0–7.2 (m, *m*-,*p*-H), 5.25 (3-H), 3.26, 2.7, 2.4, 2.1, 1.7, 1.2 (br. m, 1,4-COD), 2.48, 2.41 (*o*-CH_3), 1.66 (1-H). – $^{13}C\{^1H\}$ NMR (50.3 MHz): δ = 158.3 (C-2), 150.4 (*i*-C), 133.2, 131.8 (*o*-,*o*′-C), 128 (obscured by solvent signal, *m*-,*m*′-C), 124.7 (*p*-C), 98.2 (C-3), 24.9 (C-1), 19.2, 18.9 (*o*,*o*′-CH_3), 72.4 (d, J_{RhC} = 14 Hz), 51.1 (d, J_{RhC} = 8 Hz, C=C), 29.1 (2 C), 28.3, 25.7 (CH_2). The same material remained following hydrogenation of COE with $L_{Me}Rh(COE)$.

$L_{Me}Rh[CH_2C(Me)CMe_2](OH)$: Following hydrogenation experiments with 2,3-dimethyl-2-butene, this compound remained as a deep-green oil. All attempts to crystallize it were unsuccessful. – ^{1}H NMR (C_6H_6, 293 K, 200 MHz): δ = 6.9–7.2 (m, *m*-,*p*-H), 5.26 (3-H), 3.61, 1.84 (br. s, CH_2), 2 × 2.74, 2.57, 2.34 (*o*-CH_3), 1.84, 1.58 (1-H), 1.42, 0.73, 0.50 ($CMeCMe_2$), –1.33 (OH). – $^{13}C\{^1H\}$ NMR (75.5 MHz): δ = 156.9, 153.4 (C-2, C-2′), 153.0, 149.7 (*i*-,*i*′-C), 133.5, 132.9, 132.4, 132.3 (*o*-C), 128 (obscured by solvent signal, *m*-C), 124.4, 124.1 (*p*-,*p*′-C), 98.6 (C-3), 89.9 ($CH_2CMeCMe_2$), 67.7 (d, J_{RhC} = 12 Hz, $CH_2CMeCMe_2$), 50.7 (d, J_{RhC} = 14 Hz, $CH_2CMeCMe_2$), 23.4, 21.4 (C-1, C-1′), 19.4, 19.3, 19.2, 18.8 (*o*-CH_3), 29.0, 26.4, 17.3 ($CH_2CMeCMe_2$).

$L_{Me}Rh(COE)(H_2)$: A solution of $L_{Me}Rh(COE)$ (0.12 g) in $[D_8]$THF (0.7 mL) was cooled to –40 °C and then stirred under hydrogen atmosphere (1 bar) for 3 min. The solution was then cooled to –80 °C and transferred to a cooled NMR tube under Ar. NMR studies showed it to contain $L_{Me}Rh(COE)(H_2)$ as the main Rh complex (ca. 75% of the total; the remainder was $[L_{Me}RhH_2]_2$; see below). – ^{1}H NMR ($[D_8]$THF, 243 K, 500 MHz): δ = 1.51, 1.56 (obscured by cyclooctane signal, 1-,1′-H), 5.12 (3-H), 7.11, 7.02 (d, *m*-,*m*′-H), 7.00, 6.90 (t, *p*-,*p*′-H), 2.39, 2.28 (*o*,*o*′-CH_3), 2.45 (CH=CH), 2.12, 1.59, 1.3 (br., CH_2), –12.8 (br., Rh–H_2; T_1 = 10 ms by inversion-recovery). – $^{13}C\{^1H\}$ NMR (125.7 MHz): δ = 25.8, 22.8 (C-1, C-1′), 160.7, 160.2 (C-2, C-2′), 99.9 (C-3), 158.7, 151.1 (*i*-,*i*′-C), 133.7, 132.1 (*o*-,*o*′-C), 130.1, 129.7 (*m*-,*m*′-C), 126.7, 126.1 (*p*-,*p*′-C), 20.9, 20.2 (*o*,*o*′-CH_3), 76.1 (CH=CH, J_{RhC} = 12 Hz), 35.7, 33.3, 28.0 (CH_2).

$[L_{Me}RhH_2]_2$: The aforementioned solution of (mainly) $L_{Me}Rh(COE)(H_2)$ was transferred back to a Schlenk tube and then warmed (with stirring) to 0 °C under hydrogen atmosphere. After stirring at 0 °C for 10 min, the solution was cooled to –40 °C once more, whereupon NMR spectra were recorded. All the $L_{Me}Rh(COE)(H_2)$ was seen to have been consumed; the solution contained $[L_{Me}RhH_2]_2$ as the main Rh complex (ca. 50% of the total), accompanied by a large number of other compounds in low concentrations. The compound decomposed on standing and on evaporation of the solvent, and all attempts to isolate it were unsuccessful. – ^{1}H NMR ($[D_8]$THF, 243 K, 500 MHz): δ = 1.26 (1-H), 4.94 (3-H), 6.80 (d, *m*-H), 7.02 (t, *p*-H), 1.74 (superimposed by THF signal, *o*-CH_3), –24.23 (t, Rh–H_2, J_{RhHav} = 25 Hz). – $^{13}C\{^1H\}$ NMR (125.7 MHz): δ = 23.6 (C-1), 158.7 (C-2), 100.9 (C-3), 154.3 (*i*-C), 133.8 (*o*-C), 131.2 (*m*-C), 125.3 (*p*-C), 19.8 (*o*-CH_3).

$L_{Me}Ir(COE)H_2$: $L_{Me}Ir(cyclooctenyl)(H)$ (0.2 g) was dissolved in THF (4 mL) and the solution was stirred under hydrogen (1 bar) for 10 min. The volatiles were then removed in vacuo. The reaction was clean and virtually quantitative according to ^{1}H-NMR, but the product was found to be very soluble, even in pentane. X-ray quality crystals were obtained by dissolving the residue in pentane, concentrating the solution to a volume of 0.25 mL, and slowly cooling it to –20 °C. – ^{1}H NMR (C_6D_6, 293 K, 200 MHz): δ = 1.50 (1-H), 5.26 (3-H), 6.96 (d, *m*-H), 6.81 (t, *p*-H), 2.22 (*o*-CH_3), 2.62 (CH=CH), 2.04 (br., =CH–CH_2 *exo*), 0.9–1.3 (br., all other CH_2), –22.6 (IrH_2), –22.74 (IrHD, J_{HD} = 5.6 Hz). – $^{13}C\{^1H\}$ NMR (125.7 MHz): δ = 23.7 (br., C-1), 161 (br., C-2), 102.5 (C-3) (*i*-C not observed), 131.7 (*o*-C), 127.8 (*m*-C), 125.9 (*p*-C), 19.2 (*o*-CH_3), 62.2 (CH=CH), 35.3, 33.2, 26.7 (CH_2). – IR (KBr): $\tilde{\nu}_{Ir-H}$ = 2217 cm^{-1}.

Hydrogenation Experiments

Olefins (COE, 1-methylcyclohexene, 2,3-dimethyl-2-butene, 1-*tert*-butylcyclohexene) were dried over Na and then transferred to a cold trap in vacuo prior to use. The catalyst (ca. 50 mg) was dissolved in neat olefin (1 mL), and the solution was stirred under 1 bar of hydrogen for 2 h. By that time, no more hydrogen was being absorbed. The resulting solution was filtered through alumina to remove Rh and ligand residues, and subsequently analyzed by ^{1}H- and ^{13}C-NMR. Hydrogenation of the solid olefin bis(cyclohexylidene) was carried out in pentane solution [bis(cyclohexylidene) (0.3 g) and $L_{Me}Rh(COE)$ (0.095 g) in pentane (3 mL)]: 5 turnovers (50% conversion) after 2 h (by ^{13}C-NMR).

X-ray Structure Determinations

Crystals were mounted in thin-walled glass capillaries under Ar. Details of all structure determinations are collected in Table 3. Since the glass capillaries prevented an accurate description of the crystal shapes, empirical absorption corrections[41] were applied in most cases (see Table 3). Structures were solved using the PATTY option[42] of the DIRDIF program system.[43] Refinements were carried out with the SHELXL-97 package.[44] All nonhydrogen atoms were refined with anisotropic temperature factors. The hydrogen atoms were placed in calculated positions and refined isotropically in riding mode. All refinements were made by full-matrix least-squares on F^2. Unless otherwise noted, geometrical calculations[45] revealed neither unusual geometric features, nor unusually short intermolecular contacts. Moreover, the calculations revealed no higher symmetry and no solvent accessible areas.

Remarks for Specific Structures. –$L_{Me}Rh(C_2H_4)_2$: The hydrogens of the ethene moieties were freely refined. $L_{Cl}Rh(COE)$: The crystal showed considerable decay (up to 25%) during the measurements, resulting in somewhat higher *R* indices. $L_{Me}Rh(COD)$ and $L_{Me}Rh(COE)(MeCN)$: All hydrogen atoms were freely refined in the final cycles.

$L_{Me}Ir(COE)H_2$: The Ir-bound hydrides were not located. Crystal structure data for $L_{Me}Rh(COD)$, $L_{Me}Rh(C_2H_4)_2$, $L_{Cl}Rh(COE)$, $L_{Me}Rh(NBE)$, $L_{Me}Rh(COE)(MeCN)$, and $L_{Me}Ir(COE)H_2$; calculated total energies and atomic coordinates for the LRh and LIr complexes mentioned in the text. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-133849, CCDC-133850, CCDC-133851, CCDC-133852, CCDC-133853, and CCDC-133854. Copies of the data can be obtained free of charge on application to the CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) +44 (0)1223 336033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

We are grateful to P. P. J. Schlebos (KUN) and H. Druijven (University of Groningen) for their able assistance in carrying out some of the NMR measurements. X-ray data for $L_{Me}Ir(COE)H_2$ and $L_{Me}Rh(COE)(MeCN)$ were collected on the CCD diffractometer of the national NWO-CW X-ray facility in Utrecht. Deuteration studies on 2,3-dimethyl-2-butene were carried out by H. van der Heijden and A. B. van Oort at the Shell Research and Technology Centre, Amsterdam. Bis(cyclohexylidene) was kindly provided by R. W. A. Havenith (University of Utrecht). We thank Johnson Matthey for a generous loan of rhodium and iridium chlorides.

[6] See, e.g. M. E. Howden, R. D. W. Kemmitt, M. D. Schilling, *J. Chem. Soc., Dalton Trans.* **1980**, 1716.

[7] A distorted T-shape and easy movement of the chlorine atom in three-coordinate bis(phosphane)RhCl complexes has been predicted on the basis of extended-Hückel calculations; see ref. [3b].

[8] The best data were obtained in [D_8]THF. Spectra in [D_8]THF, [D_{12}]cyclohexane (down to 6 °C), and [D_8]toluene (down to

–40 °C) were virtually identical, indicating the absence of significant THF coordination. However, the presence of some arene complexes (to be described in a future paper) in the toluene spectra made interpretation more difficult in these cases.

[9] The allyl hydride mechanism is one of the accepted mechanisms for olefin isomerization. However, only a few examples of rapid equilibration between the two structures have been reported: J. W. Byrne, H. U. Blaser, J. A. Osborn, *J. Am. Chem. Soc.* **1975**, *97*, 3871; H. Bönneman, *Angew. Chem.* **1970**, *82*, 699 (*Int. Ed. Engl.* **1970**, *9*, 736). Decomposition of rhodium(III) allyl hydride complexes to give free olefin has also been demonstrated: J. F. Nixon, B. Wilkins, *J. Organomet. Chem.* **1972**, *44*, C25; **1974**, *80*, 129. For an example of rapid allylic C–H activation at Ir, see R. Dorta, A. Togni, *Organometallics* **1998**, *17*, 5441.

[10] Reductive elimination from palladium(II) and platinum(II) allyl hydrides has been studied computationally: S. Sakaki, H. Satoh, H. Shono, Y. Ujino, *Organometallics* **1996**, *15*, 1713.

[11] The calculated energy difference between the olefin and allyl hydride is very sensitive to the method used. Hartree–Fock gives an even stronger preference for the olefin complex, while pure DFT[2] gives a smaller energy difference and a lower barrier. Apart from correlation treatment, sources of errors could be the basis set (not very large) and the lack of an explicit treatment of direct relativistic effects on the valence electrons.

[12] Steric effects are expected to favor the allyl hydride structure over the olefin complex because of the more "central" position of the allyl group relative to the diiminate aryl groups.

[13] Formation of iridium allyl hydrides from olefin precursors has been reported previously. See, e.g. R. S. Tanke, R. H. Crabtree, *Inorg. Chem.* **1989**, *28*, 3444; Y. Alvarado, O. Boutry, E. Gutiérrez, A. Monge, M. C. Nicasio, M. L. Poveda, P. J. Pérez, C. Ruiz, C. Bianchini, E. Carmona, *Chem. Eur. J.* **1997**, *3*, 860.

[14] The calculated energy difference between the Ir allyl hydride and olefin complexes is rather modest (6 kcal/mol; barrier 11 kcal/mol). If we assume that the 12 kcal/mol error in the case of Rh also applies to Ir, we would expect a preference in the "real" system of 18 kcal/mol and a barrier of 23 kcal/mol, which is compatible with the observed static room temperature spectrum. Unfortunately, L_{Me}Ir(H)(cyclooctenyl) decomposes rapidly on heating in solution, hence we could not verify the onset of dynamic behavior expected at higher temperatures.

[15] In addition to the signals of the dimethylbutene complex, some weak but sharp signals were observed, which could be attributed to the oxidation product L_{Me}Rh(OH)[η^3-$CH_2C(Me)CMe_2$] described in the section on hydrogenation.

[16] The Rh–H distance is calculated as 1.92 Å for a hydrogen placed at a calculated position with a standard C–H bond length of 0.97 Å. The actual C–H distance must be longer, as indicated by the low $^1J_{CH}$. However, the hydrogen atom position could not be refined satisfactorily.

[21] To assess the importance of the pre-organization of NBE, we also optimized the structures of two conformations of LRh(CPE) (CPE = cyclopentene). The CPE complex would be expected to have a weaker agostic interaction since it is less favorably pre-organized. On the other hand, if the interactions were strong, one would certainly expect to see a distortion here, whereas in the NBE complex the pre-organization might be so favorable that the agostic interaction would already be optimal in the undistorted structure. In fact, the energies of the "CH_2 in" and "CH_2 out" conformations of LRh(CPE) differ by less than 3 kcal/mol, and the RhH distance is long even in the "CH_2 in" conformation (2.58 Å; RhC = 2.98 Å; C–H = 1.104 and 1.093 Å). The angle between the $CH_2CH{=}CHCH_2$ plane and the Rh–olefin bond is nearly identical in the two conformations (97° for "CH_2 in", 98° for "CH_2 out"). These observations support our hypothesis that the agostic "bond" is not strong even in the NBE complex. The attractive force is rather weak, but since there is no *repulsive* force and the olefin is pre-organized, a close Rh–H contact still results.

[22] Because of the limited temperature region in which L_{Me}Rh(COE)(H_2) can be observed, T_1(min) studies were not carried out.

[26] The presence of small amounts of a COD isomer (GC/MS) in the COE could be detected by GC. It differed from authentic samples of 1,3-COD and 1,5-COD and so was most likely 1,4-COD. Identification of the deactivation product as a 1,4-COD complex was achieved by comparison with pure L_xRh(1,4-COD) prepared from L_xRh(COE) and 1,3-COD; see details in Experimental Section.

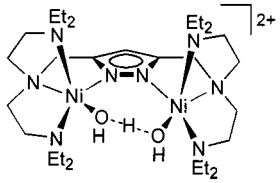
Cooperative Binding of Nitrile Moieties Within a Bimetallic Pocket: Enforcing Side-On π-Interaction With a High-Spin Nickel(II) Site

Franc Meyer,*[a] Isabella Hyla-Kryspin,[b] Elisabeth Kaifer,[a] and Peter Kircher[a]



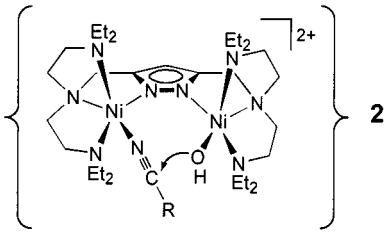
Dedicated to Prof. Dr. Peter Paetzold on the occasion of his 65th birthday

Keywords: Cooperative effects / Coordination modes / Nickel / Bimetallic complexes / π interactions

Different cooperative binding modes of nitriles within the bimetallic pocket of a pyrazolate-based compartmental dinickel(II) site have been studied. The H_3O_2-bridged dinuclear complex **1** reacts with cyanamide to yield **4**, in which a secondary hydrogencyanamido(1–) bridge spans the two metal centers at an unusually short metal–metal distance imposed by the primary ligand matrix. In **5**, a single 2-cyanoguanidine (cnge) molecule is *N*-bound to one nickel(II) ion through its nitrile part and is coordinated to the adjacent metal site through an amido nitrogen. The characteristics of the coordination spheres of the metal centers suggest an additional side-on π-bonding interaction of the nitrile moiety with the second high-spin nickel(II) ion. This unusual interaction is corroborated by comparing the IR bands for the ν(C≡N) stretching vibration of **5** with those of complex **6**, which has two end-on bound cnge molecules, and those of the related mononuclear complex **7**, which lacks a second nickel(II) ion. The nature of the π-bonding interaction in **5** is further analyzed by DFT calculations on relevant model systems. Even though the π-bonding is found to be very weak, it does include some backbonding from occupied 3d MOs at the second high-spin nickel(II) ion to the π* MOs of the nitrile. Such an unconventional π-interaction is suggested to be enforced by the constrained fixation of the nitrile unit within the highly organized coordination pocket of the bimetallic framework. In contrast, the bifunctional 2-hydroxybenzonitrile is accommodated by the distinct binding of the nitrile and phenolate functions to the different metal centers in **8**, which confirms that the simultaneous binding of both an OR-function and an end-on bound nitrile is indeed feasible within the active site pocket. Such a situation is reminiscent of the bimetallic effect that has been assumed to enable the cooperative hydration of nitriles at the dinickel(II) site of **1**. Complexes **4**·$(ClO_4)_2$, **5**·$(ClO_4)_2$, **6**·$(ClO_4)_3$, **7**·$(ClO_4)(BPh_4)$, and **8**·$(ClO_4)_2$ have been characterized structurally by X-ray crystallography.

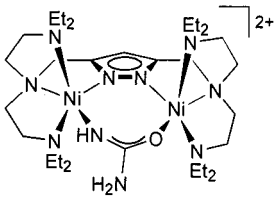
Introduction

The current interest in multinuclear transition metal complexes is often inspired by the occurrence of multimetallic sites within the active centers of various natural metalloenzymes.[1] The importance of such sites stems not only from their fascinating structural diversity but predominantly from their potential to enable synergetic reactivity of the adjacent metal centers.[2,3] This facilitates the generation of unusual coordination modes of small substrate molecules as well as unique organic transformations at the multimetallic framework which are often otherwise not accessible at monometallic centers. Consequently much effort has been devoted to the search for dinucleating ligand matrices that provide two (or more) coordination compartments in close proximity, in order to favor such sought-after cooperativity within the resulting bimetallic complexes.[4] With this intention in mind we recently investigated a class of pyrazolate-based dinuclear systems whose reactivity patterns can be selectively altered by appropriate changes of the chelating donor side-arms attached to the bridging heterocycle,[5] and which proved to allow novel binding modes and transformations of small molecules within the bimetallic pocket.[6,7] Among these, the dinickel(II) complex **1** (Scheme 1) has turned out to be a valuable system for the modeling of hydrolytic reactions at cooperative dinuclear sites, and, in particular, for investigating functional aspects of the metalloenzyme urease.[7]



1

Scheme 1. Active dinickel(II) complex **1** (see ref.[7])



The hydration of nitriles by **1** was assumed to proceed via intermediates such as **2** (Scheme 2), in which the *N*-bound substrate has replaced a water molecule of the former intramolecular H_3O_2 bridge and undergoes subsequent nucleophilic attack by the adjacent hydroxide function to finally form a secondary *N*,*O*-amidato bridge. Alternatively, **1** may exhibit basic rather than nucleophilic behavior, as exemplified by its reaction with urea, which yields an *N*,*O*-bridging

coordination mode of the deprotonated substrate within the bimetallic pocket (**3**).

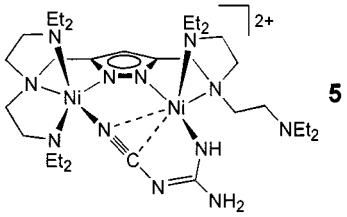
In pursuit of studying such transformations mediated by **1**, we now set out to examine whether **3** would also be accessible by hydration of the appropriate nitrile, i.e. cyanamide, according to the situation depicted in **2**. Interest in this study also arose from the fact that cyanamide itself has been recognized as a substrate for both urease (yielding carbon dioxide and ammonia)[8] and Mo-nitrogenase,[9] implying its as-yet-unresolved binding to these multimetallic enzyme active sites. Unexpectedly however, several different binding modes of nitrile moieties at the bimetallic core were found in the course of these investigations, among them an intriguing coordination of cyanoguanidine (the dimeric form of cyanamide) within the clamp of the two metal ions. The present contribution describes the structural and spectroscopic characterization as well as a theoretical study of this novel system. In addition, further structural support for the postulated nitrile hydration intermediate **2** could be obtained.

Results and Discussion

When a solution of **1**·$(ClO_4)_2$ in acetone was treated with cyanamide, a crystalline green product **4**·$(ClO_4)_2$ (Scheme 3) was isolated. This compound has a strong IR absorption of the $\tilde{\nu}$(C≡N) stretch at 2149 cm^{-1} and a single ν(N–H) band at 3282 cm^{-1}. An X-ray diffraction study showed that a hydrogencyanamido(1–) bridging ligand spans the two metal centers and occupies the accessible coordination sites within the pocket of the bimetallic framework (Scheme 3, Figure 1).

The hydrogen atom of this secondary bridge could be located close to N200, which is consistent with the pronounced difference in bond lengths [*d*(C200–N200) = 1.286(9) Å; *d*(C200–N201) = 1.176(9) Å] and confirms N200 as the amido-nitrogen. Furthermore, the μ-NCN(H) proton seems to form a weak hydrogen bond with one of the oxygen atoms of a perchlorate counteranion [*d*(N200···O6) = 3.035 Å].

Obviously the characteristic property of the Ni-bound H_3O_2 unit in **1** to act as a base, which also became apparent in the deprotonation of urea to yield **3**,[6] has caused deprotonation of the cyanamide, with concomitant incorporation of the resulting $HNCN^-$ in a bridging position. The coordination chemistry of the monoanionic cyanamido(1–) ligand has attracted some attention,[10] but only one structurally characterized example of bridging parent $HNCN^-$ has hitherto been reported.[11] In that particular case, a bis(μ-hydrogencyanamido)dicopper(II) core was shown to exhibit a large metal–metal separation of 5.16 Å in conjunction with a slightly shorter C≡N bond length of 1.15(1) Å and larger angles Cu–N≡C of 146.6(8)/144.6(8)°,[11] as compared to *d*(C200–N201) = 1.176(9) Å and Ni2–N201–C200 = 125.9(5)° for **4**. This lends support for the description of the hydrogencyanamido bridge by a significant contribution of limiting form **B** (Scheme 4) at the expense of



A **B**

Scheme 4. Limiting forms of the hydrogencyanamido(1–) bridge

form **A** in the present case **4**, this apparently being imposed by the rigid pyrazolate-based ligand matrix constraining a relatively short Ni···Ni distance of 4.458 Å. The drastic decrease of $\tilde{\nu}$(C≡N) (2149 cm^{-1} versus 2256 cm^{-1} for free cyanamide) is in accord with this view.

2-Cyanoguanidine within the Bimetallic Pocket

Besides the main product **4**·$(ClO_4)_2$, a few crystals of a different product **5**·$(ClO_4)_2$ were collected from the reaction of **1**·$(ClO_4)_2$ with cyanamide. An IR spectrum indicated the presence of a nitrile unit [major absorption for $\tilde{\nu}$(C≡N) at 2154(s) cm^{-1}] as well as a series of N–H groups (several bands in the range 3200–3450 cm^{-1}) for **5**, and the elemental analysis suggested that two equivalents of the substrate were incorporated in this compound. It thus appeared that the property of the Ni-bound H_3O_2 unit in **1** to act as a base had also induced some dimerization of excess cyanamide to form dicyandiamide (2-cyanoguanidine, cnge), a process that is known to occur readily with cyanamide at pH 8–9.5 in aqueous solution.[12] Accordingly, complex **5**·$(ClO_4)_2$ can be obtained in somewhat better yields by directly treating **1**·$(ClO_4)_2$ with cnge. The overall molecular structure of **5** (Scheme 5) was resolved by X-ray crystallography, the result of which is depicted in Figure 2 and Figure 3.

5

Scheme 5. Schematic drawing of **5**

The 2-cyanoguanidine in its deprotonated form, which is planar within 0.023 Å, is found to be coordinated to the bimetallic site in an unprecedented fashion. Its nitrile function is bound end-on to Ni2 and completes the five-coordination of the latter, which thus displays a ligation sphere intermediate between TB-5 and SPY-5, similar to the metal centers of a variety of previously characterized dinickel(II) complexes with this particular pyrazolate-based ligand framework.[5–7] On the other side the amido nitrogen atom N11 of the deprotonated cnge is coordinated to Ni1. The remaining three *N*-bound hydrogen atoms of the cnge moiety have been located as weak hydrogen bonds to oxygen atoms of the perchlorate counteranions [*d*(N11···O2) = 3.098 Å; *d*(N12···O3) = 2.973 Å; *d*(N12···O8) = 3.030 Å] with one of the latter acting as a twofold hydrogen-bond acceptor towards both N11 and N12. The equivalence of

Figure 2. Figure 3. Representation of the central bimetallic core of **5**

the three CN bond lengths of the guanidine moiety (C31–N10/N11/N12), however, suggests the likely presence of other tautomers carrying one of the hydrogen atoms at the central N10 atom.

Unexpectedly the nitrogen donor N5 of one ligand side arm – formerly bound to Ni1 – is now found uncoordinated and dangling in **5**, which leaves the respective nickel(II) ion in a peculiar fourfold coordination environment of *N*-donors [angle N1–Ni1–N11 = 154.19(9)°] with a remaining open coordination space directed towards the inside of the

bimetallic pocket. Closer inspection of the central core of **5** (Figure 3) reveals that the nitrile moiety of the cnge – already bound end-on to Ni(2) – appears to be suitably located within the bimetallic pocket between the two nickel(II) ions to additionally interact with the low-coordinate Ni1 in a side-on fashion, even though the distances *d*(Ni1–N9) = 2.963 Å and *d*(Ni1–C30) = 2.864 Å are rather long. Some nickel complexes featuring side-on coordination of a nitrile unit have previously been structurally characterized, but these generally involve low-valent nickel(0).[13,14] Consistent with the π-backbonding ability of such low-valent nickel(0) species, the CN bonds of the η^2-bound nitriles are significantly lengthened in most of these cases, and their ν(C≡N) stretching frequencies are drastically lowered (to about 1750 cm^{-1}) relative to the free nitriles.[13] The same is also valid for nitriles bound in an η^2- or a μ-η^1,η^2(σ,π)-mode to other transition metals.[15] Cnge itself has repeatedly been used as a ligand towards transition metal ions,[16–20] in particular in copper chemistry,[18–20] and has hitherto been shown to coordinate either in a monodentate form (nitrile *N*-donor, **C**, Scheme 6) or as a bidentate bridging ligand through

Scheme 6. Common binding modes of cnge

both the nitrile and imino-*N* atoms (**D,** Scheme 6), but not through the nitrile-*N* and a terminal amido-*N* as is observed in **5** for the first time.

The IR spectrum of cnge (both free and in coordination compounds) exhibits a characteristic doublet for the ν(C≡N) stretching vibration which has been attributed to the co-existence of different tautomeric forms of the guanidine moiety; the low-frequency component corresponds to the tautomer with conjugated C≡N and C=N bonds[21] (this single tautomer is depicted in all schemes of the present work and is used for the DFT calculations, see below). IR spectroscopic investigations of those cnge complexes of type **C** and **D** studied previously indicated that the ν(C≡N) doublet is generally shifted to slightly higher wavenumbers than free cnge ($\tilde{\nu}$ = 2205 and 2160 cm^{-1}), but that these features can hardly be used to differentiate between different binding modes of cnge.[19] It was furthermore noted that the perturbation of the IR spectra of cnge upon coordination depends more on the strength of its coordination to the metal than on the coordination type, i.e. a strongly bonded cnge showing a M–N–C angle close to 180° is expected to exhibit the most pronounced shift of the ν(C≡N) doublet to higher energy.[19] In the present compound **5** the angle Ni2–N9–C30 amounts to 171.2(2)°, but the main absorption for the ν(C≡N) stretch is found at 2154 cm^{-1} (Table 1). (Two further weak bands occur at somewhat higher energy, i.e. 2180 and 2229 cm^{-1}; it remains speculative whether these bands originate from different tautomers of the cnge fragment.) We tentatively assign the most intense band at lowest energy (2154 cm^{-1}) to the tautomer with conjugated C≡N and C=N bonds. This band exhibits a slight low-frequency shift with respect to free cnge (2160 cm^{-1}), but it is uncertain at this stage whether such a shift is to be attributed to a weak additional side-on interaction of the nitrile moiety with the second Ni1 ion. However, the observed bond length *d*(N9–C30) = 1.166(3) Å in **5** is typical for a CN triple bond and is virtually identical to the value of free cnge [1.1694(3) Å],[22] as is the angle N9–C30–N10 = 175.1(3)° in **5** [vs. 175.1(2)° in free cnge],[22] and hence there is no geometric indication of such an interaction. It should be noted, however, that geometrical changes of the N–C≡N unit upon weak side-on interaction with a high-spin nickel(II) ion should be much less distinct than in the case of a nickel(0) center due to the lower π-backbonding ability of the nickel(II) ion. Furthermore, a short atom distance for the CN triple bond (1.13 Å) has also been observed in the early crystallographic study of a substituted cyanamide π-bonded to a (carbonyl)nickel(0) fragment.[14]

In the case of two copper(I) complexes containing the cation $[Cu_2(cnge)_4]^{2+}$ with three-coordinate metal ions, the dimeric cations were found to stack in the crystal lattice in such a way that the nitrile function of a unidentate cnge molecule is located close to the axial position of a symmetry-related copper atom of a neighboring molecule.[18,19] However, the observed Cu^{I}···nitrile contacts [*d*(Cu···N) = 3.27–3.58 Å and *d*(Cu···C) = 3.50–3.65 Å][19] are much longer than those found for the present complex **5** and, consequently, any side-on binding has been judged unlikely for this copper system.[17]

Magnetic measurements performed on a powdered sample of **5**·$(ClO_4)_2$ confirm the presence of two high-spin nickel(II) ions with μ_{eff} = 3.25 μ_B per nickel ion at 297 K. The temperature dependence of the molar magnetic susceptibility χ and of its inverse 1/χ, as well as of the effective magnetic moment, over the range 297–5.3 K is shown in Figure 4. It reveals the absence of any significant coupling between the two metal ions (the values $|J| < 1$ cm^{-1} and g = 2.27 result from a fit of the experimental data to the

standard expression for the isotropic spin-Hamiltonian $\hat{H} = -2J\hat{S}_1,\hat{S}_2$ with $S_1 = S_2 = 1$;[23] a Curie-Weiss analysis gives $C = 2.71$ and $\varphi = -3.30$).

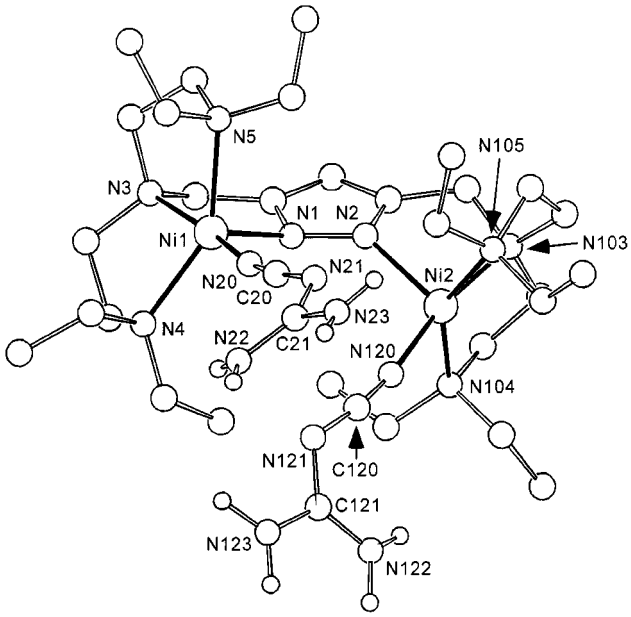
Analogous Complexes with cnge Purely End-On Bound

In order to shed some more light on a possible contribution of the Ni1 ion to the binding of the C≡N moiety in **5**, two further complexes were investigated for comparison. The first, **6**·$(ClO_4)_3$, was obtained by treating **1**·$(ClO_4)_2$ with a large excess of cnge (Scheme 7). The molecular structure of the cation **6** as elucidated by X-ray crystallography is depicted in Figure 5.

6

Scheme 7. Schematic drawing of **6**

Compound **6** features two neutral cnge ligands within the coordination pocket of the bimetallic framework, each cnge being coordinated to one of the nickel ions in a purely *end-on* fashion (type **C**, Scheme 6). The angles Ni–N–C [171.3(2) and 172.2(2)°] are basically identical to that in **5** [171.2(2)°], and, likewise, all geometric parameters of the cnge ligands in **6** are very similar to those of the cnge fragment in **5**. The cnge-bound hydrogen atoms form several weak hydrogen bonds to perchlorate counteranions or to an acetone solvent molecule included in the crystal lattice (distances N···O in the range 2.9–3.1 Å). Due to the obvious congestion caused by the binding of the two cnge molecules within the bimetallic pocket, the Ni···Ni separation is quite large (4.586 Å) and the metal ions are forced to displace rather drastically out of the plane defined by the pyrazolate heterocycle [+0.784 Å (Ni1) and –0.647 Å (Ni2)]. The exact



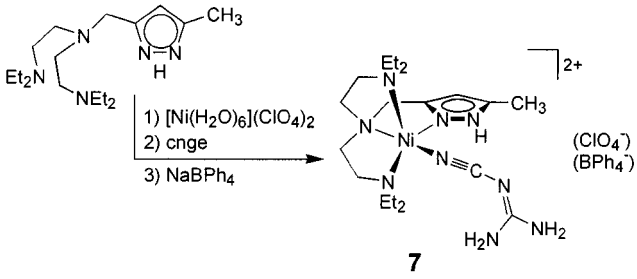


Figure 5. Molecular structure of **6**; selected interatomic distances (Å) and bond angles (°): Ni1–N1 2.035(2), Ni1–N3 2.097(2), Ni1–N4 2.125(2), Ni1–N5 2.158(2), Ni1–N20 1.983(2), Ni2–N2 2.030(2), Ni2–N103 2.097(2), Ni2–N104 2.154(2), Ni2–N105 2.137(2), N2–N120 2.000(2), N1–N2 1.389(3), N20–C20 1.162(3), C20–N21 1.295(3), N21–C21 1.334(3), C21–N22 1.325(3), C21–N23 1.329(3), N120–C120 1.152(3), C120–N121 1.304(3), N121–C121 1.338(3), C121–N122 1.331(3), C121–N123 1.331(3), Ni1···Ni2 4.586; Ni1–N20–C20 171.3(2), N20–C20–N21 170.8(3), Ni2–N120–C120 172.2(2), N120–C120–N121 172.3(3)

process leading to the formation of the tricationic complex **6** from the dicationic precursor **1** remains speculative, as no other products of the reaction could be unambiguously identified.

In order to definitely exclude any effects on the crucial ν(C≡N) vibrational frequencies caused by the distortion of the crowded bimetallic core in **6**, we prepared the corresponding mononuclear complex **7** for comparison

7

Scheme 8. Synthesis of the mononuclear complex **7**·$(ClO_4)(BPh_4)$

(Scheme 8). The compound **7**·$(ClO_4)(BPh_4)$ was obtained in crystalline form by treating the respective mononucleating ligand HL (that provides a single coordination compartment only)[7] with one equivalent each of $[Ni(H_2O)_6](ClO_4)_2$, cnge and $NaBPh_4$. An X-ray crystallographic analysis unequivocally confirmed the constitution of **7** as depicted in Figure 6.

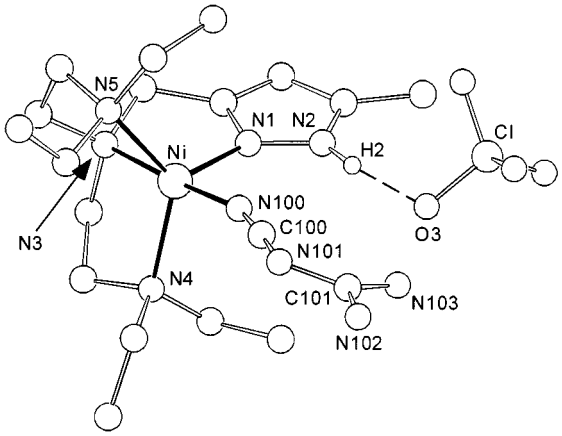

Figure 6. Molecular structure of **7** (only the major position of the disordered cnge moiety is shown); in the interests of clarity all hydrogen atoms except the pyrazole-bound H2 have been omitted; selected interatomic distances (Å) and bond angles (°): Ni–N1 1.991(3), Ni–N3 2.100(3), Ni–N4 2.105(3), Ni–N5 2.153(3), Ni–N100 1.988(4), N100–C100 1.157(7), C100–N101 1.305(7), N101–C101 1.353(7), C101–N102 1.332(7), C101–N103(7), N1–N2 1.362(4); Ni–N100–C100 163.3(4), N100–C100–N101 173.0(6), C100–N101–C101 120.8(5).

The nickel atom is nested in the tran-type coordination compartment [tran = tris(aminoalkyl)amine] and accommodates the end-on bonded cnge ligand in the remaining axial site (type **C**, Scheme 6). As anticipated, the intimate structural details of this situation closely resemble the ones observed for the nickel ions in **6** and for the Ni2 ion in **5**. The pyrazole-bound proton H2 could be located as a hydrogen bond to one of the *O*-atoms of the perchlorate counteranion [*d*(N2···O3) = 2.880 Å], where the perchlorate also forms hydrogen bonds to the terminal amino groups of the cnge [*d*(N103···O2) = 2.926 Å, *d*(N102···O4) = 2.935 Å]. Unfortunately, however, the cnge ligand was found to be disordered over two positions (ratio 85:15), and due to the moderate overall quality of the crystallographic analysis we abstain from any detailed discussion of the pivotal metric parameters of the cnge ligand.

Nevertheless, the isolation of **7** now allowed a more conclusive comparison of the ν(C≡N) stretching frequencies of free cnge with those of cnge *N*-bound to nickel(II) ions either with (**5**) or without (**6**, **7**) an adjacent second nickel(II) center, where the primary nickel(II) ions in all cases are embedded in identical pyrazolate-derived tran-type coordination environments. These values are listed in Table 1.

The complexes **6** and **7**, which feature purely *end-on* bound cnge, display similar IR bands both in acetone solution and in the solid state. As expected, their characteristic doublet for ν(C≡N) is shifted to higher wavenumbers than for free cnge. The overall differences for the low-energy component of the ν(C≡N) stretch (assigned to the tautomer with conjugated C≡N and C=N bonds[21]) are small but nonnegligible, and in the solid state a trend of decreasing frequencies in the order **6** ≈ **7** > free cnge > **5** is found. This experimental result in fact gives evidence for the presence of some (albeit very weak) side-on π-bonding interaction between the nitrile part of the 2-cyanoguanidine ligand and the proximate Ni1 ion in solid **5**. When dissolved in acetone, IR spectra in the region characteristic for ν(C≡N) are quite similar for **5** and **6**, suggesting identical structures in solution that differ from the structure observed for **5** in the solid state.

Theoretical Investigations

With the aim of further substantiating these findings, and in order to describe the electronic structure of complex **5** and to gain deeper insight into the nature of the assumed π-interaction, we have carried out DFT calculations on the simplified complexes **5a**, **7a**, and on the free ligand cnge. In **5a** and **7a** the substituents at the ligand side-arm nitrogen atoms of the parent complexes **5** and **7** have been replaced by hydrogen atoms. We started our investigations with single point calculations for the singlet, triplet, and quintuplet states of **5a** with bond lengths and bond angles taken from the X-ray data of compound **5**. Some selected results are summarized in Table 2.

Table 2. Relative energies (kcal/mol), $<S^2>$ values, atomic spin densities (ρ) and NPA charge (*q*) of the nickel atoms for the singlet, triplet and quintuplet states of **5a**

State	E_{rel}	$<S^2>$	ρNi1	ρNi2	*q*Ni1	*q*Ni2
^{5}**5a**	0.0	6.00	1.733	1.726	+1.454	+1.477
^{3}**5a**	+11.2	2.01	1.733	0.020	+1.455	+1.422
^{1}**5a**	+91.1	0.00	0.000	0.000	+1.252	+1.309

The quintuplet state of **5a** was found to be the ground state, and the states ^{3}**5a** and ^{1}**5a** lie above ^{5}**5a** by 11.2 kcal/mol and 91.1 kcal/mol, respectively. In the case of ^{5}**5a** the calculated atomic spin densities ρ as well as the NPA charges q of the nickel atoms clearly show the high-spin Ni^{II} structures. In the triplet state ^{3}**5a** the Ni2 atom adopts a low-spin configuration (ρNi2 = 0.02), while the spin density at Ni1 (1.733) remains unchanged with respect to ^{5}**5a**. The MO shapes of the metal-centered singly occupied MOs of ^{5}**5a** are shown in Figure 7.

It turns out that the singly occupied MOs of Ni1 have d_{z^2} and d_{xy} character, and consequently its three doubly occupied MOs are of $d_{x^2-y^2}$, d_{yz}, and d_{xz} character. The two latter MOs [d_{yz}, d_{xz}] are well adapted to give side-on backbonding interactions with the in-plane $\pi_\parallel$* and with the out-of plane $\pi_\perp$* MOs of the nitrile π system (Figure 8). At the same time the doubly occupied $3d_{yz}$ and $3d_{xz}$ MOs of Ni2 can give end-on backbonding interactions with the nitrogen p-component of the nitrile π* system (Figure 8). Evidently, the spatial requirements for an effective M→L backbonding in ^{5}**5a** are fulfilled and are similar to those found for Ni(0) moieties complexed to multiple π systems,[24] i.e. an electron density shift from the nickel atoms to the nitrile π* system should indeed be possible.

In order to further explore the nature and the extent of such possible backbonding interactions in complex **5** we have carried out geometry optimizations on ^{5}**5a**, ^{3}**7a**, and on the singlet state of the free cnge ligand. The optimized

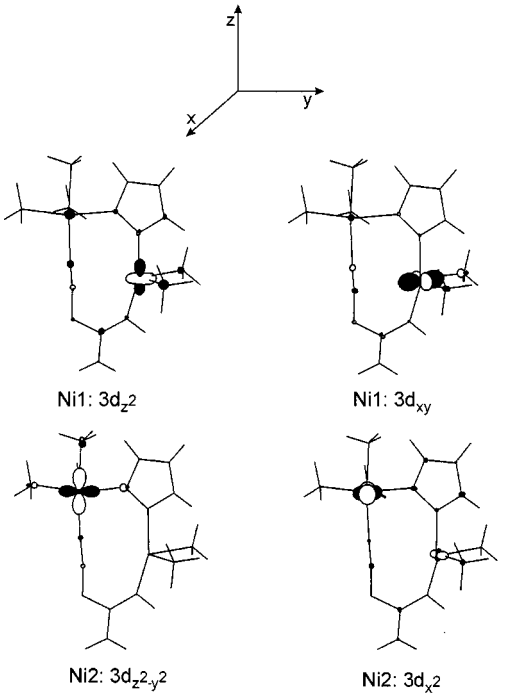

Figure 7. Shapes of the metal-centered singly occupied MOs of ^{5}**5a**

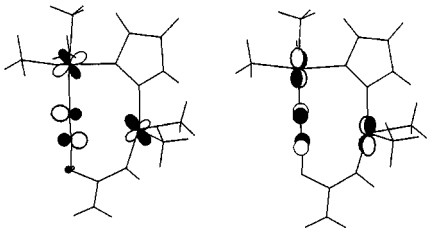

Figure 8. Possible Ni-nitrile backbonding interactions in ^{5}**5a**

structures are shown in Figure 9. According to the vibrational analyses there are no imaginary modes, and consequently these structures represent minima on the potential energy surfaces.

The optimized parameters of the free cnge molecule agree well with the known experimental data.[22] Due to the simplified nature of **5a** and **7a** some of the optimized bond lengths and bond angles differ from those determined by X-ray crystallography for the parent complexes **5** and **7** (Figures 2, 6 and 9). We ascribe these discrepancies to the spatial constraints imposed by the chelate framework of the multidentate ligands in **5** and **7**, which are not effective in the model systems **5a** and **7a**. In the case of **5a** the most striking difference is observed for the optimized Ni2–N≡C bond angle, which is 157.5° (vs. 171.2° in complex **5**). As a result, in **5a** the Ni1 atom and the N and C atoms of the C≡N unit come much closer together [*d*(Ni1–C) = 2.650 Å, *d*(Ni1–N) = 2.448 Å]. We notice, however, that the optimized Ni–N≡C bond angle of **7a** (163.9°) nicely reproduces the experimental value of the mononuclear complex **7** (163.3°). It thus seems that, in **5a**, the nitrile moiety approaches the Ni1 atom in order to enforce the side-on π-bonding interaction, while this is being prevented by the rigid dinucleating ligand matrix in the parent compound **5**.

Upon going from the free cnge ligand to **7a** and **5a**, the optimized C≡N distance increases from 1.163 Å to 1.178 Å and 1.187 Å, respectively. At the same time the calculated stretching frequency, ν(C≡N), decreases from 2209 cm^{-1} (free cnge) to 2189 cm^{-1} (**7a**) and 2143 cm^{-1} (**5a**). The trend of decreasing ν(C≡N) frequencies determined theoretically (free cnge > **7a** > **5a**) differs from that observed experimentally (**7a** > free cnge > **5a**). The calculation (for the gas phase) obviously fails to reproduce the well-known[25] increase in ν(C≡N) that occurs upon end-on binding of the nitrile (in the solid state or in solution), but it suggests that in **7a** the nitrile part of the cnge ligand receives some back-

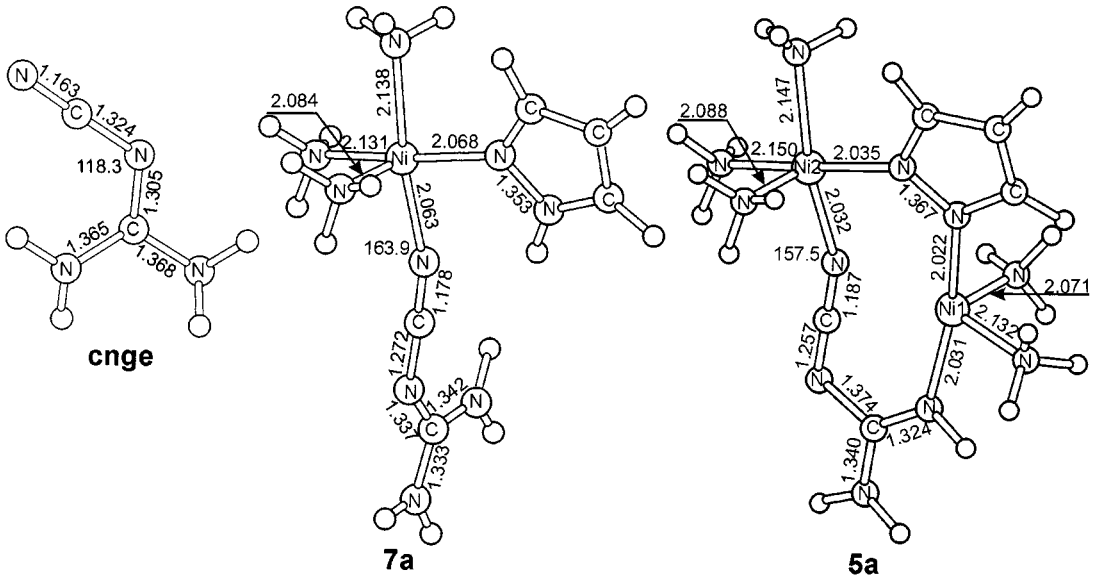

Figure 9. Optimized structures of free cnge, ^{3}**7a** and ^{5}**5a**; bond lengths are given in (Å) and bond angles in (°)

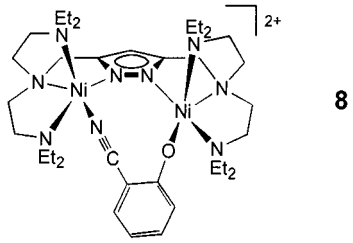
$\tilde{\nu}$(C≡N) [cm^{-1}]	2209	2189	2143



bonding from occupied MOs of the nickel ion (see Figure 8). The calculated NPA charge of the nitrile moiety changes from –0.023 (free cnge) to –0.176 (**7a**), and the population of the nitrile π* MOs increases from 0.224e (free cnge) to 0.456e (**7a**) (Table 3). We suppose that in the experimental complex **7** the end-on Ni–nitrile interactions may have a slightly different character, obviously affecting the observed ν(C≡N) stretching frequencies.

Upon going from **7a** to **5a**, an additional increase of the population of the nitrile π* MOs is discernible (Table 3), while any side-on L→M donation is negligible. With respect to **7a**, the population of the nitrile π* MOs of **5a** is greater by 0.086e. Since in the optimized structure of **5a** the Ni1 atom and the nitrile moiety come closer together than in the parent complex **5**, we also carried out NPA and NBO population analyses using the experimentally determined geometrical parameters of **5**. In this case we observe an increase of the nitrile π* MOs population by 0.049e, suggesting that in **5** the Ni1–nitrile π-bonding has to compete with the structural constraints imposed by the chelate ligands, where these constraints are enforcing a larger nickel–nickel distance and a concomitant weakening of the side-on π-interaction.

In summary, the Ni1–nitrile π-backbonding in **5** can only be characterized as a weak interaction, and this is not surprising when taking into account the large charge of the nickel(II) ion and the contracted character of its 3d shell. The positioning of the nitrile unit within the bimetallic pocket and the resulting weak Ni1–nitrile interaction in ^{5}**5a** apparently block the fifth coordination site of the Ni1 center that otherwise is occupied by an additional donor ligand in all related pyrazolate-based Ni^{II} compounds.[5–7]

Binding of 2-Hydroxybenzonitrile

The question arose as to whether the unusual binding of the C≡N moiety within the bimetallic pocket of **5** is a singular phenomenon and therefore unique to the particular nitrile cnge. We thus reacted **1**·$(ClO_4)_2$ with 2-hydroxybenzonitrile, which in its phenolate form provides a bifunctional ligand of geometric characteristics quite similar to deprotonated cnge. The resulting green complex **8**·$(ClO_4)_2$ (Scheme 9) was obtained in crystalline form, and the molecular structure of the cation as elucidated by X-ray crystallography is depicted in Figure 10.

8

Scheme 9. Schematic drawing of **8**

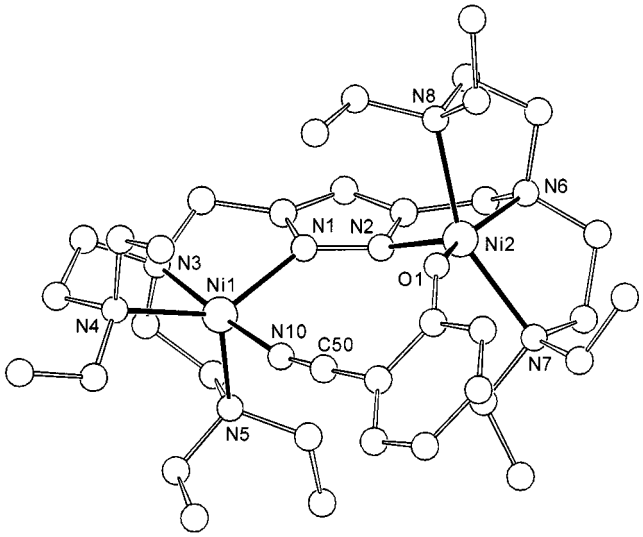


Figure 10. Molecular structure of **8**; selected interatomic distances (Å) and bond angles (°): Ni1–N1 2.050(2), Ni1–N3 2.100(2), Ni1–N4 2.172(2), Ni1–N5 2.111(2), Ni1–N10 1.988(2), Ni2–N2 2.054(2), Ni2–N6 2.087(3), Ni2–N7 2.216(2), Ni2–N8 2.208(2), N2–O1 1.934(2), N1–N2 1.386(3), N10–C50 1.135(4), Ni1···Ni2 4.587; Ni1–N10–C50 167.6(2), N10–C50–C51 176.5(3)

Obviously, the structure of **8** differs fundamentally from those of **5**. Both nickel(II) ions have retained their usual five-coordination with all the ligand side arms of the pyrazolate framework attached to the metal centers; the bifunctional 2-oxybenzonitrile(1–) ligand simply occupies the remaining active coordination sites within the bimetallic pocket. The nitrile unit exhibits plain end-on binding through its *N*-atom [angle N1–N10–C50 = 167.6(2)°] and its ν(C≡N) stretching vibration is found to be unchanged relative to those of free 2-hydroxybenzonitrile [$\tilde{\nu}$ = 2237 cm^{-1}]. These findings emphasize that particular conditions have to prevail in order to favor the weak π-bonding interaction of a nitrile unit with a nearby nickel(II) ion at the expense of the detachment of a ligand *N*-donor from the metal site, as uniquely observed for **5**.

It should finally be noted that the structure of **8** is of interest with respect to the previously proposed cooperative mechanism for the nitrile hydration mediated by **1**, which was assumed to proceed via initial end-on coordination of the nitrile to one of the nickel ions and subsequent nucleo-

philic attack by the adjacent hydroxide as shown for **2** (Scheme 2). Considering the close analogy between a metal-bound hydroxide and the metal-bound phenolate in **8**, the structure found for **8** is reminiscent of this postulated mechanism and at least demonstrates that the simultaneous binding of such an OR-function and a nitrile should, in principle, be feasible within the active site pocket of the dinuclear framework.

Conclusion

Various different binding modes of nitrile moieties at a dinuclear nickel(II) site have been characterized and studied in the present work, where the basic bimetallic framework of **1** once again proved to induce cooperative action of the two proximate metal ions. Cyanamide is incorporated as a hydrogencyanamido(1–) secondary bridge with an unusually short metal–metal separation imposed by the compartmental ligand matrix, representing only the second structurally characterized example of bridging parent $HNCN^-$. The distinct binding of a nitrile and a phenolate function at the adjacent metal centers, as observed in **8**, lends further support for the bimetallic effect that was assumed to enable the cooperative hydration of nitriles at the bimetallic site of **1**: it demonstrates that the simultaneous accommodation of both an OR-function and an end-on-bound nitrile is indeed feasible within the active site pocket of the dinuclear framework.

2-Cyanoguanidine exhibits an unprecedented binding mode within the grip of the two metal ions in **5**: while its nitrile-*N* exhibits the common end-on binding to one nickel atom, and a terminal amido-*N* is coordinated to the other metal site, the structural features suggest an additional side-on interaction of the nitrile unit with the second nickel(II) ion. Combined experimental and theoretical evidence, in particular the trend of decreasing ν(C≡N) stretching frequencies in the series **6** ≈ **7** > free cnge > **5**, as well as the proper spatial arrangement of the crucial molecular orbitals, confirm the presence of a nonnegligible (albeit weak) π-bonding of the nitrile part of the cnge ligand with the adjacent high-spin nickel(II) atom in **5**. This mainly consists of backbonding from the doubly occupied $3d_{yz}$ and $3d_{xz}$ MOs at Ni1 to the π* MOs of the nitrile. We assume that this peculiar π-bonding interaction, which is quite unusual for a high-spin nickel(II) ion nested in a purely *N*-donor environment, and which is expectedly weak, is imposed by the dinuclear pincer effect, i.e. by the seizing of the nitrile within the bimetallic pocket. Apparently, particular geometric conditions have to prevail in order to favor such side-on interaction, and this once again demonstrates the ability of two cooperating metal ions to enable unusual coordination modes by their synergetic action. One could imagine that similar interactions between π-systems and hard metal ions like high-spin nickel(II) might well play a role if enforced within highly organized and constrained substrate binding pockets, e.g. in the protein active site pockets of natural metalloenzymes.

Experimental Section

General Procedures and Methods: All manipulations were carried out under an atmosphere of dry nitrogen with standard Schlenk techniques. Solvents were dried according to established procedures. Compound **1**·$(ClO_4)_2$ and HL were synthesized according to published procedures.[7] – Microanalyses: Mikroanalytische Laboratorien des Organisch-Chemischen Instituts der Universität Heidelberg. – IR spectra: Perkin–Elmer 983G, recorded either as KBr pellets or in acetone solution. – FAB-MS spectra: Finnigan MAT 8230. – Magnetic measurement: Bruker Magnet B-E 15 C8, field-controller B-H 15, variable temperature unit ER4111VT, Sartorius microbalance M 25 D-S. Experimental susceptibility data were corrected for the underlying diamagnetism and temperature-independent paramagnetism [100×10^{-6} cm^3mol^{-1} per nickel(II) ion].[23]

Caution! Although no problems were encountered in this work, transition metal perchlorate complexes are potentially explosive and should be handled with proper precautions.

Complex 4·$(ClO_4)_2$: A solution of **1**·$(ClO_4)_2$ (0.44 g, 0.50 mmol) in EtOH/THF (1:1, 25 mL) was treated with two equivalents of cyanamide and stirred at room temperature for 2 h. All volatile material was then evaporated under reduced pressure, the residue taken up in acetone and the solution layered with light petroleum to gradually yield 0.35 g (0.40 mmol, 80%) green crystals of the product **4**·$(ClO_4)_2$. – IR (KBr): $\tilde{\nu}$ = 3282 (s), 2965 (s), 2933 (s), 2873 (m), 2149 (vs), 1467 (s), 1380 (s), 1089 (vs), 622 (s) cm^{-1}. – MS (FAB, nibeol); *m/z* (%): 779 (100) [**4**·$(ClO_4)^+$], 677/679 (98) [(**4** – 1)/(**4** + 1)$^+$]. – $C_{30}H_{62}Cl_2N_{10}Ni_2O_8$ (879.2): calcd. C 40.99, H 7.11, N 15.93; found C 41.02, H 7.13, N 15.96.

Complex 5·$(ClO_4)_2$: A solution of **1**·$(ClO_4)_2$ (0.78 g, 0.89 mmol) in EtOH/THF (1:1, 25 mL) was treated with 1.2 equivalents of cnge and stirred at room temperature for 2 h. All volatile material was then evaporated under reduced pressure and the oily residue taken up in EtOH/Et_2O (1:4, 25 mL). The green precipitate that formed was separated by filtration and dried under vacuum to afford a light green powder. This was dissolved in acetone and the solution layered with light petroleum to yield 0.16 g (0.17 mmol, 19%) of green crystals of the product **5**·$(ClO_4)_2$. – IR (KBr): $\tilde{\nu}$ = 3432 (m), 3343 (m), 3307 (w), 3232 (w), 2968 (m), 2878 (w), 2229 (w), 2180 (sh), 2154 (s), 1632 (s), 1529 (s), 1478 (s), 1468 (m), 1312 (m), 1096 (vs), 623 (s) cm^{-1}. – $C_{31}H_{64}Cl_2N_{12}Ni_2O_8$ (921.2): calcd. C 40.42, H 7.00, N 18.25; found C 39.95, H 7.07, N 17.40.

Complex 6·$(ClO_4)_2$: A solution of **1**·$(ClO_4)_2$ (0.44 g, 0.50 mmol) in EtOH/THF (1:1, 25 mL) was treated with five equivalents of cnge and stirred at room temperature for 2 h. All volatile material was then evaporated under reduced pressure, the residue taken up in acetone and again treated with three equivalents of cnge. Layering the resulting solution with light petroleum gradually afforded green crystals of the product **6**·$(ClO_4)_3$·acetone (0.11 g, 0.09 mmol, 19%). – IR (KBr): $\tilde{\nu}$ = 3433 (m), 3343 (m), 3238 (m), 2963 (m), 2877 (w), 2233 (s), 2186(s), 1699 (m, acetone), 1641 (s), 1565 (s), 1464 (m), 1259 (m), 1086 (vs), 796 (m), 623 (s) cm^{-1}. – $C_{33}H_{69}Cl_3N_{16}Ni_2O_{12}$·acetone (1163.8): calcd. C 37.15, H 6.50, N 19.26; found C 37.45, H 6.49, N 20.03.

Complex 7·(ClO_4)·(BPh_4): A solution of HL (0.17 g, 0.54 mmol) in EtOH/THF (20 mL, 1:1) was treated with $[Ni(H_2O)_6](ClO_4)_2$ (0.20 g, 0.54 mmol) and cnge (0.05 g, 0.60 mmol) and the reaction mixture stirred for 1 h at room temperature. Then $NaBPh_4$ (0.19 g, 0.56 mmol) was added and the resulting solution layered with light petroleum. Green crystals of **7**·(ClO_4)·(BPh_4)·0.5thf·0.18EtOH

gradually formed (0.33 g, 0.36 mmol, 67%). – IR (KBr): $\tilde{\nu}$ = 3421 (s), 3343 (s), 3234 (m), 3046 (m), 2976 (m), 2874 (w), 2227 (s), 2183 (s), 1636 (s), 1550 (s), 1472 (m), 1095 (s), 734 (s), 706 (s) cm^{-1}. – MS (FAB, nibeol); *m*/*z* (%): 466 (44) [$LNi(ClO_4)^+$], 450 (17) [**7**$^+$], 366 (100) [LNi^+]. – $C_{43}H_{59}BClN_9NiO_4$·0.5thf·0.18EtOH (915.3): calcd. C 59.52, H 7.06, N 13.77; found C 58.52, H 7.42, N 13.86.

Complex 8·$(ClO_4)_2$: A solution of **1**·$(ClO_4)_2$ (0.35 g, 0.40 mmol) in EtOH/THF (1:1, 15 mL) was treated with one equivalent of 2-hydroxybenzonitrile (0.048 g, 0.40 mmol) and stirred at room temperature for 1 h. All volatile material was then evaporated under reduced pressure and the residue taken up in acetone and layered with light petroleum. Green crystals of the product **8**·$(ClO_4)_2$ gradually formed (0.31 g, 0.32 mmol, 81%). – IR (KBr): $\tilde{\nu}$ = 2972 (m), 2875 (m), 2237 (s), 1594 (s), 1527 (w), 1476 (s), 1379 (w), 1092 (vs) cm^{-1}. – MS (FAB, nibeol); *m*/*z* (%): 857 (100) [**8**·$(ClO_4)^+$], 755 (90) [**8**$^+$], 378 (65) [**8**$^{2+}$]. – $C_{36}H_{65}Cl_2N_9Ni_2O_9$ (956.3): calcd. C 45.22, H 6.85, N 13.18; found C 44.84, H 6.92, N 12.95.

Calculation Details: The calculations were carried out with the density functional theory method (DFT) known in the literature by its synonym B3LYP.[26] A single extended all-electron basis set was applied in our studies. For Ni we have chosen Wachters (14s,9p,5d) basis set[27] augmented with a 4f polarization function (α_f = 1.29). The contraction scheme of [9s,5p,3d,1f] corresponds to a double- and triple-ζ basis for the core and valence electrons, respectively. The 6–311G basis[28] was used for C, N, and H. The basis set of C and N was augmented by a single 3d polarization function (α_C = 0.626, α_N = 0.913). The geometry optimizations were carried out by using analytical gradient procedures. The presented structures correspond to fully converged geometries with gradients and displacements below the thresholds implemented in Gaussian 98. Vibrational frequencies were obtained from analytic calculations of the Hessian matrices. The calculated frequencies have been scaled by a factor of 0.96. The nature and extent of charge reorganizations was characterized with the help of the natural population analysis (NPA) and natural bond orbital (NBO) methods.[29] The calculations have been carried out with the Gaussian 98 program[30] installed on the IBM RS/6000 workstations of the Universitätsrechenzentrum Heidelberg. For graphical displays we have used the Molek-9000,[31] and GaussView[32] programs.

X-ray Crystallography: The measurements were carried out on a Nonius Kappa CCD diffractometer using graphite-monochromated Mo-K_α radiation. All calculations were performed using the SHELXT PLUS software package. Structures were solved by direct methods with SHELXS-97 and refined with the SHELXL-97 program.[33] The program XPMA[34] was used for graphical handling of the data. Atomic coordinates and thermal parameters of the nonhydrogen atoms were refined in fully or partially anisotropic models by full-matrix least-squares calculation based on F^2. In general the hydrogen atoms were placed at calculated positions and allowed to ride on the atoms they are attached to. The structure of **4**·$(ClO_4)_2$ was treated as a racemic twin. The hydrogen atom H200 of the $HNCN^-$ bridge was located in the difference Fourier synthesis and refined isotropically. In the case of **5**·$(ClO_4)_2$ all hydrogen atoms of the monodeprotonated cnge ligand (H50 – H52) were located and refined. Likewise, for **6**·$(ClO_4)_3$ the protons H22 – H25 and H122 – H125 of the two cnge ligands were located in the difference Fourier map, refined once and then held fixed. One of the terminal ethyl groups (C10 and C14) of **6**·$(ClO_4)_3$ was found to be disordered over two positions (ratio 50:50). In the case of **7**·$(ClO_4)(BPh)_4$ the cnge ligand was found to be partly disordered over two positions (ratio 85:15). The pyrazol-H2 could be found and refined; hydrogen atoms H102, H112, H103, H113 corresponding to the major part of the disordered cnge were located, refined

once and then held fixed. Table 4 compiles the data for the structure determinations. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC 127490 – CCDC-127493 and CCDC-133913. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

We sincerely thank Prof. Dr. G. Huttner and Prof. Dr. R. Gleiter for their generous support. Financial support of this work by the Deutsche Forschungsgemeinschaft (SFB 247, Habilitandenstipendium for F. M.) and the Fonds der Chemischen Industrie is gratefully acknowledged.

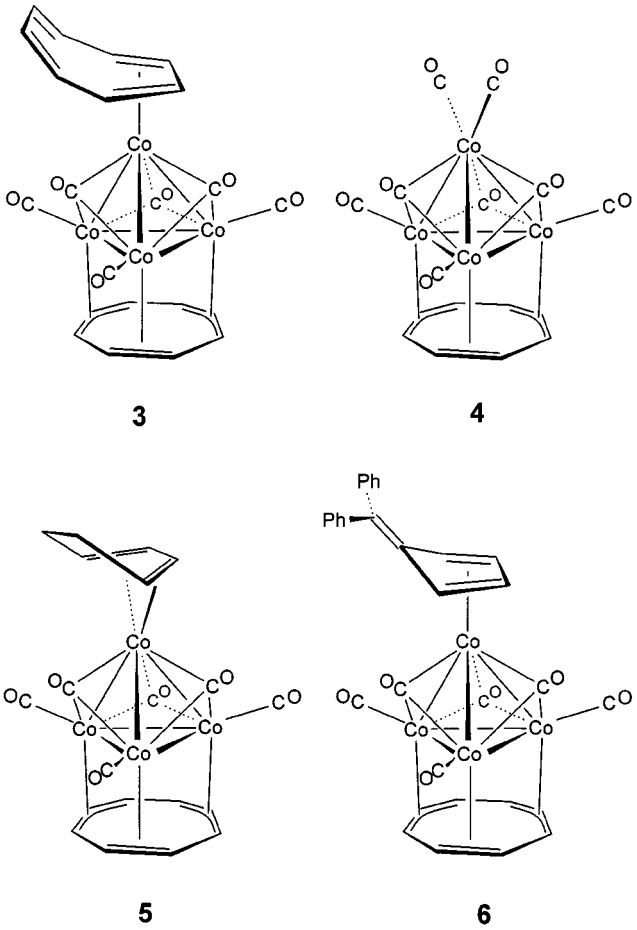
Reductive Degradation of Tetracobalt Cluster Complexes with a Facial C_8H_8 Ligand – Synthesis of $[Co_3(CO)_3(\mu_3\text{-}CO)_3(\mu_3\text{-}C_8H_8)]^-$ and $[Ru(C_5Me_5)Co_3(CO)_3(\mu_3\text{-}CO)_3(\mu_3\text{-}C_8H_8)]$

Hubert Wadepohl,*[a] Stefan Gebert,[a] Rüdiger Merkel,[a] and Hans Pritzkow[a]



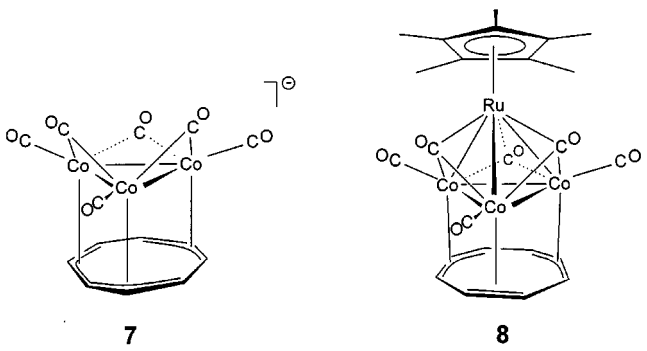
Keywords: Carbocycles / Clusters / Cobalt / Electrochemistry / Facial ligands

Chemical reduction of the cluster complexes $[Co_4(CO)_3(\mu_3\text{-}CO)_3(\mu_3\text{-}C_8H_8)L_2]$ **3** ($L_2 = C_8H_8$), **4** (L = CO), **5** ($L_2 = C_6H_8$) and **6** (L_2 = 6,6-$Ph_2C_6H_4$) gives the trinuclear anion $[Co_3(CO)_3(\mu_2\text{-}CO)_3(\mu_3\text{-}C_8H_8)]^-$ (**7**) in high yield. It is proposed that formation of **7** occurs via degradation of the radical anions $[\mathbf{3}]^-$ – $[\mathbf{6}]^-$, which can be generated reversibly via cyclic voltammetry. The anion **7** is stabilised by the facial C_8H_8 ligand and does not degrade further. Reaction of **7** with $[(C_5Me_5)Ru(NCMe)_3][BF_4]$ results in the formation of $[Ru(C_5Me_5)Co_3(CO)_3(\mu_3\text{-}CO)_3(\mu_3\text{-}C_8H_8)]$ (**8**). The crystal structures of $[NEt_4]^+$-**7**, $[(C_5H_5)_2Co]^+$-**7**, and **8** were determined. In **7** and **8**, the cyclooctatetraene ligand is coordinated to the Co_3 face of the cluster in the facial mode.

Introduction

Transfer of an electron is one of the most basic reactions of molecular metal cluster complexes.[1] Transition metal carbonyl clusters are usually prone to reduction, forming a more or less stable radical anion.[2] Frequently, reduction of the cluster is accompanied or followed by metal–metal bond scission, which may result in a modification of the cluster architecture, a change in nuclearity, or even complete degradation to mononuclear fragments. For example, when reduced electrochemically, $[Co_4(CO)_{12}]$ (**1**) was found to give the unstable monoanion $[Co_4(CO)_{12}]^-$ $[\mathbf{1}]^-$, which in the absence of other reactants decomposes to $[Co(CO)_4]^-$ and cobalt metal.[3] The products of the chemical reduction of **1** are very dependent on the reducing agent and the reaction conditions. With sodium in liquid ammonia, $[Co(CO)_4]^-$ is obtained.[4] The hexanuclear cluster anions $[Co_6(CO)_{15}]^{2-}$ and $[Co_6(CO)_{14}]^{4-}$ are formed with alkali metals or cobaltocene in THF.[5] Finally, the trinuclear $[Co_3(CO)_{10}]^-$ (**2**) can be obtained from **1** and Li[$Co(CO)_4$].[6a]

Recently we described the preparation and structures of a series of tetracobalt cluster complexes $[Co_4(CO)_3(\mu_3\text{-}CO)_3(C_8H_8)L_2]$, e.g. **3** ($L_2 = C_8H_8$), **4** (L = CO), **5** ($L_2 = C_6H_8$), and **6** (L_2 = 6,6-$Ph_2C_6H_4$) with a cyclooctatetraene ligand in the rarely-encountered facial (μ_3-) coordination mode (Scheme 1).[7] In these derivatives of **1**, the facial C_8H_8 ligand was found to resist substitution under a variety of conditions, pointing to a particular stability of the $Co_3(\mu_3\text{-}C_8H_8)$ moiety.[7,8] As described above, degradation of the Co_4 cluster takes place upon reduction of **1**. This disintegration of the metal framework is difficult to control, and frequently leads to a complete breakdown of the cluster. The presence of the facial C_8H_8 ligand might more easily stop this catastrophe at the trinuclear stage.



Scheme 1

Here we wish to report the exclusive and quantitative formation of the novel cluster complex anion $[Co_3(CO)_3(\mu_2\text{-}CO)_3(\mu_3\text{-}C_8H_8)]^-$ (**7**) from the reductive degradation of **3**–**6**, and its capping reaction with the $[(C_5Me_5)Ru]^+$ fragment

Preparative and Spectroscopic Investigations

When treated with an equimolar amount of $Li[HBEt_3]$, the tetranuclear cluster complexes $[Co_4(CO)_3(\mu_3\text{-}CO)_3(C_8H_8)L_2]$ **3–6** are cleanly converted into the trinuclear cluster anion $[Co_3(CO)_3(\mu_2\text{-}CO)_3(\mu_3\text{-}C_8H_8)]^-$ (**7**). Addition of aqueous $[NEt_4]Cl$ results in the precipitation of dark orange $[NEt_4]^+$-**7** in nearly quantitative yield. In contrast, treatment of **6** with $Na_2[Fe(CO)_4]$ in THF only results in a low frequency shift of the bands in the ν(CO) region by about 45 cm^{-1}, without changing the general appearance of the infrared spectrum. Addition of aqueous $[NEt_4]Cl$ in order to crystallise the product as the $[NEt_4]^+$ salt results in the partial reformation of the neutral starting material **6**. Treatment with $[PPh_4]Cl$ in THF causes slow reaction to give the trinuclear anion **7**.

The $[(C_5R_5)_2Co]^+$ (R = H, Me) salts of anion **7** are formed as by-products (10–20% yield) in the reactions of **3** with cyclopentadiene and pentamethylcyclopentadiene, respectively, along with $[Co_4(CO)_3(\mu_3\text{-}CO)_2(\mu_3\text{-}H)(\mu_3\text{-}C_8H_8)(\eta\text{-}C_5R_5)]$ **9a**, **b**[8] (60–70% yield) and $[(C_5R_5)Co(CO)_2]$ (20% yield) (R = H, Me). Reaction of **3** with cobaltocene in THF gives $[(C_5H_5)_2Co]^+$-**7** in nearly quantitative yield. The changes in the IR spectrum after addition of 1.1 equivalents of $Na[C_5H_5]$ to a solution of **3** in THF also indicate the quantitative formation of **7**.

When an equimolar amount of $[(C_5Me_5)Ru(NCMe)_3][BF_4]$ is added to a dichloromethane solution of $[NEt_4]^+$-**7**, a colour change from dark orange to dark red is observed. The heteronuclear cluster complex $[Ru(C_5Me_5)Co_3(CO)_3(\mu_3\text{-}CO)_3(\mu_3\text{-}C_8H_8)]$ (**8**) can be isolated in 45% yield from this mixture after column chromatography. No reaction takes place between $[NEt_4]^+$-**7** and $[Mn(CO)_5Cl]$ or $[(C_5H_5)Fe(CO)_2I]$.

Four bands in the ν(CO) region of the infrared spectrum (1977, 1938, 1782, and 1743 cm^{-1}) are displayed by dichloromethane solutions of **7**. These absorptions do not depend noticeably on the counterion. Complex **8** gives only three ν(CO) bands (2000, 1978, and 1707 cm^{-1}, in CH_2Cl_2). The NMR spectra of **7** and **8**, measured at room temperature, are very simple. The facial C_8H_8 ligand gives only one proton signal [δ = 4.10 (**7**), δ = 3.97 (**8**)] and one carbon NMR resonance [δ = 75.4 (**7**), δ = 70.3 (**8**)]. The ^{13}C NMR resonances for the carbonyl ligands could not be detected, due to the rather low solubility of the complexes. Other resonances in the ^1H and ^{13}C NMR spectra are due to the C_5Me_5 ligand of **8**, and the counterions X^+ ($[NEt_4]^+$ and $[(C_5R_5)_2Co]^+$, respectively) in X^+-**7**.

Electrochemistry

Cyclic voltammograms were recorded in CH_2Cl_2 solution at a scan rate of 100 mV/s. The electrochemical behaviour of the cluster complexes $[Co_4(CO)_6(C_8H_8)L_2]$ **3**, **5**, and **6** is characterised by pseudo-reversible reduction waves. The redox behaviour of the octacarbonyl derivative **4** (L = CO) appears to be more complex. The relevant data are given in Table 1. There are two reduction processes in every case, corresponding to the formation of the monoanions $[Co_4(CO)_6(C_8H_8)L_2]^-$ and dianions $[Co_4(CO)_6(C_8H_8)L_2]^{2-}$, respectively. For complex **4** the first reduction wave is distorted from the ideal shape, indicating a partially irreversible behaviour. The second reduction of **4** is strictly irreversible. Oxidation of the cluster complexes is irreversible, except in the case of complex **6** (L_2 = diphenylfulvene), which shows a pseudo-reversible oxidation wave (Table 1).

Table 1. Electrochemical data ($E_{1/2}$ [V] vs. SCE) for the complexes $[Co_4(CO)_6(C_8H_8)L_2]$ **3–6** (in CH_2Cl_2, supporting electrolyte $[n\text{Bu}_4N][PF_6]$, working electrode glassy carbon, reference electrode SCE, scan rate 100 mV s^{-1})

Crystal and Molecular Structure of $[NEt_4]^+$-7, $[(C_5H_5)_2Co]^+$-7, and 8

Single-crystal X-ray structure determinations were carried out with $[NEt_4]^+$-**7** and with the tetranuclear Co_3Ru cluster complex **8**. Important bond lengths and angles are collected in Table 1 and Table 3. Views of the cluster molecules are presented in Figure 1 and Figure 2. The crystal structure of $[(C_5H_5)]_2Co]^+$-**7** was also determined. Unfortunately, the quality of the diffraction data obtained from this salt did not allow a complete refinement of the structure.

The crystal structures of the salts consist of a packing of isolated cations $[NEt_4]^+$ and $[(C_5H_5)_2Co]^+$, respectively, and anions **7**. In both cases, molecular C_s symmetry is imposed on the cluster anions **7** by the space group symmetry. The isosceles triangular array of cobalt atoms is capped by the C_8H_8 ligand in the facial μ_3-η^3:η^3:η^3 coordination mode. Within the experimental errors the anions in the two structures are essentially superimposable. The metal core of complex **8** consists of a distorted Co_3Ru tetrahedron with very nearly C_{3v} symmetry. The facial C_8H_8 ligand binds to the Co_3 face of the cluster in essentially a μ_3-η^2:η^3:η^3 fashion. In both **7** and **8**, the cyclooctatetraene ligands are somewhat puckered and approach a chair-like conformation, with endocyclic torsion angles between 2 and 24°. The pattern of carbon–carbon bond lengths within the μ_3-C_8H_8 rings is rather irregular, spanning the range of 1.402(4)...1.426(6) Å in **7** and 1.372(17)...1.448(16) Å in **8**. In both **7** and **8**, every cobalt atom bears a terminal carbonyl ligand, which is at an angle of about 20° to the Co_3 plane, bent away from the facial C_8H_8 ligand. In **7**, the three remaining carbonyls are bridging the edges of the metal cluster. In complex **8**, the three Co_2Ru faces are fairly symmetrically capped by μ_3-CO ligands.

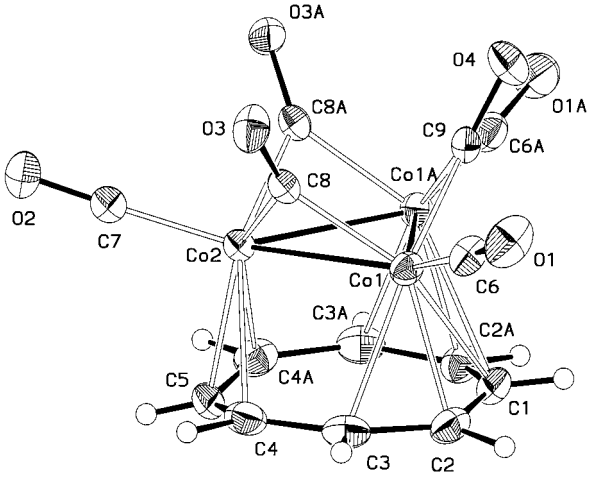

Figure 1. Molecular structure of $[Co_3(CO)_6(\mu_3\text{-}C_8H_8)]^-$ (**7**) in the crystals of $[NEt_4]^+$-**7**

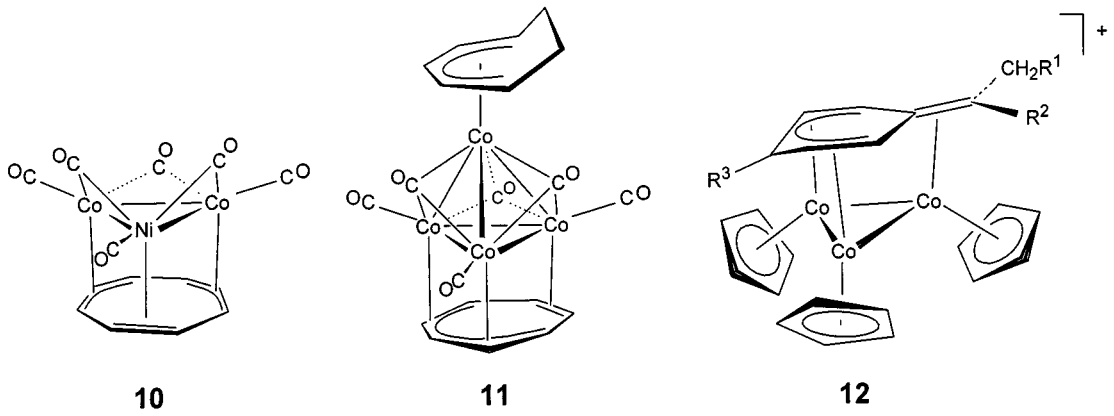
Discussion

The observed reductive degradation of the μ_3-cyclooctatetraene tetracobalt cluster complexes **3–6** to give the trinuclear **7** has a parallel in the reduction chemistry of the parent binary carbonyl, $[Co_4(CO)_{12}]$ (**1**). However, reduction of **1** is very difficult to stop at the trinuclear stage, $[Co_3(CO)_{10}]^-$ (**2**). This anion is quite unstable and only forms as an ion pair in the presence of a weakly solvated Li^+ counterion.[6] Removal of the stabilising Li^+ from the cluster, e.g. by means of addition of even small percentages of donor ligands such as THF, leads to complete decomposition.[6] As is expected for salts with fairly big organic cations, there is no ion pairing in the crystal structures of $[NEt_4]^+$-**7** and $[(C_5H_5)_2Co]^+$-**7**. These salts can even be heated under reflux in THF for hours without decomposition. Hence, the anion **7** must indeed be greatly stabilised

by the bridging C_8H_8 ligand, compared to the isoelectronic binary carbonyl cluster complex **2**.

We assume that the primary step in the formation of **7** is the transfer of an electron from the reducing agent to the starting clusters **3–6**, to give the tetranuclear radical anions $[\mathbf{3}]^-$ – $[\mathbf{6}]^-$. An alternative nucleophilic attack of **3–6** by hydride from $Li[HBEt_3]$, followed by degradation of the addition product is unlikely. Such a mechanism would not account for the formation of **7** during the reaction of **3** with the cyclopentadienes. We assume that cobaltocene or decamethylcobaltocene, respectively, is formed here from C_5R_5H and $[(C_5R_5)Co(C_8H_8)]$, which is one of the other reaction products. Reduction of the remaining **3** by $[(C_5R_5)_2Co]$ would then lead to the same intermediate as in the reaction with $Li[HBEt_3]$. This view is corroborated by the results of the direct reaction of **3** with cobaltocene that quantitatively generates $[(C_5H_5)_2Co]^+$-**7**.

Spectroscopic evidence for the transient formation of an anionic tetranuclear species comes from the reaction of **6** and $Na_2[Fe(CO)_4]$. The infrared absorptions of the primary product display the pattern characteristic of a $Co_4(CO)_3(\mu_3\text{-}CO)_3$ cluster core; their bathochromic shift relative to those of **6** ($\Delta\tilde{\nu}$ = 40–45 cm^{-1}) is consistent with an anionic tetranuclear cluster, which could be $[\mathbf{6}]^-$ or even $[\mathbf{6}]^{2-}$.



As shown by the cyclic voltammetry experiments, the anions $[\mathbf{3}]^-$, $[\mathbf{5}]^-$ and $[\mathbf{6}]^-$ have a considerable lifetime, at least in the electrochemical double layer. The fragmentation reaction observed after chemical reduction in a preparative scale could be promoted by the different solvent (THF instead of CH_2Cl_2) or else be too slow to have a great effect on the cyclic voltammograms. Complex $[\mathbf{4}]^-$ appears to be more labile in the timescale of our electrochemical experiments. It is however not clear if the observed potential current response is due to the onset of cluster degradation, or to a facile dissociation of carbon monoxide[9] from $[\mathbf{4}]^-$.[10]

The low stability of anionic tetranuclear cluster complexes of cobalt was noted by Chini 30 years ago.[5,11] A stabilisation by the presence of chelating di- and triphosphane ligands was observed.[3] We note here that capping of a Co_3 face in $[Co_4(CO)_{12}]$ (**1**) with the tripodal ligand $HC(PPh_2)_3$ results in a system which does not degrade at all upon reduction,[9,12] in contrast to our C_8H_8-capped cluster **4**.

The structure of the trinuclear anion **7** does not depend on the counterion; it is quite similar to that of its neutral isoelectronic analogue, $[Co_2Ni(CO)_3(\mu_2\text{-}CO)_3(\mu_3\text{-}C_8H_8)]$ (**10**)(Scheme 3).[13] Minor differences are the shorter mean metal–metal distance in **10** (2.514 Å),[13] due to the smaller nickel atom, and the somewhat different coordination mode of the facial C_8H_8 ligand, which is $\mu_3\text{-}\eta^3\text{:}\eta^3\text{:}\eta^3$ in **7** and more like $\mu_3\text{-}\eta^2\text{:}\eta^3\text{:}\eta^3$ in **10**. In the Co_3Ru complex **8**, the C_8H_8 ligand also attains the $\mu_3\text{-}\eta^2\text{:}\eta^3\text{:}\eta^3$ coordination mode, which is the one more commonly found for facially coordinated C_8H_8.[8] In a localised view of the bonding, the π-system of the $\mu_3\text{-}\eta^2\text{:}\eta^3\text{:}\eta^3$-cyclooctatetraene may be grouped into one η^2-coordinated ′ene′ and two η^3-′enyl′ subunits. In the $\mu_3\text{-}\eta^3\text{:}\eta^3\text{:}\eta^3$ ligand, there are three η^3-′enyl′ units, two of which are sharing one carbon atom. This atom (C1 in **7**) is at a very long distance from the nearest Co atoms [Co1 and Co1a, 2.516(5) Å in **7**]. A similar situation was encountered previously involving part of the $\mu_3\text{-}\eta^2\text{:}\eta^3\text{:}\eta^3$-cycloheptatrienyl ligand in the related complex $[Co_4(CO)_3(\mu_3\text{-}CO)_3(\eta^5\text{-}C_7H_9)(\mu_3\text{-}C_7H_7)]$ (**11**) (Scheme 3),[7] and the $\mu\text{-}\eta^3\text{:}\eta^3$-coordinated cyclohexadienyl part of the benzyl ligand in the cations $[\{(C_5H_5)Co\}_3(\mu_3\text{-benzyl})]^+$ (**12**) (Scheme 3).[14]

It should be stressed, however, that we do not wish to attach much significance to the variations in the actual orientation of the facial C_8H_8 ring relative to the bonding M_3 plane, as observed in the crystals. Topologically, there is little difference between these coordination modes; they can be converted into one another by a rather small (less than 8°) rotation of one ring. As indicated by the NMR spectra, rotation of the facial μ_3-cyclooctatetraene ′on top′ of the metal triangle is very easily accomplished in solution. Although the anisotropic displacement parameters of the C_8H_8 ring carbons do not show a large distortion, this dynamic process might be operative in the crystals as well.

The chair-like conformation and the irregular pattern of the carbon–carbon bond lengths of the $\mu_3\text{-}C_8H_8$ rings in **7** and **8** are quite similar to those established earlier for other tri- and tetranuclear cluster complexes with such li-

10 **11** **12**

Scheme 3

gands.[7,8,13] The somewhat greater spread of carbon–carbon bond lengths in the Co_3Ru complex **8** is not significant, due to the larger errors in this structure. The cobalt–cobalt distances in **8** [2.526(2)...2.531(2) Å] are also similar to the corresponding parameters in the Co_4 complexes **3–5** [2.507(2)...2.538(2) Å][7] and in the trinuclear **7** [2.507(2), 2.530(2) Å]. To our knowledge, complex **8** is the first structurally-characterised cobalt containing tetrahedral cluster with a $(C_5R_5)Ru$ vertex. A comparison with data from Co_3Ru clusters with a $Ru(CO)_{3-n}(PR_3)_n$ (n = 0, 1) vertex[15] indicates that Co–Ru bonds are generally slightly longer in these species. This is not unexpected in view of the higher formal oxidation state for Ru in **8**.

In general, the geometry of the $M_3(\mu_3\text{-}C_8H_8)$ subunit does not seem to be influenced much by the nuclearity (three in **7**, four in **3–6** and **8**) and overall charge of the cluster.

Conclusion

In contrast to $[Co_4(CO)_{12}]$ (**1**), reduction of some of its derivatives with a facial C_8H_8 ligand follows a single pathway, and leads to extrusion of a cobalt vertex from the cluster. The product $[Co_3(CO)_6(\mu_3\text{-}C_8H_8)]^-$ (**7**) is appreciably more stable than the corresponding binary carbonyl $[Co_3(CO)_{10}]^-$ (**2**). It is obvious that this is due to an effective stabilisation of the triangular array of cobalt atoms by the bridging cyclopolyene ligand.

Experimental Section

General Procedures: All operations were carried out under an atmosphere of purified nitrogen or argon (BASF R3–11 catalyst) using Schlenk techniques. Solvents were dried by conventional methods. Silica used as a stationary phase for column chromatography was heated to 180–200 °C under vacuum for several days and then stored under nitrogen. The cluster complexes **3–6** were prepared by published methods.[7] – NMR spectra were obtained on Bruker AC 200 and AVANCE DRX200 instruments (200.1 MHz for ^1H, 50.3 MHz for ^{13}C). ^1H and ^{13}C chemical shifts are reported vs. $SiMe_4$ and were determined by reference to internal $SiMe_4$ or residual solvent peaks. – Infrared spectra were recorded in CaF_2 cells with a Bruker IFS-28 Fourier transform spectrometer (optical resolution 0.5 cm^{-1}). – Electrochemical experiments were carried out using a EG & G PARC Model 173 potentiostat and a Model 175 Universal Programmer. Redox potentials are referenced to the standard calomel electrode (SCE). – Elemental analyses were performed locally by the microanalytical laboratory of the Organisch-Chemisches Institut der Universität Heidelberg and by Mikroanalytisches Labor Beller, Göttingen.

$[NEt_4]^+[Co_3(CO)_6(\mu_3\text{-}C_8H_8)]^-$ ($[NEt_4]^+$-7): An equimolar amount of $Li[HBEt_3]$ (1 M solution in THF) is slowly added to 1.63 g (2.7 mmol) of $[Co_4(CO)_6(C_8H_8)_2]$ (**3**) in THF (20 mL). The mixture is stirred for 30 min at room temperature. The solvent is removed under reduced pressure and the residue is redissolved in 5 mL of THF. A solution of 1.0 g (6.0 mmol) of $[NEt_4]Cl$ in 30 mL of water is added dropwise within 30 min. After stirring for 1 h the precipitation of the product is completed by addition of 20 mL of *n*-heptane. The precipitate is collected on a fine glass frit (D4) and

washed with water, toluene and pentane to give pure dark orange polycrystalline $[NEt_4]^+$-**7** (1.57 g, 100%). – ^{1}H NMR (in CD_2Cl_2): δ = 1.35 (m, 12 H, NCH_2CH_3), 3.24 (m, 8 H, NCH_2CH_3), 4.10 (s, 8 H, C_8H_8). – $^{13}C\{^1H\}$NMR (in C_6D_6): δ = 7.7 (NCH_2CH_3), 53.0 (t, J_{CN} = 3.0 Hz, NCH_2CH_3), 69.1 (C_8H_8). – IR (ν(CO), in CH_2Cl_2): $\tilde{\nu}$ = 1977 (s), 1938 (vs), 1782 (s), 1743 (s) cm^{-1}. – $C_{22}H_{28}Co_3NO_6$ (579.3): C 45.62, H 4.87, N 2.42; found C 45.47, H 4.93, N 2.35.

$[(C_5H_5)_2Co]^+[Co_3(CO)_6(\mu_3\text{-}C_8H_8)]^-$ ($[(C_5H_5)_2Co]^+$-7): A 285 mg (0.46 mmol) sample of **3** and 330 mg (1.7 mmol) of $[(C_5H_5)_2Co]$ are dissolved in 100 mL of toluene at room temperature. A black precipitate is formed immediately, which is collected on a glass frit and washed two times with 10 mL of toluene. The product was recrystallised from THF to give 290 mg (100%) of red $[(C_5H_5)_2Co]^+$-**7**.

$[Ru(C_5Me_5)Co_3(CO)_6(\mu_3\text{-}C_8H_8)]$ (8): A mixture of 720 mg (1.2 mmol) of $[NEt_4]^+$-**7** and 550 mg (1.2 mmol) of $[(C_5Me_5)Ru(NCMe)_3][BF_4]$ in 50 mL of CH_2Cl_2 is stirred at room temperature for 1 h. After filtration of the solution the solvent is removed under reduced pressure and the residue washed with *n*-hexane. The black residue is chromatographed on silica (20·2.5 cm). A broad yellow-brown band is removed first with *n*-hexane/toluene (1:1). The dark red band obtained with CH_2Cl_2 is collected to give black polycrystalline **8** (360 mg, 44%) after removal of solvent in vacuo. ^{1}H NMR (in CD_2Cl_2): δ = 1.84 (s, 15 H, CH_3), 3.97 (s, 8 H, C_8H_8). – $^{13}C\{^1H\}$NMR (in C_6D_6): δ = 9.2 (C_5Me_5), 70.3 (C_8H_8), 105.8 (C_5Me_5). – IR (ν(CO), in THF): $\tilde{\nu}$ = 2000 (sh), 1978 (vs), 1707 (s) cm^{-1}. – $C_{24}H_{23}Co_3O_6Ru$ (685.3): C 42.06, H 3.38; found C 42.24, H 3.41.

Crystal Structure Determinations: Single crystals were grown from a dichloromethane solution at –20 °C ($[NEt_4]^+$-**7**) or by slowly cooling a hot (80 °C) solution in toluene (**8**). Intensity data were collected on a Siemens-Stoe AED2 four circle diffractometer at low temperature and corrected for Lorentz, polarisation and absorption effects (Table 4). A semi-empirical absorption correction was applied (Psi-scans). Crystals of **8** were found to be twinned; the structure was solved and refined using only the nonoverlapping reflections of the individuum which gave the higher intensities. The structures were solved by direct methods, and refined by full matrix least squares based on F^2. All nonhydrogen atoms were given anisotropic displacement parameters. The hydrogen atoms of the cyclooctatetraene rings were located from difference Fourier syntheses and refined with isotropic displacement parameters. All other hydrogens were placed in calculated positions.[16] A limited set of reflection data was also collected from a poorly crystalline specimen of $[(C_5H_5)]_2Co]^+$-**7**. The low quality of this data set allowed the structure to be solved, but was not sufficient for a complete refinement. The calculations were performed using the programs SHELXS-86 and SHELXL-93.[17] Graphical representations were drawn with ORTEP-II[18]

Chiral Dilithiomethane Derivatives: Structure Determination and Application in Stereoselective Reactions

Jürgen F. K. Müller[a]

Keywords: Asymmetric synthesis / Chirality / Computer chemistry / Lithium / Dilithiomethane / Sulfoximines

The synthesis and X-ray analysis of chiral dilithiomethane analogues derived from sulfoximines are presented. The structures of the sulfoximine-stabilised mono- and dilithio salts have been compared and allow a rationalization of the second lithiation. Organophosphorus-based dilithiomethane derivatives are also structurally described. The gas-phase structures of *N*,*S*,*S*-trimethylsulfoximine **19** and of its mono- and dilithiated isomers **20–21** were calculated by ab initio methods employing different levels of theory. For an application in asymmetric synthesis, the dilithiation of (*N*-methyl)-*S*-ethyl-*S*-phenylsulfoximine (**11**) afforded a chiral dinucleophile that undergoes highly regio- and stereoselective alkylation reactions with electrophiles. The transmetallation of a chiral dilithiomethane reagent such as **14** with $ClTi(OiPr)_3$ followed by addition of an aldehyde, constitutes a simple one-pot process for the formation of (*E*)-alkenylsulfoximines with excellent diastereoselectivity.

1. Introduction

Since its discovery, dilithiomethane (**2**) has challenged researchers in various fields of chemistry such as synthetic organic chemistry, organometallic chemistry, and computational chemistry. The first landmark was achieved by Ziegler et al. who developed the first synthetic route to dilithiomethane.[1]

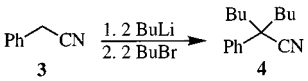
The high reactivity of **2** towards oxygen and moisture, together with its notorious instability and poor solubility in organic solvents, complicated its structural characterisation. After early solid state NMR studies, Stucky et al. suggested an X-ray structure of CD_2Li_2 in 1990 derived from powder diffraction data.[2,3] Computational studies suggested various gas phase structures and even higher aggregates of **2**.[4] For synthetic purposes, however, heteroatom-substituted organolithiums are better qualified than simple alkyllithium compounds. The same is true for heteroatom-substituted geminal dilithiated organic compounds, which have been shown in recent years to possess great synthetic potential.[5] This led to the development of new synthetic strategies, with the aim of synthesising assemblies of complex molecular structures with a minimum of chemical steps more effici-



Jürgen Friedrich Karl Müller was born in 1963. He studied chemistry at the University of Freiburg (Germany) from 1983 until 1989 and performed his PhD studies in the group of Prof. Dr. Carsten Bolm at the University of Basel (Switzerland), Department of Organic Chemistry (1990−1993). The topic of the thesis was "Enantioselective catalysis with transition metals". During a postdoctoral stay at the University of Hawaii in the group of Prof. Dr. M. Tius (1994−1995) the author worked in the field of marine natural product synthesis and structure determination. Presently J. F. K. Müller works on his "Habilitation" at the Institute for Inorganic Chemistry of the University of Basel. His general research interests are: structure determination of chiral organo(di)metallics, their application in stereoselective synthesis and computational evaluation. Asymmetric catalysis with chiral sulfur and phosphorus compounds, design and synthesis of enzyme inhibitors.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

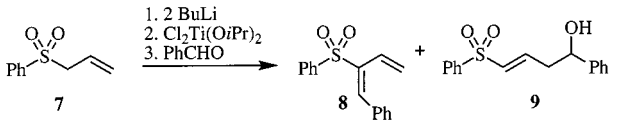
ently. For example, multiple C–C bond formations in a single reaction step have been reported from the reaction of dilithiated nitriles, sulfonamides, sulfones and phosphonates with various electrophiles.[6–9]

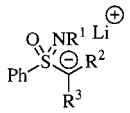


3 4

Unfortunately, a common drawback of all of these reagents is the lack of chirality, which prevents a successful application in asymmetric reactions. If such a dilithiomethane derivative bears a chiral auxiliary adjacent to its geminal dilithiated carbon atom, the two positions of the lithium atoms become nonequivalent because they are in a diastereotopic environment. We have chosen the sulfoximine group, the aza analogue of a sulfone, as a chiral auxiliary, which should allow the twofold abstraction of acidic hydrogen s bound to the adjacent carbon atom in **5**.[10] Phosphorus based chiral auxiliaries, which already have demonstrated a great versatility in asymmetric synthesis, have also to be taken in account.[11]

5 6

One would expect that the reactivity of each geminal bound lithium atom towards electrophiles differs, and might be used for synthetic purposes in asymmetric reactions. Transmetallation with one equivalent of a transition metal compound leads to mixed organodimetallics that are less reactive. This opens the possibility of directing the chemo-, regio-, and stereoselectivity by the appropriate choice of the second metal, which could induce better stereocontrol. Indeed, previous reports on an achiral sulfone **7** demonstrated that such doubly heterometallated lithium-titanium sulfones undergo highly diastereoselective addition to aldehydes forming predominantly (*E*)-alkenes **8** and **9**.[12]



7 8 9

Early investigations into the reactivity of acceptor-substituted organodilithium compounds led finally to the conclusion that, derived from trapping reactions, the intermediates in general have to be geminal dilithio species. This assumption turned out to be erroneous as the first structural investigations of such intermediates have shown. In certain cases NMR and crystallographic studies led to the discovery of the so called "Quasi Dianion Complexes" (QUADAC's), which simulate a second lithiation, but in chemical reality these are complexes between a monolithium compound and a second equivalent of a lithium base as found, for instance, for a "doubly" lithiated nitrile.[13] True dilithiomethane derivatives derived from a sulfone or nitrile are formed only in the presence of a second stabilising group such as trimethylsilyl or vinyl.[14–16] As a consequence, the demand for a structural confirmation of a chiral dilithiomethane derivative has yet to be fulfilled before its synthetic properties can be explored. Recent developments in low temperature diffraction and crystallisation techniques make X-ray crystallography the most powerful instrument for the structure determination of organolithiums.[17] We took advantage of this and started our investigations on the elucidation of the solid-state structures of mono- and dilithiated sulfoximines in combination with quantum chemical calculations, which have been shown to be the method of choice for the determination of the gas phase structures of lithiumorganic compounds.[18]

2. Solid State Structures

2.1 Monolithiated Sulfoximines

Despite their significance in asymmetric synthesis, the structures of monolithiated sulfoximines had not been extensively examined at the time we initiated our studies.

10 a: R^1 = Me, R^2 = R^3 = H
10 b: R^1 = R^2 = $SiMe_3$, R^3 = H
10 c: R^1 = $SiMe_3$, R^2 = H, R^3 = CH=C(Me)$_2$
10 d: R^1 = Me, R^2 = H, R^3 = CH=C(Ph)$_2$
10 e: R^1 = Me, R^2 = H, R^3 = Ph
10 f: R^1 = Me, R^2 = C(Ph)$_2$

Only two crystal structures of lithiated alkyl sulfoximines **10a**, **b** were known and have already been reviewed by Boche in 1989.[19–21] A striking feature in both tetrameric (!) aggregates is the presence of Li–C bonds to the C(α) atom, which are in strong contrast to the typical structures of lithiosulfones, known not to contain any Li–C bonds. It later turned out that in the case of lithiated allylic sulfoximines close similarities to lithiated allylic sulfones are present. A structural study by Gais and co-workers provided evidence for a solvent-separated contact ion pair of **10c**, which is devoid of Li–C contacts.[22] The monomeric species **10c** consists of a [Li(12-crown-4)$_2$] cation and a sulfonimidoyl-substituted allylic anion. The conformation of the lone pair in **10c** suggests a stabilising n_C-$s^*_{S–Ph}$ interaction (negative hyperconjugation) reminiscent of lithiosulfones.[23] Deprotonation induced a planarization of the anionic carbon atom and a pronounced reduction of the S–C(α) bond from 1.794(4) to 1.62(1) Å (Figure 1).

The X-ray structure of a lithiated allylic sulfoximine determined by our group uncovered different structural features.[24] In **10d**, two lithioallylsulfoximine units with opposite chirality are linked by N–Li–O bridges to give an eight-membered ring with the atom sequence (Li–N–S–O)$_2$ (Figure 2). Such a coordination is in good agreement with analogous arrangements in lithiosulfones.[21,25] In dimer **10d** the lithium cations are in a distorted *tetrahedral* environment consisting of the O atoms of two THF molecules and the

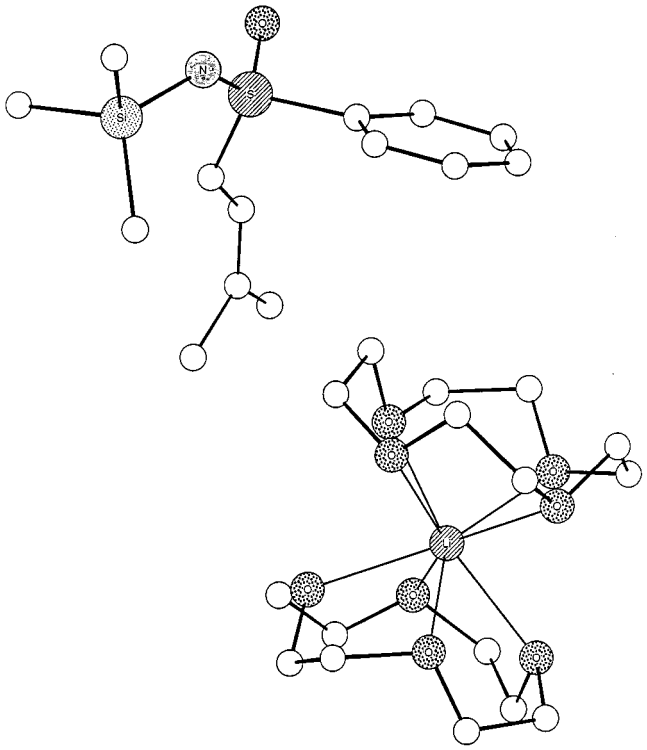


Figure 1. Molecular structure of **10c**; H atoms are omitted for clarity

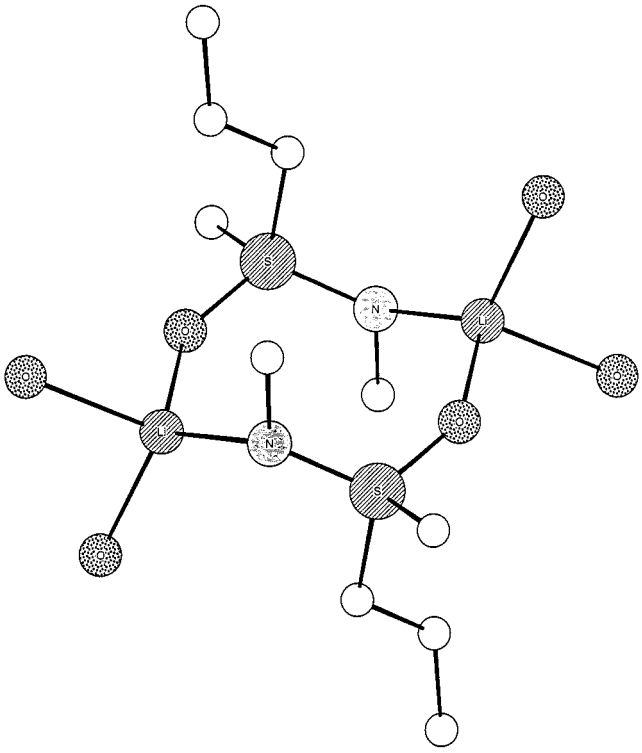

Figure 2. Molecular structure of **10d**; All H atoms, the C atoms of the phenyl groups (except the *ipso*-C's) and of the THF ligands are omitted for clarity

sulfoximine O- and N-atoms. The Li–C bond found in lithioalkylsulfoximines is absent.[19,20] The stabilisation of the negative charge at the C(α) atom by conjugation with the allylic system is more favourable than forming a Li–C bond.

Interestingly, the C(α) atom is pyramidal in spite of the conjugation with the vinyl group and the lone pair at C(α) is orientated in a *gauche* conformation between the O- and N-atoms of the sulfonimidoyl moiety. This allows a stabilisation by negative hyperconjugation.[23] Deprotonation of **10d** is accompanied by a reduction in the S–C(α) bond length of about 0.11 Å, which corresponds to the situation in **10c**. After lithiation only one of the two possible diastereomeric enantiomer pairs has been found in the crystal.

For a benzylic sulfoximine, lithiation leads to dimer **10e** with N–Li–O bridges to give an eight-membered ring with the atom sequence $(Li–N–S–O)_2$ as in **10d**.[26] The lithium cations are in a distorted *tetrahedral* coordination geometry consisting of the N atoms of two TMEDA molecules and the sulfoximine O- and N-atoms. No Li–C bond is found.

The lone pair at C(α) is orientated in a *gauche* conformation between the O and N atoms of the sulfonimidoyl moiety as found for the allylic case. The question as to whether C(α) is pyramidal or not could not be answered with certainty because the benzylic proton has not been located. A significant reduction in the S–C(α) bond length from 1.783(2) Å in the starting material to 1.66(1) Å in **10e** is observed (Figure 3).

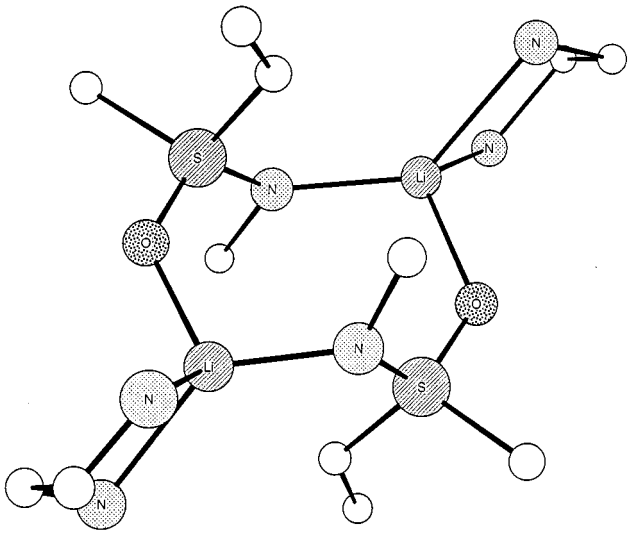

Figure 3. Molecular structure of **10e**; All H atoms, the C atoms of the phenyl groups (except the *ipso*-C's) and of the methyl groups on TMEDA are omitted for clarity

The dinuclear lithium complex **10f** of a lithiated vinylic sulfoximine is bridged through Li-sulfoximine–O bonds, forming two eight-membered rings with the different atomic sequences $(Li–O–S–N)_2$ and $(Li–O–S–C)_2$, respectively.[27] The two halves of the molecule are related by a crystallographic centre of symmetry (Figure 4).

In this complex a Li–C contact with a distance of 2.209(6) Å leads, together with the lithium coordination to the sulfoximine-N-atom, to an Li–N–S–C four-membered ring chelate. In this respect, **10f** differs both from lithiovinylsulfones and lithioallyl(or benzyl)sulfoximines, which do not show Li–C bonds, and from higher associated lithioalkylsulfoximines.[19,20,22,24,28] The *tetrahedral* four-coordination of the lithium cation is completed by coordination

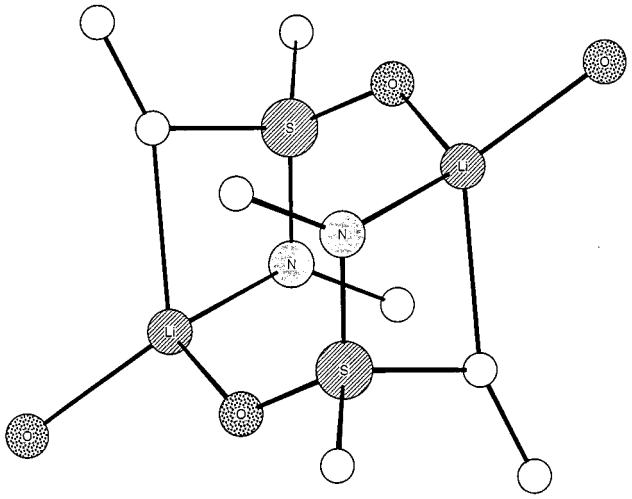

Figure 4. Molecular structure of **10f**; All H atoms, the C atoms of the phenyl groups (except the *ipso*-C's) and of the THF ligands are omitted for clarity

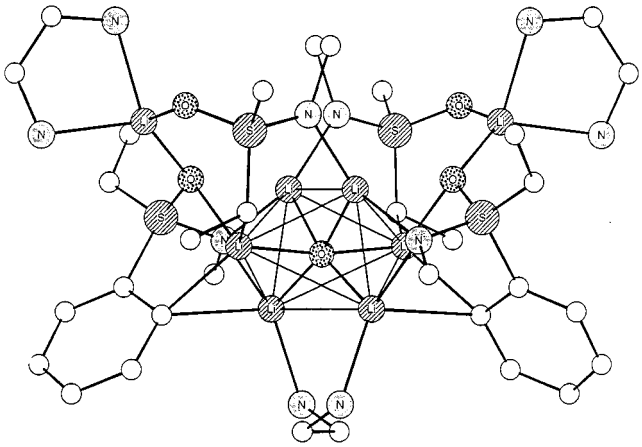

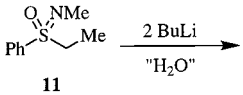

Figure 5. Molecular structure of **12**; all H atoms, the C atoms of the phenyl groups (except the *ipso*-C's) of the monolithiated sulfoximine units and of the methyl groups on TMEDA are omitted for clarity; the thin lines serve to emphasise the geometrical relationship of the Li_6–O core and are not to be considered normal bonds

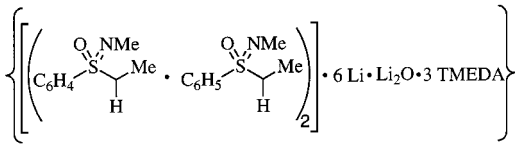


to an O atom of a THF molecule. The S–C(α) bond length is slightly shortened from 1.753(2) Å in the C–H acid to 1.734(3) Å in **10f**. Compared to lithiovinylsulfones this reduction is small and reveals the minor stabilising abilities of the sulfonimidoyl group.[28]

2.2 Dilithiated Sulfoximines

Achiral sulfone- or nitrile-based dilithiomethane compounds have already been investigated in the solid state and have been reviewed previously.[14,15,21] However, an attempt to crystallise a chiral dilithiomethane derivative was first undertaken by our group.[29] Dilithiation of **11** leads to a mixed aggregate containing mono- and dilithiated (*N*-methyl)-*S*-ethyl-*S*-phenyl-sulfoximine units in a 2:2 ratio coordinated by 3 TMEDA ligands. Compound **12** crystallises in the space group *C*2/c and the unit cell contains 4 of the clusters together with 8 disordered TMEDA molecules (Figure 5). The unit cell contains two clusters each composed of two sulfoximine dianions in the (*R*) configuration and two sulfoximine monoanions in the (*S*) configuration. Since the lattice is centrosymmetric, there are two clusters in which these configurations are reversed. This means that an internal chiral resolution has taken place within the clusters. The centre of the aggregate is characterised by a distorted *octahedral* Li_6–O unit due to incorporated Li_2O. In certain cases, Li_2O has been observed in crystalline organolithium compounds where it served as a template for crystallisation.[30] The dianionic subunit in **12** is characterised by two Li–C contacts of the *ortho* C atom to form five-membered ring chelates with the heteroatoms on sulfur and not with a geminal dilithiated structural motif. For Li(2) a coordination to the sulfoximine-O atom, a single O atom derived from Li_2O and a C(α) atom of the neighbouring sulfoximine monoanion is found, whereas Li(4) is coordinated to a sulfoximine N atom, the oxygen of the Li_2O core and an N atom of one TMEDA ligand. For such an *ortho*-directing effect only little data exist for sulfoximines in contrast to sulfones, which are known to be powerful *ortho*-directing groups.[31,32] Despite being deprotonated, a Li–C bond to the C(α) atom is not observed. This is consistent with a substantial S–C multiple bond character, which lowers the basic character of this carbon atom and is supported by a short S–C(α) distance of 1.62 Å (vs. 1.73 Å in protonated sulfoximines).[22,24]

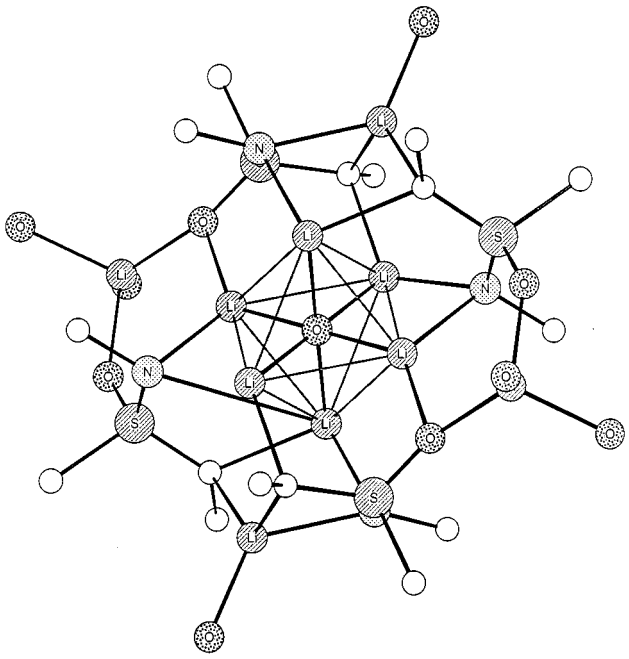
11

12

The anionic C(α) atom has a nearly planar configuration. In the monoanionic sulfoximine moiety, a Li–C(α) contact is observed (2.25 Å) whereas the two heteroatoms are coordinated to two additional Li^+ cations, an arrangement unknown for monolithiated sulfoximines.[19,20,22,24,26,27] In this case, the C(α) atom has a distinct pyramidal configuration. The C(α)–Li bond is arranged in a *gauche* conformation between the N- and O-atoms of the sulfoximine moiety. The coordination sites of the Li atom bonded to the sulfoximine–O are occupied by two nitrogen atoms of the TMEDA ligands and the O atom of the dilithiated sulfoximine, which leads to a bridging of the mono- and dilithio sulfoximine units. A significant shortening of the S–C(α) bond is found (1.66 Å vs. 1.73 Å) in the monoanion, but this is not as pronounced as for the dianionic species where the S–C(α) bond length is 1.62 Å. This additional contraction for the dianion can be explained with the threefold and twofold lithium coordination of the sulfoximine O- and N-atoms, respectively.

The first true heterochiral dilithiomethane derivative was accessible from racemic **13** with 2.5 equivalents of *n*BuLi

and traces of H_2O.[26] A tetrameric heterochiral aggregate **14**, consisting of four dilithiated sulfoximine units and one molecule of Li_2O, which acts as a template for crystallisation, was formed (Figure 6). The core of the aggregate is characterised by a distorted Li_6O-*octahedron*, a structural motif that has been found to be a characteristic feature in **12** and a dilithiated sulfone.[14]



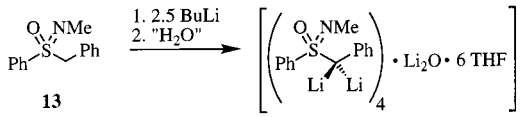


Figure 6. Molecular structure of **14**; all H atoms, the C atoms of the phenyl groups (except the *ipso*-C's) and of the THF ligands are omitted for clarity; the thin lines serve to emphasise the geometrical relationship of the Li_6–O core and are not to be considered normal bonds

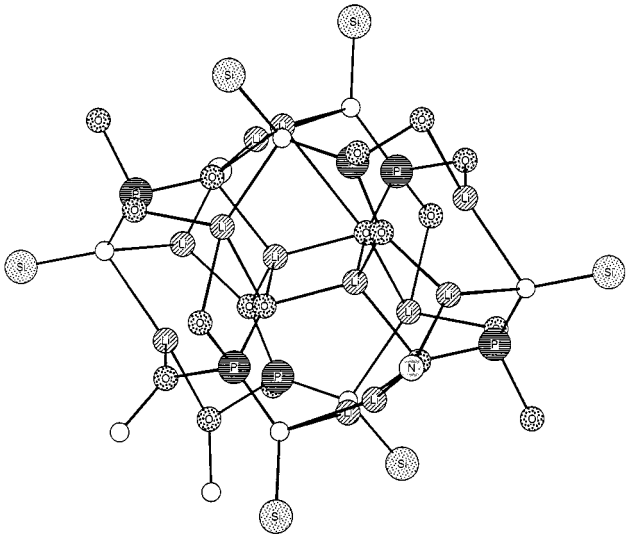
Two different dilithiated C atoms are in the asymmetric unit, each connected to two Li^+ ions and therefore distinctly pyramidalized. At C(21) the two Li^+ ions coordinate to a neighbouring sulfoximine nitrogen, forming either Li–C–S–N four-membered ring motifs, as known from monolithiosulfoximines, or C–Li–N–Li–O–S six-membered rings. They also differ in their further coordination sphere: Li(2) shows heteroatom coordination (N,O), whereas Li(5) has one additional C–Li bond, while bridging two different dimetallated C atoms, and a Li–N contact. For C(1), Li(5) is also bound to C(21), leading to a Li–C–Li–C–S–N six-membered ring. The Li^+ in the bridging position complements its fourfold coordination by complexation to a THF oxygen. Li(2) coordinates to the central O atom of the Li_6O core, inducing a six-membered Li–O–Li–O–S–C ring, via the sulfoximine oxygen. The Li–C distances [range 2.19(2)–2.21(2) Å] are similar to that in the monolithiated sulfoximine **10f**. The Li–N distance within the Li–C–S–N chelate [2.23(2) Å] is comparable to that in **10f** and those found in previous investigations. The Li–O bond length to the sulfoximine-O atoms are significantly longer than those within the (Li_6–O) core. A characteristic property is the extremely short S–C(α) bonds [1.61(1), and 1.64(1) Å] compared to **13** [1.783(2) Å] and **10e** [ca. 1.66(1) Å], which is also typical for related sulfones,[14] phosphonates,[33] phosphinimines,[34] and nitriles.[15] The geminal-bound Li atoms adopt a *gauche* conformation between the N- and O-atoms of the sulfoximine moiety and between the sulfoximine-N atom and the *ipso*-C atom, thus confirming sp^3-hybridized C(α) atoms.

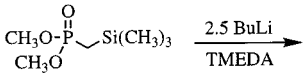
In summary, sulfoximines are clearly able to serve as chiral substrates for the creation of well defined chiral dilithio compounds. As a first rule, it seems that those monolithiosulfoximines that do contain C–Li bonds form α,*o*-dilithio salts after the second lithiation. There is no close proximity of the carbon-bound lithium ion to the *ortho* protons of the phenyl group, as one might expect to find for an *ortho* directing effect. We believe that *ortho* attack is favoured because there is less steric hindrance caused by the solvated and C(α)-bound Li^+. For sulfoximines bearing an additional stabilising substituent, such as a phenyl or vinyl group at the C(α) atom, no C–Li bonds but rather N- and O-sulfonimidoyl Li contacts are observed for its monolithiated salts. This induces a closer proximity to the *ortho* protons as in **10d**, **e**. The positioning of the Li ions in the dimeric scaffold in **10d**, **e** prevents the approach of the lithium base to the *ortho* position and directs the second lithiation to the adjacent and freely accessible C(α) atom.

2.3 Dilithiated Phosphonates

Chiral organophosphorus compounds are extraordinarily significant as reagents in asymmetric synthesis.[35] To date, however, phosphorus-stabilised dilithiomethane analogues have been rarely used in synthesis, and the lack of direct evidence led to doubt about the existence of such compounds.[36] The first experimental proof for a geminal dilithiated phosphorus compound is represented by the lithium cluster **16**.[33] The hexameric aggregate consists of six dilithiated phosphonate units and two molecules of dimethylamide. In addition, two Li^+ ions are coordinated by four TMEDA ligands in a distorted *tetrahedral* fashion, balancing the remaining two negative charges. The core of the aggregate is characterised by a Li–O–Li–O four-membered ring and contains the crystallographic inversion centre (Figure 7). Such a structural motif has been found to be an essential feature in these kinds of monolithiated phosphonate, which do not contain C–Li bonds.[37]

There are three different dilithiated C atoms in the asymmetric unit, each connected to two Li^+ ions and distinctly pyramidalized. These geminal bound Li^+ ions coordinate in a similar fashion to a neighbouring phosphonate oxygen, forming C–Li–O–Li four-membered ring motifs. The incorporation of lithium dimethylamide is due to the use of excess *n*BuLi in TMEDA, which leads to the decomposition products *N*,*N*-dimethylvinylamine and lithium dimethylamide at elevated temperatures.[38] However, the excess is essential for the formation of the aggregate because it be-





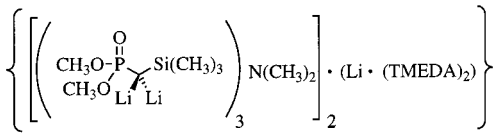


Figure 7. Molecular structure of **16**; all H atoms, the C atoms of the methyl groups on oxygen, nitrogen and silicon are omitted for clarity

15

16

haves as a bridge between the Li atoms. The Li–C distances [range 2.13(1)–2.28(1) Å] can be compared with those in monolithiated phosphonates, which have Li–C distances of 2.21–2.26 Å.[37] The Li–O distances within each C–Li–O–Li chelate [range 1.95(1)–2.85(1) Å] are significantly longer than those within the $(Li–O)_2$ core [1.895(9) and 1.903(9) Å, respectively]. A striking feature is the extremely short P–C bond lengths [1.587(6), 1.604(5) and 1.619(6) Å] compared to neutral (1.80 Å) and monolithiated phosphonates (ca. 1.68 Å). The phosphonate oxygens adopt a *gauche* conformation between the geminal Li^+ cations, clearly indicating a significant degree of pyramidalization. The foundation of this aggregate seems to be the central $(Li–O)_2$ core, which is related to the fundamental structural unit derived from several monolithiophosphonates. We therefore conclude that, after the formation of the typical four-membered rhomboid motif, the incorporation of the second lithium affects only the aggregation sphere outside of the $(Li–O)_2$ core.

2.4 Dilithiated Phosphinimines

Recently, two reports on a remarkable geminal dilithiated phosphinimine were published independently.[34a,34b] The symmetrical bisphosphinime **17** could easily be deprotonated with two equivalents of a strong lithium base to give the dimer **18** (Figure 8).

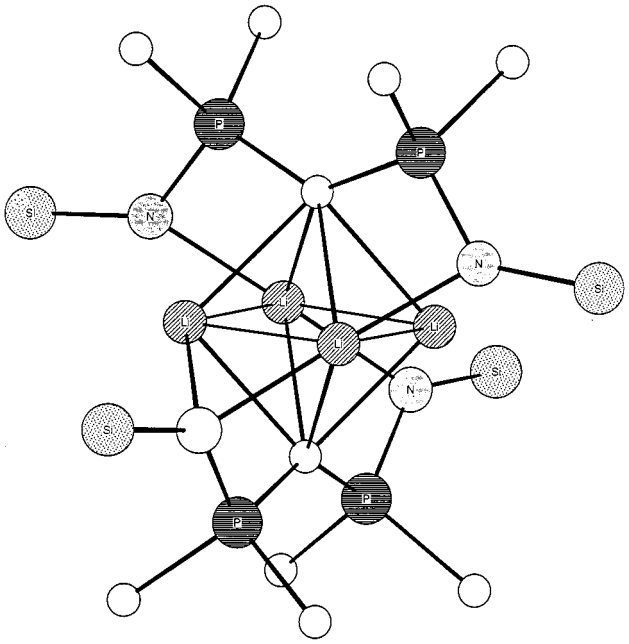

Figure 8. Molecular structure of **18**; all H atoms, the C atoms of the phenyl groups (except the *ipso*-C's) and of the methyl groups on silicon are omitted for clarity; the thin lines serve to emphasise the geometrical relationship of the Li atoms and are not to be considered normal bonds

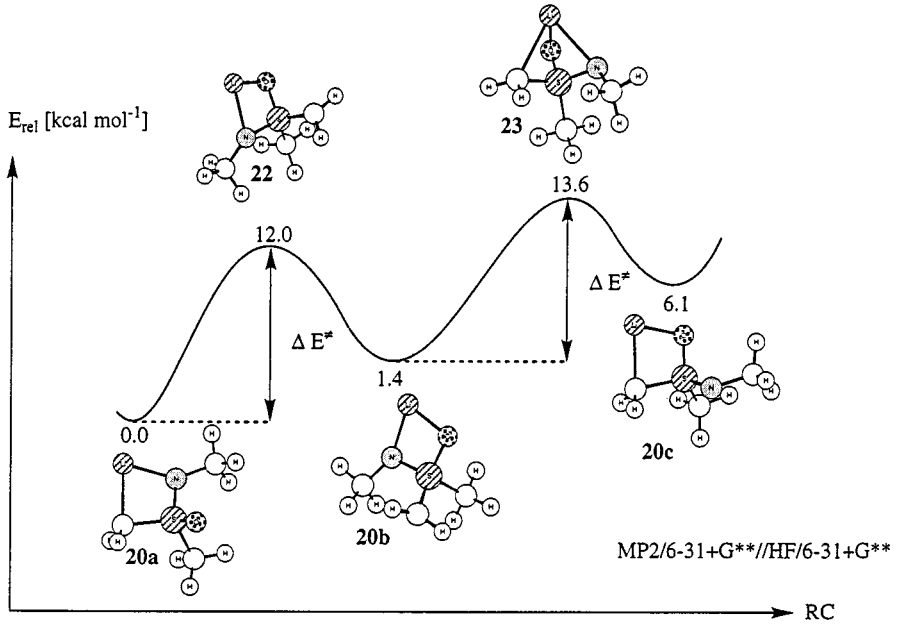
17 **18**

In this aggregate, two dilithiated phosphinimine units are connected in a "head-to-head" manner, although repulsive interactions should be expected. This is presumably compensated by the chelating properties of the imino N atoms, which bridge two lithium atoms each. The four lithium atoms form a square plane which is capped above and below by the C(α) atoms of the P–C–P ligands, inducing a slightly dissymmetric C_2Li_4 pseudo-*octahedron*. Such a structural motif has already been predicted by computational investigations.[4] The coordination geometry around the dianionic carbon atoms is most remarkable: the N–P–C–P–N units are fairly close to planarity and adopt a perpendicular orientation to each other. In addition, they are also *orthogonal* to the central lithium square. The coordination sphere around each lithium atom is markedly distorted from the ideal *tetrahedral* geometry. The Li–C (ca. 2.38 Å) and the Li–N distances (2.09–2.15 Å) are within the range of related compounds.

3. Computational Investigations

3.1 Mono- and Dilithiated Sulfoximines

Ab initio calculations have been able to determine with considerable success the gas phase structures of achiral and chiral oxygen-, nitrogen-, phosphorus-, and sulfur-stabilized (mono)lithiocarbanions.[39–42] It was our objective to extend these studies from chiral monolithio- to dilithiosulfoximines and to elucidate the possible structures and stabilities of these dilithio intermediates by classical ab initio methods and Density Functional Theory (B3LYP).[24,43] The prochiral model system (*N*-methyl)dimethylsulfoximine **19** was chosen for our computational investigations. Ab initio calculations of the lithiated dimethylsulfoximine **20** yielded 3 different major structural minima **20a–c** (Figure 9).



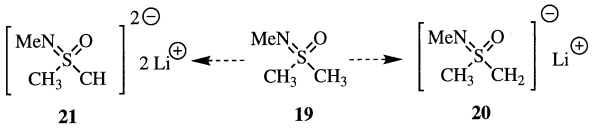


Figure 9. Local energy minima of **20a–c**

21 **19** **20**

Of these, **20a** exhibits a Li–C–S–N four-membered chelate ring; Li–O complexation and a Li–C contact are found in **20c** whereas in **20b** no Li–C contact occurs. In the latter case the sulfoximine O- and N-atoms coordinate to the lithium cation in an orientation reminiscent of typical lithiophenylsulfones and lithioallylsulfoximines.[21,24,25] The Li–N chelate **20a** represents the structure lowest in energy but, surprisingly, the sulfoximine *O*- and *N*-coordinated lithium salt **20b** is only 1.4 kcal/mol higher in energy, whereas the Li–O chelation in **20c** is clearly energetically disfavoured by 6.1 kcal/mol compared to **20a** and **20b**. Lithiation of the dimethylsulfoximine **19** causes a number of distinctive structural changes in **20a–c**: in **20a** a lengthening of the S–N (1.53 vs. 1.58 Å) bond is observed. Similarly the O,C chelation in **20c** lengthens the S–O bond from 1.45 to 1.51 Å while in **20b**, with Li–N, *O*-coordination, both the S–N and S–O bonds are lengthened. The C(α)–Li contact allows only a small shortening of the S–C(α) bond in **20a** (1.72 Å) and **20c** (1.73 Å) whereas in **20b** a significant shortening of the S–C(α) bond is observed (1.63 vs. 1.77 Å in **19**). Structure **22** shows a coordination of the lithium ion to the O and N atoms and can be interpreted as the transition state between the structure minima **20a** and **20b**. The isomers **20b** and **20c** are separated by the transition state **23** by 12.2 kcal/mol. In **23** an unsymmetrical tridentate bonding of the lithium to the O, N, and C(α) atoms is found in contrast to **22** where no Li–C bonding is observed. These characteristics suggest an interconversion mechanism of **20b** to **20c** with **23** as an intermediate. Dilithiation afforded three different local energy minima (Structures **21a–c,** Figure 10).

The isomer **21a** is lowest in energy and exhibits a dilithiospirostructure containing two Li–N–S–C and Li–O–S–C chelates with two different C(α) atoms. A small change in both S–C(α) bond lengths is observed compared to the protonated parent **19** (1.77 Å in **19** vs. 1.73 and 1.75 Å in **21a**). The Li–C distances are 2.09 Å in either case. The lone pairs at the anionic C atoms point away from one another in the direction of each lithium atom, thus minimising the repulsion caused by the two negative charges. Structure **21b** represents a local minimum that is only 2.7 kcal/mol higher in energy. It is characterised by an α,α-dilithiosulfoximine arrangement in which both lithiums are attached to the same C(α) atom. In addition, each lithium is coordinated to one of the two heteroatoms of the sulfonimidoyl moiety, thereby forming (Li–N–S–C) and (Li–O–S–C) four-membered ring chelates, respectively. The S–C(α) bond is signi-

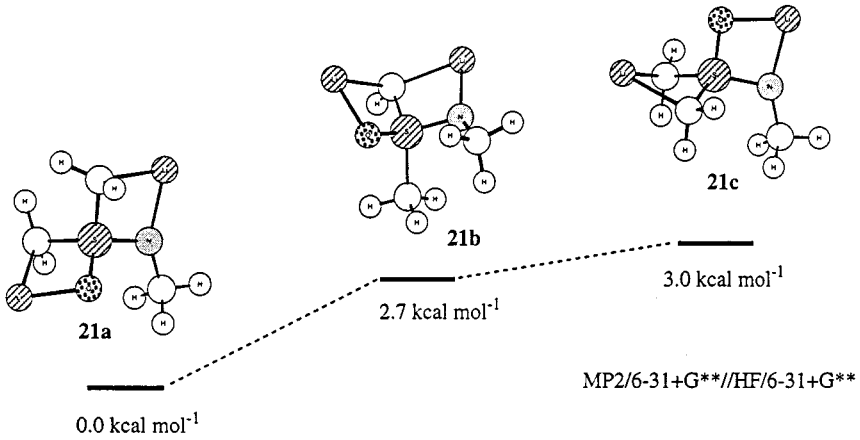

Figure 10. Local energy minima of **21a–c**

ficantly shortened after dimetallation from 1.77 Å to 1.66 Å. The lithium atom coordinating to the sulfoximine oxygen yields the longer Li–C bond with 2.11 Å. In contrast, in the N-chelate the Li–C bond is markedly shorter (2.04 Å). Both planes that are defined by the two four-membered ring chelates form a butterfly-type structure. The lithium atoms are in a diastereotopic environment, which are interesting for synthetic purposes. The local minimum structure **21c** lies 0.3 kcal/mol higher in energy than **21b**. Remarkably, in **21c** one lithium is exclusively coordinated to the heteroatoms of the sulfoximine group whereas the other shows a symmetrical bridging to the C(α) atoms. The twofold carbon coordination of the lithium is unusual, because all other chelation modes of the lithium atoms correspond to structural motifs that have already been calculated for monolithiosulfoximines. The Li–C distances are elongated to 2.23 Å in comparison to the structures **21a** (2.09Å) and **21b** (2.04 and 2.11Å).

A comparison of these major structural minima with the results of MP2(full)/6-31+G** calculations yielded only marginal changes in their geometries and energies. Greater accuracy in the determination of the relative energies may be achieved by applying CBS-Q.[44] These results show a reverse order in the relative stabilities: **21b** becomes slightly energetically favoured over **21c**, but the difference in their energies remains small (see Table 1).

Table 1. Relative energies [in kcal mol^{-1}]

	21a	21b	21c
MP2/6-31+G**//HF/6-31+G**	0.00	2.74	3.01
B3LYP/6-31+G**	0.00	4.87	2.79
CBS-Q (0 K)	0.00	2.23	1.07
CBS-4 (0 K)	0.00	0.72	2.23
MP2 (full)/6-31+G**	0.00	3.02	3.55

The same observation is made for B3LYP/6-31+G**, where **21b** is about 2.1 kcal/mol higher in energy than **21c**.[45] In conclusion, all applied methods show compound **21a** as the global minimum. The isomers **21b** and **21c** are in general 1–5 kcal/mol higher in energy and are fairly close to one another.

3.2 Gas Phase Structures of the Monolithio Sulfoximine Anions and Lithium-Free Dianions

The successive removal of a lithium cation in **21a** resulted in two different monolithiated anions **24a**$^-$ and **24b**$^-$, in which the Li–N–S–C chelate **24a**$^-$ is energetically favoured by ca. 7 kcal/mol over the Li–O–S–C complexation in **24b**$^-$ (see Figure 11 and Table 2).

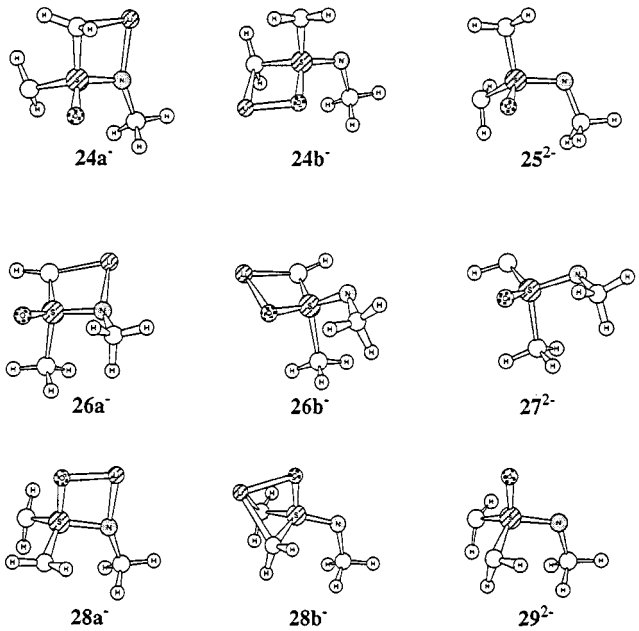

Figure 11. Structure of the monolithio anions **24a,b**$^-$, **26a,b**$^-$, **28a,b**$^-$ and the lithium-free dianions **25**$^{2-}$, **27**$^{2-}$, **29**$^{2-}$

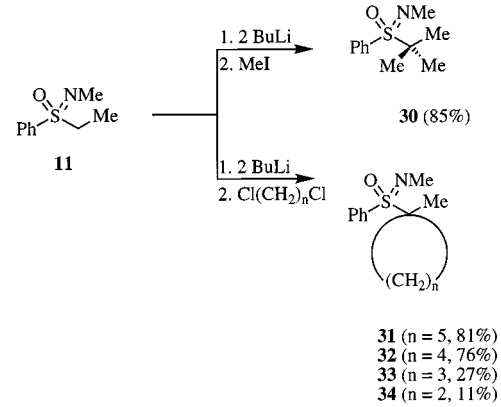
The analogous procedure was also performed with the dilithio salt **21b**. After removal of one lithium the Li–N–S–C complexation is energetically favoured over the Li–O–S–C coordination. The resulting monolithio intermediates **26a**$^-$ and **26b**$^-$ differ distinctly from the structures derived from **21a** even though the complexation energies are similar. The unusual coordination mode of the lithium cations in **21c** leads, after decomplexation of one lithium, either to an exclusively heteroatom-*N*,*O*-coordinated monolithioanion

Table 2. Relative energies of the resulting anions after removal of the lithium cations [in kcal mol^{-1} based on MP2(full)/6-31+G**// HF/6-31+G** calculations]

	Geometries Optimised	Non-optimised	ΔE
24a$^-$	171.6	180.9	9.3
26a$^-$	172.0	181.4	9.4
28a$^-$	169.1	188.3	9.2
24b$^-$	178.4	187.0	8.6
26b$^-$	177.8	192.1	12.3
28b$^-$	170.2	177.1	6.9
25^{2-}	437.6	449.4	11.8
27^{2-}	451.7	465.8	14.1
29^{2-}	439.9	447.6	7.5

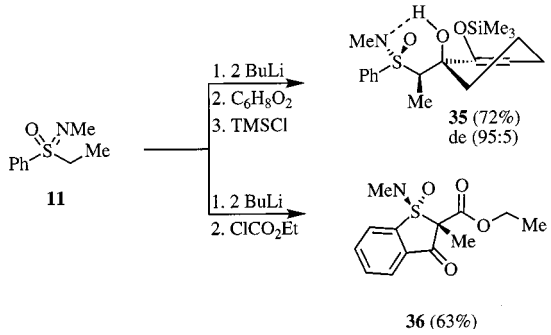


28a$^-$ or to a threefold lithium-coordinated monolithioanion **28b**$^-$. The removal of the second lithium produces a naked 1,3-dianionic species **25**$^{2-}$. The total delithiation requires 437 kcal/mol when starting from the dilithiosulfoximine **21a**. The energy required for the second delithiation amounts to 266 kcal/mol from **24a**$^-$ and 259 kcal/mol from **24b**$^-$. Removal of the second lithium cation affords the α,α-dianion **27**$^{2-}$. The energy required for the twofold delithiation of **21b** amounts to 451 kcal/mol. After removal of the second lithium ion the 1,3-dianion **29**$^{2-}$ is generated (439 kcal/mol), which is closely related to the dianionic species **25**$^{2-}$ with only small differences in their conformations and energies.

4. Applications in Asymmetric Synthesis

4.1 Regio- and Diastereoselective Cyclisations with Biselectrophiles

For the investigation into the use of a chiral dilithiated sulfoximine in asymmetric synthesis, the generated dilithio intermediate **12** has been trapped with various electrophiles.[29] Addition of MeI afforded nearly regioselectively the α,α-dimethylated *S*-*tert*-butyl-*S*-phenylsulfoximine **30** in high yield (85%). Such behaviour was unknown for sulfoximines but is not unusual for sulfones, where an α,*o*-dilithiated species has also been observed that showed a similar reactivity with alkylhalides.[46] NMR-spectroscopic studies by Gais et al. have demonstrated that a temperature dependent transmetallation of an α,*o*- to an α,α-dilithio species is possible.[16] Taking this into account, it becomes reasonable to suggest a transmetallation process as a possible explanation for the observed regioselectivity with dilithiated **11**. This means that, after the first alkylation step in the α-position, a translithiation takes place leading finally to the α,α-dialkylated product. Performing this procedure with a biselectrophile like 1,5-diiodopentane, we expected a similar regioselectivity to the reaction with MeI, which should lead to a ring closure in the α-position.

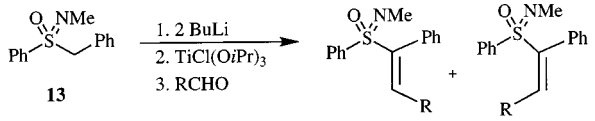


Indeed, a six-membered ring in **31** is formed without any regioisomers and in high yield (81%). With 1,4-diiodobutane a five-membered ring species **32** was obtained in good yield (76%). Cyclisation reactions with shorter bridged bis-

electrophiles showed dramatically lower yields, presumably due to undesired side reactions. The cyclobutane derivative **33** and the cyclopropyl-sulfoximine **34** are therefore only accessible in yields of 27% and 11%.

4.2 Addition to Prochiral Electrophiles

In contrast to the simple biselectrophiles discussed above, cyclohexane-1,2-dione, in the presence of TMSCl, did not undergo ring closure to a cyclopropane derivative. Instead the α,*o*-dilithio species **12** acted as a base and a nucleophile leading, in a synergistic manner in a single reaction-step, to the β-hydroxysulfoximine **35** in high yield (72%) and excellent diastereomeric ratio (95:5). The absolute stereochemistry of the major isomer of **35** has been determined by X-ray structure analysis.



Typical of β-hydroxysulfoximines is the ability to build intramolecular hydrogen bonds to the imino nitrogen to give a six-membered ring with a chair conformation.[47] The methyl group on C(α) and the larger, silyloxy-containing substituent on C(β) are oriented in a pseudo-equatorial fashion. The reaction of the dilithiosulfoximine **12** with ethyl chloroformate afforded, in good yield (63%), the heterocycle **36** as single diastereoisomer. This cyclisation must proceed by a third deprotonation step. NOE experiments confirm that the cis configuration of the C-methyl and *N*-methyl groups is present in the five-membered heterocycle.

4.3 Transmetallation and Alkene Formation

If there are two different metals bound to the same carbon atom of a chiral reagent a new stereocentre might be induced. This principle can be used for the transformation

of chiral information, but has rarely been applied in stereoselective reactions.[12,48] Our approach took advantage of the transmetallation of a geminal dilithiated sulfoximine **14** with $ClTi(OiPr)_3$. Addition of several aldehydes to such a titanated dilithiosulfoximine did not lead to β-hydroxysulfoximines and, instead, only the alkenylsufoximines **37**–**39** were formed. The reactions proceed in a highly diastereoselective fashion leading predominantly to the (*E*)-alkenes.

13

37 R = Ph, 74%, E:Z = 95:5

38 R = *t*Bu, 77%, E:Z = 99:1

39 R = Et, 68%, E:Z = 90:10

5. Conclusion

The first heterochiral dilithiomethane derivative **14** was structurally confirmed by X-ray analysis. A comparison with its monolithiated precursor **10e** revealed a dimer devoid of Li–C contacts. In our opinion, the free accessibility to the anionic C(α) atom in **10e** is responsible for the geminal dilithiation. This is not the case for lithiosulfoximines that form C–Li bonds, as can be seen in lithiated alkyl- or alkenyl-substituted sulfoximines **10a**,**b**,**f**. The second metallation leads to an α,*o*-dilithiosulfoximine. The structures of achiral phosphorus-stabilised geminal dilithio salts have only very recently been confirmed. Since chiral modifications of such compounds are easy to perform, one might expect to use the derived dilithio salts in asymmetric synthesis. The X-ray crystallographic studies on mono- and dilithiated sulfoximines were complemented by quantum chemical calculations on the lithiated (*N*-methyl)dimethylsulfoximine **19**. Three different major energy minima were obtained with the lithium-*N*,*C*-chelate **20a** and the sulfoximine-*N*,*O*-coordinated lithium salt **20b** representing the most stable isomers. In contrast, lithium-*O*,*C*-coordination in **20c** is energetically disfavoured, so that *N*,*C*- and *N*,*O*-coordination should be preferred to *O*,*C*-coordination. Three equilibrium structures for the dilithiated *N*,*S*,*S*-trimethylsulfoximine system were also found, with the dilithiospiro structure **21a** representing the most stable isomer. Only ca. 1–5 kcal/mol higher in energy were the α,α-dilithiosulfoximine **21b** and the isomer **21c**, which have heteroatom contacts to one lithium while the second lithium is associated with both anionic carbon atoms. In conclusion, these results have some important implications for asymmetric synthesis: because reactions with achiral dilithio salts are already meaningful in synthetic sequences one can imagine further synthetic approaches with chiral dilithio compounds derived from the discussed dilithiosulfoximine intermediates **21a** or **21b**. The first multiple stereoselective C–C bond formations with prochiral biselectrophiles have been applied in cyclisation reactions and have led to a new and powerful methodology for the synthesis of new carbo- and heterocycles. The reaction of the dilithiated sulfoximine **11** with cyclohexane-1,2-dione afforded a β-hydroxysulfoximine with high stereocontrol. Transmetallation of **14** with $ClTi(OiPr)_3$ followed by addition of an aldehyde allowed the highly diastereoselective synthesis of (*E*)-alkenylsulfoximines. This new methodology works for the single-step formation of multiple C–C bonds under high regio- and diastereocontrol. Our further studies will focus on this novel concept to create chiral mixed organodimetallics and to apply these compounds in asymmetric synthesis.

Microporous Titanosilicates and other Novel Mixed Octahedral-Tetrahedral Framework Oxides

João Rocha*[a] and Michael W. Anderson[b]

Keywords: Zeolites / Microporous zeolites / Titanosilicates / Transition metal

Stable microporous materials, such as zeolites, are extremely important for applications in catalysis, adsorption, ion-exchange, and separation. In this review we describe a new class of stable microporous materials that involves novel mixed octhaedral-tetrahedral framework oxides. The archetypal material is based on titanosilicates, although there is tremendous scope for introducing many other transition metals. These materials not only have potential novel applications in the fields normally associated with zeolites but also possible applications in the areas of optoelectronics, nonlinear optics, batteries, magnetic materials and sensors.

Introduction

Zeolites are crystalline, hydrated aluminosilicates with open three-dimensional structures built of $[SiO_4]^{4-}$ and $[AlO_4]^{5-}$ tetrahedra linked to each other by sharing all the oxygens to form regular intracrystalline cavities and channels of molecular dimensions.[1–3] Silicon-oxygen tetrahedra are electrically neutral when connected together in a three-dimensional network as in quartz (SiO_2). The replacement of Si^{IV} by Al^{III} in such a structure creates an electrical imbalance and, to preserve overall electrical neutrality, each AlO_4 tetrahedron needs a balancing positive charge. This is provided by exchangeable cations held electrostatically within the zeolite. Zeolites possess remarkable physical and

João Rocha was born in Portugal in 1962. Following his undergraduate studies in Physics and Chemistry at Aveiro University he became assistant in the Department of Chemistry of this University in 1985. In 1987 he joined the group of Jacek Klinowski in Cambridge. His Ph.D. thesis was entitled solid-state NMR studies of kaolinite and related materials and concentrated on the study of the important clay mineral kaolinite and related high-temperature phases.
This was followed by a post-doctoral appointment in Cambridge, still in the group of J. Klinowski, working on solid-state NMR of zeolitic materials. He was appointed Lecturer in Chemistry at University of Aveiro in 1991 and promoted to Professor of Inorganic Chemistry in 1999 and currently heads the Inorganic and Materials Chemistry Centre and the solid-state NMR laboratory. His research interests include: synthesis and characterisation of novel microporous materials; development of new materials for optoelectronics; NMR characterisation of wood and lignocellulosic materials; development of new solid-state NMR techniques for the study of quadrupolar nuclei.

Michael W. Anderson was born in Wimbledon, U.K., in 1960. Following his undergraduate studies in Chemical Physics at Edinburgh University he joined the group of John M. Thomas in Cambridge in 1981. His Ph.D. thesis was entitled Dealuminated Zeolites and concentrated on the removal of aluminium from zeolites using $SiCl_4$. This was followed by three post-doctoral appointments: University of Houston with Larry Kevan working on pulsed EPR measurements of transition metals in zeolites; University of Connecticut with Steve Suib working on catalyst poisoning; University of Cambridge with Jacek Klinowski where he developed in situ NMR methods for monitoring catalytic events in zeolites. He was appointed Lecturer in Chemistry at UMIST in 1990 and promoted to Professor of Materials Chemistry in 1998 and is currently Director of the UMIST Centre for Microporous Materials. His research interests include: experimental and theoretical NMR studies of heterogeneous catalysts; structural studies of mesoporous materials; atomic force microscopy and electron microscopy studies of crystallisation mechanisms; synthesis and applications of novel microporous materials.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

chemical properties. The most important chemical properties are selective sorption, ion exchange and catalytic activity.

During the 1980s a variety of novel microporous framework structures were synthesised based on an aluminophosphate system.[4] In their pure form the aluminophosphates are termed AlPOs and consist of alternating corner-sharing framework $[AlO_4]^{5-}$ and $[PO_4]^{3-}$ tetrahedral groups. Overall the frameworks have no net charge and, consequently, no cation-exchange properties and little catalytic potential. Framework substitutions are, however, possible and lead to silico-aluminophosphates[5] (SAPOs) and metal-substituted aluminophosphates (MeAPOs).[6] Some of these new materials have the framework topologies of known zeolites while others may have novel structures. In all these materials the framework metal atoms are ostensibly in tetrahedral coordination, although under certain circumstances (for example, various hydration conditions) the coordination might change to five- or six-fold. Porous structures comprised entirely of octahedral sites have also been generated. For example, the manganese oxides known as OMS materials contain only octahedral framework atoms.[7a]

A third, much less explored, compositional possibility for microporous frameworks are structures consisting of interlinked octahedra and tetrahedra. Although clays and related materials, in some way, fall into this category, they only possess two-dimensional co-valent connectivity. Three-dimensional connectivity is required to impart substantial structural stability and we are only concerned with such networks in this review. In 1990 Chapman and Roe were already well aware of the importance of these mixed framework materials.[8] In their words: ''While new structures and compositions of molecular sieves continue to be synthesised, there are indications that attention is turning toward a potentially large class of novel molecular sieve materials composed of interconnected octahedral- and tetrahedral-oxide polyhedra. Such materials will most likely provide examples of new topologies and novel compositions''. In this microreview it is our endeavour to show that some of the most interesting and important developments in the field of zeolites and zeotype materials are taking place in the area of mixed octahedral-tetrahedral oxides. Here, we shall only address the chemistry of silicates and will not be concerned with, in particular, the burgeoning and exciting chemistry of porous phosphates.[7b]

Synthesis

The synthesis of microporous titanosilicates[8–11] and other novel zeotype materials is usually carried out in Teflon-lined autoclaves under hydrothermal conditions with temperatures ranging from ca. 150 to 230 °C and times varying between a few hours and ca. 30 days. In certain cases, the materials have been prepared at relatively high temperatures. For example, single crystals of a titanosilicate analogue of the mineral pharmacosiderite, $Cs_3HTi_4O_4(SiO_4)_3 \cdot 4\,H_2O$, have been obtained hydrothermally in a sealed gold tube at 750 °C for 40 h.[12] The pH of the synthesis gel is normally high, in the range 10–13. Seeding the gel with a small amount of the desired phase (or even with a related solid) is a common practice. The syntheses are in general driven by kinetics, with different metastable phases being formed with time. So far, most research has concentrated on the synthesis of microporous titanosilicates. The experience gathered in this field is guiding the efforts aimed at other systems, most notably zirconosilicates. Hence, here we shall discuss in more detail the synthesis of microporous titanosilicates, particularly ETS-10 (*E*ngelhard *t*itano*s*ilicate material number 10).

The synthesis of ETS-10 was first reported by Kuznicki in 1989.[9] The titanium source used was $TiCl_3$. A slight modification of this method afforded highly crystalline and pure ETS-10 suitable for structural elucidation.[13,14] $TiCl_4$ is another much used (and cheaper) titanium source. For example, using this precursor Das et al.[15] reported a method for the rapid (< 16 h) synthesis of ETS-10. Liu and Thomas[16] have shown that under proper conditions the thermodynamically stable TiO_2 phases of anatase and rutile can be used as suitable titanium sources for the synthesis of porous titanosilicates. A few organotitanium compounds have also been used to prepare microporous titanosilicates. Because they are very sensitive to moisture, these compounds are difficult to handle and require special facilities for their transfer during the gel preparation. For example, Chapman and Roe[8] used $Ti(OC_2H_5)_4$ in the preparation of GTS-1 while Clearfield and co-workers synthesised a novel porous titanosilicate using titanium isopropoxide.[17] Sodium silicate solutions and fumed and colloidal silica are suitable silicon sources. Organosilicon compounds, such as tetraethylorthosilicate have also been used.[17] The synthesis of ETS-10 usually (although not always) requires the presence in the parent gel of both Na^+ and K^+ ions. Other phases, such as some of the AM (*A*veiro/*M*anchester) materials[18] are produced in a pure state only when a single type of cation is present. Potassium fluoride is often used for preparing ETS-10 but its presence is not crucial. A comprehensive study of the hydrothermal synthesis conditions which yield pure and highly crystalline ETS-10 from $TiCl_3$ and anatase has been reported.[19] This work examines the influence on the synthesis of the following parameters: presence of fluoride, sodium, and potassium ions, seeds, H_2O/Si and Si/Ti molar ratios, parent gel pH, temperature, and time. A similar study has been carried out by Das et al., using $TiCl_3$ as the titanium source.[20]

Most porous titanosilicates and other related new materials reported to date can be synthesised without the addition of any organic template molecules. However, several groups have prepared ETS-10 with a range of templates: tetramethylammonium chloride,[21,22] pyrrolidine, tetraethylammonium chloride, tetrapropylammonium bromide,1,2-diaminoethane,[22] choline chloride, and the bromide salt of hexaethyl diquat-5.[23] From the point of view of industrial synthesis scale-up it is very important that many of the new structures can be synthesised in the absence of

costly templating agents. Furthermore, the occluded templates usually need to be removed following synthesis in order to impart microporosity, a procedure that can be both costly and potentially damaging to the framework.

The framework substitution of titanium and silicon by other elements requires a judicious choice of the respective source, which is usually introduced in the parent synthesis gel. The following sources of aluminium, gallium, niobium, and boron for element insertion in the ETS-10 framework have been reported: $NaAlO_2$,[24] $GaCl_3$,[25] $Nb(HC_2O_4)_5$,[26] and $Na_2B_2O_4$[27] (see also refs.[28,29]). In the synthesis of microporous zirconosilicates $ZrCl_4$[30–32] and $Zr(OC_3H_7)_4$[33] have been used as the zirconium sources. The vanadosilicate AM-6, a structural analogue of ETS-10, has been prepared from $VOSO_45H_2O$.[34]

Structure

ETS-10

In 1990 Chapman and Roe published the synthesis and X-ray diffraction pattern of a microporous titanosilicate[8,11] that seemed to have the structure of the mineral zorite by comparison of the diffraction patterns. At about the same time Engelhard Corporation filed a series of patents describing a similar small-pore material, which they named ETS-4 (*E*ngelhard *t*itano*s*ilicate-4) and another wide-pore titanosilicate material named ETS-10.[9,10] Owing to its wide-pore nature and thermal stability ETS-10 is arguably the most important octahedral/tetrahedral framework microporous titanosilicate to be synthesised to date. Consequently, it is important to understand the structure of this material in some detail.

The structure of ETS-10 was solved and reported briefly in 1994 by Anderson et al.[13] and described fully by the same group the following year.[14] Two problems prevented an easy solution to the structure of ETS-10: first, the material could only be synthesised as a powder and, more importantly, the material was inherently disordered. Consequently, conventional diffraction techniques to solve the structure proved inadequate. The following strategy was therefore adopted to elucidate the structure of ETS-10: (i) target the framework ring connectivity and local disorder with high-resolution electron microscopy (HREM); (ii) determine the atomic make-up of the material by chemical analysis; (iii) determine the local silicon environment using ^{29}Si solid-state nuclear magnetic resonance (NMR); (iv) refine a trial structure using a distance-least-squares (DLS) analysis of bond angles and bond lengths; (v) combine the refined structure and known disorder to simulate powder X-ray diffraction data.

The typical crystal morphology of ETS-10 is shown in Figure 1. These scanning electron micrograph images show that (i) the particle has a pseudo-4-fold symmetry along an axis indicated by the large arrow; (ii) traces of faults that are perpendicular to the axis and are indicated by small arrows. This faulted structure is always present in ETS-10 and Figure 1 represents a high quality material.

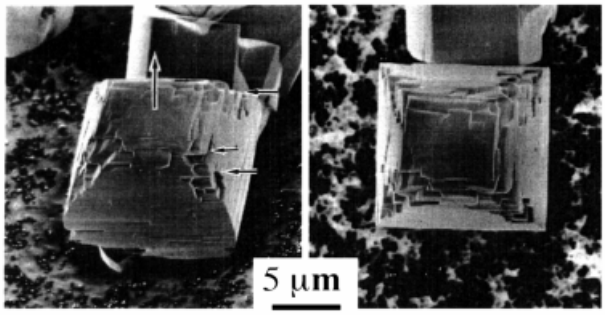

Figure 1. Scanning electron micrograph of a high-quality ETS-10 sample; large arrow depicts pseudo 4-fold axis, small arrows indicate faulting caused be intergrowths

The details of the inherent disorder and the pore structure in ETS-10 are most clearly revealed in the high-resolution electron micrograph (Figure 2). The large 12-ring pores are clearly visible. In order to discern the disorder the reader should note the stacking of these large pores from the bottom of the micrograph to the top. It will be seen that the pores stack randomly to the right or to the left.

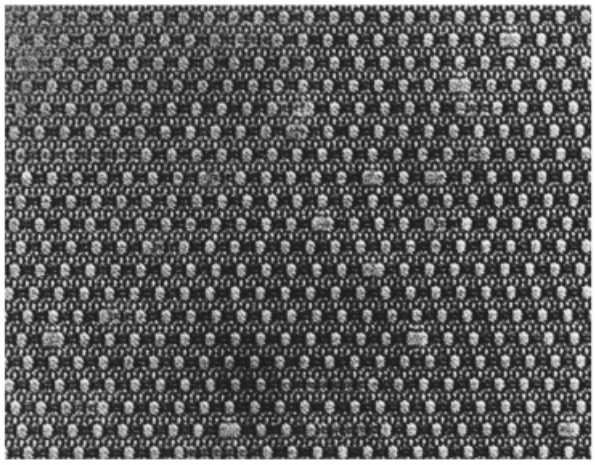

Figure 2. High-resolution electron micrograph of ETS-10

The most interesting aspect of the structure of ETS-10 is that it contains infinite –O–Ti–O–Ti–O– chains (with alternating long/short bonds[35]) that are surrounded by a silicate ring structure. These combine to make up a rod (Figure 33a and 3b) and it is this rod nature that imparts some of the interesting optical properties described in the applications section. Adjacent layers of rods are stacked orthogonal to each other (Figure 3c). These double layers are then stacked with a displacement of 1/4 unit cell in either the [100] direction or the [010] direction to give four possible connections (Figure 3d). If these four possible connections are given equal probability and the stacking is random then the disordered ETS-10 structure is constructed. The pore structure of ETS-10 has 12-rings in all three dimensions; these are straight along [100] and [010] and crooked along the direction of disorder. However, there are only a handful of microporous zeolitic materials with a 3-dimensional 12-ring pore system and in this respect ETS-10 has

excellent diffusion characteristics. It should be noted that the crooked channel is not blocked or the pore volume reduced by the disorder.

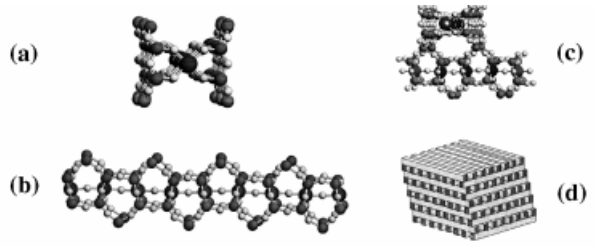

Figure 3. Structural make-up of ETS-10: (a) and (b) show the same rod section of ETS-10 in orthogonal views – large spheres Ti, medium spheres Si and small spheres O; (c) shows how these rods link; (d) shows one possible ordered arrangement of these orthogonol rods

It is interesting to conjecture whether it is possible to construct ordered variants of the ETS-10 structure. The lattice energy difference between different stacking sequences is minimal, however, different sequences result in different pore architecture. A zig-zag stacking of pores results in chiral symmetry and a spiral 12-ring pore in the third dimension. In order to synthesise such a material no doubt a chiral organic templating agent would be required but as yet this has not been achieved.

Mistakes in the stacking sequences (which occur frequently, probably as a result of the crystal growth mechanism) result in line defects in ETS-10 which are in effect double-sized pores. A schematic of the framework connectivity and the incorporation of defects is shown in Figure 4.

The framework formula of this basic unit is $Si_{40}Ti_8O_{104}^{16-}$, which is counterbalanced by 16 monovalent cations. In this original structural work it was impossible to locate the cations in ETS-10. The as-prepared material is 1/4 K^+ and 3/4 Na^+. The most likely location of the cations has been determined by a combination of molecular modelling and, for sodium, ^{23}Na solid-state NMR. Figure 5 shows the final structure of ETS-10 with the cations principally located in sites adjacent to the titanate chains where they balance the charge on the titanium centres.

Very recently a single crystal study on ETS-10 has refined a superposition cell, which essentially regards the structure as a combination of all the ordered variants and confirms in essence all of the previous structural work.[36]

ETS-4

Similar to ETS-10 the nominal structure of ETS-4 suggests that it could have very interesting applications. As noted above, the powder X-ray diffraction pattern of ETS-4 suggests strong similarities with the structure of the natural mineral zorite. In 1973 a naturally occurring alkaline titanosilicate identified as zorite was discovered[37] in trace quantities on the Siberian Tundra. The structure solution of this mineral was published[38] six years later in an article

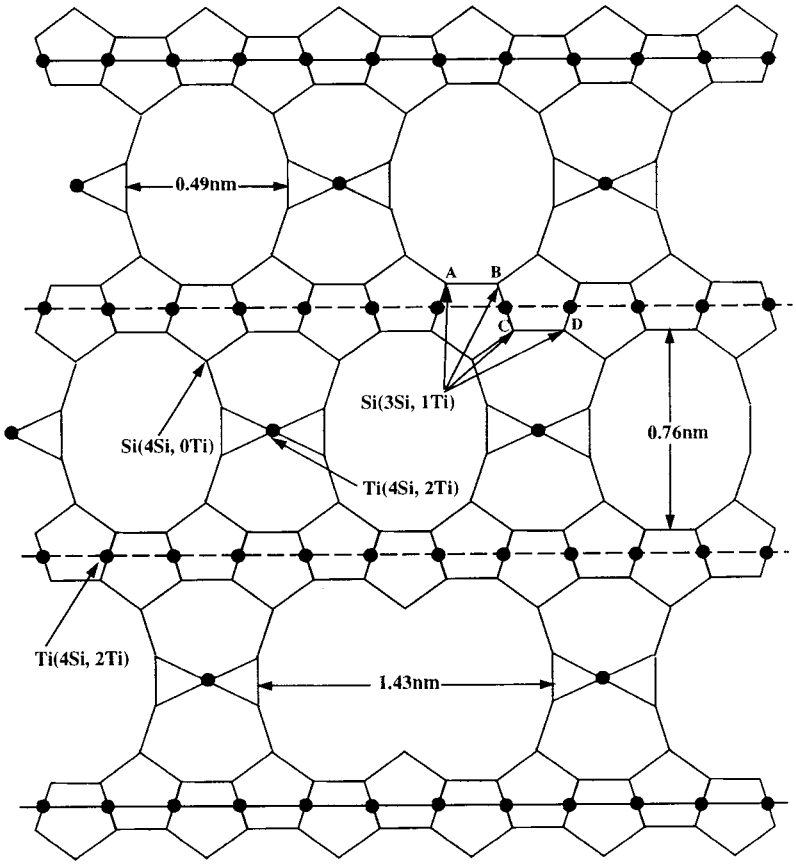

Figure 4. Framework connectivity in ETS-10 showing different chemical and crystallographic environments; also shown is the incorporation of large defects as double pores

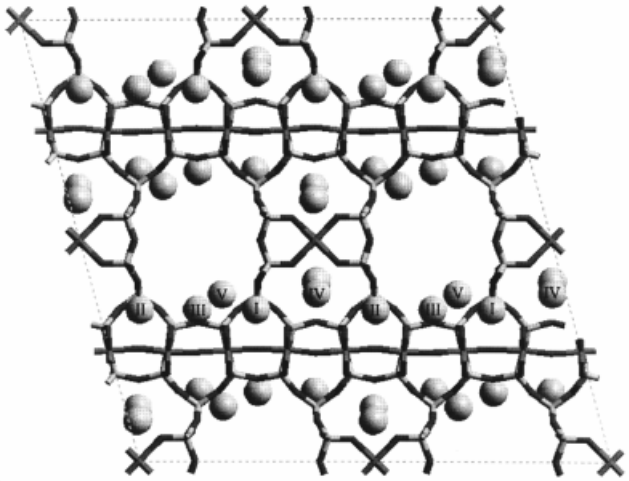

Figure 5. Five cation sites in ETS-10 and their relationship to the framework

entitled "The OD structure of Zorite". According to this contribution,[38] the structure of this mineral is characterised by a highly disordered framework with ostensibly a 2-dimensional channel system. Two orthogonal sets of channels are defined by 12-T/O atom and 8-T atom rings (T = *t*etrahedral silicon; O = *o*ctahedral titanium). In reality, the disorder in zorite results in the larger 12-ring channels becoming partitioned into sections. A molecule diffusing into this 12-T/O ring channel must make detours through the 8-T ring channel system in order to pass freely. Consequently, the adsorption characteristics of zorite are far inferior to that expected for an unfaulted material. Furthermore, zorite lacks thermal stability as internal water acts as part of the structure forming chains through the channel system. When the water is removed the framework structure collapses. Figure 6 shows the framework structure of zorite with possible stacking sequences of ordered end member polymorphs.

In zorite the titanium exists in two different chemical environments, titania rods similar to those in ETS-10, and isolated titania semi-octahedra, which are exposed to the channel system. Consequently, if ETS-4 has the structure of zorite then the accessibility of the titanium centres to the channel system may be a benefit for certain applications, despite the stability issue. The only outstanding problem with the structure of ETS-4 is that the ^{29}Si MAS-NMR spectrum does not agree with the crystal structure. The crystal structure dictates two Si environments Si(2Si,2Ti) and Si(3Si,1Ti) in a ratio of 2:1. The ^{29}Si MAS-NMR spectrum displays two signals, although these are not in the correct ratio. It is still unclear at present how this discrepancy arises but the most reasonable suggestion is that it is due to a large number of defect sites in ETS-4.[39,40]

In terms of stability, the structure of zorite or ETS-4 contains structural water bound in chains along the channel system. At temperatures of 200 °C this water is lost and the structure collapses. At temperatures above 700 °C there is a phase transformation into the dense titanosilicate structure narsarsukite.[41] Because the stoichiometry of ETS-4 and

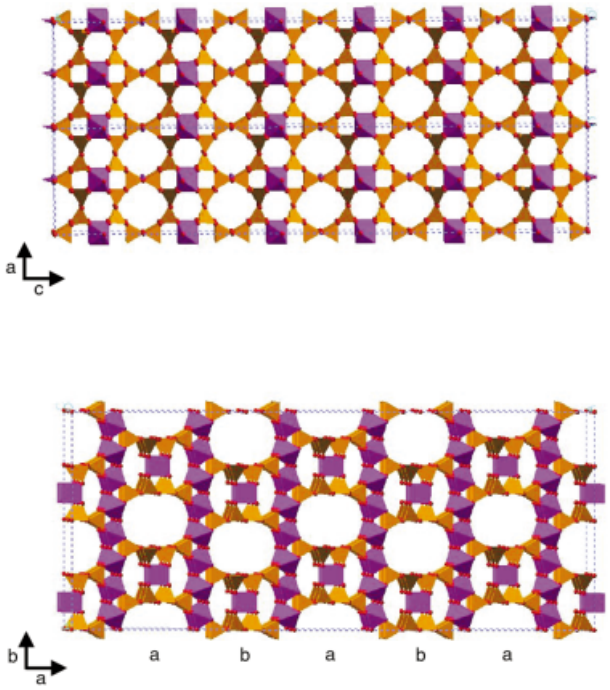

Figure 6. Two orthogonal projections of one possible ordered variant of ETS-4; purple Ti octahedra, brown Si tetrahedra, red spheres oxygens

narsarsukite are different, a quantity of silica must be added to ETS-4 in order to prepare pure narsarsukite at high temperatures.

Other Titanosilicates

In 1994 Clearfield and co-workers reported the synthesis, crystal structure, and ion-exchange properties of a novel porous titanosilicate of ideal composition $Na_2Ti_2O_3SiO_4 \cdot 2\ H_2O$.[17] The structure of this material has been solved from powder X-ray data by ab initio methods. The titanium atoms occur in clusters of four, grouped about the 4_2 axis, and are octahedrally coordinated by oxygen atoms (Figure 7a and 7b). The silicate groups link the titanium clusters into groups of four arranged in a square of about 7.8 Å in length. These squares are linked to similar squares in the *c* direction by sharing corners to form a framework that encloses a tunnel. Half the Na^+ ions are located in the framework, coordinated by silicate oxygen atoms and water molecules. The remaining Na^+ ions reside in the cavity, although some of them are replaced by protons. The Na^+ ions within the tunnels are exchangeable, particularly by Cs^+ ions.

Chapman and Roe[8] have prepared a number of titanosilicate analogues of the mineral pharmacosiderite, a non-aluminosilicate molecular sieve with a framework composition $KFe_4(OH)_4(AsO_4)_3$. Later, Clearfield and co-workers studied by powder X-ray diffraction methods the structure of pharmacosiderite analogues with composition $HM_3Ti_4O_4(SiO_4)_3 \cdot 4\ H_2O$ (M = H^+, K^+, Cs^+).[42] Harrison et al. have been able to grow single crystals of the same cesium phase and solve its structure by single-crystal

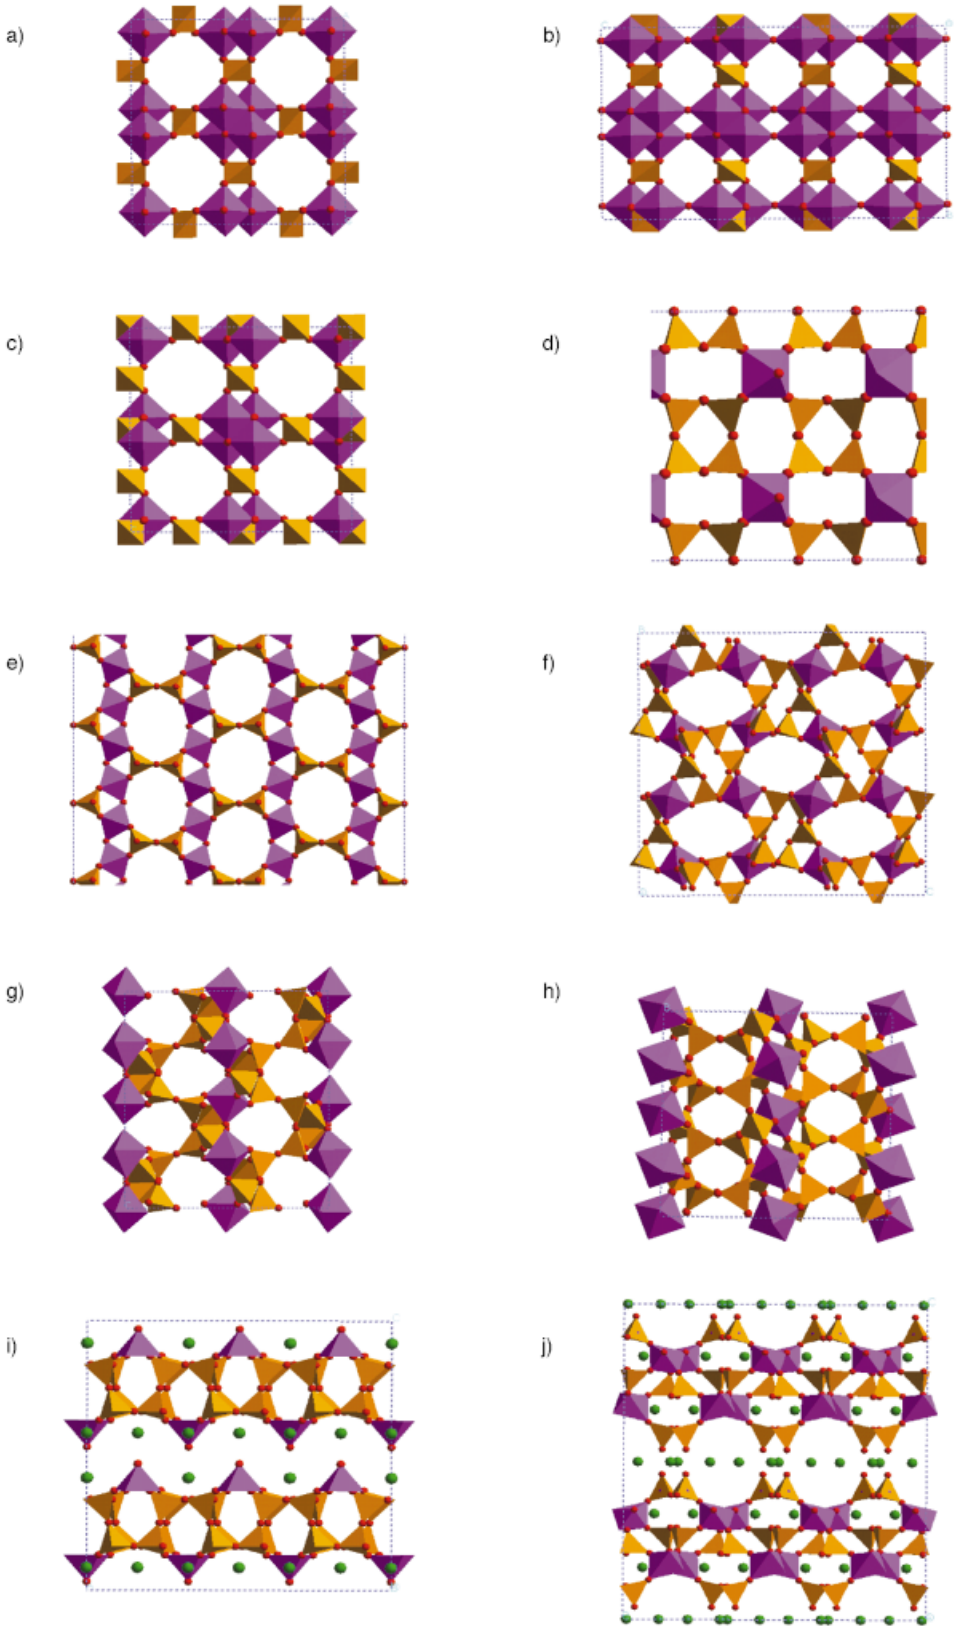

Figure 7. Projection of the structures of: (a) titanosilicate reported by Clearfield et al.[17] along the [001] and (b) [100] directions; (c) pharmacosiderite along [001]; (d) nenadkevichite along [100] and (e) [001]; (f) UND-1 along [100]; (g) penkvilksite 2*O* and AM-3 along [001] and (h) [010]; (i) AM-1 or JDF-L1 along [010]; (j) AM-4 along [100]; purple Ti octahedra, brown Si tetrahedra, green Na cations, red spheres oxygens

methods.[12] These materials possess a most interesting structure built up from TiO_6 octahedra, which share faces to form Ti_4O_4 cubes around the unit-cell corners and have silicate tetrahedra joining the titanium octahedra to form a three-dimensional framework (Figure 7c). Extra-framework Cs^+ species occupy sites slightly displaced from the centres of the intercage eight-ring windows, and also make $CsOH_2$ bonds to the water molecules that reside in the spherical cages.

Nenadkevichite is a rare mineral first found in the Lovozero region (Russia) with the composition $(Na,Ca)(Nb,Ti)Si_2O_7 \cdot H_2O$. The structure of nenadkevichite (from Saint-Hilaire, Quebec, Canada) consists of square rings of silicon tetrahedra Si_4O_{12} in the (100) plane joined together by chains of $(Nb,Ti)O_6$ octahedra in the [100] direction (Figure 7d and 7e).[43] The pores accommodate Na^+ in two partially (0.53 and 0.54) occupied sites and water molecules in two fully occupied sites. Rocha and Anderson and co-workers have been able to prepare a series of synthetic analogues of nenadkevichite with Ti/Nb molar ratios ranging from 0.8 to 17.1 and a purely titaneous sample.[44,45]

Many porous framework titanosilicates contain Ti–O–Ti linkages that often form infinite chains. Interestingly, the materials known as AM-2,[31,32,46–48] UND-1[49] and AM-3[46] do not contain any such linkages. AM-2 is a synthetic potassium titanosilicate analogue of the mineral umbite, a rare zirconosilicate found in the Khibiny alkaline massif (Russia).[50] Although the ideal formula of umbite is $K_2ZrSi_3O_9 \cdot H_2O$, a pronounced substitution of titanium for zirconium occurs. However, the natural occurrence of purely titaneous umbite is unknown. The successful synthesis of umbite materials with different levels of substitution of zirconium by titanium has been reported[31] and indicates the existence of a continuous solid solution that has not been described for any other sodium or potassium zirconosilicate. In the structure of umbite (not shown) the M octahedra, $(Zr,Ti)O_6$, and the T tetrahedra, SiO_4, form a three-dimensional MT-condensed framework.[50] The M octahedron is coordinated to six T tetrahedra. In addition to the M–O–T bonds these tetrahedra also form T–O–T links with each other. The resulting T radical has an identity period of three T tetrahedra and forms an infinite chain. The structures of umbite and the material known as UND-1 ($Na_{2.7}K_{5.3}Ti_4Si_{12}O_{36} \cdot 4\,H_2O$) are very similar.[49] The structure of UND-1 consists (Figure 7f) of six-membered rings of SiO_4 tetrahedra and isolated TiO_6 octahedra. Each TiO_6 octahedron connects, through corner-sharing, to six SiO_4 tetrahedra on the three six-membered rings, thus forming three three-membered rings, while each SiO_4 tetrahedron connects to two isolated TiO_6 octahedra and two other SiO_4 tetrahedra of the same six-membered ring. By such connections, channels running parallel to [100] are formed with eight-membered rings containing alternative –O–Si–O–Ti–O– linkages. The channel wall is covered by seven-membered rings (four SiO_4 tetrahedra and three TiO_6 octahedra) and three-membered rings. There are two cation sites in the structure. One is occupied only by K^+ and is located near the centre of the seven-membered ring of the wall. The other cation site is occupied by 33% K^+ and 67% Na^+ and is located in the large channel near the wall. AM-3 is a sodium titanosilicate analogue of the mineral penkvilksite found in Mont Saint-Hilaire, Québec (Canada), and the Kola Peninsula (Russia) with an ideal formula $Na_4Ti_2Si_8O_{22} \cdot 5\,H_2O$. The mineral occurs in two polytipic modifications, orthorhombic (penkvilksite-2*O*) and monoclinic (penkvilksite-1*M*).[51] These two polytypes have been described according to the OD theory as two of the four possible maximum degree of order polytypes within a family of OD structures formed by two layers.[51] Despite the different space group symmetries the 2*O* (*Pnca*) and 1*M* ($P2_1/c$) polytypes have the same atoms, labeled in the same way, in the asymmetric unit. They differ only in the stacking of the same building blocks. Thus, the following structure description (Figure 7 g and 7h) holds for both polytypes.[51] Penkvilksite contains two independent tetrahedra: The Si1-centred tetrahedra share two corners with other tetrahedra and two corners with TiO_6 octahedra; the Si2-centred tetrahedra share three corners with tetrahedra and one corner with a TiO_6 octahedron. Penkvilksite displays a new kind of connection among SiO_4 tetrahedra. Spirals of corner-sharing tetrahedra develop along [010] and have a periodicity of six tetrahedral units. The Si2-centred tetrahedra are shared between adjacent spirals, which are oriented in an alternate clockwise and counterclockwise fashion. The stacking of the layers along [001] gives rise to tetrahedral layers parallel to (100). The connection of neighbouring layers of tetrahedra is due to Ti^{IV} cations in an octahedral coordination. AM-3 is a synthetic analogue of penkvilksite-2*O*.[46] The synthesis of the 1*M* polytype has been reported recently by Liu et al.[52,53]

The synthesis of a few other microporous framework titanosilicates has also been reported. For example, Chapman and Roe have prepared a synthetic analogue of the mineral vinagradovite[8,54] with a framework composition $Na_8Ti_8Si_{16}O_{52}$. The structure of the mineral is composed of pyroxene chains joined to edge-sharing TiO_6 octahedra, which form brookite columns. These polyhedra define one-dimensional (4 Å) channels containing zeolitic water. A number of other minerals not yet prepared in the laboratory exhibit very interesting frameworks that are connected in a complex way (see the excellent review by J. V. Smith[55]). Verplanckite $[(Mn,Ti,Fe)_6(OH,O)_2(Si_4O_{12})_3]Ba_{12}Cl_9\{(OH,H_2O)_7\}$ has a framework with triple units of (Mn, Ti, Fe) in square-pyramidal coordination and four-rings of silicon tetrahedra.[56] The voids have a free diameter of 7 Å. Muirite, $Ba_{10}(Ca,Mn,Ti)_4Si_8O_{24}(Cl,OH,O)_{12} \cdot 4\,H_2O$, has edge-sharing trigonal prisms and eight-rings of SiO_4.[57]

When attempting to prepare novel microporous framework titanosilicates several groups have obtained layered materials, some of which have very interesting and unusual structures and show potential for being used in a number of applications such as ion exchange. One such material, known as AM-1[14,46] or JDF-L1,[58,59] has the composition $Na_4Ti_2Si_8O_{22} \cdot 4\,H_2O$. This is an unusual non-centrosymmetric tetragonal layered solid that contains five-coordin-

ated Ti^{IV} ions in the form of TiO_5 square pyramids in which each of the vertices of the base is linked to SiO_4 tetrahedra $[TiOO_4(SiO_3)_4]$ to form continuous sheets (Figure 7i).[59] The interlamellar Na^+ ions are exchangeable, for example by protonated alkylamines. AM-4, $Na_3(Na,H)Ti_2O_2[Si_2O_6]_2 \cdot 2\ H_2O$, is yet another example of a layered titanosilicate.[46,60] The crystal structure of AM-4 is built from TiO_6 (M) octahedra and SiO_4 (T) tetrahedra that form layers perpendicular to [001]. Each layer consists of a five-tier sandwich of T–M–T–M–T (Figure 7j). Between the layers are Na^+ cations and water molecules. The former also exist in small cages within the layers. The major features of the structure are zig-zag chains of edge-sharing TiO_6 octahedra running along the [100] direction that are connected together by corner-sharing pyroxene-type SiO_4 tetrahedra. Clearfield et al. reported the synthesis of a layered titanosilicate that seems to be closely related with AM-4.[61] The same group has also carried out a considerable amount of work on the evaluation of synthetic inorganic ion exchangers for cesium and strontium removal from contaminated groudwater and wastewater using (among other materials) several microporous and layered titanosilicates, some of which possess unknown structures (see, for instance, ref.[62] and references therein).

Zirconosilicates

Zirconium silicates occur widely in nature and their formation under hydrothermal conditions (from ca. 300 to 550 °C) has been given considerable attention, though mainly for the solution of general geophysical and mineralogical problems (see ref.[33] and references therein). More than 20 natural and synthetic zirconium silicates are known and for about one-third of them the crystal structures have been solved. Some of the first hydrothermal syntheses of zirconosilicates were carried out by Maurice in 1949.[63] Baussy et al. summarise the early work in this field and report the hydrothermal synthesis of (among others) analogues of the minerals catapleiite ($Na_2ZrSi_3O_9 \cdot 2\ H_2O$) and elpidite ($Na_2ZrSi_6O_{15} \cdot 3\ H_2O$) at 350–500 °C.[64] These materials have also been prepared by others.[65] Jale et al. reported the hydrothermal synthesis of a potassium analogue of elpidite at a relatively low temperature (200 °C).[32] The characteristic feature of the structure of elpidite is the presence of double chains of tetrahedra (epididymite type) connected by zirconium atoms in octahedral coordination (Figure 8a and 8b). The silicate chains form an anionic framework that is saturated by sodium ions. The double chains of tetrahedra are parallel to [100]. Two independent Na^+ cations are present. Na(2) has an octahedral coordination formed by four oxygens of the tetrahedra and two symmetrically equivalent water molecules. Na(1) occurs in a cavity formed by adjacent double chains of tetrahedra and it is bonded to seven oxygens and a water molecule.[66]

Recently, an excellent example of the interesting and promising chemistry of sodium zirconosilicates has been given by Clearfield et al.[33] These workers reported the synthesis, characterisation, and properties of three novel layered materials and five other zirconosilicates. In particular, a synthetic analogue of the mineral gaydonnayite (ideal formula $Na_2ZrSi_3O_9 \cdot 2\ H_2O$) has been prepared. This material has also been synthesised by Rocha and Anderson and co-workers (AV-4)[31] and by Jale et al.[32] The framework of gaydonnayite is composed of sinusoidal single chains of SiO_4 tetrahedra, repeating every six tetrahedra (Figure 8c and 8d).[67] The chains are extend alternately along [011] and [01–1] and are cross-linked by a ZrO_6 octahedron and two distorted NaO_6 octahedra.

Another interesting example of a microporous zirconosilicate is petarasite and its synthetic analogue AV-3.[31,68,69] This rare mineral $[Na_5Zr_2Si_6O_{18}(Cl,OH) \cdot 2\ H_2O]$ possesses a very unusual structure consisting of an open three-dimensional framework built of corner-sharing six-membered rings and ZrO_6 octahedra (Figure 8e and 8f).[68] Elliptical channels (3.5 × 5.5 Å) defined by mixed six-membered rings, consisting of pairs of SiO_4 tetrahedra linked by zirconium octahedra, run parallel to the *b* and *c* axes. Other channels limited by six-membered silicate rings run parallel to the *c* axis. The sodium, chloride and hydroxyl ions and the water molecules reside within the channels. The framework does not collapse until the release of Cl^- at ca. 800 °C.

The preparation of synthetic umbite materials has already been discussed in this microreview. The chemistry of other fascinating microporous framework solids is waiting to be explored. For instance, the mineral lemoynite, $(Na,K)_2CaZr_2Si_{10}O_{26} \cdot 5–6\ H_2O$, possesses a $ZrSi_5O_{13}$ framework with wide open channels where sodium, potassium and calcium cations and water molecules reside.[70] This framework comprises thick (7 Å) layers of hexagons of silicate groups. The sheets are bound together by six-coordinated zirconium atoms. The hexagons are tilted with respect to the layer (001) plane and the architecture of these layers is new.

Niobosilicates

Comparatively few studies are available on microporous framework niobosilicates. In this microreview we have already discussed the work carried out on nenadkevichite analogues containing titanium and niobium.[45,46] Recent work suggests that other niobosilicate materials that show potential as heterogeneous catalysts are yet to be discovered. For example, Rocha and Anderson and co-workers have reported the synthesis of AM-11, a novel microporous sodium niobosilicate.[71] Although its structure is still unknown, this material has a relatively large pore volume and seems to contain NbO_6 octahedra and local silicon environments Si(4Si, 0Nb), Si(3Si, 1Nb) and Si(2Si, 2Nb). A preliminary characterisation of the acid-base properties has shown that AM-11 dehydrates *tert*-butyl alcohol to isobutene with remarkably high activity and selectivity.

Stannosilicates

The hydrothermal synthesis of microporous framework stannosilicates has been pioneered by Corcoran et al. As pointed out by these workers, several minerals containing SnO_6 and SiO_4 polyhedra are known and a few (dense)

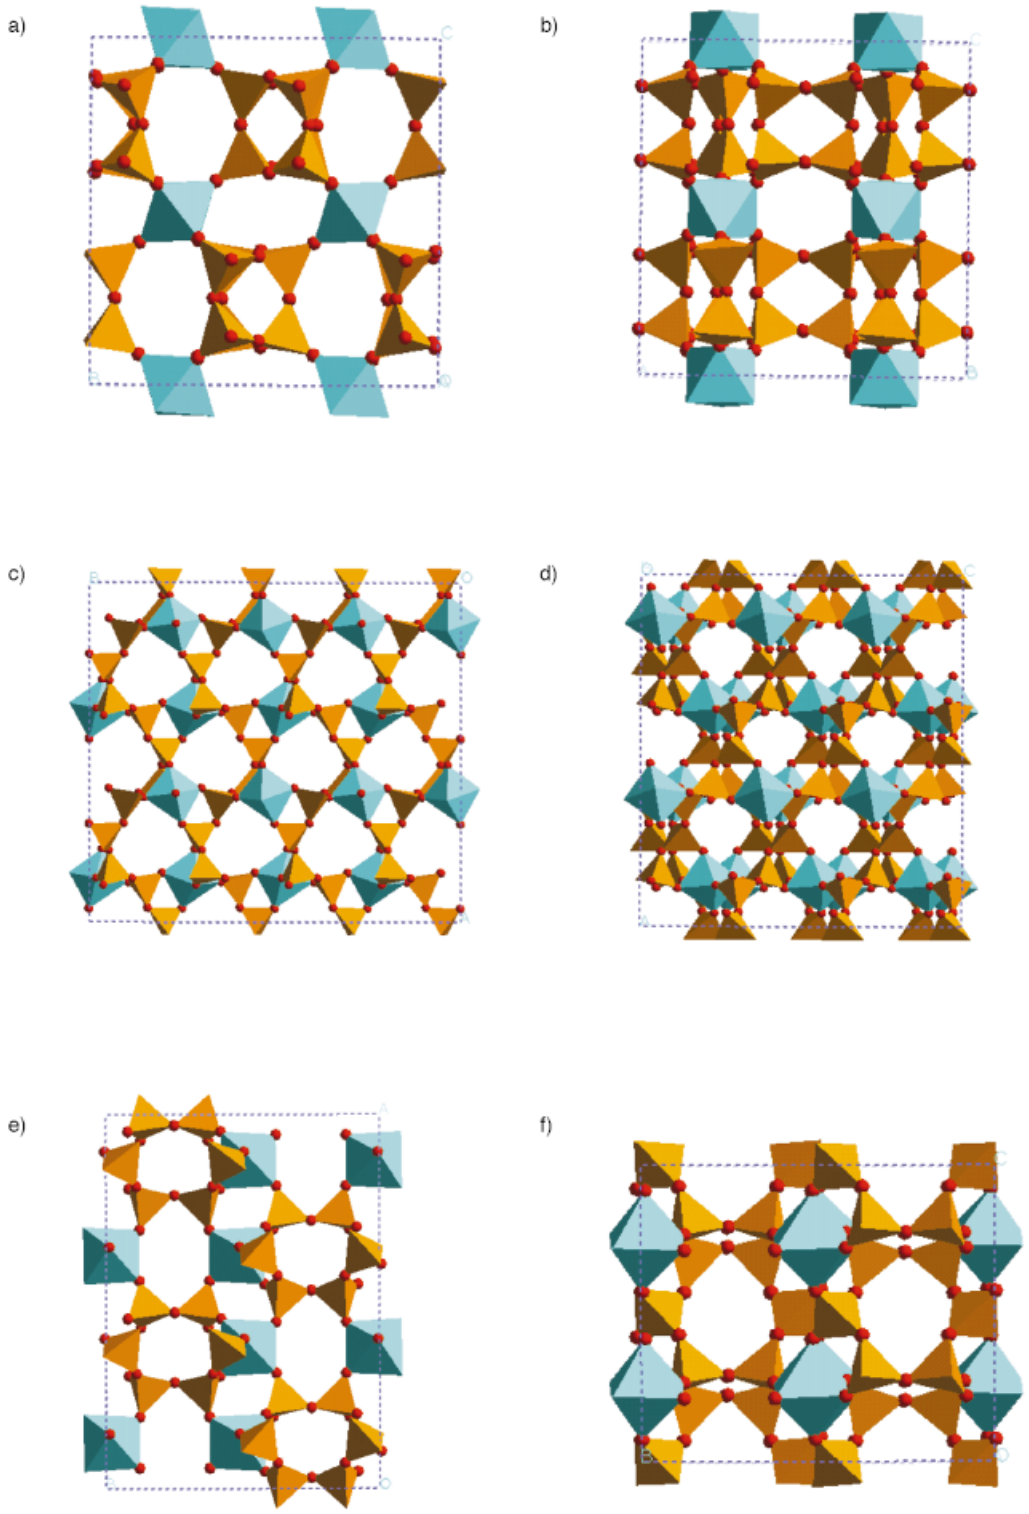

Figure 8. Projections of the structure of: (a) elpidite along the [100] and (b) [010] directions; (c) gaydonnayite and AV-4 along [001] and (d) [010]; (e) petarasite and AV-3 along [001] and (f) [100] directions; blue Zr octahedra, brown Si tetrahedra, red spheres oxygens

stannosilicate phases have been crystallised from high-temperature conditions.[72,73] Two microporous stannosilicates have been reported by Corcoran et al. The orthorhombic phase Sn-A has the composition $Na_8Sn_3Si_{12}O_{34} \cdot n\,H_2O$, while Sn–B has been formulated as $Na_4SnSi_4O_{12} \cdot n\,H_2O$. These materials show reversible water loss and have a significant ion-exchange capacity. A third, layered, stannosilicate ($Na_4SnSi_5O_{14} \cdot n\,H_2O$) has also been reported.[72] Subsequently, Dyer and Jafar reported the synthesis, characterisation and cation-exchange properties of a microporous stannosilicate with a very unusual habit and of composition $Na_{13.5}Sn_{10}Si_{15}O_{36}(OH)_5 \cdot 13.5\,H_2O$.[74] The ion-exchange

behaviour has been shown to be zeolitic in character. The crystal structures of all these solids are, as yet, unknown. Recently, Rocha et al. reported the synthesis and characterisation of two stannosilicates possessing the structures of titanosilicates umbite and UND-1 (Figure 7f).[75]

Vanadosilicates

Although vanadium has already been introduced into the framework of certain zeolites in small amounts, to the best of our knowledge only three microporous framework vanadosilicates are known to contain stoichiometric amounts of vanadium.[34,76,77] Canvasite and pentagonite, dimorphs of the mineral $Ca(VO)(Si_4O_{10}) \cdot 4\,H_2O$, have a framework formed by silicate layers of four- and eight-membered rings of tetrahedra connected vertically by V^{IV} cations that are in a square-pyramidal coordination (Figure 9).[76,77] Replacement of the VO_5 groups by two bridging oxygens would produce a tetrahedral framework topologically identical to that of the zeolite gismondine. The calcium cations and the water molecules reside in the channels formed by the eight-membered rings and between the SiO_2 layers. Canvasite has channels running parallel to the *c* direction with a free diameter of only 3.3 Å in the hydrated state. Hence, both canvasite and pentagonite are likely to behave (at best) as small-pore materials.

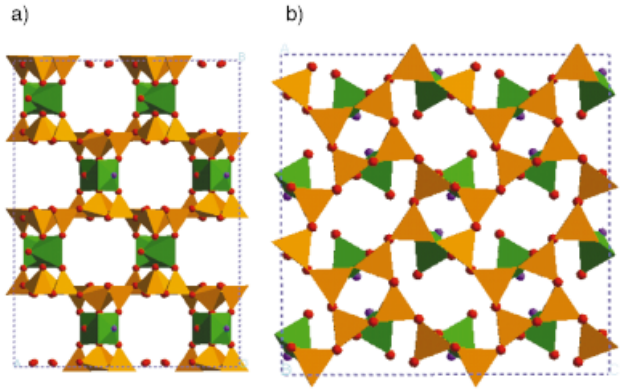

Figure 9. Projection of the structure of canvasite along the (a) [001] and (b) [010] directions; green V square pyramids, brown Si tetrahedra, red spheres oxygens

Recently, the synthesis and structural characterisation of the first large-pore vanadosilicate containing octahedral vanadium and possessing a structure similar to that of titanosilicate ETS-10 has been reported. The presence of stoichiometric amounts of vanadium in the framework of AM-6 gives this material great potential for applications as a catalyst, sorbate or functional material.[34]

Other Silicates

The synthesis of microporous framework silicates of a few other metals have been reported. One such case is AV-1, the synthetic analogue of the rare mineral montregianite (also known as UK-6).[78,79] This is an yttrium silicate, with the formula $Na_4K_2Y_2Si_{16}O_{38} \cdot 10\,H_2O$, that possesses a very unusual structure consisting of two different types of layers alternating along the [010] direction (Figure 10a and 10b):[80] (a) a double silicate sheet, where the single silicate sheet is of the apophyllite type with four- and eight-membered rings, and (b) an open octahedral sheet composed of $[YO_6]$ and three distinct $[NaO_4(H_2O)_2]$ octahedra. The layers are parallel to the (010) plane. The K^+ ions are ten-coordinate and the six water molecules are located within large channels formed by the planar eight-membered silicate rings.

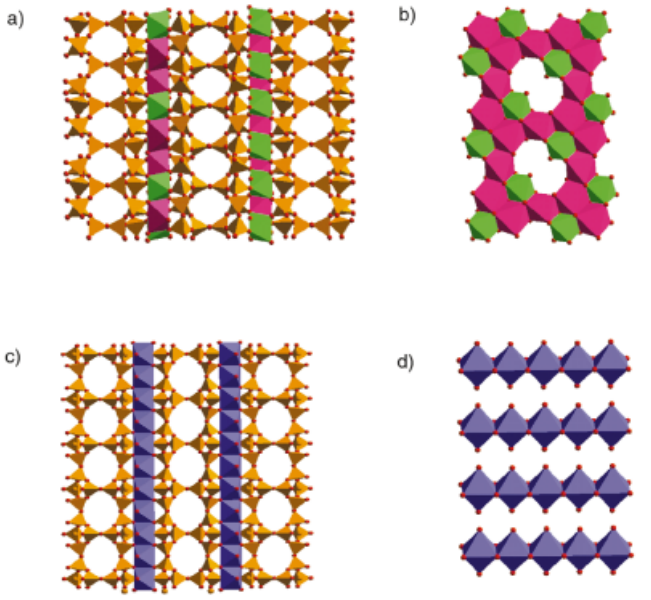

Figure 10. Projection of the structures of: (a) montregianite and AV-1 along the [001] direction; (b) one octahedral layer seen along the [010] direction; (c) rhodesite and AV-2 along [010]; (d) one octahedral layer seen along [100]; green Y octahedra, red Na octahedra, blue Ca octahedra, brown Si tetrahedra, red spheres oxygens

The structure of the alkali calcium silicate mineral rhodesite ($HKCa_2Si_8O_{19} \cdot 6\,H_2O$)[81] and its synthetic analogue AV-2[79] is closely related to that of montregianite. It consists of silicate double layers, chains of edge-sharing $[Ca(O,OH_2)_6]$ octahedra and potassium cations, and additional water molecules within the pores of the silicate double layers (Figure 10c and 10d). Rhodesite and montregianite have double silicate layers of the same topology. In fact, other minerals such as delhayelite, hydrodelhayelite and macdonaldite, all have similar double silicate sheets. In rhodesite these layers possess the maximum topological symmetry (*P*2*mm*) while in montregianite all symmetry has been lost. The structure of rhodesite contains two sets of octahedrally-coordinated calcium ions, which form single chains parallel to [001]. The octahedral chains connect adjacent silicate double layers. While Ca(2) is coordinated to six terminal oxygens that belong to six different SiO_4 tetrahedra, Ca(1) is coordinated to four terminal oxygens from four SiO_4 and two oxygens from water molecules. The extra-framework potassium ions are ten-coordinated to six bridging oxygens and four water molecules.

Characterisation

Disorder

The structures of many microporous materials are disordered and this is the case for the important microporous titanosilicates ETS-10 and ETS-4. It can be assumed that it is likely that a number of the new structures, which will undoubtedly be synthesised in the future, will also be disordered. Disorder should be distinguished from defects. Disorder usually results from the apparent intergrowth of different polymorphs of a structure. In the ideal case this will occur without a disruption in the connectivity of the framework, i.e. internal –OH groups will not be present. Sometimes disorder causes the apparent diffusion pathway through the channel system to be disrupted, as with ETS-4,[39] but sometimes the disorder causes no disruption, as with ETS-10.[13,14] Characterisation of such disordered structures can be complicated, especially if the materials can only be crystallised as microcrystalline powders. The following gives a short description of how a range of characterisation techniques can be powerfully focussed on the problem of characterising disordered materials.

Bulk characterisation techniques generally fall into two categories: those that concern short range effects and those that concern long range effects. This is an important distinction when characterising disordered materials as often, although by no means always, the disorder is manifested beyond the short-length scale. If the disorder occurs on a length scale of tens of Ångstroms, short-range techniques such as high-resolution electron microscopy (HREM), solid-state nuclear magnetic resonance with magic-angle spinning (MAS NMR), infrared spectroscopy (IR), Raman spectroscopy, electronic spectroscopy, and extended X-ray absorption fine structure (EXAFS) will give high quality data. These techniques will behave in the same manner as if there was no disorder. All diffraction techniques, which are inherently long-range techniques, will reflect both the structure and disorder in the material. Consequently, it is often sensible to begin with the short-range techniques and HREM in particular can give information about the possible pore structure and also about how disorder and defects may be incorporated within the material. This is often the cornerstone of any structural analysis. Local chemical environments may be probed in a quantitative fashion using MAS NMR and ^{29}Si is often a useful nucleus in this respect.[82] In favourable circumstances this technique will also yield crystallographic distinctions within a chemical grouping. All these new microporous phases will contain counterbalancing cations and these are often particularly difficult to locate in a disordered material. A common counterbalancing cation is sodium, which is a particularly good NMR nucleus. Because of the quadrupolar nature of ^{23}Na a number of sophisticated modern experiments have been developed known as multiple-quantum NMR spectroscopy. Infrared and Raman spectroscopies can often reveal structural units within a framework. Electronic spectroscopy will show the existence of band gaps, which can be characteristic of certain structures. EXAFS is a useful tool for homing in on a structure towards the end of an analysis. Because of the inability of this technique to distinguish different sites, the data obtained is a composite for the whole sample and is usually of little use in the early stages of structural characterisation. However, EXAFS will reveal very accurate bond lengths in a structure. EXAFS studies on ETS-10 have shown that within the titanate chain the Ti–O bonds are alternately long and short.[35] This will have marked consequences for optical properties.

In the case of ETS-10 this suite of short-range techniques was sufficient to ascertain a framework connectivity for the structure.[13,14] Atomic coordinates can then be refined using simple geometric constraints (bond angles and bond lengths). This is known as a distance-least-squares (or DLS) approach. With suitable interatomic potentials, which exist for titanosilicates[83] but not for some of the more exotic elements, energy minimisation can also be used to refine atomic coordinates. At this stage simulation of HREM images provides one of the best ways to confirm the trial structure.[84]

The diffraction data can be handled in two ways. Usually the diffraction data will consist of sharp and diffuse reflections that are characteristic of the underlying structure and the disorder. By concentrating solely on the sharp reflections it is sometimes possible to define a superposition cell. This is a unit cell that contains structural units in all possible configurations owing to the disorder. Consequently, the unit cell so defined will contain a superposition of framework units with some displacement characteristic of the disorder.

Alternatively the disorder can be incorporated into the calculation of the diffraction data, and a particularly powerful method in this regard is DIFFaX, a technique designed by Treacy, Newsam and Deem in 1991.[85] In this method the structure is built up from structurally perfect layers that are connected according to suitable rules to define the particular disorder observed for the material of interest. In this manner both sharp and diffuse reflections can be simulated. At present it is not possible to use this technique in an iterative fashion, such as Rietveld refinement, and consequently it is best used to confirm structure rather than refine structure.

Isomorphous Framework Substitution

The insertion of heteroatoms into the framework of microporous materials is an important process because it allows the fine-tuning of the their properties. Despite the fact that a considerable amount of work has been carried out on zeolites and other related systems, obtaining unequivocal evidence for framework substitution is not a trivial task and it usually requires the combined use of several techniques. Detailed studies on framework insertion of aluminium, gallium, boron, and niobium on ETS-10 have been reported and we will summarise in the following.

In an attempt to improve the acid characteristics of ETS-10 (and following up the early synthesis work by Kuznicki et al.[28,29]) Rocha and Anderson and co-workers have incorporated aluminium[86,87] and gallium[24,87] into tetrahed-

ral silicon sites, thus generating sites for zeolite-type acidity. These materials are known as ETAS-10 and ETGS-10, respectively. The main evidence for the substitution of silicon by aluminium and gallium in the framework of ETS-10 is provided by solid state NMR. The ^{29}Si MAS-NMR spectra of ETS-10, ETAS-10, and ETGS-10 are shown in Figure 11.

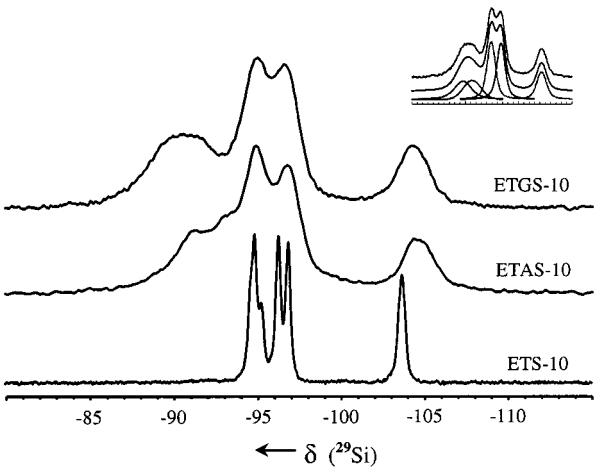

Figure 11. ^{29}Si MAS-NMR spectra of ETS-10, ETAS-10 and ETGS-10; the inset shows a deconvolution of the ETGS-10 spectrum

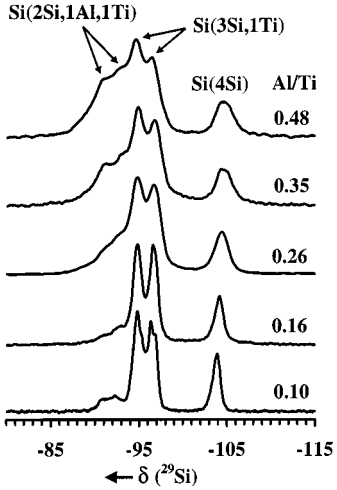
In ETS-10 there are two types of silicon chemical environments, Si(3Si, 1Ti) and Si(4Si, 0Ti), which give rise to the two groups of resonances at δ = –94 to –97 and ca. –103.7, respectively. The ratio of these environments is 4:1. The spectrum reveals a further crystallographic splitting of the Si(3Si, 1Ti) site. The spectrum of ETAS-10 contains all the ETS-10 resonances plus two other peaks ca. 4 ppm downfield from the Si(3Si, 1Ti) signals. These new peaks become stronger when the framework aluminium concentration increases (Figure 12).



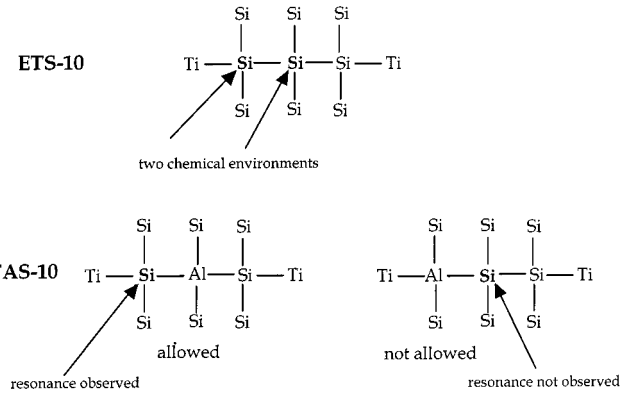


Figure 12. ^{29}Si MAS-NMR spectra of ETAS-10 with the Al/Ti ratios depicted

These signals are ascribed to the framework incorporation of aluminium to produce Si(2Si, 1Al, 1Ti) environments. It is important to note that there is no signal ca. 4 ppm downfield from the Si(4Si, 0Ti) resonance, showing no aluminium substitution neighbouring this silicon site and, hence, providing direct evidence for Al, Ti avoidance.[24,86]

The ^{27}Al MAS-NMR spectrum (not shown) is also indicative of this effect since it contains a single resonance at δ ≈ 60, which is assigned to Al(4Si).

The ^{29}Si MAS-NMR spectrum of gallium-substituted ETS-10 resembles the spectrum of ETAS-10: a broad peak is seen downfield from the Si(3Si, 1Ti) signals. This peak can be deconvoluted into two component signals, each one ca. 1.5 ppm downfield from the Si(2Si, 1Al, 1Ti) resonances, which we assign to Si(2Si, 1Ga, 1Ti) as similar downfield shifts of the ^{29}Si NMR resonances have been reported for gallium-substituted zeolites. No signals are observed in the range δ = –99 to –103.[24,86] On the other hand, the ^{71}Ga MAS-NMR spectrum of fully-hydrated ETGS-10 (not shown) displays a broad peak at δ = 160, which is characteristic of four-coordinated gallium.

Detailed analysis of spectral intensities (I_{Si}) allows framework Si/Al (or Si/Ga) and Si/Ti ratios to be calculated from Equation 1 and Equation 2.

$$\mathrm{Si/Al} = \frac{\sum_{n=0}^{4-m}\sum_{m=0}^{4-n} \mathrm{I}_{\mathrm{Si(nAl,mTi)}}}{0.25\sum_{n=0}^{4-m}\sum_{m=0}^{4-n} \mathrm{nI}_{\mathrm{Si(nAl,mTi)}}} \quad (1)$$

$$\mathrm{Si/Ti} = \frac{\sum_{n=0}^{4-m}\sum_{m=0}^{4-n} \mathrm{I}_{\mathrm{Si(nAl,mTi)}}}{0.25\sum_{n=0}^{4-m}\sum_{m=0}^{4-n} \mathrm{mI}_{\mathrm{Si(nAl,mTi)}}} \quad (2)$$

Increasing the aluminium content in ETAS-10 broadens considerably the ^{29}Si-NMR resonances (Figure 12). In particular, the peak at δ = –104.5 becomes very broad, increasing its Full-Width-at-Half-Maximum (FWHM) from 40 Hz in ETS-10 to 200 Hz in ETAS-10 with Al/Ti = 0.48.[24] In fact, there is an almost perfectly linear correlation between the FWHM of this resonance and the Al/Ti ratio (equivalent to the aluminium content as aluminium replaces silicon and not titanium) of samples. In the case of zeolites the NMR lines are broadened for a number of reasons. Structural disorder, for example, gives rise to a dispersion of chemical shifts. Another important line broadening mech-
